Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contents

Video contents viii
Foreword x
Preface xi
List of contributors xii

1 **A history of pediatric ophthalmology and strabismus** 1
David S Taylor

Section 1: Epidemiology, growth and development

2 **Epidemiology and the worldwide impact of visual impairment in children** 7
Jugnoo S Rahi and Clare E Gilbert

3 **Clinical embryology and development of the eye** 17
John R B Grigg and Robyn V Jamieson

4 **Developmental biology of the eye** 25
David R FitzPatrick

5 **Clinical aspects of normal and abnormal visual development and delayed visual maturation** 32
Ronald M Hansen and Anne B Fulton

6 **Milestones and normative data** 40
Hans Ulrik Møller and Dorte Ancher Larsen

Section 2: Core practice

7 **Examination, history and special tests in pediatric ophthalmology** 50
G Robert LaRoche

8 **Managing refractive errors in children** 60
Amy K Hutchinson and Buddy Russell

9 **Visual electrophysiology: how it can help you and your patient** 68
Dorothy A Thompson and Alki Liasis

10 **Imaging the child's eye, orbit, and visual pathways** 76
Daniel J Salchow and Nadja Kadom

11 **Genetics and pediatric ophthalmology** 94
Panagiotis I Sergouniotis and Graeme C M Black

Section 3: Infections, allergic and external eye disorders

12 **Congenital infections of the eye** 101
Luis Amaya

13 **Conjunctivitis of the newborn** 109
Megan Geloneck and Gil Binenbaum

14 **Preseptal and orbital cellulitis** 113
Richard L Scawn and Jimmy M Uddin

15 **Endophthalmitis** 124
Donal Brosnahan

16 **External eye disease and the oculocutaneous disorders** 130
Stephen J Tuft

17 **Ocular manifestations of HIV/AIDS in children** 156
Emmett T Cunningham Jr and Philippe Kestelyn

Section 4: Systematic pediatric ophthalmology

Part 1: Disorders of the eye as a whole

18 **Disorders of the eye as a whole** 163
Sunju Park and Elias I Traboulsi

Part 2: Lids, brows and oculoplastics

19 **Lids: congenital and acquired abnormalities – practical management** 175
Robert C Kersten and Richard Collin

20 **Lid and orbital infantile periocular hemangiomas (capillary hemangiomas) and other vascular diseases** 188
Christopher J Lyons

Part 3: Orbit and lacrimal

21 **Lacrimal system** 200
Caroline J MacEwen and Una O'Colmain

22 **The management of orbital disease in children** 209
Alan A McNab

23 **Neurogenic tumors** 216
Peter J Dolman and Yvonne Chung

24 **Orbital rhabdomyosarcoma** 225
Carol L Shields and Jerry A Shields

25 **Other mesenchymal abnormalities** 232
Christopher J Lyons

26 **Metastatic, secondary and lacrimal gland tumors** 239
Alan A McNab and Christopher J Lyons

27 **Histiocytic, hematopoietic, and lymphoproliferative disorders** 244
Timothy John Sullivan

28 **Craniofacial abnormalities** 250
Joanna Black and John Crompton

29 **Cystic lesions and ectopias** 267
Alan A McNab

30 **Inflammatory disorders** 277
Alan A McNab and Christopher J Lyons

Part 4: External disease and anterior segment

31 **Conjunctiva and subconjunctival tissue** 283
Venkatesh Prajna and Perumalsamy Vijayalakshmi

32 **Conjunctival tumors** 290
Jill Razor Wells and Hans Grossniklaus

33 **Anterior segment developmental anomalies including aniridia** 297
Ken K Nischal

34 **Corneal abnormalities in childhood** 314
Stephen J Tuft

35 **Corneal dystrophies** 330
Hans Ulrik Møller and Barry Lee

36 **The lens** 337
Jay Self and Christopher Lloyd

37 **Childhood cataracts** 346
Scott R Lambert

38 **Childhood glaucoma** 362
Maria Papadopoulos and Sir Peng Tee Khaw

Part 5: The uvea
39 **Pediatric iris disorders** 378
Michael O'Keefe
40 **Uveitis** 385
Clive Edelsten
41 **Albinism** 403
C Gail Summers
Part 6: Retinal and vitreous disorders
42 **Vitreous** 411
Michel Michaelides and Anthony T Moore
43 **Retinoblastoma** 424
Brenda L Gallie and Sameh E Soliman
44 **Retinopathy of prematurity** 443
Graham E Quinn and Alistair R Fielder
45 **Current treatment of retinopathy of prematurity** 456
Joshua Robinson and G Baker Hubbard
46 **Inherited retinal disorders** 462
Michel Michaelides, Graham E Holder, and Anthony T Moore
47 **Retinal dystrophies with systemic associations and the retinal ciliopathies** 487
Hélène Dollfus
48 **Inherited macular dystrophies** 502
Michel Michaelides and Anthony T Moore
49 **Congenital pigmentary and vascular abnormalities of the retina** 516
Susmito Biswas
50 **Retinal flecks, dots and crystals** 525
Panagiotis I Sergouniotis and Anthony T Moore
51 **Acquired and other retinal diseases (including juvenile X-linked retinoschisis)** 537
Mary J van Schooneveld and Jan EE Keunen
52 **Retinal detachment in childhood** 546
Martin P Snead
Part 7: Neural visual systems
53 **Congenital anomalies of the optic discs** 562
David S Taylor
54 **Hereditary optic neuropathies** 581
Jason H Peragallo, Valérie Biousse, and Nancy J Newman
55 **Other acquired optic disc abnormalities in children** 592
Stacy Pineles
56 **Demyelinating, inflammatory, infectious, and infiltrative optic neuropathies** 599
Gena Heidary
57 **The optic chiasm** 606
Michael C Brodsky
58 **Headache in children** 617
Shannon J Beres and Grant T Liu
59 **Raised intracranial pressure** 624
Robert A Avery
60 **The brain and cerebral visual impairment** 629
Creig S Hoyt

Section 5: Selected topics in pediatric ophthalmology
61 **Delivering bad news** 639
Phoebe Lenhart
62 **Common issues arising in children with visual impairment** 643
Carey A Matsuba
63 **Visual conversion disorders: fabricated or exaggerated symptoms in children** 649
David S Taylor and Luis Amaya
64 **Dyslexia** 956
Sheryl M Handler
65 **Neurometabolic disease and the eye** 664
Jane L Ashworth and Andrew A M Morris
66 **Pupil anomalies and reactions** 681
Andrew G Lee
67 **Leukemia** 691
Richard J C Bowman and Jack Bartram
68 **Phakomatoses (including the neurofibromatoses)** 700
John R B Grigg and Robyn V Jamieson
69 **Accidental trauma in children** 715
William V Good and Susan M Carden
70 **Child maltreatment, abusive head trauma, and the eye** 725
Patrick Watts
71 **Refractive surgery in children** 739
Evelyn A Paysse

Section 6: Amblyopia, strabismus and eye movements
Part 1: The fundamentals of strabismus and amblyopia
72 **Binocular vision** 746
Eileen E Birch and Anna R O'Connor
73 **Amblyopia: basics, questions, and practical management** 754
Michael X Repka
74 **Anatomy of strabismus** 762
Joseph L Demer
75 **The orthoptic evaluation** 773
Darren T Oystreck
Part 2: Esotropias
76 **Infantile esotropias** 791
Glen A Gole and Jayne E Camuglia
77 **Accommodative esotropias** 802
David R Weakley and Erika Mota Pereira
78 **Special esotropias (acute comitant, sensory deprivation, myopia-associated and microtropia)** 806
John J Sloper
Part 3: Exotropias
79 **Intermittent exotropia** 810
Michael P Clarke
80 **Special forms of comitant exotropia** 818
Stephen P Kraft
Part 4: Vertical, "pattern" strabismus and abnormal head postures
81 **Vertical strabismus** 827
Burton J Kushner
82 **"A," "V," and other pattern strabismus** 838
Burton J Kushner
Part 5: "Neurological" strabismus
83 **Congenital cranial dysinnervation disorders** 848
Ramesh Kekunnaya and Virender Sachdeva
84 **Ocular motor nerve palsies** 859
Jason H Peragallo and Scott R Lambert
Part 6: Strabismus treatment
85 **Strabismus: nonsurgical treatment** 868
Alejandra de Alba Campomanes
86 **Strabismus surgery** 876
David K Coats and Scott E Olitsky

87 **Minimally invasive strabismus surgery** 905
Saurabh Jain and Daniel Mojon
88 **Strabismus surgery complications and how to avoid them** 913
John A Bradbury and Rachel F Pilling
Part 7: Nystagmus and eye movements
89 **Nystagmus in childhood** 921
Frank Antony Proudlock and Irene Gottlob
90 **Supranuclear eye movement disorders, acquired and neurologic nystagmus** 933
Richard W Hertle and Nancy N Hanna

Section 7: Common practical problems in a pediatric ophthalmology and strabismus practice
91 **"I think my baby can't see!"** 953
Ingele Casteels
92 **"My baby's got a red eye, doctor!"** 957
Giovanni Castano
93 **"My child keeps blinking and closing his eye"** 960
Kimberley Tan
94 **"My child seems to hate the bright light"** 963
Luis H Ospina
95 **"My child's eyes keep watering!"** 967
Anthony G Quinn
96 **Proptosis at different ages** 970
Alan A McNab
97 **"My child's teacher says she can't see properly!"** 971
Hanne Jensen
98 **"My child could see perfectly but now the vision is weak!"** 975
Luis Carlos Ferreira de Sá
99 **The child with a dual sensory loss (deafblind)** 978
Nicoline Schalij-Delfos
100 **"My little girl tells me she sees strange things"** 981
Göran Darius Hildebrand
101 **Wobbly eyes in infancy** 989
Narman Puvanachandra
102 **Abnormal head postures in children** 992
Stephen P Kraft
103 **Hand defects and the eye** 996
Luis Carlos Ferreira de Sá and Chong Ae Kim
104 **Optimizing compliance in patching therapy** 1002
Christy Giligson and Vaishali Mehta
105 **Vision screening** 1005
Sean P Donahue
106 **Self-inflicted ocular injuries** 1010
David S Taylor
107 **Apps and all that … (How my smartphone changed my life)** 1012
Patrick Hamel

Index 1014

Denotes chapters with online video content.

Video contents

Chapter 19 Lids: congenital and acquired abnormalities – practical management

19.1 Insertion of prosthetic eye into postenucleation socket
Robert C Kersten and Richard Collin

Chapter 21 Lacrimal system

21.1 Probing in a young child
Caroline J MacEwen and Una O'Colmain

Chapter 31 Conjunctiva and subconjunctival tissue

31.1 A worm being removed from beneath the lateral rectus muscle
Venkatesh Prajna and Perumalsamy Vijayalakshmi

Chapter 32 Conjunctival tumors

32.1 Corneal or conjunctival tumor being treated
Jill Razor Wells and Hans Grossniklaus

Chapter 36 The lens

36.1 Subluxed lensectomy
Jay Self and Christopher Lloyd

Chapter 37 Childhood cataracts

37.1 Cataract extraction and primary intraocular lens implantation in a one-year-old child

37.2 In-the-bag secondary intraocular lens impantation in a two-year-old
Scott R Lambert

Chapter 38 Childhood glaucoma

38.1 Trabeculotomy

38.2 Goniotomy
Sir Peng Tee Khaw, Maria Papadopoulos and John L Brookes

Chapter 45 Current treatment of retinopathy of prematurity

45.1 Avastin injection for retinopathy of prematurity in neonate
Joshua Robinson and G Baker Hubbard

Chapter 81 Vertical strabismus

81.1 Dissociated vertical divergence versus inferior oblique overaction

81.2 Right orbital floor fracture simulating left superior oblique palsy

81.3 Primary inferior oblique muscle overaction

81.4 Pulley heterotopia
Burton J Kushner

Chapter 82 "A," "V," and other pattern strabismus

82.1 Pseudo inferior oblique overaction

82.2 Primary inferior oblique overaction

82.3 Anti-elevation syndrome
Burton J Kushner

Chapter 83 Congenital cranial dysinnervation disorders

83.1 Congenital fibrosis of the extraocular muscles (CFEOM) showing convergence on attempted upgaze
Virender Sachdeva and Ramesh Kekunnaya

Chapter 85 Strabismus: nonsurgical treatment

85.1 Botulinum toxin injection: closed conjunctival technique

85.2 Botulinum toxin injection: open-sky technique
Alejandra de Alba Campomanes

Chapter 86 Strabismus surgery

86.1 Fornix incision for strabismus surgery
Rohit Jolly, Naomi Tan and Saurabh Jain

86.2 Medial rectus recession 1
Amy K Hutchinson

86.3 Medial rectus recession 2
Scott R Lambert

86.4 Medial rectus resection 3
Amy K Hutchinson

86.5 Anterior transposition
Scott R Lambert

Chapter 87 Minimally invasive strabismus surgery

87.1 Minimally invasive strabismus surgery (MISS) recession plication
Daniel Mojon

Chapter 88 Strabismus surgery complications and how to avoid them

88.1 Strabismus surgery complications: pseudotendon and lost muscle
John A Bradbury

Chapter 89 Nystagmus in childhood

89.1 Changes of nystagmus with age

89.2 Nystagmus with albinism

89.3 Spasmus nutans

89.4 Achromatopsia

89.5 Increasing head posture with visual demand

89.6 Alternating head turn in manifest latent nystagmus

89.7 Idiopathic infantile nystagmus with periodic alternating nystagmus (PAN)

89.8 Manifest latent nystagmus
89.9 Surgery for nystagmus blockage syndrome
89.10 Horizontal Kestenbaum–Anderson procedure
89.11 Torsional Kestenbaum procedure
89.12 Idiopathic infantile nystagmus before and after treatment with memantine
Frank Antony Proudlock and Irene Gottlob

Chapter 90 Supranuclear eye movement disorders, acquired and neurologic nystagmus
90.1 Ocular motor neuromyotonia 1
90.2 Ocular motor neuromyotonia 2
90.3 Upbeat nystagmus
90.4 Spasmus nutans 1
90.5 Supranuclear gaze palsy
90.6 Horizontal gaze palsy
90.7 Ocular motor neuromyotonia 2
Richard W Hertle

Chapter 94 "My child seems to hate the bright light"
94.1 Paradoxical pupillary response
Luis H Ospina

Total running time approximately 2 hours.

Foreword

After publication of the fourth edition of this book we decided it was time that we ask two younger colleagues to assume the role of editors for the fifth edition. We were very pleased when Scott Lambert and Chris Lyons accepted our invitation to assume this responsibility. Both of them have spent time in our training programs and we recognized that they were uniquely qualified for the task. Both of them maintain broad interests in the field of pediatric ophthalmology and strabismus and their clinical and academic expertise is exceptional. They critically reviewed the previous editions of the book before organizing the chapters and contributors for this edition. They have maintained the important goal of masterfully compressing the information discussed in the book in order that it can be presented in a single volume. At the same time, every effort has been made to ensure that each chapter reflects our most current and thorough understanding of the topic under discussion. A wide range of illustrations including clinical and pathological photographs, graphs, and charts enhance and clarify the text. We consider this edition to be an essential resource for all of us interested in the care of children's visual problems and the management of strabismus. We wish to sincerely thank Scott and Chris and their collaborators for producing this excellent fifth edition.

David Taylor
Creig Hoyt

Preface

After editing the first four editions of *Pediatric Ophthalmology and Strabismus*, David Taylor and Creig Hoyt passed the torch to us for the fifth edition. We were honored to be asked, having both been involved since the early editions. However, we did wonder if textbooks are becoming a victim of disruptive innovation in the field of medical education. We are both actively involved in teaching of Medical students, Residents and Fellows and have witnessed the increasing use of online searches by trainees to access medical information. As a result, one of the criteria we decided on from the onset was that the content of each chapter of the fifth edition must be far superior to the results of an internet search on the topic. We believe that every chapter in this book has exceeded this goal.

Each chapter in the fifth edition has been written or updated by one of the foremost experts in the field. Many new chapters have been added to the fifth edition reflecting advances in the field of pediatric ophthalmology. These chapters range from the use of anti-VEGF agents to treat retinopathy of prematurity, the use of optical coherence tomography to image a child's eye, minimally invasive strabismus surgery (MISS), the latest technology for vision screening and apps for pediatric ophthalmology. We have also tried to make the fifth edition very practical, adding chapters on managing refractive errors in children, delivering bad news, as well as many new line drawings to the chapter on strabismus surgery. All of the videos included with the book are now narrated and like the fourth edition, there will be a digital version of the book that can be downloaded to tablets and smart phones. We have found this to be helpful with patient and trainee education in the clinic and also a wonderful resource to look up information when examining a patient.

We have enjoyed the opportunity to make new friendships and to renew old friendships in the process of soliciting and editing chapters for the fifth edition. The level of enthusiasm was invigorating. Our hope is that this textbook will "level the field" throughout the world in the care of disorders of the eye.

The Elsevier team have been wonderful to work with. Sam Crowe has been on the front lines corresponding with authors, reviewing the format of chapters and moving the book along. Russ Gabbedy has helped us understand the production process and the marketing of the book and Julie Taylor has helped considerably with the proof stage and project management.

Introduction

Aided by ophthalmologists in many countries, I have given an international and a personal perspective to the intertwined specialties of pediatric ophthalmology and strabismology. I had to leave out many important contributors to pediatric ophthalmology, naming mostly those long retired or dead.

Early beginnings

Eye diseases are common in children so they have always been found in doctor's practices. Hippocrates and his pupil Galen, the Greco-Roman philosopher, anatomist (and gladiators' physician), must have had many children as patients. So must the physicians distinguished in the management of eye conditions such as William Briggs in 17th century London and Jacques Daviel in Paris. In the 18th to 19th centuries, William Mackenzie in Glasgow, John Cunningham Saunders (a founder of Moorfields Eye Hospital), Benjamin Travers, James Wardrop, and William Cheselden in London all wrote about children's eye conditions and practiced surgery with techniques and instruments developed for adults (Fig. 1.1). In continental Europe, Georg Joseph Beer, founder of the first eye hospital, in Vienna in 1786, Hermann von Helmholtz, Franciscus Cornelis Donders, and others were pioneers of management of children's eye diseases.

Setting the background

- *Anesthesia*: Joseph Priestley and Thomas Beddoes of the philosophical–scientific 18th century Lunar Society, and Humphry Davy, discovered the anesthetic properties of nitrous oxide. Hepatotoxic chloroform and explosive ether were also used as early anesthetics, the latter being used for infant glaucoma at one hospital, which carried on to nearly the 21st century, until a flashback occurred through a "safety venting" system opening onto a roof being repaired with a blowtorch.
- *Antisepsis*: Alexander Gordon (Scotland), Louis Pasteur (France), Oliver Wendell Holmes (USA), Ignaz Semmelweiss (Hungary), and Charles White (England) pointed towards the germ theory of infection. Joseph Lister proved it with the effects of carbolic acid and layered dressings, leading to previously unbelievable low infection rates.
- *Antibiotics*: The discovery of penicillin by Alexander Fleming, Ernst Chain, and Howard Florey, and of sulfonamides by Gerhard Domagk, revolutionized management of eye diseases in children.

The 19th century: the rise of children's hospitals

Hospitals caring specifically for children by doctors with pediatric skills, if not formal training, led to the pediatric super-specialties. In London in 1741, Captain Thomas Coram, supported by William Hogarth and George Frideric Handel, established of the Foundling Hospital, a home for healthy abandoned "foundlings"; it had no medical role but had

Fig. 1.1 Cataract Surgery as practised by John Cunningham Saunders in 1811. A small team would hold the child still; restrained, the surgery would be over in a flash, the child hopefully young enough and drugged enough with liquor or opium to forget. William Mackenzie of Glasgow said, in answer to the question of when to operate, "The answer decidedly is to operate in infancy". He was aware that late operation was accompanied by a worse visual outlook and more difficult surgery. © Gillian Lee Illustrations.

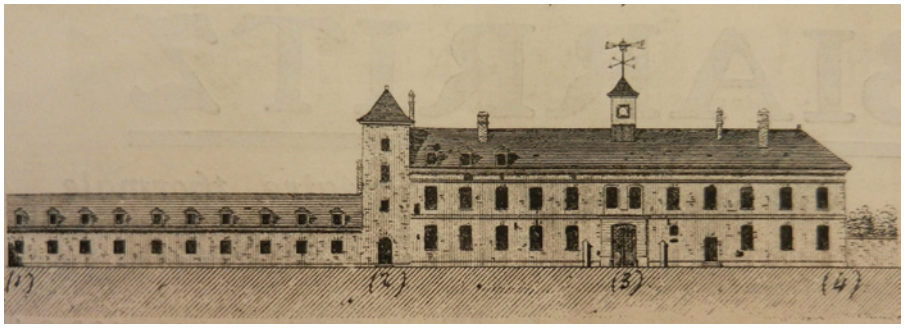

Fig. 1.2 In 1769 the London Dispensary was opened at Holborn by George Armstrong, accepting child out-patients but closed soon after. Similar institutions offered help to children during the chaos of the French Revolution but the first hospital for the treatment of sick children was the Hôpital des Enfants-Malades founded in 1802 on the Rue de Sèvres in Paris (above). Hospitals in Frankfurt, Munich, Hamburg, St. Petersburg soon followed. The Hospital for Sick Children, Great Ormond Street, London was the first in the English speaking world; it opened on the St Valentine's day in 1852. The child mortality rate at that time was truly shocking: of 50,000 persons dying annually in London, 21,000 were children under 10. From Lereboullet, Pierre. L'Hopital Des Enfants-Malades (1802-1913). Paris Médical. 1913–14;1:3–19. Written as the hospital was being demolished.

a profound social influence. Great Ormond Street (GOS) Hospital was later founded in an adjacent street. L'Hôpital des Enfants-Malades was founded in 1802 in Paris (Fig. 1.2), becoming the first effective children's hospital[1]; others in Europe soon followed.

Children's hospitals in Philadelphia (1855) and Toronto (1875), on a similar model to GOS, were for children and their pediatricians – this was the vanguard of scientific medicine. The ophthalmologists there learnt pediatric skills and embraced scientific medicine. Early GOS ophthalmologists included Robert Marcus Gunn, Edward Nettleship, George Coats, and Philip Doyne.

The 20th century: ophthalmology super-specialization in North America

By the early 20th century, the major specialties, including ophthalmology, were established. Specialist societies were often conjoined: the American Academy of Ophthalmology only separated from its partner, Otolaryngology, in 1979.

Dr Frank Costenbader of Washington DC, who had trained in ophthalmology and otolaryngology, developed particular expertise in children's eye disorders. In 1943, he limited his practice to children, becoming the first pediatric ophthalmologist.

After World War II, the pace of specialization and the quality of training quickened. Ophthalmologists trained as super-specialists through dedicated fellowships, replacing the previous apprenticeship system, i.e. "sitting at the feet" of a well-known teacher.

Dr Costenbader's first trainee, Dr Marshall Parks, became the United States' most prominent pediatric ophthalmologist with wide pediatric expertise. This first fellowship program was followed by many others run by Hermann Burian, Arthur Jampolsky, Phil Knapp, Gunter von Noorden, Martin Urist; and in Canada by Jack Crawford in Toronto, William G Pearce in Alberta, and John Pratt-Johnson and Andrew Q McCormick, both in Vancouver. Their fellows included most of the best-known names today; North American Pediatric Ophthalmology is what it is today because of their clinical activity, research, teaching and collegial behavior.

The 20th century in Europe, Asia, South America, the Middle East, Africa and elsewhere

Most European countries had, and many still have, apprenticeship systems to enter pediatric ophthalmology as a consultant. Since the 1970s, many European ophthalmologists have undertaken a fellowship before applying for definitive positions. Fellowship training in pediatric ophthalmology is available worldwide and can be supported by work in state health services, national, or international grants, including grants from the International Council of Ophthalmology for ophthalmologists from developing countries. Table 1.1 shows *some* of those who, by their teaching, research, and clinical acumen, have forged the current state of our profession.

Table 1.1 Key pioneers in pediatric ophthalmology from Europe, Asia, South America, the Middle East, Africa, and elsewhere

Above is a list of *some* of those who by their teaching, research, writing, acumen and example have forged the current state of our profession. I was greatly helped in compiling this list and the chapter as a whole by generous colleagues in 35 countries but it has been impossible to include more than a small proportion of the thousands who have made up our trainers, teachers and those who have taught by example and by lucid writing. I have included a few of those still living and only those whose practices have been predominantly involved with children.
Several countries not mentioned herein have predominantly generalist ophthalmologists who also look after children. They may not be included here despite providing high quality ophthalmology services for children and sometimes outstanding research.

Country	Name and dates (where known)	Distinguished for/in
EUROPE		
Belgium		
Belgium, Ghent	Daniel van Duyse, 1852–1924	Published extensively, mostly developmental anomalies
Belgium, Ghent	Jules François, 1907–1984	Published widely, mostly on genetic diseases
Belgium, Antwerp	Adolphe Neetens	Neuro-ophthalmologist. Vitreoretinal diseases
Belgium, Ghent	Jean-Jaques DeLaey	Retinal diseases. International work
DENMARK		
Denmark, Århus	Mette Warburg, 1926–2015	Co-founder EPOS. Management of child VI. Eponymous syndrome
Holland		
Holland, Utrecht	PJ Waardenburg, 1886–1979	Ophthalmic geneticist. Eponymous syndrome
Holland, Rotterdam	AThM van Balen	Pediatric IOLs, electrophysiology
Italy		
Italy, Rome, etc.	Giovanni B Bietti, 1907–1977	Spoke 7 languages, 14 eponymous signs or diseases. Large practice: child glaucoma. Introduced cryoRx
Italy, Rome, etc.	Bruno Bagolini, 1924–2010	Great teacher, mentor, and inventive strabismologist
Norway		
Norway, Hamar	Ruth Riise, 1934–	Co-founder EPOS. Retinal dystrophies. International work
Norway, Oslo	Sigmund Spetalen, 1937–	Electrophysiology and retinal diseases. King's gold medal
Norway, Ullevål Oslo	Jan Ytteborg, 1925–	Management of congenital glaucoma throughout Norway
Sweden		
Sweden, Stockholm	Eva Lindstedt, –2014	VI and rehabilitation. Screening for amblyopia
Sweden, Goteborg	Kerstin Strömland	Teratology: fetal alcohol and Möbius syndromes
United Kingdom		
UK, London	Arnold Sorsby, 1900–1980	Early ophthalmic geneticist. Refractive development research. Eponymous syndromes
UK	Claud Worth, 1869–1936 Bernard Chavasse, 1888–1941 James H Doggart, 1900–1989 T Keith Lyle, 1904–1987 Kenneth Wybar, 1921–1992	Writers of early publications (see text)
UK, Leeds	Brian Harcourt, 1934–1987	Prominent in national and international pediatric ophthalmology development
UK, London	Barrie Jay, 1929–2007	Co-founder EPOS. Ophthalmic genetics

Continued

Table 1.1 Key pioneers in pediatric ophthalmology from Europe, Asia, South America, the Middle East, Africa, and elsewhere—cont'd

Country	Name and dates (where known)	Distinguished for/in
SOUTH AMERICA		
Argentina, Cordoba	Alberto Urrets-Zavalía, 1920–2010	Spoke 8 languages; cyclovertical disorders, eponymous syndrome
Argentina, BA	Alberto Ciancia, 1924–	Eponymous syndrome, prolific author and teacher
Brazil, Sao Paulo	Carlos Souza Dias	Strabismus; multiple treatises
Brazil, Sao Paulo	Jorge Alberto F Caldeira	Strabismus, prolific author and teacher
ASIA PACIFIC		
Australia, Melbourne	J Ringland Anderson, 1894–1961	Cyclovertical strabismus and nystagmus
Australia, Sydney	Norman Gregg, KB, 1892–1966	Congenital rubella syndrome
Australia, Sydney	Frank Billson	Research and teaching. Political and international work
China, Tianjin	He Yu-shi, 1922–1981	Published on pediatric ophthalmology and strabismus
China, Beijing	Liu Jia-qi	Prolific author and teacher of pediatric ophthalmologists
India, Madurai	P Vijaylakshmi	Worldwide teaching and training and research
Japan, Tokyo	Yasuo Uemura, 1924–1996	Strabismus, amblyopia and ROP
Japan, Kyoto	Makoto Nagata, 1925–	ROP Rx, ERGs, eye surgery textbook in 6th edition
Korea, Seoul	Bong Leen Chang, 1939–	Pediatric neuro-ophthalmologist; prolific author and teacher
Korea, Seoul	Yoonae Choo	Prolific author and trainer of many university teachers
Philippines, Manila	Dr Evelyn Cortes	Founder PSPOS. Wide training. Multiple trainees
MIDDLE EAST AND AFRICA		
Egypt, Alexandria	Hussein Ali Hussein	Founded advanced surgery unit for childhood cataract
Iran, Tehran	Ziaeddin Yazdian	Established pediatric ophthalmology and strabismus in Iran. Prolific author
Jordan, Amman	Hasan Al-Kattan, 1959?–2004	1st Jordanian pediatric ophthalmologist. Prolific teacher
S Africa, Capetown	Justin van Selm, 1919–2009	Strabismus and intraocular surgeon; teacher and traveller

cryoRx, Cryotherapy; EPOS, European Paediatric Ophthalmological Society; ERGs, electroretinograms; IOLs, intraocular lenses; PSPOS, Philippine Society of Pediatric Ophthalmology and Strabismus; ROP, retinopathy of prematurity; VI, visual impairment.

Serendipity, clinical observation, and collaborative science in the advance of pediatric ophthalmology

An ophthalmologist in Sydney during World War II, Dr Norman Gregg, saw an increase in referrals for congenital cataract. He fortuitously overheard some of the mothers say they had rubella during pregnancy. The publication of his observations,[2] even though researched and refined, was not met with universal acclaim. Doggart[3] wrote, "Gregg found himself for a time withered by the pity of his cobbers in the antipodes … 'poor old Norman,' they said, 'he's gone nuts. This rubella's a fair cow' … Soon they were eating their words!" Worldwide honors soon followed, as well as two Nobel Prize nominations.

The management of unilateral congenital cataract illustrates the changing attitudes of ophthalmologists to the risks and benefits of management for the patient's best interests. Before the 20th century, success was measured more by the survival of both the patient and the eye operated on, rather than by measurably better vision. Even bilateral cataracts were left until the child was older. Treacher Collins,[4] in 1908, suggested "… to wait until the child is 10 months before operating … the cornea is so small and the anterior chamber so shallow …" Alexander,[5] in 1928, said, "… I would not hesitate to operate as early as 9 months."

Frank Juler[6] in 1921, on traumatic cataract, stated "… there is such a disease as amblyopia from disuse, that affects the eyes of children up to the age of six years, that it does not attack eyes after the age of seven, that it is not merely a standing still of the development of the retina or certain cerebral associations, but that it causes a real retrogression of the effective power …" Broendstrup,[7] in 1944, noted that not just the cataract but also the aphakia alone may be "ambliopiogenic." No details of refraction, near correction, or of any occlusion of the dominant eye were given.

Prudhommeaux,[8] in 1962, operated 65 cases: 17 were unilateral; all got good light perception or less. "Il faut alors poser la question: pourquoi doit-on opérer les cataractes congénitales unilatérales?" ("We must then ask the question: why should we operate unilateral congenital cataracts?").

Nutt[9] stated, "Uniocular cataracts are better left un-treated, except for cosmetic reasons … the visual result is always bad … the chances are that the affected eye is abnormal in some other respect." Jules François[10] wrote, "Everyone knows the uselessness of operating on unilateral congenital cataract." The general opinion everywhere then was against any intervention.

Along with the growing understanding of amblyopia, things changed. von Noorden and colleagues[11] wrote "It may be well worth while a trial to aspirate a unilateral mature congenital cataract (that is not accompanied by other anomalies) within the first days of life to be followed by immediate contact lens correction." No doubt there were some skeptics but not all were. Frey et al.,[12] a group in Washington DC, operated on and fitted a contact lens that was worn for up to 12 hours daily for 21 idiopathic unilateral congenital cataracts. Occlusion of the phakic eye was attempted. Three of the youngest, with good contact lens wear but unspecified occlusion, achieved 20/40 or better. The team wrote, "… the dictum of extreme conservatism in the management of monocular cataracts in children needs to be re-evaluated."

At this point, several groups were trying to unlock the door to successful treatment. A group in London[13] managed 23 cases with unilateral congenital cataract with surgery, contact lens, and graded occlusion. They agreed that later surgery gave worse visual results. They were looking towards very early surgery, contact lens wear, and graded occlusion, but they found that "… correction before 4 months of age produces less visual loss but we cannot specify the function within this period."

Creig Hoyt's group[14] in San Francisco preceded their study by talking with neonatologists about detecting neonatal cataracts and referring them early: they received cases almost as soon as they were born and published a case series of eight neonates with monocular cataract treated with immediate surgery, vigorous occlusion, and contact lenses. Five developed visual acuities of LogMAR 0.18 (6/9, 20/30, 0.67), three with LogMAR 0.6 (6/24, 20/80, 0.25). This was a stunning achievement, marred only by the time it took the skeptics, including myself, to believe it! It required great expertise and teamwork, the parents being pivotal. Many other cases were then similarly managed by individuals or teams, and good visual results weren't unusual and occasional cases even had high levels of binocular vision.

A debate arose regarding the risks and benefits for the affected baby. It was now possible to achieve good vision in unilateral congenital cataract. However, since the operated eye might become the best and one most used, the risks of glaucoma and other complications are high in the first weeks of life, and sympathetic ophthalmitis has been recorded, these risks may, in the parent's view, outweigh the benefits of having a "spare eye." That parental informed choice was paramount took some time to be accepted, and the weighing of risks and benefits became the basic currency of the contract with a patient.

Government funding has been behind many of the largest and best collaborative studies in many fields of science. In 1997, the Pediatric Eye Disease Investigator Group (PEDIG), a collaborative network facilitating multi-center clinical research in childhood eye disorders was formed in the USA. It has over 100 participant centers and has resulted in the publication of nearly 100 well-constructed collaborative studies. Another study, also government-funded by the National Eye Institute, is the Infant Aphakia Treatment Study (IATS), which asks vital questions on cataract management with intraocular and corneal contact lenses in 114 affected patients with long follow-up.

Although centrally funded research in children's eye diseases is most important in many other countries, much is essentially the result of diversely funded groups of collaborators. In the UK, for instance, these include the European Eye Epidemiology Consortium, the British Isles Congenital Cataract Interest Group, the British Childhood Onset Hereditary Retinal Disorders Network, the 1958 British Birth Cohort, the British Ophthalmological and Paediatric Surveillance Units, and the British Childhood Visual Impairment Interest Group.

Orthoptists and pediatric ophthalmology

Mary Maddox, the daughter of Ernest Maddox, an ophthalmologist with a deep interest in eye muscles, optics, refraction, and binocular vision, started a clinic in London in 1928, and was soon joined by Sheila Mayou, the daughter of a London ophthalmologist. At Moorfields Eye Hospital, High Holborn, they started a public clinic and school of orthoptics. Beryl Mayou travelled extensively during World War II and afterwards ran a training course, launching orthoptics in Brazil. They and other orthoptists, Vivien MacLennan, Sylvia Jackson, Joyce Mein, Jona Yoxall, and Barbara Lee in the UK, Birgitta Neikter in Sweden, Catherine Turbayne Lunn and Geraldine Tillson in Canada, and others in North America, France, Holland, South Africa, Australia, and Japan showed how orthoptists were *vital* colleagues in diagnosis and management of patients with strabismus, to the great benefit of patients and cost savings to service providers.

Early publications on pediatric ophthalmology and strabismus

In 1583, the first ophthalmology textbook, *Augendienst*, by Georg Bartisch, included the management of strabismus. The first strabismus surgery was claimed in 1751 by the English charlatan (and brilliant physiologist?) "Chevalier" John Taylor, but is generally attributed to Johann Dieffenbach in Berlin in 1839, whose tenotomy was practiced by George Critchett in 1855. A small book entitled *Squinting* by Carsten Holthouse was published in London in 1858. In 1903, Claud Worth published *Squint: its Causes, Pathology and Treatment*. It ran to six editions under his authorship and, read today, it is brilliant. Worth was succeeded by Bernard Chavasse on this book. Chevasse worked with the physiologist Charles Sherrington, embracing physiological concepts based on reciprocal innervation and reflexes. After World War II, James Hamilton Doggart published the first book on pediatric ophthalmology, *Diseases of Children's Eyes* (Fig. 1.3): it was meticulously organized and beautifully illustrated.

T Keith Lyle, a strabismologist and neuro-ophthalmologist, and a prolific author and lecturer, collaborated with The Hon Geoffrey Bridgman on the ninth edition of Worth and Chavasse's book and he also wrote prolifically on strabismus. Kenneth Wybar was the author of the strabismus section of Duke-Elder's *System of Ophthalmology*.

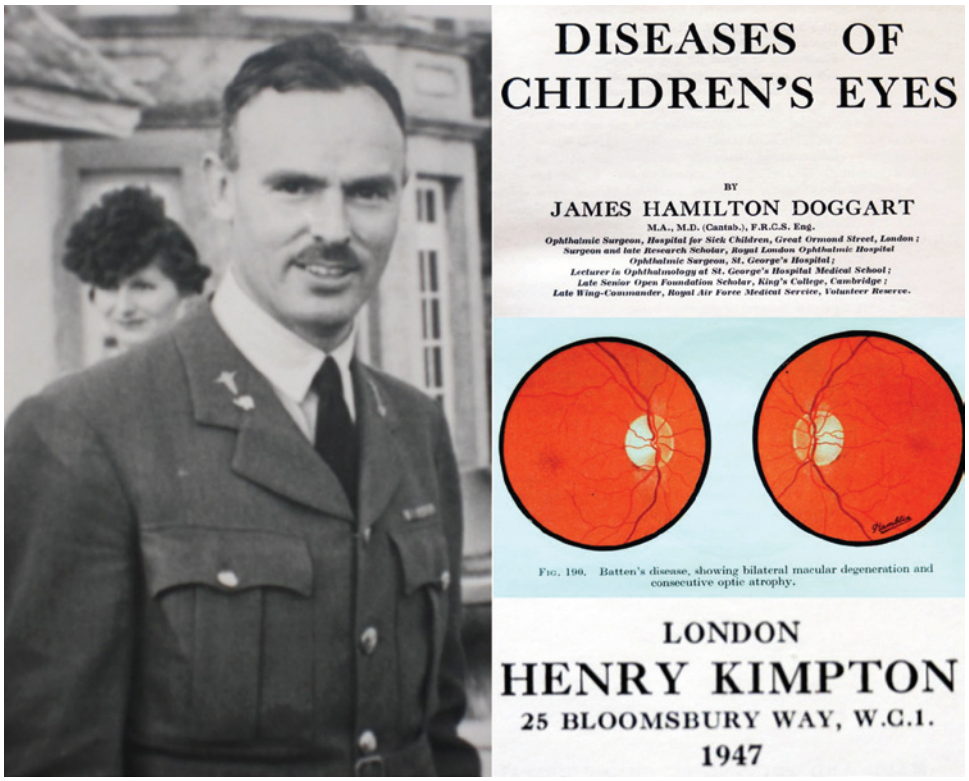

Fig. 1.3 The first textbook on pediatric ophthalmology, *Diseases of Children's Eyes* by James Hamilton Doggart (left) was published in 1947. Doggart was a mostly medical ophthalmologist who had been working in Great Ormond Street in London since at least 1937 and his main interest was in children's eye diseases. He wrote this immaculately prepared text, illustrated with 242 monochrome and colour plates both during and shortly after the World War II which was when this photograph of him was taken: it was published in London and New York in 1947 with a companion book, *Children's Eye Nursing*. This was shortly followed by *Ophthalmic Medicine* and *Slit-Lamp Microscopy* in 1949.

Other contributors to today's pediatric ophthalmology

Where would we be without David Hubel and Torsten Wiesel, Gunter von Noorden (with MLJ Crawford) and the Cambridge group working on amblyopia, the Smith Kettlewell Eye Research Institute, or the Institute of Ophthalmology in London, and so many other scientists, optometrists, instrument manufacturers, and others? It is not just people of the "eye world" to which the field of pediatric ophthalmology is indebted: in the Norwegian mining town of Røros, Dr Otto Christian Stengel (1794–1890), with brilliant observation, described Batten's disease; Carl Credé, a 19th century obstetrician, decimated ophthalmia neonatorum; and Antonie van Leeuwenhoek, a 17th century draper, invented the microscope.

The future

We cannot predict the future, but one thing is certain: the importance of research in pediatric ophthalmology. Furthermore, pediatric ophthalmologists must speak like pediatricians, think like them, and follow their way of managing patients, including the taking of a simple but detailed history, an examination that does not scare the child, well-directed further investigations, and simple, kind, honest explanations, that are understandable by both parents and their child, given by a modest ophthalmologist. We know from history that it is these things which have distinguished successful doctors, far more than the organizing of batteries of tests, brilliance in surgery, or eloquence in the lecture theatre.

Introduction

This chapter considers important issues about epidemiological studies of childhood visual impairment (VI), severe visual impairment (SVI), or blindness (Boxes 2.1 and 2.2); we synthesize current data to provide a global picture of the frequency, causes, and prevention of VI and blindness in childhood.

Specific issues in the epidemiological study of visual impairment in childhood

- Case definition: A standard definition applicable to all children continues to be challenging, see below.
- Rarity: Visual impairment and blindness in childhood are uncommon; it is difficult to obtain sufficiently large and representative samples of affected children to allow precise and unbiased study.
- Complex, multidisciplinary management: For a complete picture, information must be sought from the professionals involved in the care of VI or blind children. For many children with additional non-ophthalmic impairments or chronic disorders, this adds further complexity.
- Lifecourse approach: It is important in health research to understand the biological, environmental, and lifestyle/social influences at all life stages (preconceptional, prenatal, perinatal, and childhood), and how they combine to set and change health trajectories into adult life. Lifecourse epidemiological and epigenetics approaches are increasingly applied to the study of VI and eye disease affecting children or originating in childhood.[1]
- Developmental perspectives: In all research on children, developmental issues (as distinct from age-related issues *per se*) must be taken into account in assessing outcomes and their relationship with risk factors.
- Long-term outcomes: Assessment of meaningful outcomes, such as final visual function or educational placement, requires long-term follow-up, possibly into adult life for some outcomes. This is challenging and is increasingly addressed through health informatics research. This approach mainly relies on *routinely* collected data, often as electronic or "e" records, in health care (e health records, EHR), and other administrative systems, e.g. educational or welfare. Record (data) linkage using established methods to minimize errors creates complete datasets for analysis. This is a well-established and powerful approach in child health research[2] and has good potential for research in pediatric ophthalmology.
- Ethics. Issues of proxy consent (by parents) and children's autonomy increasingly impact on participation in ophthalmic epidemiological research.

Framing the question

Clinical or service provision decisions are ideally based on "three-part questions" reflected in the PICO mnemonic (**P**opulation **I**ntervention/**C**omparator and **O**utcomes). Thus a good question incorporates the reference population (e.g. children under 2 years with infantile esotropia), the

Box 2.1

What is ophthalmic epidemiology?

Ophthalmic epidemiology (literally "studies upon people") has both its origins and its applications in clinical and public health ophthalmology.

The aim of primary or secondary (e.g. systematic literature review, meta-analysis and modeling) research is to:

- provide quantitative information for planning services
- shed light on the causes and natural history of ophthalmic disorders
- enhance the accuracy and efficiency of diagnosis
- improve the effectiveness of treatment and preventive strategies

Box 2.2

Epidemiological reasoning

This is based on the following principles:

- the occurrence of disease is not random, rather a balance between causal and protective factors
- that disease causation, modification, and prevention are studied by systematic investigation of populations to gain a more complete view than can be achieved by studying individuals
- that any inference that an association between a risk factor and a disease is causal can only be made after two specific steps in reasoning: (1) the exclusion of chance, bias, or confounding as alternative explanations for the observed association, and (2) evidence of a consistent and strong statistical association, which is biologically plausible, in the correct temporal sequence, and preferably exhibits a dose–response relationship

risk factor or the intervention and, where appropriate, a comparator (e.g. preterm versus term birth, or strabismus surgery versus no surgery), and the outcomes (e.g. parent-reported improvement in cosmesis and objective improvement in alignment and stereopsis). The focus of the question – whether frequency, causes, or treatment/prevention of disease – determines the study design required to address it, e.g. a descriptive, cross-sectional prevalence survey, or an analytical study (either observational, e.g. case–control or cohort studies, or interventional, e.g. randomized controlled trials).

Who is a visually impaired child?

The affected child, their parents, teacher, social worker, rehabilitation specialist, pediatrician or ophthalmologist are likely to have differing, but equally valid answers to this question. The issue is not which is "correct" but which definition to choose for epidemiological research, for assessing/planning services and in clinical practice.

A standardized definition is necessary in order to compare the frequency, causes, treatment, or prevention of VI within and between countries and over time. The World Health Organization (WHO) classification (Table 2.1) is based on the acuity in the better-seeing eye (i.e. at the level of the person not the eye) and measured with optical correction, if usually worn. Until recently, uncorrected refractive error fell outside this definition, as the early categories used best corrected visual acuity. It has been adopted for epidemiological research, despite the difficulties of measuring visual acuity in very young children and those unable to cooperate with formal testing.

Table 2.1 World Health Organization classification of visual impairment

Level of visual impairment	Visual acuity in better eye with optical correction (if worn)
Slight, if acuity less than 6/7.5	6/18 or better
Visual impairment (VI)	Worse than 6/18 up to 6/60 (logMAR 0.5 to logMAR 1.0)
Severe visual impairment (SVI)	Worse than 6/60 up to 3/60 (logMAR 1.1 to 1.3)
Blind (BL)	Worse than 3/60 (worse than logMAR 1.3) to no light perception or Visual field <10 degrees around central fixation

MAR, Minimum angle of resolution.
6/7.5 = logMAR 0.10, 20/25, 0.8; 6/18 = logMAR 0.48, 20/60, 0.33; 6/60 = logMAR 1.0, 20/200, 0.10; 3/60 = logMAR 1.3, 20/400, 1.31.0.

New methods for testing vision in young children are likely to emerge from technological innovations. Nevertheless, there is a need in epidemiological research and also arguably in clinical practice for a better classification system applicable to children of different ages. This should consider other aspects of vision such as near acuity, visual fields, binocularity, and contrast sensitivity, as well as normal visual development. However its development will be challenging.

Adoption of the WHO International Classification of Functioning, Disability and Health (ICF) reflects the new underpinning framework for understanding disability and the relationship between health conditions, personal, and societal factors.[3] In tandem, the importance of measuring patient-reported outcomes (patient-reported outcome measures, PROMs) conventionally using self-completed questionnaires is now embedded within many health care systems, so as to help improve the quality of care. Two types of PROMs are particularly relevant to pediatric ophthalmology.[4]

1. *Functional vision* assesses the child's ability (difficulty or ease) for tasks of daily living dependent on vision, such as navigating independently.
2. *Vision-related quality of life* elicits the child's and/or parents' view of the gap between the child's expectations and his/her actual experiences with respect to the physical, emotional/psychological, cognitive, and social functioning of the child impacted by the visual disorder and its therapy.[4]

Measures of frequency and burden of childhood visual impairment

The analogy of a barrel of white and red grapes with a hole in the bottom can be used to illustrate measures of frequency and the burden of disease. In this analogy, white grapes represent those without the condition of interest ("healthy") and red grapes represent those who have the condition of interest ("diseased"). The total number of grapes (white plus red) in the barrel represents the population of interest (e.g. all children aged 0–15 years). The *proportion* of all the grapes in the barrel that are red at any given time denotes *prevalence*.

The *total number* of red grapes in the barrel at any given time reflects the *magnitude* or *burden of the disease* in the population. The *speed* at which red grapes enter the barrel equates with *incidence*, i.e. the rate of new occurrence of disease in a given population over a specified time. For example, in the UK the annual incidence of congenital cataract was estimated to be 2.5 per 10,000 children aged ≤1 year in 1995.[5]

However, the proportion in a population that is diseased (i.e. the prevalence) is dynamic, as some grapes (both red and white) leave the barrel through the hole in the bottom. The "diseased" (i.e. red grapes) can leave through mortality, which may be higher amongst those diseased, or by out-migration, or as a result of treatment that means they are no longer classified as diseased. At the same time, more red and white grapes are being added to the barrel. The prevalence (proportion of grapes that are red) at any given time is, therefore, a balance between how fast red (and white) grapes are added and how quickly they leave the barrel. For example, the current UK prevalence in childhood of amblyopia with an acuity of worse than logMAR 0.3 (6/12, 20/40, 0.5) is about 1%.[6]

These measures of disease frequency do not, however, give any indication of the health economic impact or consequences of the disease. These aspects are important in order to determine priorities and allocate resources, providing a metric at population level that complements patient-reported outcomes assessed at an individual level. Measures of "utility" such as disability-adjusted life years (DALYs) or quality-adjusted life years (QALYs) are often used for this purpose, as they incorporate morbidity or mortality into a single measure that can be used to compare different states of health within and between countries. Blindness is categorized in the range 0.43 (blindness from refractive errors) to 0.6 (blindness from glaucoma), where 0 equates to perfect health and 1 equates to death.[7]

Prevalence and incidence data provide *complementary* information. Incidence identifies and monitors trends *over time* that reflects changing exposure to risk factors, or emergence of new exposures. Incidence data are useful for planning the provision of services and research, e.g. estimating likely recruitment time in clinical trials. Prevalence indicates the proportion of the population with the condition *at a given time*. It helps allocate resources and can be used to evaluate services, if changes in prevalence can be attributed solely to changes in outcome or duration of disease as a result of treatment rather than changes in underlying incidence.

Potential sources of information about visual impairment

There are a number of sources of epidemiological information about childhood VI or blindness but, in reality, only a few are available in most countries. This explains the currently incomplete picture (Box 2.3).[8]

1. *Population-based prevalence studies.* These represent a source of precise, representative estimates of burden (frequency) and causes. However, the few studies of whole populations of children with VI, such as prior and upcoming national birth cohort studies in the UK,[9] need to be very large (a study of 100,000 children is required in an industrialized country to identify 100–200 children with VI or blindness): these are costly and difficult to do.
2. *Population-based incidence studies*. Studies of all-cause incident (newly occurring) VI are even more difficult, explaining the rarity of studies of this kind.[10]
3. *Special needs/disability registers, surveys, and surveillance.* Specific studies and/or surveillance systems[11] or registers of childhood disability[12] can provide information about VI, but it is important to recognize the potential for bias, as certain visually impaired children may be over-represented in these sources, e.g. those with multiple impairment.
4. *Studies of intervention/service-based populations*. In developing countries, studies of children in special education provide information on causes, but these may be biased because many affected children (particularly with additional non-ophthalmic impairments) do not have equal access to special education. With other service-based studies, e.g. from clinic attendees, the interpretation of findings and their extrapolation to other populations needs to take these biases into account.
5. *Visual impairment registers*. These exist in many industrialized countries but, if registration is voluntary and not a prerequisite for accessing special educational or social services, registers may be incomplete as well as biased, reflecting differences in parental preferences and professionals' practices regarding registration of eligible children.[13,14]
6. *Visual impairment teams*. Increasingly, children in industrialized countries are evaluated by multidisciplinary teams. They can provide useful information if these teams serve geographically defined populations.
7. *Disorder-specific ophthalmic surveillance schemes.* Uncommon eye conditions in children can be studied using population-based surveillance schemes, such as those for congenital anomalies (e.g. anophthalmia, microphthalmia, congenital glaucoma)[15,16] or others for adverse drug reactions (e.g. visual loss with vigabatrin).[17] Under-ascertainment can occur. In the United Kingdom, the national active surveillance scheme includes all senior ophthalmologists (the British Ophthalmological Surveillance Unit).[11] It supports studies of uncommon disorders, including the first population-based incidence

Box 2.3

Key gaps in current knowledge about epidemiology and the impact of visual impairment on children

For many regions of the world, there is currently very limited contemporary population-based information about frequency, burden, and etiology.

There is limited understanding of the following:

- long-term ophthalmic disease, general and mental health, educational, occupational, and social outcomes for affected children and the adults they become
- social, economic, and personal impact on the families of affected children
- economic consequences – including financial and other costs associated with medical treatment, rehabilitation, social support and care, as well as loss of productivity

The opportunities and infrastructure for research to address these questions are better in industrialized countries, so there is currently a differential information gap.

study of SVI and blindness in childhood.[10] This is an important model for pediatric ophthalmic epidemiological research.

8. *Community-based rehabilitation programs.* In many developing countries, rehabilitation of blind and VI children is occurring within the community. Where the size of the catchment population is known, it is possible to estimate prevalence and obtain population-based data on causes.[18]
9. *Case ascertainment using key informants.* In many developing countries, it may be possible to identify key community and religious leaders, health care workers, and others who know their communities well and thus can identify children believed to have VI or ocular disorders. This can be combined with the size of the population at risk, to estimate prevalence and provide population-based data on the causes.[18,19]
10. *Household surveys* are commonly used in many low-income countries to collect data on a range of health indices. This approach can also be used to identify children who are blind.[20]
11. *Data modeling* can also be used for specific conditions, as has recently been used to estimate the global incidence of blindness and visual impairment from retinopathy of prematurity.[21]

Regardless of the sources, ascertainment is often incomplete and/or biased. For example, in industrialized countries, families from socially disadvantaged groups or ethnic minorities are less likely to participate in research on health services for visually impaired children.[12] Participation/selection bias affects our ability to generalize findings, especially in research on rare disorders. Also, in some communities in low-income countries, having a disabled child is a source of stigma, which can lead to under-ascertainment. Using multiple sources generally provides a more complete and reliable picture of causes and frequency of childhood VI.[22,23]

Impact of visual impairment

Visual impairment in childhood impacts on all aspects of the child's development and shapes the adult he/she becomes, influencing employment, social prospects, and lifelong opportunities.[13–15] Although the prevalence and incidence of VI are lower in children than in adults, the years of life lived with VI ("person-years of visual impairment") are considerable.[24] Personal and social costs are important, but difficult to measure (see Box 2.3). The economic costs of childhood VI in terms of loss of economic productivity are significant,[25] a quarter of the costs of adult blindness in some countries.[26] For example, in India an estimated annual cumulative loss of gross national product attributable to childhood VI was US$ 22 billion.[26]

Visual impairment in the broader context of childhood disability

Multiple impairments

In high-income countries, at least half of all severely visually impaired and blind children also have motor, sensory, or learning impairments or chronic systemic disorders which impact on development, education, and independence.[10,27] In low-income countries, the proportion is probably smaller, reflecting the incidence of conditions such as ophthalmia neonatorum, which causes purely ocular disease, and the high mortality rates among children who are blind from conditions associated with multiple impairment, for example congenital rubella syndrome, meningitis, or brain tumors.

For *research* on etiology and interventions, and for provision of services, it may be helpful to think about two separate populations:

1. children with isolated VI;
2. children with VI and other impairments or systemic diseases.

Mortality

Children with visual impairment are more likely to die than other children. In low-income countries,[28,29] children who become blind from keratomalacia (acute vitamin A deficiency) have a very high mortality rate. Other blinding conditions are also associated with high mortality, e.g. measles infection, meningitis, congenital rubella syndrome. In high-income countries, visually impaired children also may have higher mortality rates: in the UK, 10% of SVI or blind children die within a year of diagnosis.[10]

Prevalence studies of older visually impaired children exclude those who died before school age. This underestimate of the true frequency results in bias.

Groups at high risk of visual impairment

In research and resource allocation, VI should be viewed in the context of other childhood disabilities. The social determinants of visual health are poorly defined, but some children are at increased risk of visual loss: children with low birth weight, those who are socioeconomically deprived or from ethnic minorities.[10] Because these higher risk groups are also less likely to participate in health services research,[30] selection bias may occur through sociodemographic factors.

Frequency of childhood visual impairment and blindness

Prevalence

In the absence of direct data for many settings, an approach has been developed to estimate a proxy prevalence based on the association between the prevalence of blindness in children and the under-5 mortality rates (U5MRs) for a country.[31] In high-income countries with U5MRs less than 20 per 1000 live births, the prevalence of blindness is approximately 3–4 per 10,000 children. By contrast, in countries with U5MRs of >200 per 1000 live births (e.g. the poorest countries in sub-Saharan Africa), the prevalence of blindness is nearer 12–15 per 10,000 children, as shown in Fig. 2.1. This reflects three factors:

1. exposure to risks and potentially blinding conditions not found in affluent regions (e.g. vitamin A deficiency, cerebral malaria);
2. the occurrence of conditions adequately controlled elsewhere (e.g. measles infection through immunization);

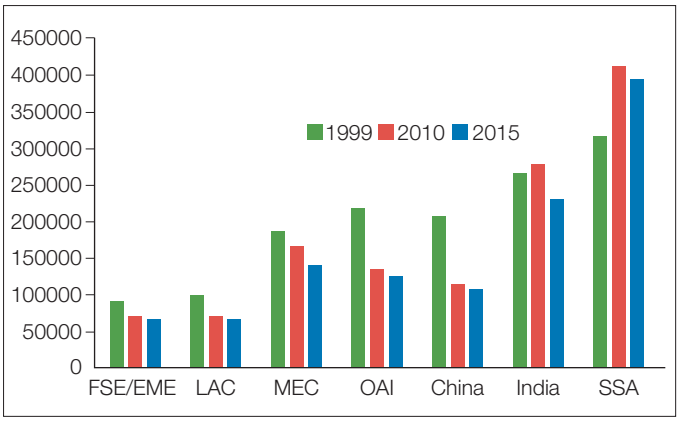

Fig. 2.1 Magnitude of blindness in children, by World Bank region. EME, Established Market Economics; FSE, Former Socialist Economics; LAC, Latin America and Caribbean; MEC, Middle East Crescent; OAI, Other Asia and Islands; SSA, Sub-Saharan Africa. Note: World Bank regions have changed over time. Data are presented according to groupings as in 1990 to allow comparison over time.

3. limited access to services and treatments that ameliorate disease progression (e.g. management of retinopathy of prematurity [ROP]) or that restore visual function (e.g. high-quality management of cataract).

VISION 2020 was launched in 1999, when it was estimated there were 1.4 million blind children in the world,[28] (using U5MRs for 1994 to reflect the midpoint of the 16 years of childhood and total child population of each country for 1999). Fig. 2.1 shows these data by World Bank regions, i.e. grouping countries by composite development indicators, such as maternal education level, which predict general child health and are associated with ophthalmic disease and visual impairment. The figures were revised in 2010 and, because of falling U5MRs, the estimate had fallen by 10% to 1.26 million.[32] A further revision in 2015, also shown in Fig. 2.1, shows an additional decrease to 1.14 million. However, there has been a differential decline by region, being greatest in China and "Other Asia and Islands" regions. In both India and sub-Saharan Africa, the 2015 estimates are lower than in 2010, reflecting improved child survival as well as a leveling off of the number of children aged 0–16 years. Nevertheless, these regions have the highest estimated absolute number of blind children, reflecting higher prevalence in larger total child populations.

Prevalence and incidence studies reported since 2000 have used various approaches. As shown in Table 2.2 and Fig. 2.2, there is a trend of higher prevalence in low-income countries, such as Sudan, Bangladesh and India, which increases as under-5 mortality rates increase. However, the low prevalence estimates for sub-Saharan African countries are probably artefactual, arising from methodological or cultural issues with the key informant method used for case ascertainment. Another explanation is that blind children in Africa have a very high mortality rate. The prevalence of VI is still not known for many regions.[32] In most settings, SVI and blindness (BL) account for one-third of all levels of visual impairment. In high-income countries, the combined prevalence of VI, SVI, and BL is about 10–22 per 10,000 children aged <16 years, while in some developing countries it is 30–40 per 10,000.[29]

Incidence

Contemporary incidence data are lacking for many countries. Since 2000, there have only been two incidence studies reported (see Box 2.3 and Table 2.2). In the UK, from a population-based study, the age group-specific incidence was reported to be highest in the first year of life at 4.0 per 10,000 per year, with the cumulative incidence (lifetime risk) increasing to 5.9 per 10,000 by 16 years of age.[10] This is likely to be applicable to countries with similar socioeconomic development and access to services, but the incidence in many lower income countries is probably higher.

Causes of visual impairment

The WHO classification has helped us to understand the relative importance of the different causes of VI, including comparisons between countries and within countries over time. This uses the principal "anatomical site" affected, as well as the underlying etiology, categorized according to the timing of action (Table 2.3).[33] It is now used extensively worldwide.

Variation by region and over time

The causes of visual impairment in children in a country reflect the balance between the biological, environmental, and social determinants of ophthalmic disorders and the strategies, policies, and resources available for their prevention or treatment – hence the regional variation in the relative importance of different disorders (Tables 2.4 and 2.5). Over the last few decades, levels of socioeconomic development have changed rapidly, together with greater provision of eye care services for children. Both factors influence the pattern of causes of blindness.[34]

Data from studies published since 2000, which used a variety of data sources ranging from special schools to visual impairment registers, are summarized in Table 2.6 (sources listed online). Many studies used the WHO categories of visual loss and classification system, making the data directly comparable. However, where necessary, data from other studies have been re-grouped to allow comparison. Lesions of the higher visual pathways, and the context of prematurity, predominate in the wealthiest countries. Acquired conditions of childhood leading to corneal scarring only occur in the poorest countries.

Insufficient data on the causes have been published between 1999 and 2015 to allow change over time to be assessed for this relatively short time period. Taking a longer-term perspective, several patterns emerge. First, in high-income countries, ophthalmia neonatorum and other causes of corneal scarring have substantially diminished and the outcomes of surgery for cataract and glaucoma have improved. At the same time, survival of extremely preterm infants has improved, meaning that cerebral VI and retinopathy of prematurity (ROP) have increased in incidence, and the inherited retinal dystrophies have become relatively more important.[18] Second, corneal scarring is declining in importance in the poorest regions, reflecting socioeconomic development and public health interventions for the control of measles and vitamin A deficiency among pre-school-age children. In many countries in these regions, un-operated cataract, or poor outcomes after surgery, are now the commonest avoidable cause of blindness. Another change is the dramatic increase in blindness due to

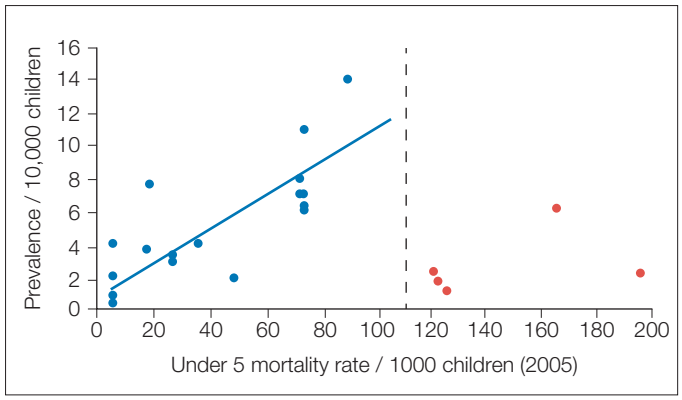

Fig. 2.2 Under-5 mortality rates (for 2005) and blindness prevalence (per 1000 children) – all countries. Studies from non-African countries are shown in blue. Studies from African countries are shown in red.

ROP, initially in Latin America and Eastern Europe in the 1990s and now in South East Asia.[35] This reflects the expansion of neonatal care services of variable quality with increased survival of premature babies. In 2000, it was estimated that 32,300 (uncertainty range 24,800–44,500) infants became blind or visually impaired due to ROP each year.[21]

Other sources of variations in the pattern of causes

The relative importance of disorders will also vary with the level of visual impairment studied. Albinism and congenital cataract are relatively more important if children with all levels of VI (VI, SVI, or BL) are studied, whereas ROP and cortical visual impairment are more important if only those with blindness are studied. Patterns may differ according to whether prevalent or incident cases are studies, as survival may be important. This may be particularly relevant in countries which have limited access to specialist health care.

None of the data presented in this chapter include children with visual impairment due to undiagnosed or uncorrected refractive error alone. This represents a large population of children – possibly 12 million currently – the majority of whom live in Southeast Asia and have uncorrected myopia (see Box 2.3).

Prevention of visual impairment and blindness in childhood: VISION 2020

Children are a priority in VISION 2020,[31] the global initiative for the elimination of avoidable blindness led by WHO and the International Agency for the Prevention of Blindness. As the causes of visual loss vary, country-specific plans and programs are being developed and implemented, based on the priorities for prevention, treatment, and rehabilitation. All programs combine disease-control strategies with the development of human resources, technology, and infrastructure. In many countries, these programs will interface with existing broader governmental initiatives to improve the health of children or improve services for children with disability. For example, reducing blindness due to ROP requires improvement of

Table 2.3 Classification of the causes of childhood visual impairment or blindness, according to the anatomical site(s) affected, and the etiological factors by their timing of action

Anatomical site(s) affected	Etiological factor(s) by timing of action
WHOLE GLOBE/ANTERIOR SEGMENT	**PRENATAL**
Microphthalmia/anophthalmia	Genetic/genomic
Anterior segment dysgenesis	Autosomal recessive or dominant
Coloboma – multiple sites	X-linked
Others	Chromosomal
GLAUCOMA	Mitochondrial
Primary	Hypoxia/ischemia
Secondary	Infection
CORNEA	Prenatal drug
Sclerocornea	Others
Keratomalacia	Presumed, but factor unknown
Other corneal scar	**PERINATAL/NEONATAL**
Dystrophy	Hypoxia/ischemia
LENS	Infection
Cataract	Non-accidental injury
Aphakia/pseudophakia	Others
Subluxed	Presumed, but factor unknown
UVEA	**CHILDHOOD**
Anidiria	Tumor
Uveitis	Nutritional
Coloboma – single site	Infection
RETINA	Hydrocephalus/raised intracranial pressure
Retinopathy of prematurity	Hypoxia/ischemia
Retinal and macular dystrophies	Abusive trauma
Albinism	Accidental injury
Retinitis/neuroretinitis	Harmful traditional practices
Retinal detachment	Specific systemic disorders
Retinoblastoma	Presumed, but factor unknown

Table 2.6 Estimates of the number of blind children and the major avoidable causes for a population of 10 million people, by level of economic development

Economic development	Blindness prevalence estimate[a] (/10,000)	Children (N)	Blind children per 10 million total population (N)	Major avoidable causes
High	3–4	2 million	600–800	Cataract Glaucoma Retinopathy of prematurity Non-accidental injury
Medium	5–7	3 million	1500–2100	Retinopathy of prematurity Cataract Glaucoma
Low	8–11	4 million	3200–4400	Cataract Corneal scarring from VADD; ON; measles Retinopathy of prematurity Glaucoma
Very low	12–15	5 million	6000–7500	Corneal scarring from VADD; ON; measles; HTER Cataract Glaucoma

[a]Estimate derived from association with under-5 mortality rates.
HTER, Harmful traditional eye remedies; ON, ophthalmia neonatorum; VADD, vitamin A deficiency disorders.

neonatal services to prevent severe disease from occurring, as well as secondary prevention through screening and early treatment. Table 2.6 lists the main "avoidable" (preventable or treatable) causes of visual impairment across the world.

Strategies to prevent visual impairment or blindness can be categorized as follows:

1. Primary prevention: to prevent the occurrence of ophthalmic disease. Examples include high-coverage rubella immunization programs, preventing congenital rubella-associated cataract; vitamin A supplementation and measles immunization to prevent corneal scarring; face washing and antibiotic treatment to control trachoma; avoidance of ocular teratogens in pregnancy through public and antenatal health education campaigns; excellent neonatal care to prevent ROP, and preconception genetic counseling of families with genetic eye disease.
2. Secondary prevention: to prevent established ophthalmic disease from causing serious visual loss. This includes both screening and surveillance to ensure early detection

and prompt referral of children with suspected ophthalmic disease, such as cataract.[36] It incorporates prompt treatment by pediatric eye care teams specializing in disorders such as ROP, cataract, glaucoma, and amblyopia.

3. Tertiary prevention: to maximize residual visual function and prevent disadvantage due to established visual impairment. This includes interventions aimed at improving visual function even though good vision cannot be achieved, e.g. management of late-presenting childhood cataract or optical iridectomy for central corneal scarring. Tertiary prevention also incorporates assessing and meeting special educational needs, providing low-vision devices and assistive technologies, mobility training, and providing social support and services to families of children with irreversible visual loss.

The role of ophthalmic professionals in prevention of childhood visual impairment

Ophthalmic professionals have a key role in the implementation of strategies through their ability to:

- Provide specialist pediatric ophthalmic care, combining medical, surgical, and optical management of specific disorders;
- Collaborate with non-ophthalmic colleagues. This includes providing education and training as required to pediatricians, family doctors, optometrists, or community eye workers, to ensure implementation of programs aimed at early detection and prompt referral of children suspected of having eye diseases, those at high risk for VI, those with major neurodevelopmental disorders, or those with a family history of blinding eye disease. One such example is working closely with neonatologists to establish appropriate screening and treatment for ROP;
- Contribute to multidisciplinary VI teams, ideally combining medical, educational, and social service professionals, to ensure comprehensive and coordinated care of all VI children and their families;
- Contribute to assessments of special educational needs and certification of eligibility for special services, in particular notification to VI registers;
- Contribute to monitoring VI in their population;
- Participate in epidemiological research that strengthens the evidence base for practice and policy.

EMBRYOGENESIS AND EYE DEVELOPMENT
EYE ORGANOGENESIS (FOURTH TO EIGHTH WEEK GESTATION IN HUMAN)
DIFFERENTIATION AND MATURATION OF ELEMENTS
EMMETROPIZATION
REFERENCES

In this chapter we will discuss the organogenesis of the eye. The differentiation of the components of the eye will then be reviewed separately.

The vertebrate eye is formed through interactions between neuroepithelium, surface ectoderm, and extraocular mesenchyme.[1] The neuroectoderm gives rise to the retina, iris, and optic nerve; the surface ectoderm forms the lens and corneal epithelium; and the extraocular mesenchyme comprising mesodermal and neural crest cells gives rise to the corneal stroma, corneal endothelium, extraocular muscles, and fibrous and vascular coats of the eye.[2]

There are three main periods in the prenatal development of the eye. The first (embryogenesis) includes the establishment of the primary organ rudiments. It finishes around the end of the third gestational week, when the optic groove (optic sulcus), precursor of the eye, appears on either side of midline at the expanded cranial end of the open neural folds. The second period (organogenesis) extends to the end of the eighth week and includes the development of the primary organ rudiments. Thereafter, the third period (differentiation) involves the differentiation of each of the primitive organs into a fully or partially active organ. During this period, the retina, optic nerve, vitreous, lens, and angle structures develop (Table 3.1).[3,4]

Embryogenesis and eye development

Early vertebrate eye formation follows a conserved sequence of events. Following gastrulation, the eye field is specified in the anterior neural plate. The first morphological landmarks are bilateral indentations (optic sulci or pits) at approximately 22 days in the neural folds at the cranial end of the embryo.

Eye organogenesis (fourth to eighth week gestation in human)

Fourth week

The optic pits deepen and form the optic vesicles (OVs), which are evaginations of the lateral walls of the diencephalon. The OVs are connected to the forebrain by the optic stalk (a short tube that eventually forms the optic nerve; Fig. 3.1A,B). During this period, interaction between the OV and surface ectoderm (SE) induces the lens placode, and the wall of the OV in contact with the surface ectoderm also thickens to form the retinal disc. Towards the end of the fourth week a process of invagination begins to transform the OV into the optic cup (OC). Also at this time, the primordia of the extraocular muscles appear as condensations in the periocular mesenchyme. Disruptions in these early steps lead to severe congenital anomalies, including absent eyes (anophthalmia), small eyes (microphthalmia), and optic fissure closure defects (coloboma).[5,6]

Fifth week

Invagination of the OV to form the OC predominates in the fifth week. Invagination involves the retinal disc, lens plate, and the ventrocaudal wall of the optic vesicle (Fig. 3.1C,D). Invagination of the retinal disc of the OV leads to formation of the inner layer of the optic cup, which becomes the neural retina, while the external layer of the optic cup will become the retinal pigment epithelium (RPE; Fig. 3.1E). The optic cup is not continuous, and forms a fold inferiorly and ventrally that is continuous with the optic stalk. This fold is called the embryonic (optic) fissure (Fig. 3.2). The optic fissure allows the hyaloid artery into the optic cup. The primary vitreous develops around the hyaloid vasculature. The process of invagination also involves the lens placode (plate), which leads to the formation of the lens pit. The lens pit deepens to become the lens vesicle. Further development leads to the lens vesicle separating from the surface ectoderm.[7] The

Table 3.1 Overview of eye development[4]

Gestational age	Developmental milestone
22 days	Optic primordia appears
Second month	Hyaloid artery fills embryonic fissure Closure of embryonic fissure begins Lid folds appear Neural crest cells (corneal endothelium) migrate centrally; corneal stroma follows Choroidal vasculature starts to develop Axons from ganglion cells migrate to optic nerve
Third month	Sclera condenses Lid folds meet and fuse
Fourth month	Retinal vessels grow into nerve fiber layer near optic disc Schlemm's canal appears Glands and cilia develop in lids
Fifth month	Photoreceptors develop inner segments Lids begin to separate
Sixth month	Dilator muscle of iris forms
Seventh month	Central fovea thins Fibrous lamina cribrosa forms Choroidal melanocytes produce pigment
Eighth month	Iris sphincter develops Chamber angle completes formation Hyaloid vessels regress Retinal vessels reach periphery Optic nerve myelination complete to lamina cribrosa Pupillary membrane disappears

resulting lens vesicle is relatively large and fills the optic cup.[8] The surface ectoderm will become the corneal epithelium (Fig. 3.1F,G).[1,3]

Sixth week

One of the principal events of the sixth week is the closure of the optic fissure. For the optic fissure to close, the edges of the optic cup must become closely apposed. The embryonic fissure closure begins midway and then extends both anteriorly and posteriorly (see Fig. 3.2). The optic cup is regionalized along several axes: dorsal–ventral, anterior (cornea)–posterior (RPE), nasal–temporal, and central (central neural retina)–peripheral (ciliary epithelium).[9]

The development of the retina progresses with the RPE forming a single layer of cuboidal cells. A primitive Bruch's membrane arises. The sensory retina thickens due to proliferation of cells in the germinative zone of the inner layer of the optic cup. At this stage, retinal ganglion cell (RGC) axons first enter the optic stalk to exit the primitive eye[4] (Fig. 3.1H,I). The secondary vitreous, a cellular structure with associated extracellular matrix, forms and starts to remodel the primary vitreous and fill the remaining retrolenticular space.[10]

Seventh week

The main events include maturation of the RPE and development of the sensory retina with the formation of outer and inner neuroblastic layers at the posterior pole. Primary lens fibers form to obliterate the cavity in the lens vesicle. The periocular mesenchyme evolves with the formation of the choroidal vasculature posteriorly and the development of the anterior segment (Fig. 3.1J,K).

The anterior periocular mesenchyme in the mammal has contributions from cells of neural crest and mesodermal origins, in contrast to the chick where there are only neural crest contributions. The mesenchymal cells migrate forward so that there are cells of neural crest and mesodermal origin contributing to the corneal stroma, endothelium, and trabecular meshwork, whereas Schlemm's canal is of mesodermal origin (Fig. 3.3).

Eighth week

Optic nerve development predominates as more ganglion cells differentiate in the sensory retina, reaching 2.67 million axons by the end of the eighth week. The axons start to make contact with the brain and establish a rudimentary chiasm.[11] RPE nears maturation with the appearance of melanosomes. Müller cells appear and start to extend radial fibers inwards to form the internal limiting membrane and outward toward the prospective external limiting membrane.

Corneal differentiation continues. The corneal endothelial cells start to form Descemet's membrane, the corneal stroma consists of 5–8 rows of cells, and the corneal epithelium is evolving to a stratified squamous epithelium.

The lens develops rapidly with the primary lens fibers filling the lens vesicle. The intracellular organelles disappear. The equatorial epithelial cells begin to divide and new cells are pushed posteriorly, then elongate to become the secondary lens fibers. This leads to development of the lens bow where the nuclei of the secondary lens fibers arc forward convexly (see Fig. 3.1H). The lens sutures develop where the secondary lens fibers meet in a linear pattern at the anterior and posterior poles of the lens. The sutures initially are a line, but then evolve to be Y shaped anteriorly and an inverted Y (Λ) posteriorly.[7,12]

The four rectus muscles insert into the sphenoid bone and the trochlea develops. The lacrimal glands form from the superotemporal quadrant of the conjunctival sac (see Fig. 3.1J).

Differentiation and maturation of elements

Cornea

The cornea forms an optically transparent window for the eye. This function derives from its unique structure and composition.[13] The cornea consists primarily of three layers: an outer layer containing an epithelium; a middle stromal layer consisting of a collagen-rich extracellular matrix (ECM) interspersed with keratocytes; and an inner layer of endothelial cells.

The corneal epithelium develops from surface ectoderm and its maturation is related to eyelid development. Rudimentary lids fuse 8 weeks after ovulation and do not separate (open) until 26 weeks.[14] Bowman's membrane, which underlies the corneal epithelium, develops from the processes of superficial mesenchymal stromal cells. It first becomes apparent around week 16 and is easily recognizable by the fifth month.[15]

(C,D) Optic vesicle invagination and lens vesicle formation (early 10.5 DG mouse ≈ 28 DG human). (E) Invagination of lens pit and bilayered optic cup forming from invaginated optic vesicle (late day 10.5 DG mouse ≈ 32 DG human). *(Rebecca Storen assisted in preparing the histological sections.)*

Continued

The beginnings of the limbus appear at the end of the eighth week. This is marked by a change in stromal appearance at the periphery of the cornea, with cells acquiring a more polymorphic shape and losing regular orientation. By week 11, this junction is well demarcated. In place of the limbal folds identifiable in adult corneas, a ridge-like structure circumscribes and demarcates the developing cornea. This is thought to represent the primitive corneal epithelial stem cell niche.[15,16]

The mature corneal endothelial and stromal layers, the mesenchymal layer of the limbus, and the trabecular meshwork in mammals each consist of two mature cell lineages, one derived from the neural crest and the other from the mesoderm. The mesoderm-derived cells mature to a mix of antigen-presenting cells. These include dendritic cells and macrophages in the limbus and peripheral cornea. Mesenchymal stromal cells of neural crest and mesodermal origin migrate into the space between the corneal epithelium and corneal endothelium and become keratoblasts. The keratoblasts synthesize high levels of hyaluronan to form the primary embryonic corneal stroma ECM. The keratoblasts differentiate into keratocytes, which synthesize high levels of collagens and keratan sulfate proteoglycans that replace the primary stroma with a densely packed collagen fibril-type ECM.[17] Proper differentiation of the stroma and endothelium depends on signals from the lens epithelium, although the nature of the responsible molecules is not known.[18]

The homogeneous distribution of regularly packed small-diameter (25–30 nm) collagen fibrils develop by processes involving keratocytes, which exhibit long-range associations with collagen bundles in the developing matrix via an extended network of actin-rich tubular cytoplasmic protrusions. These have been termed keratopodia. Synchronized alignment of keratopodia and collagen contributes to lamella formation.[19] The proteoglycans are small enough to fit in the spaces between the collagen fibrils and regulate their spacing.

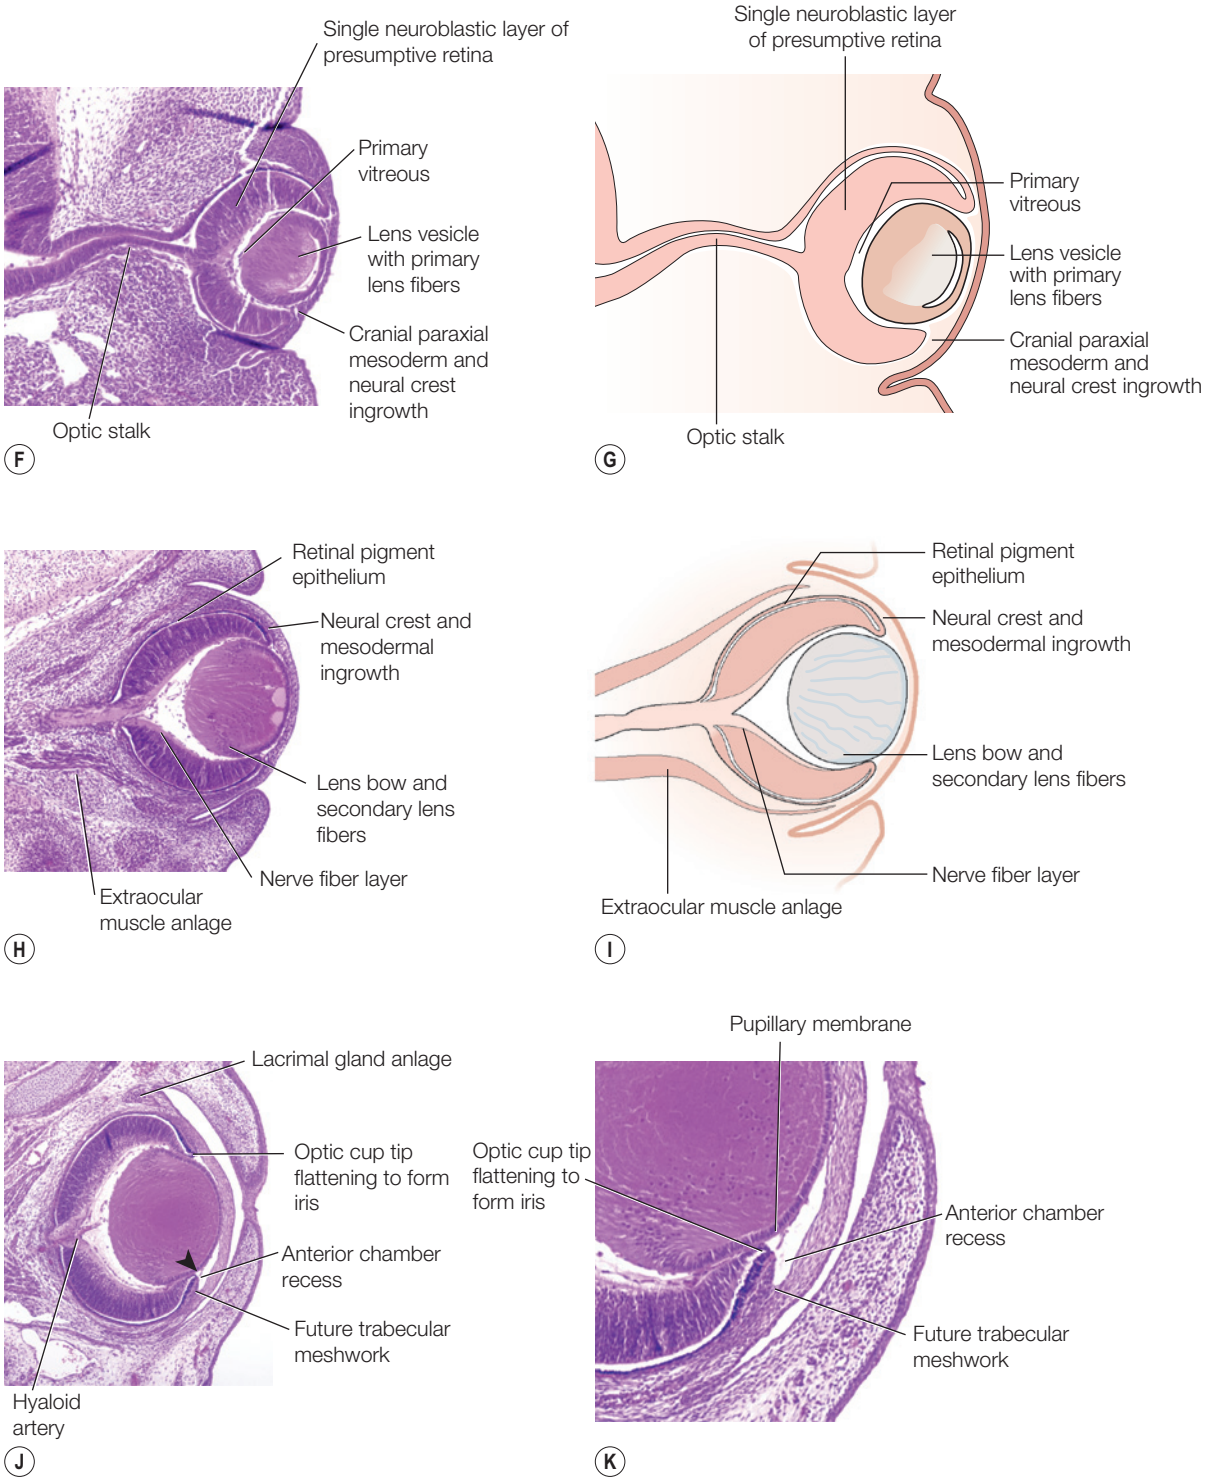

Fig. 3.1, cont'd (F,G) Optic fissure closure, lens vesicle formation and primary vitreous (12.5 DG mouse ≈ 44 DG human). (H,I) Nerve fiber layer formation, neural crest migration, and lens bow formation (14.5 DG mouse ≈ 56–60 DG human). (J) The eye at the end of organogenesis. Cornea, early iris formation, extraocular muscle anlage, and lacrimal gland clearly visible. Arrowhead shows pupillary membrane (16.5 DG mouse ≈ >60 days human). (K) Anterior chamber angle including trabecular meshwork formation results from the differentiation of mesenchymal cells to form a wedge-shaped structure that lies between the corneal endothelium and the stroma of iris. *(Rebecca Storen assisted in preparing the histological sections.)*

Anterior chamber structures

Iris

The iris arises at the end of embryonic development from both the anterior margin of the optic cup neuroepithelium and the periocular mesenchyme. This includes specification of the peripheral optic cup to a non-neuronal fate (pigmented epithelial layer of iris). Periocular mesenchymal cells proliferate and migrate along the iris epithelial layers and differentiate into the iris stroma. Between the iris stroma and the (pigmented) iris epithelium, the sphincter and dilator smooth muscles arise from neuroectoderm.[20] It is most likely that the iris stroma in mice originates from both neural crest and mesoderm.[21,22]

Ciliary body

The ciliary body (CB) shares a common embryonic origin with the iris, but develops into a functionally different structure. The two cuboidal epithelia of the ciliary body that are derived from the neurectoderm include the outer pigmented layer, which is continuous with the RPE, and the inner non-pigmented layer (NPE), which is continuous with the neural retina.

The ciliary marginal zone (CMZ) is a zone of proliferating neural progenitors at the peripheral edge of the retina in fish, frog, and chicken eyes. These progenitors produce neurons that have the ability to regenerate the retina following injury. The cells of the mammalian ciliary epithelium can be induced to become retinal stem cells (RSC), but may not represent a true CMZ.[23]

Fibrillin-rich zonular fibers produced by the NPE span the narrow cleft between the lens epithelium and the ciliary body and become intimately attached to the capsular surface. As the lens expands, the zonules elongate and fan out over the equator.[24]

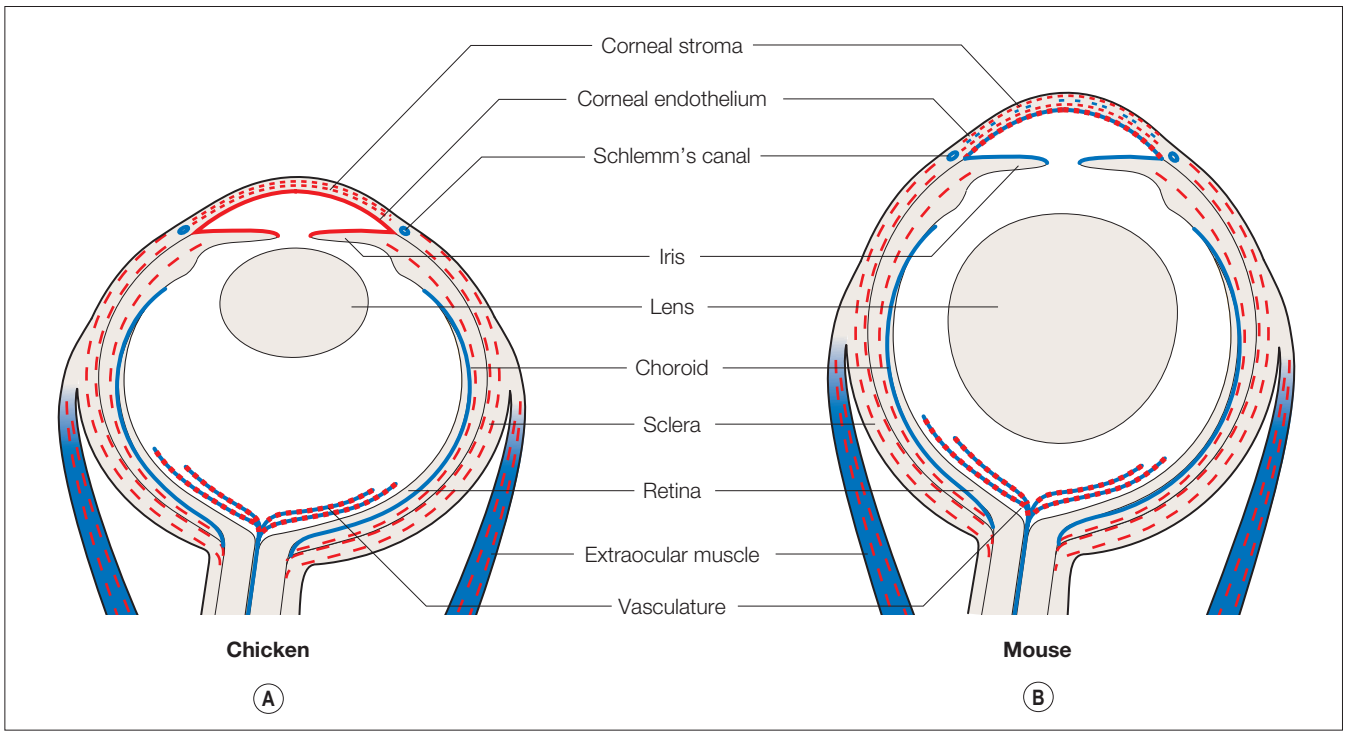

Fig. 3.3 Neural crest and mesoderm fates in bird and mammalian eyes. Cross-sectional diagrams summarizing similarities and differences in contributions of neural crest (red) and mesoderm (blue) to adult chicken and mouse eyes. The major differences occur in the anterior segment. *(Reproduced with permission from Gage PJ, Rhoades W, Prucka SK, et al. Fate maps of neural crest and mesoderm in the mammalian eye. Invest Ophthalmol Vis Sci 2005; 46: 4200–8.)*

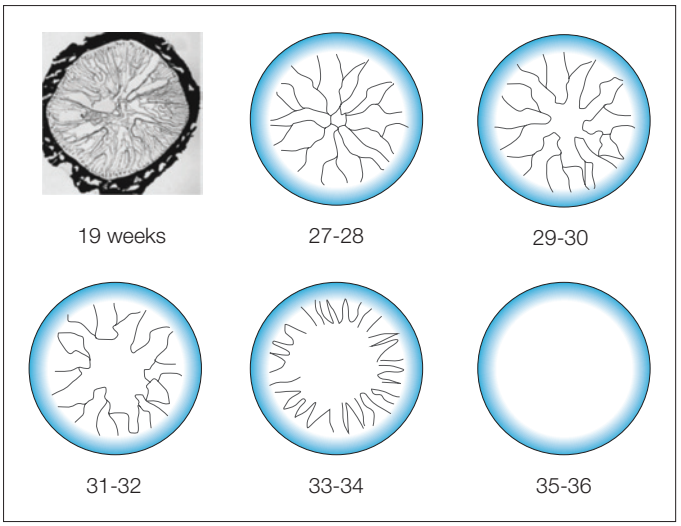

Fig. 3.4 Pupillary membrane regression. The pupillary membrane is fully developed by 13 weeks' gestation. Clinical appearance at 19 weeks' gestation (adapted from Zhu M, Provis JM, Penfold PL. The human hyaloid vasculature: cellular phenotypes and interrelationships. Exp Eye Res 1999; 68: 553–63.). Schematic regression stages modified from Hittner HM, Hirsch NJ, Rudolph AJ. Assessment of gestational age by examination of the anterior vascular capsule of the lens. J Pediatr 1977; 91: 455–8. At around 29–30 weeks, the central quarter of the membrane clears; at 31–32 weeks, the central half clears; at 33–34 weeks, only a peripheral rim of membrane remains; by 35–36 weeks, the membrane has completely regressed.

Trabecular meshwork

Trabecular meshwork formation begins around the fourth month of gestation.[25] The mesenchymal cells of the trabecular meshwork form a wedge-shaped structure that lies between the corneal endothelium and the deeper stroma (see Fig. 3.1K). During the fourth to sixth months, there is a 50% increase in cross-sectional area and a threefold increase in volume of the trabecular anlage.

Schlemm's canal (SC) forms when limbal transcleral veins begin to sprout laterally. It becomes visible in the 16th week of gestation.[26] By 24 weeks, SC is present throughout the entire circumference. By 36 weeks, the SC and outer collecting channels are clearly defined and connected by intercanalicular links. The development of this system continues postnatally, acquires lymphatic identity through upregulation of *PROX1*,[27] until an adult-like configuration is achieved by 8 years.[28]

Pupillary membrane

During mammalian lens development, a transient capillary meshwork known as the pupillary membrane (PM) forms, which is located in the pupil area. The PM reaches its maximal development by 12–13 weeks' gestation[29] (Fig. 3.4 and see Fig. 3.1K). The PM nourishes the anterior surface of the lens and then regresses to make the optical path clear. The regression may be due to iris movement leading to altered blood flow in the PM and regression of the membrane due to apoptosis.[30] The regression of the PM occurs in a programmed manner at consistent time points. The stage of regression of the PM is a useful guide to the gestational age of a premature infant. At 27–28 weeks' gestation, the pupillary membrane fully covers the pupil, and then the central vessels are progressively lost until 35–36 weeks' gestation, when the membrane is no longer present[31] (see Fig. 3.4).

Lens

Lens morphogenesis therefore depends both on the execution of the differentiation program and on the correct assembly of the epithelial and fiber cells into the three-dimensional functional structure. Recent studies exposed a key role for the Wnt/planar cell polarity (PCP) pathway in directing lens fiber morphology.[32] Lens epithelial cells start to differentiate into lens fiber cells at the interface between the lens epithelium and the primary lens fiber core, at the equator. Differentiating lens fiber cells elongate and cover the old lens fiber core, resulting in growth of the lens during development.[33] At term, the lens is approximately 6 mm in diameter and continues to grow to a diameter of approximately 9–10 mm in adult life.

Vitreous and hyaloid system

The hyaloid system is well established by 10 weeks' gestation (see Figs 3.1J and 3.4). The tunica vasculosa lentis (TVL) anastomoses with the annular vessel at the anterior border of the optic cup and connects to the choroidal vasculature. The hyaloid system is characterized by the absence of veins. All hyaloid vessels are arteries and the venous drainage is accomplished by the choroidal veins.[34] The development of the hyaloid vascular system (HVS) is complete around the fourth month and provides all nutrients to the intraocular components of the developing eye. With the appearance of the developing retinal vasculature at approximately the fifth month of gestation, the first signs of hyaloid vessel regression can be detected.[34]

The primary vitreous is a transient collection of cells originating from the neural crest and mesoderm; this structure eventually gives rise to the hyaloid vasculature. Regression of the structures derived from the primary vitreous is a critical event, important for the formation of the crystalline (secondary) vitreous.[35] Failure leads to persistent fetal vasculature. Blood flow in the hyaloid artery ceases around the seventh month, and the vessel is almost completely atrophied by birth.

Retina

The two layers of the optic cup give rise to the outer RPE and the inner neural retina (see Fig. 3.1C,D). The RPE is required for growth of the eye, and it contributes to control of proper lamination of the neural retina. The basal lamina of the RPE, Bruch's membrane (BM), forms a functional unit with the RPE and choriocapillaris.[36]

Differentiation of the neural retina begins at the end of the sixth week. At any location in the retina, there is a fixed birth sequence of retinal cells, so that ganglion cells, horizontal cells, and cone photoreceptors are born first, followed by amacrine and bipolar cells, with rod photoreceptors and Müller cells being the last to differentiate.[37] A region develops in the central retina comprising only differentiating cone photoreceptors at 10–11 weeks' gestation, and is the first indicator of the developing foveal region. Primate retinal studies identify the fovea as the initiation point for most developmental events in the retina, including: cessation of mitosis, morphological maturation, apoptosis, opsin expression, and synaptogenesis.[38] Different developmental events then radiate out from this region across the retina.[38]

Spatiotemporal patterns of neural activity, or "retinal waves," emerge during development and guide the development of

interconnections between different parts of the visual system prior to visual experience.

At week 34, cones and rods near the pure cone area of the fovea have outer segments and are forming elongated axons, which terminate in distinct synaptic pedicles in the outer plexiform layer.[38] The protracted development of the foveal region means that foveal cones are the last to attain adult morphology. In comparison, cones in the periphery are mature in the perinatal human retina.[37] Genetic ablation of the RPE or disruption of RPE specification genes result in microphthalmia, RPE-to-retina transdifferentiation, and coloboma during murine eye development.[1]

Vascularization of the retina involves proliferation and migration of astrocytes and endothelial cells, so that the vessels spread outward from the disc and reach the peripheral retina at around birth.[39] The first vessels appear around 14–15 weeks' gestation. The stimulus for vascular growth is dependent on the retinal neurons becoming metabolically active, resulting in local hypoxia. This "physiological" hypoxia causes retinal astrocytes to secrete vascular endothelial growth factor (VEGF), promoting growth of endothelial cells and formation of retinal blood vessels. In this manner, blood vessel formation is matched to oxygen demand.[40]

The foveal region is never vascularized during normal development, and the foveal avascular zone is fully demarcated by around 28 weeks' gestation in humans.[41]

At the fovea, the retina is adapted morphologically to its blood supply because the development of retinal vessels is inhibited. This is the converse of the rest of the retina and may provide a clue to the susceptibility of the macular to disease.[40]

Optic nerve

The optic nerve develops from the edges of the optic fissure. The optic fissure can be divided into two adjoining parts: the optic groove, which derives from the optic stalk, and the retinal fissure, which derives from the ventral optic vesicle (see Figs 3.1C and 3.1D). The optic disc will form at the transition between the optic groove and retinal fissure.[42] Axons and hyaloid artery at the developing optic disc become encircled by a ring of compact neuroepithelial cells, characterized by the expression of the paired-boxed transcription factor Pax2.[43]

Type I astrocytes arise from PAX2 expressing neuroepithelial cells of embryonic optic stalk and a subpopulation migrate onto the retinal surface where they associate with the surface vasculature to form the blood/retinal barrier.

RGC axons initially extend along the vitreal surface of the neural retina and follow a centripetal route towards the center of the retina. Within the retina, RGC axons grow in close contact with Müller glial cell endfeet and with the vitreal basal lamina.[2,44] The number of RGC axons entering the optic nerve peaks at 3.7 million at around 16–17 weeks' gestation, then declines, stabilizing at an estimated 1.1 million axons (adult number) by week 29 of gestation.[45] This redundancy contributes to the retinotopic organization being mapped to the cortex via activity-dependent mechanisms.

Extraocular muscles

Craniofacial muscles develop from unsegmented prechordal and paraxial mesoderm. They also receive contributions from the neural crest. The extraocular muscles (EOMs) differ from craniofacial muscles formed in the branchial arches by having different upstream activators of the muscle-regulatory transcriptional cassette.[46]

Eye movements depend on correct patterns of connectivity between cranial motor axons and the extraocular muscles.

EOMs also have unique gene expression profiles relative to other skeletal muscles, which include the presence of embryonic and cardiac muscle proteins as well as higher levels of enzymes that lead to improved calcium homeostasis and reduced oxidative stress.[47] These unique properties make the EOMs resistant to many forms of muscular dystrophy.[46]

Cranial nerves

Twelve pairs of cranial nerves (CN) form during the fifth and sixth weeks of development. They are classified into three groups based on their embryological origins. The somatic efferent cranial nerves are: oculomotor (CN III; majority of the nerve), trochlear (CN IV), abducent (CN VI), and hypoglossal (CN XII). The nerves of the branchial arches include: CN V, VII, IX, and X. The special sensory nerves are: CN I, II, and VIII.

Within the brain (as opposed to the spinal cord), motor neuron organization is subservient to neuromeric organization. The cranial motor neurons are organized within individual rhombomeres (neuromeres of the rhombencephalon) or in adjacent neuromeric pairs. The oculomotor (III) nucleus is located in the posterior midbrain, the trochlear (IV) nucleus in anterior rhombomere 1 (r1), the trigeminal (V) nucleus in rhombomeres 2 and 3, the facial (VI) nucleus in rhombomeres 4 and 5, the abducens (VII) nucleus in rhombomeres 5 and 6, and the glossopharyngeal (IX) nucleus in rhomobomeres 6 and 7. The midbrain and each hindbrain segment have their own molecular "address" reflected by the expression of a unique combination of transcription factors.[48]

Normal development and function of the efferent cranial nerves is critical for normal development of the extraocular muscles. Axon pathfinding is essential for the establishment of proper neuronal connections during development. Abnormalities lead to congenital cranial dysinnervation disorders including congenital fibrosis of the extraocular muscles (CFEOM), Duane syndrome, and Marcus Gunn jaw-winking phenomenon.[49]

Lacrimal system

Three stages in lacrimal gland morphogenesis are identified: (1) the presumptive glandular stage at 7 to 8 weeks' gestation, characterized by a thickening of the superior fornix epithelium together with surrounding mesenchymal condensation; (2) the bud stage, characterized initially by the appearance of nodular formations in the region of the superior conjunctival fornix and concluding with the appearance of lumina within the epithelial buds; fibroblast growth factor (FGF) signaling is critical for these steps[50]; (3) the glandular maturity stage at 9 to 16 weeks' gestation, when the gland begins to take on the morphology of adulthood.[51]

The excretory lacrimal system begins to develop at 6 to 7 weeks' gestation when the lacrimal groove is observed between the maxillary and external nasal processes. The lacrimal cord develops at 8 weeks' gestation, and by 9 to 16 weeks the palpebral orbicular muscle primordium has formed along with the lumen of the excretory lacrimal system and formation of the tendon, the medial palpebral ligament.[52]

Emmetropization

The human eye is programmed to achieve emmetropia in youth and to maintain emmetropia with advancing years. Eye growth is regulated in early postnatal life and optically driven mechanisms contribute to this process.[53]

The visual image is critical in refractive development, with the retina having a central role in optically regulating eye growth; each area of retina processes the retinal image and influences the growth and/or biomechanics of the overlying sclera.[54,55]

Embryology resources are well developed online and we refer the reader to http://www.emouseatlas.org/emap/analysis_tools_resources/software/jatlasviewer.html for more detailed images.

Introduction

Developmental biology aims to provide an understanding of the mechanisms controlling the four-dimensional changes in shape (*morphogenesis*), cell type diversity (*histogenesis*), and functional maturation during embryogenesis and early brain development. Ocular development has proven to be a popular system for developmental biologists, since the general structure of the eye is similar throughout vertebrate evolution and the molecular basis of development is conserved to a remarkable degree from the well-studied invertebrate animal model, the fruit fly, *Drosophila melanogaster*.

For both ethical and technical reasons, experimental developmental biology has not been possible in humans. However, the ability to induce transdifferentiation of adult human cells into induced pluripotent stem (*iPS*) cells[1] and to then differentiate these into optic vesicle-like structures[2] has significantly reduced this limitation. Combining this technology with our improved understanding of the genetic basis of human eye malformations predicts that human developmental biology will be an important and rapidly growing field in the near future. To date, however, almost all knowledge of eye development comes from model organisms: the fruit fly (*Drosophila melanogaster*); frogs (*Xenopus laevus*, *Xenopus tropicalis*); fish (zebrafish [*Danio rerio*], medaka [*Oryzias latipes*]); chick (*Gallus gallus*); and mouse (*Mus musculus*). Each model has strengths and weaknesses. For example chick embryos have been extensively used for fate mapping and tissue recombination experiments, but there are few natural mutations available for study and genetic manipulation is difficult. In mice one can inactivate almost any gene in a targeted manner via homologous recombination in embryonic stem (ES) cells, but very early development is difficult to visualize since this is a placental mammal. Although exact equivalence of animal model experimental data with orthologous processes in humans is unlikely given the expansion of gene families through evolutionary genome duplication and existence of species-specific phenomena, it is likely that many of the developmental mechanisms will be common and generalizable.

Important concepts and processes in developmental biology

Differentiation

The fertilized egg is a *totipotent* cell, i.e. one cell can give rise to all embryonic and extra-embryonic tissues. *Differentiation* can be thought of as a progressive loss of "stem-ness" associated with increasing functional specialization of the daughter cells. This process ends with *terminal differentiation*, where the cell exits the cell cycle and changes the cellular machinery to fulfill its assigned function, for example, as a rod photoreceptor. The ancestry of this cell would be represented as fertilized egg ⇨ blastomere cell ⇨ inner cell mass cell ⇨ primitive ectodermal cell ⇨ neuroectodermal cell ⇨ optic field cell ⇨ optic vesicle cell ⇨ retinal progenitor cell ⇨ photoreceptor. This sequence of any developing cell is known as the *fate map*.

Cell migration

Embryogenesis involves dramatic shape changes over short periods of time. Much of this change is due to differential rates of cell division within and between tissues. However, there is a subset of cells that migrate from their birthplace to distant regions of the embryo. The best known of these travellers are *neural crest (NC) cells*, which form on the lips of the neural fold along the length of the neural tube. The *cranial neural crest (cNC) cells* are important in eye development and will be discussed further below. The molecular basis of the movement of NC cells is becoming known and many of the master control genes for this process are also important in mediating cancer invasion and metastasis.[3]

Programmed cell death

In many developmental tissues a proportion of the constituent cells will be seen to undergo a process where there is nuclear fragmentation leading to death. This process is microscopically and molecularly distinct from senescence and is known as *apoptosis* or *programmed cell death* (PCD).[4] The correct

functioning of PCD is crucial to the normal development of many organs and appears to be used to prune cells that are excess to requirement.

Signaling

Signaling is one of the fundamental concepts in developmental biology. A diffusible ligand is produced by a cell or group of cells in the embryo that interacts with a receptor to effect a change. Protein phosphorylation and/or the transcriptional profile is altered in the receptor-bearing cell, which can be at some distance from the ligand-producing cells. Ligands can be proteins (e.g. sonic hedgehog) or small molecules (e.g. all-*trans*-retinoic acid). The receptors (e.g. fibroblast growth factor receptors) can be on the cell surface or intracellular (e.g. retinoic acid receptors). The ligand–receptor interaction will often lead to a signal transduction cascade (e.g. MAPK pathway). Some ligand–receptor interactions can activate several different signal transduction pathways. In such cases, the most commonly used pathway is known as canonical (e.g. beta catenin activation in Wnt signaling) and the alternative pathways known as non-canonical. There are many different signaling pathways used during eye development (Fig. 4.1) and many of these will be discussed in more detail below.

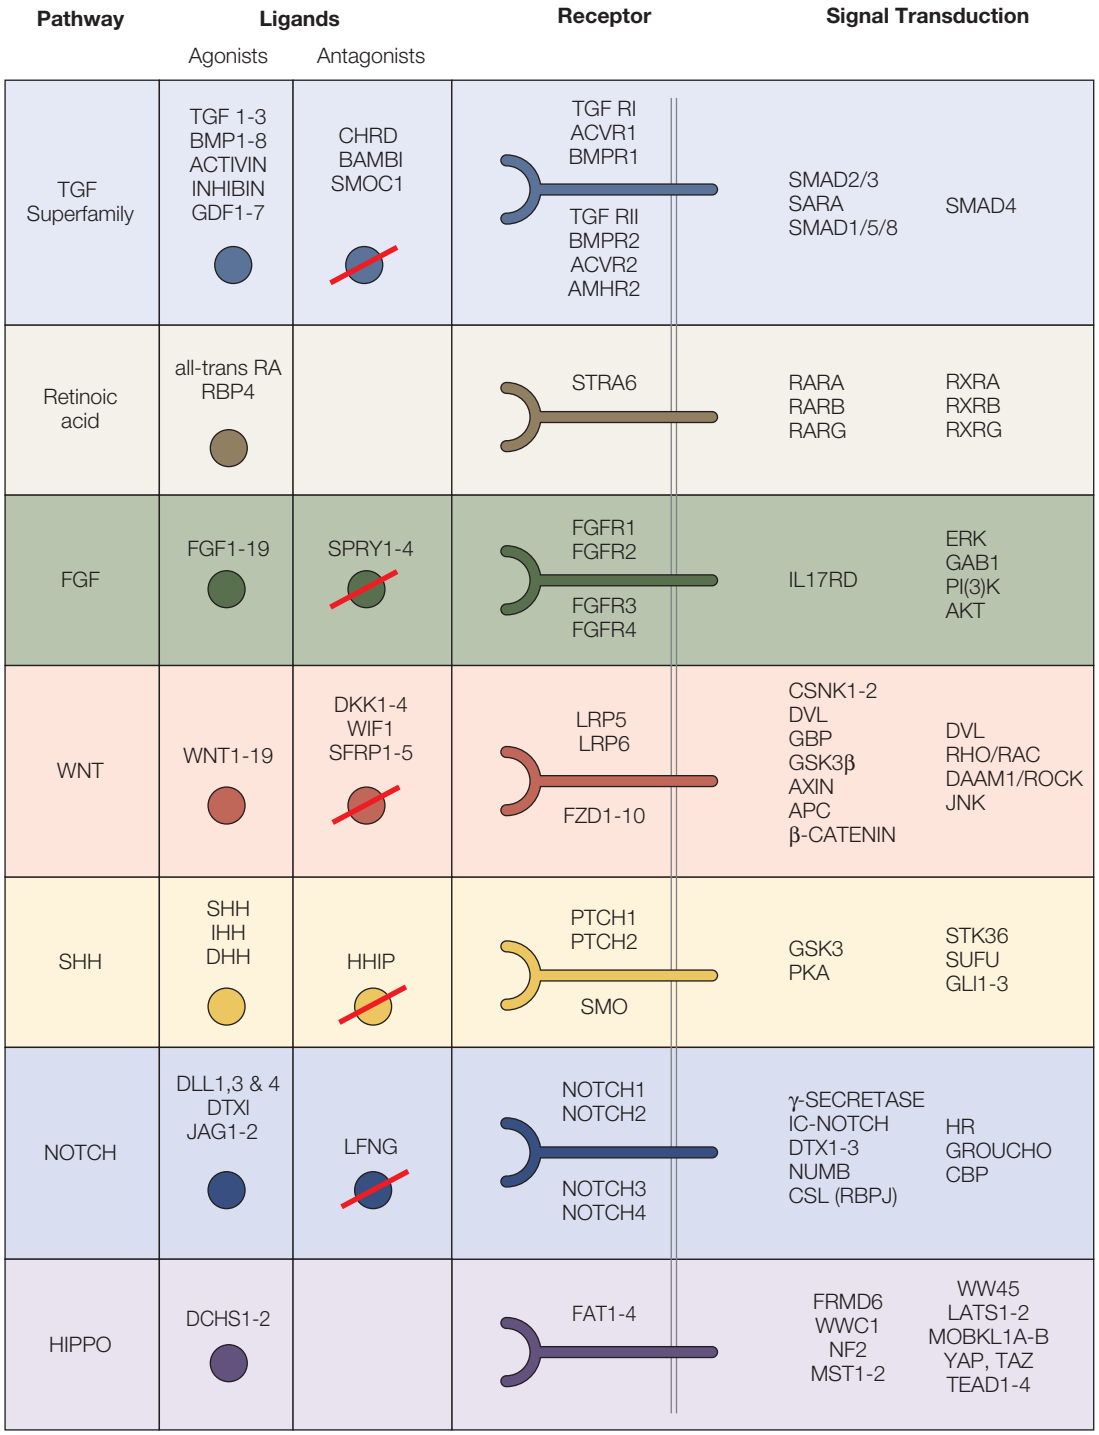

Fig. 4.1 Major signaling pathways used during eye development. The signaling pathways are made up of ligands, antagonists, receptors, and signal transduction effectors. The pathways are named after the ligands, which are either groups of proteins that are related by sequence homology or small molecules. Some receptor–ligand interactions may use more than one signal transduction cascade depending on cell context.

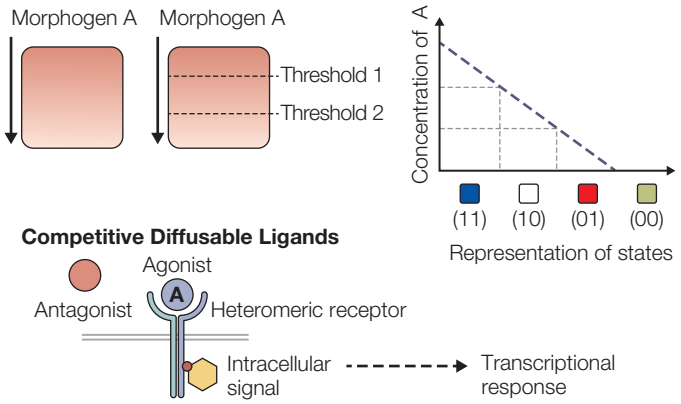

Fig. 4.2 Translation of morphogen gradients into cell state change. Morphogen gradients are created by diffusible ligands for signaling cascade. The source of ligand production will represent the peak of the concentration gradient. Factors such as the nature of the extracellular environment and the catabolism or internalization of the ligand will influence the slope and extent of the gradient. The signaling gradient is translated into changes in cell state using a threshold-dependent mechanism. This can be diagrammatically represented by the French flag model in which specific points on the slope of the signaling gradient will result in a change in the differentiated state of a group of cells that lie between the threshold points. The concept of signal transduction is represented by the competition between soluble ligands and antagonists competing for interaction with the receptor complex. If the ligand binds, it will then trigger the signal transduction to effect the proteomic or transcriptomic change within the cell.

The term "morphogen gradient" means that the diffusible ligand (morphogen) exerts concentration-dependent differential effects on target tissues.[5] This important concept is summarized in the so-called French flag model (Fig. 4.2).

Transcription factor codes

Transcription factors (TF) are proteins that reversibly bind – either alone or in combination with other TFs – to specific sequences of DNA called binding sites to exert a *cis*-regulatory effect on one of more genes. The expression of combinations of TF – the TF code – can be used to mark a region of apparently undifferentiated tissue that will become a specific structure. TFs are thus often used as marker genes to determine tissue fate. An example of this is given in the next section: the TF *RAX* is used to define the eye field.

Specific developmental events in eye development

The eye field and the preplacodal region

Following gastrulation, the three germ layers (endoderm, mesoderm, and ectoderm) are established and neural identity begins with formation of the neural plate (Fig. 4.3A,B). The first molecular evidence of eye development is a single "virtual" structure, the eye field, that extends across the midline and is defined by discrete and overlapping expression domains of different TFs – the eye field transcription factors (EFTF) including OTX2, TBX3, RAX, PAX6, SIX3, SIX6, LHX2 and NR2E1.[6] RAX is the EFTF most commonly used as a marker of the eye field (Fig. 4.3C). Mutations in the human *RAX* gene are a rare cause of human microphthalmia. Homozygous

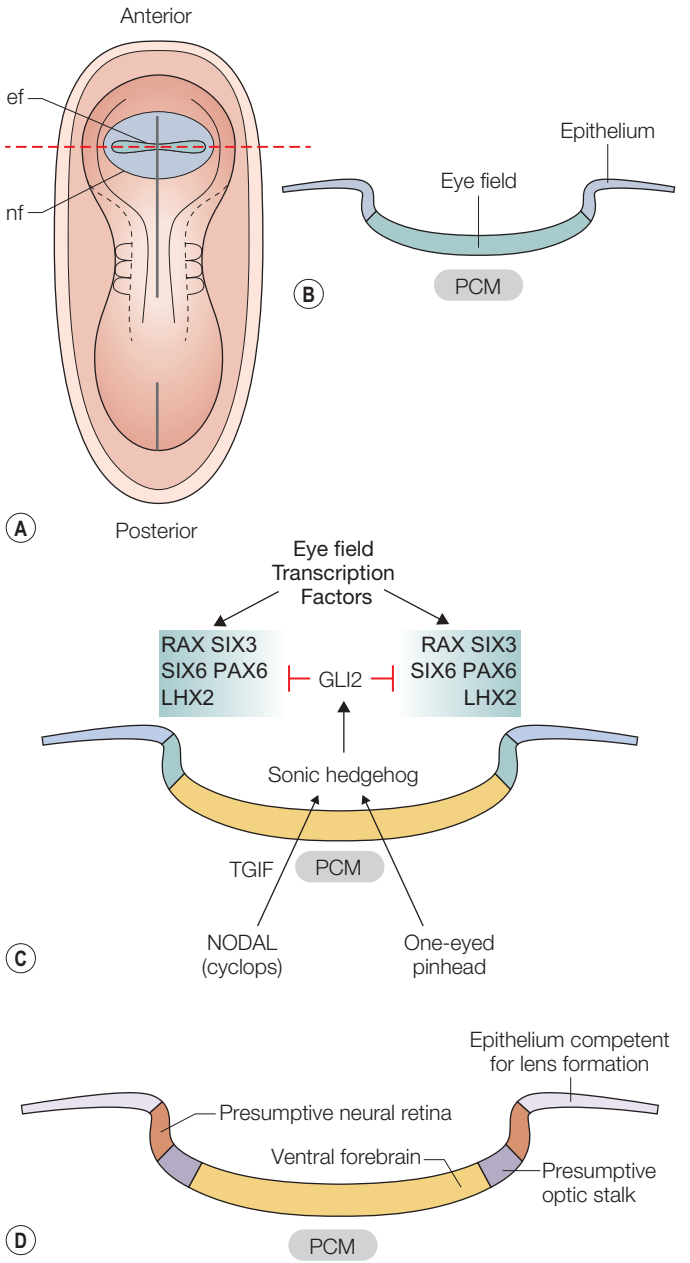

Fig. 4.3 Splitting the eye field. (A) The eye field (ef) is a virtual structure that forms within the neural field (nf) on the dorsum of the early embryo. (B) A section through the eye field shows it to be a plate of neuroepithelial cells spanning the midline and overlying a structure called the prechordal mesenchyme (PCM), which is a rostral continuation of the notochord. Expression of a group of eye field transcription factors (EFTF) mark the eye field at this stage. (C) Sonic hedgehog (SHH) signaling via GLI2 from the PCM acts to inhibit expression of the EFTF in the midline and split the eye field. (D) SHH also acts to pattern the now bilateral eye field into the medial presumptive optic stalk (green) and the more lateral presumptive neural retina (yellow). At this stage, most of the surface ectoderm is competent to produce a lens vesicle.

null mutations *Rax* in mice result in complete absence of eye structures, due to a failure in formation of the optic sulci that give rise to the optic cups. *Otx2* is the earliest molecular delineator of the eye field and heterozygous loss-of-function mutations in *OTX2* cause severe ocular malformations in humans.[7] The EFTF *Lhx2* has an expression domain within that of *Rax*. Targeted mutations in the mouse *Lhx2* gene cause

anophthalmia. As with many EFTF, LHX2 also functions later in eye development.

In common with many developmental processes, the eye field is a result of a balance of different signaling activities with competing morphogen gradients originating in neighboring tissues and often having antagonistic functions – some signals promoting formation of the eye field and others inhibiting it.[8] Ligands of the Wnt signaling system are secreted from the midbrain and paraxial mesoderm regions. A reduction or an increase in Wnt signaling will result in an increase or a decrease in the size of the eye field, respectively. For example, artificially overexpressing an inhibitor of Wnt signaling, *dickkopf1*, in zebrafish causes the eye field to get bigger; whereas, homozygous loss-of-function mutations in a different inhibitor of Wnt signaling, *axin1*, causes reduced eye size.[9] In *Xenopus* embryos, Notch signaling also induces the eye field, and hypomorphic mutations of Notch2 in mice causes bilateral microphthalmia. The eye field is surrounded by the preplacodal region, which is a band of ectoderm that subsequently migrates to form the lens placode mentioned below.

The eye field must split in the midline in order for two separate eyes to form. Failure of this process will result in a single central eye (cyclopia). Nodal signaling from the underlying prechordal plate mesoderm results in downregulation of *Pax6* and *Rax* expression in the ventral midline, with the newly separated domains demarcating the two bilateral optic primordia. Nodal ligands are members of the transforming growth factor beta (TGF-β) superfamily of signaling molecules. In zebrafish, the mutants, *Cyclops*, *oep* (one-eyed pinhead), and *sqt* (squint), all have cyclopia[10] and failure to form ventral forebrain due to a loss-of-function mutation in the Nodal pathway. The Nodal effect is mediated via inductions of *Sonic hedgehog* (*Shh*) expression, which in turn induce expression of the transcriptional repressor *Gli2* (see Fig. 4.3). Both mice and humans with *Shh*/*SHH* mutations develop cyclopia and holoprosencephaly.

Following splitting of the eye field, the bilateral presumptive neural retina (PNR) fields are visible as a pair of shallow grooves (optic sulci) on the anterior neural plate. These will ultimately form the optic vesicles. Definition of the medial and lateral boundaries of the PNR are maintained by continued Shh signaling from the prechordal mesenchyme and bone morphogenetic protein (BMP) signaling from the paraxial mesenchyme, respectively.[11] This process appears to be crucial for normal eye development; the blind cavefish *Astyanax* is anophthalmic because an evolutionary mutation produces hyperactivation of the Shh signaling cascade in the midline.[12,13] This moves the medial boundary of the PNR more laterally, resulting in smaller optic vesicles.

The optic vesicle and optic stalk

The midline gradient of Shh signaling also differentiates the optic stalk from optic cup. *Shh* induces expression of the optic stalk markers, *Pax2*, *Vax1*, and *Vax2*. Overexpression of *Shh* at this stage results in expanded expression of the ventral marker *Pax2* and the suppression of *Pax6*.[14] Reciprocal transcriptional repression between *Pax2* and *Pax6* creates a boundary demarcating the future optic stalk region and the presumptive neural retina.[15] *Pax2* expression is a marker of the presumptive optic stalk and *Pax6* a marker of the presumptive neural retina. Human loss-of-function mutations in *PAX2* cause optic nerve coloboma, a failure to complete optic fissure closure. This is presumed to be the result of an expansion of the PAX6 domain into the presumptive optic stalk region at the expense of the PAX2 domain. Similar to *Pax2*, loss-of-function mutations in *Vax2*, or its paralogue, *Vax1*, cause optic nerve coloboma in mice. Again this appears to be via failure of repression of PAX6 expression.[16] In zebrafish, *Vax1* and *Vax2* genes are expressed in overlapping ventral domains within the developing eyes and their abrogation results in failure of fissure closure and the expansion of neural retina into ventral regions. A further level of control of Vax1/2 function is via the control of the nuclear localization of these proteins through SHH signaling.[17]

Shh, retinoic acid (RA), and bone morphogenetic protein 4 (BMP4) pattern the developing optic vesicle (OV) to confer proximoventral and dorsal–distal characteristics on the neuroectoderm. *Bmp4* is expressed in the distal OV and subsequently within dorsal regions of the optic cup. Overexpression of *Bmp4* expands the *Pax6* expression domain, thus repressing *Pax2* that results in the extension of retinal pigment epithelium (RPE) into forebrain regions.[14] A similar phenotype is associated with loss of Smoc1, a BMP antagonist, in mice. *SMOC1* mutations in humans results in severe anophthalmia as part of the ophthalmo-acromelic syndrome.[18] Overexpression of another BMP antagonist, Noggin, increases *Pax2* and decreases *Pax6* expression. Treatment of *Xenopus* embryos with RA leads to ventralization of the dorsal optic vesicle with expansion of *Vax2* expression domain dorsally.[14] Loss-of-function mutations in RA nuclear receptors reduce the size of the ventral retina, resulting in failure of the optic fissure to close. Loss of multiple RA receptors results in additional ventral abnormalities, including the absence of ventral iris.[15] In humans, loss-of-function mutations in the RA receptors STRA6[19] and RARB[20] or in the enzyme that activates RA, ALDH1A3[21] each result in severe eye malformation.

Patterning of neural retina in the optic vesicle

Shh and BMP4 promote dorsal–ventral (DV) polarity within the presumptive neural retina (PNR) of the optic vesicle (Fig. 4.4). Bmp4 is induced by Lhx2 and in turn induces *Tbx5* expression in the dorsal PNR, while Shh induces *Vax2* expression ventrally. Overexpression of *Bmp4* in *Xenopus* causes expansion of *Tbx5* expression domain ventrally with suppression of *Vax2*. Tbx5 and Vax2 negatively regulate each other in the PNR to impart dorsal and ventral identity. Vsx2 (previously known as *Chx10*), a paired-like homeodomain transcription factor, is expressed in the PNR adjacent to the lens placode in response to inductive fibroblast growth factor (Fgf) signaling from the surface ectoderm. Mutations in *VSX2* lead to microphthalmia in humans and mice.[22] Removal of the lens placode from cultured OV causes abnormal differentiation that can be rescued by exogenous Fgf.

Involvement and development of the retinal pigment epithelium

The retinal pigment epithelium (RPE) develops from dorsal neuroectoderm of the early OV and is required for

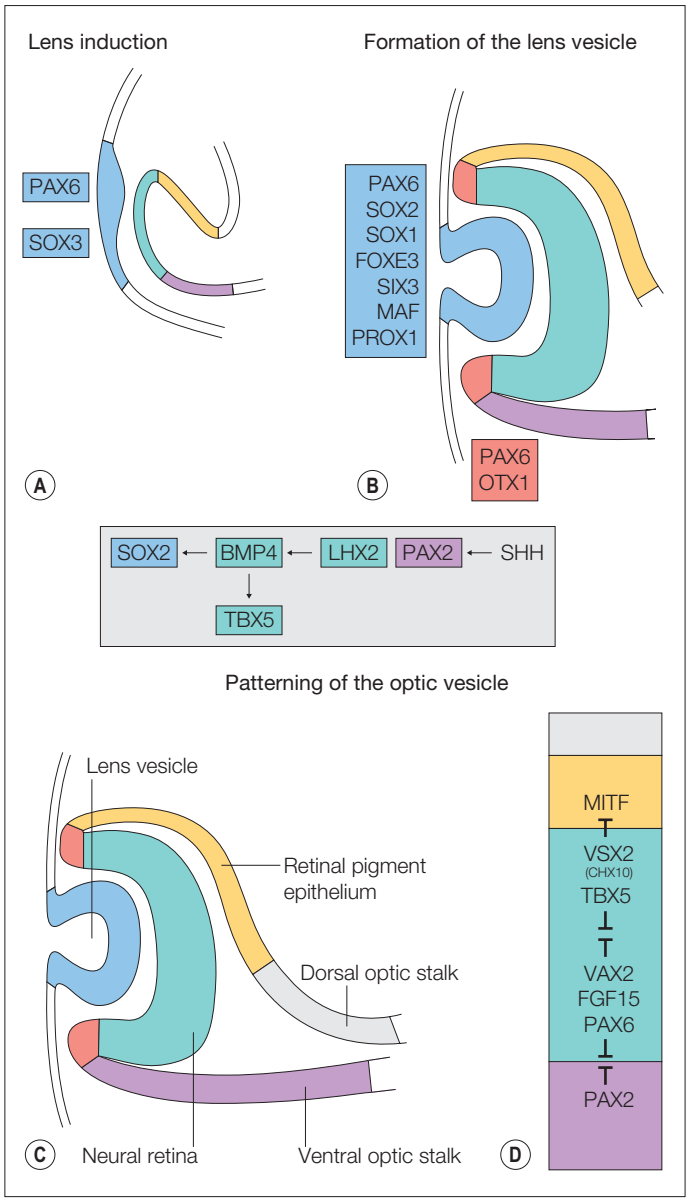

Fig. 4.4 Patterning the lens, retina and retinal pigment epithelium (RPE). (A) The formation of the lens requires signaling between the surface ectoderm and the optic vesicle to form the lens placode. The optic stalk is patterned by induction of PAX2 via SHH. LHX2 induces expression of BMP4 in the presumptive neural retina (PNR), which in turn induces SOX2 expression in the surface ectoderm. This triggers a cascade of transcription factor expression in the lens placode to induce lens vesicle formation (B,C). BMP4 also induces expression of TBX5. (D) A complex network of transcription factors act by induction and repression to form the boundaries between the optic stalk and the PNR and the PNR and the RPE.

morphogenesis of the neural retina. Microphthalmia-associated transcription factor, *Mitf*, a basic helix–loop–helix leucine zipper family gene, is expressed in the future RPE in both mouse and chick. Mutations in *Mitf* cause microphthalmia or anophthalmia in rodents and fish but not humans. *Otx1* and *Otx2* are transcription factors initially expressed throughout the PNR but later mark the presumptive RPE during optic cup formation. Loss-of-function mutations in *Otx* genes in mice result in RPE patterning defects and replacement with ectopic neural retina, while in *Mitf* mutant mice, *Otx2* expression is lost. Both proteins co-localize within nuclei of RPE cells and may cooperate to activate other RPE genes. *Mitf* is also a transcriptional target of *Pax6*; both are co-expressed in the presumptive RPE, with *Pax6* being restricted to the PNR at later stages.[23]

Lens development

As with many parts of eye development, Pax6 is a key player in lens development. Initially Pax6 is expressed throughout the head ectoderm, but then becomes restricted to the presumptive lens placode as the result of TGF-β signals from the underlying migratory cranial neural crest cells. Pax6 mis-expression in *Xenopus* results in ectopic lens formation. In developing optic vesicles,[24] Pax6, the Meis family of transcription factors, Bmp7 and Fgf signaling define the regional localization of the placode prior to ectodermal thickening.[25] Both Bmp4- and Bmp7-null mice do not induce lens development. Disruption of Fgf signaling results in a reduction in placodal Pax6 expression and causes defects in early lens development and lens pit invagination. Co-binding of Sox2 (or Sox1) and Pax6 to enhancers is necessary for early lens crystallin gene expression. The forkhead family gene FoxE3 is a Pax6 target gene, which is expressed in the presumptive lens placode. FoxE3 mutations in humans and mice cause aphakia and microphthalmia.[22] In Mab21l1 mutants, FoxE3 expression is absent in the lens placode, yet Pax6 is unaffected, suggesting that activation of Mab21l1 lies between placodal Pax6 and FoxE3 activation in the developing lens.[25] *Mab21l1-deficient mice have rudimentary lenses as a result of insufficient invagination of the placode due to insufficient expression of FoxE3 with normal expression of Pax6, Sox2, and Six3*. The MAF family of basic-leucine zipper transcription factors is also implicated in lens development and is regulated by Pax6.

Once the lens vesicle has separated from the surface ectoderm, Prox1 expression is essential for the differentiation and elongation of lens fiber cells. Prox1 mutant lenses fail to polarize and elongate, resulting in a hollow lens.[26] Pax6 remains expressed in the lens epithelium until just after the time of vacuole closure, whereas Sox2 is downregulated soon after vacuole formation. Sox1 is expressed throughout the lens at this time, replacing expression of Sox2 and being present in primary fiber cells. Mutations in mouse Sox1 cause cataracts.

Differentiation of the neural retina

The differentiation of the multipotent retinal progenitors involves the interaction of activating and repressing bHLH transcription factors.[27] Each retinal cell type has a unique bHLH factor combinatorial code. Hes1 and Hes5 are both repressive bHLH molecules and double null mutants lack optic vesicles. Retinal ganglion cells (RGCs) are generated from progenitors co-expressing Pax6 and the bHLH activator gene atoh7. Sox2 is expressed widely in neural progenitors. Human heterozygous loss-of-function mutations in Sox2 cause bilateral anophthalmia and severe microphthalmia.[28] Hypomorphic mutations in mouse Sox2 result in the loss of RGCs and cause disrupted cell lamination within the neural retina. The decreased levels of Sox2 are associated with reduced Notch1 and Hes-5 expression, while atoh7 and Pax6

are upregulated. These data are consistent with a key role for Sox2 in the maintenance of retinal neural progenitors.

Shh acts as a retinal precursor cell mitogen, increasing neuron cell numbers in culture experiments.[29] The Shh receptor Patched is expressed in the neuroblastic layer of the retina in a pattern that follows the wave of differentiating ganglion cells – first observed in the ganglion cell layer and then later within the inner nuclear layer. The bHLH activators Neurod1 and Neurod4 are expressed in differentiating amacrine cells. In double mutant mice, amacrine cells are completely missing while ganglion and Müller glial cell numbers are increased. Co-expression of Pax6/Neurod1 or Pax6/Neurod1/Neurod4 promotes amacrine cell differentiation, while co-expression of Pax6/Neurod4 results in more horizontal cells than amacrine. Bipolar cells co-express Vsx2/Neurod4/Ascl1 (another bHLH activator). Horizontal cells require co-expression of Pax6/Neurod4/Prox1/Foxn4. Rods and cones require co-expression of Neurod1, Ascl1, Crx, and Otx2. Crx is necessary for normal cone and rod function and is implicated in human photoreceptor degeneration and Leber congenital amaurosis (LCA; MIM#602225).

Closure of the optic fissure

The optic fissure begins as a deep groove that runs from the ventral rim of the optic vesicle continuously along the ventral aspect of the entire outgrowth. It provides a channel for hyaloid blood vessels that supply the primitive lens and retina. Fusion of the fissure begins with apposition of the inferior lips of the ventral-most optic cup and continues both anteriorly toward its rim and posteriorly along the optic stalk. Little is known about the genetic factors underlying the fusion event; however, failure of this process results in the commonest major eye malformation, optic fissure closure defects (OFCD; e.g. iris, retina, or optic nerve coloboma). *Pax2* and *Vax2* are expressed in the ventral optic stalk and have both been implicated in OFCD. Patients with Pax2 mutations develop optic nerve coloboma,[30] while both Pax2 and Vax2 knockout mice display colobomas, suggesting that genes expressed in the ventral portion of the optic vesicle in the early stages of development may contribute and coordinate the closure of the optic fissure. Heterozygous mutations in YAP1, the effector of the HIPPO signaling pathway, and MAB21L2 have recently been identified as causing OFCD.[22] *CHD7* mutations are a common cause of syndromal OFCD as a component of CHARGE syndrome.[31] The cause of the vast majority of nonsyndromal OFCD cases remains unknown, although *PAX6*, *SOX2*, and *SHH* mutations have been reported in a few cases.

Cornea and anterior segment development

The cornea, lens, and anterior segment structures (ciliary body, iris, vitreous, and trabecular meshwork) are formed by contributions from various cell populations from distinct origins in spatially and temporally coordinated interactions. The cornea is derived from both surface ectoderm and neural crest-derived periocular mesenchyme cells. The ectodermal cells secrete a collagen-rich matrix that attracts the surrounding mesenchymal cells to form the stroma of the future corneal epithelium. A second wave of mesenchyme cells forms the corneal endothelium, or posterior stroma. Other neural crest-derived mesenchyme cells line the anterior chamber, iris stroma, and trabecular meshwork. The transcription factor Lmxb1 is required for the normal development of the latter structure.[32] Normal dosage of PAX6 is required for formation of the iris, with haploinsufficiency leading to aniridia in humans and mice. PITX2 and FOXC1 are also crucial for normal anterior segment development.[33,34] The pigmented region of iris develops from an outgrowth from the tip of the optic cup margin, with iris muscles forming from the outer layer of the optic cup margin. The aqueous humor is secreted into the anterior chamber by the ciliary body epithelium and exits through the trabecular meshwork at the angle of the eye, which has at its anterior the cornea, while the iris is positioned at its posterior. These structures control the flux of aqueous humor in the anterior segment; maintenance of intraocular pressure is very important in both the development of the anterior segment and in the adult organ itself.

Summary

Our understanding of the molecular basis of eye development has benefited from an ongoing dialogue between basic developmental biologists and human geneticists, leading to the elucidation of critical patterning and signaling events involved in early development of the lens, retina, and RPE. The emergence of new high-throughput sequencing technologies should mean that the pace of discovery dramatically increases.

Introduction

The development of normal vision accompanies the development of the eye and brain. As the eye grows, the axons of the retinal ganglion cells find their way via the optic nerve and visual pathways within the brain to reach targets in the visual cortex. As the eye grows, its optical properties change and, normally, emmetropization occurs.[1] In the posterior segment, retinal cells re-distribute to populate the expanding periphery and to create a fovea that normally matures to mediate exquisite visual resolution.[2–4] Myelination of the optic nerve fibers continues into childhood.[5] Also after birth, myelination of brain structures continues, the volume of the brain increases, and the organization of the brain matures.[6,7]

As the infant grows and develops, visual capabilities gradually increase and become more like those in adults. Some developmental changes in visual function can be related to structural changes in the eye or brain. In other instances, the immature molecular substrate surely impacts vision, but the relationship of these immaturities to visual functions may not be demonstrable in the living subject.

Increases in visual capabilities accompany normal development. Diseases of the eye and visual system may decrease these capabilities. In patients, functional deficits may occur even if abnormalities in physical structure and molecular substrate are undetectable. In infants and children, distinguishing immaturity from disease is fundamental to the interpretation of their visual responses. Repeated measures over time may help separate effects of development (improving vision) from effects of disease (worsening vision). Longitudinal data are often of supreme value.

Rigorous, noninvasive psychophysical and electrophysiological tests, originally used to study visual development in healthy infants with normal eyes, have been modified for clinical application. For measurement of vision, stimuli must be specified in precise physical terms.[8,9] Procedures must insure that the child's response is under stimulus control. That is, there must be a reliable relationship between the stimulus and the child's response. Comparison to normal values for age is crucial for valid interpretation of a patient's vision test results. In the authors' experience, measurement provides critical information that complements important clinical history and unstructured observation. Without losing sight of the clinical context, interpretation of the patient's results includes comparison to normal values for age. Additionally, data obtained in serial measurements can be compared to the patient's own prior results in order to chart the patient's course.

In this chapter, we limit our discussion to those visual functions that are regularly measured in the clinic, such as visual acuity and visual fields, and those that have been used to investigate common pediatric disorders of the eye and visual system. In strabismus and amblyopia, the visual functions that are informative, in addition to visual acuity, are contrast sensitivity, Vernier acuity, and stereoacuity. In retinal dystrophies of early onset, the dark-adapted visual threshold provides an assessment of retinal function from infancy onward.

For each visual function, the course of normal development is shown and comment on the putative structural and neurophysiological bases is provided. Examples from patients are presented. Some visual functions discussed here are mediated by the central retina (grating and letter acuity, contrast sensitivity, Vernier acuity, stereoacuity) and others by the peripheral retina (dark-adapted rod-mediated visual threshold, visual field). The most commonly measured visual function, visual acuity, evaluates function of the entire visual pathway. Some visual functions are tested mainly to evaluate the function of the retina (dark-adapted visual threshold). Vernier acuity and stereoacuity are often cited as noninvasive assessments of processes in the brain. This chapter by no means covers all aspects of visual development. Human retinal and visual development is covered in a more comprehensive fashion elsewhere.[6,10–12]

Table 5.1 Acuity development: mean visual acuity and 95% prediction interval

cpd, Cycles per degree; Dec VA, decimal visual acuity; MAR, minimum angle of resolution; Min arc, minutes of arc.
*The prediction interval is the range within which values of 95% of the normal population are expected.[16]

Visual acuity

Visual acuity is mediated by the fovea, which projects to a large region of the primary visual cortex. Visual acuity is defined as the finest detectable detail (minimal angle of resolution MAR).[13–15] Correct identification of letters that subtend, from top to bottom, 5 minutes of arc with stroke and gap widths of 1 minute of arc is designated as 20/20 acuity; 20/20 Snellen is equivalent to 6/6, 1.0 decimal, or 0.0 logMAR (Table 5.1). 20/200 symbols are 10 times larger. Letter acuity of 20/200 is one of the main criteria for legal blindness and thus a determinant of eligibility for vision support services.

Fig. 5.1 Preferential looking test of acuity using the Teller Acuity Cards (TAC). The 15-month-old child is seated on his mother's lap. The examiner shows a series of cards with black and white stripes (gratings) on either the left or the right, starting with wide stripes. The examiner, who is unaware of the right–left position of the stripes, must judge the stripe location based on the child's head and eye movement response.[22] Acuity is taken as the narrowest stripes to which the subject responds. *(Photos courtesy of Pablo Altschwager, MD, and family.)*

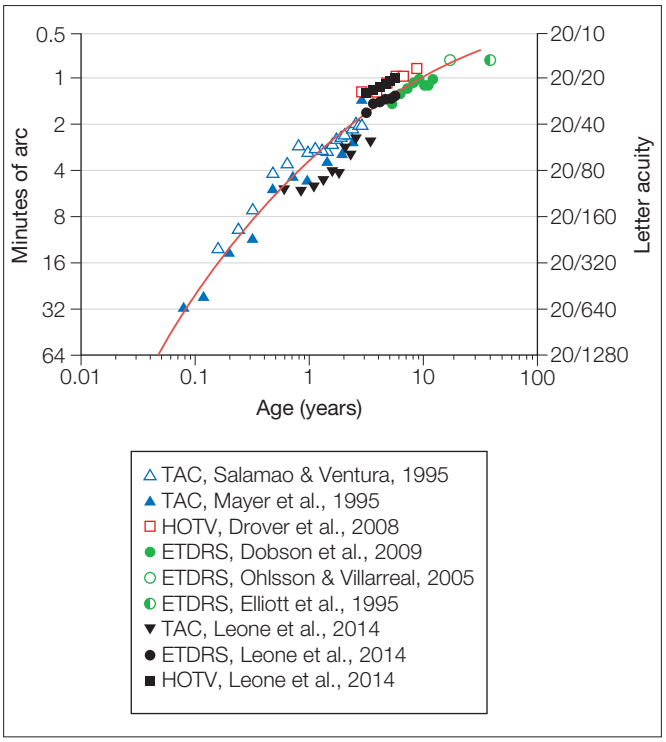

Fig. 5.2 Development of acuity in normal subjects. Mean monocular acuity is shown as a function of age. Grating acuity (triangles) from age 1 month to 4 years was obtained using the Teller Acuity Card (TAC) preferential looking procedure.[21–23] HOTV letters (squares) were used to measure acuity from age 3 to 9 years.[21,137] ETDRS letters (circles) were used for children 5 to 12 years,[21,138] 17 and 18 year olds,[139] and adults.[140] The smooth curve shows a verage acuity as a function of age which increases systematically despite the use of different stimuli (gratings, symbols) and procedures (preferential looking, matching, recognition).

In infants and children who do not have the behavioral repertoire to read letters or follow instructions for matching, acuity is tested using preferential looking (PL), psychophysical (Fig. 5.1) or visual evoked potential (VEP) electrophysiological procedures. The stimuli are repetitive patterns, most often gratings (stripes), that are specified in precise physical units (minutes of arc [min arc], cycles per degree [cpd]). The development of normal acuity is summarized in Figure 5.2. For convenience, mean values of normal acuity along with the prediction interval for normal[16] at selected ages are listed in Table 5.1. In the authors' experience, at age $2\frac{1}{2}$ to 3 years, children with typical development can be tested using symbols and a matching task. Before that age, acuity measurements are most commonly accomplished using preferential looking procedures.

During infancy, acuity measured using VEP[17–20] is better than that obtained using PL[21–23]; whereas in healthy adults, VEP acuity is poorer than letter acuity.[24] In a healthy infant at age 6 months, average PL acuity is 6 min arc and average VEP acuity is approximately 2 min arc.[25,26] A six min arc stripe subtends the same angle as a 20/120 letter; a 2 min arc stripe subtends the same angle as a 20/40 letter. The explanation offered for the VEP–PL difference usually runs along the following lines[19]: VEP acuity is constrained by processes in the eye, the pathway from the eye to the visual cortex, and the visual cortex. The same processes also constrain PL acuity, but additionally, PL acuity requires processing in higher neural areas, attention,[27] and eye–head movement indicating a behavioral looking response. Differences in stimuli, analysis techniques, and response measures also contribute to the VEP–PL difference.

During normal development, acuity is limited in part by immaturities of the fovea. The fetal fovea becomes identifiable as a ~1665 µm diameter rod-free retinal region at approximately 22 weeks' gestation.[4] By term, this diameter has decreased to ~1100 µm. The diameter continues to decrease with age. The adult diameter is approximately 350 µm.[28] Foveal maturation continues into childhood.[2,28–30] The cones first develop inner segments, which are wider than those in adults, and then outer segments. The cone center-to-center spacing decreases and the inner segments become more slender as the fovea develops.[2,31] These features of the foveal cone photoreceptors do not account fully for low acuity in young infants. There are, additionally, postreceptor retinal[32] and brain immaturities.[7,33–35]

Assessments of acuity contribute to diagnosis and to assessment of severity and course of disease (Fig. 5.3). PL acuity tests have been used widely for assessment of infants and children with ophthalmic disorders.[36–40] In pediatric patients with cognitive impairment, acuity is, on average, about one octave (a halving of spatial frequency) below normal for age, even if their eyes are normal.[41] PL and VEP tests also have a place in measurement of acuity in older patients with cognitive impairment.[42]

Grating acuity may appear to be too good. In a study of amblyopia, letter acuity for the amblyopic eye was on average 1.5 times worse than grating acuity,[43] perhaps, in part, because letters have complex spatial content. Thus, a patient's grating acuity must be interpreted with some caution. A practical issue arises if grating acuities are reported to educators and agencies without explanation. Without the ophthalmologist's explanation, children may be unnecessarily declared ineligible for services because their grating acuity test results are better than 20/200, a definition of legal blindness.[44,45]

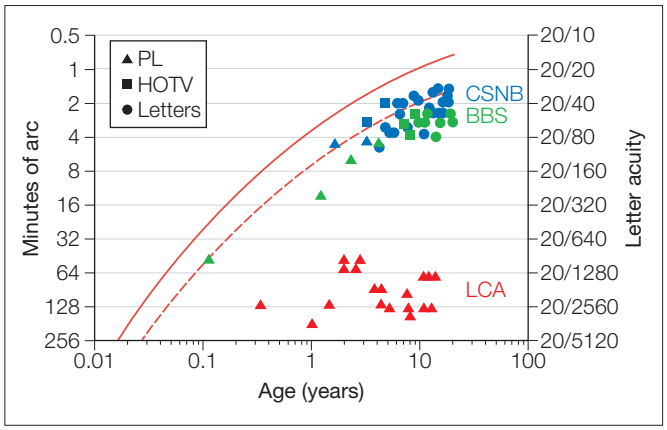

Fig. 5.3 Acuity in three patients. Data from patients with Bardet–Biedl syndrome (BBS, *BBS7*; green symbols), X-linked congenital stationary night blindness (CSNB; blue symbols), and Leber congenital amaurosis (LCA, *CRB1*; red symbols) are shown. The solid red line, re-plotted from Fig. 5.2, describes average acuity as a function of age and the dashed line the lower 95% prediction limit of normal[16]; see also Table 5.1. Age-appropriate tests were used for the patients with BBS and CSNB. In the patient with BBS, acuity remains near the lower limits of normal for age and shows a developmental increase; over the same interval, his dark-adapted visual threshold worsened. In the patient with CSNB, visual acuity remained stable, as did his dark-adapted visual threshold. Acuity in the patient with LCA (*CRB1*), who had marked macular atrophy, was measured using the gratings of the preferential looking test. This patient's dark-adapted visual threshold (youngest patient in Fig. 5.6) worsened significantly during childhood. As a rule of thumb, an octave change in repeated measures of acuity is significant.

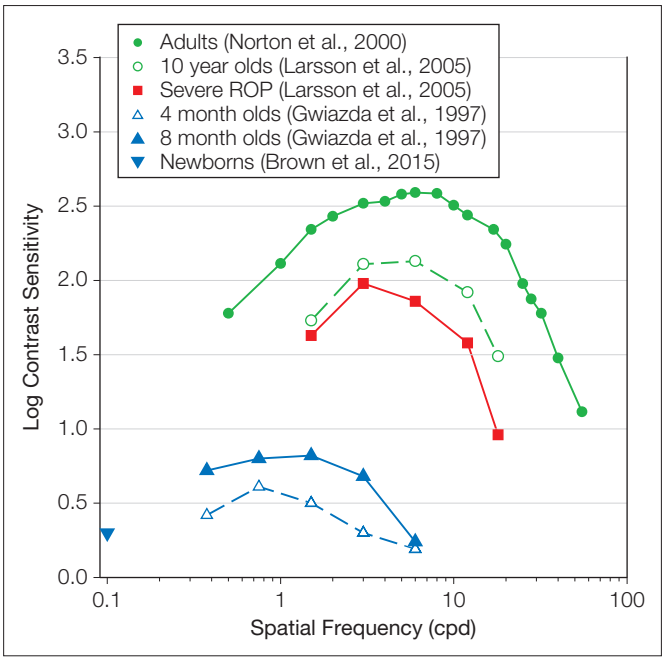

Fig. 5.4 Contrast sensitivity functions for healthy adult,[141] child,[142] and infant subjects[49] and for pediatric patients with a history of treated retinopathy of prematurity (ROP).[142] The reciprocal of the contrast necessary to detect a grating is plotted as a function of the spatial frequency of the grating. Data are re-plotted from the cited references.[48–50,141,142] All data were obtained using psychophysical procedures.

Contrast sensitivity

The real world is full of objects with widely varying contrast. Visual acuity is typically tested using high-contrast stimuli and, therefore, this fails to capture some important information about visual capabilities. For detection at lower contrast, stimulus elements must be larger than at high contrast. PL[46–50] and VEP[51–53] procedures have been modified to study development of normal contrast sensitivity and have also been used to study clinical conditions (Fig. 5.4). Contrast sensitivity is tested in older pediatric patients using commercially available charts with gratings or letters.[54,55]

Patients with retinal degenerations or optic nerve demyelination often have low contrast sensitivity.[56–58] For instance, patients with such disorders may have 20/40, or even 20/20, acuity at high contrast (>95%) and 20/100 acuity at low contrast (10%). On real world tasks, poor contrast sensitivity causes difficulty on everyday vision-mediated tasks, even though acuity measured in high-contrast conditions may indicate only mild-to-moderate deficits. This can baffle educators and other caregivers, but may be readily clarified if recognized by the ophthalmologist. Documentation of low-contrast sensitivity supports requests for appropriate educational planning.

Vernier acuity and stereoacuity

These functions depend upon integrity of the fovea and optic nerve but, importantly, also require complex cortical processing and are, therefore, considered higher-order visual processes.

Vernier acuity

Vernier acuity is the ability to detect discontinuity in a line.[14,15,59] This is critical to pattern perception. In healthy adults, Vernier acuity is nearly an order of magnitude better than letter acuity.[60] It is referred to as hyperacuity. Development of normal Vernier acuity has been studied using PL[61–65] and VEP[66] procedures. Vernier acuity and grating acuity develop at different rates (Fig. 5.5), with the level of Vernier acuity surpassing that of grating acuity during infancy[61,63] or childhood.[64,65] Vernier acuity reaches adult levels later than grating acuity.[64,66,67]

Vernier acuity is relatively tolerant to defocus, motion, and changes in luminance.[68–70] Tests of Vernier acuity are, therefore, potentially robust for clinical application. The advantages, however, are offset by susceptibility of Vernier acuity to practice effects and attention.[71,72] Although Vernier is better than letter acuity in healthy adults (see Fig. 5.5), in amblyopia, deficits in Vernier and letter acuity are similar.[43] In children with cerebral visual impairment, deficits in Vernier acuity are greater than deficits in grating acuity.[73]

Stereoacuity

Stereoacuity is the smallest disparity between images presented to the two eyes that can be detected reliably. Development of normal stereoacuity has been studied by several investigators.[74–78] Infants may demonstrate stereopsis as early as 2–3 months of age, but most show onset at age 3–5 months. Thresholds are 3–5 min arc by age 6 months (Fig. 5.5); in adults, stereoacuity is 1 min arc or better. Disorders of binocular vision, such as strabismus, affect stereopsis and depth perception. Interestingly, infantile esotropia often starts at ages during which normal stereoacuity develops rapidly.[79]

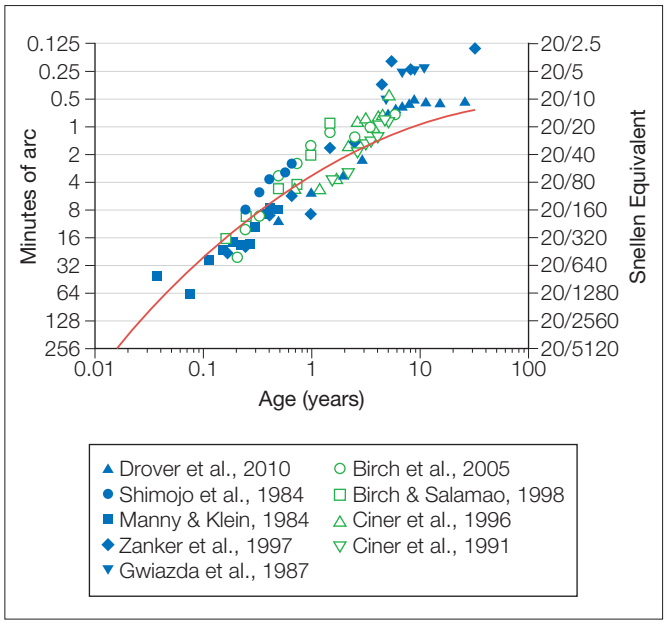

Fig. 5.5 Vernier acuity (filled symbols) and stereoacuity (open symbols) as a function of age in healthy subjects. Data are re-plotted from the cited studies.[61–65,75,77,78,143] The smooth red curve, which shows average visual acuity as a function of age, is re-plotted from Fig. 5.2.

Some investigators have championed tests of stereoacuity as a means of detecting strabismus and amblyopia,[77,80] and stereoacuity has been used to assess outcomes of treatment for esotropia.[81,82]

Dark-adapted visual threshold

The ability to detect dim spots of light in the dark is present in early infancy. The test spot must be brighter to be detected by a young infant than by an adult. With increasing age, the infant can detect dimmer test spots. For instance, at age 4 weeks, threshold is on average 1.4 log unit above that in adults.[11,83,84] By age 6 months, the threshold has become equivalent to that in adults.[84] The course of normal dark-adapted threshold development depends on maturation of the rod photoreceptors.[83,85]

To perform the test, threshold is measured following a period of dark adaptation using a modified preferential looking procedure (Fig. 5.6) as previously detailed.[86] The stimuli must be carefully specified and controlled to minimize spurious results.[11] Stimuli are chosen to favor detection by the rod system. Spectral sensitivity functions in infants as young as 4 weeks old confirm that dark-adapted thresholds are rod mediated.[83,87,88] The threshold is constrained by the rod photoreceptors' capture of quanta. The infant's retina has an adult complement of rods by term. The normal infant's rod outer segments are shorter and the retinal content of the visual pigment rhodopsin is lower than in adults.[85] Therefore, more light must fall on the infant's retina to produce the same response as in an adult.[11] Normally, there is a delay in developmental elongation of the near-peripheral (10° eccentric) rod outer segments compared to those in more peripheral (30° eccentric) retina; this is accompanied by a delay in development of the dark-adapted visual threshold at

Fig. 5.6 The dark-adapted visual threshold test. *The child is seated on his mother's lap; his eyes are positioned 50 cm from the screen when stimuli are presented. The patient reports stimulus location, by looking, pointing, or verbally reporting stimulus location to the right (A) or left (B). An adult observer (not shown) monitors the patient with an infrared viewer and reports the response to the examiner. (Photos courtesy of Pablo Altschwager, MD, and family.)*

10° eccentricity.[84] Studies of rod-mediated spatial summation show that infants' receptive fields are larger than those in the mature retina.[89–92] Rod-mediated temporal summation in infants appears to be constrained by immaturities in the activation of rod phototransduction.[93,94]

The dark-adapted rod-mediated visual threshold has also been studied in children with retinal disease, including degenerations and retinopathy of prematurity (ROP).[86,95–97] Longitudinal measurement of the dark-adapted threshold can be used to follow patients with retinal disease even when the electroretinogram is markedly attenuated.[86,98] Figure 5.7 shows representative results from patients with Leber congenital amaurosis (LCA). A 1 log unit worsening of threshold is evidence of significant progression of disease.[86] In ROP, near-peripheral (10° eccentric) threshold development is delayed relative to that in term born infants.[95] The effects of ROP on rod-mediated threshold persist into adolescence.[93,95,99–101]

Visual fields

In conventional visual field testing using commercially available equipment, adults and older children communicate

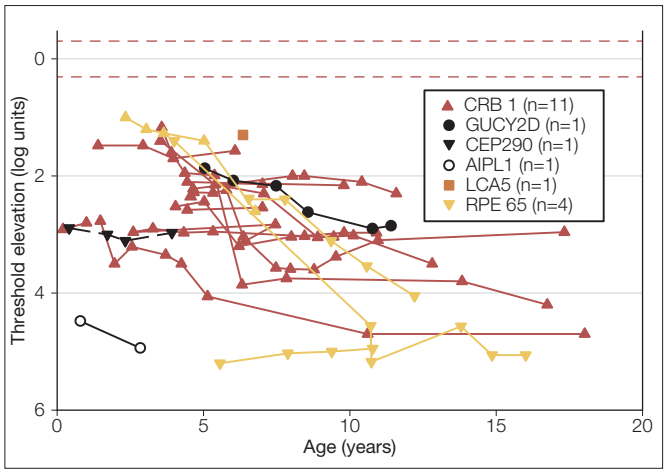

Fig. 5.7 Dark-adapted threshold as a function of age in patients with Leber congenital amaurosis. The key shows the patients' genetic diagnoses. Threshold for detecting 10° diameter, 50 ms duration spots presented 20° to the right or left of a small red fixation light is plotted as a function of age.[11,86] The course for each patient is shown by points connected by line segments. The majority of these patients had worsening thresholds. The normal mean threshold is at zero; the dashed lines indicate ±2 standard deviations.

Fig. 5.8 Confrontation visual field testing. (A) The patient's gaze is attracted to the target centered straight ahead. (B) Then a second target is presented peripherally in one quadrant. The child's looking response, or lack thereof, is noted. Each quadrant is tested in a similar manner. *(Photos courtesy of Pablo Altschwager, MD, and family.)*

their response to the stimuli (small spots of light) by buzzer press or similar activity. An eye movement to the target may be used in those unable to manage the buzzer. Acceptable reliability indices in automated static perimetry can be obtained in typically developing 8-year-olds[102,103] and, after a training session, in some children as young as 5 years.[104]

Conventional, non-automated procedures such as Goldmann kinetic perimetry are feasible in children at approximate developmental age 4 years, particularly if cast as a computer game.[105] The youngster's central fixation and subsequent head and eye movement response to the stimulus must be under strict surveillance by the examiner. Some examiners take successful mapping of the blind spot as an indicator of reliable perimetry. In the authors' opinion, conventional testing should be attempted as young as possible in children at risk for field loss.

Maturation of the peripheral visual field has been studied in typically developing infants and children. The visual field extent in term-born neonates is significantly smaller than in older children and adults.[106,107] The horizontal extent of the visual field increases steadily from age 2 months to 12 months.[106] Binocular and monocular field extent is 90–95% of that in adults by age 1½ to 4 years. In children aged 4–10 years, the visual field extent obtained using arc or hemispheric perimeters approximates that obtained by Goldmann kinetic perimetry.[106,108–115] Maturation of the nasal field may be delayed compared to temporal field, although not all studies find this.[106,110,111] Variability in infant and child visual field extent is high; the 95% confidence interval is typically ±10–20° for monocular field extent.[106,109,110] In infants and young children, visual field extent may be limited by immaturities of the visual pathways as well as by the child's attention.

Infants, young children, and also older patients with cognitive impairment or neurological limitations who cannot sustain attention sufficiently for tests using automated or other conventional perimeters, are tested using alternative procedures.[116] Some of these procedures were originally devised to study development of the peripheral visual field in normal infants.

Confrontation testing is the most commonly used alternative test (Fig. 5.8). The patient must have adequate looking behavior to respond to targets such as toys or lights. The examiner observes the patient's fixation behavior before presentation of the stimulus. The central stimulus (fixation target) is typically a small toy. Once the patient's gaze is on the central fixation target (see Fig. 5.8, upper panel), a peripheral target is presented (see Fig. 5.8, lower panel) and is moved slowly toward the center. Each quadrant must be tested in a similar fashion. To reduce spurious responses to the examiner's movements, a slender wand with lighted tip may be used. Game-like ploys, personalized by the examiner, are important for sustaining the patient's attention. Standard stimuli and procedures for confrontation testing are not established. Each quadrant should be tested using the same stimulus and procedure from one test session to the next. The stimuli are well above detection threshold and the sampling of the peripheral visual space is necessarily coarse. Thus, small scotomata will be missed. These procedures can identify large, absolute defects such as hemianopia or quadrantanopia produced by retrochiasmal disease, inferior altitudinal field loss due to white matter injury of prematurity in the parietal-occipital

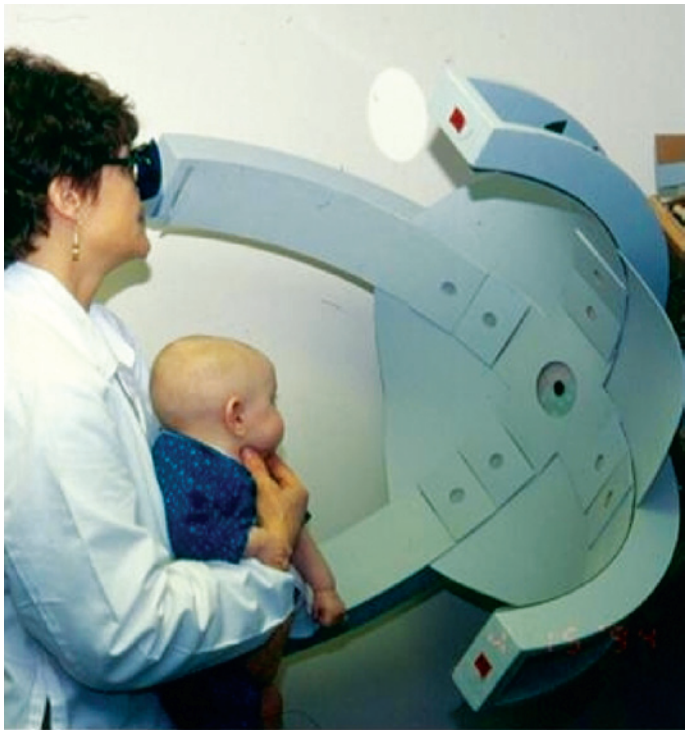

Fig. 5.9 An experimental arc perimeter used to test peripheral field in infants. A healthy infant, age 5 months, is looking at the central fixation display. The peripheral stimulus is a flickering yellow LED presented along the arcs. The infant's orienting eye–head movement response will indicate detection of the peripheral stimulus. The examiner, who is masked to the location of the yellow stimulus by wearing glasses with blue filters, uses a video system (not shown) to monitor the infant's fixation and report responses. *(From SanGiovanni JP, Ho E, Mayer DL. Photopic peripheral sensitivity of 20-week-old infants and adults. Invest Ophthalmol Vis Sci 1994; 35: ARVO Abstract 1393.)*

regions of the brain,[117] and constriction of the visual field caused by retinal degeneration or toxicity.[105,118]

An arc perimeter or modified hemispheric perimeter provides an advantage over confrontation testing because numeric results can be obtained (Fig. 5.9). A map of the patient's responses to stimuli at selected peripheral eccentricities can be drawn. Stimuli have included white spheres, LEDs, and other small lights. The minimum test should evaluate responses in each quadrant along the major obliques (45°, 135°, 225°, and 315°). Children's visual fields mapped using kinetic arc perimetry are highly variable.[116,118,119] A clinician's goal is often to complete monocular visual field testing. If this is not feasible, the results obtained with binocular viewing may yield useful information about the child's disease and/or visual capabilities.

The balance of attention between central and peripheral stimuli influences measured field extent in infants and young children. A central stimulus that is too salient may inhibit ability to disengage and orient toward the peripheral stimulus.[106,120] Ideally, the central stimulus should be similar to the peripheral stimulus in luminance and spatial extent. Stimulus characteristics, including spatial extent, rate of centrad movement, and rate of flicker all have demonstrable effect on field extent in infants and young children.[121–124] Sounds synchronized with presentation of central and peripheral stimuli may enhance attention and orienting in young infants but not in toddlers.[106]

Delayed visual responsiveness

The integrated development of structure and function of the eye and visual pathways enables visual responsiveness at a very young age. A healthy, term-born infant starts smiling responsively at approximately 5 weeks, and fixes and follows readily by age 2 months. In some infants without conspicuous ophthalmic or medical abnormalities, the visual behavior does not meet normal developmental milestones. The term "delayed visual maturation" (DVM) describes this clinical entity.[125,126]

Young infants lacking visual responsiveness are taken to the ophthalmologist because of suspected blindness. Infants with this worrying presentation will include those in whom no ophthalmic or neurological abnormality is found, those who have some ophthalmic disease, and those who have disease of the brain. Others without any specific clinical abnormalities of the eye or the brain will subsequently be diagnosed with a disorder that has associated cognitive impairment or neurodevelopmental disability. In short, the universe of visually unresponsive young infants includes diverse diagnoses. Schemes for categorizing infants with visual delays have sought to organize a mass of information.[127,128] Some generalities emerge. Among those infants in whom the results of ophthalmic and neurological examinations are normal, many rapidly develop normal visual responsiveness. A subset of such infants are subsequently found to have cognitive impairment.[128] Hoyt[126] followed for two decades patients (N=98) who in infancy had isolated delays in visual responsiveness. Nearly all developed excellent visual acuity, but more than half manifested neurodevelopmental disorders, most commonly expressed as learning disabilities.[126]

There are several specific ophthalmic conditions that are encountered repeatedly in infants with visual inattention. Structural abnormalities, should they be present, are typically discovered on the first ophthalmic examination. Optic nerve hypoplasia is a structural abnormality found in some of these infants. Detectable (although sometimes subtle) ophthalmic anomalies occur in the various forms of albinism – perhaps the most common specific diagnosis underlying visual unresponsiveness in infancy.[129]

If another diagnosis cannot be secured, evaluation for severe congenital retinal dystrophy (for example, Leber congenital amaurosis) by electroretinographic testing should be done. Even if visual inattention is profound in early infancy, patients with severe ocular disorders (including optic nerve hypoplasia and Leber congenital amaurosis) may show some developmental increments in acuity on the preferential looking test, presumably due to continuing maturation of the regions of the brain subserving vision.[37,130]

Among young, visually inattentive infants, we also find those with achromatopsia and congenital stationary night blindness – congenital anomalies of retinal function. We narrow the differential diagnosis by electroretinography and then secure the diagnosis by molecular genetic study.

If the eye is not at fault, brain disorders must be considered as the cause of the infant's visual inattention. Approximately half of the brain is dedicated to visual processing.[131] Structural abnormalities of the brain are found by magnetic resonance imaging (MRI). Some infants may have seizure activity; in particular, seizure activity in the frontal or parietal lobes is

associated with reduced visual responsiveness even in the absence of brain malformation.[126]

Acuity measured by PL or VEP in infants with delayed visual responsiveness is variable, ranging from severely reduced[127] to normal for age.[132] Overall, this variability is not too surprising given the diverse underlying diagnoses and the multiple components of the visual system that must mature to mediate visual responsiveness. Furthermore, we are reminded that Fantz and coworkers originally considered preferential looking not for vision testing but for assessment of infants' cognitive development.[133] In our experience, young infants who show little or no visual responsiveness to faces or lights may have measurable PL acuity that is within the rather broad prediction interval of normal for age. Many of these infants proceed to develop good vision. A substantial proportion of them may, however, have neurodevelopmental issues that become apparent later in infancy or childhood.

What underlies the delay in visual responsiveness in infants who clinically have normal eyes? Many answers may eventually be forthcoming. For now, we comment that functional MRI techniques show anomalous organization of vision-driven activity in the brain in mature subjects with achromatopsia or albinism, diagnoses that we find in some infants with delayed visual responsiveness.[134,135] These anomalies of the brain's circuitry are too subtle to be detected by MRI studies that are done in the course of clinical care. With advances in the clinical neurosciences, the processes that govern the turning on of an infant's vision will surely become more completely understood, including the sudden switching on of vision in those with isolated visual delays. We believe that working toward an early, accurate diagnosis is the route to the best possible care of these patients.

Finally, we caution that young infants with poor vision often have delays in motor, social, and even language development. In the absence of visual input (such as facial expressions), coordination of social cues and motor development may not occur. This situation may worry and mislead family and physicians about global developmental delay.[125,136] Early, thorough evaluation of the eyes, including electrodiagnostics if indicated, is the ophthalmologist's contribution to minimizing the likelihood of an incorrect diagnosis of global developmental delay in the visually unresponsive infant.

INTRAOCULAR PRESSURE
REFERENCES

At birth, the corneal diameter is only 1.7 mm smaller than in an adult, but the ocular volume increases threefold and the eye's weight doubles by the time maturity is reached. In the full-term newborn eye, volume is 3.25 cm^3 and weight is 3.40 g. The weight increases 40% by the middle of the second year and 70% by the fifth year.

The development of the eye parts is meticulously sequenced, and understanding the milestones of development is essential to make sense of clinical observations.

Electrophysiological examinations are made according to the International Society for Clinical Electrophysiology of Vision (ISCEV) protocols. However, each laboratory should establish normative data for its own equipment and population. The pediatric ophthalmologist must be aware that electrophysiological maturation proceeds until adulthood.[1] Thus data on electrophysiological investigations will not be discussed in this chapter.

Intercanthal distance and the eyelids

Abnormalities in the distance between the inner and the outer canthi and the size and shape of the palpebral fissure are important features in craniofacial malformations and fetal alcohol syndrome. A fast non-contact method of measuring facial components is provided in Figure 6.1A,B.[2]

Palpebral fissure changes in early childhood have been studied by analyzing digital imaging[3]: During the first 3 months of life, the upper eyelid is at its lowest position, later rising to its maximum between 3 and 6 months of age, and then declining until adulthood. The lower eyelid is close to the pupil center at birth, dropping until the age of 18 months when its position stabilizes. A single lower eyelid crease is common at birth, a double crease at the age of 36 months. Figure 6.2 shows the linear relationship between gestational age and orbital margin horizontal (OMH), as well as vertical (OMV) diameters in the unborn child.[4] There is a linear relationship between gestational age and conjunctival fornix horizontal (CFH) and conjunctival fornix vertical (CFV) diameters (Fig. 6.3).[5]

The palpebral fissure's horizontal length is 15±2 mm at 32 weeks of gestation, 17±2 mm at birth, 24±3 mm at 2 years of age, and 27±3 mm at the age of 14.[5,6] Inter-racial differences exist: The palpebral fissure is longer in Black Americans.[7]

Inner canthal distance and outer orbital distance are 16 and 59 mm, respectively, in premature infants; 20±4 and 69±8 mm in newborn babies; 26±6 and 88±10 mm at the age of 3 years; and 31±5 and 111±12 mm at the age of 14 (Fig. 6.4).[8]

A universal approach is the canthus index:

$$\text{Canthus index} = \frac{\text{Inner canthus distance} \times 100}{\text{Outer canthus distance}}\ \%$$

Normals, unrelated to age, lie between 28.4 and 38%.[9] The canthus index of over 1000 children between 6 and 18 years of age was determined as follows[10]:

	Boys	Girls
6 Years	38.2% (SD 2.1%)	38.3% (SD 1.8%)
16 Years	37.1% (SD 2.6%)	36.6% (SD 1.9%)

Tear secretion

Tearing is not a problem when holding the eyelids of the youngest premature babies open. Later, in preterm babies

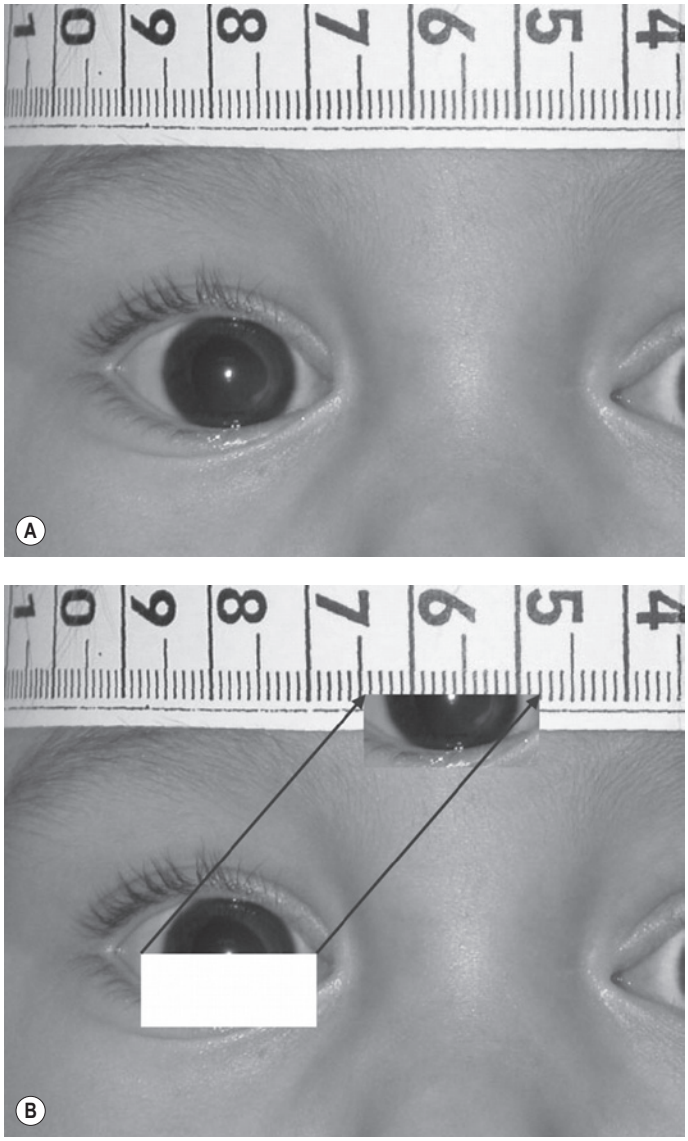

Fig. 6.1 (A) Photograph showing non-contact measurement of corneal diameter in children. Before digital photography of a child's eyes, a paper ruler was taped on the forehead. (B) After uploading the image to a computer, a rectangle is cut using the computer mouse, with the upper line passing through the cornea's widest horizontal diameter. This rectangle then is dragged to the ruler to read the corneal diameter, in this case 12.5 mm. *(From Lagrèze WA, Zobor G. A method for noncontact measurement of corneal diameter in children. Am J Ophthalmol 2007; 144: 141–2.)*

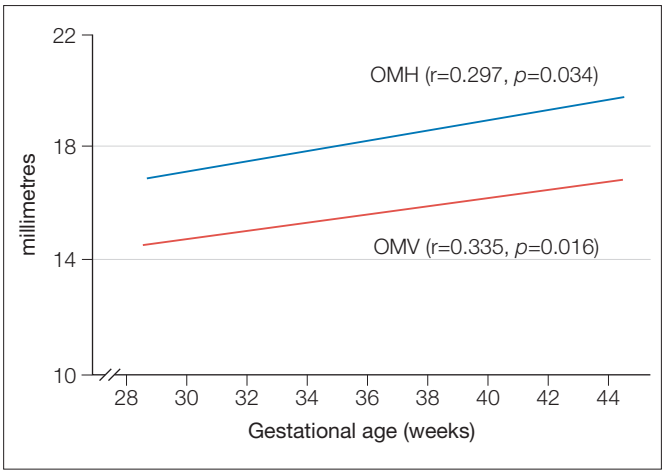

Fig. 6.2 Interocular distance. Linear regression relationship and standard error of the estimate between orbital margin horizontal (OMH) and vertical (OMV) diameters and gestational age. Correlation coefficients with *p* values are indicated. *(Data from Isenberg SJ, McCarty JW, Rich R. Growth of the conjunctival fornix and orbital margin in term and preterm infants. Ophthalmology 1987; 94: 1276–80. With permission from American Academy of Ophthalmology.)*

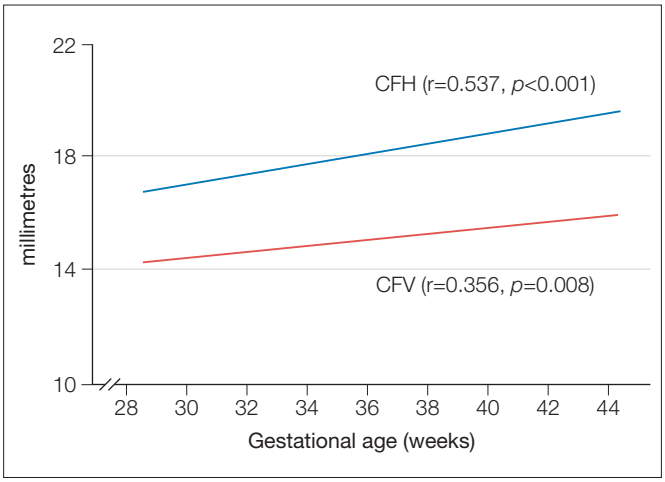

Fig. 6.3 Linear regression relationship and standard error of the estimate between conjunctival fornix horizontal (CFH) and vertical (CFV) diameters and gestational age. Correlation coefficients with *p* values are indicated. *(Data from Isenberg SJ, McCarty JW, Rich R. Growth of the conjunctival fornix and orbital margin in term and preterm infants. Ophthalmology 1987; 94: 1276–80.With permission from American Academy of Ophthalmology.)*

(30–37 weeks after conception), mean basal tear (with topical anesthesia) secretion is 6.2 (±4.5 SD) mm and at term 9.2 (±4.3) mm tested with a Schirmer tear test strip (5 minutes). Mean reflex tear secretion is 7.4 (±4.8) mm in preterm and 13.2 (±6.5) mm in term infants.[11] Non-invasive tear film break-up time in normal children was recently published to be 21.76±4.06 seconds (range 14.9–30.95 s) in children mean age 7.64 years (range 2.16–15.83 years).[12] This is considerably greater in children in comparison to adults. This is in keeping with a lower blink rate of 6 blinks per minute in newborns and 8 blinks per minute for preschool-age children.[13]

Cornea

The premature cornea lacks luster and clarity making some diagnoses difficult. Shallow anterior chambers, miotic pupils, and bluish irides are features of prematurity. The corneal diameter in infants at 25–37 weeks postconceptional age increases by 0.5 mm every 15 days from 6.2 to 9.0 mm (Fig. 6.5).[14,15] The horizontal and vertical diameters of the cornea in full-term boys are 9.8±0.33 mm and 10.4±0.35 mm, respectively, and in girls 10.1±0.33 mm and 10.7±0.29 mm.[16] Two millimeters of growth in corneal diameter (approximately 20%) occurs in early infancy and early childhood. The adult value of 11.7 mm is reached by 7 years.

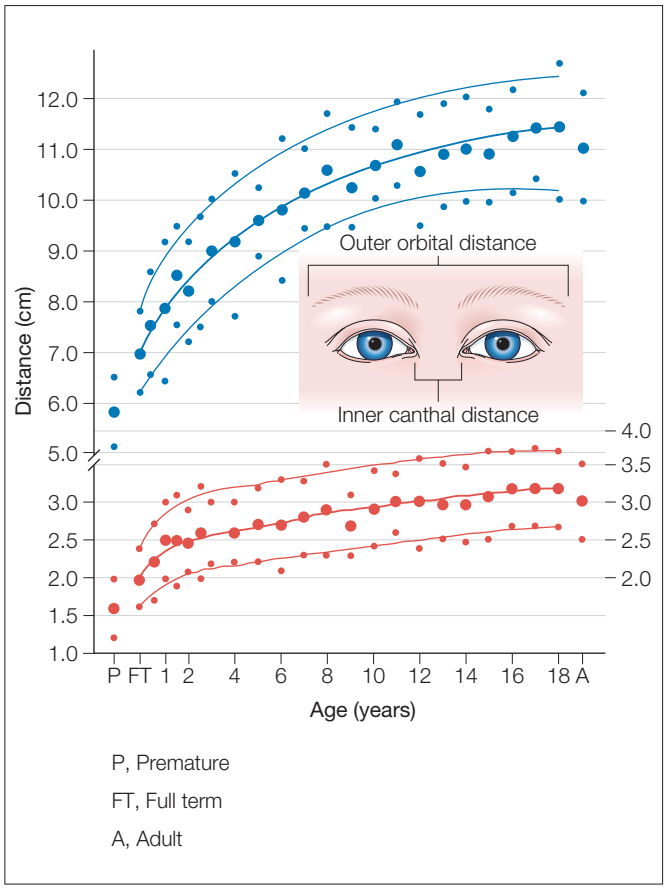

Fig. 6.4 Graphs of inner canthal and outer orbital distances. The large points represent the mean value for each age group, the smaller points represent 2 SD from the mean. The heavy line approximates the 50th percentile, while the shaded area roughly encompasses the range from the 3rd to the 97th percentile. *(Data from Laestadius ND, Aase JM, Smith DW. Normal inner canthal and outer orbital dimensions. J Pediatr 1969; 74: 465–8. With permission from Elsevier.)*

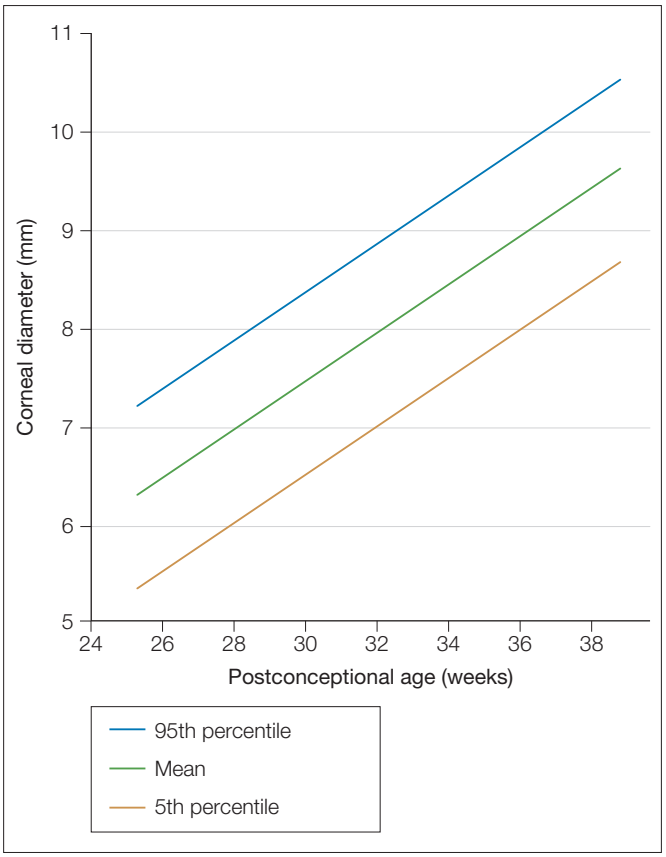

Fig. 6.5 Mean corneal diameter plotted against postconceptional age. *(From Tucker SM, Enzenauer RW, Levin AV, et al. Corneal diameter, axial length, and intraocular pressure in premature infants. Ophthalmology 1992; 99: 1296–300. With permission from American Academy of Ophthalmology.)*

Central corneal thickness

Abnormal thickness of the central cornea influences intraocular pressure measurement; corneal hysteresis may also play a role in children. Central corneal thickness (CCT) in a full-term baby is 0.54 mm which is thicker than in an older child. CCTs measured with optical pachymetry and corneal curvature are given for premature and full-term babies in Table 6.1.[17]

CCT in premature infants below 33 weeks gives a mean of 0.656 mm (SD±0.103 mm) 5 days postnatally, and 0.566 (SD±0.064) at the age of 110 days.[18] In full-term neonates,[17] CCT is 0.573±0.052 mm (range 0.450–0.691 mm) with a peripheral corneal thickness of 0.650±0.062 mm (range 0.520–0.830 mm). Table 6.2 shows the decrease in thickness during the first few days of life.

Another study[19] confirmed the above data and also measured peripheral corneal thickness: Superior corneal thickness was 0.696±0.055 mm, inferior was 0.744±0.062 mm, nasal was 0.742±0.058 mm, and temporal was 0.748±0.055 mm. A recent, very large study concluded that African American children had thinner corneas on average than those of both white and Hispanic children (P<.001 for both) by approximately 20 µm. Thicker median CCT was observed with each successive year of age from age 1 to 11 years, with year-to-year differences steadily decreasing and reaching a plateau after age 11 years at 573 µm in white and Hispanic children and 551 µm in African American children. For every 100 µm of thicker CCT measured, the intraocular pressure was 1.5 mmHg higher on average (P<.001).[20]

Keratocyte density is around 60,000 cells/mm^3 in infancy with a decline of 0.3% per year through life.

Table 6.1 Central corneal thickness (CCT) and curvature (R) in newborns and children

Age group	No.	CCT (mm ± SEM)	R (mm ± SEM)
Premature newborns	6	0.545 ± 0.014	6.35 ± 0.09
Mature newborns	19	0.541 ± 0.006	7.11 ± 0.07
Children 2–4 years	10	0.520 ± 0.007	7.73 ± 0.09
Children 5–9 years	15	0.520 ± 0.005	7.81 ± 0.09
Children 10–14 years	11	0.520 ± 0.007	8.01 ± 0.05
Adults (own group and data from literature)		~0.52	~7.8

Table 6.3 Values (mm) of the distance from sclerocorneal limbus to the ora serrata in the nasal, temporal, superior, and inferior meridians (mean ± SD) in fetuses aged 24–40 weeks[23]

Nasal meridian	Temporal meridian	Superior meridian	Inferior meridian
3.22	3.33	3.23	3.27
0.30	0.35	0.36	0.37

From Bonomo PP. Pars plana and ora serrata anatomotopographic study of fetal eyes. Acta Ophthalmol (Copenh) 1989; 67: 145–50. With permission from Blackwell Publishing Ltd.

Endothelial cell counts exceed 10,000 cells/mm^2 at 12 weeks of gestation, 50% of this at birth and 4000 cells/mm^2 in childhood. Mean endothelial cell count was 3500 cells/mm^2 in the unoperated eyes of a large cohort of 5-year-old children who had undergone cataract surgery in their fellow eyes.[21]

Pupil size and reaction to light

The pupil, in relative darkness, has a mean diameter of 4.7 mm at 26 weeks postconceptional age. The pupils subsequently become progressively smaller, reaching 3.4 mm at 29 weeks. There is no reaction to light until 30.6 weeks (±1 week) postconceptional age.[22] Figure 6.6 shows the change of pupil diameter in relative darkness (<10 ft-c) in preterm neonates. The mean pupil size is 3.8 mm (SD ± 0.8 mm) in the newborn period. The incidence of anisocoria of less than 1 mm is 21%; no difference was greater than 1 mm.[23]

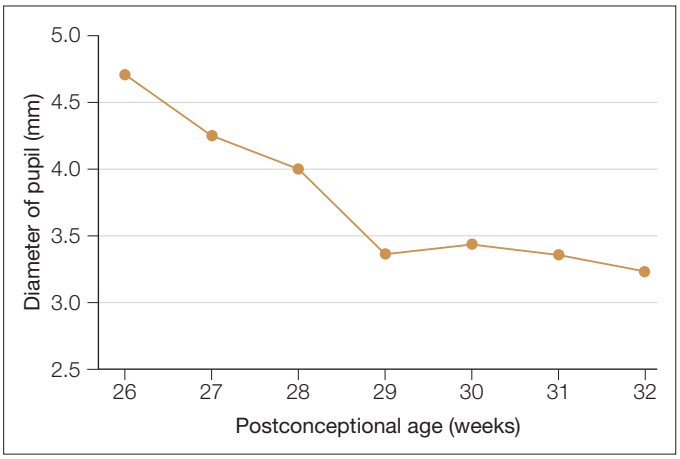

Fig. 6.6 The diameter of the pupil in relative darkness in preterm neonates. *(With permission from Isenberg SJ, Molarte A, Vazquez M. The fixed and dilated pupils of premature neonates. Am J Ophthalmol 1990; 110: 168–71.)*

The crystalline lens

The lens grows throughout life; information on lens thickness is included in the section "Axial length." The lens capsule doubles its thickness from birth to old age.

Pars plana and ora serrata

The average pars plana of third trimester fetuses is 1.17 mm in width, which is one-third that in the adult eye. The distance between the sclerocorneal limbus and the ora serrata is 3.22 mm nasally and 3.33 mm temporally (Table 6.3).[24] Similar figures were obtained from examination of 76 paraffin-embedded normal eyes from 1-week-old to 6-year-old children.[25]

Seventy-six percent of the development of the ciliary body occurs by the age of 24 months. The pars plana, which occupies 75% of the total length of the ciliary body, follows a similar course. The external distance from the limbus to the ora serrata is 0.3–0.4 mm more than the corresponding dimension of the ciliary body in these specimens.

Optic disc parameters

The diagnosis of optic nerve hypoplasia is a subjective one because it is not only optic nerve size that is important. The optic disc dimensions of 66 children of low refraction error aged 2–10 years was studied by fundus photography (Table 6.4A).[26] The vertical disc diameter, the disc area, and the cup-to-disc ratio were significantly larger in black than in white children. The optic disc dimensions (excluding the meninges) studied at autopsy[27] produce slightly different results due to fixation shrinkage (13%), but the measurements correlate well with the photographic study (Tables 6.4B and 6.4C). Approximately 50% of optic disc and nerve growth occurs by 20 weeks of gestation and 75% by birth. Ninety-five percent of the growth of the optic disc and nerve occurs before the age of 1 year. The optic nerve head in 5–16-year-old children has been assessed using Heidelberg retina tomography (HRT). The confocal scanning laser ophthalmoscope creates three-dimensional topographic images and with this technique the mean values of the optic disc area and rim area were 2.16 (SD 0.47) and 1.75 (SD 0.39) mm^2, respectively. In this age group, there were no differences in size of optic disc and rim areas regarding the age or gender of the child.[28]

Axial length

In week 9 of fetal life, the eye has a sagittal diameter of 1 mm, increasing to a mean of 5.1 mm by the age of 12 weeks.[29]

The total axial length of the premature eye (25–37 weeks postconceptional age) increases linearly from 12.6 to 16.2 mm.[14] Measurements from a later study[30] are given in Table 6.5.

Table 6.4A Optic disc parameters in 66 volunteers[25]

No. of volunteers	Race	Sex	Age	Cycloplegic refraction	Vertical disk diameter (mm)	Horizontal disk diameter (mm)	Cup-to-disk ratio	Area (mm^2)	Neuroretinal rim area (mm^2)

Ultrasound measurements of the newborn eye[31] are as follows[32,33]:

1. average anterior chamber depth (including the cornea) 2.6 mm (2.4–2.9 mm);
2. average lens thickness 3.6 mm (3.4–3.9 mm);
3. average vitreous length 10.4 mm (8.9–11.2 mm);
4. total length of the newborn eye is 16.6 mm (15.3–17.6 mm).

The postnatal growth of the emmetropic eye can be divided into three growth periods (Table 6.6 and Fig. 6.7)[32]:

1. a rapid postnatal phase with an increase in length of 3.7–3.8 mm during the first 18 months;
2. a slower phase from the second to the fifth year of life with an increase in length of 1.1–1.2 mm;
3. a slow juvenile phase lasting until the age of 13 years with an increase of 1.3–1.4 mm, which tapers off towards teenage years (ages 13–18) unless juvenile onset of myopia.[34]

Optical coherence tomography of the macula

Optical coherence tomography (OCT) has been used for quantitative and qualitative assessment of macular morphology. The technique is valuable when examining children with different retinal diseases. As in adults, the central area is the thinnest and the inner circle the thickest. Boys have slightly thicker maculae and young children appear to have thicker maculae than those in adolescence.[35,36]

Extraocular muscles and sclera

Most of the enlargement of the eye is in the first 6 months of extrauterine life. All diameters increase. The cornea and the iris have about 80% of their adult dimensions at birth. The posterior segment grows more postnatally. Therefore, in squint

surgery in the very young child, it is more difficult to predict outcomes (Tables 6.7A–C).

The thickness of the sclera in 6-, 9-, and 20-month specimens is 0.45 mm, similar to that in adult eyes.[37]

Children's visual function questionnaire

An instrument to document quality of life is retrievable from http://www.retinafoundation.org/pdf/questionnaire/cvfq.pdf, describing data for children up to 7 years of age undergoing different treatment modalities to detect resulting changes in quality of life.[38]

Visual acuity

Postnatal maturation of the visual pathways plays an important role in visual development. At birth, the macula is immature. The fovea reaches histological maturity as late as between 15 and 45 months of age. Myelination of the optic nerve is not complete until at least the age of 2 years.

The period between 1 and 3 months is a period of radical changes in visual capabilities and behavior. A rapid rise in acuity, the appearance of the low-frequency cut in contrast sensitivity, the emergence of smooth pursuit eye movements and of symmetrical optokinetic nystagmus, and possibly the establishment of functional binocular vision all occur roughly together.[39]

Lid closure is seen on illumination with a bright light in babies of 25 weeks' gestation. The pupillary reflex to light is seen from weeks 29 to 31. Discriminative visual function and "tracking" eye movements are present by 31–33 weeks' gestational age.[40]

The acuity of the newborn infant is close to 6/240, and at 7 weeks of age the infant has eye-to-face contact. Visual acuity rapidly increases to 6/180–6/90 at 2–3 months. At 6 months, visual acuity is between 6/18 and 6/9. The assessment of visual acuity, however, depends on the testing method. Table 6.8 summarizes pooled information of visual development.

Table 6.8 Visual acuity according to different methods, given as Snellen equivalents

Technique	Newborn	2 months	4 months	6 months	1 year

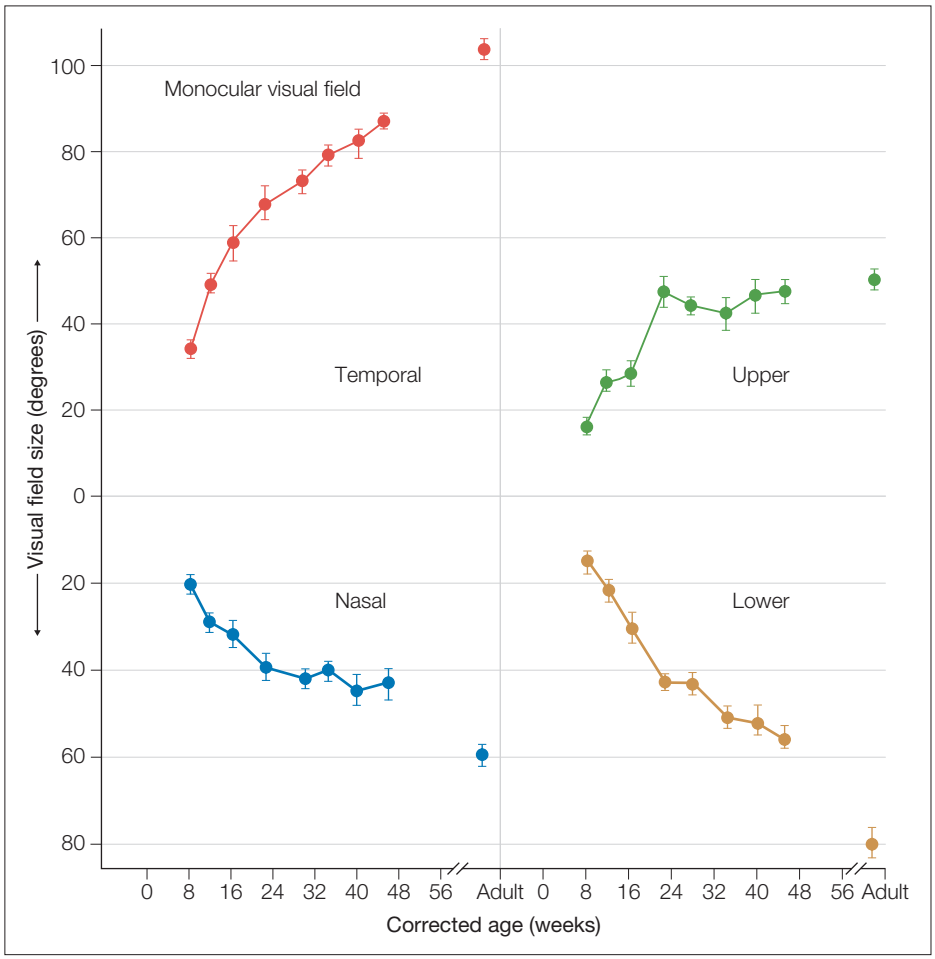

Fig. 6.8 Development of monocular visual field. The horizontal (left) and vertical (right) meridians. Error bars indicate 2 SEM. *(From Mohn G, van Hof-van Duin J. Development of the binocular and monocular visual fields of human infants during the first year of life. Clin Visual Sci 1986; 1: 51–64, as well as personal communication 1994.)*

Full accommodative ability is not established until 3–4 months of age. Yet, it does not appear to be a major limiting factor on reported acuity values.

Stereoacuity can be demonstrated by the age of 16 weeks. By 21 weeks, infants have a stereoacuity of 1 minute of arc or better.[41] Median Randot stereoacuities are 100 seconds of arc for 3-year-olds, 70 seconds of arc for 4-year-olds, 50 seconds of arc for 5-year-olds, 40 seconds of arc for 6-year-olds, and 45 seconds of arc for 7-year-olds.[42]

Results of visuoperceptual testing in a cohort of children aged 4–15 years revealed that visual acuity in the better eye was ≥1.0 (≤0.0 logMAR) in 79% of subjects. None of the children had visual acuity <0.5 (>0.3 logMAR) in the better eye. Amblyopia was found in 0.7% of the subjects. Signs of visuoperceptual problems were reported in 3% of the children.[43] Nevertheless it is difficult to know precisely at what age adult acuity is normally attained!

Visual field

The visual field of the infant depends on the distance at which the target is presented, whether static or kinetic fields are investigated, how interesting the targets are, and whether a fixation target is present. Between 2 and 4 months, the child develops the ability to switch attention to a new object.

The binocular visual field shows little development between birth and 7 weeks. After 2 months there is a rapid expansion of the field until 6–8 months of age. The visual field increases at a slower rate up to 12 months (Fig. 6.8). An asymmetry of 13° or more should be considered pathological.[44,45] Normative data for 4- to 12-year-old children are shown in Table 6.9.[45]

Table 6.9 Mean extent of visual field in degrees (± SEM) in each meridian for five age groups

Age group	ST	IT	IN	SN
RIGHT EYE				
4 years	59.2 (2.1)	84.7 (1.6)	51.4 (2.4)	47.8 (1.8)
5 years	63.4 (2.4)	88.1 (1.9)	52.4 (2.6)	51.7 (1.6)
7 years	66.8 (1.5)	86.0 (2.0)	53.6 (2.0)	58.4 (1.3)

Refraction, corneal curvature, and astigmatism

Most authorities agree that neonatal refractions are distributed in a bell-shaped curve around +2 diopters (D).[46] Later, there is a shift toward emmetropia. In a group of older Swedish children, 68% had no refractive errors, 9% were hyperopic (≥2.0 diopters in spherical equivalent), and 6% were myopic (≥0.5 diopters spherical equivalent).[43] The range of astigmatism is difficult to study due to off-axis retinoscopy errors. One study of non-cycloplegic refractions in children aged 0–6 years revealed a minus cylinder against-the-rule before the age of 4.5 years and a minus cylinder with-the-rule after that age.[47]

The smaller eyes of premature and full-term babies have a more curved cornea of 6.35 mm in curvature radius in contrast to the adult with 7.8 mm (see Table 6.1).[17] Keratometer measurements in one study were: in premature infants 53.1±1.5 diopters, in neonates 48.4±1.7 diopters, at 1 month 45.9±2.3 diopters, and at 36 months 42.9±1.3 diopters. Another study reported 47.59 diopters (SD±2.10; range 44.08–50.75 diopters) in the newborn, 45.56 diopters (SD±2.70; 40.13–52.75 diopters) in the 12- to 18-month age group, and stabilization of the cornea at the age of 54 months with an average of 42.69 diopters (SD±1.89; range 40.50–47.50 diopters).[48] Videokeratography reveals that neonates have steep, high astigmatic (generally with-the-rule) corneas at birth that flatten significantly by the age of 6 months. At birth, the central corneal power measured 48.5 diopters and astigmatism measured 6.0 diopters usually with-the-rule with a mean axis of 95°. Neonates delivered vaginally had a greater frequency of with-the-rule astigmatism than those delivered by cesarean section. By 6 months, the mean central corneal power and astigmatism decreased to 43.0 and 2.3 diopters, respectively.[49]

There is considerable variation in the nature and severity of refractive errors reported from different areas of the world.

Intraocular pressure

Intraocular pressure is easily measured in children with the use of rebound tonometry. Most studies show intraocular pressure is lower in children than in adults. Babies who were 3–11 weeks premature had a mean intraocular pressure of 18 mmHg (13–24 mmHg) with a Perkins tonometer and topical anesthesia.[50] Lower values of 11.4 mmHg have been reported in full-term neonates.[51] Somewhat different results were obtained with a hand-held Tonopen tonometer. With an applanation tonometer, a mean intraocular pressure of 10.3 mmHg was found in 70 premature babies, aged 25–37 weeks.[14]

The intraocular pressure in 460 subjects aged 0–16 years measured with a non-contact Keeler Pulsair tonometer was reported to be 9 mmHg in neonates, increasing to 14 mmHg at the age of 5 years (Fig. 6.9).[52] Averaged Pulsair readings agreed well with Perkins applanation tonometry values in a study of children measured under general anesthesia.[53] The ICare rebound tonometer, in a group of infants, gave a mean intraocular pressure of 11.8±2.7 mmHg with no statistically significant difference between two observers.[54]

THE EQUIPMENT
HISTORY: INCLUDE THE CHILD
A NO-TOUCH APPROACH AT FIRST
TARGETED EXAMINATION
NEXT STEP: TOUCHING AND OTHER METHODS OF ANNOYING THE CHILD – THE SECOND PART OF THE EXAMINATION
FINALLY: REWARDING SUCCESS
REFERENCES

A child's problem will likely be easily assessed with a little play, a few key tricks, and, mostly, a reasonable dose of spontaneity and patience. Cookie-cutter or hurried visit plans will rarely yield thorough assessments.

Assent and consent

Bonheoffer said, "The test of the morality of a society is what it does for its children." As caregivers to children and their families, we have important ethical responsibilities. Whereas in the past, the "omniscient doctor" made all the decisions, we live in a time of patient advocacy and participatory decisions, some of which are unique to children. Our responsibility is to act for the good of our young patients and their families. This entrustment of care is a form of guardianship, but we have to consider these same children as full persons with a right to the truth.[1] In the process of consent, we should determine the limits of our patients' autonomy: what decisions can a child make on the information we provide? When do children have the capacity to evaluate risks, consequences, and benefits? Do we need a child's assent before proceeding with an unpleasant examination or treatment, even when we have unequivocal parental consent?

It's all about the child

Personality, timing, and the examination itself will all influence the patient's cooperation. For example, a crying infant will not reveal his visual potential, but just a few minutes of calming breastfeeding can settle the child enough to allow the observation of a visual response to a face. A worried 3-year-old with uveitis might not volunteer for a slit-lamp examination, but given the chance to first talk about a cherished new pair of sneakers, he or she will eagerly hold the "handle bars," allowing a good view of anterior chamber cells. In fact, for the most part, it's all in the act. A teacher of mine once said, "With kids, you have to be ready to put on your monkey suit, and stand on your head."

The equipment

A successful examination room needs a few extra toys to interest the child: small near fixation targets, silent for the most part so as not to test hearing, and transmitting an internal light; an attractive, audible distant fixation target; and, finally, rewards to cap it all. How many visual targets? To paraphrase a colleague (Chris Lyons, personal communication, 2011), "One toy, one look" (Fig. 7.1). In addition to the usual ophthalmic equipment, a portable slit-lamp and tonometer, as well as appropriate vision charts, will complete the full set for a thorough examination of most children. Additional equipment may be necessary in special circumstances: testing infant vision, examining premature infants, a full orthoptic assessment, electrodiagnostic or imaging investigations. Full discussion on these will be found in other chapters.

History: include the child

Taking a history is crucial. With children, time and opportunism are crucial. While it is tempting to get most of the history from the parents, one should never forget the young patient's own story. A child's behavior and perspective on the events can be revealing. For example, a well-intentioned parent might provide a very different account of a poorly compliant amblyopic child who, in turn, describes a great summer at the grandparents' without having to wear "that darn patch," or getting the dreaded morning drop. Important details will be revealed only once we gain the child's confidence. Examples of this include the bullied child who will avoid wearing the prescribed spectacles or emergency room pellet gun stories that drastically change when the parents are not present. In

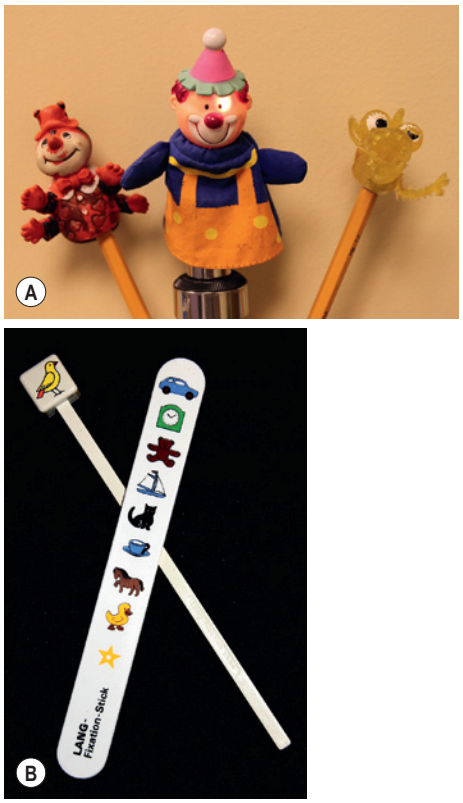

Fig. 7.1 Near fixation targets. (A) Finger puppets: all able to transmit light, giving creative possibilities to enhance their attractiveness. (B) Lang fixation stick and cube. These have become a standard the world around.

other circumstances, disagreements between guardians can suggest poor family dynamics; blame games, avoidance, and miscommunications can all be barriers. But it is also important to recognize socioeconomic and cultural issues that can hamper full cooperation from the family: repeated missed appointments, spectacles that are always "left at home," numerous children in tow at appointments, inability to repeat the instructions given, or evidence of poor hygiene. It has been long recognized in the pediatric literature that education of the mother is key to a successful outcome.[2] This also applies to amblyopia, glaucoma, or uveitis management among others, where understanding, cooperation, and engagement of the family are essential. Finally, pictures can play a big part of the historical record. For example, a few good photographs taken at home can easily give enough clues to target an otherwise difficult examination for a diagnosis of Duane retraction syndrome or Brown syndrome. Likewise, retinoblastoma is often detected from family photographs.

A no-touch approach at first

Ophthalmology is known for its sophisticated and high-tech visuals. But with children, simple observation should be the first priority, with many clues helping to clarify or support clinical findings that can be difficult to obtain otherwise. Time simply watching, while maintaining a "hands off" approach, before intervening is key. The following pages describe the chronological components of the examination for a child presenting to the office of a pediatric ophthalmologist, starting with the least intrusive ones. Specialized ancillary tests are mostly done after the initial clinical assessment and based on specific diagnostic requirements; we refer the reader to the relevant chapters for these.

Say "hi"!

Break the ice, address the child, be friendly, get down to eye level, and avoid white coats. At the first visit, the ophthalmologist is a stranger and, except for infants, most children are reluctant to initially open up to strangers. Outfit, shoes, toys, or stuffed animals' names – these are all good topics of conversation that will help start a warm exchange and create the welcoming atmosphere so important to the rest of the encounter. Remember that children love to play – the examination should therefore remain a game.

Observe

While greeting the child and family, remember to observe: the head position (a cranial nerve dysfunction or nystagmus), photophobia (corneal disease, retinal dystrophies, glaucoma), body language (evidence of a visual handicap) or unusual behavior (extreme hyperactivity of attention deficit, withdrawal in cases of abuse), and the possible clues suggesting developmental delay, especially associated with abnormal visual functions (Table 7.1).

Head/body posture

A visually impaired child will often hold the head down, even in dimmer lighting. On the other hand, the prostration of a photophobic child in regular daylight is an alarming clinical presentation. Head thrusts or nodding can be of diagnostic help with abnormal eye movements in oculomotor apraxia and spasmus nutans. An abnormal head posture that increases with visual efforts is typical of the null position of a nystagmus.

Visual behavior

A classic scenario is that of the allegedly blind infant who brightens up, follows, and fixes objects only when the lights are turned down – a scenario seen in achromatopsia. Sometimes, other clues can be useful: the excessively close focusing of a very high myope or the preferential visual attention toward objects of the autistic child who avoids eye contact.

Where to place the child for the examination

Many young children will be more comfortable, quieter, and more cooperative on their parent's lap. A few will require you to start the visit with them in their parent's arms and away from all the strange machines and equipment (Fig. 7.2).

Parents as a resource

Sometimes the child is nervous being the center of attention. It is easy to involve others in the room to relieve the tension, for instance: "Who are these people? Is this your sister, or your mom? Is that a real baby in that stroller?" This is also the time for a short, targeted history on the current problem with the guardian. With the parental version of the problem at hand, it can be most revealing to follow with the child's own story: a daily headache becomes a rare occurrence, or vice versa; a

Table 7.1 Visual developmental milestones relevant to a pediatric ophthalmology examination in young children

Age group	Fine motor-adaptive	Personal/social	Language (receptive and expressive)
0–4 weeks	Visual following from side to midline (90° arc)	Regards human faces with interest	
2 months		Smiles responsively	
3 months	Looks at object placed in hand Looks promptly at objects in midline Follows visually in 180° arc and in circular pattern		
4 months	Reach and grasp begin Looks at objects in hand	Excited when toys presented	
5 months		Distinguishes strangers from family	
6 months		Pushes adult hand away to reject	
8 months		Finger feeds	Responds to name when called (turns)
9 months	Explores pellet with index finger		
10 months		Imitates nursery tricks (modeled), e.g. pat-a-cake Bangs two cubes together in imitation	
12 months		Hands over toy on request with accompanying hand-out gesture	
24 months	Threads shoelace through hole		
48 months	Picks longer of two lines	Buttons up	Points to colors on request (red/blue, yellow/green)

Fig. 7.2 Indirect ophthalmoscopy in infants. An example of unconventional assessment techniques necessary in infants. Here the examination is carried out successfully in the patient's own comfort zone: a stroller and a good suck on the examiner's finger.

complaint of poor vision is really a wish to wear spectacles like the big sister, and so on. Next comes the family history. Looking at the family photo album is helpful. It may confirm the evolution of an abnormal head posture, or time the onset of an abnormal red reflex. However, all this should not be a protracted affair; things easily get boring or stressful for a child sitting and waiting for something to happen. Details of the history are often better gathered as one goes along with the rest of the visit.

A word of caution: too many people in the room can create havoc, as they can become a source of distraction and noise. The best scenario is to have the child in the office with a cooperative parent or two. A good friend of the same age group can also be a reliable calming agent for a 6–10-year-old. Finally, and unfortunately, in difficult situations, someone might have to *hold* a non-cooperative child. Either in decubitus, a preferred position for drop instillation, or sitting and facing the examiner, the parents quickly learn how they can help, and comfort their child at the same time (Fig. 7.3).

Targeted examination

Since opportunities are often limited by a child's cooperation, the examiner should first target the most promising component of the examination. Guided by the history and the observational clues gathered in the first minutes of the consultation, this approach will increase the yield of the encounter and minimize the frustrations of an incomplete examination. However, keep on hand a checklist to ensure all the components of a full examination are achieved. As the visit progresses, the items are checked. If necessary, other visits may have to be planned to complete the list.

The Brükner test

This is the best way to introduce ophthalmic instruments to a child.[3] It involves a quick look through a direct ophthalmoscope, at a distance of a third of a meter. The brightness, color, and the homogeneity of the pupillary areas are checked and compared in a semi-darkened room, without dilating drops; this will

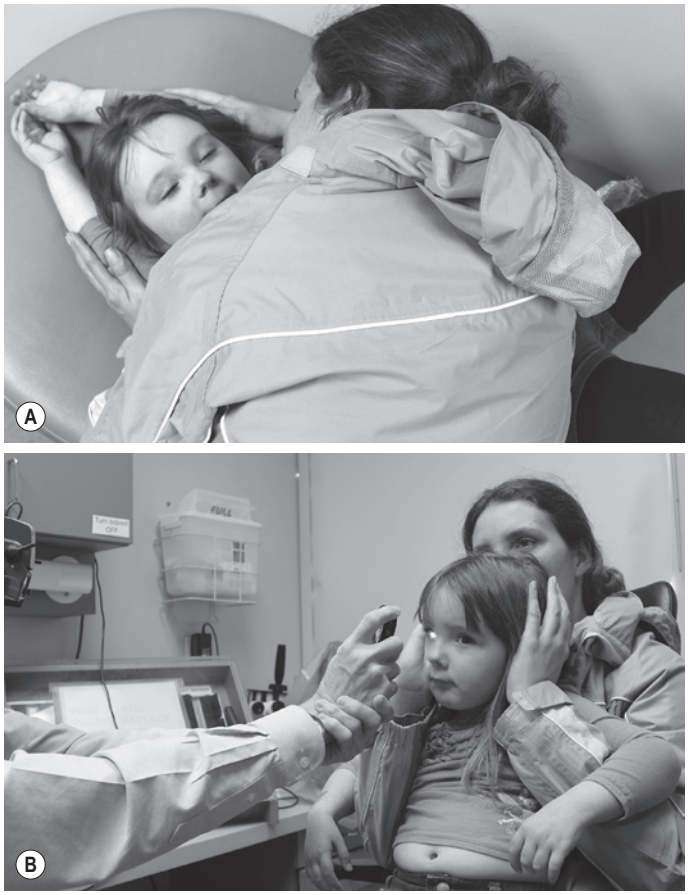

Fig. 7.3 Parent hold. Parents can help physically stabilize their children for crucial parts of the examination, either in the supine position with the elbows pressed against the head (A) or sitting facing the examiner (B). Both positions involve the close proximity of the parent and his/her soothing voice to help calm the child.

Fig. 7.4 Brückner's test. In all cases, make sure the patient is comfortable, least disturbed, and with his or her own things. Stay at about 0.6 m away with the widest beam of the ophthalmoscope encompassing both pupils. Focus the lenses for the working distance and compare both corneal reflection and fundus red reflex for symmetry, homogeneity, and brightness. *(From Goldbloom R. Pediatric Clinical Skills, 4th ed. Philadelphia, PA: Elsevier; 2011. With permission from Elsevier.)*

help detect visually significant opacities, large or asymmetric refractive errors, and some ocular misalignments (Fig. 7.4). The position of the corneal Purkinje images in each eye can reveal misalignment.

The few seconds required for the Brükner in the early stage of a consultation can help answer crucial questions: How is a cataract or corneal scar obstructing the pupillary area? Can light pass through a congenital pupillary membrane? Is this likely to be a "pseudostrabismus" or are the corneal light reflections really off-axis? Is there significant anisometropia?

Binocularity: first no dissociation

From around 2 years of age, a child's binocularity can be assessed clinically. Already at age 3 to 4 months, binocular vision has been established to some degree[4] and, as a result, infants with congenital oculomotor difficulty like Duane retraction syndrome can be seen adopting a compensatory head posture.

For formal testing and to assess a patient's performance "as if in real life," it is important to avoid binocular dissociation by occlusion of one eye or polarizing glasses. The author favors tests that do not involve holding things near the child's face. The two-pencil test (2PT), and the Frisby and the Lang stereotests assess stereopsis without the interference of dissociating components (Fig. 7.5). They can also be easily introduced into games. The 2PT involves matching a real three-dimensional (3D) target in space; it can detect stereopsis in the order of 2000–3000 seconds of arc.[5] The Frisby also involves real spatial separation of its targets, another easy game for toddlers. The Lang stereotest achieves haploscopic image dissociation to produce a stereo effect without the need for glasses and measures at least three stereoacuity levels. Children as young as 2 years of age can be observed to look at the perceived 3D targets. Eventually, more demanding and dissociating tests can be used for older children.

Vision assessment

After binocularity, monocular visual function can be assessed. The degree of intrusiveness increases but, if conducted carefully and cheerfully, testing can fit into a play scenario. The examiner should remain aware of guessing, memorizing, and peeking. The reliability of visual acuity (VA) testing is dependent on the child's concentration. VA tests vary with age, but the strategy is always the same: binocular first, to get a best acuity and establish a comfort zone for the child, then the expected better eye is measured, and finally the poorer side is measured.

Measuring binocular VA can lead to more information than just a level of vision: watch the child. For example, an increasing head turn as he or she reads down the chart will highlight an apparently mild nystagmus. Similarly, a reduced distance binocular acuity in a child with intermittent exotropia can be indicative of the accommodative efforts necessary to help control the deviation.[6]

The preferred vision assessment tools for infants are based on psychophysical observations. Healthy infants will preferentially look at a normal human face almost as soon as they are born.[7] They will do so while awake, but they also need to be calm and happy; the best time for this is halfway through a feed. In this manner, the presence of normal visual

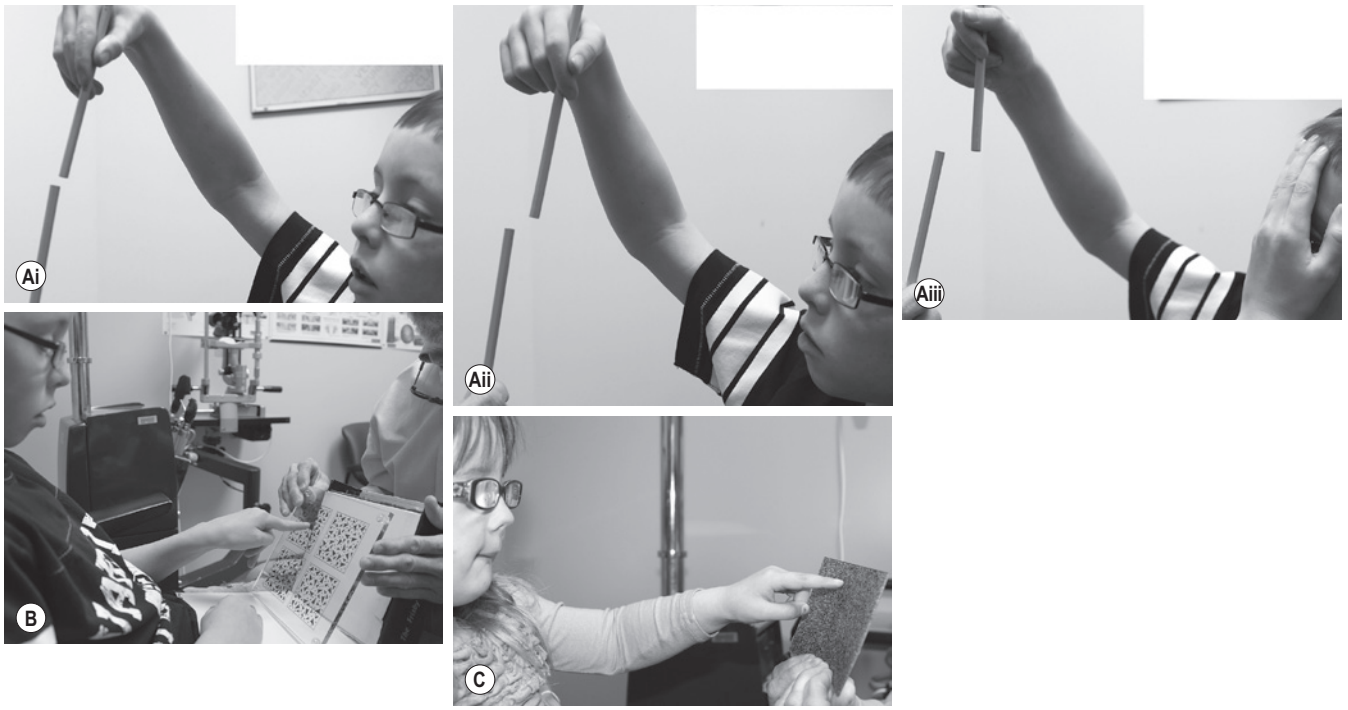

Fig. 7.5 Non-dissociating stereotests. (A) The two-pencil test (2PT) has its limitations because of the many motor components involved, but it provides a real life demonstration of "three-dimensional" vision with straight eyes, as it does here in this esotropic child with high accommodative convergence/accommodation (AC/A) ratio who shows the advantage of looking through his bifocals. Note: keep the targets at eye level. (B) The Frisby test can give false positive clues of stereopsis if the image plate is rotated on its axis or the patient's head shifts sideways. It is easy to administer and is a good test in the right conditions. (C) The Lang stereotest can be interpreted by watching the patient point or simply gaze at the targets seen only stereoscopically. Again, however, movements of either the test card or the patient's head can help find monocular clues (apparent increased scrambling of the random dot array in the location of the stereotargets). Note the curvature given to the card by the examiner to make it match the curvature of Panum's area.

Fig. 7.6 Infant following face. The examiner holds the infant with good support of the head. The child is happy and relaxed, hence receptive. The face of the examiner is slowly panned across the baby's visual field while observing the child's eyes and head turn in unison with the moving target. The intended movements of the head are easily felt by the supporting hand. The eyes of the examiner's face being of such importance here, it is suggested to remove one's glasses to avoid reflections. A moving but silent mouth with its contrasting contours has been shown to enhance the attractiveness of the target face for infants as young as 3–4 months.

processing can be confirmed (Fig. 7.6). More crudely, one can also observe the exaggerated lid opening of a sighted infant when the lights are suddenly dimmed. Similarly, we can see the quick re-fixation of a sighted baby toward a preferred visual target, like a face, after having been submitted to a spin that has generated good oculo-vestibular movements.

Visual behavior is also compared when each eye is obstructed in turn (Fig. 7.7). The CSM (central, steady, maintained) system provides a repeatable assessment of the *ocular* fixation *behavior* to a target (CSM fixation: *central*, in the middle of the pupil; *steady*, without nystagmus or other eye instability; *maintained*, even if a monocular short interruption occurs). The visual or general behavior of the child is compared as each eye is tested separately after the initial binocular assessment. Another useful method of comparing one eye to the other is to challenge a maintained fixation with a vertical prism. A 10 to 16 diopter (10–16Δ) prism is used while watching for a re-fixation movement of either eye.[8] This simple method

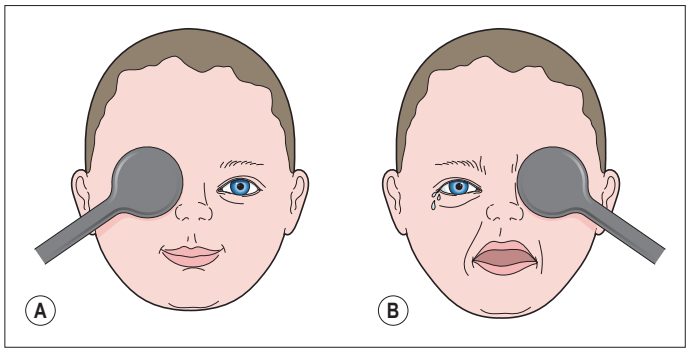

Fig. 7.7 Evaluation of vision in infants. A child with poor vision in one eye (here the right), may not object to having the poorly seeing eye covered (A), but will show displeasure when the good or better eye is covered (B). This can translate to behavioral changes or active avoidance measures with head movements or pushing of the cover with the hand. *(From Goldbloom R. Pediatric Clinical Skills, 4th ed. Philadelphia, PA: Elsevier; 2011. With permission from Elsevier.)*

can be particularly useful in the absence of a horizontal strabismus in a child with suspected vision difference between the two eyes. In esotropic youngsters that are too young for quantitative measurements, symmetry of cross fixation or latent nystagmus are indirect indicators of vision. Conversely, sine wave grating tests, including optokinetic nystagmus, visual evoked potentials, and the so-called "Teller cards" based on preferential looking, all estimate vision levels in children but are not primary diagnostic tools in most clinical settings. While they can be applied to a great number of children because of their exploitation of the visual system's innate hunger for simple high-contrast grating visual targets, they can perform unreliably in detecting interocular vision differences due to amblyopia and can overestimate the potential recognition vision capacity if one is not very careful in interpreting the results.[9,10] On the other hand, recognition quantitative visual acuity tests designed in the last few decades are well adapted to young children. They use comparison games and consist of highly standardized logarithmic distribution of optotypes. These include the HOTV and LH tests that have become standards in visual acuity testing for children who are too young to complete the ETDRS (Early Treatment Diabetic Retinopathy Study) test (Fig. 7.8). Most reports show good reliability starting at age 40 months on average.

Dynamic retinoscopy

This technique, which requires the child to focus on a target placed on the examiner's retinoscope while overcoming minus lenses, detects the presence and degree of accommodation.[11] It may be useful in conditions like trisomy-21, where hypoaccommodation to near targets is evident. Both eyes are observed simultaneously, allowing easy comparison.

Versions, ductions, null position

To evaluate all six extraocular muscles (EOM), a quick and dynamic assessment of versions can be carried by a simple technique involving the mental representation of a virtual picture frame in front of the patient's face, the corners of which are the targets to reach with a fixation object (Fig. 7.9). This facilitates the detection of muscle underaction. In a cooperative child, monocular testing will differentiate version versus duction deficits. All four horizontal muscles – hence

Fig. 7.8 LH logMAR vision chart for children. A well-standardized and validated visual acuity (VA) test, the Leah Hivarinnen comparative recognition VA chart, has become a gold standard in children of all ages. It can be used in children as young as 36 months. At 41 months, the testability in the general population is good.

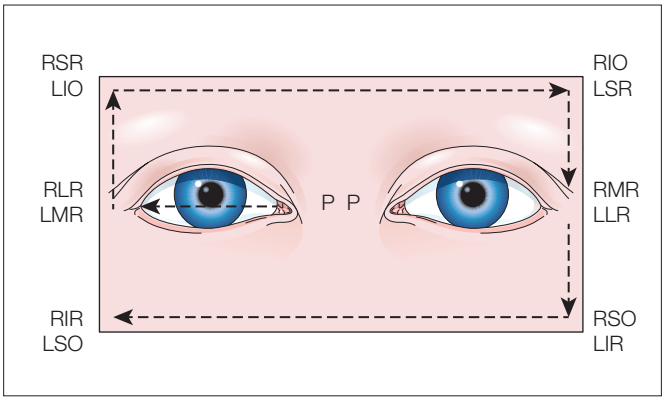

Fig. 7.9 The frame used to evaluate comitance of a strabismus. A slow continuous movement of the dim fixating light along an imaginary frame around the patient's eyes allows the assessment of all 12 extraocular muscles. LIO, left inferior oblique; LIR, left inferior rectus; LLR; left lateral rectus; LMR, left medial rectus; LSO, left superior oblique; LSR, left superior rectus; PP, primary position; RIO, right inferior oblique; RIR, right inferior rectus; RLR, right lateral rectus; RMR, right medial rectus; RSO, right superior oblique; RSR, right superior rectus. *(From Goldbloom R. Pediatric Clinical Skills, 4th ed. Philadelphia, PA: Elsevier; 2011. With permission from Elsevier.)*

cranial nerves II and VI – can easily be assessed with the doll's head maneuver. For infants, a quick turn of the examiner on a rotating stool in each direction while holding the child up in front of one's eyes, with a slight tilt forward to maximize utricular responses, will easily confirm the presence of full

Fig. 7.10 Spin the baby for horizontal extraocular movements. Horizontal strabismus can appear to have limited abduction or adduction in infants. Stimulating an oculocephalic response will elicit full movements by rotating with the child in one's arms while watching the eye movements.
Note the forward tilt of 30° to line-up the horizontal semicircular canal with the plane of rotation, enhancing the response. A sighted child will also have the ability to stop a postrotational nystagmus, in contrast to the tonic eye deviation in the direction of the rotation of the blind patient.

horizontal movements (Fig. 7.10). This can solve the frequent conundrum of a poorly abducting eye in an otherwise normal esotropic infant. For older children, if no neck anomaly exists, a quick short-amplitude forced jerk movement of the head will induce the same response and often help reveal that elusive full eye movement.

Next step: touching and other methods of annoying the child – the second part of the examination

Use the company

Take advantage of those in the room who came with the child; if they are older or looking more at ease, conduct key tests on them first. This will include the parents, of course, but a favorite stuffed animal can play the same role.

Pupils and corneal diameter

These are difficult to examine. One needs attractive and noisy fixation targets, both for near and distance. The use of magnification is sometimes useful to visualize small pupils (surgical loupes come in handy here) and a well-located light switch to change the room lighting while observing the pupils is also an asset. For pupillary light responses, the diameter, as well as the dynamic aspect of the response, provide valuable information. The observation of the pupils' behavior while turning on the room lights after 3–4 seconds of darkness can be sufficient: normal pupils will constrict, while those of an achromat will clearly dilate initially, with the opposite happening when the lights are turned back on. Finally, taking a digital photograph can provide reliable documentation of corneal diameters or anisocoria. Photographing a millimeter ruler held in the limbal plane (Fig. 7.11), the camera zoom function can be used to allow an exact match of the ruler in the photo on the camera screen against a live ruler held over

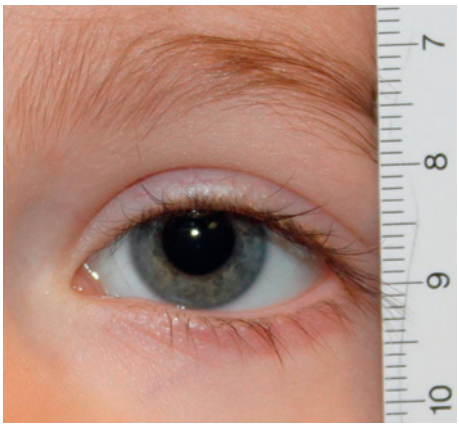

Fig. 7.11 Precise measurements by photograph. A calibrating ruler placed in the same plane as the object of interest of a photograph will provide the accurate reference for the measurement of that object, be it a pupillary or corneal diameter, or an interpalpebral fissure.

the camera screen. Once the ruler on the photo is zoomed accurately to "life size," the pupil, cornea, ptosis (or anything else in the iris plane) can be easily measured.[12]

Lids

Ptosis can be measured even in the youngest children with a bright fixation toy, and using its corneal reflexes as landmarks to measure the lid margin-to-reflex distances. One should note if the lid margin fails to clear the visual axis under normal viewing circumstances, as this could represent an amblyogenic risk. Finally, food (or liquid in a bottle) can be of great use to elicit the typical lid movements of the Marcus Gunn jaw-winking synkinesis.

Binocularity

If the preliminary testing (see above) was not sufficient, more refined binocularity testing can be used at this juncture. The necessary glasses, prisms, and various testing complexities can, nevertheless, require great acumen when interpreting the results in younger children. Note that earlier monocular testing could have dissociated the patient and disrupted fusion, influencing the results at this stage. This is typically the case in intermittent exotropia.

Confrontation fields

A reliable visual field assessment in young patients can be critical. Quantitative Goldman perimetry can be obtained from around 5 years of age in cooperative children by a dedicated perimetrist. Automated machines only become reliable later. Therefore, a good confrontation technique is important. With younger children, moving fingers (MF) are good targets, while in older patients, finger counting (FC) is best (Fig. 7.12). Very young children can mainly do binocular testing. Conversely an older child should be able to cooperate with very accurate confrontation using a 4 mm white pin, documenting the blind spot, similarly to adults.

Strabismus assessment

In addition to the observation of head posture, variable angles, and fixation behavior, the prism cover test and alternate cover

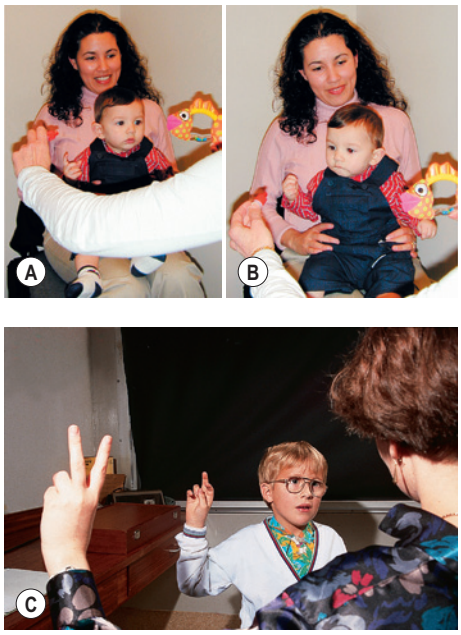

Fig. 7.12 (A) Assessing the visual field of infants. The tester attracts the baby's attention to a toy while bringing in an object, in this case a dropper bottle, silently from the child's right side to see whether the child's attention is drawn to it – which in this case it is! Although seemingly crude, if defects are detected by these methods, they are likely to be functionally significant in the future. (B) Demonstration of finger counting technique to assess visual fields in older children. While the tester watches the fixation, the child tells her when the tester's fingers are wiggling or may watch or count the fingers if able to do so. *([A], Photo by Dr Hung Pham.)*

test, as well as sensory testing, can be performed to a certain degree in children of all ages. Appropriate accommodative targets are essential for reliable measurements. At least one 6-meter target, and ideally a window to the outside world, are essential for exotropic patients. No one carries out these measurements better than a well-trained orthoptist. The great value of these professionals in the successful evaluation of children cannot be overemphasized, especially for strabismus and amblyopia.

Slit-lamp examination

The success of the anterior segment examination in children depends a lot on their degree of comfort. But even in the best of circumstances, the conventional slit-lamp's short working distance may frighten many children. Operating loupes at 2.5× magnification can be useful for surface problems and a high-magnification Brückner with the direct ophthalmoscope set at +5 D can help for media opacities. The less imposing portable slit-lamp can be of help for some less cooperative children or bedside examinations. However, infants can often be propped up with the help of adults for a conventional slit-lamp examination (Fig. 7.13).

Refraction

Good cycloplegia is essential for reliable refractions of children and it is important to achieve that goal with minimal stress and trauma. The author likes to postpone the drops needed to achieve this until the last stage of the first visit. In difficult cases, it may be helpful to teach the parents drop instillation at home. Because one drop of most cycloplegic agents is frequently

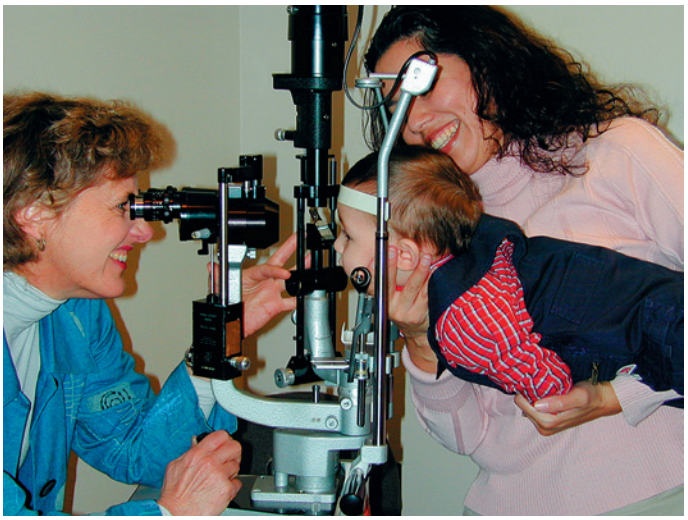

Fig. 7.13 Method for examining infants at the slit-lamp. First, the ophthalmologist sets up the slit-lamp microscope so that it is ready for the most important task (i.e. looking for transillumination using a coaxial beam). While the parent (or clinic assistant) holds the baby with the left arm under his tummy, he/she places his head on the white strap, continually encouraging him.

Fig. 7.14 Sciascopy in the axis, and cylinders. While paying attention to one's working distance, any technique that will ensure a cycloplegic refractive sciascopic measurement in the visual axis will ensure precise measurements. When cylinders are involved, an infant trial frame without temple pieces will serve wonders in providing both a good cache as well as helping to find the correct axis.

insufficient to achieve good accommodative paralysis in dark-eyed individuals, pretreatment with a topical anesthetic may be helpful. Apart from reducing the discomfort, this improves corneal penetration and increases the effectiveness of the cycloplegic agent.

The younger children often dislike having refractive trial lenses placed close to their face; a ±0.12 D lens to hold during the examination can be a great distractor. Astigmatic axis assessment is improved by ensuring a good alignment with the visual axis and by placing the lenses in a trial frame. For younger children, using the frames without the temple pieces greatly helps (Fig. 7.14). It is worth trying the phoropter with

all children who can sit straight in the examination chair and do so voluntarily. For most, it is a fun experience once you point out that their side of the machine is just like looking through the glasses of the most famous mouse cartoon character (Fig. 7.15). Finally, it cannot be emphasized enough that a calm environment is essential for refracting children. A continuous dialogue between child and refractionist in a quiet and darkened room will help even the most challenging cases.

