$[Pt(NH_3)_2Cl_2]$ is a simple looking coordination compound but it has a far reaching influence. It was the first of a series of platinum complexes that have been successful in the treatment of a wide range of cancers. Perhaps not surprisingly, it is on the World Health Organization's list of essential medicines. The therapeutic compound is introduced intravenously (using a medical set up similar to the one shown here) where the complex migrates to the inside of the tumour cell. Here the chloride concentration is low and one of the chloride ligands dissociates from the complex and is replaced by a water molecule. In turn, the water ligand is displaced and a nitrogen that is part of the DNA base guanine coordinates to the metal. The process is repeated with the remaining chloride ligand and the DNA-bound complex disrupts the replication of the DNA and the cell dies. There are two isomers of this complex only one of which, cisplatin, has therapeutic value. We touch on the reason for this in this shortly.

By the end of this section, you should be able to

- Systematically name simple coordination compounds and write a formula of a complex ion from its name.

When complexes were first discovered, they were named after the chemist who originally prepared them. A few of these names persist, as, for example, with the dark red substance $NH_4[Cr(NH_3)_2(NCS)_4]$, which is still known as Reinecke's salt. Once the structures of complexes were more fully understood, it became possible to name them in a more systematic manner. Let's use two substances to illustrate how coordination compounds are named:

How to Name Coordination Compounds

1. **In naming complexes that are salts, the name of the cation is given before the name of the anion**. Thus, in $[Co(NH_3)_5Cl]Cl_2$ we name the $[Co(NH_3)_5Cl]^{2+}$ cation and then the Cl^-.
2. **In naming complex ions or molecules, the ligands are named before the metal. Ligands are listed in alphabetical order, regardless of their charges. Prefixes that give the number of ligands are not considered part of the ligand name in determining alphabetical order**. Thus, the $[Co(NH_3)_5Cl]^{2+}$ ion is pentaamminechloridocobalt(III). (Be careful to note, however, that the metal is written first in the chemical formula.)
3. **The names of anionic ligands end in the letter *ido*, but electrically neutral ligands ordinarily bear the name of the molecules** (Table 23.5). Special names are used for H_2O (aqua), NH_3 (ammine), and CO (carbonyl). For example, $[Fe(CN)_2(NH_3)_2(H_2O)_2]^+$ is the diamminediaquadicyanidoiron(III) ion.
4. **Greek prefixes (*di-, tri-, tetra-, penta-, hexa-*) are used to indicate the number of each kind of monodentate ligand when more than one is present. If the ligand or is polydentate, the alternate prefixes *bis-, tris-, tetrakis-,* are used and the ligand name is placed in parentheses**. For example, the name for $[Co(en)_3]Br_3$ is tris(ethylenediamine)cobalt(III) bromide.
5. **If the complex is an anion, its name ends in *-ate***. The compound $K_4[Fe(CN)_6]$ is potassium hexacyanidoferrate(II), for example, and the ion $[CoCl_4]^{2-}$ is tetrachloridocobaltate(II) ion.
6. **The oxidation number of the metal is given in parentheses in Roman numerals following the name of the metal**.

Three examples for applying these rules are

$[Ni(NH_3)_6]Br_2$	Hexaamminenickel(II) bromide
$[Co(en)_2(H_2O)(CN)]Cl_2$	Aquacyanidobis(ethylenediamine)cobalt(III) chloride
$Na_2[MoOCl_4]$	Sodium tetrachloridooxomolybdate(IV)

TABLE 23.5 Some Common Ligands and Their Names

Ligand	Name in Complexes	Ligand	Name in Complexes
Azide, N_3^-	Azido	Oxalate, $C_2O_4^{2-}$	Oxalato
Bromide, Br^-	Bromo	Oxide, O^{2-}	Oxo
Chloride, Cl^-	Chloro	Ammonia, NH_3	Ammine
Cyanide, CN^-	Cyano	Carbon monoxide, CO	Carbonyl
Fluoride, F^-	Fluoro	Ethylenediamine, en	Ethylenediamine
Hydroxide, OH^-	Hydroxido	Pyridine, C_5H_5N	Pyridine
Carbonate, CO_3^{2-}	Carbonato	Water, H_2O	Aqua

When writing the formula of complexes, it is preferable to write the donor atom of the ligand closest to the metal. So $[Cu(OH_2)_6]^{2+}$ is preferred to $[Cu(H_2O)_6]^{2+}$.

Sample Exercise 23.3

Naming Coordination Compounds

Name the compounds (**a**) $[Cr(OH_2)_4Cl_2]Cl$, (**b**) $K_4[Ni(CN)_4]$.

SOLUTION

Analyze We are given the chemical formulas for two coordination compounds and assigned the task of naming them.

Plan To name the complexes, we need to determine the ligands in the complexes, the names of the ligands, and the oxidation state of the metal ion. We then put the information together following the rules listed in the text.

Solve

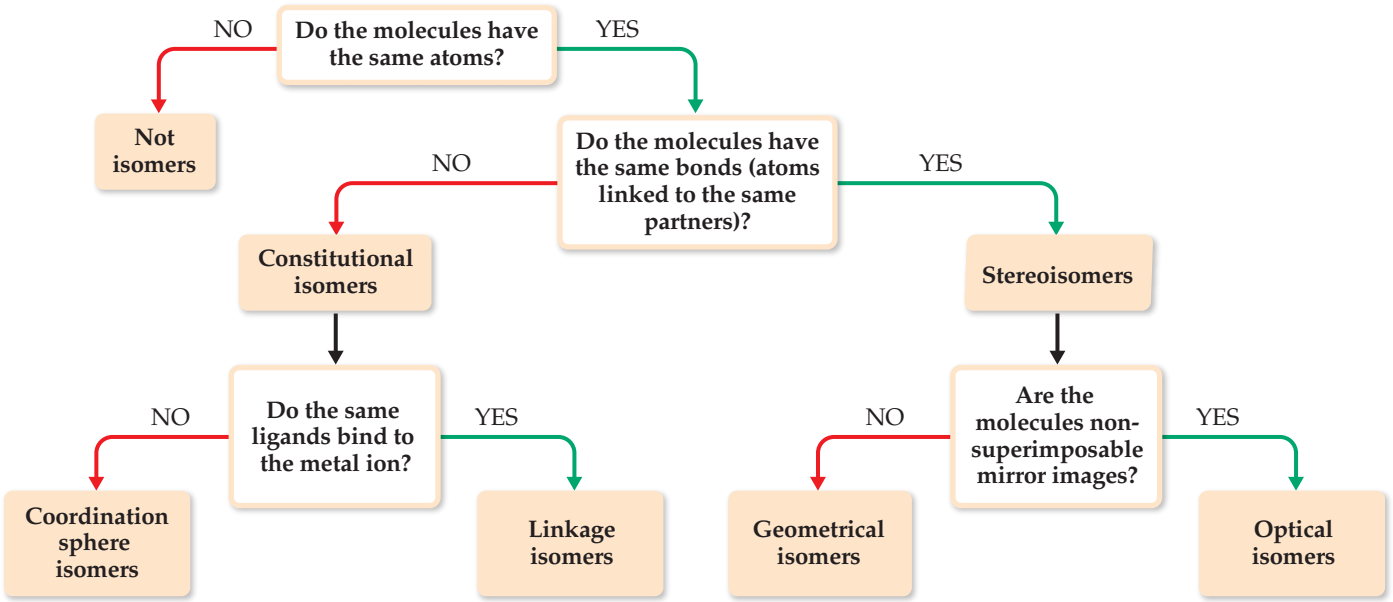
(**a**) The ligands are four water molecules—tetraaqua—and two chloride ions—dichlorido. By assigning all the oxidation numbers we know for this molecule, we see that the oxidation number of Cr is +3:

$$+3 + 4(0) + 2(-1) + (-1) = 0$$
$$[Cr(OH_2)_4Cl_2]Cl$$

Thus, we have chromium(III). Finally, the anion is chloride. The name of the compound is tetraaquadichloridochromium(III) chloride.

(**b**) The complex has four cyanide ion ligands, CN^-, which means tetracyanido, and the oxidation state of the nickel is zero:

$$4(+1) + 0 + 4(-1) = 0$$
$$K_4[Ni(CN)_4]$$

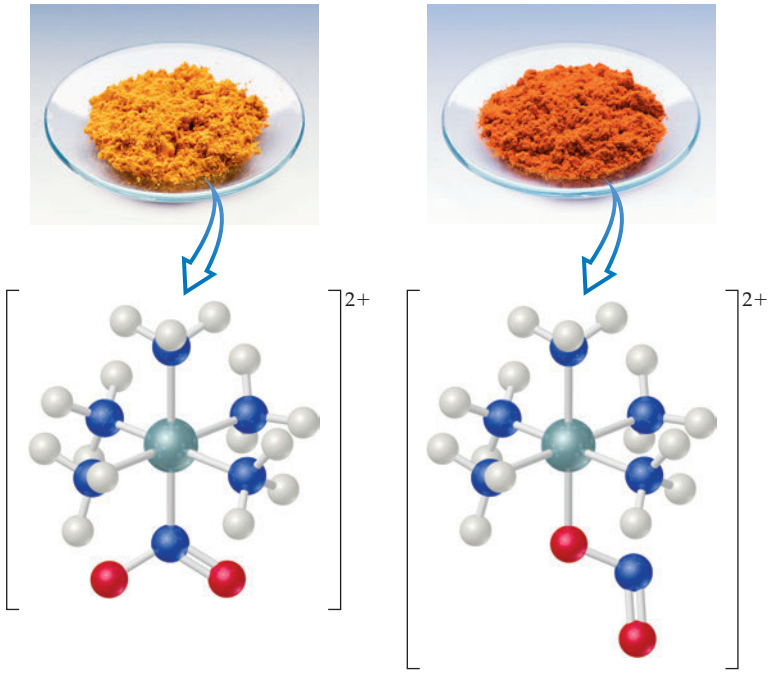


Because the complex is an anion, the metal is indicated as nickelate(0). Putting these parts together and naming the cation first, we have potassium tetracyanidonickelate(0).

Practice Exercise

What is the name of the compound $[Rh(NH_3)_4Cl_2]Cl$?
(**a**) Rhodium(III) tetraamminedichlorido chloride
(**b**) Tetraammoniadichloridorhodium(III) chloride
(**c**) Tetraamminedichloridorhodium(III) chloride
(**d**) Tetraamminetrichlorido-rhodium(III)
(**e**) Tetraamminedichloridorhodium(II) chloride

Isomerism



When two or more compounds have the same composition but a different arrangement of atoms, we call them **isomers**. Here we consider two main kinds of isomers in coordination compounds: **constitutional isomers** (which have different bonds) and **stereoisomers** (which have the same bonds but different ways in which the ligands occupy the space around the metal center). Each of these classes also has subclasses, as shown in Figure 23.19.

▲ Figure 23.19 Forms of isomerism in coordination compounds.

Go Figure

What are the chemical formula and name for each of the complex ions in this figure?

Nitro isomer
Bonding via ligand N atom

Nitrito isomer
Bonding via ligand O atom

▲ **Figure 23.20** **Linkage isomerism.**

Constitutional Isomerism

Many types of constitutional isomerism are known in coordination chemistry, including the two named in Figure 23.19: linkage isomerism and coordination-sphere isomerism. **Linkage isomerism** is a relatively rare but interesting type that arises when a particular ligand is capable of coordinating to a metal in two ways. The nitrite ion, NO_2^-, for example, can coordinate to a metal ion through either its nitrogen or one of its oxygens (**Figure 23.20**). When it coordinates through the nitrogen atom, the NO_2^- ligand is called *nitro*; when it coordinates through the oxygen atom, it is called *nitrito* and is generally written ONO^-. The isomers shown in Figure 23.20 have different properties. The nitro isomer is yellow, for example, whereas the nitrito isomer is red.

Another ligand capable of coordinating through either of two donor atoms is thiocyanate, SCN^-, whose potential donor atoms are N and S.

Coordination-sphere isomers are isomers that differ in which species in the complex act as ligands, and which are outside the coordination sphere. For example, three isomers have the formula $CrCl_3(OH_2)_6$. When the ligands are six H_2O and the chloride ions are in the crystal lattice (as counterions), we have the violet compound $[Cr(OH_2)_6]Cl_3$. When the ligands are five H_2O and one Cl^-, with the sixth H_2O and the two Cl^- out in the lattice, we have the green compound $[Cr(OH_2)_5Cl]Cl_2 \cdot H_2O$. The third isomer, $[Cr(OH_2)_4Cl_2]Cl \cdot 2\,H_2O$, is also a green compound. In the two green compounds, either one or two water molecules have been displaced from the coordination sphere by chloride ions. The displaced H_2O molecules occupy a site in the crystal lattice.

Stereoisomerism

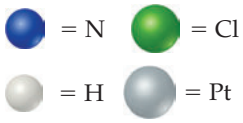
Stereoisomers have the same chemical bonds but different spatial arrangements. In the square-planar complex $[Pt(NH_3)_2Cl_2]$, for example, the chlorido ligands can be either adjacent to or opposite each other (**Figure 23.21**). (We saw an earlier example of this type of isomerism in the cobalt complex of Figure 23.8, and we will return to that complex in a moment.) This form of stereoisomerism, in which the arrangement of the atoms is different but the same bonds are present, is called **geometric isomerism**. The isomer with like ligands in adjacent positions is the *cis* isomer, and the isomer with like ligands across from one another is the *trans* isomer.

Geometric isomers generally have different physical properties and may also have markedly different chemical reactivities. For example, *cis*-$[Pt(NH_3)_2Cl_2]$, also called *cisplatin*, is effective in the treatment of testicular, ovarian, and certain other cancers, whereas the *trans* isomer is ineffective. This is because cisplatin forms a chelate with two nitrogens of DNA, displacing the chloride ligands. The chloride ligands of the *trans* isomer are too far apart to form the N-Pt-N chelate with the nitrogen donors in DNA.

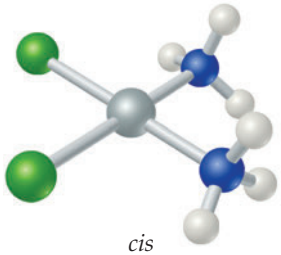
Geometric isomerism is also possible in octahedral complexes when two or more different ligands are present, as in the *cis* and *trans* tetraamminedichloridocobalt(III) ion in Figure 23.8. Because all four corners of a tetrahedron are adjacent to one another, *cis–trans* isomerism is not observed in tetrahedral complexes.

The second type of stereoisomerism listed in Figure 23.19 is **optical isomerism**. Optical isomers, called **enantiomers**, are mirror images that cannot be superimposed on each other. They bear the same resemblance to each other that your left hand bears to

your right hand. If you look at your left hand in a mirror, the image is identical to your right hand (Figure 23.22). No matter how hard you try, however, you cannot superimpose your two hands on each other. An example of a complex that exhibits this type of isomerism is the $[Co(en)_3]^{3+}$ ion. Figure 23.22 shows the two enantiomers of this complex and their mirror-image relationship. Just as there is no way that we can twist or turn our right hand to make it look identical to our left, so also there is no way to rotate one of these enantiomers to make it identical to the other. Molecules or ions that are not superimposable on their mirror image are said to be **chiral** (pronounced KY-rul).

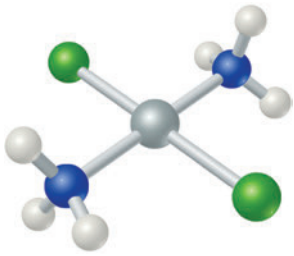


The properties of two optical isomers differ only if the isomers are in a chiral environment—that is, an environment in which there is a sense of right- and left-handedness. A chiral enzyme, for example, might catalyze the reaction of one optical isomer but not the other. Consequently, one optical isomer may produce a specific physiological effect in the body, with its mirror image producing either a different effect or none at all. Chiral reactions are also extremely important in the synthesis of pharmaceuticals and other industrially important chemicals.



Optical isomers are usually distinguished from each other by their interaction with plane-polarized light. If light is polarized—for example, by being passed through a sheet of polarizing film—the electric-field vector of the light is confined to a single plane (Figure 23.23). If the polarized light is then passed through a solution containing one optical isomer, the plane of polarization is rotated either to the right or to the left. The isomer that rotates the plane of polarization to the right is **dextrorotatory**; it is the dextro, or *d*, isomer (Latin *dexter*, "right"). Its mirror image rotates the plane of polarization to the left; it is **levorotatory** and is the levo, or *l*, isomer (Latin *laevus*, "left"). The $[Co(en)_3]^{3+}$ isomer on the right in Figure 23.22 is found experimentally to be the *l* isomer of this ion. Its mirror image is the *d* isomer. Because of their effect on plane-polarized light, chiral molecules are said to be **optically active**.

When a substance with optical isomers is prepared in the laboratory, the chemical environment during the synthesis is not usually chiral. Consequently, equal amounts of the two isomers are obtained, and the mixture is said to be **racemic**. A racemic mixture does not rotate polarized light because the rotatory effects of the two isomers cancel each other.



Go Figure

Which of these isomers has a nonzero dipole moment?

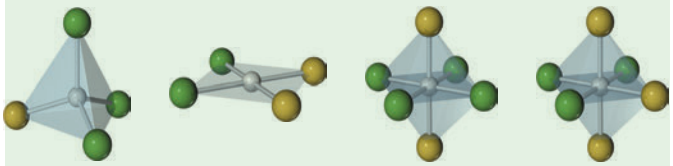
Sample Exercise 23.4

Determining the Number of Geometric Isomers

The Lewis structure :C≡O: indicates that the CO molecule has two lone pairs of electrons. When CO binds to a transition-metal atom, it nearly always does so by using the C lone pair. How many geometric isomers are there for tetracarbonyldichloridoiron(II)?

SOLUTION

Analyze We are given the name of a complex containing only monodentate ligands, and we must determine the number of isomers the complex can form.



Plan We can count the number of ligands to determine the coordination number of the Fe and then use the coordination number to predict the geometry. We can then either make a series of drawings with ligands in different positions to determine the number of isomers or deduce the number of isomers by analogy to cases we have discussed.

Solve The name indicates that the complex has four carbonyl (CO) ligands and two chlorido (Cl^-) ligands, so its formula is $Fe(CO)_4Cl_2$. The complex therefore has a coordination number of 6, and we can assume an octahedral geometry. Like $[Co(NH_3)_4Cl_2]^+$ (Figure 23.8), it has four ligands of one type and two of another. Consequently, there are two isomers possible: one with the Cl^- ligands across the metal from each other, *trans*-$[Fe(CO)_4Cl_2]$, and one with the Cl^- ligands adjacent to each other, *cis*-$[Fe(CO)_4Cl_2]$.

Comment It is easy to overestimate the number of geometric isomers. Sometimes different orientations of a single isomer are incorrectly thought to be different isomers. If two structures can be rotated so that they are equivalent, they are not isomers of each other. The problem of identifying isomers is compounded by the difficulty we often have in visualizing three-dimensional molecules from their two-dimensional representations. It is sometimes easier to determine the number of isomers if we use three-dimensional models.

Practice Exercise

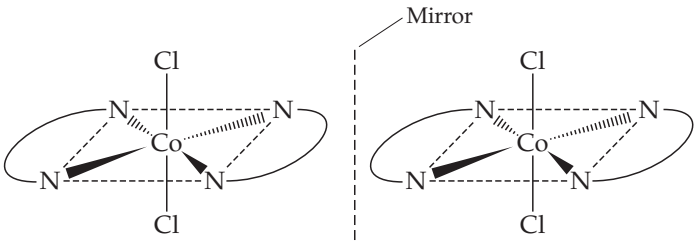
Which of the following molecules does not have a geometric isomer?

$[MX_3Y]$ (a) $[MX_2Y_2]$ (b) $[MX_4Y_2]$ (c) $[MX_3Y_3]$ (d)

Sample Exercise 23.5

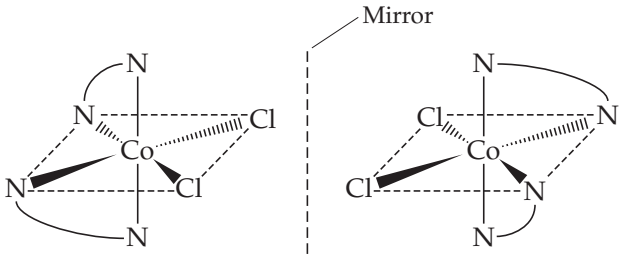
Predicting Whether a Complex Has Optical Isomers

Does either *cis*-$[Co(en)_2Cl_2]^+$ or *trans*-$[Co(en)_2Cl_2]^-$ have optical isomers?



SOLUTION

Analyze We are given the chemical formula for two geometric isomers and asked to determine whether either one has optical isomers. Because en is a bidentate ligand, we know that both complexes are octahedral and both have coordination number 6.



Plan We need to sketch the structures of the *cis* and *trans* isomers and their mirror images. We can draw the en ligand as two N atoms connected by an arc. If the mirror image cannot be superimposed on the original structure, the complex and its mirror image are optical isomers.

Solve

The *trans* isomer of $[Co(en)_2Cl_2]^+$ and its mirror image are shown here. Notice that the mirror image of the isomer is identical to the original. Consequently *trans*-$[Co(en)_2Cl_2]^+$ does not exhibit optical isomerism.

The *cis* isomer of $[Co(en)_2Cl_2]^+$ and its mirror image are shown here. In this case the two cannot be superimposed on each other. Thus, the two *cis* structures are optical isomers (enantiomers). We say that *cis*-$[Co(en)_2Cl_2]^+$ is a chiral complex.

Practice Exercise

Which of the following complexes has an optical isomer?

(**a**) Tetrahedral $[CdBr_2Cl_2]^{2-}$ (**b**) Octahedral $[CoCl_4(en)]^{2-}$ (**c**) Octahedral $[Co(NH_3)_4Cl_2]^{2+}$ (**d**) Tetrahedral $[Co(NH_3)BrClI]^-$

(b) 2

(c) 3

(d) 4

Exercises

23.16 Write the formula for each of the following compounds, being sure to use brackets to indicate the coordination sphere:

(**a**) hexaammineiron(II) nitrate

(**b**) tetraaquadibromidochromium(III) perchlorate

(**c**) ammonium hexachloridopalladate(IV)

(**d**) diammineoxolatonickel(II)

(**e**) Hexaamminemolybdenum(III) tetrachloridocuprate(II)

23.17 Write names for the following coordination compounds:

(**a**) $Na_3[Fe(CN)_5NO]$

(**b**) $[CoO(NH_3)_5]Br$

(**c**) $Na_2[NiBr_4]$

(**d**) $[Rh(OH_2)_6][Ag(CN)_2]_3$

23.18 Consider the following three complexes:

(Complex 1) $[Co(NH_3)_5SCN]^{2+}$

(Complex 2) $[Co(NH_3)_3Cl_3]^{2+}$

(Complex 3) $CoClBr \cdot 5NH_3$

Which of the three complexes can have (**a**) geometric isomers, (**b**) linkage isomers, (**c**) optical isomers, (**d**) coordination-sphere isomers?

23.19 Consider an octahedral complex, MA_2B_4. How many geometric isomers are expected for this compound? Will any of the isomers be optically active? If so, which ones?

23.20 Determine if each of the following complexes exhibits geometric isomerism. If geometric isomers exist, determine how many there are. (**a**) $[Rh(bipy)(o\text{-}phen)_2]^{3+}$, (**b**) $[Co(NH_3)_3(bipy)Br]^{2+}$, (**c**) square-planar $[Pd(en)(CN)_2]$.

23.21 Determine if each of the following metal complexes is chiral and therefore has an optical isomer: (**a**) square planar $[Pd(en)(CN)_2]$, (**b**) octahedral $[Ni(en)(NH_3)_4]^{2+}$, (**c**) octahedral *cis*-$[V(en)_2ClBr]$.

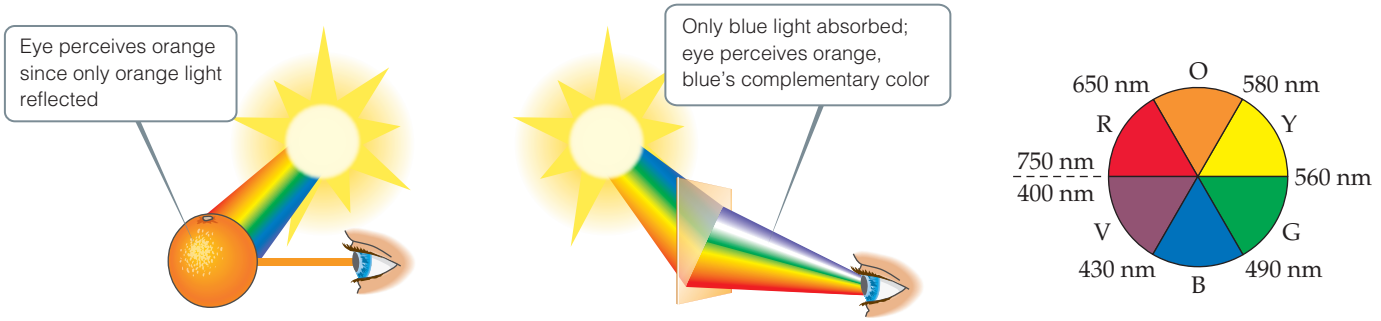
23.5 Color and Magnetism in Coordination Chemistry

Studies of the colors and magnetic properties of transition-metal complexes have played an important role in the development of modern models for metal–ligand bonding. We discussed the various types of magnetic behavior of the transition metals in Section 23.1, and we discussed the interaction of radiant energy with matter in Section 6.3. Let's briefly examine the significance of these two properties for transition-metal complexes before we develop a model for metal–ligand bonding.

By the end of this section, you should be able to

- Appreciate the relationship between absorbed light and perceived color.



Color

In Figure 23.4, we saw the diverse range of colors seen in salts of transition-metal ions and their aqueous solutions. In general, the color of a complex depends on the identity of the metal ion, on its oxidation state, and on the ligands bound to it. **Figure 23.24**, for

Go Figure Is the equilibrium binding constant of ammonia for Cu(II) likely to be larger or smaller than that of water for Cu(II)?

▲ **Figure 23.24** **The color of a coordination complex changes when the ligand changes.**

▲ **Figure 23.25 Two ways of perceiving the color orange.** An object appears orange either when it reflects orange light to the eye (left) or when it transmits to the eye all colors except blue, the complement of orange (middle). Complementary colors lie opposite to each other on an artist's color wheel (right).

instance, shows how the pale blue color characteristic of $[Cu(OH_2)_4]^{2+}$ changes to deep blue-violet as NH_3 ligands replace the H_2O ligands to form $[Cu(NH_3)_4]^{2+}$.

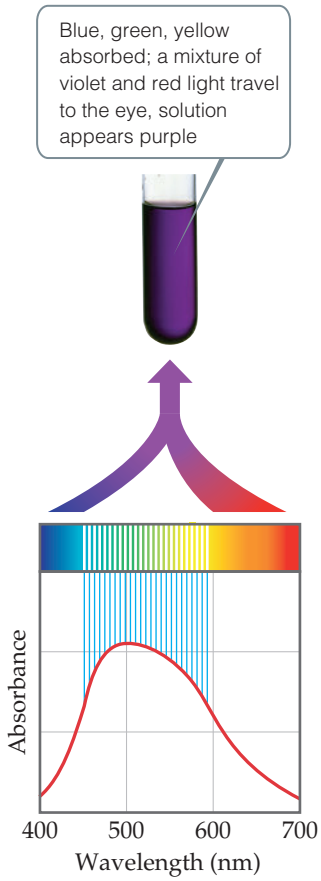
For a substance to have color we can see, it must absorb some portion of the spectrum of visible light. Absorption happens, however, only if the energy needed to move an electron in the substance from its ground state to an excited state corresponds to the energy of some portion of the visible spectrum. Thus, the particular energies of radiation a substance absorbs dictate the color we see for the substance.

When an object absorbs some portion of the visible spectrum, the color we perceive is the sum of the unabsorbed portions, which are either reflected or transmitted by the object and strike our eyes. (Opaque objects *reflect* light, and transparent ones *transmit* it.) If an object absorbs all wavelengths of visible light, none reaches our eyes and the object appears black. If it absorbs no visible light, it is white if opaque or colorless if transparent. If it absorbs all but orange light, the orange light is what reaches our eye and therefore is the color we see.

An interesting phenomenon of vision is that we also perceive an orange color when an object absorbs only the blue portion of the visible spectrum and all the other colors strike our eyes. This is because orange and blue are **complementary colors**, which means that the removal of blue from white light makes the light look orange (and the removal of orange makes the light look blue).

Complementary colors can be determined with an artist's color wheel, which shows complementary colors on opposite sides (**Figure 23.25**).

The amount of light absorbed by a sample as a function of wavelength is known as the sample's **absorption spectrum**. The visible absorption spectrum of a transparent sample can be determined using a spectrometer, as described in the "A Closer Look" box on page 667. The absorption spectrum of the ion $[Ti(H_2O)_6]^{3+}$ is shown in **Figure 23.26**. The absorption maximum is at 500 nm, but the graph shows that much of the yellow, green, and blue light is absorbed. Because the sample absorbs all of these colors, what we see is the unabsorbed red and violet light, which we perceive as purple (the color purple is classified as a tertiary color located between red and violet on an artist's color wheel).



Magnetism of Coordination Compounds

Many transition-metal complexes exhibit paramagnetism, as described in Sections 9.8 and 23.1. In such compounds, the metal ions possess some number of unpaired electrons. It is possible to experimentally determine the number of unpaired electrons per metal ion from the measured degree of paramagnetism, and experiments reveal some interesting comparisons.

Compounds of the complex ion $[Co(CN)_6]^{3-}$ have no unpaired electrons, for example, but compounds of the $[CoF_6]^{3-}$ ion have four unpaired electrons per metal ion. Both complexes contain Co(III) with a $3d^6$ electron configuration. Clearly, there is a major difference in the ways in which the electrons are arranged in these two cases. Any successful bonding theory must explain this difference, and we present such a theory in the next section.

Go Figure

How would this absorbance spectrum change if you decreased the concentration of the $[Ti(H_2O)_6]^{3+}$ in solution?

▲ **Figure 23.26 The color of $[Ti(H_2O)_6]^{3+}$** A solution containing the $[Ti(H_2O)_6]^{3+}$ ion appears purple because, as its visible absorption spectrum shows, the solution does not absorb light from the violet and red ends of the spectrum. That unabsorbed light is what reaches our eyes.

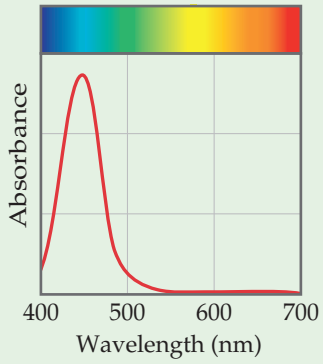
Sample Exercise 23.6

Relating Color Absorbed to Color Observed

The complex ion *trans*-$[Co(NH_3)_4Cl_2]^+$ absorbs light primarily in the red region of the visible spectrum (the most intense absorption is at 680 nm). What is the color of the complex ion?

SOLUTION

Analyze We need to relate the color absorbed by a complex (red) to the color observed for the complex.



Plan For an object that absorbs only one color from the visible spectrum, the color we see is complementary to the color absorbed. We can use the color wheel of Figure 23.25 to determine the complementary color.

Solve From Figure 23.25, we see that green is complementary to red, so the complex appears green.

Comment As noted in Section 23.2, this green complex was one of those that helped Werner establish his theory of coordination (Table 23.3). The other geometric isomer of this complex, *cis*-$[Co(NH_3)_4Cl_2]^+$, absorbs yellow light and therefore appears violet.

Practice Exercise

A solution containing a certain transition-metal complex ion has the absorption spectrum shown here.

What color would you expect a solution containing this ion to be? (**a**) violet (**b**) blue (**c**) green (**d**) orange (**e**) red

Self-Assessment Exercise

23.22 What is the electron configuration and number of unpaired electrons in a Co atom and Co^{3+} ion?

(a) Co: [Ar] $4s^2\ 3d^7$; 3 unpaired electrons. Co^{3+}: [Ar] $3d^6$; 0 unpaired electrons.

(b) Co: [Ar] $4s^2\ 3d^7$; 3 unpaired electrons. Co^{3+}: [Ar] $3d^6$; 4 unpaired electrons.

(c) Co: [Ar] $4s^2\ 4d^7$; 3 unpaired electrons. Co^{3+}: [Ar] $4d^6$; 4 unpaired electrons.

(d) Co: [Ar] $4s^2\ 3d^7$; 3 unpaired electrons. Co^{3+}: [Ar] $4s^2\ 3d^4$; 4 unpaired electrons.

Exercises

23.23 (**a**) A complex absorbs photons with an energy of 4.51×10^{-19} J. What is the wavelength of these photons? (**b**) If this is the only place in the visible spectrum where the complex absorbs light, what color would you expect the complex to be?

23.24 Identify each of the following coordination complexes as either diamagnetic or paramagnetic:

(**a**) $[ZnBr_4)]^{2-}$

(**b**) $[Mn(H_2O)_6]^{3+}$

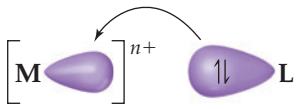
(**c**) OsO_4

(**d**) $[PtCl_4]^{2-}$

Answers to Self-Assessment Exercise

23.22 (b)

23.6 | Crystal-Field Theory

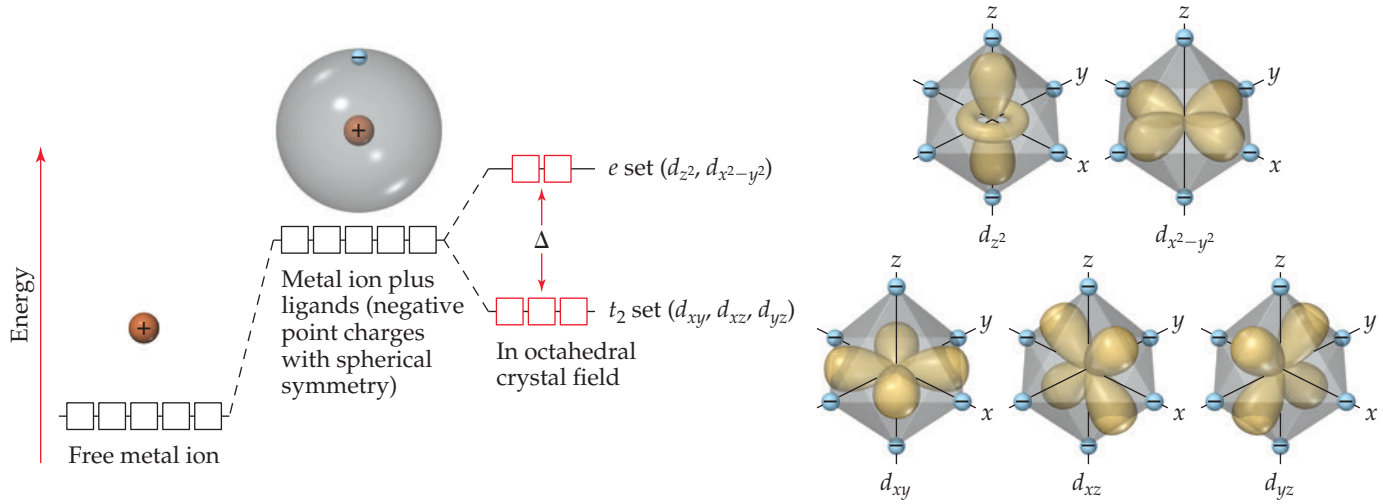


Ruby and emerald are allochromatic minerals. This means that their color arises from a trace impurity rather than from the bulk of the material. In these two cases it is the substitution of ~1% of the Al^{3+} in the crystal lattice by Cr^{3+} that gives the red color of a ruby and the green of an emerald. Why such different colors if they both arise from the same transition metal ion? The answer lies, in part, with the nature of the crystal lattice around the chromium ion. Ruby is composed of Al_2O_3, which is colorless when pure. The lattice is compact and the distance between O and a Cr^{3+} ion is relatively short, resulting in a strong interaction and absorption of green light (giving the red appearance). In emerald, which is composed of $Be_3Al_2Si_6O_{18}$, the lattice is expanded and there is a longer O—Cr^{3+} distance. This means less interaction with the Cr^{3+} ion and lower-energy red light is absorbed giving a green appearance to the mineral.

In this section, we discuss a model that explains the wide variety of colors observed in transition metal compounds. By the end of this section, you should be able to

- Predict the number of unpaired electrons in a transition metal complex.
- Use the spectrochemical series to qualitatively predict the crystal-field splitting in a complex.

Scientists have long recognized that many of the magnetic properties and colors of transition-metal complexes are related to the presence of *d* electrons in the metal cation. In this section, we consider a model for bonding in transition-metal complexes, **crystal-field theory**, that accounts for many of the observed properties of these substances.* Because many predictions of crystal-field theory are qualitatively the same as those obtained with more advanced molecular-orbital theories, crystal-field theory is an excellent place to start in considering the electronic structure of coordination compounds.



The attraction of a ligand to a metal ion is essentially a Lewis acid–base interaction in which the base—that is, the ligand—donates a pair of electrons to an empty orbital on the metal ion (Figure 23.27). Much of the attractive interaction between the metal ion and the ligands is due, however, to the electrostatic forces between the positive charge on the metal ion and negative charges on the ligands. An ionic ligand, such as Cl^- or SCN^-, experiences the usual cation–anion attraction. When the ligand is a neutral molecule, as in the case of H_2O or NH_3, the negative ends of these polar molecules, which contain an unshared electron pair, are directed toward the metal ion. In this case, the attractive interaction is of

▲ **Figure 23.27 Metal–ligand bond formation.** The ligand acts as a Lewis base by donating its nonbonding electron pair to an empty orbital on the metal ion. The bond that results is strongly polar with some covalent character.

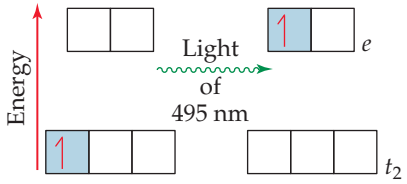
*The name *crystal-field* arose because the theory was first developed to explain the properties of solid crystalline materials. The theory applies equally well to complexes in solution, however.

Go Figure Which *d* orbitals have lobes that point directly toward the ligands in an octahedral crystal-field?

▲ **Figure 23.28** **Energies of *d* orbitals in a free metal ion, a spherically symmetric crystal-field, and an octahedral crystal-field.**

the ion–dipole type. In either case, the ligands are attracted strongly toward the metal ion. Because of the metal–ligand electrostatic attraction, the energy of the complex is lower than the combined energy of the separated metal ion and ligands.

Although the metal ion is attracted to the ligand electrons, the metal ion's *d* electrons are repulsed by the ligands. Let's examine this effect more closely, specifically the case in which the ligands form an octahedral array around a metal ion that has coordination number 6.



In crystal-field theory, we consider the ligands to be negative points of charge that repel the negatively charged electrons in the *d* orbitals of the metal ion. The energy diagram in **Figure 23.28** shows how these ligand point charges affect the energies of the *d* orbitals. First, we imagine the complex as having all the ligand point charges uniformly distributed on the surface of a sphere centered on the metal ion. The *average* energy of the metal ion's *d* orbitals is raised by the presence of this uniformly charged sphere. Hence, the energies of all five *d* orbitals are raised by the same amount.

This energy picture is only a first approximation, however, because the ligands are not distributed uniformly on a spherical surface and, therefore, do not approach the metal ion equally from every direction. Instead, we envision the six ligands approaching along *x*-, *y*-, and *z*-axes, as shown on the right in Figure 23.28. This arrangement of ligands is called an *octahedral crystal-field*. Because the metal ion's *d* orbitals have different orientations and shapes, they do not all experience the same repulsion from the ligands and, therefore, do not all have the same energy under the influence of the octahedral crystal-field. To see why, we must consider the shapes of the *d* orbitals and how their lobes are oriented relative to the ligands.

Figure 23.28 shows that the lobes of the d_{z^2} and $d_{x^2-y^2}$ orbitals are directed *along* the *x*-, *y*-, and *z*-axes and so point directly toward the ligand point charges. The lobes of the d_{xy}, d_{xz}, and d_{yz} orbitals, however, are directed *between* the axes and so do not point directly toward the charges. The result of this difference in orientation—$d_{x^2-y^2}$ and d_{z^2} lobes point directly toward the ligand charges; d_{xy}, d_{xz}, and d_{yz} lobes do not—is that an electron residing in either the $d_{x^2-y^2}$ or d_{z^2} orbitals feels more repulsion from the negatively charged ligands. Hence the energy of the $d_{x^2-y^2}$ and d_{z^2} orbitals is higher than the energy of the d_{xy}, d_{xz}, and d_{yz} orbitals. This difference in energy is represented by the red boxes in the energy diagram of Figure 23.28.

Go Figure

How would you calculate the energy gap between the t_2 and e orbitals from this diagram?

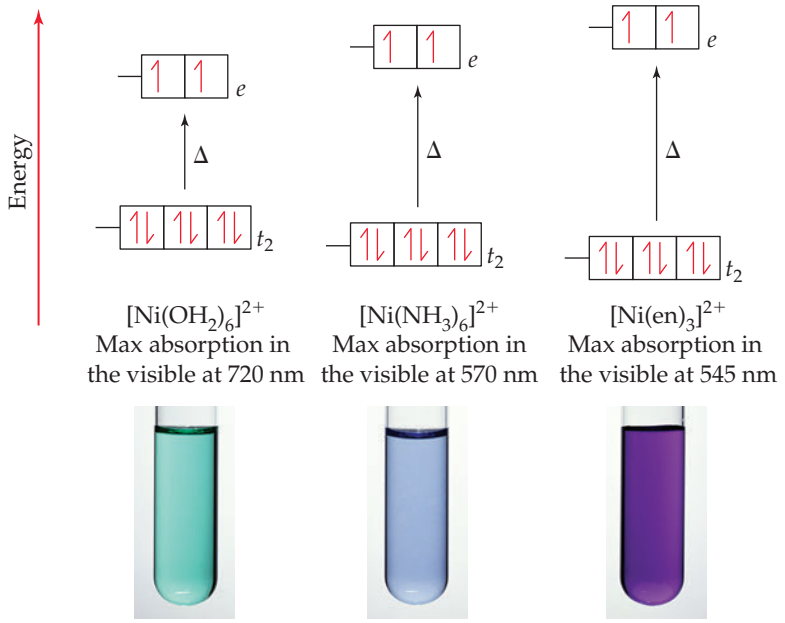
◀ **Figure 23.29** The *d-d* transition in $[Ti(H_2O)_6]^{3+}$ is produced by the absorption of 495-nm light.

The three lower-energy *d* orbitals are called the t_2 set of orbitals, and the two higher-energy ones are called the *e* set.* The energy gap Δ between the two sets is called the *crystal-field splitting energy*.

It might seem like the energy of the $d_{x^2-y^2}$ orbital should be different from that of the d_{z^2} orbital because the $d_{x^2-y^2}$ has four lobes pointing at ligands and the d_{z^2} has only two lobes pointing at ligands. However, the d_{z^2} orbital does have electron density in the *xy* plane, represented by the ring encircling the point where the two lobes meet. More advanced calculations show that two orbitals do indeed have the same energy in the presence of the octahedral crystal-field.

Crystal-field theory helps us account for the colors observed in transition-metal complexes. The energy gap Δ between the *e* and t_2 sets of *d* orbitals is of the same order of magnitude as the energy of a photon of visible light. It is therefore possible for a transition-metal complex to absorb visible light that excites an electron from a lower-energy (t_2) *d* orbital into a higher-energy (*e*) *d* orbital. In $[Ti(OH_2)_6]^{3+}$, for example, the Ti(III) ion has an $[Ar]3d^1$ electron configuration. (Recall from Section 7.4 that when determining the electron configurations of transition-metal ions, we remove the *s* electrons first.) Ti(III) is thus called a d^1 *ion*. In the ground state of $[Ti(OH_2)_6]^{3+}$, the single 3*d* electron resides in an orbital in the t_2 set (**Figure 23.29**). Absorption of 495 nm light excites this electron up to an orbital in the *e* set, generating the absorption spectrum shown in Figure 23.26. Because this transition involves exciting an electron from one set of *d* orbitals to the other, we call it a ***d-d* transition**. As noted earlier, the absorption of visible radiation that produces this *d-d* transition causes the $[Ti(H_2O)_6]^{3+}$ ion to appear purple.

The magnitude of the crystal-field splitting energy and, consequently, the color of a complex depend on both the metal and the ligands. For example, we saw in Figure 23.4 that the color of $[M(OH_2)_6]^{2+}$ complexes changes from reddish-pink when the metal ion is Co^{2+}, to green for Ni^{2+}, to pale blue for Cu^{2+}. If we change the ligands in the $[Ni(OH_2)_6]^{2+}$ ion, the color also changes. $[Ni(NH_3)_6]^{2+}$ has a blue-violet color, while $[Ni(en)_3]^{2+}$ is purple (**Figure 23.30**). In a ranking called the **spectrochemical series**, ligands are arranged in order of their abilities to increase the crystal-field splitting energy, as in this abbreviated list:



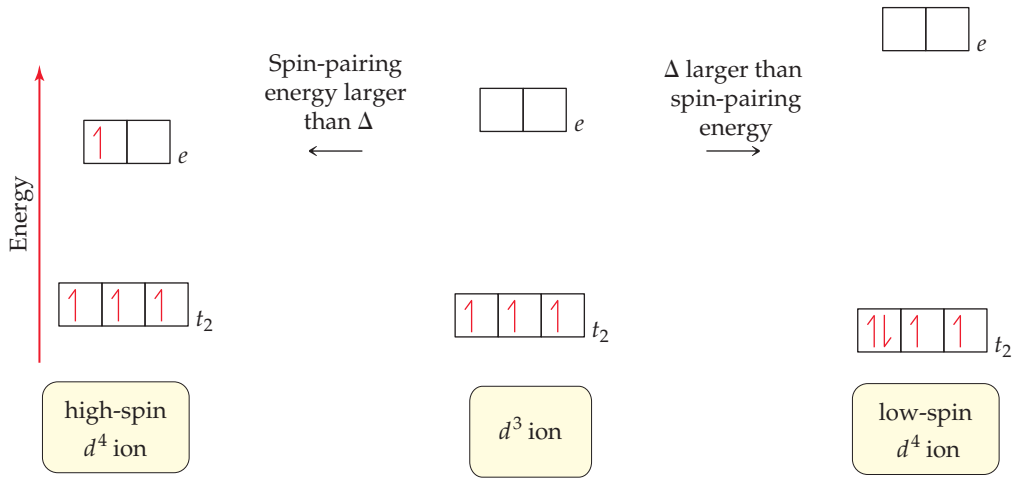
$$\text{——Increasing } \Delta \longrightarrow$$
$$Cl^- < F^- < H_2O < NH_3 < en < NO_2^-(\text{N-bonded}) < CN^-$$

The magnitude of Δ increases by roughly a factor of 2 from the far left to the far right of the spectrochemical series. Ligands at the low-Δ end of the spectrochemical series are termed *weak-field ligands*; those at the high-Δ end are termed *strong-field ligands*.

Let's take a closer look at the colors and crystal-field splitting as we vary the ligands for the series of Ni^{2+} complexes discussed earlier. Because the Ni atom has an $[Ar]3d^84s^2$ electron configuration, Ni^{2+} has the configuration $[Ar]3d^8$ and therefore is a d^8 ion. The t_2 set of orbitals holds six electrons, two in each orbital, while the last two electrons go into the *e* set of orbitals. Consistent with Hund's rule, each *e* orbital holds one electron and both electrons have the same spin.

*The labels t_2 for the d_{xy}, d_{xz}, and d_{yz} orbitals and *e* for the d_{z^2} and $d_{x^2y^2}$ orbitals come from the application of a branch of mathematics called *group theory* to crystal-field theory. Group theory can be used to analyze the effects of symmetry on molecular properties.

Go Figure If you were to use a ligand L that was a stronger field ligand than ethylenediamine, what color would you expect the $[NiL_6]^{2+}$ complex ion to have?



▲ **Figure 23.30 Effect of ligand on crystal-field splitting.** The greater the crystal-field strength of the ligand, the greater the energy gap Δ it causes between the t_2 and e sets of the metal ion's orbitals. This shifts the wavelength of the absorption maximum to shorter values.

As the ligand changes from H_2O to NH_3 to ethylenediamine, the spectrochemical series tells us that the crystal-field, Δ, exerted by the six ligands should increase. When there is more than one electron in the d orbitals, interactions between the electrons make the absorption spectra more complicated than the spectrum shown for $[Ti(H_2O)_6]^{3+}$ in Figure 23.26, which complicates the task of relating changes in Δ with color. With d^8 ions like Ni^{2+} three peaks are observed in the absorption spectra. Fortunately, for Ni^{2+} complexes we can simplify the analysis because only one of these three peaks falls in the visible region of the spectrum.* Because the energy separation Δ is increasing, the wavelength of the absorption peak should shift to a shorter wavelength. In the case of $[Ni(OH_2)_6]^{2+}$ the absorption peak in the visible part of the spectrum reaches a maximum near 720 nm, in the red region of the spectrum. So the complex ion takes the complementary color—green. For $[Ni(NH_3)_6]^{2+}$ the absorption peak reaches its maximum at 570 nm near the boundary between orange and yellow. The resulting color of the complex ion is a mixture of the complementary colors—blue and violet. Finally, for $[Ni(en)_3]^{2+}$ the peak shifts to an even shorter wavelength, 540 nm, which lies near the boundary between green and yellow. The resulting color purple is a mixture of the complementary colors red and violet.

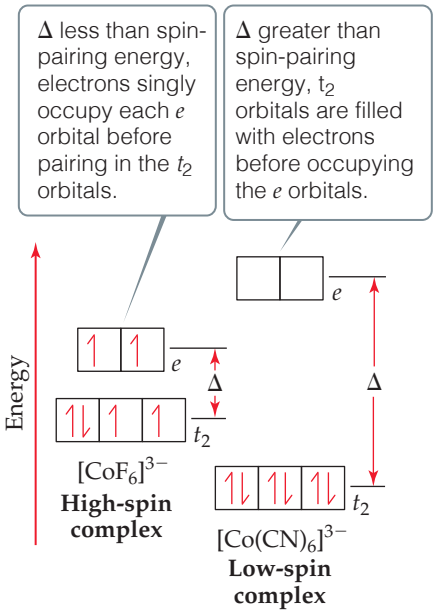
Electron Configurations in Octahedral Complexes

Crystal-field theory helps us understand the magnetic properties and some important chemical properties of transition-metal ions. From Hund's rule, we expect electrons to always occupy the lowest-energy vacant orbitals first and to occupy a set of degenerate (same-energy) orbitals one at a time with their spins parallel. Thus, if we have a d^1, d^2, or d^3 octahedral complex, the electrons go into the lower-energy t_2 orbitals, with their spins parallel. When a fourth electron must be added, we have the two choices shown in **Figure 23.31**: The electron can either go into an e orbital, where it will be the sole electron in the orbital or become the second electron in a t_2 orbital. Because the

*The other two peaks fall in the infrared (IR) and ultraviolet (UV) regions of the spectrum. For $[Ni(H_2O)_6]^{2+}$ the IR peak is found at 1176 nm and the UV peak at 388 nm.

▲ **Figure 23.31 Two possibilities for adding a fourth electron to a d^6 octahedral complex.** Whether the fourth electron goes into a t_2 orbital or into an e orbital depends on the relative energies of the crystal-field splitting energy and the spin-pairing energy.

energy difference between the t_2 and e sets is the splitting energy Δ, the energy cost of going into an e orbital rather than a t_2 orbital is also Δ. Thus, the goal of filling lowest-energy available orbitals first is met by putting the electron in a t_2 orbital.



There is a penalty for doing this, however, because the electron must now be paired with the electron already occupying the orbital. The difference between the energy required to pair an electron in an occupied orbital and the energy required to place that electron in an empty orbital is called the **spin-pairing energy**. The spin-pairing energy arises from the fact that the electrostatic repulsion between two electrons that share an orbital (and so must have opposite spins) is greater than the repulsion between two electrons that are in different orbitals and have parallel spins.

In coordination complexes, the nature of the ligands and the charge on the metal ion often play major roles in determining which of the two electron arrangements shown in Figure 23.31 is used. In $[CoF_6]^{3-}$ and $[Co(CN)_6]^{3-}$, both ligands have a 1− charge. The F^- ion, however, is on the low end of the spectrochemical series, so it is a weak-field ligand. The CN^- ion is on the high end and so is a strong-field ligand, which means it produces a larger energy gap Δ than the F^- ion. The splittings of the d-orbital energies in these two complexes are compared in **Figure 23.32**.

Cobalt(III) has an $[Ar]3d^6$ electron configuration, so both complexes in Figure 23.32 are d^6 complexes. Let's imagine that we add these six electrons one at a time to the d orbitals of the $[CoF_6]^{3-}$ ion. The first three go into the t_2 orbitals with their spins parallel. The fourth electron could pair up in one of the t_2 orbitals. The F^- ion is a weak-field ligand, however, and so the energy gap Δ between the t_2 set and the e set is small. In this case, the more stable arrangement is the fourth electron in one of the e orbitals. By the same energy argument, the fifth electron goes into the other e orbital. With all five d orbitals containing one electron, the sixth must pair up, and the energy needed to place the sixth electron in a t_2 orbital is less than that needed to place it in an e orbital. We end up with four t_2 electrons and two e electrons.

Figure 23.32 shows that the crystal-field splitting energy Δ is much larger in the $[Co(CN)_6]^{3-}$ complex. In this case, the spin-pairing energy is smaller than Δ, so the lowest-energy arrangement is to place all six electrons in the t_2 orbitals.

The $[CoF_6]^{3-}$ complex is a **high-spin complex**; that is, the electrons are arranged so that they remain unpaired as much as possible. The $[Co(CN)_6]^{3-}$ ion is a **low-spin complex**; that is, the electrons are arranged so that they remain paired as much as possible while still following Hund's rule. These two electronic arrangements can be readily distinguished by measuring the magnetic properties of the complex. Experiments show that $[CoF_6]^{3-}$ has four unpaired electrons and is paramagnetic, while $[Co(CN)_6]^{3-}$ has no unpaired electrons and is diamagnetic. The absorption spectrum also shows peaks corresponding to the different values of Δ in these two complexes.

▲ **Figure 23.32 High-spin and low-spin complexes.** The high-spin $[CoF_6]^{3-}$ ion has a weak-field ligand and so a small Δ value. The low-spin $[Co(CN)_6]^{3-}$ ion has a strong-field ligand and so a large Δ value. Because $[CoF_6]^{3-}$ has unpaired electrons it is paramagnetic, while $[Co(CN)_6]^{3-}$ is diamagnetic.

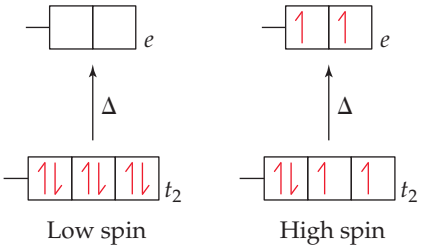
In the transition metal ions of Periods 5 and 6 (which have 4*d* and 5*d* valence electrons), the *d* orbitals are larger than in the Period 4 ions (which have only 3*d* electrons). Thus, ions from Periods 5 and 6 interact more strongly with ligands, resulting in a larger crystal-field splitting. *Consequently, metal ions in Periods 5 and 6 are invariably low spin in an octahedral crystal-field.*

Sample Exercise 23.7

The Spectrochemical Series, Crystal-Field Splitting, Color, and Magnetism

The compound hexaamminecobalt(III) chloride is diamagnetic and orange in color with a single absorption peak in its visible absorption spectrum. (**a**) What is the electron configuration of the cobalt(III) ion? (**b**) Is $[Co(NH_3)_6]^{3+}$ a high-spin complex or a low-spin complex? (**c**) Estimate the wavelength where you expect the absorption of light to reach a maximum? (**d**) What color and magnetic behavior would you predict for the complex ion $[Co(en)_3]^{3+}$?

SOLUTION



Analyze We are given the color and magnetic behavior of an octahedral complex containing Co with a +3 oxidation number. We need to use this information to determine its electron configuration, its spin state (low-spin or high-spin), and the color of light it absorbs. In part (d), we must use the spectrochemical series to predict how its properties will change if NH_3 is replaced by ethylenediamine (en).

Plan (**a**) From the oxidation number and the periodic table we can determine the number of valence electrons for Co(III), and from that we can determine the electron configuration. (**b**) The magnetic behavior can be used to determine whether this compound is a low-spin or high-spin complex. (**c**) Since there is a single peak in the visible absorption spectrum, the color of the compound should be complementary to the color of light that is absorbed most strongly. (**d**) Ethylenediamine is a stronger field ligand than NH_3, so we expect a larger Δ for $[Co(en)_3]^{3+}$ than for $[Co(NH_3)_6]^{3+}$.

Solve

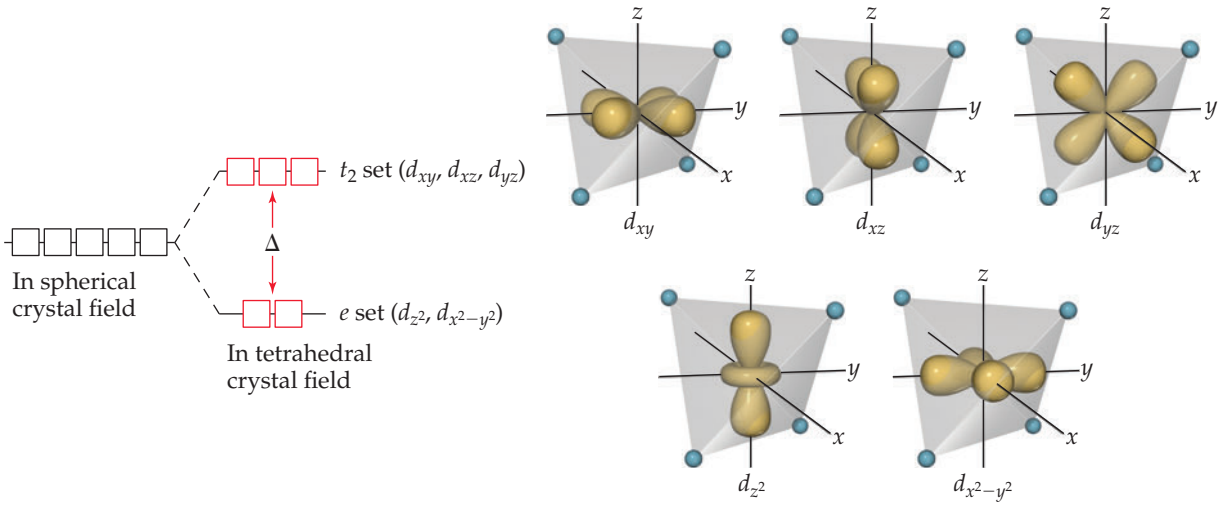
(**a**) Co has an electron configuration of $[Ar]4s^23d^7$, and Co^{3+} has three fewer electrons than Co. Because transition-metal ions always lose their valence shell *s* electrons, the electron configuration of Co^{3+} is $[Ar]3d^6$.

(**b**) There are six valence electrons in the *d* orbitals. The filling of the t_2 and *e* orbitals for both high-spin and low-spin complexes is shown here. Because the compound is diamagnetic, we know all of the electrons must be paired up, which allows us to determine that $[Co(NH_3)_6]^{3+}$ is a low-spin complex.

(**c**) We are told that the compound is orange and has a single absorption peak in the visible region of the spectrum. The compound must therefore absorb the complementary color of orange, which is blue. The blue region of the spectrum ranges from approximately 430 nm to 490 nm. As an estimate we assume that the complex ion absorbs somewhere in the middle of the blue region, near 460 nm.

(**d**) Ethylenediammine is higher in the spectrochemical series than ammonia. Therefore, we expect a larger Δ for $[Co(en)_3]^{3+}$. Because Δ was already greater than the spin-pairing energy for $[Co(NH_3)_6]^{3+}$, we expect $[Co(en)_3]^{3+}$ to be a low-spin complex as well, with a d^6 configuration, so it will also be diamagnetic. The wavelength at which the complex absorbs light will shift to higher energy. If we assume a shift in the absorption maximum from blue to violet, the color of the complex will become yellow.

Comment The compound $[Co(en)_3]Cl_3$, which contains the $[Co(en)_3]^{3+}$ ion, was made and studied by Alfred Werner. This compound forms diamagnetic, golden-yellow crystals.



Practice Exercise

Which of the following octahedral complex ions will have the fewest number of unpaired electrons?
(**a**) $[Cr(OH_2)_6]^{3+}$ (**b**) $[V(H_2O)_6]^{3+}$ (**c**) $[FeF_6]^{3-}$ (**d**) $[RhCl_6]^{3-}$ (**e**) $[Ni(NH_3)_6]^{2+}$

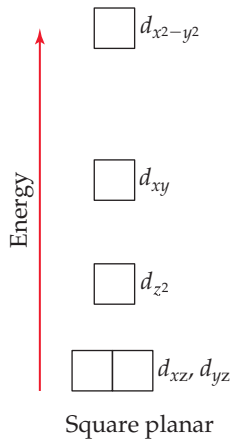
Tetrahedral and Square-Planar Complexes

Thus far we have considered crystal-field theory only for complexes having an octahedral geometry. When there are only four ligands in a complex, the geometry is generally tetrahedral, except for the special case of d^8 metal ions, which we will discuss in a moment.

The crystal-field splitting of *d* orbitals in tetrahedral complexes differs from that in octahedral complexes. Four equivalent ligands can interact with a central metal ion

▲ **Figure 23.33 Energies of the *d* orbitals in a tetrahedral crystal-field.** The splitting of the *e* and t_2 sets of orbitals is inverted with respect to the splitting associated with an octahedral crystal-field. The crystal-field splitting energy Δ is smaller than it is in an octahedral crystal-field.

most effectively by approaching along the vertices of a tetrahedron. In this geometry the lobes of the two *e* orbitals point toward the edges of the tetrahedron, exactly in between the ligands (**Figure 23.33**). This orientation keeps the $d_{x^2-y^2}$ and d_{z^2} as far from the ligand point charges as possible. Consequently, these two *d* orbitals experience less repulsion from the ligands and lie at lower energy than the other three *d* orbitals. The three t_2 orbitals do not point directly at the ligand point charges, but they do come closer to the ligands than the *e* set, and as a result they experience more repulsion and are higher in energy. As we see in Figure 23.33, the splitting of *d* orbitals in a tetrahedral geometry is the opposite of what we find for the octahedral geometry, namely, the *e* orbitals are now *below* the t_2 orbitals. The crystal-field splitting energy Δ is much smaller for tetrahedral complexes than it is for comparable octahedral complexes, in part because there are fewer ligand point charges in the tetrahedral geometry, and in part because neither set of orbitals has lobes that point directly at the ligands. Calculations show that for the same metal ion and ligand set, Δ for the tetrahedral complex is only four-ninths as large as for the octahedral complex. For this reason, nearly all tetrahedral complexes are high spin; the crystal-field splitting energy is never large enough to overcome the spin-pairing energies.



In a square-planar complex, four ligands are arranged about the metal ion such that all five species are in the *xy* plane. The resulting energy levels of the *d* orbitals are illustrated in **Figure 23.34**. Note in particular that the d_{z^2} orbital is considerably lower in energy than the $d_{x^2-y^2}$ orbital. To understand why this is so, recall from Figure 23.28 that in an octahedral field the d_{z^2} orbital of the metal ion interacts with the ligands positioned above and below the *xy* plane. There are no ligands in these two positions in a square-planar complex, which means that the d_{z^2} orbital experiences less repulsion and so remains in a lower-energy, more stable state.

Square-planar complexes are characteristic of metal ions with a d^8 electron configuration. They are nearly always low spin, with the eight *d* electrons spin-paired to form a diamagnetic complex. This pairing leaves the $d_{x^2-y^2}$ orbital empty. Such an electronic arrangement is particularly common among the d^8 ions of Periods 5 and 6, such as Pd^{2+}, Pt^{2+}, Ir^{+}, and Au^{3+}.

Crystal-field theory can be used to explain many observations in addition to those we have discussed. The theory is based on electrostatic interactions between ions and atoms, which essentially means ionic bonds. Many lines of evidence show, however, that the bonding in complexes must have some covalent character. Therefore, molecular-orbital theory can also be used to describe the bonding in complexes, but the application of molecular-orbital theory to coordination compounds is beyond the scope of our discussion. Crystal-field theory, although not entirely accurate in all details, provides an adequate and useful first description of the electronic structure of complexes.

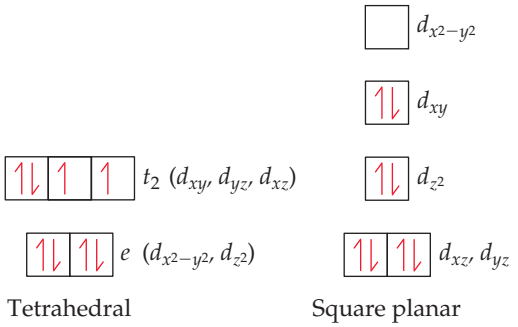
Go Figure

For which *d* orbital(s) do the lobes point directly at the ligands in a square-planar crystal-field?

▲ **Figure 23.34 Energies of the *d* orbitals in a square-planar crystal-field.**

Sample Exercise 23.8

Populating *d* Orbitals in Tetrahedral and Square-Planar Complexes



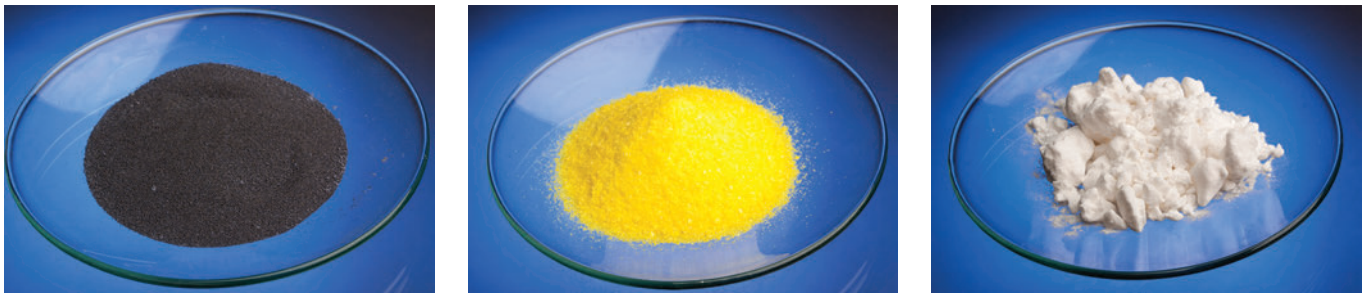
Nickel(II) complexes in which the metal coordination number is 4 can have either square-planar or tetrahedral geometry. $[NiCl_4]^{2-}$ is paramagnetic, and $[Ni(CN)_4]^{2-}$ is diamagnetic. One of these complexes is square planar, and the other is tetrahedral. Use the relevant crystal-field splitting diagrams in the text to determine which complex has which geometry.

SOLUTION

Analyze We are given two complexes containing Ni^{2+} and their magnetic properties. We are given two molecular geometry choices and asked to use crystal-field splitting diagrams from the text to determine which complex has which geometry.

Plan We need to determine the number of *d* electrons in Ni^{2+} and then use Figure 23.33 for the tetrahedral complex and Figure 23.34 for the square-planar complex.

Solve Nickel(II) has the electron configuration $[Ar]3d^8$. With very few exceptions tetrahedral complexes are high spin and square-planar complexes are low spin. Therefore, the population of the *d* orbitals in the two geometries is



The tetrahedral complex has two unpaired electrons, and the square-planar complex has none. We know from Section 23.1 that the tetrahedral complex must be paramagnetic and the square planar must be diamagnetic. Therefore, $[NiCl_4]^{2-}$ is tetrahedral, and $[Ni(CN)_4]^{2-}$ is square planar.

Comment Nickel(II) forms octahedral complexes more frequently than square-planar ones, whereas d^8 metals from Periods 5 and 6 tend to favor square-planar coordination.

Practice Exercise

How many unpaired electrons do you predict for the tetrahedral $[MnCl_4]^{2-}$ ion?
(**a**) 1, (**b**) 2, (**c**) 3, (**d**) 4, (**e**) 5.

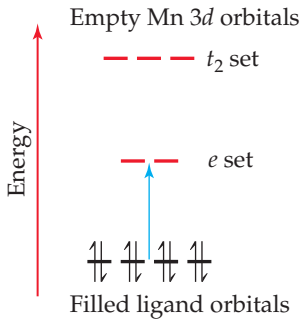
A CLOSER LOOK Charge-Transfer Color

$KMnO_4$ K_2CrO_4 $KClO_4$

▲ **Figure 23.35 The colors of compounds can arise from charge-transfer transitions.** $KMnO_4$ and K_2CrO_4 are colored due to ligand-to-metal charge-transfer transitions in their anions. Higher energy ultraviolet photons are needed to excite the charge-transfer transition in the perchlorate ion, therefore $KClO_4$ is white.

In the laboratory portion of your course, you have probably seen many colorful transition-metal compounds, including those shown in Figure 23.35. Many of these compounds are colored because of *d*-*d* transitions. Some colored complexes, however, including the violet permanganate ion, MnO_4^-, and the yellow chromate ion, CrO_4^{2-}, derive their color from a different type of excitation involving the *d* orbitals.

The permanganate ion strongly absorbs visible light, with a maximum absorption at 565 nm. Because violet is complementary to yellow, this strong absorption in the yellow portion of the visible spectrum is responsible for the violet color of salts and solutions of the ion. What is happening during this absorption of light? The MnO_4^- ion is a complex of Mn(VII). Because Mn(VII) has a $[Ar]3d^0$ electron configuration, the absorption cannot be due to a *d*-*d* transition because there are no *d* electrons to excite! That does not mean, however, that the *d* orbitals are not involved in the transition. The excitation in the MnO_4^- ion is due to a *charge-transfer transition*, in which an electron on one oxygen ligand is excited into a vacant *d* orbital on the Mn ion (Figure 23.36). In essence, an electron is transferred from a ligand to the metal, so this transition is called a *ligand-to-metal charge-transfer (LMCT) transition*.



An LMCT transition is also responsible for the color of the CrO_4^{2-}, which contains the Cr(VI) ion with an $[Ar]3d^0$ electron configuration.

Also shown in Figure 23.35 is a salt of the perchlorate ion (ClO_4^-). Like MnO_4^-, ClO_4^- is tetrahedral and has its central atom in the +7 oxidation state. However, because the Cl atom does not have low-lying *d* orbitals, exciting an electron from O to Cl requires a more energetic photon than does it in MnO_4^-. The first absorption for ClO_4^- is in the ultraviolet portion of the spectrum, so no visible light is absorbed and the salt appears white.

Other complexes exhibit charge-transfer excitations in which an electron from the metal atom is excited to an empty orbital on a ligand. Such an excitation is called a *metal-to-ligand charge-transfer (MLCT) transition*.

Charge-transfer transitions are generally more intense than *d-d* transitions. Many metal-containing pigments used for oil painting, such as cadmium yellow (CdS), chrome yellow ($PbCrO_4$), and red ochre (Fe_2O_3), have intense colors because of charge-transfer transitions.

Related Exercises: 23.96, 23.97

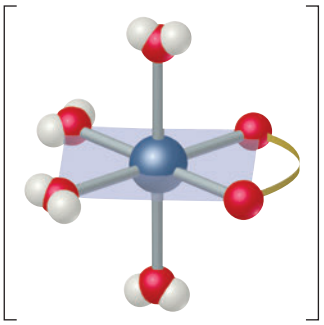
Putting Concepts Together

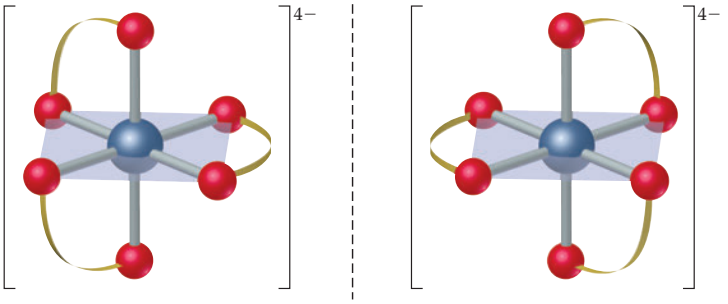


The oxalate ion has the Lewis structure shown in Table 23.4. (**a**) Show the geometry of the complex formed when this ion complexes with cobalt(II) to form $[Co(C_2O_4)(H_2O)_4]$. (**b**) Write the formula for the salt formed when three oxalate ions complex with Co(II), assuming that the charge-balancing cation is Na^+. (**c**) Sketch all the possible geometric isomers for the cobalt complex formed in part (b). Are any of these isomers chiral? Explain. (**d**) The equilibrium constant for the formation of the

Continued

cobalt(II) complex produced by coordination of three oxalate anions, as in part (b), is 5.0×10^9, and the equilibrium constant for formation of the cobalt(II) complex with three molecules of *ortho*-phenanthroline (Table 23.4) is 9×10^{19}. From these results, what conclusions can you draw regarding the relative Lewis base properties of the two ligands toward cobalt(II)? (**e**) Using the approach described in Sample Exercise 17.14, calculate the concentration of free aqueous Co(II) ion in a solution initially containing 0.040 *M* oxalate (*aq*) and 0.0010 *M* $Co^{2+}(aq)$.

SOLUTION



(**a**) The complex formed by coordination of one oxalate ion is octahedral:

(**b**) Because the oxalate ion has a charge of 2−, the net charge of a complex with three oxalate anions and one Co^{2+} ion is 4−. Therefore, the coordination compound has the formula:

$$Na_4[Co(C_2O_4)_3]$$

(**c**) There is only one geometric isomer. The complex is chiral, however, in the same way the $[Co(en)_3]^{3+}$ complex is chiral (Figure 23.22). The two mirror images are not superimposable, so there are two enantiomers:

(**d**) The *ortho*-phenanthroline ligand is bidentate, like the oxalate ligand, so they both exhibit the chelate effect. Thus, we conclude that *ortho*-phenanthroline is a stronger Lewis base toward Co^{2+} than oxalate. This conclusion is consistent with what we learned about bases in Section 16.6, that nitrogen bases are generally stronger than oxygen bases. (Recall, for example, that NH_3 is a stronger base than H_2O.)

(**e**) The equilibrium we must consider involves 3 mol of oxalate ion (represented as Ox^{2-}).

$$Co^{2+}(aq) + 3\,Ox^{2-}(aq) \rightleftharpoons [Co(Ox)_3]^{4-}(aq)$$

The formation-constant expression is:

$$K_f = \frac{[[Co(Ox)_3]^{4-}]}{[Co^{2+}][Ox^{2-}]^3}$$

Because K_f is so large, we can assume that essentially all the Co^{2+} is converted to the oxalato complex. Under that assumption, the final concentration of $[Co(Ox)_3]^{4-}$ is 0.0010 *M* and that of oxalate ion is $[Ox^{2-}] = (0.040) - 3(0.0010) = 0.037\,M$ (three Ox^{2-} ions react with each Co^{2+} ion). We then have:

$$[Co^{2+}] = x\,M, [Ox^{2-}] \cong 0.037\,M, [[Co(Ox)_3]^{4-}] \cong 0.0010\,M$$

Inserting these values into the equilibrium-constant expression, and solving for x, we obtain $4 \times 10^{-9}\,M$. From this, we see that the oxalate has complexed all but a tiny fraction of the Co^{2+} in solution.

$$K_f = \frac{(0.0010)}{x(0.037)^3} = 5 \times 10^9$$

$$x = 4 \times 10^{-9}\,M$$

Chapter Summary and Key Terms

THE TRANSITION METALS (SECTION 23.1) Metallic elements are obtained from **minerals**, which are solid inorganic compounds found in nature. **Metallurgy** is the science and technology of extracting metals from the earth and processing them for further use. Transition metals are characterized by incomplete filling of the *d* orbitals. The presence of *d* electrons in transition elements leads to multiple oxidation states. As we proceed through the transition metals in a given row of the periodic table, the attraction between the nucleus and the valence electrons increases more markedly for *d* electrons than for *s* electrons. As a result, the later transition elements in a period tend to have lower oxidation states.

The atomic and ionic radii of Period 5 transition metals are larger than those of Period 4 metals. The transition metals of Periods 5 and 6 have comparable atomic and ionic radii and are also similar in other properties. This similarity is due to the **lanthanide contraction**.

The presence of unpaired electrons in valence orbitals leads to magnetic behavior in transition metals and their compounds. In **ferromagnetic**, **ferrimagnetic**, and **antiferromagnetic** substances, the unpaired electron spins on atoms in a solid are affected by spins on neighboring atoms. In a ferromagnetic substance the spins all point in the same direction. In an antiferromagnetic substance the spins point in opposite directions and cancel one another. In a ferrimagnetic substance the spins point in opposite directions but do not fully cancel. Ferromagnetic and ferrimagnetic substances are used to make permanent magnets.

TRANSITION-METAL COMPLEXES (SECTION 23.2) **Coordination compounds** are substances that contain **metal complexes**. Metal complexes contain metal ions bonded to several surrounding anions or molecules known as **ligands**. The metal ion and its ligands make up the **coordination sphere** of the complex. The number of atoms attached to the metal ion is the **coordination number** of the metal ion. The most common coordination numbers are 4 and 6; the most common coordination geometries are tetrahedral, square planar, and octahedral.

COMMON LIGANDS IN COORDINATION CHEMISTRY (SECTION 23.3) Ligands that occupy only one site in a coordination sphere are called **monodentate ligands**. The atom of the ligand that bonds to the metal ion is the **donor atom**. Ligands that have two donor atoms are **bidentate ligands**. **Polydentate ligands** have three or more donor atoms. Bidentate and polydendate ligands are also called **chelating agents**. In general, chelating agents form more stable complexes than do related monodentate ligands, an observation known as the **chelate effect**. Many biologically important molecules, such as the **porphyrins**, are complexes of chelating agents. A related group of plant pigments known as **chlorophylls** are important in **photosynthesis**, the process by which plants use solar energy to convert CO_2 and H_2O into carbohydrates.

NOMENCLATURE AND ISOMERISM IN COORDINATION CHEMISTRY (SECTION 23.4) In naming coordination compounds, the number and type of ligands attached to the metal ion are specified, as is the oxidation state of the metal ion. **Isomers** are compounds with the same composition but different arrangements of atoms and therefore different properties. **Constitutional isomers** differ in the bonding arrangements of the ligands. **Linkage isomerism** occurs when a ligand can coordinate to a metal ion through different donor atoms. **Coordination-sphere isomers** contain different ligands in the coordination sphere. **Stereoisomers** are isomers with the same chemical bonding arrangements but different spatial arrangements of ligands. The most common forms of stereoisomerism are **geometric isomerism** and **optical isomerism**. Geometric isomers differ from one another in the relative locations of donor atoms in the coordination sphere; the most common being *cis* and *trans* isomers. Geometric isomers differ from one another in their chemical and physical properties. Optical isomers are nonsuperimposable mirror images of each other. Optical isomers, or **enantiomers**, are **chiral**, meaning that they have a specific "handedness" and differ only in the presence of a chiral environment. Optical isomers can be distinguished from one another by their interactions with plane-polarized light; solutions of one isomer rotate the plane of polarization to the right (**dextrorotatory**), and solutions of its mirror image rotate the plane to the left (**levorotatory**). Chiral molecules, therefore, are **optically active**. A 50–50 mixture of two optical isomers does not rotate plane-polarized light and is said to be **racemic**.

COLOR AND MAGNETISM IN COORDINATION CHEMISTRY (SECTION 23.5) A substance has a particular color because it either reflects or transmits light of that color or absorbs light of the **complementary color**. The amount of light absorbed by a sample as a function of wavelength is known as its **absorption spectrum**. The light absorbed provides the energy to excite electrons to higher-energy states.

It is possible to determine the number of unpaired electrons in a complex from its degree of paramagnetism. Compounds with no unpaired electrons are diamagnetic.

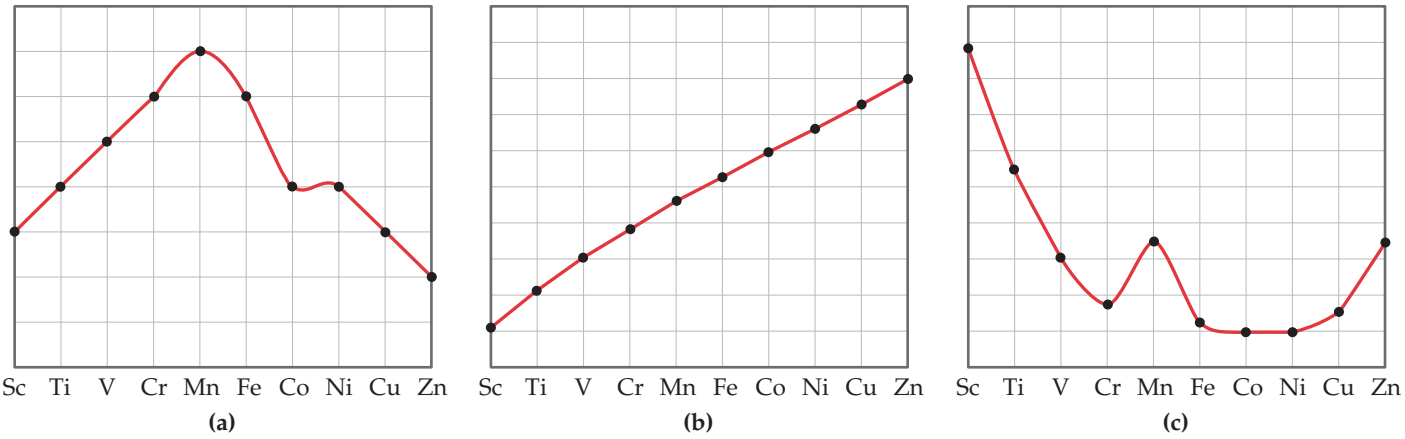
CRYSTAL-FIELD THEORY (SECTION 23.6) **Crystal-field theory** successfully accounts for many properties of coordination compounds, including their color and magnetism. In crystal-field theory, the interaction between metal ion and ligand is viewed as electrostatic. Because some *d* orbitals point directly at the ligands whereas others point between them, the ligands split the energies of the metal *d* orbitals. For an octahedral complex, the *d* orbitals are split into a lower-energy set of three degenerate orbitals (the t_2 set) and a higher-energy set of two degenerate orbitals (the *e* set). Visible light can cause a ***d-d* transition**, in which an electron is excited from a lower-energy *d* orbital to a higher-energy *d* orbital. The **spectrochemical series** lists ligands in order of their ability to increase the split in *d*-orbital energies in octahedral complexes.

Strong-field ligands create a splitting of *d*-orbital energies that is large enough to overcome the **spin-pairing energy**. The *d* electrons then preferentially pair up in the lower-energy orbitals, producing a **low-spin complex**. When the ligands exert a weak crystal-field, the splitting of the *d* orbitals is small. The electrons then occupy the higher-energy *d* orbitals in preference to pairing up in the lower-energy set, producing a **high-spin complex**. Transition metal ions from Periods 5 and 6 have large crystal-field splitting energies and adopt low spin configurations in octahedral complexes.

Crystal-field theory also applies to tetrahedral and square-planar complexes, which leads to different *d*-orbital splitting patterns. In a tetrahedral crystal-field, the splitting of the *d* orbitals results in a higher-energy t_2 set and a lower-energy *e* set, the opposite of the octahedral case. The splitting in a tetrahedral crystal-field is much smaller than that in an octahedral crystal-field, so tetrahedral complexes are nearly always high-spin complexes.

Learning Outcomes

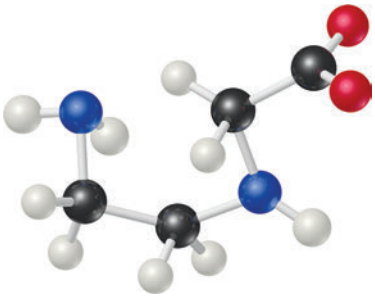
After studying this chapter, you should be able to:



- Describe the periodic trends in radii and oxidation states of the transition-metal ions, including the origin and effect of the lanthanide contraction. (Section 23.1) *Related Exercises: 23.2, 23.34, 23.44*
- Determine the oxidation number and number of *d* electrons for metal ions in complexes. (Section 23.2) *Related Exercises: 23.3, 23.4, 23.46, 23.52*

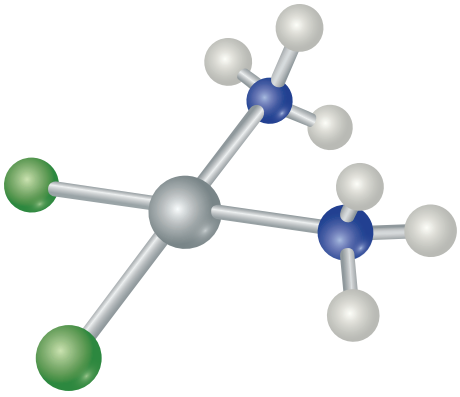
- Identify common ligands and distinguish between chelating and nonchelating ligands. (Section 23.3) *Related Exercises: 23.12, 23.53, 23.54, 23.56*
- Name coordination compounds given their formula and write their formula given their name. (Section 23.4) *Related Exercises: 23.16, 23.17, 23.57, 23.58*
- Define isomerism and differentiate between the various types of isomers. (Section 23.4) *Related Exercises: 23.18, 23.59*
- Recognize and draw the geometric isomers of a complex. (Section 23.4) *Related Exercises: 23.19, 23.20, 23.60, 23.61*
- Recognize and draw the optical isomers of a complex. (Section 23.4) *Related Exercises: 23.21, 23.62*
- Use crystal-field theory to determine the number of unpaired electrons in a complex. (Sections 23.5 and 23.6) *Related Exercises: 23.64, 23.70, 23.71, 23.72*
- Use the spectrochemical series to predict the relative crystal-field splitting energy and colors of metal complexes. (Sections 23.5 and 23.6) *Related Exercises: 23.28, 23.67*
- Differentiate between high-spin and low-spin ions, and identify the factors that stabilize each. (Section 23.6) *Related Exercises: 23.33, 23.41, 23.69, 23.72*

Exercises



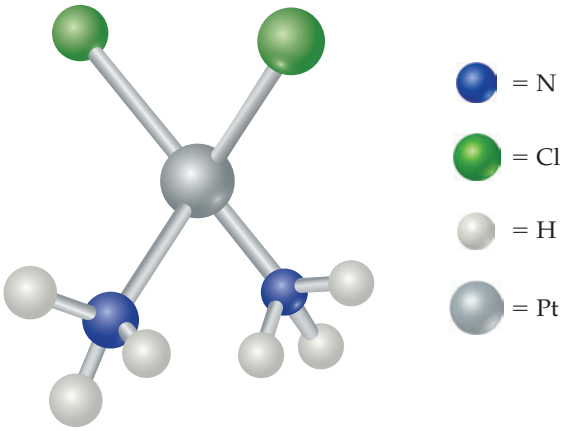
Visualizing Concepts

23.34 These three graphs show the variation in radius, effective nuclear charge, and maximum oxidation state for the transition metals of Period 4. In each part, identify which property is being plotted. [Section 23.1]



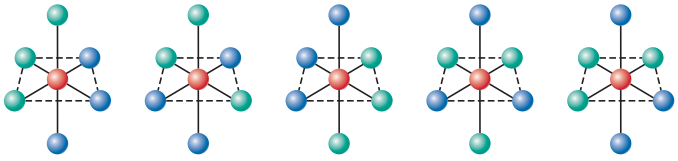
23.35 Draw the structure for $Pt(C_2O_4)(NH_3)_2$ and use it to answer the following questions: (**a**) What is the coordination number for platinum in this complex? (**b**) What is the coordination geometry? (**c**) What is the oxidation state of the platinum? (**d**) How many unpaired electrons are there? [Sections 23.2 and 23.6]

23.36 Draw the Lewis structure for the ligand shown here. (**a**) Which atoms can serve as donor atoms? Classify this ligand as monodentate, bidentate, or polydentate. (**b**) How many of these ligands are needed to fill the coordination sphere in an octahedral complex? [Section 23.2]



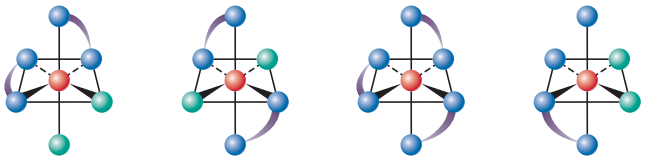
$NH_2CH_2CH_2NHCH_2CO_2^-$

23.37 Four-coordinate metals can have either a tetrahedral or a square-planar geometry; both possibilities are shown here for $[PtCl_2(NH_3)_2]$. (**a**) What is the name of this molecule? (**b**) Would the tetrahedral molecule have a geometric isomer? (**c**) Would the tetrahedral molecule be diamagnetic or paramagnetic? (**d**) Would the square-planar molecule have a geometric isomer? (**e**) Would the square-planar molecule be diamagnetic or paramagnetic? (**f**) Would determining the number of geometric isomers help you distinguish between the tetrahedral and square-planar geometries? (**g**) Would measuring the molecule's response to a magnetic field help you distinguish between the two geometries? [Sections 23.4–23.6]



square planar

tetrahedral

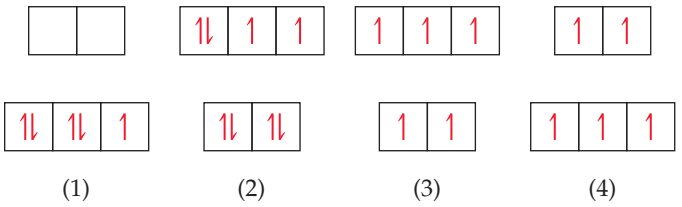


23.38 There are two geometric isomers of octahedral complexes of the type MA_3X_3, where M is a metal and A and X are monodentate ligands. Of the complexes shown here, which are identical to (1) and which are the geometric isomers of (1)? [Section 23.4]

(1) (2) (3) (4) (5)

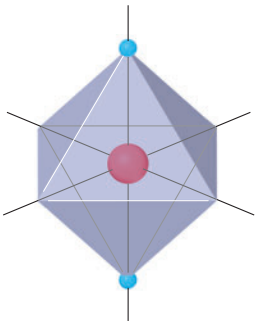
23.39 Which of the complexes shown here are chiral? [Section 23.4]

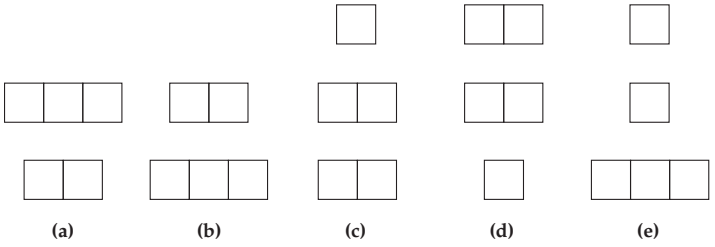
= Cr = $NH_2CH_2CH_2NH_2$ = Cl = NH_3



(1) (2) (3) (4)

23.40 The solutions shown here each have an absorption spectrum with a single absorption peak like that shown in Figure 23.26. What color does each solution absorb most strongly? [Section 23.5]





23.41 Which of these crystal-field splitting diagrams represents: (**a**) a weak-field octahedral complex of Fe^{3+}, (**b**) a strong-field octahedral complex of Fe^{3+}, (**c**) a tetrahedral complex of Fe^{3+}, (**d**) a tetrahedral complex of Ni^{2+}? (The diagrams do not indicate the relative magnitudes of Δ.) [Section 23.6]

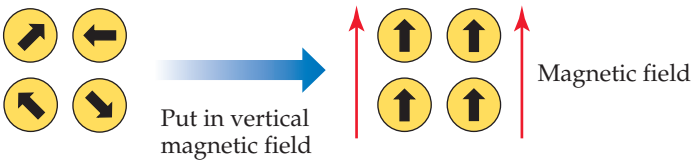
(1) (2) (3) (4)

23.42 In the linear crystal-field shown here, the negative charges are on the *z*-axis. Using Figure 23.28 as a guide, predict which of the following choices most accurately describes the splitting of the *d* orbitals in a linear crystal-field? [Section 23.6]

(a) (b) (c) (d) (e)

23.43 Two Co(III) complexes are both low spin but have different ligands. A solution of one is orange and a solution of the other is yellow. Which solution is likely to contain the complex that has the stronger-field ligand? [Section 23.6]

The Transition Metals (Section 23.1)



23.44 The lanthanide contraction explains which of the following periodic trends? (**a**) The atomic radii of the transition metals first decrease and then increase when moving horizontally across each period. (**b**) When forming ions the Period 4 transition metals lose their 4*s* electrons before their 3*d* electrons. (**c**) The radii of the Period 5 transition metals (Y–Cd) are very similar to the radii of the Period 6 transition metals (Lu–Hg).

23.45 Among the Period 4 transition metals (Sc–Zn), which elements do not form ions where there are partially filled 3*d* orbitals?

23.46 Write out the ground-state electron configurations of (**a**) Sc^{2+}, (**b**) Mo^{2+}, (**c**) Rh^{3+}, (**d**) Fe^{3+}.

23.47 Which type of substance is attracted by a magnetic field, a diamagnetic substance or a paramagnetic substance?

23.48 What kind of magnetism is exhibited by this diagram?

23.49 The most important oxides of iron are magnetite, Fe_3O_4, and hematite, Fe_2O_3. (**a**) What are the oxidation states of iron in these compounds? (**b**) One of these iron oxides is ferrimagnetic, and the other is antiferromagnetic. Which iron oxide is more likely to be ferrimagnetic? Explain.

Transition-Metal Complexes (Section 23.2)

23.50 (**a**) Using Werner's definition of valence, which property is the same as oxidation number, *primary valence* or *secondary valence*? (**b**) What term do we normally use for the other type of valence? (**c**) Why can NH_3 serve as a ligand but BH_3 cannot?

23.51 A complex is written as $NiBr_2 \cdot 6NH_3$. (**a**) What is the oxidation state of the Ni atom in this complex? (**b**) What is the likely coordination number for the complex? (**c**) If the complex is treated with excess $AgNO_3(aq)$, how many moles of AgBr will precipitate per mole of complex?

23.52 Indicate the coordination number and the oxidation number of the metal for each of the following complexes:

(**a**) $Na_2[Co(EDTA)]$

(**b**) $KMnO_4$

(**c**) $[Pt(NH_3)_4]Cl_2$

(**d**) $K_3Fe(CN)_6$

(**e**) $Rh(PPh_3)_3Cl$

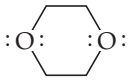
(**f**) $Zn(C_2O_4)(NH_3)_2$

Common Ligands in Coordination Chemistry (Section 23.3)

23.53 For each of the following molecules or polyatomic ions, draw the Lewis structure and indicate if it can act as a monodentate ligand, a bidentate ligand, or is unlikely to act as a ligand at all: (**a**) ethylamine, $CH_3CH_2NH_2$, (**b**) trimethylphosphine, $P(CH_3)_3$, (**c**) carbonate, CO_3^{2-}, (**d**) ethane, C_2H_6.

23.54 Polydentate ligands can vary in the number of coordination positions they occupy. In each of the following, identify the polydentate ligand present and indicate the probable number of coordination positions it occupies:

(**a**) $Cr(EDTA)^-$



(**b**) $[Ni(C_2O_4)(H_2O)_2]Br_2$

(**c**) $[Ru(en)(NH_3)_4]Cl_3$

(**d**) $K_2[Fe(o\text{-}phen)(CN)_4]$

23.55 For each of the following pairs, identify the molecule or ion that is more likely to act as a ligand in a metal complex: (**a**) carbonic acid (H_2CO_3) or carbonate (CO_3^{2-}), (**b**) water (H_2O) or hydronium ion (H_3O^+), (**c**) phosphine (PH_3) or phosphoric acid (H_3PO_4).

23.56 True or false? The following ligand can act as a bidentate ligand.

Nomenclature and Isomerism in Coordination Chemistry (Section 23.4)

23.57 Write the formula for each of the following compounds, being sure to use brackets to indicate the coordination sphere:

(**a**) triamminetriaquachromium(III) nitrate

(**b**) dichloridobis(ethylenediamine)platinum(II)

(**c**) pentacarbonyliron(0)

(**d**) ammonium diaquabis(oxalato)Co(II)

(**e**) tris(bipyridyl)cobalt(III) sulfate

23.58 Write the names of the following compounds, using the standard nomenclature rules for coordination complexes:

(**a**) $[Ag(NH_3)_2]NO_3$

(**b**) $Hg[Co(SCN)_4]$

(**c**) $[Ru(PPh_3)_3Cl_3]$

(**d**) $[Co(NH_3)_5CO_3]_2SO_4$

23.59 Consider the following three complexes:

(Complex 1) $[Co(NH_3)_4Br_2]Cl$

(Complex 2) $[Pd(NH_3)_2(ONO)_2]$

(Complex 3) $[V(en)_2Cl_2]^+$,

Which of the three complexes can have (**a**) geometric isomers, (**b**) linkage isomers, (**c**) optical isomers, (**d**) coordination-sphere isomers?

23.60 A four-coordinate complex MA_2B_2 is prepared and found to have two different isomers. Is it possible to determine from this information whether the complex is square planar or tetrahedral? If so, which is it?

23.61 Determine if each of the following complexes exhibits geometric isomerism. If geometric isomers exist, determine how many there are. (**a**) tetrahedral $[Cd(H_2O)_2Cl_2]$, (**b**) square-planar $[IrCl_2(PH_3)_2]^-$, (**c**) octahedral $[Fe(o\text{-phen})_2Cl_2]^+$.

23.62 Determine if each of the following metal complexes is chiral and therefore has an optical isomer: (**a**) tetrahedral $[Zn(H_2O)_2Cl_2]$, (**b**) octahedral *trans*-$[Ru(bipy)_2Cl_2]$, (**c**) octahedral *cis*-$[Ru(bipy)_2Cl_2]$.

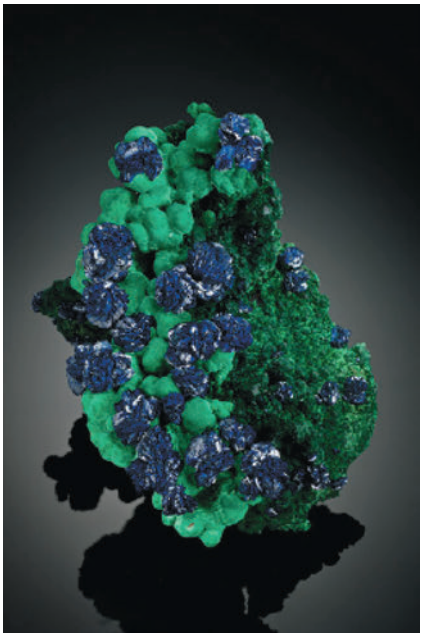
Color and Magnetism in Coordination Chemistry; Crystal-Field Theory (Sections 23.5 and 23.6)

23.63 (**a**) If a complex absorbs light at 610 nm, what color would you expect the complex to be? (**b**) What is the energy in joules of a photon with a wavelength of 610 nm? (**c**) What is the energy of this absorption in kJ/mol?

23.64 Identify each of the following coordination complexes as either diamagnetic or paramagnetic:

(**a**) $[CoBr(NH_3)_5]^{2+}$

(**b**) $[W(CN)_6]^{3-}$



(**c**) $[VF_6]^{3-}$

(**d**) $[Rh(o\text{-phen})_3]^{3+}$

23.65 If the lobes of a given *d*-orbital point directly at the ligands, will an electron in that orbital have a higher or lower energy than an electron in a *d*-orbital whose lobes *do not* point directly at the ligands?

23.66 (**a**) Sketch a diagram that shows the definition of the *crystal-field splitting energy* (Δ) for an octahedral crystal-field. (**b**) What is the relationship between the magnitude of Δ and the energy of the *d-d* transition for a d^1 complex? (**c**) Calculate Δ in kJ/mol if a d^1 complex has an absorption maximum at 545 nm.

23.67 The colors in the copper-containing minerals malachite, which is green and has an empirical formula of $Cu_2CO_3(OH)_2$, and azurite, which is blue and has an empirical formula of $Cu_3(CO_3)_2(OH)_2$, come from a single *d-d* transition in each compound. The compounds are sometimes found together in nature as shown here. (**a**) What is the electron configuration of the copper ion in each mineral? (**b**) Based on their colors, in which compound would you predict the crystal-field splitting Δ is larger?

23.68 Give the number of (valence) *d* electrons associated with the central metal ion in each of the following complexes: (**a**) $[Pt(NH_3)_2Cl_2]Cl_2$, (**b**) $K_2[Cu(C_2O_4)_2]$, (**c**) $[Os(en)_3]Cl_3$, (**d**) $[Cr(EDTA)]SO_4$, (**e**) $[Cd(OH_2)_6]Cl_2$.

23.69 A classmate says, "A weak-field ligand usually means the complex is high spin." Is your classmate correct? Explain.

23.70 For each of the following metals, write the electronic configuration of the atom and its 2+ ion: (**a**) Mn, (**b**) Ru, (**c**) Rh. Draw the crystal-field energy-level diagram for the *d* orbitals of an octahedral complex, and show the placement of the *d* electrons for each 2+ ion, assuming a strong-field complex. How many unpaired electrons are there in each case?

23.71 Draw the crystal-field energy-level diagrams and show the placement of *d* electrons for each of the following: (**a**) $[Cr(OH_2)_6]^{2+}$ (four unpaired electrons), (**b**) $[Mn(H_2O)_6]^{2+}$ (a high-spin complex), (**c**) $[Ru(NH_3)_5(OH_2)]^{2+}$ (a low-spin complex), (**d**) $[IrCl_6]^{2-}$ (a low-spin complex), (**e**) $[Cr(en)_3]^{3+}$, (**f**) $[NiF_6]^{4-}$.

23.72 The complex $[Mn(NH_3)_6]^{2+}$ contains five unpaired electrons. Sketch the energy-level diagram for the *d* orbitals, and indicate the placement of electrons for this complex ion. Is the ion a high-spin or a low-spin complex?

Additional Exercises

23.73 The *Curie temperature* is the temperature at which a ferromagnetic solid switches from ferromagnetic to paramagnetic, and for nickel, the Curie temperature is 354 °C. Knowing this, you tie a string to two paper clips made of nickel and hold the paper clips near a permanent magnet. The magnet attracts the paper clips, as shown in the photograph on the left. Now you heat one of the paper clips with a cigarette lighter, and the clip drops (right photograph). Explain what happened.

23.74 Explain why the transition metals in Periods 5 and 6 have nearly identical radii in each group.

23.75 Based on the molar conductance values listed here for the series of platinum(IV) complexes, write the formula for each complex so as to show which ligands are in the coordination sphere of the metal. By way of example, the molar conductances of 0.050 *M* NaCl and $BaCl_2$ are 107 ohm^{-1} and 197 ohm^{-1}, respectively.

Complex	Molar Conductance (ohm^{-1})* of 0.050 *M* Solution
$Pt(NH_3)_6Cl_4$	523
$Pt(NH_3)_4Cl_4$	228
$Pt(NH_3)_3Cl_4$	97
$Pt(NH_3)_2Cl_4$	0
$KPt(NH_3)Cl_5$	108

*The ohm is a unit of resistance; conductance is the inverse of resistance.

23.76 (**a**) A compound with formula $RuCl_3 \cdot 5\ H_2O$ is dissolved in water, forming a solution that is approximately the same color as the solid. Immediately after forming the solution, the addition of excess $AgNO_3(aq)$ forms 2 mol of solid AgCl per mole of complex. Write the formula for the compound, showing which ligands are likely to be present in the coordination sphere. (**b**) After a solution of $RuCl_3 \cdot 5\ H_2O$ has stood for about a year, addition of $AgNO_3(aq)$ precipitates 3 mol of AgCl per mole of complex. What has happened in the ensuing time?

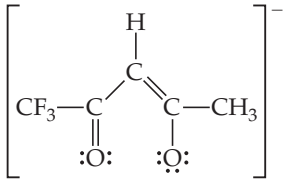
23.77 Sketch the structure of the complex in each of the following compounds and give the full compound name:

(**a**) *cis*-$[PtBrCl(NO_2)_2]^{2-}$

(**b**) $[Mn(CO)_3(C_6H_6)]^+$

(**c**) *cis*-$[CrCl_4)(OH_2)_2]^-$

(**d**) *trans*-$[Co(OH)(en)_2Cl]^+$



23.78 Does complex *d* in Exercise 23.77 have optical isomers?

23.79 The molecule *dimethylphosphinoethane* $[(CH_3)_2PCH_2CH_2P(CH_3)_2$, which is abbreviated dmpe] is used as a ligand for some complexes that serve as catalysts. A complex that contains this ligand is $Mo(CO)_4$(dmpe). (**a**) Draw the Lewis structure for dmpe, and compare it with ethylenediamine as a coordinating ligand. (**b**) What is the oxidation state of Mo in $Na_2[Mo(CN)_2(CO)_2$(dmpe)]? (**c**) Sketch the structure of the $[Mo(CN)_2(CO)_2$(dmpe)$]^{2-}$ ion, including all the possible isomers.

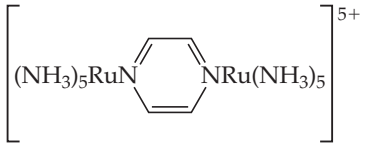
23.80 The square-planar complex $[Pt(en)Cl_2]$ only forms in one of two possible geometric isomers. Which isomer is not observed: *cis* or *trans*?

23.81 The acetylacetone ion forms very stable complexes with many metallic ions. It acts as a bidentate ligand, coordinating to the metal at two adjacent positions. Suppose that one of the CH_3 groups of the ligand is replaced by a CF_3 group, as shown here:

Trifluoromethyl acetylacetonate (tfac)

Sketch all possible isomers for the complex with three tfac ligands on cobalt(III). (You can use the symbol ↶ to represent the ligand.)

23.82 Which transition metal atom is present in each of the following biologically important molecules: (**a**) hemoglobin, (**b**) chlorophylls, (**c**) siderophores, (**d**) hemocyanine.



23.83 Carbon monoxide, CO, is an important ligand in coordination chemistry. When CO is reacted with nickel metal, the product is $[Ni(CO)_4]$, which is a toxic, pale yellow liquid. (**a**) What is the oxidation number for nickel in this compound? (**b**) Given that $[Ni(CO)_4]$ is a diamagnetic molecule with a tetrahedral geometry, what is the electron configuration of nickel in this compound? (**c**) Write the name for $[Ni(CO)_4]$ using the nomenclature rules for coordination compounds.

23.84 Some metal complexes have a coordination number of 5. One such complex is $Fe(CO)_5$, which adopts a *trigonal bipyramidal* geometry (see Figure 9.8). (**a**) Write the name for $Fe(CO)_5$, using the nomenclature rules for coordination compounds. (**b**) What is the oxidation state of Fe in this compound? (**c**) Suppose one of the CO ligands is replaced with a CN^- ligand, forming $[Fe(CO)_4(CN)]^-$. How many geometric isomers would you predict this complex could have?

23.85 Which of the following objects is chiral: (**a**) a pencil, (**b**) a computer keyboard, (**c**) a grand piano, (**d**) a molecular model of *cis*-$Fe(bipy)_2Cl_2$, (**e**) a piece of plane A4 paper?

23.86 The complexes $[CrBr_6]^{3-}$ and $[Cr(NH_3)_6]^{3+}$ are both known. (**a**) Draw the *d*-orbital energy-level diagram for octahedral Cr(III) complexes. (**b**) What gives rise to the colors of these complexes? (**c**) Which of the two complexes would you expect to absorb light of higher energy?

23.87 One of the more famous species in coordination chemistry is the Creutz–Taube complex:

It is named for the two scientists who discovered it and initially studied its properties. The central ligand is pyrazine, a planar six-membered ring with nitrogens at opposite sides. (**a**) How can you account for the fact that the complex, which has only neutral ligands, has an odd overall charge? (**b**) The metal is in a low-spin configuration in both cases. Assuming octahedral coordination, draw the *d*-orbital energy-level diagram for each metal. (**c**) In many experiments the two metal ions appear to be in exactly equivalent states. Can you think of a reason that this might appear to be so, recognizing that electrons move very rapidly compared to nuclei?

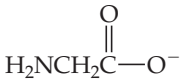
23.88 Solutions of $[Co(NH_3)_6]^{2+}$, $[Co(OH_2)_6]^{2+}$ (both octahedral), and $[CoCl_4]^{2-}$ (tetrahedral) are colored. One is pink, one is blue, and one is yellow. Based on the spectrochemical series and remembering that the energy splitting in tetrahedral complexes is normally much less than that in octahedral ones, assign a color to each complex.

23.89 Oxyhemoglobin, with an O_2 bound to iron, is a low-spin Fe(II) complex; deoxyhemoglobin, without the O_2 molecule, is a high-spin complex. (**a**) Assuming that the coordination environment about the metal is octahedral, how many unpaired electrons are centered on the metal ion in each case? (**b**) What ligand is coordinated to the iron in place of O_2 in deoxyhemoglobin? (**c**) Explain in a general way why the two forms of hemoglobin have different colors (hemoglobin is red, whereas deoxyhemoglobin has a bluish cast). (**d**) A 15-minute exposure to air containing 400 ppm of CO causes about 10% of the hemoglobin in the blood to be converted into the carbon monoxide complex, called carboxyhemoglobin. What does this suggest about the relative equilibrium constants for binding of carbon monoxide and O_2 to hemoglobin? (**e**) CO is a strong-field ligand. What color might you expect carboxyhemoglobin to be?

23.90 Consider the tetrahedral anions VO_4^{3-} (orthovanadate ion), CrO_4^{2-} (chromate ion), and MnO_4^- (permanganate ion). (**a**) These anions are *isoelectronic*. What does this statement mean? (**b**) Would you expect these anions to exhibit *d-d* transitions? Explain. (**c**) As mentioned in "A Closer Look" on charge-transfer color, the violet color of MnO_4^- is due to a *ligand-to-metal charge transfer* (LMCT) transition. What is meant by this term? (**d**) The LMCT transition in MnO_4^- occurs at a wavelength of 565 nm. The CrO_4^{2-} ion is yellow. Is the wavelength of the LMCT transition for chromate larger or smaller than that for MnO_4^-? Explain. (**e**) The VO_4^{3-} ion is colorless. Do you expect the light absorbed by the LMCT to fall in the UV or the IR region of the electromagnetic spectrum? Explain your reasoning.

23.91 Given the colors observed for VO_4^{3-} (orthovanadate ion), CrO_4^{2-} (chromate ion), and MnO_4^- (permanganate ion) (see Exercise 23.90), what can you say about how the energy separation between the ligand orbitals and the empty *d* orbitals changes as a function of the oxidation state of the transition metal at the center of the tetrahedral anion?

23.92 The blue-green color of turquoise is due to the presence of Cu(II) ions at octahedral sites which is coordinated with OH^- and H_2O. Assuming Cu(II) ions adopt an octahedral



geometry, draw the crystal-field splitting diagram for Cu(II) in this environment. Suppose that the turquoise crystal is subjected to high pressure. What do you predict for the variation in the wavelength of absorption of the turquoise as a function of pressure? Explain.

23.93 In 2001, chemists at State University of New York-Stony Brook succeeded in synthesizing the complex *trans*-$[Fe(CN)_4(CO)_2]^{2-}$, which could be a model of complexes that may have played a role in the origin of life. (**a**) Sketch the structure of the complex. (**b**) The complex is isolated as a sodium salt. Write the complete name of this salt. (**c**) What is the oxidation state of Fe in this complex? How many *d* electrons are associated with the Fe in this complex? (**d**) Would you expect this complex to be high spin or low spin? Explain.

23.94 When Alfred Werner was developing the field of coordination chemistry, it was argued by some that the optical activity he observed in the chiral complexes he had prepared was due to the presence of carbon atoms in the molecule. To disprove this argument, Werner synthesized a chiral complex of cobalt that had no carbon atoms in it, and he was able to resolve it into its enantiomers. Design a cobalt(III) complex that would be chiral if it could be synthesized and that contains no carbon atoms. (It may not be possible to synthesize the complex you design, but we will not worry about that for now.)

23.95 Generally speaking, for a given metal and ligand, the stability of a coordination compound is greater for the metal in the +3 rather than in the +2 oxidation state (for metals that form stable +3 ions in the first place). Suggest an explanation, keeping in mind the Lewis acid–base nature of the metal–ligand bond.

23.96 Many trace metal ions exist in the blood complexed with amino acids or small peptides. The anion of the amino acid glycine (gly),

can act as a bidentate ligand, coordinating to the metal through nitrogen and oxygen atoms. How many isomers are possible for (**a**) $[Zn(gly)_2]$ (tetrahedral), (**b**) $[Pt(gly)_2]$ (square planar), (**c**) $[Co(gly)_3]$ (octahedral)? Sketch all possible isomers. Use the symbol  to represent the ligand.

23.97 The coordination complex $[Cr(CO)_6]$ forms colorless, diamagnetic crystals that melt at 90 °C. (**a**) What is the oxidation number of chromium in this compound? (**b**) Given that $[Cr(CO)_6]$ is diamagnetic, what is the electron configuration of chromium in this compound? (**c**) Given that $[Cr(CO)_6]$ is colorless, would you expect CO to be a weak-field or strong-field ligand? (**d**) Write the name for $[Cr(CO)_6]$ using the nomenclature rules for coordination compounds.

Integrative Exercises

23.98 Metallic elements are essential components of many important enzymes operating within our bodies. *Carbonic anhydrase*, which contains Zn^{2+} in its active site, is responsible for rapidly interconverting dissolved CO_2 and bicarbonate ion, HCO_3^-. The zinc in carbonic anhydrase is tetrahedrally coordinated by three neutral nitrogen-containing groups and a water molecule. The coordinated water molecule has a pK_a of 7.5, which is crucial for the enzyme's activity. (**a**) Draw the active site geometry for the Zn(II) center in carbonic anhydrase, just writing "N" for the three neutral nitrogen ligands from the protein. (**b**) Compare the pK_a of carbonic anhydrase's active site with that of pure water; which species is more acidic? (**c**) When the coordinated water to the Zn(II) center in carbonic anhydrase is deprotonated, what ligands are bound to the Zn(II) center? Assume the three nitrogen ligands are unaffected. (**d**) The pK_a of $[Zn(H_2O)_6]^{2+}$ is 10. Suggest an explanation for the difference between this pK_a and that of carbonic anhydrase. (**e**) Would you expect carbonic anhydrase to have a deep color, like hemoglobin and other metal-ion-containing proteins do? Explain.

23.99 Two different compounds have the formulation $CoBr(SO_4) \cdot 5\,NH_3$. Compound A is dark violet, and compound B is red-violet. When compound A is treated with $AgNO_3(aq)$, no reaction occurs, whereas compound B reacts with $AgNO_3(aq)$ to form a white precipitate. When compound A is treated with $BaCl_2(aq)$, a white precipitate is formed, whereas compound B has no reaction with $BaCl_2(aq)$. (**a**) Is Co in the same oxidation state in these complexes? (**b**) Explain the reactivity of compounds A and B with $AgNO_3(aq)$ and $BaCl_2(aq)$. (**c**) Are compounds A and B isomers of one another? If so, which category from Figure 23.19 best describes the isomerism observed for these complexes? (**d**) Would compounds A and B be expected to be strong electrolytes, weak electrolytes, or nonelectrolytes?

23.100 An iron complex formed from a solution containing hydrochloric acid and bipyridine is purified and analyzed. It contains 9.38% Fe, 60.53% carbon, 4.06% hydrogen, and 14.12% nitrogen by mass. The remainder of the compound is chlorine. An aqueous solution of the complex has about the same electrical conductivity as an equimolar solution of $K_2[CuCl_4]$. Write the formula of the compound, using brackets to denote the iron and its coordination sphere.

23.101 The $E°$ values for two low-spin iron complexes in acidic solution are as follows:

$$[Fe(o\text{-phen})_3]^{3+}(aq) + e^- \rightleftharpoons [Fe(o\text{-phen})_3]^{2+}(aq) \qquad E° = 1.12\ V$$

$$[Fe(CN)_6]^{3-}(aq) + e^- \rightleftharpoons [Fe(CN)_6]^{4-}(aq) \qquad E° = 0.36\ V$$

(**a**) Is it thermodynamically favorable to reduce both Fe(III) complexes to their Fe(II) analogs? Explain. (**b**) Which complex, $[Fe(o\text{-phen})_3]^{3+}$ or $[Fe(CN)_6]^{3-}$, is more difficult to reduce? (**c**) Suggest an explanation for your answer to (b).

23.102 A platinum complex formed from a solution containing chloride ion and ammonia is found on elemental analysis to contain 23.63% chlorine, 9.34% nitrogen, 2.02% hydrogen by mass. The compound is slightly soluble in several organic solvents; its solutions in water or alcohol do not conduct electricity. It is found experimentally to have a net dipole moment. Write the chemical formula of this platinum complex, and indicate its probable structure.

23.103 (**a**) In early studies it was observed that when the complex $[Co(NH_3)_4Br_2]Br$ was placed in water, the electrical conductivity of a 0.05 *M* solution changed from an initial value of 191 ohm^{-1} to a final value of 374 ohm^{-1} over a period of an hour or so. Suggest an explanation for the observed results. (See Exercise 23.75 for relevant comparison data.) (**b**) Write a balanced chemical equation to describe the reaction. (**c**) A 500 mL solution is made up by dissolving 3.87 g of the complex. As soon as the solution is formed, and before any change in conductivity has occurred, a 25.00 mL portion of the solution is titrated with 0.0100 *M* $AgNO_3$ solution. What volume of $AgNO_3$ solution do you expect to be required to precipitate the free $Br^-(aq)$? (**d**) Based on the response you gave to part (b), what volume of $AgNO_3$ solution would be required to titrate a fresh 25.00 mL sample of $[Co(NH_3)_4Br_2]Br$ after all conductivity changes have occurred?

23.104 The total concentration of Ca^{2+} and Mg^{2+} in a sample of hard water was determined by titrating a 0.100 L sample of the water with a solution of $EDTA^{4-}$. The $EDTA^{4-}$ chelates the two cations:

$$Mg^{2+} + [EDTA]^{4-} \longrightarrow [Mg(EDTA)]^{2-}$$
$$Ca^{2+} + [EDTA]^{4-} \longrightarrow [Ca(EDTA)]^{2-}$$

It requires 31.5 mL of 0.0104 *M* $[EDTA]^{4-}$ solution to reach the end point in the titration. A second 0.100 L sample was then treated with sulfate ion to precipitate Ca^{2+} as calcium sulfate. The Mg^{2+} was then titrated with 18.7 mL of 0.0104 *M* $[EDTA]^{4-}$. Calculate the concentrations of Mg^{2+} and Ca^{2+} in the hard water in mg/L.

23.105 Carbon monoxide is toxic because it binds more strongly to the iron in hemoglobin (Hb) than does O_2, as indicated by these approximate standard free-energy changes in blood:

$$Hb + O_2 \longrightarrow HbO_2 \quad \Delta G^\circ = -70\ kJ$$
$$Hb + CO \longrightarrow HbCO \quad \Delta G^\circ = -80\ kJ$$

Using these data, estimate the equilibrium constant at 298 K for the equilibrium

$$HbO_2 + CO \rightleftharpoons HbCO + O_2$$

23.106 The value of Δ for the $[MoI_6]^{3-}$ complex is 198.58 kJ/mol. Calculate the expected wavelength of the absorption corresponding to promotion of an electron from the lower energy to the higher-energy *d*-orbital set in this complex. Should the complex absorb in the visible range?

23.107 A Zn electrode is immersed in a solution that is 1.00 *M* in $[Zn(NH_3)_4]^{2+}$ and 1.00 *M* in NH_3. When the cathode is a standard hydrogen electrode, the emf of the cell is found to be +1.04 V. What is the formation constant for $[Zn(NH_3)_4]^{2+}$?

Design an Experiment

Following a procedure found in a scientific paper, you go into the lab and attempt to prepare crystals of dichlorobis(ethylenediamine) cobalt(III) chloride. The paper states that this compound can be made by reacting $CoCl_2 \cdot 6\,H_2O$, an excess of ethylenediamine, O_2 from the air (which acts as an oxidizing agent), water, and concentrated hydrochloric acid. At the end of the reaction, you filter off the solution and are left with a green, crystalline product. (**a**) What experiment(s) could you perform to confirm that you have prepared $[CoCl_2(en)_2]Cl$ and not $[Co(en)_3]Cl_3$? (**b**) How could you verify that cobalt was present as Co^{3+} and determine the spin state of the cobalt complex in your product? (**c**) How many geometric isomers exist for $[CoCl_2(en)_2]Cl$? How could you determine if your product contains a single geometric isomer or a mixture of geometric isomers? (**d**) If the product does contain a single geometric isomer how would you determine which one was present? (*Hint: You may find the information in Table 23.3 helpful.*)

THE CHEMISTRY OF ORGANIC COMPOUNDS

WHAT'S AHEAD

24.1 General Characteristics of Organic Molecules
24.2 An Introduction to Hydrocarbons
24.3 Structures of Alkanes
24.4 Alkane Nomenclature
24.5 Cycloalkanes
24.6 Organic Functional Groups
24.7 Reactions of Alkanes

24.1 General Characteristics of Organic Molecules

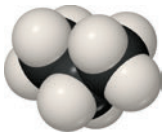
We are all familiar with how chemical substances can influence our health and behavior. Aspirin, also known as acetylsalicylic acid, relieves aches and pains. The caffeine that is in coffee and tea and the ethanol that is in wine and beer are well-known molecules that, at proper doses, give us pleasure. Spices contain a host of molecules such as capsaicin (in chili peppers) and vanillin (in the vanilla bean). Other plant-derived compounds include quinine, for treating malaria, and taxol, for treating many cancers. All of these compounds are based on carbon.

Over 20 million carbon-containing compounds are known, and approximately 90% of the new compounds synthesized each year contain carbon. The study of compounds of carbon constitutes a branch of chemistry called organic chemistry.

The term organic chemistry arose from the eighteenth-century belief that organic compounds could only be formed by living systems. This idea was disproved in 1828 when the German chemist Friedrich Wöhler synthesized urea (H_2NCONH_2), an organic substance found in the urine of mammals, by heating the inorganic substance ammonium cyanate (NH_4OCN).

By the end of this section, you should be able to:

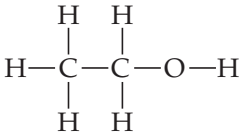
- Appreciate the general structure of organic molecules



What is it about carbon that leads to the tremendous diversity of its compounds and allows them to play such a diverse role in biology and industry? Let's consider some general features of organic molecules and, as we do so, review principles we learned in earlier chapters.

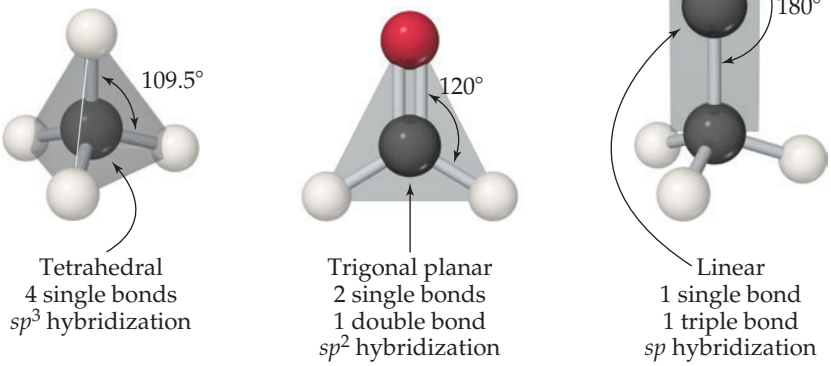
The Structure of Organic Molecules

Because carbon has four valence electrons ([He]$2s^2 2p^2$), it forms four bonds in virtually all its compounds. When all four bonds are single bonds, the electron pairs are disposed in a tetrahedral arrangement. In the hybridization model, the carbon 2*s* and 2*p* orbitals are then sp^3 hybridized.



Although it is only a model, this approach has been used widely to describe qualitatively both structure and reactivity of organic compounds. When there is one double bond, the arrangement is trigonal planar (and modelled as sp^2 hybridization). With a triple bond, it is linear (and modelled as *sp* hybridization). Examples are shown in **Figure 24.1**.

Almost every organic molecule contains C—H bonds. Because the valence shell of H can hold only two electrons, hydrogen forms only one covalent bond. As a result, hydrogen atoms are always located on the surface of organic molecules whereas the C—C bonds form the backbone, or skeleton, of the molecule, as in the propane molecule:



The Stabilities of Organic Molecules

Carbon forms strong bonds with a variety of elements, especially H, O, N and the halogens. Carbon also has an exceptional ability to bond to itself, forming a variety of molecules made up of chains or rings of carbon atoms. Most reactions with low or moderate activation energy begin when a region of high electron density on one molecule encounters a region of low electron density on another molecule. The regions of high electron density may be due to the presence of a multiple bond or to the more electronegative atom in a polar bond. Because of their strength and lack of polarity, both C—C single bonds and C—H bonds are relatively unreactive and form a stable base for the organic molecule. To understand the implications of these facts better, consider ethanol:

▼ Figure 24.1 Carbon geometries. The three common geometries around carbon are tetrahedral as in methane (CH_4), trigonal planar as in formaldehyde (CH_2O) and linear as in acetonitrile (CH_3CN). Notice that in all cases each carbon atom forms four bonds.

The differences in the electronegativity values of C (2.5) and O (3.5) and of O and H (2.1) indicate that the C—O and O—H bonds are quite polar while the C—H bond is only slightly polar and the C—C bond is non-polar. Thus many reactions of ethanol involve the C—O and O—H bonds while the hydrocarbon portion of the molecule remains intact. A group of atoms such as the C—O—H group, which determines how an organic molecule reacts (in other words, how the molecule *functions*), is called a **functional group**. As we progress through the chapter we will see that the functional group is the center of reactivity in an organic molecule.

Self-Assessment Exercise

24.1 Consider the following average bond enthalpies: C—C (348 kJ/mol), N—N (163 kJ/mol), O—O (146 kJ/mol), S—S (266 kJ/mol). Which element is most likely to form stable compounds containing chains of atoms of that element?

(a) Carbon
(b) Nitrogen
(c) Oxy

Exercises

24.2 List five elements that are commonly found in organic compounds. Which ones are more electronegative than carbon?

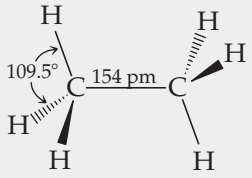
24.3 Organic compounds containing C—O and C—Cl bonds are more reactive than simple alkane hydrocarbons. Considering the comparative values of C—H, C—C, C—O and C—Cl bond energies (Table 8.4), why is this so?

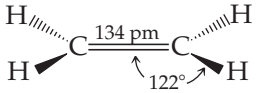
Answers to Self-Assessment Exercise

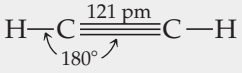
24.1 (a)

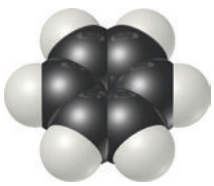
24.2 | An Introduction to Hydrocarbons

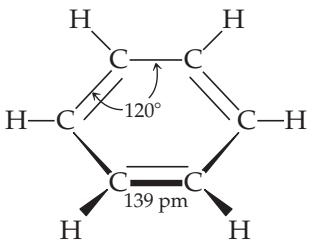
One of the most important issues of our time is global warming. The sun heats the surface of the Earth during daytime and energy is radiated back into space at night. Nitrogen and oxygen, which make up 99% of our atmosphere, are transparent to infrared radiation and allow this heat loss to occur. However, other gases, most notably water vapor, methane, and carbon dioxide, absorb infrared radiation, trapping the heat in the atmosphere. These are called greenhouse gases. Since the industrial revolution, there has been a 50% increase in the amount of carbon dioxide released into the atmosphere with a consequent warming of the planet. As our standard of living rises, our demand for energy increases. In 2018, fossil fuels (coal, oil, and gas) accounted for 80% of the world's energy production. Mitigation strategies include switching to renewable energy sources, increasing energy efficiency in power production, transportation and manufacturing, and capturing greenhouse gases from the atmosphere. We all have a role to play in reducing our 'carbon footprint' and understanding some of the chemistry behind many of our modern materials can inform our choices. Organic chemistry plays a major part in this and we examine the basics of it over the next nine chapters.











By the end of this section, you should be able to:

- Understand the general composition of the simplest of organic molecules, the hydrocarbons.
- Appreciate the link between molecular weight and a physical property such as melting point.

Because carbon compounds are so numerous, it is convenient to organize them into families that have structural similarities. Compounds that contain *only* carbon and hydrogen are called **hydrocarbons**. The key structural feature of hydrocarbons (and of most organic substances) is the presence of stable carbon–carbon bonds. Carbon is the only element capable of forming stable, extended chains of atoms bonded through single, double or triple bonds.

Hydrocarbons can be divided into four types, depending on the kinds of carbon–carbon bonds in the molecules. Table 24.1 shows an example of each type.

TABLE 24.1 The four hydrocarbon types

Type	Classification	Example			
Alkane	Saturated	Ethane	CH_3CH_3		
Alkene	Unsaturated	Ethene	$CH_2{=}CH_2$		
Alkyne	Unsaturated	Ethyne	$CH{\equiv}CH$		
Aromatic	Unsaturated	Benzene	C_6H_6		

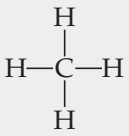
These hydrocarbons are either *aliphatic* (from the Greek work *aleiphar*, meaning oil; these include alkanes, alkenes, and alkynes) or *aromatic*, and are classified as either saturated or unsaturated. In this chapter, we will explore aliphatic hydrocarbons that are **saturated** (that is, all carbons are bound to four other atoms and there are no double or triple bonds). Such hydrocarbons are called **alkanes**. We will look at the other classes of hydrocarbons in subsequent chapters.

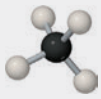
Alkanes

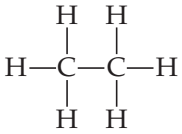
The three simplest alkanes, which contain one, two and three carbon atoms, are methane (CH_4), ethane (C_2H_6) and propane (C_3H_8), respectively. These are illustrated in Table 24.2.

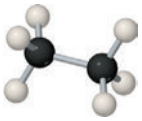
The names of the first 10 *straight-chain* alkanes are given in Table 24.3. You will notice that each aliphatic alkane has a name that ends in *-ane*. This suffix is true of all alkanes as it denotes this class of organic compounds. Alkanes longer than those described in Table 24.3 can be made by adding further CH_2 groups to the skeleton of the molecule.

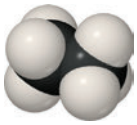
TABLE 24.2 The simplest alkanes

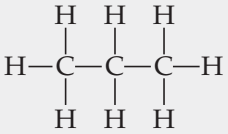


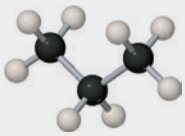


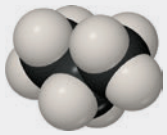












Common name	Structural formula	Condensed structural formula	Ball-and-stick model	Space-filling representation
Methane		CH_4		
Ethane		CH_3CH_3		
Propane		$CH_3CH_2CH_3$		

TABLE 24.3 First 10 members of the straight-chain alkane series

Name	Molecular formula	Condensed structural formula	Boiling point (°C)
Methane	CH_4	CH_4	−161
Ethane	C_2H_6	CH_3CH_3	−89
Propane	C_3H_8	$CH_3CH_2CH_3$	−44
Butane	C_4H_{10}	$CH_3CH_2CH_2CH_3$	−0.5
Pentane	C_5H_{12}	$CH_3CH_2CH_2CH_2CH_3$	36
Hexane	C_6H_{14}	$CH_3CH_2CH_2CH_2CH_2CH_3$	68
Heptane	C_7H_{16}	$CH_3CH_2CH_2CH_2CH_2CH_2CH_3$	98
Octane	C_8H_{18}	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$	125
Nonane	C_9H_{20}	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2CH_3$	151
Decane	$C_{10}H_{22}$	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2CH_2CH_3$	174

Notice the trend within the molecular formulas in the second column of Table 24.3. For n carbon atoms ($n = 1, 2, 3 \ldots$) there are $(2n + 2)$ hydrogen atoms, so alkanes have the general formula:

$$C_nH_{2n+2} \qquad [24.1]$$

The condensed structural formula reveals the way in which atoms are bonded to one another but does not require us to draw in all the bonds. It is one of the most useful ways of representing organic molecules.

Applications and Physical Properties of Alkanes

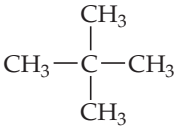
Alkanes are very important in our society, whether they are gaseous, liquid or solid. Many of their common applications, illustrated in **Figure 24.2**, will be familiar to you. Methane, a colorless and odorless gas, is the major component of natural gas and is used for home heating and in gas stoves and water heaters. Propane is the major component of the bottled gas used for home heating and cooking in areas where natural gas is not available. Butane is used in disposable lighters and in fuel canisters for gas camping stoves and lanterns. Alkanes with 5–12 carbon atoms per molecule (C_5—C_{12}) are found in petrol. This difference in application between different groups of alkanes is a result of their physical properties, such as boiling point (bp) and melting point (mp), which determine whether the alkane is a solid, liquid or gas at room temperature.

Homologous Series

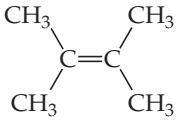
An *n*-alkane, sometimes called a "*normal*-alkane" is an alkane in which all of the carbon atoms are linked in one continuous chain. A series of compounds, like the *n*-alkanes, that differ only by the number of methine (–CH_2–) units is called a **homologous series**. Compounds in such a series possess similar chemical properties and show a gradation in physical properties as a result of increase in molecular size and mass (Table 24.3). The individual members of this series are called *homologues*. For example, pentane, decane, and octane are homologues. Physical properties in a homologous series, such as melting and boiling points or density, tend to increase smoothly with an increasing number of carbon atoms.

The difference in melting points and boiling points of hydrocarbons, including alkanes, result from *dispersion forces*. The larger the alkane molecules are, the more extensive these dispersion forces become. Hence, hydrocarbons tend to become less volatile with increasing molar mass. As a result, hydrocarbons of very low molecular weight, such as C_2H_6 (bp = −89 °C), are gases at room temperature; those of moderate molecular weight, such as C_6H_{14} (bp = 68 °C), are liquids; and those of high molecular weight, such as $C_{22}H_{46}$ (mp = 44 °C), are solids.

Hydrocarbon molecules such as alkanes are relatively nonpolar because carbon and hydrogen do not differ greatly in their electronegativities. Thus, alkanes dissolve readily in nonpolar solvents but are almost completely insoluble in water.



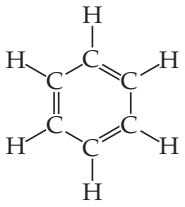
(a) (b) (c)



▶ **Figure 24.2 Applications of alkanes.** Alkanes are very important in our modern society, whether gaseous, liquid or solid. (a) Methane is used as a source of heat. (b) Butane is commonly used in lighter fluid. (c) Candles are traditionally made from waxes, which are long-chain alkanes.

Self-Assessment Exercises

24.4 Which of the following structures represents a saturated aliphatic hydrocarbon?



(a)

(b)

(c)

(d)

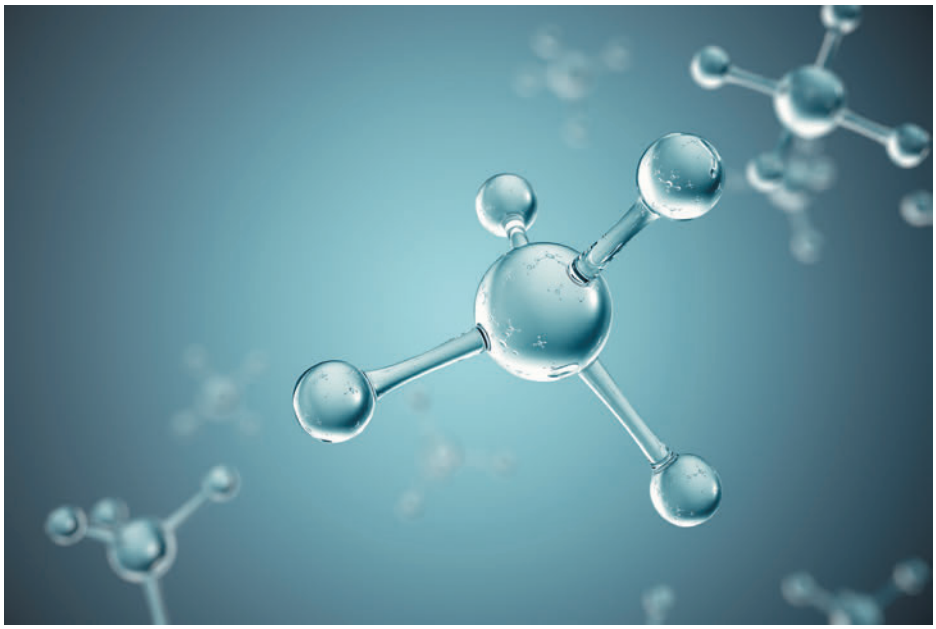
24.5 Which condensed structural formula represents the substance with the highest melting point?

(a) $CH_3CH_2CH_3$
(b) $CH_3CH_2CH_2CH_2CH_3$
(c) $CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$

Exercises

24.6 What can we tell about a compound when we know the empirical formula? What additional information is conveyed by the molecular formula? By the structural formula? Explain in each case using CH_2 as an empirical formula.

24.7 **(a)** What is a hydrocarbon? **(b)** Are all alkanes hydrocarbons? **(c)** Write the structural formula for propane (C_3H_8). **(d)** Butane is an alkane containing four carbon atoms in a line. Write a structural formula for this compound and determine its molecular and empirical formulas.



24.8 **(a)** What ending is used for the names of alkanes? **(b)** *Undecane* is an alkane with all its 11 carbon atoms in one chain. It is used as an attractant to cockroaches. Write a structural formula for this compound and determine its molecular and empirical formulas.

24.9 Rank the following in order of the strength of the London dispersion forces between two or more molecules of the same compound: $CH_3(CH_2)_4CH_3$ (hexane); CH_3CH_2OH (ethanol); $CH_3(CH_2)_{13}CH_2COOH$ (palmitic acid).

Answers to Self-Assessment Exercises

24.3 Structures of Alkanes

So much of understanding in chemistry is based on a blend of the macroscopic, the microscopic, and the symbolic. This is particularly true as we investigate the structure of alkanes. For example, we may seek to explain trends in the boiling points of alkanes. Our starting point is the macroscopic—our observation of the temperature of a boiling liquid. This depends on the microscopic—the type, number, and arrangement of atoms that constitute the alkane; and is aided by the symbolic—how we represent the atoms and the bonding between them.

CHEMISTRY AND LIFE Petroleum Products

Petroleum, also called crude oil, is a complex mixture of organic compounds, mainly hydrocarbons, with smaller quantities of other organic compounds containing nitrogen, oxygen or sulfur. The usual first step in the refining of petroleum is to separate it on the basis of boiling point as shown in **Table 24.4**. Because petrol is the most commercially important of these separated mixtures, called *fractions*, various processes are used to maximize its yield.

Petrol is a blend of volatile hydrocarbons containing alkanes. In a car engine a mixture of air and petrol vapor is compressed by a piston and then ignited by a spark plug. The burning of petrol vapor should create a strong, smooth expansion of gas, forcing the piston outward and imparting force along the drive shaft of the engine. If the petrol vapor burns too rapidly, the piston receives a single hard slam rather than a strong, smooth push. The result is a "knocking" or "pinging" sound and a reduction in the efficiency with which energy produced by the combustion is converted to work.

The octane number of a petrol blend (**Figure 24.3**) is a measure of its resistance to knocking. Petrols with a high octane number burn more smoothly and are thus more effective fuels. The octane number of unleaded petrol is obtained by comparing its knocking characteristics with those of 2,2,4-trimethylpentane (also known as isooctane) and heptane. 2,2,4-Trimethylpentane is assigned an octane number of 100, and heptane is assigned zero. Petrol with the same knocking characteristics as a mixture of 90% isooctane and 10% heptane has an octane rating of 90.

The petrol obtained directly from fractionation of petroleum contains mainly straight-chain hydrocarbons and has an octane number of around 50. It is therefore subjected to processes such as *cracking*, which convert the straight-chain alkanes into more desirable branched-chain and aromatic hydrocarbons (**Figure 24.4**). Cracking is also used to convert some of the less volatile kerosene and fuel-oil fractions into compounds with lower molecular weights that are suitable for use as motor fuel. The octane rating of petrol is also increased by adding aromatic compounds such as toluene ($C_6H_5CH_3$) and oxygenated hydrocarbons such as ethanol (CH_3CH_2OH).

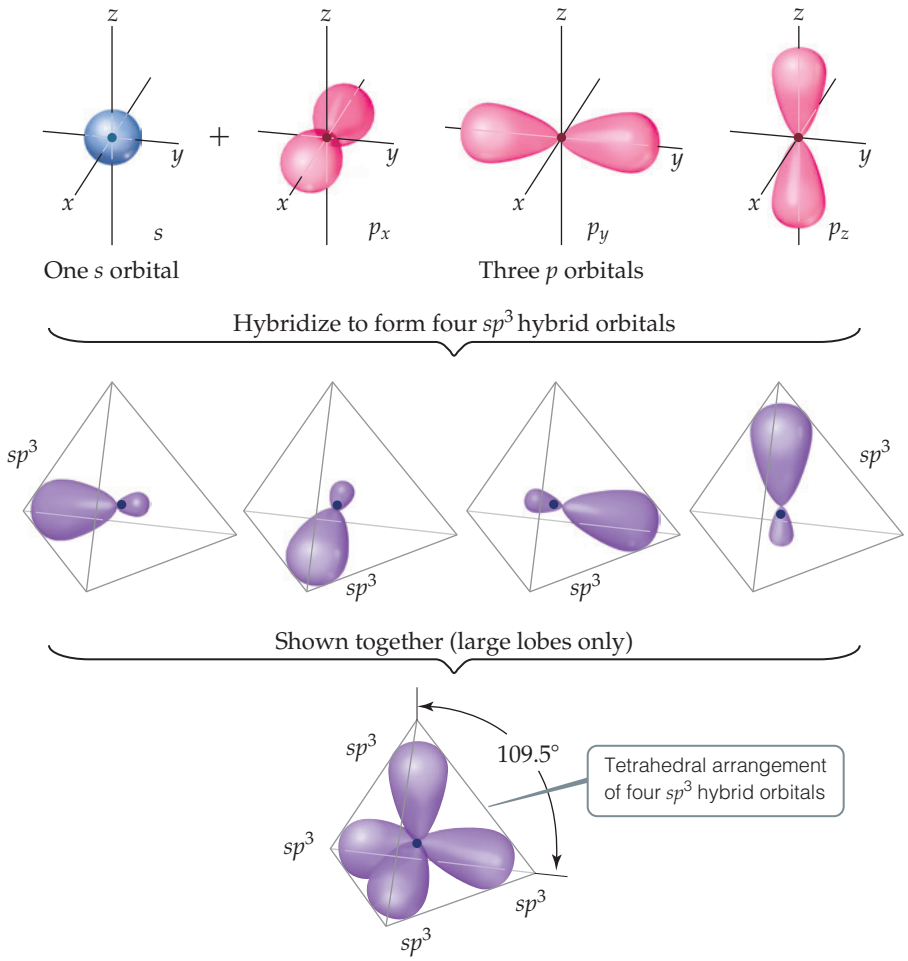
▲ **Figure 24.3 Octane rating.** The octane rating of petrol measures its resistance to knocking when burned in an engine. The octane rating of this petroleum product is 89, as shown on the face of the pump.

▲ **Figure 24.4 Fractional distillation.** Petroleum is separated into fractions by distillation and subjected to catalytic cracking in a refinery.

TABLE 24.4 Hydrocarbon fractions from petroleum

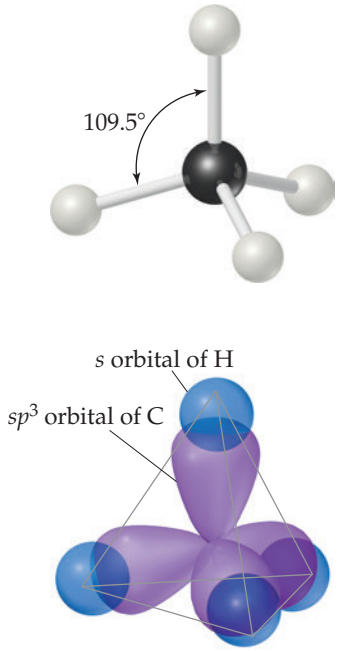
Fraction	Carbon-chain lengths	Boiling-point range (°C)	Uses
Gas	C_1 to C_5	−160 to 30	Gaseous fuel, production of H_2
Petrol	C_5 to C_{12}	30 to 200	Motor fuel
Kerosene, fuel oil	C_{12} to C_{18}	180 to 400	Diesel fuel, furnace fuel, cracking
Lubricants	C_{16} and up	350 and up	Lubricants
Paraffins	C_{20} and up	Low melting solids	Candles
Asphalt	C_{36} and up	Gummy residues	Surfacing roads

By the end of this section, you should be able to



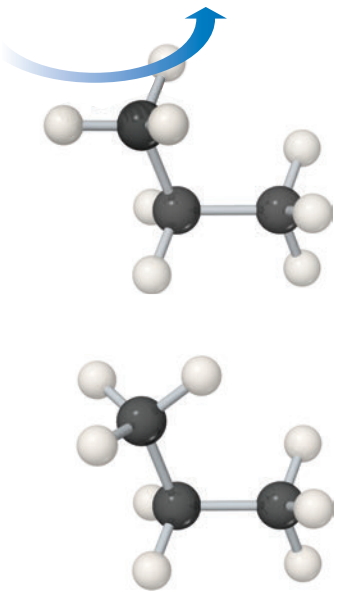
- Identify conformational isomers and recognize they are associated with different relative energies.
- Understand that alkanes with four or more carbon atoms give rise to constitutional isomers.

Recall that earlier in the text we described hybridization as the process of mixing atomic orbitals in a mathematical operation. The newly formed orbitals, called *hybrid orbitals,* are based on the atomic orbitals that constitute them (**Figure 24.5**). Hybridization and valence-bond theory are used predominantly by organic chemists to describe the bonding outcomes for carbon. In essence, the hybrid orbitals are defined by the geometry of the bonds formed by carbon that influence the overall shape and structure of the molecule. Any carbon bearing four single bonds must be tetrahedral and, hence, sp^3 hybridized.



The tetrahedral geometry leads to bond angles of 109.5°, which is the largest possible separation for the four one-electron sp^3 hybrid orbitals in free space. By way of example, the three-dimensional structure of methane can be represented as shown in **Figure 24.6**.

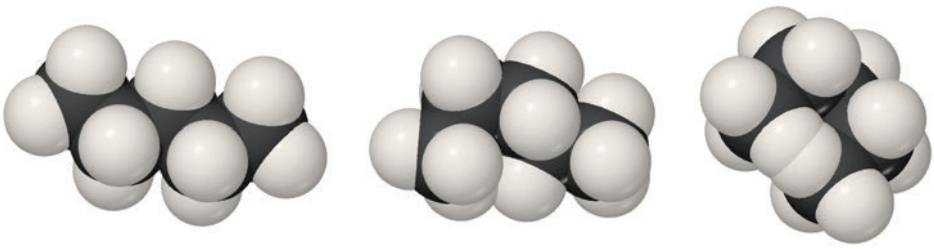
A covalent bond that is formed by the end-to-end interaction of two one-electron orbitals (either atomic, hydridized or a mixture of both), as described in Figure 24.6, is called a sigma (σ) bond.



Go Figure How many atomic orbitals contribute to form the four sp^3 hybrid orbitals?

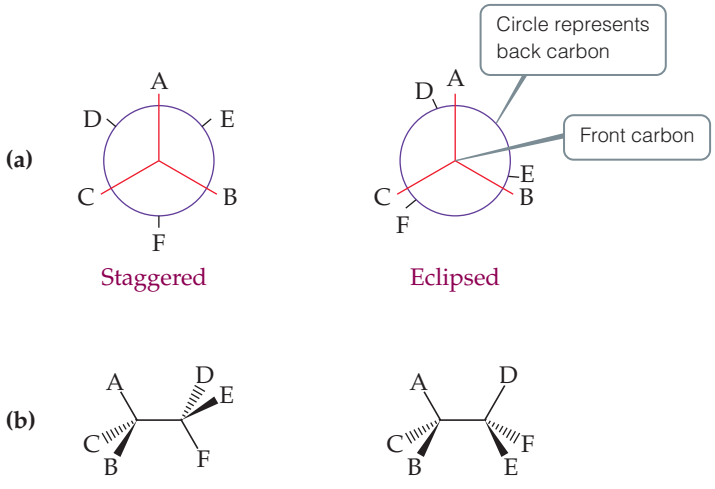
▲ **Figure 24.5 Formation of sp^3 hybrid orbitals.** One *s* orbital and three *p* orbitals can hybridize to form four equivalent sp^3 hybrid orbitals. The large lobes of the hybrid orbitals point towards the corners of a tetrahedron.

▲ **Figure 24.6 Bonds about carbon in methane.** This tetrahedral molecular geometry is found around all carbons in alkanes.

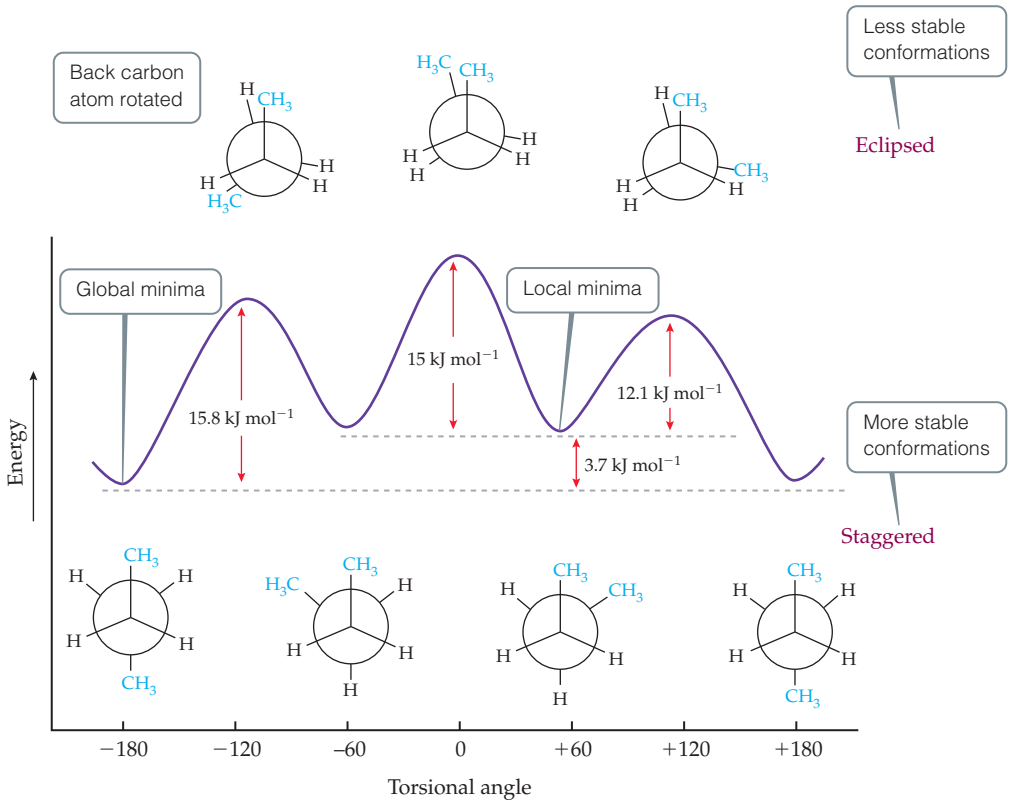


▲ **Figure 24.7 Rotation about a C–C bond occurs easily and rapidly in all alkanes.**

Alkane Shape and Conformations



Although organic molecules are drawn in a static way, remember that they are always dynamic. One of the properties of alkanes is their ability to change shape continuously (Figure 24.7). The three-dimensional arrangement of atoms in a molecule that results from rotation about a single bond is known as a **conformation**. When different conformations of a molecule are compared, they are said to be **isomers** of the same structure. Isomers are two or more compounds with the same molecular formula but different three-dimensional structure. Figure 24.8 illustrates some of the **conformational isomers** (or *conformers*) of pentane. The **Newman projection** shown in Figure 24.9 is a useful way of viewing a molecule and for gaining an idea of its energy relative to other possible conformers. Newman projections are derived by imagining you are looking along the carbon–carbon bond being rotated and comparing the positions of the three groups attached to the front carbon atom with those attached to the back carbon atom.

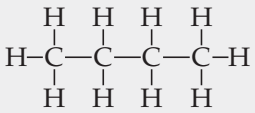


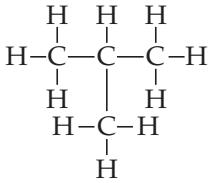
The number of conformational isomers within alkanes containing two or more carbon atoms is infinite because of free rotation about any of the carbon–carbon bonds. Each conformer, however, has a certain amount of energy associated with it. In this regard, there are two conformational isomers that are readily identifiable and usually represent the low and high energy forms. They are called **staggered** and **eclipsed**, and they define the energetic limits of all conformations. Often, a **Newman projection** is used to represent conformers. Here, the two bonded carbon atoms about which rotation will occur are imagined superimposed on one another with the front carbon atom represented as a point and the back carbon atom represented as a circle from which the other bonds associated with these carbon atoms radiate (Figures 24.9 and 24.10). Staggered conformations represent the lowest energy conformation, whereas eclipsed conformations are higher in energy. The difference in energy between the two states is due to added *non-bonded interaction* strain in the eclipsed conformation. This strain is derived from both **steric** (van der Waals interactions) and *torsional* effects, which are a resistance to twisting of the bonds. The magnitude depends on how close neighboring groups become and on the size of the two neighboring groups. For example, hydrogen atoms on adjacent carbons, as in ethane, have minimal but still measurable strain (approximately 12.1 kJ/mol separates the low and high energy conformers).

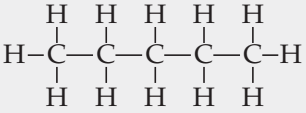
▶ **Figure 24.8 Conformers of pentane.** Rotation about carbon–carbon single bonds can result in noticeable changes in molecular shape.

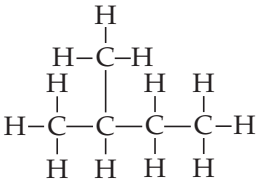
▶ **Figure 24.9 (a) Newman projection.** In the staggered representation the groups attached to the adjacent carbon atoms are arranged as far apart as possible. The eclipsed conformation causes the groups on the adjacent carbon atoms to align one behind the other. By convention, the groups are drawn slightly offset so all may be seen. **(b) Sawhorse representation.** Here the molecule is represented from the side with the bond being rotated viewed as horizontal.

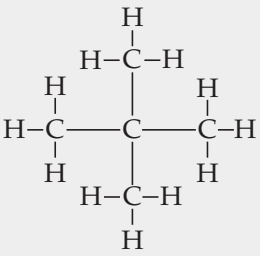
◀ Figure 24.10 Relative energy differences between staggered and eclipsed conformations of butane. Newman projections are used to illustrate the different conformers upon rotation about the C2—C3 bond.











With larger groups, such as bromo, iodo or methyl groups, the strain, and, hence, energy difference, is larger. The vast majority of bonds in acyclic aliphatic alkanes are found in a staggered conformation. The eclipsed conformation represents the activation barrier between two staggered conformations.

Let's now investigate the strain effects for rotation about C2—C3 in butane (Figure 24.10). We will consider the staggered conformation of butane with the lowest energy as a useful starting point. This would be the case where the two methyl (CH_3) groups that terminate the butane chain are as far apart as possible. Make sure at this point that you can identify that this is a Newman projection for butane. Rotation about C2—C3 by 60° yields the first eclipsed conformer. Non-bonding interactions between the methyl groups and hydrogen atoms on the adjacent carbon atom in this eclipsed form strain the molecule making it a slightly less stable arrangement of atoms (by 15.8 kJ/mol) and giving a higher-energy conformer. A further rotation of 60° relieves the strain somewhat but, in doing so, the two methyl groups are able to interact weakly making it less stable by 3.7 kJ/mol than the staggered conformer we started with, so that a *local* energy minimum is reached. Rotation of the C2—C3 bond by another 60° causes the two methyl groups to interact strongly, forming the conformer with the highest relative energy (15.8 kJ/mol above our starting point). Note that, although the hydrogen atoms also contribute to the overall energy, it is the methyl interactions that dominate in this case. Any further rotation from this point mirrors the structures that have already been discussed. Finally, the methyl groups are again opposed, resulting once more in the orientation that yields the minimum energy conformation (sometimes referred to as the *global* minimum).

Constitutional/Structural Isomers

The alkanes listed in Table 24.3 are *straight-chain aliphatic hydrocarbons* because all the carbon atoms are joined in a continuous chain. Alkanes consisting of four or more carbon atoms can also have branched chains and are called *branched-chain alkanes*. **Table 24.5** shows space-filling models, full structural formulas and condensed structural formulas for all the possible structures of alkanes containing four or five carbon atoms. Note that the molecular formula for a branched alkane *is the same* as for a straight-chain alkane with the same number of carbon atoms.

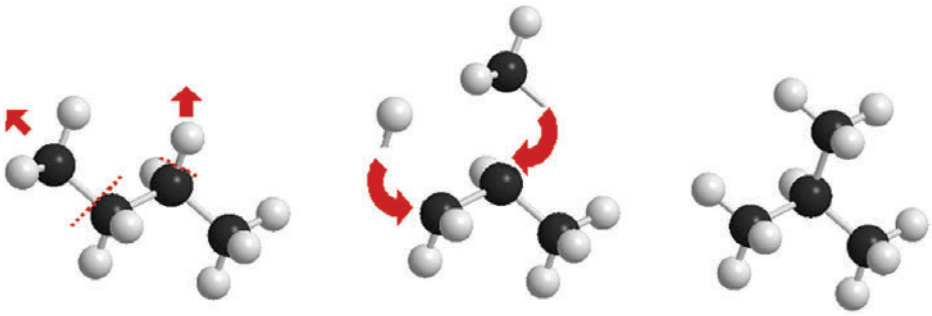


TABLE 24.5 Isomers of C_4H_{10} and C_5H_{12}

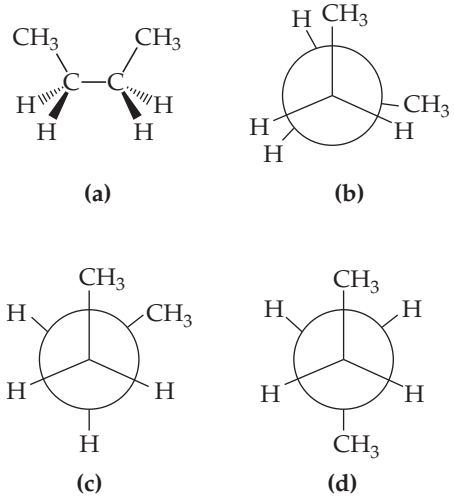
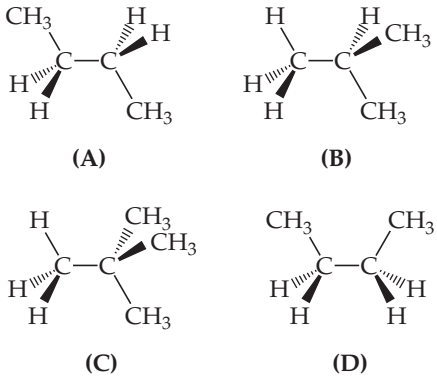
Systematic name (common name)	Structural formula	Condensed structural formula	Space-filling model	Melting point (°C)	Boiling point (°C)
Butane (*n*-butane)		$CH_3CH_2CH_2CH_3$		−138 °C	−0.5 °C
2-Methylpropane (isobutane)		$CH_3{-}CH(CH_3){-}CH_3$		−159 °C	−12 °C
Pentane (*n*-pentane)		$CH_3CH_2CH_2CH_2CH_3$		−130 °C	+36 °C
2-Methylbutane (isopentane)		$CH_3{-}CH(CH_3){-}CH_2{-}CH_3$		−160 °C	+28 °C
2,2-Dimethylpropane (neopentane)		$C(CH_3)_4$		−16 °C	+9 °C

As we saw in Chapter 23, compounds with the same molecular formula but with different bonding arrangements (and hence different structures) are called **structural** or **constitutional isomers**).

This is easily envisaged if you think of alkanes as a series of building blocks made up of C, CH, CH_2 and CH_3 groups. Figure 24.11 demonstrates the principle. Converting one constitutional isomer into another requires the breaking and making of bonds (unlike conformational isomers). Consequently, constitutional isomers are not easily interconverted at room temperature and may be separated from one another.



Constitutional isomers of a given alkane differ slightly from one another in physical properties. Note the melting and boiling points of the constitutional isomers of butane and pentane given in Table 24.5. These melting and boiling points are a measure of the energy needed to overcome weak and favourable interactions that give rise to the solid or liquid properties, respectively. The variation in melting and boiling points for a set of constitutional isomers is a result of the subtleties of molecular interactions. The number of possible constitutional isomers increases rapidly with the number of carbon atoms in the alkane. There are 18 possible constitutional isomers with the molecular formula C_8H_{18}, for example, and 75 possible isomers with the molecular formula $C_{10}H_{22}$.



◀ **Figure 24.11 Constitutional isomers of butane.** If we were to remove a terminal (end) carbon unit in butane and attach it to the middle remaining carbon, a structure different from the initial straight chain of butane would be obtained. The connectivity changes, but the molecular formula is exactly the same. There are still four carbons within the molecule and, if we were to complete the structure again, there would still be 10 hydrogens to include. The two structures differ not only in their shape but also in their physical and chemical properties.

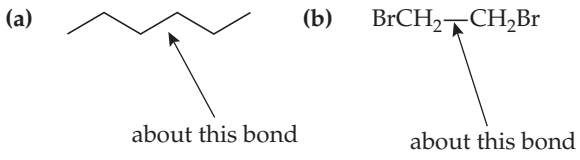
Self-Assessment Exercises

24.10 Which structure represents the lowest energy conformation of butane, C_4H_{10}?

24.11 What is the relationship between the following pairs of structures?

(a) Structures **A** and **B** are constitutional isomers.
(b) Structures **A** and **C** are conformational isomers.
(c) Structures **A** and **D** are constitutional isomers.

Exercises

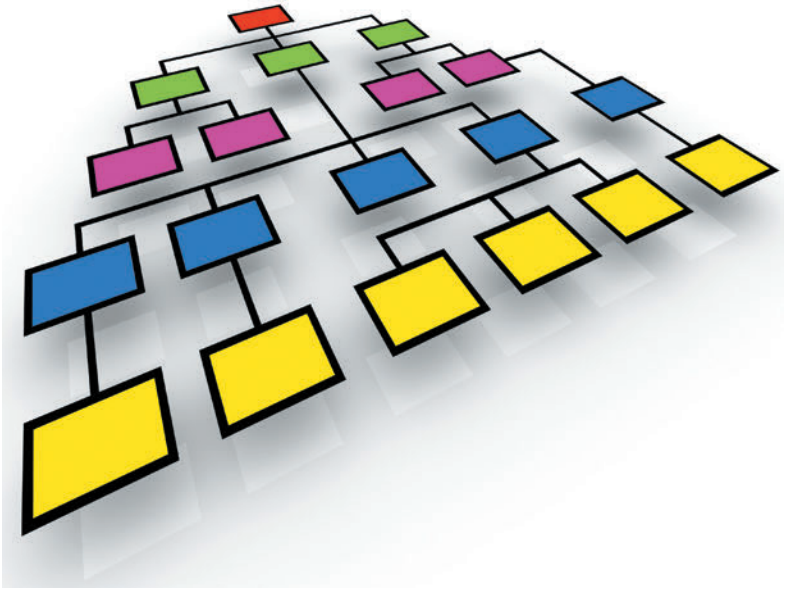


24.12 Draw representations of the following orbitals: s, p_x, p_y, p_z. How do they relate to an sp^3 hybrid orbital?

24.13 How many constitutional isomers are possible for hexane (C_6H_{14})? Draw them.

24.14 Distinguish between constitutional and conformational isomers using butane as an example.

24.15 Draw Newman projections for the most stable and least stable conformers of propane.



24.16 Using Newman projections, draw the most stable staggered form of the following compounds:

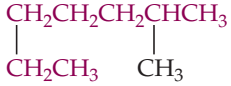
24.4 | Alkane Nomenclature

We can imagine a hierarchy of information which gives increasing detail about a substance—the empirical formula being the most basic bit of information all the way up to a name that uniquely describes a compound.

The need for a common "language" to name molecules was recognized early in the history of organic chemistry. In 1892, the International Union of Chemistry met in Geneva, Switzerland, to formulate a set of rules for systematically naming organic substances. Since that time, the task of updating the rules for naming all compounds has fallen to the International Union of Pure and Applied Chemistry (IUPAC). Chemists everywhere, regardless of their nationality or political affiliation, subscribe to a common system for naming compounds. This naming process, called **nomenclature**, provides a systematic way to define unambiguously which atoms are bonded to one another within a molecule and to be able to communicate the structure of a compound in writing.

By the end of this section, you should be able use systematic nomenclature to:

- Convert between the name and structure of a simple alkane.



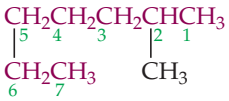
Constitutional isomerism complicates how we might describe organic molecules since a description based solely on molecular formulas is not nearly enough. Apart from ethane and propane, a number of different structures can be obtained from the same molecular formula. All of this means that we need a systematic means of naming organic compounds.

The IUPAC names for the isomers of butane and pentane are given in Table 24.5. These names, as well as those of other organic compounds, have three parts to them:

Prefix – Parent – Suffix

The following steps summarize the procedures used to arrive at the names of alkanes, all of which end with the suffix *-ane*. The prefix relates to the number, type and position of substituents (for example, the prefix 2,3-dibromo would indicate the compound contains two bromine atoms attached at positions 2 and 3). The parent name indicates the number of carbon atoms within the longest chain (for example, *eth* = two carbons, *pent* = five carbons). We use a similar approach to writing the names of other organic compounds and we develop a further understanding of organic nomenclature in Chapters 25–31.

In order to understand the steps to derive an appropriate nomenclature, let's examine how we would name the following compound:



1. ***Find the longest continuous chain of carbon atoms and use the name of this chain (Table 24.3) as the base name of the compound.***

   Because this compound's longest chain is made up of seven C atoms (colored), it is named a substituted heptane (see Table 24.3). Groups attached to the main chain are called *substituents* because they are in substitution of a hydrogen atom on the main chain.

2. ***Number the carbon atoms in the longest chain, beginning with the end of the chain that is nearest to a substituent.***

   In our example, we number the C atoms from the right because that places the CH_3 substituent on the second C atom of the chain; if we number from the lower left, the CH_3 would be on the sixth C atom. The chain is numbered from the end that gives the lowest combined number for all substituent positions.

3. ***Name and give the location of each substituent group.***

   A substituent group that is formed by removing a hydrogen atom from an alkane is called an **alkyl group**. We have already been informally introduced to this nomenclature. Alkyl groups are named by replacing the *-ane* ending of the alkane name with *-yl*. Table 24.6 lists the three simplest alkyl groups.

   The name of our example is 2-methylheptane. Note the hyphen after the number. Note also that there is *no* space, comma or hyphen between methyl and heptane. The name should also allow you to draw the structure using these same three simple steps.

4. ***Where two or more substituents are present, list them in alphabetical order, ignoring multiplying prefixes.***

   Where there are two or more of the same substituent, the number of substituents of that type is indicated by a prefix: *di-* (two), *tri-* (three), *tetra-* (four), *penta-* (five)

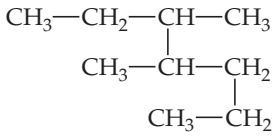


TABLE 24.6 Naming simple alkyl substituents

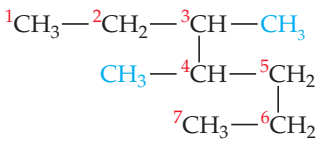
Substituent	Substituent name
CH_3	*methyl*
CH_3CH_2	*ethyl*
$CH_3CH_2CH_2$	*propyl*

Sample Exercise 24.1

Naming alkanes

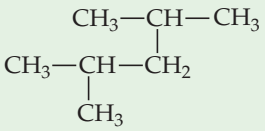
Give the systematic name for the following alkane



SOLUTION

Analyze We are given the condensed structural formula of an alkane and asked to give its name.

Plan Because the hydrocarbon is an alkane, its name ends in *-ane*. The name of the parent hydrocarbon is based on the longest continuous chain of carbon atoms. Branches are alkyl groups, named after the number of C atoms in the branch and located by counting C atoms along the longest continuous chain.



Solve The longest continuous chain of C atoms extends from the upper left CH_3 group to the lower left CH_3 group and is seven C atoms long:

The parent compound is thus heptane. There are two methyl groups branching off the main chain. Hence this compound is a dimethylheptane. To specify the location of the two methyl groups, we must number the C atoms from the end that gives the lower two numbers to the carbons bearing side chains. This means that we should start numbering at the upper left carbon. There is a methyl group on C3 and one on C4. The compound is thus 3,4-dimethylheptane.

Practice Exercise

Name the following alkane:

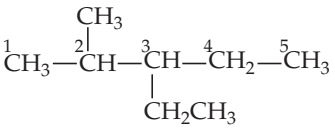
Sample Exercise 24.2

Writing condensed structural formulas

Write the condensed structural formula for 3-ethyl-2-methylpentane.

SOLUTION

Analyze We are asked to draw the molecular structure of an organic compound from its systematic name.



Plan First we need to determine the classification of the organic compound, then work backwards from the parent compound, adding in functionality and side groups.

Solve Because the compound's name ends in *-ane*, it is an alkane, meaning that all the carbon–carbon bonds are single bonds. The parent hydrocarbon is pentane, indicating five C atoms (Table 24.3). There are two alkyl groups specified, an ethyl group (two carbon atoms, C_2H_5) and a methyl group (one carbon atom, CH_3). Counting from left to right along the five-carbon chain, the ethyl group will be attached to the third C atom and the methyl group will be attached to the second C atom.

We begin by writing a string of five C atoms attached to each other by single bonds. These represent the backbone of the parent pentane chain:

C—C—C—C—C

We next place a methyl group on the second C and an ethyl group on the third C atom of the chain. Hydrogens are then added to all the other C atoms to make the four bonds to each saturated carbon, giving the following condensed structure:

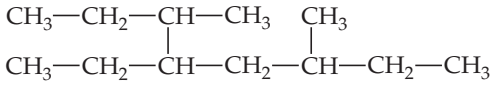
The formula can be written even more concisely in the following style:

$$CH_3CH(CH_3)CH(CH_2CH_3)_2$$

In this formula the branching alkyl groups are indicated in parentheses.

Practice Exercise

Write the condensed structural formula for 2,3-dimethylhexane.



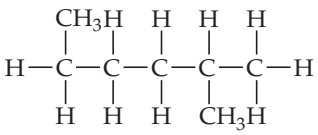
and so on. The position of each substituent is separated by a comma (for example, 2,3-dibromopentane). In the case where substituents are different, each prefix is separated from the next by a hyphen. Substituents are also listed alphabetically (ethyl, methyl, propyl and so on). Notice how the following example is named (and numbered):

for numbering because *4-ethyl-2,5-dimethylheptane* gives a lower numbering than *4-ethyl-3,6-dimethylheptane* does.

Self-Assessment Exercise

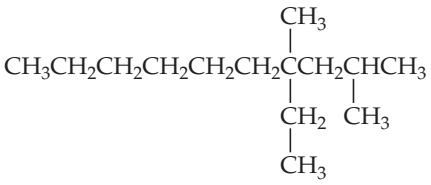
24.17 What is the systematic name of the following structure?

(a) 3-butyl-5-methylheptane
(b) 3-methyl-5-butylheptane
(c) 4-ethyl-3,6-dimethyloctane
(d) 5-ethyl-3,6-dimethyloctane



Exercises

24.18 What is the chemical formula of the propyl group?

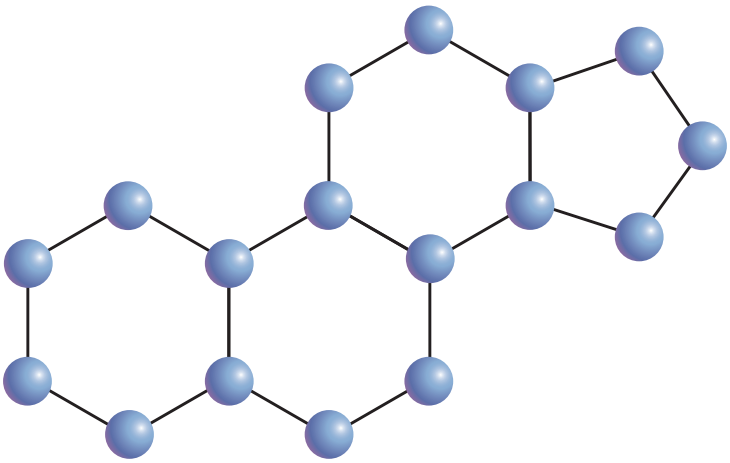


24.19 Draw all possible isomers of C_5H_{12}. Systematically name each compound.

24.20 Draw the structural formula or give the IUPAC name, as appropriate, for the following:

(a)

(b)



(c) 3-methylhexane
(d) 4-ethyl-2,2-dimethyloctane
(e) methylcyclohexane

24.21 What do ethane, ethanol, and ethylene have in common with respect to their nomenclature? What can you infer about the number of carbon atoms in each compound?

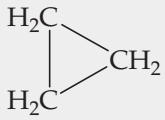
Answers to Self-Assessment Exercise

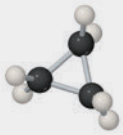
24.17 (c)

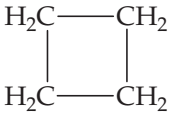
24.5 | Cycloalkanes

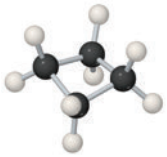
Gonane

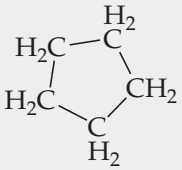
We saw in Section 24.3 that we don't need many carbon atoms before it is possible to arrange them in a number of different ways, called constitutional isomers. Another way to arrange a chain of carbon atoms is in a ring, called a cyclic compound. For a given number of carbon atoms, the formula of the chain form and the ring form differ in the number of hydrogen atoms present, so the two forms are not classed as isomers but are distinct compounds, albeit closely related ones. The structure of gonane, with four rings fused together, is the core structure on which steroids are built, which are essential for many regulation and growth processes in living cells. By the end of this section, you should be able to

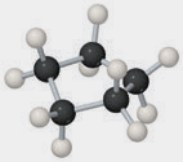


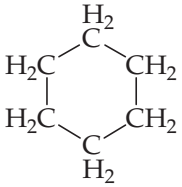


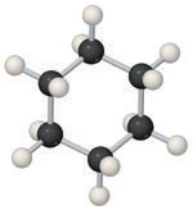


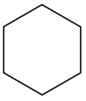












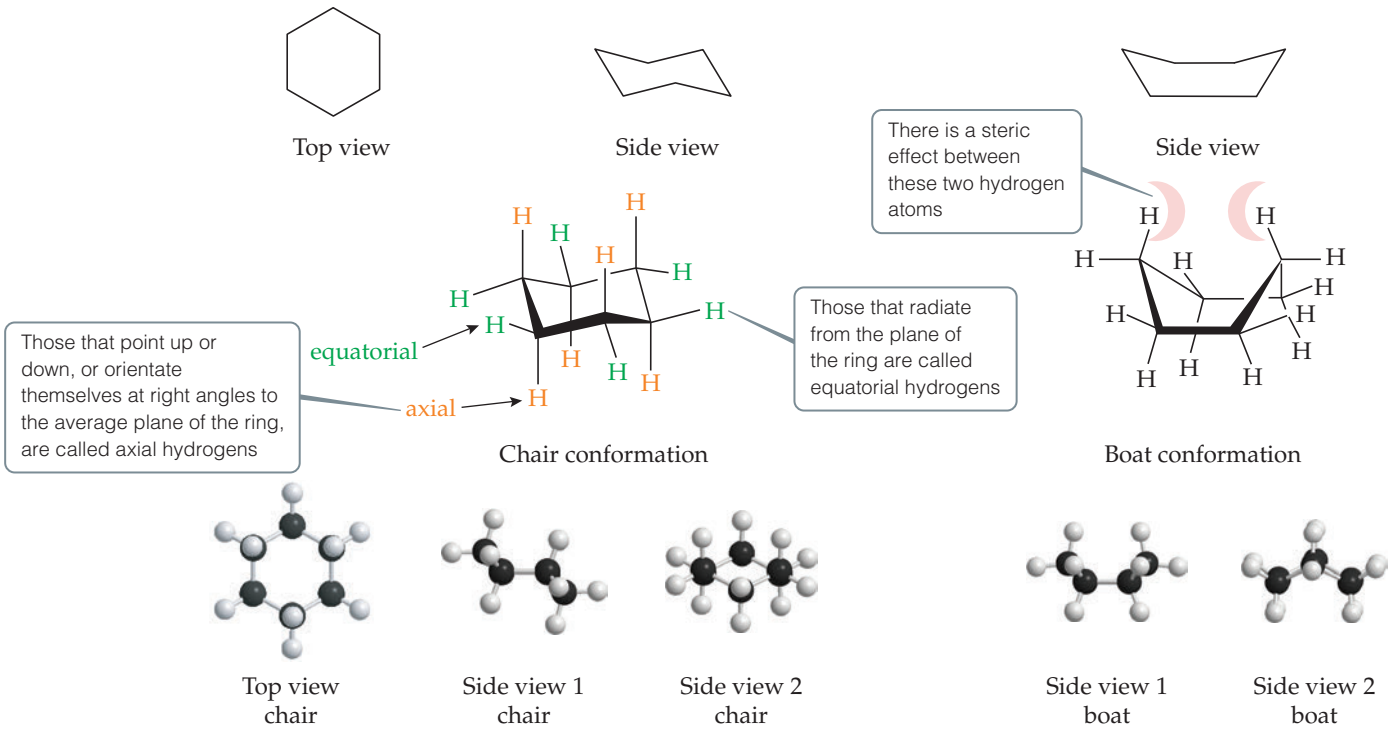
- Interpret a line drawing of a cyclic structure
- Recognize the difference between the two major conformations of cyclohexane

Hydrocarbons can form not only straight and branched chains but also rings, or cycles. Alkanes with this latter form of structure are called **cycloalkanes**. Cycloalkanes are formed by the loss of two C—H bonds and the formation of a C—C bond from the equivalent aliphatic alkane structure. As such, the general molecular formula for a cycloalkane differs from that of an alkane by two hydrogen atoms.

$$C_nH_{2n} \qquad [24.2]$$

Table 24.7 illustrates a few simple cycloalkanes. Cycloalkanes containing from three to more than 30 carbon atoms are known. The most common forms contain five- (cyclopentane) and six- (cyclohexane) membered rings. Hydrocarbon rings containing fewer than five carbon atoms are strained because the C—C—C bond angle in these

TABLE 24.7 Cycloalkanes



Cycloalkane	Structural formula	Ball-and-stick representation	Line drawing
Cyclopropane			
Cyclobutane			
Cyclopentane			
Cyclohexane			

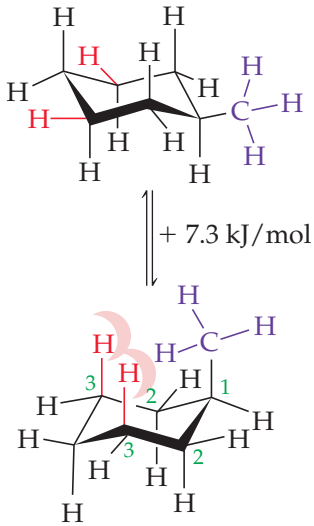
smaller rings must be much less than the 109.5° angle expected for an sp^3 hybridized atom. The amount of *ring strain* increases as the ring size gets smaller than that for cyclohexane. In cyclopropane, which has the shape of an equilateral triangle, the angle is only 60°; as a result, this molecule is much more reactive than propane, its straight-chain analogue.

Apart from model and structural formula representations, Table 24.7 also demonstrates how cycloalkane structures can be drawn as simple polygons in which each corner of the polygon represents a CH_2 group and each side represents a C—C single bond. The hydrogen atoms are still present in this *line drawing* representation—we just don't include them in the drawing. When using this representation for cycloalkanes, however, remember that you are drawing a three-dimensional structure in two dimensions and that, as a consequence, geometric subtleties are lost. In fact, cycloalkane rings with four or more carbons are not planar.

To illustrate this point, consider the structure of cyclohexane as shown in **Figure 24.12**. Looking at the structure from the top certainly gives the same hexagonal shape as represented by a line drawing. However, the view from any side tells a different and more complicated story. Two major conformations for cyclohexane are known, and they both allow bond angles of about 109.5° to be realized. The **chair conformation** is the more stable of the two types of conformers. It is called a chair structure because of its resemblance to a chair. In this case, the hydrogen atoms adopt one of two orientations. Those that point up or down, or orientate themselves at right angles to the average plane of the ring, are called **axial hydrogens**; those that radiate from the plane of the ring are called **equatorial hydrogens**. Substituents at these positions are also described in the same way. Note that

Go Figure In which conformation of cyclohexane are neighboring hydrogens staggered and in which are they eclipsed?

▲ **Figure 24.12** **Conformations of cyclohexane.**



all bonds on adjacent carbons in cyclohexane are staggered, implying that in any given hemisphere the hydrogens alternate between axial and equatorial.

The less stable of the two forms (by about 30 kJ/mol) is described as the **boat conformation**. Its relative instability is caused by the non-bonding interactions generated by the close proximity of the two hydrogen atoms on C1 and C4 that overhang the ring system in this conformation (Figure 24.12), and by the eclipsing of hydrogens along the C2–C3 and C5–C6 bonds.

Now let's consider the effect of placing a single substituent on a cyclohexane ring. The substituent has two possible orientations, axial or equatorial. The two conformers do interconvert but the equatorial conformation is preferred because the methyl group experiences destabilising **1,3-diaxial interactions** with the other two axial hydrogens on that face (**Figure 24.13**) if it is axial. These types of interactions are minimized in the equatorial conformation as the methyl group and, more importantly, the hydrogen atoms on that methyl group point away from the ring system.

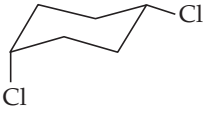
We do not need to number the position of the substituent for a cycloalkane with only one substituent, nor do we need to define the conformation as either *ax* (for axial) or *eq* (for equatorial). For example, both structures in Figure 24.13 are called methylcyclohexane, as this name is suitable enough to avoid ambiguity.

The concept of geometrical isomerism was introduced in Section 23.4 for coordination compounds. We will investigate the concept of *geometrical isomerism* in cycloalkanes in Chapter 25. Geometrical isomers occur in cycloalkanes when two or more substituents are found around the ring in axial, equatorial or both positions. Geometrical isomers differ in their physical properties and spatial orientation.

▲ **Figure 24.13** **1,3-Diaxial repulsion.** Substituents placed in an axial conformation interact strongly with the two axial hydrogens (red), destabilising this conformer relative to the equivalent equatorial conformer.

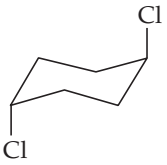
Self-Assessment Exercises

24.22 What is the molecular formula of the following structure?

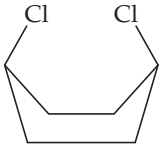


(a) C_6H_{14} **(b)** C_7H_{14} **(c)** C_7H_{16} **(d)** C_8H_{16}

24.23 Which structure represents the most stable conformer of 1,4-dichlorocyclohexane?



(a)



(b)

(c)

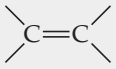
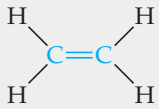
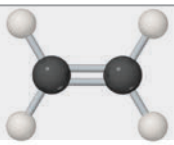
24.6 | Organic Functional Groups

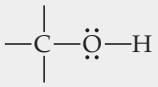
The wealth of variety in organic chemistry results from the combination of a vast number of ways that carbon chains and rings may be constructed, punctuated by a selection of functional groups. These form the reactive part of the molecule and are given special attention, rather like an ace in a card game. By the end of this section, you should

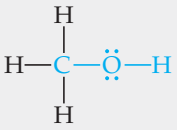
- Be able to identify the common functional groups present in organic molecules.

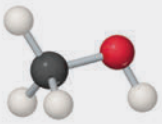


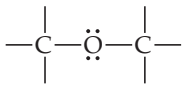


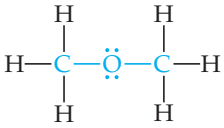


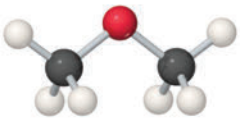


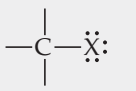


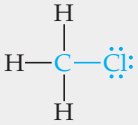


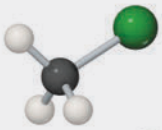


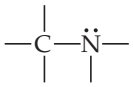


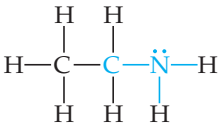


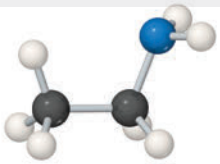


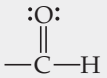


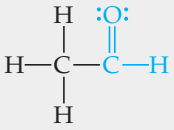


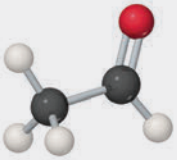


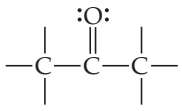


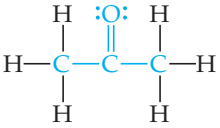


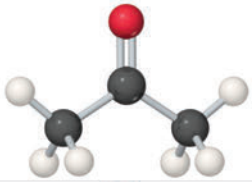


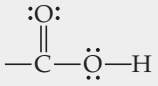


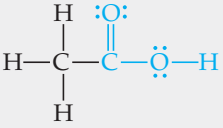


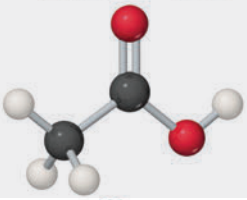


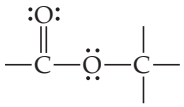


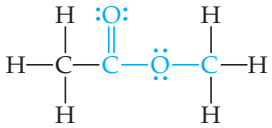


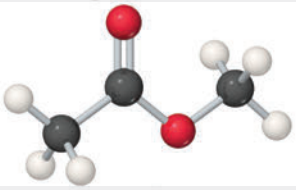


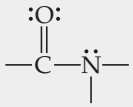


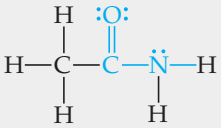


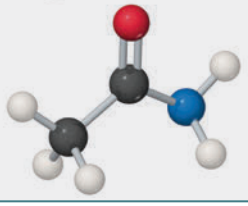








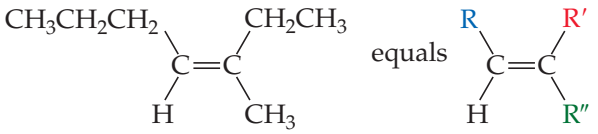




The reactivity of organic compounds can be attributed to particular atoms or groups of atoms within the molecule. A site of reactivity in an organic molecule is called a **functional group** because it characteristically controls how the molecule behaves, or functions under a given set of conditions. Functional groups define both the reactivity and class descriptions of organic molecules. As we will see in, the presence of carbon–carbon double or triple bonds in a hydrocarbon will markedly increase that compound's reactivity. Furthermore, these two functional groups undergo similar yet characteristic reactions. The same is true of other functional groups. Each distinct kind of functional group often undergoes the same kinds of reactions, regardless of the size and complexity of the molecule. Thus the chemistry of an organic compound is largely determined by the functional groups it contains.

Table 24.8 lists the most common functional groups and gives examples of each. Notice that, in addition to carbon–carbon double bonds or carbon–carbon triple bonds, there are also many functional groups that contain elements other than just C and H. In fact, many of the functional groups found within organic molecules contain other non-metals such as O and N. In later chapters we examine the structure and chemical properties of important functional groups containing oxygen, that is, alcohols and ethers (Chapter 27), aldehydes and ketones (Chapter 28), carboxylic acids and esters (Chapter 29) and those containing nitrogen, such as amines and amides (Chapter 31).

Alkane groups constitute the less reactive portions of any compound and so are typically abbreviated to the symbol "R". In describing the general features of organic compounds, chemists often use the designation R to represent any structural group: methyl, ethyl, propyl and so on (**Figure 24.14**); or, in fact, to represent a collective of atoms that do not participate in the reaction of interest. Alkanes, for example, which contain no functional group, are represented as R—H. **Alcohols**, which contain —OH, the alcohol functional group, are represented as R—OH. If two or more different structural groups are present in a molecule, we designate them R, R′, R″ and so forth.



In organic chemistry, a **heteroatom** is defined as an atom other than hydrogen or carbon. Of the different types of heteroatoms associated with a hydrocarbon skeleton,

TABLE 24.8 Common functional groups

Functional group	Compound type	Suffix or prefix	Example: Structural formula	Example: Ball-and-stick model	Example: Systematic name (Common name)
	Alkene	*-ene*			Ethene (Ethylene)
	Alkyne	*-yne*			Ethyne (Acetylene)
	Alcohol	*-ol*			Methanol (Methyl alcohol)
	Ether	*ether*			Dimethyl ether
 (X = halogen)	Haloalkane	*halo-*			Chloromethane (Methyl chloride)

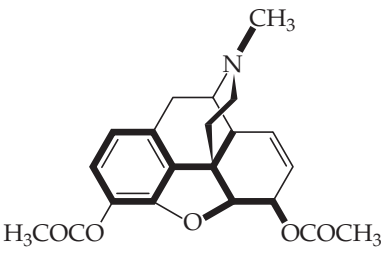
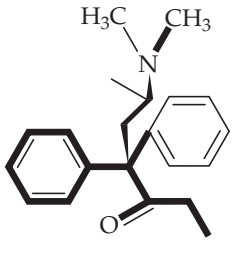
◀ **Figure 24.14** **The generalizations of organic chemistry.**

oxygen is the most prevalent. For oxygen to be added to a hydrocarbon, oxidation must occur. Because our atmosphere contains approximately 21% oxygen, oxidation reactions are always happening, and not only in the process of rusting. Carbon dioxide, water and most free radicals contain oxygen. Simple molecules containing oxygen, such as alcohols, are easily transformed into alkenes, haloalkanes, ethers, aldehydes and ketones and carboxylic acids and their derivatives. For the rest of this chapter we will investigate some of the common reactions used to functionalize alkanes.

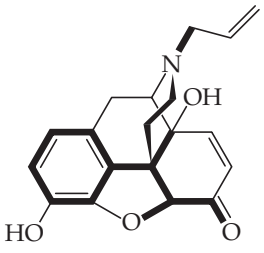


CHEMISTRY AND LIFE Structure–Activity Relationships

Medicinal chemistry research to find the best molecule to elicit a particular response in the body often involves "structure-activity" relationships. This requires synthesizing a range of similar molecules and testing them to see if a small structural difference makes them more or less active in a particular cell culture. Sometimes, molecules that at first sight look different, may adopt a similar shape when twisted into a particular conformation. The advent of sophisticated 3-D modeling of structures has helped identify similarities between molecules.



Each of the following molecules has a similar structural element highlighted in bold. Morphine is extracted from the opium poppy and is used in the management of extreme pain. It works by acting on the central nervous system, blocking pain but allowing most nerve activity to continue. One side effect of its use is drowsiness. Indeed, the name morphine is derived from Morpheus, the Greek god of dreams. The conversion of the alcohol functional groups into ester groups generates the compound heroin. This compound has been used as a recreational drug as it gives the user a feeling of euphoria. However, it is also devastatingly addictive and users quickly become physically dependent on it. Methadone is prescribed as a way of regulating, and ultimately reducing, heroin addiction. It is an *agonist*, which means that it binds to the opioid receptors in the brain and causes a response similar to that of heroin but one that is easier to control. In the case of a heroin overdose, an *antagonist*, naloxone, is used. This molecule binds strongly to the opioid receptors, displacing heroin, but does not cause any opioid response, so reversing the effect of the heroin. It is likely to precipitate withdrawal symptoms such as chills, sweating, stiffness, cramps, and anxiety.

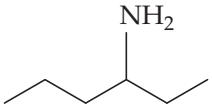


Morphine

Heroin

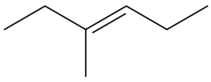
Methadone

Naloxone

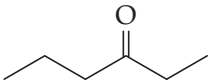


Self-Assessment Exercise

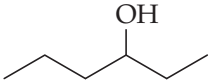
24.30 Identify the functional groups in morphine



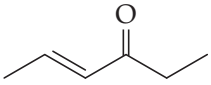
(a) alkene, amide, ether, ketone
(b) alcohol, alkyne, amine, ketone
(c) aldehyde, alkene, amide, ether
(d) alcohol, alkene, amine, ether



Exercises

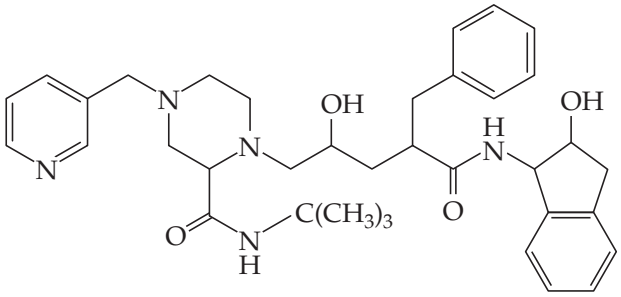


24.31 Circle the functional groups in each of the following compounds:



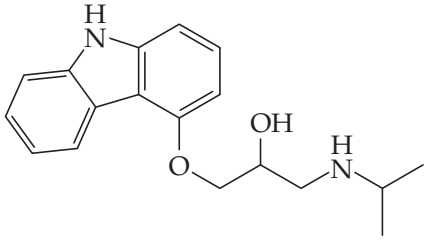
(a) 

(b) 



(c) 

(d) 



(e)

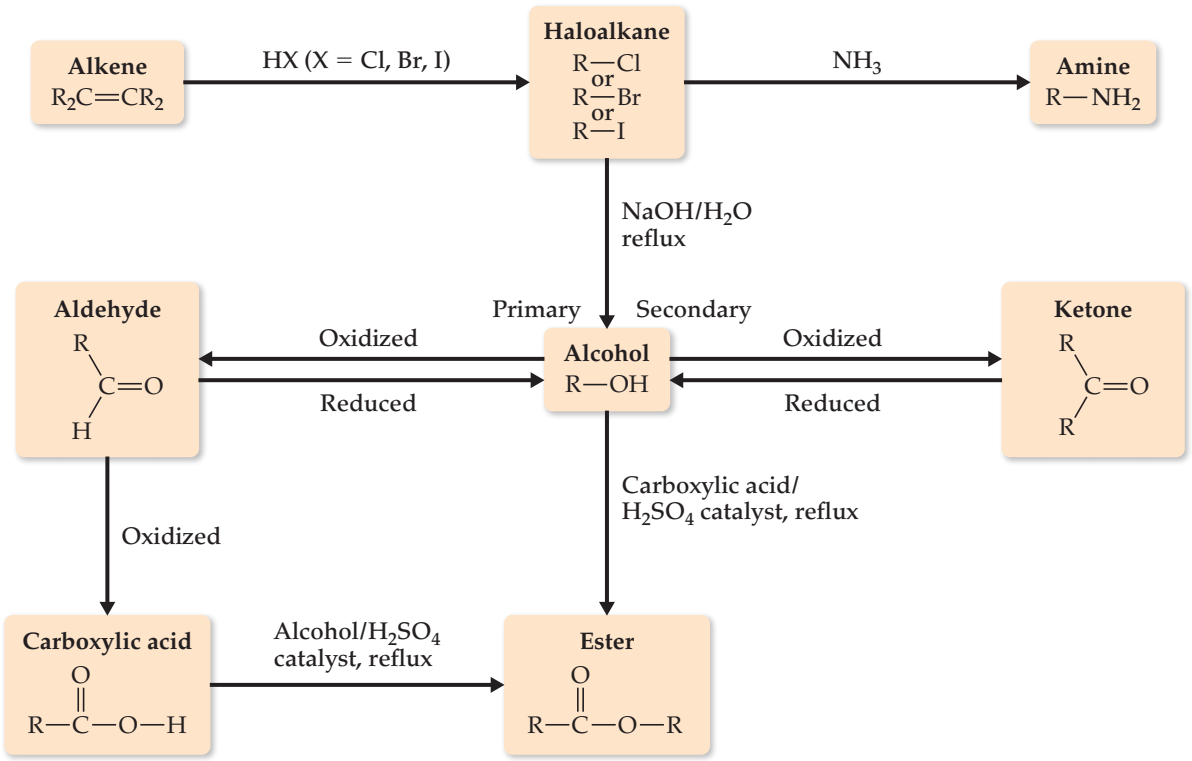
24.30 (d)

24.7 Reactions of Alkanes

The starting point for many of the manufactured materials that surround us is a combination of crude oil and natural gas that feeds the petrochemical industry. Here, it is transformed into a myriad of products that ultimately end up as polymers, plastics, synthetic fibres, solvents, glues, pharmaceuticals, paints, and fertilizers to name just a few items. In 2020, the industry was estimated to be worth USD 476 billion. While the processes used

in the industry may be rather different to those in the research laboratory, in both cases, the basic type of reactions are the same and involve the dozen functional groups that are the foundation of organic chemistry. By the end of this section, you should



- Be able to identify primary, secondary, and tertiary carbon and hydrogen atoms
- Understand the mechanism of a free-radical polymerization reaction

Alkanes contain only C—C and C—H bonds and as a result are relatively unreactive. At room temperature, for example, alkanes do not react with any common acids, bases or strong oxidizing agents, and they are not even attacked by boiling nitric acid. Their low chemical reactivity is due primarily to the strength and lack of polarity of both C—C and C—H single bonds. The whole basis of organic chemistry—that is, converting one functional group into another by making or breaking bonds, leading to the formation of new compounds (**Figure 24.15**)—would fall apart if C—H and C—C bonds reacted under mild conditions. Essentially, organic molecules are composed of an inert hydrocarbon framework punctuated by functional groups, which are the reactive parts of the molecule. Functional groups not only define the reactivity but also the classes of organic molecules.

The following chapters show that hydrocarbons can be modified to impart greater reactivity by introducing unsaturation into the carbon–carbon framework and by attaching other reactive functional groups to the hydrocarbon backbone.

Combustion

Alkanes are not completely inert, however. Their relative high stability means that either harsh reaction conditions or the use of highly reactive reagents is needed to initiate a chemical reaction. One of the most commercially important reactions of alkanes is their **combustion** reaction in air, which is the basis of their use as fuels. The complete combustion of an alkane in the presence of oxygen *always* generates carbon dioxide and water

▲ **Figure 24.15 Functional group interconversion.** Functional groups are atoms or groups of atoms within a molecule that show a characteristic set of chemical properties. Some of the more common functional groups and their interconversion are shown. The functional group is the center of reactivity in an organic molecule. R = general representation for the rest of the molecule. *Note that the basic hydrocarbon framework is unchanged in these reactions.*

▲ **Figure 24.16 Combustion.** Ignition of a mixture of oxygen with flammable gases such as hydrogen or methane can have explosive consequences.

as the products of the reaction. For example, the balanced equation for the complete combustion of ethane is:

$$2\,C_2H_6(g) + 7\,O_2(g) \rightarrow 4\,CO_2(g) + 6\,H_2O(l) \quad \Delta H = -2855\ kJ \qquad [24.3]$$

The reaction of any organic molecule with oxygen is another example of an **oxidation** reaction. We investigate these types of reactions in the context of organic chemistry in greater detail in Chapter 28.

We know from calorimetric measurements that the reaction of a simple alkane such as methane (CH_4) with oxygen is highly exothermic (Section 14.4). Indeed, the combustion of methane (which is the major component of natural gas) keeps many of our homes warm during the winter months. Although the reactions of alkanes with oxygen are exothermic, most alkanes are stable indefinitely at room temperature in the presence of air because the activation energy required for combustion is large. This activation barrier is usually overcome by heat generated from a flame or spark, typically with explosive consequences (**Figure 24.16**).

Classification of C and H

An important skill to develop in organic chemistry is the ability to recognize which functional group within a molecule will react under a given set of conditions. This ability allows the organic chemist to synthesize very complex molecules. Sometimes, however, there is a choice of positions within a molecule at which reaction is likely to occur. This is as valid with simple organic molecules, like alkanes, as it is for highly complex molecular structures. Before going on to discuss one of the few important reactions of the alkanes, we need to have a way of distinguishing between the different kinds of carbons that appear. These classifications are important whenever we are trying to recognize which functional group or part of a molecule will react.

The classification used to distinguish between types of hydrogens and carbons and the appropriate symbolism is:

Primary (1°) carbon: a carbon atom bonded to one other carbon atom
1° H: a hydrogen bonded to a 1° carbon
Secondary (2°) carbon: a carbon atom bonded to two other carbon atoms
2° H: a hydrogen atom bonded to a 2° carbon
Tertiary (3°) carbon: a carbon bonded to three other carbon atoms
3° H: a hydrogen atom bonded to a 3° carbon
Quaternary (4°) carbon: a carbon bonded to four other carbon atoms

Sample Exercise 24.3

Oxidation of alkanes

Write the equation for the complete combustion of 2-methylpropane.

SOLUTION

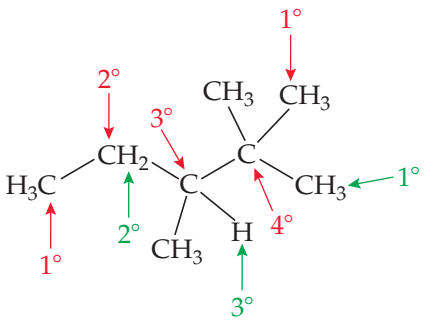
Analyze We are asked to react an alkane with oxygen under conditions that give the complete combustion products, namely CO_2 and H_2O.

Plan Write the molecular formula for 2-methylpropane and the reagent molecular oxygen on the reactants side of the equation and carbon dioxide and water on the products side. Then balance the equation for carbon, then hydrogen and finally oxygen.

Solve The molecular formula for 2-methylpropane follows the general formula for alkanes. 2-methylpropane has four carbons so its molecular formula is C_4H_{10}. So, the unbalanced equation is

$$C_4H_{10}(g) + O_2(g) \rightarrow CO_2(g) + H_2O(l)$$

Balancing for carbon and hydrogen yields



$$C_4H_{10}(g) + O_2(g) \rightarrow 4\,CO_2(g) + 5\,H_2O(l)$$

Now, balancing for oxygen using the total of oxygen present on the product side yields the balanced equation

$$2\,C_4H_{10}(g) + 13\,O_2(g) \rightarrow 8\,CO_2(g) + 10\,H_2O(l)$$

Practice Exercise
Write the equation for the complete combustion of 2,3-dimethylbutane.

Figure 24.17 illustrates this classification by identifying the different carbon atoms of 2,2,3-trimethylpentane. This method of classification is useful, as we see in the following chapters, for determining the reactivity of a range of different functional groups.

▲ **Figure 24.17 Classification of carbon and hydrogen atom types.** The classification of a selected set of hydrogen (green) and carbon (red) atoms is shown for 2,2,3-trimethylpentane.

Free-Radical Reactions and Electron Movement

The majority of alkane reactions occur through the formation of **free radicals**, either by the scission of a C—C bond or by hydrogen abstraction. Free radicals gain their reactivity from having an unpaired electron. Both C—C bond scission and hydrogen abstraction are examples of a **homolytic bond cleavage** because one electron contained with the two-electron σ-bond is transferred to each atom, yielding two free radicals.

At this point, we will use one form of free-radical chemistry to emphasize the point that a single covalent bond contains two electrons and that reactions occur by making and breaking such bonds.

The most common of all the free-radical reactions of alkanes is **halogenation**. This term simply means the incorporation of halogen (that is, F, Cl, Br, I), although chlorine and bromine atoms are the easiest and hence the most common to incorporate. This type of free-radical halogenation is generally called a **substitution reaction** because the reaction proceeds by abstracting a hydrogen atom and replacing or *substituting* it with a halogen. The chlorination of methane, for example, to yield the mono-, di-, tri- and tetra-chlorinated products (and HCl) occurs only in the presence of light (photolysis), with radiation in the range 200–500 nm most common. The reaction produces all permutations of substitution, as shown in Equation 24.5. The ratio of the four products formed is dictated by the amount of chlorine gas present, the photolysis time and the wavelength of light.

$$CH_4 + Cl_2 \xrightarrow{\text{dark}} \text{no reaction} \qquad [24.4]$$

$$CH_4 + Cl_2 \xrightarrow{\text{light}} CH_3Cl + CH_2Cl_2 + CHCl_3 + CCl_4 \qquad [24.5]$$

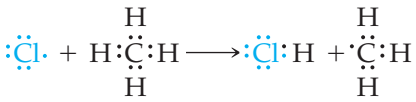
Electron movement in organic chemistry is a useful way of rationalising the conversion of starting materials to products. We call this the *mechanism* of a reaction. Remember that there are two electrons in any single covalent bond and how these electrons move gives rise to either a carbocation, carbanion or free radical, which are less stable (and hence more reactive) than the covalent bond from which they are formed. In Chapter 26, we will investigate a shorthand way of illustrating electron movement that simplifies the fundamental approach we are about to take to explain the free-radical halogenation of methane.

Here, we will begin our study of mechanisms and the three steps to a radical chain reaction:

1. **Initiation**
2. **Propagation**
3. **Termination**

using Equation 24.5 as an example. We will employ Lewis structures to demonstrate the electron movement.

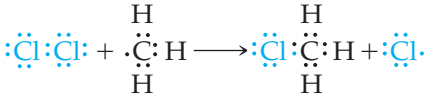
1. ***Initiation step:*** This step produces the first radicals. In this example, the absorption of light by Cl_2 causes the homolytic cleavage of the Cl—Cl bond, leading to the formation of two chlorine radicals:



[24.6]

   The generation of chlorine or bromine radicals can also be initiated by heat.

2. ***Propagation steps:*** As these newly formed radicals collide with other molecules (which are not radicals), they generate or *propagate* new radicals. In the example, a newly formed chlorine radical (chlorine atom) can remove a hydrogen atom from a methane molecule. This step produces a stable product molecule, HCl, and an unstable methyl radical that is highly reactive because its carbon has only seven valence electrons.

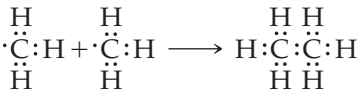


Step 1

[24.7]

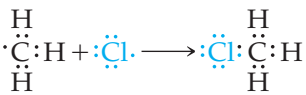
When a molecule of Cl_2 encounters the methyl radical, one chlorine atom is transferred to the carbon to form a stable molecule of chloromethane. The second chlorine atom, now formed, can react with a new molecule of methane as in step 1.

Step 2



[24.8]

The reaction of the methyl radical with chlorine (step 2) yields another chlorine radical which can propagate causing the *chain reaction*. Since each step produces a molecule of product and a newly formed radical, one radical gives rise to many product molecules. This means that only a small number of radicals need be generated during the initiation to allow the chain reaction to proceed.

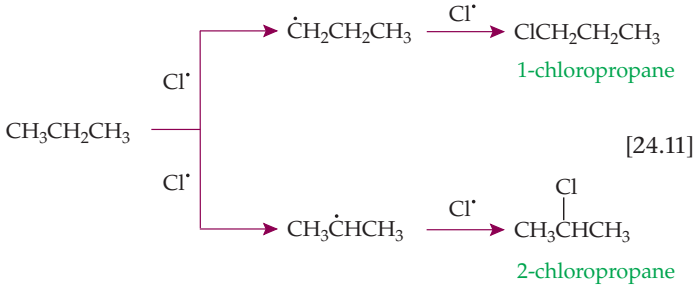


Once the amount of CH_3Cl begins to build up in the mixture, it too can have a hydrogen atom abstracted by a chlorine radical, leading to the formation of CH_2Cl_2. Chloroform ($CHCl_3$) and CCl_4 are formed by the same process.

3. ***Termination steps:*** These occur when two radicals combine to form an unreactive product. For example:

[24.9]

or



[24.10]

Termination steps such as those displayed in Equation 24.9 complicate the reaction by extending the carbon chain. Products such as those in Equations 24.9 and 24.10, which also contain C—H bonds, are also prone to further radical generation and

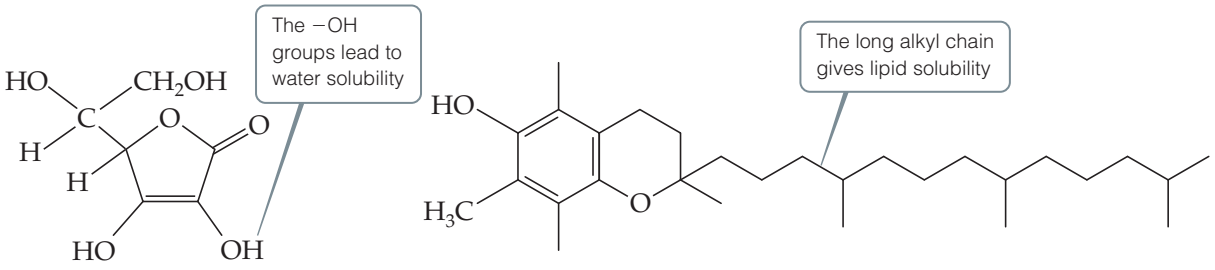
A CLOSER LOOK Reactivity by Carbon Classification

When propane is mono-halogenated two products are likely since both primary and secondary hydrogens exist (Equation 24.11).

[24.11]

The direction of the reaction—that is, via abstraction of the primary or secondary hydrogen atom—depends on two factors: the C—H bond dissociation energy and the relative stability of the two radical intermediates formed (Section 8.8). The two factors are interrelated. There is a trend that suggests the more stable the radical, the lower the energy needed to cause C—H bond homolysis. There is approximately 15 kJ/mol difference in C—H bond dissociation energies between primary C—H bonds and secondary C—H bonds, with the latter being easier to cleave. However, the size of the energy difference between homolysis of a primary and secondary C—H bond cannot fully account for the approximate 1 : 1 product ratio.

There is also a valence bond argument that supports the bond dissociation energy arguments. Alkyl free radicals have a potentially filled *p* orbital and are stabilized by **electron-donating groups** such as alkyl groups. As a consequence, the order of alkyl radical stability is:



Methyl radical < ***Primary radical*** < ***Secondary radical*** < ***Tertiary radical***
(least stable) (most stable)

At this point, it appears there is little difference between the two pathways leading to the monochlorinated products if the product ratio is 1 : 1. Actually, there is a significant difference as it is statistically *three times* more likely to abstract a primary hydrogen (there are six of these in propane) as it is to abstract a secondary hydrogen (there are two of these in propane). So, in fact, there is a large discrimination for the formation of 2-chloropropane. Typically, the ratio of selectivity for monochlorination is of the order 1° : 2° : 3° = 1 : 4 : 5.

Bromine also reacts with alkanes via a free-radical mechanism and bromination is a more selective process. The ratio of **regioselectivity** for bromination is of the order 1° : 2° : 3° = 1 : 100 : 1500.

substitution steps. The generation of a single radical can lead to the formation of many product molecules before the chain is terminated.

Free-radical chain reactions are also found in biological systems, in which harmful radicals such as ·OH attack functional and structural molecules within cells, leading to dysfunction or cell death. Natural **antioxidants** such as vitamin C (ascorbic acid) and vitamin E (α-tocopherol) react readily with free radicals, terminating their propagation.

Vitamin C
(*water soluble*)

Vitamin E
(*lipid soluble*)

Sample Integrative Exercise

Putting concepts together

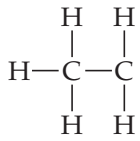
Combustion analysis of a hydrocarbon determined it contained 82.8% carbon and 17.2% hydrogen by mass. **(a)** What is the empirical formula of this compound? **(b)** Explain why your empirical formula cannot also be the molecular formula of this hydrocarbon. **(c)** If the molar mass of the compound is 58.1 g/mol, draw the structural formula of all possible constitutional isomers and give their names. **(d)** Does an equilibrium exist between the constitutional isomers at room temperature?

SOLUTION

Analyze In this problem we determine the formula of a compound and examine the relationship between its isomers.

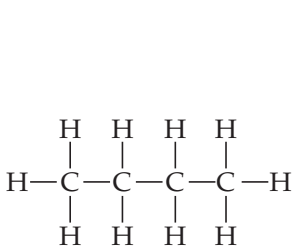
Plan First determine the empirical formula of the compound then examine the bonding arrangement of the atoms involved to see if the empirical formula and molecular formula could be the same. Next determine the molecular formula and name all possible structures with this formula. Finally consider whether the constitutional isomers may be easily interconverted at room temperature.

Solve



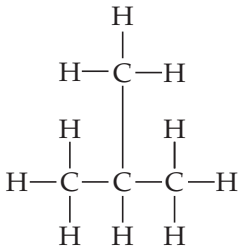
(a) A 100 g sample of the hydrocarbon will contain 82.8 g of carbon and 17.2 g of hydrogen. This represents

$$\frac{82.8\text{ g}}{12.01\text{ g/mol}} = 6.89\text{ mol carbon}$$



$$\frac{17.2\text{ g}}{1.008\text{ g/mol}} = 17.1\text{ mol hydrogen}$$

The mole ratio of C : H is 6.89 : 17.1 = 1 : 2.48 or 2 : 5
The empirical formula of the hydrocarbon is therefore C_2H_5.



(b) In a stable bonding arrangement hydrogen forms one bond and carbon forms four bonds. The odd number of hydrogen atoms mean that it is not possible to construct a compound in which all atoms have a stable bonding arrangement; one carbon has just three bonds.

(c) An empirical formula of C_2H_5 would have a molar mass of 29.06 g/mol; the actual molar mass is double this and so the molecular formula is C_4H_{10}. The structural isomers with this formula are:

butane

2-methylpropane

(d) To convert one constitutional isomer to another involves the breaking of chemical bonds. This requires quite a lot of energy and does not spontaneously occur at room temperature. So no equilibrium exists between the two isomers at room temperature.

Self-Assessment Exercises

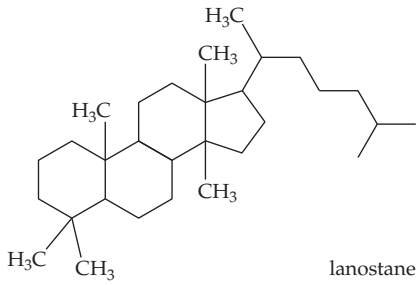
24.34 How many primary, secondary and tertiary hydrogens are there in 2-methylbutane?

(a) 3 × 1° H; 2 × 2° H; 1 × 3° H
(b) 9 × 1° H; 2 × 2° H; 1 × 3° H
(c) 1 × 1° H; 2 × 2° H; 9 × 3° H

24.35 Name, in order of occurrence, the three steps in a radical polymerization.

(a) Initiation, propagation, termination
(b) Initiation, termination, propagation
(c) Propagation, initiation, termination
(d) Termination, propagation, initiation

Exercises



24.36 **(a)** Write a balanced equation for the complete combustion of propane. **(b)** Use table 8.3 and your answer to part (a) to estimate ΔH for this reaction.

24.37 An unknown aliphatic alkane, A, yields 4.800 g CO_2 and 2.475 g H_2O when fully combusted. Suggest a plausible molecular formula for A that is less than or equal to C_6H_{14}.

24.38 Propose structures for compounds with formulas less than C_6H_{14} containing:

(a) two tertiary carbons
(b) three primary carbons
(c) a quaternary carbon
(d) only two methyl groups.

24.39 The structure of lanostane, a biogenic precursor of steroids, is shown here. Classify each carbon atom as primary, secondary, tertiary, or quaternary.

lanostane

24.40 Draw Lewis structures for the following radicals:

(a) methyl radical
(b) chlorine atom
(c) isopropyl radical.

24.41 **(a)** What ratio of cyclohexane to chlorine would you suggest in order to achieve a monochlorination? **(b)** The free-radical chlorination of cyclohexane is much cleaner and occurs in far greater yield than that of hexane under the same conditions. Account for this difference.

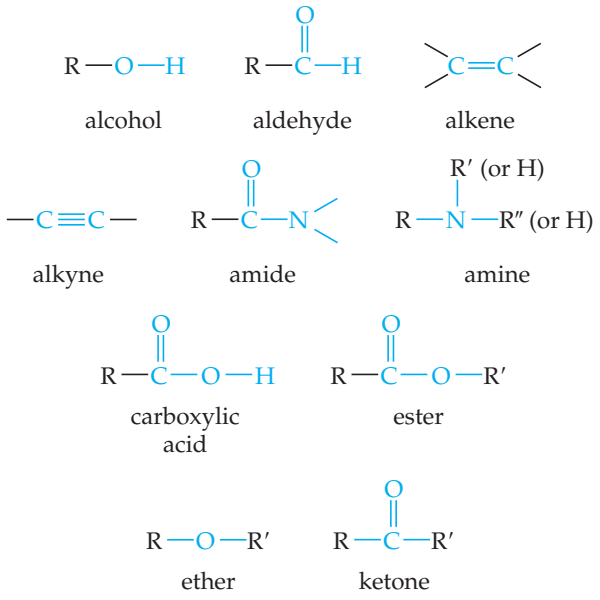
Answers to Self-Assessment Exercises

24.34 (b) **24.35** (a)

Chapter Summary and Key Terms

INTRODUCTION AND SECTION 24.1 **Organic chemistry** is the study of compounds that contain carbon. We have encountered many aspects of organic chemistry in earlier chapters. Carbon forms four bonds in its stable compounds.

SECTION 24.2 The simplest class of organic molecules consists of **hydrocarbons**, which contain only carbon and hydrogen. Alkanes are hydrocarbons that contain only single bonds. Alkanes have names that end in *-ane*, such as methane and ethane. **Alkanes** are **aliphatic**, forming straight-chain, branched-chain and cyclic arrangements.



Alkanes are used primarily as fuels. Their properties, such as melting and boiling point, change in a regular fashion as the length of the chain increases. These properties are known as a **homologous series**.

SECTION 24.3 **Hybridization** is used as a model to rationalize the bonding geometry of a saturated carbon atom (109.5°). The rotation about C—C single bonds gives rise to different **conformations**, ranging from **staggered** to **eclipsed** forms. The staggered forms dominate due to the added **steric** interactions involved in the eclipsed forms of a molecule. We can use **Newman projections** to describe the different conformers easily. **Structural** or **constitutional isomers** have the same molecular formula but a different connectivity of atoms.

SECTION 24.4 The **nomenclature** used for hydrocarbons is based on the longest continuous chain of carbon atoms in the structure and contains a prefix, parent and suffix. The locations of **alkyl groups**, which branch off the chain, are specified by numbering along the carbon chain.

SECTION 24.5 Alkanes with ring structures are called **cycloalkanes**. Five- and six-membered rings are most common. Cyclohexane has two conformations, **chair** and **boat** forms. The chair form is more stable as it reduces unfavourable steric interactions and has two types of hydrogen positions, **axial** and **equatorial**. When a substituent is added to the ring, it typically adopts an equatorial position to minimize **1,3-diaxial interactions**.

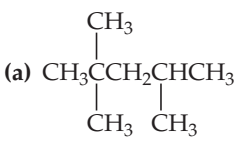
SECTION 24.6 The chemistry of organic compounds is dominated by the nature of their **functional groups**. The functional groups we have considered are:

R, R' and R" represent hydrocarbon groups—for example, methyl (CH_3) or ethyl (CH_2CH_3). **Alcohols**, which contain —OH, the alcohol functional group, are represented as R—OH. Organic molecules need the reactivity imparted by **heteroatoms** in order to demonstrate their usefulness. Of the types of heteroatoms available, oxygen plays a major role.

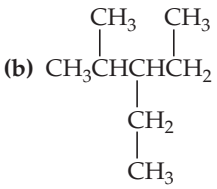
SECTION 24.7 Alkanes and cycloalkanes are relatively unreactive. They do, however, undergo **combustion** in air (**oxidation**), and their main use is as sources of heat energy (exothermic reaction). Recognition of carbon and hydrogen atoms as primary, secondary or tertiary is important for determining the product distribution in organic reactions. **Free-radical** reactions are typically initiated by heat or light which leads to **homolytic bond cleavage** of halogens, leading to **halogenation**. The three phases of a free-radical reaction are **initiation**, **propagation** and **termination**. The preference of substitution is 3° H > 2° H > 1° H and is assisted by the presence of **electron-donating groups** around the carbon-centerd radical. The preference for one product over its isomer is called **regioselectivity**. **Antioxidants** such as vitamins E and C eliminate free-radicals within the human body.

Key Skills

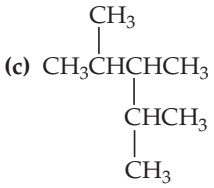
- Draw alkane structures based on their names and name alkanes based on their structures. (Sections 24.2 and 24.3)
- Understand trends in the alkane homologous series. (Section 24.2)
- Be able to describe the concept of sp^3 hybridization and σ-bonds. (Section 24.3)
- Be able to name systematically alkanes from structures and draw structures from systematic names. (Section 24.4)
- Be able to draw cycloalkanes containing 3–8 carbon atoms. (Section 24.5)
- Understand the difference between equatorial and axial positions in cyclohexane. (Section 24.5)
- Know the structure of the functional groups: alkene, alkyne, alcohol, ether, aldehyde, ketone, carboxylic acid, amine, amide. (Section 24.6)
- Be able to identify primary, secondary and tertiary carbon atoms. (Section 24.6)
- Be able to demonstrate the making and breaking of σ-bonds in a free-radical reaction. (Section 24.7)



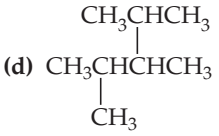
Key Equations



- General formula for alkanes C_nH_{2n+2} [24.1]
- General formula for cycloalkanes C_nH_{2n} [24.2]

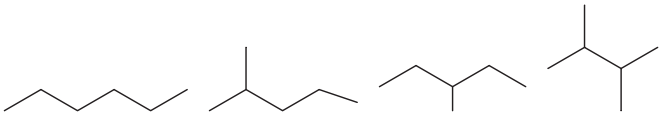


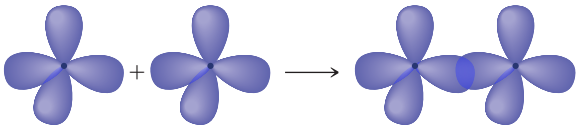
Exercises

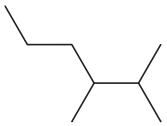


Visualizing concepts

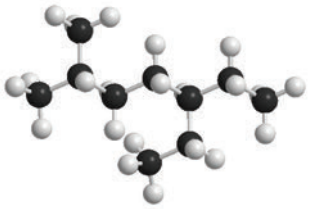
24.42 All the structures that follow have the same molecular formula, C_8H_{18}. Which structures are of the same molecule? [Section 24.2]



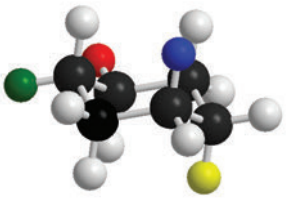




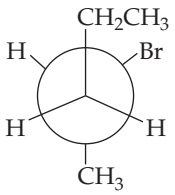
24.43 Which constitutional isomer is missing? [Section 24.3]



24.44 Define the following bond. [Section 24.3]



24.45 The structure of an alkane is drawn here as a line drawing representation. Is 2-propyl-3-methylbutane a suitable systematic name for this compound? Provide a better name using the guidelines in Section 24.4.



24.46 Draw the structural formula for the following molecular model. [Section 24.3]

24.47 A selection of hydrogen atoms on the chair conformation of cyclohexane are colored red, green, blue and yellow. Identify the position of each colored ball (that is, axial or equatorial). What happens to these positions if an interconversion occurs to produce the other possible chair conformation. [Section 24.5]

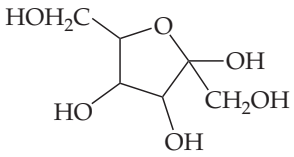
24.48 Convert the following Newman projection into a standard structural formula. [Section 24.3]

24.49 **(a)** Write the propagation steps leading to the formation of dichloromethane from chloromethane.

$$CH_3Cl + Cl^{\bullet} \rightarrow CH_2Cl_2$$

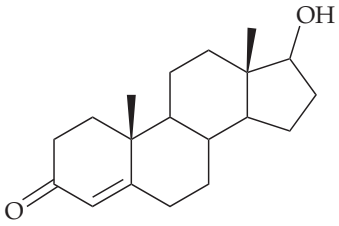
(b) Explain why free-radical halogenations usually give rise to mixtures of products. **(c)** Comment on the stoichiometry of chloromethane and chlorine needed to form carbon tetrachloride as the major product. [Section 24.7]

$$CH_3Cl + Cl^{\bullet} \rightarrow CCl_4$$



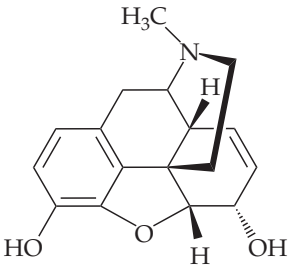
24.50 Identify each of the functional groups in the following molecules. [Section 24.6]

(a)



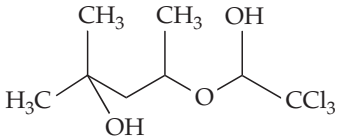
an anaesthetic

(b)



fructose

(c)



testosterone
(a male sex hormone)

(d)

morphine
(an alkaloid extracted
from poppies)

(e)

Chlorhexadol
(a depressant)

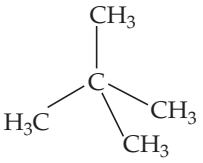
General Characteristics of Organic Molecules (Section 24.1)

24.51 Are carbon monoxide or ammonia considered organic molecules? Why or why not?

24.52 Urea has been identified as an organic molecule. What features make it so?

24.53 **(a)** What are the approximate bond angles about carbon in an alkane? **(b)** What are the characteristic hybrid orbitals employed by carbon in an alkane?

An Introduction to Hydrocarbons (Section 24.2)



24.54 Give the molecular formula of a hydrocarbon containing six carbon atoms that is **(a)** an alkane, **(b)** aromatic.

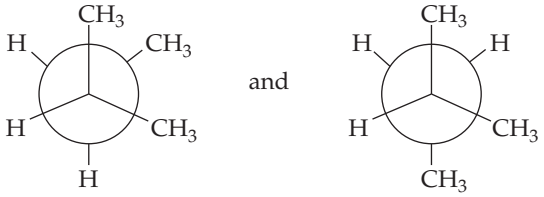
24.55 What structural features help us identify a compound as **(a)** an alkane, **(b)** a cycloalkane, **(c)** a saturated hydrocarbon?

24.56 Rank the following compounds in order of increasing boiling points and explain your choice of order.

heptane

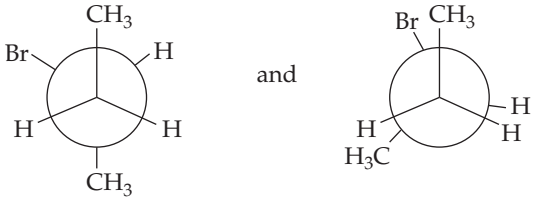
2,2-dimethylpropane
(neopentane)

2,4-dimethylpentane



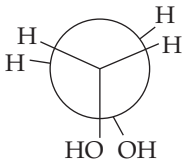
ethane

Structure of Alkanes (Section 24.3)



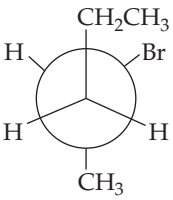
24.57 Draw a valence-bond description for ethane. Include the hybridization for each carbon atom.

24.58 Which conformer in each pair of Newman projections is lower in energy?

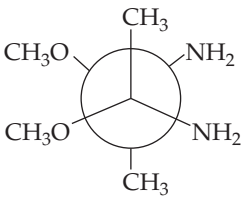


(a)

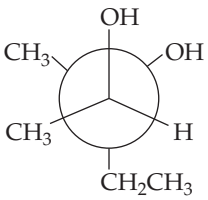
(b)



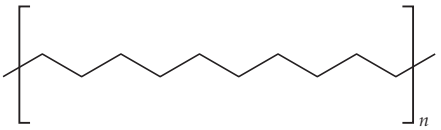
24.59 Ethylene glycol ($HOCH_2CH_2OH$) prefers to exist almost entirely in the following eclipsed form in the vapor phase. Give an explanation for this.



24.60 Convert the following Newman projections into their standard structural formula.

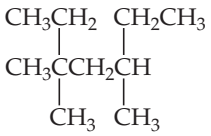


(a)

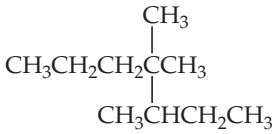


(b)

(c)



24.61 Polyethylene is a polymer used in many plastic applications, such as food wrap and soft-drink bottles. A general structure for polyethylene is shown here. Would such a polymer be more soluble in an organic solvent such as hexane or in water? Why?

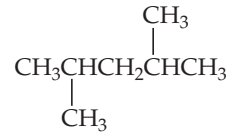


Alkane Nomenclature (Section 24.4)

24.62 Draw the structural formula or give the systematic name, as appropriate, for the following:

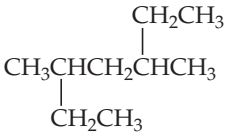
(a)

(b)



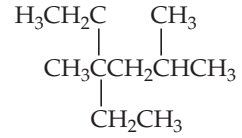
(c) 2,5-dimethylnonane

(d) 3-ethyl-4,4-dimethylheptane

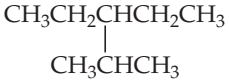


(e) 1-ethyl-4-methylcyclohexane

24.63 Give IUPAC names for the following alkanes:



(a)



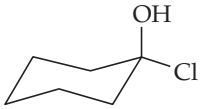
(b)

(c)

(d)

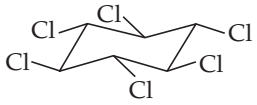
24.64 Draw 3-ethyl-2,3-dimethylbutane. What would be the correct systematic name for this compound?

24.65 Butane and 2-methylpropane are both non-polar molecules and have the same molecular formula, yet butane has the higher boiling point (−0.5 °C compared with −11.7 °C). Explain.



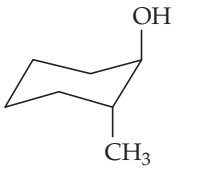
Cycloalkanes (Section 24.5)

24.66 The molar heat of combustion of gaseous cyclopropane is $-2089\ kJ\ mol^{-1}$; that for gaseous cyclopentane is $-3317\ kJ\ mol^{-1}$. Calculate the heat of combustion per CH_2 group in the two cases, and account for the difference.

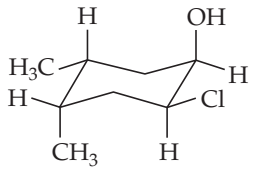


24.67 Draw both possible cyclic structural isomers of C_4H_8. Systematically name each compound.

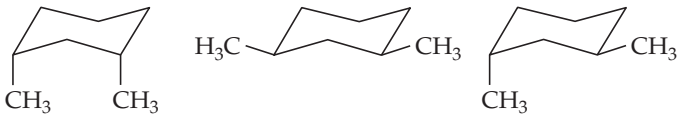
24.68 Label each CH_3, OH or Cl group in the following compounds as axial or equatorial.



(a)

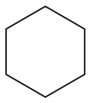


(b)

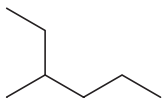


(c)

(d)



24.69 Place the following dimethylcycloalkanes in order of relative stability.

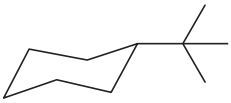


24.70 Why is geometric isomerism possible for cycloalkanes but not for alkanes?

24.71 Draw a cyclic, straight-chain or branched-chain constitutional isomer for each of the following:

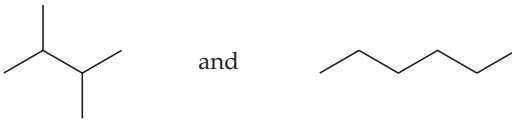
(a)

(b)



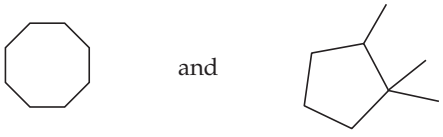
(c)

(d)

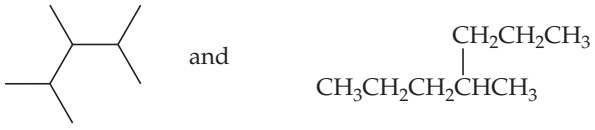


(e)

24.72 Which of the following pairs are constitutional isomers?



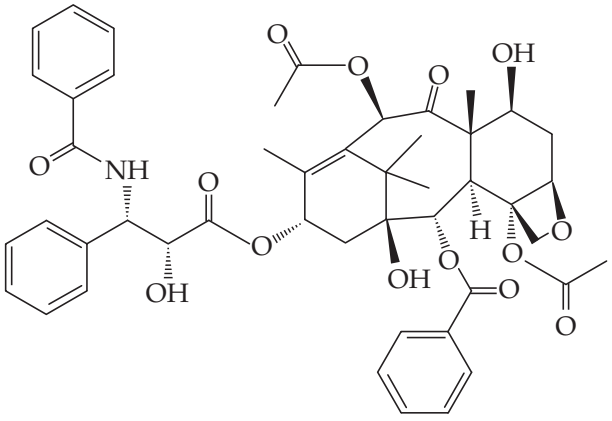
(a)



(b)

(c)

(d)



Functional Groups (Section 24.6)

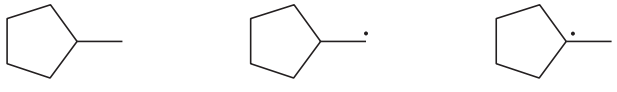
24.73 **(a)** What is a functional group? **(b)** Why are functional groups important?

24.74 List three functional groups that are important in biology (there are more than three).

24.75 Taxol is a clinically important anticancer compound isolated from the bark of *Taxus*, the Pacific yew tree. Identify the following functional groups and the number of each present in the structure of Taxol: **(a)** alcohol; **(b)** ether; **(c)** amine; **(d)** amide; **(e)** carboxylic ester; **(f)** alkene; **(g)** ketone.

Reactions of Alkanes (Section 24.7)

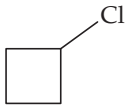
24.76 **(a)** What is the difference between a substitution reaction and an oxidation reaction? **(b)** Using condensed structural formulas, write the balanced equation for the free-radical substitution reaction of 2,2,4-trimethylpentane with Br_2 in the presence of light. Explain, using this reaction as an example, what is meant by a regioselective reaction. **(c)** Write a balanced chemical equation for the complete combustion of 2,2-dimethylpropane.



24.77 When cyclopropane is treated with HI, 1-iodopropane is formed. A similar type of reaction does not occur with cyclopentane or cyclohexane. What physical aspect of cyclopropane might account for its reactivity?

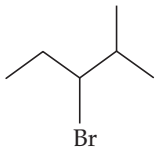
24.78 **(a)** How much oxygen is required for the complete combustion of 70 g of cyclohexane? **(b)** How much carbon dioxide is produced in this reaction?

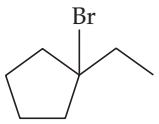
24.79 **(a)** Write the propagation steps leading to the formation of dichloromethane, CH_2Cl_2, from methane. **(b)** Describe how termination of this chain reaction is possible.



24.80 Rank each radical in order of its relative stability.

(a)





(b) $(CH_3)_2\dot{C}CH_2CH_3$ $(CH_3)_2CHCH_2\dot{C}H_2$ $\dot{C}H_3$

24.81 Which of the following alkyl halides can be prepared in good yield by radical halogenation?

(a) 

(b) 

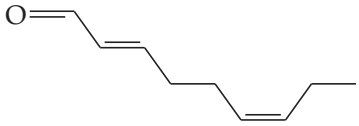
(c) 

(d) 

24.82 Draw all monobromo derivatives of 3-methylhexane. Which one of these configurational isomers would be produced in highest yield by the reaction of bromine with 3-methylhexane?

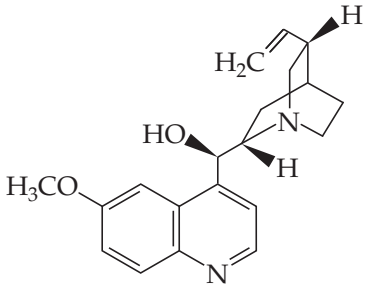
Additional Exercises

24.83 Draw the condensed structural formulas for two different molecules with the formula C_3H_4O.



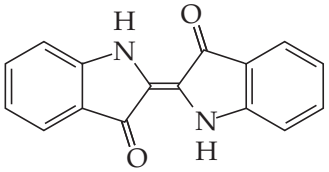
24.84 How many structural isomers are there for a five-member straight carbon chain with one double bond? For a six-member straight carbon chain with two double bonds?

24.85 Draw the condensed structural formulas for the *cis* and *trans* isomers of 2-pentene. Can cyclopentene exhibit *cis–trans* isomerism? Explain.



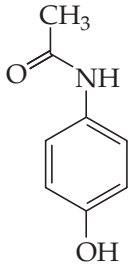
24.86 If a molecule is an "ene one", what functional groups must it have?

24.87 Write the structural formulas for as many alcohols as you can think of that have empirical formula C_3H_6O.



24.88 Identify each of the functional groups in these molecules:

(a) 



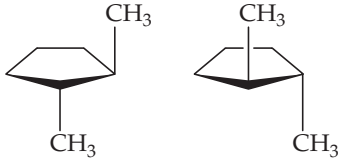
(Responsible for the odor of cucumbers)

(b) 

(Quinine—an antimalarial drug)

(c) 

(Indigo—a blue dye)



(d) 

(Acetaminophen—aka Paracetamol)

24.89 Write a condensed structural formula for each of the following: **(a)** an acid with the formula $C_4H_8O_2$, **(b)** a cyclic ketone with the formula C_5H_8O, **(c)** a dihydroxy compound with the formula $C_3H_8O_2$, **(d)** a cyclic ester with the formula $C_5H_8O_2$.

Integrative Exercises

24.90 **(a)** What type of isomeric relationship exists between pentane and 2-methylbutane? **(b)** What is the relationship between the two shown here? **(c)** Name this compound. **(d)** Identify the most likely point(s) for bromination in each molecule.

24.91 **(a)** Draw a relative energy profile similar to that shown in Figure 24.16 to illustrate the stability of the different conformers produced by rotation about one C—C single bond in propane. **(b)** What is the product of the complete combustion of propane? **(c)** How much energy is released upon the complete combustion of 44 dm^3 of propane? **(d)** Propane is converted into 2-bromopropane by a first-order process. The rate constant is $5.4 \times 102\ h^{-1}$. If the initial concentration of propane is 0.150 M, what will its concentration be after 24.0 h?

24.92 An unknown substance is found to contain only carbon and hydrogen. It is a liquid that boils at 49 °C at 1 bar pressure. Upon analysis it is found to contain 85.7% carbon and 14.3% hydrogen by mass. At 100 °C and 735 torr, the vapor of this unknown has a density of 2.21 g dm^{-3}. When it is dissolved in hexane solution and bromine water is added, no reaction occurs. What is the identity of the unknown compound?

24.93 Methane is a greenhouse gas that is present at a concentration of 1.8 ppm and has a half-life in the atmosphere of approximately 10 years. **(a)** What is the partial pressure of methane assuming the total pressure is 102 kPa? **(b)** If no new methane was added to the atmosphere, how long would it take for the concentration to drop to a pre-industrial level of 0.5 ppm assuming first-order kinetics?

Design an Experiment

The precise mixture of alkanes contained in a crude oil sample depends on the origin of the oil. A small amount of oil has washed up on the shore close to a major shipping lane and, as a member of the local environmental protection agency, you want to determine the origin of the oil and, hence, the tanker it came from. How would you collect samples of the oil to ensure they were representative of the spill? What physical property of alkanes enables you to separate them? How would you quantify the amount of the different alkanes present? How might you identify the alkanes present?

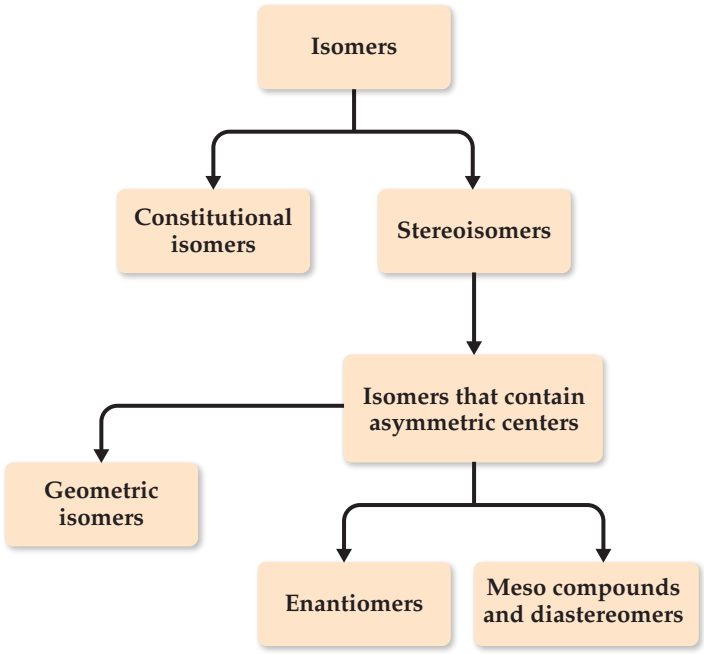
25.1 | Stereochemistry in Organic Chemistry

Stereochemistry is about the three-dimensional shape of a molecule. This may sometimes be of crucial importance in determining the physical properties of a compound. Recall that coordination compounds that exhibit stereochemistry give rise to different properties such as color. Stereochemistry may also play a role in the chemical reactions of a compound. This is most clearly seen when an organic molecule interacts with a complex biological molecule such as an enzyme.

For example, the compound limonene is responsible for the distinct smells of both oranges and lemons. Limonene is a colorless liquid hydrocarbon containing 10 carbon atoms, yet it can adopt two different shapes. These shapes are mirror images of one another—rather like a right hand and a left hand—and this subtle difference in shape results in a different interaction with the smell receptors in our noses. One mirror image form smells of lemons and the other of oranges.

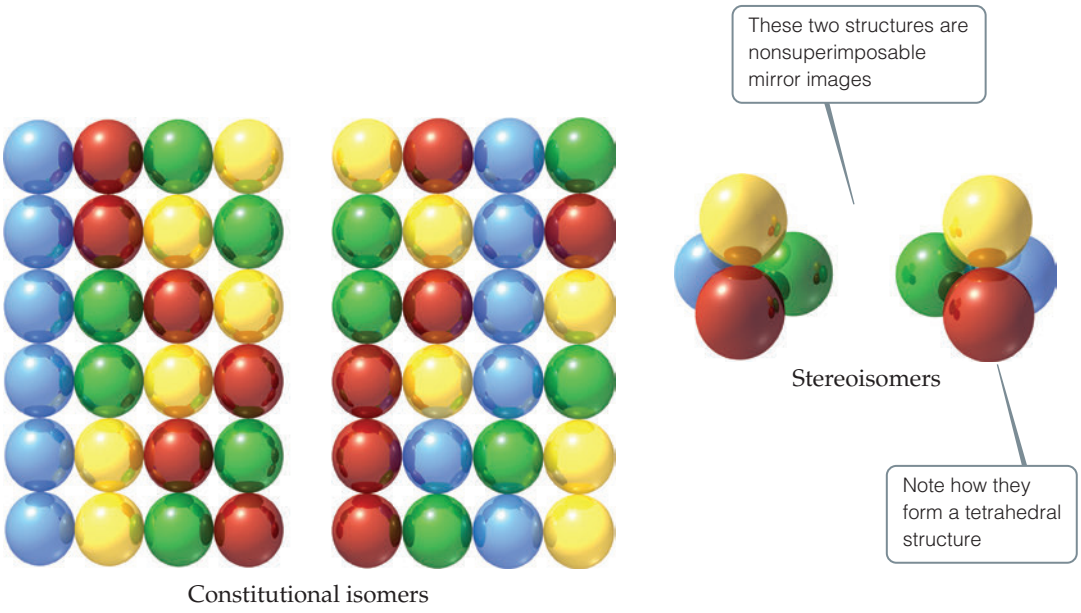
When you finish this section, you should be able to:

- Understand the relationship between different classes of isomers



We have already discussed the dimensionality of simple organic molecules and seen that structure is responsible for a compound's physical properties, such as melting point, boiling point and density. As we see in this chapter, and again in Chapter 31, the three-dimensional structure of a molecule is also important for its chemical properties, especially in a biological environment.

The term *isomers* is used to describe molecules with the same molecular formula but some difference in structure **Figure 25.1** illustrates the relationship between the different classes of isomers. Constitutional isomers have a different bonding arrangement; for example, a straight-chain and a branched-chain alkane both of the formula C_6H_{14}.



Stereoisomers have the same molecular formula and the same connectivity of atoms, but may be quite different in their physical and chemical properties. Stereoisomers can exist in several forms. Of these forms, there are three distinct classes: **geometric isomers**, **enantiomers**, and **diastereomers** (also called diastereoisomers). Stereoisomers cannot be interconverted without the breaking and remaking of a covalent bond.

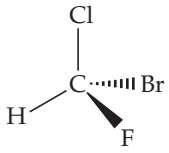
We can begin our understanding of stereochemistry by considering simple representations of atoms, such as four colored balls—blue, green, red, and yellow. When the balls are laid in a row, there are 12 possible permutations, taking into account the ability to read from right to left or left to right (**Figure 25.2**). The relationship between any or all permutations can be described as *constitutional isomers*. In essence, the balls act as building blocks, in the same way as we described atoms or groups of atoms in Table 24.8. You can

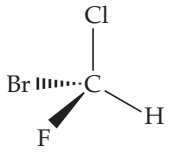
Go Figure Can propane demonstrate constitutional isomerism?

▲ **Figure 25.1 There are several different forms of isomerism.** Although constitutional, geometric and diastereomers vary in their physical properties, enantiomers vary only when in a chiral environment.

▲ **Figure 25.2 Understanding isomerism.** Orientation of colored balls can be used as imagery to describe constitutional isomerism and stereoisomerism.

see from this example how easy it is to build up a library of compounds with the same molecular formula.





What happens when we change from a pseudo one-dimensional shape of the four balls, as occurs in a row, to one that is three-dimensional, such as a pyramid? The answer is a simplification in the number of permutations to just two. Notice that there is no way of superimposing the two pyramidal structures in Figure 25.2 onto one another—they are different. The two structures represented are, in fact, mirror images of each other. In chemical terms, they are stereoisomers and, more specifically, *enantiomers*.

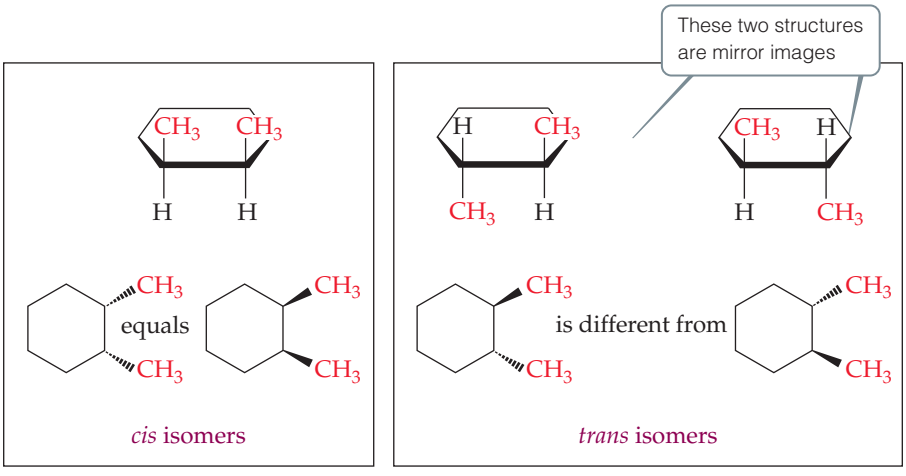
25.2 | *Cis–Trans* Isomerism in Cycloalkanes



Inositol is a type of sugar that has a ring of six carbon atoms, each bearing an —OH group. It is important in the synthesis of neurotransmitter molecules and has been sold as a health supplement to improve brain function. There are eight geometries with different relative positions of the alcohol groups, only one of which is active in the body. In this section, we will look at the isomers possible in a cyclic compound with just two substituents.

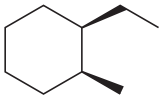
When you finish this section, you should be able to:

- Identify the geometric isomers of a disubstituted cyclic compound

The three isomers of 1,2-dimethylcyclohexane shown in **Figure 25.3** differ in the relative locations of their methyl groups. These three compounds are *stereoisomers*. That is, they are compounds that have the same molecular formula and the same connectivity between atoms but differ in the spatial arrangement of these groups. Thus, the ***cis*** isomer of 1,2-dimethylcyclohexane has the two methyl groups orientated on the same side of the plane of the ring, whereas the ***trans*** isomers have the methyl groups orientated on opposite sides.

The three-dimensional orientation of groups within a structural formula or line drawing can be described using bold and dashed wedges, as shown in Figure 25.3. The notation employs the two-dimensional plane of the paper to draw a three-dimensional object. A bold wedge (▬) indicates that this bond extends towards you out of the plane of the

▶ **Figure 25.3 Geometric isomerism in disubstituted cycloalkanes.** *Cis* and *trans* isomerism is a feature of cycloalkanes. The easiest way to remember which isomer is which is to remember that *trans* (as in transpacific or transport) means "across".



paper. A dashed wedge (·····) indicates that this bond is directed into the paper. This symbolism will become important in Section 25.3, where we investigate three-dimensional structure in more detail.

Despite the ability of C—C bonds to rotate under normal conditions, their ability to do so in a cycloalkane is greatly restricted by ring strain. Hence, the three stereoisomers shown in Figure 25.3 cannot be interconverted without breaking and remaking C—C bonds.

Sample Exercise 25.1

Naming *cis* and *trans* Isomers

Write the systematic name for the following cycloalkane:

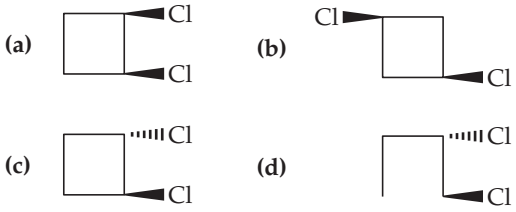
SOLUTION

Analyze We are given the structure of a cycloalkane bearing two substituents and asked to name it, taking into account stereochemistry.

Plan Understand the type of cycloalkane, the names of the substituents and their relative orientation to each other using the wedged nature of the bonds.

Solve The cycloalkane has six carbons associated with the ring structure, so the full name is derived from cyclohexane. The two substituent groups are an ethyl group at position 1 and a methyl group at position 2 based on nomenclature rules.

The name for this alkane would be 1-ethyl-2-methylcyclohexane. However, this name tells us nothing about the relative orientations of the alkyl substituents. These two groups are *cis* to one another because the symbolism used in the line drawing has both substituents extending out of the page in the same direction. Hence, a full systematic name would be cis-1-ethyl-2-methylcyclohexane.



Practice Exercise

Write the systematic name for the following cycloalkane:

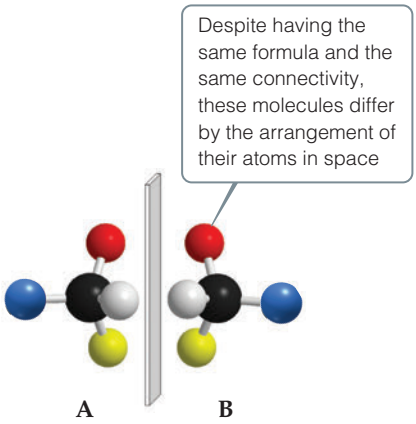
25.3 | Chirality in Organic Compounds



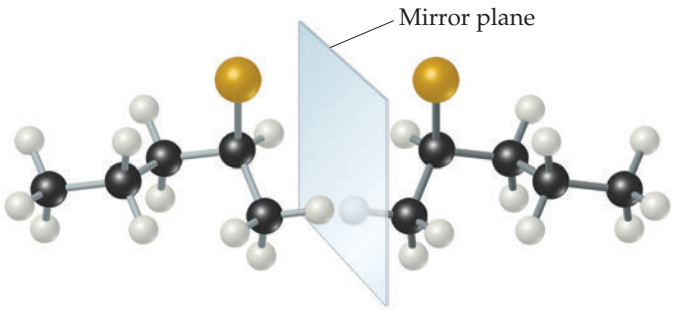
In 1875, a book by Charles Darwin was published titled *On the Movements and Habits of Climbing Plants*. One observation Darwin made was that some species of vines always twisted up a stake in a clockwise direction, while other species adopted an anti-clockwise direction. The two different spirals are mirror images of one another. There are many instances in nature of this sort of symmetry and a preference to adopt one form over the other. Our hands are an example of a mirror-image pair in which the two elements are not superimposable on one another. The very specific interactions this may lead to are shown by pulling on a pair of gloves and finding it is impossible to wear the glove that is not matched to the correct hand. Certain molecules possess non-superimposable mirror images and are called *optical isomers*.

When you finish this section, you should be able to:

- Identify the stereogenic center in a chiral molecule
- Draw the mirror-image structures of a chiral molecule

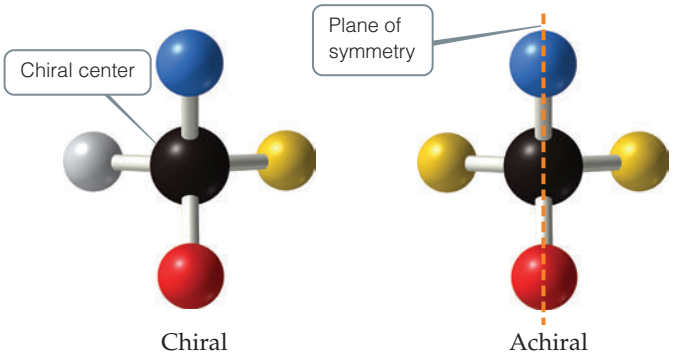
Let us begin our discussion of **optical isomers** in organic chemistry by looking at Figure 25.4. Molecule **A** consists of a tetrahedral carbon atom with four different groups attached, represented by the white, blue, red, and yellow balls. Is **A** identical to its mirror image, **B**? This question is best explored by making three-dimensional models and trying to overlay them; alternatively, try to imagine rotating **A** by 180° and placing it on top of **B**. What happens? The blue, black and white balls align, but the red and yellow are reversed. In fact, any way you try to overlay these two molecules, the result is the same—three of the balls are superimposable but the other two are not.

▲ **Figure 25.4 Mirror images.** These two molecules are non-superimposable mirror images. Being able to move molecules around mentally in three-dimensional space to prove two molecules are non-superimposable is extremely difficult and will require practice before it is mastered.



Molecules possessing non-superimposable mirror images, such as **A** and **B**, are termed **chiral** (Greek *cheir*, "hand"; pronounced *ky-ral*)—that is, they show handedness. In fact, *all molecules containing a single carbon atom bearing four different groups are chiral*. The fact that molecules **A** and **B** cannot be overlaid demonstrates that they are *different substances*. The relationship between two molecules that are non-superimposable mirror images is described by the term **enantiomer**. Hence, molecules **A** and **B** are enantiomers. For example, Figure 25.5 shows the two enantiomers of 2-bromopentane.

All enantiomers have a **chiral center** (also known as a **stereogenic center** or simply a **stereocenter**)—an atom (usually carbon) to which four different groups are attached.

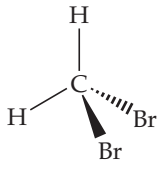


Molecules that have superimposable mirror images are **achiral**, meaning *not chiral*. Achiral molecules can usually be identified because they possess a plane of symmetry (Figure 25.6).

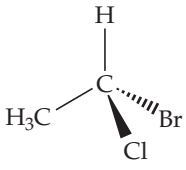
We can make the following general rules at this point:

1. *Stereocenters within any compound can be recognized because they have four different groups bonded to them.*
2. *The presence of one or more stereocenters always results in stereoisomers.*

◀ **Figure 25.5 The two enantiomeric forms of 2-bromopentane.** The mirror-image isomers are not superimposable with each other.

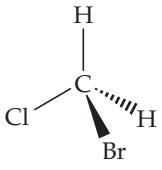


◀ **Figure 25.6 Chiral and achiral.** A molecule that contains one chiral center (stereocenter) is chiral (left). If a plane of symmetry exists, as in the molecule on the right, that molecule is said to be achiral.

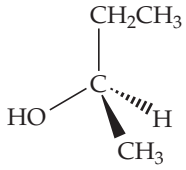


Sample Exercise 25.2

Predicting Chirality



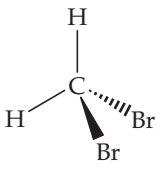
Determine which of the following structures is chiral:



I

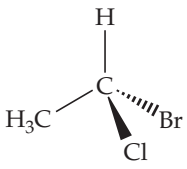
II

III



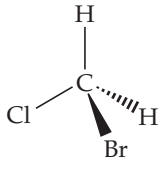
IV

SOLUTION

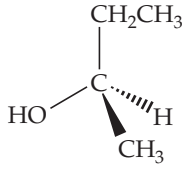


Analyze We are given four structures containing wedged bonds and are asked to determine which are chiral.

Plan Identify any planes of symmetry among the structures to determine achiral molecules. If there is no plane of symmetry, identify the stereogenic center to determine chirality.

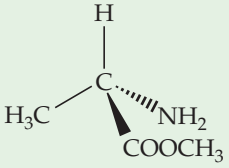


Solve Two compounds are chiral: II and IV. Compounds I and III have at least one plane of symmetry—in fact, compound I has two planes of symmetry. Note that methyl and ethyl groups are classed as different groups, as are the halogens, chlorine, and bromine. Remember, the alternative (and sometimes easier) way to determine whether a molecule is chiral or not is to check each carbon atom to see whether it is a stereocenter.

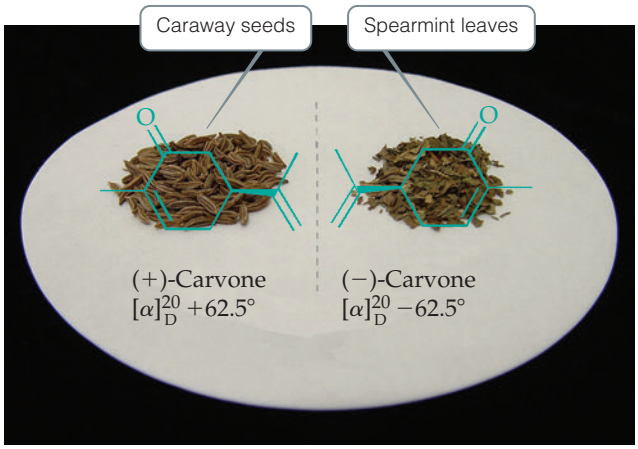


I
achiral

II
chiral



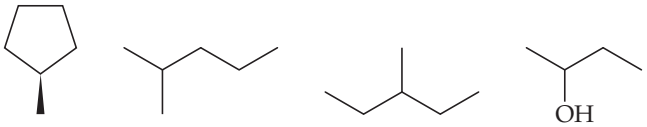
III
achiral



IV
chiral

Practice Exercise

Identify the chiral center in the following molecule and label it with an asterisk. Draw the molecule's mirror image.



▶ **Figure 25.7 Enantiomers of carvone.** Caraway seeds smell very different from spearmint leaves or oil. The difference is a result of how each molecule interacts with the chiral receptors in the nose.

Most of the physical and chemical properties of enantiomers are identical because each enantiomer contains the same functional groups and the same non-bonding interactions. Enantiomers, such as the two forms of 2-bromopentane shown in Figure 25.5, have identical physical properties, such as melting and boiling points, and identical chemical properties when they react with achiral reagents. The properties of two enantiomers *differ only if they are in a chiral environment*. An easy way of demonstrating the differences between enantiomers in a chiral environment is to purchase caraway seeds and spearmint leaves from your local supermarket. Each product contains a different enantiomer of carvone (**Figure 25.7**). Now smell them and note the stark difference.

The difference in their smell is a result of the chirality of the receptors contained within your nose. Each enantiomer fits into the receptor's binding site in a similar way to how our right or left hands would fit into a left-hand glove. For one enantiomer, the fit is perfect, leading to a maximum interaction between the molecule and receptor. The other enantiomer fits awkwardly, leading to less than perfect binding and a different response, perhaps a different smell or taste.

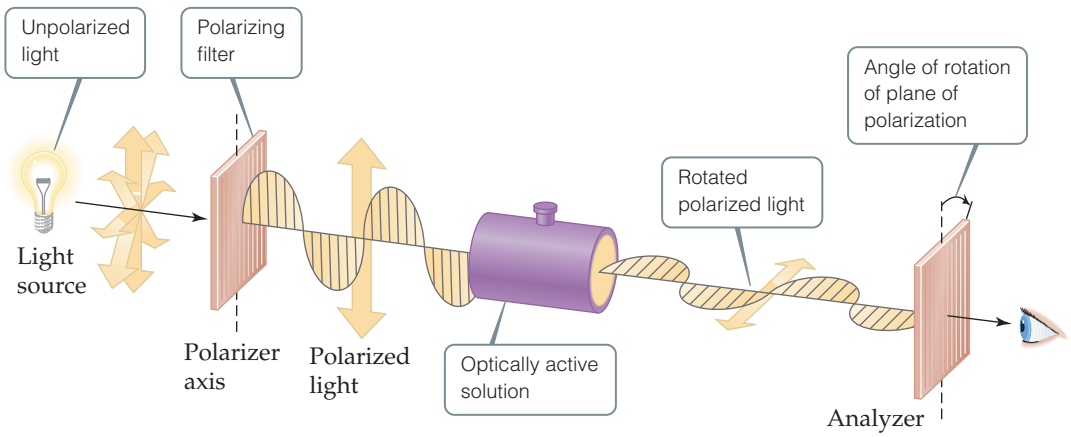
25.4 Measuring Optical Activity



Louis Pasteur (1822–1895) was a French chemist and biologist. He was responsible for some of the most important concepts and applications of modern science, including the discovery of the science of microbiology, the process of pasteurization, and molecular asymmetry. In 1848, Pasteur noticed that a saturated solution of sodium ammonium tartrate crystallized to form crystals that were mirror images of one another. He separated "right-handed" crystals from "left-handed" crystals using a microscope and a pair of tweezers. Dissolving the two crystalline forms in water and subjecting them to plane-polarized light, Pasteur was able to demonstrate that the optical activity of the mirror image crystals was opposite to one another. White wines contain a relatively high concentration of tartaric acid and crystals of calcium tartrate may sometimes be seen on corks of wine after long cellaring.

In this section, we will learn about the optical properties of chiral compounds and, by the end, you will:

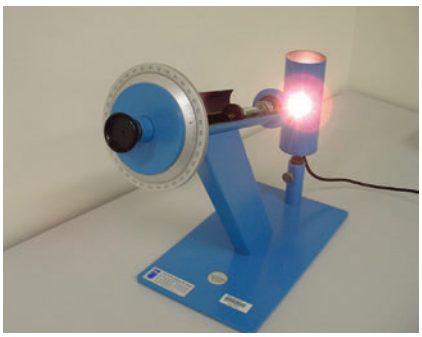
- Understand the relationship between non-superimposable mirror images and rotation of plane polarized light.

Chiral molecules are said to be optically active because of their effect on plane-polarized light. If light is polarized—for example, by passage through a polarizing filter—the light in only one particular plane is allowed to pass through, as shown in **Figure 25.8**. If the

▲ **Figure 25.8 Optical activity.** Effect of an optically active solution on the plane of polarization of plane-polarized light. The unpolarized light is passed through a polarizer. The resultant polarized light then passes through a solution containing a dextrorotatory optical isomer. As a result, the plane of polarization of the light is rotated to the right relative to an observer looking towards the light source and so the optically active compound is dextrorotatory.

plane-polarized light is passed through a solution containing one enantiomer, this plane is rotated through an angle a, measured in degrees, to the right (clockwise, or +) or to the left (anticlockwise, or −) as viewed by an observer. The isomer that rotates plane-polarized light to the right is **dextrorotatory** (Latin *dexter*, "right"); it is labelled the (+)-isomer. Its enantiomer rotates plane-polarized light to the left and is called **levorotatory** (Latin *laevus*, "left"); it is labelled the (−)-isomer.

Figure 25.7 provides information on the results of the plane-polarized light experiment for the enantiomers of carvone. Notice that one enantiomer rotates light in a positive direction while the other rotates light in a negative direction. The term $[\alpha]_D$ is known as the **specific rotation** (Equation 25.1) and takes into account the concentration of the sample c (g cm^{-3}) and the path length l of the sample (dm, 1 dm = 0.1 m) confined within a solution cell, as well as the observed rotation α (degrees). The specific rotation is usually expressed in degrees, even though the units formally should be ° cm^3 dm^{-1} g^{-1}.



$$[\alpha]_D^{20} = \frac{\alpha}{c \times l} \qquad [25.1]$$

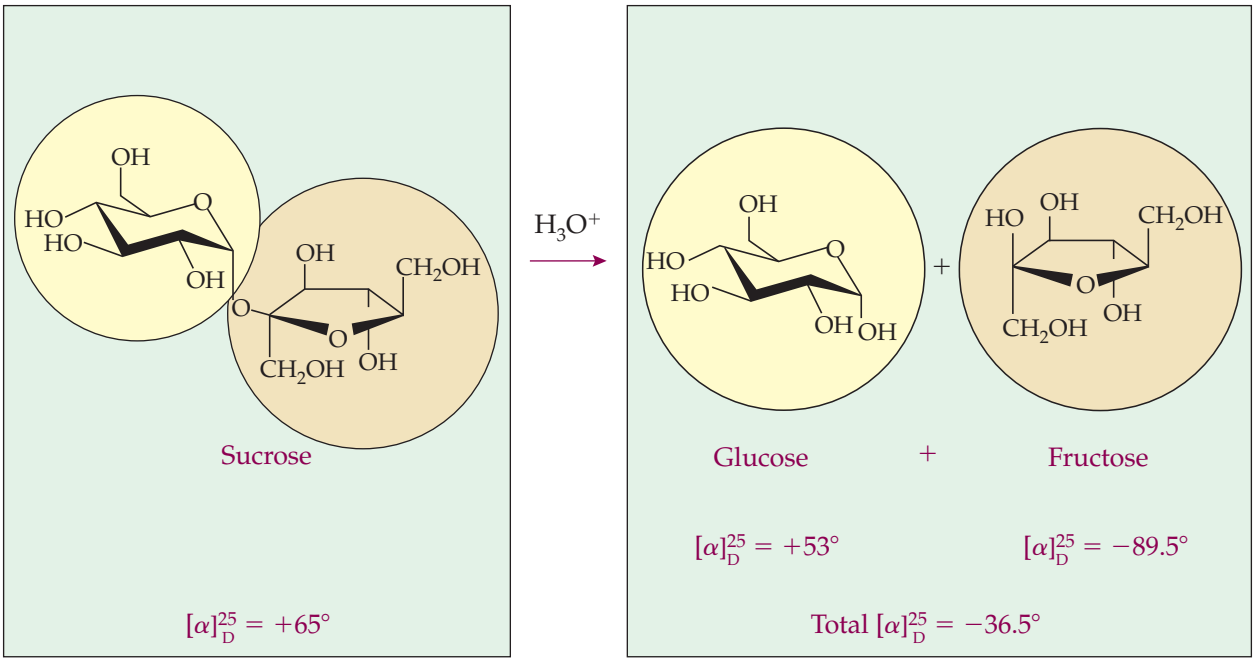
The subscript D refers to the source of monochromatic radiation used for the measurement (typically the sodium-D line, λ = 589 nm). The superscript 20 above the D refers to the temperature (in degrees Celsius) of the measurement, as optical activity is temperature dependent. Note that the magnitudes of the specific rotation for (+)- and (−)-carvone are identical—only the sign changes. An example of the instrument used to perform this optical experiment, called a **polarimeter**, as well as the type of solution cell used, is shown in Figure 25.9.

Optical rotation is a useful way of determining whether a compound is **enantiomerically pure**—that is, contains a single enantiomer. Failure to obtain the same specific rotation for a compound prepared in the laboratory as that reported in the literature most often happens because some of the other enantiomer is present. Often, no rotation can be observed for a substance whose molecules contain a chiral center. This usually means a 50 : 50 mixture of the two enantiomers has formed under the reaction conditions. A mixture with an equal amount of both enantiomers is called a **racemic mixture**, or *racemate*. A racemic mixture of enantiomers does not rotate plane-polarized light because the two enantiomeric forms rotate the light to equal extents in opposite directions, cancelling out any optical effect. Since a racemic mixture contains equal amounts of the (+) and (−) enantiomer it is often designated (±) or (*dl*).

Table 25.1 lists the specific rotation for several well-known organic compounds. Note that *specific rotation is an experimental quantity* and neither the magnitude nor the sign is easily predicted from the structure. An example of the difficulties in prediction is shown in the acid hydrolysis of sucrose, a compound that contains nine stereogenic centers. Here we need not concentrate so much on the complex sugar structures as on the sign and magnitudes of the specific rotation of starting materials and products.

Sucrose, $[\alpha]_D^{25}$ = +65°, is hydrolysed (broken up by the addition of water) under acidic conditions to give glucose, $[\alpha]_D^{25}$ = +53°, and fructose, $[\alpha]_D^{25}$ = −89.5° (Figure 25.10). The 1 : 1 mixture of glucose and fructose that is obtained upon the hydrolysis of sucrose is called *invert sugar* because the specific rotation of the mixture is dominated by the negative rotation of fructose. Since the total specific rotation is effectively the sum of individual specific

(a)



(b)

▲ **Figure 25.9 A polarimeter and solution cell.** A polarimeter (a) is used to measure the rotation of plane-polarized light as it passes through a sample contained within a 1 dm cell (b).

TABLE 25.1 Specific rotations, $[\alpha]_D$, of some common organic compounds

Compound	$[\alpha]_D$ (°)	Compound	$[\alpha]_D$ (°)
Cholesterol	−39	*d*-Camphor	+44
Penicillin-V	+233	*l*-lactic acid	−4
Sucrose	+66.5	Quinine	−178
Morphine	−132	*d*-Tartaric acid	+12
Strychnine	−139	Maltose	+141
Fructose	−92	Glucose	+53

▲ **Figure 25.10 Forming invert sugar.** The complete hydrolysis of sucrose gives glucose and fructose as products. Complete hydrolysis of sucrose yields a specific rotation of −36.5°. Fructose is the sweetest common sugar, being about twice as sweet as sucrose; consequently, invert sugar is sweeter than sucrose. The enzyme *invertase*, which bees use in making honey, accomplishes the same chemical result as the acid-catalysed hydrolysis of sucrose.

rotations, hydrolysis changes the optical properties of the solution from rotating light clockwise (+) to anticlockwise (−), despite very little molecular difference between the two sides of the equation. Hence, specific rotation is extremely sensitive to molecular structure.

Sample Exercise 25.3

Specific Rotation

The specific rotation of (−)-carvone is −62.5°, measured at 20 °C. Calculate the observed rotation at 20 °C for a solution prepared by dissolving 1000 mg of (−)-carvone in 30 cm^3 of ethanol and placing it in a solution cell 10 cm long.

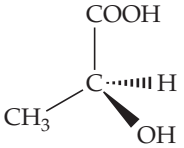
SOLUTION

Analyze We are given the specific rotation, temperature, concentration and path length and asked to determine the observed rotation.

Plan These variables are all related by Equation 25.1, where $[\alpha]_D = -62.5$, $l = 10\text{ cm} = 1\text{ dm}$, $c = 1/30\text{ g cm}^{-3}$. We can solve for α.

Solve Substituting into Equation 25.1 yields

$$-62.5 = \frac{30\alpha}{1 \times 1}$$



$$\alpha = -2.1°$$

Practice Exercise

The observed rotation of a solution of camphor prepared by dissolving 1.6 g in 20 cm^3 of hexane was +2.4°. Determine the specific rotation of this sample, which was contained in a 1 dm-long cell, and use Table 25.1 to conclude whether the sample is that of a single enantiomer.

Self-Assessment Exercise

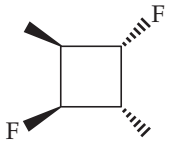
25.15 Lactic acid is a chiral molecule with the structure:

One enantiomer has a specific rotation of +2.6°. What is the specific rotation of the other (mirror image) enantiomer?

(a) 0.0°.

(b) −2.6°.

(c) +2.6°.



(d) It is impossible to tell from the data given

Exercises

25.16 Is it possible to determine the sign and magnitude of the optical rotation from the structure of the molecule?

25.17 Does 3-chloro-3-methylhexane have optical isomers? Why or why not?

25.18 Is the following compound optically active?

25.19 An 8 g sample of sucrose, $[\alpha]_D = +65°$, was dissolved in 25 cm^3 of water and placed in a solution cell of 5 cm length. What was the observed rotation? Is sucrose levorotatory or dextrorotatory?

25.20 The specific rotation, $[\alpha]_D$, of a pure compound obtained from plant material was found to be $-20°$. Explain the symbolism used to describe specific rotation and comment on what the result means.

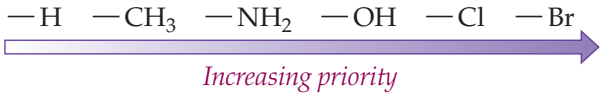
25.5 | Absolute Stereochemistry

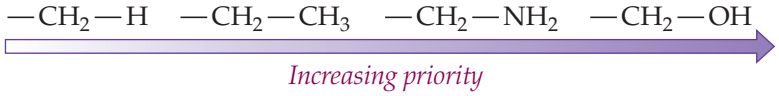
Using Priority Rules to Find a Stereocenter's Absolute Configuration

The "Hammerhead ribozyme" shown in the picture carries out a simple reaction but at a very specific site in RNA. This is a complex molecule, but even a molecule with one stereocenter, in a biological system, may show reactions of one enantiomer that are very different from its pair. While we can measure optical activity for the enantiomers, we need a system to describe the actual shape of each mirror image. The British chemists Robert Cahn (1899–1981) and Christopher Ingold (1893–1970), together with Vladimir Prelog (1906–1998), a Yugoslav chemist based in Switzerland, proposed a set of rules in 1956 to bring some order to the complex world of organic stereochemistry. Prelog was awarded the Nobel Prize in Chemistry in 1975 (jointly with Australian-born Sir John Cornforth) for his work on stereochemistry and complex naturally occurring chemical products.



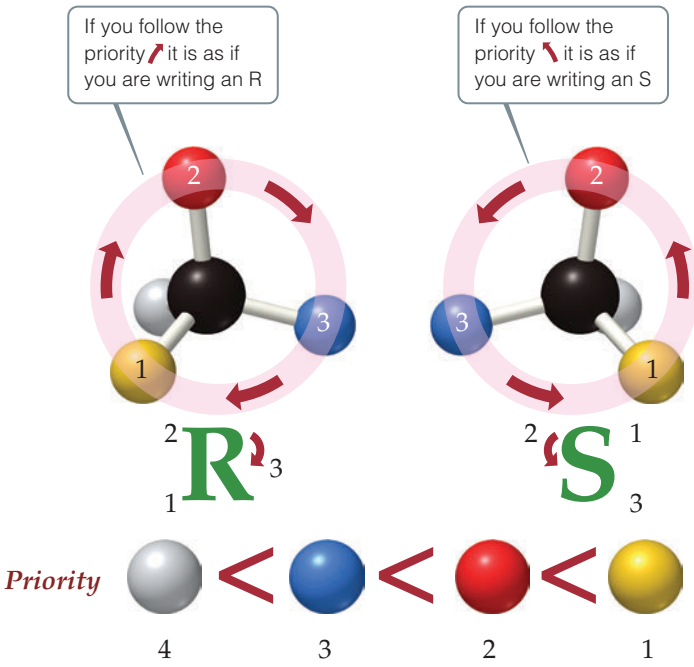
By the end of this section, you will be able to:

- Assign the configuration to a stereocenter using the nomenclature *R* or *S*.



Although the (+)- and (−)-notation yields important experimental information about a compound, it tells us nothing about the **absolute configuration** (that is, the exact three-dimensional structure) of the molecule. To remove any ambiguity when describing the absolute configuration at a stereocenter, the **Cahn–Ingold–Prelog *R,S* notation** has been employed. The Cahn–Ingold–Prelog notation uses **sequence priority rules** to determine a stereocenter's absolute configuration.

We can use the following steps to determine the absolute configuration of a stereocenter:

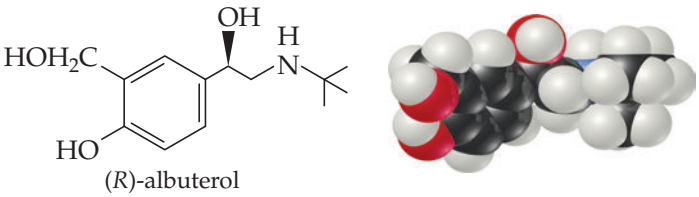


1. Locate the stereocenter.
2. Assign a priority to each substituent from 1 (highest) to 4 (lowest) based on the *atomic number* of the four atoms directly attached to the stereocenter. The higher the atomic number, the higher the priority. A representative set of groups in increasing priority order is

   If two atoms are identical in terms of priority, you need to move out along the respective chains until a difference in priority is encountered. Continue to reapply rule 2 to determine priority or until the end of the group is reached. If no difference is found, the molecule has symmetry and is therefore achiral. Examples of increasing priority fragments are

3. Orient the molecule so that the group with the lowest priority (often hydrogen) is directed away from you, that is, it is connected to the stereocenter by a dashed wedge (·····).

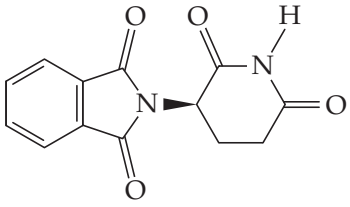
4. Read the three groups orientated towards you in order from highest (1) to lowest (3) priority.
5. If the numbers increase from 1–3 in a clockwise manner, the configuration is *R* (from the Latin *rectus*, "straight, correct, right"). If the numbers increase in an anticlockwise manner, the configuration is *S* (from the Latin *sinister*, "left").
6. If the compound containing the stereocenter is *R*, then its enantiomer is *S*, and *vice versa*.



CHEMISTRY AND LIFE Chiral Drugs

Many drugs of importance in medicine are chiral substances. When a drug is prepared, sold and administered as a racemic mixture, it often turns out that only one of the enantiomers has beneficial results. The other enantiomer is either inert or nearly so, or may even have a harmful effect. For the last reason, a great deal of attention has been given in recent years to methods for synthesising the desired enantiomer of chiral drugs. Chemical research directed at understanding how to control the stereochemistry of a reaction has led to new synthetic methods that make it not only possible, but relatively cost-effective, to produce chiral molecules in *enantiomerically pure* form. Worldwide sales of single-enantiomer drugs amounts to over $225 billion annually.

Albuterol is a good example of the different physiological behaviour of enantiomers. The drug (*R*)-albuterol (Figure 25.11) is an effective bronchodilator used to relieve the symptoms of asthma. Its enantiomer, (*S*)-albuterol, is not only ineffective as a bronchodilator but actually counters the effects of (*R*)-albuterol.



The non-steroidal analgesic ibuprofen (marketed under the trade names Advil™ and Nurofen™) is a chiral molecule usually sold as a racemic mixture. The more active enantiomer, (*S*)-ibuprofen (Figure 25.12), relieves pain and reduces inflammation, whereas the weakly active *R* enantiomer, which isn't as easily utilized, is actually converted by enzymes within the body to the active S form.

In the 1950s and 1960s the drug thalidomide was administered to pregnant women as an anti-emetic to combat morning sickness. It was found to be teratogenic, being responsible for severe deformities in over 12 000 foeteuses worldwide. The case against thalidomide has two sides, however. First, rigorous testing of all chiral drug candidates has now been made mandatory for both enantiomers after the thalidomide experience. The *R* enantiomer of thalidomide was active in preventing morning sickness during pregnancy, whereas the *S* enantiomer was responsible for the terrible side-effects in humans. Unfortunately, racemization of (*R*)-thalidomide (to form the *S* enantiomer) occurs easily within the body, so even the useful *R* enantiomer has no therapeutic use for pregnant women. Thalidomide has also been approved by the US Food and Drug Administration for the treatment of leprosy. Trials are also under way for epilepsy and HIV.

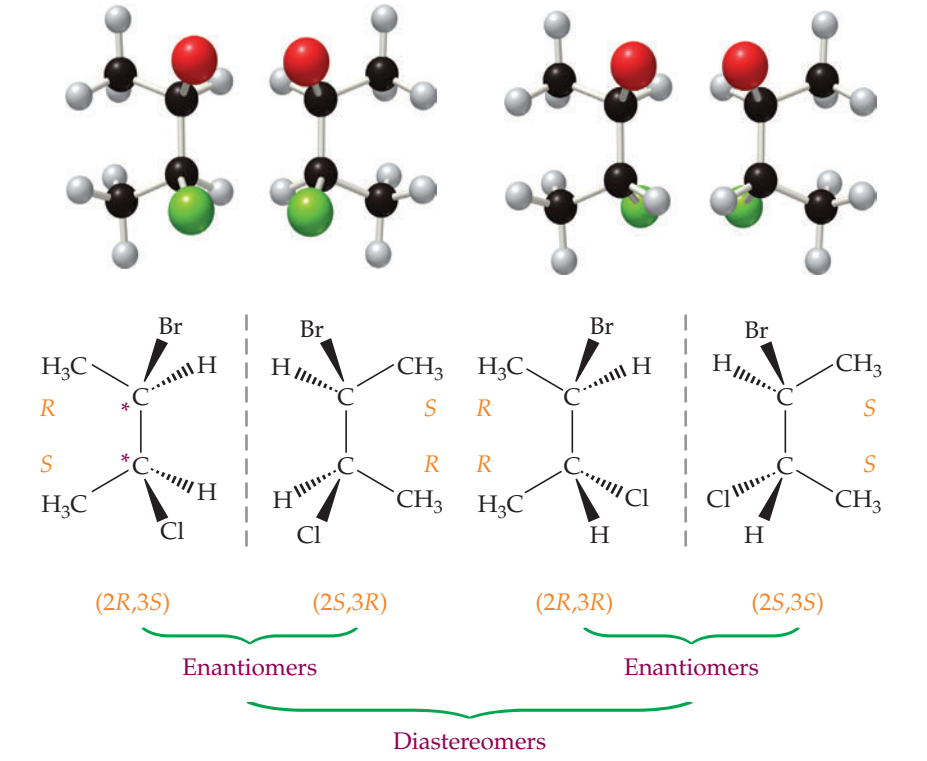
25.6 Molecules with More than One Stereocenter

A diet rich in saturated fat can result in an excess of cholesterol in the body. When this surplus is deposited on the walls of arteries, it can restrict the flow of blood to vital organs such as the heart or brain and lead to heart attack or stroke. Cholesterol is a chiral molecule with eight stereocenters and a possible 256 different stereoisomers. Remarkably, only one of these isomers is produced naturally.

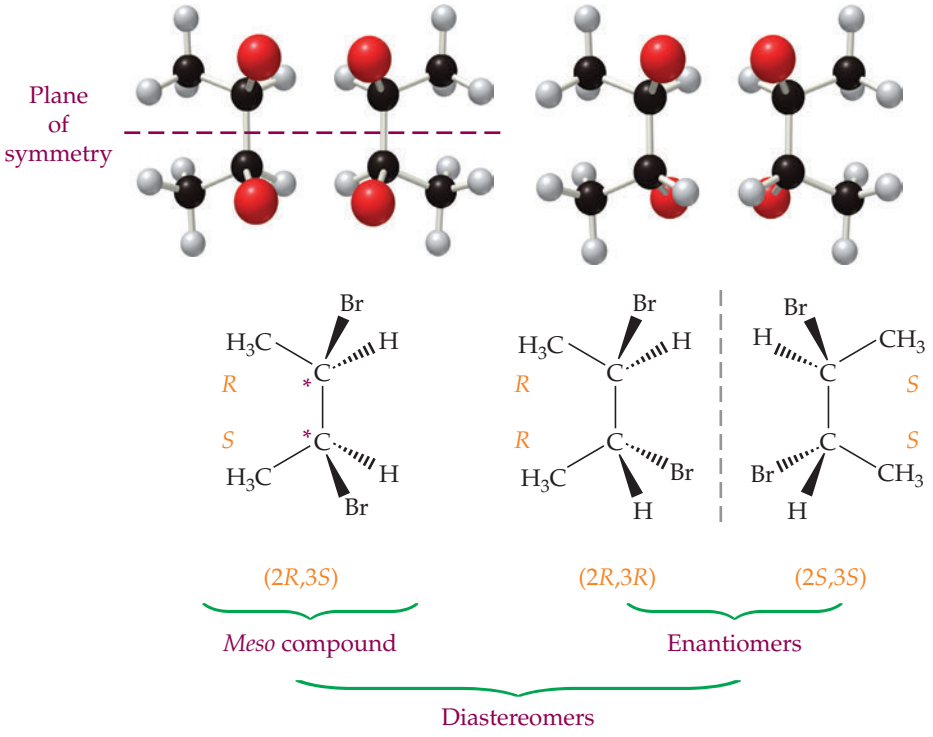
In this section, we examine molecules containing two stereocenters, and by the end, you will:

- Recognize the relationship between different isomers of the same molecule
- Appreciate one method by which enantiomers may be separated



A chiral molecule with one stereocenter can exist as one of two enantiomers, *R* or *S*. Generally, for a molecule with *n* stereocenters, the maximum number of stereoisomers possible is given by Equation 25.2

$$\text{Number of stereoisomers} = 2^n \qquad [25.2]$$



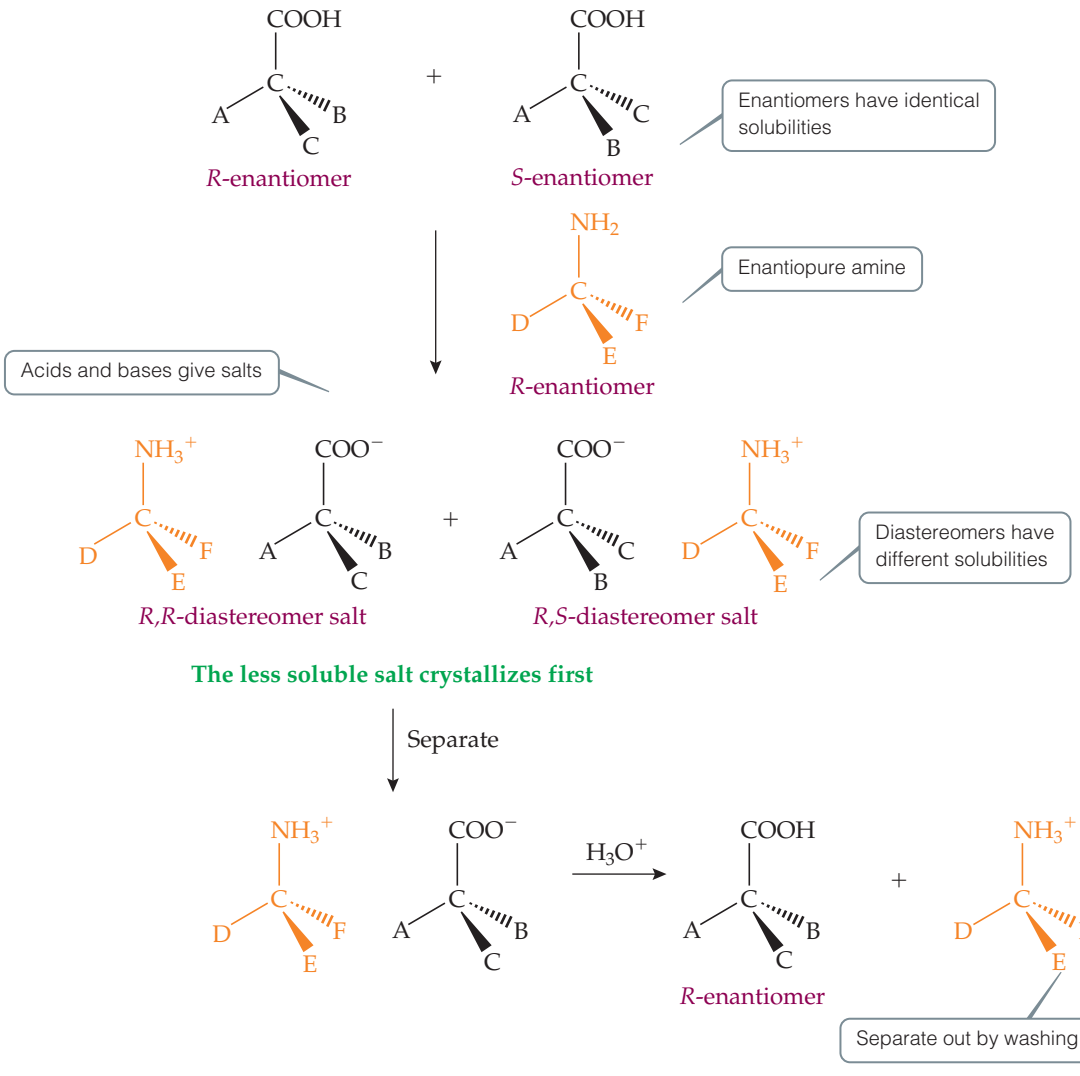
Let us consider a molecule with two stereocenters—that is, a molecule that can exist as a maximum of four stereoisomers. All the possible stereoisomeric permutations for the compound 2-bromo-3-chlorobutane are shown in **Figure 25.13**. This compound contains two stereocenters (labelled with an asterisk) and so can exist in (2*R*,3*S*), (2*S*,3*R*), (2*R*,3*R*), (2*S*,3*S*) forms. This notation is used to describe the stereochemistry at each stereocenter: the number represents the position of the chiral carbon atom on the longest chain and the *R*,*S* notation is used to describe the absolute stereochemistry at that position.