Intraocular pressure measurement

One reliable measurement in clinic can make the difference between a discharge or many more visits, including examinations under sedation or anesthesia. Reliability of readings is a major issue, not only because of the variability of thickness of the pediatric cornea, but also because of the profound effect the conditions of examination can have on the measurements obtained. General anesthetics all modify the pressure to some extent, most decreasing them, and any kind of crying or forceful lid opening will dramatically raise the values. Some instruments are reliable only in a certain range of pressure reading (e.g. Tonopen and iCare types), while others are difficult to use in smaller eyes (e.g. Perkins, Goldmann). All require a relaxed wide-eyed patient and, for that reason, careful scheduling to take advantage of feeding and nap times is essential (Fig. 7.16).

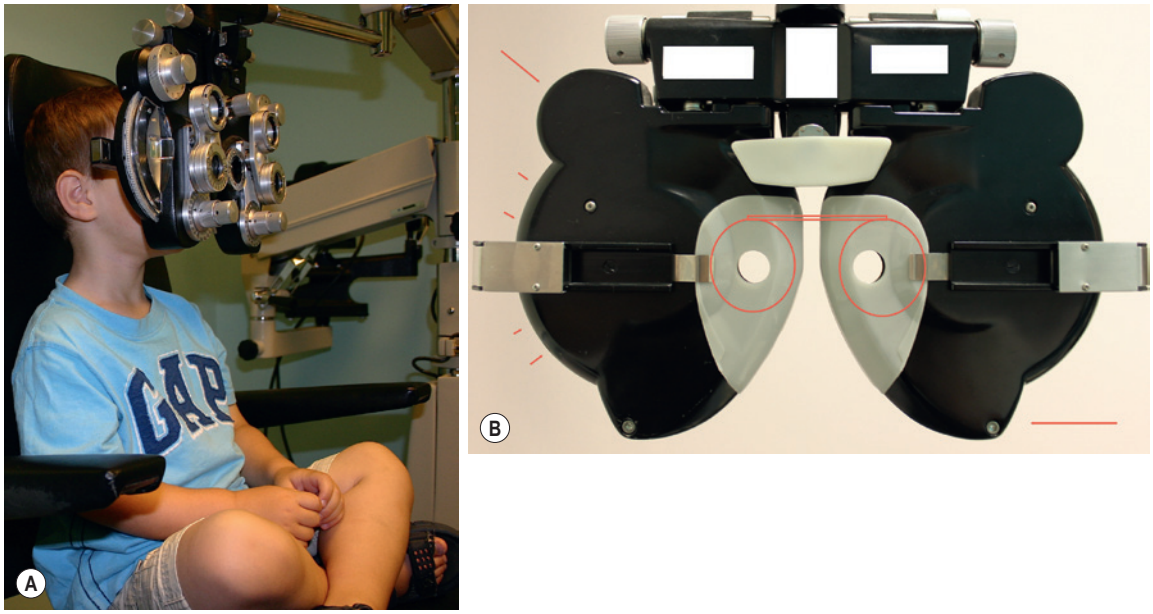

Fig. 7.15 The phoropter and children. (A) As soon as a child can sit, in theory, the phoroptor can be used for refractions. A sitting position with good stable posture is essential. (B) On the patient's side, familial features of the famous iconic cartoon mouse become obvious with a little imagination: ears, cheeks, whiskers.

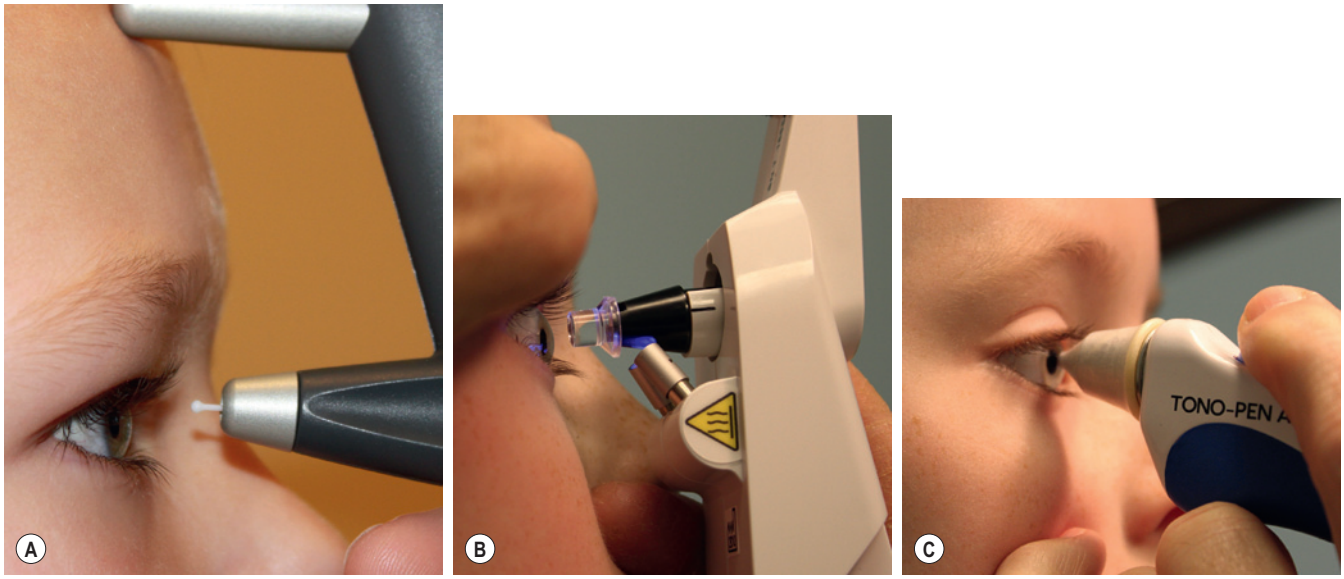

Fig. 7.16 Tonometers in the pediatric age. Note the wide-eyed relaxed-looking child in all these photos. Anything other than this will give you a faulty reading with any instrument.

Fundus examination

This is often what will break the magic spell of a pleasant visit. Most children will not object even to the bright indirect ophthalmoscope, and will cooperate for a direct ophthalmoscopic examination, so long as an interesting fixating target is made available to them for the other eye. The liberal use of fantastical themes to describe what one sees in that fundus helps allay fears and improve cooperation. The child's own body parts are perfect visual targets for the peripheral retinal exam; most know where their left big toe or shoulder is, and will look in the right direction, especially if asked to move the targeted body part. For most examinations, the regular use of the 20 D aspheric lens with the indirect ophthalmoscope will facilitate the estimation of vessel caliber, disk size, and macular health and position. The 28 D is sufficient for an overview of things, but should only be used in conjunction with the 20 D in each case. Here, a word of encouragement: However fleeting the view, a satisfactory mental montage will emerge in most patients. Children who cooperate with the slit-lamp will readily allow a good exam with the 78 D or 90 D lenses for a detailed assessment of the posterior pole structures. These are the same patients who will also readily allow excellent photographic or optical coherence tomography images. For the uncooperative younger individuals, a good restraining technique rarely fails to achieve a reasonable fundus examination. Obviously, the level of suspicion will dictate the quality of the examination required and the efforts put into it; but, for the most part, the clinic setting will be satisfactory. For this, or for some difficult refractions, the parents are always invited to participate and help. It is better for them to know and understand what takes place than be alarmed by cries and screams from the other side of a door.

Finally: rewarding success

A good visit cannot end without celebration. A child who receives positive feedback after showing some goodwill or after controlling great fears will remember that reward, that gift. These are well worth their minimal cost considering the time and efforts saved by a happy child. Stickers are universally welcomed as long as they are current, so keep up with the cultural icons of your young patients. "High fives," handshakes, and hugs all have their place in the right situation, as long as the parents are agreeable. Specific to amblyopia treatment, colorful patches with printed designs are welcome as a novelty by many children. A photo club poster of patching children, and a certificate for those who reach their goal, are popular in our clinic. Parents should also be rewarded: for example, a chart of a child's vision progress helps to celebrate gains and reinforces the need to increase efforts when needed.

TREATMENT OF REFRACTIVE ERRORS IN CHILDREN
PREVENTION OF ONSET AND PROGRESSION OF MYOPIA
REFERENCES

Introduction

Refractive errors cause blurred vision and potentially amblyopia through inability to form a perfectly focused image on the retina. Emmetropia is the state of a perfectly focused eye when the focusing power of the cornea and lens are exactly appropriate for the axial length of the eye (Fig. 8.1A); this is uncommon in young children because their eyes have not completely matured and a mild hyperopic refractive error is frequently present.[1] Not all refractive errors require treatment. This chapter reviews the current state of diagnosis, treatment, and prevention of refractive errors in children.

Diagnosis of refractive errors in children

Cycloplegia

In children, cycloplegia is required to measure refractive error accurately because accommodation is active, causing overestimation of myopia and underestimation of hyperopia. Phenylephrine 2.5% is often added to enhance dilation. Toxicity from cycloplegic agents is uncommon. Signs and symptoms of anticholinergic effects include flushing, fever, rash, rapid or irregular heartbeat, dry mouth, and mental status changes. These should be reported immediately. Cycloplegic agents include atropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1 %. Atropine provides the most complete cycloplegia, but has the longest time to onset, duration of effect, and the most severe side effect profile. Tropicamide has the shortest onset and is better tolerated because of its shorter duration of action and low side effect profile, but residual accommodation remains.[1,2] Table 8.1 outlines the cycloplegic agents employed in the authors' practice based on age. Cyclopentolate 0.2% is available in the USA as "Cyclomydril." It is primarily used for pupillary dilatation of premature infants.

Techniques

Useful techniques for measuring refractive errors in children include retinoscopy, autorefraction, and post-cycloplegic subjective manifest refraction. Ocular biometry and corneal topography are useful adjunctive measures in selected children.

Cycloplegic retinoscopy

Cycloplegic retinoscopy is useful in very young and developmentally delayed children. Cycloplegic retinoscopy is also useful to confirm findings of autorefraction. In addition, cycloplegic retinoscopy performed over existing glasses or contact lenses can be a rapid way to determine whether there has been a significant change in glasses prescription, or whether media irregularities are present that may preclude successful neutralization of refractive error with spectacles. A description of the technique is beyond the scope of this chapter but is published elsewhere.[3]

Dynamic retinoscopy

Dynamic retinoscopy can help to confirm accommodative dysfunction, which is sometimes present in children with cerebral palsy, Down syndrome, and other neurodevelopmental concerns. To perform dynamic retinoscopy, the authors use the monocular estimate method (MEM).[4] The authors have our patient fixate on a detailed target held in the plane of the retinoscope. Testing is performed with the spectacle correction in place. Room lights are dim, but bright enough for the child to be able to see the target. The examiner should use a working distance of about 40 cm. If the patient is accommodating appropriately, the retinoscopy reflex should be neutral when the child fixates on the target. If a "with" reflex is present, there is a "lag" in accommodation, and if an "against" reflex is present, there is a "lead" in accommodation. A small lag in accommodation is normal (1 D or less), but children who have larger amounts of accommodative lag can benefit from correction of hyperopia and possibly even reading glasses or bifocals. Occasionally, infants will present with a delay in development that is due to moderate-to-high hyperopia and poor accommodation. Dynamic retinoscopy is invaluable in identifying this disorder (Fig. 8.2).

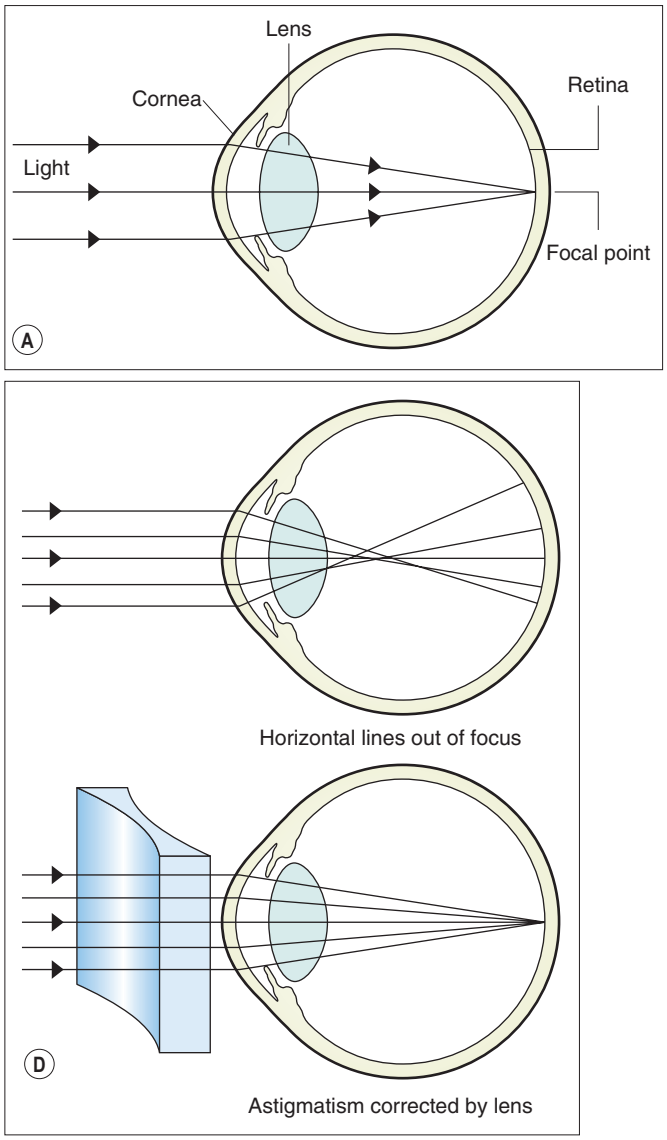

Fig. 8.1 (A) In emmetropia, the focusing power of the lens and cornea are exactly balanced by the length of the eye so that the light emanating from an object forms a perfectly focused image on the plane of the retina. (D) With astigmatism there is a difference in power of the two principal meridians of the eye due to a toric curvature of the cornea and/or lens resulting in an inability to bring light into a point of focus on the retina. A toric lens brings both meridians into focus.

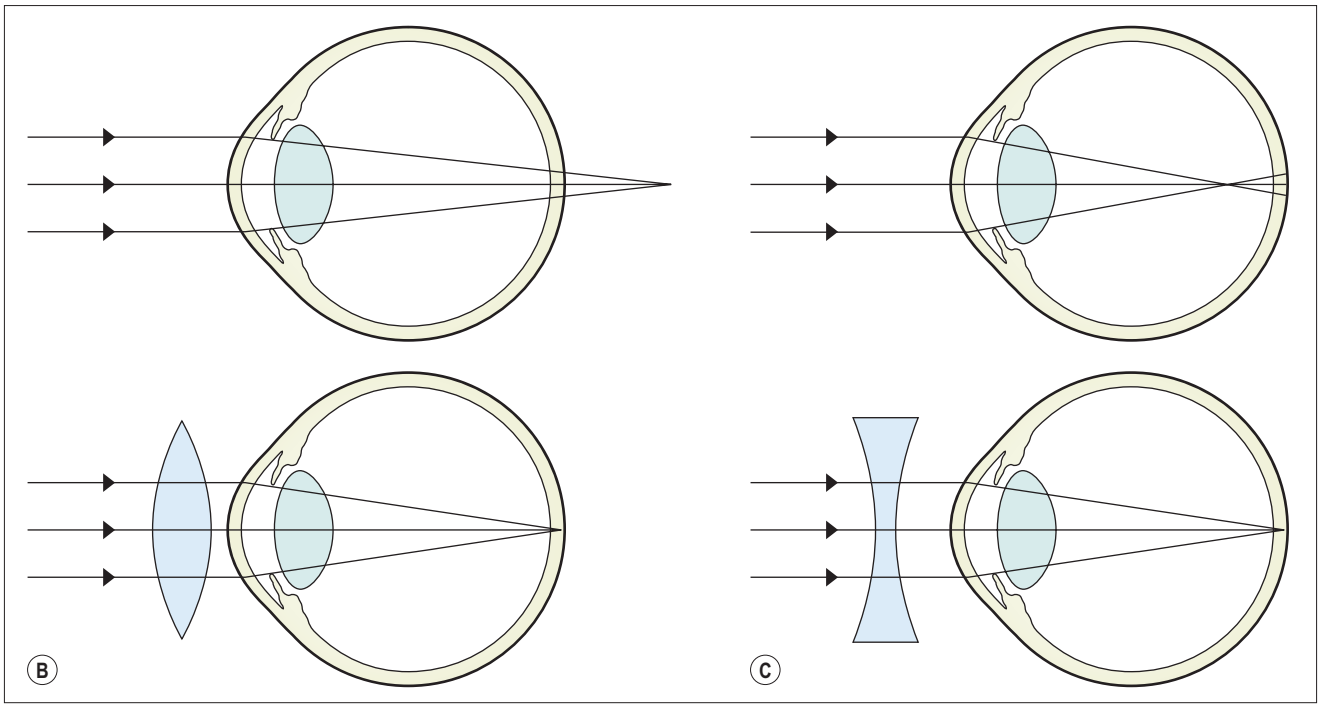

Fig. 8.1 (A) Continued online. (B) Hyperopia occurs when the focusing power of the eye is too weak, and/or the length of the eye is too short, such that the light rays focus behind the retina. A biconvex lens can be used to bring the image into focus. (C) Myopia occurs when the focusing power of the eye is too strong, and/or the length of the eye is too long, such that the light rays focus in front of the retina. A biconcave lens can be used to bring the image into focus. (D) Continued online.

Table 8.1 Recommended cycloplegic agents[2]

Age	Recommended agent	Dosage	Onset of cycloplegia	Duration of cycloplegia + mydriasis	Side effect profile
Preterm to 3 months	Cyclomydril (cyclopentolate 0.2% and phenylephrine 1%)	Two sets of one drop every 5 minutes	20–60 minutes	6–48+ hours	Minimal
3 months to 1 year	Cyclopentolate 0.5%	Two sets of one drop every 5 minutes	20–60 minutes	6–48+ hours	Moderate
1 to 12 years	Cyclopentolate 1% or	Two sets of one drop every 5 minutes	20–60 minutes	6–48+ hours	Moderate
	Atropine 1% drops or ointment	One drop twice a day for 3 days	Hours	1–2+ weeks	High
12 years and older	Tropicamide 1%	Two sets of one drop every 5 minutes	25–40 minutes	2–6+ hours	Low

Adapted from Mutti DO, Zadnik K, Egashira S, et al. The effect of cycloplegia on measurement of the ocular components. Invest Ophthalmol Vis Sci 1994; 35: 515–27.

Autorefraction

The authors have found in their practice that autorefraction performed monocularly and with cycloplegia using late model stationary devices provides very accurate measurements of refractive errors and can be used in cooperative children as young as 2 years of age (Fig. 8.3). Autorefraction may more accurately detect astigmatism than retinoscopy.[5] Nevertheless, we recommend confirming autorefraction findings with retinoscopy and visual acuity measurements rather than prescribing spectacles based on autorefraction alone.

Post-cycloplegic subjective manifest refraction

Post-cycloplegic subjective manifest refraction can be useful in children. Often, a prescription can be written for the full refractive error detected with cycloplegic refraction, but sometimes it can be helpful to have the patient return to the office for manifest refraction after the cycloplegic agent has worn off. Examples include children with high hyperopia who do not tolerate the full plus correction, children who have significant changes in refractive error over relatively short periods of time, children with incomplete cycloplegia, and

Fig. 8.2 This infant was seen at 2.5 months of age for parental concerns about poor visual interest. Hyperopia of 6 D was detected. Parents were reassured but returned when the child was 4 months old for similar concerns. Dynamic retinoscopy revealed 4 D of accommodative lag. Spectacles were prescribed. The parents noted immediate improvement in the child's visual interest and development with the +6 D spectacles.

Fig. 8.3 Autorefraction can be successfully performed on cooperative children as young as 2 years of age.

children with irregular red reflexes that limit the ability to perform retinoscopy or autorefraction.

Corneal topography

Corneal topography can be a useful diagnostic tool in children with significant corneal astigmatism to confirm the axis of astigmatism, to diagnose irregular or asymmetric astigmatism and early keratoconus, and to identify lenticular astigmatism. It can also be useful during contact lens fitting.

Ocular biometry

A-scan ultrasound or non-contact optical biometry measurement of axial length, anterior chamber depth, and lens thickness can be useful to determine the etiology of refractive errors, and is invaluable in determining intraocular lens power for cataract surgery, but is not used routinely to diagnose refractive errors.

Common refractive errors in children

A refractive error is present if parallel incident light rays in a non-accommodating eye with clear media are not perfectly focused on the retina. This occurs if the focusing power of the eye is too strong or weak for the length of the eye.

Hyperopia

In hyperopia, the focusing power of the eye is "too weak" and/or the axial length of the eye is "too short." In the non-accommodating hyperopic eye, the light rays coming from an object at infinity will come into focus behind the retina (Fig. 8.1B). A biconvex (plus powered) lens is needed to bring the light rays onto the retina. Severe hyperopia is seen with aphakia, which occurs because of surgical removal or spontaneous dislocation of the lens.

Mild hyperopia is normal in infancy and early childhood before the eye has reached its full adult size. Newborn infants have about 3 D of hyperopia, which usually decreases to about 1 D by the age of 1 year.[6] Since infants and young children can normally accommodate 14 D or more,[7] correction of mild and symmetric hyperopia in young children is usually not required. However, if esotropia is present, the authors recommend prescribing the full hyperopic correction, as determined by cycloplegic refraction. If the hyperopia exceeds 4.5–5 D, there is accommodative lag, or the child is symptomatic the authors recommend prescribing at least a partial hyperopic correction. If anisometropia is present (hyperopia is not the same magnitude in both eyes) the authors usually prescribe if the hyperopic anisometropia exceeds 1.5 D (sometimes less in children with over 4 D of hyperopia). After the age of 3, correction of hyperopia can be based on subjective testing of visual acuity and patient complaints.

In some cases, children do not tolerate the full hyperopic correction because they have difficulty relaxing their accommodative tone, which renders them myopic when wearing the full correction. In such cases, the authors will either cut up to 2 D of hyperopia from the spectacle prescription, or treat with atropine 1%, one drop daily for 1 week to relax accommodation.

The American Academy of Ophthalmology's (AAO's) consensus-based recommendations for correction of hyperopia in young children to age 3 are listed in Table 8.2.[8] A review of 19,372 pediatric refractions performed at the Children's Hospital of Philadelphia over 4.5 years[9] revealed that the rate of adherence to these guidelines was fairly high in children over the age of 1 year; however, in many cases, treatment of even large amounts of hyperopia in children under the age of 1 was postponed, likely due to the rapid shifts in refractive error expected with growth.

Myopia

In myopia, the focusing power of the eye is "too strong" and/or the eye is "too long." In the myopic eye, the light rays from an object at infinity will come into focus in front of the retina (Fig. 8.1C). A biconcave (minus powered) lens is needed to focus the light rays on the retina. Myopia occurs as a result of a variety of genetic and environmental factors. The decision whether to treat myopia is based on the visual needs of the child, which in turn are heavily dependent on age. The

AAO recommends treatment of isoametropic myopia when it exceeds 5 D in children under age 1, 4 D in children age 2, and 3 D in children age 3 (see Table 8.2).[8] After age 3, treatment is based on subjective visual acuity and patient complaints. Anisometropic myopia is better tolerated, and there is less risk of isoametropic amblyopia than with hyperopia, most likely because each eye will be in focus at some distance. Consequently, the AAO recommendations for the correction of anisomyopia are 4 D in children under age 1, and 3 D in children aged 2–3 years. As with hyperopia, compliance with AAO guidelines is high in children 2 years of age and older, but treatment is often postponed in children less than 1 year of age.[9]

Astigmatism

With regular astigmatism there is a difference in power of the two principle meridians of the eye due to toric curvature of the cornea and/or lens resulting in an inability to bring light into a point of focus on the retina (Fig. 8.1D). Irregular astigmatism, which is less common, occurs when the principle meridians are not 90° apart, and is usually caused by corneal scarring or ectasia. Although moderate levels of astigmatism can be well tolerated, the AAO recommends treatment of over 2 D of bilateral or anisometropic astigmatism in children over the age of 2 years (see Table 8.2),[8] although this recommendation is not consistently followed, especially in symmetric cases.[9] Many patients tolerate astigmatism remarkably well, and are more likely to reject astigmatic correction than correction for myopia or hyperopia. Since anisometropic astigmatism can cause amblyopia, the authors usually recommend correction for 1.5 D or more.

Table 8.2 American Academy of Ophthalmology guidelines for refractive correction in infants and young children

Condition	Refractive errors (diopters)		
	Age <1 years	Age 1–2 years	Age 2–3 years
ISOAMETROPIA (SIMILAR REFRACTIVE ERROR IN BOTH EYES)			
Myopia	−5.00 or more	−4.00 or more	−3.00 or more
Hyperopia (no manifest deviation)	+6.00 or more	+5.00 or more	+4.50 or more
Hyperopia with esotropia	+2.50 or more	+2.00 or more	+1.50 or more
Astigmatism	3.00 or more	2.50 or more	2.00 or more
ANISOMETROPIA (WITHOUT STRABISMUS)*			
Myopia	−4.00 or more	−3.00 or more	−3.00 or more
Hyperopia	+2.50 or more	+2.00 or more	+1.50 or more
Astigmatism	2.50 or more	2.00 or more	2.00 or more

NOTE: These values were generated by consensus and are based solely on professional experience and clinical impressions because there are no scientifically rigorous published data for guidance. The exact values are unknown and may differ among age groups; they are presented as general guidelines that should be tailored to the individual child. Specific guidelines for older children are not provided because refractive correction is determined by the severity of the refractive error, visual acuity, and visual symptoms.
*Threshold for correction of anisometropia should be lower if the child has strabismus. The values represent the minimum difference in the magnitude of refractive error between eyes that would prompt refractive correction.

Treatment of refractive errors in children

Spectacles

Because of their safety and availability, spectacles are the most common method of treating refractive errors in children and are usually the authors first line of treatment. Spectacles come in a wide variety of shapes and sizes. Children who are aphakic or pseudophakic or who have a high accommodative convergence to accommodation ratio benefit from bifocal lenses. Spectacles also provide a measure of safety when shatter-resistant lenses such as polycarbonate or trivex are used. Safety is an important consideration in all children, but is especially important in children with moderate to profound amblyopia in one eye to safeguard the healthy eye.

Large amounts of anisometropia can lead to image size disparity when corrected with spectacles. Despite Knapp's law, the authors treat primarily with contact lenses regardless of whether the etiology is axial or refractive (see below). When conditions exist that preclude the use of contact lenses, adjustments in spectacle index of refraction, lens thickness, and vertex distance are required to balance the image size of the two eyes. Commercially available programs such as Aniseikonia Inspector can be employed to facilitate this process.

Contact lenses

Indications for contact lenses in children

There are medical and non-medical indications for using contact lenses in children. The CLIP (Contact Lenses in Pediatrics) study showed children as young as 8–12 years of age are capable of assuming at least some of the responsibility for the insertion, removal, and care of contact lenses, although this age group required more time training than children aged 13–17.[10] In both age groups, over 80% of children were able to manage care and cleaning using 2-week disposable soft lenses. In addition, the self-perception of physical appearance, athletic competence, scholastic competence, and social acceptance in a group of children aged 8–11 years randomized to contact lens wear was higher than an age-matched control group randomized to spectacles.[11,12] In these studies, the rates of contact lens-associated complications were very low. Nevertheless, poor hygiene, lack of maturity, prolonged fitting times, and high cost of contact lens-related complications in children can preclude the use of contact lenses for non-medical indications in children, especially when spectacles are an acceptable alternative.

Medical indications for contact lenses in children include anisometropia, irregular corneal astigmatism, large-magnitude refractive errors, and nystagmus. Correction of anisometropia with spectacles can improve amblyopia, but can result in aniseikonia (unequal image sizes), which can adversely affect stereopsis.[13–15] In practice, the authors usually consider contact

lenses when large amounts (3 D or more) of anisometropia are present. Similarly, optimal correction of the higher-order aberrations of irregular astigmatism is not possible with spectacles and requires contact lenses as the first step toward management of amblyopia in affected children. Spectacle correction of large refractive errors such as aphakia and high myopia induces distortion, prismatic effects, and magnification (hyperopia) or minification (myopia), so contact lenses are sometimes preferred in these settings. Finally, the authors have observed improved quality of life and improved optical correction of refractive errors in patients with nystagmus who wear contact lenses, when compared to spectacles.[16] Although the authors commonly use contact lenses for the above medical indications, they are reluctant to rely on contact lenses alone in settings of moderate-to-profound amblyopia in one eye. In such cases, the preferred option is safety glasses, sometimes in combination with a contact lens in the amblyopic eye only..

Lens selection

A variety of contact lens materials are available. In general, soft contact lenses are better tolerated by children and are preferred over rigid gas-permeable (GP) lenses in most cases of myopia, hyperopia, and mild astigmatism. Soft lens materials range in water content and ionicity and are categorized by the Food and Drug Administration in the United States as 1–5, with 5 representing silicone hydrogel materials. Custom soft contact lenses are available when the parameters needed are not available with conventional lens products. Soft toric contact lenses are practical up to a power of approximately 2 D cylinder. With higher amounts of cylindrical correction, variable vision often results due to lens instability and rotation. Frequent replacement of soft lenses reduces complications, and patients should always adhere to the manufacturers recommendations for replacement. Whenever possible, single-use lenses should be considered for use in children, since they eliminate the need for a care system and promote compliance. GP lenses are preferred in children with severe or irregular astigmatism, since they provide a smooth refracting surface. Hybrid lenses and tandem ("piggy back" lenses) are sometimes useful in children who cannot tolerate a GP lens.[17] Cost of lenses also factors into lens selection.

Lens fitting

Children have small tight palpebral fissures and strong Bell's reflexes, and so it can be challenging to fit contact lenses. Soft contact lenses should demonstrate good centration with full corneal coverage, allowing approximately 2 mm of overlap on the sclera while still allowing for some movement. When digitally displaced to the side, the lens should re-center gradually on the cornea. If it "springs back" immediately, it is probably too tight, and if it stays off-center while manually closing the lid, it is probably too loose. In addition, the red reflex should maintain clarity before, during, and after a blink.

GP fitting in children can be guided by keratometric readings obtained at the time of surgery or an exam under anesthesia, but application and evaluation of a diagnostic lens provides the best results. Good centration and stability of the lens is desired and is easier to achieve with larger-diameter lenses. A good rule of thumb is that if the lens frequently dislodges from the eye, it is too tight, and if it frequently displaces to the bulbar conjunctiva, it is too loose.

Application, removal, and care of contact lenses in children

The application of any contact lens to the eye of a small child by an eye care professional or caregiver is initially a daunting task. Through practice and good technique, the skill can be mastered. In general, GP and silicone hydrogel lenses are easier to apply and remove than soft contact lenses. Proper hand washing should always take place before application or removal of contact lenses. A contact lens can be applied to a small eye by gently sliding the leading edge under the upper lid and then massaging the lens into the correct position. A soft lens can be removed by pinching the lens with the thumb and ring finger to release the lens from the eye. The removal of a GP lens from a young patient can be aided with a DMV suction cup. However, one must be able to hold the eye open wide enough to apply the tool to the anterior lens surface. Scissoring a GP lens off of the eye can be achieved by sliding the lower lid under the lens edge in order to dislodge it. A GP lens can also be removed from the eye by the young patient by "popping" the lens out. By opening both eyes wide and maintaining fixation, the ring finger is placed between the temporal upper and lower lids then pulled laterally. The lens is then easily dislodged by the upper lid with a blink.

Whenever daily-wear disposable lenses are not possible, a care system is required. Daily care of the lens storage case consists of removing the storage solution, wiping the case with a lint free cloth, and allowing it to air dry. In addition, the storage case should be scalded once a week in boiling water and replaced monthly. Lens care systems should include an approved cleaner and lens disinfectant. Approved oxidative care systems for both GP and soft lens modalities should be considered to maximize microbial efficacy and avoid hypersensitivities.

Despite newer lens materials that maximize oxygen delivery, overnight wear of any contact lens carries a greater chance of microbial keratitis.[18,19]

The use of overnight-wear materials can be considered but primarily prescribed as a daily-wear modality. In addition, daily application and removal of the contact lens improves facility in handling and managing the lens.

Safety of contact lenses in children

Contact lens wear in children is safe in most circumstances. Contact lens complications can be categorized as infectious, inflammatory, and mechanical, are usually easily treated, and occur in about 18% of contact lens wearers overall.[20] Children have more mechanical adverse events than adults during their learning period of contact lens wear.[21] Late adolescent and young adult patients have a higher contact lens complication rate than younger children.[22] A child who is motivated to wear contact lenses for specific activities and is instructed properly by the eye care professional can enjoy many years of safe contact lens wear. Children should be given verbal and written instructions concerning lens hygiene, which should be reviewed at each follow-up visit.

Refractive surgery

Refractive surgery is a promising option for correcting refractive errors in children with developmental and other disorders that preclude the use of spectacles and contact lenses (see Chapter 71).

Prevention of onset and progression of myopia

The increasing prevalence of myopia, especially in Asian populations (which reaches 80% in some regions) and other groups with high educational demands, had led to a heightened interest in the factors that contribute to myopia onset and progression.[23] In turn, novel preventative strategies have been introduced to minimize the long-term morbidity associated with moderate-to-high myopia (retinal detachment, early-onset cataract, glaucoma, optic nerve anomalies, and choroidal neovascularization).[24]

In addition, treatment strategies for preventing the progression of keratoconus have been introduced in recent years. This section provides an overview of these evolving practices.

Modification of outdoor and near activities

Several observational studies have shown that outdoor activities seem to protect against myopia. The proposed mechanisms include increased dopamine release in the retina (which inhibits axial elongation in experimental studies), increased light intensity outdoors (which constricts the pupil and improves focus, presumably slowing eye growth), reduced accommodative demand, and possibly a substitution of distance for near work.[24,25] Conversely, a relationship between increased near work and onset or progression of myopia has been shown in some studies, but not others, and the association remains controversial. Multiple genetic and environmental factors contribute to the effect of outdoor time and near work on myopia, and are not completely understood.[24] Nevertheless, the authors recommend counseling patients and their parents about the importance of balancing time spent doing near work and play with time spent working and playing outdoors.

Pharmacologic intervention

The ability of atropine to retard progression of myopia was recognized almost 100 years ago. The mechanism by which atropine and other antimuscarinic agents such as pirenzepine and cyclopentolate work to slow progression of myopia has still not been clearly elucidated. Proposed mechanisms include inhibition of accommodation and increased collagen cross-linking of sclera (caused by increased pupillary dilation/increased ultraviolet light exposure), but are most likely caused by direct biochemical effects on the retina and sclera.[24] Known side effects of traditional concentrations of 0.5% and 1% atropine (pupillary dilation, loss of accommodation) have limited its widespread use. Recent studies have confirmed a dose-dependent effect of atropine on reducing progression of myopia, with concentrations as low as 0.01% showing a significant effect.[26] A rebound effect is observed after discontinuation of all concentrations of atropine; however, a recent report suggests that 0.01% atropine has a more modulated and sustained effect (Fig. 8.4).[26,27] In addition, pupillary dilation and loss of accommodation were mild, and recovered quickly after discontinuing this concentration. Consequently, the authors concluded that 0.01% atropine could be considered a reasonable approach to retarding myopia progression in children. It is commercially available in only a limited number of countries.

Optical treatment strategies to reduce the progression of myopia

Undercorrection of myopia

Undercorrection of myopia has been used in some clinical settings as a strategy to slow myopia progression in children.[28] Although myopic defocus has been shown to slow myopic progression in animal studies, this finding has not been replicated in most human studies.[24] Several recent clinical

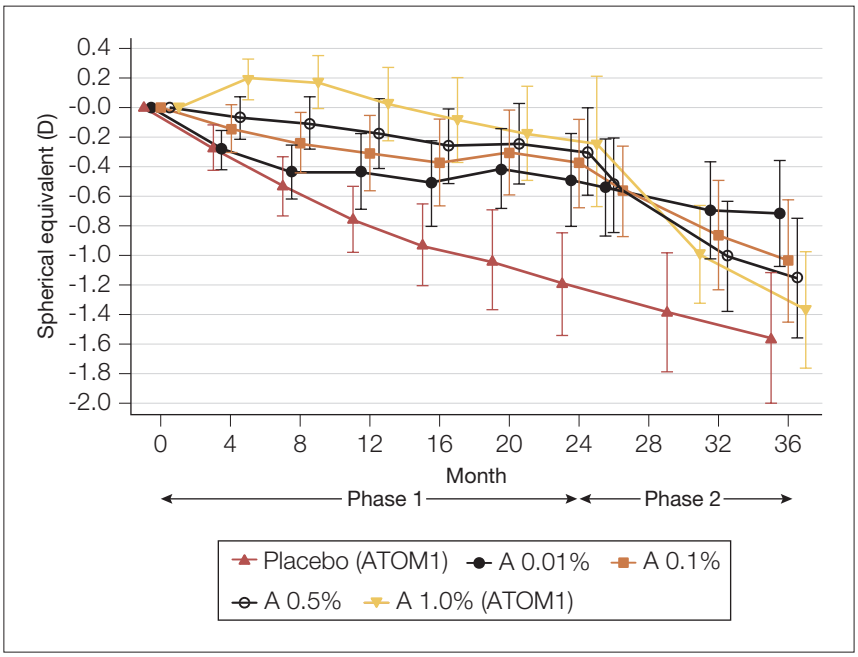

Fig. 8.4 Results of the ATOM1 and ATOM2 study show a sustained effect of 0.01% atropine on retarding progression of myopia. *(From Chia A, Chua W-H, Wen L, et al. Atropine for the treatment of childhood myopia: changes after stopping atropine 0.01%, 0.1% and 0.5%. Am J Ophthalmol 2014; 157: 451–57.e1.)*

studies have concluded that undercorrection of myopia may actually accelerate myopic progression in children.[28–30] Hence, the authors recommend providing the full correction for myopic children.

Reduction of relative peripheral hyperopia

Historically, the use of bifocal and progressive addition spectacle lenses (PALs) to slow myopia progression was based on the belief that accommodative lag during near work causes foveal hyperopic defocus that accelerates axial growth of the eye.[24] Indeed, PALs, flat-top D bifocals, executive bifocals, and executive bifocals with base-in prism (in order of increasing effect) have all been shown to have modest effects on slowing of the progression of myopia, especially in children with high accommodative lag.[24,25,31] An alternative mechanism is that reduction in *peripheral* hyperopic defocus slows myopia progression. Peripheral hyperopic defocus occurs when myopia is corrected with spectacles or single-vision contact lenses, and light rays falling on the peripheral retina are focused behind the plane of the retina (Fig. 8.5A). This theory is supported by animal studies that suggest that visual signals coming from the retinal periphery may dominate refractive development,[25] as well as clinical observations that show significant reduction in myopic progression when bifocal glasses, multifocal contact lenses, or overnight corneal reshaping therapy (orthokeratology) are used to reduce peripheral hyperopic defocus.[32] These lenses place the image shell on to the mid-peripheral retina, reducing peripheral hyperopic defocus in contrast to spectacles or conventional contact lenses (Fig. 8.5B). Although the clinical effect of these optical interventions has been consistently shown in multiple randomized controlled trials (Table 8.3),[3,6,33–39] the underlying mechanism is still a matter of debate.[40]

Orthokeratology (corneal reshaping therapy)

Reverse geometry GP designs are used to redistribute and thin central epithelial power. The initial application for this method of correction allowed patients to wear lenses at night and function during the day without myopic correction. Researchers then found this form of correction also slowed myopic progression, presumably due to the oblate cornea and resultant peripheral retinal focus as described above. However, these designs are not without risks, due to overnight wear. Center distance soft multifocal designs have shown similar

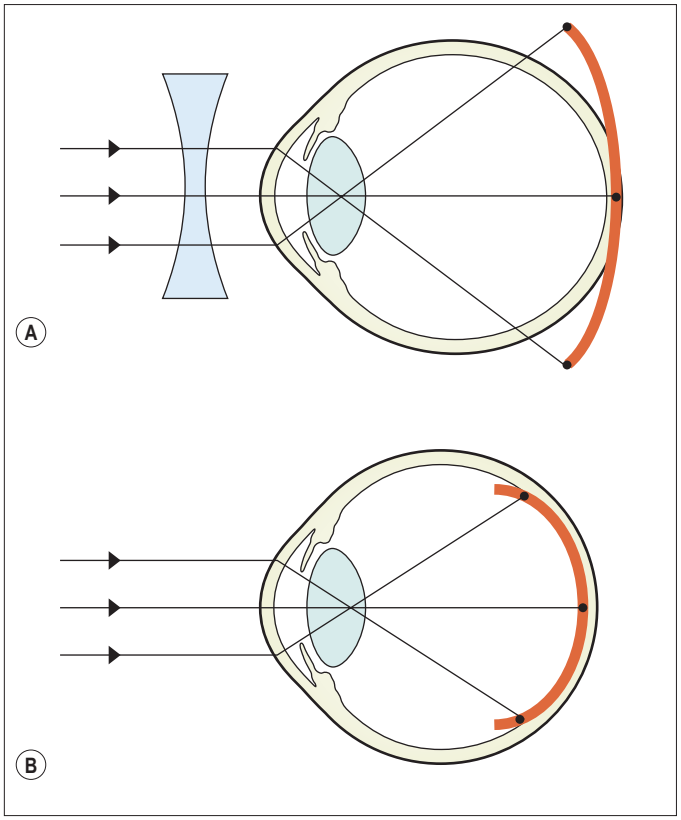

Fig. 8.5 (A) Peripheral hyperopic defocus occurs when a biconcave lens is used to correct myopia. (B) Corneal reshaping therapy (orthokeratology) induces peripheral myopic defocus.

Table 8.3 Randomized clinical trials of contact lenses to slow progression of myopia

Author	Year	Lens type	Range of myopia[a] (D)	Age range	Number of patients	Reduction of axial growth[b]	Duration of study
Sankaridurg et al.[34]	2011	Peripheral gradient contact lens	–0.75 to –3.5	7–14	43	34%	1 year
Anstice et al.[35]	2011	Dual focus contact lens	–1.25 to –4	11–14	40	49%	10 months (phase 1)
Walline et al.[33]	2013	Multifocal contact lens	–1 to –6	8–11	32	29%	2 years
Lam et al.[36]	2014	Defocus incorporated contact lens	–1 to –5	8–13	65	31%	2 years
Cho et al.[37]	2012	CRT	–0.5 to –4	6–10	37	43%	2 years
Charm et al.[38]	2013	Partial CRT	–5 to –8	8–11	26	NR	1 month

CRT, corneal reshaping therapy (orthokeratology).

outcomes related to myopia control while being worn on a daily-wear schedule.[33] The risk of complications associated with modern day orthokeratology has improved in recent years. Good compliance with prescribed maintenance regimen is essential.[41]

Acupuncture

Traditional Chinese medicine practitioners advocate for the use of acupuncture for the treatment of myopia. A Cochrane Review and Preferred Practice Guidelines from the AAO both conclude that the use of acupuncture to treat myopia has not been sufficiently studied, and the decision to use acupuncture to control myopia should be individualized to the patient's needs and preferences.[42]

Collagen cross-linking

Collagen cross-linking has been used to manage progressive pediatric keratoconus. The timing and technique is currently debated. Parents should be informed about the possibility of the need for re-treatment – especially in very aggressive forms.[43]

Bonus e-book content online

Fig. 8.1 (A) In emmetropia, the focusing power of the lens and cornea are exactly balanced by the length of the eye so that the light emanating from an object forms a perfectly focused image on the plane of the retina.

Fig. 8.1 (D) With astigmatism there is a difference in power of the two principal meridians of the eye due to a toric curvature of the cornea and/or lens resulting in an inability to bring light into a point of focus on the retina. A toric lens brings both meridians into focus.

Introduction

Pediatric visual electrophysiology can be a challenge, but provides information about the function of the retina and visual pathways that cannot be obtained by other means. This quantifiable functional assessment helps us with early diagnosis, prognosis, and is an objective means of monitoring neurologic and ocular sequelae.

There are international guidelines and minimum standards for performing visual electrophysiologic investigations (e.g. from the International Society for Clinical Electrophysiology of Vision [ISCEV] at http://www.iscev.org or the International Federation of Clinical Neurophysiology at http://www.ifcn.info). The authors use and extend ISCEV adult protocols in children who are able to sit still and follow instructions for 30 minutes or more. With younger or less compliant children, adapted protocols are used that are robust enough to provide comparable information without restraint, sedation, or anesthesia.

Much encouragement and distraction are often needed to obtain reproducible results in children with short attention spans. For these patients, one also has to be flexible and responsive during the test and able to adapt the protocol, and the order of tests within a protocol, to ensure that the clinical question is answered. This may be prompted by ongoing analysis and interpretation of online findings, or by changes in the child's compliance. These modified protocols and distraction techniques enable clinicians to meet the needs of a child in ways they enjoy in a time-efficient way! The overarching aim is to minimize stress and anxiety to child, carer, and staff. This optimizes results and the chance of reliable monitoring in the future.

The tests

Clinical visual electrophysiologic tests include the electro-oculogram (EOG) and the electroretinogram (ERG), which assess the function of the retinal pigment epithelium (RPE) and retina, and the visual evoked potential (VEP), which assesses the integrity of the postretinal pathways to the striate visual cortex, particularly the macular pathways.

Behavioral compliance and tolerance are limiting factors in pediatric visual electrophysiology testing. Full adult protocols are lengthy and demanding. For example an EOG requires a child to make accurate saccades every minute for 15 minutes in the dark then 15 minutes in the light. The multifocal ERG (mfERG) and pattern ERG (PERG) require steady fixation; in addition the PERG needs good focus. A full-field ERG (ffERG) demands 20 minutes of dark adaptation and 10 minutes of light adaptation. PERGs, mfERG, and ffERGs optimally require corneal electrodes. These may be tolerated by exceptional youngsters, but they are more likely to be acceptable from the ages of 5 years upwards. The authors' adaptive protocol may be applied from birth onwards and aims for a total investigation time of 30 minutes, during which time pattern VEPs (PVEPs) are carried out, followed by contemporaneous flash VEPs and ERGs. ERGs are recorded with skin electrodes, natural pupils, and no formal dark adaptation, but use scotopic blue and red flashes to help separate rod and cone contributions after viewing the pattern stimulator in a darkened room. These adapted test data are compared with a robust reference range and provide physiologically similar results to adult protocols.[1]

To illustrate the approach, the authors have applied their Great Ormond Street Hospital (GOSH) protocol to two common questions arising at different ages. The flow chart outlines the diagnostic algorithm and hierarchy of testing (Fig. 9.1). Short notes on the technical aspects of the methodology have been provided at the end of the chapter. Artifacts can mimic physiologic responses and must be excluded before

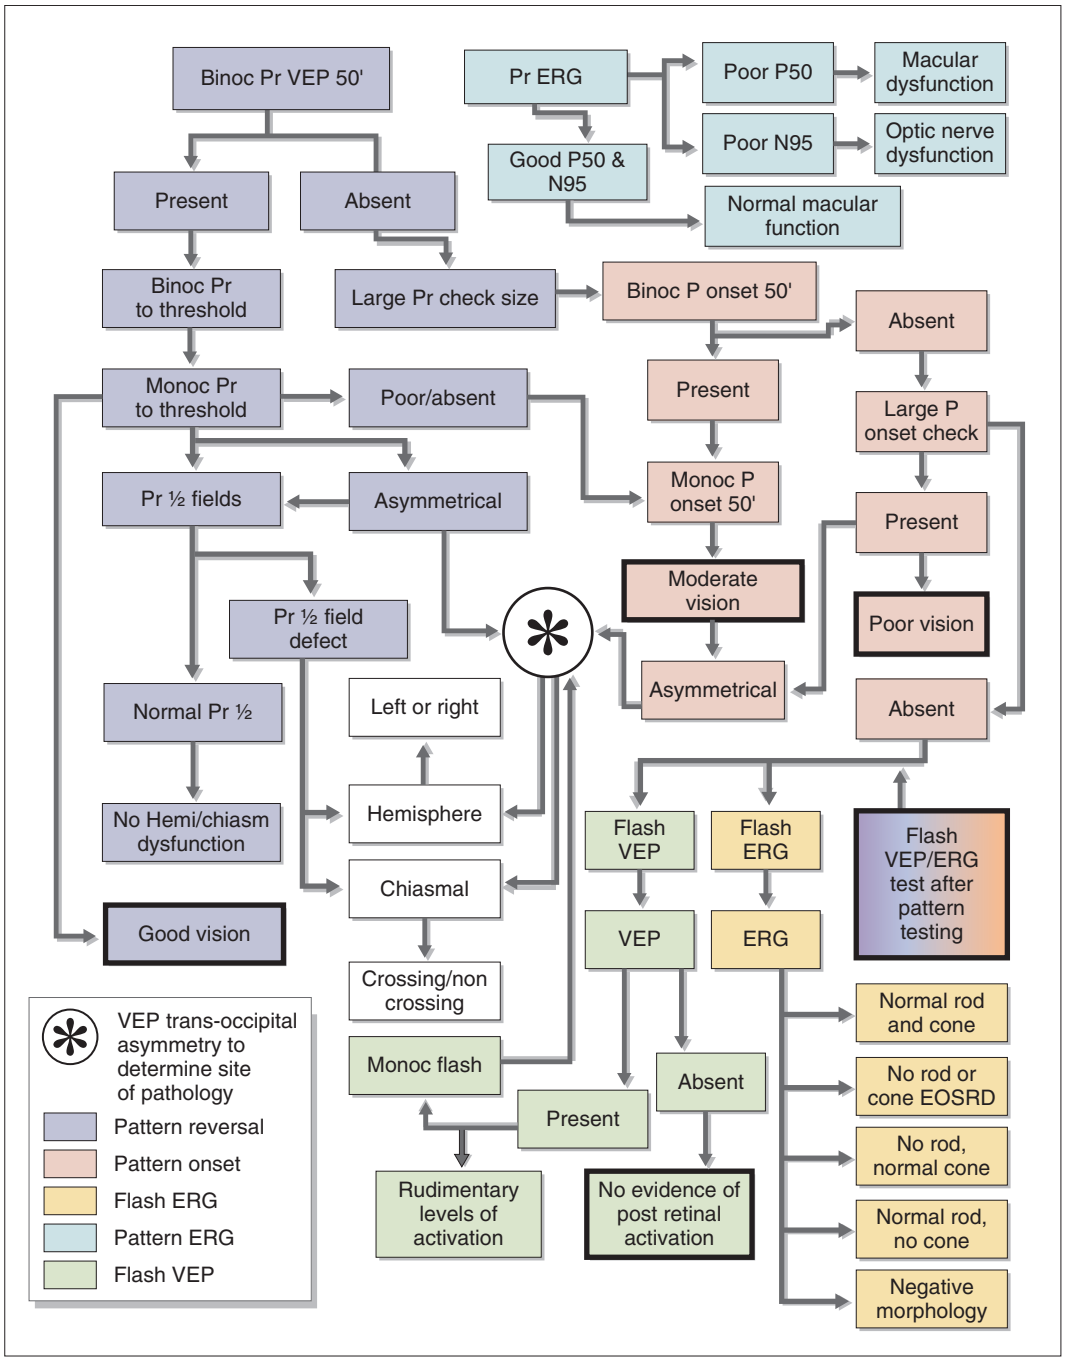

Fig. 9.1 All testing can start with pattern-reversal 50′ checks presented to both eyes. Depending upon the response, one may proceed to smaller reversing checks and monocular testing, or divert to pattern-onset stimulation. After pattern stimulation is completed, flash stimulation is used to contemporaneously record electroretinograms (ERGs) and visual evoked potentials (VEPs). Transoccipital asymmetries are noted throughout and explored in all three stimulus modalities and, when possible, with half-field stimulation. With suspected voluntary defocus, the pattern electroretinogram (PERG) is recorded simultaneously with the pattern-reversal VEP (PVEP). This robust combination strategy can be used to investigate diverse clinical questions as the two examples outlined:

1. Babies: unstable eye movements, is this congenital motor nystagmus? Looking for an anterior visual pathway problem. Possibilities:
   i. Retina: early-onset severe retinal dystrophy (EOSRD), cone dysfunction and congenital stationary night blindness (CSNB) – *need stimuli to separate rod and cone activity and distinguish photoreceptors from inner retina activity (a- and b-wave).*
   ii. Optic nerve: optic nerve hypoplasia – *need monocular flash and PVEPs to compare interocular amplitudes and latency on the midline electrode.*
   iii. Chiasmal anomaly: albinism (require flash infancy and pattern-onset stimulation for older children), chiasmal hypoplasia, glioma – *need monocular stimulation and a transoccipital array of electrodes to look for transoccipital distribution of VEP.*
2. Teenagers: questioning whether there is a functional element to measured subnormal vision:
   Simultaneous PERG and PVEP – *control defocus: cycloplegic full correction for viewing distance, observe direction of gaze.*

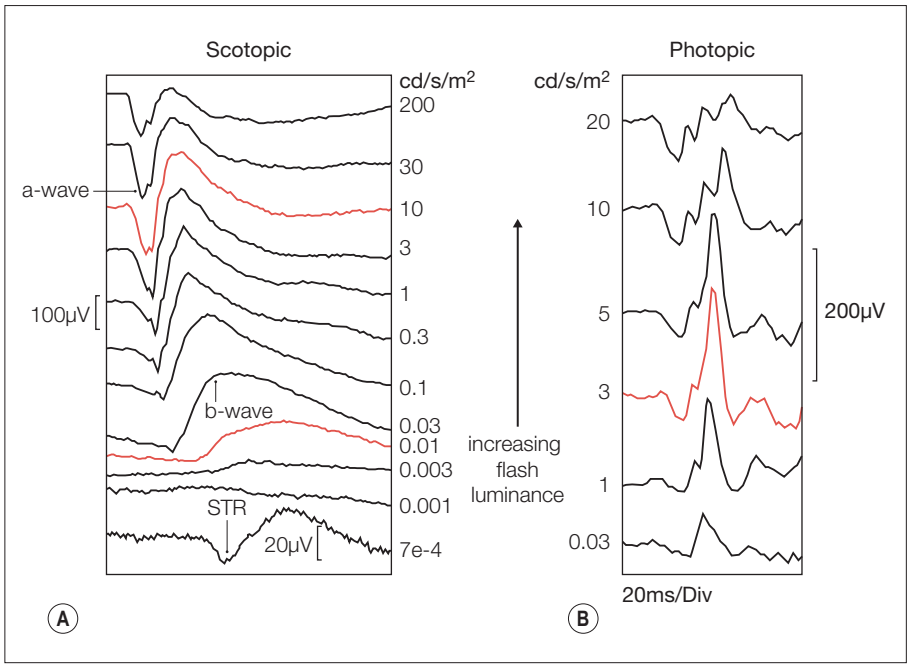

Fig. 9.2 Scotopic (A) and photopic (B) luminance response series. Electroretinograms (ERGs) to International Society for Clinical Electrophysiology of Vision (ISCEV)-standard flash strengths are shown in red. (A) From bottom to top, shows first the development of the rod driven b-wave and then the a-wave as flash strength increases. (B) Shows the photopic hill phenomenon with smaller b-wave amplitude to higher flash strengths.

findings from complementary tests are interpreted as consistent (see Fig. 9.1).

What do the responses tell us? An aide memoire for the busy clinician

The electro-oculogram

The EOG is used to investigate if a maculopathy is due to retinal pigment epitheliopathy. It depends upon the integrity of the RPE interface with photoreceptors. The RPE has a transepithelium potential between its apical and basal surfaces of around 6 mV, with maximal positivity detected at the corneal apex. Electrodes placed on the medial and lateral canthi will record a potential change during a saccade: the electrode closest to the cornea becomes positive relative to the electrode furthest from the cornea. This is the EOG and if it is displayed as a voltage/time plot it can be used to record eye movements, including nystagmus. The transepithelium potential increases in light and decreases in the dark.[2] This variation can be expressed as the Arden ratio (light rise/dark trough) of the maximum and minimum amplitude of EOGs to saccades made in light and dark. Ratios below 1.6–1.8 are considered abnormal. A spuriously normal Arden Index can arise if the dark trough is subnormal due to lowered resistance of RPE tight junctions.[3] An EOG may also reflect the extent of photoreceptor loss, e.g. in pigmentary retinopathy (RP) when the rod ERG is subnormal too. The EOG is diagnostically potent when the Arden ratio is abnormal and the rod ERG is normal as this discriminates a primary retinal condition from an epitheliopathy, e.g. bestrophin mutations.[4]

The flash electroretinogram

The flash ERG is used to distinguish cone from rod and photoreceptor from inner retinal function. The ERG waveform, size, and time to peak will depend upon the relative proportion of rods and cones that are excited and the area of the retina stimulated.[5] The ffERG has no significant contribution from the macula. Rods and cones can be preferentially stimulated by flashes of different colors, strength, and duration presented under different states of dark and light adaptation. Examples of changes in ERG waveforms with increasing flash strength under scotopic and photopic conditions are shown in Figure 9.2. To very dim lights, a small scotopic threshold response (STR) has been described, but clinically this is difficult to achieve and is used rarely. As flash strength increases, a positive b-wave emerges. This is the rod-driven b-wave, DA 0.1, which reflects inner retinal activity of depolarizing on-bipolar cells mainly, and Müller cells. The change of b-wave amplitude with flash strength can be described by a Naka–Rushton function, derived from the Michaelis–Menton equation, but the derived parameters will vary according to the method of curve fitting. In clinical circumstances, these need to be interpreted with care.[6]

$$V/V_{max} = \mathrm{Int}/\mathrm{Int} + K$$

where V = trough-to-peak amplitude of the b-wave, V_{max} = maximum value of trough-to-peak amplitude, Int = flash strength in troland/second, K = semisaturation value, i.e. when Int = K, V is $V_{max}/2$.

As the flash strength further increases an early negative a-wave precedes the b-wave. The a-wave becomes larger and has a shorter time to peak with increasing flash strength reflecting photoreceptor hyperpolarization. To the brightest flashes, DA 200, the leading edge of the scotopic a-wave models rod phototransduction.[7] After light adaptation, the LA 3 b-wave is cone mediated and faster by ~30ms. It reflects both on and off bipolar contributions. Measures of a- and b-waves are most useful clinically, but other ERG waves can be useful. These include:

1. oscillatory potentials – a series of wavelets between the a- and b-waves, vulnerable to disturbances of retinal circulation and spiking neurons.[8]

2. the photopic negative response, the descending limb of the photopic b-wave – reflecting proximal retinal activity, vulnerable in glaucoma and in potassium channelopathies.[9]
3. the c-wave – related to the EOG, due to a depletion of potassium ions in the space between RPE.
4. the d-wave – an off-pathway response. Rods use the on-pathway through the inner retina; cones use both on- and off-pathways. The d-wave is associated with decreases in light under photopic conditions, and is best seen in response to prolonged on–off flashes (on >90 ms).[10] Usually b- and d-waves are superimposed in the ERGs to short-duration (<10 ms) flashes.

ISCEV-standard ffERGs have distinctive shapes and Figure 9.3 shows a reference array of diagnostic standard ERGs with clinical examples in lower rows to aid interpretation of shape changes in pathology.

Flash ERG amplitudes are proportional to the area of functional retina and the summated ERG can mask a small, localized lesion, e.g. maculopathy. Localized areas of retina can be stimulated by focal flashes on bright backgrounds, or with patterned and multifocal stimuli that avoid intraocular light scatter; these methods require steady fixation.

PERGs are elicited by pattern-reversing checks. The waveform is biphasic with positivity at 50 ms and negativity at 95 ms, termed p50 and n95, respectively. The p50 reflects both pre- and postganglion cell activity, whilst the n95 characterizes spiking neuron and ganglion cell function. PERGs are used to investigate suspected early maculopathy, and distinguish it from optic nerve (retinal ganglion cell) dysfunction.[11] The authors record PERGs simultaneously with PVEPs using a large (30°) field and small (15°) fields to additionally distinguish maculopathy and optic nerve dysfunction from visual pathway and cortical dysfunction. The localized retinal area stimulated means PERG signals have small amplitudes, (around 0.5–8 μV). Corneal electrodes that allow good focus, and stringent artifact-rejection criteria and signal averaging to avoid blinks and eye movement artifacts, are needed (Fig. 9.4).

Multifocal stimulation allows focal ERG responses to be recorded simultaneously from many regions of the retina.[12] An array of hexagons are scaled in size with retinal eccentricity to elicit responses of equal size. Each hexagon flashes on and off in pseudorandom sequence (an M-sequence) that guarantees that no stimulus sequence is repeated during an examination. At any one time, on average, half of the hexagons are black and the other half white. The stimulation rate is high, causing a flickering appearance of the screen, but with relatively stable mean luminance. Each element starts the sequence at a different place to every other element. If the difference in starting point in the sequence (the lag) is longer than the response duration, each element generates a response uncorrelated with every other element. Responses unaffected by stimulation of other areas are termed first-order components; second-order components represent temporal interactions between flashes and short lags relative to the duration of the response. It is important to interpret the trace arrays rather than rely on the associated isopotential contour maps, which can be misleading. The mfERG waveforms are mathematical constructs not tiny ERGs, and do not directly reflect a- and b-wave sources. mfERGs, like PERGs, are very sensitive to fixation instabilities and evidence of a blind spot should be sought in trace arrays. Application in children remains largely untried.

The visual evoked potential

The VEP is recorded from the occipital region of the scalp. It reflects depolarization of lamina 4c of the striate cortex (area V_1) by the retinogeniculo afferent volley.[13,14] Retinotopic activity from the central 5°, predominantly lower field, dominates the VEP, and PVEPs in children can act as a surrogate index of macular pathway function. If the PVEP is abnormal, it is important to rule out primary retinal dysfunction at the macula using PERG, mfERG, and/or fundal imaging. Even in the presence of known maculopathy or degraded/absent PERG/mfERGs the PVEP waveform may still provide useful information about residual macular and paramacular function. The authors record PVEPs with both eyes open before monocular testing. They use a transoccipital array of electrodes, large full field (30°) and, where possible, half-field stimulation, to discriminate optic nerve, chiasmal, and hemisphere anomalies (Fig. 9.5).

Use of different types of stimulation: pattern reversal, pattern onset, and flash stimulation

Pattern-reversal VEPs have a simple triphasic waveform that is maintained across the lifespan, with a major positive peak around 100 ms by 7 months of age, called p100 (components are defined by their polarity: p for positive, n negative; the numbers are the latency of the peak after the stimulus). The shape of the full-field pattern-reversal VEP may become bifid (p-n-p) if a central scotoma reduces the macular contribution, e.g. seen in dominant optic atrophy. The bifid waveform is due to enhancement of paramacular contributions n105 and p135. Half-field stimulation can delineate macular and paramacular peaks. The authors use a wide range of check sizes from 400′ to 6.25′ presented at 3/s after 6 weeks of life.

Pattern-onset stimulation is attention grabbing, robust to eye movements, and is preferred in nystagmus or to prevent active defocus. Its waveform is complex and three components have spatially separate generator sources: CI, a positivity around 90 ms; CII, negativity at about 110 ms; and CIII, a prominent positivity at around 180–200 ms.[15,16] Different peaks emerge at different ages: the initial positive CI is most prominent in children and depends upon contrast and luminance. CII emerges in later childhood and depends more on contour. These changes mean it can be difficult to use pattern onset VEPs for monitoring longitudinally.[17]

Flash stimulation is robust and can be effective through closed lids. A control ERG recorded at the same time as the VEP can ensure the level of retinal stimulation. The authors use both flash and pattern stimulation, and often both pattern reversal and onset stimulation to provide corroborating evidence of visual pathway function, particularly transoccipital asymmetries.

Flash and pattern reversal VEPs show paradoxical localization. For example, the right half field stimulates the pathways of the left hemisphere and is detected over the right occipital electrode. This is due to orientation of the cortex activated and is a consequence of the authors' use of large-field stimulation and midfrontal reference electrode site.[18] Pattern-onset VEPs do not show this. The right half field response is recorded

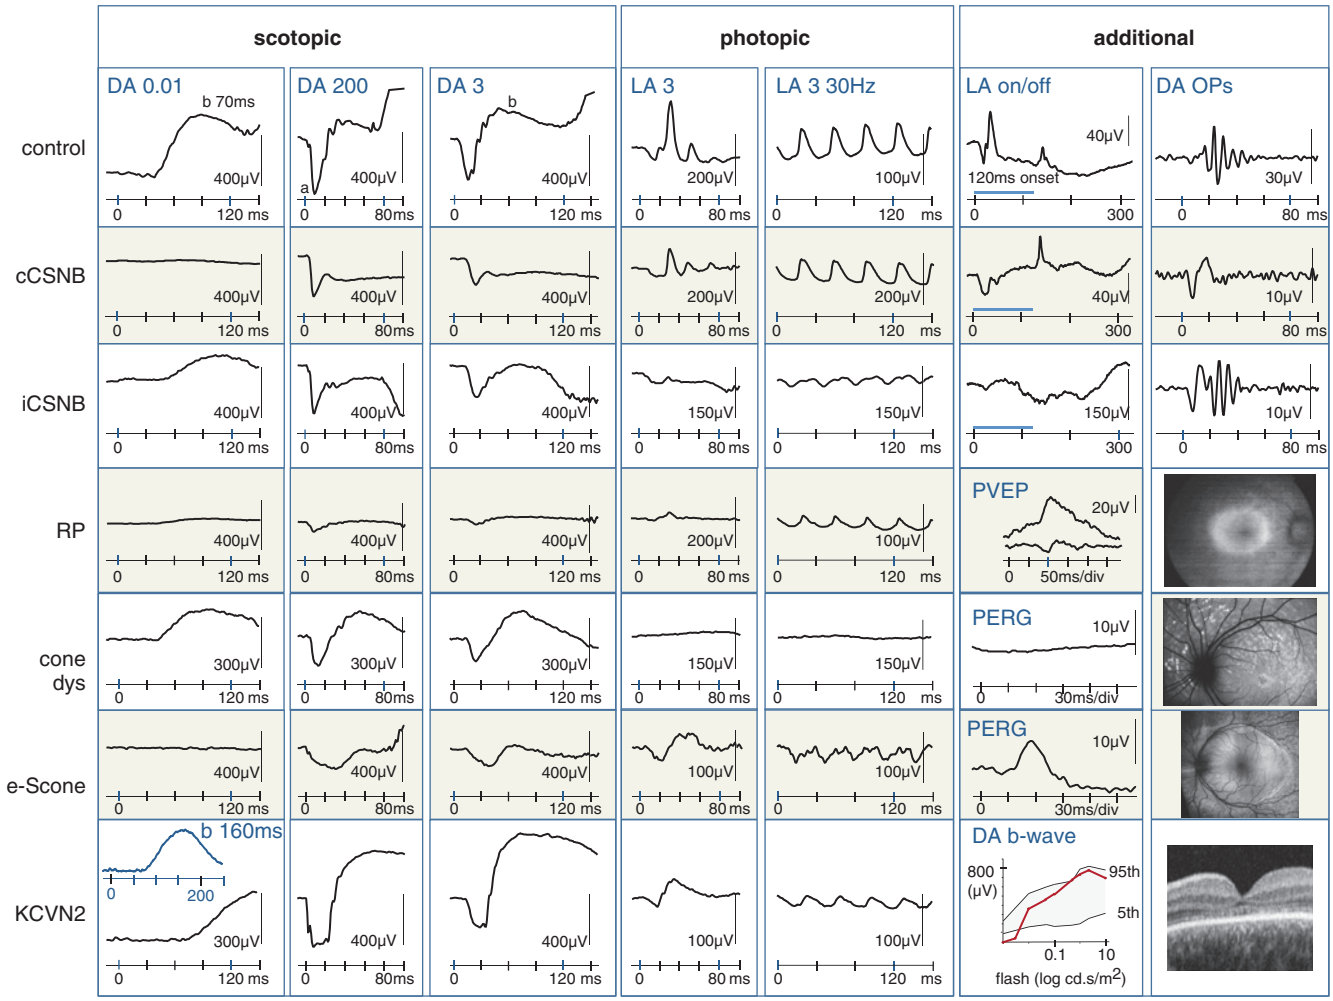

Fig. 9.3 Template of standard diagnostic electroretinograms (ERGs).
Row 1 shows normal traces. The columns moving from left to right show dark-adapted (DA) and light-adapted (LA) ERGs recorded to flashes of different strengths. The last two columns show diagnostically useful additional data, e.g. prolonged on–off ERGs (LA on/off), oscillatory potentials (OPs), pattern-reversal VEP (PVEP), and pattern electroretinogram (PERG). The characteristic ERG waveforms are shown in response to flash stimuli. DA 0.01: large rod-driven b-wave and no a-wave; DA 200: emphasizes the rod a-wave; DA 3: an a- and b-wave mixture of rod and cone contributions; LA 3: a cone-specific response comprised of both on and off bipolar cell activity; LA 3 30 Hz flicker is a cone-sensitivity response reflecting inner retinal responses; LA on/off flashes separate responses of the bipolar on-pathway and off-pathways.
The rows below the normal traces show examples of clinically distinctive electrophysiological findings. Rows 2 and 3 are examples of electronegative ERGs when the b-wave does not rise above the baseline.
Row 2: complete congenital stationary night blindness (cCSNB) is due to a signaling defect, which prevents on-bipolar depolarization. Thus the rod DA 0.01 b-wave is absent and the maximal flash ERG is electronegative. The shape of LA 3 cone a-wave is a broad trough, as the absence of the on-pathway contribution reveals the photoreceptor and off-bipolar responses. The flicker ERG has a saw-tooth shape. LA on–off ERG show an electronegative on-response and a well preserved off response. Later OPs are missing.
Row 3: incomplete CSNB (iCSNB) defects occur at the photoreceptors and affect on- and off-pathways. There is some residual DA 0.01 rod-driven b-wave, a severely attenuated LA 3 cone response and a bifid flicker waveform.
Row 4: pigmentary retinopathy (RP). The very small DA 200 rod a-wave indicates rod photoreceptor loss. Residual cone ERGs reflect peripheral to central progression of photoreceptor loss. If the macula region is preserved, e.g. within the ring of hyper fundus autofluorescence (FAF) shown, then PVEPs may be recorded as they arise from the central 2–5°. PVEPs may help indicate the extent of central retinal preservation when ERGs in RP are non-detectable.
Row 5: cone dysfunction syndrome (conedys). DA rod ERGs are preserved, but the LA cone responses and PERG are attenuated markedly. Such an array of ERGs may occur in Stargardt disease: the typical Stargardt FAF is shown in the last column of this row. Attenuation of the PERG p50 will be noted first indicating maculopathy, but the relative preservation of cone and rod ERGs can be used prognostically.
Rows 6 and 7 are examples of two pathognomonic ERG arrays.
Row 6: e-Scone syndrome (e-Scone). The retina is populated only by S-cones, which use the on-bipolar pathways. There is no DA 0.01 rod driven b-wave. Characteristically, the DA 3 and LA 3 have similar waveforms, the S-cone ERG will be larger than usual, the PERG p50 is typically delayed, as shown, as is the flicker ERG, which may be smaller than the cone a-wave. In childhood hyper FAF dots are seen around the arcades.
Row 7: KCVN2 retinopathy (cone dysfunction with supra normal rod response) shows absent DA rod-driven b-waves to low flash strengths, but to higher flash strengths a very late b-wave suddenly appears (see insert showing the DA 0.01 ERG on a longer time *x*-axis). The DA b-wave amplitude grows rapidly over a small range of flash strengths (plotted as a red line on amplitude vs. flash strength, with the gray area highlighting normal response growth). The DA 200 a-wave shows a distinctive flat-bottomed trough. KCVN2 retinopathy can be associated with bull's eye maculopathy and older children may show a distinctive "toothy" foveal optical coherence tomography (OCT) appearance in the photoreceptor layers.

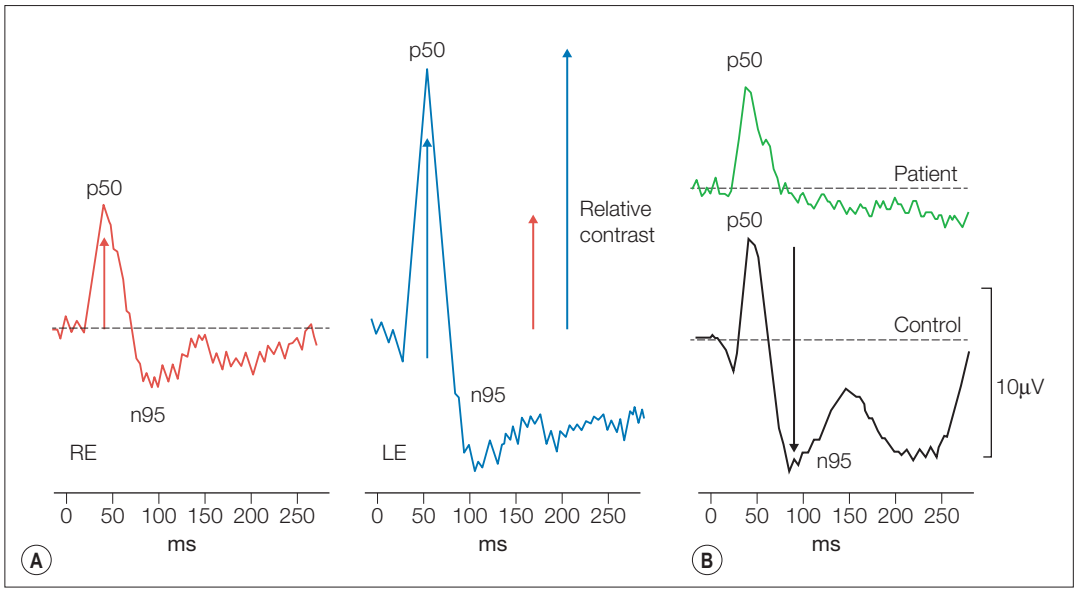

Fig. 9.4 (A) Right eye (RE) and left eye (LE) pattern electroretinograms (PERGs) to 50′ from a 3-year-old patient with RE posterior lenticonus. p50 amplitude is proportional to contrast. The RE PERG amplitude reflects the relative contrast loss due to RE cataract. (B) Top trace is RE PERGs to 25′ from 6-year-old patient with kidney failure. Loss of n95 indicates visual loss due to ON compromise not retinal dysfunction.

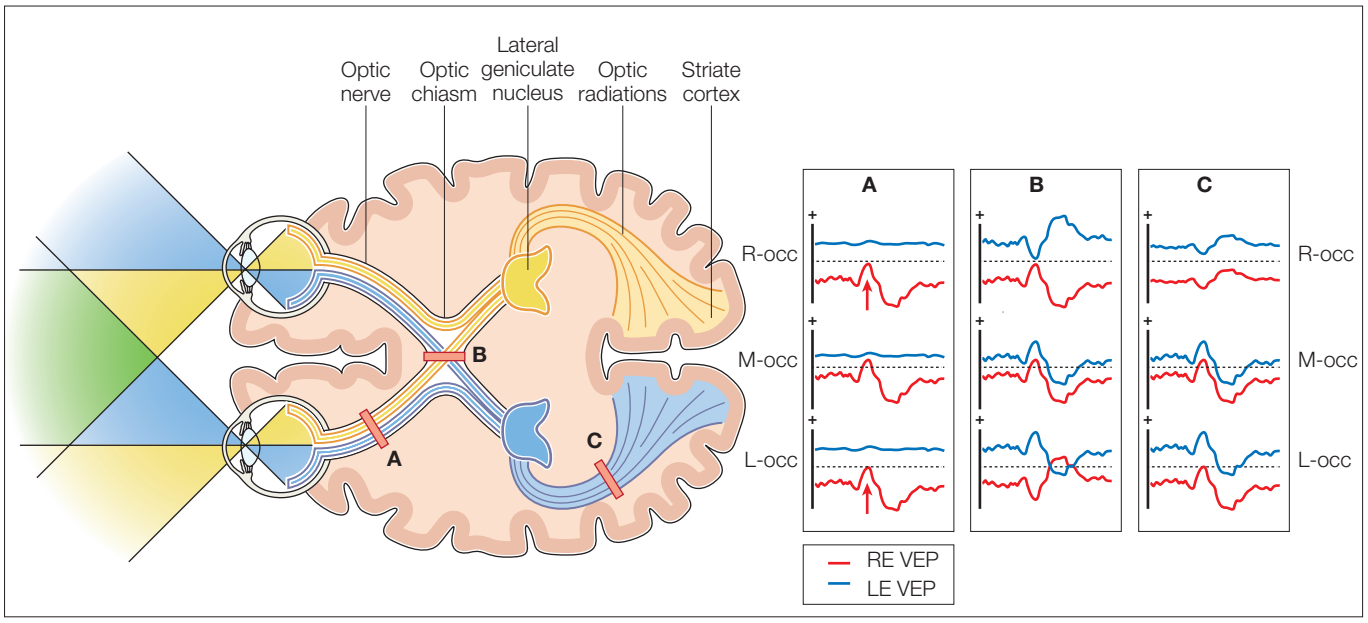

Fig. 9.5 Schematic projection of the right (blue shade) and left (yellow shade) half fields of each eye (RE, right eye; LE, left eye). The black bars superimposed on the pathway represent lesions at (A) left optic nerve, (B) chiasm, and (C) left optic radiations and occipital cortex. The occipital distribution of schematic visual evoked potentials (VEPs) caused by these lesions are shown from RE (in red) and LE (in blue) aligned with the electrode sites right (R-occ) and left (L-occ) lateral and the midoccipital (M-occ) channels. Column A shows a reduced LE VEP and a symmetric distribution of the RE VEP where lateral channel amplitudes are similar (arrowed). Column B shows a crossed asymmetry where the transoccipital distribution of one eye is the mirror image of the other, i.e. the RE VEP is negative (downwards deflection) on the left occiput and the LE VEP is negative over the right occiput. This indicates chiasmal dysfunction. Column C shows that each eye has the same, homonymous, distribution reduced over the right occiput. This homonymous distribution or uncrossed asymmetry suggests hemisphere dysfunction. Due to paradoxical lateralization this distribution of flash and pattern-reversal VEPs means dysfunction of the right half field representation in the left hemisphere.

anatomically appropriately over the left occiput. A comparison of full-field pattern-onset and -reversal VEP transoccipital asymmetries is at times useful to determine if VEP occipital asymmetry is due to pathology, especially in those children with flat or asymmetric skulls who cannot manage half-field stimulation.[19]

Visual acuity and the VEP

It is alluring to try to condense PVEPs into a single-number descriptor of vision acuity; unfortunately, the relationship is not so simple. In normal children, an estimate of visual acuity may be based on the amplitude of PVEPs elicited by patterns of decreasing element size.[20] Threshold VEP acuity is derived from the smallest pattern size to give a response above noise level, or an extrapolation to zero amplitude on a graph of amplitude versus spatial frequency.[21] Although PVEPs show some correlation with behavioral acuity, it is not realistic to expect a direct correlation in a clinical population. For example, as neurons are lost in optic atrophy, the PVEPs will become markedly attenuated and degraded, yet if the receptive fields of the few remaining functioning neurons are closely spaced in the

central field, recognition acuity can be surprisingly good, even with marked optic disc pallor. Estimates of acuity development are higher with VEP techniques in the first 12–18 months of life; after this, behavioral estimates exceed VEP acuity.[22] Recognition acuity is an interpretation of high contrast, static images by higher association areas. Discrepancies from a VEP measure of striate cortex activity should not be surprising. Nevertheless, PVEPs are a useful index of macular pathway function and provide a qualitative indication of the vision level that the retinogeniculate pathway can support. In the authors' opinions, a pattern-reversal VEP to 50′ or smaller checks suggests good vision levels; to 100′–200′, moderate vision levels; and to 400′, poor vision levels. If a flash VEP is detected, but no PVEP is recorded, this suggests vision is rudimentary. PVEPs show little intersession variation and are reliable for serial monitoring. They are particularly useful for interocular comparisons in infancy.[23,24]

When the rate of stimulation increases, individual transient PVEP waveforms merge and become sinusoidal. This is a steady-state response and is used in sweep VEPs, where many different pattern sizes or contrast levels are swept through rapidly.[25,26] The steady-state VEP is analyzed by Fourier techniques into magnitude and phase data. It is possible to determine signal-to-noise thresholds during acquisition before proceeding to smaller patterns – a step acuity VEP. The sweep technique can provide a number (usually in cycles per degree [cpd]) to describe acuity or contrast sensitivity quickly, but there is a loss of information about waveform and often transoccipital distribution. These fast stimulation rates drive the maturing visual system faster than optimal for highest acuity. As VEP waveforms are such important diagnostic indicators the authors prefer transient PVEP recording for routine clinical practice (Fig. 9.6).

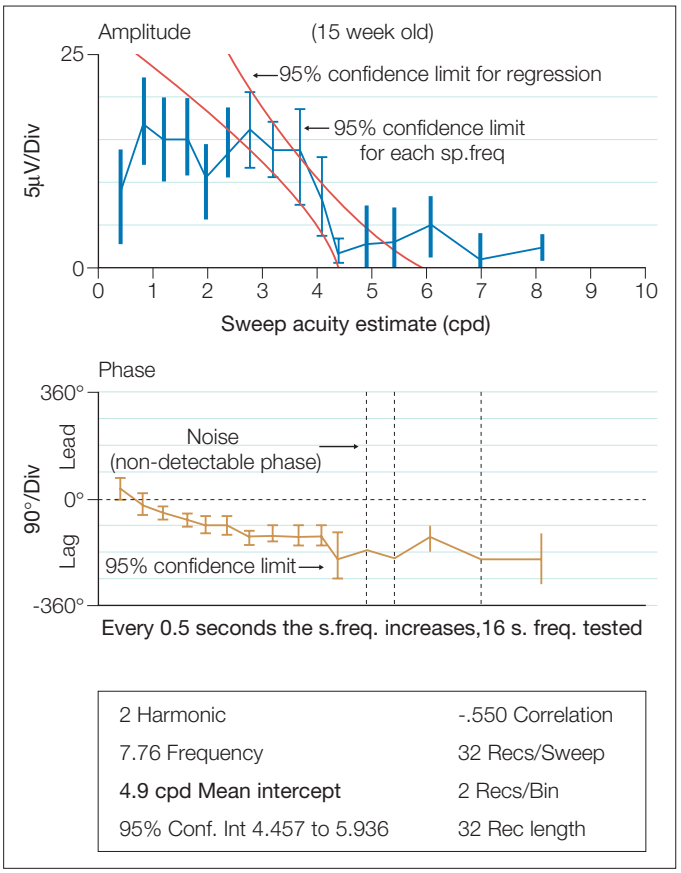

Fig. 9.6 Sweep visual evoked potential (VEP). Rapid stimulation rates are used to elicit a quasi-sinusoidal VEP characterized by its amplitude and phase. A range of spatial frequencies is presented. There is a trend for VEP amplitude to decrease with increasing spatial frequency. A regression to the baseline or noise level is computed to give an acuity estimate, in this case 4.9 cpd.

Technical factors

Visual stimuli include transient flashes of different intensities, durations, temporal rates, colors, patterns, and multifocal mosaics.

Visual stimulators

Flash

Commercial flash stimulators include hand-held strobes, which are helpful for pediatric testing. They can easily follow an alert but restless child, and the child's eye position can be directly observed. Ganzfeld stimulators scatter light uniformly over the retina. They are available as static domes with chin rests, or smaller hand-held LED versions held close to the eye. It is important that these have integral cameras to ensure the eye is open and stimulated properly. Some versions measure natural pupil area and determine flash dose necessary for standard retinal illuminance.

Patterns

Patterned stimuli are computer generated and presented on cathode ray tube (CRT) and plasma display panels (PDP), which are no longer commercially available, or liquid crystal diode (LCD), back projection systems, or super-bright organic light-emitting diode arrays. Triggers for response acquisition with CRTs synchronize with the raster rate generating the image. If running at 50 Hz, there could be a 20-ms difference in latency between a PVEP recorded looking at the top-left of the screen compared to the bottom-right. LCD screens have an inherent luminance flash artifact generated in the pattern due to timing differences in on and off switching. PDPs avoid both these issues. The authors use a large-field PDP with the advantage of the near-simultaneous generation of a pattern uniformly over the screen without luminance artifact. Its multisynch capabilities allow us to switch quickly between the stimulus and a cartoon DVD during the test to maintain attention, whilst a separate audio output keeps soundtrack continuity when patterns are presented.

Field size

Large field sizes (around 30°) are important in pediatric practice, allowing a child some variation of gaze direction whilst still fully stimulating a central, macular, 10° field. Smaller fields are more prone to spurious transoccipital asymmetries when fixation direction varies to the edge of the field.

Check sizes

Patterns prevent light scatter by containing equal numbers of black-and-white elements (usually checks, more rarely gratings) that either counterphase (reverse from black to white) or appear from a background of uniform gray field of equal

mean luminance (pattern onset). A wide range of check sizes is important to ensure consistency, provide a broad baseline for monitoring, and intraocular comparison. The diagonal dimension of a single check gives the cpd equivalent.

ERG electrodes

A range of different sized contact lens electrodes is needed for pediatric work, but these are not used often in the UK and Europe because of concerns about cross-infection. Disposable corneal electrodes (e.g. DTL, gold foil, and HK loop electrodes) are preferred and inferior periorbital skin electrodes are used frequently in younger children.[27] An ERG recorded with a skin electrode is smaller, 12–15% of the amplitude of a corneal electrode, but still substantial, i.e. exceeding 10 μV (with corneal electrodes mfERG are measured in nanovolts, PERGs are under 2–5 μV, and adult VEPs ≤5 μV).[28,29] The skin ERG waveform and timings are similar to corneal electrode ERGs. It is important to ensure the cornea is positioned towards the skin electrode, e.g. a child is encouraged to look downwards, or if there is strabismus, or a shallow midface, the skin electrode may be displaced and gaze directed over it. If the child is asleep and eye rolls up, it is possible to record a completely inverted ERG trace.[29]

Refractive error

The PERG is sensitive to 0.5 DS blur, but the pattern-reversal VEP is robust to 8 D blur of 60′ checks. These two responses can be recorded together to ensure accurate focus. If there is a doubt about focus, as may occur in patients with suspected functional overlay, then PERGs and PVEPs may be recorded after cycloplegia and correction for stimulator distance, e.g. +1 D added for a viewing distance of 1 m.

Dilatation

For the authors' combined protocol, best focus for pattern-reversal VEPs is required. The authors do not dilate for the flash ERG protocol, which immediately follows the PVEP recording. Pupillary dilatation aims to standardize amplitudes, but causes only 12–15% amplitude change.[28,29] Extremes of pupil size or anisocoria are noted, but numerical correction factors for variation in retinal illuminance rarely are applied to clinical ERGs. Recording ERGs to a wide a range of flash strengths ensures this is overcome empirically.

Dark adaptation

It is not practical to have pediatric normative data for abbreviated dark adaptation. Ranges would be required for each 5-minute dark interval for each month of the first year of life. The authors take the same time point under darkened conditions without long dark adaption and stimulate with dim blue flashes to bias the photoreceptor contribution to be predominantly rod driven. The ERG waveform shape provides feedback about the predominant contributing cells as the retina acts like an adaptive photometer.

Maturation

Retinal sensitivity is poor at birth. ISCEV-defined flash stimuli include the possibility of non-detectable ERGs in early infancy.[30] In essence, brighter flash stimuli are needed. If anesthesia is used, this can delay the time to peak and diminish the b-wave in particular.[31] Myelination and synaptogenesis and pruning influence the latency of the pattern reversal VEP, which shortens rapidly to within 10% of adult values in the first 7 months of life. A newborn VEP latency is around 240 ms. It is better to stimulate at 1/second and increase the acquisition time window to 450 ms to capture baby responses. After 8 weeks of age, stimulation of 3/second and shortening the time window to 300 ms speeds up data acquisition. There continue to be morphologic changes throughout life and it is important for each laboratory to acquire full normative reference data sets, sampling frequently in the first 12 months of life.

Summary

Visual electrodiagnostic tests (EDTs) are noninvasive, objective indices of function and are ideal tests for children. To get the most information from each child in the least time, the authors combine and adapt stimulation protocols according to individual need. Distraction is used, interleaving cartoon DVDs with patterned stimuli, having continuous sound tracks, music, audio books, noisy toys, and, most importantly, reassurance and encouragement through personal interaction and play. These are key to directing attention and gaze for a successful recording. Responses are compared against age-matched reference data, after artifacts and confounders are excluded. Data obtained from a combined ERG and VEP assessment can localize dysfunction along the visual pathway and provide a qualitative estimate of vision. The authors provide complementary and supplementary information in many diverse clinical presentations, ranging from an infant who does not fix and follow and has unusual eye movements, to amblyopia not responding to patching, investigation of headaches, and assessment of children who cannot communicate for behavioral assessments.

The prognostic significance of visual EDT results must be weighed in the light of clinical data and with an awareness of maturational changes. Clinical visual EDTs assess the "visual hardware," but do not tell us about the "software." They may suggest the quality of pattern vision that the retinogeniculostriate pathway may support, but clinical EDTs cannot tell how well a child will be able to use the visual data that reaches the striate cortex.

Bonus e-book content online

Fig. 9.1 All testing can start with pattern-reversal 50′ checks presented to both eyes.

Depending upon the response, one may proceed to smaller reversing checks and monocular testing, or divert to pattern-onset stimulation. After pattern stimulation is completed, flash stimulation is used to contemporaneously record electroretinograms (ERGs) and visual evoked potentials (VEPs). Transoccipital asymmetries are noted throughout and explored in all three stimulus modalities and, when possible, with half-field stimulation. With suspected voluntary

Bonus e-book content online—cont'd

defocus, the pattern electroretinogram (PERG) is recorded simultaneously with the pattern-reversal VEP (PVEP). This robust combination strategy can be used to investigate diverse clinical questions as the two examples outlined:

1. Babies: unstable eye movements, is this congenital motor nystagmus? Looking for an anterior visual pathway problem. Possibilities:
   - i. Retina: early-onset severe retinal dystrophy (EOSRD), cone dysfunction and congenital stationary night blindness (CSNB) – *need stimuli to separate rod and cone activity and distinguish photoreceptors from inner retina activity (a- and b-wave).*
   - ii. Optic nerve: optic nerve hypoplasia – *need monocular flash and PVEPs to compare interocular amplitudes and latency on the midline electrode.*
   - iii. Chiasmal anomaly: albinism (require flash infancy and pattern-onset stimulation for older children), chiasmal hypoplasia, glioma – *need monocular stimulation and a transoccipital array of electrodes to look for transoccipital distribution of VEP.*
2. Teenagers: questioning whether there is a functional element to measured subnormal vision:

Simultaneous PERG and PVEP – *control defocus: cycloplegic full correction for viewing distance, observe direction of gaze.*

In 1850/1851, Hermann von Helmholtz (1821–1894) designed the direct ophthalmoscope, enabling the founders of modern ophthalmology to see the living ocular fundus for the first time. Completely new disorders were described, making this instrument essential in establishing the young specialty of ophthalmology. Until ophthalmic photography became available, ophthalmic imaging was performed by artists who meticulously drew and painted detailed renditions of the ocular diseases they had observed. The advent of scanning laser ophthalmoscopy (SLO) in 1981[1] and of optical coherence tomography in 1991[2] dramatically enhanced ophthalmic imaging. Thirty-five millimeter film photography was the standard in external, anterior segment, and fundus photography for decades but has now been replaced by digital photography. Camera systems and optics have remained relatively unchanged, with the exception of the development of non-mydriatic fundus cameras, which allow imaging of the fundus without pupil dilation.[3]

Several new techniques to examine and image the eye have been established over the past few decades. This progress has resulted in a shift in the role of ophthalmic imaging from simple documentation to powerful analysis of the eye and its components, significantly enhancing our understanding of many ocular diseases.

Nevertheless, a careful clinical examination of the patient is essential to decide which type of imaging is needed. Using imaging techniques indiscriminately can result in confusion, the waste of resources, anxiety, and potentially, the provision of unnecessary treatment. Accurate documentation of clinical findings also has a medicolegal dimension. In this chapter, we attempt to provide a framework for the physician to facilitate decisions regarding which imaging technique to use. Specific findings in certain entities are discussed in their respective chapters.

Photography

External photography

In many settings, external ophthalmological findings can be documented. For example, lid fissure height and margin reflex distance are important parameters in patients with upper lid ptosis; ocular motility in patients with strabismus and eyelid swelling and erythema in cellulitis can be photographed. Children might not tolerate instruments close to their face, which makes photography helpful (Fig. 10.1).

Anterior segment photography

In young children, slit-lamp examination is often impossible and photography may allow the clinician to document findings. Measuring the corneal diameter helps to establish the diagnosis in some patients (microphthalmos, infantile glaucoma) and is best done photographically. Judging and comparing lens opacities in pediatric cataract or the extent of subluxation of the lens (e.g. in Marfan syndrome) is facilitated by photographic documentation.

The RetCam (Clarity Medical Systems, Inc., Pleasanton, CA) is a contact digital photography system. With special lenses, it can be used for anterior segment photography. The anterior chamber angle may be visualized and good agreement with slit-lamp gonioscopy in detecting angle closure has been reported.[4]

Fundus photography

When evaluating newborns for retinopathy of prematurity, sequential photographic documentation of retinal findings is helpful. The use of digital fundus photos for remote diagnosis (telemedicine), which holds promise in areas with limited medical care is another possibility. Retinal lesions can be documented, which is particularly important in managing tumors such as retinoblastoma.

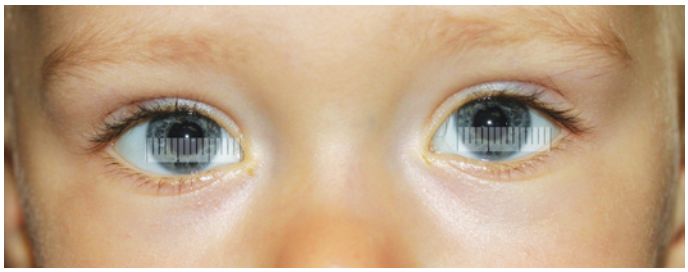

Fig. 10.1 External photograph of a young boy showing symmetric lid fissures and normal corneal diameters. The superimposed scales help to obtain precise measurements, which may be difficult in uncooperative children.

Optic disc characteristics such as the color, sharpness of its borders, as well as size and shape of the optic cup can be assessed on a photograph (using magnification if necessary) and comparison with subsequent photographs is possible, helping to highlight progressive change.

Red-free fundus photography

In red-free fundus photography, the imaging light illuminating the fundus is filtered to remove red colors, allowing light with wavelength 495–570 µm to pass. Since hemoglobin absorbs light of this wavelength well, retinal vessels and hemorrhages appear dark and may be more easily seen than on color photographs. Visualization of retinal holes (darker than surrounding retina) is also facilitated. Drusen (macular and optic disc), exudates, cotton-wool spots, and defects in the retinal pigment epithelium (RPE) are lighter on red-free photography. The retinal nerve fiber layer (RNFL) is lighter and defects appear as darker areas with arcuate borders of RNFL bundles.

Infrared fundus photography

Infrared fundus photography is usually obtained using scanning laser ophthalmoscopy (SLO). Compared with regular white flash fundus photography or photography using a laser with a shorter wavelength (blue, green), it offers better visualization of lesions located in the outer retina or under the retina (Fig. 10.2).

Confocal microscopy

Confocal microscopy (CM) has been used in other tissues since 1955,[5] and was first used to study the cornea in 1990.[6] Like specular microscopy, CM can image the cornea at a cellular level. Unlike light microscopy, which is limited by scattered light and reflections outside the focal plane, in CM the illumination and detection paths have the same focal plane. CM is helpful in diagnosing acanthamoeba keratitis (amoebic cysts and swollen corneal nerves can be detected) and visualizing pathology in individual layers of the cornea (e.g. guttae in endothelium in Fuchs's endothelial dystrophy).

Corneal topography

The first keratoscope was described by Henry Goode in 1847 and used the reflection of a square object on the corneal surface.[7] The *Placido disc* was described by Antonio Placido in 1880. The disc consists of concentric light and dark rings with a central opening to observe the reflections of these rings on the cornea. Any corneal irregularity (astigmatism, scars) will distort the reflection, so that the rings do not appear circular. Videokeratoscopy became available in the 1980s and made analysis of several thousands of sampling points possible. With Placido disc-based topography, a corneal map can be created and color-coded based on corneal curvature or elevation. Advantages of this technology include noninvasiveness and intuitive interpretation. Regular and irregular astigmatism are easily distinguished and corneal disorders such as keratoconus can be identified based on their characteristic appearance. Disadvantages of this technology include the absence of information about the posterior corneal surface and limited corneal coverage (60%).[7]

Fig. 10.2 Infrared image of the normal macula of a 13-year-old girl obtained with a scanning laser ophthalmoscope. The optic disc (right edge of photograph) is sharply demarcated, its neural rim appears dark, the cup white. There is a circular brighter area around the optic disc. Retinal vessels are dark. In the central macula (fovea) a brighter signal is seen.

Slit-scanning elevation topography provides an elevation map of the anterior and posterior corneal surface. The Orbscan II (Bausch and Lomb, Inc., Irvine, CA) is the only commercially available unit using this principle; it provides two-dimensional color-coded maps. Corneal elevation is measured from a reference sphere. This reference sphere is adjusted to each patient's cornea and is called "best-fit sphere." Maps of corneal elevation (anterior and posterior) and curvature as well as corneal thickness can be computed.

Scheimpflug imaging is based on the principle that Theodor Scheimpflug, a captain in the Austrian Navy, described in 1904.[7] Although first used in ophthalmology in the late 1950s, it was not until 1995 that it was used regularly in clinical practice. Diagnostic setups based on the Scheimpflug principle include the Pentacam (Oculus Optikgeräte GmbH, Wetzlar,

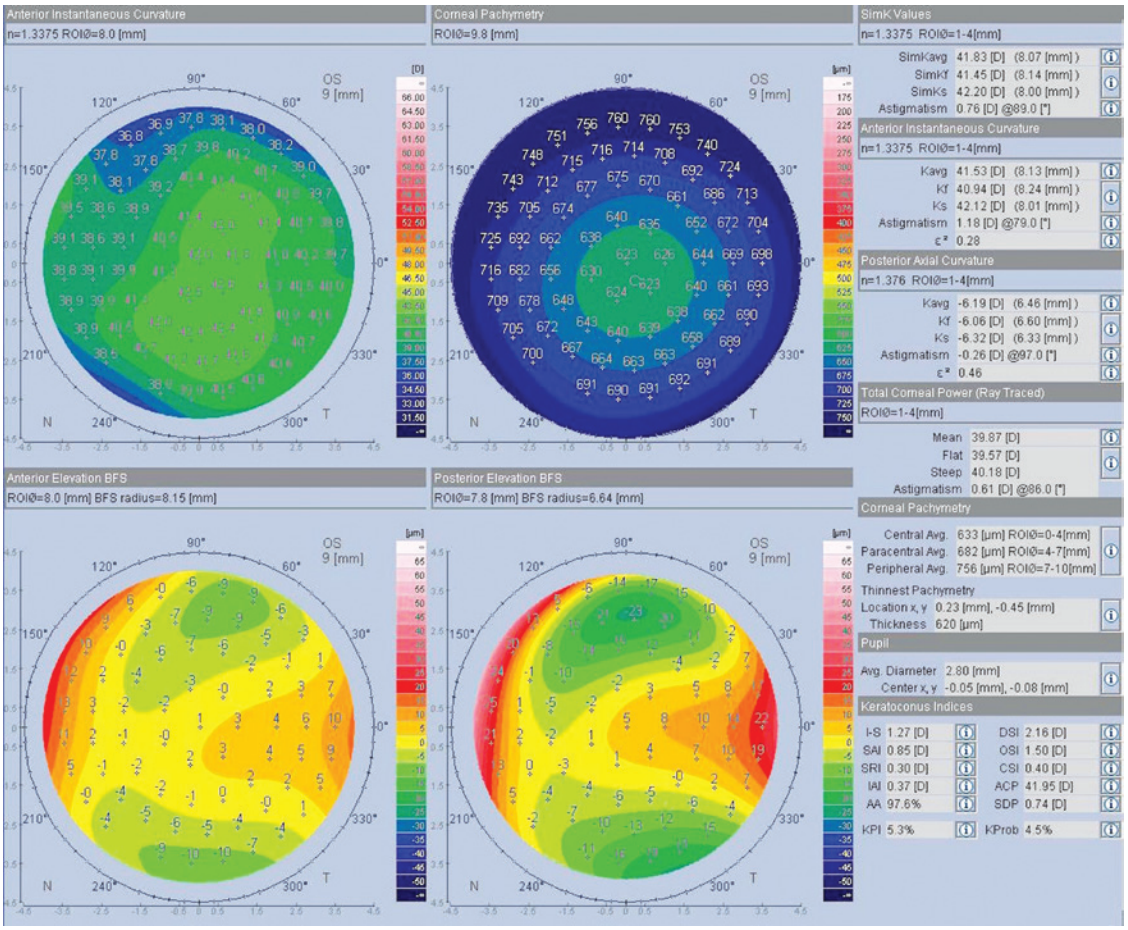

Fig. 10.3 Corneal analysis based on the Scheimpflug principle using Gallilei.* Upper left, anterior corneal curvature is shown (with absolute values and a color-coded corneal map for intuitive interpretation). Upper right, corneal pachymetry is shown; thinner parts are color-coded in warmer colors (red and pink) in order to alert the clinician to corneal thinning. Lower left, an anterior corneal elevation map is shown, in relation to the best-fit sphere (see text). Lower right, a posterior corneal elevation map is shown. Elevation maps are helpful in identifying corneal ectasias such as keratoconus. **Ziemer Ophthalmic Group, Port, Switzerland.*

Germany), the Gallilei (Ziemer Ophthalmic Systems AG, Port, Switzerland) and the Orbscan II (Fig. 10.3). They can measure corneal elevation, thickness, and curvature of the anterior and posterior corneal surface, as well as anterior chamber depth, pupil diameter, anterior chamber angle size, lens opacification, and lens thickness.[7]

Ultrasonography

Ultrasonography can usually be performed without sedation or general anesthesia and is available in many ophthalmologists' offices.[8] It can be performed if fundoscopic examination is inconclusive or not possible. Ultrasonography is based on the emission of high-frequency sound waves, which are reflected by tissues. Shorter wavelengths allow for higher resolution, but tissue penetration is lower. Higher ultrasound frequencies (50 MHz) are used to image the anterior segment (ultrasound biomicroscopy [UBM]), lower frequencies (10–20 MHz) to perform biometry and to image the entire globe.

Ultrasound travels more slowly in fluid and faster in solid material. Velocities in the eye are 1532 m/s in aqueous humor and vitreous and 1641 m/s in the cornea and lens.[9] In silicone oil, sometimes used to fill the vitreous cavity after a vitrectomy, ultrasound has a reduced velocity (980–1040 m/s). Ultrasound is absorbed by any medium it travels through. Denser media absorb more ultrasound, resulting in weaker echoes behind them. It is also reflected by any medium and an echo is generated. Based on the ability to generate an ultrasound echo, the normal cornea is isoechoic to the skin of the eyelids, the fluid-filled anterior chamber is anechoic, iris and ciliary body are isoechoic to the lens, the vitreous is anechoic, and the retina has a relatively strong echo. The optic nerve is a hypoechoic band between the relatively strong echoes of the retina and the choroid anteriorly and the orbital fat posteriorly. Calcium is highly echogenic and casts a dark shadow behind it (posterior extinction).

The ultrasound probe emits sound waves, registers the echoes, and converts them into an electric signal. In an A-scan, a thin ultrasound beam is emitted; vertical spikes on the screen represent the recorded echoes. The height of these spikes corresponds to the strength of the echo (Fig. 10.4). By means of an oscillating beam, A-scans can be combined to form B-scans to image a slice of tissue (Fig. 10.5). Here, reflectivity values are represented by dots of different brightness; stronger echoes generate brighter dots. For both A- and B-scans, the angle of incidence (angle at which the sound beam hits structures) is crucial: the more perpendicular the probe is positioned relative

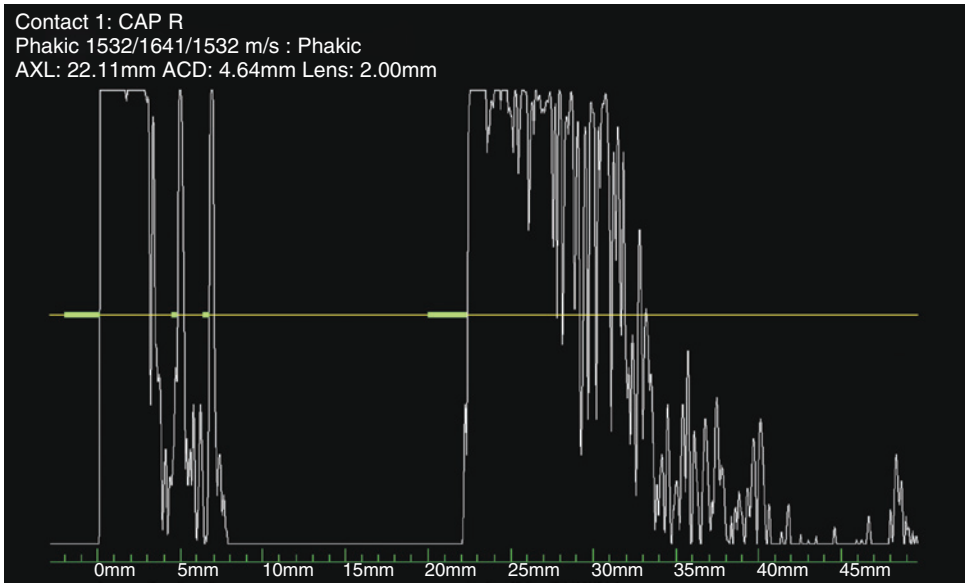

Fig. 10.4 A-scan ultrasound image of the normal eye of a child. This scan was obtained using the contact method, where the ultrasound probe gently touches the anesthetized cornea. From left to right, the first spike represents the cornea, followed by the less echogenic anterior chamber. The two following spikes are the anterior and posterior surface of the lens, followed by the low echo of the vitreous cavity. The steep retinal spike is followed by a gradual decline of the echo, representing the choroid, sclera, and orbital tissues.

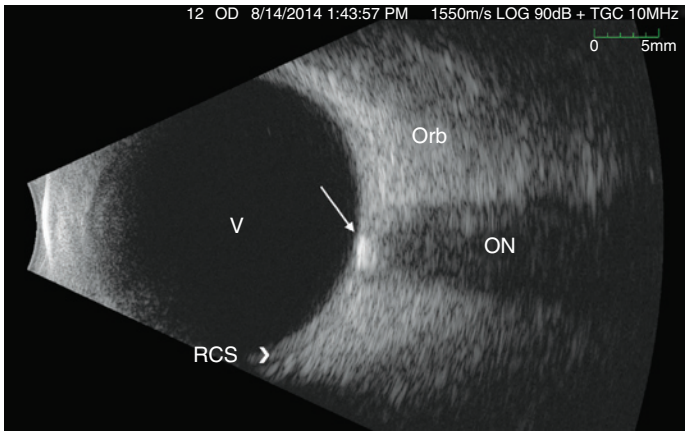

Fig. 10.5 Ocular B-scan ultrasound image of the right eye of a 12-year-old child. Cornea, lens, and iris are not imaged because the scan was obtained through the closed eyelid. The vitreous (V) is clear. Retina, choroid, and sclera (RCS) can be distinguished from the orbital tissue. The optic nerve (ON) is hypoechogenic relative to the orbital tissue (Orb). In this otherwise normal B-scan, a bright (highly echogenic) structure can be seen at the level of the optic disc (arrow) – an optic disc druse.

to the structure of interest, the more the echo is reflected to the probe and the clearer the image becomes. On an A-scan, this is seen as steeply rising spikes (e.g. lens, retina); on a B-scan this results in brighter dots and higher contrast.

Anterior segment ultrasound (ultrasound biomicroscopy)

Various developmental and genetic disorders can cause anterior segment pathology in children (e.g. Peters anomaly and sclerocornea) and need to be identified to select the most appropriate therapeutic approach.[10]

Iris cysts are usually seen on biomicroscopy, but UBM can help distinguish them from solid masses. Ciliary body cysts are usually asymptomatic but they may displace the iris anteriorly and can cause glaucoma. On UBM, they appear as round-walled structures with anechoic interior within the ciliary body.

Posterior segment ultrasound

Posterior segment ultrasonography is important when direct ophthalmoscopic visualization is not possible (opaque media, small pupils). When ruling out intraocular foreign bodies in ocular trauma, ultrasound has the advantage of not using a magnet such as magnetic resonance imaging (MRI). MRI is contraindicated when a metallic foreign body is suspected, because it can dislocate the foreign body and cause more extensive injury.

Ultrasound findings in selected ocular disorders

In eyes with persistent fetal vasculature (PFV), ultrasonography may visualize involvement of the retina. Spectral Doppler ultrasonography can demonstrate blood flow in a persistent hyaloid artery. In Coats disease, exudative retinal detachment may develop and the primary role of the ultrasound is to exclude a tumor in these eyes.

Retinoblastoma is the most common intraocular tumor in children. With ultrasonography, retinoblastoma lesions appear as irregular solid masses with heterogeneous internal reflectivity.[8,11] Calcification is present in 90% of the lesions,[8] and may be more easily detected on ultrasound than on computed tomography (CT).[12]

In retinal detachment (RD), the retina is seen as a curvilinear structure with high reflectivity, which may extend to the optic disc posteriorly and the ora serrata anteriorly. The points of attachment distinguish a RD from a choroidal detachment (biconvex echogenicity not extending to the optic disc) and from vitreous membranes.

In papilledema, the optic nerve sheath diameter (ONSD) may increase. ONSD is measured 3 mm behind the globe. In infants up to 1 year of age, 4 mm is the normal upper limit; in older children, 4.5 mm; and in adults, 5.7 mm.[13,14]

Optic disc drusen may cause the optic disc to appear swollen. They tend to calcify and appear as hyperechoic bodies in the anterior part of the optic nerve (Fig. 10.5).[15] Scleral thickening can be seen in patients with mucopolysaccharidoses.

Orbital ultrasound

Anophthalmos means the absence of ocular tissue. Most often, however, a small cyst can be seen on ultrasound. The term

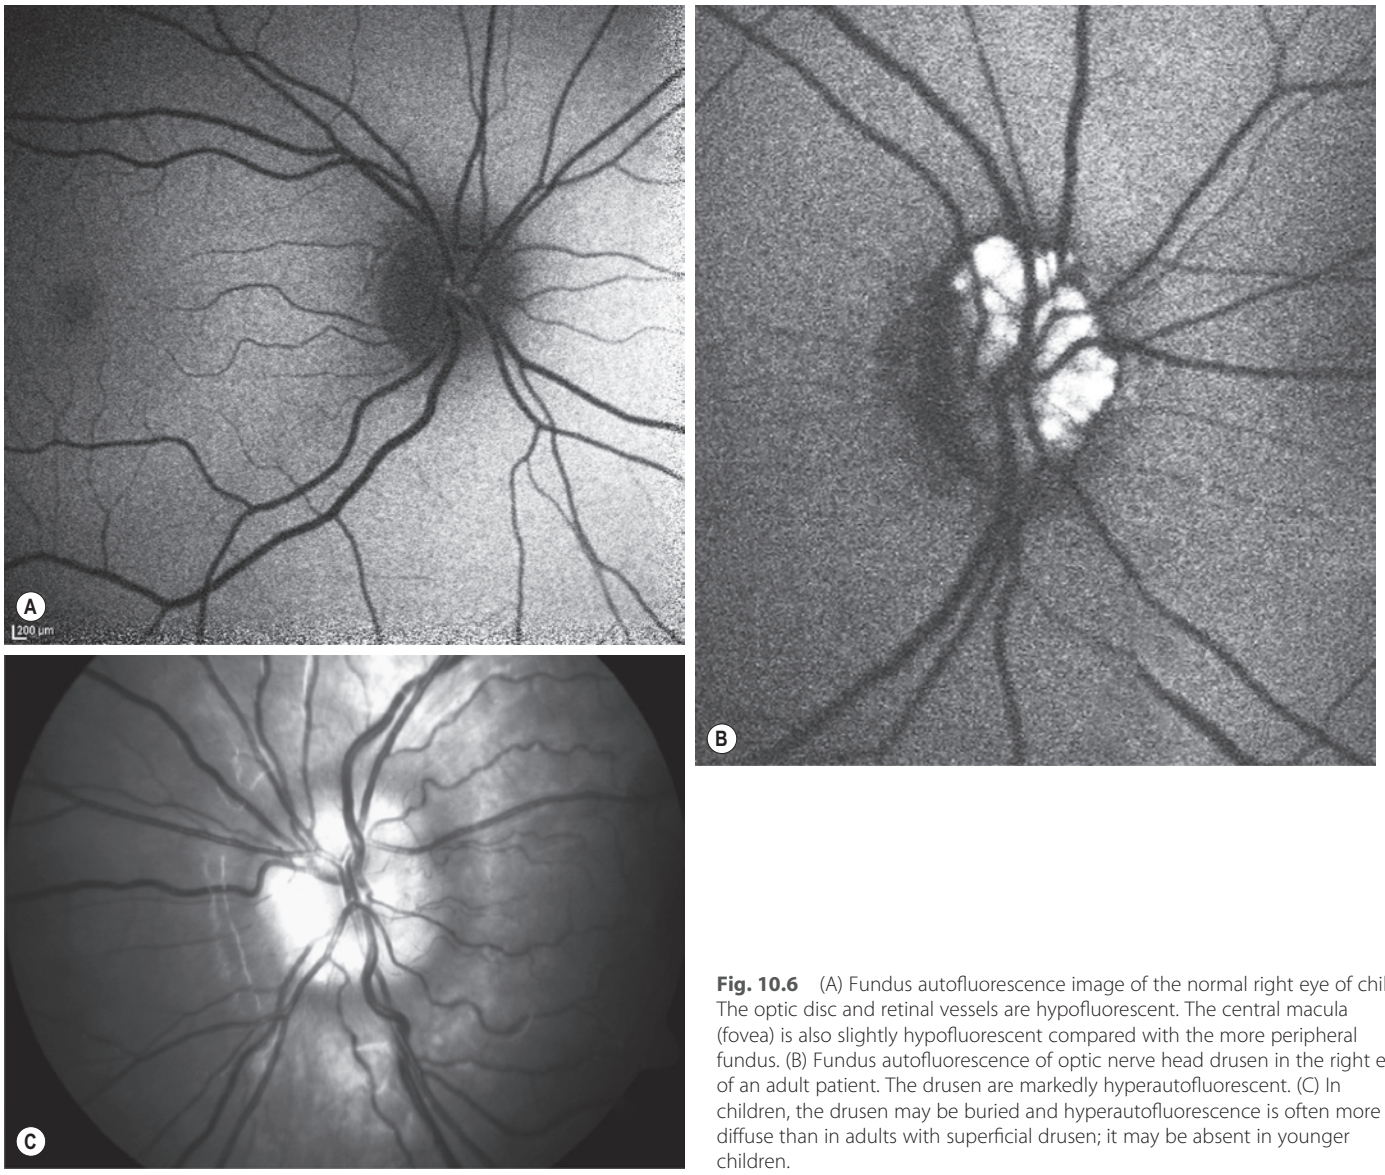

Fig. 10.6 (A) Fundus autofluorescence image of the normal right eye of child. The optic disc and retinal vessels are hypofluorescent. The central macula (fovea) is also slightly hypofluorescent compared with the more peripheral fundus. (B) Fundus autofluorescence of optic nerve head drusen in the right eye of an adult patient. The drusen are markedly hyperautofluorescent. (C) In children, the drusen may be buried and hyperautofluorescence is often more diffuse than in adults with superficial drusen; it may be absent in younger children.

microphthalmos is used when an eye is less than two-thirds of the age-appropriate size and is structurally abnormal. Nanophthalmos describes a small but normally developed eye. Ultrasound helps to make these distinctions. Nanophthalmos or microphthalmos may be present in a number of disorders including CHARGE, Goldenhar syndrome, clefting disorders, and others.[16]

Ultrasound pachymetry

Corneal thickness is increased in corneal edema, for example in congenital hereditary endothelial dystrophy (CHED) or childhood glaucoma. Corneal thickness may have an effect on intraocular pressure measurements, so it is important factor to consider when caring for patients with glaucoma.

Fundus autofluorescence

Normal retinal function depends on photoreceptor and RPE metabolism. RPE cells phagocytose photoreceptor outer segments and break down the ingested material.[17] Some of the breakdown products act as fluorophores: if they are excited by light of a certain wavelength, they emit light of a different wavelength – this is called "fundus autofluorescence" (FAF). Lipofuscin (LF) has been identified as a major source of FAF. A prominent component of LF is *N*-retinyl-*N*-retinylidene ethanolamine (A2E), which is likely toxic to RPE cells. Because LF accumulates in RPE cells, FAF primarily provides information about the state of RPE cells. In Box 10.1, pertinent disorders and their effects on FAF are listed. FAF may identify subtle pathologic findings not visible on funduscopy, for example in retinal dystrophies such as Leber congenital amaurosis and retinitis pigmentosa. In Stargardt disease, a central oval-shaped area of hypoautofluorescence is usually found in children. If pisciform retinal flecks are present, these may be centrally hyperautofluorescent, hyperautofluorescent with surrounding hypoautofluorescence, or hypoautofluorescent.[18,19] FAF is particularly helpful in detecting optic nerve head drusen, which appear as hyperautofluorescent bodies in the optic disc (see Fig. 10.6).

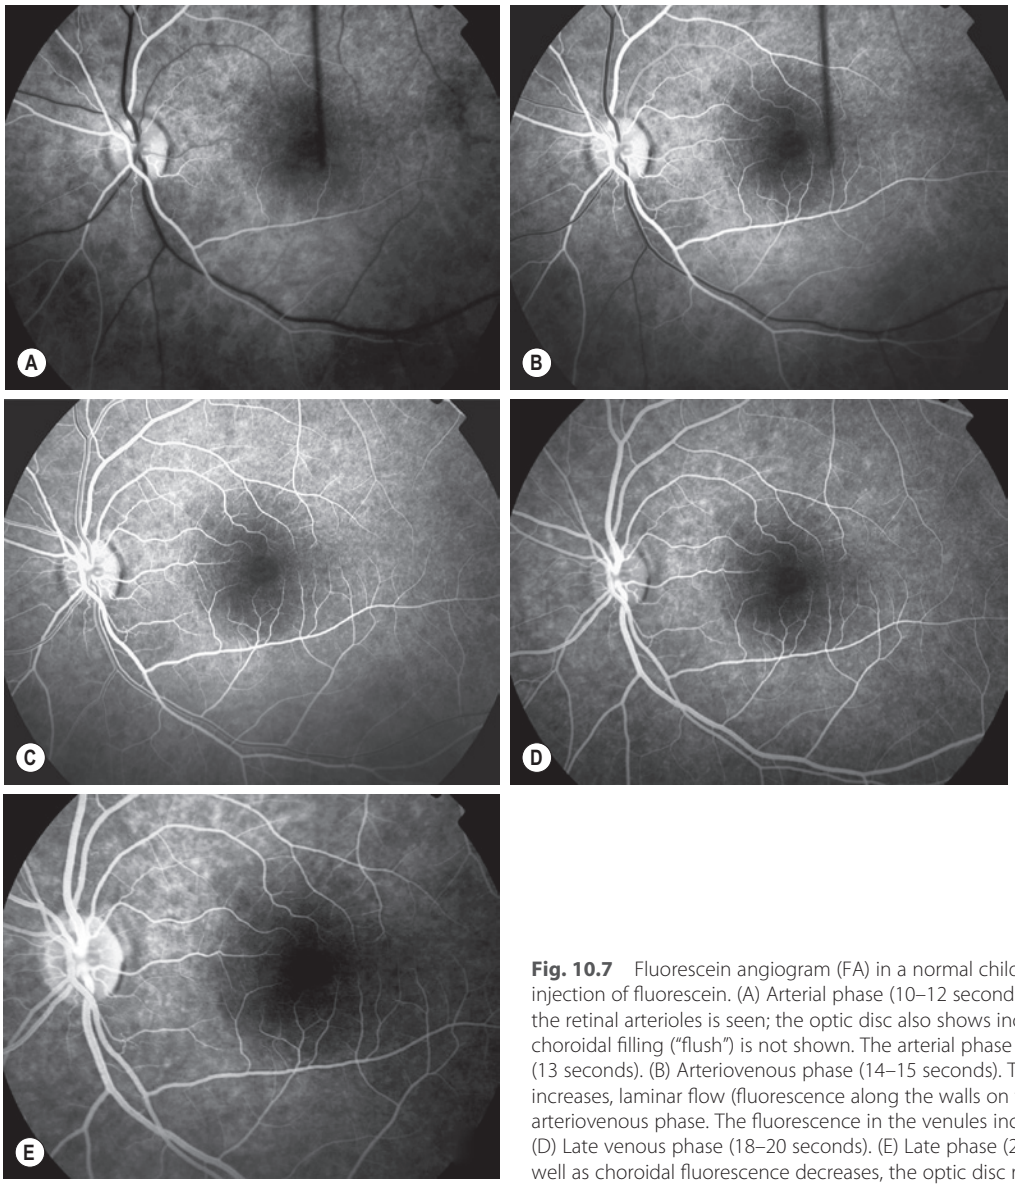

Fig. 10.7 Fluorescein angiogram (FA) in a normal child. Times refer to time point after intravenous injection of fluorescein. (A) Arterial phase (10–12 seconds). Choroidal fluorescence and fluorescence in the retinal arterioles is seen; the optic disc also shows increasing fluorescence. The preceding choroidal filling ("flush") is not shown. The arterial phase is followed by the capillary transition phase (13 seconds). (B) Arteriovenous phase (14–15 seconds). The choroidal and arterial fluorescence increases, laminar flow (fluorescence along the walls on the retinal venules) can be seen. (C) Later arteriovenous phase. The fluorescence in the venules increases, as does the choroidal fluorescence. (D) Late venous phase (18–20 seconds). (E) Late phase (2–5 minutes). Fluorescence in the vessels as well as choroidal fluorescence decreases, the optic disc retains fluorescence (normal staining).

Angiography

To perform angiography, a dye is injected intravenously. Light of a given wavelength (which is passed through a excitation filter) is projected onto the structure of interest (usually the ocular fundus). The light excites the dye, which gives off fluorescence of a different wavelength. The emitted fluorescence is filtered (barrier filter) and detected photographically. In ophthalmology, fluorescein angiography (FA) and indocyanine green angiography (ICG) are used clinically. Angiography is an invasive test with known side effects and risks. Although both FA and ICG are generally well tolerated, nausea and vomiting are observed in 5–10% of patients and allergic as well as anaphylactic reactions (potentially life-threatening) have been reported.

Fluorescein angiography

Fluorescein is a relatively small molecule (molar mass 332.31 g/mol), used to image the retinal circulation. It leaks from the fenestrated choroidal vessels, and is not optimal for angiography of the choroid. Since fluorescein is excreted through the kidneys, the urine will be yellow for several hours after intravenous application. Renal insufficiency or dialysis is not a contraindication to FA.[3] The excitation wavelength illuminating the retina is 465–490 nm (blue light). The barrier filter allows only yellow-green light (usual wavelength of 525 nm) from the fluorescence to reach the camera. After 10–20% fluorescein sodium is injected intravenously, the dye enters the eye through the internal carotid artery via the ophthalmic artery, which supplies the choroid through the short posterior ciliary arteries. The retina is supplied via the central retinal artery. Normal findings are shown in Figure 10.7. Pathological findings are divided into *hyper*fluorescence and *hypo*fluorescence. Causes for hyperfluorescence include (1) transmission or window defects (a layer that normally blocks fluorescence is missing), (2) leakage (e.g. from incompetent blood vessels, aneurysms, neovascularization), (3) pooling (fluorescein gradually fills a fluid-filled space), (4) staining (normally the optic disc and sclera stain;

Box 10.1

Important causes for abnormal fundus autofluorescence (FAF) signal in children and adolescents (modified from Schmitz-Valckenberg et al.[18])

Causes for reduced FAF signal

Absence/reduction in retinal pigment epithelium (RPE) lipofuscin density
Hereditary retinal dystrophies (e.g. *RPE65* mutations)
Increased RPE melanin content (e.g. RPE hypertrophy)
Absorption from extracellular material, cells, or fluid anterior to RPE
Intraretinal fluid (e.g. macular edema*)
Intraretinal and subretinal lipid
Fresh intraretinal and subretinal hemorrhages
Fibrosis, scar tissue, borders of laser scars
Retinal vessels
Angioid streaks
Macular pigment (lutein and zeaxanthin)
Media opacities (vitreous, lens, anterior chamber, cornea)

Causes for increased FAF signal

Excessive RPE lipofuscin accumulation
Lipofuscinopathies including Stargardt disease, Best disease, and adult vitelliform macular dystrophy
Occurrence of fluorophores anterior or posterior to the RPE cell monolayer
Intraretinal fluid (e.g. macular edema*)
Subretinal fluid leading to separation of the outer segments of the photoreceptors from the underlying RPE, which leads to improper outer segment turnover
Macrophages containing lipofuscin in the subretinal space (choroidal tumors such as nevi and melanomas)
Migrated RPE cells or macrophages containing lipofuscin or melanolipofuscin (seen as pigment clumping or hyperpigmentation by funduscopy)
Older intraretinal and subretinal hemorrhages
Choroidal vessel in the presence of RPE and choriocapillaris atrophy (e.g. in the center of laser scars or within patches of RPE atrophy)
Lack of absorbing material
Depletion of luteal pigment (e.g. in idiopathic macular telangiectasia type 2)
Displacement of luteal pigment (e.g. cystoid macular edema)
Optic nerve head drusen
Artifacts

*Some diabetic patients with macular edema can have either increased or decreased autofluorescence.

pathology such as disciform scars or drusen may stain), and (5) abnormal vasculature (e.g. neovascularization). Causes of hypofluorescence include blocking (e.g. blood, retinal or non-vascularized preretinal lesion) and filling defect (e.g. capillary non-perfusion, vascular obstruction).

In clinical practice FA is mainly used to study the ocular fundus. Rarely, iris angiograms are performed for anterior segment ischemia.

Indocyanine angiography

Indocyanine green (ICG, molecular weight 774.96 g/mol) does not leave intact choroidal vessels and is used to image the choroidal circulation. ICG absorbs light between 600–900 nm (peak spectral absorption approximately 800 nm) and emits fluorescence between 750–950 nm. The infrared light used for excitation penetrates the retina well, allowing imaging of deeper layers. Since ICG is excreted via the liver; liver failure is a contraindication to ICG angiography. In practice, ICG angiography is used in age-related macular degeneration (AMD) and other diseases affecting the choroid, such as choroidal tumors, choroidal neovascularization, and other vascular abnormalities.

Optical coherence tomography

Since optical coherence tomography (OCT) was introduced to clinical ophthalmology in 1991,[20] significant advances in technology have increased its resolution and decreased the test time of this noninvasive, non-contact imaging modality. OCT provides high-resolution cross-sectional images of tissues. It uses low-coherence interferometry to determine the time delay of backscattered light reflected by tissue.

Technology

The older time-domain (TD) OCT has an axial resolution of approximately 10 µm, a transverse resolution of 20–25 µm and a scan speed of approximately 400 A-scans per second. TD-OCT uses a moving reference mirror to encode the time information for a given reflection. The process of moving this mirror limits acquisition speed. A detailed review on TD-OCT findings in pediatric ophthalmology is available.[21] TD-OCT has largely been replaced by spectral-domain (SD) OCT, which was first used to image ocular structures in 2002.[22] SD-OCT acquires time delay and reflectivity information simultaneously. It evaluates the frequency spectrum of the interference between the reflected light and a stationary reference mirror,[23] allowing for faster scan acquisition. Current SD-OCT systems acquire 27,000–52,000 A-scans per second, have an axial resolution of 2.5–5 µm and a transverse resolution of 10–15 µm. The development of the human macula has been studied in detail and correlated with histology.[24]

An OCT can usually be obtained in unsedated children aged 4 years and up and sometimes even younger.[25] Reproducibility of the OCT of the RNFL and macula in children is good.[26] Thickness of retinal layers (e.g. RNFL thickness) may not be comparable between TD- and SD-OCT, and different SD-OCT machines may give different results.[27] It is advisable to use the same OCT machine for longitudinal follow-up of a patient.

Artifacts

Several types of image artifacts can affect the accuracy of OCT measurements. Using TD-OCT, one study found artifacts in 43.2% and erroneous retinal thickness measurements in up to 62.2% of all scans.[28] In a study on SD-OCT, 28.2% of macular scans and 19.9% of the RNFL contained artifacts.[29] The most common reason for artifacts is the presence of ocular pathology, especially epiretinal membranes. Because the OCT is an optical method, it depends on clear ocular media. In patients with an opaque cornea or lens, it may be impossible to image the structures posterior to the opacity. Contact lens wear does not seem to affect OCT measurements of the macula and RNFL using TD-OCT,[30,31] but studies

found small effects of contact lens power on RNFL thickness measurement (higher values with stronger minus lenses) using the SD-OCT.[32,33]

Macular analysis

Imaging the macula is one of the most important uses of OCT; it has revolutionized the clinician's ability to detect subtle pathology. Using SD-OCT, retinal sublayers can be discerned (Fig. 10.8).

Retinal thickness in the central 1 mm circle has been reported as 255–274 µm in healthy children irrespective of their gender.[34,35] Central retinal thickness in children also seems to increase with age.[35,36] There are many situations where a macular OCT is helpful, including macular edema (e.g. in children with uveitis or after cataract surgery) and in patients with retinal dystrophies. In children with congenital nystagmus, it may show foveal hypoplasia and help establish the diagnosis of albinism in subtle cases. In X-linked retinoschisis, it can show macular schisis cavities before they are noted with ophthalmoscopy.

Retinal nerve fiber layer

RNFL thickness may be reduced in optic atrophy, optic nerve hypoplasia, or glaucoma. It may be increased in acute optic neuritis, papilledema, and other types of optic neuropathy. Routine RNFL thickness programs offer automatic identification of the RNFL, which is highly reflective (Fig. 10.9). With SD-OCT (Heidelberg Spectralis SD-OCT, Heidelberg Engineering, Heidelberg, Germany), average global RNFL thickness in normal children has been found to be 106–107 µm,[34,35] but may be thinner when measured with different SD-OCT systems (Cirrus, Carl Zeiss Meditec, Dublin, CA).[27] The RNFL is thickest in the superior and inferior quadrants, thinner nasally, and thinnest temporally (Table 10.1). There is considerable inter-individual range in normal subjects, which makes clinical correlation and interpretation of OCT measurements necessary.

Anterior segment

Using anterior segment (AS) OCT, the cornea can be imaged and evaluated, its layers can be differentiated, and their thickness measured (Fig. 10.10). AS-OCT allows for non-contact biometry of the anterior segment and for evaluation of the anterior chamber angle (goniometry), where its findings correlate well with gonioscopy. AS-OCT is particularly helpful in evaluating the anterior chamber angles of children who do not tolerate

Table 10.1 Average retinal nerve fiber layer thickness in normal children (using the Spectralis OCT*) as reported in two studies

Sector	Yanni et al.[35]	Turk et al.[34]
Global	107.6 (1.2)	106.45±9.41 (83.33–141.17)
Temporal	76.5 (1.9)	74.31±9.45 (53–106)
Temporal superior	145.1 (2.2)	138.97±17.58 (104–191)
Temporal inferior	147.0 (2.1)	144.64±17.16 (110–183)
Nasal	84.5 (1.9)	71.54±10.03 (49–102)
Nasal superior	116.2 (2.8)	102.84±15.96 (78–145)
Nasal inferior	125.4 (3.0)	106.4±19.13 (78–162)

*Heidelberg Engineering, Heidelberg, Germany.
Values are in micrometers; for Yanni et al., mean (±standard error of the mean) is given; for Turk et al., mean (±standard deviation [range]) is given.

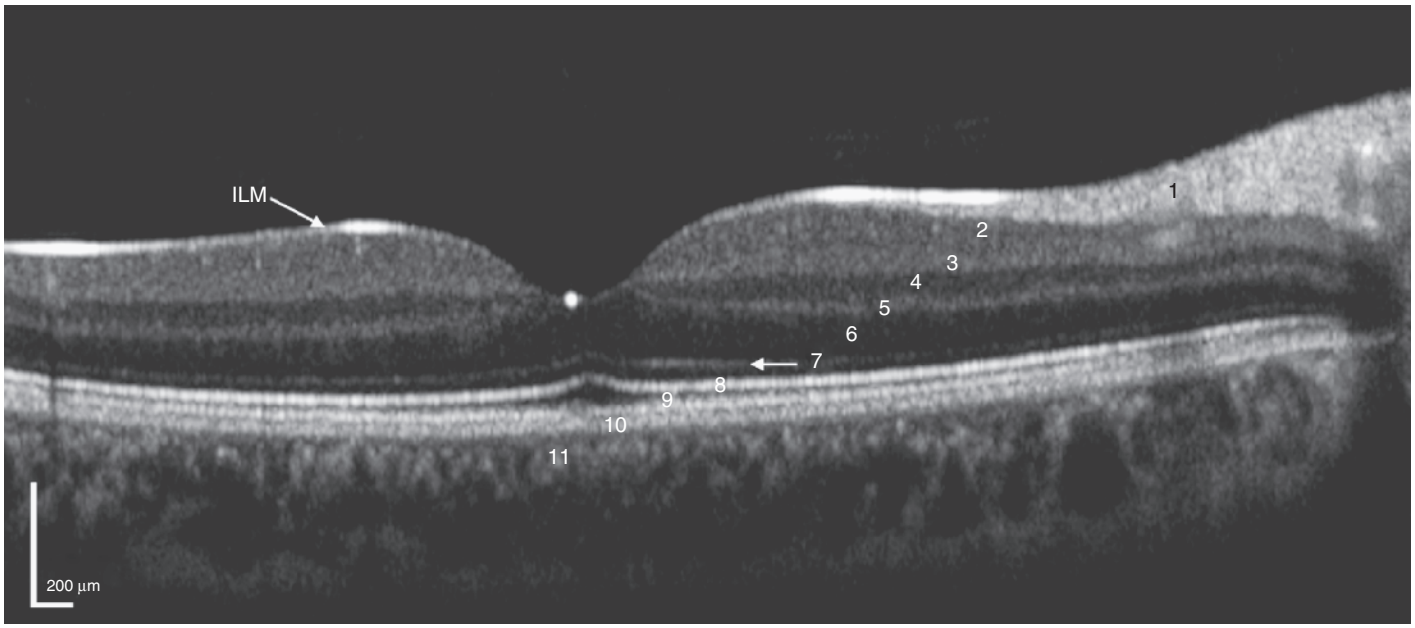

Fig. 10.8 Spectral-domain optical cohere tomography (SD-OCT) line scan through the macula of a 15-year-old boy. The optic nerve is on the right of the picture, where the retinal pigment epithelium (RPE) ends and the retinal nerve fiber layer is thickest. Retinal layers can be distinguished: ILM, internal limiting membrane; 1, retinal nerve fiber layer (high reflectivity); 2, ganglion cell layer (low reflectivity); 3, inner plexiform layer (medium reflectivity); 4, inner nuclear layer (low reflectivity); 5, outer plexiform layer and photoreceptor synapses (high reflectivity); 6, outer nuclear layer (low reflectivity); 7, external limiting membrane (thin band of higher reflectivity); 8, photoreceptor inner segment ellipsoids (high reflectivity); 9, photoreceptor outer segments (low reflectivity); 10, retinal pigment epithelium, consisting of two highly reflective bands; 11, choroid (heterogeneous reflectivity).

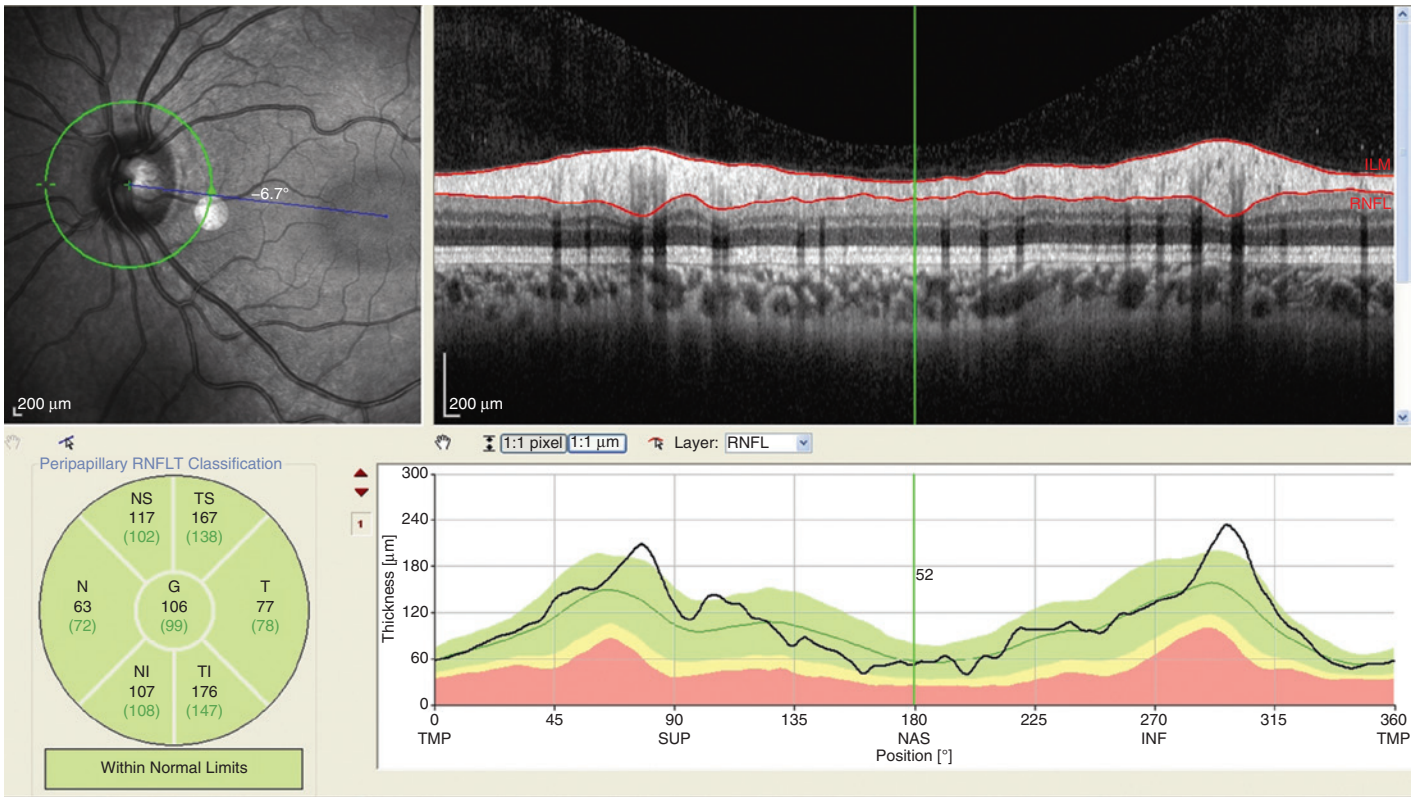

Fig. 10.9 Retinal nerve fiber layer (RNFL) thickness analysis using spectral-domain optical coherence tomography (Spectralis OCT, Heidelberg Engineering, Heidelberg, Germany). In the upper left corner, location of the circular scan around the optic disc is shown. Below in the lower left, global RNFL thickness (central field) and RNFL thickness in different sector is given. A color scheme indicates whether or not the values fall into the normal range of the database of the OCT machine. In the upper right, the circular scan is shown and the RNFL segmentation is outlined in red. In the lower right, RNFL thickness is plotted against the normative database. Green indicates that the value measured has a probability greater than 5% of falling within the normal range; yellow indicates a probability of less than 5% of being normal; red that the probability is less than 1%.

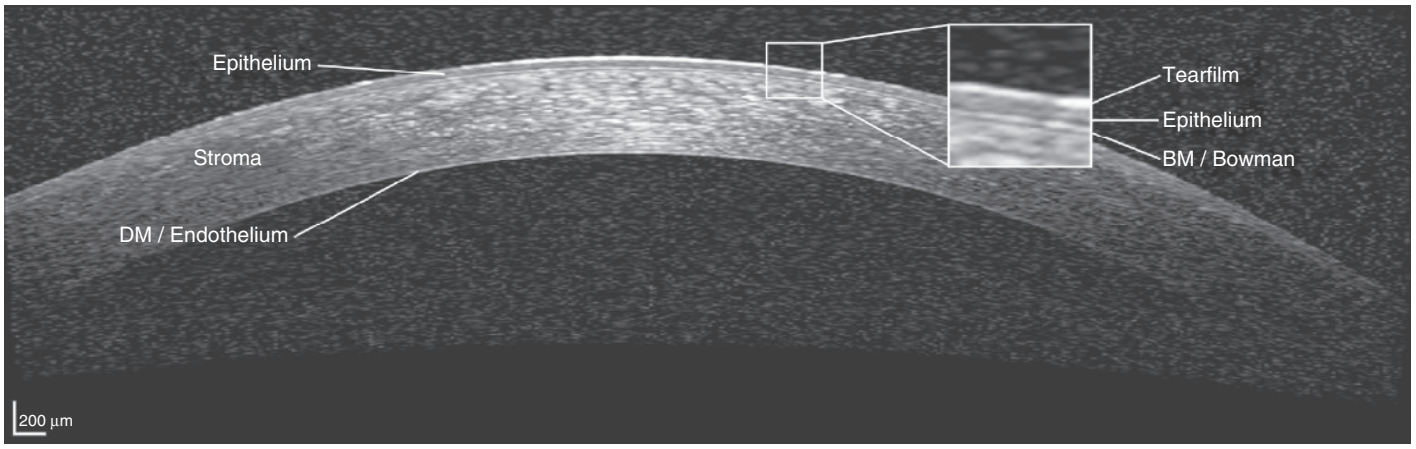

Fig. 10.10 Anterior segment optical coherence tomography of a normal cornea. The interface between air and corneal epithelium/tear film is highly reflective and appears bright. The corneal stroma has less homogenous reflectivity then the epithelium, because of its composition (cells, collagen fibers, extracellular matrix). The Descemet membrane (DM)–endothelium complex is more reflective than the stroma and generates a brighter band; the anterior chamber has practically no reflectivity. Inset, details of the anterior corneal layers can be appreciated (BM, basement membrane of the corneal epithelium; Bowman, Bowman's membrane).

gonioscopy.[37] Sensitivity and specificity of AS-OCT in detecting an occludable angle – identifying patients at risk for angle closure glaucoma – is high.[38] Iris configuration can be assessed, but pigmentation of the angle cannot be evaluated. Important anterior chamber angle parameters include (normal adult values in parentheses): anterior chamber angle (ACA nasal 44.9±9.1°, temporal 47.1±8.7°) and anterior chamber opening distance measured 500µm (AOD500) and 750µm (AOD750) from the scleral spur (AOD500 nasal 0.52±0.18 mm, temporal 0.53±0.15 mm; AOD750 nasal 0.71±0.26 mm, temporal 0.71±0.23 mm),[39] see Figure 10.11. Anterior chamber depth and iris thickness can also be measured.

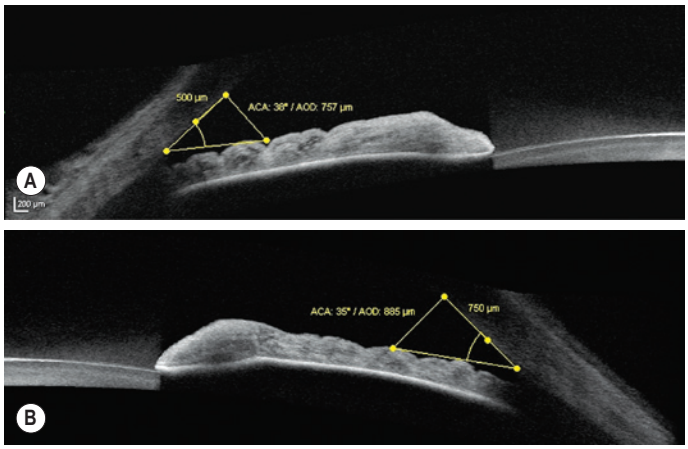

Fig. 10.11 Spectral-domain optical coherence tomography (SD-OCT) imaging of the normal anterior chamber angle, iris, and anterior lens surface. (A) Temporal angle; (B) nasal angle. Anterior chamber angle parameters can be measured, including anterior chamber angle (ACA), anterior chamber opening distance measured 500 µm central to the scleral spur (AOD 500, yellow overlay, upper part) and 750 µm central to the scleral spur (AOD 750, lower part). For these parameters, the distance between the posterior surface of the cornea and the anterior surface of the iris is measured at a right angle to the posterior corneal surface.

Extraocular muscle insertions can be identified and measured using OCT.[40] Although there is considerable variation between individuals, it may become a valuable tool in clinical ophthalmology (e.g. when evaluating a patient for a slipped muscle after strabismus surgery or for myositis).[41] In children, AS-OCT has been used for the following: to image the cornea of patients with Peters anomaly, after penetrating keratoplasty, to visualize tube placement after glaucoma drainage device implantation, to demonstrate closure of the anterior chamber angle, and in other clinical scenarios.[42] Grading inflammation in patients with uveitis is an interesting application and good correlation between clinical anterior chamber cells and OCT findings (bright spots in the normally dark anterior chamber) have been reported.[43,44]

OCT Angiography

Recently, OCT has been used to image retinal and superficial choroidal blood vessels. In contrast to conventional FA and ICG angiography, no dye is required. OCT angiography detects blood flow by using decorrelation of the signals of sequential OCT b-scans. In other words, several OCT scans taken at the same location are compared and the differences registered. Since intravascular blood cells (mainly erythrocytes but also leukocytes) are usually the only moving objects at the ocular fundus (provided the patient fixates steadily), blood flow can thus be registered. OCT angiography can detect blood flow only above a certain minimum threshold, because it relies on change between consecutive b-scans. This slowest detectable velocity is determined by the time lapse between two scans. Increasing this time may increase the sensitivity to detect slow blood flow but also increases motion artifacts.[45]

Most OCT angiography units have preset algorithms to facilitate identification of the retinal vessels. However, the examiner can manually choose the level and thickness of the plane to be examined, depending on the pathology (Fig. 10.12).

OCT angiography affords a higher resolution than FA and ICG angiography (it can image retinal capillaries), but it does not show extravascular blood (in contrast to FA, which can show leakage and staining). Furthermore, OCT angiography lacks the dynamic information which FA and ICG angiography can provide (such as arterio-venous transit time or delayed filling) and does not give information about the characteristics of blood flow in retinal and choroidal vessels.

Nevertheless, it has been shown to add valuable information in disorders such as age-related macular degeneration, choroidal neovascularization, and retinal vascular occlusion.[45] OCT angiography may prove helpful in evaluating children with disorders such as ROP, familial exudative vitreoretinopathy (FEVR), and Coats disease.

Scanning laser ophthalmoscopy

The SLO is a non-contact, noninvasive modality. It uses monochromatic, low-energy laser light for illumination and a confocal scanning laser microscopy technique to image the ocular fundus or cornea. Lasers with different wavelengths (and different tissue penetration) may be combined – the resulting image is a pseudo-color image of the fundus. SLO allows for FA and ICG angiography.

Infrared imaging is helpful when studying subretinal pathology such as drusen or deposits using the SLO. Infrared light penetrates optical media opacities (e.g. cataract, vitreous hemorrhage) better than shorter wavelengths (Fig. 10.13). Infrared reflectance may image epiretinal membranes and cystoid macular edema better than other photographic techniques. Retinal crystals (e.g. in Bietti crystalline retinopathy, metabolic and toxic crystalline retinopathy) are seen as bright dots throughout the fundus.

SLO is also used to image the optic disc (Fig. 10.12). The SLO does not distinguish different retinal layers and does not measure RNFL thickness directly. By longitudinally comparing the images of the same optic disc, changes in its contour and loss of neuroretinal rim can be detected. Normal optic disc values in children have been reported (Table 10.2).[46] Some SLO machines offer real-time eye tracking, so that different images can be superimposed and averaged, improving measurement accuracy. In the case of SLO-based FA, this results in the need for less intravenous dye.

SLO technology can be used to obtain wide-field (up to 200 degrees) fundus pictures. For example, the current Optos camera (Optos plc, Dunfermline, UK) utilizes an ellipsoid mirror eliminating the need for bright illumination lighting or a contact lens. Two lasers (red, 635 nm and green, 523 nm) scan the fundus in 0.4 seconds and these scans may be combined to generate a composite color fundus image with a resolution of up to 14 µm (Fig. 10.14). Red-free and fundus autofluorescence imaging, as well as fluorescein and indocyanine angiography are possible (for angiography, additional laser wavelengths are required). Mydriasis facilitates imaging but is not necessary.

In adaptive optics SLO (AOSLO), the SLO is used in conjunction with adaptive optics to remove optical aberrations from the images. This technique allows for the visualization of individual retinal cells *in vivo*.

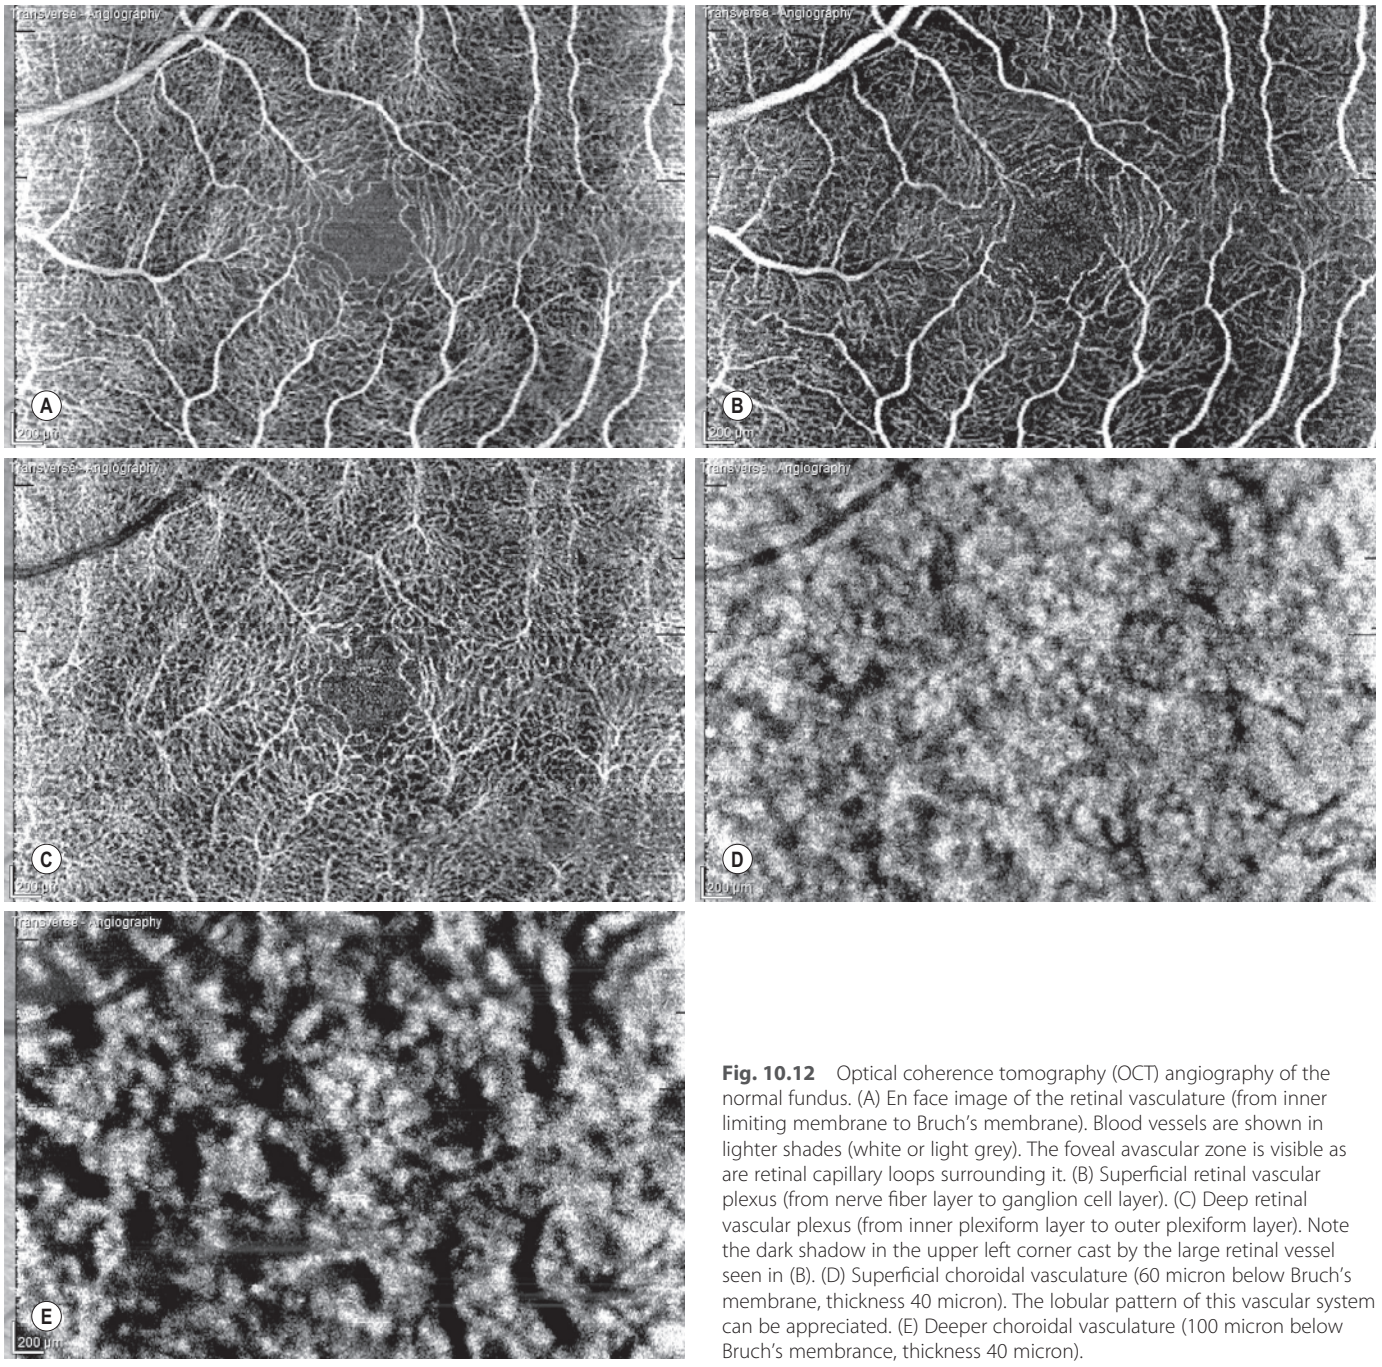

Fig. 10.12 Optical coherence tomography (OCT) angiography of the normal fundus. (A) En face image of the retinal vasculature (from inner limiting membrane to Bruch's membrane). Blood vessels are shown in lighter shades (white or light grey). The foveal avascular zone is visible as are retinal capillary loops surrounding it. (B) Superficial retinal vascular plexus (from nerve fiber layer to ganglion cell layer). (C) Deep retinal vascular plexus (from inner plexiform layer to outer plexiform layer). Note the dark shadow in the upper left corner cast by the large retinal vessel seen in (B). (D) Superficial choroidal vasculature (60 micron below Bruch's membrane, thickness 40 micron). The lobular pattern of this vascular system can be appreciated. (E) Deeper choroidal vasculature (100 micron below Bruch's membrance, thickness 40 micron).

Radiology imaging in pediatric ophthalmology

The following radiology imaging modalities can be used for the evaluation of orbital contents, the intracranial optic pathway, and the visual cortex in children: CT, conventional MRI, advanced MRI techniques such as fetal MRI, diffusion tensor imaging, and functional MRI. There is essentially no diagnostic role for plain film imaging of the orbit currently, because of superior sensitivity and specificity of cross-sectional imaging modalities.[1]

Computed tomography

Many pediatric specialists avoid CT imaging in children due to radiation exposure concerns. Generally, children are at higher risk for radiation-induced morbidities due to higher mitotic rates in growing tissues and a longer lifespan to experience these morbidities. However, the risk is strongly dependent on the imaging technique used by the local radiology practice, the frequency of radiation exposure, and the imaged body part. For example, radiology practices should have dedicated pediatric CT protocols and use radiation-reduction techniques, such as iterative reconstruction algorithms. Patients undergoing

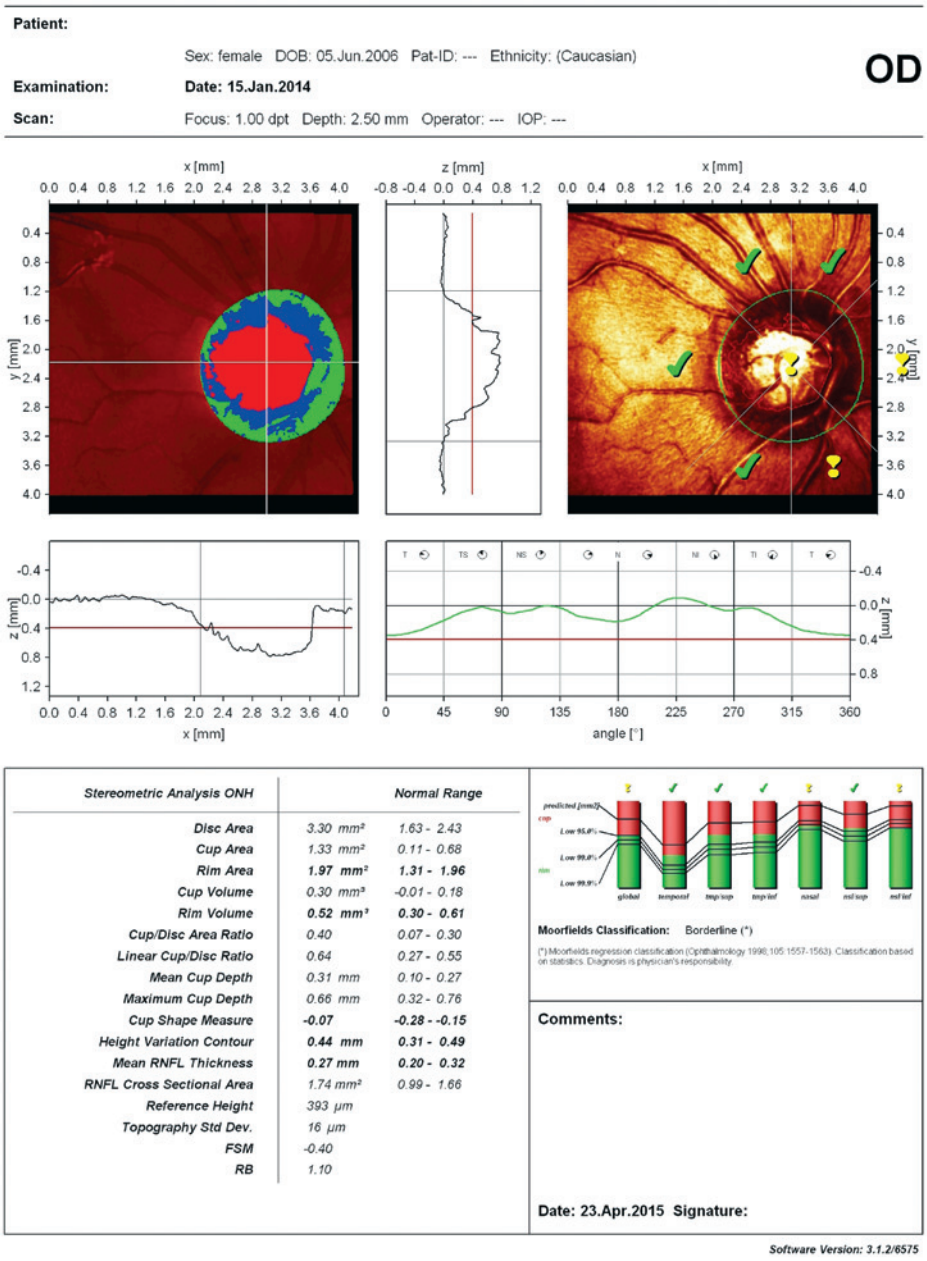

Fig. 10.13 Scanning laser ophthalmoscopy analysis of the optic disc with Heidelberg Retina Tomography.* The upper section contains demographic patient data. Below left, a false color image of the optic disc topography is shown. Green areas represent "stable" neural rim, blue sloping of the neuroretinal rim, red the optic disc cup. Next to it is the vertical height profile (white line in the topography image on the left). On the right, a false color reflection image is shown, the brighter the color, the more light is reflected. Six disc sectors are compared with the normative database and classified using the Moorfields regression analysis. According to the patient's age and optic disc size, findings are classified as "within normal limits" (green check marks), "borderline" (yellow exclamation marks), and "outside normal limits" (red crosses – not shown). The horizontal height profile along the white line in the topography image is shown in the section below on the left. Next to it, the "mean height contour graph" shows the retinal surface height along the drawn green contour line. The lower red line represents the reference line separating the neuroretinal rim and the optic cup, defined as a plane 50 µm below the papillomacular bundle (in the temporal sector between 350° and 356°). The black line represents the mean peripapillary retinal surface height, which serves as the zero point of the height (*z*-axis). The height profile starts temporally at 0° and proceeds clockwise for right eyes and counterclockwise for left eyes. The difference between the height profile line and the reference line corresponds to the retinal nerve fiber layer thickness along the contour line. In the box at the bottom, optic disc parameters are provided, values outside the normal range for the reference database are highlighted in bold. *Cup shape measure* describes the three-dimensional shape of the optic cup, determined as the distribution frequency of depth values within the optic cup. More positive values indicate a more abnormal (glaucomatous) cup shape. *Height variation contour* represents the difference between most elevated and most depressed point along the contour line. It is decreased in diffuse nerve fiber loss and increased if a localized nerve fiber layer defect is present. *Mean RNFL Thickness* is measured along the contour line relative to a reference plane and not directly, which applies also to *RNFL cross sectional area*. A parameter for image quality is *topography std dev*. in micrometer, values <10 are considered excellent; 10–20, very good; 20–30, good; 30–40, acceptable; 40–50 indicates that the study needs improvement; >50 low quality (scan should not be used). *FSM* (discriminant function) is a linear combination of three parameters (cup shape measure, rim volume, and contour line height variation). Positive values are normal, negative values classify the disc as glaucomatous. *RB* (discriminant function) is a linear function, which has a high specificity but poor sensitivity for the detection of early glaucoma; values less than zero suggest glaucomatous damage. **Heidelberg Engineering, Heidelberg, Germany – according to information provided on the manufacturer's website at heidelbergengnieering.com, accessed May 2015.*

Table 10.2 Average optic disc parameters measured with the Heidelberg Retina Tomography (HRT)* in normal children 5–16 years old[46]

Parameter	Mean (standard deviation)	Range
Disc area (mm^2)	2.16 (0.47)	1.15–3.09
Cup area (mm^2)	0.41 (0.33)	0.00–1.37
Rim area (mm^2)	1.75 (0.39)	0.92–2.59
Cup/disc area ratio	0.18 (0.12)	0.00–0.49
Rim/disc area ratio	0.82 (0.12)	0.51–1.00
Cup volume (mm^3)	0.09 (0.12)	0.00–0.58
Rim volume (mm^3)	0.41 (0.17)	0.12–1.01
Mean cup depth (mm)	0.16 (0.08)	0.04–0.41
Maximum cup depth (mm)	0.49 (0.21)	0.10–0.88
Height variation (mm)	0.32 (0.09)	0.17–0.56
Cup shape measure (mm)	–0.24 (0.08)	–0.43 to 0
Mean RNFL thickness (mm)	0.21 (0.05)	0.13–0.34

*Heidelberg Engineering, Heidelberg, Germany.
RNFL, Retinal nerve fiber layer.
"Cup shape measure" describes the overall three-dimensional shape of the optic cup, determined as the distribution frequency of depths values within optic cup. More positive values indicate a more abnormal (glaucomatous) cup shape.

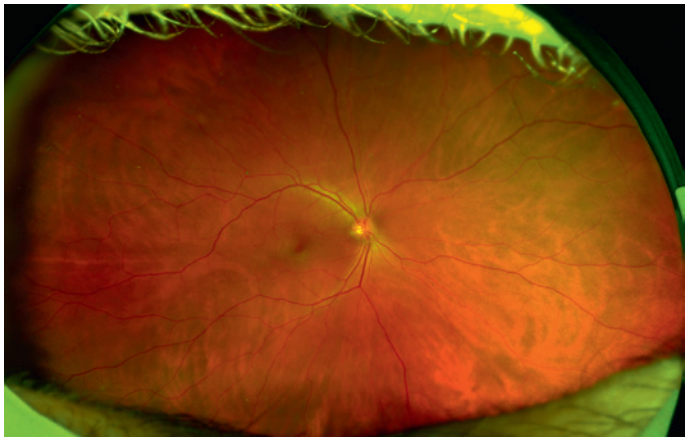

Fig. 10.14 Wide-field imaging of the normal ocular fundus obtained with Optos Daytona scanning laser ophthalmoscope through the undilated pupil (Optos plc, Dunfermline, UK). Composite color image of the green and red laser images is shown.

repeat CT imaging, such as children with chronic diseases, are at higher risk than a patient who undergoes a single CT study in a lifetime. Radiation exposure of the orbit can affect the highly radiosensitive lens, leading to cataracts (based on atomic bomb survivor studies after single brief exposure).[2] Physicians need to weigh risks against benefits when ordering CT orbit and brain studies in children. Benefits of CT imaging in general include the ubiquitous availability, fast access, and fast image acquisition obviating the need for sedation most of the time.

Non-contrast CT is useful in the evaluation of orbital trauma and associated complications and is sufficient in the evaluation of thyroid ophthalmopathy. Dermoid cysts can be evaluated with non-contrast CT. Contrast-enhanced CT is the imaging modality of choice for orbital infections. CT imaging is of little use in the evaluation of the intracranial visual pathway.

Conventional magnetic resonance imaging

Many pediatric specialists prefer MRI over CT to avoid radiation exposure in children. Disadvantages of MRI are limited availability, delayed access, and long study acquisition times requiring sedation in most children under the age of 8 years.

MR imaging is the modality of choice for evaluation of the intracranial visual pathway and the visual cortex. It is also superior to CT in the evaluation of orbital masses. Frequently, MRI of the orbits is performed in conjunction with MRI of the brain, for example in multiple sclerosis or orbital masses. A state-of-the-art MRI study of the orbits should be performed pre- and postcontrast, and should include both orbits in axial and coronal planes, the cavernous sinus, and the brainstem to the level of cranial nerve VI nuclei. Dedicated oblique imaging along the long axis of the intraorbital optic nerve may be acquired for specific clinical questions. Standard whole brain MRI images should include diffusion-weighted imaging (DWI), fluid-attenuated inversion recovery (FLAIR), T2, and pre- and postocontrast T1 images. Generally, non-contrast MRI is sufficient for detection of structural abnormalities or post-traumatic changes, while if there is a concern for infection, inflammatory disease, or neoplastic processes the scan should be performed with the use of intravenous contrast. The use of MRI may be limited in patients who cannot be safely screened, such as patients with certain pacemakers or other metallic implants. The safe use of MRI contrast (Gadolinium) depends on kidney function and other safety considerations, such as pregnancy and lactation status. National screening and safety guidelines should be applied when using these techniques.

Advanced magnetic resonance imaging

Fetal MRI structural assessment of the orbit is an integral part of the fetal imaging evaluation. The assessment includes identification of the lenses and the vitreous, shape of the globe, and various biometrics, such as binocular diameter, interocular distance, ocular diameter, lens diameter, and anteroposterior diameter. These assessments may help in identifying hypo- and hypertelorism, anophthalmia, and coloboma, which can aid in the diagnosis of various genetic disorders.[47]

Diffusion tensor imaging (DTI) infers directions of axonal tracts based on directional diffusion properties of water in the brain. This technique has been used to identify the location of the intracranial optic nerves in children with suprasellar masses and may be helpful in making decisions regarding surgical approach.[48] In children with optic pathway gliomas (OPG), DTI can provide additional information about the integrity of the entire optic pathway and may in the future help differentiate indolent from progressive OPG.[49]

Functional blood-oxygen level dependent (BOLD) MRI is used to detect cortical responses to visual stimuli based on local changes in cortical perfusion that cause differences in the ratio of oxygenated to deoxygenated blood. This technique

has been used in so-called retinotopic mapping,[6] where visual stimuli are presented to different portions of the visual field, generating a map of the visual field on the visual cortex using BOLD-fMRI.

Functional connectivity imaging is fMRI in the absence of external stimuli and can be used to detect resting state activities of the brain and brainstem. This requires advanced MR imaging capability, as well as advanced image postprocessing. The technique explores temporal relationships by selecting specific anatomical regions and searching for distant regions that show activation or deactivation at the exact same point in time, implying the two anatomical regions are related through excitation or depression of stimuli. Recently, the technique has been applied to brainstem nuclei,[50] which could yield future useful insights into eye movement disorders.

Cross-sectional imaging of the orbit

Trauma Non-contrast CT is considered the gold standard in the evaluation of orbital trauma and is superior to MRI in the depiction of fractures and orbital foreign bodies. In fact, the possible presence of metallic foreign bodies in the orbit is considered a contraindication to MRI because when exposed to the magnetic field they could damage adjacent structures through movement and/or heating (Fig. 10.15). CT and MRI can both be used to evaluate traumatic muscle and fat herniations, muscle deformities, hematomas, and orbital fat edema/hematoma (Fig. 10.16). However, optic nerve injury is not well seen on CT and is better evaluated with ophthalmology exam or MRI (Fig. 10.17).

Infection Contrast-enhanced CT is the imaging modality of choice for any infectious process, most commonly used to detect paranasal sinusitis with orbital involvement (Fig. 10.18) and to assess for postseptal involvement in children with orbital cellulitis. MRI of the orbits and brain is preferred in patients with intracranial involvement, such as empyema (Fig. 10.19), encephalitis, and venous sinus thrombosis.

Inflammatory conditions Pediatric *optic neuritis* is frequently immune-mediated in the setting of viral or other infections or after immunizations. However, a small percentage of children may have multiple sclerosis, neuromyelitis optica (NMO), or chronic relapsing inflammatory optic neuropathy (CRION). The imaging work-up should include contrast-enhanced MRI of the orbits and brain to exclude any compressive lesions. The MRI appearance of acute optic neuritis is characterized by increased T2 signal, swelling, and contrast enhancement of the

Fig. 10.15 Axial non-contrast orbit computed tomography. A 13-year-old boy with BB projectile (arrow) within the left vitreous. This represents a contraindication to a magnetic resonance imaging study because the BB could move when exposed to a magnetic field and cause additional injuries.

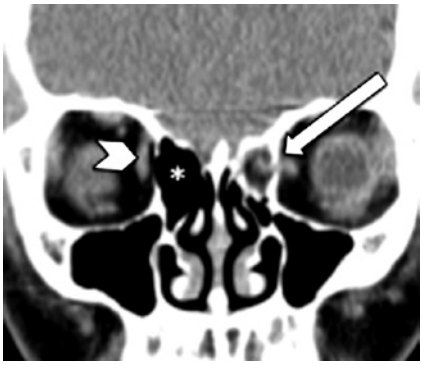

Fig. 10.16 Coronal reformats, axial non-contrast orbit computed tomography. An 8-year-old girl with left lamina papyracea fracture (arrow). Note the entrapment of the left medial rectus muscle and herniation of fat into the left ethmoid air cells when compared to the normal right medial rectus muscle (arrowhead) and normal air within the right ethmoid cells (asterisk).

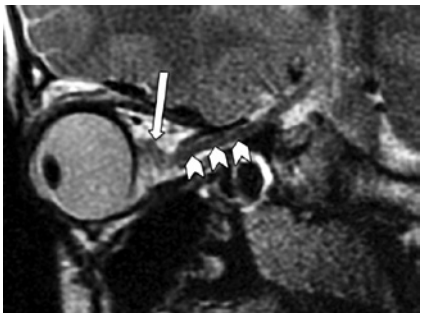

Fig. 10.17 Oblique sagittal T2 magnetic resonance imaging through the left optic nerve. A 16-year-old girl with orbit trauma caused by a motor vehicle collision. The image shows increased T2 signal and abnormal tortuosity of the proximal optic nerve (long arrow), compatible with contusion or rupture. Note normal optic nerve at the apex and within the optic canal (arrowheads).

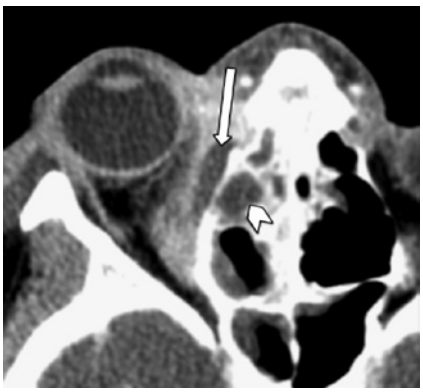

Fig. 10.18 Axial postcontrast orbit computed tomography. A 9-year-old girl with ethmoid sinusitis and orbital involvement. There is a peripherally enhancing subperiostial collection over the right lamina papyracea (arrow), compatible with subperiostial abscess. This collection caused mass effect on the orbit that resulted in proptosis and pain. There is peripherally enhancing fluid in an adjacent ethmoid air cell, compatible with sinusitis (arrowhead).

Fig. 10.19 Axial postcontrast orbit computed tomography (CT). An 8-year-old boy with frontal sinusitis and intracranial involvement. Clinically, the patient has sinusitis and headaches. There is complete opacification of the frontal sinuses (only partially shown, arrowhead). There are multiple extra-axial fluid collections over the left frontal and temporal lobes (arrows), compatible with empyema. Magnetic resonance (MR) imaging is usually required preoperatively and also can depict associated encephalitis better than CT. Both CT and MR venogram can help in detection of associated venous sinus thrombosis.

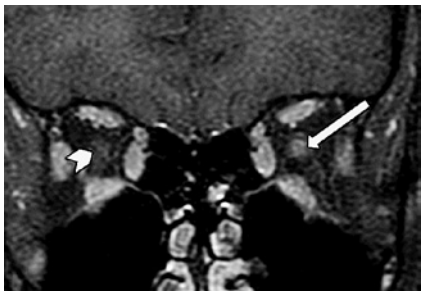

Fig. 10.20 Coronal postcontrast T1 magnetic resonance imaging (with fat suppression) through the optic nerves. An 8-year-old girl with a first episode of left optic neuritis. There is increased size and contrast enhancement of the left optic nerve (arrow) compared to the normal right optic nerve (arrowhead), consistent with optic neuritis.

affected optic nerve (Fig. 10.20). Chronic optic neuritis usually results in T2 bright signal and volume loss of the affected optic nerve; contrast enhancement may not be seen outside the acute flare. Detection of concomitant white matter lesions with brain MRI is associated with a higher risk of developing multiple sclerosis.

Thyroid orbitopathy results in edema of the extraocular muscles as well as the orbital fat. The increased volume of orbital contents causes proptosis and also inhibits venous drainage, which can result in eyelid swelling. In children, non-contrast MRI should be the imaging study of choice. Other inflammatory conditions of the orbit have been lumped under the term *orbital inflammatory disease* (OID) and comprise dacryoadenitis, myositis, cellulitis, optic perineuritis, periscleritis, orbital apicitis, and a focal inflammatory mass.[51] Rarely, OID may be diffuse. Imaging in OID is indicated to exclude other pathology, such as malignancies, infections, and post-traumatic changes. The best imaging modality for OID is contrast-enhanced orbital MRI due to its higher sensitivity in detection of inflammatory changes compared to CT. In the setting of orbital apicitis, the cavernous sinus should be included in the MRI to detect involvement (Tolosa–Hunt syndrome).

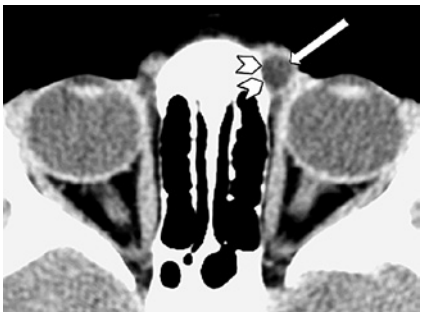

Fig. 10.21 Axial noncontrast orbit computed tomography. A 2-year-old girl with a firm, non-tender and non-discolored mass of the left medial canthus. There is a well-defined cystic lesion (arrow) with flattening of the underlying bone (arrowheads), consistent with a dermoid cyst. Bone flattening usually indicates slow growth and/or longstanding pressure.

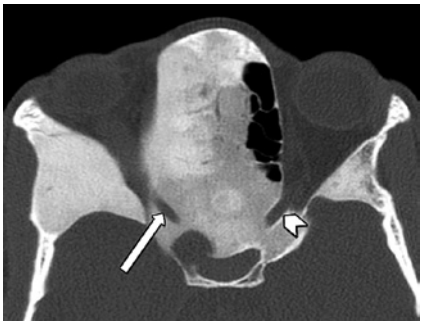

Fig. 10.22 Axial noncontrast orbit computed tomography. A 12-year-old boy with fibrous dysplasia with deterioration of right-sided visual acuity. The patient has groundglass thickening of bilateral temporal, ethmoid, and sphenoid bones, right worse than left. Note the narrowing of the right optic canal (arrow) compared to the less involved left optic canal (arrowhead).

Congenital lesions Non-contrast CT or MRI is usually sufficient to evaluate *dermoid and epidermoid cysts*, which are typically low-density lesions with a thin cyst wall, often related to bony sutures. They may cause some bone remodeling (Fig. 10.21) or may extend into the bone. A variety of *vascular lesions* may be found in the orbits and are best evaluated with contrast enhanced MRI: hemangiomas are typically well-defined, lobulated masses with bright T2 signal, vascular flow voids, and strong homogeneous contrast enhancement; venous malformations are characterized by non-enhancing cysts and presence of phleboliths; lymphatic malformations are macro- or microcystic, with fluid-fluid levels, cyst wall enhancement, and without calcifications. Evaluation of *fibrous dysplasia* is probably best accomplished with CT imaging to better assess mass effect on optic canal and superior orbital fissure (Fig. 10.22). Orbitotemporal plexiform neurofibromas may well be evaluated with contrast enhanced orbital MRI alone. The benefit of MRI evaluation of orbitotemporal plexiform neurofibromas is to better determine worsening over time in patients without significant vision loss and to assess the involved anatomical spaces prior to debulking surgery in patients with vision loss, which is usually caused by ptosis and/or anisometropia.[52]

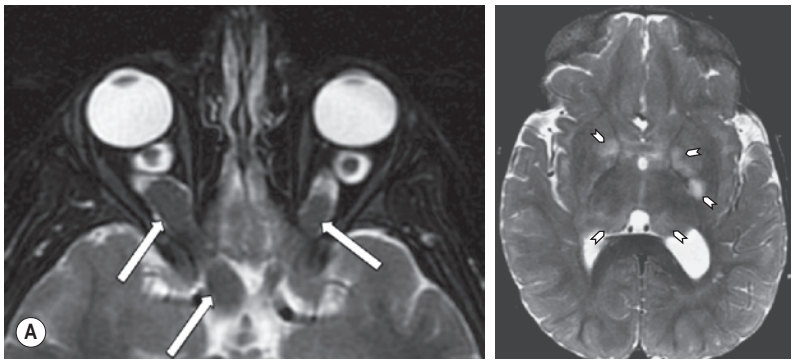

Fig. 10.23 (A) Axial T2 magnetic resonance imaging (MRI) (with fat suppression) through the optic nerves. (B) Axial T2 MRI (with fat suppression) of the brain. A 12-year-old girl with neurofibromatosis type I. (A) Bilateral soft tissue masses of the optic nerves, right larger than left (arrows), compatible with bilateral optic nerve glioma. (B) Numerous T2 bright lesions of the basal ganglia and thalami (arrowheads), consistent with neurofibromatosis type I.

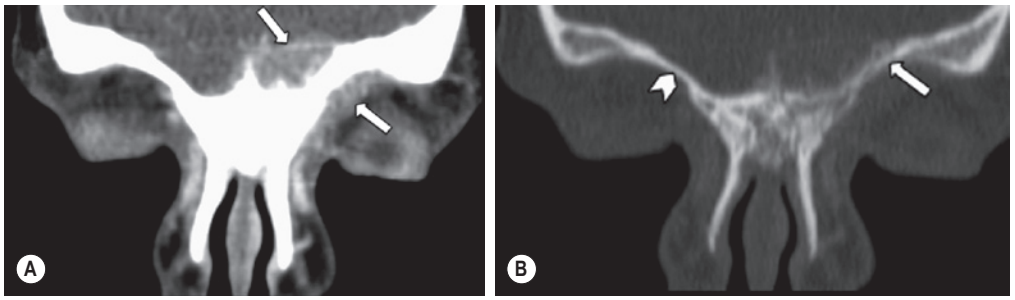

Fig. 10.24 Coronal reformats, axial noncontrast orbit computed tomography: (A) soft tissue window, (B) bone window. A 2-year-old girl with orbital ecchymoses, for evaluation of fracture or infectious process. (A) Soft tissue mass of the anterior skull base, extending both intracranially and into the orbit (arrows). (B) Note the spiculated appearance of the left orbital roof (arrow) when compared to the normal right side (arrowhead).

Cross-sectional imaging of orbit and brain

Orbital tumors Most orbital tumors should be evaluated with MRI and should include both imaging of the orbit and the brain, pre- and postcontrast. In patients with *optic glioma*, MRI is best suited to differentiate masses of the optic nerve from optic nerve sheath tumors, to evaluate for intracranial extension, and to assess for other brain pathology, such as T2 bright lesions that could indicate neurofibromatosis type 1, which can significantly affect prognosis and treatment (Fig. 10.23). In *retinoblastoma*, inclusion of brain imaging is important to detect intracranial involvement and possible trilateral disease affecting the pineal gland. The orbit can be a site for *rhabdomyosarcoma* and imaging of the brain should be included if there is associated bone destruction (parameningeal type). *Langerhans histiocytosis* primarily presents with lytic bone lesions, but it can also cause cerebellar lesions, lesions of the pituitary stalk and hypothalamus, as well as pineal lesions. In children with *leukemic retinopathy*, MRI imaging may be helpful in differentiating optic nerve infiltration from papilledema secondary to central nervous system leukemia.[53] *Metastatic neuroblastoma* is usually detected with CT imaging in children who present with eyelid ecchymosis ("raccoon eyes") and who are initially being evaluated for skull base trauma. Metastatic neuroblastoma typically presents with multiple bone lesions with a soft tissue component and a spiculated periosteal reaction (Fig. 10.24). Contrast-enhanced MRI brain/orbits is more sensitive than CT in further delineating intraorbital and intracranial mass effect of these lesions; rarely intraparenchymal metastatic neuroblastoma lesions may be found.

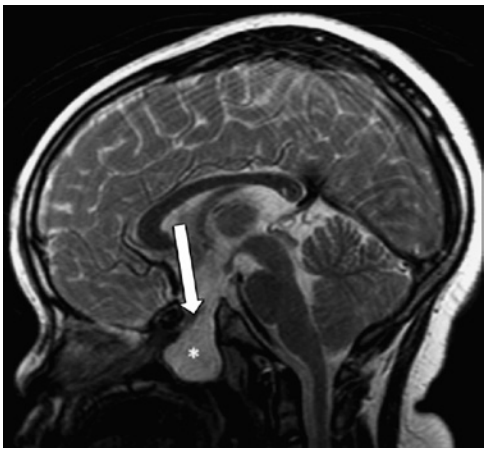

Fig. 10.25 Sagittal T2 magnetic resonance imaging (MRI) through the midline of the brain. An 18-month-old girl with unilateral morning glory and transsphenoidal encephalocele. Lack of chondrification of the intersphenoidal synchondrosis during fetal development results in persistence of the craniopharyngeal canal through which intracranial contents can herniate. Note the inferior displacement of the optic chiasm (arrow) and the extension of the mass into the nasopharynx (asterisk). The pituitary stalk and gland are not definitely seen.

Congenital malformations Malformed optic discs could indicate associated brain malformations and may benefit from non-contrast brain MRI. For example, morning glory disc anomaly may be seen in children with transsphenoidal encephaloceles (Fig. 10.25). Small (hypoplastic) optic nerves can be seen in the setting of septo-optic dysplasia (Fig. 10.26).

Multiple sclerosis While the majority of pediatric optic neuritis is unrelated to multiple sclerosis, it is important to screen

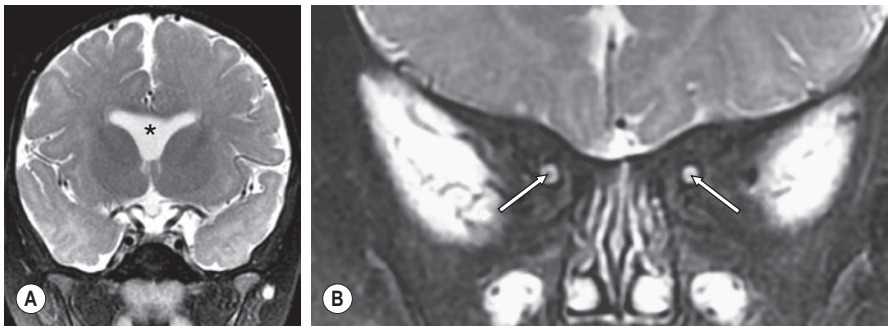

Fig. 10.26 (A) Coronal T2 magnetic resonance imaging (MRI) (with fat suppression) through the brain; (B) coronal T2 MRI (with fat suppression) of the optic nerves. A 6-month-old girl with septo-optic dysplasia. (A) Absence of the interventricular septum (septum pellucidum) (asterisk) and (B) hypoplasia of the optic nerves, left worse than right (arrows), these are typical features of septo-optic dysplasia.

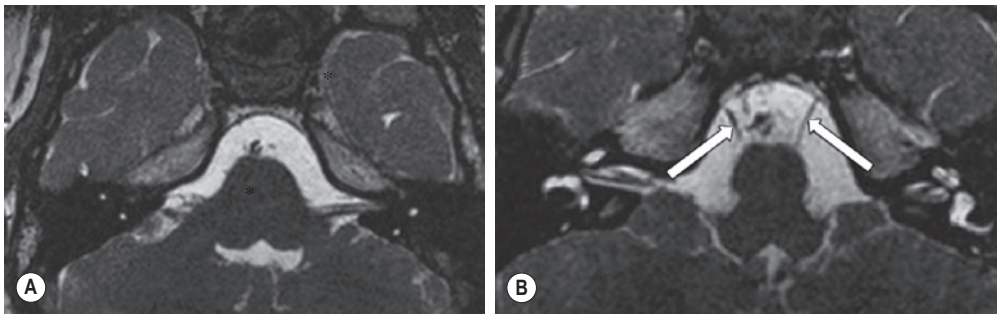

Fig. 10.27 Axial high-resolution T2 magnetic resonance imaging through the brainstem: (A) Duane syndrome, (B) normal anatomy. A 17-year-old boy with Duane syndrome. Note bilateral absence of cranial nerves VI in the prepontine cistern ([A]) compared to normal cranial VI nerves in an unaffected patient ([B], arrows).

children with recurrent optic neuritis for signs of multiple sclerosis or neuromyelitis optica, which requires contrast-enhanced MRI brain and spine imaging in search of enhancing and non-enhancing lesions.

Cranial nerve imaging Children with cranial nerve palsies are best evaluated with contrast-enhanced MRI of brain and orbits to detect/exclude etiologies such as stroke, intracranial masses, traumatic brain injury, infectious disease, or causes of increased intracranial pressure. High-resolution imaging studies of the cranial nerves can also help in confirming congenital abnormalities of cranial nerves, such as absence of the abducens nerve(s) in Duane syndrome (Fig. 10.27). Children may also experience ophthalmoplegic migraines and MRI can detect associated thickened enhancement at the oculomotor nerve root exit zone.[54] MRI angiography can be useful in detection of aneurysms that cause cranial nerve symptoms in patients with disorders that put them at risk for vasculopathy.

Horner syndrome imaging In children with Horner syndrome, the clinical exam may be difficult and may not be possible to determine whether the oculo-sympathetic pathway is affected at the central, preganglionic, or postganglionic level. Rarely, malignancies can account for pediatric Horner syndrome, most notably neuroblastoma. It may, therefore, be prudent to image the orbits, brain neck, and upper chest to the aortic arch, preferably with MRI to avoid radiation exposure.[55]

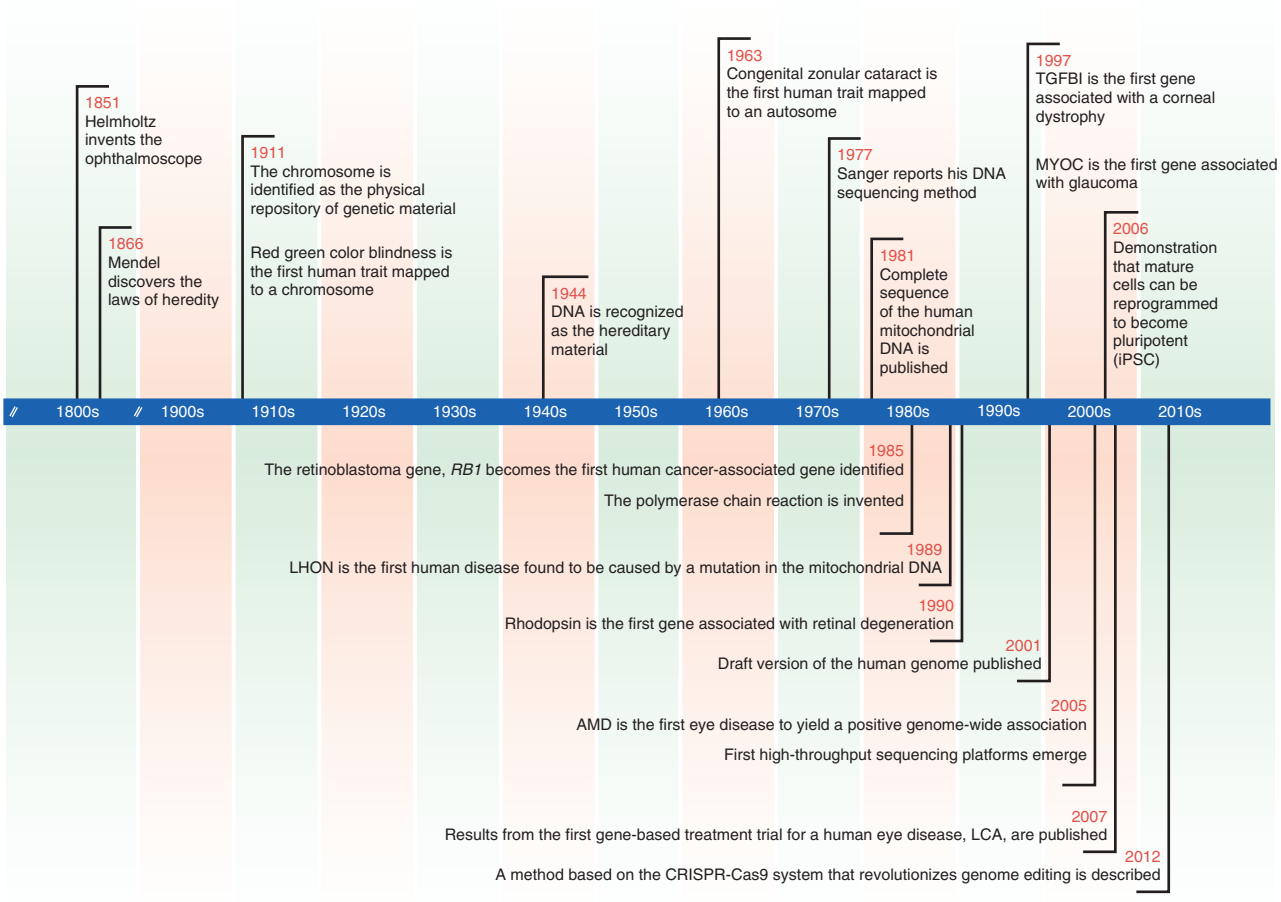
Introduction

The modern era of genetic ophthalmology began in 1985 with the discovery of the retinoblastoma gene[1,2] (Fig. 11.1 sets out a timeline of historic discoveries). Exciting progress in deciphering the genetic bases of eye disease has been made since that time. Hundreds of genes associated with a wide variety of common and rare disorders have been discovered leading to clinically valuable diagnostic tests (e.g. for pediatric cataract[3]), meaningful disease classifications (e.g. for corneal dystrophies[4]), and novel therapeutic strategies (e.g. for retinal dystrophies[5,6]). This chapter focuses on genetics in pediatric ophthalmic practice; we discuss the different types of genetic disorders and modes of inheritance, and the principles of genetic testing and counseling.

Genetic disorders

Genetic conditions account for a third of childhood severe visual impairment/blindness worldwide, a figure that is likely to be an underestimate, especially in medium- and high-income countries.[7–9] Disorders referred to in this context are defined by their predominantly monogenic inheritance. This means that each is caused by a fault or *mutation* in a single gene, and that the detection of such mutations can predict the disease development with relatively high accuracy. Such monogenic or *Mendelian* disorders can be recognized by the characteristic pedigree patterns they give.

The human genome (i.e. the totality of one's DNA) is divided among 46 physically distinct chromosomes: 22 pairs of autosomes (non-sex chromosomes) plus two sex chromosomes (two X chromosomes in female, one X and one Y chromosome in male). Monogenic disorders can be associated with genes on autosomes (chromosomes 1–22) or on the X and Y chromosomes. Autosomal characters in both genders and X-linked characters in females can be dominant or recessive. This section will focus on the three main Mendelian pedigree patterns: autosomal dominant, autosomal recessive, and X-linked recessive (Fig. 11.2A–D). Mitochondrial inheritance, an atypical mode of inheritance that can be viewed as an expansion of Mendelian concepts, is also described (Fig. 11.2E). For a more detailed discussion of pedigree patterns, including the rare X-linked dominant, Y-linked, and digenic inheritance, see[10].



Autosomal dominant inheritance

In autosomal dominant conditions, affected individuals carry one normal and one mutated copy of a gene. This means that a single copy of the mutation is sufficient to cause disease (i.e. the condition is expressed in the *heterozygous* state). Typically, an affected person has at least one affected parent and there are affected individuals in multiple generations. A person with an autosomal dominant disorder has a 1 in 2 chance of passing the mutated gene to an offspring (i.e. of having an affected child). This basic Mendelian pattern can be disguised by phenomena such as non-penetrance (see Fig. 11.2B), variable expressivity, and new/*de novo* mutations (see below).

Autosomal recessive inheritance

In autosomal recessive conditions, affected individuals carry defects on both copies of a given gene. They can be either *homozygotes*, if both copies harbor the same mutation, or *compound heterozygotes*, if each copy carries a different mutation. Typically, affected individuals are born to asymptomatic carrier parents; this means that the parents carry one normal and one mutant gene copy but are not affected, as the normal copy is sufficient to produce normal function and structure. After the birth of a child with an autosomal recessive condition, each subsequent child has a 1 in 4 chance of being affected.

Autosomal recessive disorders can appear as "sporadic" in a family where all parents and siblings are healthy; this is

LHON, AMD and LCA denote Leber hereditary optic neuropathy, age-related macular degeneration, and Leber congenital amaurosis, respectively.

Fig. 11.1 Timeline of landmarks in genetic ophthalmology.

particularly common in small families. In real life, predicting autosomal recessive inheritance can be challenging and may be inferred on the basis of unaffected parents ("lack of vertical transmission") and exclusion of X-linked inheritance.

A major risk factor for autosomal recessive disorders is parental consanguinity.[11] A consanguineous marriage is in general defined as a union between a couple related as second cousins or closer.[12] Although these unions increase the likelihood that spouses carry an identical gene mutation, in many ethnic groups they are an important part of family culture. Personalized genetic counseling should be offered to consanguineous couples, but this must be done with sensitivity and appreciation of cultural issues.

X-linked inheritance

An X-linked condition is caused by a mutation in a gene carried on the X chromosome. Males have only one X chromosome and, consequently, such a mutation will be manifest. Females have two copies of each X chromosome gene and the presence of a normal copy leads to partially or completely preserved structure and function.

The essential features of X-linked inheritance are the presence of affected males (of greater severity than females) and the lack of father-to-son (male-to-male) transmission. The mothers of affected males are obligate carriers and have a 1 in 2 chance of passing the mutation to their offspring; each son has a 1 in 2 chance of being affected and each daughter has a 1 in 2 chance of being a carrier.

Classically, it is assumed that X-linked recessive conditions only affect males. This is true for conditions such as X-linked retinoschisis and Norrie disease. However, for others such as X-linked retinitis pigmentosa, there may be phenotypic manifestations in heterozygous females, although these will usually be milder and of later onset than in males.[13] In these cases, it might be difficult to distinguish X-linked from autosomal dominant inheritance, especially in the absence of a detailed family history. Notably, phenotypic manifestations of X-linked disorders in females are highly variable; this is mainly due to a genetic phenomenon termed *X chromosome inactivation* or lyonization (for more information see Wu et al.[14]). It is of interest that in a number of X-linked conditions including choroideremia and Lowe syndrome, females may show characteristic ocular signs despite the absence of symptoms. These signs can help the identification of apparently unaffected female carriers.[15,16]

Complications to the basic Mendelian pedigree patterns

Various clinical phenomena can often disguise an underlying Mendelian inheritance pattern. An example of such a

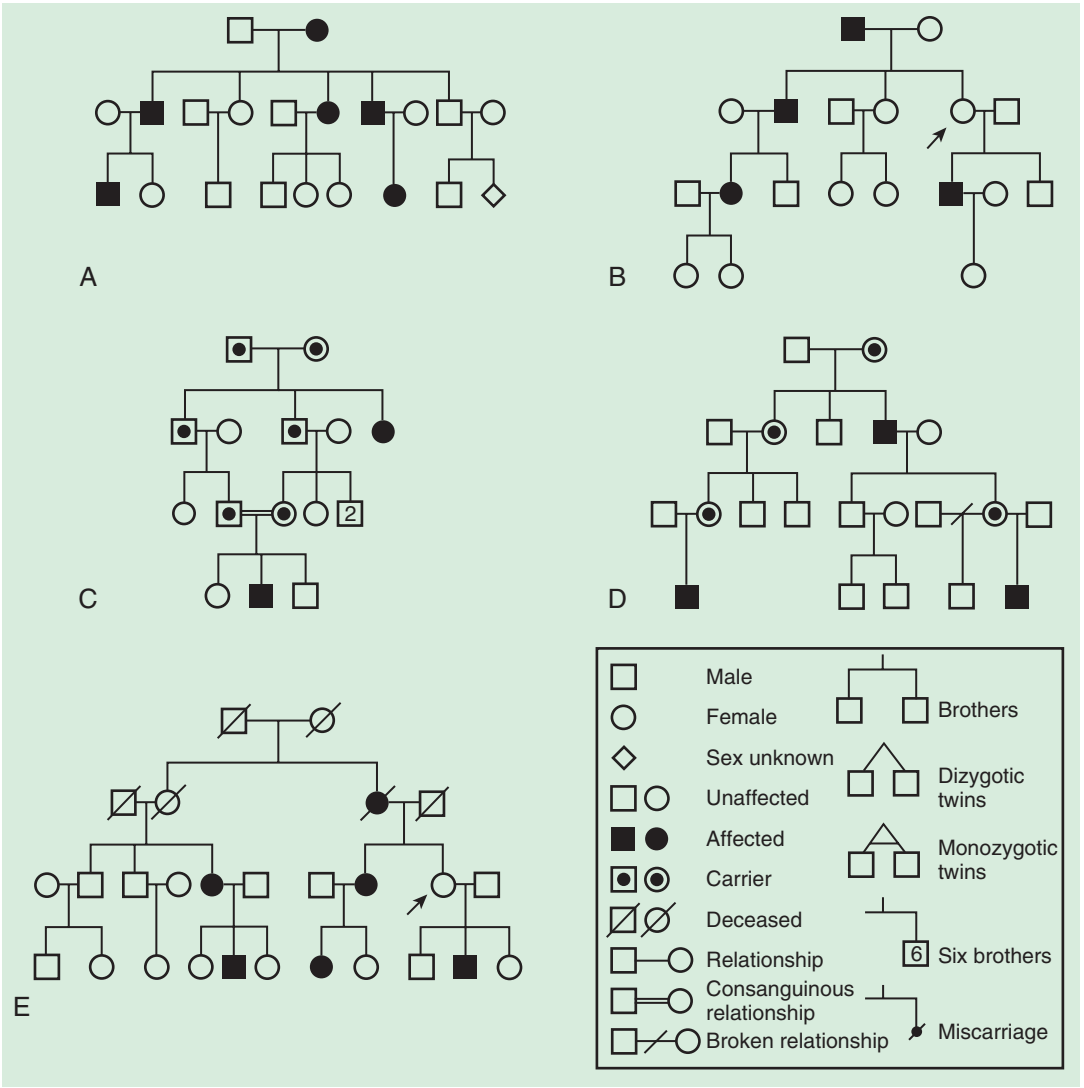


Fig. 11.2 Pedigree patterns of autosomal dominant (A,B), autosomal recessive (C), X-linked recessive (D), and mitochondrial (E) conditions. Arrows highlight non-penetrant carriers of an autosomal dominant (B) and a mitochondrial (E) disorder.

complication is *reduced penetrance*.[17] Reduced penetrance is common in dominant disorders where heterozygous mutation carriers are classically expected to be affected. However, in reality, the probability of a mutation carrier developing symptoms is rarely 100% – that is mutations often show reduced penetrance. In practice, this means that for many conditions including pediatric cataract, coloboma, and some forms of autosomal dominant retinitis pigmentosa, individuals may carry a mutation but have no signs of the disorder. An extreme example is an asymptomatic individual with an affected parent and children; such a pedigree structure would suggest that he/she certainly carries the mutation but there is non-penetrance (see Fig. 11.2B).

Another genetic phenomenon with similarities to reduced penetrance is variable expressivity, also frequently seen in the context of dominant disease. A mutation is said to demonstrate variable expressivity if, within a family, affected individuals carry the same genetic defect but the manifestations of the condition vary widely. The cause for variable expressivity is the same as for reduced penetrance: environmental factors or other genes can have some influence on the development of symptoms.[18] Examples of variable expressivity include von Hippel–Lindau disease and Stickler syndrome, in which ocular and extraocular manifestations vary among those who carry a mutation.[19,20] In these cases, disease severity in one individual may give little or no indication of the likely disease severity for siblings or offspring. Reduced penetrance and variable expressivity are important reasons for examining apparently unaffected parents of children with conditions such as pediatric cataract or anterior segment dysgenesis. Importantly, the presence of mild features can predict the risk for future offspring.

Many cases of severe dominant disease are the result of new mutations.[21] These so-called *de novo* mutational events arise as a result of a copying error from a parent's DNA and manifest without warning in families with no previous history of the disorder. This phenomenon is observed in many individuals with aniridia (Fig. 11.3) or retinoblastoma.[22,23] In such cases, the recurrence risk for future siblings is much lower than 1 in 2. However, the figure will not be zero due to the risk of *gonadal mosaicism* (i.e. one parent carrying the mutation only in a proportion of his sperm or her eggs).

The exact nature of a *de novo* mutation is difficult to predict. For cases of sporadic/non-familial aniridia, a deletion

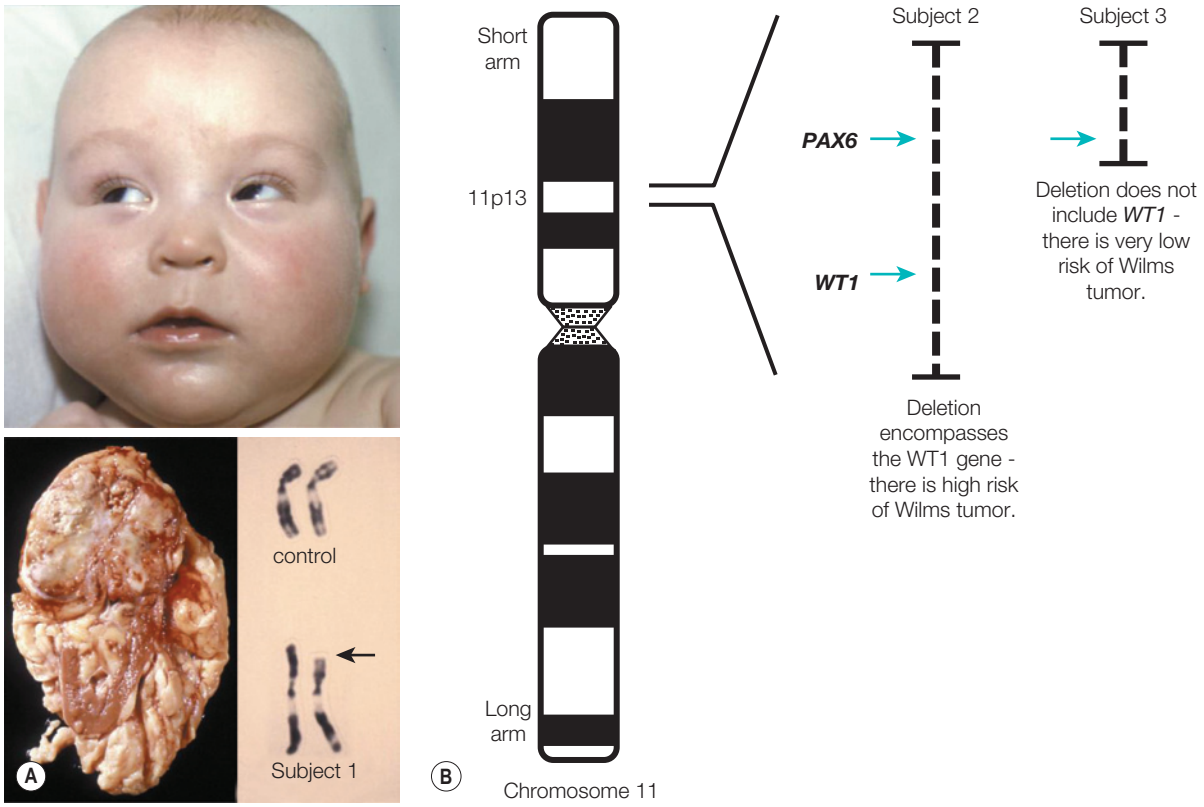

Fig. 11.3 Aniridia caused by deletions in chromosome 11. (A) A child presented with cognitive impairment, genitourinary abnormalities, and aniridia (subject 1, top row); there was no relevant family history. He was subsequently found to have a Wilms tumor in the superior pole of his kidney (bottom row, left). Karyotype analysis revealed a deletion in the short arm of chromosome 11, which encompasses the PAX6 (aniridia) and the WT1 (Wilms tumor) genes (bottom row, right; arrow highlights the deleted region). (B) Individuals 2 and 3 were born with sporadic aniridia. Karyotype analysis was normal but further cytogenetic analysis revealed submicroscopic deletions in both patients. The deletion in subject 2 removed a copy of the PAX6 and WT1 genes (deletion shown as interrupted line). The deletion in subject 3 was smaller and only removed a copy of the PAX6 gene; the WT1 gene was unaffected with two normal copies. Consequently, subject 2 is at high risk of developing Wilms tumor (one WT1 gene copy), while subject 3 is not at risk (two WT1 gene copies).

can remove other neighboring genes; this is seen in WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, and intellectual retardation). These contiguous gene deletions are the reason why individuals with sporadic aniridia require either renal ultrasound screening or molecular evidence that the Wilms tumor gene, *WT1*, is unaffected by the mutation (see Fig. 11.3).[23,24]

Mitochondrial inheritance

Mitochondria are cytoplasmic cellular organelles that contain a small genome (~16,500 bases) that is distinct from the nuclear genome (~3,200,000,000 bases).[25,26] Like mutations carried on the nuclear chromosomes, mutations in the mitochondrial DNA (mtDNA) can be associated with disease. Among the small number of proteins encoded by mtDNA are important components of the electron-transport chain. Mutations in these genes can cause Leber hereditary optic neuropathy (LHON) and Kearnes–Sayre syndrome.[27,28]

Mitochondria are inherited exclusively from the ovum and an mtDNA mutation can only be passed on from a mother to her child. Consequently, while mitochondrially inherited disorders can affect both genders, they are transmitted only by mothers who carry the mtDNA defect. Although, at first sight, the pedigree pattern may appear dominant, it should be noted that affected fathers never transmit the condition.

Maternally inherited conditions are typically highly variable, making the estimation of prognosis challenging. In many cases where individuals carry mtDNA mutations in all of their cells, as is seen for most LHON patients, the basis for this variability is poorly understood.[29,30] However, with mitochondrial myopathies such as Kearnes–Sayre syndrome, only a proportion of the mitochondria carry mtDNA mutations and, since each cell has many mitochondria, variability can arise.[31] This state is termed *heteroplasmy* and is associated with a variable ratio of mutant to normal mitochondria between the cells/tissues of a single individual or between different individuals of the same family.

Heterogeneity in genetic disorders

There is very rarely a one-to-one correspondence between genes and genetic disorders and this has implications for diagnosis, counseling, and genetic testing. Two types of heterogeneity are observed:

1. *Locus heterogeneity* is when defects in more than one gene can cause indistinguishable phenotypic manifestations. Examples include Leber congenital amaurosis and Bardet–Biedl syndrome, which are not single disorders but groups of clinically similar genetic conditions.[32,33]

2. *Clinical heterogeneity* is when mutations in the same gene produce two or more apparently distinct disorders in different individuals (e.g. *SOX2* mutations can cause microphthalmia, anophthalmia, or coloboma[34]). As the clinical outcome of a mutation can be influenced by its position, type, and effect on the encoded protein, clinical heterogeneity may be associated with different effects of distinct mutations.

Multifactorial disorders

Although overall monogenic eye disorders are common, they are individually fairly rare. Notably, many of the common pediatric ophthalmic conditions appear to show familial clustering and are likely to be caused by a complex interplay of multiple genes and the environment (e.g. esodeviations[35,36]). In these multifactorial disorders, the presence of any one of the disease-associated variants is not highly predictive of the development of disease.[37] It is clear that there is a continuum of disorders from fully penetrant monogenic to multifactorial conditions, and that compartmentalizing genetic disorders into "monogenic, simple, and rare" and "multifactorial, complex, and common" is an oversimplification.[38]

Epigenetics

Differences in phenotype often result from chemical modifications of DNA and its associated proteins (histones) rather than changes in the primary DNA sequence. Such *epigenetic modifications* can control gene activity, switching genes on and off. These changes may be induced by the environment (toxins, nutrition, stress) and can endure for varying times.[39] While epigenetic alterations have a role in normal cellular processes and development, they can also be responsible for certain inherited disorders.[40] Furthermore, epigenetically regulated process such as genomic imprinting can influence how some genetic conditions are inherited.[41]

Key molecular mechanisms of epigenetic control include DNA methylation, histone modification and non-coding RNA gene silencing.[42] The expansion of our understanding of these mechanisms has highlighted the potential for translating this knowledge into a new class of treatment options to combat blinding disorders.[42,43]

Variants and mutations

Although the term "mutation" can be used in different senses, it has developed a negative connotation and is typically used to indicate a disease-causing DNA change; that is a change that contributes mechanistically to disease but may not be sufficient in isolation to cause disease (e.g. in cases with reduced penetrance). In contrast, the term "variant" is used to indicate any difference in a DNA sequence in comparison with the normal reference sequence. A variant may or may not affect the function of a gene/protein; variants for which a functional effect is unknown are called "variants of unknown significance".[44,45] Other ways to classify variants include common versus rare and small-scale versus large-scale.

Human genetic variation ranges from single base/nucleotide changes (known as SNPs, single nucleotide polymorphisms) through to structural variants (see Fig. 11.3) and gains or losses of whole chromosomes. Substitutions of a single base/nucleotide are the most numerous variants.[46] These small-scale DNA sequence alterations may result in the substitution of one encoded amino acid for another (missense changes) or convert an internal amino acid of a protein into a termination codon (nonsense changes). Small insertions/deletions (indels), in which up to 21 bases/nucleotides are inserted and/or deleted, are another common subtype of small-scale DNA variation. Notably, if the overall loss or gain of bases is not a multiple of three, the reading frame of the gene will be altered and a premature termination codon will be probably introduced.

Some changes can alter transcription (i.e. the process of copying a particular segment of DNA into mRNA) and in particular the stage during which the immature mRNA molecule (consisting of introns and exons) is modified to form mature mRNA (consisting of joined exons only). This process is called splicing and requires the interaction of a large protein complex, the spliceosome, with mRNA. Many mutations, especially those that lie at or close to the junctions between introns and exons, cause disease by interrupting splicing. These splicing mutations lead to reduced transcription of a gene and therefore reduced gene expression.

Any sequence change can be described using the conventions set out on the website of the Human Genome Variation Society (http://www.hgvs.org/mutnomen/[47,48]); common prefixes include "c." (coding DNA level) and "p." (protein level). Useful variant databases include the Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/[49]) and ClinVar (http://www.ncbi.nlm.nih.gov/clinvar/[50–52]), two online repositories of disease-associated variants, as well as the Exome Aggregation Consortium database (http://exac.broadinstitute.org/) which includes variant data from over 60,000 unrelated individuals.

Genetic testing

Genetic testing for ophthalmic disorders aims to provide accurate diagnosis, to facilitate appropriate counseling to the patient and family members, and to determine inclusion in gene-based clinical trials.[53,54] A genetic test, in the broad sense, can be a clinical or a laboratory investigation. For example, the identification of multiple iris nodules in the child of a person with neurofibromatosis type 1 will have similar ramifications as the identification of a NF1 gene mutation in a standard DNA-based test. One key difference though is that a DNA-based method can establish the predisposition to a genetic disease long before the disorder will be detectable by even the most sensitive clinical tools (*presymptomatic testing*).[37]

Advances in DNA sequencing technologies have reduced the cost of genetic testing,[55] shortened the turnaround time of tests, and facilitated the evaluation of numerous genes and molecular hypotheses concurrently (*parallel testing*).[56] As a result, clinically useful tests now exist for dozens of inherited eye disorders.[3,37,53,57] The focus of these tests is presently monogenic disease, and ophthalmologic societies have issued recommendations on when genetic testing is advisable (the current recommendations of the American Academy of Ophthalmology Task Force on Genetic Testing can be found online at http://www.aao.org/).

Genetic testing is typically performed on DNA extracted from a tissue sample. Peripheral blood is the most commonly

used and reliable source, but mouthwashes or buccal scrapes can be used when sampling must be noninvasive; for prenatal diagnosis, amniotic fluid or chorionic villi are normally utilized. Depending on the clinical indication, different techniques can be subsequently employed (see Fig. 11.1).[58] DNA sequencing is by far the most commonly used approach in inherited eye disease.

Testing options that use DNA sequencing have greatly expanded over the past decade. Notably, there has been a fundamental shift away from the traditional Sanger sequencing-based technique to newer technologies, referred to as high-throughput or next-generation sequencing.[56] These approaches have transformed genetic testing and are the basis of tools such as multigene panel testing, exome sequencing (i.e. sequencing the protein-coding, informative 1% of the genome[59]) and genome sequencing (i.e sequencing the totality of the nuclear DNA).

Sanger sequencing is only able to analyze one small portion of DNA at a time. Using this approach may still be a sensible testing strategy in certain conditions associated with one specific gene such as Sorsby dystrophy (*TIMP3* gene[60]) or stromal corneal dystrophies (*TGFBI* gene[61]). However, single-gene eye disorders are rare and most inherited eye diseases are either associated with large and complex genes (e.g. *ABCA4* in Stargardt disease[62]) or exhibit locus heterogeneity (e.g. Usher syndrome[63]). In these cases, Sanger sequencing, a technology unable to generate large sequence output, is an arduous, time-intensive, and expensive means of diagnosis.

In contrast, high-throughput sequencing approaches allow rapid inspection of many genes at once, resulting in high diagnostic rates, especially in heterogeneous disorders.[21,64–66] Multigene panel tests utilizing high-throughput sequencing technologies are presently the preferred method for diagnostic testing of retinal dystrophies[53,67] and pediatric cataract.[3] This approach inspects hundreds of known disease-causing genes and has been shown to not only be more sensitive than exome sequencing but also to reduce the potential for incidental findings (see below).[68] Exome and genome sequencing can assess >95% of the protein-coding sequence of the human genome (~19,000 genes) and have been adopted as standard approaches in genetic research; however, their implementation in the clinical setting has been slower. At present, genome sequencing appears to outperform exome sequencing not only in detecting large-scale/structural variants, but also in covering protein-coding regions.[64,69,70]

With the advent of these high-throughput sequencing technologies, genetic data acquisition and DNA sequence variant identification are no longer the rate limiting steps. However, there is a huge interpretive burden: pinpointing the disease-causing variant among the considerable background of detected rare variants can be an onerous task.[71,72] A well-informed clinical, pre-test hypothesis is key, making a knowledgeable clinician one of the most important components of the genetic testing process. Another major issue with extensive parallel testing, a characteristic of exome and genome sequencing, is the collateral discovery of numerous clinically relevant findings that are unrelated to an individual's presenting symptoms. The terms "incidental" and "secondary" are used to describe these findings.[37,73] One example of such a secondary finding is the discovery of a mutation increasing the risk of breast cancer in a patient who had exome sequencing for childhood-onset glaucoma.

Genetic counseling and ethical issues

The primary aim of genetic counseling is to communicate information, in an appropriate manner, to individuals about a genetic disorder. This includes discussing the risk to family members and the options around reproduction and genetic testing. An accurate diagnosis and a close collaboration between the clinic and the laboratory are central to effective genetic counseling.

A genetic test can have significant and far-reaching consequences for an individual and his/her family. Guiding families through the testing process can be challenging, especially given the increasing complexity of the results of high-throughput sequencing-based tests. Informed consent and effective genetic counseling are essential and can maximize the benefits and minimize the risks associated with each test.

Pre-test considerations

It is crucial to maintain realistic expectations for finding the causative mutation and to alert the patient/family that, in most cases, a positive result is unlikely to change management decisions or to improve the prognosis.[74] If exome or genome sequencing have been identified as appropriate for a child, the parents should be engaged in a decision-making process. They should be aware that these strategies involve a broad evaluation of thousands of genes and, as a result, there is a chance that genetic susceptibility to a condition unrelated to the indication of the test could be identified. Current recommendations are to include analysis of a small set of genes that are deemed to be highly medically actionable (e.g. genes associated with familial hypercholesterolemia) in every subject tested with exome or genome sequencing; this analysis is performed regardless of the specific indication of the test, but it is common to allow a patient opt-out clause.[73,75]

Informed consent

Consent forms can be lengthy and technical, and just asking the parents to navigate the forms on their own is often not appropriate. The consenting individual should make a checklist of the essential points in the form and ensure that these are discussed with the family.[76] According to standard practice, after pre-test counseling to the parents and child, one or both parents with custodial responsibility should agree in writing with the decision to perform the test. Importantly, communication needs of visually impaired individuals should be taken into account and information should be provided in suitable formats.

Post-test considerations

High-throughput sequencing-based tests are rarely positive/negative assays. Distinguishing true- from false-positives can be challenging and may require additional history taking or examination (e.g. one may look for clinical features of a previously unrecognized syndrome). The conclusion that an identified variant is indeed disease-causing is the result of integrating submitted clinical information with laboratory test results; reviewing available data from trusted medical sources (PubMed or textbooks) may also be required.[64] A negative test should prompt re-evaluation of the clinical findings and

the limitations of the conducted test. Notably, a negative result often suggests that the current state of research has not identified the gene that is associated with the patient's condition.

Presymptomatic and carrier testing

In late-onset conditions where the causative gene mutation is known (e.g. *EFEMP1* in autosomal dominant drusen[77]), asymptomatic at-risk individuals may choose to have a predictive genetic test to discover if they are likely to develop the disorder. This will allow them to make informed reproductive or career decisions at a time when the disease is not yet clinically detectable.[37] Another common situation is unaffected females from families segregating an X-linked disorder (e.g. X-linked retinitis pigmentosa), choosing to have carrier testing in order to make decisions around reproduction, prenatal testing, or preimplantation genetic diagnosis.[78]

Testing asymptomatic children for untreatable disorders should be avoided except in exceptional circumstances.[37] For these few cases, careful counseling and engagement of parents in shared decision-making is essential. For conditions that are asymptomatic until adulthood, it is generally advised to wait until an individual is old enough to make their own decisions.

Conclusions

The field of ophthalmic genetics is evolving very rapidly. Genetic tests that greatly enhance diagnostic precision are now available and should be routinely considered as part of the clinical evaluation of children with inherited eye disease. Importantly, recent progress in genome editing, gene transfer, and stem cell biology have made the prospect of halting disease progression in currently untreatable inherited eye disorders a realistic possibility.

Maternal infection during pregnancy can have significant consequences to the developing fetus, including involvement of the visual system; it is an important cause of childhood blindness in the world, particularly in developing countries.[1] The term "TORCHES" refers to toxoplasmosis, other agents (varicella, lymphocytic choriomeningitis, West Nile virus, human immunodeficiency virus [HIV]), rubella, cytomegalovirus, herpes viruses, and syphilis. Improved screening and prophylaxis of pregnant women at risk will reduce these potentially devastating infections.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular parasite, which typically affects the brain and the eyes in humans. There are three different strains. Congenital disease in humans is associated mostly with types I and II; type III is found only in animals.[2]

Systemic manifestations include hydrocephalus, microcephalus, intracranial calcifications (Fig. 12.1), anemia, petechiae due to thrombocytopenia, deafness, seizures, jaundice, fever, hepatosplenomegaly, mental and growth retardation, spasticity and palsies, lymphadenopathy, maculopapular rash, vomiting, and diarrhea.[3,4] Around 90% of neonates are asymptomatic; however, some of these infants later in life develop retinochoroiditis, hydrocephalus, mental retardation, and, deafness.[5] Clinical manifestations are more severe in premature infants, and congenital abnormalities are worse if the infection is acquired during the first trimester of gestation, but only 10–15% of these babies have serological evidence of vertical transmission.[6] When maternal *Toxoplasma* infection occurs during the third trimester, fetal transmission is around 75%, but there are minimal if any abnormalities.[7]

Ocular manifestations include retinochoroiditis[2] (Fig. 12.2A,B), microphthalmos (Fig. 12.3), cataracts, panuveitis (Fig. 12.4), optic atrophy, retinal detachment, pthisis, active vitritis (Fig. 12.5), active retinitis, nystagmus, and strabismus. Active chorioretinitis (Fig. 12.6) develops in 85% of patients with subclinical congenital infection[8]: it is usually bilateral and has a predilection for the macula; peripheral lesions are found in 64% of cases.[9] The chorioretinal scarring is usually heavily pigmented and associated with areas of chorioretinal atrophy (see Fig. 12.2). Chorioretinitis is progressive; the incidence can increase from 11% at 1 year of age to 23% by 7 years of age.[10]

Human infection is acquired from eating bradyzoites in undercooked meat, but it can also result from ingestion of oocysts in water, soil, or food contaminated by cat feces. Toxoplasmosis can also be a sexually transmitted disease via semen.[11] Marked regional differences in the prevalence of seropositivity occur due to differing dietary practices and sanitation standards. Up to one third of the world's population has serologic evidence of past *Toxoplasma* infection. *Toxoplasma* is responsible for the majority of congenital and acquired infectious uveitis. The incidence of congenital toxoplasmosis syndrome is 1–10 per 10,000 live births.[12,13] The prevalence of *Toxoplasma* seropositivity varies with age; in children under 5 years of age, the antibodies are found in less than 5% of the population, whereas they are present in 60% of adults

over age 80 years. Since 70% of the obstetric population has negative antibodies, this is a risk for transmission to the fetus.[14] Likewise, women of childbearing age emigrating from an area of low immunity to a region of high immunity are at the greatest risk of contracting toxoplasmosis.

The diagnosis of maternal toxoplasmosis is confirmed by testing serum for antibodies. If both immunoglobulin (Ig) G and IgM antibodies are absent, infection has not occurred. Positive IgG titers with negative IgM titers suggest prior infection.[15] The presence of IgM antibodies with or without positive IgG titers warrants a further workup with confirmatory testing including the Sabin–Feldman test, IgG avidity (measures the strength of antigen binding to antibody)[15], and enzyme-linked immunosorbent assay (ELISA) for IgG, IgM, and IgA. High IgG avidity indicates a less recent infection.[16] Polymerase chain reaction (PCR) testing of amniotic fluid can have 98% sensitivity and 100% specificity.[17,18] Cerebrospinal fluid PCR is considered to be highly sensitive for diagnosis of congenital toxoplasmosis in infants with neurological disorders.[19]

Women who contract toxoplasmosis during pregnancy must be treated with spiramycin, a macrolide that does not cross the placenta, believed to only reduce the sequelae among infected infants but not the rate of maternal–fetal transmission.[20] However, in a recent prospective cohort trial in Brazil, only 58% of newborns from spiramycin-treated mothers had congenital infection compared to 73% of infants whose mothers were not treated.[21] When maternal infection occurs during the third trimester, maternal treatment with pyrimethamine and sulfadiazine can be administered. In immunocompromised women, vertical transmission can occur without recent acute infection[22]; therefore, HIV-infected women with CD4+ count of 200/mm^3 or less should be treated with spiramycin for the duration of their pregnancy.

Recurrence has been reported to occur in only 13% of treated infants, compared to 44% of untreated patients; recurrences occur in areas contiguous to old scars or in uninvolved retina. It is recommended that all neonates with serological evidence of an intrauterine toxoplasmosis infection, even if there are no chorioretinal lesions or signs of active infection, be treated with a 1-year course of pyrimethamine and sulfadiazine with concurrent administration of folinic acid to reduce the hematotoxicity of pyrimethamine.[3] There is resolution of active disease within weeks of starting the treatment and long term follow-ups confirm improved visual outcomes.[23] Recent studies have shown that diclazuril can be effective and well tolerated for the treatment of maternal and congenital toxoplasmosis in a murine model, and it helps to eliminate the cycle of toxoplasma infection in cats, which are the definitive host.[24]

Prevention includes not eating raw or undercooked meat and avoiding cat feces during pregnancy. Fruits and vegetables that might be contaminated with toxoplasmosis oocytes, should be washed carefully before being eaten. Routine serological screening of pregnant women for toxoplasmosis is still

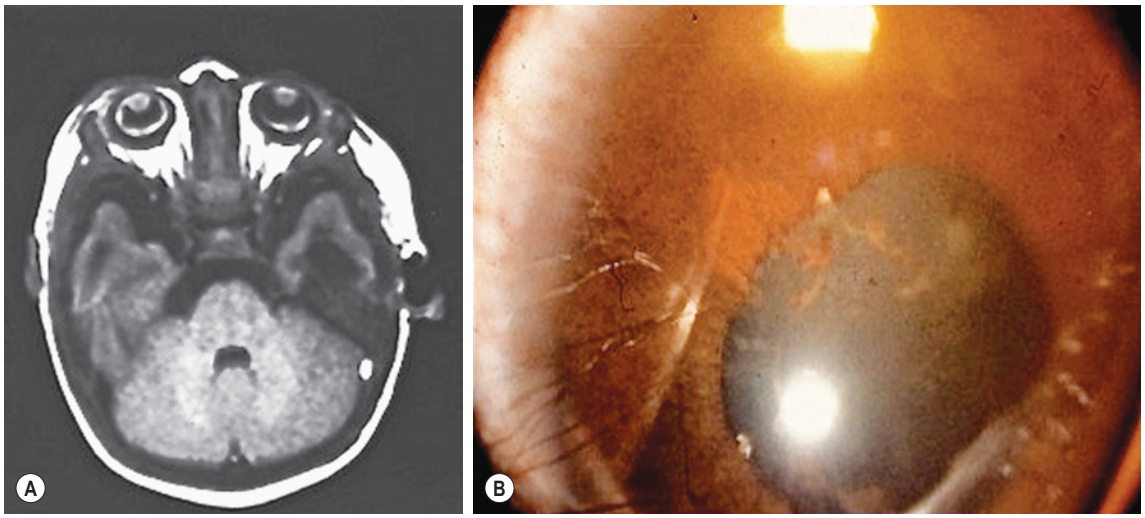

Fig. 12.5 Congenital Toxoplasmosis. (A) CT scan showing bilateral microphthalmos, panuveitis. (B) Slit-lamp view showing marked panuveitis. The vitreous was very hazy making fundal view impossible.

controversial, and it is not carried out in many countries, but in those areas where the disease is endemic, pregnant women should be screened throughout the pregnancy.

Rubella

Congenital rubella was first described in Australia in 1941 by Norman Gregg after an epidemic affecting 78 children. The findings included congenital cataracts, congenital heart disease, and deafness.[25] Other systemic manifestations are intrauterine growth retardation, mental retardation, microcephaly, osteopathy, lymphadenopathy, thrombocytopenic purpura, hepatitis and hepatomegaly, diabetes and other endocrine abnormalities, and hypospadias.[26,27] The most common finding is hearing loss, present in 44% of cases.[28]

The virus is transmitted to the fetus through the placenta during the viremic phase in the mother. The prevalence of abnormalities correlates with the gestational stage at which the infection occurs: the rate of congenital defects is 100% in the first 11 weeks, 30% in weeks 11–20, and 0% after that. The incidence of congenital infection is also dependent on the gestational month when exposure to the virus occurred; it is 90% in the first 11 weeks, 50% during weeks 11–20, 37% during weeks 20–35, and 100% during the last week of pregnancy.[29]

Ocular manifestations include cataracts, present in 20–30% of children with the congenital rubella syndrome,[30] and they

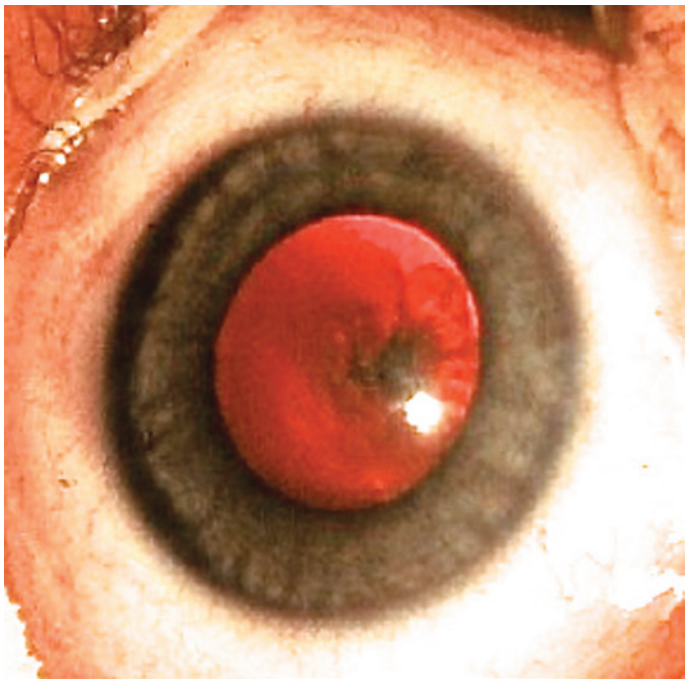

Fig. 12.7 Congenital rubella with cataracts and microphthalmos.

Fig. 12.8 Salt and pepper congenital rubella retinopathy.

occur when the virus infection occurs during the first 3 months of gestation. They are bilateral in 75% of cases. The cataracts can be nuclear, total, or membranous.[27] The virus has been cultured from cataractous lenses of children affected with the rubella syndrome up to 4 years of age, and it causes the severe inflammatory reaction observed after cataract surgery in these babies.[31] Microphthalmos is present in 10% of patients and it is usually associated with cataract[8] (Fig. 12.7).

The cornea may be hazy, due to keratitis secondary to the presence of the virus in the aqueous; it may resolve in weeks or months. Glaucoma can also be present in 10% of cases,[32] and it is seen usually associated with microphthalmic eyes or eyes with iris hypoplasia. It can be due to developmental abnormalities of the angle, chronic iridocyclitis, or even angle closure due to a large cataractous lens.[33] Keratoconus,[27] and dacryostenosis also may occur.[34] Some babies have a chronic granulomatous iridocyclitis,[34] causing focal necrosis of the pigment epithelium of the iris and the ciliary body. Iris colobomas, posterior synechiae, anisocoria, persistent pupillary membrane, and mesodermal dysgenesis have also been reported.[35]

Pigmentary retinopathy is the most common ocular abnormality. Present in 40% of affected babies, it is bilateral and is described as "salt and pepper" retinopathy, characterized by mottled pigmentary changes throughout the fundi (Fig. 12.8). Histopathologically, there is depigmentation of the retinal pigment epithelium without inflammation. The distribution varies, but the changes are most marked in the posterior pole. In spite of striking changes, the visual function is unaffected, and the electroretinogram (ERG) is normal. Primary optic atrophy has also been reported.

The diagnosis is confirmed by the presence of IgM antibodies to rubella in cord blood; serial rising IgG titers from serum sampling or throat virus culture can also be useful.[29]

Treatment of congenital rubella is mainly supportive. Unfortunately the visual outcome after modern surgical management of rubella-induced congenital cataracts remains poor.[36]

Prevention with the introduction of the attenuated rubella virus vaccine (RA-27) has dramatically reduced the incidence of rubella in the developed world. The Americas have eliminated endemic transmission of rubella and congenital rubella syndrome.[37] It is still, however, a major cause of blindness in developing countries where universal vaccination programs are not in place.[38] About 110,000 infants are affected every year with congenital rubella syndrome.[37,39]

Cytomegalovirus

Cytomegalovirus (CMV), which is part of the herpes virus group, is the most common cause of intrauterine infection. It occurs in 0.5–2.4% of live births,[40] but only 10% of children with congenital CMV are symptomatic as newborns.[41] The prevalence of latent infection in young adults is higher in developing countries and with increasing age.[42]

Transmission can occur prenatally during primary maternal infection, re-infection, or re-activation of latent infection[43]; the risk of transmission is highest when primary infection occurs during the third trimester.[44,45] Neonatal infection can occur due to exposure to genital secretions at the time of delivery or the ingestion of breast milk.[29]

Intrauterine CMV infection causes tissue necrosis causing disruption of organogenesis.[46] Systemic manifestations that are exclusively seen in infants born to mothers with primary infection include intrauterine growth retardation, thrombocytopenic purpura, microcephaly, periventricular calcifications (Fig. 12.9), hepatosplenomegaly, jaundice, pneumonia, sensorineural deafness, and psychomotor retardation.[47]

Ocular manifestations are uncommon and include keratopathy, glaucoma, cataracts, microphthalmos, optic atrophy, optic nerve hypoplasia, and optic nerve coloboma.[48] Retinochoroiditis is present in 22% of symptomatic babies.[48] The chorioretinal scars are similar to toxoplasmosis lesions,

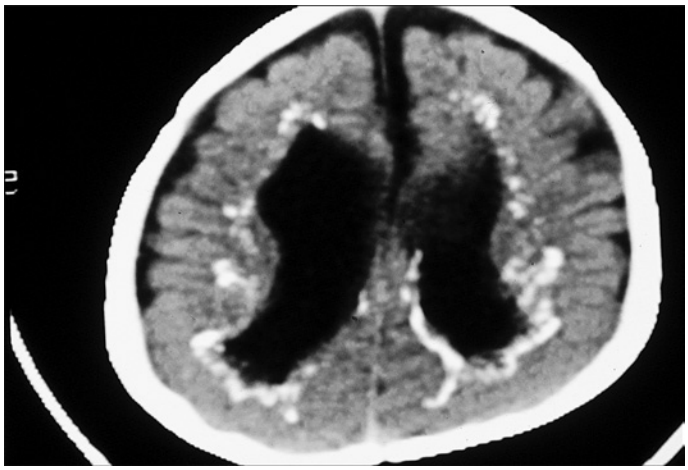

Fig. 12.9 Congenital cytomegalovirus infection with periventricular calcification, hydrocephalus, and cerebral atrophy shown on computed tomography scan.

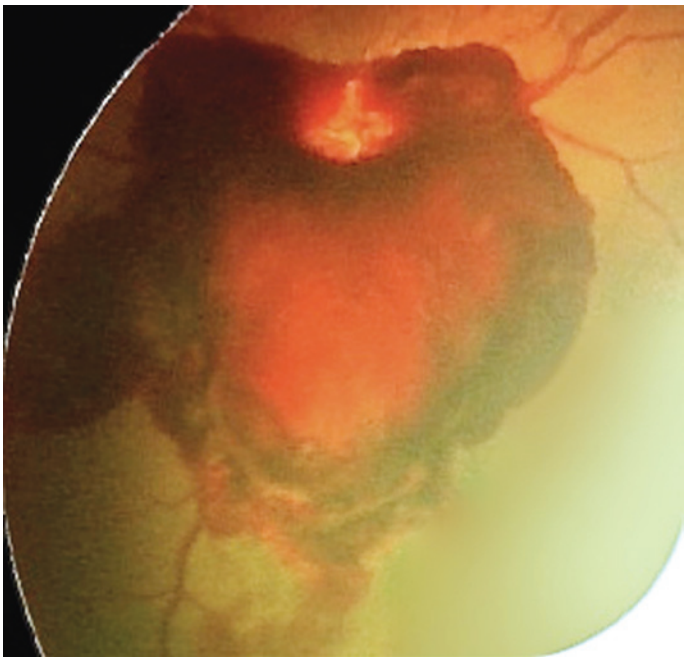

Fig. 12.10 Severe retinal arteritis affecting a newborn baby with congenital herpetic infection.

but less heavily pigmented. Chorioretinal scars can be the only clinical sign of congenital CMV infection, and can develop several weeks after birth.[49] Cyclopia and anophthalmia have also been reported in babies with congenital CMV infection.[50]

Diagnosis is suspected from the presence of IgM antibodies in the baby, and can be definitely confirmed by isolating and culturing the virus from urine or saliva. Culturing the virus from an infant during the first 3 weeks of life confirms the diagnosis.[51]

Intravenous treatment with ganciclovir and foscarnet reduce the severity of hearing loss, but ganciclovir does not seem to alter the time of resolution of CMV retinitis.[52] Trials also show that viruria returns to pretreatment levels after cessation of the drug.[53]

Maternal CMV infection appears to develop after exposure to young children at home or at group childcare settings, so seronegative pregnant women should be vigilant to avoid contracting infection.[47]

Herpes simplex

Infection by herpes simplex virus (HSV) is predominantly a neonatal disease. The transmission occurs at birth by aspirating infected vaginal secretions in 86% of cases usually after a primary genital infection. A congenital infection occurs in 4% of cases, and is due to maternal viremia with transplacental transmission, or an ascending infection into the uterus after premature rupture of the amniotic membranes. Postnatal infection occurs in 10% of cases; possible entry sites include the eyes, scalp, skin, and umbilical cord.[54] The majority of neonatal infections are due to HSV-2, which is the genital strain.[55] HSV-1 is the oral strain, which affects the mouth, eyes, and causes encephalitis.[56]

Neonatal infection can rapidly spread causing systemic involvement and even death; infected infants usually become symptomatic 5–15 days after birth with lethargy, temperature alterations, respiratory distress, anorexia, vomiting, cyanosis, hepatitis, pneumonia, disseminated intravascular coagulation, or encephalitis. The mortality rate of disseminated disease is very high, up to 49%, and a high percentage of babies with encephalitis are neurologically handicapped. Only 26% of survivors develop normally.[56] Patients with the congenital type of disease can have low birthweight, microcephaly, seizures, diffuse brain damage, intracranial calcifications, scars on the skin or digits, pneumonitis, and hepatomegaly.[57]

Ocular manifestations can vary from blepharoconjunctivitis with vesicles on the eyelids, keratitis with epithelial dendrites, to iridocyclitis, iris atrophy, posterior synechiae, and cataracts.[58] Chorioretinitis with vitritis and optic atrophy can occur, especially in infants with central nervous system involvement. Chorioretinal scarring results in well-circumscribed hyperpigmented lesions that typically involve the peripheral retina. White vitreous masses have also been described.[59] Acute retinal necrosis may develop later in life from recrudescence of the virus in scars,[60] which spreads rapidly and circumferentially, with occlusive vasculopathy, arteriolar involvement (Fig. 12.10), and vitreous and anterior chamber inflammation.[61] Microphthalmos may also be associated with microcephaly and intrauterine growth retardation.[59]

The diagnosis should be suspected in infants with progressive icterus, fever, hepatosplenomegaly, and cutaneous vesicular lesions, and is confirmed by isolating the virus from fresh vesicles, nasal secretions, conjunctival secretions, and cerebrospinal fluid (CSF).[56]

Systemic treatment with intravenous acyclovir is the treatment of choice for disseminated disease, but because of the high risk of rapid spread, it also applies for infants with limited cutaneous or ocular involvement, particularly in babies less than 1 month of age. The dose is 30 mg/kg per day for 10 days to 4 weeks.[62] Vidarabine is also administered as a single intravenous infusion of 15 mg/kg per day over 12 hours. Debridement of epithelial keratitis and antiviral topical treatment (acyclovir, vidarabine, idoxuridine, or trifluorothymidine) is also necessary. Herpes simplex blepharoconjunctivitis should

also be treated with topical antiviral therapy as prophylaxis against the development of keratitis.

Syphilis

Congenital syphilis occurs when the fetus is exposed to *Treponema pallidum* after the 16th gestational week. Transmission during the first trimester usually results in death. Virtually 100% of babies exposed to primary maternal infection during pregnancy are affected, and most infants born to mothers with secondary syphilis show signs of congenital syphilis.[63] Half a million pregnancies are affected annually.[64,65] Incidence of the infection decreased in the 1980s and 1990s, but congenital syphilis has increased as a consequence of more primary infections in adults.[63] Transplacental transmission can occur even during periods of maternal seronegativity.[29]

Congenital syphilis has early manifestations due to active infection, or late manifestations that occur later in childhood secondary to ongoing inflammation. Early manifestations include skeletal abnormalities, rhinitis, maculopapular rash, fissures of the lips, nares, and anus, hepatosplenomegaly, anemia, and uveitis. Late manifestations that occur after 2 years of life include nerve deafness, bone changes, dental abnormalities, and interstitial keratitis.[64] Hutchinson's triad is the association of nerve deafness, malformed incisors, and interstitial keratitis.

Ocular manifestations include chorioretinitis, interstitial keratitis, anterior uveitis, iridoschisis, and optic atrophy. Up to 40% of children with untreated congenital syphilis develop interstitial keratitis, which is bilateral in 80% of cases, and develops at 5–20 years of age.[66] This is an infectious and hypersensitivity keratitis, which may progress despite adequate intravenous antibiotics, so treatment with topical steroids is necessary. It is characterized by sectorial or diffuse corneal edema infiltrated by interstitial vessels. It is accompanied by iridocyclitis and iris atrophy. Stromal neovascularization is also usually present and secondary glaucoma can develop. Corneal scarring and residual ghost vessels can cause significant visual loss. Congenital and acquired cataracts are usually due to uveal inflammation. Chorioretinitis affects peripheral areas and manifests as pigment mottling. Severe cases may result in extensive retinal pigmentary changes resembling retinitis pigmentosa.

Pregnant women should be screened for syphilis early in pregnancy and again before delivery to prevent congenital syphilis, which occurs predominantly in the offspring of young, unmarried women with poor antenatal care. Serologic testing includes treponemal tests such as the fluorescein antibody absorption test (FTA-ABS), the microhemagglutination assay for *T. pallidum* (MHA), and the *T. pallidum* particle agglutination assay (TP-PA). Non-treponemal tests include the Venereal Disease Research Laboratory test (VDLR) and the Rapid Plasma Reagin (RPR). Serological tests may be negative in newborns (who can also be asymptomatic initially), making the diagnosis difficult. A quantitative assay of non-treponemal serology with titers four times higher than maternal titers indicates a congenital infection. Treponemal tests are almost always positive in infants with congenital syphilis and should be performed with a non-treponemal test to increase specificity. The treponemes can be isolated from active cutaneous lesions and seen by dark-field microscopy. Additionally, any child with congenital syphilis must have a lumbar puncture and CSF serology examination even if there are no symptoms of neurosyphilis.

Pregnant women with HIV are at a higher risk of having active syphilis, but a higher rate of false negatives occurs in these patients. It is important that infants born to HIV-positive women should be screened for any clinical manifestations of congenital infection in addition to having serologic testing.

The treatment of choice is parenteral penicillin G for 10–14 days, which is usually adequate. Serologic testing should be repeated every 3 months after treatment until serum VDRL or RPR is negative or titers are less than four times their original value. Sometimes repeated parenteral penicillin treatment is necessary if antibody titers remain elevated or begin to rise.

Varicella zoster virus

Intrauterine infection by varicella zoster virus, also known as chickenpox, is rare, since more than 90% of women of childbearing age have virus-specific immunity.[67] However, nearly one-third of affected infants die during the first few months.[68] Infection in the first and second trimesters may lead to congenital varicella syndrome (CVS); maternal infection near term may result in neonatal disseminated infection. Fetal infection occurs by transplacental transmission.

Systemic manifestations include cicatricial skin lesions (Fig. 12.11), limb hypoplasia, and since the virus has high affinity for the central nervous system, seizures, neurologic defects, and cortical atrophy can be present; they can also have low birthweight for gestational age and neuropathic bladder. Ocular manifestations include chorioretinitis, which is the most common ocular manifestation, characterized by single or multiple deeply pigmented chorioretinal scars and atrophy closely resembling toxoplasmosis lesions[69] (Fig. 12.12). Cataracts, microphthalmos, optic nerve hypoplasia, and Horner syndrome have been reported as well.

The congenital varicella syndrome may be overlooked since the clinical findings may be subtle and non-specific. The diagnosis is confirmed by detection of the viral DNA in the infant, presence of specific IgM antibodies and/or persistence of IgG antibodies beyond 7 months of age, or the appearance of zoster during early infancy.

Prevention includes vaccination of seronegative women prior to pregnancy and avoidance of exposure to varicella

Fig. 12.11 Cicatrical skin lesions on a child with congenital varicella.

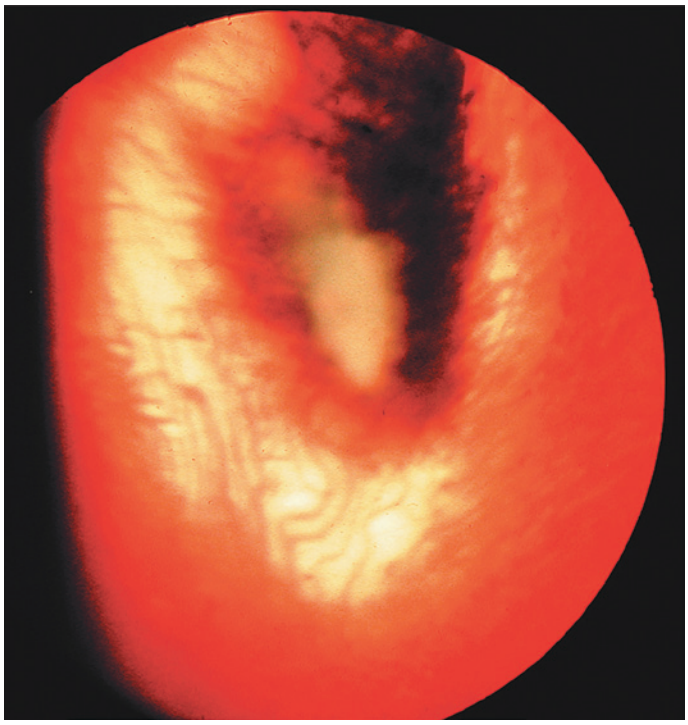

Fig. 12.12 Chorioretinal scar in a child with congenital varicella syndrome.

zoster during pregnancy. Pregnant women exposed to varicella who are seronegative should receive an injection of varicella zoster immunoglobulin. However, there are no controlled studies on the utility of antiviral therapy in preventing fetal transmission.[70]

Other

Lymphocytic choriomeningitis virus is an RNA virus with a rodent reservoir. Transmission to humans may be airborne, from contamination of food by infected mouse urine, feces, and saliva, or from bites of infected mice. Transmission of the fetus occurs during maternal viremia.

Systemic finding in the neonate include macrocephaly or microcephaly, hydrocephalus, meningitis, hepatosplenomegaly, and neurological abnormalities such as cerebral palsy, mental retardation, and seizures. The most common ocular manifestation is chorioretinal scarring, which is indistinguishable from toxoplasmosis scars; they can affect the peripheral retina or the macula. Optic atrophy can also be present.[71,72] There is no known effective treatment.

West nile virus is an RNA flavivirus transmitted to humans by mosquitos. Transmission can occur transplacentally and through breast milk. Most infections are asymptomatic. Systemic manifestations include pharyngitis, arthralgia, skin rash, encephalitis, meningitis, or paralysis. The most common ocular manifestation is chorioretinitis, which has been reported in congenital infection.

Human immunodeficiency syndrome intrauterine infection has decreased significantly with the advent of new drugs. These patients can present with CMV or toxoplasmic chorioretinitis.[73]

Fig. 12.13 Fundus of a 37 week gestation Brazilian baby born with microcephaly. The mother had an asymptomatic pregnancy. The macular area shows an oval, well circumscribed punched out chorioretinal lesion. Courtesy of Dr Camila Ventura.

Zika virus is a member of the Faviviridae virus; mosquitoes from the Aedes family are the vectors, which infect humans by direct inoculation.[74] An infection from a pregnant woman can spread to the foetus causing serious brain malformations and microcephaly,[75-76] as well as ophthalmic abnormalities which including focal pigment mottling and chorioretinal atrophy that can affect the macula (Fig. 12.13). These can be circumscribed areas with no choroidal vessels visible, or circumscribed areas of pigmentary clumping. Other ocular findings include optic nerve hypoplasia, severe optic disc cupping, lens subluxation, and iris colobomas.[77]

A widespread outbreak of Zika virus began in April 2015 in Brazil, and has spread to other countries in South America, Central America, Mexico and the Caribbean. 1.5 million people have been infected by Zika in Brazil, and more than 3,500 cases of microcephaly were reported between October 2015 and January 2016. [78-79]

There is no vaccine to prevent infection, and at present there is no treatment available.[80]

Neonatal conjunctivitis or ophthalmia neonatorum is an inflammation or infection of the conjunctiva occurring within the first month of life. It is the most common infection in the first month of life, with an incidence from 1% to 24%, depending upon geographic region.[1] The three etiologies of neonatal conjunctivitis are chemical, bacterial, and viral. Though some types of conjunctivitis are self-limited and not vision threatening, others have important systemic associations or can cause blindness.

Common signs include conjunctival injection, chemosis, discharge, and eyelid edema. Some signs, such as laterality, severity of inflammation, character of discharge, and presence of pseudomembranes or skin vesicles, can be suggestive of a specific etiology, as can the clinical and maternal history. Generally, age at onset of conjunctivitis is not a reliable indicator of etiology.

Prophylaxis

Credé first described the use of ocular prophylaxis in newborns.[2] The widespread use of prophylaxis resulted in a great reduction in conjunctivitis-related blindness, but unfortunately ophthalmia neonatorum-related corneal scarring remains a leading cause of childhood blindness in developing countries.[3,4]

Types of prophylaxis include silver nitrate 1%, povidone iodine 2.5%, erythromycin ointment 0.5%, and tetracycline ointment 1%. These agents are meant to be administered to the inferior conjunctival fornix of both eyes within 1 hour of an infant's delivery. Silver nitrate is the agent most likely to cause a chemical conjunctivitis. Silver nitrate and tetracycline have demonstrated equal efficacy (83–93%) in the prevention of gonococcal ophthalmia neonatorum.[5] In a randomized controlled trial of 3117 Kenyan newborns, povidone iodine 2.5% was more effective than erythromycin or silver nitrate for prophylaxis of infectious conjunctivitis (13.1% vs. 17.5% vs. 15.2%).[6] In a smaller trial involving 410 Israeli newborns, the rate of infectious conjunctivitis appeared higher with povidone iodine (10.4%) than tetracycline (5.4%), but the difference failed to reach statistical significance ($p=0.052$); as expected, povidone iodine was more likely to cause a chemical conjunctivitis compared to tetracycline (5% vs. 0%).[7] When using povidone iodine, care should be taken to use a prep solution and not a scrub formulation, which causes significant chemical conjunctivitis and even corneal decompensation.

In the United States, erythromycin 0.5% is used as the topical prophylactic agent, as the other agents are not commercially available there. During an erythromycin shortage in 2009, the Centers for Disease Control recommended topical azithromycin 1% solution, or, if unavailable, topical gentamicin 0.3% or tobramycin 0.3% ointments. However, azithromycin is approximately 10 times more costly than povidone iodine prepared by a hospital pharmacy,[8] and topical gentamicin can cause periocular ulcerative dermatitis and should be avoided.[9]

Term colostrum shows insufficient antibacterial activity to be used as prophylaxis for neonatal conjunctivitis, and term milk shows no inhibitory activity.[10]

Chemical conjunctivitis

Chemical conjunctivitis develops within 1–2 days after the administration of a topical agent and is bilateral. Gram stain shows leukocytes but no organisms. Conservative management typically results in gradual resolution of symptoms within a couple of days.

Chlamydial conjunctivitis

The prevalence of *Chlamydia trachomatis* among pregnant women ranges from 2% to 20%; the higher rates are among younger women, and those without prenatal care.[11] The likelihood that an infant born to a mother with untreated *C. trachomatis* infection develops symptomatic conjunctivitis ranges from 20% to 50%.[5,12]

Chlamydial conjunctivitis (Fig. 13.1A) typically develops 5–14 days after delivery but can begin earlier. Though more

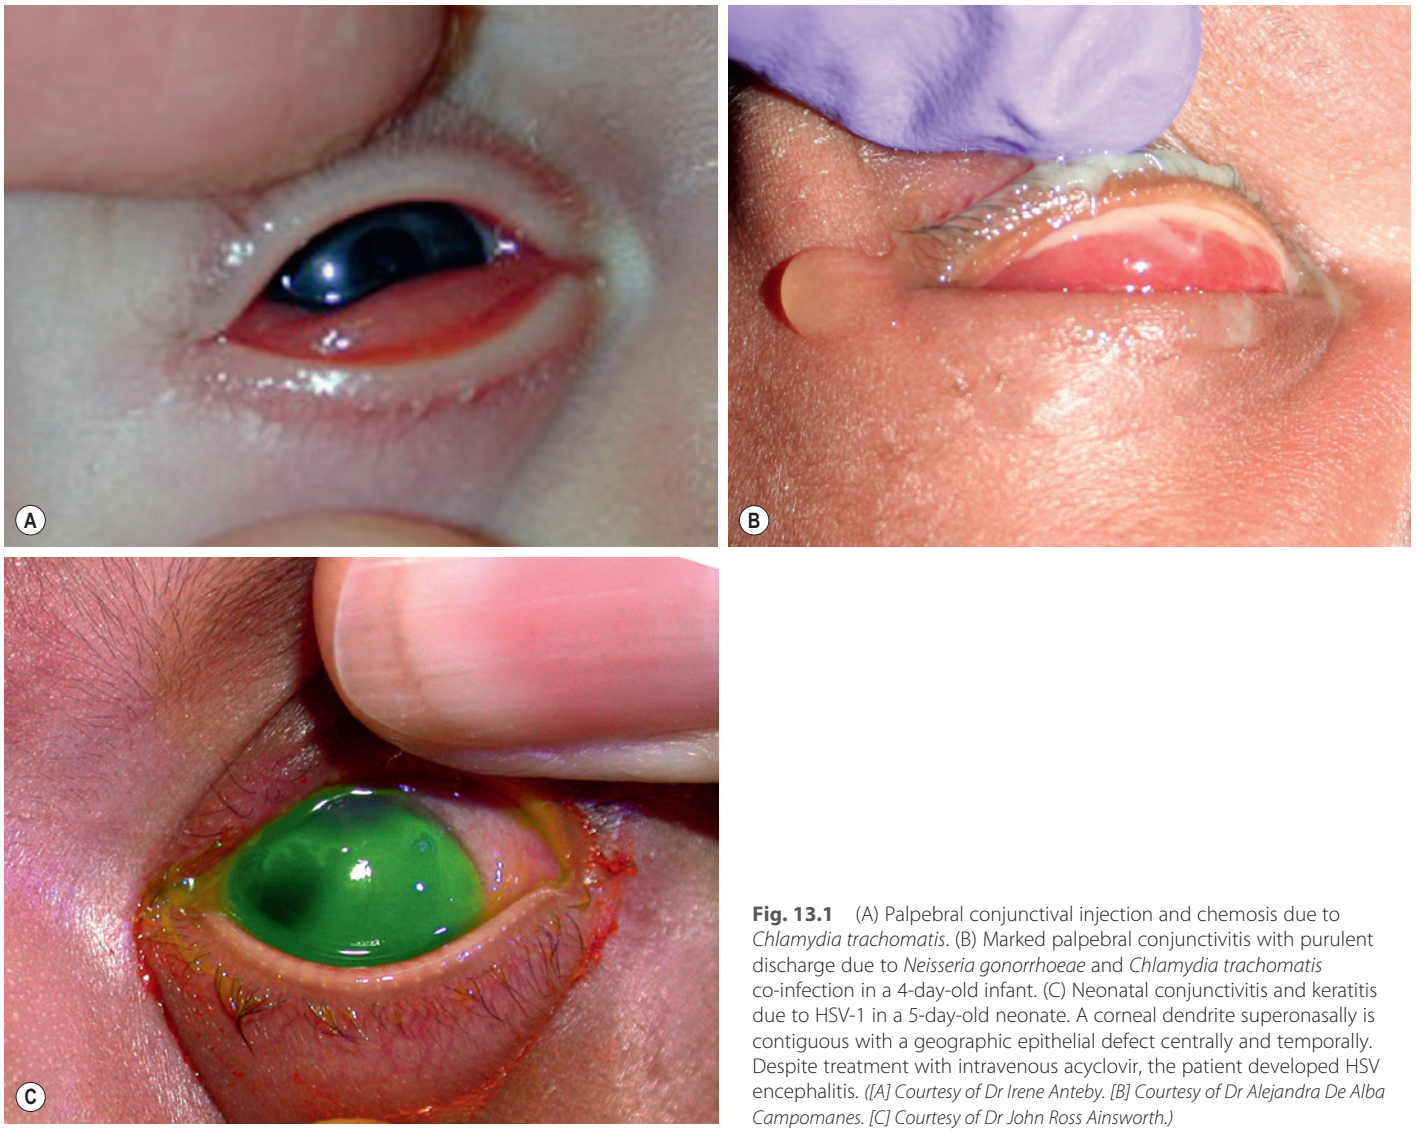

Fig. 13.1 (A) Palpebral conjunctival injection and chemosis due to *Chlamydia trachomatis*. (B) Marked palpebral conjunctivitis with purulent discharge due to *Neisseria gonorrhoeae* and *Chlamydia trachomatis* co-infection in a 4-day-old infant. (C) Neonatal conjunctivitis and keratitis due to HSV-1 in a 5-day-old neonate. A corneal dendrite superonasally is contiguous with a geographic epithelial defect centrally and temporally. Despite treatment with intravenous acyclovir, the patient developed HSV encephalitis. *([A] Courtesy of Dr Irene Anteby. [B] Courtesy of Dr Alejandra De Alba Campomanes. [C] Courtesy of Dr John Ross Ainsworth.)*

common among infants born vaginally, it can follow cesarean section delivery. The conjunctivitis can be unilateral or bilateral, with mucopurulent discharge and possible pseudomembrane formation. Untreated, the conjunctivitis resolves after weeks to months, but can cause conjunctival and corneal scarring, which can be blinding. Furthermore, if left untreated, it is contagious, posing a public health threat to others.

Classically, the diagnosis is made by isolating *Chlamydia* via culture obtained by scraping the palpebral conjunctiva for epithelial cells. Intracellular inclusions can be demonstrated on Giemsa stain. Recently, polymerase chain reaction (PCR) detection was found to have higher sensitivity (100%) and similarly high specificity (95%) compared with culture and Giemsa stain, and may be superior in mild disease.[13,14]

Chlamydial conjunctivitis is associated with systemic disease including otitis media, nasal congestion, and pneumonitis occurring later, at 4–12 weeks of life. Chlamydial conjunctivitis is treated with oral erythromycin (50 mg/kg divided into 4 daily doses) for 14 days.[11] Asymptomatic infants born to mothers with untreated *C. trachomatis* infection are not treated prophylactically, in part because erythromycin can cause infantile hypertrophic pyloric stenosis.[15] For infants with conjunctivitis but no sign of pneumonia, systemic erythromycin can be delayed while awaiting confirmatory diagnostic tests for *Chlamydia*, but the infant should be monitored closely for systemic signs. Oral azithromycin (20 mg/kg daily for 3 days) is an alternative, though experience with its use in neonates is limited. The mother and her sexual partners should be treated with a single dose of oral azithromycin (1 g) and be evaluated for other sexually transmitted diseases. Some areas with a high incidence of trachoma are instituting annual or biannual mass prophylaxis with oral azithromycin to reduce the incidence of *C. trachomatis*, with moderate success.[16]

Gonococcal conjunctivitis

The prevalence of gonococcal cervical infection among women in developed countries is typically less than 1%; however, the prevalence in some countries is as high as 22%.[17] Newborns of mothers with gonococcal infection who do not receive prophylaxis have a 30–47% likelihood of developing conjunctivitis after vaginal delivery.[12,17] The gonococcal transmission rate increases to 68% if the mother is also infected with *Chlamydia*.[12]

Gonococcal conjunctivitis is also possible among infants born by caesarean section.

Infants typically exhibit symptoms 2–5 days after delivery, but can present later. The conjunctivitis has an aggressive course, with profuse purulent discharge, and severe conjunctival injection, chemosis, and eyelid edema (Fig. 13.1B). Gonococcus can invade the cornea through intact epithelium, leading to keratitis, ulceration, perforation, and endophthalmitis, or corneal scarring with neovascularization. Corneal involvement begins with coarse white peripheral infiltrates. Ulceration can progress rapidly, so aggressive treatment is required.[5] One study showed that 4 of 25 patients (16%) with gonococcal conjunctivitis developed corneal involvement.[18]

All infants born to *N. gonorrhoeae*-infected mothers, whether or not conjunctivitis is present, should be treated prophylactically with a single dose of intravenous (IV) or intramuscular (IM) ceftriaxone (25–50 mg/kg up to 125 mg maximal) or cefotaxime (100 mg/kg IM or IV) if the infant has hyperbilirubinemia.[11] Infants with suspected gonococcal conjunctivitis should undergo Gram stain, culture using modified Thayer-Martin medium, and/or PCR testing, if available, prior to beginning antibiotics, though unnecessary delays in treatment should be avoided. Identification of gram-negative diplococci on Gram stain has a sensitivity of 86% and specificity of 90% for gonococcal conjunctivitis.[18] In febrile infants, blood and cerebrospinal fluid (CSF) cultures should be obtained to assess for bacteremia and meningitis, and the baby should be monitored clinically for septic arthritis. Due to frequent maternal co-infection with *Chlamydia*, Giemsa stain and chlamydial culture and/or PCR testing should also be performed. In the presence of systemic infection, the cephalosporin course is extended to 7–14 days. Antibiotic eye drops may be used, particularly if there is corneal involvement, and frequent (i.e. hourly) saline lavage of the purulent discharge should be performed. The mother and her sexual partners should be treated for gonococcus and presumptively for *Chlamydia*, and should be evaluated for other sexually transmitted diseases.

Other bacterial conjunctivitis

Neonatal nasopharyngeal colonization rather than maternal vaginal colonization is implicated in most bacterial conjunctivitides not due to *Chlamydia* or *Gonococcus*.[19] *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus viridans*, *Enterococcus* spp., and *Haemophilus* spp. are more commonly isolated from conjunctival swabs in neonates with conjunctivitis compared to controls without.[19,20] Bacterial conjunctivitis typically presents at days 5–14 of life and can be unilateral or bilateral. Bacteria can be cultured on chocolate and blood agar. Some positive cultures represent colonizing rather than disease-causing bacteria. A broad-spectrum topical antibiotic can be used until culture results are available, but many cases resolve without treatment.

Herpetic conjunctivitis

Herpes simplex virus (HSV) can rarely cause neonatal conjunctivitis. Neonates can become infected via vaginal delivery or ascending intrauterine infection if the mother has genital HSV. The risk of infection is far greater if the mother has primary rather than re-activated genital HSV (25–60% vs. 2%). Neonates can also become infected via direct contact with caregivers who have herpes labialis or herpetic whitlow.[11]

Ophthalmic manifestations of neonatal HSV include eyelid vesicles and erythema, conjunctivitis, keratitis, and anterior uveitis (Fig. 13.1C). The keratitis can involve all layers of the cornea and does not follow the disease patterns seen in adults. Ophthalmic manifestations usually occur 5–14 days after exposure. Neonatal HSV keratoconjunctivitis typically occurs in the setting of systemic disease, which can include disseminated disease (pneumonitis, hepatitis), skin disease (dermatitis, mucositis), and central nervous system (CNS) disease (meningoencephalitis). The onset of systemic disease can be delayed up to 6 weeks from birth.

HSV culture or PCR testing (of conjunctiva, corneal epithelium, or skin vesicle scraping), CSF analysis, including HSV PCR, and liver function tests should be obtained in neonates with suspected HSV keratoconjunctivitis. Other rapid diagnostic techniques include direct fluorescent antibody staining or enzyme immunoassay detection of HSV antigens within scrapings. However, serum HSV antibody testing is not useful in neonates.

Asymptomatic infants are treated with prophylactic IV acyclovir if they are born to mothers with primary genital HSV at the time of vaginal delivery or if surface testing detects HSV. Neonatal HSV infection is treated with IV acyclovir (60 mg/kg per day divided into three doses) for 14 days, or for 21 days in the presence of disseminated or CNS disease.[11] Adjunctive therapy with topical trifluorouridine 1%, iododeoxyuridine 0.1%, or vidarabine 3% can be considered, but topical ganciclovir 0.15% ophthalmic gel has less corneal toxicity. A topical steroid may be added for corneal stromal and endothelial disease if the corneal epithelium is intact, and topical steroid and cycloplegia for uveitis. Babies with neonatal HSV have a high risk of death and are hospitalized for the duration of IV treatment.[11] They are also at high risk of HSV re-activation, and prophylactic acyclovir should be continued for at least 6 months after hospital discharge.[21]

Neonatal conjunctivitis in the hospital

Hospitalized neonates acquire infection via hospital workers and instruments, and via assisted ventilation, which is thought to increase the contact of nasopharyngeal flora with the eye.[21] Most of these infants are premature or have multiple comorbidities. Coagulase-negative staphylococci, *Staphylococcus aureus* and *Klebsiella* spp. were the most commonly isolated species in a study of 200 neonates in a US intensive care nursery.[22] *Serratia marcescens* is another common cause of conjunctivitis outbreaks in neonatal intensive care nurseries, and has been found to cause 27% of conjunctivitis in some parts of the world.[23,24] Methicillin-resistant *Staphylococcus aureus* has also caused conjunctivitis outbreaks in neonatal intensive care units,[25] and its incidence is possibly increasing.[26]

Laboratory testing

While the clinical history can sometimes help to guide appropriate laboratory testing, multiple infectious causes are

typically in the differential diagnosis, so broad laboratory testing including the following is usually required:

- Gram stain.
- Chlamydial culture, PCR, or Giemsa stain.
- Gonococcal culture on Thayer-Martin medium or PCR.
- Bacterial cultures using blood or chocolate agar.
- HSV culture, PCR, direct fluorescent antibody, or enzyme immunoassays.

Approximately half of clinically evident neonatal conjunctivitides have negative culture results; therefore, empiric treatment is often the mainstay of management.[19]

REFERENCES

The diagnosis of infective preseptal and orbital cellulitis is clinical. The goal is to prevent rapid deterioration and serious sequelae such as visual loss, cavernous sinus thrombosis, cerebral abscess, osteomyelitis, and septicemia. It must be managed promptly with appropriate antibiotics and medical support from a multidisciplinary team consisting of pediatricians, ophthalmologists, ear, nose and throat (ENT) surgeons, nurses, and radiologists. Regular evaluation for progression of signs or deterioration of the clinical picture is essential. Neuroimaging may be necessary to determine the extent of the disease.

Anatomy and terminology

The orbital septum marks the anterior extent of the orbit. Its firm attachment to the orbital rim along with the attachment of the orbital periosteum is referred to as the arcus marginalis; it extends to the upper and lower tarsal plates. Preseptal cellulitis is a descriptive term for patients who present with symptoms and signs of inflammation confined largely to the eyelids: pain, redness, and swelling. The orbital septum acts as a physical barrier to lesions spreading posteriorly to the orbit. Orbital cellulitis involves infection of the postseptal space and usually results from adjacent infected sinuses, commonly the ethmoids. Many vessels and nerves pierce the thin lamina papyracea between the ethmoid sinuses and the orbit: infection easily spreads through these and other naturally occurring perforations, and may lift off the loosely attached periosteum within the anterior orbit, resulting in a subperiosteal abscess. An orbital abscess results from an infectious breach of the periosteum or seeding into the orbit. Extension of infection from the ethmoids into the brain may result in meningitis and cerebral abscesses. The presence of decreased, painful eye movements, proptosis, optic neuropathy, or radiological evidence of orbital inflammation or collections signifies orbital cellulitis.

The drainage of the eyelids, sinuses, and orbits is largely by the orbital venous system, which empties into the cavernous sinus via the superior and inferior orbital veins. Since it is devoid of valves, infection may spread in both preseptal and orbital cellulitis, leading to the serious sight- and life-threatening complication of cavernous sinus thrombosis.

Classification

Infective orbital cellulitis and its complications can be classified into five types that are not mutually exclusive and do not necessarily progress in that order[1] (Table 14.1):

1. preseptal cellulitis;
2. orbital cellulitis;
3. subperiosteal abscess;
4. orbital abscess;
5. cavernous sinus thrombosis.

Preseptal cellulitis

Preseptal cellulitis is five times more common than orbital cellulitis, especially in children under the age of 5 years.[2,3] It is often secondary to lid and cutaneous infections – styes, impetigo, erysipelas, herpes simplex, varicella, or dacryocystitis (Figs 14.1, 14.2, and 14.3). It is also associated with upper respiratory tract infections, uncomplicated sinusitis (Fig. 14.4), or lid trauma.

Infective preseptal cellulitis must be distinguished from other causes of lid edema such as adenoviral keratoconjunctivitis, atopic conjunctivitis, or, rarely, Kawasaki disease.[4] In one series, 16% of children referred with preseptal cellulitis were found to have adenoviral keratoconjunctivitis.[5]

Clinical assessment

History

Children with preseptal cellulitis associated with an upper respiratory tract infection or sinusitis present in the winter

months with preceding nasal discharge, cough, fever, localized tenderness, and general malaise, followed by unilateral eyelid swelling. Bilateral involvement is rare. There is history of a localized lid infection or trauma with swelling spreading from an identifiable point.

Examination

The child may be generally unwell and febrile. The cellulitis ranges from a mild localized involvement, with or without an abscess, to generalized tense upper and lower lid edema spreading to the cheek and brow, precluding examination of the eye. Localized causes such as styes, trauma, and dacryocystitis should be evident. There is an absence of proptosis; optic nerve functions and extraocular movements are normal.

It can be difficult to differentiate between preseptal and orbital cellulitis and the diagnosis may change from preseptal to orbital cellulitis if orbital signs become more obvious, clinically or by imaging.[6]

Table 14.1 Classification of orbital cellulitis

Stage	Signs and symptoms	Computed tomography findings
Preseptal cellulitis	Eyelid swelling, occasional fever	If performed, sinusitis may be present
Orbital cellulitis	Proptosis, decreased painful eye movements, chemosis	Sinusitis, mild soft tissue changes in the orbit
Subperiosteal abscess	Signs of orbital cellulitis, systemic involvement	Subperiosteal abscess, globe displacement, soft tissue changes in the orbit
Orbital abscess	Signs of orbital cellulitis, systemic involvement, ophthalmoplegia, visual loss	Orbital collection of pus with marked soft tissue changes of the fat and muscles
Intracranial complication	Signs of orbital or rarely preseptal cellulitis, marked proptosis, cranial nerve palsies (III, IV, V, VI)	Intracranial changes: cavernous sinus thrombosis, extradural abscess, meningitis, and osteomyelitis

Fig. 14.1 Preseptal cellulitis secondary to eczema herpeticum.

Fig. 14.2 (A) Preseptal cellulitis associated with a lid abscess. Normal eye movements with a white eye (patient looking up). (B) Intravenous antibiotics and surgical drainage resolved her condition.

Fig. 14.3 (A) Cellulitis associated with dacryocystitis in a 1-year-old child. (B) Acute infection resolved with antibiotics. Patient subsequently underwent probing to treat the underlying nasolacrimal duct obstruction.

Fig. 14.4 Preseptal/orbital cellulitis treated successfully with intravenous antibiotics. (A) At presentation with swollen lids and possibly mild proptosis. Patient was admitted under pediatricians, ophthalmologist, and ENT. She was treated immediately with intravenous antibiotics. No imaging was performed. (B) Responding to antibiotics within 12 hours. (C) Fully resolved at 4 days.

The clinical picture varies with the organism involved. In staphylococcal infections there is a purulent discharge, while *Haemophilus* infection leads to a non-purulent cellulitis with a characteristic bluish-purple discoloration of the eyelid with irritability, raised temperature, and sometimes otitis media (Fig. 14.5). In streptococcal infection there is usually a sharply demarcated red area of induration,[7] heat, and marked tenderness (Fig. 14.6A,B). Preseptal cellulitis may be complicated by meningitis, particularly if the infection is due to *Haemophilus influenzae* type B.[8]

Management

In children who develop preseptal cellulitis following an upper respiratory tract infection, cultures should be taken from the nose, throat, conjunctiva, and any accessible aspirates of the periorbital edema.

Children with mild-to-moderate preseptal cellulitis can be managed in the same way as uncomplicated sinusitis on an outpatient basis with oral broad-spectrum antibiotics, or as an inpatient with intravenous antibiotics if more severe (Table 14.2).[9,10]

Admission, intravenous antibiotics, and close observation may be more appropriate in more severe preseptal cellulitis, young children, the immunocompromised, or those who are systemically unwell.

Neuroimaging to assess orbital, sinus, and brain involvement is indicated when lid swelling prevents an adequate examination of the eye.[11]

Children with a local cause for the periorbital edema, such as dacryocystitis, need specific treatment for the underlying condition and rarely need further investigation.

Fig. 14.5 Preseptal cellulitis due to *Haemophilus influenzae* in a 6-month-old infant.

Table 14.2 Initial antibiotic treatment of preseptal and orbital cellulitis

Preseptal cellulitis	Associated with upper respiratory tract infection Cefuroxime 100–150 mg/kg per day or amoxicillin-clavulanate (Augmentin) or ampicillin 50–100 mg/kg per day
Orbital cellulitis	Empiric combination of two or more antibiotics may be initiated. This may include a third-generation cephalosporin with good CNS penetrance coupled with gram-positive antibiotic cover. Metronidazole can be added according to clinical suspicion of anaerobic organisms. Flucloxacillin: 50 mg/kg qds IV (max 2 g/dose) Co-amoxiclav: 30 mg/kg tds (max 1.2 g/dose) Metronidazole: 7.5 mg/kg tds (max 500 mg/dose) Vancomycin should be considered in resistant cases Clindamycin should be added in necrotizing fasciitis

Note: You should consult your own pharmacy for correct doses.
The exact dose will vary with age and severity of infection.
There may be local variations in pathogens and antibiotic resistance.
Development of a local antibiotic policy in conjunction with a microbiologist is recommended

Fig. 14.6 (A) Streptoccocal preseptal cellulitis in a 12-month-old child. (B) It is useful to mark the extent of cellulitis for monitoring purposes. This 10-year-old girl had proptosis and responded to intravenous antibiotics.

Fig. 14.7 Beta-hemolytic *Streptococcus* may cause necrotizing fasciitis, as shown here. *(Courtesy of Mr G. Rose.)*

Lid trauma may result in suppurative cellulitis, when the causative agent is *Staphylococcus aureus* or a beta-hemolytic *Streptococcus*. It is usually sufficient to culture the wound discharge, as there is rarely any bacteremia; blood cultures are usually negative.[12] Parenteral antibiotics are administered and tetanus prophylaxis is provided, if appropriate. If the skin has been penetrated by organic material or animal bites, antibiotics should include coverage for anaerobic organisms.

Rarely, beta-hemolytic *Streptococcus* may cause necrotizing fasciitis. It is characterized by a rapidly progressive tense and shiny cellulitis with excessive edema and poorly demarcated borders with a violaceous skin discoloration. Necrosis develops and streptococcal toxic shock syndrome is common (Fig. 14.7). Treatment is with immediate hospitalization involving a multidisciplinary team implementing resuscitation and medical support with immediate high-dose intravenous antibiotics including a penicillin or third-generation cephalosporin and clindamycin. Surgical debridement should be considered if there is not a clear response to medical treatment.[13,14]

Orbital cellulitis

Etiology

Infective orbital cellulitis is more frequent in children over 5 years (average age 7 years). In over 90% it is secondary to sinusitis,[12,15] especially of the ethmoid. It is more common in cold weather when the frequency of sinusitis increases. Other less common causes are penetrating orbital trauma, especially when there is a retained foreign body, dental infections,[16] extraocular muscle and retinal surgery,[17] and hematogenous spread during a systemic infectious illness.

Orbital cellulitis is always serious and potentially sight- and life-threatening, giving rise to a variety of systemic and ocular complications (Box 14.1). In the pre-antibiotic era, one-fifth of patients died from septic intracranial complications; one-third of the survivors lost vision in the affected eye.[18] This poor outlook has been dramatically altered by effective antibiotics and the changing spectrum of causative organisms, but prompt diagnosis and vigorous treatment are still essential.

History

The usual presentation is with a painful red eye and increasing lid edema in a child who has had a recent upper respiratory tract infection. The child is usually miserable, pyrexial, and unwell.

Box 14.1

Complications of orbital cellulitis

Optic neuritis
Optic atrophy
Exposure keratitis
Central retinal artery occlusion[19]
Retinal and choroidal ischemia[20]
Subperiosteal and orbital abscess[23,24]
Cavernous sinus thrombosis
Meningitis[12]
Brain abscess
Septicemia[22]

Table 14.3 The differential diagnosis of inflammatory proptosis

Infection	Orbital cellulitis or cavernous sinus thrombosis
Idiopathic and specific inflammation	Orbital idiopathic inflammation, myositis, sarcoidosis, and Wegener granulomatosis
Neoplasia	Leukemia, Burkitt lymphoma, rhabdomyosarcoma, extra-scleral retinoblastoma, metastatic carcinoma, histiocytosis X (Letterer–Siwe variety), dermoid cyst (rupture and inflammation), and ethmoid osteoma
Trauma	Traumatic hematoma, orbital emphysema, retained foreign body
Systemic	Sickle cell disease (bone infarction) conditions
Endocrine	Dysthyroid exophthalmos (very rare) dysfunction

Modified from Jain A, Rubin PA. Orbital cellulitis in children. Int Ophthalmol Clin 2001; 41: 71–86.

Examination

There are signs of orbital dysfunction, including proptosis, reduced and painful extraocular movements, and optic nerve dysfunction. There may be involvement of cranial nerves III, IV, and VI, especially with superior orbital fissure and cavernous sinus involvement. Visual loss, when it occurs, is usually due to an optic neuropathy but may also be caused by exposure keratitis or a retinal vascular occlusion.[19,20]

The acute, sometimes explosive, onset of pain, fever, and systemic illness helps to differentiate orbital cellulitis from most other causes of inflammatory proptosis, which should always be considered when seeing a patient with cellulitis (Table 14.3 and Fig. 14.8A–D).

Orbital cellulitis is partially constrained by the septum at the arcus marginalis; the preseptal soft tissue signs may be less dramatic than those in preseptal cellulitis. Conjunctival chemosis and injection may be subtle or even absent.

Management

Children with orbital cellulitis should be admitted under the care of pediatricians, ophthalmologists, ENT surgeons, and the infectious disease team. Blood cultures, nasal, throat, and conjunctival microbiology swabs may be taken. These are often negative, but a positive result is helpful in planning antibiotic treatment. This should not delay immediate and appropriate intravenous antibiotics and fluid resuscitation where necessary.

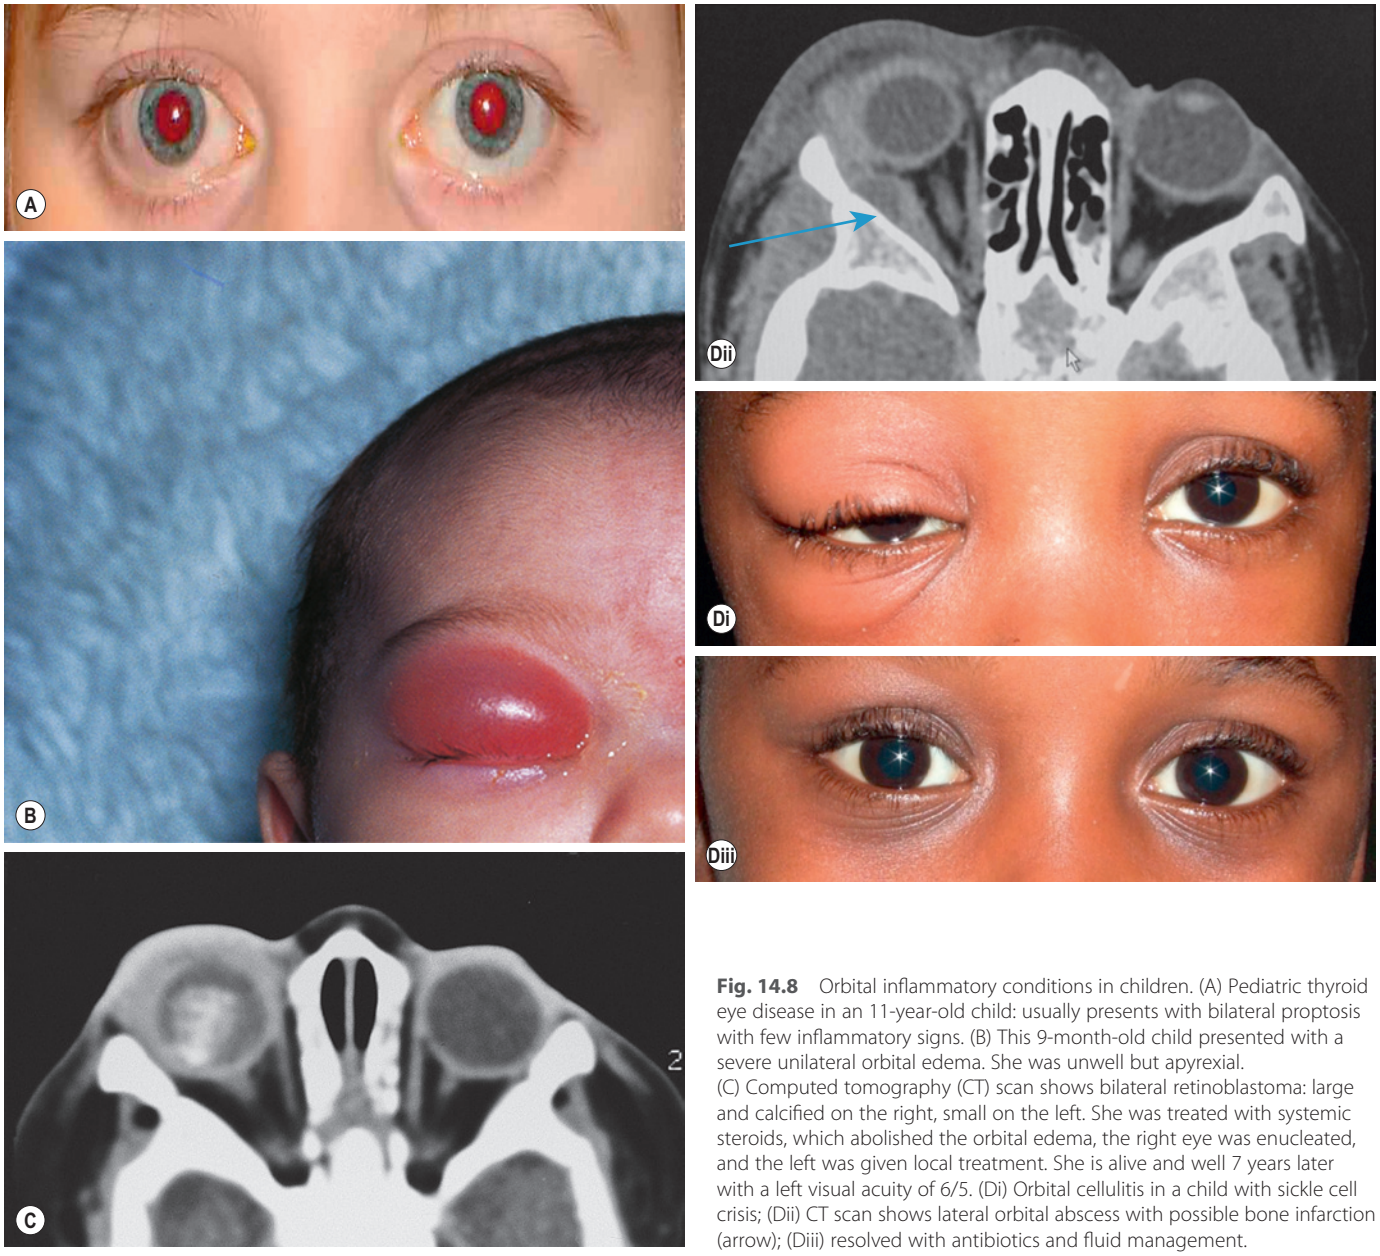

Fig. 14.8 Orbital inflammatory conditions in children. (A) Pediatric thyroid eye disease in an 11-year-old child: usually presents with bilateral proptosis with few inflammatory signs. (B) This 9-month-old child presented with a severe unilateral orbital edema. She was unwell but apyrexial. (C) Computed tomography (CT) scan shows bilateral retinoblastoma: large and calcified on the right, small on the left. She was treated with systemic steroids, which abolished the orbital edema, the right eye was enucleated, and the left was given local treatment. She is alive and well 7 years later with a left visual acuity of 6/5. (Di) Orbital cellulitis in a child with sickle cell crisis; (Dii) CT scan shows lateral orbital abscess with possible bone infarction (arrow); (Diii) resolved with antibiotics and fluid management.

The initial treatment of orbital cellulitis in infants should be with a high-dose intravenous third-generation cephalosporin, such as cefotaxime, ceftazidime, or ceftriaxone, combined with a penicillinase-resistant penicillin. Given the potential intracranial complications of orbital cellulitis, antibiotics with good blood–brain barrier penetration are thought to be advantageous.[21] In older children, sinusitis is frequently caused by mixed aerobic and anaerobic organisms so clindamycin may be substituted for penicillinase-resistant penicillin. Metronidazole is now being increasingly used in younger children. An alternative regimen is the combination of penicillinase-resistant penicillin with chloramphenicol (see Table 14.2). The initial regime may be modified after culture results. Nasal decongestants such as ephedrine may be helpful in promoting intranasal drainage of infected sinuses. The child should be monitored closely for deterioration of ocular and systemic signs and management modified.

Steroids in orbital cellulitis

Evidence for the use of steroids in pediatric orbital cellulitis is emerging, but remains limited.[22,23] The potential for immunosuppression in the presence of infection courts controversy. However, advocates of adjuvant steroids cite improved outcomes with steroids in meningitis and two recent studies of orbital cellulitis within pediatric populations demonstrated some benefits when steroids were added. One of these studies randomized patients with orbital cellulitis over 10 years age who had already received intravenous antibiotics for 3–5 days and shown a clinical response to either receive steroids or continue antibiotic therapy.[22] Steroids appeared to hasten clinical recovery, although long-term outcomes were similar in each treatment group. The second study investigated whether systemic steroids offered a benefit and also used C-reactive protein (CFP) as a marker for initiating treatment.[23]

The authors concluded that children receiving oral steroids once the CRP has fallen below 4 g/dl were discharged from hospital earlier. It will be interesting to see whether further evidence leads to wider adoption of steroids and at what point in treatment algorithms steroids should be considered.

Orbital imaging

Computed tomography (CT) is the investigation of choice. CT is usually readily available. The quick acquisition of images (compared to magnetic resonance imaging [MRI]) makes it ideal for children in the urgent-care setting of orbital cellulitis. CT will define the extent of sinus disease, intracranial involvement, subperiosteal or orbital abscesses, and should include coronal views to avoid potentially missing an abscess in a third of patients.[24] Although a CT scan may detect subperiosteal (Figs 14.9 and 14.10) and orbital abscesses not apparent clinically or on plain films,[11,25] the management of mild and moderate orbital cellulitis without optic nerve compromise or intracranial complications is initially medical. Imaging may be unnecessary unless there is a poor response to intravenous antibiotics, increasing systemic signs, progression of orbital signs, or expectant surgical management. MRI scanning is advantageous in that there is no radiation exposure, but the long acquisition time and the need for sedation or anesthesia in children makes it a second-line modality. It is more sensitive than CT in detecting intracranial complications such as cavernous sinus thrombosis where a false negative CT is more likely in early disease. MRI may be more sensitive than CT in delineating the extent of fungal sinus disease. The T2-weighted MRI in mycotic infection may appear hypodense due to paramagnetic material produced by the fungi.[26]

Sinus X-rays may be difficult to interpret in small children due to the lack of development of the sinuses and are generally unhelpful.

Microbiology of preseptal and orbital cellulitis

Historically, the most feared pathogen in both preseptal and orbital cellulitis, as well as sinusitis, was *H. influenzae* type B (Hib). Vaccination against Hib was widely available from 1990. In a study of 315 preseptal and orbital cellulitis cases, 297 were preseptal and 18 were orbital cellulitis. Before 1990, 12% were found to be Hib-related cellulitis and after 1990, 3.5%. The overall rate of cellulitis also declined by 60% in the 1990s.[3] The dramatic decline of culture-positive infection may be due to higher threshold for admission (managed care), improved general child health, and earlier and more aggressive outpatient use of antibiotics (e.g. oral cephalosporins).

In younger children, the most common pathogens, in the post-Hib-vaccine era, became *Staphylococcus aureus* and *Staphylococcus epidermidis*; *Streptococcus pneumoniae*, *Strep. pyogenes*, and *Strep. sanguinis*; and *Moraxella catarrhalis*.[3,6] These organisms mirror the microbiology of sinusitis. Older children have bacteriologically more complex sinus infections and, therefore, orbital cellulitis.[27] Polymicrobial infections and anaerobic infections are more common in older children

Methicillin-resistant *Staph. aureus* (MRSA) orbital cellulitis is a serious concern. Increasing prevalence, especially in the community, has led to empiric antibiotic choices changing, with the increasing use of vancomycin. MRSA was reported in as many as 73% of all *Staph. aureus* orbital cellulitis isolates in one US study.[28] However, two other contemporary studies reported 1% of patients or 12% of *Staph. aureus* isolates to be methicillin resistant.[29,30] The variation highlights the need for obtaining microbiology samples where possible and developing a locally tailored antibiotic policy in conjunction with a microbiologist. Treatment options for MRSA orbital cellulitis include vancomycin or clindamycin.[31] MRSA infections present a challenge, not only due to their antibiotic resistance, but also because of the production of powerful leucocidins and enterotoxins blunting the immune response and enhancing their pathogenicity.[32,33] In Liao and Harris's 2002–2012 pediatric and adult orbital subperiosteal abscess (SPA) series, all four MRSA-positive pediatric cases presented with advanced disease prompting emergency drainage.[33] MRSA orbital cellulitis infections may also present in an atypical fashion.[31] A preceding upper respiratory tract infection with sinusitis is typically absent, as is any penetrating skin injury. Lacrimal gland abscess was a feature in five of six children in a series of MRSA orbital cellulitis reported by Mathias et al., and surgical drainage was required in almost all cases.[31]

Fungal infections are rare but should be considered when orbital cellulitis occurs in an immunosuppressed or diabetic child.[34] Children with cystic fibrosis are more likely to be infected with *Pseudomonas aeruginosa* or *Staph. aureus*.

Subperiosteal and orbital abscess

The incidence of subperiosteal and orbital abscesses complicating orbital cellulitis was about 10%,[35] but is now declining. Most have sinus infection. In subperiosteal abscess, a purulent infection within a sinus, usually the ethmoid, breaks through the thin orbital bony wall (lamina papyracea) and lies beneath the loosely adherent periosteum, which is easily lifted off the bone, giving a convex "lens" type of appearance on CT scan. An orbital abscess occurs either when a subperiosteal abscess breaches the periorbita or when a collection of pus forms within the orbit.

The most common causative organism is *Staphylococcus*, but *Streptococcus*, *H. influenzae*, and anaerobic organisms may also be responsible. MRSA may be suspected when there is marked systemic toxicity and orbital signs, or when orbital cellulitis is slow to respond to adequate intravenous antibiotics.[33] The presence of subperiosteal abscess may be indicated by lateral displacement of the globe away from the infected sinus, impaired adduction, and resistance to retropulsion.[36]

All studies have recommended hospitalization for intravenous antibiotic therapy (see Table 14.2) and repeated eye examinations to evaluate progression of infection or involvement of the optic nerve.

CT scanning (see Fig. 14.4) at presentation is not always necessary, especially if there is mild orbital cellulitis with sinusitis and no optic nerve compromise or intracranial signs. It is indicated if the presentation is unusual, severe, in an older child, or there are optic nerve or intracranial signs. If the child does not respond to treatment, it is advisable to image the sinuses, orbits, and intracranial compartment with a CT scan (Figs 14.11 and 14.12). A contrast-enhanced scan gives additional information in differentiating an abscess, which

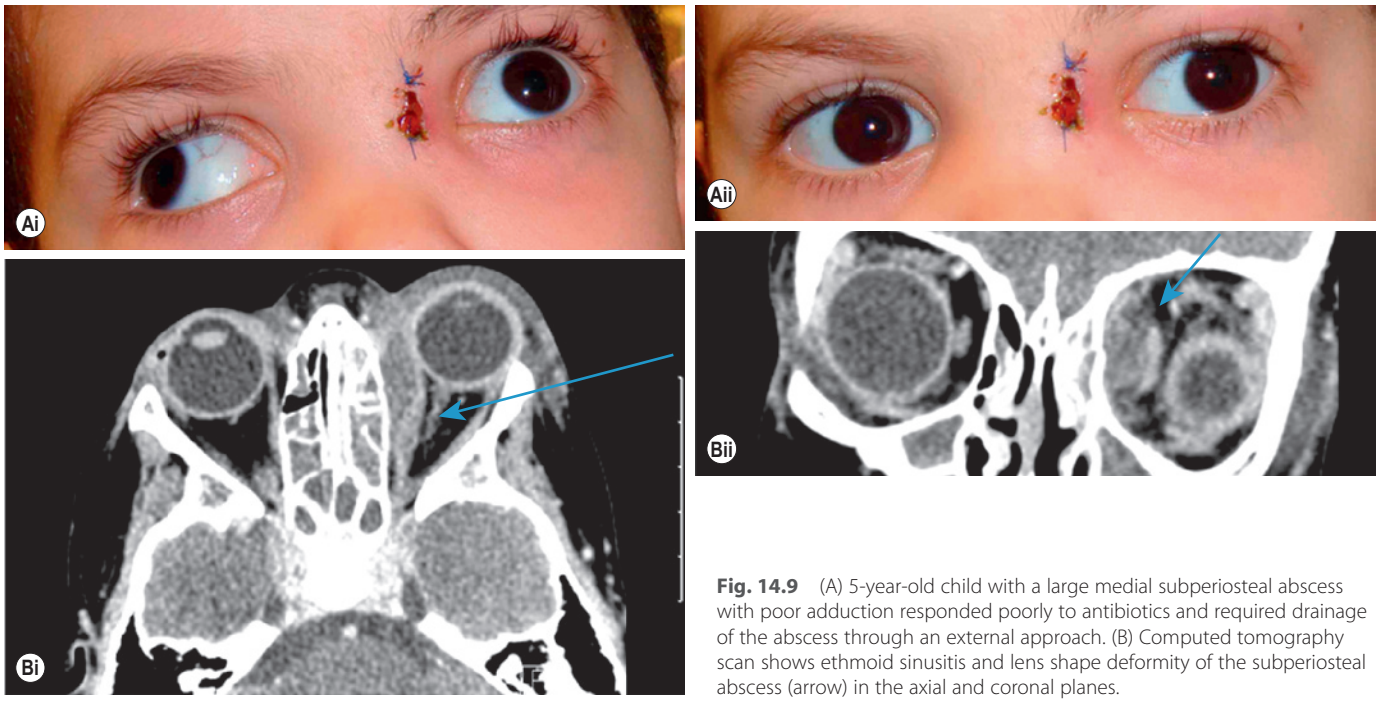

Fig. 14.9 (A) 5-year-old child with a large medial subperiosteal abscess with poor adduction responded poorly to antibiotics and required drainage of the abscess through an external approach. (B) Computed tomography scan shows ethmoid sinusitis and lens shape deformity of the subperiosteal abscess (arrow) in the axial and coronal planes.

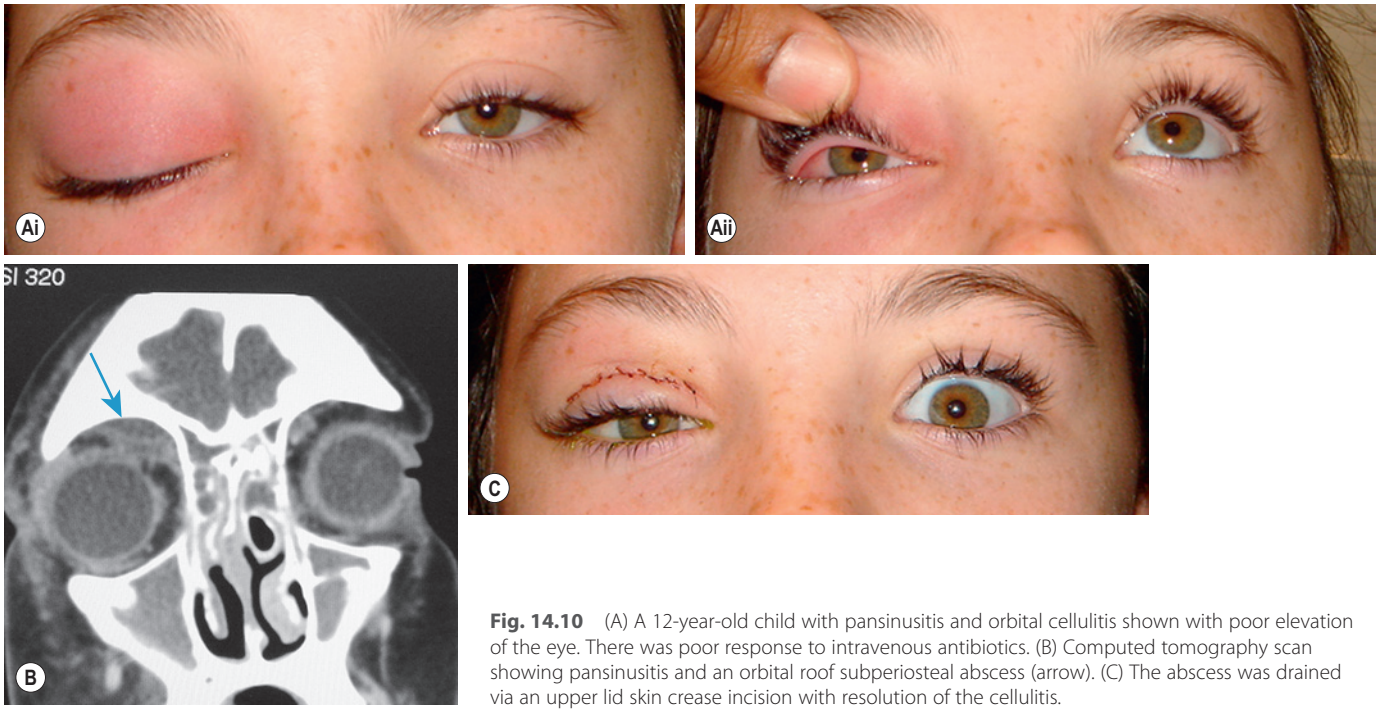

Fig. 14.10 (A) A 12-year-old child with pansinusitis and orbital cellulitis shown with poor elevation of the eye. There was poor response to intravenous antibiotics. (B) Computed tomography scan showing pansinusitis and an orbital roof subperiosteal abscess (arrow). (C) The abscess was drained via an upper lid skin crease incision with resolution of the cellulitis.

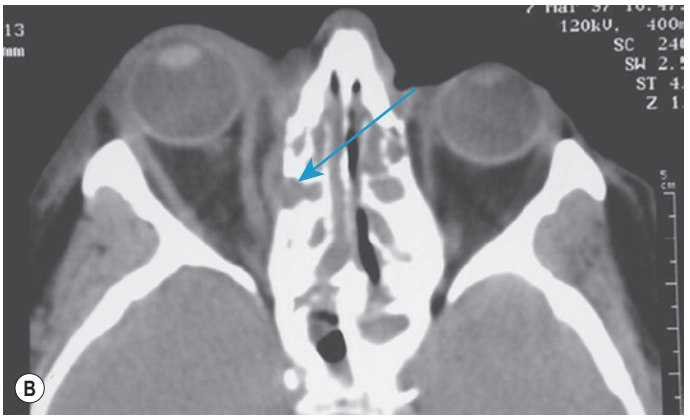
is amenable to drainage, from a phlegmon (purulent tissue inflammation), which is not.

An orbital abscess should be drained. The management of subperiosteal abscess is more controversial[6] because they may resolve with medical treatment.[6,27,37]

In a review of 37 patients with subperiosteal abscess secondary to sinusitis, resolution occurred in 83% of patients under 9 years of age who were treated medically or who had negative cultures on drainage.[38] In contrast, only 25% of those aged between 9 and 14 years cleared without drainage or had negative cultures on drainage. The remaining group, aged 15 years and over, were refractory to medical therapy alone. In a review of the management of subperiosteal abscess, the authors found that if the maximum abscess width was smaller than 10 mm medical treatment alone was successful in 81% of patients. In contrast, 92% of patients with an abscess larger than 10 mm underwent surgery.[39]

Nine children (2 months to 4 years) with subperiosteal abscesses were managed with a third-generation cephalosporin and vancomycin in the first 24–36 hours; only one required



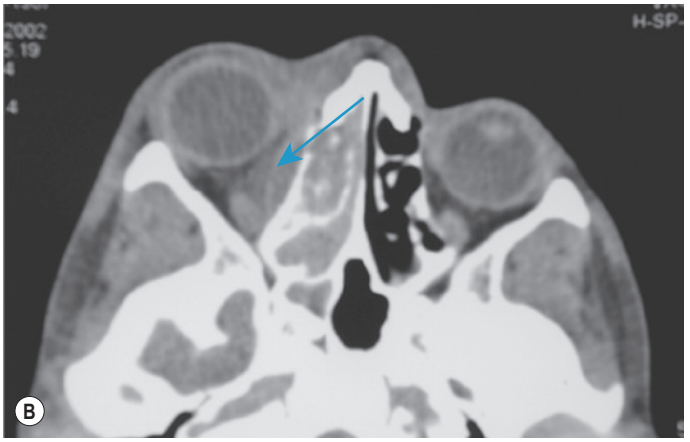


Fig. 14.11 (A) 7-year-old child with right orbital cellulitis, proptosis, white eye, limitation of eye movements, but no optic nerve compromise. (B) Computed tomography scan shows ethmoid sinusitis, significant proptosis, and a small medial subperiosteal abscess (arrow). He was successfully treated with antibiotics alone and did not need surgical intervention.

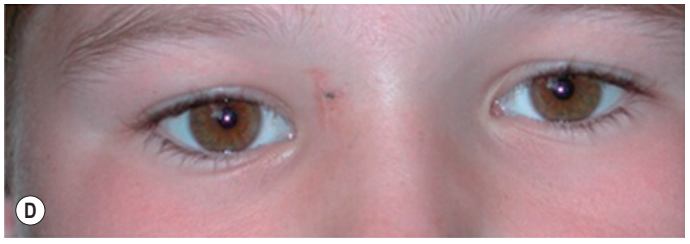

Fig. 14.12 (A) Orbital cellulitis with a white eye. (B) Computed tomography scan shows sinusitis and a subperiosteal abscess (arrow). Child deteriorated despite adequate intravenous antibiotics. (C) Drainage of ethmoid sinus and subperiosteal abscess was performed. (D) Patient made a good recovery.

surgical drainage and this case was culture-negative. This supports an initial medical management approach for most patients with subperiosteal or orbital abscesses resulting in orbital cellulitis.[6]

Garcia and Harris[27] advocate a non-surgical management of subperiosteal abscess if four criteria are met:

1. age less than 9 years;
2. no visual compromise;
3. medial abscess of modest size;
4. no intracranial or frontal sinus involvement.

In their prospective study of 29 patients fulfilling the above criteria, 27 (93%) were managed successfully with only medical therapy. Only two patients had surgical intervention with successful outcomes.[27]

It seems reasonable to initially treat medically if vision is normal, there is no intracranial extension, the subperiosteal abscess is of moderate size, and the child is under 9 years of age (see Figs 14.11 and 14.12). The recently published follow-up series by Liau and Harris concluded that these guidelines remain appropriate. However they noted in younger children, who might classically be expected to resolve with conservative

management, the emergence of more aggressive organisms, such as MRSA, makes emergent drainage necessary more often due to advanced clinical disease at presentation.[33]

Osteomyelitis of the superior maxilla

This rare condition, which usually presents in the first few months of life with fever, general malaise, and marked periorbital edema, may be confused with orbital cellulitis or subperiosteal abscess. The diagnosis should be suspected if there is pus in the nostril and edema of the alveolus and palate on the affected side. An oral fistula may be present. Imaging supports the diagnosis. *Staphylococcus aureus* is the usual infecting organism. Treatment is with high-dose intravenous antibiotics chosen on the basis of culture and sensitivity, and surgical drainage of the abscess preferably via the nose.

Cavernous sinus thrombosis

Since the introduction of antibiotics, this dreaded complication of orbital cellulitis has become rare. Previously, mortality was almost 100%.[40] In its early stages, cavernous sinus thrombosis may be difficult to distinguish clinically from orbital cellulitis. There is more severe pain, a marked systemic illness, proptosis develops rapidly, and there may be third, fourth, and sixth cranial nerve palsies, in contrast to the mechanical limitation seen in orbital cellulitis.

Hyperalgesia in the distribution of the fifth cranial nerve is common. The presence of retinal venous dilatation and optic disc swelling, especially if bilateral, is very suggestive of cavernous sinus thrombosis. In the later stages, bilateral involvement in cavernous sinus thrombosis makes the clinical distinction from orbital cellulitis easier.

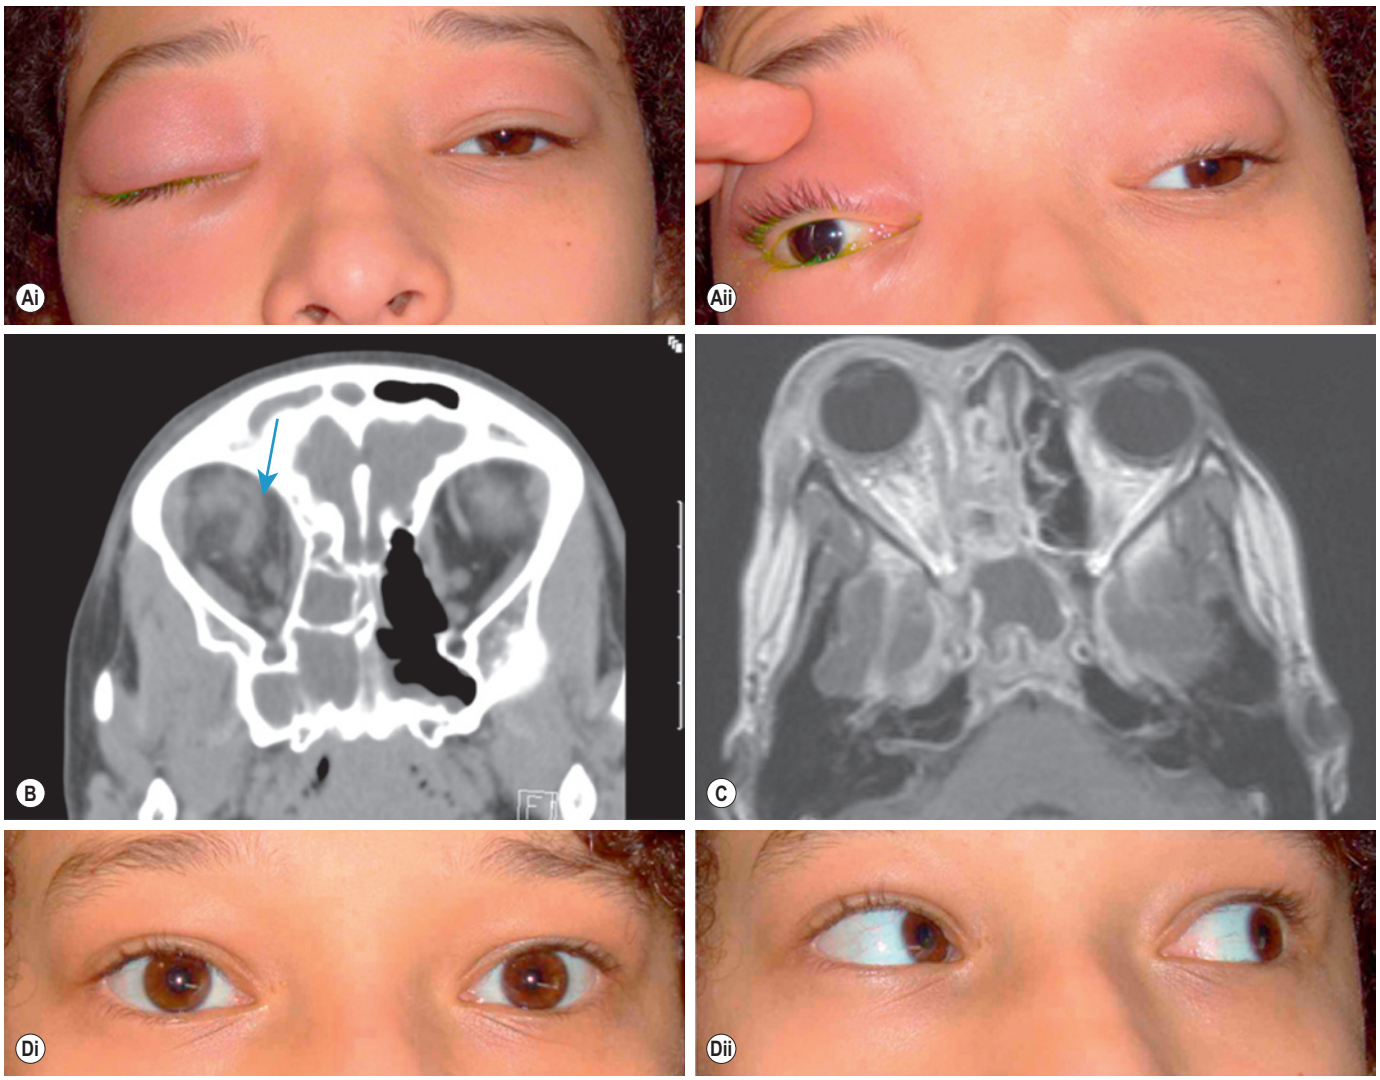

Fig. 14.13 (A) A very unwell 13-year-child with orbital cellulitis, proptosis, and reduced eye movements. (B) Computed tomography scan showed pansinusitis including the ethmoids and sphenoid sinus, and a dilated cavernous sinus and superior ophthalmic vein (arrows). (C) Magnetic resonance imaging confirmed a cavernous sinus thrombosis, with flow voids. (D) She made an excellent recovery with antibiotics and anticoagulation.

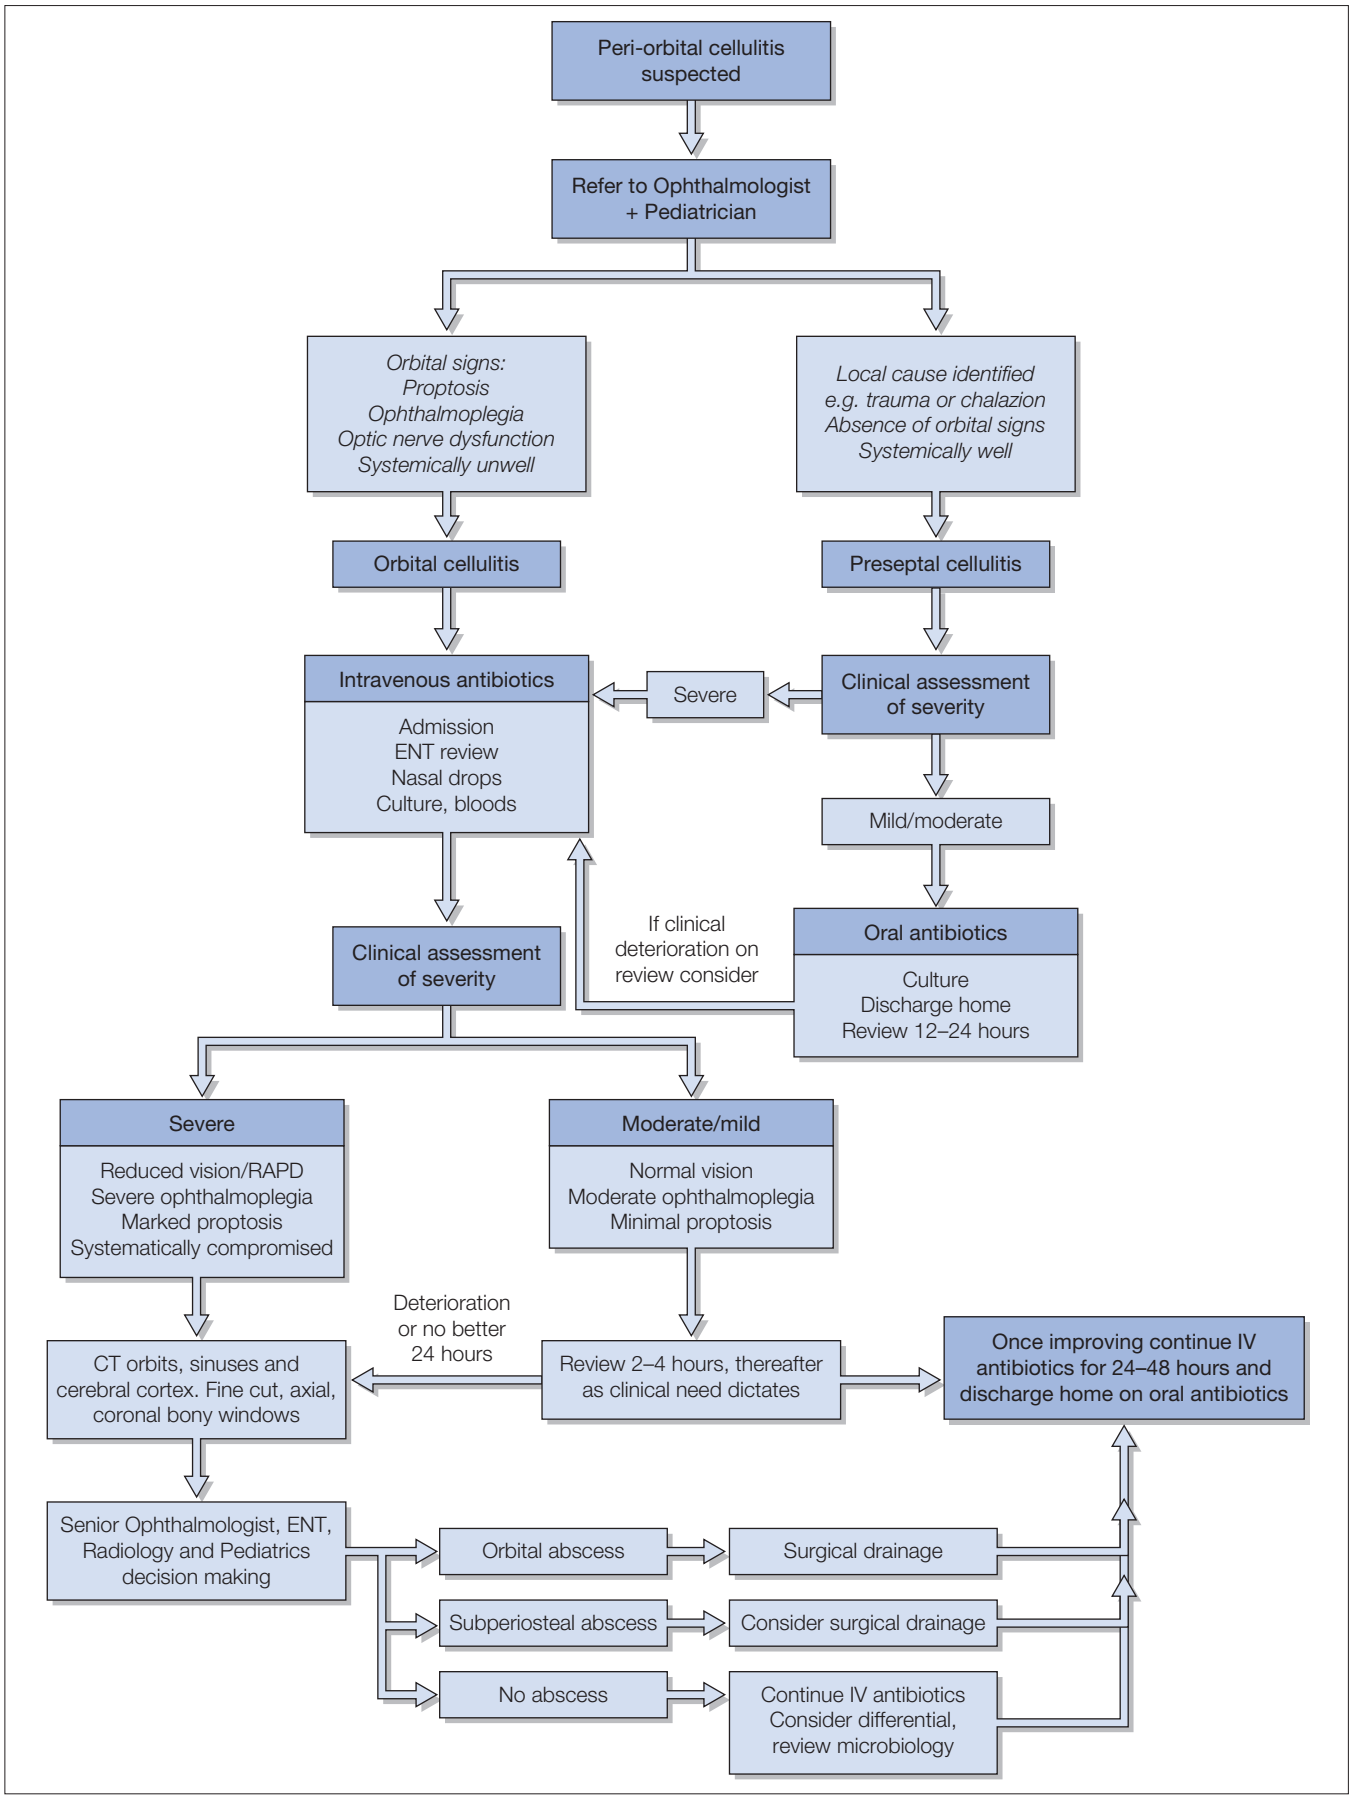

Fig. 14.14 Management of preseptal and orbital cellulitis.

Diagnosis can be supported by CT findings but is better confirmed with an MRI scan. Cavernous sinus thrombosis is most frequently associated with *Staph. aureus* infection[41] (Fig. 14.13).

Management is best undertaken by a pediatric neurologist or neurosurgeon and involves treatment with high-dose intravenous antibiotics. The use of anticoagulants and systemic steroids requires careful consideration.

Fungal orbital cellulitis orbital mucormycosis

Orbital fungal infection should be suspected in any diabetic or immunosuppressed[25] child or one with gastroenteritis and metabolic acidosis[42] who develops a rapidly progressive orbital cellulitis, especially if accompanied by necrosis of the skin or nasal mucosa.

Fungal orbital cellulitis has been described in otherwise healthy children.[43,44] Untreated, it is rapidly fatal.

Colonization of the sinuses by spores followed by direct or hematogenous spread to the orbit occurs, which is heralded by periorbital pain, marked lid edema, conjunctival chemosis, and proptosis. Later, spread to the orbital apex results in third, fourth, and sixth cranial nerve palsies and optic neuropathy. Mucomycosis and aspergillosis have a tendency to invade vessel walls causing thrombosis and subsequent ischemia. Involvement of the facial arteries causes gangrene of the nose, palate, and facial tissues resulting in necrosis. Central retinal artery occlusion and cerebral infarction can result. Once spread to the cavernous sinus and intracranial vessels occurs, the prognosis is very poor.

Scrapings from infected tissues should be cultured and Gram and Giemsa stained. Larger tissue biopsies should be fixed in 10% formalin and processed for histologic examination. These fungi have an affinity for hematoxylin and are, therefore, easily recognized in hematoxylin and eosin sections.

The management consists of specific antifungal therapy, correction of the underlying metabolic or immunologic abnormality, and surgical debridement of necrotic tissues. The specific treatment of choice is amphotericin B, which should be given intravenously and may also be used locally to irrigate infected sinuses.[45] It is nephrotoxic so renal function should be carefully monitored.

For further information on the management of preseptal and orbital cellulitis please see Figure 14.14.

CLINICAL PRESENTATION
EXOGENOUS BACTERIAL ENDOPHTHALMITIS
ENDOGENOUS BACTERIAL ENDOPHTHALMITIS
EXOGENOUS FUNGAL ENDOPHTHALMITIS
ENDOGENOUS FUNGAL ENDOPHTHALMITIS
REFERENCES

Infectious endophthalmitis occurs when bacteria, fungi, parasites, or viruses enter the eye following a breach of the outer wall of the eye (exogenous endophthalmitis), or when microorganisms enter the eye from a source elsewhere in the body (endogenous endophthalmitis). Exogenous endophthalmitis most frequently arises following surgery but may be a consequence of trauma. Endogenous endophthalmitis usually results from hematogenous spread of infection. Exogenous endophthalmitis may be subclassified into acute and chronic. The classification of endophthalmitis is important as each type has a characteristic clinical setting, differing spectrum of microorganisms, and varying visual prognosis.

Clinical presentation

The presentation of bacterial endophthalmitis depends on the route of infection and the virulence of the microorganism. Acute postoperative endophthalmitis typically presents 1–3 days after surgery with pain and decreased vision. There is often lid swelling, conjunctival injection, corneal edema, and chemosis. Intraocular findings include uveitis, hypopyon, vitreous cells, and occasionally sheathing of blood vessels. In children, presentation and treatment are often delayed, particularly following trauma where occult penetration may go undetected.

Infection with less virulent organisms may result in chronic or late-onset endophthalmitis, which may run an indolent course with exacerbations and remissions. Intraocular inflammation is less severe, but hypopyon and vitreous activity may be present. The presence of creamy white plaques on the posterior capsule following cataract surgery is suggestive of *Propionibacterium* infection. In endophthalmitis following penetrating injury, there may be a persistent severe uveitis and vitreous haze with infiltration of the wound edges. Retinal periphlebitis may be an early sign of bacterial endophthalmitis. Endophthalmitis should be suspected after intraocular surgery or traumatic perforation whenever the inflammation is greater than expected. Serial and frequent examinations may be necessary. The main differential diagnoses are fungal endophthalmitis and severe uveitis. Rarely, retinoblastoma or metastatic tumor may present with uveitis and hypopyon.

Exogenous bacterial endophthalmitis

Cataract surgery

Exogenous endophthalmitis in adults occurs most frequently following intraocular surgery (70–80%). Cataract extraction has a reported incidence of postoperative endophthalmitis of 0.029–0.38%[1,2] (Fig. 15.1). Good et al. reported an incidence of 0.45% in a retrospective review of 641 cases of cataract extraction in children.[3] Wheeler et al. reported an incidence of 0.07% in children undergoing cataract and glaucoma surgery.[4]

A study of 464,996 cataract surgeries undertaken in Sweden over 6 years found perioperative communication with the vitreous and non-use of intracameral cefuroxime showed a statistically significant association with endophthalmitis.[2] Surgery for congenital cataract, whether lensectomy or lens aspiration, usually involves breach of the posterior capsule. Therefore, one might expect a higher incidence of postoperative endophthalmitis similar to that reported in intracapsular cataract, posterior capsular tear, and anterior vitrectomy.

Toxic anterior segment syndrome (TASS) may be difficult to distinguish from infective endophthalmitis. TASS is a sterile inflammatory response usually occurring in the first 48 hours following cataract surgery. Clinical features include corneal edema, raised intraocular pressure, and absent vitritis. If doubt exists as to whether the patient has endophthalmitis or TASS, vitreous biopsy and intravitreal antibiotics are warranted.

The Endophthalmitis Vitrectomy Study (EVS) studied 420 cases of infectious endophthalmitis presenting within 6 weeks of cataract extraction or secondary intraocular lens implantation.[5] Positive culture was obtained from 69.3% of intraocular specimens. Gram-positive bacteria were isolated in 94.2% of cases and gram-negative bacteria in 6.5% of isolates. *Staphylococcus epidermidis*, normal skin flora, was by far the most common gram-positive isolate (70%), followed by *Staphylococcus aureus* (9.9%), *Streptococcus* spp. (2.2%), and *Propionibacterium acnes*. *Proteus* and *Pseudomonas* were

Fig. 15.1 Bacterial endophthalmitis following infant cataract surgery and intraocular lens implantation.

the most common gram-negative organisms. *Haemophilus influenzae* has also been identified in other series.[6] Gower et al. noted patients developing streptococcal endophthalmitis following cataract surgery were 10 times more likely to have poor final visual acuity than patients with coagulase-negative staphylococcal endophthalmitis.[7] Weinstein's study of children with endophthalmitis reported similar results, 75% of culture-positive cases being caused by gram-positive organisms.[8] *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, and *Staphylococcus aureus* have been identified as the most frequent infecting agents in children following cataract extraction.

Trauma

Trauma is a significant cause of exogenous endophthalmitis in children. Endophthalmitis following penetrating injury accounted for 44% of cases in a 10-year review of pediatric endophthalmitis.[9] The incidence of endophthalmitis after penetrating injury ranges from 4% to 20% and is particularly high when injury occurs in a rural setting.[10] Eight-five percent of patients in the EVS achieved final visual acuity of 20/400 or better, while only 22–42% achieved this level of acuity following post-traumatic endophthalmitis.[4,11]

Poor visual outcome results from delayed diagnosis and treatment. Damage to ocular structures and retained intraocular foreign body are also contributory factors to poor visual outcome. In adults with post-traumatic endophthalmitis, *Staphylococcus epidermidis* and *Bacillus* spp. are the most frequent pathogens. In a review of post-traumatic endophthalmitis in children *Streptococcal* spp. were isolated in 25.9%, *Staphylococcus* in 18.5%, and *Bacillus* spp. in 22% of cases.

Glaucoma filtration surgery

Infection associated with filtration surgery is often subclassified into blebitis, defined as mucopurulent material in and around the bleb associated with anterior segment activity but without hypopyon. If a hypopyon is present, or there is evidence of vitreous activity, a diagnosis of endophthalmitis is made. Endophthalmitis may occur soon after surgery, but is frequently reported many years after surgery. Antimetabolites such as 5-fluorouracil (5-FU) and mitomycin C are used to augment filtration surgery in childhood glaucoma. While improving the success rate of filtration surgery, they increase the risk of postoperative endophthalmitis. When intraoperative 5-FU is used, the reported incidence of endophthalmitis is 1–5.7%. The incidence of endophthalmitis is 0.3–4.9% when mitomycin C is applied.[12] Use of antimetabolites may result in thin and avascular blebs that are predisposed to infection.

Implantation of glaucoma drainage devices is associated with increased rates of endophthalmitis. A review of 542 eyes with Ahmed valve insertion noted a significantly higher endophthalmitis rate in children. The incidence in adults was 1.7%, compared to 4.4% in children.[13] Endophthalmitis is often associated with conjunctival erosion and tube exposure; inferior placement of bleb or drainage device is also associated with higher rates of infection. When endophthalmitis is related to glaucoma surgery, the spectrum of microorganisms differs from that in cataract surgery in that streptococcal species predominate. *Haemophilus influenzae* is also isolated more frequently than *Staphylococcus epidermidis*. This difference may reflect the fact that endophthalmitis is often of late onset with invasion of microorganisms through thin-walled or leaking blebs.[14] Jampel et al. found increased incidence of endophthalmitis associated with full-thickness filtration procedures, inferior-placed blebs, bleb leakage, and the use of mitomycin.[15] If endophthalmitis develops in the early post-operative period, *Staphylococcus epidermidis* is more frequently cultured.

Strabismus surgery

Endophthalmitis following strabismus surgery is rare, with an incidence of 1:3,500 to 1:185,000.[16] Scleral perforation is thought to be a prerequisite for the development of endophthalmitis following strabismus surgery. Spatulated needles have greatly reduced the frequency of scleral perforation during strabismus surgery. Needles and sutures are frequently contaminated despite the use of preoperative povidone-iodine. Carothers et al. noted 19% of needles and 24% of sutures were culture positive in patients undergoing strabismus surgery.[17] When scleral perforation has been noted, a dilated fundal examination is indicated and laser photocoagulation of any retinal lesions should be considered. Many surgeons would ask a retinal surgeon to help with this (see Chapter 86). Periocular and systemic antibiotics may reduce the risk of endophthalmitis following perforation.

Streptococcus pneumoniae, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Staphylococcus epidermidis* have been isolated in cases of endophthalmitis associated with strabismus surgery. It appears that infection with more virulent organisms is more frequent than after cataract surgery. Visual prognosis is poor as a consequence of delayed diagnosis and the virulence of the infecting organisms.

Intravitreal injection

Anti-vascular endothelial growth factor (anti-VEGF) is an effective treatment for some forms of retinopathy of prematurity. Anti-VEGF is delivered by intravitreal injection. In adults, endophthalmitis rates range from 0.019% to 0.07% when it is used to treat age-related macular degeneration.[18] In contrast to endophthalmitis following incisional surgery, *Staphylococcus* species (38.24%) and *Streptococcus* species (29.41%) were identified more frequently in a meta-analysis of infectious endophthalmitis after injection of anti-VEGF agents for age-related macular degeneration, diabetic macular edema,

and retinal vein occlusion.[19] Endophthalmitis caused by *Streptococcus* species is associated with poorer visual prognosis.

Exogenous endophthalmitis may also arise secondary to infectious keratitis associated with exposure or trauma.

Prevention

The patient is the most common source of postoperative infection. Children with extraocular infection, blepharitis, conjunctivitis, or with impaired nasolacrimal drainage should have their surgery delayed until these are remedied. Surgery should also be deferred in the presence of upper respiratory tract infection.

Preoperative application of aqueous povidone-iodine 5% solution to the conjunctival sac decreases bacterial counts and is the only prophylaxis, apart from intracameral antibiotics, for which there is an evidence base. It must be applied at least 3 minutes prior to surgery. In cases of penetrating injury, povidone-iodine should not be applied.

A prospective study by the European Society of Cataract and Refractive Surgeons demonstrated a five-fold decrease in the incidence of postoperative endophthalmitis in patients undergoing phacoemulsification surgery when intracameral cefuroxime (1 mg in 0.1 ml of normal saline) was administered at the end of surgery.[20] It is likely that intracameral cefuroxime results in reduced infection rates in pediatric cataract surgery. Antibiotics in irrigating solutions and subconjunctivally have largely been supplanted by the intracameral approach. There may be a beneficial effect from administering intravitreal antibiotics after repair of penetrating injuries, where there is a known higher rate of endophthalmitis.

Management

If endophthalmitis is suspected, it is essential to proceed rapidly and obtain aqueous and vitreous samples before starting antibiotic treatment (Box 15.1). General anesthesia will be required to allow thorough examination, collection of specimens, and delivery of intravitreal antibiotics. The microbiologist should be informed to ensure that appropriate culture media are available in the operating room and also to perform Gram and Giemsa stains. Specimens should be sent immediately to the laboratory. Aqueous and vitreous specimens are plated on appropriate agar to facilitate culture of the potential pathogens, e.g. blood agar, chocolate agar, and Sabouraud dextrose agar. Specimens should be placed on glass slides for Gram and Giemsa stains. Culture for up to 2 weeks is required to allow growth of anaerobes such as *Propionibacterium* spp. and fungal species. *Propionibacterium acnes* may be sequestered in folds of the posterior capsule and, if suspected, removal of capsular remnants for culture may be helpful in confirming the diagnosis.

Polymerase chain reaction (PCR) is a highly sensitive and specific test, which can be employed to rapidly identify bacteria, fungi, and viruses resulting in early diagnosis and appropriate antibiotic therapy. It is particularly helpful in culture-negative cases or when the patient has been commenced on antimicrobial therapy before samples are obtained. Care must be taken to minimize the risk of contamination of the specimen with environmental organisms, which may cause a false-positive PCR result. Positive PCR results with a negative culture must be interpreted with caution; always consider whether the PCR result is a recognized ocular pathogen and also consider the clinical context. Newer techniques such as real-time PCR have been shown to identify the bacteria from aqueous and vitreous in 95% of patients with endophthalmitis in one case series.[21]

Vitreous samples are preferably obtained using a mechanical cutter: 0.2 ml is removed for culture and staining. Care must be taken in infants as the pars plana is poorly developed; therefore, sclerotomies should be anteriorly placed. If an intraocular lens has not been inserted, an anterior approach is possible.

Once vitreous sampling has been completed, antibiotics are injected into the vitreous cavity: vancomycin, 1 mg in 0.1 ml of normal saline, and ceftazidime, 2 mg in 0.1 ml of normal saline. Vancomycin is effective against gram-positive bacteria and ceftazidime against gram-negative organisms. Dexamethasone, 0.4 mg in 0.1 ml, may also be given intravitreally to reduce the inflammatory response. Antibiotics are delivered with a 30-gauge needle using separate syringes for each antibiotic. Most antibiotic has left the eye by 48 hours and consideration should be given to repeating the injections after this period depending on clinical response.

The EVS did not show any additional benefit from using systemic antibiotics to supplement intravitreal therapy. In the EVS, systemic treatment consisted of amikacin and ceftazidime; however, this may be suboptimal as vancomycin is more effective against gram-positive cocci. As intravitreal antibiotics only remain in the eye for a short period, patients with severe endophthalmitis should have systemic antibiotics. Systemic antimicrobial therapy is indicated in cases of endogenous endophthalmitis secondary to bloodstream infection or infection at a distant focus.

Subconjunctival antibiotics do not penetrate the vitreous cavity well and have limited use. Topical antibiotics may be used to supplement intravitreal injection if there is superficial infection or infectious keratitis (vancomycin 50 mg/ml and ceftazidime 50 mg/ml or amikacin 25 mg/ml). Treatment regimens need to take into account the clinical setting and the likely infecting microorganisms. Antibiotic therapy should be reviewed in the light of clinical response and culture results.

Box 15.1

Initial antibiotic treatment of bacterial endophthalmitis

Intravitreal antibiotics

Vancomycin 1 mg in 0.1 ml of normal saline and ceftazidime 2 mg in 0.1 ml of normal saline

or

Amikacin 0.4 mg in 0.1 ml of normal saline and ceftazidime 2 mg in 0.1 ml of normal saline

Systemic antibiotics

Vancomycin 44 mg/kg per day and ceftazidime 100–150 mg/kg per day

or

Ciprofloxacin 5–10 mg/kg per day

Topical antibiotics

Vancomycin 50 mg/ml hourly and ceftazidime 50 mg/ml hourly

or

Gentamicin 14 mg/ml hourly

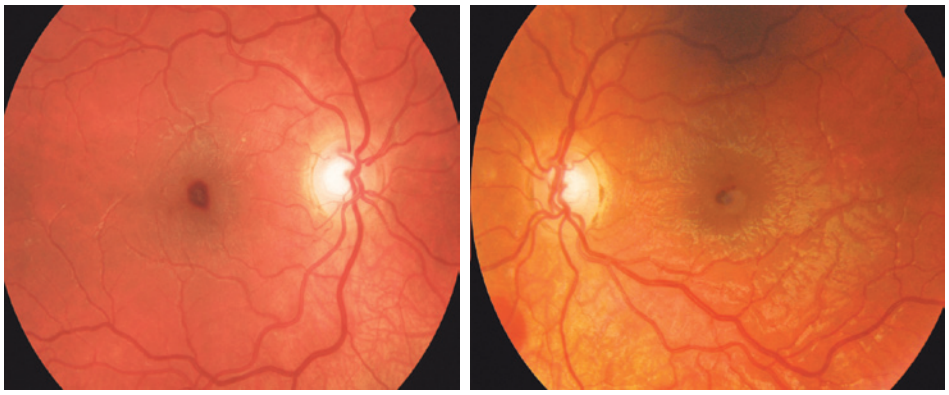

Fig. 15.2 Bilateral Roth's spots in a case of bacterial endocarditis.

Consult with your vitreoretinal colleagues for consideration of early virectomy. The management of endophthalmitis following cataract has been greatly influenced by the EVS. The key findings of this study were:

1. Immediate vitrectomy is not indicated if the visual acuity is better than light perception.
2. If visual acuity is light perception only, then there is a significant benefit from vitrectomy.

It should be noted that the EVS study was undertaken 20 years ago and improved vitreoretinal instrumentation and techniques now favor a more aggressive surgical approach with better visual outcomes. Vitrectomy decreases the bacterial load and removes toxins and inflammatory mediators from the eye. Removal of opaque vitreous will hasten visual rehabilitation. It may be very difficult in some children to establish a reliable visual acuity. It should be noted that in this study the systemic antibiotics used differed from those given intravitreally and therefore would not have helped to maintain intraocular antibiotic levels. The role of vitrectomy in endophthalmitis associated with strabismus or glaucoma surgery has not been established. However, the same general principles apply.

Endogenous bacterial endophthalmitis

Endogenous or metastatic bacterial endophthalmitis results from hematogenous spread from a distant focus such as bacterial endocarditis (Fig. 15.2), meningitis (Fig. 15.3), abdominal sepsis or otitis media (Box 15.2). Between 2% and 8% of all bacterial endophthalmitis cases are endogenous and are frequently bilateral (14–50%).[22] Although symptoms and signs are similar to exogenous endophthalmitis, the clinical setting is different. Systemic symptoms may predominate. Initially, ophthalmological features may be mild, delaying the diagnosis. The presence of red eye in a patient with sepsis should prompt early and full ophthalmological examination.

Endogenous endophthalmitis most frequently results from gram-positive organisms such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Listeria monocytogenes*. Gram-negative infection results from *Neisseria meningitides*, *Haemophilus influenzae*, *Klebsiella* spp., and *Escherichia coli*. gram-positive organisms predominate in North America and Europe with gram-negative organisms more frequently isolated in Asia.[23] *Klebsiella* species predominate in East Asia, often associated with cholangiohepatitis and liver abscess. Premature infants are more likely to develop endophthalmitis secondary to *Pseudomonas aeruginosa* and *Streptococcus pneumoniae*. These infants are immunocompromised and often dependent on ventilators and humidifiers, which may be a source of nosocomial infection.

Once the diagnosis is suspected, systemic antimicrobial therapy should be commenced. If an infective agent has not

been identified from blood culture, aqueous and vitreous specimens should be obtained and intravitreal antibiotics administered covering both gram-positive and gram-negative organisms. Blood cultures are positive in up to 72% of cases and are useful in guiding initial antibiotic therapy. Should the child present to the ophthalmologist, urgent assessment by a pediatrician or infectious diseases specialist is indicated. The role of vitrectomy is not established; no prospective studies have been undertaken.

Exogenous fungal endophthalmitis

Exogenous fungal endophthalmitis may complicate penetrating eye injury, especially when it occurs in a rural setting and in the presence of a retained organic foreign body or fungal keratitis. Presentation may not be until weeks or months after injury. Progressive uveitis, hypopyon, vitritis, and vitreous abscess following penetrating injury should give rise to suspicion of fungal endophthalmitis. Aqueous and vitreous samples should be obtained promptly. Giemsa stain may identify hyphae, confirming the diagnosis and facilitating early treatment with intravitreal amphotericin B. Vitrectomy should be considered if there is significant vitreous involvement.

Endogenous fungal endophthalmitis

Endogenous fungal endophthalmitis is usually associated with candida septicemia. Risk factors include immunosuppression, intravenous feeding, and prematurity (see Box 15.2). *Candida albicans* is the organism most commonly identified in endogenous fungal endophthalmitis although *Aspergillus fumigatus* and *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatiditis*, *Cryptococcus neoformans*, and *Sporotrichum schenckii* have all been implicated.

Neonatal endophthalmitis is almost always endogenous and results from systemic candidiasis. In neonates, candidemia is associated with central venous catheters, parenteral nutrition, and the use of broad-spectrum antibiotics. A recent review of the incidence of neonatal endogenous endophthalmitis in the United States demonstrated a significant reduction in the incidence (8.71 cases per 100,000 live births in 1998 and 4.14 cases per 100,000 live births in 2006).[24] This decrease may result from improved care and earlier treatment of neonates with candidemia. Candidemia, retinopathy of prematurity, and low birth weight were significant risk factors in the development of endophthalmitis in this study. The presence of retinopathy of prematurity was associated with a two-fold increase in the rate of endophthalmitis.

Ocular involvement may take the form of chorioretinitis where pale creamy-white lesions are noted in the choroid with a predilection for the posterior pole. These lesions may extend into the vitreous to form "puff balls" which, when multiple, have a "string of pearls" appearance (Fig. 15.4). There may be areas of retinal hemorrhage with white centers similar to Roth's spots. Vitreous inflammation is variable. The anterior segment may be involved and secondary cataract has been reported. Early diagnosis and systemic treatment will prevent the progression of chorioretinal lesions to diffuse endophthalmitis. *Aspergillus* endophthalmitis is typically more severe with large confluent areas of chorioretinitis.

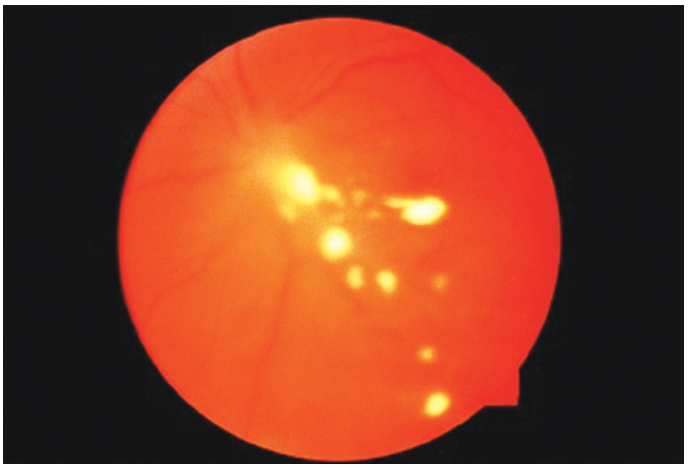

Fig. 15.4 Endogenous *Candida* endophthalmitis in an immunosuppressed child. Note characteristic "string of pearls" appearance of vitreous infiltrates.

Clinical features may suggest the diagnosis; however, blood and urine cultures are useful in diagnosis. If there are positive cultures from blood or urine, it is not necessary to perform vitreous sampling. Giemsa stain and Sabouraud media are used to identify and culture fungi. PCR is also employed and can rapidly identify fungi from intraocular samples.

In endophthalmitis associated with candidemia, systemic administration of fluocytosine is indicated. Fluocytosine has superior ocular penetration to amphotericin B and is less toxic. If a species other than *Candida* is suspected or confirmed, amphotericin B is more appropriate as it is active against a broader range of fungi. Amphotericin B has significant systemic side effects including nephrotoxicity, neutropenia, and hypokalemia. The use of the liposomal version of amphotericin B (L-AMB) is less toxic than the deoxycholate forms. In cases where there is only chorioretinal involvement without significant vitreous involvement, systemic treatment may suffice. In the presence of vitreous involvement, intravitreal amphotericin B (5 μg in 0.1 ml of normal saline) may be given as an adjunct to systemic therapy. The use of intravitreal steroid remains controversial.

Chapter contents

BLEPHAROKERATOCONJUNCTIVITIS
CONJUNCTIVITIS
KERATITIS
REFERENCES

This chapter focuses on the most common external eye conditions in children (Fig. 16.1).

Blepharokeratoconjunctivitis

Blepharitis is a disorder of the lid margins with or without ocular surface inflammation. Lid disease can involve the anterior lid margin (lash follicles) or posterior lid margin (meibomian glands). Corneal disease occurs with both. The clinical features include:

- styes and meibomian cysts;
- conjunctivitis, phlyctenulosis and episcleritis;
- keratitis with vascularization and scar;
- dermatologic disease.

In children, dermatologic associations (facial rosacea and acne vulgaris) are less common than in adults and may be mild or absent, but corneal disease is more likely to progress to significant vision loss without obvious surface inflammation, termed blepharokeratoconjunctivitis (BKC) or ocular rosacea (Table 16.1). In developed countries it is second only to allergy as a cause for ocular surface disease in children.

Keratitis is uncommon in *acute* blepharitis, commonly caused by styes, impetigo, herpes simplex infection, or infected meibomian cysts.

Pathogenesis of blepharokeratoconjunctivitis

BKC is a delayed hypersensitivity response to *Staphylococcus aureus* or *Propionibacterium acnes* bacterial antigens and lipases released into the tear film. A proposed role for *Demodex* is unproven. Breakdown products of meibomian gland lipid may also cause inflammation and an unstable tear film that amplifies the effect through surface drying. Posterior lid margin disease is not the result of infection. Histologically, there is keratinization of the ductules of the meibomian glands and meibomian gland "drop out" can be demonstrated with infrared imaging. The prevalence is thought to be higher in females and in South and East Asian than white populations.[1]

The age of onset of BKC is bimodal with a peak at 5–7 years and a second peak at adolescence. However, onset can be in the first months of life. There is often a delay of months or years between the onset of symptoms and diagnosis. The symptoms of early cases of BKC are eye rubbing with chronically uncomfortable red eyes (Fig. 16.2). The disease can be very asymmetric or unilateral, with photophobia and epiphora if there is keratitis (see Table 16.1). There may be crusting in the morning, but discharge is not a major feature. The disease can be relatively asymptomatic until reduced vision or a corneal opacity alerts the patient or parents.

Table 16.1 Features of pediatric blepharokeratoconjunctivitis

Associated skin disease (absent in 50% of cases)	Symptoms[a]	Signs[b]		
		Lids[c]	Conjunctiva[c]	Cornea
Acne rosacea Acne vulgaris	Photophobia Pain Eye rubbing Redness Watering Discharge Blur (older children)	Inspissated meibomian ducts Crusting and collarettes Telagiectasia Notching of lid margins Meibomian cysts Styes	Bulbar hyperemia Tarsal papillary hyperplasia Tarsal follicles Lipid crystals Phlyctenules	Punctate epitheliopathy Marginal keratitis Phlyctenules Axial supepithelial scar Thinning Sectorial vascularization

[a]Some patients may be asymptomatic until visual loss is detected.
[b]Signs may be very asymmetric or even unilateral.
[c]Lid and conjunctival change can be minimal even with corneal disease.

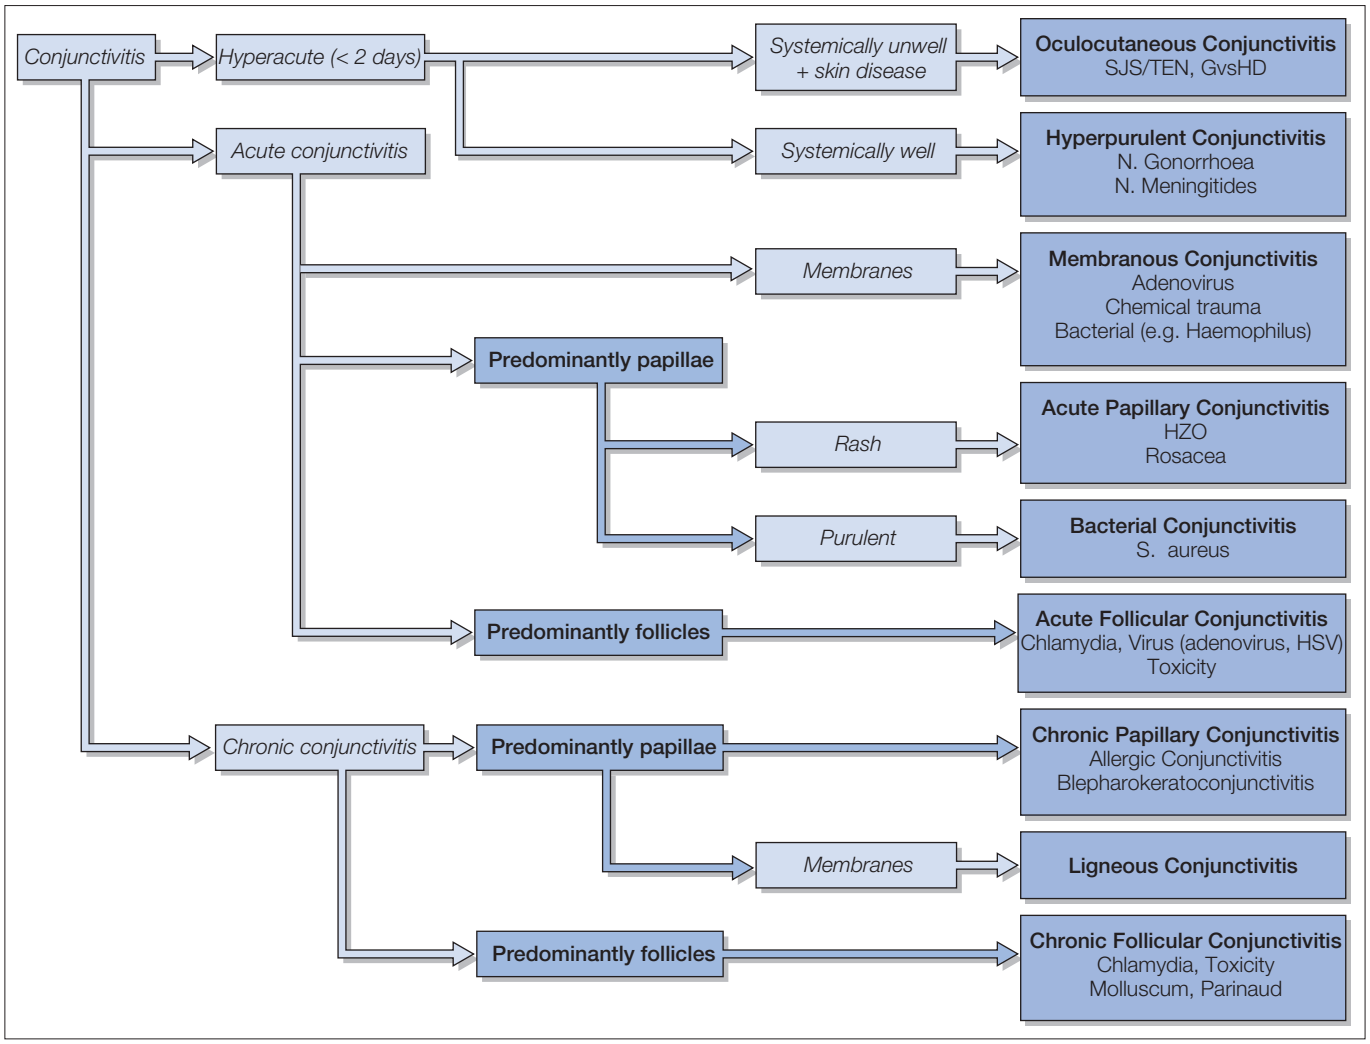

Fig. 16.1 Algorithm for assessment of conjunctivitis.

Fig. 16.2 Red and watery right eye of child with blepharokeratoconjunctivitis. There is anterior blepharitis and a reactive ptosis.

Approximately half of patients with BKC do not have facial skin changes, but a papular rash on the cheeks or acne can develop. Lid signs of anterior blepharitis include scales and collarettes at the bases of the lashes (Fig. 16.3). The appearance of the posterior lid margin can be surprisingly normal, or there may be telangiectasia and inspissation of the meibomian gland openings with expression of white sebum following gentle lid pressure. In more active disease, there is a mixed papillary and follicular change, especially in the upper and lower tarsal conjunctiva (Fig. 16.4), with limbitis and conjunctival or corneal phlyctenules (Figs 16.5 and 16.6). A phlyctenule

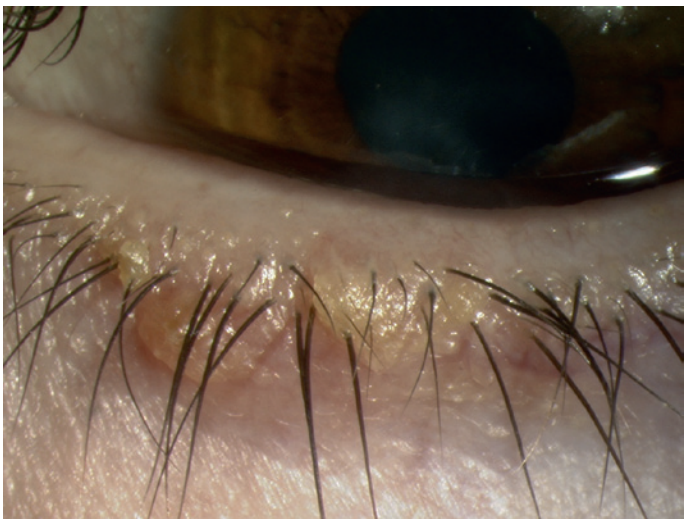

Fig. 16.3 Crusting at the base of the lashes in anterior blepharitis.

(or phlycten) is a small white collection of polymorphs and leukocytes with an overlying epithelial defect. Subconjunctival crystals are not always present but are a specific sign for this condition (Fig. 16.7). The corneal epithelial signs range from a reversible mild inferior punctate keratopathy to diffuse

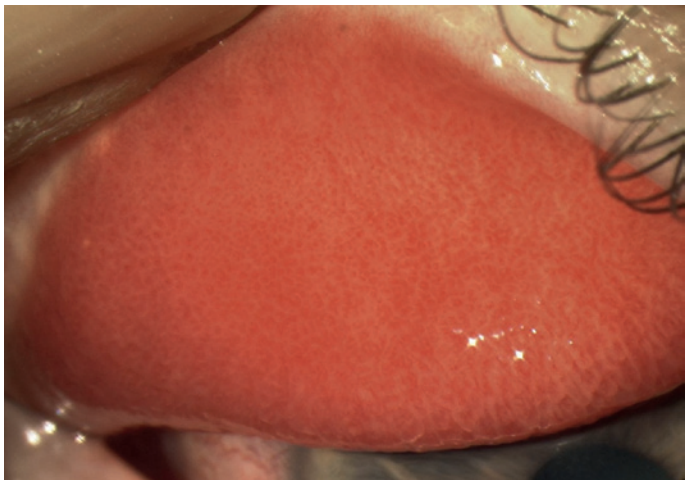

Fig. 16.4 A predominantly papillary response in a patient with very active blepharokeratoconjunctivitis.

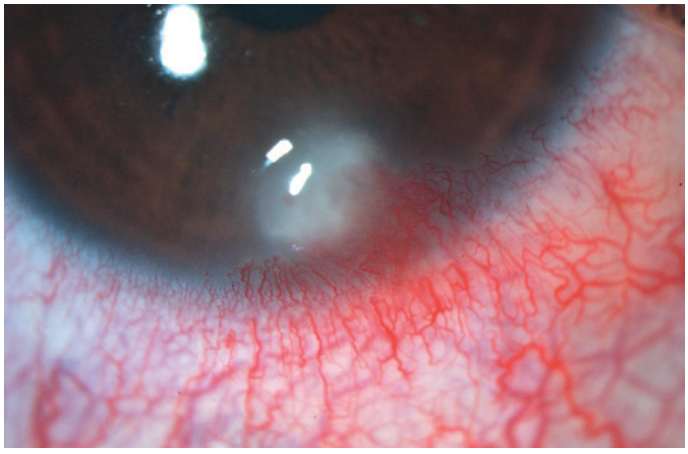

Fig. 16.5 Acute phlyctenule at the limbus. The lesion is raised with an epithelial defect. There is early corneal vascularization.

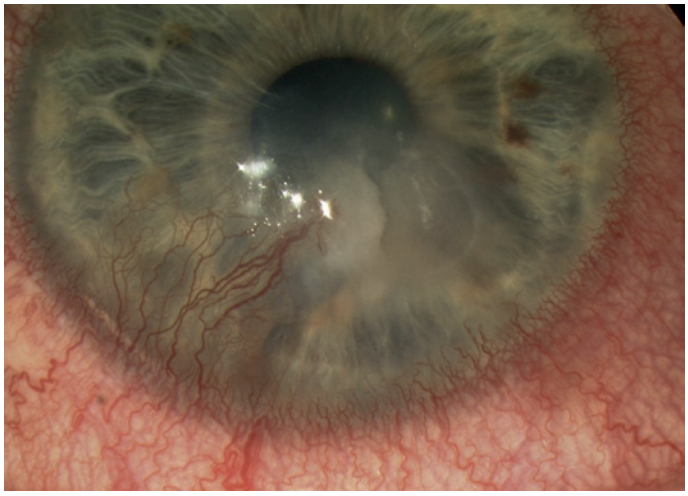

Fig. 16.6 A recurrent corneal phlyctenule. There is scar, thinning, and vascularization of the cornea that reduce vision.

corneal stain with fluorescein (Fig. 16.8). More severe corneal changes include corneal thinning or perforation and sectorial vascularization at the site of previous phlyctenules (Fig. 16.9). Vision loss may be insidious and severe.

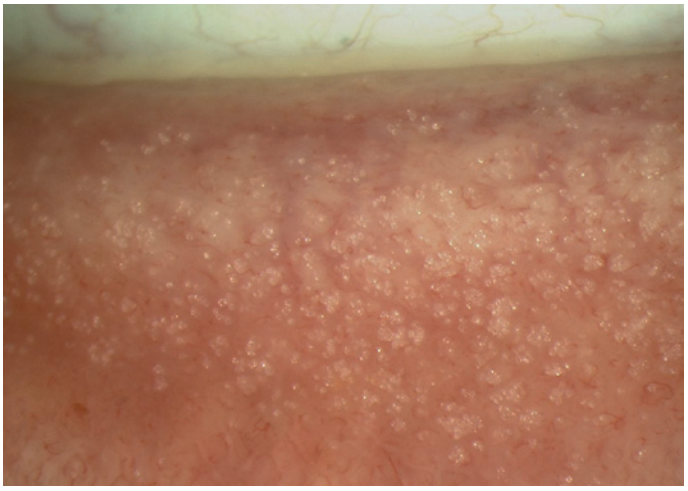

Fig. 16.7 Numerous subconjunctival crystalline deposits in blepharokeratoconjunctivitis shown in the tarsal conjunctiva of the everted lower lid.

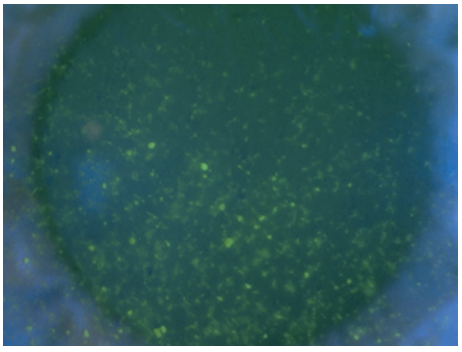

Fig. 16.8 Punctate epithelial erosion and microcysts secondary to blepharitis. Stained with fluorescein.

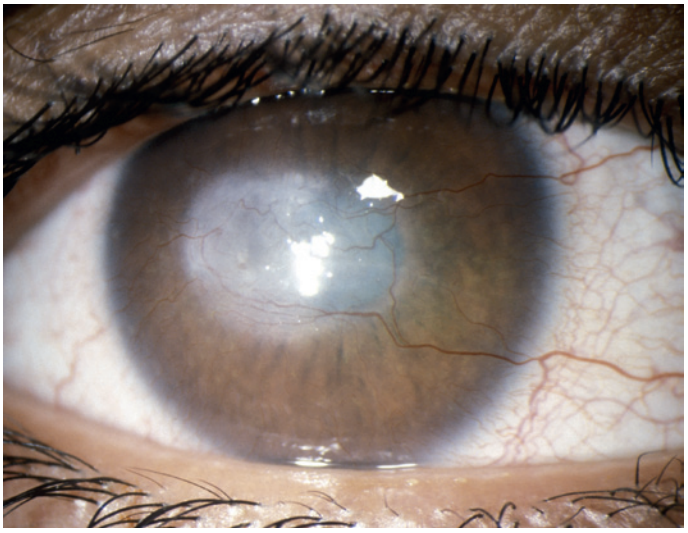

Fig. 16.9 Dense axial cornea scar associated with blepharokeratoconjunctivitis. The patient was relatively asymptomatic until a corneal opacity was noted.

Treatment of blepharokeratoconjunctivitis

There are no controlled clinical trials to guide therapy.[2] A hierarchical treatment strategy has been suggested.[3] Options include the following:

- Treat acute infection or styes with a warm compress and a short course of topical antibiotic (Table 16.2).

Table 16.2 Management options for blepharokeratoconjunctivitis

Option	Agent	Protocol
1. Lid scrubs		Daily
2. Topical antibiotic	Oc chloramphenicol 1% Oc azithromycin 1.5% Oc metronidazole 0.75%	Nocte bd Skin of face
3. Oral antibiotic	Erythromicin (<9 years) Doxycycline[a] (>9 years) Azithromycin	20 mg/kg/day for 3 months 2.2 mg/kg/day for 3 months 5 mg/kg/day for 5 days
4. Topical anti-inflammatory	e.g. Fluoromethalone 1% or cyclosporin 2%	As required
5. Omega-3 oil	Flaxseed	2.5 ml for 6 months
6. Immunosuppression[b]	Mycophenolate Corticosteroid	Supervision by pediatrician
7. Non-medical management	Fine-needle diathermy Corneal glue Lamellar keratoplasty Rigid contact lens	For progressive vascularization For perforation For perforation and scar For irregular astigmatism

[a]Doxycycline should not be used in children under 9 years and patients should be warned about skin sensitivity to sunlight and gastrointestinal side effects.
[b]Immunosuppression is reserved for sight-threatening and uncontrolled inflammation.

- Meibomian cysts tend to resolve spontaneously, but they should be incised if they do not resolve after 3 months or if they affect vision by altering lid position. A course of oral antibiotic (e.g. erythromycin, doxycycline, or azithromycin) should be considered if there are recurrent cysts.
- For chronic disease, a daily warm compress followed by lid cleaning with a cotton bud moistened in boiled water followed by application of a topical antibiotic (e.g. chloramphenicol, azithromycin). This can take 4–6 weeks to work and long-term maintenance therapy may be required. Long-term low dose (sub-antimicrobial) oral tetracycline or macrolide antibiotic, e.g. erythromycin, azithromycin, or doxycycline, are thought to work through an anti-inflammatory effect. Lid scrubs with chlorhexidine 0.02% may help if there is severe lid margin inflammation.[3]
- Topical immunosuppression with corticosteroid is the basis of treatment for most cases of BKC if there are conjunctival phlyctenules or significant corneal disease. For example, fluoromethalone 0.1% four times a day, reducing to once daily or less after 4 weeks. Long-term treatment (i.e. for years) with low-dose steroid may be required. Intraocular pressure should be monitored even with very low-dose therapy. A short course of intensive treatment (e.g. prednisolone 1% hourly) may be required to control intense inflammation. Topical cyclosporin or tacrolimus are alternatives to topical corticosteroid.
- Topical metronidazole gel can help facial skin disease.
- Treat visually significant keratitis with long-term (8–12 weeks) low-dose oral antibiotic. Systemic antibiotics reduce the frequency and severity of relapses.
- The effect of manual expression of the meibomian gland secretions or duct probing is debated and it is difficult to perform without sedation in young children.
- Dietary supplement with oral omega-3 (e.g. flaxseed oil) has been recommended.
- Rarely, for inexorable corneal opacification, or if corneal surgery is planned, systemic immunosuppression (e.g. oral corticosteroid, mycophenolate, or azathioprin) is required.
- Secondary microbial keratitis should be treated immediately.
- An axial corneal opacity or irregular astigmatism may cause amblyopia. Visual correction may be possible in older children using a rigid contact lens.
- Corneal perforation should be managed immediately with application of cyanacrylate glue before lamellar keratoplasty.[4]

Many cases of BKC require very prolonged treatment and even with all these options an estimated 10% of cases do not respond.

The great majority of cases of phlyctenular disease in developed countries are associated with staphylococcal lid margin disease, but phlyctenules are a reported association with tuberculosis, and very rarely with helminthiasis, leishmaniasis, and candidiasis. In areas where tuberculosis is endemic, a child with a phlyctenule should be screened for tuberculosis.

Other uncommon causes of chronic blepharokeratoconjunctivitis

Lesions of discoid lupus erythematosus at the lash margin may mimic chronic blepharitis. These may respond to topical treatment with corticosteroid but systemic therapy (e.g. hydroxychloroquine) is usually required. Lash or eyebrow infestation by crab lice (*Phthirus pubis*) can cause low-grade irritation and conjunctivitis (Fig. 16.10). Manual removal of the eggs (nits) and lice at the slit-lamp, followed by application of white soft paraffin eye ointment to the lid margin twice daily

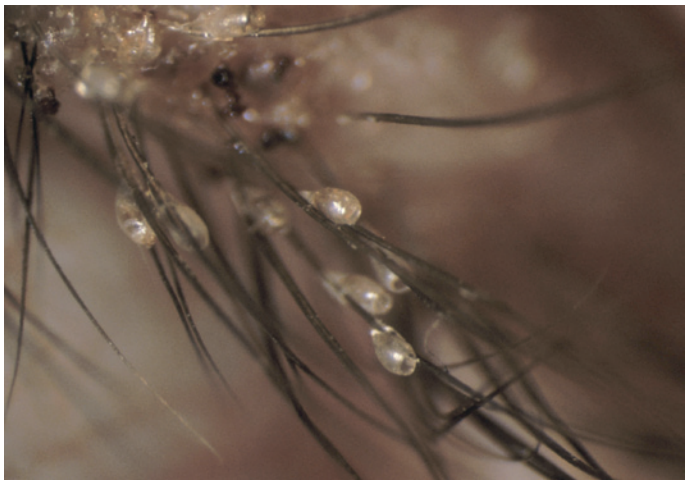

Fig. 16.10 *Phthirus pubis* infestation of the lashes. Adults can be seen superiorly at the bases of the lashes with eggs (nits) adherent to the shaft of the lashes.

for 10 days to smother the lice and eggs, is effective. Insecticides (e.g. permethrin 5%, malathion 1%) are not licensed for ocular use; they are used in shampoos or creams, but they cause ocular irritation. Decontamination of bed wear is essential. Because of the possibility of child abuse, a pediatrician should be involved and screening for sexually transmitted infections such as chlamydia may also be indicated.

Conjunctivitis

The causes of conjunctivitis are outlined in Fig. 16.1. Cultures are only necessary when there is:

1. associated corneal disease (microbial keratitis);
2. hyperacute conjunctivitis;
3. chronic conjunctivitis (symptoms >2 weeks);
4. ophthalmia neonatorum (infection before 28 days) (discussed in Chapter 13).

Acute conjunctivitis

Acute bacterial conjunctivitis is common in young children. It is bilateral in 70% of cases with a mucopurulent discharge, diffuse bulbar redness, and papillary hypertrophy of the upper tarsal plate conjunctiva. *Haemphilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Staphylococcus aureus* are the most common pathogens. One-quarter of children with conjunctivitis have a symptomatic otitis media, which usually resolves spontaneously. Viruses (adenovirus, picornovirus, herpes simplex virus [HSV]) are isolated in 6% of community acquired cases,[5] and preauricular adenopathy is a characteristic feature of viral infection. Chemical irritation (toxicity), BKC, and allergic conjunctivitis should be considered as alternative causes.

Acute infective conjunctivitis is typically self-limiting and resolves spontaneously over 2 weeks (65% in 2–5 days) (Fig. 16.11). Sight-threatening complications are uncommon. Management for most cases is irrigation with boiled water and is generally sufficient, with removal of secretions on the lid with a moist cotton pad. Antibiotics are unnecessary for most cases, although if used within 5 days of onset, they accelerate the resolution of symptoms and bacterial clearance. Complications of untreated disease are unusual. There is no evidence to support the superiority of any particular antibiotic. It is not necessary to exclude children from school unless adenoviral infection is suspected.[6]

Fig. 16.11 Acute bacterial conjunctivitis. Bilateral purulent discharge is an index of bacterial infection.

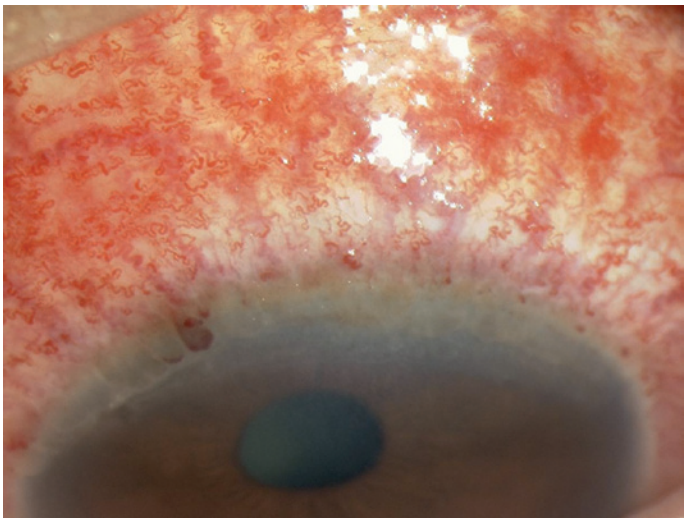

Fig. 16.12 *Neisseria gonorrhoeae* conjunctivitis. There is intense congestion of the vessels with petechial hemorrhages. There may be a hyperpurulent discharge and a tendency for corneal thinning at the superior limbus.

Hyperpurulent conjunctivitis

Hyperpurulent conjunctivitis requires urgent attention: it may be associated with severe corneal and systemic disease. Patients are typically febrile with a rapid onset of periocular swelling, mucopurulent discharge, pain, hemorrhagic conjunctivitis, and chemosis, with possible preauricular lymphadenopathy. Lid swelling and photophobia may make examination difficult. It is important to exclude infection with *Neisseria gonorrhoeae* and *N. meningitidis*, although *Staphylococcus*, *Streptococcus*, *Haemophilus*, and *Pseudomonas* spp. may rarely cause a similar picture (Figs 16.12 and 16.13). *Neisseria gonorrhoeae* conjunctivitis is not always sexually acquired, although this possibility should be excluded. Infection has occurred with the use of traditional medicines containing infected urine. *Neisseria gonorrhoeae* causes a rapidly progressive ulcerative keratitis with a characteristic superior corneal gutter that can rapidly perforate. *Neisseria meningitidis* conjunctivitis is usually acquired by airborne spread within schools or colleges. Although less severe, in 15% it causes epithelial breakdown

and ulcerative keratitis. Metastatic spread of *N. meningitidis* to the eye can occur as a terminal event following septicemia.

Membranous conjunctivitis

Differentiating membranous and pseudomembranous conjunctivitis is not useful. Any severe conjunctivitis (infectious, chemical, immune) can lead to membrane formation with corneal infiltrates and epithelial sloughing. Resolution may be accompanied by conjunctival scarring with non-progressive symblepharon and secondary entropion or trichiasis. Potential causes include:

- adenovirus and HSV
- *Neisseria* spp.

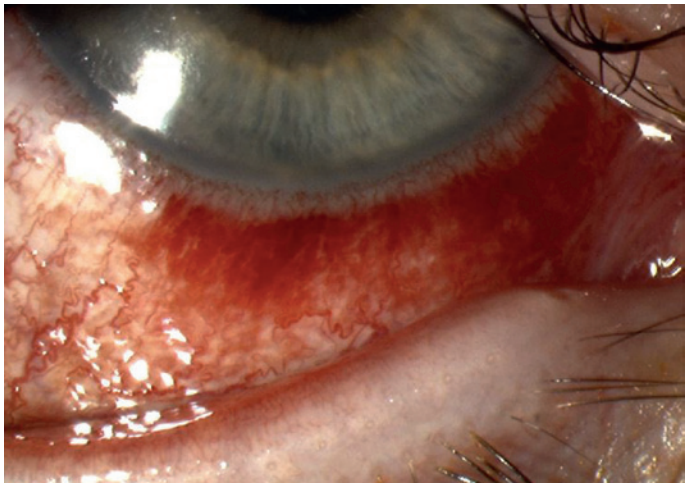

Fig. 16.13 Primary *Neisseria meningitidis* conjunctivitis in a child. Subconjunctival hemorrhages and epithelial defects are a common feature.

- Stevens–Johnson syndrome, toxic epidermal necrolysis;
- *Corynebacterium diphtheriae* (rare in developed countries);
- *Streptococcus pyogenes, Haemophilus influenzae, Staphylococcus aureus;*
- accidental or non-accidental chemical injury.

Diagnosis and investigation of conjunctivitis

Microbial investigation is only indicated for chronic conjunctivitis or hyperpurulent conjunctivitis. Samples should include an urgent Gram stain and culture on blood agar. Polymerase chain reaction (PCR) should exclude *Neisseria* spp., *Chlamydia*, adenovirus, and HSV. Treatment guidelines are presented in Table 16.3.

Systemic treatment for microbial conjunctivitis

Systemic treatment is usually required for patients with hyperpurulent conjunctivitis, if there is evidence of generalized infection, and immunosuppressed patients. These patients should be admitted until the diagnosis and management have been confirmed. Consultation with an infectious diseases specialist should be made. Patients with otitis media and hyperpurulent conjunctivitis may harbor identical strains of *Haemophilus influenzae* in both sites and systemic therapy is indicated.

Acute follicular conjunctivitis

Acute follicular/mixed conjunctivitis is characteristic of infection by viral or chlamydial organisms.

Table 16.3 Antibiotic treatment for conjunctivitis

Indication + common pathogens	First-line treatment	Alternative
Acute conjunctivitis[a]		
• *Haemophilus influenzae* • *Moraxella catarrhalis* • *Streptococcus pneumoniae* • *Staphylococcus aureus*	Observation, or G chloramphenicol 0.5% qds for 7–10 days	A fluoroquinolone, e.g. G Levofloxacin 0.5% qds for 7 days (prescribe if Gram-negative infection suspected)
Hyperacute bacterial conjunctivitis		
• *Neisseria gonorrhoeae*[b] • *Neisseria meningitidis*	IM Ceftriaxone once daily for 3 days	IM Spectinomycin once daily for 3 days (if penicillin allergy)
Note: Seek opinion from genitourinary and infectious diseases specialist	PLUS G Cefuroxime (PF) 5% hourly for 24 hours, then six times a day until resolved	PLUS G Ceftazidime (PF) 5% or a fluoroquinolone hourly for 24 hours, then six times a day until resolved
***Chlamydia* conjunctivitis**		
• *Chlamydia trachomatis*	G Azithromycin 1.5% tds for 3 days	PO Doxycycline 100 mg bd OR 200 mg daily for 7 days for children over 12 years of age
Note: Seek genitourinary opinion Treat sexual partners of parents/carers if necessary	PLUS PO Azithromycin 1 g STAT (for children who weigh ≥45 kg)	

[a]Acute conjunctivitis has a 65% chance of resolving without treatment within 2–5 days.
[b]Culture essential due to problems with resistance.

Viral infectious keratoconjunctivitis

This is an important cause of ocular morbidity and visual loss worldwide. HSV, varicella-zoster virus (VZV), adenovirus, and enterovirus are common causes.

Adenoviral keratoconjunctivitis

In many parts of the world, adenoviral keratoconjunctivitis is the most common viral infection of the ocular surface, causing community- or clinic-based epidemics. It accounts for approximately 8% of cases seen in primary care and 62% of cases seen in the ophthalmic emergency room. The clinical signs of the ocular pathogenic strains (serotypes 8, 19, and 37) are indistinguishable. Classification of disease subtypes (pharyngoconjunctival fever, epidemic keratoconjunctivitis) related to specific serotypes is of limited value.

Adenovirus infection causes acute lid swelling, a mixed papillary and follicular conjunctivitis, petechial hemorrhages, conjunctival membranes, and preauricular lymphadenopathy (Fig. 16.14). There may be an upper respiratory tract infection, vomiting and abdominal pain, urethritis, and cervicitis. Corneal epithelial sloughing and anterior uveitis can occur. Usually, a focal epithelial keratitis develops in 3–5 days, followed after 2 weeks by the development of immune-mediated focal subepithelial infiltrates (Fig. 16.15). After 3 weeks, the epithelial changes subside, leaving subepithelial scarring that can result in irregular astigmatism that often resolves over 6 months but which may be permanent. Subconjunctival scarring is common but not progressive or clinically significant. Diagnosis in the acute stage can be confirmed by PCR or commercially available enzyme-linked immunosorbent assay (ELISA)-based kits for use in the clinic. Because there may be 4–10 days of virus shedding before clinical disease is apparent, and because adenovirus can survive for days on dry surfaces, spread of infection between patients and clinicians is common.

There are no controlled trials showing benefit of topical steroid or antiviral therapy for the final outcome of adenoviral keratoconjunctivitis.[7] Treatment is based on symptomatic relief such as cold compress. Removal of conjunctival membranes can improve comfort but not the final outcome.

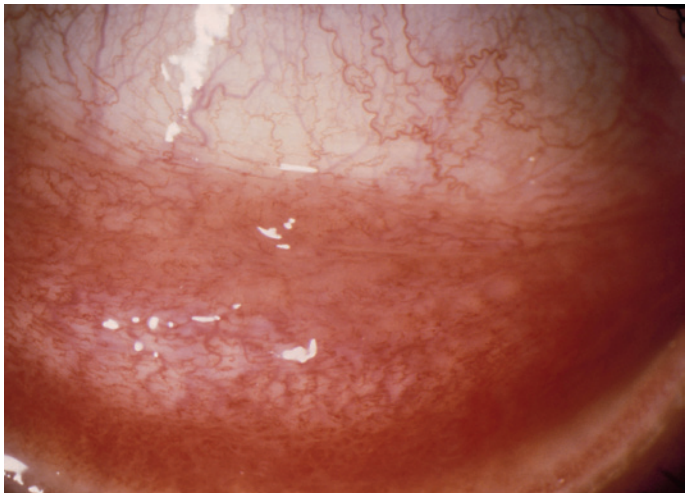

Fig. 16.14 Conjunctival follicular response in acute adenovirus infection. A papillary change may predominate over the upper tarsal conjunctiva.

Topical corticosteroid should be restricted to cases with visual reduction secondary to keratitis or if there is a membranous conjunctivitis or uveitis, but this may lengthen the period of virus shedding. Topical steroid is unlikely to precipitate herpetic epithelial disease even if there is HSV conjunctivitis. Topical non-steroidal agents, interferon, and antivirals (e.g. acyclovir, trifluorothymidine) have no effect and should not be used (Table 16.4). The lack of effective treatment has led to strict protocols to limit nosocomial virus spread. Patients with an acute conjunctivitis should be seen promptly in a separate area of the clinic where they cannot mix with other patients; equipment should be decontaminated after use.[8]

Herpes simplex blepharoconjunctivitis

Herpes simplex conjunctivitis or blepharoconjunctivitis (Fig. 16.16) is less common than bacterial conjunctivitis in children. It may be the result of a primary infection or recurrent disease following asymptomatic primary infection. It is often unilateral, with a mixed papillary and follicular response, and is associated with preauricular lymphadenopathy. Blepharoconjunctivitis can be particularly severe if there is co-existing atopic dermatitis (eczema herpeticum). There

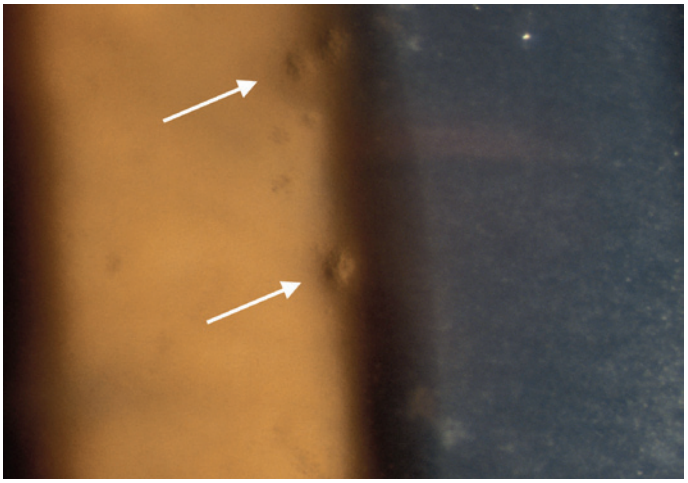

Fig. 16.15 Raised epithelial lesions of acute adenovirus keratitis (arrows). After a week the lesions flatten with the onset of anterior stromal scarring and irregular astigmatism.

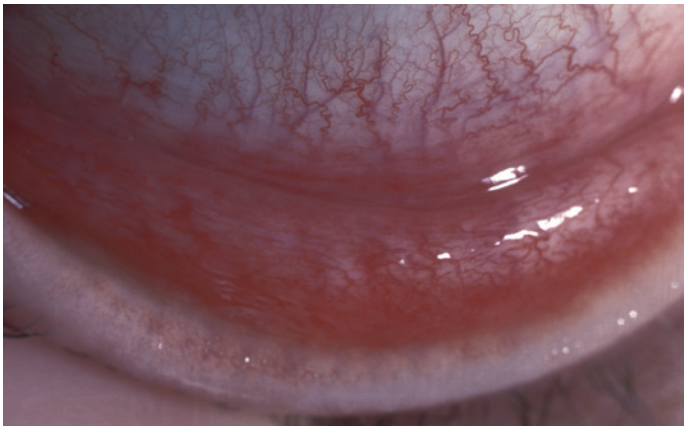

Fig. 16.16 A mild follicular conjunctivitis associated with herpes simplex infection. Confirmed by polymerase chain reaction.

Table 16.4 Treatment options for viral conjunctivitis

Common pathogens	First-line treatment[b]	Alternative
• Herpes simplex virus Note: Usually subsides without treatment within 4–7 days unless complications occur	Acyclovir eye ointment 3% or trifluorothymidine eye drops 1% 5× daily for 7 days (or continue for at least 3 days after complete healing) or Oral acyclovir 200 mg 5× daily for 5 days	Ganciclovir 0.15% gel 5× daily for 7 days
• Varicella (herpes) zoster virus Note: Exclude HIV/immunosuppression	Oral acyclovir 5× daily for 3 days	
• Adenovirus[a] • Enterovirus Note: Highly contagious. Self-limited, with improvement of symptoms and signs within 5–14 days	Nil	

[a]For adenovirus infection, instruct patient to avoid sharing personal items (towels, sheets, pillows, etc.), use meticulous hand washing, and avoid close personal contact for approximately 2 weeks. There is no effective treatment for adenovirus infection; however, artificial tears, topical antihistamines, or cold compresses may be used to mitigate symptoms.
[b]Dose reduction required when using oral antivirals in renally impaired patients.

may be a diffuse punctate keratitis or a dendritic ulcer, with multiple dendrites or geographic lesions in the presence of vernal keratoconjunctivitis. It is often self-limiting, but healing is accelerated by treatment with an antiviral such as acyclovir ointment or trifluorothymidine drops five times a day for 1 week. Oral acyclovir and an oral antibiotic (e.g. erythromycin) to treat staphylococcal superinfection is effective for eczema herpeticum.

Acute hemorrhagic conjunctivitis

Large outbreaks of acute hemorrhagic conjunctivitis caused by enterovirus 70 or coxsackievirus A24 occurred in central Africa and Asia in the 1980s. It has a rapid onset and resolution with characteristic petechial subconjunctival hemorrhages, without permanent corneal change. Direct inoculation and the use of traditional eye medicines, rather than the fecal–oral route, spreads the infection. Confirmation of infection is by PCR. There is no effective treatment; management relies on infection control. The outcome is usually benign, although a polio-like paralysis (radiculomyelitis) has rarely been reported with enterovirus 70 infection.

Chlamydia conjunctivitis

Outside the neonatal period, infection with *Chlamydia trachomatis* serotypes D–K is usually sexually acquired. There is a mixed follicular and papillary conjunctivitis with mucopurulent discharge and preauricular lymphadenopathy. The follicles may be prominent in the lower tarsal and bulbar conjunctiva. These should be distinguished from normal childhood follicles that are often present in the fornix and at the superior border of the tarsal plate. Keratitis is infrequent but the superior cornea can show a superficial punctate keratitis followed by subepithelial opacities and peripheral vessels. Diagnosis is by PCR of tear fluid. Local treatment is with topical azithromycin but systemic treatment with a single dose of oral azithromycin or a course of erythromycin or doxycycline is required to eradicate infection. Children should be investigated for other sexually transmitted diseases (e.g. *N. gonorrheae)*, and assessed for potential sexual abuse.

Trachoma

This is an important cause of external eye disease and the leading infectious cause of blindness. Repeated infection with serotypes A–C of *Chlamydia trachomatis* can cause conjunctivitis in children that progresses to scarring and blindness as adults. Without re-infection, it is a self-limiting disease. In 2014, it was estimated that 232 million people had blinding trachoma. It is endemic in 51 countries, principally in poor rural communities in developing countries. It has disappeared from most developed countries. Transmission is by direct contact with eye or nasal secretions, eye-seeking flies, or by aerosol.[9]

In some endemic areas, 80% of children have active disease and scarring disease can be seen in late childhood. Active disease in children is usually characterized by a mixed follicular and papillary response, best seen over the everted upper tarsal plate, often accompanied by a severe inflammatory response that obscures the underlying vessels over the tarsal plate, and a superior corneal pannus. Resolved follicles at the superior limbus leave depressions (Herbert's pits) that are pathognomonic of previous infection. Corneal blindness is the result of trichiasis, dry eye, secondary infection, and vascularization.

Control of the disease is by implementation of the SAFE strategy:[10]

S=**S**urgery for trichiasis
A=mass distribution of **A**ntibiotics
F=**F**acial cleanliness
E=**E**nvironmental improvement

Treatment of acute conjunctivitis is with a single dose of oral azithromycin (20 mg/kg body weight), or 6 weeks of 1% tetracycline ointment or azithromycin drops. Mass treatment is recommended when the prevalence of active infection is >5%. Clinical signs may persist for months after active infection has been eliminated. If there is trichiasis, lash epilation and lid taping are short-term options prior to lid eversion surgery.

Chronic follicular conjunctivitis

Chronic re-infection with *Chlamydia trachomatis* is a cause of chronic follicular conjunctivitis along with other rare chlamydial infections (feline pneumonitis, psittacosis, and

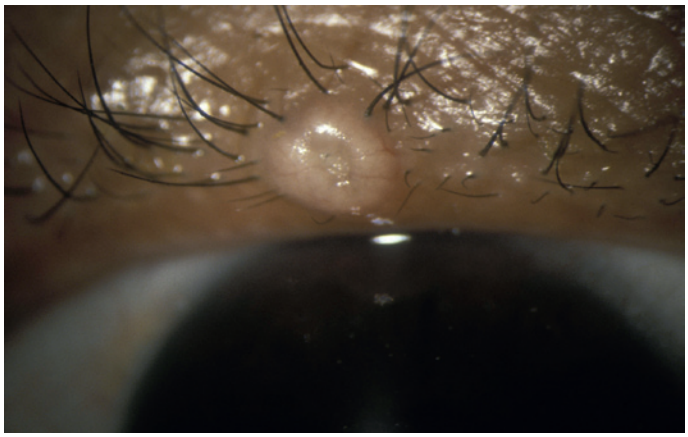

Fig. 16.17 An umbilicated lesion of molluscum contagiosum on the lid margin. There may be an associated follicular conjunctivitis and corneal vascularization in neglected cases.

lymphogranuloma venereum). Chronic canaliculitis and secondary conjunctivitis caused by *Actinomyces* spp. is rare in children. Hypersensitivity or toxicity to medications (preservatives such as benzalkonium chloride, especially in ocular hypotensives) can produce a follicular response. Other potential causes are described below.

Molluscum contagiosum

Molluscum contagiosum is a double-stranded DNA poxvirus. Transmission is by direct contact or autoinoculation to the eye. Molluscum lesions are umbilicated; when on the lid or close to the lash line they can easily be missed (Fig. 16.17). In this location they can cause a chronic follicular conjunctivitis, usually unilateral with a peak incidence at ages 2–4 years. Multiple facial lesions can develop in patients with atopy and in the immunosuppressed. Treatment is by expression or curettage of the core of the lesion, facilitated by making a small incision in the inner margin of the lesion with the tip of a needle – cautery or cryotherapy may cause depigmentation of the lid margin and loss of lashes; resolution is then rapid and topical steroid is not required. Chronic cases can develop a punctate keratopathy with secondary peripheral vascularization.

Parinaud oculoglandular syndrome

This rare condition causes a unilateral granulomatous conjunctivitis with surrounding follicles, often associated with fever and ipsilateral regional lymphadenopathy. It is a rare feature of cat-scratch disease, which is usually caused by a Gram-negative bacterium, *Bartonella henselae*, following a scratch from a cat or inoculation of contaminated cat flea feces into the conjunctiva. The diagnosis is confirmed by a rising immunoglobulin (Ig)G serology, indirect fluorescent antibody for *Bartonella* spp., or PCR from tears. There is a tendency to spontaneous resolution but treatment is with oral azithromycin, doxycycline, or ciprofloxacin. Other rarer causative agents are tularemia (*Francisella tularensis*), HSV, sporotrichosis, tuberculosis, and chlamydia.

Ophthalmia nodosa

This is a granulomatous reaction of the conjunctiva or cornea to implanted plant or insect hairs. There is rapid onset of irritation, photophobia, and chemosis after exposure. Migration of barbed hairs into the tissue is aggravated by eye rubbing. Intraocular penetration of the hairs can occur, with symptoms of chronic keratoconjunctivitis, uveitis, vitritis or chorioretinitis. Caterpillar hairs (setae) were the first reported causative agent, but hairs from pet tarantulas (e.g. Chilean rose tarantula – *Grammostola rosea*) are now more common. Tarantulas release a cloud of hairs as a defensive ploy when threatened. Protruding hairs can be removed, but physical removal of buried hairs is usually impossible. Mild topical steroid is effective to control inflammation. Conjunctival granulomas can be excised (Fig. 16.18).

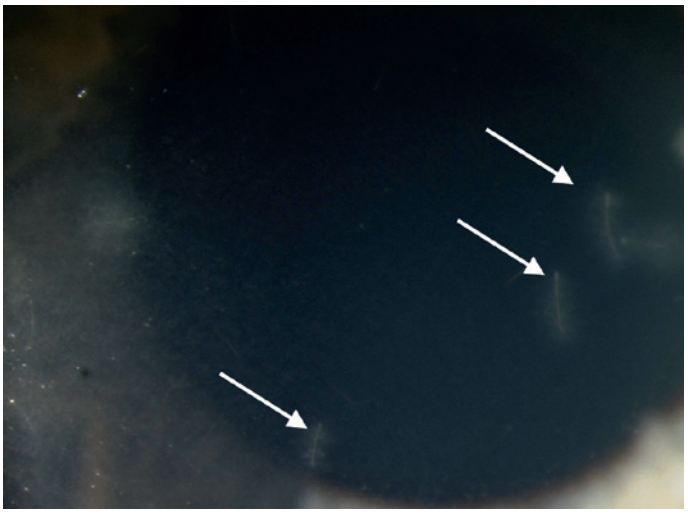

Fig. 16.18 Tarantula hairs embedded in the cornea (arrows). There was an associated mild conjunctivitis but no granuloma.

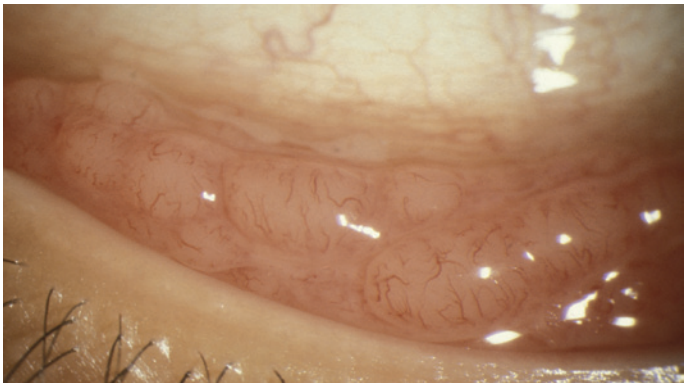

Fig. 16.19 Numerous large follicles in the inferior fornix (folliculosis). The patient was asymptomatic.

Conjunctival folliculosis

Folliculosis is a marked follicular response without other signs of ocular inflammation mostly seen in adolescents and young adults. There may be only mild discomfort; the follicles may have been noted coincidentally. The follicles may be present on the tarsal, forniceal, and bulbar conjunctiva (Fig. 16.19). Treatment or investigation is not usually required. A trial of topical steroid or oral doxycycline is appropriate but spontaneous resolution occurs; it may take years.

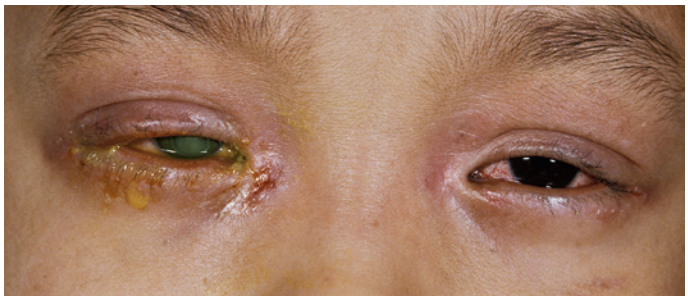

Fig. 16.20 Severe signs in a 6-year-old child with vernal keratoconjunctivitis. The lids are thickened with loss of lashes. There is also an abrasion on the side of the nose from eye rubbing. A right corneal plaque has developed.

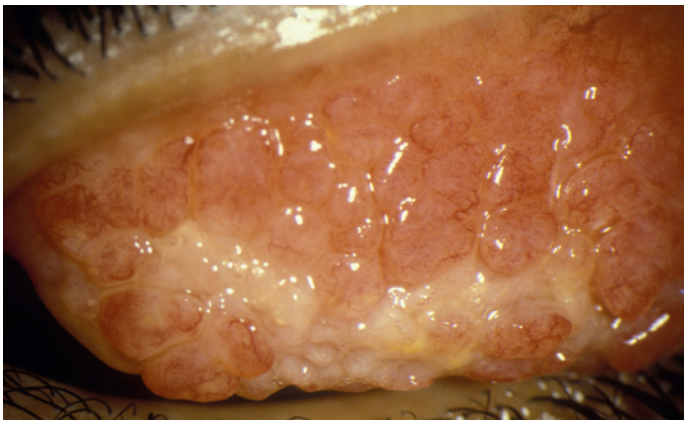

Fig. 16.21 Active palpebral vernal keratoconjunctivitis. There are giant papillae with adherent mucus.

Chronic papillary conjunctivitis

Vernal keratoconjunctivitis

Vernal keratoconjunctivitis (VKC) is an atopic disease in which an allergic response is mounted to common environmental allergens, dust or pollen. The mild ocular allergic diseases are seasonal and perennial allergic conjunctivitis. The severe allergic eye diseases are VKC that has an early onset with a high expectation for eventual resolution, and atopic keratoconjunctivitis that is unremitting, typically developing in older patients with severe facial atopic dermatitis (eczema).

Clinical features

VKC usually develops in the first decade of life (82% by age 10 years, with a mean age of 7 years). In 95% of cases there is remission by the late teens. In Africa, India, and the Middle East, it is a substantial public health problem, accounting for 3% of eye clinic patients and 10% of outpatient attendances. It affects 3–10% of children in Africa and the Middle East. The prevalence in Western Europe is less than 0.03%.[11] VKC is more common in males, although the gender difference is less marked in the tropics. In temperate regions, 45–75% of patients have a history of asthma or eczema; in tropical regions this is lower (0–40%). There is a family history of atopy in 50% of patients, although the expression (eczema, asthma, or allergic rhinitis) may vary in different family members. Limbal VKC is more frequent in patients of African or South Asian descent; this racial predisposition persists after migration to temperate regions.

Symptoms of VKC consist of itch, photophobia, discomfort, blepharospasm, blurred vision, and mucous discharge. The disease can be markedly asymmetric. The skin of the lids may be eczematous with excoriation at the canthi and a reactive ptosis (Fig. 16.20). Papillary hypertrophy and cellular infiltration over the upper tarsal plates obscures the pattern of underlying vessels. Giant papillae (>1 mm diameter) give a cobblestone appearance and, in active disease, mucus accumulates between the papillae (Fig. 16.21). Papillae can form at the limbus, appearing as gelatinous or vascular mounds with white Horner–Trantas dots (aggregates of degenerated eosinophils and epithelial cells) on the apices (Fig. 16.22). Reticular scarring can develop over the upper tarsal plate, rarely of clinical significance. VKC is classified as palpebral, limbal, or combined disease according to the distribution of the giant papillae. Palpebral or combined limbal and palpebral diseases behave similarly, whereas purely limbal disease, which is the more common form in tropical regions, is a more benign variant in temperate regions.

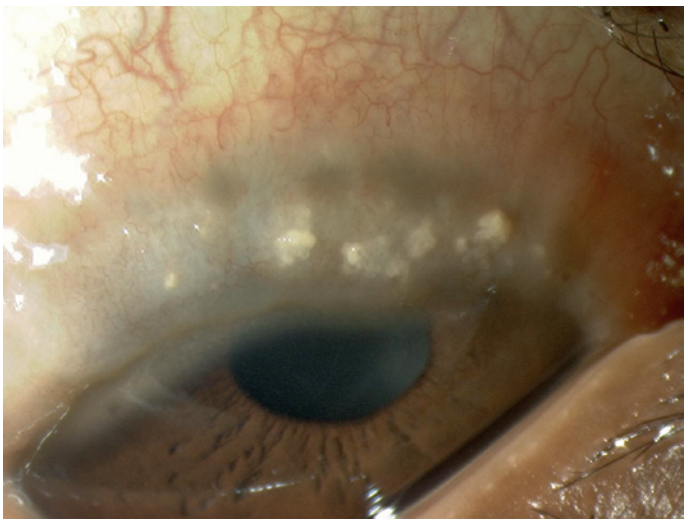

Fig. 16.22 Limbal vernal keratoconjunctivitis. White Trantas' dots have formed on the apices of the limbal papillae. There is a secondary pseudogerontoxon centrally.

Corneal changes

In mild disease there may be punctate epithelial erosions on the superior and central cornea. If there is active palpebral disease, mucus may be deposited on the superior corneal epithelium (Fig. 16.23), which can stimulate the formation of superficial corneal neovascularization. If there is severe palpebral disease, this may progress to corneal epithelial necrosis (macroerosion) caused by the toxic agents (e.g. eosinophilic major basic protein) released from the epithelium of the upper tarsal conjunctiva (Fig. 16.24). An epithelial erosion may heal completely with early intensive treatment, but in neglected cases mucus and calcium deposition on Bowman's layer can prevent re-epithelialization and a vernal plaque (shield ulcer) develops (Fig. 16.25). These plaques rarely vascularize, but they cause intense discomfort. Because there is a risk of secondary

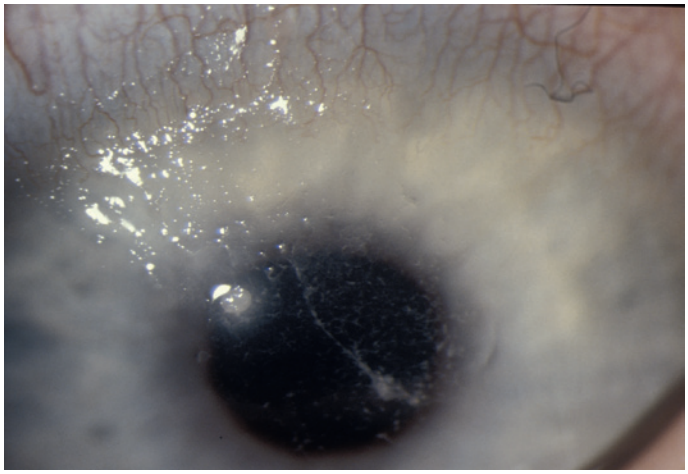

Fig. 16.23 Mucus adherent to the superior corneal epithelium in a case with palpebral vernal keratoconjunctivitis.

infection, including crystalline keratopathy, a prophylactic antibiotic should be prescribed (Fig. 16.26). Although visual loss from limbal disease is uncommon, an arcuate infiltrate can develop adjacent to limbal papillae (pseudogerontoxon), and there may be cystic degeneration of the conjunctiva in previously affected areas. In tropical regions, untreated limbal VKC is an important cause of visual loss.

Associated disease

Patients with VKC may have other conditions that affect their vision, including:

1. herpes simplex keratitis;
2. keratoconus in up to 26% of patients;
3. a characteristic anterior capsular cataract in 8%;
4. complications of unsupervised steroid treatment (glaucoma, cataract) in up to 20%.

The risk of visual loss is greatest in tropical regions, varying between 0% and 10%. The higher rate of visual loss in tropical

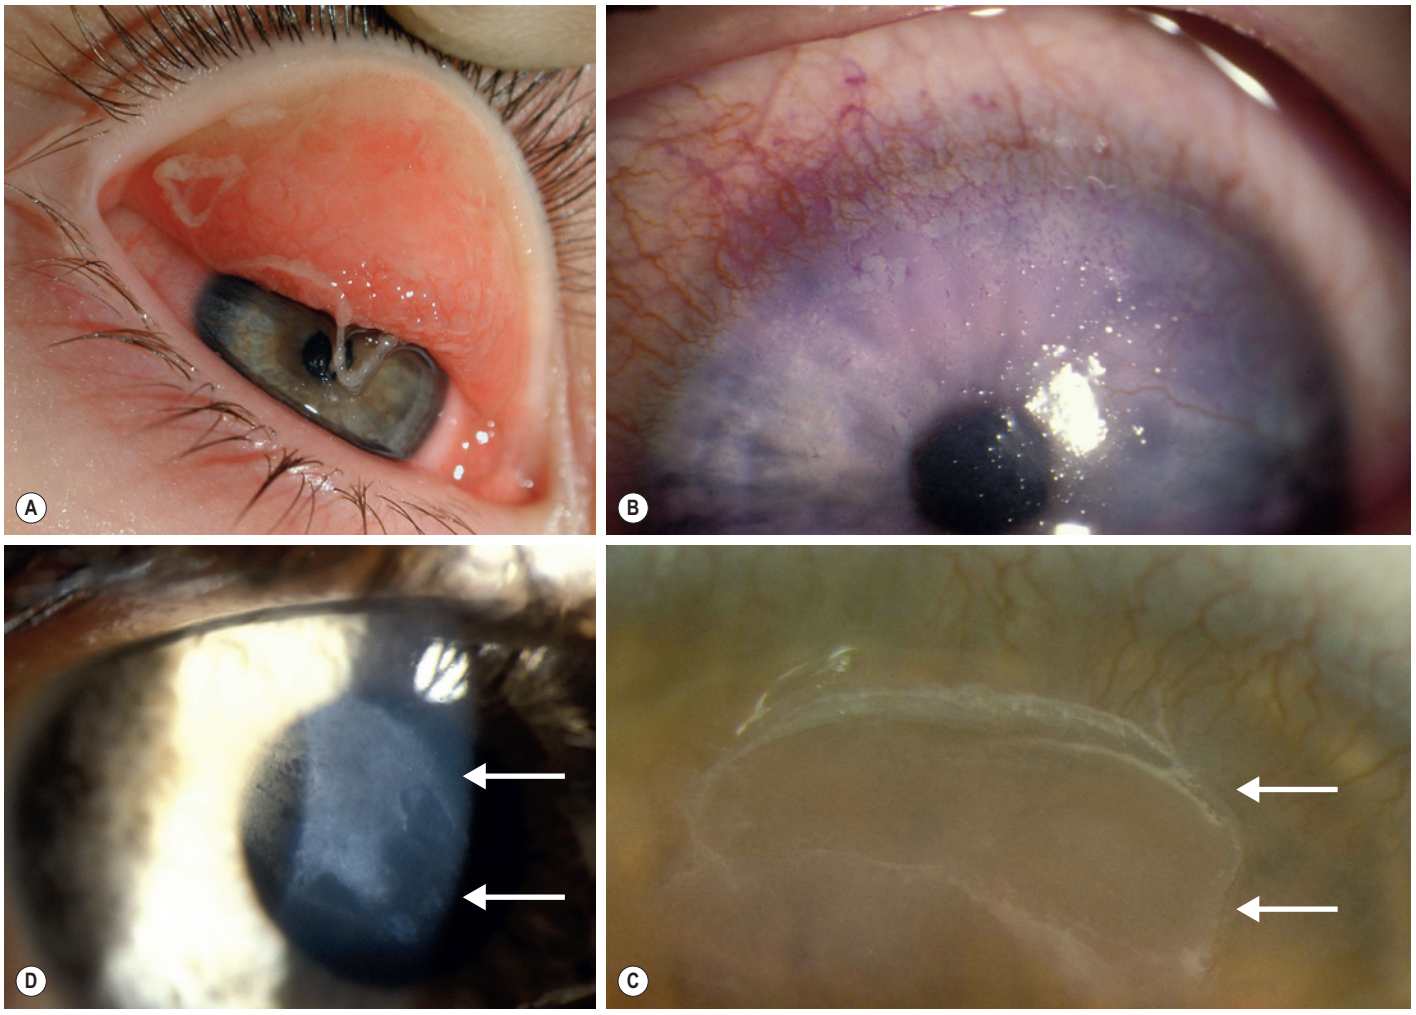

Fig. 16.24 The pathogenesis of vernal plaque. (A) The tarsal conjunctiva becomes inflamed with increased mucus production due to mast cell degranulation and histamine release. Eosinophil degranulation releases cationic proteins that are epitheliotoxic resulting in (B) associated corneal punctate keratopathy with adherent mucus highlighted with Rose Bengal stain. (C) If the inflammation continues, a confluent area of epithelium breaks down to form a macroerosion. Epithelial and eosinophilic debris are deposited on Bowman's membrane in the base of the macroerosion to form a vernal plaque (arrows). (D) Whether this is removed with lamellar dissection or epithelializes a ring scar results.

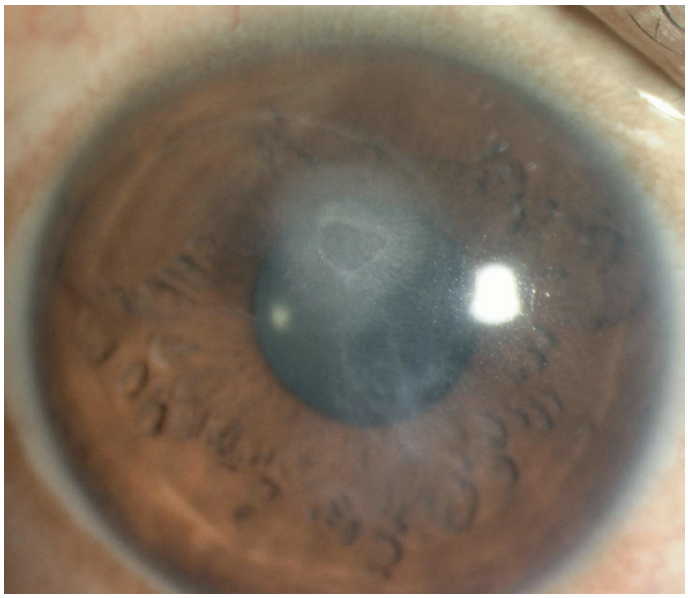

Fig. 16.25 Large corneal plaque in a case with palpebral vernal keratoconjunctivitis. The base of the defect is calcified.

areas is related to poor access to treatment and co-existent disease such as trachoma and bacterial conjunctivitis. In developed countries, minor visual loss from corneal scar occurs in about 6% of patients; 25% of patients with palpebral VKC in Western Europe develop corneal complications.

Disease mechanisms

In atopy, a subpopulation of T lymphocytes (Th2) is abnormally expanded; these cells drive the disease process via the type I (IgE-mediated) immediate hypersensitivity response. Th2 cells generate cytokines and interleukins (IL-3, IL-4, and IL-13) that promote the synthesis of IgE by B cells. When an allergen comes into contact with conjunctival mast cells coated with IgE antibodies specific to that allergen, the mast cell degranulates and releases histamine and other cytokines that recruit other inflammatory cells such as eosinophils, which in turn attract more inflammatory cells. Additional inflammatory mediators are released into the tissue and tears. Tarsal and limbal papillae consist of a central vascular core of mononuclear cells surrounded by edematous connective tissue infiltrated with plasma cells, mast cells, activated eosinophils, and lymphocytes. Squamous metaplasia of the overlying epithelium may also contain mast cells but a reduced number of goblet cells. Scar tissue (collagen type III) forms in the core of the papillae.

Mechanical irritation can precipitate a clinical picture similar to VKC termed "contact lens-associated giant papillary conjunctivitis" (GPC). The role of secondary irritation (diesel particles, infection, or smoke) amplifying the symptoms of VKC has not been fully explored. The genetic basis for VKC is not fully determined. An altered epithelial and mucosal barrier function is important, allowing environmental allergens access to the immune system. Truncation mutations in the filaggrin gene, a protein crucial to maintaining the epithelial barrier function, may be significant.

The diagnosis of VKC is based on characteristic clinical signs. Investigations to support the diagnosis are not usually necessary or widely available. The following may be helpful:

- Total serum IgE and tear IgE are usually elevated, but these measurements are also non-specifically elevated if there is atopic dermatitis. Commercial kits to measure total tear IgE are available.
- Measurement of local IgE production by radio-allergosorbent test, and conjunctival challenge to allergens can confirm allergic conjunctivitis but they are only available in some specialist departments.
- A conjunctival biopsy or a cytology specimen, taken by swabbing the conjunctiva with a nylon brush, will contain eosinophils and MC_T mast cells (tryptase positive, chymase negative) if there is severe allergic eye disease.
- "Allergy skin testing" is not indicated in the majority of patients. In temperate regions, epidermal or conjunctival challenge testing shows that at least 50% of patients are sensitive to house dust mite allergen, pollens, and animal dander. Testing for local environmental allergens (pollens, house dust mite, etc.) can support an atopic basis for the disease, but patients may react to several allergens with no indication as to which is causing the allergic conjunctivitis. Conversely, allergen-specific conjunctival provocation may reveal sensitivity to allergens that do not provoke a response by skin testing. In the same individual, the allergens provoking asthma and allergic conjunctivitis may be different. Advice should be sought from a clinical allergist if the disease is refractory.

Management

There is an excellent potential to retain good vision in the majority of cases of VKC, and iatrogenic disease must be avoided.[12] The presence of papillae alone is not a good indicator of activity. This is best reflected by conjunctival injection, the presence of mucus between the papillae, Trantas dots, mucus adherent to the corneal epithelium, as well as corneal epithelial breakdown, vascularization, and ulceration. Medical management is proportional to symptoms and signs; intensive topical corticosteroid is reserved for crises (Fig. 16.27). The following should be considered[13]:

- Allergen avoidance by eliminating feather pillows, carpets, pets. Allergens are often locally distributed, but

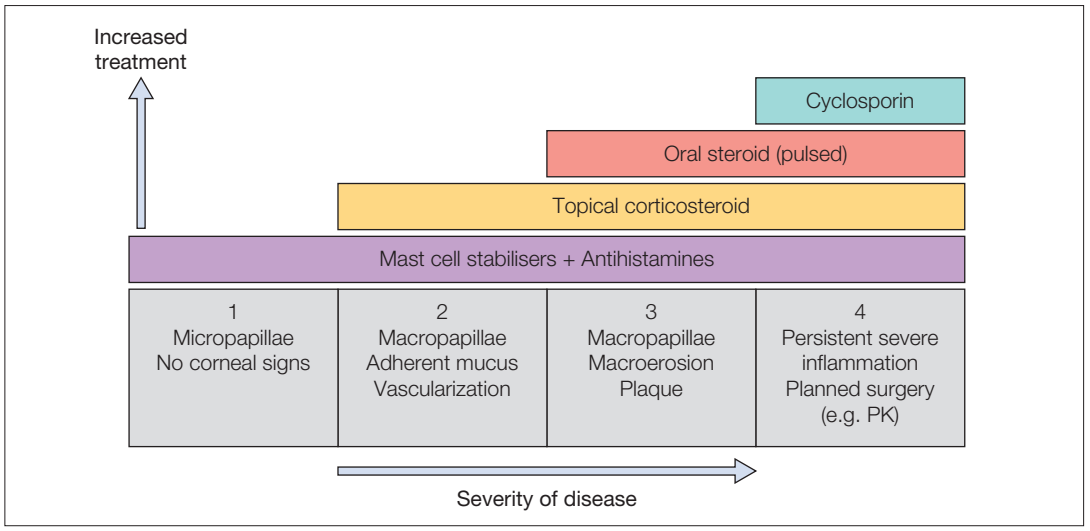

Fig. 16.27 The stepladder of treatment for severe allergic eye disease. With increasing severity of clinical signs (grades 1–4) treatment is added to control the disease. PK, penetrating keratoplasty.

geographic treatment by relocation may not be practical. The patient's school may need to be informed that VKC is not an infection. School staff may need to administer treatment during the school day.

- An oral antihistamine can help sleep and reduce nocturnal eye rubbing.
- Topical non-steroidal medications are effective, but no one agent is superior. For mild disease, topical histamine (H_1) antagonists (levocobastine 0.05%, emedastine 0.05%) produce rapid symptomatic relief. Topical cromones (sodium cromoglycate 2–4%, nedocromil sodium 2%) and other mast cell stabilizers (lodoxamide 0.1%) prevent mast cell degranulation. Dual action agents active against H_1 receptors and mast cell degranulation (e.g. olopatadine 0.1%) are well tolerated. All are safe for long-term maintenance therapy, reducing the number and severity of exacerbations and the need for supplementary topical corticosteroid.
- Topical acetylcysteine 5–10% reduces mucus adherence to the cornea during exacerbations.
- The role of topical non-steroidal agents (diclofenac 0.1%, ketorolac 0.5%), a potentially safe option, needs better evaluation.
- Topical corticosteroid is very effective, but patients should be carefully monitored for side effects (glaucoma, cataract, and ocular herpetic infection). Synthetic steroids (fluoromethalone, loteprednol, rimexolone) may reduce the risk of glaucoma and cataract. Steroid ointment, such as betamethasone, may be useful at night to reduce treatment frequency.
- Steroid injected into the supratarsal space after lid eversion (0.5–1.0 ml of either dexamethasone [4 mg/ml] or triamcinolone [40 mg/ml]) is reserved for severe disease not responding to topical treatment, or given at the time of surgery for a vernal plaque.
- Cyclosporin A (0.05% to 2%) or tacrolimus 0.03% is safe in children. It is an alternative to topical corticosteroid, but generally less well tolerated.
- Systemic immunosuppression with corticosteroids, cyclosporin A, tacrolimus, or azathioprine is reserved for severe unremitting disease with corneal complications. Leukotriene receptor antagonists (e.g. montelukast) appear to only be effective if there is associated atopic asthma. Molecular antagonists of IgE (e.g. omalizumab) and immunoglobulin are very expensive but may have a role in the acute management of severe disease.
- Surgical excision or cryotherapy of papillae produces only temporary remission as the papillae tend to re-grow. Application of mitomycin 0.02% after excision may reduce the rate of recurrence. Cryotherapy for limbal papillae risks causing corneal stem cell failure.
- Treatment of vernal plaque is by superficial keratectomy after the local allergic disease has been medically controlled. A short (3-day) course of oral corticosteroid (prednisolone 1 mg/kg) can help to rapidly bring severe disease under control. The epithelium should be reflected to show the full extent of the plaque and the plaque debrided or "peeled" from the surface. A minimum depth of tissue should be removed. There is no advantage in using laser phototherapeutic keratectomy. An amniotic membrane graft may rarely be required for a large persistent epithelial defect. A bandage contact lens is not an alternative to effective medical management. It increases the risk of secondary infection.

For severe unremitting disease, a short period of supervised treatment in hospital may be required to confirm compliance with treatment.

Treatment for GPC includes replacing scratched contact lenses or prostheses, optimizing their fit to reduce conjunctival trauma, and the use of a rigorous hygiene and protein-removing tablets 1–2 times weekly. Topical corticosteroids can be used freely if there is a prostheses. Protruding sutures should be removed.

Stevens–Johnson syndrome and toxic epidermal necrolysis

Stevens–Johnson syndrome (SJS) and the more severe variant, toxic epidermal necrolysis (TEN), are a spectrum of disease with potentially devastating ocular consequences. SJS is

defined as having <10% body surface area skin involvement and TEN as >30% affected. There is a characteristic prodrome of fever, malaise, and upper respiratory infection. The typical erythematous skin macules and target lesions can progress to vesicular lesions and necrosis. In severe disease, even slight rubbing leads to exfoliation of the outer epidermis (Nikolsky's sign). Any mucosal surface can be affected; lesions are most common on the lips and oral mucosa. The mortality rate of SJS is 1–5%, and of TEN is 25–35%; this can rise to 90% if large areas of epidermis are involved. The annual incidence in all ages is approximately 1.9 per 10^6 in Europe, lower in some ethnic groups. The incidence in human immunodeficiency virus (HIV)-positive patients is much higher. Eighty percent of patients hospitalized for treatment of SJS/TEN will develop eye disease, and 35% continue with chronic disease.[14] Acute eye involvement is usually more common with TEN than SJS but the proportions with late complications are similar.[15] It is the eye disease that causes the most profound long-term morbidity because it can progress over years after the acute episode has resolved.

The most commonly associated trigger factor for these diseases is exposure to drugs. HSV infection and mycoplasma is less common. Sulfonamides, phenobarbital, carbamazepine, and lamotrigine are strongly associated with a risk of SJS or TEN in children, with lesser associations with valproic acid, non-steroidal anti-inflammatory drugs, and paracetamol. In some cases no precipitating factor is identified.

The mechanism of disease involves Fas–Fas ligand interaction and cytotoxic T-lymphocyte activation that results in keratinocyte apoptosis, which is the basis of the skin and mucosal lesions. Histologically, there is lymphocyte aggregation at the dermal/epidermal interface and a perivasculitis.

It is essential that an ophthalmologist examines patients at the onset of disease. Acute ocular complications usually occur concurrently with the skin disease but may precede it by several days. The early signs include conjunctivitis with a mucous discharge, conjunctival membranes, and sloughing of the conjunctival epithelium (Figs 16.28 and 16.29). Conjunctival ulceration over the tarsal plates is common but may be difficult to confirm due to lid swelling. Corneal epithelial defects may progress to corneal ulceration with the potential for microbial superinfection (Fig. 16.30). Progressive sight-threatening corneal complications require lifelong management and can

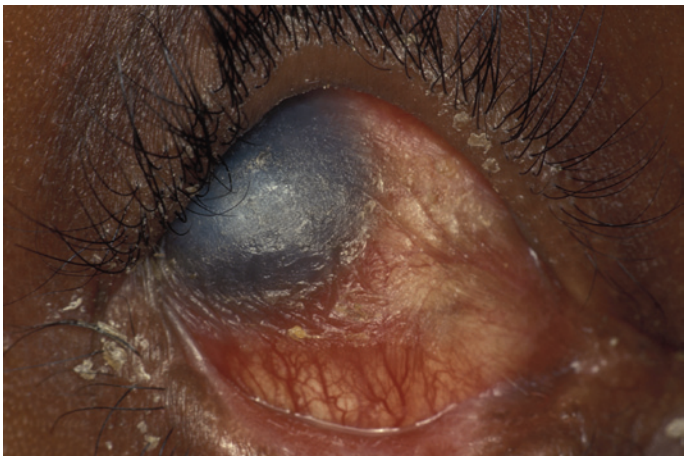

Fig. 16.34 A dry keratinized ocular surface in end-stage ocular disease following Stevens–Johnson syndrome.

result from conjunctival scarring involving the lid margin, tarsus, and loss of the fornix. Late complications may result from damage to the limbal epithelial stem cells, dry eye disease from obliteration of the lacrimal ductules and goblet cell loss, and from chronic inflammation or infection causing corneal opacity and neovascularization (Figs 16.31–16.34).

Management of SJS/TEN

Supportive management in the acute phase of the disease is essential. Patients are critically ill and require transfer to a regional burns unit or intensive care department for skin care and medical support. Identification and removal of the inciting agent is important. There is some evidence that systemic corticosteroids or intravenous immunoglobulin (IVIG) improve the prognosis of SJS compared to supportive care alone, while IVIG or other agents such as tumor necrosis factor alpha inhibitors (e.g. infliximab) and oral cyclosporin improve the prognosis of TEN. However, this is controversial.[16] There is no robust evidence that any of these systemic treatments improve the final visual outcome.

The goals of acute management of ocular involvement are minimization of inflammation and adhesions, infection prophylaxis, and the prompt identification and treatment of complications such as exposure and microbial keratitis. There is no standardized treatment for the prevention of ocular complications. Ocular hygiene with topical anesthetic and saline will remove inflammatory debris and periodic lysis of conjunctival adhesions with a squint hook or forceps to remove membranes, or scissors to divide early adhesions, is often performed, although there is no proof of long-term benefit. Lid taping or lubricant ointment and a moist chamber with polyethylene film must be used if the patient is anesthetized to prevent exposure keratitis. A topical antibiotic (quinolone) should be used if there is corneal epithelial breakdown. Topical corticosteroid or cyclosporin may help reduce severe conjunctival inflammation, but they should be used cautiously when there is a corneal epithelial defect because they may mask signs of infection, and bacterial or candida superinfection of an epithelial defect can progress rapidly. An amniotic membrane secured with absorbable sutures to cover the entire ocular surface, or secured over a conformer, may limit symblepharon formation and prevent limbal stem cell

Table 16.5 Ocular effects of chronic ocular surface disease

Ocular effects	Symptoms and signs
Loss of goblet cells	Poor tear film
Loss of lacrimal gland	Dry eye disease
Meibomian gland drop out	Punctate corneal epithelial stain
Posterior lid margin loss	Persistent epithelial defect
Posterior migration of meibomian gland orifices	Vascularization
Keratinization, particularly of the posterior lid margin	Scar
Conjunctival scarring and symblepharon	Visual loss
Entropion	Pain
Trichiasis	
Exposure	
Ocular surface stem cell failure	

failure if performed within 2 days of onset of symptoms.[17,18] Episodes of conjunctival inflammation may persist after the systemic disease has resolved or recur much later (recurrent SJS) in a clinical pattern similar to ocular mucous membrane pemphigoid. These recurrences do not occur in non-ocular tissues; their pathogenesis is obscure.

In the chronic phase of the disease (>1 month from onset), treatment focuses on management of chronic ocular surface disease by eliminating or minimizing toxicity from topical treatments and the introduction of immunosuppressive therapy if there is recurrent inflammation or progressive cicatrization. Successful management depends on the identification of the contributing components of the ocular surface disease, which must all be managed for successful control of the disease (see below). Severe conjunctival inflammation leads to the following sequence of events (Table 16.5):

- Loss of goblet cells and the accessory conjunctival lacrimal glands.
- Loss of the posterior lid margin with migration of the openings of the meibomian glands onto the posterior lid surface with meibomian gland dysfunction. Metaplasia of the meibomian gland duct epithelium is accompanied by abnormal lashes that grow from the gland opening (distichiasis). Keratinization extending onto the posterior lid margin is a particular risk for progressive corneal vascularization and opacification.
- An unstable tear film and a secondary punctate keratopathy causes chronic discomfort, photophobia, and reduced vision. Keratinization of the corneal surface results in severe discomfort and loss of vision.
- Conjunctival inflammation leads to a coarse reticular pattern of scarring over the upper tarsal plate. Conjunctival scarring can lead to lid shortening and entropion, resulting in corneal abrasion from trichiasis. Incomplete lid closure (lagophthalmos) is common.
- Trichiasis, dry eye disease, exposure, and poor surface healing mean that any abrasion can lead to a persistent corneal epithelial defect. This may progress rapidly to corneal stromal melt and perforation, particularly if there is microbial infection.
- Acute severe inflammation or chronic ocular surface disease may lead to ocular surface failure from loss of corneal epithelial stem cells.

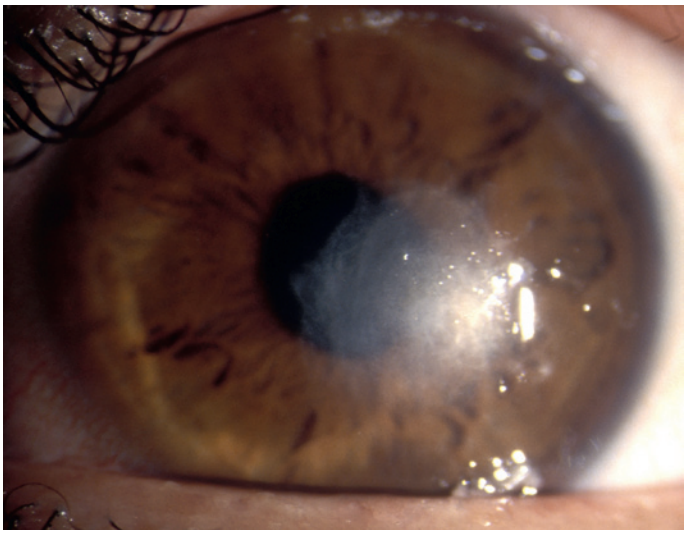

Fig. 16.35 Bacterial keratitis complicating dry eye disease in a child who developed graft-versus-host disease following bone marrow transplantation.

Graft-versus-host disease

Hemopoietic allogeneic stem cell transplantation (allo-HSCT) is used to treat a number of malignant and non-malignant hematologic disorders and some inherited diseases. The main complication of allo-HSCT developing in 40% to 60% of patients after an HLA-matched graft (<3 months after graft) is acute systemic graft-versus-host disease (GVHD). A proportion progress to chronic disease. The mechanism is the recognition by donor cytotoxic T lymphocytes of host alloantigens on antigen-presenting cells. GVHD affects the gastrointestinal tract, liver, skin, and lungs. Ten percent of patients develop conjunctival involvement during acute GVHD, with hyperemia and edema, the formation of conjunctival membranes, subconjunctival hemorrhage, and corneal epithelial breakdown. The severity of acute GVHD, and skin and mouth involvement, are all predictors of the development of chronic GVHD. The reported incidence of ocular involvement in chronic GVHD varies widely between 30% and 85% with a median onset of about 9 months and ocular can precede systemic disease. Corneal disease and chronic uveitis are the primary causes of visual loss. The principal ocular complication is dry eye disease from goblet cell loss and fibrosis of the lacrimal ducts, developing in 40–60% of patients, with a poor tear film, punctate erosions, and filamentary keratitis. There may be necrosis of the lid margins with secondary keratinization of the posterior lid margin and conjunctiva, trichiasis, and entropion. GVHD is a potentially blinding disease. In one study, severe ocular complications (bacterial keratitis or corneal perforation) occurred in 13% of 620 patients who had received bone marrow transplantation or allo-HSCT (Fig. 16.35). The incidence of severe ocular complications may be reduced by regular ophthalmic review and early treatment. Patients are also at risk during the required bone marrow suppression before an allo-HSCT of corneal involvement from herpes virus infections (simplex, zoster, Epstein–Barr).[19,20]

Initial management is intensive preservative-free lubricants (e.g. hyaluronic acid). A hematologist should supervise the management of systemic GVHD with treatment with systemic corticosteroid, cyclosporin A, or mycophenolate.[21] Additional

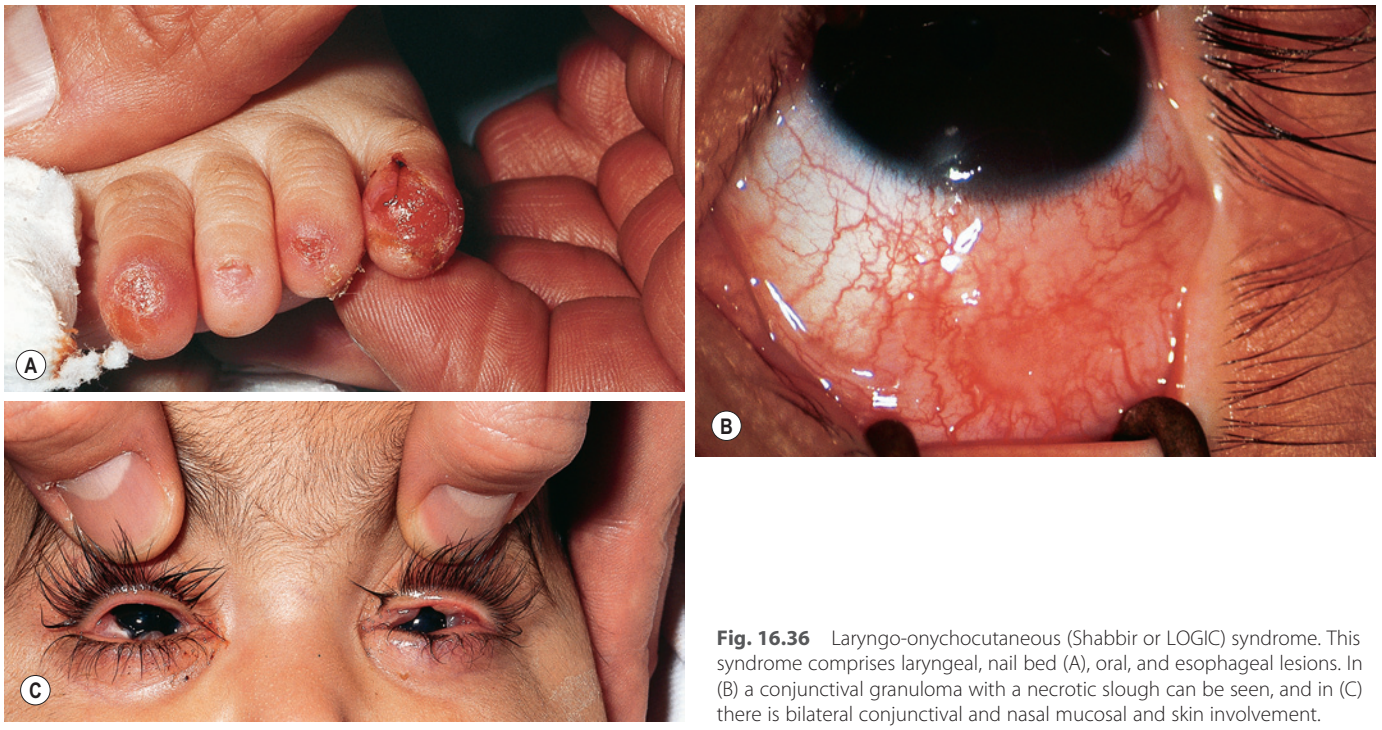

Fig. 16.36 Laryngo-onychocutaneous (Shabbir or LOGIC) syndrome. This syndrome comprises laryngeal, nail bed (A), oral, and esophageal lesions. In (B) a conjunctival granuloma with a necrotic slough can be seen, and in (C) there is bilateral conjunctival and nasal mucosal and skin involvement.

management options for chronic ocular surface disease are described below.

Inherited abnormalities of the epidermal microfilament assembly structure can cause severe corneal and ocular surface disease. Epidermolysis bullosa is described in Chapter 34. Laryngo-onychocutaneous syndrome (LOGIC or Shabbir syndrome) is another example that falls within this group of diseases. It is a very rare autosomal recessive condition described in consanguineous Punjabi Muslim families that comprises skin, laryngeal, and ocular mucous membrane sloughing and granulation tissue. It is evident in the first year of life and is relentlessly progressive (Fig. 16.36). The conjunctival changes are resistant to treatment, although fornix reconstruction using amniotic membrane may be partly effective. The condition is the result of mutations of the *LAMA3* gene that encodes the laminin subunit alpha-3.[22] Other loss-of-function mutations of this gene cause the lethal skin disorder Herlitz type junctional epidermolysis bullosa.

Corneal limbus stem cell failure (ocular surface failure)

Corneal epithelial stem cells are located in the basal layer of the epithelium at the limbus. Epithelial stem cell deficiency can result from chemical or thermal injury, or develop after acquired inflammation in conditions such as SJS of VKC. Congenital causes include aniridia, ectodermal dysplasia, in which there is an absence of the meibomian gland orifices, and the autoimmune polyendocrinopathies (Fig. 16.37). The final common pathway of disease is conjunctivalization of the surface of the cornea in which the epithelial layer contains goblet cells and the epithelial cells themselves express an altered cytokeratin profile (CK19) that is characteristic of conjunctiva (Fig. 16.38). There is often poor vision from vascularization

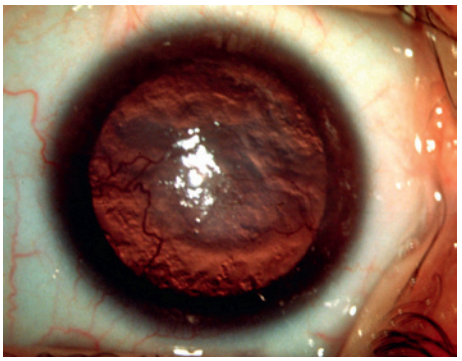

Fig. 16.37 Corneal vascularization and scarring in a child with autoimmune polyendocrinopathy. The mechanism is thought to be corneal limbus stem cell failure.

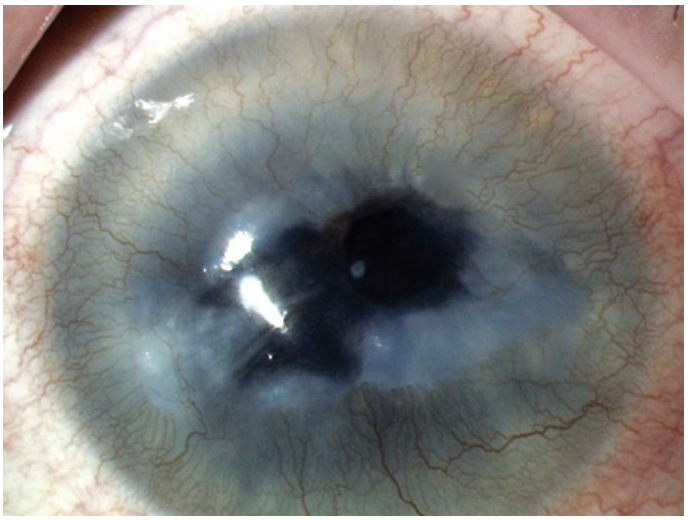

Fig. 16.38 Peripheral conjunctivalization of the cornea in a child with aniridia. There is superficial vascularization and scar of the peripheral cornea. With time the abnormal epithelium may advance to cover the whole cornea.

and subepithelial scarring. In aniridia, vision is further reduced by macular hypoplasia. The eye is uncomfortable due to an unstable epithelial surface. In bilateral disease there is often a severe reduction in quality of life.

Ocular surface failure is a difficult management problem. For unilateral disease (e.g. burns) a corneal epithelial phenotype can be restored by direct transfer of limbal tissue from the unaffected eye or the use of laboratory-cultivated cells.[23] In bilateral disease, a living related donor (parent, sibling) may donate tissue, or a cadaveric donor can be used, but this must be combined with systemic immunosuppression. An oversized or eccentric keratoplasty that includes part of the limbus can also be used if there is associated corneal stromal opacity. In adults, a successful outcome at 3 years following an autograft has been reported in 74–100% of cases; in childhood, the outcome is not clear. The results using unrelated donor tissue are much worse (21–54%). Laboratory-based techniques of cultured limbal epithelial transplantation have also been developed. The cells are obtained from a biopsy of limbal tissue or oral mucosa. A sheet of cultured epithelial cells, rich in stem cells or transient amplifying cells, attached to a carrier such as amniotic membrane or fibrin is transplanted onto the prepared surface of the recipient cornea. Laboratory-based methods are expensive and only available in a small number of specialist centers.

Management of severe ocular surface disease

The following options apply to the management of severe ocular surface disease, whatever the cause:

- Dry eye disease: use non-preserved lubricants with an ointment (e.g. white soft paraffin) at bedtime. Hyaluronic acid drops 0.1% to 0.4% have a long surface residence time. Autologous or pooled donor serum drops are effective. Temporary punctual occlusion with silicone plugs or permanent punctal occlusion with diathermy conserves tears.
- Chronic surface inflammation: preservative-free topical corticosteroid (e.g. prednisolone 0.5%); calcineurin antagonists (cyclosporin 0.05% to 2%, or tacrolimus 0.03%, if available). Filamentary keratitis: mucolytic drops – acetylcysteine 5–10%.
- Toxicity: eliminate preservatives in drops, especially benzalkonium chloride. Avoid aminoglycoside antibiotics. Recovery from the effects of toxicity may take several weeks.
- Trichiasis: epilate lashes in the short term. Electrolysis for occasional lashes, cryotherapy for groups of misdirected lashes, and surgery for trichiasis with entropion.
- Blepharitis: lid hygiene, topical antibiotic ointment, and oral erythromycin or doxycycline.
- Keratinization: topical all-*trans* retinoic acid 0.05% (not vitamin A) is effective but only available from specialized manufacturing pharmacies.
- Persistent corneal epithelial defect: treat exposure, infection, and trichiasis if present. Try intensive preservative-free lubricants, then therapeutic lenses (e.g. silicone hydrogel, or rigid corneal lens, or scleral lenses in very dry eyes) (Fig. 16.39). If this is unsuccessful, close the eye with tape, a temporary botulinum toxin tarsorrhaphy or a lid suture. Alternatively, an amniotic membrane onlay graft with a protective soft contact lens or temporary tarsorrhaphy.
- Corneal perforation: temporize with therapeutic contact lenses and/or corneal glue. If a keratoplasty is necessary, perform a lamellar rather than a penetrating procedure.
- Disease unresponsive to topical therapy (intense conjunctival inflammation, secondary corneal disease, progressive conjunctival scarring): systemic immunosuppressives may be required. Azathioprine and cyclosporin can be used separately or combined. A short course of high-dose oral prednisolone (1 mg/kg) can be used for rapid control until other agents are effective.
- Secondary corneal neovascularization: isolated vessels can be occluded by fine-needle diathermy. Topical steroid or subconjunctival bevacizumab are options for more diffuse vascularization.
- Management of end-stage bilateral corneal opacity due to scarring, neovascularization, and keratinization can be formidable, especially with severe dry eye disease. The results of ocular surface reconstruction by limbal allograft are poor in the presence of dry eye. A Boston keratoprosthesis, if the eye is moist, or osteo-odontokeratoprosthesis for cases with severe dry eye, may be considered. A conjunctival flap may be more appropriate if the eye is uncomfortable and there is no visual potential.

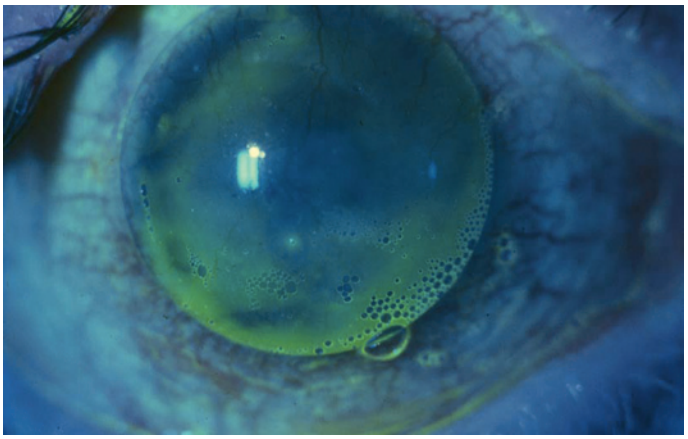

Fig. 16.39 A limbal-fit rigid contact lens used to improve vision following corneal scarring from Stevens–Johnson syndrome. This may also help correct the irregular astigmatism of aniridic keratopathy.

Toxic and hypersensitivity keratoconjunctivitis

In children who require long-term topical medication for glaucoma, allergic conjunctivitis, or recurrent herpes simplex keratitis, toxicity should be considered as a cause for conjunctival hyperemia, follicular and papillary conjunctival reactions, or delayed epithelial healing (Fig. 16.40). Secondary conjunctival scarring (pseudopemphigoid) and punctal stenosis can occur. There may be redness and an eczematous change of the periorbital skin. The most common sensitizing agents are atropine, pilocarpine, guanethidine, epinephrine, antivirals, benzalkonium chloride (as a preservative), and aminoglycosides. Treatment is elimination of the causative agent and a short course of topical steroid if there is severe inflammation.[24]

Fig. 16.40 Severe contact dermatitis following topical application of a cromoglycate for allergic eye disease.

Fig. 16.41 Ligneous conjunctivitis showing typical membranes. The central area of thickened hyperemic conjunctiva on the upper tarsus is the appearance that is sometimes seen in chronic cases, which may no longer have membranes.

Corneal or conjunctival artefacta

Conjunctivitis artefacta is uncommon in children. Self-medication (e.g. topical anesthetic abuse) or self-harm are common causes in adults and may be seen in older children. Non-accidental injury from parents or carers should be considered (see Chapter 70). Suggestive features of artefacta are signs that do not fit established patterns of disease, such as epithelial defects extending onto the conjunctiva, unilateral disease, involvement of only a defined region of the ocular surface, and failure to improve on therapy. It is often very difficult to be certain of the diagnosis. "Mucous fishing" in allergic conjunctivitis, corneal anesthesia, and molluscum should be excluded. There should be a frank discussion with the child and parents of the possibility that this may be the diagnosis, and involvement of a pediatrician and social services if necessary.

Ligneous conjunctivitis

Ligneous conjunctivitis is the most common manifestation of type I plasminogen deficiency (hypoplasminogenemia). There is an inability to break down fibrin clots due to an absence of plasmin; wound healing is arrested at the stage of granulation tissue formation. It is usually seen in infants and young children of all ethnic groups, with a slight female preponderance. Untreated the disease can persist for decades.[25] It is usually an autosomal recessive disorder with a homozygous or compound heterozygous defect in the plasminogen gene (*PLG*; 6q26). Typically, it involves the upper tarsal conjunctiva although the bulbar and lower tarsal conjunctiva may be involved (Fig. 16.41). Lesions have a yellow-white or red appearance and a woody texture. The disease may be precipitated by infection, trauma, or surgery. Fifty percent of cases are bilateral. Secondary corneal involvement occurs in 30% of cases with associated loss of vision. Lesions of extraocular mucosal sites are less common but include the gingiva, ear, respiratory tract, female genitourinary tract, skin, and renal collecting system. Several children with ligneous conjunctivitis have developed hydrocephalus.

Management should involve a hematologist. There will be early recurrence if surgical excision is performed without appropriate ancillary treatment. Conservative therapy should be considered in patients who are asymptomatic without corneal involvement. Before the demonstration of the role of plasminogen, or if plasminogen is unavailable, a success of 75% was achieved with excision with meticulous hemostasis, and immediate hourly application of topical heparin and steroid continued until inflammation had subsided.[26] Multiple treatments were sometimes required. Systemic or topical plasminogen concentrates are now the treatment of choice; systemic treatment is preferred as this is a multisystem disorder. Unfortunately, plasminogen concentrate is currently not available commercially for either systemic or local treatment. Topical plasmin is ineffective; it is rapidly broken down in the tear film.

Keratoconjunctivitis is one of the ocular manifestations of biotinidase deficiency, a condition treated with oral biotin (vitamin B_7) supplements. If untreated, children may have seizures, hypotonia, alopecia, seborrhoic dermatitis, and optic atrophy.

Keratitis

Corneal infection is rare in the normal eye because of the protective effects of corneal sensation and the blink reflex, as well as the presence of innate antimicrobial agents (e.g. defensins) in the tear film and ocular surface. Keratitis can occur if any of these are compromised. Visual rehabilitation and prevention of amblyopia are particular concerns in younger children with corneal inflammation.

Microbial keratitis

The main risk factors for microbial infection in children are trauma, ocular surface disease (VKC, trichiasis, BKC), congenital corneal anesthesia, exposure from propotosis or lagophthalmos, dry eye disease, systemic disease (systemic immunodeficiency, SJS/TEN, vitamin A deficiency and measles), and prior corneal surgery. Orthokeratology (correction of refractive error by molding the cornea with a soft contact lens) in adolescents is a particular risk, reported mostly from East Asian countries. The relative contribution of these risk factors varies with age, gender, and geographic location. In children up to 3 years of age, systemic illness and congenital external ocular disease are the main risk factors. In developing countries, protein-energy malnutrition and vitamin A deficiency is a significant risk factor under 5 years. In adolescents, contact lens wear has become an important cause of microbial keratitis in the developed world. Boys have a higher rate of microbial keratitis than girls, possibly because of higher rates of trauma (Figs 16.42–16.45).

The organisms responsible vary. All centers report high rates of coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, and *Streptococcus* spp. in younger children. *Pseudomonas* infection

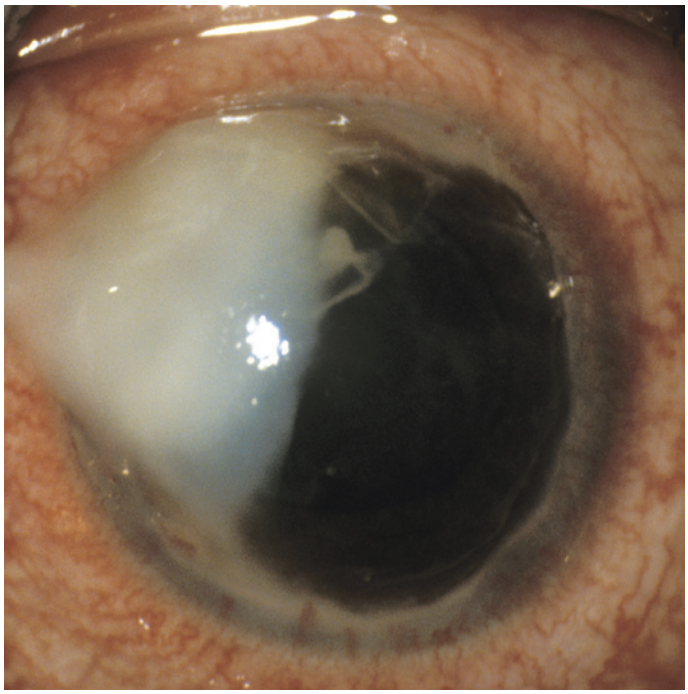

Fig. 16.42 Severe corneal ulceration and lysis secondary *Pseudomonas aeruginosa* in a 10-year-old girl with dry eye disease from graft-versus-host disease. A large-diameter tectonic keratoplasty was required.

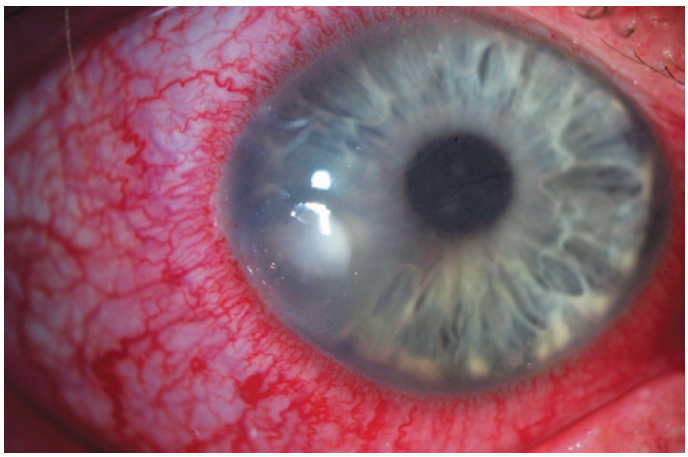

Fig. 16.43 Peripheral corneal ulceration secondary to *Pseudomonas aeruginosa* in an adolescent wearing a soft contact lens for myopia.

is more common in older children and is associated with contact lens wear. Because of the high risk of Gram-negative infection, contact lens-associated keratitis should never be treated with chloramphenicol. Fungus infection accounts for 10–18% of cases and filamentary fungal infections (*Fusarium*, *Aspergillus*) are common following trauma in subtropical and tropical environments, with yeast (*Candida* spp.) a particular risk factor in debilitated children. Polymicrobial infections can occur and should be considered if there is a failure to respond to treatment.

Immune (sterile) keratitis can occur. It results from immune-mediated inflammation. Immune infiltrates tend to be small and peripheral on the cornea, without a large epithelial defect. They respond rapidly to topical antibiotic and low-dose topical

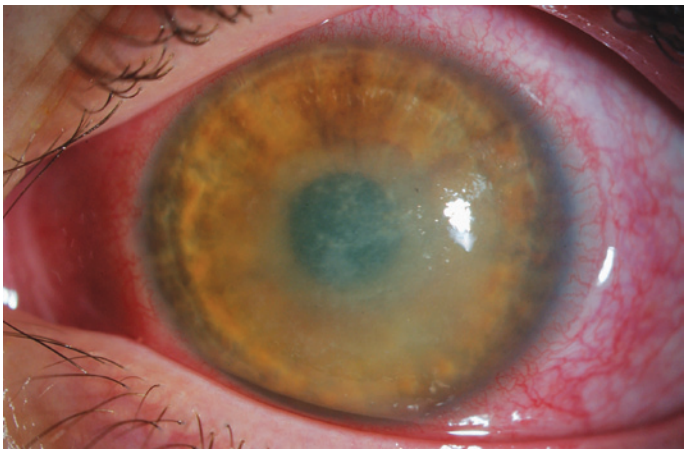

Fig. 16.44 *Acanthamoeba* keratitis in a 12 year old. Initial diagnosis was herpes keratitis, which delayed the initiation of the correct treatment for several weeks.

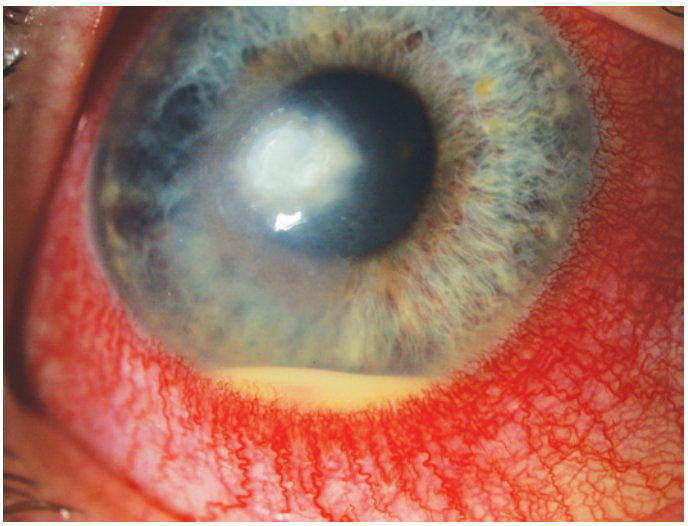

Fig. 16.45 Filamentary fungal keratitis following trauma. The edges of the lesion are "feathered" and there is a hypopyon.

Table 16.6 Distinguishing features of suppurative keratitis and sterile keratitis

Presumed microbial	Presumed sterile
Central lesions	Peripheral lesions
Lesions >1 mm diameter	Lesions <1 mm in diameter, or >1 mm diameter at the limbus
Epithelial defect	Intact epithelium (early) or small epithelial defect
Severe, progressive pain	Mild, non-progressive pain
Severe corneal suppuration with lysis	Mild corneal suppuration
Uveitis	No uveitis

corticosteroid. If the diagnosis is in doubt, they should be managed as infectious keratitis (Table 16.6).

Initial examination

This should record:

- dimensions of the lesion: the maximum length and width of the epithelial defect and infiltrate, and distance from limbus;

- stromal thinning, expressed as a percentage of normal corneal thickness;
- anterior chamber activity, including presence of fibrin, cells, and flare;
- the presence and height of a hypopyon;
- evidence of perforation;
- remediable risk factors for infection such as trichiasis or exposure;
- specific risk factors, e.g. contact lens (amoeba), trauma (filamentary fungus).

Investigation

Children with suspected microbial infection should be treated immediately with an appropriate broad-spectrum antibiotic. Diagnostic tests are not essential and may require sedation of the patient. Obtaining a sample for culture and sensitivity testing provides epidemiologic data and guidance for alternative treatment if there is failure to respond or deterioration on treatment. Culture is essential if:

- the clinical diagnosis is uncertain;
- there is a failure to respond to empiric first-line treatment;
- an unusual pathogen is suspected (e.g. fungus, amoeba).

Minimum investigation should include a slide for microscopy and Gram stain with material inoculated on blood agar plates (Table 16.7). Most fungi will grow on blood agar. Non-nutrient agar and Sabaraud agar should be included if *Acanthamoeba* or fungi are suspected. Samples should be inoculated directly onto the media or placed in transport culture media (e.g. brain heart infusion) before processing in the laboratory. Samples can be taken with a blade or a 21-guage hypodermic needle from the edges of the lesion. Growth of most pathogens can be expected after 48 hours. Cultures for fungi and *Acanthamoeba* should be incubated for up to 7 days. Sensitivity testing is normally reported for bacteria, but not *Acanthamoeba*, and fungal samples will need to be forwarded to a reference laboratory. Samples should also be taken for PCR (bacteria, fungi, *Acanthamoeba*) if this is available. Confocal microscopy can confirm the presence of fungi and *Acanthamoeba* cysts; this procedure may be possible in older children. Biopsy is only necessary for cases with chronic or progressive keratitis with prior negative cultures. Histologic examination should include immunohistochemistry for *Acanthamoeba* cysts and trophozoites and a silver stain for fungal hyphae.

Table 16.7 Investigations for suspected microbial keratitis

Organism	Histology	Culture
Common bacterial isolates[a]	Gram stain	Blood agar Nutrient broth
Facultative bacterial isolates		
• *Mycobacteria* spp.	Ziehl–Neelson	Lowenstein–Jensen
• *Nocardia* spp.	Gram stain	
Anaerobes	Gram stain	Thioglycolate broth
Acanthamoeba[a]	Immunofluorescence Calcofluor white	Non-nutrient agar seeded with killed *Escherichia coli*
Fungi[a]	Silver stain Calcofluor white	Sabouraud agar Blood agar
Microsporidia	Gram stain Periodic acid–Schiff	No growth *in vitro*

[a]Polymerase chain reaction probes available for all of these organisms

Treatment

The goals of treatment are sterilization of the cornea and healing. Sterilization may be rapid; it precedes epithelial healing and resolution of inflammation.

Choice of initial antibiotics

This depends on local epidemiologic data on the common corneal pathogens and their antimicrobial susceptibilities (Table 16.8). In temperate climates, bacterial isolates account for over 90% of the infections. In tropical climates, 50% may be fungal infection. Polymicrobial infection is present in 5–10% of cases. The choice of topical antibiotics for bacterial keratitis is outlined in Table 16.8 but selections should be modified if regionally appropriate. The first-line option should be broad-spectrum therapy to cover Gram-positive and Gram-negative bacteria, such as a fluoroquinolone monotherapy or a combination of a fortified aminoglycoside and fortified cephalosporin (neither are commercially available). In adults, these alternatives are comparable in effect. Although aminoglycoside and fluoroquinolone resistance is a problem in some parts of the USA and India, it is not currently in the UK. Because fluoroquinolones may not adequately treat streptococcal species, it is prudent to use a combination of a fluoroquinolone and a fortified cephalosporin if streptococcal infection is suspected in young children.

Sterilization phase

Treatment with hourly drops is given initially: 48 hours' duration gives a wide margin of safety. Admission is preferable unless good compliance is guaranteed. Topical treatment is reduced to four times daily until healing has occurred (i.e. re-epithelialization of the cornea). Fungal and amoebic infections require prolonged treatment to ensure sterilization. Systemic antimicrobials are only necessary for ulcers adjacent to the limbus to prevent scleral spread, or if there is actual or incipient corneal perforation, or if there is recent perforating corneal surgery (e.g. penetrating keratoplasty). Adjunctive therapies may include cycloplegia, analgesics, and hypotensive agents for secondary glaucoma. A subconjunctival injection of a broad-spectrum antibiotic can be given if an examination under anesthesia has been necessary or if there is poor compliance, but it does not achieve a sustained higher corneal concentration than topical treatment.

Once treatment has been started, there can be an initial increase in inflammatory signs due to endotoxin release. Definite evidence of progression after 48 hours (increased stromal thinning or a clear expansion of the ulcer) implies the patient is insensitive to treatment or there is poor compliance. Patients should be admitted if necessary and the microbiology results reviewed. A change to an alternative therapy is not indicated at this stage unless there is antimicrobial resistance to the primary therapy. Complications are common in children. Even with early recognition and appropriate management surgery rates range from 6% to 28%. If there is threatened

Table 16.8 Treatment options for microbial keratitis

Common pathogens	First-line treatment	Alternatives
• *Staphylococcus aureus* • *Streptococcus pneumoniae* • *Pseudomonas aeruginosa* • *Serratia marcescens*	Fluoroquinolone, e.g. G Levofloxacin 0.5% hourly (day and night) for 2 days, then hourly (day) for 3 days, then qds until resolution	G Cefuroxime 5% hourly then taper according to severity until resolution PLUS G Gentamicin 1.5% hourly then taper The following antibiotics can be used if available according to sensitivity results: G Penicillin 0.3% G Amikacin 2.5% G Ceftazidime 5% G Vancomycin 5%
Mycobacterium keratitis		
• *M. chelonae* • *M. fortuitum* • *M. flavescens*	G Amikacin 2.5% hourly PLUS G Levofloxacin 0.5% hourly	G Clarithromycin 1% hourly PLUS G Azithromycin
Fungal keratitis[31]		
• *Candida* spp. • *Aspergillus* spp. • *Fusarium* spp.	G Natamycin 5% hourly, then taper frequency until resolution (active against *Candida* spp. and some *Aspergillus* spp.) OR G Voriconazole 1% (active against *Candida* spp., *Aspergillus* spp. and *Fusarium* spp.) OR G Amphotericin 0.15% (active against *Candida* spp. and *Aspergillus* spp.) For lesions that potentially extend into the anterior chamber or into the sclera: add systemic therapy PO Fluconazole bd (active against *Candida*) OR PO Voriconazole bd (active against *Aspergillus*) – dose adjusted by weight and age	G Econazole 1% OR Miconazole 1% (arachis oil) (active against *Candida* spp. and some *Aspergillus* spp.) ADD G Chlorhexidine 0.2% for severe infection (no evidence for benefit of dual therapy) PO Voriconazole (active against *Fusarium* spp., *Aspergillus* spp., and fluconazole-resistant *Candida* spp.) Intralesional voriconazole or amphotericin 50 μg in 0.1 ml repeat weekly as needed (reconstituted from a 200 mg IV vial)[a]
Acanthamoeba spp.		
Recommended regimen: Hourly day and night for 48 hours, then hourly by day for 72 hours, then every 2 hours for 3–4 weeks, then tailored to each individual case No clinical evidence to suggest that dual therapy is more effective than monotherapy with polyhexamethylene biguanide alone	G Polyhexamide (polyhexamethylene biguanide) 0.02% OR G Chlorhexidine digluconate 0.02% PLUS G Propamidine 0.1% isethionate (Brolene) OR G Hexamidine 0.1% diisethionate (Desomedine)	If unresponsive to both combinations of first-line therapy consider G PHMB 0.06% OR G Chlorhexidine 0.2%

[a]May increase risk of perforation

or actual perforation, application of cyanoacrylate glue may stabilize the situation. Urgent lamellar or penetrating keratoplasty (PK) may be required, although there is a high risk of graft failure and amblyopia. A conjunctival flap may be more appropriate for large perforations in infants. If there is deterioration or indolent inflammation after 1 week, repeat culture for fastidious organisms or a biopsy are indicated.

The healing phase

Even after sterilization of the corneal ulcer, healing may be delayed by persistent inflammation, toxicity to treatment, or failure to treat the precipitating causes (e.g. exposure, trichiasis, dry eye disease). Non-preserved medications should be used if possible, and ocular surface disease should be treated (Fig. 16.46).

Use of topical corticosteroids

Topical corticosteroids reduce inflammation that may be delaying healing. However, they must be introduced cautiously because they potentiate the growth of fungi and herpes simplex infection. In adults, there is no clear benefit for the use of corticosteroids as adjunctive therapy in the management of bacterial keratitis.[27] Healing without topical steroid will occur but is slower than when steroid is used. Early treatment with topical corticosteroid has an adverse effect on the outcome of *Acanthamoeba* keratitis and filamentary fungus.[28] In patients with a PK in whom fungal infection is excluded, topical corticosteroid therapy should be introduced at the outset of infection to protect against allograft rejection. Topical cyclosporin is an alternative to control inflammation in cases of fungal infection; this does not potentiate fungal growth.

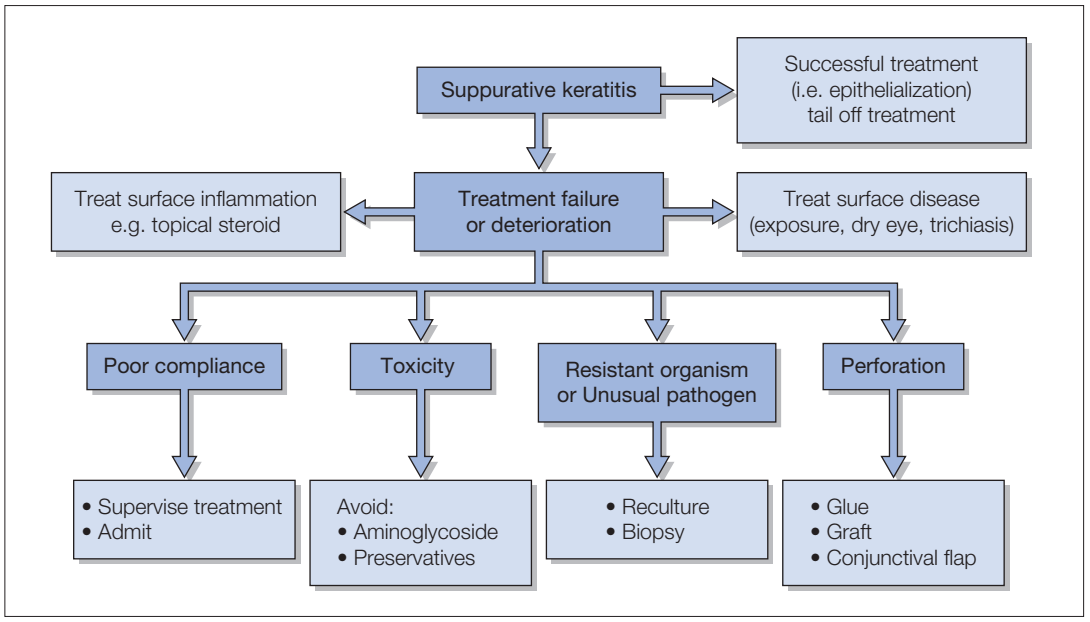

Fig. 16.46 Algorithm for evaluating response to treatment of suppurative keratitis.

Progressive or indolent microbial keratitis

Progressive microbial keratitis after 5 days of intensive broad-spectrum topical antibiotic treatment is an indication for re-culture using specialist media (see Table 16.7) or corneal biopsy. Stopping treatment for 24 hours prior to re-culture may increase the chance of recovering a pathogen, but this must be balanced against the risk that an infection could advance rapidly during this time. When a biopsy is performed, half should be sent for histology, the other half pulverized and cultured. A microbiologist should be consulted regarding optimum media for isolation, which would normally include a modified Ziehl–Neelsen plate. Slow-growing pathogens can take 3 weeks to grow in culture and the laboratory should be asked to perform extended incubation. A trial of therapy directed at the organism most likely to be causing the infection on clinical and epidemiologic grounds can be started while waiting for the pathology results.

Fungal keratitis is characterized by a raised white stromal infiltrate with feathery borders, satellite lesions, "solid" hypopyon, and endothelial plaque formation. Treatment is dependent on local epidemiologic data. Suggested antifungal therapies are shown in Table 16.8. Commercially available natamycin 5% is the drug of choice for filamentary fungal infection, with amphotericin B used for *Candida* spp. Oral treatment is recommended for deep stromal filamentary fungal infection because of risk of hyphal growth through Descemet's layer into the anterior chamber. Subconjunctival or intracameral injection of amphotericin are additional treatment options to achieve therapeutic levels of drug, but intrastromal injection can increase the risk of perforation. Early excisional keratoplasty may be required to control progressive filamentary fungal infections.

Acanthamoeba infection in children is rare but may be associated with contact lens wear, with showering or swimming in lenses a particular risk. Delay in diagnosis and early treatment with topical steroid can seriously affect outcome. Treatment options are presented in Table 16.8. While epithelial disease is relatively easy to eliminate, stromal infection can require months of treatment before the *Acanthamoeba* cysts are killed. More detailed management options are presented elsewhere.[29]

Microsporidium keratitis is an emerging cause of corneal infection in some regions. Large series from Singapore and Southern India report infections in immunocompetent patients, related to soil contamination, trauma, and contact lens wear. The most common appearance is a coarse punctate epitheliopathy. Diagnosis is confirmed by histologic examination of an epithelial biopsy. Although topical fluoroquinolones have been recommended, the disease is self-limiting with a good visual outcome. *Microsporidium* stromal disease is extremely rare and difficult to eradicate. Excisional keratoplasty is often required. Treatment options for stromal disease include topical Fumadil-B 0.3% (active drug fumagillin) and oral albendazole.

There is currently no convincing evidence of a benefit of corneal collagen cross-linkage as an ancillary option to standard therapy for antimicrobial keratitis.

Herpes simplex virus keratitis

HSV is the most common infectious cause of corneal blindness in developed countries. It is also an important cause of visual loss in developing countries, particularly in association with endemic measles. It is less common in children than adults.

Primary infection with HSV may be subclinical and remote from the site of recurrent disease. Acute conjunctivitis may represent primary infection. After infection, the virus is carried to the sensory ganglion where a latent infection is established. Stimuli such as fever, hormonal change, ultraviolet radiation, trauma, and trigeminal nerve injury may then reactivate HSV, which is transported in axons to the ocular surface causing recurrent disease. The virus may maintain latency within the cornea and HSV can be spread by corneal transplantation. The HSV-1 strain is usually responsible for ocular or labial disease; HSV-2 causes urogenital infection and is associated with herpetic ophthalmia neonatorum. HSV-1 and HSV-2 reside equally in almost all ganglia; local factors favor HSV-1 reactivation from the trigeminal ganglion. Transmission of HSV is facilitated in conditions of crowding and poor hygiene.

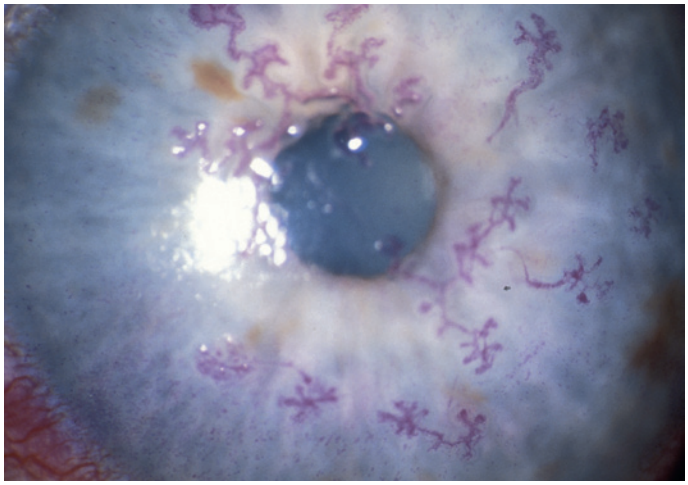

Fig. 16.47 Multiple dendrites from herpes simplex infection complicating vernal keratoconjunctivitis.

Malnutrition, measles, and malaria may suppress cell-mediated immunity and be associated with severe unilateral and bilateral HSV infection.

Because primary HSV infections may be asymptomatic in two-thirds of cases, clinical surveys underestimate the incidence and prevalence. Serology is used to define the prevalence of prior infection, and this reflects latency. Age, geographic location, and socioeconomic status affect the prevalence. Using PCR, the detection of HSV in the trigeminal ganglion suggests a prevalence of 18.2% by 20 years of age, but crowding may be a risk factor for early exposure and in Africa 70–80% have HSV-1 antibodies by adolescence. Ten million people worldwide may have herpetic eye disease.

There are different patterns of HSV keratitis. The clinical picture may vary over time and multiple features may be present in the same cornea:

- Epithelial lesions (dendritic ulcer, geographic ulcer): This is the result of virus replication and is the most common presentation of recurrent ocular HSV (Fig. 16.47). A geographic ulcer is nominally >1 mm diameter and associated with concurrent topical corticosteroid treatment or allergic eye disease.
- Neurotrophic keratitis (metaherpetic ulceration, persistent epithelial defect) is secondary to corneal anesthesia or toxicity from treatment.
- Necrotizing keratitis (immune keratitis): Active stromal infection with an inflammatory response causing stromal melting.
- Endothelialitis (disciform keratitis): The primary target of viral replication is the corneal endothelium, which is damaged, with secondary edema of the overlying stroma.

Following a first episode of keratitis, the rate for recurrence of ocular HSV increases from 20% at 2 years postinfection, to 40% at 5 years, and 70% at 7 years. After the first episode of corneal involvement, 32–40% of the patients experience a recurrent herpetic ulcer: 25% experience disciform keratitis or stromal keratouveitis; 5% experience ocular hypertension; and 6% develop scarring sufficient to decrease visual acuity. Bilateral disease occurs in 12% of patients, especially in atopes (who are at risk of eczema herpeticum) and the immunosuppressed. HSV is more severe in children than in adults, especially if they are immunosuppressed, in whom viral shedding and recurrences are more common. Recurrent disease is associated with visual loss, but with prompt treatment the visual consequences can be minimized; 90–94% of patients maintain vision of >6/12 but 3% are ≤6/36. HSV keratitis accounts for 3–10% of all PKs performed in the UK and the USA.

Table 16.9 Treatment options for viral keratitis

Pathogen	First-line treatment	Alternative
• Herpes simplex virus (HSV)	Oc acyclovir 3% or G trifluoridine 1% 5× daily For prophylaxis of stromal keratitis and keratouveitis: PO acyclovir 400 mg bd under specialist supervision (modify dose according to age)	G Ganciclovir 0.15% 5× daily Valacyclovir 500 mg

Management

Summary guidelines are:

- Epithelial HSV disease (dendritic ulcer or geographic ulcer) is the result of viral replication, and is treated with a topical antiviral agent (Table 16.9). Oral antiviral and topical corticosteroid is not required.[30]
- Stromal disease is treated with steroid to reduce destructive inflammation, but covered with an antiviral agent to prevent enhanced viral replication (dendritic keratitis). Both treatments are gradually reduced as the inflammation subsides.
- Latent virus cannot be eliminated. Although acquired viral resistance is uncommon, it can occur following prolonged antiviral treatment and in the immunosuppressed.

The antiviral agents used to treat HSV disease are purine or pyrimidine analogs that are incorporated to form abnormal viral DNA (see Table 16.9). Topical trifluorothymidine (F_3T, trifluridine), acycloguanosine (acyclovir), and or ganciclovir (Virgan) have low toxicity and achieve virucidal concentrations in the stroma and anterior chamber, effectively covering adjunctive steroid treatment. Acyclovir has the advantage that it can be used systemically. All are active against HSV-1 and HSV-2 and are equivalent for the treatment of dendritic or geographic ulcers. Foscarnet should be considered if thymidine kinase-resistant HSV is suspected. Topical interferon α2 has a small additional effect when used in conjunction with a topical antiviral, but it is expensive and not generally available. Oral acyclovir did not hasten healing of epithelial disease when used in combination with topical treatment. Debriding infected corneal epithelium is effective, but adjunctive virucidal agents are needed to avert an early recurrence of epithelial keratitis. The sample obtained from epithelial debridement can be sent for PCR confirmation of HSV infection.

Other Herpes Eye Disease Study Group treatment guidelines are as follows:

- For stromal disease (e.g. disciform keratitis), topical steroid (1% prednisolone phosphate four times daily), in conjunction with topical antiviral cover, reduces recovery time by 68% with no increased risk of recurrence at 6 months.