Each of the chiral molecules in Figure 25.13 is related to the other three. Notice that two pairs of enantiomers exist. Thus, one pair of enantiomers is labelled (*R*,*R*) and (*S*,*S*), while the other pair will be labelled (*R*,*S*) and (*S*,*R*). The two pairs of enantiomers are also related (for example, compare (*R*,*S*) and (*R*,*R*)). They are neither non-superimposable nor mirror images and are called **diastereomers**. Diastereomers, by definition, are any set of stereoisomers that are not enantiomers. *Whereas enantiomers have identical physical and chemical properties in an achiral environment, diastereomers always have different chemical and physical properties*.

Let's now consider 2,3-dibromobutane as an example (**Figure 25.14**). This compound has two stereocenters. However, a plane of symmetry exists through the C—C single bond between the two stereocenters in the (*R*,*S*) form, making it identical to the (*S*,*R*) form. The two forms are now superimposable and so are not enantiomers. From our earlier definition, a molecule possessing a plane of symmetry is not chiral. An achiral compound possessing two or more stereocenters is known as a ***meso* compound**.

▶ **Figure 25.13 Enantiomers and diastereomers.** Compounds with two stereocenters have a maximum of four stereoisomers. These stereoisomers have a relationship to each other. The name describing the relationship differs if the two molecules in question are non-superimposable mirror images (enantiomers) or not (diastereomers).

▶ **Figure 25.14 *Meso* compounds.** Despite possessing two stereocenters, 2,3-dibromobutane has only three stereoisomers. The *meso* form is achiral because it contains a plane of symmetry.

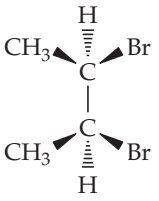


Resolution: Separating Enantiomers

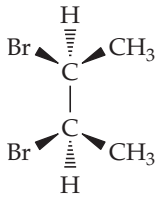
Separating a racemic mixture into two enantiomers with high optical purity is extremely difficult to do without the aid of a chiral auxiliary. Pasteur was indeed fortunate that the racemic tartaric salts crystallized in such a way as to contain a single enantiomer within one crystalline form. More often than not, the two enantiomers co-crystallize to form crystals that are indistinguishable from each other. Even with the aid of chiral separating agents, this process of separating enantiomers (called **resolution**) is extremely

expensive and time-consuming. We can, however, use the different chemical and physical properties of diastereomers to perform a clever experiment to resolve two enantiomers. The trick is to convert the enantiomers into diastereomers in order to separate them.

The resolution process is explained schematically in **Figure 25.15**. Whenever possible, the chemical reactions involved in the formation of diastereomers and their conversion into separate enantiomers are acid–base reactions. The reason for this is simple: organic salts crystallize well in almost any solvent (including water) and the acid–base chemistry employed is uncomplicated. For example, a racemic mixture of a chiral carboxylic acid is reacted with a single enantiomer of an amine such as (*R*)-α-methylbenzylamine (RAMBA). The two salts that form are diastereomeric because they each contain two chiral centers, yet are not mirror images. Separation of one diastereomeric salt from the other is typically achieved by crystallization methods. In order to maximize enantiomeric purity, the crystallization is repeated several times. The pure enantiomer is subsequently liberated by treatment with aqueous acid.

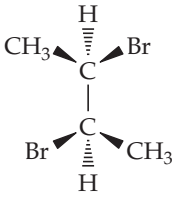


The method described in Figure 25.15 is also widely used for the resolution of chiral amines, using an *enantiopure* carboxylic acid such as the naturally occurring carboxylic acid, (*S*)-malic acid. Other methods, depending on the functionality present within the *racemate*, have also been developed. One of the more interesting methods involves an enzymatic resolution. Since biological systems such as enzymes are highly specific for a particular enantiomer, they can be conveniently used to perform simple derivatizations to a single enantiomer in a racemic mix. Derivatization (for example, hydrolysis of an ester functionality) changes both the physical and chemical properties, allowing for easy separation and hence resolution.

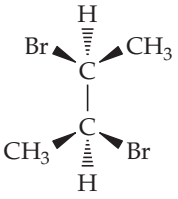


◀ **Figure 25.15**
Resolution. Enantiomers, especially those containing a carboxylic acid functionality, can be separated by converting them into diastereomeric salts. Typically, crystallization leads to the separation of one diastereomeric salt over the other. Conversion of the salt back to the carboxylic acid yields a purified enantiomer.

Self-Assessment Exercises



25.27 Consider the following structures of 2,3-dibromobutane:



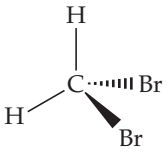
A

B

C

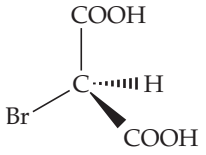
D

What is the relationship between the following pairs of structures?



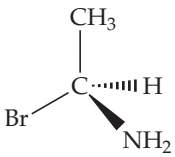
(a) **A** and **B** are enantiomers; **C** and **D** are enantiomers

(b) **A** and **B** are identical (the *meso* form); **C** and **D** are enantiomers

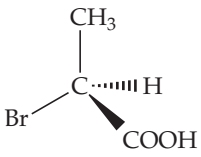


(c) **A** and **C** are diastereomers; **C** and **D** are identical (the *meso* form)

(d) **A** and **B** are identical (the *meso* form); **C** and **D** are diastereomers

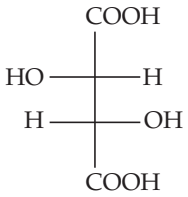


25.28 Which of the following molecules could be used to resolve a racemic mixture of a chiral amines?



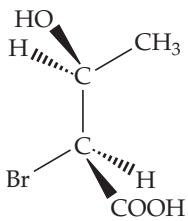
(a)

(b)



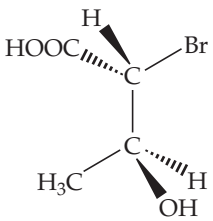
(c)

(d)



Exercises

25.29 Draw all possible stereoisomers of tartaric acid and comment on their relationship. Identify any *meso* compounds.



25.30 Assign *R* or *S* configurations to each stereocenter in the following molecules:

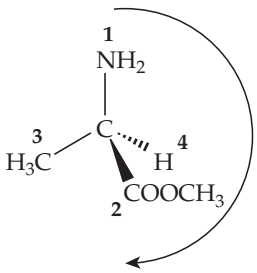
Sample Integrative Exercise

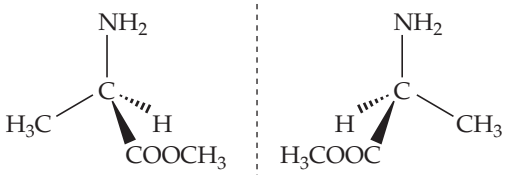
Putting Concepts Together

Alanine is one of the 20 most common naturally occurring amino acids. A methyl ester derivative ($RCOOCH_3$), prepared in the laboratory, had the following stereochemistry:



alanine methyl ester

(a) Identify the chiral center in alanine methyl ester. How many possible stereoisomers exist for alanine? **(b)** List the groups attached to this chiral center in *decreasing order* of sequence rule priority, then state whether the compound has the *R* or *S* configuration about this center. **(c)** Draw the other enantiomer of alanine methyl ester. **(d)** Describe how a pure sample of this compound may be obtained from a racemic mixture.



SOLUTION

(a) The central carbon atom in alanine methyl ester is the only chiral center since it has four different groups attached to it. Having only one stereocenter means that only two stereoisomers are possible.

(b) Using the sequence priority rules in Section 25.5, $NH_2 > COOCH_3 > CH_3 > H$. Since the lowest-priority group is already oriented back into the page, this compound has an *R* configuration.

(c)

(d) It is very difficult to separate enantiomers directly, and in quantity. Since this compound contains an amine functional group, the best way to achieve resolution would be to react it with a single enantiomer of a chiral carboxylic acid such as (*S*)-malic acid. This would form the *R,S* and *S,S* diastereomeric salts, which can be separated by fractional crystallization. Once isolated, addition of base would re-generate the amine, which could be separated by extraction from the water-soluble carboxylate salt and dried. Removing the solvent leaves the pure enantiomer.

(See also Exercise 25.40.)

Chapter Summary and Key Terms

SECTION 25.1 **Stereoisomers** are isomers with the same connectivity of atoms (bonding) but different arrangement of their atoms in space. The most common forms of stereoisomerism are **geometric isomers**, **enantiomers** and **diastereomers**.

SECTION 25.2 Two substituents on a cycloalkane can be ***cis*** or ***trans*** to each other. *Cis* and *trans* isomers are called geometric isomers. Geometric isomers differ from one another in their chemical and physical properties.

SECTION 25.3 **Optical isomers** are non-superimposable mirror images of one another. They are molecules that contain a **stereocenter**. Optical isomers, or enantiomers, are **chiral**, meaning that they have a specific "handedness" and their physical and chemical properties differ only in the presence of a chiral environment. Molecules that are superimposable are **achiral**, meaning not chiral.

SECTION 25.4 Optical isomers can be distinguished from each other by their interactions with **plane-polarized light**; solutions of one

enantiomer rotate the plane of polarization to the right (**dextrorotatory**, +) and solutions of its mirror image rotate the plane to the left (**levorotatory**, −) with the same magnitude. Chiral molecules, therefore, are **optically active**. A **polarimeter** is used to determine the **specific rotation** of a chiral sample. A compound that is **enantiomerically pure** contains a single enantiomer. A mixture with an equal amount of two enantiomers is called a **racemic mixture**, or *racemate*.

SECTION 25.5 The **absolute configuration** around a stereocenter can be described with the **Cahn–Ingold–Prelog *R,S* notation**. This notation uses a set of **sequence priority rules** to assign priority to each group around a stereocenter.

SECTION 25.6 Molecules with two or more chiral centers can form enantiomers and *diastereomers*. Diastereomers have different physical and chemical properties, a trait that can be used in the **resolution** of enantiomers from a *racemic mixture* to yield an enantiomerically pure compound. An achiral compound possessing two or more stereocenters is known as a ***meso* compound**.

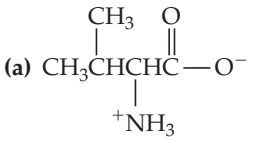
Key Skills

- Be able to draw three-dimensional structures in two dimensions using bold and dashed wedges. (Sections 25.1 and 25.3)
- Understand the concept of chirality and be able to identify a chiral center. (Section 25.3)
- Use the Cahn–Ingold–Prelog rules to describe unambiguously the absolute configuration of a stereocenter. (Section 25.5)
- Calculate the number of potential stereoisomers based on the number of chiral centers. (Section 25.6)

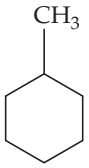
Key Equations

- Specific rotation

$$[\alpha]_D^{20} = \frac{\alpha}{c \times l} \qquad [25.1]$$



- Maximum number of stereoisomers for a compound with n stereocenters



$$\text{No. of stereoisomers} = 2^n \qquad [25.2]$$

CHEMISTRY OF ALKENES AND ALKYNES

26.1 The Structure of Unsaturated Hydrocarbons

Unsaturated hydrocarbons contain a double or triple bond between two carbon atoms, and they differ greatly from alkanes in much of their chemistry. Understanding the molecular basis of this different reactivity allows us to predict what reactions may occur and enhances our ability to use basic chemicals to synthesize more complex substances. These, in turn, may be built into the modern materials that surround us and used, for example, in construction, medicine and technology.

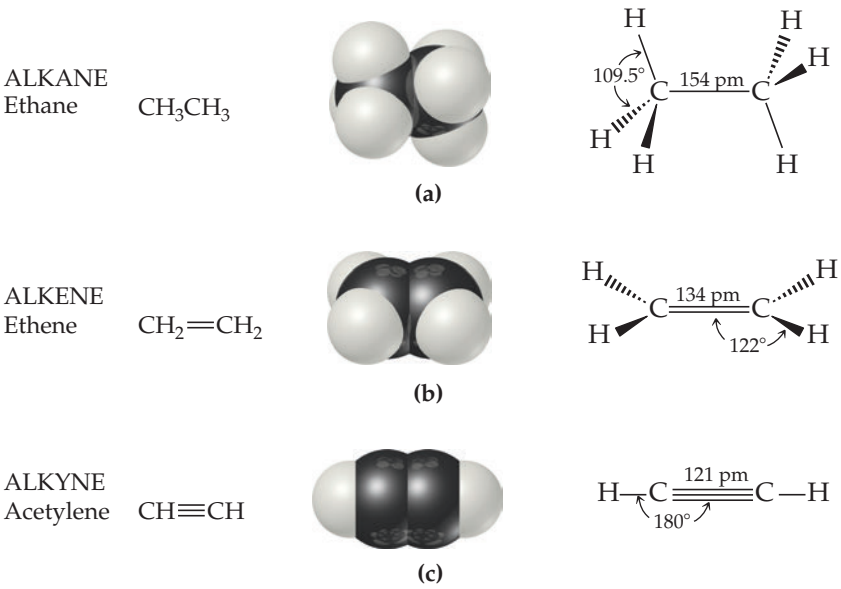
When you finish this section, you should be able to:

- Recognize alkene and alkyne functional groups
- Understand the characteristics of a π-bond including the effect it has on the geometry of a molecule

Alkenes, also known as olefins, are unsaturated hydrocarbons that contain a carbon-carbon double bond. They have the general formula:

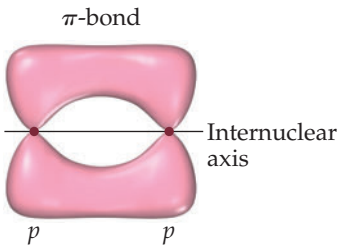
$$C_nH_{2n} \qquad [26.1]$$

The simplest alkene is $CH_2{=}CH_2$, called ethene (IUPAC name) or ethylene (common name). Ethene is a plant hormone that plays important roles in seed germination and fruit ripening. The carbon-carbon double bond makes ethene much more reactive than ethane.



Alkynes are hydrocarbons that contain a carbon-carbon triple bond, as in acetylene (HC≡CH), whose systematic name is ethyne. When acetylene is burned in a stream of oxygen, as in an oxy-acetylene torch, the flame reaches about 3200 K. The oxy-acetylene torch is used widely in welding, which requires high temperatures. Acetylene, and alkynes in general, are highly reactive molecules. Because of their higher reactivity, they are not as widely distributed in nature as alkenes; alkynes are, however, important intermediates in many industrial processes. Alkynes have the general molecular formula

$$C_nH_{2n-2} \qquad [26.2]$$



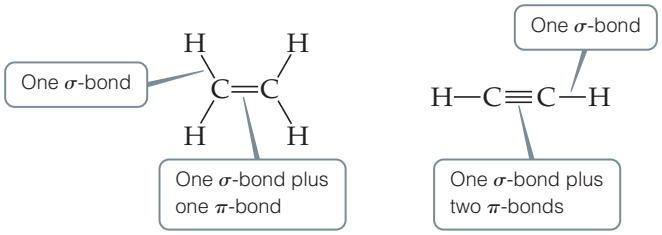
The π-bond

In the types of covalent bonds we have considered so far, the electron density is concentrated symmetrically about the line connecting the nuclei (the *internu clear axis*). In other words, the line joining the two nuclei passes through the middle of the electron overlap region. These bonds are all called **sigma (σ)-bonds**.

To describe the bonding in unsaturated hydrocarbons, we must consider a second kind of bond, one that results from the overlap between two *p* orbitals perpendicular to the internuclear axis (**Figure 26.2**). This "sideways" overlap of *p* orbitals produces a **pi (π)-bond**. A π-bond is a covalent bond in which the electron overlap regions lie above and below the internuclear axis. Unlike a σ-bond, in a π-bond there is no probability of finding an electron on the internuclear axis. Because the *p* orbitals in a π-bond overlap sideways rather than directly facing each other, the total overlap in a π-bond

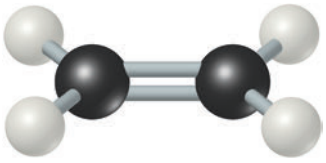
▲ **Figure 26.1** **Three hydrocarbon types for a two-carbon system.**

▲ **Figure 26.2** **The π-bond.** When two *p* orbitals overlap in a sideways fashion, the result is a π-bond. Note that the two regions of overlap constitute a *single* π-bond.



tends to be less than that in a σ-bond. As a consequence, π-bonds are generally weaker than σ-bonds.

We can summarize unsaturation in the following way:



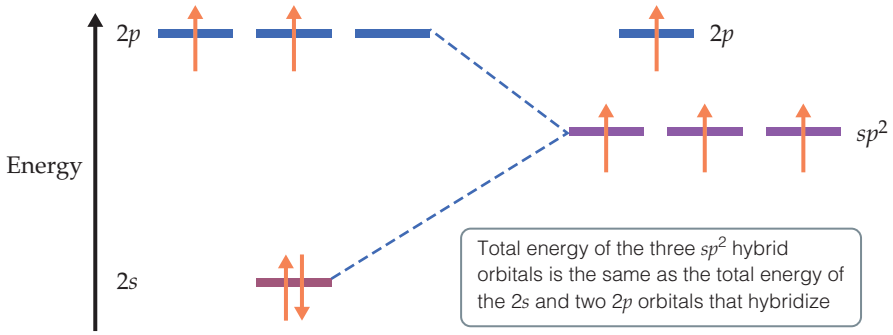
C—C single bonds are σ-bonds.

C=C double bonds consist of one σ-bond and one π-bond.

C≡C triple bonds consists of one σ-bond and two π-bonds.

Bonding in Alkenes

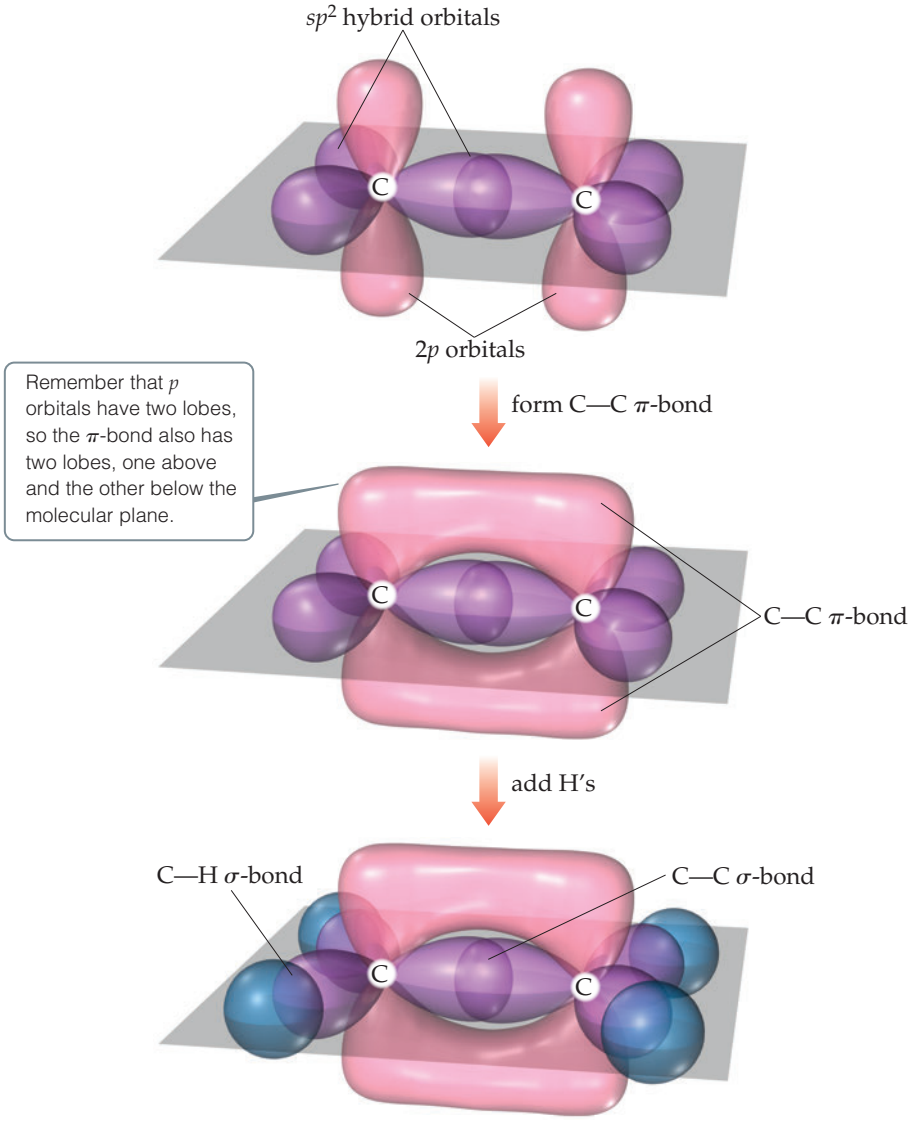
▲ **Figure 26.3 The molecular geometry of ethene.** Ethene, C_2H_4, has one carbon–carbon σ-bond and one π-bond.



In order to rationalize the bonding and geometry of an alkene (**Figure 26.3**), let us consider ethene (C_2H_4). The bond angles about carbon in ethene are all approximately 120° (Figure 26.3), suggesting that each carbon atom uses sp^2 hybrid orbitals (Figure 9.18) to form σ-bonds with the other carbon and with two hydrogens. Because carbon has four valence electrons, after sp^2 hybridization carbon still has one electron remaining in the *unhybridized* 2*p* orbital (**Figure 26.4**).

The unhybridized 2*p* orbital is directed perpendicular to the plane that contains the three sp^2 hybrid orbitals. The hybrid orbitals separate within the same plane to give inter-orbital angles of 120°. This orbital pattern gives rise to a trigonal planar arrangement of σ-bonds.

Each sp^2 hybrid orbital on a carbon atom contains one electron. **Figure 26.5** shows how the four C—H σ-bonds are formed by overlap of sp^2 hybrid orbitals on C with the 1*s* orbitals on each H atom. We use eight electrons to form these four electron-pair bonds. The C—C σ-bond is formed by the overlap of two sp^2 hybrid orbitals, one on each carbon atom, and requires two more electrons. Thus 10 of the 12 valence electrons in C_2H_4 are used to form five σ-bonds.



The remaining two valence electrons reside in the unhybridized 2*p* orbitals, one electron on each carbon atom. These two 2*p* orbitals can overlap with each other in a sideways fashion, as shown in Figure 26.2. The resultant electron density is concentrated above and below the C—C bond axis, forming a single π-bond. Thus the carbon-carbon double bond in ethene consists of one σ-bond and one π-bond. Note carefully that the unhybridized *p*-orbital overlap above and below the plane forms a single π-bond and not two π-bonds.

Although we cannot experimentally observe a π-bond directly (all we can observe are the positions of the atoms), the structure of ethene provides strong support for its presence. First, the carbon-carbon bond length in ethene (134 pm) is much shorter than in compounds with carbon-carbon single bonds (154 pm), consistent with the presence

◀ **Figure 26.4 Degeneracy of hybrid orbitals.** Mixing 2*s* and two 2*p* orbitals yields hybrid orbitals whose energies lie between those of the original atomic orbitals.

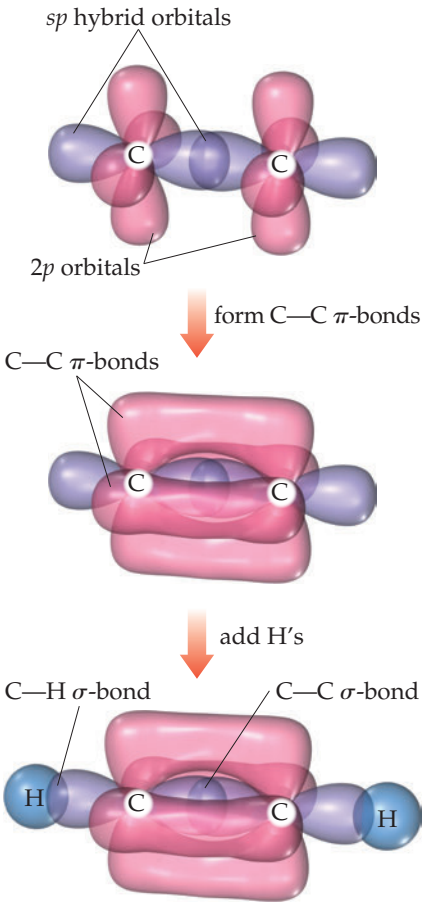
Go Figure Why is it important that the sp^2 hybrid orbitals of the two carbon atoms lie in the same plane?

▲ **Figure 26.5 Hybridization in ethene.** The σ-bonding framework is formed from sp^2 hybrid orbitals on the carbon atoms. The unhybridized 2p orbitals on the C atoms are used to make a π-bond.

of a stronger carbon-carbon double bond (Table 26.1). Second, all six atoms lie in the same plane, and stay in the same plane (Figures 26.3 and 26.5). If the π-bond were absent, there would be no reason for the two CH_2 fragments of ethene to lie in the same

TABLE 26.1 Carbon–carbon bond lengths, general molecular formulas and bond enthalpies for ethane, ethene and ethyne

Molecule	General formula of class	C—C bond length (pm)	Approximate bond enthalpy (kJ mol^{-1})
Ethane	$CH_3—CH_3$	154	350
Ethene	$CH_2=CH_2$	134	620
Ethyne	$CH\equiv CH$	121	840



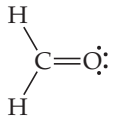
plane, as they could rotate with respect to each other in a similar way to alkanes. As a result, the introduction of one or more π-bonds introduces a degree of rigidity into molecules.

Note the difference in bond strength (bond enthalpy) between ethane and ethene in Table 26.1. The C—C double bond is not twice as strong (meaning twice as hard to break) as a single bond, nor is a triple bond three times as strong as a single bond. The fact that each π-bond is weaker than a σ-bond is part of the reason why alkenes and alkynes are far more reactive than alkanes.

Bonding in Alkynes

The bonding and geometry of carbon-carbon triple bonds can also be explained by hybridization. Ethyne (more commonly known as acetylene, C_2H_2), for example, is a linear molecule containing a triple bond: H—C≡C—H. The linear geometry about the triple bond suggests that each carbon atom uses *sp* hybrid orbitals to form σ-bonds with the other carbon and with one hydrogen. Each carbon atom thus has two remaining unhybridized 2*p* orbitals at right angles to each other and to the axis of the *sp* hybrid set (**Figure 26.6**). These *p* orbitals overlap to form a pair of π-bonds. Thus the triple bond in acetylene consists of one σ-bond and two π-bonds.

Go Figure Based on the models of bonding in ethene and acetylene, which molecule should have the higher carbon–carbon bond energy?



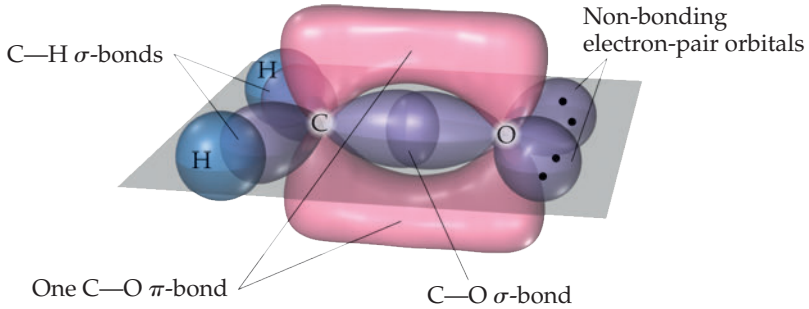
▲ **Figure 26.6 Formation of two π-bonds.** In acetylene, C_2H_2, the overlap of two sets of unhybridized carbon 2*p* orbitals leads to the formation of two π-bonds.

Sample Exercise 26.1

Describing σ-bonds and π-bonds in a molecule

Formaldehyde has the Lewis structure

Describe how the bonds in formaldehyde are formed in terms of overlap of appropriate hybridized and unhybridized orbitals.

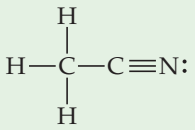


SOLUTION

Analyse We are given a structure containing several types of bonds and are asked to interpret these bonds in terms of hybrid orbitals.

Plan Single bonds are of the σ type, whereas double bonds consist of one σ-bond and one π-bond. The ways in which these bonds form can be deduced from the geometry of the molecule, which we predict using the VSEPR model.

Solve The C atom has three electron domains around it, which suggests a trigonal planar geometry with bond angles of about 120°. This geometry implies sp^2 hybrid orbitals on C. These hybrids are used to make the two C—H and one C—O σ-bonds to C. There remains an unhybridized $2p$ orbital on carbon, perpendicular to the plane of the three sp^2 hybrids.

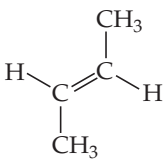


The O atom also has three electron domains around it, so we assume that it has sp^2 hybridization as well. One of these hybrids participates in the C—O σ-bond, while the other two hybrids hold the two non-bonding electron pairs of the O atom. Like the C atom, therefore, the O atom has an unhybridized $2p$ orbital that is perpendicular to the plane of the molecule. The unhybridized $2p$ orbitals on the C and O atoms overlap to form a C—O π-bond, as illustrated in Figure 26.7.

▲ **Figure 26.7 Formation of σ-bonds and π-bonds in formaldehyde, H_2CO.**

Practice Exercise

Consider the acetonitrile molecule:



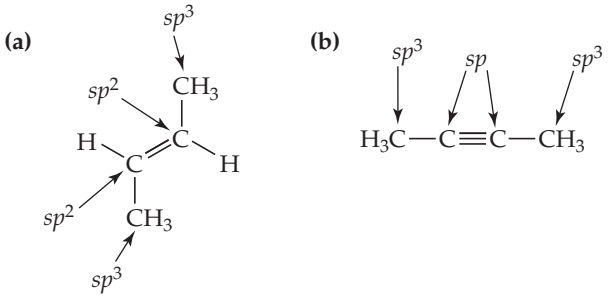
(a) Predict the bond angles around each carbon atom; **(b)** describe the hybridization at each of the carbon atoms; **(c)** determine the total number of σ-bonds and π-bonds in the molecule.

Sample Exercise 26.2

Determining hybridization

Locate the sp^3, sp^2 and sp hybridized carbon atoms in the following compounds.

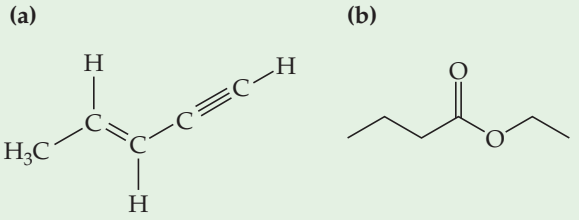
(a) 



(b) $H_3C—C\equiv C—CH_3$

SOLUTION

Analyse We are given two compounds and are asked to relate the bonding types to a level of hybridization.

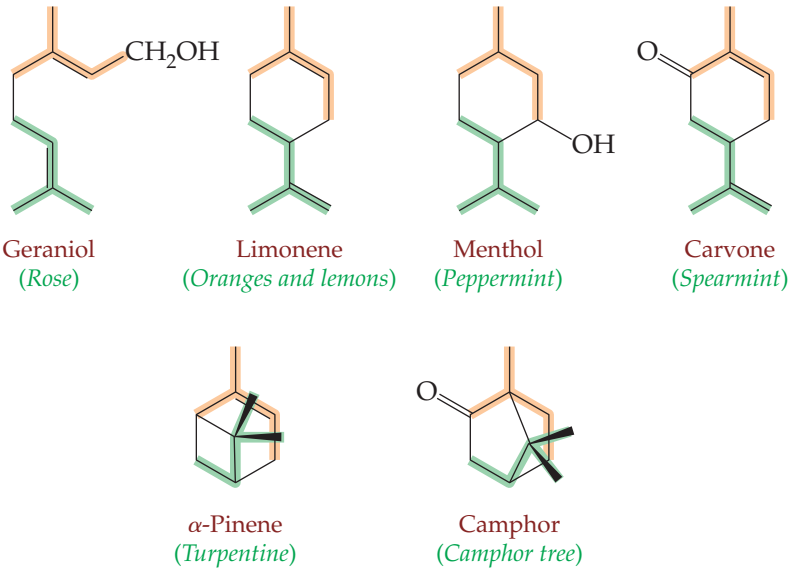


Plan This type of question is made easier by remembering that all carbons are sp^3 hybridized, except for those containing a double bond (in which case they are sp^2 hybridized) and those containing a triple bond (which are *sp* hybridized).

Solve Using these observations:

▶ Practice Exercise

Locate the sp^3, sp^2 and *sp* hybridized carbon atoms in the following compounds.



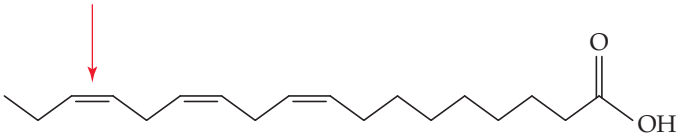
CHEMISTRY AND LIFE Terpenes and Isoprene

Terpenes are a class of naturally occurring compounds whose carbon skeleton can be divided into two or more isoprene units—a five-carbon unit whose systematic name is 2-methyl-1,3-butadiene (Figure 26.8). Terpenes are among the most widely distributed and utilized of all compound classes. Compounds such as camphor, menthol, pinene, geraniol, carvone and limonene are terpenes and each is divisible into two isoprene units.

Distant forest covered hills often appear to have a bluish haze, particularly on hot days. Isoprene is partly responsible for this. This haze is rich in isoprene, oxidized derivatives of isoprene, and other simple terpenes. The worldwide emission rate of these natural hydrocarbons by vegetation has been estimated to be 5×10^{11} kg / year. Eucalyptus trees are a particularly rich source of isoprene and are found covering the Blue Mountains, just west of Sydney, Australia (Figure 26.9).

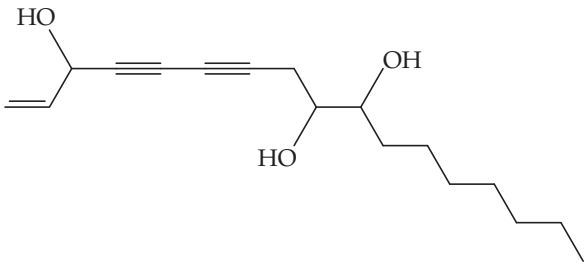
Isoprene is a colourless liquid with a distinct aromatic odour. Large petroleum-based companies such as Shell Chemicals manufacture large quantities of it as a by-product of ethene production. The polymer polyisoprene is used in a wide variety of rubber applications including medical equipment, baby bottle teats/nipples, toys, shoe soles, tyres and the elastic films used inside golf balls. It is also used in adhesives and in paints and coatings.

As shown in the Chemistry and Life box in Section 26.3, several biologically important terpenes, such as vitamin A, play a large role in vision. The terpenes demonstrate effectively how nature uses simple building blocks such as isoprene to construct larger and more complex molecules with even more complex functions.



▲ **Figure 26.8 Well-known terpenes.** Geraniol, limonene, menthol, pinene and camphor are common terpenes. The positions of the isoprene units are highlighted. Note that the isoprene units are "linked" head-to-tail.

▲ **Figure 26.9 The Blue Mountains in Australia.** The blue haze is caused in part by isoprene emitted by the plants of the region.



Self-Assessment Exercises

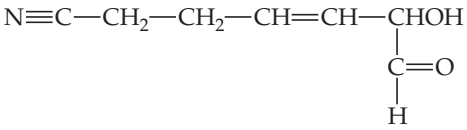
26.1 Many plant oils contain unsaturated fats, of which linolenic acid is an example of an omega-3 fatty acid.

Identify the functional group indicated by an arrow in linolenic acid? (**a**) alkane (**b**) alkene (**c**) alkyne (**d**) alcohol

26.2 Panaxytriol is a natural product found in ginseng. It has the following structure:

How many π-bonds are present in panaxytriol? (**a**) 1 (**b**) 2 (**c**) 3 (**d**) 5

Exercises



26.3 What structural features help us identify a compound as (**a**) an alkene, (**b**) an alkyne?

26.4 Give the molecular formula of a hydrocarbon containing five carbon atoms that is (**a**) an alkane, (**b**) an alkene, (**c**) an alkyne. Which are saturated and which are unsaturated hydrocarbons?

26.5 Give the molecular formula of a cyclic alkane, a cyclic alkene and a linear alkyne that in each case contains six carbon atoms. Which are saturated and which are unsaturated hydrocarbons?

26.6 What are the approximate bond angles (**a**) about carbon in an alkane, (**b**) about a C—C double bond in an alkene, (**c**) about a C—C triple bond in an alkyne?

26.7 Identify the carbon atom/s in the following structure that has/have each of the following hybridizations: (**a**) sp^3, (**b**) sp, (**c**) sp^2.

26.2 | Isomerism and Nomenclature

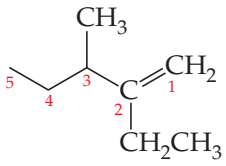
The π-bond of an alkene introduces a rigidity to the carbon–carbon chain at the double bond, which is not seen in an alkane. It is rather like the crosspiece of a five-barred gate lending strength to the structure. The consequence of this is that we may have two distinct

geometries resulting from a molecule of a single constitution. This is another example of the wonderful variety that arises from even simple molecules. The two different shapes of a double bond in the protein rhodopsin are central to the way we see and, in the area of polymers, we have a single monomer producing rubber with its elastic nature or gutta percha, which is a rigid material used as a filler in dental root canal therapy.

When you finish this section, you should be able to:

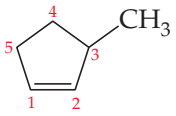
- Name simple alkene and alkyne molecules
- Recognize where geometric isomers arise and be able to assign a stereochemical descriptor to the name of the structure

Alkene nomenclature is based on the longest continuous chain of carbon atoms that *contains* the double bond. The name given to this longest chain is obtained from the name of the corresponding alkane (Table 24.3), by noting the position of unsaturation, and by changing the ending from *-ane* to *-ene*. Examples of an alkene and cycloalkene and their systematic names are shown in **Figure 26.10**. Note that the longest carbon chain in 2-ethyl-3-methylpent-1-ene is not the one that contains the double bond. This chain is ignored because the longest chain *containing the double bond* takes precedence in naming. Note too that the double bond is always given the lowest position number possible.



The general formula for a cycloalkene is

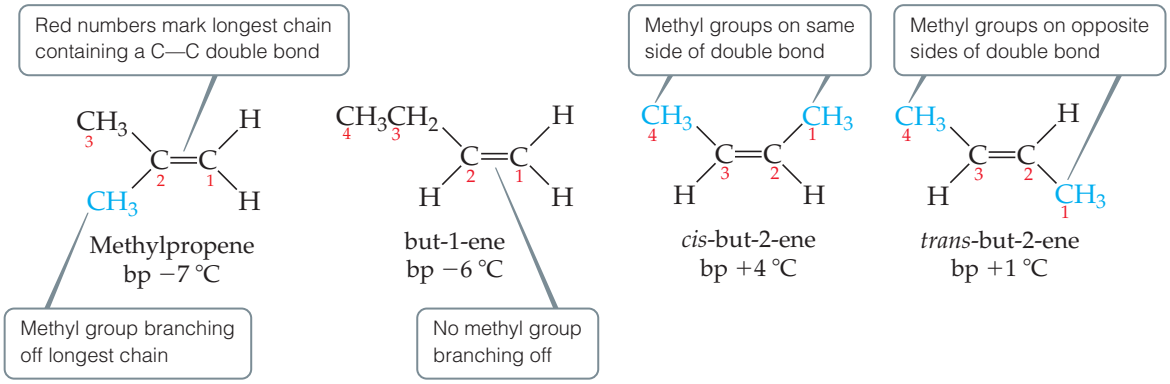
$$C_nH_{2n-2} \qquad [26.3]$$



which is the same as that of an alkyne. Hence, cycloalkenes and alkynes with the same number of carbon atoms are constitutional isomers.

The location of the double bond along an alkene chain is indicated by a prefix number. The chain is always numbered from the end that brings us to the double bond sooner and hence gives the smallest-numbered prefix. In propene the only possible location for the double bond is between the first and second carbons; thus a prefix indicating its location is unnecessary. For butene (**Figure 26.11**) there are two possible positions for the double bond: either after the first carbon (but-1-ene) or after the second carbon (but-2-ene).

If a substance contains two or more double bonds, each one is located by a numerical prefix. The ending of the name is altered to identify the number of double bonds: diene (two), triene (three) and so forth. For example, $CH_2{=}CH{-}\ CH_2{-}CH{=}\ CH_2$ is named penta-1,4-diene.

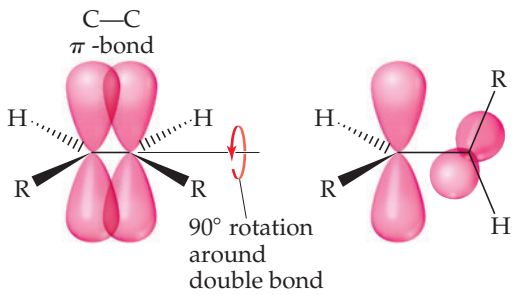


2-Ethyl-3-methylpent-1-ene

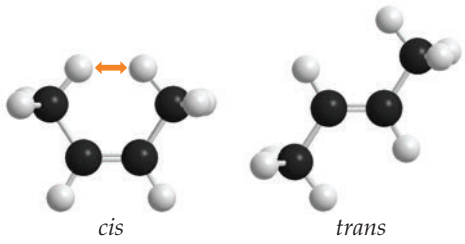
3-Methylcyclopentene

▶ **Figure 26.10 Nomenclature of alkenes.** Alkene nomenclature is derived from the longest carbon chain containing the double bond. The position of the double bond is always assigned the lowest position number possible. The position of the double bond in a cycloalkene is arbitrarily assigned as spanning positions 1 and 2.

Go Figure How many isomers are there for propene, C_3H_6?



▲ **Figure 26.11 C_4H_8 structural isomers.** Full structural formulas names and boiling points of alkenes with the molecular formula C_4H_8.



Isomerism in Alkenes—The *E*, *Z* System

Alkenes with two or more different substituents that lie on either side of the carbon-carbon double bond occur as geometrical isomers. For example, the two structures *cis*-but-2-ene and *trans*-but-2-ene (Figure 26.11) are geometric isomers. Their molecular formula and connectivity are the same; they differ only by the spatial arrangement of the two methyl groups. Geometric isomers, like diastereomers, possess distinct physical properties, such as boiling point, and often differ significantly in their chemical behaviour. This isomerism is a result of the restricted rotation about the carbon-carbon double bond, which in turn is caused by the *p*-orbital overlap required for formation of the π-bond (**Figure 26.12**). The carbon–carbon bond axis and the bonds to the hydrogen atoms and to the alkyl groups (designated R) are all in a plane. The *p* orbitals that overlap sideways to form the π-bond are perpendicular to the molecular plane. As Figure 26.12 shows, rotation around the carbon–carbon double bond requires the π-bond to be broken, a process that requires considerable energy (about 250 kJ/mol). Although rotation about a double bond doesn't occur easily, it is a key process in the chemistry of vision (see Chemistry and Life box later in Section 26.3).

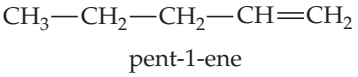
Cis-alkenes tend to be less stable than *trans*-alkenes because of the extra steric interactions that occur when both alkyl substituents are on the same side of the double bond. **Figure 26.13** illustrates this point using the geometric isomers of but-2-ene.

▲ **Figure 26.12 Rotation about a carbon–carbon double bond.** In an alkene, the overlap of the *p* orbitals that form the π-bond is lost in the rotation. For this reason, rotation about carbon–carbon double bonds does not occur readily, usually requiring the absorption of energy.

▲ **Figure 26.13 Steric interactions in alkenes.** Alkenes such as *cis*-but-2-ene are less stable than their *trans* counterpart due to added steric interactions.

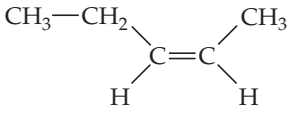
Sample Exercise 26.3

Drawing isomers



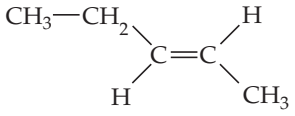
Draw all the structural and geometric isomers of pentene, C_5H_{10}, that have an unbranched hydrocarbon chain.

SOLUTION



Analyse We are given the name of an alkene and asked to derive all possible isomer permutations.

Plan Because the compound is named pentene and not pentadiene or pentatriene, we know that the five-carbon chain contains only one carbon–carbon double bond. Thus we can begin by first placing the double bond in various locations along the chain, remembering that the chain can be numbered from either end. After finding the different distinct locations for the double bond, we can consider whether the molecule can have *cis* and *trans* isomers.

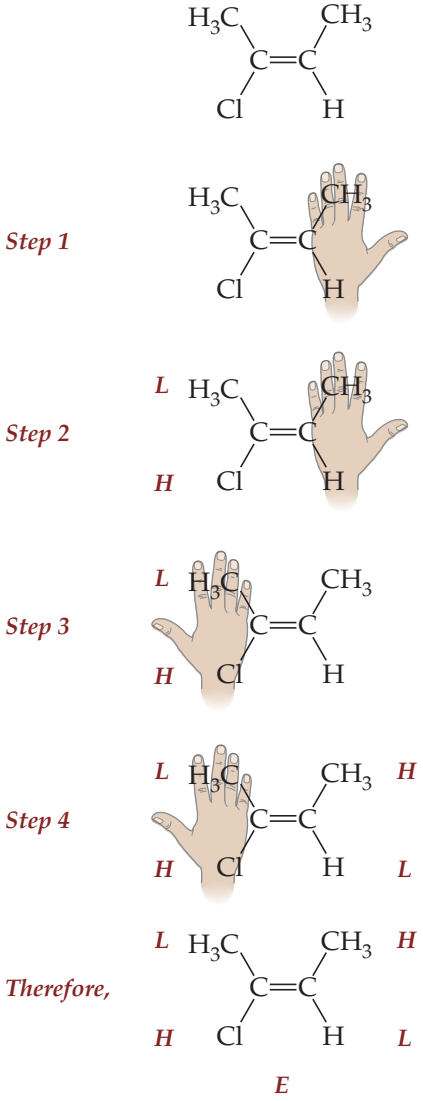


Solve There can be a double bond after either the first carbon (pent-1-ene) or second carbon (pent-2-ene). These are the only two possibilities because the chain can be numbered from either end. (Thus what we might erroneously call pent-4-ene is actually pent-1-ene, as seen by numbering the carbon chain from the other end.) Because the first C atom in pent-1-ene is bonded to two H atoms, there are no *cis*–*trans* isomers. However, there are *cis* and *trans* isomers for pent-2-ene. Thus the three isomers for pentene are

pent-1-ene

cis-pent-2-ene

trans-pent-2-ene

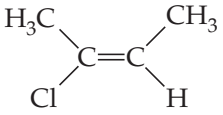


(You should convince yourself that *cis*- or *trans*-pent-3-ene is identical to *cis*- or *trans*-pent-2-ene, respectively.)

Practice Exercise

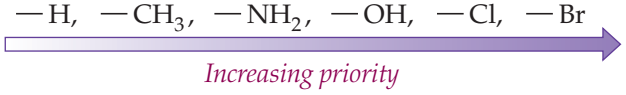
How many straight-chain isomers are there of hexene, C_6H_{12}?

Go Figure



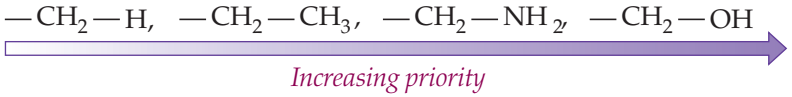
What stereoisomer would you get if you replaced Cl with H in this example? *E* or *Z*?

▲ **Figure 26.14 Assignment of *E* and *Z* isomers.** The hand acts to remove one side of the molecular structure from consideration.



Although *cis* and *trans* nomenclature is useful to describe simple geometric isomers, it fails to describe more complex isomers accurately. To remove any ambiguity in naming geometric isomers, the IUPAC has established a set of priority rules similar to the Cahn–Ingold–Prelog priority rules used for determining stereochemistry.

The system for naming isomers is known as the ***E, Z* system**. An alkene is designated *E* (from German *entgegen*, meaning "opposite") or *Z* (from German *zusammen*, meaning "together") based on specific priority rules. The priority rules are listed and their application to the geometric isomer of 2-chloro but-2-ene is shown in **Figure 26.14**.

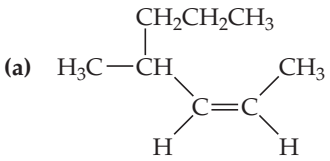


2-chloro-but-2-ene

1. Split the molecule through the C—C double bond into two parts and concentrate on setting the priority for one side at a time.
2. Assign a priority to each substituent using H for highest priority and L for lowest priority, based on the *atomic number* of the two atoms directly attached to the sp^2 carbon atom. The higher the atomic number, the higher the priority. A representative set of groups in increasing priority order is:

If two atoms are identical in terms of priority, you need to move out along the respective chains until you encounter a difference in priority. Reapply rule 2 to determine priority. If no difference is found, the two substituents must be identical and no *E*/*Z* isomerism is possible. An example of increasing priority fragments is:

3. Repeat step 2 for the other side of the C—C double bond.
4. If the two higher-priority groups are on the same side of the double bond, the alkene is the *Z* isomer. If they occur on opposite sides, as in the example shown in Figure 26.14, the alkene is the *E* isomer.



Alkynes

Alkynes are unsaturated hydrocarbons containing one or more C—C triple bonds. Alkynes are named by identifying the longest continuous chain in the molecule *containing the triple bond* and modifying the ending of the name, as listed in Table 24.3, from *-ane* to *-yne*, as shown in Sample Exercise 26.4. Alkynes are linear about the C—C triple bonds, so geometric isomerism is not possible about the triple bond. Alkynes are, however, constitutional isomers of cycloalkenes.

Sample Exercise 26.4

Naming unsaturated hydrocarbons

Name the following compounds:

Continued

SOLUTION

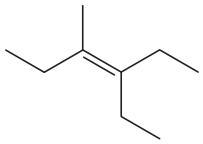
Analyse We are given the structural formulas for two compounds—the first an alkene and the second an alkyne—and asked to name them.

Plan In each case, the name is based on the number of carbon atoms in the longest continuous carbon chain that contains the multiple bond. In the case of (a), care must be taken to indicate whether *E, Z* isomerism is possible and, if so, which isomer is given.

Solve

(a) The longest continuous chain of carbons that contains the double bond is seven carbons in length. The parent compound is therefore heptene. Because the double bond begins at carbon 2 (numbering from the end closest to the double bond), the parent hydrocarbon chain is named hept-2-ene. A methyl group is located at carbon atom 4. Thus the compound is 4-methylhept-2-ene. The geometrical configuration at the double bond is *Z* (that is, the alkyl groups are bonded to the double bond on the same side). Thus the full name is *Z*-4-methylhept-2-ene.

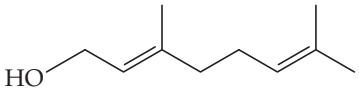
(b) The longest continuous chain of carbon atoms containing the triple bond is six, so this compound is a derivative of hexyne. The triple bond comes after the first carbon (numbering from the right), making it a derivative of hex-1-yne. The branch from the hexyne chain contains three carbon atoms, making it a propyl group. Because it is located on the third carbon atom of the hexyne chain, the molecule is 3-propylhex-1-yne.



Practice Exercise

Draw the condensed structural formula for 4-methylpent-2-yne.

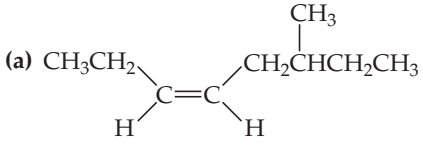
In Chapter 32, we will discuss the techniques used to determine the molecular structure of alkenes and alkynes—namely nuclear magnetic resonance spectroscopy, infrared spectroscopy and mass spectrometry.



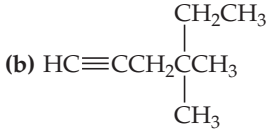
Self-Assessment Exercises

26.8 What is the correct name for this structure?

(**a**) 2,3-diethylpent-2-ene (**b**) 3-ethyl-4-methylhex-3-ene (**c**) 3,4-diethylpent-3-ene



26.9 What is the correct descriptor (*E* or *Z*) for the double bonds in geraniol, a component in citronella oil.



(**a**) both *E* (**b**) both *Z* (**c**) one *E* and one *Z* (**d**) only one double bond has stereochemistry and that is *E* (**e**) only one double bond has stereochemistry and that is *Z*

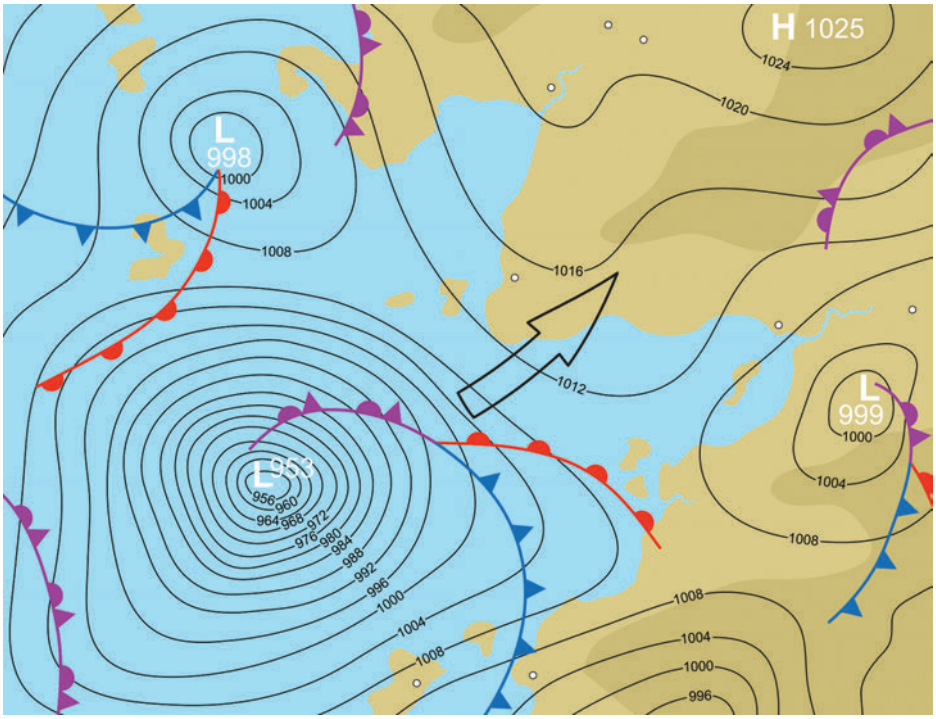
Exercises

26.10 Name the following compounds systematically:

(a) 

(b) 

(c) 



26.11 Why is geometric isomerism possible for alkenes, but not for aliphatic alkanes and alkynes?

26.12 Draw the condensed structural formulas for the *E* and *Z* isomers of pent-2-ene. Can cyclopentene exhibit *E, Z* isomerism? Explain.

26.3 Arrow Notation and Resonance Structures: Electron Counting

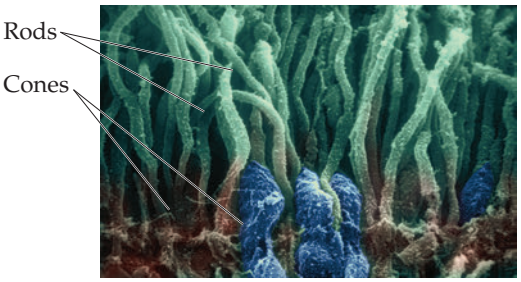
From the results of many experiments, we can learn the product we get from mixing two chemicals together. However, if we understand how the molecules interact to give this product, then our knowledge allows us to predict the outcome of reactions that have yet to be tried. Using a few basic rules, we can construct a likely *mechanism* for the reaction. While it is very difficult to see individual molecules reacting with one another (and even that through the use of highly advanced technology), the reaction mechanism can help us visualize what is going on at a molecular level. One tool we use to aid us with this is the drawing of "curved arrows". These arrows represent the movement of electrons either within a molecule or between two molecules and allow us to keep track of what is going on. Rather like predicting the weather, we use a combination of observations of past events with a model of how change occurs to predict outcomes.

When you finish this section, you should be able to:

- Draw curved arrows to show the electron movements in a resonance structure
- Extend the concept of curved arrows to a reaction between an electron donor and an electron acceptor

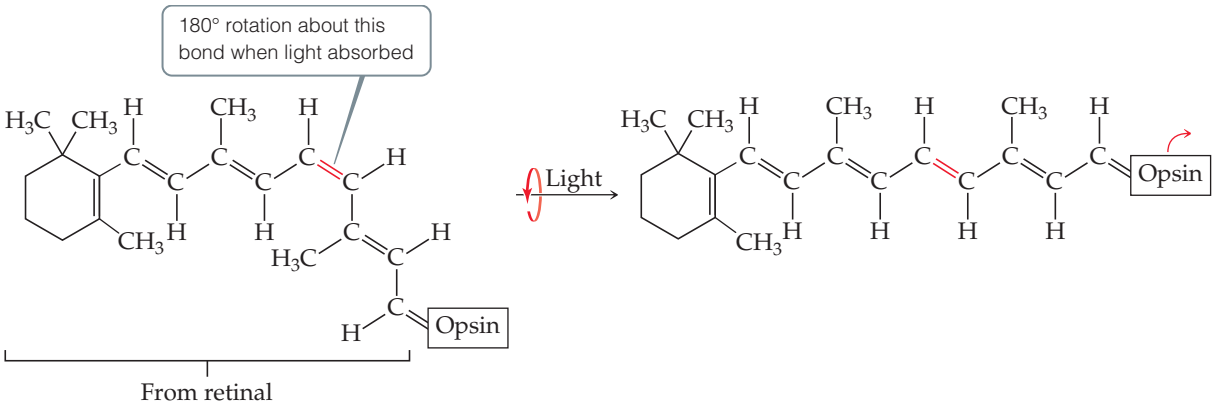
A "straight" arrow indicates the transformation of a reactant into a product in a chemical equation. Arrows can also be used to track the flow of electrons that is occurring. In this case a curved arrow is used so there is no confusion about which process we are showing. The curved arrows always start from where the electrons are coming from and end where the electrons are going to. Curved arrows are used for three common types of electron redistribution:

1. From a bond to an adjacent atom—this forms a lone pair on the receiving atom, or joins two molecules together.
2. From an atom to an adjacent bond—this uses a lone pair on the donor atom to form a π-bond.
3. From one bond to an adjacent bond—this redistributes the electrons although, overall, the same number of σ- and π-bonds is retained.



CHEMISTRY AND LIFE The Chemistry of Vision

Scientists have begun to understand the complex chemistry of vision. Vision begins when light is focused by the lens onto the retina, the layer of cells lining the interior of the eyeball. The retina contains *photoreceptor* cells known as rods and cones (**Figure 26.15**). The human retina contains about 3 million cones and 100 million rods. The rods are sensitive to dim light and are used in night vision. The cones are sensitive to colours. The tops of the rods and cones contain a substance called *rhodopsin*. Rhodopsin consists of a protein, called *opsin*, bonded to a reddish-purple pigment called *retinal*, which is similar in structure to β-carotene. Structural changes around a double bond in the retinal portion of the molecule trigger a series of chemical reactions that result in vision. Our recent discussions now allow us to appreciate another aspect of double bonds: the rigidity that they introduce into molecules.

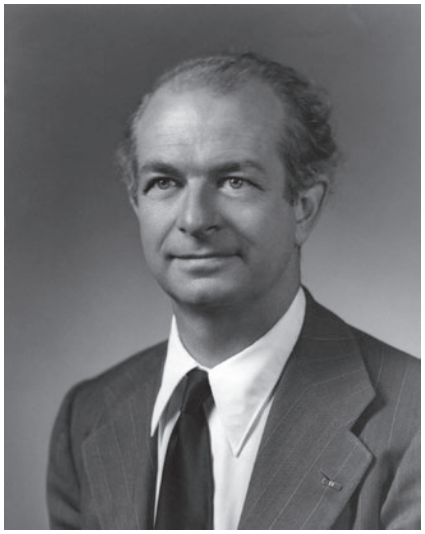


Imagine taking the $-CH_2$ group of the ethene molecule and rotating it relative to the other $-CH_2$ group, as shown in Figure 26.12. This rotation destroys the overlap of *p* orbitals, breaking the π-bond, a process that requires considerable energy. Thus the presence of a double bond restricts the rotation of the bonds in a molecule.

Our vision depends on this rigidity in retinal. In its normal form, retinal is held rigid by its double bonds, as shown on the left in **Figure 26.16**. Light entering the eye is absorbed by rhodopsin, and the energy is used to break the π-bond portion of the indicated double bond. The molecule then rotates around this bond, changing its geometry. The retinal then separates from the opsin, leading to conformational changes that trigger the reactions producing a nerve impulse. The brain interprets this impulse as the sensation of vision. It takes as few as five closely spaced molecules reacting in this fashion to produce the sensation of vision. Thus only five photons of light are necessary to stimulate the eye.

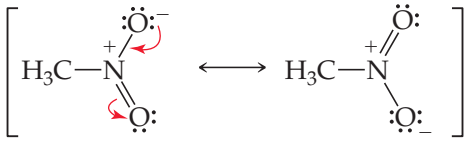
Enzymes in the retina revert the retinal to its original form and reattach it to the opsin. The slowness of this process helps to explain why intense bright light causes temporary blindness. The light causes all the retinal to separate from the opsin, leaving no further molecules to absorb light.

▲ **Figure 26.15 Inside the eye.** A colour-enhanced scanning electron micrograph of the rods (yellow) and cones (blue) in the retina of the human eye.



▲ **Figure 26.16 The chemical basis of vision.** When rhodopsin absorbs visible light, the π component of the double bond (shown in red) breaks, allowing rotation that produces a change in molecular geometry.

The use of curved arrows is a useful way to rationalize all your organic reactions or to demonstrate stability. Following this set of simple rules will help you master this technique. All structures generated using curved arrows must:



1. have the same number of valence electrons as the starting structure,
2. obey the rules of covalent bonding—for example, no more than four formal bonds to carbon,
3. differ only in the distribution of valence electrons,
4. have the same number of paired or unpaired electrons.

The concept of resonance was advanced in the 1930s by Linus Pauling (1901–1994) (**Figure 26.17**). He rationalized that many molecules and ions are best described by writing two or more Lewis structures, and that individual Lewis structures are *contributing structures*.

▲ **Figure 26.17 Linus Pauling,** a scientist of the highest calibre who won a Nobel Prize in 1954 for his contributions to chemistry. He was also very socially aware, using his scientific knowledge and his influence to combat nuclear testing in the 1950s and 1960s. For this effort, he was awarded the Nobel Peace Prize in 1962 and is still the only person in history to have won two unshared Nobel Prizes.

Let us consider the two contributing (resonance) structures of nitromethane using curved arrow notation to interconvert contributor A and contributor B:

Contributor A Contributor B

The curved arrows, shown in red, are placed on the first structure to show how the electrons move during the transformation into the second structure. In this case a lone pain on one oxygen atom becomes the new π-bond while the electron pair of the π-bond in contributor. A shifts to become a lone pair on the second oxygen atom. Note that the curved arrow indicates the movement of an electron *pair* and not of single electrons.

The two different contributing structures of nitromethane are linked by a double-headed (resonance) arrow as opposed to a set of equilibrium arrows ($\rightleftharpoons$) and are grouped together in square brackets since they both contribute to the same structure. This means that the actual molecule (or ion) is a hybrid of the various contributing structures. In other words the "real" structure of nitromethane is neither contributor A nor contributor B, but something in between—that is, a structure in which the negative charge is spread across both oxygens. We say that the negative charge is *delocalized* across the two N—O bonds. We can observe this delocalization experimentally by looking at the N—O bond lengths in *nitro* compounds. The two bond lengths are equal at 121 pm and lie between the size of a single N—O bond and a double N—O bond.

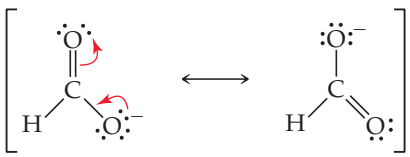
The presence, or absence, of contributing resonance structures plays a large part in the reactivity of molecules and ions. We will see a lot more of this, especially when discussing what constitutes a good leaving group and the reactivity of phenols.

A CLOSER LOOK Describing Charge

⊕ or +? Organic chemists tend to circle positive and negative signs on molecules to distinguish charge from bonds and plus signs. It also helps when describing electron redistribution. From here on, we will use this form of notation in our mechanistic considerations.

Sample Exercise 26.5

Resonance and curved arrows



Draw two equivalent resonance structures for the formate ion, HCO_2^- using curved arrows to indicate movement of electrons.

SOLUTION

Analyse Draw the two contributing forms and note the differences.

Plan Redistribute valence electrons on the oxygen bearing the negative charge and within the double bond.

Solve

Practice Exercise

Which of the following molecules or ions will exhibit delocalized bonding: SO_3^{2-}, H_2CO, O_3, NH_4^+?

Arrow notation can also be used to rationalize a reaction's pathway or *mechanism*. A simple and general reaction may look like this:

$$Nu^-: + E^+ \longrightarrow Nu{-}E \qquad [26.4]$$

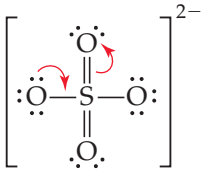
where "Nu" is not the fictional element "nubrium" but a nucleophile—that is, any molecule or ion with a lone pair of electrons available for reaction. We can use the arrow notation to describe pictorially how the lone pair on Nu is able to form a new covalent bond with an electrophile E (electro, meaning *negative*; phile, meaning *loving*), which is an electron-pair acceptor:

$$Nu^-: \curvearrowright E^+ \longrightarrow Nu{-}E \qquad [26.5]$$

An example of this type of reaction is

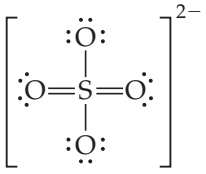
We will gain significant experience at using arrow notation in the next section and throughout the next five chapters as we discuss the reactivity of functional groups.

Self-Assessment Exercises



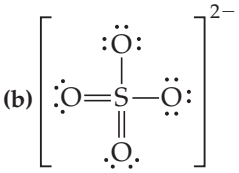
26.13 What does a curved arrow represent?

(**a**) The transformation of reactants into products

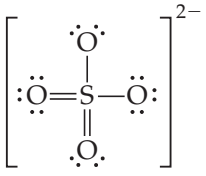


(**b**) The movement of a single electron

(**c**) The movement of a pair of electrons



26.14 Which resonance structure results from the curved arrows shown in this contributor to the sulfate ion:

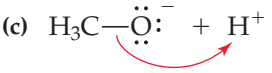


(a)

(b)

(c)

26.15 Which curved arrow correctly represents the following reaction:

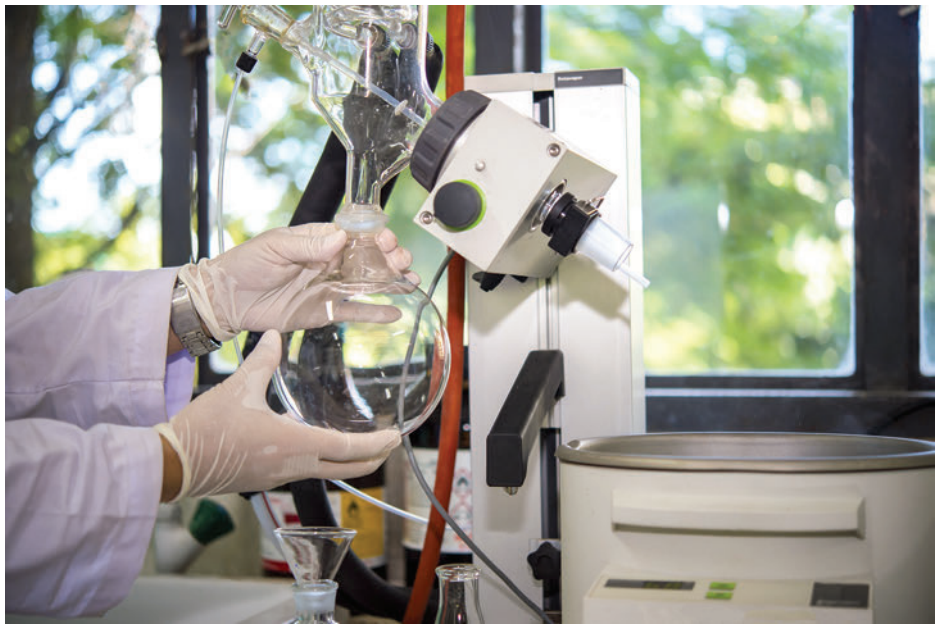


(a)

(b)

(c)

Exercises



26.16 **(a)** Write a single Lewis structure for acetate, CH_3COO^-. **(b)** Are there other equivalent Lewis structures for the molecule? **(c)** Would you expect CH_3COO^- to exhibit delocalized π-bonding? **(d)** Draw the curved arrows that represent the electron movement linking the two resonance contributors of the acetate ion. Explain.

26.17 Draw the curved arrows representing the electron pair movement in the neutralization reaction of the acetate ion, CH_3COO^-, with H^+.

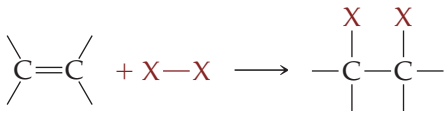
26.4 Electrophilic Addition Reactions

A synthetic organic research chemist is someone whose focus is to transform chemicals that are cheap and readily available into new molecules that have a specific purpose, for example as pharmaceuticals or a new type of glue or a material with a high strength to weight ratio. In this section, we see how the process may start as we look at reactions of unsaturated hydrocarbons. A few different combinations of chemicals can lead to a wide variety of products. While this may seem confusing at first, we find that the reactions all occur by the same basic mechanism so by visualizing what happens on a molecular level enables us to predict the outcome of all electrophilic addition reactions. There is a distinct pattern to what is occurring!

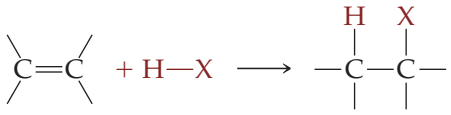
When you finish this section, you should be able to:

- Predict the outcome of any electrophilic addition reaction
- Understand the mechanism by which these reactions occur
- Use your knowledge of the reaction mechanism to rationalize the regioselective and stereoselective characteristics of the reaction



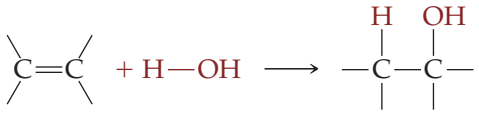
The presence of carbon–carbon double or triple bonds in a compound markedly increases its chemical reactivity. The most characteristic reactions of alkenes and alkynes are **addition reactions**, in which a reactant is added across the two carbon atoms that form the multiple bond. Three main types of addition reactions are typical of alkenes and alkynes, leading to increasing the degree of functionality within a hydrocarbon: **halogenation**, **hydrohalogenation** and **hydration**. These reactions involve the addition of X_2 (X = Cl, Br), HX (X = Cl, Br, I) and HOH (water), respectively. **Figure 26.18** shows a general representation of each reaction.

The reason why alkenes and alkynes are so reactive is twofold. In both cases, the unhybridized *p* orbitals that form the π-bonds are electron-rich, so would be expected to attract electron-deficient species. Also, we have seen that in carbon, π-bonds are weaker than σ-bonds, so would be expected to react to form σ-bonds wherever possible. Moreover, the shape of alkenes and alkynes make them easily accessible to reagents (**Figure 26.19**). The electron-rich nature of a multiple bond leads to enhanced reactivity with electrophiles. Hence, **electrophiles** are molecules that accept a pair of electrons in a chemical reaction. Reactions of alkenes and alkynes with electrophiles are called electrophilic addition reactions.



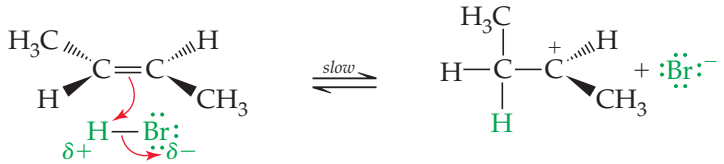
Addition Reactions Involving HX (X = Cl, Br, I)

Let's consider the addition reaction between HBr and but-2-ene as a representative of this reaction type. The reaction proceeds in two steps. In the first step, which is



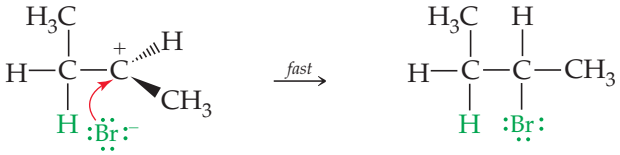
(a) Halogenation

(b) Hydrohalogenation



(c) Hydration

▲ **Figure 26.18 Addition reactions of alkenes and alkynes (X = halogen).** Halogenation, hydrohalogenation and hydration of an alkene are useful and efficient ways of preparing alkyl halides and alcohols. The addition reactions of alkynes follow those of the alkenes.

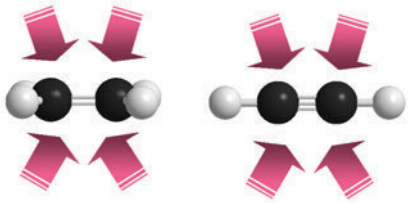


rate-determining, the electron-rich double bond attacks the hydrogen of HBr (the electrophile), which transfers a proton to one of the two alkene carbons and produces a bromide ion in the process:

[26.6]

The pair of electrons that formed the π-bond between the carbon atoms in the alkene are used to form the new C—H bond. As a result, one carbon has fewer valence electrons associated with it. This carbon is now electron-deficient, as indicated by the positive charge. Organic molecules bearing a positive charge on carbon are called **carbocations**. Carbocations are classified as *primary* (1°), *secondary* (2°) or *tertiary* (3°), depending on the number of carbon units bonded to the positively charged carbon. For example, the carbocation formed on the right-hand side in Equation 26.6 is secondary, as the carbon bearing the positive charge has two other carbons bonded directly to it.

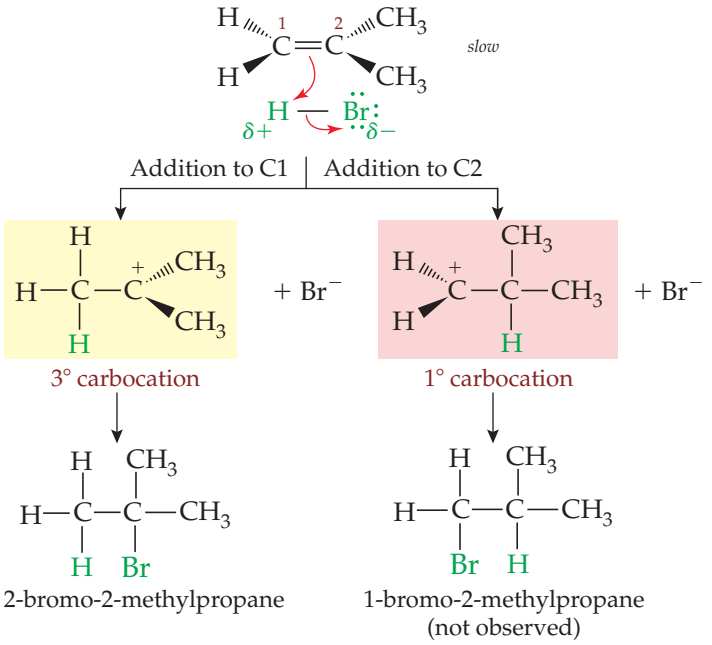
The second step, involving the addition of Br^- to the carbocation, is faster:



[26.7]

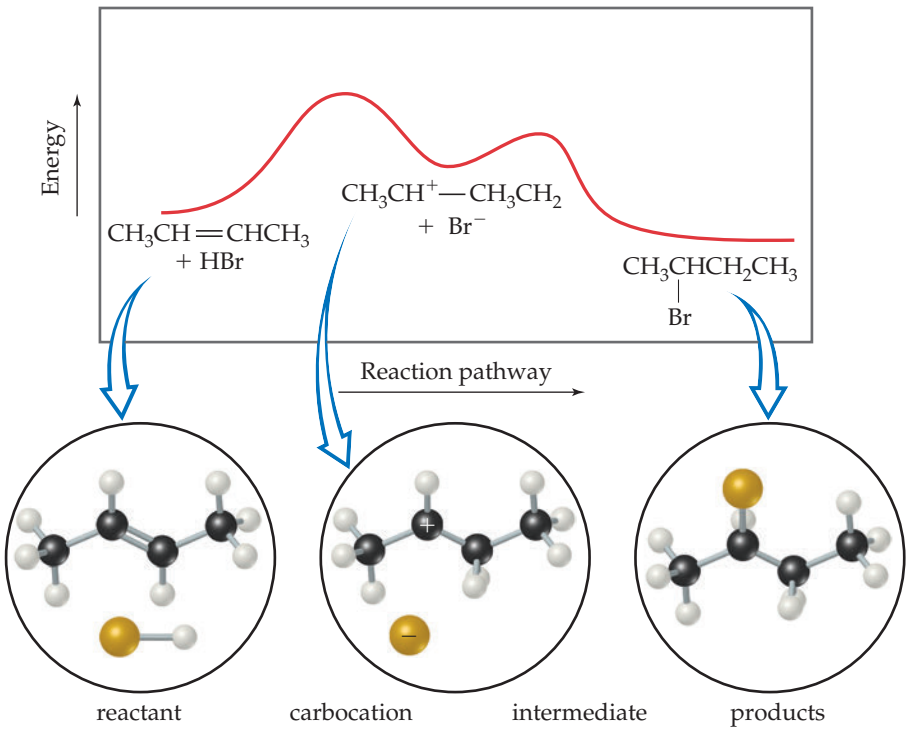
In this step the bromide ion donates a pair of electrons to the carbocation, forming the new C—Br bond. The bromide ion is behaving as a **nucleophile** (*nucleus-loving*). A nucleophile is a species that donates a pair of electrons in a chemical reaction. Nucleophiles are electron-rich species.

Since the first step in the reaction involves both the alkene and hydrogen halide, the rate law for the reaction is second order, first order in both the alkene and HBr:



$$\text{Rate} = -\frac{\Delta[CH_3CH{=}CHCH_3]}{\Delta t} = k[CH_3CH{=}CHCH_3][HBr] \qquad [26.8]$$

▲ **Figure 26.19 The accessibility of alkenes and alkynes.** The trigonal planar and linear geometries of alkenes and alkynes makes the addition of halogens easier through the exposed faces, as indicated by the arrows. Alkynes have two additional regions of accessibility, one directed out of the page and the other into the page.



The energy profile for the reaction is shown in **Figure 26.20**. The first energy maximum represents the transition state in the first step of the mechanism. The second maximum represents the transition state for the second step. Notice that there is an energy minimum between the first and second steps of the reaction. This energy minimum corresponds to the intermediate carbocation.

Let us now consider the reaction of 2-methylpropene with HBr. This reaction is a *regioselective reaction* meaning that one product, 2-bromo-2-methylpropane, is formed predominantly. The first step of the addition leads to the possible formation of two intermediate carbocations:

[26.9]

Go Figure As shown, is this reaction endothermic or exothermic?

▲ **Figure 26.20** **Energy profile for addition of HBr to but-2-ene.**

From a large body of experiments, we know that 3° carbocations are more stable and require a lower activation barrier to formation than either 1° or 2° carbocations. Hence the product distribution can be rationalized based on which intermediate is formed in preference.

The relative stability of primary, secondary and tertiary carbocations is:

less stable 1° < 2° < 3° *most stable*

and is based on how easily the alkyl groups around the positive charge can spread the charge away. This is known as an *inductive effect*. The larger the area the positive charge is spread over, the more stable the carbocation. In the case of hydrocarbons, as the number of alkyl groups increases so too does the stability of the carbocation increase.

The first person to note the regioselectivity in hydrohalogenations (and hydrations) was Vladimir Markovnikov (1837–1904). The general rule for electrophilic additions to alkenes bears his name. **Markovnikov's rule** states:

In the addition of HX to an alkene, the hydrogen adds to the carbon atom of the double bond bearing the greater number of hydrogen atoms bonded directly to it.

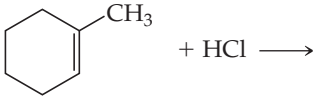
This can also be written:

In the addition of HX to an alkene, the hydrogen adds to the least substituted carbon atom of the double bond.

This rule provides an easy way to predict the major product of an addition reaction involving HX.

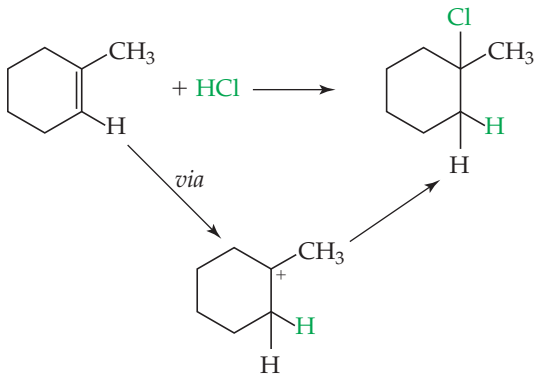
Returning to Equation 26.9, C1 has two hydrogens directly attached whereas C2 has none (those on the methyl group hydrogens do not count because they are not directly attached to the sp^2 hybridized carbon of the double bond). The product predicted by using Markovnikov's rule is certainly the one predicted on the basis of carbocation stability.

Sample Exercise 26.6



Addition of HX to alkenes

Name and draw the structural formula for the major product formed when 1-methylcyclohexene reacts with HCl. Justify your choice for the major product.

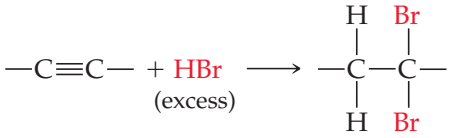


SOLUTION

Analyse We are asked for several things here, including knowing something about nomenclature and converting names into structures, as well as the reactivity of alkenes.

Plan Begin by drawing the structure of the reactants and identify the reaction as the addition of HCl to the double bond:

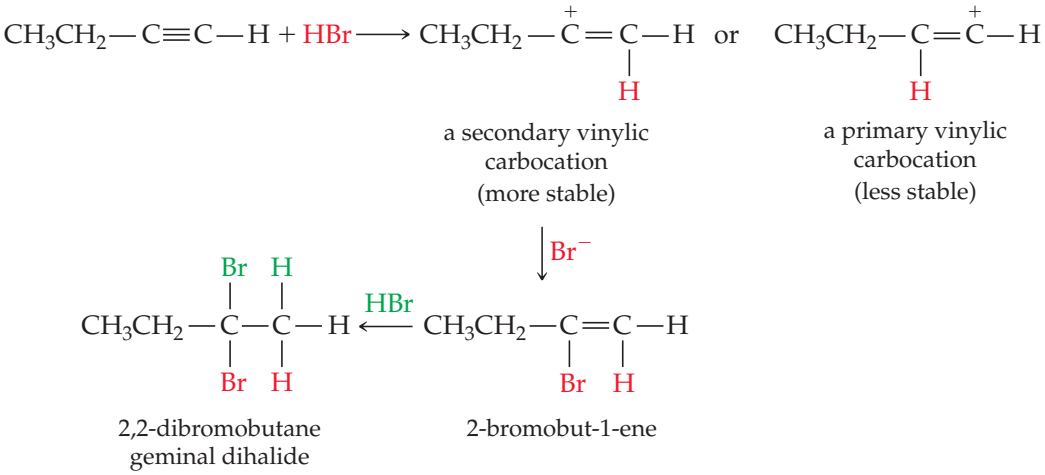
Solve Using Markovnikov's rule, the hydrogen atom of HX should add to the double bond on the side with the most number of hydrogens:



Hence our answer is *1-chloro-1-methylcyclohexane*. Our justification comes from the relative stabilities of the possible carbocation intermediates. Our chosen product forms a 3° carbocation intermediate over the alternative 2° carbocation intermediate because it is more stable due to enhanced inductive effects. To say "*because Markovnikov said so*" is not satisfactory.

Practice Exercise

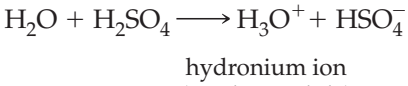
Addition of HCl to an alkene forms 2-chloro-3-methylbutane. What is the alkene?



The addition of HX across an alkyne forms a *geminal* dihalide. The term *geminal* refers to two groups occupying the same carbon. Equation 26.10 demonstrates reactions of this class.

[26.10]

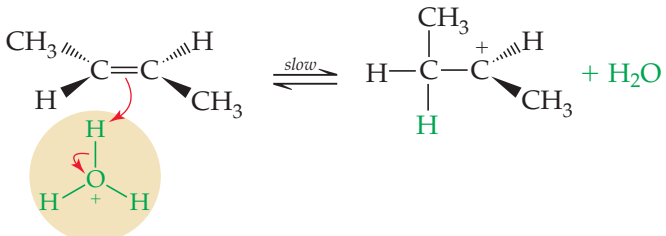
geminal dihalide



In the case of a terminal alkyne, for example but-1-yne, protonation occurs at the terminal carbon due to the formation of a stabilized secondary vinylic carbocation, which is relatively more stable than the alternative primary carbocation. Notice that the trend of carbocation stability is the same as that discussed for the addition of HBr to alkenes. Further reaction of this carbocation with the bromide nucleophile leads to 2-bromobut-1-ene as the sole product. Further addition of HBr to the alkene follows Markovnikov's rule, leading to the geminal dibromide 2,2-dibromobutane.

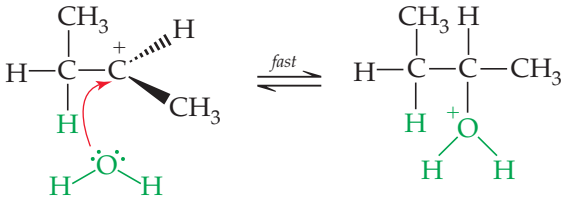
Addition Reactions Involving H_2O

The *hydration* of alkenes and alkynes is not as easy to accomplish as either the halogenation or hydrohalogenation of the same compounds. Hydration reactions need to be catalysed by a small amount of a strong acid, such as H_2SO_4. The reason is easily demonstrated mechanistically. Again, we can use but-2-ene as our alkene to illustrate this example.



The addition of a few drops of sulfuric acid to a reaction mixture containing but-2-ene and water leads to the formation of the hydronium ion, as shown:

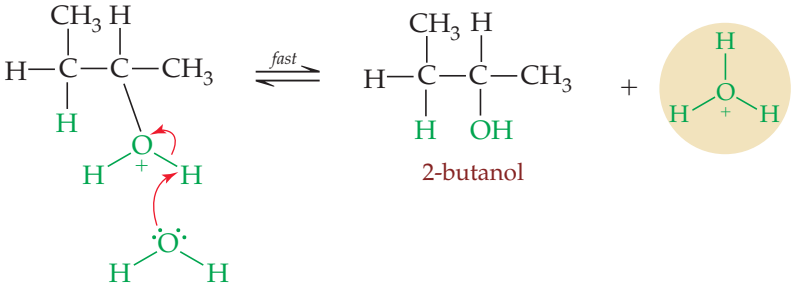
[26.11]



hydronium ion (an electrophile)

In terms of the addition of water, the hydronium species is the active electrophile. The reaction proceeds as shown in Equations 26.12 to 26.14. The first step involves the addition of a proton from the hydronium ion to one of the carbons that make up the double bond. This step is slow and rate-determining.

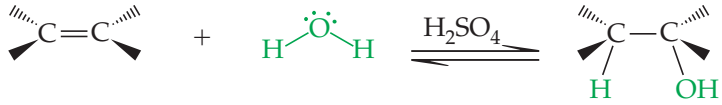
[26.12]



A molecule of water can then act as a nucleophile forming a C—O bond with the valence electrons of one of its two lone pairs. Note that a nucleophile need not be negatively charged; it just needs to be a species capable of donating a pair of electrons. In this case, an oxonium ion is formed.

oxonium ion

[26.13]

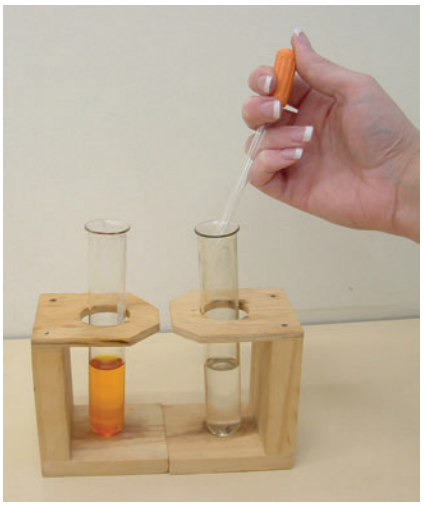


Loss of a proton from the oxonium ion yields the final alcohol product. The other product formed is a new hydronium ion. This ion is capable of reacting further with another alkene in the same way described in Equations 26.12 to 26.14. Theoretically, an amount of sulfuric acid large enough to initiate the formation of a single hydronium ion is enough to allow the reaction to proceed. In practice, more is required to make sure the reaction is completed in a timely manner.

2-butanol

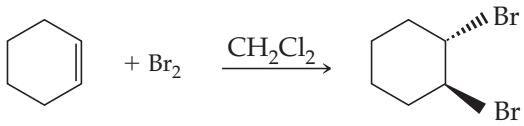
[26.14]

You may have noticed in Equations 26.12 to 26.14 that equilibrium arrows are used to describe each step of the reaction mechanism. This is because the reverse reaction—that is, the *dehydration* of alcohols—is also catalysed by H_2SO_4. In fact, this reverse method is a very useful way of preparing alkenes.



[26.15]

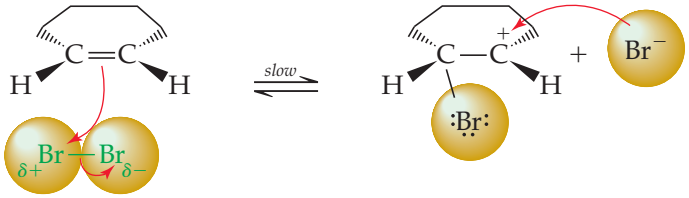
The direction of the equilibrium, shown in equation 26.15—that is, to maximize the yield of the alkene from the alcohol (right to left) or the alcohol from the alkene (left to right)—can be manipulated by adjusting the amount of water present in the reaction mixture. Large amounts of water (usually as aqueous acid) favour alcohol formation, whereas using concentrated acid and eliminating water favour alkene formation. By using these simple techniques, the alkene prepared in high yield.



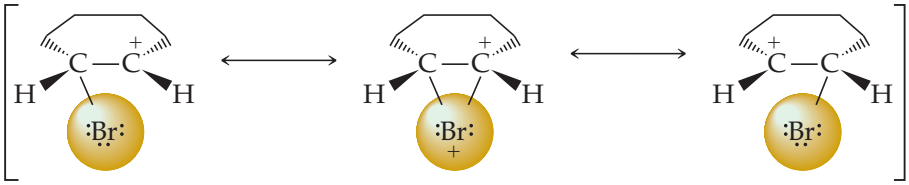
Halogenation: Addition of Br_2 and Cl_2

One of the easiest and most dramatic reactions in organic chemistry has to be the reaction of Br_2 with an alkene. Bromine is a dense orange liquid, whose colour persists if made into a solution in hexane. The addition of a slight excess of an alkene to this solution (**Figure 26.21**) at room temperature immediately turns the solution colourless. Undertaking this reaction in the presence of an alkane also demonstrates the large difference in reactivity between alkanes and alkenes towards bromination. This reaction and its dramatic colour change is a useful qualitative test for the presence of a C = C double bond in a compound.

The addition of bromine or chlorine to an alkene is an example of a **stereoselective reaction**: a reaction in which the product has one particular geometry in preference over another. Observe how in Equation 26.16 the two bromine atoms add to opposite sides of the plane of the cyclohexene molecule. Let us now investigate the reaction of bromine with cyclohexene, as an example of a halogenation, in more detail.

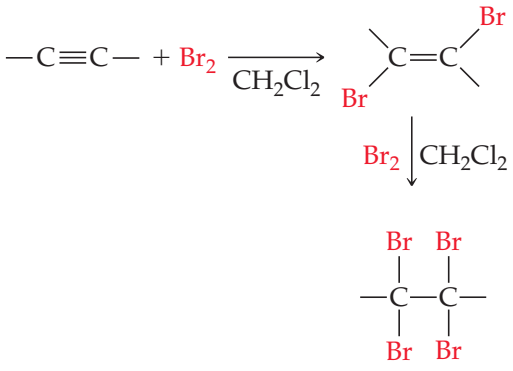


▲ **Figure 26.21 Bromine test for alkenes.** The bright orange colour of bromine solution is in contrast to the colourless solution produced by the addition of an alkene to the same solution.



[26.16]

The reasons for the stereoselectivity observed in the bromination of alkenes involve both steric and electronic components. The enormous size of a bromine atom compared with a hydrogen atom means that the incoming nucleophile (Br^-) cannot attack the carbocation from the same face as the initial electrophile (as shown in Equation 26.17). In the case of a cyclic structure, restricted rotation about the C—C bonds ensures that only the *trans*-dihaloalkane is formed. Chlorination is not as stereoselective because of chlorine's comparatively smaller size.

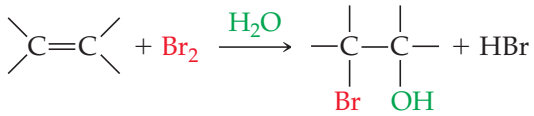


[26.17]

Three contributors to the resonance structure of the intermediate carbocation are possible because of the electron-rich nature of the bromine atom and its accessibility to the carbocation due to its size. Of these, the middle structure bearing the *bromonium ion* is the largest contributor to the intermediate's overall structure.

[26.18]

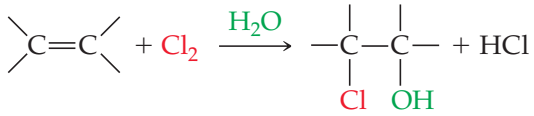
The bromination and chlorination of alkynes follows a similar mechanism. The stepwise addition of bromine, by way of example, is shown in Equation 26.19. In each step, dichloromethane (CH_2Cl_2) is the solvent.



[26.19]

Addition of one equivalent of bromine leads to the formation of the dibromo-alkene in which the two bromo groups occupy a *trans* arrangement across the double bond as a result of the bromonium intermediate formed. A further equivalent of bromine leads to the tetrabrominated alkane in which all four positions around the carbon-carbon triple bond are occupied by halogen. Tetrahalogenation occurs when an excess of bromine or chlorine to the alkyne is used.

Halohydrin Formation

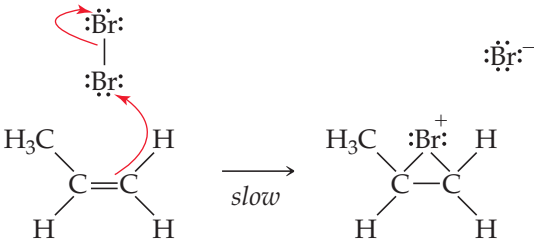


Let us now extend what we have learned about the mechanisms associated with the bromination and hydration of alkenes to more complicated additions. To do this, we will investigate the formation of the *halohydrins*—a class of compound containing halogen and OH functional groups. If the halogen and OH groups are on adjacent carbon atoms,

the compound is called a *vicinal halohydrin*. Equations 26.20 and 26.21 illustrate the reaction type:

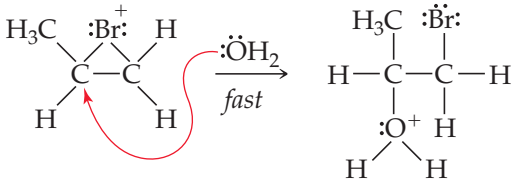
[26.20]

a vicinal halohydrin



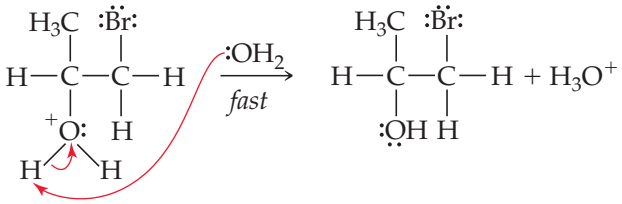
[26.21]

The halogen of the halohydrin originates from the source you are familiar with (being Br_2 or Cl_2) and the OH group of the halohydrin occurs typically through the introduction of water to the reaction. This can be achieved either by adding water to the solvent of choice or as the solvent, depending on practicality.



The mechanism of bromohydrin formation has three steps. Here we look at the formation of the bromohydrin derived from propene in more detail:

Step 1

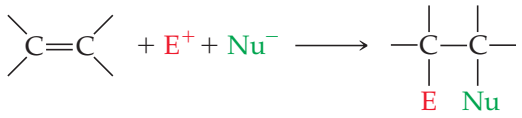


[26.22]

Step 2

[26.23]

Step 3



[26.24]

A cyclic bromonium ion is formed in the first step because Br^+ is the only electrophile in the reaction mixture (the corresponding cyclic chloronium ion would form if chlorine is used). This cyclic bromonium ion rapidly reacts with any nucleophile present. In the present case, two nucleophiles are present in solution. The two nucleophiles are Br^- and H_2O. But because H_2O is in the solvent, it is present in a higher concentration than Br^-. Consequently, reaction between the cyclic bromonium ion and H_2O is more likely. The protonated bromohydrin is a strong acid, and so reacts readily with water to form the halohydrin.

Notice throughout Equations 26.23–26.24 that the *regioselectivity* is well-defined with very little of the alternative bromohydrin formed. The product distribution follows *Markovnikov's rule,* as do all the additions we have studied so far. You may recall that for the addition of HCl across a double bond, the hydrogen adds to the side of the double bond with the most hydrogens. In the example of HCl addition, H^+ is considered to be the electrophile. In the case of halohydrin formation, the electrophile is Br^+, yet the outcome is still the same, that is, the electrophile adds to the side of the double bond with the most hydrogens.

While the major organic product of the reactions shown in Equations 26.20 and 26.21 is the vicinal halohydrin (called a bromohydrin or chlorohydrin, respectively), the corresponding dihalides are also formed to some extent. This is due to the competition between the two nucleophiles present, bromide ion and water.

Halohydrin formation suggests we can generalize addition reactions in the following way:

[26.25]

where the requisite nucleophile and electrophile can come from different starting materials. This means that provided you are able to identify a range of electrophiles (E^+) and nucleophiles (Nu^-) from a broad range of reagents, you will be able to convert alkenes into many highly functionalized compounds. **Table 26.2** lists some common electrophile (E^+) and nucleophile (Nu^-) combinations and the addition products.

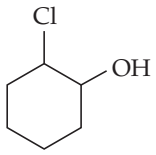


TABLE 26.2 Summary of addition reactions to an alkene by electrophile (E^+) and nucleophile (Nu^-) from Equation 26.25

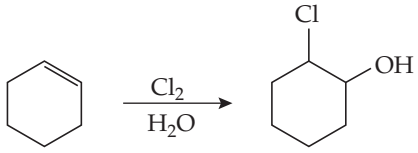
Reagents	Electrophile	Nucleophile	Product
Br_2	Br_2	Br^-	—C(Br)—C(Br)—
H_2O/H_2SO_4	H_3O^+	H_2O	—C(H)—C(OH)—
Cl_2	Cl_2	Cl^-	—C(Cl)—C(Cl)—
Br_2/H_2O	Br_2	H_2O	—C(Br)—C(OH)—
NBS/H_2O	Br_2	H_2O	—C(Br)—C(OH)—
Cl_2/CH_3OH	Cl_2	CH_3OH	—C(Cl)—C(OCH_3)—
$Br_2/NaCl$	Br_2	Cl^-	—C(Br)—C(Cl)—
$Cl_2/NaBr$	Cl_2	Br^-	—C(Cl)—C(Br)—
NBS/NH_4Cl	Br_2	Cl^-	—C(Br)—C(Cl)—
NBS/NH_4F	Br_2	F^-	—C(Br)—C(F)—

Sample Exercise 26.7

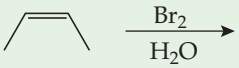
Addition reactions leading to halohydrins

Indicate how the following alcohol can be prepared from an alkene:

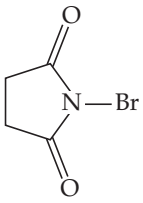


SOLUTION

Analyse We are asked to work backwards from a given structure to determine how we could make it from an alkene.

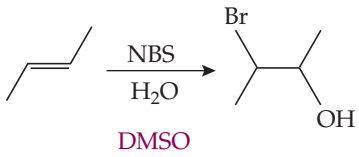


Plan Understand the differences between the starting alkene and the chlorohydrin product. Use our general equation [26.25] to determine from what reagents the electrophile and nucleophile are derived.



Solve The alkene required for this reaction is cyclohexene. This is deduced by placing the double bond between the positions occupied by the introduced Cl and OH functional groups. To get the addition of Cl and OH to the alkene, the reagents of choice must be Cl_2 and water. The water acts as both solvent and nucleophile.

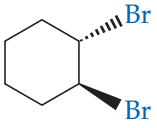
Practice Exercise



What are the major and minor products of the following reaction?

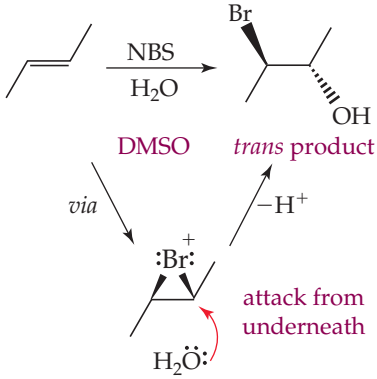
▲ **Figure 26.22** ***N*-Bromosuccinimide,** or NBS, can act as an electrophilic source of bromine by decomposing slowly in the presence of water to form a tiny amount of Br_2.

To develop the concept shown in Equation 26.22 further, let us now investigate another source of electrophilic bromine, which is *N*-bromosuccinimide (**Figure 26.22**). A general reaction utilizing *N*-bromosuccinimide (abbreviated NBS) as an electrophilic source of bromine is shown in Equation 26.26.



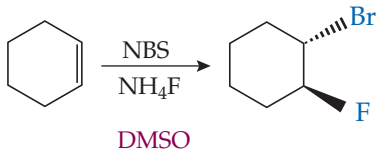
[26.26]

Here, the NBS reacts with an alkene in the presence of water and dimethylsulfoxide (DMSO) ($(CH_3)_2S{=}O$), which is a polar organic solvent miscible with water. Under these conditions, the NBS decomposes slowly to form a small amount of Br_2, which then undergoes reaction to form the bromohydrin. Because only a small amount of Br^- is ever generated, the concentration of water is always in excess and so the bromohydrin is always formed in high yield.



A CLOSER LOOK Stereochemistry in Halohydrin Formation

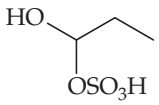
Stereoselectivity plays a part in the formation of the bromohydrin. Recall from Equation 26.16 that the product of the bromination of cyclohexene is the *trans* dibromide.



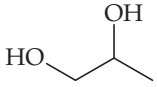
trans-1,2-dibromocyclohexane

Because the bridged halonium ion ring is opened by backside attack of H_2O in the halohydrin formation, addition of X and OH occurs in an *anti* (opposite) fashion and the *trans* product is most often formed.

[26.27]



We can see the similarity more clearly in the following example where ammonium fluoride (NH_4F) provides a source of fluoride, which acts as the nucleophile, and DMSO acts as the solvent. Again, the *trans* product is formed.



[26.28]

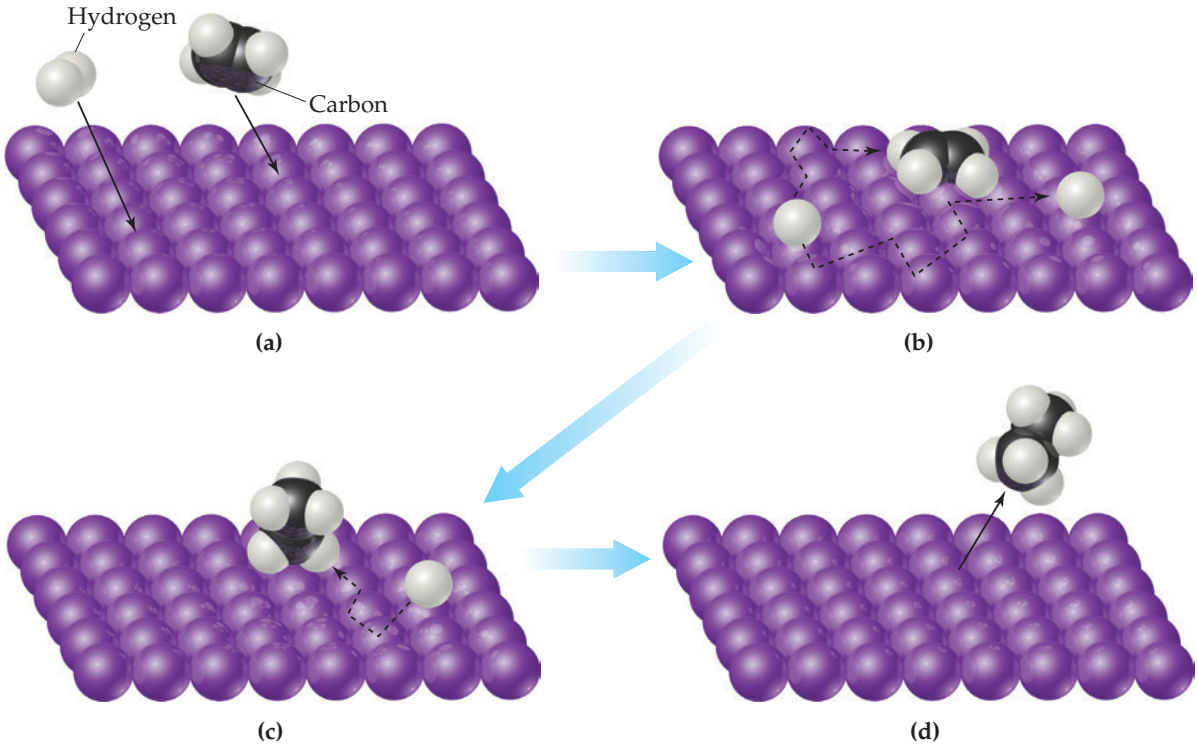
26.5 Alkanes from Alkenes: Catalytic Hydrogenation

Catalysts play a very important role in hydrocarbon chemistry. "Catalytic cracking" is used in oil refineries to convert high molecular weight hydrocarbons to the more useful, lower molecular weight, feedstock for the chemical industry. Catalysts are also used in the addition of hydrogen to alkenes and alkynes both in the research laboratory as well as for the manufacture of margarine from plant oils.

When you finish this section, you should be able to:

- Identify the conditions required to add hydrogen gas to an alkene or alkyne
- Understand the stereochemical outcome of hydrogenation of disubstituted cyclic alkenes

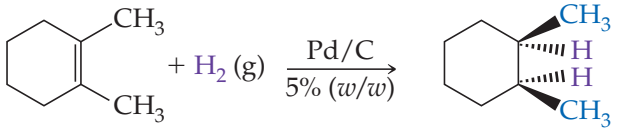
The reaction between an alkene and molecular hydrogen (H_2), referred to as hydrogenation, does not occur readily under ordinary conditions of temperature and pressure. One reason for the lack of reactivity of H_2 towards alkenes is the high bond enthalpy of the H_2 molecule. To promote the reaction, it is necessary to use a catalyst that assists in rupturing the H—H bond. The most widely used catalysts are finely divided metals capable of adsorbing H_2, such as Pt, Pd and Ni. The hydrogenation reaction is often called a **catalytic hydrogenation**, since only a small amount of the solid metal is necessary to promote the reduction of the alkene to the corresponding alkane in solution. Because the alkene and catalyst exist in different phases, this type of reaction undergoes *heterogeneous catalysis*.



The reaction of hydrogen gas with ethene gas to form ethane gas provides an example of heterogeneous catalysis:

$$\underset{\text{ethene}}{C_2H_4(g)} + H_2(g) \xrightarrow{Pt} \underset{\text{ethane}}{C_2H_6(g)} \qquad \Delta H^\circ = -137\ \text{kJ/mol} \qquad [26.29]$$

We can understand the role of the catalyst in this process by considering the bond enthalpies involved (Table 8.3). In the course of the hydrogenation reaction, the H—H σ-bond and the carbon-carbon π-bond must be broken, and to do so requires the input of energy, which we can liken to the activation energy of the reaction. The formation of the new C—H σ-bonds *releases* an even greater amount of energy, making the reaction *exothermic*. When H_2 and C_2H_4 are bonded to the surface of the catalyst, less energy is required to break the bonds, lowering the activation energy of the reaction.



A CLOSER LOOK Hydrogenation

The mechanism by which the reaction is thought to occur is shown schematically in **Figure 26.23**. Both ethene and hydrogen are adsorbed on the metal surface (Figure 26.23(a)). Upon adsorption the H—H bond of H_2 breaks, leaving two H atoms that are bonded to the metal surface, as shown in Figure 26.23(b). The hydrogen atoms are relatively free to move about the surface. When a hydrogen atom encounters an adsorbed ethene molecule, it can form a σ-bond to one of the carbon atoms, effectively destroying the C—C π-bond and leaving an *ethyl group* (C_2H_5) bonded to the surface *via* a metal-to-carbon bond (Figure 26.23(c)). This bond is relatively weak, and when the other carbon atom also encounters a hydrogen atom, a second C—H σ-bond is readily formed and the resulting ethane molecule is released from the metal surface (Figure 26.23(d)). The site is ready to adsorb another ethene molecule and thus begin the cycle again.

▲ **Figure 26.23 Mechanism for reaction of ethene with hydrogen on a catalytic surface.** (a) The hydrogen and ethene are adsorbed at the metal surface. (b) The H—H bond is broken to give two adsorbed hydrogen atoms. (c) These hydrogens migrate to the adsorbed ethene and bond to the carbon atoms. (d) As C—H bonds are formed, the adsorption of the molecule to the metal surface is decreased and ethane is released.

Catalytic hydrogenations favour a *cis* stereochemistry. For example, the reaction of 1,2-dimethylcyclohexene with hydrogen in the presence of 5% (*w*/*w*) palladium on carbon (Pd/C) yields the alkane in 100% yield, with >75% of the alkane having the *cis* stereochemistry. Palladium on carbon is a standard synthetic catalyst for hydrogenation.

[26.30]

Sample Exercise 26.8

Identifying the product of a hydrogenation reaction

Write the structural formula for the product of the hydrogenation of 3-methyl-1-pentene.

SOLUTION

Analyse We are asked to predict the compound formed when a particular alkene undergoes hydrogenation (reaction with H_2).

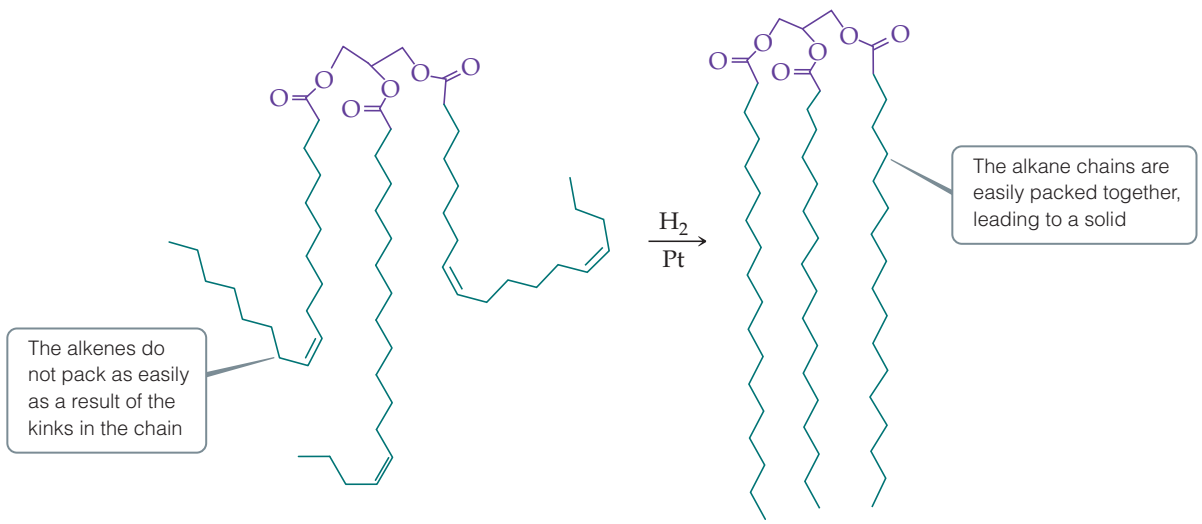
Plan To determine the structural formula of the reaction product, we must first write the structural formula or Lewis structure of the reactant. In the hydrogenation of the alkene, H_2 adds to the double bond, producing an alkane. (That is, each carbon atom of the double bond forms a bond to an H atom, and the double bond is converted to a single bond.)

Solve The name of the starting compound tells us that we have a chain of five C atoms with a double bond at one end (position 1) and a methyl group on the third C from that end (position 3):

$$CH_2{=}CH{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH_2{-}CH_3$$

Hydrogenation—the addition of two H atoms to the carbons of the double bond—leads to the following alkane:

$$CH_3{-}CH_2{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH_2{-}CH_3$$



Comment The longest chain in the product alkane has five carbon atoms; its name is therefore 3-methylpentane.

Practice Exercise

Draw all the possible products (including stereochemistry) for the complete hydrogenation of the theoretical compound hexamethylcyclohexatriene, assuming 100% *cis* addition per double bond. Do not account for chair and boat conformations.

Hydrogenation is a useful commercial process for the preparation of fats from *polyunsaturated oils*. These oils, as the name suggests, contain many alkenes. Oils are generally **triglycerides** rich in linoleic ($C_{18}H_{32}O_2$), oleic ($C_{18}H_{34}O_2$), arachidonic ($C_{20}H_{32}O_2$) and other unsaturated fatty esters which, because of their structure, are liquids at room temperature (Section 26.2). Their conversion to stearic ($C_{18}H_{36}O_2$) and arachidic esters ($C_{20}H_{40}O_2$) by hydrogenation leads to **fats**, whose properties are more those of solids or semi-solids at room temperature. The reason for the change in physical properties has to do with the ease of packing the long alkyl chains over those chains that are "kinked" by the introduction of double bonds (Figure 26.24).

The process of converting oils to fats is called **hardening**. This process is especially relevant to the manufacture of margarine and cooking fats. The final hardened product is typically white. In the past, β-carotene was added to colour the margarine so that it looks like butter.

▲ **Figure 26.24 Hydrogenation of vegetable oil leads to a more solid product.**

Self-Assessment Exercises

26.29 What catalyst is required in the hydrogenation reaction of an alkene?

(**a**) H^+ (**b**) Fe (**c**) Pd/C

26.30 Partial hydrogenation of but-2-yne produces but-2-ene. What is the stereochemistry of the product?

(**a**) *Z* (**b**) *E* (**c**) a mixture of *Z* and *E* isomers

Exercises

26.31 Draw the products resulting from the catalytic hydrogenation of the following molecules.

26.32 How many moles of hydrogen are required to completely hydrogenate pent-1-en-3-yne?

26.33 Draw the structures of all possible alkenes and alkynes that could be used in a catalytic hydrogenation to form 2-methylbutane.

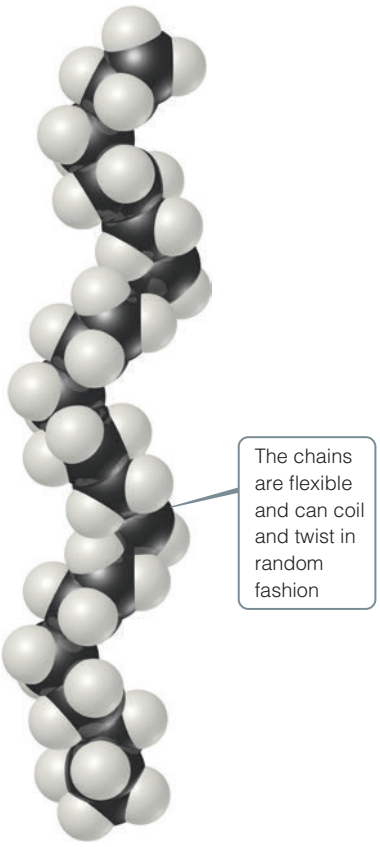
26.6 Addition Polymerization

In nature, we find many substances of very high molecular mass that make up much of the structure of living organisms and tissues. Some examples include starch and cellulose (which abound in plants) and proteins (found in both plants and animals). In 1827 Jons Jakob Berzelius (1779–1848) coined the word **polymer** (from the Greek *poly*, "many", and *meros*, "parts") to denote molecular substances of high molecular mass formed by the *polymerization* (joining together) of **monomers**, that is, molecules with low molecular mass. An example is the reaction of ethene monomers to form polyethene:

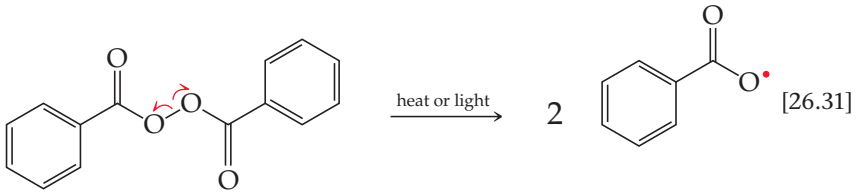
ethene polyethene



When you finish this section, you should be able to:

- Recognize the relationship between a monomer and a polymer
- Understand the three stages of addition polymerization
- Make the link between macroscopic properties such as density and the molecular level properties of crystallinity and cross linking

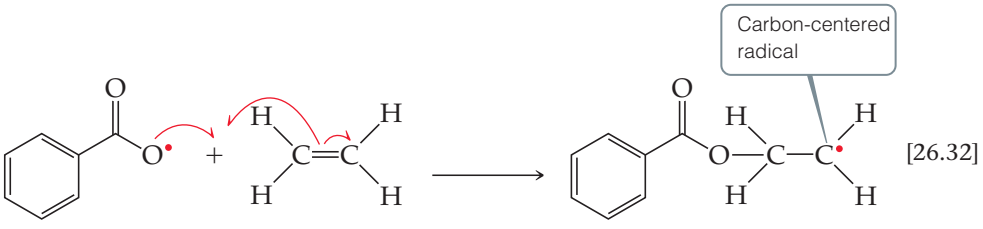
For a long time, humans have processed naturally occurring polymers, such as wool, leather, silk and natural rubber, into usable materials. Over the last century, however, chemists have learned to form synthetic polymers by polymerizing compounds through controlled chemical reactions. A great many of these synthetic polymers have a backbone of carbon–carbon bonds because carbon atoms have an exceptional ability to form strong stable bonds with one another.



Plastics are materials that can be formed into various shapes, usually by the application of heat and pressure. **Thermoplastic** materials can be reshaped. For example, plastic milk containers are made from a polymer known as *polyethene,* which has a high molecular mass. These containers can be melted down and the polymer recycled for some other use. In contrast, a **thermosetting plastic** is shaped through irreversible chemical processes and thus cannot be readily reshaped.

▲ **Figure 26.25 A segment of a polyethene chain.** The segment shown here consists of 28 carbon atoms. In commercial polyethene, the chain lengths range from about 10^3 to 10^5 CH_2 units.

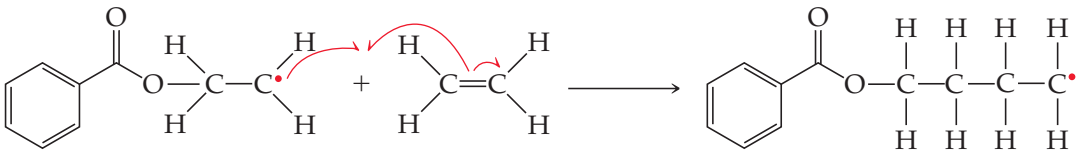
Making Polymers



Polyethene (**Figure 26.25**) is a solid substance that is used to make thousands of plastic products, such as plastic bags, food containers and laboratory equipment. In making polyethene, a reactive center is formed that adds sequentially to the double bond in each ethene, extending the polymer chain and regenerating the reactive center. Such reactions are classified as chain-growth or **addition polymerizations** and polyethene is an **addition polymer**. In ethene polymerization, the reactive center is frequently a free radical, which can be derived from a radical initiator such as lauroyl peroxide. Peroxides dissociate to form two radicals upon heating or irradiation with light because of the very weak O—O bond:

[26.31]

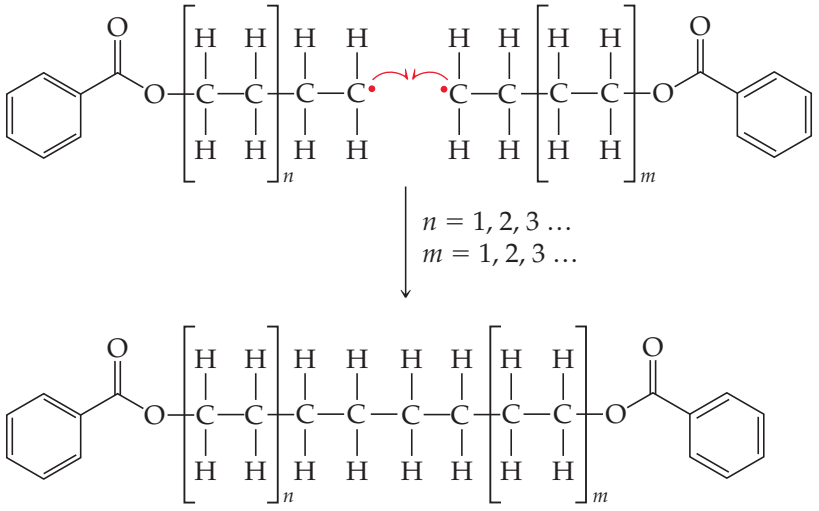
Note the use of *fishhook arrows* in Equation 26.31. They differ from the arrows we have studied to date, which were "arrow"-headed. Fishhook arrows represent the movement of a single electron rather than an electron pair.



Once formed, the benzoyl radical can react with ethene to form a new carbon-centered radical. This step is called the **initiation** step. The relative stabilities of alkyl radicals follow a similar pattern to that of carbocations, namely 3° > 2° > 1° alkyl radicals.

[26.32]

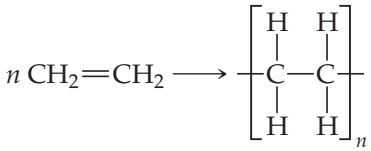
The next stage of reaction is known as **propagation**. In this stage, the chain is extended by the consecutive addition of more ethene units through C—C bond formation:



Propagation

[26.33]

The propagation continues until two radical polymer chains react to form a completed polymer by a final C—C bond formation that terminates the radical. This is known as the **termination** step. In Equation 26.34, *n* and *m* are normally large integers, which may or may not have the same value.



Termination

[26.34]

The reactive center in a chain-growth polymerization need not be a radical: depending on the monomer used, it may be an anion, cation or coordination complex. The most common process for polyethene production is *Ziegler–Natta* polymerization, named after the two scientists who developed the reaction in the 1950s. This process typically involves titanium and aluminum complexes, with a coordination complex as the reactive center, and is used in the formation of high-density polyethene (HDPE), a hard plastic. Radical polymerization of polyethene gives a polymer with occasional long branches, rather than simple straight chains, which makes it harder to pack the molecules together—this is low-density polyethene (LDPE), used in stretchy plastic wrap.

We can write the overall equation for the polymerization of ethene as follows:

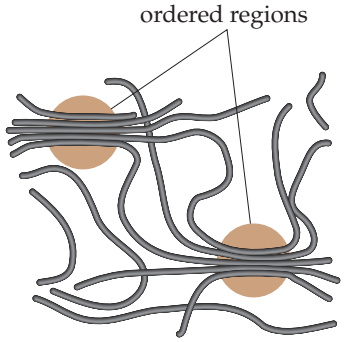
[26.35]

Here, *n* represents the large number—ranging from hundreds to many thousands—of monomer molecules (ethene, in this case) that react to form one large polymer molecule. Within the polymer, a repeat unit (the unit shown in brackets in Equation 26.35) appears along the entire chain.

Polyethene is a very important commercial material; more than 10 billion kilograms are produced globally each year. Although its composition is simple, the polymer is not easy to make. Only after many years of research were the right conditions identified for manufacturing it. Today many different forms of polyethene, varying widely in physical properties, are known. Polymers of other chemical compositions provide still greater variety in physical and chemical properties. **Table 26.3** lists several other common polymers obtained by addition polymerization.

TABLE 26.3 Addition polymers of commercial importance

Monomers	Addition Polymer	Structure	Uses
$CH_2{=}CH_2$	Polyethene	$+CH_2{-}CH_2+_n$	Films, packaging, bottles
$CH_2{=}CH(CH_3)$	Polypropylene	$+CH_2{-}CH(CH_3)+_n$	Kitchenware, fibres, appliances
$CH_2{=}CH(C_6H_5)$	Polystyrene	$+CH_2{-}CH(C_6H_5)+_n$	Packaging, disposable food containers, insulation
$CH_2{=}CHCl$	Poly(vinyl chloride) (PVC)	$+CH_2{-}CHCl+_n$	Pipe fittings, clear film for meat packaging
$CH_2{=}C(CH_3)COOCH_3$	Poly(methyl methacrylate)	$+CH_2{-}C(CH_3)(COOCH_3)+_n$	Perspex, paints, moulded articles



The names of polymers are simply derived from the monomers employed (Table 26.3). Poly(vinyl chloride) (PVC), for example, is made from vinyl chloride, poly(methyl methacrylate) is made from methyl methacrylate and polystyrene is made from styrene.

Structure and Physical Properties of Addition Polymers

The simple structural formulas given for polyethene and other polymers are deceptive. Since each carbon atom in polyethene is surrounded by four bonds, the atoms are arranged in a tetrahedral fashion, so that the chain is not straight as we sometimes depict it. Furthermore, the atoms are relatively free to rotate around the C—C single bonds. Thus rather than being straight and rigid, the chains of an addition polymer are very flexible, folding readily. The flexibility in the molecular chains can cause the polymer material itself to be very flexible

Both synthetic and naturally occurring polymers consist commonly of a collection of *macromolecules* (large molecules) of different molecular weights. Depending on the conditions of formation, the molecular weights may be distributed over a wide range or be closely clustered around an average value. In part, because of this distribution in molecular weights, polymers are largely amorphous (non-crystalline) materials. Rather than exhibiting a well-defined crystalline phase with a sharp melting point, they soften over a range of temperatures. They may, however, possess short-range order in some regions of the solid, with chains lined up in regular arrays, as shown in Figure 26.26. The extent of such ordering is indicated by the degree of **crystallinity** of the polymer. The crystallinity of a polymer can be enhanced with mechanical stretching, which aligns the polymer chains as the molten polymer is drawn out. Intermolecular forces between the polymer chains hold the chains together in the ordered crystalline regions, making the polymer denser, harder, less soluble and more resistant to heat. Table 26.4 shows how the properties of polyethene change as the degree of crystallinity increases.

The simple linear structure of polyethene is conducive to intermolecular interactions that lead to crystallinity. However, the degree of crystallinity in polyethene strongly

▲ **Figure 26.26 Interactions between polymer chains.** In the circled regions, the forces that operate between adjacent polymer-chain segments lead to ordering analogous to the ordering in crystals, though less regular.

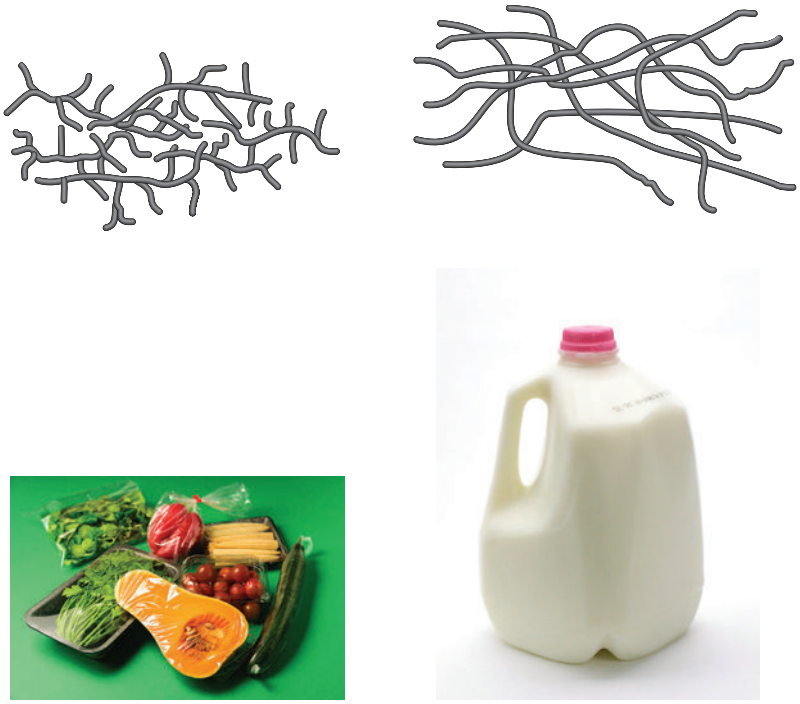
TABLE 26.4 Properties of polyethene as a function of crystallinity

	Crystallinity				
	55%	62%	70%	77%	85%
Melting point (°C)	109	116	125	130	133
Density (g cm^{-3})	0.92	0.93	0.94	0.95	0.96
Stiffness* (MPa)	12	17	13	29	35
Yield stress* (MPa)	170	320	520	830	1140

* These test results show that the mechanical strength of the polymer increases with increased crystallinity. Discussion of the exact meaning and significance of these tests is beyond the scope of this text.

CHEMISTRY AND LIFE Recycling Plastics

If you look at the bottom of a plastic container, you are likely to see a recycle symbol (**Figure 26.27**) containing a number, as shown in **Table 26.5**. The number and letter abbreviation below it indicate the kind of polymer from which the container is made, as summarized in Table 26.5. These symbols make it possible to sort containers by composition. In general, the lower the number, the greater the ease with which the material can be recycled.

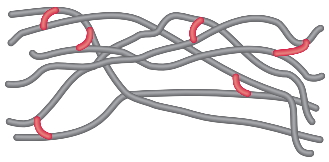


▲ **Figure 26.27** Recycling symbols.

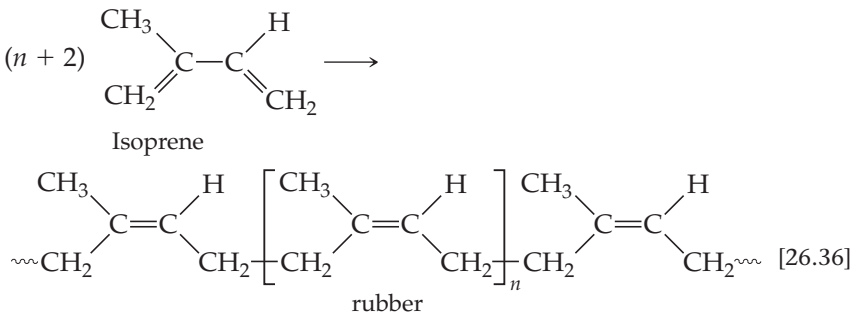
TABLE 26.5 Categories used for recycling polymeric materials

Recycling number	Abbreviation	Polymer
1	PET or PETE	Polyethene terephthalate
2	HDPE	High-density polyethene
3	V	Polyvinyl chloride (PVC)
4	LDPE	Low-density polyethene
5	PP	Polypropylene
6	PS	Polystyrene
7	—	Others

depends on the average molecular mass. Polymerization results in a mixture of macromolecules with varying values of *n* and hence varying molecular masses. So-called low-density polyethene (LDPE), used in forming films and sheets, has an average molecular mass in the range of 10^4 u and has substantial chain branching. That is, side chains occur off the main chain of the polymer, much like spur lines that branch from a main railway line. These branches inhibit the formation of crystalline regions, reducing the density of the material. High-density polyethene (HDPE), used to form bottles, drums and pipes, has an average molecular mass in the range of 10^6 u. This form has less branching and thus a higher degree of crystallinity. Low-density and high-density polyethene are illustrated in **Figure 26.28**. Thus the properties of polyethene can be "tuned" by varying the average length, crystallinity and branching of the chains, making it a very versatile material.



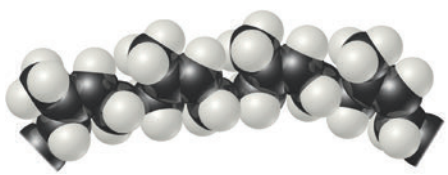
The physical properties of polymeric materials can be modified extensively by adding substances with lower molecular mass, called *plasticizers*, to reduce the extent of interactions between chains and thus to make the polymer more pliable. Poly(vinyl chloride) (PVC) (Table 26.3), for example, is a hard, rigid material of high molecular mass that is used to manufacture drainpipes. When blended with a suitable substance of lower molecular mass, however, it forms a flexible polymer that can be used to make rainboots and doll parts. In some applications, the plasticizer in a plastic object may be lost over time because of evaporation. As this happens, the plastic loses its flexibility and becomes subject to cracking.



(a) (b)

▲ **Figure 26.28 Two types of polyethene.** (a) Schematic illustration of the structure of low-density polyethene (LDPE) and food-storage bags made of LDPE film. (b) Schematic illustration of the structure of high-density polyethene (HDPE) and containers formed from HDPE.

Polymers can be made stiffer by introducing chemical bonds between the polymer chains, as illustrated in **Figure 26.29**. Forming bonds between chains is called **cross-linking**. The greater the number of cross-links in a polymer, the more rigid the material. Whereas thermoplastic materials consist of independent polymer chains, thermosetting materials become cross-linked when heated. The cross-links allow them to hold their shapes. An important example of cross-linking is the **vulcanization** of natural rubber, a process discovered by Charles Goodyear in 1839 (see the Chemistry and Life, page 1246). Natural rubber is formed from a liquid resin derived from the inner bark of *Hevea brasiliensis,* or rubber tree. Chemically, it is a terpene, a polymer of isoprene, C_5H_8. In the process of vulcanization a controlled number of sulfur cross-links are introduced by reacting the carbon-carbon double bonds of adjacent chains with elemental sulfur in the presence of an accelerator and activator compound.



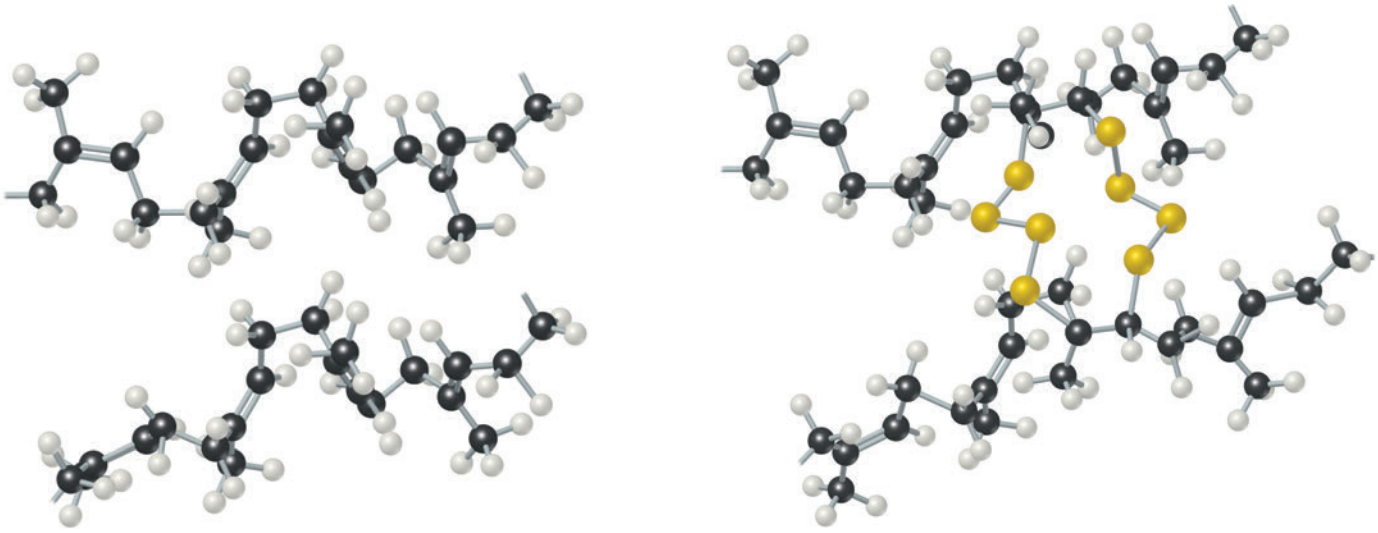
▲ **Figure 26.29 Cross-linking of polymer chains.** The cross-linking groups (red) constrain the relative motions of the polymer chains, making the material harder and less flexible than when the cross-links are not present.

Isoprene

rubber [26.36]

CHEMISTRY AND LIFE The Accidental Discovery of Teflon®

In 1938 a scientist at Du Pont named Roy J. Plunkett (1910–1994) made a rather curious observation: a tank of gaseous tetrafluoroethene ($CF_2{=}CF_2$) that was supposed to be full seemed to have no gas in it. Rather than discard the tank, Plunkett decided to cut it open. He found that the inside of the tank was coated with a waxy white substance that was remarkably unreactive towards even the most corrosive reagents. That compound was formed by the addition polymerization of tetrafluoroethene:



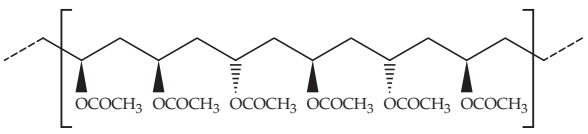
$$n CF_2{=}CF_2 \xrightarrow{\text{polymerization}} {+}CF_2{-}CF_2{+}_n$$

As it turned out, the properties of this material, called Teflon®, were ideal for an immediate and important application in the development of the first atomic bomb. Uranium hexafluoride (UF_6), which was used to separate fissionable ^{235}U by gaseous diffusion, is an extremely corrosive material. Teflon® was used as a gasket material in the gaseous diffusion plant. It is now used in a variety of applications, from non-stick cookware to space suits.

Plunkett's desire to know more about something that just didn't seem right is a wonderful example of how natural scientific curiosity can lead to remarkable discoveries.

CHEMISTRY AND LIFE Vulcanization

Natural rubber is not a useful polymer because it is too soft and too chemically reactive. Charles Goodyear (1800–1860) accidentally discovered that adding sulfur to rubber and then heating the mixture makes the rubber harder and reduces its susceptibility to oxidation or other chemical attack. The sulfur changes rubber into a thermosetting polymer by cross-linking the polymer chains through reactions at some of the double bonds, as shown schematically in **Figure 26.30**. Cross-linking of about 5% of the double bonds creates a flexible, resilient rubber. When the rubber is stretched, the cross-links help to prevent the chains from slipping, so that the rubber retains its elasticity. Nature also uses a sulfide crosslink to rigidify and preserve certain protein structures, such as insulin.

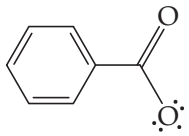


(a) (b)

▲ **Figure 26.30 Vulcanization of rubber.** (a) In natural rubber, carbon–carbon double bonds occur at regular intervals along the chain. (b) Chains of sulfur atoms have been added across two polymer chains, by the opening of a carbon–carbon double bond on each chain.

Self-Assessment Exercises

26.34 Identify the monomer unit in poly(vinyl acetate) from this fragment of the polymer chain.

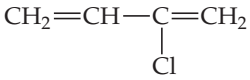


(a) $CH_2{=}CH{-}C(=O){-}O{-}CH_3$

(b) $CH_2{=}CH{-}O{-}C(=O){-}CH_3$

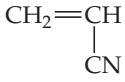
(c) $CH_3{-}CH_2{-}C(=O){-}O{-}CH_3$

26.35 A radical such as the benzoyloxy radical is often used in which stage of polymerization?



(**a**) Initiation (**b**) Propagation (**c**) Termination

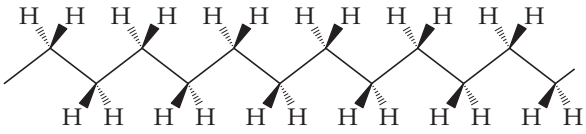
26.36 A polymer with a high degree of cross-linking is likely to show which characteristics? **(a)** a soft flexible material **(b)** elasticity **(c)** a low melting point **(d)** a rigid structure



Exercises

26.37 Draw the structure of the monomer(s) employed to form each of the following polymers: **(a)** poly(vinyl chloride), **(b)** polystyrene, **(c)** polypropylene.

26.38 Write the chemical equation that represents the formation of **(a)** polychloroprene (neoprene) from chloroprene

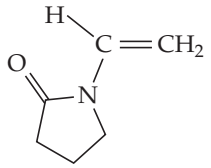


(Neoprene is used in road pavement seals, expansion joints, conveyor belts and wire and cable jackets.); **(b)** polyacrylonitrile

(Polyacrylonitrile is used in home furnishings, craft yarns, clothing and many other items.)

26.39 What molecular features make a polymer flexible? Explain how cross-linking affects the chemical and physical properties of the polymer.

26.40 Although polyethene can twist and turn in random ways, the most stable form is a linear one with the carbon backbone oriented as shown in this figure:



(a) What is the hybridization of orbitals at each carbon atom? What angles do you expect between the bonds?

(b) Now imagine that the polymer is polypropylene rather than polyethene. Draw the structures for polypropylene in which (i) the CH_3 groups lie on the same side of the plane of the paper (this form is called isotactic polypropylene), (ii) the CH_3 groups lie on alternating sides of the plane (syndiotactic polypropylene), and (iii) the CH_3 groups are randomly distributed on either side (atactic polypropylene). Which of these forms would you expect to have the highest crystallinity and melting point, and which the lowest? Explain in terms of intermolecular interactions and molecular shapes.

(c) Polypropylene fibres have been employed in athletic wear. The product is said to be superior to cotton clothing in wicking moisture away from the body through the fabric to the outside. Explain the difference between polypropylene and cotton (which has many –OH groups along the molecular chain), in terms of intermolecular interactions with water.

26.41 Poly(vinyl pyrrolidone) is commonly used in cosmetics and in wine clarification. Draw a representative segment of the polymer prepared from *N*-vinyl pyrrolidone:

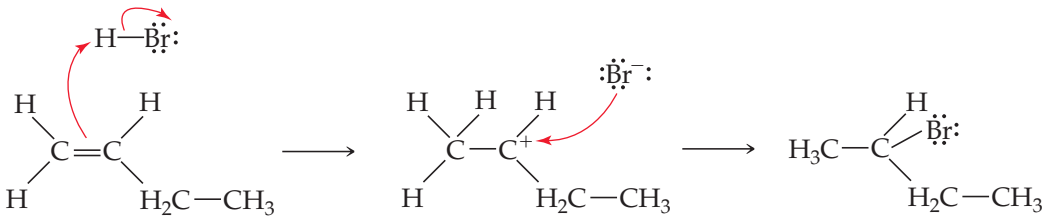
26.42 How would you expect the properties of vulcanized rubber to vary as the percentage of sulfur increases?

Answers to Self-Assessment Exercises (a) **26.34** (b) **26.35** (d) **26.36**

Sample Integrative Exercise

Putting concepts together

In an example of an electrophilic addition reaction 1-butene reacts with hydrogen bromide to give 2-bromobutane. **(a)** Draw out the mechanism of this reaction including the carbocation intermediate. Show all the atoms attached to the double bond and use curved arrows to indicate electron-pair movements. **(b)** What are the hybridization and molecular geometry of the two atoms C1 and C2 in the starting material, intermediate and product? **(c)** Indicate the stereogenic carbon center in the product with *. **(d)** Explain why the product is formed as a racemic mixture.

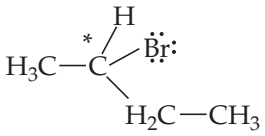


SOLUTION

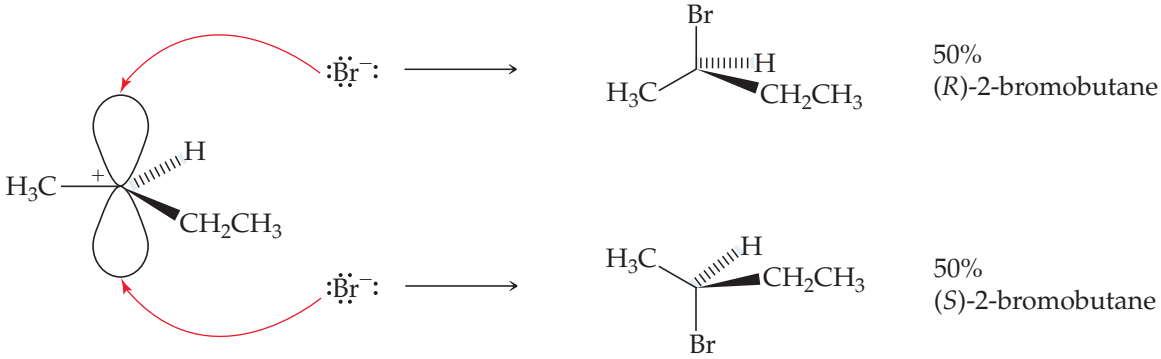
Analyse In this problem we examine the mechanism of an electrophilic addition reaction and how the shape of the intermediate relates to the chirality of the product.