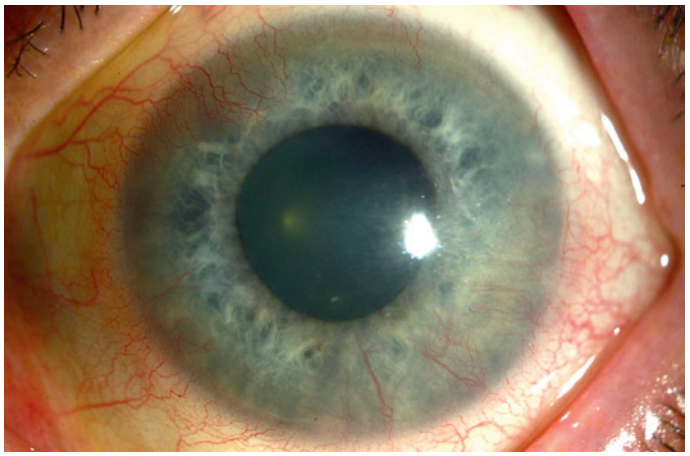

Fig. 16.48 Peripheral corneal vascularization and opacity following herpes zoster ophthalmicus.

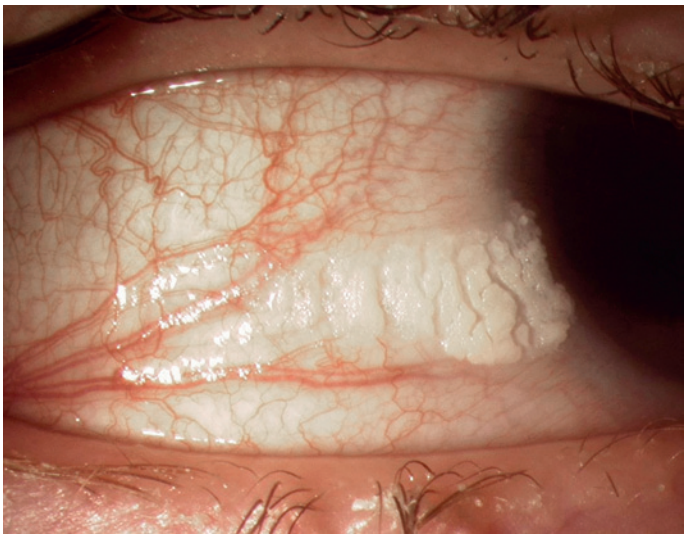

Fig. 16.49 Conjunctival keratin plaque associated with hereditary benign intraepithelial dyskeratosis.

- There is no additional effect of oral acyclovir over topical steroid and F_3T when treating stromal keratitis.
- After epithelial HSV, a 3-week course of oral acyclovir (400 mg five times a day) does not prevent stromal disease in the subsequent year.
- Prophylactic treatment with acyclovir (400 mg bd) reduces epithelial recurrences and stromal recurrences in patients with prior stromal disease by about 50% over 12 months. Prophylactic antiviral treatment is usually restricted to patients with bilateral disease, prior HSV keratitis in atopes, or the immunosuppressed, especially following corneal surgery.
- Oral acyclovir (400 mg bd for 6 months) reduces the risk of HSV recurrence and graft failure after PK.

Herpes zoster ophthalmicus

Following a primary infection (chicken pox) the varicella virus can become latent in sensory ganglia in up to 100% of cases. The diagnosis of herpes zoster ophthalmicus (HZO) is usually clinical, with a painful rash over the upper lid and forehead with a particular risk of corneal involvement if the side of the nose is involved (Hutchinson's sign). However, the rash may be minimal and PCR testing can be used to confirm infection. There is a gradual increase in exposure to VZV with age; in developed countries antibodies to VZV are present in 99% of the population by the age of 40 years. The incidence of HZO in children <18 years is less than 1.5 : 1000 individuals. HZO is normally associated with reducing antibodies to VZV and it is, therefore, uncommon in children unless they are immunosuppressed (e.g. chemotherapy or radiotherapy). Immunosuppression can trigger a re-activation of vesicular rash. Between 9% and 16% of patients have trigeminal involvement (HZO), of whom 50–72% have ocular involvement, and 20% have corneal involvement. It is not known how vaccination of children for VZV (against chickenpox) will affect the incidence and severity of HZO.

Corneal involvement during the early stages of herpes zoster ophthalmicus can present as a dendritic or stromal keratitis (Fig. 16.48), occasionally associated with uveitis, glaucoma, progressive outer retinal necrosis, and scleritis. The epithelial disease of acute HZO is the result of mucus accumulation on the epithelial surface rather than viral replication, but co-infection with HSV is possible. The use of topical antiviral at this stage is a wise precaution. Recurrent corneal inflammatory disease after 2–3 months is not always the result of viral replication and a topical antiviral is not normally prescribed.

Oral antivirals reduce the severity of acute HZO and the frequency of late-onset inflammatory corneal disease by 50%, but have no proven effect on reducing late complications such as neurotrophic keratitis or postherpetic neuralgia. Oral acyclovir is generally prescribed for 3 days within 72 hours of the onset of rash. Topical acyclovir is not recommended to treat the rash of zoster. Management of neurotrophic keratitis is with topical lubricants or corneal protection (e.g. tarsorrhaphy) (see Chapter 34).

Hereditary benign intraepithelial dyskeratosis

Hereditary benign intraepithelial dyskeratosis is an autosomal dominant disorder characterized by elevated epithelial plaques on the ocular and oral mucous membranes (Fig. 16.49). It occurs primarily, but not exclusively, in individuals of American Indian heritage. It is the result of a duplication in chromosome 4 (4q35). There is photophobia and blepharospasm with secondary corneal scarring and vascularization. Vitamin A deficiency should be excluded as a cause of conjunctival keratinization. Topical lubricants provide symptomatic relief.

HIV/AIDS: GLOBAL AND REGIONAL EPIDEMIOLOGY
TRANSMISSION OF HIV IN CHILDREN
DIAGNOSIS OF HIV/AIDS IN CHILDREN
OCULAR MANIFESTATIONS OF HIV/AIDS IN CHILDREN
OPHTHALMIC SCREENING AND MONITORING OF HIV-INFECTED CHILDREN
REFERENCES

While the annual incidence of human immunodeficiency virus (HIV) infection has decreased steadily over the past two decades, HIV/acquired immune deficiency syndrome (AIDS)-related illnesses continue to be among the leading causes of morbidity and mortality worldwide.[1] In 2014, roughly 36.9 million people were living with HIV/AIDS, 2.6 million (7.0%) of whom were children 15 years of age or less (Table 17.1). Approximately 220,000 (8.5%) of these children were newly infected during that year – an incidence of about 600 children per day. This number decreased by approximately 40% since 2009, due, in large part, to increased use of antiretroviral therapy by HIV-positive pregnant woman. Ocular complications occur in at least 70% of adults and up to 50% of children with HIV/AIDS if not treated with antiretroviral therapy.[1,2]

The introduction of multidrug combination therapy changed the face of HIV/AIDS-related eye disease. Termed "highly active antiretroviral therapy" (HAART), this regimen uses a combination of potent antiretrovirals to inhibit replication of HIV. Patients on HAART experience a dramatic improvement in helper CD4+ T cell populations and a marked decline in viral titers, resulting in fewer opportunistic infections, reduced morbidity and mortality, and improved quality of life. Despite the decline in the incidence of ocular complications in patients taking HAART, they continue to occur and remain an important cause of disability in HIV-infected patients. This is particularly true in the developing world, where access to HAART varies considerably from country to country.[2]

HIV/AIDS: global and regional epidemiology

The 2014 report from the Joint United Nations Program on HIV/AIDS (UNAIDS) and the World Health Organization (WHO) on the global HIV/AIDS epidemic estimated that 36.9 million (34.3–41.4 million) people were living with HIV in 2014, 90% of whom were unaware of their infection. Roughly 17.4 million (16.1–20.0 million) were women and 2.6 million (2.4–2.8 million) were children under 15 years of age (Table 17.1). The prevalence of HIV infection in children varies, with over 85% of all children with HIV/AIDS living in sub-Saharan Africa (Fig. 17.1). Roughly 1.4 million (1.2–1.5 million) people were newly infected with HIV in 2014, 220,000 (190,000–230,000) of whom were children. During that same year, 1.2 million (980,000–1.6 million) people died from HIV/AIDS, 150,000 (12.5%; 140,000–170,000) were children.[1]

Transmission of HIV in children

While high-risk behaviors such as injection drug use, unprotected commercial sex, and unprotected sex between men contributes to HIV transmission, most HIV infections in adults occur during unprotected heterosexual intercourse.[2] Most HIV-positive children acquired their infection *in utero*, at delivery, or while breastfeeding – so-called mother-to-child transmission (MTCT). Prior to the advent of obstetric and antiretroviral interventions, up to 40% of infants born to infected mothers contracted HIV infection. This included 20–25% of infections that occurred *in utero*, 35–50% that occurred during delivery, and 25–35% who were HIV negative at birth and within the first 6 weeks of delivery, but who became infected later, presumably as a result of transmission through breast milk.[3] These rates have since declined dramatically in North America, Western Europe, and other resource-rich regions, where current total perinatal transmission rates vary from 1% to 3%. The incidence of MTCT in many resource-poor regions remains high due to the high prevalence of HIV in women of childbearing age, a lack of access to antiretroviral prophylaxis, and few feasible alternatives to breastfeeding. Sub-Saharan Africa has the highest burden of HIV disease overall, accounting for 80–90% of perinatal infections and children infected by HIV (Fig. 17.1).[1]

Diagnosis of HIV/AIDS in children

The Centers for Disease Control and Prevention (CDC) case definition[4] of HIV infection among children aged less than 18 months recognizes four categories:

1. definitely HIV infected;
2. presumptively HIV infected;

3. presumptively uninfected with HIV;
4. definitively uninfected with HIV.

The presence of maternal antibodies can make diagnostic laboratory testing for HIV infection among children aged less than 18 months unreliable; these children with perinatal HIV exposure who develop an AIDS-defining illness (Box 17.1) are considered presumptively HIV infected.

Table 17.1 Global summary of HIV/AIDS as of 2014

Number of people living with HIV/AIDS in 2014	
Total	36.9 million (34.3–41.4 million)
Adults	34.3 million (31.8–38.5 million)
Women	17.4 million (16.1–20.0 million)
Children under 15 years of age	2.6 million (2.4–2.8 million)
Number of people newly infected with HIV in 2014	
Total	2.0 million (1.9–2.2 million)
Adults	1.8 million (1.7–2.0 million)
Children under 15 years of age	220,000 (190,000–260,000)
Number of HIV/AIDS-related deaths in 2014	
Total	1.2 million (980,000–2.2 million)
Adults	1.8 million (1.7–2.0 million)
Children under 15 years of age	150,000 (140,000–170,000)

The numbers in parentheses represent confidence intervals based on the best available information.
From UNAIDS. 2014 Global Statistics: http://www.unaids.org/sites/default/files/media_asset/20150714_FS_MDG6_Report_en.pdf (accessed January 2016).

A child aged less than 18 months is categorized as definitively HIV infected if born to an HIV-infected mother and testing of the infant (excluding cord blood testing) shows a positive result on two separate specimens from one or more of the following HIV-virologic (non-antibody) tests:

- HIV nucleic acid (DNA or RNA) detection;
- HIV p24 antigen test, including neutralization assay, for a child aged ≤1 month;
- HIV isolation (viral culture).

A child aged less than 18 months born to an HIV-infected mother is categorized as definitively uninfected with HIV if:

1. the criteria for definitive HIV infection are not met, and;
2. at least two negative HIV DNA or RNA virologic tests from separate specimens are obtained.

The CDC laboratory criteria for reportable HIV infection among persons aged 18 months to less than 13 years exclude confirmation of HIV infection through the diagnosis of AIDS-defining conditions alone. Laboratory confirmation of HIV infection is required for all reported cases of HIV infection among children in this age group.

Children aged 18 months to less than 13 years are categorized as having AIDS if the criteria for HIV infection are met and at least one of the AIDS-defining conditions has been documented (see Box 17.1). Once HIV infection has been established, early initiation of both HAART and *Pneumocystis jirovecii* pneumonia prophylaxis, followed by scheduled administration of routine vaccinations for infants is recommended.[5]

In 2007, the World Health Organization (WHO) revised the HIV infection and AIDS clinical staging system and the clinical and surveillance case definitions.[6] They recommended reporting cases of HIV infection as HIV infection or advanced HIV disease (AHD), which includes AIDS. All cases of HIV infection, AHD, and AIDS require a confirmed diagnosis of HIV infection based on laboratory testing. The revised WHO surveillance case definitions include the following four stages:

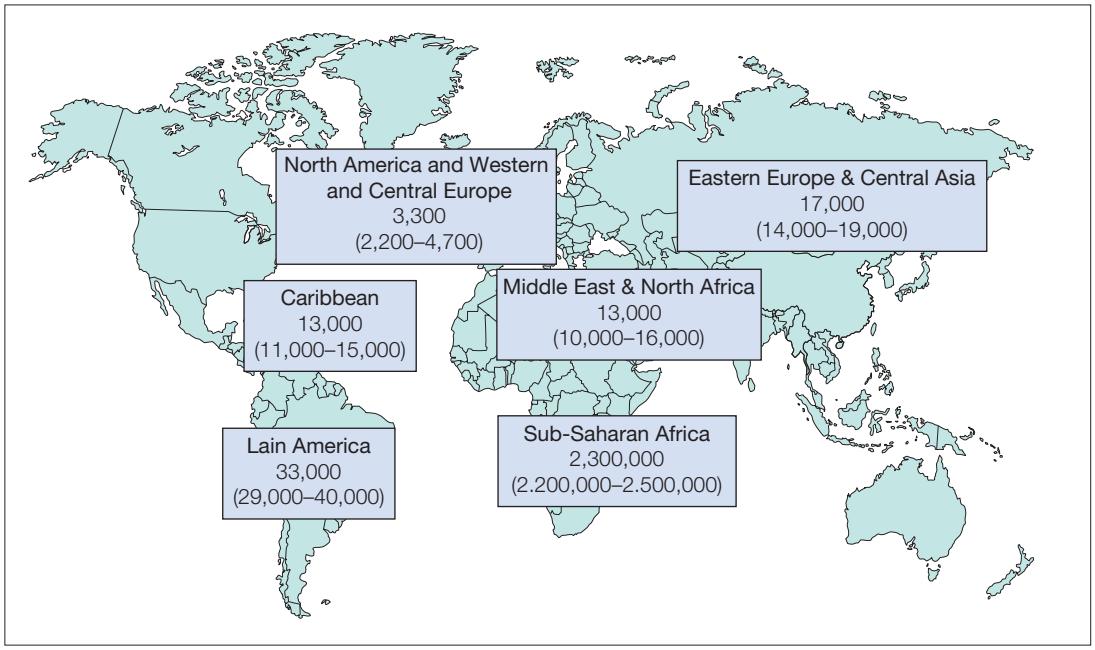

Fig. 17.1 The number of children <15 years of age with HIV/AIDS by region in 2014. Roughly 85% of the 2.6 million children estimated to be infected by HIV live in sub-Saharan Africa. *(From UNAIDS. 2014 Global Statistics: http://www.unaids.org/sites/default/files/media_asset/20150714_FS_MDG6_Report_en.pdf [accessed January 2016].)*

Box 17.1

AIDS-defining conditions for children less than 13 years of age, adolescents, and adults

- Bacterial infections, multiple or recurrent[a]
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis of esophagus[b]
- Cervical cancer, invasive[c]
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (greater than 1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
- Cytomegalovirus retinitis (with loss of vision)[b]
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcers (greater than 1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age greater than 1 month)
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (greater than 1 month's duration)
- Kaposi sarcoma[b]
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex[a,b]
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary[b]
- *Mycobacterium tuberculosis* of any site, pulmonary,[b,c] disseminated,[b] or extrapulmonary[b]
- *Mycobacterium*, other species or unidentified species, disseminated[b] or extrapulmonary[b]
- *Pneumocystis jirovecii* pneumonia[b]
- Pneumonia, recurrent[b,c]
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain, onset at age less than 1 month[b]
- Wasting syndrome attributed to HIV

[a]Only among children aged less than 13 years. (CDC. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR 1994; 43[No. RR-12].)
[b]Condition that might be diagnosed presumptively.
[c]Only among adults and adolescents aged ≥13 years. (CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 1992; 41[No. RR-17].)
For surveillance purposes patients are categorized as having AIDS only if the criteria for HIV infection are met.
Adapted from Schneider E, Whitmore S, Glynn KM, et al. Centers for Disease Control and Prevention (CDC). Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged <18 months and for HIV infection and AIDS among children aged 18 months to <13 years – United States, 2008. MMWR Recomm Rep. 2008; 57(RR-10): 1–12.

asymptomatic HIV infection, or stage 1; mildly symptomatic HIV infection, or stage 2; AHD, or stage 3; and AIDS, or stage 4.[6,7] An HIV-positive child's level of immunosuppression may be staged using circulating CD4+ T cell levels. Whereas absolute CD4+ T cell counts are typically used in adults, absolute counts normally decline dramatically over the first 5 years of life; so, for young children, CD4+ T cell percentages provide best estimates of disease severity. The WHO classification of HIV-associated immunodeficiency in young children is shown in Table 17.2. A similar system recommended by the CDC grades the immune status of HIV-infected children using either CD4+ T cell counts or percentages as stages 1, 2, and 3 (Table 17.3).[8] In comparison, adults with an absolute CD4+ T cell count less than 200 cells/mm^3 are characterized as having AIDS; those with a count less than 100 cells/mm^3 are considered profoundly immunosuppressed and at greatest risk of developing one or more ocular complications, including cytomegalovirus (CMV) and other necrotizing herpetic retinitis.[8]

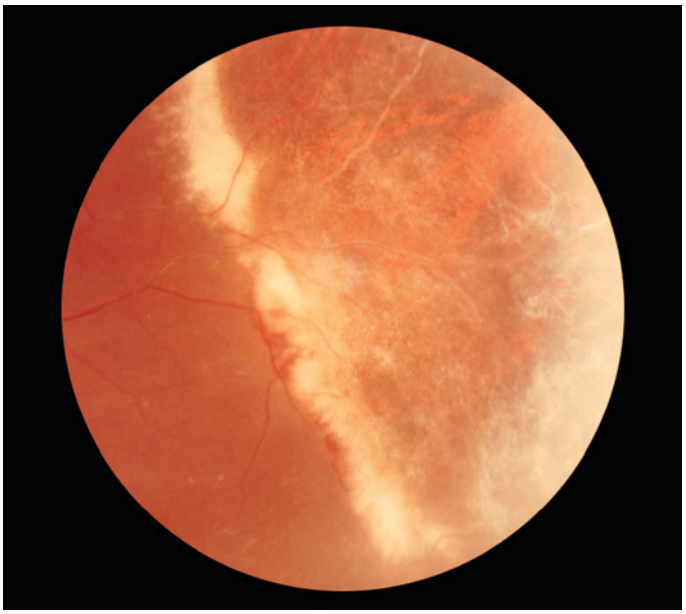

Fig. 17.2 Cytomegalovirus retinitis with an active leading edge in a child with AIDS from Rwanda.

Ocular manifestations of HIV/AIDS in children

Literature on the ocular manifestation of HIV/AIDS in children is limited (Table 17.4),[8–22] but suggests that ocular aspects of HIV infection differ between children and adults in several important respects. First, ocular complications of HIV/AIDS are less common in children than in adults. This is particularly true for CMV retinitis (Fig. 17.2) and HIV retinopathy (cotton-wool spots), which occur in fewer than 5% of untreated HIV-positive children, compared to 30% or more of untreated adults.[8] Herpes zoster ophthalmicus (HZO; Fig. 17.3) appears to be less common in HIV-infected children as compared to adults,[23] although zoster dermatitis has been reported as an early complication of immune reconstitution in children receiving HAART.[24,25] Second, a distinctive retinal vasculitis[26] (Fig. 17.4), not commonly recognized in adults, is seen in about 3% of HIV-infected children in the USA[10] and France,[11] and from approximately 10% to 40% of HIV-positive children in Africa and India.[14,15,20,21] Vascular inflammation is typically bilateral and peripheral with periphlebitis occurring three times more often than periarteritis. This peripheral retinal vasculitis may be associated with a generalized lymphadenopathy, including salivary and lacrimal gland involvement, and lymphocytic interstitial pneumonia (LIP), suggesting that these children

Table 17.2 WHO classification of HIV-associated immunodeficiency using CD4+ T cell counts and percentages

Classification of HIV-associated immunodeficiency	Age-related CD4+ T cell values			
	≤11 months (CD4%)	12–35 months (CD4%)	36–59 months (CD4%)	≥5 years (cells/mm^3 or CD4%)
Not significant	>35%	>30%	>25%	>500 cells/mm^3
Mild	30–35%	25–30%	20–25%	350–499 cells/mm^3
Advanced	25–29%	20–24%	15–19%	200–349 cells/mm^3
Severe	<25%	<20%	<15%	<200 cells/mm^3 or <15%

Table 17.3 Surveillance case definition for HIV infection among adults and adolescents (aged ≥13 years) – United States, 2008

Stage	Laboratory evidence[a]	Clinical evidence
Stage 1	Laboratory confirmation of HIV infection *and* CD4+ T-lymphocyte count of ≥500 cells/μl *or* CD4+ T-lymphocyte percentage of ≥29	None required (but no AIDS-defining condition)
Stage 2	Laboratory confirmation of HIV infection *and* CD4+ T-lymphocyte count of 200–499 cells/μl *or* CD4+ T-lymphocyte percentage of 14–28	None required (but no AIDS-defining condition)
Stage 3 (AIDS)	Laboratory confirmation of HIV infection *and* CD4+ T-lymphocyte count of <200 cells/μl *or* CD4+ T-lymphocyte percentage of <14[b]	*Or* documentation of an AIDS-defining condition (with laboratory confirmation of HIV infection)[b]
Stage unknown[c]	Laboratory confirmation of HIV infection *and* no information on CD4+ T-lymphocyte count or percentage	*And* no information on presence of AIDS-defining conditions

[a]The CD4+ T-lymphocyte percentage is the percentage of total lymphocytes. If the CD4+ T-lymphocyte count and percentage do not correspond to the same HIV infection stage, select the more severe stage.
[b]Documentation of an AIDS-defining condition supersedes a CD4+ T-lymphocyte count of ≥200 cells/μL and a CD4+ T-lymphocyte percentage of total lymphocytes of ≥14. Definitive diagnostic methods of these are in the 1993 revised HIV classification system and the expanded AIDS case definition (CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition of AIDS among adolescents and adults. MMWR 1992;41 (No. RR-17) and from the National Notifiable Diseases Surveillance System.
[c]Although cases with no information on CD4+ T-lymphocyte count or percentage or on the presence of AIDS-defining conditions can be classified as stage unknown, every effort should be made to report CD4+ T-lymphocyte counts or percentages and the presence of AIDS-defining conditions at the time of diagnosis. Additional CD4+ T-lymphocyte counts or percentages and any identified AIDS-defining conditions can be reported as recommended. (Council of State and Territorial Epidemiologists. Laboratory reporting of clinical test results indicative of HIV infection: new standards for a new era of surveillance and prevention [Position Statement 04-ID-07]; 2004. Available at http://c.ymcdn.com/sites/www.cste.org/resource/resmgr/PS/04-ID-07-FINAL.pdf.)

might have the same immunopathological response occurring at different body sites. Prior to the introduction of HAART, HIV-positive children with LIP had a relatively good survival as compared to overall cohorts of HIV-infected children. LIP with salivary and lacrimal gland involvement in HIV-positive children may be analogous to diffuse infiltrative lymphocytosis syndrome (DILS) in adults – an HIV-associated disorder characterized by chronic circulating and visceral CD8+ T cell infiltration, including involvement of the lung and salivary and lacrimal glands.[14]

Fig. 17.3 An HIV-positive adolescent with active herpes zoster ophthalmicus.

Orbital and adnexal complications of HIV/AIDS occur in adults, and include orbital cellulitis and tumors, most notably lymphoma and Kaposi sarcoma.[8] Orbital and adnexal involvement in HIV-positive infants and children is less common, although a single HIV-infected child with preseptal cellulitis was reported[9] (see Table 17.4). A "fetal AIDS syndrome" consisting of downward obliquity of the eyes, prominent palpebral fissures, hypertelorism, and blue sclerae has been described.[26]

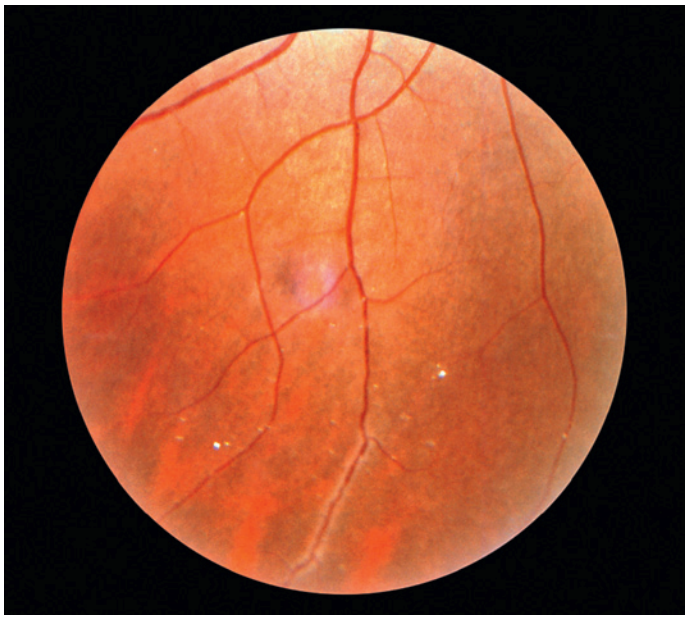

Fig. 17.4 An HIV-positive child from Africa with peripheral retinal vasculitis and several nearby superficial, small, punctate, white retinal lesions.

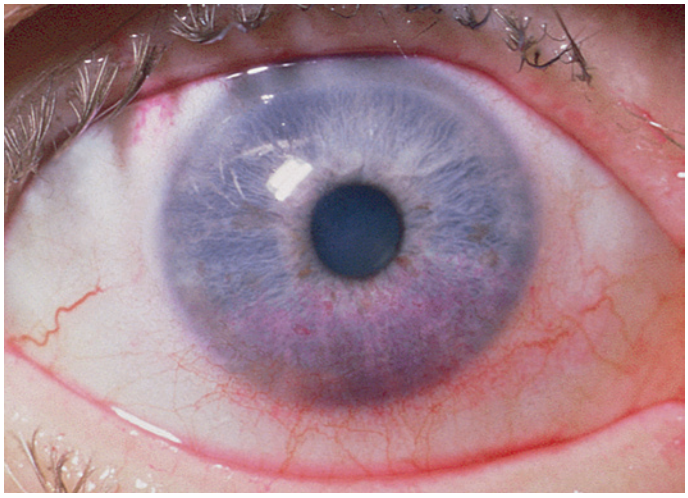

Fig. 17.5 An HIV-positive patient with keratoconjunctivitis sicca and prominent Rose Bengal staining of the inferior conjunctiva and cornea.

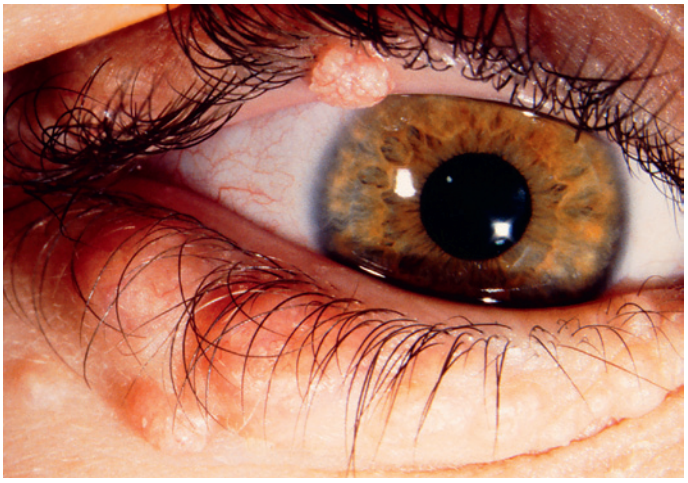

Fig. 17.6 An HIV-positive adolescent with hemophilia and both upper and lower lid molluscum contagiosum lesions.

Fig. 17.7 Severe conjunctival and corneal xerosis in a young Asian boy. A prominent mucus strand is evident near the lateral canthus. *(Courtesy of Dr Alfred Sommer.)*

Prior to the introduction of HAART, up to 20% of HIV/AIDS adults had anterior segment complications, most notably conjunctival telangiectasis, keratoconjunctivitis sicca (Fig. 17.5), infectious keratitis, and molluscum contagiosum (Fig. 17.6).[8] Similar complications occur in children (see Table 17.4). Almeida et al.[18] observed dry eye in 2 of 111 HIV-infected children in Brazil. Conjunctival xerosis (Fig. 17.7), presumably due to the combined effects of malnutrition, vitamin A deficiency, and HIV-related malabsorption and diarrhea, has been noted in Africa[13–16] in 1.2%[14] to 24.2%[14] of pediatric HIV/AIDS patients. Zaborowski et al.[27] described seven black African boys from South Africa with HIV-associated arthritis and bilateral intraocular inflammation, including three with anterior uveitis and four with intermediate uveitis. Five of 10 affected eyes had cataract and two had cystoid macular edema. Although the intraocular inflammation resembled juvenile idiopathic arthritis-associated uveitis, being insidious and asymptomatic in onset and bilateral and non-granulomatous in character, patients with HIV-associated arthritis and uveitis are different. They all were male, antinuclear antibody negative, and six of the seven had polyarticular joint involvement. Isolated cases of bacterial conjunctivitis, allergic conjunctivitis, otherwise unspecified keratitis and conjunctivitis, conjunctival telangiectasis, subconjunctival hemorrhage, and blepharitis have also been noted in HIV-infected children (see Table 17.2). The relationship of these findings to the child's underlying HIV infection has yet to be established.

In addition to isolated cases of CMV retinitis, HIV retinopathy, and the distinctive peripheral retinal vasculitis, posterior segment complications in children with HIV/AIDS include isolated cases of increased retinal vascular tortuosity, disc swelling, macular edema, *Toxoplasma* retinochoroiditis, non-CMV herpetic retinitis,[28] small punctate white retinal lesions (see Fig. 17.4), chorioretinitis of undetermined cause, and dideoxyinosine toxicity (see Table 17.4). Some of these

Table 17.4 Prevalence of ocular complications in clinic-based pediatric cohorts

HSV, Herpes simplex virus; NR, not reported.

findings may have been unrelated to the HIV status of the children.

Children infected by HIV are at increased risk of neurodevelopmental delay and increased incidence of neuro-ophthalmic complications. Isolated cases of optic atrophy of undetermined cause have been noted in children with HIV/AIDS.[13,15,20,21] De Smet et al.[10] and Livingston et al.[13] each found heterotropia in approximately 6% of their cohorts, whereas Rutar et al.[22] identified various forms of strabismus in over 18% of HIV-positive children. Kasi et al. described a 15-year-old boy from Zimbabwe, Africa, with HIV-related vitritis, phlebitis, optic neuritis, and multifocal retinal infiltrates.[29] All ocular findings resolved following treatment with HAART.

Ophthalmic screening and monitoring of HIV-infected children

Recommendations for ophthalmic screening and monitoring of HIV-infected children are not available. However, we recommend that all infants of HIV-positive mothers be screened for ocular complications shortly following birth and then every 2–3 months until their HIV status is known. Once HIV positivity is established, screening of children without ocular complications should be determined by overall level of immunosuppression (see Table 17.2). In the absence of ocular signs or symptoms, we recommend that children with severe immunosuppression receive a dilated eye examination every 2–3 months, that those with advanced immunosuppression be examined every 6 months, and that those with mild or no immunosuppression be seen annually. Once one or more ocular complications of HIV/AIDS have been identified, follow-up varies and depends upon the treatment status of the complication(s), as well as the age and immune status of the child.

ANOPHTHALMOS AND MICROPHTHALMOS
OTHER DISORDERS OF THE EYE AS A WHOLE
CLINICAL EVALUATION AND MANAGEMENT OF ANOPHTHALMOS AND MICROPHTHALMOS
REFERENCES

The ophthalmologist needs to make an exact diagnosis in patients with eyes that are smaller than normal, or with malformations affecting anterior or posterior structures. A precise diagnosis allows good counseling of patients and families and an educated guess at visual outcomes and screening for possible future complications. Conditions that are associated with a small ocular size include microphthalmos and anophthalmos, nanophthalmos, persistent fetal vasculature, and some cases of aniridia and Peters' anomaly.

Anophthalmos and microphthalmos

Anophthalmos and microphthalmos are rare, with an incidence of between 6 and 13 per 100,000 live births.[1–4] The birth prevalence of anophthamos ranges from 0.6 to 4.2 per 100,000 births, whereas the birth prevalence of microphthalmos ranges from 2 to 17 per 100,000 births.[5] They are often associated with systemic malformations. Although reported risk factors include maternal age over 40 years, multiple births, low birth weight, and low gestational age, there is no unifying causation. Clustering of cases, which might suggest an environmental cause, probably does not occur.[1,2,6,7]

Anophthalmos

The term "anophthalmos" is used when the eye is non-existent (Fig. 18.1) or, more commonly, when it is not visible and a very small cystic remnant of the eye is identified on pathology. The term "clinical anophthalmos" emphasizes that there is a spectrum in which anophthalmos merges with microphthalmos. True anophthalmos is sometimes associated with absence of the optic nerve and chiasm, as in some patients with *SRY-BOX2* (*SOX2*) mutations.[8]

Secondary abnormalities of the orbit occur; orbital growth is always retarded to some extent. Extraocular muscles may be absent and the optic foramen size is often decreased. The conjunctival sac may be small. Although the absence of a developing eye does not affect the initial development of a bony orbit,[9] the growth of the orbit is highly influenced by the presence or absence of the globe and its size. The mean axial length of the human full-term neonatal and adult eyes are approximately 17.0 and 23.8 mm, respectively,[10] with the normal neonatal eye measuring 70% of the adult size.[11] Orbital volume increases dramatically during the first 3 years of life, especially in the first year.

While orbital volume cannot be assessed using plain radiographs, the horizontal and vertical sizes of the orbital openings from the orbital rim can be measured and are reduced in adults with congenital anophthalmos, or in those enucleated within the first year of life. This retardation of orbital growth is halved when an orbital implant is used, and the severity of the overall reduction in volume diminishes if the insult occurs at a later date. Orbital growth appears to be complete by the age of 15 years; subsequent enucleation will not result in appreciable size difference.[12]

In anophthalmos, there is a complete failure of budding of the optic vesicle or early arrest of its development. In consecutive or degenerative anophthalmos, an optic vesicle forms, but subsequently degenerates. The presence of optic nerves, chiasm, or tract with anophthalmos may indicate this pathogenesis.

Many causes for anophthalmos have been proposed; these merge with the causes of microphthalmos (see below). Bilaterality and increased severity imply an early teratogenic or genetic developmental event.[13] In isolated cases, inheritance may be autosomal dominant[14] or autosomal recessive.[15] In families with clear Mendelian inheritance, ocular pathology may be asymmetric or even unilateral. Mutations in *SOX2* are one of the more common causes of anophthalmos.[16] Several other genes have been implicated in anophthalmos as well (Table 18.1).

Microphthalmos

It is important for the clinician to distinguish between isolated microphthalmos, colobomatous microphthalmos, and microphthalmos associated with systemic disorders. Making the proper diagnosis will direct appropriate counseling of patients and their families.

The volume of a microphthalmic eye is reduced. Often, clinical suspicion arises from a corneal diameter less than

10 mm in adults. Although microphthalmos is usually associated with a small cornea, there may be microphthalmos with a normal cornea, and microcornea without microphthalmos.[17,18] Ultrasonographic determination of an axial length less than 21 mm in an adult or 19 mm in a 1-year-old child substantiates a diagnosis of microphthalmos.[19] This represents a reduction of 2 standard deviations or more from normal.

Bilateral microphthalmos[20] occurs in approximately 10% of blind children.[21] The effect of microphthalmos on vision depends on whether it is bilateral, the severity of the microphthalmos, and the presence of concurrent ocular malformations – specifically, the degree of retinal maldevelopment, involvement of the macula and optic nerve head, and the presence or absence of cataract and coloboma.[22]

Fig. 18.1 Bilateral anophthalmos in a girl with a *SOX2* mutation. There was absence of all visual pathways.

Microphthalmos may be simple (without other ocular defects) or complex (associated with anterior segment malformations, cataracts, colobomas, retinal or vitreous disease, or more complex malformations).[19,23] It can be further divided into colobomatous (Fig. 18.2) and non-colobomatous on the basis of associated uveal abnormalities.[17,24] The association between eye growth and closure of the fetal fissure is important since closure of the cleft is completed early in development.[25]

Microphthalmos represents a non-specific growth failure of the eye in response to prenatal insults and/or genetic defects. Inadequate postnatal growth, secondary to decreased size of the optic cup, altered vitreous composition, and low intraocular pressure, may play a role in the pathogenesis of simple micophthalmos.[23] Posterior segment abnormalities and complex microphthalmos may be secondary to inadequate production of secondary vitreous.[19] Microphthalmos can be classified according to mode of inheritance, environmental causes, chromosomal aberration, as well as syndromic associations that have additional systemic abnormalities. (For a complete search of inherited conditions associated with microphthalmos and anophthalmos, consult Online Mendelian Inheritance in Man (OMIM) at http://omim.org/).[9,17]

Table 18.1 Genes linked to anophthalmos

Gene symbol	Gene	Locus	Inheritance	Description
ALDH1A3	*Aldehyde Dehydrogenase 1 Family, A3*	15q26.3	Autosomal recessive	Encodes A3 isoform of aldehyde dehydrogenase 1
BMP4	*Bone Morphogenetic Protein 4*	14q22–23	Sporadic; complex inheritance	Secretes signaling molecule in the TGF-β superfamily
BMP7	*Bone Morphogenetic Protein 7*	20q13.31	Sporadic; complex inheritance	Secretes signaling molecule in the TGF-β superfamily
GDF3	*Growth Differentiation Factor 3*	12p13.1	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily
GDF6	*Growth Differentiation Factor 6*	8q22.1	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily
OTX2	*Orthodenticle, Drosophila, Homolog of, 2*	14q22–23	Sporadic; complex inheritance	Bicoid homeodomain transcription expressed in neuroretina and brain
PAX6	*Paired Box 6*	11p13	Autosomal dominant	Encodes a transcriptional regulator involved in oculogenesis and other developmental processes
RAX	*Retina and Anterior Neural Fold Homeobox*	18q21.32	Autosomal recessive	Encodes retina and anterior neural fold homeobox
RBP4	*Retinol-Binding Protein 4*	10q23.33	Autosomal dominant	Encodes retinol-binding protein
SOX2	*SRY-Box 2*	3q26.3–27	Autosomal dominant	Encodes transcription factor containing an HMG domain
STRA6	*Stimulated By Retinoic Acid 6*	15q24.1	Autosomal recessive	Encodes cell membrane receptor for retinol binding protein

HMG, High-mobility-group; TGF-β, transforming growth factor beta.

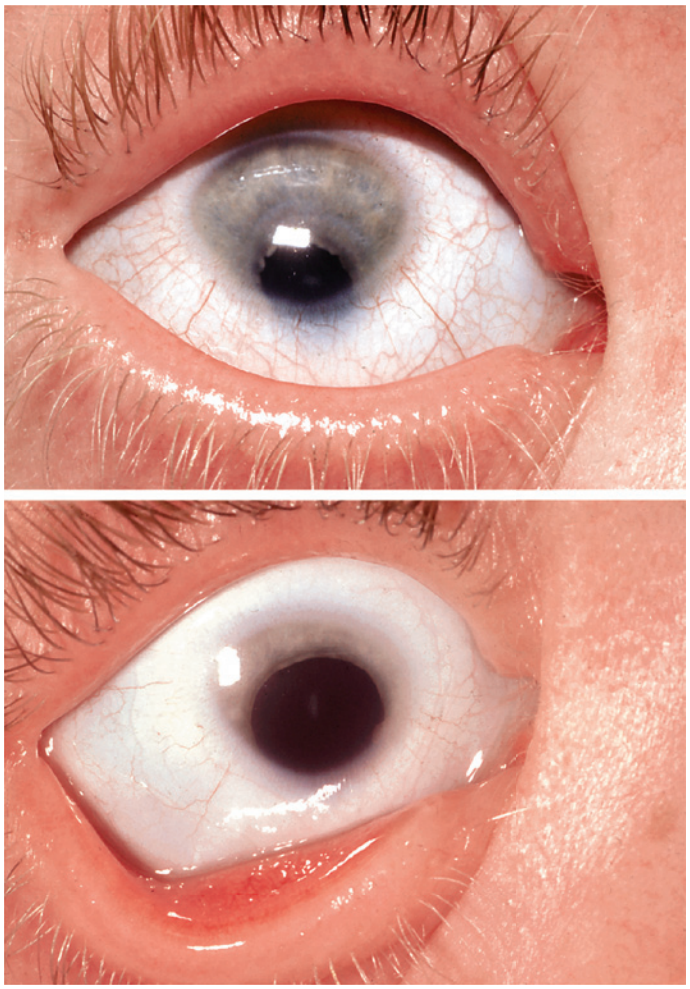

Fig. 18.2 Colobomatous microphthalmos. Both eyes are generally small with an inferior coloboma in the fundus. Although vision was limited to an acuity of 2/60 in each eye, the patient had a useful field and navigated without problems.

Fig. 18.3 (A) Bilateral marked non-colobomatous microphthalmos. (B) Mother of the child in (A) showing bilateral non-colobomatous microphthalmos.

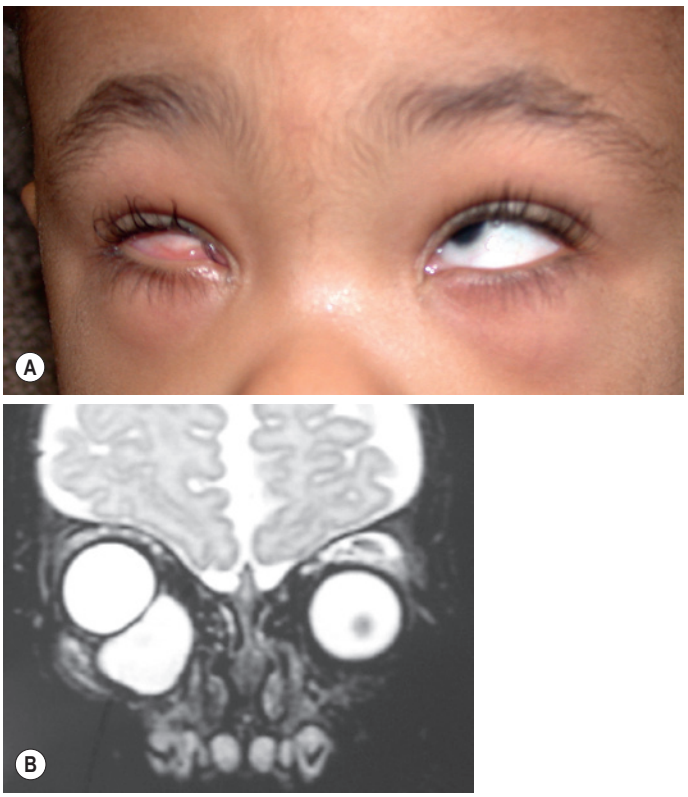

Fig. 18.4 (A) Bulge in right lower lid is due to pressure from cyst behind it. Ipsilateral eye is microphthalmic and has a coloboma. (B) Magnetic resonance imaging of same patient shows small eye with attached cyst.

Idiopathic isolated microphthalmos

Vision is variably affected, depending on the degree to which the eye is microphthalmic as well as associated high errors of refraction and consequent amblyopia.

Inherited isolated microphthalmos

Although most cases were previously thought to be sporadic,[26] many have been found to be autosomal dominant or autosomal recessive.[27,28] Some families (Fig. 18.3) have dominant inheritance of colobomatous microphthalmos and variable expression, with extreme microphthalmos at one end of the spectrum and coloboma at the other. A high rate of consanguinity suggests an autosomal recessive inheritance in some cases.[15,29] X-linked recessive inheritance occurs, sometimes with mental retardation.[30]

Microphthalmos with orbital cyst

This form of microphthalmos presents with a bulge behind the lower lid from birth (Fig. 18.4A). It is secondary to failure of optic fissure closure and the protrusion of a cyst from the coloboma. It has been confused with a congenital cystic eye,[31]

but the two are different. In the latter, the eye is replaced by a cystic structure and there is no lens or other normal eye structures. In microphthalmos with cyst, the small eye often cannot be seen and a neoplasm may be suspected. The cyst usually communicates with the eye.[32–34] Presentation may be as an orbital mass distending the lids and hiding the eye, or as proptosis in which a microphthalmic eye is visible. Ultrasonography and computed tomography (CT) or magnetic resonance imaging (MRI) aid in diagnosis (Fig. 18.4B).[33] Most cases of microphthalmos with cyst are sporadic; familial cases have been reported, with presumed autosomal recessive inheritance.[32,35,36]

Management is initially conservative, especially for small cysts. Large cysts may be managed with repeated aspiration or by surgical removal.[35,37–39] If the cyst is not growing rapidly, it may be left in place until some orbital growth is achieved. Because the cyst communicates with the eye, its removal may deflate the microphthalmic eye necessitating the removal of the latter.

Microphthalmos with cryptophthalmos

Cryptophthalmos implies varying degree of skin covering the eyeball, with variable cutaneous adhesions to the cornea.[40] It is usually bilateral with asymmetric degrees of severity. Unilateral cases have been described.

Francois described three subgroups of cryptophthalmos[41]:

1. Complete cryptophthalmos (Fig. 18.5): the lids are replaced by a layer of skin without lashes or glands that is fused with the microphthalmic eye without a conjunctival sac. Normal electrophysiological responses have been recorded.[42]
2. Incomplete cryptophthalmos (Fig. 18.6): the lids are colobomatous (often medially) or rudimentary and there is a small conjunctival sac. The exposed cornea is often opaque.
3. An abortive form: the upper lid is partly fused with the upper cornea and conjunctiva and may be colobomatous.[40] The globe is often small.

A fourth autosomal dominant type exists in which the upper lid is very tall and fused with the lower one at the margins. There is a normal complement of lashes. A dimple in the upper lid indicates where it is attached to the underlying eyeball.[43]

The systemic associations of cryptophthalmos and microphthalmos include nose deformities, cleft lip and palate, syndactyly, abnormal genitalia, renal agenesis, mental retardation, and many others.[40,44,45]

Microphthalmos with ocular and systemic malformations

Other eye malformations and systemic abnormalities are frequent in microphthalmos. Numerous syndromes are associated with microphthalmos. (http://omim.org/).[46]

Microphthalmos with ocular abnormalities

Microphthalmos represents the outcome of a non-specific response to a wide variety of influences. It occurs in conjunction with a number of severe eye diseases, including anterior segment malformations such as Peters' anomaly or cataracts, especially in the context of a chromosomal abnormality,[47] persistent fetal vasculature (PFV),[48] and multisystem syndromes such as the oculo-dento-digital syndrome.[49] Microphthalmos may be secondary to severe, widespread intraocular disease including retinopathy of prematurity, retinal dysplasia, retinal folds,[50] retinal degeneration, and glaucoma. A three-generation family has been described with aniridia, anophthalmos, and microcephaly.[51] Coloboma is the most common associated ocular malformation with microphthalmos and is found in many microphthalmos syndromes.[52,53]

Microphthalmos with systemic malformations

Up to 50% of patients with anophthalmos and microphthalmos have associated systemic abnormalities.[11,54] Many patients with microphthalmos-associated syndromes, especially chromosomal disorders, are developmentally delayed[30,55,56] or have cleft palate with and without macrosomia.[57]

The most common syndromic cause of colobomatous microphthalmos is the CHARGE syndrome (coloboma, heart abnormalities, atresia of the choanae, retardation of growth and development, genitourinary abnormalities, and ear/hearing abnormalities).[52] Affected patients can have cranial nerve abnormalities such as facial nerve palsy, craniofacial clefting, dysphagia/esophageal abnormalities, duplication of the thumb, and congenital brain abnormalities, particularly of the forebrain.[58,59] Although most cases are sporadic, autosomal dominant transmission has been reported.[60] Mutations in the *Chromodomain Helicase DNA-Binding Protein 7* (*CHD7*) gene are responsible for 60% of CHARGE cases, with possible genotype–phenotype correlation.[61,62] *CHD7* encodes a putative

Fig. 18.5 Complete cryptophthalmos. Note the characteristic continuation of the forehead skin onto the cheek. There is an abnormal hairline extending to the brow.

Fig. 18.6 Partial cryptophthalmos of the left eye. The eye is small and the cornea is opaque. There is a colobomatous upper lid and a characteristic "lick" of hair from the temple to the brow with a unilateral nose abnormality.

chromodomain protein widely expressed in the neuroectoderm and in neural crest cells during human development.[63] Mutations in the *Semaphorin 3E* (*SEMA3E*) gene can also result in CHARGE syndrome.[64]

The Temple–al-Gazali syndrome (Fig. 18.7) also referred to as X-linked dominant microphthalmos with linear skin defects (MLS) syndrome, and also known as the microphthalmos, dermal aplasia, and sclerocornea (MIDAS) syndrome, results from mutation of the *Holocytochrome C Synthase* (*HCCS*) gene and maps to Xp22.2.[65–68] Patients have linear, irregular areas of skin aplasia especially of the head and neck, microphthalmos with variable sclerocornea, and, sometimes, abnormal intelligence.[69–71] The condition is lethal in XY males.

Fryns "anophthalmos plus" syndrome is microphthalmos or anophthalmos, cleft lip or palate, and sacral neural tube defect.[72] The branchio-oculo-facial syndrome combines a broad nose with large lateral pillars, branchial sinuses, and orbital cysts.[73,74] Other microphthalmos syndromes with facial defects include fronto-facio-nasal dysplasia (Fig. 18.8),[75] and the cerebro-oculo-nasal syndrome in which there is an association of anophthalmos/microphthalmos, abnormal nares, and central nervous system anomalies.[76]

In Delleman syndrome, there is an association of skin tags, punched-out lesions of the skin on the ears and elsewhere, mental retardation, hydrocephalus, brain malformations, and orbital cysts.[77,78]

Microphthalmos has been described in patients with growth retardation, microcephaly, brachycephaly, oligophrenia syndrome (GOMBO syndrome).[79]

The eyes can be quite small in some patients with the oculo-dento-digital syndrome, characterized by bilateral digital anomalies (Fig. 18.9) with cutaneous syndactyly of fingers and camptodactyly,[49,80] thin nose with hypoplastic alae nasi and small nares, partial dental agenesis, enamel hypoplasia, and glaucoma.[81,82]

Patients with the less common recessive variety are more likely to have microphthalmos.[83] The syndrome results from mutations in Connexin 43. Iris cysts and anomalous retinal development may occur.[84]

Waardenburg recessive anophthalmos syndrome includes microphthalmos with syndactyly, oligodactyly, and other limb defects, and mental retardation.[85]

Patients with the X-linked recessive Lenz microphthalmos syndrome have microphthalmos with mental retardation, malformed ears, and skeletal anomalies.[53,86,87] The gene has been identified as *BCL6 Corepressor* (*BCOR*) and maps to Xq27–q28.[88,89]

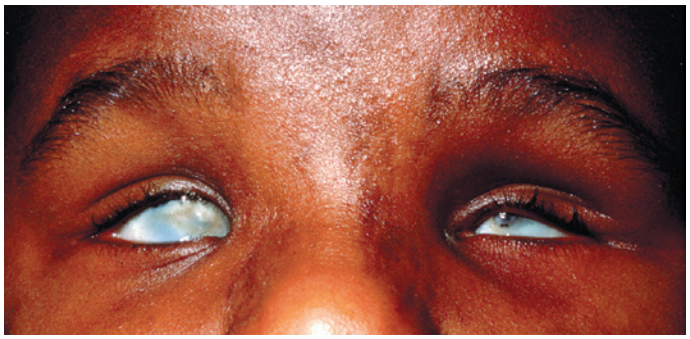

Fig. 18.7 Microphthalmos, dermal aplasia, and sclerocornea (MIDAS or Temple–al-Gazali) syndrome showing extreme microphthalmos and characteristic skin lesions.

Fig. 18.8 Right clinical anophthalmos, left microphthalmos in a child with bilateral cleft lip and palate associated with fronto-facio-nasal dysplasia.

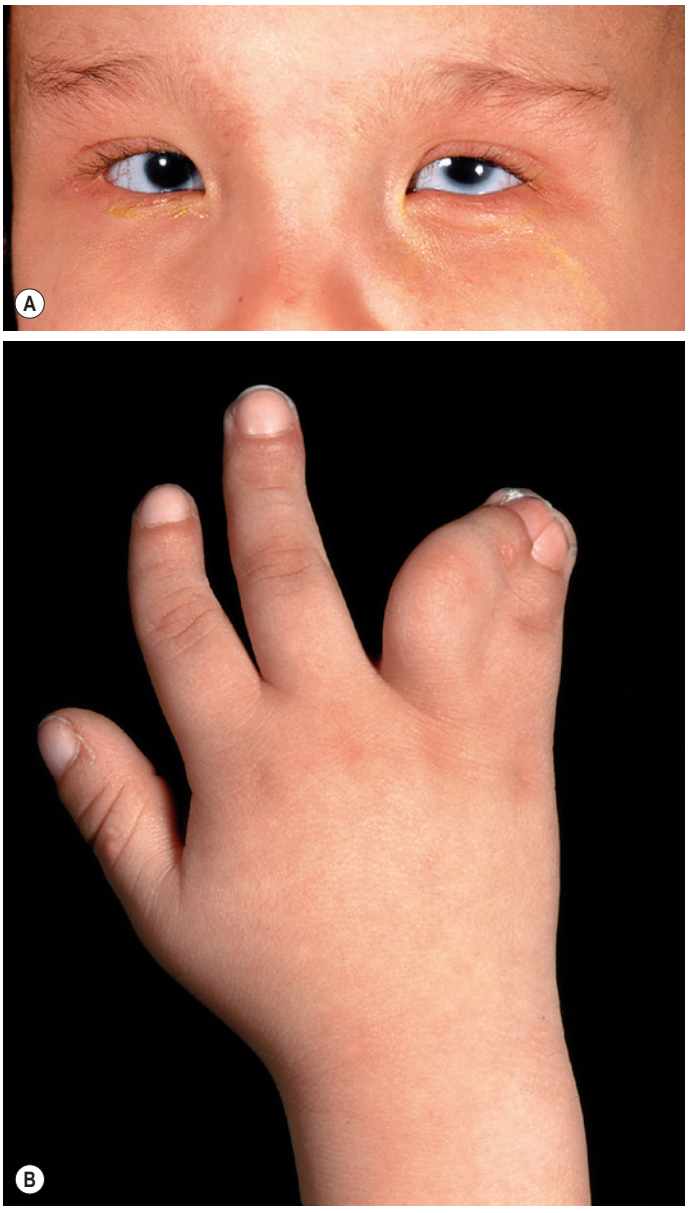

Fig. 18.9 (A) Bilateral microphthalmos, thin nose, and epicanthic folds in a patient with the oculo-dento-digital syndrome. (B) Cutaneous syndactyly of fingers and camptodactyly in the oculo-dento-digital syndrome.

The autosomal recessive Warburg MICRO syndrome comprises microphakia, microphthalmos, characteristic lens opacity, atonic pupils, cortical visual impairment, microcephaly, developmental delay by 6 months of age, and microgenitalia in males.[90,91] It can be caused by mutations in the *RAS-Associated Protein RAAB18* (*RAB18*) gene encoding the catalytic subunit of the RAB3 GTPase-activating protein complex (RAB3GAP).[92,93]

Gene mutations associated with anophthalmos and microphthalmos

A large number of chromosomal deletions, duplications, and translocations have been linked to anophthalmos and microphthalmos, often in association with well-delineated syndromic conditions.[94] Mutations in single genes have also been identified as causes of anophthalmos and microphthalmos.

SOX2 (*SRY-Box 2*)

The *SOX2* gene located at 3q26.3–27 is a major causative gene of microphthalmos and anophthalmos with an autosomal dominant inheritance pattern. *De novo* heterozygous loss-of-function point mutations account for 10–20% of bilateral anophthalmos and severe microphthalmos.[16] It is expressed at critical stages of eye development[95] and mutations have been associated with sclerocornea, cataract, persistent fetal vasculature, optic disc dysplasia, mental retardation, neurologic abnormalities,[8] facial dysmorphism, failure to thrive, and anomalies of the gastrointestinal, pituitary gland, and genital systems.

PAX6 (*Paired Box Gene 6*)

Mutations in this gene on chromosome 11p13 generally cause aniridia, but may rarely cause autosomal dominant panocular malformations, microphthalmos, and anophthalmos.[3,96] *PAX6* and *SOX2* interact and play a regulatory role in lens induction in several animal models.[97]

PAX2 (*Paired Box Gene 2*)

Mutations in *PAX2* are found in cases of the renal-coloboma syndrome (ocular colobomas, vesicoureteral reflux, and kidney anomalies).[98] The eyes are sometimes small (see Chapter 53).

VSX2 (Visual System Homeobox 2)

Formerly known as *CEH10 Homeodomain-Containing Homolog* (*CHX10*).

Human *VSX2* is expressed in progenitor cells of the developing neuroretina and in the inner nuclear layer of the mature retina. The human microphthalmos locus was mapped on chromosome 14q24.3; *VSX2* mutations were identified in non-syndromic autosomal recessive microphthalmos, cataracts, and severe abnormalities of the iris.[99]

FOXE3 (*Forkhead Box E3*)

Mutations in this gene on chromosome 1p32 have been associated with microphthalmos and lens agenesis.[100] The locus had been previously linked to congenital primary aphakia.

OTX2 (*Orthodenticle, Drosophila, Homolog of, 2*)

This gene located at 14q22–23, is a bicoid-type homeodomain transcription factor expressed in the neuroretina and brain. Heterozygous loss-of-function mutations account for 2% of anophthalmos and severe microphthalmos.[95]

BMP4 (*Bone Morphogenetic Protein 4*)

This gene, also at 14q22–23, is associated with anophthalmos and microphthalmos.[28] As a member of the transforming growth factor-β1 superfamily of secretory signaling molecules, it is important in optic vesicle formation, lens induction, and anterior and posterior segment development.[95]

ALDH1A3 (*Aldehyde Dehydrogenase 1 Family, A3*)

Mutations in this gene encoding the A3 isoform of the aldehyde dehydrogenase 1 have been linked to both anopthalmos and microphthalmos. This enzyme is critical in the formation of a retinoic acid gradient along the dorsoventral axis during early eye formation. Inheritance is autosomal recessive and occurs primarily in the setting of consanguinity. This gene maps to chromosome 15q26.3.[28,101–107]

Additional mutations associated with microphthalmos and anophthalmos have been identified in *Retina and Anterior Neural Fold Homoeobox* (*RAX*) gene,[108,109] *BCL6 Corepressor* (*BCOR*),[110] *Stimulated by Retinoic Acid 6* (*STRA6*), and *Growth/Differentiation Factor 6* (*GDF6*) among others.[111,112] Several loci for dominant, recessive, and X-linked inherited microphthalmos have been identified (http://omim.org; Tables 18.2–18.4)

While cluster studies have failed to identify causal links between environmental factors and microphthalmos/anophthalmos,[7] prenatal infection with rubella, toxoplasmosis, varicella, cytomegalovirus, parvovirus B19, influenza, and coxsackie A9 have been implicated.[2,11,113,114] Maternal vitamin A toxicity,[115] hyperthermia,[116] X-ray exposure, and prenatal drug exposure (thalidomide, warfarin, alcohol, the fungicide benomyl) have been postulated as potential non-infectious etiologies.[10]

Other disorders of the eye as a whole

Nanophthalmos

Nanophthalmos (Fig. 18.10) is a rare condition characterized by eyes whose axial length is less than 20 mm in adults. There is high hypermetropia, a weak but thick sclera with abnormal collagen,[117] a tendency toward angle closure glaucoma in young patients,[118] and uveal effusion. Some cases are autosomal recessive. Sundin and associates found a frameshift mutation in the original recessive nanophthalmos kindred and four independent mutations in the *MFRP* gene on 11q23.3.[119,120] Additional genes have been identified for nanophthalmos (Table 18.5). There is an increased fibronectin level in nanophthalmic sclera and cells; fibronectin is involved with cellular adhesion and healing.[121]

Intraocular surgery on nanophthalmic eyes may be complicated by severe uveal effusion.[122–125]

Cyclopia and synophthalmos

Complete (cyclopia) or partial (synophthalmos) fusion of the two eyes is very rare. The brain fails to develop two hemispheres and the orbit has gross deformities.[126–128] Fetuses with cyclopia generally do not survive. The brain is almost always malformed; the telencephalon fails to divide and a large dorsal cyst develops. The orbit is markedly affected as a consequence of the abnormal development of midline mesodermal structures. The normal nasal cavity is replaced

Table 18.2 Genes linked to isolated microphthalmos

Gene symbol	Gene	Locus	Inheritance	Description
ALDH1A3	*Aldehyde Dehydrogenase 1 Family, A3*	15q26.3	Autosomal recessive	Encodes A3 isoform of aldehyde dehydrogenase 1
BMP4	*Bone Morphogenetic Protein 4*	14q22–23	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily
FOXE3	*Forkhead Box E3*	1p32	Autosomal dominant or recessive with variable expressivity	Encodes forkhead box E3
GDF3	*Growth Differentiation Factor 3*	12p13.1	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily
GDF6	*Growth Differentiation Factor 6*	8q22.1	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily
PAX6	*Paired Box 6*	11p13	Autosomal dominant	Encodes a transcriptional regulator involved in oculogenesis and other developmental processes
RAX	*Retina and Anterior Neural Fold Homeobox*	18q21.32	Autosomal recessive	Encodes retina and anterior neural fold homeobox
RBP4	*Retinol-Binding Protein 4*	10q23.33	Autosomal dominant	Encodes retinol-binding protein
VSX2	*Visual System Homeobox 2*	14q24.3	Autosomal recessive	Encodes visual system homeobox 2

Table 18.4 Genes linked to microphthalmos associated with systemic disorders

Gene symbol	Gene	Locus	Inheritance	Description	Findings
BCOR	*BCL6 Corepressor*	Xp11.4	X-linked recessive	BCL6 corepressor gene	Lenz microphthalmos syndrome
BMP4	*Bone Morphogenetic Protein 4*	14q22–23	Autosomal dominant	Secretes signaling molecule in the TGF-β superfamily	Microphthalmos or clinical anophthalmos with brain and digit developmental anomalies
CHD7	*Chromodomain Helicase DNA-Binding Protein 7*	8q12.1–q12.2	Autosomal dominant	Encodes CHD7 trascriptional regulator	CHARGE syndrome
GJA1	*Gap Junction Protein, Alpha-1*	6q22.31	Autosomal dominant	Encodes connexin-43	Oculo-dento-digital syndrome
HCCS	*Holocytochrome C Synthase*	Xp22.2	X-linked dominant	Mitochondrial holocytochrome synthetase	Microphthalmos with linear skin defects (MLS); microphthalmos, dermal aplasia, sclerocornea syndrome (MIDAS)
HMGB3	*High Mobility Group 3*	Xq28	X-linked dominant	Inhibits B-cell and myeloid differentiation	Colobomatous microphthalmos with microcephaly, short stature, psychomotor retardation
HMX1	*H6 Family Homeobox 1*	4p16.1	Autosomal recessive	Encodes transcription factor	Oculoauricular syndrome (OCACS)
MAB21L2	*Mab21 C. Elegans, Homolog-Like 2*	4q31.3	Autosomal dominant or autosomal recessive	Cell fate specification gene; participates in formation of sensory organs	Colobomatous microphthalmos or clinical anophthalmos with or without rhizomelic skeletal dysplasia
OTX2	*Orthodenticle, Drosophila, Homolog of, 2*	14q22–23	Autosomal dominant	Bicoid homeodomain transcription expressed in neuroretina and brain	Microphthalmos or clinical anophthalmos with coloboma, microcornea, retinal dystrophy, hypoplasia or agenesis of optic nerve, possible agenesis of corpus callosum or other pituitary abnormalities
RAB18	*Ras-Associated Protein RAAB18*	10p12.1	Autosomal recessive	Encodes catalytic subunit of the RAB3 GTPase-activating protein complex	Warburg MICRO syndrome
SEMA3E	*Semaphorin 3E*	7q21.11	Autosomal dominant	Encodes semaphorin 3E	CHARGE syndrome
SMOC1	*SPARC-Related Modular Calcium-Binding 1*	14q24.2	Autosomal recessive	Encodes calcium-dependent glycoprotein	Microphthalmos with limb anomalies
SOX2	*SRY-Box 2*	3q26.3–27	Autosomal dominant	Encodes transcription factor containing an HMG domain	Microphthalmos, anophthalmos, coloboma, sclerocornea, cataract, persistent fetal vasculature, optic disc dysplasia, mental retardation, neurologic abnormalities, facial dysmorphism, failure to thrive, anomalies of gastrointestinal/pituitary gland/genital systems
STRA6	*Stimulated by Retinoic Acid 6*	15q24.1	Autosomal recessive	Encodes cell membrane receptor for retinol-binding protein	Pulmonary hypoplasia, diaphragmatic hernia/eventration, anophthalmos/microphthalmos, cardiac defect (PDAC)
TFAP2A	*Transcription Factor AP2-Alpha*	6p24.3	Autosomal dominant	Encodes activating enhancer-binding protein 2-alpha	Branchio-oculo-facial syndrome
YAP1	*YES-Associated Protein 1, 65-KD*	11q22.1–q22.2	Autosomal dominant	Encodes protein that binds to SH3 domain of YES tyrosine kinase	Colobomatous microphthalmos with or without hearing impairment, cleft lip/palate, and/or mental retardation

CHARGE, **C**oloboma of the eye, **h**eart defects, **a**tresia of the nasal choanae, **r**etardation of **g**rowth and/or development, **g**enital and/or urinary abnormalities, and **e**ar abnormalities and deafness HMG, high-mobility-group; SH3, SRC homology 3; TGF-β, transforming growth factor beta.

Fig. 18.10 (A) Patient with nanophthalmos wearing high hypermetropic glasses. The phakic correction was +10.00 D right, +11.00 D left. (B) Patient with nanophthalmos with small eyes and abnormal red reflex with co-axial illumination. (C) Shallow anterior chamber in patient with nanophthalmos. The eyes are prone to angle closure glaucoma. (D) Retinal appearance in a patient with nanophthalmos showing a crowded optic disc and prominent yellow foveal pigment with a fold between the fovea and the macula. Nanophthalmic eyes are very prone to choroidal effusions spontaneously or in response to intraocular surgery.

Table 18.5 Genes linked to nanophthalmos

Gene symbol	Gene	Locus	Inheritance	Description
MFRP	*Membrane-Type Frizzled-Related Protein*	11q23.3	Autosomal recessive	Encodes membrane-type frizzled-related protein
NNO1	*Nanophthalmos 1*	11p	Autosomal dominant	Associated with high incidence of angle closure glaucoma
NNO2	*In progress*	11q23.3	In progress	Caused by homozygous or compound heterozygous mutation in *MFRP* gene
NNO3	*In progress*	2q11–q14	In progress	
NNO4	*Nanophthalmos 4*	17q11.2	Autosomal dominant	Caused by heterozygous mutation in *TMEM98* gene
TMEM98	*Transmembrane Protein 98*	17q11.2	Autosomal dominant	Encodes transmembrane protein

Data from Online Mendelian Inheritance in Man (http://omim.org).

by the "pseudo-orbit."[129] The eyes are more commonly partly fused with one optic nerve and no chiasm. Other intraocular abnormalities such as fetal vasculature, cataract, coloboma, and microcornea may exist.[130] Chromosomal aberrations are common.[131] Several causative genes have been identified (Table 18.6). Familial occurrences and association with consanguineous marriages have also been noted.[132] Other etiologic considerations include maternal health and toxic factors.[133]

Clinical evaluation and management of anophthalmos and microphthalmos

The ophthalmologist faced with a new patient with microphthalmos must address several questions:

1. Is this an isolated ocular problem or are there associated systemic malformations?
2. What is the level of vision?
3. What is the refractive error? Is amblyopia present?
4. Are colobomas present? Do they involve the fovea?
5. Are there other ocular malformations?
6. Is there evidence of congenital infection, chromosomal abnormality, or environmental factors?
7. Is this genetically determined and heritable with recurrence risks in siblings?
8. Are there life-threatening associations (cardiac, brain, or renal defects) or factors that may alter parental expectations (mental retardation or deafness)?

Following family and medical history, physical examination, review of systems, appropriate chromosomal tests and molecular genetic tests are ordered. Neuro- and orbital imaging and possibly renal ultrasonography and audiological assessment may be needed.

Clinical diagnosis of anophthalmos may be difficult. To differentiate between anophthalmos and extreme microphthalmos, the examiner can palpate the lids to feel for any globe movements from residual extraocular muscle function. Bulging of the lower lid may be observed in patients with microphthalmos with cyst. Unilateral anophthalmos is often associated with anomalies of the other eye. Detailed examination of both eyes is crucial.[134] Parents and siblings should also be examined. Small visually insignificant colobomas in otherwise normal eyes indicate carrier state of the mutation.

Vision should be assessed and may require electrodiagnostic testing in infants (see Chapter 9). Visual evoked potential may demonstrate reduced, but useful, function in patients with

Table 18.6 Genes linked to cyclopia

Gene symbol	Gene	Locus	Inheritance	Description
CDON	*Cell Adhesion Molecule-Related/ Downregulated by Oncogenes*	11q24.2	In progress	Encodes cell surface receptor of immunoglobulin/fibronectin type III
GLI2	*GLI-Kruppel Family Member 2*	2q14.2	Autosomal dominant	Encodes vertebral transcription factor involved in *SHH* signal transduction
HPE1	*Holoprosencephaly 1*	21q22.3	Autosomal recessive	
HPE2	*Holoprosencephaly 2*	2p21	Autosomal dominant	Caused by mutation in *SIX3* gene
HPE3	*Holoprosencephaly 3*	7q36.3	Autosomal dominant	Caused by mutation in *SHH* gene
HPE4	*Holoprosencephaly 4*	18p11.31	Autosomal dominant	Caused by mutation in *TGIF* gene
HPE5	*Holoprosencephaly 5*	13q32.3	Autosomal dominant	Caused by heterogzygous mutation in *ZIC2* gene
HPE6	*Holoprosencephaly 6*	2q37.1–q37.3	In progress

HPE8	*Holoprosencephaly 8*	14q13	In progress	
HPE9	*Holoprosencephaly 9*	2q14.2	Autosomal dominant	Caused by heterozygous mutation in *GLI2* gene
HPE10	*Holoprosencephaly 10*	1q41–q42	Isolated cases	
HPE11	*Holoprosencephaly 11*	11q24.2	In progress	Caused by heterozygous mutation in *CDON* gene
PTCH1	*Patched, Drosophila, Homolog of, 1*	9q22.32	In progress	Encodes transmembrane protein
SHH	*Sonic Hedgehog*	7q36.3	Autosomal dominant	Encodes sonic hedgehog protein involved in establishing cell fates during development
SIX3	*Sine Oculis Homeobox, Drosophila, Homolog of, 3*	2p21	Autosomal dominant	Encodes proteins which may be involved in determining DNA-binding specificity and in mediating protein–protein interactions
ZIC2	*Zinc Finger Protein of Cerebellum 2*	13q32.3	Autosomal dominant	Homolog of Drosophila "odd-paired" gene; encodes proteins important in brain and distal limb development

Data from Online Mendelian Inheritance in Man (http://omim.org).

clinical anophthalmos. The evaluation of visual potential is imperative; it may guide the approach to socket expansion if indicated. Ophthalmologists should withhold prognostication of visual potential based on degree of microphthalmos and ocular malformation. Patients with very small eyes and even large colobomas may have preserved vision.

Neuroimaging or ultrasound may demonstrate extremely microphthalmic eyes, but histological sectioning is needed to determine the presence of neural ectoderm-derived cells (in microphthalmos) or their absence (in anophthalmos). Ultrasound is useful to determine a decreased axial length in microphthalmic eyes. MRI is important as many conditions associated with microphthalmos and anophthalmos affect brain development.[135]

Ophthalmic interventions may be limited to the prescription of glasses to offset amblyogenic refractive errors, helping the ocularist in management and fitting of cosmetic shells or contact lenses in non-seeing eyes, and diagnosing and treating glaucoma and cataracts. Cataract extraction may improve vision.[136] Microphthalmic eyes with corneal opacities may rarely require corneal grafting, but such interventions should be weighed against the risk of making the situation worse by precipitating glaucoma or more corneal opacification with graft failure. In patients with unilateral microphthalmos and poor vision, protective glasses should be prescribed.

Underdevelopment of the bony orbit, eyelids, and fornices leads to the inability to retain a prosthesis later in life. Mild microphthalmos may be managed with enlarging conformers, which should be transparent if there is vision. While anophthalmos is initially managed similarly with a conformer in the first several weeks of life, serial static implants or expandable implants may be used after 6 months of age to increase orbital volume. Complications of orbital implants include wound dehiscence, extrusion, or inadequate stimulation of bony growth.[10] Hydrophilic expanders held in place by tarsorrhaphy may allow growth of the bony orbit.[11] Controversially, some advocate early removal of a non-seeing microphthalmic eye with replacement of tissue by dermis fat graft or ball implant. In cases of microphthalmos with cyst, surgical intervention may be delayed, as orbital growth is more likely if the eye and cyst are left in place.[11]

Management by multidisciplinary teams is optimal. Because midline neurologic and pituitary abnormalities are common, referral to neurology and endocrinology may be indicated. In cases of bilateral anophthalmos or severe microphthalmos with no light perception, melatonin may establish regular nocturnal sleep patterns.[11] If no syndromic findings are identified initially, evaluation may be repeated at 3–5 years. Many syndromes may not fully manifest until later in childhood. Referral to a low vision specialist, occupational therapist, and other agencies may be indicated.

The benefits of genetic evaluation are three-fold. In cases of severe vision loss, identification of a potential cause may ease the guilt felt by some parents. Known syndromic findings of mutations of certain genes or chromosomal rearrangements may drive multidisciplinary approach and screening. Genetic counseling may aid in risk assessment for future siblings of the affected child. However, given the number of genes identified with a link to anophthalmos and microphthalmos, genetic counseling may be difficult. Even when a causal mutation is identified, gonadal mosaicism and variable penetrance may make recurrence risk prediction difficult.[10,95] For example, there have been observations of normal parents of affected children carrying loss-of-function *SOX2* and *OTX2* mutations.[10] Given systemic comorbidities identified with many mutations, the patient's siblings may be tested for genetic abnormalities. With unbalanced chromosomal translocation, with parents having rearrangements, the risk to siblings is higher and genetic testing should be recommended.

Prenatal diagnosis can be made by ultrasound early in the second trimester[137] when transvaginal ultrasound can identify anophthalmos and microphthalmos. Cytogenetic studies may be conducted on amniotic fluid samples at 14 weeks' gestation, or on chorionic villus samples at 10–12 weeks' gestation. These may be useful when an anomaly is identified on ultrasonography, to identify gene mutations associated with neurologic anomalies and other systemic findings.

See online for supporting video for this chapter.

This chapter concentrates on the practical management of congenital and acquired eyelid lesions. The main indications for eyelid surgery in children are to optimize the potential for useful vision in severe congenital malformations, to prevent amblyopia, to control exposure and breakdown of the ocular surface, and to improve cosmesis. These aims are aligned, as reconstructive lid surgery usually results in both improved function and cosmesis.

Complex cases require a careful treatment plan. However, flexibility is often required in oculoplastic surgery, and the surgeon often enters the operating room with the realization that plans may need to be modified.

Management of congenital lid conditions

Lid coloboma

The treatment of lid coloboma is directed toward treating sight-threatening corneal exposure, preventing amblyopia, and improving cosmesis. Occasionally, underlying abnormalities that limit ocular motility may need to be addressed.

The coloboma is described in terms of its position using the Tessier classification,[1] and in terms of its extent. An examination is carried out to exclude associated ocular and systemic abnormalities. Initial management aims to protect the ocular surface with lubrication and occlusive dressing – taking care not to induce amblyopia with them. A forced duction test is performed on all children with an eyelid coloboma for underlying adhesions,[2] which need early treatment. This usually requires an examination under anesthesia. A small coloboma can be closed under the same anesthetic. If a more complicated repair is required, timing depends on the underlying ocular surface protection, but delaying repair allows growth of soft tissues, increasing options for advancement and closure. If corneal exposure cannot be controlled, the eyelid reconstruction is urgent. A defect of less than 25% of the lid length can be repaired by excision of the coloboma margins and direct closure. For defects of 25–50% of lid length, a lateral canthotomy and cantholysis allows the wound edges to come together. For defects of 50% or more, tissue will need to be added from elsewhere. In the lower eyelid, the posterior lamella can be reconstructed using tarsoconjunctival grafts from the upper lid, together with advancement myocutaneous eyelid flaps or skin grafts. In the upper eyelid, larger defects are generally better closed with a lower lid rotation flap, provided there is sufficient lower lid tissue available. The lower lid is rotated into the upper lid. The pedicle is divided after about 2 weeks and aggressive occlusion therapy is started to limit amblyopia.

The coloboma in Treacher Collins syndrome (see Chapter 28) is a pseudocoloboma in which there is a defect of subcutaneous tissue rather than a true eyelid discontinuity. The syndrome is variably severe, including an abortive form. Severe cases may require craniofacial surgery prior to eyelid surgery in order to re-establish malar support. In less severe cases, the lids can be built with oculoplastic surgery alone. In mild cases, the lateral canthus can be repositioned with a lateral canthoplasty, but extensive undermining and repositioning of the periocular soft tissues is necessary to maintain the new canthal position. In moderate cases, with absence of vertical and horizontal eyelid soft tissue, the lid can be reconstructed with the use of mucous membrane grafts, ear cartilage, or a spacer to support the lid. The lateral canthus can be secured with wire fixation to bore holes in the lateral orbital rim. Moderately severe cases may require transposition flaps from the upper to lower lids with a lateral canthal strip.

Cryptophthalmos

Cryptophthalmos is a rare condition in which the upper eyelid and eyebrow fail to develop and the cutaneous epithelium is

continuous with conjunctiva at the superior fornix. There is usually severe dysgenesis of the anterior segment as well. The condition can be complete, incomplete, or partial (congenital symblepharon) (see Chapter 31).

In complete cryptophthalmos there is no real chance of gaining vision, even with reconstructive surgery. In incomplete cryptophthalmos there may be some chance of achieving useful vision or reasonable cosmesis, but this is unusual: then the same concerns pertain as in eyelid colobomas. The urgency of surgery depends on whether the condition is unilateral or bilateral, the presence of visual potential, and the degree of corneal exposure. If the condition is unilateral, no visual potential exists, and exposure is controlled, surgery should be delayed to allow for the relaxation of tissues, which occurs as the infant matures.[3]

Surgery reconstitutes the components of the anterior and posterior lamellae. Pedicle rotation flaps from the cheek or brow, eyelid sharing, full-thickness skin grafts, and mucous membrane grafts are used. The success of complex lid reconstruction is limited by defective tear production, a lack of healthy conjunctiva, and underlying ocular defects associated with the condition, such as corneal and anterior segment dysgenesis.

Ablepharon

Complete failure of eyelid development is rare. Urgent treatment is required to protect the ocular surface followed by early lid reconstruction. The results depend on the severity of the lid changes and the integrity of the underlying structures. Treatment of true ablepharon has poor results; however, treatment of milder cases (microblepharon), by vertical stretching of the lid and anchoring at the lateral orbital rim, is more successful. Although the eyelid may open minimally initially due to "bow-stringing" of the tight eyelid, this improves significantly within 6–8 weeks of surgery.

Ankyloblepharon

In ankyloblepharon the eyelid margins are partially or completely fused together with a reduction in the palpebral aperture. Ankyloblepharon filiforme adnatum is a similar condition in which one or more skin tags join the two lids and there is usually a normal horizontal palpebral aperture: it is treated by division of the tag or tags.

Ankyloblepharon must be differentiated from blepharophimosis, in which the palpebral aperture is reduced and there is telecanthus, but the eyelid margins are normal. Recognition of ankyloblepharon necessitates systemic examination to detect associated abnormalities such as genitourinary, cardiac, and syndactyly. The lids are opened along the line of fusion with sharp scissors or a scalpel. A thin strip of skin and orbicularis is excised and the bare lid margin allowed to conjunctivalize. The lid structure and tarsus are usually otherwise normal.

Euryblepharon

Euryblepharon is congenital primary enlargement of the palpebral aperture, usually greatest laterally. There is a localized outward and downward displacement of the lateral canthus and downward displacement of the lower lid. Mild cases may require no treatment or simple lubrication. If there is a danger of corneal exposure, the lateral canthus may be tightened and positioned more superiorly and posteriorly. Wide undermining and repositioning of the soft tissues is necessary or the tissues tend to migrate to their original location. If the eyelid is short vertically, skin grafts and/or posterior lamellar grafts with overlying soft tissue advancement may be required. Free grafts usually result in suboptimal cosmesis in young children.

Fig. 19.1 Bilateral ectropion due to shortage of the anterior lamella in a patient with euryblepharon and blepharophimosis.

Ectropion

The initial treatment of ectropion in childhood is conservative, using lubrication to prevent exposure keratitis. Surgery is aimed at treating the underlying cause: shortage of skin or increased lid laxity (paralytic ectropion is discussed later) and is usually delayed until the child is older and has more soft tissue with which to work. Ectropion associated with a shortage of skin occurs in congenital conditions such as Down syndrome, blepharophimosis (Fig. 19.1), and acquired conditions such as ichthyosis, dermatomyositis, and trauma. A localized scar can be lengthened with a Z-plasty, and a generalized shortage of skin corrected with a skin flap or graft. Increased lid laxity causing ectropion is found in congenital conditions such as megaloblepharon and euryblepharon and can occur after trauma. It is treated with lid-tightening procedures.[4]

Eversion

Treatment of congenital eversion is aimed at repositioning the everted eyelids so that the underlying soft tissue swelling and chemosis can resolve. Once this has occurred, the eyelids remain in proper position. Repositioning the eyelids and pressure patching or taping for 5–7 days is usually sufficient. More severe cases can be treated by intermarginal sutures.

Epiblepharon

Epiblepharon is a horizontal fold of skin across the upper or lower eyelid that may push the lashes against the cornea. The lid margin remains in a normal position. Epiblepharon usually resolves by 5–6 years of age as the facial bones grow. It is usually asymptomatic and is seldom associated with keratitis (Fig. 19.2). Surgical intervention is reserved for those patients in whom it causes corneal compromise despite conservative treatment (i.e. lubrication) or it persists into adolescence. Quickert sutures can be used in milder cases, or excision of an ellipse of skin and orbicularis muscle with tarsal fixation is used in more severe cases.[5,6]

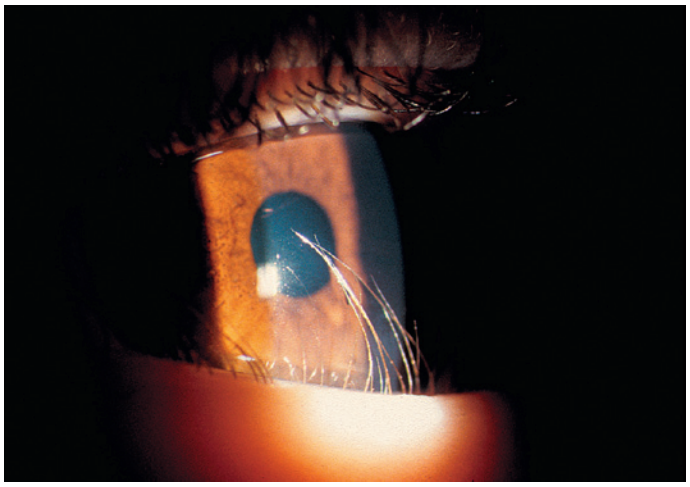

Fig. 19.2 Epiblepharon. In this child the lower lid lashes have turned in from birth, but the cornea has remained undamaged. Spontaneous improvement usually occurs.

Entropion

In congenital entropion the eyelid margin is inverted (Figs 19.3 and 19.4). This often requires prompt surgical intervention to prevent corneal infection and scarring. It should be distinguished from epiblepharon, where a skin fold causes a secondary turning of the lower lid lashes. Surgery is directed toward re-everting and stabilizing the eyelid with excision of skin and orbicularis, reattachment of the lower eyelid retractors to the inferior border of the tarsus, and then re-fixating the skin edges to the inferior tarsal border.

Tarsal kink/upper lid entropion

Congenital upper lid entropion is rare but often associated with a horizontal kinking of the tarsus. As with lower lid entropion, there is a risk of corneal scarring and infection. It can be corrected by incising the tarsus along the kink, and then repositioning the anterior lamella of the eyelid (Fig. 19.5).

Distichiasis

Distichiasis is a developmental abnormality in which a second row of cilia emerges from the meibomian gland orifices posterior to the normal eyelashes. The abnormal lashes may be asymptomatic or cause superficial corneal problems. If the patient is symptomatic or has significant corneal staining, treatment is indicated. Electrolysis is the treatment of choice, but is time consuming and has a high failure rate unless the lash roots can be exposed and destroyed directly. The lid is everted with a clamp under the microscope. A small, partial-thicknesss, vertical cut is made through the conjunctivalized surface of the tarsus to expose the whole eyelash from the lid margin to the lash root. This is then electrolyzed under direct vision. The alternative for large numbers of lashes is cryotherapy with a double freeze–thaw cycle for 20 seconds. In the upper lid, a gray line split between the anterior and posterior lamellae allows cryotherapy to be applied directly to the tarsus, avoiding damage to the normal lash roots and, in dark-skinned patients, discoloration of the skin. The posterior lamella is then advanced, leaving the raw surface of the tarsal plate to granulate. This prevents contraction of the tarsal plate leading to entropion.

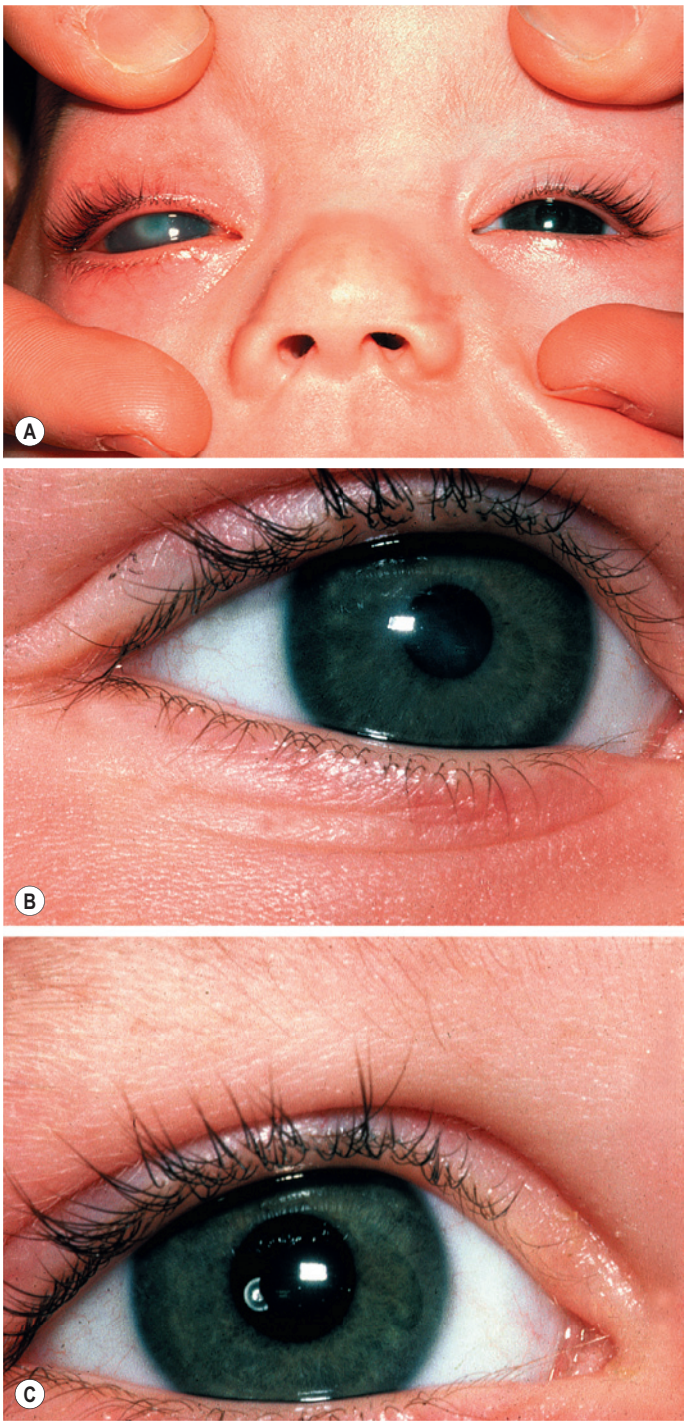

Fig. 19.3 Congenital entropion. (A) Shortly after birth this child's eye was found to be swollen. During examination under anesthetic right upper lid entropion was found with a corneal abrasion caused by the entropion. (B) After taping the lids, the entropion resolved, and (C) ultimately there was only minimal subepithelial opacity.

Epicanthic folds

Epicanthal folds are folds of skin that extend from the upper eyelid toward the medial canthus. The fundamental difference

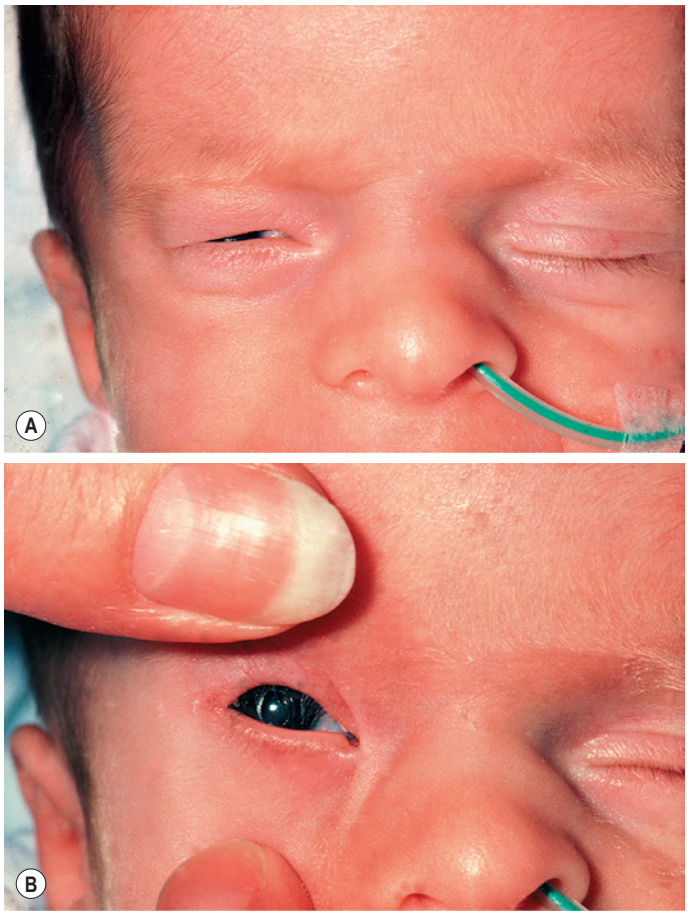

Fig. 19.4 Congenital entropion. (A) This child presented with irritability and an abnormality of the right lids, which were slightly swollen. (B) Same child with the lid everted, showing the lashes inturned and abrading the cornea without damage at this stage. It was treated with simple lid suture and resolved without complication.

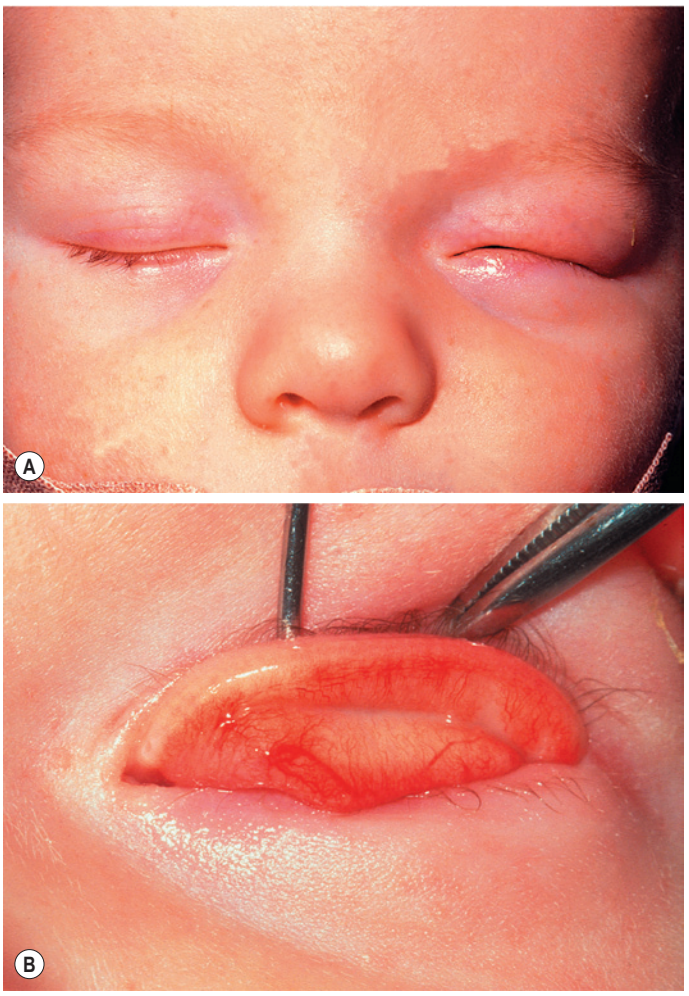

Fig. 19.5 Horizontal tarsal kink. (A) This child presented with a swollen and sore left eye with blepharospasm. (B) On eversion of the lid the horizontal kink in the tarsus can be seen. It runs the whole length of the tarsal plate, which is bent to 90°. It was treated by forced eversion using a strabismus hook to straighten the tarsus by force while the margin of the lid was held. This was followed by a week of lid suture, and the condition resolved following that treatment, but there was severe corneal scarring and the eye was blind.

between epicanthic folds and epiblepharon is that epicanthic folds are caused by a relative shortage of skin where the soft tissue is stretched tautly between the medial eyelid and the medial canthus instead of following the contour of the nasal angle. Epicanthic folds only require urgent treatment if they cause trichiasis or obstruct vision. They are largely an esthetic issue and become less prominent with development of the bridge of the nose and stretching of the overlying skin. As the folds represent lines of skin shortage, they can be broken up and lengthened with various different flaps. A simple epicanthic fold can be treated with a Z-plasty. Two separate Z-plasties can be used when a fold affects both the upper and lower lids. A mild epicanthic fold associated with telecanthus can be treated with a Y–V plasty and shortening of the underlying medial canthal tendon. If there is a marked epicanthic fold associated with telecanthus, a double Z-plasty can be combined with a Y–V plasty.[7,8]

Telecanthus

Telecanthus is an increased width between the medial canthi, with a normal interpupillary distance. If there is an overgrowth of bone with an increase in the interorbital and interpupillary width the condition is referred to as hypertelorism. Telecanthus can usually be improved by shortening the medial canthal tendons without involving a significant reduction in bone.[9] Mild cases can be treated by medial canthal plication with a non-absorbable or wire suture combined with a Y–V plasty. More severe cases may require transnasal wiring combined with a Y–V plasty. Posterior placement of the wire is necessary for a good cosmetic result. The thickness of the anterior lacrimal crest and medial orbital wall bone can be reduced with a burr at the same procedure. If a transnasal wire is required, it is essential to have preoperative radiologic evidence of the height of the cribriform plate to avoid damage to the intracranial structures. The correction of hypertelorism requires craniofacial surgery to mobilize the orbital rims and reduce the intervening ethmoid bones.

Blepharophimosis

Blepharophimosis means "small eyelids." In the blepharophimosis syndrome, the horizontal palpebral aperture is reduced

and this is associated with epicanthus inversus, ptosis, and telecanthus. Treatment is directed first toward promoting visual development and then improving cosmesis.

If the resting lid level obstructs a significant part of the pupillary aperture or causes astigmatism, urgent ptosis surgery is indicated. This is to prevent amblyopia and strabismus, which are common.[10] It usually involves a frontalis sling with non-autogenous material that, in severe cases, may be indicated in the first few months of life. The procedure may need to be repeated if the lid level drops and, again, starts to occlude the pupillary aperture.

When the child is about 3½–4 years old, a decision can be taken about if and when to repair hypertelorism, telecanthus, and epicanthic folds. Various techniques have been described to rearrange the medial canthal tissues, but a simple Y-to-V advancement with medial canthal tendon plication, or, in the case of more severe telecanthus, transnasal wiring, is most effective. The epicanthic folds can be corrected at the same time or left until the bridge of the nose has developed at puberty, which may by itself improve the cosmesis. After any medial canthal surgery there may be a need to correct residual ptosis. This usually involves a frontalis sling procedure using autogenous fascia lata or temporalis fascia, as the levator function is very poor (Fig. 19.6). Any lateral canthoplasty to widen the horizontal palpebral aperture is best delayed until after puberty when there is less scarring.

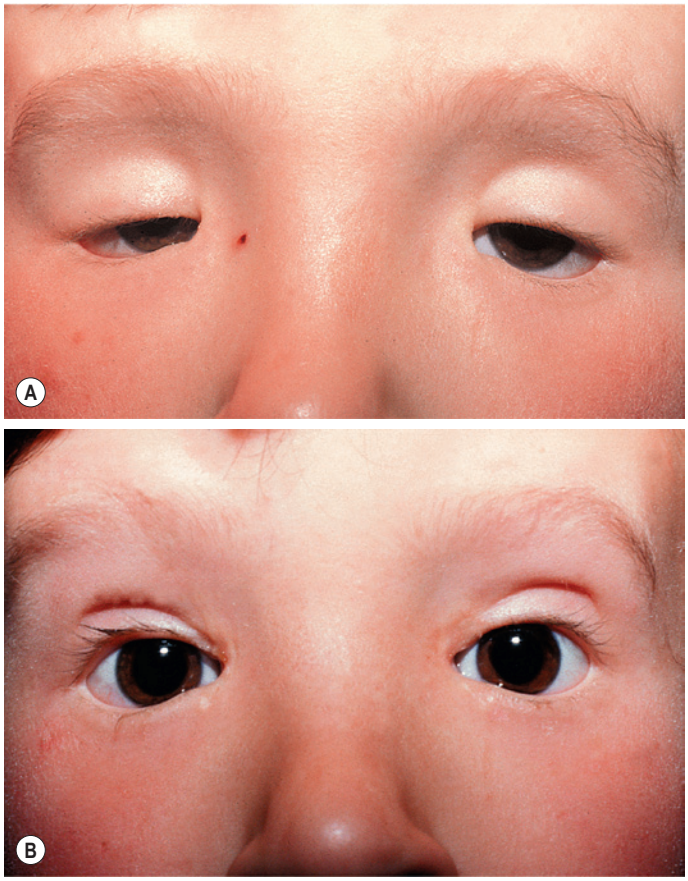

Fig. 19.6 Blepharophimosis. (A) This patient has blepharophimosis syndrome with blepharophimosis, ptosis, and telecanthus. (B) The same child after Y–V canthoplasties followed by brow suspensions with autogenous fascia lata.

Management of congenital and acquired ptosis

Congenital ptosis is usually associated with a dysgenesis of the levator muscle. There is a direct relationship between the levator muscle function, i.e. the excursion of the upper lid between full upgaze and downgaze, and the number of healthy striated muscle fibers. This is the main factor influencing the choice of ptosis surgery. Causes of acquired ptosis include aponeurotic defects, third nerve palsy and associated syndromes, Horner syndrome, ocular myopathies, and myasthenia. These will influence the choice of surgery by affecting Bell phenomenon, levator function, the variability of ptosis, etc.

History and examination

A careful history to confirm the congenital or acquired nature of the condition and associated phenomenon is important. With congenital ptosis, the parents may report that the condition seemed to improve initially after birth and then plateaued after a few months.

A full eye examination should be performed, with attention to the position of the lid on downgaze, levator excursion from down- to upgaze, extraocular motility, facial or eyelid dysmorphism or mass, aberrant movements of the lid associated with ocular or jaw movements, pupillary size and reactivity, and variability in eyelid height. Best corrected visual acuity, fixation preference, and retinoscopy or subjective refraction should be performed to rule out associated amblyopia. Further investigations may be indicated, for instance with third nerve palsies or Horner syndrome.[11] Early acquired Horner syndrome may be associated with neuroblatoma in the cervical region or internal carotid abnormalities. True congenital Horner syndrome should have associated heterochromia, the ipsilateral iris having lighter pigmentation.

The degree of ptosis should be assessed by comparing the vertical interpalpebral aperture measurements on both sides and assessing the height of the lid above the corneal reflex from a spot source of light (margin–reflex distance). This obviates inaccuracies from malposition of the lower eyelid. The levator function should be measured by pressing over the brow to prevent any frontalis action and then measuring the excursion of the lid between full up- and downgaze, if the child is old enough to cooperate. The position of the skin crease on both sides and the presence or absence of Bell phenomenon should be noted, as well as orbicularis strength.

Treatment

This depends on the diagnosis and physical findings. Surgical correction is urgent only if there is a risk of amblyopia because the eyelid is inducing asymmetric astigmatism or occluding part of the pupillary aperture. Even in the setting of severe unilateral ptosis, a chin-up head position is often adopted to maintain binocular fusion. Hence, ptosis surgery often may be delayed until the child is old enough for an accurate assessment of levator function, but regular examinations to monitor amblyopia are mandatory. Underlying strabismus should be corrected before undertaking ptosis repair, as eyelid height may be affected by strabismus surgery.

With congenital ptosis, the levator function and degree of ptosis govern the choice of operation. In mild congenital

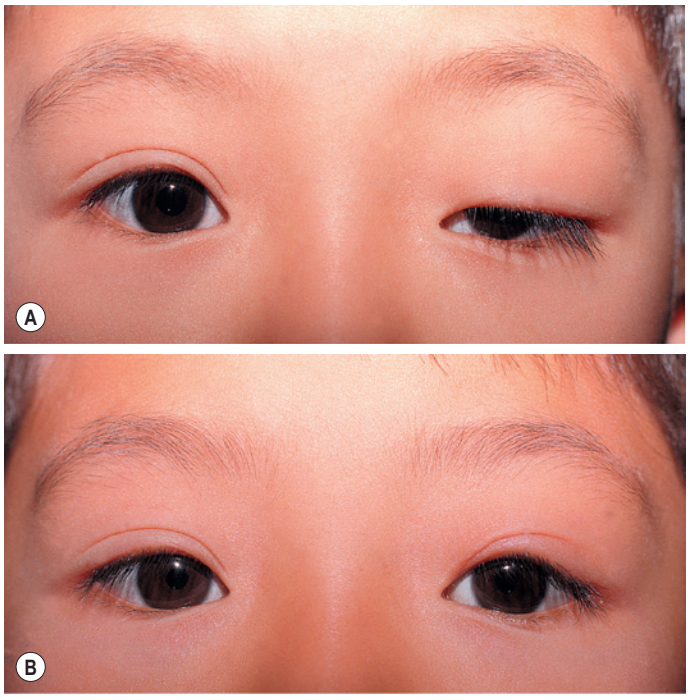

Fig. 19.7 (A) Unilateral simple congenital ptosis. (B) The same child after levator resection.

ptosis, if there is about 2 mm of ptosis with good levator function of 10 mm or more, a Fasanella Servat procedure or Müller muscle resection predictably elevates the eyelid.

In moderate congenital ptosis with levator function between 5 and 10 mm, a graded levator resection, depending on the amount of levator function and degree of ptosis (Fig. 19.7), is attempted. Either an anterior or a posterior approach to the levator can give satisfactory results. The posterior approach has the advantage that the resected levator muscle is held by pull-out sutures that are tied in the skin crease. If an overcorrection occurs, these can be removed in the early postoperative period and the eyelid lowered. The anterior approach is suitable for a maximum levator resection; it allows wider exposure of the levator muscle and the creation of an enhanced lid fold by directly fixating skin to the underlying distal edge of the cut levator muscle. The disadvantage of a large levator resection is that it increases lagophthalmos and lid lag on downgaze.

In severe congenital ptosis with less than 5 mm of levator function, a frontalis sling is usually necessary. The success of this procedure relies on the intrinsic reflex recruitment of the ipsilateral frontalis muscle. Internal attachment between the frontalis and the eyelid is carried out so that frontalis elevation results in a more efficient eyelid elevation. If it is necessary to elevate an eyelid urgently to prevent amblyopia, this can be done with a unilateral procedure using a non-autogenous material. Many materials have been utilized, but non-autogenous materials carry risk of infection, extrusion, migration due to "cheese-wiring," or degradation with breakage or loss of strength. Of the various options, a 4-0 prolene suture, 3-0 Supramid, or 1 mm silicon rod are the simplest to insert and do not carry the risk of granuloma formation associated with integratable materials such as Mersilene mesh or Gore-Tex. If there is no concern about amblyopia, it is better to wait until the child's leg is large enough to harvest autogenous fascia lata (usually 3–4 years) to use as the sling material. A pentagonal sling with opening of the eyelid crease and direct suturing the sling material to tarsal plate allows for excellent symmetry of eyelid creases. Intraoperative adjustment of lid height and contour can be effected depending on placement of the fixation sutures on the tarsal plate. Controversy exists as to whether unilateral ptosis with poor levator function should be treated with a unilateral sling or whether better symmetry can be achieved by excising the normal levator muscle and lifting both eyelids symmetrically with a bilateral brow suspension (Fig. 19.8). Excellent symmetry in the primary position can usually be obtained with unilateral surgery, but asymmetric lid lag will be visible in downgaze. Bilateral surgery involves sacrificing the normal anatomy, which may be unacceptable to some parents. Although excellent symmetry may be obtained if both brows work symmetrically, asymmetrical swelling or bleeding at the time of surgery may produce some degree of asymmetry in the final lid levels. A frontalis sling is usually ineffective if there is amblyopia, as there will be no stimulus for recruitment of the frontalis to clear the visual axis if there is no drive to obtain binocular vision. In this case, a maximal levator resection may be performed. The levator muscle is dissected free of it attachments, including Whitnall ligament, and the muscle maximally resected (up to 30 mm) and re-sutured to the tarsal plate through an anterior approach. The goal is to leave the eyelid margin at the level of the superior limbus. This approach may lead to lagophthalmos and exposure keratopathy, but most young patients will tolerate this with the aid of initial aggressive corneal lubrication. Lagophthalmos usually improves over time because a severely dysgenetic levator muscle is heavily infiltrated with fatty tissue and tends to stretch, but this can also lead to recurrence of the ptosis over time.

Specific conditions

In the blepharophimosis syndrome, levator function is usually poor and bilateral autogenous fascia lata brow suspensions are required. If the levator function is good, bilateral levator resections can be performed. The epicanthus inversus is usually best treated with a medial canthoplasty about 6 months before the lids are lifted.

In Marcus Gunn syndrome, if the jaw-winking element is unobtrusive, the ptosis alone can be corrected based on the levator function. If the jaw-winking is severe, it can be abolished or diminished by transecting the levator muscle and attaching it to periorbita behind the supraorbital rim. The ptosis must then be corrected with a brow suspension procedure. In some patients, the "wink" becomes less noticeable over time if they learn to control their jaw movements. It may be justifiable to delay surgery until the child is old enough to determine the ultimate degree of jaw-wink.

With cranial nerve III lesions, the eye should be straightened first with strabismus surgery. Correction of the ptosis depends on the levator function. If Bell phenomenon is defective, there is a risk of exposure keratitis, and ptosis surgery should be more conservative. Congenital third nerve lesions may often display aberrant innervation with cross-signaling between the medial rectus and levator palpebrae superioris (see Chapter 84). In this case, extirpation of the levator and frontalis sling surgery is required. A similar approach is used if there is cyclic third nerve dysfunction.

Fig 19.8 (A) Left ptosis with poor levator function in a 6-month-old baby. It can be seen that there is no lid crease on the right while it is present on the left. The child is looking down during this photograph and the normally ptotic lid is slightly higher than the normal lid. The failure of the affected levator to relax in downgaze suggests a dysgenetic etiology. (B) Same child at 2 years of age preoperatively. (C) Same child after a bilateral levator sling procedure.

Horner syndrome usually does well with a Fasanella Servat or Müller muscle resection procedure.

Patients with myasthenia gravis should first be managed medically. If ptosis persists, silicone rod frontalis sling allows elevation of the eyelid and postoperative adjustment of eyelid height, if necessary. The two ends of the rod are attached to each other by placing them through a Watzke sleeve; the ends are left long with about 1 cm of excess rod on either side. If necessary, the eyebrow incision may be re-opened later over the sleeve to loosen the sling.

Aponeurotic defects occurring congenitally, traumatically, or secondary to blepharochalasis syndrome should be repaired by advancing the levator aponeurosis. This is best done under local anesthesia when the child is older, so that eyelid height and contour can be adjusted intraoperatively.

In the congenital cranial dysinnervation disorders (see Chapter 83), a brow suspension with careful postoperative management to prevent exposure may give good results.

Lid retraction in infancy

Lid retraction in infancy can be caused by various conditions. Major lid retraction with corneal exposure requires urgent treatment with lubrication and early surgery to protect the cornea. Cases of mild lid retraction may benefit from cosmetic surgery that may be delayed into early childhood.

The upper lid can be lowered and the lower lid elevated by recessing the lid retractors, provided there is no shortage of skin or conjunctiva. Upper lid retractor recessions through a posterior approach can be used to release Müller muscle and aponeurosis and correct up to 2 mm of lid retraction. However, posterior approach upper lid retractor recessions inevitably cause a raised skin crease. This does not matter in mild or bilateral cases, but is important in severe unilateral cases. In these, the retractors should be lengthened via an anterior approach levator recession or Z-myotomy, or a spacer graft, and the skin crease reformed at the desired level. More recently, transverse blepharotomy has proven useful, with full-thickness transverse blepharotomy followed by skin closure. Lower lid retraction may be corrected by retractor recession, usually in combination with a spacer graft.[12]

Seventh nerve palsy

In the newborn, the incidence of facial palsy is 0.2%. Birth trauma is the cause of 78% of facial paralyses in this group, and can be caused by forceps delivery, pressure from the maternal sacrum, pressure from the fetal shoulder, or intracranial hemorrhage. Nearly 90% of newborn facial palsies completely recover without treatment, usually by 5 months of age.[13] In infancy or childhood, acquired facial palsy is most often associated with otitis media and mastoiditis, or idiopathic Bell palsy, which is less common in children than in adults. It is manifest as a sudden onset of paralysis of all five divisions of the facial nerve without signs of ear or cerebellopontine angle disease. It is bilateral in 0.3–2% of cases, and recurrent in 9% of cases.

In bilateral palsies, the resultant disability is dramatically more severe, and can be associated with severe feeding problems. In the newborn it may be associated with Möbius syndrome (see Chapter 83). In childhood, the most common cause in endemic areas is Lyme disease, followed by otitis media and idiopathy.[14]

Although facial nerve palsy in children has a good prognosis, it may be the initial manifestation of a life-threatening disorder such as an intracranial neoplasm or vascular malformation.

If there are other neurologic findings, imaging studies are indicated. Progression of facial nerve palsy is usually due to a tumor; in 20% of patients with recurrent facial weakness, a tumor is eventually discovered.

The main problems caused by a seventh nerve palsy are corneal exposure, paralytic ectropion, epiphora, and poor cosmesis.[15]

Corneal exposure

Corneal exposure does not usually result from poor lid closure alone, as Bell phenomenon is good in infants; there are usually additional risk factors. These include inadequate Bell phenomenon, reduction in corneal sensation, lower lid ectropion, treatment on a ventilator, prematurity, or reduction in tear production if the lesion is proximal to the geniculate ganglion. A reduction in corneal sensation is more common after surgical treatment of intracranial tumors, although it may be present in Möbius syndrome.

Initial treatment is with lubricants, taping at night, and occasionally occlusive dressings may be required. The lubricants can be stopped for 2–3 hours a day, or the other eye patched in order to avoid amblyopia. Occasionally, a temporary lateral tarsorrhaphy may be required to protect the cornea. If there is continued corneal exposure after 6 months, or earlier if there is no chance of recovery, the palpebral aperture can be reduced permanently. The vertical palpebral aperture can be reduced by raising the lower lid with a lateral tarsorrhaphy and medial canthoplasty, by lowering the upper lid with a recession of Müller muscle and the levator muscle, or with a full-thickness blepharotomy. Lid closure can be improved mechanically with upper lid gold weights or springs.

Paralytic ectropion

Paralytic ectropion can be treated by a medial canthoplasty. If required, this can be combined with lateral canthal tightening.

Epiphora (see Chapter 21)

Epiphora is due to the loss of the lacrimal pump mechanism and is exacerbated by lower lid ectropion. Persistent watering after 6 months may be improved by correction of any ectropion with a lateral canthal tightening and medial canthoplasty.

Watering may also occur due to "crocodile tears" in which tearing is associated with salivation due to aberrant innervation of the lacrimal gland by parasympathetic fibers intended for the salivary glands. Crocodile tears may be improved by injections of 2.5 units of botulinum toxin into the palpebral lobe of the lacrimal gland, but this requires a general anesthetic in a child. Severe epiphora of any cause may require a Lester Jones tube: this is difficult to manage in a small child.

Cosmesis

Surgery to raise the brow, reduce the palpebral aperture, and correct ectropion may help. Lower facial paralysis tends to cause progressive facial asymmetry; facial slings or nerve grafting may help restore facial tone and position.

Lid tumors

Nevi

Surgery for nevi is indicated if there is malignant potential, amblyopia due to lid malposition, and for cosmetic reasons.

Large, or giant, congenital nevi are associated with a risk of malignant transformation. The risk is proportional to the size of the lesion and may be up to 20% in very large congenital hairy nevi. The incidence of malignant transformation in small and medium congenital nevi is controversial, but probably is negligible. Divided nevi ("kissing nevi") are a form of congenital melanocytic nevus that involves mirror surfaces of the upper and lower lids (Fig. 19.9). Malignant transformation has not been reported in congenital nevi limited to the eyelids. Peak onset of malignant transformation occurs by 2–3 years of age. The lesions are difficult to treat due to their size. Surgery may require numerous stages, with skin grafts and flaps, and the use of tissue expanders. The multiple procedures may result in marked scarring. Dermabrasion, within the first few months and preferably weeks of life, may reduce the chance of malignant transformation, improve cosmesis, and reduce the extent of further surgery.[16]

Acquired nevi are rarely a concern in children, but these lesions are monitored.

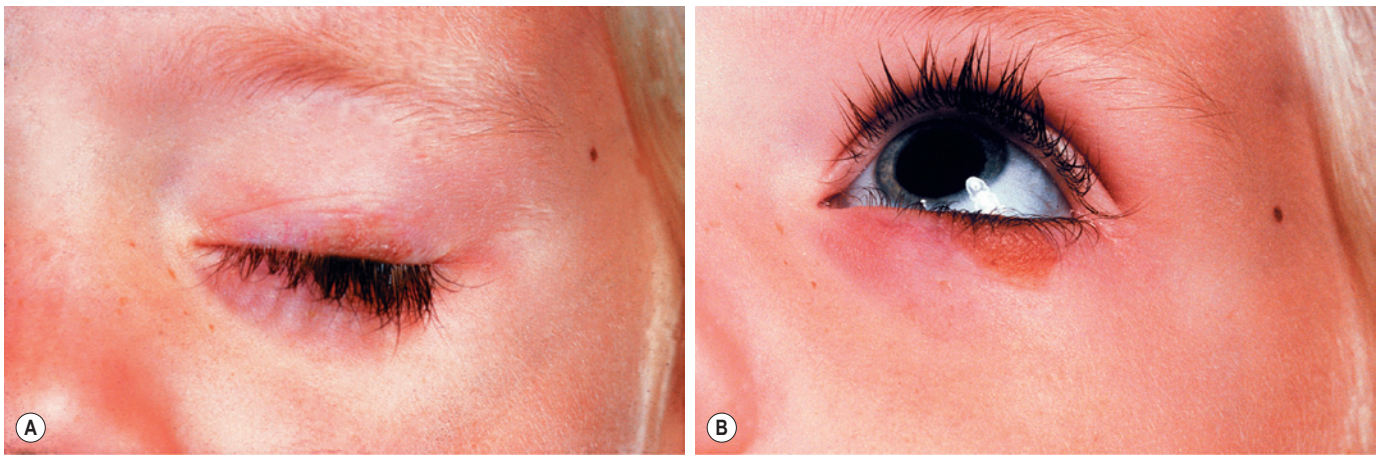

Fig. 19.9 Divided nevus.

Fig. 19.10 Large molluscum contagiosum lesion. *(Dr Susan Day's patient.)*

Fig. 19.11 Molluscum contagiosum showing multiple lesions and a follicular conjunctivitis.

Fig. 19.12 Molluscum contagiosum showing "kiss" lesions on upper and lower lids.

Molluscum contagiosum

Molluscum contagiosum are viral lesions that frequently occur on the eyelids (Fig. 19.10). They may rarely obtain large size; "kissing" lesions may occur on the upper and lower lids (Fig. 19.11). They are often associated with a follicular conjunctivitis (Fig. 19.12), which does not resolve until the lesions near the eyelid are eradicated (see Chapter 16). Treatment modalities include curettage and diathermy of the core of the lesion, cryotherapy, and chemical ablatives.

Juvenile xanthogranuloma

Juvenile xanthogranuloma (see Chapter 27) is a benign disease characterized by the development of small yellowish rubbery cutaneous lesions, including eyelid lesions, measuring 1–10 mm, in the first 1–9 months of life. They are occasionally associated with ocular xanthogranuloma lesions, particularly in the iris; spontaneous hyphema and glaucoma may result.

Complex choristoma

These are rare lid tumors that consist of variable combinations of ectopic tissues (see Chapter 29). They resemble other choristomas such as dermoids and lipodermoids. When acinar elements compose the majority of the tissue, they may have a fleshy appearance or resemble an ectopic lacrimal gland. Mild growth may occur during puberty, but malignant transformation is very rare. They can involve the underlying tissue. Conjunctival lesions may involve the underlying globe; therefore, excision is performed with caution.

Pilomatrixoma (calcifying epithelioma of Malherbe)

A small hard nodule in the eyebrow is likely to be a pilomatrixoma. The overlying skin is intact and may have a pink to purple discoloration. It may be mistaken for a chalazion or dermoid. Treatment is excision.

Lid hamartoma

Lid hamartomas include infantile hemangiomas (see Chapter 20), plexiform neurofibromas (see Chapter 68), lymphangiomas (venolymphatic malformations) (see Chapter 20), and congenital nevi.

Indications for surgery for plexiform neurofibroma and lymphangioma include mechanical ptosis, occlusion amblyopia, astigmatic anisometropic amblyopia, and cosmetic deformity. Surgery for both these lesions is challenging. The lesions may be extensive, involving the lids, orbits, and surrounding facial tissues. Due to their infiltrative nature there may be an increase in growth around puberty. Treatment should be planned in conjunction with allied surgical specialties. In general, less surgical intervention is better than more. Serial procedures may be necessary over the lifetime of the patient.

Meibomian gland diseases

Chalazia (meibomian cysts)

A chalazion is a lipogranulomatous inflammatory reaction of the meibomian gland that results from obstruction of the gland duct and is usually located in the mid-portion of the tarsus. It may occur on the lid margin if the opening of the duct is involved. A secondary bacterial infection of the surrounding tissue may develop with swelling of the entire lid. Chalazia may cause pressure on the globe and induce astigmatism. Most chalazia ultimately resolve spontaneously; this may be

hastened by frequent application of warm compresses. These can be made using a cup of uncooked rice placed in a thin sock and heated for 1 minute in a microwave oven. If the chalazion is inflamed or secondarily infected, treatment with oral azithromycin (once a week for 3 weeks) is often helpful. There is little role for topical antibiotic drops or ointment since these do not penetrate the tarsal plate. Incision of the posterior tarsal wall of the lesion and curettage is sometimes necessary. This is avoided whenever possible in young children since it requires general anesthesia. Chronic meibomitis and blepharitis may predispose to recurrent chalazia, and can be treated by lid cleaning and antibiotic/hydrocortisone ointment and oral azithromycin (see Chapter 16).

Other diseases of the meibomian glands include the following:

1. absent or deficient glands: primary congenital ectodermal dysplasia or ichthyosis, or secondary to lid disease;
2. replacement: primary distichiasis, or secondary distichiasis due to metaplasia;
3. meibomian seborrhea: associated with seborrheic dermatitis and acne rosacea. The meibum is greasy and solidified;
4. meibomitis: often occurs with blepharitis. The orifices are red and swollen and sometimes there is tenderness to palpation with associated lid edema. Treatment is similar to blepharitis.

Acute blepharitis

Acute blepharitis (see Chapter 16) presents with ulceration of the lid margins and is usually caused by *Staphylococcus aureus*, other organisms, and viruses, including *Moraxella* spp., herpes simplex, and various fungi in immunosuppressed patients (Fig. 19.13). Staphylococcal and *Moraxella* blepharitis usually respond well to antibiotic cream and lid hygiene.

Chronic blepharitis

Chronic blepharitis (see Chapter 16) is much more common than the acute form. It presents as irritable, red, and scaly eyelids that are sometimes edematous (Fig. 19.14). The anterior lid margin is usually most affected, but occasionally the posterior lid margin is more red and swollen when the meibomian glands are affected (chronic meibomitis). Chronic infection with *S. aureus*, *Propionibacterium acnes*, or coagulase-negative staphylococcal species may play a role.[17]

Most of the cases of chronic blepharitis have a seborrheic element with greasy, scaly lids associated in some cases with seborrheic dermatitis of the scalp (dandruff), or elsewhere.

Treatment is by regular lid cleaning, with particular attention to the lid margins. Expression of meibomian secretion by firm pressure may help the symptoms of burning and irritation. A 3-week course of oral azithromycin may be effective in reducing inflammation. Recurrent or severe cases, associated with keratoconjunctivitis, may be treated by a short course of steroid–antibiotic combination ointment.

Lid lice

Lid lice (see Chapter 16) are usually pubic lice rather than head lice because their body shape is more suited to the wider spacing of the lashes. They may be found on slit-lamp examination of the bases of the lashes; their eggs ("nits") may be found attached to the lashes. The pubic hair must be treated with a topical anti-lice shampoo. The lice and nits can be manually removed from the eyelashes and topical non-medicated ointment applied to the lashes three times a day will often asphyxiate remaining lice. Topical physostigmine or pilogel can be applied.

Trichiasis

Trichiasis is an acquired condition of the eyelash roots in which the cilia are misdirected posteriorly causing corneal and conjunctival irritation. In the large majority of cases, it is caused by subtle cicatricial entropion, as evidenced by the anterior migration of the mucocutaneous junction relative to its normal location at the posterior lid margin. The more common causes of trichiasis include chronic blepharitis, Stevens–Johnson syndrome, burns, trachoma, and pemphigus (usually in adults).

The treatment of trichiasis depends on the number of abnormal lashes. One or a few lashes can be treated with electrolysis or surgery to excise the lash roots or resect the affected portion of the eyelid margin. More numerous lashes are best treated with cryotherapy, but all the lashes in

Fig. 19.13 Acute blepharitis with lid ulceration and stye formation.

Fig. 19.14 Chronic blepharitis associated with chronic *Staphylococcus* infection.

the treated area are liable to be destroyed and it may cause depigmentation. In heavily pigmented patients, cryotherapy can be combined with a lid-splitting technique as described above for distichiasis. Tarsal fracture and rotation provides a superior cosmetic result, but may be followed by recurrence in cases of severe cicatricial entropion.

Socket management

Contracted socket

Early socket growth is rapid (see Chapter 6). At 3 months, the face is only 40% of its adult size; by 5½ years it is 80% of its adult size. The presence of an eye is necessary for normal orbital growth. The loss of an eye, microphthalmia, or anophthalmia all result in abnormal orbital growth, but lack of a normal globe during development *in utero* leads to much more severe socket hypoplasia than loss of an eye after birth. The aims of socket management in infants are to increase the size of the bony orbit, conjunctival space, and palpebral length, and to promote the normal development of the lid margins and lashes.

Treatment must be started early to avoid a poor esthetic result. If the patient has an orbital cyst associated with microphthalmos or anophthalmos, this may be left to aid socket expansion (see Chapter 18).[18] The socket soft tissues can be expanded using increasing sizes of orbital conformer. Expandable conformers that do not require serial changes and can be increased in size by injecting saline through a port have become available. These can be placed in the intraconal space and connected to a remote injection port under the skin (e.g. over the ear) or in the conjunctival sac with an anterior port directly accessible through the palpebral fissure.

An alternative is the self-inflating hydrogel expander. This is made of a modified copolymer of methylmethacrylate and vinylpyrrolidone, similar to contact lens material but with more capacity for fluid imbibition (i.e. the capacity to absorb fluid). It swells 10–12 times in volume, taking about 2–6 weeks to expand to its full size in the orbit.

Orbital volume replacement

Sometimes orbital expansion results in an increase in the anteroposterior dimension of the socket without increasing the palpebral fissure length and forniceal depth. The resultant conformer is round and deep and will not promote an increase in vertical and horizontal lid length, and will be difficult to retain. An orbital implant can be inserted, and a thinner conformer used to improve the fornices. Alternatively, if hydrogel expanders are used, a lens-shaped expander can be used to expand the conjunctival space, followed by a spherical expander for the orbit.

The lateral fornix is often difficult to enlarge. It may need to be constructed surgically with a mucous membrane graft in order to retain a prosthesis.

Orbital implants available include porous implants of hydroxyapatite and polypropylene, non-porous implants made from silicone and acrylic, and dermis fat grafts. The porous implants have the advantage that they may become integrated into the socket and may be less likely to extrude. However, their more abrasive surface may increase the erosion of the overlying conjunctiva and Tenon capsule, resulting in increased likelihood of exposure. There may be the option of pegging the porous implant to improve motility later. However, integration into the socket tissues makes these implants more difficult to remove if an implant needs to be replaced for a larger size. No study has supported the concept that porous implants give better motility unless they are pegged. Since pegging is rarely done due to a 30–40% incidence of complications, silicone or acrylic implants are generally preferred. Dermis fat grafts have several advantages.[19] In adults, they tend to atrophy, but in children they grow as the child grows and help with socket expansion. They may grow so much that they require debulking.[20] The conjunctiva can be attached to the edge of the graft, allowing the conjunctival epithelium to grow over the surface of the graft and increase the size of the conjunctival sac. If further volume augmentation is required, an orbital implant can be placed posterior to the graft.[21] The main disadvantage is donor site morbidity (usually the abdomen), although this is seldom a problem.

If treatment has failed to achieve adequate orbital expansion, resulting in marked facial asymmetry, craniofacial surgery may be required to augment or repair the orbit. Vascularized flaps to increase soft tissue may be used, for example, in cases of tissue atrophy secondary to radiotherapy.

Discharging sockets

Socket discharge is a common problem in patients with a prosthesis. The common causes are[22]:

1. prosthesis: poor fit, mechanical irritation, hypersensitive reaction, and poor prosthetic hygiene;
2. orbital implant: extrusion of implant, conjunctival inclusion cyst, and granuloma formation;
3. lid: poor closure and infected focus;
4. socket lining: contracture resulting in a mixture of skin and mucous membrane;
5. lacrimal system: defective tear production or drainage and dacryocystitis.

Management is to treat the underlying cause.

Lid and adnexal trauma (see Chapter 69)

Etiology

The majority of pediatric lid and adnexal injuries are accidental in nature, most commonly occurring during domestic activity, play time, or sporting activity.[23,24] Injuries from dog bites are frequent. Accidental penetration by common objects such as pencils or toys occurs frequently when a child stumbles and falls. Lid injuries include contusions, crush injuries, abrasions, lacerations, puncture wounds, and burns. These frequently occur in combination.

Immediate management

A history is taken, noting the time of the injury, nature of any projectile (was it sharp or blunt, metallic or vegetable), the speed of the projectile (was it thrown or shot), height of a fall and the type of surface the child landed on, any loss of consciousness, and any witnesses.

The assessment of the patient starts by examining and treating all injuries. Any necessary basic life support is given, and a full systemic examination may be required, including a neurologic examination if there is any suspicion of intracranial injury. It is not uncommon for long narrow objects such as pencils to penetrate the intracranial cavity via the orbit when a child carrying them stumbles and falls. A full ocular examination is performed. Visual function is assessed; if possible the visual acuity is taken. In a young child, one evaluates fixation and checks the patient's tolerance of occlusion of the uninjured eye. Check the pupil responses for a relative afferent defect.

The injury is assessed by looking for any damage not readily visible. A small penetrating lid laceration may have extensive underlying damage, including intracranial injury, orbital fractures, optic neuropathy, and injury to the globe. Avulsion injuries of the upper or lower eyelid (e.g. dog bites) are usually accompanied by canalicular injury; since this is the weakest part of the eyelid it is often the first to tear. The patient is examined for any evidence of a retained foreign body, missing tissue, and damage to the lacrimal system. The levator function should be noted in upper lid lacerations. If a large hematoma is present, there should be a greater suspicion of damage to the orbit and globe. Computed tomography (CT) scans are used to look for retained foreign bodies and fractures; magnetic resonance imaging (MRI) can be useful to look for a retained organic foreign body and more fully assess intracranial injury. Photographs are taken of any injury for future reference. A tetanus toxoid booster is given as appropriate.

The results of eyelid surgery are not prejudiced by waiting for up to 48–72 hours if this allows more time and better facilities to be available.[25] However, upon initial exam, the wound should be cleansed and irrigated copiously to prevent infection, subsequent tattooing, or retained foreign bodies. It is examined carefully and the tissues repositioned as accurately as possible. The skin can be closed with absorbable sutures, such as 6-0 Vicryl, avoiding a further anesthetic for suture removal. Tissue should not be excised or discarded, as the eyelid region has an excellent blood supply; any pedicle should be preserved. It is not usually necessary to cut or "freshen" the wound. In contaminated wounds such as animal bites, copious irrigation is paramount. Prophylactic intravenous antibiotics are given within 1 hour followed by a 1-week course of oral antibiotics.

After initial repair, major revision should be delayed for 6–9 months. At that time, secondary defects such as lid retraction or ptosis can be addressed unless the patient develops symptoms of corneal exposure that cannot be controlled with simple lubrication or is at risk of developing amblyopia.[25]

Lid margin defects require careful approximation of the lash line and tarsal plate to avoid lid notch, rotation of the lid, and lash abnormalities. The lid margin sutures are usually incorporated in the lash line sutures to prevent their coming in contact with the cornea.

Traumatic ptosis

Traumatic ptosis can be caused by:

1. direct injury or stretching of the aponeurosis or levator muscle;
2. loss of orbital contents or phthisical eye, lowering the fulcrum of the levator complex;
3. injury to the superior division of the third nerve or sympathetic nerve supply;
4. mechanical restriction due to conjunctival, lid, or deep orbital scarring.

Most levator defects should be sutured at the time of the primary repair; however, minor defects can be left, as they are likely to heal spontaneously and excessive surgery may lead to lid retraction. Residual ptosis may be repaired at a later date, usually after 6 months or after any improvement has ceased. Early intervention is indicated if there is any risk of amblyopia. A temporary frontalis sling using removable material such as a Prolene or Supramid suture or a silicone rod may be required. Secondary repair is via an anterior approach. Excision of the scar tissue may leave a gap in the levator complex, requiring a spacer. A dermis fat graft can be used to prevent the reformation of dense adhesions. Treatment of ptosis due to nerve injury is described earlier in this chapter.

Lacrimal drainage injuries

It was formerly believed that the lower canaliculus played a greater role in tear drainage than the upper system. Therefore, some authors recommended that only inferior canalicular lacerations be repaired. Studies of lacrimal scintigraphy after occlusion of either upper or lower punctum have concluded that both play an equal role in tear drainage; injury to either one deserves surgical repair. Although many patients will be asymptomatic as long one of their two canaliculi remains functioning, at least 10% of patients will have epiphora if one punctum is occluded. This increases to more than 50% when subject to globe irritation by exposure to the elements.

The canaliculus should be repaired by suturing the two severed ends over an indwelling silicone stent, which is usually left in place for 3 or more months. The white color of the canalicular epithelium can usually be seen with loupe magnification, although the aid of an operating microscope may be required. Injection of fluorescein-stained viscoelastic via the opposite punctum (or directly into the sac in cases of upper and lower canalicular damage) may help to identify the canaliculus. Use of a pigtail probe passed through the intact punctum in an attempt to find the lacerated cut end is controversial; it may damage healthy tissue (especially the older hooked instruments). With the use of an operating microscope, good hemostasis, and a thorough knowledge of the anatomy, this is seldom required.

If the canaliculi are to be anastomosed, they are intubated with a self-retaining monocanalicular stent, or with bicanalicular stents. The peri-canalicular soft tissues are closed with 7-0 Vicryl sutures. Care is taken to repair the posterior limb of the medial canthal tendon, which is immediately posterior to the medial canaliculus. This maintains the lid in apposition to the globe. In repairing the canaliculus, the sutures should be passed into the tissues immediately around the canaliculus and not through its epithelium.[26]

Common canalicular injury is repaired, or opened into the lacrimal sac, the canaliculi intubated, and a dacryocystorhinostomy performed.

Canalicular damage near the punctum can be treated by a retrograde dacryocystorhinostomy with marsupialization of the canaliculus into the conjunctival sac. Blockage near the lacrimal sac can be re-treated by excision of the scar and connection of the patent canaliculus to the sac. In either case, at least 8 mm of one canaliculus is necessary for success.

Medial canthal tendon injuries

The anterior limb of the medial canthal tendon seldom needs repair; however, if the posterior limb is damaged and only the anterior limb is repaired, the lid will be anteropositioned. The method of repair of the posterior limb depends on the posterior fixation point available. If the lacrimal drainage system is intact and there is a firm and reasonably positioned medial wall fixation point, the posterior limb and eyelid tissues can be directly attached to the medial orbital wall. If the lacrimal sac must be opened for dacryocystorhinostomy and the tissues behind the lacrimal sac are adequate, a non-absorbable suture can be passed behind the opened lacrimal sac and used to re-attach the medial canthus and eyelid tissues medially and posterior to the posterior lacrimal fascia. If there is no adequate ipsilateral fixation point, a "T-shaped" mini-plate can be attached to the anterior lacrimal crest and the tendon sutured to one of its posterior fixation points, or a transnasal wire can be used to reposition the medial canthus posteriorly.

Burns

In the acute stage, burns are treated with heavy lubrication or occlusive therapy to protect the cornea. To avoid amblyopia in the young child, the eye may be left for 2–3 hours a day without lubrication or the other eye can be patched. In severe cases of exposure, a conjunctival flap may be required to protect the cornea in the chronic stage. Cicatricial contracture of the eyelids is a frequent problem and tarsorrhaphies, lid-sharing procedures, split-thickness skin grafting, and Frost sutures may be necessary to protect the ocular surface. Re-operation is often required due to progressive wound contracture, which may continue for months. After 30 days, the lids are reconstructed. Split skin grafts may be required; lid-sharing procedures are avoided where possible to avoid the risk of amblyopia.

Lid and orbital infantile periocular hemangiomas (capillary hemangiomas) and other vascular diseases

Christopher J Lyons

Chapter contents

TUMORS
VASCULAR MALFORMATIONS
REFERENCES

Vascular lesions of the orbit include tumors such as infantile hemangioma and hemangiopericytoma, as well as malformations such as venous-lymphatic malformations (lymphangiomas), orbital varices, and arteriovenous malformations. Infantile periocular hemangiomas (capillary hemangiomas) are common benign vascular tumors that are characterized by rapid growth during the first year of life and show regression over the next several years.[1,2] Venous-lymphatic malformations are vascular malformations that infrequently present in early childhood and are complicated by bouts of hemorrhage and rapidly progressive enlargement. Varices and arteriovenous malformations primarily present in the second and third decades.

Tumors

Infantile periocular hemangioma (capillary hemangioma)

Infantile periocular hemangioma, a hamartoma, is the most common childhood orbital tumor. It occurs more frequently in females than males in a ratio of 3:2 with no inheritance pattern.[3] There is an increasing incidence with prematurity and reduced birth weight: up to 23% in infants weighing less than 1000 g have at least one infantile hemangioma, compared with 1–4% of full-term infants.[4,5] It is distinguished from other orbital vascular lesions by spontaneous regression. Numerous techniques are available to manage this potentially disfiguring disorder, which can affect vision. There is no "one size fits all" approach for this unpredictable tumor; lesions that resolve rapidly with treatment could have done so without treatment. We are fearful of uncontrolled growth, as illustrated by Fig. 20.1. Treatment of periocular hemangiomas is a team effort involving pediatricians, dermatologists, and ophthalmologists. Decisions to treat are based on the position of the lesion, the potential for amblyopia, rapidity of growth, and discussion of risk/benefits with informed parents. Children must be followed closely, watching for rebound growth and for amblyopia.

The histopathology varies with the clinical phase: in its early proliferative phase, it consists mostly of numerous dividing endothelial cells; vascular spaces are rare and small. It is rich in mast cells, whose function is not clear. There may be numerous mitotic figures, which could lead to an incorrect diagnosis of malignancy in rapidly enlarging lesions. The characterization of poorly differentiated lesions may be helped by reticulin stains or by the identification of factor VIII, which is produced by the endothelial cells, using peroxidase or fluorescein antibody techniques.[3] In more mature tumors, vascular spaces are larger, with fewer flattened endothelial cells. The tumor is not encapsulated and tends to infiltrate surrounding structures. In the involutional phase, the endothelial cells are replaced by adipocytes and there is deposition of fibrous tissue.

The natural history of infantile periocular hemangioma, with its rapid enlargement followed by spontaneous involution, is unique for vascular tumors. The vascular endothelium expresses placenta-associated antigens,[6] which are not expressed by other vascular tumors or normal skin, leading some to speculate that infantile hemangiomas develop either from angioblasts abnormally differentiating toward placental vascular phenotypes or as the result of placental cell embolization into fetal tissues.[6,7] Infantile hemangiomas could also be the result of somatic mutations in a gene mediating endothelial cell proliferation. Alternatively, an endothelial progenitor cell could be implicated.[8] Hypoxia has also been implicated, either systemically or in localized areas of poorly perfused tissue. This could stimulate endothelial progenitor cells to proliferate inappropriately.[9]

Clinical features

One-third of infantile periocular hemangiomas (Fig. 20.2) are present at birth; all have appeared by the age of 6 months. The appearance of the tumor may be preceded by a faint cutaneous flush. Usually, rapid growth lasting 3–6 months is followed by a period of stabilization and then regression (Fig. 20.3). Margileth and Museles[1] found that 30% of 336 hemangiomas had regressed by the age of 3 years, 60% by 4 years, and 76% by 7 years.

Infantile periocular hemangiomas are most commonly found in the upper lid or orbit (see Fig. 20.3). Their appearance varies according to the depth of involvement (see Fig. 20.3A); superficial cutaneous lesions have a red lobulated appearance, giving rise to the name "strawberry nevus" (see Fig. 20.8A). These superficial lesions consist initially of a confluence of telangiectasias that progress to raised, nodular lesions. They may enlarge and become bluish in color with crying. Subcutaneous hemangiomas are often bluish in color. Lesions situated deep to the orbital septum may present with proptosis without cutaneous discoloration. Occasionally, the proptosis is severe enough to cause corneal exposure. One-third of hemangiomas involve several levels of depth. A deeply situated lesion causing only proptosis with no cutaneous signs may present a diagnostic dilemma. A helpful diagnostic sign is the increase in proptosis with crying (see Fig. 20.2). In 30% of patients, "strawberry nevi" are found at other cutaneous sites.[2] Occasionally, enormous growth occurs, obliterating facial structures (see Fig. 20.1).

Amblyopia is common with orbital infantile hemangioma, with a prevalence between 43% and 60%.[2,10] This can result from occlusion of the visual axis by a bulky tumor, but more often,

Fig. 20.1 Massive facial and orbital infantile periocular hemangioma (capillary hemangioma).

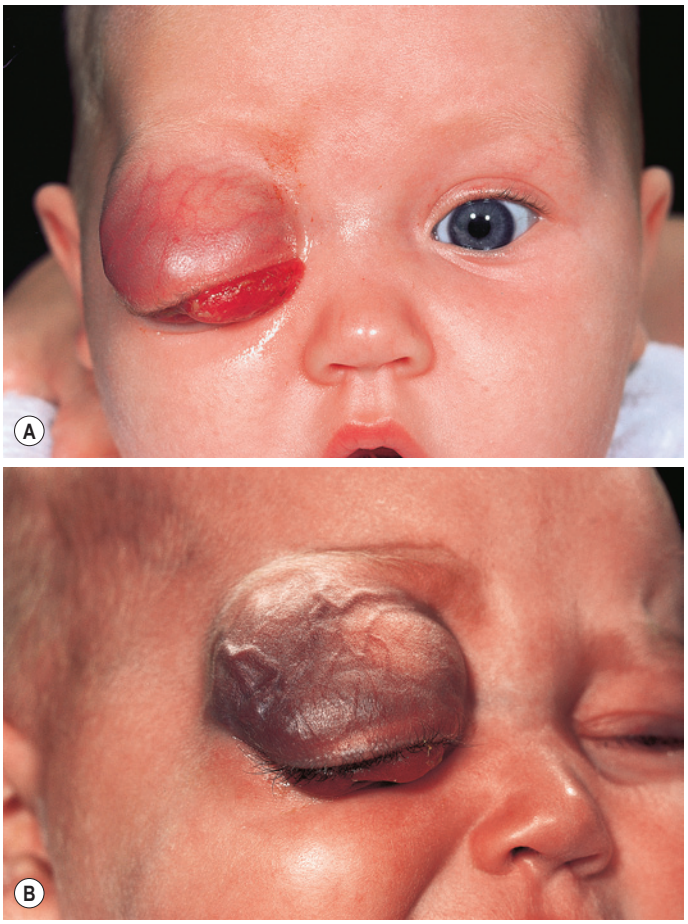

Fig. 20.2 (A) Infantile periocular hemangioma of the anterior orbit and lid. (B) Same patient when crying, showing engorgement and mild increase in size.

Fig. 20.3 (A) Orbital infantile periocular hemangioma. The mother of this child was accused of having injured her child. (B) Orbital infantile periocular hemangioma in a child aged 2 months. (C) Same patient as (B) aged 9 years after some spontaneous resolution and surgery. Surgery is usually not necessary and best avoided in most instances.

distortion of the globe by tumor causes corneal astigmatism; generally, the axis of the corrective plus cylinder is directed toward the tumor. This may persist after the hemangioma has regressed but usually resolves, at least partially, particularly if the hemangioma resolves or is treated early.[11,12] Prolonged occlusion can result in ipsilateral myopia[13] and the resultant anisometropia may be another amblyogenic factor. Secondary strabismus is common as a result of the interruption of fusion and binocularity.

Systemic complications of infantile periocular hemangiomas are rare; they include[3]:

1. Kasabach–Merritt syndrome: a potentially life-threatening coagulopathy resulting from consumption of fibrinogen and platelet entrapment within a large vascular hemangioma. It usually responds to platelet replacement and corticosteroids.
2. PHACE(S) syndrome (**p**osterior fossa abnormalities, **h**emangioma, **a**rterial lesions, **c**ardiac abnormalities, **e**ye and **s**ternal abnormalities): this condition has serious cardiovascular and neurologic complications and frequent ocular involvement, including amblyopia, strabismus, anterior polar cataract, ptosis, and optic neuropathy.[14] A careful ocular, cardiac, and neurologic examination is necessary for patients with extensive facial infantile periocular hemangiomas.

Investigation

In the majority of children presenting with proptosis, lid involvement or the presence of other cutaneous hemangiomas suggest the diagnosis.

Doppler ultrasound may help to secure the diagnosis.[15] The extent of the lesion can be assessed by computed tomography (CT) scanning. A soft tissue density mass is seen to infiltrate the orbit, with smooth or nodular margins, often crossing boundaries between compartments such as the muscle cone or orbital septum. Bony erosion may be seen. Enhancement is variable, according to the vascularity of the lesion and its stage of development. T2-weighted magnetic resonance imaging (MRI) is useful to delineate the tumor since the lesion is hyperintense due to its intrinsic blood flow (Fig. 20.4). T1-weighted gadolinium-enhanced views with fat suppression to improve contrast give the best assessment of the anatomic

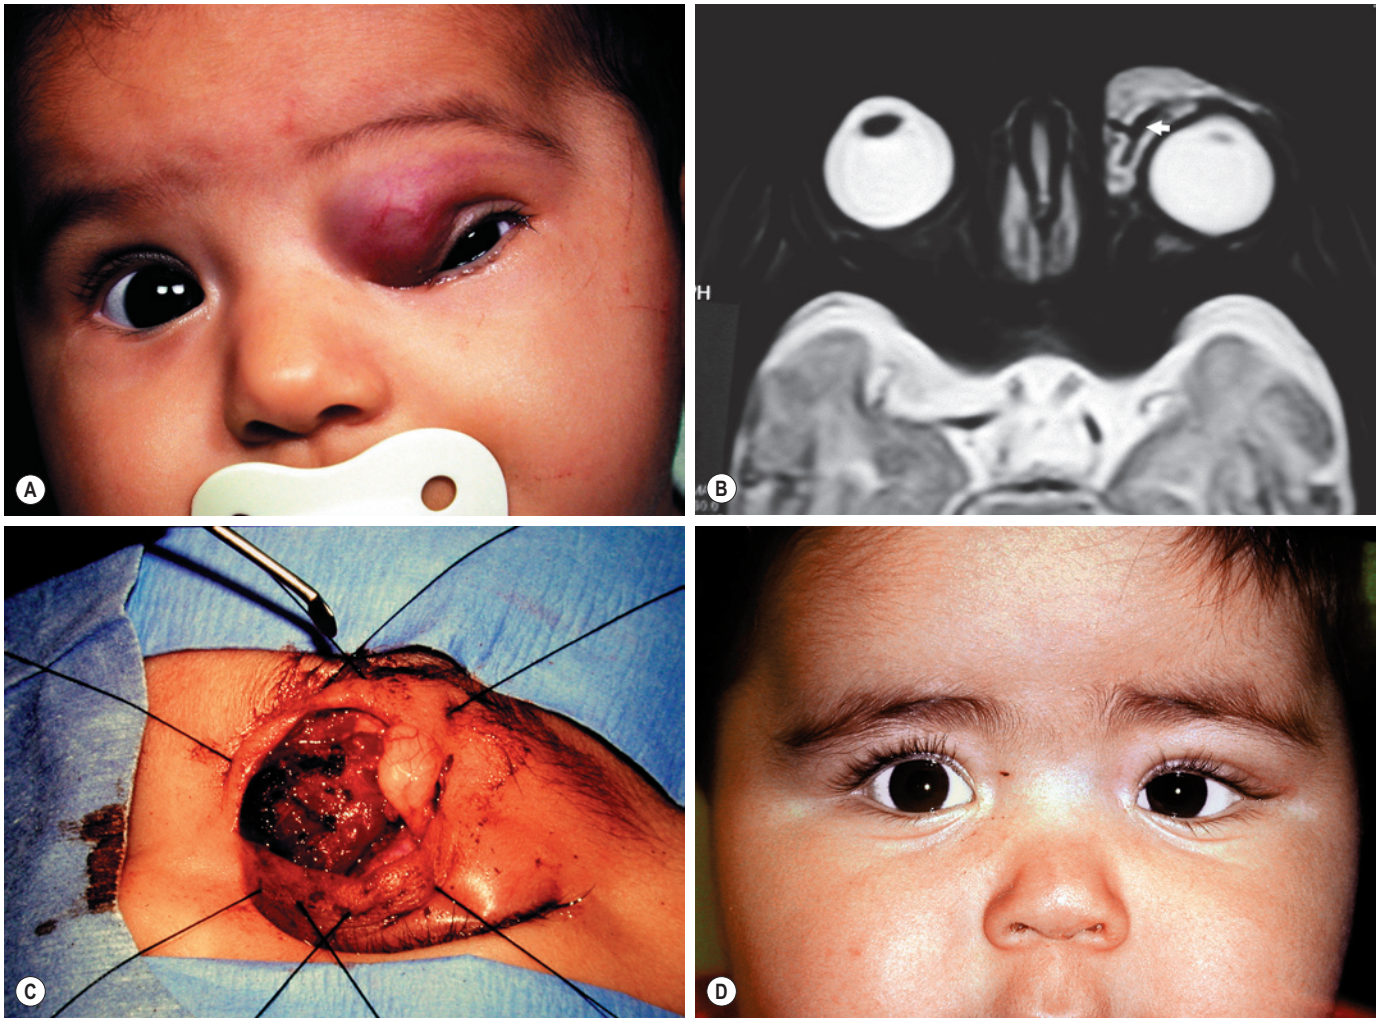

Fig. 20.4 (A) This child aged 2½ months presented with a large subcutaneous infantile periocular hemangioma that was unresponsive to steroids and inducing significant astigmatism. (B) T2-weighted MRI demonstrated a relatively well-defined anterior orbital mass with a large central flow void (arrow). (C) Operative photo of the same lesion during excision. (D) After surgery, she had minimal ptosis, and her astigmatism regressed. *(Patient of the University of British Columbia. (A) and (B) reproduced with permission from Rootman J. Diseases of the Orbit: A Multidisciplinary Approach, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002: 542.)*

relationships of the tumor. Obtaining a magnetic resonance angiogram and venogram (MRA and MRV) at the time of the MRI may rule out other vascular anomalies that can mimic hemangiomas. Lesions confined to the posterior orbit, especially during a period of growth, may occasionally be mistaken for a malignant tumor such as rhabdomyosarcoma; biopsy may be indicated.

Management

Management should be conservative, with treatment of significant refractive error and amblyopia while awaiting spontaneous regression (Fig. 20.5). The appearance of superficial pale stellate areas of scarring ("herald spots") on a "strawberry" lesion is a useful early indicator of spontaneous regression. Amblyopia therapy should be accompanied by correction of the astigmatic error of the affected eye with appropriate glasses (Fig. 20.6).

Active treatment to reduce the size of the tumor is only indicated if there is occlusion of the visual axis or if a posterior lesion results in progressive proptosis with optic nerve compression, corneal exposure, and significant or progressive amblyopia. Many methods of treatment are available. Topical or systemic beta-blockers are considered "first line."[16–19] Local or systemic steroids,[12,20,21] or surgical excision may be used for patients in whom beta-blockers are ineffective or contraindicated.[22] Cryotherapy is another potentially useful treatment modality.[23] Radiotherapy, laser,[24] and injection of sclerosing agents are rarely indicated.

A dramatic reduction was noted in the size of infantile hemangiomas (IH) in children treated with propranolol (Fig. 20.7).[25] At doses of 1–3 mg/kg/day, a response may be seen within a few days. Subsequent studies have shown a response rate of up to 90%; side effects such as hypotension, bronchospasm, bradycardia, heart block, and hypoglycemia can be avoided with careful monitoring.[16,17] This method of treatment is now the first choice for most ophthalmologists.[19] Topical timolol 0.5% solution or gel rubbed gently onto the surface of the IH twice daily is also effective, with fewer side effects than systemic treatment.

Steroids may still be a useful "second line" alternative to beta-blockers. Slow intralesional injection of a depot preparation such as triamcinolone (Kenalog)[26] results in tumor regression within 2–4 weeks. Further injections may be necessary (Fig. 20.8). Complications are rare but may include visual loss from central retinal artery embolization. Adrenal suppression,[3,20] local fat atrophy, skin hypopigmentation, eyelid necrosis, and periorbital calcification have also been reported.

Systemic steroids (1.5–5.0 mg/kg/day) may be preferable for very extensive or posteriorly situated lesions (Fig. 20.9). The response is over 90% for doses greater than 3 mg/kg/day but falls to less than 70% for doses of 2 mg/kg/day and less.[20] The side effects of growth retardation, gastrointestinal bleeding, behavior changes, and adrenal suppression make this therapy less attractive. A rebound increase in size has been noted after discontinuation of oral steroid.

Sight-threatening lesions that have failed to respond to beta-blockers or steroids may respond to treatment with interferon alpha-2a,[27,28] although the response to this treatment may be slow and the side effects uncertain in infants. Other immunomodulators, vincristine and cyclophosphamide, have been used to treat hemangiomas (primarily visceral). The

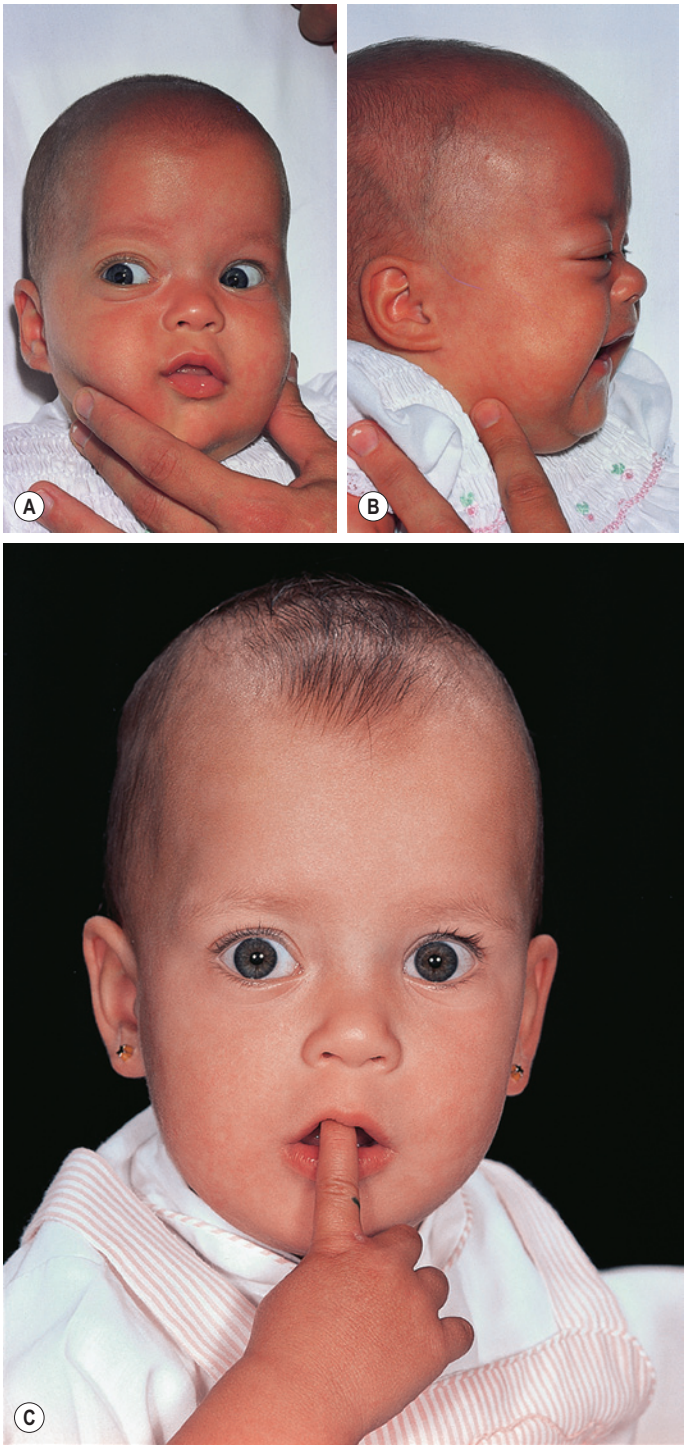

Fig. 20.5 (A,B) Right orbital infantile periocular hemangioma in a child aged 5 months. (C) Complete resolution without treatment.

carbon dioxide, argon, yttrium–aluminum–garnet (YAG), and dye lasers have been used to treat hemangiomas. Their use is limited by scarring, although the dye laser tuned to 577 or 585 nm with a 10-ms pulse duration may allow selective thermal damage of capillary tissue with minimal scarring and accelerated regression.[24,29] Radiotherapy and sclerosing agents should no longer be used.

Previously, surgical excision was deferred until the lesion stopped regressing, often after 6 or 7 years of age when any

residual cosmetic defect was corrected.[30] However, well-defined lesions causing significant amblyopia through obstruction or astigmatism can safely be removed surgically. The technique requires meticulous hemostasis, but the tumor is readily removed microsurgically after failure to respond to treatment with beta-blockers or steroids, or as a primary treatment[22,31] (Fig. 20.10).

Diffuse neonatal hemangiomatosis

This rare condition is characterized by the presence at birth or in the first month of life of multiple (sometimes 100 or more) hemangiomas involving the skin, bones and viscera.[32] These have similar growth and involutional characteristics to cutaneous infantile hemangiomas. Complications, related to visceral and notably liver involvement, include high-output cardiac failure, hemorrhage, involvement of brain or lung, as well as severe hypothyroidism.[33] These result in a mortality rate of approximately 60% for this condition.

Clinicians should recognize this rare disorder. Hepatic involvement, a significant risk factor, is more likely in infants with five or more cutaneous hemangiomas.[34] Treatment modalities include systemic corticosteroid, embolization, vincristine or interferon. More recently, propranolol has been shown to be effective.[35]

Fig. 20.6 Deep infantile periocular hemangioma in a 6-month-old boy. A faint bluish tinge is evident in the left lower lid. There is a +·4.0 diopter induced cylinder. Occlusion is vital in virtually every case. This child's inventive parents devised a novel method of preventing him from removing the patch. Eighteen months later the lesion had resolved, as had the cylinder. *(Patient of the University of British Columbia.)*

Hemangiopericytoma

This rare tumor, which ranges from benign to malignant, is derived from the pericyte. It is usually seen in adults but has been reported in childhood[36] and early infancy.[37] Its behavior is unpredictable; the usual presentation is with gradually

Fig. 20.7 (A) A large segmental infantile periocular hemangioma in a 4-month-old old girl causing inverse ptosis and astigmatism. The hemangioma had grown rapidly in the first month of life and was unresponsive to oral and intralesional steroid treatment. A systemic work up for PHACE syndrome was negative. (B) After 2 months of oral propranolol treatment, the size and thickness of the lesion decreased and the visual axis cleared. *(Courtesy of Tina Rutar.)*

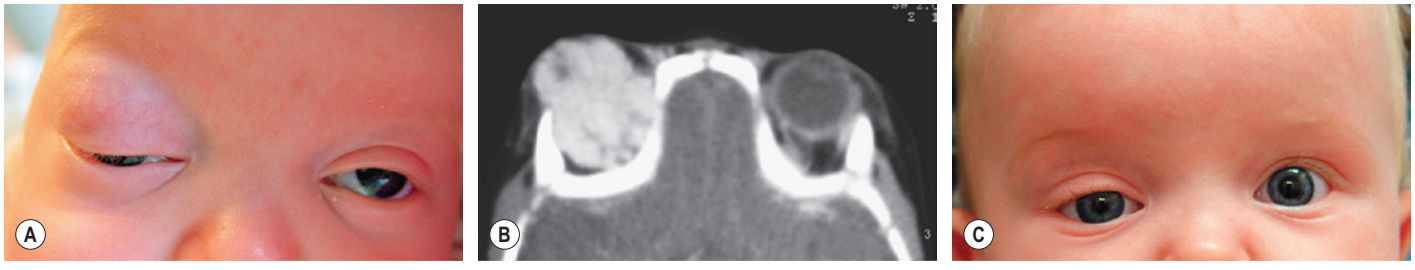

Fig. 20.8 This infant was born at 27 weeks' gestation. Right upper lid swelling was noted at age 6 weeks, and she was seen in our clinic at 16 weeks of age (A). (B) Computed tomography scan confirmed infantile periocular hemangioma showing a poorly defined, enhancing lesion in the superior orbit. An intralesional injection of 40 mg triamcinolone and 20 mg methylprednisolone was given at this time. Repeat injection was planned for 8 weeks later but was deferred due to her clinical improvement. Part-time occlusion of the left eye was used. (C) Three months later, she was equally visually attentive with each eye. No further treatment was necessary. *(Patient of the University of British Columbia.)*

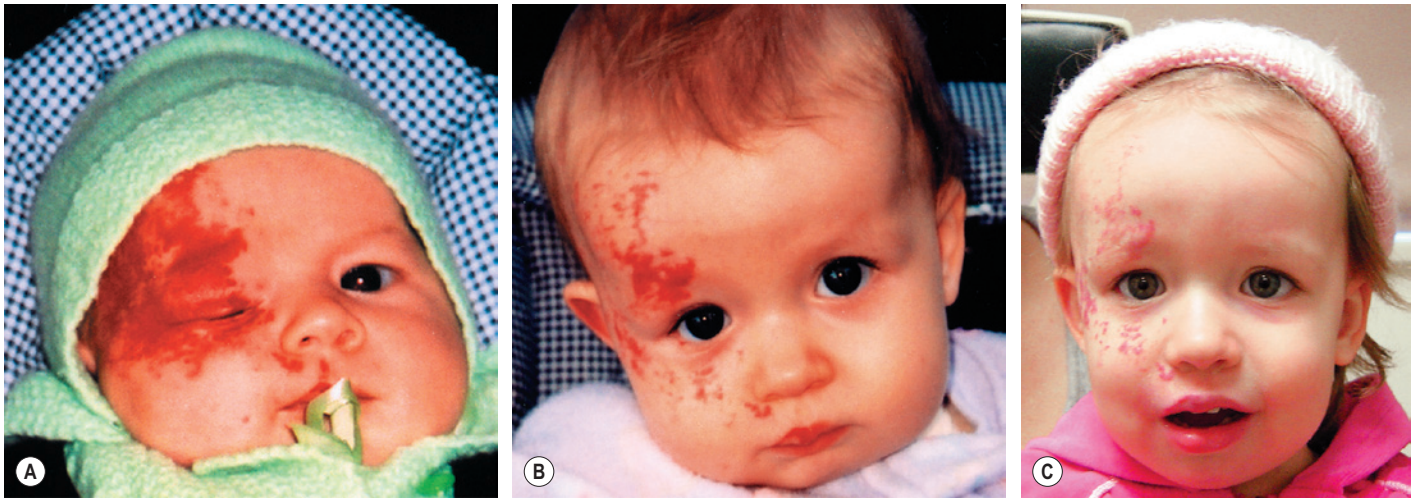

Fig. 20.9 (A) This 6-week-old infant was noted to have right upper lid swelling and discoloration from the second week of life, increasing on crying. There is complete closure of the right eye. Oral steroids were started at 6 weeks of age at 5 mg/kg/day, tapering to nothing over 6 months. (B) By 9 months of age, her cushingoid features have resolved; the infantile periocular hemangioma no longer obstructs the right visual axis. (C) At 11 months, the cutaneous changes have largely disappeared. There is no amblyopia. *(Patient of the University of British Columbia.)*

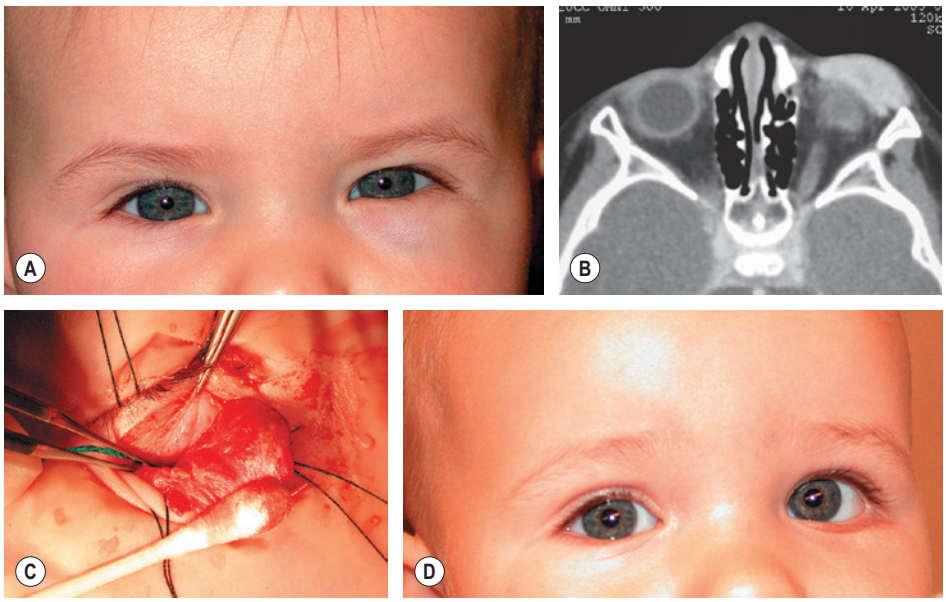

Fig. 20.10 (A) Clinical photograph of an 8-month-old child who presented with a progressive mass of the lower lid, causing astigmatism (+2.50 cylinder at 90°) and upward displacement of the left globe. (B) Contrast-enhanced CT scan demonstrates a relatively well-defined anterior orbital mass involving the left lid and inferior orbit. (C) Intraoperative photo of the same patient at the time of excision of the infantile periocular hemangioma. (D) One month after surgery, his astigmatism resolved. *(Patient of the University of British Columbia.)*

increasing proptosis and mass effect related to a tumor that is usually superiorly placed. On CT scan, it is well circumscribed, showing marked, homogeneous contrast enhancement. There is a pronounced early blush on angiography. It is usually a locally invasive tumor, which recurs locally unless completely excised within its pseudocapsule. This is technically challenging, as the tumor is very friable. Between 10% and 15% develop distant metastasis. Occasionally, these tumors behave very aggressively. In these cases, exenteration may be necessary.

Vascular malformations

Vascular malformations of the orbit are derived from venous (varices and venous-lymphatic malformations [lymphangiomas]) and arterial (arteriovenous malformations) vascular anlagen, and constitute an important cause of orbital tumors in childhood. They are best understood in the context of their hemodynamics and can be divided into three types.[38]

1. High-flow lesions such as aneurysm, arteriovenous fistula or malformation.
2. Low-flow lesions, which may be: venous malformations (distensible or non-distensible-cavernous) or lymphatic malformations (macrocystic, microcystic, or mixed).
3. Combined lymphaticovenous malformations, in which venous or lymphatic components may be predominant.

Venous-lymphatic malformations (lymphangiomas)

These vascular anomalies usually arise in childhood and are often difficult to manage. They may enlarge gradually, but their expansion can be sudden from hemorrhage into the lesion. Unlike infantile hemangiomas, they do not undergo

spontaneous regression. Deeply situated lesions are difficult to excise; their margins are poorly defined and they arborize widely throughout the orbit.

Venous-lymphatic malformations (lymphangiomas) account for a small proportion of orbital tumors.[39] In one-third of cases, the lesion is apparent at birth or within the first weeks of life,[40] and over three-quarters of patients present in the first decade. A female preponderance (ratio 2–3 : 1) has been reported.[40]

Their occurrence within the orbit is puzzling in view of the absence of lymphatic drainage from the retroseptal tissues. It has been suggested that venous-lymphatic malformations arise from primitive vascular elements within the orbit.[41] However, ultrastructural analysis and immunochemistry have identified lymphatic endothelium in orbital venous-lymphatic malformation.[42] They do not appear to grow by cellular proliferation; the full extent of the malformation is present at birth, insinuating itself within the normal orbital tissues. Since the vascular channels have characteristics of both lymphatic and venous vessels, the histologic differentiation of venous-lymphatic malformations from orbital varices has been a source of debate.[43–45] Hemodynamically, venous-lymphatic malformations and varices are part of a continuum of venous-derived lesions, differentiated according to the presence or lack of connection to the venous system. Whereas varices are connected, and therefore expand with Valsalva maneuver or supine posture, venous-lymphatic malformations are isolated and do not. Lesions may be mixed with both venous and lymphatic components represented within a single mass. The extremes of the spectrum can be differentiated histopathologically; the venous-lymphatic malformations element has distinctive electron microscopic features.[46] The pathogenesis of these lesions relates to the lack of blood flow and the tendency for sludging, neovascularization, hemorrhage with recurrent inflammatory episodes, and the formation of isolated "chocolate cysts."[47]

Histopathologically, they consist of diaphanous, serous fluid-filled channels lined by endothelium. These have characteristics of true lymphatic channels as well as areas of dysplastic channels. Lymphoid follicles are often present in the stromal components.

The clinical features of venous-lymphatic malformations vary with the extent and depth of orbital involvement.

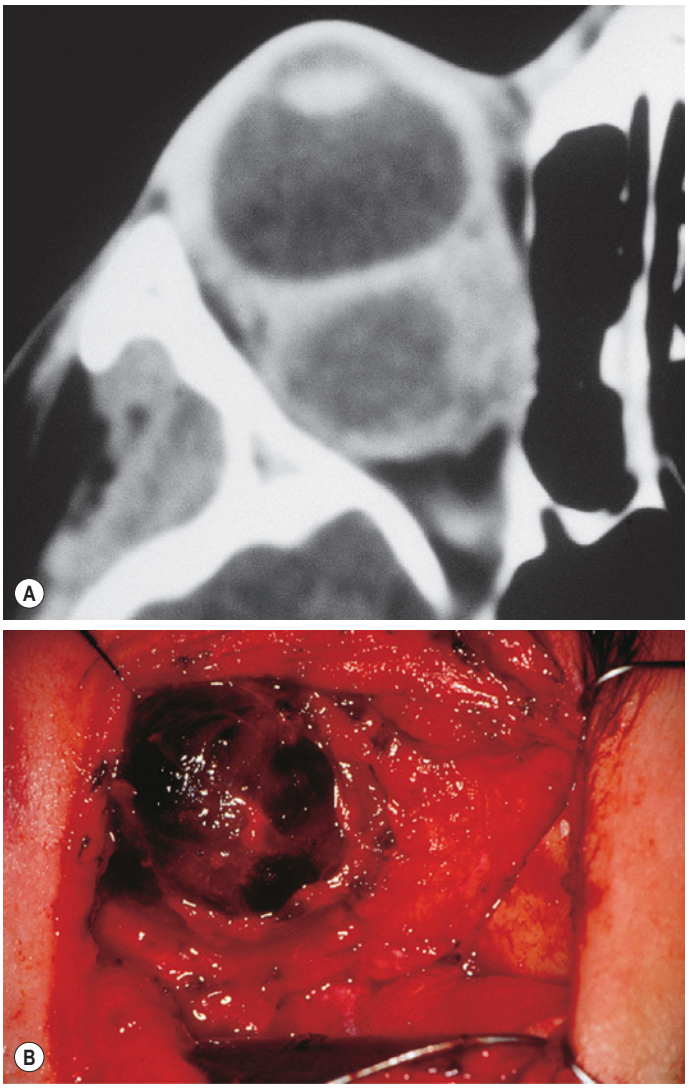

Fig. 20.11 Previously asymptomatic 8-year-old presenting with sudden-onset axial proptosis overnight, decreased vision, afferent pupillary defect, and optic disc swelling. (A) Computed tomography shows a cystic mass indenting the globe posteriorly. (B) At surgery, the chocolate cyst was identified and decompressed. *(Patient of the University of British Columbia.)*

Superficial

Isolated superficial involvement is comparatively rare and consists of multiple conjunctival cysts filled with clear or xanthochromic fluid, or a subcutaneous bluish cystic swelling of the eyelid. The latter may transilluminate and present with an abrupt localized change in color due to hemorrhage into a pre-existing lesion.[48] Superficial venous-lymphatic malformations are easily accessible and, if unsightly, may be excised with good results.

Deep

The hallmark of deeply situated orbital venous-lymphatic malformations is proptosis (Figs 20.11 and 20.12). Deep venous-lymphatic malformations may present with gradually increasing proptosis, with or without ptosis. In contrast to infantile hemangiomas, the proptosis is variable. An increase with upper respiratory tract infections and other generalized inflammatory states has been attributed to lymphoid activity within the lesion.

The most typical presentation, however, is with sudden proptosis resulting from hemorrhage into a hitherto-unsuspected lesion. The differential diagnoses include other causes of rapidly increasing proptosis such as rhabdomyosarcoma (see Chapter 24), neuroblastoma (see Chapter 26), etc. Examination of the nasal and palatal mucosa may be helpful if it reveals mixed clear fluid and blood-filled blebs of widespread venous-lymphatic malformation (Fig. 20.13). Optic nerve compression may occur with rapidly expanding blood-filled "chocolate cyst"[49] (see Fig. 20.11) with decreased visual acuity and disc swelling. It is an indication for urgent orbital intervention to decompress or excise the lesion.

Combined lesions (lymphohemangiomas)

These usually present in infancy, gradually enlarging over many years. Long-standing lesions may be associated with

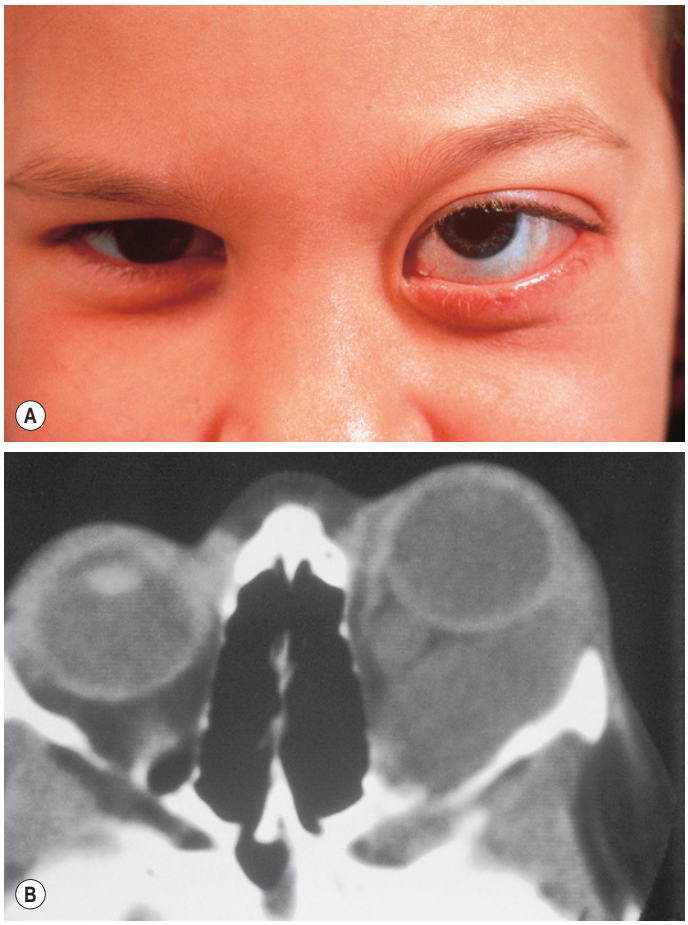

Fig. 20.12 Orbital venous-lymphatic malformation (lymphangioma). (A) Sudden onset of proptosis in the left eye of a previously asymptomatic 5-year-old child. (B) Computed tomography scan shows diffuse soft tissue density lesion arborizing through the retrobulbar tissues. *(Patient of the University of British Columbia.)*

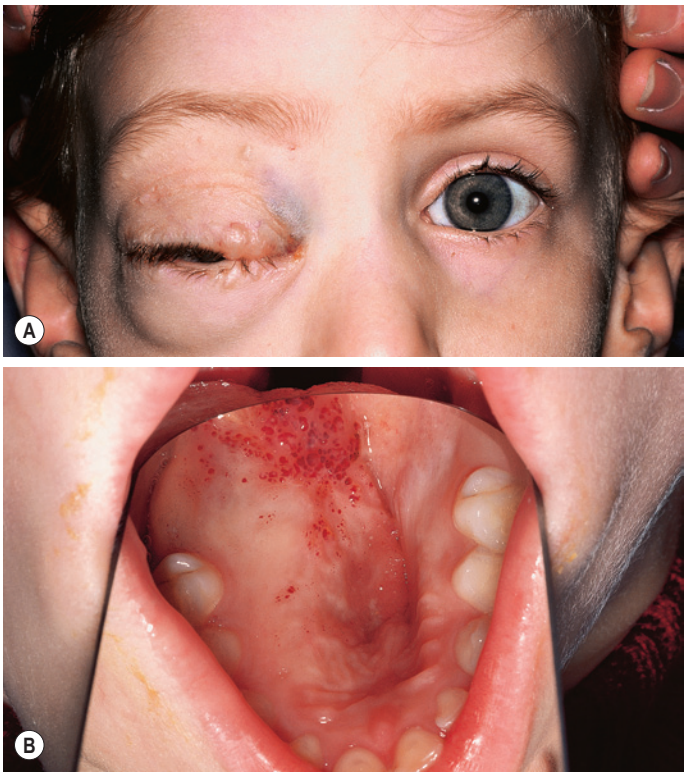

Fig. 20.13 (A) This 4-year-old boy was born after a 32-week gestation. Right proptosis developed by 4 weeks and was progressive despite orbital surgery, until the age of 3 years. It has been static since then. The diagnosis was a venous-lymphatic malformation. (B) Same patient showing clear and blood-filled cystic lesions on the palate.

orbital enlargement. The presence of telltale conjunctival and lid changes is helpful in making the diagnosis of venous-lymphatic malformation (see Fig. 20.13). Hemorrhage into superficial lesions may result in the striking appearance of blood menisci within the conjunctival cysts (Fig. 20.14). These may be accompanied by recurrent subconjunctival hemorrhage and lid ecchymosis. Deep hemorrhage results in proptosis, commonly associated with compressive optic neuropathy. Combined lesions may be large enough to simultaneously involve every orbital space, producing gross proptosis and facial deformity, some from extension through the superior orbital fissure. Non-contiguous intracranial vascular abnormalities may occur.[50] Since the latter are at risk of bleeding, brain imaging is indicated in patients with orbital venous-lymphatic malformation.

Investigation

CT scanning shows a soft tissue density mass with poorly defined margins and non-homogeneous enhancement after injection of contrast medium. Bony destruction is absent but large lesions can result in smooth enlargement of the orbit. The presence of a cystic component helps differentiate venous-lymphatic malformations from infantile hemangiomas. Since hemoglobin has paramagnetic qualities that change as blood denatures, blood-containing "chocolate cysts" are well visualized by MRI scanning[51] (Fig. 20.15). The age of intralesional hemorrhages can be assessed since oxyhemoglobin in fresh hemorrhage is hypointense on T1- and T2-weighted images, gradually becoming hyperintense as it is converted to methemoglobin. Later, degradation to ferritin and hemosiderin once again produces a hypointense image. Intravenous contrast in the case of CT scan or gadolinium in MRI is helpful in imaging the most active component of the lesion, which should be removed if surgery is contemplated. A review of brain images is indicated for non-contiguous intracranial vascular anomalies.[50]

Management

Complete surgical excision is difficult in all but the most superficial lesions and can precipitate further hemorrhage. Since hemorrhagic cysts tend to shrink with time, a conservative approach is usually preferable. Bed rest, alone or with cold compresses, can result in a good outcome, even in cases with marked acute proptosis.[52]

Impressive early results have been reported from interventional radiology for patients with macrocysts. Image-guided intralesional injection of bleomycin resulted in significant reduction in lesion volume with few complications.[53,54]

Surgery or neuroradiological intervention is indicated if there is optic nerve dysfunction, corneal exposure, pain and nausea from raised orbital pressure, or the risk of amblyopia from astigmatism or strabismus. It is possible to temporize by aspirating the cyst contents through a needle under ultrasound

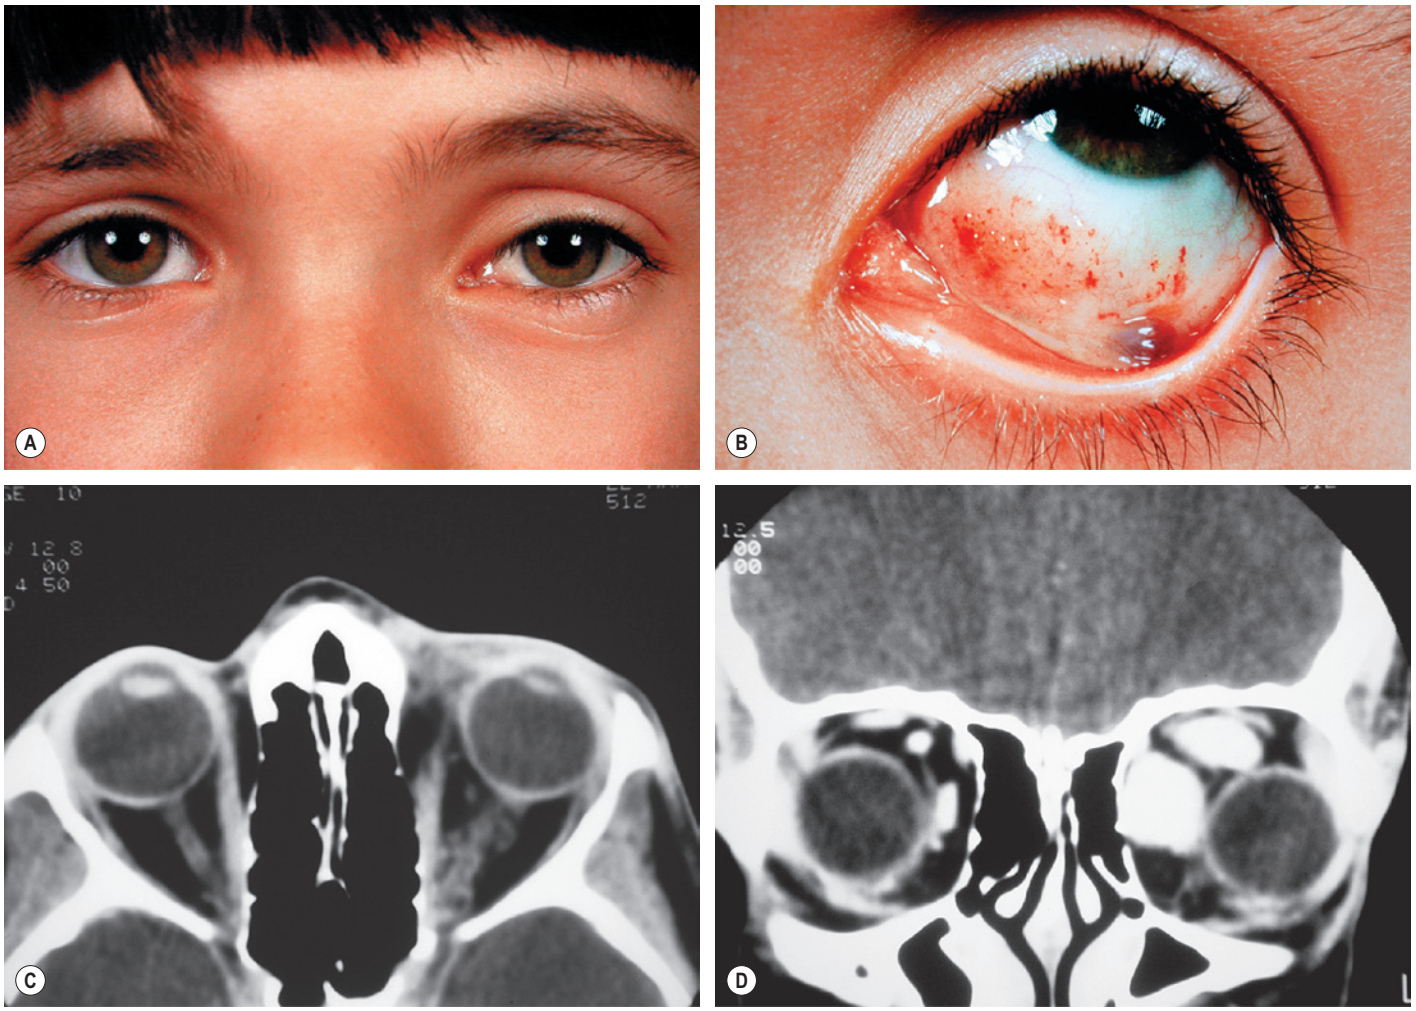

Fig. 20.14 (A) This 12-year-old child presented with an epibulbar lesion on the left side associated with fullness of the upper and lower lids and slight ptosis. (B) The epibulbar surface demonstrates a gelatinous-appearing lesion medially containing many clear fluid-filled cysts along with focal blood cysts, many of which appear to have menisci. In addition, in the inferolateral fornix, there appears to be a dark varix. The conjunctival lesion was proven on biopsy to be consistent with a venous-lymphatic malformation histologically and by electron microscopy. It was noted also that the superior sulcus appeared somewhat deepened on the left. (C) Post-contrast computed tomography scan in the axial view shows an irregular lesion occupying the anteromedial orbit around and behind the caruncle. On direct coronal view (D), there is evidence of a posterior orbital varix that appeared with increased venous pressure. This lesion represents a combined venous-lymphatic malformation and varix. *(Patient of the University of British Columbia.)*

guidance. Poor results and frequent morbidity have been reported from attempts at subtotal excision. The authors feel that surgery, when indicated, should excise as much of the venous-lymphatic malformation as is safe, particularly removing the active tissue as well as draining blood cysts with release of their contents. Unlike dermoid or sebaceous cysts, excision of the whole cyst wall is not necessary to avoid recurrence. The carbon dioxide laser may be useful in reducing hemorrhagic complications associated with subtotal excision surgery.[55] Systemic steroids[56] or intralesional OK-432 (group A *Streptococcus pyogenes* of human origin)[57] may reduce the size of these tumors. Recently sildenafil (Viagra) has been shown to be effective in two children with extensive orbital venous-lymphatic malformations.[58]

Congenital orbital varices

Varices are of high- and low-flow types. Low-flow varices are clinically similar to venous-lymphatic malformations, with a tendency for sudden, often recurrent, hemorrhage,[59] whilst high-flow varices expand with increased jugular venous pressure and rarely bleed.[47]

Distensible orbital varices expand only slowly during childhood and rarely give rise to visual problems. There is often a subconjunctival component (see Fig. 20.14). They often present in adolescence with discomfort on bending over and slow development of enophthalmos and deepening superior sulcus due to fat atrophy and enlargement of the orbit, which may be seen on plain X-rays, along with phleboliths. The main indications for surgical excision are removal of the superficial component for cosmetic reasons or removal of deeper lesions for grave, persistent pain. A combined neuroradiologic method with gluing followed by excision may be worthwhile in cases that demonstrate isolation from the venous system and do not share out-flow with critical orbital structures.[60] Detachable coil embolization may be considered before proceeding with surgery.[61] Some orbital varices may be associated with intracranial varicosities (Fig. 20.16).

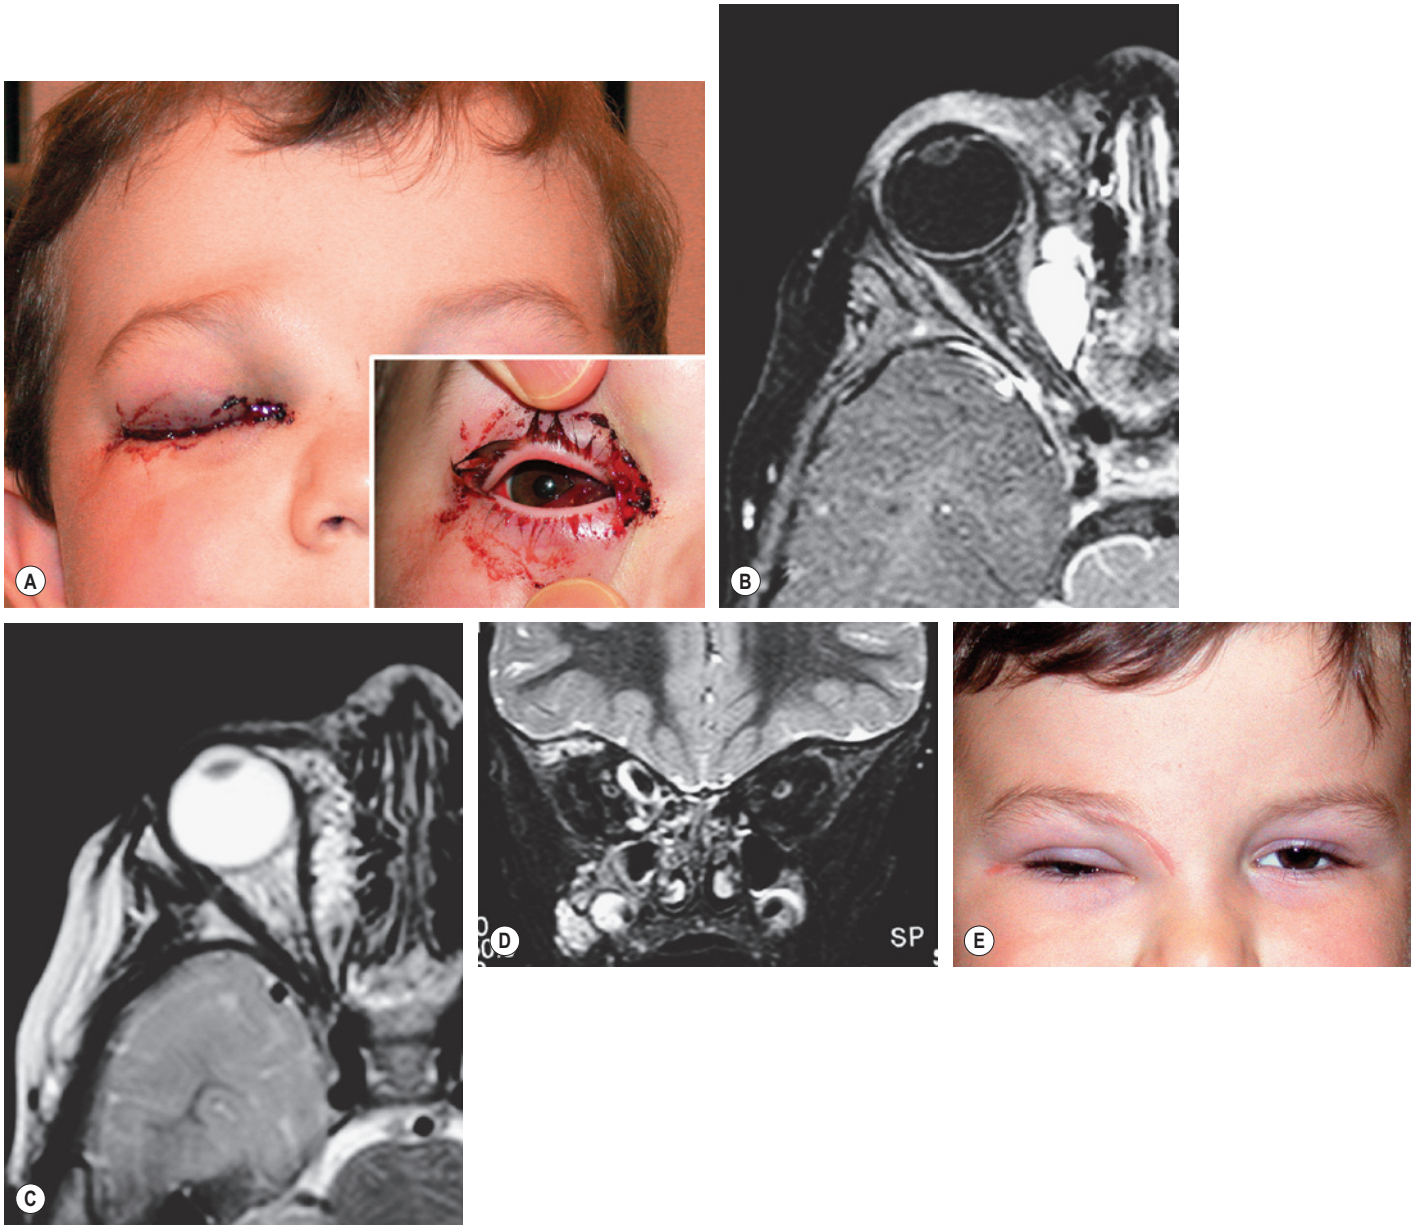

Fig. 20.15 (A) This 2½-year-old boy was born with a swollen right eye. At age 1, he developed spontaneous bruising and a gelatinous lesion on the surface of the right globe, treated at the time with steroids with improvement. He continued, however, to have constant bleeding from the epibulbar surface, progressive lid closure, and swelling. (B–D) MRI scans demonstrate an extraconal medial lesion that involves the lid and forehead and extends to the apex of the right orbit. Posteriorly, note the cystic components consistent with venous-lymphatic malformation. The patient underwent excision of his venous-lymphatic malformation. (E) He did well postoperatively (seen here at 1 month following surgery) with a residual ptosis and persistent lid involvement, which will require future surgery. *(Patient of the University of British Columbia. (B–D) with permission from Rootman J. Vascular malformations of the orbit: hemodynamic concepts. Orbit 2003; 22: 103–20.)*

Arteriovenous malformations

Arteriovenous malformations are characterized by the development of pulsating exophthalmos with episodes of hemorrhage, thrombosis, or extended, tortuous and engorged vessels secondary to arterialization of out-flow venous channels. They may have an audible bruit and can cause pain when engorged by Valsalva maneuver. Typically, they present in late adolescence or early adult life.

On imaging, arteriovenous malformations are characterized by irregular, rapidly enhancing masses. Doppler studies and CT or MR angiography demonstrate high-flow characteristics. With selective angiography, the lesions consist of engorged proximal arterial supply, a tangled malformation, and a distal venous out-flow (Fig. 20.17).

Arteriovenous malformations can largely be observed. The indications for intervention include recurrent hemorrhage or persistent pain. The malformations can be removed using selective gluing or embolization of in-flow vessels followed by excision.[62]

Sturge–Weber syndrome (SWS) (see Chapters 38 and 68)

This neurocutaneous disorder is a sporadic congenital condition affecting 1 in 20,000–50,000 live births.[63] A child

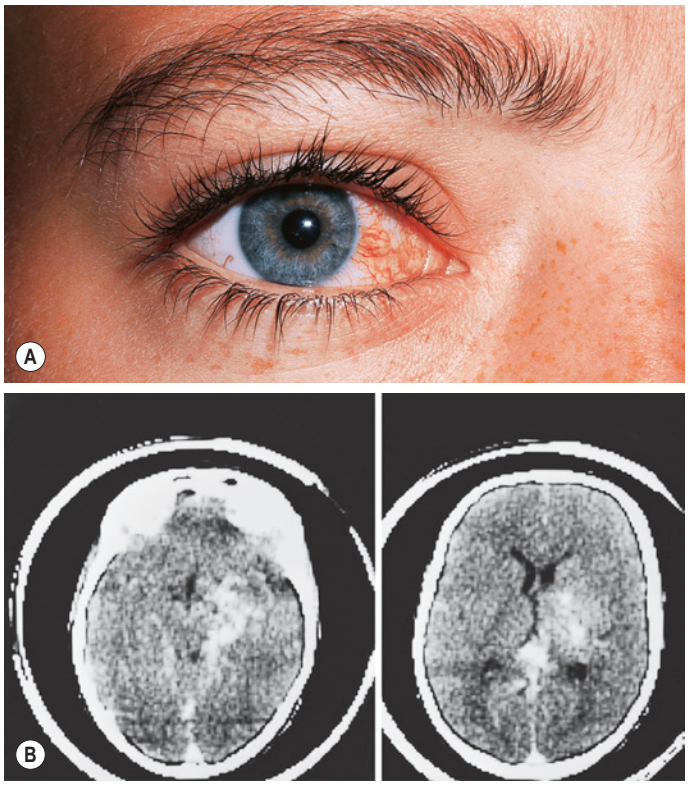

Fig. 20.16 (A) Subconjunctival varicosities in a patient with an orbital and intracranial hemangioma. (B) Contrast-enhanced computed tomography scans showing the intracranial lesion (same patient).

with a facial port wine stain has approximately 6% chance of having SWS[64]; if the cutaneous lesion is in the V1 distribution, this probability increases to 26%.[65] The disorder is thought to be due to a somatic mutation of GNAQ.[66]

The port wine stain in Sturge–Weber syndrome can be confused with early-stage infantile hemangioma. Infantile hemangiomas grow in thickness and breadth within the first few weeks of life; in contrast, the vascular lesion of Sturge–Weber syndrome remains unchanged. In addition to the triad of glaucoma, port wine stain, and cerebral vascular malformation, SWS can be associated with choroidal hemangioma leading to serous retinal detachment. Orbital involvement is rare,[67] with ipsilateral nevus flammeus and orbital vascular malformation causing proptosis without intracranial involvement.

Early results of the use of pulsed dye lasers for nevus flammeus have been encouraging. Treatment with pulsed dye laser in the first few years of life can prevent thickening of the skin lesion and results in lightening of the color. The associated local hypertrophy may also be reduced. Regular intraocular pressure monitoring is indicated.

Rare vascular lesions of the orbit

Klippel–Trénaunay–Weber syndrome (see Chapter 68)

This syndrome comprises multiple cutaneous nevi associated with various angiomas of one or more limbs, which may show hypertrophy of the soft tissues. Orbital varix is a rare finding.[68]

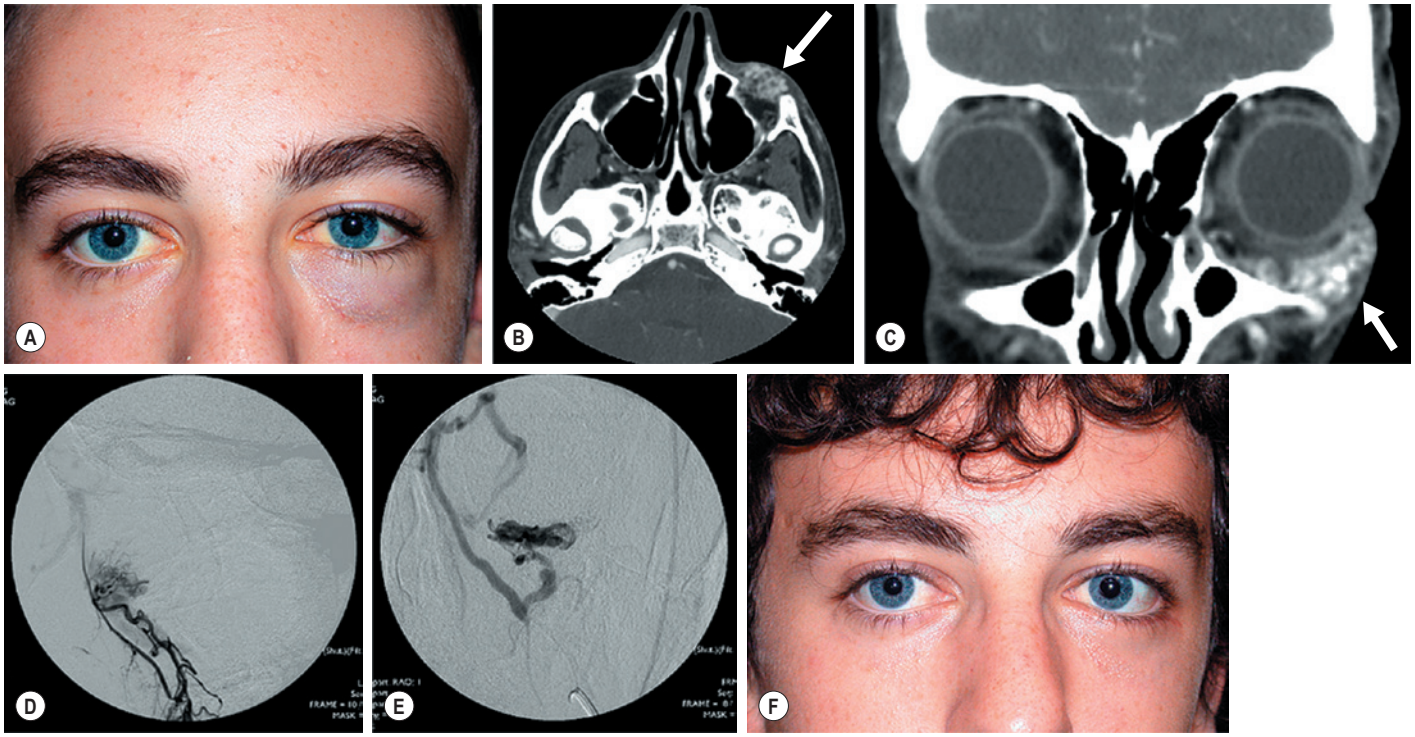

Fig. 20.17 (A) This 15-year-old boy presented first at age 12 with a fullness of the left lower lid and transient visual obscuration episodes on exertion, due to an arteriovenous malformation. He was observed for 2½ years, during which time the lesion progressed, and it was decided to intervene. He underwent combined embolization and excision of his mass. (B,C) Computed tomography angiograms demonstrate the tangle of the arteriovenous malformation in the left inferior orbit and lid (arrow). (D) Selective external carotid angiogram shows the external maxillary supply, while the anterior–posterior venous phase angiogram (E) reveals the venous out-flow to the facial and superior ophthalmic veins with facial compression. (F) Photograph of the patient 4 months after his surgery shows his postoperative result. *(Patient of the University of British Columbia.)*

Blue rubber bleb nevus syndrome

This rare syndrome usually presents in childhood. It consists of multiple bluish cutaneous vascular anomalies associated with angiomas of the gastrointestinal tract, lung, heart, and central nervous system.[69] Gastrointestinal hemorrhage is a rare complication of this disorder. The cutaneous lesions are soft, rubbery, and compressible. Most cases are sporadic, but autosomal dominant inheritance has been reported. Conjunctival, iris, and retinal angiomas may occur, as well as orbital venous malformation.[70]

Chapter contents

INTRODUCTION
LACRIMAL GLAND
THE LACRIMAL DRAINAGE SYSTEM
REFERENCES

See online for supporting video for this chapter.

Introduction

The lacrimal system consists of a secretory portion and a drainage system. The secretory portion is the lacrimal and accessory lacrimal glands. With the meibomian glands and the goblet cells, they secrete the components of the tear film. The tear film has three layers: the inner mucin layer secreted by the conjunctival goblet cells, the intermediate aqueous layer secreted by the lacrimal and accessory lacrimal glands, and the outer, oily layer secreted by the meibomian glands. The accessory lacrimal glands produce basal tear secretion; the lacrimal gland is responsible for reflex tearing in response to noxious or emotional stimuli.

The drainage system consists of the lacrimal puncta, canaliculi, lacrimal sac, and the nasolacrimal duct. This active system pumps tears from the conjunctival sac into the inferior meatus of the nose.

Tears flow along the lid margins and conjunctival fornices. They are spread across the surface of the eye by blinking. Tears protect the eye by surface lubrication, provision of oxygen and antibacterial substances such as immunoglobulin (Ig)A, IgG, and lysozyme, and mechanical removal of irritating substances and cellular debris.

Lacrimal problems in children usually relate to underproduction of tears, causing dry eyes, which is rare but potentially sight threatening, or reduced drainage of tears, which is much more common but less serious (Box 21.1).

Lacrimal gland

Embryology

The lacrimal gland develops from ectoderm that is supported by mesodermal connective tissue. It continues to grow 3–4 years after birth. Basal tearing is present in infants from birth, and reflex tearing begins at any time from birth to several months of age.[1]

Anatomy

The lacrimal gland is an exocrine gland in the anterior aspect of the superotemporal orbit within the bony lacrimal fossa. The majority of the gland lies within this fossa, but the lateral horn of the levator palpebrae superioris separates this orbital part from the palpebral lobe, which extends anteriorly into the superotemporal conjunctival cul-de-sac. The ducts of the gland pass through the palpebral lobe and open on to the conjunctiva in the superior fornix. The lacrimal gland is innervated via the facial (afferent) and trigeminal (efferent) nerves. The accessory glands of Kraus and Wolfring sit in the superior conjunctival fornix.

Congenital abnormalities

Congenital absence of the lacrimal gland is rare, usually occurring in conditions with reduced conjunctiva: anophthalmos, cryptophthalmos, and the lacrimo-auriculo-dento-digital (LADD) syndrome. Anomalous lacrimal ductules that secrete tears on to the skin rather than the conjunctival sac may be found near the lacrimal gland, around the lateral canthus, or in the preauricular region. These are rare but may require dissection and excision.[2]

The embryology of the lacrimal gland is closely linked to that of the conjunctival epithelium.

Other congenital anomalies include orbital ectopic lacrimal gland tissue. A drainage system may not be present in such cases and an enlarging orbital mass may develop. Neoplasms can occur within such ectopic tissue.

Crocodile tears (see Chapter 95) occur from congenital aberrant innervation between the fifth and seventh cranial nerves causing tearing with chewing or sucking.[3]

Dry eyes in children

Congenital causes

Congenital alacrima is rare. It may be due to absence of the lacrimal gland or to it being ectopic in the orbit. Alacrima may be associated with systemic conditions such as the Riley–Day syndrome (familial dysautonomia), anhydrotic ectodermal dysplasia, and Allgrove syndrome (familial alacrima, achalasia of the cardia, and adrenal deficiency).

Box 21.1

Causes of watery eyes in children

Excess tear production (lacrimation)

Allergic rhinitis
Upper respiratory tract infection
Epiblepharon
Subtarsal foreign body
Iritis
Corneal abrasion/ulceration
Conjunctivitis
Glaucoma

Drainage failure (epiphora)

Congenital nasolacrimal duct obstruction
Skeletal and sinus abnormalities
Lid malposition
Punctal malposition
Punctal occlusion
Anomalous drainage system

Acquired causes

Acquired tear deficiency may be due to pathology of the lacrimal gland, causing failure of tear production, or to conjunctival damage (see Chapter 31), leading to ductule obliteration. The lacrimal gland may be damaged by Epstein–Barr infection, as the result of human immunodeficiency virus (HIV) infection, or in patients with bone marrow transplantation (often associated with graft-versus-host disease). The conjunctiva may be affected by injury (burns), infection, the sequelae of trachoma, Stevens–Johnson syndrome, or toxic epidermal necrolysis.

Sjögren syndrome is rare in children. It can be a primary autoimmune event or associated with rheumatoid arthritis or systemic lupus erythematosus. Children with Sjögren syndrome often have lacrimal gland enlargement. They may have recurrent parotid gland swelling and salivary gland involvement. Sjögren syndrome should be considered in any child with recurrent parotiditis, keratoconjunctivitis sicca, and early tooth decay due to xerostomia.[4]

Chronic blepharitis is uncommon. It usually presents with recurrent chalazia, although the lids may appear normal. The tear film is deficient causing surface dryness. The associated peripheral corneal vascularization and scarring can be sight threatening.

Isotretinoin treatment for acne is a cause of dry eyes in adolescence. This is usually reversible at cessation of the drug.

Children with dry eyes present with irritable, uncomfortable, gritty, red eyes. A reduced tear meniscus is evident with punctate keratopathy, particularly affecting the interpalpebral zone. Staining occurs with fluorescein and Rose Bengal dyes. Severe keratopathy due to concomitant corneal hypoesthesia can be a problem in the Riley–Day syndrome.

Treatment of dry eyes involves copious use of artificial tears and temporary or permanent punctal occlusion in severe cases. Immunomodulation may have a role to play in secondary lacrimal gland failure, including that due to infections. Blepharitis should be treated with lid hygiene, lubricants, and systemic antibiotics such as erythromycin or azithromycin. Oral tetracyclines should be avoided in children prior to their second dentition.

Dacryoadenitis

Dacryoadenitis is usually associated with viral infection, mumps, infectious mononucleosis, herpes zoster, tuberculosis, brucellosis, histoplasmosis, or gonococcal infection. Lacrimal gland swelling may rarely be a sign of childhood Sjögren disease.

A primary clinical feature of dacryoadenitis is the "S sign" in which there is drooping of the lateral aspect of the upper lid. In acute inflammatory cases, the overlying skin is inflamed. Neuroimaging confirms enlargement and helps rule out other orbital masses. In the long term, dacryoadenitis may damage the lacrimal gland and cause reduced tear secretion.

Dacryoadenitis must be differentiated from a lacrimal gland infarct, which occurs in children with a sickle cell crisis. The onset is rapid, like acute dacryoadenitis.

Treatment of acute dacryocystitis is aimed at the underlying cause.

Lacrimal tumors (see Chapter 26)

Lacrimal tumors are very rare in children. Pseudotumor causing painful swelling may affect the lacrimal gland.[5] Malignant epithelial tumors, including mixed cell adenocystic and other carcinomas, have been recorded in childhood.[6]

Lacrimal gland enlargement is also found in conditions such as sarcoidosis or leukemia. Prolapse of the lacrimal gland, which is commonly bilateral, may present as a subconjunctival mass in the upper outer fornix. This may occur with craniofacial anomalies (see Chapter 28) due to reduced orbital volume and increased orbital pressure.

The lacrimal drainage system

Embryology

The lacrimal outflow system develops between the maxilla and the lateral nasal process from surface ectoderm. By the end of the first trimester, this tissue begins to canalize. The puncta usually open with the eyelids during the sixth month of gestation. The nasolacrimal duct opens into the inferior meatus of the nose just before or after term birth. There may be a failure of this canalization process at any part of the system, but this is most frequent at the lower end.[7]

Anatomy

Understanding the lacrimal outflow system is important for the pediatric ophthalmologist, especially for performing probing.

The puncta should be in contact with the globe at the medial aspect of the upper and lower lids. The proximal part of the canaliculus, the ampulla, is a slightly dilated vertical portion 1 mm in length in the young child. The canaliculus then turns 90° to run medially in a horizontal direction. The upper and lower canaliculi join to form the common canaliculus that enters the lateral wall of the lacrimal sac. Rosenmüller's valve prevents reflux of tears from the sac into the canaliculus. The lacrimal sac sits in the bony lacrimal fossa, separated from the

middle meatus of the nose by the maxilla and lacrimal bone. The lacrimal sac extends superiorly under the medial canthal ligament to form its fundus. The nasolacrimal duct exits from the lower end of the sac and passes in a downward, lateral, and slightly posterior direction. This duct is surrounded by bone in its upper part but becomes membranous inferiorly. The nasolacrimal duct opens into the medial wall of the inferior meatus of the nose via the valve of Hasner. This ostium is found under the inferior turbinate of the nose, approximately 1 cm directly behind the entrance of the nose in the baby.

Physiology

Tears are actively pumped through the outflow system. During blinking, when the lids close, the canaliculi are shortened and narrowed by contraction of the pretarsal orbicularis muscles. Simultaneously, the same muscles pull the lateral sac wall, creating negative pressure inside the sac, sucking fluid into the expanded sac. Further lid closure causes contraction of the orbicularis oculi muscle, which squeezes the tears from the sac into the nasolacrimal duct. At the end of each blink, the sac is empty. As the lids open, the canaliculi and the sac elastically expand. This causes a vacuum within the system into which tears enter via the puncta, and the cycle begins again.

Congenital abnormalities

Common abnormalities, include narrowing (stenosis), blockage (atresia), complete absence (agenesis), or duplication (accessory channels) of any part of the system. A membranous obstruction at the distal end of the nasolacrimal duct is the commonest abnormality, causing congenital nasolacrimal duct obstruction.[7] Obstruction at other sites is rare, but more relevant in older children.

Children with craniofacial abnormalities (see Chapter 28), particularly clefting syndromes, have complex anomalies of the lacrimal outflow system that may involve large areas being either blocked or absent.

Congenital dacryocystocele (dacryocele)

A dacryocystocele (syn. dacryocele) is a congenital swelling located at the medial canthus due to trapped fluid inside the lacrimal sac and nasolacrimal duct.[8] The fluid is unable to escape from either the upper or lower end of the drainage system as both are blocked. This presents as a tense, blue, non-pulsatile swelling below the medial canthus. It is evident at, or shortly after, birth (Fig. 21.1A). The inferior end of the dacryocystocele projects into the nose (Fig. 21.1B) and in some cases may be responsible for breathing difficulties.[9] If respiratory compromise occurs, urgent treatment is required.

Congenital dacryocystocele must be differentiated from a meningoencephalocele, a meningocele, a midline nasal dermoid cyst (see Chapter 29), or an infantile hemangioma (see Chapter 20). Routine imaging is unnecessary; the diagnosis is usually made clinically but in ambiguous cases a magnetic resonance imaging (MRI) scan is helpful in identifying the dilated sac and nasolacrimal duct and excluding other pathology.

Treatment of a dacryocystocele involves observation during the first 2 weeks of life, during which time most spontaneously improve. Massage over the lacrimal sac may be undertaken to encourage rupture of the distal cyst into the nasal cavity.[10] If

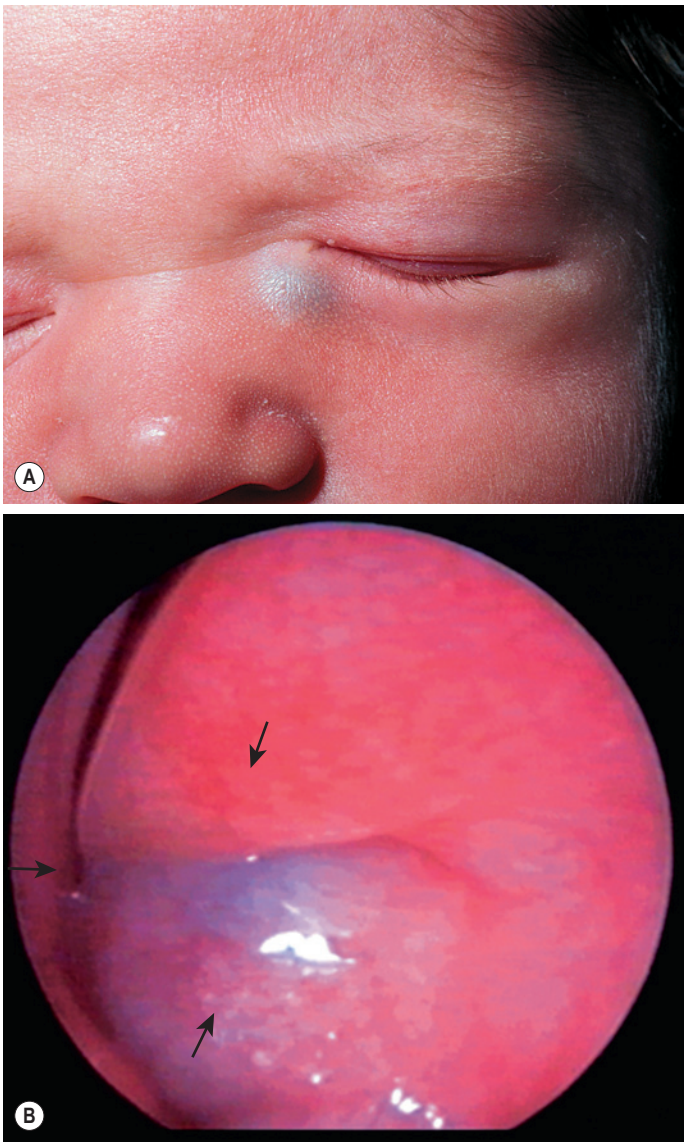

Fig. 21.1 Congenital dacryocystocele. (A) A bluish swelling is seen below the medial canthal tendon. It can present as nasal obstruction. (B) Dacryocystocele viewed from inside the nose, demonstrating the dilated nasolacrimal duct protruding into the nasal cavity, which may cause respiratory distress (left nostril).

it does not settle within the first 2 weeks of life, or if acute dacryocystitis (Fig. 21.2) or respiratory difficulties develop, then endoscopic drainage of the dacryocystocele into the nose is indicated and the nasal mucosa over the dacryocystocele excised. If acute dacryocystitis develops, intravenous antibiotics should be given prior to surgery.

Congenital nasolacrimal duct obstruction

Congenital nasolacrimal duct obstruction results from delayed maturation of the lacrimal system where it enters the nose, resulting in a persistent membranous obstruction at the valve of Hasner. The diagnosis is made on a history of a watery eye that has been present from the first few weeks of birth. This is usually unilateral but may be bilateral. If so, it is commonly asymmetrical. Some children develop a

mucopurulent discharge that may be constant or intermittent. The eye remains "white" without evidence of active infection, although conjunctivitis may complicate the condition. The child is well with no evidence of irritation or photophobia. The skin around the eye may become red and excoriated. Although usually an isolated abnormality, congenital nasolacrimal duct obstruction may be more frequent in certain conditions, such as EEC syndrome (ectrodactyly, ectodermal dysplasia, clefting; Fig. 21.3) branchio-oculo-facial syndrome, craniometaphyseal or craniodiaphysial dysplasia, Down syndrome, LADD syndrome, and the CHARGE syndrome (**c**oloboma of the eye, **h**eart defects, **a**tresia of the nasal choanae, **r**etardation of growth and/or development, **g**enital and/or urinary abnormalities, and **e**ar abnormalities and deafness; Table 21.1).

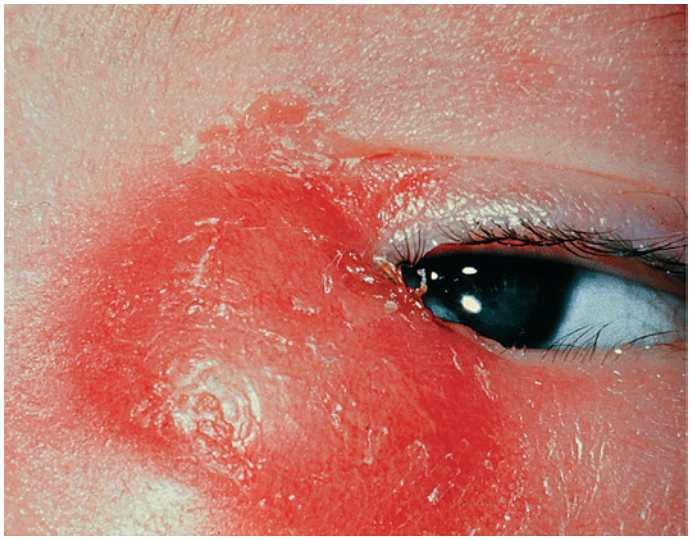

Fig. 21.2 Acute dacryocystitis in a baby with a congenital dacryocystocele. A dacryocystocele is not normally inflamed.

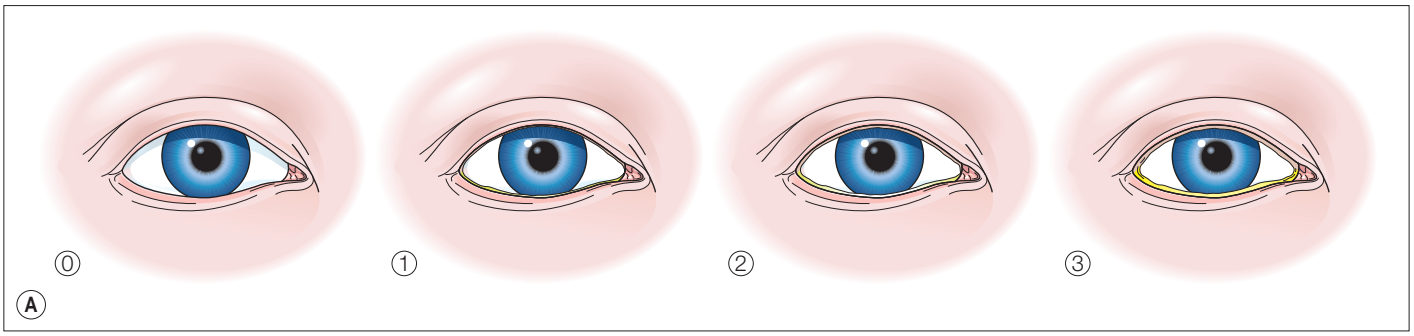

Fig. 21.3 (A) The ectrodactyly, ectodermal dysplasia, clefting (EEC) syndrome is associated with nasolacrimal duct obstruction and (B) "lobster claw" deformity of the hands.

Table 21.1 Systemic associations of nasolacrimal duct obstruction in children

Syndrome	Genetics	Other eye findings	Systemic findings
Down syndrome (see Chapters 37, 39)	Trisomy 21, mosaic or translocation	Up-slanting palpebral fissures, strabismus amblyopia, cataract, blepharitis	Short stature, hypotonia, simian crease, mental retardation, flat nose, small mouth and ears
EEC (see Chapters 16, 46; see Fig. 21.3)	AD	Photophobia, absent eye lashes	Ectrodactlyly, hypoplasia or aplasia of middle digits, ectodermal dysplasia (absent sweat glands, hair, eyelashes, and brows), clefts (palate/lip)
Branchio-oculo-facial	AD; mutations in *TFAP2A* gene	Hypertelorism, microphthalmos, cataract, coloboma	Postauricular branchial cleft defects, cleft lip/palate, low-set ears, malformed nose, hemangiomas of chest and neck
Craniometaphyseal dysplasia	AD/AR; mutations in ANK membrane protein gene	Optic atrophy	Hyperostosis of cranial bones, splayed metaphyses, palsies cranial nerve VII and VIII, delayed teething
Craniodiaphyseal dysplasia	AR/AD	Optic atrophy, strabismus, hypertelorism, exophthalmos	Generalized hyperostosis and sclerosis, growth retardation, parasnasal bossing, deafness, cylindrical long bones
LADD (lacrimo-auriculo-dento-digital)	AD Loss of FGF signaling	Ptosis, keratitis sicca	Hypoplasia, aplasia, or atresia of lacrimal and salivary glands, abnormalities of forearms and fingers, ear anomalies
CHARGE syndrome (see Chapter 53)	AD/sporadic mutations in *CHD7*	Coloboma	Coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, ear abnormalities/deafness
Goldenhar syndrome (see Chapters 28, 29)	Usually sporadic	Lid coloboma, epibulbar/limbal dermoid, Duane syndrome	Macrostoma, hemifacial microsomia, atresia ear canal, ear deformity, misshapen tongue, hemivertebrae, preauricular tags

AD, Autosomal dominant; AR, autosomal recessive; FGF, fibroblast growth factor.
Further information: http://www.orpha.net; http://rarediseases.info.nih.gov.

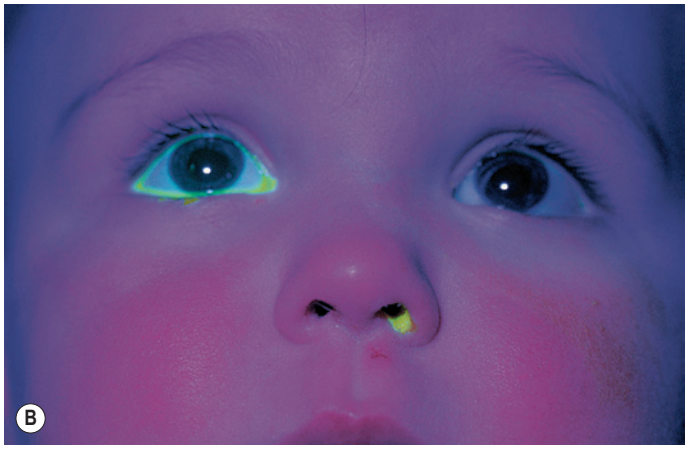

Fig. 21.4 The fluorescein disappearance test. (A) Grading the test is usually performed at 5 or 10 minutes.[24] (B) This child has evidence of delayed fluorescein disappearance test from the right eye, and a patent left system is confirmed in cobalt blue light by the presence of fluorescein in the nostril.

There is an increased tear meniscus and there may be stickiness or crusting on the lashes. A mucocele may develop. The contents can be expressed into the conjunctival sac.

A fluorescein disappearance test should be performed on children with epiphora to determine if there is evidence of lacrimal outflow obstruction.[11] Fluorescein 1% is instilled into each lower conjunctival fornix and cobalt blue light from the slit-lamp or indirect ophthalmoscope illuminates the eyes. The tear meniscus is evaluated at 2 and 5 minutes (and at 10 minutes in equivocal cases). Normally, the fluorescein disappears by 5 minutes (graded 0 or 1), but it remains present in children with obstruction, helping to secure this diagnosis (Fig. 21.4).

Natural history

Congenital nasolacrimal duct obstruction is evident in up to 20% of infants, of which the vast majority become symptomatic during the first month. The natural history is spontaneous resolution with maturation.[12–15] Spontaneous resolution is rapid[12–15] (Fig. 21.5) during the first year of life and continues, at a reduced rate, beyond this into childhood.[16,17]

Conservative treatment

Because of the high rate of spontaneous resolution, observation is recommended until the child is at least 1 year old and even older. Parental education should provide reassurance and information about the etiology and natural history.

Cleansing the lids and lashes with cooled boiled water, gently expressing the contents of the lacrimal sac proximally into the conjunctival sac,[18] maintains flow in the system and prevents stagnation, reducing any sticky discharge. Massage of the sac may also increase hydrostatic pressure within the lacrimal system. This increases resolution by rupturing the membranous obstruction.[19–21] Parents find this difficult and need clear instructions: press on the sac below the medial canthus with the little finger 2–3 times per day if possible. Vaseline (or liquid paraffin) should be applied to the periocular skin to protect and treat any areas of redness or broken skin.

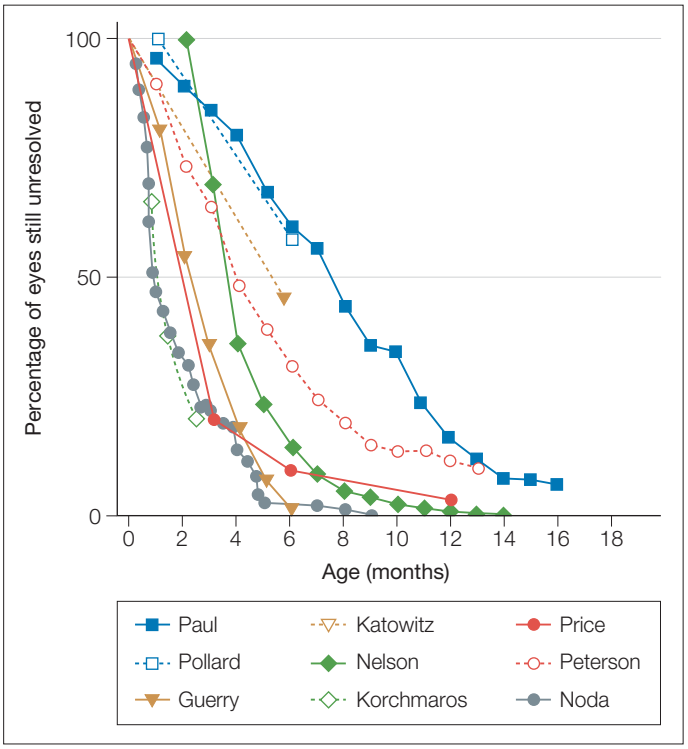

Fig. 21.5 The rate of spontaneous resolution of nasolacrimal duct obstruction expressed as a percentage of those still unresolved at a given age in months.

Antibiotics are not required and should be avoided unless there is evidence of conjunctivitis. Swabs for bacterial growth should only be performed under these conditions, as "pathogenic" bacteria are frequently commensals in the conjunctival sacs of normal infants and do not require antibiotic treatment in white watering eyes.[22]

Syringing and probing

If epiphora persists, syringing and probing the lacrimal drainage system is the treatment of choice. The optimum time to intervene remains controversial. In the past, probing was advocated at presentation or after a short period of conservative treatment.[23,24] However, this has become less favored due to better understanding of the natural history of the condition. It has been shown that the earlier probing is performed, the greater is the success rate.[25,26] However, the higher failure rate in older children is probably unrelated to the age of the child, but is due to a process of natural selection.[27–32] As children grow older, more complex and severe obstructions become common because cases of simple membranous obstruction spontaneously resolve. This reduces the success rate of probing in older children and increases the requirement for more extensive surgery.[16] Observation is as effective as probing in children up to the age of 2 years, but probing provides a more rapid result if performed around 12 months of age.[16]

The decision to probe is based on the natural history, severity, and informed parental request. Probing under 12 months of age is generally not recommended, and there is no evidence that it is detrimental to wait until 2 years of age[16,27–31] and probably later, if desired, with regards to spontaneous resolution.

"Office probing," carried out on awake, restrained babies, which is favored in the USA, is less popular elsewhere because it must be performed at an age when between 50 and 73% of those undergoing probing would not require intervention if left until 1 year of age.[14,33] In environments where office probing is performed, the parents should be fully counseled about the possible benefits of earlier resolution against the risks of it being an unnecessary intervention in the majority of children.[33]

Probing should be carried out in a pediatric environment with the child anesthetized. Probing is diagnostic, as well as therapeutic. In the small number of cases that remain symptomatic, the cause of failure can be identified and a management plan formed. This can only be achieved under general anesthesia using a laryngeal mask following full nasal preparation. Probing should be carried out in a step-wise fashion, identifying the patency or obstruction of each area between the puncta and end of the nasolacrimal duct. Probing is a blind procedure and depends on awareness of resistance to the probe as it passes through the system. The use of a nasal endoscope permits direct visualization of the lower end of the nasolacrimal duct, which assists in the diagnosis and management.[31]

Each punctum is dilated using a Nettleship dilator. This is introduced in a vertical direction for approximately 1 mm and then rotated through 90° medially to run horizontally parallel to the lid margin to dilate the proximal canaliculus. This is easier if the lid is held taut by pulling the eyelid laterally to straighten out the canaliculus. The lacrimal system should be syringed with fluorescein-stained saline using a disposable cannula. Syringing takes place via each punctum and any areas of resistance or any regurgitation of fluid or mucus are noted. The inside of the nose should be inspected with an endoscope or fluorescein retrieved via a nasal or pharyngeal aspirate. The passage of fluorescein and the amount of resistance are important factors in deciding the site and nature of any abnormality of the lacrimal outflow system.

The following features of syringing are useful in identifying the nature of the obstruction:

- Stenosis at the valve of Hasner, or a narrow inferior meatus caused by a tight inferior turbinate: difficulty in injecting the fluid, regurgitation of clear fluid via the other punctum and fluorescein is identified in the nose.
- Atresia at the lower end of the nasolacrimal duct: resistance to flow of fluid, regurgitation of mucus via the other punctum, and no fluorescein is retrieved from the nose.
- Agenesis (rare): severe resistance to flow, clear fluid regurgitation, no fluorescein in nose.
- Physiologic/functional blockage: free and easy flow of fluorescein into the nose in symptomatic children, indicating a normal anatomic pathway.

If a nasal endoscope is used, it should be introduced into the inferior meatus after infracture of the inferior turbinate. This maneuver is often therapeutic as it opens up a narrow inferior meatus and may stretch a stenotic ostium.[34] The fluorescein-stained fluid should be syringed through the system and observed through the endoscope.

- Atresia is identified as ballooning of the submucosa with no passage of fluorescein.
- Stenosis appears as a poor flow through the narrow valve (Fig. 21.6A).
- A clear free flow indicates either that the infracture has been effective or that the patient has "functional" epiphora.

The system should then be probed via the upper canaliculus, as this is anatomically favorable for the onward, downward passage of the probe into the nasolacrimal duct and therefore may be less likely to result in canalicular damage. The smallest probe available should be used (usually a Bowman size 0000). The probe is passed in the same manner as the dilator until it reaches a hard stop that indicates the medial wall of the sac. The probe is withdrawn slightly and rotated 90° so that its tip is pointing downward. It is then advanced gently downward but also slightly posteriorly and laterally to follow the path of the nasolacrimal duct. During passage of the probe, the operator should note the level of any resistance. If the probe perforates a persistent membrane at the valve of Hasner, this may be felt as it enters the inferior meatus.

If being performed with endonasal control, in a successful procedure, the probe will be observed entering the inferior meatus through the valve of Hasner (Fig. 21.6B).

Unsuccessful probings are observed when the probe:

- fails to perforate the atretic mucosa (Fig. 21.6C); or
- creates a false passage by missing the valve of Hasner, and either carries on in a submucosal plane to the floor of the nose or enters the meatus through a false and usually ineffective passage.

In the first instance, a cut down onto the probe may be required; in the other it may be possible to steer the probe

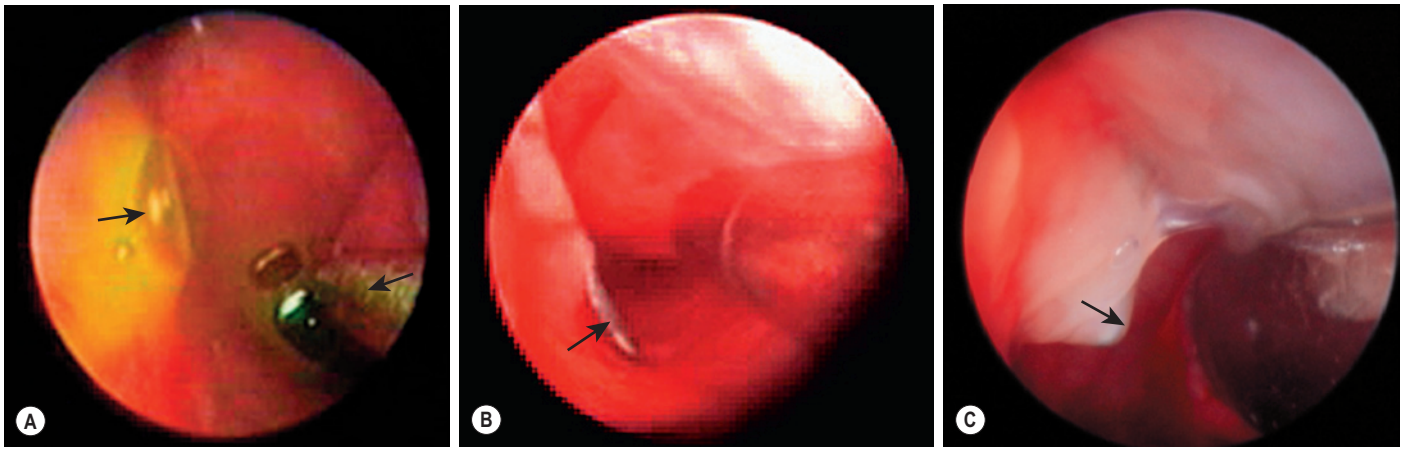

Fig. 21.6 (A) Stenotic flow through the valve of Hasner – right nostril. (B) Probe entering the inferior meatus via the valve of Hasner – right nostril. (C) Probe distending, but not perforating, the mucosa in a case of atresia of the lower end of the nasolacrimal duct – right nostril. *(Courtesy of Paul White.)*

under direct visualization toward and through the stenotic or atretic valve of Hasner. If the perforation is inadequate and felt to be tight, the probe size should be increased to a maximum size 1. Larger probes should be avoided as they may induce canalicular damage. To confirm patency, the syringing should be repeated with fluorescein-stained saline.

Postoperatively a steroid/antibiotic combination should be instilled for 2 weeks. Improvement is usually noted within a few days of the probing. If there has been no improvement by 1 month, it is unlikely that the treatment has been successful.

What to do if probing fails

If probing fails, it is important to identify the reason for failure. Failure is generally due to one of three causes:

1. Failure to create an anatomically patent passage due to:
   - **a.** a tight inferior meatus due to a large inferior turbinate;
   - **b.** failure to perforate the mucosa with the probe;
   - **c.** submucosal passage of the probe;
   - **d.** false passage formation; or
   - **e.** inadequate size of the perforation.
2. Physiologic (functional) epiphora. Functional epiphora is persistent watering despite a clear, patent, free-flowing syringing, observed endoscopically in the inferior meatus and no resistance felt on probing. All other causes of lacrimation or epiphora must be eliminated. The fluorescein disappearance test demonstrates delay. The cause is probably physiologic pump failure. Such children may have an upper respiratory cause, such as large adenoids. A history regarding nasal symptoms should be taken.
3. Complex abnormalities of the outflow system. Abnormalities of the canaliculi or the proximal nasolacrimal duct become commoner in older children. These abnormalities may be complex, especially in children with abnormal bony facial structure.[35–37]

A major advantage of endoscopic probing is that these common causes of failure can be identified and treated at the first probing, improving the success rate.[38]

If endoscopic probing was not performed on the first occasion, then this approach is useful in re-probings. It will identify the most frequent causes of failure and permit appropriate treatment.[38] If the initial procedure was an endoscopic procedure, subsequent treatment is dependent on the original findings. Another option is intubation of the system with silicone tubes.[39] However, intubation carries risk of damage to the ocular surface and lacrimal system. It may be unnecessary (e.g. in functional cases), and is no more effective than endoscopic probing in repeat cases.[40]

One of the possible complications of probing is the creation of a false passage, a situation when the probe passes out with the anatomical lacrimal outflow system. This can occur in a variety of places along the lacrimal outflow channels but the commonest sites are: (1) when the probe perforates the nasal mucosa at the end of the bony nasolacrimal duct above the valve of Hasner (which may be stenosed or atretic); and (2) when the probe misses the valve of Hasner and continues submucosally towards the roof of the mouth. These are easy to see when using an endoscope and the probe can be directed towards the correct exit point – the valve of Hasner – which can be seen as a small dimple in the mucosa. It is more difficult to envisage without endoscopy, but if there is no sensation of overcoming a small resistance or if no fluorescein can be retrieved from the nose following the post-probing flush, then the possibility of false passage should be considered.

Intubation

Indications for silicone tubes include upper nasolacrimal duct obstruction and canalicular stenosis.[39] Intubation can be employed to treat "failed probings,"[41] but the etiology of the failure should be clarified prior to intubation. Tubes may be bicanalicular or monocanalicular; insertion of monocanalicular tubes can require either retrieval of the distal end of the tube from the nasal cavity ("Monoka") or "pushed" insertion of the tube from the proximal end using a metal introducer ("Masterka"). Both techniques have been used with successful outcomes.[42–44]

Intubation should take place under general anesthetic after the nose has been prepared with decongestant. Nasal endoscopic guidance is used to view the inferior meatus. Tubes come with a metal introducer. Each end is placed through the system via the canaliculi, into the sac, and down the nasolacrimal duct into the inferior meatus. They should be

retrieved under direct visualization. Ritleng tubes – silicone tubes, inserted via hollow probes which are placed in the lacrimal system – are easier to insert, less traumatic, and more likely to be successful, especially in the hands of a novice.[45] Postoperative treatment consists of a topical antibiotic and steroid preparation into the conjunctival sac.

Possible complications of intubation include cheese-wiring through the canaliculi, dislocation superiorly or inferiorly, infection, epistaxis, sinusitis, granulomatous reaction, and scarring of the drainage system; the ocular surface can be affected by conjunctival irritation and corneal abrasion.[46]

The optimal time to leave tubes in place is not known, but 3–6 months is usually recommended.[41–47] Tubes should be removed under general anesthetic via the nose to prevent aspiration of the tube. The system is then irrigated to remove debris and to confirm patency.

Balloon catheter dilatation of the lacrimal system is an alternative to intubation in patients with failed probing.[48] This has a high success rate, similar to that of intubation,[49] but is significantly more expensive. It has been suggested that balloons have a role in the primary treatment of congenital nasolacrimal duct obstruction, but the results are no better than "blind probing."[50] The role of balloon dacryoplasty in the management of congenital nasolacrimal duct obstruction still needs to be fully evaluated.

Dacryocystorhinostomy

Children rarely require a dacryocystorhinostomy (DCR), but indications include persistent epiphora despite probing and intubation, complex congenital abnormalities of the lacrimal outflow apparatus (particularly involving the upper nasolacrimal duct), and acquired disease usually caused by infection or trauma.[51] External and endoscopic routes are possible. Excellent success rates, comparable to those of adult DCR, have been reported.[52–54]

Congenital fistulae of the lacrimal outflow system

Fistulae of the lacrimal system in which tracts open onto the skin directly from the puncta, canaliculi, lacrimal sac, or nasolacrimal duct are rare. They may appear as double puncta, or appear in the region of the medial canthus (Fig. 21.7). They are usually non-functioning and should be left untreated unless they allow flow of tears onto the face or result in epiphora (rare). Treatment involves excision of the fistula after ensuring that the remaining outflow system is patent.

Punctal and canalicular abnormalities

Failure of the proximal end of the lacrimal drainage system to canalize may result in punctal stenosis or atresia. This is often asymptomatic especially if only one punctum is abnormal. Narrow puncta should be dilated. Membranous obstruction should be pierced with a needle and dilated. These cases do well, but are often associated with distal abnormalities and a syringing should always be performed.

Abnormalities proximal to the sac result in surprisingly few symptoms. Agenesis should be suspected if the papilla is not readily obvious.[55] If only one punctum is missing, syringing via the other one detects the extent of the damage. Surgery to construct these areas is specialized. Retrograde probing from an external DCR incision may be attempted through the sac; otherwise, a Jones tube is required. This type of surgery may be left until the child is in their teens.

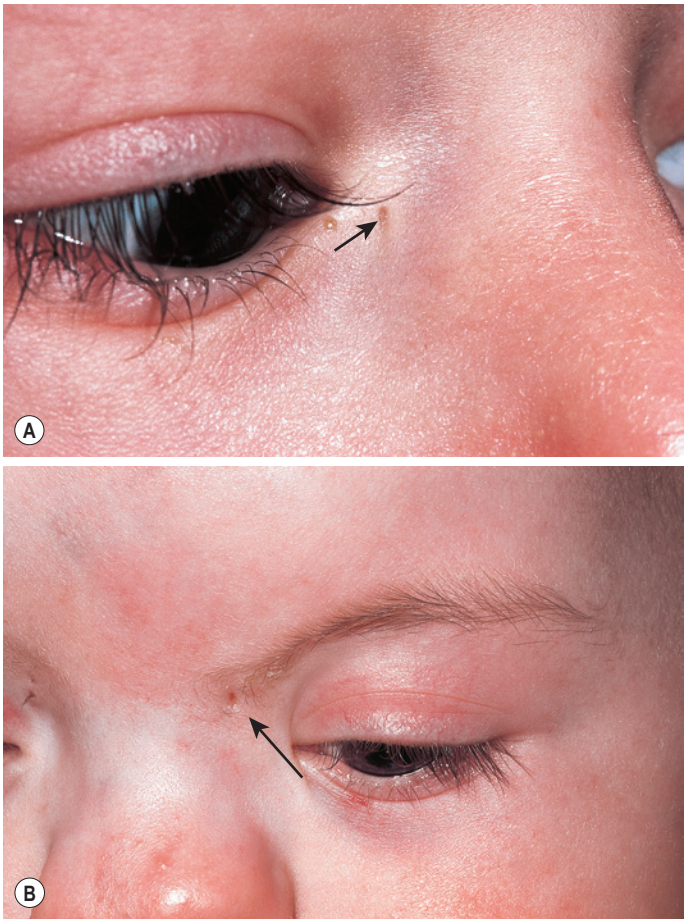

Fig. 21.7 Congenital fistula of the nasolacrimal system. A fistula can be seen as a tiny mark (A) below or (B) above the medial canthus.

Acquired conditions of the lacrimal drainage apparatus

Canaliculitis

Canaliculitis in children is uncommon but may be due to bacterial or primary herpes simplex infection. Management involves obtaining viral and bacterial cultures and treatment with antibiotics or antiviral agents depending on the clinical and laboratory findings. Probing in the active phase should be avoided.

Acute dacryocystitis

Acute dacryocystitis may accompany non-patent nasolacrimal systems or may occur as a primary event. This is particularly common in infants with dacryocystocele.[56] Treatment comprises prompt intervention with intravenous antibiotics as retrobulbar abscesses may occur. Cultures should be taken of any pus or discharge that can be expressed through the punctum. Probing should not be performed as damage to the congested epithelium may cause false passage and lead to orbital cellulitis and fistula formation.[57] Skin incisions should not be made during the acute phase as an external fistula may occur. If a mass remains after resolution, evacuation can

be performed through the skin with a needle through the lower pole of the sac, although the pus may be inspissated or loculated. Once the infection has resolved, probing should be performed if epiphora persists.

Acquired nasolacrimal duct obstruction

Acquired nasolacrimal duct obstruction may be caused by diseases of the nose or paranasal sinuses, especially chronic allergic rhinitis or persistent upper respiratory tract infections with enlarged adenoidal lymphoid tissue. These are commoner in older children and adolescents.[58] Rarely, acquired obstruction may herald a more sinister cause such as fibrous dysplasia, cranial metaphysial or cranial diaphysial dysplasia, or tumor formation (see Chapter 25). Treatment should be aimed at the underlying cause.

ORBITAL DISEASE AND AGE
CLINICAL ASSESSMENT
INVESTIGATIONS
SURGERY
REFERENCES

Orbital abnormalities in childhood may be congenital or acquired. Congenital developmental abnormalities can be confined to the orbit or part of a more widespread craniofacial malformation. For example, proptosis may be related to shallow or small orbits in the craniosynostoses (Fig. 22.1). The relationship between the orbits may also be disturbed: in hypertelorism the orbits are widely separated; in hypotelorism, they are set close together. An orbital wall defect may allow prolapse of intracranial tissue with pulsating exophthalmos or enophthalmos. Orbital growth occurs throughout childhood and congenital absence of the globe, enucleation, or radiotherapy results in failure of normal growth of the orbits and the adjacent facial structures (Fig. 22.2).

Children with acquired orbital disorders most commonly present with signs and symptoms of a mass leading to proptosis, either axial or non-axial, soft tissue signs, and in some cases a palpable mass. Other presentations include reduced vision, restriction of eye movements, pain, and inflammation. Occasionally, a child may present with enophthalmos, for example following orbital fracture.

The relative frequency of the conditions causing proptosis in childhood varies considerably,[1–8] depending, in part, on the source of the report. Series from eye hospitals[3] differ from those from neurosurgical[2] or pediatric units.[6] Geographic factors can have a major impact. The major causes of proptosis in African,[4] Indian,[9] or Turkish[10] children are different from those seen in Europe and North America. In developing countries, secondary involvement of the orbit by advanced and neglected retinoblastoma is a common cause of proptosis, but this is a rare cause in developed countries. Series that rely solely on tissues specimens[1,5,7,8] exclude the many conditions that can be diagnosed and treated without biopsy or surgery, such as infantile periocular hemangioma, or those in which biopsy may be more conveniently obtained at another site of involvement, such as neuroblastoma or Langerhans cell histiocytosis. Population-based studies have shown that the incidence of pediatric orbital tumors has remained fairly constant. Conversely, there has been a steady increase in the incidence of orbital tumors, particularly lymphoma, in adults.[11]

Orbital disease and age

Within the childhood years, defined here as ages up to and including 16 years, knowledge of the trends in the incidence of orbital disorders at different ages can help the diagnostic process.

Clinical data of 326 children seen by the orbital service in Vancouver, Canada, from 1976 provide useful information (Table 22.1). Neoplasia and structural abnormalities (including cysts) account for the great majority of children presenting with orbital disease (Fig. 22.3). This is quite different from adults, in whom over 60% of presentations are due to inflammatory diseases, most commonly Graves' orbitopathy, and structural abnormalities account for less than 15% of cases. The distribution of orbital disease in children aged over 11 years resembles the adult pattern (Fig. 22.4).

Fortunately, only a small proportion of pediatric orbital neoplasms are malignant, similar to other published series from North America.[6,7,12] Under 2 years of age, the major causes of proptosis are infantile hemangiomas and venous-lymphatic malformations (lymphangioma), dermoids and other epithelial cysts, and other structural abnormalities. Fig. 22.5 shows that while some lesions are distributed evenly throughout childhood (venous-lymphatic malformation, varices, and arteriovenous malformations), others tend to occur within a specific age range. Seven patients with rhabdomyosarcoma were seen, whose ages ranged from 2 to 11 years. The seven patients with Langerhans cell histiocytosis ranged in age from 3 to 9 years. Infantile hemangioma was overwhelmingly more common in early infancy. Inflammatory conditions were increasingly frequent after the age of 5 years, especially orbital cellulitis, idiopathic orbital inflammatory disease (6 years and over), and thyroid orbitopathy (11 years and over). It is noteworthy that there were two cases of lacrimal gland carcinoma and four of granulomatosis with polyangiitis in this series, a reminder that, although rare, these potentially lethal conditions can occur in childhood.

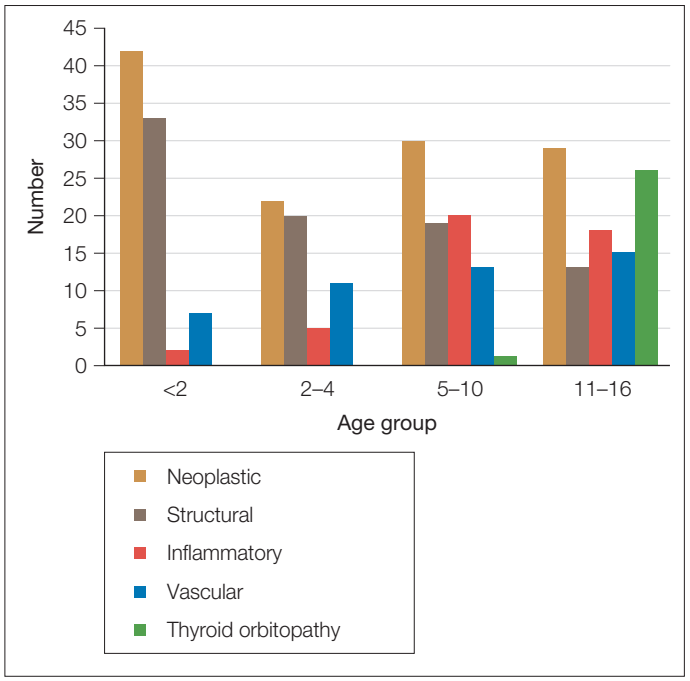

Fig. 22.3 Distribution of orbital disease by age group in patients less than 17 years of age.

Clinical assessment

When assessing a child with orbital disease, a history, examination, and differential diagnosis in the context of the child's age are essential before investigations can be planned.

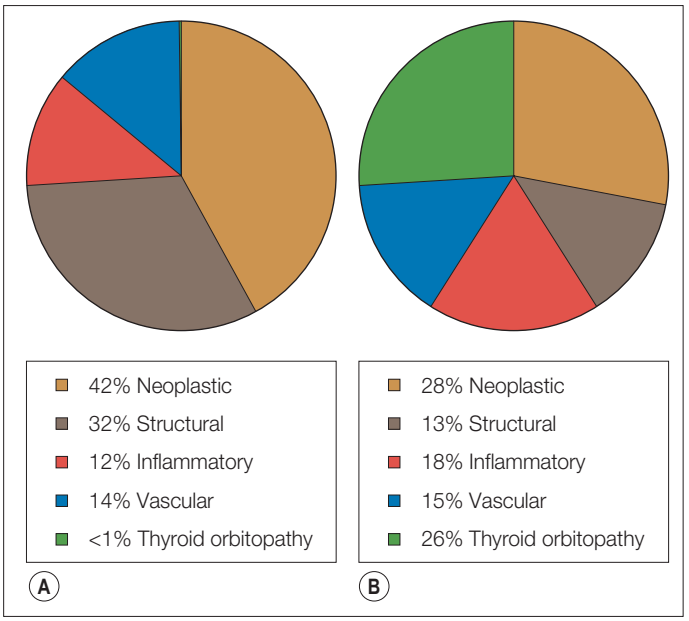

Fig. 22.4 (A) Distribution of orbital disease in patients less than 11 years of age. (B) Distribution of orbital disease in patients 11–17 years.

History

The age of onset, laterality (unilateral or bilateral), and the tempo of onset are important clues to the diagnosis. The duration may be difficult to determine accurately and a review of old photographs may be helpful.

Bilateral proptosis in early infancy is often due to shallow orbits in craniofacial malformations (see Fig. 22.1). This can occasionally be unilateral, as in plagiocephaly. Usually, however, unilateral proptosis is due to the globe being displaced by a mass within the orbit.

Some masses such as optic nerve glioma or dermoid cyst grow slowly. Rapidly increasing proptosis suggests a metastatic deposit or rapidly growing tumor such as rhabdomyosarcoma. Rapid tumor growth may be associated with necrosis and hemorrhage, resulting in signs of inflammation and periorbital ecchymosis. The presence of bilateral ecchymosis is suggestive of metastatic neuroblastoma.

A catastrophic onset (within hours) implies hemorrhage within an often unsuspected, pre-existing lesion, such as a venous-lymphatic malformation (lymphangioma). Occasionally, the onset of orbital cellulitis may be very sudden. It is usually accompanied by pain, local inflammation, and limitation of ocular motility in a child who is generally ill and febrile. The presence of clinically detectable orbital and periorbital inflammatory symptoms and signs in childhood is overwhelmingly associated with infection or non-specific orbital inflammatory disease. Although inflammation is part of the classical description of rhabdomyosarcoma, it is not typical and was absent in all six patients in the above series from Vancouver, even though all had a rapid onset of symptoms.

Most round-cell tumors in childhood, including rhabdomyosarcoma, granulocytic sarcoma (chloroma, or tumefactive extramedullary myeloid leukemia) and Ewing sarcoma, present as a mass developing over weeks in a subacute manner. Metastatic neuroblastoma can present with onset of proptosis over days.

NSOIS, Non-specific orbital inflammatory syndrome; PNS, peripheral nerve sheath.

An increase in proptosis with crying or straining is suggestive of infantile periocular hemangioma, venous malformations, or absence of the sphenoid wing (as in neurofibromatosis type 1 [NF1]). When very obvious, its presence helps to exclude malignancy as a cause of the proptosis.

Pulsating exophthalmos may be associated with congenital defects of the orbital wall (as seen in NF1 or encephalocele). Occasionally, large periocular infantile hemangiomas (capillary hemangiomas) pulsate due to their rich arterial blood supply, as may high-flow arteriovenous malformations, though the

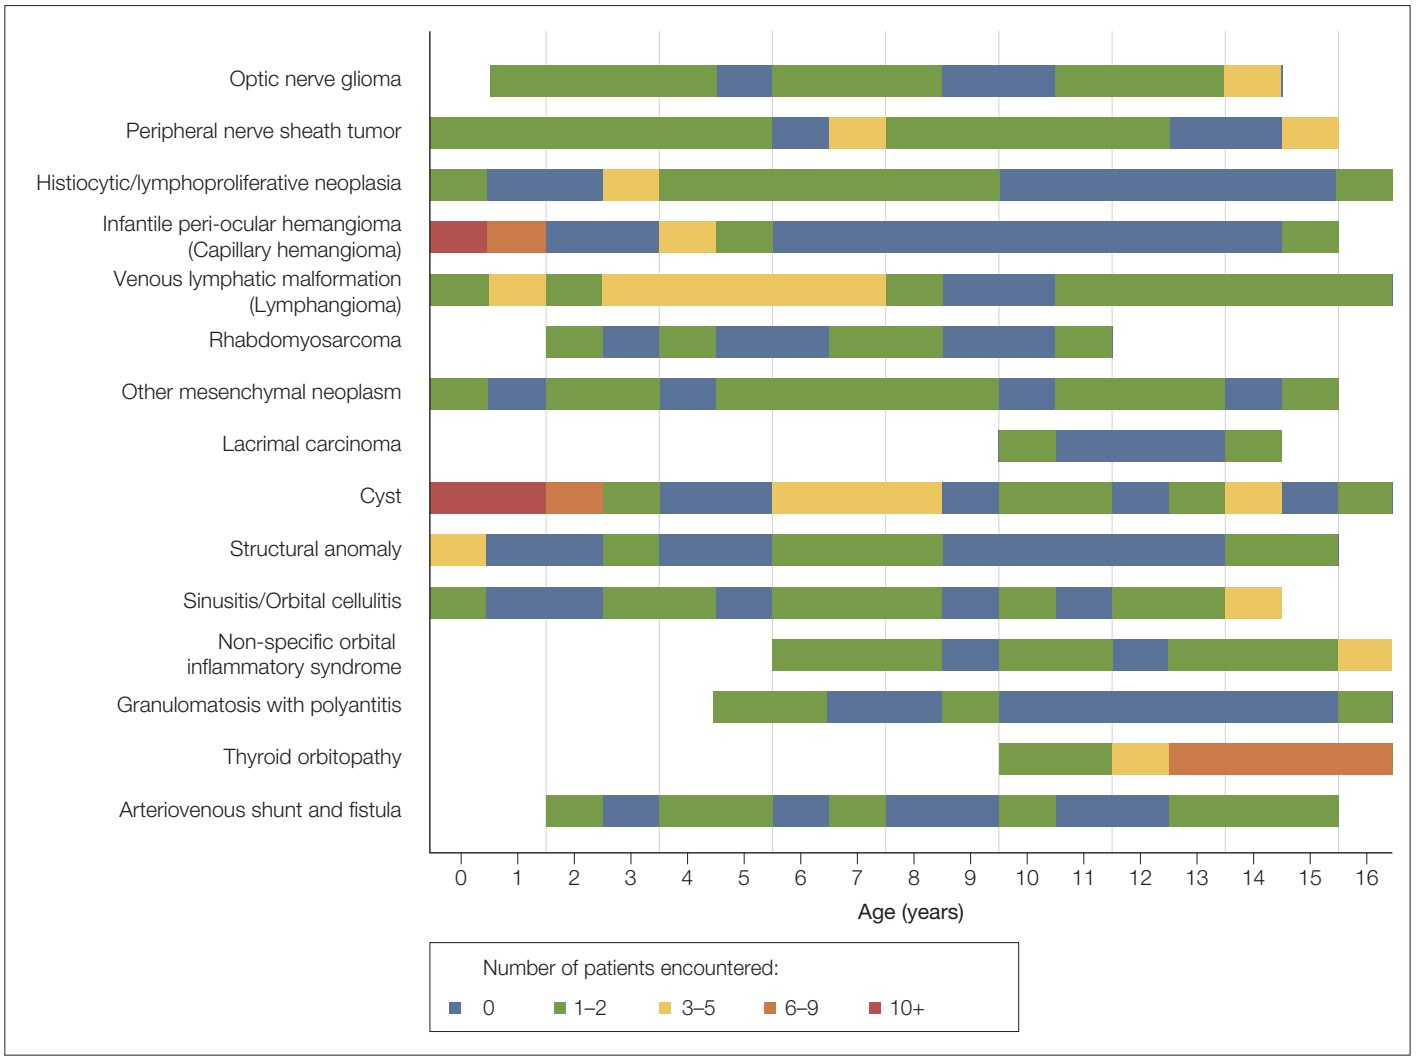

Fig. 22.5 Age distribution of common orbital diseases.

latter are rare in childhood and more common in adolescence or young adulthood.

Skin discoloration may offer a clue to the underlying etiology. Red is suggestive of the arterial supply of infantile periocular hemangioma, which, when superficial to the septum, almost invariably involves the overlying skin. When deep, these may have a blue or purple hue. Venous or venous-lymphatic malformations (lymphangiomas) appear blue or purple, as do some cystic lesions, lacrimal or conjunctival cysts. Some cystic lesions, for instance the cysts associated with colobomatous microphthalmos, are bluish but transilluminate with a focal light. The brownish cutaneous discoloration of hemosiderin is usually caused by previous bleeds into a venous-lymphatic malformation (lymphangioma) or, rarely, by metastatic neuroblastoma. Both of these may present with spontaneous ecchymosis.

Children with blunt orbital trauma and orbital wall fractures may present with severe restrictive strabismus and symptoms of vagal stimulation such as nausea, vomiting, and hypotension, often induced by attempted eye movements.[13] The absence of external signs of orbital trauma may make the diagnosis less obvious (Fig. 22.6).

Examination

Children with proptosis must have a visual assessment. In infants, this may be limited to observing fixation. Resentment to covering of the contralateral eye suggests poor vision. The 10-prism diopter base down test may be useful if poor vision is suspected in an orthotropic child. A cover test should be performed, and ocular ductions and versions assessed. Limitation of ductions may be due to mechanical restriction by tumor, muscle infiltration, inflammation, edema, or entrapment. Third, fourth, and sixth cranial nerve function should be tested, as well as sensory testing of the first and second divisions of the trigeminal nerve, if possible. Occasionally, in an older child with a blow-out fracture, a forced duction test may be useful to detect muscle restriction, but clinical signs will usually suggest the diagnosis without subjecting the child to this intervention.

The site of an orbital mass may be indicated by the direction in which the eye is displaced. A posterior or intraconal tumor results in axial proptosis (Fig. 22.7); an extraconal tumor will usually displace the eye vertically or horizontally. For example, in fibrous dysplasia of the orbit, which most commonly affects

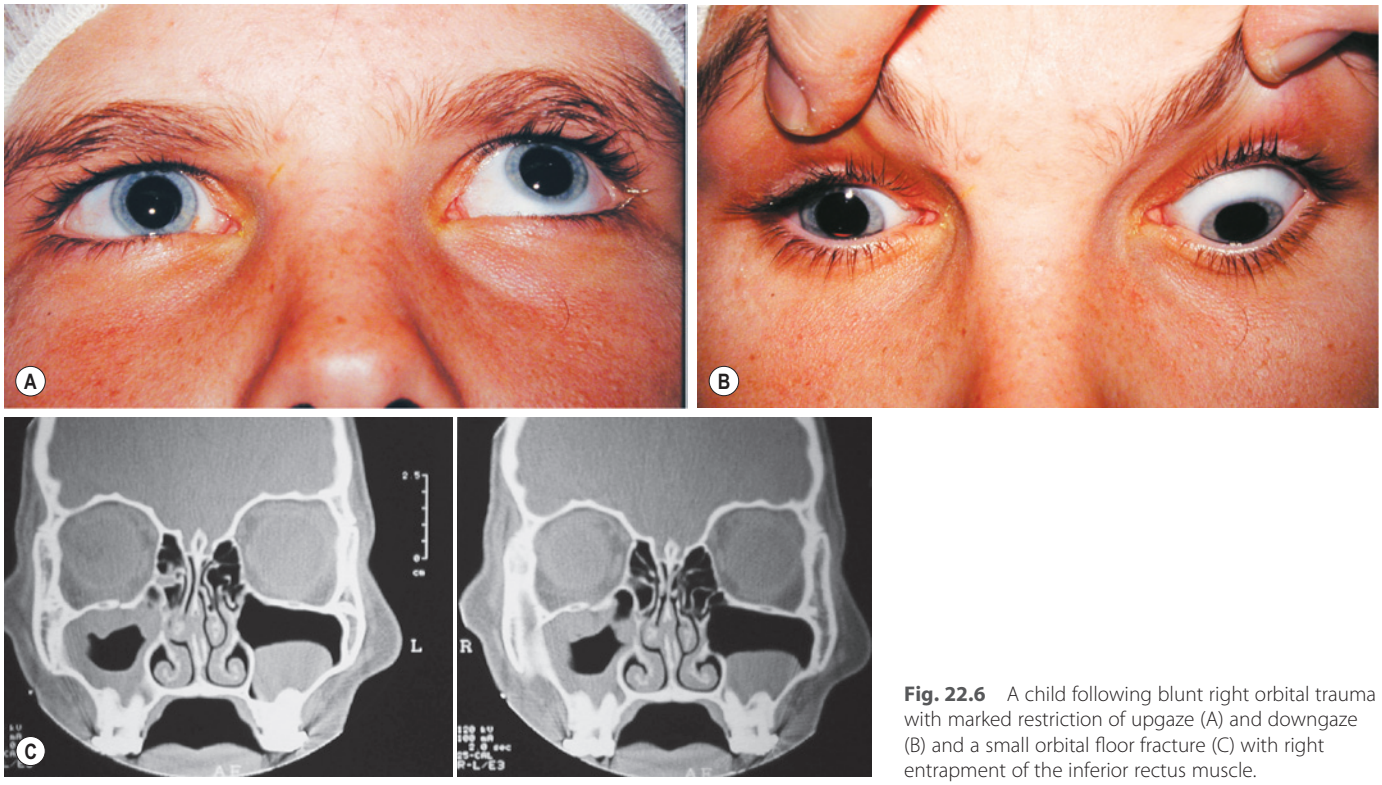

Fig. 22.6 A child following blunt right orbital trauma with marked restriction of upgaze (A) and downgaze (B) and a small orbital floor fracture (C) with right entrapment of the inferior rectus muscle.

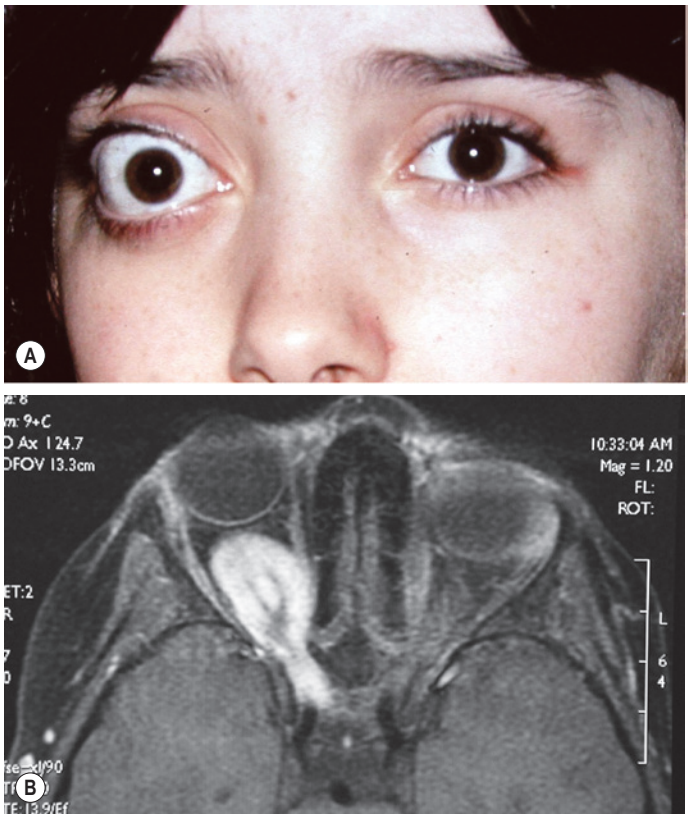

Fig. 22.7 An 11-year-old girl with right axial proptosis (A) due to an optic nerve glioma that extends through the optic canal (B).

the frontal bone, and in juvenile ossifying fibroma, which also commonly involves the orbital roof, the globe is usually displaced downwards and forwards (Fig. 22.8). Orbital cellulitis secondary to ethmoidal sinus infection usually displaces the globe laterally. Although the globe is displaced away from most mass lesions, it can be displaced toward them, as in the case of cicatrizing lesions within the orbit.

Enophthalmos may occur in several childhood scenarios, including following radiotherapy (see Fig. 22.2), with sphenoid wing dysplasia (in NF1), in Parry–Romberg syndrome or hemifacial atrophy, and as the result of orbital wall fractures.

Globe position should be recorded using an exophthalmometer and a transparent ruler is used to measure the amount of vertical and horizontal displacement. It is difficult to measure proptosis accurately in infants, but careful observation from above or below often helps to highlight its presence.

Eyelid position should be recorded. Eyelid retraction or lag on downgaze may suggest thyroid orbitopathy, but may also indicate tethering by tumors.

Slit-lamp examination may show dilated dysmorphic venous channels in the conjunctiva of patients with vascular malformations. Venous-lymphatic malformations (lymphangioma) may be associated with visible conjunctival lymphangiectasis or cysts, which occasionally contain a meniscus of blood. Lisch nodules on the iris are diagnostic of NF1, increasing in number with age, and may assist in the diagnosis of plexiform neurofibroma (Fig. 22.9) or sphenoid wing dysplasia with encephalocele as causes of proptosis. Juvenile cataract is a marker for NF2. Meningioma and schwannoma are important causes of orbital mass in this disorder.

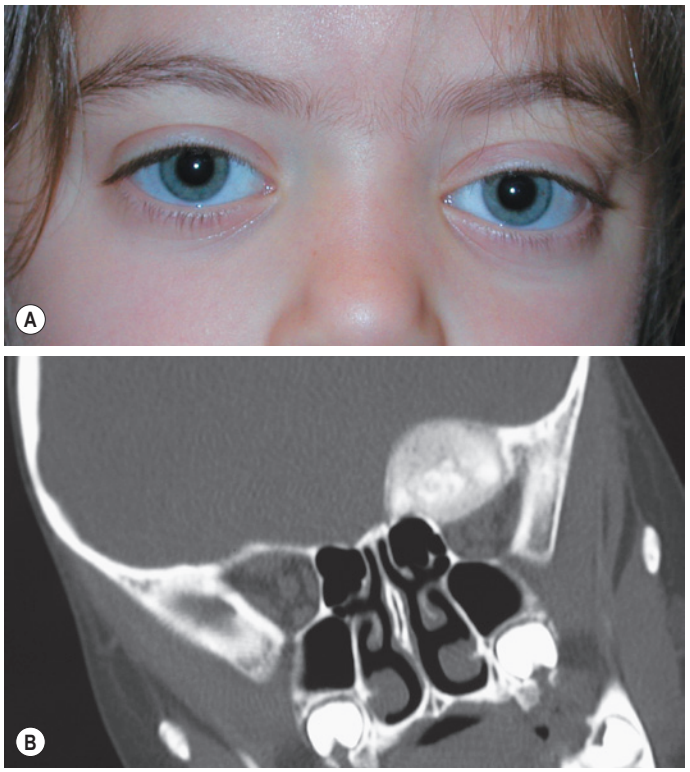

Fig. 22.8 A 7-year-old girl with non-axial left proptosis (A) due to an ossifying fibroma of the orbital roof (B).

Fig. 22.9 A 13-year-old girl with left hypoglobus, a thickened and hyperpigmented upper eyelid and temple due to plexiform neurofibroma in neurofibromatosis type 1.

The presence of an afferent pupillary defect suggests optic neuropathy, which may be due to intrinsic optic nerve disease, such as glioma, or to extrinsic compression, as in fibrous dysplasia involving the optic canal, which is rare. Visual field testing, if feasible in older children, is helpful in assessing and documenting optic neuropathy. In older children, color vision can be assessed using subjective red desaturation or an Ishihara chart to confirm the presence of optic neuropathy.

Cycloplegic refraction is important to detect astigmatism due to distortion of the globe by an orbital mass. Retrobulbar lesions tend to result in a hyperopic shift, and lesions anterior to the equator may produce astigmatism. These are important causes of amblyopia.[14] Occasionally, unilateral axial myopia or buphthalmos may mimic proptosis. Long-term occlusion of an eye, as in uncorrected unilateral ptosis due to infantile periocular hemangioma (capillary hemangioma), can result in ipsilateral axial myopia.

Optic disc swelling or atrophy can appear in patients with optic nerve compression or glioma. If the mass is close behind the globe, choroidal folds may be present. Optico-ciliary shunt vessels, classically associated with primary optic nerve sheath meningioma (PONM), are much more frequently seen in optic nerve glioma in children, because PONM is much rarer in children.

Palpation of the orbit reveals the consistency of a localized mass. Infantile periocular hemangiomas (capillary hemangiomas) feel firm and spongy. Their contents cannot be expelled by applied pressure, whereas orbital varices are easily drained of blood, even with gentle pressure. Dermoids should be examined for mobility or fixation and the presence of a posterior margin or a tail extending into the orbit or temporalis fossa. A posterior extension or extension through the lateral wall of the orbit is more likely to be present in dermoids that are situated inside the orbital rim than in those directly overlying the rim.

The evaluation of children with orbital disease should include a general examination, as this may give useful clues to the diagnosis. Café-au-lait spots suggest NF1, and skin pigmentation may be seen in some forms of fibrous dysplasia (McCune–Albright syndrome). Characteristic skin lesions may also be present in Langerhans cell histiocytosis and juvenile xanthogranuloma. Infantile periocular hemangioma (capillary hemangioma) of the orbit is often associated with cutaneous infantile periocular hemangiomas (capillary hemangiomas) elsewhere. In suspected metastatic disease there may be other involved sites such as an abdominal mass in neuroblastoma or skin, scalp, or bony lesions in Langerhans cell histiocytosis. Thyroid orbitopathy may be accompanied by general symptoms and signs of hyperthyroidism.

Finally, obtaining opinions from other specialists, particularly general pediatricians, pediatric neurologists and ear, nose, and throat (ENT) surgeons, may help to determine the cause of proptosis in a child.

Investigations

Investigating children with proptosis should be guided by the history and clinical findings and tailored to each patient. Some disorders can be diagnosed clinically without the need for further diagnostic tests. In others, further tests will be necessary to confirm the suspected diagnosis or to assess the degree of orbital involvement. When other systems are involved, such as extension of tumor into the brain or sinuses or systemic involvement in malignancy, investigation of the child should be planned with the other specialists who may become involved in the child's care.

Radiology

Plain X-rays

Except where computed tomography (CT) or magnetic resonance imaging (MRI) is unavailable, plain X-ray has a very limited role. Detection of a radio-opaque foreign body is one potential use of plain X-rays. In general, plain X-rays are inadequate in the evaluation of orbital disease or trauma.

Computed tomography and magnetic resonance imaging

Diagnostic imaging of orbital structures was revolutionized by CT, and later by MRI. Modern CT scanners have very short acquisition times, which means that younger children may be scanned without the need for general anesthesia, and often with relatively mild sedation. If possible, children should be scanned on the most modern scanners available in order to minimize exposure to radiation. Modern scanners are able to provide high-resolution reconstructed images in coronal, sagittal and other planes. CT provides information about intracranial as well as orbital structures.[15] It yields more information on the presence of calcification and on bony detail, which can be important in assessing orbital fractures, and in surgical planning. CT can also be used when a ferromagnetic foreign body is suspected. The differential diagnostic yield is increased by the use of contrast agents, which enhance vascular lesions, inflammations, and some malignancies.

Sedation is usually necessary under the age of 3–4 years, though the speed of data acquisition has increased significantly. Data capture for orbital CT scan with a 16-slice scanner takes under 10 seconds, and more modern 32- or even 64-slice scanners reduce this to a fraction of that time. The relatively high dose of radiation makes CT useful for initial diagnosis but undesirable for regular follow-up, especially for patients with tumor suppressor gene mutations (retinoblastoma, neurofibromatosis, and rhabdomyosarcoma).

MRI provides higher resolution of soft tissue without exposure to ionizing radiation.[12] This is important if repeat imaging is necessary, for example a child with NF1 and optic nerve glioma who is being followed regularly. Any plane can be chosen at the time of the examination. Orbital views may be obtained with a 0.5–3.0 tesla field, and surface coils should be used to increase the surface-to-noise ratio. Contrast enhancement can be obtained for similar indications to those outlined above for CT, using gadolinium, which results in T1 shortening. Because fat has a bright signal on T1-weighted images, fat saturation techniques must be used to maximize the effect of contrast enhancement in the orbit. This is essential to examine the optic nerve, which would otherwise be swamped by the bright fat signal, potentially obscuring an important finding such as optic nerve sheath meningioma, which would be more obvious with CT.

Multiple image sequences can provide characteristic signal patterns, such as the fluid/fluid levels typical of low- or no-flow vascular malformations and aneurysmal bone cysts. Identification and dating of blood within hemorrhagic lesions such as venous-lymphatic malformations (lymphangiomas), presence or absence of flow within mass lesions, and contrast enhancement of the optic nerve in optic neuritis are further strengths of this technique.

Disadvantages include the time taken to image an orbit – 20 to 30 minutes – compared with CT, which takes seconds; CT can be used without sedation for much younger patients who can lie still for 2 or 3 minutes. Conversely, most patients under the age of 6 years require sedation or anesthesia (often using only intravenous propofol as opposed to intubation or laryngeal mask) for MRI because of the noise and duration of the procedure. MRI is generally contraindicated for patients with ferromagnetic foreign bodies which is often relevant to teenagers with their dental braces. A more specific problem of MRI for orbital work is its relative inability to image bone and calcification clearly, which may be important when differentiating glioma from meningioma in the orbit.

Surgery

The surgical approach to the child's orbit differs significantly from that taken in adult orbital disease. This is due to the relative shallowness of the orbit in childhood. Lateral orbitotomy, with lateral orbital wall removal, is unnecessary in most cases since lesions can usually be reached via the anterior approach. If possible, incisions should be hidden in the upper eyelid crease, or transconjunctival approaches used, to avoid obvious scars.

Introduction

Primary neurogenic tumors of the orbit arise from the optic nerve, from peripheral sensory or motor nerves, or from the autonomic ciliary ganglion. Secondary neurogenic tumors include retinoblastomas and intracranial meningiomas that invade directly from contiguous structures or neuroblastomas and peripheral neuroectodermal tumors (Ewing sarcoma) that spread hematogenously; these are discussed in other chapters.

Fundamental science

Basic anatomy and origin of primary orbital neurogenic tumors

The optic nerve (cranial nerve [CN] II) extends from the optic disc to the chiasm and is divided into four parts: the intraocular portion within the sclera; the intraorbital portion, which pursues a sinuous course from the globe to the orbital apex; the intracanalicular portion within the narrow bony optic canal; and the intracranial portion from the canal to the chiasm.[1] The nerve carries axonal bundles (95% retinal ganglion axons and 5% supportive astrocytes) and is surrounded by a pial sheath containing capillaries, the arachnoid layer, and a thick protective dural coat.[2] The nerve is an extension of the central nervous system (CNS), and the myelin surrounding its axons is produced by CNS oligodendrocytes rather than by perineural Schwann cells, as seen in peripheral nerves. Unlike peripheral nerves, it is not surrounded by neurilemma and so cannot regenerate itself.[3] Optic nerve gliomas arise from pial astrocytes within the substance of the nerve, while primary optic nerve sheath meningiomas arise from cap cells of the arachnoid around the intraorbital or intracanalicular portion of the nerve.

The orbital peripheral nerves are either sensory branches of the trigeminal nerve (CN V) or motor branches to the extraocular muscles and eyelid retractors. These consist of bundles of axons, each of which is an extension of a single nerve cell, and is surrounded by Schwann cells that myelinate the fibers to improve conductivity. The endoneurium is a loose matrix of collagen and extracellular matrix between the axons. Perineurium surrounds individual fascicles and the epineurium is the fibrous coating encasing the complete nerve, and contains within it the blood supply (Fig. 23.1).[4] Common benign peripheral nerve sheath tumors include neurofibromas (proliferations of axons, fibroblasts, and Schwann cells) and schwannomas (composed predominantly of Schwann cells). Rare lesions include the perineurioma and malignant peripheral nerve sheath tumors.

The ciliary ganglion lies just temporal to the optic nerve, 1 cm behind the globe, and houses the parasympathetic short ciliary cell bodies. A rare tumor arising from non-chromaffin tissue around the ganglion and ciliary nerves is the paraganglioma.[5]

All of these specific primary neurogenic tumors will be described individually.

Pediatric versus adult orbital neurogenic tumors

Orbital neurogenic tumors differ between the pediatric and adult population in incidence and behavior. The optic nerve glioma is the most common neurogenic tumor in children and is relatively benign when isolated to the orbit, in contrast to the adult form, which is rare and often highly aggressive.[6] Neurofibromas are the next most common lesions in children. These are often plexiform neurofibromas associated with neurofibromatosis type 1 (NF1; see below), which may rarely transform into a malignant variant after adolescence. Adult-onset neurofibromas are rare and typically are solitary benign lesions.[7] Primary optic nerve sheath meningiomas are more common in adults and tend to be relatively indolent sporadic lesions, whereas in children they are more aggressive lesions often associated with neurofibromatosis type 2 (NF2).[8]

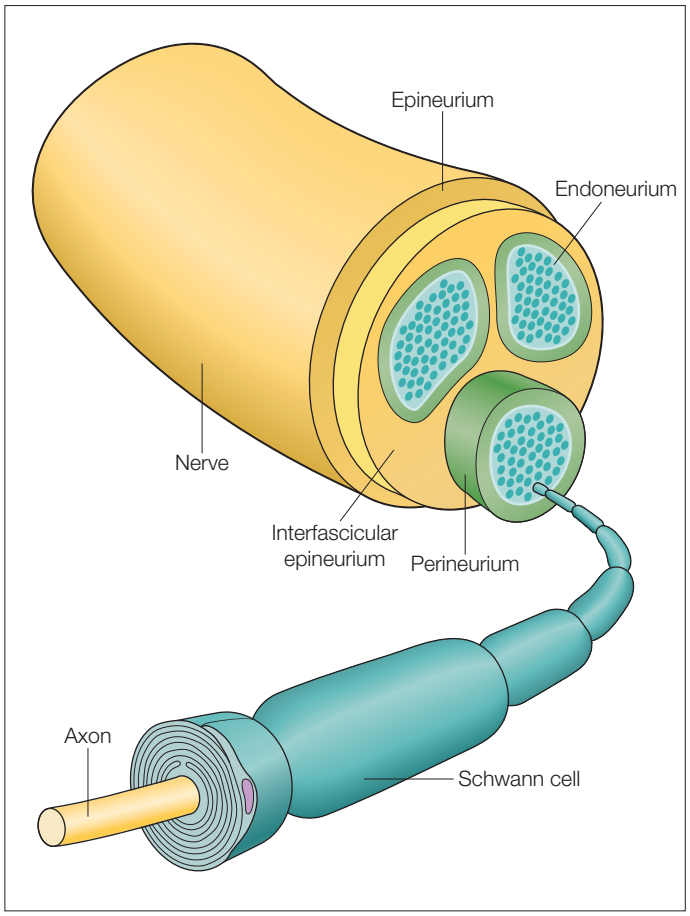

Fig. 23.1 Illustration of peripheral nerve with nerve fascicles containing bundles of axons, each wrapped with Schwann cells. The perineurium surrounds each fascicle and the epineurium surrounds the entire nerve.

Neurofibromatosis (NF1 and NF2)

Most pediatric neurogenic tumors may be associated with one of the seven neurofibromatoses. These syndromes are caused by specific gene mutations and are characterized by various cutaneous pigmentary disorders, and peripheral or central nervous system benign and malignant neurogenic tumors. They are discussed in detail in Chapter 68, but features of the two most common variants, NF1 and NF2, are summarized here.

NF1 (von Recklinghausen disease) is an autosomal dominant genetic disorder occurring in 1 in 2600 births, and is due to a mutation in the *NF1* gene at chromosome 17q11.[9] Cutaneous lesions are the first manifestations and include multiple café-au-lait macules, axillary freckles, iris Lisch nodules and neurofibromas.[10] Sphenoid wing bone anomalies and optic pathway gliomas (occurring in 15% of NF1 patients) appear by the age of 3 years. Malignant transformation of tumors may occur in late adolescence or adulthood.[11]

NF2 is a much rarer autosomal dominant genetic disorder caused by abnormalities in the *NF2* gene on chromosome 22[12]; this gene produces merlin, a tumor suppressor protein, and affected individuals are predisposed to various nervous system neoplasia including bilateral vestibular schwannomas, intracranial and optic nerve sheath meningiomas, and spine tumors.[13]

Optic pathway gliomas

Pathogenesis

Optic pathway gliomas (OPG) are pilocytic astrocytomas arising from astrocytes within the optic nerve or its surrounding pial layer.[14] Anterior OPG involve the intraorbital or intracanalicular optic nerve, while posterior OPG involve the chiasm or post-chiasmal radiations near the hypothalamus.

Although some have suggested they are hamartomas based on their benign behavior, most consider them to be neoplastic as they are histologically indistinguishable from other intracranial pilocytic astrocytomas and they can behave aggressively. Also, BRAF-KIAA and other chromosomal deletions associated with tumor suppression genes have been identified in sporadic tumors.[15]

Epidemiology

Optic pathway gliomas comprise 2% of cerebral gliomas. They occur primarily in children; 90% have been identified before the age of 20.[16] Thirty percent are associated with NF1 and usually appear early in childhood involving the anterior pathway.[6] A small number are associated with NF2, but most occur sporadically.

Clinical presentation

Orbital optic nerve gliomas are slow-growing masses typically presenting in early childhood with proptosis or globe displacement, often first noticed by the parents or relatives. Strabismus and restriction in ocular ductions (particularly upgaze) may develop with growth of the tumor (Fig. 23.2A). Decreased central, color, and peripheral vision may be detected on first presentation (Fig. 23.2B), and often deteriorate over time with growth of the tumor and gradual compression of the nerve or its blood supply. The child may be aware of diplopia but is often not as bothered by the loss of visual acuity. Occasionally corneal exposure or pressure on sensory nerves may cause discomfort or pain. Optic nerve edema and later pallor may develop with ensuing optic atrophy.[17]

In some cases, the clinical features may wax and wane over time, and even some large lesions have been reported to spontaneously involute (possibly as a result of resorption of cystic degeneration), so that several follow-up visits may be required to assess the behavior of a particular case.

Posterior pathway gliomas have no orbital findings, but present with visual disturbances, with bitemporal visual field defects for chiasmal lesions or hemifield loss for post-chiasmal lesions. Precocious puberty may develop in over a third of children with NF1-associated chiasmal gliomas.[18] Sporadic cases of posterior OPGs tend to present more with raised intracranial pressure and obstructive hydrocephalus.[19]

Investigations

Computed tomography (CT) scans

CT scans identify tubular optic nerve enlargement of the orbital portion of an optic nerve glioma, often with a characteristic kink or bend at the junction of the tumor with normal nerve.[20] Calcification within the tumor is considered to be evidence of slow growth and a lower grade histology. Clear zones within the tumor mass may be areas of cystic degeneration.

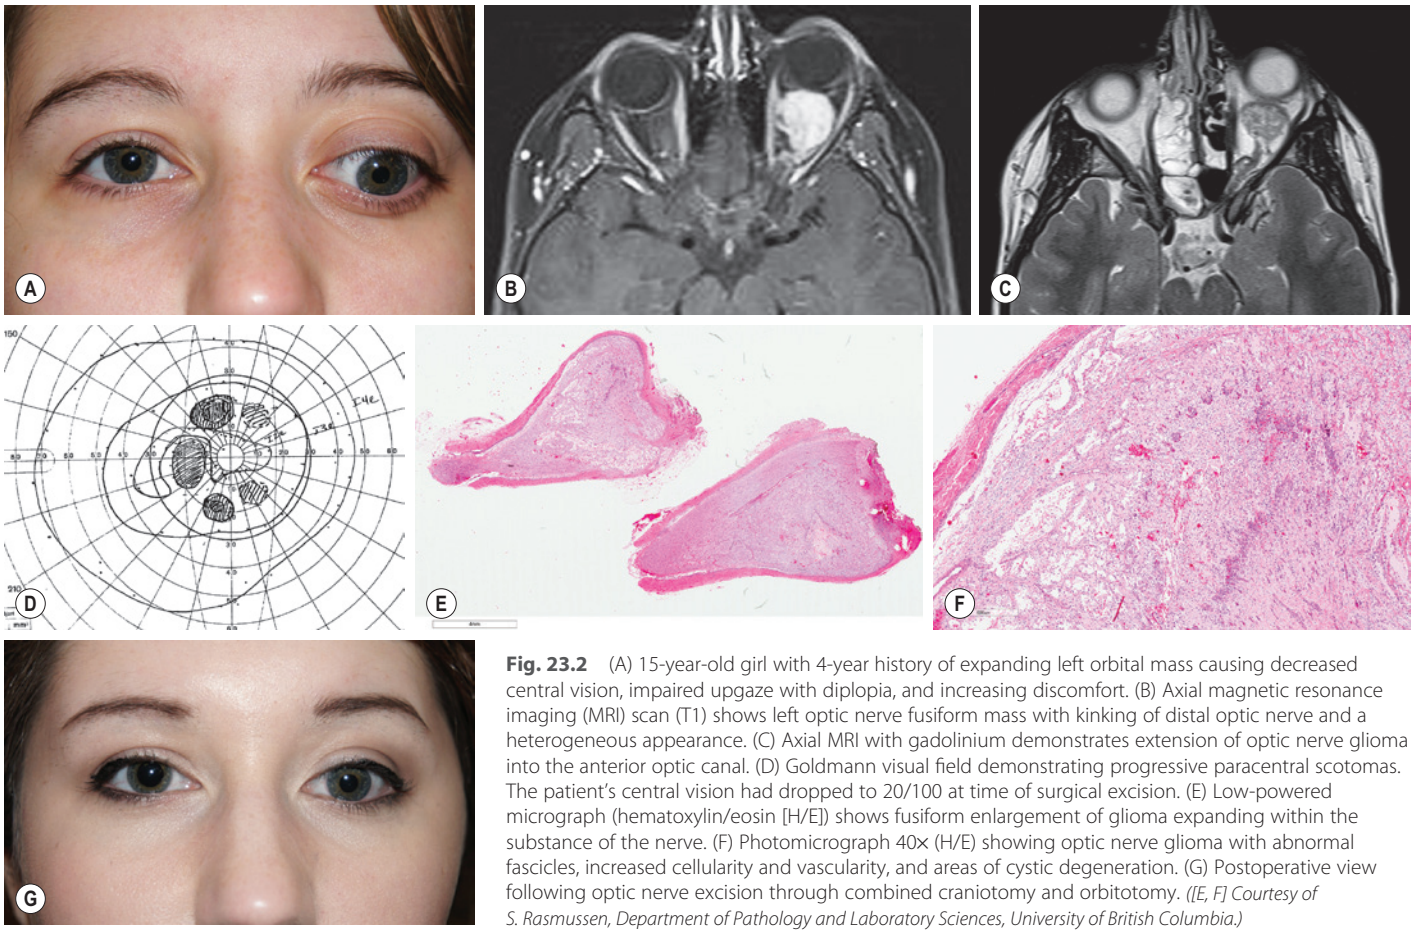

Fig. 23.2 (A) 15-year-old girl with 4-year history of expanding left orbital mass causing decreased central vision, impaired upgaze with diplopia, and increasing discomfort. (B) Axial magnetic resonance imaging (MRI) scan (T1) shows left optic nerve fusiform mass with kinking of distal optic nerve and a heterogeneous appearance. (C) Axial MRI with gadolinium demonstrates extension of optic nerve glioma into the anterior optic canal. (D) Goldmann visual field demonstrating progressive paracentral scotomas. The patient's central vision had dropped to 20/100 at time of surgical excision. (E) Low-powered micrograph (hematoxylin/eosin [H/E]) shows fusiform enlargement of glioma expanding within the substance of the nerve. (F) Photomicrograph 40× (H/E) showing optic nerve glioma with abnormal fascicles, increased cellularity and vascularity, and areas of cystic degeneration. (G) Postoperative view following optic nerve excision through combined craniotomy and orbitotomy. *([E, F] Courtesy of S. Rasmussen, Department of Pathology and Laboratory Sciences, University of British Columbia.)*

Bone erosion or remodeling within the optic canal may indicate presence or invasiveness of the glioma and are best seen with CT.[21]

Suprasellar tumors may extend into the optic nerves, or posteriorly into the optic tracts.

Magnetic resonance imaging (MRI) scans

MRI scans are the best modality to identify the extent of spread of tumor along the optic nerve or tracts and also helps delineate involvement of surrounding intracranial tissues including the hypothalamus (Fig. 23.2B,C).[22]

Visual fields

Visual fields are useful for following visual decline associated with these tumors (Fig. 23.2D).

Differential diagnosis

The differential diagnosis for pediatric orbital optic nerve masses includes primary optic nerve sheath meningiomas, optic nerve sarcoidosis, and leukemic infiltrates. Optic nerve meningiomas may have a more exophytic growth pattern and a more aggressive growth pattern in children. Their primary association with NF2 rather than NF1 may help in their differentiation. Optic nerve sarcoidosis is rare in children, appears as a more exophytic mass radiologically, and may be associated with elevated serum angiotensin-converting enzyme or hilar adenopathy identified on chest X-ray or CT scans. Leukemic infiltrates of the optic nerve may be ruled out with blood counts and lumbar puncture.[23]

The differential diagnosis for suprasellar masses includes craniopharyngioma, germinoma, sarcoidosis, and lymphoma. If MRI scan does not show evidence of optic nerve or tract involvement, these other choices are more likely than glioma, and biopsy is recommended.

Management

In most cases, management is decided through consensus of a multidisciplinary team including the ophthalmologist, pediatric oncologist, radiologist, radiation oncologist, and neurosurgeon.

Anterior (optic nerve) gliomas

Optic nerve gliomas restricted to the orbit are best observed with serial ocular examinations (checking for pain, visual disruption, cosmetic concerns, visual deterioration, exposure, or strabismus). Serial MR scans allow monitoring of tumor growth with particular attention to the speed of growth, and extension intracranially. The intervals between checks depends on the association with NF1 (these tend to progress more slowly than sporadic cases), proximity to the optic canal or chiasm, and the documented growth rate.[24]

Chemotherapy may be considered for progressive cases where vision remains good and the globe is not excessively displaced or exposed. Various combination therapies are available, including cycles every 3 weeks with vincristine in combination with carboplatin or cisplatin. Single therapy with vinblastine has also been described. This may delay progression of disease for several years, particularly in NF1-associated gliomas.[25]

Radiotherapy is avoided in patients with NF1 because of the risk of inducing malignant transformation of pre-existing peripheral nerve sheath tumors or new-onset rhabdomyosarcomas. It may be employed for progressive sporadic optic nerve gliomas that have failed chemotherapy, in order to avoid or delay surgery.[26]

Surgical excision of the optic nerve is the definitive treatment for optic nerve gliomas that are expanding in size with poor vision and significant cosmetic concerns, or pain from nerve compression, or corneal breakdown. This is typically performed by an orbital surgeon and pediatric neurosurgeon through a combined craniotomy and orbitotomy, with resection of the optic nerve from the back of the globe to the chiasm (Fig. 23.2E,F). A small portion of the nerve anterior to the chiasm may be spared to prevent a visual field defect on the opposite eye from von Willebrand's knee. Complications of surgery include transient or permanent facial nerve palsy (from the craniotomy) or oculomotor or trochlear palsy from the orbital resection.

Posterior (intracranial) optic pathway gliomas

These lesions carry a worse prognosis and are more commonly seen in adults and non-NF1 patients.

Initial observation may be considered for younger patients with NF1 as these tumors are likely to grow more slowly. Surgery is indicated in cases of obstructive hydrocephalus with possible tumor resection and shunting. Chemotherapy is offered in younger children to delay or avoid the cognitive and endocrine side effects associated with radiotherapy around the chiasm.[27] Radiotherapy has shown efficacy at shrinking chiasmal OPGs, reducing obstructive hydrocephalus, improving vision, and delaying recurrences. In children less than 5 years of age, it carries significant morbidity from cognitive impairment and endocrine disruption. Stereotactic radiotherapy and proton beam therapy may improve accuracy of treatment with fewer side effects.[28]

Prognosis

Although gliomas in adults follow a very aggressive course similar to a malignant glioma, in children they follow a generally indolent course, particularly NF1-associated gliomas, which tend to involve the anterior nerves alone. In most cases of optic nerve glioma, the tumor progresses slowly, and management ranges from observation through chemotherapy and ultimately surgery. In some cases, spontaneous improvement has been reported. While vision is sacrificed in surgery, the cosmesis is usually restored with globe-sparing surgery and subsequent strabismus repair if needed, and median survival is 15 years (Fig. 23.2G).

Chiasmal gliomas have a worse prognosis, often requiring chemotherapy, radiotherapy, and surgery. However, if associated with NF1, these tumors may also stabilize or even regress spontaneously.

Primary optic nerve meningiomas

Pathogenesis

Primary optic nerve meningiomas arise from arachnoid cap cells within the optic nerve dural sheath; tumors typically expand within the sheath, compressing the underlying optic nerve, but eventually grow through the dura.[29]

They are distinguished from secondary orbital meningiomas, which expand into the orbit from intracranial meningiomas, usually through the posterior and lateral bony walls.

Epidemiology

Primary optic nerve sheath meningiomas account for 20% of all orbital meningiomas. The majority occur in adults with a mean age of presentation in the fourth decade. However, 25% occur in children, usually associated with NF2.[13] Those occurring in children behave more aggressively. There is a strong male preponderance in children.[30]

Clinical presentation

These lesions are characterized by progressive, painless vision loss. Transient visual obscurations may be an initial symptom, although depending on the age of the child, this may not be reported.

Anterior lesions are usually associated with proptosis, while apical lesions may develop fullness in the temporal fossa or impaired ocular motility because of hyperostosis within the lateral and posterior orbital bone.

Most cases are unilateral, although bilateral cases may occur in those associated with NF2.[31]

Investigations

CT scans

CT is often the initial imaging modality and best shows degenerative calcification, if present. Meningiomas enhance with contrast but may be missed on non-contrast CT scans. Extension into the optic canal may cause widening of the canal or surrounding hyperostosis.[32]

MRI scans

MRI is best suited to identify posterior extension. Gadolinium scans on T1 fat-suppressed images show homogeneous enhancement of the lesions while T2-weighted fat-suppressed scans may demonstrate distension of the arachnoid space between the tumor and the posterior globe because of impaired cerebrospinal fluid flow from tumor blockage (Fig. 23.3A,B).[33]

Growth patterns are most commonly tubular (expansion parallel to the optic nerve because of sheath confinement), exophytic (outpouching at the site of a break in the durad), and fusiform (oval shape as a result of a combination of the previous two patterns).

Differential diagnosis

The differential diagnosis and the means of distinguishing them was discussed in the preceding section on optic nerve gliomas.

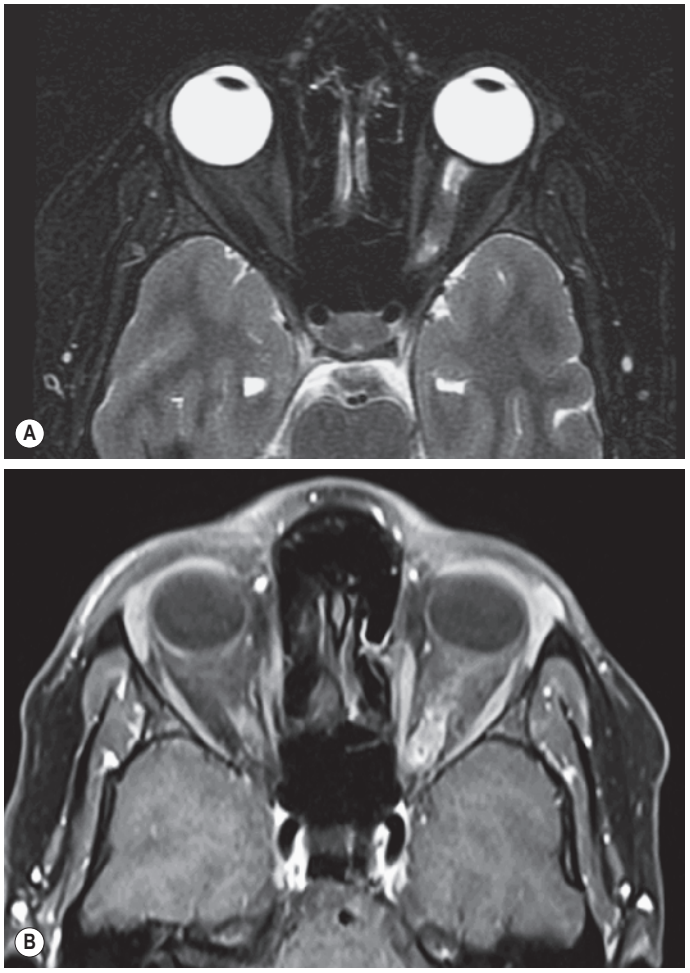

Fig. 23.3 (A) Magnetic resonance imaging (MRI) axial scan (T2) in a 24-year-old with neurofibromatosis type 1 and blind left eye from optic nerve meningioma. (B) MRI axial scan (T1 with gadolinium and fat suppression) shows a possible right subclinical apical meningioma.

Management

Conservative management

Conservative management with regular clinical and radiologic screening is recommended for cases with minimal vision loss and tolerable levels of proptosis. The ophthalmologist should assess for progressive visual loss (including central, color, and peripheral vision) or advancing proptosis.

Surgical biopsy is occasionally indicated where diagnosis is uncertain and specific conditions need to be ruled out. Sheath fenestration or excision of exophytic lesions have been tried with disappointing results.[34]

In cases of progressive posterior growth threatening intracranial spread or involvement of the opposite optic nerve, excision of the nerve with consequent loss of vision is recommended.

External beam radiotherapy or stereotactic radiotherapy

This modality may be employed as primary therapy and has been shown to delay growth of the tumor in adults.[35] It may also be used as an adjunct to excisional surgery, both pre- and postoperatively. In pediatric cases with NF2, it should be used with caution to avoid risk of malignant transformation of other nerve sheath tumors.

Orbital neurofibromas

Pathogenesis

Neurofibromas are benign peripheral nerve tumors composed of a mixture of Schwann cells, perineural cells, and fibroblasts. They typically grow within peripheral nerves and so are interspersed with axons separated by the tumor mass, a feature that distinguishes them from schwannomas histologically.[36]

They are classified by their pattern of growth: plexiform, isolated, or diffuse.

Epidemiology

Plexiform neurofibromas are the most common orbital subtype, usually manifest within the first decade of life, and are commonly associated with NF1.

Isolated neurofibromas (which may be solitary or multiple) may involve the skin of the eyelids and body, or grow along larger sensory, motor, and autonomic nerves. Solitary neurofibromas are most typically encountered in adults and typically are not associated with the neurofibromatoses.[37] However, multiple cutaneous neurofibromas are highly suggestive of NF1.

Diffuse neurofibromas infiltrate soft tissues and cause generalized hypertrophy: these occur rarely in the orbit, but should also raise suspicion for NF1.

Clinical presentation

Plexiform neurofibromas

These are poorly defined lesions commonly appearing early in the first decade of life, often involving the lateral third of the upper lid, temporal orbit, and temporal fossa. These poorly defined tumors are comprised of an infiltrating tangle of thickened peripheral nerves, with a characteristic ropy consistency like a "bag of worms." The overlying skin and eyelid tissue often becomes hypertrophic and stretched, and there may be an associated S-shaped mechanical ptosis with the risk of amblyopia, strabismus, and anisometropia in more than half of individuals with these lesions (Fig. 23.4A).[38,39] Proptosis, pulsatile enophthalmos, and temple swelling suggest orbital extension with underlying craniofacial bony abnormalities, including absence of the greater wing of sphenoid, and hypoplastic ethmoid and maxillary sinuses. Optic atrophy has been known to occur in severe cases.[39]

Isolated neurofibromas

Although common elsewhere in the body, they are relatively rare in the orbit, and very rare in children, unless an early manifestation (with reduced penetrance) of NF1.[38] Solitary tumors also present later in middle-aged adults but are slow growing, discrete, and well circumscribed on imaging. Patients may present with a mass, associated with local or radicular pain, or with sensorimotor neurologic symptoms and signs.

Diffuse neurofibromas

These rarely may diffusely infiltrate orbital fat or muscle but are uncommon in children unless associated with NF1.

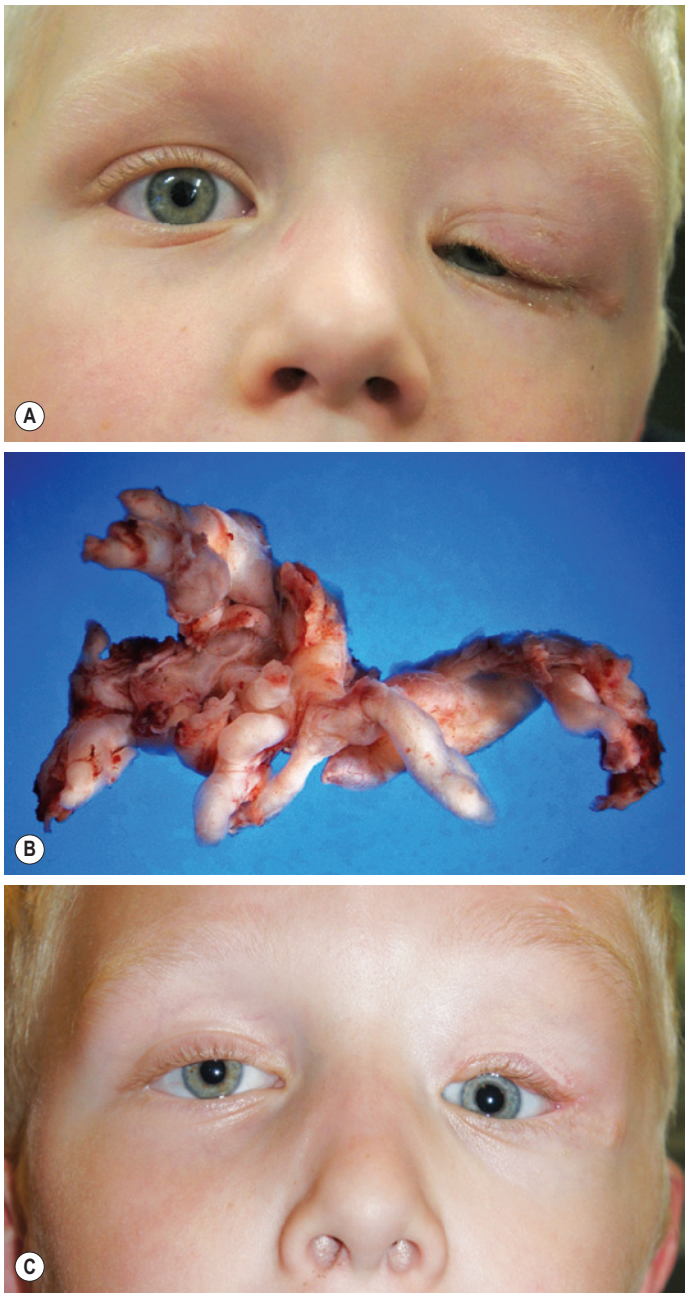

Fig. 23.4 (A) A 5-year-old boy with neurofibromatosis type 1 and plexiform neurofibroma of left upper lid and anterior orbit and temple. He developed amblyopia and patching was instituted. (B) Intraoperative surgical specimen of plexiform neurofibroma with a network of enlarged lacrimal branch of cranial nerve V sensory nerve. (C) Postoperative view following a debulking of tumor mass and horizontal shortening of lid followed at a later surgery with a frontalis sling (brow suspension).

Investigations

CT and MRI of plexiform neurofibromas show large multilobulated, poorly defined, irregular soft tissue infiltration of affected structures and neural tissue. Expansion of the tumor through the orbital fissures or through defects in the sphenoid wing may also be seen. Involvement of motor nerves may cause extraocular muscle enlargement. They are highly vascular and show enhanced signal on MR T2-weighted images.[40]

Isolated neurofibromas are well circumscribed and usually associated with a specific sensory or motor nerve.

Differential diagnosis

Orbital plexiform neurofibromas might be confused with infantile hemangiomas or possibly cutaneous lymphatic malformations. Infantile hemangiomas grow for the first 2 years and then involute, and are highly vascular on imaging. Lymphatic malformations wax and wane and are avascular, with cystic spaces on imaging.

Orbital discrete neurofibromas may be confused with schwannomas and perineuromas.

Management

A child with plexiform neurofibroma should be evaluated to identify the genetic cause, to determine other clinical manifestations, to identify pathology in family members, and to counsel the family about the syndrome.

Initial management is observation unless a lid lesion becomes cosmetically unsightly or there is a risk of occlusion amblyopia, or an orbital lesion expands to cause significant globe displacement.[41] Patching should be instituted to prevent amlyopia, and definitive treatment for strabismus delayed until the disease has stabilized.[39]

Surgical intervention is challenging because of the vascular and diffuse infiltrative nature of these lesions (Fig. 23.4B).[42,43] Debulking is often associated with significant bleeding and care must be taken to avoid damage to normal structures. Enlargement and mechanical stretching of the soft tissues of the eyelid may require surgical horizontal shortening. Damage to the levator muscle through tumor infiltration or aggressive surgery may result in significant ptosis requiring a frontalis sling (Fig. 23.4C). Lesions in the orbit and temporal fossa or forehead may be debulked, but care must be taken to avoid damage to frontalis and temporal branches of the facial nerve.

Multiple sequential surgeries may be required and the results are often suboptimal. In severe cases with significant globe displacement, enucleation or exenteration may ultimately be considered.[42,43]

Discrete orbital neurofibromas may be observed or surgically excised if they cause pain or significant proptosis, but anesthesia or paresthesia may ensue.

Orbital schwannomas (neurilemmomas)

Pathogenesis

These are well-defined, benign, solitary tumors arising from differentiated Schwann cells within the sheath of either orbital sensory or motor nerves. They are histologically characterized by two patterns: Antoni A (tight, compact bundles) and Antoni B (more random, looser, myxoid pattern). Verocay bodies (palisading nuclei) and a fibrous capsule incorporating the peripheral nerve may be identified. They contain less mucopolysaccharide than neurofibromas and are S100 protein positive. Degenerative changes, such as vessel hyalinization, hemorrhage, focal necrosis, and calcifications may be seen in chronic cases.

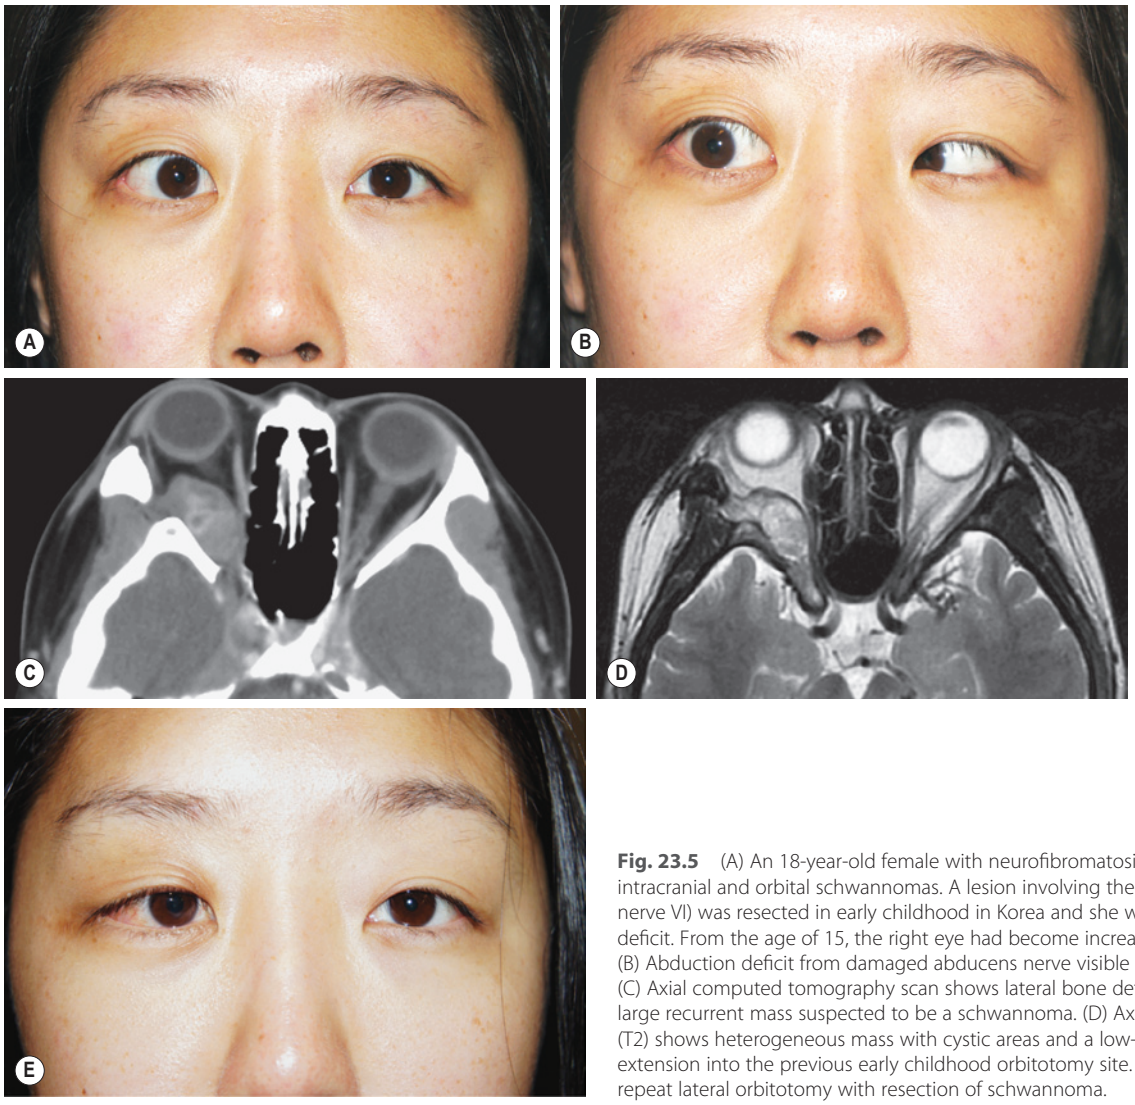

Fig. 23.5 (A) An 18-year-old female with neurofibromatosis type 2 and multiple intracranial and orbital schwannomas. A lesion involving the right abducens nerve (cranial nerve VI) was resected in early childhood in Korea and she was left with an abduction deficit. From the age of 15, the right eye had become increasingly proptotic again. (B) Abduction deficit from damaged abducens nerve visible with attempted right gaze. (C) Axial computed tomography scan shows lateral bone defect from previous surgery and large recurrent mass suspected to be a schwannoma. (D) Axial magnetic resonance imaging (T2) shows heterogeneous mass with cystic areas and a low-signal capsule, with an extension into the previous early childhood orbitotomy site. (E) One month following right repeat lateral orbitotomy with resection of schwannoma.

Epidemiology

While orbital schwannomas are more common in adults than neurofibromas, constituting 3% of orbital neoplasia, they are relatively rare in childhood. They typically arise between 20–50 years of age. They may be associated with NF2 (where bilaterality or multifocal lesions may be seen) and less commonly with NF1. Most arise from the trigeminal sensory nerve, with a propensity for the superior and lateral orbit, sometimes extending through the superior orbital fissure into the cavernous sinus.[42]

Clinical presentation

Schwannomas are slow growing and non-invasive masses. Early signs may include proptosis, globe displacement and lid swelling (Fig. 23.5A). Numbness or paresthesia from involvement of the first division of the trigeminal nerve has been reported; pain may occur with larger lesions. Involvement of the motor nerves or compression of nerves within the cavernous sinus may cause diplopia (Fig. 23.5B). Apical tumors may cause visual compromise or an orbital apex syndrome.

Investigations

Imaging confirms the suspicion of a discrete orbital mass, with the differential including other peripheral nerve sheath tumors (solitary neurofibroma), solitary fibrous tumor, or cavernous hemangioma.[40]

CT scans show a well-defined ovoid lesion, hypodense to muscle with mild enhancement to contrast (Fig. 23.5C).

MRI shows a signal intensity similar to muscle on T1-weighted scans and high intensity on T2-weighted scans (with low intensity in cystic spaces and in the surrounding capsule).[40] The peripheral nerve may be identified coursing adjacent to the tumor (unlike the neurofibroma that incorporates the nerve) and low-density cystic areas are more typical of schwannomas (Fig. 23.5D).

Visual fields are useful in documenting visual impairment and monitoring tumor progression.

Differential diagnosis

The differential diagnoses for Schwannoma include peripheral nerve sheath tumors (neurofibromas, perineurinoma, and

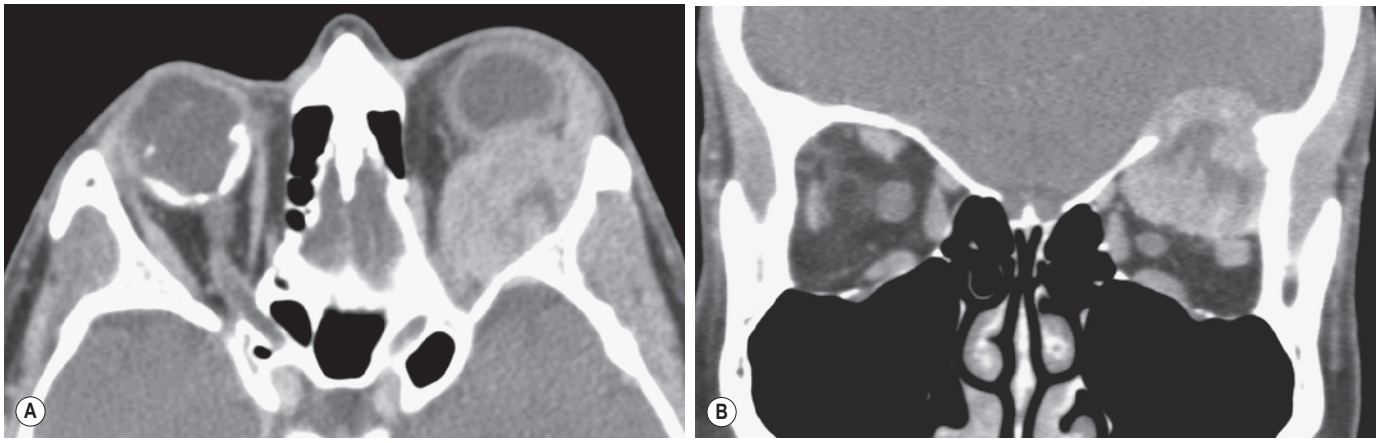

Fig. 23.6 (A) Axial computed tomography (CT) scan of a 35-year-old woman with neurofibromatosis type 1 and a malignant transformation of a plexiform neurofibroma of right thigh, present since age 5. She was treated with radiotherapy to the leg lesion in childhood. This peripheral nerve sheath sarcoma metastasized to her left orbit and brain. (B) Coronal CT scan shows extension through the orbital roof into the cranium.

malignant peripheral nerve sheath tumors), as well as other discrete encapsulated orbital lesions (solitary fibrous tumor, fibrous histiocytoma, cavernous venous malformation). In many cases, the diagnosis is only confirmed at time of biopsy.

Management

These well-circumscribed lesions may be observed clinically and radiologically, especially if small, asymptomatic, and difficult to reach surgically.

Tumors causing proptosis, discomfort, or visual compromise are best surgically removed. Care should be taken to dissect the lesion off important sensory or motor nerves, but often they may arise from small sensory branches, so that sensory loss may be minimal even if the associated nerve is damaged. Dissection into the superior orbital fissure may require careful piecemeal removal (Fig. 23.5E).[44,45]

Prognosis

Prognosis after surgical resection is good, although recurrences may occur if the tumor is only partially removed.[45,46] Malignant transformation is rare and occurs only in adults.

Perineurioma

Perineuriomas are tumors arising from perineurial cells, and so are most commonly seen growing extraneurally within the orbit. Their fusiform shape and contiguity with peripheral nerves makes them indistinguishable from schwannomas, so they are usually only diagnosed histologically. They are most common in young adults (20–30 years old). Surgical excision is recommended for neurologic compromise or pain.[47]

Peripheral nerve sheath malignancies (PNSM)

Pathogenesis

PNSM are malignant sarcomas arising from peripheral nerve cells: they may arise *de novo* or from pre-existing plexiform neurofibromas, schwannomas, perineuriomas, or secondary to radiation therapy.[48–50] Orbital PNSM usually arise from major nerve trunks, such as the trigeminal nerve and its branches.[51]

Typical histopathology shows highly cellular, spindle cells with cytologic atypia and necrosis.[52] Immunohistochemistry reveals positivity for S100, CD56 (myelin basic protein) and p53. BRAF V600E mutations[53] and somatic mutations of *SUZ12*[54] have been identified in certain cases.

Epidemiology

Orbital PNSM are rare. Cases have been reported in children as young as 2 years of age, but most occur in adults. Roughly 50% are associated with NF1, often with an earlier onset of disease.[55,56]

Clinical presentation

Orbital PNSM may present with periorbital swelling, proptosis, and radicular pain that may be associated with hypo- or hyperesthesia. PNSMs associated with NF1 can also present as a rapidly expanding orbital mass over several months. Involvement of the eyelid has also been reported.[57]

Investigations

Imaging features for PNSMs are similar to other orbital peripheral nerve tumors.

CT scans show a heterogenous intraorbital mass with potential invasion through bone into sinus or brain (Fig. 23.6A,B). CT body scans help identify distant metastases.

MR scans demonstrate heterogeneity with low-to-intermediate signal intensity on T1-weighted imaging and high intensity on T2-weighted scans. Margins may be ill-defined.

Management

Treatment of these aggressive tumors is with exenteration of the orbit, sometimes requiring a combined craniotomy to resect intracranial extension. Adjuvant chemotherapy and radiotherapy are often offered, but their benefit remains unproven.[58,59]

Paragangliomas

These are very rare, slow-growing, large tumors arising from mature sympathetic ganglion cells. Few orbital cases have been reported in the literature.[5] They usually present as encapsulated large tumors in adolescent children or adults, with a female preponderance.

Orbital involvement is often heralded with proptosis or occasionally pupil abnormalities from ciliary ganglion dysfunction. Treatment is surgical excision.

General points

Rhabdomyosarcoma (RMS) is a highly malignant neoplasm that can develop in children or adults. This is the most common soft tissue sarcoma of the head and neck in children and represents 5% of childhood cancers.[1–10] RMS can occur in any anatomic location of the body where there is skeletal muscle, as well as other sites without skeletal muscle, such as the soft tissues of the orbit. The primary sites of RMS include head and neck (including orbit, 40%), genitourinary tract (20%), extremities (20%), trunk (10%), and others (10%).[10]

The ocular region, particularly the orbital soft tissues, is an important anatomic location for RMS, which is the most common primary orbital malignancy of childhood.[5,6] In rare instances, RMS has been known to arise in the eyelid, conjunctiva, and the intraocular structures.[2,3] Furthermore, this malignancy can invade the orbit as a metastatic tumor from a distant location or secondarily extend in the orbit from an adjacent primary neoplasm in the paranasal sinuses. In a clinical series of 1264 patients with orbital tumors in children and adults, there were 35 cases (3%) of orbital RMS, but this accounted for 97% of myogenic tumors.[5]

Orbital RMS generally occurs in the first two decades of life with a mean age at diagnosis of 8 years; however, orbital RMS has been observed in adults and has occurred as a second cancer following treatment of primary retinoblastoma.[2–4]

Prompt diagnosis and treatment by the ophthalmologist can save the life of the affected patient. Therefore, eye care physicians should be aware of this tumor, recognize the clinical features, and refer the patient for immediate treatment.

Clinical features

The clinical features of orbital RMS include proptosis (80%), globe displacement (80%), blepharoptosis (55%), conjunctival swelling (60%), and eyelid edema (60%)[1–4] (Figs 24.1–24.3) More advanced cases show downward and lateral displacement of the globe due to the typical superior or superonasal location of the mass.

Ophthalmoscopy can occasionally reveal choroidal folds, retinal venous tortuosity, and optic disc edema. Pain is an uncommon symptom and usually occurs in more advanced cases. Visual impairment is usually minimal unless the tumor becomes advanced. In regions where medical care is not readily available, RMS can attain immense proportions and destroy the eye.

Diagnostic approaches

Any child in the first two decades of life who presents with symptoms and signs of an orbital mass should be evaluated for RMS. The child should have a detailed history, office examination, and imaging studies, particularly computed tomography (CT) or magnetic resonance imaging (MRI).

Computed tomography

Computed tomography is important in the assessment of children with suspected RMS, particularly for the detection of bony involvement by the tumor. With CT, the tumor appears in the early stages as a well-circumscribed, homogeneous, round-to-ovoid mass that is isodense to muscle.[1–4] It is usually extraconal in location and most often found in the superonasal aspect of the orbit. It is usually confined to the orbital soft tissues and does not appear to arise from the extraocular muscles or bone, although it can often cause displacement of the rectus muscles. In general, the smaller tumors do not invade bone, but larger ones can occasionally erode bone and

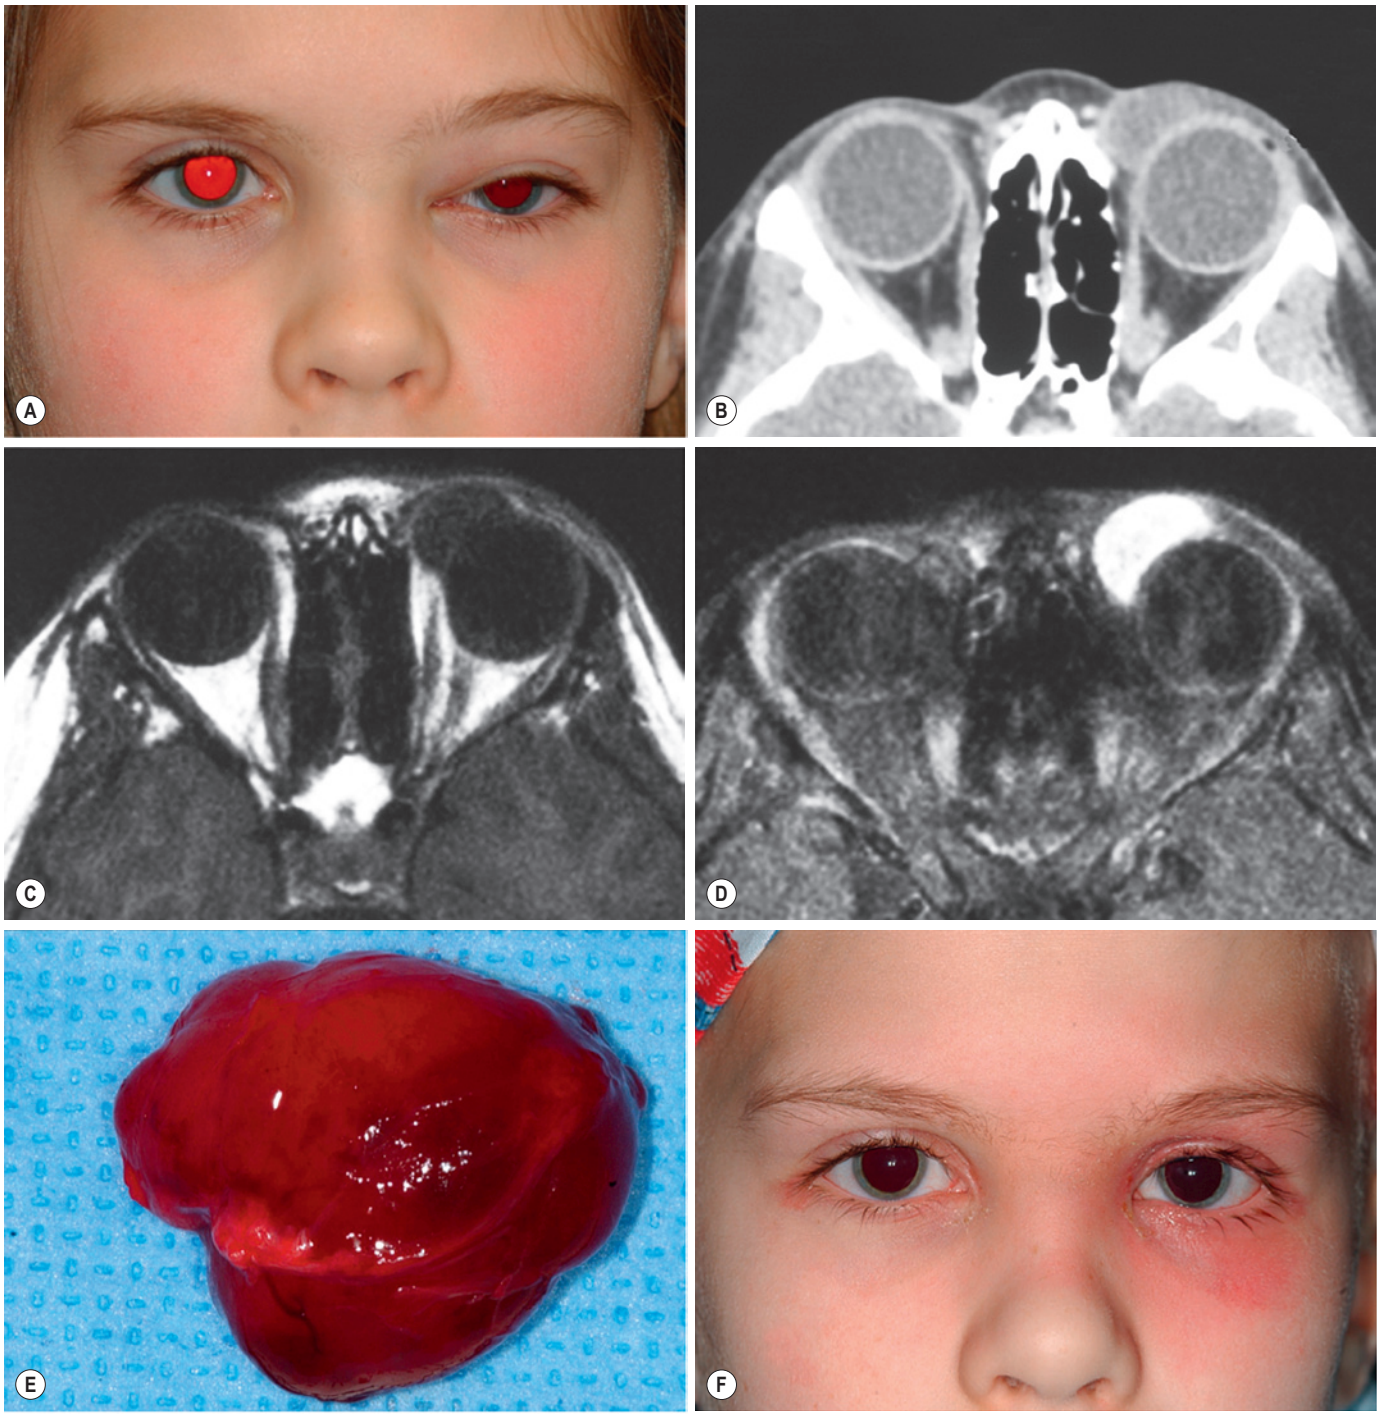

Fig. 24.1 Orbital rhabdomyosarcoma in a young girl. (A) Facial appearance showing downward displacement of left eye. (B) Computed tomography showing solid mass in orbit superonasally. (C) Magnetic resonance imaging (MRI) in T1-weighted image without enhancement depicting circumscribed orbital mass. (D) MRI in T1-weighted image with gadolinium showing uniform enhancement of the malignancy. (E) Circumscribed tumor after surgical excision. (F) Slight erythema of periocular skin following radiotherapy.

extend into the sinuses or nasopharynx. Orbital RMS shows moderate to marked enhancement with contrast agents.

Magnetic resonance imaging

MRI is a valuable method for diagnosis of soft tissue tumors and surgical planning for treatment. With T1-weighted MRI images, the tumor appears as a round-to-ovoid mass that is most commonly located in the orbital soft tissue superonasally. RMS typically has a hypointense signal with respect to orbital fat, but is isointense with respect to extraocular muscles. RMS generally shows moderate to marked enhancement with gadolinium and is best delineated with fat suppression techniques.[1–4] On T2-weighted images, RMS is hyperintense to extraocular muscles and orbital fat. It is usually noncystic, but rare cavitary RMS can resemble a cystic lesion.

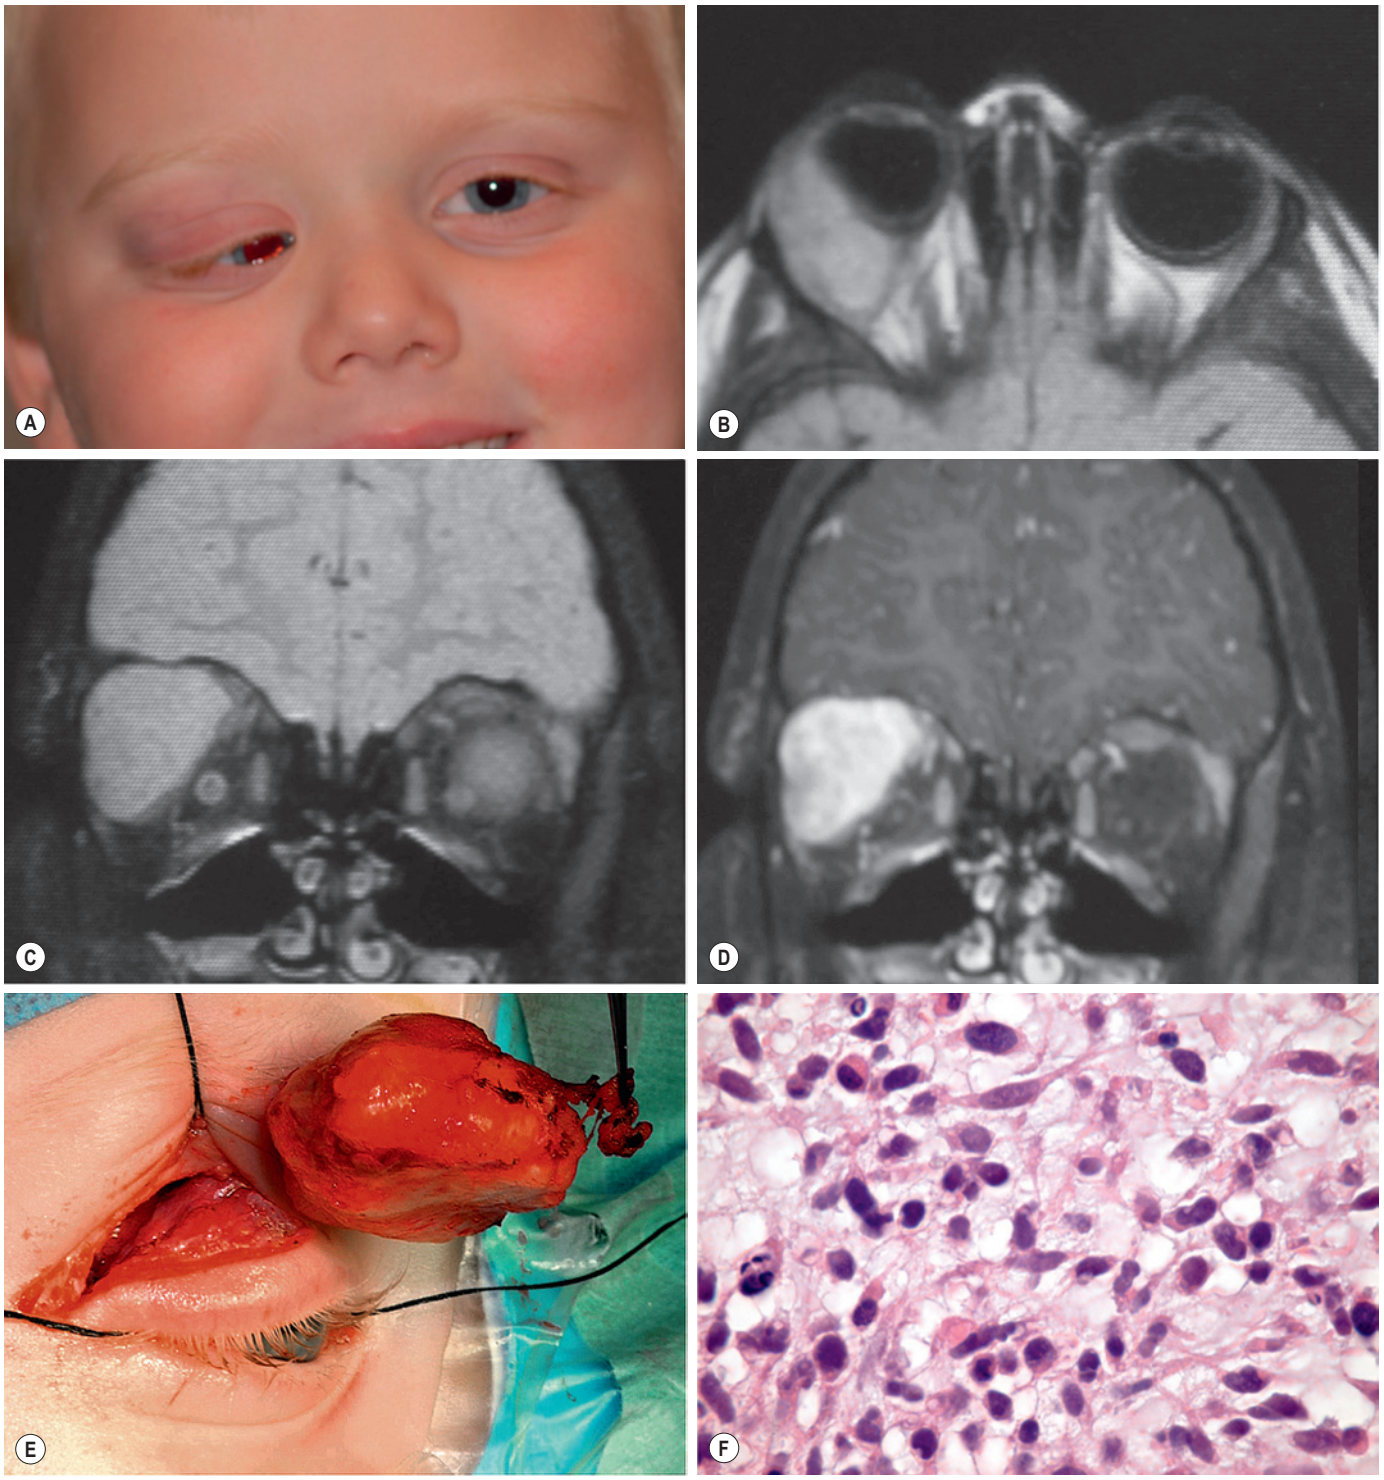

Fig. 24.2 Orbital rhabdomyosarcoma in a young boy. (A) Facial appearance showing proptosis and downward and medial displacement of right eye. (B) Axial magnetic resonance imaging (MRI) showing large superotemporal orbital mass. (C) Coronal MRI showing superotemporal mass. (D) Coronal MRI after gadolinium enhancement showing uniform enhancement of the vascular malignancy. (E) Tumor removed by superolateral orbitotomy. (F) Histopathology showing malignant elongated strap cells and round cells, consistent with orbital rhabdomyosarcoma.

Biopsy

A complete excisional biopsy is preferred in cases of suspected RMS in order to establish the diagnosis and minimize adjuvant therapy. Excisional or incisional biopsy can be considered, depending on the degree of involvement. Care is made to avoid local dissemination of tumor cells with incisional biopsy. Occasionally, fine-needle aspiration biopsy (FNAB) is performed to establish the diagnosis and avoid open surgery.

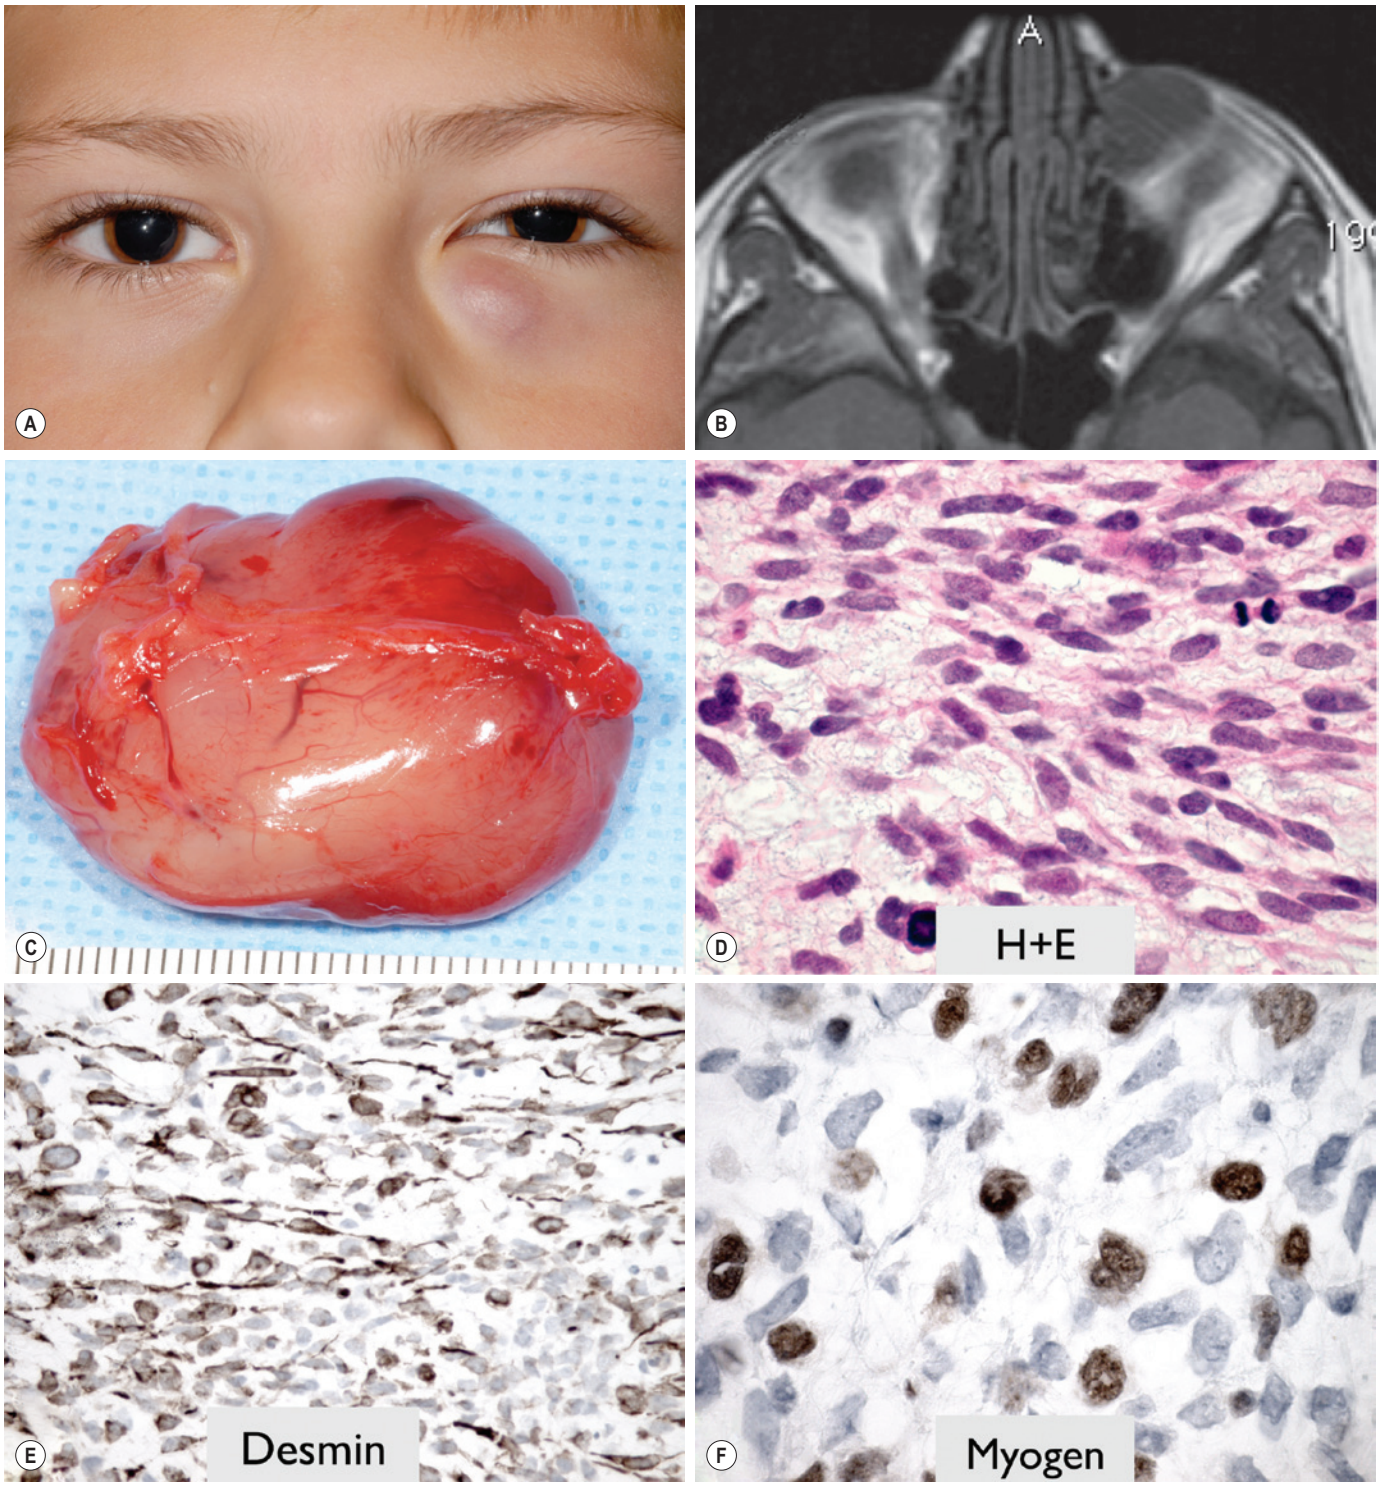

Fig. 24.3 Orbital rhabdomyosarcoma following trauma. (A) Facial appearance showing presumed, traumatic hemorrhagic mass below left lower eyelid. (B) Axial magnetic resonance imaging (MRI) showing low signal inferonasal orbital mass. (C) At surgery the mass was excised completely. (D) Histopathology revealing spindle-shaped cells (hematoxylin and eosin, ×150). (E) Special stain revealing positive desmin stain (×100). (F) Special stain revealing positive myogen stain (×250).

Pathology

Orbital RMS probably arises from primitive pluripotential mesenchymal cells with a propensity to differentiate toward skeletal muscle. Several histopathologic variations of RMS occur in the orbit. Generally, RMS is classified into four major subtypes including embryonal (57%), alveolar (19%), botryoid (6%), and pleomorphic (1%), with the remainder too undifferentiated (10%) or heterogenous (7%) for classification.[1–4,11] The embryonal type is most common, whereas the alveolar type appears to be the most malignant.

Embryonal RMS is characterized histopathologically by spindle-to-round cells that show features of skeletal muscle in various stages of embryogenesis.[11] The predominant cell is an elongated spindle cell that can assume a variety of arrangements and degree of differentiation. The cytoplasm is generally eosinophilic, and cross-striations can sometimes be identified on routine histopathologic sections or with special stains. The alveolar type appears as loosely arranged, malignant cells with septae that are reminiscent of the pulmonary alveoli. The botryoid type may be a variant of the embryonal type that assumes a papillary configuration.

Immunohistochemical studies have provided assistance in the confirmation of RMS and in the differentiation from other spindle cell tumors. Immunohistochemical markers include antibodies against desmin, muscle-specific actin, and myogen (myoglobin) that typically show positive reaction to RMS, but negative reaction to other round or spindle cell tumors (Fig. 24.3).

Classification

Intergroup rhabdomyosarcoma study

In 1972, the Intergroup Rhabdomyosarcoma Study Group (IRSG) was established to increase knowledge and to improve therapeutic results for RMS. Over the past four decades, several treatment protocols have been tested in multicenter trials, and dramatic improvements in patient outcomes have been achieved as a result of these trials.[12–20] Following biopsy, the patient is staged according to the IRSG classification (Table 24.1) and therapy with chemotherapy plus possible radiotherapy is provided. Slightly modified therapeutic protocols are delivered according to the European Pediatric Soft Tissue Sarcoma Study Group (EpSSG) and, more recently, the Soft Tissue Sarcoma Committee of the Children's Oncology Group.[21–23]

AJCC classification

The American Joint Committee on Cancer (AJCC) classification of orbital sarcoma (including RMS) has been introduced. This classification depends on tumor (T), node (N), and metastasis (M) localization. For the AJCC clinical classification of RMS see Table 24.2.

Management

Historical aspects

Until the late 1960s, orbital exenteration was considered the treatment of choice for orbital RMS. It was believed that complete surgical removal of the tumor would offer the patient the best chance of survival. However, the mortality rate continued to be poor at 70% death rate in the early 1970s. Subsequently, as a result of the IRSG, there has been major improvement in diagnosis and treatment of orbital RMS. Education of physicians, use of CT and MRI, and better treatment protocols have been introduced for improved survival. Currently, over 90% of patients with orbital RMS demonstrate survival at mean 8 years follow up.[1–10]

Table 24.1 Intergroup Rhabdomyosarcoma Study Group (IRSG) staging classification

Group	Description	Treatment
I	Completely resected localized disease with gross and microscopic confirmation of complete resection and absence of regional lymph node involvement	VA × 32 weeks
Ia	Confined to muscle or organ of origin	
Ib	Contiguous involvement outside the muscle or organ of origin	
II	Residual disease and/or regional lymph node involvement	VAC × 32 weeks plus 3600 cGy CFI
IIa	Grossly resected localized tumor with microscopic residual disease and no evidence of gross residual tumor or regional lymph node involvement	
IIb	Completely resected regional lymph node and no microscopic residual tumor	
IIc	Grossly resected regional lymph nodes with microscopic residual tumor	
III	Incomplete resection with gross residual disease	VAC × 52 weeks plus 4500 cGy CFI or VAI × 52 weeks plus 4500 cGy HFI or VIE × 52 weeks
IV	Distant metastatic disease present at onset	Management based on metastatic site

A, Actinomycin D; C, cyclophosphamide; CFI, conventional fractionated irradiation, E, etoposide, HFI, hyperfractionated irradiation; I, ifosfamide; V, vincristine.

Table 24.2 The American Joint Committee on Cancer (AJCC) clinical classification of rhabdomyosarcoma

Clinical feature	Tumor
Tx	Tumor cannot be assessed
T0	Tumor not evident
T1	Tumor ≤15 mm in greatest dimension
T2	Tumor >15 mm in greatest dimension and without invasion of globe or bony wall
T3	Tumor any size with invasion of orbital tissues and/or bony walls
T4	Tumor invasion of globe, eyelids, temporal fossa, nasal cavity, paranasal sinuses, and/or central nervous system
Nx	Regional lymph node cannot be assessed
N0	Regional lymph node metastasis absent
N1	Regional lymph node metastasis present
M0	Distant metastasis absent
M1	Distant metastasis present

Surgery

The diagnosis of orbital RMS is based on histopathologic findings following surgery. The ultimate goal of surgery is complete removal of the tumor intact; however, that is not always possible, especially when the tumor is large and invasive into normal orbital structures. The excised tissue should be submitted immediately for routine histopathologic examination and special immunohistochemical staining. The orbital surgeon should decide on the approach to biopsy and preferably do a complete excisional biopsy, if possible, to confirm the diagnosis, debulk the mass, and promptly refer the patient to a pediatric oncologist where further management is decided based on tumor stage and published protocols. This often involves a collaborative decision by the ocular oncologist, pathologist, pediatric oncologist, and radiation oncologist, preferably following the guidelines of IRSG. The surgical method of orbital exenteration is rarely used as a primary treatment, but can be utilized if there is recurrent deep tumor.

Chemotherapy

Chemotherapy is the first line of treatment for children with orbital RMS. The exact regimen varies depending on the IRSG stage and involves agents including vincristine, actinomycin D, cyclophosphamide, etoposide, or ifosfamide.[12–23] These agents are generally prescribed for 32–52 weeks.

Radiotherapy

External beam radiotherapy, proton beam radiotherapy, or intensity-modulated radiotherapy are considered for patients with IRSG stages II, III, and IV (see Table 24.1). The use of radiotherapy is controversial and varies from center to center, depending on the stage of disease. The radiation dose has varied from 3600 cGy to 4500 cGy or more and can be associated with short-term and long-term ocular complications. Irradiation is often necessary following orbital exenteration for tumor recurrence after standard irradiation and chemotherapy have failed to control the tumor.

Prognosis

Orbital RMS is a highly aggressive, fast-growing malignancy with tendency for local invasion and remote metastases to lung, lymph nodes, and other sites. However, using modern therapeutic regimen described above, the survival has improved. Today, the survival is greater than 95% for orbital RMS.[1–4] Factors responsible for the better prognosis for RMS in the orbital region include a more favorable anatomic location, earlier stage of disease at detection, more favorable tumor morphology, and perhaps patient age. Overall survival at 5-year follow-up is 92% and at 10 years is 87% for stages I, II, and III.[8]

Summary

RMS is the most common primary orbital malignancy of childhood. It requires prompt diagnosis and treatment. This tumor most commonly occurs in the first two decades of life, at which time the patient develops rapidly progressive proptosis and displacement of the eye. The tumor can arise primarily in the orbit or it can arise in the adjacent sinuses or nasal cavity and secondarily extend to involve the orbit.

Orbital RMS probably arises from primitive pluripotential mesenchymal cells with a propensity to differentiate toward skeletal muscle. Several histopathologic variations of RMS occur in the orbit. The embryonal type is most common whereas the alveolar type appears to be the most malignant.

Ophthalmologists should be aware of the clinical features of RMS and understand the need for high-quality imaging studies to determine the extent of the disease. A carefully planned biopsy should be performed with tumor confirmation on histopathology and staging according to the IRSG protocol. Collaboration with pediatric oncologists and radiation oncologists to plan therapy is advised.

REFERENCES

Rhabdomyosarcoma is discussed in Chapter 24. Every mesenchymal component of the orbit can give rise to sarcomatous tumors, but these are exceedingly rare and will not be discussed. Nevertheless, they are part of the differential diagnosis of rhabdomyosarcoma.

Dysplasias

Fibrous dysplasia of the orbit

Fibrous dysplasia (FD) is a rare benign disorder, characterized by the replacement of normal bone by a cellular fibrous stroma containing islands of immature bone and osteoid, which does not remodel along lines of stress into lamellar bone. It has no predilection for either gender. It has been reported in infancy[1] but usually presents in childhood; its onset is insidious and it may remain asymptomatic until adulthood. Progression usually slows in the second or third decade, when "bone maturity" is reached, although growth may continue into the fourth decade in some cases. It is important to distinguish it from meningioma[2] and osteosarcoma.

FD may be confined to a single site (monostotic form) that tends to occur after the late teens. Conversely, the rarer polyostotic form, which involves multiple bony sites, tends to occur in childhood and stabilizes around puberty. Polyostotic FD co-existing with cutaneous pigmentation and endocrine abnormalities constitutes the McCune–Albright syndrome.[3] FD is a non-inheritable disorder caused by missense mutations occurring post-zygotically. Activating *GNAS* complex mutations on chromosome 20 result in upregulation of osteoclast function, causing excessive bone resorption and dysplastic fibrous growth.[4] The GSα mutation can be tested for in peripheral blood.[5]

Clinical features

Three-quarters of patients with orbital FD have the monostotic form affecting several contiguous bones but the disease usually remains unilateral. The craniofacial area is affected in 20% of patients, with a predilection for the frontal, sphenoid, and ethmoid bones. Typically, there is a painless, firm, bony swelling with contour distortion; in the orbit, there is an accompanying mass effect. The clinical presentation depends on the predominant wall involved, most commonly the roof, resulting in proptosis and downward displacement of the globe and orbit.[6,7] The lacrimal fossa may be affected, mimicking a lacrimal gland tumor.[8] Maxillary disease (Fig. 25.1) displaces the eye upwards, with persistent epiphora if the nasolacrimal duct is affected.[9] Sphenoid involvement results in optic nerve compression[6,7] from narrowing of the optic canal (Fig. 25.2) or by an associated sphenoid sinus mucocele.[10] Rarely, involvement of the sella turcica may result in chiasmal compression.[11] Other uncommon neuro-ophthalmic complications include cranial nerve palsies,[12] trigeminal neuralgia, raised intracranial pressure, and papilledema.[12,13] Extensive craniofacial involvement can result in severe cosmetic deformity. Pain may occur, either localized or as a diffuse ipsilateral headache. Visual loss is not uncommon.[6,14] Malignant transformation to osteosarcoma, fibrosarcoma, chondrosarcoma, and giant cell sarcoma occurs in 0.5% of cases, increasing to 15% if there has been previous radiotherapy.[14] The accompanying signs are rapid progression, worsening pain, and infiltration of surrounding structures.

The main radiographic feature of FD is expansion of bone. The lesions may be sclerotic, with a dense ground-glass homogeneity, lytic, with increased lucency, or show a mixed picture with alternating areas of lucency and increased density. Most orbital cases are easily diagnosed since they are sclerotic.[6] The main radiologic differential diagnosis includes histiocytosis-X, hyperostotic meningioma, Paget disease (both rare in children), and some bone tumors. On magnetic resonance imaging (MRI) there is a correlation between T1 and T2 signal intensity and clinical and pathologic activity of the lesion.[15] Occasionally, large cystic lesions form in the orbital wall.[6] These may contain blood (Fig. 25.3) and necrotic debris and can be mistaken for aneurysmal bone cysts.[14] Involvement of a neighboring sinus may mimic mucocele.[14,16] Computed tomography (CT) scanning with the possible addition of MRI is the best modality to evaluate the extent of cranial and orbital involvement. The optic canal and chiasm should be assessed for signs of compression.

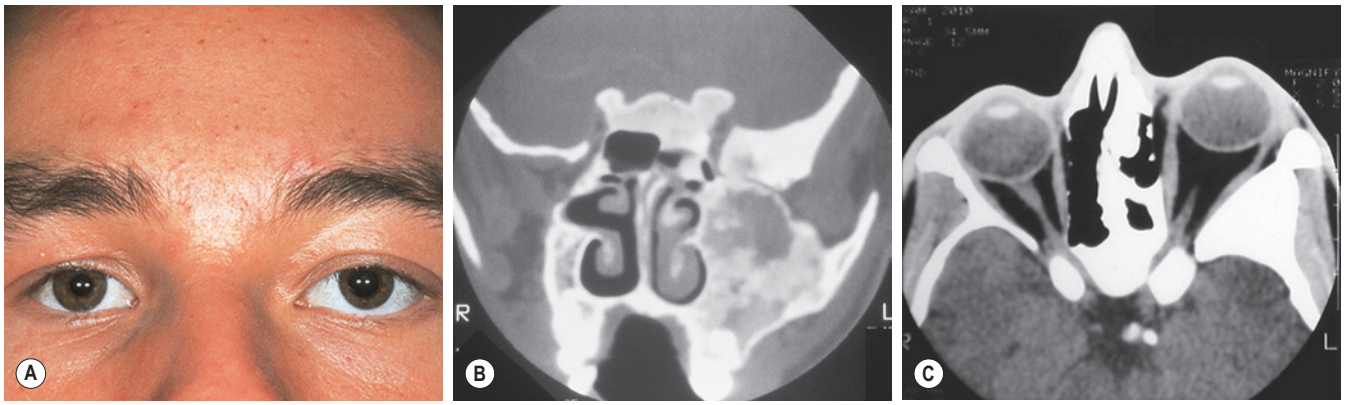

Fig. 25.1 (A) This 16-year-old presented with a history of progressive facial distortion and decreasing vision in the left eye to 20/40. Compressive optic neuropathy was diagnosed secondary to fibrous dysplasia. (B) Computed tomography (CT) scan of the same case showing cystic fibrous dysplasia involving the orbital apex. (C) Axial CT scan shows optic canal involvement. This was surgically decompressed. *(Patient of the University of British Columbia.)*

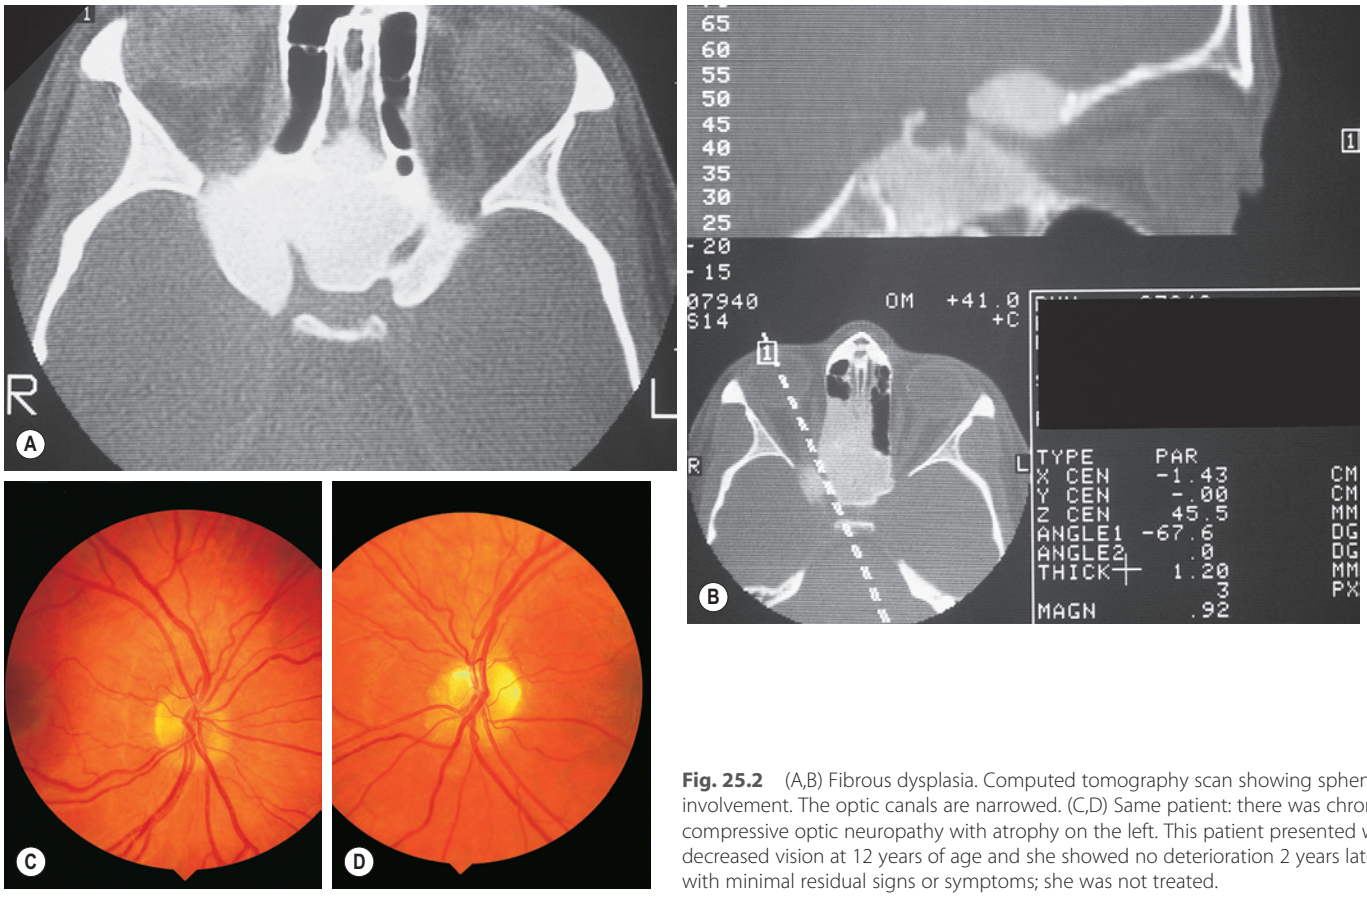

Fig. 25.2 (A,B) Fibrous dysplasia. Computed tomography scan showing sphenoid involvement. The optic canals are narrowed. (C,D) Same patient: there was chronic compressive optic neuropathy with atrophy on the left. This patient presented with decreased vision at 12 years of age and she showed no deterioration 2 years later with minimal residual signs or symptoms; she was not treated.

Management

FD is usually benign and self-limiting. However, the final extent and time of arrest of the lesion are unpredictable. Treatment aims to prevent complications, especially optic nerve compression, and improve cosmesis while waiting for spontaneous arrest.

When there is little doubt about the diagnosis, initial observation and repeat radiologic assessment is best. If the lesion in the orbital wall is lytic or cystic, biopsy is usually necessary to confirm the diagnosis. Outside the orbit, the risk of malignant change after radiotherapy is high[17] and is not used.

Surgery is indicated for cosmetic disfigurement, intractable pain, or optic nerve compression. Since dysplastic bone can be vascular, preoperative blood cross-matching is advisable. Resection of dysplastic bone around the optic canal can reverse visual loss of early compressive optic neuropathy.[10,14] Steroids may also be useful.[18] When decompressing the optic nerve, rongeurs rather than high-speed drills (heat producing) should be used to protect the nerve. Surgery traditionally consisted of debulking the lesion. However, the margins of the affected bone are difficult to define clinically and recurrence was common.[7] In the last 20 years, there has been a shift toward more radical excision of all diseased bone and immediate facial

Fig. 25.3 (A) This 22-year-old developed sudden proptosis of the right eye after a history of slowly progressive facial asymmetry from early childhood. (B) Computed tomography scan showed the fluid level of a hemorrhage within the cystic dysplastic bone. The diagnosis was fibrous dysplasia. *(Patient of the University of British Columbia.)*

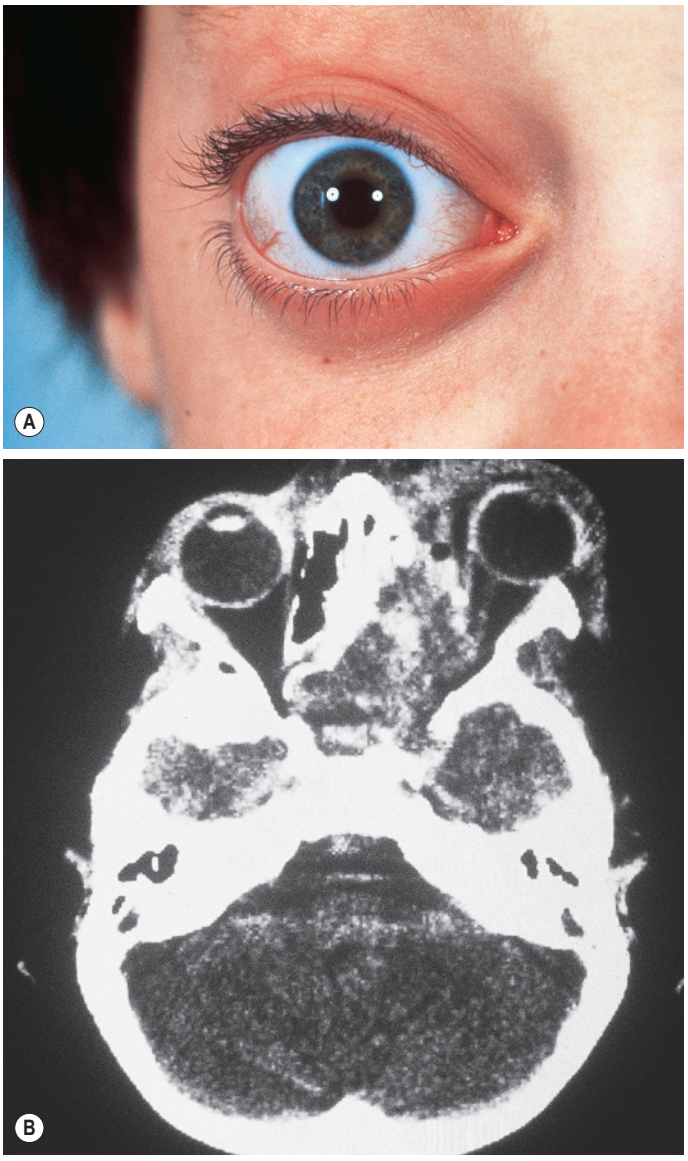

Fig. 25.4 This 10-year-old had a 1-month history of progressive proptosis of the right eye and lateral displacement of the globe. There was gradual loss of vision. Reparative granuloma was diagnosed by intranasal biopsy and the patient underwent lateral rhinotomy and excision of lesion via the ethmoid and maxillary sinuses. *(Patient of the University of British Columbia.)*

and orbital reconstruction using bone grafts[6,19] by combined ophthalmology/craniofacial teams. While some groups report no visual function deterioration following early optic canal decompression, there have been reports of blindness complicating prophylactic nerve decompression.[20] Visual loss is not usually the result of progressive optic canal stenosis, but from the rapid expansion of cystic components, FD mucoceles, or hemorrhage.[21] Prophylactic optic canal decompression is not indicated and a conservative approach is warranted. In this context, serial visual fields, color vision and optical coherence tomography can be helpful.[22] Optic canal decompression should be reserved for patients with progressive or sudden deterioration of visual function.[23]

Bone tumors

Reparative granuloma

Reparative granuloma and aneurysmal bone cyst are parts of a spectrum of reactive giant cell lesions; it may be difficult to differentiate them histologically.

Reparative granulomas (also known as giant cell granulomas) are rare. They affect patients in the first and second decades of life and occur in the mandible, maxilla, and phalanges.[14] The lesion may spread to the maxilla, ethmoid,[24] and sphenoid bones, involving the orbit (Fig. 25.4) and causing proptosis.[25,26] The presentation may be sudden and dramatic if intralesional hemorrhage occurs.[14] Histopathologically, there is a spindle cell stroma with profuse hemorrhagic and hemosiderin content. Osteoblastic giant cells are present within the stroma and new bone may be laid down at the edge of the lesion.

The course is usually benign. Treatment is by surgical curettage; healing occurs by new bone formation. Curettage may need to be repeated or the bony margins resected if the lesion recurs. Radiotherapy is rarely necessary.[25]

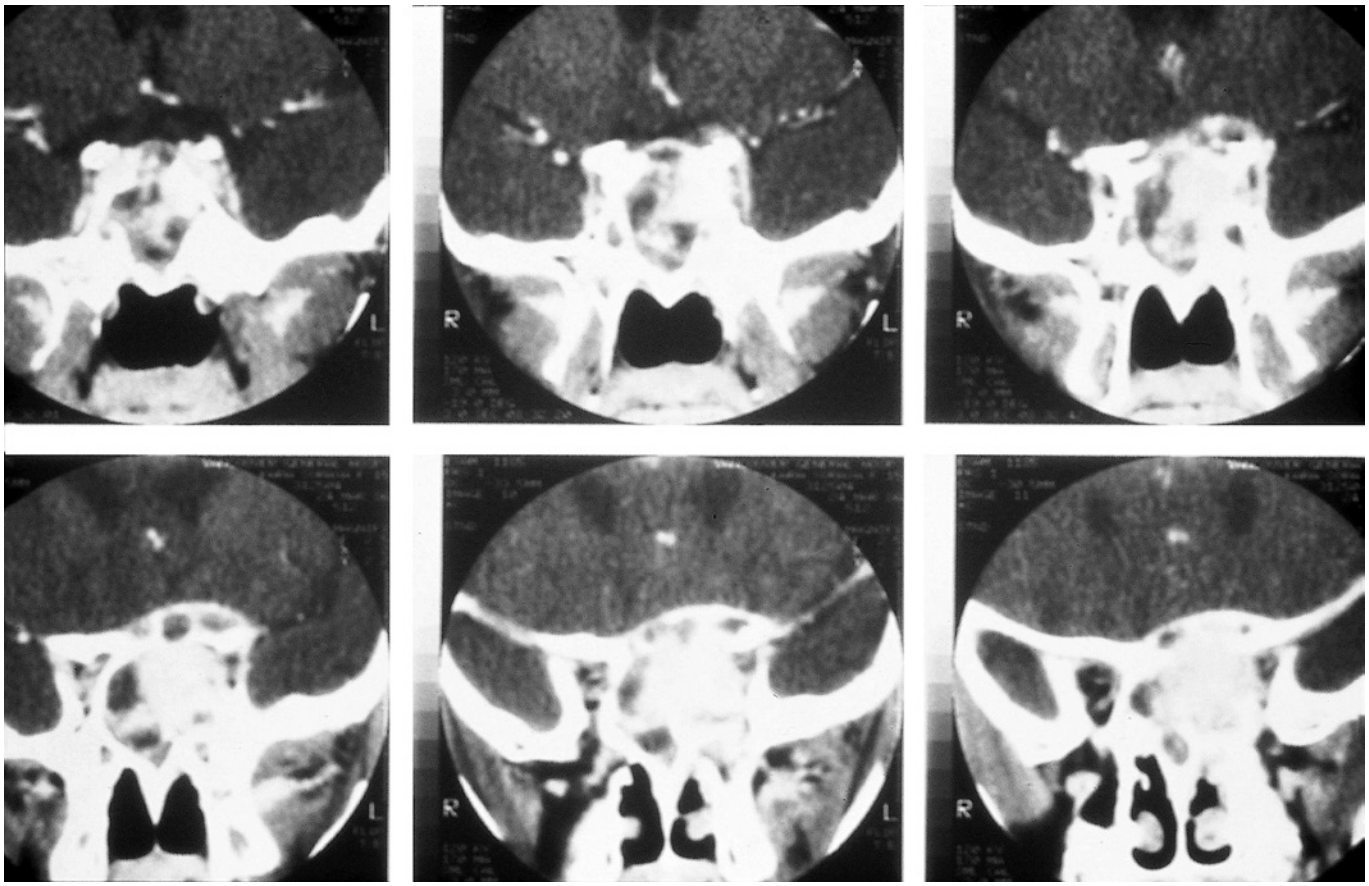

Fig. 25.5 This 12-year-old girl presented with gradual loss of vision. A sphenoid and ethmoid mass was apparent on computed tomography scan. This was shown to be an aneurysmal bone cyst by intranasal biopsy and she underwent cranio-orbitotomy. *(Patient of the University of British Columbia.)*

Aneurysmal bone cyst

This uncommon lesion usually affects the metaphysis of long bones or the spine, often preceded by trivial trauma. The skull is affected in less than 1% of cases; about one-quarter of these affect the orbit.[27] It is a benign lesion that can usually be differentiated from reparative granuloma by the presence of large blood-filled channels lined by multinucleate giant cells and fibroblasts. However, they can be solid, making this differentiation difficult. The two may co-exist.[28]

Aneurysmal bone cysts of the orbit (Fig. 25.5) have been periodically reviewed.[29–31] Most present in the second decade; there is a 5:3 female:male ratio. The history is usually shorter than 3 months, with presentations including proptosis, diplopia, ophthalmoplegia,[32] ptosis, headache, visual deterioration due to optic nerve compression, nasal congestion,[27] epistaxis,[33] and epiphora.[34] Most cases involve the orbital roof and result in gradually increasing unilateral proptosis and downward displacement of the globe.[35] The medial and lateral orbital walls can also be involved. Like reparative granulomas, intralesional hemorrhage may occur, leading to a sudden presentation with signs related to mass effect, occasionally mimicking orbital malignancy in early childhood.[36] Large cysts with intracranial extension may give rise to raised intracranial pressure, papilledema,[37] and optic nerve compression.[14]

Radiologically, irregular expansion with destruction of bone is seen on CT scan, with a thin shell of bone outlining the limits of the lesion. There may be patchy enhancement of the mass or its rim. Hemorrhage and multiple fluid-fluid levels[30] may be evident on MRI or ultrasound.

The treatment of choice is complete surgical excision or curettage with frozen section[14] and grafting with autogenous bone chips. Repair of the orbital wall with a plate,[30] or craniofacial reconstruction may be indicated at the time of surgery.[29,38] The prognosis is good despite a recurrence rate as high as 66%,[39] usually within 2 years of treatment. Cryotherapy and irradiation have also been used, although the latter carries a later risk of osteosarcoma.

Neoplasias

Juvenile ossifying fibroma of the orbit

This rare disorder arises in the bony wall of the orbit, presenting with slowly progressive proptosis. It is similar to, but distinct from, FD.[14]

It usually presents with slowly progressive painless globe displacement in adolescence or early adulthood; younger cases have been reported. The orbital roof (Fig. 25.6) or ethmoid bone are the most common sites[40,41]; rarely, maxillary involvement may cause upward displacement of the globe.[42] There may be massive enlargement with considerable morbidity and disfigurement.[41] Diplopia may occur, and posterior tumors

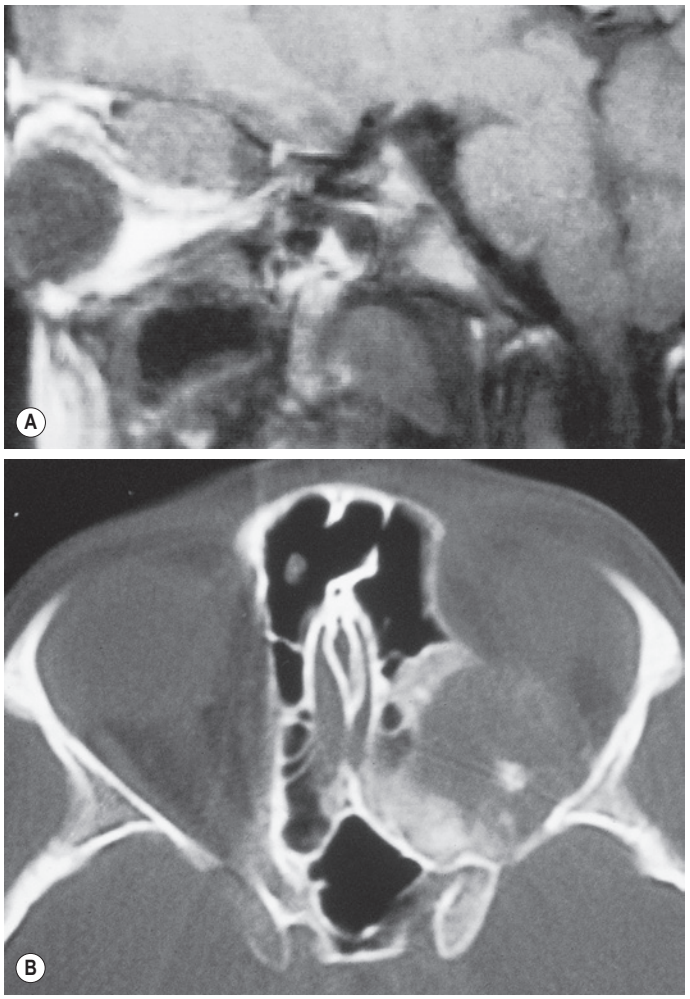

Fig. 25.6 (A) Ossifying fibroma. This 7-year-old child presented with progressive proptosis of the right eye and downward displacement of the globe. The magnetic resonance imaging scan shows a mass in the orbital roof displacing the levator–superior rectus complex, the globe and the optic nerve downwards. (B) Same patient: computed tomography scan showing the sclerotic margin of the fibroma.

may cause apical crowding. Occasionally, inflammation is a feature.[43]

CT scan, which is preferable to MRI,[44] shows a homogeneous central zone with a sclerotic margin expanding a single bone. The lesion is usually clearly demarcated but may grow to involve surrounding bones, sometimes crossing the midline to the other orbit.

Histopathologically, the predominant feature is a central whorled, cellular, vascular stroma surrounded by varying amounts of bone. The more aggressive psammomatoid variant contains islands of lamellar bone or "ossicles", surrounded by a rim of osteoid and osteoblasts resembling the psammoma bodies of meningioma. The tumors enlarge insidiously; surgery becomes necessary for most cases. The treatment of choice is complete excision since recurrence is common, especially in the presence of residual tumor and with psammomatoid histopathology,[41] when regular follow-up is indicated by a multidisciplinary team.[45] Extragnathic cementomas are tumors that behave in a similar fashion.

Other mesenchymal tumors

Osteoblastoma

This benign tumor rarely involves the orbit[46] but can originate from the orbital roof and ethmoid sinuses. It presents with mass effect, globe displacement, reduced ocular motility, and headache.[46,47] Radiologically, osteoblastomas are well circumscribed and may have a lucent center with foci of calcification. The treatment of choice is surgical, either with curettage or more radical excision and reconstruction; both of these may be associated with profuse bleeding due to the vascularity of the tumor. Histologically, it may be difficult to differentiate these from osteoid osteomas.[48] Osteoblastomas tend to be larger, more vascular, and have potential for progressive growth and recurrence. The prognosis is reasonably good, but in the spine and long bones they have a 10–15% recurrence rate after curettage.[49] Since recurrence and sarcomatous transformation have been reported in the skull,[50] complete excision is indicated, preferably by a multidisciplinary team.

Post-irradiation osteosarcoma of the orbit (also see Chapter 43)

Survivors of familial retinoblastoma are at greater risk of developing a second tumor,[51,52] even in the absence of radiotherapy, due to their genetic predisposition. Current retinoblastoma treatment regimes avoid or minimize the use of radiotherapy for this reason. Most of these tumors are osteosarcomas,[52] which may occur within the field of radiation or at a distant site. In 1984, Abramson et al. reported 693 patients with bilateral retinoblastoma. Eighty-nine developed second tumors[52]; 58 occurred within the radiation field and 31 outside. The latent period from completion of radiotherapy to development of the second tumor ranged from 10 months to 23 years (mean 10.4 years). The prognosis of osteosarcoma of the orbit is extremely poor; most patients die within a year of diagnosis.

Infantile cortical hyperostosis (Caffey disease)

This uncommon disorder of unknown etiology affects infants in the first few months of life. It is characterized by sudden onset of fever, irritability, and soft tissue swelling. The soft tissue over the involved bone is swollen and tender. Plain X-rays show subperiosteal new bone formation and cortical thickening. There is usually leukocytosis and raised erythrocyte sedimentation rate. The mandible is the most common bone to be involved, in which case the infants have a characteristic facial appearance with swollen cheeks. It is generally self-limiting and the radiologic appearance reverts to normal within a few months. Involvement of the facial and skull bones may lead to periorbital edema and even proptosis.[53,54] The management is conservative: initially, observation and follow-up radiologic examination of the involved bones. Systemic steroids may be used for persistent disease, or to hasten remission if there is gross swelling.

Osteopetrosis

This is a group of rare genetic bone disorders caused by mutations in at least eight genes,[55] in which defective bone

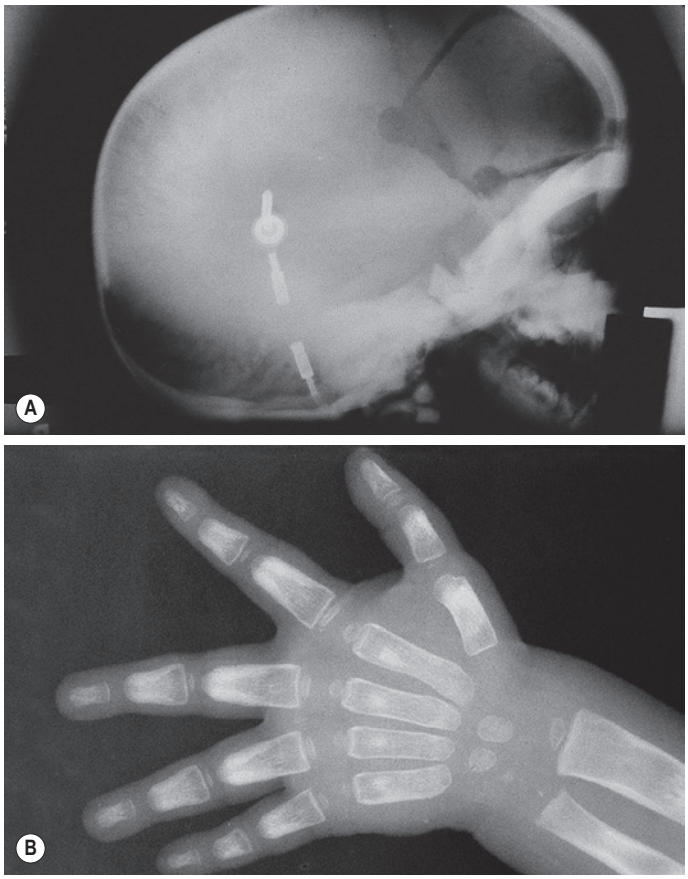

Fig. 25.7 (A) Osteopetrosis. This infant had a bilateral compressive optic neuropathy that failed to respond to optic nerve decompression. He also has a shunt *in situ*. Bone marrow transplantation has been successful in some cases. (B) X-ray of the hands showing increased density of distal ends of the phalanges (same patient).

Fig. 25.8 X-linked hypophosphatemic rickets. Computed tomography scan showing increased bone density, especially of the cortical bone. There was chronic optic nerve compression, which did not deteriorate over a 10-year period while it was monitored by measuring acuity, color vision, pupil reactions, visual fields, and visual evoked potentials.

resorption by osteoclasts results in increased bony thickness and density. There is increased fragility of long bones with narrowing of the marrow cavity. The bony foramina of the skull are also narrowed (Fig. 25.7). Most patients presenting in childhood have one of the autosomal recessive forms of osteopetrosis characterized by a presentation in infancy. This very severe disease, formerly called "malignant" osteopetrosis, is soon fatal if untreated. Another less aggressive form appears in the first decade.

The malignant form presents in infancy with failure to thrive, anemia, and thrombocytopenia. Extramedullary hematopoiesis results in hepatosplenomegaly and lymphadenopathy. Affected infants may present with neonatal hypocalcemia due to defective calcium absorption[55] and unopposed osteoblastic function,[56] which may cause seizures. Bony involvement may result in small orbits with proptosis,[57] narrowing of the cranial foramina, temporal bossing, and nasolacrimal duct obstruction.[58] Narrowing of the optic canal may cause optic nerve compression resulting in optic atrophy.[59,60] Compression of other cranial nerves may result in facial palsy and deafness.

The bone density on X-ray is uniform without corticomedullary demarcation (see Fig. 25.7). There is broadening of the metaphyses and pathologic fractures are common.

Visual function needs to be monitored with electrophysiology in affected infants.[61,62] Vision may be preserved or improved by early decompression of the optic canal,[63,64] but the procedure is difficult due to the increased density of the bone. *LRP5* mutations have been implicated in autosomal dominant osteopetrosis.[65] Also, in a subgroup of patients with infantile malignant osteopetrosis, visual loss results from a rod–cone dystrophy[61,62,66,67]; they may have evidence of widespread neuronal degeneration. A macular chorioretinal abnormality has also been reported.[67] Ocular involvement by age 2 months occurred in half of 33 patients with autosomal recessive osteopetrosis[68]; three had retinal degeneration. Thus, in evaluating a child with osteopetrosis with visual loss, an electroretinogram should always precede optic nerve decompression. Depending on the underlying mutation and severity of the disease, treatment with bone marrow or hematopoietic stem cell transplantation is the best option.[69]

Some forms of autosomal dominant osteopetrosis may be discovered in adulthood, with no ophthalmic complications and a normal life expectancy but numerous orthopedic problems.

Other bone dysplasias

These include craniometaphyseal dysplasia, cranioepiphyseal dysplasia, X-linked hypophosphatemic rickets (Fig. 25.8), and many others, which may be characterized by bone thickening, foraminal occlusion, and orbital narrowing.

Metastatic, secondary and lacrimal gland tumors

Alan A McNab and Christopher J Lyons

Chapter contents

METASTATIC DISEASE
SECONDARY DISEASE
LACRIMAL GLAND TUMORS
REFERENCES

Neuroblastoma and Ewing sarcoma account for most childhood orbital metastatic disease.[1] Wilms tumor, testicular embryonal sarcoma, ovarian sarcoma, and renal embryonal sarcoma occasionally metastasize to the orbit.[2]

It is important to differentiate between blood-borne deposits of a malignant tumor (metastatic disease) and direct extension of a tumor into the orbital tissues from an adjacent structure (secondary disease). Rhabdomyosarcoma and retinoblastoma are the most important sources of secondary orbital disease in children (see Chapters 24 and 43).

Metastatic disease

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor of childhood, accounting for 9% of all childhood cancers, and is the third leading cause of cancer-related death in children. Its incidence peaks in infancy with a median age at diagnosis of 17 months. It arises from postganglionic sympathetic neuroblasts. Most primary tumors involve the adrenal medulla but they can occur anywhere within the sympathetic nervous system in paraspinal ganglia, the neck, or pelvis. It is the commonest source of pediatric orbital metastasis, accounting for 41 of 46 cases reported by Albert et al.,[1] but is a rare cause of orbital disease overall, representing only 1.5% and 3% of pediatric orbital tumors in two large series.[2,3]

Biologic subtypes and genetics

Based on biologic factors and a better understanding of the molecular development of neural crest cells, neuroblastic tumors have been categorized into three biological types:

- *Type 1*: characterized by gains and losses of whole chromosomes. It expresses the TrkA neurotrophin receptor, is hyperdiploid, and tends to spontaneously regress.
- *Type 2A:* characterized by copy number alterations in portions of chromosomes. Type 2A expresses the TrkB neurotrophin receptor and its ligand, has gained an additional copy of chromosome 17q, has loss of heterozygosity of 14q or 11q, and is genomically unstable.
- *Type 2B:* generally has the *MYCN* gene amplified and has a gain of chromosome 17q, loss of chromosome 1p, and expression of the TrkB neurotrophin receptor and its ligand.[4]

Up to 1–2% of cases have a positive family history. Neuroblastoma arises from the interaction of multiple common predisposing genomic variations. The genetic characteristics of each tumor have important prognostic significance; high levels of *MYCN* (N-myc) proto-oncogene amplification are found in approximately 20% of primary tumors and are associated with a worse prognosis.[5,6]

Hyperdiploidy of tumor cell DNA content confers an improved prognosis for infants under 1 year of age at diagnosis. Conversely, segmental chromosomal alterations are associated with more aggressive disease.[7] The most frequent somatically acquired copy number abnormality is allelic gain of distal chromosome 17q, identified in over 50% of primary tumors. An unbalanced gain is associated with more aggressive disease and decreased survival. Cellular genomic aberrations are a better prognostic predictor of the tumor's biological behavior than clinical factors such as age and stage at diagnosis. This is important for treatment planning since it is not uncommon for these tumors to regress spontaneously (stage 4s), even if already widely disseminated. If identified early, these infants can be spared the harmful adverse effects of chemotherapy since their survival rate exceeds 95%.[8] In contrast, children with high-risk neuroblastoma are often resistant to multimodality treatment and have a 5-year survival rate of 40%.

Clinical presentation

Most cases occur under 3 years of age[9] and 90% are diagnosed by age 5, with fewer cases occurring up to the late teens. The adrenals are the primary site in 51% of cases, but it can arise in the cervical sympathetic chain, mediastinum, or pelvis.[10] Neuroblastoma is also more common in patients with neurofibromatosis type 1 (NF1).

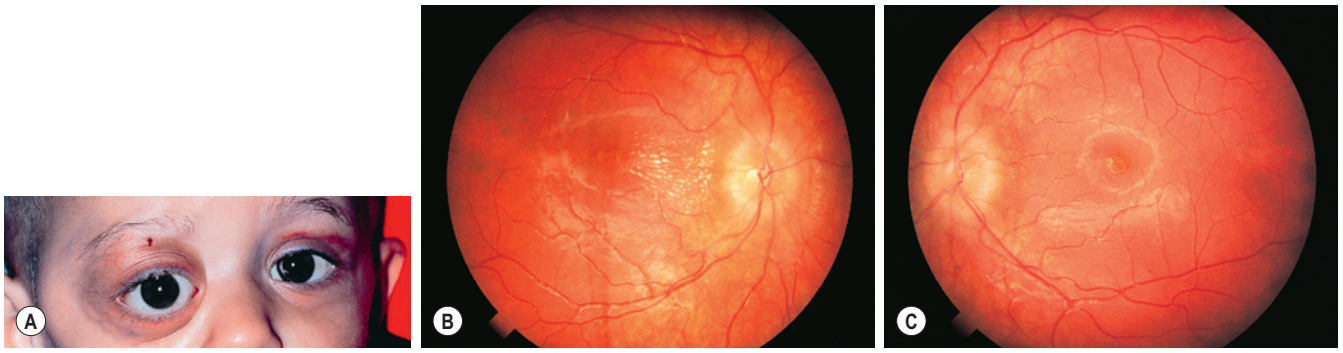

Fig. 26.1 Neuroblastoma. (A) This child presented with bilateral orbital bruising and right proptosis. (B,C) This patient had widespread orbital and cranial bone involvement with raised intracranial pressure and papilledema. *([A] Patient of Dr S. Day.)*

The clinical features vary according to the site of origin, tendency for multiple metastases, any hormone secretion, or paraneoplastic syndrome. Pain, fever, and weight loss are common; cerebellar encephalopathy (ataxia, myoclonic jerks, opsoclonus of unknown cause), diarrhea (from tumor vasoactive peptide production), Horner syndrome (sympathetic chain involvement), and hypertension with flushing episodes (catecholamine production) are classic signs of neuroblastoma.

The diagnosis is often not made until the patient has widespread metastases[11]; 40% have metastases at presentation, increasing to 55% in patients over the age of 1 year. As noted, about 10% of tumors and their metastases (stages 1 to 4s) undergo spontaneous regression, a feature occurring 100 times more commonly than for any other cancer.[12] This underlies the cautious treatment approach outlined below.

Tumor histology ranges from undifferentiated (neuroblastoma) to mature ganglion cells (ganglioneuroblastoma or ganglioneuroma). The histopathological characteristics such as the amount of stroma, degree of differentiation, and number of mitotic figures, reflected in the Shimada classification, do have some prognostic value.

Ninety percent of patients have abnormally high levels of vanillylmandelic acid (VMA) in their urine due to catecholamine secretion. The urinary VMA concentration can be useful for diagnosis and to monitor treatment.

Ophthalmic and orbital features

Neuroblastoma in the mediastinum or cervical sympathetic chain may present with Horner syndrome. This caused two of 10 childhood cases of Horner syndrome reviewed by Woodruff et al.[13] Tonic pupils have been reported as a paraneoplastic effect of adrenal neuroblastoma.[14] Uveal metastases from abdominal neuroblastoma have rarely been described.

The presence of opsoclonus (see Chapter 90), a striking large-amplitude erratic ocular flutter, also known as "dancing eyes syndrome," with or without ataxia and myoclonus, suggests occult localized neuroblastoma.[11] The primary tumor is in the chest or abdomen and not the brain. It is usually associated with a good prognosis, possibly because only single copies of the *MYCN* oncogene are present within the tumor cells,[15] but opsoclonus can also be present with multiple *MYCN* copies, signaling a poorer outcome.[16]

Presentation

In 93% of 46 cases reported by Albert et al.,[1] the primary tumor was diagnosed prior to presentation with orbital signs.

Fig. 26.2 Periorbital ecchymoses in a patient with orbital neuroblastoma.

Ninety percent of the 60 patients with orbital metastases reviewed by Musarella et al.[11] had a primary abdominal tumor. Orbital metastases commonly present with sudden onset and rapidly progressive proptosis (Fig. 26.1), unilateral or bilateral. Eyelid ecchymosis (Fig. 26.2) is present in 25% of cases.[11] The lesion is usually in the superolateral orbit and zygoma but may occur anywhere within the orbit. Bony lesions give rise to swelling of overlying tissues, so periorbital swelling and ptosis may be present. This may mimic orbital cellulitis or other rapidly progressive orbital tumors such as rhabdomyosarcoma, Ewing sarcoma, medulloblastoma, Wilms tumor, and acute lymphoblastic leukemia.[17] Hemorrhage into a pre-existing undiagnosed venous lymphatic malformation (lymphangioma) may also present with sudden proptosis and ecchymosis. The ecchymosis can also lead to suspicion of child abuse and diagnostic delay.[18]

Treatment

The main prognostic factors are the age at diagnosis, stage of disease (Table 26.1), *MYCN* status, Shimada histology, and ploidy for infants. Survival rates for low-risk groups are 90–100%, whilst those for high-risk groups range from 20% to 60%. Infants under 1 year have a 92% 5-year survival; those aged 1 to 4 years, 68%; 5 to 9 years, 52%; and 10 to 14 years, 66%.

Low-risk neuroblastoma (stages 1 and 2) is treated surgically. The cure rate is greater than 90% for stage 2 neuroblastomas

Table 26.1 International neuroblastoma staging system (INSS)

Stage	Description
1	Tumor confined to organ or origin
2	Tumor extends beyond organ of origin but not beyond midline
2a	No lymph node involvement
3	Tumor extends beyond midline with or without bilateral lymph node involvement
4	Tumor disseminated to distant sites
4s	Children younger than 1 year of age with dissemination to liver, skin, or bone marrow without bone involvement and a primary tumor that would otherwise be stage 1 or 2

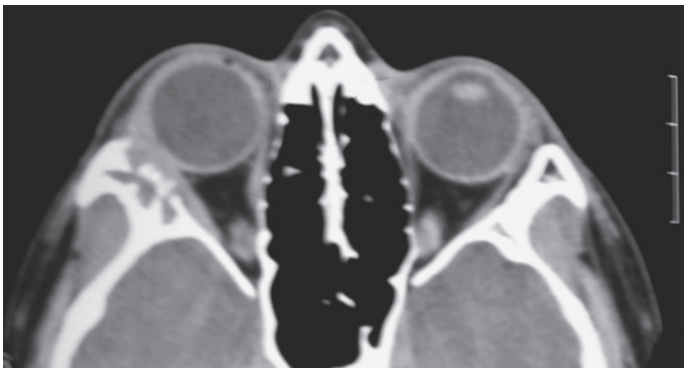

Fig. 26.3 Ewing sarcoma. An axial computed tomography scan of a 9-year-old boy with Ewing sarcoma of the lateral orbital wall. Systemic investigation revealed no other lesions and it was treated with chemotherapy to shrink the lesion followed by complete excision, with long-term cure.

with no further treatment, even if small amounts of tumor remain after surgery.[19] Chemotherapy or radiation can cure local recurrence. Stage 4s has a favorable prognosis; the survival rate is almost 100% with observation and supportive care only.[20] Treatment for intermediate-risk neuroblastoma includes surgery and chemotherapy with agents including carboplatin, cyclophosphamide, cisplatin, etoposide, and doxorubicin over several months. Radiotherapy is used for incomplete response to chemotherapy. Children with stage 3 and infants with stage 4 under 1 year of age and otherwise favorable features have an excellent prognosis of more than 90% survival with moderate treatment. It is important to obtain sufficient material for histopathological and genetic study to determine these patients' moderate risk and spare them the high doses necessary for higher-risk groups. High-risk patients receive induction chemotherapy followed by high-dose chemotherapy and bone marrow transplantation with additional *cis*-retinoic acid treatment.[21]

Ewing sarcoma

Ewing sarcoma is highly malignant and an important cause of mortality and morbidity. The usual age of onset is 10–25 years, with highest incidence in the early teens. It is very rare in African and Chinese children. Four percent of primary tumors arise in the head and neck, usually the maxilla or mandible.[22] Spread from contiguous structures such as the sinuses may occur. There is a marked tendency to spread to adjacent soft tissues, other bones, and the lungs.[23] Immunohistochemical characteristics differentiate Ewing's from other small round cell tumors such as rhabdomyosarcoma, neuroblastoma, and lymphoma. Ewing sarcomas are often S100, neuron-specific enolase, and surface glycoprotein MIC-2 positive, and negative for muscle markers such as desmin or actin. A reciprocal translocation, t(11 : 22)(q24;q12) is present in 83% of tumors.[24] There is a cytogenetic rearrangement on the long arm of chromosome 22 fusing the *EWS* gene (whose function is unknown) and members of the ETS family of transcription factors (FLI-1, ERG). This causes deregulation of other genes within the cell and development of the malignant phenotype.[25] In undifferentiated tumors, the diagnosis may be secured by cytogenetic analysis for the translocation or polymerase chain reaction (PCR) for chimeric fusion gene products EWS/FLII or EWS/ERG.

There are numerous reports of primary Ewing sarcoma involving the orbit, arising from the ethmoid and sphenoid sinuses, roof of the orbit, lesser wing of the sphenoid, and temporal bone. A short history is typical, featuring swelling, globe displacement, strabismus with duction limitation, headache, visual loss, pain, and localized bony tenderness.[1,26]

On computed tomography (CT) scan, there is a "moth-eaten" unevenly enhancing appearance of the involved bone, associated with a soft tissue mass (Fig. 26.3). The differential diagnosis includes neuroblastoma, rhabdomyosarcoma (if extraskeletal), Langerhans cell histiocytosis, and osteomyelitis.

In apparently primary orbital tumors, the patient should be evaluated for metastatic disease. Adequate amounts of fresh tissue should be obtained for histopathologic and cytogenetic studies. Treatment of the primary tumor is with multiagent chemotherapy to shrink the tumor before surgical excision. Vincristine, doxorubicin, and cyclophosphamide are the main treatments with, in addition, ifosfamide and etoposide. Although these tumors are radiosensitive and local control may be achieved by radiotherapy, surgery is preferable due to the risk of late radiotherapy complications including osteosarcoma. Histologically clear margins are essential. The prognosis for metastatic disease remains poor and only one-third survive long term. Since there is an appreciable risk of late recurrence or development of a second malignancy, such as osteogenic sarcoma, prolonged follow-up is indicated.

Secondary disease

Retinoblastoma (see Chapter 43)

Retinoblastoma confined within the eye poses little threat to life and is curable.[23] The prognosis is greatly worsened by extension into the orbit (Fig. 26.4) or central nervous system, or by metastatic disease. The consequences of trans-scleral spread to the orbit and extension into the optic nerve are considered in Chapter 43.

Malignant melanoma

Intraocular melanoma very rarely occurs in infancy and childhood and secondary orbital melanoma is exceedingly rare. Occasionally, orbital malignant melanoma occurs in the neonatal period with extensive involvement of orbital and other facial tissues at presentation.

Lacrimal gland tumors

Dermoid cysts are the commonest lesion of the lacrimal fossa region in childhood.[2] Inflammatory lesions, including non-specific dacryoadenitis, granulomatosis with polyangiitis, immunoglobulin G4 (IgG4)-related dacryoadenitis, and angiolymphoid hyperplasia may also occur in childhood. Granulocytic sarcoma (chloroma) is rare but can present with a mass in the region of the lacrimal gland.

Primary epithelial tumors of the lacrimal gland are rare in children, and more frequent over the age of 10 years. Pleomorphic adenoma of the lacrimal gland can occur in childhood[3]; Rose and Wright reported that three of their 78 cases had onset of symptoms in the second decade of life.[27] Cure is effected by complete removal of the tumor, with recurrence and possible late malignant transformation if excision is incomplete.[27]

Adenoid cystic carcinoma does rarely occur in children, and is commoner than pleomorphic adenoma in this age group.[3,28,29] Six of 38 cases from Moorfields Hospital had their first symptom in the first two decades of life.[30] These tumors often develop rapidly. Alternatively, a longer standing lesion can present acutely with symptoms of pain and paresthesia due to perineural invasion, which often extends microscopically well beyond the tumor mass.

Fig. 26.4 Retinoblastoma. This child with extensive orbital involvement with lymphatic spread (note the preauricular gland involvement) is a common presentation in developing countries.

Radiologically, bone erosion is highly suggestive of malignancy. However, it is important to note that absence of erosion does not exclude malignancy (Fig. 26.5). Since bony remodeling occurs rapidly in childhood, localized bony expansion may still be seen with rapidly growing masses such as adenoid cystic carcinoma, whereas in adults, this sign would indicate a slow-growing mass such as pleomorphic adenoma.

These tumors may be difficult to distinguish clinically from other lacrimal lesions such as low-grade infections, non-specific

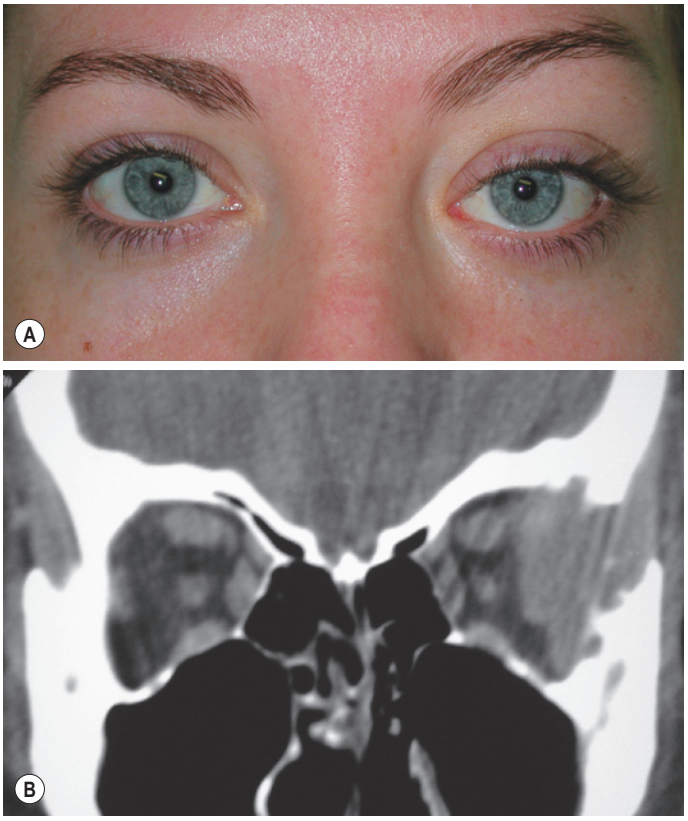

Fig. 26.6 Adenoid cystic carcinoma. (A) A 16-year-old girl had 9 months of increasing left globe dystopia, pain, and numbness over the lateral upper eyelid. (B) A coronal computed tomography scan shows a mass in the region of the lacrimal gland with adjacent bone destruction. Biopsy confirmed basaloid adenoid cystic carcinoma with bone and perineural invasion. She died from metastatic disease within 12 months despite surgery, radiation, and chemotherapy.

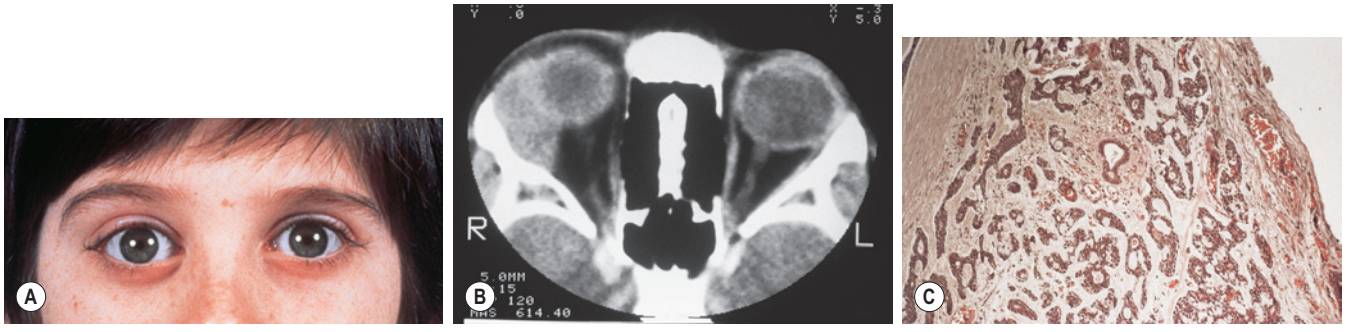

Fig. 26.5 Adenoid cystic carcinoma. (A) This 10-year-old boy presented with a 1-year history of gradual right proptosis and upper lid swelling. There was no pain or sensory loss. (B) Computed tomography scan showed a lacrimal gland mass excavating the frontal bone, without erosion. Even rapidly growing lesions may cause excavation in childhood. (C) It was an adenoid cystic carcinoma of the lacrimal gland. The patient was alive and well 23 years later. *(Patient of the University of British Columbia.)*

inflammation, or leukemic deposits, and biopsy is required for diagnosis.

Adenoid cystic carcinoma is locally invasive, may metastasize, and has a poor prognosis despite surgery, radiotherapy, and chemotherapy (Fig. 26.6).[30] Local excision and radical proton beam irradiation may provide longer disease-free survival.[31]

LANGERHANS CELL HISTIOCYTOSIS
JUVENILE XANTHOGRANULOMA
ROSAI–DORFMAN DISEASE
LEUKEMIA
LYMPHOMA
REFERENCES

Histiocytic disorders occasionally affect the eye and ocular adnexae. The broad histology-based categories of histiocytic lesions seen by the ophthalmologist are: Langerhans cell histiocytosis (LCH), juvenile xanthogranuloma (JXG), Rosai–Dorfman disease (RDD), and Erdheim–Chester disease (ECD). While LCH and JXG are predominately pediatric disorders, there are many pediatric adnexal RDD cases and a few ECD adnexal cases in children.

Langerhans cell histiocytosis

Early in the twentieth century, Hand–Schüller–Christian disease was described as a combination of a skin rash, bony lesions, and diabetes insipidus. Letterer, in 1924, and Siwe, in 1933, described a histologically similar entity with more extensive involvement including hepatic, splenic, and marrow abnormalities.[1] Solitary eosinophilic granulomas were subsequently reported.[2] The common histopathological features of these three disorders was noted by Lichtenstein who suggested the term "histiocytosis X" to denote the histiocytic origin but unknown pathogenesis.[3] Breathnach and Birbeck described pentalaminar zipper-like intracytoplasmic inclusions (Birbeck granules) in cutaneous Langerhans cells contemporaneously with Nezelof and Bassett, describing identical structures in the lesions of histiocytosis X using electron microscopy.[4]

This led to the belief that the Langerhans cell was the cell of origin in these disorders, henceforth dubbed Langerhans cell histiocytosis. The pathological histiocyte demonstrates a nucleus with a central stripe, reminiscent of a coffee bean, eosinophilic cytoplasm, and positivity for CD1a, CD207 (langerin), and S100 (Fig. 27.1). Standard light microscopy also revealed an abundant infiltrate of eosinophils, lymphocytes, and macrophages, suggesting an inflammatory process rather than a neoplastic process.[5] However, clonality was demonstrated by Yu and Wilmann in 1994. It is now known that *BRAF* mutations are found in 60% of cases, mutually exclusive *MAP2K1* mutations in 15–40%, as well as rarer *ARAF* mutations, confirming LCH to be a neoplastic process with an associated inflammatory response.[5] The pathological histiocytes do have some differences from epidermal Langerhans cells, lacking the typical dendritic spines and demonstrating a gene expression profile consistent with a precursor myeloid dendritic cell rather than a cutaneous dendritic cell. Thus, importantly, LCH is now classified as a myeloid neoplasia.[6]

All the mutations in LCH appear to be directed to the mitogen-activated protein kinase (MAPK, ERK) signaling pathway, which has numerous roles but influences cell cycle in terms of proliferation, apoptosis, and senescence. ERK is extracellular signal-regulated kinase, a key enzyme late in the pathway. The other mutations (*BRAF*, *MAK2K1*) lead to ERK activation. This pathway is the same one involved in neurofibromatosis and melanoma development. The timing of the mutation appears to determine which clinical syndrome manifests. BRAF mutations were present in peripheral blood of all patients with widespread high-risk disease, a small number of those with multifocal low-risk disease and no patients with single-system disease.[7] Other epigenetic influences or additional mutations might also account for variations in disease behavior.

The pediatric incidence of LCH is about five cases per million in population-based studies.[8] The majority of ocular adnexal involvement is from single site, single-system disease, the so-called eosinophilic granuloma (Fig. 27.2A). This is more common in boys. In one large series, 80% presented with a painless swelling of the superior orbit (eosinophilic granuloma). Only 6% manifested multifocal multisystem disease, presenting with signs of diabetes insipidus due to posterior pituitary involvement associated with bilateral proptosis[9] (Fig. 27.2B). Visual loss is unusual but can occur due to optic nerve compression or prolonged raised intracranial pressure. It is important for ophthalmologists to be aware of the possibility of systemic involvement and arrange for appropriate systemic investigation and oncological assessment. Usually imaging with computed tomography (CT) or magnetic resonance imaging (MRI) will be performed to assess the orbital lesion[9] (Fig. 27.3). While MRI is the preferred initial investigation in children, CT does delineate the lytic bony lesions well. Subsequent biopsy will confirm the diagnosis,

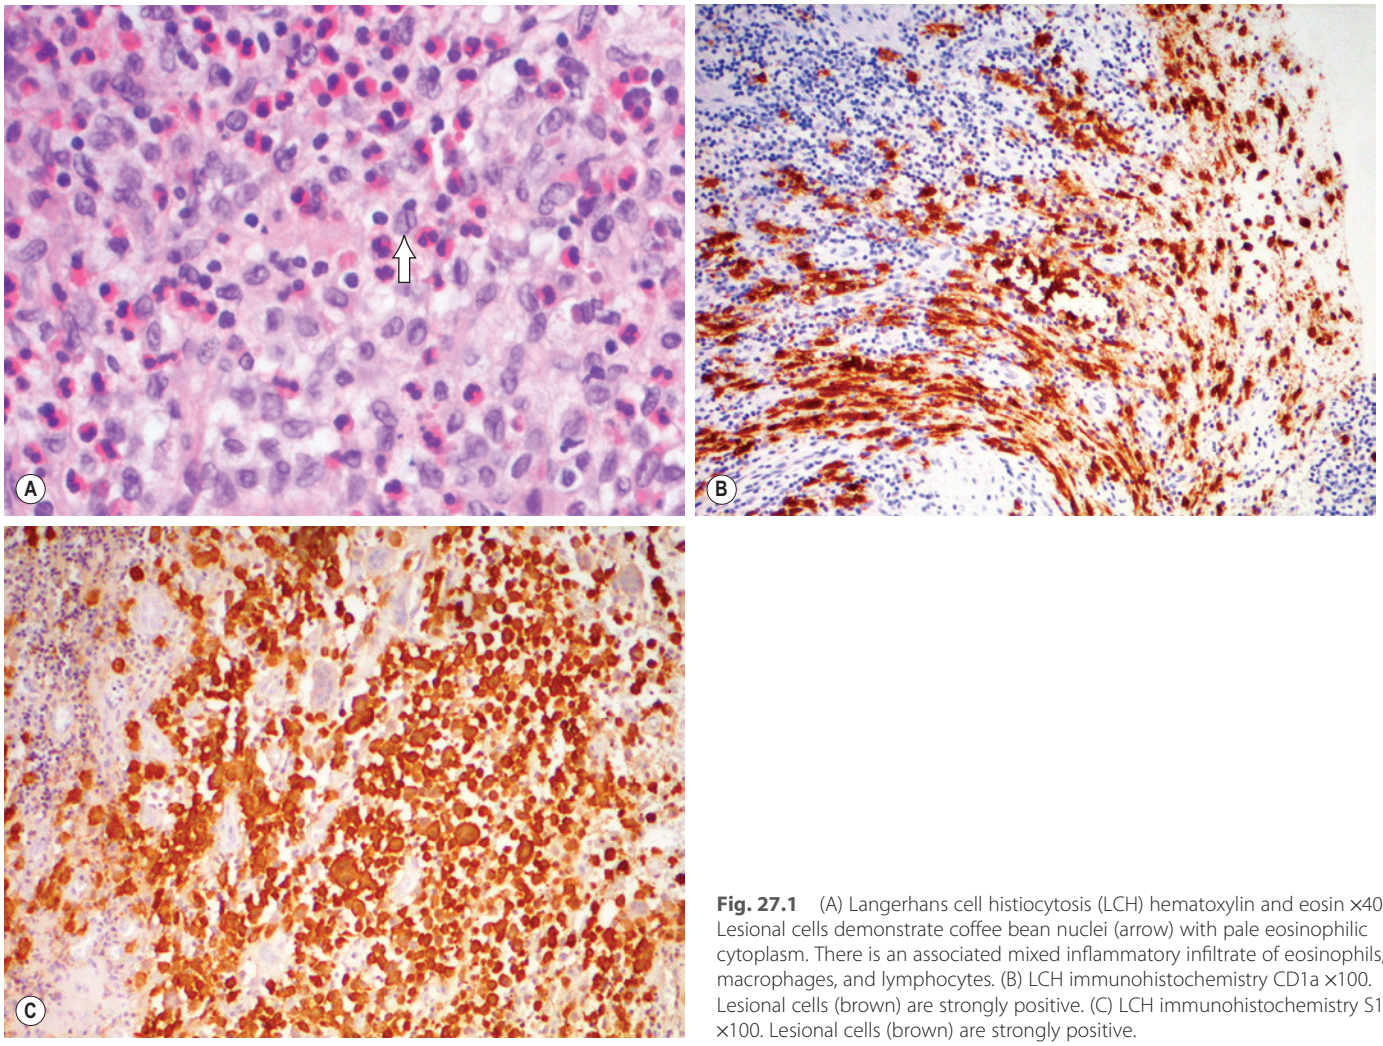

Fig. 27.1 (A) Langerhans cell histiocytosis (LCH) hematoxylin and eosin ×400. Lesional cells demonstrate coffee bean nuclei (arrow) with pale eosinophilic cytoplasm. There is an associated mixed inflammatory infiltrate of eosinophils, macrophages, and lymphocytes. (B) LCH immunohistochemistry CD1a ×100. Lesional cells (brown) are strongly positive. (C) LCH immunohistochemistry S100 ×100. Lesional cells (brown) are strongly positive.

pre-empting further investigation and referral. The initial evaluation should include full blood count, liver function tests, electrolytes, coagulation studies, sedimentation rate, lactate dehydrogenase, immunoglobulins, uric acid, and ferritin. Positron-emission tomography (PET)/CT scanning, systemic CT and MRI, and bone marrow and lower gastrointestinal endoscopy are also mandated.[10] One of the characteristic MRI findings in LCH is the loss of the normal posterior pituitary enhancement due to infiltration with affected tissue. Other central nervous involvement includes various soft tissue deposits and diabetes insipidus.

Management of the orbital lesion generally involves confirmatory biopsy with curettage, to remove as much lesion tissue as possible, and perilesional steroids. With a unifocal,

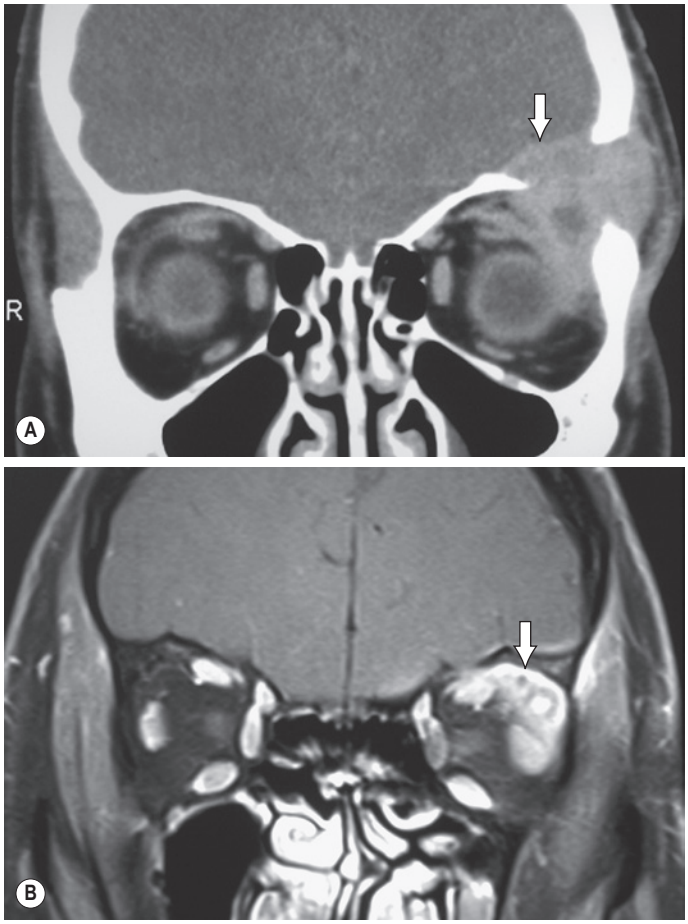

Fig. 27.3 (A) Langerhans cell histiocytosis (LCH) coronal computed tomography scan showing marked destruction of the left frontal bone and orbital roof with an associated soft tissue lesion. (B) LCH coronal magnetic resonance imaging scan, T1 weighted with gadolinium enhancement, showing the enhancing soft tissue component of LCH.

unisystem involvement, other treatment is unnecessary.[10,11] However, appropriate systemic investigation must be performed and if there is multifocal or multisystem disease, oncological management is appropriate. The Histiocyte Society has conducted international multicenter randomized trials, LCH I–IV, and other multicenter studies in Europe and Japan have contributed to management approaches, which have largely been vinblastine- and prednisolone-based from the LCH trials, with cytarabine regarded as a sound option from the Japanese studies and LCH IV. With multisystem, multifocal disease, refractory or relapsed lesions occur frequently and cladribine, clofarabine, and cytarabine have all been used in this setting. Targeted therapy with BRAF inhibitors such as vemurafenib has induced strong response in patients with the *BRAF* mutation. Other agents directed toward the MAPK pathway may also have a role, especially in BRAF-negative lesions. Bony lesions have also responded to prostaglandin therapy, especially for symptomatic unifocal osseous involvement. Where patients do not respond to these treatments, stem cell transplantation has a role. The vast majority of the lesions seen by ophthalmologists are unifocal single-system lesions, and they do well. The prognosis for multisystem multifocal disease remains guarded, but is improving with improved understanding of the pathogenesis, the cell of origin, and the use of targeted therapies.[10]

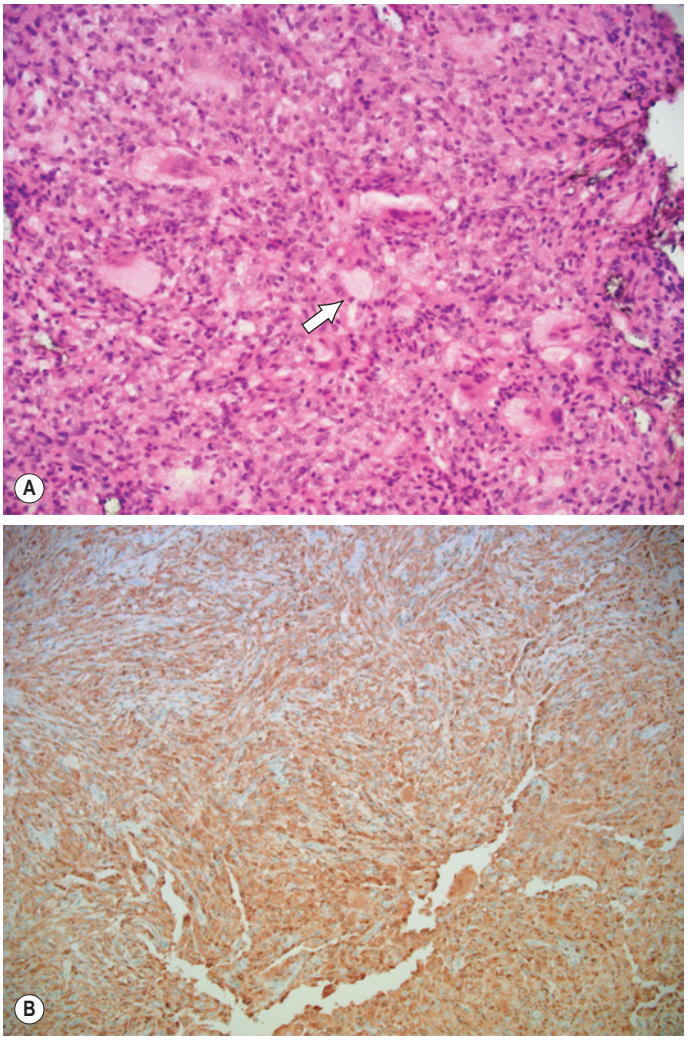

Fig. 27.4 (A) Juvenile xanthogranuloma (JXG) histology, hematoxylin and eosin ×200. Shows a mixed inflammatory cell infiltrate characterized by Touton giant cells. (B) JXG immunohistochemistry CD68, showing strong positivity.

Juvenile xanthogranuloma

The pathology of JXG is different from that of LCH. The cells are epithelioid with an eosinophilic cytoplasm and do not have the coffee bean nucleus. CD1a and CD207 are not expressed, differentiating JXG from LCH. Cells have a consistent immunophenotype for CD14, CD163, CD68, fascin, and factor 13a. Birbeck granules are absent on electron microscopy. There is a mixed inflammatory infiltrate characterized by the presence of Touton giant cells[5] (Fig. 27.4). The presentation is also different, usually with skin lesions. These may be transient in patients with neurofibromatosis type 1 (NF1), sometimes as the initial feature. There is also an association with juvenile myelomonocytic leukemia. Ophthalmic series generally report a preponderance of ocular lesions involving the iris, conjunctiva, or, less commonly, the choroid, with a mean age at presentation of 3 years. Ocular adnexal eyelid or orbital involvement is seen much less frequently but does occur.[12] This may present as a domed xanthomatous skin lesion or a deeper orbital mass in a slightly older child with a mean age of presentation of 6 years (Fig. 27.5). Extraocular muscle

Fig. 27.6 (A) Massive bilateral proptosis in acute lymphoblastic lymphoma (ALL). (B) Extensive orbital involvement with ALL demonstrated on computed tomography scan.

involvement may be seen. There is a case report of extensive involvement of the orbit, sinus, infratemporal fossa, and brain in a newborn, which was managed expectantly.[13] The yellowish cutaneous and other lesions are an important clue to the underlying diagnosis. This is confirmed by excisional biopsy of the most accessible lesions, which normally represents adequate therapy. Iris involvement is often complicated by recurrent hyphema and glaucoma. Biopsy is liable to precipitate bleeding, and treatment with topical steroids with frequent careful follow-up is often efficacious in this context.

Rosai–Dorfman disease

RDD is a benign, idiopathic, inflammatory lesion that may include a range of manifestations, including extranodal disease, typically seen in the orbit and ocular adnexa.[5] RDD was formerly known as "sinus histiocytosis with massive lymphadenopathy". These patients usually present with a painless soft tissue mass causing proptosis, or with ptosis or motility disturbances and diplopia. The orbital disease may present well before sinus involvement or lymphadenopathy.[14] CT imaging findings are generally of an homogenous extraconal mass with some contrast enhancement but no associated tissue or bone destruction, although sphenoid wing erosion may occur. MRI reveals lesional tissue to be hypointense with respect to brain, and with significant enhancement with gadolinium contrast.[15] Biopsy reveals pathology characterized by a process known as "emperipolesis." Typically, large histiocytes phagocytose intact erythrocytes, lymphocytes, and plasma cells, contained within intracellular vacuoles in the abundant pale to clear cytoplasm. These cells are CD14-, CD68-, CD163- and S100-positive but negative for CD1a and CD207. Some cells may stain for immunoglobulin G4 but usually do not meet the criteria for diagnosis of that disorder.[5]

Treatment of this unusual histiocytic disorder is not always necessary since about half the cases resolve spontaneously. Surgical excision or debulking at the time of initial biopsy is appropriate if this can be performed without significant risk to vital orbital structures. Occasional orbital cases result in optic neuropathy that may warrant chemotherapy or even low-dose radiotherapy.

Most cases resolve spontaneously or respond to treatment; however, a small number of recalcitrant cases result in disseminated chronic lymphadenopathy. There is a low mortality associated with RDD, predictably in people with multiple nodal and concomitant extranodal lesions.

Leukemia

Leukemia can involve any ocular adnexal structure, either directly from tumor infiltration or deposits, or with secondary effects due to hemorrhage, infection, or neuro-ophthalmic signs[16] (Fig. 27.6). Pediatric leukemias include acute lymphoblastic (ALL) (75%), acute myelogenous (AML) (20%), and

chronic myelogenous (CML) (5%). The incidence of ophthalmic involvement varies widely in different reports from 10–90%, which might reflect the different methodologies.[17] Rigorous prospective evaluation yields a higher incidence, and many patients who are asymptomatic may harbor adnexal involvement.[18] Ophthalmic involvement may be the presenting feature of leukemia, and in one series of 31 cases of granulocytic sarcoma, there was no prior history of leukemia in any case, but 40% were found to have AML on systemic investigation and 75% of the remainder developed AML within 21 months.[19] Granulocytic sarcoma was previously named "chloroma" due to its greenish color from the myeloperoxidase present in lesional cells.[20]

Adnexal disease may also be a sign of a relapse after treatment, representing the most common site for relapse of ALL in one series. For these reasons, ophthalmic examination at diagnosis is recommended. Generally these patients demonstrate unilateral or bilateral proptosis, eyelid swelling or edema, or pain. The deposits may involve the intra- or extraconal spaces, the extraocular muscles, or the lacrimal gland. The presence of orbital or ocular lesions is adversely associated with prognosis for both acute myeloblastic and acute lymphoblastic leukemia. The prognosis for granulocytic sarcoma remains poor, with a majority of patients surviving only 30 months in Zimmerman and Font's 1975 series.[5] In 2014, Aggarwal published a series of patients with granulocytic sarcoma who progressed to AML; their average survival was 9.2 months.

Lymphoma

Ocular adnexal lymphoma is much less common in the pediatric population than in adults. Nonetheless, it occurs in a few settings. Historically there has been an awareness of the Epstein–Barr virus-mediated Burkitt lymphoma in the sub-Saharan African population, but this same lesion can occur sporadically in non-endemic situations.[21]

There have also been limited reports of both B cell and T cell lesions, classified according to the World Health Organization's modification of the Revised European–American Classification of Lymphoid Neoplasms (REAL classification)[22] (Fig. 27.7). These include primary extranodal marginal zone lymphoma (EMZL), diffuse large B cell lymphoma (DLBCL), and B-precursor lymphoblastic lymphoma of the orbit.[23,24] These tumors have presented as mass lesions, proptosis, or eyelid swelling. Imaging findings with CT and MRI show well-circumscribed molded-mass lesions that enhance moderately. Once a tissue diagnosis has been established, systemic staging using the American Joint Committee for Cancer, 7th edition, is undertaken.[25] Primary orbital disease without systemic involvement is usually treated with radiotherapy or with chemotherapy/immunotherapy. The indolent EMZL generally responds well and has a better prognosis. DLBCL is more aggressive but seems to have good survival in the pediatric population, whereas T cell lymphomas have a poorer prognosis.

The final setting for lymphoma or lymphoproliferative disease is as a manifestation of the post-transplantation lymphoproliferative disorder (PTLD), which is strongly associated with Epstein–Barr virus infection.[26,27] In this setting, the post-transplant immunosuppression is reduced or discontinued, in conjunction with chemotherapy and immunotherapy with rituximab, with resolution of the lesions and reduction in the Epstein–Barr viral titer.

Introduction

This chapter discusses two main groups of disorders:

1. Craniosynostoses, in which premature closure of sutures causes an abnormally shaped skull, e.g. Crouzon and Apert syndromes.
2. The clefting syndromes, in which there is a failure of apposition or fusion of fetal tissues. These include the mandibulofacial dysostoses, e.g. Treacher Collins and Goldenhar syndromes.

In addition, frontoethmoidal meningoencephaloceles, midline facial clefts, and amniotic bands are discussed.

Craniosynostosis

Craniosynostosis is premature fusion of one or more cranial vault sutures with resultant skull deformity. It occurs in approximately 1 in 2500 births and may be primary or secondary. Thirty percent of cases are syndromic, usually with multiple suture involvement and associated primary malformations in the face, trunk, or extremities. Syndromic craniosynostosis patients present with significant cosmetic challenges and face complex neurologic, ophthalmologic, and airway difficulties. Non-syndromic ("simple") craniosynostosis may have neurologic or ophthalmologic complications. Some cases of simple craniosynostosis represent the mild end of a spectrum of syndromic disease.[1]

Pathophysiology

Pathogenesis and genetics[1]

Between 30% and 70% of cases are caused by mutations in hotspots in the fibroblast growth factor receptor genes FGFR1, FGFR2, and FGFR3 or in the TWIST1 gene. Other genes unequivocally associated with the condition when mutated include MSX2, EFNB1 and EFNB2, RAB23, and FREM1. The majority are involved in the process of cell proliferation and ossification, and many belong to a common molecular pathway.[2] The most common syndromes are autosomal dominant. *De novo* mutations are of paternal origin and increase with paternal age, thought to be due to a co-location with mutations promoting clonal expansion within male germline progenitors (the "selfish spermatological selection" theory). The reader is referred to genetic databases such as the Online Mendelian Inheritance in Man (OMIM) Database (http://www.omim.org/). Environmental factors have also been implicated in the etiology of craniosynostosis, including maternal smoking and altitude, and intrauterine head constraint.[3] Craniosynostosis may occur secondary to various conditions, including shunted hydrocephalus, metabolic disorders such as hyperthyroidism and rickets, and hematologic disorders such as thalassemia and sickle cell anemia.[3]

Effects on the skull

Cranial sutures are fibrous joints providing a malleable quality to the head, allowing vaginal birth and growth of the brain during early development. Although a particular skull suture prematurely fused does not always correlate with a specific head shape abnormality, most commonly cranial growth perpendicular to the fused suture is restricted and compensatory growth occurs at the remaining open sutures (Fig. 28.1). The principal clinical manifestations have been given Greek or Latin descriptors; recently synostotic disorders have tended to simply be named according to the suture involved. Trigonocephaly ("triangular head") is metopic suture synostosis; scaphocephaly ("boat-shaped head") is sagittal suture synostosis; plagiocephaly ("twisted head") is either unilateral coronal or unilateral lambdoid suture synostosis; and brachycephaly ("short head") is bilateral coronal suture synostosis (Table 28.1). Multiple suture involvement results in more complex head morphologies, such as tryphyllocephaly (Kleeblatschadel, clover leaf, or trilobed skull) or oxycephaly ("towering head"). Premature synostosis also occurs in the

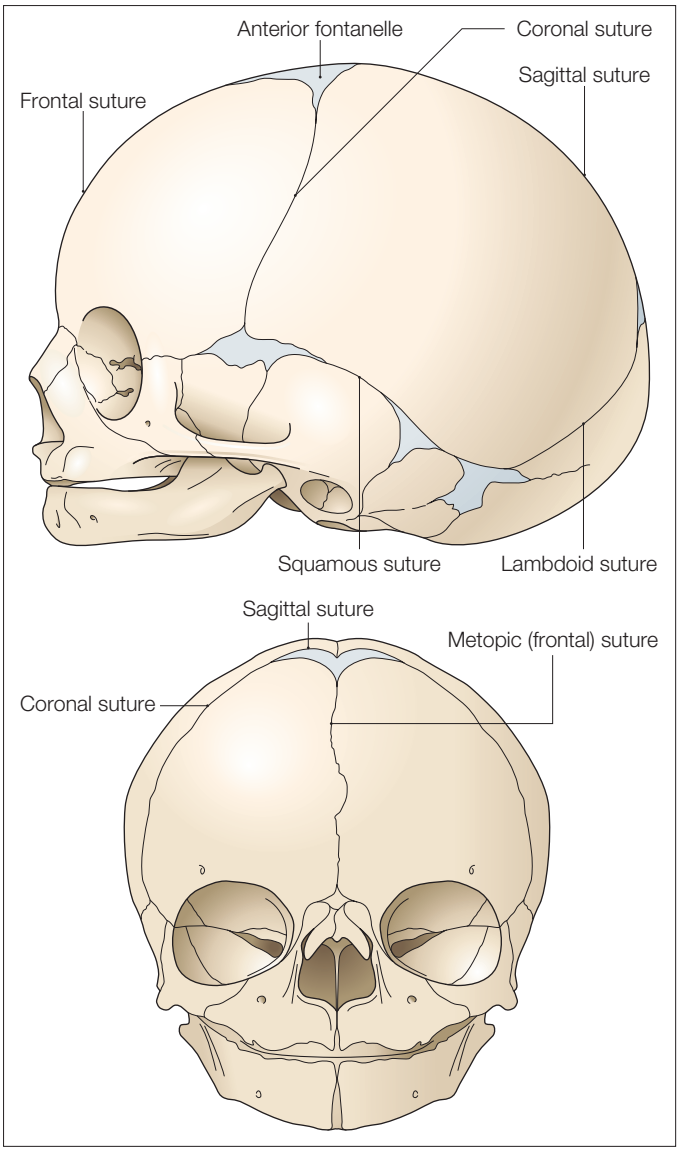

Fig. 28.1 The cranial sutures and fontanelles in an infant skull.

cranial base and facial skeleton. Cranial base underdevelopment compounds primary midfacial hypoplasia through its indirect effects on midfacial growth. The resulting abnormalities of palate, dentition, airway, and hearing may be severe.

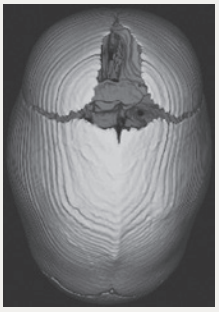
Effects on intracranial pressure, the brain, and optic nerve

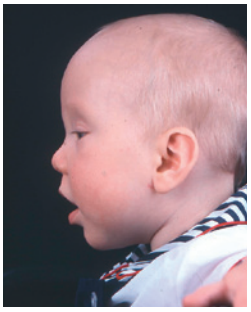
Brain development is intimately tied to growth of the skull; children with craniosynostosis may have developmental delay.[4,5] Reported incidences vary widely. Increased intracranial pressure (ICP) may occur in 75% of syndromic patients and 20% of single-suture craniosynostosis patients. In syndromic patients, four dynamic factors may contribute to raised ICP: restricted skull volume ("craniostenosis"), intracranial venous hypertension, hydrocephalus, and sleep apnea caused by facial deformity.[6] Due to its slowly progressive nature, the majority of patients have no warning symptoms. Radiologic findings are not necessarily related to intracranial pressure recordings and optic nerve swelling is frequently absent. Fibroblast growth factor receptor (FGFR) gene products are found in the optic

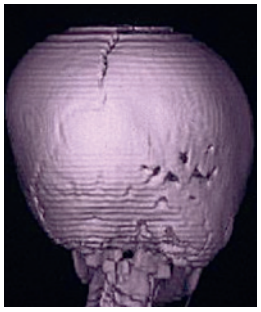
Fig. 28.2 Saethre–Chotzen syndrome. Axial computed tomography of a patient with Saethre–Chotzen syndrome demonstrating shortened orbits and proptosis.

nerve sheath and, when these are mutated, its failure to dilate may be due to abnormal fibrous tissue in the optic nerve sheath or lamina cribrosa.[7] This increased resistance and the limited autoregulatory capacity within the sheath increases the susceptibility of the optic nerve to decreased cerebral perfusion pressure due to raised ICP, venous hypertension, and obstructive sleep apnea-related CO_2 retention.[8] Sleep apnea-related hypoxia may also contribute to brain and optic nerve damage.

Effects on the orbit







In syndromic craniosynostosis, midfacial hypoplasia and underdevelopment of the skull base lead to shallowing of the orbits, retrusion of the orbital rims, and proptosis (Fig. 28.2). Vision–threatening corneal exposure or globe prolapse may occur. Keratinocyte growth factor receptor is a splice variant of FGFR2, and corneal epithelial healing may be abnormal with some FGFR mutations. Lowering of the cribriform plate and anterior cranial fossa floor with overgrowth of the ethmoid complex results in failure of anterior rotation of the orbital axes in fetal life (see Chapter 3), creating divergent orbital axes and hypertelorism (see Chapter 22). This divergence may be greater in the frontal than maxillary planes, resulting in ex-cyclorotation of the orbits (Fig. 28.3). The external manifestation of this is the antimongoloid palpebral fissure. Premature closure of the metopic suture may result in hypotelorism. These changes in orbital axis and angulation increase the likelihood of strabismus, which is seen in up to 90% of patients. FGFR2 is expressed in the extraocular muscles (EOMs); this may explain some of the EOM abnormalities, including bifid, hypoplastic or absent muscles, microscopic abnormalities, and a gristly, inelastic feel.[7] FGFR2 is also expressed in the embryonic rat lens and cornea. This may account for the high incidence of refractive error in these patients.

Management

Diagnosis[2]

Simple craniosynostoses are summarized in Table 28.1 and the most common craniosynostosis syndromes are described in Table 28.2. Syndromic craniosynostosis is readily detected

Table 28.1 Simple craniosynostosis

Suture involved	Features
METOPIC   	Ridging of metopic suture Depressed superolateral orbital rims Narrowed intercanthal distance
UNILATERAL CORONAL  	Ipsilateral forehead and frontoparietal flattening Contralateral frontoparietal bulging Ipsilateral anterior displacement of the zygoma and ear Deviation of nose to contralateral side Shortened orbital roof and superior oblique imbalance
SAGITTAL   	Biparietal narrowing Frontal bossing Ridging of the sagittal suture
UNILATERAL LAMBDOID    	Ipsilateral occipital flattening Ipsilateral frontal bossing

and may be diagnosed *in utero* (Fig. 28.4). There are a number of differential diagnoses to consider with simple synostoses. History and examination will usually resolve any uncertainty. Attention should be paid to:

1. the angle of the palpebral fissure;
2. the position of the ear;
3. any twisting of the nasal tip;
4. a "bird's eye view" of the head.

The sutures may be palpated for abnormal ridging or immobility. Deformational plagiocephaly, a common condition since the introduction of the "back to sleep" intervention to reduce the risk of sudden infant death syndrome, may be confused

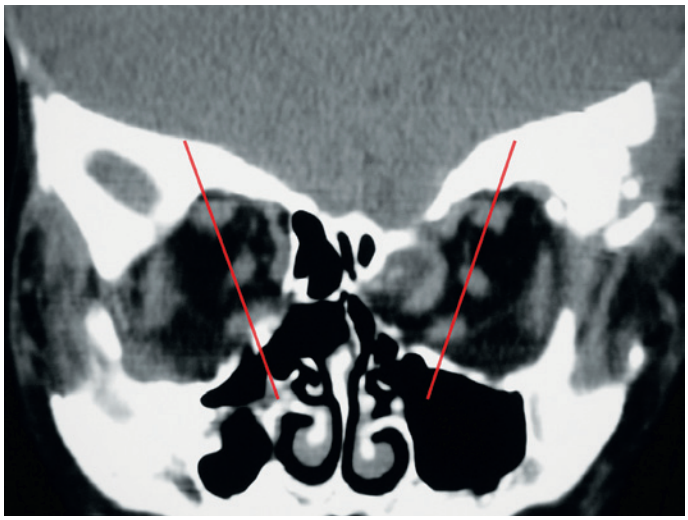


Fig. 28.3 Crouzon syndrome. Coronal computed tomography in a patient with Crouzon syndrome demonstrating ex-cyclorotation of the orbits and their contents. A line drawn between the centers of the superior and inferior rectus muscles emphasizes the angle.

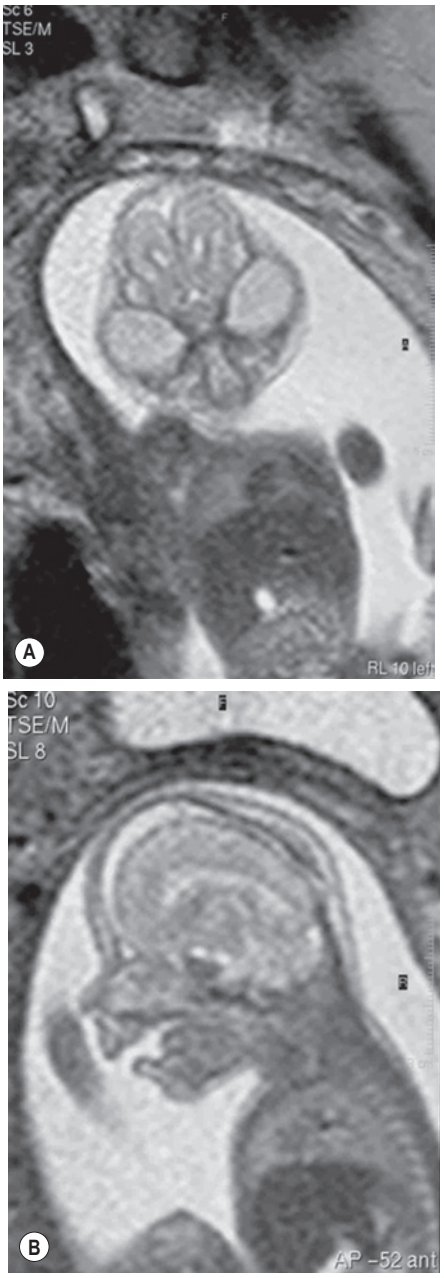

Fig. 28.4 Antenatal ultrasound images of a fetus with Pfeiffer syndrome.

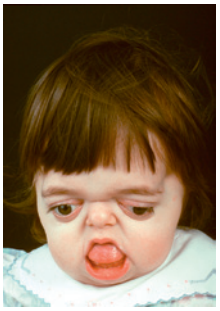

with lambdoid synostosis, which is exceptionally rare. Deformational plagiocephaly is characterized by a history of development of the head shape in the first few months of life in association with persistent positioning on one side, torticollis, or an inactive or developmentally delayed infant. The resultant occipitoparietal flattening may be differentiated from unilateral lambdoid synostosis by a parallelogram-shaped head seen from above and anterior displacement of the ipsilateral ear. Unilateral lambdoid synostosis results in a trapezoidal-shaped head from above with the ear posteriorly displaced (Figs 28.5 and 28.6). The relatively large head and poor neck muscle tone of the premature baby results in a laterally turned head, and may result in a long narrow head. The distinction from sagittal synostosis can be made by the mobile sagittal suture and correction of the head shape at 3 months of age as head control increases. Metopic synostosis may present some diagnostic difficulty; it is a spectrum of disease. At one end is the development of a metopic ridge in the first year of life, which usually requires no treatment. This may be differentiated from premature closure of the metopic suture seen in primary microcephaly by normal head circumference. At the other end of the spectrum is classic trigonocephaly, characterized by metopic ridging in association with supraorbital recession and hypotelorism (see Chapter 22). Where doubt arises, a skull X-ray to check for suture patency is useful, if performed and interpreted by an experienced pediatric radiologist. A computed tomography (CT) scan can be considered where head shape is worsening or doubt persists.

Craniosynostosis is very complex. Decisions about timing and indications for surgery are made with input from specialists from craniofacial, neurosurgical, ear, nose and throat, dental, orthodontic, anesthetic, psychology, audiology, speech therapy, nursing, and ophthalmologic services, forming a craniofacial team. Patients require care from birth until their growth is complete at maturity. Treatment options are exclusively surgical, with a broad range of available surgical techniques. A primary procedure is typically performed in the first 6 months of life, to allow safe growth of a rapidly expanding brain. Removal of the affected suture by strip craniectomy has largely been replaced by more extensive remodeling procedures and expansion of the cranial cavity, most commonly by fronto-orbital advancement. The growing brain may then exert pressure on the released calvaria and dura, allowing for good correction of the cerebrocranial disproportion and deformity. Bone growth is also good and minimizes the risk of bone defects. From this age until the age of 10 years, craniosynostosis should be managed expectantly, with careful monitoring for evidence of raised intracranial pressure, corneal exposure, and airway problems. Some cases may require further cranial expansion surgery or midfacial distraction; expectation would be for recurrence where surgery has been performed at a young age. Surgery in the second decade of life is directed at reducing residual deformity. Best results are achieved the closer to completion of growth the procedure is performed.

Table 28.2 The most common craniosynostosis syndromes

Syndrome	Clinical features
APERT  	Genetics: AD, FGFR3 CS: bicoronal (antenatal), lambdoid, brachycephaly, cranial base (late childhood) CNS (up to 90%): megalencephaly, anomalies septum pellucidum, low IQ, hydrocephalus Face: cleft palate, dental crowding, malocclusion Other: syndactyly (universal), cervical spine fusions, tracheal cartilaginous fusions
CROUZON  	Genetics: AD, variable expressivity, FGFR2, FGFR3 CS (usually in infancy): bicoronal +/– sagittal or lambdoid, cranial base. Head shape variable (scaphocephaly, trigonocephaly, trilobed) CNS (common): Chiari malformation, jugular foramen stenosis, hydrocephalus Face: exorbitism, midfacial hypoplasia, beaked nose, narrow palate, dental crowding, malocclusion Other: cervical vertebral fusion, tracheal cartilaginous fusions, conductive hearing loss
PFEIFFER     	Genetics: AD, incomplete penetrance, FGFR1, FGFR2, FGFR3 Type 1: coronal +/– sagittal CS, normal IQ and life expectancy Type 2: cloverleaf skull, low IQ, synostosis of elbow and forearm Type 3: simple CS, short cranial base, synostosis of elbow and forearm Face: exorbitism, ptosis, ocular anterior segment dysgenesis, midfacial hypoplasia, malocclusion Other (all 3 types): low set ears, ear tags, broad thumbs and great toes, brachydactyly, syndactyly, cervical vertebral fusions, tracheal cartilaginous fusions, cardiovascular, gastrointestinal, urogenital anomalies

Table 28.2 The most common craniosynostosis syndromes—cont'd

Syndrome	Clinical features
MUENKE 	Genetics: AD, FGFR3, variable expressivity CS: coronal Other: low IQ, midfacial hypoplasia, ptosis, hand anomalies
SAETHRE–CHOTZEN  	Genetics: AD, TWIST CS (not universal): coronal, metopic, lambdoid. Often asymmetric Other: ptosis, high forehead, low hairline, maxillary hypoplasia, narrow or cleft palate, broad great toes, brachydactyly, partial cutaneous syndactyly
ANTLEY–BIXLER 	Genetics: AR, FGFR2 (POR) CS: coronal, lambdoid Other: severe midfacial hypoplasia, stenosis or atresia of choanae, low set protruding ears

AD, Autosomal dominant; CNS, central nervous system; CS, craniosynostosis; IQ, intelligence quotient.

Complications include blood loss, bone defects, scalp scarring, and, most commonly, incomplete correction of the deformity. Residual deformity is particularly common in unilateral or asymmetric synostosis. Although fever is common in any surgery penetrating the dura, infection is very rare in procedures not entering the nasopharynx. Despite extensive subperiorbital dissection in fronto-orbital advancement surgery, ophthalmic complications are rare. The effects on ocular alignment are discussed below. Genetic studies have provided potential targets for pharmacologic or genetic treatment modalities. The development of such nonsurgical treatment options may complement or replace current invasive techniques.[9]

Ophthalmic management in craniosynostosis

The ophthalmologist should manage craniosynostosis patients in conjunction with a multidisciplinary specialized craniofacial unit. Examination may be limited by developmental and speech delay, breathing difficulties, and exposure keratopathy-related photophobia. Ophthalmic genotype–phenotype correlations have been reported in syndromic craniosynostosis.[10,11] The visual complications among non-syndromic craniosynostosis will vary with diagnosis.[12,13] However, similar ophthalmic complications may be seen in patients with any diagnosis.

Vision loss

The most important roles of the ophthalmologist are to ensure adequate protection of exposed corneas, monitor for raised intracranial pressure, and detect and treat vision loss. Syndromic craniosynostosis patients have a visual acuity of 6/12 or worse in at least one eye in 65% of cases – in 40% of cases in the better eye.[14,15] Vision loss is rare in simple metopic and sagittal suture synostosis, but is frequent in unilateral coronal synostosis. The majority of non-syndromic and

Fig. 28.5 Bird's eye views demonstrating the parallelogram head malformation seen in deformational plagiocephaly (A) and the trapezoidal head malformation seen in lambdoid suture synostosis (B).

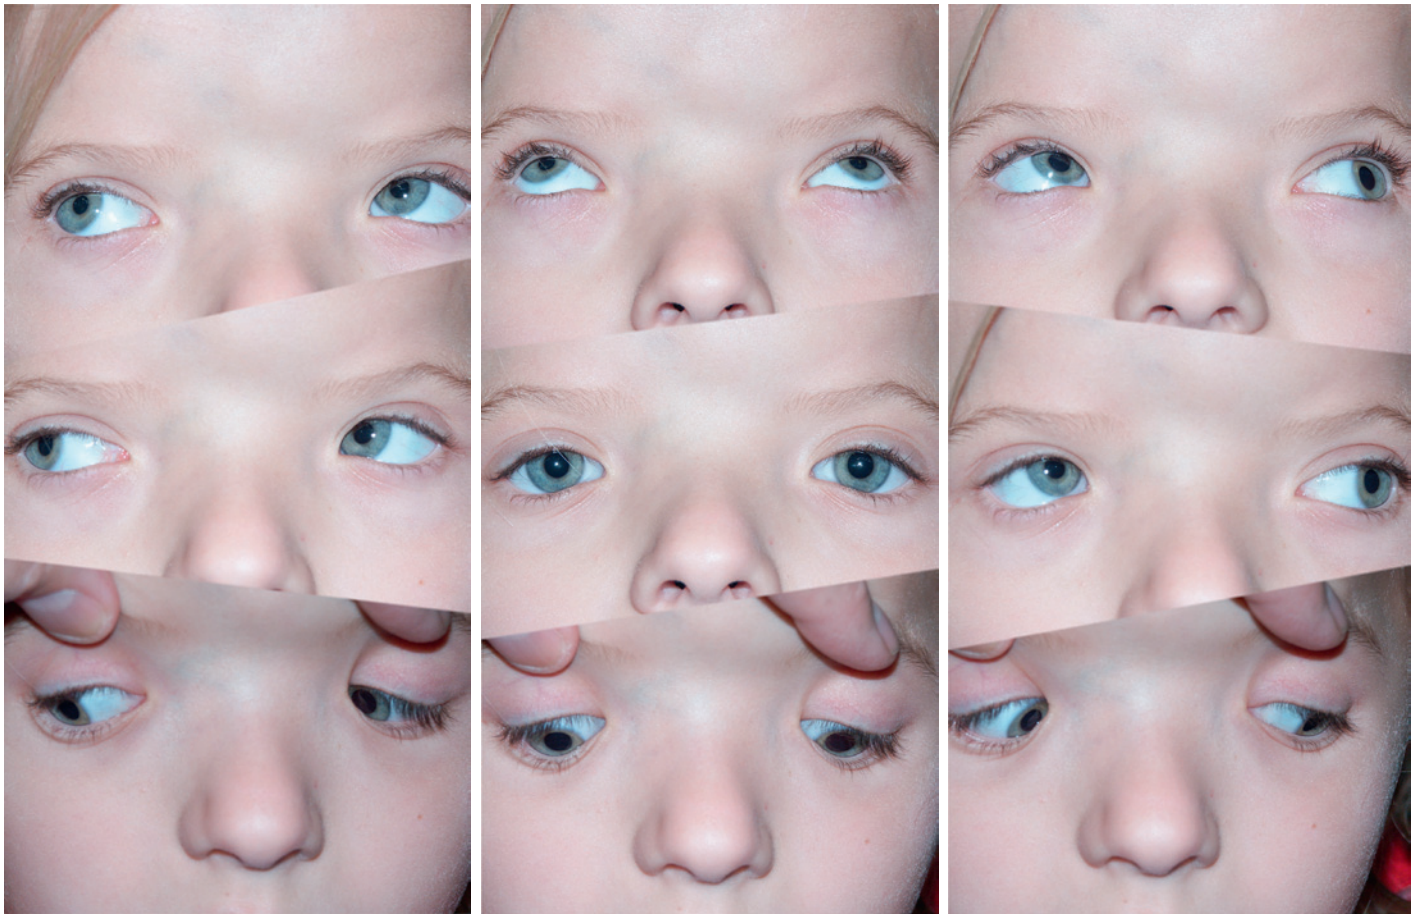

Fig. 28.6 V pattern and pseudo inferior oblique overaction in a patient with Crouzon syndrome.

nearly half of syndromic vision loss is due to treatable causes: astigmatism, anisometropia, and amblyopia.[15–17] Astigmatism may be severe, secondary to the shape of the orbits, ptosis, and corneal scarring. Spectacles may need to be customized to allow comfort and acceptance of wear. Atropine penalization may be preferable to occlusion therapy for amblyopia when there is significant proptosis of the globe. Exposure keratopathy due to a shortened orbit is common in syndromic craniosynostosis and causes discomfort, photophobia, examination difficulties, infection, vision loss, and scarring. The cornea should be protected with lubricants; tarsorrhaphy may be necessary, especially in cases of spontaneous globe prolapse or during periods of significant perioperative chemosis and swelling. In some cases with apparent tissue shortage, levator division may

be necessary to achieve closure. Tarsorrhaphy, however, may result in lid margin changes, which will undermine ocular surface health in the long term. The definitive treatment is midfacial or frontofacial advancement, something which the ophthalmologist may need to advocate for in discussions with the craniofacial team. Distraction devices are the method of choice for this in younger patients; in older patients, surgery may be considered

The optic nerve is susceptible to damage in craniosynostosis, and optic neuropathy may manifest as visual acuity or field loss. Photophobia may make assessment of the optic nerve difficult. Papilledema is frequently absent despite raised ICP. Serial pattern reversal visual evoked potentials (VEPs) are a sensitive and reversible marker of visual pathway dysfunction in raised intracranial pressure due to craniosynostosis.[18,19] Since radiology is also unreliable in detecting raised ICP in craniosynostosis, prolonged invasive ICP monitoring is often required to select patients needing early cranial vault expansion surgery. VEP monitoring provides a valuable noninvasive alternative.[19]

Anterior segment dysgenesis has been reported in Pfeiffer syndrome.[20] Findings include prominent Schwalbe's lines, corectopia, and Peters anomaly. It is prudent to monitor Pfeiffer syndrome patients for glaucoma.

Strabismus

Strabismus is reported in as many as 90% of craniosynostosis patients; exotropia is more frequent than esotropia. Dissociated eye movements, most commonly overelevation in adduction and V pattern, occur in as many as 44%. Theories as to the cause include desagittalization of the obliques due to divergent orbital axes, increased contact of the inferior oblique and globe due to short orbits, and ex-cyclorotated orbits and EOMs.[21] Ex-cyclorotation of all the EOMs will create an abnormal abducting force in elevation from the superior rectus muscles and an abnormal adducting force in depression from the inferior rectus muscles, resulting in a V pattern. The medial rectus muscles will have an abnormal elevating force in adduction and lateral rectus muscles an abnormal depressing force in abduction, mimicking inferior oblique overaction. Craniosynostosis patients have an abnormally high incidence of absent EOMs: superior oblique and superior rectus muscles are the most commonly affected. Strabismus may be multifactorial in some patients.

Success may be limited in strabismus surgery in craniosynostosis patients; however, a patient's condition is rarely worsened and a measured degree of optimism may be held. The timing of surgery takes into account any prior or planned craniofacial reconstruction. Routine fronto-orbital advancement has little effect on strabismus, but surgery to correct hypertelorism often results in an eso-shift. Craniofacial surgery may involve extensive subperiosteal orbital dissection and may result in subconjunctival fibrosis, making surgery more difficult. For these reasons, strabismus surgery should usually be deferred for some time postoperatively.[22] Some surgeons advocate early surgery when craniofacial reconstruction has been deferred beyond the first year of life, to establish binocularity. However, the likelihood of a second, post-reconstruction procedure must be considered. Perfect alignment may be very difficult to achieve and a binocular patient may face a higher risk of postoperative diplopia.

In V patterns and overelevation in adduction, the surgeon should have a high index of suspicion of ex-cyclorotation or muscle anomaly. Other indicators of ex-cyclorotation include ex-cyclorotation of the fundus and torsional movements with vertical optokinetic nystagmus stimulation. Preoperative imaging is useful. The EOMs are most easily identified on coronal CT or magnetic resonance imaging (MRI) immediately posterior to the globe (see Fig. 28.3). Although MRI is the "gold standard" imaging technique, three-dimensional ultrasound imaging is a safe and accurate alternative. Due to short reconstruction times, it may be performed at the time of surgery. It is less accurate at determining extraocular muscle position.[23] If imaging is not possible, surgical alternatives should be planned prior to operation. Some advocate exploration of all six EOMs, although anterior segment ischemia is a risk, especially if muscles are absent.

Horizontal deviations in primary gaze may be treated by standard recession and/or resection surgery; transposition of the rectus muscles may improve the dissociated movements. Coats et al. reported on 14 operated craniosynostosis patients with V pattern with severe oblique dysfunction.[24] Only inferior oblique (IO) myectomy or denervation and extirpation were consistently effective at treating IO overaction; only IO denervation and extirpation improved the superior oblique (SO) underaction. Isolated IO anteriorization and infraplacement of the medial rectus muscles were ineffective. The antielevation syndrome seen after temporal spreading of the insertion in IO anteriorization could worsen the IO overaction of the opposite, adducting eye. Hussein et al. reported nine cases of absent superior oblique tendon, confirmed by the exaggerated traction test, seven of which had craniosynostosis.[25] They reported good reduction in IO overaction and divergence in upgaze with IO nasal and anterior transposition. The best responses were seen in those with unilateral absent SO. Holmes et al.[26] believe that superior oblique tuck surgery addresses ex-cyclorotation of the globe, normalizing the vector forces of the rectus muscles, and they reported a good result in one patient in association with inferior transposition of the medial rectus. Good correction of hypotropia due to imaging-confirmed superior rectus muscle absence can be obtained with a Foster modification of the Knapp procedure.[22] The surgery in one case induced a horizontal deviation.

Clefting syndromes

The second major group of craniofacial abnormalities comprises the clefting syndromes and results from defective apposition or failure of fusion of neighboring structures during embryonic development. Tessier[27] introduced a descriptive classification, numbering clefts from 0 to 14 in clockwise rotation around the orbit (Fig. 28.7). Clefts of midline structures of the nose and forehead are numbered 0 and 1 below the level of the medial canthus and 13 and 14 above. Nasolacrimal and medial canthal clefts are numbered 2, 3, and 4 below and 10, 11, and 12 above, and so on. Cleft number 30 is of the mandibular symphysis. Clefts resulting from failure of embryonic closure of the nasolacrimal furrow or from amniotic bands are simply numbered according to their location relative to the eye.

Tessier's system encompasses the eponymously named syndromes of the face including Treacher Collins and Goldenhar, as well as craniofacial microsomia, formerly grouped together as mandibulofacial dysostoses, that are primarily due to retarded differentiation of the first branchial arch mesoderm.

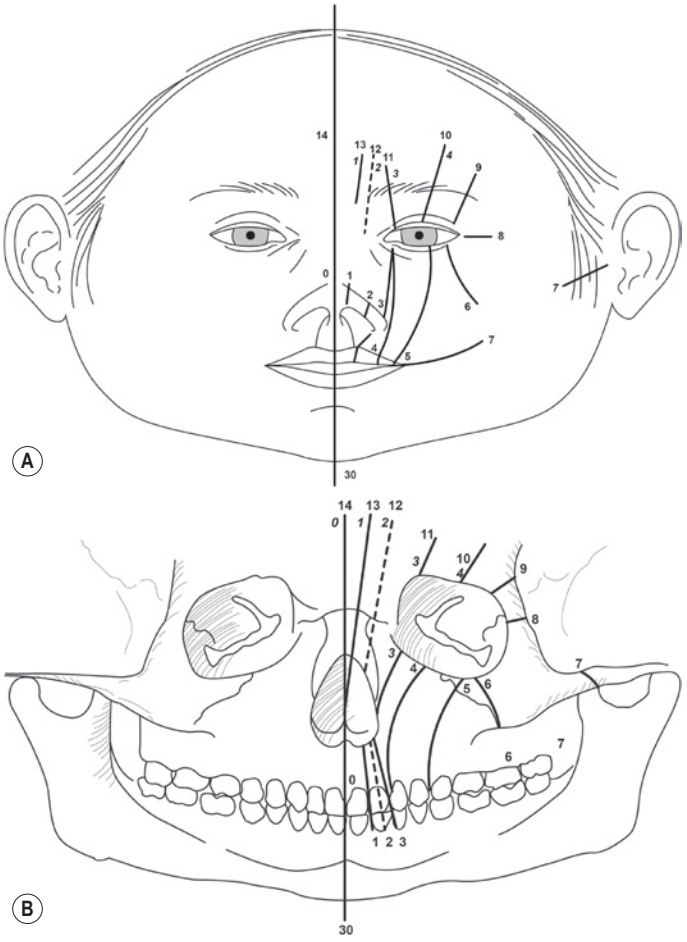

Fig. 28.7 Tessier classification of craniofacial clefts. (A) Soft tissue. (B) Skeletal. *(Modified from David DJ, Moore MH, Cooter RD. Tessier clefts revisited with a third dimension. Cleft Palate J 1989; 26: 163–84.)*

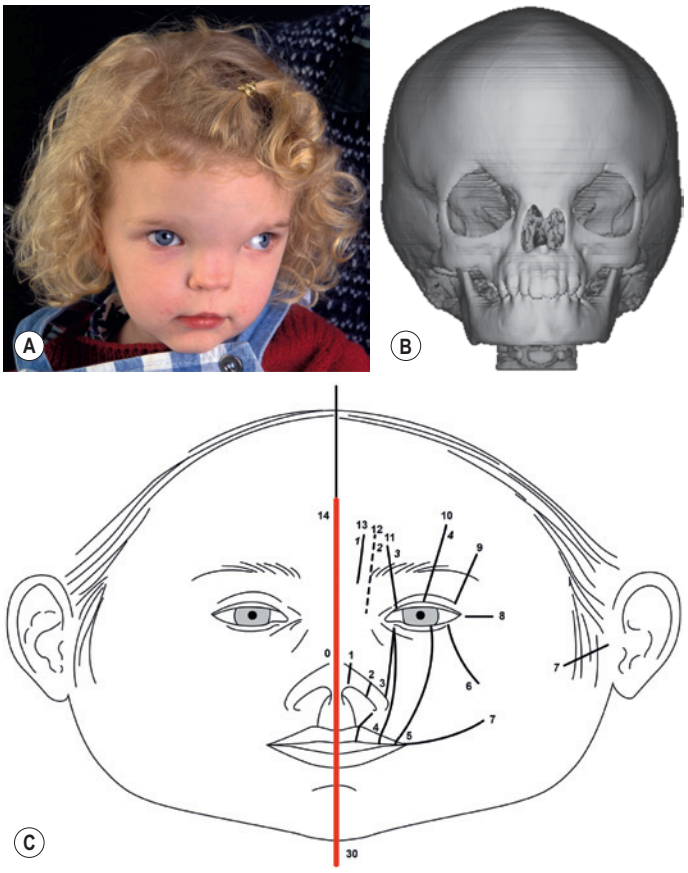

Fig. 28.8 (A) A 5-year-old girl with untreated midline craniofacial cleft (Tessier type 0–14) showing midline depression of the nose, and exotropia. (B) Computed tomography reconstruction shows widely displaced orbits and widened nasoethmoid region. (C) Cleft marked in red.

Van der Muelen et al.[28] have developed a different classification, replacing "cleft" with "dysplasia" based on the embryology of the brain, face, and cranium. This classification explains deformities ranging from anencephaly to lymphangioma by facial clefting and craniosynostosis. However, this system competes with the more simplistic topographic classification of Tessier used here.

Figures 28.8–28.13 are examples of the individual numbered clefts (with the cleft highlighted on the three-dimensional CT scan) – some have combinations of clefts.

Cleft number	Common ocular problem
3 & 11	epibulbar dermoid
4 & 10	iris coloboma
5 & 9	microphthalmos
9, 10, 11	upper lid cleft
3, 4, 5, 6	lower lid cleft

Types of lacrimal problems include: the puncta may be displaced laterally or be absent and the canaliculi may be disrupted or elongated; the lacrimal sac and/or nasolacrimal duct may be absent, and there may be bony defects of the lacrimal fossa.

Treacher Collins syndrome

Although Treacher Collins syndrome (TCS) was first described by Berry, Treacher Collins emphasized the malar deformity; it was expanded by Franceschetti and Zwahlen. The incidence is 1 : 50,000 live births.[29] The mode of inheritance is autosomal dominant with complete penetrance but variable expressivity of a gene on the long arm of chromosome 5 (5q32–33.3).[30] Various gene deletions encoding RNA polymerases 1 and 111 have been identified, confirming the heterogeneity of TCS, thus supporting the hypothesis that TCS is a ribosomopathy.[31]

General findings

- Complete form of TCS involves Tessier clefts 6, 7, and 8 (see Fig. 28.13).
- Characteristic facies include hypoplasia of malar and zygomatic bones with deficient inferolateral orbital angles (Fig. 28.14A).
- Bird- or fish-like profile results from absence of the nasofrontal angle (Fig. 28.14B).
- Lower jaw is hypoplastic with abnormal dentition.
- Respiratory problems result from choanal atresia and mandibular retrusion.
- Malformations of the external ear are common.
- Deafness (50% of cases) results from ossicular chain or inner ear malformations. *Early audiologic assessment is essential.*
- Accessory auricular appendages and blind fistulae occur between the angle of the mouth and ear.

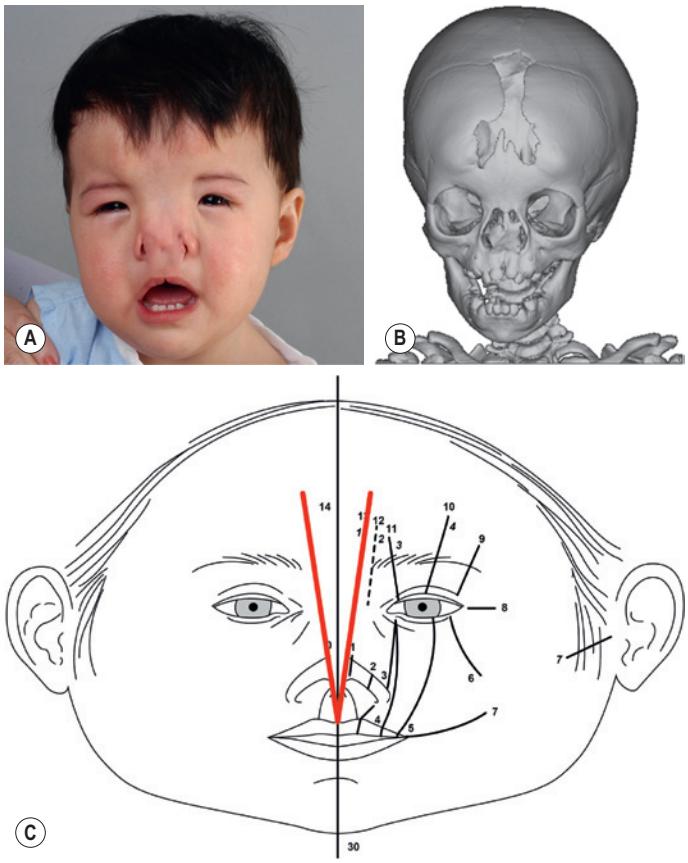

Fig. 28.9 (A) A boy with Tessier type 1–13 cleft: central cleft lip and cleft alae with flattened dorsum of nose. (B) Computed tomography reconstruction: widened nasoethmoid region. (C) Clefts marked in red.

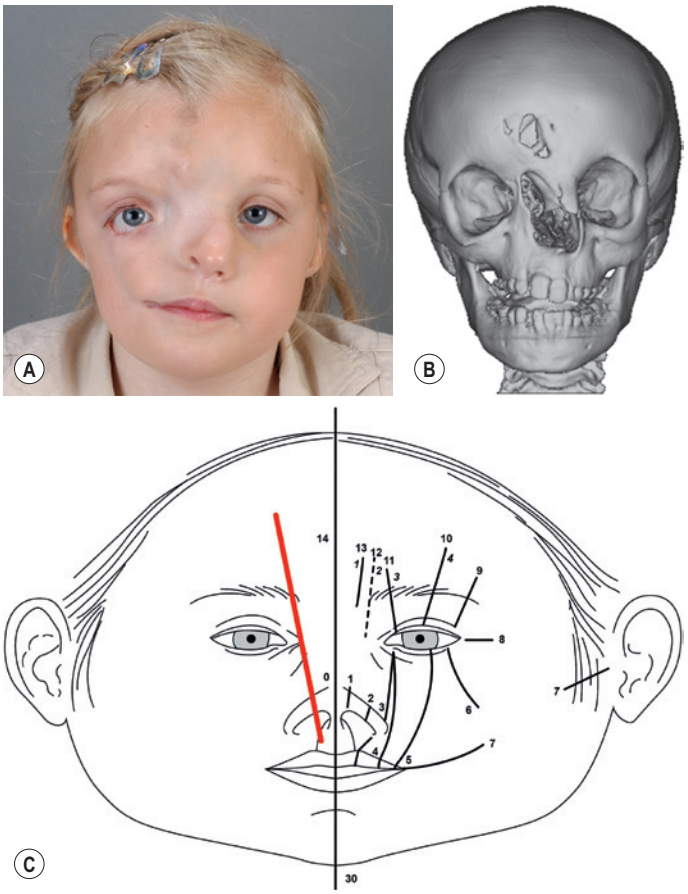

Fig. 28.10 (A) This girl with Tessier type 2–12 cleft shows a soft tissue groove above the distorted right nostril extending up her forehead and a type 5 cleft with vertical soft tissue deficiency between the lateral portion of the lip and the right lower eyelid cleft. (B) Computed tomography reconstruction: 2–12 cleft through ethmoids to frontal bone displacing the orbit laterally; 5: abnormal inferolateral orbital rim. (C) Only the 2–12 cleft is shown in red while her right 5 cleft corresponds to that shown in black on the left.

Ocular findings

- Antimongoloid slant of palpebral fissure.
- Coloboma of lateral one-third of lower lid (common) or pseudocoloboma with hypoplastic cilia, subcutaneous tissues, and muscle; absent lashes on the medial one-third of lower lids (common).
- Canthal dystopia.
- Nasolacrimal obstruction.
- Limbal or orbital dermoids (common), high astigmatism in severely affected cases.
- Severe risk of cognitive deprivation due to astigmatism plus deafness.
- Difficult to fit spectacles in presence of hearing aids and external ear abnormalities.

Management protocol[32]

1. Birth–2 years: airways and feeding problems, hearing problems.
2. 2–12 years: speech therapy and education, removal of limbal dermoid, oculoplastic repair of lid coloboma, and facial reconstruction with bone or vascular bone flaps.
3. 13–18 years: orthognathic surgery, final facial revision.
4. The abnormal anatomy causes airway management difficulties necessitating anesthetic expertise.

Goldenhar syndrome

Goldenhar described a syndrome of epibulbar dermoids, preauricular appendages, and mandibular hypoplasia (or hemifacial microsomia), which was expanded by Gorlin et al.[29] to the "oculoauriculovertebral spectrum." Most cases are sporadic but familial cases have been associated with a deletion on the long arm of chromosome 22 (22q11.2).[33]

Expression is variable, ranging from a few preauricular appendages only to bilateral clefting extending from the angles of the mouth to the tragus as well as of the palate and from either side of the frontonasal process to the medial canthi.

General findings

- Facial abnormalities may be bilateral but are usually more severe on one side (Fig. 28.15).
- Preauricular appendages – usually anterior to the tragus +/– fistula to ear.
- Facial asymmetry.
- Bilateral clefting from angle of mouth to tragus and of palate and either side of frontonasal process to medial canthi.