Plan First identify the structure of the starting material and product from the names given. Then draw the mechanism of the reaction and identify how the molecular geometry of C1 and C2 changes as the reaction progresses. Finally identify the features of the geometry change that result in a racemic mixture being produced.

Solve



(a)



(b)

	Hybridization—C1	Geometry—C1	Hybridization—C2	Geometry—C2
Starting material	sp^2	Trigonal planar	sp^2	Trigonal planar
Intermediate	sp^3	Tetrahedral	sp^2	Trigonal planar
Product	sp^3	Tetrahedral	sp^3	Tetrahedral

(c)

(d) The carbocation is sp^2 hybridized and trigonal planar in shape. The positive charge may be thought of as an empty *p* orbital pointing above and below the plane containing the carbocation. The final stage of this reaction involves attack by the bromide ion on the carbocation and there is equal probability of this occurring to the top or the bottom face of the intermediate.

Chapter Summary and Key Terms

SECTION 26.1 **Unsaturated hydrocarbons** are those hydrocarbons that contain multiple bonds. Two main classes—**alkenes** and **alkynes**—are dealt with in this chapter. Alkenes contain one or more double bonds. Each double bond consists of one **σ-bond** and one **π-bond**. The π-bond is formed by the overlap of the unhybridized *p* orbitals on adjacent sp^2 hybridized carbon atoms. Alkynes contain one or more triple bonds. Each triple bond consists of one σ-bond and two π-bonds. The order of bond lengths is triple bond < double bond < single bond.

SECTION 26.2 The names of alkenes and alkynes are based on the longest continuous chain of carbon atoms that contains the multiple bond, and the location of the multiple bond is specified by a numerical prefix. The ***E,Z* system** is used to name the geometric isomers of alkenes and is based on the same priority system used in *R,S* nomenclature.

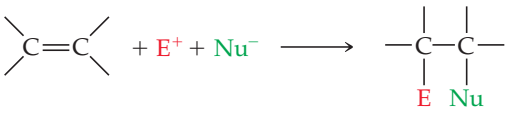
SECTION 26.3 Organic chemists use **curved arrow notation** to describe the redistribution of valence electrons. Arrow notation can also be used to describe resonance structures or to rationalize a reaction mechanism.

SECTION 26.4 Alkenes and alkynes readily undergo **addition reactions** to the carbon–carbon multiple bonds. There are three main classes of addition reactions: **halogenation**, **hydrohalogenation** and **hydration**. Additions of acids, such as HBr, proceed via a rate-determining step in which a proton is transferred to one of the alkene or alkyne carbon atoms, forming a **carbocation**. This addition follows **Markovnikov's rule**, which states that the hydrogen of HX (X = halogen, OH) adds to the side of the double bond with the most hydrogens. The carbocation is a form of **electrophile** that readily reacts with a **nucleophile**, in this case Br^-, to form the product. The addition of bromine to cyclohexene is an example of a **stereoselective reaction**.

SECTION 26.5 **Catalytic hydrogenation** can be used to convert alkenes or alkynes to alkanes using molecular hydrogen and a metal catalyst such as Ni, Pd or Pt. Oils are **triglycerides** that contain double bonds. They may be hydrogenated to **fats** in a process called **hardening**.

SECTION 26.6 **Polymers** are molecules of high molecular mass formed by joining together large numbers of smaller molecules, called **monomers**. In a chain growth or **addition polymerization** reaction, the molecules form new linkages by opening existing bonds. Polyethene is an example of an **addition polymer**. Three stages exist in this type of polymerization: **initiation**, **propagation** and **termination**.

Plastics are materials that can be formed into various shapes, usually by the application of heat and pressure. **Thermoplastics** can be reshaped, perhaps by heating, in contrast to **thermosetting plastics**, which are formed through an irreversible chemical process and cannot be reshaped.



Polymers are largely amorphous, but some materials possess a degree of **crystallinity**. High-density polyethene, for example, with not much side-chain branching and a high molecular mass, has a higher degree of crystallinity than low-density polyethene, which has a lower molecular mass and a higher relative degree of branching. Polymer properties are also strongly affected by **cross-linking**, in which short chains of atoms connect the long polymer chains. Rubber is cross-linked by short chains of sulfur atoms in the process called **vulcanization**.

Key Skills

- Understand how to name alkenes and alkynes. In the case of alkenes, be able to determine *E, Z* isomerism. (Sections 26.1 and 26.2)
- Describe and understand the rules for using curved arrow notation and their application to describe the mechanism of a chemical reaction. (Section 26.3)
- Be able to draw the products of addition reactions using a range of reactants (e.g. Br_2, HCl) and understand their product distribution. (Sections 26.4 and 26.5)
- Understand the importance of alkenes to the industrial manufacturing of plastics. (Section 26.6)
- Be able to draw polymers formed by the addition polymerization of alkene monomers and understand some of their properties. (Section 26.6)

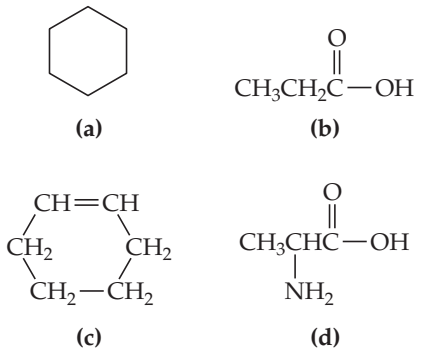
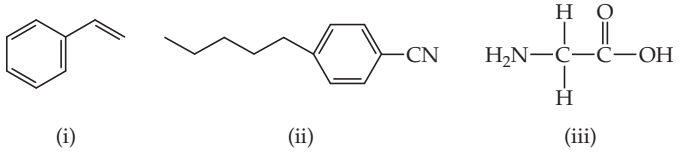
Exercises

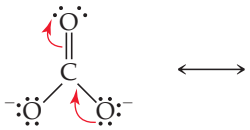
Visualizing concepts



26.43 Which of the following molecules is unsaturated? [Section 26.1]



26.44 Consider the hydrocarbon drawn here. **(a)** What is the hybridization at each carbon atom in the molecule? **(b)** How many σ-bonds are there in the molecule? **(c)** How many π-bonds? [Section 26.1]

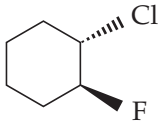


26.45 Which of the following molecules will most readily undergo an addition reaction? [Section 26.4]

26.46 Consider the molecules shown here. Which of these would be most likely to form an addition polymer? [Section 26.4]

26.47 Draw the product of the following valence electron movements. [Section 26.3]

Structure, Bonding and Naming (Sections 26.1, 26.2 and 26.3)



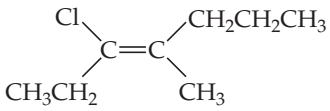
26.48 Give the general molecular formula for any cyclic alkene. What other general class of hydrocarbon has the same general formula?

26.49 What are the characteristic hybrid orbitals employed by **(a)** carbon in an alkane, **(b)** carbon in a double bond in an alkene, **(c)** carbon in a triple bond in an alkyne?

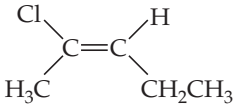
26.50 Name the following compounds systematically:

(a) *trans*-$CH_3CH{=}CHCH_2CH_2CH_3$

(b)

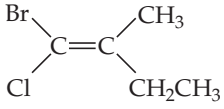


(c)

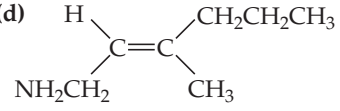


26.51 **(a)** Using butene as an example, distinguish between structural (constitutional) and geometric isomers. **(b)** The compound 4-chloropent-2-ene exists as four stereoisomers. Explain how these four isomers arise by drawing the structures of all four stereoisomers and showing the relationship between them.

26.52 Systematically name the following alkenes, assigning their geometry as *E* or *Z* where appropriate.



(a)



(b)

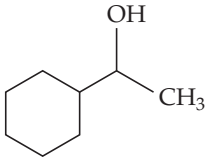
(c)

(d)

26.53 1,3-butadiene, C_4H_6, is a planar molecule that has the following carbon–carbon bond lengths:

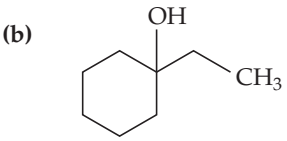
(a) Predict the bond angles around each of the carbon atoms, and sketch the molecule. **(b)** Compare the bond lengths with the average bond lengths listed in Table 26.1. Can you explain any differences?

26.54 **(a)** What is the difference between a localized π-bond and a delocalized one? **(b)** How can you determine whether a molecule or ion will exhibit delocalized π-bonding? **(c)** Is the π-bond in NO_2^- localized or delocalized?



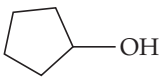
Addition Reactions of Unsaturated Hydrocarbons (Sections 26.4 and 26.5)

26.55 Using condensed structural formulas, write a chemical equation for each of the following reactions: **(a)** hydrogenation of cyclohexene; **(b)** addition of H_2O to *trans*-pent-2-ene, using H_2SO_4 as a catalyst (draw both likely products); **(c)** reaction of propene with bromine in water solvent.

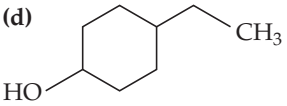


26.56 The rate law for the addition of Br_2 to an alkene is first order in Br_2 and first order in alkene. Does this fact prove that the mechanism of addition of Br_2 to an alkene proceeds in the same manner as for addition of HBr? Explain.

26.57 What alkenes would you hydrate to obtain the following alcohols?



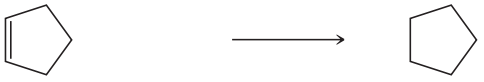
(a)



(b)

(c)

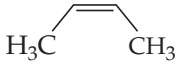
(d)



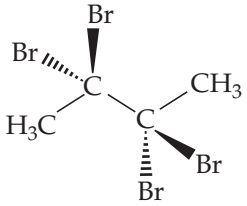
26.58 **(a)** When but-1-yne is hydrohalogenated with HCl a geminal dichloride is formed in preference. Draw its structure. **(b)** Give a reason for your choice.

26.59 **(a)** In the bromination of propene, a cyclic bromonium ion is formed in the first step. Draw it. **(b)** The addition of a nucleophile ($Nu^{\ominus}$) to this bromonium ion yields a single major product. Why is this the case and what product is formed? **(c)** Is this product chiral if Nu═OH? **(d)** What if Nu═Br?

26.60 Suggest suitable reagents for the following reactions:



(a)



(b)

(c) $H_3C{-}C{\equiv}C{-}CH_3$ ⟶

(d) $H_3C{-}C{\equiv}C{-}CH_3$ ⟶

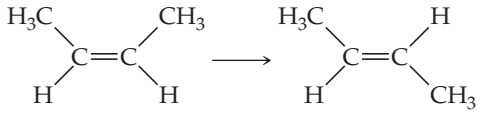
(e)

26.61 **(a)** Write the structural formula for the product of the hydrogenation of 3-methyl pent-1-ene. What is the systematic name of the product? **(b)** When D_2 reacts with ethene (C_2H_4) in the presence of a finely divided catalyst, ethane with two deuteriums, $CH_2D—CH_2D$, is formed. (Deuterium, D, is an isotope of hydrogen of mass 2.) Very little ethane forms in which two deuteriums are bound to one carbon (for example, $CH_3—CHD_2$). Use the sequence of steps involved in the reaction to explain why this is so.

Addition Polymerization (Section 26.6)

26.62 The structure of decane is shown in Table 24.3. Decane is not considered to be a polymer, whereas polyethene is. What is the distinction?

26.63 What is a monomer? Give three examples of monomers, taken from the examples given in this chapter.



26.64 Teflon® is a polymer formed by the polymerization of $F_2C=CF_2$. Draw the structure of a section of this polymer. What type of polymerization reaction is required to form it?

26.65 What molecular structural features cause high-density polyethene (HDPE) to be denser than low-density polyethene (LDPE)?

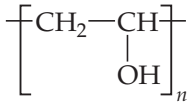
26.66 Are high molecular masses and a high degree of crystallinity always desirable properties of a polymer? Explain.

Integrative Exercises

26.67 But-2-ene, C_4H_8, can undergo *cis–trans* isomerization:

cis-but-2-ene *trans*-but-2-ene

As discussed in the Chemistry and Life box on the chemistry of vision, such transformations can be induced by light and are the key to human vision. **(a)** What is the hybridization at the two central carbon atoms of but-2-ene? **(b)** The isomerization occurs by rotation about the central C—C bond. With reference to Figure 26.5, explain why the π-bond between the two central carbon atoms is destroyed halfway through the rotation from *cis*- to *trans*-but-2-ene. **(c)** Based on average bond enthalpies (Table 8.3), how much energy per molecule must be supplied to break the C—C π-bond? **(d)** What is the longest wavelength of light that will provide photons of sufficient energy to break the C—C π-bond and cause the isomerization? **(e)** Is the wavelength in your answer to part (d) in the visible portion of the electromagnetic spectrum? Comment on the importance of this result for human vision.



26.68 Ethene ($CH_2=CH_2$) reacts with hydrogen gas in the presence of a catalyst to give ethane (CH_3CH_3). **(a)** Draw the structures of the reactants and the product for this reaction and indicate the number of σ- and π-bonds that have been broken and have been formed in this reaction. Use average bond enthalpies in Table 8.3 to estimate **(b)** the enthalpy change for this reaction and **(c)** the average energy of a carbon–carbon σ-bond and π-bond. **(d)** Draw the electron distribution in a π-bond and explain why it is weaker than a σ-bond between the same atoms.

26.69 Consider the electrophilic addition of hydrogen chloride to propene. **(a)** Draw the reaction showing the primary and secondary carbocation intermediates and the products that arise from each intermediate. **(b)** Sketch an energy profile, similar to Figure 26.20, for the two possible pathways in this reaction showing the relative energies of the intermediates and indicating which carbocation is the more stable. **(c)** If the temperature of the reaction mixture was increased would the relative proportions of the two possible products change?

26.70 A sample of a polyunsaturated oil is hydrolysed to give either linoleic acid ($C_{18}H_{32}O_2$) or arachidonic acid ($C_{20}H_{32}O_2$) and you have to find out which one. You take a 1.0 g sample of the unknown acid and perform a hydrogenation reaction under catalytic conditions. This will hydrogenate the carbon–carbon double bonds present but not the carbon–oxygen double bond of the carboxylic acid group. **(a)** Calculate the double bond equivalents in linoleic acid and arachidonic acid. **(b)** Determine the number of carbon–carbon double bonds present in each of the acids. Your sample of unknown acid absorbs 299 cm^3 of hydrogen gas under STP conditions. **(c)** Calculate the number of moles of hydrogen gas used and identify which acid you have.

26.71 Acetylene (H—C≡C—H) can explosively form benzene (). **(a)** Write a chemical equation for this reaction and **(b)** calculate the heat of reaction given $\Delta_f H°$ (benzene) = 83 kJ mol^{-1} and $\Delta_f H°$ (acetylene) = 227 kJ mol^{-1}.

26.72 Polyvinyl alcohol is a polymer with the following structure.

(a) What intermolecular forces exist between polymer chains in polyvinyl alcohol? **(b)** Do you expect polyvinyl alcohol to be water soluble?

Design an Experiment

Many nuts, seeds and some fish are a good source of polyunsaturated fats in which the fat molecule contains two or more double bonds. These fats are liquid at room temperature (oils). Hydrogenation of some of the double bonds present increases the melting point of the fat and produces a semi-solid product that is easier to spread than a fully saturated fat such as butter. Imagine that you are an industrial chemist charged with monitoring the hydrogenation of an oil and stopping the reaction when some, but not all, of the double bonds have been saturated. In your experiment you take a small sample from the reaction mixture at regular time intervals after the hydrogenation commenced. (a) How would you ensure you took the same sized sample each time? (b) what type of solvent would you use to dissolve the sample? (c) What reagent can you think of that changes colour when it reacts with a double bond? (e) Can you think of a way of quantifying the amount of reagent you add and so relating it to the number of double bonds remaining in the sample.

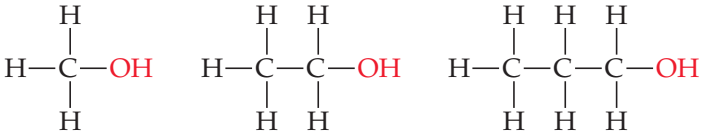
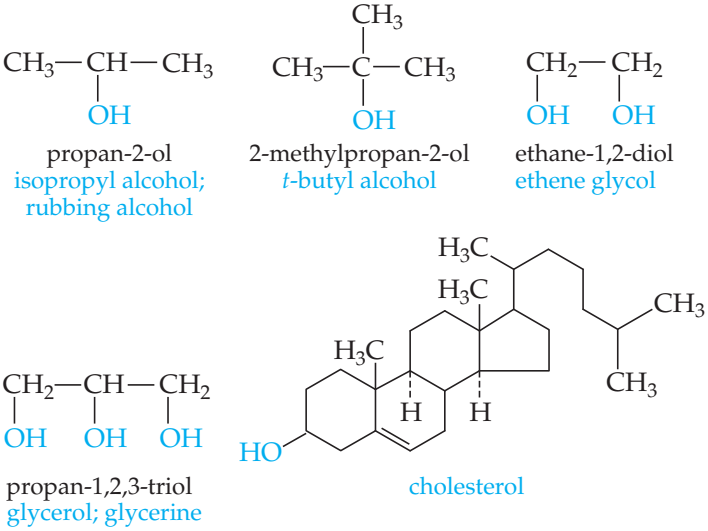
27.1 | Alcohols: Structure, Properties, and Nomenclature



Whether white, red, or something in between, wine is a complex mixture of chemicals. One of the main constituents of wine is, of course, ethanol. Produced by the yeast fermentation of the sugars within the fruits from which it is made, much of the popularity of wine comes from its intoxicating effect. The science of wine and wine making is called *oenology*, and today it helps sustain a multibillion-dollar industry worldwide.

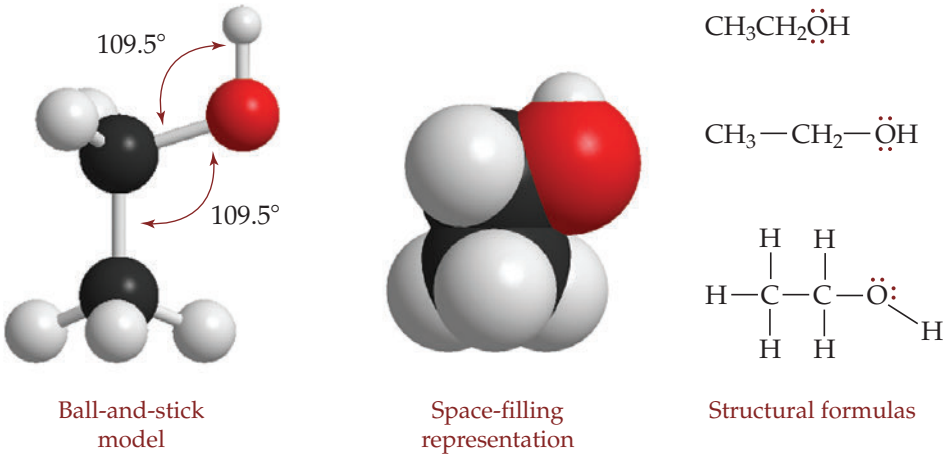
Currently, ethanol is valued more than ever. Its uses are as diverse as a substitute for, or additive in, petrol; as a solvent in the manufacture of varnishes and perfumes; as a fluid in thermometers; in the manufacture of acetic acid; in the preparation of essences and flavorings and as a disinfectant. Ethanol is miscible with water in all proportions. Absolute ethanol contains >99% *v/v* ethanol and is purified from industrial ethanol by first applying fractional distillation, which produces a liquid that is 95% *v/v* ethanol, then by azeotropic distillation.

In this section, we take an introductory look at the structure of alcohols, some of their physical properties, and how to name them. By the end of the section, you should be able to:



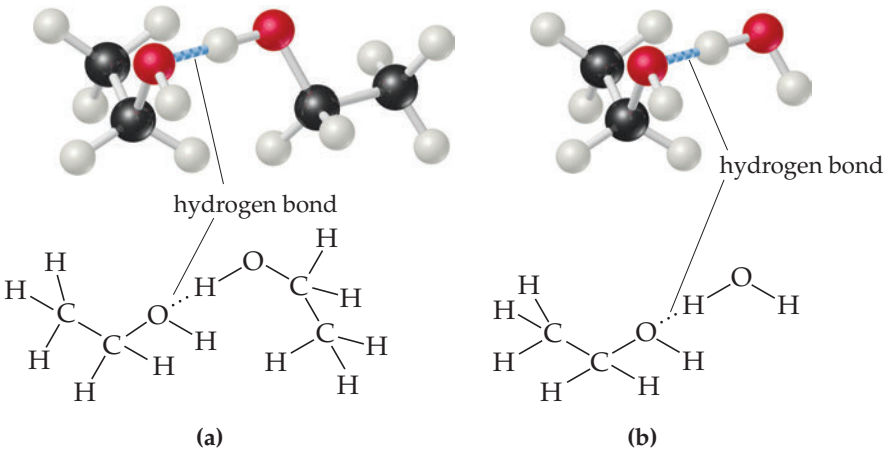
- Have an idea of the solubility of alcohols in water or hydrocarbons
- Be able to name simple alcohols
- Recognize the classification of an alcohol as primary, secondary, or tertiary

Alcohols are hydrocarbon derivatives in which one or more hydrogens have been replaced by a *hydroxyl* group, OH. **Figure 27.1** shows the structural formulas and names of the three simplest straight-chain alcohols together with five other important alcohols. The simple alcohols are named by changing the last letter in the name of the corresponding alkane to *-ol*; for example, ethan*e* becomes ethan*ol*. Where necessary, the location of the OH group is designated by an appropriate numeral prefix that indicates the position of the OH group (Figure 27.1).



The oxygen atom of the hydroxyl group is sp^3 hybridized, having a tetrahedral arrangement of its bonds and lone pairs (**Figure 27.2**). Two of the sp^3 hybrid orbitals of the oxygen atom form σ-bonds with carbon and hydrogen. Each of the other two orbitals contain a pair of unshared electrons, or **lone pair**. The bond angles about the oxygen atom of an alcohol are very similar to those around sp^3 carbon centers. Any variation from the ideal 109.5° bond angle is due to the comparatively large size of the lone pairs.

▼ Figure 27.1 Structural formulas of six important alcohols. Common names are given in blue.



The properties of alcohols are very different from those of the alkanes from which they are derived. For example, methane, ethane and propane are all colorless gases under normal conditions, whereas methanol, ethanol, and propanol are colorless liquids. The reason for the difference in physical properties lies in the fact that the O—H bond is polar, with the difference in electronegativity values between the oxygen and hydrogen atoms being 1.4. As a result, the —OH functional group can participate in intermolecular hydrogen bonding, which increases the attractive forces between the molecules of the alcohol. The strength of a hydrogen bond is approximately 20 kJ/mol, which is considerably weaker than an O—H covalent bond (about 460 kJ/mol); however, it is strong enough to have a significant effect on the alcohol's physical properties. As a result, the boiling points of alcohols are much higher than those of their parent alkanes. The ability of alcohols to form hydrogen bonds is also why they are much more soluble in polar solvents such as water, than in the corresponding

◀ **Figure 27.2 The structure of ethanol.** A number of representations for ethanol are shown.

Go Figure What is the maximum number of hydrogen bonds a single ethanol molecule could possess?

▲ **Figure 27.3 Hydrogen-bonding interactions.** (a) Between two ethanol molecules and (b) between an ethanol molecule and a water molecule.

hydrocarbons (**Figure 27.3**). For example, the solute–solute, solvent–solvent and solute–solvent forces are not greatly different within a mixture of CH_3CH_2OH and H_2O. As a result, there is no major change in the environments of the molecules as they are mixed.

Liquids that mix completely in another liquid are said to be *miscible*, whereas solids that dissolve in a liquid are said to be *soluble* in that liquid. Pairs of liquids, such as ethanol and water, that mix in all proportions are miscible; those that do not mix are *immiscible*. For example, hexane (C_6H_{14}) is immiscible in water. The attraction between the polar water molecules and the nonpolar hexane molecules is not sufficiently strong to allow the formation of a solution.

The number of carbon atoms in an alcohol affects its solubility in water. As the length of the carbon chain increases, the polar OH group becomes an ever-smaller part of the molecule, and the compound behaves more like a hydrocarbon. The solubility of the alcohol in water decreases correspondingly. By contrast, the solubility of the alcohol in a nonpolarsolvent like hexane increases as the nonpolar hydrocarbon chain increases in length. The series of alcohols in **Table 27.1** demonstrates that polar liquids tend to be miscible in other polar liquids and nonpolar liquids in nonpolar ones. This phenomenon is simply stated as "*like dissolves like*".

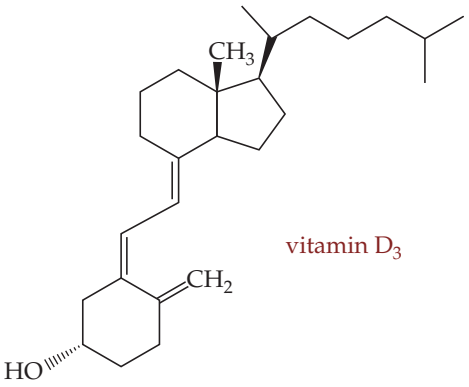


TABLE 27.1 Solubilities of some alcohols in water and in hexane*

Alcohol	Solubility in H_2O	Solubility in C_6H_{14}
CH_3OH (methanol)	∞	0.12
CH_3CH_2OH (ethanol)	∞	∞
$CH_3CH_2CH_2OH$ (propan-1-ol)	∞	∞
$CH_3CH_2CH_2CH_2OH$ (butan-1-ol)	0.11	∞
$CH_3CH_2CH_2CH_2CH_2OH$ (pentan-1-ol)	0.030	∞
$CH_3CH_2CH_2CH_2CH_2CH_2OH$ (hexan-1-ol)	0.0058	∞
$CH_3CH_2CH_2CH_2CH_2CH_2CH_2OH$ (heptan-1-ol)	0.0008	∞

* Expressed in mol alcohol/100 g solvent at 20 °C. The infinity symbol indicates that the alcohol is completely miscible with the solvent.

CHEMISTRY AND LIFE Vitamin D

Vitamin D, an alcohol, is a steroid hormone derived from cholesterol. The biologically active form of the hormone is vitamin D_3 whose primary function is to regulate calcium and phosphorus homeostasis and maintain bone density in the body. Food provides us with a precursor molecule which is converted to vitamin D_3 under the skin by the action of sunlight. Hence it is sometimes called the sunshine vitamin (Figure 27.4). Milk is fortified with vitamin D as a dietary safeguard in countries where outdoor exposure is often limited. Recent evidence suggests there is a need, for children especially, to spend more time outdoors. The "stay out of the sun" campaigns, in conjunction with the great popularity of computer games, have been linked to an increased risk of vitamin D deficiency and the resulting underdevelopment of bone in children, called *rickets*. Rickets is characterized by improper mineralization during the development of bones and results in soft bones, curved spines, and knock-knees. Nevertheless, a sensible approach to sun exposure is also required.

vitamin D_3

Food sources:
Cheese
Margarine
Butter
Fortified milk
Healthy cereals
Fatty fish

Sample Exercise 27.1

Predicting Solubility Patterns in Organic Compounds

Predict whether the following compounds are more likely to dissolve in water or hexane (C_6H_{14}) solvent: cyclohexanol ($C_6H_{11}OH$), acetic acid (CH_3COOH), chloroform ($CHCl_3$), heptane (C_7H_{16}), and glycerol (Figure 27.1).

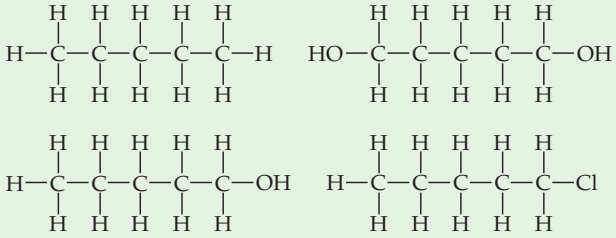
SOLUTION

Analyze We are asked to differentiate between various compounds by their solubility or miscibility in either hexane or water.

Plan *Like dissolves in like.*

Solve Although cyclohexanol contains an OH group, the addition of the C_6 ring system would make its properties comparable with 1-hexanol. Given the choice of solvents, cyclohexanol dissolves better in hexane because the molecule is more "alkane-like".

Acetic acid is a very polar compound, containing little alkane character. This compound dissolves better in water as a solvent.



Chloroform is a moderately polar liquid because of its tetrahedral geometry. Chlorine atoms are poor hydrogen-bonding groups, however, and so this compound would be more miscible with hexane.

Heptane is an alkane, so it is nonpolar. This compound is miscible with hexane.

Glycerol is a small organic compound containing three OH groups. It is very soluble in water.

Practice Exercise

Arrange the following substances in order of increasing solubility in water:

Common Alcohols

Figure 27.5 shows several commercial products that consist entirely or in part of an alcohol. Let's consider how some of the more important alcohols are formed and used. The simplest alcohol, methanol, has many important industrial uses and is produced on a large scale. Carbon monoxide and hydrogen are heated together under pressure in the presence of a metal oxide catalyst:

$$CO(g) + 2\,H_2(g) \xrightarrow[400\ ^\circ C]{200-300\ bar} CH_3OH(g) \qquad [27.1]$$

Because methanol has a very high octane rating as a car fuel, it is used as a petroleum additive and as a fuel in its own right.

Ethanol is a product of the fermentation of carbohydrates such as sugar and starch. In the absence of air, yeast cells convert carbohydrates into a mixture of ethanol and CO_2, as shown in Equation 27.2. In the process, yeast derives energy necessary for growth.

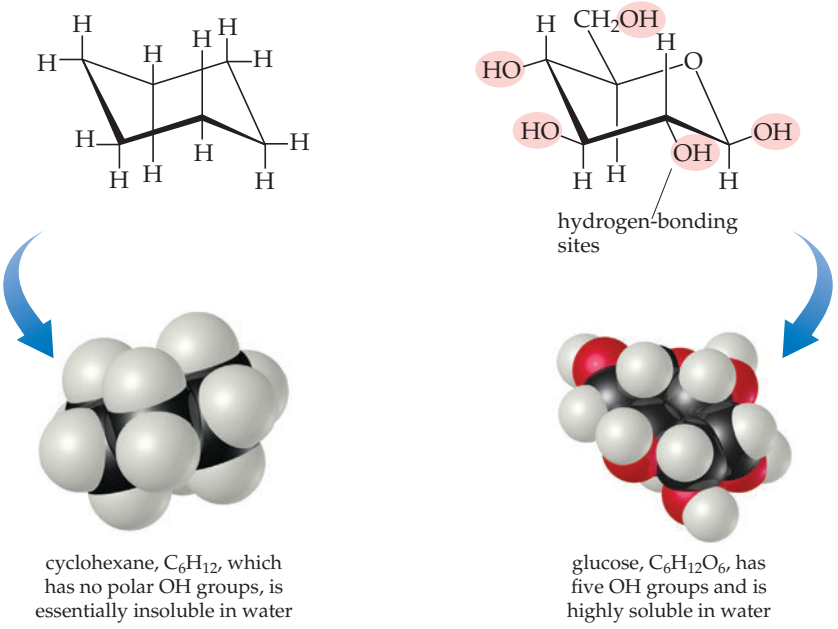
$$C_6H_{12}O_6(aq) \xrightarrow{\text{yeast}} 2\,C_2H_5OH(aq) + 2\,CO_2(g) \qquad [27.2]$$

This reaction is conducted under carefully controlled conditions to produce beer, wine, and other beverages in which ethanol is the active ingredient.

Many polyhydroxyl alcohols (those containing more than one OH group) are known. The simplest of these is ethane-1,2-diol (ethylene glycol, $HOCH_2CH_2OH$). This substance is the major ingredient in car radiator coolant. Another common polyhydroxyl alcohol is propane-1,2,3-triol (glycerol, $HOCH_2CH(OH)CH_2OH$). This is a viscous liquid that dissolves readily in water and is widely used as a skin softener in cosmetic preparations. It is also used in foods and confectionary to keep them moist.

Cholesterol is classed as a *steroid* but here we will look at it as a biochemically important alcohol. The OH group forms only a small component of this rather large molecule, so cholesterol is virtually insoluble in water (0.2 g per 100 cm^3 of H_2O) and has a waxy feel. Cholesterol is an essential component of our bodies; when present in excessive amounts, however, it may precipitate from solution. If it precipitates in the gall bladder, it may form crystalline lumps called *gallstones*. Cholesterol may also precipitate against the walls of veins and arteries and thus contribute to high blood pressure and other cardiovascular problems. The amount of cholesterol in our blood is determined not only by how much cholesterol we eat but also by total energy intake. There is evidence that excessive caloric intake leads the body to synthesize excessive amounts of cholesterol.

▲ **Figure 27.5 Everyday alcohols.** Many of the products we use every day—from rubbing alcohol and throat lozenges to hair spray and radiator coolant— are composed either entirely or mainly of alcohols.

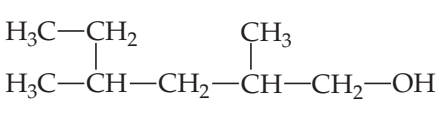


Naming Alcohols

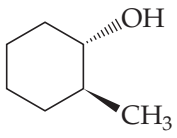
Alcohol nomenclature is based on selecting the longest chain containing the OH group. This chain is numbered to give the OH group the lowest possible number. Alcohols that are *normal*—that is, they contain the OH functional group on the first carbon of a straight-chain alkyl group—are listed in Table 27.1. Sometimes, you may see these compounds named as *n*-butanol, *n*-hexanol, and so on. In these cases, the *n* stands for normal.

CHEMISTRY AND LIFE The Solubility Nexus

The solubility of organic molecules is an important issue, especially in the area of medicine. Not only must a drug be effective, but it must have sufficient solubility in water for aqueous administration in the blood. These two criteria are seldom satisfied collectively and are complicated further by the need for a drug candidate to pass through hydrophobic cell membranes and/or the blood–brain barrier.

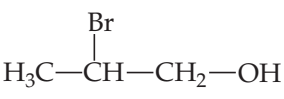


One way to enhance the solubility of a substance in water is to increase the number of polar groups it contains. For example, increasing the number of OH groups along a carbon chain of a solute increases the extent of hydrogen bonding between that solute and water, thereby increasing solubility. Glucose ($C_6H_{12}O_6$) has five OH groups, which makes the molecule very soluble in water (83 g dissolves in 100 cm^3 of water at 17.5 °C). Glucose is shown in **Figure 27.6** and is compared structurally with cyclohexane, its hydrocarbon analogue. The solubility of cyclohexane in water is extremely low due to its inability to hydrogen-bond to water. The second approach to increasing polarity is to add charge. As we will see in Chapters 29 and 31, negative charge can be added through *carboxylate groups* and positive charge through *ammonium salts*. Both are proven and common ways to make drugs soluble in water.

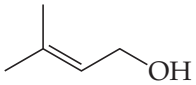


▲ **Figure 27.6 Hydrogen bonding and aqueous solubility.** The presence of OH groups capable of hydrogen bonding with water enhances the aqueous solubility of organic molecules.

It is more appropriate, however, to use IUPAC nomenclature, which names these compounds using a positional prefix—for example, butan-1-ol, hexan-1-ol. Note that methanol and ethanol do not need a prefix.



The names of some simple alcohols are given here. Each molecule contains extra functionality or branching, yet all the names are derived from the name of the alcohol. Their names illustrate, to some extent, the hierarchy of nomenclature.

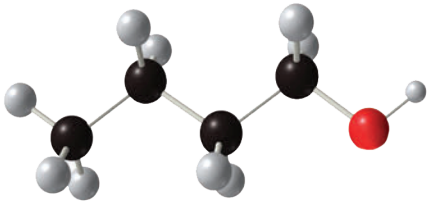


2,4-dimethylhexan-1-ol

(*1S,2S*)-2-methylcyclohexanol is better than *trans*-2-methylcyclohexanol

2-bromopropan-1-ol

3-methyl-2-buten-1-ol

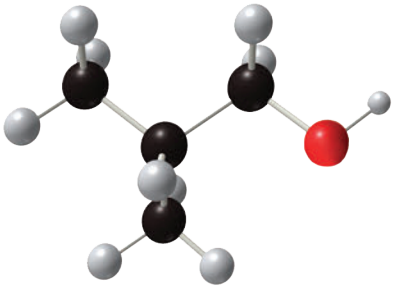


Systematic naming using the IUPAC conventions does not distinguish between, for example, 1-hexanol and hexan-1-ol as the most satisfactory way to name a functionalized

alcohol. Both methods unambiguously describe the position of the OH group and could be used. The latter naming style is better suited to molecules that contain an alkene as well as the OH group. In such cases, "*an*" would be replaced by "*en*" to represent the incorporation of the alkene. Compounds of this type are called *unsaturated alcohols*.

The 2-methylcyclohexanol example illustrated earlier demonstrates two nomenclature principles. The alcohol functional group, when bonded to a cyclic structure, is assigned position 1, based on the arguments we used to discuss the nomenclature of cycloalkenes (Section 26.2). Although *trans* satisfactorily describes the orientation of the OH and CH_3 groups, it does not unambiguously describe the molecule (there is another enantiomer with a *trans* arrangement—can you draw it?). In this case, the absolute stereochemistry at each position should be described.

The OH group is not always located at position 1. **Figure 27.7** illustrates the different $C_4H_{10}O$ alcohols that are possible, as well as their systematic and common names. Alcohols, like alkanes, are classified as primary, secondary or tertiary. We discuss this in more detail in the following section.



Go Figure Which of the alcohols shown in this figure are chiral?

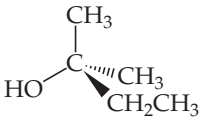
Sample Exercise 27.2



Naming Alcohols

Systematically name the following alcohols, taking stereochemistry into account where appropriate.

(a)

(b)

SOLUTION

Analyze We are given two structures and asked to name them.

Plan Name each compound using the longest chain possessing the OH group. Assign stereochemistry based first on symmetry then on the Cahn–Ingold–Prelog rules in Chapter 25.

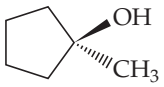
Solve

(a) This example has no stereochemical consequence because a plane of symmetry exists within the molecule. The compound is derived from cyclopentane. Its systematic name is 1-methylcyclopentanol.

(b) This example also has no stereochemical consequences because a plane of symmetry exists within the molecule. The compound is derived from butanol, as the longest chain bearing the OH group is four carbons long. Its systematic name is 2-methylbutan-2-ol.

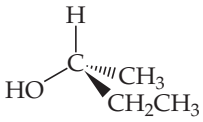
Practice Exercise

Draw the structures corresponding to the following names: **(a)** (*R*)-4-methylpentan-2-ol **(b)** (*Z*)-3-penten-1-ol



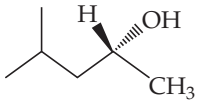
Alcohols containing two or three OH groups are called **diols** and **triols**, respectively. Common examples are shown in Figure 27.1.

Sample Exercise 27.3



Classifying Alcohols

Classify each of the following alcohols as primary, secondary or tertiary.



(a)

(b)

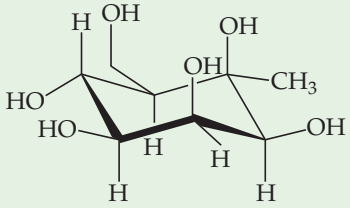
(c)

SOLUTION

Analyze We are given the structures of three alcohols and asked to classify them.

Plan Locate the carbon bearing the OH group and determine the number of carbons attached to this carbon.

Solve



(a) The carbon bearing the OH group has three carbons attached to it: two from the ring and one from the methyl group. Therefore, this is a tertiary alcohol.

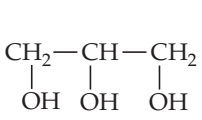
(b) The carbon bearing the OH group has two carbons attached to it, one from the methyl group and the other from the ethyl group. This compound can be classed as a secondary alcohol.

(c) The carbon bearing the OH group has two other carbons attached. Hence it too is secondary.

Practice Exercise

Classify all alcohol functional groups in the following molecule as 1°, 2° or 3°.

Classifying Alcohols



The classification and notation used to distinguish between types of alcohols are:

Primary (1°) alcohol:	The carbon atom bearing the OH group is bonded to only one other carbon atom.
Secondary (2°) alcohol:	The carbon atom bearing the OH group is bonded to two carbon atoms.
Tertiary (3°) alcohol:	The carbon atom bearing the OH group is bonded to three carbon atoms.

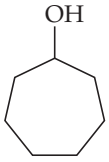


Figure 27.7 illustrates this classification within a series of butanol isomers. There is a big difference in reactivity between 1°, 2°, and 3° alcohols. An important part of your understanding of the chemistry of alcohols is the ability to recognize an alcohol's class and to use this knowledge to predict the product of a reaction. Each classification of alcohol—namely primary, secondary and tertiary—reacts differently to a range of reactants. As we see in the following chapters, this classification allows us to predict the type of product and/or the necessary reagents with which to undertake certain functional-group manipulations.

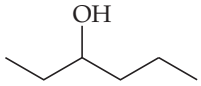
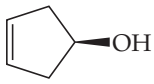
Self-Assessment Exercises



27.1 Which of the following molecules would you expect to be miscible in water?

(a)



(b)

(c)

27.2 Give the full systematic name of the following alcohol:

(a) Cyclopent-1-en-3-ol
(b) Cyclopent-1-en-4-ol
(c) Cyclopent-3-enol
(d) (*R*)- Cyclopent-3-enol

27.3 Which of the structures in self-assessment exercise 27.1 contains a primary alcohol?

Exercises

27.4 Suppose the hydrogens on the OH group of glycerol (Figure 27.1) were replaced with methyl groups, CH_3. Would you expect the solubility in water of the resulting molecules to be higher than, lower than or about the same as the solubility of glycerol?

27.5 Write the structural formulae for as many alcohols as you can think of that have the empirical formula C_3H_6O.

27.6 Explain why propan-1-ol is miscible with water yet hexan-1-ol is not.

27.7 Write the condensed structural formula for each of the following compounds: **(a)** butan-2-ol, **(b)** 1,2-ethanediol, **(c)** diethyl ether.

27.8 Classify the isomeric alcohols with molecular formula $C_4H_{10}O$ as primary, secondary or tertiary.

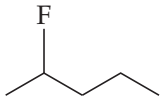
27.2 | Haloalkanes

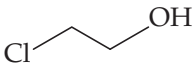
A class of haloalkanes you may be familiar with are the **chlorofluorocarbons**, or **CFCs**. Compounds of this category were typically used as refrigerants, as propellants in aerosols, and as industrial solvents. They were usually marketed under the name *Freon*. CFCs are odorless, non-toxic, non-flammable, and non-corrosive compounds and so found great industrial utility. During the mid-1970s, however, research into CFCs showed they had a harmful effect on the environment. Being relatively chemically inert means that CFCs can persist in the atmosphere for a long time. Thus, they are not broken down in the troposphere but find their way into the stratosphere, where they are decomposed by the action of ultraviolet (UV) radiation. In this process, a reaction sequence is initiated that depletes the ozone layer—a thin layer of the Earth's atmosphere that acts as a shield against excess UV radiation. The attributed result is not only a greater prevalence in skin cancer, but also a higher risk of global warming as chlorofluorocarbons are also much more effective as greenhouse gases than carbon dioxide. In the late 1980s, the United Nations Environment Program put in place a number of agreements to phase out the use of CFCs by 1996. For their work in this area and for their forewarning of the implications, Sherwood Rowland, Mario Molina, and Paul Crutzen were awarded the 1995 Nobel Prize in Chemistry.

In this section, we will introduce haloalkanes with some examples and names. By the end of the section, you should be able to:



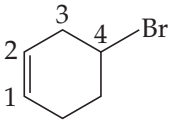
- Write the name of simple haloalkanes

Aliphatic or cyclic hydrocarbons containing a halogen directly bonded to an sp^3 hybridized carbon are called **haloalkanes**. They are generally written as:



$$R—X \qquad \text{where } X = F, Cl, Br, I$$

Haloalkanes are also commonly referred to as alkyl halides.



Haloalkane nomenclature is derived from the longest chain bearing the halogen. The position number is taken to be the lowest possible, bearing all other substituents in mind. Halogen substituents are indicated by the prefixes fluoro-, chloro-, bromo- and iodo-. The derived name places these substituents in alphabetical order:

2-fluoropentane

2-chloroethanol

4-bromocyclohexene

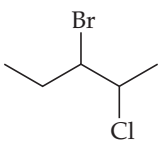
We should also note here that the halogen functional group is second only to alkyl groups as the lowest functional group in the nomenclature hierarchy. All other substituents take precedence in deriving a compound's name, and the numbering used is determined by the location of the other group. For example, 2-chloroethanol is named as the alcohol and not the haloalkane. 4-Bromocyclohexene is named by taking into account the position of the double bond before the halogen.

Many haloalkanes have common names. Some examples are:

methylene chloride
(dichloromethane)

chloroform
(trichloromethane)

vinyl chloride
(chloroethene)

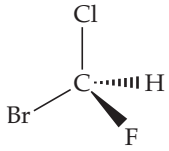


Compounds such as dichloromethane and chloroform are useful solvents in organic synthesis. Compounds of the form CHX_3 are often called **haloforms**, of which chloroform is an example. Perfluorinated compounds (in which all hydrogens are replaced by fluorine) are also very useful. One example we are all familiar with is Teflon™ (polytetrafluoroethene, $(CF_2CF_2)_n$) with its application in non-stick cookware among others.

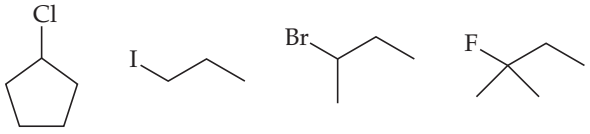
Having properties very different from both water and hydrocarbons, perfluorinated compounds have been used as solvents since they are easily partitioned from both water and most organic solvents. The polar structure also has application in medicine. For example, perfluorocarbons are able to dissolve oxygen at levels greater than blood. As a result, they are undergoing trials in dramatic experiments as blood substitutes in cases where trauma results in severe blood loss with no time to match blood types.

Haloalkanes have a wealth of chemistry associated with them. We have already seen how they can be formed from alkenes and alkanes. Later in this chapter we will explore two reaction types in detail—nucleophilic substitution (Section 27.5) and β-elimination (Section 27.6)—in which haloalkanes are reactants. Later, in Chapter 28, we will explore the use of haloalkanes for the preparation of Grignard reagents.

Self-Assessment Exercises



27.9 Write the systematic name of:



(a) 3-bromo-4-chloropentane
(b) 4-chloro-3-bromopentane
(c) 2-chloro-3-bromopentane
(d) 3-bromo-2-chloropentane

Exercises

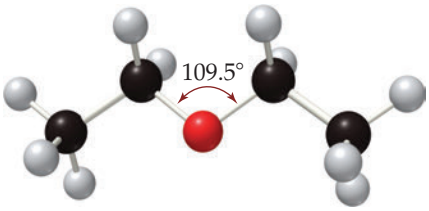
27.3 Ethers: Structure, Properties, and Nomenclature

Diethyl ether, originally called just "ether", was used in medicine for the treatment of some illnesses more than 200 years ago. However, it was not until 1846, when Boston dentist William T G Morton administered its vapors to a patient and extracted a tooth, apparently painlessly, that its potential for use in surgery was quickly realized, and the era of modern anesthetics began. The word anesthesia comes from the Greek for "without sensation". Nowadays, there are many safer anesthetics and ether is no longer used.

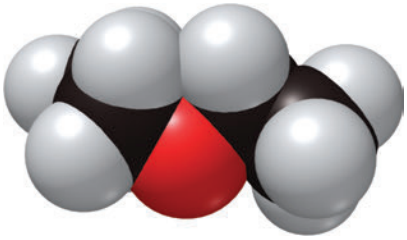


In this section, we introduce you to the ether functional group and its nomenclature. By the end of this section, you should be able to:

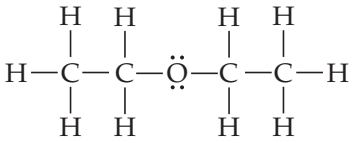
- Name alkyl ethers

We can think of alcohols as compounds in which one hydrogen atom and one hydrocarbon group are bonded to an oxygen atom. Compounds in which two hydrocarbon groups are bonded to one oxygen atom are called **ethers**. As for alcohols, the oxygen atom is sp^3 hybridized with the two C—O bonds subtending an angle of approximately 109.5°. Two of the sp^3 hybrid orbitals of the oxygen atom form σ-bonds with two carbon atoms adjacent to them. Each of the other two hybridized orbitals contains a pair of unshared electrons. **Figure 27.8** illustrates the Lewis structure and other molecular model representations of diethyl ether, the most commonly used of all the ethers.

Ethers are polar molecules, but because of the steric hindrance due to the alkyl groups attached, only weak dipole–dipole interactions exist between molecules. As a result of having alkyl groups bonded to the central oxygen atom, there is no opportunity for hydrogen bonding or other strong electrostatic interactions, so the physical properties of ethers are closer to those of alkanes than to those of alcohols. This moderate polarity is, however, advantageous as it allows ethers to dissolve a wider range of organic compounds than hexane would as a comparative solvent.



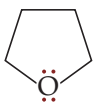
Ethers resemble hydrocarbons in their inertness to chemical reactions. As a consequence, ethers make excellent solvents in which to undertake chemical reactions. Two commonly used solvents are diethyl ether and tetrahydrofuran (THF). Diethyl ether, as we have already seen, is an acyclic ether (Figure 27.8), whereas THF (**Figure 27.9**) is a cyclic ether derived, as the name suggests, from furan, that has a structure given here.



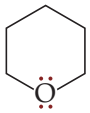
Ball-and-stick model

$CH_3CH_2\ddot{O}CH_2CH_3$

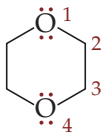
$H_3C-CH_2-\ddot{O}-CH_2-CH_3$



Space-filling representation

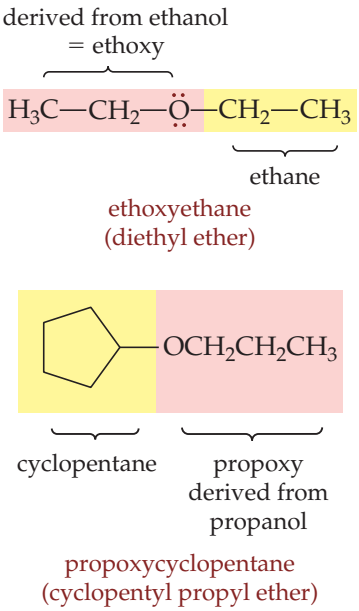


Structural formulae



◀ **Figure 27.8 The structure of diethyl ether.** A number of representations for diethyl ether are shown.

tetrahydrofuran (THF)



tetrahydropyran (THP)

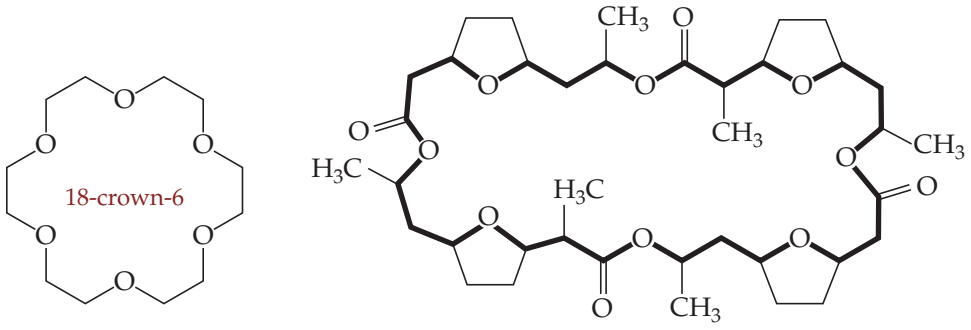
1,4-dioxane

◀ **Figure 27.9 Cyclic ethers.** Simple cyclic ethers such as tetrahydrofuran (THF) and 1,4-dioxane are excellent solvents. Tetrahydropyrans (THP) are useful reagents in organic synthesis.

▲ **Figure 27.10 Ether nomenclature.** Systematic names are derived from the longest alkyl chain present that is attached to the ether oxygen and the residual alkoxy group. Examples of common names are shown in brackets.

TABLE 27.2 Physical properties of the constitutional isomers butan-1-ol and diethyl ether

Compound	Structure	Melting point	Boiling point	Density g/cm^3
butan-1-ol	$CH_3CH_2CH_2CH_2OH$	−90 °C	118 °C	0.81
diethyl ether	$CH_3CH_2OCH_2CH_3$	−116 °C	35 °C	0.70



The structural difference between alcohols and ethers has a marked effect on the properties and chemical reactivity. Butanol and diethyl ether are constitutional isomers and representative molecules within their respective classes. Table 27.2 illustrates the differences in three of their principal properties.

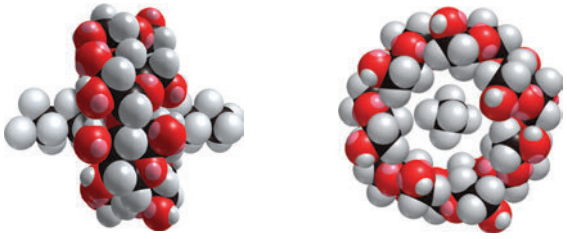
Naming Ethers

Acyclic ethers are named systematically by selecting the longest chain and adding to it the name of the attached **alkoxy** (–OR) **group**. Common names are used more freely with this class of compounds, as the IUPAC method leads to lengthy names quite quickly. These common ether names are derived from the two alkyl groups that are attached to the ether oxygen. Figure 27.10 illustrates how to derive the systematic and common names of acyclic ethers.

Cyclic ethers, such as tetrahydrofuran, are **heterocyclic compounds** whose names are derived in some instances from the parent heterocycle. Heterocyclic compounds are derivatives of cyclic hydrocarbons in which one of the ring carbons is replaced with another atom, usually O or N, but many other hetero atoms have also been incorporated (for example, S, Se, P). Figure 27.9 showed the structure of the most common cyclic ethers.

Cyclic polyethers such as 18-crown-6 (Figure 27.11) are useful in organic synthesis as phase transfer catalysts and metal ion complexation agents. Discovered and developed by Charles Pedersen in the 1960s, **crown ethers** are a synthetic analogue of naturally occurring antibiotics such as nonactin.

▲ **Figure 27.11 Macrocyclic ethers.** Naturally occurring cyclic ethers like nonactin can transport ions across biological membranes. In doing so, they act as potent antibiotics. Crown ethers such as 18-crown-6 are synthetic analogues of nonactin that are also useful for the separation of heavy metal salts from waterways, as catalysts of reactions involving carbanions and as phase transfer catalysts.



A CLOSER LOOK Crown Ethers

Supramolecular chemistry, also known as "chemistry beyond the molecule", is a multidisciplinary science that came to prominence in the late 1980s. This was in part due to the award of the 1987 Nobel Prize in Chemistry to Charles Pedersen (1904–1989), Donald Cram (1919–2001) and Jean-Marie Lehn (b 1939), three of the founders and early developers of supramolecular chemistry. This field began with Pedersen's pioneering work on crown ethers and their metal ion complexes (**Figure 27.12**). The potential of supramolecular chemistry to bridge the gap between chemistry and biology, thereby finding applications in medicine, materials and environmental science, biotechnology and nanotechnology, has seen interest in this field grow rapidly over the past 10–15 years.

Supramolecular chemistry is seen by some as either a molecular art form or as *molecular engineering*. During its development throughout the 1980s and 1990s, supramolecular chemistry was used as a tool to create the most unlikely molecular topologies. For example, rotaxanes (*rota*, wheel; *axa*, axle) are a chemical curiosity containing two molecular components (**Figure 27.13**). The molecular shapes of the two components differ, one resembling a wheel and the other an axle. The axle component is threaded through the center of the wheel component, and is usually terminated by bulky groups to stop the wheel falling off. The use of the bulky stoppers means that the wheel and axle components are mechanically interlocked—they cannot be removed from each other without breaking a covalent bond. Rotaxanes are being investigated as molecular electronic switching and optical binary devices due to their ability to undergo conformational isomerism.

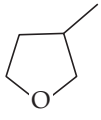
▲ **Figure 27.12** **18-crown-6 complex of K^+.**

▲ **Figure 27.13** **Rotaxanes are mechanically interlocked molecules.** In this illustration, the axle component, a simple alkane, is threaded through the wheel or ring component, a cyclodextrin.

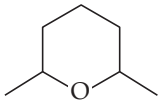
Self-Assessment Exercise

27.13 What is the systematic name of the following structure?

(a) Ethyl propyl ether
(b) Propyl ethyl ether
(c) Propoxy ethane
(d) Ethoxy propane



Exercises



27.14 Explain why the boiling point of ethanol (78 °C) is much higher than that of its isomer, dimethyl ether (−25 °C), and why the boiling point of CH_2F_2 (−52 °C) is far above that of CF_4 (−128 °C).

27.15 Give names for the following ethers (ignore stereochemistry):

(a)

(b)

(c)

(d)

27.16 Write the structures for all the isomeric ethers with molecular formula $C_5H_{12}O$ and give a name for each.

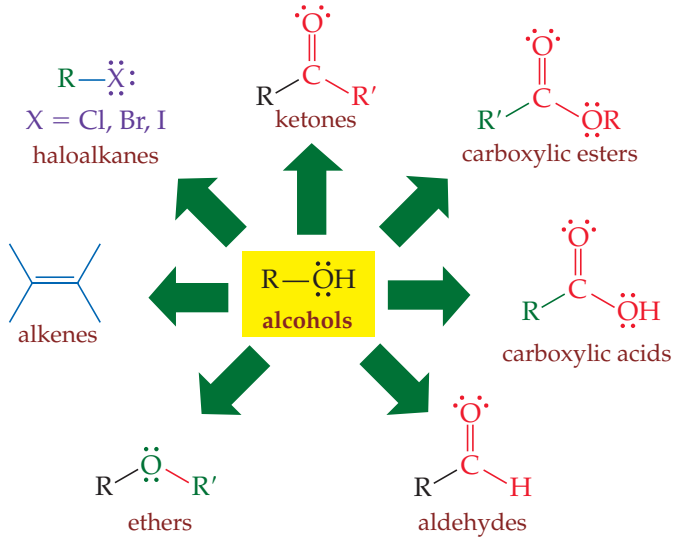
27.17 List two criteria that would make a liquid a good solvent in which to undertake chemical reactions.

27.18 What properties of 18-crown-6 make it possible to complex metal ions such as Na^+ or K^+?

Answers to Self-Assessment Exercise

27.13 (d)

27.4 Reactions of Alcohols



In this section, we start to examine some of the reactions that alcohols can undergo and begin to see how functional groups may be interconverted. Some reactions show a visible change. For instance, when sodium metal reacts with ethanol to form a solution of sodium ethoxide, the metal dissolves and bubbles of hydrogen are evolved. Other reactions take place entirely within the solution phase, but a knowledge of the chemistry involved allows us to predict the outcome of the reaction.

When you finish this section, you should be able to

- Know the conditions to convert an alcohol to an alkoxide
- Recognize two different reagents commonly used to transform alcohols to haloalkanes
- Understand the mechanism of a dehydration reaction

Alcohols are central to organic chemistry. **Figure 27.14** illustrates the relationships between alcohols and the other seven major classes of functional groups introduced in this text.

▲ **Figure 27.14** **Functional group interconversion.**

Four of these functional groups, highlighted in red, can be arrived at through oxidation of a suitable alcohol.

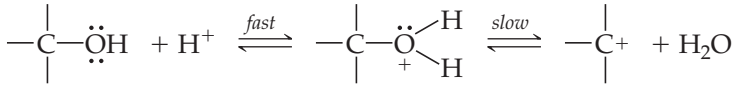
In this section we explore further the interconversion of alcohols to alkenes and haloalkanes. Ethers are formed by taking advantage of the high reactivity of the conjugate base of an alcohol, called an **alkoxide**. Alkoxides are as strong a base as hydroxide and also make excellent nucleophiles.

Alkoxides

Alcohols react with alkali metals to form alkoxides in the same way that water reacts with alkali metals to form hydroxide. The reaction is irreversible, since the other product of the reaction, hydrogen gas, is evolved.

$$2\,H_2O + 2\,Na \longrightarrow 2\,HO^-Na^+ + H_2(g) \qquad [27.3]$$

sodium hydroxide



$$2\,ROH + 2\,K \longrightarrow 2\,RO^-K^+ + H_2(g) \qquad [27.4]$$

potassium alkoxide

The name of the alkoxide is derived from the alcohol undergoing reaction. For example, the reaction of ethanol with sodium gives sodium ethoxide, the reaction of *tert*-butanol (2-methyl-2-propanol) with potassium metal yields potassium *tert*-butoxide. Reactions involving alkoxides invariably use the corresponding alcohol as the solvent for ease of preparation.

Basicity of Alcohols

The ability of an alcohol's OH group to accept a proton is an important property that is important in the context of dehydration (loss of $-H_2O$). An alcohol can act as a weak base, forming an oxonium ion under acidic conditions. The oxonium ion ($pK_a \sim -2$) is a slightly better acid than the hydronium ion (H_3O^+, $pK_a \sim -1.7$), but of greater importance to organic synthesis is the ability of the oxonium ion to lose water, forming a carbocation intermediate:

an oxonium ion a carbocation [27.5]

As we discussed in the context of Markovnikov's rule, the stability of the carbocation intermediate is an enormous driving force for the reactivity of a species, and even dictates the reaction pathway.

Alcohols to Haloalkanes

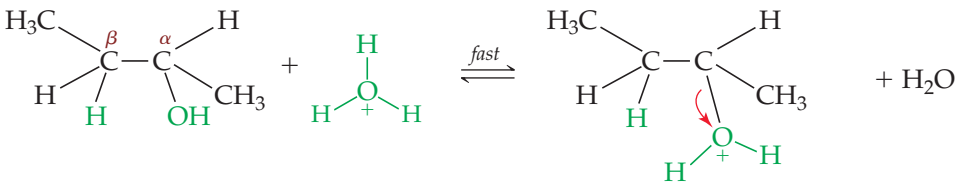
Alcohols can be converted into haloalkanes by treatment of a halogenating agent, usually under acidic conditions. In this reaction, the OH group of the alcohol is substituted by a halogen. The reaction is classed as a **nucleophilic substitution (S_N) reaction** and we will see much more of this in the next section.

A nucleophilic substitution reaction is any reaction in which one nucleophile is substituted for another.

In using mineral acids (e.g. HCl, HBr, HI) as the halogenating agent, the first stage of substitution is protonation of the alcohol to form an oxonium ion. This is followed by elimination of water to form the intermediate carbocation as indicated in Equation 27.5. This last step is rate-determining, being faster for formation of a 3° carbocation than 2° and 1°.

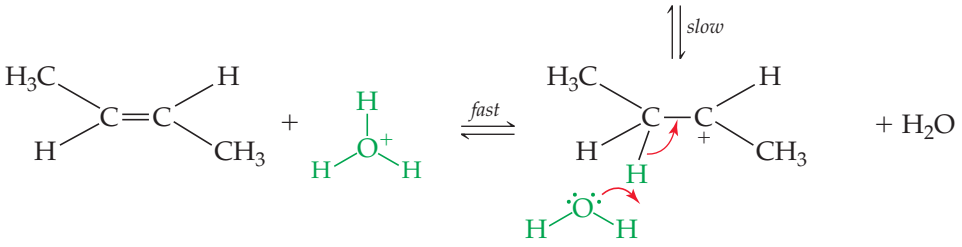
The stability of the intermediate carbocation is the major factor allowing the substitution reaction to dominate for 3° alcohols. For example, the conversion of 2-methyl-2-propanol to 2-bromo-2-methylpropane using HBr is a reaction that occurs readily at room temperature using HBr.

$$(CH_3)_3COH + HBr \longrightarrow (CH_3)_3CBr + H_2O \qquad [27.6]$$



Secondary alcohols also undergo substitution using mineral acids, but they require heating and longer reaction times. Primary alcohols require extreme conditions to substitute using this method, and are impractical. The most efficient way of achieving this conversion is to react the primary alcohol with thionyl chloride:

$$\underset{\text{butan-1-ol}}{CH_3CH_2CH_2CH_2OH} + \underset{\text{thionyl chloride}}{SOCl_2} \longrightarrow \underset{\text{1-chlorobutane}}{CH_3CH_2CH_2CH_2Cl} + \underset{\text{sulfur dioxide}}{SO_2(g)} + HCl \qquad [27.7]$$



The reason this reaction works well is that one of the products (SO_2) is gaseous, so once it is liberated the reaction goes to completion.

Dehydration of Alcohols

We have already indicated that alcohols can be dehydrated to form alkenes (see Equation 26.15). Equation 27.8 illustrates the accepted mechanism. This acid-catalyzed dehydration process has, as one of its intermediates, an oxonium ion. The rate-determining step is the elimination of water to form the corresponding carbocation. Removal of a small group from a larger molecule, as in this case, is called an *elimination reaction*. Water is classed as a *good leaving group* because of its stability and relatively unreactive nature. Hydroxide ion, however, does not eliminate easily and so is classed as a *poor leaving group*.

[27.8]

Leaving groups can be classified as good or poor based on their reactivity. In general, the better leaving groups are those that are conjugate bases of strong acids. A relative order of leaving group is:

$$\underset{\text{Good leaving group}}{I^- > H_2O > Br^- > Cl^-} \gg \underset{\text{Poor leaving group}}{F^- > CH_3COO^- > OH^- > NH_2^-}$$

Once water has been eliminated from the oxonium ion in Equation 27.8, the reaction proceeds rapidly to the formation of the alkene by the loss of a proton from a carbon atom located in a neighboring position (called the β-position) to the original C—OH bond. The two electrons that once formed the C_β—H bond will now form the π-bond of the alkene. Without the β-hydrogen atom, the dehydration reaction does not proceed.

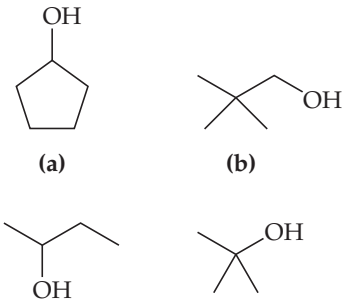
The nature of the equilibrium is such that removal of water or distillation of the alkene (which generally will have a lower boiling point than the corresponding alcohol) will maximize the formation of the alkene by driving the equilibrium in the forward direction.

Self-Assessment Exercises

27.19 Can you use an aqueous solution of ethanol to form sodium ethoxide?

(a) Yes

(b) No

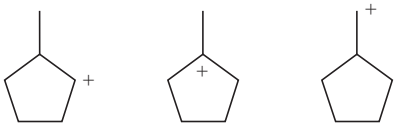


27.20 Which is the reagent of choice to convert butan-1-ol to 1-chlorobutane?

(a) Cl_2

(b) HCl

(c) $SOCl_2$



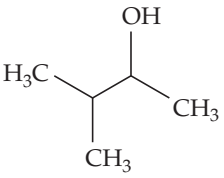
27.21 Which of the following molecules would *not* undergo a dehydration reaction?

(a) **(b)** **(c)** **(d)**

Exercises

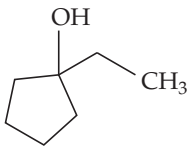
27.22 Which of the following carbocations is most stable? Which is least stable?

(a) **(b)** **(c)**



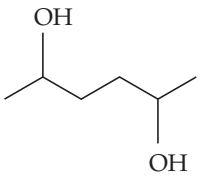
27.23 **(a)** Write a chemical equation for the substitution reaction of butan-2-ol with HBr. **(b)** Write a stepwise mechanism for this reaction. **(c)** Would butan-1-ol undergo the substitution reaction more quickly or more slowly than butan-2-ol?

27.24 **(a)** Which of the following is the *best* leaving group: (i) fluoride, (ii) iodide, (iii) hydroxide, (iv) chloride or (v) bromide? **(b)** Why, in a polar protic solvent, is iodide a better nucleophile than fluoride?

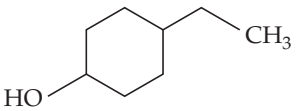


27.25 The addition of water to an alkene in the presence of H_2SO_4 leads to the formation of an alcohol, as shown in Equation 26.15. This reaction is in equilibrium with the dehydration of the newly formed alcohol to re-form the alkene. Describe a way of controlling the equilibrium so as to improve the yield of the alcohol.

27.26 What alkenes are formed as the major products from the dehydration of the following alcohols?



(a)



(b)

(c)

(d)

How many sets of stereoisomers are formed in each product case?

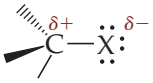
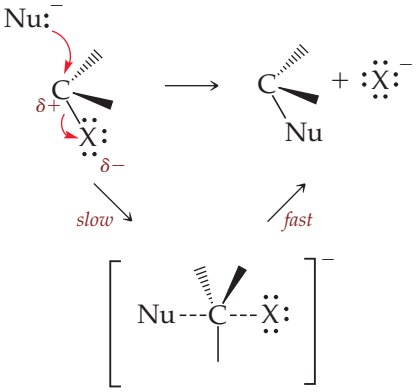
27.5 Nucleophilic Substitution Reactions of Haloalkanes



Between 20% and 30% of pharmaceuticals currently on the market have fluorine in their structure. These substances are active in a wide range of physiological situations, including cholesterol regulation (eg Lipitor®), antidepressant medication (eg Prozac®), for treatment of some cancers (fluorouracil), and are also present in many broad-spectrum antibiotics and in inhaled anesthetics (isoflurane). The strong carbon–fluorine bond resists metabolism and delays excretion from the body allowing for longer time periods between doses. The presence of fluorine also makes the substance more lipophilic, a useful property for anesthetics. In contrast, the bond between carbon and chlorine, bromine or iodine, is more reactive than a typical carbon–carbon single bond, which makes these haloalkanes excellent intermediates in chemical synthesis.

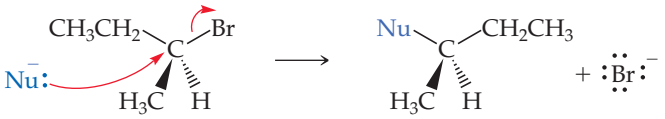
By the end of this section, you will be able to:

- Appreciate the scope of reactions undergone by haloalkanes.



The conversion of alcohols to haloalkanes by substitution opens up a large library of functional group manipulation, limited only by imagination. The reactivity of haloalkanes manifests itself from the difference in electronegativity between carbon (2.5) and the halogens (2.6–4.0), which means the carbon bearing the halogen is susceptible to nucleophilic attack.

Where X = F, Cl, Br, I

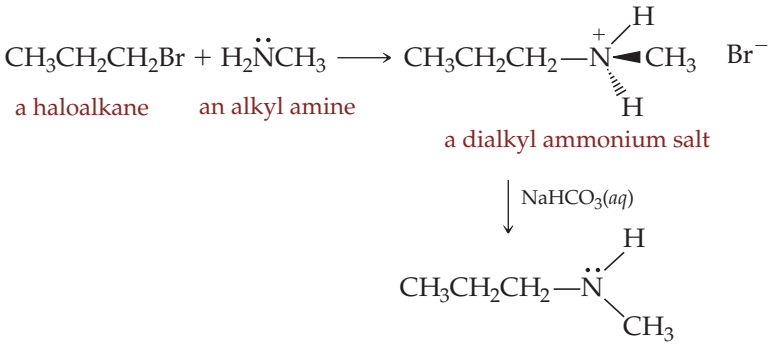


Nucleophilic substitution reactions of haloalkanes proceed by attack of the nucleophile (Nu:) at the carbon bearing the halogen. The trigonal-bipyramidal transition state formed in this reaction has long Nu—C and C—X bonds, signifying the strengthening bond formation of the incoming nucleophile and the weakening C—X bond of the outgoing halide. One of the driving forces for this reaction is the stability of the halide ion, which is an excellent leaving group.

As you can see in (Figure 27.15), the transition state that leads to the product involves both the haloalkane and the nucleophile in the rate-determining step. As such, this reaction is classed as $\mathbf{S_N2}$ for bimolecular (2), nucleophilic (N) substitution (S) reaction.

▲ Figure 27.15 Nucleophilic substitution reactions.

If the starting haloalkane is chiral about the carbon bearing the halogen, then the S_N2 reaction shown in Equation 27.9 usually proceeds with inversion of stereochemistry:



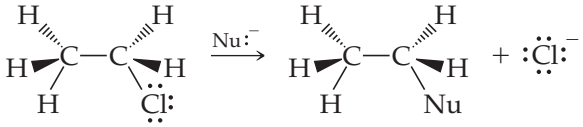
(*S*) stereochemistry (*R*) stereochemistry [27.9]

Inversion of stereochemistry can be thought of as the inversion of an umbrella that happens on a windy day (**Figure 27.16**). In this analogy, consider the umbrella canopy as three groups around a tetrahedral center that do not participate in an S_N2 reaction. Upon nucleophilic attack, the canopy is inverted, with some strain, to yield a new conformation.

However, the inversion of stereochemistry depends on the nature of the nucleophile and leaving group, the substituents about the stereocenter and the reaction conditions (for example, the solvent used).

Table 27.3 lists common nucleophiles employed in nucleophilic substitution reactions, as well as the classes of organic compound formed by the substitution. We have already investigated some of these in detail. Two nucleophile classes we have yet to discuss in any detail involve amines (which are neutral molecules) and the cyanide ion (CN^-). The addition of ammonia to a haloalkane, for example, leads initially to an **alkyl ammonium salt**. Such salts are characterized by four groups around nitrogen of which at least one is an alkyl group. Provided the ammonium ion is of the form R_3NH^+, $R_2NH_2^+$ or RNH_3^+, they are easily transformed into **amines** by the addition of base.

a haloalkane an alkyl amine a dialkyl ammonium salt



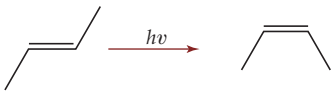
a dialkyl amine

N-methyl-1-propanamine [27.10]

◀ **Figure 27.16** The mechanism of an S_N2 reaction is analogous to an umbrella on a windy day.

TABLE 27.3 Common nucleophilic substitution reactions based on the reaction:

Nucleophile	Product	Class of compound
$^{-}$:ÖH	CH_3CH_2OH	an alcohol
$^{-}$:ÖR	CH_3CH_2OR	an ether
$^{-}$:Ï:	CH_3CH_2I	an alkyl iodide
$^{-}$:CN	CH_3CH_2CN	a nitrile
:NH_3	$CH_3CH_2NH_3^+X^-$	an alkyl ammonium salt
ÖH_2	CH_3CH_2OH	an alcohol



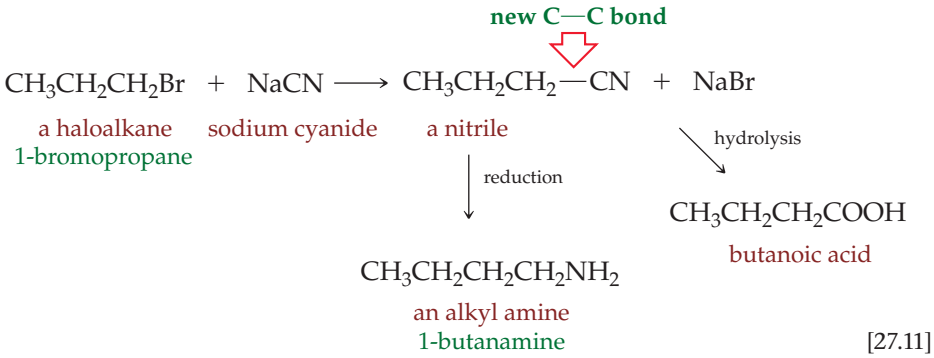
A CLOSER LOOK Molecularity

The molecularity of a reaction describes the number of atoms or molecules of reactant taking part in an elementary reaction. Remember that an overall reaction mechanism is composed of several elementary reactions. Most elementary reactions involve one (*unimolecular*) or two (*bimolecular*) species. Though most reactions are monitored by the loss of reactants or the formation of products, ultimately it is the molecularity of the rate-determining step that defines the observed kinetics of the overall reaction and hence whether a reaction is unimolecular or bimolecular. Molecularity should not be confused with reaction order.

Simple unimolecular reactions include decomposition of chlorine by homolytic bond cleavage or isomerization reactions. In both cases, the rate of reaction depends directly on the concentration of the only reactant. In this case, it is easy to see why this is a unimolecular reaction.

homolytic bond cleavage $Cl_2 \xrightarrow{h\nu} 2Cl\cdot$

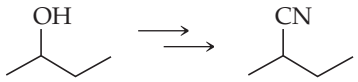
isomerization



In a bimolecular reaction, two species are required to give rise to the product, for example the dimerization of $NO_2^{\cdot}$ or the addition of HCl to an alkene. In each case, the rate of reaction depends directly on the concentration of the two reactants, which need to collide before reaction can proceed.

$2NO_2 \longrightarrow N_2O_4$

The reaction of cyanide ion (CN^-) with a haloalkane (producing a **nitrile**) is extremely useful in organic synthesis despite the obvious toxicity problems, due to its ability to form a new C—C bond upon substitution. Reduction of the nitrile yields an alkyl amine which differs from the starting haloalkane by the addition of an extra CH_2 group, as well as the change in functional group.

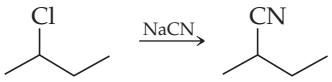


[27.11]

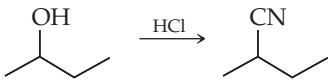
Sample Exercise 27.4

Nucleophilic Substitution Reactions

Using 2-butanol as a starting material, design a synthesis of 2-methylbutyronitrile in two steps:

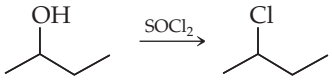


SOLUTION

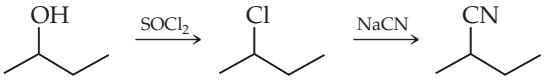


Analyze We are asked to design a substitution reaction for replacing a secondary OH group by CN.

Plan For a synthesis problem like this, it is usually helpful to consider the sequence of steps starting from the product you want. You know from Table 27.3 that nitriles can be synthesized from the haloalkane by substitution.

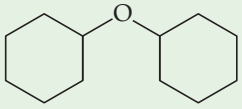


Solve In the following example the chloride is chosen, although the bromide is just as efficient:



Formation of the alkyl chloride from the alcohol can occur in two ways. Since 2-butanol is a secondary alcohol, reaction with either HCl or thionyl chloride, $SOCl_2$, will yield 2-chlorobutane.

or



Thus the overall two-step reaction sequence is:

Practice Exercise

Describe how you would prepare this ether from cyclohexanol.

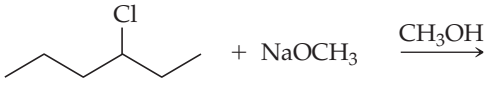
Self-Assessment Exercise

27.27 What is the product of the reaction between (*S*)-2-bromobutane and the hydroxide nucleophile, OH^-?

(a) butan-1-ol

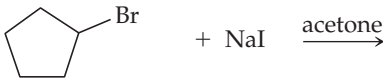
(b) (*S*)-butan-2-ol

(c) (*R*)-butan-2-ol

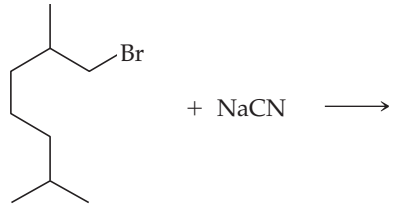


Exercises

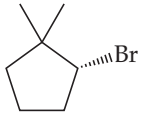
27.28 Write the structure of the major organic product expected from the following reactions:



(a)



(b)



(c)

(d)

27.29 Name the product formed when methoxide reacts with:

27.30 Draw the mechanism of the reaction of chloroethane with cyanide. Use curly arrows where appropriate and show the structure of the trigonal bipyramidal transition state.

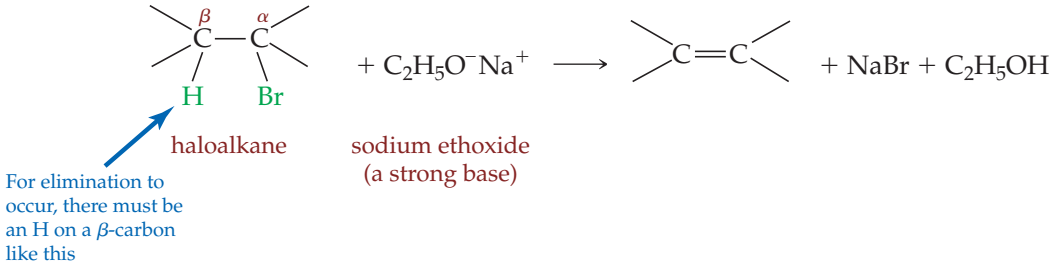
27.31 Hydroxide, OH^-, can act as both a base and a nucleophile. Explain the difference between these two terms and give a reaction to illustrate each case.

27.32 Design a synthesis of methoxymethane (CH_3OCH_3) starting from methanol as the only carbon containing compound.

Answers to Self-Assessment Exercise

27.27 (c)

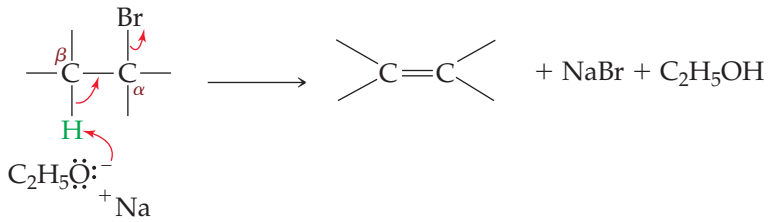
27.6 Haloalkanes to Alkenes: β-Elimination



In the laboratory, there is often more than one way to approach the synthesis of a target molecule. The way chosen will depend on a range of factors including availability of starting materials, cost, what byproducts are formed, and the compatibility of the transformation with other functional groups that may be present. We have already seen that alkenes may be formed by the acid catalyzed dehydration of alcohols, they may also be formed from haloalkanes in an elimination reaction.

By the end of this section, you should be able to:

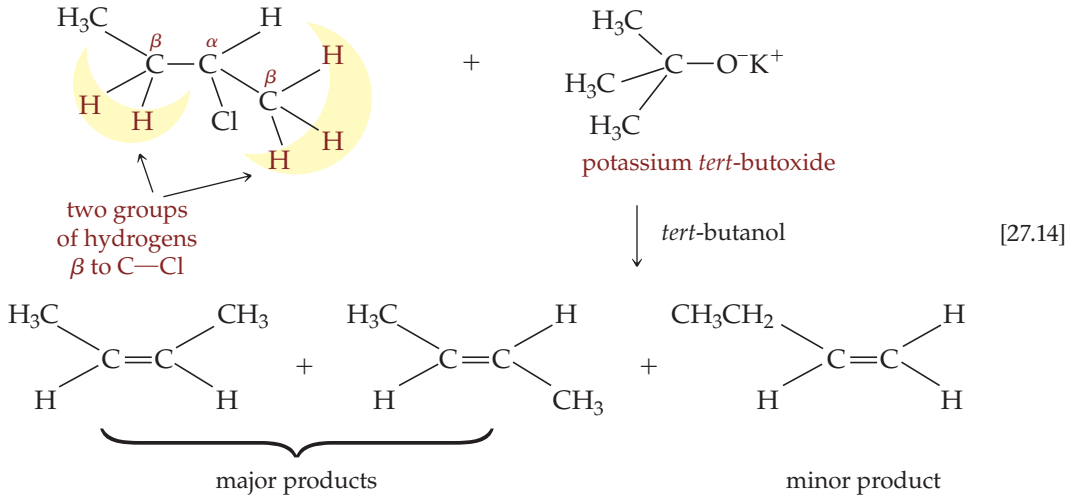
- Recognize which haloalkanes undergo elimination and predict the product formed.



The process of eliminating a good leaving group, as outlined for the dehydration of an alcohol, is quite general. For example, haloalkanes undergo elimination under basic conditions. This process, called a ***β*-elimination reaction**, involves the *dehydrohalogenation*

of the haloalkane—that is, the loss of a hydrogen atom and a halogen atom from the same molecule. For the reaction to proceed, a hydrogen atom on the carbon atom adjacent to the carbon bearing the halide (that is, the β-carbon) must be present and be removed.

[27.12]

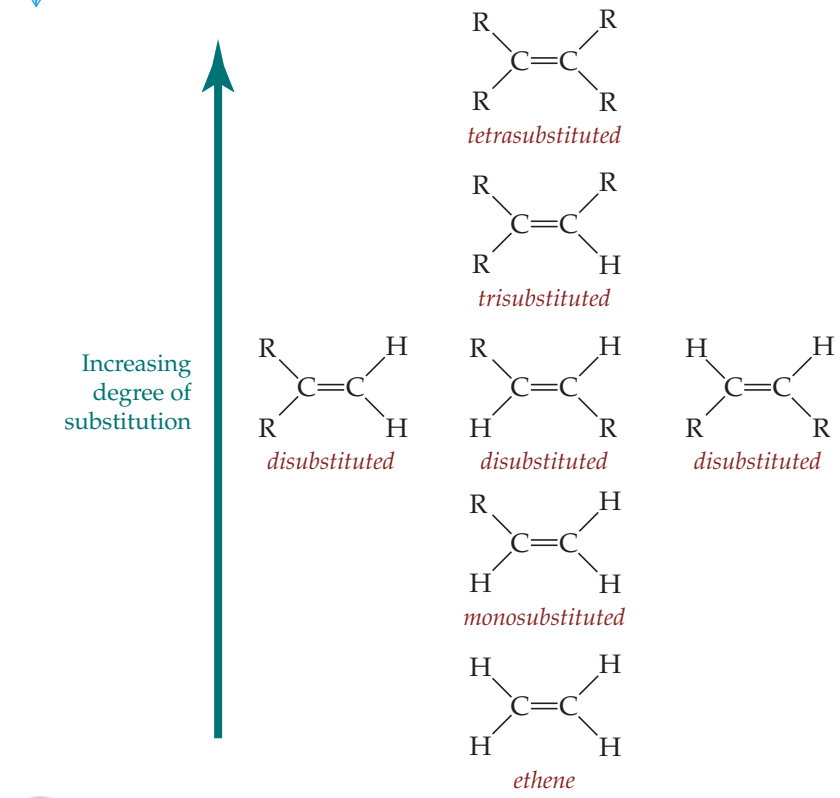


The reaction is not as fast as the corresponding dehydration of an alcohol, requiring the use of a strong base (for example, sodium ethoxide) to proceed. The mechanism can be shown to occur in a single (and essentially irreversible) step:

[27.13]

Typically, the hydrogen atoms of hydrocarbons do not react in this way. However, the inductive effect of the halogen atom on the α-carbon draws electron density out of the C—H bond, causing the β-hydrogen to become more acidic by weakening the C—H bond. Because this reaction involves the haloalkane and strong base in the rate-determining step, this **elimination reaction** is known as an **E2** or bimolecular (2) elimination (E) reaction.

Let us now consider the reaction of 2-chlorobutane with potassium *tert*-butoxide, another strong organic base:



[27.14]

In this case, there are two sets of β-hydrogens as highlighted in Equation 27.14. Although β-elimination can lead to the formation of two alkenes, one elimination product is formed in preference to the other.

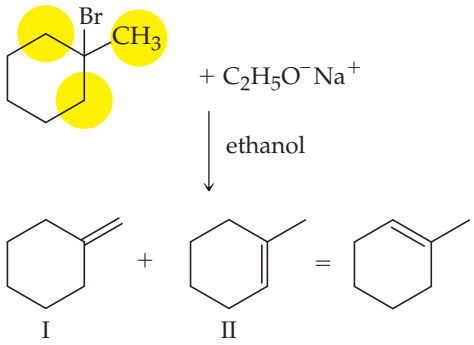
The major alkene formed by dehydrohalogenation is the one containing the more substituted double bond. This preference is known as **Zaitsev's rule**. The more substituted double bond is the one with the greater number of substituents (excluding hydrogen) attached to the two carbons of the double bond. For example, the but-2-ene formed in Equation 27.14 has two methyl groups connected to the carbons of the double bond, whereas but-1-ene has a single ethyl group connected. Because but-2-ene has two non-hydrogen substituents, it is the more substituted of the two alkenes formed. **Figure 27.17** illustrates what is meant by a substituted alkene.

Go Figure Which of these alkenes are isomers?

▲ **Figure 27.17** **Substituted alkenes in which R is a non-hydrogen atom, typically being carbon.**

Sample Exercise 27.5

β-Elimination in Haloalkanes



Draw the structural formula for the major product formed when 1-bromo-1-methylcyclohexane is reacted with sodium ethoxide in ethanol. Systematically name the major product.

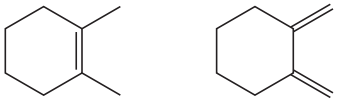
SOLUTION

Analyze We are asked to determine the product of the reaction of a sterically hindered haloalkane with a strong base.

Plan Begin by structurally identifying the compounds involved. Look for β-hydrogens then determine the types of alkenes possible.

Solve

There are two different sets of β-hydrogens highlighted in yellow, those on the methyl group and two equivalent sets on the cyclohexane ring. Hence two different alkenes, I and II, are formed. The major product will be the one that satisfies the criterion of Zaitsev's rule. The more substituted double bond is found in II, and so it is formed in preference.



Alkene II is named *1-methylcyclohexene*.

Practice Exercise

2-Methylpent-2-ene can be formed by the reaction of potassium *tert*-butoxide and which bromoalkane?

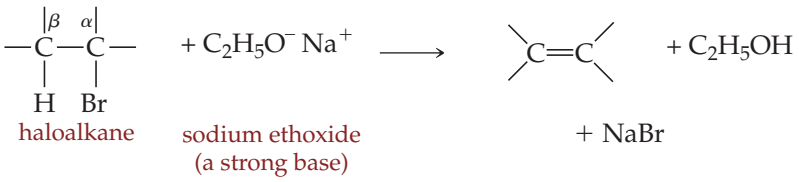
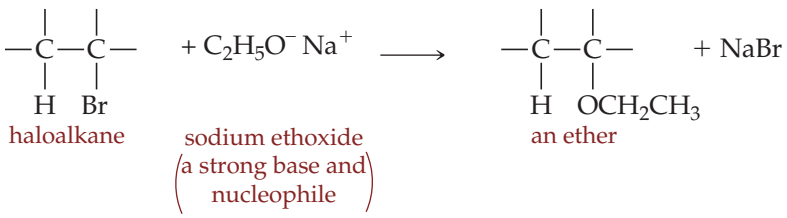
27.7 | Substitution versus Elimination



There are many situations in chemistry where two or more reaction pathways compete to give different products. One of the skills we introduce in this section is to recognize the molecular structures, choice of reagents, solvents, and conditions that favor one pathway over a different one. In this way, we optimize the formation of the compound we want and minimize waste. By the end of this section, you should be able to:

- Identify the features that distinguish substitution and elimination pathways.



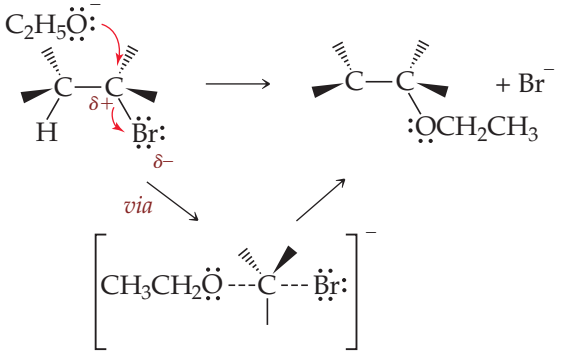
We consider four types of reactions in this section, E1, E2, S_N1 and S_N2. We have already encountered two of these formally (E2 and S_N2). As we will see, each reaction type does not operate in isolation, but together they form a competing process. Which direction a reaction proceeds in depends on several factors, including starting material and reagents, type of solvent, and electronic and steric effects.

We have already seen in this chapter that alkoxides are a strong base, able to deprotonate haloalkanes in a β-elimination reaction.

[27.15]

However, as we saw in Section 27.5, alkoxides are able to react with haloalkanes in another way. Instead of providing a means of elimination, alkoxides can also interact with haloalkanes to form ethers. The classic example is the *Williamson ether synthesis*, in which the halide is replaced by the alkoxide in a substitution reaction.

[27.16]



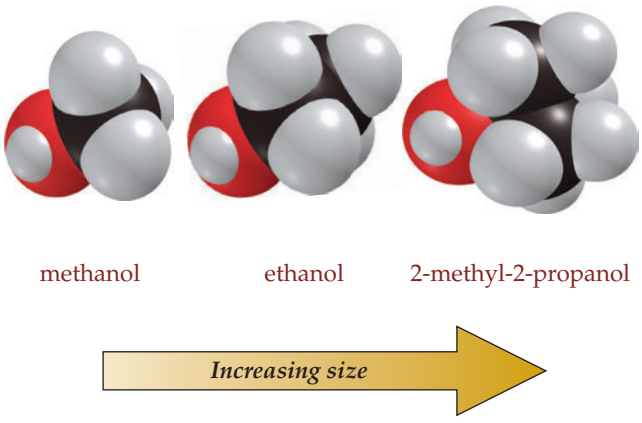
A CLOSER LOOK Nucleophile or Lewis Base?

Whether a reaction follows an elimination or substitution pathway is dependent on whether the added reagent acts as a Lewis base or nucleophile, respectively. Recall that a Lewis base is an electron-pair donor, the same as a nucleophile. In broader definitions, a Lewis base can donate its electron pair to something other than H^+. By this definition, both a nucleophile and Lewis base can form new covalent bonds. So what's the difference?

The answer is nothing. We usually invoke the term Lewis base when there is a proton abstraction process, as in an elimination reaction, and the term nucleophile in all other cases. So, a Lewis base can be a good nucleophile if there are no sterically bulky groups around the electron donor.

Related Exercise: 27.68

The mechanism for this substitution reaction involves attack of the nucleophilic alkoxide on the weakly electrophilic carbon atom bearing the halide. Note that strong bases are typically good nucleophiles. The carbon atom bearing the halogen is made more electrophilic by the inductive effects of the halogen. This reaction type is called a *nucleophilic substitution (S_N) reaction*. The reaction goes through a trigonal-planar carbon state with elongated bonds for the incoming alkoxide and the outgoing halide. Eventual loss of Br^- yields the ether. The reaction shown in Equation 27.17 can be further defined as an S_N2 reaction, since the rate-determining step requires the addition of the alkoxide in concert with the loss of halide.



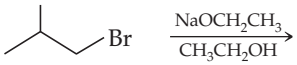
[27.17]

The β-elimination reaction (Equation 27.12) is in fact in competition with the substitution reaction. Generally, *S_N2 reactions are in competition with E2 reactions*. Which mechanism predominates in the reaction is dictated by a variety of factors:

1. The size of the alkoxide: the bulkier the alkoxide, the more elimination is favored. **Figure 27.18** illustrates this change in size. Alkoxides such as that generated from 2-methyl-2-propanol (*tert*-butanol) favor E2 because of their large size, while those generated from methanol favor S_N2.
2. The accessibility of the carbon bearing the halogen: the more accessible it is, the more substitution is favored.
3. The accessibility of the hydrogen atom in the β-position: the more accessible it is, the more elimination is favored.

Any alkyl groups positioned off the α-carbon of the haloalkane tend to favor β-elimination. This is particularly true of the larger halogens, Br and I.

▲ **Figure 27.18** Size increases with substitution.



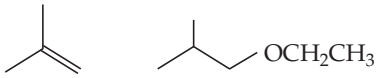
E1 and S_N1 Reactions

In Section 27.4 we discovered that generating a carbocation intermediate leads rapidly to formation of the alkene. The stability of the carbocation formed in the dehydration is also the driving force for that reaction. That is, the conditions needed to dehydrate a tertiary alcohol are much milder than those needed to dehydrate a primary alcohol, due to the relative stabilities of the intermediate tertiary and primary carbocations, respectively. In this case, the rate-determining step is the loss of water to form the carbocation intermediate as shown in Equation 27.5. As such, this elimination reaction is *unimolecular*

Sample Exercise 27.6

Predicting Substitution or Elimination

What is the major organic product from the following reaction? Indicate whether this is an S_N2 or E2 reaction.

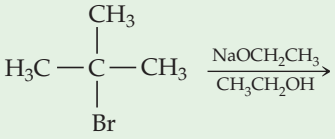


SOLUTION

Analyze We are given the reaction of a haloalkane with a strong base also capable of acting as a good nucleophile. We are asked to determine the product and the mechanism.

Plan We need to consider both elimination and substitution products in our deliberation, as well as the nature of the base and whether a β-hydrogen is present and accessible.

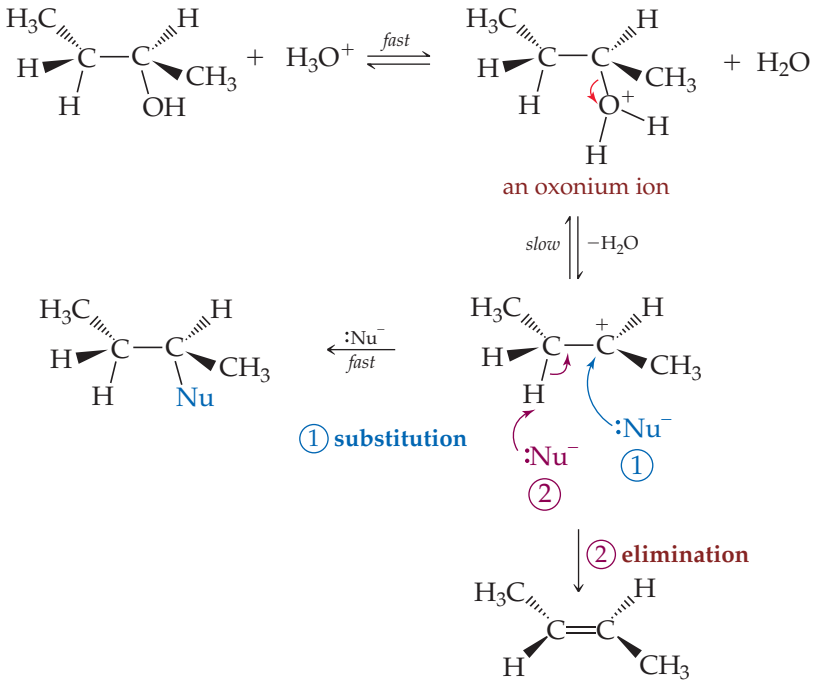
Solve The elimination and substitution products are:



elimination product | substitution product

The α-carbon in the starting bromoalkane is essentially unhindered despite the bulk of the two methyl groups nearby and the bromine atom. This implies that substitution would occur readily. In contrast, the β-hydrogen is more restricted by the same steric groups. This factor suggests that substitution predominates. The substitution follows an S_N2 mechanism.

This practice exercise shows how the yield of alkene may be optimized.

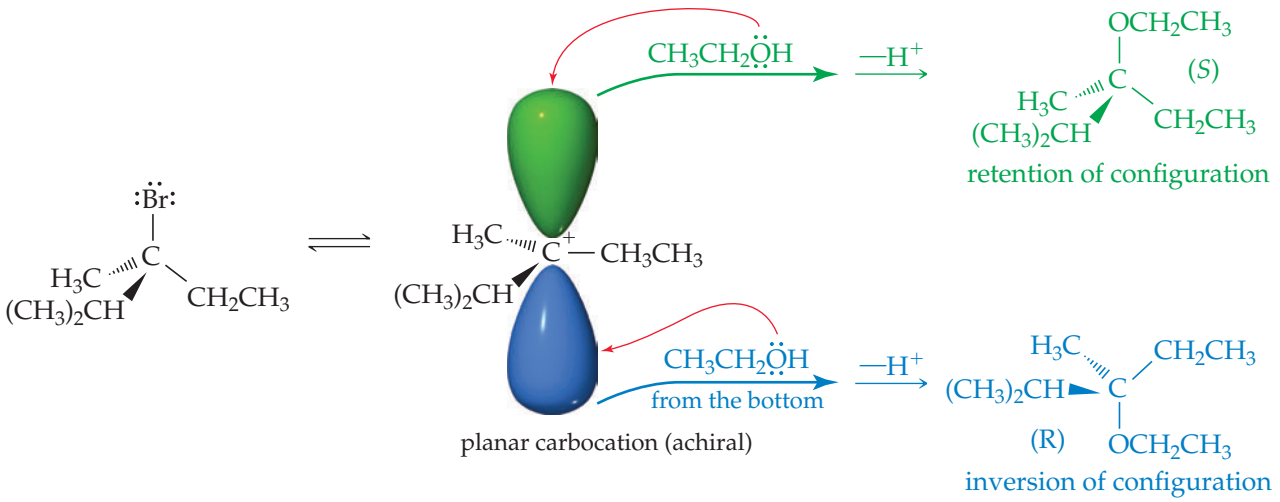


Practice Exercise

What is the major organic product from the following reaction?

and is designated as an **E1** mechanism. A summary of this mechanism and its competing substitution reaction is shown in Figure 27.19.

The β-elimination reaction, shown as route 2 in Figure 27.19, is also in competition with a nucleophilic substitution reaction, shown as route 1 in Figure 27.19. If a nucleophile is present within the reaction mixture, then substitution is also likely. The equilibrium arrows shown in Figure 27.19 between the oxonium ion and the carbocation in fact display this very principle. In this case, water acts as the leaving group in one reaction direction



▶ **Figure 27.19 Substitution and elimination reactions.** The rate-determining step is the generation of the carbocation intermediate common to both reactions.

(from top to bottom) and as the nucleophile in the other direction (from bottom to top). The result of the latter reaction leads only to formation of more of the starting alcohol. However, what if another nucleophile, such as Cl^-, is also present? The result is the formation of a haloalkane. Since the rate-determining step is still the same (and unimolecular), this type of substitution is known as an **S_N1** reaction.

As opposed to the typical inversion of stereochemistry seen in S_N2 reactions, S_N1 reactions result in, a racemic mix—or at the very least a less optically pure compound than the starting material. This is because in the S_N1 mechanism the carbocation intermediate is sp^2 hybridized and planar (**Figure 27.20**). A nucleophile can attack the carbocation from either face leading to retention or inversion of stereochemistry.

Table 27.4 summarizes the important parameters for substitution and elimination reactions discussed in this chapter.

▲ **Figure 27.20** **S_N1 Racemization.**

TABLE 27.4 General patterns of reactivity for substitution and elimination reactions at a sp^3 carbon

Property	S_N2	S_N1
Rate of reaction Reason:	$1° > 2° \gg 3°$ Steric	$3° > 2° \gg 1°$ Carbocation stability
Products	Substitution (major) E2 (minor)	Substitution (major) E1 (major)
Stereochemistry	Stereospecific, inversion	Racemic product
Kinetics	2nd order (substrate, base)	1st order (substrate)
Leaving group	Important	Important
Nucleophile effect on rate	Important	No effect
	E2	**E1**
Rate of reaction Cause:	$3° > 2° \gg 1°$ Steric	$3° > 2° \gg 1°$ Carbocation stability
Products	Alkene (major), S_N2 (minor)	Most stable alkene

Answers to Self-Assessment Exercise

27.39 (b)

Sample Integrative Exercise

Putting Concepts Together

An unknown organic product was characterized by combustion analysis. You find the compound contains 59.96 % carbon and 13.42 % hydrogen and the remainder is oxygen.

(a) Determine the empirical formula of the compound. **(b)** If the molar mass is found to be 60.09 g mol^{-1}, draw and name all possible constitutional isomers of the compound and identify the functional groups present. **(c)** Your compound is not very soluble in water and has a boiling point close to room temperature; suggest the identity of the compound. **(d)** How would you synthesize this compound?

SOLUTION

Analyze This question provides some data which we use to obtain the formula of an unknown compound. Using Lewis structures we represent the structure of the possible compounds and, with the aid of some observations of the physical properties, we are asked to suggest the identity of the compound.

Plan Combustion analysis gives the empirical formula of a compound. This, together with a molar mass, enables us to determine the molecular formula from which we can construct all constitutional isomers. This allows us to identify the functional groups present and relate them to likely physical properties of the material.

Solve

(a) The percentage of oxygen in the compound is 100% − (59.96 + 13.42)% = 26.62%. The number of moles of each element in 100 g of the compound is;

$$\text{Moles of C} = \frac{59.96\ \text{g}}{12.01\ \text{g mol}^{-1}} = 4.992\ \text{mol C}$$

$$\text{Moles of H} = \frac{13.12\ \text{g}}{1.008\ \text{g mol}^{-1}} = 13.31\ \text{mol H}$$

$$\text{Moles of O} = \frac{26.62\ \text{g}}{16.00\ \text{g mol}^{-1}} = 1.664\ \text{mol O}$$

Dividing by the smallest number of moles present (1.664) gives the whole number ratio of the elements.

$$\text{Moles of C : H : O} = \frac{4.992\ \text{mol}}{1.664\ \text{mol}} : \frac{13.31\ \text{mol}}{1.664\ \text{mol}} : \frac{1.664\ \text{mol}}{1.664\ \text{mol}}$$
$$= 3 : 8 : 1$$

So the empirical formula is C_3H_8O.

(b) The molar mass of C_3H_8O is 60.09 g mol^{-1} which is the same as that determined for the unknown compound so we can conclude the molecular formula of the compound is also C_3H_8O. There are three possible constitutional isomers.

$H_3C—CH_2—CH_2—OH$

1-propanol

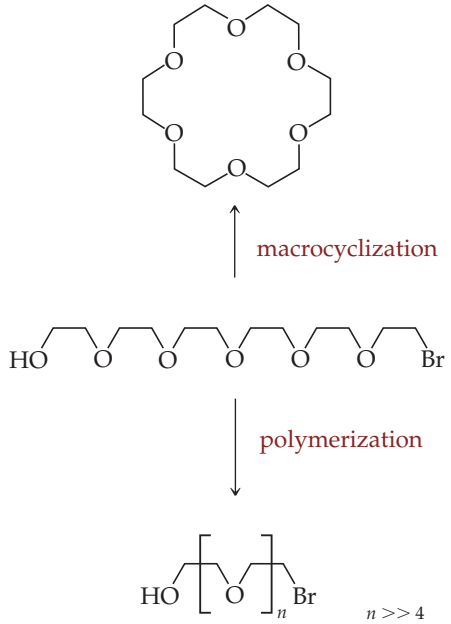
$H_3C—\underset{\displaystyle OH}{\underset{|}{CH}}—CH_3$

2-propanol

$H_3C—CH_2—O—CH_3$

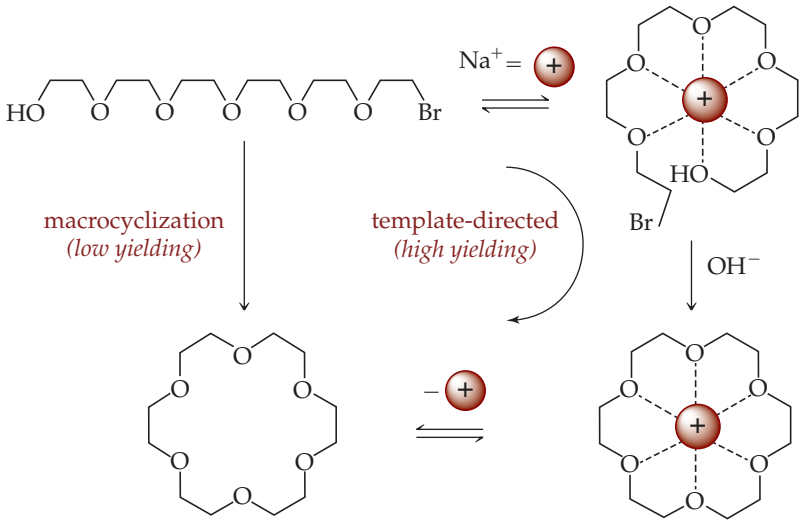
methoxyethane

The first two structures are alcohols (a primary alcohol and secondary alcohol, respectively) and the final structure is an ether.



(c) Boiling point and solubility are directly related to the intermolecular forces present. As all the molecules have the same formula we assume the strength of the dispersion forces are similar in the three cases. Two compounds contain an alcohol functional group which can form hydrogen bonds and the third compound is an ether which, when pure, shows no hydrogen bonds between molecules. As a consequence of the hydrogen bonds the alcohols are likely to display an appreciably higher boiling point and greater solubility in water than the ether. The unknown compound is likely to be methoxyethane.

(d) A Williamson ether synthesis of iodomethane and ethanol in the presence of sodium metal would form methoxyethane. Note that forming the product from iodoethane and methanol will lead to the formation of ethene as a side product. This occurs through an elimination of HI using the sodium methoxide generated *in situ* as a base.



CHEMISTRY AND LIFE Polymerization versus Macrocyclization

The preparation of cyclic ethers (Section 27.3) has always involved two competing processes: the desired macrocyclization and an unwanted polymerization. **FIGURE 27.21** illustrates these two processes using the crown ether, 18-crown-6, as the example. Intramolecular reaction of the OH group on the bromide in the presence of base yields the crown ether, 18-C-6, via substitution. Intermolecular reaction of the OH group on the bromide of a *second* molecule in the presence of base yields the polyether, also via substitution. Since both processes are competing, the result has always been a low (<20%) isolated yield of the macrocycle. Intramolecular processes are usually faster than intermolecular processes because of the proximity of reactive functional groups; however, this is true only of small molecules. In the example of crown ether synthesis shown in Figure 27.21 the longer the starting acyclic polyether, the lower the yield of the crown ether.

We can, however, take advantage of the affinity of polyethers for metal cations to bias the reaction outcome. In this case, the spherical cation acts as a *template* to promote the formation of the cyclic crown ether by allowing the polyether to wrap around the cation (**FIGURE 27.22**). In this orientation, the carbon bearing the bromine atom and the OH group are brought into close proximity, enabling the intramolecular substitution reaction to occur in preference to the polymerization upon the addition of base—for example, hydroxide ion. Removal of the cationic template yields the macrocycle in 60–80% yield. This very practical reaction is analogous to the approach taken by nature in the formation of highly complex and functioning molecules such as DNA, in which a template strand is necessary to build the double helix using DNA polymerases I and II.

▲ **Figure 27.21** Competition between (formation of) a crown ether and a polymer.

▲ **Figure 27.22** The template effect.

Chapter Summary and Key Terms

SECTION 27.1 **Alcohols** are hydrocarbon derivatives containing one or more OH groups. Alcohols are more **miscible** with water than ethers of comparable size, due to their ability to hydrogen-bond as a result of the **lone pairs** on oxygen. Alcohols that have two or three OH groups, such as ethene glycol and glycerol, are called **diols** and **triols**, respectively. Alcohols are classed as **primary** (1°), **secondary** (2°) or **tertiary** (3°). Short-chain alcohols are miscible with water.

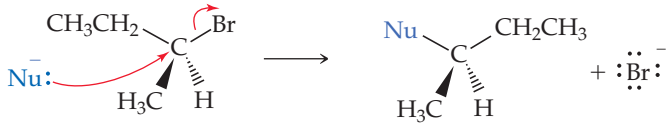
SECTION 27.2 **Haloalkanes** are hydrocarbons containing one or more halogens, usually generalized as RX (X = F, Cl, Br, I). They are also commonly referred to as alkyl halides. Compounds of the form CHX_3 are often called **haloforms**, of which chloroform is an example. **Chlorofluorocarbons**, or **CFCs**, are odorless, non-toxic, non-flammable and non-corrosive compounds that were typically used as refrigerants, propellants in aerosols and industrial solvents before being phased out due to their harmful effects on the ozone layer in the atmosphere.

SECTION 27.3 **Ethers** contain a bridging oxygen atom between two hydrocarbon chains. Cyclic ethers are a subclass of a large group of organic compounds known as **heterocyclic compounds**. Ethers contain both alkyl and **alkoxy** groups. Larger **cyclic polyethers** such as the **crown ethers** are able to complex metal ions within their cavity. Ethers make good solvents.

SECTION 27.4 The reaction of sodium metal with an alcohol leads to an **alkoxide**. Alkoxides are as strong a base as hydroxide. Potassium *tert*-butoxide and sodium ethoxide are examples cited frequently in this chapter. Alcohols act as a weak base, generating an oxonium ion under acidic conditions. Alcohols can be converted into haloalkanes by treatment of a halogenating agent, usually under acidic conditions. In this reaction, the OH group of the alcohol is substituted by a halogen in a **nucleophilic substitution (S_N) reaction**. Alcohols can also dehydrate to form alkenes.

SECTION 27.5 Nucleophilic substitution reactions of haloalkanes proceed by attack of the nucleophile at the carbon bearing the halogen. Because of the difference in electronegativity between carbon and any of the halides, this bond is polarized such that the carbon becomes mildly electrophilic. If the transition state that leads to the product involves both the haloalkane and the nucleophile in the rate-determining step, the reaction is classed as an **S_N2** or bimolecular (2), nucleophilic (N), substitution (S) reaction. The reaction of haloalkanes with **amines** leading to **alkyl ammonium salts,** is one such example. **Nitriles** are formed when haloalkanes are reacted with cyanide.

SECTION 27.6 Alkenes are readily formed from haloalkanes through a process called a ***β*-elimination reaction**. An **elimination reaction** involves the removal of a small group from a larger molecule. An **E2** reaction is a bimolecular (2) elimination (E) reaction. The alkene that forms in preference is the one that follows **Zaitsev's rule**, which states that the more substituted double bond predominates.



SECTION 27.7 Substitution and elimination reactions are competing reactions. Bimolecular substitution reactions (S_N2) compete against bimolecular elimination reactions (E2); which mechanism predominates in the reaction is dictated by a variety of steric factors. Tertiary alcohols undergo unimolecular reactions in which the rate-determining step is the elimination of water leading to a carbocation intermediate. In this case **E1** or **S_N1** reactions are likely depending on the reaction conditions.

Key Skills

- Understand how to derive the names of simple alcohols, ethers and haloalkanes. Learn the common names for the simplest cases. Learn how to classify alcohols as 1°, 2° or 3°. (Sections 27.1, 27.2 and 27.3)
- Learn the basic functional group manipulation shown in Figure 27.14. (Section 27.4)
- Be able to explain the difference between S_N1, S_N2, E1 and E2 mechanisms and have a qualitative understanding of when one predominates over another to predict reaction outcomes. (Sections 27.5, 27.6 and 24.7)

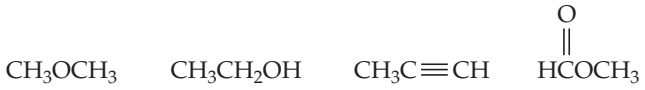
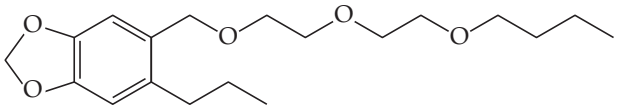
Exercises



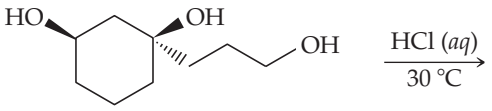
Visualizing Concepts

27.47 Propan-1-ol ($CH_3CH_2CH_2OH$) and propan-2-ol (also known as isopropyl alcohol $(CH_3)_2CHOH$), whose space-filling models are shown, have boiling points of 97.2 °C and 82.5 °C, respectively. Explain why the boiling point of propan-1-ol is higher, even though both have the molecular formula of C_3H_8O. [Section 27.1]



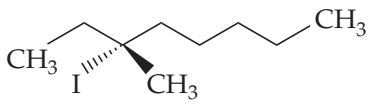
propan-1-ol propan-z-ol

27.48 What features must a molecule have to participate in hydrogen bonding with other molecules of the same kind? Which of the following compounds would you expect to **(a)** have the highest boiling point, **(b)** be least soluble in water? Explain. [Section 27.1]



(i) (ii) (iii) (iv)

27.49 Piperonyl butoxide is used commercially as an additive to pyrethrum-based insecticides to enhance their effect. Copy the structure and highlight the atoms that constitute the cyclic ether and the acyclic polyether. [Section 27.3]

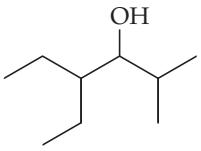


piperonyl butoxide

27.50 Draw the carbocation that triol 1 would form under the indicated conditions. Explain your answer. [Section 27.4]

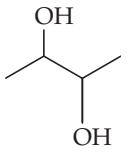
1

27.51 How many distinct alkene products (including stereochemistry) are possible when the iodoalkane shown here undergoes E2 elimination? [Section 27.5]



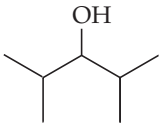
Alcohols: Structure, Properties, and Nomenclature (Section 27.1)

27.52 Two oxygen-containing compounds have the same empirical formula. One substance is a gas, the other is a liquid. How is it possible for two substances with the same empirical formula to have markedly different properties?

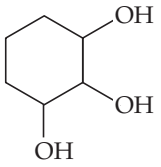


27.53 Draw the structures of **(a)** hexan-2-ol, **(b)** propane-1, 2, 3-triol, **(c)** 4,4-dimethylcyclohexanol, **(d)** *cis*-1, 2-cyclopentanediol, **(e)** 2-methylpropan-2-ol.

27.54 Name the following alcohols, ignoring stereochemistry:

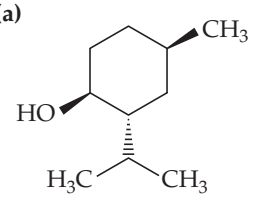


(a)



(b)

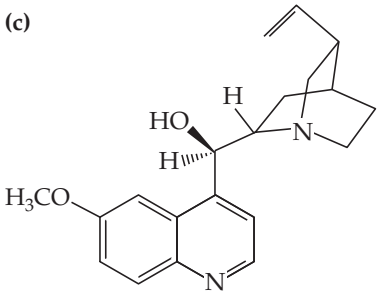
(c)



(d)

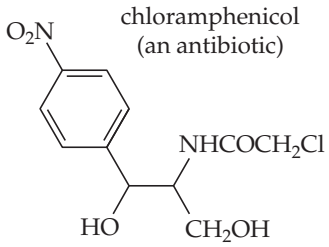
27.55 Classify the following alcohols as primary, secondary, or tertiary.

(a)



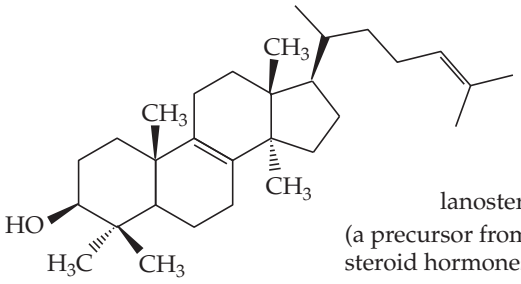
menthol

(b)



patchoulol

(c)



quinine
(an antimalarial drug)

(d)

chloramphenicol
(an antibiotic)

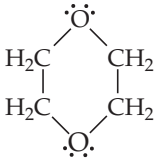
(e)

lanosterol
(a precursor from which all steroid hormones are made)

Haloalkanes (Section 27.2)

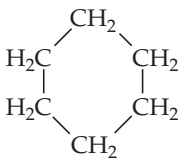
27.56 Eight isomers have the molecular formula $C_5H_{11}Cl$. How many of these are tertiary chloroalkanes?

27.57 Describe the carbon–chlorine bond of chloroalkanes as polar or nonpolar. Why?



Ethers: Structure, Properties, and Nomenclature (Section 27.3)

27.58 Ethene glycol ($HOCH_2CH_2OH$), the major substance in antifreeze, has a normal boiling point of 198 °C. By comparison, ethanol (CH_3CH_2OH) boils at 78 °C at one atmospheric pressure. Ethene glycol dimethyl ether ($CH_3OCH_2CH_2OCH_3$) has a normal boiling point of 83 °C, and ethyl methyl ether ($CH_3CH_2OCH_3$) has a normal boiling point of 11 °C. **(a)** Explain why replacement of a hydrogen on the oxygen by CH_3 generally results in a lower boiling point. **(b)** What are the major factors responsible for the difference in boiling points of the two ethers?

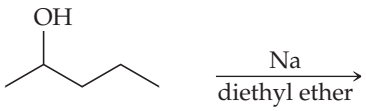


27.59 **(a)** Give the empirical formula and structural formula for the cyclic ether containing four carbon atoms in the ring. **(b)** Write the structural formula for a straight-chain compound that is a structural isomer of your answer to part (a).

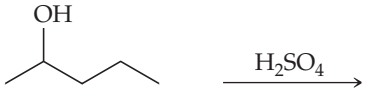
27.60 Why do ethers make good solvents, whereas alcohols usually make poor solvents in which to undertake a chemical reaction? When might an alcohol make an appropriate solvent?

27.61 Which would you expect to be more soluble in water, cyclohexane or dioxane? Explain.

dioxane



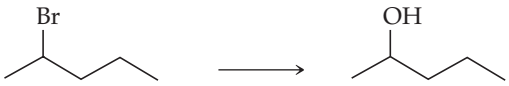
cyclohexane



Reactions of Alcohols and Haloalkanes (Sections 27.4 and 27.5)

27.62 Suggest a possible stable reaction product for each of the following reactions:

(a)



(b)

27.63 Sodium wire is normally used to "dry" tetrahydrofuran before distillation and use in water-sensitive reactions. **(a)** Write an equation for the reaction of sodium metal with water. **(b)** This reaction is very exothermic and care should be taken as to how "wet" the tetrahydrofuran is. What alternative to water might you use to destroy excess sodium, and what precautions should you take?

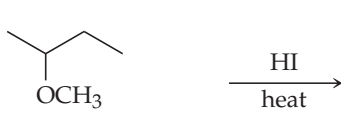
27.64 Suggest ways of conducting the following transformations.

(a)

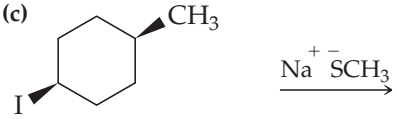
(b)

(c)

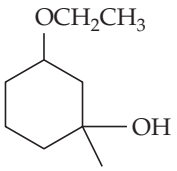
(d)



27.65 Provide the structure of the major organic product of the following reactions.



(a)



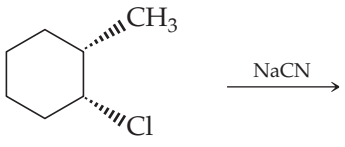
(b)

(c)

27.66 Describe a synthesis of A starting from 3-methylcyclohexene-3-ol.

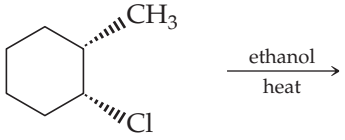
A

Haloalkanes to Alkenes: β-Elimination (Section 27.6)



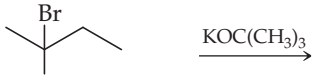
27.67 When sodium ethoxide ($NaOCH_2CH_3$) reacts with 2-chlorobutane, a haloalkane and three unsaturated products are likely (including stereochemistry). **(a)** Draw them. **(b)** Which ones are likely to be formed in higher yield?

27.68 Which base, sodium ethoxide or potassium *tert*-butoxide, would you employ for the efficient dehydrohalogenation of 1-bromo-2-ethylbutane. Why?

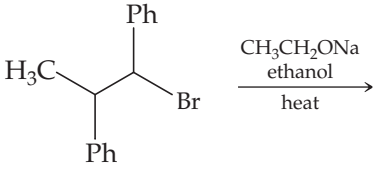


27.69 **(a)** Define bimolecular. **(b)** Using diagrams, give an example of a bimolecular reaction using diagrams.

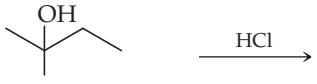
27.70 What is the major product formed in the following reactions and what mechanisms predominate?



(a)



(b)



(c)

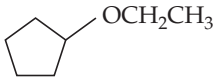
(d)

(e)

Substitution versus Elimination (Section 27.7)

27.71 When haloalkanes react with alkoxides a competition exists between elimination and substitution reactions. Which product is formed can be biased by the judicious choice of haloalkane and alkoxide. The following ethers can only be prepared in high yield by the combination of one alkoxide ion and one haloalkane.

What is the correct combination in each case?



(a)

(b)

(c)

27.72 **(a)** What is the substitution product of the following reaction? **(b)** What is the elimination product of this reaction?

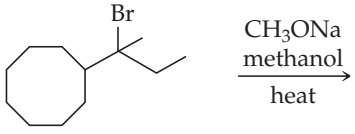
$CH_3CH_2Br + HO^- \rightarrow$

27.73 Which of the following S_N2 reactions is the *fastest*? Why?

(a) $CH_3CH_2CH_2I + HO^- \rightarrow CH_3CH_2CH_2OH + I^-$

(b) $CH_3CH_2CH_2Br + HO^- \rightarrow CH_3CH_2CH_2OH + Br^-$

(c) $CH_3CH_2CH_2I + H_2O \rightarrow CH_3CH_2CH_2OH + HI$

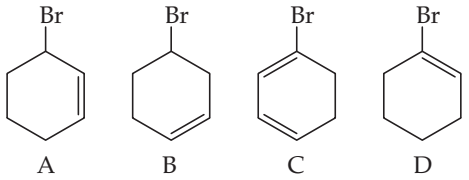


(d) $CH_3CHICH_3 + HO^- \rightarrow CH_3CHOHCH_3 + I^-$

27.74 The reaction of a tertiary bromoalkane with iodide follows. **(a)** Assuming no other changes, what is the effect of *doubling* the concentration of the haloalkane? **(b)** Assuming no other changes, what is the effect of doubling *only* the concentration of the nucleophile?

27.75 When 2-bromo-3-methyl-1-phenylbutane is treated with sodium methoxide, why is the major product 3-methyl-1-phenyl-1-butene?

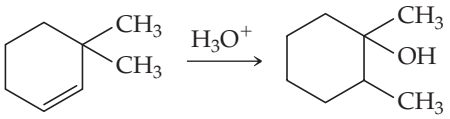
27.76 What is the major organic product of the following reaction? Why?



Additional Exercises

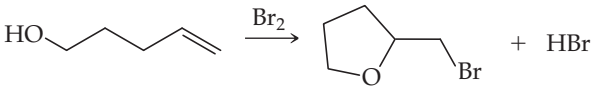
27.77 Consider the following experimental data for the rate of an elimination reaction for a tertiary bromide. What is the mechanism for the reaction?

Experiment No.	[Bromoalkane]	[Base]	Rate
1	0.01	0.01	1
2	0.02	0.01	2
3	0.01	0.02	1



27.78 Which of the following bromides forms the most stable carbocation? Why?

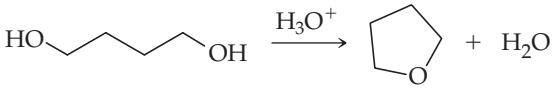
27.79 **(a)** Dehydrohalogenation of 2-bromobutane in the presence of a strong base proceeds via which mechanistic pathways? **(b)** Why is the E1 not a likely mechanism when 1-chloropentane is heated in ethanol? **(c)** Predict the two most likely mechanisms (substitution and elimination) for the reaction of 2-iodohexane with sodium ethoxide and give the products of these reactions. **(d)** Can primary haloalkanes react by S_N2, S_N1, E2 and E1 mechanisms? Are any of these mechanisms prohibited? What conditions favor a particular mechanism?



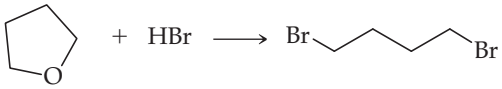
Integrative Exercises

27.80 This question relates to the hydration of 3,3-dimethylcyclohexene and the development of an appropriate mechanism to account for the formation of 1,2-dimethoxy-1-cyclohexanol.

(a) Draw a mechanism leading to the first carbocation intermediate. **(b)** The next step involves a methyl migration from carbon 3 to carbon 2. Draw this intermediate and comment on why this is favored. **(c)** Use water as a nucleophile and draw the next step of the mechanism. **(d)** Complete the mechanism to generate the product. What does this mechanism tell you about the requirement of acid?

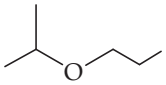


27.81 Provide a detailed, step-by-step mechanism for the following reaction.

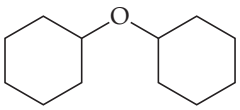


27.82 Describe a way of converting but-2-ene into but-2-yne using a bromination as the first step.

27.83 Describe a way of converting hex-3-ene into hex-3-yne.



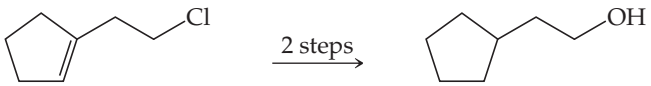
27.84 Propose a mechanism for the following reaction:



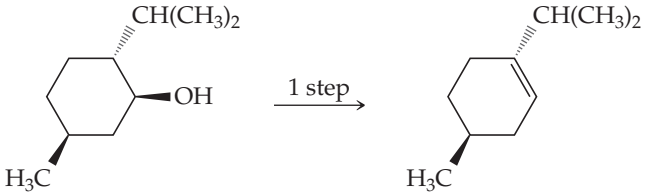
27.85 Propose a mechanism for the following reaction:

27.86 Starting with propan-1-ol as the only organic material, synthesize isopropyl propyl ether.

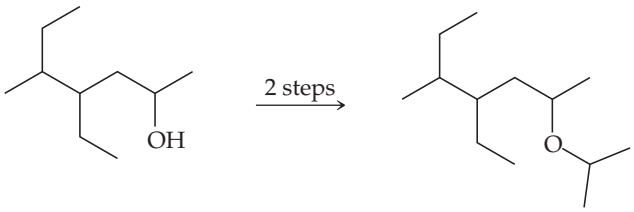
27.87 Describe how you would prepare this ether from cyclohexene.



27.88 How would you accomplish the following transformations?



(a)



(b)

(c)

(d)

27.89 Consider the three alkenes: ethene, propene and 2-methylpropene. **(a)** For each alkene, draw the reaction showing the acid-catalyzed hydration to form one major product. Include the carbocation intermediate in each case. **(b)** Write the systematic name of the alcohols produced. Classify the intermediate carbocations and the alcohol products as *primary, secondary* or *tertiary*. **(c)** What is the connection between the classification of the carbocations and the alcohols that arise from them?

27.90 In the S_N2 reaction of 1-bromobutane with hydroxide ions we imagine a smooth interchange between the leaving group and the attaching nucleophile, while the S_N1 reaction of 2-bromo-2-methylpropane involves the formation of a carbocation intermediate. Sketch the energy profile (similar to Figure 15.17) for the two mechanisms. Use labels to show which part of your sketch represents a transition state, which an intermediate and which energy changes represents E_a and ΔH for the reaction.

27.91 The conversion of 2-methyl-2-propanol to 2-bromo-2-methylpropane using concentrated hydrobromic acid occurs at room temperature. As the reaction proceeds, the reaction mixture separates into two layers. **(a)** Why does this occur? Treatment of the product, 2-bromo-2-methylpropane, with sodium ethoxide gives 2-methylpropene. **(b)** What is the geometry and hybridization observed for the central carbon atom in both the haloalkane and alkene? 2-Methylpropene is a gas at room temperature. **(c)** What is the maximum volume of gas produced, at 25 °C and 101.3 kPa, if 5.0 g of 2-bromo-2-methylpropane reacted completely to form 2-methylpropene?

Design an Experiment

Imagine yourself in a research laboratory where you are going to investigate the factors that affect the outcome of a reaction. The compounds that you want to investigate are the haloalkanes and the competing substitution and elimination reactions they undergo. For each set of experiments that you devise, formulate a research question that the experiments may answer, and give a rationale for how your experiment may address that question. Variables in the experiment could include: the halide used, the structure of the haloalkane, the reagent employed, the concentrations of the components, the solvent used, and the temperature conditions of the reaction. Think also how you may determine the outcome of the reaction and what changes may be observed during the course of the reaction.

ALDEHYDES, KETONES, AND CARBOHYDRATES

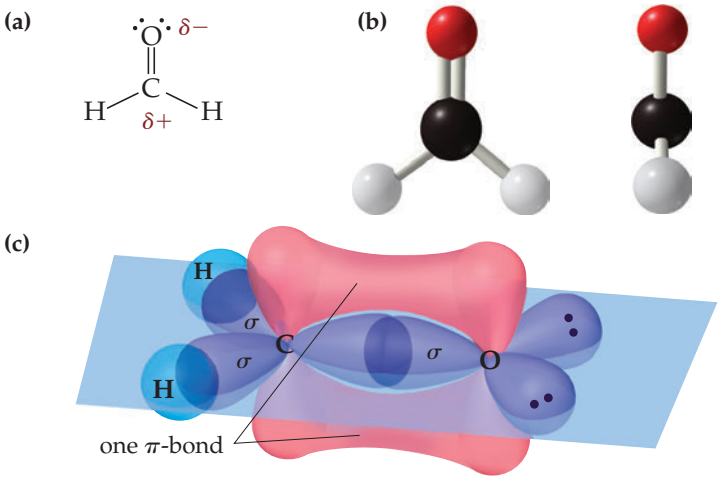
28.1 | Aldehydes, Ketones, and the Carbonyl Group

The first written reference to a chemist occurred about 4000 years ago. The perfume maker Tapputi is mentioned on a cuneiform tablet from Mesopotamia. She is said to have distilled flowers and essential oils in order to extract their fragrant essence. Over the centuries, there have been many reports in documents right across the ancient world of similar activities. There are, of course, very many different substances that are used in the perfume industry however, the aldehyde and ketone functional groups are frequently encountered.

For example, a class of compounds called the ionones are central to the fragrance of roses and violets. They may be formed from α-carotene by an enzyme-mediated reaction. For example, a class of compounds called the ionones are central to the fragrance. A mixture of α-ionone and β-ionone results in the scent of violets, while β-ionone is a significant contributor to the scent of roses.

α-ionone β-ionone

By the end of this section, you should be able to:



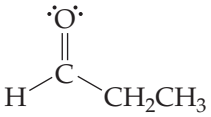
- Recognize and systematically name simple aldehydes and ketones.

Many important functional groups contain a double bond between carbon and oxygen—a combination of atoms called the **carbonyl group**. In Table 24.8, the carbonyl group appears in the aldehyde, ketone, carboxylic acid, ester and amide functional groups. The chemistry of the latter three functional groups differs from that of aldehydes and ketones and so will be dealt with in the next chapter. The geometry of the carbonyl group is similar to that of an alkene. The presence of the carbon–oxygen double bond (**Figure 28.1**) signifies that both the carbon and oxygen atoms are sp^2 hybridized. That is, a set of hybridized orbitals forms the σ-bond and a set of unhybridized *p* orbitals forms the π-bond of the carbon–oxygen double bond by direct overlap. Figure 28.1(c) illustrates the bonding in methanal (formaldehyde), the simplest of all the carbonyl-containing compounds. Because the oxygen in the carbonyl group is sp^2 hybridized, its lone pairs have a trigonal planar arrangement. Notice the polarity of the C—O group, which is due to the difference in electronegativity between the carbon atom and the more electron-rich oxygen atom. This polarity, and the nature of the π-bond, is very important for the reactivity of carbonyl compounds.

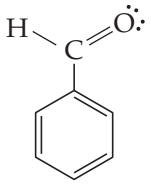
The carbonyl double bond is shorter, stronger and more polarized than a carbon–carbon double bond.

	Length	Bond enthalpy
C=O	123 pm	745 kJ/mol
C=C	134 pm	611 kJ/mol

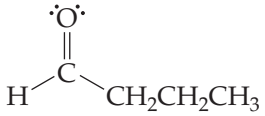
Go Figure What does the structure of CO_2 look like?



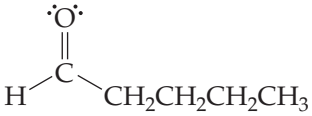
▲ **Figure 28.1 The carbonyl group of methanal.** (a) The structural formula; (b) a molecular model representation, in front-on and side-on views; (c) a molecular orbital view of the bonding, indicating σ- and π-bonds.



An **aldehyde** is characterized by the functional group CHO. The structures and systematic names of five simple aldehydes (with common names in blue) are:

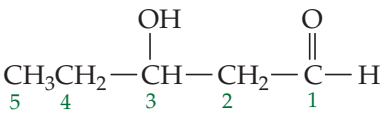


ethanal
(acetaldehyde)



propanal
(propionaldehyde)

benzaldehyde

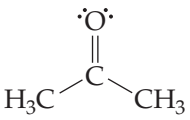


butanal
(butyraldehyde)

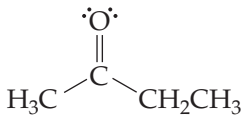
pentanal

Aldehyde nomenclature requires the selection of the parent alkane (longest alkyl chain) containing the carbonyl group. The carbon of the carbonyl group constitutes part of that parent alkane's name. The suffix *-ane* is partly retained, replacing the *e* with *al*. (Note the difference with benzaldehyde. Here the aldehyde group lies outside the ring system. Aromatic compounds such as this have their own unique nomenclature.) As you can see from these examples, an aldehyde group, by definition, must also occur at the beginning (or end) of a hydrocarbon chain. As a result, there is no need to number the position of the aldehyde—it is always assigned position 1.

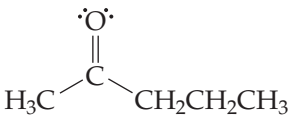
In terms of hierarchy, the aldehyde group takes precedence over alkene and alkyne functionality. Two aliphatic aldehyde examples illustrate this:



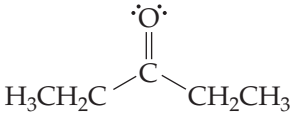
3-hydroxypentanal



pent-2-enal



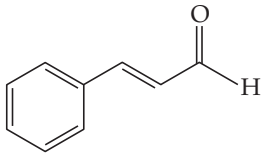
In **ketones** the carbonyl group occurs within the interior of a hydrocarbon chain and is therefore flanked on either side by carbon atoms:



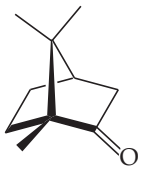
propanone
(acetone)

butanone

2-pentanone or pentan-2-one

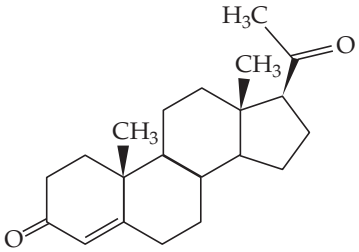


3-pentanone or pentan-3-one

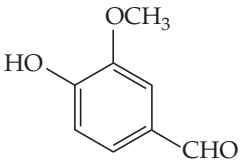


In naming ketones, the parent alkane is derived from the longest chain containing the carbonyl group. The suffix *-ane* is partly retained, replacing the *e* with *one*. Ketones containing parent alkanes greater than C4 can exist as constitu- tional isomers, so require numbering to define unambiguously the position of the carbonyl group. Two representations of the names to describe the compound are shown and are commonly interconverted.

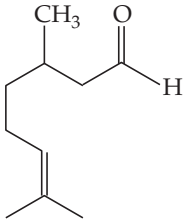
Many compounds found in nature possess an aldehyde or ketone functional group. Vanilla and cinnamon flavorings are derived from the naturally occurring aldehydes, vanillin, and cinnamaldehyde. Citronellal is a naturally occurring insect repellent. Carvone



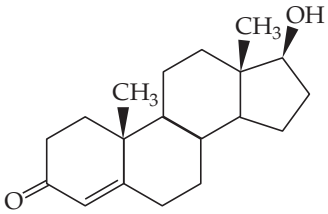
(see figure 27.7) and camphor are ketones that impart characteristic flavors and scents. Steroids, such as testosterone and progesterone, are also ketones. Testosterone is predominantly a male hormone; progesterone is predominantly a female hormone used by the body to stop further ovulation after an ovum has been fertilized.



cinnamaldehyde (cinnamon)



camphor



progesterone

4-hydroxy-3-methoxybenzaldehyde (vanillin)

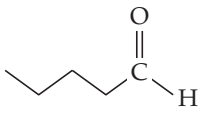
citronellal

testosterone

Ketones are less reactive than aldehydes and are used extensively as solvents. Acetone, which boils at 56 °C, is the most widely used ketone. Acetone is completely miscible with water, yet it dissolves a wide range of organic substances. These features made it ideal for use as an early nail polish remover, among other domestic uses. Butanone ($CH_3COCH_2CH_3$), which boils at 80 °C, is used as an industrial solvent.

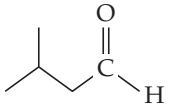
Sample Exercise 28.1

Naming Aldehydes and Ketones



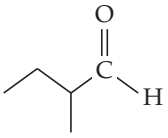
Write the structural formulas for all aldehydes and ketones of molecular formula $C_5H_{10}O$ and name each structure systematically.

SOLUTION

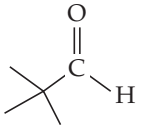


Analyze We are given a molecular formula and asked to generate as many different aldehydes and ketones as possible. We are given one oxygen atom in the molecular formula.

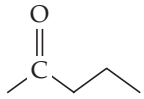
Plan Draw out the carbon skeleton, add the carbonyl group starting at one end (this will give an aldehyde) then progress this along the chain.



Solve



pentanal



3-methylbutanal

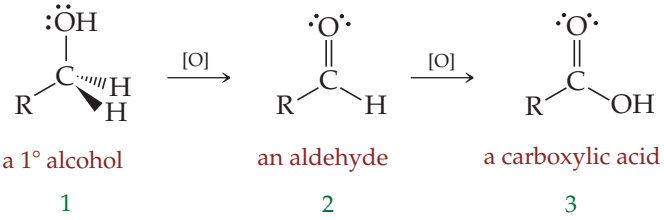
28.2 Preparation of Aldehydes and Ketones

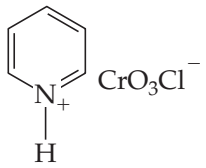


Vitamin A is essential for the function of vision as well as many other processes involving our immune system, gene transcription, and skin health. This group of vitamins may be obtained directly from animal sources, for example cod liver oil, or derived from the carotenes, which are present in many fruits and vegetables. The orange color of carrots is due to β-carotene, which is the principle vegetable source of retinol—Vitamin A1. Retinol is the form in which the vitamin is stored in the body and may be easily converted to retinal, which enters the visual cycle.

In this section, we look at the synthesis of aldehydes and ketones by two methods, the principal of which is the oxidation of an alcohol to the carbonyl compound. By the end of the section, you should be able to:

- Understand the preparation of aldehydes and ketones by an oxidation reaction.

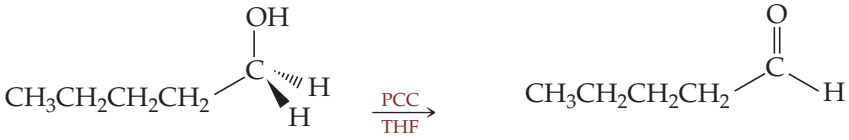
Go Figure What is the major organic product formed by the oxidation of 1-propanol, 2-propanol?



▲ **Figure 28.2 Oxidation of primary alcohols.** Primary alcohols are converted to carboxylic acids under standard experimental conditions. The symbol [O] represents an oxidation. To demonstrate the oxidation (that is, addition of oxygen) imagine C═O as being 2 × C—O.

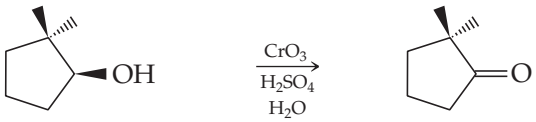
Aldehydes and ketones are generally prepared by using similar reactions. Here, we concentrate on two sample types. The first involves the oxidation of alcohols, which is the standard technique for their preparation. The second involves the ozonolysis of alkenes.

Oxidation of 1° and 2° Alcohols



When primary alcohols are oxidized using strong oxidising agents such as potassium dichromate ($K_2Cr_2O_7$) in H_2SO_4 or chromic acid ($CrO_3/H_2O/H_2SO_4$), they are usually converted to the corresponding carboxylic acid, via the intermediary aldehyde (**Figure 28.2**).

Pyridinium chlorochromate (PCC), on the other hand, is a mild oxidizing agent capable of converting primary alcohols to aldehydes.

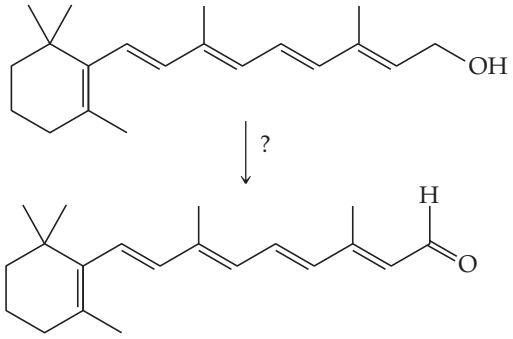


pyridinium chlorochromate

Unlike other oxidising agents, PCC is soluble in organic solvents such as tetrahydrofuran (THF) and dichloromethane. The oxidation of pentan-1-ol using this reagent yields the aldehyde as the major oxidation product.

pentan-1-ol pentanal [28.1]

Secondary alcohols are oxidized by PCC, chromic acid or potassium dichromate to yield the corresponding ketone. Further reaction is restricted because it would require the breaking of a C—C bond.