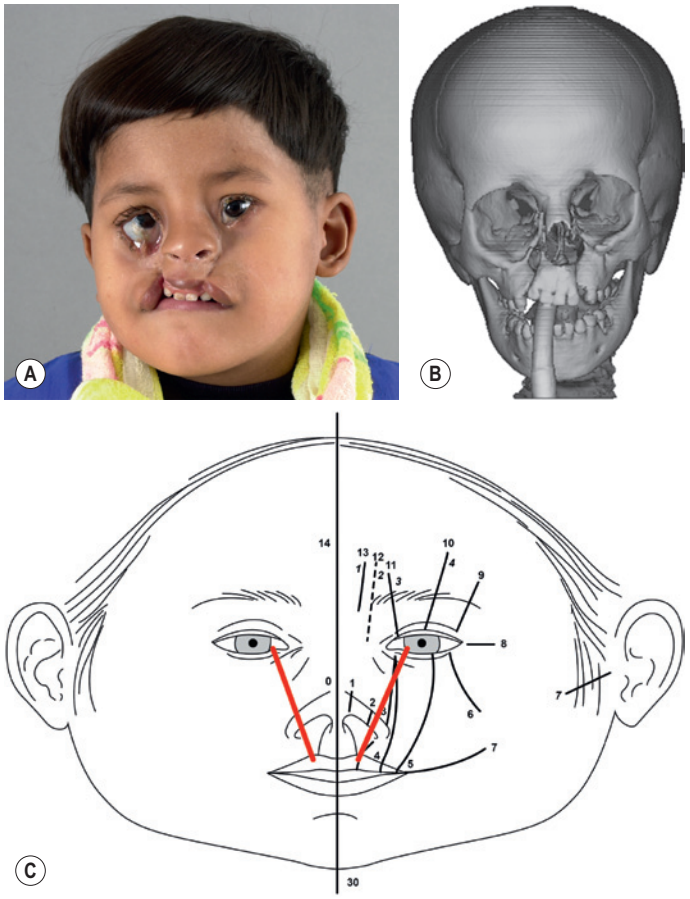

Fig. 28.11 (A) This boy has bilateral Tessier type 4 clefts with severe vertical soft tissue deficiency in the medial cleft lip extending toward the medially placed clefts in the lower and upper eyelids together with marked right orbital dystopia. (B) Computed tomography reconstruction shows bilateral clefts of anterior maxillae into orbital rims and the right orbital dystopia. (C) The no. 4 clefts are shown in red.

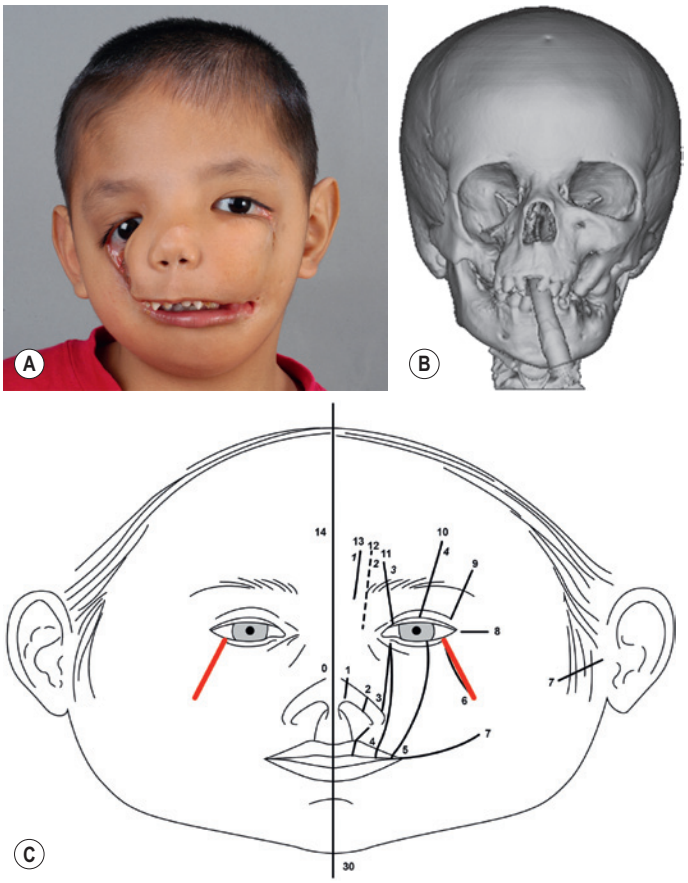

Fig. 28.12 (A) A boy with bilateral Tessier type 6 clefts: severe vertical soft tissue cleft from the oral commissure on the right and a furrow on the left to laterally placed lower eyelid clefts. There is antimongoloid obliquity of the palpebral fissures, some ectropion, and marked right orbital dystopia. (B) Computed tomography reconstruction: cleft in region of the right zygomaticomaxillary suture with hypoplasia of the maxilla and orbital rim. (C) Both no. 6 clefts shown in red.

- The "expanded Goldenhar complex" includes vertebral, cardiac, renal, pulmonary, and central nervous system abnormalities (including severe hydrocephalus and mental retardation).

Ocular findings

- Dermolipoma: usually yellowish, subconjunctival, superotemporal orbit. Rarely enlarges – can often be left alone (Fig. 28.16A).
- Epibulbar dermoid: unilateral 50%, bilateral 25%; nil 25%, usually inferotemporal limbus but can occur anywhere on the globe or within the orbit. White but often infiltrate of lipid at leading edge in cornea (Fig. 28.16B). May have irritating hairs (Fig. 28.16C). Can increase in size and cause astigmatism and amblyopia.
- Coloboma of iris: cosmetic defect +/– glare problems. May need cosmetic contact lens with painted iris.
- Microphthalmos – common.
- Ocular motility disturbance – common. Duane syndrome/esotropia/exotropia found in about 25%.[29]
- Ptosis.
- Nasolacrimal duct obstruction and fistula.
- Coloboma of mid-third of upper lid in 20%, often with ipsilateral epibulbar lesion.

Goldenhar syndrome shares a number of features with Treacher Collin syndrome; a combination of both has been reported.

Frontoethmoidal meningoencephalocele

These are subclassified as to their location: nasofrontal, nasoethmoidal and naso-orbital, their exit hole from the anterior cranial fossa being the foramen cecum. The extruding intracranial contents covered in meninges distort the developing face producing telecanthus, orbital dystopia, elongation of the face, and dental malocclusion (Fig. 28.17).

The clinical presentation depends on the location and extent of the lesion and can vary between a small soft cystic swelling over the bridge of the nose, depressing the nasal structures, to nasal obstruction causing difficulty with breathing and eating. Hypertelorism occurs, particularly if there is associated facial clefting producing a midline defect. Ocular problems include strabismus, amblyopia, and nasolacrimal drainage problems.

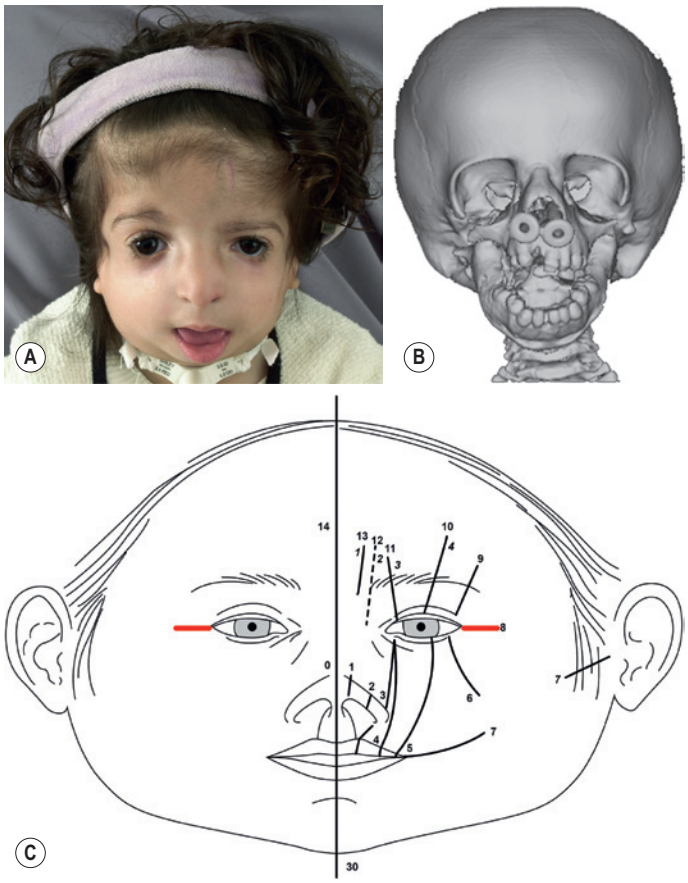

Fig. 28.13 (A) This girl has severe Treacher Collins syndrome and Tessier cleft type 8 with choanal atresia and mandibular retrusion (hence the tracheostomy), lower eyelid pseudocolobomata, and external ear abnormalities. (B) Computed tomography reconstruction: deficient lateral orbital wall, rim, and floor with hypoplastic malar and zygomatic bones bilaterally. (C) Type 8 clefts shown in red.

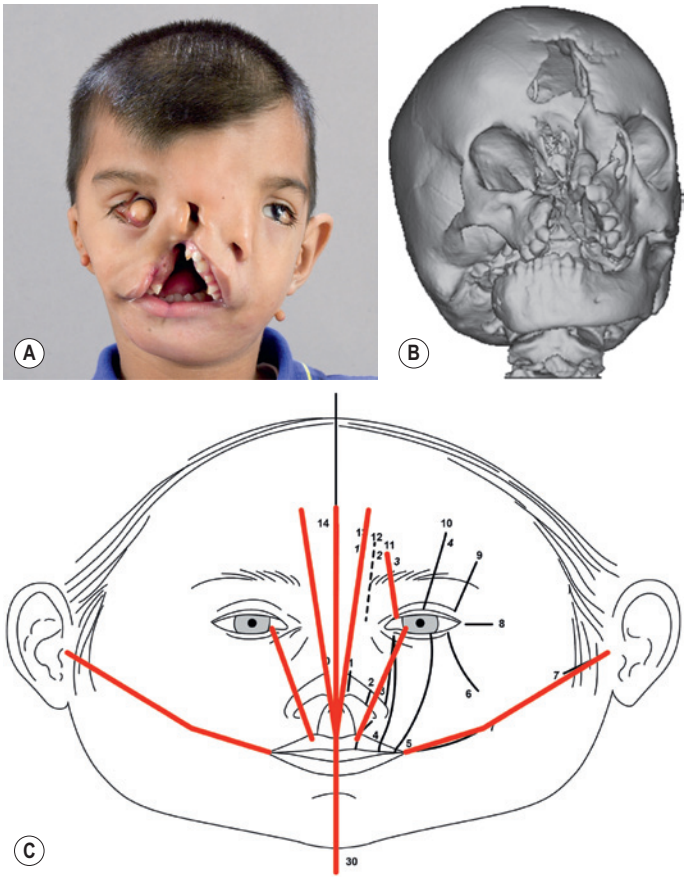

Fig. 28.15 (A) This highly intelligent boy has all the elements of Goldenhar syndrome combined with complex, multiple midline clefts (Tessier types 30, 0–14, 1–13, 3, 7) with a coloboma of the middle third of the right upper lid with bilateral inferotemporal epibulbar dermoids impairing vision and preauricular appendages. The right lower lid coloboma was part of his maxillary cleft. (B) Computed tomography reconstruction shows the frontal defect, the gross orbital dystopia, the maxillary cleft, and the absence of the right mandible and temporomandibular joint. (C) His multiple clefts are shown in red.

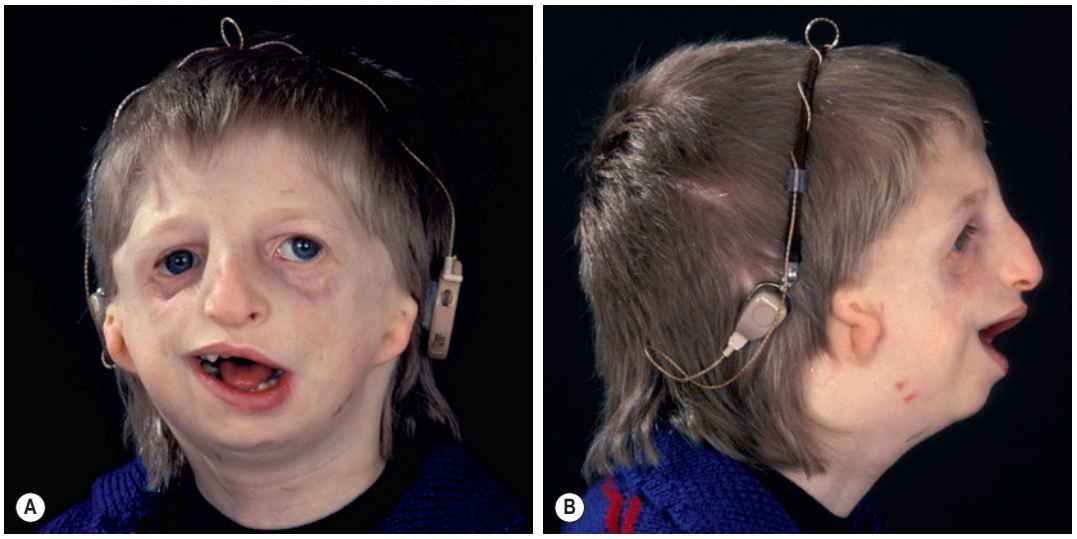

Fig. 28.14 (A) A boy with Treacher Collins syndrome with midface hypoplasia, antimongoloid slant of palpebral fissures, pseudocoloboma of lateral one-third of lower lid, nasolacrimal obstruction, deafness, and external ear abnormalities. (B) Typical "fish-like" profile (absent nasofrontal angle), hypoplastic lower jaw, and mouth breathing due to nasal airway obstruction.

Fig. 28.16 (A) Yellowish subconjunctival dermolipoma in the superotemporal orbit. (B) Epibulbar dermoid at inferotemporal limbus with leading edge lipid infiltrate in cornea. (C) This epibulbar dermoid had irritating hairs growing from it.

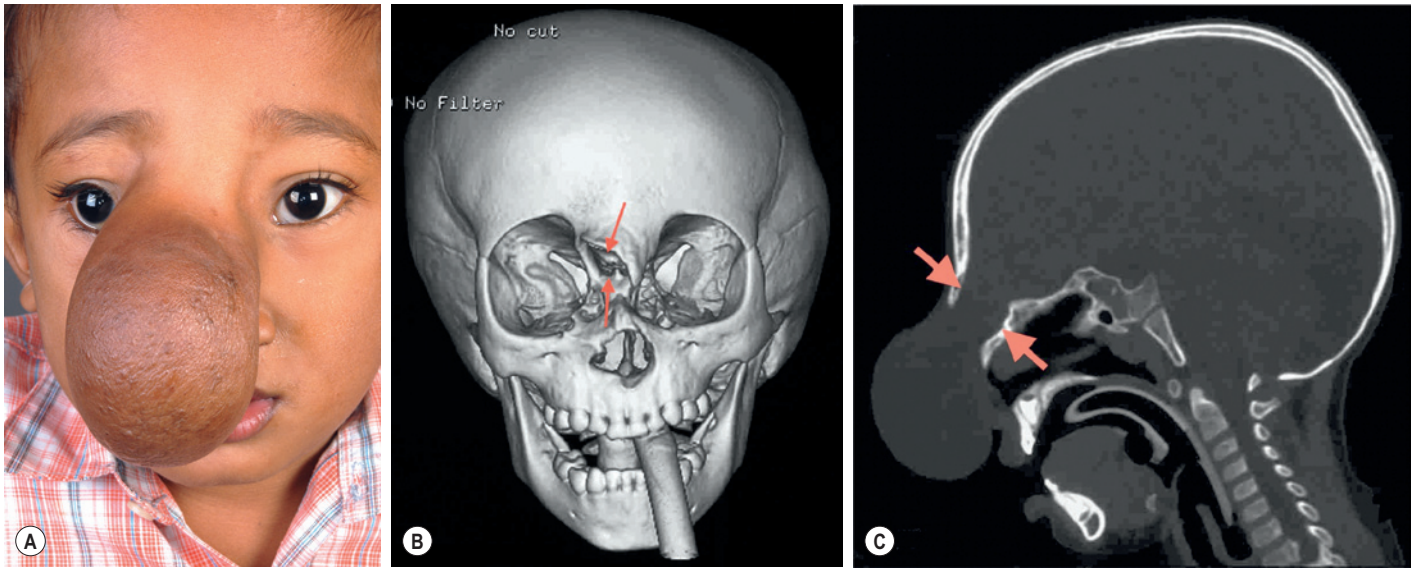

Fig. 28.17 (A) This boy from South East Asia has a very large nasoethmoidal variety of frontoethmoidal meningoencephalocele causing an exotropia and typical elongation of the face. (B) Computed tomography (CT) reconstruction with arrows indicating the bony cranial base defect. (C) This sagittal CT scan shows the dysfunctional brain tissue extruding through the region of the foramen cecum (arrowed).

Frontoethmoidal encephaloceles are more frequent in South East Asia (1:5000 live births), Africa, Malaysia, and Russia.

Management

Hydrocephalus, when present, must be dealt with first, then excision of the cele, watertight closure of the dural defect, followed by reconstruction of the skull defect. Early removal of the meningoencephalocele by the craniofacial route allows re-establishment of normal facial growth.[34] The prognosis depends on the presence of additional congenital anomalies.[35] Post craniofacial surgical problems include hydrocephalus, rhinorrhea, secondary encephalocele (if there is raised ICP and inadequate reconstruction of the frontal bone). Postoperative strabismus nearly always resolves, as does epiphora, which is surprising as the lacrimal drainage system is significantly distorted by the developing cele.

Midline facial cleft

These may include cleft lip and palate, midline bifid nose, and midline encephalocele plus other intracranial abnormalities.

Subtle signs such as a small notch in the upper lip or in the middle of the nose should alert the clinician to an underlying defect (Fig. 28.18).

Six patients in one series[36] all had midline cleft lip and palate, hypertelorism, absent corpus callosum, and sphenoethmoidal (basal) encephalocele, and five of the six had pituitary deficiency. Two had unilateral and one had bilateral peripapillary staphyloma. Two had bilateral optic disc hypoplasia, whereas another had a staphyloma in one eye and a morning glory disc anomaly (MGDA) in the other. An MGDA or optic disc hypoplasia should trigger neuroradiologic investigation to rule out these midline brain defects.

Amniotic bands

These occur when bands of amnion encircle parts of the developing fetus, restricting local growth. When the head is affected, the resulting clefts do not follow usual developmental patterns. However, major craniofacial malformations may occur (Fig. 28.19). This sporadic condition affects both sexes equally.[37]

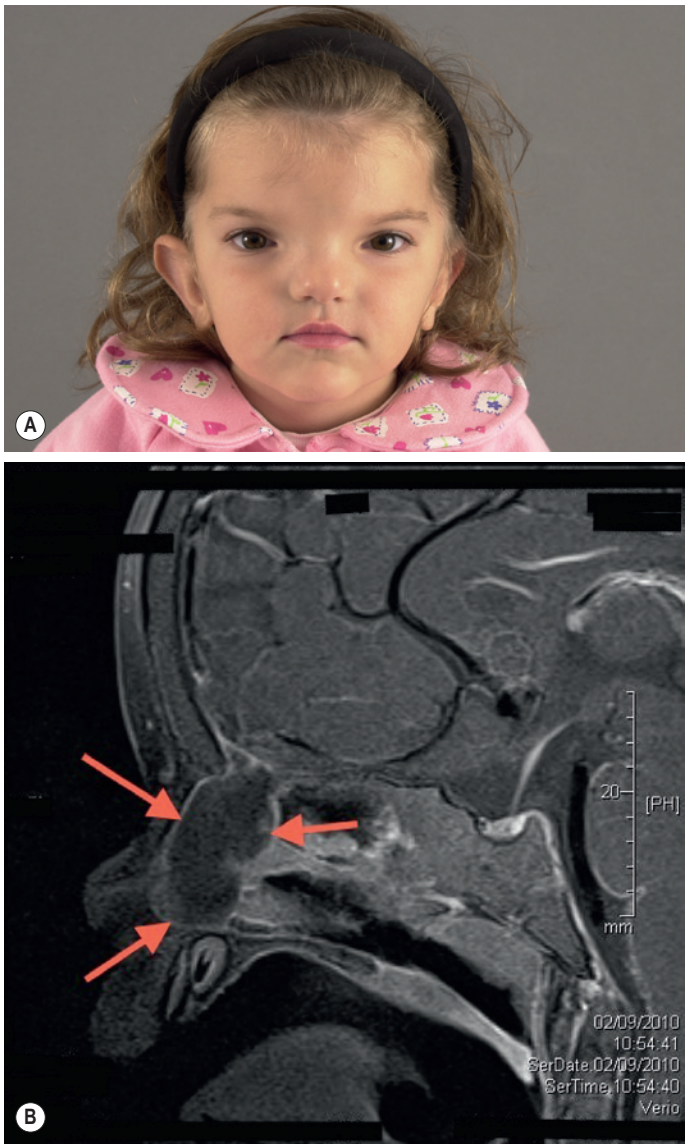

Fig. 28.18 (A) This little girl has subtle external signs of her midline cleft and basal encephalocele: midline nasal furrow and hypertelorism. (B) This other girl's sagittal magnetic resonance imaging scan shows a midline basal encephalocele (arrows). She presented with noisy breathing and examination showed cerebrospinal fluid rhinorrhea and a whitish mass up her nostril.

The most common ocular malformations are congenital corneal leukomas or acquired corneal opacities secondary to exposure and eyelid colobomas. The eyelid defects appear to be extensions of facial clefts and are often located adjacent to the corneal opacities. Other associations are microphthalmos, strabismus, hypertelorism, and rarely coloboma of iris and retina.

Craniofacial surgery

The use of nylon skulls,[38] created from three-dimensional CT scans of the patient, facilitates planning of complex staged reconstructions (Fig. 28.20).

While bone grafting and craniofacial osteotomies correct the underlying skeletal abnormalities, the ultimate success of these reconstructions is limited by the deficiency of skin and soft tissue. Tissue expansion (Fig. 28.21) prior to the primary correction or the secondary surgery allows tension-free closure and improved aesthetic results. Surgical protocols for the various conditions will often need to be individualized. The relative rarity of many of these syndromes makes outcome comparison and statistical analysis of results difficult.

The ophthalmologist needs to be aware of the various complications of this specialized surgery.[39]

Neurosurgical and ophthalmic complications

- Dural damage, more common in surgical correction of craniosynostosis, leading to cerebrospinal fluid (CSF) leak with potential for infection and, rarely, a growing fracture.
- Persisting CSF fistula, especially with hypertelorism or frontoethmoidal encephalocele correction.
- Intracranial hematoma, especially from vascular lesions found in midline clefts.
- Acute hydrocephalus, especially after correction of frontoethmoidal meningoencephaloceles.
- Cerebral ischemia can lead to gliosis and epilepsy.

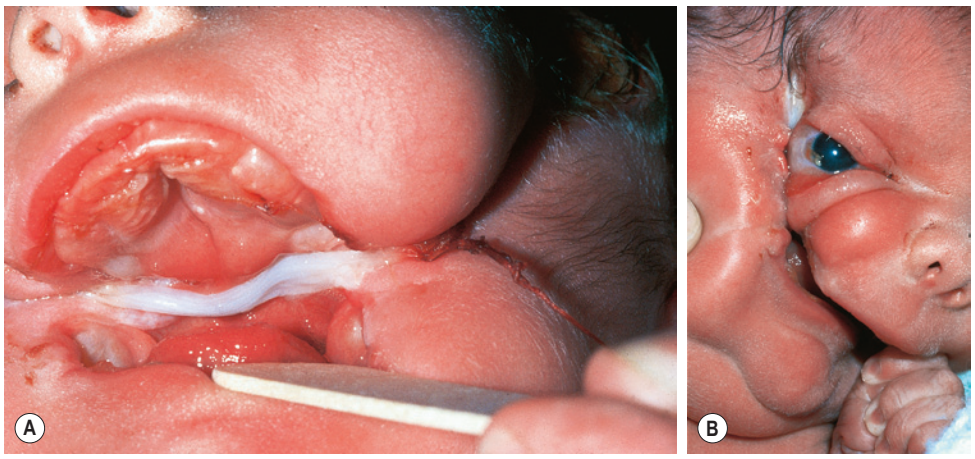

Fig. 28.19 Amniotic bands. (A) A white band can be seen traversing the palate, ending as a cord. (B) The cord cleaves the right maxilla and orbit.

Fig. 28.20 This nylon model constructed from a three-dimensional computed tomography scan of a patient with a midline cleft shows not only the deformity but also how the model can be used for surgical planning and rehearsal.

Aspects of ocular complications prior to, during, and after craniofacial surgery include:

- Adequate corneal protection to prevent drying, ulceration, and scarring with long-term measures required if poor lid function.
- Monitoring visual acuity and its correction to prevent amblyopia.
- Correction of strabismus.
- Canthal and lid position must be optimized prior to lacrimal surgery.

Diplopia can complicate malposition of the whole orbit, malposition of the globe within the orbit, or injury to the EOMs. However, few of the children with very significant orbital deformities are binocular; alternating strabismus is common with suppression of the deviating eye. Binocularity, when present, will be retained postoperatively provided the visual axes remain parallel. About 10% require squint surgery.

Dystopia can be minimized if the craniofacial surgeon preserves a frontal bar of bone as a reference point for orbital repositioning. Following orbital repositioning, for example for hypertelorism, sixth cranial nerve palsies are common but transient: 90% recover in 6–12 months in the authors' experience.

Canthal dystopia is a frequent problem medially with clefts with a medial lid coloboma or deficient canthal ligament. Wedge excision, lower lid advancement, Z-plasties, or other flaps may be needed.

Epiphora is common and probably due to crumpling of the canaliculi. The drainage system is often not present or functional in Tessier no. 3 clefts and in frontoethmoidal meningoencephaloceles. If dacryocystorhinostomy is indicated, it may not be possible to fashion usual nasolacrimal flaps and so out-fracturing techniques from sac to nasal cavity with dilators (e.g. Hegar's cervical) followed by packing with cellulose sponge is often required. Use of Lester Jones or other tubes may not be practical, as they require careful follow-up care.

Enophthalmos is common after correction of naso-orbital frontoethmoidal meningoencephalocele. It is difficult to correct, even with extensive bone grafting.

A "tight orbit" or "orbital compartment syndrome" is a dreaded (early?) postoperative complication due to marked edema or hemorrhage, causing optic nerve or retinal ischemia or infarction. Pupillary responses and visual acuity must be closely monitored. In such an event, the appropriate orbital decompressive technique will be dictated by the previous operative procedure.

Pressure on the globe or optic nerve by a malpositioned bone graft can occur, but direct trauma to those structures is very rare.

The authors are aware of only three cases of postoperative blindness from 17,000 individual non-trauma craniofacial patients treated to date by their clinic – the last occurring 3 years ago in a patient with Pfeiffer syndrome who lost vision in one eye while being operated on in a prone position. Infection is rare considering the nasal sinuses are opened in craniofacial procedures. Appropriate aseptic techniques and postoperative antibiotic regimes must be followed.

The ophthalmologist as an important member of the craniofacial team

These developmental conditions obviously involve more than just the eye and adnexae. Hence the ophthalmologist should be a member of the craniofacial surgical team taking a coordinated role in the assessment, planning, surgical correction, and rehabilitation of the patient.

The ophthalmologist must accurately record the preoperative state including visual acuity, presence or otherwise of binocular vision, strabismus, and ptosis. The team planning meeting coordinates the sequence of management and surgical steps required by the many surgical specialties involved. Postoperatively, the role is reassessment and management of any surgical complications, followed by visual rehabilitation. The whole process usually extends over many years – at least until after visual system maturation and often well after cessation of craniofacial growth.

Sadly, patients with craniofacial defects may be stigmatized by society. The ophthalmologist can contribute by improving their visual function and cosmesis and is richly rewarded when the patient is enabled to take their rightful place in society.

Acknowledgment

Signed parental consent for publication of all the clinical photographs is held by the Australian Cranio-Facial Unit, Adelaide, South Australia.

Cystic lesions

A variety of cystic lesions may occur in and around children's orbits.[1] By far the commonest is the dermoid cyst, but other cystic choristomas may occur in and around the orbit, including congenital cysts lined by conjunctival and respiratory epithelium. Other cystic lesions include microphthalmos with cyst, congenital cystic eyeball, lacrimal ductal cyst, meningocele and encephalocele, sinus mucocele, and teratoma. In some parts of the world, parasitic cysts involving organisms such as *Echinococcus* (hydatid cyst) and *Cysticercosus* are common, but they are rare in Europe and North America.[2] Hemorrhage within orbital venous-lymphatic malformations (lymphangiomas) may give rise to "chocolate" cysts. Cystic lesions of the orbital bones may be seen in fibrous dysplasia, ossifying fibroma, and aneurysmal bone cyst.

Dermoid cyst

Dermoid cysts of the orbit and periorbital region are common in childhood, accounting for between 3% and 42% of orbital lesions in children in different reported series.[2–5] They are developmental cystic choristomas, which arise from ectodermal rests trapped at suture lines or within mesenchyme during orbital development.

The cysts are lined by keratinized stratified squamous epithelium. Adnexal structures such as hair follicles, sebaceous and sweat glands are found within their wall. Cyst leakage or rupture may give rise to an acute inflammatory response, followed by a chronic low-grade granulomatous inflammation. This inflammatory response is often subclinical, but is commonly seen surrounding longer-standing dermoid cysts.

Dermoids may be superficial or deep.[6] Superficial dermoids are usually outside the orbit, and overlie the orbital rim, without a component deep to the orbital septum, and are therefore strictly periorbital rather than orbital. Most dermoids presenting in childhood are superficial.

Some orbital cystic choristomas are lined by other types of epithelium, such as conjunctiva or respiratory epithelium, or even a mixture of these with stratified squamous epithelium (see below).

Superficial dermoids

These often present in infancy as a rounded mass, typically at the superotemporal (Fig. 29.1) margin of the orbit.[7] One-quarter arise in the superomedial orbit[7,8] (Fig. 29.2A,B). They are painless, smooth, non-tender, firm, non-fluctuant, often mobile, or in some cases relatively fixed to the underlying periosteum and bone. Since they are usually situated outside the orbit, they cause no displacement of the globe. The orbital rim is usually palpable behind their posterior edge. Unsuspected deep extension into the temporal fossa, posterior orbit, or even intracranial space occasionally occurs in apparently superficial dermoid cysts, but these deeper-extending dermoid cysts are usually clinically more deeply located, less mobile, and it is not possible to pass a finger behind their medial margin to palpate the orbital rim.

The radiologic appearance of a dermoid cyst is characteristic: on computed tomography (CT) scan, the best modality to highlight bony features, a rounded discrete mass is associated with thinning and smooth erosion or remodeling of the underlying bone. The contents are often of heterogeneous density on CT and magnetic resonance imaging (MRI). Fat lucency was noted in 71% of 70 patients,[9] and its presence within the cyst is considered diagnostic.[10] Fluid levels within the cyst may sometimes be seen as the lighter oily secretions of sebaceous glands float upon more aqueous fluid.

Fig. 29.1 A right external angular dermoid.

Preoperative assessment of any dermoid cyst is essential to rule out deep extension. If the cyst is small, mobile, and easily palpable for its entire extent, imaging may not be necessary. Larger cysts with ill-defined, deep margins are best assessed with a CT scan or MRI.

Excision of superficial dermoid cysts is relatively simple (Fig. 29.2C). It is preferable to do this by the age of 5 years to avoid accidental rupture or inflammatory episodes related to spontaneous leakage.[11] The incision may be situated directly over the lesion, above, below, or through the eyebrow. A skin-crease approach[12,13] or endoscopic removal[14] leaves a less conspicuous postoperative scar, but often these lesions lie beyond the natural upper lid crease. Although excision of the intact cyst is desirable, intraoperative rupture is not disastrous if the contents and the entire cyst wall are carefully removed.

Fig. 29.2 (A) An adolescent boy with a superomedial dermoid cyst. (B) Computed tomography scan shows the rounded low-density lesion medial to the left globe. (C) The cyst was excised intact through an upper eyelid skin crease incision.

Decompression of larger cysts may be helpful to expose the underlying bone. Failure to excise the cyst wall completely, or residual cyst contents, can elicit a chronic inflammatory reaction with sinus formation and persistent discharge. In the series by Satorre et al., dramatic inflammatory signs were present in only four of 17 patients with ruptured cysts.[15] A low-grade lipogranulomatous response was more common.

Deep dermoids

These usually present in adolescence and adulthood with gradual enlargement and displacement of orbital contents, but they can present similarly in infancy.[16] Deeper cysts may have only a squamous epithelial lining, and are therefore classified as epidermoid cysts. Deep dermoids are often not palpable, but sometimes their smooth and rounded anterior margin can be palpated, although they may extend to the orbital apex.[17,18] Proptosis and/or globe displacement are predominant features but ocular motility,[7,19] visual disturbances, and pain may occur. Dermoid cysts rarely may be within[19,20] or attached to the lateral rectus muscle.[21]

Some orbital dermoids may straddle the orbit and temporal fossa, with a communication between the two parts passing through the lateral orbital rim or wall (Figs 29.3 and 29.4). These "dumbbell" dermoids may present with the typical signs of a more superficial dermoid, but extend into the temporal

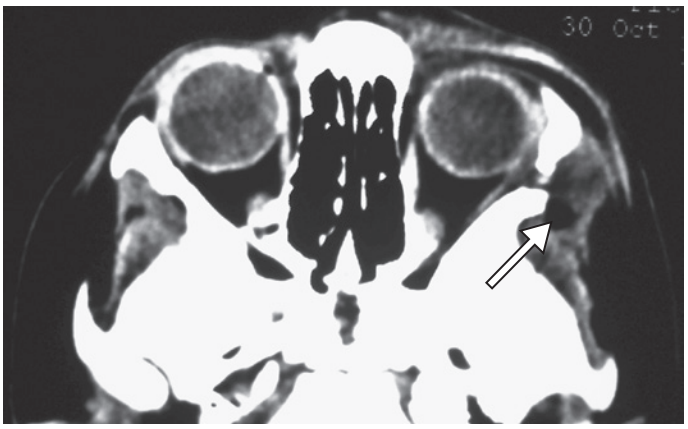

Fig. 29.3 An axial computed tomography scan of a "dumbbell" dermoid cyst with low-density contents extending through a defect behind the lateral orbital rim to involve both the orbit and temporal fossa (arrow).

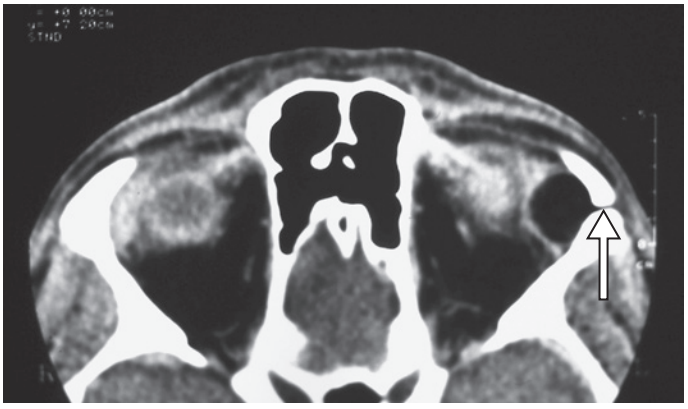

Fig. 29.4 An axial computed tomography scan shows a superotemporal dermoid cyst with a very narrow defect in the underlying lateral orbital wall (arrow), with a small extension of the cyst into the temporal fossa.

fossa in an hour-glass configuration (see Fig. 29.3) and may be associated with temporalis swelling in 1.5–34% of such cases.[9,12] Very rarely, proptosis with or without visual impairment triggered by mastication (masticatory oscillopsia) can result from pressure on a communicating cyst by temporalis muscle contraction with chewing.[22] Presentation with orbital cellulitis related to a discharging sinus tract arising from an orbital dermoid has been reported.[23] Very rarely, simultaneous orbital and temporalis fossa dermoid cysts without communication have been described.[24]

The CT findings of deep dermoids are similar to those of superficial dermoids except for the frequent presence of irregular orbital wall defects as well as sclerosis, irregular scalloping, or notching of the underlying bone (Figs 29.5 and 29.6). The walls of large dermoid cysts may demonstrate irregular "egg-shell" calcification. There may be evidence of surrounding inflammation and scarring from subclinical episodic leakage of the cyst contents.

The management of deep dermoids can be difficult[17,25,26] since total surgical excision is necessary to prevent complications. Preoperative clinical and radiologic assessment is essential to plan the appropriate surgical approach, which may involve combined anterior and lateral orbitotomies or focal marginotomies.[17] Although it has been recommended that this surgery be delayed until bone growth has ceased,[26] such delay may not be necessary to safeguard facial bony growth. A neurosurgical approach with craniectomy may be necessary for safe and complete excision of an orbital dermoid extending intracranially.[27]

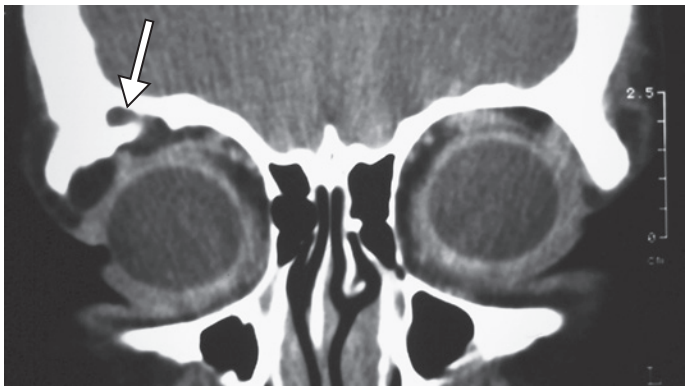

Fig. 29.5 Computed tomography coronal scan of deep dermoid, showing the presence of irregular orbital wall defects (arrow).

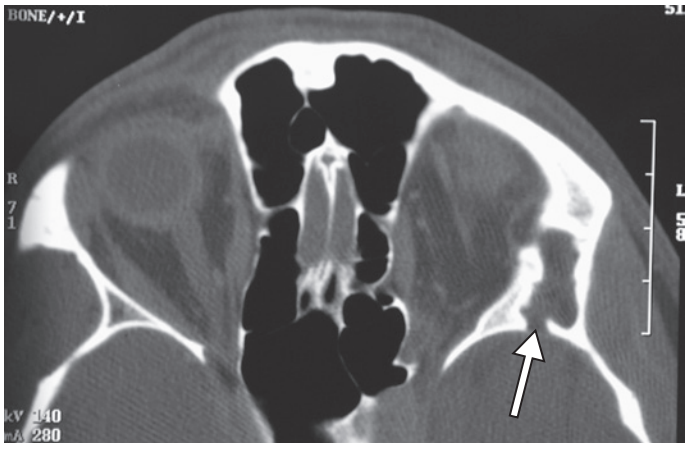

Fig. 29.6 Computed tomography axial scan of deep dermoid, showing the presence of irregular orbital wall defects (arrow).

Conjunctival cysts

Cystic choristomas lined by conjunctival epithelium are usually called "conjunctival dermoids." One-half of these arise in the medial orbit, usually in teenagers and young adults[17] (Figs 29.7 and 29.8). They are not attached to the orbital bones, and are lined by typical conjunctival epithelium with goblet cells and, sometimes, adnexal structures with mucinous or mixed content in the cyst. They are managed by complete excision (Fig. 29.9). Such cysts may have a mixture of conjunctival and dermal lining. Congenital cysts lined by conjunctiva in the region of the common sheath of the superior rectus and levator palpebrae muscles have been described.[28,29]

Conjunctival dermoids should not be confused with conjunctival inclusion cysts, which are acquired lesions due to the implantation of conjunctival epithelium within the orbit after trauma or surgery, most commonly strabismus or vitreoretinal surgery. They may present many decades after trauma or surgery.[30]

Respiratory epithelial cysts

Cysts lined by respiratory epithelium can occur in the orbit as congenital lesions, but also may occur after trauma, with the implantation of respiratory epithelium from the nasal cavity or paranasal sinuses. A mucocele arising from the paranasal sinuses is also lined by respiratory epithelium, often very attenuated, but is a different entity (see below).

Congenital respiratory epithelial cysts are rare.[31–33] They may present in childhood or later in adult life, particularly deeper lesions.[32]

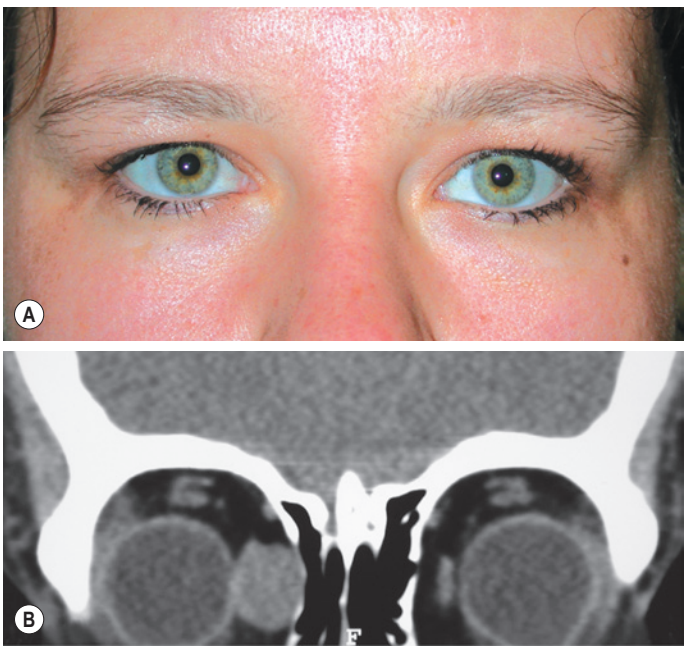

Fig. 29.7 (A) A teenage girl with right globe dystopia due to a medial "conjunctival dermoid" cyst. (B) A coronal computed tomography scan shows the well-circumscribed cyst with contents of higher density than seen on true dermoids.

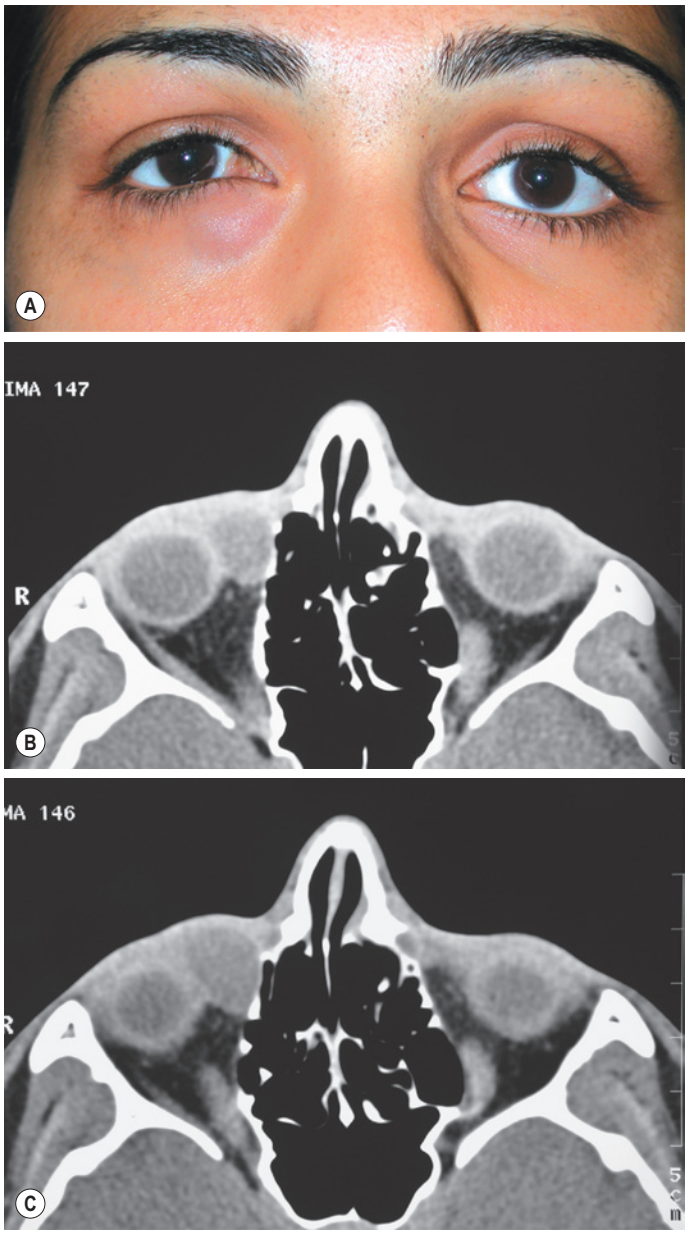

Fig. 29.8 (A) A young woman with longstanding and increasing right globe displacement upward from an inferomedial congenital "conjunctival dermoid" cyst. (B and C) An axial computed tomography scan showing the cyst lying inferomedial to the globe with contents similar in density to the vitreous.

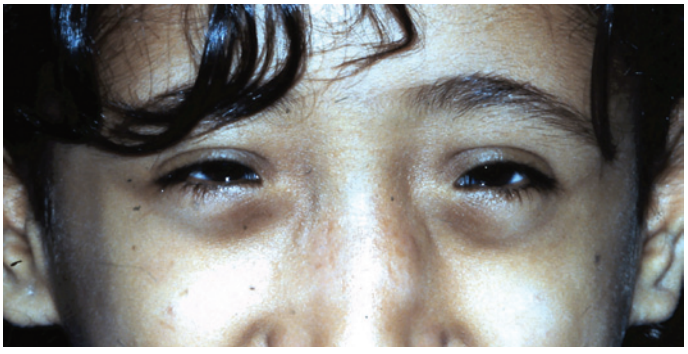

Fig. 29.10 A young girl with hypertelorism and telecanthus from a midline encephalocele.

Orbital meningocele and meningoencephalocele (see Chapter 60)

These rare abnormalities may be congenital or acquired. Congenital lesions arise from a presumed defective separation of neuroectoderm from surface ectoderm, resulting in a bony dehiscence with a "cystic" herniation of dura into the orbit, either alone (meningocele) or with brain tissue (meningoencephalocele). They may be associated with an optic disc anomaly;[34] basal encephalocele should always be excluded in a child with a morning glory disc, especially if there is a midline facial anomaly such as hypertelorism (Fig. 29.10), notched or cleft lip or palate[35] (see Chapters 28 and 53). Significant cerebral vascular anomalies may accompany the presence of a morning glory disc.[36] Orbital encephaloceles may be acquired as a result of head injury and orbital fracture, with herniation of the dura, with or without brain, through the bony defect.[37,38] Occasionally, after relatively trivial trauma, an orbital roof fracture in a child may progressively expand (a "growing fracture") as the leptomeninges herniate into the fracture, forming a "cyst." This may expand, leading to progressive proptosis which may be pulsatile.[39,40]

Congenital orbital encephaloceles may be anterior or posterior.[41] Anterior lesions herniate through single or multiple defects[42] in the region of the sutures dividing the frontal, ethmoid, lacrimal, and maxillary bones. They usually present as a congenital cystic swelling of the medial orbit extending onto the face, accompanied by telecanthus and, frequently, epiphora. They may present in infancy and early childhood with gradually increasing forward and lateral globe displacement. The medial canthal tendon is usually displaced in an inferolateral direction. Atypical presentations occur, such as the 10-mm bluish cystic mass in the superonasal fornix of a 1-month-old patient, which was found to be a meningoencephalocele.[43]

Classically, the cyst increases in size on straining or crying.[44,45] It may be fluctuant, pulsatile, reducible with gentle pressure, and it may transilluminate. Anterior encephaloceles are important in the differential diagnosis of any medial canthal swelling.

They may be mistaken for sinus mucoceles, dermoid cysts, or nasolacrimal duct mucoceles.[46] A bony defect with intracranial communication is evident on CT scan. Three-dimensional CT reconstruction may be helpful in planning surgery,[47] which is usually performed by craniofacial, neurosurgical and/or maxillofacial teams. Posterior encephaloceles herniate into the orbit via the optic foramen, orbital fissures, or a bony defect. They present with slowly progressive, sometimes pulsatile, proptosis. Occasionally, posterior encephaloceles present later in life.

Typically, the eye is displaced forward and downward[44] and the proptosis increases on straining or crying. Plain X-rays demonstrate enlarged foramina or a bony defect of the posterior orbit. CT scan demonstrates the size and contents of the cyst. Posterior encephaloceles are particularly associated with the sphenoid wing dysplasia of neurofibromatosis type 1 (NF1). They can also be associated with enophthalmos.

Paranasal sinus mucocele

The paranasal sinuses are of clinical relevance to childhood orbital disease and it is important to be familiar with their development. All the sinuses are present at birth in a rudimentary form, except the frontal sinus, which first appears at the age of 2 years. There are two spurts of enlargement: at the age of 6 or 7 years, coinciding with the eruption of the second dentition, and again at puberty.[48] Since the frontal sinus is the source of most mucoceles, this disorder is rare in childhood. Ethmoidal sinus mucoceles, however, may present in early life,[49] particularly with cystic fibrosis. In one series of paranasal sinus mucoceles, six of 10 children had cystic fibrosis.[50] Infants and children with cystic fibrosis more commonly develop sinus mucoceles from the maxillary sinuses, which may be bilateral.[51–53]

A mucocele is a cystic expansion of a paranasal sinus, resulting from obstruction of its ostium. The normal mucous secretions of the respiratory epithelial lining accumulate within the sinus, leading to a gradual expansion, with loss of its bony structure. With further expansion, the cystic mass transgresses the orbital wall and displaces the orbital contents. It may also erode into the intracranial space.[54] Eventually, the cyst contents consist of viscous material which may be white, yellow, or brown, and enclosed by a fibrous capsule.

Most mucoceles arise anteriorly, affecting frontal or anterior ethmoid sinuses. The usual presentation is with gradually increasing proptosis with inferolateral or lateral displacement of the globe, appearing clinically as hypertelorism. A firm cystic non-compressible, non-inflammatory swelling may be palpable in the medial orbit. Its extension above the medial canthal tendon should differentiate it from a mucocele of the lacrimal sac. The absence of pulsatility, expansion with straining, and bony skull defect differentiate it from an encephalocele. Sphenoid sinus mucoceles are rare in childhood,[55] but sudden blindness from optic nerve compression by a sphenoid sinus mucocele has been reported.[56]

On CT scan, a smooth-walled cystic lesion, sometimes with egg-shell calcification of the margins, arises from the affected sinus (Fig. 29.11). In childhood, this is most commonly the ethmoid, and there is expansion into the medial orbit with thinning of the wall and destruction of the internal septae.

The mucocele should be marsuplialized to the nasal cavity to prevent recurrence and to re-establish sinus drainage.

Fig. 29.11 An axial computed tomography scan of an ethmoidal mucocele expanding into the medial orbit (arrow), and with egg-shell new bone formation.

Excision or drainage of the mucocele is usually performed endoscopically by an ear, nose and throat surgeon.[57] The transcaruncular approach has been recommended for the management of frontoethmoidal mucoceles.[58] After medial incisions are used, careful repositioning of the trochlea is advised to avoid postoperative superior oblique underaction.[59] Other cystic lesions arising in the sinuses, including dentigerous cysts, may also cause proptosis.[60]

Congenital cystic eyeball (anophthalmos with cyst) (see Chapter 18)

True anophthalmia is very rare. More commonly, complete or partial failure of invagination of the optic vesicle before the 7 mm stage results in a "congenital cystic eye" or "anophthalmos with cyst."[61] No recognizable globe is present within the orbit. The congenital cystic "eye" is lined by neuroglial tissue without any normal ocular structures such as lens, ciliary body, or retina. The wall of the cyst is fibrous connective tissue with attached extraocular muscles. The absence of surface ectoderm-derived ocular structures is a common feature, which may help with the correct diagnosis. Congenital cystic eyeball is rare compared to microphthalmos with cyst, caused by a later defect in embryogenesis.[62]

It presents at birth as a large cystic swelling within the orbit. In contrast to microphthalmos with cyst, the cystic eyeball is usually centrally placed or distends the upper lid.[61,63] The cyst may occasionally be inferior.[62] The fellow eye is usually normal, but contralateral microphthalmos with cyst,[64] persistent hyperplastic primary vitreous, or bilateral congenital cystic eyes have been reported.[62]

The histology is similar to the cystic portion of anophthalmos with cyst: multiple cavities filled with proliferating glial tissue.[62,63] These cystic orbital lesions, occurring in neonates, should be distinguished from teratomas.

Microphthalmos with cyst

Incomplete closure of the fetal fissure between the 7 and 14 mm stage of embryonic development may result in a variety of

colobomatous defects of the eye.[65] Eyes with severe colobomas are often microphthalmic, and proliferation of neuroectoderm at the lips of the persistent fetal fissure may result in the formation of an orbital cyst that communicates with the eye. The size of the cyst varies enormously.

Several genetic mutations are known to cause anophthalmia and microphthalmia (see Chapter 18). Their association with systemic abnormalities makes their identification particularly important. Many are autosomal dominantly inherited, so future siblings are at risk. SOX2,[66] OTX2, PAX2, and PAX6, as well as CHD7 (CHARGE syndrome) are the most frequently implicated mutations. Involvement of a geneticist is advisable. Ragge et al. have reviewed the diagnosis and multidisciplinary management of anophthalmia and microphthalmia.[67]

Clinical presentation

The manifestations are variable, ranging from an apparently normal eye with a clinically unapparent cyst, an obvious cyst in association with a deformed eye, to an invisible eye displaced by a cyst occupying the whole orbit. Typically, a bluish cystic transilluminating lesion bulges inferiorly into the lower fornix and lid, displacing a microphthalmic or rudimentary eye under the upper lid[68] (Fig. 29.12). Rarely, the cyst may be present in the upper lid and the eye is displaced downward[69] (Fig. 29.13). Occasionally, the eye cannot be identified clinically,[68] even under anesthesia. Bilateral involvement is not uncommon. The cyst communicates with the eye via a variably narrow stalk. The microphthalmic eye usually has extremely poor vision and an associated optic nerve and retinal coloboma. The eye, though often very small, usually achieves differentiation with cornea, iris, ciliary body, and lens choroid and retina. The other eye may be normal or may also have an optic nerve or retinal coloboma.[68,70] The extent of the cystic component is best delineated by CT scan, although B-scan ultrasound can also be useful. Small asymptomatic cysts may be found incidentally on CT scan. The glial nature of the cyst lining can be demonstrated by immunohistochemistry.[71]

Management

Most cases require no immediate surgical intervention[70] since the cyst contributes to socket expansion.[64,67] Cyst enlargement resulting in an unsightly appearance can be managed by aspiration; repeated aspiration may be necessary and after multiple aspirations surgery may be indicated. Although it may be difficult to excise the cyst without sacrificing the globe, this can be achieved in patients with mild microphthalmos, with a satisfactory cosmetic outcome.[72]

The presence of an eye is important in inducing normal bony orbital growth. A congenitally anophthalmic socket will have deficient orbital and eyelid growth and shallow conjunctival fornices, which may prevent satisfactory prosthetic fitting. Early orbital volume replacement with an appropriate implant and/or prosthesis is advocated if the globe is small or absent. Various types of conformers and socket expanders can be used to maintain the conjunctival fornices, palpebral fissures, and, perhaps, promote orbital growth.[67] Small sockets and eyelids can be expanded with hydrophilic expanders.[73]

Early enucleation produces a bony volume reduction. Good cosmetic results may be achieved with the use of a large orbital implant at the time of enucleation.[74]

Orbital teratoma

Teratomas are tumors that arise from pluripotent embryonic stem cells and consist of elements derived from more than one germ cell layer. Although classically all three layers are represented, only mesoderm is invariable; ectodermal or

Fig. 29.12 Microphthalmos with cyst. This boy was born with a bluish swelling of the right lower lid, which gradually enlarged. At 6 months, a large cyst filled the right orbit and distorted the lower lid, leading to conjunctival prolapse and exposure.

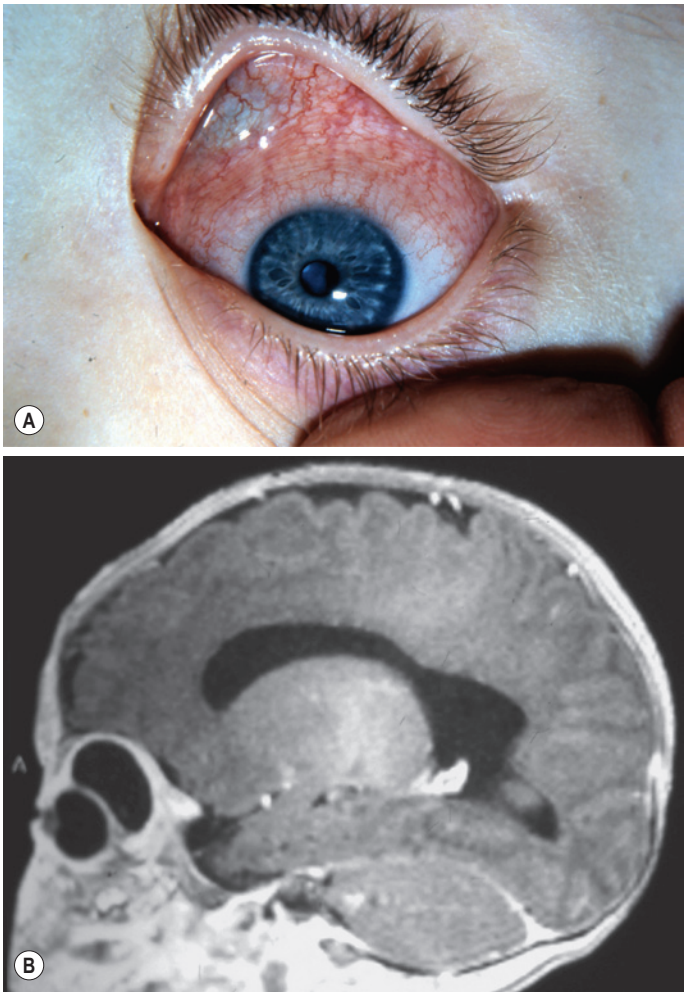

Fig. 29.13 (A) A 4-year-old boy with a bluish superomedial orbital cyst, displacing a small but well-formed microphthalmic eye downward. (B) A sagittal magnetic resonance image shows the cyst with material within it indistinguishable from vitreous.

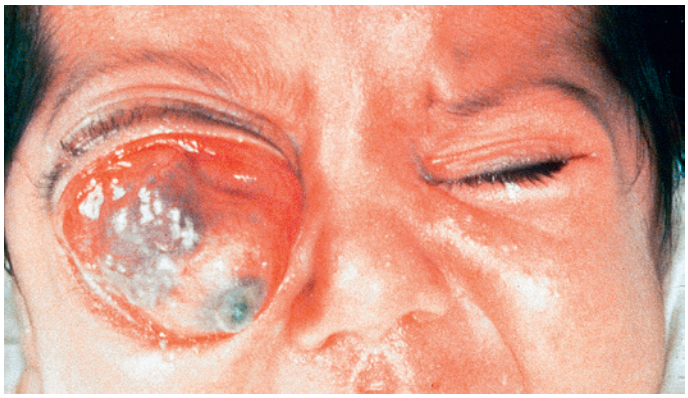

Fig. 29.14 Orbital teratoma in an infant with massive proptosis from a multiloculated cystic lesion.

endodermal elements can be absent. Such tumors should be called "teratoid." The extent of the tumor can be limited to the orbit (primary orbital teratoma) or it may involve the intracranial compartment, cavernous sinus,[75] nose, and sinuses. Occasionally, a much larger primary intracranial tumor invades the orbit secondarily. This usually manifests prenatally as polyhydramnios and is rarely compatible with life.

The usual presentation of a primary orbital teratoma is with unilateral, often massive, proptosis in a newborn child[76] (Fig. 29.14). Teratomas are more common in females by a ratio of 2:1. The globe is often of normal size or slightly small but it is surrounded by intensely chemotic conjunctiva. It is displaced by a large cystic mass, which is often fluctuant and transilluminates but may appear solid. The mass is often intraconal, giving rise to axial displacement with indentation by the four recti. Superior or inferior teratomas can occur. Typically, there is rapid growth after birth as secretions from the epithelial elements of the tumor accumulate within its cystic spaces. Exposure keratopathy, ulceration, and even perforation can complicate the resultant lagophthalmos. The tumor may stretch and adhere to the optic nerve, with optic atrophy. Occasionally, teratomas grow very slowly.[77] They may also rarely present later in childhood, with preserved vision.[78]

On ultrasound, the tumor is of heterogeneous density and may contain foci of calcification, which, along with orbital enlargement, are evident on plain X-rays. CT and MRI delineate the lesion, define any intracranial extension, and highlight variable density with cystic elements, fat, and, occasionally, teeth (Fig. 29.15).

The treatment of choice is early surgical excision, with preservation of the globe if possible.[76,77,79] Intraoperative aspiration of fluid from the cystic mass may facilitate tumor removal. With intracranial involvement, a combined orbitotomy and craniotomy is necessary to remove the tumor. Total excision can be difficult. Vision may be preserved in the affected eye.[80,81] The long-term outlook depends on the histologic differentiation and the extent of the tumor. Respiratory obstruction carries a poor prognosis.[82] Residual tumor can give rise to late recurrence and malignant change,[83] but this is rare in the orbit.[84]

Lacrimal ductal cyst

Lacrimal ductal cysts (also called dacryops) are very rare in childhood but form a part of the differential diagnosis of

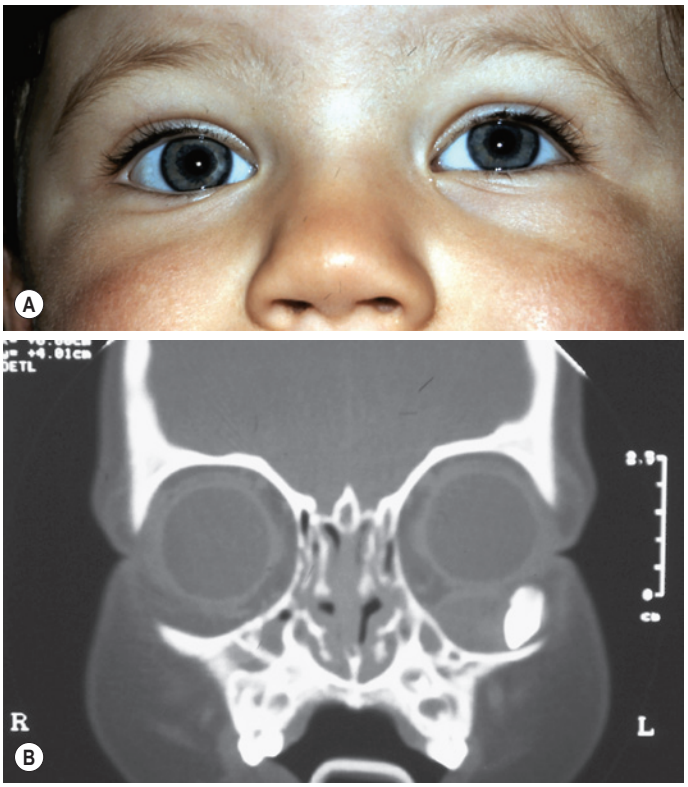

Fig. 29.15 (A) A 3-year-old girl presented with gradually increasing left proptosis and globe dystopia. (B) Computed tomography scans revealed a multiloculated inferior orbital lesion in an expanded orbit with a fully formed tooth within it.

Fig. 29.16 A typical lacrimal ductal cyst.

an orbital mass in the lacrimal gland region. Bullock et al.[85] suggested that lacrimal cysts should be classified by their site of origin: palpebral lobe (simple dacryops), orbital lobe, accessory glands, or ectopic lacrimal gland. Clinically, they may be confused with a superficial conjunctival dermoid cyst (though these are more commonly medial) or inclusion cysts, as well as parasitic cysts.

Lacrimal ductal cysts most commonly arise from the palpebral lobe in adults but they may occur in teenagers, sometimes with a history of trauma or inflammation. A smooth, transilluminating mass slowly enlarges in the lateral aspect of the upper lid (Fig. 29.16) and may be evident on lid eversion as a bluish cyst. Rarely, they enlarge with crying and

can be tender or painful, occasionally resolving spontaneously as the cyst decompresses with a gush of tears. Histologically, ductal cysts of the palpebral lobe are lined by an outer layer of myoepithelium and an inner layer of cuboidal cells, unlike congenital orbital lobe cysts whose epithelial lining is cuboidal. If the patient is symptomatic, careful surgical excision of the intact cyst is curative, with care to avoid damage to adjacent ductules. Marsupialization of larger cysts may be necessary.

Cysts in the orbital lobe are very rare, but may present in infancy or early childhood as a tense mass in the lacrimal fossa.[44] Cysts of the accessory glands of Krause and Wolfring may occur, resulting in swelling in the conjunctival fornix. These can be excised via the conjunctiva.

Lacrimal tissue may occasionally occur ectopically within the eye and orbit with an associated cystic component (see below).

Parasitic cysts

Echinococcosis (hydatid cyst)

The tapeworm *Echinococcus* is an intestinal parasite of dogs and foxes. Sheep, cattle, or rodents may ingest contaminated feces and become hosts, and dogs become infected by eating their carcasses. Humans ingest ova in contaminated meat, berries, unclean vegetables, or feces from poor hand hygiene. The ova hatch in the intestine, and larvae migrate throughout the body, settling in various organs to form slowly enlarging, fluid-filled cysts full of larvae. Due to the distribution of blood from the portal tract, there is a predilection for the right lobe of the liver. Approximately 1% of infestations involve the orbit,[2] especially the superior and posterior orbit.

Sheep- and cattle-rearing areas in the developing world may have a high prevalence. It has largely been eliminated in the developed world. Clinically, orbital echinococcosis presents with insidious signs of mass effect, which may be accompanied by chemosis, diplopia, restricted ocular motility, visual loss, and optic atrophy. Rupture of the cyst can result in an acute inflammatory episode.

The diagnosis of orbital echinococcosis is aided by ultrasonography, CT (Fig. 29.17), or MRI scanning, which show a cystic mass whose wall is occasionally calcified and contains fluid that is isodense with vitreous. Other confirmatory findings include eosinophilia on a blood film, and positive enzyme-linked immunosorbent assay (ELISA) for echinococcal antibodies. This has over 90% sensitivity and specificity for *Echinococcus*.

Systemic treatment with albendazole is effective and a suitable alternative to surgery in uncomplicated cases.[86] Orbital cysts may be excised intact via a direct or lateral orbitotomy. Intraoperative rupture should be avoided if possible, since it may be complicated by inflammation and implantation of daughter cysts.[87] Cyst aspiration followed by irrigation with hypertonic saline may destroy daughter cysts.[88] Hydatid cyst surgery should be accompanied by treatment with albendazole.

Other parasitic infestations of the orbit include cysticercosis and trichinosis, both acquired from pork. Cysticercosis is a common cause of proptosis in children in India. In a series of 171 cases of orbital cysticercosis from India, the median age was 13 years.[89] Over 80% had cysts in relation to the extraocular muscles. Nearly all patients are managed with oral albendazole and prednisolone.

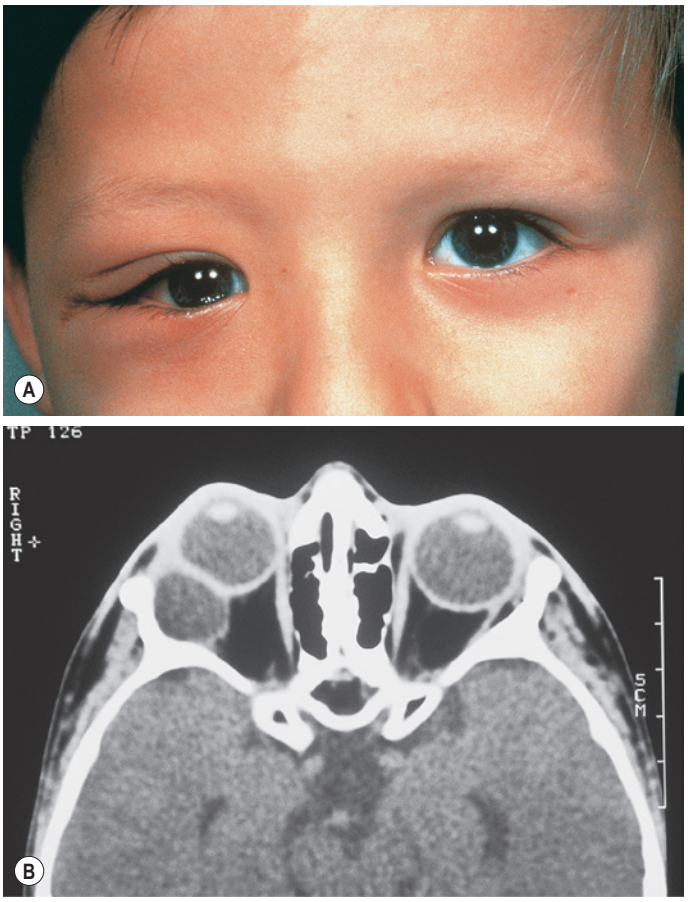

Fig. 29.17 (A) This 9-year-old refugee, who lived in unsanitary conditions, presented with a 6-month history of increasing right upper lid swelling. He had 4 mm of right proptosis, downward displacement of the globe, and lateral ptosis. (B) On computed tomography scan, a cystic lesion was found situated posterolaterally to the globe; this was an echinococcal cyst, which was excised intact. *(Patient of the University of British Columbia.)*

Ectopias

Dermolipoma

These congenital lesions are a maldevelopment of the lateral canthal area and lateral bulbar epithelium. They can be classified as solid choristomas. They may occur alone or as part of the oculoauriculovertebral spectrum (OAVS, Goldenhar syndrome) with combinations of lid coloboma, limbal dermoids, preauricular skin tags, hemifacial microsomia (Fig. 29.18), jaw and cervical spine, facial nerve, palatal, and ear and hearing abnormalities. About one-third of patients with dermolipomas will have features of OAVS.[90] They are situated laterally on the bulbar surface, are pink to yellow in color, with surface epithelium closer to skin than conjunctiva (Fig. 29.19). They may have surface hairs, which can cause irritation. Rarely, they may contain bony tissue.[91] Frequently, their superior and posterior extensions are close to the lacrimal ducts and levator muscle.[92] There is often a poorly formed lateral canthus with a band of fibrous tissue from the canthus to the lesion. The fatty tissue under the surface epithelium is usually continuous with the orbital fat with no clear separation.

Surgery, in response to symptoms of irritation, should be performed with great care. The lesion can be debulked with

Fig. 29.18 A young girl with a right dermolipoma and ipsilateral hemifacial microsomia, but no other features of oculoauriculovertebral (Goldenhar) syndrome.

Fig. 29.19 A typical dermolipoma with slightly thickened whitish surface epithelium and underlying adipose tissue. Note the typical improperly formed lateral canthus with a band from the canthus to the surface of the lesion.

preservation of the surface epithelium, and this minimizes the risk of scarring leading to limited eye adduction.[44,93] The excision should spare the component of the lesion adjacent to the palpebral lobe of the lacrimal gland to avoid damaging its ductules. Additionally, the lateral rectus muscle should be isolated and protected. Attempts at complete excision of dermolipoma with orbital dissection are risky and may cause dry eye, restrictive symblepharon, strabismus, and ptosis.[91,94]

Ectopic lacrimal gland

Lacrimal gland tissue may occasionally occur at ectopic sites within the orbit. Most commonly, it is found in the eyelid or conjunctiva, but it may occur on the cornea or even the iris and choroid.[95] Green and Zimmerman reported eight cases,[96] and more have since been added to the literature, often in children or teenagers. The ectopic tissue may be situated intra- or extraconally. Typically, the patients present with proptosis. Double vision is a common symptom due to muscle restriction from the inflammatory response, which the ectopic tissue often incites. The differential diagnosis includes true orbital neoplasms. Investigation, including CT scan, often shows a cystic component.[97] The treatment of choice is surgical excision. If this is incomplete, proptosis may recur.[96] The aberrant tissue may give rise to tumors such as pleomorphic adenoma or adenocarcinoma.[96]

Ectopic brain in the orbit

There have been rare reports of ectopic brain occurring in the orbit.[98–101] Most cases present in infancy. In some cases, the ectopic tissue has grown slowly, in others it has appeared static over several years' follow-up.[102] When ectopic brain is reported in association with clinical anophthalmia, it is more likely that the abnormal tissue is neural tissue that is well described to occur with congenital anophthalmia, microphthalmia, and congenitally cystic eye.[103] Cases with abnormal extraocular muscle development have been reported.[104]

Chapter contents

THYROID-ASSOCIATED ORBITOPATHY
SPECIFIC CAUSES OF ORBITAL INFLAMMATION
NON-SPECIFIC (IDIOPATHIC) ORBITAL INFLAMMATORY SYNDROMES
REFERENCES

Non-infectious orbital inflammation in childhood is uncommon. As in adults, the commonest cause is thyroid-associated orbitopathy (TAO). The remainder can be divided into: (1) specific forms of inflammation, which include granulomatosis with polyangiitis (GPA, previously called Wegener granulomatosis), sarcoidosis, and the more recently characterized entity of immunoglobulin (Ig)G4-related ophthalmic disease; and (2) non-specific orbital inflammation or idiopathic orbital inflammation (IOI). Infective orbital inflammation is most commonly due to bacterial orbital cellulitis and this is discussed in Chapter 14.

Thyroid-associated orbitopathy

TAO is by far the commonest cause of proptosis in adults, but it is relatively rare in children. In most series, about half develop ophthalmic signs.[1,2] Despite its relative rarity, if several large series of orbital disorders are combined, TAO is the second commonest cause of orbital disease after orbital cellulitis (see Table 22.1). Neonatal TAO may affect the infant of a mother with Graves disease, due to transplacental passage of thyroid-stimulating hormone receptor and other antibodies. In the neonate, it tends to be a self-limiting disease.

Although TAO may occur in early childhood, it becomes commoner in the second decade of life (Fig. 30.1). It is more prevalent in girls, by a ratio of between 2 and 7:1.[2–5] There is commonly a family or past history of hyperthyroidism. Associations with other autoimmune disorders and diabetes have been reported. Most patients will be hyperthyroid at the time of diagnosis of TAO (88.6%), with a small number being hypothyroid (2.9%) or euthyroid (8.6%).[5]

The orbital involvement is generally relatively mild, and signs of active inflammation are generally absent.[3] There may be proptosis, sometimes asymmetric, which rarely warrants orbital decompression.[5,6] Lid retraction and lagophthalmos are also common. In East Asian children, an acquired form of lower lid epiblepharon with trichiasis may develop and lead to keratopathy.[3]

Up to 1 in 4 patients will develop restriction of ductions[2] (Fig. 30.2 A,B). The severity of the orbitopathy tends to increase with age.[1] Optic neuropathy and sight-threatening corneal problems have not been described in children. Orbital imaging may show enlarged muscles (Fig. 30.1C) with characteristic sparing of the tendons, or an increase in orbital fat volume.

Treatment is usually conservative with supportive measures. Eyelid or orbital decompression surgery is rarely required.[5]

Specific causes of orbital inflammation

The most common cause of orbital inflammation in childhood is bacterial orbital cellulitis (see Chapter 14). Other childhood orbital inflammatory diseases are comparatively rare, and called "specific" since they have a defined clinical, radiologic, biochemical, and histopathologic spectrum, though their underlying cause has not been clearly determined.

Granulomatosis with polyangiitis (GPA, previously called Wegener granulomatosis)

This is a necrotizing granulomatous vasculitis, which has a predilection for the upper and lower airways and the kidneys. The limited form of the disease in which the kidneys are spared has a better prognosis and is more commonly associated with orbital disease.[7] Both forms have the same incidence of ocular and orbital involvement, ranging in different studies from 28% to 45%.[8] Before the introduction of cyclophosphamide, over 90% of affected patients died within 2 years. Although this is not a common disease of childhood, it does occur under the age of 18. Its rarity in childhood commonly leads to a delay in diagnosis.[9]

Clinical features

In childhood GPA, the median age of onset is about 11 years.[9,10] In pediatric series of GPA, the incidence of ophthalmic disease has been between 18% and 35%.[9,10] The onset of orbital GPA is often preceded by a history of subacute or chronic low-grade disease, with sudden aggravation leading to presentation. The main features are proptosis, which is frequently bilateral, with ocular and facial pain, which may be severe. An orbital mass usually develops (Fig. 30.3), displacing the globe,

even in patients who initially present with scleritis. The latter is typically nodular and necrotizing, accompanied by characteristic marginal corneal infiltration, which can progress to ulceration. Decreased vision is common and can be related to optic neuropathy.

Fig. 30.1 8-year-old girl with Graves orbitopathy and a 6-month history of proptosis. Four months earlier she underwent a total thyroidectomy. She subsequently underwent bilateral orbital decompression.

Lacrimal gland involvement with lid swelling and brawny discoloration may occur. The orbital disease may be bilateral. Midline disease (nasal and paranasal sinus disease) and lacrimal gland involvement are common. Nasal symptoms frequently precede presentation by several months. These include nasal blockage, discharge or bleeding, pain over the paranasal or mastoid sinuses, and hearing loss or tinnitus. Ocular involvement may be the presenting feature of GPA in children.[11]

Computer tomography (CT) scans show an orbital mass with infiltrative margins obscuring fat and adjacent muscles. Midline bony erosion and sinus involvement may be evident. Histologic changes include areas of fat disruption and focal necrosis with lipid-laden macrophages, giant cells, and evidence of acute inflammatory cells. Vasculitis is often difficult to find in these specimens.[7] Fibrosis is common. Stains for fungi and mycobacteria should be performed to exclude these important differential diagnoses.

The antibiotic combination of trimethoprim and sulfamethoxazole is a first-line treatment for this condition. Azathioprine is a second-line drug. Cyclophosphamide is effective in GPA but, due to its oncogenic potential, it is reserved for children who have not responded to the above or who present with severe disease. Rituximab has also been shown to be effective in GPA,[12] and may be used in the pediatric age group. Antineutrophil cytoplasmic antibodies (cANCA) are specific markers for GPA if there is a "cytoplasmic" staining

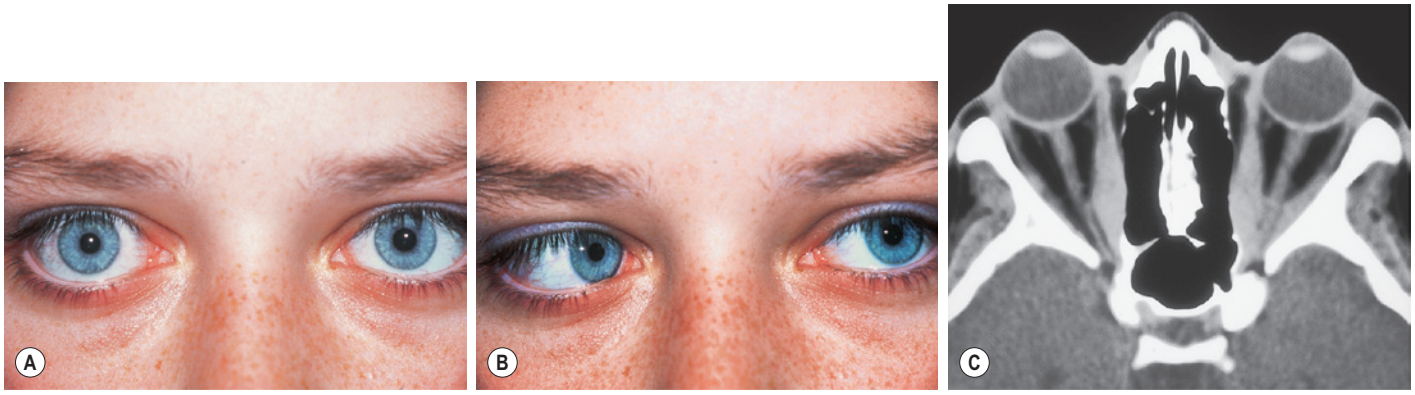

Fig. 30.2 This girl had a 6-year history of double vision at the extremes of gaze. Her past medical history included autoimmune hepatitis and hyperthyroidism, treated with radioiodine. There is lid retraction (A), lid lag, and restriction of abduction with esotropia in lateral gaze (B). Bilateral medial rectus enlargement involving the muscle belly but sparing the tendons is evident on computed tomography scanning (C). *(Patient from the University of British Columbia.)*

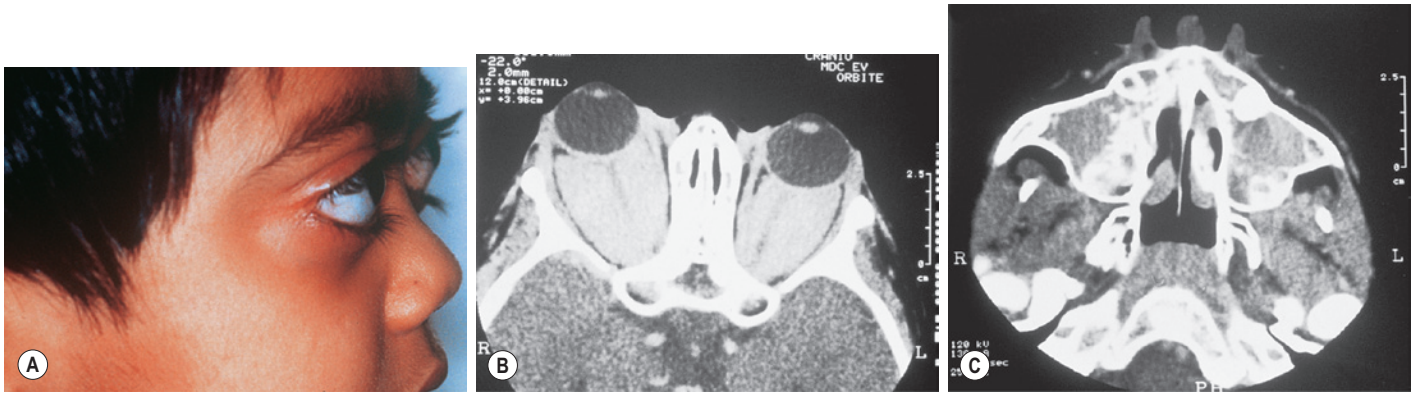

Fig. 30.3 A 7-year-old boy presented with a 3-month history of progressive bilateral proptosis (A). He has positive antineutrophil cytoplasmic antibodies (ANCA) titers. Computed tomography (B,C) shows widespread involvement of the orbital soft tissues and maxillary sinuses. *(Patient from the University of British Columbia.)*

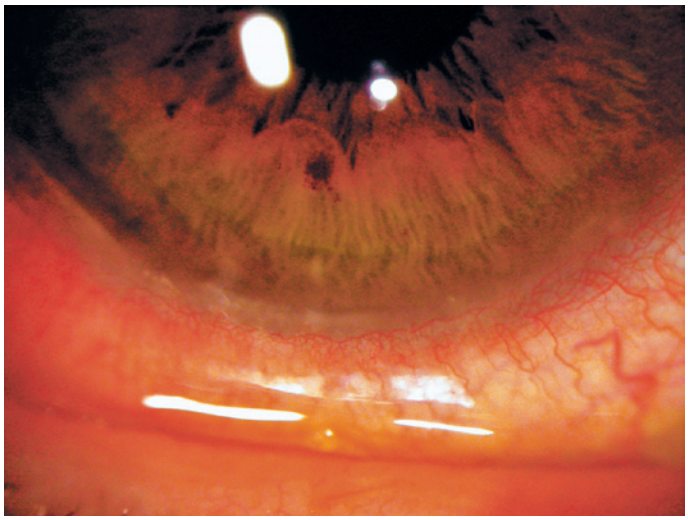

Fig. 30.4 Granulomatosis with polyangiitis (GPA, or Wegener granulomatosis). Photograph or cornea demonstrates marginal infiltration with a clear zone between the infiltrate and limbus, a feature characteristic of the disease. *(Patient from the University of British Columbia.)*

pattern. Their plasma level correlates with disease activity. Failure of these to return to normal after clinical improvement with treatment indicates a high risk of relapse.[13]

GPA is rare but it does occur in childhood. Clinicians should remain alert for this potentially lethal disorder especially in patients with bilateral orbital involvement, particularly with scleritis accompanied by characteristic marginal corneal infiltration (Fig. 30.4). Respiratory tract or sinus (including the mastoid sinuses) involvement further supports the diagnosis.

Sarcoidosis

This chronic granulomatous inflammatory disease of unknown cause occasionally affects children; several hundred cases have been documented in children under the age of 15 years. The incidence of the disease rapidly increases in the late teens, peaking in the third decade. The risk is increased 3–10 times in African-Americans versus Caucasians, with a slight female preponderance. Age defines to some extent the pattern of systemic involvement: children aged 5 years or less develop uveitis, arthropathy, and skin rash; those aged 8 to 15 have lung involvement with ocular, skin, and spleen involvement in approximately one-third.[14]

Anterior uveitis, which may be chronic and granulomatous or acute, is the commonest finding at presentation, affecting one-quarter to one-half of patients. The eyelid, conjunctiva, sclera, episclera, and lacrimal glands may be involved. Orbital infiltration causing unilateral proptosis has been reported in a 5-year-old child with arthritis.[15] Cornblath et al.[16] reported a 15-year-old boy with pain, diplopia, and ophthalmoplegia from generalized involvement of the extraocular muscles. There was diffuse enlargement of all the muscles on CT, suggesting orbital myositis or thyroid orbitopathy. Unlike the latter, the muscle insertions were enlarged on CT scan.

IgG4-related ophthalmic disease (IgG4-ROD)

IgG4-related disease is a recently recognized fibro-inflammatory disorder, characterized by tumefactions infiltrated with large numbers of IgG4-postive plasma cells. Almost any organ can be affected, but the most common are pancreas, hepatobiliary tract, salivary glands, lymph nodes, retroperitoneum, and orbit. Orbital disease, in various patterns, is relatively common.[17] Ophthalmic disease (IgG4-ROD) has been described in several children[18] including in the form of dacryoadenitis.[19]

The diagnosis depends on finding large numbers of IgG4-positive plasma cells in tissues using immunohistochemical stains, in a ratio of over 40% compared to IgG-postive plasma cells, as well as a characteristic lymphoproliferative infiltration, significant numbers of eosinophils, and fibrosis, classically described as storiform. The pathological changes must be correlated with the clinical and imaging findings to reach an appropriate diagnosis; the finding of increased numbers of IgG4+ plasma cells alone is insufficient as it occurs in many other conditions, including GPA, xanthogranulomatous disease, rheumatoid arthritis, Castleman disease, and others.[18]

IgG4-ROD highlights the need to obtain tissue for histopathological examination whenever possible to secure a diagnosis in orbital inflammatory disease. Without tissue, this and many other forms of specific inflammation cannot be diagnosed. IgG4-ROD responds well to oral corticosteroids, but relapse is common. Other immunosuppressants and rituximab may be used in recalcitrant cases.[17]

Non-specific (idiopathic) orbital inflammatory syndromes

Definition

The child's orbit is occasionally the site of acute or subacute inflammation of unknown cause.[20,21] This entity was previously known as "orbital inflammatory pseudotumor," a term which, with the advent of CT and magnetic resonance imaging (MRI) and pathologic studies, has been abandoned. Instead, the site of inflammation is identified,[22] including anterior, diffuse, apical, myositic, and lacrimal types. Children tend to develop the anterior and diffuse types, but myositis and lacrimal gland inflammation may occur. Apical involvement is rare. Non-specific sclerosing inflammation of the orbit is very rare in childhood.

These syndromes present acutely or subacutely with inflammatory signs. Although apparently idiopathic, they have many features of an orbital immune reaction.[23] Histologically, there is an influx of lymphocytes, plasma cells, sparse neutrophils, and macrophages. Inflammatory mediators cause edema, vascular dilatation and pain without systemic malaise. In contrast, more chronic inflammations, including IgG4-ROD, and granulomatous diseases cause mass effect as their predominant feature, without clinical features of acute inflammation. The common CT profile of acute or subacute non-specific orbital inflammatory syndromes (NSOIS) is a poorly defined margin to the inflammatory focus, as well as contrast enhancement.[24] With MRI, T2-weighted sequences with fat suppression and gadolinium can highlight areas of fluid accumulation indicative of inflammatory foci.

Anterior idiopathic orbital inflammation: acute and subacute

This is the most common type of NSOIS in childhood. The inflammatory process is centered on the anterior orbit and

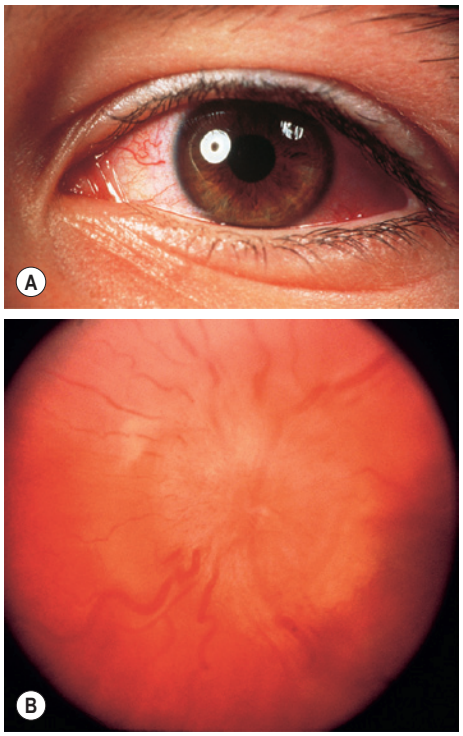

Fig. 30.5 Anterior non-specific orbital inflammatory syndrome in a 6-year-old boy who presented with a red eye (A), pain on eye movement and decreased vision of 3 days, duration. Fundoscopy (B) shows choroidal swelling and papillitis. *(Patient from the University of British Columbia.)*

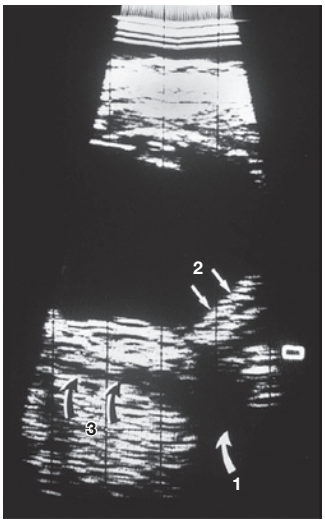

Fig. 30.6 Ultrasound scan of anterior non-specific orbital inflammatory syndrome showing the T-sign. There is doubling of the optic nerve shadow (1), shallow retinal detachment (2), and accentuation of Tenon's space (3). *(Patient from the University of British Columbia.)*

adjacent globe (Fig. 30.5). Pain, proptosis, lid swelling, conjunctival injection, and decreased vision are the main presenting features, with an onset over days or occasionally weeks. Children are more likely to have an associated anterior and posterior uveitis, which can potentially lead to misdiagnosis and erroneous treatment with topical steroid.[25] The disc may be swollen. Systemically, the erythrocyte sedimentation rate may be raised, and there is often cerebrospinal fluid pleocytosis. Disturbances in thyroid function tests and hypothyroidism have also been reported in association with NSOIS.[26] CT scans show diffuse anterior orbital inflammation centered on the globe, producing scleral and choroidal thickening with or without serous retinal detachment. The junction of the globe and optic nerve is characteristically obscured on CT scan with inflammatory changes extending along the nerve sheath. On ultrasound, there is a uniform-density infiltrate corresponding to sclerotenonitis, with accentuation of the sub-Tenon's space and doubling of the optic nerve shadow producing a T-shaped shadow (or T-sign) (Fig. 30.6).

Diffuse idiopathic orbital inflammation: acute and subacute

This is clinically similar to the anterior form, although the symptoms and clinical signs are more severe (Fig. 30.7). The eye movements are more restricted and the visual acuity is worse due to serous retinal detachment and/or optic neuropathy. Inflammatory soft tissue changes permeate the whole orbit on CT scan, with a white-out appearance whose density is proportional to the severity of the clinical signs, and which resolves as the condition settles. Again, the T-sign is evident on ultrasonography.

Anterior and diffuse non-specific orbital inflammatory syndromes: differential diagnoses and management

The differential diagnoses include infection such as orbital cellulitis, scleritis, sudden enlargement of a pre-existing lesion such as a ruptured dermoid, hemorrhage into a venous-lymphatic malformation (lymphangioma) or malignancy, which, in childhood, may be rhabdomyosarcoma, neuroblastoma, Ewing sarcoma, or leukemic infiltration. Anterior and diffuse NSOIS are also part of the differential diagnoses of uveitis and serous retinal detachment in childhood. Biopsy of involved orbital tissues should be considered in all but the most typical cases.

Treatment with oral non-steroidal anti-inflammatory drugs such as flurbiprofen is tried first. Systemic steroids may be used in addition, or as an alternative, in doses for prednisolone of 1–1.5 mg/kg per day. There is usually rapid improvement in symptoms, especially pain, as well as clinical signs. Progress can be monitored by resolution of the clinical, CT, and ultrasound features. This disease may have a recalcitrant course, with frequent recurrences and steroid dependence. High-dose steroid is re-started for recurrence and tapered as quickly as clinical progress will allow, usually over a few weeks. Failure to respond suggests the need for biopsy and the renewed search for a specific etiology. Low-dose radiotherapy has been advocated for biopsy-proven cases that do not respond to steroids. Combined steroids and immunosuppressives may be necessary.

Idiopathic orbital myositis: acute and subacute

This is characterized by proptosis, pain and limitation of eye movement with diplopia, ptosis, lid edema, and conjunctival chemosis. Strabismus is often present with duction limitation in the direction of action of the involved muscle(s).[27] Spasm of the affected muscle also causes restriction of the ipsilateral antagonist with a positive forced duction test. Globe retraction and narrowing of the lid fissure similar to Duane syndrome is a frequent finding.

CT scan shows diffuse muscle enlargement with irregular margins. The muscle enlargement frequently involves the tendon, in contradistinction to thyroid-associated orbitopathy

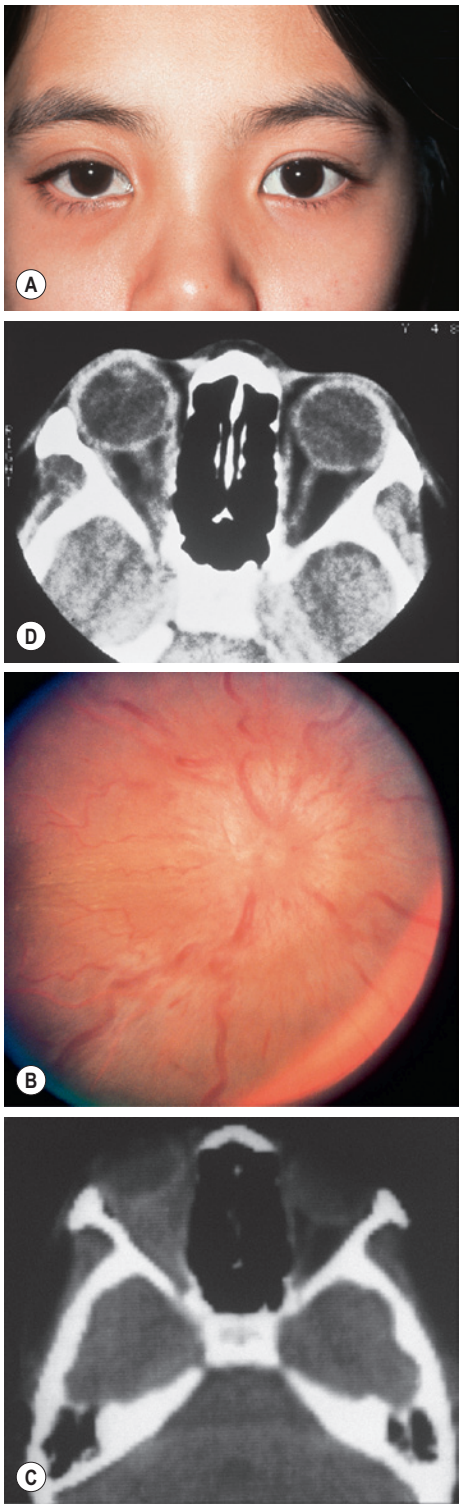

Fig. 30.7 Diffuse non-specific orbital inflammatory syndrome in a 12-year-old girl who presented with a retrobulbar ache, associated with ptosis (A), and pain on eye movement. There was right-sided uveitis with marked disc swelling (B). On computed tomography scanning (C), there was a "white-out" appearance of the right orbit (similar patient), which resolved after treatment with systemic steroids (D). *(Same patient from the University of British Columbia.)*

Fig. 30.8 Left superior rectus myositis in a 16-year-old boy. Ptosis (A) and pain limitation of upgaze with diplopia were the presenting signs; this was due to left superior rectus myositis shown as a thickened muscle complex on computed tomography scan (B). *(Patient from the University of British Columbia.)*

where, typically, the tendon is spared. The superior rectus–levator complex (Fig. 30.8) or medial rectus are the most common muscles to be involved, but any muscle can be affected, including the obliques. More than one muscle may simultaneously be involved and bilateral disease may occur.

The cause of orbital myositis is unknown but a number of associations have been reported, including upper respiratory tract infection,[28] Lyme disease, Whipple disease, and other autoimmune diseases.[29]

The differential diagnoses include thyroid-associated orbitopathy, which differs from idiopathic orbital myositis in that a preceding or concurrent history of thyroid disorder is common, pain is absent, the inferior recti tend to be the first muscles involved (although any muscle may be involved), and sparing of the tendon is apparent on CT scan. In some cases, differentiating between these two conditions can be very difficult and misdiagnosis is not uncommon. Early orbital cellulitis, orbital metastasis, and trichinosis are other differential diagnoses.

Non-steroidal anti-inflammatory treatment has been advocated,[8] but the rapid and dramatic response to steroids is almost diagnostic. We recommend an initial dose of prednisolone of 0.5–1 mg/kg per day, tapering to nothing over 2–4 weeks. Delay in diagnosis and initiation of therapy is associated with recurrence and incomplete resolution of signs. Biologic agents such as adalimumab, a monoclonal antibody directed against tumor necrosis factor alpha, has been reported to be effective in recalcitrant cases of orbital myositis in children.[30]

Idiopathic lacrimal gland inflammation (dacryoadenitis): acute and subacute

Pain, tenderness, and swelling over the lateral aspect of the upper lid are typical presenting features of this disorder.[31] The lid may have an S-shaped configuration with ptosis, which is more marked laterally than medially. The globe is often slightly displaced downward and medially. This may be accompanied by superotemporal conjunctival injection, and chemosis and pouting of the excretory lacrimal duct orifices. Limited abduction may be seen. There is no uveitis. On CT scans, the inflammation is centered on the lacrimal gland, often extending diffusely into the lateral orbit and involving the adjacent globe. The differential diagnoses include bacterial and viral dacryoadenitis, the latter often occurring in association with childhood infections such as mumps or

infectious mononucleosis (Epstein–Barr virus infection), and IgG4-related dacryoadenitis. In this situation, the child is likely to be ill, and generalized lymphadenopathy or salivary gland enlargement may be noted, along with lymphocytosis. Inflammation related to leakage from a dermoid cyst and neoplasia, including chloroma (granulocytic sarcoma), are other rare possibilities. Lacrimal gland involvement in orbital sarcoid tends to be chronic, presenting with signs and symptoms of dry eyes, and is rare in childhood.

Acute or subacute lacrimal gland swellings in childhood do not need biopsy if they are related to an obvious viral illness such as mumps, or if there are other findings suggestive of mononucleosis. Atypical lesions in patients whose signs and symptoms fail to respond to treatment should have an early biopsy to exclude specific forms of inflammation.

Idiopathic lacrimal gland inflammation is usually treated with moderate-dose systemic steroids, tapering with resolution of symptoms and signs.

ANATOMY
CONJUNCTIVA IN SYSTEMIC DISEASE
MISCELLANEOUS DISORDERS OF CONJUNCTIVA
REFERENCES

See online for supporting video for this chapter.

Anatomy

The conjunctiva is a thin, translucent, vascular mucous membrane that lines the inner surface of the eyelids and the anterior surface of the eyeball as far as the limbus. This tissue is arranged in a sac-like fashion and is composed of a palpebral region (covering the inner aspects of the lids), a bulbar region (covering the surface of the sclera), a forniceal region, and a medial semilunar fold.

The palpebral part of the conjunctiva is more adherent to the underlying tarsus than the bulbar part. The loose adherence is responsible for the occurrence of chemosis of the bulbar conjunctiva during inflammation. The bulbar conjunctiva has attachments with the lateral rectus muscle through fine fibrous slips, and hence plays a role in the maintenance of the horizontal movements of the eyeball. While the palpebral conjunctiva shares its blood supply with the eyelids, the bulbar component is supplied by the anterior ciliary arteries. The nerve supply to the conjunctiva is through the lacrimal, supraorbital, supratrochlear, and infraorbital branches of the trigeminal nerve.

The conjunctival epithelium varies from two to five cells in thickness and is continuous with the corneal epithelium at the limbus and with the skin at the margin of the lids. While the bulbar conjunctiva is lined by a stratified non-keratinized squamous epithelium, the forniceal and tarsal regions are lined by columnar and cuboidal types, respectively. A key constituent of the cellular architecture is the presence of goblet cells, which accounts for 10% of the basal cells of the conjunctival epithelium. These cells are more prevalent in the medial forniceal and palpebral regions, and play a vital part in secreting the mucin component of the tear film. There is an increase in the number of these cells during chronic inflammation of conjunctiva, while conditions like pemphigoid and vitamin A deficiency causes a decrease. Other cell types that nestle within the epithelial layers include melanocytes, Langerhans cells, and intraepithelial lymphocytes.

Beneath the epithelium lies a loose structure called the substantia propria. This structure contains different cell types that mediate immune responses (mast cells, plasma cells, eosinophils, and lymphocytes) interspersed in a vascular network. This arrangement of immune cells, commonly referred to as conjunctiva-associated lymphoid tissue, existing in a vascular environment, is continuously exposed to potential external infective agents and allergens and thus serves as a perfect setting for inflammation to set in.

Beneath the conjunctiva lies a fibroelastic tissue, Tenon's capsule, which surrounds the eyeball from the corneoscleral junction to the optic nerve. In children, the conjunctiva–tenon complex is thicker, with a larger proportion of fibroblasts, compared to adults. In consequence, surgeries like trabeculectomy performed in children, especially without adjuvant procedures like intraoperative use of antimetabolites, may fail due to the aggressive healing response induced by these fibroblasts.[1]

Conjunctiva in systemic disease

Vitamin A deficiency

The ocular manifestation of vitamin A deficiency is termed xerophthalmia, and affected individuals present with night blindness, conjunctival xerosis, Bitot's spots, corneal xerosis, keratomalacia, and the "xerophthalmic" fundus (see Chapter 50).

In xerophthalmia, the conjunctival epithelium is transformed from the normal columnar to the stratified squamous type. There is an associated loss of goblet cells, formation of a granular cell layer, and keratinization of the surface. The conjunctiva loses its normal luster and becomes dry or unwettable (Fig. 31.1). It is almost always bilateral. A classic ocular sign is Bitot's spots, which is a superficial, scaly, gray area on the interpalpebral region of the bulbar conjunctiva (Fig. 31.2). *Corynebacterium xerosis* can colonize these spots, and produce a foamy appearance because of the gas-forming nature of these organisms. If untreated, the condition involves the cornea, causing corneal xerosis and finally corneal melting (keratomalacia).

The diagnosis of xerophthalmia can usually be made clinically. In doubtful cases, impression cytology of the

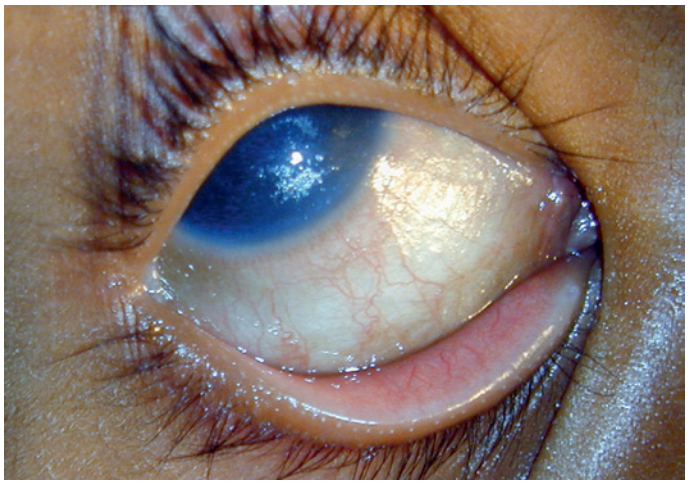

Fig. 31.1 Xerophthalmia. Dry, lusterless, inferior bulbar conjunctiva showing a wrinkled appearance. Associated corneal xerosis is also seen. *(Courtesy of Dr P. Vijayalakshmi, MS.)*

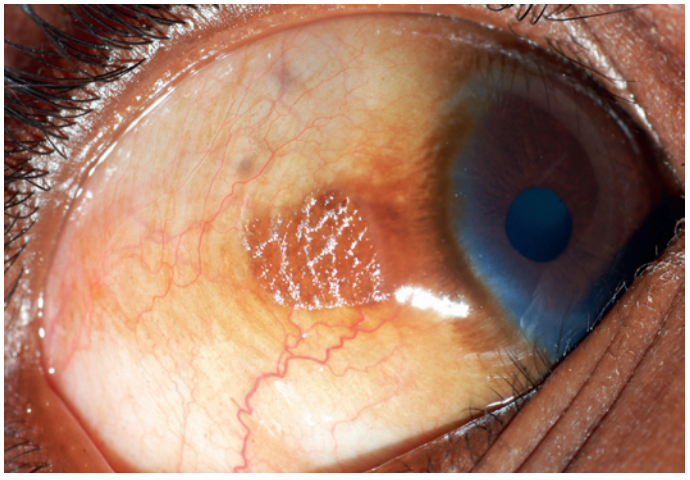

Fig. 31.2 Bitot's spot. A superficial, scaly, foamy Bitot's spot of the bulbar conjunctiva.

superficial layers of the conjunctival epithelium may be helpful to show the loss of goblet cells and keratinization of epithelial cells. In children 12 months of age or older, retinol palmitate (110 mg) or retinol acetate (200 000 IU) are given orally immediately, and the dose is repeated the following day. An additional dose should be given 2 weeks later to boost liver resources. Children between 6 and 11 months should receive only half this dose, and children less than 6 months only one-quarter.

Parenteral administration is indicated in children with gastrointestinal problems. In these cases, intramuscular injection of 55 mg of water-miscible retinol palmitate (100 000 IU) is administered, which replaces the first oral dose. This is repeated the next day. Children less than 1 year old are treated with vitamin A in half the prescribed dosage. After the acute phase is over, dietary supplements with provitamin A-rich foods, should be provided.[2]

Xeroderma pigmentosa

Symptoms appear in early childhood. (Fig. 31.3A). Conjunctival involvement occurs mostly in the interpalpebral area

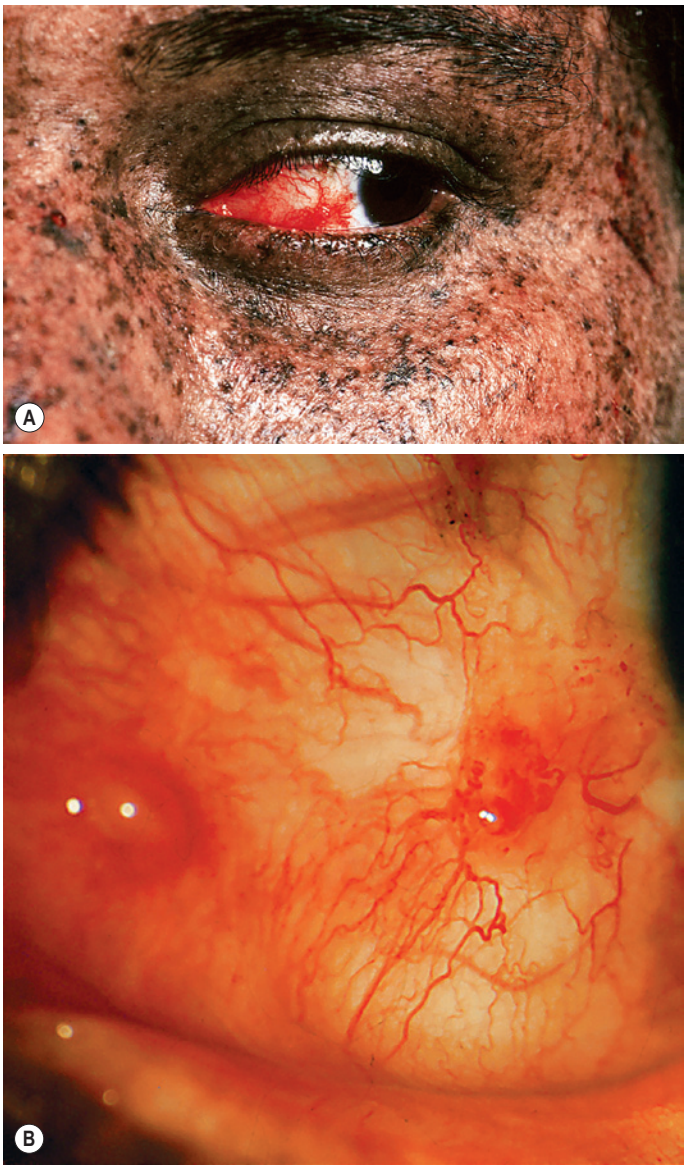

Fig. 31.3 Xeroderma pigmentosa. (A) The widespread skin pigmentation can be seen in this girl of Indian origin. (B) The conjunctiva was affected by multifocal recurrent squamous cell carcinomas.

in the form of xerosis, telangiectasia, chronic conjunctival congestion, pigmentation, pinguecula, and pterygium. Ocular surface neoplasms such as squamous cell carcinoma, basal cell carcinoma, and malignant melanoma may occur, with a predilection for the limbal area (see Chapter 32) (Fig. 31.3B). Corneal changes include exposure keratitis, band-shaped nodular keratopathy, scarring, ulceration, vascularization, and perforation.

Sturge–Weber syndrome

This is a congenital disorder with a classical triad of cutaneous facial angioma, leptomeningeal angioma, and ocular involvement (see Chapters 20 and 68). The facial angioma typically occurs in the distribution of the ophthalmic division of the trigeminal nerve. Dilated episcleral and conjunctival vessels with aneurysm formation in the limbal area are commonly seen.

Fig. 31.4 Ichthyosis. (A) There is keratinization of the upper palpebral conjunctiva secondary to ectropion of the upper lids. (B) The classical "stretched out" skin lesions are seen predominantly around the mouth and neck.

Glaucoma is a frequent accompaniment (see Chapter 38), especially in patients with severe conjunctival involvement.[3]

Ichthyosis

Ichthyosis is a heterogeneous family of at least 28 genetic skin disorders. Most pedigrees are either autosomal dominant or X-linked in their inheritance pattern. A rare autosomal recessive form, lamellar ichthyosis, occurs. In all these conditions, dry scaly lesions are present, predominantly over the upper half of the body, mainly around the neck, mouth, and trunk. The conjunctiva may become inflamed, primarily or secondarily, due to lid anomalies like ectropion.[4] A papillary reaction may develop (Fig. 31.4). The treatment is to provide adequate lubrication and to correct the lid abnormalities, if present.

Measles keratoconjunctivitis

Measles typically produces a bilateral keratoconjunctivitis. The characteristic Koplik's spots may be seen in the conjunctiva. The plica semilunaris may be swollen. Epithelial keratitis may supervene early in children and late in adults. Treatment is symptomatic and topical anti-inflammatory therapy may provide relief. In children with protein/energy malnutrition, this disease can be particularly devastating. If vitamin A deficiency is also present, this may rapidly progress to keratomalacia.

Ataxia telangiectasia (Louis-Bar syndrome)

This is a rare autosomal recessive disorder characterized by early onset cerebellar ataxia, oculocutaneous telangiectasia, ocular motor apraxia (saccadic initiation failure), dysarthria, and immunodeficiency. Ataxia is the first sign and is progressive. Chromosomal fragility and increased susceptibility to ionizing radiation result in a predilection to malignant disorders such as lymphomas and leukemias. Affected individuals tend to have raised serum levels of alpha-fetoprotein.

The most characteristic ocular sign is conjunctival telangiectasia that appears around 10 years of age. This is usually seen in the interpalpebral bulbar conjunctiva, but may extend to the fornices. It is caused by ultraviolet (UV) damage and can be prevented or minimized by early and consistent use of 100% UV filter lenses. Other associated disorders include hypometric saccades, horizontal ocular motor apraxia, deficient accommodative ability, strabismus, and nystagmus.[5]

Osler–Weber–Rendu syndrome

This is a rare autosomal dominant disorder of blood vessels that can cause excessive bleeding. It is characterized by vascular dilatations in a variety of organ systems. Systemic features include epistaxis, dyspnea on exertion, gastrointestinal bleeding, hemoptysis, and hematuria. The classical ocular abnormality detected is conjunctival telangiectasia.[6] It may present with bloody tears or frank external hemorrhage. Retinal telangiectasia and arteriovenous malformations have also been reported. Fabry disease is another entity where conjuctival vascular tortuosity, telangiectasia, and cornea verticillata are seen (see Chapter 65).

Sickle cell disease

The conjunctival signs in this condition are fairly specific. Comma-shaped capillary and venular microaneurysms, which disappear under the heat of the examining lamp, are noted in the inferotemporal quadrant of an otherwise pale conjunctiva. These aneurysms reappear after application of a mild vasoconstrictor. These vascular anomalies are exaggerated during sickling crises.

Ocular cicatricial pemphigoid (OCP)

This group of systemic autoimmune diseases may affect the skin and other mucous membranes. Their hallmark feature is chronic cicatrizing conjunctivitis.[7] The lids may have trichiatic lashes, chronic blepharitis, cicatricial fornix foreshortening, conjunctival shrinkage, keratinization, and subepithelial fibrosis. The cornea may also become involved in advanced disease. Immunohistochemical studies are diagnostic and reveal linear deposition of immunoreactants (immunoglobulin [Ig]G, IgA, complement component C3 or C4). Treatment is mainly systemic immunosuppression. Adjunct surgical modalities include epilation, punctal occlusion, fornix reconstruction, amniotic membrane transplantation, and keratoprosthesis.

Miscellaneous disorders of conjunctiva

Pyogenic granuloma

An aberrant healing response following trauma or surgery involving the conjunctiva can result in an exaggerated fibrovascular response, erroneously referred to as pyogenic granuloma. However, this condition is neither an infection nor a typical granulomatous reaction, but a granulation tissue formation. Rapid growth may simulate a malignancy. A history of preceding trauma or surgery helps in making the diagnosis. The condition may resolve spontaneously, but usually some form of treatment is required. A short course of topical steroids may be given, but excision biopsy is the treatment of choice.

Subconjunctival hemorrhage

A subconjunctival hemorrhage may occur after trivial blunt trauma (Fig. 31.5). It can also be seen in conditions that cause a rise in central venous pressure such as a seizure, violent coughing, or sudden straining. Its presentation may be dramatic and cause considerable worry. It usually resolves spontaneously within 2 weeks and does not require any treatment. Subconjunctival hemorrhages are also seen in conditions such as leukemia

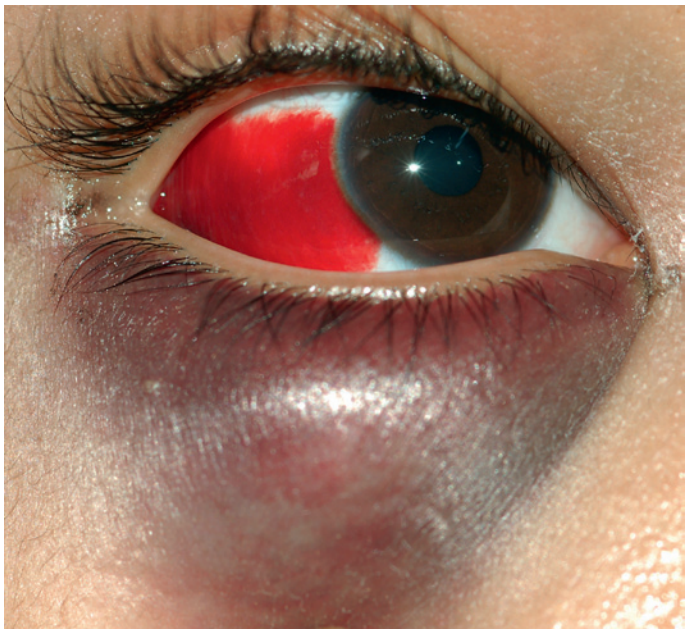

Fig. 31.5 Subconjunctival hemorrhage following a fist injury to the eye. An associated ecchymosis of the lower lid is also seen.

and as a sequel to some forms of conjunctivitis. After head injury, the presence of a subconjunctival hemorrhage with a poorly defined posterior margin could be an indication of a possible intracranial etiology, a matter of concern that has to be investigated radiologically.

Conjunctival inclusion cyst

These are smooth, thin walled lesions that commonly occur in inferior fornix. They are lined with epithelial cells and usually filled with clear fluid (Fig. 31.6). There may be a history of trauma (surgical or non-surgical). Symptomatic lesions may need surgical excision.

Conjunctival granulomas

The presence of a variety of lymphoid cells in the substantia propria serves as a perfect setting for the development of inflammatory granulomas following some systemic and local disorders. The systemic diseases and disorders that can cause conjunctival granulomas include sarcoidois, tuberculosis, Parinaud oculoglandular syndrome, Wegener granulomatosis, trematode-induced granulomas, and rhinosporidiosis and trauma.

Sarcoid nodules are small light-brown nodules in the conjunctiva[8] and show aggregates of epithelioid histiocytes on histopathological evaluation.

Tuberculosis of the conjunctiva may cause granulomas, tarsal necrosis, conjunctival masses, and small miliary palpebral conjunctival ulcers. A phlyctenular conjunctival response can also be seen in some cases (Fig. 31.7). Although the phlyctenular response is correlated with various organisms, *Mycobacterium tuberculosis* is the main causative agent for phlycten[9] in developing countries. It appears as a raised pink-to-gray amorphous nodule, 1–2 mm in diameter, surrounded by conjunctival injection (Fig. 31.8).

Trematodes are known to cause conjunctival granulomas.[10] They are acquired by children while swimming in infested

Fig. 31.6 A freely mobile subconjuctival cyst.

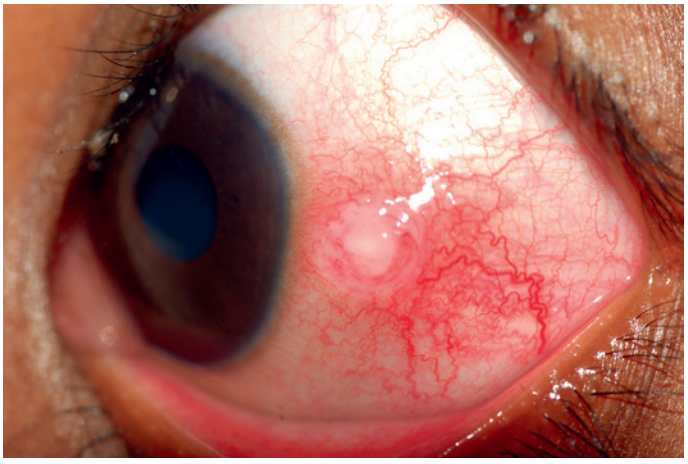

Fig. 31.7 An elevated nodular lesion seen in a 7-year-old girl on anti-tuberculous treatment.

fresh water ponds. The granuloma is usually seen as a smooth, nodular lesion in the bulbar conjunctiva (Fig. 31.9). Co-existent anterior chamber granuloma and corneal inflammation are evident in some cases. A specific inflammatory reaction known as Splendore–Hoeppli phenomenon has been described with helminthic infections, though the helminths themselves have rarely been isolated. Histopathologically, a central deposit of granular, acellular eosinophilic material is surrounded by eosinophils, epithelioid cells, histiocytes, and lymphocytes. Small granulomas may be treated with topical corticosteroids. Large lesions and those that fail conservative management should undergo an excisional biopsy.

Rhinosporidiosis may present as pedunculated granulomas, commonly in in the palpebral conjunctiva[11] (Fig. 31.10). The surface is granular and careful examination reveals pearly white studded spores, which have a tendency to bleed on contact. Treatment is by complete excision followed by cryotherapy. This lesion has an extraordinary tendency to bleed during surgery.

Ophthalmia nodosa is a granulomatous nodular conjunctivitis caused by irritation of the eye due to retained capillary hairs of caterpillars, spiders, or bees. Children presenting with this condition often give a history of a fall. Small nodules may be seen in the conjunctiva along with patterned corneal abrasions.

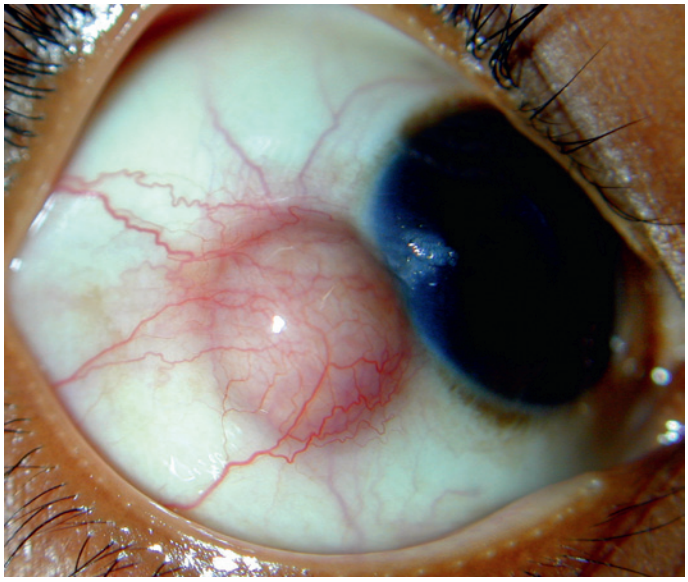

Fig. 31.9 River water granuloma. Well-circumscribed smooth elevated nodular lesion seen in the bulbar conjunctiva. *(Courtesy of Dr Rathinam, DNB.)*

Parasitic infestation of the conjunctiva

This condition is common in endemic areas and usually presents in the cyst form. The common parasitic cysts are cysticercus and hydatid. They may present with inflammation. These parasitic cysts have to be removed *in toto* along with cryotherapy of the base. Cysticercosis is caused by the larval form of *Taenia solium* known as cysticercosis cellulosae. The cysts are usually subconjunctival in location with a thin translucent wall (Fig. 31.11). Adjacent orbital structures and muscles may be involved. A chalky white area representing the scolex may be seen, which clinches the diagnosis.[12] Spontaneous expulsion of these cysts has been reported. A complete ophthalmic and systemic evaluation is needed to look for other involved areas. Treatment is by mechanical removal with supplementation of

systemic antihelminthic treatment. Exuberant inflammatory responses may need a course of systemic steroid therapy.

Ophthalmomyiasis

This term refers to the infestation of the eye by the larval forms of flies (maggots), the order Diptera. Implicated species include *Oestrus ovis* (transmitted from sheep and goats by gravid adult flies), *Dermatolabia hominis* (transmitted from cattle and fowl by mosquitoes), *Cuterebra*, *Hipoderma bovi*, *Chrysomyia*, and *Cordylobia*.[13]

In the United States, conjunctival myiasis is usually caused by the cattle fly *Hipoderma bovi*. Conjunctival involvement causes irritation, foreign body sensation, redness, and chemosis. There may be pseudomembrane formation with petechial hemorrhages. Patients may experience the perception of movements and slit-lamp examination shows the larvae. The aim of the treatment is to extract the worm mechanically. The worm may be caught with a forceps or pulled out with a suture passed through the larva.

Occasionally, adult worms can be seen presenting in the subconjunctival space (Fig. 31.12). The treatment is by

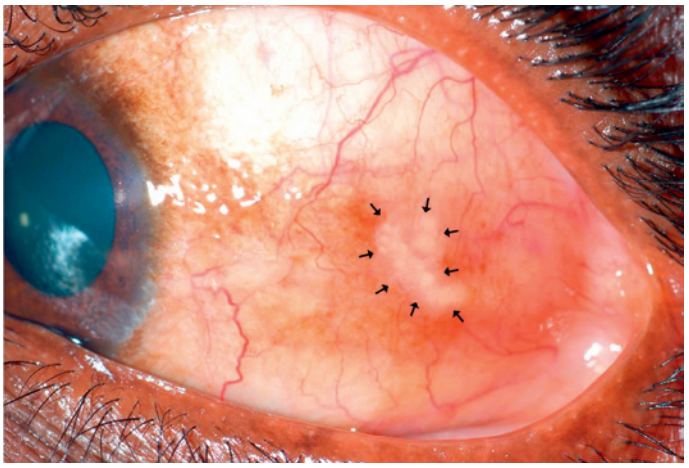

Fig. 31.12 Subconjunctival worm. The contour of this worm, identified later as *Filaria,* is clearly seen (arrows).

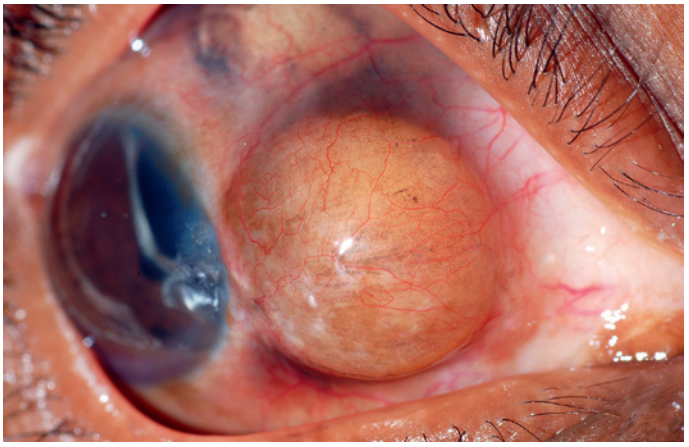

Fig. 31.14 Phacocele. A traumatically anteriorly dislocated lens mimicking a subconjunctival cyst.

Fig. 31.13 Subconjunctival foreign body. A small twig embedded in the conjunctiva required mechanical removal.

Fig. 31.15 Pseudopterigium with symblepharon. This condition warrants a surgical removal because of severe astigmatism.

mechanical removal of the worm using a forceps. In some instances, the worm is entrapped beneath the conjunctiva in close proximity to the extraocular muscles. In these situations, care should be taken to isolate the muscle and extract the worm without injuring the muscle.

Conjunctival trauma and foreign bodies

The upper tarsal conjunctiva is a common site for foreign bodies. An examination after lid eversion is mandatory for any history of trauma and suspicion of foreign body. Various foreign bodies that have been described include insect wings, beetles, cilia, caterpillar hair, seed husk, pieces of wood, twigs (Fig. 31.13), and natural and synthetic fibers. Any foreign body lodged in the conjunctiva evokes an acute inflammatory reaction with a copious outpouring of tears. However, if the foreign body has a large surface area, it may become embedded, resulting in a chronic inflammatory response. This causes a granuloma containing epithelioid and foreign body giant cells. The symptoms rapidly abate after the removal of the foreign body. Very rarely, blunt injuries in the eye, especially in older children and young adults, can cause the lens to dislocate anteriorly into the subconjunctival space and may present as a cystic lesion beneath the conjunctiva. This condition, which may mimic a subconjunctival cyst, is called a phacocele (Fig. 31.14), which may also be a presenting sign of Ehlers–Danlos syndrome type 6.

Symblepharon

In this condition, there is an adhesion between the bulbar and palpebral conjunctiva. It commonly occurs in association with congenital lid coloboma. Other causes include a chronic dry eye, chemical burns, and Stevens–Johnson syndrome where the goblet cells are destroyed. Localized symblepharon, without compromise to the visual apparatus, need not be treated. Surgical release and forniceal reconstruction using amniotic membrane or mucous membrane grafts is indicated in patients with visual symptoms or significant lagophthalmos (Fig. 31.15)

ANATOMY
EXAMINATION
CLASSIFICATION
SPECIFIC TUMORS
REFERENCES

See online for supporting video for this chapter.

Although rare, several conjunctival tumors can occur in the pediatric population. These tumors range from benign lesions including the most common, conjunctival nevi, to malignant lesions such as melanoma or Kaposi sarcoma. Fortunately, most pediatric conjunctival tumors are benign. However, even benign lesions can lead to ocular morbidity and loss of vision; therefore, an understanding of the clinical appearance, diagnosis, and treatment is necessary.

Compared to publications on conjunctival tumors in adults, the number of articles regarding conjunctival tumors in children is quite small. There are only three published large series on conjunctival tumors in children, two of which are from a histopathological perspective.[1–3] The only large clinical series of this entity was published in 2007 by Drs Jerry and Carol Shields and included 262 children.[1]

Anatomy

The conjunctiva is a translucent, vascularized mucous membrane that is freely mobile over the globe and in the fornix, but firmly adherent to the posterior eyelid surface at the tarsal plate. It is composed of: (1) epithelium, which contains goblet cells and melanocytes; and (2) stroma, a fibrovascular connective tissue, which contains collagenous and elastic tissue as well as lymphocytes, plasma cells, vessels, mast cells, and accessory lacrimal glands.

Examination

When examining the conjunctiva, a slit-lamp examination is helpful. In addition to the easily viewed bulbar conjunctiva, it is important to evaluate the fornices and, if possible, to evert the upper lid to check for extension of a lesion or a second tumor. If a malignancy is suspected, palpate the preauricular and submandibular lymph nodes for enlargement. When describing the lesion, note the location (bulbar, palpebral, fornix, or caruncle), size including thickness, consistency of the surface (smooth, rough with keratin, granular, gelatinous, or papillary), mobility over underlying sclera (freely mobile or firmly adherent), shape (flat, nodular, or pedunculated), and composition (cystic or solid).

Classification

Pediatric conjunctival tumors are typically classified as congenital (including choristomas and hamartomas), epithelial, or stromal tumors. Epithelial tumors are further grouped into non-melanocytic and melanocytic subtypes. Non-melanocytic tumors include benign entities (squamous papilloma, keratoacanthoma, oncocytoma, and dacryoadenoma) as well as premalignant and malignant entities (actinic keratosis, conjunctival intraepithelial neoplasia, and squamous cell carcinoma). Melanocytic tumors are also compromised of benign lesions (nevus) and malignant lesions (melanoma). Stromal lesions include vascular, fibrous, xanthomatous, neural, myxoid, leukemic, and lymphoproliferative. It is also important to be aware of non-neoplastic conditions simulating tumors including epithelial inclusion cysts, inflammatory lesions, foreign bodies, and granulomas. (Table 32.1).

Specific tumors

Hamartomas

Hamartomas are congenital overgrowths of normal tissue at their naturally occurring site. The most common are hemangiomas including infantile periocular (capillary) and cavernous. Infantile hemangioma is the more common and occurs as an isolated conjunctival lesion or may be continuous with an orbital or lid lesion. They appear as soft, red, vascular nodules shortly after birth and may grow for the first year and then involute years later[4] (Fig. 32.1). Most of these isolated conjunctival capillary hemangiomas do not need treatment. However, they often involute more rapidly if treated with topical timolol. Cavernous hemangiomas are typically larger and appear as multiloculated vascular masses. Because these do not regress spontaneously and may cause recurrent spontaneous subconjunctival hemorrhages, excision is the best treatment.

Table 32.1 Types of conjunctival tumors

Classification	Subtypes
Epithelial	Melanocytic; non-melanocytic
Stromal	Vascular; fibrous
	Xanthomatous; neural
	Myxoid; leukemic
	Lymphoproliferative
Congenital	
Simulating lesions

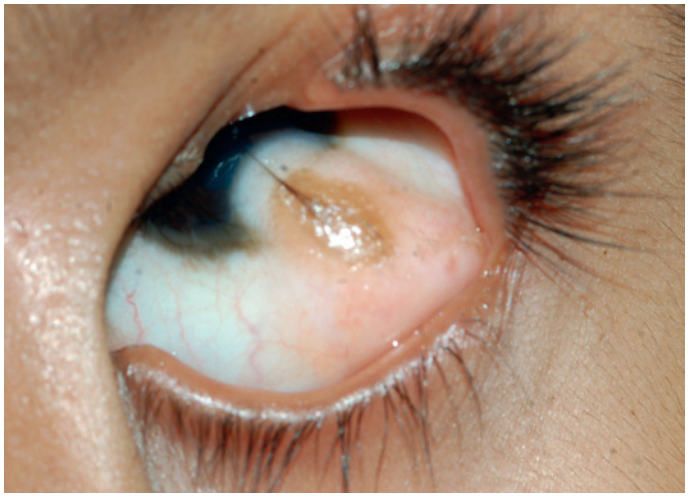

Fig. 32.2 Dermoid. A temporal limbal dermoid in a 5-year-old boy causing significant astigmatism. Hair growth is seen on the surface.

Choristomas

Choristomas are congenital tumors consisting of displaced tissue elements in an abnormal location. The most common conjunctival choristomas are dermoids and lipodermoids. Conjunctival dermoids are congenital, well-circumscribed, firm yellow-white solid masses with a predilection for the limbus. The surface can be smooth or coarse, with keratin and even hair formation (Fig. 32.2). They may appear in isolation or as part of Goldenhar syndrome, which is also known as oculoauriculovertebral dysplasia, in which structures derived from the first branchial arch are affected resulting in preauricular appendages, deafness, and vertebral anomalies.[5] Dermoids may be observed if asymptomatic, or excised if causing disfigurement or significant astigmatism. Lipodermoids (dermolipomas) are soft, mobile, yellow-colored lesions arising at the lateral canthal region and are typically observed (Fig. 32.3).

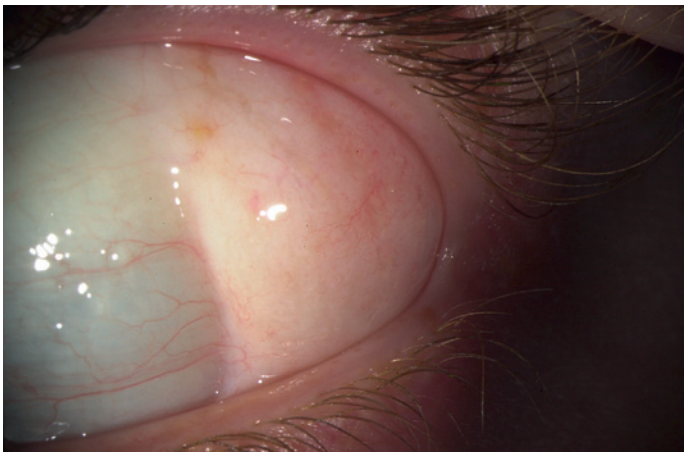

Fig. 32.3 Lipodermoid. Soft, mobile, yellow-white lesion arising at the lateral canthal region.

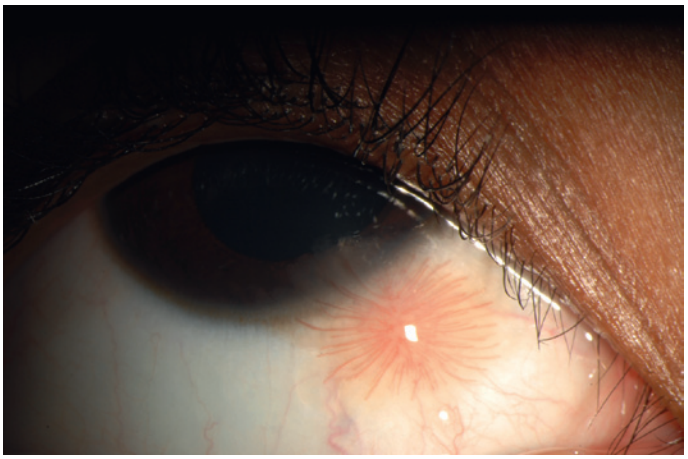

Fig. 32.4 Conjunctival papilloma. Sessile papilloma in a 5-year-old girl.

Papilloma

Squamous papillomas are benign tumors that appear as pink vascular fronds of tissue arranged in a sessile or pedunculated configuration, often with corkscrew vessels (Fig. 32.4). In children, papillomas have been documented to be associated with human papilloma virus (HPV; mostly subtypes 6, 11, and 16).[6] They are often located in the inferior fornix or bulbar conjunctiva. They are typically solitary, but can be bilateral and multiple. Small lesions may be observed for spontaneous resolution, but larger tumors require excision with a no-touch technique in order to prevent the spread of the papilloma-related virus.[7] Cryotherapy should be applied in a double freeze–thaw fashion to the surrounding conjunctival edges and the base of the tumor in order to reduce the risk of recurrence.[8]

Fig. 32.5 Conjunctival papillomas. Multiple pedunculated papillomas in a 5-year-old. These recurred after initial excision and were then treated with excision, cryotherapy, and interferon alpha-2b. Three years later she has had no recurrence.

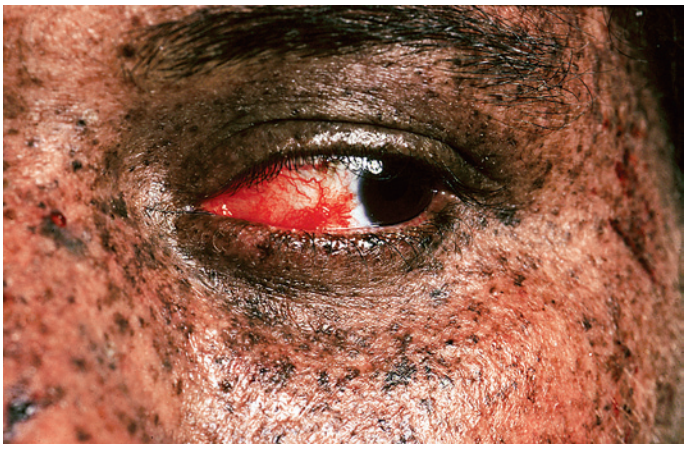

Fig. 32.6 Xeroderma pigmentosa. Widespread skin pigmentation can be seen in this girl of Indian origin.

Conjunctival papillomas tend to recur and, for these cases, topical or subconjunctival interferon alpha-2b may be used to prevent recurrence (Fig. 32.5).[9, 10] Other treatment options include mitomycin C, oral cimetidine, and carbon dioxide laser vaporation.[11–13]

A conjunctival papilloma in an infant or young child could result from acquisition of HPV during a vaginal delivery. The mother should be notified of this and referred for evaluation and treatment if necessary. If dysplasia is noted histopathologically, then the term "premalignant" is often used. If no dysplasia is noted, then the papilloma is benign.

Keratoacanthoma

Keratoacanthomas appear as solitary, gelatinous or leukoplakic, grayish-white nodules that grow rapidly over 3–4 weeks. Although benign, these lesions clinically may simulate squamous cell carcinoma and therefore the treatment is surgical excision with cryotherapy.

Hereditary benign intraepithelial dyskeratosis

This is a rare, benign, autosomal dominant condition that originated in North Carolina among an isolated number of Caucasians, African Americans, and Native Americans.[8] It is characterized by bilateral elevated fleshy plaques in the interpalpebral conjunctiva. Patients appear to have a chronic red eye and may complain of foreign body sensation, photophobia, and tearing. On histopathologic examination, there is acanthosis, dyskeratosis on the surface and deep epithelium, and severe chronic inflammation in the stroma.

Conjunctival intraepithelial neoplasia/ Squamous cell carcinoma

These entities encompass malignancies of the surface epithelial cells. Dysplasia is a term used to define various degrees of cellular atypia that involve various thicknesses of the epithelium starting with the basal layer outwards. Carcinoma *in situ* represents total loss of normal cellular maturation affecting the full thickness of the epithelium but the basement membrane is intact. Invasive squamous cell carcinoma shows features similar to carcinoma *in situ*, but the basement membrane is violated and the subepithelial tissue is invaded. Clinically, these lesions can be difficult to differentiate between one another and histopathologic examination is necessary. They typically occur in the interpalpebral fissure near the limbus, but may appear anywhere on the conjunctiva. They may appear papillary, gelatinous, leukoplakic, nodular, and, in some cases, pigmented. Most cases appear in adults, but it is important to remember that children who are medically immunosuppressed, who are infected with human immunodeficiency virus, or who have underlying DNA-repair abnormalities like xeroderma pigmentosa are at a higher risk of developing conjunctival squamous cell carcinoma.

Xeroderma pigmentosa is a genetic disorder inherited as an autosomal recessive disease. It is due to mutations of one of eight genes that are involved in nucleotide-excision repair. Ultraviolet light causes DNA damage to everyone's cells, but people without this mutation are able to repair their DNA. Xeroderma pigmentosa patients incur an accumulation of DNA damage leading to chromosomal mutations and cell death resulting in neoplasia.[14] They are at an increased risk for malignant lesions in the sun-exposed skin, ocular structures, and mucocutaneous areas. There is a 1000-fold increased risk of developing cutaneous malignancies.[15] Ophthalmic complications are present in about 20% of cases and may include eyelid pigmentary changes, keratitis, eyelid basal cell carcinoma, squamous cell carcinoma, and melanoma (Fig. 32.6).[16] Conjunctival involvement takes the form of xerosis, pigmentation, squamous cell carcinoma, and melanoma, which can result in corneal changes consisting of exposure keratitis, band keratopathy, vascularization, and even perforation (Fig. 32.7). Treatment includes excision with double freeze–thaw cryotherapy. If the cornea is involved with neoplasia, epitheliectomy with alcohol is recommended. Extensive tumors or those that are recurrent may be successfully managed with adjuvant topical and subconjunctival interferon alpha-2b.

Ocular melanocytosis

While this condition does not affect the conjunctiva, it is included in this section because it may be mistaken for a pigmented conjunctival lesion and should be considered in the differential diagnosis. This is a congenital pigmentary

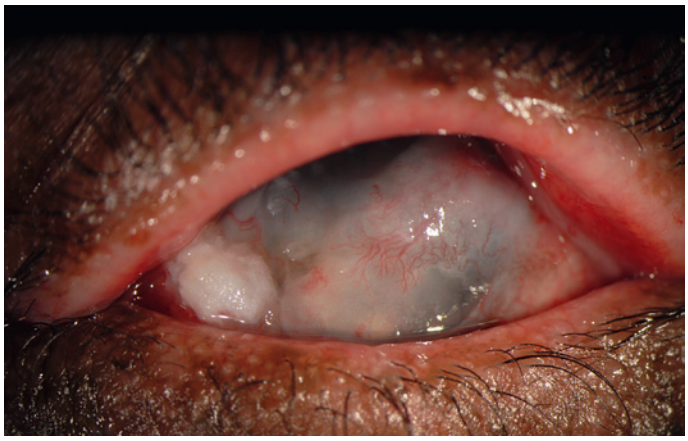

Fig. 32.7 Xeroderma pigmentosa. Conjunctival dysplasia in a young male. His other orbit was exenterated for squamous cell carcinoma 5 years previously as a teenager.

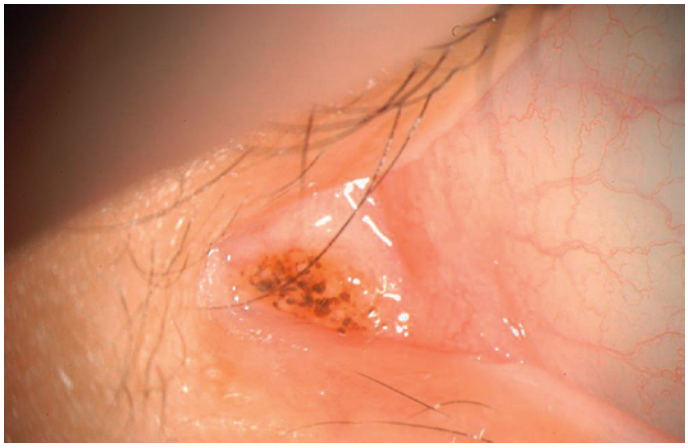

Fig. 32.8 Conjunctival nevus. A pigmented conjunctival nevus in the caruncle. Note the presence of clear cysts.

condition of the periocular skin, sclera, orbit, meninges, and soft palate. The uvea may also show a diffuse darker degree of pigmentation compared to the other eye. There is a 1/400 risk of developing uveal melanoma but no extra risk for conjunctival melanoma.[17] A recent study showed that the risk of metastasis from uveal melanoma is higher if the patient has a ocular melanocytosis.[18]

Nevus

Conjunctival nevus is the most common melanocytic tumor. In a clinical series of 262 pediatric patients with conjunctival tumors, 65% were found to be melanocytic.[1] A nevus typically becomes clinically apparent in the first two decades of life as a discrete, variably pigmented, elevated mass. Most are located in the interpalpebral bulbar conjunctiva near the limbus and rarely involve the cornea. They may become darker or lighter, but usually do not change after adolescence. A key feature of a nevus is the presence of clear cysts within the lesion, found in 65% of cases (Fig. 32.8).[1] While most are pigmented, 16% are completely non-pigmented (Fig. 32.9).[1] Histopathologically, nevi can be classified as junctional, compound, or subepithelial. In junctional nevi, the melanocytes are restricted to the basilar epithelium. Compound nevi extend into the substantia propria,

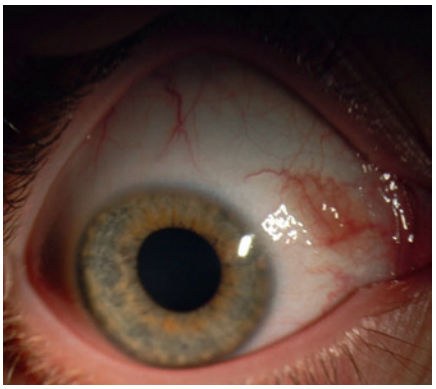

Fig. 32.9 Conjunctival nevus. A non-pigmented conjunctival nevus in a 3-year-old. The lesion was excised and the histopathology confirmed the diagnosis.

but maintain an intraepithelial component. The subepithelial type loses its connection with the basilar epithelium and is confined within the substantia propria.

The overall risk of malignant transformation is about 1%.[19] The management is periodic observation with photographic comparison. Indications for complete excision include documented growth, recent color change, cosmetic concerns, clinical suspicion of melanoma, interference with contact lenses, and recurrence of an excised lesion. At the time of excision, the lesion is completely removed. Cryotherapy may be applied in a double freeze–thaw fashion to the conjunctival margins to help prevent a recurrence.[8]

Melanoma

Conjunctival melanoma typically arises in middle-aged to older adults but rarely can occur in children. Conditions such as dysplastic nevus syndrome, xeroderma pigmentosa, and neurofibromatosis increase the risk of children developing a malignant melanoma. Clinically, the melanoma can appear pigmented or non-pigmented, yellow or pink, and may show rapid growth with feeder vessels. Involvement of Tenon's capsule and the sclera may restrict the mobility of the tumor over the ocular surface. It is important to check the preauricular and submandibular lymph nodes for enlargement. The primary treatment of conjunctival melanoma is excision of the entire tumor with a surgical margin of at least 3 mm. When deep limbal and scleral involvement is suspected, scleroconjuntivectomy should be considered. Cryotherapy in a double freeze–thaw fashion should be applied to the base and the conjunctival margins.[20]

Lymphangioma

Conjunctival lymphangiomas are rare and are hamartomatous proliferations lined by endothelium. There is no known hereditary or systemic association. They can occur in isolation, but more often represent the superficial component of an orbital lymphangioma. They typically appear in the first decade of life and present as clear vessels with variable sized clear fluid-filled cysts, either alone or interspersed amongst blood-filled hemangioma vessels. They have been referred to as "chocolate cysts." They may increase in size with Valsalva maneuvers. The treatment is often difficult because surgical resection or radiotherapy may not completely remove the mass and therefore observation may be preferred. Carbon dioxide laser and brachytherapy have been used to treat conjunctival lymphangiomas with partial success.[21–22]

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common malignant orbital tumor in children (see Chapter 24). Conjunctiva is the source of the primary tumor in around 12% of patients with orbital rhabdomyosarcoma.[23] The superior and superonasal areas are commonly involved. They present as light-brown colored elevated lesions and may be confused with focal areas of inflammation, papillomas, capillary hemangiomas, or conjunctival cysts. Lack of response to medical management and rapid progression is a characteristic feature that should alert the clinician. Histopathologically, this tumor comprises loosely coherent spindle cells in a myxoid stroma. Magnetic resonance imaging is needed to reveal orbital extension if present.

Kaposi sarcoma

The diagnosis of Kaposi sarcoma is made less frequently now that there are more effective treatments for acquired immunodeficiency disorder (AIDS) in medically advanced countries. This tumor is rare in children but can be found in those with AIDS or those who are immunosuppressed while receiving treatment for leukemia. Clinically, this sarcoma appears as one or more painless, reddish vascular masses that resemble hemorrhagic conjunctivitis. Histopathology shows a malignant tumor composed of spindle-shaped cells with elongated oval nuclei, well-formed capillary channels, and vascular slits containing erythrocytes, but without an endothelial lining. They have been shown to respond to chemotherapy and low-dose radiotherapy.[24] Surgical excision may be appropriate for small lesions.

Xanthogranuloma

Conjunctival xanthogranulomas may appear in children as a manifestation of juvenile xanthogranuloma. This is an idiopathic cutaneous condition that results in the presence of painless, pink skin papules with spontaneous resolution, generally in young children under the age of 2 years. Conjunctival involvement is very rare and these lesions usually appear as a solitary, elevated round orange-pink stromal mass, typically near the corneoscleral limbus (Fig. 32.10). If the classic skin lesions are noted or the patient has a known diagnosis of juvenile granulomatosis, the conjunctival lesion may be observed for spontaneous resolution or treated with topical steroids.[8] If the diagnosis has not been established, excisional biopsy is recommended, looking for typical findings of histiocytes and Touton's giant cells in addition to lymphocytes, plasma cells, and eosinophils.

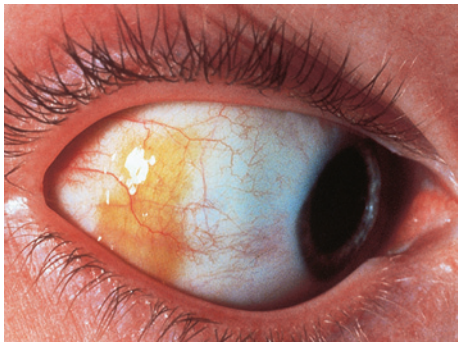

Fig. 32.10 Juvenile xanthogranuloma. A slowly enlarging yellowish lesion was noted in the conjunctiva of this 15-year-old boy. Histopathology showed Touton's giant cells, characteristic of juvenile xanthogranuloma. *(Patient of the University of British Columbia)*

Lymphoid tumors

Lymphoid tumors can occur in the conjunctiva as isolated tumors or as a manifestation of systemic lymphoma.[25] This is more common in adults and rarely occurs in children. They typically appear as a diffuse, slightly elevated, pink mass resembling smoked salmon, frequently referred to as a "salmon patch." Clinically, it is not possible to differentiate benign lymphoid tumors such as reactive lymphoid hyperplasia and atypical lymphoid hyperplasia from the malignant variant, conjunctival lymphoma. Therefore, a biopsy is needed to confirm the diagnosis and a systemic evaluation should be performed. The lymphoid tumors found in children are typically reactive or atypical lymphoid hyperplasia and are not associated with systemic lymphoma (Fig. 32.11).[1] Treatment includes chemotherapy if the patient has systemic lymphoma. If the lesion is localized to the conjunctiva and is found to be reactive lymphoid hyperplasia, topical steroid may help with resolution. Other options include external beam radiation, excision and cryotherapy, and local interferon injections.[8]

Leukemic tumors

Leukemic infiltrates of the eye are most commonly found in the choroid and retina but may occur in the conjunctiva. Conjunctival involvement of leukemia generally manifests as hemorrhages from anemia and thrombocytopenia rather than leukemic infiltration.[26] However, leukemic infiltration may be the initial sign of disease or of a relapse and therefore early recognition is important. Affected individuals present initially with congestion of the bulbar or the palpebral conjunctiva. In some instances, the conjunctiva may be erythematous and chemotic. The lesions are firm and non-tender and often associated with subconjunctival hemorrhage. Histopathologically, the cells infiltrate all layers of the substantia propia. The infiltration may be diffuse or patchy and typically localized around blood vessels. Treatment of the systemic condition with systemic chemotherapy will usually result in rapid resolution.

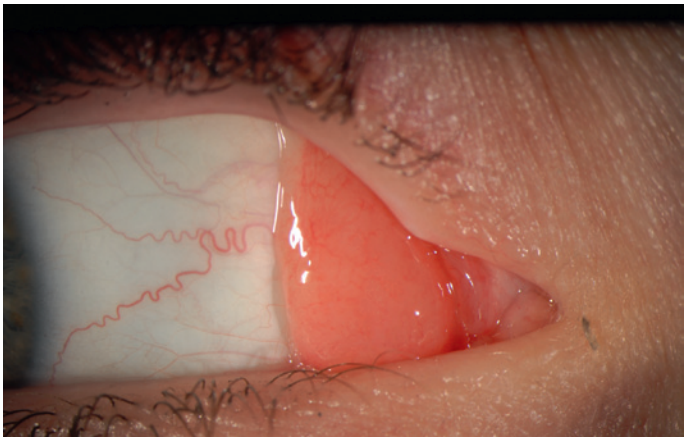

Fig. 32.11 Biopsy of this smooth, pink, "salmon patch" lesion showed atypical lymphoid hyperplasia.

Fig. 32.12 A 5-year-old with a pyogenic granuloma.

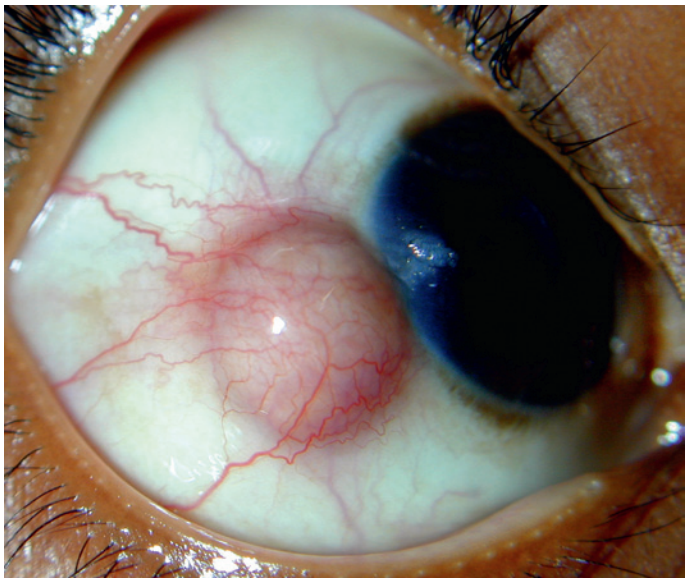

Fig. 32.13 River water (trematode-induced) granuloma. Well-circumscribed, smooth, elevated nodular lesion seen in the bulbar conjunctiva. *(Courtesy of Dr Rathinam, DNB.)*

Non-neoplastic lesions simulating conjunctival tumors

There are a number of non-neoplastic lesions that may be confused with a neoplasm. A pyogenic granuloma is a common condition that can be mistaken for a tumor (Fig. 32.12). A pyogenic granuloma is an exaggerated fibrovascular response following trauma or surgery.[27] The term is a misnomer, as it is neither an infection nor a typical granulomatous reaction, but a granulation tissue formation. Rapid growth may simulate a malignancy. A history of preceding trauma or surgery helps in making the diagnosis. The condition may spontaneously resolute, but some form of treatment is typically necessary. A short course of topical steroids may be attempted, but most will require excisional biopsy.

The presence of a variety of lymphoid cells in the substantia propia serves as a perfect setting for the development of inflammatory granules following some systemic and local disorders. The common systemic diseases that can cause conjunctival granulomas include sarcoidosis,[28] tuberculosis, Parinaud oculoglandular syndrome, Wegener granulomatosis, trematode-induced granulomas[29] (Fig. 32.13), and rhinosporidiosis[30] (Fig. 32.14).

Anterior segment developmental anomalies (ASDA) are rare but potentially visually devastating. It is important for the pediatric ophthalmologist to be aware of the causes, evaluation, and treatment of these conditions. However, their etiology is just as important, because associated extraocular conditions may need to be treated and the family may need counseling for future pregnancies.

Gene mutations causing anterior segment developmental anomalies

The majority of several disease-causing genes proven to play critical roles in ASDA all encode transcription factors (Table 33.1), which act by regulating the transcription of their downstream target genes. Examples of the commonest transcription factors involved in the etiology of ASDA are PAX6, PITX2, FOXC1, FOXE3, and MAF.[1,2]

Gene expression in the developing anterior segment: sites of gene action

The patterns of expression of genes whose mutation causes ASDAs can be considered as three types: those expressed within migrating periocular neural crest cells (*FOXC1*, *PITX2*); those expressed only within the developing lens (*FOXE3*, *MAF*); and those expressed within the whole eye including the lens, of which *PAX6* is the only example.[2]

The lens plays an essential role in the induction of anterior segment differentiation.[3] Two genes are implicated in causing ASDA by affecting the inductive properties of the lens. *MAF* and *FOXE3* mutation both cause ASDA with cataracts. Recent work has shown that homozygous mutations in *FOXE3* result in primary congenital aphakia.[4]

Clinical conditions due to anterior segment developmental anomalies

ASDAs may be considered in terms of their embryologic origin. Therefore they may be:

- of neural crest cell origin;
- of ectodermal origin;
- of global origin.

Anterior segment developmental anomalies of neural crest cell origin

Posterior embryotoxon

This prominent, anteriorly displaced Schwalbe's line, seen in 8–15% of the normal population appears as a whitish, irregular ridge up to several millimeters from the limbus and is often incomplete (Fig. 33.1). It may be inherited in an autosomal dominant fashion.

Ocular associations may include iris adhesions with or without iris changes such as hypoplasia, pseudopolycoria, or corectopia, in which case it forms part of the spectrum of the Axenfeld–Rieger anomaly or syndrome (Fig. 33.2).

The presence of posterior embryotoxon in a jaundiced neonate is suggestive of the autosomal dominant condition Alagille syndrome (arteriohepatic dysplasia),[5] which is characterized by intrahepatic cholestasis, peripheral pulmonary artery stenosis, peculiar facies, and butterfly vertebral arch defects. Posterior embryotoxon is seen in 90% of all cases and 77% of cases also have iris strands.[5]

Since isolated posterior embryotoxon is not associated with glaucoma, there is no need for regular review unless

Table 33.1 Genes essential for the normal development of the anterior segment and whose mutation causes ASDAs

Human gene	Type	Chromosome location	Human disease	OMIM number
CYP1B1	Enzyme	2p22	Congenital glaucoma	601771
EYA1	Transcription factor	8q13	Branchiootorenal dysplasia ASDA	601653

SLC4A11	Sodium borate cotransporter	20p13–p12	Corneal dystrophy, Fuchs endothelial, 4	610206
JAG1	Ligand of the Notch Receptor	20p12	Alagille syndrome with posterior embryotoxon, iris hypoplasia, small corneal diameter, iridocorneal synechiae, and corectopia	601920
LAMB2	Extracellular matrix protein, laminin	3p21	Pierson syndrome with microcoria or ASDA	15032
BMP4	Regulatory molecule	14q22–q23	ASDA with or without anophthalmia/microphthalmia	112262

other members of the family have features of Axenfeld–Rieger anomaly/syndrome.

Axenfeld–Rieger anomaly and syndrome

Axenfeld–Rieger syndrome (ARS) has ocular and non-ocular features.[6–9] The ocular features consist of posterior embryotoxon with iris strands attached, some of which may be very broad and thick and others thread-like. Historically, if these were the only findings, the term Axenfeld anomaly was used. If, in addition, iris defects were present, then this was termed Rieger anomaly. Axenfeld–Rieger anomaly (ARA) now encompasses both. Iris findings range from stromal hypoplasia, pseudopolycoria, corectopia (displaced anomalous pupil; Figs 33.2–33.4), and ectropion uveae. Occasionally the iris may be almost completely absent – a severe form of hypoplasia. It is important to differentiate this from PAX6-related aniridia; the lack of foveal hypoplasia, polar lens opacities, nystagmus, and sometimes corneal pannus gives the clue to the diagnosis of ARA. The anterior chamber angle is usually open though there may be a high insertion of the iris into the posterior portion of the trabecular meshwork. Occasionally the pupil corectopia is severe enough to warrant surgical pupilloplasty. The pupil may still become progressively more eccentric over years despite surgery.

Angle and iris changes are usually stable. Glaucoma develops in 50–60% of patients with ARS, usually manifesting itself

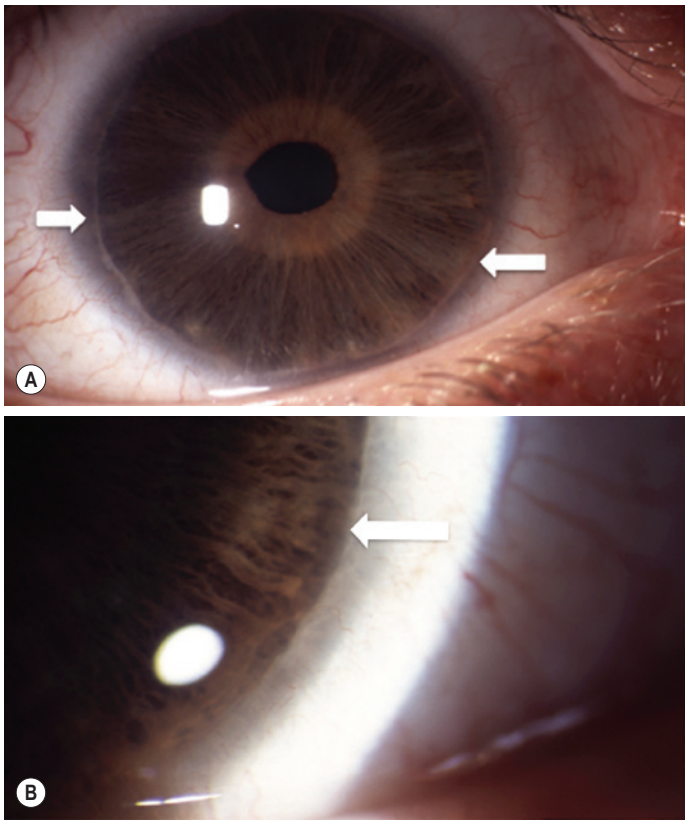

Fig. 33.1 Posterior embryotoxon. (A) Marked posterior embryotoxon with iris strands attached (Axenfeld–Rieger anomaly), white arrows. (B) Posterior embryotoxon with no associated ocular anomalies is a common but subtle anomaly seen on slit-lamp examination.

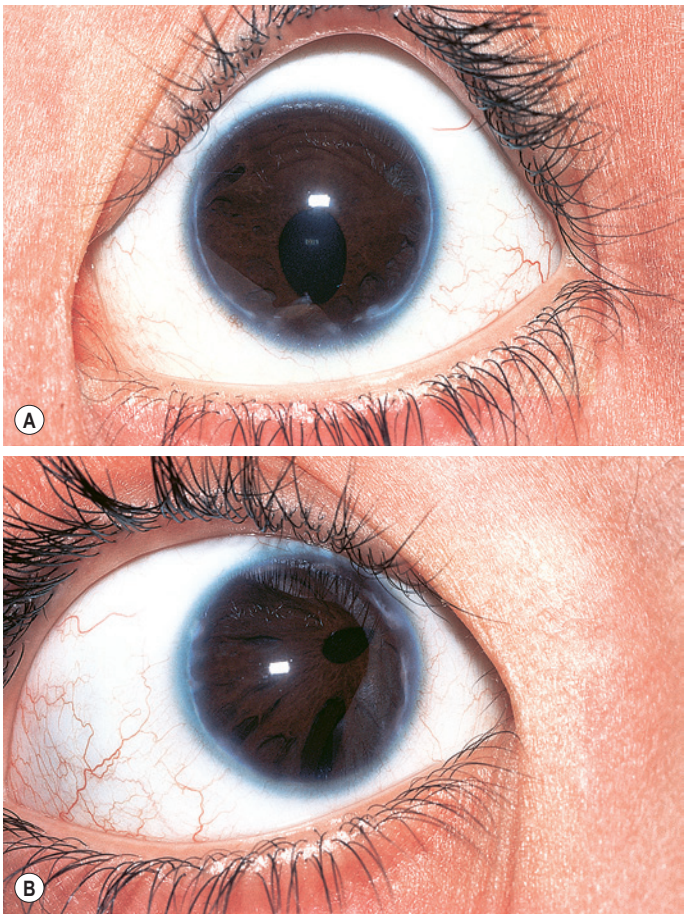

Fig. 33.2 Axenfeld–Rieger anomaly. There is iris hypoplasia, posterior embryotoxon, pseudopolycoria (A), and corectopia with the pupil drawn peripherally (B).

in childhood or young adulthood. Incomplete development of the trabecular meshwork and Schlemm's canal is thought to result from development arrest occurring during the third trimester, causing obstruction to aqueous outflow.[6–9] Other ocular features may include strabismus, cataracts, limbal dermoids, retinal detachment, macular degeneration, chorioretinal colobomas, and choroidal and optic nerve head hypoplasia.

Familial glaucoma iridogoniodysplasia has been described in one pedigree and entails marked iris hypoplasia, iridocorneal angle anomalies, and, frequently, glaucoma.[7] Iridogoniodysgenesis anomaly (IGDA) has been described as iridocorneal angle anomalies, iris stromal hypoplasia, and glaucoma in 50% of cases.[7] Iridogoniodysgenesis syndrome (IGDS) is a rare condition in which iris hypoplasia and iridocorneal angle anomalies are associated with non-ocular features such as jaw and dental abnormalities.[6–9] Both IGDA and IGDS are caused by mutations in *PITX2* and *FOXC1*.

The characteristic non-ocular features of ARS are maxillary hypoplasia, mild prognathism, hypodontia (decreased but evenly spaced teeth), anodontia/oligodontia (focal absence of teeth), microdontia (reduction in crown size), cone-shaped teeth (Fig. 33.5), and excess periumbilical skin (Fig. 33.6) with or without hernia. Hypertelorism, telecanthus, and a broad flat nose have also been described.[6–9] Other systemic features may include growth hormone deficiency and short stature, heart defects, middle ear deafness, mental deficiency, cerebellar anomalies (*FOXC1* mutations), oculocutaneous albinism,

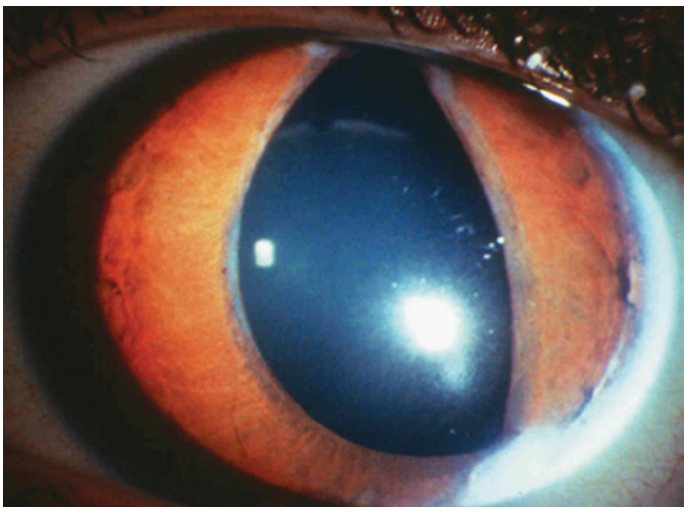

Fig. 33.3 Axenfeld–Rieger syndrome. Marked corectopia with pupil distortion and posterior embryotoxon.

hypospadias, abnormal ears, and, in one pedigree, myotonic dystrophy and Peters' anomaly.[6–9]

Management depends on the presenting complication of the structural anomalies. Some authors suggest that every child with ARS should get a magnetic resonance imaging (MRI) scan

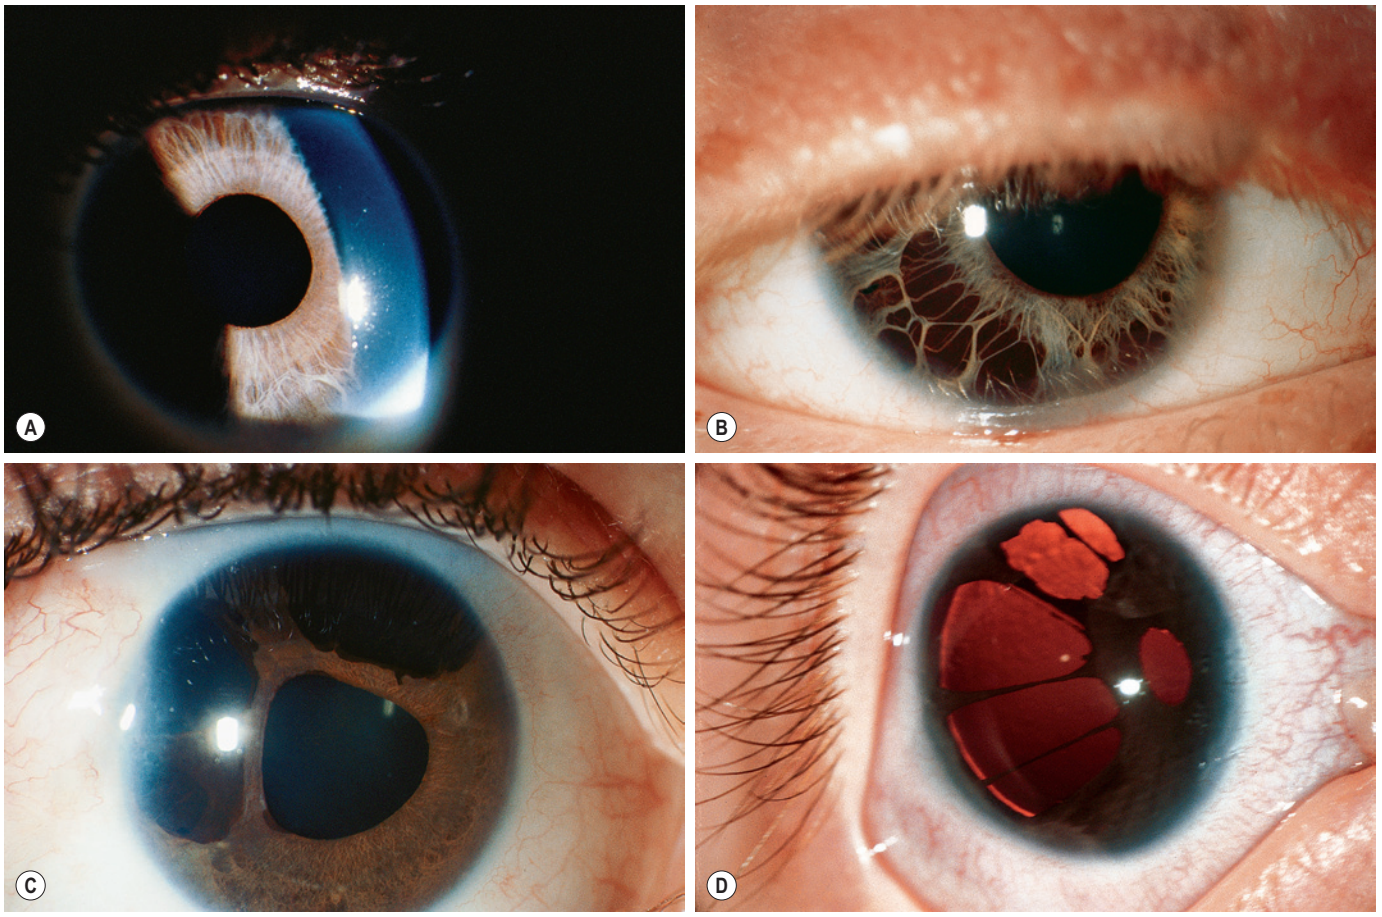

Fig. 33.4 Iris hypoplasia. (A) Iris hypoplasia showing the loss of stroma giving rise to prominence of the sphincter muscle. (B) Marked stromal hypoplasia revealing the posterior pigmented epithelium. (C) Marked stromal hypoplasia giving rise to pseudopolycoria in Axenfeld–Rieger anomaly (ARA). (D) Pseudopolycoria in ARA seen in retroillumination.

given the increased incidence of intracranial anomalies found in PITX2- or FOXC1-positive ARS.

Occasionally there is severe pupillary stenosis for which a large pupilloplasty is required, which may be complicated by lens damage and/or late contraction. Severe corectopia without severe stenosis can be adequately treated with occlusion therapy of the less affected eye. Sometimes the pupil is very large, irregular and, distorted (see Fig. 33.5).

Medical therapy should be used for glaucoma prior to surgical intervention with the exception of infantile cases, where goniotomy/trabeculotomy is first choice of treatment. Miotics should be used with caution, since they may cause trabecular meshwork collapse, with a reduction in aqueous outflow.

Trabeculectomy with antimetabolite augmentation appears to be the procedure of choice for most patients with glaucoma secondary to ARS, especially in older children. The use of cycloablation should be considered for children with limited cooperation where a drainage procedure would be unsuitable. Draining procedures other than trabeculectomy include the use of drainage tubes with or without antimetabolite.[10]

Congenital iris ectropion

This is a rare, usually unilateral, condition in which there is a congenital, non-progressive, non-tractional hyperplasia of the posterior pigment iris epithelium onto the anterior surface of the iris (ectropion).[11] The child is often thought to have mydriasis and anisocoria because of the dark color of the posterior pigment epithelium. The ectropion may be circumferential (Fig. 33.7) or sectorial. Other ocular features include iris stromal hypoplasia, a high iris insertion into the trabeculum with goniodysgenesis, and secondary glaucoma.

The clinical features are thought to result from an arrest in development with abnormal retention of primordial endothelium, which explains the central iris and angle changes. Although the affected pupil reacts to light and accommodation, it may not do so at the same speed as the unaffected eye.[11] Glaucoma occurs in the majority of these patients, usually between early childhood and puberty. Neurofibromatosis type 1 and Prader–Willi syndrome may be associated.

Management of the glaucoma can be difficult, with medical therapy often being unsuccessful; augmented trabeculectomy is often the surgical operation of choice.[11] Goniotomy is usually unsuccessful in these cases and if trabeculectomy fails, a drainage tube is often needed. Some authors prefer to use the drainage tube as the first line of treatment if medical management fails. Recently success with trabeculotomy has been reported in this condition.[12]

Congenital mydriasis

Congenital fixed dilated pupils (congenital mydriasis) is due to hypoplasia of the iris muscles, with absence of iris between the collarette and pupillary border resulting in a scalloped

pupillary margin. Often there are wisps of persistent pupillary membrane. This condition has been shown to be part of a multisystem smooth muscle cell dysfunction syndrome with associated moyamoya-like cerebrovascular disease, patent ductus arteriosus, thoracic aorta aneurysm, and other dysfunction of smooth muscle cells throughout the body. As of now, every affected individual has been shown to have a p.R179H heterozygous mutation in the *ACTA2* gene (see Chapter 39).[13]

Fig. 33.5 Axenfeld–Rieger syndrome (ARS). (A) Widely spaced teeth, some conical; partial anodontia and caries. (B) Dental X-ray of a patient with ARS.

Congenital hereditary endothelial dystrophy (CHED)

Please see Chapter 35, but it is noteworthy that there is only one recognized form of CHED now, with clear evidence suggesting that all previous dystrophies referred to as CHED1 were, in fact, posterior polymorphous dystrophy.[14]

Posterior polymorphous dystrophy

Please see Chapter 35.

Primary congenital glaucoma

Please see Chapter 38.

ICE syndromes

The iridocorneal endothelial (ICE) syndromes, thought to be due to a primary neural crest cell abnormality, include

Fig. 33.6 Axenfeld–Rieger syndrome (ARS). Excess periumbilical skin in ARS.

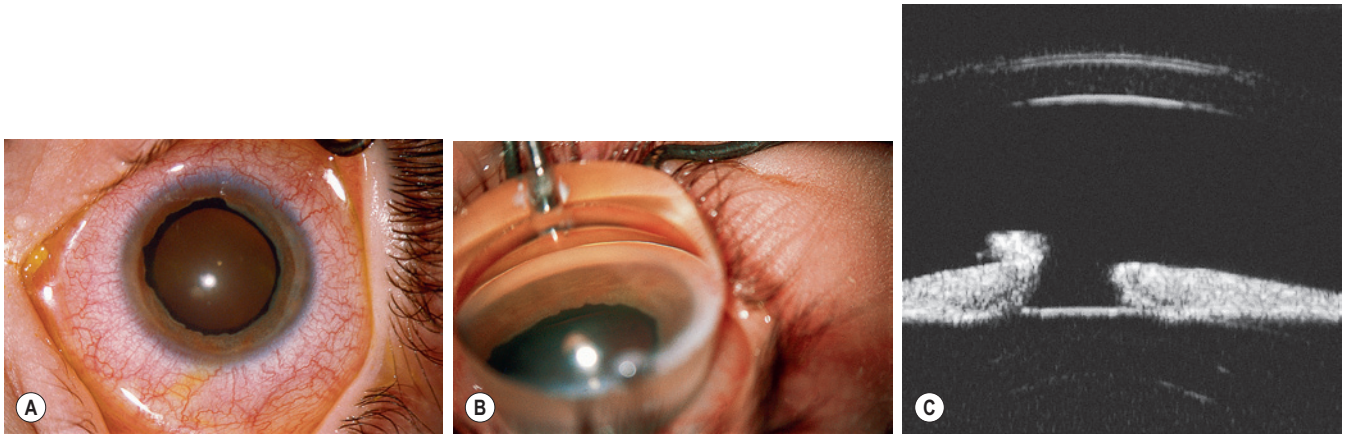

Fig. 33.7 Congenital ectropion uveae. (A) Ectropion uveae, shown as a wide, irregular, dark-brown margin to the pupil in a child with glaucoma. (B) Gonioscopic view showing high iris insertion. (C) High-frequency ultrasound image of a child with congenital iris ectropion. Note the frill of posterior pigment epithelium displaced anteriorly.

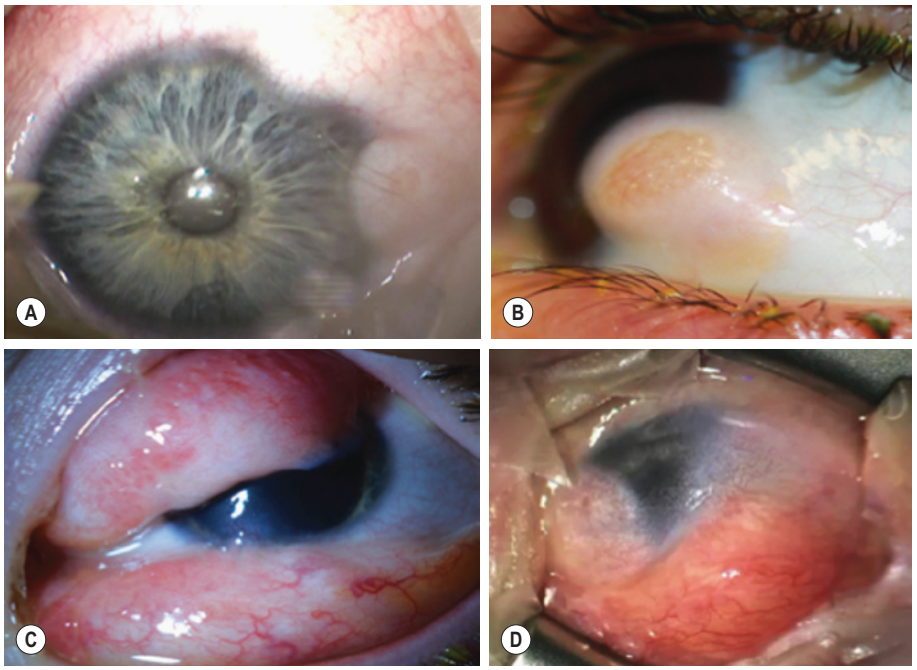

Fig. 33.8 Composite showing variations of limbal dermoids that can be isolated or associated with Goldenhar syndrome (A,B and C); and extensive corneal dermoids seen in encephalocraniocutaneous syndrome (D).

progressive essential iris atrophy, Chandler syndrome, and the iris-nevus syndrome (also known as Cogan–Reese syndrome).[15]

These rare syndromes are even rarer in children, and in fact the youngest reported case is in a 16-year-old. Descriptions of the trabecular meshwork in this 16-year-old with ICE syndrome show collapsed trabecular beams and decreased intertrabecular spaces.[16]

These disorders are unilateral; females are affected more frequently than males and they almost exclusively affect in Caucasians. Specular microscopy almost always reveals mild corneal and iris abnormalities in the "unaffected" eye.

Specular microscopy studies[15] of early cases of ICE syndrome suggest that a subpopulation of corneal endothelial cells are congenitally abnormal and subsequently slowly migrate/proliferate, resulting in a delayed onset of symptoms or diagnosis. These cells may migrate over the angle and onto the iris to cause glaucoma and peripheral anterior synechiae. While the condition can look like Axenfeld–Rieger anomaly (corectopia, iris ectropion, pseudopolycoria, peripheral anterior synechiae, and glaucoma) the conditions can be distinguished by the unilaterality of ICE syndromes and the progressive nature of the ocular features. The cornea can appear normal in this condition but the endothelium may appear similar to that of Fuchs dystrophy.

Iris-nevus syndrome consists of iris changes either of a nodular type or a flattish, pigmented type. These lesions may be associated with varying degrees of iris atrophy and/or corneal endothelial changes.[15–16] Older patients present with visual disturbance, whereas younger ones usually present due to the finding of pupil disturbance, pseudopolycoria, or pigmentary change of the iris.

Management is purely of any glaucoma that may occur in the first instance. Children are unlikely to require corneal grafting, but may do so in their adult lives.[17] Glaucoma management should be attempted initially with aqueous production-suppressing topical treatment, but filtering surgery may be needed. Usually antimetabolite augmented trabeculectomy is favored, but some authors also advocate the use of drainage tubes.

Anterior segment developmental anomalies of ectodermal origin

The two main conditions in this category are limbal and corneal dermoids, which may be associated with Goldenhar syndrome with up to 30% of patients being affected[18,19] (Fig. 33.8 and see Chapter 28). In addition to the systemic association of Goldenhar (in which case the reader is forewarned to check the child's corneal sensation, as hypoesthesia can be seen in Goldenhar syndrome), there is also linear sebaceous nevus syndrome (also known as encephalocraniocutaneous syndrome). The dermoids here are usually more flat and more extensive than those usually seen in Goldenhar. The clue is that the child often has areas of waxy alopecia on the same side as the affected eye. An MRI scan is important because there can be intracranial abnormalities predisposing to seizures.[19]

One further type of corneal dermoid is described as flat and reticular. This is pathognomonic almost for trisomy 8 mosaicism.[19,20] This sign is so important that if the evaluation for trisomy 8 mosaicism returns as negative, the laboratory doing the test must be asked to repeat the test but with a greater number of cells tested for the trisomy 8 anomaly (200 cells instead of the routine 50).

Anterior segment developmental anomalies of a global origin

The anomalies in this category include megalocornea, microcornea, aniridia, autosomal dominant keratitis, Peters' anomaly, cornea plana, sclerocornea, microphthalmos, and

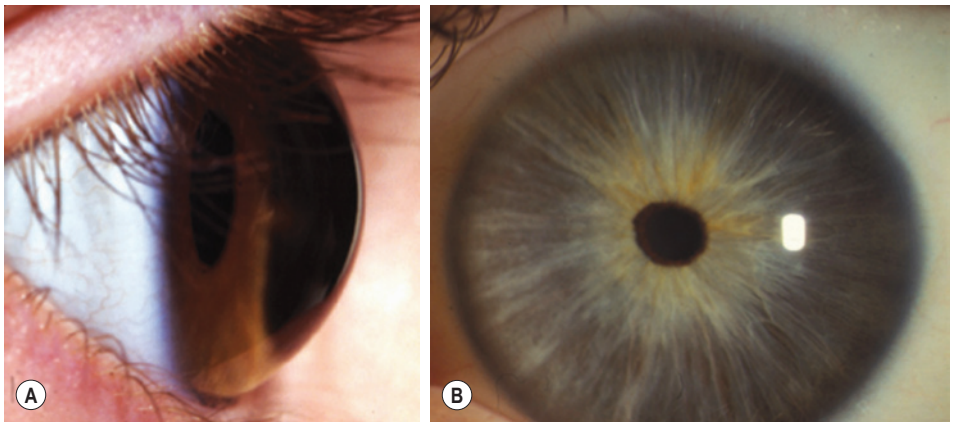

Fig. 33.9 Congenital megalocornea. The horizontal corneal diameter is 13.5 mm (B), and the anterior chamber is deep as seen in (A). In (A) it is possible to view the iridocorneal angle without a gonioscope.

anophthalmos. Of these, microphthalmos and anophthalmos are discussed in Chapter 18.

Congenital megalocornea

This rare, usually bilateral, condition, thought to be due to defective optic cup growth, results in the cornea growing larger in an attempt to close the gap. Usually inherited as an X-linked recessive trait, mapping to Xq21.3–q22, 90% of patients are males.[21–22] Female carriers may have slightly enlarged corneal diameters. The remaining cases are autosomal dominant or occasionally autosomal recessive. It is a non-progressive corneal enlargement with a horizontal diameter of more than 13 mm, without glaucoma and without Haab striae (Fig. 33.9). Myopia is most commonly seen, often accompanied by with-the-rule astigmatism. Associated ocular features include Krukenberg's spindle, increased pigmentation in the trabecular meshwork, iris stromal hypoplasia with iris transillumination, cataracts, ectopia lentis, mosaic corneal dystrophy, and later-onset glaucoma. This can be difficult to assess because the cornea is usually thinner than it should be centrally, which can result in artificially lower intraocular pressure measurements using applanation tonometry. Reported associations include Alport syndrome, craniosynostosis, dwarfism, Down syndrome, facial hemiatrophy, Marfan syndrome, mucolipidosis type II, Frank–ter Haar syndrome (OMIM 249420), and megalocornea-mental retardation syndrome (also known as Neuhauser syndrome).[21]

Management consists of careful observation for complications such as cataract formation, dislocated lens, and glaucoma. The iris transillumination can result in difficulty in bright light (usually outdoors), and some patients benefit from tinted spectacles. Lagophthalmos can be a problem due to improper closure of the eyelids at night, and a lubricating eye ointment may be used to prevent exposure problems. The lower lid can often turn in and cause irritation and corneal erosions. Lubrication at night is especially helpful. Contact lenses can be considered for children with high astigmatism.

Microcornea

This is an uncommon condition defined as any cornea with a horizontal diameter less than normal for age. It may be the result of overgrowth of the tips of the optic cup and may be inherited in an autosomal dominant or recessive manner. If it is an isolated finding and the rest of the eye is normal, it is called "microcornea," whereas if the anterior segment and the rest of the eye is small, the term is "microphthalmos."

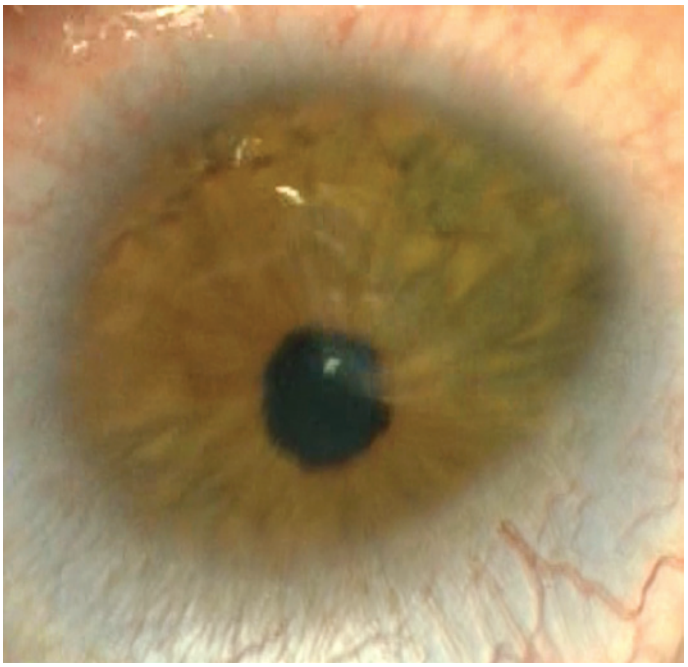

Fig. 33.10 Microcornea in a child with cornea plana.

Microcornea may be unilateral or bilateral and is usually associated with hypermetropia. Associated ocular findings may include cornea plana, iris colobomas, corectopia, cataracts, microphakia, persistent hyperplastic primary vitreous, retinopathy of prematurity, angle closure glaucoma, infantile glaucoma, and chronic open angle glaucoma (occurring in up to 20% of patients later in life) (Fig. 33.10).

Systemic associations include Ehlers–Danlos syndrome, Marfan syndrome, Rieger syndrome, Norrie syndrome, trisomy 21, rubella, Turner syndrome, Waardenburg syndrome, acrorenoocular syndrome, microsyndrome, and oculodentodigital syndrome.[23–26]

Visual acuity may be normal if it is an isolated finding and if any refractive error is corrected early to avoid amblyopia but often complex contact lens fitting needs to be considered to give maximum visual rehabilitation (see Fig. 33.18).

Developmental anomalies affecting corneal clarity

The prevalence of congenital corneal opacity (CCO), including Peters' anomaly, "sclerocornea," congenital hereditary endothelial dystrophy (CHED), and posterior polymorphous dystrophy is approximately 3/100,000.[27]

The terminology for neonatal corneal opacities is at best confused and at worst misleading. In a large review of the literature, only five reports used anterior segment imaging of any description to assess the anterior segment in cases of corneal opacity.[20]

This has led to confusion when attempting phenotype–genotype correlation. Recent publications emphasize the use of a classification system that considers corneal opacities to be primary corneal disease or secondary corneal disease (Box 33.1).[19,28]

Peters' anomaly

This is also considered as a secondary corneal opacity to either iridocorneal adhesion or keratolenticular adhesion resulting in central or eccentric, localized, or total corneal opacification (Fig. 33.11). The pathogenesis of Peters' anomaly is controversial. None of the theories adequately explains all the clinical and histopathologic findings in all forms of Peters' anomaly. Peters' anomaly should be regarded as a sign and not a disease entity *per se*. It is likely that where a genetic basis is responsible for this sign, accompanying ocular conditions may point to the likely mutation, e.g. aniridia and Peters' anomaly is likely to be due to a *PAX6* mutation whereas Axenfeld–Rieger anomaly/syndrome with Peters' anomaly is likely to be due to *FOXC1* or *PITX2* mutations.[19]

Most cases are sporadic, but autosomal recessive and dominant inheritance have been reported. Classical Peters' anomaly is defined as a congenital central corneal opacity with corresponding defects in the posterior corneal stroma, Descemet's membrane, and endothelium. Eighty percent of cases are bilateral. Glaucoma is present in 50% to 70% of cases.

Peters' anomaly has been often classified into three groups[29,30]:

1. Posterior corneal defect with leukoma alone.
2. Posterior corneal defect with leukoma and adherent iris strands.
3. Posterior corneal defect with leukoma, adherent iris strands, and keratolenticular contact or cataract.

Posterior corneal defect with leukoma alone is the simplest form of Peters' anomaly and the least documented in the literature.[31] The iris and lens are normal, but a defect in the posterior cornea has produced an overlying opacity, which varies from a mild haze to an elevated vascularized lesion. This may decrease in the first few years of life. Occasionally the defect is so severe as to cause relative clearing centrally with opacification in the mid-periphery of the cornea (Fig. 33.12). The peripheral cornea is usually clear, allowing visualization of the lens–cornea adhesion with a gonioscope (see Fig. 33.16), although scleralization of the limbus is common.[32] In a recent publication, the author showed mutations in *CYP1B1* associated with congenital corneal opacification and suggest that the original description of von Hippel's ulcer could be explained by such a *CYP1B1* "cytopathy"[31]; besides glaucoma, no additional ocular sign is seen. If glaucoma is present and not treated aggressively, the eye can become severely ectatic (Fig. 33.13).

If there are iridocorneal adhesions, these usually arise from the collarette and vary from fine strands to broad bands. Keratolenticular adhesions may occur and can be described as one of the following types:

Box 33.1

Classification of congenital corneal opacities (CCO)[19]

A. Primary CCO

Developmental anomalies of cornea only

i. Corneal dystrophies
   - CHED
   - PPMD
   - X-linked endothelial dystrophy

ii. Isolated sclerocornea (cornea plana)

iii. Corneal structural defects due to dermoids
   - Peripheral due to limbal dermoid
   - Central corneal dermoid

B. Secondary CCO

I. Kerato-irido-lenticular dysgenesis

a. Lens fails to separate from cornea
   i. Developmental
   ii. Mechanical: clues to this include
      - Lens epithelium discernible
      - Evidence of persistent pupillary type membrane(s)
      - Intact iris stroma architecture on high frequency ultrasound

b. Lens separates but fails to form thereafter
   - More likely to present as total corneal opacification

c. Lens fails to form (primary congenital aphakia – see text)

d. Due to PHPV
   - Pushing lens forward and causing keratolenticular touch/adhesion (again may present as PA)

e. Iridocorneal adhesions

II. Iridotrabecular dysgenesis

a. Infantile glaucoma

b. Axenfeld-Rieger anomaly/syndrome

c. Aniridia

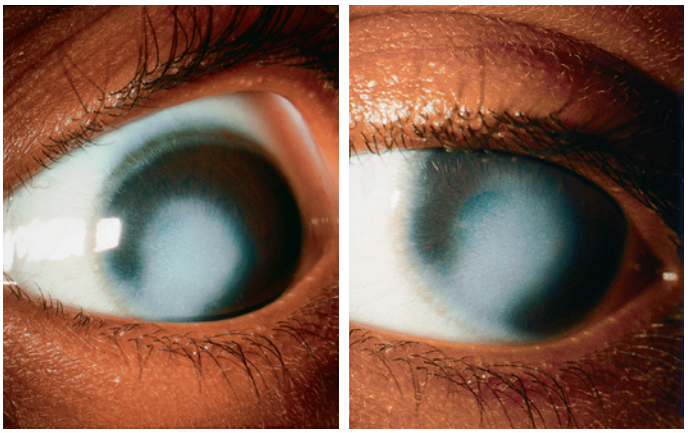

Fig. 33.11 Bilateral Peters' anomaly with eccentric opacification. Anterior segment imaging will determine whether the cause is iridocorneal adhesions and/or keratolenticular adhesion.

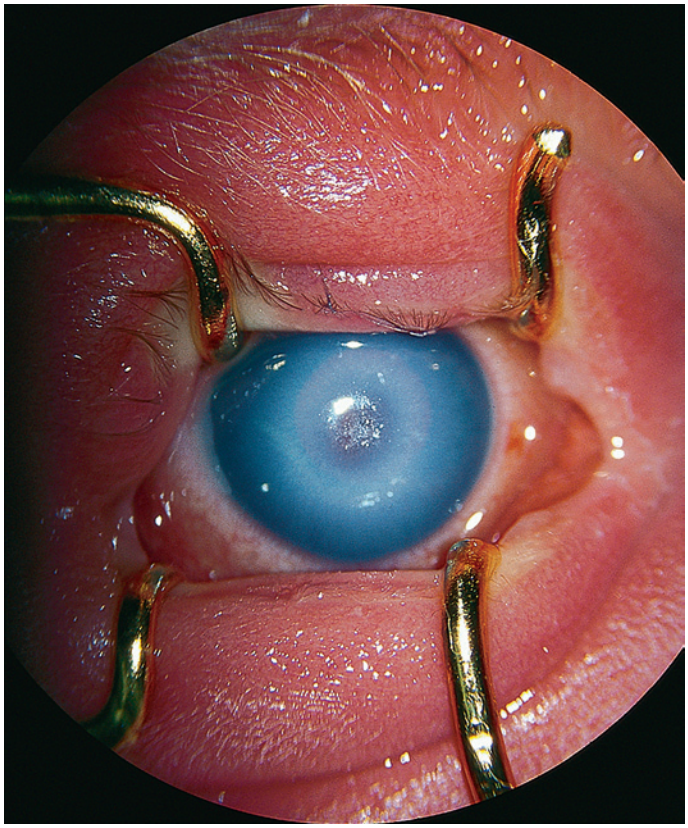

Fig. 33.12 A variant of Peters' anomaly. The posterior corneal defect is so great so as to give relatively clear appearance centrally.

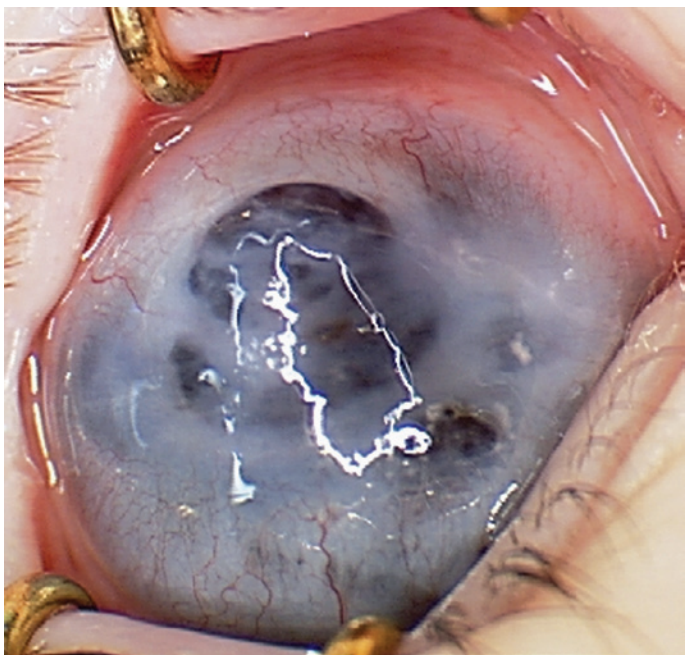

Fig. 33.13 Severe corneal ectasia secondary to glaucoma and congenital corneal opacity.

1. The lens may be adherent to the corneal stroma with absence of Descemet's membrane and lens capsule.
2. The lens may be located in a forward position, but only apposed and not adherent to the posterior surface of the cornea.
3. The lens may be in place, but with a portion of the anterior capsule and lens cortex in contact with or embedded in the posterior corneal surface.
4. The lens is in place but has a cone-shaped pyramidal cataract axially aligned with a posterior corneal defect.
5. The lens may be in place, but has an axial anterior polar or nuclear cataract.

Associated ocular features include Axenfeld–Rieger syndrome or aniridia, microphthalmia, persistent fetal vasculature, and retinal dysplasia.[32]

Systemic associations include craniofacial anomalies, congenital heart disease, pulmonary hypoplasia, syndactyly, ear anomalies, genitourinary disorders, central nervous system abnormalities, dwarfism, fetal alcohol syndrome, and chromosomal abnormalities. Peters'-plus syndrome[33] is a rare autosomal recessive disorder comprising short-limb dwarfism, smooth philtrum with thin upper lip, hearing loss, cleft lip/palate, brachymorphism, with short hands and tapering brachydactyly, mental retardation, and bilateral Peters' anomaly. It is associated with mutations in the *B3GALTL* gene.[33]

Histologically findings may vary, but include diffuse thickening of Bowman layer, mild atrophic changes in the overlying epithelium, normal anterior stroma, compressed posterior stromal lamellae partially replaced by fibrous tissue, and a broad central defect of Descemet membrane and endothelium. The periphery of the cornea usually has an intact Descemet's membrane and endothelium. The anterior chamber is usually deep, except in areas of iridocorneal or keratolenticular adhesions (Fig. 33.14). In other cases, absence of Bowman's layer with anterior stromal edema and posterior corneal defect has been described.[34]

Management of congenital corneal opacification is quite difficult and, despite early diagnosis and prompt medical treatment or surgery, many of these cases have a poor outcome. Essentially, however, by determining the etiology, parents can be counseled much better. For example, evidence exists that Peters' anomaly due to iridocorneal adhesions alone (type 1) fares much better than corneal transplantation for those cases with keratolenticular adhesion.[35]

Early penetrating keratoplasty, within the first 3 months, offers the infant the best hope for good vision. Suture removal after 4–6 weeks, followed by contact lens fitting and treatment of any amblyopia, is only successful if all involved are committed and motivated. If the reader keeps in mind that the goal of treatment is to achieve developmental vision at the very least, then this allows a better way to counsel parents. Graft rejection is a real issue, but evidence for the use of artificial corneas such as the Boston K-pro in infants is probably not robust yet.[36] However, the use of the Boston K-pro in children who have undergone previous corneal grafts that have eventually been rejected should be considered.

Sclerocornea

This is a poor term if describing total corneal opacification, mainly because it is usually due to an intraocular abnormality often involving the lens[19] and this may be due to keratolenticular adhesion or even absence of the lens (primary aphakia)[4,19] (Fig. 33.15). However, when it describes peripheral scleralization with central clearing, it refers to an uncommon, non-inflammatory, non-progressive condition where there is

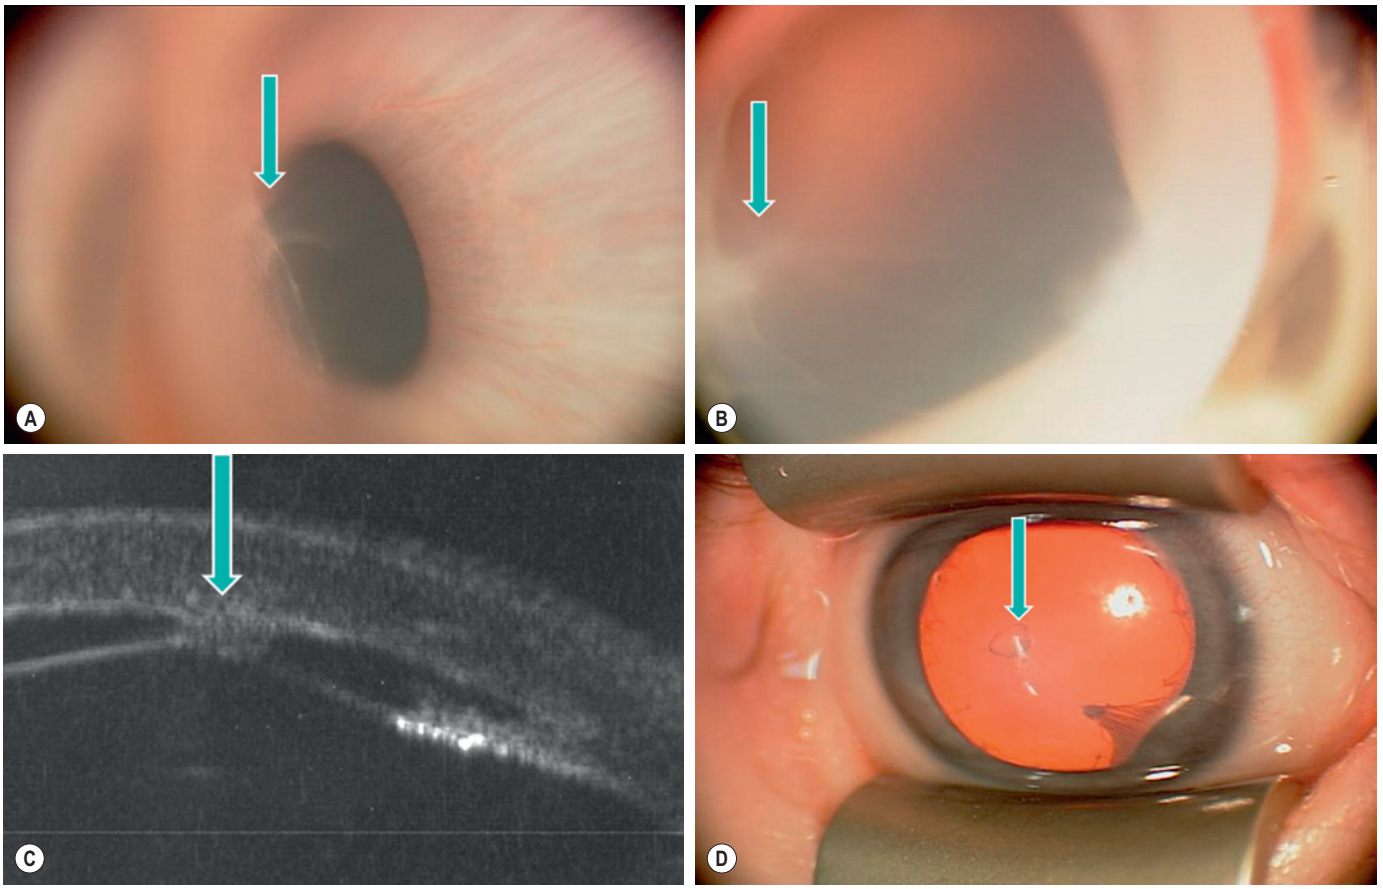

Fig. 33.14 Keratolenticular adhesion (arrow) seen with ultrasound biomicroscopy and clinically. This is a very mild Peters' anomaly.

extension of opaque scleral tissue and fine vascular conjunctival and episcleral tissue into the peripheral cornea, obscuring the limbus. It is bilateral in 90% of cases and almost always associated with cornea plana. It may be autosomal dominant or recessive (more severe), with 50% of cases being sporadic.

Management of sclerocornea consists of surveillance for glaucoma or cataract with correction of the often high hypermetropia seen. In bilateral cases where there is total corneal opacification, penetrating keratoplasty may be performed but postoperative glaucoma is a major problem. Preoperative assessment with high-frequency ultrasound is advisable to assess the presence of iridocorneal and keratolenticular adhesions, so that appropriate counseling can be given with respect to prognosis and so surgical planning can be done more methodically.[37]

Cornea plana

Cornea plana may be due to an arrest in development at the 4-month fetal stage, which results in a bilateral or unilateral flattening of the corneal curvature with a curvature of less than 43 D (Fig. 33.16). The cornea is almost always associated with sclerocornea characterized by peripheral corneal scleralization (Fig. 33.17) but a view of the eye through the center of the cornea is possible (Figs 33.18 and 33.19).

Hypermetropia and microcornea are commonly also seen. The recessive and dominant forms share clinical signs such as reduced corneal curvature, indistinct limbus, and arcus lipoides at an early age. The two forms are distinguished by a central, round, and opaque thickening, approximately 5 mm in width, only seen in recessive cases. Both forms may be associated with fine iridocorneal adhesions.[24]

Autosomal recessive cornea plana (CNA2) may be caused by mutations in the *KERA* gene (12q22), which encodes for keratocan. Keratocan, lumican, and mimecan are keratan sulfate proteoglycans, which are important to the transparency of the cornea.[38]

Associated ocular findings include peripheral sclerocornea, infantile glaucoma, angle closure glaucoma and chronic open angle glaucoma, retinal aplasia, anterior synechiae, aniridia, congenital cataracts, ectopia lentis, choroidal and iris coloboma (Fig. 33.20), blue sclera, pseudoptosis, and microphthalmos. Reported systemic associations include osteogenesis imperfecta, epidermolysis bullosa, and oculodentodigital syndrome.[39]

Management consists of cycloplegic refraction and correction of any refractive error and surveillance for glaucoma.

Fig. 33.15 A composite showing four different eyes from four different patients. All four were labeled as sclerocornea (when describing total corneal opacification). Anterior segment ultrasound showed that (A) had keratolenticular adhesion, as did (C), but (B) had primary aphakia, and (D) showed a very shallow anterior chamber but with normal lens. This demonstrates that the term "sclerocornea" for total corneal opacity is not useful.

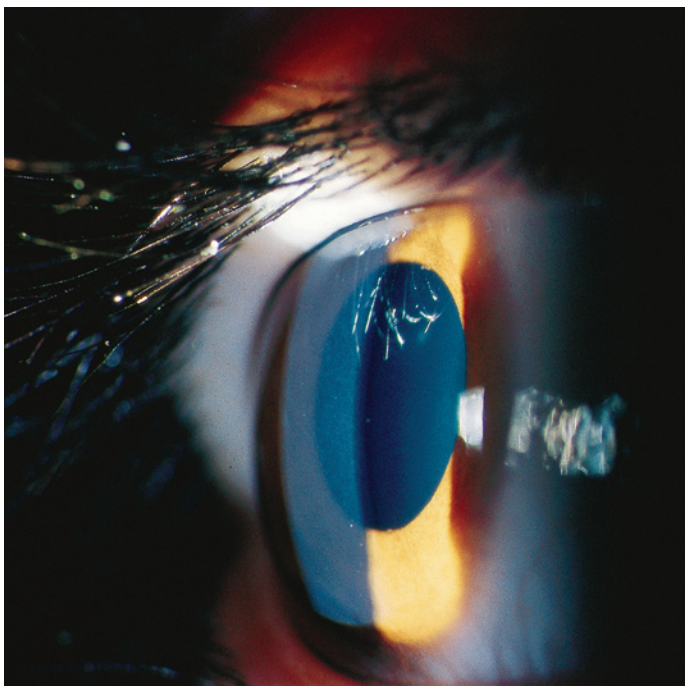

Fig. 33.16 Cornea plana. In profile, the flat nature of the cornea is clearly seen.

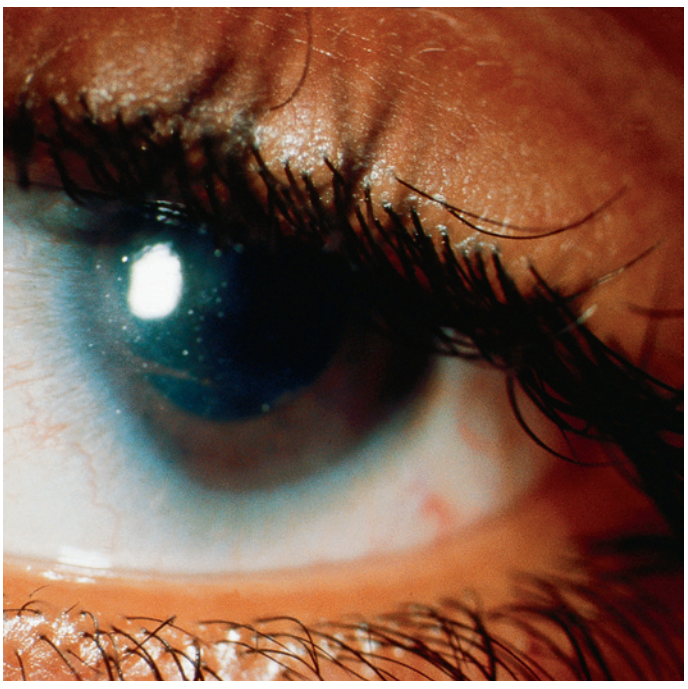

Fig. 33.17 Sclerocornea with cornea plana (S-CNA[20]). There is peripheral scleralization, most likely CNA2.

Fig. 33.18 A child with cornea plana (CNA2) in whom the hypermetropia is so high that his optic disc is visible without an ophthalmoscope.

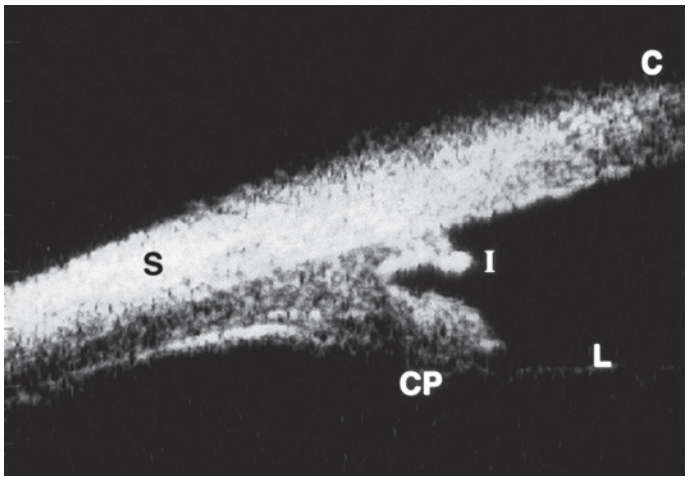

Fig. 33.19 Aniridia. A high-frequency ultrasound of an adolescent with aniridia. Note the iris stump (I), ciliary processes (CP), cornea (C), sclera (S), and lens (L).

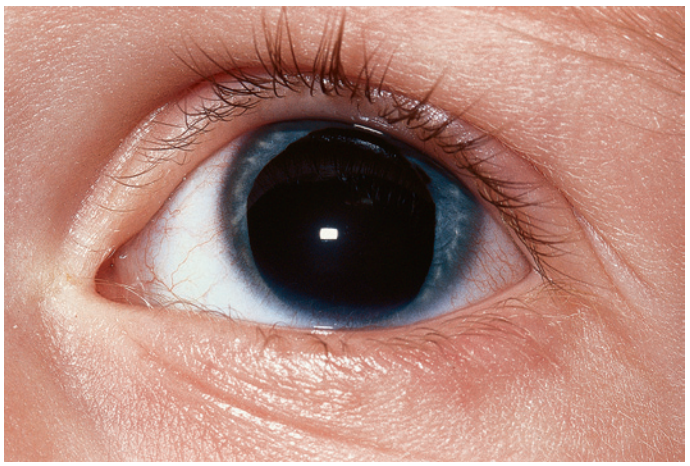

Fig. 33.20 Partial aniridia in a member of an autosomal dominant pedigree.

Complex contact lenses may be needed to give maximal visual rehabilitation (see Figs 33.17 and 33.18).

Autosomal dominant keratitis

This rare recurrent stromal keratitis and corneal vascularization has been shown to be due to mutations in *PAX6*, which are also known to cause aniridia.

The child usually presents with an irritated red eye and is photophobic. It may be associated with foveal hypoplasia. Being autosomal dominant, there is variable expressivity and penetrance within the same pedigree, with the mildest phenotype resulting in a 1 or 2 mm circumferential band of corneal opacification and vascularization contiguous with the limbus.[40,41]

Management is difficult and examination under anesthesia may be needed to clinch the diagnosis. Lubrication with artificial tears and ointments is essential. The role of limbal stem cell transplantation is unclear in this condition but early recurrence after penetrating keratoplasty has been noted. It is thought that this condition may be a variant of aniridia. If this is so, limbal stem cell transplantation might be a viable option.[41]

Aniridia

Aniridia has a prevalence of 1 in 50,000.[42] It is now well established that mutation or deletion of the *PAX6* gene and/or chromosomal rearrangements involving the *PAX6* gene on 11p13 underlies most cases of aniridia.[42]

Mutations in *PAX6* are responsible for human aniridia,[42] which is a panocular, bilateral disorder with absence of much (Figs 33.19–33.22) or most of the iris tissue, although iris hypoplasia may also be seen. Foveal and optic nerve hypoplasia are variably present (Fig. 33.23), resulting in a congenital nystagmus and leading to reduced visual acuity to 6/30 or worse.

Associated ocular features include anterior polar cataracts, often with attached persistent pupillary membrane strands, cortical cataract glaucoma, and corneal opacification, all of which often develop later in childhood. Glaucoma occurs in up to half of all cases; a recent study suggested that up to the age of 40 years, 15% of patients are diagnosed with glaucoma per age decade.[43]

Corneal opacification occurs secondary to limbal stem cell deficiency. Lens subluxation (Fig. 33.24) can also be associated with aniridia, often with glaucoma.[42,43] The typical presentation is a baby with nystagmus who has the appearance of absent irides or dilated unresponsive pupils. Photophobia may be present.

Aniridia can be sporadic or familial. The familial autosomal dominant form has complete penetrance but variable expressivity. Two-thirds of all aniridia children have affected parents. It is said that sporadic aniridia is associated with Wilms tumor in up to one-third of cases.[44]

The Wilms tumor gene *WT1* locus lies close to the *PAX6* gene locus on 11p13. A chromosomal deletion involving both loci results in the association of Wilms tumor with aniridia. In Denmark,[44] patients with sporadic aniridia have a relative risk of 67 (confidence interval: 8.1–241) of developing Wilms tumor. None of the patients with smaller chromosomal deletions or intragenic mutations were found to develop Wilms tumor. Familial aniridia patients are said not to be at risk for Wilms tumor; however, one case has been reported in a child with familial aniridia, but this probably represents a familial 11p13 deletion.[44]

When associated with aniridia, Wilms tumor is diagnosed before the age of 5 years in 80% of cases. The median age at diagnosis is 3 years.

Sporadic aniridia has also been associated with genitourinary abnormalities and mental retardation (AGR triad), a constellation that has been linked with a deletion of the short arm of chromosome 11 (11p-). Some, but not all, of these patients get Wilms tumor (WAGR association), a syndrome due to a contiguous gene deletion encompassing both *PAX6* and *WT1*. Individuals, particularly children under 6 years old, with *WT1* deletion may predispose to Wilms tumor, a kidney tumor with childhood onset. Defining the accurate breakpoints of the 11p13 deletion may contribute to the genetic counseling, disease prognosis, and prevention.[45]

Aniridia can also rarely be associated with ataxia and mental retardation (Gillespie syndrome). Multisystem syndromes and chromosomal abnormalities such as ring chromosome 6 can also include aniridia.[45]

Management includes genetic analysis to exclude chromosomal deletion. Until the result is known, all children with sporadic aniridia should have repeated abdominal ultrasonographic and clinical examinations. One protocol advised that the child be examined every 3 months until the age of 5 years, every 6 months until the age of 10 years, and once a year until the age of 16 years. However, the examinations are best continued until chromosomal and then intragenic mutational analyses have confirmed a *PAX6* mutation only. If a contiguous deletion involving *WT1* is found, then 3-monthly scans should be performed and the child transferred to the care of a nephrologist.

Management of the ocular condition consists of conservative measures such as correction of any refractive errors with filter lenses to reduce glare, and surveillance for onset of glaucoma. These patients often suffer from chronic angle closure glaucoma, which usually develops later and is difficult to treat. For this reason,[46] prophylactic goniotomy is sometimes advocated (Fig. 33.25). Cyclodiode laser, drainage tubes, and trabeculectomy with antimetabolite (usually mitomycin) have all been advocated for treatment of established glaucoma uncontrolled by topical medication alone. It is essential that the ocular microenvironment be assessed for dry eyes or meibomian gland dysfunction as this can accelerate the corneal opacification due to limbal stem cell abnormality. Usually corneal opacification occurs in adulthood but may occur in children. This may necessitate limbal stem cell transplant and corneal graft.[47]

Recent work has demonstrated a potential treatment to arrest or retard at least the corneal opacification. The majority (72%) of intragenic mutations in *PAX6* causing aniridia do so because they result in premature stop codons that result in a truncated protein and approximately 50% of all these mutations are in-frame nonsense mutations. Workers have shown that by adopting a nonsense mutation-suppression approach for in-frame premature stop codons, as long as the premature termination codon is not in a critical position for protein activity, then a functional protein could be produced

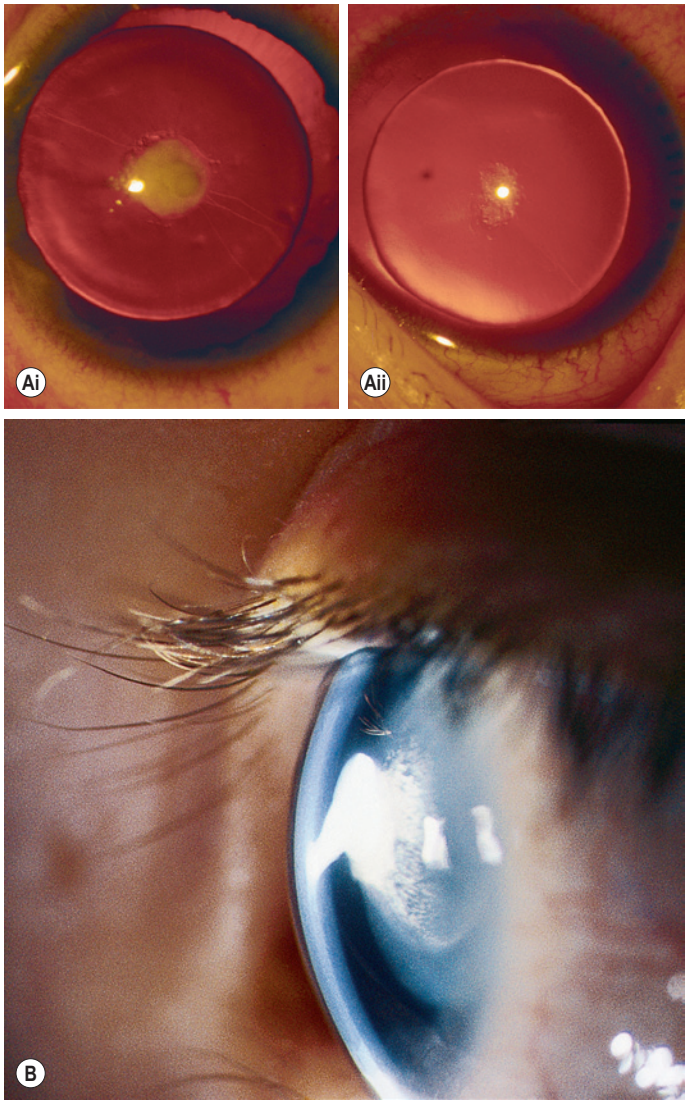

Fig. 33.21 Aniridia. (A) Aniridia with anterior polar cataract. (B) Aniridia with anterior extension of an anterior polar cataract with attachment to the cornea.

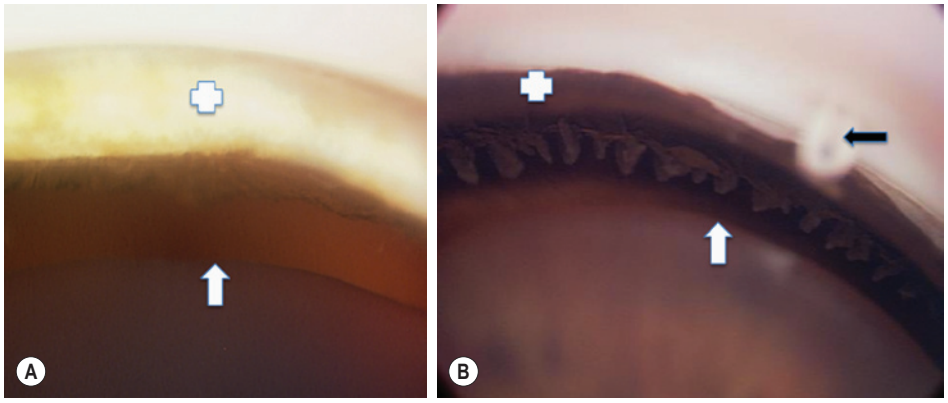

Fig. 33.22 Gonio views of the angle in two cases of aniridia. In (A) the cause is a mutation in *PAX6* but in (B) the cause is a mutation in *FOXC1*. This is a reminder that absence of the iris, while most commonly associated with mutations in *PAX6*, may also be seen in mutations in *FOXC1*. White arrows = lens edge; white crosses = iris remnant; black arrow = Ahmed tube in eye.

with the potential to provide therapeutic benefit. Recently, nonsense-suppressing small molecules with limited toxic effects have been described.[48]

Penetrating keratoplasty for anterior segment developmental anomalies

Infant penetrating keratoplasty has historically been thought to be a thankless endeavor with poor results.[49,50] However, 35% graft survival at 7 years post-graft has been reported in cases of Peters' anomaly,[51] and good visual results have been reported following early penetrating keratoplasty (PKP).[51,52] The definition of success, however, needs to be re-aligned for the infant, since we are dealing with a developing neurobiological system, in which lack of sensory input has a profound effect on global development. The role of amblyopia also plays an enormous part, such that a clear surviving graft in the presence of dense amblyopia cannot be considered an outright success.[53]

Crucial to penetrating keratoplasty in children is the acknowledgment that pediatric ocular tissue behaves differently from that of the adult. The age at which the child's eye becomes more like that of an adult is controversial, but experience suggests that a child over the age of 10 years will have ocular tissue that behaves almost like that of an adult.[54–56]

High-frequency ultrasound is a well-established tool for the examination of the anterior segment, especially in eyes with corneal opacity.[37] It is one of the most challenging conditions to treat surgically, but the use of high-frequency ultrasound evaluation helps determine a more appropriate entry into the anterior chamber.

All cases require a Flieringa ring because the sclera is much less rigid than that of an adult (Fig. 33.26). This is sutured using 8/0 nylon in four quadrants, and the suture is left long so as to stabilize the eye with the long suture ends using Steri-Strips.[52] A pediatric radial corneal marker is used to mark the cornea and allow centration, which aids placement of the trephine. A small paracentesis is made and the anterior chamber hyperinflated with viscoelastic, usually Healon GV.

Prior to trephination of the host, mannitol is infused according to the weight and age of the child to reduce the intraocular pressure and reduce the risk of expulsive hemorrhage. To this end, the child should be paralyzed and the end tidal pCO_2 should be below 30.

A manual trephine is used and, if keratolenticular adhesions or extensive iridocorneal adhesions are present, the anterior chamber is not entered with the trephine. Vacuum trephines such as the Barron-Hessburg are usually not manufactured to a small enough diameter.

The host button is fashioned after initial trephination with a 15° disposable blade so as to avoid excessive damage to the iris and/or lens. In cases of keratolenticular adhesion, the lens may be carefully peeled off the cornea but this usually results in cataract formation within a few weeks of the graft. Therefore, there is an argument for lens aspiration with sparing of the posterior capsule; this needs surgical capsulectomy through a pars plicata approach, usually within a few weeks also, but at least the donor cornea is a little more protected from trauma, since the capsulectomy occurs a little deeper in the eye away from the corneal endothelium. All cases of congenital corneal opacification have an iridectomy in four quadrants to try to reduce the incidence of glaucoma. The donor corneal button is oversized by 1 mm in all these cases, also to increase the anterior chamber depth. There is evidence that this improves outcome.[56] Grafts are sutured using at least 16 10/0 nylon interrupted sutures.[52,54]

All cases receive subconjunctival antibiotic and steroid injection at the end of the procedure. The author uses intracameral dexamethasone routinely, although some have advocated use of intracameral triamcinolone.

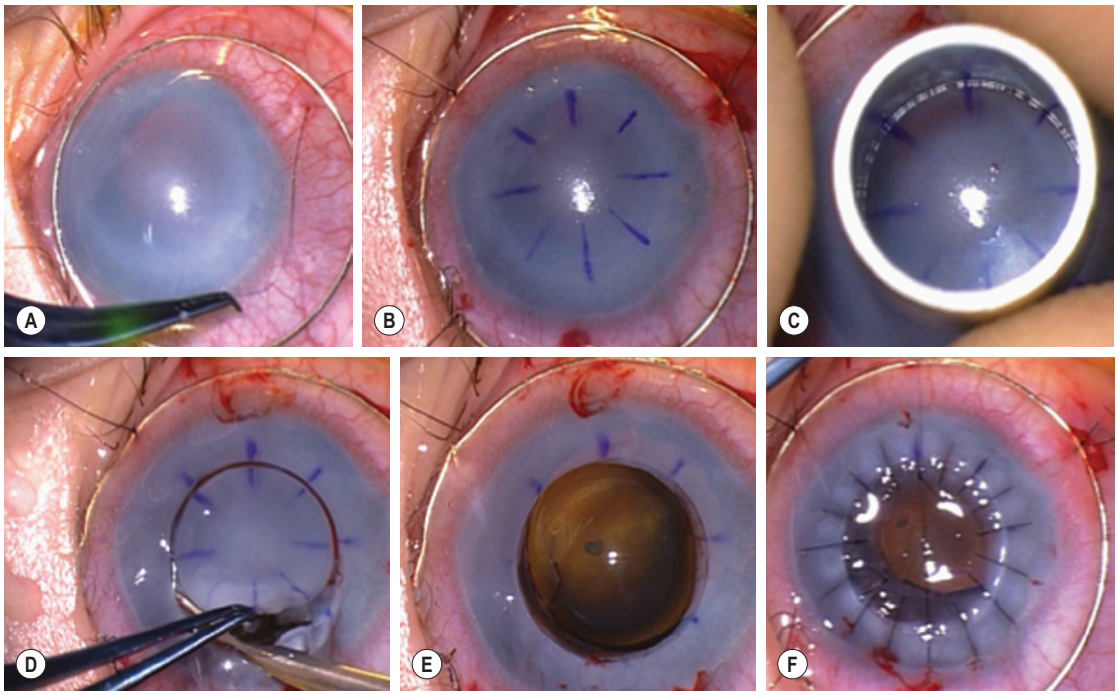

Fig. 33.26 Composite showing penetrating keratoplasty in an infant. The Flieringa ring is secured with four interrupted 8/0 nylon sutures and secured to brow and cheek with Steri-Strips (A,B). A manual trephine is used (C) for a partial-thickness trephine and the host button then excised with scissors so as not to damage the lens (D). The donor is then secured with 16 interrupted 10/0 nylon sutures (E,F).

Fig. 33.27 Infant keratoplasty. (A) There is mucous plug formation around loose sutures only 4 weeks post penetrating keratoplasty (PKP) for this case of complete sclerocornea. (B) The same case as in (A) 4 months later. There is peripheral opacification and scarring encroaching on the visual axis. (C) Two years post PKP for Peters' anomaly (not the same case as that shown in [A] and [B]).

The presence or absence of glaucoma must be assessed. If glaucoma is present preoperatively, this again is a poor prognosticator. In these circumstances, and if the corneal opacification is bilateral, laser cycloablation (usually cyclodiode laser) is used under ultrasound biomicroscopy guidance to treat the inferior half of the ciliary processes.[57] This allows control of the glaucoma with appropriate topical medication, and penetrating keratoplasty can then be performed with the expectation that a drainage tube will probably be needed to be placed at a later stage to control the glaucoma. Simultaneous PKP and drainage tube placement in infant eyes is not a route favored by this author.

The tissue reactivity in infants is such that intensive topical steroid/antibiotic preparations are a necessity to prevent fibrin formation, synechiae, and rejection. These are applied half-hourly for the first 24 hours, with cycloplegic drops three times daily and antibiotic/steroid ointment at night to allow the infant to sleep. The intensity of drops is tailed off over 2 months, and cycloplegia may continue for the same period. Infants are reviewed twice weekly for the first 6 weeks because the slightest hint of a loose suture or suture vascularization necessitates removal of the offending suture under anesthesia within 24 hours (Fig. 33.27). Failure to do so results in rapid epithelial rejection. In any case, all sutures are removed in infants at the latest by 6 weeks postoperatively.

There is no doubt that if it is understood that the aim of surgery is to give functional vision and not perfect vision and that a partially clear graft that allows delivery of functional vision is still a successful outcome, then infant PKP can be very rewarding for the patient and the surgeon[50,53] (see Figs 33.27 and 33.28).

Alternatives to PKP

There are occasions where penetrating keratoplasty may not be appropriate and the social circumstances (multiple children,

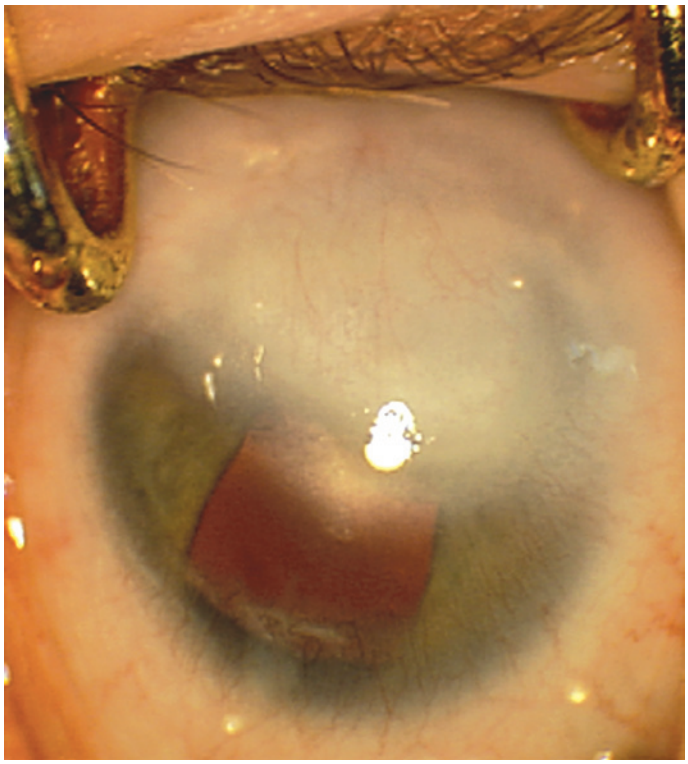

Fig. 33.28 A child with Peters' anomaly due to iridocorneal adhesion causing an eccentric corneal opacity in his only functioning eye. A broad iridectomy has been done to visually rehabilitate the child.

economic considerations, distance to travel for intense follow up) make PKP ill advised. Under these circumstances, if the opacity is eccentric, a broad iridectomy may work very well indeed and should be considered[58] (Fig. 33.28). Autorotational keratoplasty has also been described[59] but in this author's opinion is not an advisable option in developmental corneal opacities due to the crowded or shallow anterior chambers usually present. Also, reports recently have described the use of deep stromal and endothelial keratoplasty (DSEK) in Peter' anomaly; although the long-term visual outcomes are questionable, the rate of rejection appears lower than for PKP (see chapter 35).[60]

One other option is to consider if the coincidental presence of cataract in Peters' anomaly due to keratolenticular adhesion is causing a significant part of the visual deprivation. In such cases, removal of the cataract with judicious iridectomy may allow adequate visual rehabilitation.[61]

CORNEAL DEGENERATION
REFERENCES

Abnormalities of the cornea may be classed as an abnormality of shape or opacity. The etiology determines the management of any associated visual loss or amblyopia (Fig. 34.1).

Abnormal corneal shape

Keratoconus

Keratoconus is bilateral progressive thinning and ectasia of the cornea.[1] This results in visual loss from keratometric myopia and irregular astigmatism (Fig. 34.2). Rare variants are pellucid marginal degeneration, in which there is an arc of thinning close to the inferior limbus, and keratoglobus in which there is diffuse thinning of the whole cornea. The incidence of keratoconus in North European adults has been estimated to be 1 : 1105,[2] although the disease is significantly more common in South Asian and black populations. Early onset and South Asian ethnicity are associated with rapid progression. There is a strong genetic contribution to the disease with modification by environmental factors such as eye rubbing or allergic conjunctivitis. At present, the etiology is unknown. Although several genetic loci have been mapped for the disease, no causative genes have been identified.[3] Only a small proportion of individuals with keratoconus are syndromic, and although a large number of associations have been reported it is likely the majority result from chance. The main conditions associated with keratoconus are chronic allergic eye disease, Down syndrome, and Leber congenital amaurosis – all of which may act through a tendency for severe eye rubbing. Keratoconus may also be a feature of some connective tissue disorders, e.g. Ehlers–Danlos syndrome and brittle cornea syndrome, although it is rarely a presenting sign for these conditions. The onset of keratoconus is rare before the age of 10 years.

Early diagnosis of keratoconus is important as corneal collagen cross-linking can arrest its progression. Diagnosis depends on the documentation of increasing astigmatism, a scissors reflex at refraction, and characteristic changes on computerized corneal tomography. Serial computerized imaging is now the standard of care to monitor for progression.

Complications of keratoconus are uncommon and include corneal hydrops, from an acute split in the Descemet's layer, leading to corneal scar but rarely infection or perforation. In children, an acute corneal hydrops may be the presenting sign of keratoconus. It is associated with sudden onset of discomfort and blur with a dense central corneal opacity with tissue swelling due to entry of aqueous into the corneal stroma (Fig. 34.3). The natural history of a corneal hydrops is for gradual resolution over 3–4 months, but there is often a residual corneal scar that can flatten the corneal contour but reduce vision due to opacity. Secondary corneal neovascularization can occur if there is a large hydrops adjacent to the limbus, or if there is severe allergic eye disease, in which case topical corticosteroid should be considered until the hydrops resolves. Topical antibiotic is indicated if there is an epithelial defect, but other treatments such as hypertonic 5% saline are ineffective. Intracameral injection of a long-acting gas, e.g. perfluoropropane, has been proposed to speed up the resolution of a hydrops, but it is not always effective and the visual outcome is unchanged. Gas injection also carries a significant risk of iris ischemia and cataract from pupil block.

The management of keratoconus aims to restore functional vision. In early disease this may be achieved with glasses, but as the disease progresses glasses will not correct the irregular component of the astigmatism and contact lenses may then be required. Rigid gas-permeable contact lenses give a better level of vision than soft or soft toric contact lenses, with less risk of secondary complications (infection, corneal neovascularization). Keratoplasty for keratoconus is only indicated if there is advanced bilateral disease when a contact lens cannot be retained, or if there is poor vision (<6/12) even with contact lens correction. It is uncommon for the disease to progress to this stage in childhood. In the absence of a prior corneal hydrops, a deep anterior lamellar keratoplasty (DALK) is the treatment of choice rather than a penetrating keratoplasty because there is a lower risk of allograft rejection and less risk of wound dehiscence following injury. If there is

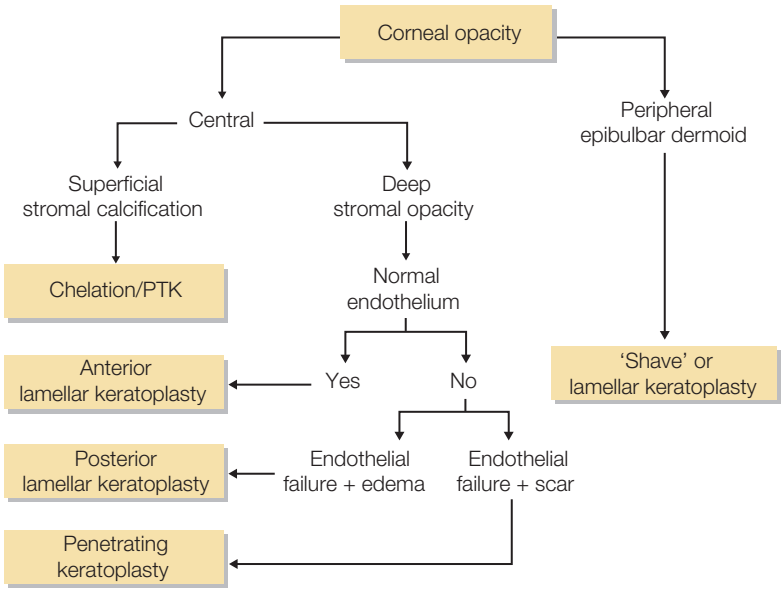

Fig. 34.1 Simplified algorithm for the surgical management of corneal opacity.

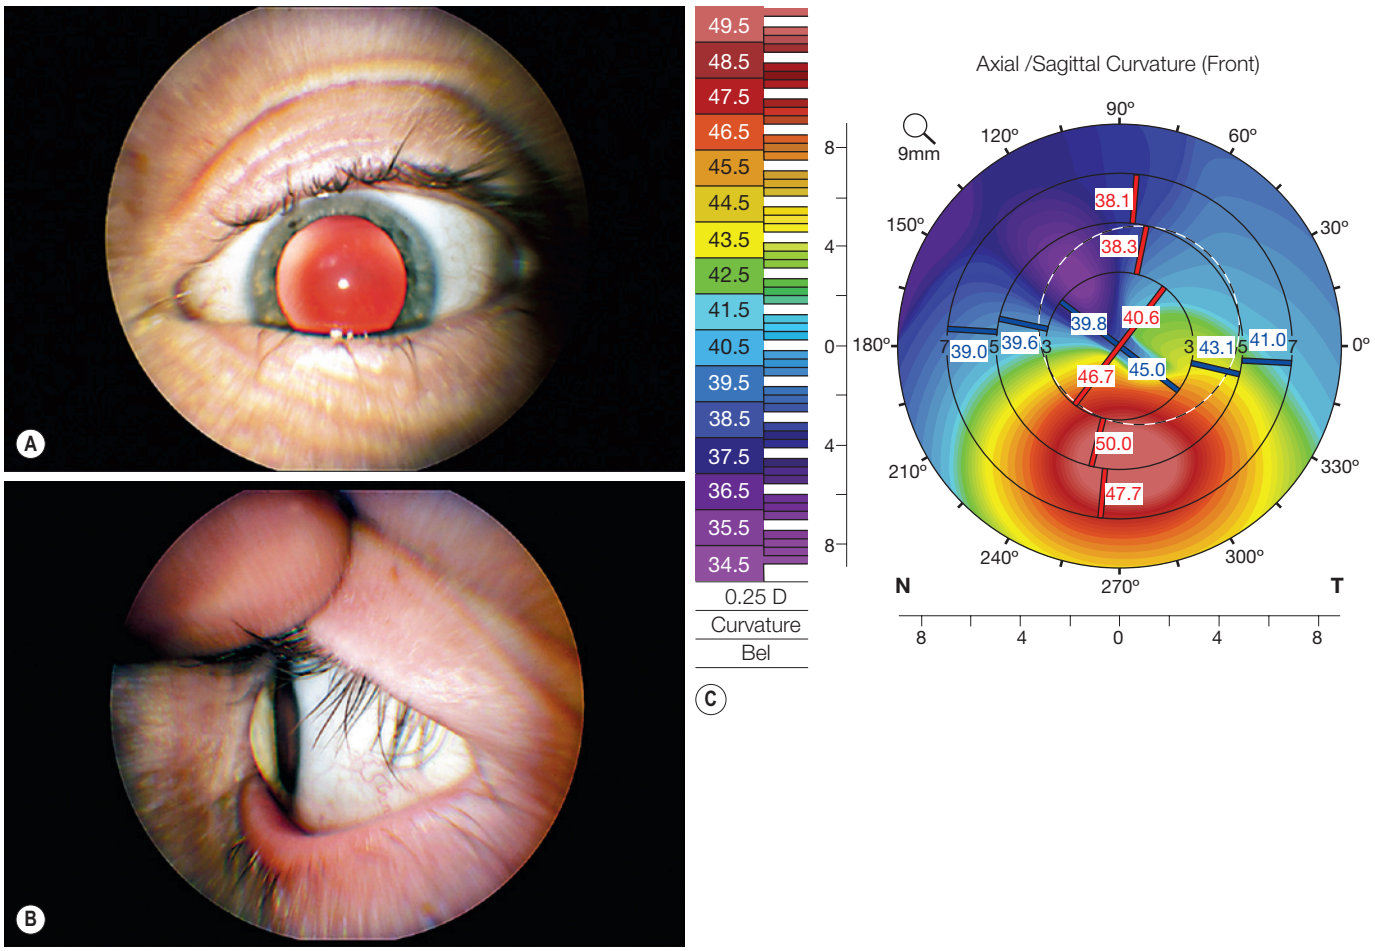

Fig. 34.2 Keratoconus. (A) The retinoscopy reflex in keratoconus has no clear end point and may have a scissors pattern. (B) Lateral view showing the conical cornea. (C) Computed tomography showing ectasia of the inferior cornea.

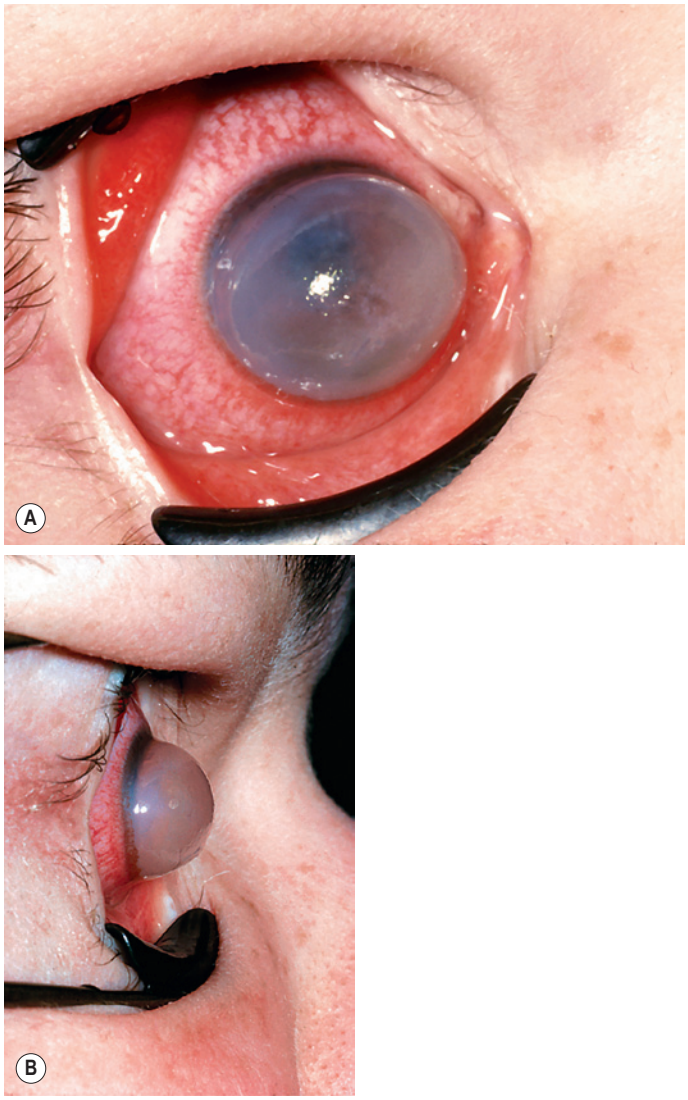

Fig. 34.3 Keratoconus. (A) Acute hydrops in a child with Down syndrome and keratoconus. (B) Side view showing extreme ectasia due to corneal swelling. The swelling will resolve over months but with a risk of secondary vascularization.

poor compliance, e.g. in Down syndrome, an epikeratoplasty should be considered as an alternative.

Corneal collagen cross-linking (CXL) is the only intervention that has been demonstrated to arrest the progression of keratoconus.[4] The ability to do this at a stage when there is still useful spectacle-corrected vision is a major benefit and early referral of suspected cases is therefore imperative. The preferred technique is to remove the corneal epithelium to allow penetration of topical riboflavin into the corneal stroma, followed by irradiation with ultraviolet B (UVB). This can normally be performed in children with topical anesthetic, although mild sedation may be required. Controlled clinical trials of CXL have, as yet, only been performed in adults, and the safety and efficacy of CXL in children has not been demonstrated.[5] The clinical criteria for treatment are under review (Table 34.1), but it is usual practice to confirm that the keratoconus has progressed before treatment is performed. Treatment failure has been documented in 10% of cases and it is not known whether repeat CXL treatment is safe. Potential complications include microbial infection and corneal scar.

Table 34.1 Minimum criteria to confirm progression of keratoconus

Parameter	Change
Refractive astigmatism increase	>1 D
CDVA loss	>1 line lost
Kmax increase if Kmax <55 D	>1.0 D
Minimum corneal thickness loss	>16 μm

Demonstrated progression is a reason for collagen cross-linking to stabilize the cornea.
CDVA, Corrected distance visual acuity; Kmax, maximum keratometry.

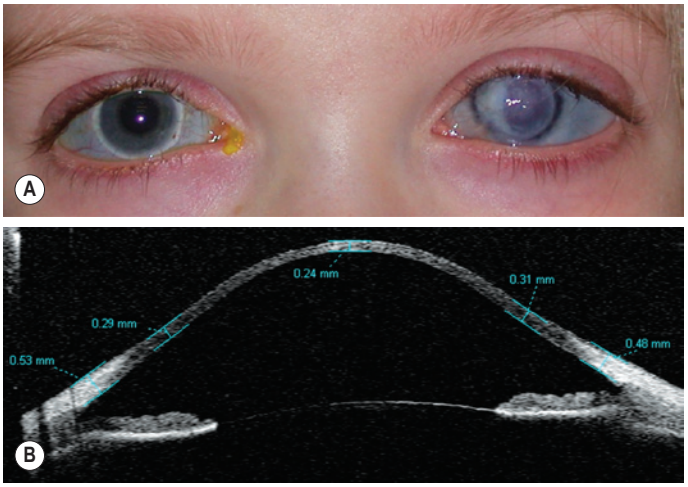

Fig. 34.4 Brittle cornea syndrome. (A) There is blue sclera. The right eye has had an onlay lamellar keratoplasty. The left eye is blind following corneal rupture. (B) Ocular coherence tomography of the anterior segment showing generalized thinning of the cornea and sclera. Central corneal thickness was 240 microns and thickness at the limbus was 310 microns.

Brittle cornea syndrome

Brittle cornea syndrome (BCS) is a rare autosomal recessive condition characterized by blue sclera and extreme thinning of the cornea, with a risk of corneal rupture after minor trauma (Fig. 34.4). BCS1 is caused by mutations in *ZNF469* and BCS2 is caused by mutations in *PRDM5*, although the corneal phenotype is similar.[6] It is a generalized connective tissue disorder with associated joint hypermobility and hyperelasticity of the skin. Affected individuals should wear protective acrylic glasses at all times to reduce the risk of accidental traumatic eye rupture. Scleral lenses may be an alternative in older patients. Extreme secondary central corneal ectasia (keratoconus) can occur, and in these individuals the option of a limbal-sparing onlay graft to reinforce the cornea should be considered.

Blue sclera

Blue-tinged sclera is a rare sign that is usually the result of scleral translucency or thin sclera with choroidal show-through. It may be present in normal children, particularly if there is high myopia. Blue sclera is associated with a wide range of skin and musculoskeletal abnormalities, but it is most frequently seen

in association with pseudoxanthoma elasticum, osteogenesis imperfecta, Ehlers–Danlos syndrome, Marfan syndrome, alkaptonuria, or hypophosphatasia syndrome. Early referral to a pediatrician for systemic review is essential. The multiple fractures of osteogenesis imperfecta may occasionally prompt erroneous referral for suspected non-accidental injury; the finding of a blue sclera in this context is an important diagnostic marker.

Abnormal corneal diameter

Increased diameter

Buphthalmos

This is enlargement of the cornea associated with a raised intraocular pressure from congenital glaucoma. Although the corneal diameter is enlarged (>13.0 mm) and the cornea thin, the anterior chamber depth may be relatively normal (in contrast to the deep anterior chamber that is a feature of X-linked megalocornea). Chronically raised intraocular pressure, splits in Descemet's layer (Haab striae), or subsequent cataract or glaucoma surgery can lead to endothelial decompensation and irreversible corneal edema (Fig. 34.5). If the edema does not clear after the intraocular pressure has been controlled, a keratoplasty should be considered. A posterior lamellar endothelial keratoplasty (DSAEK) will give more rapid visual recovery than a penetrating keratoplasty, with less risk of globe rupture following accidental injury.[7] However, a penetrating keratoplasty may be required if there is significant stromal scar. Interrupted sutures should be used if the peripheral host cornea is markedly thinned. Cataract surgery may also be required with an iridoplasty if the pupil is markedly eccentric.

Forceps injury can cause unilateral corneal edema from birth, although the cornea is not enlarged. The edema will usually resolve leaving characteristic oblique splits in Descemet's layer (Fig. 34.6), with oblique astigmatism. There is a high risk of amblyopia.

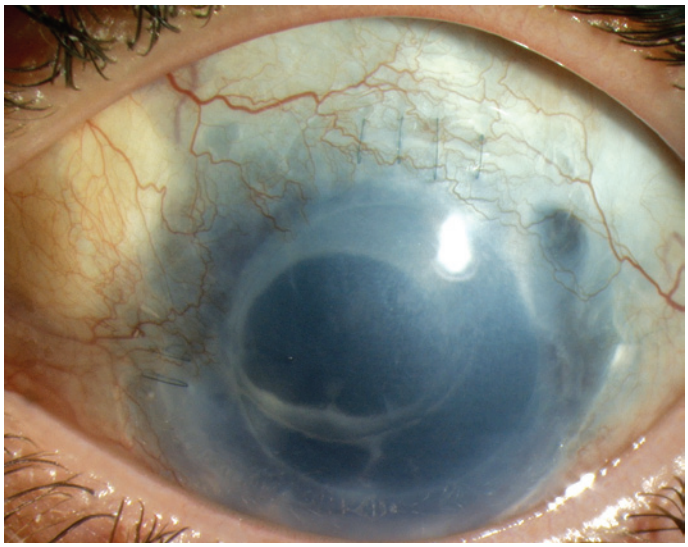

Fig. 34.5 Buphthalmos. The corneal diameter is enlarged and the eye is pseudophakic. There is a scleral patch over a drainage tube superiorly. A posterior lamellar keratoplasty has been performed to treat secondary corneal decompensation.

X-linked megalocornea (MGC1)

X-linked megalocornea is a disorder in which both corneas are symmetrically and markedly enlarged from birth. Features include clear corneas with bilateral horizontal diameters of 14–16 mm, a deep anterior chamber (4–6 mm), generalized reduced corneal thickness (470–500 µm) but with normal intraocular pressures (Fig. 34.7). Secondary changes in older individuals include shagreen corneal degeneration, corneal arcus juvenilis, lens dislocation, and mild iris atrophy with pigment dispersion. The genetic cause is a mutation in the *CHRDL1* gene, which encodes ventroptin, a secreted bone morphogenetic protein (BMP) antagonist. It is proposed that an absence of ventroptin during development permits unrestricted growth of the anterior segment.[8]

MGC1 is almost always a benign condition. The corneal thinning does not progress and it is not associated with juvenile glaucoma. It is therefore important to distinguish MGC1 from primary congenital glaucoma (PCG) during infancy. The limbal architecture is normal in MGC1 with a crisp cornea–sclera transition as opposed to the broadened

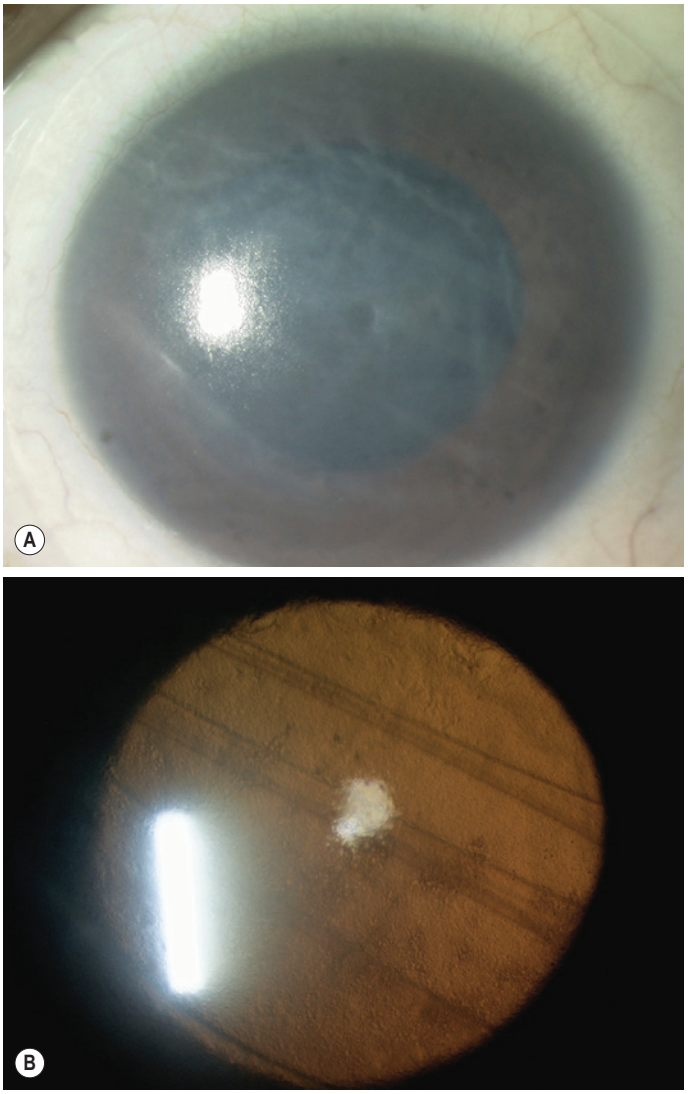

Fig. 34.6 Descemet breaks following presumed forceps injury. (A) There is diffuse unilateral corneal edema with normal intraocular pressure. (B) Oblique breaks in Descemet's layer can be seen on retroillumination.

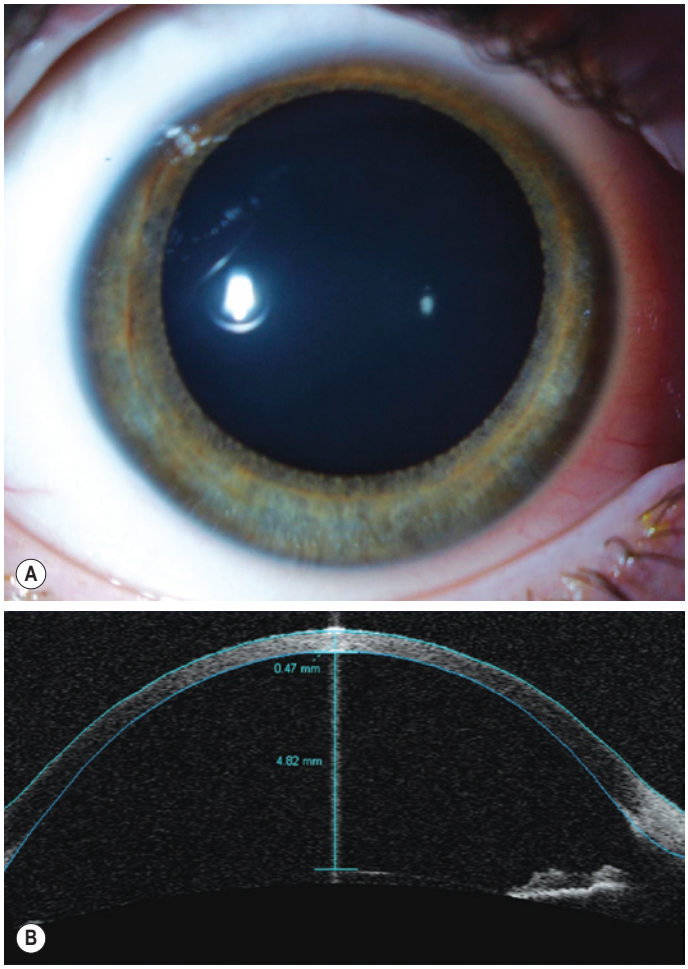

Fig. 34.7 X-linked megalocornea. (A) The cornea is clear with a diameter of 16 mm (pupil has been dilated). (B) Ocular coherence tomography showing reduced corneal thickness and deep anterior chamber.

"smeary" limbus of buphthalmic glaucomatous eyes. Infants with suspected MGC1 should have genetic screening for changes in the *CHRDL1* gene to exclude PCG. In the absence of genetic testing the deep anterior chamber in MGC1 and the low ratio of anterior chamber depth to axial length is a reliable indicator.[9]

Megalocornea is also a feature of megalocornea–mental retardation (MMR; Neuhäuser syndrome). The condition is rare and associated with neurological symptoms including mental retardation, hypotonia, and seizures. Syndromic facial features include a prominent forehead, broad nasal root, epicanthus, large low-set ears, long upper lip, and anteverted nostrils. The genetic cause of MMR syndrome is currently unknown.[9]

Microcornea

Microcornea is a corneal horizontal diameter of ≤9 mm. It may be uni- or bilateral and may be an isolated finding or associated with dysmorphism, microphthalmos or nanophthalmos. It may be associated with posterior polar cataract (microcornea–cataract syndrome with mutations of crystallin genes) (Fig. 34.8), coloboma, sclerocornea, Peter's anomaly, or oculocerebrofacial syndrome.[10] B scan ultrasonography is essential for a full assessment.[11] The cornea can be clear with a normal thickness, but is more usually flat with low keratometry values and a resultant hyperopia, with a risk of secondary glaucoma. When microcornea is an isolated finding, there is a good visual prognosis with correction of refractive error, but other ocular or systemic associations often reduce the vision.

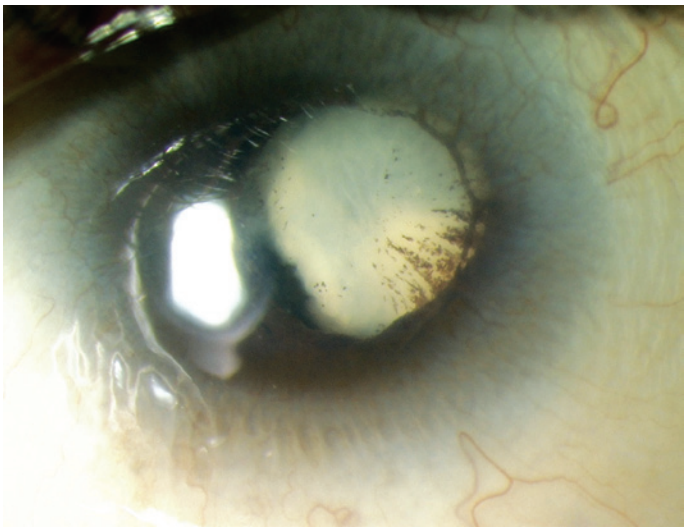

Fig. 34.8 Microcornea and cataract. The corneal diameter was reduced (10 mm) with a flat keratometry (32 diopters). There is a dense cataract and iris abnormality.

Corneal opacity

Congenital corneal opacity is most commonly a feature of (1) genetically determined abnormalities of the anterior segment (dysgenesis) in which there are associated abnormalities of the iris, anterior chamber angle and lens (e.g. Peter's anomaly, congenital glaucoma; see Chapter 33); (2) corneal dystrophy, in which the cornea is usually affected in isolation (e.g. CHED2, sclerocornea/cornea plana; see (Chapter 35); (3) metabolic disease in which abnormal products are deposited in the cornea (e.g. mucopolysaccharidosis; see Chapter 65); (4) choristoma (e.g. dermoid); or (5) external injury from trauma, inflammation or infection (see Chapters 16, 30 and 69). An algorithm for the initial interpretation of congenital corneal opacity is presented in Figure 34.9.

Corneal opacity in older children includes the following conditions.

Superficial keratopathy

This may be a focal, linear, or vortex pattern. The common causes for focal superficial lesions include punctate epitheliopathy from dry eye disease, Thygeson superficial keratopathy (Fig. 34.10), staphylococcal hypersensitivity spots, and adenoviral keratoconjunctivitis. Linear epithelial lesions include dendritic ulceration (herpes simplex) or mucous plaque keratopathy (herpes zoster). A very rare linear kerotopathy associated with tyrosinemia type II is also described as pseudodendritic. Tyrosinemia type II (Fig. 34.11) is due to mutation of the *TAT* gene encoding tyrosine aminotransferase. There is bilateral keratitis with intense photophobia and associated palmar and plantar lesions (palmoplantar keratoderma) and

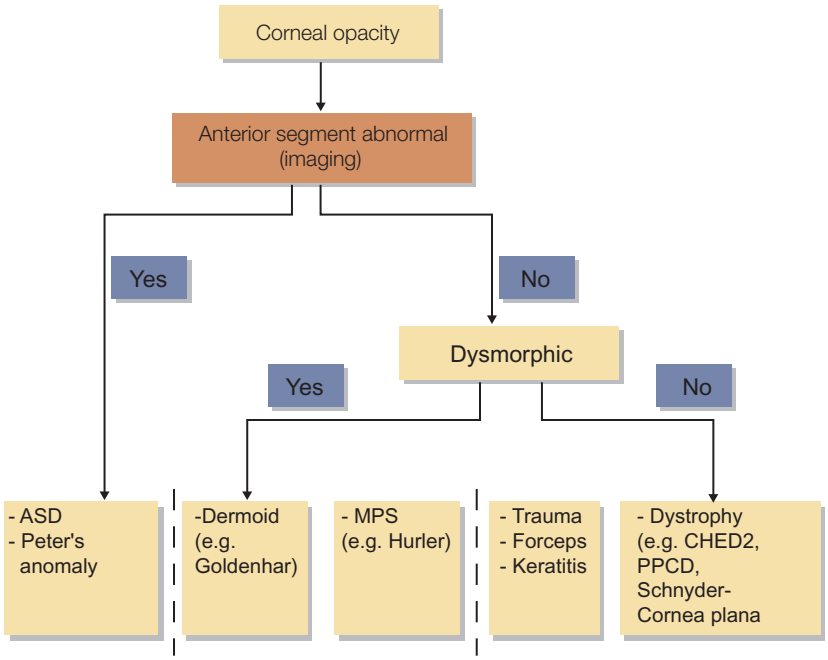

Fig. 34.9 Algorithm for the interpretation of congenital corneal opacity. ASD, Anterior segment dysgenesis, MPS, mucopolysaccharidosis; CHED, congenital hereditary endothelial dystrophy; PPCD, posterior polymorphous dystrophy.

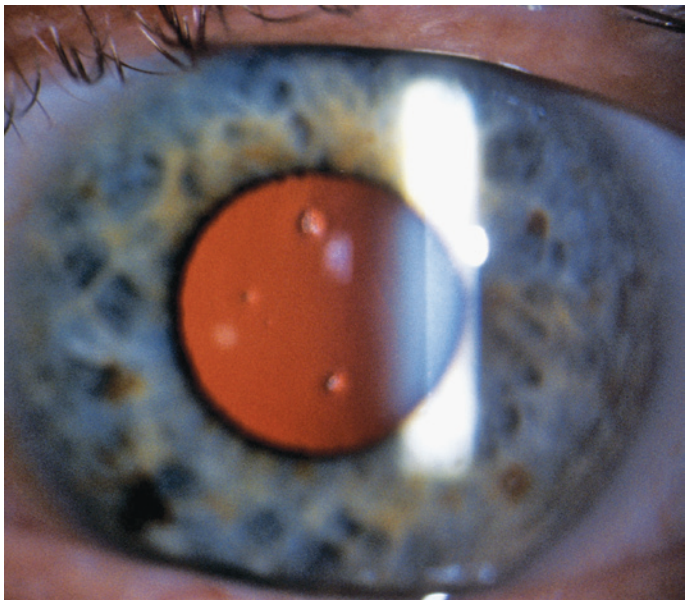

Fig. 34.10 Thygeson superficial keratopathy. Focal lesions are seen in retroillumination. There is no associated inflammation.

Fig. 34.11 Tyrosinemia type II. (A) Skin lesions on pressure points of the sole. (B) Skin lesions on the pressure points of the palms.

developmental delay in 50% of individuals.[12] It is treatable with a low-tyrosine and low-phenylalanine diet.

Vortex keratopathy occurs during epithelial healing, but may also develop following chronic drug ingestion (e.g. amiodarone) (Fig. 34.12), and it is also a feature of Fabry disease, an X-linked recessive lipidosis caused by α-galactosidase-A deficiency, with deposition of glycosphingolipid in the cytoplasm of the epithelial cells. There may also be conjunctival and retinal vascular tortuosity and spoke-shaped cataract.[13]

Thygeson superficial punctate keratitis

This can occur even in children as young as 2 years. There may be photophobia, discomfort, and blurred vision. Coarse elevated epithelial lesions (1 to 50) with minimal stromal

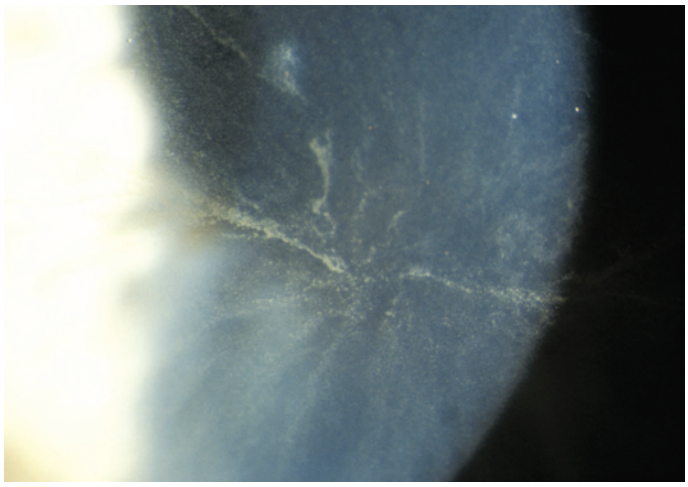

Fig. 34.12 Vortex keratopathy due to chronic drug ingestion (amiodarone).

reaction and an absence of peripheral corneal vascularization or upper tarsal conjunctival inflammation are characteristic (see Fig. 34.10). The cause is a presumed immune response against an, as yet, unidentified pathogen (possibly viral). Initial treatment is with topical lubricants. Low-dose topical steroid (e.g. fluoromethalone 0.1% once daily or less) is effective but may prolong the course of the disease. Topical cyclosporin drops or ointment are also effective.[14] Daily-wear therapeutic contact lenses may be an option for chronic irritation in older children. The lesions recur after epithelial debridement or laser phototherapeutic keratectomy (PTK). Despite a potentially protracted course, the visual prognosis is excellent.

Corneal deposits and crystals

Corneal deposits occur in several conditions; some indicate localized disease, but some have important systemic associations. Corneal deposits are of different types: (1) lipid (e.g. Schnyder crystalline corneal dystrophy), Tangier disease (lecithin–cholesterol acyltransferase deficiency [LCAT]); (2) protein (cystinosis, monoclonal gammopathy); (3) mucopolysaccharide, including Hurler, Scheie, and Hurler–Scheie syndromes (MPS I), Morquio syndrome (MPS IV), and Maroteaux–Lamy syndrome (MPS VI) (Fig. 34.13); (4) bacteria and bacterial biofilm (infectious crystalline keratopathy); (5) mineral deposits (band-shaped degeneration of calcium, calcareous degeneration, hyperuricemia, iron, copper, silver, lead, gold); (6) drug (topical ciprofloxacin, chlorpromazine, chloroquine). In the majority of cases a history of drug therapy, or associated systemic or ocular pathology, will help guide the diagnosis. Biopsy is only rarely indicated for diagnosis.

Cystinosis

Cystinosis is a rare lysosomal storage disease caused by accumulation of the amino acid cystine in lysosomes. There is intracellular crystal formation in tissues including the kidneys, bone marrow, pancreas, muscles, brain, and eye. It is autosomal recessive and caused by mutation of the *CTNS* gene that encodes cystinosin, which is the membrane transport protein for cystine. Cystinosis is classified as nephropathic cystinosis that is further classified as (a) infantile or juvenile onset, accompanied by Fanconi syndrome, or (b) isolated (adult) ocular cystinosis with corneal crystal deposition (Fig. 34.14) but without

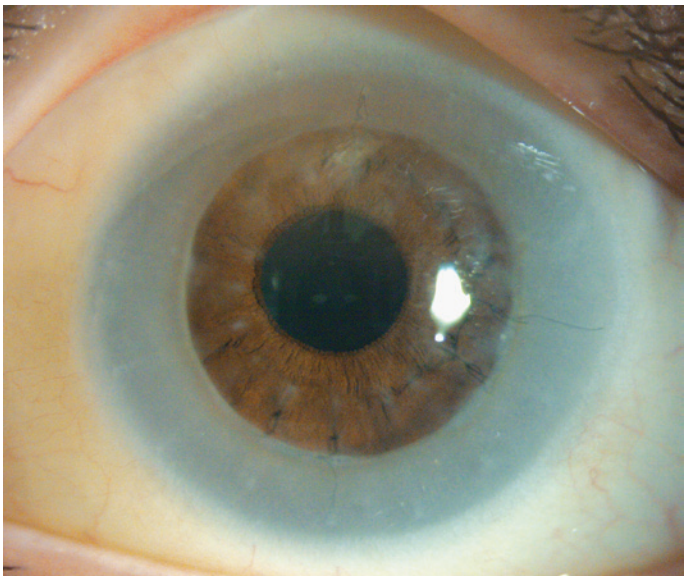

Fig. 34.13 Mucopolysaccharidosis. Lamellar corneal graft 4 years after surgery for a patient with Hurler–Sheie syndrome. The peripheral cornea is hazy but the cornea over the visual axis is clear.

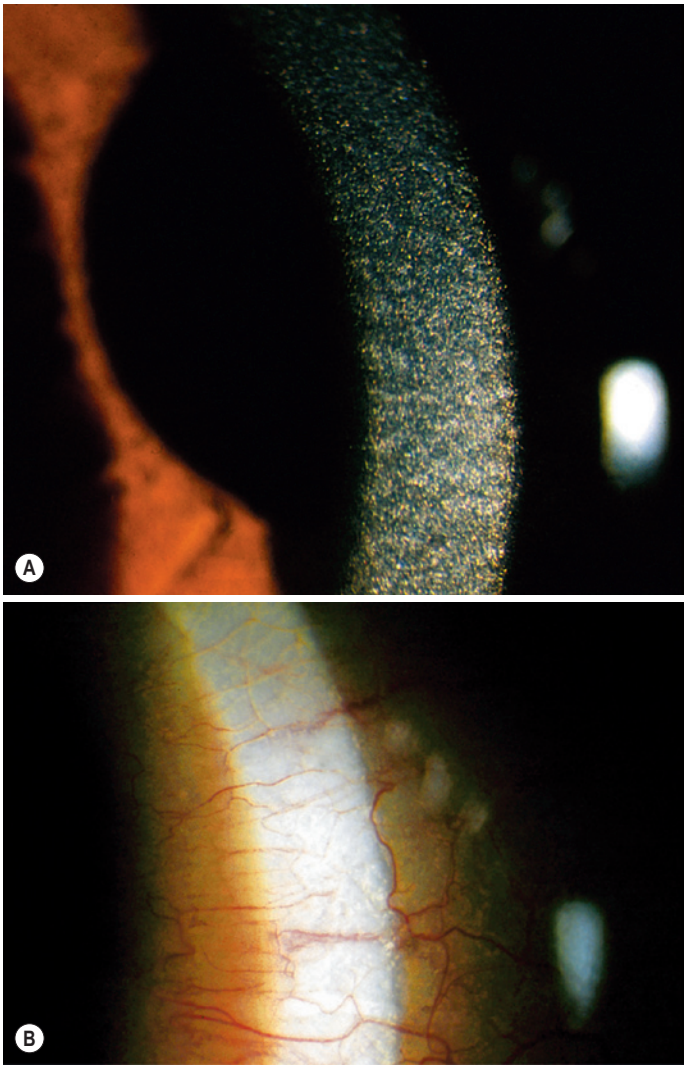

Fig. 34.14 Cystinosis. (A) Corneal crystals can be seen by slit-lamp microscopy. These children are often very photophobic. (B) Crystal deposition occurs in many tissues throughout the body, including the conjunctiva.

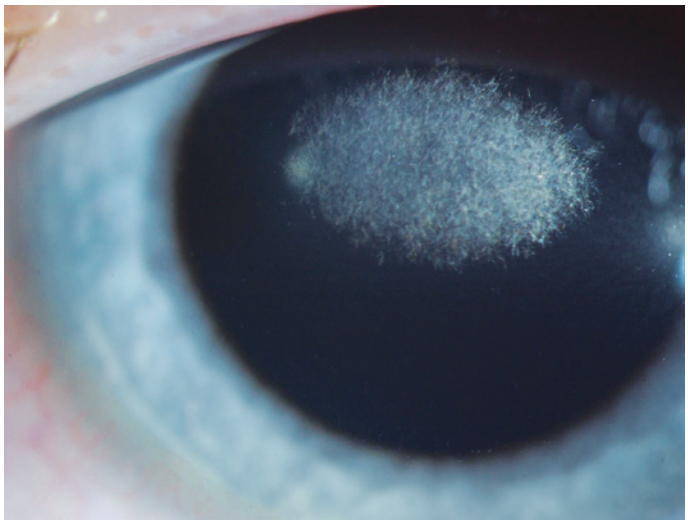

Fig. 34.15 Schnyder corneal dystrophy. Deep stromal crystals present at 8 years of age and acuity of 6/24. The family history was not available.

systemic disease. If there is renal disease, tubular damage leads to loss of carbohydrates and amino acids in the urine with polyuria. Infantile nephropathic cystinosis is the most common and severe form. Systemic manifestations include growth retardation and renal failure between 6 and 12 months of age, with later onset in the juvenile form. There may be end-stage renal disease by 10 years of age. Retinal depigmentation also appears by 3–7 years of age, progressing to legal blindness in 15% of cases. Abnormalities of the anterior chamber angle from crystal deposition in the trabecular meshwork can lead to secondary glaucoma. In the adult form, corneal crystals are present but without significant renal disease.[15]

Patients in all subtypes may be severely photophobic, although the visual acuity may be preserved in reduced light. The corneal appearance is of myriads of needle-shaped, highly refractile crystals, initially concentrated in the anterior periphery, but with spread to involve all layers of the cornea including the endothelium. They are easily identified at the slit-lamp. Secondary corneal changes include superficial punctate keratopathy, recurrent corneal epithelial erosion, filamentary keratitis, and band-shaped keratopathy.

Systemic cysteamine is the treatment of choice for nephropathic disease. This breaks down cystine into smaller products that can traverse the lysosome membrane. Early treatment can protect tubular function and minimize any retinopathy. Oral treatment does not reduce corneal crystal accumulation, probably due to inadequate tissue concentration, but topical cysteamine is a safe and effective alternative. The recommended dose is 0.44% cysteamine hydrochloride solution used 10–12 times per day.[16,17]

Other causes of corneal crystalline deposits include Schnyder corneal dystrophy (Fig. 34.15),[18] which is an uncommon autosomal dominant corneal dystrophy caused by mutation of the *UBIAD1* gene.[19] It presents in young children from 3 to 4 years of age with axial stromal crystalline deposits of lipid (cholesterol), as opposed to the diffuse stromal haze seen in adults. Corneal arcus and superficial stromal crystals are also more characteristic of the disease in adults. Lamellar keratoplasty may be indicated if there is glare and reduced vision. The stromal crystals are normally too deep to be removed by laser phototherapeutic keratectomy.

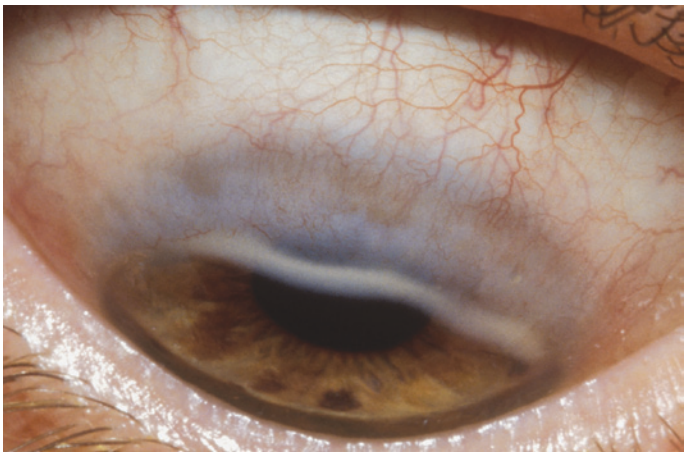

Fig. 34.16 Corneal arcus (pseudogerontoxon). There is lipid deposition central to an area of recurrent inflammation from limbal vernal keratoconjunctivitis.

The corneal crystals of Bietti retinopathy are tiny, peripheral, and do not affect vision.

Lipid deposition

The deposition of lipid in the cornea is normally preceded by corneal neovascularization (e.g. following recurrent stromal herpes simplex virus [HSV] keratitis or vernal keratoconjunctivitis), but may also develop in an arc (pseudogerontoxon) central to an area of recurrent conjunctival or episcleral inflammation at the limbus (e.g. limbal vernal keratoconjunctivitis) (Fig. 34.16). It may also develop as a complication of congenital vascularization (e.g. perilimbal dermoid or aniridic keratopathy). Treatment is only required if the lipid is progressive and approaches the visual axis.

Corneal arcus

Corneal arcus is the deposition of phospholipids, low-density lipoproteins, and triglycerides in the stroma and of the peripheral cornea in the absence of an epithelial defect (Fig. 34.17). When this appears in children, familial hypercholesterolemia (Fredrickson type II) and hyperlipoproteinemia (type III) should be excluded.[20]

Diffuse lipid infiltration and opacity can occur in other diseases of lipid metabolism such as lecithin–cholesterol acyltransferase deficiency (LCAT) deficiency, fish eye disease and Tangier disease.[18]

Corneal vascularization

Acquired corneal neovascularization is most frequently seen as a result of ocular surface diseases. The primary stimulus in tissue is thought to be hypoxia. It can affect vision by opacity, secondary lipid deposition, or irregular astigmatism. The first step in management is to remove the precipitating stimulus (e.g. contact lens wear) and control any ocular surface inflammation (e.g. chronic allergic eye disease, herpes simplex infection). This can be supplemented by the careful use of topical steroid. If secondary lipid deposition threatens to cross the visual axis, the feeder arteriole can be ablated by fine-needle diathermy.[21] To guide treatment, the feeder arteriole can be visualized by indocyanine green angiography.[22] Although it

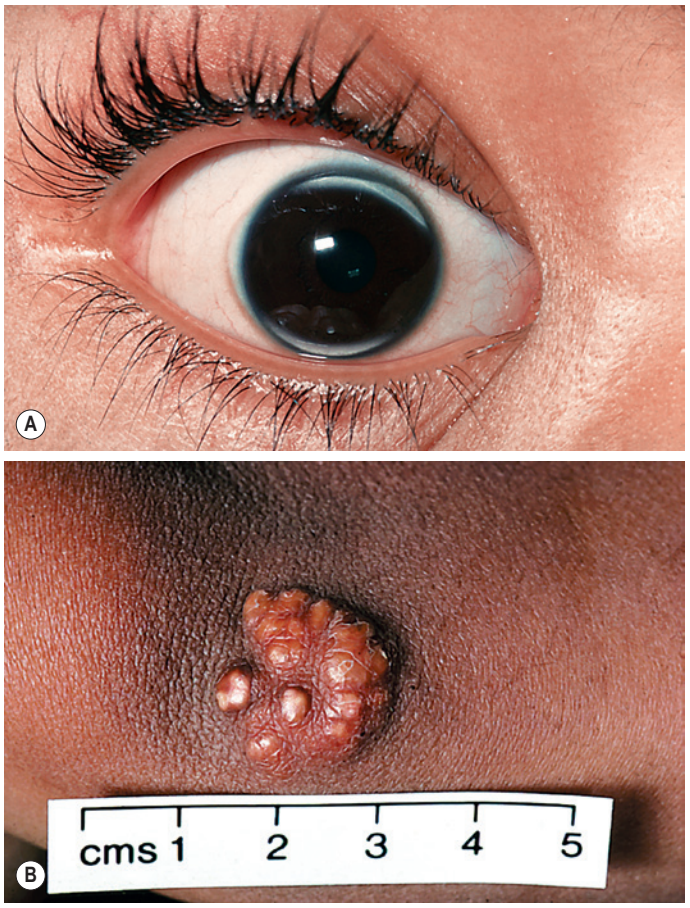

Fig. 34.17 Corneal arcus. (A) Corneal arcus in a patient with hyperlipidemia. (B) Skin xanthoma in hypercholesterolemia.

is used in adults, the safety of local anti-vascular endothelial growth factor (VEGF) treatment (e.g. bevacizumab) in children has not been confirmed.[23,24] Even after the feeder vessels have regressed, the lipid may takes months or years to regress, and only partial regression is usual. Established vascularization (>6 months duration) will not respond to anti-VEGF therapy and lamellar keratoplasty may be indicated.

Epibulbar dermoid

A dermoid is a choristoma, which is a collection of normal tissues in an abnormal location. They are a combination of ectodermal (keratinized epithelium, hair, sebaceous glands) and mesodermal elements (fibrous tissue, fat, and blood vessels) (Figs 34.18–34.20). Most are sporadic and unilateral (Chapter 29), but they may be multiple and associated with oculoauriculovertebral dysplasia (Goldenhar–Gorlin syndrome) or the sebaceous nevus syndrome (Fig. 34.21). Epibulbar (limbal) dermoids are usually situated at the inferotemporal corneoscleral junction but they may be much more widespread and overlie a microphthalmic or staphylomatous eye. They can involve the entire thickness of the cornea and sclera and may affect vision by occlusion of the visual axis, induced astigmatism or secondary lipid keratopathy, any of which can result in amblyopia.[25] A central corneal choristoma may occur sporadically but may also be a feature of trisomy 8 mosaic (see Fig. 34.20).

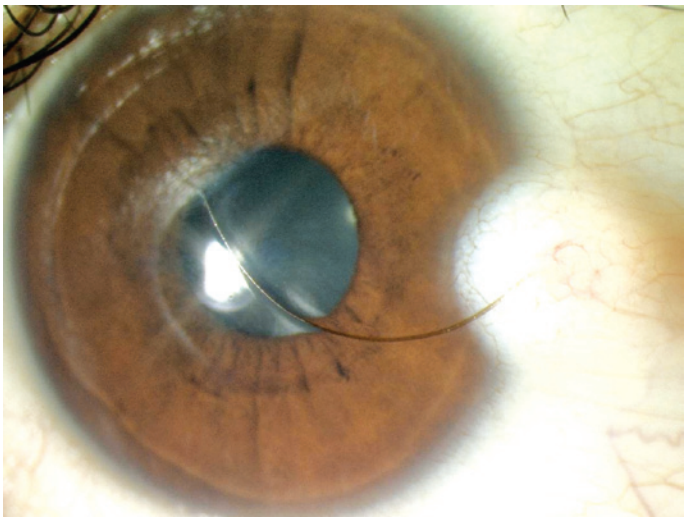

Fig. 34.18 Epibulbar dermoid. An aberrant lash is abrading the cornea.

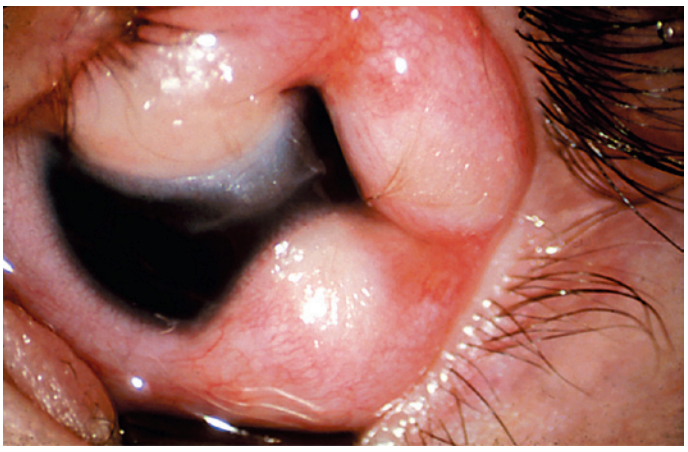

Fig. 34.19 Multiple epibulbar dermoids in a patient with Goldenhar syndrome.

The primary indications for treatment are for cosmesis, to remove irritating keratin or abrading lashes, for dellen formation from drying, or to prevent progressive lipid keratopathy. Because the lesion is often full thickness, excision may not improve vision or reduce astigmatism. High-resolution biomicroscopy can help determine the extent of the mass. Elevated dermoids can simply be resected to a plane level with the surrounding tissue. Alternatively, a deeper lamellar keratectomy can be performed with placement of a donor corneal lamellar graft (Fig. 34.22). Lamellar excision should be performed with care as there may be no plane for deep dissection through the abnormal tissue, and perforation is possible. The cosmetic result following lamellar keratoplasty may not be substantially better than "shaving" if there is deep opacity. Topical mitomicin applied to the base of the excision during surgery may reduce the risk of secondary conjunctival overgrowth onto the cornea (pseudopterygium).[26] If there are multiple dermoids over a microphthalmic eye, enucleation may be considered, delaying treatment if possible to allow for orbital growth.

Corneal vascularization can also be a component of presumed limbal epithelial stem cell failure, related to inherited

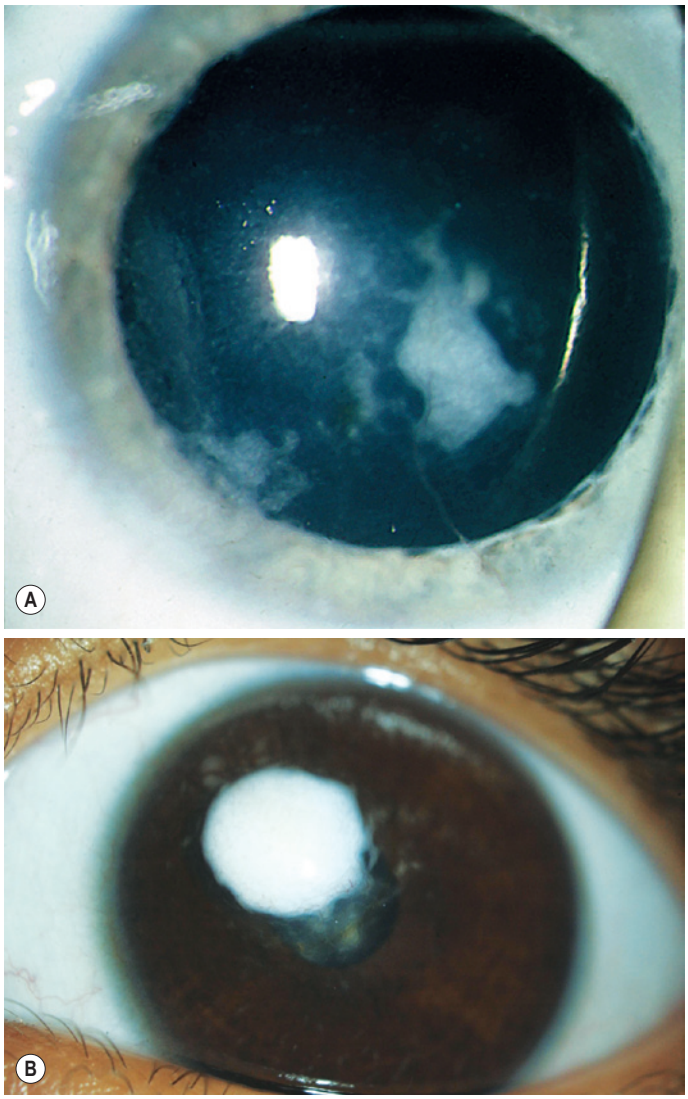

Fig. 34.20 Central corneal dermoid (choristoma). (A) Trisomy 8 mosaic syndrome with characteristic geographic corneal opacity. (B) Sporadic case without other association.

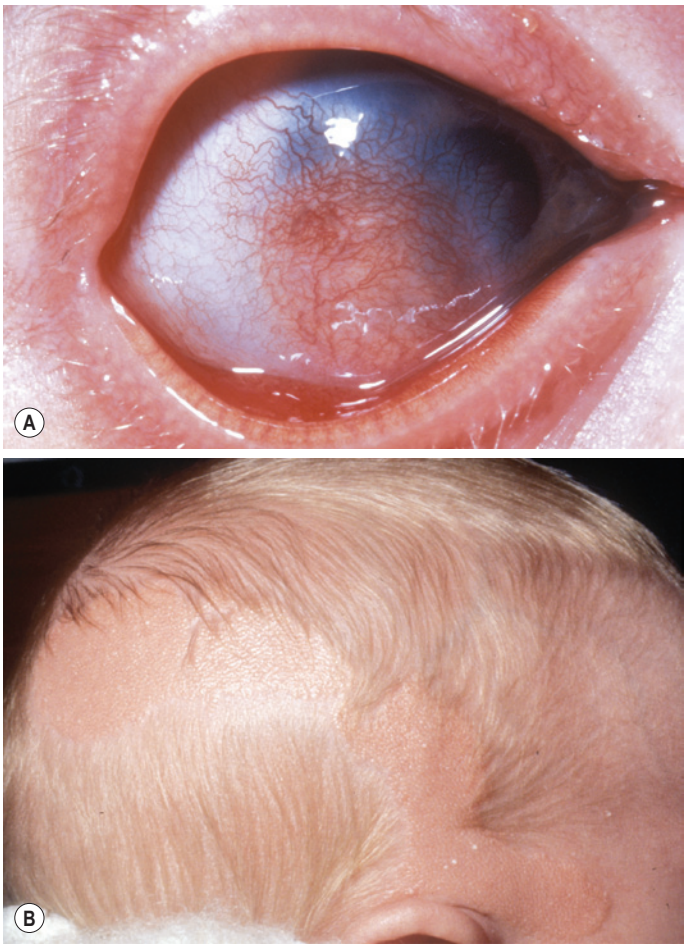

Fig. 34.21 Sebaceous nevus syndrome. (A) Associated with a flat limbal dermoid. (B) Characteristic scalp lesion of patient with sebaceous nevus syndrome.

conditions such as anirida and ectodermal dysplasia, or injury following chemical or thermal burns.

Aniridic keratopathy

Aniridia is an anterior segment developmental disorder (see Chapter 33). In sporadic cases, the WAGR (Wilms tumor, aniridia, genitourinary abnormality, retardation) syndrome should be excluded. WAGR is the result of deletion of a contiguous region of genes on chromosome 11, including the *PAX6* gene. One component of aniridia is peripheral superficial corneal vascularization and subepithelial scarring that is thought to be the result of limbal epithelial stem cell failure (Fig. 34.23). The changes typically progress very slowly but can eventually involve the entire corneal surface. The more severe changes in familial cases are linked to loss of function and *C*-terminal mutations of *PAX6*.[27] Children with poor vision and an unexplained corneal vascularization with scar in the absence of inflammation should be screened for *PAX6* mutations as part of any genetic work-up. Topical corticosteroid or fine-needle diathermy does not prevent progression of the keratopathy and is not indicated. If cataract surgery is required, the axial subepithelial scar can be peeled off to improve visualization during surgery. Unfortunately, there is a strong tendency for recurrence of aniridic keratopathy after simple excision. It is unknown if the topical application of mitomycin during surgery reduces the risk of recurrence. A tinted rigid contact lens should be considered for older children if there is irregular astigmatism.

Ectodermal dysplasia

The ectodermal dysplasias are a large heterogenous group of disorders in which there are abnormalities of the ectoderm, involving the skin and its appendages. Many are X-linked or autosomal recessively inherited with abnormal or absent eccrine glands, wispy or absent hair, and abnormal teeth or nails. One of the most frequently encountered for ophthalmic review is the ectrodactyly, ectodermal dysplasia, cleft (EEC) syndrome in which there are obvious cleft palate and hand and foot deformities associated with mutations in the *TP63* gene.

Ocular abnormalities include anterior blepharitis, conjunctivitis, superficial corneal vascularization with scarring, and symblepharon, entropion, and trichiasis (Fig. 34.24). Meibomian and lacrimal abnormalities may lead to secondary ocular surface disease resulting in keratopathy, infection, and

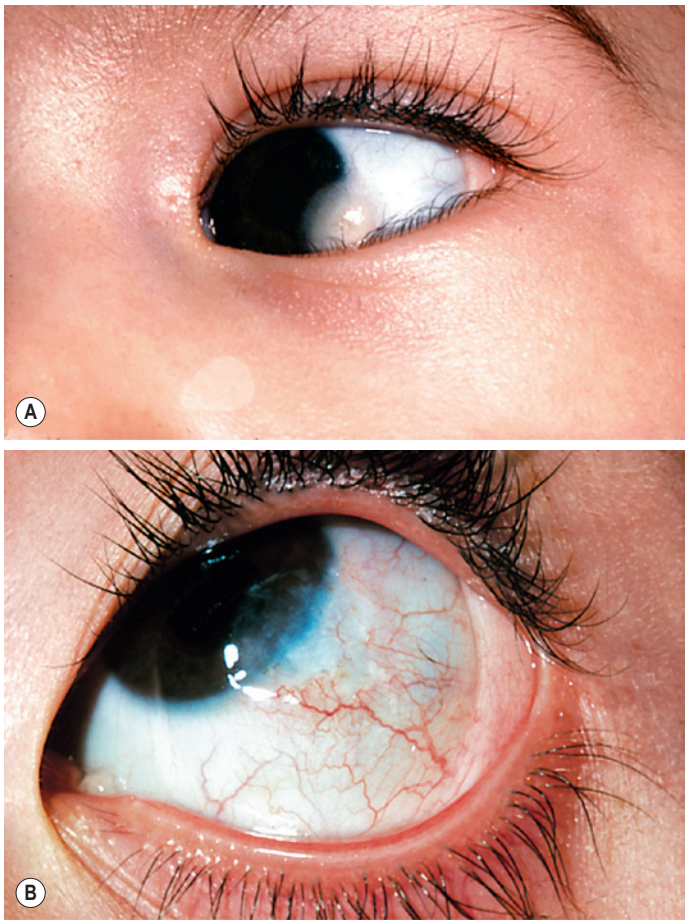

Fig. 34.22 Limbal dermoid. (A) The indication for surgery was the cosmetic appearance. (B) Same case as in (A) after lamellar keratectomy. Although there is still some residual corneal opacity the lesion is now flat and cosmetically improved.

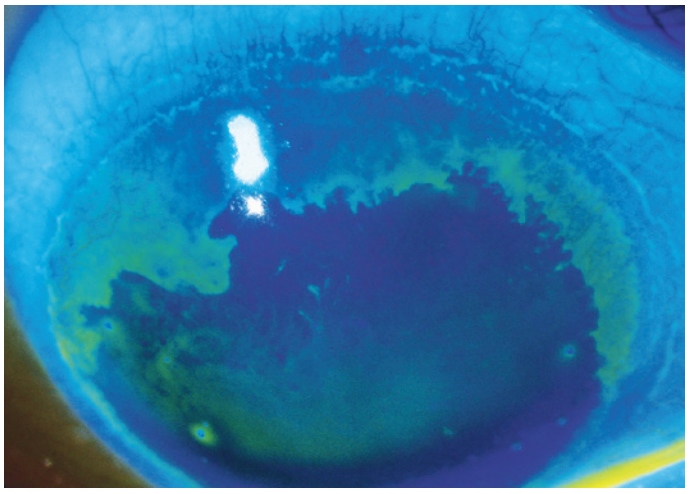

Fig. 34.23 Aniridic keratopathy. There is late stain with fluorescein in the peripheral cornea. This is thought to represent encroachment on a conjunctival cell phenotype. This can progress to vascularization and scar involving the visual axis.

scarring. Management is generally supportive with topical lubricants. Primary or secondary limbal stem cell deficiency is thought to be the mechanism for corneal vascularization and a limbal allograft has been suggested as a strategy to improve the ocular surface.

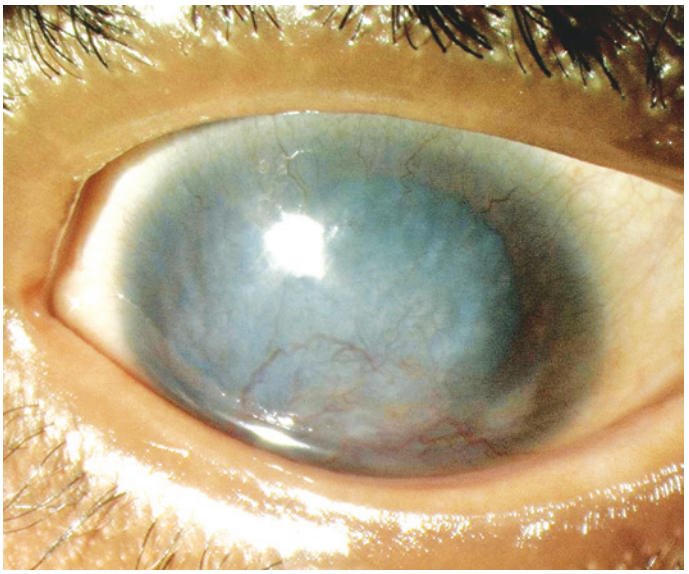

Fig. 34.24 Ectodermal dysplasia. Severe ocular surface failure in a patient with EEC (ectrodactyly, ectodermal dysplasia, cleft) syndrome. Many cases are not as severe as this. Note that the meibomian gland orifices are absent.

Prominent corneal nerves

Corneal nerves and nodules are normally visible passing radially from the periphery toward the center of the cornea. They may be more prominent in children in certain conditions, but their presence is rarely of diagnostic or prognostic value except if there is a perineural infiltrate (*Acanthamoeba* infection). Prominent nerves may be present in:

1. keratoconus
2. Riley–Day dysautonomia
3. leprosy
4. Refsum disease
5. ichthyosis
6. multiple endocrine neoplasia (MEN) type IIa and IIb

Neurotrophic keratitis

Corneal sensation is provided by the fifth cranial nerve. The origin of neurotrophic keratitis is the result of loss of the trophic stimuli (e.g. nerve growth factors) delivered to the cornea by retrograde axonal flow. This can be exacerbated by corneal exposure, mechanical trauma, and drying.[28] Any severe keratitis can lead to a reduced corneal sensation, and a recurrent keratitis with a relative lack of symptoms is suggestive of anesthesia.

Neurotrophic keratitis can be chronic, recurrent, and severe. It is rarely congenital in familial dysautonomia (Riley–Day syndrome) (Fig. 34.25), but is more commonly acquired following trauma, herpes zoster or simplex infection, and brain stem lesions or tumors, particularly of the cerebello-pontine angle or pons. The presence of scars on the forehead may suggest trigeminal anesthesia or previous shingles. Corneal anesthesia can be profound and care should be taken during an assessment to avoid causing an abrasion. Patients with

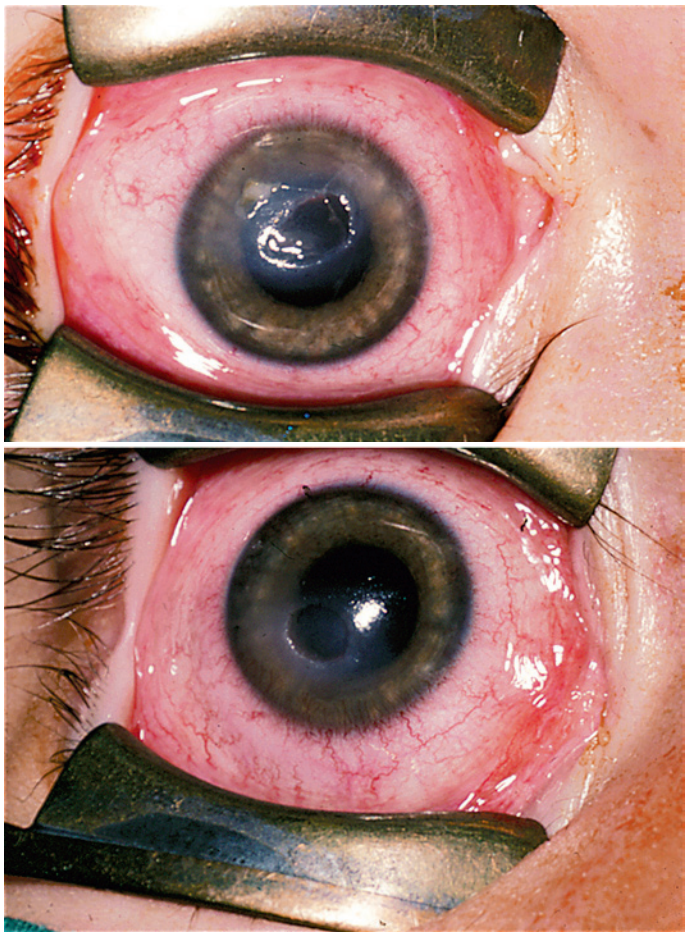

Fig. 34.25 Riley–Day syndrome. This child had a combination of anesthetic corneas and dry eyes that had been treated for several months by topical wetting agents without success. He responded well to a bilateral tarsorrhaphy and lubricant ointment. Later, punctal occlusion allowed enough wetting of his eyes to allow the tarsorrhaphies to be undone.

acquired loss of corneal sensation in the absence of prior keratopathy should be referred for neurological evaluation.

Treatment in infancy

A high level of parental involvement is essential. In mild cases, the frequent use of topical (non-preserved) lubricant drops can help prevent epithelial breakdown. An acute epithelial defect should be treated with antibiotic drops or ointment or temporary taping of the eye. If there is recurrent epithelial breakdown or a persistent epithelial defect, the eye should be closed. Taping is a useful temporary measure, but a tarsorrhaphy is more effective. An outer-third tarsorrhaphy can be partially opened at a later date. A period of arm-splinting may be necessary to prevent eye rubbing in infants.

Treatment in childhood

In older children a therapeutic soft contact lens should be considered. A scleral contact lens will maintain a reservoir of tears on front of the cornea, even if there is incomplete lid closure. Serum tears drops (autologous or pooled) are an option if there is a persistent epithelial defect. Synthetic nerve growth factor is a promising option, although it is not yet widely available.

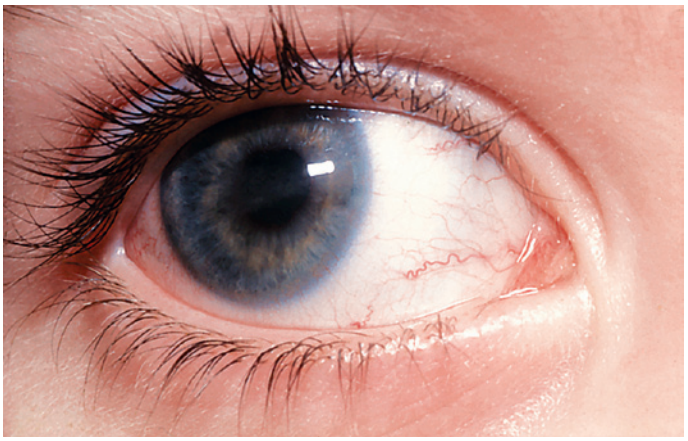

Fig. 34.26 Band keratopathy. A patient with juvenile idiopathic arthritis (see Chapter 40).

Corneal degeneration

Band-shaped corneal degeneration

Superficial band keratopathy occurs in children with juvenile idiopathic arthritis (see Chapter 40), chronic corneal edema (congenital glaucoma), or following vitrectomy, particularly if silicone oil is left *in situ*. The band (Fig. 34.26) is a precipitate of calcium hydroxyapatite in Bowman's layer and the superficial corneal stroma.[29] It typically develops in the interpalpebral zone, often with a clear zone between the deposit and the limbus, and there may be clear areas in the band surrounding perforating nerves. Less commonly, conditions causing systemic hypercalcemia or hyperphosphatemia can cause band keratopathy, e.g. chronic renal failure, sarcoidosis, or hyperparathyroidism. Deep corneal calcification (calchosis) is more common in phthisis bulbi, chemical trauma, Stevens–Johnson syndrome, and graft-versus-host disease. It can also occur following the use of drops with a high concentration of phosphate buffer.

In cooperative older children, a superficial smooth band keratopathy can be removed by excimer laser PTK using topical anesthesia. This removes 30–50 µm of stromal tissue. Unfortunately, because of the location of most lasers, this is rarely an option if general anesthesia is required. An alternative is chelation of the superficial band following debridement of the epithelium and direct application of 3.8% EDTA on a soaked cotton-tipped applicator. EDTA is an irritant, so avoid the conjunctiva. It can take several minutes for the band to disperse. A dense irregular band keratopathy that is eroding the epithelium is more easily removed by a limited superficial keratectomy using a crescent blade. There is a strong tendency for the band to recur, but the treatment can be repeated as required. There is no topical treatment that will reduce the tendency for recurrence.

Dermatological associations

The most common skin changes associated with corneal opacity are acne vulgaris and rosacea, atopic dermatitis (see Chapter 16), Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN), and graft-versus-host disease (see Chapter 16). Other recognized associations are given below.

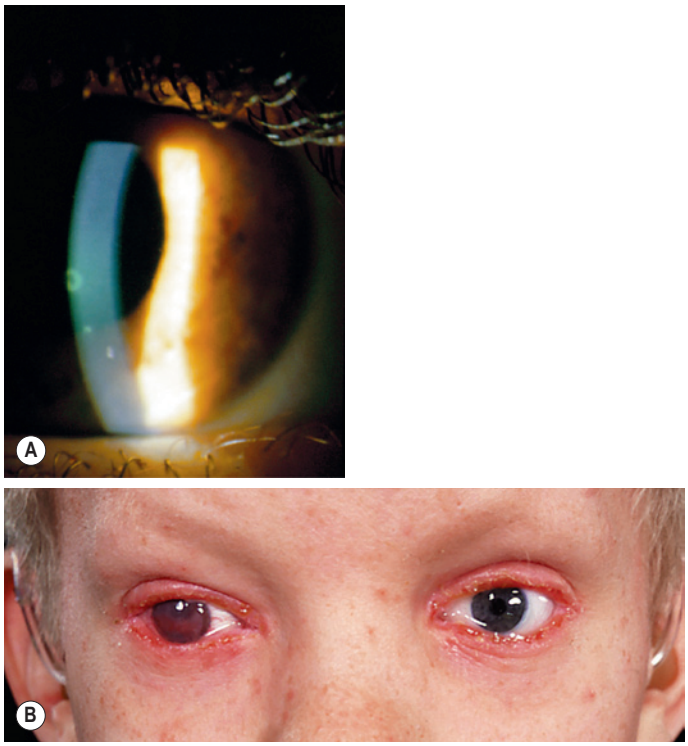

Fig. 34.27 Ichthyosis. (A) Fluorescein-staining superficial corneal lesions. (B) KID (keratitis, ichthyosis, deafness) syndrome with deafness (the patient is using hearing aids) and severe bilateral keratopathy. The left is an artifical eye following enucleation.

Ichthyosis

Lamellar ichthyosis and ichthyosis linearis circumflexa are severe autosomal recessive disorders associated with tight skin that gives rise to secondary ectropion and corneal disease from exposure, with scarring, infection, and perforation. Keratitis is also a major feature of the KID (keratitis, ichthyosis, deafness) syndrome (Fig. 34.27). KID syndrome is caused by mutations in the *GJB2* gene that codes the epithelial gap junction protein connexion 26. The keratitis has variously been attributed to keratin obstruction of the lacrimal gland ductules, recurrent epithelial breakdown, or limbal stem cell deficiency. Treatment with lubricants and topical corticosteroids has a limited effect.

X-linked ichthyosis is the result of mutations in the steroid sulfatase (*STS*) gene. Affected individuals have scaling of the scalp, face and neck, abdomen, and limbs. Superficial punctate keratopathy occurs and scarring may be exacerbated by eyelid abnormalities. A diffuse pre-Descemet's "dystrophy" is rarely visually significant.

Incontinentia pigmenti

This autosomal dominant condition is due to an X-linked dominant mutation of the *NEMO* (*IKBKG*) gene and is thus much more common in females. It is associated with retinopathy and characteristic linear pigmented changes (Chinese writing) of the skin in older children (see Chapter 42). Some individuals develop large numbers of small intraepithelial cyst-like corneal deposits (Fig. 34.28). These may be associated with photophobia and discomfort, but rarely cause erosion. They rapidly recur after epithelial debridement. There is no specific treatment but topical lubricants or a therapeutic bandage contact lens may be helpful.

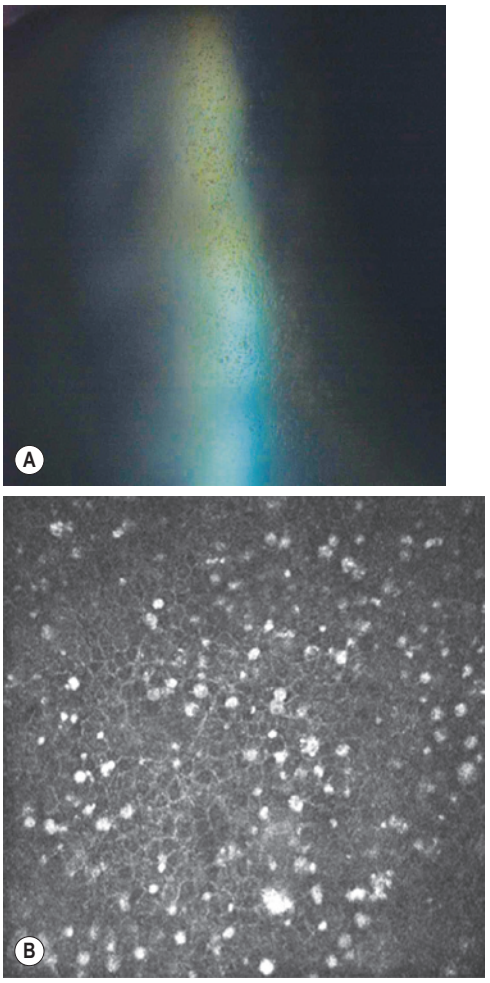

Fig. 34.28 Incontinentia pigmenti. (A) Tiny intraepithelial inclusions associated with photophobia and discomfort. (B) Inclusions visualized with confocal microscopy.

Recurrent corneal epithelial erosion

This occurs less commonly following an injury (e.g. finger nail) in children than adults. Management is with topical lubricants and an ointment at night, continued for several weeks after symptoms resolve to prevent recurrence. An extended-wear soft contact lens should be considered if symptoms persist. Alcohol delamination of the epithelium, or laser PTK, are options for severe cases. Meesmann dystrophy (mutations of *KRT3* or *KRT12*) and epithelial recurrent erosion dystrophy (ERED; *Col17a1* mutation) can both cause pain and photophobia in children, however they are rare and there is usually a strong family history. The *TGFB1*-associated corneal dystrophies (e.g. Reis–Buckler, lattice dystrophy) rarely progress to cause epithelial erosion in childhood (see Chapter 35). Recurrent erosion and scar can also be a feature of epidermolysis bullosa (Fig. 34.29).

Interstitial keratitis

Interstitial keratitis (IK) is an immune-mediated, non-ulcerative inflammation of the corneal stroma (Fig. 34.30). The epithelium and endothelium are often unaffected. In a minority of cases, it is associated with potentially severe systemic disease that requires medical management. HSV is the

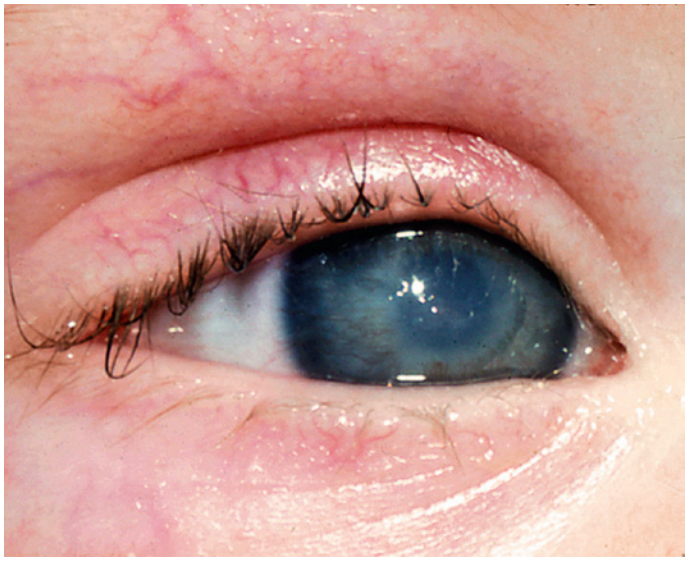

Fig. 34.29 Epidermolysis bullosa. Although many cases of epidermolysis bullosa do not have corneal changes, some, like this patient, develop acute epithelial erosions as a result of minor trauma, which if repeated result in permanent corneal opacity and vascularization.

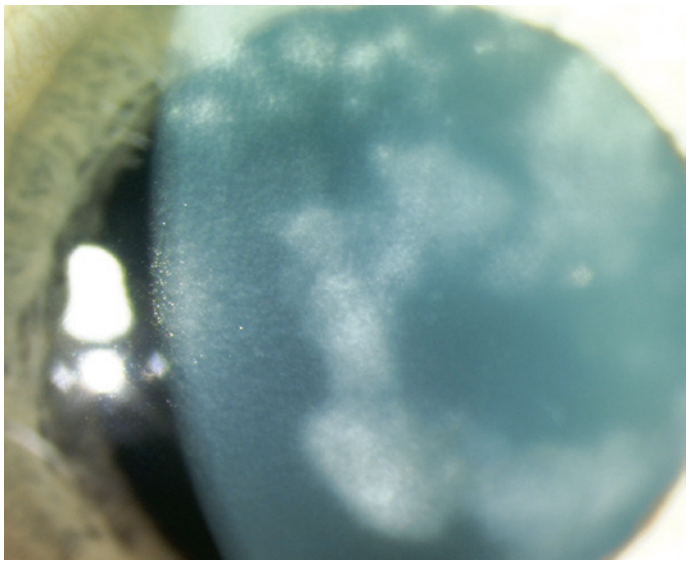

Fig. 34.30 Interstitial keratitis. Deep stromal opacities in a 10-year-old associated with Epstein–Barr virus infection.

most common cause, and although there are numerous other causes the majority are rare. IK may be unilateral or bilateral, diffuse, sectorial, peripheral, or focal, and may affect any layer of the stroma. There may be vascularization or an associated uveitis. It should be distinguished from lipid infiltration or scar.

Symptoms include photophobia and discomfort, although some cases may be asymptomatic and first noted by the parents. There is corneal opacity often with perilimbal injection. Untreated the inflammation can lead to secondary neovascularization, with residual ghost vessels when the acute phase settles, and Descemet's layer wrinkles or scrolls. It is thought to be the result of a hypersensitivity response to antigens, or antigen-bearing cells, in the corneal stroma. Treatment with topical steroids is effective unless there is associated secondary scarring or lipid keratopathy, which will be permanent. If HSV is a potential diagnosis, treatment should include topical or oral acyclovir.

The principal causes are viral, bacterial, and protozoal. However, if the IK is inactive, the majority of cases have no identifiable cause (i.e. idiopathic).

- Herpes simplex stromal keratitis is the most common cause for active IK in developed countries, accounting for over 70% of cases.
- Herpes zoster stromal keratitis is the second most common cause, presenting as either a focal anterior stromal keratitis or a late diffuse keratitis associated with scarring, vascularization, and lipid deposition. There may be a history of shingles or forehead scarring.
- Epstein–Barr virus and mumps virus can cause multifocal discrete anterior stromal opacities that develop several days or weeks after systemic disease. It may respond to topical steroid. Systemic antiviral therapy is not required.
- Congenital syphilis (acquired infection with the spirochete *Treponema pallidum*) is rare in children, although it was once synonymous with IK and is still a major cause of IK worldwide. Screening during pregnancy and treatment with antibiotics has dramatically reduced the incidence. The features are diffuse corneal edema that is bilateral in 80% of cases followed by circumferential intense deep vascularization (salmon patch). Secondary degenerative changes progress into adulthood. The associated signs of congenital syphilis are nerve deafness, abnormal teeth, and characteristic changes of the nose and face. Diagnosis in collaboration with an infectious diseases consultant is confirmed by serologic testing, a positive non-treponemal test (the Venereal Disease Research Laboratory test [VDRL] or rapid plasma reagin test [RPR]) confirmed with a treponemal test (the fluorescent treponemal antibody absorption test [FTA-ABS]) or microhemagglutination. Systemic treatment is essential, but the corneal changes are helped by topical steroid.
- Tuberculosis is most frequently associated with granulomatous uveitis, but IK may be associated with sectorial sclerokeratitis.
- Leprosy is uncommon in children. The stromal infiltration of leprosy is a bilateral superotemporal wedge of infiltration followed by vascularization. Secondary corneal anesthesia and lagophthalmos due to involvement of the fifth and seventh cranial nerves is more common in adults.
- Lyme disease is caused by tick-transmitted infection with a number of different species of the spirochete *Borrelia*. There may be a history of travel to endemic areas in North America and Eurasia and preceding flu-like symptoms and skin lesions (bull's eye rash, erythema migrans), central nervous system, heart, and joint involvement. The commonest ocular feature (10% of cases) is a mild transient conjunctivitis and periorbital edema, with corneal changes (3% of cases) a late feature, with nummular opacities that may vascularize in untreated disease. Optic neuritis, intermediate uveitis, retinal vasculitis, and cranial nerve palsies may occur. Diagnosis is confirmed by an enzyme-linked immunosorbent assay (ELISA) or polymerase chain

reaction (PCR) of serum, and systemic treatment with amoxicillin or doxycycline is required, although the corneal changes respond to topical steroid.

- Onchocerciasis (river blindness) is a regionally important cause of corneal opacity that is becoming less common with eradication programs. It is caused by infection by the parasitic helminth *Onchocerca volvulus* that is transmitted by *Similium* blackflies in endemic areas. Inflammation is stimulated by microfilaria that have migrated from the conjunctiva into the cornea where they have died. In children, a pattern of superficial punctate lesions (snowflake keratitis) due to inflammation stimulated by dead parasites in the cornea is seen. In adults, this may progress to sclerosing keratitis that spreads centrally from the limbus in the interpalpebral zone accompanied by deep vascularization. Vision may be lost as a result of retinitis or secondary glaucoma. Treatment is with oral ivermectin, usually given as part of a community-based eradication program.

  Leishmaniasis and trypanosomiasis are protozoal infections that can cause IK.
- Cogan syndrome is a rare autoimmune disease that can occur in children, although the mean age of onset is in the 30s. There is inflammation directed against an antigen found in the cornea and inner ear, with an associated vasculitis. Onset of eye discomfort, redness, and photophobia is preceded by an upper respiratory tract infection in half of cases. The early corneal changes are bilateral peripheral focal posterior stromal opacities with subepithelial infiltrates, with mild secondary vascularization. There may be a gradual onset of symptoms of nausea, vertigo, and tinnitus similar to Ménière disease. Atypical Cogan syndrome may have conjunctivitis, subconjunctival hemorrhage, episcleritis, uveitis, and retinal vasculitis. Atypical features should alert the clinician to the possibility of alternative diagnoses, such as juvenile arthritis, ulcerative keratitis, etc. There are no specific laboratory abnormalities. The importance of recognizing this condition is the association with deafness and vestibular symptoms. Urgent treatment with high doses of oral corticosteroid and subsequent immunosuppression is required to prevent rapid progression of auditory loss, although this develops in 50% of cases despite treatment. Late onset aortitis can occur.[30]
- Reactive arthritis (Reiter syndrome) characterized by inflammatory arthritis of large joints, urethritis, and ocular inflammation is commonly associated with conjunctivitis and iridocyclitis. Approximately 75% of individuals are HLA-B27-positive, with inflammation possibly triggered by infection (e.g. *Chlamydia*). Mainly peripheral anterior stromal keratitis, epithelial erosions, and more diffuse subepithelial and anterior stromal infiltrates associated with fine conjunctival papillae occur. These lesions resolve with topical corticosteroids but systemic management is also required.

Keratomalacia

The conjunctival features of hypovitaminosis A are described in Chapter 31. If there is severe and chronic A deficiency, the corneal surface can become involved with severe punctate keratitis, vascularization, and edema. Keratomalacia is acute liquefactive necrosis of the cornea, often precipitated by measles infection, diarrhea, herpes simplex, or the use of traditional eye medicines. Management for superficial changes is vitamin supplements. The natural history of keratomalacia is adherent leukoma and vascularization of the cornea, or phthisis (Fig. 34.31). Systemic vitamin supplements and topical antibiotic may halt the progression of the corneal melting. A tectonic keratoplasty (if available) may be required, although the visual outcome is poor, or a conjunctival flap.[31]

Corneal exposure

Exposure keratitis is damage to the ocular surface from inadequate lid protection. This initially results in epitheliopathy, subepithelial and anterior stromal scarring, and, later, corneal neovascularization. In severe cases, often associated with infection, persistent epithelial defect, stromal thinning, and corneal perforation can occur (Fig. 34.32).

Eyelid defects (colobomas, etc.), seventh cranial nerve palsy, or tight skin (lamellar ichthyosis) may cause exposure keratitis. Amniotic bands may be associated with congenital

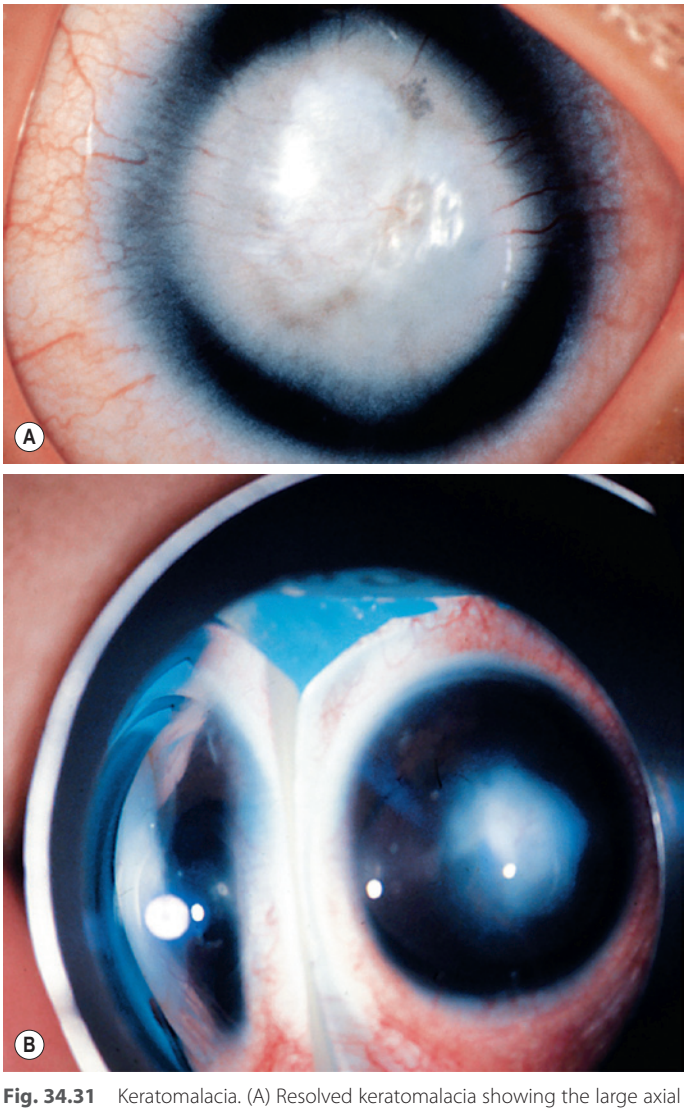

Fig. 34.31 Keratomalacia. (A) Resolved keratomalacia showing the large axial scar. (B) Gonioscopic view showing the iris attached to the posterior surface of the cornea – an adherent leukoma.

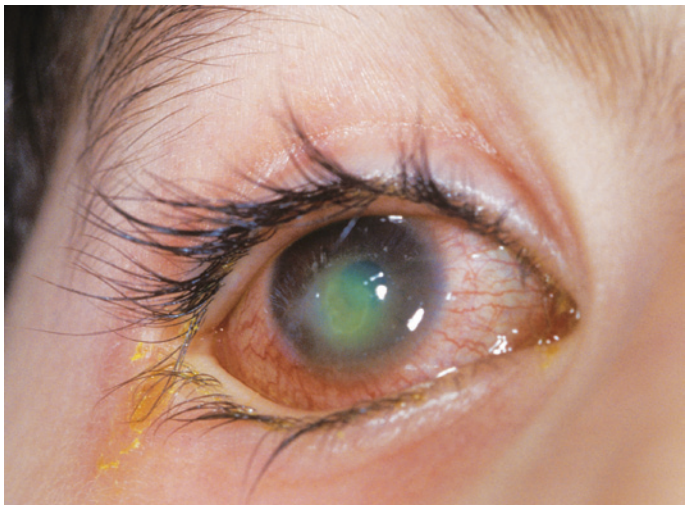

Fig. 34.32 Corneal exposure. Patient with Möbius syndrome. There is poor eye movement and incomplete lid closure leading to epithelial breakdown.

corneal leukomas or with exposure keratitis from lid defects. Exophthalmos from orbit disease or craniofacial abnormalities (see Chapter 28) can result in poor lid closure. The combination of exposure from seventh nerve palsy and neurotrophic keratopathy from fifth nerve palsy, as in Möbius syndrome, is a major management problem. Immediate management requires protection of the eye with ointment and lubrication, or a moist chamber fashioned from plastic drape taped to the periocular skin; however, surgical intervention, usually tarsorrhaphy, to establish better eyelid protection of the ocular surface is usually required.

Chapter contents

DEFINITION
CLASSIFICATION
MUTATION RATE
MANAGEMENT
REFERENCES

Corneal dystrophies are rare Mendelian inherited conditions that exhibit bilateral and usually symmetrical corneal changes.

Nomenclature has been difficult because of controversies about phenotype definitions. Many authors have reported different phenotypes using the same headings, or the same phenotype using different headings (see below under "Classification"). This chapter will focus on a few classic dystrophies, highlighting the clinical presentation in children and emphasizing the differences from adults. It is difficult to document photographically the subtle changes associated with corneal dystrophies in children. The clinical pictures in this chapter look almost alike. However, when examining children for a corneal dystrophy, do not look for the slit-lamp appearance found in adults. You need to look for subtle opacities, which may be similar to the adult clinical picture, but the final diagnosis is made after examining the whole family. Most of the dystrophies are progressive, and the figures illustrate how different the clinical picture may be in children.

The literature on pediatric corneal dystrophies is meager.[1] The one exception is lattice corneal dystrophy.[2] Only a few of the 22 entities called *Corneal Dystrophies* in the International Committee for Classification of Corneal Dystrophies (IC3D)[3] system are included in this chapter.

Definition

The term "dystrophy" is derived from the Greek words *dys* (wrong or difficult) and *trophe* (nourishment). There is no universally accepted definition of the term dystrophy. The word was first used 150 years ago for a group of entities that were clearly not traumatic or infectious in origin. They were believed to be due to poor nerve supply or nourishment and later proved to be genetic in origin, but the word "dystrophy" stuck to this group of inherited diseases.

Corneal opacification associated with systemic conditions such as cystinosis are not included in this chapter. Degenerations are secondary, non-genetic processes resulting from aging or previous corneal inflammation.

Classification

Recently, an international group of cornea specialists published the second version of a list of conditions considered to be dystrophies.[3] The committee developed a series of descriptive categories as shown in Box 35.1 and a paper that included hundreds of references and clinical pictures of adults with these dystrophies.

Mutation rate

The prevalence and clinical significance of the conditions vary. The founder effect (i.e. an increase in the number of cases of a certain genetic trait due to the occurrence of a new mutation in an isolated population) has, in some countries, given rise to large pedigrees of conditions that may be almost non-existent elsewhere.

As the mutation rates for many of the corneal dystrophies are low, it is important to be cautious when diagnosing sporadic cases. A family history *and examination* of family members are mandatory.

Dystrophies related to mutations in the *TGFBI* gene

Genetic information describes the different allelic mutations within the *TGFBI* (transforming growth factor-beta induced) gene on chromosome 5q31. They account for many of the classic corneal dystrophies, which are allelic variations of dominant entities of the same gene. Thus, genetic knowledge is bringing order to this field of ophthalmology. Although naming the diseases according to mutation number has not gained universal recognition, most ophthalmologists rely on a genetic analysis to distinguish between the rarer varieties.

Granular dystrophies

Granular corneal dystrophy, type 1 (a category 1 dystrophy)
Granular corneal dystrophy, type 1 is distinguished by discrete granular-appearing corneal opacities in an otherwise clear cornea. This type has several hundred granules in one cornea (mutation R555W).

Box 35.1

The International Committee for Classification of Corneal Dystrophies (IC3D): the four levels of corneal dystrophies

Category 1: A well-defined corneal dystrophy in which the gene has been mapped and identified and specific mutations are known

Category 2: A well-defined corneal dystrophy that has been mapped to one or more specific chromosomal loci, but the gene(s) remains to be identified

Category 3: A well-defined clinical corneal dystrophy in which the disorder has not yet been mapped to a chromosomal locus

Category 4: This category is reserved for a suspected new, or previously documented, corneal dystrophy, although the evidence for it being a distinct entity is not yet convincing

The category of a specific corneal dystrophy can be expected to change over time as knowledge advances. Eventually, all valid corneal dystrophies should attain category 1.

Note: The classification paper comprising an extensive description of each condition, clinical pictures, key references, and a few words on onset in childhood can be retrieved as a PDF file free of charge probably best by searching online for IC3D Classification of corneal dystrophies version 2.

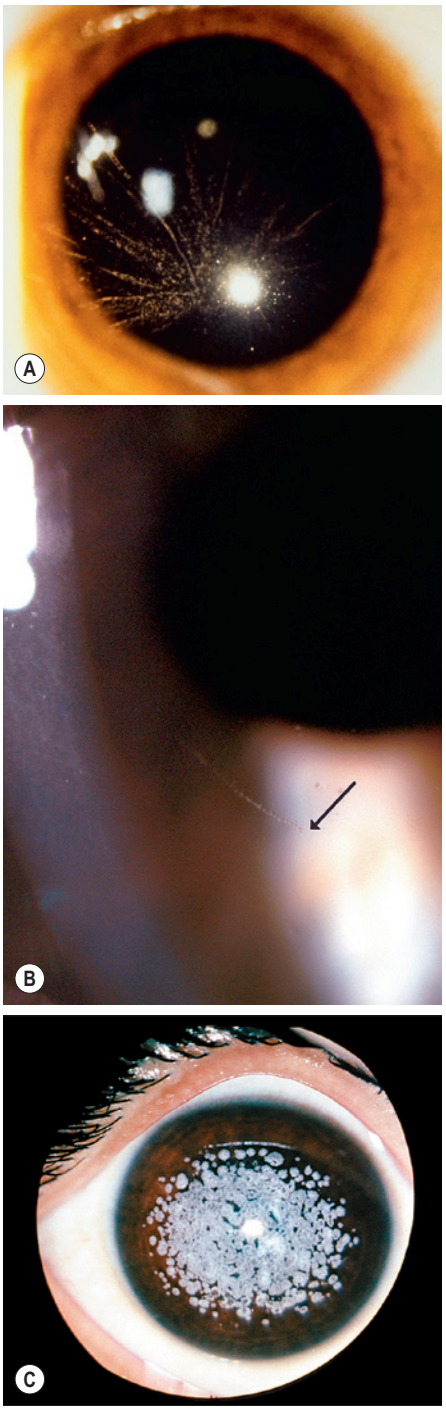

Fig. 35.1 (A) Granular corneal dystrophy, type 1 showing a verticillata-like configuration of the corneal opacities. (B) Granular corneal dystrophy, type 2. A few of these discrete opacities may be all that is visible in a young child. (C) A 7-year-old homozygous patient; granular corneal dystrophy, type 2.

The opacities are white in direct illumination, and transparent, like a crack in glass, by retroillumination. At about 5 years of age, these may be brownish and superficial to Bowman's membrane and present in a verticillata configuration (Fig. 35.1A). The granules increase in number and size and progress into the stroma during late childhood when visual deterioration is moderate. There is always a 2-mm clear limbal zone. Unlike most dominant disorders, the expressivity is nearly constant between generations.

Granular corneal dystrophy, type 2 (a category 1 dystrophy)

Granular corneal dystrophy, type 2 (mutation R124H) is probably the most common corneal dystrophy worldwide. In the past, it was incorrectly called Avellino dystrophy. When patients with this condition from the Italian province of Avellino were first described, it was not recognized that the phenotype had been described decades earlier by others. Clinically and on electron microscopy, this mutation looks like a mixture of a granular and lattice dystrophy with fewer, but larger, opacities in the cornea, particularly later in life. Vision is affected only if the granules are located in the central cornea. It is rarely possible to diagnose this condition until the late teen years. Thus a parent carrying this mutation may need genetic analysis to know whether their children have inherited the trait (Fig. 35.1B). A variety (Fig. 35.1C) with almost a white central cornea before the age of 10 years has also been described. These patients are homozygous for this dominant gene.

Molecular genetic testing is now available for granular dystrophies using buccal mucosal swabs.

Lattice corneal dystrophy (a category 1 dystrophy)

Lattice dystrophy (type I, mutation R124C) is also an autosomal dominant condition of the *TGFBI* gene. Several subtypes have been described; they should be distinguished by genetic analysis. Its hallmark is deposition of amyloid, recognized in a child by three distinct slit-lamp findings[2]:

1. tiny, non-refractile, whitish spots that are round or ovoid (Fig. 35.2A);
2. diffuse axial, anterior stromal haze;
3. white, anterior, stromal dots and filamentary lines that are refractile on indirect illumination in older patients (Fig. 35.2B).

The deposition may be symmetrical or asymmetrical. The stroma becomes increasingly hazy over time, resulting in glare and worsening of vision. Lattice lines gives rise to the name of the condition, but usually are only present in adults. Many patients with this condition have recurrent corneal erosions.

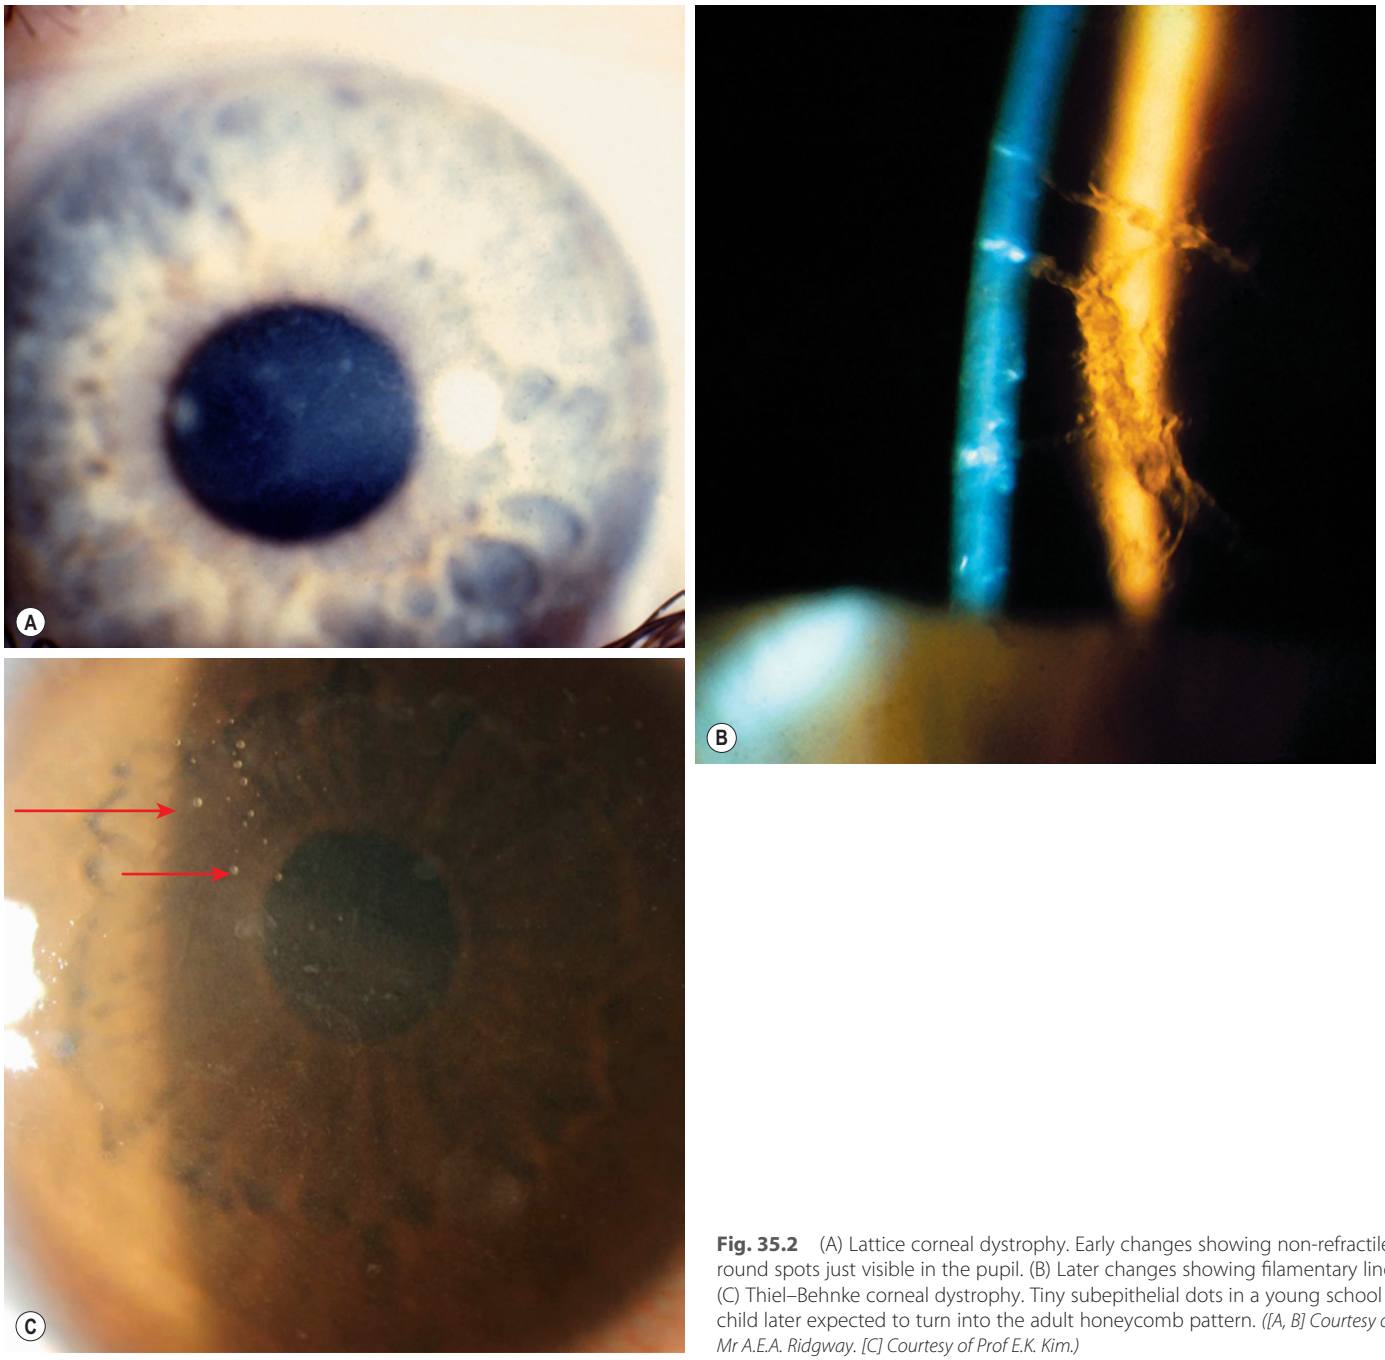

Fig. 35.2 (A) Lattice corneal dystrophy. Early changes showing non-refractile round spots just visible in the pupil. (B) Later changes showing filamentary lines. (C) Thiel–Behnke corneal dystrophy. Tiny subepithelial dots in a young school child later expected to turn into the adult honeycomb pattern. *([A, B] Courtesy of Mr A.E.A. Ridgway. [C] Courtesy of Prof E.K. Kim.)*

Reis–Bücklers and Thiel–Behnke corneal dystrophies (category 1 dystrophies)

Mutations in the same gene also give rise to Reis–Bücklers (mutation R124L) and Thiel–Behnke corneal dystrophy (mutation R555Q). Both have early-onset recurrent corneal erosions. Reis–Bücklers has confluent irregular subepithelial opacities showing rod-shaped bodies on electron microscopy similar to granular corneal dystrophy. Thiel–Behnke corneal dystrophy has a honeycomb slit-lamp appearance and curly fibers on electron microscopy. Both have subtle superficial opacities at presentation that progress to create visual problems (Fig. 35.2C).

Dystrophy due to mutations in other genes

Macular corneal dystrophy (a category 1 dystrophy)

Macular dystrophy is rarely diagnosed in young children since the findings are very subtle and hard to diagnose, particularly if there is no family history of the disease. They comprise nebulous, whitish opacities in the center of the cornea (Fig. 35.3). Over the years, the corneal stroma becomes increasingly hazy between the opacities with an irregular surface. Deposition of glycosaminoglycan in the cornea causes the opacification. As it is inherited as an autosomal recessive trait, there is often a history of consanguinity. The high prevalence of macular

Fig. 35.3 Macular corneal dystrophy in a 13-year-old girl. Typical macular opacities. What cannot be seen in the picture is the opaque ground substance between opacities.

dystrophy in Iceland is an example of the founder effect. Macular dystrophy has been linked to chromosome 16; several mutations exist in the *CHST6* gene. Progressive visual deterioration is symmetrical and usually occurs in the second or third decade.

Posterior polymorphous corneal dystrophy (some subtypes are a category 1, some a category 2 dystrophy)

This autosomal dominant dystrophy may be seen in the very young. The acronym PPCD is suggested by the recent corneal dystrophy classification system. It is often asymmetrical and progression, if it occurs, is slow. Thus the corneas in affected children and adults appear similar. Slit-lamp examination shows small, round, discrete, transparent, vesicular lesions (Fig. 35.4) surrounded by a ring of opacity deep in the cornea at the level of Descemet's membrane; geographical and band varieties exist. As the name suggests, there is usually deep involvement in contrast to most other corneal dystrophies and the opacities may have varying appearances. The opacities are best seen on retroillumination.

Three subtypes of posterior polymorphous dystrophy have been linked to chromosome 20q11 (unknown gene) and 1p34.3–p32.3 in the *COL8A* gene and 10p11.2 in the *ZEB1* gene. The symptoms are often mild and vision unaffected.

Meesmann corneal dystrophy (a category 1 dystrophy)

This condition has a variable expression. It may be asymptomatic or present in early childhood with ocular irritation and photophobia due to recurrent erosions and a mild blurring of vision. Scarring may later cause changes in the slit-lamp appearance. The typical patient has a large number of tiny epithelial vesicles (Fig. 35.5). In the young child, small areas may be spared. Vision is rarely affected in children.

Mutations at two loci, 12q13 and 17q12, of the *KRT3*/*KRT12* gene have been reported.

Schnyder corneal dystrophy (a category 1 dystrophy)

This autosomal dominant corneal dystrophy can be diagnosed in children but may have a variable expression. The central anterior cornea has a slowly progressing, disc-like central opacification with or without polychromatic crystals (Fig. 35.6). It may be visible in the first decade of life. However, it is not until their twenties that patients develop arcus lipoides and a diffuse stromal haze. Vision is variably affected, as some patients have no central crystals. The crystals contain cholesterol and other lipids. The affected gene, *UBIAD1*, is localized on 1-p36.

Congenital hereditary endothelial dystrophy

Congenital hereditary endothelial dystrophy was first described by Maumenee. His name is still used as an eponym, although the dystrophy is more commonly referred to using the acronym CHED. It is recessive (chromosome 20p13, *SLC4A11* gene) and presents at birth with diffuse avascular haziness, ground-glass, bluish-white opacity of the cornea (Fig. 35.7), and nystagmus. The cornea is thicker than normal. The previously so-called dominant form (chromosome 20p11.2–q11.2) that develops during the first or second year of life and progresses slowly and is now considered a variety of posterior polymorphous corneal dystrophy.[3]

It is important to differentiate CHED from congenital glaucoma using corneal pachymetry, intraocular pressure, and corneal diameter measurements.

Management

Most children with corneal dystrophies in the anterior layers of the cornea do not need treatment. Symptoms requiring treatment include decreased vision from corneal opacity or corneal edema and recurrent corneal erosions. The latter may produce photophobia, redness, irritation, blurred vision, or pain. Medical management may be useful for recurrent erosion symptoms with temporary therapeutic contact lens wear, isotonic or hypertonic artificial tear supplementation, or lubricant ointments. Surgical treatments may include superficial keratectomy or phototherapeutic keratectomy (PTK). However, in granular type 1, it may cause scarring.[4] While excimer laser ablation may be helpful in treating some dystrophies, the logistics of administering general anesthesia to these young children at the time of laser treatment remains a challenge. Superficial keratectomy is performed under general anesthesia followed by placement of a therapeutic contact lens. While this may be helpful in severe cases, supportive medical therapy is typically the mainstay of therapy with placement of a therapeutic soft contact lens and topical lubricants. Meesmann dystrophy is particularly challenging to treat with surgical methods, as recurrence is rapid and persistent over time. Promotion of scarring of the cornea with superficial keratectomies may be helpful in rare situations but may lead to reduced visual acuity. The mainstay of treatment for Meesmann dystrophy is supportive, with therapeutic bandage soft contact lenses, and topical lubricants.

In cases with significant corneal opacification and decreased vision from dystrophic deposition in the central cornea, penetrating keratoplasty (PK) or anterior lamellar keratoplasty (ALK) may be indicated. Any dystrophy with normal endothelium such as the *TGFBI* dystrophies can be treated with deep or superficial anterior lamellar keratoplasty depending on the depth of the dystrophic lesions. Dissections can be made using air (Anwar's technique), femtosecond

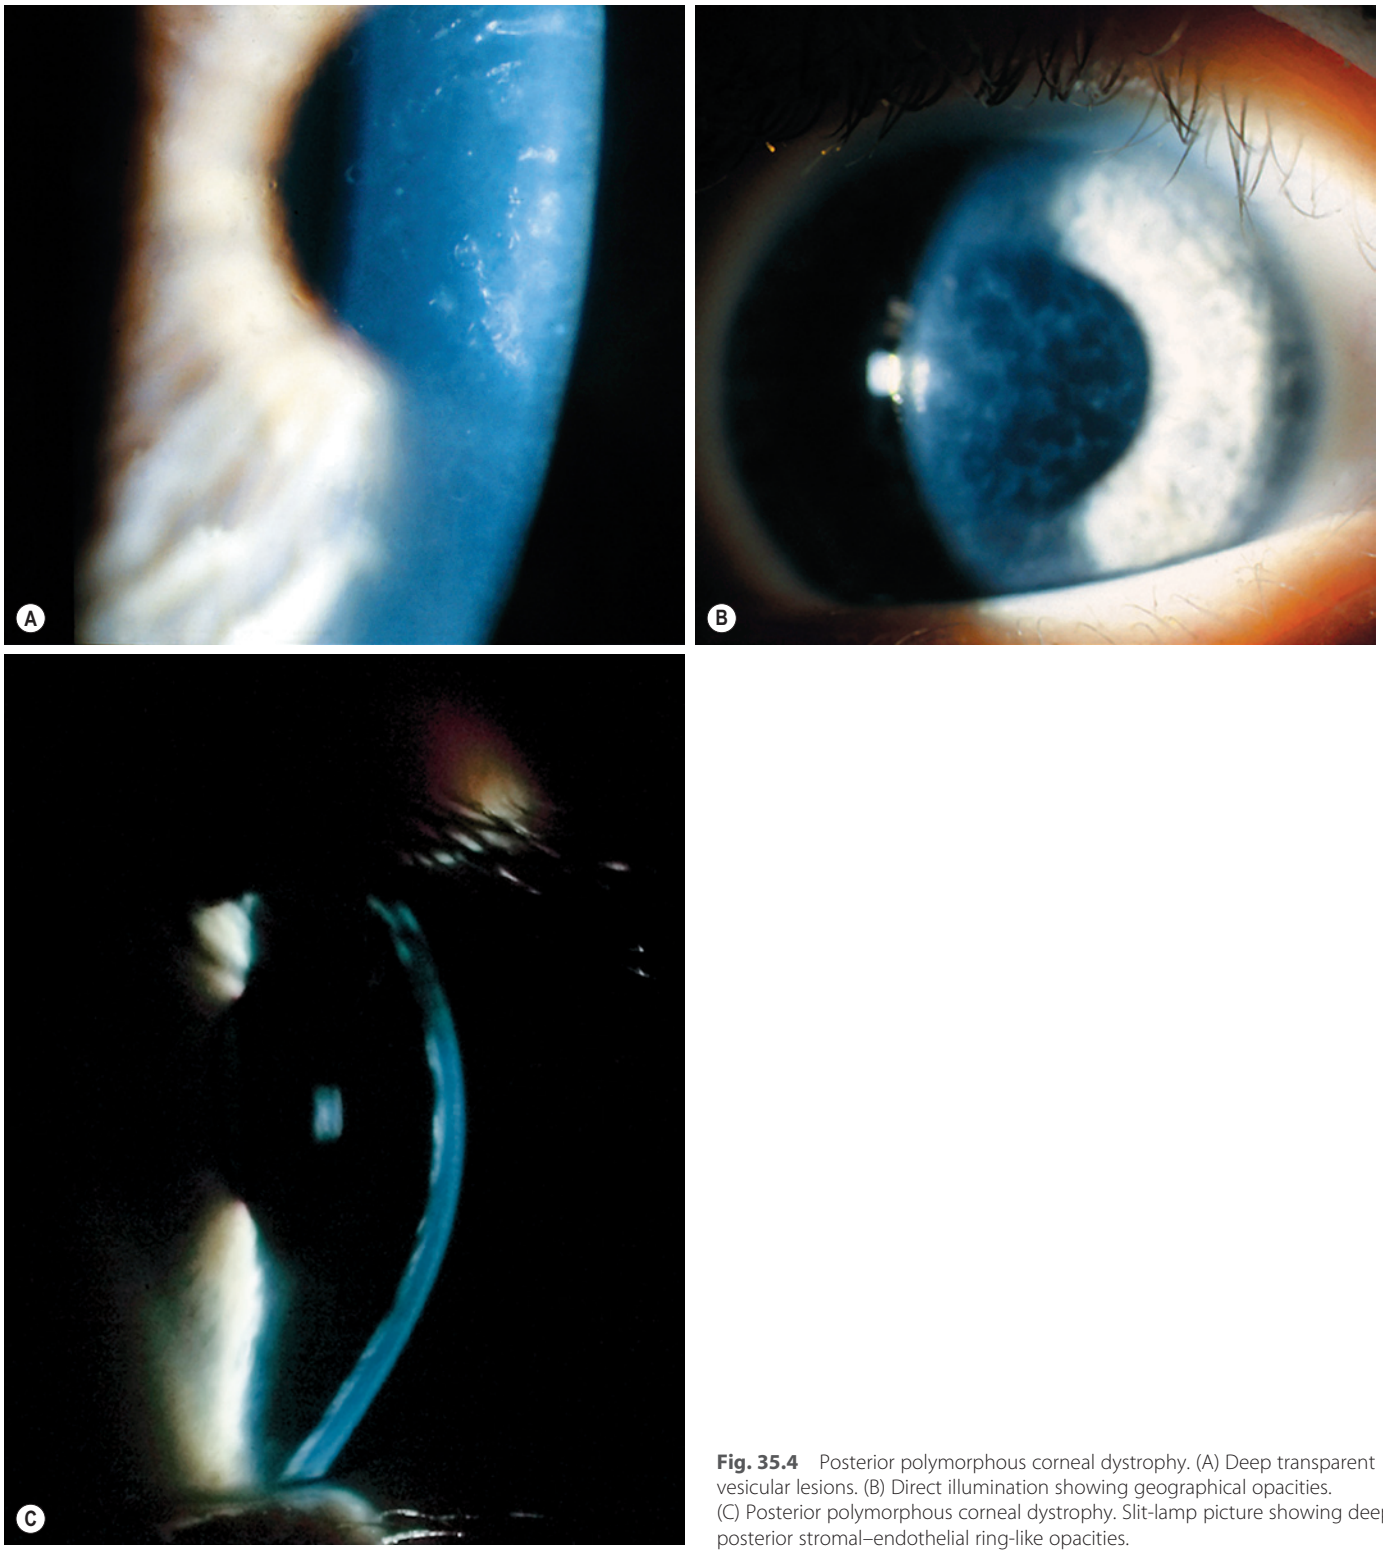

Fig. 35.4 Posterior polymorphous corneal dystrophy. (A) Deep transparent vesicular lesions. (B) Direct illumination showing geographical opacities. (C) Posterior polymorphous corneal dystrophy. Slit-lamp picture showing deep posterior stromal–endothelial ring-like opacities.

lasers, or mechanical microkeratomes.[5] Advantages of ALK techniques over PK are particularly evident in children and include avoidance of endothelial graft rejection, avoidance of an intraoperative open sky, quicker taper of corticosteroids, and increased resistance to trauma from better tectonic stability.[6] Graft success, whether PK or ALK, is high for anterior/stromal corneal dystrophies, yet recurrence of dystrophic material remains a high risk over the patient's lifetime.

When pediatric endothelial dystrophies such as PPCD and CHED cause severe vision loss from severe corneal edema, endothelial keratoplasty is the treatment of choice over PK to reduce the risk of amblyopia. Fortunately most cases of PPCD

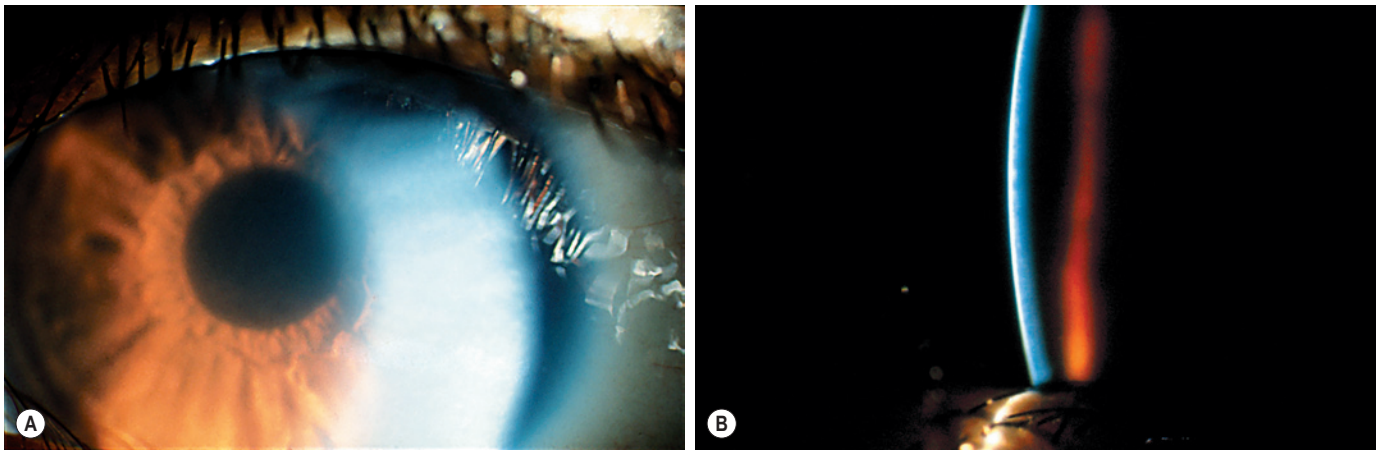

Fig. 35.7 Congenital hereditary endothelial dystrophy. (A) Opaque cornea. (B) Opaque and thickened cornea on slit-lamp illumination.

do not need treatment, whereas probably most cases of CHED do. The most often utilized endothelial keratoplasty technique is Descemet-stripping automated endothelial keratoplasty (DSAEK).[7,8] Endothelial keratoplasty affords a smaller incision size, avoidance of an open sky, quicker visual recovery, quicker vision stability, and less induced astigmatism compared to PK.[9] Due to the smaller incision size, minimal corneal sutures are needed for endothelial keratoplasty so suture related complications are virtually negated with added increased tectonic stability compared to PK.[9] Descemet membrane endothelial keratoplasty (DMEK) is a newer technique of endothelial keratoplasty that has been shown to provide better best-corrected visual acuity and less risk of endothelial rejection compared to DSAEK in adults. The anatomic differences in pediatric eyes compared to adults including smaller corneal diameters, tighter adherence of Descemet's membrane to the stroma (more challenging to strip Descemet's membrane), shallow anterior chambers, and increased posterior pressure remain challenges for DMEK in children. Thus DSAEK may remain the procedure of choice for children requiring surgical treatment for endothelial dystrophies.

Anatomy

The crystalline lens, like the cornea, has two principal optical properties: transparency and refractive power. Its structure reflects this. It is a transparent, biconvex, avascular mass of uniquely differentiated epithelial cells. It lies immediately posterior to the iris and is held in position behind the pupil by zonular fibers from the ciliary body.

The lens has an equatorial diameter of 6.5 mm at birth and a maximum anteroposterior thickness of 3.5 mm at the poles. It is completely enveloped by a collagenous capsule, the basement membrane of the cuboidal epithelial cells, which lie beneath it in a single layer. The cuboidal cells at the equatorial region of the lens develop throughout life to form spindle-shaped secondary lens fibers. This addition of fibers at the equatorial region slowly changes the morphology of the lens from a near-spherical fetal shape, to an elliptical biconvex shape (with a diameter of approximately 9 mm and an anteroposterior depth of 5 mm) in childhood and early adulthood. The embryonic and fetal nuclei are present at birth. The fetal nucleus is demarcated from the embryonic nucleus by Y-shaped upright sutures anteriorly and inverted Y-shaped sutures posteriorly. Successive nuclear zones are laid down during development and those deposited after birth contribute to the adult nucleus. The surrounding cortex is formed from less densely packed lens fibers.

Embryology

The lens develops as a thickening of the surface ectoderm overlying the optic vesicle. This "lens placoid" appears on day 26–27 in the human embryo. The mitotically active surface ectoderm is fixed in place, resulting in cell crowding, elongation, and thickening of the placoid.[1] Adhesion of the optic vesicle to the lens placode ensures eventual alignment of the lens and retina in the visual axis. However, there is no direct cellular contact between the basement membranes of the optic vesicle and surface ectoderm. The lens placode then invaginates to form the lens pit. This becomes the lens vesicle. Lens vesicle detachment is the initial event leading to formation of the anterior segment of the eye (day 33). It is accompanied by migration of epithelial cells via a keratolenticular stalk, cellular necrosis, and basement membrane breakdown.[2] This goes someway to explaining the common association of major or minor anterior segment developmental abnormalities (see Chapter 33) in children with lens disorders. The detached lens vesicle is lined by a single layer of columnar epithelial cells surrounded by a basal lamina, the future lens capsule. Primary lens fiber formation occurs in the epithelial cells lining the posterior surface of the lens vesicle and is promoted by the adjacent retinal primordium.[3] The primary lens fibers fill the lumen of the lens vesicle. Elongation of lens cells adjacent to the retina forms the embryonal lens nucleus. The anterior lens cells nearest the corneal primordium remain a cuboidal monolayer and become the lens epithelium. This remains mitotically active for life, providing future lens fiber cells. Epithelial cells differentiate into secondary lens fibers at the lens equator (lens bow). These fibers elongate both anteriorly and posteriorly and insert over the primary lens fibers. They are thickest at the equator. Secondary lens fibers meet anteriorly and posteriorly at the Y sutures.

Zonular fibers are derived from the non-pigmented ciliary epithelium during the fifth month of gestation. The glycoprotein fibrillin is the main component of the ciliary zonules. There are two well-studied isoforms (FBN1 and FBN2) and the more recently discovered FBN3 isoform, which is unique to humans.[4] The monomers are long, flexible molecules that form extended polymers and comprise the backbone of microfibrils, which are important scaffolding structures and are arranged in parallel bundles to form the lens zonules. Fibrillin isoforms interact with many related proteins including the transforming growth factor (TGF)β complex, elastin, and the ADAMTS-like proteins, and are involved in TGFβ and bone morphogenetic protein (BMP) signaling.[5] Interestingly, all isoforms are present in the eye during human embryonic development, but fibrillin-1 predominates in the postnatal zonule, suggesting that fibrillin-2 and -3 play an early scaffolding role for ocular development.[4]

Disorders affecting the structure or function of these interacting proteins result in zonular dysfunction, in particular ectopia lentis, and are discussed below.

The tunica vasculosa lentis (TVL) is a vascular network derived from the hyaloid artery posteriorly and a parallel radial palisade of anastomoses with the annular blood vessel laterally. It envelops the developing lens and nourishes it at a time when aqueous production and formation of the anterior chamber have not yet begun. This intraocular network of vessels begins to develop in the first month of gestation, is maximal in the second to third month, and begins to regress by the fourth month. It has largely disappeared at birth.[6] Persistent TVL is commonly seen in premature neonates and failure of regression of the TVL, hyaloid arteries, and anterior structures can cause a range of developmental anomalies collectively termed persistent fetal vasculature (PFV).

Developmental abnormalities of the lens

Anomalous lens development can often be seen in the context of more global developmental abnormalities of the eye and broadly include: complete absence of the lens (primary aphakia) and anomalies of lens size, shape, position, and transparency.

Congenital aphakia

Congenital aphakia is rare and is invariably associated with significant anterior/posterior segment developmental abnormalities. Primary congenital aphakia (PCA) can result from a variety of teratogenic events (e.g. congenital rubella) in the first 4 weeks of embryogenesis and usually results in microphthalmos, and severe anterior and posterior segment developmental abnormalities.[7,8] Recently, autosomal recessive mutations in the *FOXE3* gene have been identified in some pedigrees with PCA.[8] Secondary congenital aphakia occurs as a result of spontaneous absorption or expulsion of the developing lens. It is associated with less severe ocular anomalies such as PFV.

Microspherophakia

Microspherophakia is a developmental anomaly characterized by a spherically shaped lens of reduced size and diameter (Fig. 36.1). It can occur as an isolated autosomal recessive disorder with mutations in the *LTBP2* gene identified in one pedigree[9] or as part of a known systemic disorder such as Weill–Marchesani syndrome (WMS) or homocystinuria[10] (discussed later). It has also been described in other more global ocular developmental disorders such as aniridia and Axenfeld–Rieger syndrome.[11] It is often accompanied by ectopia lentis and glaucoma (Fig. 36.2).

Lens duplication

Duplication of the lens is a very rare anomaly associated with corneal metaplasia, uveal coloboma, and cornea plana.[12] It is presumed that metaplastic changes in the surface ectoderm prevent normal lens placode formation and thus lead to multiple lens vesicles.

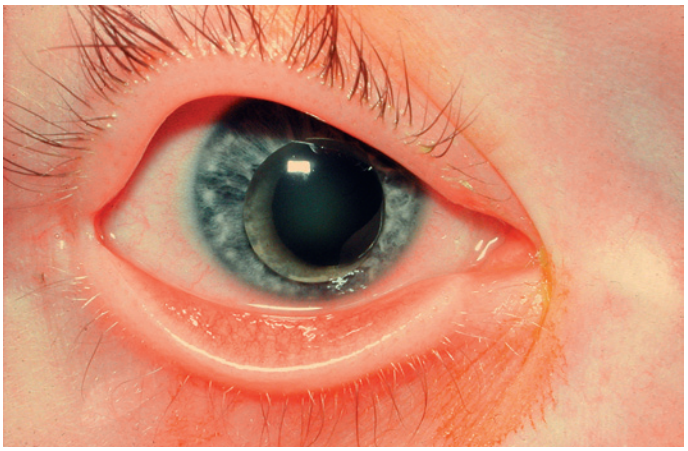

Fig. 36.1 Weill–Marchesani syndrome. Microspherophakia with anterior dislocation.

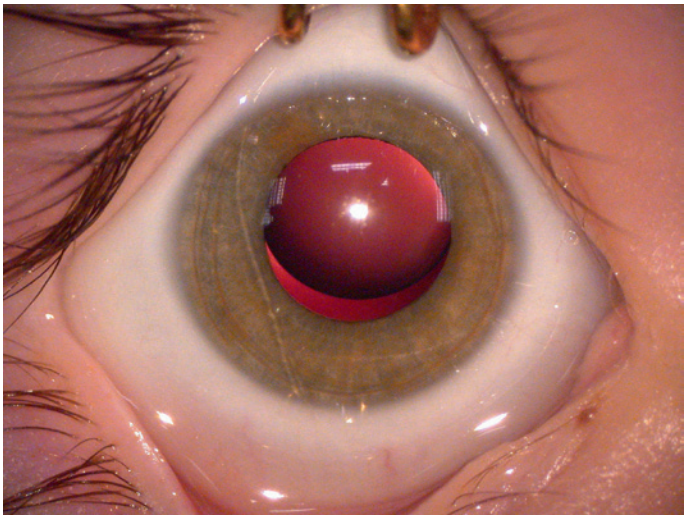

Fig. 36.2 Weill–Marchesani syndrome. Microspherophakia and upward lens subluxation.

Lens coloboma

Lens coloboma (Fig. 36.3) occurs in areas of the lens where there is a failure of zonular development. Scalloped defects in the lens edge demarcate areas of absent zonules. They may occur unilaterally as an isolated anomaly or bilaterally as part of a uveoretinal coloboma phenotype. Lens colobomas may be seen secondary to zonular damage by a congenital ciliary body tumor medulloepithelioma.[13] A localized opacity is often found in the region of the lens coloboma.

Lenticonus and lentiglobus

Lenticonus (Figs 36.4–36.6) and lentiglobus are developmental malformations of the anterior or posterior lens surfaces. Lenticonus is a conical defect and lentiglobus a spherical defect. However, distinguishing lenticonus from lentiglobus can be difficult clinically; accordingly, there has been significant overlap in the use of these terms in the literature. Therefore, the laterality of the defect, and especially its anterior or posterior location, are of greater clinical utility than the defect's conical or spherical morphology. Broadly, posterior

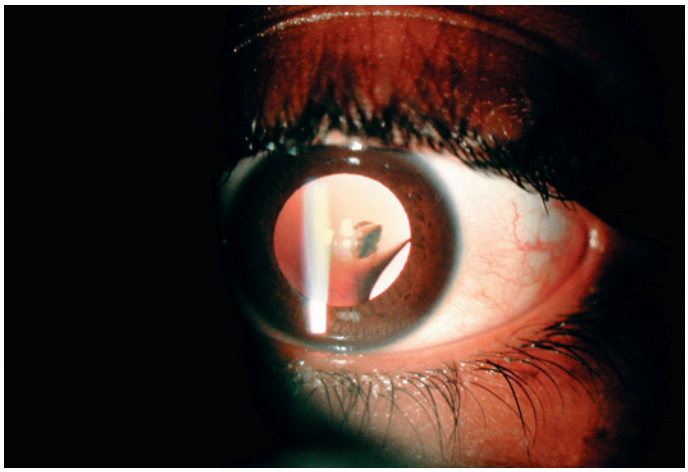

Fig. 36.3 Lens coloboma. Note small cataract adjacent to the coloboma. *(Patient of Dr S. Day.)*

surface abnormalities are more common than anterior surface anomalies and all are usually axial. The resulting refractive error through the central lens is often much more myopic and astigmatic than through the peripheral lens.

Posterior lentiglobus is possibly more common than lenticonus and is usually unilateral.[14] Most cases (95%) are not associated with systemic or other ocular anomalies. When unilateral, there is usually little evidence of a genetic cause. By contrast, bilateral posterior lentiglobus more often has a genetic cause, can be inherited as an X-linked or an autosomal dominant trait,[12] and is occasionally associated with microcornea, Duane syndrome, and anterior lenticonus. The associated cataract is thought to be caused by mechanical stretching of lens fibers.

Posterior lenticonus, like posterior lentiglobus, when unilateral is rarely genetic in origin and can be seen in the presence of a persistent hyaloid artery remnant (see Fig. 36.6). Bilateral posterior lenticonus is more commonly associated

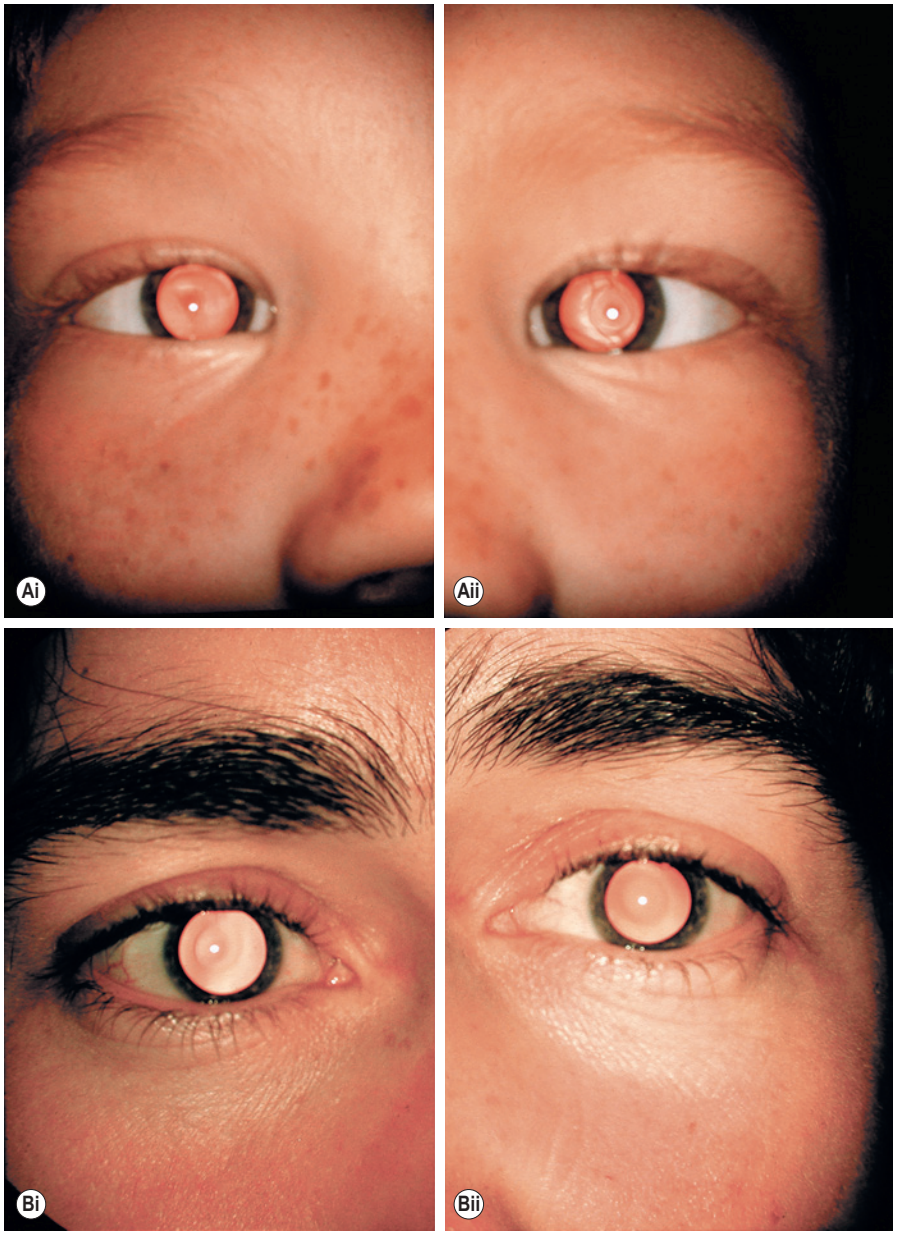

Fig. 36.4 Lenticonus. (A) Although the reflex is a dynamic phenomenon seen on retinoscopy, it can be seen here as a static change in the homogeneity of the red reflex. (B) Mother of patient in (A). Posterior lenticonus is more frequent in boys and may be X-linked.

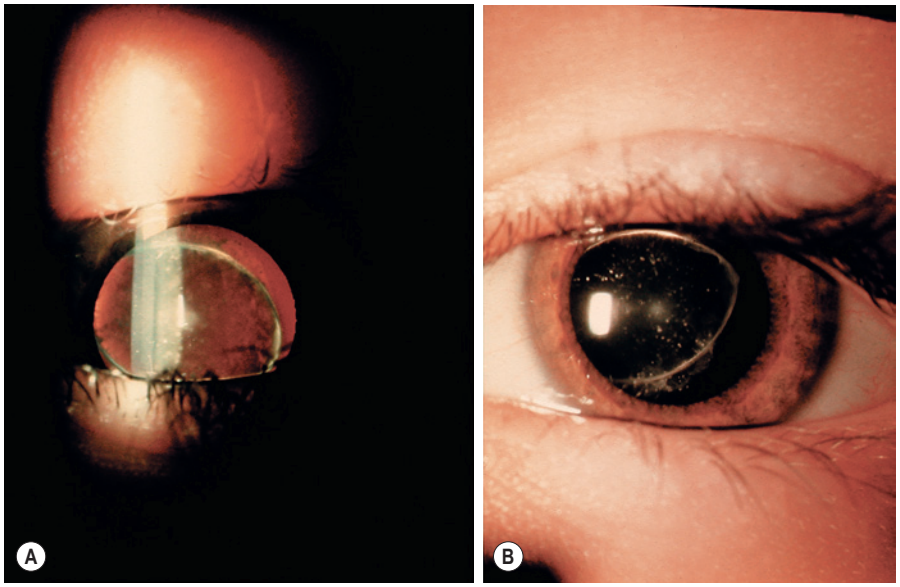

Fig. 36.5 (A) Lenticonus with posterior extension and cataract formation occurring in a healthy girl. (B) Operative photograph with retroillumination on the left showing the defect in the posterior capsule (same patient).

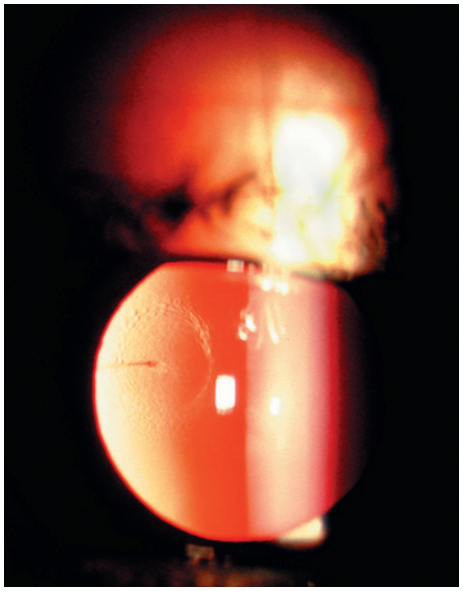

Fig. 36.6 Lenticonic area on the posterior surface of the lens associated with a hyaloid remnant. The presence of the persistent hyaloid remnant suggested that it was important in the pathogenesis.

with an underlying genetic etiology and has been described in many congenital cataract pedigrees, Down syndrome, Pai syndrome,[15] and Pierson syndrome.[16] It can be also be inherited as an isolated autosomal dominant or X-linked recessive trait (see Figs 36.4 and 36.5).

Anterior lentiglobus has rarely been described in the literature and anterior lenticonus is more commonly described. It occurs secondary to an abnormally thin anterior capsule centrally. Approximately 90% of bilateral cases are seen in association with Alport syndrome, which is a rare basement membrane disorder caused by anomalous type IV collagen and is characterized by progressive renal failure, sensorineural hearing loss, and ocular abnormalities. Alport syndrome is often X-linked (85%), although it can be autosomal recessive (10%) or dominant (5%). Mutations have been identified in *COL4A1–6* genes on three different chromosomes, all of which encode type IV collagen. Males with the X-linked form (*COL4A5*) are usually severely affected but females tend to have a mild form, often with only microscopic hematuria and normal renal function. The ocular abnormalities include: a dot-and-fleck retinopathy (85%), peripheral retinal thinning, anterior lenticonus (25%), corneal opacity, and, more rarely, a posterior polymorphous corneal dystrophy and giant macular hole.[17]

Persistent fetal vasculature (PFV)

Persistence of components of the fetal lens vasculature system (PFV) can lead to persistent pupillary membranes, epicapsular stars, iridohyaloid blood vessels, persistence of the posterior fetal fibrovascular sheath, posterior lenticonus, and Mittendorff dots (see Chapter 37).

Ectopia lentis

Ectopia lentis or lens dislocation is most commonly due to disorders that disrupt the fibrillin-rich microfibrils of the ciliary zonule, affecting its structure and function. Displacement of the lens can range from subtle subluxation, to total dislocation due to breakage of most or all of the zonular attachments. Ectopia lentis usually results in reduced visual acuity due to induced refractive error in the first instance. The most common causes of ectopia lentis include Marfan syndrome and related type-1 fibrillinopathies, trauma, homocystinuria, and Weill–Marchesani syndrome. In addition to the refractive effects, subluxation or luxation can lead to sectoral shallowing of the anterior chamber, subluxation of the lens into the anterior chamber, and glaucoma.

Marfan syndrome and the type-1 fibrillinopathies

The fibrillin-1 gene (*FBN1*, ch:15) codes for the FBN1 protein, which is a major constituent of microfibrils and the lens zonules. As detailed above, the fibrillin glycoproteins include FBN1 to 3. Types FBN2 and the newly described FBN3 are important for early ocular development, whereas FBN1 is a major constituent of the mature lens zonule. FBN1

interacts closely with many of the other proteins implicated in ectopia lentis, including ADAMTS10, ADAMTS-like proteins, and the TGFβ complex. Mutations in the *FBN1* gene result in the connective tissue disorder Marfan syndrome (MFS), as well as a group of related clinical phenotypes collectively termed the type-1 fibrillinopathies.[18] These range from the severe neonatal MFS (usually fatal by the age of 2 years) to isolated "simple" ectopia lentis. Autosomal dominant Weill–Marchesani syndrome type 2 has been described due to a *FBN1* mutation in one pedigree. Over 2000 unique mutations have been identified in the *FBN1* gene but, with the exception of a clustering of mutations associated with neonatal MFS, there is no clear genotype–phenotype correlation. MFS has an incidence of approximately 1 in 10,000 births and is an autosomal dominant disorder, although recessive inheritance has been rarely described. Diagnosis is made using the Ghent criteria, which incorporate major clinical findings with family history and the results of molecular studies. Associated skeletal abnormalities include tall stature (Fig. 36.7), arachnodactyly (Fig. 36.8), chest wall deformities, and scoliosis. The typical cardiac abnormalities are dilation of the aortic root, mitral valve prolapse, and aortic aneurysm. Ocular findings include ectopia lentis in 60%, axial myopia, corneal flattening, cataract, hypoplasia of the ciliary muscle and iris, open angle glaucoma, and strabismus. The lens in MFS can sublux in any direction, but most commonly upward (Fig. 36.9). Zonular fibers in ectopia lentis are fewer in number, thin, stretched, and irregular in diameter.[19] The insertion and ultrastructure of zonular fibers

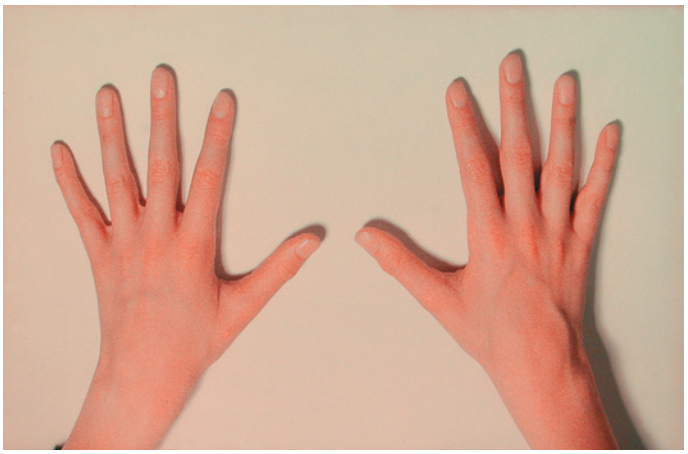

Fig. 36.8 Marfan syndrome. Arachnodactyly.

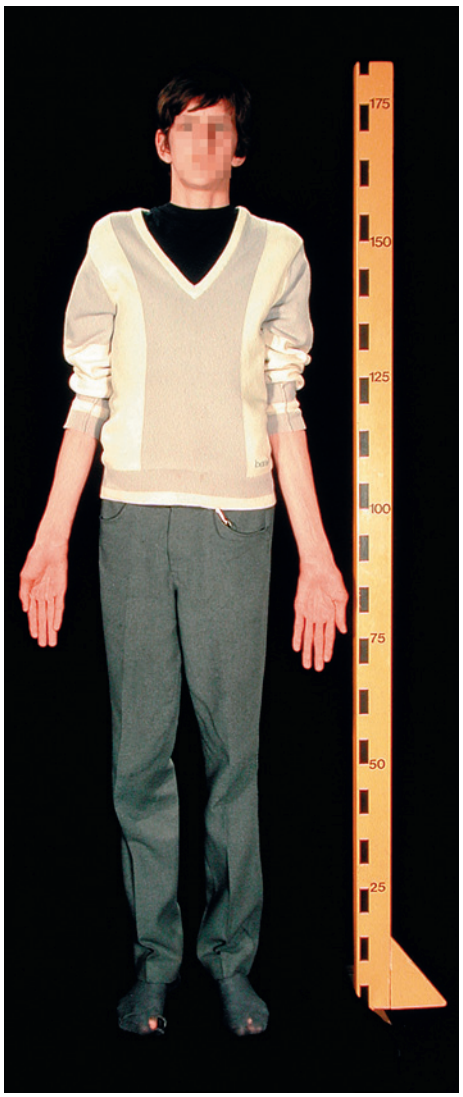

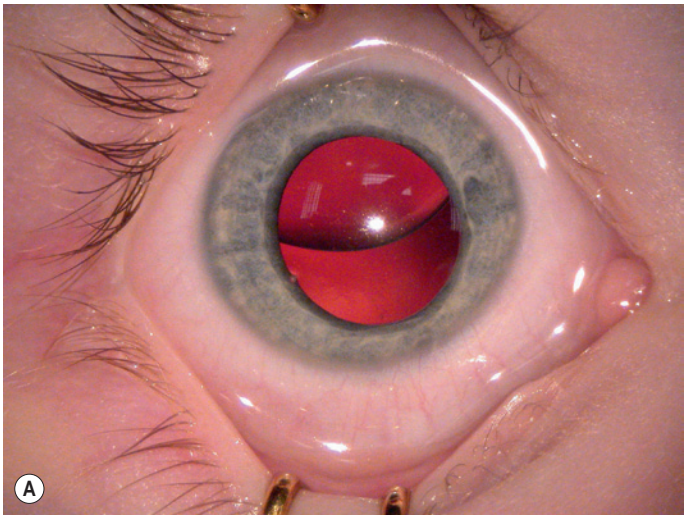

Fig. 36.7 Marfan syndrome. At 15 years of age he is 1.75 m in height. He has very long limbs, arachnodactyly, and pectus excavatum.

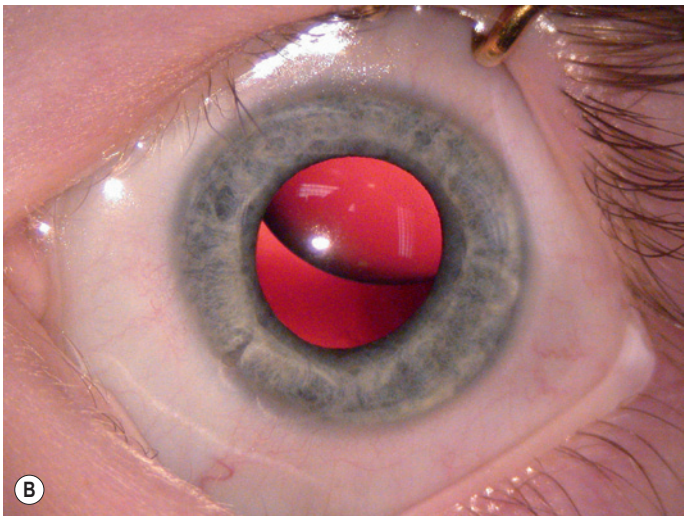

Fig. 36.9 Marfan syndrome. Upward lens subluxation in the right (A) and left (B) eyes of the same child.

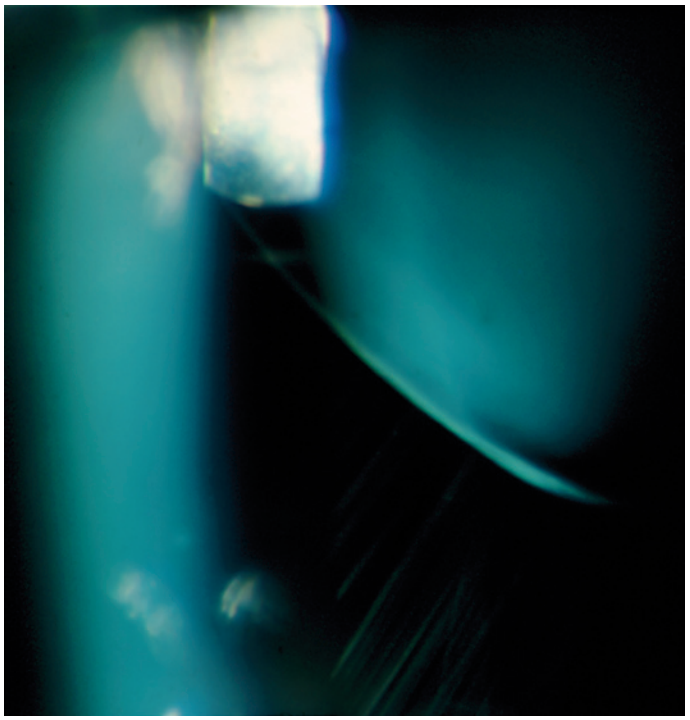

Fig. 36.10 Marfan syndrome. Dislocated lens with intact stretched zonules. The shadow on the left is the slit beam (out of focus) passing through the cornea.

attached to the lens capsule in MFS is also abnormal. Reduced synthesis of fibrillin-1 combined with proteolytic degradation of microfibrils accounts for the variable and occasionally progressive nature of some of the clinical manifestations of MFS.[19]

Zonular fibers typically elongate (Fig. 36.10) and accommodation may be affected. Progression of subluxation is relatively unusual in older childhood and in our experience rarely requires surgical intervention after the age of 10.

Mutations in the *TGFβR2* and *TGFβR1* genes have also been described in MFS-like disorders, which, in some cases, lack the ocular phenotype of MFS and are referred to as MFS-related connective tissue disorders under the heading of the TGFβ signallopathies. *FBN2* mutations can cause Beals syndrome, which has many overlapping clinical features with MFS but, importantly, lacks the ocular features, including ectopia lentis.

Similarly, there is clinical overlap with disorders caused by another FBN1-interacting protein, *ADAMTSL4*. Mutations in this gene are a common finding in pedigrees with apparent isolated ectopia lentis[20] and have been described in patients with ectopia lentis et pupillae (ELeP).[21]

Homocystinuria

Most homocystine, an intermediate compound of methionine degradation, is remethylated to methionine. It is not ordinarily detectable in plasma or urine. The accumulation of homocysteine and its metabolites (homocystinemia or homocystinuria) is caused by disruption of any of the three interrelated pathways of methionine metabolism:

- Type 1: deficiency in the enzyme cystathionine beta-synthase (CBS).
- Type 2: defective methylcobalamin synthesis.

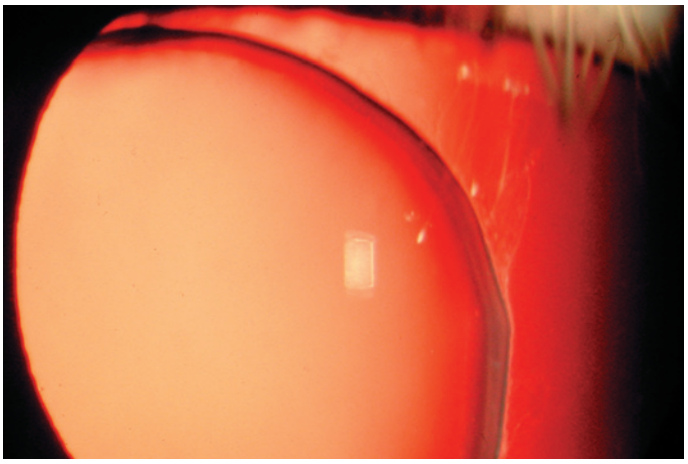

Fig. 36.11 Homocystinuria. Inferiorly dislocated lens with broken, short, and curly zonules. In homocystinuria, the zonules tend to break in their central portion and curl up adjacent to the lens.

- Type 3: abnormality in the enzyme methylene tetrahydrofolate reductase.

Homocystinemia is a milder clinical entity than homocystinuria and describes raised plasma levels of homocysteine. It is associated with cardiovascular disease. It may occur in the absence of homocysteinuria and can be caused by genetic predisposition ± environmental factors.

Type 1 homocystinuria is the most prevalent inborn error of methionine metabolism and is an autosomal recessive condition. It occurs in 1:300,000 to 1:500,000 live births. It is more common in Ireland, where there is an incidence of 1:52,000. Affected individuals are normal at birth but during early childhood may show neurodevelopmental delay and failure to thrive. Ectopia lentis occurs later, along with osteoporosis, fits, psychiatric disorders, and thromboembolic phenomena. However, diagnostic delay is common. Untreated, 90% of individuals develop progressive ectopia lentis.[22] Slit-lamp examination of individuals with ectopia lentis reveals broken and matted zonular fibers (Fig. 36.11). The lens typically subluxates inferiorly or anteriorly and may cause pupil block glaucoma (Fig. 36.12). Patients with homocystinuria are usually tall with elongated limbs and arachnodactyly. They have fair complexions, blue irides, and a malar flush (Fig. 36.13). Kyphoscoliosis, pectus excavatum, high arched palate, and generalized osteoporosis are also common. Other ophthalmic features include progressive myopia, iridodonesis, cataract, iris atrophy, retinal detachment, central retinal artery occlusion, optic atrophy, anterior staphylomas, and corneal opacities.[23] Early diagnosis and medical treatment significantly improve ophthalmic and non-ophthalmic outcomes.[24] Anesthesia can be complicated by thromboembolic events. Lens dislocation and pupil block glaucoma are common indication for surgery.[23] Heel prick testing for this disorder is performed in many countries and so new, undiagnosed presentations in infancy are rare.

Weill–Marchesani syndrome

Weill–Marchesani syndrome (WMS) is a rare systemic connective tissue disorder. Features include: microspherophakia, ectopia

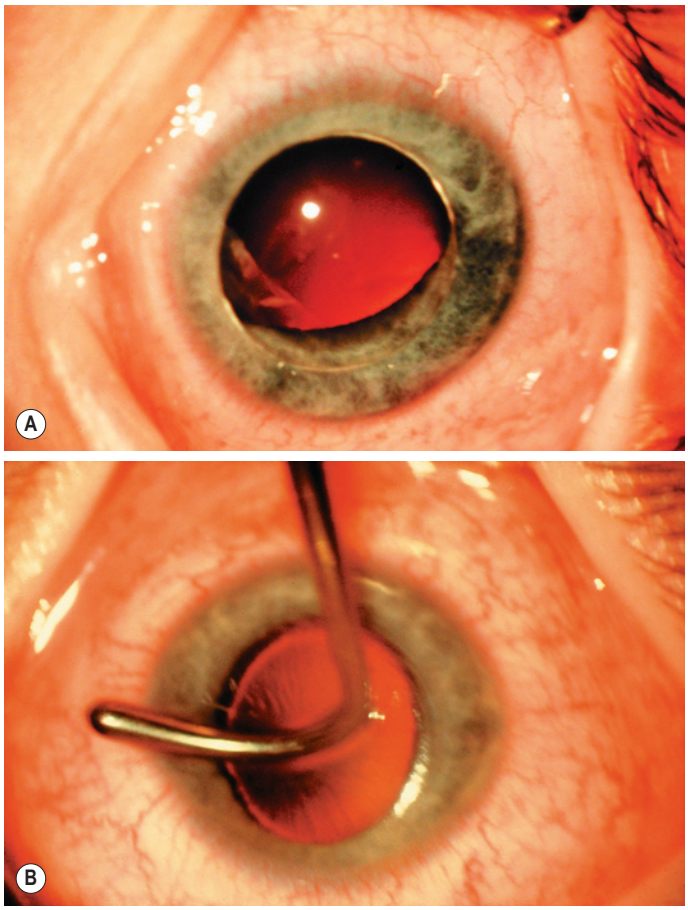

Fig. 36.12 Homocystinuria. (A) Anterior/inferior dislocation of the lens, which is jammed in the pupil. (B) Homocystinuria with anterior dislocation and glaucoma. The lens is being repositioned under local anesthetic with a strabismus hook.

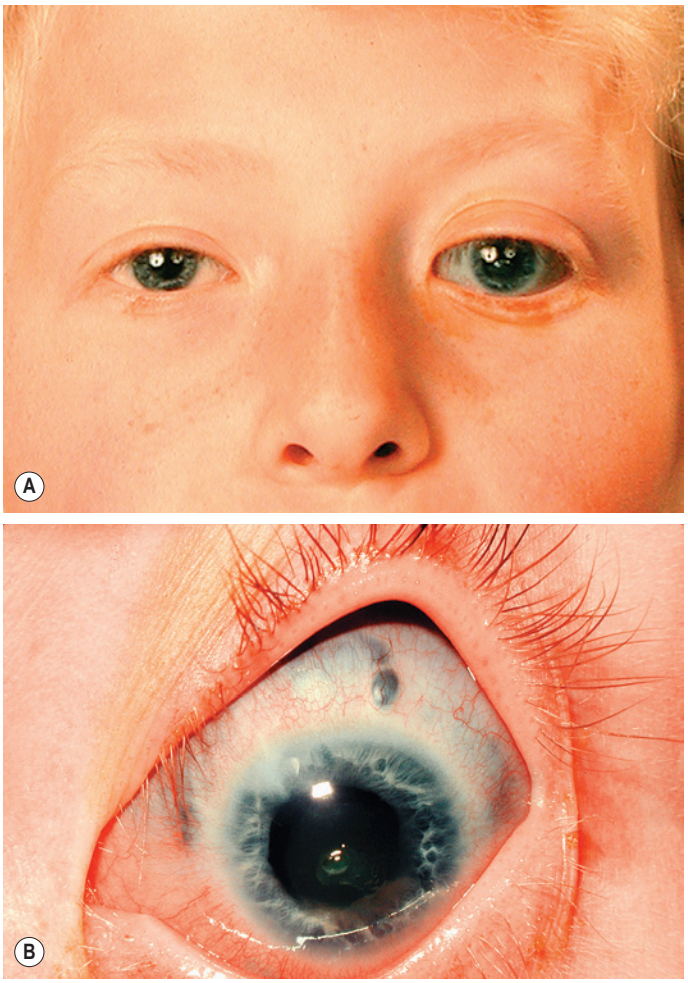

Fig. 36.13 Homocystinuria. (A) Fair-haired boy with chronic glaucoma following unreported anterior dislocation of the lens. (B) Despite his age the left eye had become buphthalmic.

lentis, lenticular myopia, and glaucoma in association with short stature, brachydactyly, and joint stiffness. The lens commonly dislocates into the anterior chamber, causing pupil block glaucoma. Presenile vitreous liquefaction is also reported.[25] It is usually an autosomal recessive disorder, which can be caused by mutations in the *ADAMTS10* gene.[26] Autosomal dominant WMS has also been described in a pedigree with a mutation in the *FBN1* gene (which more commonly causes MFS). A WMS-like syndrome has also been described in association with a mutation in the *ADAMTS17* gene on chromosome 15.[27] ADAMTS10 and ADAMTS17 belong to a family of proteins called the ADAMTS proteases. A related family of proteins, the ADAMTS-like proteins, includes the ADAMTSL4 protein, the gene which has been found to be mutated in some pedigrees with isolated autosomal recessive ectopia lentis and ELeP. Again, the clinical overlap between these conditions and MFS is explained by the known protein interactions of FBN1, the TGFβ complex, ADAMTS, and ADAMTS-like proteins.

Ectopia lentis et pupillae

ELeP is a rare condition that usually exhibits an autosomal recessive inheritance pattern, although a dominant pedigree has been described.[21] It is closely related to autosomal recessive ectopia lentis. Lenticular and pupillary ectopia occur in opposite directions, resulting in an oval- or slit-shaped pupil. Poor pupillary dilatation, axial myopia, glaucoma, megalocornea, and iris transillumination defects are also described. Membrane formation on the posterior aspect of the iris has been observed both in histologic sections and on ultrasound biomicroscopy and suggests that the pathogenesis of this condition may be mechanical tethering of the pupil by a membranous structure with co-existent zonular disruption.[21] Mutations in the *ADAMTSL4* gene have been identified in some pedigrees with ELeP and some with autosomal recessive ectopia lentis.

Aniridia (see Chapter 33) and congenital glaucoma (see Chapter 38)

Aniridia is rarely complicated by ectopia lentis. This may be secondary to associated advanced infantile glaucoma and buphthalmos. Sturge–Weber syndrome may also cause secondary ectopia lentis by the same mechanism.

Megalocornea

Ectopia lentis (often inferior) in association with megalocornea (in the absence of raised intraocular pressure) has been described. Cataract may co-exist.[28]

Ehlers–Danlos syndrome

Ectopia lentis may rarely occur in association with high myopia in Ehlers–Danlos syndrome.

Trauma

Trauma to the eye may result in zonular damage and ectopia lentis.[29] Rarely this may occur as a result of non-accidental injury.

Sulfite oxidase deficiency and molybdenum cofactor deficiency

These related disorders are rare autosomal recessive inborn errors of sulfite metabolism. The diagnosis is suggested in neonates by the association of seizures, abnormal tone, severe neurodevelopmental delay, and ectopia lentis. Affected children usually die in early childhood.[30]

Xanthine oxidase deficiency

This is a very rare cause of ectopia lentis. It is associated with low serum uric acid levels.

Management of ectopia lentis

The ophthalmologist's primary aims for eyes affected by ectopia lentis are restoration of visual function, avoidance of, or treatment of, amblyopia, and the appropriate management of any complications such as glaucoma. Correction of acquired myopia/astigmatism with simple optical measures is all that is required for many children. However, where there is asymmetrical (or unilateral) ectopia lentis, the use of a contact lens may be necessary to avoid aniseikonia. If the crystalline lens is extensively subluxed, correction of the refractive error of the aphakic zone of the pupil can be attempted; however, in most instances, this degree of subluxation leads to significant lens edge effects, anterior chamber sectoral shallowing, and possible glaucoma.

Bilateral ametropic amblyopia has been reported in up to 50% of individuals with ectopia lentis despite good conservative management.[31] This was found to be particularly evident where the lens edge was adjacent to the center of the pupil but where the visual axis was still primarily phakic. Axial high myopia is common in such cases and is possibly secondary to amblyopia.[32] It has been postulated that early lens surgery may avoid induced axial myopia and the subsequent increased risk of retinal detachment. Posteriorly dislocated lenses may be managed conservatively but should be monitored. Signs of glaucoma, uveitis, or retinal degenerative changes are indications for vitreo-lensectomy. The lens is most likely to dislocate anteriorly in homocystinuria. This is often associated with pupil block glaucoma. Lens repositioning can be carried out after pupillary dilatation by using supine positioning of the patient and allowing gravity to direct the lens posteriorly behind the pupil. In addition, mechanical pressure on the cornea with a squint hook can be used, although this may cause some endothelial damage. The pupil is then miosed (see Fig. 36.12B).

Microsurgical techniques yield very good results following either limbal or pars plana approach lensectomy for ectopia lentis.[32,33] If the limbal technique is adopted, the vitreous cutter should be introduced into the area of greatest subluxation (Fig. 36.14). Aspiration of the lens material from within the capsular bag prior to completing the capsulectomy and anterior vitrectomy ensures lens material is not displaced into the vitreous cavity. Retinal detachment, a frequent problem prior

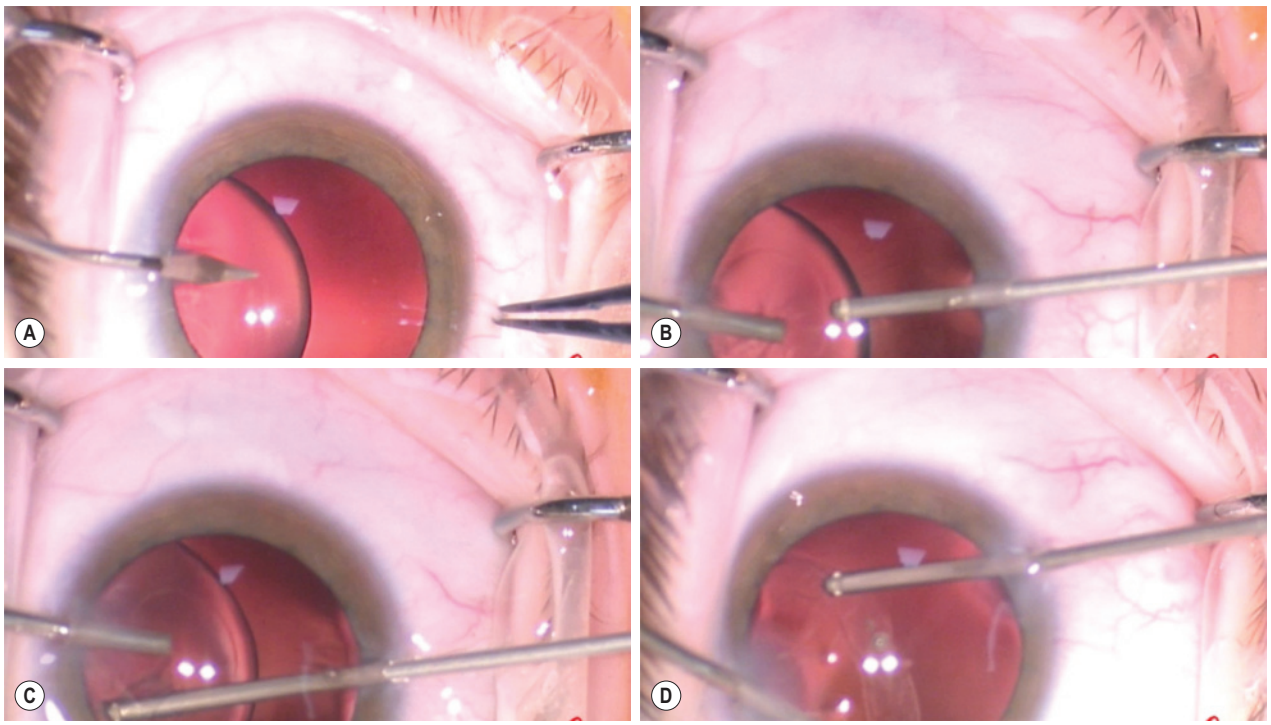

Fig. 36.14 Marfan syndrome: lens surgery. (A) A 23G knife is used to make a corneal incision and to pierce the lens capsule. (B) After completion of a small anterior continuous curvilinear capsulorhexis (CCC) using microrhexis forceps and a bimanual technique, a 23G cutter is inserted into the lens. (C) All of the lens material is aspirated. (D) A 23G vitrector is used to clear the remains of the capsule and perform a small anterior vitrectomy.

to lensectomy procedures using vitreous-cutting instruments, is now a rare complication.[34] Many centers will now use a 23G technique. Contact lens or spectacle correction of subsequent aphakia is effective and relatively straightforward for many children. In one large study, the best-corrected visual acuity of approximately 90% of eyes with ectopia lentis was improved by 2 Snellen lines or more following lensectomy.[34]

YAG laser zonulysis is an alternative technique for moving a lens edge out of the pupillary axis[35] and allows subsequent aphakic correction. However, this technique is now rarely employed.

The use of intraocular lenses (IOLs) for treatment of aphakia following lensectomy for ectopia lentis has been a controversial topic. Techniques include sclerally fixed IOLs, iris claw lenses, iris clip lenses, and "in the bag" surgery utilizing capsular anchoring devices or sutured CTRs.[36–39] Reported complications include corneal endothelial cell loss (an average of 14% in the early postoperative period in one study), suture breakage, and/or lens decentration (33% within a few years follow-up in one study) and visual axis opacification requiring surgery for "in the bag" techniques (70% of cases in some studies). Most studies describing techniques utilizing IOLs in the management of ectopia lentis have little long-term outcome data and tend to describe non-inferiority to aphakia corrected with contact lenses rather than superior visual outcomes.

However, in recent years, the use of anteriorly placed iris claw lenses has been gaining popularity. Data from a number of groups have shown good results in children, with small case series reporting over 10-year follow-up.[37,40,41] Complications requiring explantation or replacement occur, but are rare. The use of iris claw lenses in children following ocular trauma and in aphakic adults is well described, but there are no large, long-term case series in children following surgery for non-traumatic ectopia lentis. Concerns about long-term endothelial damage in already abnormal pediatric eyes, compounded by a lack of specular microscopy technology suitable for young children, limits the more widespread use of these IOLs for children. Posterior fixation of iris claw lenses has been described[42] in an attempt to minimize long-term endothelial damage, but this approach can be technically more challenging and is associated with iris pigment cell loss. It is rarely employed in children.

Given the abnormal ocular morphology in children with ectopia lentis, the lack of large, long-term case series, and the reported complications with IOLs, many pediatric ophthalmic surgeons continue to prefer the traditional gold standard for management of children with significant ectopia lentis requiring surgery, i.e. contact lenses/spectacles to treat aphakia following lensectomy. However, concurrent (or subsequent) insertion of an iris claw IOL is now a well-accepted technique in some centers, and continues to gain popularity in others.

Incidence

Cataracts, which are opacities of the crystalline lens, are an important problem in children worldwide. The incidence varies, but in the UK the adjusted cumulative incidence at age 1 year is 2.49/10,000, increasing to 3.46/10,000 by age 15 years.[1] Bilateral cataracts are more common than unilateral.

Detection

Because of visual deprivation with both unilateral and bilateral cataracts, successful management requires early detection and referral for treatment. The red reflex should be assessed by direct ophthalmoscopy in the newborn nursery and at well-child check-ups. If an abnormality is detected, referral should be made to an ophthalmologist. Pupillary dilation may be necessary to detect some incomplete cataracts.

Children with visually significant unilateral cataracts often present with strabismus and dense amblyopia. However, visual behavior will usually be unaffected by a unilateral cataract, and for this reason the parents may not be aware of it. In contrast, dense bilateral cataracts are usually associated with impaired visual behavior (Fig. 37.1). If nystagmus develops, visual prognosis is worse, although it may be reversed by prompt treatment.[2]

Morphology

The morphology of cataracts offers important clues to their age of onset and visual prognosis. In addition, it provides insights into the etiology of a cataract. When possible, a slit-lamp examination is invaluable in identifying the morphology. Refinements in the morphology can be obtained intraoperatively.[3] The morphology is largely determined by the timing and nature of the insult and the anatomy of the lens (Box 37.1).

Some types of cataracts have a better prognosis than others. For example, anterior polar (Figs 37.2 and 37.3), lamellar (Fig. 37.4), and posterior lentiglobus (Figs 37.5 and 37.6) cataracts are associated with the best visual prognoses, whereas nuclear (Fig. 37.7), and posterior polar (Fig. 37.8) cataracts have poorer visual prognoses.[4] Acquired cataracts generally have a more favorable visual prognosis than congenital cataracts.

Certain types of cataracts are frequently associated with other ocular abnormalities. For example, nuclear cataracts are often associated with microphthalmos (see Fig. 37.7) while anterior polar cataracts (see Figs 37.2 and 37.3) are more commonly associated with astigmatism. Partially reabsorbed cataracts in an infant boy are suggestive of Lowe syndrome or Hallermann–Streiff–François syndrome (Fig. 37.9). Wedge-shaped or sectional cataracts (Fig. 37.10) may occur with Stickler syndrome and Conradi syndrome and may be due to lyonization.

Persistent fetal vasculature

The term "persistent fetal vasculature" (PFV) describes a wide spectrum of ocular anomalies that may include a retrolental plaque (Fig. 37.11) in a microphthalmic eye with prominent blood vessels on the iris and lens capsule, a shallow anterior chamber, and elongated ciliary processes.[5] Less commonly, these patients may present with a vascularized pupillary

Box 37.1

Morphological classification of infantile cataract

Anterior polar Central opacity on anterior capsule.

Nuclear Opaque lens material between anterior and posterior "Y" suture that may spread into the surrounding (especially posterior) cortex and often associated with posterior capsule plaque.

Lamellar Anterior and/or posterior cortical opacity not involving the nucleus.

Persistent fetal vasculature A combination of one or more of the following: retrolental membrane with or without visible vessels, patent or non-patent persistent hyaloid vessel, or stretched ciliary processes.

Posterior polar Opacity of the posterior capsule often with opacification of the adjacent cortex.

Posterior lentiglobus Posterior bowing of the posterior capsule with or without a pre-existing posterior capsule defect.

Total Entire lens is white.

Fig. 37.1 Nuclear cataracts. This 4-month-old child presented with nystagmus and bilateral nuclear cataracts. His parents had noted that he would stare at room lights. After bilateral lensectomies and contact lens correction, his nystagmus improved. After long-term follow-up, his best-corrected visual acuity is 20/25 when both eyes are tested together, but 20/50 when each of his eyes are tested separately due to latent nystagmus.

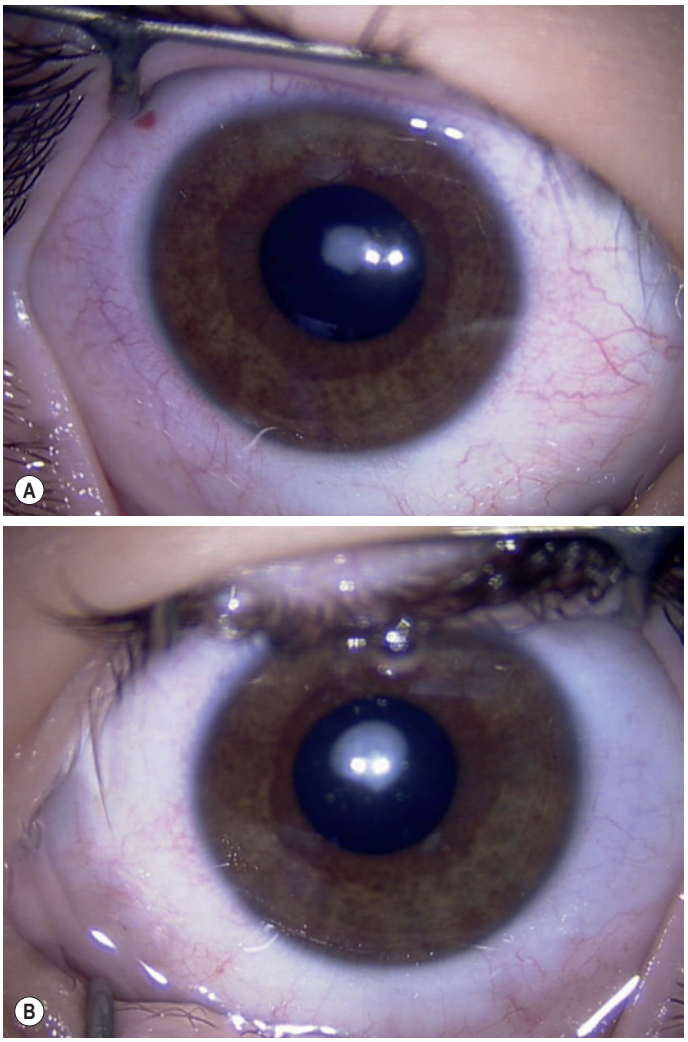

Fig. 37.3 Anterior polar cataracts in the right (A) and left (B) eyes. The child's mother, sister, and brother also had bilateral anterior polar cataracts.

Fig. 37.2 Anterior polar cataract. A small anterior polar cataract generally results in minimal visual deprivation, but may be associated with anisometropic amblyopia.

membrane, microcoria, and an anterior capsular cataract (Fig. 37.12).[6] PFV is almost always unilateral. Over time, the lens may undergo spontaneous absorption or become swollen with loss of the anterior chamber and glaucoma. Usually the posterior pole is normal, but fibrous tissue from the hyaloid remnants may contract, causing peripapillary distortion or tractional retinal detachment. In some cases, the retrolental plaque may be adherent to the peripheral retina and a retinotomy may be required to extricate the retina from the retrolental plaque.

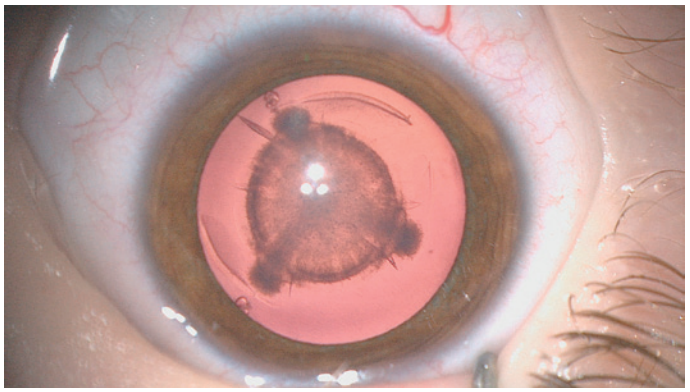

Fig. 37.4 Lamellar cataract.

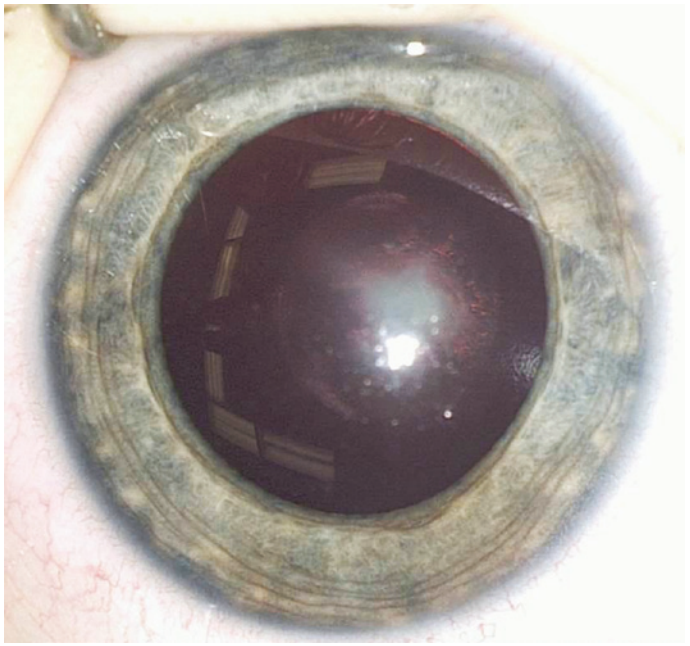

Fig. 37.5 Posterior lentiglobus.

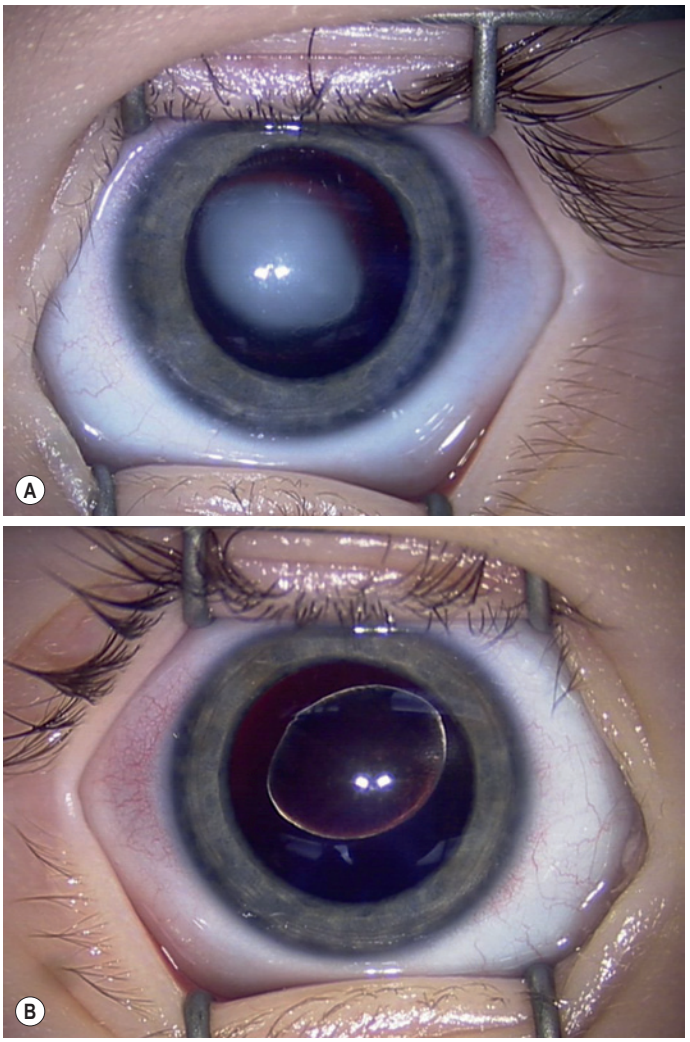

Fig. 37.6 Bilateral posterior lentiglobus. This 8-month-old child presented with lentiglobus in both eyes. (A) There is a dense cataract overlying the lentiglobus in the left eye. (B) The lens cortex is still clear over the lentiglobus in the right eye.

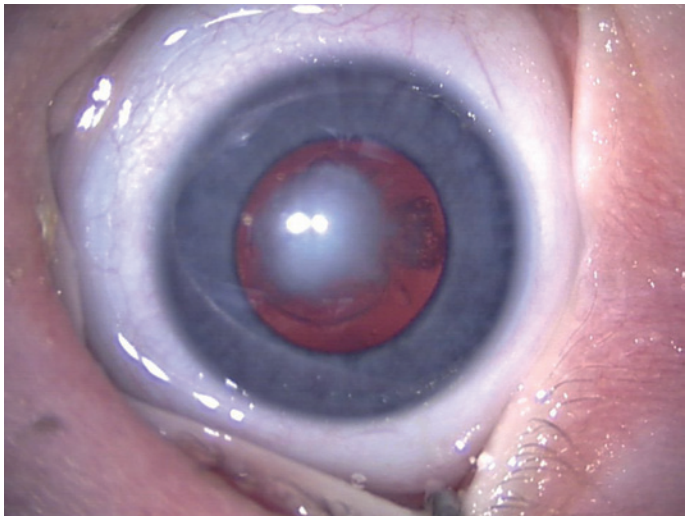

Fig. 37.7 Nuclear cataract. This child underwent a lensectomy and anterior vitrectomy in the right eye when 4 weeks of age. The lens was normal in the left eye. Both eyes had corneal diameters of 10 mm, but the axial length was only 15.74 mm in the right eye compared to 17.32 mm in the left eye.

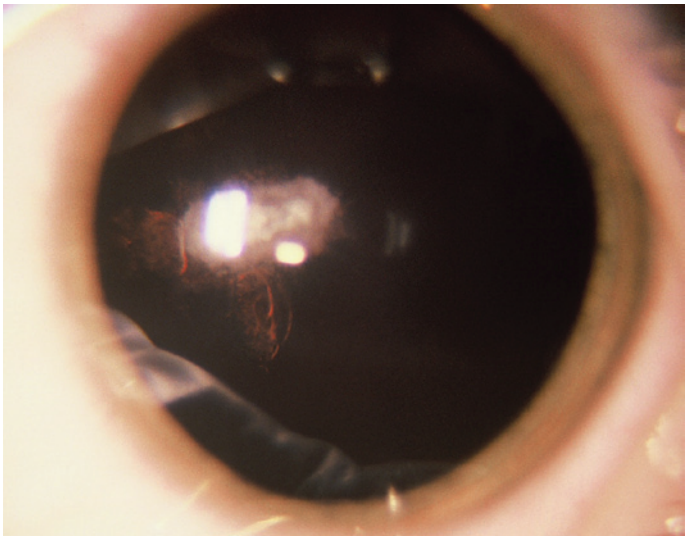

Fig 37.8 Posterior polar cataract. This 4-year-old child was found to have 20/100 visual acuity in his left eye at preschool vision screening. Visual acuity improved to 20/40 with patching therapy. Visual acuity improved further to 20/25 after cataract extraction and intraocular lens implantation.

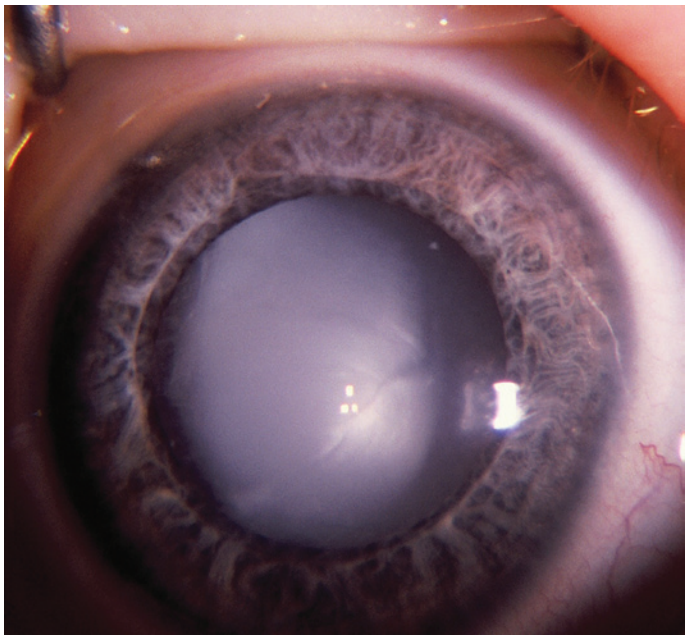

Fig. 37.9 Membraneous cataract. Partially reabsorbed membraneous cataract in a child with Hallermann–Streiff–François syndrome.

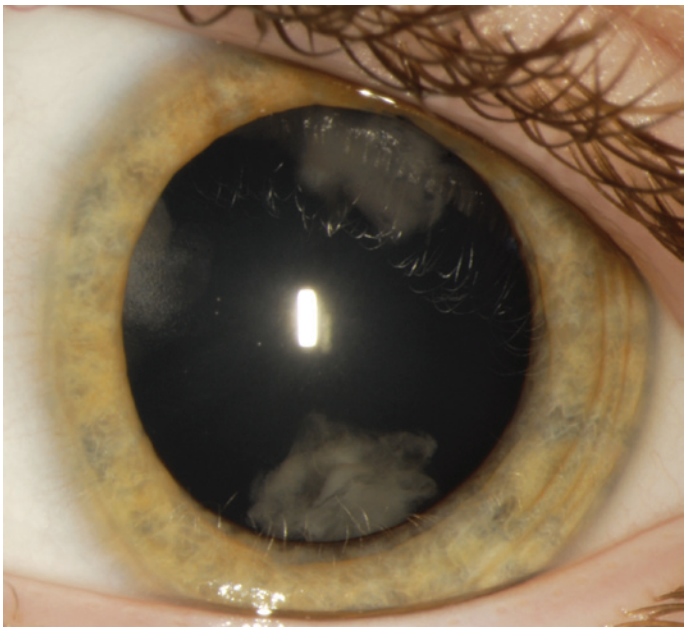

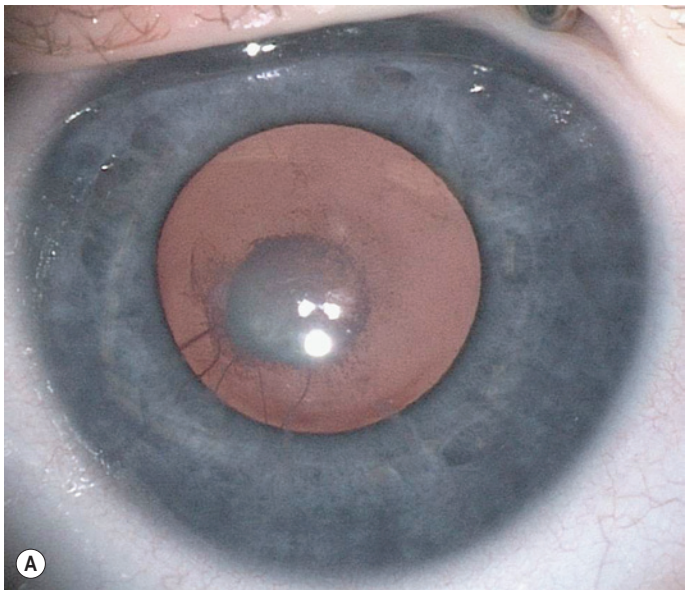

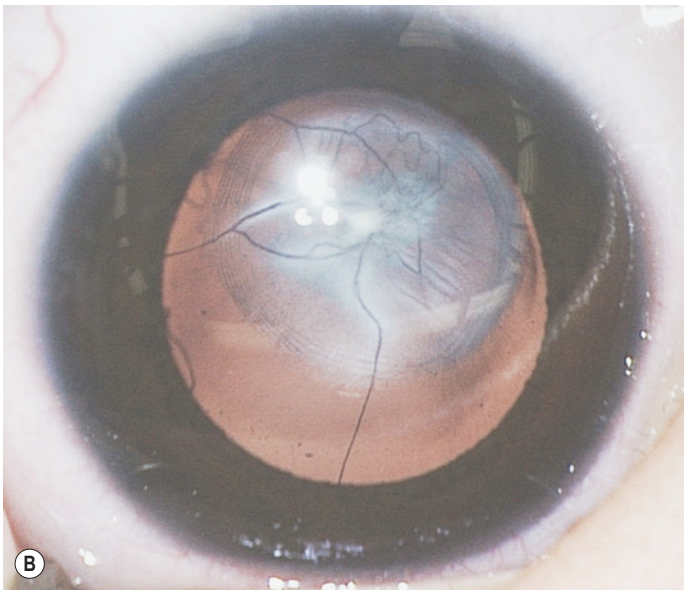

Fig 37.10 Wedge-shaped cataracts. Peripheral wedge-shaped cataracts in a child with autism. Similar appearing cataracts occur in children with Stickler syndrome.

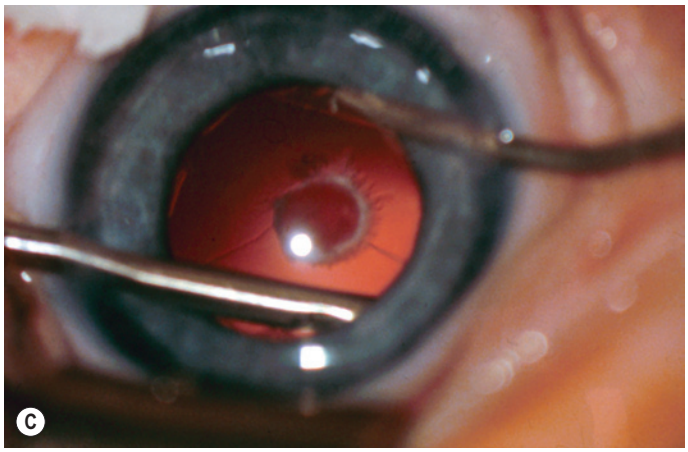

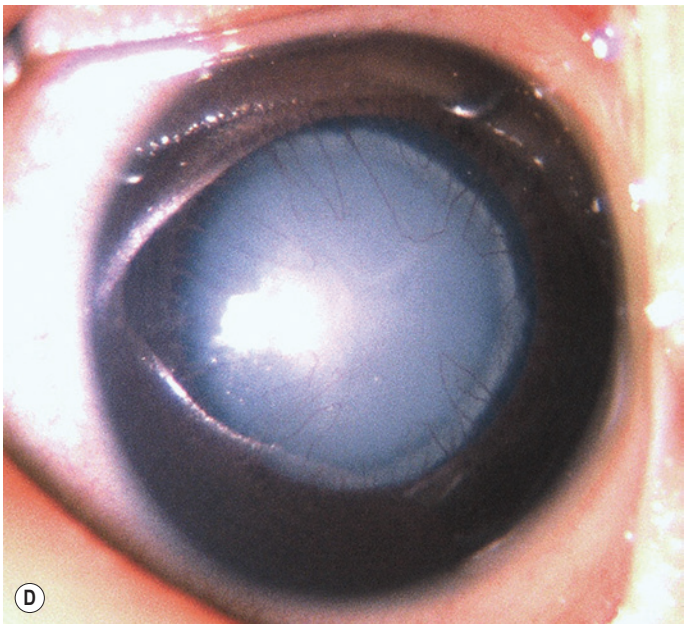

Fig. 37.11 Persistent fetal vasculature (PFV). (A) Mild PFV with hyaloid vessels attached to retrolenticular plaque. (B) Mild PFV with prominent iridohyaloid vessels and a large retrolenticular plaque. (C) Small vascular PRF with a "blood lake" representing a low flow shunt centrally in an eye with PFV.

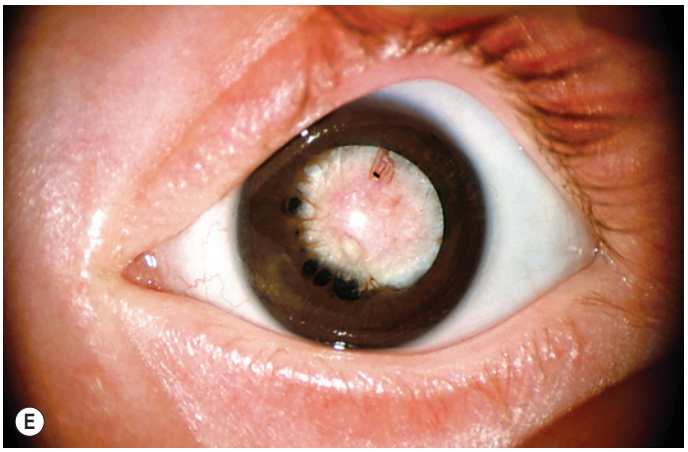

Fig. 37.11 (D) PFV with a dense cataract and hairpin loops. (E) Severe PFV with stretching of the ciliary processes nasally and a dense cataract.

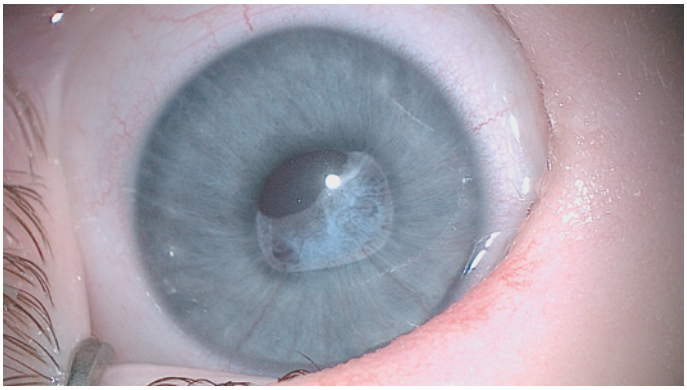

Fig. 37.12 Anterior persistent fetal vasculature. Vascularized pupillary membrane and prominent iridohyaloid vessels in an infant with microcoria.

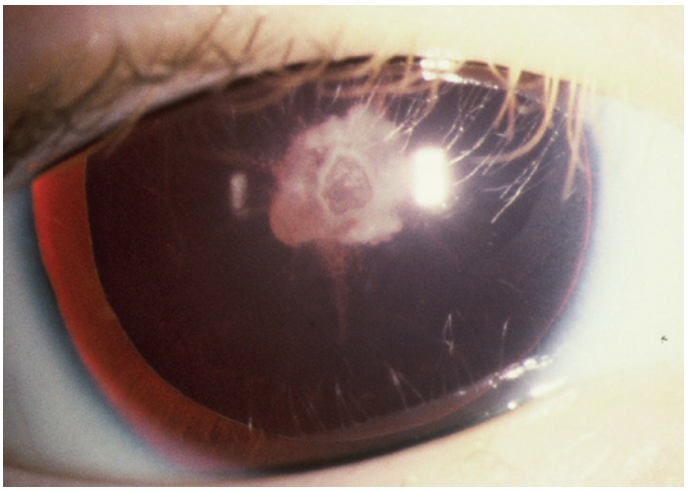

Fig. 37.13 Aniridia. Polar cataracts in a child with aniridia. Macular hypoplasia is the limiting factor for vision in this eye rather than cataract.

Etiology

Bilateral

An etiology can be established in about 50% of children with bilateral congenital cataracts. The most common etiology in Europe and the US is autosomal dominantly inherited cataracts. Less frequently, cataracts can be associated with aniridia (Fig. 37.13), trisomy 21 (Figs 37.14–37.16), Lowe syndrome (Fig. 37.17), Hallermann–Streiff–François syndrome (Fig. 37.18), or a variety of other ocular disorders and syndromes (Box 37.2). Congenital rubella syndrome is a common cause of cataracts where rubella immunization rates are low.[7]

Acquired cataracts may arise secondary to poorly controlled diabetes mellitus, the use of corticosteroids, or external beam radiation therapy (Fig. 37.19).

Unilateral

Many eyes with unilateral congenital cataracts have PFV.[8] They are infrequently associated with systemic disorders. Trauma is the most common cause of an acquired unilateral cataract in a child. On occasion, there is no history of ocular trauma, but iris sphincter tears or a corneal scar can help to establish a traumatic etiology (Fig. 37.20). Cataracts also may develop after laser photoablative therapy for retinopathy of prematurity (Fig. 37.21)[9] or intraocular surgery.

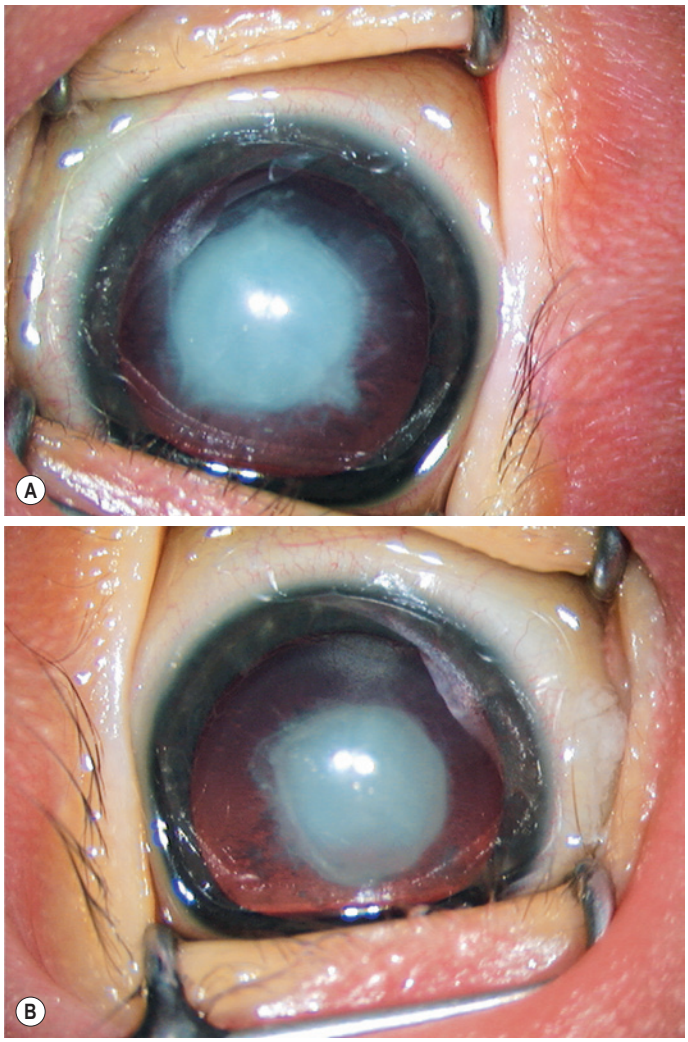

Fig. 37.14 Trisomy 21. Nuclear cataracts in right (A) and left (B) eyes of an infant with trisomy 21.

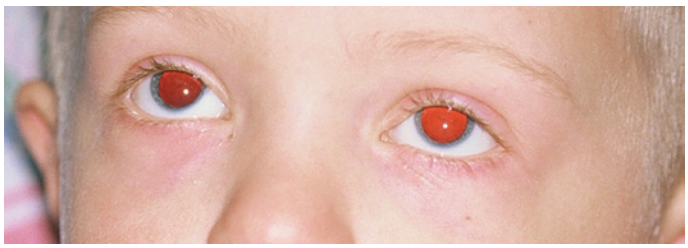

Fig 37.15 Trisomy 21. Lamellar cataracts in a 3-year-old child with trisomy 21.

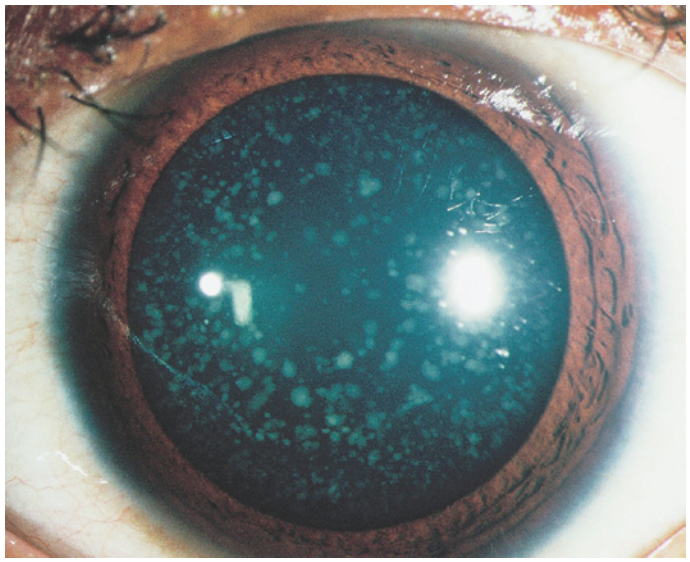

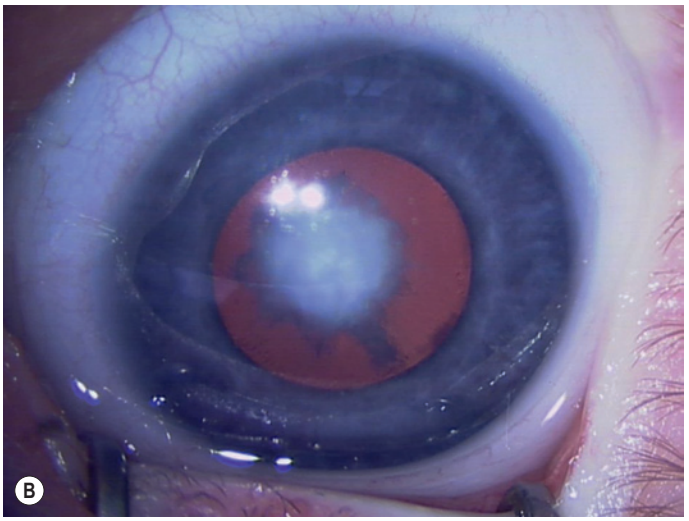

Fig 37.16 Trisomy 21. Cerulean cataract in a teenager with trisomy 21. A similar cataract was present in the fellow eye. Visual acuity was normal.

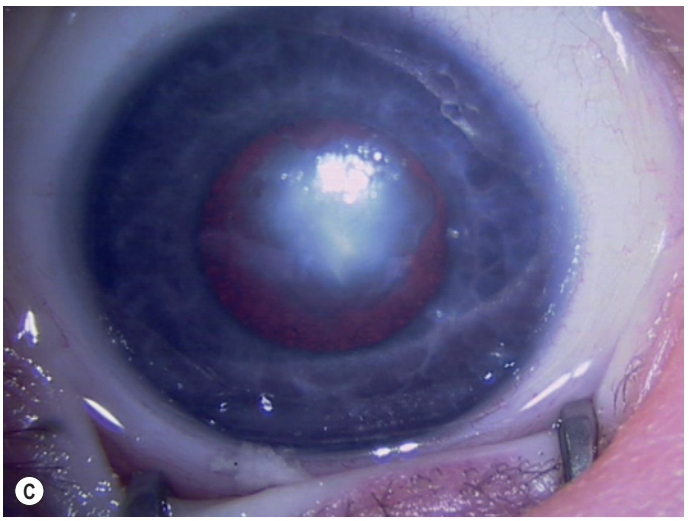

Fig. 37.17 Lowe syndrome. (A) "Chubby" cheeks and rounded forehead. Dense nuclear cataracts in right (B) and left (C) eyes.

Fig. 37.18 Hallermann–Streiff–François syndrome. Note the receding hairline and the vascular, small, red, upturned nose.

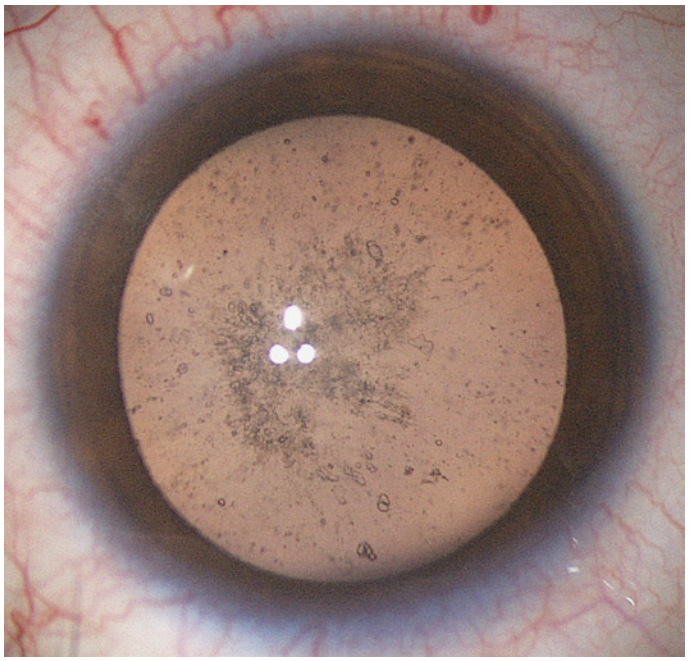

Fig. 37.19 Posterior subcapsular cataract. A posterior subcapsular cataract in a 9-year-old child following external beam radiation therapy for orbital rhabdomyosarcoma.

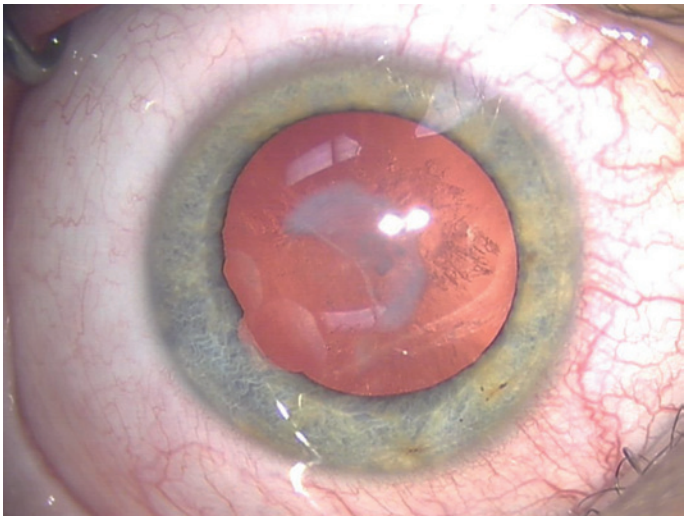

Fig. 37.20 Traumatic cataract. This teenager developed a hyphema, iris sphincter tears, and an anterior subcapsular cataract in his right eye after a paintball injury.

Fig. 37.21 Cataract following diode laser retinal photoablation. This 4-month-old baby developed a dense cataract immediately following diode laser photoablation of the peripheral retina to treat retinopathy of prematurity.

History

The history should determine if there is a family history of childhood cataracts, exposure to corticosteroids or radiation therapy, and ocular trauma. Comorbidities may suggest certain systemic diseases such as diarrhea with cerebrotendinous xanthomatosis.[10] The age the child was first noted to squint or to have leukocoria should be noted. In children with bilateral cataracts, the parents should be asked when they first noted abnormal visual behavior or nystagmus. Reviewing photographs of the child is particularly helpful in children with unilateral cataracts because the abnormal red reflex can be compared to the normal red reflex in the fellow eye (Fig. 37.22). The most informative photographs are taken indoors with a flash and the child looking slightly eccentrically.[11]

Ocular examination

The visual acuity of older children should be assessed using optotypes. In younger children, the ability to fix and follow with each eye should be assessed. The pupillary reflexes should be evaluated for an afferent pupillary defect suggesting associated retinal or optic nerve disease. A slit-lamp examination should

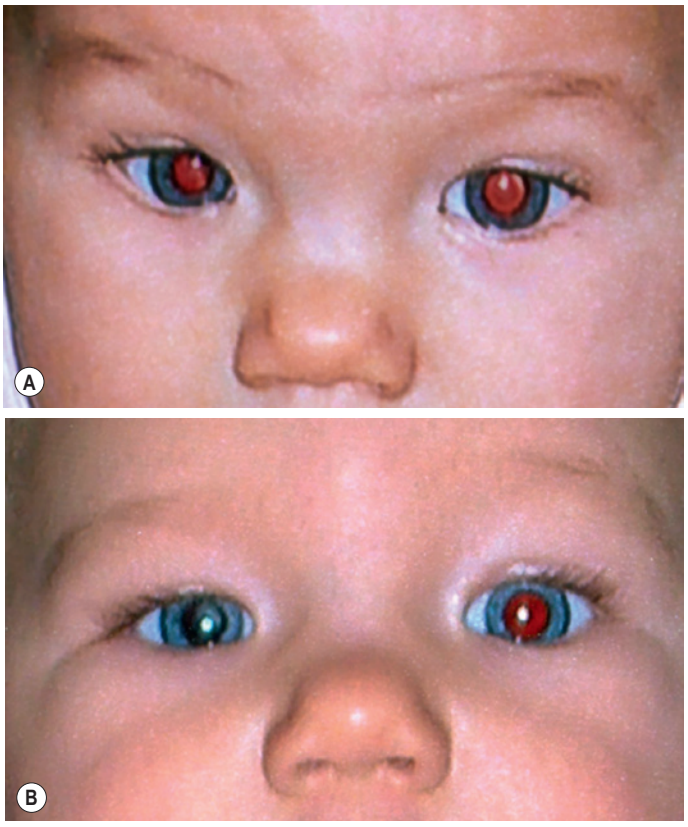

Fig. 37.22 Personal photographs. (A) Personal photograph of an infant taken when 4 months of age showing normal red reflexes in both eyes. (B) Personal photograph of the same infant 2 months later showing loss of the red reflex in the right eye. At the time of cataract surgery, the right eye was found to have a dense central cataract and persistent fetal vasculature.

be performed to evaluate the cornea, iris, and morphology of the cataract. In young children, a hand-held slit lamp is often better tolerated. Slit-lamp examination of other family members can be helpful in establishing a hereditary basis for the cataracts (Fig. 37.23). The retina and optic discs should be assessed using indirect ophthalmoscopy. If the density of the cataract precludes an adequate view of the fundus, a B-scan ultrasound examination should be performed prior to surgery to exclude disease of the posterior segment of the eye that might alter the management of the cataract (e.g. retinal detachment).

Laboratory work-up

A systemic investigation is not usually indicated for children with unilateral cataracts since most are isolated ocular problems, but it can be helpful in selected children with bilateral cataracts. Where rubella vaccination is not routinely performed, infants with bilateral congenital cataracts should be screened for rubella immunoglobulin M (IgM) titers. Male infants with cataracts, hypotonia, problems with weight gain, delayed milestones, and feeding difficulties should be screened for Lowe syndrome by assaying urine amino acids. If urine amino acids are elevated, the diagnosis can be confirmed by testing inositol polyphosphate 5-phosphatase (*OCRL-1*) activity in cultured skin fibroblasts (affected males have <10% normal activity) and *OCRL* gene testing. Children with acquired cataracts and chronic infantile-onset diarrhea should be screened for cerebrotendinous xanthomatosis by measuring plasma levels of cholestanol. Infants with cataracts and failure to thrive should undergo metabolic and genetic testing for galactosemia. While newborn metabolic screening usually diagnoses neonates with galactosemia, false negatives may occur. Children with cataracts and systemic findings

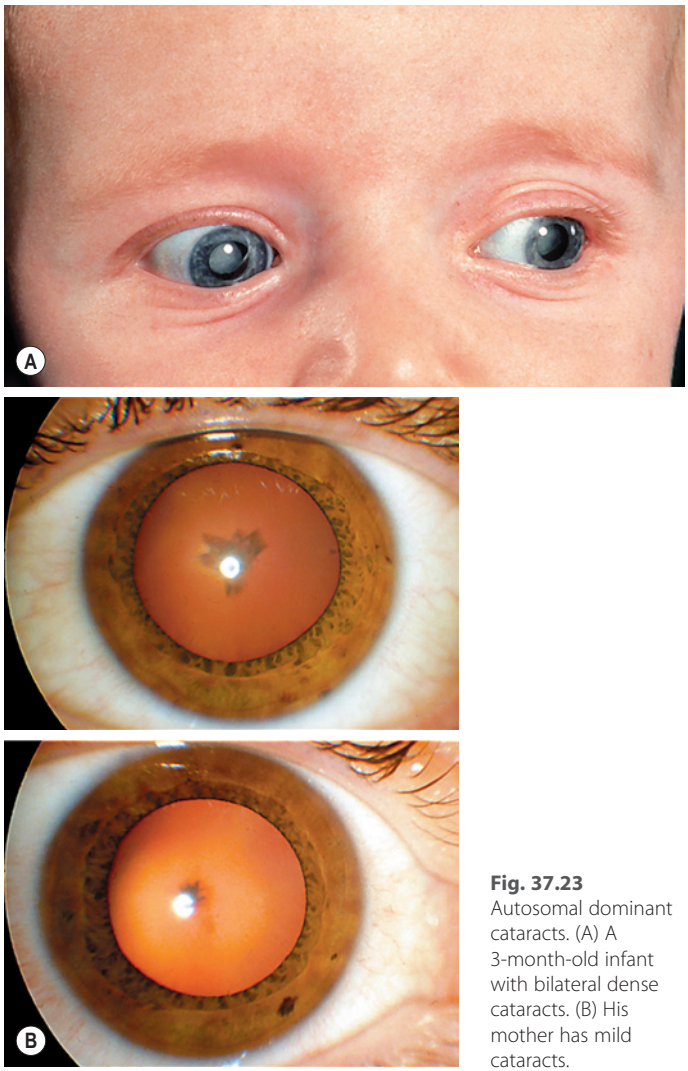

Fig. 37.23 Autosomal dominant cataracts. (A) A 3-month-old infant with bilateral dense cataracts. (B) His mother has mild cataracts.

suggestive of an intrauterine infection should be evaluated by a pediatrician (Fig. 37.24). Children with cataracts and dysmorphic features should be referred to a geneticist. Next-generation sequencing has made it possible to screen children for >100 genes associated with childhood-onset cataracts.[12] Genetic testing will have a more important role in establishing the etiology of congenital and childhood-onset cataracts as these tests become more readily available and affordable. Most autosomal dominant cataracts are caused by mutations of the genes encoding for crystallins and connexins.[13] Since there can be marked heterogeneity in the age of onset and pheonotypes of autosomal dominant cataracts, genetic testing may make it possible to identify asymptomatic children with an increased risk of developing cataracts (Fig. 37.25).

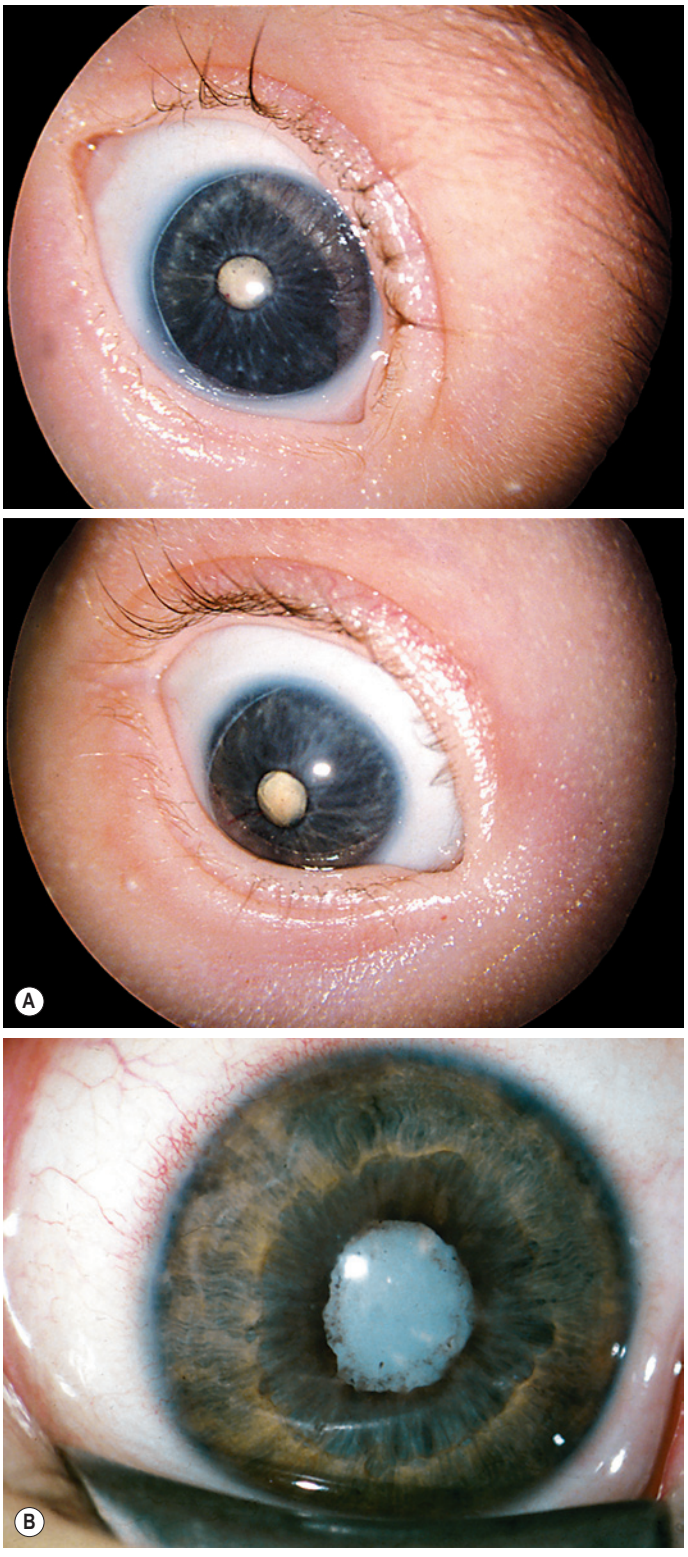

Fig. 37.24 Congenital cataracts with intrauterine infections. (A) Bilateral cataracts and microphthalmos in a child with congenital toxoplasmosis syndrome. (B) Congenital cataract in a child with congenital varicella syndrome. If there is a cataract in a child with an intrauterine infection, it is very likely that there is severe intraocular disease.

Management

Nonsurgical: patching, dilation

Although dense bilateral congenital cataracts should be removed during infancy, incomplete bilateral cataracts should only be removed after a careful assessment of the child's visual

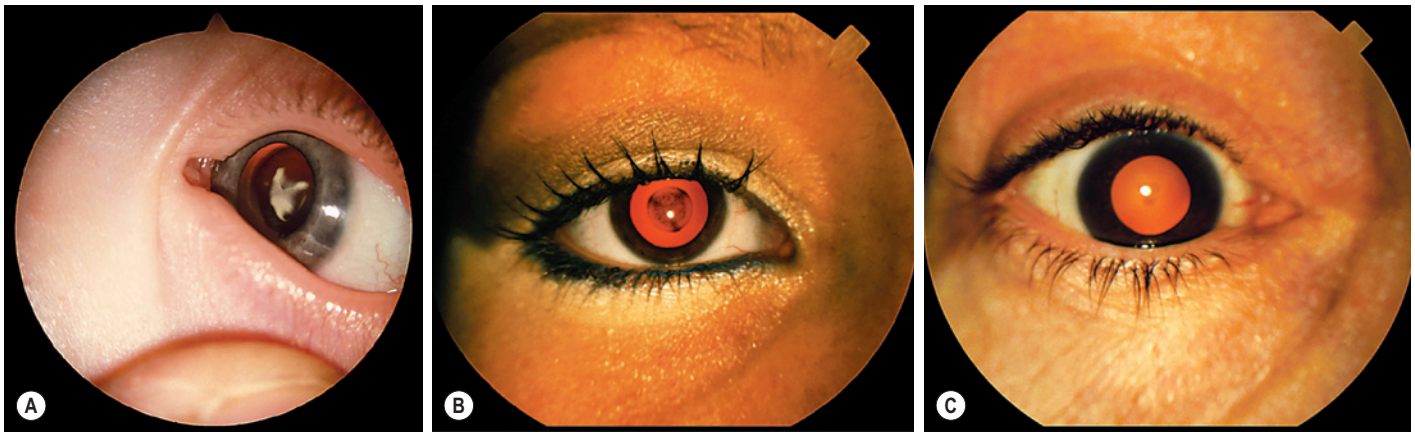

Fig. 37.25 Heterogeneity in autosomal dominant cataracts. (A) A dense central cataract in an infant who presented with leukocoria in both eyes. (B) His asymptomatic mother had mild lamellar cataracts in both eyes. Her vision is good enough to drive a car. (C) His grandmother had visually insignificant lamellar cataracts in both eyes.

behavior (Fig. 37.26). The density rather than the size of the lenticular opacity correlates best with the visual prognosis for children with bilateral incomplete cataracts. Nuclear cataracts, although smaller in size than lamellar cataracts, have a worse visual prognosis. If major blood vessels in the fundus cannot be distinguished through the central portion of the cataract, significant visual deprivation can be expected. If the incomplete cataract(s) is unilateral or asymmetrical, part-time patching therapy of the normal/better eye may be beneficial to improve or maintain vision in the most affected eye. Chronic dilation of the pupils may be helpful in some children with bilateral incomplete cataracts, particularly if the lens opacities are central and the child has miotic pupils. If a cycloplegic drop is used to achieve long-term dilation, bifocals should be used to correct any hypermetropia and to facilitate near vision.

Surgical

Cataract surgery should be performed during infancy if the cataracts are visually significant. Most surgeons prefer to wait until children are 4 weeks of age to perform cataract surgery since there is evidence that surgery during the first month of life increases the risk of an eye developing glaucoma.[14] The optimal time to perform cataract surgery for a full-term infant with a visually significant unilateral congenital cataract is between 4 and 6 weeks of age, and before 8 weeks of age if the cataracts are bilateral. For premature infants, cataract surgery is usually deferred until the child has a postmenstrual age of at least 40 weeks, but other comorbidities may result in the cataract surgery being delayed until a later age. For children with bilateral cataracts, surgery on the second eye should not be performed more than one week after the first eye to minimize the risk of amblyopia developing in the second eye. Immediate sequential bilateral cataract surgery should be considered for infants with comorbidities that increase the risk of general anesthesia.[15] However, parents should be informed that this increases the risk of bilateral endophthalmitis. Precautions should be taken to reduce this risk such as using different trays of instruments for each eye, disposable cannulas, re-draping between eyes, and using different lots of irrigating solution and medications for each eye.

Surgical techniques

In infants, cataract surgery should be performed using a closed eye system. A scleral tunnel, limbal, or clear corneal incision should be created superiorly to introduce a 20- or 23-gauge vitrector and a lateral incision should be created at the limbus for inserting an infusion cannula into the

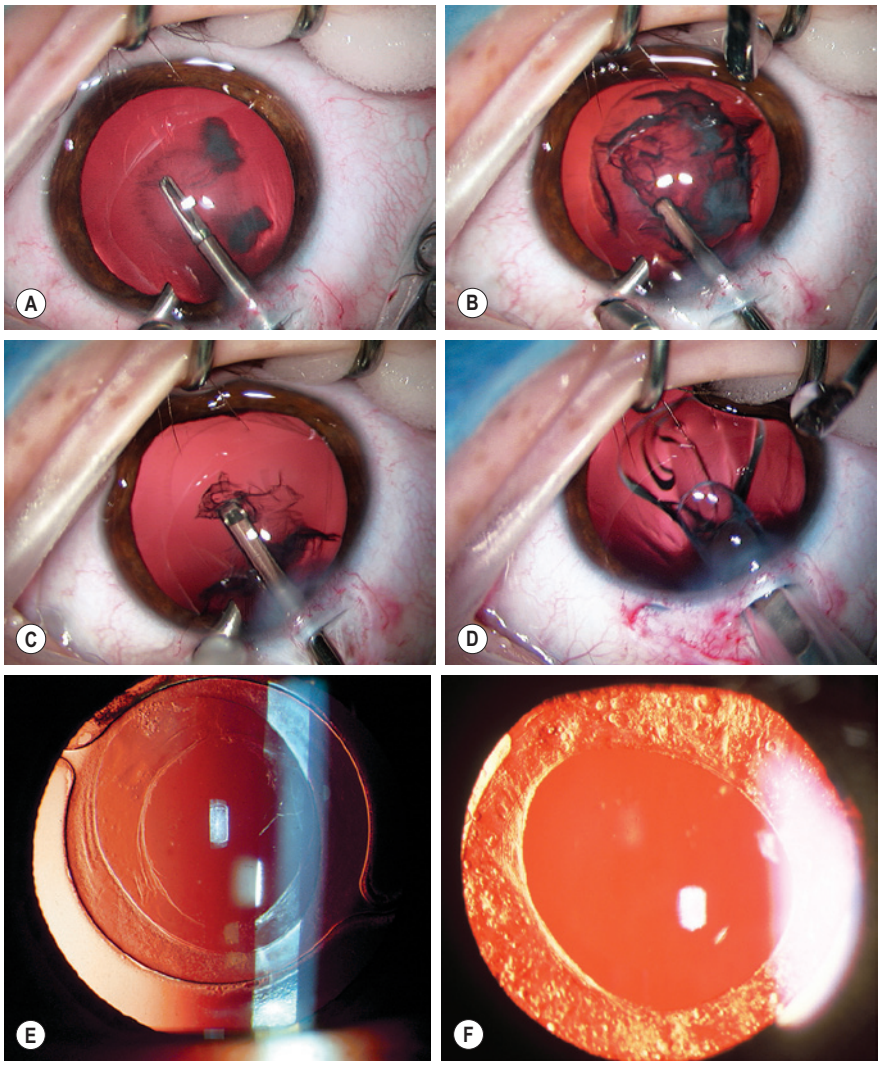

Fig. 37.27 Extracapsular cataract extraction and intraocular lens implantation in a 3-year-old child with a lamellar cataract. After (A) performing a manual anterior capsulorrhexis, (B) the lens cortex is aspirated, (C) a primary posterior capsulotomy and anterior vitrectomy is performed, and (D) a foldable acrylic lens is then implanted in the capsular bag. (E) Polymethylmethacrylate (PMMA) intraocular lens (IOL) in an infant's eye. The central posterior capsulotomy is smaller than the anterior capsulotomy, which facilitated in-the-bag fixation of the IOL. (F) Soemmerring ring in a child following in-the-bag IOL implantation.

anterior chamber. If a lensectomy is planned, an anterior capsule vitrectorrhexis should be performed so the entire cataract surgery can be performed without having to insert and remove additional instruments from the eye. With a low cutting speed, the vitrectorrhexis is initiated by making an opening in the center of the anterior capsule with the port of the vitrector facing downwards. The vitrectorrhexis is then gradually enlarged to 5–6 mm by moving the vitrector away from the center of the lens. If cataract extraction with intraocular lens (IOL) implantation is planned, a continuous curvilinear capsulorrhexis is preferable since the capsular edge created using this technique is less likely to tear during IOL implantation. The capsulorrhexis should be performed with the anterior chamber filled with an ophthalmic viscoelastic device. In infants and young children, vector forces should be directly centripetal rather than tangential during the capsulorrhexis to compensate for the increased elasticity of the anterior capsule. Trypan blue staining of the anterior capsule can be helpful to enhance visualization of the anterior capsule in a patient with a white cataract. If the lens is intumescent, the center of the lens should be decompressed with a needle prior to initiating the capsulorrhexis to prevent the capsule from tearing peripherally. Ideally, the capsulorrhexis should be slightly smaller than the optic of the IOL that will be implanted. Alternatively, a femtosecond laser may be used to create an anterior capsulotomy to more precisely control the size and centration of the anterior capsulotomy.[16] In almost all cases, the lens nucleus and cortex of a pediatric cataract can then be aspirated using a vitrector. Phacoemulsification is rarely required in children. Removing subincisional cortex can be facilitated by switching the entry sites for the vitrector and the infusion cannula. A foldable IOL is preferred in children to minimize the width of the entry site. A smaller entry site reduces the risk of iris prolapse intraoperatively and wound dehiscence postoperatively. When implanting an IOL in the eye of a child <5 years of age, a primary posterior capsulotomy and anterior vitrectomy should be performed given the rapidity of posterior capsular opacification in young children (Fig. 37.27). Posterior capsular opacification makes it difficult to refract children and can also result in amblyopia. In older children, in whom posterior capsular opacification may be delayed for several years and who are less susceptible to amblyopia, a primary posterior capsulotomy and anterior vitrectomy may be omitted if it is possible to follow the child at regular intervals and the child will cooperate with a YAG laser capsulotomy performed in a clinic setting. The posterior capsulotomy can

Fig 37.28 Aphakic contact lenses. The child has successfully worn contact lenses since undergoing lensectomies at 3 weeks of age.

be performed using a limbal or a pars plana approach. The limbal approach has the advantage that the same incision site used for cataract surgery can be used, but it makes it more difficult to implant the IOL in the capsular bag. Capsular bag fixation can be facilitated after creating posterior capsulotomy using a limbal approach by separating the capsular leaflets with a high-viscosity ophthalmic viscoelastic device. A primary capsulotomy can also be performed through the pars plana after implanting the IOL. This simplifies IOL implantation into the capsular bag, but does require a second entry site in the pars plana. The distance of the entry site from the corneal limbus can be based partially on the age of the child (<12 months, 1.5–2.0 mm; 1–4 years, 2.0–2.5 mm; >4 years 3.0–3.5 mm), but the axial length of the eye must also be taken into consideration. After completing the cataract surgery, the limbal incision sites should be closed with 9-0 or 10-0 absorbable sutures and the pars plana incision site with an 8-0 absorbable suture. Any ophthalmic viscoelastic material remaining in the eye should be aspirated and the anterior chamber should be re-formed with balanced salt solution. Antibiotics should then be injected into the anterior chamber[17] and topical 1% atropine and a combination steroid/antibiotic ointment should be applied to the eye. Lastly, the eye should be patched and covered with a protective shield.

Optical correction

One of the major obstacles in children following cataract surgery is optical correction of the induced aphakia.

Contact lenses

Contact lenses remain the standard method of optically correcting infant aphakia (Fig. 37.28). Several different types of contact lenses may be used. Rigid gas-permeable contact lenses are available in a wide range of powers and they are able to correct large astigmatic refractive errors. In addition, they are easily inserted and removed even in uncooperative children.[18] The biggest obstacle for their use is the greater expertise required to fit them. In addition, they must be worn on a daily wear basis. Silicone lenses have the advantage that they can be worn on an extended wear basis, but they are more expensive and are only available in a limited range of powers and sizes. Furthermore, it becomes increasingly difficult to keep proteinaceous deposits from accumulating on the surfaces of these lenses as children become older. Parents are advised to remove the lenses if the eye becomes inflamed or irritated, or if excessive discharge develops. Inadequate care can result in keratitis and corneal scarring. Poor compliance with contact lens wear is most commonly due to poor patient cooperation, rather than complications from their use. Contact lens powers must be changed on a regular basis in young children and they are easily lost. The high cost of purchasing and cleaning contact lenses is a significant deterrent for many families using this method of optical correction. In addition, there are occasions when contact lenses cannot be safely worn (e.g. if a child has a conjunctivitis). For this reason, aphakic children wearing contact lenses should be prescribed a pair of glasses to be worn on a back-up basis.

Fig 37.29 Aphakic spectacles. Aphakic spectacles are safe and the power can be easily changed, but they have optical and cosmetic disadvantages.

Spectacles

Aphakic spectacles are better tolerated than contact lenses by some children with bilateral aphakia, especially between 18 months and 5 years of age. In addition, some parents prefer their ease of use compared to contact lenses. They also have the advantage of magnifying the apparent size of microphthalmic eyes. Their disadvantages include restricting peripheral vision and a poor cosmetic appearance with the high plus powers often required (Fig. 37.29).

Intraocular lenses

IOL use in young children is complicated by the increased number of additional intraocular operations associated with

their use, primarily to remove visual axis opacities, and the difficulty of predicting the optimal IOL power.[19,20] In young children, an IOL power is generally chosen that undercorrects the eye, in anticipation of a myopic shift. Immersion A-scan biometry in an anesthetized young child or optical biometry in an older child are the most accurate means of measuring axial length. No IOL formula has been specifically developed for pediatric eyes. The T2, SRK/T, and Holladay 1 IOL calculation formulas have been shown to be associated with the lowest absolute prediction errors in young children.[21] However, even using these formulas, the mean absolute prediction error is typically much larger in children (e.g. 1.0–1.5 D) than adults. An international panel of pediatric ophthalmologists recently recommended the following age-based undercorrections when implanting IOLs in the eyes of children: age <6 months, +6–10 D; 6–12 months, +4–6 D; 1–2 years; +3–4 D; 3–4 years, +3 D; 4–6 years, +2–3 D; 6–8 years, +1–2 D, >8 years, 0 to +1 D. "In-the-bag" IOL implantation is the preferred procedure when performing primary IOL implantation in a child. IOL implantation in-the-bag may also be achieved as a secondary procedure in many children by opening the Soemmerring ring at the junction of the anterior and posterior lens capsules, aspirating its contents, filling the capsular bag with an ophthalmic viscoelastic device, and then positioning the IOL between the capsular leaflets.[22] It is important to leave a rim of capsule for 360° at the time of the lensectomy to facilitate secondary IOL implantation into the capsular bag later in childhood. If insufficient capsular remnants are available for in-the-bag fixation, the IOL can be implanted into the ciliary sulcus if there is a continuous rim of lens capsule. Implantation of an IOL into the anterior chamber may be required if there is insufficient capsular support for a ciliary sulcus-fixated IOL. Anterior chamber IOLs may be attached to the iris by enclavation or suture fixation or fixated in the angle. IOLs offer the advantage of a constant optical correction. An overcorrection with spectacles or contact lenses is usually necessary to fully focus the eye.

Postoperative care

The frequent administration of topical corticosteroids is critical after pediatric cataract surgery to blunt the exuberant inflammatory response that usually occurs in these eyes. The frequency and duration of their use depends on many variables such as the age of the child, the difficulty of the surgery, and whether an IOL was implanted. A topical cycloplegic agent should also be administered to prevent the pupil from becoming miotic. Because of the increased risk of the eye being rubbed, spectacles or a shield should be worn over the eye during the immediate postoperative period. Broad-spectrum topical antibiotic should also be prescribed.

Postoperative complications

Amblyopia (see Chapter 73)

Amblyopia is nearly universal in children with dense congenital cataracts. It arises as a result of the retina receiving a defocused image when the central visual pathways are forming. Uncorrected aphakia or induced anisometropia can exacerbate amblyopia even after the removal of a cataract. Whatever optical correction is worn, frequent re-examinations are necessary to ensure that the correction is up to date. Each examination should include an assessment of fixation behavior or grating acuity in preverbal children and optotype acuity in verbal children to detect or manage amblyopia. When amblyopia is present, occlusion therapy of the preferred eye should be initiated. The duration of patching each day depends on the severity of the amblyopia. Good visual outcomes can be achieved in children undergoing unilateral congenital cataract surgery by patching the fellow eyes for 30–50% of waking hours.[23] Patching the fellow eye for longer periods of time each day may result in subtle visual deficits in the fellow eye, strabismus, and impaired binocularity. Patching therapy is most important during the critical period of visual development during early childhood. It may be discontinued when children are 7 years of age. Amblyopia can be treated in a child wearing contact lenses to optically correct bilateral aphakia by delaying insertion of the contact lens in the preferred eye for a specified time each day. Occlusion therapy is not usually necessary in older children with bilateral acquired cataracts or unilateral traumatic cataract when treated promptly.