(*S*)-2,2-dimethylcyclopentanol 2,2-dimethylcyclopentanone [28.2]

Tertiary alcohols resist oxidation altogether, as a C—C bond would have to be broken for any oxidation to occur.

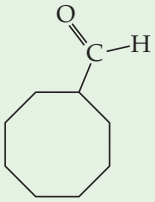
Sample Exercise 28.2

Oxidation of Alcohols

What reagent would you use to convert retinol (vitamin A) into retinal in the laboratory?

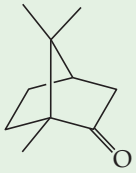
SOLUTION

Analyze We are asked how to convert an alcohol to an aldehyde.



Plan Determine the type of alcohol, where the conversion takes place and what is retained from starting material to product.

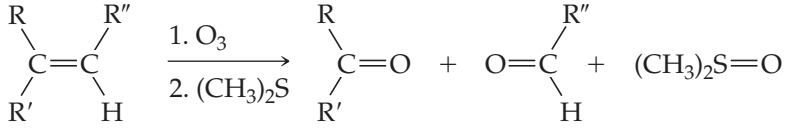
Solve This conversion is the oxidation of a primary alcohol to an aldehyde. To achieve this, pyridinium chlorochromate in acetone is the best reagent. The mild reactivity of this reagent does not affect the alkene groups and produces the aldehyde in excellent yield. Note that the reaction is conducted in acetone solvent. This solvent is useful for oxidations because it cannot be further oxidized under the experimental conditions employed.



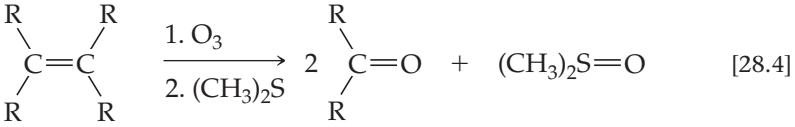
Practice Exercise

What starting alcohol would you use to prepare the following compounds?

(a)



(b)

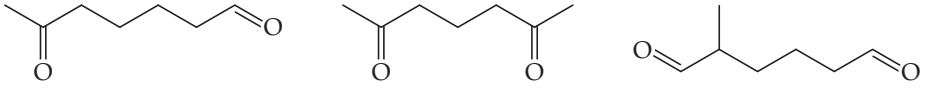


Ozonolysis

Aldehydes and ketones can be prepared in good yield by the reaction of alkenes with ozone, followed by a mild reduction using dimethylsulfide. This process, called **ozonolysis**, is a synthetically useful way of generating aldehydes and ketones.

an alkene a ketone an aldehyde dimethylsulfoxide [28.3]

Whether an aldehyde, ketone or a mixture of the two are formed depends solely on the substitution of the alkene. For symmetrical alkenes, only one product is formed.

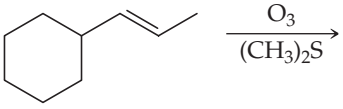


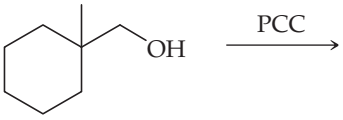
[28.4]

In some instances, ozonolysis leads to the formation of one high molecular weight and one low molecular weight product, which can easily be separated by distillation.

Self-Assessment Exercise

28.6 Which carbonyl compound is formed on treatment of 1-methylcyclohexene with ozone followed by dimethyl sulfide?





(a) **(b)** **(c)**

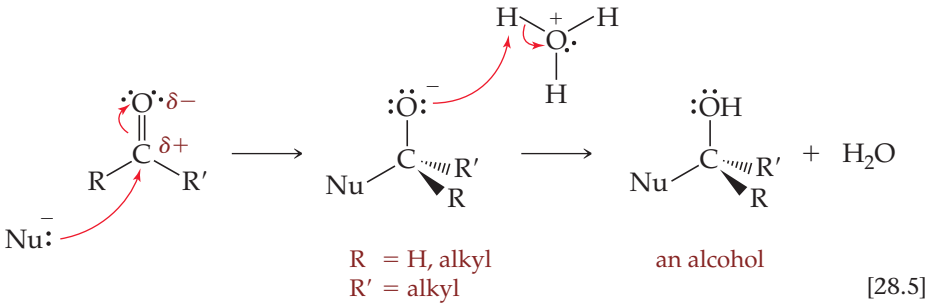
Answers to Self-Assessment Exercises

28.6 (a)

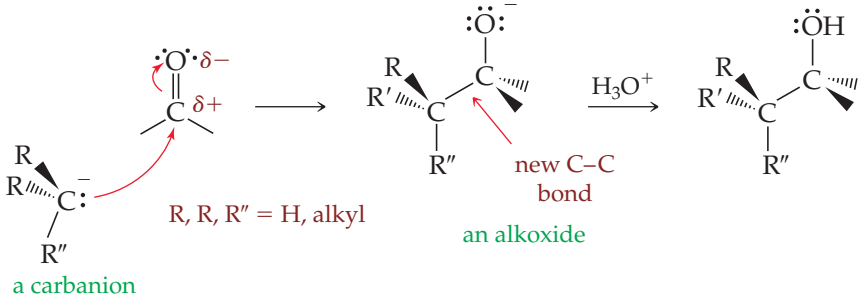
28.3 Reactions of Aldehydes and Ketones



Throughout history, dyes have been used to color fabrics, as paints, and for skin coloring. The Picts of ancient Scotland were literally "The Painted People," who used the leaves of the woad plant (*Isatis tinctorial*) to produce a deep blue color. A more abundant source was provided by the plant *Indigofera tinctorial*, which grows in the tropics. As early as two thousand years ago, there was trade in the dye from India to the Mediterranean, where the highly prized dye became known as indigo. It was one of the few dyes that could color cotton in a process that involved soaking the cloth in a vat containing the water-soluble, reduced form of the dye and hanging the cloth to dry where aerial oxidation would produce the insoluble blue pigment familiar to us in denim jeans. The dye was very expensive, and, when Adolf von Baeyer discovered a synthetic route to indigo from 2-nitrobenzaldehyde and acetone, a new industry was born. He was awarded the Nobel Prize in chemistry in 1905 "in recognition of his services in the advancement of organic chemistry and the chemical industry, through his work on organic dyes and hydroaromatic compounds".

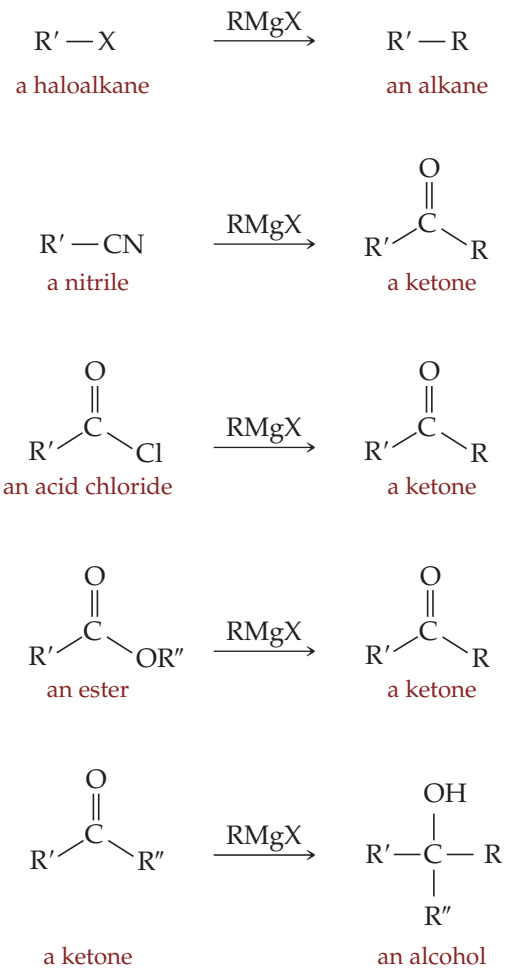
Carbonyl compounds form the basis of many important synthetic transformations, and, by the end of this section, you should be able to:

- Recognize a variety of nucleophilic addition reactions to carbonyl compounds
- Identify the structural factors that allow tautomerism
- Understand the mechanism of substitution α to a carbonyl group



The carbon in a carbonyl group has a partial positive charge. Consequently it is susceptible to nucleophilic attack. Many important synthetic reactions depend on this fact. In this section we concentrate on reactions where the tetrahedral intermediate formed from the initial attack on an aldehyde or ketone by a nucleophile is reacted with acid to produce an alcohol. Generally, the reaction can be described as:

[28.5]



Addition of Carbon Nucleophiles—Grignard Reactions

Of the reaction types available to organic chemists, those that form new C—C bonds are especially useful. One example of C—C bond formation is the reaction of carbon nucleophiles, or **carbanions**, with carbonyl compounds:

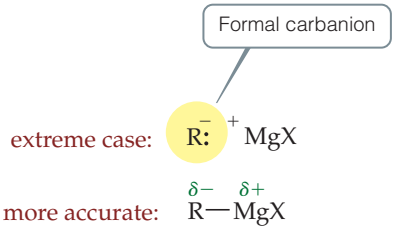
[28.6]

Organometallic compounds such as Grignard reagents are a useful source of carbanions. An organometallic compound contains a bond between a carbon atom and a metal (designated C—M, where M = metal). The nature of the C—M bond can be ionic or covalent, depending on the choice of the metal. A **Grignard reagent** is one that uses magnesium as the metal, forming organomagnesium compounds of the general

▲ **Figure 28.3** **The versatility of Grignard reagents.**

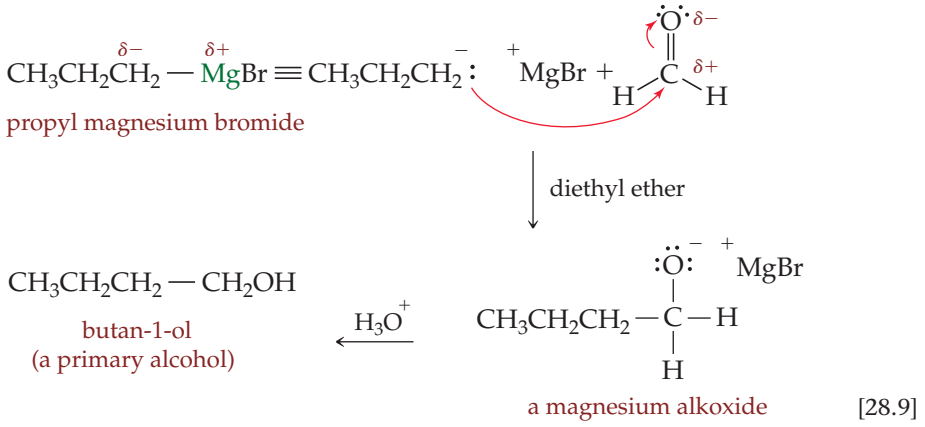
type RMgX, where R = alkyl or aryl, and X = halide. For this discovery in 1902 and the general usefulness of these reagents in organic synthesis (**Figure 28.3**), Victor Grignard (1871–1935) shared the 1912 Nobel Prize for Chemistry with Paul Sabatier (1854–1941).

Many C—M bonds are covalent, but in bonds between carbon and more electropositive metals, the electrons that make up the bond reside closer to the carbon atom. Most C—M bonds, such as those formed between carbon and magnesium, are classed as polar covalent (**Figure 28.4**). Although an alkyl group bonded to a metal is not formally a carbanion, we can approximate it as such. Grignard reagents are formed by the addition of magnesium metal to a haloalkane in an ether solvent (for example, THF or diethyl ether). This exothermic reaction is sometimes called an oxidative metallation because the magnesium metal is oxidized to Mg^{2+}. The Grignard reagents are named as the alkyl magnesium halide.



$$\underset{\text{1- bromobutane}}{CH_3CH_2CH_2\overset{\delta+}{C}H_2\overset{\delta-}{Br}} + Mg \xrightarrow{THF} \underset{\text{butyl magnesium bromide}}{CH_3CH_2CH_2\overset{\delta-}{C}H_2\overset{\delta+}{Mg}Br} \qquad [28.7]$$

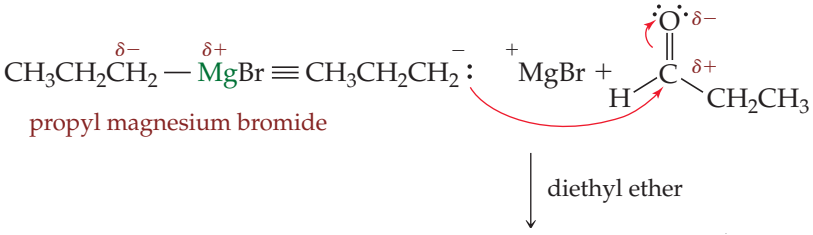
The effect of magnesium insertion changes the polarity of the carbon that used to bear the halogen from positively polarized to negatively polarized. This change has a dramatic effect on reactivity.

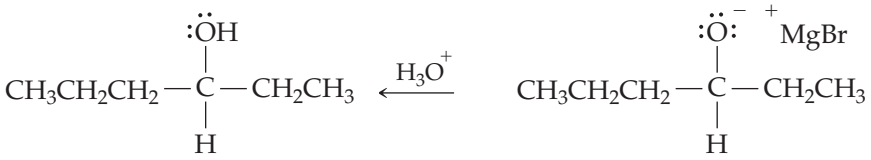


Grignard reagents are strong bases (as well as nucleophiles), so they are moisture-sensitive and tend to be prepared when needed rather than stored in a bottle. The presence of water will immediately protonate the Grignard reagent and generate the corresponding hydrocarbon.

$$\underset{\text{butyl magnesium bromide}}{CH_3CH_2CH_2\overset{\delta-}{C}H_2\overset{\delta+}{Mg}Br} \xrightarrow[THF]{H_2O} \underset{\text{butane}}{CH_3CH_2CH_2CH_3} \qquad [28.8]$$

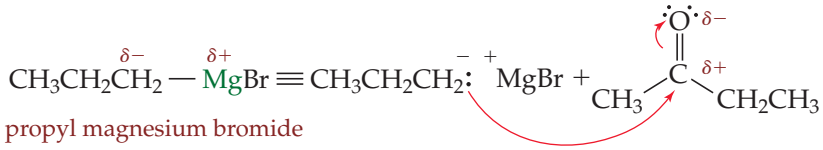
The type of alcohol formed (1°, 2° or 3°) in a Grignard reaction is dictated by the nature of the carbonyl compound used. For example, addition of the Grignard reagent propyl magnesium bromide to formaldehyde yields butan-1-ol, a 1° alcohol, upon aqueous workup.



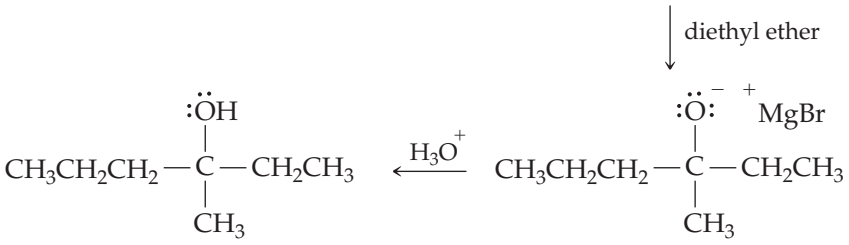


▲ **Figure 28.4** **Grignard reagents as carbanion equivalents.** The bonding between carbon and magnesium is best described as polar covalent. It is still useful to think of Grignard reagents as a form of carbanion.

[28.9]



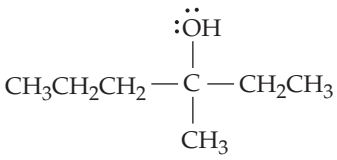
The addition of propyl magnesium bromide to any other aldehyde—for example, propanal—yields a 2° alcohol upon aqueous workup.



hexan-3-ol (a secondary alcohol) — a magnesium alkoxide [28.10]

The addition of propyl magnesium bromide to any ketone, such as 2-butanone, yields a 3° alcohol upon aqueous workup.

propyl magnesium bromide

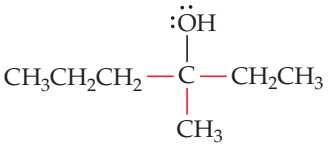


3-methylhexan-3-ol (a tertiary alcohol) — a magnesium alkoxide [28.11]

Sample Exercise 28.3

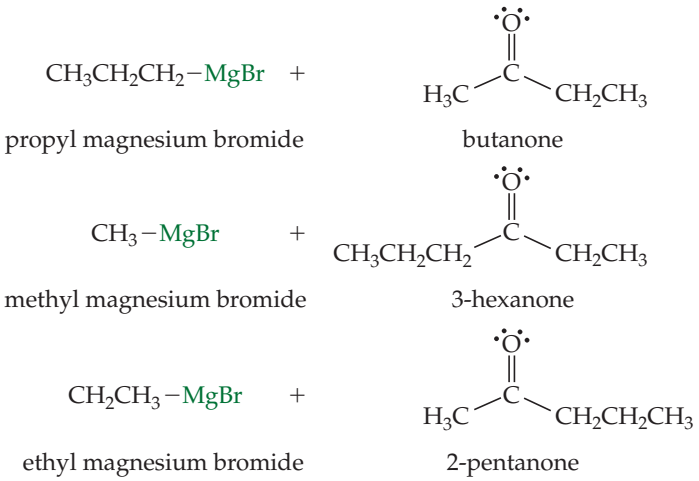
Addition of Grignard Reagents

The compound 3-methylhexan-3-ol can be prepared from three different combinations of ketones and Grignard reagents. Show each combination.



3-methylhexan-3-ol

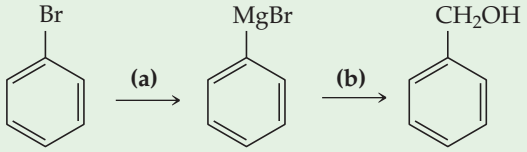
SOLUTION



Analyze How can 3-methylhexan-3-ol be formed from three different ketones?

Plan Tertiary alcohols can be formed from ketones by reaction with carbanions and their equivalents. Since reaction about the C=O group leads to the formation of a C—C bond, we need to investigate the groups tethered off the C—OH group.

Solve First, let us identify in red the three C—C bonds that could be formed about the carbonyl carbon. This gives us a clue to the identification of ketones and Grignard reagents:



The C—OH grouping is derived from the carbonyl of the starting ketone. The substituents attached to this group could each be used to form the Grignard reagent. Hence, the three combinations are:

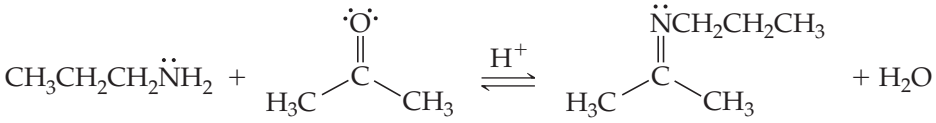
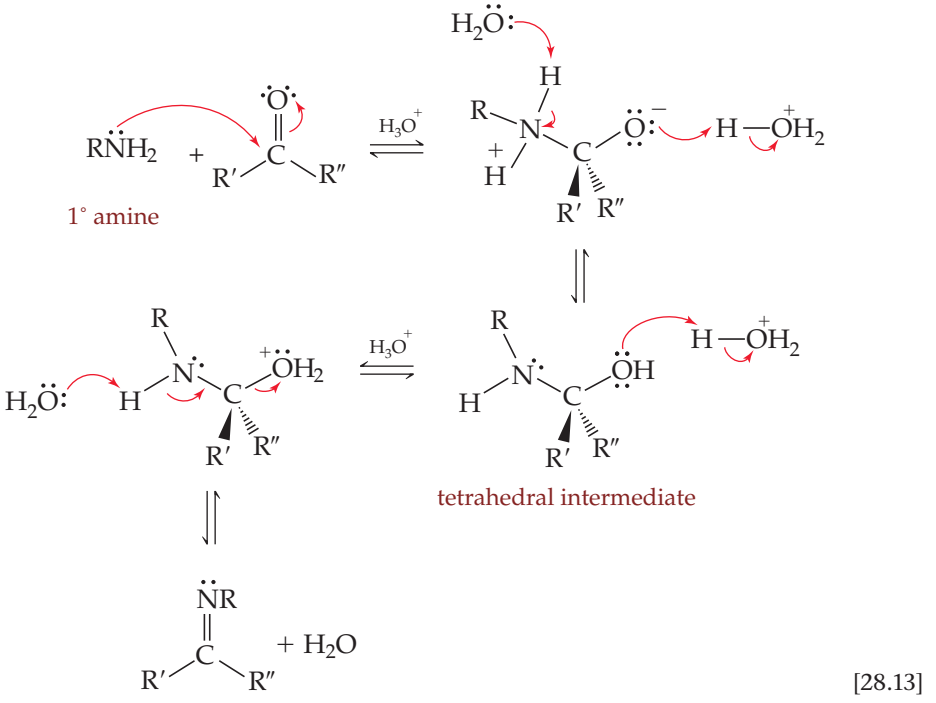
Practice Exercise



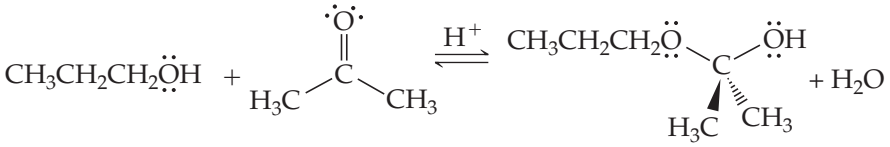
What reagents would you use to bring about the following transformations?

Addition of Nitrogen and Oxygen Nucleophiles: Formation of Imines and Acetals



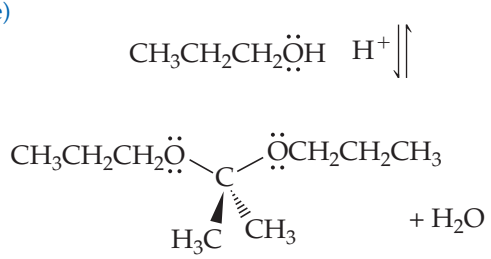
The formation of new C—C bonds through the reaction of a carbonyl compound with a Grignard reagent is not only high yielding, but also occurs only in the forward direction. This means that the reaction is not under the same level of equilibrium control we have discussed for the hydration of an alkene or the dehydration of an alcohol. However, other nucleophiles are able to react with carbonyl compounds, under equilibrium conditions, to form stable compounds. The two most important reactions are those of carbonyl compounds with amines (nitrogen-containing weak organic bases) to form *imines*, and those of carbonyl compounds with alcohols to form *acetals* and *hemiacetals*. Both reactions have biological significance.

Imines, also known as Schiff bases, are formed by the acid-catalyzed condensation of a *primary amine* (RNH_2, R = alkyl, aryl) an aldehyde or ketone. For example, the reaction of propanamine, an aliphatic 1° amine, with propanone is shown here. Imines are characterized by a C—N double bond. They have geometries similar to those of alkenes, with the lone pair occupying one of the trigonal planar positions.



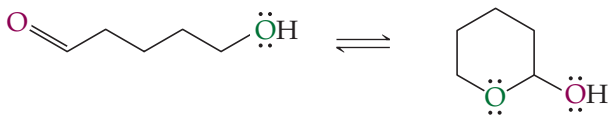
propanamine propanone an imine [28.12]

The mechanism of imine formation is shown in Equation 28.13. Attack of the nucleophilic amine on the electrophilic carbonyl carbon atom leads to a tetrahedral intermediate amino alcohol. The acid-catalyzed dehydration of this intermediate yields the imine. The reaction usually occurs at room temperature and in high yield. Removal of water as the reaction proceeds ensures near quantitative yields.

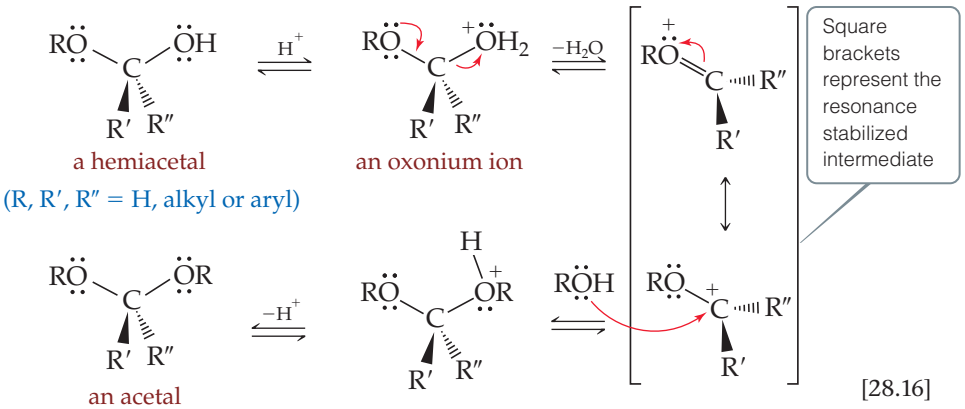


[28.13]

Acetals and **hemiacetals** are formed by the reaction of alcohols with aldehydes and ketones in the presence of an acid catalyst. In such reactions, the hemiacetal is formed in minor yield because it is relatively unstable. Further reaction with alcohol usually yields the acetal and water. Acetals are stable under basic and nucleophilic conditions, so provide a common way to protect aldehydes and ketones during complex reaction sequences in organic synthesis. Because the reaction is in equilibrium, acetal formation can be reversed by the addition of H_3O^+.



propan-1-ol propanone (acetone) a hemiacetal



an acetal [28.14]

Hemiacetals are important in the function of *carbohydrates*, a class of biologically active molecules, of which sugars and cellulose are members. Carbohydrates gain their stability by undergoing *intramolecular* hemiacetal formation. To do this, carbohydrates must have aldehyde and alcohol functionality within the same molecule and at a distance apart that allows for cyclization. Typically, cyclic hemiacetals are five-membered (furanose) or six-membered (pyranose) systems. The equilibrium between cyclic and acyclic compounds is heavily favored towards the cyclic hemiacetal. The cyclization of 5-hydroxypentanal demonstrates the principle.

5-hydroxypentanal a cyclic hemiacetal [28.15]

The mechanism of acetal formation can be divided into two steps. The first, formation of the hemiacetal, follows a mechanism similar to that described for the reaction of amines with carbonyl compounds (without loss of water, Equation 28.13). Formation of the acetal from the hemiacetal is an acid-catalyzed process involving the generation of an oxonium ion. Loss of water leads to a resonance-stabilized carbocation. This carbocation reacts with another molecule of alcohol, which, after proton transfer, yields the acetal.

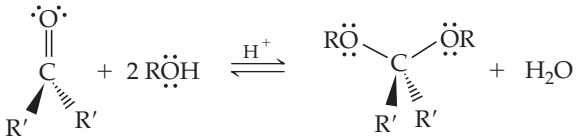
an acetal [28.16]

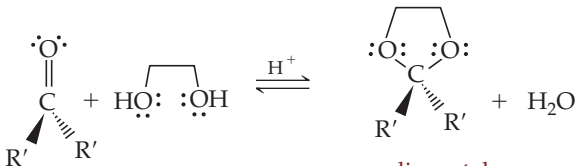
Sample Exercise 28.4



Acetals

Diols such as ethene glycol (1,2-ethanediol) are useful reagents with which to protect aldehydes and ketones in chemical syntheses. Give the product of the acid-catalyzed reaction of ethene glycol and cyclohexanone.

SOLUTION

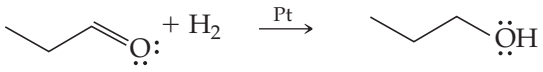


Analyze We are asked for the outcome of a reaction between an alcohol functional group and a ketone.

Plan Acetals require the acid-catalyzed addition of two alcohols to a ketone:

an acetal

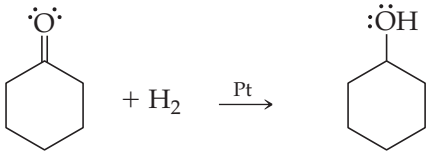
Solve Ethene glycol acts to satisfy this need because it is a diol. Hence the product of this reaction is



a cyclic acetal

Practice Exercise

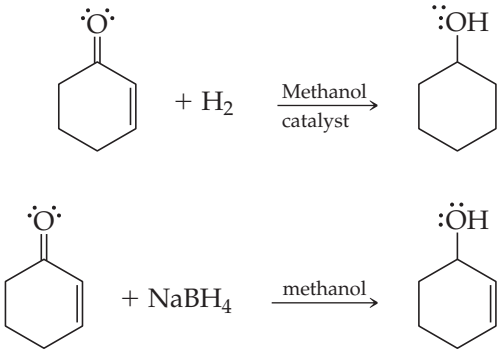
What product would you expect from the acid-catalyzed reaction of benzaldehyde and ethanol?



Reduction Reactions

Aldehydes and ketones are easily reduced to the corresponding primary and secondary alcohols, respectively. Catalytic hydrogenation, using Pd, Pt, Ni or Rh metal catalysts, is typically a high-yielding reaction and the product is easily isolated and purified.

aldehyde 1° alcohol



[28.17]

ketone 2° alcohol

[28.18]

In a laboratory situation, the reduction of aldehydes and ketones using **metal hydrides** is preferred over catalytic hydrogenation because it selectively reduces the carbonyl group rather than any alkene double bonds present and no gas-handling equipment is required.

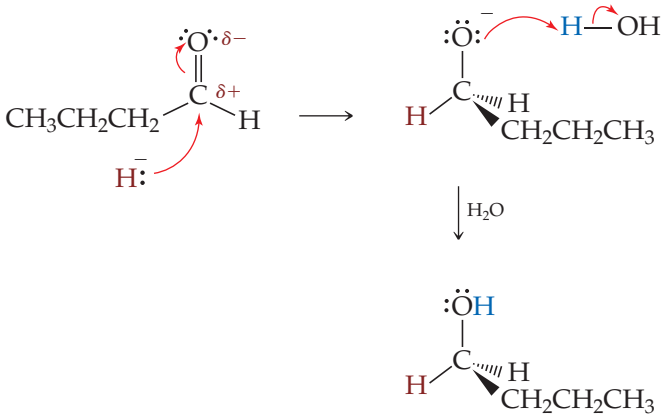
[28.19]

The two most common metal hydride reagents are sodium borohydride ($NaBH_4$) and lithium aluminum hydride ($LiAlH_4$). These compounds behave as a source of **hydride ion** (H^-),

Go Figure How soluble would sodium borohydride be in typical organic solvents? Why?

sodium borohydride
Non-reactive in water or methanol
Mild reductant
Selective for aldehydes and ketones

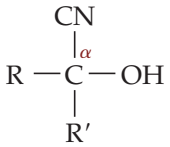
lithium aluminum hydride
Highly reactive in water or methanol
Powerful reductant
Reduces aldehydes, ketones, carboxylic acids and esters



▲ **Figure 28.5 Metal hydrides.** The two most common metal hydrides for reduction are sodium borohydride and lithium aluminum hydride.

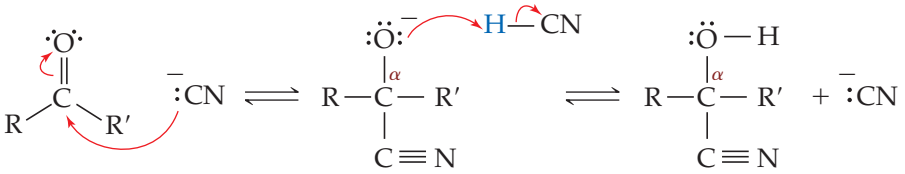
which is a powerful nucleophile. **Figure 28.5** shows the structural formula of both metal hydrides and compares their chemical reductive properties.

Metal hydrides act as a source of hydride ion (H^-) because they contain polar metal–hydrogen bonds, which place a partial negative charge on hydrogen in the same way as a negative charge is placed on carbon within a Grignard reagent:



In fact, the mechanism for the reduction of an aldehyde or ketone by a metal hydride, which involves nucleophilic attack on the carbonyl group by hydride, followed by protonation, follows a similar pathway to that demonstrated for the Grignard reaction in Equation 28.10. A typical mechanism, showing the reduction of butanal using hydride, is

[28.20]



Cyanohydrins

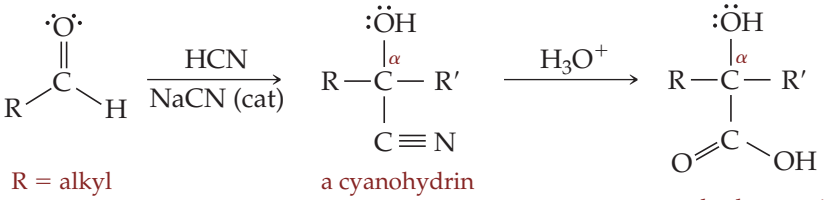
Cyanohydrins are a class of compounds containing a hydroxy (—OH) and nitrile (—CN) group, both directly bonded to an α-carbon. Organic compounds containing the CN group are called **nitriles**. A cyanohydrin is therefore an *α-hydroxynitrile*.

a cyanohydrin

Cyanohydrins are formed by the addition of the cyanide ion ($^-$CN) to an aldehyde or ketone. Cyanide ion is the conjugate base of hydrogen cyanide (HCN), which is itself a weak acid ($pK_a \sim 9.2$). The cyanide ion is small, and because it is both a base and a strong nucleophile, it can add to the carbonyl group by a **nucleophilic addition** mechanism.

R, R′ = H, alkyl — a tetrahedral intermediate — a cyanohydrin [28.21]

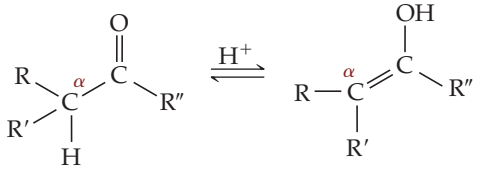
In the first step, the strong $^-$CN nucleophile adds to the electropositive carbonyl carbon to give a tetrahedral alkoxide intermediate. Protonation of the alkoxide yields the cyanohydrin. Note that in the example here, the protonation step regenerates cyanide ion. Thus the process is truly catalytic in the addition of cyanide ion and this reaction is classed as a *base-catalyzed reaction*.



As shown by the mechanism in Equation 28.21, cyanohydrin formation is reversible. The formation of cyanohydrins is best with aldehydes, with formaldehyde being quantitative. Ketones are slower to react, though for simple ketones the yields are still greater than 90%. Bulky ketones do not react well, being slow and poor yielding. Note that the reversibility of cyanohydrin formation is put to use by the millipede *Apheloria corrugata,* which releases the cyanohydrin mandelonitrile from a storage gland to an outer chamber (**Figure 28.6**). There it is enzymatically degraded to benzaldehyde and hydrogen cyanide before being sprayed at an enemy as a defense mechanism. Cyanohydrins can be formed by using HCN with a catalytic amount of sodium or potassium cyanide to initiate reaction. Hydrogen cyanide, however, is highly toxic and volatile. A more practical method is to use sodium or potassium cyanide in a stoichiometric quantity dissolved in a protic solvent such as ethanol.

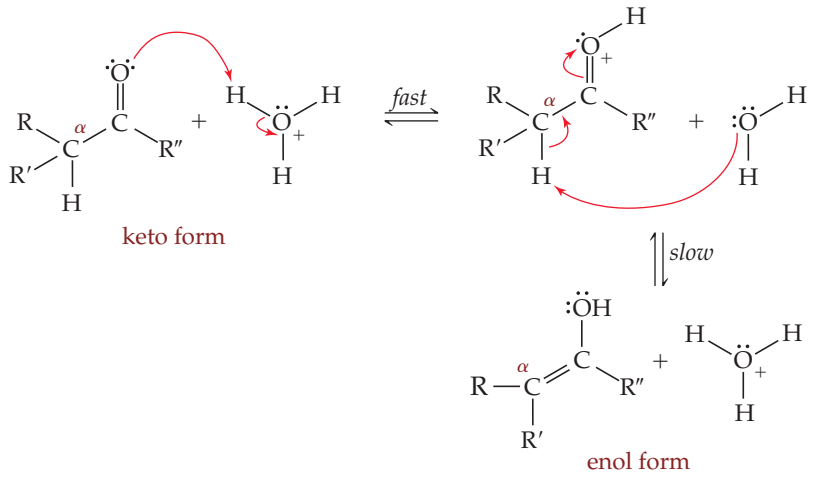
Nitriles such as those found in cyanohydrins are readily hydrolyzed to carboxylic acids under acidic conditions. In this case, cyanohydrins hydrolyze to give *α-hydroxy acids*.

Go Figure Suggest the structure of the organic compound produced by the generation of HCN from mandelonitrile.



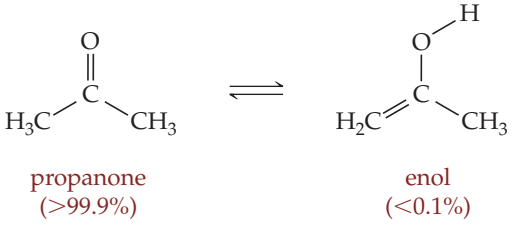
▲ **Figure 28.6 Millipede defense.** *Apheloria corrugata* releases mandelonitrile as part of its defense strategy. The nitrile is degraded to hydrogen cyanide which is deadly to predators.

[28.22]



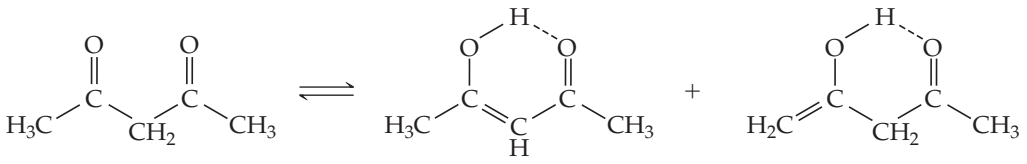
Tautomerism in Aldehydes and Ketones

Aldehydes and ketones bearing an α-hydrogen (that is, a hydrogen on a carbon atom next to the carbonyl carbon) are able to undergo tautomerism to form enols ("ene ols", or a compound bearing a double bond (alkene) and a hydroxyl group (alcohol)). Enols are constitutional isomers of their respective *keto* form (that is, an aldehyde or ketone). **Tautomerism** is the process by which two isomers, in this case the aldehyde or ketone and the enol, are interconverted by a formal movement of an atom or group, following normal valency rules. Hence an enol and its keto form are *tautomers* of the same structure.



[28.23]

Aldehydes and ketones are in equilibrium with their enol forms and this equilibrium is acid catalyzed. The process involves two separate proton transfers rather than a single proton jump, as might be expected just by looking at Equation 28.23. What tautomerism exploits is essentially the relative acidity of the α-hydrogen (pK_a ~9–13).



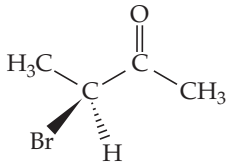
[28.24]

The extent of tautomerization depends very much on the aldehyde or ketone. For example, propanone (acetone) exists >99.9% in the ketone form, whereas 2,4-pentanedione exists preferentially as the enol (~80%) by virtue of stabilising hydrogen bonding.

[28.25]

2, 4-pentanedione (20%) | major enol formed | minor enol formed

(80%)



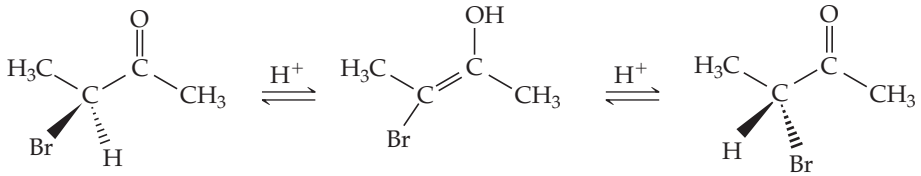
[28.26]

Though many aldehydes and ketones do not exist in the enol form to a large extent, enols do play a significant part in the reactivity of aldehydes and ketones. One example, that of halogenation, is the next topic of discussion.

Sample Exercise 28.5

Keto–enol Tautomerism

Some ketones, such as the one shown here, are chiral. In solution, such compounds are quite stable and retain their optical activity. However, the addition of a small amount of acid causes the optical rotation to tend to 0° over time. Comment on why this is so.

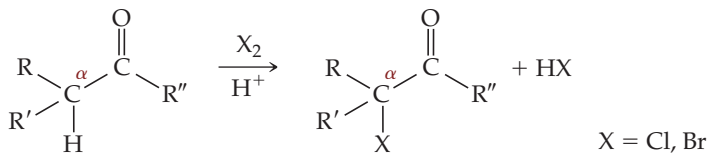


SOLUTION

Analyze We are asked about the acid-catalyzed stereoisomerization of ketones bearing a stereocenter on the α-carbon.

Plan Ketones undergo tautomerism to the enol form if they possess a hydrogen atom alpha to the carbonyl group. We need to explain the loss of optical activity.

Solve There are two possible causes. Since this ketone has an α-hydrogen, and optical activity is lost under acidic conditions, there is a high chance that tautomerism is occurring, leading to the achiral enol. However, we know that tautomerism is an equilibrium, so the enol is able to reconvert to the keto form. In this case, the proton could add from behind the page (leading to the original structure) or it could add from in front of the page, leading to the enantiomer. Since there is nothing to favour the addition from one face or the other, both are equally likely, leading to a racemic mix. This can be summarized as the following:



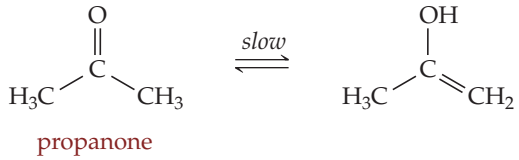
keto form | enol form | keto form

Practice Exercise

Draw the enol forms of **(a)** cyclohexanone, **(b)** 3-pentanone and **(c)** propanal.

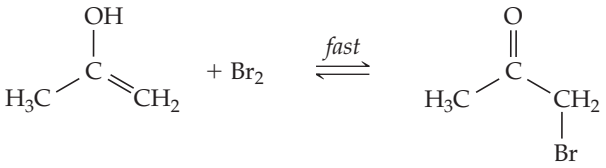
Halogenation of Aldehydes and Ketones

Aldehydes and ketones undergo a substitution reaction at the α-carbon in the presence of molecular chlorine or bromine in good yield.



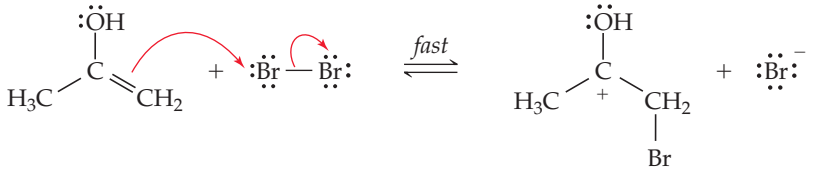
aldehyde or ketone | α-halo aldehyde or ketone

X = Cl, Br



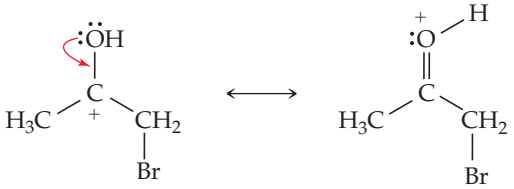
[28.27]

This reaction is *regiospecific* in that *only* the α-hydrogen is substituted under these conditions. Interestingly, when the reaction was first studied mechanistically by Arthur Lapworth (1872–1941) in 1904, he discovered that the rates of chlorination, bromination and iodination were all the same. This meant that halogenation occurred after the rate-determining step. We now know that the rate-determining step is the conversion of the ketone to its enol isomer. Let us look at this reaction in more detail, using the bromination of propanone (acetone) as the example.



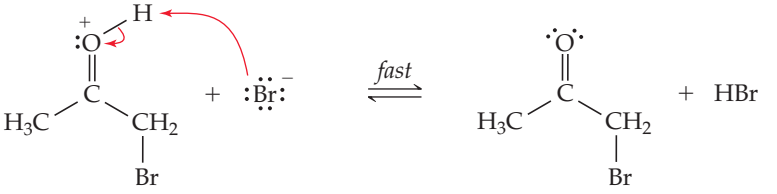
propanone

[28.28]



[28.29]

We can understand the enol halogenation by comparing it to the halogenation of an alkene. The first step involves attack of the double bond of the enol on bromine.



[28.30]

If the reaction followed the bromination of an alkene, then the next phase of the mechanism would be the formation of the second C—Br bond by attack of the bromide ion on the carbocation intermediate in an *intermolecular* reaction. However, in this case, the lone pair on the oxygen can stabilize the carbocation by resonance with the major resonance contributor being the oxonium ion.

[28.31]

The final stage is loss of a proton to yield the desired α-haloketone.

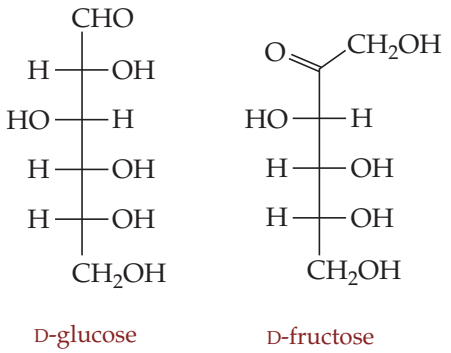
28.4 Carbohydrates

Sugar is one of the oldest and best documented of all commodities. The crystallinity of the popular sugars—mainly sucrose, lactose, and fructose—as well as their sweet flavor has made them popular for over two millennia.

Sugar is classified as a member of the carbohydrate food group, and its main natural sources are sugar cane (*Saccharum* spp.) and sugar beets (*Beta vulgaris*), in which sugar can account for 12% to 20% of the plant's dry weight. During the times of Alexander the Great,

sugar cane arose as a popular alternative to honey, with people chewing on the raw cane to extract its sweetness.

Today, most sugar cane comes from countries with warm climates, such as Brazil, India, China, Thailand, Mexico, and Australia, the top sugar-producing countries in the world. From a regional perspective, Asia produces more sugar cane than any other region.



Refined sugar can be made by dissolving raw sugar and purifying it using phosphoric acid. Alternative methods of purification include a carbonation process involving calcium hydroxide and carbon dioxide, or various filtration strategies. The sugar is then further purified by filtration through a bed of activated carbon or bone char, depending on where the processing takes place. White refined sugar is typically sold as granulated sugar, which has been dried to prevent clumping.

Understanding the chemistry of sugars and appreciating their structure requires a grounding in the chemistry of the carbonyl (C═O) group from which aldehydes and ketones are formed. By the end of this section, you should be able to:

- Understand the components that make up a carbohydrate
- Be able to identify an anomeric carbon atom
- Recognize the meaning of the different parts that make up a name of a carbohydrate molecule

Carbohydrates are an important class of naturally occurring substances, found in both plant and animal matter. They perform a variety of vital functions, such as energy storage; they act as structural components in plants; and they are an essential component of the nucleic acids, DNA and RNA, which store genetic information. The name **carbohydrate** (hydrate of carbon) comes from the empirical formulas for most substances in this class, which can be written as $C_x(H_2O)_y$ (x, y integers). For example, **glucose**, the most abundant carbohydrate, has the molecular formula $C_6H_{12}O_6$, which could also be written as $C_6(H_2O)_6$. Carbohydrates are not really hydrates of carbon; rather, they are polyhydroxyaldehydes and ketones. Glucose, for example, is a six-carbon aldehyde sugar; *fructose*, the sugar that occurs widely in fruit, is a six-carbon ketone sugar (Figure 28.7).

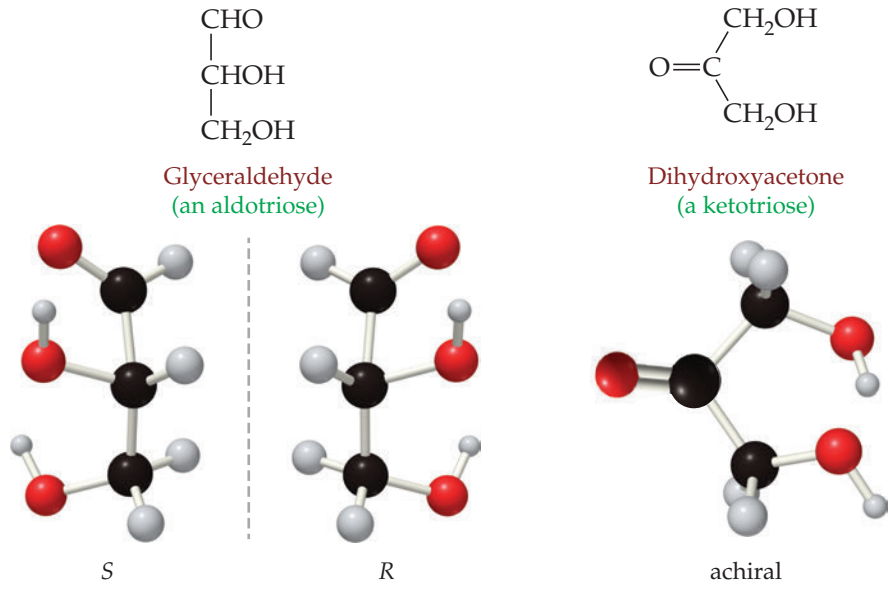
Go Figure How many chiral centers are there in the open-chain form of glucose?

D-glucose D-fructose

▲ **Figure 28.7 Linear structure of glucose and fructose.** Together with galactose, glucose and fructose are the most common carbohydrates found in nature.

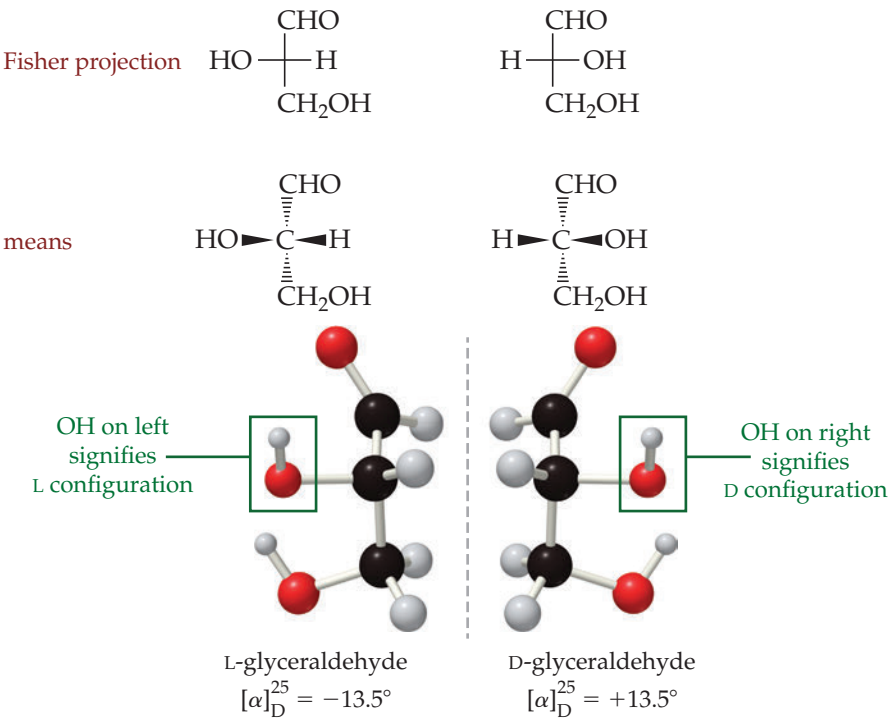
Monosaccharides

Both glucose and fructose are examples of **monosaccharides**—simple sugars that can't be broken into smaller molecules by hydrolysis with aqueous acids. Monosaccharides have the general formula $C_nH_{2n}O_n$ (where the integer $n = 3$ to 8). They are classified by their functionality as well as by the number of carbon atoms they contain.



Polyhydroxyaldehydes are known as **aldoses** to signify the aldehyde functional group, while polyhydroxyketones are classified as **ketoses** to signify the ketone group within the molecule. For example, *glucose* is an *aldose* and *fructose* is a *ketose* (see Figure 28.7). Table 28.1 lists the names of different monosaccharide classes based on the number of carbon atoms within that molecule. Based on this table, glucose can be further classified as an *aldohexose*, and fructose as a *ketohexose*. The simplest monosaccharides are the trioses: glyceraldehyde and 1,3-dihydroxyacetone (Figure 28.8). These two molecules are constitutional isomers. Glyceraldehyde, an aldotriose, is chiral because the central carbon atom is a stereocenter. The achiral dihydroxyacetone is classified as a ketotriose.

TABLE 28.1 Classifying monosaccharides

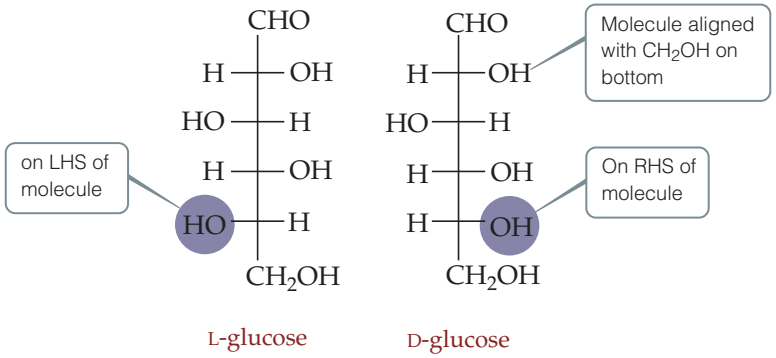


Name	Formula
Triose	$C_3H_6O_3$
Tetrose	$C_4H_8O_4$
Pentose	$C_5H_{10}O_5$
Hexose	$C_6H_{12}O_6$
Heptose	$C_7H_{14}O_7$
Octose	$C_8H_{16}O_8$

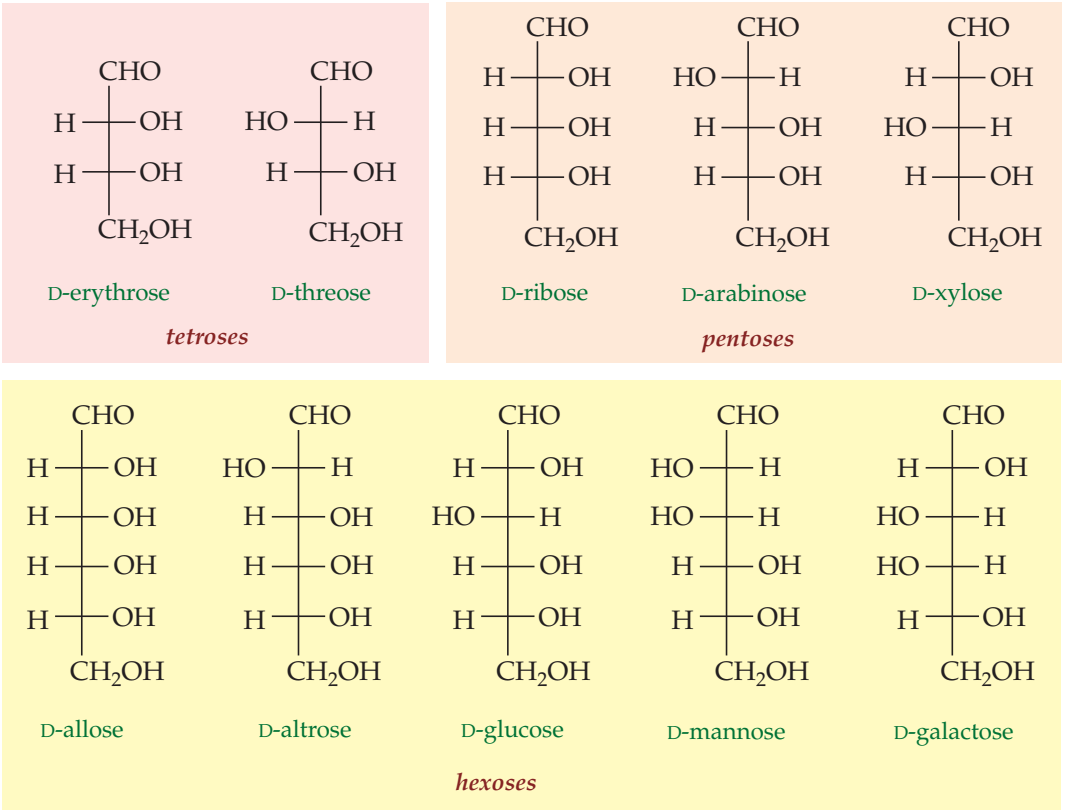
Let's return to Figure 28.7. Notice that the structures have been named D-glucose and D-fructose, yet there is no indication of stereochemistry using the now customary bold and dashed wedges. In fact, these two molecules do infer stereochemistry and are being shown as **Fischer projections**. This representation, which is most common among carbohydrates, is a two-dimensional representation of chiral centers. The carbon stereocenters are not shown, which is an indication that Fischer projections are being used. Figure 28.9 illustrates how the Fischer projections for glyceraldehyde relate to the types of structures you have become familiar with. Fischer projections are drawn so that the most oxidized carbon (usually the aldehyde or ketone) is positioned at the top of the drawing. The vertical lines

Go Figure Why is dihydroxyacetone achiral?

▲ **Figure 28.8 Glyceraldehyde and dihydroxyacetone.** A structural formula and ball-and-stick representations of the two trioses are shown. Glyceraldehyde, which contains a stereocenter, is chiral and can exist as an *S*- or *R*-enantiomer.



◀ **Figure 28.9 Fischer projections.** The D and L nomenclature for monosaccharides is referenced from D- and L-glyceraldehyde. The reference point is the position of the carbon stereocenter furthest away from the carbonyl group (aldehyde or ketone).

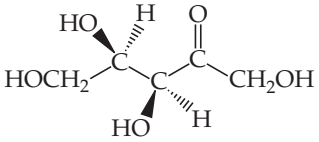


represent bonds oriented back into the page, while the horizontal lines represent bonds coming out of the page. The point at which they cross indicates a stereocenter.

The trioses D- and L-glyceraldehyde serve as the reference for determining whether a carbohydrate has the D or L configuration. According to the conventions proposed by Fischer, the D form of a carbohydrate implies that the OH group on the carbon stereocenter furthest away from the aldehyde (or ketone) is positioned on the right-hand side of the molecule, as is the case for D-glyceraldehyde (**Figure 28.10**). Conversely, a carbohydrate is in

▶ **Figure 28.10** **Fischer projections of D- and L-glucose.**

▶ **Figure 28.11** **Configurational relationships between selected naturally occurring aldoses.**

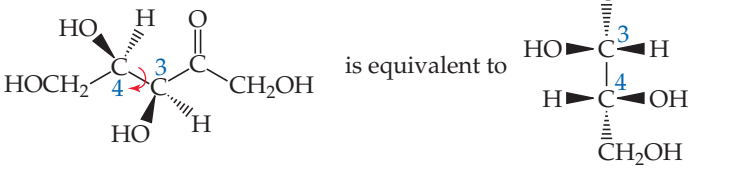


the L form when the OH group on the furthest stereocenter from the aldehyde (or ketone) is positioned on the left-hand side of the molecule. Almost all biological carbohydrates are of the D form. Several of the more common naturally occurring carbohydrates are shown in **Figure 28.11**.

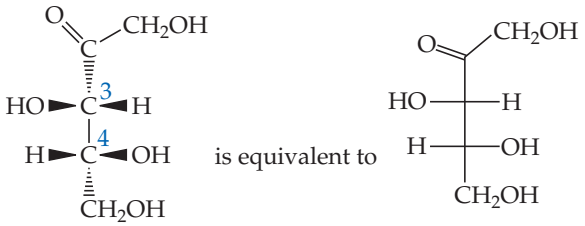
Sample Exercise 28.6

Fischer Projections

Draw the Fischer projection of the following carbohydrate. By what name would you classify this molecule? Is this molecule in the D or L configuration?



SOLUTION

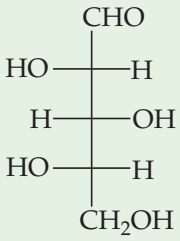


Analyze We are asked to convert the open-chain form of a carbohydrate into its Fischer projection, class it as aldose or ketose, and determine its configuration using the D, L nomenclature.

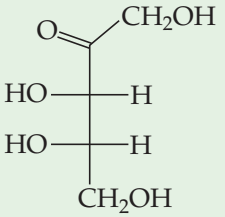
Plan To begin, we need to arrange the molecule in such a way that the OH groups and H atoms point out of the page and convert this to a Fischer projection. The Fischer projection will also help determine D, L configuration based on glyceraldehyde. We can classify this carbohydrate based on the number of carbon atoms present and the carbonyl functional group contained—whether aldehyde or ketone.

Solve Arranging the structure in such a way that the OH groups and H atoms point out of the page is achieved by rotating about the C3–C4 bond:

Position the structure in such a way that the ketone group is at the top of the molecule. From this point, the conversion from a stereoview to the Fischer projection is:



This molecule is classified as a *ketopentose*. It has the D configuration because the OH group on the stereocenter furthest from the ketone is positioned on the RHS, comparable with D-glyceraldehyde.



Practice Exercise

Which molecules are D-monosaccharides and which are L-monosaccharides? What are their classifications?

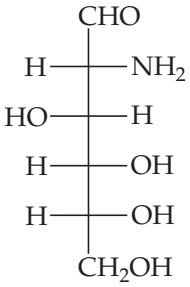
Cyclic versus Open-Chain Structures



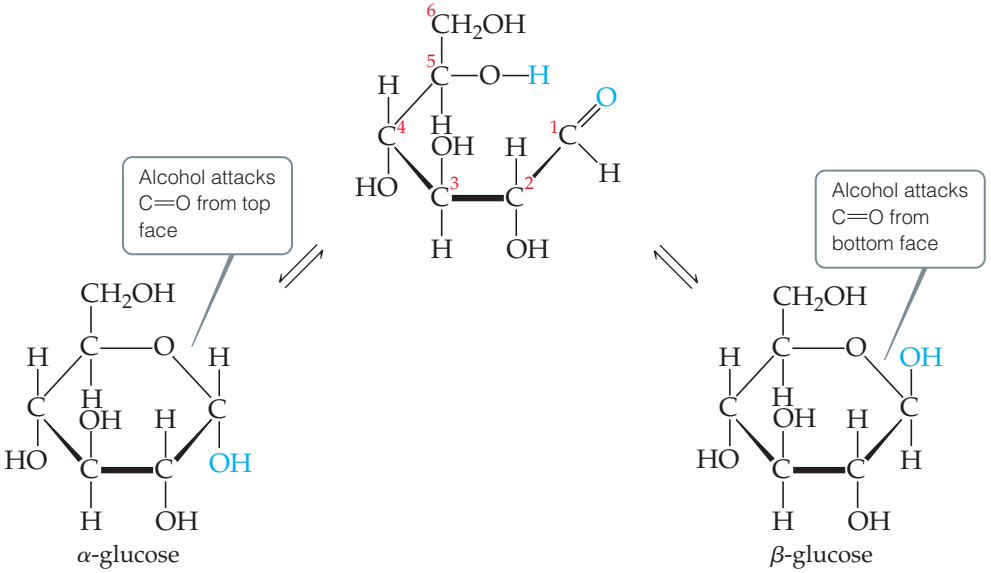
In Section 28.3 we discussed the reaction of aldehydes and ketones with alcohols to form hemiacetals and acetals. We also discussed the formation of cyclic hemiacetals by an intramolecular reaction between a hydroxyl group and an aldehyde or ketone. For example, 5-hydroxypentanal forms a cyclic six-membered hemiacetal. Notice that this reaction converts an acyclic, achiral molecule into a cyclic, chiral molecule. The new stereocenter created in forming the cyclic structure is called the **anomeric carbon**.

5-hydroxypentanal a cyclic hemiacetal [28.33]

CHEMISTRY AND LIFE Glucosamine

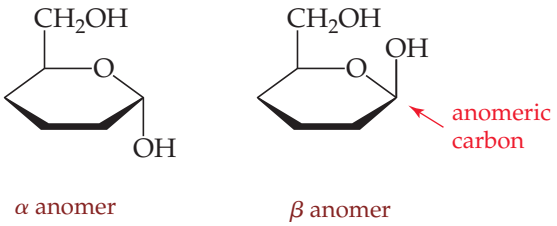
Amino sugars such as glucosamine contain an NH_2 group in place of one of the OH groups (Figure 28.12). Only three amino sugars are commonly found in nature: D-glucosamine, D-mannosamine and D-galactosamine. D-Glucosamine is an amino derivative of glucose that is found especially in the polysaccharides contained within chitin, shellfish and cell membranes. Its use in the formation and repair of cartilage has more recently seen its popularity increase as a *nutraceutic*—a natural product with the capacity to prevent or heal disease.

D-glucosamine



▲ **Figure 28.12 Glucosamine is sold as a dietary supplement.**

Glucosamine and its salts, most commonly the hydrochloride or sulfate salts, have been included in recent guidelines as therapy options for people with symptomatic osteoarthritis, especially in the knees. Osteoarthritis is a condition that involves damage to the cartilage in the joints of humans and animals, causing pain and stiffness. Glucosamine can be isolated in quantity from shellfish or shark cartilage or prepared synthetically.

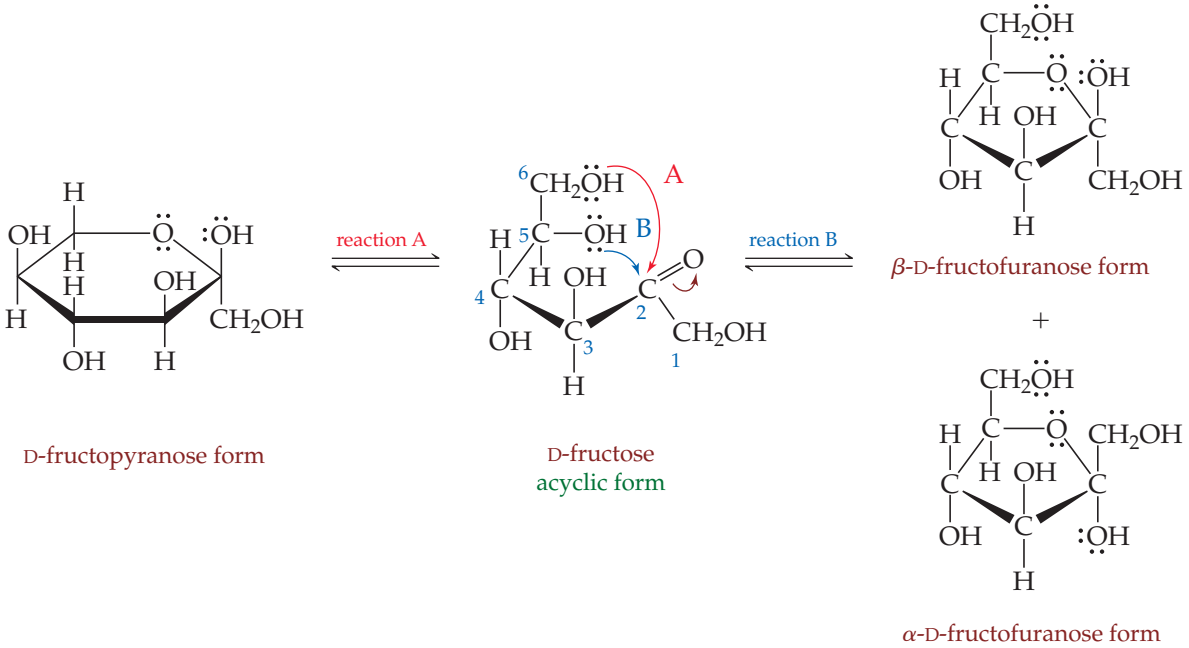


Glucosamine and its salts are widely available as licensed products or health supplements, and may also be combined with chondroitin, vitamins and various herbs. In Australia, glucosamine is classified as a complementary medicine and is available as over-the-counter supplements. It is thought that supplementing glucosamine levels in the body will replace the deficit and restore the proper glucosamine balance.

Glucose, having both hydroxyl and carbonyl groups, and a reasonably long and flexible backbone so as to form an unstrained ring structure, can also react intramolecularly to form a six-membered ring structure, as shown in Figure 28.13. In fact, only a small percentage of glucose molecules are in the open-chain form in aqueous solution. Of the two cyclic forms for D-glucose, the β form is present in greater proportion in glucose solutions. Although the ring is often drawn as if it were planar, the molecules are actually non-planar because of the tetrahedral bond angles around the C and O atoms of the ring. This planar way of representing the cyclic structures of monosaccharides is known as a **Haworth projection**. Named after W. Norman Haworth (1883–1950), recipient of the 1937 Nobel Prize for Chemistry for research in carbohydrate chemistry, this representation is a simplified way to visualize the complexities of cyclic saccharides. Convention is to write the structure with the anomeric carbon on the right side and the hemiacetal ring oxygen in the back right position.

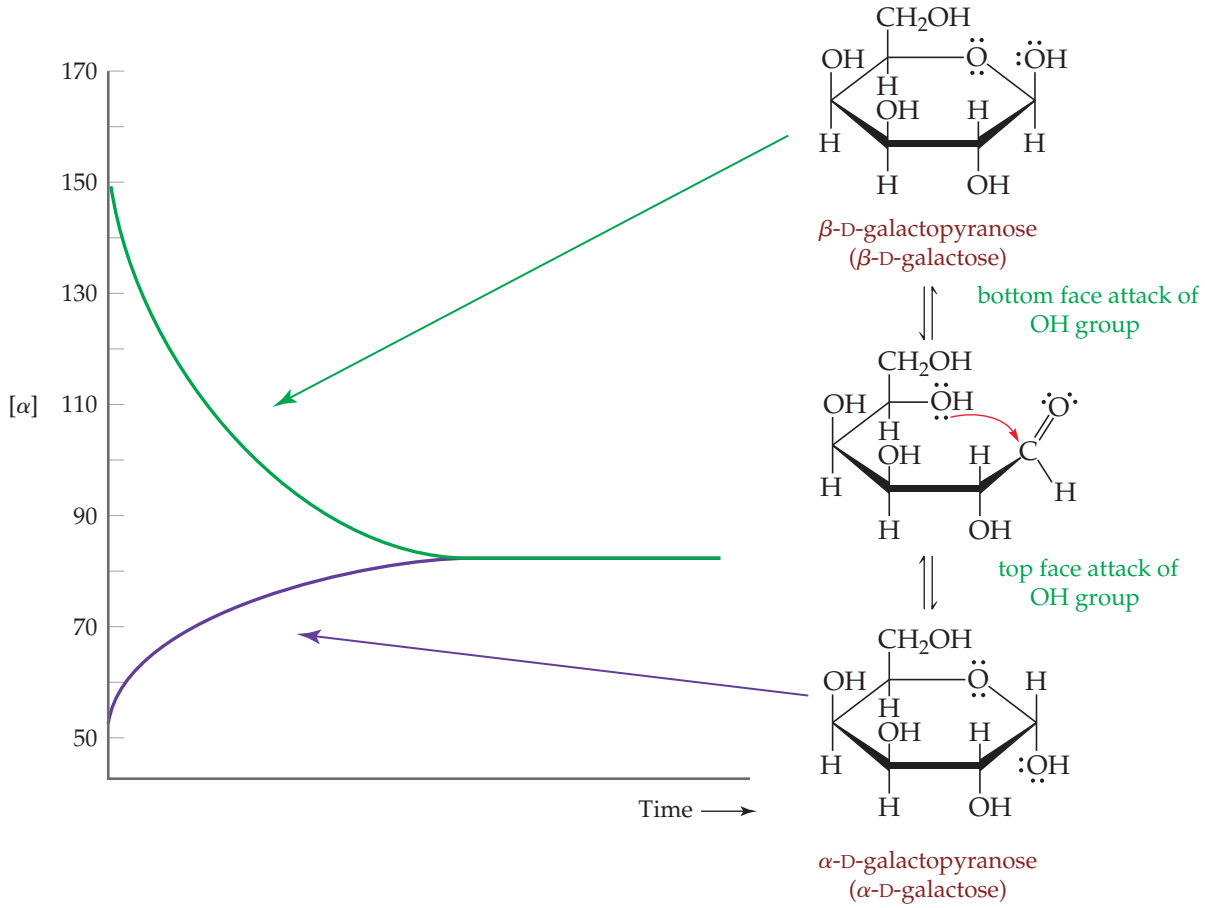
Go Figure How many hydroxyl groups are in an equatorial position in β-glucose?

▲ **Figure 28.13 Cyclic glucose.** The carbonyl group of a glucose molecule can react with one of the hydroxyl groups to form either of two six-membered ring structures, designated α and β.



◀ **Figure 28.14 Anomers.** The α and β anomers differ by their orientation to the CH_2OH group outside the ring.

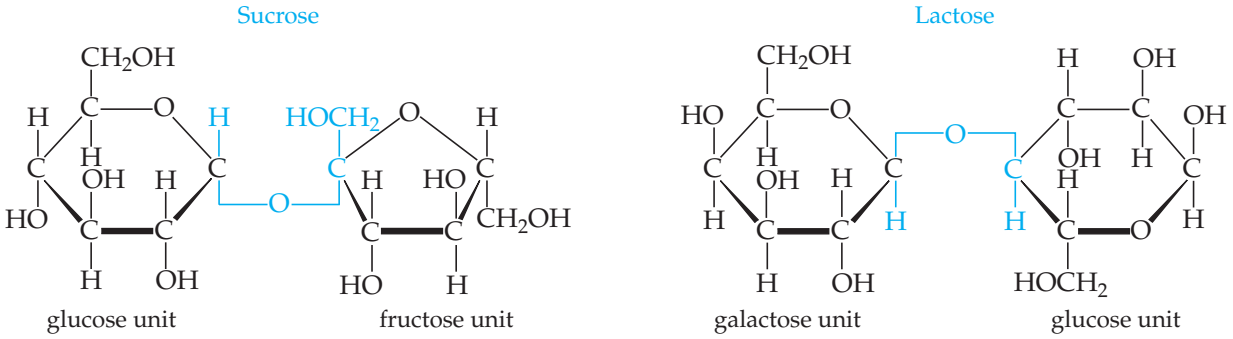
Figure 28.13 indicates that the ring structure of glucose can have two relative orientations at the anomeric carbon. In the α form, the OH group on the anomeric carbon (C1) and the CH_2OH group on C5 point in opposite directions. In the more stable β form, the OH group on the anomeric carbon and the CH_2OH group on C5 point in the same direction. The α and β forms are called **anomers** (Figure 28.14). Although the difference between the α and β forms might seem small, it has enormous biological consequences. As we will soon see, this one small change in structure accounts for the vast difference in properties between the biopolymers starch and cellulose.



Fructose can cyclize to form either five- or six-membered rings (Figure 28.15). The five-membered ring forms when the OH group on C5 reacts with the carbonyl group on C2 (reaction B in Figure 28.15). The six-membered ring results from the reaction between the OH group on C6 and the carbonyl group on C2 (reaction A in Figure 28.15). Monosaccharides that exist as six-membered rings are named as derivatives of the oxygen-containing heterocycle, pyran. Hence, a cyclic monosaccharide that forms a six-membered ring is named a *pyranose*. Five-membered ringed monosaccharides are named as derivatives of the oxygen-containing heterocycle, furan. Hence, a cyclic monosaccharide that forms a five-membered ring is named a *furanose*.

We are now armed with enough information to name a cyclic monosaccharide unambiguously. For example, the top right-hand structure shown in Figure 28.15 has the name

▲ **Figure 28.15 Fructofuranose and fructopyranose.** Fructose is just one of many monosaccharides that are able to exist in furanose and pyranose forms.



▲ **Figure 28.16 Mutarotation of D-galactose.** At equilibrium, D-galactose exists as a 72 : 28 mixture of α : β anomers. The mutarotation process is easily followed by changes in the specific rotation of pure samples of both anomers.

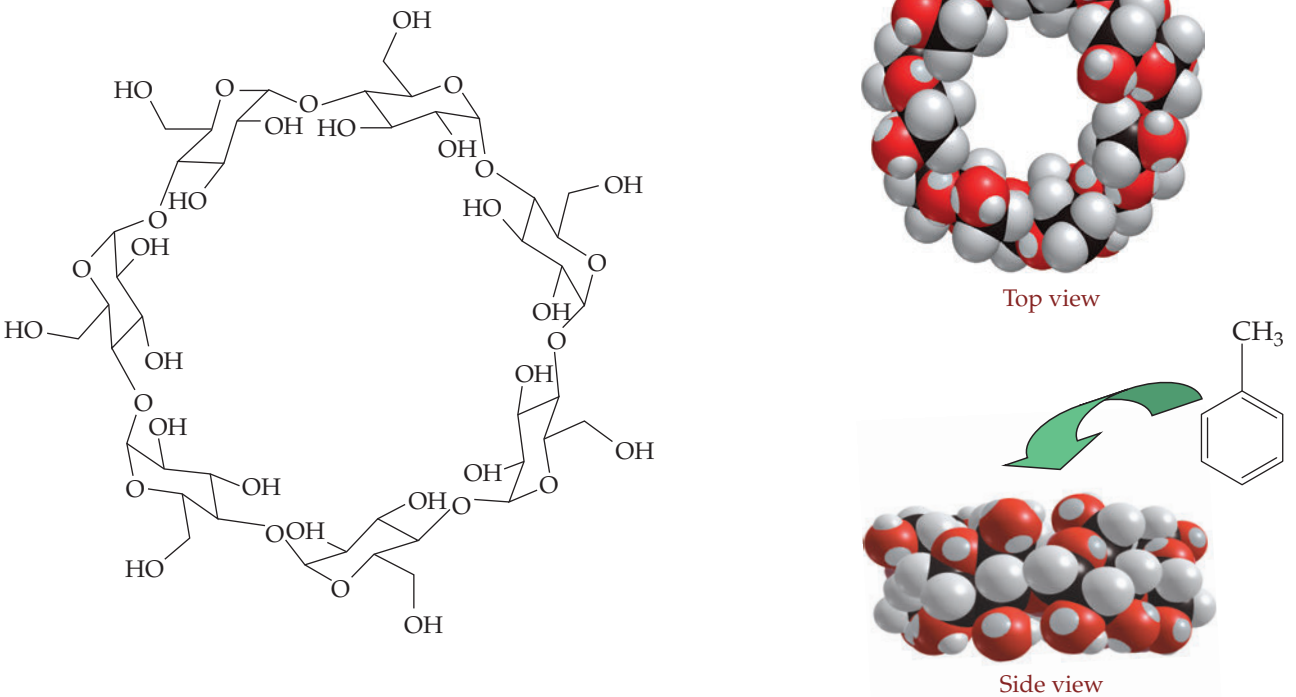
β-D-fructofuranose. This name indicates that the five-membered cyclic monosaccharide is derived from D-fructose. The β anomer has the OH and CH_2OH group found on C5 of the furanose form on the same side, which allows us to put in place the only unanswered variable from the open-chain form. As a point of completion, the two structures in Figure 28.13 are fully named α-D-glucopyranose and β-D-glucopyranose, although α-D-glucose and β-D-glucose are also acceptable.

The inference that the α and β anomers are interconvertible through an acyclic intermediate, as shown in Figure 28.15, is entirely true. This process, called **mutarotation**, is common to all carbohydrates that exist in a cyclic hemiacetal form. Mutarotation is easily observable by monitoring the specific rotation of an aqueous solution of either anomer over time. For example, a solution prepared by dissolving crystalline β-D-galactose in water shows an initial rotation of +151°. Over time, this value decreases until, at equilibrium, a rotation value of +80° is observed (**Figure 28.16**). The value of the rotation corresponds to a 72 : 28 ratio of α : β anomers in solution. A similar experiment can be performed using crystalline α-D-galactose. Initially, the rotation of a solution of α-D-galactose in water is +53°. Over time, this value rises as a result of the mutarotation, forming larger quantities of β-D-galactose. At equilibrium, a rotation value of +80° is also achieved (Figure 28.16). The value of the rotation still corresponds to a 72 : 28 ratio of α : β anomers in solution at equilibrium.

Oligosaccharides and Polysaccharides

Two monosaccharide units can be linked together by a condensation reaction to form a *disaccharide*. The structures of two common disaccharides, *sucrose* (table sugar) and *lactose* (milk sugar), are shown in **Figure 28.17**. The word *sugar* makes us think of sweetness. All

▲ **Figure 28.17 Two disaccharides.** The structures of sucrose (left) and lactose (right). Note that the glycosidic bond (blue) is often shown with a 90°-kink in it. This is for ease of representation and does *not* indicate an extra carbon atom.

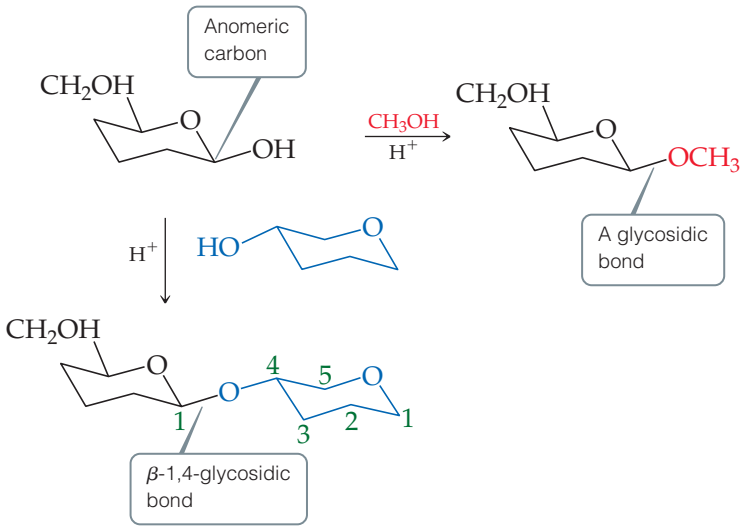


sugars are sweet, but they differ in the degree of sweetness we perceive when we taste them. Sucrose is about six times sweeter than lactose, slightly sweeter than glucose, but only about half as sweet as fructose. Disaccharides can react with water (hydrolysis) in the presence of an acid catalyst to form two monosaccharides. When sucrose is hydrolyzed, the

CHEMISTRY AND LIFE Cyclodextrins

Cyclodextrins, such as the one shown in **Figure 28.18**, are *macrocyclic* compounds with the ability to include small organic molecules within their cavity. These cyclic molecules, which are composed of glucose units, have a *hydrophobic* (water-hating) interior and a *hydrophilic* (water-loving) exterior, due to the fact that the OH groups radiate out from the macrocycle rather than in towards the center. This feature causes cyclodextrins to be water soluble. Molecules that are hydrophobic (that is, do not mix with water) are easily included within the cyclodextrin cavity, provided they are not too large.

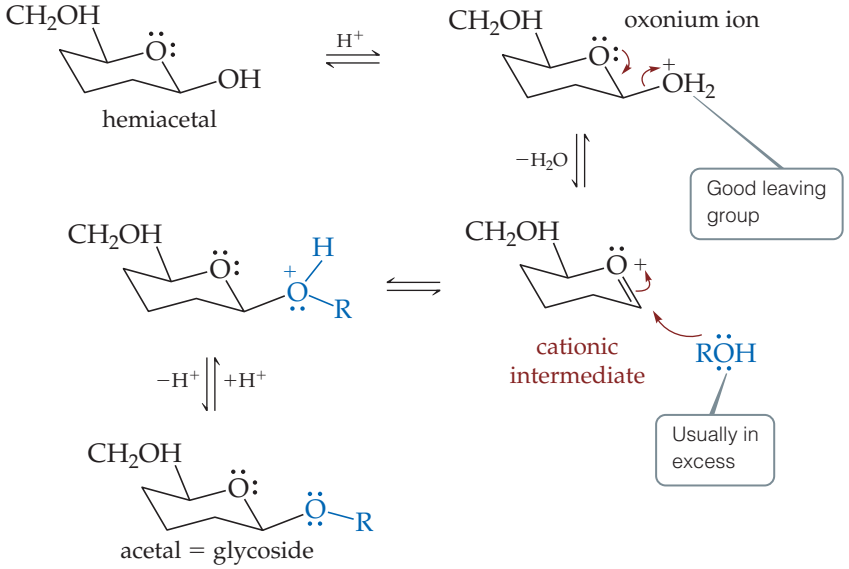
Cyclodextrins have found uses recently as solubilising agents. For example, toluene is immiscible with water, forming a separate layer when added to water. The addition of cyclodextrin to the aqueous layer causes the two layers to mix by providing a way of optimising the interactions between cyclodextrin, water and toluene. The use of cyclodextrins in the pharmaceutical industry is ever-increasing as scientists realize their benefits as both a non-toxic solubilising agent at physiological pH and as a chiral "reaction vessel" with which to carry out enantioselective reactions.



Cyclodextrins are formed by the enzymatic action of cyclodextrin glucanotransferase (CGTase) on glucose. Using this green process, tonnes of cyclodextrin can be prepared industrially.

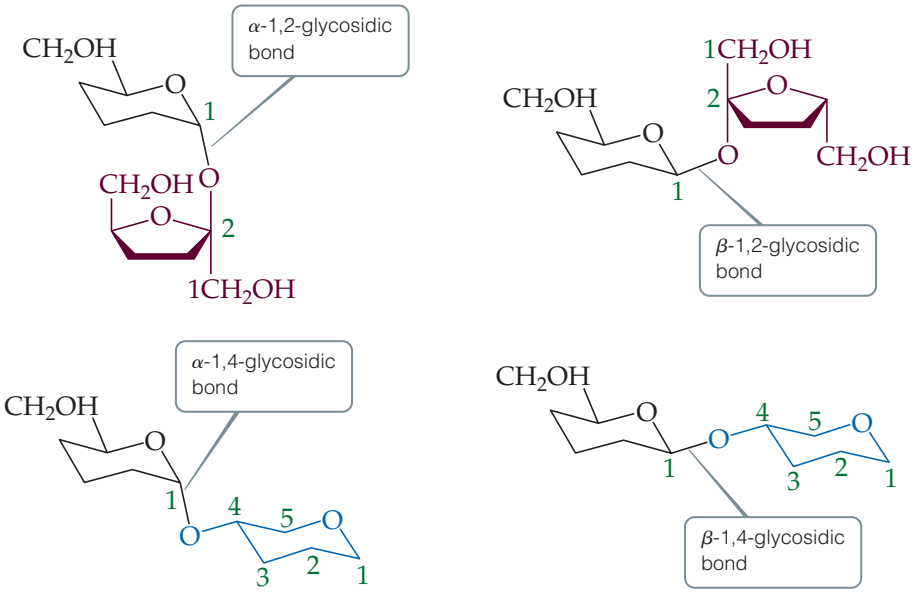
▲ **Figure 28.18 Cyclodextrins as solubilising agents.**

mixture of glucose and fructose that forms, called *invert sugar*, is sweeter to the taste than the original sucrose. The sweet syrup present in canned fruits and lollies is largely invert sugar formed from the hydrolysis of added sucrose.



You might recall from our discussion on the formation of acetals in Section 28.3 that, provided there is an excess of alcohol present, the major product of the acid-catalyzed reaction of an aldehyde or ketone with an alcohol is the acetal and not the intermediate hemiacetal. The same can be stated for cyclic monosaccharides, which in the presence of excess alcohol form acetals, as illustrated by the following reactions:

[28.34]

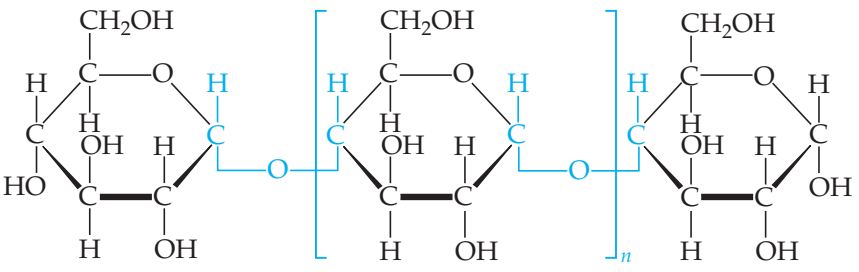


A cyclic acetal formed from a monosaccharide is called a **glycoside**. Both sucrose and lactose are *glycosides*. The bond between the anomeric carbon and the exocyclic alkoxy group of the acetal is called a **glycosidic bond**. Glycosides are stable in water, unlike simple acetals, and *do not* undergo mutarotation since, unlike the hemiacetal, the glycoside is not in equilibrium with its open-chain form in neutral solution. Hydrolysis of the glycoside is possible in aqueous acid, as is shown by the example of invert sugar.

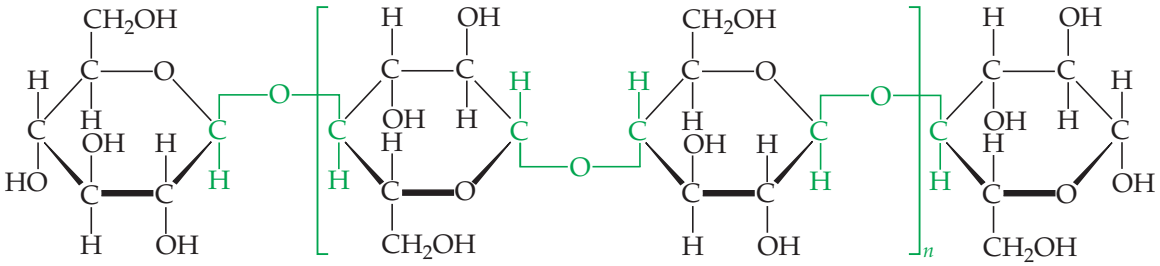
The mechanism for the formation of the glycoside from the cyclic hemiacetal is illustrated in the set of equilibria given in Equation 28.35 for a simplified β-monosaccharide and the general alcohol, ROH. The acid-catalysed reaction occurs mainly by an elimination pathway. Elimination of H_2O by use of one of the lone pairs on the endocyclic oxygen yields the cationic intermediate (Equation 28.35). Attack at what used to be the anomeric carbon by ROH leads to an intermediate oxonium ion, which on proton loss yields the glycoside. This reaction pathway is unique to carbohydrate chemistry.

[28.35]

The position of the glycosidic bond in a carbohydrate is important for the properties it exhibits. Glycosidic bonds are classified by their orientation—that is, whether they are α or β bonds (equating to axial and equatorial bonds in the chair conformation, respectively), as well as on which carbons link the two monosaccharide subunits. Some examples of naming glycosidic bonds are:



Polysaccharides are made up of many monosaccharide units, joined together by a bonding arrangement similar to those shown for the disaccharides in Figure 28.17. The most important polysaccharides are starch, glycogen and cellulose, which are formed from repeating glucose units.



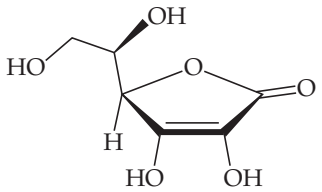
Starch is not a pure substance. The term refers to a group of polysaccharides found in plants, composed of glucose units bound by α-1,4-glycosidic bonds. Starches serve as a major method of food storage in plant seeds and tubers. Corn, potatoes, wheat and rice all contain substantial amounts of starch. These plant products serve as major sources of food energy for humans. Enzymes within the digestive system called *amylases* catalyze the hydrolysis of starch to glucose. Starch molecules that form unbranched chains are called **amyloses**, whereas those that are branched are called **amylopectins**. Figure 28.19 illustrates an unbranched structure of starch. In this structure, the glucose units are in the α form.

Glycogen is a starch-like substance synthesized in animals, consisting of glucose units connected by α-1,4- and α-1,6-glycosidic bonds. Glycogen molecules vary in molecular weight from about 5000 u to more than 5 million u. Glycogen acts as a kind of energy bank in the body and is concentrated in the muscles and liver. In muscles it serves as an immediate source of energy; in the liver it serves as a storage place for glucose and helps to maintain a constant glucose level in the blood.

Cellulose forms the major structural unit of land plants. Wood is about 50% cellulose; cotton fibres are almost entirely cellulose. Cellulose consists of unbranched chains of glucose units linked by β-1,4-glycosidic bonds, with molecular weights averaging more than 500 000 u. The structure of cellulose is shown in Figure 28.20. At first glance

◀ **Figure 28.19 Structure of a starch molecule.** The molecule consists of many glucose units of the kind enclosed in brackets, joined by linkages of the α form. Note the glycosidic bond (blue) is often shown with a 90°-kink in it. This is for ease of representation and does *not* indicate an extra carbon atom.

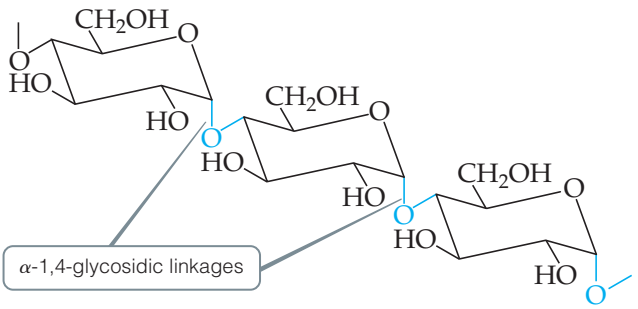
▲ **Figure 28.20 Structure of cellulose.** Like starch, cellulose is a polymer. The repeating unit is shown between brackets. The linkage in cellulose is of the β form, different from that in starch (see Figure 28.19).



this structure looks very similar to that of starch. In cellulose, however, the glucose units are in the β form.

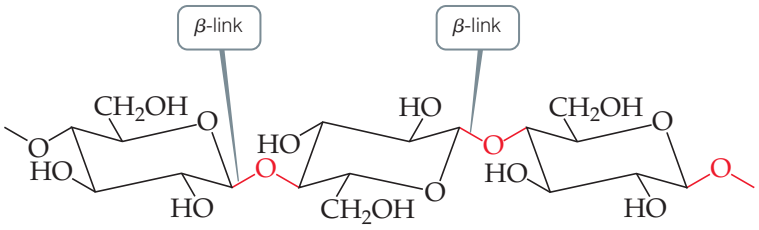
The distinction between starch and cellulose is made clearer when we examine their structures in a more realistic three-dimensional representation, as shown in **Figure 28.21**. The individual glucose units have different relationships to one another in the two structures. Because of this fundamental difference, enzymes that readily hydrolyze starches do not hydrolyze cellulose.

CHEMISTRY AND LIFE Vitamin C



L-Ascorbic acid, more commonly known as vitamin C, is derived from D-glucose via the uronic acid pathway. Although many animals synthesize vitamin C, primates (and guinea pigs) cannot. The structural formula of L-ascorbic acid resembles the furanose form of a cyclic monosaccharide.

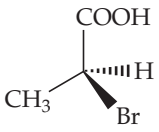
The most important reaction requiring ascorbate as a cofactor is the hydroxylation of proline residues in collagen. This reaction is required for the maintenance of normal connective tissue, as well as for healing wounds. The best-known functions of vitamin C are its use as a reducing agent and antioxidant. Deficiency in vitamin C leads to the disease *scurvy*. Scurvy is characterized by easily bruised skin, muscle fatigue, soft swollen gums, decreased wound healing, haemorrhaging, osteoporosis and anaemia.



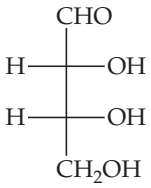
vitamin C

▶ **Figure 28.21 Structural differences in starch and cellulose.** These representations show the geometrical arrangements of bonds about each carbon atom. The glucose rings are orientated differently with respect to one another in the two structures.

(a) starch

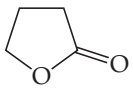


(b) cellulose

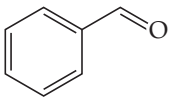


You might eat a kilogram of cellulose and receive no caloric value from it whatsoever, even though the heat of combustion per unit weight is essentially the same for both cellulose and starch. A kilogram of starch, in contrast, would represent a substantial caloric intake. The difference is that the starch is hydrolyzed to glucose, which is eventually oxidized with release of energy. Cellulose, however, is not readily hydrolyzed by enzymes present in the body, so it passes through the digestive system relatively unchanged. Many bacteria contain enzymes, called *cellulases*, that hydrolyze cellulose. These bacteria are present in the digestive systems of grazing animals, such as cattle, which use cellulose for food.

Self-Assessment Exercises

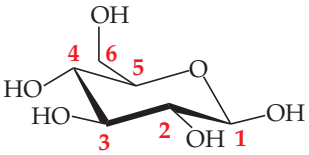


28.22 Which of the following structures represent a carbohydrate molecule?



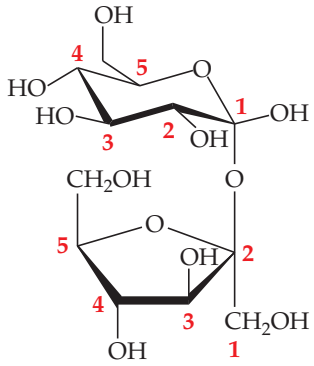
(a)

(b)



(c)

(d)

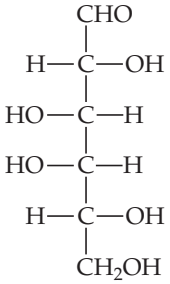


28.23 One representation of D-glucose looks like this:

The carbon atoms are numbered as shown in red. Which atom is the anomeric carbon?

(a) 1 **(b)** 2 **(c)** 3
(d) 4 **(e)** 5 **(f)** 6

28.24 Sucrose is a disaccharide composed of glucose and fructose, shown here with some of the carbon atoms numbered:



How is the linkage between the two sugars described?

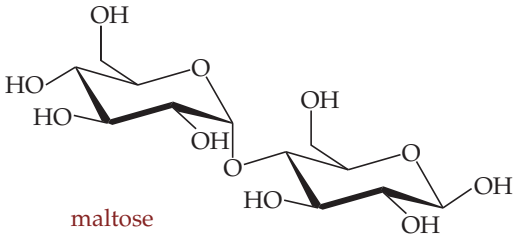
(a) α-1,1-glycosidic bond
(b) β-1,1-glycosidic bond
(c) α-1,2-glycosidic bond
(d) β-1,2-glycosidic bond

Exercises

28.25 **(a)** What is the difference between α-glucose and β-glucose? **(b)** Show the condensation of two glucose molecules to form a disaccharide with a 1,4-α-linkage; **(c)** with a 1,4-β-linkage.

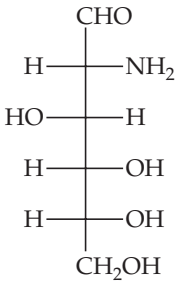
28.26 The structural formula for the linear form of galactose is:

(a) How many chiral carbons are present in the molecule? **(b)** Draw the structure of the pyranose ring form of this sugar.



28.27 **(a)** What is the empirical formula of cellulose? **(b)** What is the unit that forms the basis of the cellulose polymer? **(c)** What form of linkage joins these monomeric units?

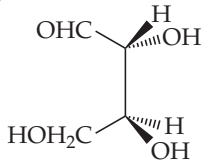
28.28 Monosaccharides can be categorized in terms of the number of carbon atoms (pentoses have five carbons and hexoses have six carbons) and according to whether they contain an aldehyde (prefix *aldo-*, as in aldopentose) or ketone group (prefix *keto-*, as in ketopentose). Classify galactose and ribose in this way.



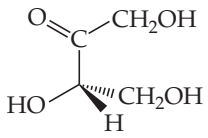
28.29 Aqueous solutions of pure α-D-galactose and β-D-galactose have specific rotations of +52.8° and +150.7°, respectively. After standing for several hours, a solution of α-D-galactose is found to have a new specific rotation of +80°. **(a)** Name the process observed. **(b)** Calculate the percentage of the α-anomer in the solution.

28.30 The structure of maltose is drawn here. **(a)** Is this a monosaccharide, disaccharide and/or a glycoside? **(b)** Identify the anomeric carbon/s. **(c)** Highlight the glycosidic bond and determine its connectivity—for example, 1,2-, 1,3-, 1,4-. **(d)** The identity of the anomer of maltose drawn below can

be determined by the orientation of the OH group on the non-glycosidic anomeric carbon. Which anomer is it?



28.31 The open-chain structure of glucosamine is drawn here. **(a)** Determine whether the structure drawn is D- or L-glucosamine. **(b)** Draw glucosamine in its β-pyranose form.



28.32 Convert each compound to a Fischer projection and hence class it as having D or L configuration.

Answers to Self-Assessment Exercises

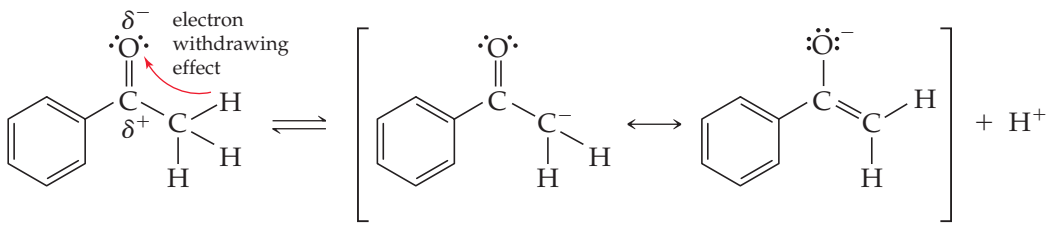
28.22 (b) **28.23** (a) **28.24** (c)

Sample Integrative Exercise

Putting Concepts Together

The halogenation of an aldehyde or ketone is promoted by the presence of a base, for example:

A hydrogen attached to a carbon atom is not normally acidic. **(a)** Suggest a reason why the hydrogen atom α to the carbonyl group may be lost as H^+. The equilibrium between the ketone and the enolate ion lies heavily on the left-hand side. **(b)** Explain what happens to the equilibrium when iodination takes place. **(c)** Predict whether the remaining α hydrogen atoms of the iodomethyl ketone are more or less acidic than those of the starting material. If excess hydroxide solution and iodine are used in this reaction, formation of iodoform, CHI_3, occurs rapidly. **(d)** Predict the structure of the other product formed.

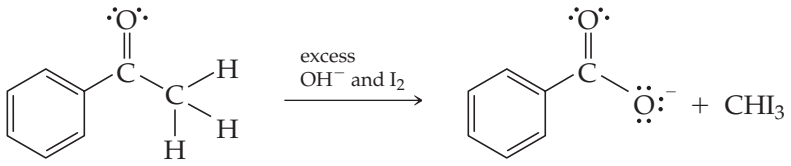


SOLUTION

Analyze This question focuses on factors that affect an acid–base equilibrium.

Plan Examine the structure or equilibrium involved and determine the relative stability of the species involved.

Solve



(a) There are two factors at work here. The carbonyl group has an electron withdrawing influence on the adjacent atoms which increases the ease with which H^+ is lost from the α carbon atom and the resulting anion is resonance stabilized.

(b) Reaction of iodine with the enolate ion lowers the concentration of the enolate ion, which shifts the equilibrium to the right-hand side. Even though there is a very small amount of enolate present at any time, the reaction can go almost to completion as more enolate ion is generated as the iodination reaction proceeds.

(c) Substitution of a hydrogen atom with a more electronegative halogen atom increases the electron withdrawing effect on the remaining hydrogen atoms and consequently makes them more acidic.

(d) A carboxylic acid is the other product from this reaction which, under the basic conditions present, will exist as the carboxylate ion.

Chapter Summary and Key Terms

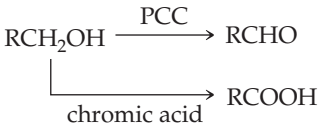
SECTIONS 28.1 AND 28.2 **Aldehydes** and **ketones** are compounds containing a **carbonyl group** (C═O). Aldehydes contain the functional group CHO, whereas ketones contain a carbonyl group within a hydrocarbon chain. The polarity of the carbonyl group makes it susceptible to nucleophilic attack on carbon. Aldehydes and ketones can be prepared by the oxidation of 1° or 2° alcohols, respectively. Another approach to their preparation is through the **ozonolysis** of alkenes.

SECTION 28.3 The conversion of ketones and aldehydes to alcohols can occur by attack of an **organometallic compound** such as a **Grignard reagent** (RMgX) that acts as the nucleophile. Grignard reagents are equivalent to **carbanions** in reactivity. Reaction of aldehydes and ketones with amines yield **imines** and with alcohols yield **hemiacetals** and **acetals**. Imines can be catalytically hydrogenated to yield amines. **Metal hydrides** such as sodium borohydride act as a source of **hydride ion**, which can reduce ketones and aldehydes to alcohols. The **nucleophilic addition** reaction of aldehydes and ketones with cyanide ion ($^-$CN) leads to the formation of **cyanohydrins**, which can be converted to α-hydroxy acids by hydrolysis of the nitrile group. Compounds containing the CN functional group are often called **nitriles**. **Tautomerism** occurs in carbonyl compounds bearing an **α-hydrogen**.

SECTION 28.4 **Carbohydrates**, which are polyhydroxyaldehydes and ketones, are the major structural constituents of plants and are a source of energy in both plants and animals.

Glucose is the most common **monosaccharide**, or simple sugar. Monosaccharides are classed as **aldoses** or **ketoses** depending on what functional group is present in its open-chain form. The open-chain form of a monosaccharide is often drawn as a **Fischer projection**, which is an easy way to determine whether the monosaccharide is of the D- or L-form.

Monosaccharides are usually drawn as a **Haworth projection** in their cyclic form. Two cyclic forms are common: the pyranose (six-membered ring) and furanose (five-membered ring) forms. Monosaccharides are classed as one of two **anomers** according to the stereochemistry of the groups on the **anomeric carbon**. **Mutarotation** occurs when the two anomeric forms come to equilibrium in solution. A **glycoside** is formed when some group other than OH is bonded to the anomeric carbon. Glycosides do not interconvert between anomeric forms and do not exist in open chain and cyclic forms. The link between two monosaccharide units via the anomeric carbon is termed the **glycosidic bond**.



Two monosaccharides can be linked together by means of a condensation reaction to form a disaccharide. **Polysaccharides** are complex carbohydrates made up of many monosaccharide units joined together. The three most important polysaccharides are **starch**, which is found in plants; **glycogen**, which is found in animals; and **cellulose**, which is also found in plants. Starch molecules that form largely unbranched chains are called **amylose**, whereas those that are highly branched are called **amylopectins**.

Key Skills

- Understand how to identify aldehyde and ketone functional groups and use systematic approaches to naming. (Section 28.1)
- Be able to predict that the oxidation of primary alcohols gives aldehydes and oxidation of secondary alcohols give ketones and be able to quote the reagents necessary to undertake these interconversions. (Section 28.2)
- Understand the generality of nucleophilic addition to carbonyl compounds in the context of acetals, hemiacetals, imines and cyanohydrins. (Section 28.3)
- Be able to form and use Grignard reagents for nucleophilic addition. (Section 28.3)
- Be able to identify the major carbohydrates and identify whether a sugar is a mono-, di- or polysaccharide. (Section 28.4)
- Understand the stereochemistry of carbohydrates, the difference between α- and β-anomers, D and L and how it relates to carbohydrates. (Section 28.4)
- Be able to draw and interpret Fischer projections. (Section 28.4)

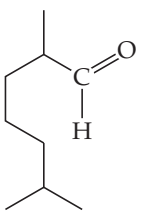
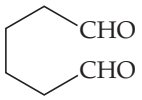
Visualizing concepts

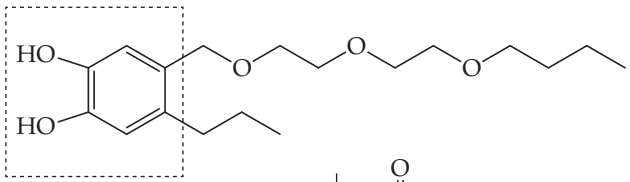


28.33 Draw the structure of the alcohol precursor, its systematic name and the reaction conditions you might use to obtain the following compounds by oxidation. [Section 28.2]

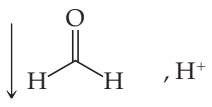
(a)



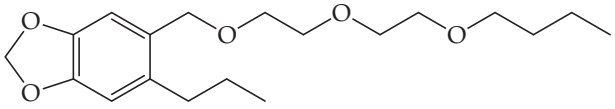
(b) $CH_3CH_2CH_2CH_2CH_2CHO$



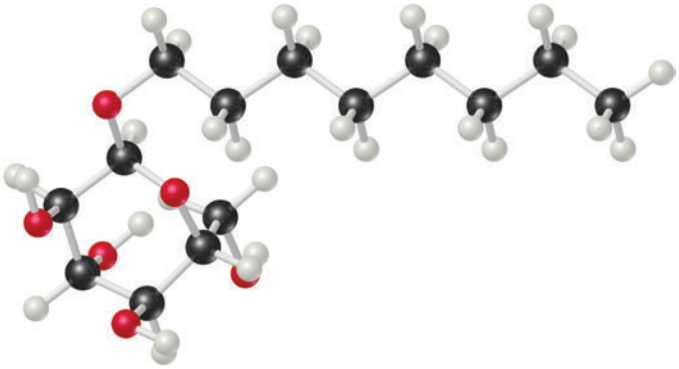
(c)



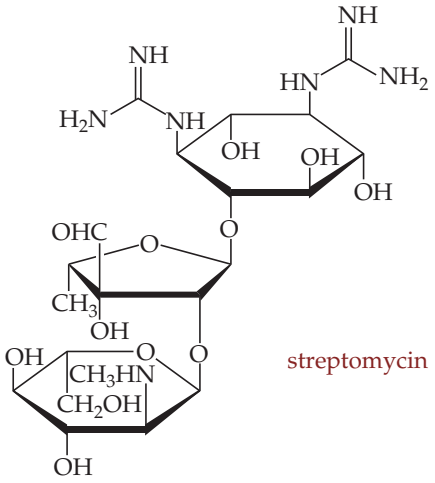
(d)



28.34 Piperonyl butoxide is used commercially as an additive to pyrethrum-based insecticides to enhance their effect. In this case, the cyclic ether is prepared by the action of formaldehyde on a catechol derivative. By what other functional group might this cyclic ether be named? [Section 28.3]

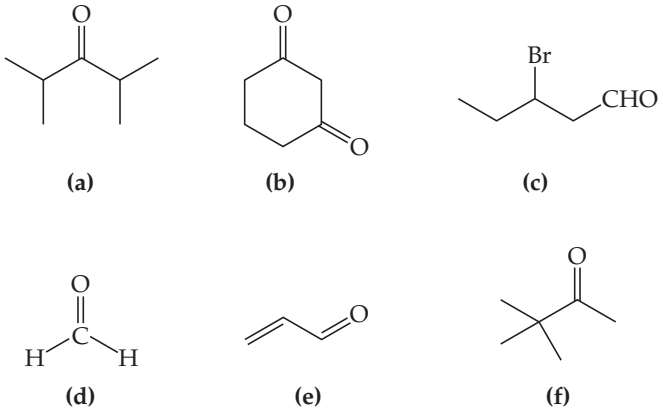


a catechol



piperonyl butoxide

28.35 The molecule *n*-octylglucoside is widely used in biochemical research as a non-ionic detergent for "solubilizing" large hydrophobic protein molecules. What characteristics of this molecule are important for its use in this way? [Section 28.4]



28.36 Streptomycin is a potent antibiotic produced by certain soil types. Its structure is shown here. Highlight the furanose and pyranose rings in streptomycin. [Section 28.4]

streptomycin

Aldehydes, Ketones and the Carbonyl Group (Section 28.1)

28.37 Name the following compounds:

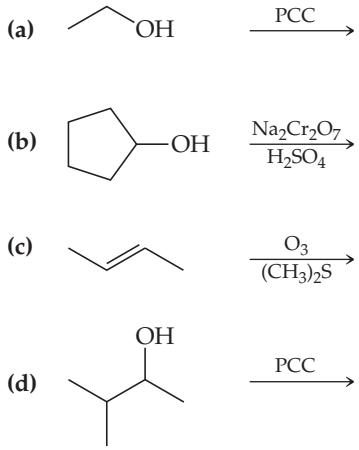
(a) (b) (c) (d) (e) (f)

28.38 Draw the structural formula for the following aldehydes or ketones: **(a)** propanal, **(b)** 2-pentanone, **(c)** 3-methylbutanone, **(d)** 2-methylbutanal.

28.39 Draw the condensed structural formulas for two molecules containing a carbonyl group with the formula C_3H_4O.

28.40 Identify the functional groups in each of the following compounds:

(a) $CH_3\overset{\overset{O}{\|}}{C}CH_2CH_3$ **(b)** $CH_3C(=O)OH$



(c) $CH_2CH_2CH_3$ (OH) **(d)** $CH_3O\overset{\overset{O}{\|}}{C}CH_2CH_3$

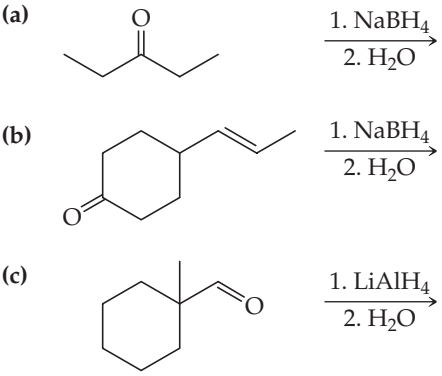
(e) $H_2N\overset{\overset{O}{\|}}{C}CH_3$ **(f)** $CH_3CH_2NHCH_3$

Preparation of Aldehydes and Ketones (Section 28.2)

28.41 A chemical oxidation requires the species being oxidized to lose electrons. Write the half-equation for the oxidation of 2-propanol to propanone

28.42 Provide the structure for the major organic product in the following reactions:

(a) OH —PCC→



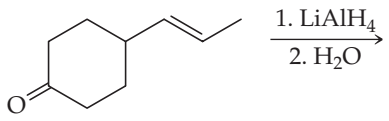
(b) OH —$Na_2Cr_2O_7$, H_2SO_4→

(c) —O_3, $(CH_3)_2S$→

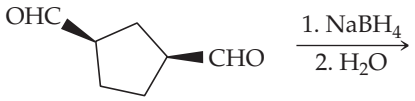
(d) OH —PCC→

Reactions of Aldehydes and Ketones (Section 28.3)

28.43 Provide the major organic product(s) of the following reactions:



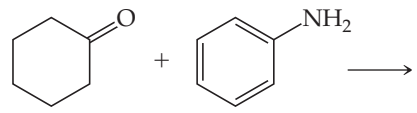
(a) —1. $NaBH_4$, 2. H_2O→



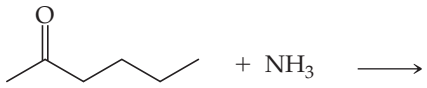
(b) —1. $NaBH_4$, 2. H_2O→

(c) —1. $LiAlH_4$, 2. H_2O→

(d)

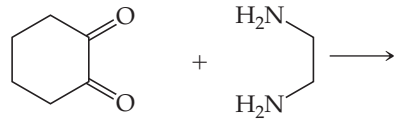


(e)



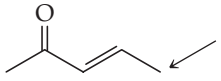
28.44 Why is it only possible to from imines with primary amines?

28.45 Draw the major product expected under the following conditions:

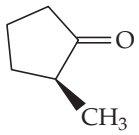


(a)

(b)



(c)

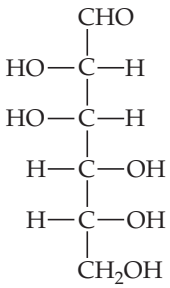


28.46 Write a mechanism for the acid-catalyzed reaction of methanol with propanal to form an acetal. What solvent would you choose to maximize the conversion of propanal to its acetal?

28.47 **(a)** Draw the product formed when acid is added to a solution of 5-hydroxypentanal. **(b)** What general class of compound is this?

28.48 **(a)** Draw the resonance contributors for the structure you would form by deprotonating at the methyl group indicated with the arrow. **(b)** Identify the keto and enolate forms. **(c)** What might you say about the acidity of these methyl protons compared to pentane? **(d)** What other tautomer is possible?

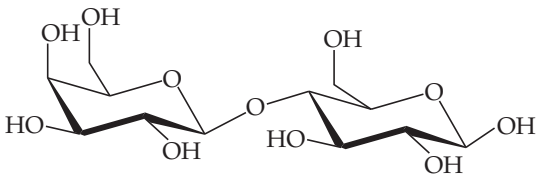
28.49 How many Hs in this compound are replaced by Ds when it is shaken in D_2O containing trace acid?



28.50 How would you prepare 2-cyanocyclohexanone from cyclohexanone?

Carbohydrates (Section 28.4)

28.51 In your own words, define the following terms: **(a)** carbohydrate, **(b)** monosaccharide, **(c)** disaccharide, **(d)** anomer, **(e)** glycoside.

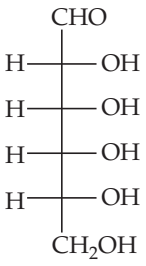


28.52 The structural formula for the linear form of D-mannose is as follows:

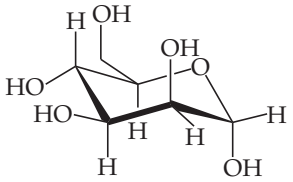
(a) How many chiral carbons are present in the molecule? **(b)** Draw the structure of the pyranose ring form of this sugar.

28.53 Starch, glycogen, and cellulose are all polymers of glucose. **(a)** What are the structural differences between them? **(b)** Explain the structural differences that cause the difference in water solubility between these polymers.

28.54 The structure of lactose is shown. **(a)** Is this a monosaccharide, disaccharide and/or a glycoside? **(b)** Identify the anomeric carbon/s. **(c)** Highlight the glycosidic bond and determine whether it is a 1,2-, 1,3- or 1,4-glycosidic bond.

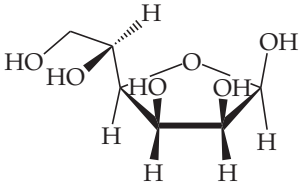


lactose

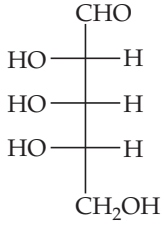


28.55 *Arbutin* is the principal antibacterial agent of the traditional herbal medicine called *uva-ursi*. Its systematic name is 4-hydroxyphenyl-β-D-glucopyranoside. Draw the structure of arbutin.

28.56 Convert each into a Haworth projection.

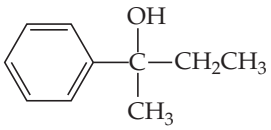


(a) Convert into an α-pyranose form



(b) Convert into an α-pyranose form

(c) Convert into an α-pyranose form



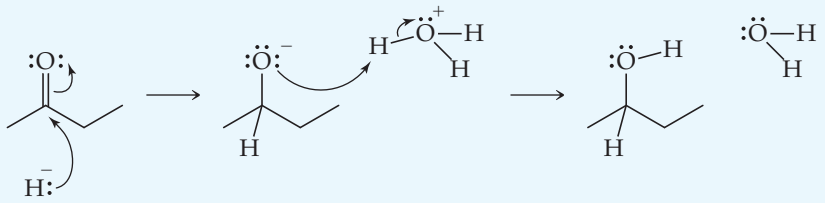
(d) Convert into a β-furanose form

28.57 Give the structure of the alkene that would yield propanone and propanal upon ozonolysis.

Integrative Exercises

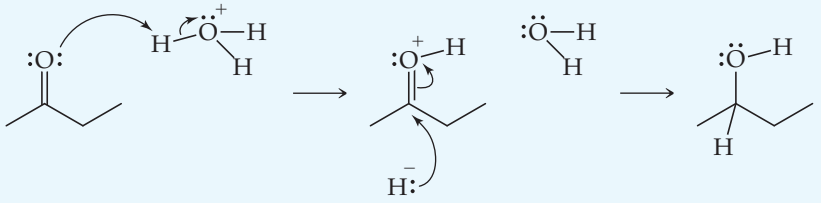
28.58 2-Phenyl-2-butanol can be synthesized by three different combinations of a Grignard reagent and a ketone. Show each combination.

28.59 Acetone, $(CH_3)_2CO$, is widely used as an industrial solvent. **(a)** Draw the Lewis structure for the acetone molecule, and predict the geometry around each carbon atom. **(b)** Is the acetone molecule polar or non-polar? **(c)** What kinds of intermolecular attractive forces exist between acetone molecules? **(d)** 1-Propanol, $CH_3CH_2CH_2OH$, has a molecular weight that is very similar to that of acetone, yet acetone boils at 56.5 °C and 1-propanol boils at 97.2 °C. Explain the difference.



28.60 **(a)** How many stereocenters are present in 3-methylpentan-2-ol? List the configuration of the stereocenters for each possible isomer and indicate the relationship (enantiomers or diastereoisomers) that exists between the isomers. **(b)** Write the equation for the reaction of 3-methylpentan-2-ol with acidified dichromate solution. **(c)** How many stereoisomers are there in the product of this reaction? **(d)** Draw two structures representing the enol forms of this product. **(e)** Describe the change in optical rotation that you might expect if you performed this reaction on a single stereoisomer of starting material.

28.61 Use Figure 8.8 on page 283 to determine the difference in electronegativity of the following pairs of atoms and classify the bond between them as ionic, polar covalent or non-polar covalent: Na—Cl; Mg—Cl; H—Cl; C—Cl; C—Mg; C—C.



28.62 Use the following data to determine whether glucose ($C_6H_{12}O_6$) or sucrose ($C_{12}H_{22}O_{11}$) provides the greatest energy per gram. $\Delta_{combustion}H°$ (glucose) = −2803 kJ mol^{-1}; $\Delta_{combustion}H°$ (sucrose) = −5640 kJ mol^{-1}.

Design an Experiment

A nucleophilic addition reaction, the reduction of a ketone for example, is a two-step process in which the nucleophile adds to the carbon of the carbonyl followed by protonation of the oxygen. The mechanism may be written as follows:

But what if protonation of oxygen was the first step? This is shown in this mechanism:

How are you going to distinguish the two possibilities? Assuming that the first step in each case is the slow step of the reaction, describe the kinetic experiments you might conduct to determine which mechanism is the likely one. What precautions do you need to take if you were to add a water-sensitive compound such as lithium aluminum hydride to a substrate that had been treated with aqueous acid? The intermediate drawn in the second mechanism is resonance stabilized. Draw the other resonance contributor. From your knowledge of Lewis structures, is the contributor you have just drawn or the intermediate in the first mechanism likely to be more stable? Why?

CARBOXYLIC ACIDS AND THEIR DERIVATIVES

29.1 | Carboxylic Acids

Carboxylic acids are weak acids that are widely distributed in nature and are commonly used in consumer products.

One of the most common carboxylic acids is acetic acid, which is the primary ingredient of vinegar. The acetyl group is central to the metabolism of carbohydrates and fats through its role in the enzyme acetyl CoA. Acetic acid is also an important industrial chemical with a global production of approximately 6.5 million metric tons each year. For example, aspirin (acetylsalicylic acid) is formed by the reaction of acetic acid with salicylic acid. Vinyl acetate is just one polymer precursor that is also derived from acetic acid. When vinyl acetate is polymerized, the product is poly(vinyl acetate), which is used in water-based latex paints and in glues for paper and wood.

By the end of this section, you should be able to:

- Recognize the carboxylic acid functional group and name simple molecules containing it
- Understand the connection between acid–base chemistry and solubility

Carboxylic acids contain the *carboxyl* functional group (a combination of *carbo*nyl and hydr*oxyl* groups), which is often written as COOH or CO_2H.

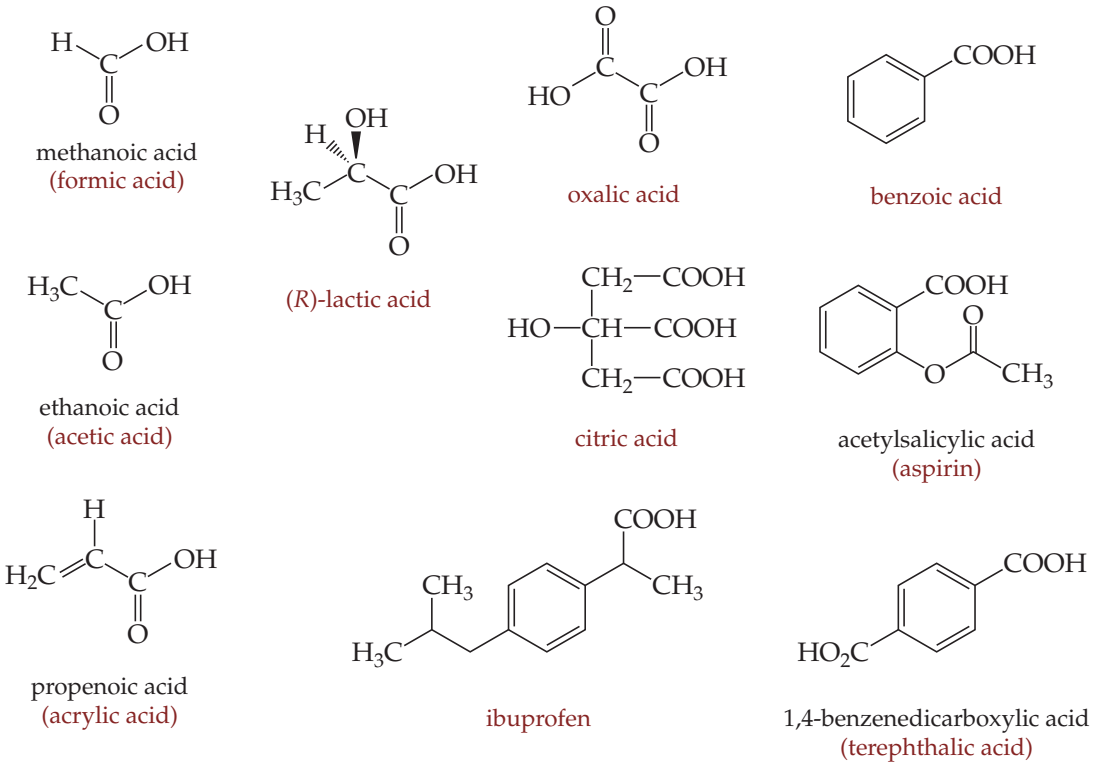

Figure 29.1 shows the structural formulas of several carboxylic acids. Notice that oxalic acid and citric acid contain two and three carboxyl groups, respectively. Oxalic acid, which is found in high concentration in rhubarb leaves, is poisonous if ingested. Terephthalic acid is a key component of PET, a durable polymer used in packaging. Lactic acid is generated in muscle cells and tissue during the synthesis of adenosine triphosphate (ATP) from carbohydrates during sustained exercise. Ibuprofen is an analgesic, used to treat pain and inflammation. Benzoic acid is often used as a fungicide.

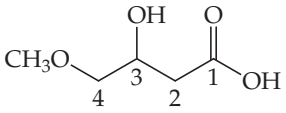
Structure, Properties, and Nomenclature

The carboxyl functional group (COOH) that characterizes carboxylic acids is constituted by a sp^2 hybridized carbon atom bonded to two oxygen atoms. One oxygen is sp^2 hybridized, leading to the formation of σ- and π-bonds with carbon (leading to a C—O double bond). The other oxygen is sp^3 hybridized, leading to a C—O single bond.

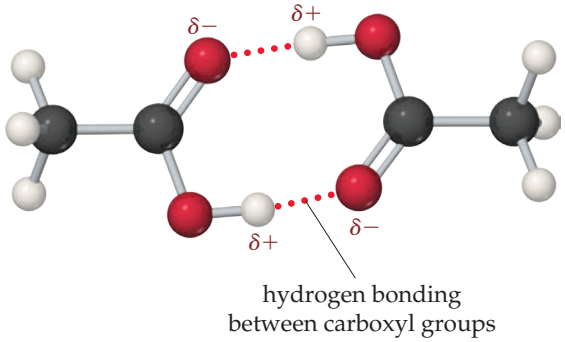
In Chapter 11, we studied the phenomenon of hydrogen bonding. We have already described the need for two components: a hydrogen bond donor (such as O—H, N—H) and a hydrogen bond acceptor, which is usually an electronegative atom containing a lone

Go Figure Which of these substances have both a carboxylic acid functional group and an alcohol functional group?



▲ **Figure 29.1 Structural formulas of some common carboxylic acids.** The IUPAC names are given in black type for the monocarboxylic acids, but they are generally referred to by their common names.

pair of electrons such as O, N or F. In the case of carboxylic acids, both hydrogen bond donor and acceptor are present in the same functional group in a favourable geometry. As a result, carboxylic acids are able to dimerize (**Figure 29.2**) in concentrated solutions or as neat (without solvent) liquids. Dimerization is as a result of the intermolecular hydrogen bonding between the carbonyl oxygen and the OH group. Consequently, carboxylic acids have relatively high boiling points (**Table 29.1**).

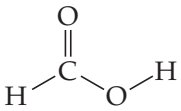


Alkane-derived carboxylic acids have the general formula $C_nH_{2n}O_2$, and are named based on the longest carbon chain (parent alkane) bearing the carboxyl group, although sometimes common names are still employed (**Figure 29.6**). The *e* of the alkane is replaced by *oic acid* to signify the carboxylic acid. Table 29.1 gives the names of the first 10 straight-chain carboxylic acids, their condensed formulas and their melting points.

In terms of the nomenclature hierarchy we have been developing for organic chemistry, the carboxylic acids sit at the pinnacle. All other functional groups we have come across are named as substituents if a carboxylic acid group is present. For example, 3-hydroxy-4-methoxybutanoic acid is *not* named as the alcohol, but rather the carboxylic acid.

3-hydroxy-4-methoxybutanoic acid

Go Figure Would dimerization be aided by polar or non-polar solvents?



▲ **Figure 29.2 Carboxylic acid dimerization.** In concentrated solution or as neat liquids, carboxylic acids are able to dimerize through intermolecular hydrogen bonding.

TABLE 29.1 First 10 members of the aliphatic carboxylic acid series

Molecular formula	Condensed structural formula	IUPAC name (common name)	Melting point (°C)*	Boiling point (°C)*
CH_2O_2	HCOOH	Methanoic (formic) acid	8	101
$C_2H_4O_2$	CH_3COOH	Ethanoic (acetic) acid	17	118
$C_3H_6O_2$	CH_3CH_2COOH	Propanoic (propionic) acid	−24	141
$C_4H_8O_2$	$CH_3CH_2CH_2COOH$	Butanoic (butyric) acid	−6	163
$C_5H_{10}O_2$	$CH_3CH_2CH_2CH_2COOH$	Pentanoic (valeric) acid	−20	186
$C_6H_{12}O_2$	$CH_3CH_2CH_2CH_2CH_2COOH$	Hexanoic (caproic) acid	−4	205
$C_7H_{14}O_2$	$CH_3CH_2CH_2CH_2CH_2CH_2COOH$	Heptanoic (enanthylic) acid	−10	223
$C_8H_{16}O_2$	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2COOH$	Octanoic (caprylic) acid	16	239
$C_9H_{18}O_2$	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2COOH$	Nonanoic (pelargonic) acid	9	253
$C_{10}H_{20}O_2$	$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2CH_2COOH$	Decanoic (capric) acid	29	219

* Rounded to the nearest degree.

Carboxylic acids have higher melting and boiling points than their corresponding alkanes, alcohols, aldehydes or ketones because of their added polarity and ability to hydrogen bond (Table 29.1). Although the boiling points of carboxylic acids increase with molecular size in a regular manner, their melting points do not. Unbranched acids made up of an even number of carbon atoms have melting points higher than their odd-numbered homologues, having one more or one less carbon. This difference reflects subtle changes in intermolecular attractive forces in the solid state. The even-numbered carboxylic acids are able to interact more strongly than their odd-numbered homologues, which increases the amount of energy needed to break the interactions in order to melt, thus increasing the melting point. For example, decanoic acid is a waxy solid at room temperature. Formic acid and acetic acid are special in that their melting points seem appropriate for much higher molecular weight species. The reason is that the properties of formic acid and acetic acid are dominated by the hydrogen bonding interactions of the carboxyl group with other molecules. These interactions occur more often because the COOH group makes up a large proportion of the molecule.

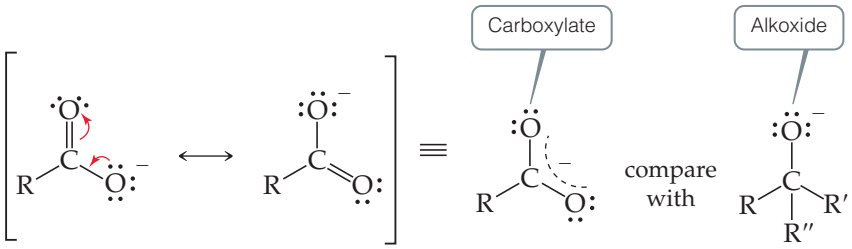
formic acid

The number of carbon atoms in the carboxylic acid chain not only affects its melting point, but also its solubility in water. Typically, a carboxylic acid is more water soluble than its alcohol analogue because of more extensive hydrogen bonding capacity. For example, formic, acetic, propanoic and butanoic acids are all infinitely soluble in water. As the length of the carbon chain increases, however, the polar COOH group becomes an ever decreasing proportion of the molecule, and the molecule behaves more like a hydrocarbon in terms of its solubility. The solubility of the carboxylic acids in water decreases correspondingly. In contrast, the solubility of carboxylic acids in non-polar solvents increases as the non-polar hydrocarbon chain length increases. Hence decanoic acid is more "alkane-like" than acetic acid.

Acidity

We have already mentioned that carboxylic acids are weak acids. **Table 29.2** compares the pK_a values for several organic and inorganic acids. Being a weak acid, carboxylic acids dissociate by the following equation:

$$RCOOH + H_2O \rightleftharpoons RCOO^- + H_3O^+ \qquad [29.1]$$

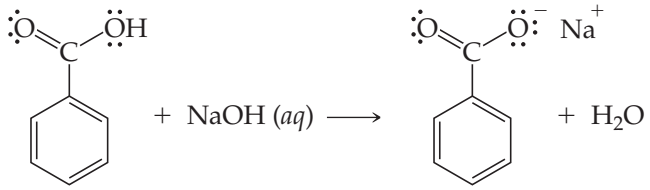


One of the main contributing factors that allows the pK_a of a carboxylic acid to be lower than that of the corresponding alcohol—for example, acetic acid (pK_a 4.8) compared with ethanol (pK_a 16)—is the relative stability of the two conjugate bases, that is, the **carboxylate anion** versus the alkoxide anion. The carboxylate anion is resonance stabilized (**Figure 29.3**), having two contributors to the overall structure, whereas the alkoxide

TABLE 29.2 Relative pK_a values for selected carboxylic acids*

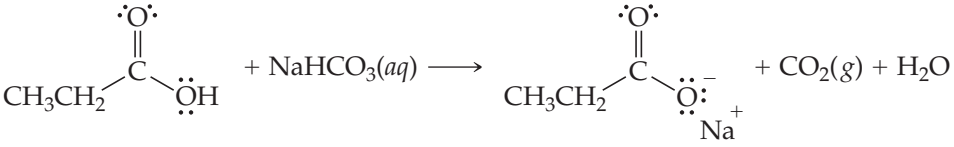
Compound	Structural formula	pK_a	
Hydrogen chloride	HCl	−7	**Strong acid**
Sulfuric acid	H_2SO_4	−5	
Trichloroacetic acid	Cl_3CCOOH	0.7	
Dichloroacetic acid	$Cl_2CHCOOH$	1.5	
Chloroacetic acid	$ClCH_2COOH$	2.8	
Acetic acid	CH_3COOH	4.8	
Water	H_2O	15.7	**Weak acid**

* Error in measurement ± 0.2.



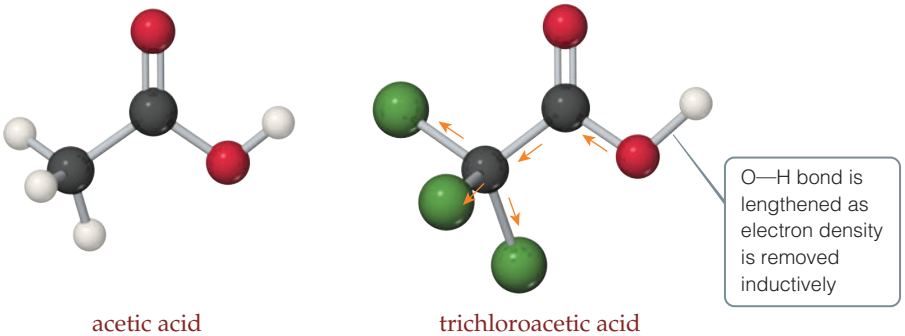
▶ **Figure 29.3** **The carboxylate anion is resonance stablilized.**

is not resonance stabilized. As a result, the carboxylate anion is not as reactive as the alkoxide.



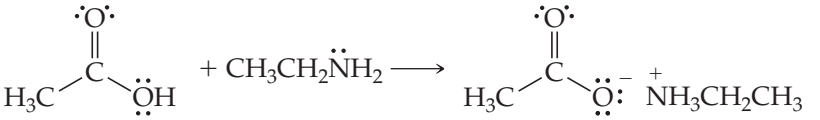
The pK_a of a carboxylic acid can be influenced inductively by substituents (Table 29.2). The addition of an electron-withdrawing substituent such as a halide adjacent to the COOH group reduces the pK_a by weakening the carboxyl O—H bond (**Figure 29.4**). For example, the pK_a of acetic acid is 4.8 whereas the pK_a of chloroacetic acid is 2.8. The addition of more chlorine atoms reduces the pK_a further (for example, pK_a of trichloroacetic acid is 0.7). The inductive effect is reduced dramatically as the number of intervening bonds between the electron-withdrawing substituent and the COOH group increases. Such an effect is seen in amino acids.

Carboxylic acids react with bases such as NaOH, $NaHCO_3$ or Na_2CO_3 to form the corresponding sodium carboxylate salt. For example, when benzoic acid reacts with an aqueous solution of NaOH, sodium benzoate and water are formed. The conversion of the acid form to the carboxylate salt enhances aqueous solubility. Note that the salts of carboxylic acids are named in the same order as other salts: first cation, then anion. The name of the anion is derived from the carboxylic acid by replacing *-oic acid* with *-oate*.



benzoic acid sodium benzoate [29.2]

When propanoic acid is reacted with a solution of sodium hydrogen carbonate ($NaHCO_3$), the products are sodium propanoate, carbon dioxide and water. The reaction of carboxylic acids with carbonates such as $NaHCO_3$, Na_2CO_3, K_2CO_3 and $CaCO_3$ has special significance. Oral tablets such as Berocca™ and Aspro Clear™ combine carbonates with vitamin acids or citric acid to dissolve the tablet contents in water. The fizz associated with their dissolution is caused by the release of CO_2.



propanoic acid sodium propanoate [29.3]

▶ **Figure 29.4** **Inductive effect on pK_a.** Electron-withdrawing substituents (for example, Cl, NO_2) adjacent to the carboxyl group are able to weaken the carboxyl O—H bond relative to acetic acid, making the compound a stronger acid. Any effect of a substituent that acts "through bonds" rather than by providing an alternative resonance structure, is called an **inductive effect**.

acetic acid trichloroacetic acid

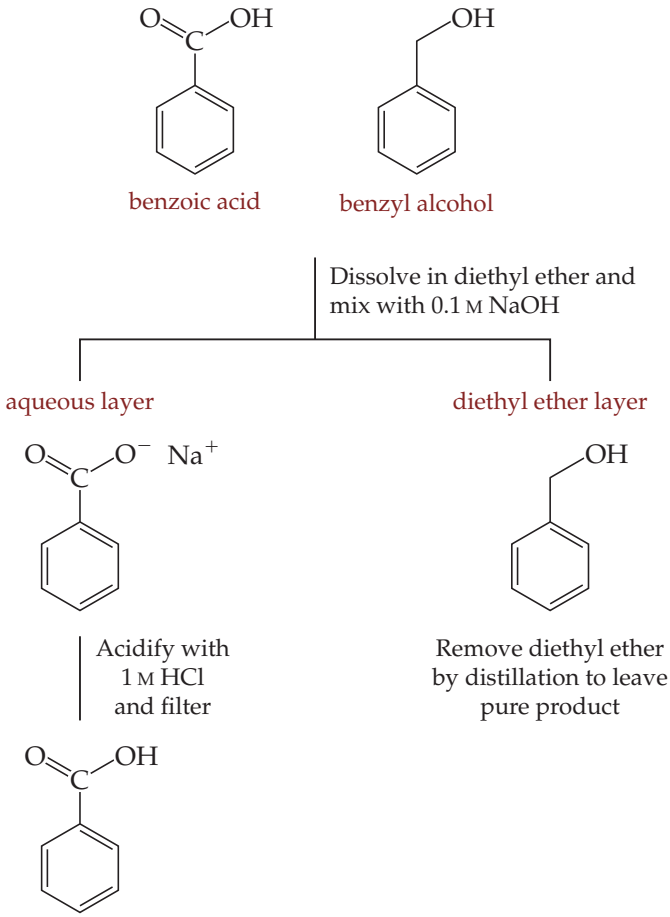
Carboxylic acids react with amines to form ammonium salts. For example, the reaction of acetic acid with ethanamine yields the ammonium salt, ethyl ammonium acetate:

[29.4]

The reaction types demonstrated in Equations 29.2–29.4 are extremely useful in the preparation of water-soluble compounds, particularly for the pharmaceutical industry. The salt products are highly soluble in aqueous solutions and can be achieved under mild conditions or formed *in situ*, as in the case of soluble aspirin. Water solubility aids in absorption of the therapeutic agent. This reaction is also useful in the *resolution* of chiral carboxylic acids.

Sample Exercise 29.1

Properties of Carboxylic Acids



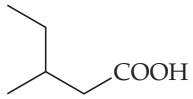
Describe a way of separating benzoic acid from benzyl alcohol.

SOLUTION

Analyze We are asked how to separate an alcohol from a carboxylic acid containing a similar structure.

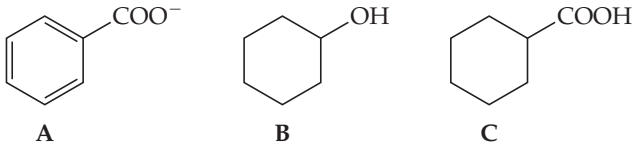
Plan The carboxylic acid and alcohol functional group have a different reactivity and so can be separated using chemical reactions.

Solve In this case, we can use the differences in acidity between the two compounds and the aqueous solubility of the benzoate anion to separate them.



Practice Exercise

List the following set of carboxylic acids in order of acidity (lowest first): **(a)** butanoic acid, **(b)** 2-iodobutanoic acid, **(c)** 2-fluorobutanoic acid, **(d)** trifluoroacetic acid, **(e)** 3-iodobutanoic acid.



Self-Assessment Exercises

29.1 Name:

(a) 2-ethylbutanoic acid
(b) 3-ethylbutanoic acid
(c) 3-methylpentanoic acid

29.2 Order the following species in terms of increasing solubility in water.

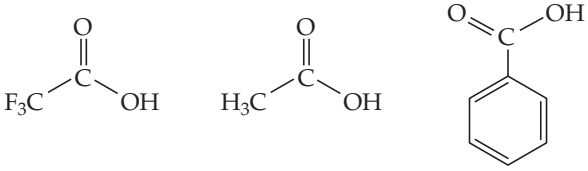
(a) A < B < C
(b) A < C < B
(c) B < C < A
(d) B < A < C

Exercises

29.3 Give the IUPAC name for each of the following acids:

(a) HCOH (O double-bonded)

(b) $CH_3CH_2CH_2COH$ (O double-bonded)

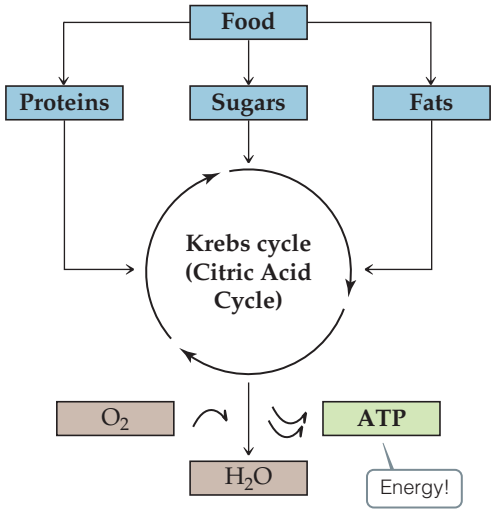


(c) $CH_3CH_2CHCH_2COH$ (O double-bonded; CH_3 branch)

29.4 Draw the structure for 2-bromobutanoic acid and indicate any stereogenic center within the molecule. How many stereoisomers are possible?

29.5 **(a)** Would you expect pure acetic acid to be a strongly hydrogen bonded substance? **(b)** How do the melting and boiling points of the substance support your answer? (See Table 29.1.)

29.6 Describe how you would distinguish between a carboxylic acid and its ester, using nothing more than an aqueous solution of sodium hydrogencarbonate ($NaHCO_3$, sodium bicarbonate).



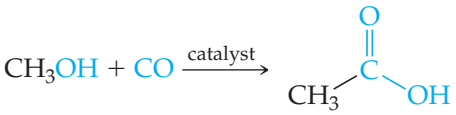
29.7 Which of the following carboxylic acids is the most acidic? Why?

Answers to Self-Assessment Exercises

29.1 (c) **29.2** (c)

29.2 | Preparation of Carboxylic Acids

Citric acid is a tricarboxylic acid with the structure shown in Figure 29.1. It is used in the food industry as a flavoring agent and acidifier and naturally occurs in fruits, particularly citrus fruits, where it may by up to 8% of the dry weight of lemons and limes. It plays a central role in the metabolism of all animals, plants, and bacteria as part of the Citric Acid Cycle, which is also called the Tricarboxylic Acid Cycle (TCA cycle) or Krebs Cycle. While the cycle has a number of important functions, it is responsible for converting the fats and carbohydrates we eat, together with oxygen, into a usable source of energy. Not surprisingly, it is one of the most studied biochemical pathways. The 1953 Nobel prize in Physiology and Medicine was awarded to Hans Adolf Krebs for his pioneering work on the cycle.

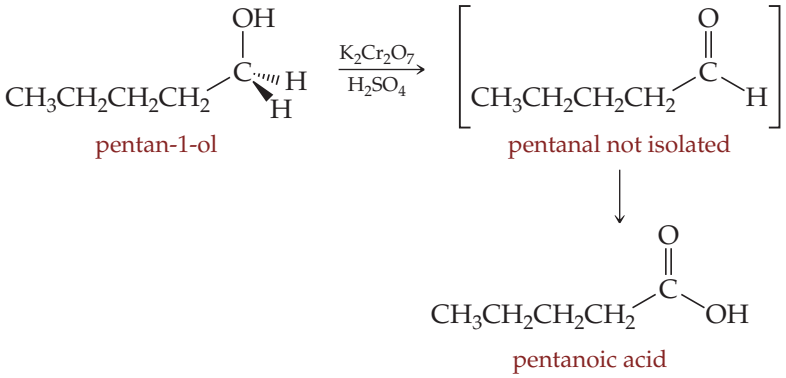


By the end of this section, you should be able to:

- Identify a number of preparation routes to simple carboxylic acids

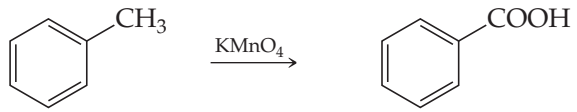
Carboxylic acids can be synthesized through the oxidation of 1° alcohols, such as ethanol or propan-1-ol. Under appropriate conditions, the corresponding aldehyde may also be isolated as the first product of oxidation.

The oxidation of ethanol to acetic acid in air (with help from enzymes within wine) is responsible for causing wines to turn sour, producing vinegar.



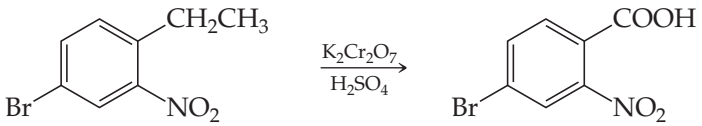
Acetic acid is produced industrially by the reaction of methanol with carbon monoxide in the presence of a rhodium catalyst:

[29.5]



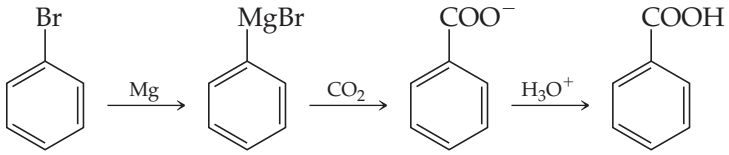
This reaction involves, in effect, the insertion of a carbon monoxide molecule between the CH_3 and OH groups. A reaction of this kind is called *carbonylation*.

When primary alcohols are oxidized using strong oxidising agents such as potassium dichromate ($K_2Cr_2O_7$) in H_2SO_4 or chromic acid ($CrO_3/H_2O/H_2SO_4$), they are converted to the corresponding carboxylic acid via the intermediary aldehyde. Aldehydes are more prone to oxidation than alcohols. In fact, left to stand, aldehydes are oxidized readily by the oxygen within air, also forming carboxylic acids. Hence, when the oxidation reaction of a primary alcohol proceeds, any aldehyde formed within the reaction is quickly converted to the carboxylic acid. For example, the oxidation of pentan-1-ol in the presence of acidic $K_2Cr_2O_7$ gives pentanoic acid as the major product:

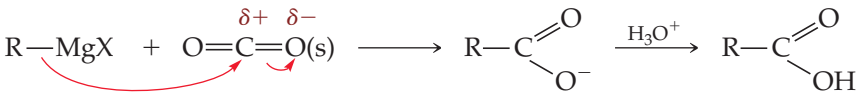


[29.6]

Toluene and other aromatics containing a benzylic CH group are easily oxidized to the corresponding benzoic acid on boiling with solutions of potassium dichromate ($K_2Cr_2O_7$) or potassium permanganate ($KMnO_4$). This occurs even if the benzylic carbon contains one, two or three C—C bonds.



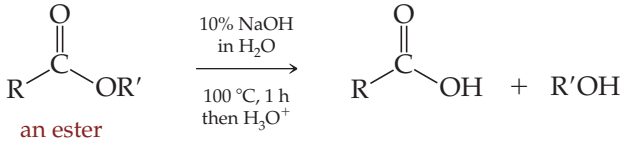
toluene benzoic acid [29.7]



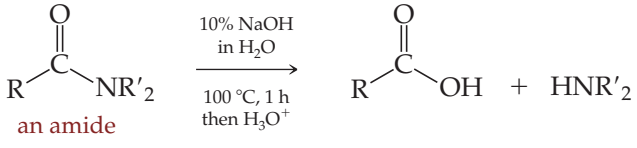
4-bromo-1-ethyl-2-nitrobenzene 4-bromo-2-nitrobenzoic acid [29.8]

Benzoic acids can also be prepared by the reaction of phenylmagnesium bromide with carbon dioxide (in the form of dry ice), followed by protonation.

[29.9]

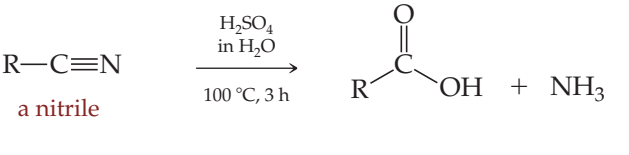


Recall from Chapter 28 that Grignard reagents make excellent nucleophiles, capable of reacting with carbonyl-containing compounds such as aldehydes and ketones. Generally speaking, the action of Grignard reagents (RMgX) on solid carbon dioxide to form carboxylic acids occurs by the following mechanism:



[29.10]

Carboxylic acids are also formed by the hydrolysis of certain functional groups. In the next section we discuss the reaction of carboxylic acids with alcohols to give an ester and with amines to give amides. We will also discuss the hydrolysis of esters to give carboxylic acids, using both acidic and basic conditions.



Carboxylic acids can be prepared by the hydrolysis of amides. It is fair to say that secondary and tertiary amides hydrolyse more slowly than primary amides under the conditions shown here. Finally, carboxylic acids can be formed readily by the hydrolysis of nitriles (RCN) under acidic conditions.

an ester [29.11]

an amide [29.12]

a nitrile [29.13]

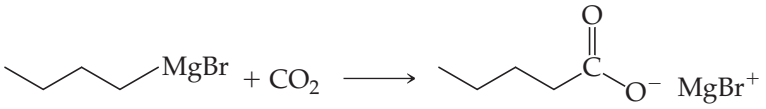
Sample Exercise 29.2

Preparation of Carboxylic Acids

Describe a way of preparing pentanoic acid from 1-bromobutane.

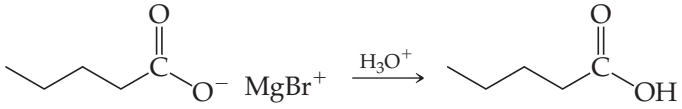
SOLUTION

Analyze We are asked to propose a synthesis of a carboxylic acid from a specific starting material and note that the target compound contains one more carbon atom than the reactant.



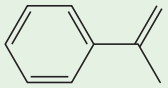
Plan There are two common methods of extending the number of carbon atoms in a chain: either a nucleophilic substitution by the cyanide ion or the addition of a Grignard reagent to a compound containing a C=O bond. Both could be extended to form a carboxylic acid. In the first case, hydrolysis of a nitrile under acid conditions will yield a carboxylic acid. In the second case, reaction of a Grignard reagent with carbon dioxide followed by dilute acid will furnish a carboxylic acid. We will choose the second route.

Solve Grignard reagents are very sensitive to moisture so are usually formed at the time they will be used in a "one pot" reaction. First, 1-bromobutane is treated with magnesium in diethyl ether solvent.

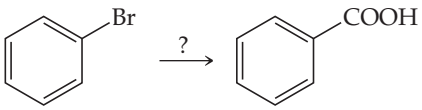


butyl magnesium bromide

Next, carbon dioxide in the form of dry ice is added to the reaction vessel.



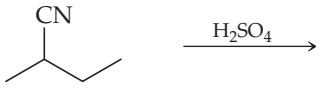
Finally, dilute acid is added to give the desired carboxylic acid.



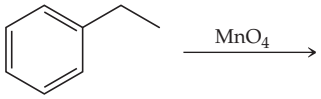
Practice Exercise

Write the structural formula of the carboxylic acid formed by treatment of chlorobenzene with magnesium, followed by carbon dioxide and finally aqueous acid.

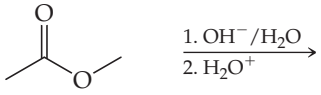
Self-Assessment Exercise



29.8 What reagents are used to synthesize benzoic acid from bromobenzene?

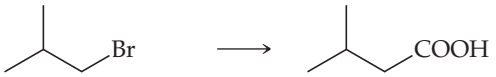


(a) 1) Mg 2) CO_2 3) H_3O^+
(b) 1) OH^- 2) K_2CrO_7/H_2SO_4
(c) 1) O_3 2) $(CH_3)_2S$
(d) $KMnO_4$



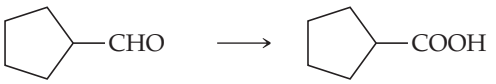
Exercises

29.9 What is the major organic product in the following reactions?

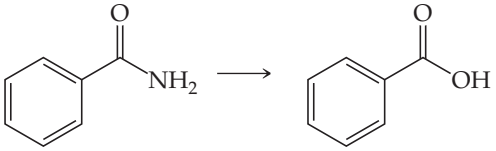


(a)

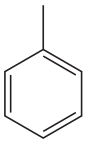
(b)

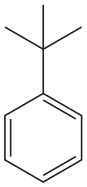


(c)



(d)





29.10 What reagent(s) are used in the following transformations?

(a)

(b)

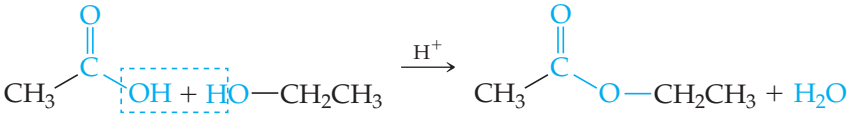
(c)

(d)

29.11 Toluene,  is converted to benzoic acid by $KMnO_4$ but *tert*-butylbenzene,  is not. Explain.

Answers to Self-Assessment Exercise

29.8 (a)



29.3 Esters and Esterification

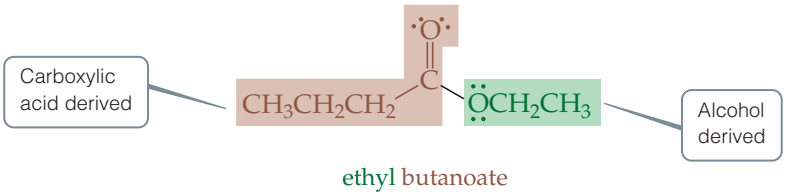
The smell of ripe fruit results from a mixture of volatile compounds. Many of these are esters and, quite often, a single ester dominates the aroma of a particular fruit. In general, esters are sweet smelling and have a lower boiling point than carboxylic acids of similar molecular mass. By the end of this section, you should be able to:

- Understand the synthesis and hydrolysis of the ester functional group.

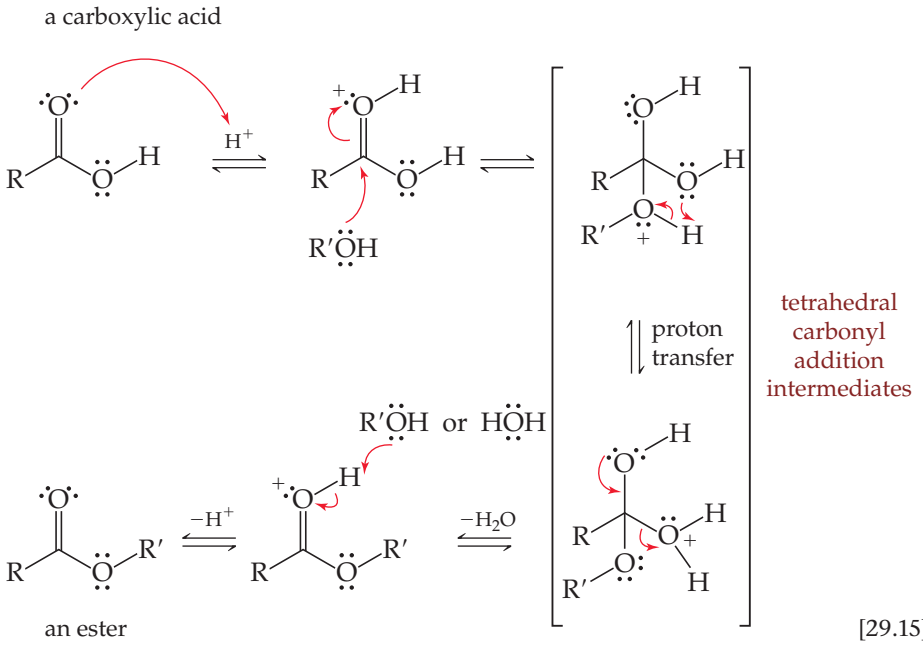
Carboxylic acids can undergo acid-catalyzed condensation reactions with alcohols to form **esters**:

acetic acid ethanol ethyl acetate [29.14]

The reaction is termed a *condensation reaction* due to the loss of one mole of water per mole of acid and alcohol. This reaction is commonly known as the **Fischer esterification**, named after the German chemist Emil Fischer (1852–1919), who was awarded the Nobel Prize for Chemistry in 1902.



Esters are compounds in which the OH group of a carboxylic acid is replaced by an OR group:

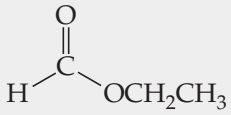


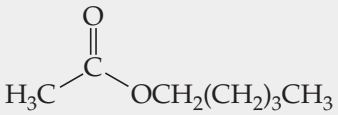
▲ **Figure 29.5 Everyday carboxylic acids and esters.** Many sunburn lotions contain the ester benzocaine; some nail polish remover is ethyl acetate; vegetable oils are also esters.

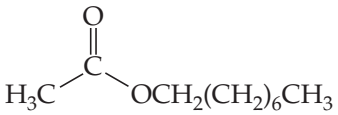
Figure 29.5 shows some common esters, which are named by using first the group from which the alcohol is derived and then the group from which the acid is derived. For example, ethyl butanoate is derived from ethanol and butanoic acid:

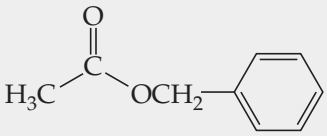
Esters generally have pleasant odours and are largely responsible for the pleasant aromas of fruit. **Table 29.4** lists some common esters and the structures, fragrances and flavors associated with them.

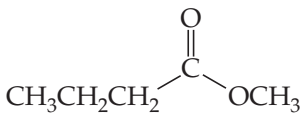
The mechanism of formation of an ester by the acid-catalyzed condensation of an alcohol and a carboxylic acid can be shown as follows:

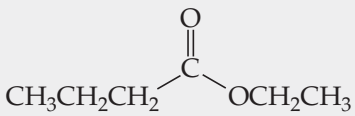


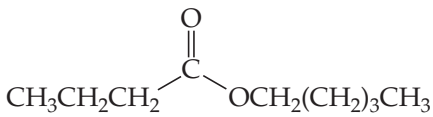


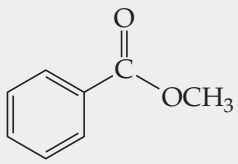


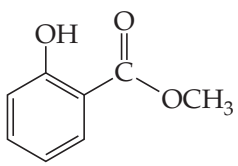


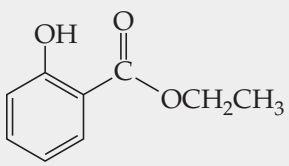


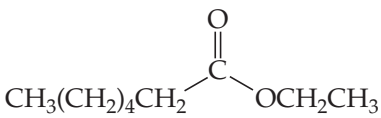




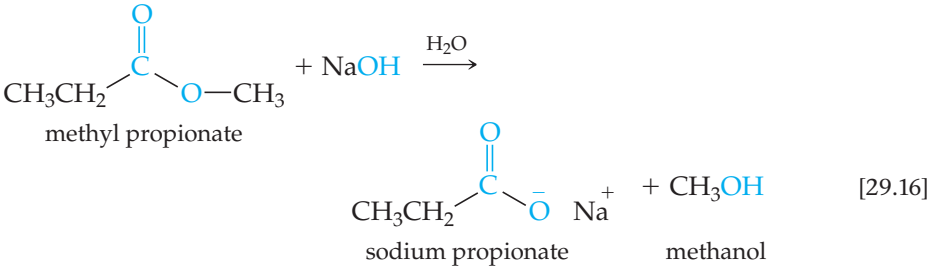








[29.15]



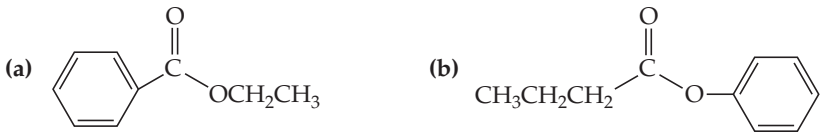
As with aldehydes and ketones, the basis of reactivity of the carboxylic acid occurs at the carbonyl group. The electronegativity of two oxygen atoms on the carbonyl carbon makes this carbon more electropositive than the corresponding carbon of either an aldehyde or ketone. Note from Equation 29.15 that the esterification reaction is fully reversible at each step and that formation of the ester from the carboxylic acid requires an excess of alcohol to drive the reaction in the direction that favors ester formation.

From the mechanism shown in Equation 29.15, it should become apparent that carboxylic acids can be formed from esters by the addition of excess water in the presence of an acid catalyst. This reaction, called hydrolysis, is the reverse of that described and is an important reaction in organic synthesis, as esters are often prepared to protect carboxylic acids.

TABLE 29.4 Simple esters as flavors and fragrances

Ester	Formula	Flavor/fragrance
Ethyl methanoate		rum
Butyl acetate		raspberry
Pentyl acetate		banana
Octyl acetate		orange
Benzyl acetate		jasmine
Methyl butanoate		apple
Ethyl butanoate		pineapple
Pentyl butanoate		pear or apricot
Methyl benzoate		almond
Methyl salicylate		oil of wintergreen
Ethyl salicylate		mint
Ethyl heptanoate		grape

The hydrolysis of esters is also possible in a basic aqueous medium, such as sodium hydroxide solution:



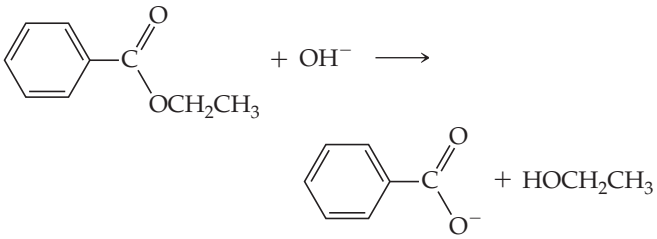
[29.16]

The products of the reaction are the sodium salt of the carboxylic acid and the alcohol. Distillation of the methanol and acidification of the aqueous solution of the sodium carboxylate yields the carboxylic acid. The hydrolysis of an ester in the presence of a base is called **saponification**, a term that comes from the Latin word for soap (*sapon*). The traditional synthesis of soap from animal fat is an example of this reaction.

Sample Exercise 29.3

Naming Esters and Predicting Hydrolysis Products

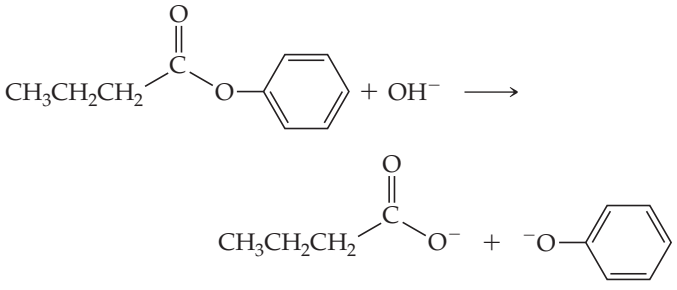
Name each of the following esters and indicate the products of their reaction with aqueous base.



SOLUTION

Analyze We are asked to name each ester and to determine their saponification products.

Plan To name an ester, we must analyze its structure and determine the identities of the alcohol and acid from which it is formed. Identifying these two components will also allow us to determine the products of the saponification.



Solve Esters are formed by the condensation reaction between an alcohol and a carboxylic acid. We can identify the alcohol by adding an OH to the alkyl group attached to the O atom of the carboxyl (COO) group. We can identify the acid by adding an H group to the O atom of the carboxyl group. We've learned that the first part of an ester name indicates the alcohol portion and the second part indicates the acid portion. The name conforms to how the ester undergoes hydrolysis, reacting with base to form an alcohol and a carboxylate anion.

(a) This ester is derived from ethanol (CH_3CH_2OH) and benzoic acid (C_6H_5COOH).Its name is therefore ethyl benzoate. The net ionic equation for reaction of ethyl benzoate with hydroxide ion is:

The products are benzoate ion and ethanol.

(b) This ester is derived from phenol (C_6H_5OH) and butanoic acid ($CH_3CH_2CH_2COOH$). The residue from the phenol is called the phenyl group. The ester is therefore named phenyl butanoate. The net ionic equation for the reaction of phenyl butanoate with hydroxide ion is

The products are butanoate ion and phenoxide ion.

Practice Exercise

Write the structural formula for the ester formed from propanol and propionic acid.

Self-Assessment Exercise

29.12 What are the products of base hydrolysis of ethyl propanoate?

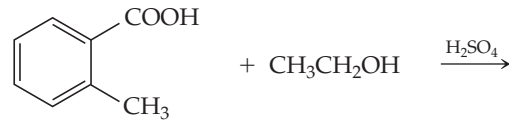
(a) CH_3COOH and $CH_3CH_2CH_2OH$

(b) CH_3CH_2COOH and CH_3CH_2OH

(c) $CH_3CH_2COO^-$ and CH_3CH_2OH

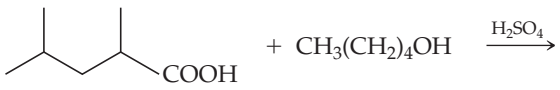
(d) CH_3CH_2COOH and $CH_3CH_2O^-$

Exercises



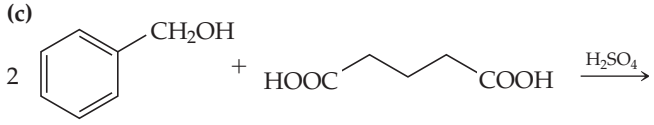
29.13 Identify the functional groups in each of the following compounds:

(a) $CH_3\overset{\overset{O}{\|}}{C}CH_2CH_3$ **(b)** $CH_3\overset{\overset{O}{\|}}{C}H$ (OH)



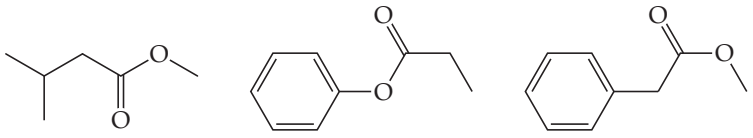
(c) $CH_2CH_2CH_3$ (OH) **(d)** $CH_3O\overset{\overset{O}{\|}}{C}CH_2CH_3$

29.14 Draw the products of the following reactions. In each case, the sulfuric acid acts as a catalyst.



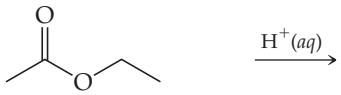
(a)

(b)



(c)

(d)



29.15 Give the condensed formulas for the carboxylic acid and alcohol from which each of the following esters may be formed.

(a) **(b)** **(c)**

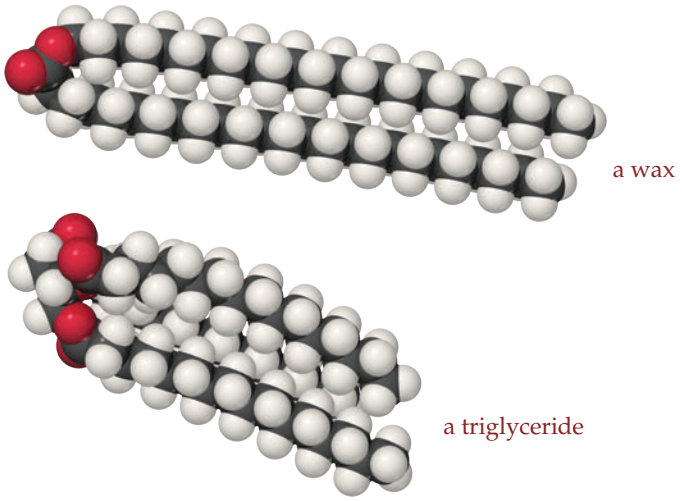
29.4 | Fats, Oils, and Waxes

Obesity is an increasing issue in modern society and is considered the main preventable cause of death in the western world. It significantly increases the risk of cardiovascular disease and type 2 diabetes as well as a range of other conditions. Typically, obesity results from a combination of eating too many sweet or fatty foods, which are high in energy-rich carbohydrates or lipids, respectively, while not getting enough exercise but other factors such as depression and genetic susceptibility may contribute. A change of diet and increase in physical activity is used to combat obesity but may require considerable willpower to implement. Obesity is defined by a body mass index (BMI) greater than 30 kg/m^2. BMI is calculated by dividing a person's weight in kg by the square of their height in m.

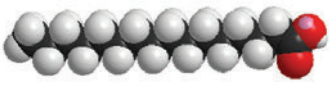
"Lipid" is a term that covers a range of molecules, all of which are hydrophobic. Fats, oils, and waxes are examples of lipids that we will now examine. By the end of this section, you should be able to:

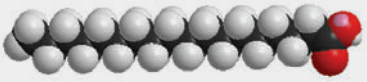


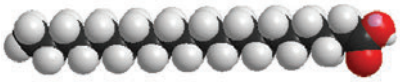
- Recognize the common structural unit of a lipid

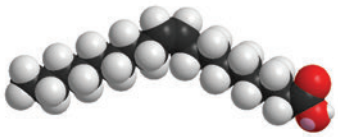
Lipids are naturally occurring substances that can be extracted from cells and tissues by non-polar organic solvents. Common examples of lipids include cholesterol (a steroid), turpentine (a terpene), beeswax and olive oil. Even from this very limited group of compounds, it is quite clear that although lipids can contain a variety of functional groups, their overriding feature is the large proportion of hydrocarbon within the structure. The name "lipid" is derived from a property rather than from any functional group class (the Greek *lipos* means fat). **Complex lipids** are those that can be broken down into smaller constituents, usually by hydrolysis. **Simple lipids** are those that are not easily hydrolysed.

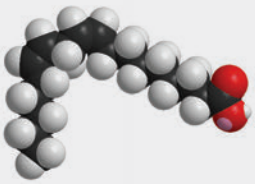
In this section we discuss a group of complex lipids that are esters of long-chain carboxylic acids called **fatty acids**. Two major groups of esters are derived from fatty acids: the waxes and triglycerides. **Waxes**, such as beeswax, are single esters made from fatty acids and long-chain alcohols. **Triglycerides** (more correctly known as triacyl glycerols) are triesters of glycerol and include common fats and oils. **Figure 29.6** shows two general examples of complex lipids. As you can see, even without investigating the type of functional group, both these molecules have alkyl chains of significant length. Their properties are derived from this feature. Waxes are typically greasy solids or semi-solids, while triglycerides can be solid or liquid at room temperature.

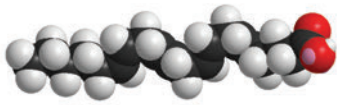












The most common triglycerides are those in which each fatty acid component is unbranched and has an alkyl chain more than 12 carbon atoms long. **Table 29.5** shows some of the more common saturated and unsaturated fatty acids found naturally.

Go Figure What structural features of a triglyceride molecule cause it to be insoluble in water?

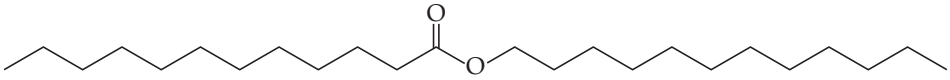
▲ **Figure 29.6 Complex lipids.** A general example of the structure of a wax ($C_{25}H_{51}COOC_{24}H_{49}$) and a triglyceride using the C_{16} fatty acid, palmitic acid.

TABLE 29.5 Structure and names of some common fatty acids

Name	Chain length	Structure	Melting point (°C)
		Saturated acids	
Lauric acid	C12		45
Myristic acid	C14		53
Palmitic acid	C16		62
Stearic acid	C18		70
Arachidic acid	C20		75
		Unsaturated acids	
Oleic acid	C18 (1 × *cis* double bond)		13
Linoleic acid	C18 (2 × *cis* double bonds)		−5
Arachidonic acid	C20 (4 × *cis* double bonds)		−50

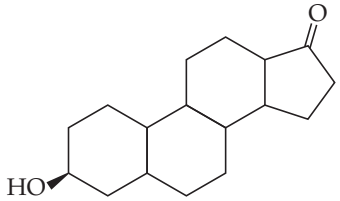
Note the difference in overall shape between saturated and unsaturated fatty acids. This shape difference is responsible for the different physical properties exhibited by the fatty acids and their corresponding triglycerides and waxes. For example, the melting point of stearic acid (mp = 70 °C), a saturated fatty acid, is 57 °C higher than oleic acid (mp = 13 °C) and 75 °C higher than linoleic acid (mp = −5 °C), despite the fact they all contain 18 carbon atoms. The reason is that "kinked" fatty acids—that is, fatty acids that contain one or more double bonds—cannot pack as closely or efficiently as the saturated fatty acids.

Most saturated triglycerides are **fats** because they are solid at room temperature. Most triglycerides containing double bonds do not pack as well as their saturated analogues and so are classed as **oils**. Oils are triglycerides that are liquid at room temperature. The term *polyunsaturated* simply means there is more than one double bond contained within the triglyceride.



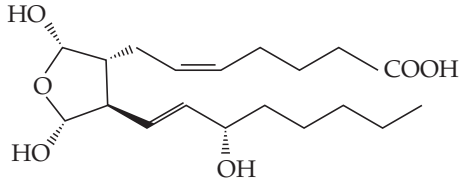
Consumers have come to realise that polyunsaturated vegetable oils are more easily digested than saturated ones. However, this has not always been the case. For many decades, the use of *lard*—a soft, white solid obtained by rendering pig fat—for cooking and baking meant that consumers wanted solid fats instead of liquid oils. Vegetable oils, cheaper to produce and polyunsaturated, are still converted to fats through a process called **hardening**. As chemists, we know this process as catalytic hydrogenation. The basic principle is not to reduce all the double bonds within an unsaturated triglyceride, but to reduce enough of them to yield the required properties and consistency. Needless to say, the process is carefully controlled. Margarine obtained from canola oil is a classic example.

Sample Exercise 29.4

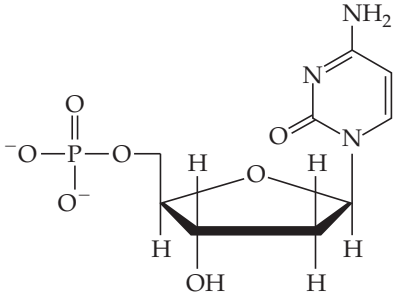


Lipids

Which of the following compounds is *not* classified as a lipid?



(a)



(b)

(c)

(d)

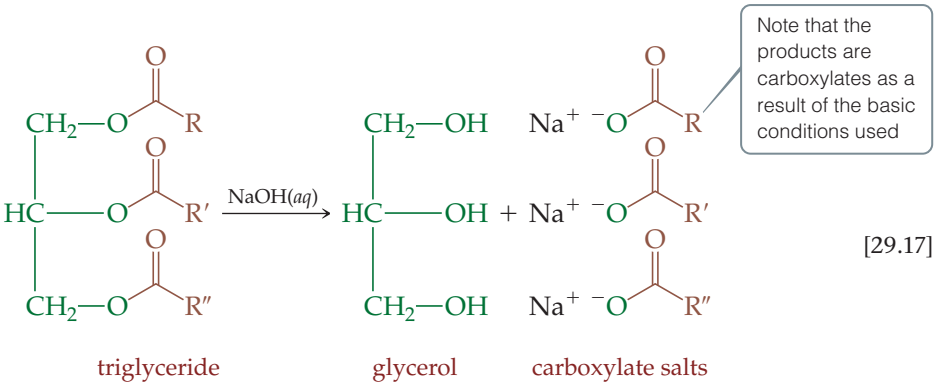
Continued

SOLUTION

Analyze We are asked to differentiate between compounds based on their functionality and to class them accordingly.

Plan By definition, *lipids* are naturally occurring substances that can be extracted from cells and tissue by non-polar organic solvents such as hexane. So we will use this definition as a means of classification.

Solve Structure **(a)** is a wax, similar to beeswax. It is soluble in hexane and so is classed as a lipid. Structure **(b)** is a member of the steroid hormones. Its large carbon framework suggests this compound will be soluble in non-polar solvents. Hence this compound can be generally classed as a lipid. Structure **(c)** is a prostaglandin. Despite the presence of three OH and a carboxylic acid group, the two large alkyl chains would suggest this molecule is hexane soluble. This compound is also a lipid. Structure **(d)** is a nucleotide. Its collection of nitrogen- and oxygen-containing heterocycles and polar phosphate group would mean this compound is more aqueous than hexane soluble. Therefore, this class of compound is not a lipid.



Practice Exercise
Draw the structure of a triglyceride containing lauric acid.

Soaps and Detergents

Historically, in the soap-making process a triglyceride (animal fat or a vegetable oil) was boiled with a strong base, usually NaOH. The resultant soap consisted of a mixture of sodium salts of long-chain carboxylic acids, the fatty acids, which formed during the saponification process (Figure 29.7).

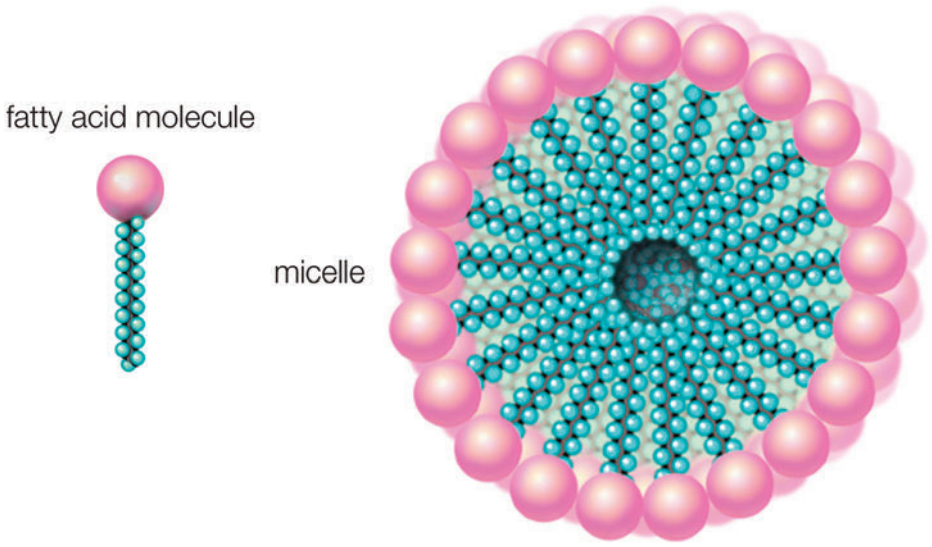
▲ **Figure 29.7 Saponification.** Saponification of fats and oils has long been used to make soap. This etching shows a step in the soap-making process during the nineteenth century.

[29.17]

(R, R′, R″ are long alkyl chains)

The cleansing power of a soap is due to its ability to act as an emulsifying agent. That is, it is a substance that can sit at the interface between a hydrophobic liquid and a hydrophilic liquid, allowing the hydrophobic liquid to be dispersed in microscopic droplets. Many common forms of dirt (for example, grease, oil, fat) are hydrophobic and soaps allow them to be dispersed in waste water.

In water, soap forms a cloudy solution of **micelles**, as shown in Figure 29.8. Micelles form as a result of the hydrophobicity of the alkyl chains and the hydrophilicity of the polar carboxylate group. Micelles are stabilized by dispersion forces between alkyl groups and by hydrogen bonding between carboxylate anions and water molecules.



A common disadvantage of soap is the presence of *soap scum*, an insoluble precipitate or film that is difficult to remove from household areas such as bathrooms. This scum can be produced in two common ways. Foremost is the reaction of a fatty acid with Ca^{2+}, Mg^{2+} or Fe^{2+} ions found in *hard water*. This reaction, called a *counterion exchange* reaction, converts the sodium salt to the calcium salt, which is insoluble in water.

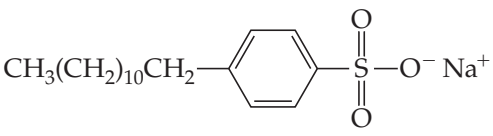
$$2\,CH_3(CH_2)_{16}COO^-\,Na^+ + Ca^{2+} \longrightarrow Ca[CH_3(CH_2)_{16}COO]_2 + 2\,Na^+$$

sodium salt of a fatty acid (soluble in water as micelles) → calcium salt of a fatty acid hard-water scum (insoluble in water)

[29.18]

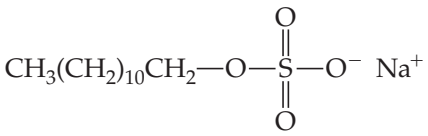
The other common way of building up soap scum is through the precipitation of fatty acids in hard water that has been acidified by some means—for example, acid rain.

◀ **Figure 29.8 Soap micelle.** In water, soap forms a cloudy solution of micelles. The hydrophobic hydrocarbon chains cluster in the middle of the micelle and the polar (hydrophilic) carboxylate groups are on the surface. The Na^+ counterions are dissolved in the water around the micelle. Note: Micelles are not circular as drawn, but spherical (this is just a slice through a micelle).



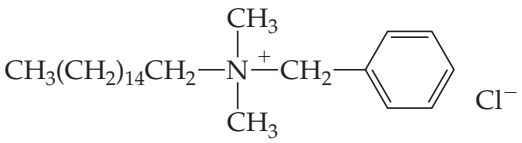
Without the ionisable carboxylate group, the fatty acid floats to the top of a water-based solution as a scum.

$$2\ CH_3(CH_2)_{16}COO^-\ Na^- \ +\ H^+ \longrightarrow CH_3(CH_2)_{16}COOH(s) + Na^+ \qquad [29.19]$$



sodium salt of a fatty acid (soluble in water as micelles) — fatty acid acidic-water scum (insoluble in water)

Synthetic detergents have been designed with the problem of soap scum in mind. Essentially, the same desirable characteristics of a fatty-acid soap must be maintained; that is, the detergent should contain a long hydrocarbon chain and a polar head group. It is desirable that this polar head group should not form insoluble salts with Ca^{2+}, Mg^{2+} or Fe^{2+} ions, in particular. Sodium salts of sulfonic acids, called sulfonates or sulfates, provide useful analogues to the carboxylate group. Being stronger acids than carboxylic acids means that sulfonic acids are not as easily protonated, even under the lowest pH conditions found domestically. Of even greater significance is the fact that calcium, magnesium and iron salts of sulfonic acids are soluble in water.



Not all detergents need to contain an anion. Benzalkonium chloride is one used in a variety of domestic liquid cleaning and disinfectant products. **Figure 29.9** illustrates some common examples of synthetic detergents.

sodium 4-dodecylbenzene sulfonate

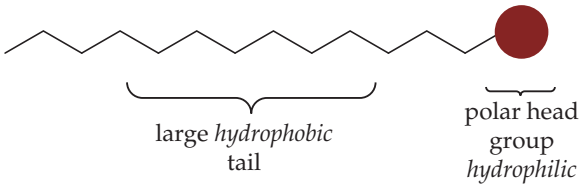
sodium dodecyl sufate (SDS) (sodium lauryl sulfate)

benzylcetyldimethylammonium chloride (benzalkonium chloride)

◀ **Figure 29.9 Synthetic detergents.** Detergents can be anionic or cationic, but still retain the features of a soap derived from a fatty acid.

Sample Exercise 29.5

Soap Structure



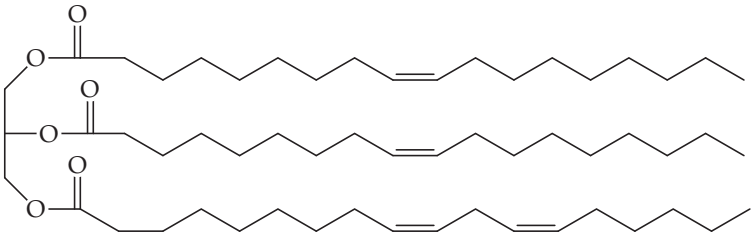
Draw the general structure of the main constituent of a soap micelle and indicate the hydrophilic and hydrophobic regions.

SOLUTION

Analyze We are asked to draw a schematic of the sodium or potassium salt of a fatty acid and indicate polar and non-polar regions.

Plan Since soaps are prepared from the carboxylate salt of a fatty acid, this question requires you to draw a long alkyl chain and a polar carboxylate head group.

Solve Using a simple circle for a head group and the line drawing of a long alkane, we get:



Practice Exercise

Detail the common features of a soap and a detergent.

Self-Assessment Exercise

29.17 Olive oil is composed of a number of fatty acids, but a typical molecule has the structure:

Name the fatty acids present in this structure.

(a) Stearic acid + 2 × oleic acid

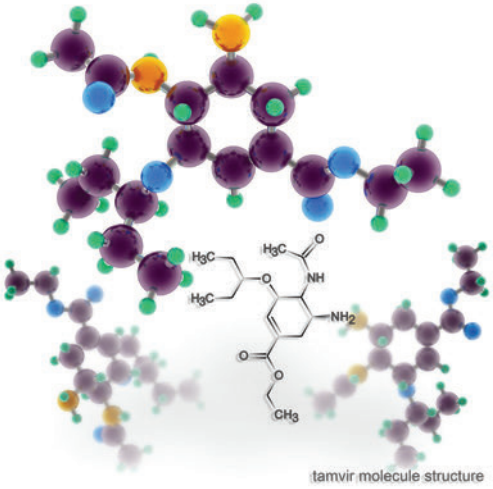
(b) 2 × Oleic acid + linoleic acid

(c) 2 × Oleic acid + arachidonic acid

(d) Oleic acid + 2 × linoleic acid

Exercises

29.18 **(a)** What is the difference between a fat and an oil? **(b)** What is the difference between an fat and a wax? Draw an example of each to illustrate your point.



29.19 Write a balanced chemical equation using condensed structural formulas for **(a)** the formation of butyl propanoate from the appropriate acid and alcohol, **(b)** the saponification (base hydrolysis) of methyl benzoate.

29.20 Triglycerides are formed from fatty acids and glycerol (1,2,3-propanetriol). **(a)** Draw a general formula for the structure of a triglyceride. **(b)** Describe the difference between a saturated and an unsaturated fatty acid. **(c)** Indicate the difference in melting point between a saturated triglyceride and a comparable polyunsaturated triglyceride.

29.5 | Acid Chlorides, Anhydrides, and Nucleophilic Acyl Substitution

Most molecules around us contain more than one functional group. In our efforts to produce effective pharmaceuticals, we arrive at a substance that may have three, four, or more different functional groups in one molecule. This presents a difficulty in synthesis. How do we react one part of a molecule without affecting another functional group present? For example, treating a compound that contains both an aldehyde and a carboxylic acid group with an alcohol under acidic conditions will result in both an acetal and an ester being formed. As molecules become more complex and the number of functional groups they contain increases, the ability to do a reaction on one part of the molecule without interference from another functional group becomes increasingly difficult.

Sometimes the order in which we conduct a multi-stage synthesis allows us the selectivity we seek. In other cases, we may use "protecting groups". These are transformations that render one part of the molecule inactive while retaining the reactivity of another part. For example, a molecule that contains an alkene and a ketone will react with bromine by an electrophilic addition to the alkene and α-substitution to the carbonyl. If, however, we "protect" the ketone by forming an acetal first, bromination will only occur at the alkene, after which we can "deprotect" the acetal to re-form the original ketone. For this strategy to be efficient, the protecting group chemistry needs to be high-yielding and reversible. The formation of carboxylic acid derivatives, such as esters, is one example of the use of an effective protecting group. While protecting group chemistry is used extensively in a synthesis research laboratory, it is also employed in the manufacture of some pharmaceuticals such as oseltamivir—synthesized by Hoffmann-La Roche as an antiviral medication and marketed under the trade name of Tamiflu®.

(-)-Shickmic acid

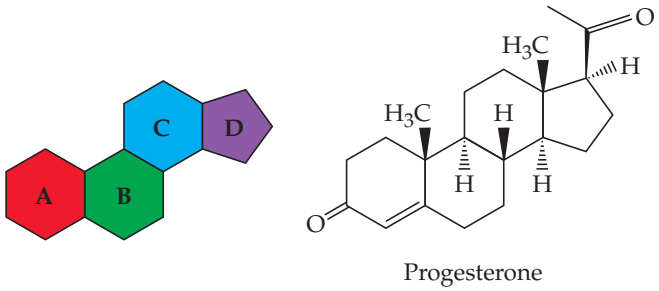
The starting material contain three alcohol groups.
The formation of a "cyclic ketal" with the two *cis* OH groups allows the selcetive transformation of the third OH in high yield.

Oseltamivir

At the end of this section, you should be able to:

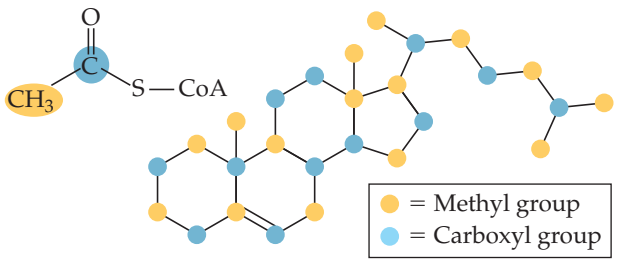
- Recognize the different functional groups that contain an acyl group
- Know the reagents necessary to convert between the different functional groups

Several functional group classes are derived from the carboxyl group. We have already introduced carboxylic acids and esters. Two others of note are the **acid anhydrides** and



CHEMISTRY AND LIFE Steroids

Hormones are chemical messengers capable of stimulating or inhibiting particular biochemical processes. One major class of hormones is the steroids. Because steroids are non-polar compounds, they are considered lipids. Their non-polar character allows them to cross cell membranes so they can leave the cells in which they were synthesized and enter their target cells. There have been five Nobel prizes in the area of steroid chemistry giving it a rich and important history across chemistry and medicine.

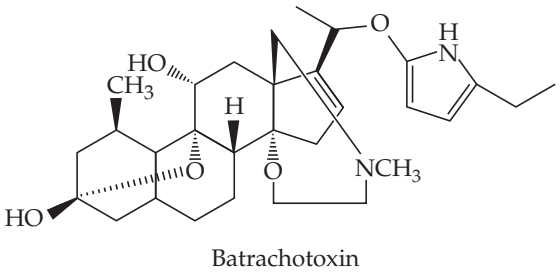


Bile salts are steroids with detergent properties able to emulsify lipids in foodstuff passing through the intestine to enable fat digestion and absorption through the intestinal wall. *Cholesterol* is a steroid found in animal tissues and various foods that is normally synthesized by the liver and is important as a constituent of cell membranes and influences membrane fluidity; it's actually a precursor to all steroid hormones. *Mineralcorticoids* such as aldosterone are secreted by the adrenal cortex and regulate the balance of water and electrolytes or salts (Na^+, Cl^-, HCO_3^-) in the body. The addition of aldosterone causes increased Na^+ readsorption, for example. *Glucocorticoids* such as cortisol (also called hydrocortisone) is also produced by the adrenal cortex and are involved in carbohydrate, protein and fat metabolism. They also have excellent anti-inflammatory properties. The most noted of the steroids are the sex hormones such as the estrogens (for example, progesterone and estrone) and the androgens (for example, testosterone). The estrogens and androgens affect the growth and function of the reproductive organs, the development of secondary sex characteristics and the behavioural patterns of animals. The structure of progesterone is shown in **Figure 29.10**. Anabolic steroids such as stanolozol aid in the development of muscles and are man made.

All steroids contain the characteristic rigid tetracyclic backbone based on the androstane ring system: the four rings are designated A, B, C and D as shown in Figure 29.10. The A, B and C rings are six-membered rings; D is a five-membered ring. In steroids, the rings are all fused with trans stereochemistry.

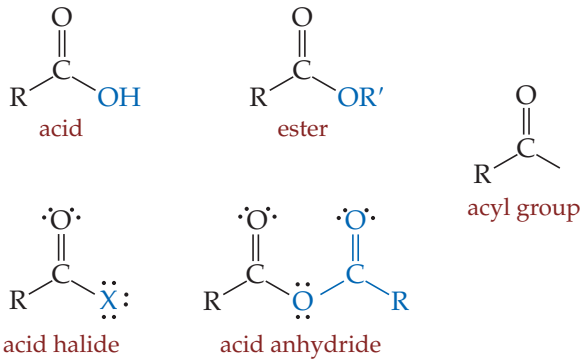
Steroids are made available from terpenes, which are readily made in nature from acetic acid.

▲ **Figure 29.10 The central tetracyclic structure to all steroids.** Progesterone is an estrone that plays a role in maintaining pregnancy.

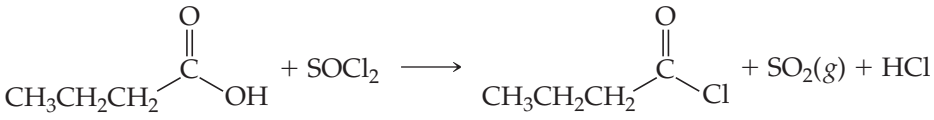


▲ **Figure 29.11 The tetracyclic backbone of all steroids can be traced back to acetic acid.** The methyl carbons in acetic acid are indicated as yellow dots, and the carbonyl carbons are represented in blue.

Figure 29.11 shows the origin of the acetic acid carbon atoms in a typical steroid structure. There are about 40 enzyme-catalyzed steps to prepare cholesterol from acetic acid through biosynthesis.



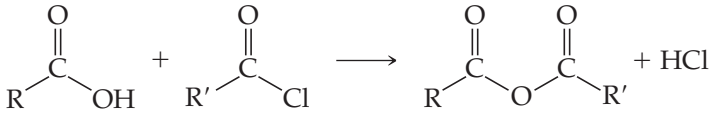
Poison dart frogs are fascinating creatures in that they secrete four steroid toxins from glands located on the back and behind the ears—one of them being among the most toxic substances known to man, batrachotoxin (**Figure 29.12**). Batrachotoxin contains the tetracyclic ring structure of the steroids. As a neurotoxin it affects the nervous system by increasing Na^+ permeability of cellular ion channels. It becomes lethal by permanently blocking nerve signal transmission to muscles, leading to cardiac arrest. The estimated lethal dose for this steroid poison in humans is somewhere between 2 and 200 μg.



▲ **Figure 29.12 Poison dart frogs excrete batrachotoxin, a steroid-based structure and one of the most toxic compounds known.**

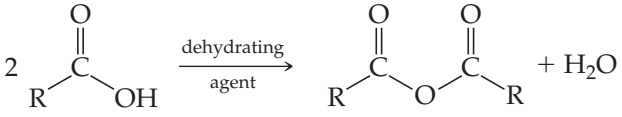
acid halides. The functional group known as an acid anhydride has two **acyl groups** (RCO–) linked by an oxygen atom. An acid halide has a single acyl group bonded to a halogen atom:

Acid chlorides, which are the most common and practical acid halides, are usually prepared by treatment of a carboxylic acid with thionyl chloride ($SOCl_2$). You may recall this reagent as a useful way of converting alcohols to chloroalkanes (Section 26.5). Acid chlorides are named by replacing the suffix *-oic acid* with *-oyl halide*. For example, $CH_3CH_2CH_2COCl$ is named butanoyl chloride and is derived from butanoic acid.



butanoic acid
a carboxylic acid

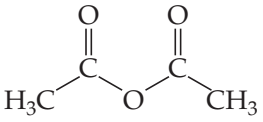
butanoyl chloride
an acid chloride



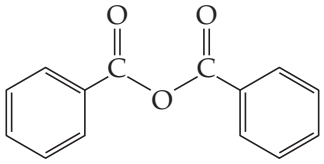
[29.20]

Acid anhydrides such as acetic anhydride, $(CH_3CO)_2O$, are usually prepared by reaction of a carboxylate anion with an acid chloride. In this way, both symmetrical anhydrides (same acyl group) and unsymmetrical anhydrides (different acyl groups) can be produced. Another general method is to dehydrate the carboxylic acid using a suitable dehydrating reagent, such as a more reactive anhydride. In some cases, especially 1,2-dicarboxylic acids such as phthalic acid or succinic acid, anhydrides can be formed by heating.

carboxylic acid acid chloride an acid anhydride

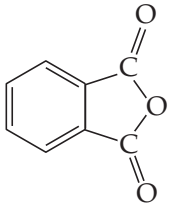


[29.21]

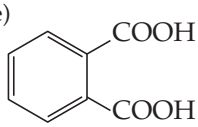


a carboxylic acid an acid anhydride

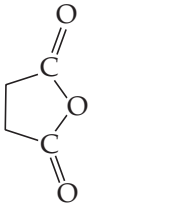
R = H, alkyl, aryl [29.22]



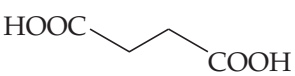
Anhydrides from simple carboxylic acids and cyclic anhydrides from dicarboxylic acids are named by replacing the word *acid* with *anhydride*.



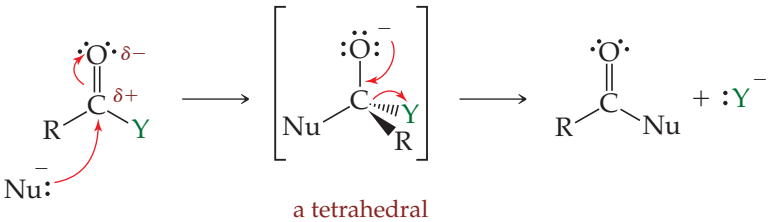
acetic anhydride
from acetic acid



benzoic anhydride
from benzoic acid



phthalic anhydride
from phthalic acid (accompanying figure)

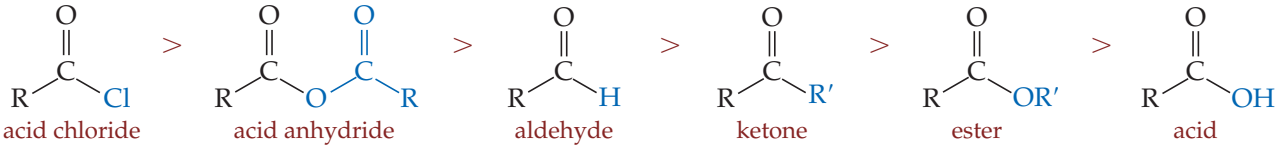


succinic anhydride
from succinic acid (accompanying figure)

Nucleophilic Acyl Substitution

Esters, acid chlorides and acid anhydrides all undergo nucleophilic substitution reactions at the acyl carbonyl group by the following general mechanism:

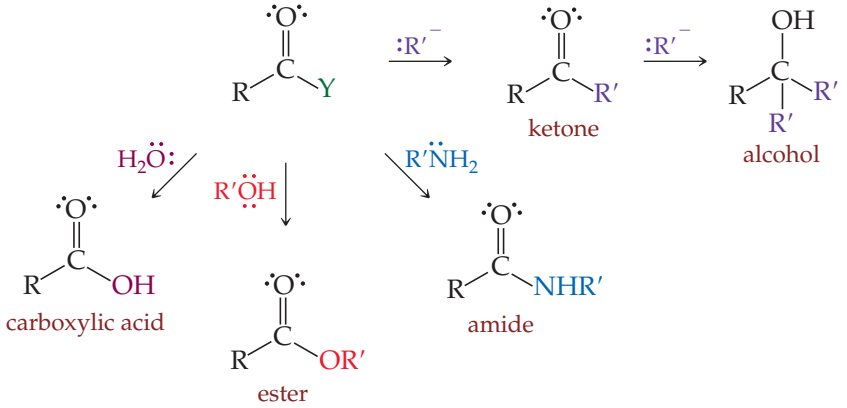
an acid chloride, anhydride or ester



a tetrahedral intermediate

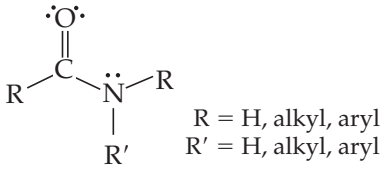
R = H, alkyl, aryl
Y = Cl, OR, OCOR

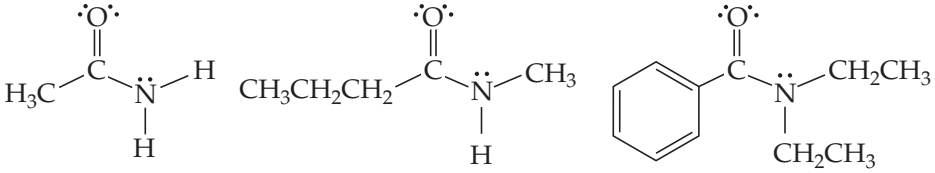
[29.23]



Such a reaction is called a **nucleophilic acyl substitution** and differs from nucleophilic reactions of aldehydes and ketones by the fate of the tetrahedral intermediate formed (compare the middle structure in equations 28.5 and 29.23). In this case, this intermediate collapses to regenerate the carboxyl group, thereby eliminating the group (Y)—which is typically a *good leaving group*—as a stable anion.

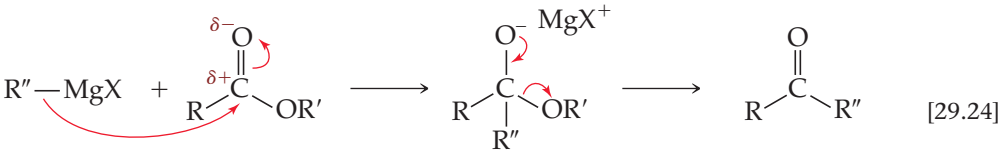
The reactivity of carbonyl compounds towards nucleophilic attack can be summarized as:



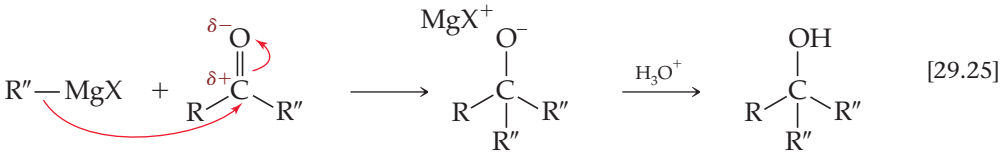


This relative reactivity is governed by two factors: the electropositive nature of the carbonyl carbon atom by substituent inductive effects, and the stability of the leaving group (Y^-) displaced by substitution. Some useful interconversions using this reaction type are shown in **Figure 29.13** including the reaction of amines with acid chlorides, anhydrides and esters to form **amides**. Amides have an acyl group bonded to a trivalent nitrogen atom, usually of the form RCONHR'. Amide bonds are the key structural features that join amino acids together to form polypeptides and proteins. Amides are named by replacing the suffix *-oic acid* with *amide*. The *N* in the names shown here refers to functionalization on nitrogen. So, for *N*-methylbutanamide, the methyl group is bonded to nitrogen.

Go Figure What role do water, alcohol and amine play in these interconversions?

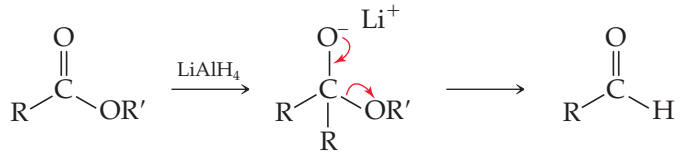


▲ **Figure 29.13 Functional group interconversions.** Acid halides, anhydrides and esters are versatile starting materials, leading to a range of different functional groups. Y = Cl, OR or OCOR.

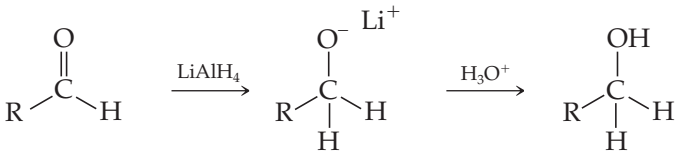


acetamide *N*-methylbutanamide *N,N*-diethylbenzamide

A second interconversion from Figure 29.13 to highlight involves the reaction of acid chlorides, anhydrides and esters with carbanions, such as those generated through Grignard reagents, to form alcohols via a ketone intermediate. The addition of a strong nucleophile such as a Grignard reagent to an ester (or acid chloride or anhydride) usually yields the corresponding 3° alcohol as the final product instead of the expected ketone (based on a stoichiometric addition). For this reason, usually two equivalents of the Grignard reagent are added to the reaction mixture to drive the reaction to completion. Mechanistically, collapse of the tetrahedral intermediate from the ester, after attack of the first equivalent of RMgX, yields a ketone. The ketone is more electrophilic than the ester (and so more reactive towards a second equivalent of RMgX), so it undergoes further reaction to yield the stable alkoxide in preference. Upon the addition of acid, the tertiary alcohol is formed.



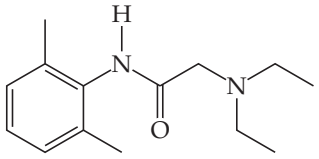
an ester a ketone [29.24]



a ketone a tertiary alcohol [29.25]

We can extrapolate this result to other nucleophiles such as hydride (H^-), which comes in the form of lithium aluminum hydride ($LiAlH_4$), a powerful reducing agent. As shown in Equation 29.26, collapse of the tetrahedral intermediate from the ester yields an aldehyde, which again is more reactive than the ester, and which undergoes a second addition of hydride to form the alkoxide. The addition of mild acid protonates the alkoxide, forming a primary alcohol.

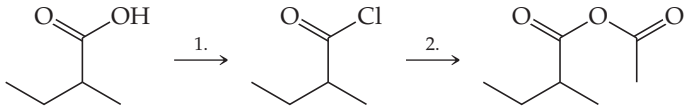
an ester an aldehyde [29.26]



an aldehyde a primary alcohol [29.27]

Hence, by appropriate choice of nucleophile, esters can be easily converted into both primary and tertiary alcohols.

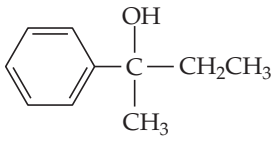
- Recognize the different functional groups that contain an acyl group
- Know the reagents necessary to convert between the different functional groups



Self-Assessment Exercises

29.21 Lidocaine is used as a local anesthetic. What functional groups does it contains?

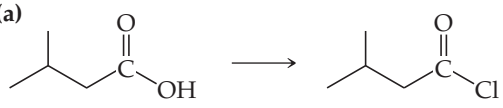
(a) amine and amide
(b) amine and ester
(c) carboxylic acid and amide



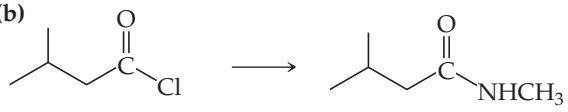
29.22 What reagents would carry out the following transformation?

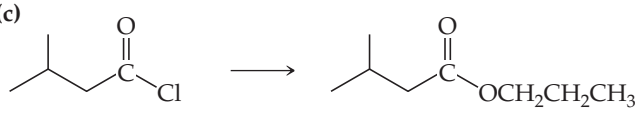
(a) 1. Cl_2 2. CH_3COOH
(b) 1. $SOCl_2$ 2. CH_3COCH_3
(c) 1. $SOCl_2$ 2. CH_3COOH
(d) 1. HCl 2. CH_3COCl

Exercises

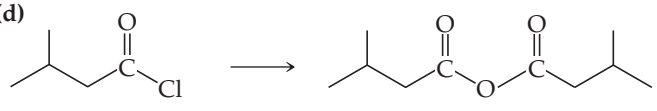


29.23 2-Phenyl-2-butanol can be synthesized by a combination of a Grignard reagent and an ester. Show the combination.





29.24 Draw the condensed structures of the products formed from **(a)** butanoic acid and methanol, **(b)** benzoic acid and 2-propanol, **(c)** the reaction of propanoic acid with $SOCl_2$ and then dimethylamine. Name the compound in each case.



29.25 Acetic anhydride is formed from acetic acid in a condensation reaction that involves the removal of a mole of water from between two acetic acid molecules. Write the chemical equation for this process, and show the structure of acetic anhydride.

29.26 Suggest plausible reagents for the following transformations.

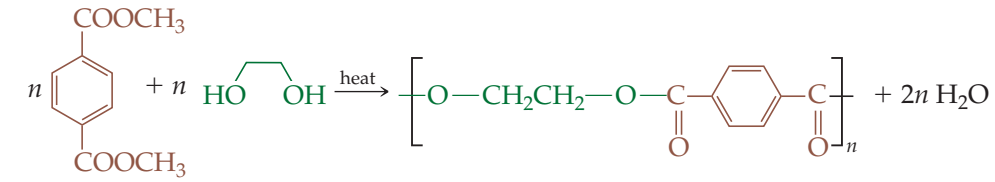
29.6 | Condensation Polymerization

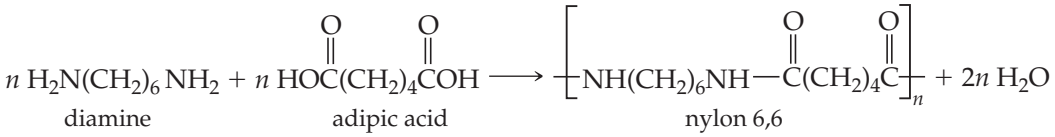


Polymers are an integral part of modern life. They are very large molecules constructed of just a few small molecules that are repeated many times. Their use in our lives is incredibly diverse and ranges from soft-drink bottles to components of life-saving heart valve replacements. A St Jude valve uses the polyester Dacron® to attach it to the surrounding heart tissue. Dacron® is Du Pont's trade name for the fiber formed from polyethene terephthalate (a polyester). About 250,000 valve-replacement procedures are performed annually worldwide, most using a St Jude valve. The valve is secured to the surrounding tissue via a biocompatible polyester sewing ring. The polar, oxygen-containing functional groups along the biocompatible polyester chain afford attractive interactions to facilitate tissue growth.

By the end of this section, you should be able to:

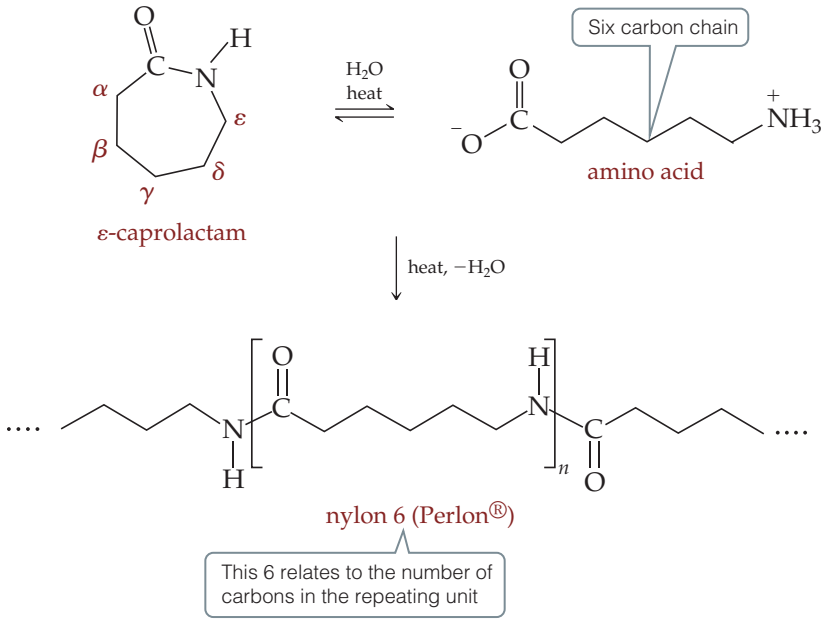
- Recognize the components of a condensation polymer.

In Chapter 26, we discussed one of the major classes of commercially important polymers and their formation by addition polymerization. A second general reaction used to synthesize commercially important polymers is **condensation polymerization** or *step-growth polymerization*. This type of polymerization usually employs difunctional molecules as the monomers, with each new bond being created in a separate step. We discuss two types of condensation polymers in this section: **polyesters** and **polyamides**.



Polyesters are formed by the reaction of a diacid, diacid chloride or diester with a diol. Polymers formed from two different monomers are called **copolymers**. PET (polyethene terephthalate), or *Dacron*®, is the most common polyester copolymer used today.

dimethyl terephthalate | ethene glycol | PET (Dacron®)

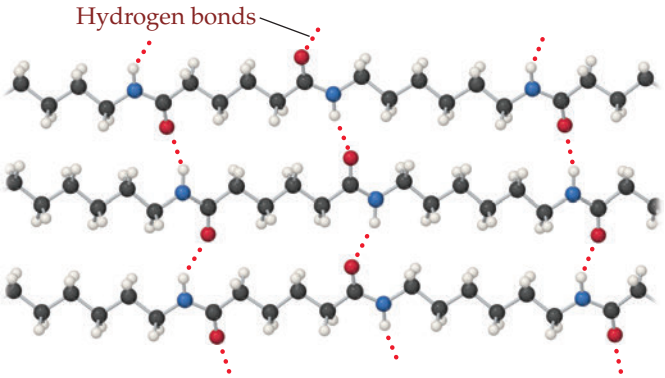


[29.28]

Polyamides are formed by the polycondensation of a diamine with a diacid, diacid chloride or diester. The best known of the polyamides is nylon 6,6, discovered by Wallace Carothers (1896–1937) and his associates at Du Pont in 1934. It is named with the notation 6,6 because it is made by the reaction of adipic acid (a diacid within a six-carbon chain) and 1,6-hexanediamine (a six-carbon chain diamine). Nylons are used in home furnishings, apparel, carpet, fishing line and toothbrush bristles, to name but a few.

[29.29]

Nylon 6, also called *Perlon*®, is made from ε-caprolactam, a cyclic amide. Its uses include ropes and ties. When ε-caprolactam is heated with a small amount of water, some of it is hydrolysed to the amino acid. Continued heating gives condensation and polymerization to yield molten nylon 6. Note that a single-digit notation is used because nylon 6 is a polymer made up of one monomer containing six carbons. The monomer can be symbolized as A, which in polymer form creates the same simple repeating unit -A-A-A-A-. Nylon 6,6 is a polymer comprising two different monomers, symbolized as A and B, which forms copolymers of the form -A-B-A-B-.



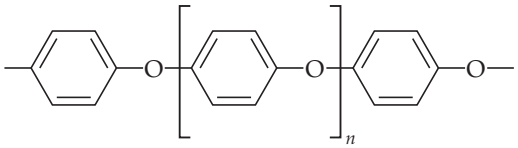
[29.30]

Polymers such as nylon and polyesters can also be formed into *fibres* that, like hair, are very long relative to their cross-sectional area and are not elastic. These fibres can be woven into fabrics or cords and fashioned into clothing and other useful objects.

Fibres of nylon 6,6 are cold-drawn, meaning they are drawn out at room temperature. As the fibres are drawn, hydrogen bonds form between individual polymer strands, such that the carbonyl of one amide bond hydrogen bonds to an amide hydrogen atom on another strand (**Figure 29.14**). The tensile strength and stiffness of nylon 6,6 are attributable to the hydrogen bonding that occurs in these fibres.

Various substances may also be added to polymers to provide protection against the effects of sunlight or against degradation by oxidation. For example, manganese(II) salts and copper(I) salts, in concentrations as low as $5-10^{-4}$ % (*w*/*w*), are added to nylons to provide protection from light and oxidation and to help maintain whiteness.

Go Figure What role do the hydrogen bonds play in a polymeric material such as nylon?



▲ **Figure 29.14 Hydrogen bonding in nylon 6,6.** The unusual and desirable physical properties of nylon 6,6 are a result of intermolecular hydrogen bonding.

CHEMISTRY AND LIFE Towards the Plastic Car

Many polymers can be formulated and processed to have sufficient structural strength, rigidity and heat stability to replace metals, glass and other materials in a variety of applications. The housings of electric motors and kitchen appliances such as coffee makers and can openers, for example, are now commonly made from specially formulated polymers. Engineering polymers are tailored to particular applications through choice of polymers, blending of polymers and modifications of processing steps. They generally have lower costs or superior performance over the materials they replace. In addition, shaping and colouring of the individual parts and their assembly to form the final product are often much easier.

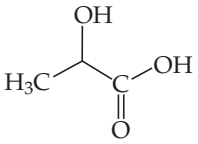
The modern car provides many examples of the inroads engineering polymers have made in car design and construction. Car interiors have long been formed mainly of plastics. Through development of high-performance materials, significant progress has been made in introducing engineering polymers as engine components. **Figure 29.15**, for example, shows the manifold in a series of Ford V-8 utility and van engines. The manifold, which is made of nylon, must be stable at high temperatures. The use of an engineering polymer in this application eliminates machining and several assembly steps.

Car body parts can also be formed from engineering polymers. Components formed from engineering polymers usually weigh less than the components they replace, thus improving fuel economy. The bumper bars of Volkswagen's New Beetle (**Figure 29.16**), for example, are made of nylon reinforced with a second polymer, poly(phenylene ether) (PPE), which has the following structure:

Because the poly(phenylene ether) polymer is linear and rather rigid, it confers rigidity and ensures shape retention.

A big advantage of most engineering polymers over metals is that they eliminate the need for costly corrosion protection steps in manufacture. In addition, some engineering polymer formulations permit manufacturing with the colour built in, thus eliminating painting steps.

▲ **Figure 29.15 Plastic engines.** The intake manifold of some Ford V-8 engines is formed from nylon.

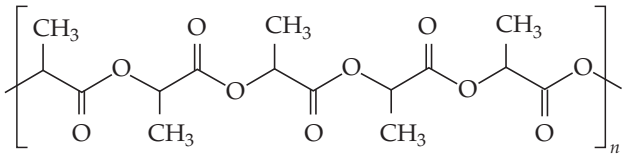


▲ **Figure 29.16 Plastic fenders.** The bumper bars of this Volkswagen Beetle are made of General Electric Noryl GTX, a composite of nylon and poly(phenylene ether).

Sample Exercise 29.6

Condensation Polymers

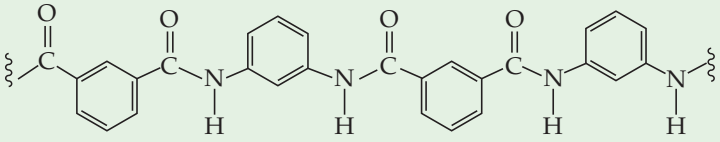
What is the structure of the polymer formed from lactic acid, a naturally occurring compound obtained from carbohydrates?



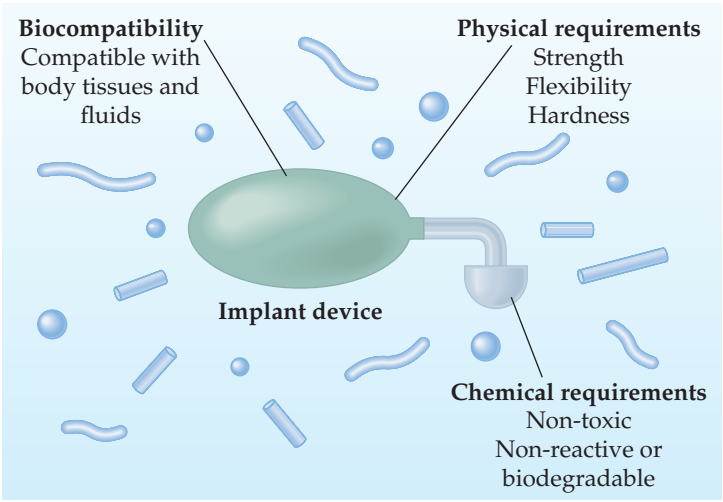
SOLUTION

Analyze We are given the structure of lactic acid and asked to derive the structure of the polymer made through self-condensation.

Plan Identify functional groups capable of forming a condensation polymer, then draw the polymer linking these functional groups up.



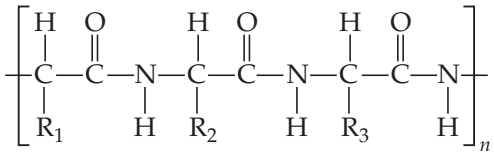
Solve Identification of the alcohol and carboxylic acid functional groups is important to determine the place of condensation. Condensation occurs by the formation of ester groups.



poly(lactic acid)

Practice Exercise

Indicate whether the following polymer is a step (condensation) or chain (addition) growth polymer. Draw the structure of the monomer/s used in the preparation of this polymer.



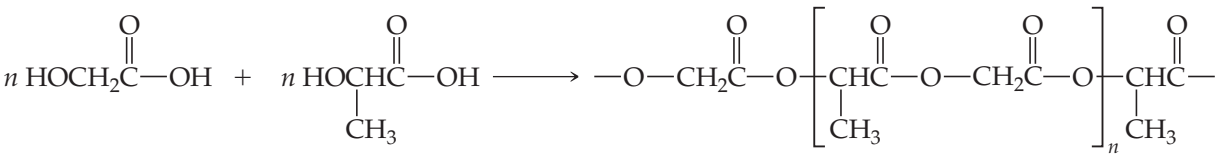
▲ **Figure 29.17 Schematic illustration of a human-made device implanted in a biological system.** To function successfully, the device must be biocompatible with its surroundings and meet the necessary physical and chemical requirements, some of which are listed for illustrative purposes.

Polymers for Medicine

Increasingly, modern synthetic materials such as polymers are being used in medical and biological applications. For our discussion here, a **biomaterial** is any material that has a biomedical application. The material might have a therapeutic use in a treatment, injury or disease or it might have a diagnostic use as part of a system for identifying a disease or for monitoring a quantity such as the glucose level in blood. Whether the use is therapeutic or diagnostic, the biomaterial is in contact with biological fluids, so it must have properties that meet the demands of that application. For example, a polymer used to make a disposable contact lens must be soft and have an easily wetted surface, whereas the polymer used to fill a dental cavity must be hard and wear resistant. The most important characteristics that influence the choice of a biomaterial are biocompatibility, physical requirements and chemical requirements, as illustrated in Figure 29.17.

Specialized polymers have been developed for a variety of biomedical applications. The degree to which the body accepts or rejects the foreign polymer is determined by the nature of the groups along the chain and the possibilities for interactions with the body's own molecules. Our bodies are composed largely of biopolymers such as proteins, polysaccharides (sugars) and polynucleotides (RNA, DNA). We will learn more about these molecules in Chapter 31. For now, we can simply note that the body's biopolymers have complex structures, with polar groups along the polymer chain. Proteins, for example,

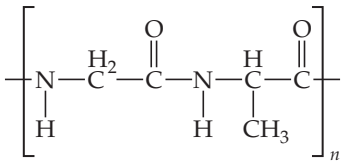
are long strings of amino acids (the monomers) that have formed a condensation polymer. The protein chain has the following structure:



where the R groups vary along the chain ($-CH_3$, $-CH(CH_3)_2$, and so on). Twenty different amino acids are used in different combinations to make up proteins in humans. By contrast, synthetic polymers are simpler, formed from a single repeating unit or perhaps two different repeating units. This difference in complexity is one of the reasons why synthetic polymers are identified by the body as foreign objects. Another reason is that there may be few or no polar groups along the chain that can interact with the body's aqueous medium.

Polymers can be characterized by their physical properties. Elastomers are used as biomaterials in flexible tubing, over leads for implanted heart pacemakers and as catheters (tubes implanted into the body to administer a drug or to drain fluids). Thermoplastics, such as polyethene or polyesters, are employed as membranes in blood dialysis machines and as replacements for blood vessels. Thermoset plastics find limited, but important, uses. Because they are hard, inflexible and somewhat brittle, they are most often used in dental devices or in orthopedic applications, such as joint replacements. To fill a cavity, for example, the dentist may pack some material into the cavity, then shine an ultraviolet lamp on it. The light initiates a photochemical reaction that forms a hard, highly cross-linked thermoset polymer.

CHEMISTRY AND LIFE Biodegradable Sutures



Until the 1980s, if you had to have stitches in a wound, you had to go back later to get the stitches removed. Stitches that are used to hold living tissue together are called *sutures*. Since the 1980s, biodegradable sutures have been available. After the sutures have been applied to the tissue, they slowly dissolve away and do not release any harmful by-products. Today biodegradable sutures are made out of lactic acid—glycolic acid copolymers that slowly hydrolyze over time.

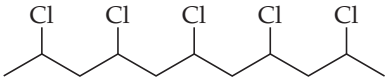
glycolic acid lactic acid copolymer [29.31]

Self-Assessment Exercise

29.28 The material that makes up much of a spider's web is a polymer with the structure:

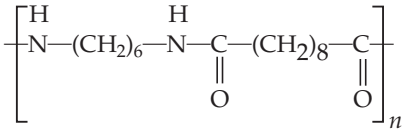
Identify the monomer units a spider uses to make its web.

(a) $NH_2-CH_2-NH_2$ and $HOOC-CH(CH_3)-COOH$



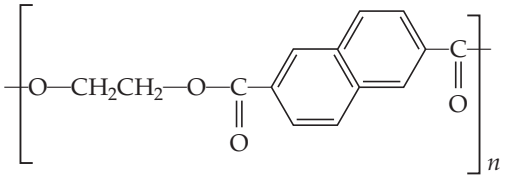
(b) $HOOC-CH_2-COOH$ and $NH_2-CH(CH_3)-NH_2$

(c) NH_2-CH_2-COOH and $NH_2-CH(CH_3)-COOH$



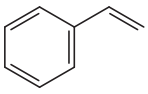
Exercises

29.29 Write a chemical equation for the formation of a polymer via a condensation reaction from the monomers succinic acid ($HOOCCH_2CH_2COOH$) and ethenediamine ($H_2NCH_2CH_2NH_2$).

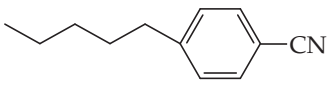


29.30 Draw the structure of the monomer/s employed to form each of the following polymers: **(a)** poly(vinyl chloride), **(b)** nylon 6,10 and **(c)** poly(ethene naphthalate).

poly(vinyl chloride)

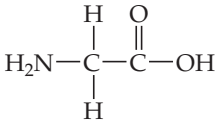


nylon 6,10

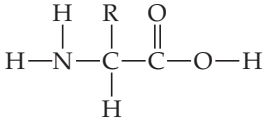


PEN

29.31 Consider the molecules shown here. **(a)** Which of these would be most likely to form an addition polymer? **(b)** Which would be most likely to form a condensation polymer?

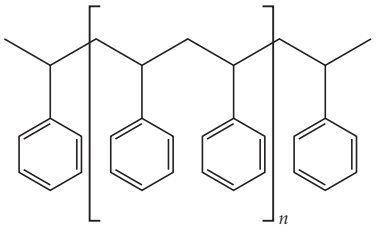


(i)

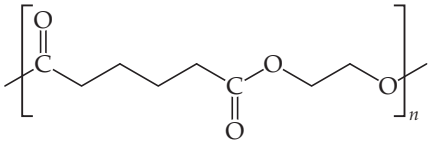


(ii)

(iii)

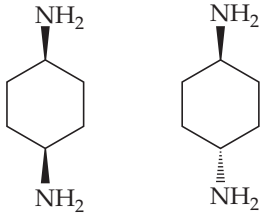


29.32 Proteins are polymers formed by condensation reactions of amino acids, which have the general structure



In this structure, R represents —H, $—CH_3$ or another group of atoms. Draw the general structure for a poly(amino acid) polymer formed by condensation polymerization of the molecule shown here.

29.33 On the basis of the structure of polystyrene and poly(ethene adipate) shown here, which class of polymer would you expect to form the most effective interface with biological systems? Explain.



polystyrene

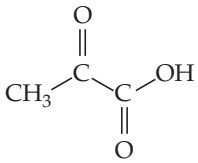
poly(ethene adipate)

29.34 If you were going to attempt to grow skin cells in a medium that affords an appropriate scaffolding for the cells and you had only two fabrics available, one made from polystyrene and the other from PET, which would you choose for your experiments? Explain.

29.35 **(a)** Draw the structure of Qiana®, a polyamide synthesized by the reaction of hexanedioic acid with *trans*-1,4-cyclohexanediamine. **(b)** What effect, if any, would there be in using *cis*-1,4-cyclohexanediamine instead of *trans*-1,4-cyclohexanediamine?

cis *trans*

1,4-cyclohexane diamine



Answers to Self-Assessment Exercise

29.28 (c)

Sample Integrative Problem

Putting Concepts Together

Pyruvic acid has the following structure:

It is formed in the body from carbohydrate metabolism. In the muscle it is reduced to lactic acid in the course of exertion. The acid-dissociation constant for pyruvic acid is 3.2×10^{-3}. **(a)** Why does pyruvic acid have a higher acid-dissociation constant than acetic acid? **(b)** Would you expect pyruvic acid to exist primarily as the neutral acid or as dissociated ions in muscle tissue, assuming a pH of about 7.4 and an acid concentration of 2×10^{-4} M? **(c)** What would you predict for the solubility properties of pyruvic acid? Explain. **(d)** What is the hybridization of each carbon atom in pyruvic acid? **(e)** Assuming H atoms as the reducing agent, write a balanced chemical equation for the reduction of pyruvic acid to lactic acid. (Although H atoms don't exist as such in biochemical systems, biochemical reducing agents deliver hydrogen for such reductions.)

SOLUTION

(a) The acid ionization constant for pyruvic acid should be somewhat greater than that of acetic acid because the carbonyl function on the α-carbon atom exerts an electron-withdrawing effect on the carboxylic acid group. In the C—O—H bond system, the electrons are shifted from hydrogen, facilitating loss of the hydrogen as a proton.

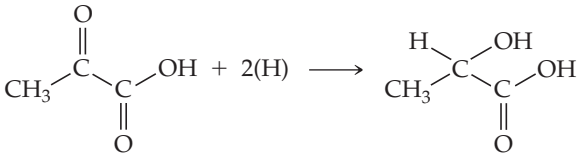
(b) To determine the extent of ionization, we first set up the ionization equilibrium and equilibrium constant expression. Using HPv as the symbol for the acid, we have

$$\text{HPv} \rightleftharpoons \text{H}^+ + \text{Pv}^-$$

$$K_a = \frac{[\text{H}^+][\text{Pv}^-]}{[\text{HPv}]} = 3.2 \times 10^{-3}$$

Let $[\text{Pv}^-] = x$. Then the concentration of undissociated acid is $2 \times 10^{-4} - x$. The concentration of $[\text{H}^+]$ is fixed at 4.0×10^{-8} (the antilog of the pH value). Substituting, we obtain

$$3.2 \times 10^{-3} = \frac{[4.0 \times 10^{-8}][x]}{[2 \times 10^{-4} - x]}$$



Solving for x, we obtain $x[3.2 \times 10^{-3} + 4.0 \times 10^{-8}] = 6.4 \times 10^{-7}$

The second term in the brackets is negligible compared with the first, so $x = [\text{Pv}^-] = 6.4 \times 10^{-7}/3.2 \times 10^{-3} = 2 \times 10^{-4}$ M. This is the initial concentration of acid, which means that essentially all the acid has dissociated. We might have expected this result because the acid is quite dilute and the acid-dissociation constant is fairly high.

(c) Pyruvic acid should be quite soluble in water because it has polar functional groups and a small hydrocarbon component. It is miscible with water, ethanol and diethyl ether.

(d) The methyl group carbon has sp^2 hybridization. The carbon carrying the carbonyl group has sp^2 hybridization because of the double bond to oxygen. Similarly, the carboxylic acid carbon is sp^2 hybridized.

(e) The balanced chemical equation for this reaction is

Essentially, the ketonic functional group has been reduced to an alcohol.

Chapter Summary and Key Terms

SECTION 29.1 **Carboxylic acids** are weak acids. They react with bases to form **carboxylate anions**, which are very stable due to resonance. Carboxylic acids readily form hydrogen bonded dimers in concentrated solution or neat.

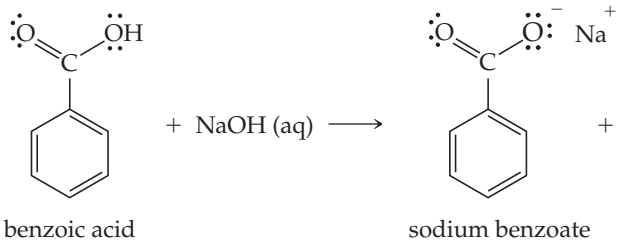
SECTION 29.2 Carboxylic acids are commonly prepared by oxidation of primary alcohols or aldehydes or by the oxidation of benzylic carbon atoms, yielding benzoic acid derivatives. They can also be prepared by hydrolysis of nitriles, amides and esters.

SECTION 29.3 **Esters** are formed by the condensation reaction of carboxylic acids and alcohols. This reaction is called the **Fischer esterification**. Esters can form amides by a condensation reaction with amines. Esters undergo hydrolysis, called **saponification**, in the presence of strong bases.

SECTION 29.4 Esters such as **fats**, **oils**, **waxes** and **triglycerides** are abundant in biological systems. They form part of a general class called **lipids**. Lipids come in two forms; **complex** and **simple**, depending on

the chemical properties of the lipid. Polyunsaturated triglycerides can be hardened by catalytic hydrogenation, which changes the texture of the triglyceride from a liquid form to a solid/semi-solid form. This process is called **hardening**. The saponification of a triglyceride leads to a **soap**. In water, soaps form a **micelle**, encapsulating dirt particles. Hard waters that contain Ca^{2+} often leave an insoluble scum. **Synthetic detergents** are designer soaps that eliminate the unwanted properties associated with the formation of calcium salts.

SECTION 29.5 **Acid anhydrides** and **acid halides** also contain an **acyl group** and are more reactive than their ester or carboxylic acid analogues. Both the anhydrides and acid halides are useful starting materials with which to make esters and **amides** through **nucleophilic acyl substitution** reactions.



SECTION 29.6 A **condensation polymerization** occurs when a small molecule is lost upon reaction. The two main types of condensation polymers are **polyesters** and **polyamides**. A polymer formed from two different monomers is called a **copolymer**. A **biomaterial** is any biocompatible material that has a biomedical application. Biomaterials are commonly polymers with special properties matched to the application.

Key Skills

- Be able to prepare carboxylic acids from a range of starting materials. (Section 29.2)
- Know how to name carboxylic acids, esters, amides and acid chlorides and to discern these functional groups. (Sections 29.3–29.5)
- Be able to define terms such as lipid, oil and fat and reference these terms to classes of compounds. (Section 29.4)
- Understand the differences and similarities between a soap and a detergent. (Section 29.4)
- Be able to determine the products of acyl nucleophilic substitution of esters, acid chlorides and anhydrides with a range of nucleophiles. (Section 29.5)
- Be familiar with the chemistry of carboxylic acids—including their acidity, the stability of carboxylate salts, their reaction with alcohols to form esters and their reaction with amines to form amides. (Sections 29.2–29.5)
- Be able to draw and name polyesters from monomers and identify monomers within polyesters. (Section 29.6)

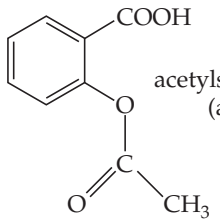
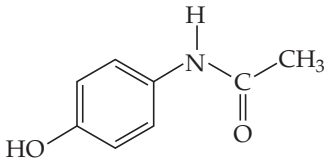
Exercises

Visualizing Concepts



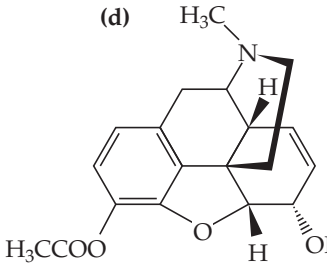
29.36 Identify each of the functional groups in the following molecules. [Sections 29.1 and 29.2]

(a)



chloramphenicol (an antibiotic)

(b)



acetylsalicylic acid (aspirin)

(c)

paracetamol

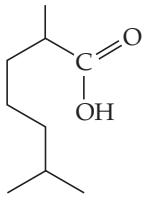
(d)

heroin

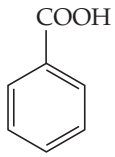
29.37 What features must a molecule have to participate in hydrogen bonding with other molecules of the same kind? Which of the following compounds would you expect to **(a)** have the highest melting point, **(b)** be most soluble in mild aqueous base? Explain. [Section 29.1]

(i) (ii) (iii) (iv)

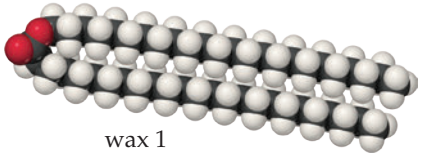
29.38 Draw the structure of the alcohol precursor, its systematic name and the reaction conditions you might use to obtain the following compounds by oxidation. [Section 29.1]



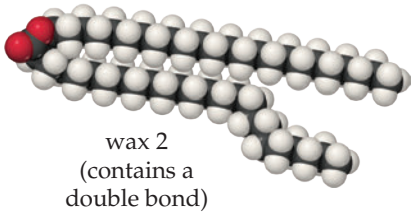
(a)



(b)



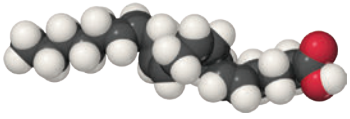
(c)



(d)

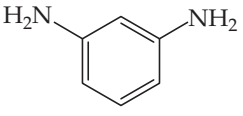
29.39 Which of the following waxes will have the lower melting point? [Section 29.4]

wax 1

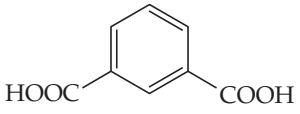


wax 2 (contains a double bond)

29.40 Which of the following fatty acids, when reacted with potassium hydroxide, would form better micelles and hence make the best soap? Explain. [Section 29.4]



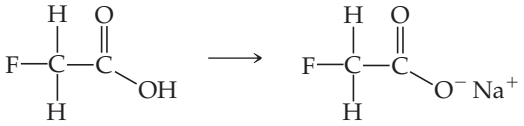
arachidic acid



arachidonic acid

29.41 The polyamide Nomex is prepared from the condensation polymerization of 1,3-benzenediamine with 1,3-benzenedicarboxylic acid. **(a)** Draw a structural formula representation of the polymer, being sure to indicate the repeat unit. **(b)** Would you expect such a polymer to have applications requiring high strength and high temperature, or to be more useful as a *glad-wrap* alternative? Explain your answer. [Section 29.6]

1,3-benzenediamine



1,3-benzenedicarboxylic acid

Carboxylic Acids (Section 29.1)

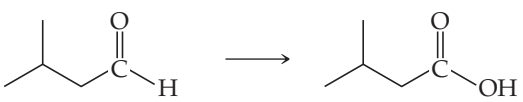
29.42 Although carboxylic acids and alcohols both contain an −OH group, one is acidic in water and the other is not. Explain the difference.

29.43 "Bath bombs" contain calcium carbonate and citric acid. When placed into water, they fizz and dissolve rapidly. What are the products of this reaction?

29.44 **(a)** Sodium monofluoroacetate, known as "1080", is a commonly used rabbit and fox poison. What reagent could be used to convert fluoroacetic acid into 1080? **(b)** Explain why the pK_a for fluoroacetic acid ($pK_a = 2.59$) is lower than the pK_a of acetic acid (CH_3COOH, $pK_a = 4.76$).

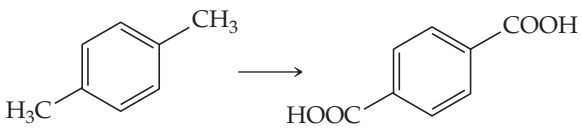
fluoroacetic acid 1080

29.45 **(a)** The structural formula for acetic acid is shown in this table. Replacing hydrogen atoms on the carbon with chlorine atoms causes an increase in acidity, as follows:



Acid	Formula	K_a (25 °C)
Acetic	CH_3COOH	1.8×10^{-5}
Chloroacetic	$CH_2ClCOOH$	1.4×10^{-3}
Dichloroacetic	$CHCl_2COOH$	3.3×10^{-2}
Trichloroacetic	CCl_3COOH	2×10^{-1}

Using Lewis structures as the basis of your discussion, explain the observed trend in acidities in the series. Calculate the pH of a 0.010 *M* solution of each acid.



Preparation of Carboxylic Acids (Section 29.2)

29.46 Suggest plausible reagents for the transformations shown here.

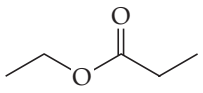
(a)

(b)

29.47 Describe methods for preparing butanoic acid from each of the following:

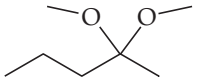
(**a**) butan-1-ol

(**b**) butanal



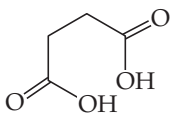
(**c**) methyl butanoate

(**d**) butanoyl chloride

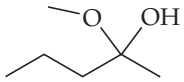


Esters and Esterification (Section 29.3)

29.48 Classify the following compounds as acetals, alcohols, hemiacetals, carboxylic acids, esters or ethers:



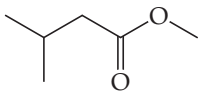
(a)



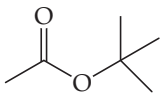
(b)

(c)

(d)



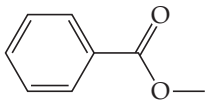
29.49 Name the following esters and draw the starting materials needed to synthesize them.



(a) **(b)** **(c)**

29.50 Draw the products of the following hydrolysis reactions.

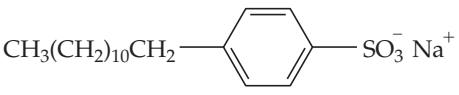
(a)



(b)

(c) $CH_3CH_2COOCH_2CH_2CH_3$ $\xrightarrow{H^+(aq)}$

(d)

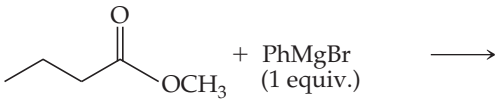


Fats, Oils, and Waxes (Section 29.4)

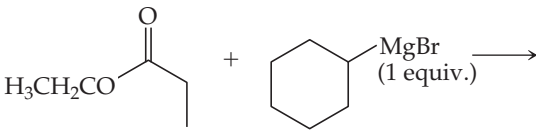
29.51 Write a balanced chemical equation using condensed structural formulas for the saponification (base hydrolysis) of **(a)** methyl propionate, **(b)** phenyl acetate.

29.52 Locate the stereogenic center/s in a triglyceride bearing one palmitic acid, one stearic acid and one arachidic side chain (see Table 29.5).

29.53 The structure of a synthetic detergent is shown here. **(a)** What features make this compound act like a natural soap? **(b)** Draw a simple micelle using this molecule to demonstrate the detergent's application. Label the hydrophobic and hydrophilic regions of the micelle.



sodium 4-dodecylbenzene sulfonate (SDS)

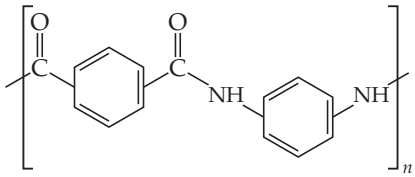


Nucleophilic Acyl Substitution (Section 29.5)

29.54 Draw the major product expected under the following conditions (Ph = C_6H_5):

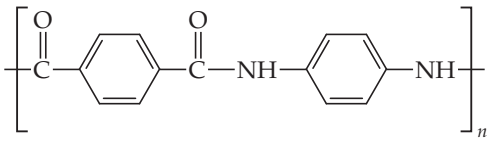
(a)

(b)



29.55 Draw the condensed structure of the compounds formed by reactions between **(a)** benzoic acid and ethanol, **(b)** ethanoyl chloride and methylamine, **(c)** acetic acid and phenol. Name the compound in each case.

29.56 γ-Hydroxybutanoic acid (GHB) can be prepared enzymatically from 1,4-butanediol. **(a)** Devise a method of preparing GHB in the laboratory from 1,4-butanediol. What compromise did you have to make? **(b)** GHB can form a cyclic ester under acidic conditions. Draw the structure of this ester.

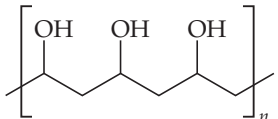


Condensation Polymerization (Section 29.6)

29.57 The nylon Nomex®, a condensation polymer, has the following structure:

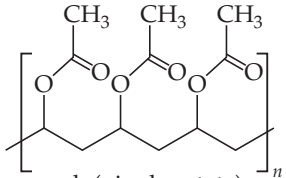
Draw the structures of the two monomers that yield Nomex®.

29.58 Kevlar®, a high-performance polymer, has the following structure:



Write the structural formulas for the two compounds that are condensed to form this polymer.

29.59 In addition to the condensation of dicarboxylic acids with diamines, nylons can also be formed by the condensation reactions of aminocarboxylic acids with themselves. Nylon 4, for example, is formed by the polycondensation of 4-aminobutyric acid ($NH_2CH_2CH_2CH_2COOH$). Write a chemical equation to show the formation of nylon 4 from this monomer.



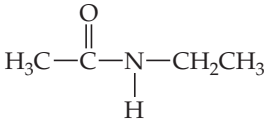
29.60 Briefly explain why it is important to achieve correct 1:1 stoichiometry of monomers in a condensation polymerization.

29.61 PET soft drink bottles can be recycled by heating the PET with methanol in the presence of an acid catalyst. The result of this reaction is the isolation of ethene glycol and dimethyl terephthalate (the dimethyl ester of terephthalic acid). These compounds are then reused in the manufacture of new PET-containing products. Write a reaction for the acid-catalyzed degradation of PET with methanol.

29.62 Poly(vinyl alcohol), PVA, is a useful water-soluble polymer. It cannot be prepared directly from vinyl alcohol, because vinyl alcohol tautomerizes spontaneously to acetaldehyde. It can, however, be prepared from poly(vinyl acetate). Design an experiment for the conversion of poly(vinyl acetate) to poly(vinyl alcohol).

poly(vinyl alcohol)

poly(vinyl acetate)



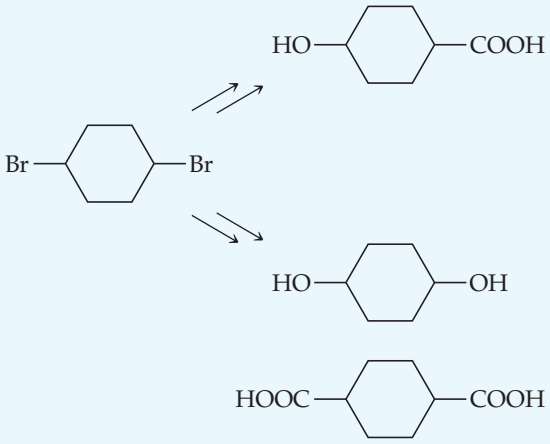
29.63 Glyptal® resin makes a strong thermoset polymer with applications in the electronics and car industries. It is prepared by the condensation of terephthalic acid and glycerol. Draw the structure of Glyptal® and explain its remarkable strength and rigidity.

Integrative Exercises

29.64 Bromobenzene is reacted first with magnesium, then carbon dioxide followed by dilute acid in a Grignard reaction. **(a)** Draw the structure of the product of this reaction. A 0.0050 *M* solution of the product has a pH of 3.25. **(b)** What is the K_a of the product? **(c)** The conjugate base of the product is a resonance-stabilized anion. Draw all the major resonance structures of this anion.

29.65 Many esters are volatile compounds with distinct fragrances. The boiling point of an ester is often lower than you might expect from the boiling points of the carboxylic acid and alcohol from which it is derived. For example, ethyl methanoate has a boiling point of 54 °C and the boiling points of ethanol and methanoic acid are 78 °C and 100 °C, respectively. **(a)** Draw the structure of ethyl methanoate and indicate the approximate bond angle associated with the carbonyl carbon and ether oxygen atom. **(b)** What intermolecular force is responsible for an increase in boiling point as molecular mass increases in a series of similar compounds? **(c)** What additional intermolecular forces are present in carboxylic acids and alcohols that are not present in the related ester?

29.66 Ethene is an important product from the petrochemical industry. Devise a synthesis of *N*-ethyl acetamide using ethene as the only carbon source. [*Hint*: NH_2^- is a powerful nucleophile.]



N-ethyl acetamide

Design an Experiment

Imagine you are a materials chemist working on a new polyester based on cyclohexane. You want to investigate the difference between a copolymer formed from a dicarboxylic acid with a diol and the polymer formed from a single monomer unit containing both carboxylic acid and alcohol functional groups. For economy of manufacture, you start with 1,4-dibromocyclohexane to make both types of monomer.

How do you synthesize the starting monomers? Do you need to pay attention to the relative quantities of reagents that you use? When making 4-hydroxycyclohexanecarboxylic acid is it important which order you use to install the two different functional groups? How might you carry out the polymerization reaction? What sort of properties do you anticipate for your polymer?

30.5 Electrophilic Aromatic Substitution (EAS) Reactions

30.1 The Structure of Benzene

The history of benzene and the discovery of its unusual structure is an interesting story. In 1825, Michael Faraday isolated a pure compound from the oily mixture that condensed from illuminating gas, the fuel burned in gaslights common at the time in England. The compound had a boiling point of 80 °C and a pungent odour. Elemental analysis of the compound showed it had a carbon-to-hydrogen ratio of 1:1, corresponding to an empirical formula of CH. About nine years later, German chemist Eilhard Mitscherlich (1794–1863) synthesized the same compound by heating benzoic acid in the presence of lime:

$$\underset{\text{gum of benzoin (benzoic acid)}}{C_6H_5COOH} + \underset{\text{calcium oxide}}{CaO} \xrightarrow{\text{heat}} \underset{\text{benzene}}{C_6H_6} + \underset{\text{calcium carbonate}}{CaCO_3}$$

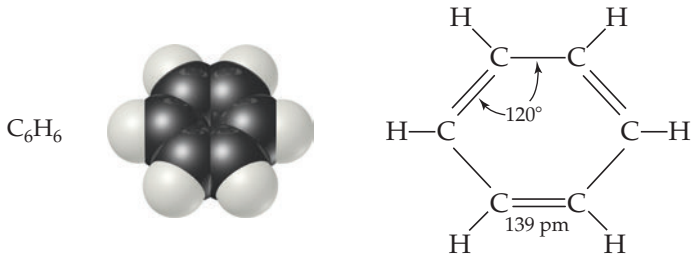
He further used vapor-density measurements to determine the molecular weight of 78 u. He named the new compound *benzin*, after the gum benzoin from which he derived it. We now know this compound as benzene.

However, benzoic acid had been known for several hundred years before Mitscherlich's experiment. Benzoic acid is the white odourless compound isolated from benzoin resin, a substance extruded by several types of Southeast Asian trees of the genus *Styrax*. It is often used as a topical fungicide.

Although the experiments of Mitscherlich showed that benzene must have the formula C_6H_6, it was not clear what the structure of the molecule could be. Only after 1860, when the concept of unsaturation was introduced, did August Kekulé (1829–1896) propose a suitable model. Kekulé was instrumental in developing much of the structural theory of organic chemistry, but he is best known for his work on benzene (1865). How he came to propose the structure of benzene is the truly fascinating part of this story. Kekulé recalled falling asleep on a London bus, and while he was dozing, he conjured images of "dancing atoms" that connected into snakes. As the snakes twisted and turned, eventually one caught its own tail, giving the image leading to the now famous structure of alternating double and single bonds. In his theory, however, two interconvertable structures were possible. As we know now, the structure is subtly different, but considering the level of chemical knowledge at this point in time, and more importantly, on the chemistry of benzene, Kekulé's proposed structure was revolutionary.

By the end of this section, you should be able to:

- Understand the unusual structure that benzene possesses.

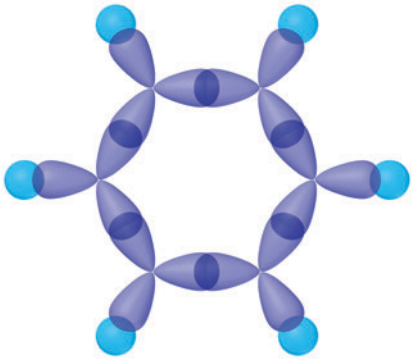


In Chapter 26, we discussed the structure of both alkenes and alkynes and described the carbon atoms that form the molecular skeleton as *unsaturated*. The trigonal-planar bonding geometry of an alkene carbon was rationalized based on the hybridization of one 2*s* and two 2*p* orbitals available to carbon. Recall that the overlap of unhybridized *p* orbitals forms a π-bond. One other class of hydrocarbon also takes advantage of π-bonding—the *aromatic hydrocarbons*.

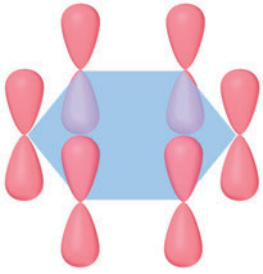
Benzene is the simplest example of an **aromatic hydrocarbon** (also called an **arene**). This class of hydrocarbon contains a planar ring structure, usually drawn with either a circle in the middle (for reasons we discuss shortly), or alternating single and double bonds (**Figure 30.1**). Although aromatic hydrocarbons involve sp^2-hybridized carbons, they are not alkenes, and undergo very different chemical reactions.

Bonding in Benzene

In many of the molecules we have discussed so far, the bonding electrons are *localized*. By this we mean that the σ- and π-electrons are associated totally with the two atoms that form the bond. In some molecules, however, we cannot adequately describe the bonding as being entirely localized. One molecule that cannot be described with localized π-bonds is benzene (C_6H_6).



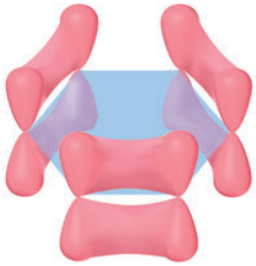
Go Figure How does the structure of benzene relate to cyclohexane?



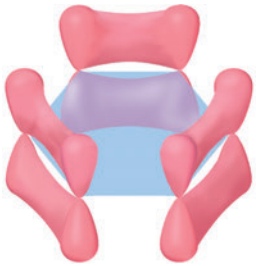
▲ **Figure 30.1 Benzene.** Molecular formulas and geometrical representations for benzene.

To describe the bonding in benzene, we first choose a hybridization scheme consistent with the geometry of the molecule (see Figure 30.1). As each carbon is surrounded by three atoms at 120° angles, the appropriate carbon hybrid orbital set is sp^2. Six localized C—C σ-bonds and six localized C—H σ-bonds are formed from the sp^2 hybrid orbitals, as shown in **Figure 30.2(a)**. This leaves a $2p$ orbital on each carbon atom that is oriented perpendicularly to the plane of the hydrocarbon ring. The situation is very much like that in ethene, except we now have six carbon $2p$ orbitals arranged in a ring (Figure 30.2(b)). Each of the unhybridized $2p$ orbitals is occupied by one electron, meaning a total of six electrons have to be accounted for by π-bonding.

We could imagine using the unhybridized $2p$ orbitals of benzene to form three *localized* π-bonds—that is, π-bonds defined formally between neighboring carbon atoms. As shown in **Figure 30.3(a) and (b)**, there are two equivalent ways to make these localized bonds and each diagram corresponds to one of the resonance structures of the molecule. A representation that reflects *both* resonance structures has the six π-electrons distributed among all six carbon atoms, as shown in Figure 30.3(c). Notice how this figure corresponds to the "circle-in-a-hexagon" drawing often used to represent benzene.



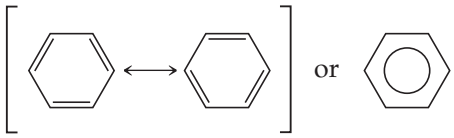
(a) σ-bonds



(b) $2p$ atomic orbitals

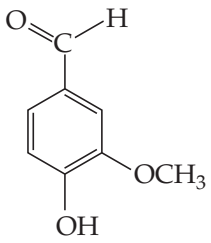
◀ **Figure 30.2 The σ- and π-bond networks in benzene, C_6H_6.** (a) The C—C and C—H σ-bonds all lie in the plane of the molecule and are formed by using carbon sp^2 hybrid orbitals. (b) Each carbon atom has an unhybridized $2p$ orbital that lies perpendicular to the molecular plane. These six $2p$ orbitals form the π-orbitals of benzene.

(a) Localized π-bonds

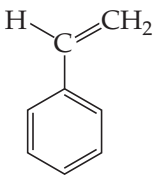


(b) Localized π-bonds

(c) Delocalized π-bonds

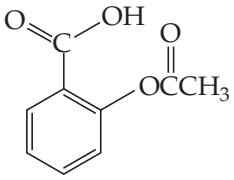


◀ **Figure 30.3 Delocalized π-bonds in benzene.** (a) The six $2p$ orbitals of benzene, shown in Figure 30.2(b), can be used to make three C—C π-bonds. (a) and (b) show two equivalent ways to make localized π-bonds. These π-bonds correspond to the two resonance structures for benzene. (c) A representation of the delocalization of the three C—C π-bonds among the six C atoms.

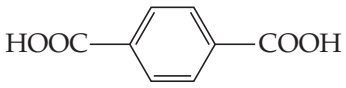


The model described in Figure 30.3(c) leads to the description of each carbon–carbon bond as having an identical bond length, which is between the length of a carbon–carbon single bond (154 pm) and the length of a carbon–carbon double bond (134 pm). This is consistent with the observed bond lengths in benzene (139 pm).

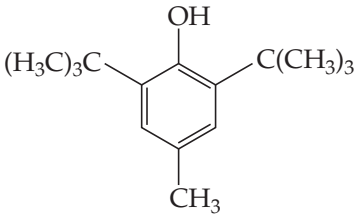
Since we cannot describe the π-bonds in benzene as individual electron-pair bonds between neighboring atoms, we say that the π-bonds are *delocalized* among the six carbon atoms. In Section 30.3 we investigate the effects of delocalization on reactivity and the concept of *aromaticity*. **Figure 30.4** shows the structures of some common aromatic compounds.



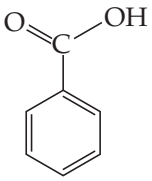
Go Figure Identify the functional groups attached to benzene in these examples.



vanillin
(from vanilla beans)



styrene
(used to make polystyrene)



acetylsalicylic acid
(aspirin)

terephthalic acid

Self-Assessment Exercise

30.1 Naphthalene, $C_{10}H_8$, has two benzene rings fused together along a common edge. How many π-electrons are there in naphthalene?

(a) 6
(b) 8
(c) 10
(d) 12

Exercises

30.2 Pyridine is an analog of benzene in which one of the sp^2 carbon atoms is replaced by nitrogen. **(a)** Does this molecule have delocalized π-bonds? **(b)** Draw a representation for pyridine that illustrates how this delocalization comes about. **(c)** How might the lone pair on nitrogen orientate itself within pyridine?

30.3 What structural features help us identify a compound as an aromatic hydrocarbon?

30.4 Name another compound that has the same empirical formula as benzene.

Answers to Self-Assessment Exercises

30.1 (c)

30.2 Isomerism and Nomenclature in Aromatic Compounds

Benzene and its derivatives play an important role in much of society. For example, when polymerized styrene forms polystyrene, a substance used for insulation and as a building material; tyrosine and phenylalanine are important naturally occurring amino acids that are benzene derivatives; phenols, the hydroxylated form of benzene, are the principal components of the tannins and are responsible for the antioxidant capacity of red wine; vanillin is the compound responsible for the very pleasant sweet, buttery smell associated with the extract of the vanilla plant. Finally, many drugs are composed around a benzene core, including aspirin and paracetamol.

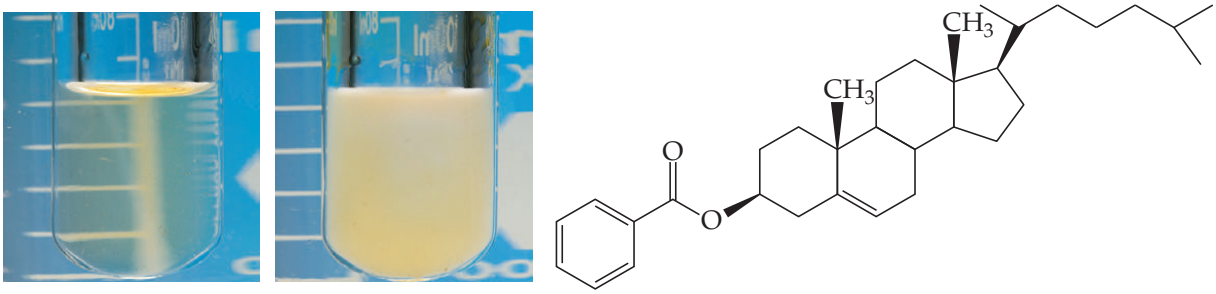
Aspirin, for example, is the common name of acetylsalicylic acid, a benzene-containing compound used commonly as an analgesic for pain relief. Aspirin was developed by Bayer in 1853 though salicylic acid present in willow bark had been known to relieve headaches since around 450 BCE.

Many other compounds isolated during the 19th century were related to benzene. For example, toluene was extracted by distillation from the balsam of the tolu tree in the 1840s. Each of these compounds had a low C : H ratio and many, such as vanillin, had pleasant rather than pungent aromas. As a result, this group of compounds were called aromatic compounds. We will see in Section 30.3 that, as the unusual properties of aromatic compounds were investigated, the term "aromatic" came to be applied to compounds with an unusual stability, regardless of their odor.

By the end of this section, you should:

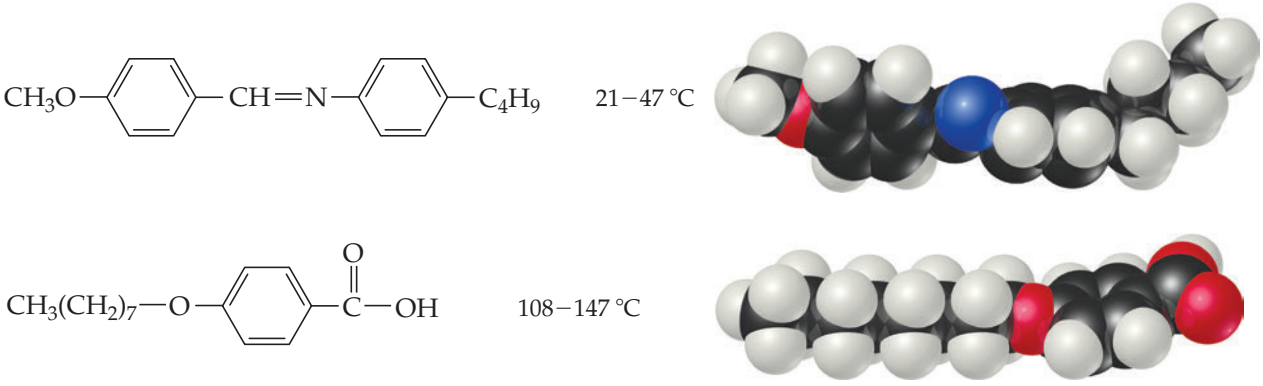
- Know the names of simple aromatic compounds

Aromatic compounds or *arenes* are a large and important class of organic compounds. The simplest member of the series is benzene (C_6H_6) and further arenes are formed essentially by fusing another C_6 skeleton to benzene. Each aromatic ring



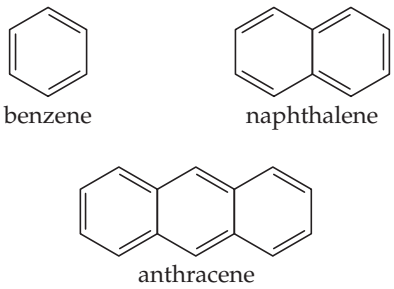
CHEMISTRY AND LIFE The Discovery of Liquid Crystals

In 1888 Frederick Reinitzer (1857–1927), an Austrian botanist, discovered that an organic compound he was studying, cholesteryl benzoate, had interesting and unusual properties. When heated, the substance melts at 145 °C to form a viscous milky liquid; at 179 °C the milky liquid suddenly becomes clear. When the substance is cooled, the reverse process occurs. Reinitzer's work represents the first systematic report of what we now call a *liquid crystal* (Figure 30.5).

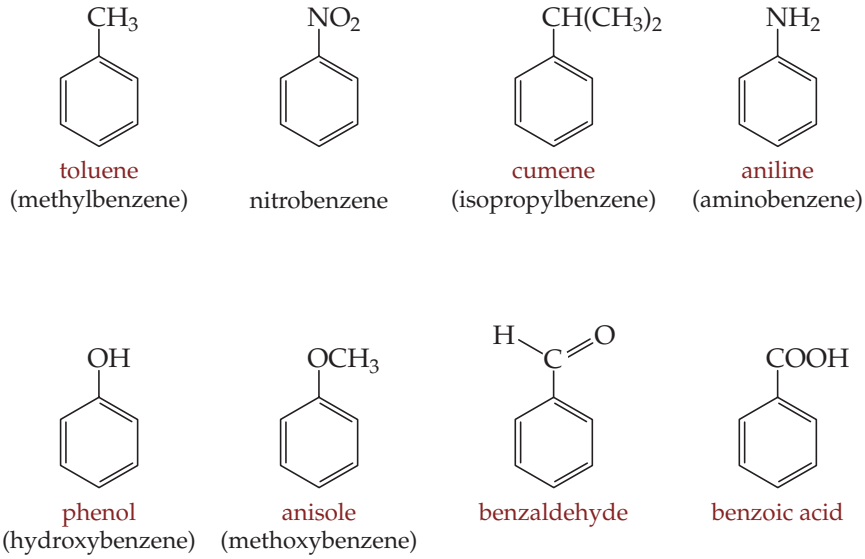


Instead of passing directly from a solid to the liquid phase when heated, some substances, such as cholesteryl benzoate, pass through an intermediate liquid crystalline phase that has some of the structure of solids and some of the freedom of motion possessed by liquids. Because of partial ordering, liquid crystals may be very viscous and possess properties between that of a solid and a liquid. The region in which they exhibit these properties is marked by sharp transition temperatures, as in Reinitzer's example of cholesteryl benzoate.

From the time of their discovery in 1888 until about 30 years ago, liquid crystals were largely a laboratory curiosity. However, researchers found that the weak intermolecular forces that hold the molecules together in a liquid crystal are easily affected by changes in temperature, pressure and electric fields. As a result, liquid crystals are now widely used as temperature and pressure sensors and in the displays of electrical devices such as digital watches, calculators, mobile phones and laptop and hand-held calculators.

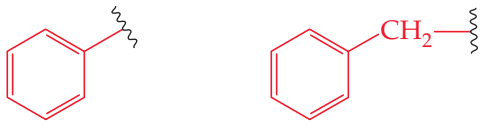


Substances that form liquid crystals are often composed of long, rod-like molecules. They usually contain a long-chain alkane component (minimum chain length of five carbons) linked to an aromatic group such as benzene (Figure 30.6). The liquid crystalline properties they exhibit are in fact due to the ordered interplay of London dispersion forces and aromatic–aromatic interactions, also called π–π interactions.



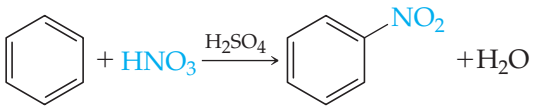
▲ **Figure 30.5 Liquid and liquid crystal.** (a) Molten cholesteryl benzoate at a temperature above 179 °C. In this temperature region the substance is a clear liquid. Note that the printing on the surface of the beaker behind the sample test tube is readable. (b) Cholesteryl benzoate at a temperature between 179 °C and its melting point, 145 °C. In this temperature interval, cholesteryl benzoate exists as a milky liquid crystalline phase. (c) The structure of cholesteryl benzoate.

▲ **Figure 30.6 Structures and liquid crystal temperature intervals of two typical liquid crystalline materials.** The temperature interval indicates the temperature range in which the substance exhibits liquid crystalline behavior.



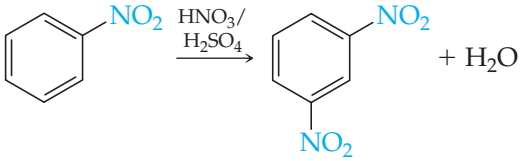
▲ **Figure 30.7 Condensed structural formulas and common names of several aromatic compounds.** The aromatic rings are represented by hexagons with a circle inscribed inside to denote aromatic character. Each corner represents a carbon atom. Each carbon is bound to three other atoms—either three carbons or two carbons and a hydrogen. The hydrogen atoms are not shown.

▲ **Figure 30.8 Benzene derivatives containing a single functional group.** The eight most common monosubstituted benzenes are listed together with their systematic and common names.



system is given a common name, as shown in **Figure 30.7**. The systematic names of monosubstituted benzenes are usually derived from benzene, although some common names are still used. For example, methylbenzene is known more commonly as toluene. The common names phenol, anisole, benzaldehyde, benzoic acid and aniline are also retained. **Figure 30.8** illustrates some systematic and common names.

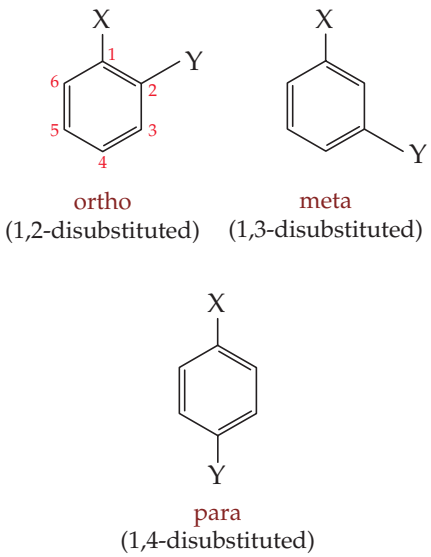
The substituent group C_6H_5 formed by the loss of a hydrogen atom from benzene is called a **phenyl group**. The loss of a hydrogen atom from toluene leads to a **benzyl group**.



phenyl group benzyl group

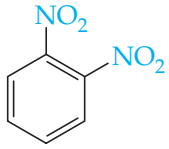
When a benzene ring has two substituents, they can form three possible constitutional isomers—*ortho*, *meta* and *para* (**Figure 30.9**). When benzene is warmed in a mixture of nitric and sulfuric acids, for example, hydrogen is substituted by the nitro group, NO_2:

[30.1]



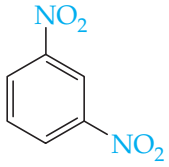
More vigorous treatment results in substitution of a second nitro group into the molecule:

[30.2]

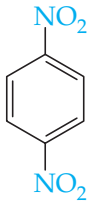


Go Figure

How many *ortho*, *meta* and *para* positions exist in a monosubstituted benzene?

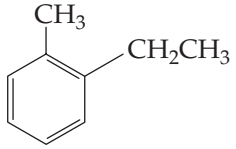


▲ **Figure 30.9 Substitution on benzene.** There are three ways of arranging two substituents on benzene—as *ortho*, *meta* and *para* substitution. Each isomer has different physical and chemical properties.

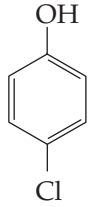


The three possible isomers of benzene with two nitro groups attached are *ortho*-, *meta*- and *para*-dinitrobenzene:

ortho-dinitrobenzene
mp 118 °C

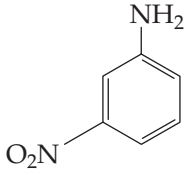


meta-dinitrobenzene
mp 90 °C

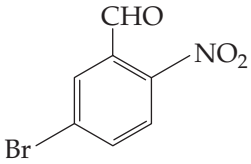


para-dinitrobenzene
mp 174 °C

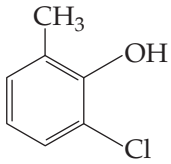
The *meta* isomer is formed as the major product of the reaction of nitric acid with nitrobenzene. We will explore the reason for this further in Section 30.5.



When one of the two substituents on the ring is able to impart a common name (for example, aniline, toluene, phenol), the compound is named based on that parent molecule. The substituent that imparts the common name occupies position number 1. When neither group imparts a common name, the two substituents are listed alphabetically (with the lowest position numbers possible) before ending in *benzene*. The same rules apply to three or more substituents.



2-ethyltoluene or
o-ethyltoluene

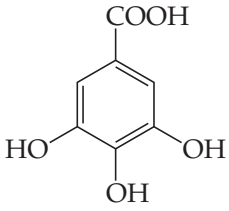


4-chlorophenol or
p-chlorophenol

3-nitroaniline or
m-nitroaniline

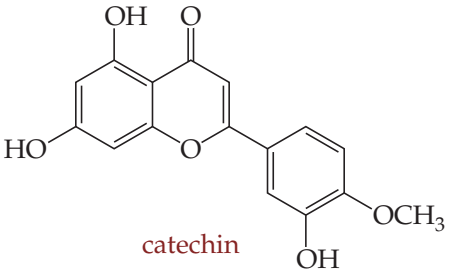
5-bromo-2-nitrobenzaldehyde

2-chloro-6-methylphenol



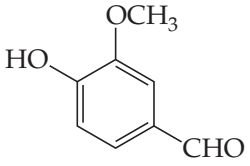
In naming disubstituted benzenes, either position numbers or the use of *o* for *ortho*, *m* for *meta* and *p* for *para* is acceptable. For the more substituted benzenes, only position numbers are used. As with other nomenclature we have studied, these position numbers need to be made as small as possible while maintaining the parent molecule group at position 1. Where a choice of parent group exists, there is a hierarchy similar to that used for multifunctional alkanes. For example, 2-chloro-6-methylphenol is named as such and not as 3-chloro-2-hydroxytoluene. This hierarchical method of naming is based on which functional group is of higher order. A useful, though not exhaustive, order is:

$$\textit{toluene} < \textit{aniline} < \textit{phenol} < \textit{benzaldehyde} < \textit{benzoic acid}$$



Phenols

Phenols, or hydroxybenzenes, are named after the parent compound, phenol, which was first isolated from coal tar in 1834. The phenol structure is based on the direct attachment of the OH group to a benzene ring. This connectivity confers unique properties on phenols. Some phenol derivatives are named as substituted phenols, others as hydroxy compounds, depending on which other functional groups are present. Many have trivial names.



Phenols are an important class of natural product, widely distributed throughout nature. Several examples of naturally occurring phenols are shown here and in **Figure 30.10**. Gallic acid and catechin are phenols found in wines. One of their properties is to act as an antioxidant. Compare their structure with another phenolic antioxidant, vitamin E. Vanillin is the compound responsible for the odour produced by vanilla beans. The cresols, of which *p*-cresol is shown, are isolated from coal tar. They found use in the 1960s–1980s as a wood preservative. There is evidence to suggest that due to their antioxidant properties, the polyphenols in fruit and vegetable juice, and in wine, may play an important role in delaying the onset of colds and in more specific conditions such as Alzheimer's disease.

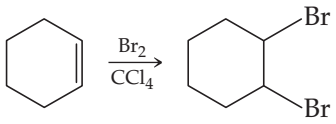
30.3 | Aromaticity

The illustration portrays an atomic model of a carbon nanotube. The fact that carbon nanotubes can be made either semiconducting or metallic is unique among all solid-state materials. Because the basic elements of the transistor are semiconductors and metals, there is great interest in building nanoscale electronic circuits using only carbon nanotubes. Carbon nanotubes are also being explored for their mechanical properties. Experiments on individual carbon nanotubes suggest that they are stronger than steel of the same dimensions. Carbon nanotubes have also been spun into fibres with polymers, adding great strength and toughness to the composite material.



By the end of this section, you should be able to:

- Recognize an aromatic compound based on three criteria

The planar, highly symmetrical structure of benzene, with its 120° bond angles, suggests a high degree of unsaturation. You might therefore expect benzene to resemble the unsaturated hydrocarbons and be highly reactive. The chemical behavior of benzene, however, is unlike that of alkenes or alkynes. Benzene and the other aromatic hydrocarbons are much more stable than alkenes and alkynes because the π-electrons are delocalized in the unhybridized *p* orbitals (Section 30.1).

Let's consider two molecules, cyclohexene and benzene, and their reactions with bromine. Although cyclohexene reacts readily with bromine at room temperature, benzene does not react with bromine at all under these conditions.

The systematic and common names are listed.

[30.3]

[30.4]

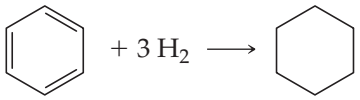


FIGURE 30.12 illustrates the structure of cyclohexatriene and its difference from benzene. This difference is due to the property of **resonance**. Resonance is an extremely important concept in describing the bonding in and stability of organic molecules, particularly aromatic and other highly conjugated molecules. For many molecules and ions, no single Lewis structure provides a truly accurate representation, so a set of **resonance structures** is often used to describe a molecule or ion. For example, there are two equivalent Lewis structures for benzene, each of which satisfies the octet rule. These two structures are in resonance, each resonance structure showing three C—C single bonds and three C—C double bonds, but the double bonds are in different places in the two structures. The actual structure is neither of these two but somewhere intermediate to both.

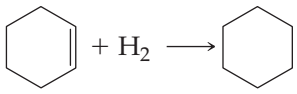
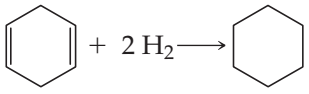
In the case of benzene, curved arrows can also be used to interconvert the two canonical structures as shown in **FIGURE 30.13**.

So far we have discussed benzene as an aromatic compound, but what is aromaticity? Originally, molecules derived from benzene were called aromatic purely because of their smell. Later, however, the German chemist Eric Hückel (1896–1980) defined what an aromatic compound is through a set of criteria. It must:



1. be cyclic and planar;
2. have at least one unhybridized *p* orbital on each atom of the ring; and
3. have $[4n + 2]$ π-electrons, where n is an integer $n = 0, 1, 2, 3 \ldots$

Aromatic molecules resist any move to break that aromaticity. This resistance is quantified as aromatic stabilization or **resonance energy**. We can estimate the stabilization of the π-electrons in benzene by comparing the energy released when hydrogen gas reacts with benzene (a reaction known as *hydrogenation*) to form a saturated compound, with the energy required to hydrogenate certain alkenes. The hydrogenation of benzene to form cyclohexane can be represented as



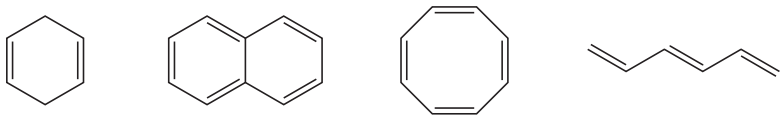
$$\Delta H^\circ = -208 \text{ kJ/mol} \qquad [30.5]$$

The enthalpy change in this reaction is −208 kJ/mol. The heat of hydrogenation of the cyclic alkene cyclohexene is −120 kJ/mol:

$$\Delta H^\circ = -120 \text{ kJ/mol} \qquad [30.6]$$

Similarly, the heat released on hydrogenating 1,4-cyclohexadiene is −232 kJ/mol^{-1}:

$$\Delta H^\circ = -232 \text{ kJ/mol} \qquad [30.7]$$



From these last two reactions, it appears that the heat of hydrogenating each double bond is roughly −116 kJ/mol. Since benzene has the equivalent of three double bonds, we might expect that the heat of hydrogenating benzene would be about three times −116 kJ/mol (or −348 kJ/mol). Instead, the heat released is 140 kJ less, indicating that benzene is more stable than would be expected for three double bonds. The difference of 140 kJ/mol^{-1} between the "expected" heat of hydrogenation, −348 kJ/mol, and the

observed heat of hydrogenation, −208 kJ/mol, is due to stabilization of the π-electrons through delocalization.

Many other molecules apart from aromatic hydrocarbons show aromaticity. These molecules typically contain one or more **heteroatoms** (for example, O, N, S). Such compounds, called **heterocyclic compounds**, tend to be biologically active and are dealt with in more detail in Chapter 31.

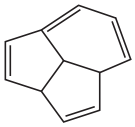
Self-Assessment Exercise

30.8 Which of the following compounds is aromatic?

(a) (b) (c) (d)

Exercises

30.9 **(a)** Use the concept of resonance to explain why all six C—C bonds in benzene are equal in length. **(b)** The C—C bond lengths in benzene are longer than C—C single bonds but shorter than C—C double bonds. Use the resonance model to explain this observation.



30.10 **(a)** Briefly discuss some of the evidence that has been used to demonstrate the phenomenon of aromaticity. **(b)** Briefly discuss the valence-bond model of aromaticity.

30.11 **(a)** What *two* experimental results prove that cyclohexatriene is a poor representation of the real structure of benzene? **(b)** Benzene has six sp^2-hybridized carbons. How many electrons are left in each of the six *p* orbitals of benzene? How many electrons in the π-system of benzene? **(c)** With the aid of resonance structures, describe how the structure of benzene and the hypothetical cyclohexatriene differ.

30.12 **(a)** Draw a benzylic cation. **(b)** Use arrow notation to describe why this intermediate is more stable than that for the corresponding methylcyclohexane primary carbocation.

30.13 List the criteria that compounds must meet in order to be considered aromatic.

30.14 **(a)** How many π-electrons should an aromatic molecule contain? **(b)** Is the following molecule aromatic?

Answers to Self-Assessment Exercise

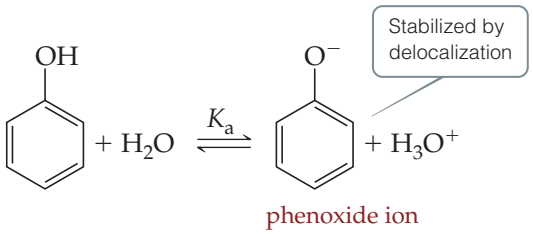
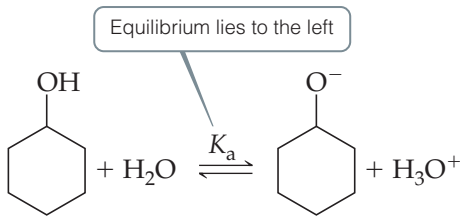
30.4 | Acidity of Phenols



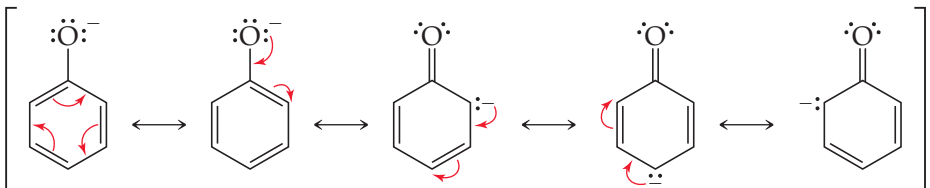
In 1907, the New York–based chemist Leo Baekeland invented the first plastic to be made from synthetic components. He named it Bakelite, after himself, and was granted a patent two years later. It is a thermosetting plastic, which means that, once made, it cannot be melted and reshaped. It is made from phenol and formaldehyde in the presence of a catalyst and a filler such as wood dust or asbestos fibers to form a rigid, highly cross-linked polymer resin. The components can be mixed and even formulated into a powder with the final stage of the curing process being conducted in a mold involving both heat and pressure. Only a couple of minutes were required for the resin to set into a hard, durable, solvent resistant, slightly shiny material which could be turned from the mold while still hot. This made production rapid and the electrical insulating properties of Bakelite meant it was quickly adopted for casings of electrical equipment such as telephones, radios, and light switches. This was expanded to include a lot of household items, toys and games, equipment, and jewelry.



In this section, we look at phenol and, in particular, the acidity of phenol and its derivatives. By the end of the section, you should be able to

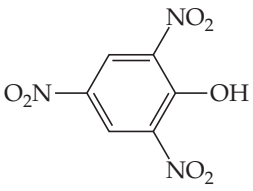
- Understand the factors that affect the acidity of a phenol.

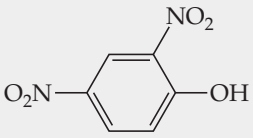
Phenols are approximately 10^6 times stronger acids than alcohols. Phenol was originally named carbolic acid, due to its unusually high acidity for an alcohol. To illustrate the difference in acidity of alcohols and phenols, let us consider two molecules: phenol and cyclohexanol. The chemical equations for their acid-dissociation constants are:

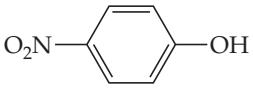


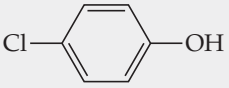
phenoxide ion [30.8]

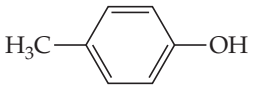
cyclohexoxide ion [30.9]

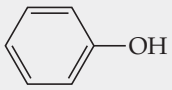




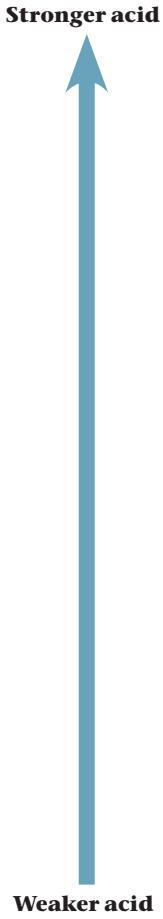








The pK_a of phenol is about 10, while that for cyclohexanol is about 16 (recall that $pK_a = -\log_{10}K_a$). The difference in acidity between phenol and cyclohexanol is due to the stability of the corresponding anion products. Phenols are more acidic because of the **resonance-stabilized** nature of the anion formed upon deprotonation relative to the alkoxide. This delocalization can be seen in the contributing structures illustrated in **Figure 30.11**.



The stability of the phenoxide ion arises from resonance. The last three structures on the right in Figure 30.11 illustrate, using curved arrow notation, how the charge is

▲ **Figure 30.11 Resonance stabilization.** Phenoxide ions are stabilized relative to alkoxide ions because phenoxide ions are able to resonance stabilize the negative charge around the aromatic ring.

TABLE 30.1 Relative pK_a values for selected alcohols and phenols*

Compound	Structural formula	pK_a
Hydrogen chloride	HCl	−7
Picric acid		0.5
2,4-Dinitrophenol		4
4-Nitrophenol		7
4-Chlorophenol		9
p-Cresol		10
Phenol		10
Water	H_2O	15.7
1-Propanol	$CH_3CH_2CH_2OH$	16

* Error in measurement ±0.2.

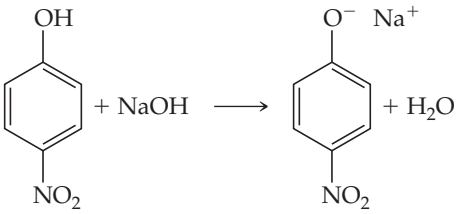
distributed to the *ortho* and *para* positions of the aromatic ring. This charge distribution through resonance is important to the reactivity of aromatic compounds.

In contrast to phenoxide, the cyclohexoxide ion doesn't allow for charge delocalization; the charge is localized on oxygen. Although arrow notation and the use of contributing structures allow us to rationalize why phenols are more acidic, they do not give us quantitative information on how strong an acid they might be. The pK_a value needs to be determined experimentally.

Table 30.1 compares the pK_a of several alcohols and phenols. Electron-withdrawing groups on the phenyl ring of phenol increase the acidity through **inductive effects**. **Electron-withdrawing groups** are those that are more electronegative than carbon. They can be atoms (for example, F, Cl, Br) or a collection of atoms such as the *nitro group*, NO_2, which, combined, are electron deficient. Each of these groups is able partially to withdraw electron density out of the O—H bond, making this bond weaker and hence the phenol more acidic. They can also contribute to the charge delocalization of the resulting phenoxide ion.

Sample Exercise 30.1

Utilizing the acidity difference



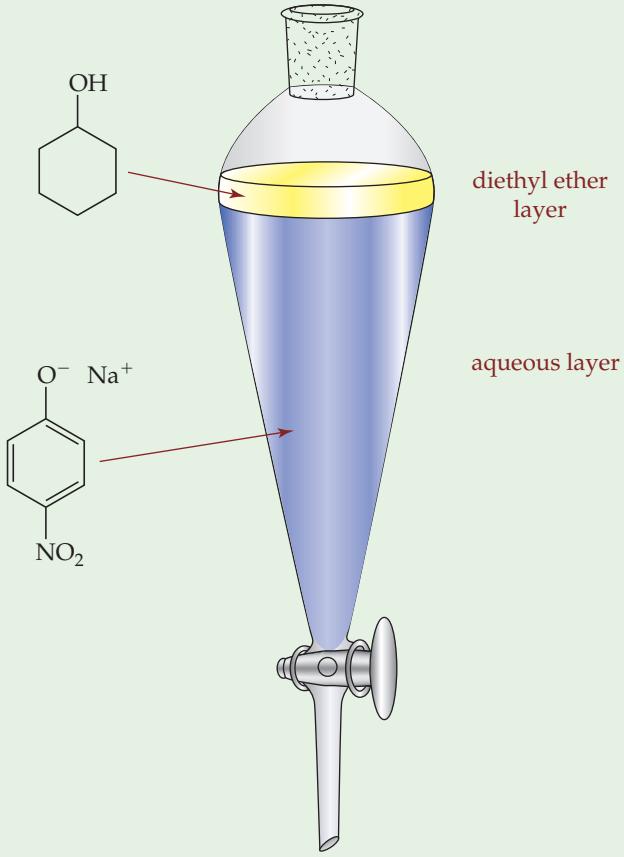
Suggest a method of separating 4-nitrophenol (pK_a = 7) and cyclohexanol (pK_a = 16) in a solution of diethyl ether.