Visual axis opacities

Visual axis opacities may arise from fibrin forming a pupillary membrane, opacification of the residual posterior lens capsule, or lens re-proliferation extending into the visual axis. It is particularly common after IOL implantation during infancy (Fig. 37.30). Because of the almost universal occurrence of posterior capsular opacification in children, a primary posterior capsulotomy and anterior vitrectomy are recommended in children under 5 years of age. In older children, the posterior capsule can be left intact and a YAG laser capsulotomy can be performed later when the posterior capsule opacifies.[24] The procedure should not be delayed after the posterior capsule opacifies because of the increased difficulty of opening a thickened posterior capsule and the risk of developing amblyopia in a child under 7 years

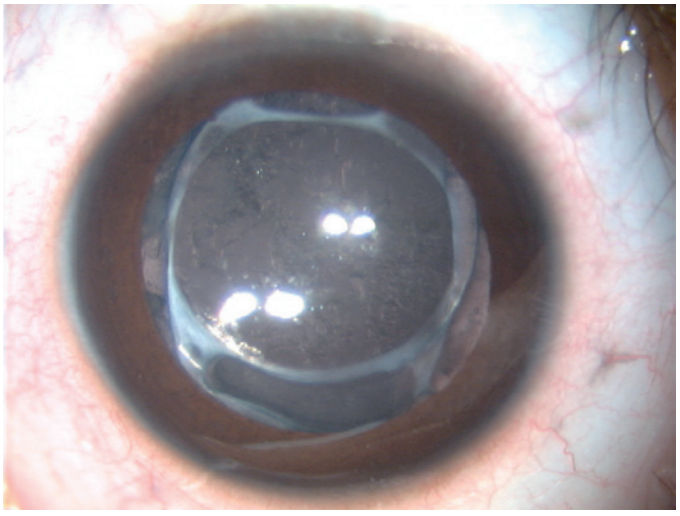

Fig. 37.30 Posterior capsular opacification. The posterior capsule was left intact at the time of cataract surgery and intraocular lens implantation. The posterior capsule was too thickened to open with a YAG laser so a membranectomy was performed.

Fig. 37.31 Anterior capsular phimosis. The capsulorrhexis has undergone progressive phimosis, which makes it difficult to perform retinoscopy.

of age. If the posterior capsule is too dense to open with a YAG laser, a pars plana or limbal membranectomy may be performed with a vitrector. A Soemmerring ring develops in children's eyes after cataract surgery. In most cases, the re-proliferating lens material is confined to the retro-iridial space, but it may extend into the pupil. Re-proliferating lens material commonly extends into the pupillary space after IOL implantation during infancy presumably because the IOL prevents the margins of the anterior and posterior capsular leaflets from fusing together. In these instances, intraocular surgery may be necessary to clear the visual axis. Capsular phimosis may also develop for either the anterior or posterior capsulotomy, making it difficult to refract the child (Fig. 37.31). In some cases, capsulotomies must be enlarged surgically in order to perform refractions and to examine the fundi.

Glaucoma (see Chapter 38)

Glaucoma may arise during the early postoperative period or years later. It is a serious problem and is difficult to manage. Pupillary block glaucoma has a higher incidence in neonates following lensectomy due to vitreous prolapse into the anterior chamber or pupillary membrane formation. This complication can largely be averted by performing an adequate anterior vitrectomy and atropinizing the pupil postoperatively. A prophylactic peripheral iridectomy is generally not performed in a child's eye because of the increased risk of inflammation associated with any manipulation of a child's iris. Affected patients usually have ocular pain, corneal edema, and iris bombé. Open angle glaucoma is one of the most common late complications of pediatric cataract surgery, particularly in children undergoing cataract surgery during early infancy and in eyes with PFV. The risk of glaucoma increases twofold by performing cataract surgery at 1 month compared to 2 months of age.[24] Unlike infantile-onset glaucoma, which is usually associated with readily detectable signs and symptoms such as bupthalmos, corneal edema, and epiphora, juvenile-onset glaucoma is usually more subtle in its onset. Intraocular pressure should be assessed at each outpatient examination after cataract surgery to screen for ocular hypertension. Rebound tonometry is better tolerated by young children than applanation tonometry.[25] Anatomical signs of glaucoma in young children include cupping of the optic disc, an increase in axial length or the corneal diameter, or a rapid myopic shift.

Strabismus

Strabismus is often the presenting sign of a unilateral cataract in a child. Esotropia is more commonly observed in a child with a congenital cataract, while exotropia is more frequently observed in a child with an acquired cataract. A delay in the removal of an acquired cataract or optical correction in an older child can result in diplopia after cataract surgery even after the eyes are surgically aligned due to a disturbance of central fusion.

IOL complications

Posterior chamber IOLs may become subluxated secondary to trauma or if the suture securing a haptic at the pars plana breaks (Fig. 37.32A). In most instances, the IOLs can be re-positioned and re-fixated with one or more prolene sutures (Fig. 37.32B). Eyes with IOLs in the anterior chamber fixated in the angle may develop the UGH syndrome (uveitis, glaucoma, and hyphemas) if the IOL is incorrectly sized. Movement of the IOL may also result in a haptic rotating though a periperhal iridotomy (Fig. 37.33). A large myopic shift may also occur after IOL implantation during early childhood. This may even occur when the eye is undercorrected when the IOL is implanted. In some cases, exchanging the IOL for a lower power IOL may be indicated. Generally the IOL used to replace the original IOL will need to be positioned in the ciliary sulcus.

Irregular pupil

An irregular pupil is a frequent complication of infantile cataract surgery and is most noticeable in children with lightly colored irides. Most commonly it arises secondary to posterior synechaie between the iris and the residual lens capsule. It may also develop secondary to iris trauma occurring intraoperatively. Strands of vitreous extending to the surgical incision site may cause peaking of the pupil. This may be averted by turning off the infusion line before removing the vitrector from the eye, maintaining a low flow of irrigating solution, and minimizing the number of times the vitrector is inserted and removed from the eye. Even when the pupil is round after cataract surgery, it frequently is less reactive to light and pharmacological dilation.

Heterochromia iridis

Cataract surgery during infancy is commonly associated with increased iris pigmentation in the operated eye (Fig. 37.34). This is likely due to the release of prostaglandins following cataract surgery.[26]

Endophthalmitis

Bacterial endophthalmitis is an uncommon, but devastating, complication after cataract surgery. A concurrent nasolacrimal

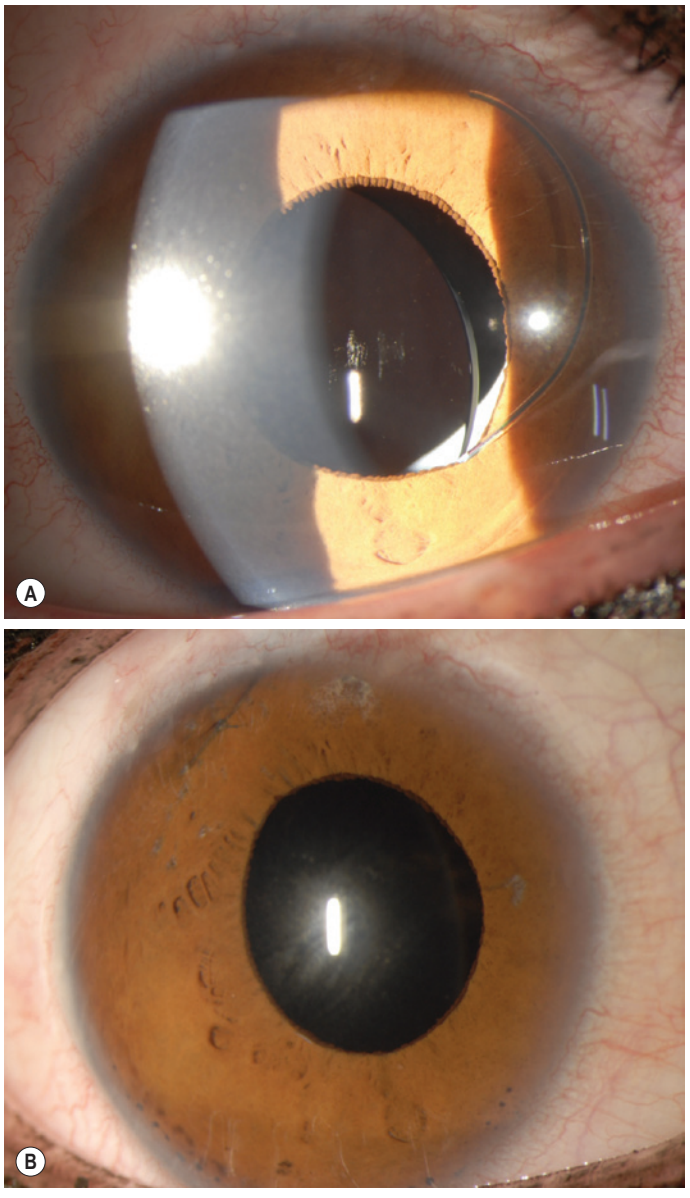

Fig. 37.32 Subluxated ciliary sulcus-fixated intraocular lens (IOL). (A) The IOL spontaneously subluxated in this active teenager 10 years after being implanted in the ciliary sulcus. (B) The inferior haptic was re-positioned over the capsular rim and the superior haptic was sutured to the iris at 11 o'clock using a 10-0 prolene suture.

duct obstruction, upper respiratory infection, or periorbital skin disease increases the risk. The most common organisms causing it in children are *Staphylococcus aureus* and *Streptococcus pneumoniae*.

Even though most cases are diagnosed during the early postoperative period, the visual prognosis is poor. In one series, 65% of affected eyes ended up with no light perception despite aggressive treatment with intravitreal and systemic antibiotics.[27] The incidence of this complication can be minimized by using strict sterile techniques and delaying surgery for children with ocular infections. Intracameral antibiotics at the end of cataract surgery have been shown to reduce the incidence of this complication.[27]

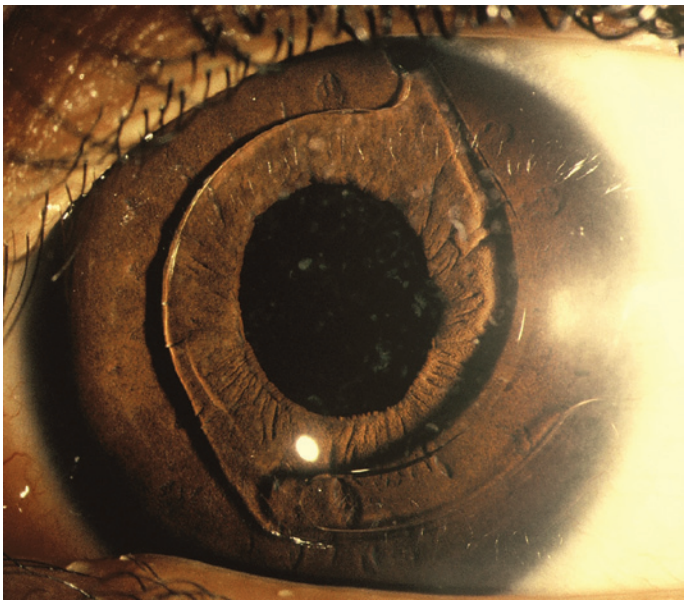

Fig. 37.33 Anterior chamber intraocular lens (IOL). Anterior chamber IOL in an aphakic child. The superior haptic has subluxed through a peripheral iridotomy.

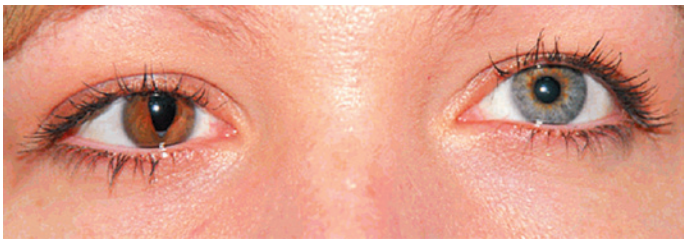

Fig. 37.34 Hetererochromia iridis. This 32-year-old woman underwent a lensectomy in her right eye when 1 year of age. The iris often becomes darker in the operated eye after cataract surgery during infancy.

Retinal hemorrhages and detachments

A hemorrhagic retinopathy develops in some infants after a lensectomy and anterior vitrectomy. In most cases, this consists of flame-shaped hemorrhages in the posterior pole that resolve without sequelae in 1–2 weeks.[28] Occasionally, a hemorrhage may occur in the fovea and result in a severe reduction of vision. In these cases, even after the hemorrhage has resolved, the visual acuity may remain reduced by amblyopia.

Retinal detachments are infrequent and usually occur decades after the removal of a congenital cataract. They are particularly common in developmentally delayed children following cataract surgery due to self-inflicted trauma. Retinal detachments are frequently bilateral, and the visualization of the retinal breaks may be hampered by miotic pupils and Soemmerring rings.

Cystoid macular edema

Cystoid macular edema is rare in children following cataract surgery unless there are other comorbidities such as uveitis.

Corneal edema

Corneal edema may result from excessive corneal trauma after a long cataract surgery or secondary to toxic anterior segment syndrome.[29] Disposable cannulas should be used whenever possible and toxic chemicals such as formaldehyde should not be used to clean instruments for intraocular surgery to avoid toxic anterior segment syndrome. Corneal edema after cataract surgery in children usually resolves in a few days.

Visual outcomes

Many factors influence the visual outcome after cataract surgery including:

1. the age of onset of the cataracts;
2. the laterality of the cataracts;
3. associated ocular and systemic conditions;
4. the age when cataract surgery is performed;
5. compliance with optical and patching therapy.

Children who develop cataracts when 7 years of age or older usually have an excellent visual prognosis. Children with early-onset bilateral cataracts also have an excellent visual prognosis with prompt cataract surgery and optical correction. Children with early-onset unilateral cataracts have the worst visual prognosis. However, it is possible for these children to have an excellent visual outcome with early cataract surgery and good compliance with their optical correction and patching therapy of the fellow eye.[30] The Infant Aphakia Treatment Study showed that in the USA one of the best predictors of a good visual outcome in a child with a unilateral congenital cataract was the parents having private health insurance.[31] This was likely a surrogate for better compliance with optical correction and patching therapy. Concomitant ocular abnormalities such as corneal opacities, glaucoma, retinal abnormalities, and nystagmus worsen the visual prognosis. Binocular vision is uncommon after cataract surgery in children, but it can be achieved even in children with early-onset unilateral cataracts.[32]

Introduction

Glaucoma in children is a rare, potentially blinding condition characterized by elevated intraocular pressure (IOP)-related damage to the eye and is caused by a diverse group of conditions. Clinical presentation can vary because, depending on the age of onset, elevated IOP can affect the whole eye and not just the optic nerve by characteristic cupping. The goal is to provide a lifetime of vision where possible. Successful control of IOP is crucial in achieving this goal but can be challenging, especially when surgery is necessary. The correction of ametropia and amblyopia therapy is also vital to maximize visual function.

Clinical presentation

A child suspected of having glaucoma can present in many ways: Firstly, they may present with clinical manifestations of elevated IOP as occurs in infancy. Secondly, they may present with a condition that predisposes them to glaucoma, e.g. aphakia. Thirdly, glaucoma may be found during screening when there is a family history of childhood glaucoma. Lastly, they may present after having failed routine school vision testing.

Glaucoma from any cause in a neonate or infant is synonymous with the *classic triad of lacrimation, blepharospasm, and photophobia* due to corneal edema from elevated IOP. These signs are not entirely specific but are very suggestive of glaucoma and may appear before the hazy cornea and characteristic buphthalmos become obvious. *Buphthalmos* (*ox eye*), a descriptive term, refers to the generalized ocular enlargement by elevated IOP from any cause in infancy (Fig. 38.1). It is a unique finding of glaucoma in infancy because the young eye increases in size from increased IOP due to corneal and scleral collagen immaturity. The potential for corneal enlargement usually ceases by the age of 3 years, although the sclera remains deformable until around 10 years of age. As the IOP rises, Descemet membrane eventually ruptures, with one edge usually retracting as a scroll to form a ridge known as *Haab stria* (Fig. 38.2). As the underlying endothelium is torn, localized or diffuse corneal edema results from aqueous influx into the stroma causing a sudden cloudiness (Fig. 38.3). With successful lowering of IOP, corneal clouding typically begins clearing first in the periphery (Figs 38.4 and 38.5). Photophobia may still persist with normalization of IOP due to the Haab striae. Beyond the age of 3 years, children are more likely to present with progressive myopia, strabismus, or after having failed vision testing.

Differential diagnosis

The differential diagnosis of glaucoma in children is broad (Box 38.1). Many conditions mimic glaucoma and must be excluded before labeling a child with glaucoma. The IOP is normal and the signs will usually not be progressive in patients with other diagnoses.

Classification

Childhood glaucoma can simply be classified as: *primary* where there is only a developmental abnormality of the anterior chamber (AC) angle; and *secondary* where aqueous outflow is reduced by non-acquired (congenital) or acquired ocular diseases or systemic disorders[1] (Box 38.2).

Primary childhood glaucoma

Primary congenital glaucoma

Primary congenital glaucoma (*PCG*) is typically bilateral (70–80%) but asymmetric, and usually manifests in the first year of life. Diagnosis is based on the finding of isolated angle anomaly, i.e. *isolated trabeculodysgenesis*. It is subclassified based on the age of onset of signs, which influences the response to angle surgery.

Demographics

PCG is the commonest glaucoma in infancy but has a reported incidence of only about 1 in 10,000–20,000 live births in Western countries.[2] The highest reported incidence is 1:1250

Fig. 38.1 Infant with right buphthalmos.

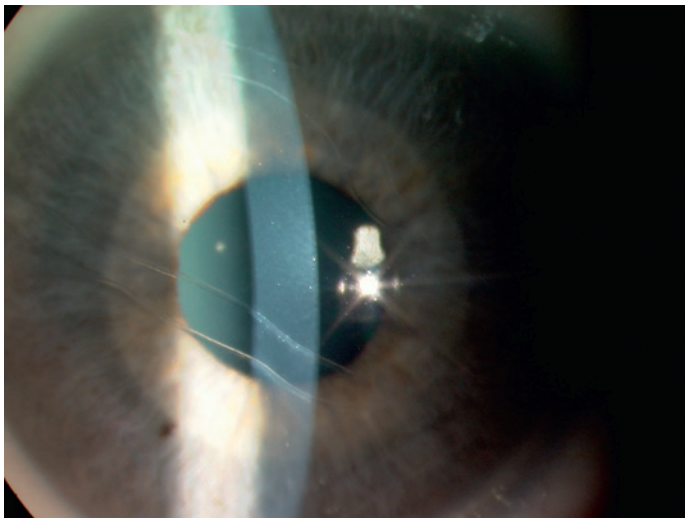

Fig. 38.2 Haab striae, pathognomonic of glaucoma in infancy in the presence of an enlarged cornea.

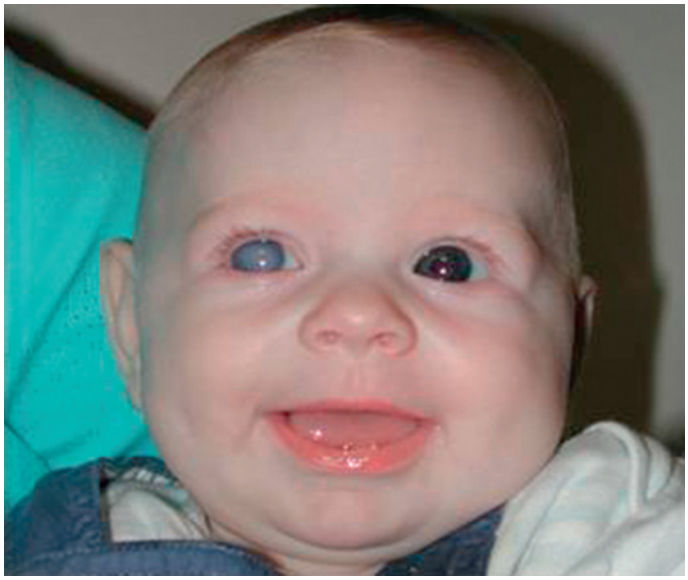

Fig. 38.3 Right stromal edema from ruptured Descemet membrane due to elevated intraocular pressure.

in Slovakian Romani people. Parental consanguinity, especially cousin–cousin marriages, is thought to be responsible for the higher prevalence in certain ethnic groups. PCG occurs more frequently in males than females with a ratio of between 2–2.5 : 1.

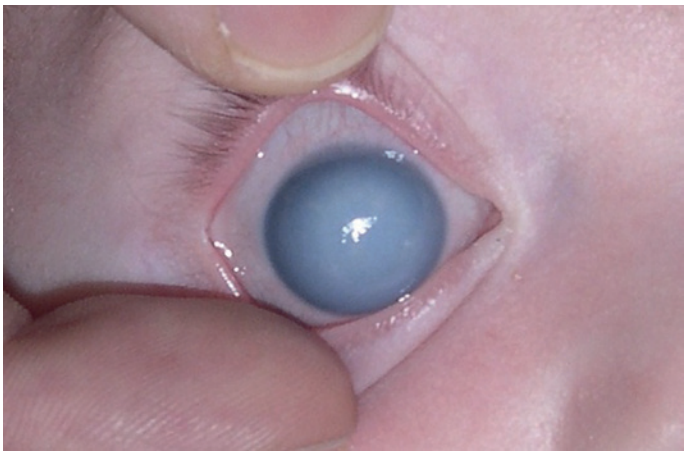

Fig. 38.4 Right corneal stromal edema from uncontrolled intraocular pressure before surgery.

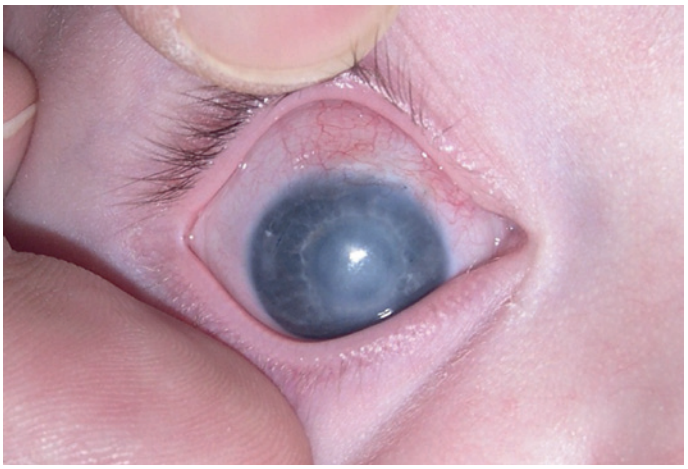

Fig. 38.5 Same eye with clearing of cornea edema following successful lowering of intraocular pressure with trabeculectomy.

Genetics

Most cases of PCG are sporadic. A family history of glaucoma is reported in 10–40% of cases associated with autosomal recessive inheritance and variable penetrance ranging from 40–100%. The GCL3A is the major locus for PCG and has been mapped to the short arm of chromosome 2 (2p21), the GLC3B locus to chromosome 1p36, and GLC3C to chromosome 14q24.3. Other loci are speculated to exist. The majority of cases of PCG relate to mutations of the *CYP1B1* gene associated with the GLC3A locus[3] but its frequency varies according to populations, ranging from 100% in Slovakian Roma to around 20% in the Japanese. It encodes for enzyme cytochrome P4501B1 that is thought to participate in the development and function of the trabecular meshwork (TM). Oxidative stress early in development has been postulated to cause trabecular dysgenesis and result in PCG.[4] *CYP1B1* mutations are associated with variable expressivity. Neonatal presentations of PCG are more likely to have *CYP1B1* mutations, but the same mutations can be associated with less severe PCG or no glaucoma in childhood at all. Attempts at genotype–phenotype correlations have been inconclusive, as have attempts at establishing a relationship between genotype and surgical outcomes.

Box 38.1

Differential diagnosis of childhood glaucoma

Cornea enlargement

(No Descemet membrane splits or corneal edema, symmetrical)

1. X-linked megalocornea (non-progressive, optic disc normal, very deep anterior chamber with shortened vitreous length, follow-up necessary for refractive amblyopia and exclusion of glaucoma)
2. Congenital high myopia (physiological cupping with tilted disc, peripapillary scleral crescent)
3. Connective tissue disorders, e.g. osteogenesis imperfecta, Marfan syndrome
4. *LTBP2* mutations (primary congenital megalocornea, spherophakia, ectopia lentis, and secondary lens-related pupil block glaucoma)

Corneal splits

(No corneal enlargement, normal optic nerve)

1. Trauma (obstetric, non-accidental, history)
2. Hydrops (history)

Corneal edema or opacity

(Usually no corneal enlargement unless associated with glaucoma which is rare)

1. Trauma (obstetric, non-accidental)
2. Congenital corneal dystrophies, e.g. congenital hereditary endothelial dystrophy
3. Metabolic disorders, e.g. mucopolysaccharidoses, mucolipidoses, cystinosis
4. Infection, e.g. congenital rubella, herpes simplex keratitis
5. Sclerocornea

Watering and "red eye"

(No Descemet membrane splits, corneal or ocular enlargement, normal optic nerve and intraocular pressure [IOP])

1. Conjunctivitis (often discharge, red eye)
2. Nasolacrimal duct obstruction (purulent discharge, no photophobia, no "runny nose")
3. Corneal epithelial defect/keratitis (history and examination very important)
4. Ocular inflammation

Congenital optic nerve cupping

(No corneal enlargement or edema, normal IOP)

1. Physiological cupping in large optic nerves
2. Congenital optic nerve pits, colobomata
3. Papillorenal syndrome
4. Optic nerve hypoplasia with periventricular leukomalacia

The risk of PCG in siblings and offspring of Caucasian patients (low parental consanguinity) is low (<5%), but it is prudent to examine the siblings and offspring of patients, especially in the first 6 months of life. However, the risk is higher if there is a history of consanguinity, making screening of siblings essential. If both disease-causing alleles in an affected family member have been identified, it is possible to perform carrier testing for at-risk relatives and prenatal diagnosis.

Pathogenesis

The immature angle appearance is thought to result from the developmental arrest of tissues derived from cranial neural crest cells in the third trimester of gestation. The severity of the abnormality varies according to the stage at which development was arrested. Obstruction to outflow was historically thought to be due to the presence of an impermeable membrane (*Barkan membrane*) but this has never been verified histopathologically. It is now thought that thick, compacted trabecular sheets obstruct outflow and also prevent the normal posterior migration of the uveal tract (iris and ciliary body).[5]

Gonioscopic findings

The characteristic gonioscopic appearance includes a flat iris insertion and the absence of an angle recess. Some of the changes seen are due to the physical stretching of structures from elevated IOP. These include: a thin and hypopigmented iris stroma, peripheral scalloping of the posterior pigmented iris layer, and easily visible, hyperemic iris vessels with circumferential vessels running tortuously in the peripheral iris or on the ciliary body (Fig. 38.6). In unilateral disease, the fellow eye usually shows typical gonioscopic findings with a large corneal diameter and axial length (AL), but the disc is normal and may represent drainage angles that have continued to mature after *spontaneous arrest* of the disease. Hence, the fellow eye of apparently unilateral cases must be followed as closely as the affected eye, as the glaucoma may relapse at any stage.

Fig. 38.6 Classic immature primary congenital glaucoma angle appearance with scalloped posterior iris pigment epithelium.

Treatment

Medical therapy is almost always ineffective for long-term IOP control. Angle surgery, goniotomy and trabeculotomy is typically the procedure of choice but requires an experienced surgeon and often more than one operation to achieve IOP control. There is a similarly high rate of success after multiple attempts in favorable cases, such as those with onset of signs between 3–12 months of age. The recent introduction of circumferential

Box 38.2

Classification of childhood glaucoma

Primary childhood glaucoma

Primary congenital glaucoma (isolated trabeculodysgenesis)
- Neonatal or newborn onset (0–1 month)
- Infantile onset (>1 month to 2 years)
- Late onset or late recognized (>2 years)
- Spontaneously arrested (non-progressive buphthalmos, Haab striae, normal intraocular pressure [IOP] and optic nerves)

Juvenile open angle glaucoma

Secondary childhood glaucoma

Glaucoma associated with non-acquired ocular anomalies

Conditions with predominantly ocular anomalies *present at birth* that may or may not be associated with systemic signs

Axenfeld–Rieger anomaly ("syndrome" if systemic associations)

Peters anomaly ("syndrome" if systemic associations)

Congenital ectropion uveae

Congenital iris hypoplasia

Aniridia

Persistent fetal vasculature (PFV) (if glaucoma present before cataract surgery)

Oculodermal melanocytosis (nevus of Ota)

Microphthalmos/microcornea

Ectopia lentis

Simple ectopia lentis (no systemic associations)

Ectopia lentis et pupillae

Glaucoma associated with non-acquired systemic disease or syndrome

Conditions predominantly with known syndromes, systemic anomalies, or systemic disease *present at birth* that may be associated with ocular signs:

Phacomatoses
- Sturge–Weber syndrome
- Neurofibromatosis (NF-1)
- Klippel–Trenaunay–Weber syndrome

Chromosomal disorders such as trisomy 21 (Down syndrome)

Connective tissue disorders
- Marfan syndrome
- Weill–Marchesani syndrome
- Stickler syndrome

Metabolic disorders
- Homocystinuria
- Lowe syndrome
- Mucopolysaccharidoses

Rubinstein–Taybi

Congenital rubella

Glaucoma associated with acquired condition

Conditions that are not inherited or present at birth but that *develop after birth*:

Uveitis

Trauma (hyphema, angle recession, ectopia lentis)

Steroid induced

Tumors (benign/malignant, ocular/orbital)

Retinopathy of prematurity (ROP)

Post-surgery other than cataract surgery

Glaucoma following cataract surgery

Subdivided into three categories based upon cataract type and there being *no glaucoma prior to cataract surgery*:

Congenital idiopathic cataract

Congenital cataract associated with ocular anomalies/systemic disease or syndrome

Acquired cataract

Adapted from Beck A, Chang TCP, Freedman S. Definition, classification and differential diagnosis. In: Weinreb RN, Grajewski A, Papadopoulos M, et al., editors. Childhood Glaucoma. WGA Consensus Series – 9. Amsterdam: Kugler Publications, 2013: 3–10.

(360°) trabeculotomy with an illuminated microcatheter, for improved safety, has been a significant advance as it potentially incises the whole angle in one operation and minimizes anesthetic exposure.[6] An *ab interno* trabeculotomy approach has also been recently described. The options in children that fail angle surgery are either trabeculectomy with anti-scarring agents or glaucoma drainage device (GDD) surgery.

Juvenile open angle glaucoma (JOAG)

Juvenile open angle glaucoma refers to a distinct group of patients who have no ocular anomalies or systemic features and usually present with glaucoma late in childhood up to the age of 35. Often there is a strong family history of glaucoma with autosomal dominant inheritance. Up to 20% of patients have mutations of the *myocilin/TIGR* (*trabecular meshwork inducible glucocorticoid response*) gene at the GLC1A locus on chromosome 1q23. These patients typically have high pressures (40–50 mmHg), a normal angle appearance and respond well to prostaglandin analogs. If medical treatment fails, a trabeculectomy with anti-scarring agents can be considered.

Secondary childhood glaucoma

With conditions that predispose to secondary glaucoma, it is important to remember the potential lifelong risk of glaucoma. Those at risk need regular IOP review to prevent devastating late presentations of glaucoma that are usually associated with a poor long-term visual prognosis. Consistently elevated IOP should be treated medically. Patients with conditions known to be associated with systemic findings should be referred to a pediatrician for assessment. Family screening and genetic counseling is indicated for inherited conditions. Disorders commonly associated with glaucoma are reviewed below.

Glaucoma associated with non-acquired ocular anomalies

Axenfeld–Rieger anomaly covers a spectrum of disease involving neural crest mesenchyme with overlapping clinical features that was traditionally divided into distinct entities: *Axenfeld anomaly*, defined by posterior embryotoxon (anteriorly displaced, prominent Schwalbe line) with attached iris strands; and Rieger anomaly, these changes in addition to iris changes such as

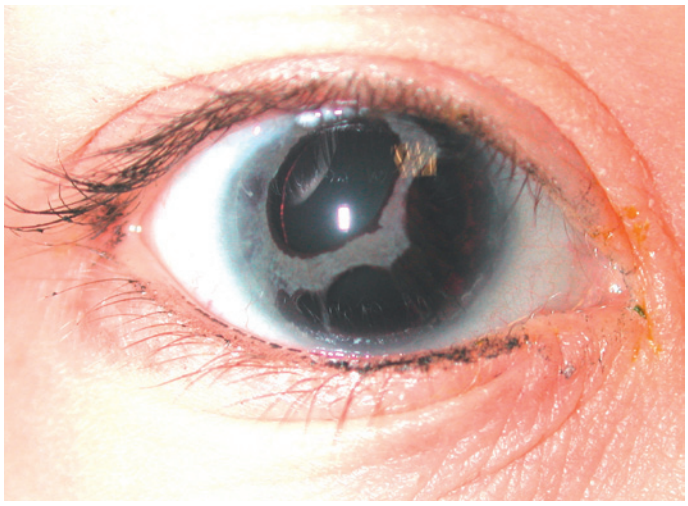

Fig. 38.7 Axenfeld–Rieger anomaly with corectopia and posterior embryotoxon.

Fig. 38.8 Axenfeld–Rieger syndrome with small conical widely spaced teeth.

corectopia or iris stromal thinning (Fig. 38.7). In association with systemic anomalies such as hypertelorism, periumbilical skin tags, dental and cardiac abnormalities, it is referred to as *Axenfeld–Rieger syndrome* (Fig. 38.8). It is usually bilateral, asymmetrical, and autosomal dominantly inherited. Examination of family members, including gonioscopy, is essential to determine both whether the patient is a sporadic or familial case, and to identify undiagnosed cases. Two major genes have been identified, *PITX2* gene at chromosome 4q25 and *FOXC1* at 6p25. Systemic findings are more likely to be associated with *PITX2* defects. The risk of glaucoma is greatest in decreasing order with: *FOXC1* duplication, *PITX2* mutations, and *FOXC1* mutations.[7]

Peters anomaly is characterized by a congenital, central corneal opacity with underlying defects in stroma, Descemet membrane, and endothelium. The opacity can be variable in size and density and clears with time. It may be an isolated finding or be associated with iris and lens involvement. When associated with systemic features it is referred to as *Peters plus syndrome* and carries a higher risk of glaucoma. It is usually bilateral (80%) and sporadic. Peters anomaly may result from abnormalities of the *PITX2*, *FOXC1*, *CYP1B1* and *PAX6* genes.

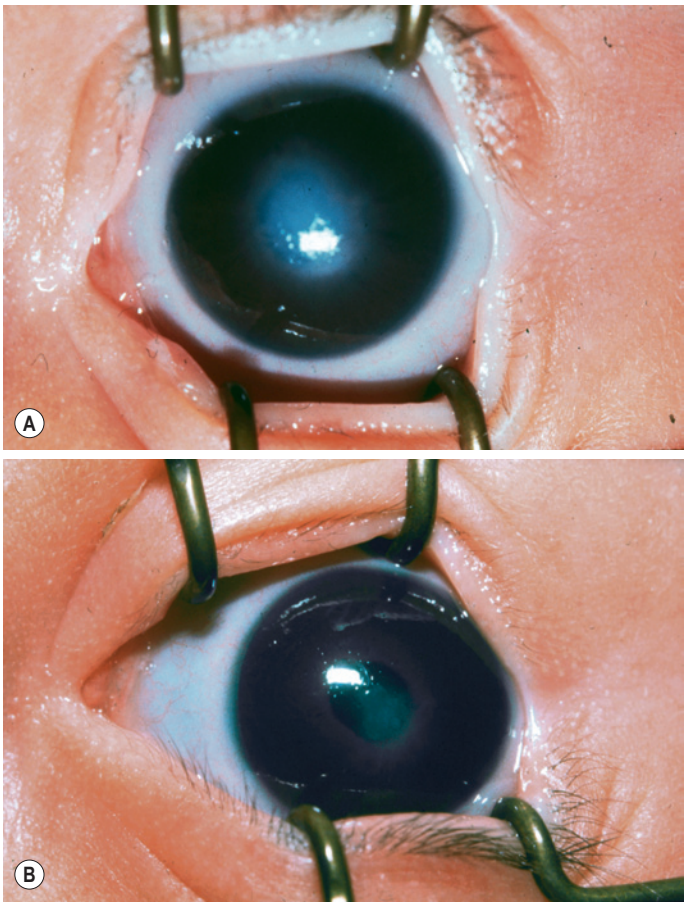

Fig. 38.9 (A) Uncontrolled intraocular pressure (IOP) and dense central corneal opacification before mitomycin C trabeculectomy. (B) Same eye with controlled IOP in low teens and improved corneal clarity after surgery.

The risk of glaucoma with the above conditions is 50%, so lifelong surveillance is indicated. Glaucoma usually occurs in childhood or young adulthood, very rarely in infancy, and is thought to be due to an underlying trabeculodysgenesis from arrested maturation of angle structures. The IOP is often labile. Medical therapy is usually tried first. Angle surgery is potentially more complicated and less successful than in PCG. Often trabeculectomy with anti-scarring agents is necessary to control the IOP. The more disorganized the anterior segment, the greater the risk of failure and the more potent the anti-scarring agent required, i.e. mitomycin C (MMC). MMC is more likely to achieve a low IOP and so significantly reduce corneal opacification in cases of Peters anomaly (Fig. 38.9A,B). Primary GDD surgery may be indicated in the more severe cases.

For dense corneal opacities and when the lens is clear, pupil dilation or a broad optical iridectomy can be performed (via a scleral approach to prevent further corneal scarring) at the site of maximum corneal clarity. Penetrating keratoplasty is associated with disappointing results,[8] especially in infants, but can be considered in at least one eye in the setting of bilateral dense opacities if the child has a dedicated caregiver.

Aniridia is a bilateral condition characterized by a variable congenital absence of iris. It results from abnormal neuroectodermal development secondary to *PAX6* gene mutations at chromosome 11p13. Inheritance is usually autosomal dominant with high penetrance and variable expressivity. Sporadic aniridia is associated in 30% of cases with

nephroblastoma (Wilms tumor), genitourinary abnormalities, and mental retardation (WAGR) related to large deletions of 11p13 (see also Chapters 33 and 11).[9]

Glaucoma occurs in half to two-thirds of cases usually presenting in pre-adolescence or early adulthood. It may be due to progressive angle closure by the iris stump or more commonly can be associated with an open angle. Medical therapy should always be tried first, with preservative-free drops if possible. Goniotomy in cases of documented progression of angle closure both as therapy (with poor results) and prophylaxis has been described, but the latter is not widely practiced due to the potential risk of lens trauma. In the presence of a clear lens, we perform a MMC trabeculectomy. If significant cataract is present or trabeculectomy fails then GDD surgery is indicated.[10] Consider placement of the tube obliquely over the zonules, away from the lens to mimimize tube-related trauma. Hypotony should be avoided at all costs due to the danger of lens–corneal touch, which will cause both cataract and corneal decompensation. Symptomatic relief of photophobia can be achieved with lubricants and tinted spectacles.

Glaucoma associated with non-acquired systemic diseases or syndromes

The commonest phakomatosis associated with glaucoma is *Sturge–Weber syndrome* (encephalotrigeminal angiomatosis), a sporadic, congenital condition characterized by a facial cutaneous vascular malformation (port wine stain) and ocular vascular lesions (episcleral and choroidal hemangioma). It is associated with a somatic mutation in the *GNAQ* gene on chromosome 9q21 (see Chapter 68).

Glaucoma occurs in around 30–50% of cases at any time from birth to adulthood and is thought to arise from elevated episcleral venous pressure (EVP). There may be an element of goniodysgenesis with infantile presentations. Port wine stains involving the ophthalmic division of V1 (especially upper lid and bilateral involvement) and the presence of episcleral vascular malformation or choroidal hemangioma (40%) increase the risk of glaucoma.

When medical treatment fails, surgery is indicated. The surgical plan depends on the age of onset and the mechanism of glaucoma. Congenital or infantile presentations may respond to angle surgery if there is evidence of goniodysgenesis. After failed angle surgery or in older children with increased EVP, either trabeculectomy with anti-scarring agents or a GDD is indicated. In the presence of a choroidal hemangioma, the potential for serious complications is high as it may give rise to expulsive choroidal hemorrhage if rapid decompression of the globe occurs or to choroidal effusions if there is prolonged hypotony. Preoperative radiotherapy should be considered if the hemangioma is very thick (>5 mm). Trabeculectomy or GDD surgery can be considered. All surgery in these patients must be coupled with measures to minimize hypotony. Trabeculectomy should have tight scleral flap closure and GDD a tight tube tunnel into the AC along with an extraluminal occlusive suture (6/0 vicryl) and an intraluminal stent (3/0 supramid) in non-flow-restricted implants. Smaller surface area implants, e.g. Baerveldt 250 mm^2, reduce the risk of hypotony and should be considered especially in infants. An AC maintainer should be used in all cases to avoid intraoperative hypotony. When surgery is planned it is important to take into consideration anticoagulation the child may be taking for stroke-like episodes, which have been reported in these patients.

Other phakomatoses can be associated with glaucoma, although with a lower incidence than Sturge–Weber syndrome: *Klippel–Trenaunay–Weber syndrome*, characterized by a triad of cutaneous vascular malformations and varicosities involving one limb and hypertrophy of bone and soft tissue; and Neurofibromatosis 1, an autosomal dominant condition, which may first present with iris abnormalities, e.g. ectropion uveae and glaucoma, before the systemic disease is apparent.

For rare conditions associated with childhood glaucoma, determining the mechanism of the glaucoma by a thorough history and examination, along with an assessment of risk factors for surgical failure, results in the best treatment plan. For example, *Weill–Marchesani syndrome* and *homocystinuria* may give rise to childhood glaucoma that is usually associated with lens displacement, secondary pupil block, and angle closure. In this context, prophylactic iridectomy and chronic miosis may be required to prevent pupil block glaucoma or dislocation of the lens into the AC.

Glaucoma associated with acquired conditions

Glaucoma may arise following inflammation from any cause but is most commonly seen in juvenile idiopathic arthritis (30%), usually 2–3 years after presentation. *Uveitic glaucoma* is multifactorial due to chronic cellular trabecular obstruction, trabeculitis, peripheral anterior synechiae (PAS), secondary pupil block, lensectomy, and following chronic topical steroid usage. Children with uveitis develop more severe glaucoma than adults. The IOP can potentially rise dramatically and be associated with rapid progression of optic disc cupping with severe visual loss. The principles of management are firstly to aggressively treat the uveitis with topical ± systemic steroids and steroid-sparing therapy (non-biological, e.g. methotrexate, and biological, e.g. infliximab) in association with a pediatrician, and secondly to control the IOP.

This type of glaucoma is characteristically challenging to manage because of its multifactorial etiology; it is often refractory to treatment, especially medical treatment, which is first line. If surgery is planned, perioperative systemic immunosuppression, particularly steroids, is essential to optimize outcome. Angle surgery often requires medical treatment to control IOP. Trabeculectomy with MMC can be considered but recurrent ocular inflammation may compromise long-term success. The authors' preference is for primary GDD surgery, especially if lensectomy is contemplated in the future or if aphakia is present. With any surgery, the risk of postoperative hypotony is high, even in the absence of overdrainage due to compromised aqueous production. We suggest a smaller surface area GDD, e.g. Baerveldt implant 250 mm^2, with measures to restrict flow as previously described, or an Ahmed implant (184 mm^2). Cyclodiode treatment is associated with poor success rates as primary treatment.[11] We avoid cyclodiode treatment as it aims to reduce the function of an already compromised ciliary body from inflammation, potentially leading to chronic hypotony.

Rarely, childhood tumors such as *leukemia* or *retinoblastoma* may cause glaucoma from outflow obstruction by tumor cells or secondary hemorrhage. The diagnosis of these rare conditions is important, as surgery allowing malignant cells to escape into extraocular tissues worsens the prognosis for life. The treatment of glaucoma in these circumstances is generally conservative. The primary disorder is treated, along with topical medical treatment and cyclodestruction.

Glaucoma following cataract surgery

Glaucoma following cataract surgery occurs after pediatric cataract removal of either congenital idiopathic cataract, cataract associated with an ocular or systemic syndrome, and acquired cataract.

Glaucoma following congenital cataract surgery is one of the commonest secondary childhood glaucoma and a serious cause of late visual loss after successful surgery. Removal of the cataract is what places the eye at risk of glaucoma, which can occur at any time, in either aphakic or pseudophakic eyes. Both chemical (inflammatory cells, lens remnants, and vitreous-derived factors) and mechanical (lack of ciliary body tension and TM collapse) theories have been proposed, combined with developmental reasons, i.e. arrest of postnatal angle maturation due to surgical insult. The incidence of glaucoma following childhood cataract surgery varies with duration of follow-up and ranges from 5% with simple aspiration[12] to 17% with lensectomy and ocutome vitrectomy with a least 5 year follow-up.[13] The angle is usually open, but PAS may be present. Acute angle closure from secondary pupil block is rare but usually results in long-term glaucoma despite relief of pupil block with iridectomy/vitrectomy. Risk factors for glaucoma such as microcornea, early surgery (especially less than 4 weeks of age), the need for secondary surgery, and nuclear cataract are well documented. Selection bias is an important confounder in studies showing a protective effect from intraocular lens implantation. The role of posterior capsule integrity is debated. Following meticulous cataract surgery, lifelong surveillance for glaucoma is crucial. The diagnosis can be easily missed as patients are often asymptomatic, the signs may be subtle, and examining these patients is often difficult. It is essential to monitor the optic disc appearance for progressive cupping on a regular basis. Excessive loss of hyperopia may also be a useful sign, as may contact lens intolerance.

Glaucoma following congenital cataract surgery is often refractory to treatment. Medical treatment is first line but only controls IOP in 50% cases. Angle surgery often does not provide good long-term control. Trabeculectomy with MMC not only has a poor success rate[14] but often excludes postoperative contact lens use in the presence of a thin, avascular cystic bleb due to the risk of endophthalmitis. Cyclodiode laser provides temporizing treatment with occasional long-term control after multiple treatments.[15] However, it is difficult to titrate and so marked inflammation and phthisis are possible, especially in microphthalmic eyes, in which case less energy should be considered. Furthermore, it may predispose future surgery to failure and possibly chronic hypotony. GDD surgery probably has the highest chance of long-term success and allows contact lens use.[16] However, aphakic eyes have higher rates of complications, especially suprachoroidal hemorrhage if hypotony occurs. Techniques minimizing the risk of catastrophic hypotony with GDD are mandatory (described above).

Management

Assessment

Any suspicion of glaucoma in a child should always be treated seriously and with urgency to minimize visual impairment. This requires examination in either the clinic, office, or under anesthesia depending on the child's age and ability to cooperate. A neonate who is feeding or an infant asleep can be thoroughly examined in the clinic or office. Examination under anesthesia (EUA) is usually necessary until 4–5 years of age. However, children should be encouraged onto the slit-lamp for more accurate assessment of IOP and the optic disc whenever this is possible.

The initial consultation and assessment is an absolutely vital part of management. It is the beginning of what may potentially be a lifetime relationship between the ophthalmologist, patient, and their parents. The aim of the initial assessment is either to make a diagnosis of glaucoma and determine the type (primary or secondary, which is necessary in determining management) or if glaucoma cannot be ruled out, to establish that enough evidence exists to justify further appropriately timed follow-up or an EUA for a more complete examination and possible surgery.

History

In a neonate or infant, inquire about a history of epiphora, photophobia, blepharospasm, and change in ocular appearance. It is important to determine: the age of clinical onset for prognosis, associated systemic problems for anesthetic risk, problems during pregnancy (rubella) or labor (use of forceps), a family history of pediatric glaucoma, and parental consanguinity. In older children, a history of trauma, ocular inflammation or surgery, and corticosteroid use may be relevant.

Examination

It is important to begin the examination by assessing the patient's overall appearance and visual behavior including the presence or absence or nystagmus or strabismus. Following the determination of visual acuity, the ambient illumination can be reduced to allow the neonate or infant to open their eyes, permitting a more complete examination. When indicated, it is important to examine the patient's parents as the presence of subtle signs of Axenfeld–Rieger anomaly in the parents may change the genetic advice given and alter the management of subsequent siblings.

Intraocular pressure measurement

Measuring IOP in children can be challenging because it can be influenced by many factors, e.g. type of anesthetic, instrumentation, corneal thickness and opacities. The reference standard for measuring IOP is with Goldmann applanation tonometry. In cases of Peters anomaly a Tono-Pen allows you to measure the IOP more accurately in the peripheral cornea than over the central corneal opacity, which may give you a falsely high IOP. However, Tono-Pen, similar to pneumotonometry, is known to overestimate the IOP compared to Perkins, in both normal children and those with glaucoma.[17,18]

More recently, the iCare Pro portable rebound tonometer has become available for IOP measurement without the instillation of topical anesthetic drops in both supine and upright positions. It is well tolerated and thought to have a similar reliability to Tono-Pen with a tendency to overestimate in known or suspected glaucoma cases compared to applanation tonometry.[19,20] The discrepancy between the Goldmann tonometer and the iCare increases with the level of IOP and

with higher central corneal thickness.[20] In light of the above, it is advisable to use the same tonometer for serial examinations. It is important to note that regardless of the instrument used, lid squeezing and crying may falsely elevate the IOP.

The reference standard for tonometry in children undergoing EUA is the Perkins hand-held tonometer with a blue filter after instillation of fluorescein. Avoid the use of a lid speculum and pressure on the eye. Preferably, the eyes should be in the primary position and motionless, as pressure readings may be altered by eye movements. The IOP should always be measured several times in both eyes. As IOP measurement is influenced by the type of anesthetic, tonometry under anesthesia generally provides us only with an approximation of the true tension. *It should never be the sole method by which the presence or control of glaucoma is assessed.* If IOP measurement is out of keeping with other clinical findings, it may be inaccurate and tactile estimation of the IOP may be useful.

Anterior segment examination

The cornea must be examined for the presence of posterior embryotoxon, edema, opacities, and Haab striae. Oblique illumination and magnification are necessary as the signs can sometimes be subtle. During an EUA, a portable slit-lamp should be used if possible. When a deep AC in a neonate or young infant is associated with an enlarged cornea, glaucoma should be strongly suspected. It is important to remember that the presence of *corneal enlargement with splits with or without edema indicates raised IOP at some stage in infancy*. Persistent corneal edema may be a sign of poorly controlled glaucoma. Excluding primary corneal pathology is important, and a useful finding is the absence of corneal or ocular enlargement.

Detecting iris or pupil abnormalities or co-existing lens opacities is important as the latter may require treatment and influence the choice of glaucoma surgery.

Corneal diameter measurement

The normal horizontal neonatal diameter is up to 10.5 mm, increasing by about 1 mm in the first year of life. A corneal diameter greater than 11 mm in a newborn and 12 mm in an infant less than 1 year is very suggestive of raised IOP, but with Haab striae it is diagnostic. A measurement of greater than 13 mm in a child of any age and asymmetrical corneal diameters is abnormal. During EUA, the horizontal corneal diameter is measured with calipers from limbus to limbus and checked with a graduated ruler with estimation to the nearest 0.25 mm. Serial corneal diameter measurements are useful in monitoring glaucoma progression until the age of 3 years. An increasing corneal diameter may indicate inadequate control of IOP requiring further treatment.

Central corneal thickness

Central corneal thickness (CCT) influences the accuracy of tonometry. Patients with PCG and JOAG have thinner corneas and in theory a tendency for under reading the IOP. Conversely, an increase in corneal thickness, as is found in patients with aphakia and aniridia, may lead to an over estimation of IOP. However, children with aphakia and markedly thickened corneas, regardless of the theoretical overestimation of the IOP, do develop glaucomatous cupping and visual field defects.[21] This may be due to altered biomechanical properties in children with glaucoma, the importance of which is yet to be determined.[22] *Therefore, the role of pachymetry in childhood glaucoma is uncertain and standard correction factors cannot be used.* Regardless of corneal thickness, the emphasis remains on the optic disc appearance.

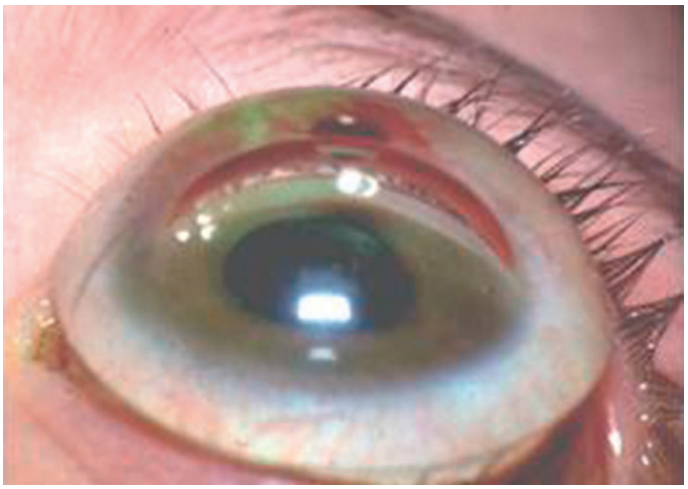

Fig. 38.10 Koeppe lens for direct gonioscopy.

Gonioscopy

Gonioscopy is crucial in making the correct diagnosis, which determines the most appropriate operation and prognosis. It should be performed at least once when possible. In an EUA, direct gonioscopy can be performed with a variety of lenses including a *Koeppe* lens (Fig. 38.10) or a wide-angled goniolens specially modified for angle surgery (Ocular Instruments, Bellevue, WA, USA).

Posterior segment examination

The appearance of the optic disc is by far the most important and sensitive parameter for both diagnosis and progression of glaucoma, as it is influenced neither by anesthesia nor the effect of growth. Richardson noted a cup:disc ratio (CDR) of greater than 0.3 in only 3% of 468 *normal* Caucasian newborn eyes,[23] in contrast to Shaffer who found a CDR of greater than 0.3 in 61% of 85 eyes in infants less than 1 year with *congenital glaucoma*.[24] A CDR *>0.3 in a Caucasian infant less than 1 year or >0.5 in a child and disc asymmetry should greatly increase suspicion of glaucoma.*

The optic disc and the nerve fiber layer should be examined through a dilated pupil and carefully recorded with a drawing and preferably a photograph as a baseline for future comparison. Optic disc photographs can be taken with a Retcam while under EUA. An increase in disc cupping is definite evidence of poorly controlled glaucoma and the need for further treatment, regardless of IOP measurement obtained. Prior to an EUA, the pupil is not dilated as this may alter the angle appearance, spuriously raise IOP, and increase the risk of lens damage if surgery is required. Consider dilating the infant in the office or as an outpatient days before the EUA if angle surgery is contemplated. Examining the optic disc in infants may only be possible after the cornea has cleared. An indirect ophthalmoscope with a small pupil facility can be very useful in obtaining a view of the disc in infants whose pupils dilate poorly.

Disc cupping in children can be reversible if IOP reduction occurs before irreversible nerve atrophy. The younger the child, the greater the potential for disc-cupping reversal (Fig. 38.11A,B). It is thought to represent a "pre-laminar" phenomenon where reversible laminar bowing is associated

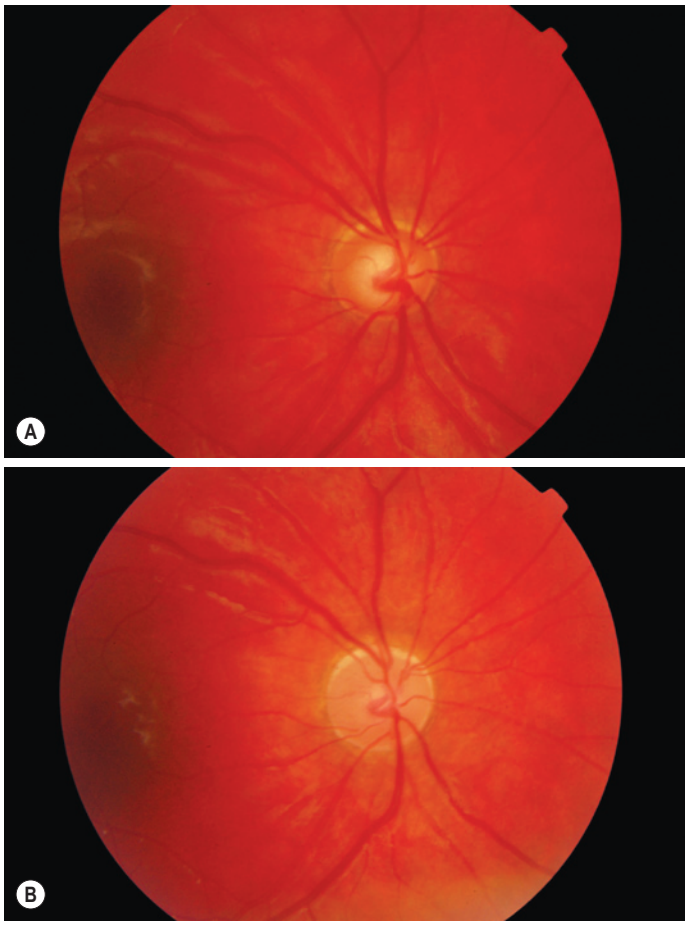

Fig. 38.11 Reversal of optic disc cupping after successful intraocular pressure lowering with surgery. (A) Preoperative disc appearance. (B) Postoperative optic disc appearance.

with compression and stretching of the pre-laminar neural tissue. Once the IOP is normal, the compression is relieved allowing the laminar to move anteriorly, "filling in" the cup. However, despite disc-cupping reversal, retinal nerve fiber layer thinning may persist postoperatively.[25]

The remainder of the fundus should be examined for any associated abnormalities such as foveal hypoplasia associated with aniridia, choroidal hemangiomas in Sturge–Weber syndrome, and pigmentary retinopathy associated with rubella.

Refraction

A significant loss of hypermetropia or the presence of myopia in a neonate or infant is often evidence of glaucoma. Progressive myopia or a myopic shift in aphakic patients suggests inadequate IOP control, especially in the context of progressive increase in axial length.

Examination under anesthesia (EUA)

The decision to examine a child under anesthesia should not be taken lightly and only performed when the information to be acquired will assist in the diagnosis or provide follow-up data important to clinical decision making. To avoid unnecessary anesthesia and delay, preferably the ophthalmologist undertaking the initial EUA should be capable of performing the definitive surgery under the same anesthetic.

As a general rule, all anesthetics lower the IOP with the exceptions of ketamine and chloral hydrate. Inhalation anesthetics, such as sevoflurane, may substantially lower the IOP by 10–30 mmHg; the amount is idiosyncratic and unpredictable. Furthermore, sevoflurane causes progressive lowering of IOP with time from induction. This makes an appropriate anesthetic vital in the assessment of these patients, especially in subtle cases, where it can have a profound impact on the timing of the diagnosis and the visual prognosis. Furthermore, it follows that the finding of a normal IOP with the use of agents known to reduce IOP does not exclude glaucoma. Whichever agent is used, it is important to have a consistent approach using the same agent for serial examinations and to measure the IOP first.

It is the authors' preference to use ketamine hydrochloride, which is believed to result in IOP measurements that are commensurate with those taken in awake infants.[26] It is given intravenously following the use of local anesthetic patches. Children are premedicated with atropine, which reduces bronchial secretions, and oral midazolam, which acts as a sedative and an amnesic. It can cause a transient rise in IOP for a few minutes and so the IOP should be measured several times. Its duration is short, usually lasting 10–15 minutes.

Establishing a routine in recording findings during an EUA is useful to avoid errors. It is important to record IOP (along with anesthetic agent, tonometer), corneal diameters, axial lengths and cup:disc ratio, along with other clinical findings such as corneal clarity at every EUA to assess glaucoma control. While the patient is under anesthesia, a general examination and venesection for laboratory investigation (e.g. screening for infective agents and chromosome studies) can also be performed.

Investigations

Ultrasound

Axial length (AL) measurement is useful for baseline assessment; if it is outside normal limits it is strongly suggestive of glaucoma. Serial AL can be valuable in children for detecting progression when the eye is still distensible. In glaucoma, AL measurements are usually asymmetrical, in contrast to X-linked megalocornea and normal eyes. There usually is a decrease in AL following successful lowering of IOP. In an eye with opaque media, high-resolution B-scan or ultrasound biomicroscopy (UBM) may be a useful to detect the presence of severe cupping or exclude posterior segment pathology such as choroidal hemangioma.

Visual fields

Visual fields are usually possible around the age of 7–8 years, but there is a learning curve. Visual field defects must be reproducible, so defects must be confirmed by repeating the test. Furthermore, the defects must correspond to the optic disc appearance. If this is not the case, and associated with unexplained reduction in visual acuity and color vision, then other causes of visual loss should be considered, especially in children with systemic disease such as Neurofibromatosis 1.

Quantitative optic disc imaging

As in adult studies, differences have been reported between normal and glaucomatous eyes in children using optical coherence tomography (OCT). A prospective, observational study in children with glaucoma revealed retinal nerve fiber layer and macular thickness measurements declined with increasing severity of glaucomatous disc damage as seen in

stereophotographs.[27] All automated optic disc imaging is limited by the lack of a normative pediatric database and the portability of the devices.

Interpretation of findings

The age of glaucoma onset determines the relevant questions to ask during history taking, the clinical findings to elicit, and the investigations to perform. In other words, IOP measurement and optic disc appearance are fundamental features of the examination throughout a child's life with glaucoma, but in an infant whose eye is still vulnerable to the effects of elevated IOP, the physical consequences of elevated IOP (enlarged corneal diameter, increasing axial length, and progressive myopia) need also to be taken into consideration and regularly assessed. So in infants, the diagnosis or progression of glaucoma must be based on the overall clinical findings and investigation results. The most important clinical sign is the optic disc appearance. If the diagnosis is unclear but there is a high risk of glaucoma, then further follow-up (including EUAs) is necessary to confirm pathology before committing the patient to treatment – especially surgery.

As the child grows older, the cornea and sclera become less elastic, so findings such as corneal diameter and AL changes become less useful measurements. With increased cooperation, the IOP can be assessed more accurately on the slit-lamp, as can the optic disc and the nerve fiber layer with greater magnification. Hence, the child should be encouraged onto the slit-lamp for evaluation as soon as possible. Eventually, visual fields become feasible to assess functional vision. This is especially useful in advanced cases.

If glaucoma is confirmed, it is important to explain to the parents the chronic nature of the condition, the possible need for repeat surgery, and definite lifelong follow-up, as glaucoma can relapse at any stage and may develop in the fellow eye of "unilateral" glaucoma.

Treatment

Managing glaucoma in childhood is one of the greatest challenges in the field of glaucoma. Medications play a vital role in management, as they are first-line therapy for most glaucomas; however, sustained efficacy is less likely in neonates and infants, especially those with PCG. Medications are frequently needed to lower the IOP before surgery and are often required as adjunctive therapy after partially successful surgery. Most children with glaucoma will require surgery in their lifetime. However, surgery is challenging, largely because of its greater potential for failure and complications as compared to adults. No treatment is curative, so lifelong follow-up is necessary to ensure IOP control and to detect complications, which can occur at any time, even after years of stability. Furthermore, parents and, later, patients should be warned that minor blunt trauma in buphthalmic eyes may result in severe visual loss. Protective eyewear should be recommended, especially in monocular patients.

Medical therapy

Although drugs used in childhood glaucoma are similar to those in adults, great care must be exercised when prescribing in children as they are at a higher risk of systemic, potentially fatal side effects from topical administration. Warn parents of potential systemic side effects and instruct them on punctal occlusion.[28]

β Blockers

The use of β blockers in premature or newborn infants, children with asthma or any cardiac problems, including arrhythmias, should be avoided. It is important to inquire about asthma symptoms, which may manifest with nocturnal cough in children rather than wheezing. *Timolol 0.1%, timolol gellan 0.25%* are the β blockers of choice as first-line treatment, due to their superior risk profile and efficacy.

Carbonic anhydrase inhibitors

Although *oral acetazolamide* is more potent in reducing IOP than dorzolamide, its use in children is limited by serious systemic side effects such as failure to thrive, disturbed hyperactive behavior, and bed-wetting. Therefore, it should be considered only on a very short-term basis prior to surgery. *Brinzolamide* is less irritating than *dorzolamide* and both are useful as second-line drugs or when β blockers are contraindicated.

Prostaglandin analogues

Latanoprost is the first agent to be approved for use in children.[29] It is thought to be at least as effective as timolol but may be less efficacious in children in combination with other medications. Patients with JOAG may respond particularly well and it should be considered first line in these patients.

Sympathomimetics

Brimonidine crosses the blood–brain barrier and can cause drowsiness to the point of coma and apnea in infants. The authors avoid it in children less than the age of 6 years or less than 20 kg bodyweight. The use of *apraclonidine* in children is theoretically safer as it is less lipophilic.

Parasympathomimetics

Parasympathomimetic agents are useful in the postoperative management of PCG after angle surgery as it may enhance aqueous outflow and prevent anterior synechiae formation. They may be highly effective in some cases of glaucoma following congenital cataract surgery.

Surgical therapy

The principal treatment modality of childhood glaucoma is surgical. The available surgical procedures have varying indications with both advantages and disadvantages and potentially good success rates, especially when performed at referral centers where there is sufficient volume to ensure both skillful surgery and safe anesthesia. Lack of familiarity with buphthalmic eyes can lead to severe complications. The procedure of choice is largely determined by the type of glaucoma and may be further influenced by age of onset, corneal clarity, degree of optic nerve damage, associated ocular disease, history of previous surgery, and the surgeon's experience.

As further surgery is often inevitable, making the right choice initially is paramount as the first operation has the greatest chance of success. In eyes that have undergone multiple procedures, it is important to make the next operation the definitive one, otherwise these eyes are at risk of the downward spiral from repetitive unsuccessful procedures. Once the procedure has been chosen, surgery must be meticulous to minimize complications.

Angle surgery

Goniotomy Although goniotomy is simple in concept and brief in execution, it is a difficult procedure to perform, requiring

considerable experience and rare surgical skills[30] (Box 38.3 and Table 38.1). Adequate *visualization of the angle is the key to successfully performing this procedure* (Fig. 38.12). Epithelial debridement with absolute alcohol provides an adequate view of the angle to allow goniotomy in more than 90% of Caucasian patients.[31]

Goniotomy is an effective operation, with success following multiple goniotomies usually ranging from 70% to 90% with medium term follow-up.[31] Risk factors for failure in PCG include: age of manifestation (onset at or within 3 months of birth), enlarged ocular dimensions (corneal diameter ≥14 mm and AL >24 mm).

Box 38.3

Advantages and disadvantages of diode laser cyclodestruction

Advantages

- Short surgical time and rapid rehabilitation
- Good short-term response rate
- Very useful in high-risk surgery, particularly in only eyes
- Technically less demanding than other procedures

Disadvantages

- Often needs to be repeated in more than 50% of cases due to recovery of ciliary body
- Most patients remain on medical therapy
- Intraocular pressure in the low teens usually not achieved in comparison to filtering surgery
- Potential for significant inflammation and may accelerate cataract formation
- Danger of long-term phthisis with recurrent treatment
- May affect future drainage surgery: hypotony due to hyposecretion and failure due to effect on blood aqueous barrier releasing stimulatory cytokines into aqueous and drainage site

Trabeculotomy Since corneal opacification does not prevent the performance of trabeculotomy, it has greater application than goniotomy but is more invasive, causing conjunctival scarring, an important point considering the potential need for further surgery in the child's lifetime. In light of this, a temporal incision is preferable. *Accurate localization of Schlemm canal (SC) is the key to successful trabeculotomy.*[30] However, abnormally stretched limbal anatomy in buphthalmic eyes makes it difficult to identify and it may not be found at all in 4–20% of patients, especially if the anterior chamber is inadvertently entered before the canal is found. Conventional trabeculotomy with a trabeculotome incises up to one-third of the angle, whereas the use of a blunted 6/0 polypropylene suture[32] or an illuminated microcatheter[33] threaded into SC can potentially incise 360° (circumferential trabeculotomy) in one operation (see Table 38.1). Success is not always possible with

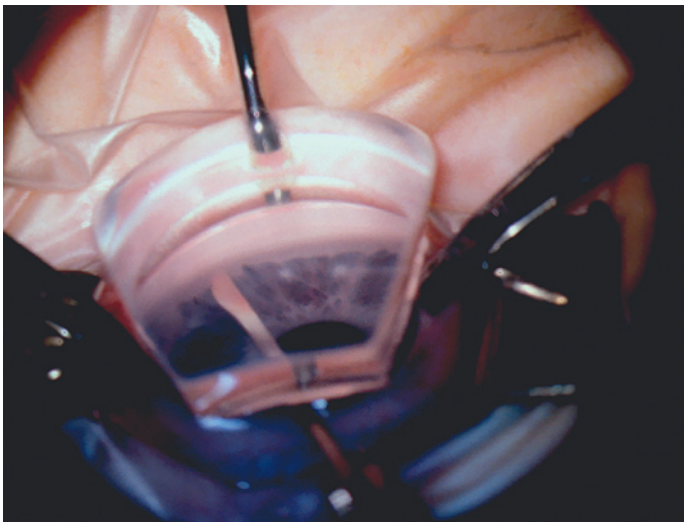

Fig. 38.12 Goniotomy performed in primary congenital glaucoma.

Table 38.1 Comparison of angle surgery techniques

	Goniotomy	Trabeculotomy (probe)	Trabeculotomy (360°)		Trabeculotomy–trabeculectomy
			Suture	Illuminated microcatheter	
Conjunctival incision	–	+	+	+	+
Possible with opaque cornea (angle structures not clearly visible)	–	+	+	+	+
Angle visualization	+	–	– (only with gonio lens)	+	–
Specialized instruments/skills	++	+	+	++	++
Extent of surgical trauma	+	++	++	++	+++
Potential for complications	+	++	++	+	++
Duration of surgery	+	++	++/+++	++/+++	++
Can be repeated	++	++	–	–	+
Bleb related complications	–	–/+	–/+	–/+	+

a single incision and severe hypotony along with misdirected (subretinal) sutures have been reported.

Success rates of conventional trabeculotomy and prognostic factors in PCG are similar to those of goniotomy.[34] However, results of circumferential trabeculotomy suggest greater success than goniotomy and combined trabeculotomy–trabeculectomy (CTT) and respectively.[35,36]

Angle surgery is the procedure of choice for PCG, the exact choice being influenced by the corneal clarity, the surgeon's experience and preference. Success rates for secondary childhood glaucomas are generally not as good as for PCG. Russell-Eggitt[31] reported a 20% relapse rate over a 30-year period with no peak age of relapse.

Trabeculotomy combined with trabeculectomy Trabeculotomy has the added advantage of being combined with trabeculectomy to provide, in theory, two major outflow pathways and so improve results. In practice, the clinical benefit is unclear. Some authors have reported greater success than with either procedure performed alone, especially in populations at high risk of failure, such as in East Asia and the Middle East.[37] Others have found no difference in success between the three procedures.[38] Technically, it is a more complex procedure with potentially significant complications, especially with the use of anti-scarring agents.

Trabeculectomy

One of the main indications for trabeculectomy is failed angle surgery. It may be the primary procedure of choice when: the surgeon has no or limited experience with angle surgery; the patient is unlikely to respond sufficiently to angle surgery (very early or late presentations); very low target pressures are required (improved cornea clarity, advanced disc cupping); and for most secondary glaucomas.

Technically it is a more demanding procedure and more likely to fail in children due to a vigorous wound healing response. The propensity to failure necessitates the use of MMC, which is associated with higher complication rates. However, with recent simple modifications to the surgical technique (Moorfields Safer Surgery System)[39] and to the intraoperative application of MMC, trabeculectomy can be associated with more favorable bleb morphology, reduced complications, and satisfactory outcomes in appropriate cases, even infants[40,41] (Fig. 38.13). For a summary of technique, refer to Table 38.2. If significant conjunctival inflammation is present at the drainage site, subconjunctival 5-fluorouracil (5-FU) (0.1–2 ml of 5-FU 50 mg/ml) and steroids such as betamethasone can be injected adjacent to the bleb while under EUA. The advantages and disadvantages of trabeculectomy are summarized in Table 38.3.

With MMC, trabeculectomy cumulative success rates of 59–90% at 2 years reducing to 51% at 5 years have been reported.[42–44] Reported risk factors for failure are: age less than 1 year and aphakia.[14,43,45] The potential for complications after trabeculectomy, especially with MMC, cannot be overstated in children. Early complications relate to hypotony (shallow or flat AC, hypotony maculopathy, choroidal effusion, suprachoroidal hemorrhage) and late complications are associated with thin avascular, cystic blebs prone to leakage and potentially blinding infection. When trabeculectomy fails to control IOP, bleb needling may be attempted with an anti-scarring agent if the bleb architecture allows and the sclerostomy is patent.

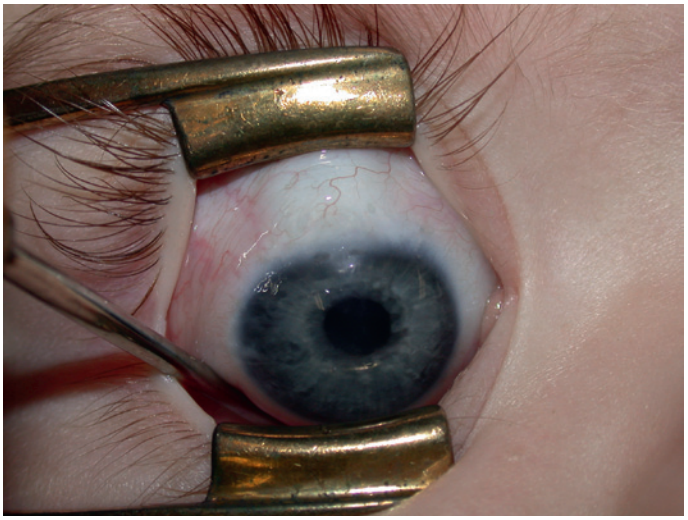

Fig. 38.13 Mitomycin C trabeculectomy in a child with fornix-based conjunctival flap and large antimetabolite treatment area.

Non-penetrating surgery (*deep sclerectomy*) for congenital glaucoma has been performed in an attempt to avoid trabeculectomy-related complications, such as early hypotony. However, it has not been widely adopted because of the technical challenges in bupthalmic eyes with thin sclera. This may also explain the significant rate of conversion to trabeculectomy.[46,47]

Glaucoma drainage devices (GDDs)

Glaucoma drainage devices are an important part of the therapeutic repertoire in childhood glaucoma as they offer the best chance of long-term IOP control in patients whose disease relentlessly progresses despite conventional surgical treatment. As primary surgery, indications include children: with uveitis who are aphakic or pseudophakic; who develop glaucoma following cataract surgery; who have a cataract that will need future imminent removal; and those with very severe disease with onset at birth, as these cases have a very high failure rate, even with MMC trabeculectomy. The prevailing current opinion is that GDDs are best implanted sooner rather than later in the hope of achieving early, definitive IOP control and, in doing so, optimizing long-term visual prognosis. The advantages and disadvantages of GDDs drainage surgery are summarized in Table 38.4.

Success rates of approximately 80% are reported with a mean follow-up of 2 years or less,[48–50] falling to around 50% with longer term follow-up.[51,52] The use of adjunctive MMC has been reported but there are no prospective studies in children to suggest improved outcomes with its use. There is no clear superiority of one GDD over another. Adult studies suggest the Baerveldt implant provides better long-term IOP control than the Ahmed implant.[53] Although the Ahmed implant has fewer complications, it is associated with a 2.6 higher chance of needing further glaucoma surgery (including diode).[53]

Common to all studies, regardless of the implant, is the ongoing decline in success with duration of follow-up and the requirement for adjunctive topical medication to control IOP.[54] Plate encapsulation is a major cause of late failure. Needling or capsule excision may be attempted but

Table 38.2 Important surgical points in pediatric trabeculectomy technique aimed at encouraging posterior flow and formation of diffuse bleb

Surgical steps	Surgical points/rationale
Corneal traction suture (7/0 Mersilk)	Allows adequate exposure Avoids hemorrhage from superior rectus muscle suture
Fornix-based conjunctival flap	Less likely to form a scar limiting posterior flow Allows better visualization of limbal anatomy
Wet field cautery	Hemostasis Avoids scleral shrinkage (important in thin sclera)
Anti-scarring agents	Diffuse large treatment to minimize risk of a focal, avascular bleb
Scleral flap	Consider fashioning scleral flap first before anti-scarring treatment to enable treatment under scleral flap Posterior edge must be well beyond limbus to prevent cheese-wiring of flap Dissection forward into cornea avoids iris, ciliary body and vitreous incarceration Short radial cuts enough to allow reflection of scleral flap for the sclerostomy • Greater the scleral elasticity (incision gap), the smaller the radial cuts • Directs aqueous flow posteriorly to prevent cystic blebs • Valve effect to prevent hypotony Large (5 mm posterior cut) and as thick as possible • Sutures less likely to cheese-wire • Greater resistance to aqueous outflow
Preplaced scleral flap sutures before sclerostomy	Easier to place with formed globe Reduces duration of intraoperative hypotony after sclerostomy and peripheral iridotomy (PI) performed Can be adjusted or removed under anesthetic or slit-lamp without laser Releasables along posterior borders of scleral flap, and fixed sutures at corners if scleral flap gapes, e.g. in infants Releasable loop buried in cornea so suture can be left indefinitely (reduces risk of endophthalmitis)
Paracentesis for AC maintainer	Oblique, peripheral, long tunnel (21G needle) minimizes risk of inadvertent lens damage, avoids wound leak, and stabilizes infusion cannula Allows maintenance of IOP intraoperatively preventing hypotony and potential for choroidal effusions, suprachoroidal hemorrhage, vitreous prolapse with PI Allows anterior chamber (AC) reformation Must turn off when tying scleral flap sutures tight to prevent cheese-wiring Used to gauge flow through sclera flap and ensure adequate flap closure
Sclerostomy	Small sclerostomy punch (500 μm diameter) allows increased control of aqueous outflow both intra- and postoperatively and is quicker to perform As anterior as possible prevents iris, ciliary body, and vitreous incarceration
Scleral flap closure	Tight closure vital with anti-scarring agent use Add additional sutures as required to reduce flow
Fornix-based conjunctival closure	10-0 nylon retains tension longer than dissolvable sutures with minimal inflammation Purse string sutures at peritomy edges, with limbal vertical mattress sutures
Prevention of postoperative hypotony	Short radial cuts create valve effect and minimize leakage from scleral flap sides Tight scleral flap sutures with option to adjust/release at later stage Watertight conjunctival closure Suture paracentesis May leave viscoelastic in AC if flow rate too high despite maximal suturing, or if ciliary body shut down anticipated (uveitic cases) Air bubble in AC

Adapted from Papadopoulos M, Edmunds B, Chiang M, et al. Glaucoma surgery in children. In: Weinreb RN, Grajewski A, Papadopoulos M, et al., editors. Childhood Glaucoma. WGA Consensus Series – 9. Amsterdam: Kugler Publications, 2013: 95–134.

published studies suggest outcomes inferior to additional GDD implantation.[55] Sequential GDD surgery may result in more corneal complications. The authors' preference is for the Baerveldt 350 mm^2 implant with restrictive-flow measures because of its larger surface area. The 250 mm^2 is favored for uveitic eyes, which are prone to aqueous hyposecretion, and microphthalmic eyes, which have smaller anterior chambers that can easily shallow with hypotony. Once failure has occurred, the authors usually prefer diode laser as the next procedure before proceeding with a second GDD.

GDDs have a significant complication profile. Consistently reported more commonly in children compared to adults is tube malposition, with migration anteriorly causing tube corneal touch, or posteriorly leading to retraction (requiring surgical revision in 33% of cases) along with tube erosion and endophthalmitis in up to 10% of cases.[54] Hypotony is another major complication that buphthalmic eyes are especially prone to, and occurs even with the use of valved implants. Modifications to minimize complications are summarized in Table 38.5.

Table 38.3 Advantages and disadvantages of trabeculectomy with mitomycin C (MMC)

ADVANTAGES
"Titration" of postoperative intraocular pressure (IOP) possible with releasable sutures and postoperative subconjunctival 5-fluorouracil (5-FU) and steroid under examination under anesthesia
Lower mean IOP achievable compared to glaucoma drainage device (GDD)
Less dependent on medication for IOP control compared to GDD
Less postoperative surgical revision compared to GDD
May significantly clear cloudy corneas and avoid potential corneal surgery
Many surgeons have experience performing trabeculectomy
DISADVANTAGES
More invasive and higher complications than angle surgery
Significant lifetime risk of endophthalmitis if bleb thin and avascular (more likely with small treatment areas of MMC and limbal based conjunctival flap)
Poor results in aphakic/pseudophakic patients even with MMC
Need close follow-up

Table 38.4 Advantages and disadvantages of glaucoma drainage device (GDD) surgery

ADVANTAGES
Very effective in reducing intraocular pressure (IOP) long term, even if previously failed mitomycin C trabeculectomy
Most likely to survive future intraocular surgery, e.g. penetrating keratoplasty, lensectomy, vitrectomy; therefore best option in these circumstances
Contact lens wear possible in aphakic/pseudophakic patients
DISADVANTAGES
Potentially long surgical time with non-flow-restricted implants
Often dependent on medication for IOP control
High surgical revision rate
Higher risk of corneal decompensation compared to trabeculectomy

Table 38.5 Strategies to minimize glaucoma drainage device (GDD) complications

Complication	Preventative strategies
Anterior tube migration	Secure plate and tube well to sclera to minimize migration Baerveldt plate behind the muscles to prevent migration is preferable
Posterior tube migration	Secure plate and tube well to sclera to minimize migration Avoid very short tube
Corneal decompensation	Aim to place tube away from cornea and as posterior as possible in anterior chamber Avoid long tube
Intra- or postoperative hypotony	Anterior chamber (AC) maintainer (e.g. Lewicky cannula) Relatively long, snug limbal tunnel incision (e.g. 25G needle usually adequate for tube entry as sclera is elastic) Intraluminal stent in non-valved implant (e.g. 3/0 Supramid suture) Extraluminal ligating vicryl suture in non-valved (e.g. 6/0 Vicryl) with venting "Sherwood" slit anterior to suture Viscoelastic or gas in AC at end of surgery if IOP low Two-stage implantation
Tube obstruction	Aphakic cases with AC/sulcus tubes, ensure no vitreous present or likely to prolapse into AC otherwise consider vitrectomy For pars plana tube placement, extensive posterior vitrectomy required Treat inflammation aggressively Avoid short tube in uveitics: reduces risk of iris-related tube obstruction from peripheral anterior synechiae
Tube erosion	Intrascleral tunnel with AC entry at or as posterior to limbus as possible – avoid corneal tunnel, which is more likely to erode Oblique entry into eye rather than 90°, which may produce knuckle of tube at entry point Patch graft along whole of tube length – sclera or cornea, other tissue (e.g. pericardium) Avoid conjunctival tension at limbus with closure Tube entry when inferiorly placed should be covered by lower lid

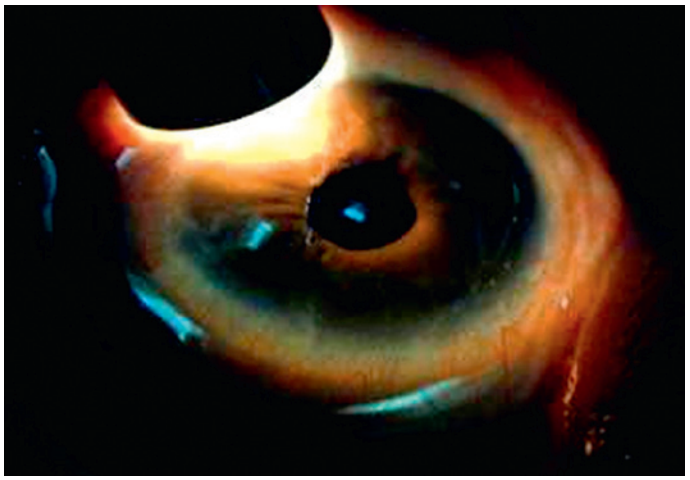

Fig. 38.14 Cyclodiode laser. Transillumination is crucial for correct placement of burns on the ciliary body.

Fig. 38.15 Child with Sturge–Weber syndrome wearing myopic spectacle correction.

Cyclodestruction

The indications for cyclodestruction are: (1) a blind painful eye; (2) poor visual potential; (3) poor surgical prognosis; and (4) surgery is technically impossible or when other treatments have failed. The advantages and disadvantages of diode laser cyclodestruction are summarized in Box 37.3.

Contact transscleral semiconductor diode laser (810 nm) has become increasingly more popular than Nd:YAG laser and cyclocryotherapy as a method of ciliary body ablation because it is better tolerated and associated with fewer complications. As buphthalmic eyes often have distorted anatomical landmarks, transillumination of the eye is essential to ensure accurate placement of the laser burns (Fig. 38.14). Care must be taken to avoid areas of pigmentation, hemorrhage, and scleral thinning, as scleral perforation in a buphthalmic eye has been reported.[56]

Transscleral diode laser has limited long-term success, often requires retreatment, and the continuation of medications.[15,57] Results are similar to those achieved with endoscopic diode with a lower retreatment rate. Overall visual loss rates of up to 18% have been reported, usually in eyes with pre-existing poor vision.[58]

Refractive correction and amblyopia therapy

The ultimate aim of preserving lifelong vision in children with glaucoma is dependent not only on IOP control, but also several inter-related factors such as the treatment of ametropia and amblyopia (Fig. 38.15). All children with glaucoma within the vulnerable age range should be examined regularly for the presence of amblyopia. Refraction should be part of the periodic examination with glasses prescribed as appropriate when the cornea clears and is practical. Occlusion therapy for amblyopia should be attempted in all children in whom there is potential for visual improvement.

Anatomy

The iris is the most anterior element of the uveal tract. It divides the anterior segment into anterior and posterior chambers. It is composed of blood vessels, connective tissue, muscles, melanocytes, and pigment cells. Its stroma is made up of pigmented and non-pigmented cells, collagen fibrils, and hyaluronic acid. The stroma contains multiple crypts and is covered by connective tissue cells. Differences in color relate to the amount of pigmentation in the anterior border of the deep stroma; blue irides are lightly pigmented and brown irides have densely pigmented stroma. Blood vessels form the bulk of the iris stroma. They run a radial course arising from the major arterial circle located at the apex of the ciliary body, passing to the center of the pupil. Myelinated and non-myelinated nerve fibers provide sensory and motor functions throughout the stroma.

Embryology

The posterior surface of the iris is densely pigmented and is continuous with the non-pigmented epithelium of the ciliary body. The dilator muscle layer is parallel and anterior to the posterior pigment epithelium. The muscle dilates in response to sympathetic adrenergic stimulation, and parasympathetic stimulation has an inhibitory effect. The sphincter muscle is located near the pupillary rim in the deep stroma. It receives parasympathetic nerve fibers to cause constriction.

The uveal tract develops from the neuroectoderm, neural crest, and mesoderm. The iris sphincter and dilator muscles and posterior iris epithelium develop from the neuroectoderm. Pigment differentiation and migration continue into the second and third trimesters. The smooth muscle of the iris develops from the neural crest. Iris formation starts with the closure of the fetal cleft at 35 days' gestation. The sphincter muscle first appears at the optic margin at 10 weeks' gestation, becoming myofibrils at 10–12 weeks. The smooth muscle of the ciliary body is present at 4 months' gestation before the iris stroma develops. The blood vessels arise from the mesoderm and neural crest. The pupillary membrane regresses shortly before term. The pupil is small at birth but it enlarges as the dilator muscle develops. Pigmentation is complete at one year and the irides get darker in the first year of life.

Signs and symptoms of iris disease

Pain and photophobia are features of iritis. Congenital structural and developmental abnormalities of the pupil include iridodonesis, aniridia, micropupil, polycoria, corectopia, ectropia, coloboma, iris sphincter atrophy, and dilated oval pupils (Boxes 39.1 and 39.2; Figs 39.1 and 39.2).

Acquired abnormalities include trauma (Fig. 39.3), ischemia, hemorrhages, or infiltration of the iris with tumors such as lymphoma, leukemia, juvenile xanthogranuloma, Lisch nodules, and neurofibromas. Anisocoria, a difference in pupil size, occurs in approximately 20% of the normal population. It may be transmitted as an autosomal dominant trait with variable expression.[1]

Congenital idiopathic microcoria is a developmental abnormality of the pupillary membrane. It is usually unilateral with an absent or eccentric pupil. It is autosomal dominant and is associated with myopia and corectopia.[2] Congenital fibrovascular pupillary membranes are likely a variant of persistent fetal vasculature.[3] Bilateral microcoria is associated with microphthalmos and posterior segment anomalies.[4]

Persistent pupillary membranes

Congenital persistent pupillary membranes result from incomplete involution of the tunica vasculosa lentis during the third trimester. These are often still present in premature infants before complete involution has occurred. These membranes are formed by buds from the annular iris vessels growing centrally to form the anterior vascular envelope of the lens. They may span the entire pupil and can be attached to the anterior capsule of the lens with or without cataract. They may occur in association with microcoria, megalocornea,

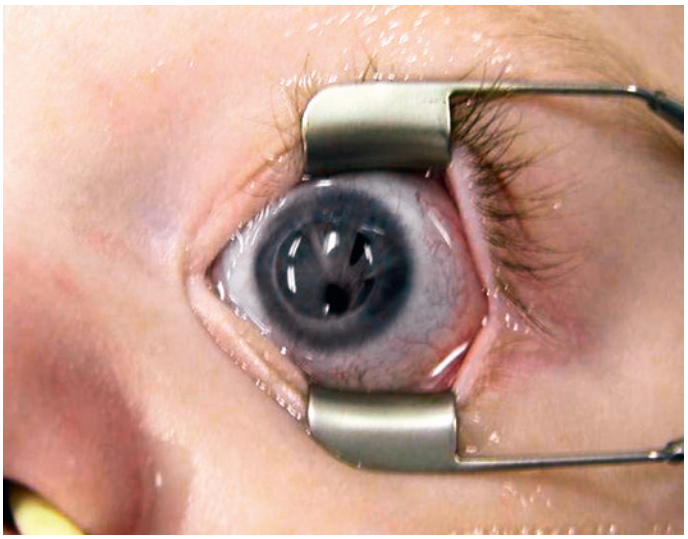

Fig. 39.2 Child with Peters' anomaly showing corectopia through a corneal transplant.

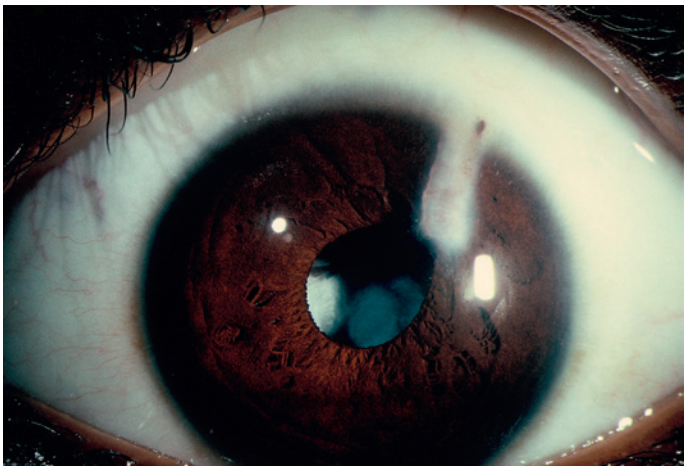

Fig. 39.3 Iris incarceration after a penetrating injury that was never repaired surgically.

microphthalmos, and coloboma. Most are asymptomatic and require no treatment.[5] It is sometimes difficult to assess whether a membrane is amblyogenic. Removal involves surgery with viscoelastics and excision with microscissors or vitrector[6] (Figs 39.4 and 39.5). Complications of surgery include cataracts, sphincter damage, or iridodialysis.[7] Laser lysis uses a Nd:YAG laser to disrupt the adhesions between the strands of the membrane and the normal iris.[8] Complications include pigment dispersion and hyphema and cataract. The visual prognosis is good,[9] but poor initial visual acuity is an indication of a poor outcome. Myopic and hyperopic anisometropia may accompany persistent pupillary membranes.

Congenital iris and stromal crypts

Iris cysts may be congenital resulting from an accumulation of fluid within the epithelial lining. They are found in either the pigment epithelium or stroma and have a squamous epithelial or neuroepithelial lining. Iris pigment cysts are

usually stationary with a transparent wall and vascular lining at the pupillary margin. Stromal cysts are progressive and are located in the anterior surface of the iris. While some advocate a conservative approach, many require surgery. A variety of treatments have been tried, including aspiration with or without cryotherapy applied to the base of the cyst near the limbus, the injection of alcohol or sclerosing agents, surgical excision with sector iridectomy, Nd:YAG or argon laser, or irradiation.[10] The differential diagnosis of congenital iris cysts includes epithelial cell implantation from surgery, trauma, and tumors. Complications include glaucoma, cataract, and spontaneous detachment, when an iris cyst may become free-floating.

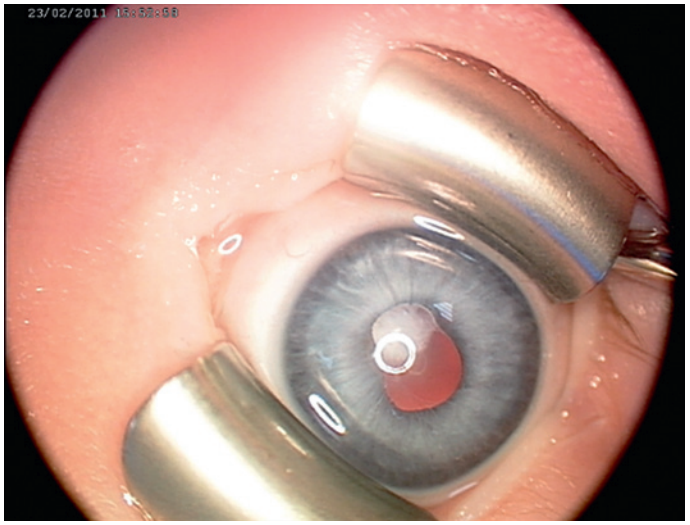

Fig. 39.4 Persistent pupillary membrane. A five-week-old baby presented with a persistent pupillary membrane in the left eye. Our initial treatment was patching and pupil dilation; however, she was intolerant of patching. We removed the membranes through a small corneal incision and using microscissors and viscoelastic. She had a clear visual axis post-operatively. She tolerated patching and now has equal vision in each eye.

Ciliary body cysts are less common; they may be solid or filled with fluid, and may cause astigmatism and amblyopia (Fig. 39.6).

Multisystemic smooth muscle dysfunction syndrome

Multisystemic smooth muscle dysfunction syndrome is a recently described genetic disease characterized by dysfunction of the smooth muscles throughout the body. It manifests as congenital fixed pupils with lack of accommodation. Affected patients may have persistent ductus arteriosus, aortic and cerebrovascular disease, hypotonic bladder, intestinal hypoperistalsis, and pulmonary hypertension.[11] It is thought

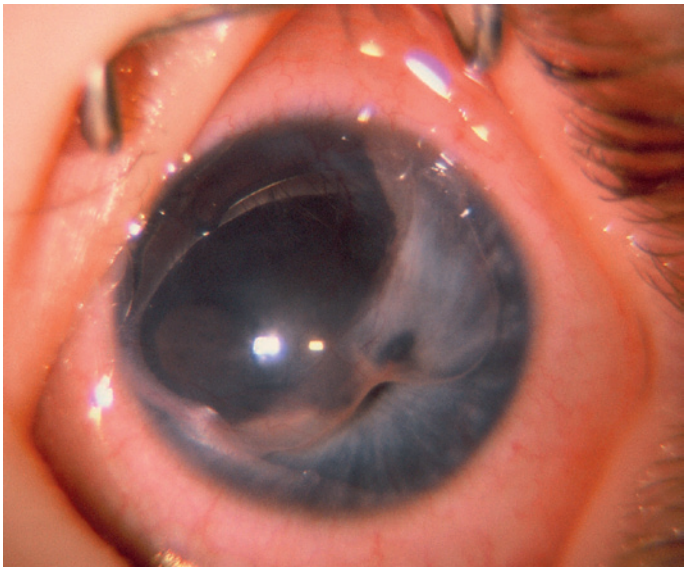

Fig. 39.6 Iris stromal cyst in a 10-month-old child involving the visual axis.

to be caused by a *de novo* mutation of the *ACTA2* gene, on chromosome 10 (10q23.3).

Iris ectropion or ectropion uveae

Ectropion uveae (Fig. 39.7) is characterized by extension of the posterior pigment epithelium onto the anterior surface of the iris. It may be congenial or acquired.[12] It can be associated with glaucoma, neurofibromatosis type 1 (NF1), or anterior segment dysgenesis. This should be distinguished from iris flocculi, which are excrescences of the pigment epithelium at the pupil margin. These may be a marker of familial aortic aneurysms.[13]

Heterochromia iridis

A difference in iris color can be congenital or acquired. In congenital heterochromia (Fig. 39.8), the involved iris is darker, an indicator of ocular melanocytosis, oculodermal melanocytosis, or a sector hamartoma syndrome. Congenital Horner syndrome results in ipsilateral hypopigmentation miosis and ptosis (Fig. 39.9). Waardenburg syndrome (WS) is an autosomal dominant condition with sensorineural deafness, white forelock, and heterchromia iridis. Type 1 WS includes lateral displacement of the inner canthi, a prominent root of the nose, and unusual eyebrows, which may meet across the midline (synophrys). It is caused by mutations in the *PAX3* gene.[14] Type 2 WS does not include facial dysmorphism or dystopia canthorum, where telecanthus can result in an abnormal displacement of the inner canthal relative to the globe. Type 3 is similar to type 1 with limb abnormalities. Type 4 is associated with Hirschprung disease. The gene has been localized to 3p–12:p141[15]; however, several genes may be implicated.

Iris sector heterochromia and Hirschprung disease is an autosomal recessive condition due to a neural crest cell lineage abnormality.[16]

In acquired heterochromia the iris may become darker through processes such as nevus formation, melanomatous tumors, and deposits of iron within the iris (siderosis). Hemosiderosis results from iron deposition from a longstanding hyphema.[17] Conversely, the iris may become lighter. Fuchs heterchromic iridocyclitis is the commonest cause, but others such as juvenile xanthogranuloma, metastatic malignancy, and leukemia are differentials. Acquired Horner syndrome infrequently leads to heterochromia; this may only appear after some years. William syndrome is a rare autosomal dominant disorder. Associated systemic features include aortic valve disease, hypercalcemia, elfin facial feature, prominent lips, hyperacusis, and developmental delay.[18] It is associated with a unique stellate appearance of the iris.[19] Other ocular features include strabismus, hyperopia, and retinal vein tortuosity.

Juvenile xanthogranuloma (JXG) is a benign condition of unknown etiology that occurs in infancy and early childhood. There is a proliferation of non-Langerhans histiocytes, plasma cells, and occasional eosinophilic and Touton giant cells.[20] Xanthogranulomas are more common in children with neurofibromatosis 1. The skin is most commonly involved, but lesions may occur in the eye. Children with cutaneous JXG rarely have eye involvement, and eye screening in these children is of little merit.

Risks factors for ocular involvement include an increased number of skin lesions and age under 2 years. Within the eye, the iris is the most common location, but the choroid, orbit, cornea, conjunctiva, and sclera may be involved. Iris lesions may be localized or diffuse and are mostly unilateral.

Fig. 39.7 Ectropion uveae and a cystic drainage bleb. A 2-year-old girl was referred with raised intraocular pressure (IOP) and grossly cupped optic disc. She had unilateral, ectropion uveae glaucoma. After a mitomycin-enhanced trabeculectomy, her IOP was reduced to 8 mmHg. Six years later, her vision is LogMAR 0.48 (Snellen equivalent, 6/15).

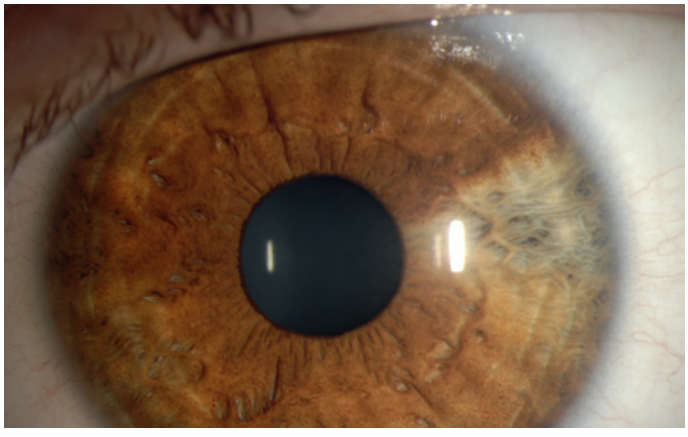

Fig. 39.8 Sectoral heterochromia.

Fig. 39.9 Congenital Horner syndrome with iris heterochromia.

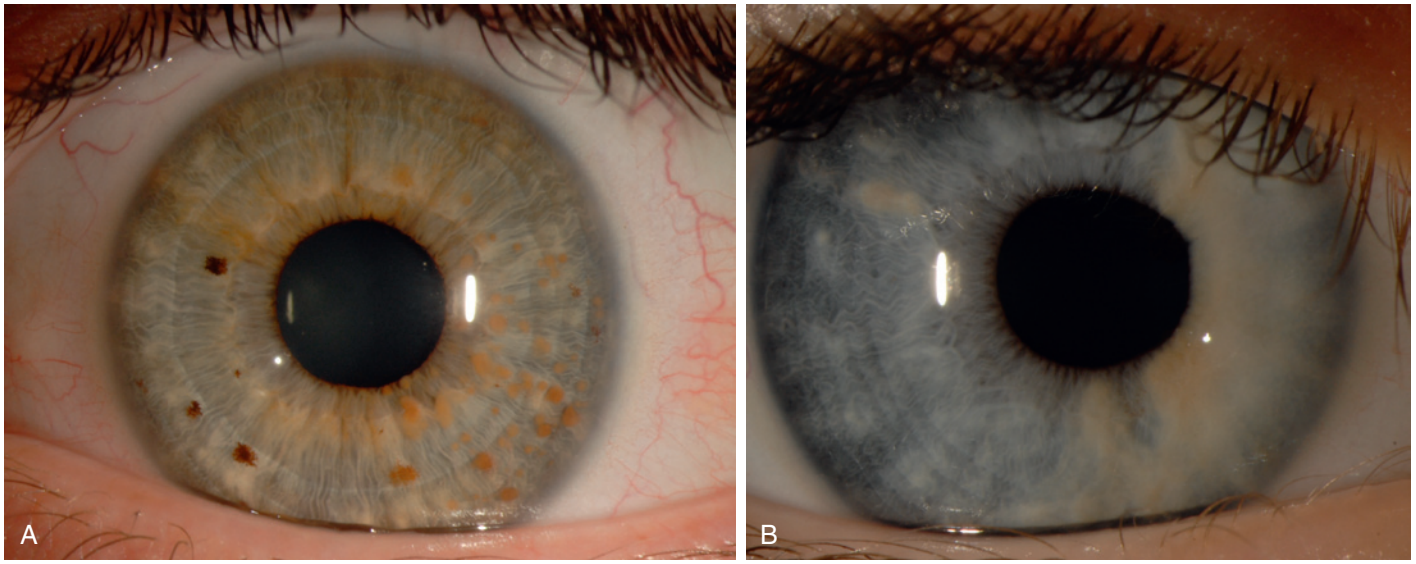

Fig. 39.10 Lisch nodules. (A) The father has multiple Lisch nodules. (B) The son has hypopigmented Lisch nodules and sectoral depigmentation of his iris temporally. Both the father and son have neurofibromatosis type 1.

They are usually highly vascular and frequently bleed spontaneously, resulting in a hyphema, an elevation of the intraocular pressure, and corneal edema. Amblyopia is a significant risk in affected infants. If the child presents with a spontaneous hyphema, the differential diagnoses include juvenile xanthogranuloma, retinoblastoma, fibrosis secondary to persistent fetal vasculature, and iris corneal malformations.

The diagnosis can usually be established by biopsy of a skin lesion. However, in children with only ocular involvement, the diagnosis can be made by performing a paracentesis over an iris lesion and examining the cells in the aspirate histopathologically. Iris biopsy carries a high risk of operative hyphema and it is contraindicated if retinoblastoma is suspected. Treatment options include topical corticosteroids and low-dose radiotherapy.[21]

Lisch nodules

Lisch nodules are dome-shaped lesions on the anterior surface of the iris (Fig. 39.10). They are brown/orange in color, round, and bilateral. In dark irides they appear lighter than the background. Their size varies widely. Histopathologically they are melanocytic hamartomas. In NF1, they are present in one-third of 2-year-olds, 50% of 5-year-olds, 75% of 15-year-olds, and 100% of patients over 21 years of age.[22] Rarely, they can also occur in patients with NF2.

Brushfield spots

Brushfield spots are areas of normal or hypercellular iris tissue with surrounding stromal hypoplasia. They occur in a quarter of normal individuals, where they were initially described, but Thomas Brushfield considered them to be characteristic of Down syndrome, although they are not always present in these children. They differ from iris pigment spots and freckles in that they are more central and numerous.

Fig. 39.11 Iris coloboma of the right eye and severe microphthalmos of the left eye.

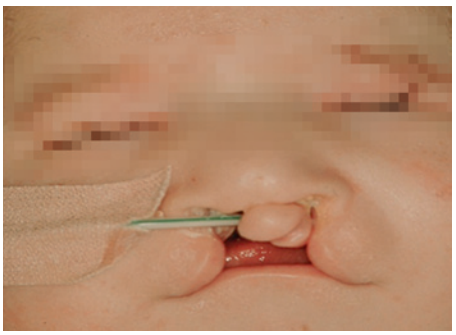

Fig. 39.12 Patau syndrome.

Iris colobomas

Iris colobomas may be typical or atypical, complete or partial. Typical colobomas are caused by a failure of fetal fissure closure at the inferior nasal quadrant and are referred to as "keyhole" pupils (Fig. 39.11). They can involve the iris, ciliary body, retina, and optic nerve. Atypical colobomas are those found anywhere other than the inferior nasal quadrant and are usually restricted to the iris. "Typical" colobomas are part of a continuum that includes microphthalmos and anophthalmos.[23] Autosomal dominant colobomas can be isolated lesions or manifestations of microphthalmia and anophthalmos.[24] Several syndromes (Box 39.3) and chromosomal disorders (Box 39.4 and Fig. 39.12) are associated with ocular colobomas. The most

Box 39.3

Syndromes associated with colobomas

Aircardi syndrome
CHARGE syndrome
Goldenhar syndrome
Goltz syndrome (focal dermal hypoplasia)
Median facial cleft syndrome
Warburg syndrome
Rubinstein–Taybi syndrome
Linear nevus sebaceus syndrome
Meckel syndrome
Klinefelter syndrome
Turner syndrome

Box 39.4

Chromosomal disorders associated with colobomas

Trisomy 13 (Patau syndrome)
Cat-eye syndrome
4p, 119, 139, 189, 18F, 18T
Trisomy 18 (Edwards syndrome)

Fig. 39.13 Iris coloboma in a child following closure with modified McCannel suture technique. (Blackmon DM, Lambert SR. Congenital iris coloboma repair using a modified McCannel suture technique. Am J Ophthalmol 2003; 135: 730-732).

common associated condition is CHARGE syndrome[25] (coloboma associated with heart disease, choroidal atresia, mental retardation, genital hypoplasia, and deafness). There is also an association between uveal colobomas and teratogens such as thalidomide.

Children with coloboma should have a complete eye and medical examination. The family history should be documented and relatives examined. A child with coloboma should be followed for potential amblyopia, anisometropia, and retinal detachment. An iris coloboma can be closed surgically, but is usually not indicated unless it is combined with cataract surgery (Fig. 39.13).

Box 39.5

Tumors of the iris

Iris nevi
Medulloepithelioma
Leiomyoma
Hemangioma
Iris melanoma

Iris melanosis and iris mammillations

Iris melanosis is rare. The iris is hyperpigmented. It is associated with scleral pigmentation and choroidal hyperpigmentation. It is usually autosomal dominant.[26] Heavily pigmented irides commonly have pigmented protuberances called iris mammillations, which are distributed uniformly, often covering much of the anterior surface of the iris. They are associated with iris nevi (Fig. 39.13).[27] There is a risk of glaucoma with both conditions. Cogan–Reese syndrome is a unilateral iris nevus with peripheral anterior synechiae and ocular hypertension.

Iris tumors (Box 39.5)

Iris leiomyomas are rare, benign, slow-growing smooth muscle tumors that are more common in girls. They usually present with pupillary distortion and hyphema, and later may develop glaucoma and cataract. They can be indistinguishable from melanomas.[28] If they enlarge, surgical excision is advised.

Iris hemangiomas are rare. They are most common on the inferior sector of the iris and they may cause spontaneous hyphema. They may be isolated or associated with multiple cutaneous and even visceral hemangiomas.[29] Iris melanomas are rare in childhood. They tend to occur in the inferior iris and can present with a hyphema. Histologically, most are spindle cells with a low risk of metastasis. The differential diagnosis includes juvenile xanthogranuloma, iris rhabdomyosarcoma, and iris foreign body. Medulloepitheliomas (diktyomas) are unilateral solid or cystic tumors occurring in the iris and extending to the non-pigmented ciliary body epithelium. They can appear in infancy or early childhood and are often associated with glaucoma, leukocoria, distorted pupil, or hyphema. Histologically, they are composed of membranes, tubes, and rosettes, and they may undergo malignant transformation. The potential for spread is low. If the tumor is anterior, local resection or cryotherapy is the recommended treatment. When the diagnosis is delayed and there is a risk of extraocular extension, enucleation is the recommended treatment.

Spontaneous hyphemas

Spontaneous hyphemas occur secondary to anomalous iris capillary loops; tumors such as juvenile xanthogranuloma, medulloepithelioma, or retinoblastoma; retinopathy of prematurity; persistent fetal vasculature; and blood dyscrasias. In older children, scarring and iris rubeosis should also be included in the differential diagnosis. Leukemic infiltration

of the iris may cause hyphema and glaucoma and hypopyon. Studies to determine the underlying cause include: ultrasonography, magnetic resonance imaging, and general physical examination. Hematological screening for blood disorders is also necessary.

Differential diagnosis of childhood intraocular inflammation

Unreported trauma or intraocular foreign body
Neoplasia
- Diffuse retinoblastoma
- Juvenile xanthogranuloma
- Relapse of leukemia
- Rosai–Dorfman disease

Photoreceptor dystrophy, especially where retinal pigment epithelium (RPE) changes have not yet developed or where RPE changes resemble choroiditis
Retinochoroidal dysgenesis
Hereditary vitreoretinal degeneration
Retinal vascular abnormalities that leak or bleed: Coats disease, vasoproliferative tumors
Congenital disc abnormalities, especially with secondary vascular complications
Infection, especially in the congenitally or iatrogenically immunodeficient

Introduction

This chapter will discuss endogenous childhood ocular inflammation including uveitis and the vasculitides. There is considerable overlap with conditions causing orbital inflammation and central nervous system (CNS) vasculitis. Infections are a significant differential, precipitating or co-existing diagnosis, but are not the primary focus of this chapter.

The differential diagnosis of autoimmune and auto-inflammatory ocular inflammation in this age group is wide (Box 40.1). Uveitis is a relatively common feature of several localized autoinflammatory diseases that have both unique and shared genetic associations (Table 40.1). There is often a family history of autoimmune and autoinflammatory conditions in pediatric idiopathic uveitis. Despite the various genetic associations, a family history of uveitis is rare, unless caused by a dominant single-gene disorder such as Blau syndrome or a strong family history of HLA-B27-related disease.

Experimental models of uveitis have concentrated upon antigen-specific autoimmune mechanisms of inflammation. Sympathetic ophthalmia and phacoanaphylaxis may be examples of organ-specific autoimmunity, but the majority of childhood uveitis syndromes are secondary to localized or generalized disorders of the control of inflammation. Advances in population immunogenetics and study of the differential response to treatments have led to a continuing re-appraisal of disease classifications and treatment indications.

General considerations

When considering ocular inflammation in childhood one needs to ask:

1. Why has the inflammation started in childhood rather than adulthood?
2. Will the age of onset influence the disease phenotype?
3. Is there a genetic disorder of the control of inflammation?
4. Is there a genetic predisposition to autoimmunity?
5. Does the age influence treatment efficacy?

Table 40.1 Major inflammatory diseases associated with childhood uveitis

SYSTEMIC AUTOINFLAMMATORY DISEASES				
Diagnosis	**Systemic signs**	**Ocular signs**	**Gene**	**Inheritance**
Familial Mediterranean fever	Peritonitis, rash, arthritis	Uveitis	*MEFV*	Recessive
Chronic infantile neurologic cutaneous articular syndrome	Rash, arthritis, hepatosplenomegaly, deafness, chronic meningitis	Disc edema, uveitis, keratitis	*CIAS1*	Dominant
Muckle–Wells syndrome	Rash, arthralgia, deafness	Conjunctivitis, disc edema	*CIAS1*	Dominant
Blau syndrome	Rash, arthritis	Panuveitis, CAU, MFC	*CARD15*	Dominant
LOCALIZED AUTOINFLAMMATORY DISEASES				
Diagnosis	**Systemic signs**	**Type of uveitis**	**HLA Gene associations**	**Ethnicity**
Juvenile idiopathic arthritis	Joint	CAU	DRB*0801, 1101, 1301, DPB1*02	Worldwide
Behçet disease	Mucosal ulceration, follicular rash, vasculitis	Pan	B-51	Eastern Mediterranean to Orientals
Enthesis-related arthritides	Joint	Acute anterior	B-27	N. Europeans
Sarcoidosis	Skin, joints, hepatosplenomegaly, lymphadenopathy, CNS, lung	Pan, CAU, MFC	DRB*04, DQB1*0301, DRB1*1201, DRB1*1101	N. Europeans, Afro-Caribbeans
Ulcerative colitis	Large bowel, joints	Acute anterior, RV	DRB1*150 2, 0103	
Crohn disease	Small bowel, joints	Acute anterior, RV	DRB1*03	
Vogt–Koyanagi–Harada syndrome	Skin, CNS, vitiligo	Pan	DRB1*04	Native Americans, Orientals, Asians
Tubulointerstitial nephritis and uveitis syndrome	Kidney	CAU, MFC	DRB1*0102	
Multiple sclerosis	CNS	IU	DRB1*1501	N. Europeans
Psoriasis	Skin, joints	CAU, IU	Cw6	

CAU, Chronic anterior uveitis; CNS, central nervous system; IU, intermediate uveitis; MFC, multifocal choroiditis.

Consanguinity, familial clustering, or unusual disease patterns suggests rare or novel mutations. The immune system develops through childhood and adolescence when most infections are first encountered. An unusual ocular inflammatory response to a common childhood infection may be the first expression of a congenital systemic immune disorder (Box 40.2).

Organization of service

Childhood uveitis requires an organizational approach:

1. Early therapeutic decisions have to be made; early referral pathways to relevant clinicians are required.
2. Long-term social and educational planning needs to be in place for those with visual loss and/or poor treatment compliance.
3. Multiple surgical and medical specialties may be required simultaneously to form a treatment plan.
4. Transition to adult services may need a multidisciplinary approach.
5. Clinically relevant outcomes may differ from those used in adult ocular inflammatory disease.[1,2]
6. Screening for juvenile idiopathic arthritis (JIA)-uveitis needs public health support as with other screening programs.

Box 40.2

Immunodeficiency diseases associated with uveitis

Cyclic neutropenia
Chronic granulomatous disease of childhood
X-linked lymphoproliferative disease with Epstein–Barr virus (EBV) persistence and hypogammaglobulinemia
EBV viremia with CD27 deficiency or T-cell/NK-cell deficiency
- Common variable immunodeficiency
- Immunoglobulin (Ig)G2 deficiency
- Hyper IgM disease with hypogammaglobulinemia

STAT3 gain of function
- Hypereosinophilic syndrome
- Hypocomplementemic vasculitis

Interleukin (IL)-1 and IL-10 receptor deficiency
Cartilage hair hypoplasia syndrome
Nijmegen breaking

Evaluation for systemic disease

Ocular inflammation may herald systemic disease; subclinical systemic disease may have developed before presentation (see Table 40.1). Symptoms of systemic disease may occur later than ocular disease in juvenile idiopathic arthritis, sarcoidosis,

Behçet disease, psoriasis, inflammatory bowel disease (IBD), multiple sclerosis (MS), and Vogt–Koyanagi–Harada (VKH) syndrome. Since arthritis is the most frequent systemic association of childhood uveitis, pediatric rheumatologists are most commonly involved in the systemic assessment.

Skin changes are frequent in a variety of relevant systemic diseases and the ophthalmologist needs to enquire about these and refer appropriately.

Associated CNS inflammation is difficult to diagnose if it presents with behavioral changes, deafness, retrobulbar optic neuritis, headaches, or movement disorders in preverbal toddlers. Sensorineural hearing loss related to a systemic inflammatory disease may have developed earlier and been diagnosed as congenital in origin: hearing loss may need to be re-evaluated (Table 40.2).

Optic disc edema is frequent in childhood uveitis and scleritis; the diagnosis of optic disc changes (Figs 40.1 and 40.2) may be challenging. Raised intracranial pressure can occur in meningoencephalitis associated with sarcoidosis, systemic lupus erythematosus (SLE), and chronic infantile neurologic cutaneous and arthritis (CINCA) syndrome, as well as secondary to venous sinus thrombosis, idiopathic intracranial hypertension, and systemic steroid withdrawal.

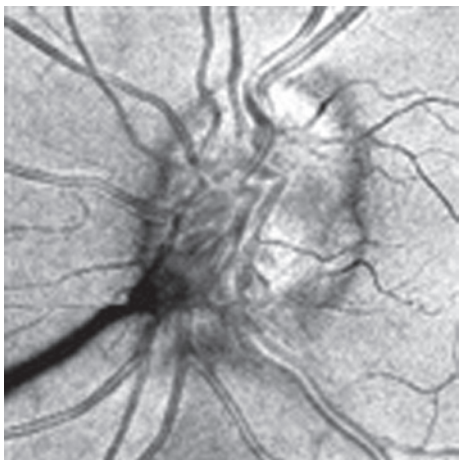

Fig. 40.1 Persistent optic disc edema with anterior inferonasal vitreous band to disc, 1 year after remission of intermediate uveitis.

Fig. 40.2 Optical coherence tomography of persistent optic disc edema 15 years after onset of juvenile idiopathic arthritis-associated uveitis.

Epidemiology of pediatric uveitis

The incidence of uveitis is uncommon at 17–25/100,000; it increases with age and peaks in the fifth decade. In 0- to 4-year-olds, the incidence is 3/100,000; in 10- to 14-year-olds, 6/100 000.[3] Childhood uveitis comprises 5% of most series of uveitis patients. Twenty-six percent of visual loss from all types

Table 40.2 Structural complications of juvenile idiopathic arthritis-associated uveitis (JIA-uveitis) and intermediate uveitis (IU)

JIA-uveitis	Intermediate uveitis
ANTERIOR SEGMENT CHANGES	
AC cells and flare	AC signs only in "anterior and intermediate uveitis"
Band keratopathy	
Extensive posterior synechiae	Rare
Progressive anterior synechiae	
Iris hyperemia and, rarely, neovascularization	
Unexplained hyphema	
Pupillary membrane	
Early irreversible ciliary body damage with chronic hypotony and phthisis	Hypotony rare
High risk glaucoma	Low risk glaucoma
Early cataract formation	Often late developing despite persistent cellular activity
Persistent diffuse vitreous flare and opacities with minimal vitritis	Vitritis necessary for diagnosis
Rarely, minimal snowball formation	Acute IU may cause dense central anterior floaters Chronic opacities tend to be dependent and aggregate – snowballs, snowbanks
Diffuse macular and disc edema and subretinal fluid with minimal vitritis	Disc edema can be marked in absence of macular edema
Disc neovascularization	Disc and peripheral retinal neovascularization
Vitreous hemorrhage	Vitreous hemorrhage
Retinal detachment, rare in phakic patients or without coexisting hypotony	Retinal detachment, pars plana cysts, localized peripheral detachments.
	Retinoschisis
POSTOPERATIVE COMPLICATIONS	
IOL membrane formation	Usually tolerates IOL
Frequent posterior capsular opacification	
Membrane formation following capsulotomy	

Box 40.3

Commonest types of uveitis by age

- 0–6 years: JIA-CAU
- 7–12 years: Idiopathic CAU, IU
- 13–16 years: IU, B27-associated AAU
- Adult: B27-associated AAU

For abbreviations, see text.

of uveitis with severe visual impairment in the Netherlands is due to non-infectious uveitis.[4]

The most common type is idiopathic. The most common pattern in children under 8 years of age is chronic anterior uveitis (CAU); in those aged 8–16 years it is intermediate uveitis (IU). After the age of 16, the pattern is that of adult disease (Box 40.3). Idiopathic painful bilateral CAU, idiopathic IU, and idiopathic panuveitis are also not uncommon in children. Specific uveitis syndromes, such as birdshot retinochoroidopathy and Fuchs heterochromic cyclitis[5] are exceptionally rare in children.[6]

JIA is the most common extraocular disease reported in tertiary referral series followed by those with no systemic disease (idiopathic uveitis), enthesitis-related arthritis (ERA), sarcoidosis, IBD, and Behçet disease. Even in countries with high rates of Behçet disease, Behçet uveitis is uncommon in childhood.[7] Behçet disease and VKH syndrome are 10–100 times more common in some Oriental, Asian, and Mediterranean groups than in Caucasians.

Tubulo-interstitial nephritis and uveitis syndrome (TINU), MS, and sarcoidosis are more common in North Europeans; there are also high rates of sarcoidosis in Afro-Caribbeans and high rates of ERA in Middle America.

Epidemiology of pediatric vasculitis

The commonest type of childhood systemic vasculitis is Henoch–Schonlein purpura in which ocular involvement is very rare; giant cell arteritis is the commonest vasculitis in the elderly and is exceptionally rare in childhood. The incidence of childhood SLE is 0.8/10,000 and juvenile dermatomyositis (JDM) is 0.4/100,000. Childhood polyarteritis nodosa (PAN) is the fourth most common childhood vasculitis and ocular involvement is not uncommon. Granulomatous polyangitis (GPA), Behçet disease, and microscopic polyangiitis (MPA) are very rare – each less than 0.1/100,000.

Takayasu disease (TAK) and Kawasaki (KAW) disease are more common in Asians and Orientals. In Japan, the incidence of KAW in children under 5 years of age is 110/100,000; in the UK it is about a hundred times less frequent.

Clinical types of uveitis

Idiopathic uveitis

Classification is based on the site and course of inflammation: unilateral or bilateral, acute or chronic, painful or painless, and redness present or not (Fig. 40.3). Chronic unilateral uveitis suggests an infective cause but should not preclude a search for systemic disease. Twenty percent of JIA-uveitis remains unilateral.

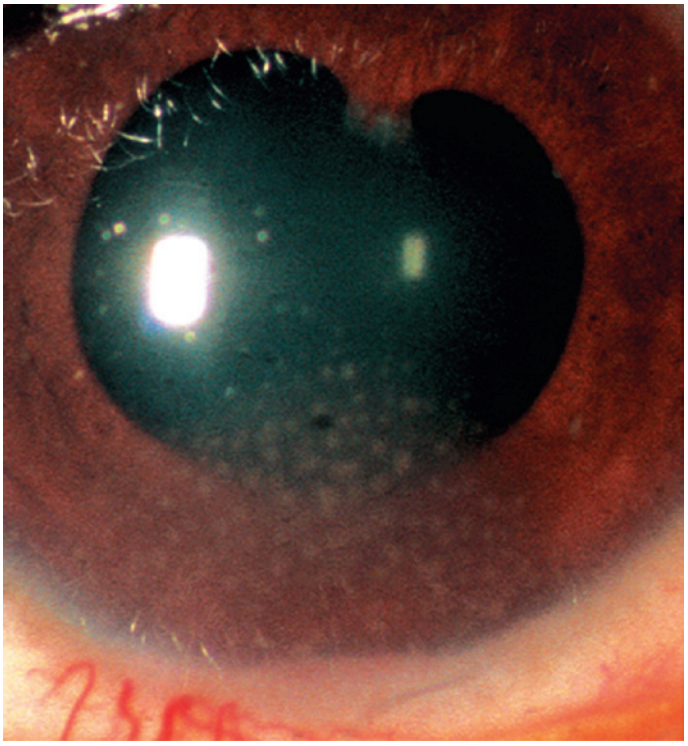

Fig. 40.3 Idiopathic chronic anterior uveitis with granulomatous keratic precipitates and limbal inflammation.

Although "acute" and "chronic-onset" are classifying terms, they rely on a history and are less helpful classifying terms in children. It is more practical to introduce a distinction between red and painful eyes at presentation.

Painful anterior uveitis

Unilateral, painful, acute anterior uveitis (AU) is most frequently associated with HLA-B27-related diseases. They present in later childhood and rarely before 6 years of age; an infective or posterior segment cause is likely in this age group. Bilateral painful AU is the most frequent uveitis type following infection or severe systemic inflammation and is a common pattern of uveitis in otherwise healthy 7- to 14-year-olds where it can persist for a couple of years. This pattern is common in TINU and sarcoid. Complications, other than ocular hypertension, are uncommon in chronic painful AU despite the length of disease when compared to the painless CAU of JIA.

Painless anterior uveitis

Chronic painless AU without systemic disease is common in young children. The arthritis of JIA may develop up to 7 years after the onset of painless CAU (Fig. 40.4). Investigation of renal function for TINU syndrome, sarcoidosis, and possible immunodeficiency is also indicated in this type. Skin rashes are a common manifestation of sarcoid, Blau early-onset sarcoidosis syndrome, and CINCA. Rashes in these conditions are frequently misdiagnosed or ignored prior to the definitive diagnosis: they are easy to biopsy. Fuchs heterochromic cyclitis is very rare.

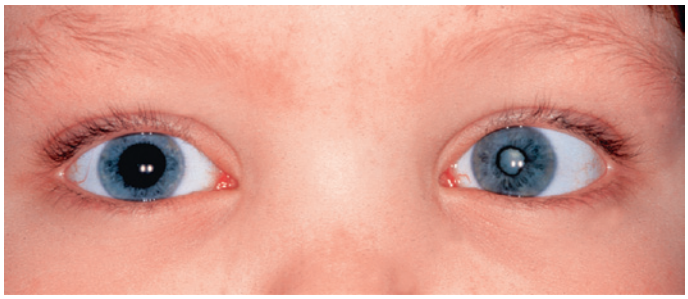

Fig. 40.4 Idiopathic chronic anterior uveitis in white eyes presenting with left cataract in a 4-year-old. Juvenile idiopathic arthritis developed 7 years later.

Intermediate uveitis

This refers to vitritis with a variable-level retinal inflammation and minimal anterior segment inflammation (see Table 40.2). The peak age of onset is 9–13 years.[8–11] Children present late compared to adults, and there may be extensive retinal complications. Children are less likely to develop macular edema but it is more difficult to resolve. Optic disc edema with chronic vitritis is more common than in adults. Peripheral vascular abnormalities are difficult to detect and may only be suspected when they cause hemorrhage. Neovascularization of the optic disc and retina may be caused solely by inflammation and can subside with immunosuppression.

Changing signs in the inferior fundus are useful to monitor disease progression as the level of vitritis is difficult to monitor in children and visual acuity may be maintained despite progressive extramacular damage. Sarcoidosis produces aggregates of white cells in the inferior vitreous ("snowballs") rather than pars planitis ("snow bank"), and multifocal choroiditis is characteristic. IU associated with MS rarely produces significant vitreous opacities. Focal retinal pigment epithelial scars can develop inferiorly at sites of previous retinal inflammation and do not necessarily indicate the development of choroiditis. Retinal vascular leakage and periphlebitis may be marked in acute IU but are not diagnostic of any specific cause.

Posterior uveitis, panuveitis, and multifocal choroiditis

Unifocal, unilateral choroiditis suggests infection such as toxoplasmosis. Multifocal, bilateral disease suggests systemic disease or a white spot syndrome. Both are rare in childhood. Many children with multifocal choroiditis (MFC) and vitritis resemble sarcoidosis or Blau syndrome, with no evidence of extraocular disease. In some children, the patches of choroiditis and retinal pigment epithelium (RPE) atrophy are small and limited to the inferior fundus. A similar human leukocyte antigen (HLA) profile to that found in TINU has been reported in these cases.[12,13] Some infections such as brucellosis, borreliosis, and varicella may also mimic sarcoid choroiditis. Multifocal choroiditis and panuveitis rarely occur in childhood. They can be complicated by severe visual loss from secondary choroidal neovascularization and warrant aggressive control of inflammation (Fig. 40.5). If the fundus cannot be seen in children with AU it must be assumed they have panuveitis. Ultrasound may disclose scleritis, focal infection, or tumor.

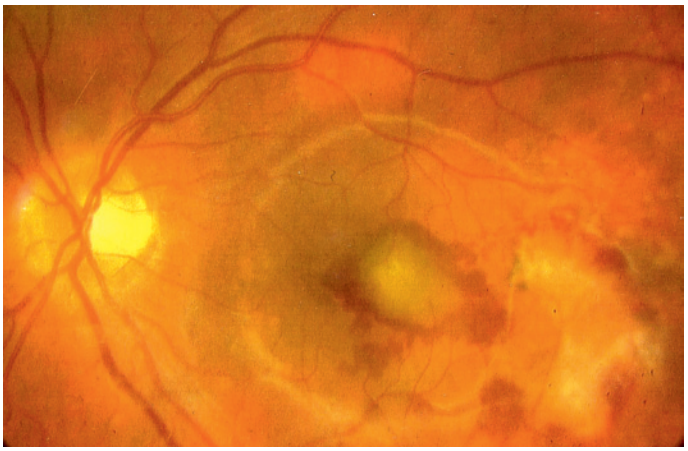

Fig. 40.5 Idiopathic panuveitis and multifocal choroiditis complicated by cataract, glaucoma, and choroidal neovascular membranes.

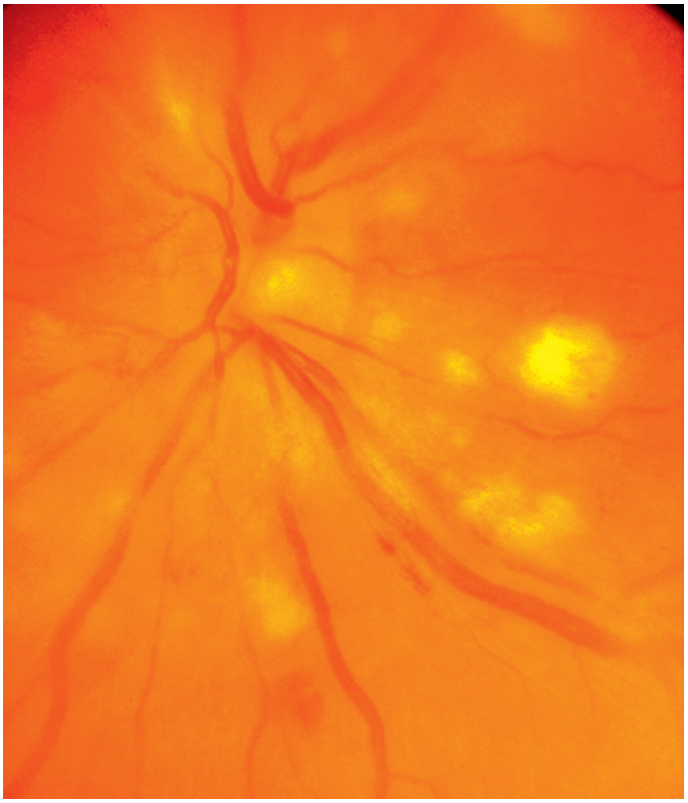

Fig. 40.6 Postviral retinitis with multiple retinal infiltrates and normal acuity.

Retinitis

Focal infiltrates of the inner retina with little overlying vitritis are typical of acute viral infections (Fig. 40.6). They are more discrete and persistent and yellower than cotton-wool spots. Retinal infiltrates in Behçet disease are accompanied by signs of retinal vasculitis.

Frosted branch angiitis

This is a hyperacute extravasation of multiple retinal vessels that may be post-infectious, but can also be the presenting

signs of small vessel vasculitis such as Behçets disease.[14] It may be accompanied by hemorrhage and does not always resolve benignly.[15]

Neuroretinitis

In neuroretinitis, swelling of the neuroretina, maximal at the optic disc, is out of proportion to signs of posterior segment inflammation. Exudates around the fovea form a macular star. Children are more likely to develop edema in response to infections that trigger optic neuritis and neuroretinitis. Cat-scratch disease typically involves the posterior segment in this manner.

Specific uveitis syndromes

Post-traumatic uveitis

Trauma may provoke an autoimmune response to ocular antigens. Children are as prone as adults to these rare conditions.

Sympathetic ophthalmia

There is a bilateral chronic panuveitis with peripheral multifocal choroiditis with many clinical and histologic similarities to VKH and sarcoidosis.[16] Vitritis may be severe. It follows unilateral penetrating trauma, cycloablation, or intraocular surgery. It may co-exist with lens-induced uveitis.

Lens-induced uveitis

This is a granulomatous panuveitis that may occur hours to months after the release of lens material and can complicate severe uveitis from other causes.

Parainfectious uveitis

Childhood is a time when community-acquired pathogens are first encountered and transient ocular inflammation may result. Varicella and streptococcal infections are frequent causes of reactive uveitis. Reported associations may be coincidental and identification of intraocular viruses in specific uveitis types remains rare.[17] Clusters of severe acute panuveitis in children have been reported from Tanzania and Nepal; in the former, the incidence was 540/100,000 in children under 9 years of age. There are no reports of epidemic outbreaks of post-streptococcal uveitis: the causal association between streptococcal infection and uveitis remains weak.

Acute AU can follow varicella, but mild retinal vasculitis, a self-limiting retinitis, and MFC can occur, usually within 4 weeks (see Fig. 40.6). Chronic inflammation and progressive retinitis is an absolute indication for antiviral treatment, but not usually necessary for AAU.

Enteric infections triggering reactive arthritis may cause a reactive uveitis: HLA-B27 positivity is a risk factor. Reactive arthritis with urethritis and uveitis and/or keratitis is very rare but does occur in children.

Localized autoinflammatory diseases: juvenile idiopathic arthritis

JIA describes chronic joint inflammation starting before 16 years of age and lasting more than 6 weeks. Early-onset rheumatoid arthritis, vasculitides, and ERA are rare causes of arthritis under the age of 7 years. A family history of psoriasis and HLA-B27-associated disease are used in the classification of JIA, but not the presence of uveitis.

Box 40.4

Levels of risk in juvenile idiopathic arthritis-associated uveitis, evidence based where possible

1. Baseline risk factors
2. Male gender, non-Caucasian ethnicity, antinuclear antibody positive, complications at presentation
3. Additional levels of risk
   a. No risk: no cells, flare, steroid treatment, or ocular hypertension
   b. Possible risk: any topical steroid treatment, any anterior chamber (AC) cells, persistent activity >3 months
   c. Probable risk: topical steroids more than once daily, persistent AC cells >1+, persistent activity >3 years
   d. Higher risk, one of: topical steroids more than once daily for several months, AC cells >1+, for more than 3 months, any activity >6 years, transient flare, any episode of macular or disc edema
   e. Definite increased risk, any of: continuous topical steroids more than three times daily, persistent AC cells >2+, persistent flare, previous surgery, multiple episodes of macular and disc edema
   f. Extreme risk: multiple risk factors

Epidemiology

The incidence of JIA is 10/100,000 children. Half of these have oligoarticular or polyarticular subtypes. The incidence of JIA-uveitis is 1/100,000, almost entirely in younger patients with these subtypes. Oligoarticular JIA is defined by the involvement of less than five joints at the onset of disease. If more joints become involved later, it is named *extended* oligoarticular JIA. If more than five joints are involved at onset, it is classified as *polyarticular*. The cut-off is artificial, and age at onset of arthritis and antinuclear antibody (ANA) status are as important as the number of joints in defining JIA phenotypes. ANA status and specific age at onset of arthritis are not used in the classification but are major independent risk factors for uveitis.

There are genetic similarities between oligoarticular and polyarticular JIA in the youngest groups. Older children with ANA-negative polyarticular JIA may have a distinct pattern of arthritis and be at a much lower risk of CAU. JIA is found in all races; JIA-uveitis may be more common in Caucasians (Box 40.4).

Several genes are associated with different clinical types of JIA. Oligoarticular-onset JIA is associated with HLA genes common to polyarticular JIA (DRB1*08), psoriatic arthropathy (DRB1*1301), and systemic onset JIA (DRB1*11), as well as unique associations such as DPB1*02. Uveitis is associated with the DRB1*13 haplotype, which is most frequently found in oligoarticular JIA, and DPB1*02. ERA and early-onset rheumatoid arthritis are clinically and genetically distinct from the types of JIA associated with CAU.

Uveitis is primarily associated with oligoarticular JIA, ANA-positivity, and JIA of early onset (less than 6 years); the highest risk groups may have a frequency of uveitis of over 50%. The risk of uveitis is minimal in those whose arthritis starts

after 13 years of age, and the upper age limit for developing uveitis may be earlier in those with polyarticular ANA-negative JIA. ANA status does not change the risk sufficiently to alter screening policy; it is not clear yet whether female gender is an independent risk for developing uveitis.[18]

In those developing uveitis, arthritis typically starts at a mean of 28 months and uveitis 13 months later: 86% have oligoarticular JIA, 75% are female, and 80% are ANA-positive.

Investigation of CAU with arthritis

All children with chronic painless AU require screening for asymptomatic arthritis as well as for other relevant signs of systemic disease. Routine laboratory testing in CAU can be limited to white count, serum angiotensin-converting enzyme (sACE), ANA, immunoglobulins, antistreptolysin (ASO) titers, electrolytes, and C-reactive protein. Other autoantibodies, such as double-stranded DNA, anticardiolipin, and perinuclear antineutrophil cytoplasmic, as well as raised ASO titers, may occur in JIA. Raised sACE, immunoglobulins, and a lymphopenia suggest sarcoid, which may present with arthritis indistinguishable from JIA but have low specificity, and the relevant secondary investigations need to be guided by relevant specialists.

Other JIA types

Systemic-onset JIA involves the eye in only 1–2% of cases; the uveitis usually occurs within months of presentation of extraocular disease.

Psoriasis is associated with ERA, IBD, and Behçet disease. It may also be an independent risk factor for uveitis. Psoriasis present in a family member changes the rheumatologic classification, but the accompanying arthritis may be indistinguishable from oligoarticular JIA; some patients with a personal and/or family history of psoriasis have a distinctive pattern of arthritis – *psoriatic arthritis* with dactylitis and nail changes. Eight percent of children with psoriatic arthritis develop uveitis. The presence of psoriasis with JIA does not alter the need for uveitis screening. Psoriasis may develop years after the onset of JIA and uveitis.

Childhood-onset ERA presents with peripheral arthritis and enthesitis (inflammation of the bony attachments of tendons or ligaments), rather than the sacroiliitis seen in adults. In younger children, the arthritis of ERA may be indistinguishable from oligo/polyarticular JIA and patients need to be screened routinely for uveitis until a definite clinical diagnosis of ERA. A family history of ERA is highly suggestive of the diagnosis but also does not preclude the need for uveitis screening in younger children. The usual form of uveitis is AAU, as in adults, and screening has no role once this has developed. AAU with definite ERA is rare before the age of 10 years.

Early-onset rheumatoid arthritis starts around the age of 11 years and is not associated with uveitis. The presence of a positive rheumatoid factor in children with JIA does not equate to a diagnosis of juvenile rheumatoid arthritis; it should not alter screening in oligo/polyarticular JIA.

IBD and IBD-related arthropathy may also be associated with uveitis. Patients may develop arthritis first and diagnosed with JIA and later develop IBD. Uveitis associated with IBD may be CAU-like JIA but these patients may also suffer AAU, scleritis, and retinal vasculitis.

Screening

The period of risk of developing uveitis largely depends on the age at onset of the arthritis. Those developing arthritis below the age of 3 years remain at risk for 7 years. Those developing arthritis after the age of 6 years are at risk for 3 years. In those regularly screened, the development of uveitis after the age of 13 years is rare. The optimal screening interval is not known. There seems little value in screening at intervals of more than 3 months if the primary purpose is to reduce the risk of structural changes at diagnosis, although this is widely recommended for low-risk subgroups. The UK screening program (2006) can be found at http://www.bspar.org.uk/pages/clinical_guidelines.asp.

Screening involves the exclusion of anterior chamber cells and keratic precipitates by a slit-lamp examination. Younger children require experienced ophthalmologists to perform the initial checks; frequent checks may be needed at the onset until the child is happy to cooperate. When patients are old enough to cooperate, monitoring can be devolved to less specialist practitioners. The age at which this is possible depends on each individual child and local facilities.

Physicians should be encouraged to refer patients for screening as soon as the diagnosis of JIA is being considered and not wait until a definitive diagnosis is made: the speed of the initial screen is the single most important manageable risk factor of subsequent visual loss.

Monitoring

Subclinical and clinical uveitis may develop while on systemic arthritis treatment; uveitis may recur vigorously when systemic immunosuppression is reduced abruptly, and patients should be checked within a few weeks of dose reductions. As systemic treatment for arthritis may also completely suppress uveitis, stopping it may result in uveitis presenting clinically for the first time. Patients in remission and off all treatment may relapse, and monitoring needs to continue for 3 years. Patients on long-term immunosuppression for systemic disease may develop uveitis well beyond the established risk period.

Clinical signs

The course of uveitis has a wide range of aggressiveness, severity, and chronicity (see Table 40.2). Late presentation has a profound effect on the severity and risk of long-term complications. Mild disease is a painless CAU; severe disease may cause a painful AU and IU. A red eye occurring at each relapse, hypopyon, or scleritis in the absence of uveitis, may occur after years of painless CAU. It is not clear whether the patient's age or the longstanding inflammation and treatment alter the pattern of inflammation.

Minimal disease may produce "dusting" of the corneal endothelium only. A severe cellular reaction with 4+ cells, hypopyon, or fibrin is unusual. Band keratopathy accompanying even mild uveitis is characteristic, but not universal. Progression of keratopathy on treatment indicates aggressive disease (Figs 40.7–40.9).

Persistent flare, iris hyperemia, which may be mistaken for rubeosis, and a persistent intraocular pressure (IOP) less than 10 mmHg are signs of severe disease, and may be reversible if treated aggressively. Fibrovascular sheets may cover the pupil and impede a view of the posterior segment despite a clear

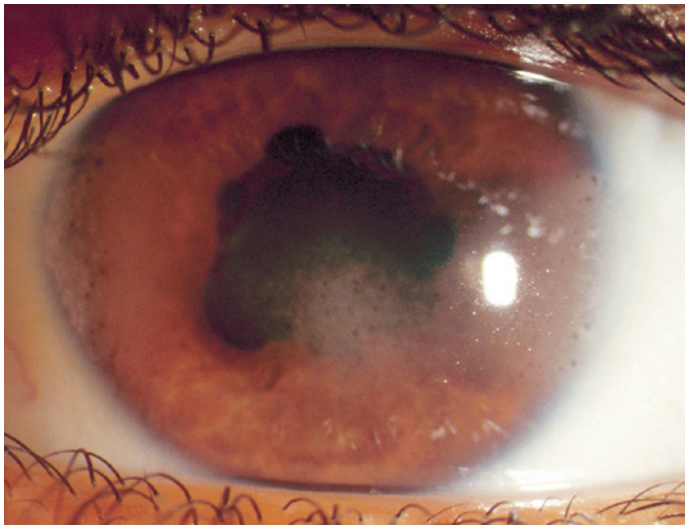

Fig. 40.7 Mild paracentral band keratopathy not affecting acuity.

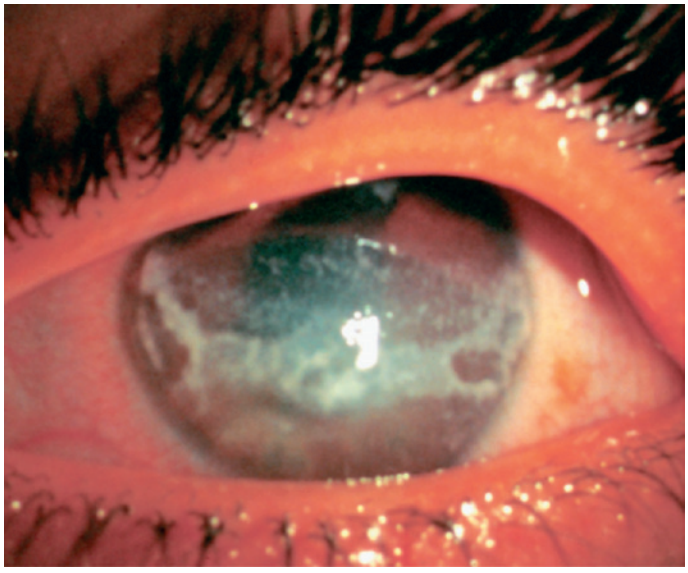

Fig. 40.8 Severe progressive band keratopathy.

lens. Iris bombé is not uncommon. Sometimes posterior synechiae are not obvious without mydriasis if they occur in mid-iris and are not present at the pupil margin.

Anterior chamber (AC) cells rarely "spill over" into the vitreous in significant numbers as with adult AAU, but a dense vitreous haze with fibrin clumps that takes several weeks of systemic steroids to clear, may occur in untreated disease.

Aphakic patients on treatment may experience relapses that largely consist of worsening macular edema, vitreous haze, and low IOP with little accompanying increase in anterior chamber or vitreous cells. Macular edema can be more extensive than in adult uveitis. Disc edema can be profound and persistent, and mimic papilledema. Increased inflammation is associated with reduced IOP. Permanent ciliary body damage is associated with reduced IOP and secondary hypotonous maculopathy – this usually requires an IOP chronically less than 5 mmHg. Only a treatment trial can determine if low IOP is irreversible, or if edema is due to inflammation or hypotony. Hypotony and

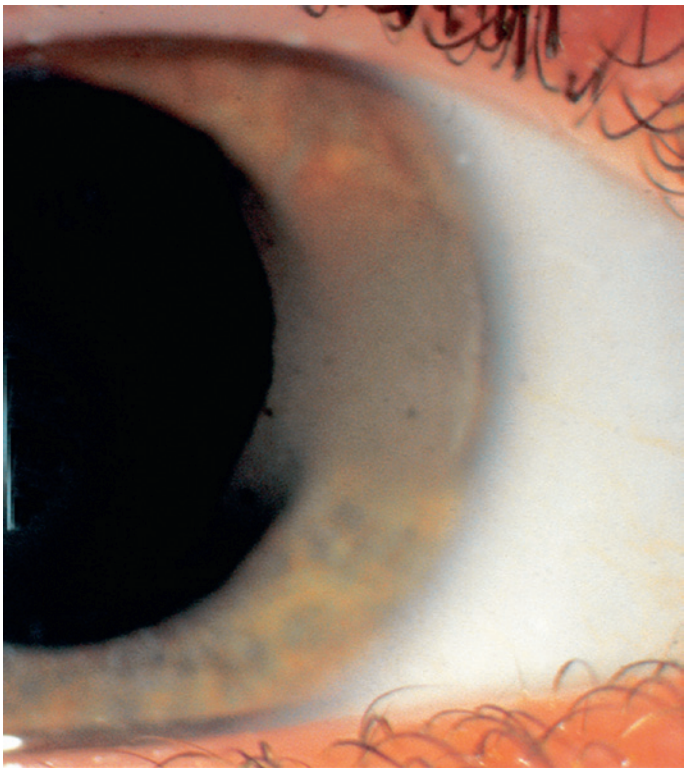

Fig. 40.9 Clear central cornea following excimer laser removal of band keratopathy.

inflammation also accompany retinal detachment, which may be difficult to diagnose if inferior in a poorly visible fundus.

Patients require screening for glaucoma. To reduce the need for examination under anesthetic, children need to be trained to accept tonometry as soon as feasible; rebound tonometry has proved very useful for younger children. Baseline disc appearances and changes must be documented at the initial visit and subsequent changes documented. There should be a low threshold for examination under anesthesia in newly diagnosed cases where IOP measurement is difficult, as inflammatory glaucoma can progress rapidly. Large fluctuations in IOP are typical and disc damage may occur during periods of unrecorded high IOPs and only noted when the IOP has normalized some weeks later.

Course

Patients may take several weeks to develop irreversible complications, even with aggressive disease: the inflammation changes slowly compared to other forms of uveitis. Posterior synechiae are usually the first to develop. Relapses are usually unaccompanied by redness or pain.

The majority of those entering life-long remission will have done so within 7 years of disease onset, but even with contemporary treatment only 30–40% will obtain long-term, complication-free remission. Some patients may develop increasingly severe disease 3 or 4 years after a mild onset. Exacerbations in late teenage years are common in those with longstanding disease; both poor compliance and weakening treatment efficacy may play a role.[19]

The risk and nature of complications change through the course of the disease and the benefits of treatment regimens may alter over time. This is especially true when steroid

treatment is used and where complete remission has not been achieved. Twenty-five percent of complications occur more than 10 years after disease onset in those who have not achieved a significant period of complete remission. The risks of new severe visual loss continue for more than 15 years after disease onset.

Indications for treatment

With such a wide range of outcomes it is important to match treatment risks and costs to the risk of patient-centered quality outcomes such as functional visual loss, surgical interventions, and frequent hospital attendance.[20]

Complete remission is the aim of treatment since it halts the onset of new inflammatory complications. Prolonged periods of low activity may precede complete remission. The threshold of AC activity beyond which complications develop is not clearly defined. Isolated AC cell counts may have limited value as a prognostic indicator. Cataracts form at similar rates in those with a trace of AC cells and those with 2+ cells. AC cell counts are of less importance than AC flare in increasing risk of complications. The presence of activity is more significant than the level of activity. Patients who achieve more than 6 months remission in the first 2 years of disease are highly likely to enter long-term remission. Cataract surgery further increases the risk of additional sight-threatening complications. The reduction of cataract risk should be a secondary aim of treatment. There is a wide range of reported outcomes; incidence of blindness ranges from zero to 25% over 3 years.[21,22]

Without clear descriptions of the risks of patient populations at referral, it is not possible to infer any regional differences in outcome. The range of outcomes is probably due to differences in screening efficacy and referral speed to specialist centers rather than differences in prescribing patterns. More aggressive and earlier therapy of arthritis by rheumatologists and improved glaucoma surgical techniques likely account for the improved outcomes of the past few decades.

Prognostic factors

Structural damage at presentation is the greatest risk factor associated with subsequent visual loss. Complications are more likely in males, non-Caucasians, and those with episodes of macular edema, hypotony, or frequent relapses.

The range of risk is great: females with no complications at diagnosis may have an 80% chance of complete, complication-free remission within 15 years. Males with cataract at presentation may have 50% risk of blindness over 15 years.

Glaucoma

Glaucoma occurs in 10–20% in recent studies, less than earlier reports[23]; the SITE (Systemic Immunosuppressive Therapy for Eye Diseases) study of US referral patients has an incidence of ocular hypertension of 19% per patient year.[21] Steroid-induced ocular hypertension (OHT) and aphakia are major risk factors; inflammatory glaucoma may contribute and usually develops after 2 or 3 years of CAU, not at presentation. Steroid-induced OHT is expected in 5% and is usually evident within a few months. Angle closure glaucoma can occur if the early presentation was complicated by iris bombé but is rarely the sole cause in late-developing glaucoma. The cause of IOP changes is usually complex in severely damaged eyes, as outflow obstruction may be combined with severe ciliary body damage with aqueous hyposecretion.

Hypotony

Childhood CAU has the highest risk of hypotony of all uveitis types.[24] The ciliary body is the initial site of inflammation in JIA-uveitis. Cyclitis causes aqueous hyposecretion and, eventually, atrophy. A vigorous treatment trial with systemic steroids is required to establish whether subnormal IOP is reversible. The IOP at which hypotonous maculopathy or progression to phthisis occur is not clear; a pressure of 5 mmHg is the conventional definition of hypotony. Secondary hypotony from ciliary body detachment, cyclitic membranes, or retinal detachment need to be distinguished from that due to ciliary body atrophy by appropriate examination. As ciliary membranes usually co-exist with ciliary atrophy, it is not clear whether their removal can help reduce the risk of phthisis.

Other localized autoinflammatory diseases

Behçet disease

Systemic features

Recurrent, painful, oropharyngeal and genital ulceration with uveitis are major criteria for the diagnosis. Ulceration may precede the full expression of disease by 2 years. Mild symptoms such as arthralgia, erythema nodosum, gastrointestinal inflammation, and ulceration are non-specific. Acne, folliculitis, epididymitis, and intestinal ulcers are more specific. Spondylitis may occur in one-third of cases.

Diagnosis is clinical. The disease is characterized by episodic severe localized inflammation and there is a strong association with HLA-B51; genetic variations in interleukin (IL)-10 and IL-23 pathways may contribute. Anti-tumor necrosis factor alpha (TNF-α), anti-IL-1, and interferon alpha2 (IFN-α2) biologics have been used where conventional immunosuppressants have not led to disease control.

Vascular thrombosis and CNS disease are the major causes of morbidity. Thrombosis is more common in veins than in arteries. CNS inflammation can be primary, with demyelination, or secondary to thrombosis. Basal ganglia and brainstem are most commonly involved, but there may be a diffuse, acute meningoencephalitis with behavioral changes.

Children may have milder disease and more delay to the complete syndrome: arthritis may be more common and ulceration less common. Neonatal onset has been reported. Childhood neuro-Behçet disease has a mean onset at 11 years of age.[25]

Ocular features

There is a panuveitis with explosive relapses, hypopyon, and sudden small and large retinal vein occlusion with white patches of retinitis. Retinal arteries may be involved; macular edema occurs in a minority. Retinal ischemia frequently leads to neovascularization.

A non-granulomatous CAU may occur, but chronic IU is unusual. Conjunctivitis, episcleritis, or scleritis may occur. Choroidal involvement is rare. The optic nerve may be involved with an inflammatory optic neuropathy, papilledema

from CNS involvement, particularly sinus venous thrombosis. Secondary optic atrophy is common. The natural course of retinal vasculitis and ischemia leads to a high risk of bilateral blindness and a quarter of eyes may eventually lose vision despite immunosuppression.

Sarcoidosis

Systemic features

This chronic granulomatous inflammation can affect any part of the body. Histologically, non-caseating epithelioid cell granulomas are seen, with an accumulation of CD4+ T-lymphocytes. The adult form involves the lung in 90% of cases and is the predominant type after the age of 12. In two-thirds of patients, the disease remits, usually within 2 years, the majority requiring no treatment.[26]

Childhood sarcoidosis rarely involves the lung.[27] Skin, joint, and eye involvement are common; the arthritis can mimic JIA. Biopsy is essential for definitive diagnosis. Skin, synovium, and liver are good sites. Joints can develop tenosynovial hypertrophy with little pain or restriction in the early stages. A delayed diagnosis is common. Skin involvement consists of a follicular or nodular rash. Renal involvement is not uncommon with interstitial nephritis and nephrocalcinosis. Most childhood sarcoid arthritis cases have uveitis. Serum ACE levels are elevated in only one-third of cases and gallium-67 scanning and other imaging may be needed to detect nodal and visceral disease. Meningoencephalitis, which may present with seizures, is more common in childhood sarcoidosis and in those with posterior segment inflammation. Childhood sarcoidosis is more common in Caucasians. Familial sarcoidosis occurs in 4%, and this is distinct from Blau syndrome.

Ocular features

Anterior uveitis may start with pain and redness and become chronic and painless. Iris and angle granulomas may distinguish the CAU from JIA-uveitis; band keratopathy is less common and inflammatory ocular hypertension more common than other types of CAU. Sarcoid may involve the lid margins and cornea more frequently in childhood (Fig. 40.10).

Sarcoid rarely causes chronic IU without other features. Panuveitis can develop with MFC that may be very widespread (Fig. 40.11). Visual loss may result from choroidal neovascularization. Optic disc swelling is frequent, caused by a granulomatous optic neuropathy, raised intracranial pressure, or secondary to uveitis. There may be a necrotizing vasculitis. Unilateral posterior segment or optic nerve disease may occur.

As young children with sarcoid may present with uveitis, disease may be very advanced at presentation. Uveitis frequently requires more prolonged and intensive immunosuppression than extraocular sarcoid to obtain clinical remission.

Inflammatory bowel disease

Crohn disease and ulcerative colitis are associated with ocular inflammation. Both may present with a mild arthritis in childhood, IBD arthropathy, which may be initially misdiagnosed as JIA (see Fig. 40.10).

AAU and episcleritis are the most frequent presentations: rarely, there may be a severe retinal vasculitis or acute hypopyon.

Vogt–Koyanagi–Harada syndrome

Systemic features

There is an acute-onset meningoencephalitis with headache, vitiligo, poliosis, tinnitus, and dysacusia. Stroke may result.[28] The skin may be painful to touch in the acute phase. Childhood cases often present with panuveitis with later vitiligo.

Ocular features

There is a painful, bilateral panuveitis with granulomatous anterior uveitis. Ciliary body edema may result in shallowing of the anterior chamber and increasing or lowering of the IOP. Scleral perforation may occur. Serous retinal detachments occur,

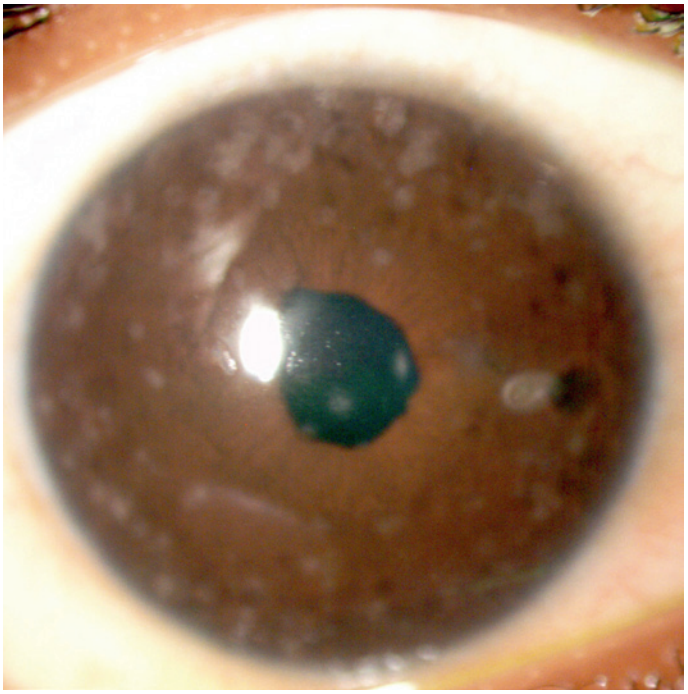

Fig. 40.10 Sarcoid multifocal keratitis.

Fig. 40.11 Sarcoid multifocal choroiditis.

especially inferiorly. Disc edema and peripheral choroiditis are frequent and angiography may demonstrate widespread pinpoint sites of RPE leakage. After repeated inflammation, depigmentation of the RPE and choroid lead to a "sunset glow fundus."

Children are more likely to have worse outcomes; 61% of eyes lose sight compared to 26% in adults.

Tubulointerstitial nephritis and uveitis syndrome

Systemic features

Acute tubulointerstitial nephritis and uveitis (TINU) occur within a few weeks of each other. Screening renal function in newly presenting pediatric uveitis is essential.[29] The commonest symptoms are fever, malaise, and weight loss; one-third have signs of ocular inflammation. Twenty percent present with uveitis up to 2 months before renal involvement. The median age of onset is 15 years; the youngest reported is 9 years. Renal disease consists of an eosinophilic and mononuclear infiltrate, but granulomas can also be found in the lymph nodes and marrow.

Interstitial nephritis is a sign, not a diagnosis, and occurs in other conditions associated with uveitis such as sarcoidosis, Behçet disease, Sjögren syndrome, and postviral syndromes. Uveitis has also been reported with immunoglobulin (Ig)A nephropathy.

Ocular features

There is a painful CAU; there may be granulomatous features.[30–32] Posterior involvement occurs in one-fifth with retinal periphlebitis, hemorrhages, disc edema, and multifocal choroiditis. The mean duration is 2 years and visual outcome is usually good.

Uveitis and non-vasculitic neurological disease

Multiple sclerosis

This is rare in childhood. It can occasionally present with uveitis, usually a mild IU.

Rasmussen syndrome

This is a chronic, unilateral encephalitis associated with an ipsilateral chronic uveitis that may present in childhood. It has been associated with cytomegalovirus infection.[33,34]

Systemic autoinflammatory disorders and familial granulomatous diseases

Several familial disorders present with periodic fevers, urticarial rashes, and joint and ocular inflammation. The most frequent are cryopyrin gene mutations.[35]

Blau syndrome and familial sarcoidosis may present in childhood with fevers, rashes, joint, and eye involvement. Single-gene disorders of inflammation, like some vasculitides, may be associated with very localized disease.

Cryopyrin-associated periodic fever syndromes

These immune disorders have a prevalence of 3 per million. Mutations of the *NLRP3* gene lead to uncontrolled activation of inflammasomes, multimolecular intracellular complexes composed of cryopyrin, leading to increased production of active IL-1β, IL-18, and IFN-γ. There are three clinical groups: familial cold autoinflammatory syndrome (FCA), Muckle–Wells syndrome (MWS), and CINCA.

Severity ranges from transient rashes and fevers to persistent inflammation with renal amyloidosis, deafness, chronic uveitis, and arthropathy. Forty percent of CINCA patients do not have a recognized genetic abnormality; some may be mosaics. There are overlap syndromes within the three groups.

Familial Mediterranean fever is rarely accompanied by uveitis.[12,36]

CINCA syndrome

Systemic

A neonatal urticarial rash occurs on the trunk and limbs as well as a large joint arthritis with endochondral ossification. Chronic meningoencephalitis can lead to developmental delay and papilledema. There is frequent sensorineural deafness from cochlear inflammation. Renal failure may result from amyloidosis. CINCA commonly arises from *de novo* mutations with a severe phenotype whereas milder syndromes are usually familial. Anti-IL-1 biologics are used.[37,38]

Ocular

The chronic meningitis is associated with a cellular cerebrospinal fluid (CSF) and raised intracranial pressure, with chronic disc swelling and optic atrophy. A mild CAU develops around 7 years of age without synechiae formation or redness; band keratopathy may occur.

Familial granulomatous disease

Blau syndrome (familial) and early-onset sarcoidosis (sporadic) are sometimes grouped as "pediatric granulomatous arthritis."

The gene *CARD15* encodes the NOD2 receptor; mutations may lead to inappropriate inflammation in response to bacterial peptidoglycan and result in IL-1 overproduction. The *CARD15* mutations associated with Blau syndrome are separate to those associated with Crohn disease. The type of mutation may influence the severity of ocular involvement in Blau syndrome. Other *CARD15* mutations may be associated with early-onset sarcoidosis and psoriatic arthritis.

Systemic features

Blau syndrome is a familial, early-onset granulomatous disorder; it resembles childhood sarcoidosis.[39–41] There is a transient punctate erythematous rash in the first year evolving into a scaly ichthyosiform rash. The arthritis is a polyarticular granulomatous tenosynovitis, with mean onset at 2 years and commonly involves wrists and fingers. There are also dysplastic joint changes including giant synovial cysts and camptodactyly. Hepatic and renal involvement may occur but not the lung. A vasculopathy may develop involving small and large vessel.[42] There is earlier onset in successive generations and incomplete forms may occur. The genetic mutation may not be clinically expressed. One-third are sporadic cases.

Ocular features

Uveitis occurs in 80%, usually within 2 years of the arthritis at 4 years of age; the youngest recorded is 18 months.[40] A JIA-like

CAU with band keratopathy is the most frequent presentation. Subepithelial corneal opacities and peripapillary atrophy have been reported to be diagnostic but also occur in sarcoidosis. Later IU occurs in 64%; MFC in 18%. The vasculopathy may affect the optic nerve, retina, and cranial nerves. The disease can be severe: half require immunosuppression and 14% develop severe visual loss.[39] Anti IL-1 therapy has been used in addition to conventional immunosuppression.

Other granulomatous diseases include sporadic sarcoidosis, Crohn disease, vasculitides (giant cell arteritis [GCA], Takayasu's arteritis [TAK], granulomatous polyarteritis [GPA], primary angiitis of the CNS (PACNS), cancer-associated chronic granulomatous disease (CGD) and secondary to anti-TNF therapy. Granulomatous infection such as tuberculosis must always be considered in the differential diagnosis.

Vasculitides

Vasculitis is uncommon in childhood and ocular involvement is rare. They can be life-threatening diseases that present with ophthalmic signs and sight-threatening disease. Their treatment may require prolonged immunosuppression, which may result in drug-associated ocular complications (e.g. hydroxychloroquine and steroids) and an increased risk of infection. Some infections may predispose to vasculitis such as streptoccocal and hepatitis B infections. Some congenital immunodeficiencies such as CGD and Blau syndrome may predispose to vasculitis.

Classification

Primary vasculitides are classified by the size of the vessel involved and clinical presentation; there are variable vessels involved and variable presentations in most syndromes.[43] Vasculitic syndromes may be limited in extent but otherwise have identical pathology to more widespread presentations such as orbital GPA. Some conditions are associated with highly specific autoantibodies and their testing methods continually develop (Table 40.3).

Secondary vasculitides may occur with connective tissue disorders, autoinflammatory diseases, and immunodeficiencies. Retinal vasculitis is not included in contemporary systemic vasculitis classifications and mostly describes conditions with secondary vasculitis or variable vessel vasculitis such as Behçet disease, sarcoidosis, and inflammatory bowel disease.[44]

Chronic vasculitis may result in secondary aneurysm formation, e.g. polyarteritis nodosa (PAN), luminal obliteration from endothelial cell proliferation, and secondary thromboembolism seen in antiphospholipid syndrome and Sneddon disease.[45] Small arteriolar occlusion may be transient in inflammatory conditions such as Susac syndrome[46] and in genetic endotheliopathies such as MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes).

As fluorescein angiography and reliable static perimetry is often not possible in small children, previous vascular occlusions may only be detected by signs of focal retinal thinning on optical coherence tomography.

Ocular involvement in vasculitis

There are few diagnostic ocular signs as the pathologic processes may be common to different vasculitis syndromes.

Table 40.3 Classification of vasculitides and diagnostic autoantibodies

Antibody class	Antibodies	Disease	Type of vasculitis
		TAK	Large
		GCA	Large
ANCA	pANCA-MPO rare	PAN	Medium
		KAW	Medium
	C1q	HUV	Small-immune complex
	GBM	anti-GBM	Small-immune complex
		CV	Small-immune complex
		IgA-HSP	Small-immune complex
ANCA	cANCA PR3	GPA	Small-ANCA associated
ANCA	pANCA	EGPA	Small-ANCA associated
ANCA	pANCA-MPO	MPA	Small-ANCA associated
		CS	Variable
		BD	Variable
		PCNSV	Single organ
		Ocular	Single organ
	ACA	APL	With systemic disease
ENA	RF	RA	With systemic disease
ENA	RNP	MCTD	With systemic disease
ENA	Scl-70	Scleroderma	With systemic disease
ENA	Sm	SLE	With systemic disease
ENA	SS-A, Ro and SS-B, La	Sjögrens	With systemic disease
		Sneddon	With systemic disease
		Susac	With systemic disease
		Sarcoid	With systemic disease
		Relapsing polychondritis	With systemic disease
		HVZ vasculitis	With probable etiology

APL, antiphospholipid syndrome; BD, Behçet disease; CS, Cogan syndrome; CV, cutaneous vasculitis; EGPA, eosinophilic granulomatosis with polyangiitis; GBM, glomerular basement membrane; GCA, giant cell arteritis; GPA, granulomatous polyangiitis; HUV, hypocomplementemic urticarial vasculitis; HVZ, herpes varicella zoster; IgA-HSP, IgA vasculitis/Henoch–Shönlein purpura; KAW, Kawasaki disease; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; PAN, polyarteritis nodosa; PCNSV, primary central nervous system vasculitis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TAK, Takayasu disease.

Vasculitis occurs in 2% of adults with uveitis and is usually a monoepisodic or recurrent AAU. In adults, prolonged uveitis accompanying vasculitis is most uncommon: ocular involvement secondary to vasculitis is usually an inflammatory or ischemic optic neuropathy, sclerokeratitis, or orbital inflammation.

An acute red eye in children with vasculitis needs full evaluation. Episcleritis is more likely to be accompanied by systemic disease in children than in adults; in contrast, most childhood posterior scleritis is idiopathic.

Types of ocular involvement

1. Bilateral inflammatory signs of severe systemic disturbance: conjunctivitis, episcleritis, scleritis, anterior uveitis, retinopathy, and optic disc edema and papilloedema.
2. Localized ocular vasculitis: varying with vessel size: peripheral ulcerative keratitis, scleritis, episcleritis, retinal vasculitis, choroidopathy (and central serous retinopathy), optic neuropathy, and orbital inflammation.
3. CNS inflammation, which may be diffuse (e.g. lupus encephalopathy) or focal and secondary to cerebral vasculitis (PACNS).
4. Hypertensive retinopathy secondary to renal vasculitis.
5. Acute and chronic ischemic complications within the eye and CNS from medium and large vessels occlusion.

Types of vasculitis

Large vessel

Takayasu disease (TAK)

Systemic This is an inflammation of the aorta and its major branches. It is 100 times more common in East Asia, nine times more common in females and, in one-third, starts before the age of 20. Phases of systemic inflammation may precede chronic occlusive vasculopathy by several years. Cardiac failure may result.[47]

Ocular Ocular symptoms are secondary to chronic carotid and vertebral artery occlusion and collateral formation.[48]

Medium vessel

Polyarteritis nodosa (PAN)

Systemic PAN is a necrotizing segmental vasculitis of small and medium arteries with frequent aneurysm formation. Diagnosis requires tissue biopsy or abdominal angiography when the clinical picture is unclear. Thrombosis of involved arteries is frequent. It can be secondary to infections such as hepatitis and streptococci as well as neoplasia. Disease may be limited to the skin but half of children with PAN present with fever, rashes, musculoskeletal pain, neuropathy, and renal impairment. The main age of onset is 7–11 years.[49] Seizures from CNS involvement are more frequent than peripheral nerve involvement.

Ocular Conjunctivitis, episcleritis and necrotizing scleritis, and peripheral ulcerative keratitis are found in up to 20% of patients. AAU and bilateral panuveitis are rare. Choroidal vasculitis is a common histologic change but is usually asymptomatic; retinal involvement is usually an arteriolitis but veins may also be involved.

Kawasaki disease (KAW)

Systemic There is an acute conjunctivitis, a red tongue and lips, and erythema of the trunk, palms, and soles. It may present with uveitis.[50] There may be marked edema of hands and feet. The skin of the soles and hands desquamate on recovery. Later, 20% develop coronary artery aneurysms, some of which may resolve with treatment, but there may be long-term cardiac sequelae. CNS involvement is uncommon; there may be hearing loss.[51]

Ocular AAU and conjunctivitis occur in the majority in the acute phase and appear to be benign: disc edema and congested retinal vessels may occur.

Small vessel, ANCA-associated vasculitides (AAV)

Granulomatous polyangiitis (GPA, formerly Wegener granulomatosis)

Systemic Diagnosis requires three of six criteria: involvement of kidneys; upper airways; laryngotracheobronchial system; lung parenchyma; positive biopsy; or classic antineutrophil cytoplasmic antibody (cANCA) positivity.[52] The ophthalmologist is usually involved with orbital and CNS cases without renal involvement. The normal age of onset is the sixth decade.

Tissue damage from respiratory tract granulomas can be extensive. Subglottic stenosis and nasal deformity are more common in children.[53,54] Limited forms without cANCA positivity can occur, including cases limited to the CNS.

Ocular Ocular presentation occurs in 10%. Focal, necrotizing scleritis with adjacent keratitis is the most common presentation. Orbital inflammation may be diffuse or from adjacent sinus involvement. A panuveitis or AAU can occur rarely.

Urticarial vasculitis

There is a leukocytoclastic vasculitis that mostly occurs in middle-aged women; half have reduced complement. It has been associated with uveitis, scleritis, and idiopathic intracranial hypertension.

Vasculitis accompanying connective tissue disease

Systemic lupus erythematosus (SLE)

Systemic The vasculopathy involves small arteries, arterioles, and capillaries, resulting in fibrinoid necrosis. A hypersensitivity vasculitis occurs in 28%. Thrombosis is more likely in the presence of anticardiolipin antibodies, and these may also occur as an independent phenomenon in the antiphospholipid syndrome, or precede the development of SLE by several years. CNS disease may be caused by diffuse vasculopathy and localized thrombosis exacerbated by the presence of anticardiolipin antibodies. It may originate from abnormal DNA methylation in T cells leading to autoreactivity.

Ocular Five percent of children with SLE have ocular involvement. The most frequent ocular involvement is dry eye; chronic inflammation is unusual. Lupus retinopathy is a sign of severe systemic vasculopathy and may be complicated by hypertensive changes. AAU, scleritis, episcleritis, and keratitis are uncommon and may indicate uncontrolled systemic disease.

Scleroderma (SSC)

Systemic Limited forms start with skin involvement of the extremities but may progress to the diffuse form with proximal limb and organ involvement (systemic sclerosis). The mean age of onset in childhood is 9 years; most are female. Localized scleroderma is more common in young females and may involve isolated patches of skin (morphea) or a linear patch on the face (*en coup de sabre*).

Ocular Thirteen percent of those with localized scleroderma have eye involvement, and it is not always related to the site of skin disease. Uveitis may occur, especially in scleroderma *en coup de sabre*. Choroidopathy is relatively common, arising from choroidal capillary closure and perivascular mucopolysaccharide deposition. The retinal circulation is usually spared but hypertensive changes may occur.[55,56]

Sjögren syndrome

Very rare in childhood, this usually presents with dry eyes and mouth and is associated with several connective tissue disorders.[57]

IgG4 disease

This may mimic Sjögren involvement of the lacrimal and salivary glands. It can also cause orbital inflammation and uveitis. Infraorbital nerve involvement is characteristic. Histology may resemble GPA.[58–62]

Juvenile dermatomyositis (JDM) and polymyositis

Dermatomyositis is the commonest inflammatory myopathy of childhood presenting with gradual muscle weakness. A purple heliotrope rash on the eyelids commonly precedes the myopathy. Extramuscular features are more common in children, including subcutaneous calcification and vasculitis. A retinal microangiopathy may occur.[63]

Relapsing polychondritis (RPC)

Systemic There is recurrent inflammation of cartilage in the ear, nose, trachea and larynx, and joints with an adjacent dermal vasculitis. One-quarter of patients have other connective tissue disease, particularly rheumatoid arthritis. It is rare in childhood.

Ocular Up to 60% have ocular involvement and 25% present with ocular symptoms. Episcleritis and scleritis are the most frequent patterns, with keratitis, uveitis, and retinal vasculitis occurring rarely. A CNS vasculitis may occur.

Other vasculitides

Cogan syndrome (COG)

Systemic Typically, acute interstitial keratitis, deafness, and systemic vasculitis occur in the third decade. There may be an autoantigen shared between the cornea, large vessels, and the inner ear.[64,65] Acute hearing loss and keratitis can occur in other vasculitides. There is aortitis in classic disease; other vessels are more frequently involved in atypical disease including CNS vasculitis.

Ocular Interstitial keratitis is found in two-thirds of cases. Episcleritis and scleritis are found in 36% and retinal vasculitis in 24%. Uveitis and conjunctivitis may be the sole manifestation in a minority. Keratitis can be severe, leading to corneal perforation and extensive neovascularization (Figs 40.12 and 40.13).

Vasculitis also occurs in conditions covered in the uveitis section such as Behçet disease, IBD, and sarcoidosis.

Pediatric inflammatory brain disease and localized vasculitis

Pediatric inflammatory brain disease may cause focal neurological events such as stroke or diffuse inflammation presenting with encephalitis: there is a large differential diagnosis which includes many conditions causing ocular inflammation and systemic vasculitis. Visual disturbance is more commonly associated with encephalopathic and vasculitic disorders.[66]

There are several ocular inflammatory conditions in which the predominant CNS sign is sensorineural deafness (Table 40.4).

Monophasic CNS and retinal vasculitis may follow infection such as herpes varicella zoster. Other secondary vasculitides

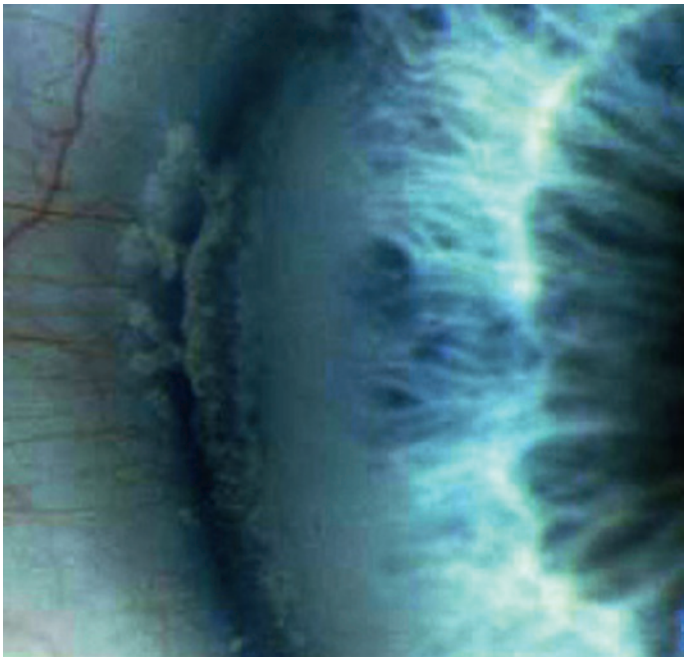

Fig. 40.12 Cogan keratitis. Early limbal deposits.

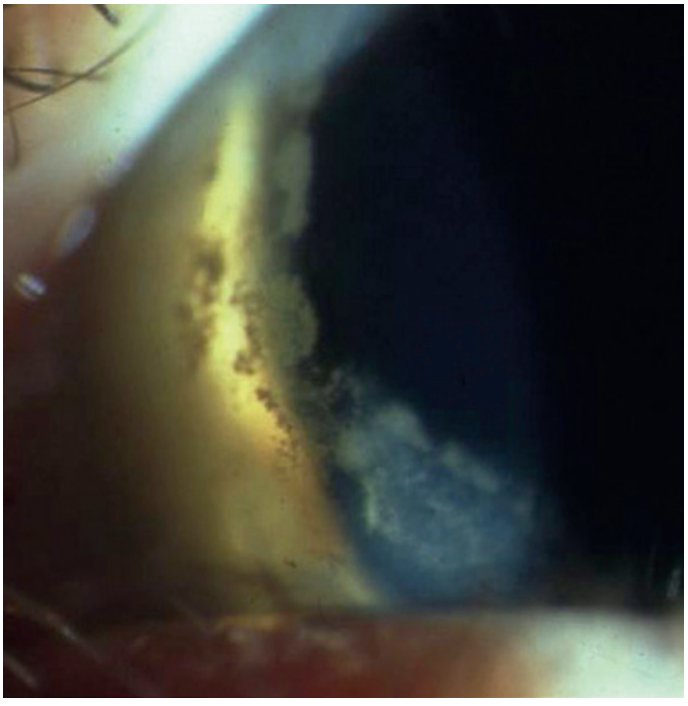

Fig. 40.13 Cogan keratitis. Later paralimbal deposits.

Table 40.4 Associations of uveitis and hearing loss and CNS disease

Type of disease	Type of vaculitis	Diagnosis	Uveitis	Hearing loss	Other CNS
Localized	Secondary	Sarcoid	✓	✓	✓
Localized	Autoinflammatory disease	VKH	✓	✓	✓
Systemic	Autoinflammatory disease	CINCA	✓	✓	✓
Systemic	Autoinflammatory disease	MWS	✓	✓	
Vasculitis	AAV	GPA		✓	
Vasculitis	Other	Susac		✓	✓
Vasculitis	LVV	KAW	✓	✓	
Vasculitis	VVV	Cogan	✓	✓	
Vasculitis	MVV	PAN		✓	✓
Vasculitis	Localized	PACNS			✓
Vasculitis	Seondary	SLE			✓

AAV, ANCA-associated vasculitides; CINCA, chronic infantile neurologic cutaneous and arthritis; Cogan, Cogan syndrome; GPA, granulomatous polyangiitis KAW, Kawasaki disease; LVV, large vessel vasculitis; MVV, medium vessel vasculitis; MWS, Muckle–Wells syndrome; PACNS, primary angiitis of the central nervous system; PAN, polyarteritis nodosa; SLE, systemic lupus erythematosus; Susac, Susac syndrome; VKH, Vogt–Koyanagi–Harada syndrome; VVV, variable vessel vasculitis.

with CNS involvement include SLE, IBD, and human immunodeficiency virus (HIV).

Non-diagnostic multifocal magnetic resonance imaging (MRI) changes and non-specific inflammatory CSF abnormalities are frequent and brain biopsy is sometimes required for diagnosis if angiography is not diagnostic.

Primary angiitis of the CNS diagnosed on angiography is the commonest pediatric inflammatory brain disorder in referral centers. It is a granulomatous and necrotizing vasculitis and there may be paravascular demyelination.

Ocular involvement in demyelinating disorders of childhood primarily present with optic neuritis and rarely progress to relapsing MS.

Medical treatment of ocular inflammation

The initial treatment of most anterior uveitis is topical steroids. There is little evidence that any specific steroid is optimal for both disease control in CAU and reducing the risk of secondary ocular hypertension. There is little evidence for the benefit of the chronic use of non-steroidal anti-inflammatory agents, although their short-term use in severe relapse with AC flare and macular edema may be warranted. Complex, frequent regimens of drops are to be avoided: compliance is greatly reduced particularly at school. It is preferable to use a single steroid and vary its frequency rather than swap between steroid preparations. If needed more than four times a day, then a different route of steroid use is indicated. Some patients with CAU may avoid relapse on regimens of topical steroid as infrequent as twice weekly.

The aim of treatment is to minimize the acute risk of damage at times of high activity, achieve remission, and maintain this for a sufficient length of time to reduce the risk of short-term relapse. AAU in adults commonly has a natural course of a couple of months and rapid reduction of treatment is appropriate. The natural course of most relapses in CAU is of the order of several months and so inappropriately reducing treatment as soon as remission is found simply leads to an early relapse. Maintaining the dose of steroid at which remission is achieved for at least 4–8 weeks and reducing treatment in monthly, rather than weekly, steps will diminish the risk of relapse. In relatively benign forms of CAU, cycles of very frequent steroid followed by rapid tapering may result in unnecessary morbidity.

Systemic treatment: indications

At some point, the risks of cataract and glaucoma with continuous topical steroid treatment are sufficiently high to justify systemic immunosuppression if prolonged remission is never achieved. Topical steroids cannot treat adequately the posterior segment complications even when AC activity is controlled.

The aim of treatment is to achieve a sufficiently long remission that withdrawal of treatment is not followed by an early recurrence. This differs in different types of uveitis but is likely to be of the order of 12–18 months in JIA-uveitis. It may be best to achieve 3 years of remission before tailing off treatment in those who are at most risk.[67,68]

About half of patients given methotrexate (MTX) for JIA arthritis will relapse on withdrawal of treatment. Less than 20% of patients with JIA-uveitis started on immunosupression will enter long-term remission off treatment within 5 years. In contrast, other types of CAU, such as TINU syndrome, and idiopathic IU may only need treatment for 2–4 years and are at low risk of later relapse.[9,69]

Conventional immunosuppressants.

MTX is in widespread use because of trial evidence in the treatment of arthritis in JIA and adult rheumatoid arthritis, and because there is long-term safety data. Its efficacy in uveitis has only been directly compared to mycophenolate mofetil.[70] The

response rate of patients with uveitis to MTX in a meta-analysis was 73%.[71] Serum predictors of relapse may aid decisions about the timing of treatment withdrawal.[72]

The dose of MTX required to control arthritis in JIA is frequently insufficient to control uveitis, and ophthalmologists and rheumatologists have to collaborate closely to optimize dose and timing of treatment changes.

Azathioprine,[73] everolimus,[74] ciclosporin,[75] and tacrolimus[76] have all shown efficacy in childhood and adult uveitis. These immunosuppressive agents are less successful in treating the arthritis of JIA; it is not uncommon for arthritis to present in children taking other immunosuppressants for an apparently idiopathic CAU.

It remains unclear whether dual therapy with conventional immunosuppressives adds benefit, and treatment switching of single agents ought to be considered before using multiple therapies, which greatly increase drug toxicity and complications.[77]

The use of systemic steroids is often vital in the acute control of ocular inflammation; their long-term use in childhood leads to growth retardation, in addition to their well-known side effects in adults, and alternatives are required wherever relapse occurs after an appropriately tapered dose reduction.

Biologics

Biologic agents are monoclonal antibodies that bind specific molecular targets, in contrast to conventional immunosuppressants. Their use in treating inflammatory disease first developed in adult inflammatory arthritis. Inadequate control of arthritis in JIA with MTX usually leads to the addition of an anti-TNF agent, and etanercept was the first trialed in childhood uveitis. A wide range of biologics is now licensed for use in adult inflammatory arthritis and additional classes of biologics in vasculitis, MS, and systemic autoinflammatory disease. Several classes other than anti-TNF agents, are now licensed in arthritis and patients are often prescribed sequences of agents from different classes in order to maintain a clinical response.[78]

Although the use of biologics in uveitis is guided by the efficacy of treating extraocular manifestations of the associated systemic disease, it cannot be guaranteed that uveitis will respond in a similar way.[79,80] Etanarcept appears less efficacious than other anti-TNF agents for treating the uveitis in JIA although it has similar efficacy in treating the arthritis. Most series include patients previously and concomitant treated with multiple conventional and biologic treatments, at different time points in disease and with different ocular comorbidities – usually unspecified. This makes treatment effect difficult to predict.

The use of many biologics has been reported in pediatric uveitis; recent reviews rely on case series only and do not indicate a clearly preferred class specifically more efficacious in the various uveitis types.[81–83] The most effective biologics may have a clinical effect in 70–80%, with a quarter of patients showing relapse over the subsequent 2 years; these effect sizes are similar to those found in trial data of biologics approved for use in inflammatory arthritis. Since response of all treatments is likely to be related to the level of ocular damage at time of treatment initiation, the timing of treatment escalation is critical. Generally, insufficient control within 3–6 months of initiation justifies a treatment switch.[84,85]

Switching between anti-TNF agents may provide benefit in about one-quarter of patients.[86] Etanercept appears to have less effect on uveitis activity compared to other anti-TNF agents; anti-TNF agents other than etanercept are suggested in recent guidelines for JIA-uveitis[87,88] and are the subject of ongoing trials.[89]

Trials in adult uveitis are usually of heterogenous types excluding CAU, but their results are likely to be relevant to pediatric populations. The choice of biologic is likely to be determined largely by cost and regulatory restrictions rather than high-level clinical evidence.

Indications of treatment efficacy

The ocular signs relevant to titrate treatment remain unclear in all forms of uveitis although cell counts and vitreous flare are both central to drug trials.[90] Visual loss is of prime patient concern, and useful in auditing, but has only a distant connection to the short-term measures of clinical activity. There may also be an entirely different set of measures relevant to assessing treatment response in those already under treatment, i.e. markers of disease relapse under treatment as opposed to markers of activity in untreated disease.

As complete remission is associated with no further inflammatory complications, this it is the aim of treatment. Visual loss is associated with surgery for cataract, glaucoma, as well as hypotony, so treatment should be aimed at preventing these conditions. It is not known what level of AC cellular activity leads to complications; AC flare is much less responsive to anti-inflammatory treatment, but may reverse in some patients and have a stronger association than AC cells with future complications.[74,91,92] Cataracts form at statistically similar rates in those with a trace of AC cells and those with 2+ of cells, although the trend increases with increasing cell counts.

Surgical treatment

Cataracts

The indications for cataract surgery are:

1. the prevention of amblyopia;
2. to allow the management of posterior segment disease;
3. to improve visual function with an acceptable risk.

Surgery should not be embarked upon lightly. Children with mild bilateral cataracts and persistent inflammation can undergo a normal education with 6/18 vision and surgery might be deferred for long periods, until disease activity subsides.

Surgery on a unilateral cataract during the first years of life may often result in an aphakic amblyopic eye that adds little to the visual function, but also allows monitoring of posterior segment disease, which, if untreated, may result in an unsightly painful eye. Families need to understand the limited choices available in this situation.

Disease activity must be rigorously controlled, as postoperative inflammation can be unpredictable and severe. When cataract surgery is planned, patients should be started on systemic immunosuppression in order to see whether disease can be completely controlled without topical medication. Treatment should be increased before, at the time of surgery, and for at

least 2 months after. Some patients with preoperative macular edema require 4 or 5 months of systemic steroids as well as second-line immunosuppression before maximum postoperative acuity is achieved. When planning surgery in cases with a short history, one should assume that inflammation may become more difficult to control for some years afterwards. Periocular or intraocular steroids given intraoperatively reduce the need for systemic steroid in the perioperative period but increase the risk of glaucoma.

The surgical view may be compromised by band keratopathy; preoperative excimer laser, or EDTA, may precede intraocular surgery. Posterior synechiae can be more extensive than is apparent on slit-lamp examination and intraoperative iris damage is frequent. Pupillary membranes may be vascularized and bleed intraoperatively but occasionally may be simply peeled off the anterior capsule.

Techniques of lens removal depend on the possibility of capsulorrhexis, visibility, and hardness of the lens. Often the lens can be aspirated even if white. Occasionally, calcified subcapsular plaques and pigment clumps related to posterior synechiae complicate capsulorrhexis.

Posterior capsule opacification is universal and a posterior capsulorrhexis is advisable, especially in a child who would require GA for YAG laser capsulotomy. An anterior vitrectomy may reduce the risk of pupillary and posterior intraocular lens (IOL) membrane formation, but a more extensive vitrectomy may add other risks.

Intraocular lenses are easy to put in but very difficult to take out. JIA-uveitis, especially, has a high rate of IOL "cocooning," synechiae, and membrane formation. It may be prudent to delay IOL implantation until months after lens extraction. The drawbacks of aphakia are trivial compared to the profound visual loss that may result from complications of IOL explantation, so families should be fully informed of the added risk to the visual outcome that IOL implantation provides.[93]

In contrast, IOL implantation in other types of childhood uveitis may have little risk, including late-developing cataract in JIA-uveitis. The outcomes of unilateral cataract surgery in children prone to amblyopia are poor and this is also the case in JIA-uveitis. Patients and their parents should be counseled preoperatively about the need for vigorous patching after surgery.

Treatment of glaucoma

Many glaucoma surgical treatments have been tried including goniotomy and cycloablation. As patients may have compromised aqueous production, despite raised IOP, all procedures need caution when the eye has been severely inflamed due to the great risk of postoperative hypotony.

The use of tube drainage devices has greatly improved the prognosis of aphakic glaucoma. Steroid-induced glaucoma in a quiet eye may respond well to conventional assisted trabeculectomy. Whatever the success of angle surgery and cyclodestructive procedures in the short-term, they may reduce the effectiveness of later drainage procedures.

Introduction

Albinism, derived from the Latin *albus*, meaning white, is an inherited disorder of melanin biosynthesis, which results in absent or reduced melanin production and causes phenotypic heterogeneity. Melanogenesis requires complex interactions of enzymes and proteins within melanosomes to produce eumelanin (brown or black pigment) or pheomelanin (yellow or red pigment), encoded by genes known to cause albinism (Fig. 41.1).[1] Oculocutaneous albinism (OCA) and syndromes associated with OCA are inherited in an autosomal recessive manner, whereas ocular albinism (OA1) is associated with X-linked inheritance. Current terminology is based on the specific gene in which mutations can be found to define a particular type of albinism.[2] Older terms, such as partial, imperfect, incomplete, or complete albinism and tyrosinase-positive or tyrosinase-negative albinism, which were based on results of hair bulb incubation with L-tyrosine, are no longer used. Several laboratories provide panels for genetic testing of individuals with the phenotype of albinism.

Classification of albinism by genes

Non-syndromic oculocutaneous albinism

Although the rate of albinism varies geographically, albinism occurs with a frequency of approximately 1 in 20,000 worldwide, and more than 1% of the population carries a heterozygous mutation in a gene that causes albinism.[3–5] The most common types are OCA1 and OCA2. OCA1 is due to mutations in the tyrosinase (*TYR*) gene, which is essential in the initial and rate-limiting steps of melanin biosynthesis. Children with OCA1A (previously tyrosinase-negative) produce no melanin pigment in their skin, hair, or eyes over their lifetime. Those with OCA1B have some residual enzyme activity so they produce some melanin pigment in their hair, their eyelashes darken, their skin develops a slight tan, and melanin pigment can be detected in the posterior iris epithelium and occasionally in the macular retinal pigment epithelium (RPE) (Fig. 41.2).[6–8] OCA1 includes those diagnosed with minimal pigment or temperature-sensitive albinism, and those previously classified as having yellow albinism.[9–11] Those with OCA2, due to the mutations in the *OCA2* gene, often have blond or red hair at birth (Fig. 41.3).[12–14] Persons with OCA2 can often be difficult to discern from persons with OCA1B due to their pigmenting phenotype. In sub-Saharan Africa, there is a predominance of OCA2 due to a 2.7-kb interstitial deletion in *OCA2*, related to a founder effect.[15] Other types of OCA include OCA3, OCA4, OCA5, OCA6, and OCA7 (Table 41.1).[16–21]

Syndromic albinism

Syndromes associated with oculocutaneous albinism are less common than non-syndromic albinism and include Hermansky–Pudlak syndrome (HPS), in which affected individuals have absent dense bodies (delta granules) in their platelets, which interferes with the secondary phase of irreversible aggregation. Thus, individuals with HPS have easy bruising, epistaxis, and prolonged bleeding after procedures such as dental extraction, childbirth, and surgery.[22–26] Nine types of HPS have been identified and all have autosomal recessive inheritance.[27–35] Some types are associated with pulmonary fibrosis and intestinal accumulation of ceroid, causing granulomatous colitis (see Table 41.1).[36] Whole-mount electron microscopy of platelets without dense bodies can identify those with HPS, but genetic testing identifies the specific type of HPS and the potential for other systemic abnormalities.[37,38] The phenotype for oculocutaneous albinism in HPS is variable and can overlap with non-syndromic types of albinism.[39]

Chédiak–Higashi syndrome (CHS) is also associated with oculocutaneous albinism, inherited as an autosomal recessive disorder.[40,41] Persons with CHS have frequent infections and can progress to a lymphoproliferative phase.[42,44] They are treated with hematopoietic stem cell transplantation, preferably prior to the accelerated phase. If untreated, they will also develop neurological abnormalities and eventually succumb to an overwhelming infection.[45] Although these individuals have the ocular and cutaneous features of albinism, their hair has a

Fig. 41.2 Both boys have mutations in *TYR*. The one on the left makes no melanin pigment (OCA1A) whereas the one on the right makes a moderate amount of melanin pigment (OCA1B).

subtle silvery sheen, often prompting investigation to establish the diagnosis. Peripheral blood smear shows giant intracellular granules in neutrophils.[43]

Ocular albinism

In ocular albinism (OA1), which occurs less frequently than OCA,[46–48] there is a mutation in the *GPR143* gene on the X chromosome. Males with OA1 have the typical ocular features of albinism, but their cutaneous and hair pigment is nearly normal.[49–51] Some may have hypopigmented macules; skin biopsy may show macromelanosomes, but they are not pathognomonic.[52,53] Without careful eye examination, these individuals may be identified as having uncomplicated infantile nystagmus syndrome. Mothers of children with OA1 will typically show some iris transillumination and pigmentary mosaicism in the retina (Fig. 41.4), although the obligate carrier is rarely symptomatic.[53–57] Pigmentary mosaicism, noted in 80% to 90%, represents expression of Lyonization with pigmented RPE adjacent to non-pigmented areas, most notable in the mid-periphery of the fundi. Some males and females with almost normal pigmentation have been given a diagnosis of autosomal recessive ocular albinism, but many have been found to have oculocutaneous albinism with genetic testing, most often due to mutations in the *TYR* gene.[58–61] If a deletion in *GPR143* occurs, contiguous genetic disorders may be associated with OA1, e.g. ichthyosis of the skin (*STS*),[62] Kallman syndrome (*KAL1*),[63] and chondrodysplasia punctata (*ARSE*).[64]

Clinical phenotype

Ocular features

The ocular features in albinism vary from one individual to another, within a family, and within a specific type of albinism, due to interaction of heterogeneity in the type of albinism and the constitutional genotypes.[65–67] A clinical diagnosis of albinism is based on a constellation of findings and may be confirmed with genetic testing.

Reduced visual acuity

Many parents report that their infants with albinism close their eyes when exposed to bright light and do not appear to be as visually attentive as their children without albinism were, but most agree that there is evidence of improvement in

Fig. 41.3 This girl with African American heritage has mutations in the *P* gene that causes OCA2.

visual attentiveness by 5 to 6 months of age.[68,69] Vision often continues to improve as the child matures.[69–72] The spectrum of best-corrected visual acuity in persons with albinism ranges from 20/20 to worse than 20/400.[68–70,73–77] A spectrum of visual acuity is noted across and within the different types of albinism, and persons with OCA1A generally have worse visual acuity than persons with other types of albinism. High refractive errors are common in albinism, with large amounts of astigmatism being particularly noted in OCA1A.[73,77,78] Early correction of large refractive errors and careful re-evaluation of the refractive error over time maximizes the visual outcome by reducing ametropic amblyopia and improving binocular alignment.[79,80] Other reasons for reduced visual acuity include foveal hypoplasia, light scattering, nystagmus, and possibly retinostriate misrouting. Certain features associated with relatively better visual outcomes include demonstration of some stereoacuity and the presence of granular melanin pigment in the macula.[74,77,81]

Nystagmus

Most persons with albinism develop nystagmus within the first 2 to 3 months of life. Nystagmus is often horizontal and pendular, but rotary, jerk, and periodic alternating nystagmus have also been reported. In general, the amplitude of nystagmus diminishes as the children age, due, in part, to the development of a head posture as they develop better head control, and their visual attentiveness to smaller targets improves. The head posture damps the nystagmus amplitude and provides the best visual acuity.[74,80,82] The preferred position of the eyes, whether eccentric or in primary gaze, is called the null point of the nystagmus. In some persons with albinism who have better visual acuity, nystagmus may be undetectable, even when the eyes are examined with the slit-lamp biomicroscope or ophthalmoscope.[70,74,77,81,83] Others, particularly adults with albinism, may show only latent nystagmus.

Iris transillumination

Another feature common in albinism is iris transillumination, occasionally noted by parents as pink or translucent irides. Iris transillumination is best detected with retroillumination in a darkened room with a small, bright light of the slit-lamp directed toward the undilated pupil. Iris transillumination varies from complete, indicating that there is no melanin pigment present, as in OCA1A, to scattered punctate areas of iris transillumination, indicating the presence of a marked amount of melanin pigment in the posterior iris epithelium, derived from neuroectoderm (Fig. 41.5).[84] Stromal melanocytes, derived from the neural crest, can also restrict transillumination.

Foveal hypoplasia

At least some degree of foveal immaturity and deficiency of melanin pigment in the retinal pigment epithelium, derived from neuroectoderm, are common in albinism. At times, there is no foveal development and in other patients, typically with better visual acuity, an annular reflex is noted in the macula even though an umbo is not detected.[74,77,81,85] Optical coherence tomography has documented these structural findings and adaptive optics has shown variation in cone packing.[75,77,85–89] In many persons with albinism, the choroidal vessels are easily visualized in the macula, and the retinal vessels do not normally form a wreath around the intended fovea, whereas, in others, choroidal vessels are not seen in the macula even though they are often seen outside the macula (see Fig. 41.5).[75,84,86,88–90] With magnification, some individuals with albinism can be seen to have granular melanin pigment within the macula (Fig. 41.6); this is often associated with relatively better vision and measurable stereoacuity.[74,81] The optic nerve appears mildly hypoplastic in albinism, with a complete or incomplete scleral ring around the optic nerve head, and the disc can appear to be gray with indirect ophthalmoscopy.[91]

Strabismus and positive angle kappa

One finding that is helpful in the more pigmented individual, in whom one questions if albinism is the correct diagnosis, is the presence of a moderately positive angle kappa, determined with the subject fixing monocularly on a small light source.[77,92,93] A moderately positive angle kappa can mask an esotropia that measures 15 prism diopters or more and can make an exotropia appear larger than measured.[92] Both esotropia and exotropia are common in albinism, presumably related to abnormal binocular interaction from retinostriate misrouting.[4,70,76,83] Such a positive angle kappa relates to the

Table 41.1 Genetic classification of albinism

Type of albinism	MIM#	Gene	Locus	Encoding function	Comments
OCA1* OCA1A OCA1B	606933 203100 606952	*TYR*	11q14–21	Tyrosinase, which catalyzes several steps in melanogenesis	OCA1A: no melanin; OCA1B: varying amounts of melanin are present
OCA2	203200	*OCA2* (previously called *P* gene)	15q11.2–12	Melanosomal membrane protein	Common in sub-Saharan Africa due to 2.7–kb deletion; includes Brown OCA
OCA3	203290	*TYRP1*	9p23	Stabilizes tyrosinase and regulates eumelanin production	Previously called red or rufous OCA
OCA4	696574	*SLC45A2* (previously called *MATP* and *AIM1*)	5p13.2	Membrane transport protein	Minimal to near normal melanin; phenotype similar to OCA2; common in Japan
OCA5	615312	Unknown	4q24	Unknown	Described in Pakistani family
OCA6	609802	*SLC24A5*	15q21.1	Melanosome maturation	Described in Chinese family
OCA7	615179	*C10orf11*	10q22.2–q22.3	Melanocyte differentiation	Described in families in Faroe Islands and Denmark
OA1	300500	*GPR143*	Xp22.2–22.3	Regulation of melanosome distribution	Nettleship–Falls OA; pigmentary mosaicism in obligate carrier
HPS-1	203300	*HPS1*	10q23.1–23.3	Transmembrane protein in BLOC-3 within BLOC-4 and BLOC-5	Common in northwestern Puerto Rico due to founder effect; progressive pulmonary fibrosis and colitis
HPS-2	608233	*ADTB3A*, *AP3B1*, *HPS2*	5q14.1	Lysosomal trafficking	Neutropenia and/or immune defects; pulmonary fibrosis, conductive hearing loss, dysplastic hip
HPS-3	614072	*HPS3*	3q24	Vesicle-related protein	Found in central Puerto Rico; mild systemic findings; colitis
HPS-4	614073	*HPS4*	22q11.2–12.2	Involved in BLOC-3 and BLOC-4	Pulmonary fibrosis, colitis
HPS-5	614074	*HPS5*, *RU2*, *KIAA1017*	11p15–p.13	Organelle biogenesis	Hyperlipidemia, elevated creatinine clearance
HPS-6	614075	*HPS6, RU*	10q24.32	Organelle biogenesis	Mild systemic findings
HPS-7	614076	*DTNBP1, HPS7*	6p22.3	Component of BLOC-1	Mild lung disease
HPS-8	614077	*BLOC1S3, HPS8*	19q13.32	Vesicular transport protein	Mild systemic findings
HPS-9	614171	*BLOC1S6, PLDN, PA, HPS9*	15q21.1	Intracellular vesicle trafficking	Few cases described
HPS-10	NA	*AP3D1*	NA	Lysosomal biogenesis	Microcephaly, seizures, immunodeficiency
CHS	214500	*LYST* (previously *CHS1*)	1q42.1–42.2	Lysosomal trafficking regulator protein	Frequent infections due to immunodeficiency; may have bleeding diathesis

*OCA1 includes previously described temperature-sensitive OCA, minimal pigment OCA, and yellow OCA.
AP, Adapter protein; *BLOC*, biogenesis of lysosomal-related organelles complex; CHS, Chédiak–Higashi syndrome; *GPR*, G protein-coupled receptor; HPS, Hermansky–Pudlak syndrome; *LYST*, lysosomal trafficking regulator; MIM, Mendelian inheritance in man; NA, not available; OA, ocular albinism; OCA, oculocutaneous albinism; *PLDN*, pallidin; *SLC*, solute carrier family; *TYRP1*, tyrosine-related protein-1.

Fig. 41.4 Examination of the fundus of the obligate carrier for OA1 typically shows pigmentary mosaicism, with some areas having normal melanin pigment and other areas having no melanin pigment, as a manifestation of Lyonization.

Fig. 41.6 Careful microscopic examination of the fundus may show granular melanin pigment in the macula.

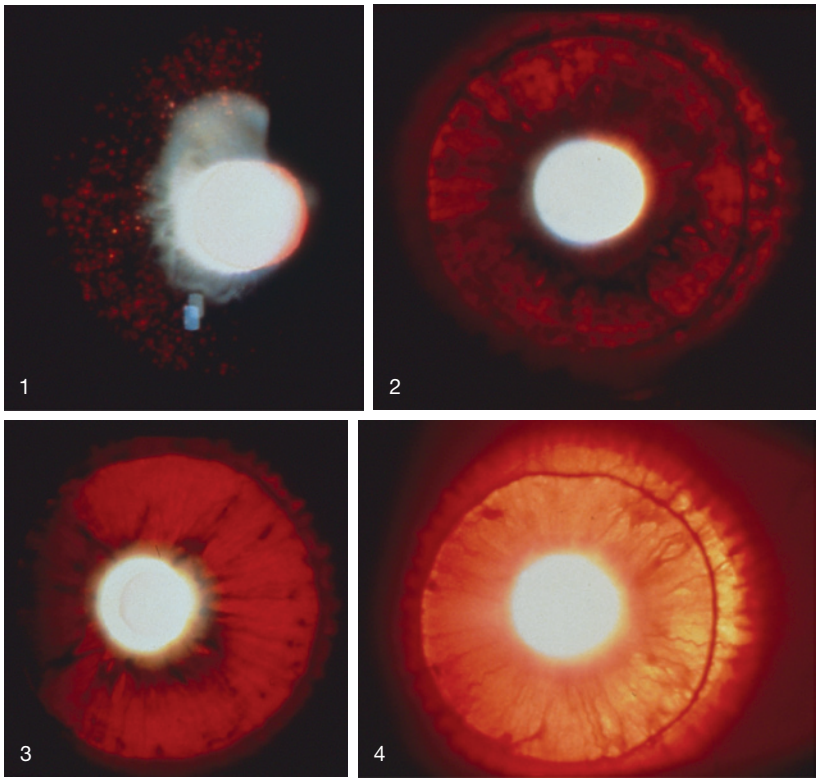

Fig. 41.5 Iris transillumination varies from punctate transillumination (top left, grade 1) to full iris transillumination (bottom right, grade 4) in albinism. *(Reprinted from Summers CG, Knobloch WH, Witkop CJ, Jr, King RA. Hermansky–Pudlak syndrome. Ophthalmic findings. Ophthalmology 1988; 95: 545–554, © 1988 with permission from Elsevier.)*

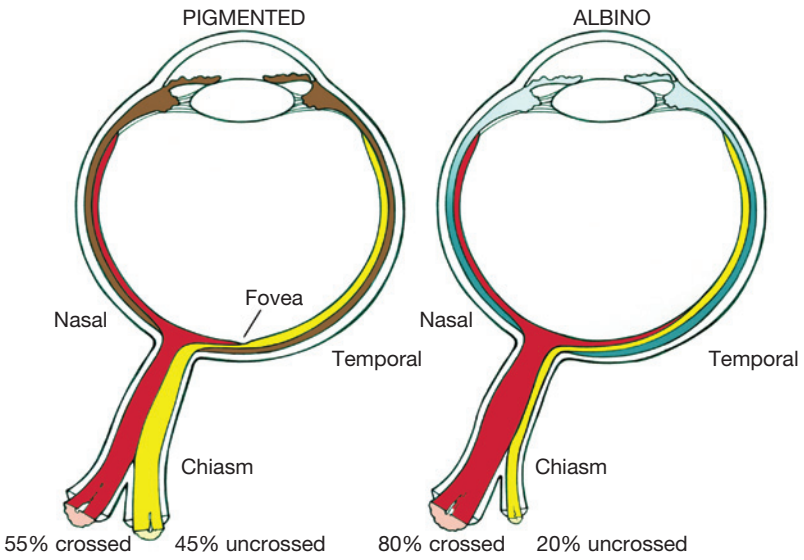

Fig. 41.7 Normal retinostriate routing (left) shifts from contralateral (crossed) to ipsilateral routing (uncrossed) at the fovea, whereas in albinism (right), the point of routing ipsilaterally is temporal to the fovea, resulting in a greater number of retinal ganglion fibers decussating at the chiasm (crossed) and being routed to the contralateral lateral geniculate nucleus. *(Reprinted from Creel DJ, Summers CG, King RA. Visual anomalies associated with albinism. Ophthalmic Paediatr Genet 1990; 11: 193–200. © 1990, with permission from Taylor & Francis.)*

neural fibers temporal to the expected location of the fovea crossing at the chiasm to synapse in the contralateral lateral geniculate nucleus, compared to normal eyes (Fig. 41.7).[94]

Neurophysiological alterations

Albinism is associated with absent or reduced stereoacuity.[74,81,95] This is most likely related to the excessive retinostriate decussation of the nerve fibers at the chiasm in albinism, developing early in embryogenesis (see Fig. 41.7).[94,96] With a reduced number of nerves coursing ipsilaterally, the normal pattern of layering of the lateral geniculate nucleus is disrupted. Although the reason for this misrouting is unknown, it can be detected with a specialized pattern onset or flash visual evoked potentials (VEP) recorded with occipital electrodes.[94,96,97] Misrouting has also been documented with positron emission tomography and functional magnetic resonance imaging.[24,98–103] Abnormal decussation may contribute to strabismus and nystagmus.

Cutaneous features

Males with OA1 typically have hair and cutaneous pigment that is similar to or slightly lighter than others in the family, as the OA1 phenotype involves primarily the eyes. However, all types of non-syndromic and syndromic albinism have at least some degree of skin hypopigmentation that places them at risk for damaging sunburns that can lead to cutaneous malignancies later in life. Hair color depends on the type of OCA, with it being white in OCA1A, blond to brown in pigmenting types of albinism, and silvery brown in Chédiak–Higashi syndrome.[4]

Differential diagnoses

Other disorders with incomplete foveal development include aniridia and achromatopsia.[104,105] Persons with aniridia or achromatopsia also typically have nystagmus. Individuals with congenital stationary night blindness also have nystagmus and when associated with high myopia, it may appear that the fovea is poorly developed.[106] Distinguishing albinism from these disorders can be difficult, particularly if the irides have been dilated prior to slit-lamp biomicroscopy. Examination showing normal color vision, a positive angle kappa, absent stereoacuity, and perhaps a VEP showing misrouting can help to establish a diagnosis of albinism. Cursory examination of the person with a pigmenting type of albinism may lead to the erroneous diagnosis of infantile nystagmus syndrome not associated with albinism, or nystagmus in males due to a *FRMD7* mutation, which has X-linked inheritance.[107] Examination of the obligate carrier of OA1 can help to elucidate the correct diagnosis.[53–57]

Occasionally a child with a retinal dystrophy presents with nystagmus, foveal blunting, and some granular pigment in the macula, similar to some individuals with albinism. Early on, no significant pigment change is noted in the retinal periphery. These children with a retinal dystrophy can be correctly identified by observing paradoxical pupillary constriction when room lights are dimmed and by performing full-field electroretinography, as persons with albinism do not show a paradoxical pupillary response and their electroretinogram is normal or supranormal.[108]

The occasional person with albinism presents with mildly subnormal visual acuity and no nystagmus, and an annular reflex in the macula that might be interpreted as normal. In these individuals, a high index of suspicion for albinism will prompt the astute clinician to look for other signs of albinism and consider a VEP to demonstrate misrouting of the retinostriate fibers.[96,97]

Management

Making the diagnosis

The hair bulb incubation test[109] is not precise for diagnosis and is no longer used. In some persons with suspected albinism, the diagnosis can be established with genetic testing for mutations in a gene known to cause albinism. Panels that evaluate several

genes causing albinism are readily available. Until treatment that requires knowledge of the mutations is available, those with lifelong absence of melanin pigment in their skin, hair, and eyes (OCA1A), and those with only ocular features and the finding of pigmentary mosaicism in the obligate carrier may not need molecular testing, as the phenotype defines the specific type of albinism.

Providing counseling

Counseling by a geneticist or a genetics counselor can be helpful to obtain a pedigree, explain inheritance patterns, and indicate that a negative gene test does not necessarily mean that the person does not have albinism.[60,61,77,110,111] Individuals with autosomal recessive albinism can be counseled that they will not have a child with albinism unless their partner has the same type of albinism or carries a mutation in the same gene. Those with OA1 will pass the mutation to none of their sons and to all their daughters who will be carriers.

Supporting educational needs

Quality of life in persons with albinism has been shown to be impaired, particularly for distance visual acuity.[112] Their refractive error should be corrected for the best visual acuity and evaluation by a low vision specialist should be considered. Although it is rare that persons with albinism need to learn Braille, orientation and mobility training is important for those with severely reduced visual acuity. Current electronic technology to enlarge reading matter has supplemented the use of magnifiers and bifocals. Many will prefer to reverse the black/white setting on computers and other electronic aids to reduce asthenopia due to photosensitivity. Self-advocacy should be encouraged in early education.[113] Additional education and support for families are available, e.g. the National Organization of Albinism and Hypopigmentation in the United States (www.NOAH.org), the Albinism Fellowship of Australia (www.albinismaustralia.org), the Albinism Fellowship of the United Kingdom and Ireland (www.albinism.org.uk) and the Hermansky–Pudlak Syndrome Network (www.hps.network.org).

Children with albinism may require preferential seating and enlargement of print when they start school. Electronic media are used well by children with low vision. A teacher for the visually impaired can help to assure that the child's needs are being met. As children mature, more reading is required and print size in texts becomes smaller. A bifocal can help with near work, and audio books can be used when an electronic version is not available. An increased rate of attention deficit and hyperactivity disorder has been reported in children and adults with albinism, not related to visual acuity.[114]

Social issues

Sensitivity to the social issues surrounding a diagnosis of albinism is essential. Parents with dark pigmentation may have difficulty understanding how they could have a child with oculocutaneous albinism and may have difficulty raising a child in their culture. Persons with albinism are no longer referred to as "albinos." Attempts have been made to eliminate the negative portrayal of persons with albinism in media and the false notion that those with albinism have magical powers. Albinism is not associated with intellectual disability. Health care providers for persons with albinism may be the first to be informed about taunting behavior by peers and should alert the school system so that such behavior is not tolerated.

Follow-up eye care

Children with albinism require periodic updating of glasses prescriptions; filtering lenses and a cap or hat are helpful, especially if the individual is photosensitive. Contact lenses are often used successfully in conjunction with sunglasses. In some cases, extraocular muscle surgery is recommended to restore binocular alignment in those with strabismus and/or to improve a head posture in those with an eccentric null point.[69,76,115–118] Such surgery may produce minimal improvement in visual acuity.

If genetic testing has not identified mutations in a gene known to cause albinism, each examination in a child with OCA should include an inquiry about easy bruising, epistaxis, or other excessive bleeding. When the answer is affirmative, consideration is given to evaluating platelets for absent dense bodies[4]; if dense bodies are absent, genetic testing for HPS is considered, to assess the risk of associated systemic abnormalities. Those with HPS should avoid aspirin and non-steroidal anti-inflammatory agents, and have medical information available for severe trauma or surgery. Desmopressin (1-desamino-8-D-arginine-vasopressin or DDAVP) and a platelet infusion can be administered when hemostasis is needed.

Skin care

Children with OCA should establish regular care with a dermatologist in view of their increased risk of damaging sunburns, later resulting in cutaneous malignancies.[4] Sunscreens with ultraviolet A (UVA) and UVB protection and a sun protection factor (SPF) of at least 30 should be used regularly and liberally, even on cloudy days if outside, and should be re-applied every few hours. Use of hats, caps, UV-protective clothing, sunglasses, and SPF lip protection are recommended. Outdoor exposure in midday sunlight should be avoided. The risk of DNA-altering sunburn is increased near water, snow, concrete, and sand.[1,5] Most individuals obtain enough incidental ultraviolet light to produce vitamin D, but if there is concern about hypovitaminosis D, a vitamin D level can be obtained by the primary care provider.

Treatment

Drug trials have been performed in an attempt to improve the symptoms noted by those with albinism. Oral levodopa has not been shown to improve visual acuity in oculocutaneous albinism.[119] A study of nitisinone, which darkens the coat and iris color in mice,[120] is under way in humans with OCA1B. To date, gene therapy has not been tried in albinism.

INTRODUCTION
DEVELOPMENTAL ANOMALIES OF THE VITREOUS
VITREORETINAL DYSPLASIA
INHERITED VITREORETINAL DISORDERS
ACQUIRED DISORDERS OF THE VITREOUS
REFERENCES

Introduction

The vitreous, a transparent gelatinous structure that fills the posterior four-fifths of the globe, is firmly attached to the pars plana and loosely to the retina and optic nerve posteriorly. In childhood there is a firm attachment to the lens.

The development of the vitreous body and zonule can be divided into three stages:

1. The *primary* vitreous is formed during the first month of gestation and is a vascularized mesodermal tissue separating the developing lens vesicle and the neuroectoderm of the optic cup. It contains branches of the hyaloid artery that later regress.
2. The *secondary* vitreous starts at 9 weeks and develops throughout embryonic life. It forms the vitreous body, is avascular and transparent, and displaces the primary vitreous, which becomes Cloquet's canal, running from the optic disc to the lens. By the third month, the secondary vitreous fills most of the developing vitreous cavity.
3. The *tertiary* vitreous lies between the ciliary body and lens, separated from the secondary vitreous as well-formed fibrils, which later develop into the zonule.

Developmental anomalies of the vitreous

Persistence of the primary vitreous or part of its structure may give rise to a number of congenital abnormalities.

Persistent hyaloid artery (see Chapter 36)

Persistence of all, or more frequently part, of the hyaloid artery is a common congenital abnormality. Hyaloid artery remnants occur in 3% of full-term infants but are commonly seen in premature infants, with most regressing. Rarely, the whole artery may run from the disc to the lens. Posterior remnants may give rise to a single vessel running from the center of the disc or to an elevated bud of glial tissue – Bergmeister's papilla. Anterior remnants of the hyaloid system may be seen as a small white dot on the posterior lens capsule – Mittendorf's dot. They are non-progressive and do not interfere with vision.

Vitreous cysts

Acquired cysts occur with inflammatory disease and, rarely, with X-linked retinoschisis. Congenital cysts are usually found in otherwise normal eyes. Their origin is unknown but, as blood vessels are sometimes seen within them, they may develop from hyaloid artery remnants.

Cysts may lie in the vitreous immediately behind the lens (Fig. 42.1) or in the posterior vitreous. They may be mobile or attached to the lens or optic disc. Mostly, intervention is not required; occasionally laser treatment (Nd:YAG or argon laser) may be used to collapse the cyst if it is symptomatic. However, repeat Nd:YAG therapy of an anterior pigmented cyst has resulted in a cataract.[1]

Persistent fetal vasculature (persistent hyperplastic primary vitreous) (see Chapter 37)

Persistent fetal vasculature (PFV), also referred to as persistent hyperplastic primary vitreous (PHPV) in the past, is caused by failure of the primary vitreous to regress. Most cases are sporadic and unilateral; there may be minor abnormalities in the fellow eye. Bilateral and familial cases have been reported but these are likely to represent cases of vitreoretinal dysplasia (see below).

For anterior PFV, see Chapter 37. In posterior PFV, the ocular abnormality is confined to the posterior segment, and may present with leukocoria, strabismus, microphthalmia, or nystagmus. The lens is usually clear. There is often a fold of condensed vitreous and retina running from the optic disc to the ora serrata or lens (Fig. 42.2), often associated with a retinal detachment. Ultrasound and computed tomography (CT) imaging help in differentiating PFV from retinoblastoma (see Chapter 43).

Enucleation should be avoided because a prosthesis may be less acceptable cosmetically, and there may be decreased growth of the orbit giving facial asymmetry. A limbal or pars plicata approach may be used to remove the lens and retrolental

Fig. 42.2 Posterior persistent hyperplastic primary vitreous. A fold of condensed vitreous running from the optic disc can be seen. The left optic disc is normal.

tissue to clear the visual axis, improve cosmesis, deepen the anterior chamber, and prevent angle closure glaucoma caused by anterior chamber shallowing. However, in many cases, surgical intervention is not required.

Vitreoretinal dysplasia

Maldevelopment of the vitreous and retina, vitreoretinal dysplasia, is seen either as an isolated abnormality or associated with systemic abnormalities.[2] Syndromes such as Norrie disease and Warburg syndrome may have bilateral vitreoretinal dysplasia. It also occurs in trisomy 13, trisomy 18, triploidy, and in association with cerebral malformations.

There appears to be no relationship between the histologic findings and the various syndromes in which retinal dysplasia is reported. The dysplastic retina contains rosettes that resemble retinoblastoma rosettes but contain Müller cells with an abnormal relationship between the retina and retinal pigment epithelium (RPE).

Norrie disease

Clinical and histologic findings

Norrie disease is an X-linked recessive disorder; affected males are blind at birth or in early infancy. Twenty-five percent of affected males are developmentally delayed and one-third later develop cochlear deafness, usually starting in late teenage years. A more severe systemic phenotype is seen in patients with large chromosomal deletions encompassing the Norrie gene locus. Ocular findings include bilateral cataracts, bilateral retinal folds, retinal detachment, vitreous hemorrhage, and bilateral vitreoretinal dysplasia (Fig. 42.3). The retinal detachments are usually of early onset and have been observed *in utero* by ultrasonography. Most cases progress to an extensive vitreoretinal mass and bilateral blindness.

Angle closure glaucoma may develop; this is best managed by lensectomy. Late signs include corneal opacification, band keratopathy, and phthisis bulbi (see Fig. 42.3).

Carrier females do not usually show any ocular abnormality and electroretinography (ERG) is normal. An affected female has been reported, born to a carrier mother who had a retrolental mass in the right eye and a retinal fold with a tractional retinal detachment in the left. Molecular genetic testing confirmed that she was a manifesting heterozygote. She showed skewed X-inactivation in her peripheral blood lymphocytes, suggesting non-random inactivation, with inactivation occurring more frequently in the normal rather than the mutant X chromosome. A female with Norrie disease with an X autosome translocation has also been described.[3]

Histopathology of a vitreoretinal biopsy suggested arrest of normal retinal development during the third or fourth month of gestation, but the eyes of an aborted 11-week fetus with Norrie disease showed no evidence of primary neuroectodermal maldevelopment of the retina, suggesting a later disorder of development, probably related to abnormal retinal vascular development (see below).

Molecular genetics and pathogenesis

More than 100 mutations have been identified in the Norrie disease gene *NDP*. The gene is expressed in the neural layers of the retina, throughout the brain, and in the spiral ganglion and stria vascularis of the cochlea. The encoded protein, Norrin, is a component of the Wnt signaling pathway, a key regulator of various stages of ocular development, including retinal field establishment, maintenance of retinal stem cells, vasculogenesis in the retina, formation of the ciliary body, and cornea and lens development.[4] Wnt signaling is important in retinal development: uncontrolled, it may cause other retinal diseases including familial exudative vitroretinopathy, the osteoporosis–pseudoglioma syndrome, and Norrie disease. The association of Norrie disease with peripheral vascular disease affecting the lower limbs is evidence for a role of the Norrin gene in extraocular angiogenesis.

The identification of the Norrie disease gene allows molecular genetic diagnosis of the carrier state and prenatal diagnosis. Norrie disease may be associated with chromosomal deletions involving the *NDP* locus, the adjacent monoamine oxidase genes *MAOA* and *MAOB*, and additional genetic material. Children with such deletions have a more severe ("atypical") phenotype.[5] In addition to the characteristic retinal dysplasia, the "atypical" phenotypes may include: severe

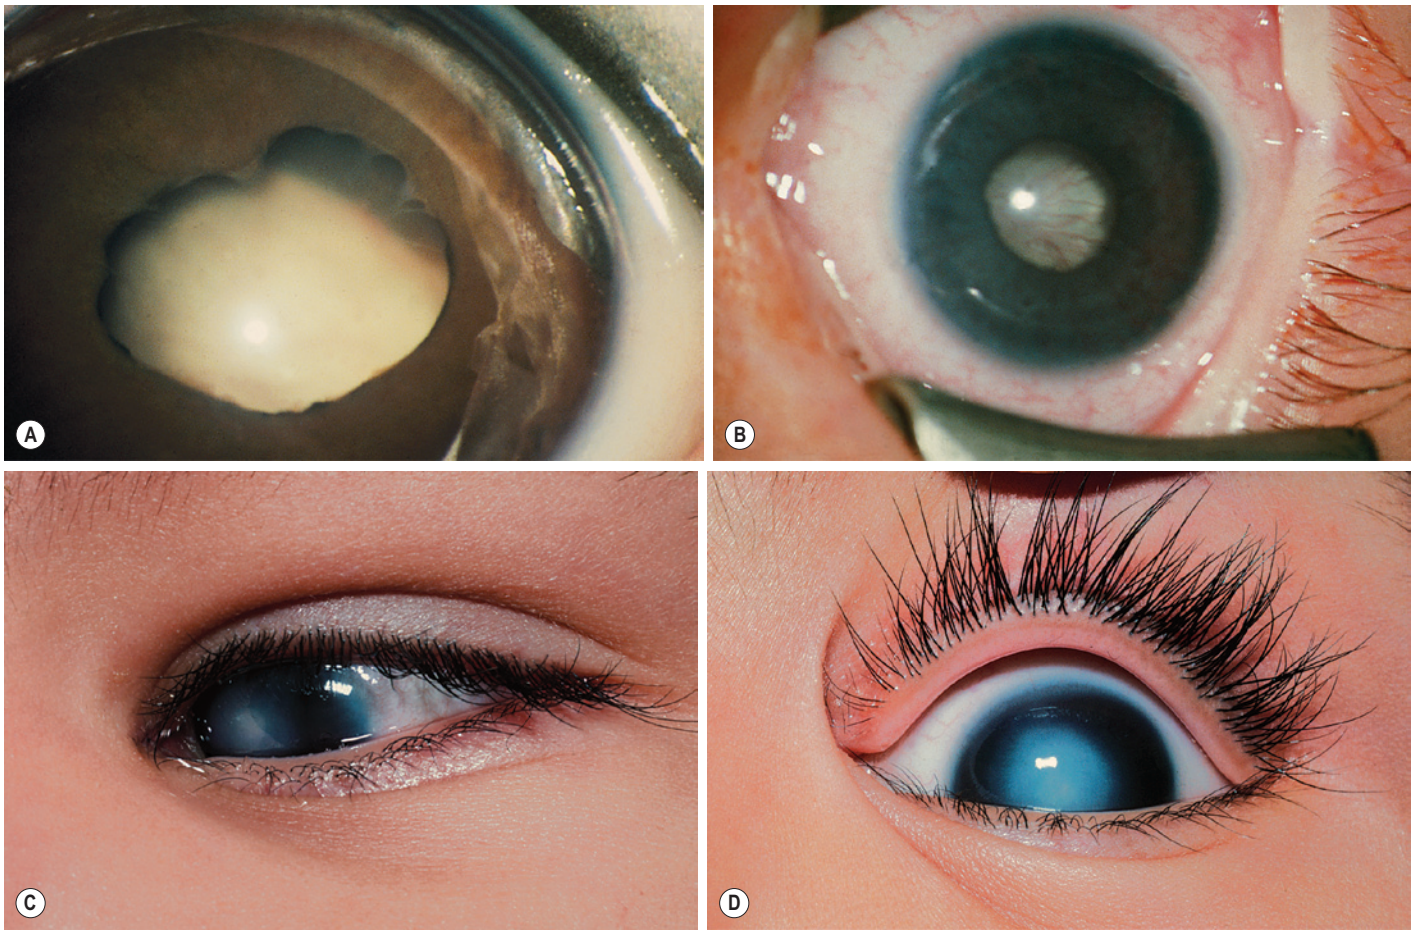

Fig. 42.3 Norrie disease. (A) Posterior synechiae, shallow anterior chamber, and retrolental white mass. (B) Brother of patient in (A) showing vascularized white retrolental mass. (C,D) Flat anterior chambers and lens–cornea adhesions.

learning difficulties, involuntary movements, atonic seizures, hypertensive crises, and hypogonadism.[5]

Mutations of the Norrie disease gene may be responsible for another rare vitreoretinal disorder, X-linked familial exudative vitreoretinopathy (see below).

Coats disease may be caused by somatic mutations in *NDP* only in the retina of affected eyes; the somatic mutations result in deficiency of Norrin with consequent abnormal retinal vascular development, the hallmark of Coats disease.

The role of the *NDP* gene in retinopathy of prematurity (ROP) is controversial. Some case–control studies have suggested that sequence variants in the *NDP* gene may predispose to stage 5 ROP; other studies have been negative.[6,7] The controversy will not be resolved until larger studies have been performed.

NDP knock-out mouse models have a similar ocular phenotype to humans, with fibrous masses in the vitreous cavities, disorganization of retinal ganglion cells, and sporadic degeneration of other retinal cell types. The retinal vasculature is abnormal by postnatal day 9, with abnormal vessels in the inner retina and few vessels in the outer retina. This is further evidence for disordered retinal vascular development being the primary cause of the retinal detachment in Norrie disease. As in humans, these mice have progressive hearing loss leading to profound deafness, with abnormal vasculature and eventual loss of most of the vessels in the stria vascularis (the main vasculature of the cochlea), suggesting a principal function of Norrin in regulating the interaction of the cochlea with its vasculature.

Management

In most cases of Norrie disease, affected males have bilateral total retinal detachment from birth and vitreoretinal surgery is not indicated. Lensectomy may be indicated when there is shallowing of the anterior chamber and a risk of pupil-block glaucoma. It is important that children and their families have good educational and social support and are referred for genetic counseling to discuss the risk of further affected pregnancies. Molecular diagnosis is possible in the majority of cases and prenatal and pre-implantation diagnosis is possible where the causative mutation is known. Recently, early delivery of a fetus known to carry a Norrin mutation followed by anti-vascular endothelial growth factor (VEGF) and laser treatment of the retina was shown to result in a good outcome with normal foveal structure.[8] This suggests that in some families who choose this option, prenatal diagnosis, preterm delivery, and prompt laser treatment may prevent retinal detachment.

Trisomy 13

Clinical and histologic findings

Trisomy 13 (Patau syndrome) is the chromosomal abnormality most consistently associated with severe ocular defects.

Box 42.1

Ocular abnormalities in trisomy 13

- Microphthalmos
- Coloboma of the uveal tract
- Cataract
- Corneal opacities
- Retinal dysplasia
- Persistent hyperplastic primary vitreous
- Dysplastic optic nerves
- Cyclopia

Systemic abnormalities include microcephaly, cleft palate, congenital cardiac defects, polydactyly, skin hemangiomas, umbilical hernia, and malformation of the central nervous system. Most children die within the first few months of life.

Bilateral ocular abnormalities are seen in almost all cases of trisomy 13; the common ocular findings are detailed in Box 42.1. There is total disorganization of the vitreous and retina; extensive retinal dysplasia is evident histologically. Intraocular cartilage, which is frequently present, may be a characteristic feature.

Incontinentia pigmenti (Bloch–Sulzberger syndrome)

Clinical and histologic findings

Incontinentia pigmenti (IP) is an uncommon X-linked dominant disorder affecting the skin, bones, teeth, central nervous system, and eyes, which is usually lethal *in utero* in males, leading to a marked female preponderance. The characteristic skin lesions appear soon after birth with a linear eruption of bullae predominantly affecting the extremities (Fig. 42.4A). The bullae gradually resolve to leave a linear pattern of pigmentation (Fig. 42.4B).

Ocular abnormalities are common including amblyopia, strabismus, nystagmus, optic atrophy, and retinal changes.[9] The retinal changes are the cause of severe visual impairment that may be seen in IP. Corneal abnormalities include whorl-like epithelial keratitis with epithelial microcysts, subepithelial anterior stromal opacities, and mild mid-stromal haze.

The most serious complication is retinal detachment, which may lead to severe visual impairment. Retinovascular abnormalities are common and include retinal vascular tortuosity, capillary closure, and peripheral arteriovenous shunts (Fig. 42.4C–E). These are most marked in the temporal periphery and may be associated with retinal neovascularization. Fluorescein angiography demonstrates areas of non-perfusion in the temporal periphery (Fig. 42.4E). Retinal neovascularization, if left untreated, may lead to tractional retinal detachment.

An ophthalmologist should regularly assess affected females soon after diagnosis and during infancy, in order to detect those cases of retinal vascular non-perfusion requiring treatment, usually occurring in the first 2–3 years of life. In very young infants referred early, an examination in the clinic with a lid speculum may be sufficient to obtain a peripheral fundus examination. If the retinal vessels are normal and extend into zone 3 then an examination under anesthetic can be avoided. If any peripheral retina abnormality is identified, and in those infants where it is not possible to see the periphery well, then a single baseline examination under anesthetic with RetCam photography and fluorescein angiography is indicated. Laser treatment is indicated when there is significant capillary non-perfusion (Fig. 42.4F–H). Careful follow-up in infancy and early childhood is necessary for those infants that have incomplete retinal vascularization. Established retinal detachment is difficult to manage and has a poor visual outcome (Fig. 42.4I). It is rarely bilateral.

Strabismus, refractive errors, and amblyopia are common in patients with IP, and clinic visits for retinal examination are also an opportunity for examination of visual acuity, refraction, ocular alignment, and treatment of amblyopia where necessary.

Molecular genetics and pathogenesis

IP is caused by mutations in the ubiquitously expressed gene *NEMO* (also known as *IKBKG*, NF-κB essential modulator). The NEMO protein is the regulatory component of the IκB kinase (IKK) complex, a central activator of the NF-κB transcriptional signaling pathway.[10] In IP, loss-of-function mutations in *NEMO* lead to a susceptibility to cellular apoptosis in response to tumor necrosis factor (TNF)-α.[8]

A recurrent genomic deletion within *NEMO* accounts for 90% of mutations. This deletion eliminates exons 4–10 (*NEMOΔ4–10*) and abrogates protein function. The remaining mutations are small duplications, substitutions, and deletions. Most *NEMO* mutations cause premature protein truncation, which is predicted to eliminate NEMO function and thereby cause cell death. Expression analysis of human and mouse *NEMO*/*nemo* has shown that the gene becomes active early during embryogenesis and is expressed ubiquitously, suggesting a vital role in embryonic and postnatal development.

Irrespective of the mutation causing IP, X-inactivation is likely to modulate the severity in females and account for some of the phenotypic variation. Some females carry the common deletion but are clinically normal, suggesting that selection against mutant cells commenced very early in prenatal development, as in mouse models, in which surviving $nemo^{+/-}$ female mice show marked skewing of X-inactivation. Although X-inactivation may account for the female phenotypic variation, a role for modifier genes cannot be excluded. In males, X-inactivation is not an issue, and most *NEMO* mutations are lethal because they abolish NF-κB activity, making cells susceptible to TNF-α-induced apoptosis, a finding also demonstrated in *nemo*-null male mice.

Less deleterious mutations can give rise to surviving males and an ectodermal dysplasia-like phenotype with immunodeficiency. Males with skin, dental, and ocular abnormalities typical of those seen in female patients with IP are rare. To date, all carried the common deletion *NEMOΔ4–10*, normally associated with male death *in utero*. Survival in one patient was explained by a 47,XXY karyotype and skewed X-inactivation. The three other patients had a normal 46,XY karyotype, with both wild-type and deleted copies of the *NEMO* gene, and thereby represent somatic mosaics for the common mutation: they acquired the deletion at a post-zygotic stage. There are, therefore, three mechanisms for survival of males carrying a *NEMO* mutation: mild mutations, a 47,XXY karyotype, and somatic mosaicism.

Walker–Warburg syndrome (HARD ± E) and related syndromes

Clinical findings

The acronym "HARD ± E" stands for hydrocephalus, agyria, retinal dysplasia, with or without encephalocele (Fig. 42.5).

Fig. 42.5 Walker–Warburg syndrome. (A) Shallow anterior chamber and a retrolental mass. (B) Computed tomography scan showing hydrocephalus, lissencephaly, and colpocephaly.