SOLUTION

Analyze We are asked to find a way of separating a phenol and alcohol in an organic solution.

Plan Take advantage of the difference in pK_a between the two compounds and use the extraction method to remove one from the ether. Sodium phenoxides are salts, and many salts (including organic salts) are soluble in water. Cyclohexanol is not soluble in water because of the large cyclohexyl ring, which makes this compound more hydrophobic. The result is that the phenol can be separated into the water layer while the cyclohexanol stays in the diethyl ether layer.

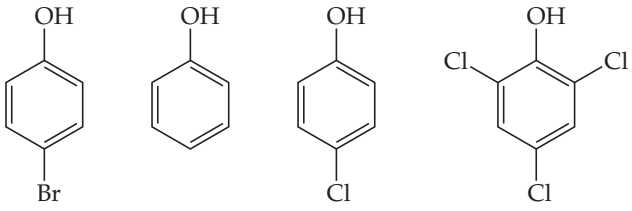
Solve The pK_a of phenols is such that an aqueous 1 M sodium hydroxide (NaOH) solution is basic enough to deprotonate the phenol, but not the cyclohexanol, by the following chemical equation:



a sodium phenoxide

Once reaction has occurred, two layers are formed—an diethyl ether layer and an aqueous layer. The layers are then separated using a separating funnel.

Once the two solutions are separated, the diethyl ether can be distilled off (bp 35 °C) to leave the pure cyclohexanol. Acidification of the aqueous layer using 1 M HCl yields 4-nitrophenol as a solid, which can be filtered off and dried.



Practice Exercise

Arrange these compounds in increasing order of acidity: 2,4-dichlorophenol, phenol, 2,6-dinitrophenol and 4-nitro-2-chlorophenol, using the trends in Table 30.1.

Self-Assessment Exercise

30.15 Order the following in terms of increasing acidity.

(A) **(B)** **(C)** **(D)**

(a) A < B < C < D
(b) B < A < C < D
(c) B < C < D < A
(d) D < C < A < B

Exercises

30.16 The phenolate ion gains stability through contributing resonance structures unlike the alkoxides ion. What does this tell you about the relative basicity of the alkoxide and phenolate ions?

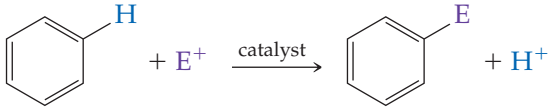
30.17 The acidity of the chlorophenols increases in the order *p*-chlorophenol < *m*-chlorophenol < *o*-chlorophenol. Explain this effect.

30.18 Draw a flow diagram to show how you could separate *p*-chlorophenol from *p*-chlorotoluene.

Answers to Self-Assessment Exercise

30.15 (b)

30.5 Electrophilic Aromatic Substitution (EAS) Reactions

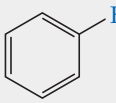


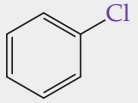
In the mid-1939s, Louis Hammett conducted pioneering work on what became known as linear free-energy relationships. His starting point was to look at how the acidity of benzoic acid changed when substituents were placed in either the *meta* or *para* positions. He then examined different reactions of aromatic compounds and determined how their rates compared for a particular substituent. This enabled him to construct a set of constants, one of which depended on the substituent present and the other on the type of reaction conducted. In this way, he was able to quantify, and understand better, the effect that a substituent has on the reaction of an aromatic compound. He coined the term "physical organic chemistry" to describe this area of the physical measurements of organic reactions.

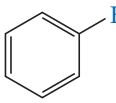
In this section, we look at the substitution reactions of aromatic compounds and see that they are influenced by what is already attached to the ring. A patten emerges! By the end of this section, you should:

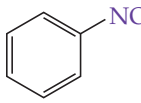
- Have a basic knowledge of the scope of the substitution reactions of aromatic compounds
- Be able to predict the effect a substituent has on the rate and position of substitution in EAS reactions

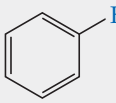
Although aromatic hydrocarbons are unsaturated, they do not readily undergo addition reactions. The delocalized π-bonding causes aromatic compounds to behave quite differently from alkenes and alkynes.

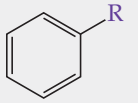


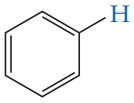


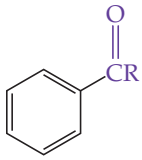










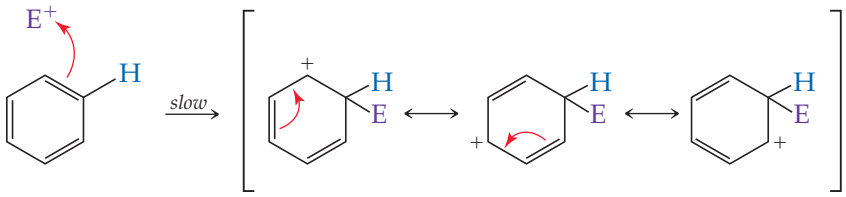


Benzene, for example, does not react with Cl_2 or Br_2 under ordinary conditions. In contrast, aromatic hydrocarbons undergo substitution reactions relatively easily. Such a reaction is called an **electrophilic aromatic substitution (EAS)** reaction. In a substitution reaction, one atom of a molecule is replaced (substituted) by another atom or group of atoms. These reactions occur in the presence of an electrophile, usually given the symbol E^+. A catalyst is usually needed to generate the electrophile.

[30.10]

Table 30.2 illustrates the four most common EAS reactions, their names and the nature of the electrophile used. Halogenation, employing either the *bromonium ion* (Br^+)

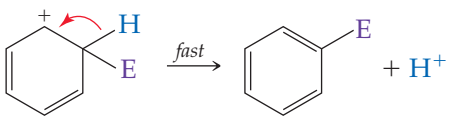
TABLE 30.2 The four most common forms of electrophilic aromatic substitution reaction



Reaction name	E^+	Reagent	Catalyst	Products
Halogenation	Cl^+ chloronium		$FeCl_3$	 + HCl
Nitration	NO_2^+ nitronium		H_2SO_4	 + H_2O
Friedel–Crafts alkylation	R^+ alkyl carbocation		$AlCl_3$	 + HX
Friedel–Crafts acylation	 acylium ion		$AlCl_3$	 + HX

Note: The R group represents a general group (for example, alkyl, aryl).

or *chloronium ion* (Cl^+), and nitration, employing the *nitronium ion* (NO_2^+), are useful ways of introducing new functionality to the benzene ring.



The Friedel-Crafts alkylation and acylation reactions generate new C—C bonds. Discovered in the late 1870s, they are two of the most important methods in forming new C—C bonds to the aromatic ring. The alkylation reaction uses carbocations to accomplish the substitution reaction. Tertiary carbocations react more cleanly and more efficiently than 2° or 1° carbocations. The *acylium ion* is formed from an activated carboxylic acid as the electrophile in a Friedel-Crafts acylation. This reaction generates aromatic ketones in high yields.

The mechanism of an electrophilic aromatic substitution reaction involves two steps. The initial step is rate-determining and leads to the formation of a resonance-stabilized carbocation intermediate, sometimes called a Wheland intermediate or sigma complex.

[30.11]

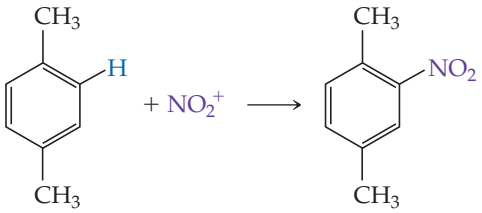
This resonance stabilized intermediate is able to lose H^+ to regain aromaticity—the driving force in making this reaction a substitution rather than an addition reaction.

[30.12]

Sample Exercise 30.2

Electrophilic aromatic substitution

Draw the structural formula for the major product formed when *p*-xylene (1,4-dimethylbenzene) is reacted with HNO_3/H_2SO_4. Justify your choice for the major product.



Continued

SOLUTION

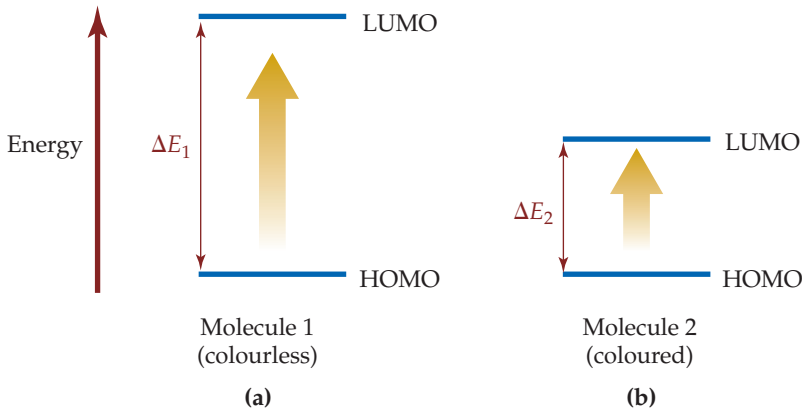
Analyze We are asked to determine the major product of the reaction of 1,4-dimethylbenzene with a mixture of nitric and sulfuric acid.

Plan The reaction of nitric acid with sulfuric acid yields the nitronium ion, NO_2^+, which is a useful electrophile. We will use this electrophile in a reaction with 1,4-dimethylbenzene.

Solve The major product is identified through the following reaction:

Because of the symmetry of *p*-xylene, substitution occurs in one of four equivalent positions.

Practice Exercise



Addition of iodomethane to an aromatic compound, in the presence of $AlCl_3$, yields significant amounts of 4-chlorotoluene. What is the aromatic compound?

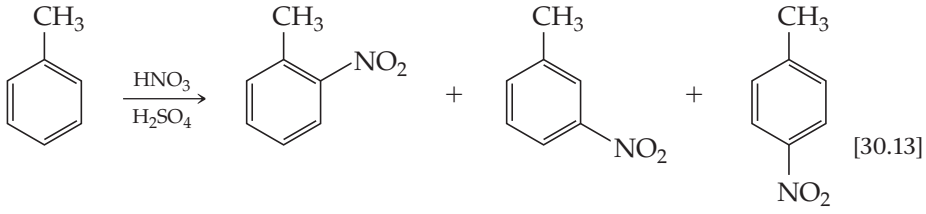
A CLOSER LOOK Organic Dyes

Light excites electrons in molecules. In a molecular orbital picture, we can envisage light exciting an electron from a filled molecular orbital (MO) to an empty one at higher energy. Because the MOs have definite energies, only light of the proper wavelength can excite electrons. The situation is analogous to that of atomic line spectra. If the appropriate wavelength for exciting electrons is in the visible portion of the electromagnetic spectrum, the substance will appear colored as certain wavelengths of white light are absorbed, whereas others are not.

In using MO theory to discuss the absorption of light by molecules, we focus on two MOs in particular. The *highest occupied molecular orbital* (HOMO) is the MO of highest energy that has electrons in it. The *lowest unoccupied molecular orbital* (LUMO) is the MO of lowest energy that does not have electrons in it. The energy difference between the HOMO and the LUMO—known as the HOMO–LUMO gap—is related to the minimum energy needed to excite an electron in the molecule. Colorless or white substances usually have such a large HOMO–LUMO gap that visible light is not energetic enough to excite an electron to the higher level (**Figure 30.12**). For example, the typical energy needed to excite an electron in naphthalene corresponds to light with a wavelength of 200–300 nm, which is far into the ultraviolet part of the spectrum. As a result, naphthalene cannot absorb any visible light and is therefore colorless.

Many of nature's rich colors, such as the green of plants and the bright hues of flowers, and the colors found in an ink-jet printer, are due to *organic dyes* **Figure 30.13**, organic molecules that strongly absorb selected wavelengths of visible light. Organic dyes contain extensively delocalized π-electrons as a result of *conjugation*. The HOMO–LUMO gap in such molecules decreases as the number of conjugated double bonds increases, making it easier to excite the molecule with lower-energy (longer-wavelength) radiation (Figure 30.12). Generally, then, the more conjugated a compound is, the more colored that compound will be.

▲ **Figure 30.12 Molecules absorbing light.** The smaller the energy gap between the HOMO and LUMO within a molecule, the greater the likelihood that the molecule is colored. This is because a light of longer wavelength (lower energy) can be absorbed by the molecule to allow the excitation.

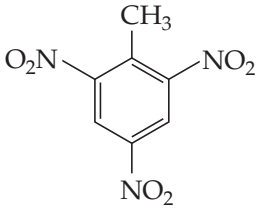


▲ **Figure 30.13 Organic dyes.** Many of the bright colors we see in our lives are a result of aromatic compounds.

Directing Groups and Substitution Effects

So far we have only considered benzene as the starting material for an electrophilic aromatic substitution reaction. Now we ask, what effects will other functional groups have on electrophilic aromatic substitution?

Let us begin to answer this question by looking at the nitration of toluene. In this case, three products, corresponding to the three possible isomers, are formed.



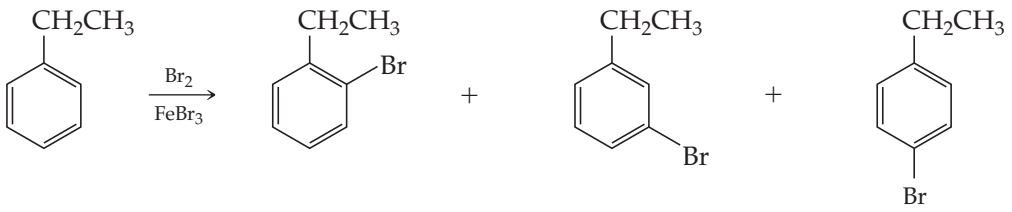
[30.13]

toluene — 2-nitrotoluene (60%) *ortho* — 3-nitrotoluene (5%) *meta* — 4-nitrotoluene (35%) *para*

Two things are to be noted here:

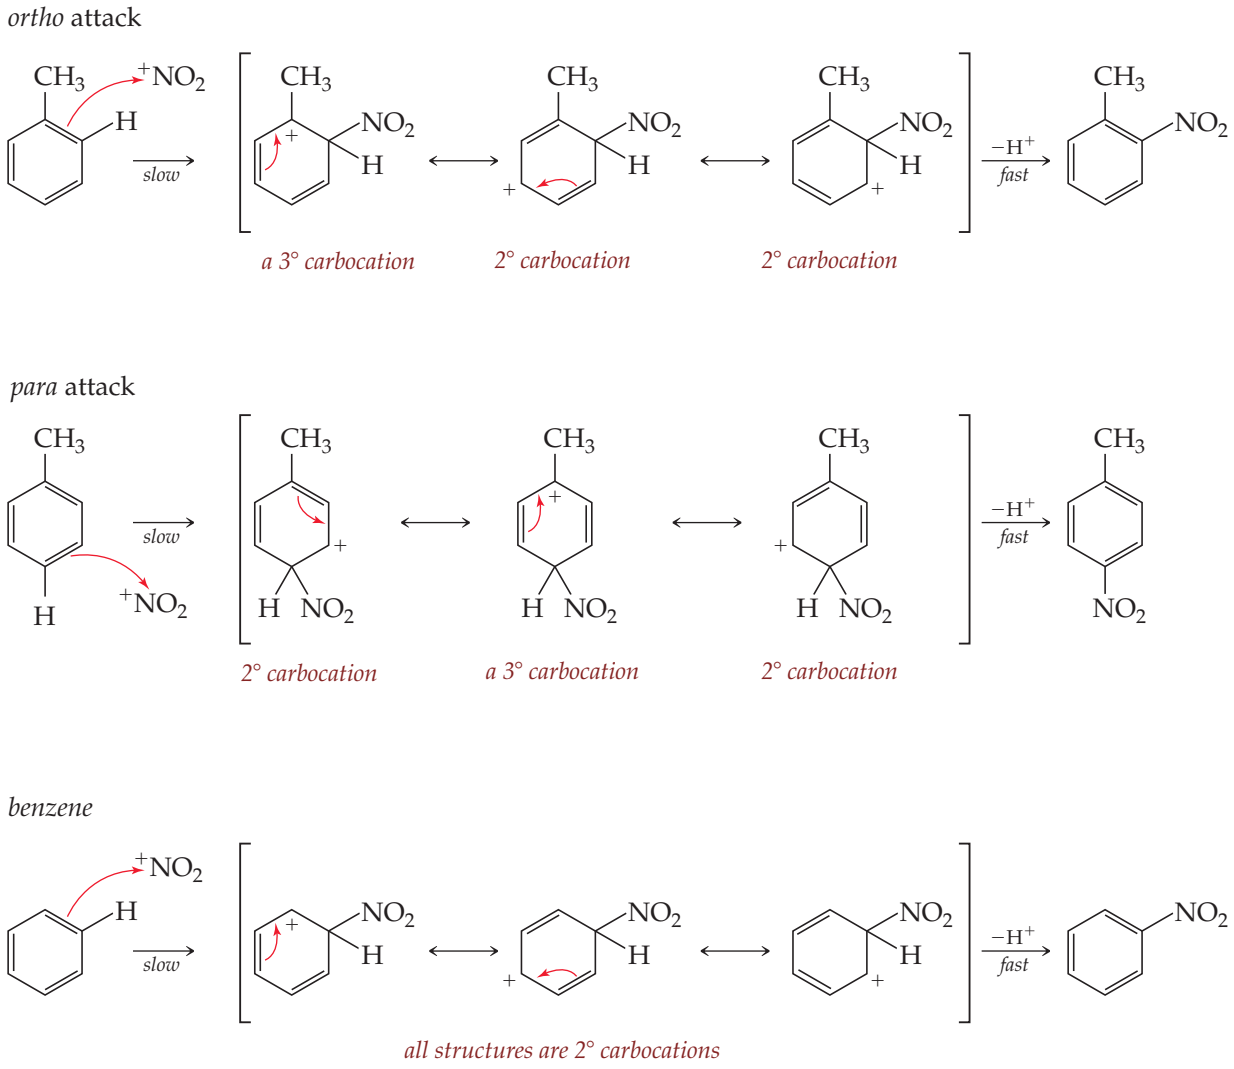
1. The nitration of toluene is approximately 25 times faster than that of benzene. In this case we say that toluene is **activated** towards electrophilic aromatic substitution. Therefore the methyl group can be classed as an **activating group**. The fact that nitration only occurs once (dinitration does not happen easily under these conditions) suggests that the nitro group is a **deactivating group**. Further nitration is possible under forcing conditions to give 2,4,6-trinitrotoluene (TNT) (**Figure 30.14**).
2. The product ratio strongly favors both *ortho* and *para* substitution. If all positions on the phenyl ring of toluene were equally reactive, the ratio of nitration at *ortho*: *meta*: *para* should be statistical at 40: 40: 20 (there are two *ortho* and *meta* positions to one *para* position). This is not the case, so this means that the methyl group is an ***ortho*, *para*-director**. In other words, the methyl group directs a second substituent to the *ortho* and *para* positions, but not to the *meta* position.

Go Figure Why might TNT be explosive?



▲ **Figure 30.14 TNT.** Actually TNT is an acronym for 2,4,6-trinitrotoluene, a highly unstable and explosive compound if a force is applied to it.

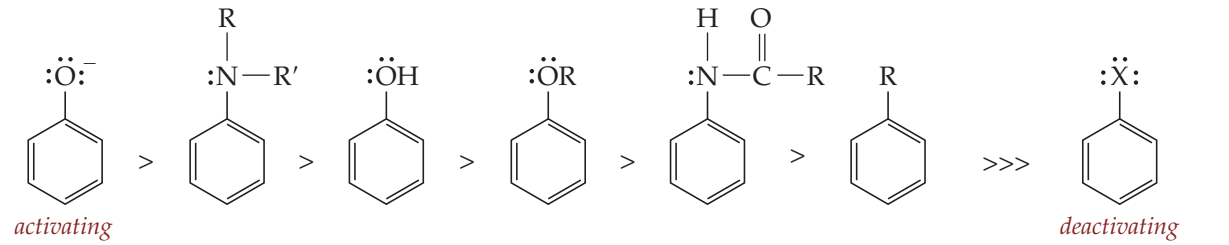
Both the activation and product distribution can be rationalized by looking at the intermediates formed after the addition of the electrophile and their relative stabilities, and then comparing this to the nitration of benzene (**Figure 30.15**). We can look at these intermediates because the rate-determining step in this reaction is the addition of the electrophile rather than the re-aromatization leading to the nitrobenzene product.



In both *ortho*- and *para*-attack, an intermediate resonance contributor can be drawn that form a 3° carbocation. As we saw in previous chapters, tertiary carbocations are more stable than either primary or secondary carbocations. In the case of benzene (shown) and for *meta*-attack, only 2° carbocation intermediates are formed. As a result, the overall stability of the intermediates for *ortho*- and *para*-attack are both favored and lower in energy.

Bromination of ethylbenzene using bromine and iron(III) tribromide (ferric bromide) also follows the same trend, with *ortho*- and *para*-substituted isomers favored. Here, because of steric effects around the ethyl group, the *para*-isomer is favored over the *ortho*-isomer.

toluene — 2-bromoethylbenzene (38%) *ortho* — 3-bromoethylbenzene (<1%) *meta* — 4-bromoethylbenzene (62%) *para*

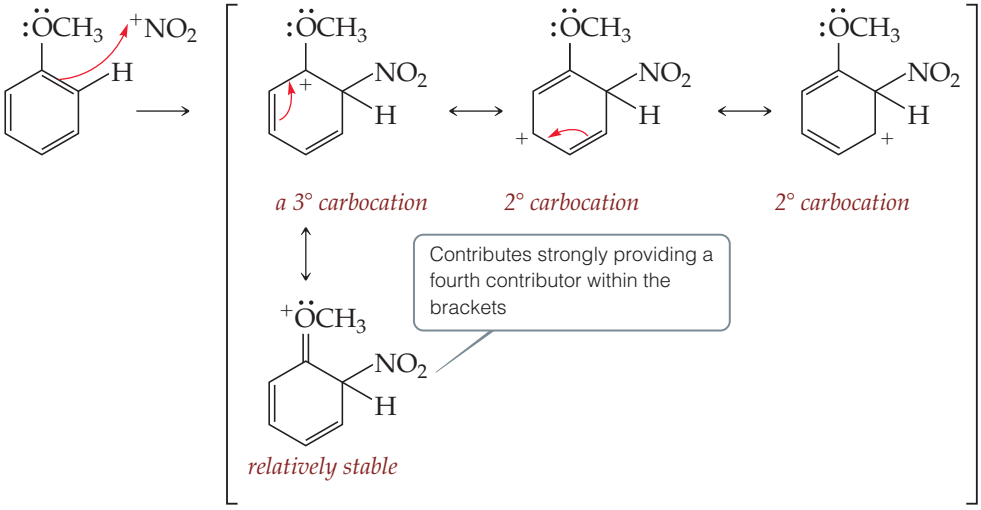


The methyl group in toluene or the ethyl group in ethylbenzene are slightly electron donating, stabilizing the intermediates formed upon the first step of an EAS reaction.

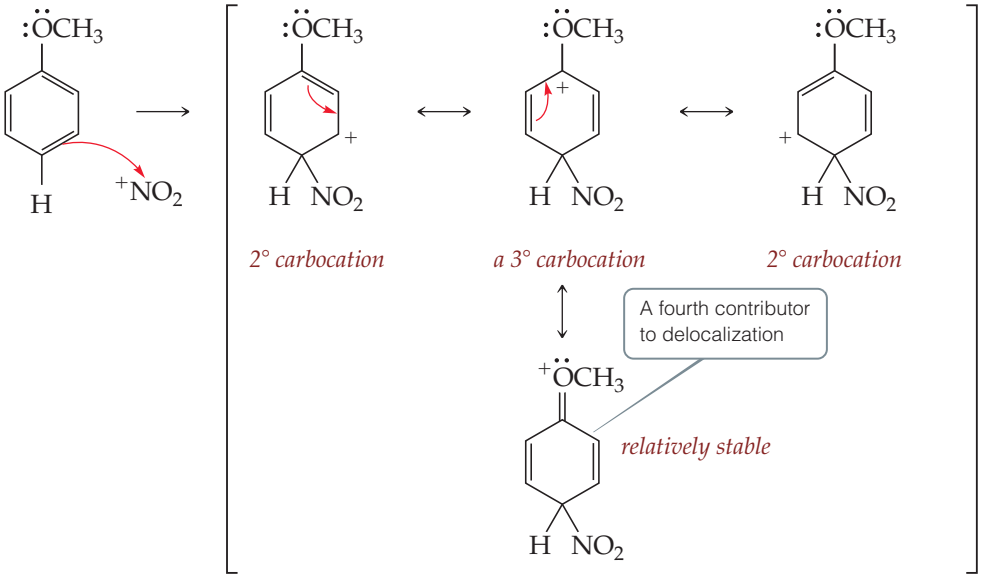
▲ **Figure 30.15 Intermediates of nitrating toluene and benzene.** The intermediates of electrophilic aromatic substitution reactions reveal information about which isomer dominates in a reaction.

Generally speaking, *electron-donating groups are ortho, para-directors and activating towards electrophilic aromatic substitution.*

Ortho-, *para*-directing groups and their relative activation for EAS are:

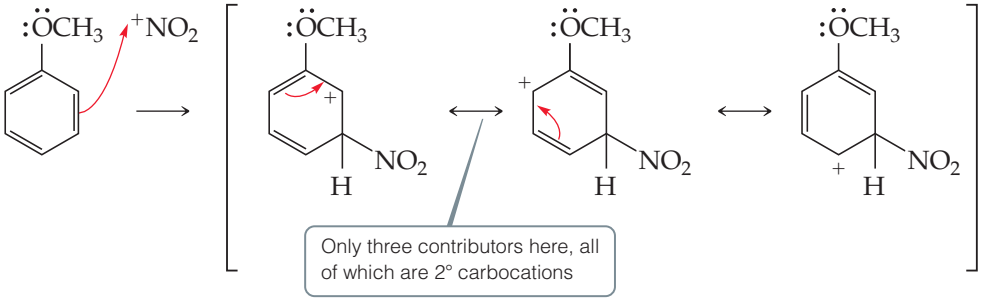


Notice that in many of these cases, the functional group contains a lone pair capable of playing a stabilizing role in the intermediates of an EAS reaction. This effect, which occurs in the first five examples and halobenzenes, is called *resonance stabilization*. In the case of alkylbenzenes, the donation of electron density into the ring is called *inductive stabilization*. In each case, however, some electron density is donated into the ring to stabilize the positive charge generated in the intermediates.

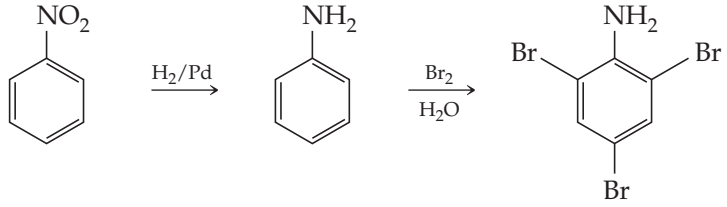


Although the halobenzenes (F, Cl, Br, I) are weakly deactivating by virtue of their inductive electron-withdrawing effects, they are still *o,p*-directing because of their ability to resonance stabilize the cationic intermediates.

To help with your understanding of resonance stabilization, let's look at the intermediates of the nitration of anisole. Here, the alkoxy group (—OR) is able to use its non-bonding lone pair to participate in resonance stabilization, forming a very stable fourth contributor in both *ortho*- and *para*-intermediates that is not available in the *meta* case. This difference in the number of contributors is used to rationalize the product distribution. The effect of the methoxy group's activation is such that anisole nitrates 10 000 times faster than benzene.



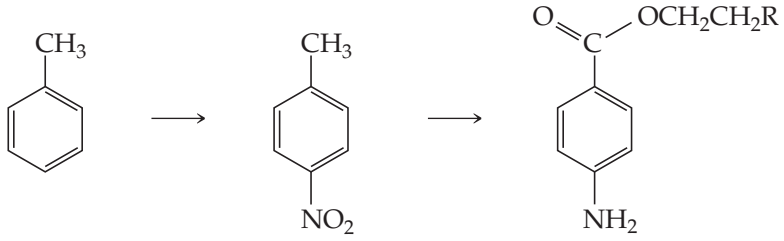
ortho-attack



para-attack

meta-attack

Anilines are very reactive towards EAS and are highly activated *ortho*-, *para*-directors. For example, the bromination of aniline occurs rapidly and without the addition of a catalyst to give the tribromoaniline in excellent yield:



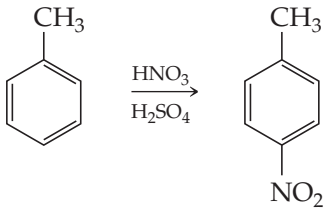
[30.14]

nitrobenzene aniline 2,4,6-tribromoaniline (>95%)

Sample Exercise 30.3

EAS reaction

4-Nitrotoluene is the starting material for the synthesis of the local anaesthetics benzocaine and procaine. Describe a synthesis of 4-nitrotoluene starting from toluene.

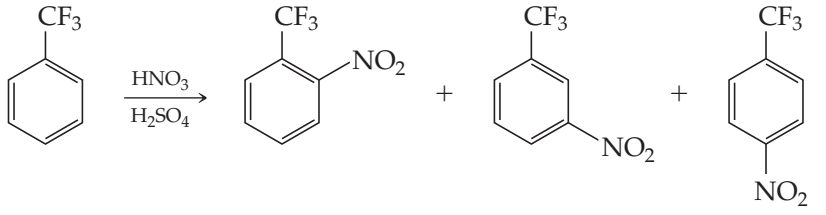


benzocaine (R=H)
procaine (R=NEt_3)

SOLUTION

Analyze We are asked to synthesize 4-nitrotoluene from toluene.

Plan To begin this exercise we look at the functional group differences between starting materials and products. In this reaction, the introduction of a *para*-nitro substituent is made, which can be achieved by EAS.

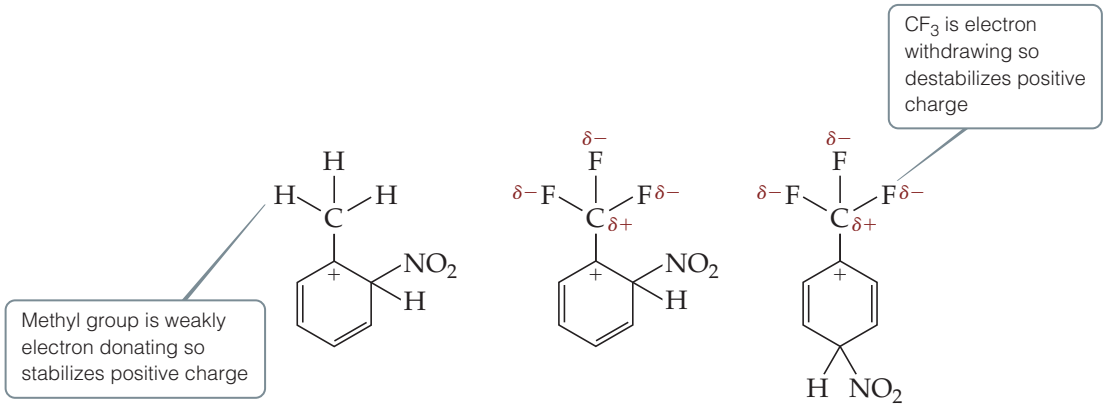


Solve Since methyl groups are *ortho*-, *para*-directing, 4-nitrotoluene can be formed by nitration of toluene and separation of the *ortho*- and *para*-isomers:

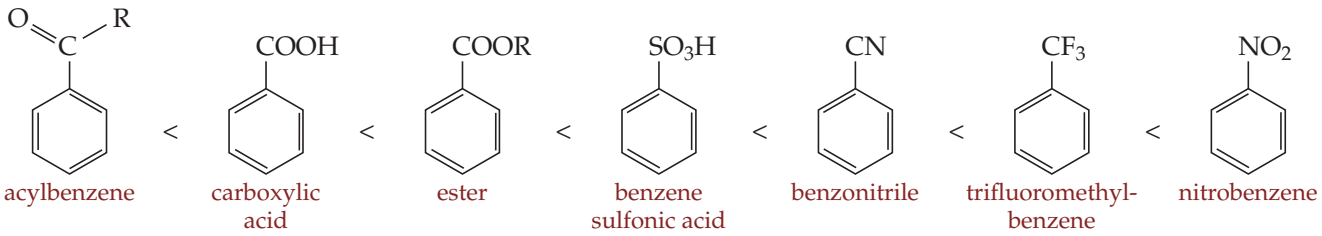
Practice Exercise

(a) Would *tert*-butylbenzene (2-methyl-2-phenylpropane) be more or less reactive than benzene towards nitration?
(b) Comment on which position would be favored and why.

So far we have dealt with electron-donating substituents. Now let's see what happens with the nitration of (trifluoromethyl)benzene, an analogue of toluene where each of the methyl hydrogens is replaced with fluorine. In this case, the *meta* product 3-nitro(trifluoromethyl)benzene is almost exclusively formed (~90% yield).



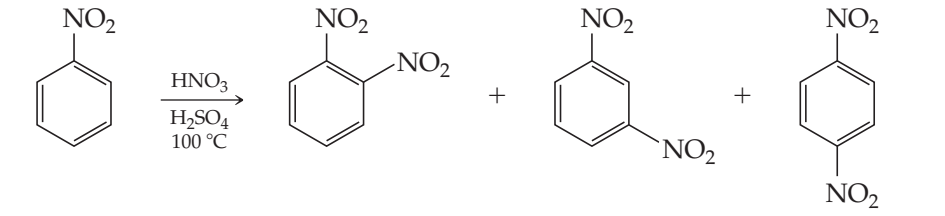
[30.15]



(trifluoromethyl) benzene *ortho* (~5%) *meta* (~90%) *para* (~5%)

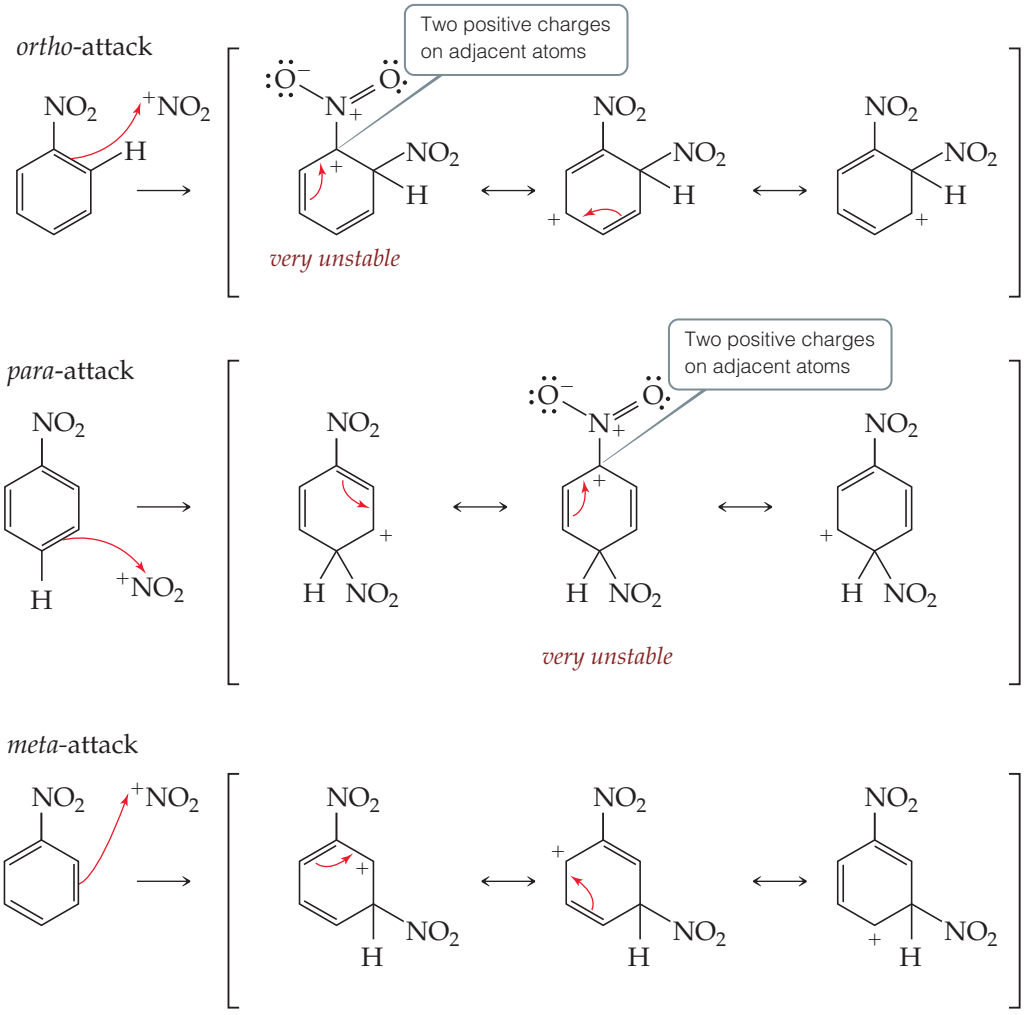
The near exclusive formation of the *meta* isomer means that the trifluoromethyl group is a ***meta*-director**. Though similar in size, there is a marked difference between the inductive properties of methyl and trifluoromethyl groups. The electronegativity of F compared to H means that inductively the trifluoromethyl group is electron withdrawing. This has two implications.

1. The electron-withdrawing nature means that attack on the electrophile by the electrons of the aromatic ring is impeded. This leads to deactivation.
2. The second is that in the case of *ortho*- and *para*-attack, the once favorable 3° carbocation of toluene is now significantly destabilized by the CF_3 group. This makes the *meta* substitution pathway more favorable. The instability relates to the neighboring location of the carbocation with the electropositive carbon bearing the three fluoro groups. This situation is analogous to that for carbonyl compounds attached to an aromatic ring where the carbonyl carbon is also δ+.



Many groups are *meta*-directing and deactivating. A series of mono-substituted benzenes and their relative deactivation for EAS include:

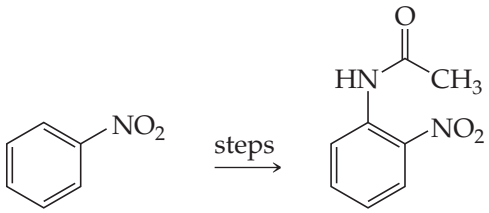
Generally speaking, electron-withdrawing groups are *meta*-directors and deactivating towards electrophilic aromatic substitution.



Let us complete our appreciation of directing groups by studying the nitration of nitrobenzene. The nitration of nitrobenzene is approximately 100 000 times slower than the nitration of benzene. In this case, the nitro group is said to be *strongly deactivating* and more forcing conditions are required to nitrate. This is due to the inductive electron-withdrawing effects of the nitro group, weakening the attack of the aromatic ring on the electrophile.

[30.16]

nitrobenzene — 1,2-dinitrobenzene (6%) — 1,3-dinitrobenzene (93%) — 1,4-dinitrobenzene (>1%)

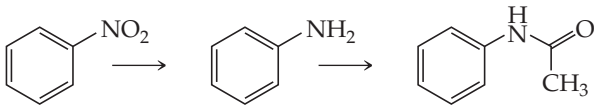


The reason why nitro groups are *meta*-directors becomes more obvious when investigating the resonance forms of the intermediates upon nitration. The proximity of the two positive charges in one resonance form of the *ortho* and *para* cases, in which they are on adjacent atoms, severely destabilizes this group of intermediates, disfavoring *ortho*-, *para*-attack in favor of *meta*-attack.

Sample Exercise 30.4

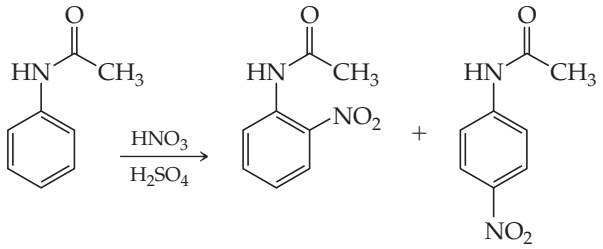
Directing groups

Determine a suitable pathway for forming 2-nitrophenylacetamide from nitrobenzene.



SOLUTION

Analyze We are asked to form 2-nitrophenylacetamide from nitrobenzene.

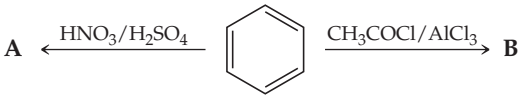


Plan Identify the differences in structure to determine what functionality needs to be added. Our knowledge of directing groups will also play a significant role in the pathway we follow. We also need to have some idea of synthetic transformations.

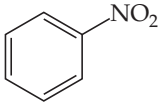
Solve The acetamide group can be formed in two steps from the nitro group by reduction, using catalytic hydrogenation or $SnCl_2$ forming the amine (aniline in this case). Acetylation using acetic anhydride or acetyl chloride leads to the acetamide:

Continued

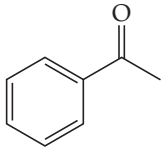
Acetamides and anilines are *o*-, *p*-directing and activating but nitro groups are *m*-directing and deactivating. Hence it makes sense to nitrate either the aniline or acetamide to give the desired product. You will need to separate the *o*- from *p*-isomer, however.



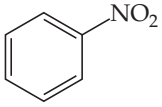
Trying to elaborate a synthesis from the nitrobenzene will undoubtedly lead to *meta* substitution, so this pathway should not be followed in this case.



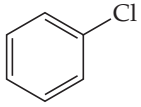
Practice Exercise



Which reacts more rapidly with HNO_3/H_2SO_4: anisole, toluene or nitrobenzene?



Self-Assessment Exercise



30.19 What product is formed in each of the following reactions?

Sample Integrative Exercise

Putting concepts together

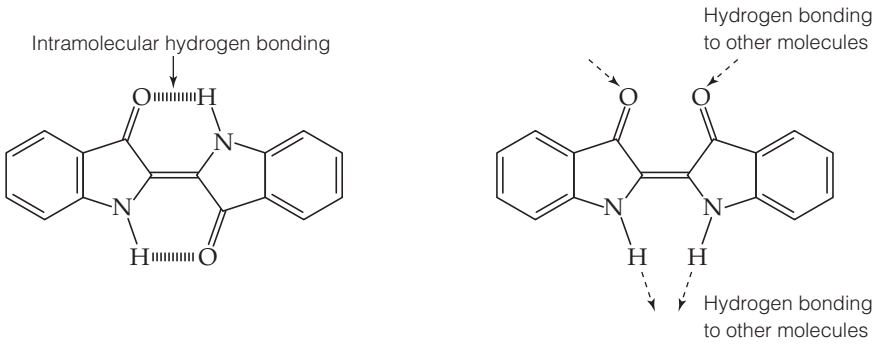
Indigo is a dark blue dye with the following structure.

Indigo Indigo white

(a) Classify the central double bond as either *E* or *Z*. **(b)** Intramolecular hydrogen bonding occurs in indigo but only intermolecular hydrogen bonding occurs in the related diastereoisomer. Explain why this is so. **(c)** The ring containing the nitrogen atom in indigo is planar. What does this suggest about the hybridization of the nitrogen atom? **(d)** Indigo is very insoluble in water. In order for it to be used as a dye, it is first converted to a water-soluble form (indigo white). The cloth is impregnated with solution and, upon oxidation, the blue dye is precipitated in the cloth. What structural feature of indigo white is responsible for the increase in water solubility? **(e)** Is indigo white aromatic?

SOLUTION

Analyze This exercise focuses on the structure of indigo and the effect this has on hydrogen bonding and solubility.



Plan Determine the priority of the groups attached to the central double bond in order to classify it as *E* or *Z* then identify hydrogen bonding sites within the molecule and its isomer. Work out the hybridization of the N atom and examine factors that may influence water solubility.

Continued

Solve

(a) In assigning priorities to the groups at either end of the central double bond, nitrogen has a higher priority than carbon. Consequently indigo has the two high priority groups in an *E* arrangement.

(b) The hydrogen bonding in indigo forms six-member rings which are stable. In the *Z* isomer of this compound the hydrogen bond donor atoms and hydrogen bond acceptor atoms are not matched with each other and consequently can only hydrogen bond to appropriate surrounding molecules.

(c) A planar nitrogen atom with three bonds suggests sp^2 hybridization with the lone pair in a *p* orbital.

(d) Reduction of a ketone to an alcohol group will be accompanied by an increased opportunity for hydrogen bonding and will increase the water solubility of the material.

(e) Yes, it follows the $(4n + 2)$ rule for aromaticity. The lone pair on nitrogen forms part of the aromatic structure.

Chapter Summary and Key Terms

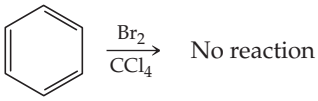
SECTION 30.1 **Aromatic hydrocarbons**, or **arenes**, are compounds containing multiple sp^2-hybridized carbons, most often in a six-membered ring, which we call benzene. They are less reactive than alkenes and undergo very different chemical reactions because of the delocalization of their π-electrons.

SECTION 30.2 Aromatic hydrocarbons larger than benzene that incorporate multiple rings are given trivial names. Simple aromatic hydrocarbons bearing a single substituent are named based on benzene—for example, nitrobenzene. The substituent C_6H_5 is called a **phenyl group**. Loss of a hydrogen from toluene leads to a **benzyl group**. **Phenols** are a benzene derivative bearing a hydroxyl group. Disubstituted benzenes occur as three isomers labelled *ortho*, *meta*, *para*.

SECTION 30.3 Aromatic compounds are stabilized by the contributions of two or more **resonance structures**. **Resonance** is an extremely important concept in describing the bonding and stability of aromatic compounds. The **resonance energy** associated with benzene is the difference in energy between hydrogenating benzene and the theoretical molecule 1,3,5-cyclohexatriene. Compounds are aromatic if they follow Hückel's criteria. The major criterion states that a compound is aromatic if it has $[4n + 2]$ π-electrons and is cyclic. **Heterocyclic compounds** contain a **heteroatom**—that is, an atom other than carbon.

SECTION 30.4 Phenols are an unusual class of compound prevalent in nature. Their acidity differs greatly from another common and closely related class, the alcohols, because of the relative stability of the phenoxide ion. The anion is **resonance-stabilized** as a result of the phenolate's ability to distribute the electron density around the aromatic ring. **Electron-withdrawing groups** on the phenyl ring of phenol increase the acidity through **inductive effects**.

SECTION 30.5 Addition reactions are difficult to carry out with aromatic hydrocarbons, but **electrophilic aromatic substitution (EAS) reactions** are easily accomplished in the presence of a catalyst. Two general reactions are halogenation, which substitutes hydrogen for a single halogen (typically Cl or Br), and nitration, which substitutes a hydrogen for NO_2. Two new types of reactions discussed are the **Friedel–Crafts alkylation** and **acylation reactions**. Each of these reaction types is useful as they produce new C—C bonds. Substituted benzenes also undergo EAS, though the substituent can act as an **activating** or **deactivating** depending on whether it is electron donating or electron withdrawing. Generally, electron-donating groups are ***ortho-***, ***para-*directing** whereas electron-deficient groups are ***meta-*directing**.



Key Skills

- Know how to derive the name of simple mono- and disubstituted aromatic compounds by positional numbering, for example 1,2-dibromobenzene, as well as by *ortho*, *meta* and *para* nomenclature, for example *o*-dibromobenzene. (Section 30.2)
- Learn the common names such as toluene, phenol, aniline, etc. and the hierarchy of functional groups. (Section 30.2)
- Be able to use the curved arrow notation introduced in Chapter 26 to understand the stability and directive properties of different functional groups on the aromatic structure. (Section 30.5)

- Be able to draw Wheland intermediates to show the directive influences of substituents on benzene in EAS. (Section 30.5)
- Understand why phenols are acidic and be able to describe this through drawing resonance contributors to an intermediate structure. (Section 30.4)
- Be able to identify electrophiles from a given set of reagents, and in the case of substituted benzenes understand qualitatively their directive influences on the product outcome. (Section 30.5)

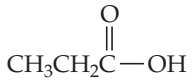
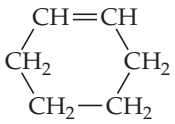
Exercises

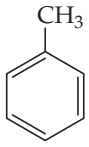


Visualizing Concepts

30.28 **(a)** Draw a six-membered ring as a line drawing and demonstrate how sp^2 hybrid orbitals interact, as in benzene. **(b)** Illustrate how the p orbitals overlap to form a stable aromatic structure. [Section 30.1]

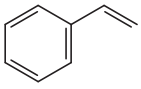


30.29 Which of the following molecules will readily undergo an electrophilic substitution reaction? [Section 30.5]

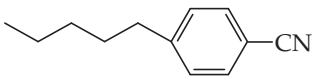


(a)

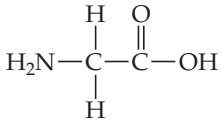
(b)



(c)

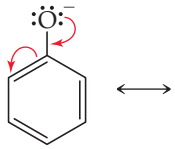


(d)

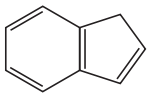


30.30 Consider the following molecules. Which of these would be most likely to exhibit liquid crystalline behavior? [Section 30.3]

(i)

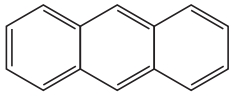


(ii)



(iii)

30.31 Draw the product of the following valence electron movements. [Section 30.4]

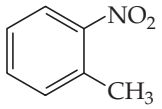


30.32 Which of the following structures is aromatic? [Section 30.3]

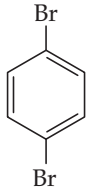
(a)

(b)

(c)

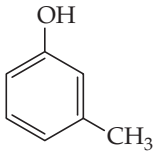


(d)

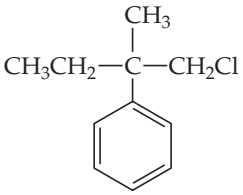


Benzene Structure and Nomenclature (Sections 30.1 and 30.2)

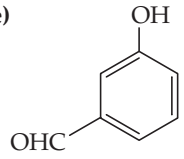
30.33 Name the following compounds systematically:



(a)



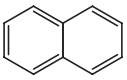
(b)



(c)

(d)

(e)

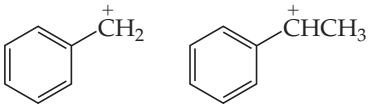


30.34 What observations made by Reinitzer on cholesteryl benzoate suggested that this substance possesses a liquid crystalline phase?

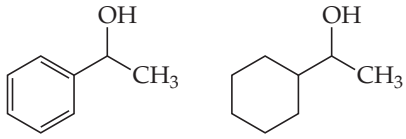
30.35 In contrast to ordinary liquids, liquid crystals are said to possess "order". What does this mean?

Aromaticity (Section 30.3)

30.36 Which hydrogens are more acidic, those of cyclohexane or benzene? Why?



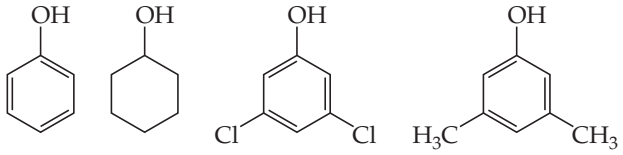
30.37 Mothballs are composed of naphthalene, $C_{10}H_8$, the structure of which consists of two six-membered rings of carbon that are fused along an edge, as shown in the following incomplete Lewis structure:



(a) Write two different complete Lewis structures for naphthalene. **(b)** The observed C—C bond lengths in the molecule are intermediate between C—C single and C—C double bonds. Explain. **(c)** Represent the resonance in naphthalene in a way analogous to that used to represent it in benzene.

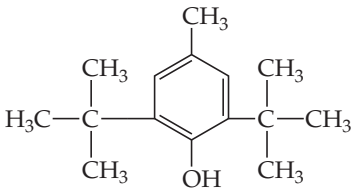
30.38 **(a)** What is the difference between a localized π-bond and a delocalized one? **(b)** How can you determine whether a molecule or ion will exhibit delocalized π-bonding? **(c)** Demonstrate with the aid of a diagram the delocalization in benzene. **(d)** Is the π-bond in $CH_3CO_2^-$ localized or delocalized?

30.39 Which of the following compounds is more stable? Explain.



30.40 Which of the following alcohols undergoes dehydration more rapidly when heated with H_2SO_4? Why?

30.41 **(a)** One test for the presence of an alkene is to add a small amount of molecular bromine and look for the disappearance of the brown color. This test does not work for detecting the presence of an aromatic hydrocarbon. Explain.



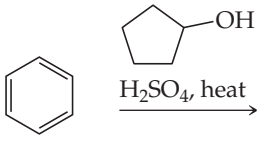
Properties of Phenols (Section 30.4)

30.42 Place the following in decreasing order of acidity:

30.43 **(a)** Draw the structure of phenoxide. **(b)** Use arrow notation to describe why this intermediate is more stable than that for the corresponding cyclohexanol anion.

30.44 Butylated hydroxytoluene (BHT) has the following molecular structure:

BHT



It is widely used as a preservative in a variety of foods, including dried cereals. **(a)** Based on its structure, would you expect BHT to be more soluble in water or in hexane (C_6H_{14})? Explain. **(b)** Identify phenol within this structure.

Electrophilic Aromatic Substitution Reactions (Section 30.5)

30.45 Using condensed structural formulas, write a chemical equation for each of the following reactions: **(a)** hydrogenation of cyclohexatriene; **(b)** bromination of 1,4-dimethoxybenzene using $FeBr_3$ as a catalyst; **(c)** reaction of 2-chloropropane with benzene in the presence of $AlCl_3$.

30.46 Suggest a method of preparing ethylbenzene, starting with benzene and ethene as the only organic reagents.

30.47 **(a)** What would be the electrophile in the following reaction? **(b)** What is the EAS product?

30.48 Rank the following groups in order of increasing activating power in electrophilic aromatic substitution reactions: $-OCH_3$, $-CH_2CH_3$, $-Br$.

30.49 Draw the most important contributor to the resonance hybrid formed when toluene undergoes *para* nitration.

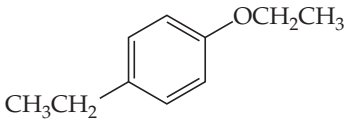
30.50 What factors affect the *ortho*:*para* ratio in electrophilic aromatic substitution reactions?

30.51 **(a)** What is the effect of a chlorine substituent on EAS? **(b)** What is the effect of a nitro substituent on EAS?

30.52 What is the *major* product (including regioisomer) when ethylbenzene is reacted with $Br_2/FeBr_3$?

30.53 Give a reason why nitrobenzene can be used as a solvent for Friedel-Crafts alkylation.

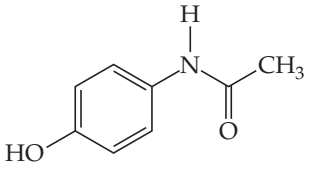
30.54 Give an explanation why direct nitration of aniline using HNO_3 yields, among other products, *m*-nitroaniline.



30.55 Devise a method for preparing *m*-chloroaniline from benzene.

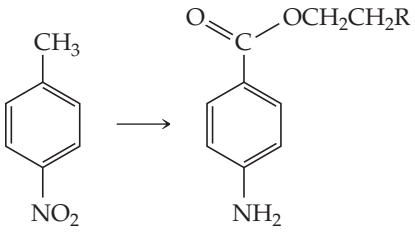
30.56 Provide a series of synthetic steps by which 2-bromo-4-nitrobenzoic acid can be prepared from toluene.

30.57 What is the *major* product of the bromination of 4-methylphenol by Br_2 in the presence of $FeBr_3$?



30.58 What is the *major* product of the nitration of 4-bromoanisole?

30.59 What is the major mononitration product of 1-ethoxy-4-ethylbenzene?



Integrative Exercises

30.60 **(a)** Devise a synthesis of the analgesic acetaminophen (paracetamol) from phenol.

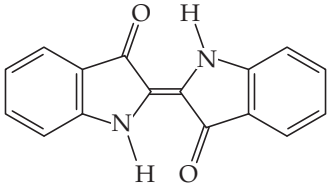
(b) Does the name *paracetamol* tell you anything about the structure of the molecule?

30.61 4-Nitrotoluene is the starting material for the synthesis of the local anaesthetics benzocaine and procaine. Describe a synthesis of benzocaine starting from 4-nitrotoluene.

benzocaine (R=H)
procaine (R=NEt_3)

30.62 The heat of combustion of decahydronaphthalene ($C_{10}H_{18}$) is -6286 kJ mol^{-1}. The heat of combustion of naphthalene ($C_{10}H_8$) is -5157 kJ mol^{-1}. (In both cases, CO_2(g) and H_2O(l) are the products.) Using these data and data in Appendix C, calculate the heat of hydrogenation of naphthalene. Does this value provide any evidence for aromatic character in naphthalene?

30.63 The *cyclopentadienide ion* has the formula $C_5H_5^-$. The ion consists of a regular pentagon of C atoms, each bonded to two C neighbors, with a hydrogen atom bonded to each C atom. All the atoms lie in the same plane. **(a)** Draw a Lewis structure for the ion. According to your structure, do all five C atoms have the same hybridization? Explain. **(b)** Chemists generally view this ion as having sp^2 hybridization at each C atom. Is that view consistent with your answer to part (a)? **(c)** Your Lewis structure should show one non-bonding pair of electrons. Under the assumption of part (b), in what type of orbital must this non-bonding pair reside? **(d)** Are there resonance structures equivalent to the Lewis structure you drew in part (a)? If so, how many? **(e)** The ion is often drawn as a pentagon enclosing a circle. Is this representation consistent with your answer to part (d)? Explain. **(f)** Both benzene and the cyclopentadienide ion are often described as systems containing six π-electrons. What do you think is meant by this description?



30.64 Both 3-aminobenzoic acid and 4-aminobenzoic acid are precursors to condensation polymers. **(a)** What type of isomers are these molecules? **(b)** Draw the structure of both of these molecules and the repeating unit of the polymer each forms. **(c)** Both compounds may be synthesized from toluene using the following reactions (not given in the correct order).

- Reduction of a nitro group using hydrogen gas and a palladium catalyst.
- Nitration using concentrated nitric acid and concentrated sulfuric acid.
- Oxidation of the aromatic alkyl group with acidified potassium permanganate.

Use your knowledge of the directing effect of a substituent to give the correct sequence of reactions for the synthesis of both compounds.

30.65 The pK_b of methylamine and analine is 3.36 and 9.40 respectively. Which molecule is the stronger base? Explain the reason for this difference.

30.66 Indigo is a blue dye that was originally extracted from plants but now is produced synthetically.

Indigo

(a) List the functional groups present in indigo. **(b)** What is the hybridization of the carbon atoms? **(c)** Explain why the overall shape of indigo is planar. **(d)** The molecule absorbs at 613 nm in the visible region of the spectrum. What energy does this correspond to?

Design an Experiment

There is often more than one way to prepare a compound and a research scientist has to consider the advantages and drawbacks of each route. For example, you are asked to prepare 3-nitrobenzoic acid from benzene. How do you do it? Note the carboxylic acid group cannot be introduced into the ring directly but could be obtained by either a Grignard reaction on a halobenzene or the oxidation of an alkylbenzene. You need to consider the directing effect of a group prior to installing the second substituent onto the ring and whether the group is activating or deactivating. An activating group will give a product under much milder conditions that may have economic advantages. Draw out as many different routes to 3-nitrobenzoic acid as you can and assess each one for its viability. At what point do you purify your compound to remove unused reagents and biproducts? How might you do the purification? If you started with 78 g of benzene, what quantities of reagents do you need for each route?

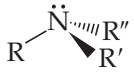
NITROGEN-CONTAINING ORGANIC COMPOUNDS

31.1 | Amines and the Amide Bond

The discovery of penicillin in 1928 by Alexander Fleming was serendipitous. He had left an uncovered petri dish containing staphylococci bacteria on the windowsill of his laboratory at the St. Mary's Medical School of London University. Mold spores blew in through the open window and started to grow on the culture medium. Some days later, Fleming observed that the bacteria surrounding the mold was dying. He surmised that it was not the mold itself (from the *Penicillium* genus), but a metabolite of the mold that was causing the effect and named it penicillin. Fleming did little to capitilize on his discovery, but Ernst Chain, a biochemist working at Oxford University's Sir William Dunn School of Pathology, as well as Howard Florey, who headed the school, recognized the enormous potential of the discovery to medicine. Work commenced on isolating this "mold juice" and involved fermenting thousands of liters of mold broth in vessels exposed to air. By 1945, Dorothy Hodgkin had determined the chemical structure of penicillin using X-ray crystallography and found it was a relatively small molecule centered around a four membered ring containing a cyclic amide called a β-lactam. The 1945 Nobel prize in physiology or medicine was awarded jointly to Fleming, Florey, and Chain.



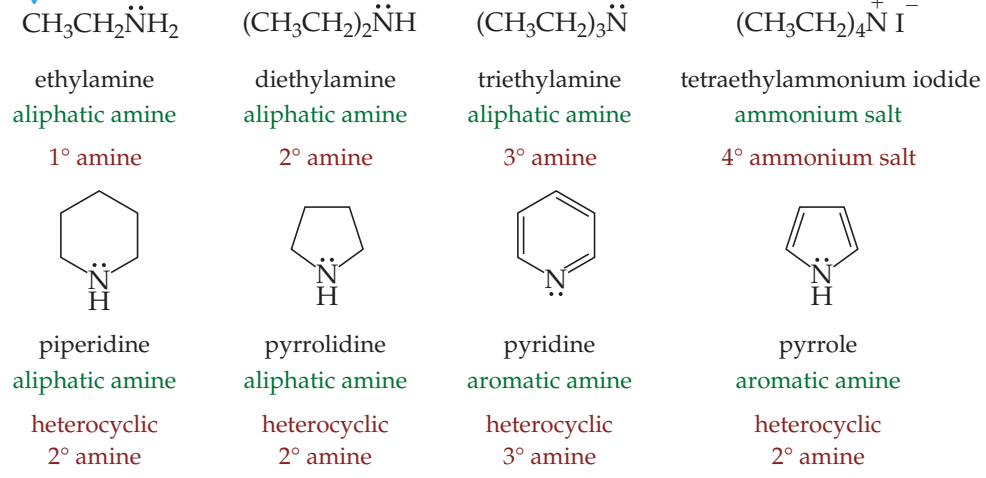
Chapters 27–29 introduced the chemistry of oxygen-containing compounds; in this chapter we will examine the complementary role played by nitrogen-containing molecules. In fact, nitrogen-containing organic compounds form an incredibly large and important class in their own right.

By the end of this section, you should be able to

- Name simple amines and amides
- Recognize several methods by which amines may be synthesizes
- Understand the acid-base properties of amines

Amines

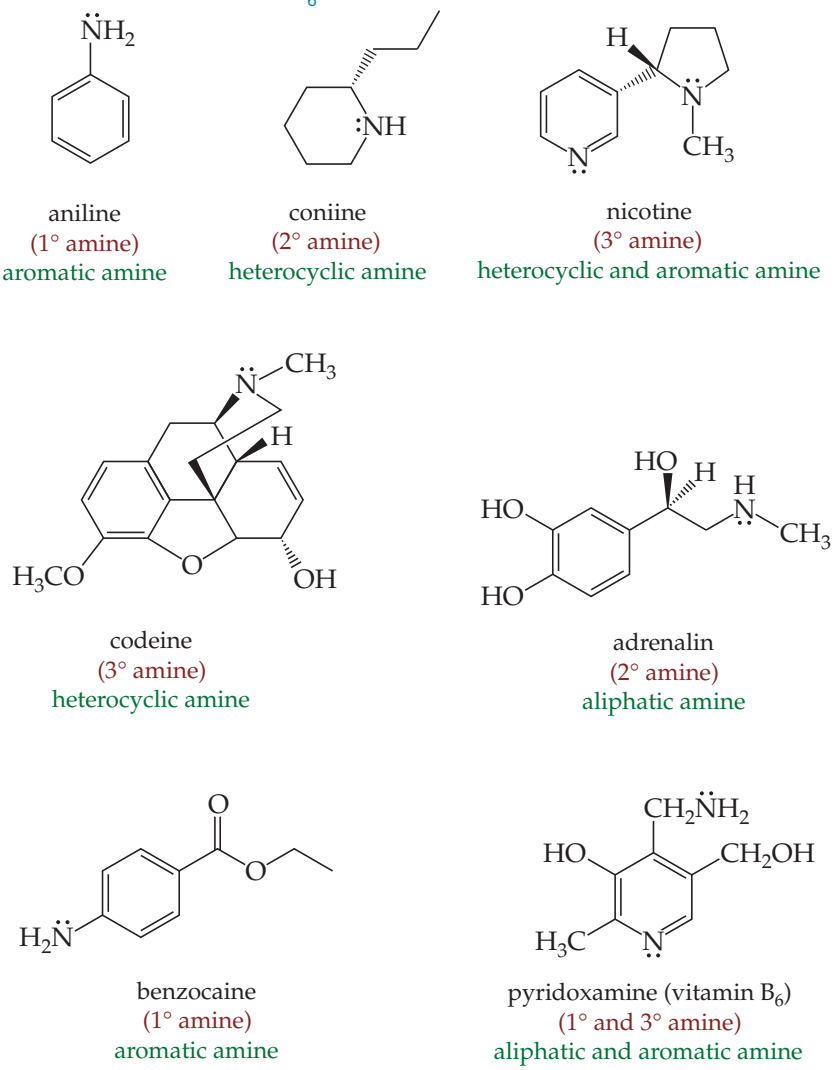
Amines are organic bases with the general formula



where R, R′ and R″ may be H or a hydrocarbon group. Amines containing alkyl groups are called **aliphatic amines**. Aniline is the parent molecule of a class of amines known as **aromatic amines**. This class is characterized by a covalent bond between the nitrogen atom and at least one aromatic group (for example, phenyl or naphthyl). Amines that form part of a cyclic structure are called **cyclic amines** or *heterocycles*. A special class of heterocyclic compounds contains a nitrogen atom within an aromatic ring (for example, pyridine). We also class these amines as aromatic amines. In many cases the lone pair found on nitrogen in an aromatic amine can contribute to the aromaticity. Figure 31.1 gives some examples of amine classes, including the five- and six-membered heterocycles pyrrolidine and piperidine, and the aromatic heterocycles pyrrole and pyridine.

Amines are further classified as primary, secondary or tertiary.

- **Primary (1°) amine**: contains *one* alkyl or aryl group bonded to nitrogen.
- **Secondary (2°) amine**: contains *two* alkyl or aryl groups bonded to nitrogen.
- **Tertiary (3°) amine**: contains *three* alkyl or aryl groups bonded to nitrogen.
- **Quaternary (4°) ammonium salts**: contain *four* alkyl or aryl groups directly attached to nitrogen.

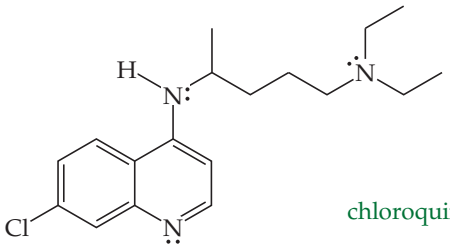


Go Figure What makes an amine secondary?

▲ **Figure 31.1** **Amine classes.**

Figure 31.2 shows the structure of some industrially and biologically important amines. Aniline, for example, is an aromatic amine used extensively in the manufacture of dye stuffs. A significant number of amines are derived from plant material, such as roots, leaves and bark. Amines that are derived from plant material and contain a basic nitrogen atom are commonly called **alkaloids**. Alkaloids form an enormous class of compounds whose physiological properties have been studied intensively for over 150 years. Coniine, for example, is a highly toxic alkaloid, found to be the active ingredient in "poison hemlock", which was responsible for the death of Socrates. Nicotine is a highly addictive alkaloid found in tobacco leaves. Codeine and morphine, are both analgesics and alkaloids extracted from opium poppies. Adrenaline is a principal compound in a group of compounds known as the *phenylethylamines*. Adrenaline is not an alkaloid; it is a *hormone* that is released into the body in response to stress. It causes increased blood flow to the muscles and brain, accelerates respiration and heart rate, and stimulates the release of stored energy into the blood. When injury to the body occurs, it potentiates the healing process. At times, adrenaline also functions as a neurotransmitter. Pyridoxamine, or vitamin B_6, is a water soluble vitamin that exists in three major chemical forms: pyridoxine, pyridoxal

Go Figure Can you identify which amine is 1° and which is 3° in vitamin B_6?

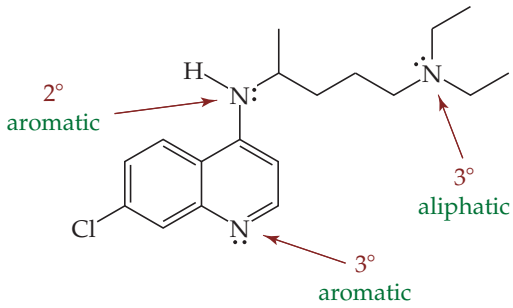


▲ **Figure 31.2 Industrially and biologically important amines.** The lone pair on nitrogen has been added to highlight its position in these compounds.

Sample Exercise 31.1

Classifying Amines

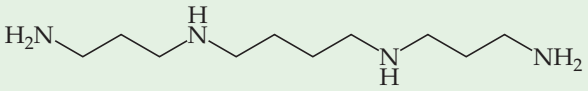
Classify each amino group of chloroquine, a compound used for the treatment of malaria, as primary, secondary or tertiary. Comment also on whether they are aliphatic or aromatic amines.



chloroquine

SOLUTION

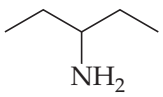
Analyze We are asked to classify each amine in chloroquine.



Plan Look for each nitrogen atom and determine if aromatic or aliphatic as a result of the nature of the bonding around them. Classify each as primary, secondary or tertiary by determining how many N—C bonds exist.

Solve

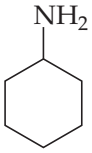
Practice Exercise



Classify each amino group of spermine, a compound isolated from semen, as primary, secondary or tertiary.

spermine

and pyridoxamine. Its role in the body is varied but essential for good health. Benzocaine is an effective local and topical anesthetic used in sting medication, sunburn cream and by dentists in mucosal tissue.

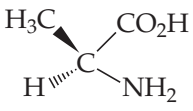


The systematic naming of simple monoaliphatic amines follows the same guidelines as for alcohols. The *e* of the parent alkane is replaced by *amine* (as opposed to *ol* for alcohols). Otherwise, the name is derived from the alkyl group attached to nitrogen and named as the alkylamine. For example:

3-pentanamine

propane-1,3-diamine

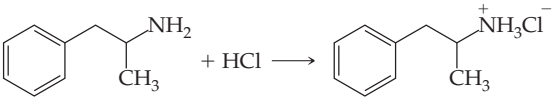
cyclohexylamine



For amines containing multiple alkyl groups bonded to carbon, the amine is named based on those alkyl groups (Figure 31.1). Amines have a low priority in the nomenclature hierarchy. In many instances, the **amino group** is named as a substituent rather than as the class of an organic compound:

1-aminobut-2-ene

3-aminopropan-1-ol



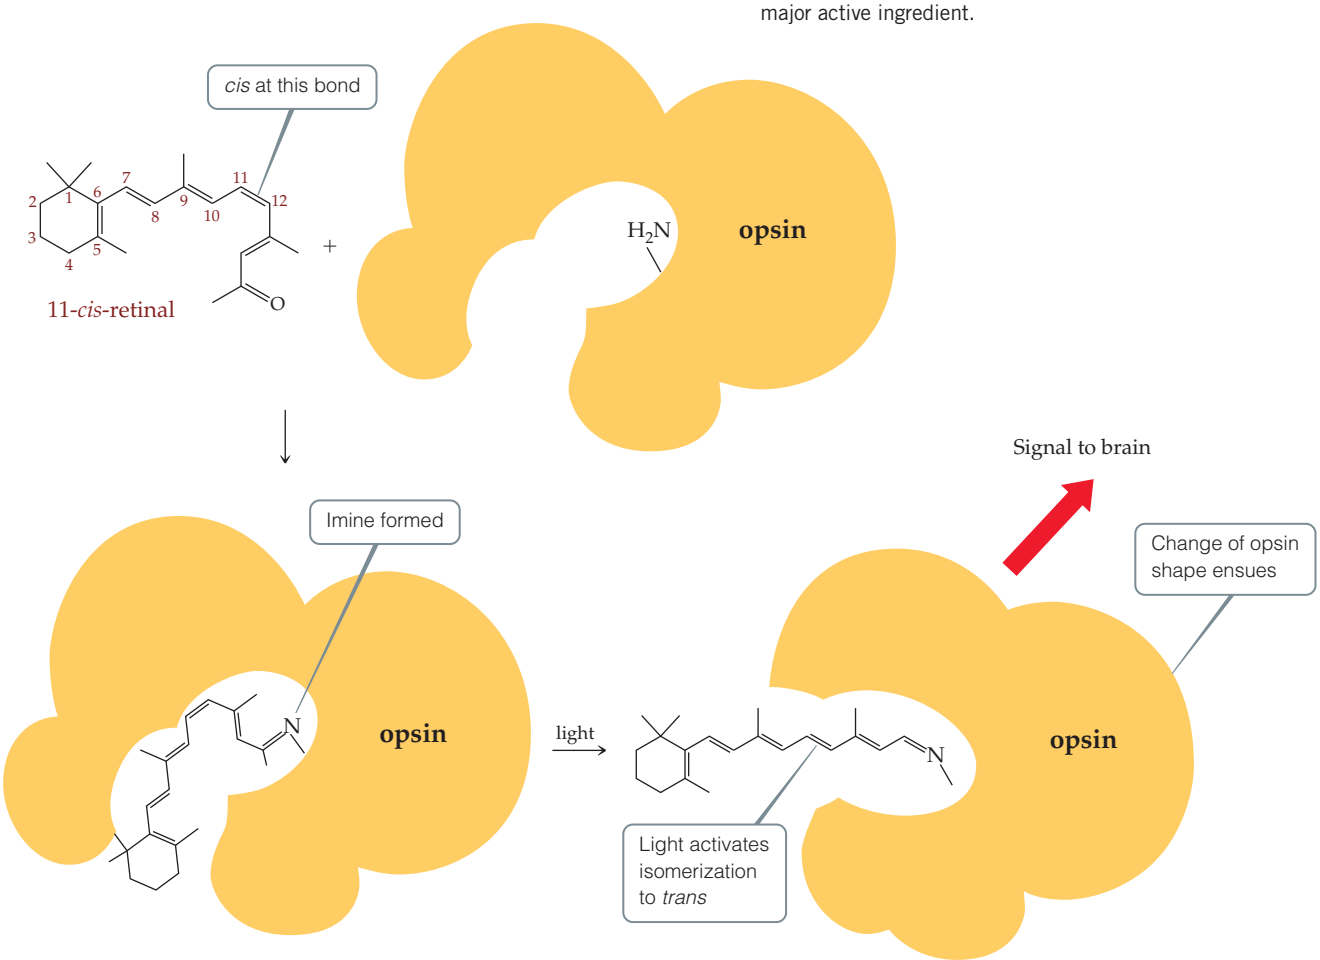
(*S*)-2-aminopropanoic acid

CHEMISTRY AND LIFE Amines and Amine Hydrochlorides

Many amines with low molecular weights have unpleasant "fishy" odors. Amines and ammonia (NH_3) are produced by the anaerobic (absence of O_2) decomposition of dead animal or plant matter. Two such amines with very disagreeable odors are $H_2N(CH_2)_4NH_2$, known as *putrescine*, and $H_2N(CH_2)_5NH_2$, known as *cadaverine*. Despite their usually unpleasant odors, amines and the products of their reactions are very important compounds in biological systems.

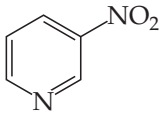
The pigment of vision, rhodopsin, is prepared by the formation of an imine bond between the biologically active aldehyde 11-*cis*-retinal and the protein opsin (**Figure 31.3**). When rhodopsin absorbs a photon of light, the *cis* double bond at C11 undergoes an isomerization to the *trans* geometry, which triggers a change in the shape of rhodopsin, leading to nerve impulses that are detected by the brain as a visual image.

Many drugs, including quinine, codeine, caffeine and amphetamine (benzedrine), are amines. Like other amines, these substances are weak bases; the amine nitrogen is readily protonated by treatment with an acid. The resulting products are called ammonium salts. For example, amphetamine hydrochloride is the ammonium salt formed by treating amphetamine with HCl.

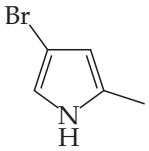


amphetamine amphetamine hydrochloride [31.1]

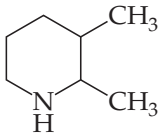
Such ammonium salts are less volatile, more stable and generally more water soluble than the corresponding neutral amines. Many drugs that are amines are sold and administered as ammonium salts for this very reason. Some examples of over-the-counter medications and cleaning products that contain amine hydrochlorides as active ingredients are shown in **Figure 31.4**.



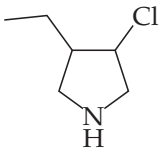
▲ **Figure 31.4 Ammonium salts.** Many commercial products, such as over-the-counter medications and antiseptics, contain amine hydrochlorides as the major active ingredient.



▲ **Figure 31.3 Rhodopsin.** Imine formation between 11-*cis*-retinal and the protein opsin is important for vision.

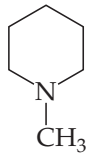


The names of heterocyclic amines are derived from the parent aliphatic or aromatic heterocycle; for example:

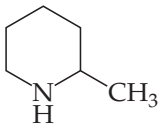


3-nitropyridine

4-bromo-2-methylpyrrole



2,3-dimethylpiperidine



3-chloro-4-ethylpyrrolidine

When more than one type of alkyl group (for example, methyl and ethyl groups) are bonded to nitrogen in the same molecule, the name must also reflect the position of the alkyl groups on nitrogen by using the prefix *N*. For example, the name *N*-methylpiperidine indicates that the methyl substituent is located on the nitrogen of the piperidine ring and not located on the carbon framework (for example, 2-methylpiperidine). The name *N,N*-diethyl-1-butanamine is used to describe both ethyl groups bonded to nitrogen. This compound differs from *N*-ethyl-2-ethyl-1-butanamine and 4-ethyl-3-hexanamine. All three compounds are constitutional isomers.

Sample Exercise 31.2

Naming Amines

Write the systematic or IUPAC name for the following amines:

(a) $CH_3CH_2CH_2CH_2CH_2NH_2$ **(b)**

(c) $(CH_3)_3N$

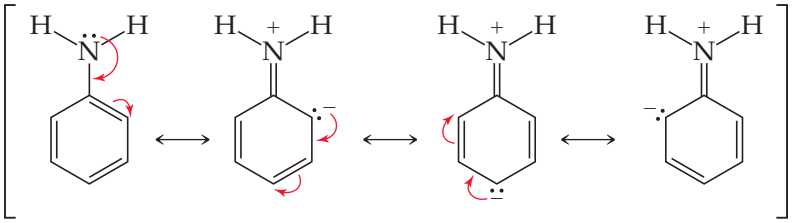
SOLUTION

Analyze We are asked to provide systematic names for three different amines

Plan Use the rules described earlier to structure the names.

Solve

(a) 1-pentanamine—derived from pentane.

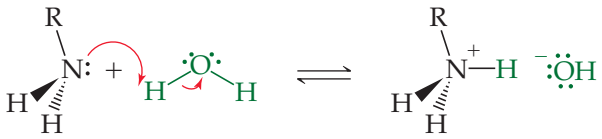


(b) Benzylamine—derived from the benzyl group. This is better than naming the structure phenylmethanamine.

(c) Trimethylamine—derived from the three methyl substituents attached to nitrogen. Note that the prefix *N* is not required.

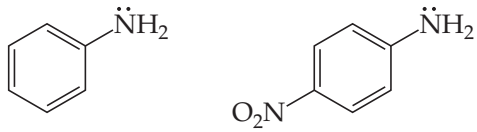
Practice Exercise

Draw the structures for the following amines:
(a) *tert*-butylamine, (b) 4-nitroaniline,
(c) *N*-methyl-2-hydroxypiperidine



Go Figure Why is cyclohexylamine a stronger base than aniline?

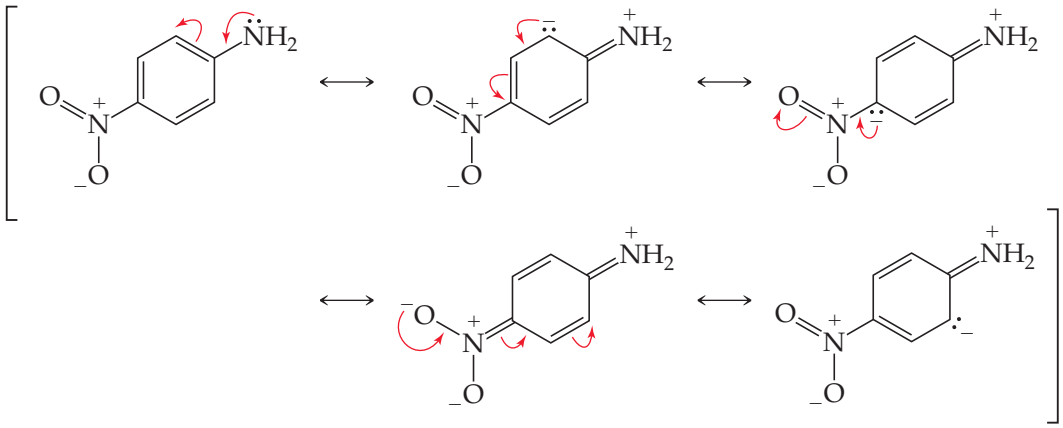
▲ **Figure 31.5 Resonance contributors for aniline.** The electron pair distribution responsible for the mild basicity and nucleophilicity in aromatic amines.



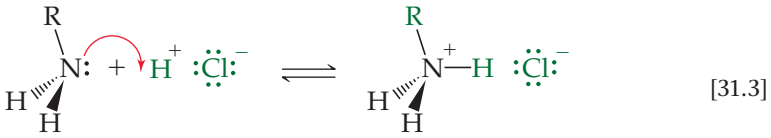
Reactivity of Amines

We introduced the nucleophilic nature of amines in Chapter 28. Along with this nucleophilicity is the ability of primary, secondary and tertiary amines to act as a weak base. The presence of the amine functional group allows for extensive solvation in aqueous media. This means that most amines have some solubility in water and hence can be tested with litmus paper to determine their presence. The acid–base reaction for a primary amine in aqueous solution can be written generally as:

an amine an alkyl ammonium ion [31.2]



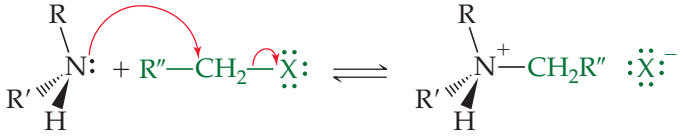
There are a few features to note in this reaction. First, the reaction is an equilibrium reaction, although this equilibrium lies to the left for all amines. Primary, secondary and tertiary alkylamines are over 10^6 times more basic (pK_b = 3–4) than comparable aromatic amines (pK_b = 9–10). The difference in basicity can be attributed to the resonance effects available to aromatic amines, such as shown for aniline in **Figure 31.5**. By distributing electrons around the ring, the nucleophilicity and basicity of aromatic amines is weakened compared with their aliphatic counterparts.



pK_b = 9.4 pK_b = 13.0

The basicity of aromatic amines is also influenced by the substituents on the aromatic ring. For example, 4-nitroaniline (**Figure 31.6**) is a much weaker base than aniline, due to resonance and inductive effects leading to a redistribution of electron density onto the NO_2 group.

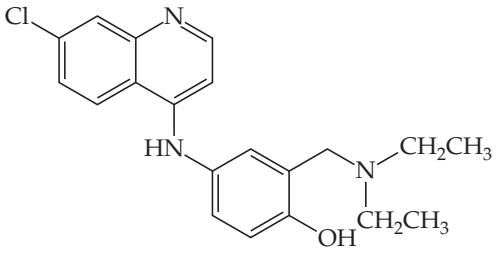
The second feature to note is that the acid–base reaction is written so that it involves the lone pair on nitrogen. The two electrons in this lone pair form a new N–H covalent bond. Finally, the product of the reaction is an **alkyl ammonium salt**, also known as a 4° ammonium salt. Such ammonium salts are easily formed in essentially quantitative yield by reaction of an amine with strong acid such as aqueous HCl:



▲ **Figure 31.6 Rationalising the basicity of 4-nitroaniline.** There are more resonance contributors to the structure of 4-nitroaniline when compared to aniline, suggesting the basicity (and nucleophilicity) of the substituted aniline is less. This situation is accentuated by the electron-withdrawing effect of the nitro group, which is inductive throughout the molecule.

a primary amine — an alkyl ammonium salt [31.3]

Such salts are usually highly soluble in water. Alkyl ammonium salts can also be formed by the reaction of amines with haloalkanes. In the following example, a secondary amine is reacted with a haloalkane to form an alkyl ammonium salt:



a secondary amine — a trialkyl ammonium salt [31.4]

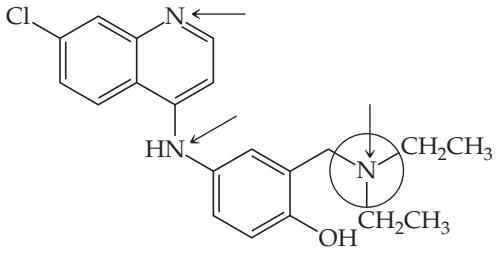
The alkylation reaction is general but care needs to be taken in stoichiometry of reagents, choice of solvent and choice of haloalkanes in order to limit further alkylation.

Sample Exercise 31.3

Amine Basicity

Amodiaquin is commonly used to treat quinine-resistant malaria. Identify the amine groups within this compound and indicate which of the nitrogen atoms of amodiaquin is the most basic.

amodiaquin

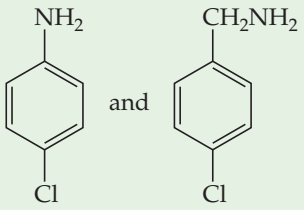


Continued

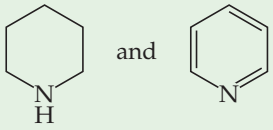
SOLUTION

Analyze We are asked to classify the amines located within the structure of amodiaquin and from there, which is the most basic.

Plan Identify the amines and look for aliphatic amines as the most basic.



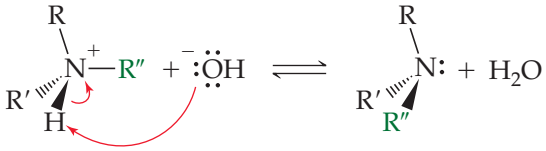
Solve The comparison here is between two aromatic amines and an aliphatic amine (all amine groups indicated by an arrow). The aliphatic amine (circled) is most basic.



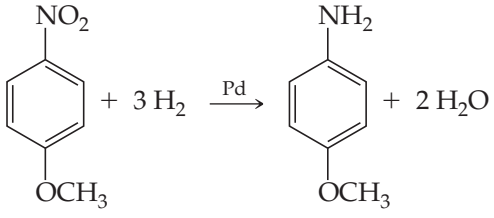
Practice Exercise

Select the stronger base from each amine pair.

(a)

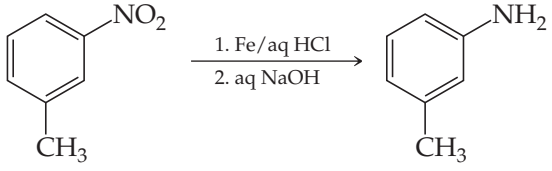


(b)



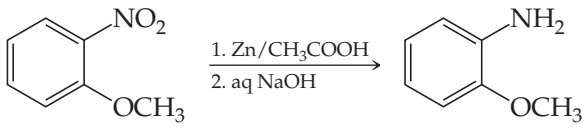
Synthesis of Amines

Amines can be formed in several ways, some simple and some complex. We look at three of the most common ways to form amines. Equation 31.4 illustrates the nucleophilicity of amines and their reactivity towards alkyl halides. The ammonium ion formed in the reaction is a weak acid (pK_a = 9–11), comparable in pK_a to phenols. Addition of an aqueous base during workup (see Equation 31.5) leads in this case to the tertiary amine. Hence, by a simple *alkylation* we have chemically transformed a secondary amine into a tertiary amine.

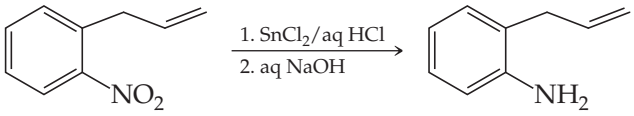


a tertiary amine [31.5]

Aromatic amines such as 4-methoxyaniline are easily prepared by reduction of the corresponding nitro compound. This reduction is usually achieved by catalytic hydrogenation—that is, using H_2 in the presence of a metal catalyst such as Ni, Pd or Pt. Although this reaction is very general, easily accomplished and high yielding, care needs to be taken to ensure that other groups susceptible to hydrogenation, such as double bonds, are not also reduced (recall that benzene does not react like an alkene towards addition type reactions).

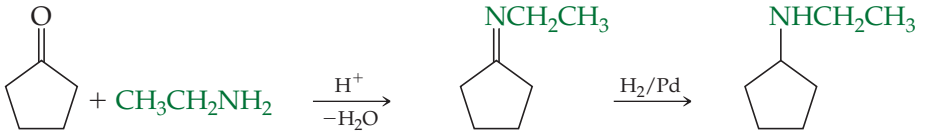


[31.6]

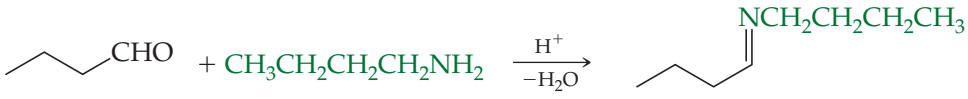


A metal reduction can also be used to effect the same transformation. Metals such as Fe and Zn, and metal salts such as $SnCl_2$, can be used. For example, reduction of the nitro group in Equation 31.6 by hydrogenation (H_2/Pd) would also reduce the alkene group. The use of tin(II) chloride as a reducing agent is more selective for the nitro group, yielding the desired product.

[31.7]

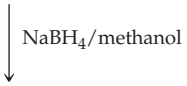


[31.8]



[31.9]

Recall that imines are formed by the reaction of aldehydes and ketones with primary amines. The reactivity of the imine group resembles that of a carbonyl group, meaning that both functional groups are susceptible to hydride reduction and catalytic hydrogenation. This method, known as a **reductive amination**, is an easy way of producing secondary amines from primary amines.

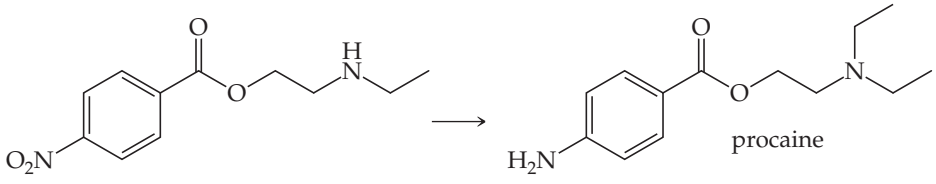


[31.10]

cyclopentanone ethanamine *N*-ethyl-cyclopentanimine, an imine *N*-ethyl-cyclopentanamine

[31.11]

butanal 1-butylamine *N*-butylbutanimine, an imine



$HN(CH_2CH_2CH_2CH_3)_2$

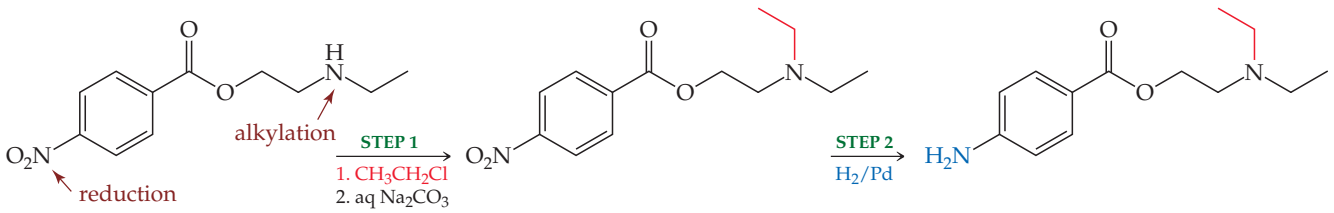
dibutylamine

Sample Exercise 31.4

Amine Synthesis

Describe a synthesis for procaine, a local anaesthetic, from the suggested starting material. You may choose any reagents and conditions you like that will affect the transformations needed.

SOLUTION



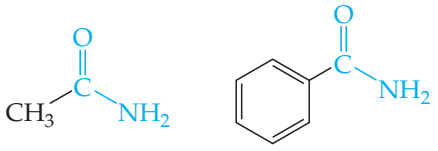
Analyze We are given a compound and asked to devise a synthesis of procaine.

Plan Identify the functional group differences between starting material and product and then a plan of attack to make the necessary interconversions.

Solve In this case, the differences in functional groups can be achieved by an alkylation, introducing the ethyl group, and a reduction of the nitro group to give the amine. *Be very careful with the order of reaction*. In this example, alkylation must occur before reduction in order to yield procaine. Reducing the nitro group to the amino group, followed by alkylation, would be likely to cause a reaction to occur on both nitrogens. The difference in

Continued

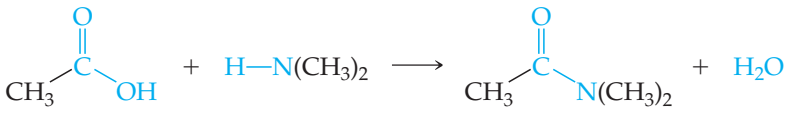
nucleophilicity is not significant enough to cause alkylation of just the aliphatic amine.



Practice Exercise

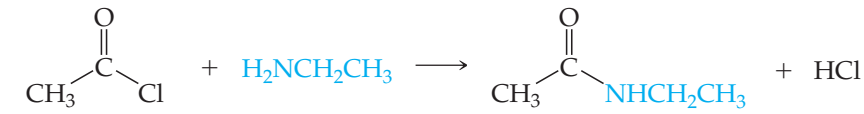
Describe a method for separating a mixture of nitrobenzene from aniline in diethyl ether solution.

Amides



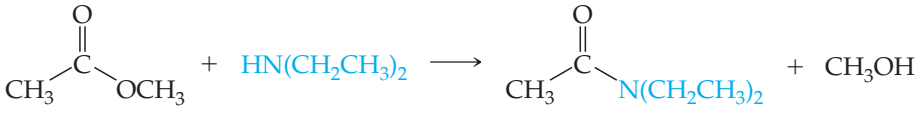
Amides are derivatives of carboxylic acids in which the OH group of the carboxylic acid group has been replaced with a NRR′ group (R, R′ = H, alkyl, aryl), as in these examples:

ethanamide
acetamide

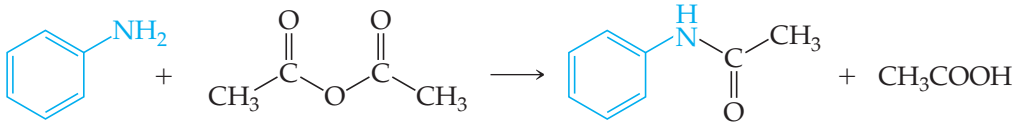


phenylmethanamide
benzamide

An amide can be considered as the condensation product of an amine and a carboxylic acid:

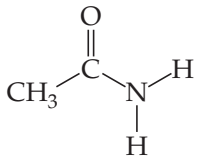


[31.12]



In Section 29.5, we saw that amides can also be formed by reaction of an acid anhydride, acid chloride or ester with ammonia, a primary or secondary amine. Examples of such reactions are:

acetyl chloride (an acid chloride) + ethanamine (a 1° amine) → *N*-ethylacetamide (an amide) + HCl [31.13]

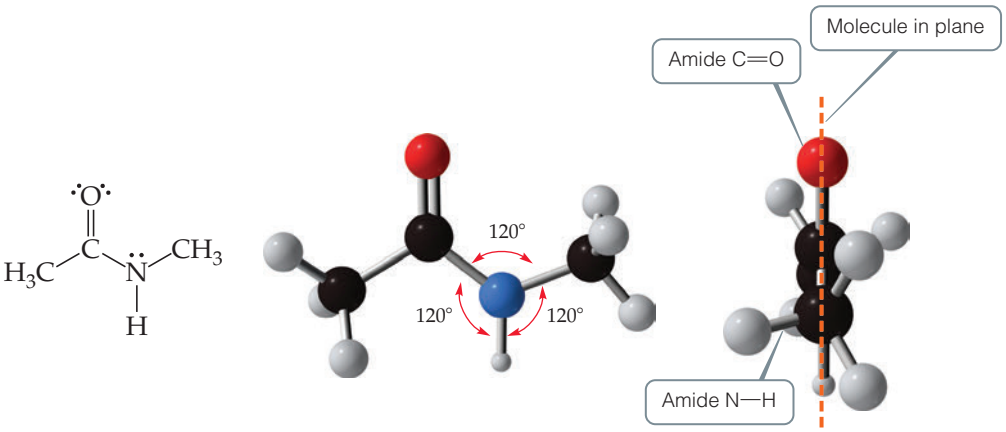


ethyl acetate (an ester) + diethylamine (a 2° amine) → *N,N*-diethylacetamide (an amide) + CH_3OH [31.14]

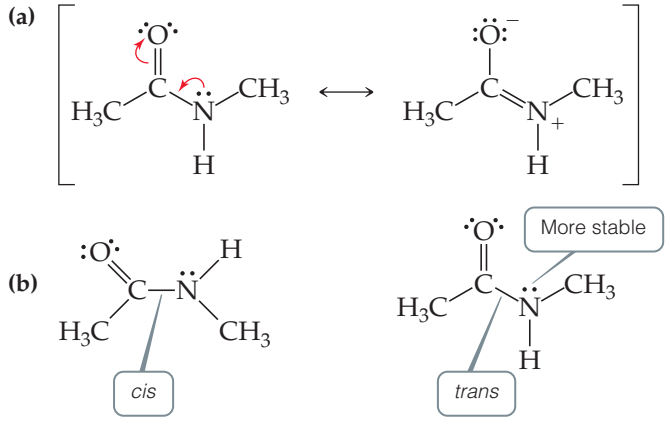
aniline (an aromatic amine) + acetic anhydride (an acid anhydride) → *N*-phenylacetamide (an amide) + CH_3COOH [31.15]

Amides are classified as primary, secondary or tertiary, depending on their substitution at the amide nitrogen.

- **Primary (1°) amide**: the nitrogen of the amide group is bonded to one carbon atom, which is that of the carbonyl group. For example:



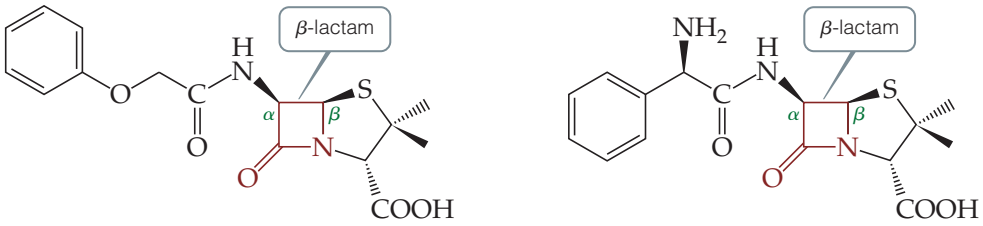
acetamide
1° amide



- **Secondary (2°) amide**: the nitrogen of the amide group is bonded to two carbon atoms, one of which is a carbonyl group; for example *N*-phenylacetamide.
- **Tertiary (3°) amide**: the nitrogen of the amide group is bonded to three carbon atoms, one of which is a carbonyl group. The other two carbon atoms usually belong to alkyl or aryl groups; for example *N,N*-diethylacetamide.

The geometry of the amide bond is quite unexpected. At first glance, you would expect the bonding geometry about the nitrogen atom to be a trigonal pyramid, similar to what you would find for an amine. During the 1930s Linus Pauling discovered that an amide is planar through the CONR group (**Figure 31.7**), commensurate with the observed bond angles of approximately 120° about the amide nitrogen.

Pauling rationalized the unusual geometry of the amide bond by describing two resonance hybrid structures (**Figure 31.8(a)**). One structure has a single bond between the carbonyl carbon and nitrogen, whereas the other has a carbon-nitrogen double bond. The overall structure is neither of these, but a hybrid containing a significant amount of carbon-nitrogen double-bond character. It is this double-bond character that makes the six



◀ **Figure 31.7 The geometry of the amide bond.** Bond angles of approximately 120° are seen about the amide nitrogen. This trigonal-planar geometry is coplanar with the amide carbonyl group.

◀ **Figure 31.8 Conformation and rationalization.** (a) The planar nature of the amide bond can be rationalized by resonance delocalization. (b) Amides can exist as *cis* or *trans* conformers known as rotamers because there is limited rotation about the C—N bond. The *trans* conformer is favoured because it reduces any steric strain caused by substituents.

▶ **Figure 31.9 Structure of penicillins.** Penicillin V and amoxicillin are two examples of lactams.

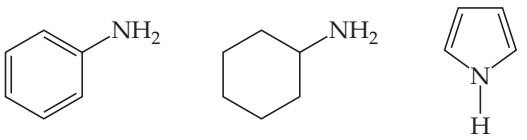
penicillin V amoxicillin

atoms about the amide bond planar. As a result of the restricted rotation about the C—N bond, two conformations are possible for the amide bond, *cis* and *trans* (Figure 31.8(b)). The *trans* isomer is favoured because it reduces any steric strain imposed by substituents on either side of the amide bond.

Cyclic amides are called **lactams**. We do not deal with these in any detail except to say that a very potent form of antibiotic, the **penicillins**, all contain a four-membered lactam ring, known as a β-lactam, fused to a five-membered ring containing sulfur (**Figure 31.9**).

Self-Assessment Exercises

31.1 What is the correct name of the following amine?

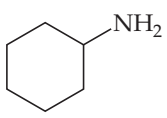


(a) *N*-methyl-*N*-ethyl-1-butanamine
(b) *N*-ethyl-*N*-methyl-1-butanamine
(c) *N*-methyl-3-hexanamine

31.2 What is/are the best reagent(s) to perform the following conversion?

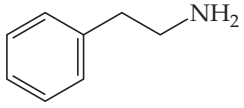
(a) H_2/Pd catalyst
(b) $SnCl_2$/aq HCl
(c) i) $SnCl_2$/aq HCl ii) aq NaOH

31.3 Rank the following amines from the most basic to the least basic.



aniline cyclohexylamine pyrrole

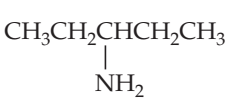
(a) aniline > cyclohexylamine > pyrrole
(b) cyclohexylamine > aniline > pyrrole
(c) cyclohexylamine > pyrrole > aniline
(d) pyrrole > aniline > cyclohexylamine



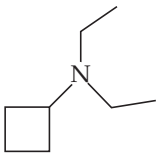
Exercises

31.4 Give names for the following amines:

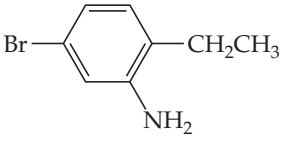
(a)



(b)



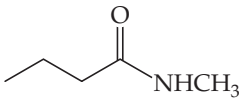
(c) $CH_3CH_2NHCH_3$



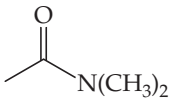
(d)

(e)

(f)

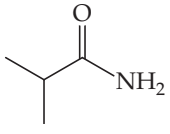


31.5 Provide a structural formula for each of the following compounds:

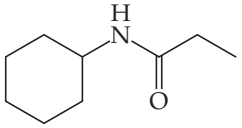


(a) 4-nitropyridine
(b) benzylamine
(c) *N,N*-dimethylpropylamine
(d) 2,4-diaminobenzoic acid
(e) 2-ethyl-1-butanamine

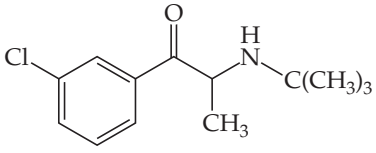
31.6 Give names for the following amides:



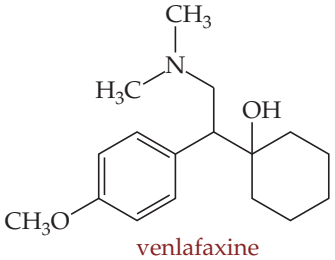
(a)



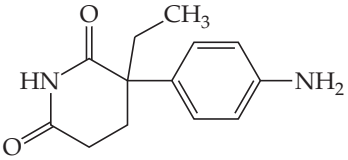
(b)



(c)

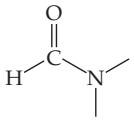


(d)



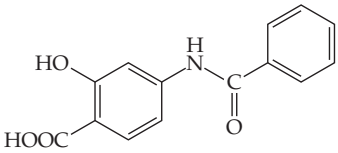
31.7 *Bupropion* is an antidepressant drug also used to treat attention-deficit hyperactivity disorders. *Venlafaxine* (sold under the brand name Effexor®) is an antidepressant drug. *Aminoglutethimide* has been used as an anticonvulsant. Classify bupropion, venlafaxine and aminoglutethimide as primary, secondary or tertiary amines.

bupropion



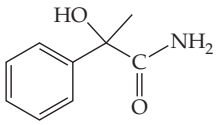
venlafaxine

aminoglutethimide



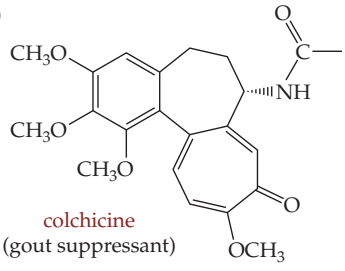
31.8 Define the following amides as primary, secondary or tertiary:

(a)



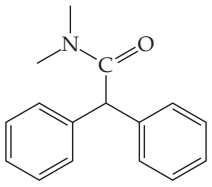
N,N-dimethylformamide
(solvent for organic synthesis)

(b)



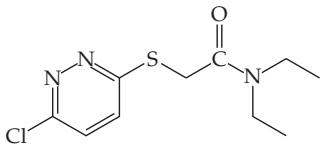
benzoylpas
(an antibacterial)

(c)



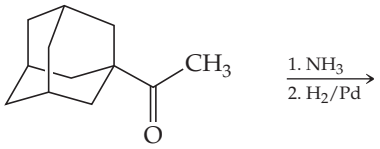
atrolactamide
(an anticonvulsant)

(d)



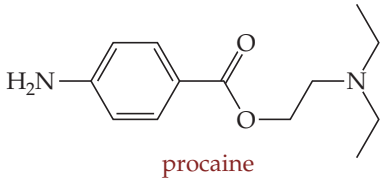
colchicine
(gout suppressant)

(e)



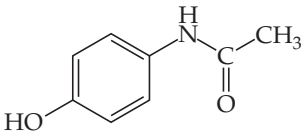
dipenamide
(a herbicide)

(f)



azintamide
(a choleretic)

31.9 *Rimantadine* is effective in preventing infections caused by the influenza A virus. It can be formed from the ketone and the reagents shown. Suggest a structure for rimantadine consistent with the reaction conditions. [*Hint:* The reaction is undertaken in two steps.]



31.10 *Procaine* was one of the first local anaesthetics used. Its hydrochloride salt is marketed as *Novocaine*®.

procaine

(a) Draw the product of the reaction of procaine with 1 mole equivalent of HCl. **(b)** Suggest a synthesis for procaine starting with 4-nitrobenzoic acid.

31.11 Devise a synthesis for *paracetamol* beginning with 4-nitrophenol.

paracetamol

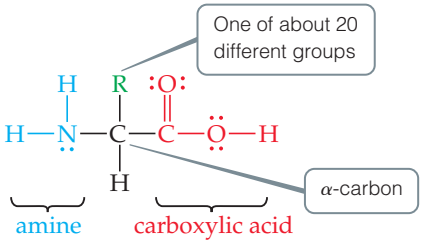
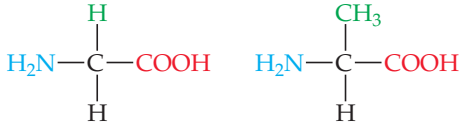
31.2 Amino Acids



Phenylalanine is one of the two amino acids that make up the sweetener aspartame, an artificial sweetener sold under the trade names "Equal®" and "Nutrasweet®". Phenylalanine also happens to be one of the essential amino acids, which means that we must have it in our diets to survive long term. However, in about one out of 10,000 to 20,000 Caucasian or Asian births, the enzyme that converts phenylalanine to another amino acid, tyrosine, is completely or nearly completely absent because of a genetic defect. The result is that phenylalanine accumulates in the blood and in body tissues. The disease that results is called phenylketonuria (PKU), which causes intellectual disability and seizures. This is why cans of diet soft drink sometimes carry the warning "Phenylketonurics: contains phenylalanine". Newborns are routinely tested for PKU when they are about three days old.

Although biological systems are unimaginably complex, they are nevertheless constructed of molecules of quite modest size. The example here illustrates that, in order to understand biology, we need to understand the chemical behavior of molecules with low molar mass, as well as much larger molecules, which form the basis of *biological chemistry*.



By the end of this section, you should be able to:

- understand the acid-base properties of an amino acid
- know how an amino acid can be made in the laboratory

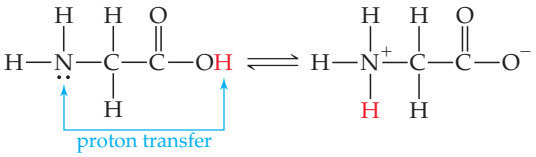
Amino acids contain both an amino group and a carboxyl group. An **α-amino acid** is an amino acid in which the amino group is bonded to the carbon adjacent to the carboxyl group. α-Amino acids play a large role in biological chemistry as the building blocks of protein, and their properties are dictated somewhat by the nature of the R group.

In *glycine*, which is the simplest amino acid, R is a hydrogen atom; in *alanine*, R is a methyl group.

Because amino acids contain a carboxyl group, they can serve as weak acids. They also contain the NH_2 group, characteristic of amines, and thus they can also act as weak bases.

Amino acids, therefore, are **amphiprotic**. For glycine, we might expect that the acid and the base reactions with water would be as follows:

Acid:



$$H_2NCH_2COOH(aq) + H_2O(l) \rightleftharpoons H_2NCH_2COO^-(aq) + H_3O^+(aq) \quad [31.16]$$

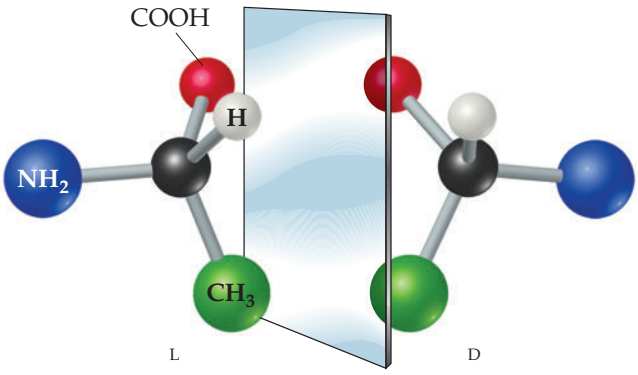
Base:

$$H_2NCH_2COOH(aq) + H_2O(l) \rightleftharpoons {}^+H_3NCH_2COOH(aq) + OH^-(aq) \quad [31.17]$$

The pH of a solution of glycine in water is about 6.0, indicating that it is a slightly stronger acid than a base.

The acid–base chemistry of amino acids is somewhat more complicated than shown in Equations 31.16 and 31.17, however. As a result of the fact that the COOH group can act as an acid and the NH_2 group can act as a base, amino acids undergo a "self-contained" Brønsted–Lowry acid–base reaction in which the proton of the carboxyl group is transferred to the basic nitrogen atom:

[31.18]



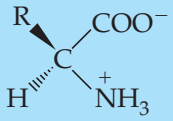
neutral molecule zwitterion

Although the form of the amino acid on the right side of Equation 31.18 is electrically neutral overall, it has a positively charged end and a negatively charged end. A molecule of this type is called a **zwitterion** (German for "hybrid ion"). This doubly ionized form predominates at near-neutral values of pH. Amino acids are more properly written as the zwitterion because of this fact, although there are many instances in science (not necessarily chemistry) where the un-ionized form (left side of Equation 31.18) is commonly written.

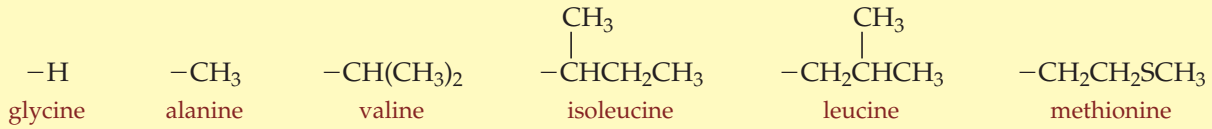
Do amino acids exhibit any properties indicating that they behave as zwitterions? If so, they should behave in a similar manner to ionic substances. Crystalline amino acids (**Figure 31.10**) have relatively high melting points, usually above 200 °C, which is characteristic of ionic solids. Amino acids are far more soluble in water than in non-polar solvents. In addition, the dipole moments of amino acids are large, consistent with a large separation of charge in the molecule. Thus the ability of amino acids to act simultaneously as acids and bases has important effects on their properties.

With the exception of glycine, all naturally occurring amino acids have at least one stereocenter, the α-carbon. **Figure 31.11** shows the two enantiomers of the amino acid alanine. For historical reasons, the two enantiomers are distinguished by the labels D and L. All amino acids normally found in proteins have the L configuration at the stereocenter (except for glycine, which is not chiral). In terms of absolute stereochemistry, all naturally occurring α-amino acids have the *S* configuration (Section 25.3). This means that the enantiomer or D-amino acid has R configuration.

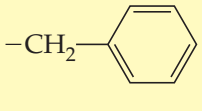
Figure 31.12 shows the structural formulas of the 20 most common α-amino acids found in proteins. Our bodies can synthesize 10 of these α-amino acids in sufficient



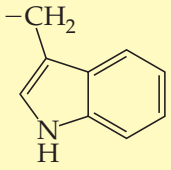
▲ **Figure 31.10 Lysine.** One of the amino acids found in proteins, lysine is available as a dietary supplement. The L in the name L-Lysine refers to a specific configuration of atoms that is found in naturally occurring amino acids.



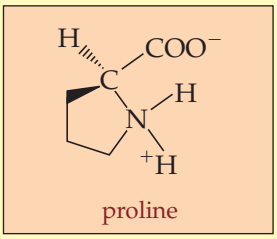
Go Figure Are all α-amino acids chiral?



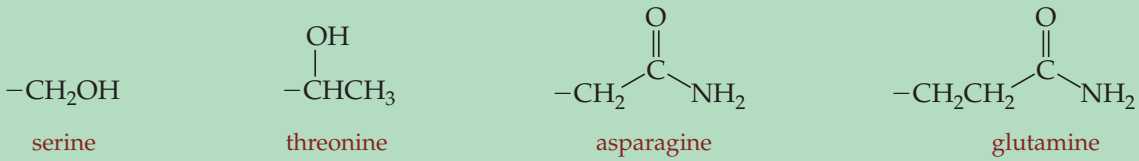
▲ **Figure 31.11 Alanine enantiomers.** The middle carbon of alanine is stereogenic, and therefore there are two enantiomers, which by definition are non-superimposable mirror images of each other.

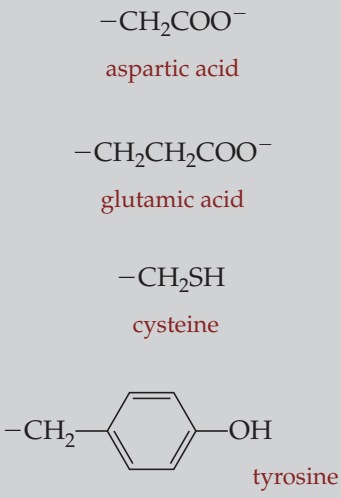


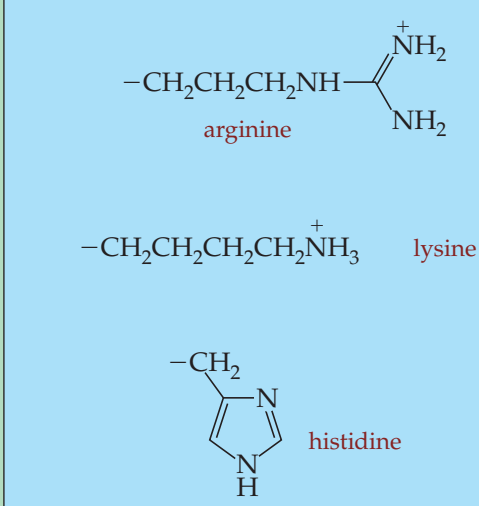
L-amino acid general structure



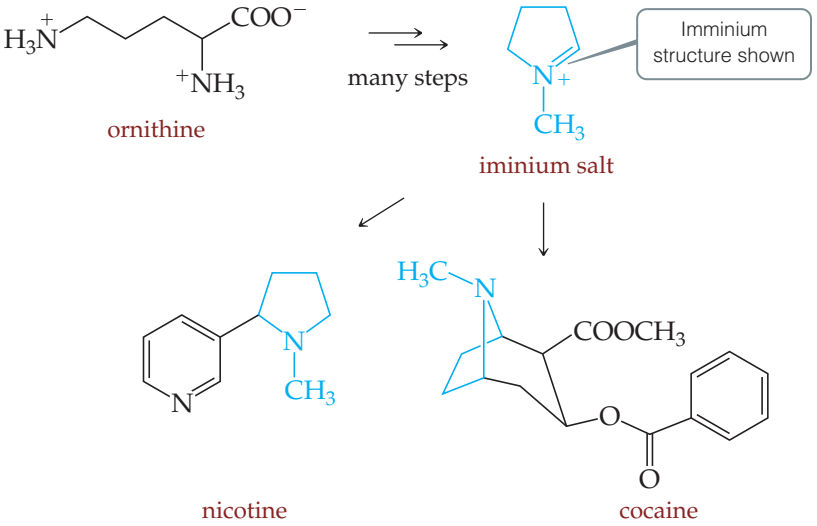
Non-polar side chains (R=)







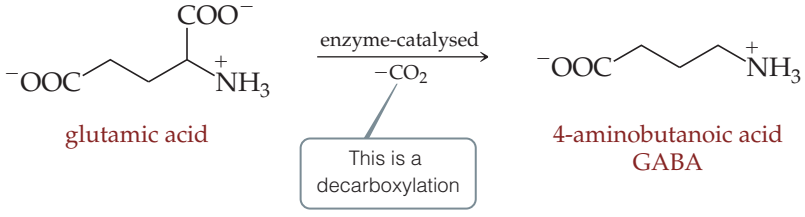
Polar side chains (R=)



Acidic side chains (R=)

Basic side chains (R=)

▲ **Figure 31.12 The 20 common α-amino acids found in the human body.** Each ionizable group within the acidic and basic classes is shown in the form present in highest concentration at pH = 7.0.

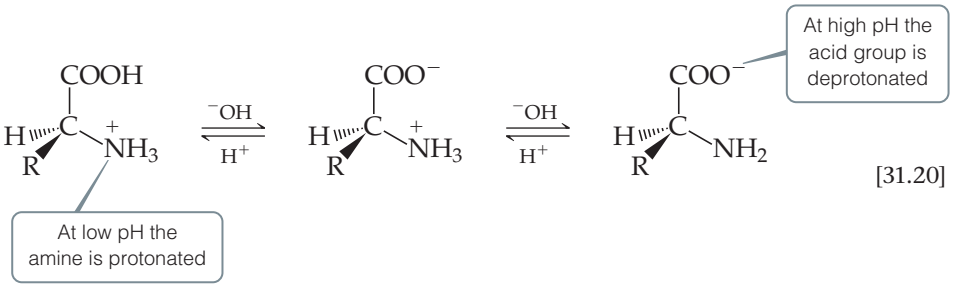


◀ **Figure 31.13 Ornithine.** This amino acid is a relative of lysine but with a shorter side chain.

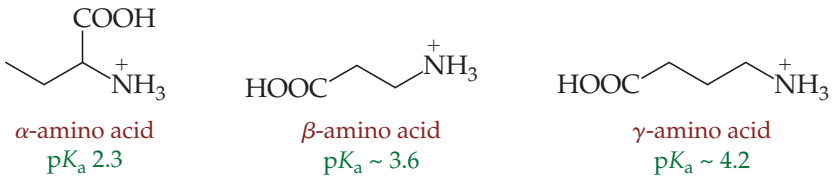
amounts for our needs. The other 10 must be ingested and are called *essential amino acids* because they are necessary components of our diet.

α-Amino acids, which make up the 20 most common naturally occurring amino acids, can be classified by the nature of their **side chain**, which is bonded to the amino acid's α-carbon. These side chains are used to classify amino acids as polar and non-polar. The polar amino acids can be further classified as ionized (for example, containing acidic and basic side chains) and un-ionized (that is, neutral-polar side chains). Proline is a cyclic amino acid, which differs from the acyclic nature of the other 19 amino acids.

Although all amino acids are chiral, with the exception of glycine, isoleucine and threonine also contain a second stereocenter. Four stereoisomers are possible, but only *one* of the four stereoisomers is found in proteins.



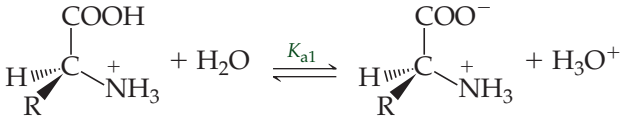
Two amino acids not listed in Figure 31.12 deserve special mention because of their social and medicinal importance. Ornithine is an amino acid found in the liver, with importance in the urea cycle. It is also a precursor for the biosynthesis of nicotine and tropane alkaloids such as cocaine (**Figure 31.13**). GABA (γ-aminobutyric acid) is a neurotransmitter (a substance that transmits nerve impulses across a synapse), found exclusively in the brain and central nervous system (CNS). It has been implicated in several neurodegenerative conditions, including memory loss. GABA is formed within the CNS by the enzyme-catalyzed decarboxylation of glutamic acid. Its systematic name, 4-aminobutanoic acid, is less commonly used than its acronym, GABA.



[31.19]

Acid–Base Properties

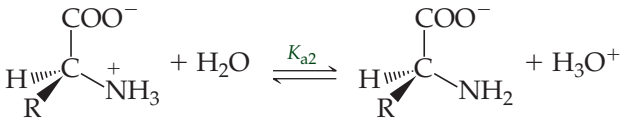
The amphiprotic nature of α-amino acids can be described by the following equation:



[31.20]

▶ **Figure 31.14 Carboxyl group acidity.** The inductive effect of the ammonium ion changes the pK_a of the COOH of amino acids. The effect of the ammonium group is connectivity dependent and approaches that of a normal carboxylic acid as the number of intervening bonds increase.

At low pH the basic amino group is protonated, forming the ammonium ion. In neutral solution the zwitterion is formed. The pH at which the zwitterion concentration is the highest is called the **isoelectric point**. In basic solution, the carboxylic acid group is ionized to form the carboxylate group. Notice that amino acids are ionic at all pHs, which makes them highly water soluble and difficult to purify by the normal procedures used in organic chemistry.

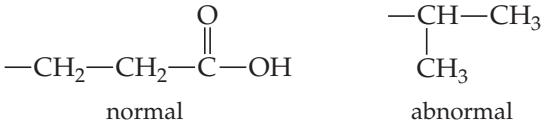


Consider the following reaction:

[31.21]

The average pK_a value (pK_{a1}) for the carboxyl group of an α-amino acid is ~2. This value is considerably lower than that for acetic acid (pK_a = 4.76), which implies that α-amino acids are stronger acids than acetic acid. The reason for this difference in pK_a can be attributed to the inductive electron-withdrawing effect of the ammonium group, which draws electron density out of the O—H bond, making it weaker relative to the same bond in acetic acid. **Figure 31.14** shows how this inductive effect weakens as the number of intervening bonds increases.

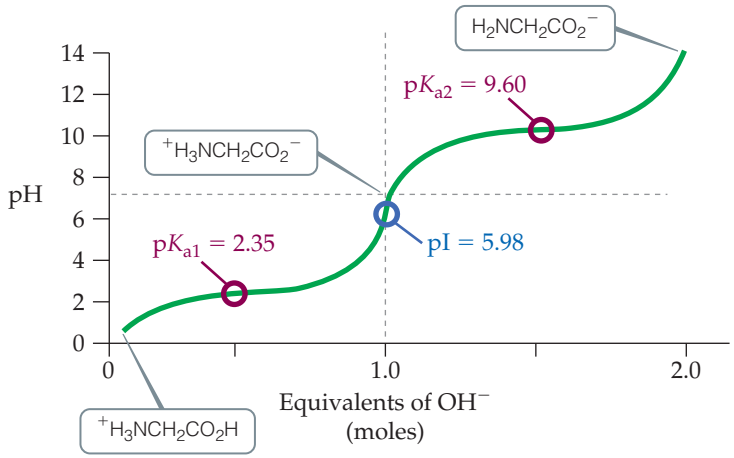
The ammonium group of an α-amino acid is a stronger acid than a comparable aliphatic ammonium ion due to the weak inductive effect of the carboxyl group. The average pK_a for an α-amino acid (pK_{a2}) is ~9.5, compared with pK_a ~10.5 for an aliphatic amine. This implies that the amine of an α-amino acid is generally a weaker base than a 1° aliphatic amine.



[31.22]

A CLOSER LOOK Sickle-Cell Anemia

Our blood contains a complex protein called hemoglobin, which carries oxygen from the lungs to other parts of the body. In the genetic disease known as sickle-cell anemia, hemoglobin molecules are abnormal and have a lower solubility, especially in their unoxygenated form. Consequently, as much as 85% of the hemoglobin in red blood cells crystallizes from solution.



The reason for the insolubility of hemoglobin in sickle-cell anemia can be traced to a structural change in one part of an amino acid side chain. Normal hemoglobin molecules contain glutamic acid, which contributes to the solubility of the hemoglobin molecule in water. In the hemoglobin molecules of people suffering from sickle-cell anemia, the glutamic acid residue is replaced by valine:

Valine is non-polar (hydrophobic), and its presence leads to the aggregation of the defective form of hemoglobin into particles too large to remain suspended in biological fluids. It also causes the cells to distort into a sickle shape, as shown in **Figure 31.15**. The sickled cells tend to clog the capillaries, causing severe pain, physical weakness and gradual deterioration of the vital organs. The disease is hereditary and, if both parents carry the defective genes, it is likely that their children will possess only abnormal hemoglobin.

▲ **Figure 31.15 Normal and sickled red blood cells.** Normal red blood cells are about 1 μm in diameter.

◀ **Figure 31.16 Titration of glycine with aqueous NaOH solution.** pK_{a1} relates to the pK_a of the carboxylic acid, while pK_{a2} relates to the pK_a of the ammonium ion.

Let us now investigate what the pK_a value of an α-amino acid means and what information it provides. To do this, we need to consider the pH titration of a simple amino acid, such as glycine, with aqueous sodium hydroxide solution (**Figure 31.16**).

At low pH, glycine is in its fully protonated form, $^+H_3NCH_2CO_2H$. The addition of OH^- sees a gradual rise in pH until a plateau is reached (also described as a *point of inflexion* on the titration curve). At this point, which corresponds to the addition of 0.5 mol of OH^-, the pH = pK_{a1}. This is the point at which the concentration of the zwitterion equals that of the ammonium ion:

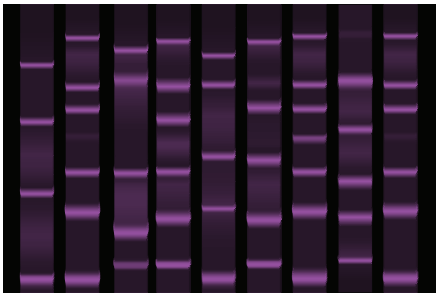
$$\text{when pH} = pK_{a1},\ [^+H_3NCH_2CO_2H] = [^+H_3NCH_2CO_2^-]$$

A pH value *lower* than pK_{a1} means that the ammonium ion predominates. A pH value *higher* than pK_{a1} means the zwitterion predominates in solution.

The endpoint of this first reaction is reached when 1 mole equivalent of OH^- is added. This point, known as the *isoelectric point*, is where the zwitterion $^+H_3NCH_2CO_2^-$ is at its maximum concentration. At the isoelectric point, pI, the amino acid has no net charge. The pI of an amino acid usually lies at the midpoint of pK_{a1} and pK_{a2}. We can represent this mathematically by:

$$\text{pI} = \tfrac{1}{2}(pK_{a1} + pK_{a2}) \qquad [31.23]$$

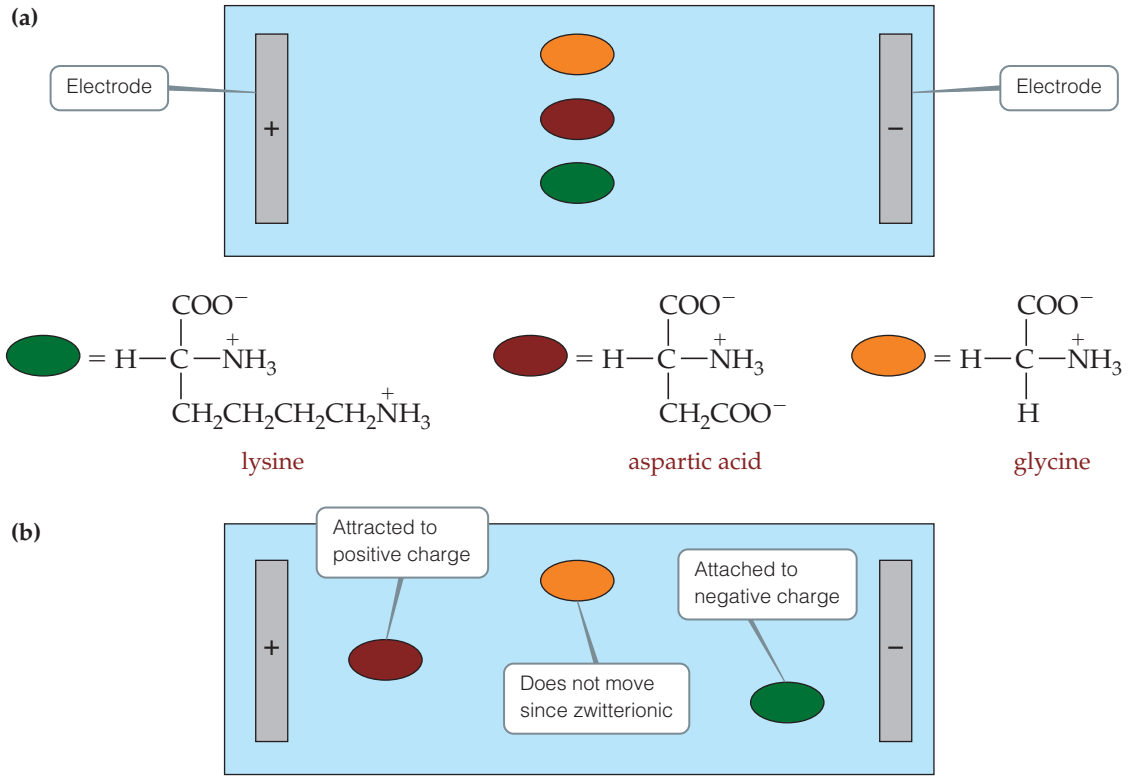
$$\text{for glycine,} \qquad \text{pI} = \tfrac{1}{2}(2.35 + 9.60) = 5.98$$



The addition of another 0.5 molar equivalents of OH^- causes the pH to rise, then plateau. This point of inflexion indicates pK_{a2}, the pK_a value associated with the ammonium group. This is the point at which the concentration of the zwitterion equals that of the carboxylate ion:

$$\text{when pH} = pK_{a2},\ [^+H_3NCH_2CO_2^-] = [H_2NCH_2CO_2^-]$$

A value of pH *lower* than pK_{a2} means that the zwitterion ion predominates. A value for the pH *higher* than pK_{a2} means that the amine and carboxylate groups predominate in solution.



The net charge of an amino acid is easily estimated using the pI value. As pH values fall below pI, the amino acid exists more and more as the ammonium ion, which is positively charged. At pH values higher than the pI, the amino acid exists as the carboxylate ion, which is negatively charged.

Knowledge about the pI of an amino acid is also useful for purification by **electrophoresis**, a process used to separate molecules based on charge (**Figure 31.17**). This useful technique uses either paper or gel as a separating medium and electric charge to separate amino acids, proteins and other charged molecules (**Figure 31.18**). You will learn more about this technique in courses devoted to biochemistry and cellular biology, where the separation of amino acids (and proteins) by this technique is a fundamental tool in the laboratory.

▲ **Figure 31.17 A typical electrophoresis result.** The bands highlighted under UV light represent different amino acids, peptides or proteins that have been separated in a gel matrix. Each species can be isolated and then identified.

Go Figure How would tyrosine, pI = 5.66, act at pH 5.66 in electrophoresis? Would this change at pH 9?

▲ **Figure 31.18 Separation of amino acids by electrophoresis.** By running an electrophoresis experiment at pH 5.98, we can separate three amino acids, based on their pI values. At pH 5.98, glycine has no net overall charge because of its zwitterionic state. Aspartic acid (pI 2.77) is deprotonated at pH 5.98 and is attracted to the positive electrode. Lysine (pI 9.74) is protonated at pH 5.98 and is attracted to the negative electrode. (a) At time = 0, (b) at time > 0.

Sample Exercise 31.5

Acid–Base Properties of Amino Acids

Draw structural formulas for the predominant form of glycine (pK_a 2.35, 9.60) in aqueous solution at pH 1, 6 and 12.

SOLUTION

Analyze We are asked to draw the form of an amino acid at a given pH knowing the pK_a.

Plan When working through a problem like this, it is important to identify the relationship between the pH and the closest pK_a value.

Solve At pH 1, glycine is predominantly in the fully protonated form:

$$^{+}H_3NCH_2CO_2H$$

The reason is that pH < pK_{a1}.

pH 6 is between the two given pK_a values, so the zwitterion is the major form:

$$^{+}H_3NCH_2CO_2^{-}$$

At pH 12, the carboxylate form predominates:

$$H_2NCH_2CO_2^{-}$$

The reason is that pH > pK_{a2}.

To verify the answer to this problem, you could use Figure 31.16.

Practice Exercise

Draw structural formulas for the predominant forms of serine (pK_a 2.21, 9.15) in aqueous solution at pH 2, 7 and 10.

We can predict which species predominates at a certain pH in a much more quantitative way. For example, the equation for the acid-dissociation constant K_{a1}, shown in Equation 31.21, can be written as follows:

$$K_{a1} = \frac{[H_3O^+][R'-CO_2^-]}{[R'-COOH]} \qquad [31.24]$$

$$\text{where } R' = RCH\overset{+}{N}H_3$$

Rearrangement gives

$$\frac{K_{a1}}{[H_3O^+]} = \frac{[R'-CO_2^-]}{[R'-COOH]} \qquad [31.25]$$

Knowing the value of pK_{a1} and the pH of the solution (which determines the value of $[H_3O^+]$), we can calculate the exact ratio of the fully protonated and zwitterion forms at values between pH = 0 and the pI, as well as the net charge on the α-carboxyl group at that pH.

In a similar way, the equation for the acid-dissociation constant K_{a2}, shown in Equation 31.22, can be written as follows:

$$K_{a2} = \frac{[H_3O^+][R'-NH_2]}{[R'-NH_3^+]} \qquad [31.26]$$

$$\text{where } R' = RCHCO_2^-$$

Rearrangement gives

$$\frac{K_{a2}}{[H_3O^+]} = \frac{[R'-NH_2]}{[R'-NH_3^+]} \qquad [31.27]$$

Knowing the value of pK_{a2} and the pH of the solution, we can calculate the exact ratio of the amine and zwitterion forms at values between pI and pH = 14, as well as the net charge on the α-amino group at that pH.

These calculations are similar to those used for buffer solutions using the Henderson–Hasselbalch equation for weak acid/conjugate base pairs:

$$pH = pK_a + \log \frac{[\text{conjugate base}]}{[\text{weak acid}]} \qquad [31.28]$$

Sample Exercise 31.6

Estimating Net Charge

Let's reconsider the question posed in Practice Exercise 31.5. Estimate the net charge on serine at pH = 2.

SOLUTION

Analyze We are asked to determine the percentage of each species in solution to determine the net charge at a given pH.

Plan Use the Henderson–Hasselbalch equation to determine the ratio of acid to conjugate base, hence the percentage of each in solution.

Solve Using Equation 31.28 and substituting in values:

$$pH = 2 \text{ and } pK_a = 2.21$$

gives

$$2 = 2.21 + \log \frac{[R'CO_2^-]}{[R'CO_2H]}$$

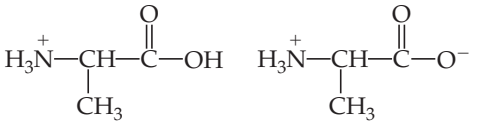
$$\frac{[R'CO_2^-]}{[R'CO_2H]} = 0.62$$

Continued

This ratio concludes that the amino acid exists as 38% $R'CO_2^-$ and can be calculated using:

$$\frac{x}{100-x} = 0.62$$

where x = the percentage of $R'CO_2^-$



A similar calculation for the amino group gives

$$2 = 9.15 + \log \frac{[R'NH_2]}{[R'NH_3^+]}$$

$$\frac{[R'NH_2]}{[R'NH_3^+]} = 7.1 \times 10^{-8}$$

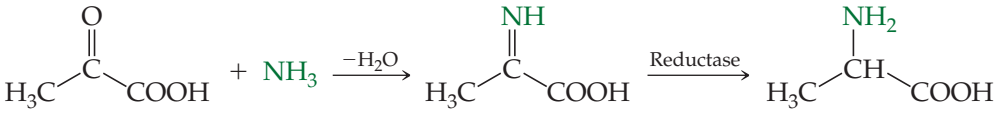
which indicates that the amino group is > 99.9% protonated at pH 2.

The average charge of the amino acid in solution can be calculated from the contributions of each charged species at pH 2. That is, at pH 2 the following two species exist:

62% 38%

Their respective charges are +1 and 0.

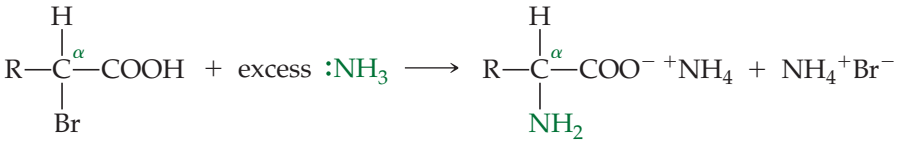
Therefore, based on their relative proportions in solution,



$$\text{Average charge} = 0.62 \times 1.0 + 0.38 \times 0 = +0.62$$

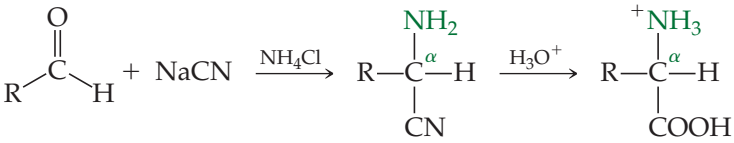
Practice Exercise

Estimate the net charge on serine at pH = 7 and pH = 10.



Reactions Involving Amino Acids

There are several biological pathways for synthesising amino acids. For example, the bacterium *Bacillus subtilis* synthesizes alanine from pyruvic acid in the following way:

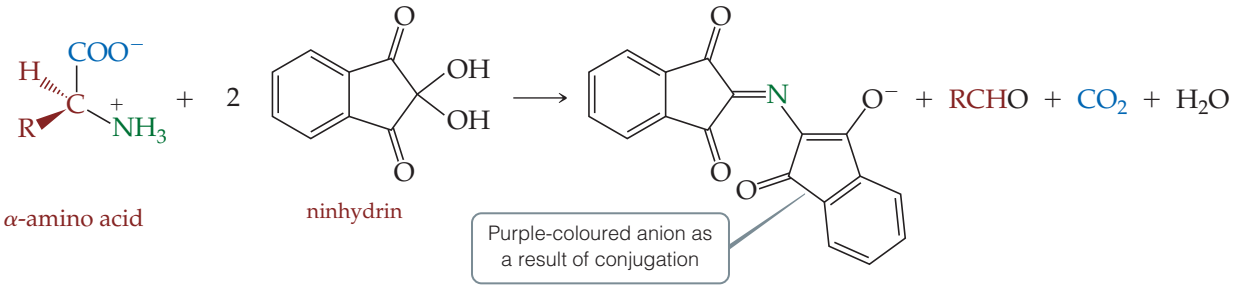


pyruvic acid an imine alanine [31.29]

In a laboratory, there are two main ways of synthesising α-amino acids. The first method involves nucleophilic substitution of an α-halo carboxylic acid with ammonia:

α-halo carboxylic acid α-amino acid salt [31.30]

The second method is called **Strecker synthesis** of α-amino acids. This three-step reaction converts aldehydes to α-amino acids in the presence of cyanide ion.



aldehyde amino nitrile α-amino acid [31.31]

Treatment of the aldehyde with cyanide ion in the presence of ammonium chloride yields the intermediate amino nitrile. This reaction is twofold: reaction of the aldehyde with ammonium chloride yields an imine, which undergoes addition of the cyanide ion to form the amino nitrile; the nitrile group is then hydrolyzed to the carboxylic acid in the presence of aqueous acid.

The methods described in Equations 31.30 and 31.31 are not ideal because the products are typically formed as racemates, which need to be separated to form the enantiomerically pure compounds. In some instances, separation is easily achieved by chiral resolution techniques. In other cases, more complicated and expensive techniques are required.

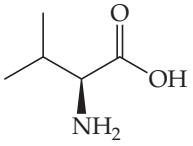
Since most amino acids are neither colored nor fluorescent, their detection requires the use of a dye. The most common dye used, called ninhydrin, reacts specifically with α-amino acids to produce a purple-colored anion, an aldehyde, CO_2 and water.

[31.32]

The fact that a purple-colored solution is formed from colorless starting materials is important for the use of ninhydrin in quantifying the amount of α-amino acid present in a sample using absorption spectroscopy at 580 nm. Note that only α-amino acids containing a primary amino group react to form the purple-colored anion. Proline, which has a secondary amino group, does not react in the same way.

Self-Assessment Exercises

31.12 Methionine has pK_a values of 2.28 and 9.21. At what pH do you get the maximum concentration of the zwitterionic form of methionine?



(a) 2.28

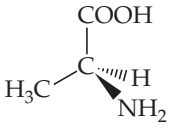
(b) 5.75

(c) 7.00

(d) 9.21

31.13 In the Strecker synthesis of valine, what is the starting aldehyde?

valine



(a) 3-methylbutanoic acid

(b) 3-methylbutanal

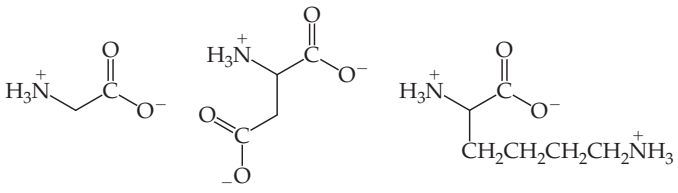
(c) methylpropanal

Exercises

31.14 Describe the relationship between β-alanine and L-α-alanine.

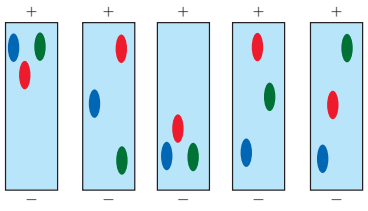
L-α-alanine

β-alanine



31.15 Alanine can exist in water in several ionic forms. **(a)** Suggest the form of alanine at low pH and at high pH. **(b)** Amino acids are reported to have two pK_a values, one in the range of 2 to 3 and the other in the range of 9 to 10. Alanine, for example, has pK_a values of about 2.3 and 9.6. Suggest the origin of the two pK_a values.

31.16 Glutamic acid has pK_a values of 2.19, 4.25 and 9.67. **(a)** What would be the predominant species in solution at pH 2? **(b)** What would be the predominant species in solution at pH 8? **(c)** Estimate the isoelectric point, pI, for glutamic acid.

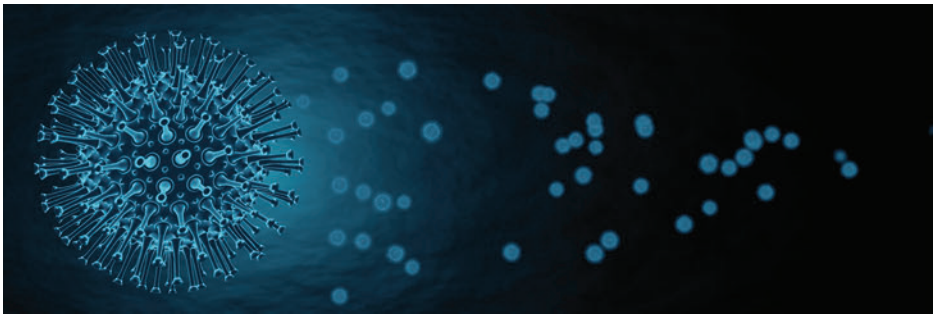


31.17 Using Equation 31.28, estimate the average charge on glutamine **(a)** at pH 3, **(b)** at pH 7. Glutamine has pK_a values of 2.17 and 9.13.

31.18 Why is the average pK_a value (pK_{a1}) for the carboxyl group of an α-amino acid ~2 when that for acetic acid is about 4.8?

31.19 Which of the following electrophoresis results could represent the separation of the following three compounds if a mixture is applied to the center of the strip? Explain.

amino acid A amino acid B amino acid C



31.20 Outline a synthesis of phenylalanine **(a)** from 2-bromo-3-phenylpropanoic acid and **(b)** by the Strecker synthesis from 2-phenylethanal.

31.3 | Proteins, Peptides, and Enzymes

Research at the interface of chemistry and biology, termed *biological chemistry*, is an exciting and dynamic area for scientists in both disciplines. Biological chemists apply the principles of chemistry to understand the molecular basis of biological processes relevant to medicine, biotechnology, and other life sciences, such as structural biology, biochemistry, genetics, pharmacology, and physiology. They then apply this knowledge to new chemical transformations, in materials science, or in the area of medicinal chemistry. This differs from the area of science known as *biochemistry*, which aims to understand life in terms of its processes and reactions, but not necessarily on a molecular scale. In the next two sections, we present a brief overview of some of the elementary aspects of biological chemistry—proteins, vitamins, and nucleic acids—from a molecular point of view and discuss the importance of nitrogen in each case.

Many biologically important molecules are very large. Nevertheless, they may be understood by first breaking them down into their component parts, each containing the functional groups that we have studied in the last five chapters. The synthesis of large molecules is remarkable and one that places large demands on the chemical systems in

Palytoxin

living organisms. Organisms build complex biomolecules (as, for example, in the coronavirus disease COVID-19) from much smaller and simpler substances that are readily available in the biosphere. The synthesis of large molecules requires energy because most of the reactions required are endothermic and also represent a decrease in entropy as a random mix of raw materials is assembled into an ordered structure. The ultimate source of this energy is the sun. Mammals and other animals have no capacity for using solar energy directly; rather, they depend on plant photosynthesis to supply the bulk of their energy needs.

By the end of this section, you should be able to:

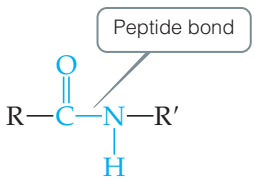
- Understand the components of protein structure
- Know how a protein sequence may be determined

We have introduced some important biochemical applications of fundamental chemical ideas in the Chemistry and Life boxes that appear throughout this text. Hydrogen bonding, for example, is critical to the function of many biological systems. The geometry of, and functional groups within, molecules can govern their biological activity. Many of the large molecules in living systems are polymers of much smaller molecules. These polymers, called *biopolymers*, can be classified into three broad categories: proteins, polysaccharides (carbohydrates) and nucleic acids.

Proteins are macromolecular substances present in all living cells and viruses. About 50% of your body's dry weight is protein. Proteins serve as the major structural components in animal tissues; they are a key part of skin, nails, cartilage and muscles. Other proteins catalyze reactions, transport oxygen, serve as hormones to regulate specific body processes and perform other tasks. Whatever their function, all proteins are chemically similar, being composed of the same basic building blocks—amino acids.

Proteins can be classified in two ways, as simple or conjugated proteins or as globular and fibrous proteins. **Simple proteins** are those that yield only amino acids upon hydrolysis; for example, blood serum albumin. **Conjugated proteins** yield other compounds, such as carbohydrates, lipids or metal complexes, as well as amino acids on hydrolysis. Examples include myoglobin and ferrichrome. In fact, conjugated proteins are more common in the body than simple proteins. **Globular proteins** are tightly bundled proteins that are named because of their globular or spherical shape. These proteins, which include albumins, enzymes, immunoglobulins and insulin, are water soluble and typically mobile within cells. They have non-structural functions, such as combating the invasion of foreign objects, transporting and storing oxygen and acting as catalysts. **Fibrous proteins**, such as collagen and keratins, are arranged like filaments or fibers. In these substances the long coils align themselves in a more or less parallel fashion to form long, water insoluble fibers. Fibrous proteins provide structural integrity and strength to many kinds of tissue and are the main components of muscle, tendons and hair. **Table 31.1** summarizes some common protein classes and their functions.

Peptide is the name given to a short polymer (oligomer) of amino acids joined by *peptide amide bonds*. Peptides are classified by the number of amino acids in the chain. For example, a *dipeptide* is a molecule containing two amino acids joined by a peptide bond. A *tripeptide* is a molecule containing three amino acids joined by peptide bonds. **Polypeptides** are formed when many amino acids are linked together by peptide bonds. They are classed as *macromolecules* or *biopolymers*.



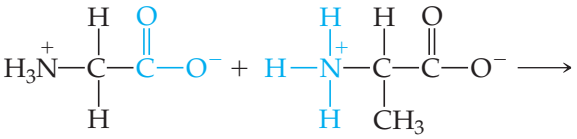


TABLE 31.1 Some common protein classes and their function

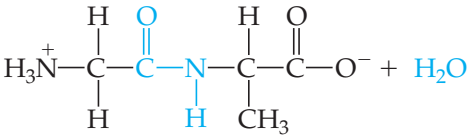

Name of class	Composition examples	Definition and functions
Glycoproteins	Contain carbohydrates, e.g. ovalbumin (egg white)	A ubiquitous family of proteins containing oligosaccharides (carbohydrates), which impart properties of solubility, ligand affinity, cellular targeting and stability. Many proteins released by cells to the blood and other fluids are glycoproteins. For example, Antarctic fish survive near-freezing water temperatures as a result of freezing-point depression of their blood serum by a globular glycoprotein.
Lipoproteins	Contain fats, oils or steroids (lipids), e.g. low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs)	Lipoproteins serve as carriers of hydrophobic ligands through solubility barriers such as aqueous body fluids. LDLs are the main transport for cholesterol through the body. HDLs carry excess cholesterol to the liver for processing.
Metalloproteins	Contain coordinated metal ions, e.g. hemoglobin, ferredoxin, NADH dehydrogenase, coenzyme Q, cytochrome c reductase	Metalloproteins are proteins that contain a metal cofactor. The metal may be an isolated ion or may be coordinated with a non-proteinaceous organic compound, such as the porphyrin found in hemoproteins. In some cases, the metal is coordinated with a side chain of the protein and an inorganic non-metallic ion.
Nucleoproteins	Contain nucleic acids, e.g. chromatin, RNA binding proteins, ribosomes	Nucleoproteins are any supramolecular complex of protein and nucleic acid; or any protein usually found closely associated with nucleic acid. They contain a diverse group of viral and genetic regulatory proteins which bind in a sequence-specific manner to DNA.
Phosphoproteins	Contain a phosphate group, e.g. synapsins, caesins (milk)	Phosphoproteins are any of a group of proteins containing chemically bound phosphoric acid. Protein phosphorylation is probably the most ubiquitous and diverse molecular mechanism of biological signaling and regulation.

Coding Peptides

A **peptide bond** is formed by a condensation reaction between the carboxyl group of one amino acid and the amino group of another amino acid. Alanine and glycine, for example, can react to form the dipeptide glycylalanine:

Glycine (Gly) Alanine (Ala)

[31.33]

Glycylalanine (Gly-Ala)

The amino acid that furnishes the carboxyl group for peptide bond formation is named first, with a *-yl* ending; then the amino acid furnishing the amino group is named second. To make the naming of peptides easier, especially those that are more than 25 amino acids long, series of three-letter and single-letter codes have been devised (**Table 31.2**). Based on the three-letter codes for the amino acids from Table 31.2, glycylalanine can be abbreviated Gly-Ala. In this notation it is understood that the unreacted amino group is on the left and the unreacted carboxyl group on the right. The artificial sweetener *aspartame* (**Figure 31.19**) is the methyl ester of the dipeptide of aspartic acid and phenylalanine, Asp-Phe:

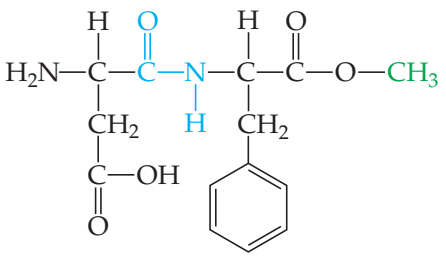

TABLE 31.2 Amino acid codes for proteins and peptides

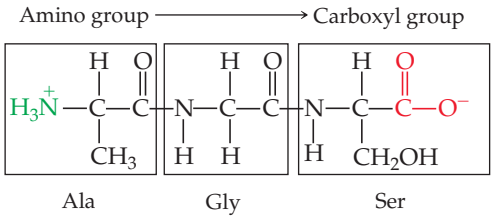
Amino acid	Three-letter code	Single-letter code
Glycine	Gly	G
Alanine	Ala	A
Valine	Val	V
Leucine	Leu	L
Isoleucine	Ile	I
Methionine	Met	M
Phenylalanine	Phe	F
Tryptophan	Trp	W
Proline	Pro	P
Asparagine	Asn	N
Glutamine	Gln	Q
Serine	Ser	S
Threonine	Thr	T
Aspartic acid	Asp	D
Glutamic acid	Glu	E
Cysteine	Cys	C
Tyrosine	Tyr	Y
Arginine	Arg	R
Histidine	His	H
Lysine	Lys	K

▲ **Figure 31.19 Sweet stuff.** The artificial sweetener aspartame is the methyl ester of the dipeptide Asp-Phe.

Proteins are linear (that is, unbranched) polypeptide molecules with molecular weights ranging from about 5000 to over 50 million u. Proteins differ from polypeptides in that proteins are capable of some function, whether chemical or structural, as a result of their three-dimensional structure. Because 20 different amino acids are commonly linked together in proteins and because proteins consist of hundreds of amino acids, the number of possible arrangements of amino acids within proteins is virtually limitless.

Sample Exercise 31.7

Drawing the Structural Formula of a Tripeptide

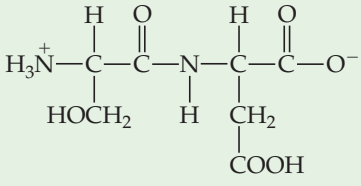


Draw the full structural formula for alanylglycylserine.

SOLUTION

Analyze We are asked to draw a tripeptide.

Plan The name of this substance suggests that three amino acids—alanine, glycine and serine—have been linked together, forming a *tripeptide*. Note that the ending *-yl* has been added to each amino acid except for the last one, serine. By convention, the first-named amino acid (alanine, in this case) has a free amino group and the lastnamed one (serine) has a free carboxyl group. Thus, we can construct the structural formula of the tripeptide from its amino acid building blocks.

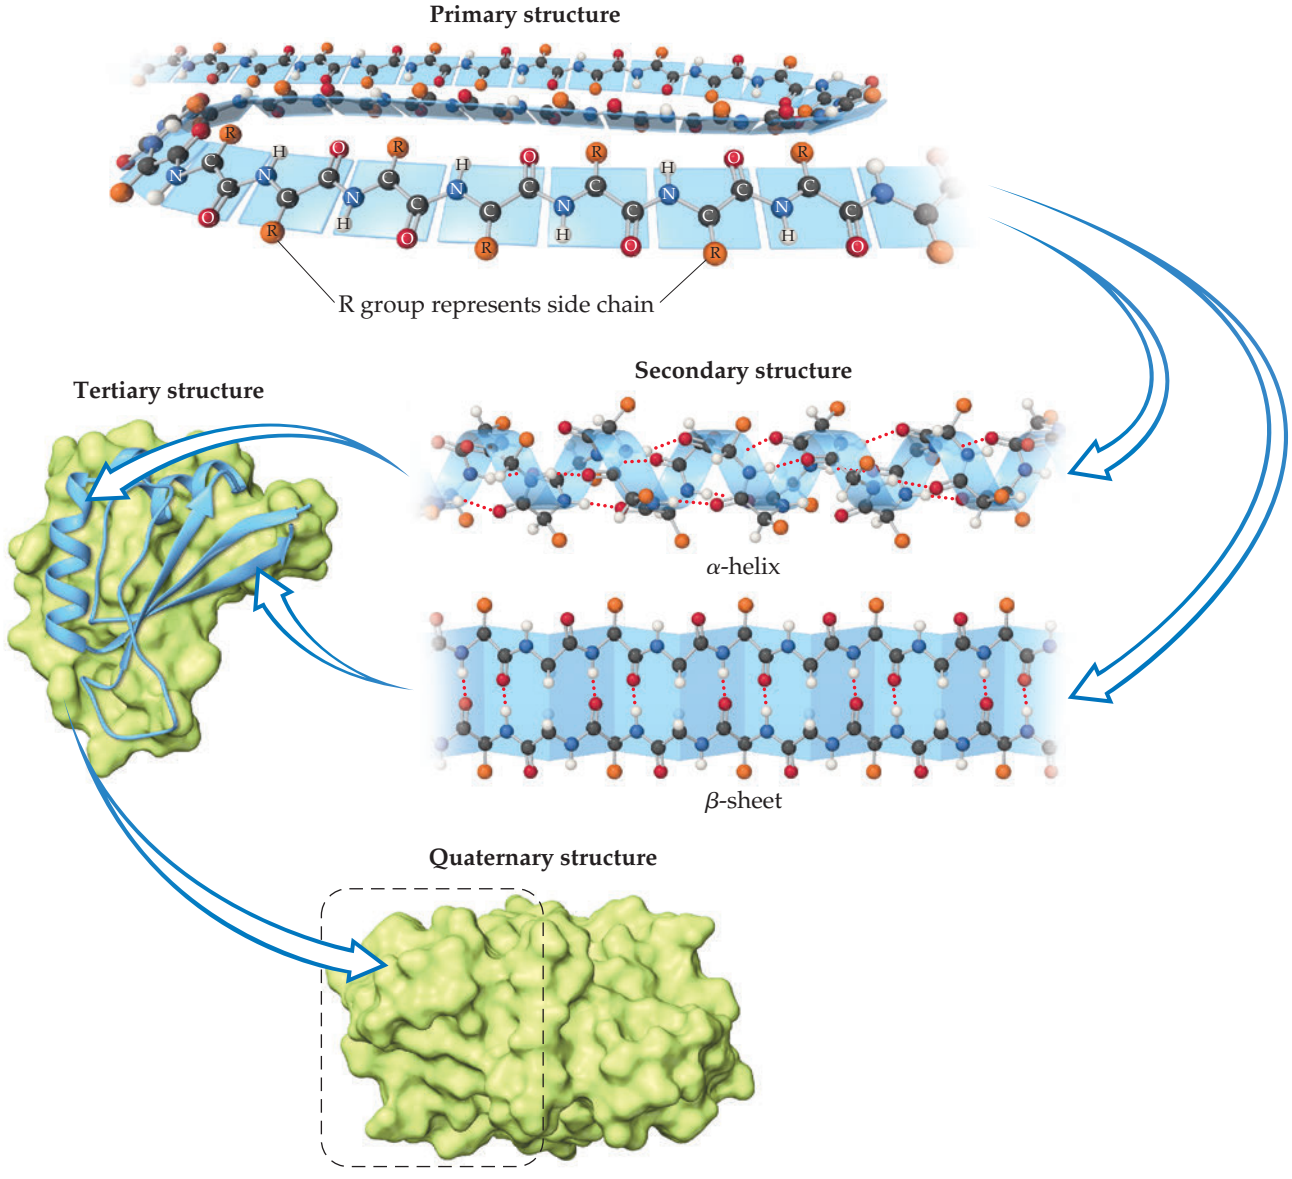


Solve We first combine the carboxyl group of alanine with the amino group of glycine to form a peptide bond and then the carboxyl group of glycine with the amino group of serine to form another peptide bond. The resulting tripeptide consists of three "building blocks" connected by peptide bonds:

We can abbreviate this tripeptide as Ala-Gly-Ser, or AGS.

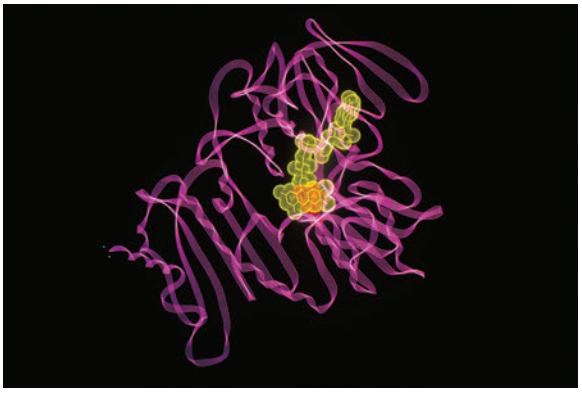
Practice Exercise

Name the dipeptide that has the following structure and give its abbreviation:



Protein Structure

The arrangement, or sequence, of amino acids along a protein chain is called its **primary structure**. The primary structure gives the protein its unique identity. A change in even one amino acid can alter the biochemical and physiological characteristics of the protein. For example, sickle-cell anemia is a genetic disorder resulting from a single replacement in a protein chain in hemoglobin. The chain that is affected contains 146 amino acids. The substitution of a single amino acid with an acidic functional group for one that has a hydrocarbon side chain alters the solubility properties of the hemoglobin, and normal blood flow is impeded (see the A Closer Look box in Section 31.2).

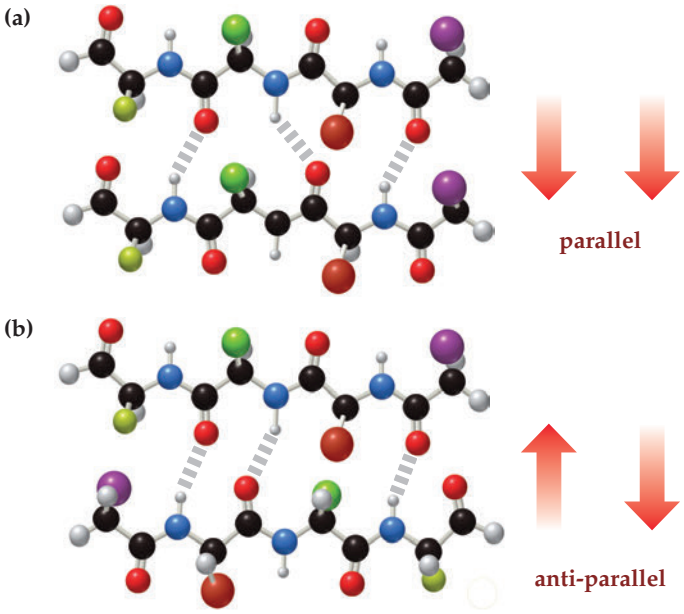


Another example occurs within the free-radical scavenging Zn/Cu enzyme, superoxide dismutase (SOD1). A single mutation in the primary structure of SOD1—for example, by replacing Gly with Ala at the 93rd position of the peptide sequence—is enough to implicate this mutant enzyme as a contributor to motor neuron disease (MND).

Proteins in living organisms are not simply long, flexible chains with random shapes. Rather, the chains coil and stretch in particular ways. The **secondary structure** of a protein refers to how segments of the protein chain are orientated in a regular pattern as seen in Figure 31.20.

▲ Figure 31.20 The four levels of structure of proteins.

One of the most important and common secondary-structure arrangements is the **α-helix** (Figure 31.20), first proposed by Linus Pauling and Robert B. Corey (1897–1971). Imagine winding a long protein chain in a helical fashion around a long cylinder. The helix is held in position by hydrogen bond interactions between N—H bonds and the oxygen atoms of nearby carbonyl groups. The pitch of the helix and the diameter of the cylinder must be such that (1) no bond angles are strained and (2) the N—H and C═O functional groups on adjacent turns are in a proper position for hydrogen bonding. In fact, each C═O group is hydrogen bonded to an N—H group four amino acid units away from it. An arrangement of this kind is possible for some amino acids along the chain, but not for others. Large protein molecules may contain segments of the chain that have the α-helical arrangement, interspersed with sections in which the chain is in a random coil. Typically, the α-helix has 3.6 amino acids per turn. The N—H groups of the amino acid point along the axis of the helix and all orientate themselves in the same direction. The C═O groups of the amino acids also point along the axis but in the opposite direction to the N—H groups, as a result of the *trans* arrangement of the peptide bond. All R groups point away from the helix structure.



▲ **Figure 31.21 An enzyme containing a substrate.** A computer-generated model of an enzyme showing the amino acid backbone as a green ribbon. The substrate (violet) is shown to interact with a specific part of the protein called the active site.

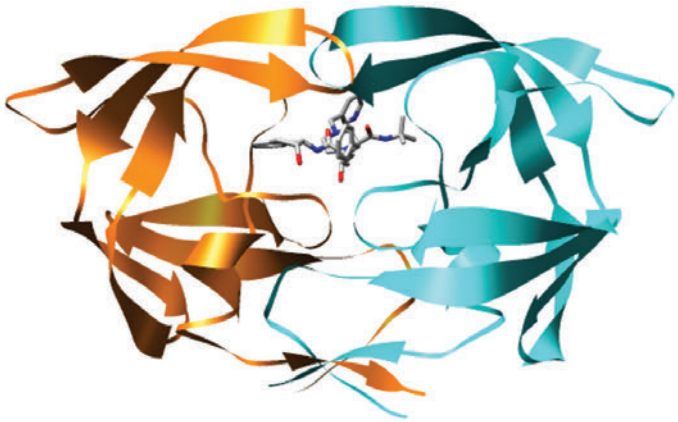


Figure 31.21 shows the structure of an enzyme containing a small molecular substrate. The important aspect of this protein is the highly coiled nature of the amino acid backbone (depicted as a ribbon). These coils are α-helices, which help give rise to the overall three-dimensional structure of the protein.

Another form of secondary structure that is often seen in proteins is the **β-pleated sheet**. This structure is not restricted to *intramolecular* hydrogen bonding structure, as is the α-helix, but may also form an intermolecular hydrogen bonding arrangement with another peptide chain (**Figure 31.22**). Since the peptide backbone contains only the α-carbon, NH and carbonyl carbon in an alternating manner from the *N*- to *C*-terminus, the two peptide chains can hydrogen bond in one of two orientations: parallel or anti-parallel. Both orientations are seen in natural proteins, although anti-parallel is the most common form. **Figure 31.23** shows an example of a protein with extensive β-sheets. These β-sheets are formed by the interaction of two or more peptide chains in an anti-parallel manner (as indicated by the direction of the arrows). Note that it is not necessary for all the peptide chains contributing to the sheet structure to be of the same size.

Proteins are not active biologically unless they are in a particular form in solution. The process by which the protein adopts the biologically active form is called **folding**.

◀ **Figure 31.22 β-sheet form of a protein.** F, Cl, Br and I are used along the peptide backbone to describe the two orientations possible for a β-sheet formation. (a) A parallel sheet, in which the two peptides orientate in the same direction from *N*- to *C*-terminus. (b) An anti-parallel sheet in which the two halide trends (F to I) occur in opposite directions.

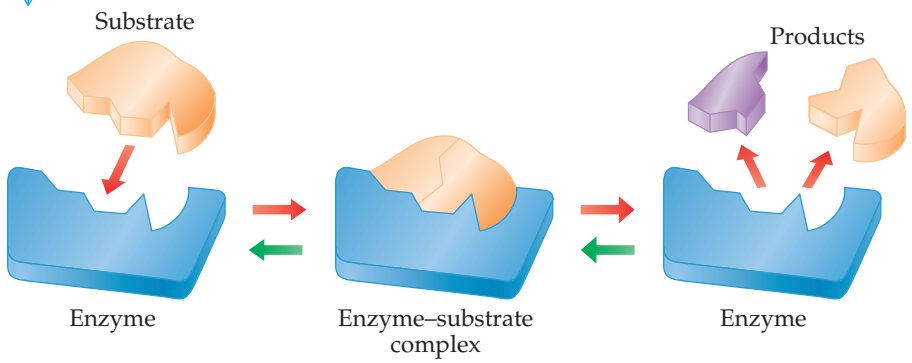
▶ **Figure 31.23 A dimeric protein containing β-sheets.** The arrowed ribbons represent the directions of peptide chains that undergo intermolecular hydrogen bonding, forming β-sheet structures. The substrate in the middle fits nicely into the void made by the two halves of this protein dimer.

The overall shape of a protein in its folded form, determined by all the bends, kinks and sections of rod-like α-helical and flat β-sheet structures, is called the **tertiary structure**.

The tertiary structure of a protein is maintained by many different interactions. Certain folding of the protein chain leads to lower-energy (more stable) arrangements than other folding patterns. For example, a globular protein dissolved in aqueous solution folds in such a way that the non-polar hydrocarbon portions are tucked within the molecule, away from the polar water molecules. Most of the more polar acidic and basic side chains, however, project into the solution, where they can interact with water molecules through ion–dipole, dipole–dipole or hydrogen bonding interactions. The result of a mis-folding based on the change of a polar group was seen clearly in the example of sickle-cell anemia.

Some proteins are more complicated and have a fourth level of structure known as the **quaternary structure**. This level of structure involves the aggregation of two or more protein substructures into a larger macromolecular assembly. For example, the protein shown in Figure 31.23 has a quaternary structure, made up of two identical protein substructures that interact non-covalently with each other. The function the protein exhibits is only possible due to the quaternary (dimeric) structure and not by either substructure separately.

Enzymes

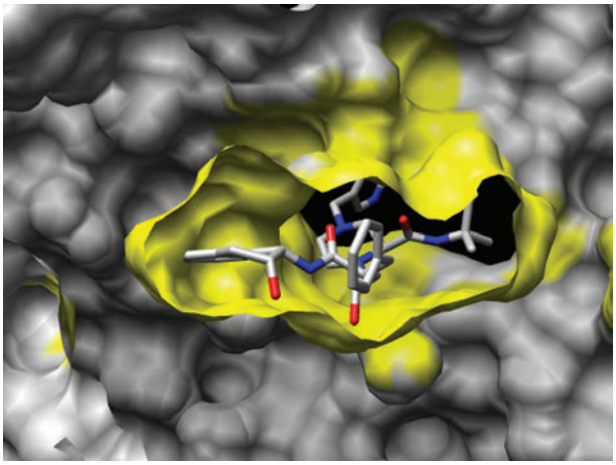


One of the most important classes of proteins are the **enzymes**, large protein molecules that serve as catalysts. Enzymes usually catalyze only very specific reactions. Their tertiary and quaternary structures generally dictate that only certain substrate molecules can interact with the enzyme (Figures 31.21 and 31.23).

Many of the most interesting and important examples of catalysis involve reactions within living systems. The human body is characterized by an extremely complex system of interrelated chemical reactions. All these reactions must occur at carefully controlled rates and at 37 °C in order to maintain life. Enzymes enable these reactions to take place in the proper order and at the correct rate. Most enzymes are proteins with molecular weights ranging from about 10 000 to about 1 million u. They are very selective in the reactions they catalyze, and some are absolutely specific, operating for only one substance in only one reaction. The decomposition of hydrogen peroxide, for example, is an important biological process. Because hydrogen peroxide is strongly oxidizing, it can be physiologically harmful. For this reason, the blood and livers of mammals contain an enzyme, *catalase*, which catalyzes the decomposition of hydrogen peroxide into water and oxygen (Equation 15.33). **Figure 31.24** shows the dramatic acceleration of this chemical reaction by the catalase in beef liver.

▲ **Figure 31.24 Effect of an enzyme.** Ground-up beef liver causes hydrogen peroxide to decompose rapidly into water and oxygen. The decomposition is catalyzed by the enzyme *catalase*. Grinding the liver breaks open the cells, so that the reaction takes place more rapidly. The frothing is due to escape of oxygen gas from the reaction mixture.

Go Figure Why might this be called a lock-and-key model?



▲ **Figure 31.25 The lock-and-key model for enzyme action.** The correct substrate is recognized by its ability to fit the active site of the enzyme, forming the enzyme–substrate complex. After the reaction of the substrate is complete, the products separate from the enzyme. The reaction is just as suited to forming covalent bonds (right to left) as it is in breaking them (left to right).

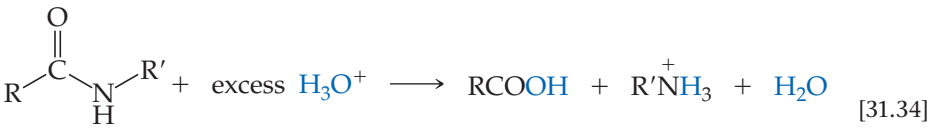
Although an enzyme is a large molecule, the reaction is catalyzed at a very specific location in the enzyme, called the **active site**. The substances that undergo reaction at this site are called **substrates**. A simple explanation for the specificity demonstrated by enzymes is provided by the **lock-and-key model** illustrated in Figure 31.25. The substrate is pictured as fitting neatly into a special place on the enzyme (the active site), much like a specific key fitting into a lock. The active site is created by the coiling and folding of long protein chains to form a space, something like a pocket, into which the substrate molecule fits. Figure 31.26 shows a model of an enzyme's active site (cross-sectioned) with a bound substrate molecule.

The combination of the enzyme and the substrate is called the enzyme–substrate complex. Although Figure 31.25 shows both the active site and its complementary substrate as having rigid shapes, there is often a fair amount of flexibility in the active site. Thus, the active site may change shape as it binds the substrate. The binding between the substrate and the active site involves intermolecular forces such as dipole–dipole attractions, hydrogen bonds and London dispersion forces.

As the substrate molecules enter the active site, they are activated so that they are capable of extremely rapid reaction at mild (for example, 37 °C) temperatures. This activation may result from the enzyme withdrawing or donating electron density at a particular bond. In addition, in the process of fitting into the active site, the substrate molecule may be distorted and thus made more reactive. Once the reaction occurs, the products then depart, allowing another substrate molecule to enter. This means that the products must

◀ **Figure 31.26 Molecular model of an active site.** The active site (shown in yellow) has been cut away to show how well the substrate fits into the different depressions and pockets, like a hand in a glove. Compare this representation to that in Figure 31.23 of the same protein.

bind more weakly to the active site than does the substrate. If the reverse were true, inhibition of the enzyme's activity would be observed.

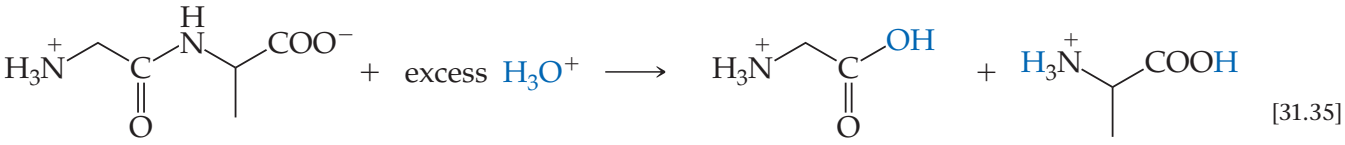


The activity of an enzyme is also destroyed if some molecule in the solution is able to bind strongly to the active site and block the entry of the substrate. Such substances are called *enzyme inhibitors*. Nerve poisons and some toxic metal ions, such as lead and mercury, are believed to act in this way to inhibit enzyme activity. Other poisons act by attaching elsewhere on the enzyme, thereby distorting the active site so that the substrate no longer fits.

Enzymes are typically more efficient than human-made catalysts. The number of individual catalyzed reaction events occurring at a particular active site, called the *turnover number*, is generally in the range of 10^3 to 10^7 per second. Such large turnover numbers correspond to very low activation energies. This is an area of chemistry of intense study because of its benefits associated with (a) mild reaction conditions, (b) high turnover numbers, (c) the sustainability of using microbes, bacteria and other organisms to promote reaction and (d) the removal of hazardous chemicals and solvents. Remember, most biological processes occur in water.

Sequencing of Peptides and Proteins

As a result of the almost endless permutations of amino acid sequences and the very specific nature of a protein's function, chemists and biochemists have come up with some clever ways of determining the precise structure of a protein. Let's consider the problem. There are three aspects of sequencing that need to be elucidated: (1) which amino acids are present; (2) what amounts of each amino acid are present; and (3) what order do these amino acids take in the primary structure of the protein.

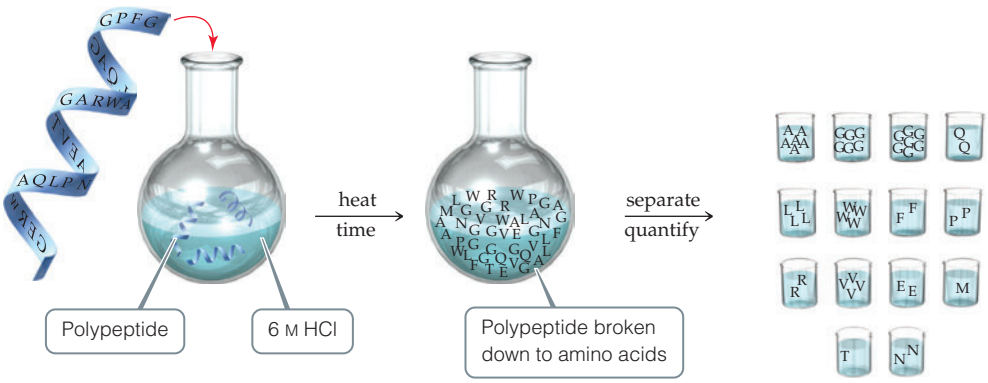


The first two of these questions are easily answered provided the protein is pure. Amide bonds are hydrolyzed in excess aqueous 6M HCl to yield the ammonium salt and carboxylic acid:

amide — carboxylic acid — ammonium salt

[31.34]

For a simple dipeptide such as Gly-Ala, the products are the ammonium salts of glycine and alanine:

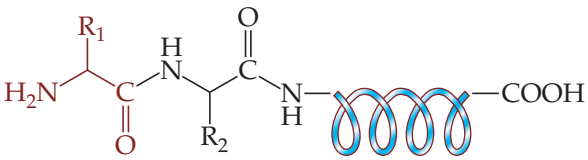


Gly-Ala — Gly — Ala

[31.35]

Amino acids can be separated from each other by electrophoresis (Figure 31.18) and other separating methods such as chromatography. The amount of each amino acid is then quantified using ninhydrin by the reaction shown in Equation 31.32. **Figure 31.27** summarizes this entire process using a general protein.

Knowing which amino acids are present, as well as their relative amounts, is only the beginning. The specific sequence of amino acids within the protein, which gives rise to the protein's function, is critical. Even, the simple dipeptide Gly-Ala is different from Ala-Gly. The processes required to sequence a protein need to be very specific and efficient. Two approaches are possible. Either the whole protein can be sequenced, or the protein can be cleaved at specific points to make smaller peptides, which are then sequenced. Both approaches have their advantages, although the latter is more practical. **Table 31.3** lists three common methods of undertaking the cleavage of peptide bonds at specific amino acid sites.



◀ **Figure 31.27 Amino acid analysis.** Note that the single-letter codes for the amino acids (Table 31.2) have been used in this example.

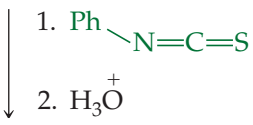


TABLE 31.3 Useful reagents for protein cleavage

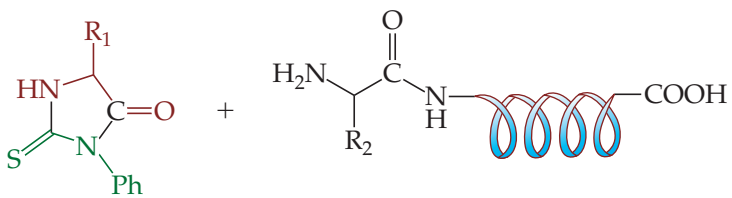

Reagent	Cleavage point(s) at the carboxyl group of
Cyanogen bromide (BrCN)	Methionine
Trypsin	Arginine and lysine
Chymotrypsin	Phenylalanine, tryptophan and tyrosine
6 M HCl (partial hydrolysis)	Indiscriminant

The most widely used method of sequencing proteins was developed by Pehr Edman (1916–1977) in the 1950s. The process is a laborious one and has been automated to save time and sample amounts. Modern instruments can sequence as little as 0.1 μg of a protein. The general idea of his approach, called the **Edman degradation**, is to cleave and identify one amino acid at a time from the *N*-terminus of the peptide chain. The process is repeated until the entire sequence is known. The Edman degradation requires treatment of the peptide with phenyl isothiocyanate (Ph—N=C=S), followed by mild acid hydrolysis. The product of this reaction, a phenylthiohydantoin, is collected and compared with known phenylthiohydantoin derivatives of the 20 common amino acids to identify which amino acid is cleaved. The new peptide (which is now one residue shorter) is also subjected to the same conditions to characterize the second amino acid residue and so on.

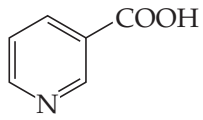
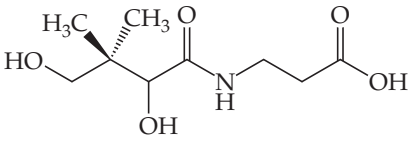
CHEMISTRY AND LIFE B Group Vitamins

Vitamins are small organic molecules that must be obtained through diet. They are usually required in trace amounts for proper growth. Many vitamins are used as coenzymes by the body; that is, they are required for the catalytic function of certain enzymes. All of the major B-group vitamins are nitrogen-containing compounds.

Vitamin B_1 is also known as thiamin, a water soluble heterocyclic structure made up of a substituted pyrimidine and a thiazole ring coupled by a methylene (CH_2) bridge. Thiamin is converted to its active form, thiamin pyrophosphate (TPP), in the brain and liver. In this form, thiamin acts as a cofactor for reductase enzymes responsible for, among other things, the reduction of pyruvate (Equation 31.29). A deficiency in thiamin may lead to *fatigue* and *depression*. Riboflavin, or vitamin B_2, is employed as a coenzyme for flavoproteins, which have a wide range of redox roles within the body. Riboflavin is found in useful quantities in eggs, milk, meat and cereal. A deficiency in vitamin B_2 leads, among other things, to *cracked lips* and *scaly skin*.

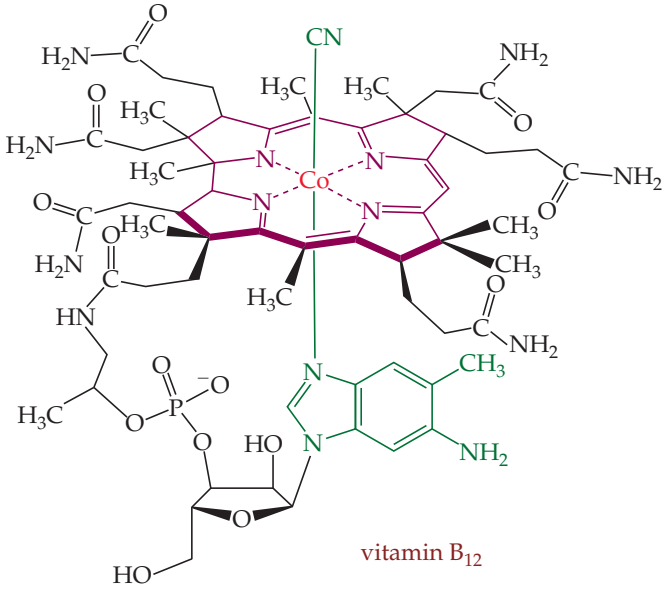


vitamin B_1



vitamin B_2

Nicotinic acid is the most common source of Vitamin B_3, also known as niacin. The human body uses vitamin B_3 in the form of NAD^+ (nicotinamide adenine dinucleotide) and $NADP^+$ (nicotinamide adenine dinucleotide phosphate) as a coenzyme in more than 50 enzyme-based reactions. Vitamin B_3 is instrumental in the release of energy from carbohydrates. It is necessary for proper brain function and is also involved in fat and cholesterol metabolism. A deficiency in vitamin B_3 may lead to *dermatitis, diarrhoea* and *dementia*. Vitamin B_5, also known as pantothenic acid, is found in abundance in whole-grain cereals, legumes and meat, and is usually formed from β-alanine and pantoic acid. Vitamin B_5 is required for the synthesis of coenzyme A (CoA), an acyltransferase, and for the metabolism of carbohydrates, fats and proteins. A deficiency in vitamin B_5 leads to *weight loss* and *irritability*.



nicotinic acid

vitamin B_5

One of the most complicated and essential of the vitamins is vitamin B_{12}. Vitamin B_{12} is unusual as it is the only metal-ion-containing vitamin. The tetrapyrrole macrocycle (purple) of vitamin B_{12} is called a *corrin*, which is related to the porphyrin structure found in myoglobin, hemoglobin and chlorophyll. Centrally coordinated to the corrin macrocycle is a cobalt(II) ion with an octahedral geometry (red). The cyano (CN) and benzimidazole ligands (green) bind axially to the metal ion.

vitamin B_{12}

Vitamin B_{12} is synthesized exclusively by microorganisms and is found in the liver of animals. The liver can store up to six years' supply of vitamin B_{12}, so deficiencies in this vitamin are rare. Vitamin B_{12} helps to protect nerves and is involved in the formation of red blood cells in bone marrow which prevents anemia. Vitamin B_{12} is necessary in the catabolism of fatty acids.

Sample Exercise 31.8

Sequencing Peptides

An unknown pentapeptide was subjected to a range of different experiments to ascertain its structure. The following results were obtained:

Experiment	Fragment result
Total hydrolysis	Arg, Glu, His, Phe, Ser
Edman degradation	Glu
Chymotrypsin hydrolysis	Glu-His-Phe, Arg-Ser
Trypsin hydrolysis	Glu-His-Phe-Arg, Ser

What is the pentapeptide sequence?

SOLUTION

Analyze We are asked to sequence a small peptide based on the fragments obtained by different chemical reactions.

Plan Identify the reactions and what type of fragment each leads to. Determine the number of different amino acids listed through the hydrolysis products. Construct the peptide one fragment at a time.

Solve Total hydrolysis yields five amino acids, which is the total required for the pentapeptide. Hence, each amino acid occurs only once in the sequence. Peptides are always written from the *N*- to *C*-terminus. The Edman degradation yields the *N*-terminus residue, Glu. Chymotrypsin hydrolyzes at the carboxyl end of Phe, which indicates the first three residues are Glu-His-Phe. At this point, the sequence can be only one of two possibilities: Glu-His-Phe-Arg-Ser or Glu-His-Phe-Ser-Arg. Since trypsin cleaves at the carboxyl group of Arg, leaving the single amino acid residue, Ser, the pentapeptide sequence was:

Glu-His-Phe-Arg-Ser

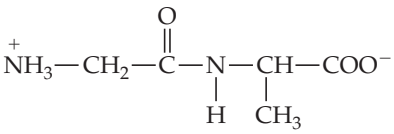
Practice Exercise

The partial hydrolysis of an unknown hexapeptide gave the following fragments: Gly-Ala-Phe, Phe-Tyr-His, Tyr-His-Glu. What is the sequence of the hexapeptide?

Self-Assessment Exercises

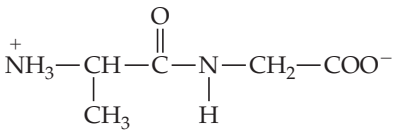
31.21 Does Gly-Ala have the same structure as Ala-Gly?

(a) Yes



(b) No

31.22 What information does the acid hydrolysis of a peptide provide on its composition or structure?



(a) The amino acids present

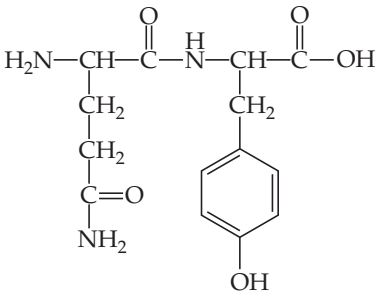
(b) The primary structure of the peptide

(c) The secondary structure of the peptide

gly-ala

ala-gly

Exercises



31.23 **(a)** Draw the two possible dipeptides formed by the condensation reaction between serine and lysine. **(b)** If a racemic mixture of both amino acids is used, how many stereoisomers will result?

31.24 **(a)** Draw the condensed structure of the tripeptide Ile-Ala-Cys. **(b)** How many different tripeptides can be made from the amino acids serine, threonine and phenylalanine? Give the abbreviations for each of these tripeptides, using the three-letter and one-letter codes for amino acids.

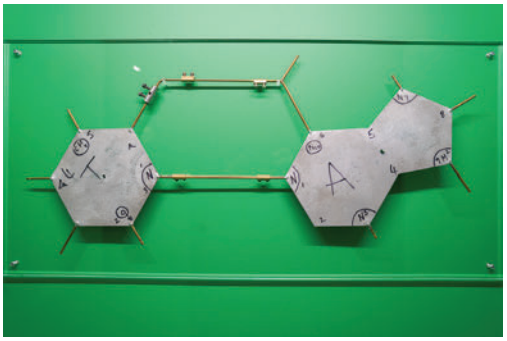
31.25 Describe what is meant by the primary, secondary and tertiary structures of proteins. Give examples to illustrate your answer.

31.26 Glutathione is a tripeptide found in most living cells. Partial hydrolysis yields Cys-Gly and Glu-Cys. What is the structure of glutathione?

31.27 Name the dipeptide that has the following structure, and give its one-letter and three-letter abbreviations:

31.28 Bradykinin is a small peptide containing nine amino acids. Partial hydrolysis gave the following fragments:

Arg-Pro-Pro, Ser-Pro, Pro-Phe-Arg, Gly-Phe-Ser, Pro-Pro-Gly



What is the primary structure of bradykinin?

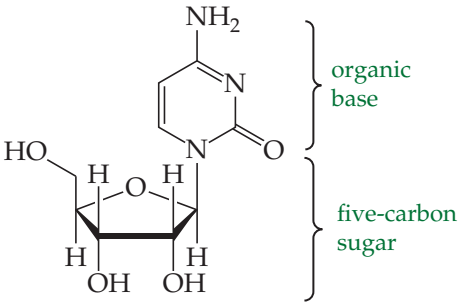
31.29 The abbreviation for a peptide is VAKG. **(a)** Draw the structural formula for this peptide. **(b)** Is this peptide neutral, acidic or basic? **(c)** What would be the products of a trypsin digestion? **(d)** Which amino acid would be identified in VAKG by the Edman degradation?

Answers to Self-Assessment Exercises

31.21 (b) **31.22** (a)

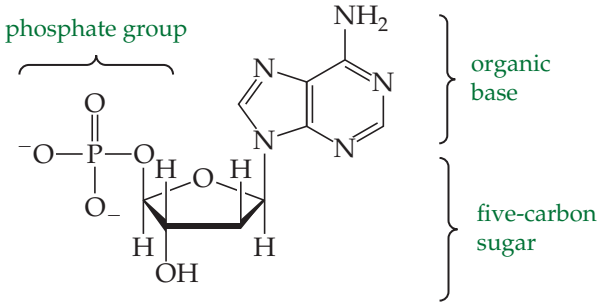
31.4 Nucleic Acids and DNA

Gregor Mendel, who made a careful study of 8000 pea plants, was the first to recognize that there were some specific characteristics passed from one generation to the next. He published his findings in 1866, but it was not until forty years later that the term "gene" was coined. At this time, proteins were thought to be the repository of inherited information until the 1940's when experiments concluded that DNA was fundamental to the process. There were many people contributing vital information that eventually led James Watson and Francis Crick to propose the structure of DNA in 1953. DNA was discovered in 1869 by Friedrich Miescher, while the Russian born biochemist Phoebus Levene, working in the early twentieth century in America, determined the component parts that made up this biopolymer—a sugar, a phosphate group, and four nitrogen heterocyclic compounds, referred to as "bases". Erwin Chargaff studied these bases and found that, irrespective of the organism the DNA was extracted from, the amount of adenine (A) present was always similar to the amount of thymine (T) present and amount of guanine (G) similar to the amount of cytosine (C). This became known as Chargaff's rule. This, together with the pioneering work of Rosalind Franklin and Maurice Wilkins on the X-ray crystallographic analysis of DNA, led Watson and Crick to believe the paring of "bases" A+T and G+C was central to the structure of DNA. They used cardboard cutout models of the bases to determine the patten. At first, nothing seemed to fit, but after Jerry Donohue suggested a more likely tautomeric form of the bases, the jigsaw fell into place. Watson and Crick proposed the now famous double-stranded helix held together



by hydrogen bonding between pairs of bases. They celebrated their discovery with a beer in "The Eagle", Cambridge, where a plaque commemorates the place where they first announced their discovery to the public.

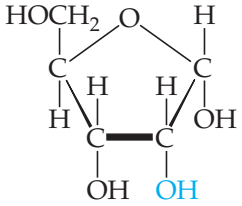
In this section, we introduce one of the most remarkable known biopolymers. By the end of section, you should:



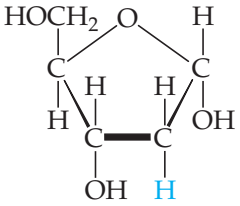
- Understand the components and functioning of DNA.

Nucleic acids make up a class of biopolymers that are the chemical carriers of an organism's genetic information. **Deoxyribonucleic acids (DNA)** are huge molecules whose molecular weights may range from 6 million to 16 million u. **Ribonucleic acids (RNA)** are smaller molecules, with molecular weights in the range of 20000 to 40000 u. DNA is found primarily in the nucleus of the cell, whereas RNA is found mostly outside the nucleus in the *cytoplasm*, the non-nuclear soup enclosed within the cell membrane. DNA stores the genetic information of the cell and specifies which proteins the cell can synthesize. RNA carries the information stored by DNA out of the nucleus of the cell into the cytoplasm as part of the *transcription* process. Once in the cytoplasm, the information, transcribed into messenger RNA (mRNA), is used in protein synthesis. The process of protein synthesis from genetic material, known as *translation*, also involves two other forms of RNA, called ribosomal RNA (rRNA) and transfer RNA (tRNA), which bring together the programmed amino acids in the correct sequence for polypeptide synthesis.

The monomers of nucleic acids can come in two forms. **Nucleosides** are compounds containing a five-carbon sugar and a nitrogen-containing organic base. **Nucleotides** are nucleosides containing an additional phosphate group.



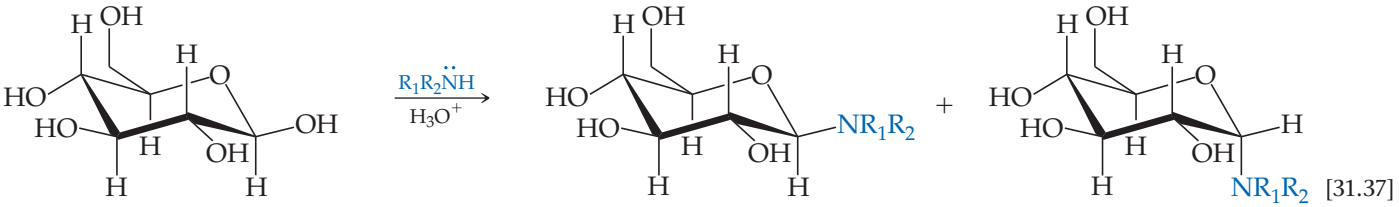
cytidine
a ribonucleoside



deoxyadenine monophosphate
a deoxyribonucleotide

The sugar component of RNA is *ribose*, whereas that in DNA is *deoxyribose*. *Deoxy*ribose differs from ribose only in that it lacks the OH group at carbon 2:

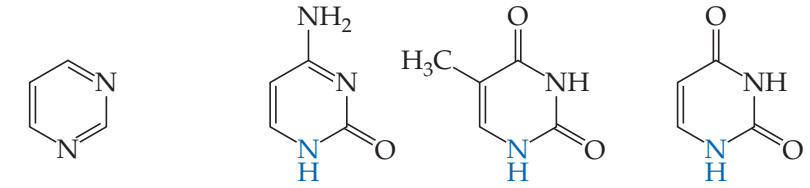
ribose



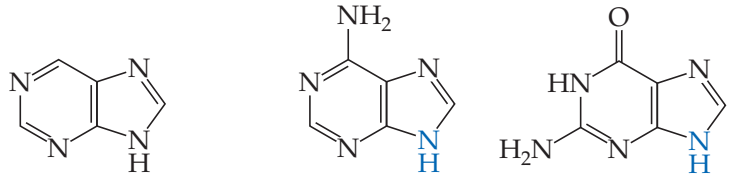
deoxyribose

Hence, nucleosides and nucleotides can be either ribose or deoxyribose based. For example, a nucleoside derived from ribose is called a *ribonucleoside* and is found in RNA.

A nucleotide derived from deoxyribose is called a *deoxyribonucleotide* and is found in DNA.



Nucleosides are also known generally as ***N*-glycosides**. An *N*-glycoside is formed when a monosaccharide reacts with an amine in the presence of acid. A general reaction for the formation of an *N*-glycoside is

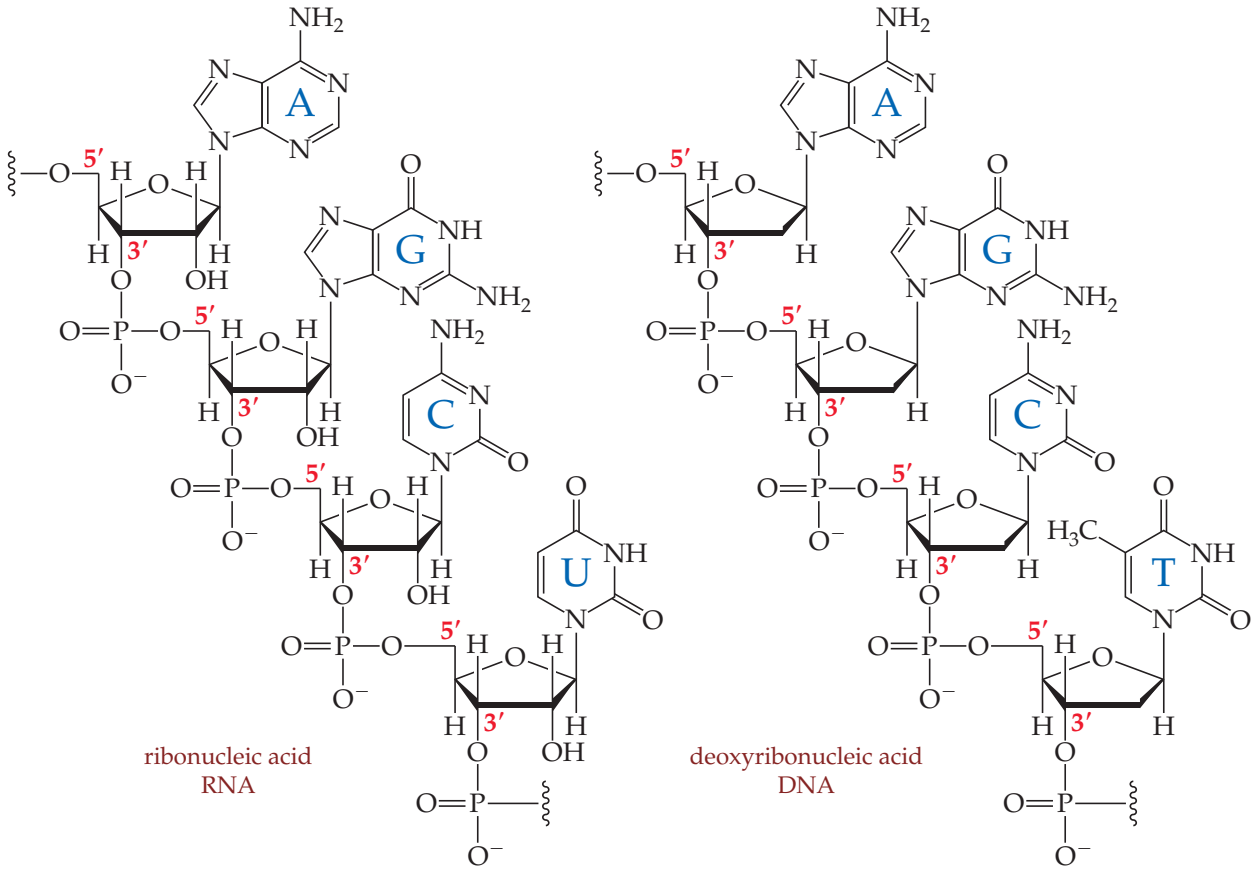


[31.37]

β-*N*-glycoside *α*-*N*-glycoside

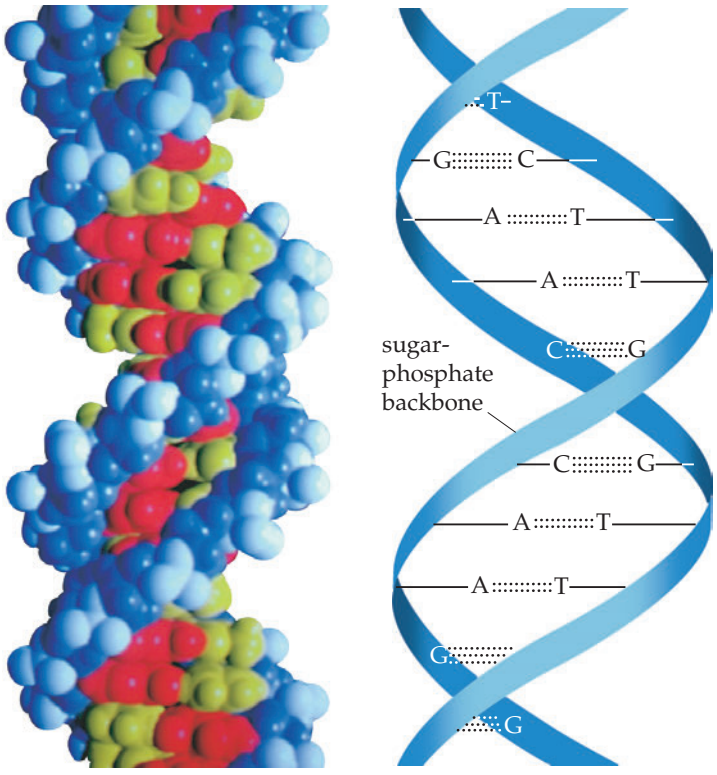
In the case of DNA and RNA, the amines used are derived from the aromatic heterocycles **pyrimidine** and **purine**. The heterocycles adenine (A), thymine (T), cytosine (C) and guanine (G) form the four bases of DNA used to store the genetic code.

pyrimidine cytosine **C** thymine **T** uracil **U**



purine adenine **A** guanine **G**

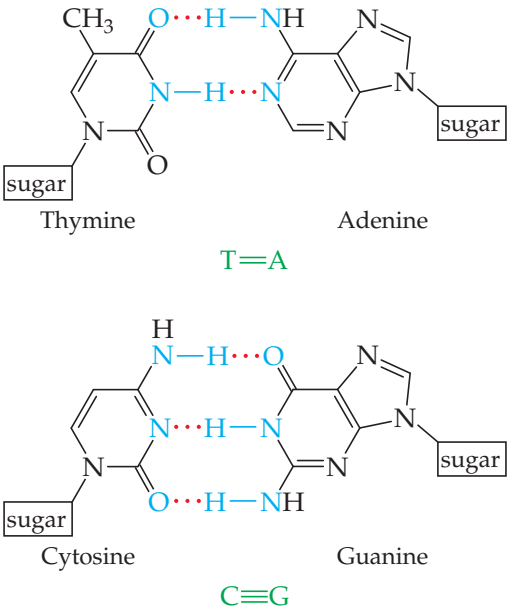
RNA differs from DNA not only in the monosaccharide used, ribose or deoxyribose, but also in the replacement of thymine (T) by uracil (U) within the base code.



Nucleic acids are polynucleotides formed by condensation reactions between an OH group of the phosphoric acid unit at the 5′ position on one nucleotide with the OH group at the 3′ position of another nucleotide. **Figure 31.28** shows a portion of the polymeric chain of DNA and RNA, illustrating the 3′–5′ linkage and the different bases employed by each nucleic acid.

DNA molecules consist of two deoxyribonucleic acid chains or strands that are wound together in the form of a **double helix**, as shown in **Figure 31.29**. The drawing in Figure 31.31(b) has been simplified to show the essential features of the structure. The sugar and phosphate groups form the backbone of each strand. The bases (represented by the letters A, T, C, and G) are attached to the sugars. The two strands are held together by attractions between the bases in one strand and those in the other strand. These attractions involve both London dispersion interactions and hydrogen bonds.

Go Figure Is DNA positively charged, negatively charged, or neutral in aqueous solution at pH 7?



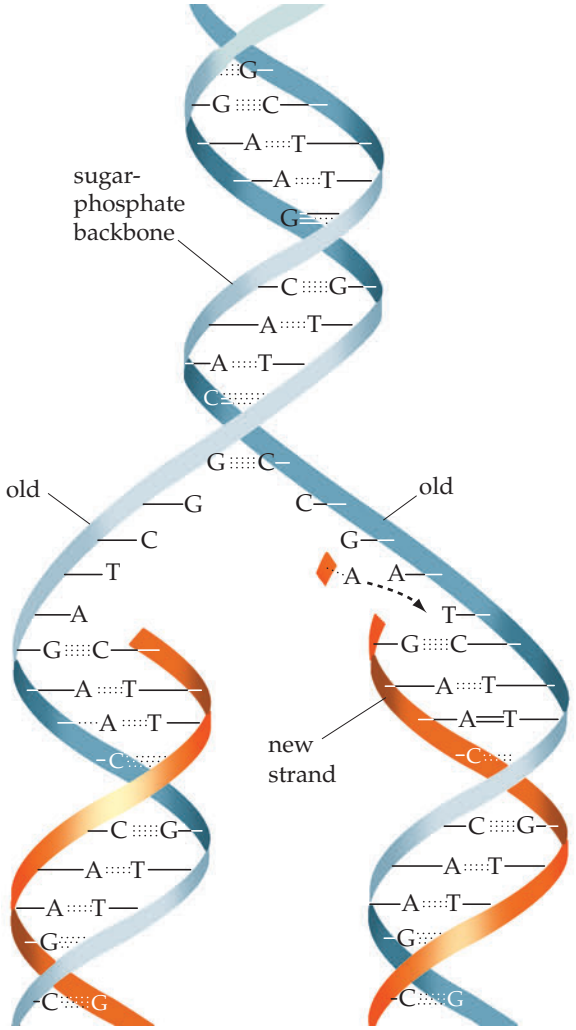
▲ **Figure 31.28 Structure of a polynucleotide.** The general structure of DNA and RNA is shown, demonstrating the differences between the two types of nucleic acids.

◀ **Figure 31.29 Two views of DNA.** (a) A computer-generated model of a DNA double helix. The dark blue and light blue atoms represent the sugar-phosphate chains that wrap around the outside. Inside the chains are the bases, shown in red and yellow-green. (b) A schematic illustration of the double helix showing the hydrogen bond interactions between complementary base pairs.

Go Figure Which pair of complementary bases, A—T or G—C, would you expect to bind more strongly?

▲ **Figure 31.30 Hydrogen bonding between complementary base pairs.** The hydrogen bonds are responsible for the formation and stability of the double-stranded helical structure of DNA, shown in Figure 31.29(b).

▲ **Figure 31.31 James Watson (1928–) and Francis Crick (1916–2004).** Nobel laureates 1962, along with Maurice Wilkins (1916–2004), for their role in the determination of the structure of nucleic acids.



As shown in **Figure 31.30**, the structures of thymine (T) and adenine (A) make them perfect partners for hydrogen bonding. Likewise, cytosine (C) and guanine (G) form ideal hydrogen bonding partners. In the double-helix structure, therefore, each thymine on one strand is opposite an adenine on the other strand. Likewise, each cytosine is opposite a guanine. This *base-pairing* of C—G and A—T is called **Watson–Crick pairing**, after two of the scientists who were instrumental in solving the structure of DNA (**Figure 31.31**). The double-helix structure with complementary bases on the two strands is the key to understanding how DNA functions.

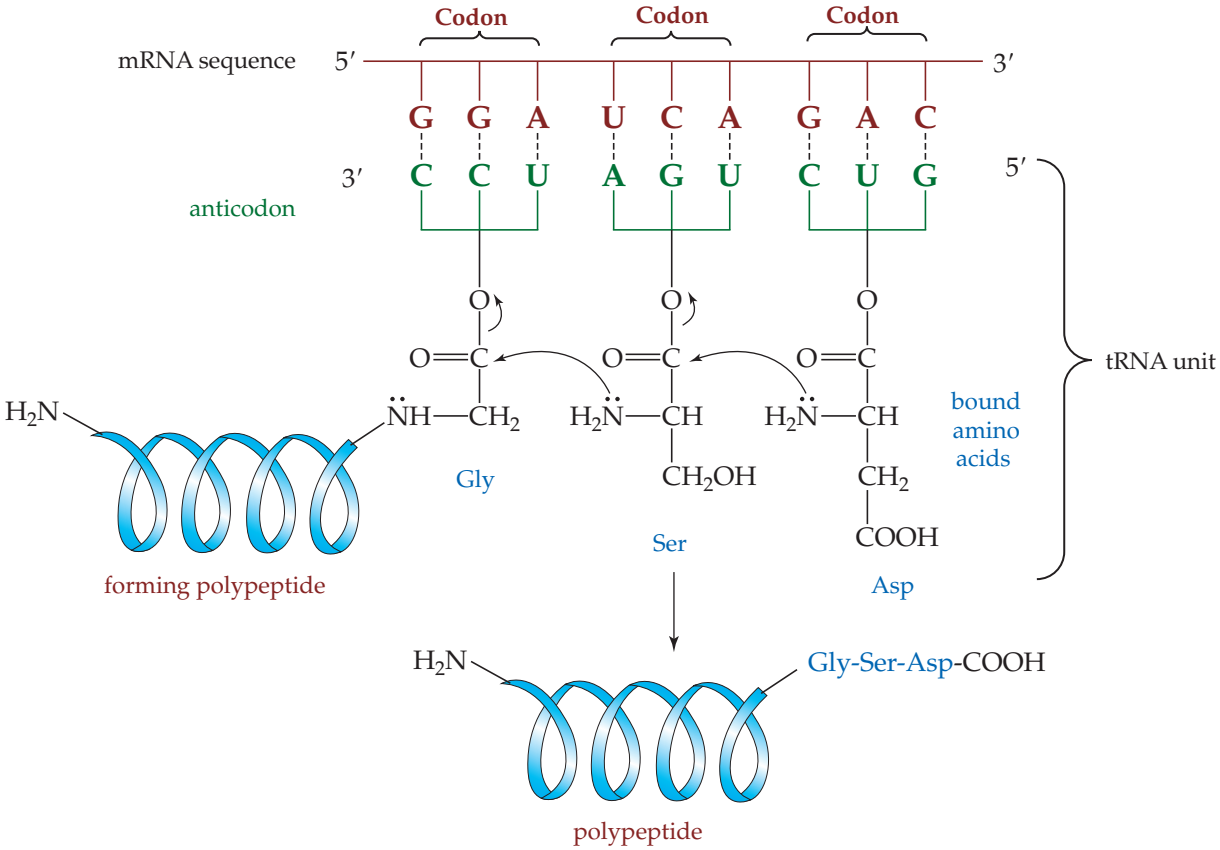
The two strands of DNA unwind during cell division, and new complementary strands are constructed on the unravelling strands (**Figure 31.32**). This enzyme-catalyzed process results in two identical double-helix DNA structures, each containing one strand from the original structure and one newly synthesized strand. This replication process allows genetic information to be transmitted when cells divide.

The structure of RNA and its relationship to DNA is also the key to understanding protein synthesis, the means by which viruses infect cells, and many other problems of central importance to modern biology and medicine. The basis of taking the information stored in DNA and processing it to form proteins is shown in **Figure 31.33**. The mechanism for protein biosynthesis takes place within a *ribosome*, a complex piece of biological machinery composed of protein and rRNA, which reads the code contained within the mRNA to be translated. This code determines the order of the amino acid sequence within the polypeptide being synthesized.

So how is it possible for just four bases to code for all 20 naturally occurring amino acids? The answer is by using the ribonucleotides, A, C, G and U, in a triplet coding called a **codon**. Each codon is specific for a given amino acid (**Table 31.4**). For example, the codon CAU on mRNA codes for histidine to be incorporated into the growing peptide chain, whereas the codon GCA on mRNA codes for alanine to be incorporated into the growing peptide chain.

The reason why translation uses a triplet code is very easy to understand. Using a triplet code based on the four ribonucleotides means that there are $4^3 = 64$ possible triplet

◀ **Figure 31.32 DNA replication.** The original DNA double helix partially unwinds, and new nucleotides line up on each strand in complementary fashion. Hydrogen bonds help align the new nucleotides with the original DNA chain. When the new nucleotides are joined by condensation reactions, two identical double-helix DNA molecules result.



◀ **Figure 31.33 From DNA to protein.**

codes, which is the smallest number of permutations possible greater than 20, which counts for the 20 naturally occurring amino acids. Of the possible 64 permutations for the codons, 61 are used for specific amino acids. Most amino acids are specified by more than one codon, with the exception of methionine (Met) and tryptophan (Trp). The amino acids serine, leucine and arginine are all specified by any one of six codons. The three remaining codons are used to terminate the synthesis of the polypeptide and release it from the ribosome. These codons are called *stop codons*.

The construction of the polypeptide using the 61 codons sequenced on mRNA requires complementary sequence codons, called *anticodons*, on tRNA. For example, the codon series, 5′-UCA GAC, sequenced on mRNA requires a serine-bound tRNA with the complementary sequence, 3′-AGU-5′, as well as an aspartic acid-bound tRNA with the complementary sequence, 3′-CUG-5′. Once bound in the correct orientation, the two units are added to the growing peptide chain by an enzymatic process that cleaves the amino acid from the tRNA anticodon. **Figure 31.34** illustrates the process schematically.

TABLE 31.4 Codon assignments

First base 5′ end	Second base	Third base 3′ end: U	C	A	G
U	U	UUU = **Phe**	UUC = **Phe**	UUA = **Leu**	UUG = **Leu**

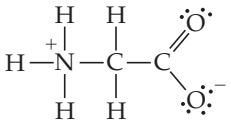
▲ **Figure 31.34 Translation.** The codons on mRNA orientate the tRNA anticodons bearing amino acid residues. Once bound, enzyme-mediated processes cause the amino acid to be cleaved from the anticodon and covalently bound to the growing peptide chain.

Sample Integrative Problem

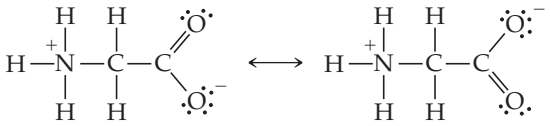
Putting Concepts Together

Glycine, NH_2CH_2COOH, the simplest of all naturally occurring amino acids, has a melting point of 292 °C. The pK_a of the acid group is 2.35 and the pK_a associated with the amino group is 9.78. **(a)** Draw a Lewis structure that indicates the charges on the molecule at the physiological pH of 7.4. **(b)** Use your structure to illustrate the concept of resonance. **(c)** Describe the hybridization of the two carbon atoms and the nitrogen atom in glycine and the geometry of the atoms surrounding these three atoms. **(d)** Glycine has an unusually high melting point for a small molecule. Suggest a reason for this.



SOLUTION

Analyze We are asked about the structure of a simple amino acid at a particular pH. This includes considering the hybridization and molecular geometry of some of the atoms and commenting on a physical property.



Plan First draw the Lewis structure of glycine and determine the ionization state of the amine and the carboxylic acid groups.

Solve

(a) A pH of 7.4 is several units on the base side of 2.35, consequently the carboxylic acid ($pK_a = 2.35$) will exist in the conjugate base form. Conversely physiological pH is more than two units on the acid side of 9.78 and so the amine will exist in the conjugate acid form ($pK_a = 9.78$). The Lewis structure will be:

(b)

(c) N: sp^3 hybridized, tetrahedral geometry, CH_2: sp^3 hybridized, tetrahedral geometry, COO^-: sp^2 hybridized, trigonal-planar geometry

(d) Glycine exists as a zwitterion and strong electrostatic attraction between molecules results in some ionic-like characteristics such as a relatively high melting point.

Self-Assessment Exercise

31.30 What codon sequence on mRNA would give the tripeptide: Val-Gly-Gly?

(a) GUU GGC GGA

(b) UUG GGG GGC

(c) GUC GAA GAG

(d) UGC AGU CAG

Exercises

31.31 Describe a nucleotide. Draw the structural formula for the nucleotide deoxycytidine monophosphate, which contains cytosine in the organic base.

31.32 Imagine a single DNA strand containing a section with the following base sequence: ACTCGA. What is the base sequence of the complementary strand?

31.33 An mRNA strand has the following sequence: GUCAG-GAAUCUU. What would be the sequence of the parent DNA strand that led to this transcription?

31.34 *Chargaff's rule* states that DNA contains equimolar amounts of guanine and cytosine and also equal amounts of adenine and thymine. **(a)** Does this imply that there are equimolar amounts of purine and pyrimidine bases in DNA? **(b)** Does Chargaff's rule apply only to double-stranded DNA or is it also applicable to single-stranded DNA? Explain.

31.35 Poly U added to a cell-free system containing all the necessary materials for biosynthesis yields a polypeptide comprising a single amino acid. **(a)** What is that amino acid? **(b)** What synthetic addition polymer might have similar properties to the one formed by translating poly U?

31.36 The motion picture *GATTACA* (1997) is set around a society that strives for human perfection through genetic selection. Its name is a play on the genetic code, comprising the bases A, T, C and G. **(a)** What is the complementary DNA sequence for GATTACA? **(b)** Transcribe this sequence into mRNA.

31.37 What amino acid sequence is encoded by the following mRNA sequence?

UUU CCA GUG GAU CCG AUC UAA

Answers to Self-Assessment Exercise

31.30 (a)

Chapter Summary and Key Terms

SECTION 31.1 **Amines** are hydrocarbon derivatives containing one or more basic nitrogen atoms. **Aliphatic amines** contain alkyl chains. **Heterocycles** containing a basic nitrogen atom are classed as either **cyclic** or **aromatic amines**. **Alkaloids** are amines found in the bark, leaves and roots of plants, for example cocaine, nicotine and morphine. The **amino group** of a primary (RNH_2), secondary (RR′NH) or tertiary (RR′R″N) amine can be converted to an **alkyl ammonium salt** by the addition of acid or alkyl halide. Amines can be synthesized by the **reductive amination** of aldehydes and ketones. The condensation of an amine with a carboxylic acid yields an amide. Amides can be **primary**, **secondary** or **tertiary** based on the number of hydrogen atoms bonded to the amide nitrogen. The amide bond is highly planar due to resonance. **Lactams**, such as those found in the **penicillins**, are cyclic amides.

SECTION 31.2 Compounds containing both carboxylic acid and amine functional groups are called **amino acids**. **α-Amino acids** are chiral substances, with only the L enantiomers found naturally. Since both acidic and basic groups are found within the same molecule, amino acids are said to be **amphiprotic**. At neutral pH, amino acids exist as **zwitterions**. The **isoelectric point** of an amino acid is the pH where the neutral zwitterion predominates in solution. The 20 common naturally occurring amino acids are classed as α-amino acids. They differ only in the identity of their **side chains**. These side chains give the α-amino acids their different physical properties and allow their separation from each other by techniques such as **electrophoresis**. Amino acids can be formed by the **Strecker synthesis**, which converts aldehydes to α-amino acids in the presence of cyanide ion.

SECTION 31.3 **Proteins** are functional polymers of amino acids. The amino acids within proteins are linked by **peptide** (amide) **bonds**. A **polypeptide** is a polymer formed by linking many amino acids by peptide bonds. A **peptide** is the name given to a short sequence of amino acids. Proteins are classed as either **simple** or **conjugated** based on their constituents. They can be classed also as **fibrous** or **globular** based on their macromolecular shape. Protein structure is determined by the sequence of amino acids in the chain (its **primary structure**), the coiling or stretching of the chain (its **secondary structure**), the overall shape of the complete molecule (its **tertiary structure**) or its interaction with other proteins (its **quaternary structure**). The most important secondary structure arrangements are the **α-helix** and **β-pleated sheet**. The process by which a protein assumes its biologically active tertiary structure is called **folding**. The primary structure of a peptide or protein can be elucidated using the **Edman degradation**. Some proteins, called **enzymes**, function as catalysts. Enzymes contain an **active site**, which is the area of reactivity for a **substrate**. The active site and substrate form a very specific and functioning complex, much like a **lock and key**.

SECTION 31.4 **Nucleic acids** are biopolymers that carry the genetic information necessary for cell reproduction and development through control of protein synthesis. The building blocks of these biopolymers are **nucleosides** and phosphoric acid, which react to form **nucleotides**. Nucleosides are also generally known as ***N*-glycosides**. There are two types of nucleic acids: the **ribonucleic acids (RNA)** and the **deoxyribonucleic acids (DNA)**. These substances consist of a polymeric backbone of alternating phosphate and sugar groups, with **pyrimidine-** or **purine**-derived organic bases attached to the sugars. The DNA forms a **double helix** held together by hydrogen bonding between matching organic bases on the two strands. The specific nature of **Watson–Crick pairing** is the key to gene replication and protein synthesis. Each set of three nucleotides, or **codon**, within messenger RNA (mRNA) codes for a particular amino acid. This process, called translation, converts the genetic code into protein.

Key Skills

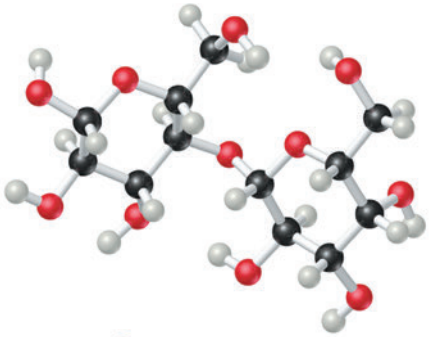
- Be able to name and classify amines and amides. (Section 31.1)
- Recall that amines are both bases and nucleophiles and appreciate relative pK_a values. (Section 31.1)
- Prepare amines and amides from other functional groups. (Section 31.1)
- Know the 20 most common amino acids and their three-letter codes. Expand this to describe small peptides. (Section 31.2)
- Be able to use the Henderson–Hasselbalch equation. (Section 31.2)
- Have an understanding of the importance to biological processes of nitrogen-containing compounds. (Sections 31.3 and 31.4)
- Know the general classes of proteins and describe what is meant by primary, secondary, tertiary and quaternary structure of a protein. (Section 31.3)
- Be able to sequence a peptide through the fragment approach. (Section 31.3)
- Identify the purine and pyrimidine bases used in nucleic acids. (Section 31.4)
- Be able to show A/T and C/G complementarity in a DNA/DNA or RNA/DNA sequence. (Section 31.4)
- Have an understanding of the process of translation and transcription. (Section 31.4)

Key Equations

- Isoelectric point

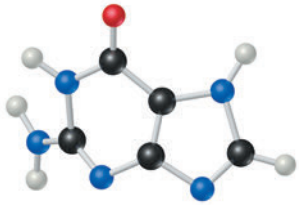
$$\mathrm{pI} = \tfrac{1}{2}(\mathrm{p}K_{a1} + \mathrm{p}K_{a2}) \qquad [31.23]$$

- Henderson–Hasselbalch equation



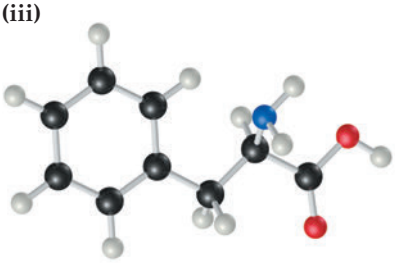
$$\mathrm{pH} = \mathrm{p}K_a + \log \frac{[\text{conjugate base}]}{[\text{weak acid}]} \qquad [31.28]$$

Exercises

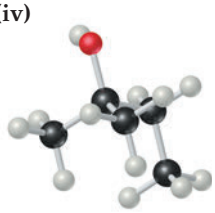


Visualizing Concepts

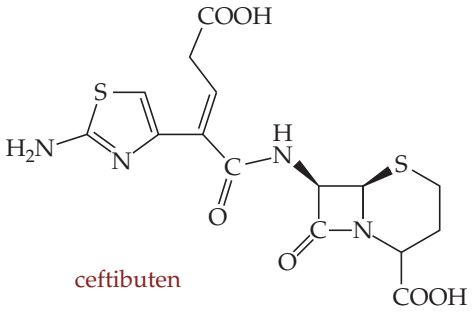
31.38 From examination of the following ball-and-stick molecular models, choose the substance that **(a)** can be hydrolyzed to form a solution containing glucose, **(b)** is capable of forming a zwitterion, **(c)** is one of the four bases present in DNA. [Sections 31.2 and 31.4]



(i)

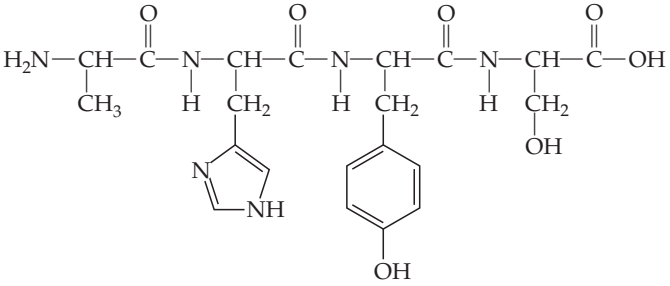


(ii)

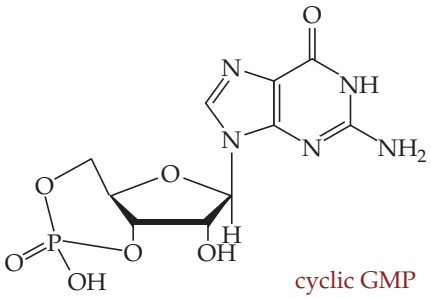


(iii)

(iv)

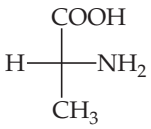


31.39 Ceftibuten is an orally active cephalosporin antibiotic. Identify the β-lactam, secondary amide, primary amine and heterocyclic amine in this structure. [Section 31.1]

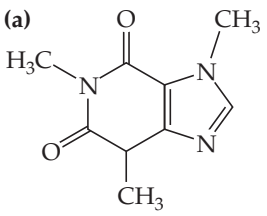


ceftibuten

31.40 What are the three-letter and one-letter codes for the following tetrapeptide? [Section 31.3]

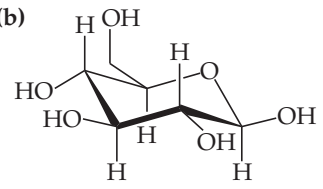


31.41 Cyclic GMP is a cellular regulatory agent found in animal and bacteria cells in concentrations of 10^{-6} moles kg^{-1}. Cyclic GMP is also implicated in the action and potency of Viagra. **(a)** Can you suggest what GMP might stand for? **(b)** What is the name given to the monosaccharide central to the structure of cyclic GMP? **(c)** Can cyclic GMP be classified as a glycoside? If so, what type of glycoside? [Section 31.4]

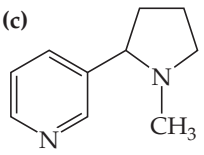


cyclic GMP

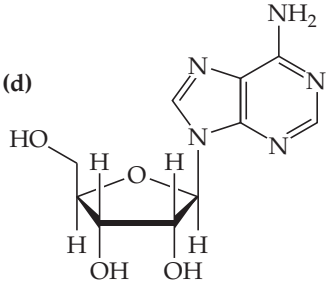
31.42 The configuration of an amino acid is drawn here as a Fischer projection. **(a)** Name the amino acid. **(b)** Assign its absolute stereochemistry as *R* or *S*. [Section 31.2]



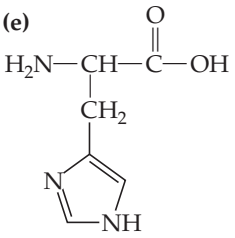
31.43 Classify the following compounds as an alkaloid, amino acid, nucleoside, or carbohydrate. [Sections 31.1, 31.2 and 31.4]



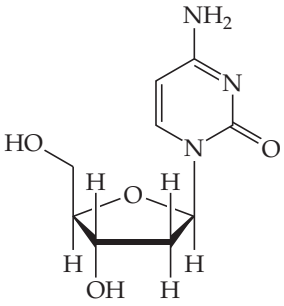
(a)



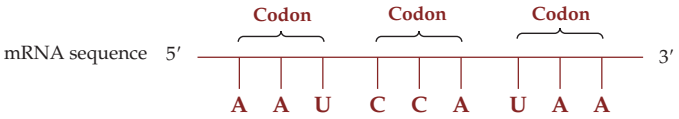
(b)



(c)

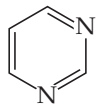


(d)

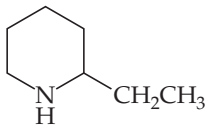


(e)

(f)

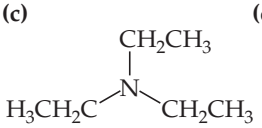


31.44 Identify the peptide formed by the mRNA sequence following translation. [Section 31.4]



Amines and the Amide bond (Section 31.1)

31.45 Give names for the following amines:



(a)

(b)

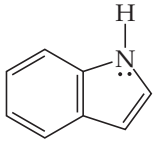
(c)

(d)

31.46 Provide a structural formula for each of the following compounds:

(a) 2-propanamine

(b) 2-aminobutanoic acid



(c) *N,N*-dimethylcyclopentanamine

(d) 2-methylcyclohexylamine

(e) 2-methyl-3-ethylpyrrole

31.47 **(a)** Draw a primary, secondary, and tertiary amine with the molecular formula $C_6H_{15}N$. What relationship exists between the three compounds you have drawn? **(b)** How would you expect the boiling points of these three amines to vary, and why? **(c)** Propylamine is entirely miscible with water; trimethylamine has reasonably high solubility in water. What accounts for these data, considering that isobutane ($(CH_3)_3CH$) is considerably less soluble than trimethylamine?

31.48 Indole smells rather terrible in high concentrations but has a pleasant floral odor when highly diluted. It has the following structure:

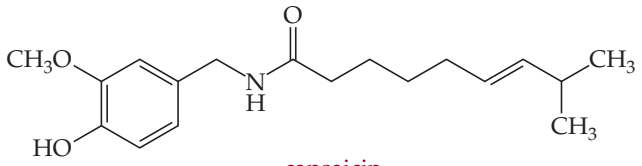
Indole is a planar molecule. The nitrogen is a very weak base, with a K_b of 2×10^{-12}. Explain how the K_b indicates that the indole molecule is aromatic in character.

31.49 Aniline is prepared by catalytic hydrogenation of nitrobenzene. **(a)** Write an equation for this reaction including reagents and catalyst. **(b)** Devise a chemical procedure based on the basicity of aniline to separate it from any unreacted nitrobenzene. [*Hint:* Both compounds are soluble in diethyl ether and insoluble in water.]

31.50 Provide a structural formula for each of the following compounds:

(a) 2-methylpropanamide

(b) acetamide

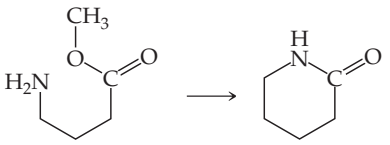


(c) *N*-phenylacetamide

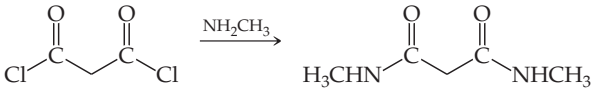
(d) *N,N*-dimethyl-1-pentanamide

(e) *N*-ethylbenzamide

31.51 Draw a primary, secondary and tertiary amide with the molecular formula $C_5H_{11}NO$. What isomeric relationship exists between the three compounds you have drawn?

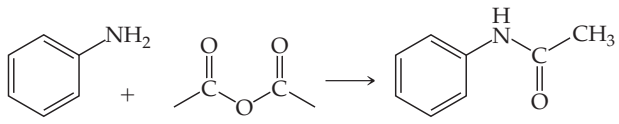


31.52 *Capsaicin*, shown in the accompanying figure, is the compound responsible for the sensation felt when chillis are eaten. It is often used as a tool in neurobiological research and has application as a topical analgesic. **(a)** Draw the structure of the carboxylic acid and amine that lead to capsaicin. **(b)** What is the general name given to this type of reaction?

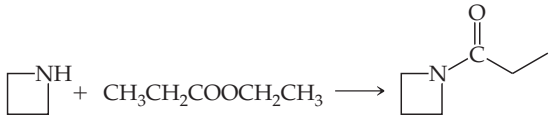


capsaicin

31.53 Propose a mechanism for the following reactions:



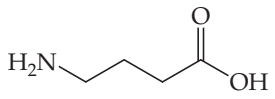
(a)



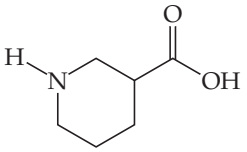
(b)

(c)

(d)

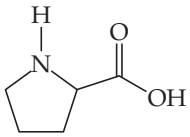


Amino Acids, Proteins, and Peptides (Sections 31.2 and 31.3)

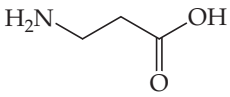


31.54 What properties of the side chains (R groups) of amino acids are important in affecting the amino acid's overall biochemical behaviour? Give examples to illustrate your answer.

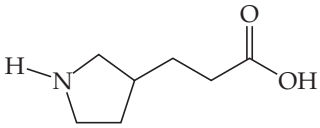
31.55 Classify the following five molecules as α-, β-, γ- or δ-amino acids:



(a)



(b)



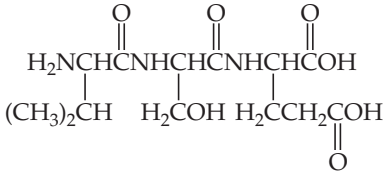
(c)

(d)

(e)

31.56 Aspartic acid is reported to have three pK_a values, one in the range of 2 to 3, another in the range 3 to 4, and the last in the range of 9 to 10. Suggest the origin of the three pK_a values.

31.57 **(a)** What is meant by the term *isoelectric point*? **(b)** Valine has pK_a values of 2.32 and 9.69. Determine the isoelectric point, pI, for valine.



31.58 Using Equation 31.28, estimate the average charge on phenylalanine **(a)** at pH 1, **(b)** at pH 5.5, **(c)** at pH 8. Phenylalanine has pK_a values of 2.58 and 9.24.

31.59 **(a)** Draw leucine and lysine in their zwitterionic forms. **(b)** The pI for leucine and lysine are 5.98 and 9.74, respectively. How could you use this information to separate a mixture of the two amino acids by electrophoresis?

31.60 Outline a synthesis of isoleucine **(a)** from 2-bromo-3-methylpentanoic acid and **(b)** by the Strecker synthesis.

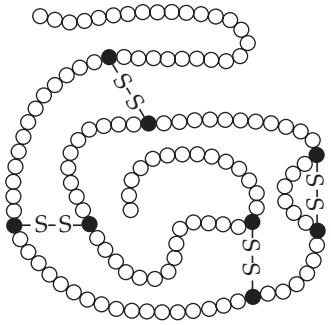
31.61 **(a)** Write a chemical equation for the formation of methionyl glycine from its constituent amino acids. **(b)** If a racemic mix of both amino acids is used, how many stereoisomers will result?

31.62 **(a)** What amino acids would be obtained by hydrolysis of the following tripeptide?

(b) How many different tripeptides can be made from the amino acids glycine, serine and glutamic acid? Give the abbreviation for each of these tripeptides, using the three-letter codes for amino acids.

31.63 **(a)** Describe the role of hydrogen bonding in determining the α-helical structure of a protein. **(b)** Suggest a reason why proline is never found within a protein α-helix.

31.64 **(a)** Draw the condensed structural formula of each of these tripeptides: Val-Gly-Asp, Phe-Ser-Ala. **(b)** What general properties would you expect each tripeptide to have based on their side chains—for example, are they hydrophobic or hydrophilic, acidic or basic?



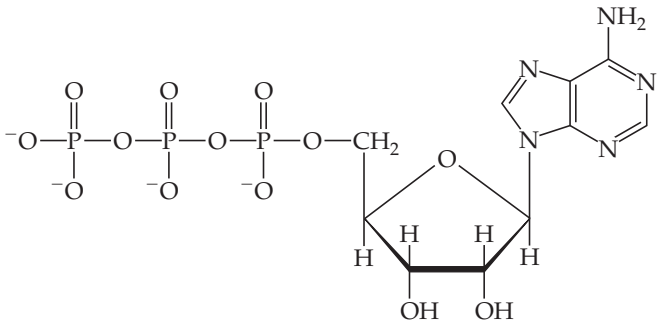
31.65 Draw the full structural formula for alanylglycylserine.

31.66 A new cyclic pentapeptide has been isolated from a marine sponge. Total hydrolysis of the cyclic peptide yielded the following amino acid composition:

Lys Gly Phe Cys

(a) What experimental conditions and reagents could be used to perform this hydrolysis? **(b)** What techniques could be used to cleave the cyclic peptide at specific sites to help identify the structure?

31.67 The protein ribonuclease A in its native, or most stable, form is folded into a compact globular shape. **(a)** Does the native form have a lower or higher free energy than the denatured form, in which the protein is an extended chain? **(b)** What is the sign of the entropy change in going from the denatured to the folded form? **(c)** In its folded form, the ribonuclease A has four –S–S– bonds that bridge parts of the chain, as shown in the diagram here. What effect do you predict that these four linkages have on the free energy and entropy of the folded form as compared with a hypothetical folded structure that does not possess the four –S–S– linkages? Explain. **(d)** A gentle reducing agent converts the four –S–S– linkages to eight –S–H bonds. What effect do you predict this would have on the tertiary structure of the protein?

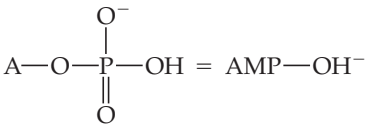


native ribonuclease A

Nucleic Acids and DNA (Section 31.4)

31.68 A nucleoside consists of an organic base of the kind shown in Section 31.4, bound to ribose or deoxyribose. Draw the structure for deoxyguanosine, formed from guanine and deoxyribose.

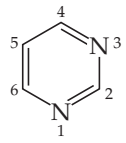
31.69 When samples of double-stranded DNA are analysed, the molar quantity of adenine present equals that of thymine. Similarly, the molar quantity of guanine equals that of cytosine. Explain the significance of these observations.



31.70 One of the most important molecules in biochemical systems is adenosine triphosphate (ATP), for which the structure is:

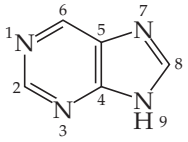
ATP

ATP is the principal carrier of biochemical energy. It is considered an energy-rich compound because the hydrolysis of ATP to yield adenosine diphosphate (ADP) and inorganic phosphate is spontaneous under aqueous biochemical conditions. **(a)** Write a balanced equation for the reaction of ATP with water to yield ADP and inorganic phosphate ion. **(b)** What would you expect for the sign of the free energy change for this reaction? **(c)** ADP can undergo further hydrolysis. What would you expect for the product of that reaction?



31.71 The monoanion of adenosine monophosphate (AMP) is an intermediate in phosphate metabolism:

where A = adenosine. If the pK_a for this anion is 7.21, what is the ratio of [AMP—OH^-] to [AMP—O^{2-}] in blood at pH 7.4?



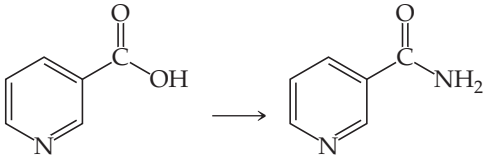
31.72 **(a)** Draw the structure of adenine and thymine and indicate how they interact through Watson–Crick base pairing. **(b)** Draw the structure of cytosine and guanine and indicate how they interact through Watson–Crick base pairing. **(c)** Why doesn't guanine base-pair with thymine? Explain.

31.73 *Broxuridine* is used to replace thymine during replication to cause radiosensitivity. Its systematic name is 5-bromo-2′-deoxyuridine or 5-bromouracil deoxyriboside. Draw the structural formula for broxuridine.

pyrimidine

31.74 *Cladribine* is a substituted purine nucleoside with antileukaemic activity. Its systematic name is 2-chloro-2′-deoxyadenosine. Draw the structural formula for cladribine.

purine



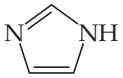
31.75 **(a)** What amino acid sequence is encoded by the following mRNA sequence?

AGG ACU GCA UCG CAA

(b) What anticodon sequence of tRNAs is needed for the synthesis of this peptide?

Integrative Exercises

31.76 Devise a synthesis for nicotinamide starting from nicotinic acid.



nicotinic acid nicotinamide

31.77 **(a)** How many amide groups are there in vitamin B_{12}? See page 1436. **(b)** What type of glycoside is found in vitamin B_{12}? **(c)** Is the sugar component a furanose or pyranose form?

31.78 What general features of a vitamin allow you to predict whether it is a hydrophilic or a lipophilic vitamin?

31.79 Quinine is a natural product that has anti-malarial properties. It was originally extracted for therapeutic use from the bark of the cinchona tree, but is now synthesized by the pharmaceutical industry. Quinine is generally administered as the hydrochloride salt ($C_{20}H_{24}N_2O_2$•HCl). The pK_a of this salt is 4.32. **(a)** What are the advantages of using the hydrochloride salt of quinine in medicine? **(b)** What is the pH of a 0.053 *M* solution of quinine hydrochloride?

31.80 Imidazole is a cyclic amine with the following structure.

(a) Draw a tautomer of imidazole. **(b)** Imidazole is a highly polar molecule; draw a resonance structure that demonstrates this polarity. **(c)** Imidazole is aromatic with six π-electrons; identify the π-electrons involved. **(d)** Protonation of imidazole occurs on only one of the nitrogen atoms. Which nitrogen atom is protonated and explain why this is so? Imidazole forms part of the side chain of the amino acid histidine and coordinates to iron in the oxygen transport protein, hemoglobin. **(e)** What part of the imidazole molecule acts as a donor in this coordination?

Design an Experiment

You are tasked with identifying the sequence of a peptide in the most efficient way possible. You conduct a series of experiments and collect the following data:

- Edman degradation on the peptide yields Cys.
- Chymotrypsin hydrolysis gives two fragments; one fragment contains the amino acids Cys and Lys and the other fragment contains Cys, Gly, and Phe.
- Trypsin hydrolysis also gives two fragments; one containing the amino acids Cys, Gly, Lys, and Phe and another composed of just Cys.

What is the sequence of the peptide? If you had repeated the Edman degradation until you had identified each of the amino acids present, how many experiments would this have involved? If you had conducted an acid hydrolysis to release all of the amino acids in a single experiment, can you think of a way to quantify the amino acids present?

WHAT'S AHEAD

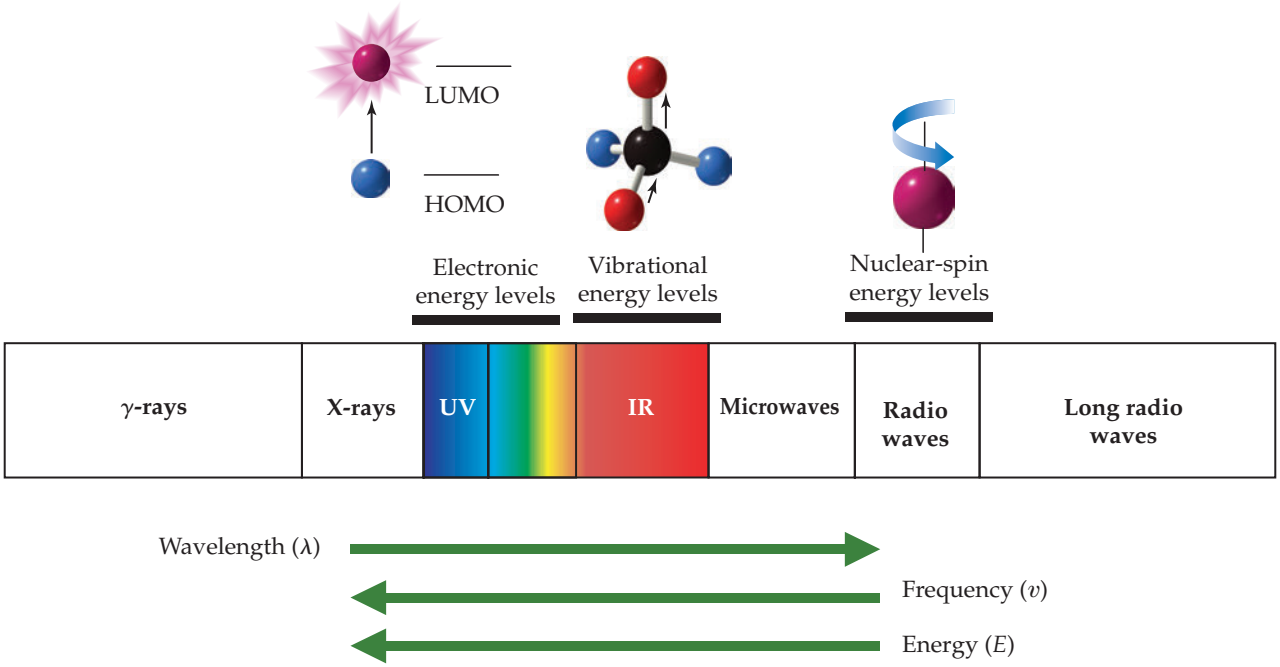
32

SOLVING MOLECULAR STRUCTURE

32.1 The Electromagnetic Spectrum

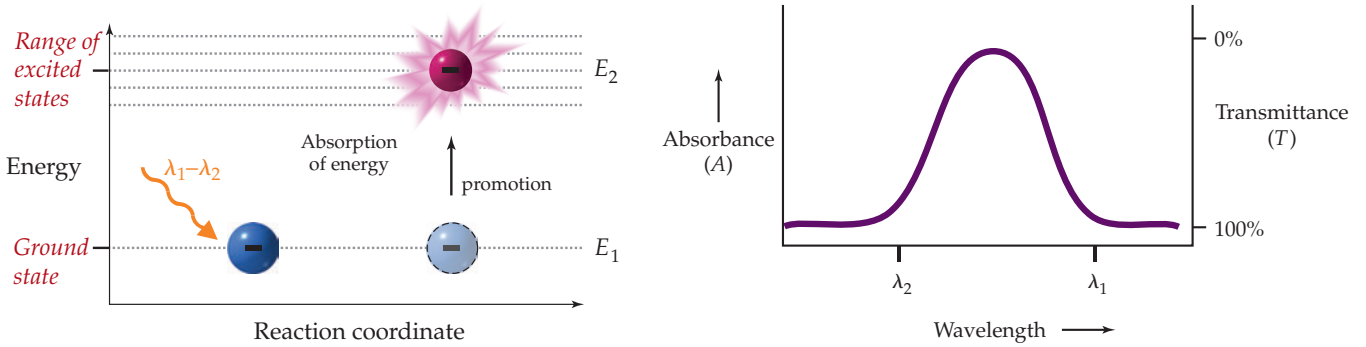
In 1666, Isaac Newton used a prism to disperse white light into the colors of the rainbow. He observed that a round beam of white light would produce an oblong image of colors. From this, he concluded that different colors are bent by the prism at different angles. This indicated that color was a property of light rather than of an object that the light illuminates. We now recognize that the electromagnetic spectrum is far more extensive than the visible portion that



we see and different parts of it correspond to different physical processes that may occur within a molecule. By the end of this section, you should:

- Understand the parts of the spectrum that are used in the analysis of molecules

In Chapter 6, we introduced the electromagnetic spectrum and the concepts of wavelength (λ) and frequency (υ).



Three regions of the electromagnetic spectrum are particularly important to the organic chemist (**Figure 32.1**). The UV (ultraviolet) and visible region of the spectrum is of an energy that equates to the transition of electrons between electronic energy levels within a molecule (**Figure 32.2**). The technique, aptly named **UV-visible spectroscopy**, is particularly useful for aromatic and π-conjugated compounds. The infrared (IR) region of the spectrum corresponds to transitions between the vibrational energy levels within a molecule. This region of the electromagnetic spectrum is lower in energy than that required to excite an electron from the ground state using ultraviolet radiation, and provides unique information on the types of functional groups present in a molecule. The third region of importance is found at the frequency of radio waves. In this region, the energies relate to transitions between nuclear-spin energy levels. The energies required here are much lower than for either IR- or UV-visible spectroscopy.

When an organic molecule is exposed to a spectrum of electromagnetic radiation, it absorbs energy at certain wavelengths in the ultraviolet and visible region and allows other wavelengths to pass through. Figure 32.2 illustrates the process. A molecule initially in the lower-energy E_1 state, referred to as the *ground state*, can undergo a transition to E_2, the *excited state*, only by absorption of electromagnetic energy of wavelength λ. This wavelength is related to the difference between E_1 and E_2 by Equations 6.1 and 6.2, so $\lambda = hc/(E_2 - E_1)$. In atoms, the absorptions occur at very defined energies giving a spectrum of sharp lines. In molecules, each electronic energy level has a stack of much smaller vibrational energy levels associated with it and this results in a broader absorption. The UV-visible absorption spectrum of a molecule is characteristic for each different substance.

▲ **Figure 32.1 The electromagnetic spectrum.** Energy depends upon wavelength. The regions are described in terms of atomic transitions and the type of related spectroscopy.

Go Figure The absorption characteristics displayed by molecules have an analogy in everyday life. Why do dark-colored cars get hotter inside than light-colored cars?

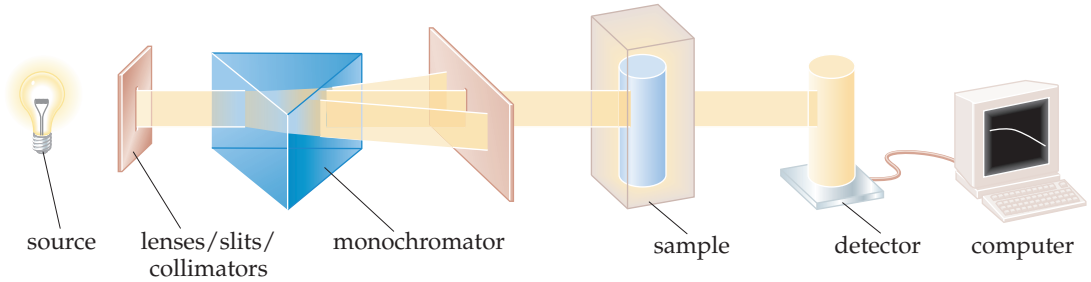
▲ **Figure 32.2 An absorption spectrum** is generated when a molecule absorbs electromagnetic radiation of a particular wavelength range ($\lambda_1 - \lambda_2$).

UV-visible spectroscopy is one of several spectroscopic techniques in which energy interacts with a molecule to give a characteristic absorption spectrum. Modern spectroscopic techniques use only minute amounts of material, which in most cases may be recovered unchanged after the analysis. These are called *non-destructive* techniques. Other methods of analysis do destroy the compound and are sometimes unavoidable, for example, mass spectrometry.

In this chapter, we deal with three powerful and complementary techniques that form the cornerstone of modern synthetic organic chemistry. Each technique is useful because it provides a vital piece of evidence, using very small amounts of sample. The chemical detective can draw a logical conclusion to the structural problem by combining two, but usually more, pieces of evidence. The techniques are:

- *infrared (IR) spectroscopy*, which observes the vibrations of covalent bonds and provides useful evidence for the presence of functional groups;

A CLOSER LOOK Using Spectroscopic Methods to Measure Reaction Rates



A variety of techniques can be used to monitor the concentration of a reactant or product during a reaction. Spectroscopic methods, which rely on the ability of substances to absorb (or emit) electromagnetic radiation, are some of the most useful. Spectroscopic kinetic studies are often performed with the reaction mixture in the sample compartment of a spectrometer. The spectrometer is set to measure the light absorbed at a wavelength characteristic of one of the reactants or products. In the decomposition of HI(g) into H_2(g) and I_2(g), for example, both HI and H_2 are colorless, whereas I_2 is violet. During the course of the reaction, the color increases in intensity as I_2 forms. As the concentration of I_2 increases and its color becomes more intense, the amount of light absorbed by the reaction mixture increases, causing less light to reach the detector.

Figure 32.3 shows the basic components of a spectrometer. The spectrometer measures the amount of light absorbed by the sample by comparing the intensity of the light emitted from the light source with the intensity of the light that emerges from the sample.

Beer–Lambert's law relates the amount of light being absorbed to the concentration of the substance absorbing the light:

$$A = \varepsilon c l \qquad [32.1]$$

In this equation, A is the measured absorbance, ε is the molar extinction coefficient (a characteristic of the substance being monitored at a particular wavelength), l is the path length through which the radiation must pass, and c is the molar concentration of the absorbing substance. Thus, for a constant path length, the concentration is directly proportional to absorbance.

▲ **Figure 32.3 Basic components of a spectrometer.**

- *nuclear magnetic resonance (NMR) spectroscopy*, the technique of choice for the organic chemist. This method observes nuclear transitions within a strong magnetic field and yields information on the connectivity of atoms;
- *mass spectrometry (MS)*, which typically bombards a very small amount of sample with electrons to ionize the molecules. Analysis of the mass of these ions gives the molecular mass. Mass spectrometry often provides clues to the structure and functional groups within a molecule, through either fragmentation or isotopic patterns. This technique is often used routinely because it needs only μg amounts of sample.

Self-Assessment Exercise

32.1 What portion of the electromagnetic spectrum corresponds to the energy difference between vibrational energy levels?

(a) UV-visible light
(b) Infrared radiation
(c) Radio waves

Answers to Self-Assessment Exercises

32.1 (b)

32.2 | Infrared (IR) Spectroscopy

A high body temperature is usually an indicator that the body is fighting an infection. In times of epidemics, such as COVID-19, temperature measuring devices are frequently employed at the entrance to hospitals, at transport hubs and even large shopping centers to screen the general public for the first signs of an infection. It is important these devices do not touch the skin to prevent the risk of transmitting any possible infection from one person to another. Infrared thermometers are often used in these situations and provide a lightweight, robust, and relatively cheap device that is easy for the operator to hold in their hands. The heat we radiate is directly related to our body temperature and is detected as infrared radiation.

In this section, we use infrared radiation in the non-destructive analysis of molecules to determine if they contain some common functional groups. By the end of this section, you should be able

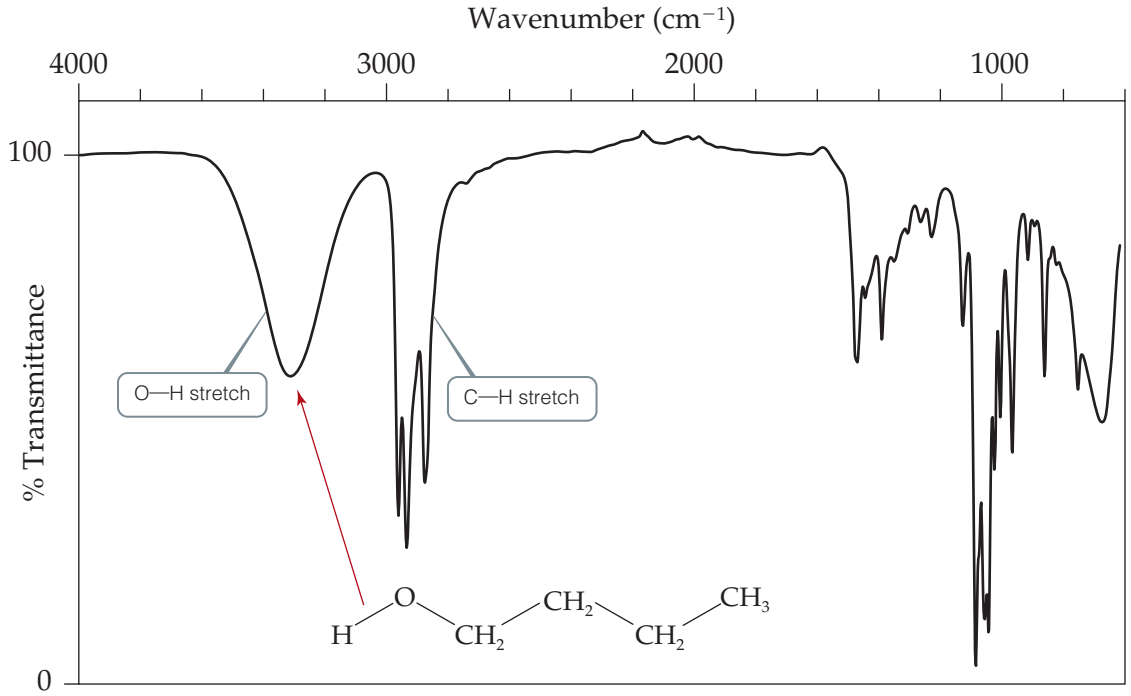
- To recognize if an analyte contains certain functional groups from their characteristic IR frequency of absorption.

Infrared photons (*infra*, Latin, meaning below or beneath) do not have enough energy to cause electronic transitions, but they can cause groups of atoms to vibrate about their respective bonds. These vibration transitions correspond to distinct energy levels. Molecules and, more importantly, the different functional groups contained within them, absorb IR radiation at specific wavelengths to induce the different vibrational modes within a covalent bond (that is, single, double, triple bonds). **Infrared spectroscopy** is the technique that records the absorption of infrared energy of a molecule as a function of energy. It identifies functional groups, but gives little structural information.

The position of an infrared band in an *IR spectrum* is defined by a **wavenumber** value (abscissa) and the band's percentage transmittance (%T) (ordinate), as shown in **Figure 32.4**. The wavenumber has traditionally been the most common method of specifying IR absorption, although sometimes the wavelength value (in microns) is also employed. The wavenumber is a type of frequency unit and is the true frequency divided by the speed of light. It corresponds to the number of waves per unit distance, chosen to be centimeters in IR spectroscopy (and, therefore, written in terms of cm^{-1}).

The absorbance of a sample is related to the **transmittance** by the equation:

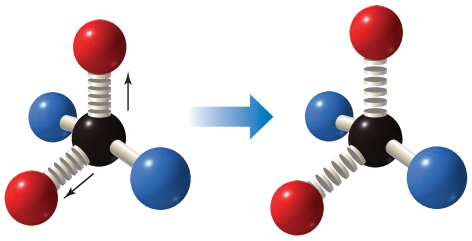
$$\text{Absorbance} = -\log_{10}(\text{transmittance})$$



or

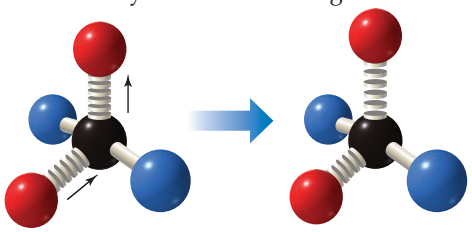
$$A = -\log_{10} T \qquad [32.2]$$

The value of transmittance (T) always lies between the values of 0 and 1 and the %T between 0 and 100.



The Spring Model

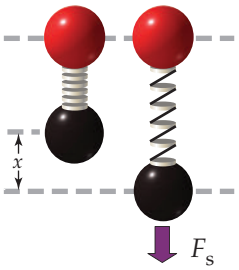
Before discussing the characteristics of IR absorptions, it is helpful to understand some theory on molecular vibrations. To do this, let's consider the covalent bond between two atoms as a spring (**Figure 32.5**). This spring can be stretched (shown), compressed, bent or twisted, and then released from the input leading to the distortion. The output, which can be observed as a band within the IR spectrum, is in fact a vibration. The force needed



▲ **Figure 32.4 IR spectrum of butan-1-ol.** This IR spectrum is measured as a function of wavenumber (cm^{-1}). The ordinate describes the intensity, measured as percentage transmission (%T). In this spectrum of butan-1-ol, the broad, strong absorption at 3300 cm^{-1} is due to the strong O—H stretching vibrations that occur at this frequency.

Go Figure Do loose springs oscillate with a higher or lower frequency than tight springs?

Symmetric stretching



Asymmetric stretching

▲ **Figure 32.5 Spring model.** IR spectroscopy can be more easily understood by thinking of covalent bonds as springs. The stretching, bending or torsion of the spring leads to vibrations of a particular frequency. The vibrations can be modelled using Hooke's law.

to cause the vibration follows **Hooke's law**, which states that the elongation of a spring is proportional to the load applied. Mathematically:

$$F_s = -kx \qquad [32.3]$$

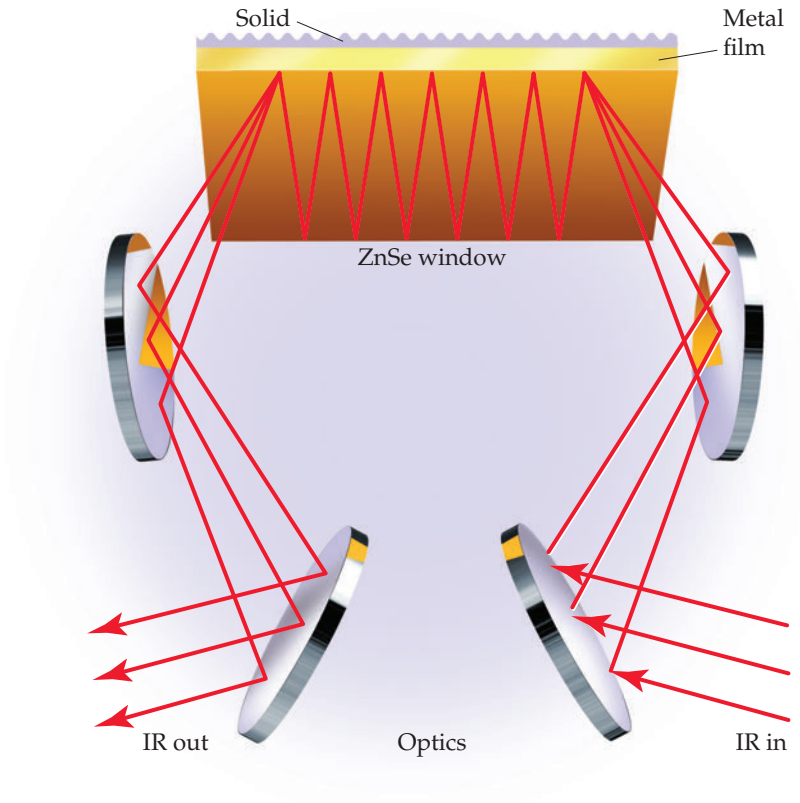
where F_s is the applied force (which equals the force exerted by the spring, only opposite in sign) in units of newtons (N), k is the spring constant (N m^{-1}) and x is the deformation of the spring (for example, stretching, with units m) from an equilibrium position (Figure 32.6). The strain in the spring is directly proportional to the load. In any system that can be described by Hooke's law, there exists a fundamental frequency of vibration, $\upsilon = \frac{1}{2}\pi\left(\frac{k}{m}\right)^{\frac{1}{2}}$. This is also true for molecules, so the frequency of vibration of any chemical bond depends on the mass (m) of atoms at the moving end of the bond and the stiffness (k) of the bond.

▲ **Figure 32.6 Hooke's law** of elasticity applied to a spring system states that the elongation of a spring is proportional to the load applied.

In a group of bonds with similar bond energies, the frequency decreases with an increase in atomic weight of the atoms. Of more interest to the organic chemist is the fact that stronger bonds (for example, double bonds) are generally "stiffer" than single bonds and require more force to stretch or compress them. As a result, stronger bonds usually vibrate faster than weaker bonds. For example, O—H bonds (D(O—H = 463 kJ/mol) are stronger than C—H bonds (D(C—H = 413 kJ/mol), so O—H bonds vibrate at higher wavenumber. Carbon–carbon triple bonds are stronger than carbon-carbon double bonds, so triple bonds vibrate at higher wavenumbers than do double bonds. In a group of bonds with atoms of similar masses, the frequency increases with increasing bond energy.

The absorption of energy into molecular vibrations is recorded in an IR spectrum. This spectrum gives a record of the energy absorbed as a function of the energy of radiation. An IR spectrum is recorded on an IR spectrophotometer. In the context of this course, we consider only certain vibrations: O—H stretching, C—H stretching, C=C stretching, C—C stretching, N—H stretching and C=O stretching. These stretching vibrations give rise to the easy identification of the most common functional groups in organic chemistry. The low-wavenumber region within the IR spectrum contains most of the complex vibrations and is commonly called the **fingerprint region** of the spectrum (300–1400 cm^{-1}). Although it is useful to know of this region, its use in identifying organic molecules is limited because of the complexity of the spectrum in this region. Inorganic chemists

find this region useful for the identification of metal–ligand (M—L) interactions. Organic chemists use the fingerprint region primarily to confirm the identity of a sample, by comparing it with an authentic spectrum of a known compound thought to be the same as the sample under investigation.



Stretching vibrations in the region 1550–3800 cm^{-1} are the most characteristic and predictable.

At this point, we should also recognize that not all molecular vibrations absorb IR radiation. Generally, only bonds with dipole moments (for example, O—H, C═O, N—H bonds) are IR active and hence result in IR absorptions. A dipole moment between two covalently bonded atoms is achieved when the two atoms differ significantly in their electronegativity.

If the molecule is placed in an electromagnetic field, its bonds interact with the field, usually leading to a change in the vibration of the covalent bond, and a change in the dipole moment of the bond. If a bond is symmetrical or has zero dipole moment, the applied field does not interact with the bond as strongly, and this very weak vibration is said to be *IR inactive*.

Measuring IR Spectra

IR spectra are measured using liquid, solid or gaseous samples placed in a beam of infrared light. Typically, if the sample is a liquid, the compound can be thinly spread *neat* (without solvent) between two thick plates of sodium chloride, which are transparent to infrared light for most of the important wavelength regions. Solid samples are usually prepared by grinding a sample into a paste with an organic oil known as nujol (a type of paraffin oil) forming a mull, which is also sandwiched between two thick NaCl plates. A more modern approach is to place a solid on an ATR diamond or ZnSe window cell and a spectrum taken directly (**Figure 32.7**). ATR stands for attenuated total reflectance. Gases typically require specialized cells.

▲ **Figure 32.7 Attenuated total reflectance (ATR) IR spectroscopy.** Modern IR spectrometers use a direct approach by measuring the transmittance of electromagnetic radiation through a sample placed on a diamond or ZnSe surface.

TABLE 32.1 Bond-stretching frequencies and their relationship to functional groups

Functional group	Stretching vibration frequency (cm^{-1})	Strength of IR band	Bond energy ($kJ\ mol^{-1}$)*
O—H	3200–3500	Strong, broad	465
N—H	3100–3500	Medium	390
C—H	2700–3100	Strong to medium	415
C≡N	2200–2400	Strong to medium	890
C≡C	2000–2200	Weak	840
C=O	1630–1800	Strong	800
C=N	1630–1680	Strong	615
C=C	1600–1680	Weak	615

* Bond energies rounded to the nearest 5 kJ mol.

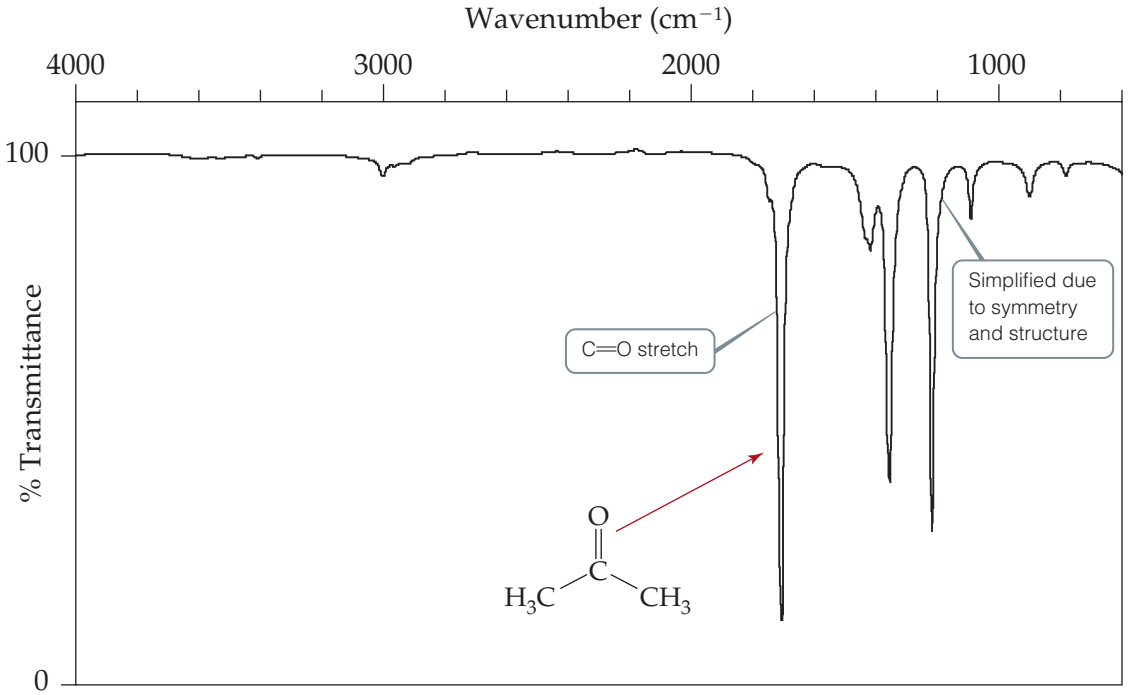


Table 32.1 illustrates the predicted regions where the most common functional groups absorb IR radiation. As mentioned earlier, strong bonds generally absorb at higher frequencies because of their greater "stiffness." Thus C—C single bonds absorb around 1200 cm^{-1}, C=C double bonds around 1600–1680 cm^{-1} and C≡C triple bonds around 2200 cm^{-1}. The absorption of C=C double bond vibrations in an IR spectrum are diagnostic and useful for structure determination. The position of C—C single bond absorptions in an IR spectrum are not very diagnostic because they occur in most organic compounds as part of the molecules' framework. Most double bonds produce observable absorptions in the region 1600–1680 cm^{-1}. Conjugation of the double bond has the effect of reducing the stretching frequencies from 1620–1640 cm^{-1} (in the case of an aliphatic C=C) to approximately 1600 cm^{-1} for an aromatic C=C. The lowering in frequency can be attributed to the loss of electron density in the double bonds due to the conjugation. As a result, conjugated double bonds are a little less stiff and vibrate a little more slowly than isolated double bonds, giving them lower frequencies of absorption.

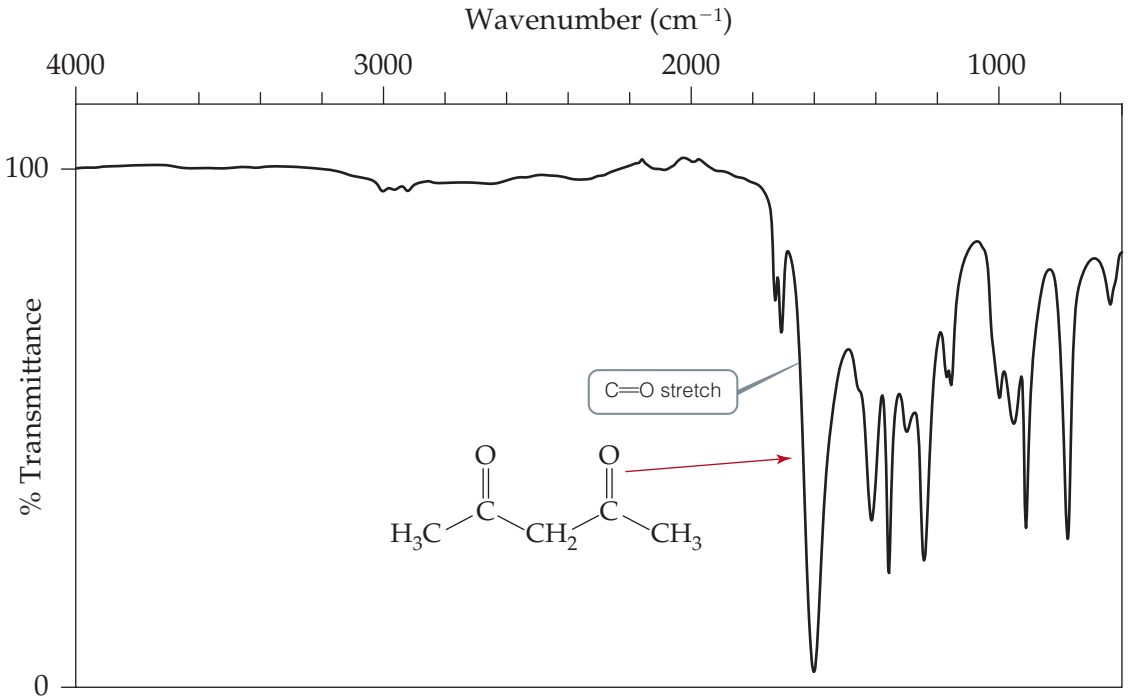
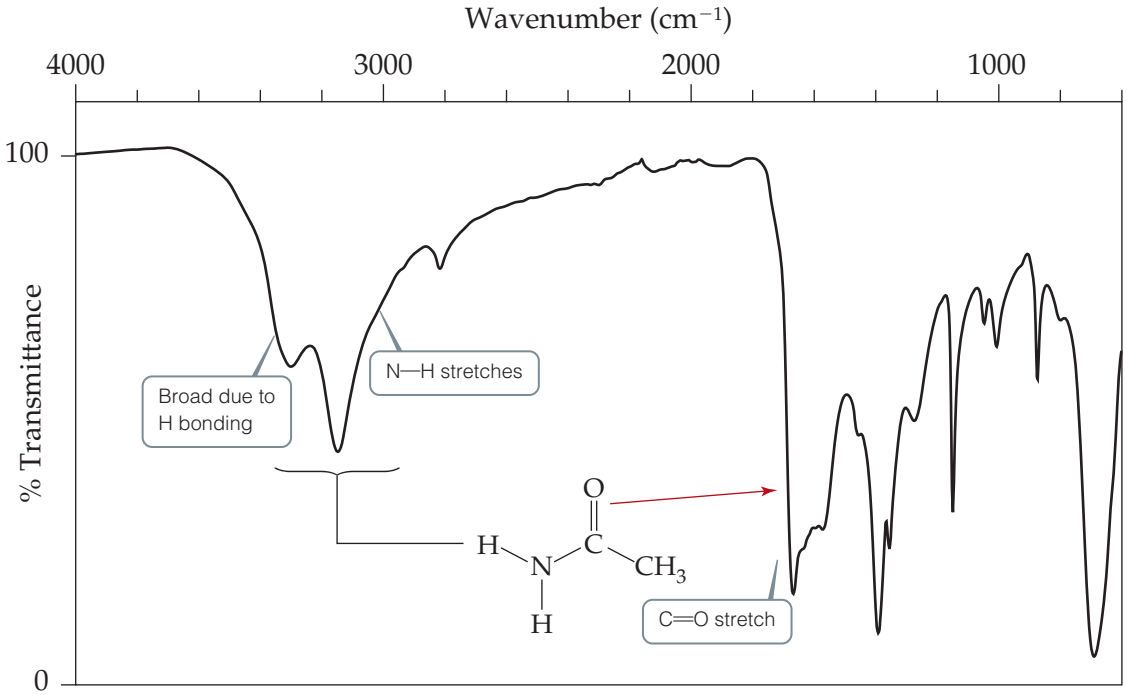
Alkanes, alkenes, and alkynes have characteristic C—H stretching bands around 3000 cm^{-1}. Because of the prevalence of C—H bonds in organic molecules, the presence of a band at 3000 cm^{-1} makes it easy to identify the presence of an organic compound by IR spectroscopy. However, some organic molecules have very weak absorbances in this area. For example, the C—H stretching band in an IR spectrum of propanone (**Figure 32.8**) is very weak.



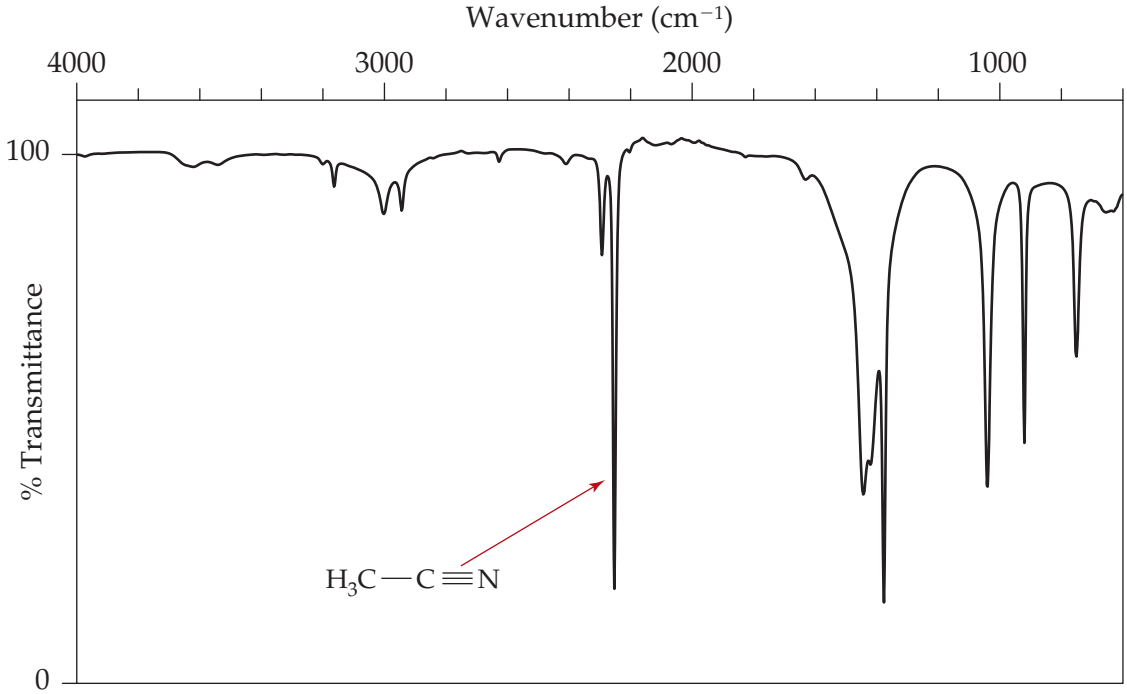
The large dipole moment change associated with the C=O double bond produces a strong IR stretching band around 1700 cm^{-1} as shown in Figure 32.8. The exact position of this band within the IR spectrum depends on the specific functional group present (ketone, aldehyde, amide, carboxylic acid or ester) and the environment created by the rest of the molecule. For these reasons, IR spectroscopy is often the best method for detecting and identifying the type of carbonyl group in an unknown compound.

The C=O double bond stretching vibrations of simple ketones, aldehydes and carboxylic acids occur around 1710 cm^{-1} (**Figure 32.9**). These are slightly higher than those of a C=C double bond because of the relative bond strengths (C=C < C=O, see Table 32.1). Some carbonyl absorptions do occur above 1710 cm^{-1}. For example, simple carboxylic esters absorb around 1735 cm^{-1} and ring-strained carbonyl groups, such as those found in cyclobutanone, occur around 1785 cm^{-1}. In addition to the C=C stretching band, an aldehyde shows the characteristics of two C—H stretching bands around 2700 cm^{-1} and 2800 cm^{-1} corresponding to the aldehyde C—H stretch, whereas a ketone or an acid does not produce these absorptions. Carboxylic acids produce a characteristic O—H absorption around 3000 cm^{-1} in addition to the intense carbonyl stretching absorption. The position of this O—H stretch within the IR spectrum is usually complicated as a result of the carboxyl group participating in hydrogen bonding, which also results in the broadening of the strong carbonyl absorption.

The carbonyl groups of amides absorb at particularly low IR frequencies (1640–1680 cm^{-1}). This very low frequency might be mistaken for an alkene C=C stretch if it weren't for two important features of its IR spectrum. The amide carbonyl absorption is much stronger than that of an alkene bond due to the difference in dipole moment



▲ **Figure 32.8 IR spectrum of propanone (acetone).** Note the simplicity of the spectrum and the presence of the dominant C═O stretch at 1710 cm^{-1}.



▲ **Figure 32.9 IR spectrum of 2,4-pentanedione.** Note the intense carbonyl stretching band at 1700 cm^{-1}.

between the two unsaturated bond types. Primary and secondary amides are also identified by the addition of a N—H stretching absorption around 3200 cm^{-1} (**Figure 32.10**).

The only other multiple bond stretch that we need to consider is that of the nitrile bond (C≡N). Because of the polarity of this C≡N triple bond, nitriles usually exhibit very strong absorbances around 2200 cm^{-1} (**Figure 32.11**) within their IR spectra. This value is similar to that for an alkyne (C≡C) stretch, although nitriles tend to absorb above 2200 cm^{-1} whereas alkynes absorb below 2200 cm^{-1}.

▲ **Figure 32.10 IR spectrum of acetamide.** This spectrum was taken of a sample as a crystalline solid, hence there is more information contained within the spectrum than is usually needed for functional group identification.

▲ **Figure 32.11 IR spectrum of acetonitrile.** This simple nitrile shows the characteristic and distinctive IR absorption band for C≡N at 2280 cm^{-1}.

The vibrational frequencies of O—H bonds (alcohols) and N—H bonds (amines) occur at higher wavennumbers than for C—H bonds. Alcohol O—H bands are typically broad, absorbing over a wide range of frequencies centered around 3300 cm^{-1}. Their broadness is attributed to hydrogen-bonding arrangements between functional groups within the same molecule—that is, they are *intramolecular*—or to interactions with other molecules, including solvent or absorbed water, interactions that are described as *intermolecular*. Therefore, the purity of a sample with respect to absorbed water needs to be taken

Sample Exercise 32.1

Distinguishing between constitutional isomers

How would you be able to use IR spectroscopy to distinguish between the following compounds:
(a) butan-1-ol and diethyl ether,
(b) ethyl acetate and butanoic acid?

SOLUTION

Analyze We are asked to differentiate between functional groups in compounds using IR.

Plan We need to identify the difference in functional groups between the two isomers in each set.

Solve Butan-1-ol shows a strong absorption in the O—H stretching frequency region, 3100–3300 cm^{-1}. Diethyl ether is devoid of any characteristic functional group absorptions $> 1500\ cm^{-1}$, apart from C—H stretching vibrations. In this case, the absence of the O—H absorption is diagnostic.

Both ethyl acetate and butanoic acid show a strong C=O stretching frequency absorption around 1710–1730 cm^{-1}. Although variations in this stretching frequency are possible and somewhat diagnostic, the best answer to this question is the addition of a strong absorption in the O—H stretching frequency region, approximately 3100 cm^{-1} for butanoic acid.

Practice Exercise

How would you be able to use IR spectroscopy to distinguish between these compounds:
(a) cyclohexane and cyclohexene,
(b) acetamide and ethylamine?

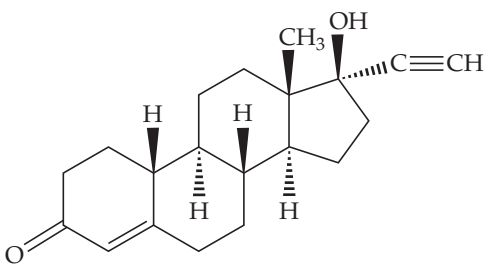
into account. Any water that is present will also absorb at these frequencies, complicating the results by giving a false positive for an O—H group. This is usually overcome by extended drying of the sample before analysis by IR spectroscopy.

The amine N—H bond also has a stretching frequency around 3300 cm^{-1} and, like alcohols, these amines participate in *intra-* and *inter*-molecular hydrogen bonding. The difference between O—H and N—H stretches lies in the shape of the band. Although O—H stretches are broad, N—H stretches are sharper. Primary amines typically have two absorptions in their N—H absorption band, whereas secondary amines have only a single absorption band. The presence of water in an amine sample typically leads to one or two sharp spikes superimposed on the broad area of the water O—H stretching absorption. Again, drying the sample distinguishes a wet sample from one containing both an O—H and N—H functional group.

Being able to interpret an IR spectrum is a useful skill. Typically, IR spectra need to be interpreted in conjunction with other techniques. Sections 32.3 and 32.4 deal with two other powerful spectroscopic techniques.

Self-Assessment Exercise

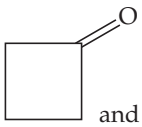
32.2 A molecule of formula C_4H_8O has a weak absorption around 1600 cm^{-1}, no absorption in the region 1630–1800 cm^{-1} and no absorption in region 3200–3500 cm^{-1}. Which of the following compounds would fit this data?



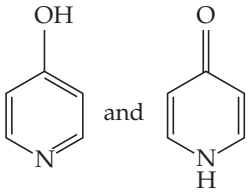
(a) but-3-en-1-ol
(b) butanal
(c) butanone
(d) ethoxyethene

Exercises

32.3 Identify a possible functional group that might be responsible for the following IR absorptions:



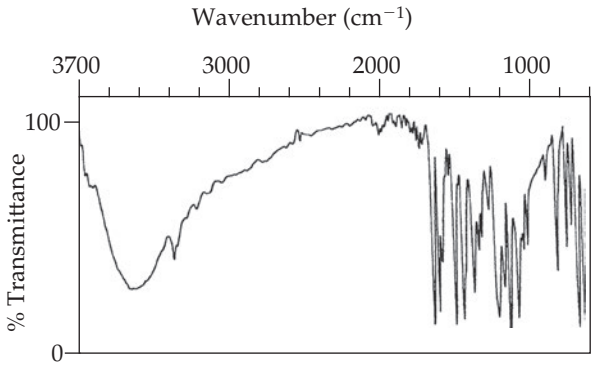
(a) 3500 cm^{-1}
(b) 1705 cm^{-1}
(c) 1650 cm^{-1}
(d) 1710 and 3400 cm^{-1}
(e) 1680 and 3200 cm^{-1}



32.4 Norethidrone is a steroid used primarily as an oral contraceptive. Its synthesis was first achieved in 1951. Indicate which parts of the structure of norethidrone have characteristic absorptions identifiable by IR spectroscopy. Indicate their approximate positions in wavenumbers (cm^{-1}).

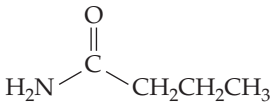
32.5 How might you use IR spectroscopy to help distinguish between the following pairs of compounds?

(a) $CH_3CH_2OCH_2CH_3$ and $CH_3CH_2CH_2CH_2OH$

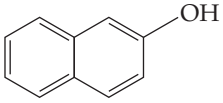


(b)  and $CH_2{=}CHCH_2OH$

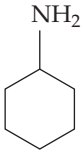
(c) 



(d)  and $CH_3CH{=}CHCH_2CH_3$



(e) $(CH_3)_3N$ and $CH_3CH_2NHCH_3$



32.6 Which of the following structures is consistent with the IR spectrum shown here?

(a) 

(b) 

(c) 

(d) 

Answers to Self-Assessment Exercises

32.2 (d)

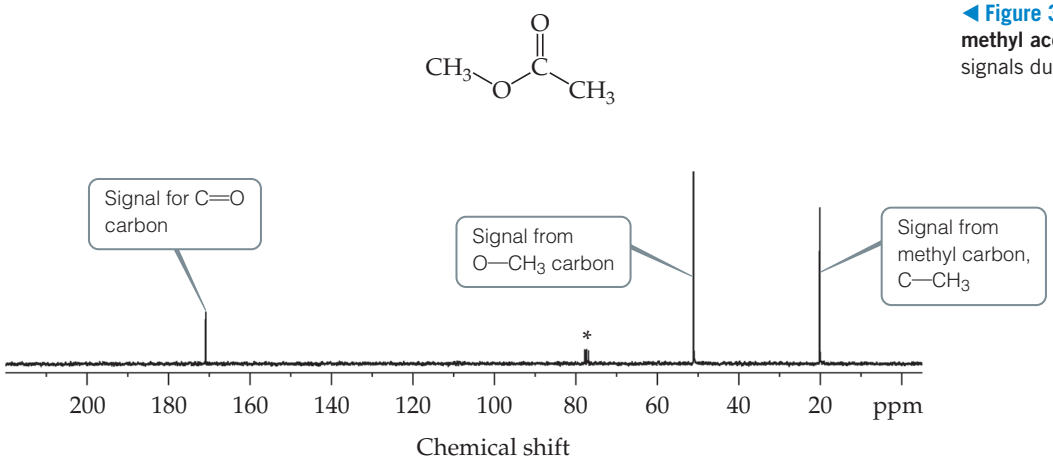
32.3 Nuclear Magnetic Resonance (NMR) Spectroscopy

The twin discoveries that led to superconducting magnets were made by Dutch man Heike Kamerlingh Onnes. In 1908, he was the first to liquify helium, and, three years later, he was the first to observe superconductivity in metals cooled to extreme temperatures.

Helium boils at −269 °C, just four degrees above absolute zero, and it was at this temperature that Onnes observed that the resistance of a mercury wire dropped to zero. He adopted the term *superconductivity* to describe this new state and recognized the potential to construct extremely strong magnets. However, it was not for another forty years that a material (niobium) was found that could handle the large current densities present in an ultra-strong magnet. Now, a niobium-titanium or a niobium-tin alloy is used in superconducting magnets. This metal core is cooled by liquid helium, which is surrounded by a jacket of liquid nitrogen. The magnet field produced is typically ten times stronger than can be achieved with traditional iron-core magnets as well as being a more stable, homogenous field.

The discovery of superconducting magnets opened many doors. In this section and the next, we examine two techniques, both of which utilize superconducting magnets in order to achieve very high-resolution analysis. Superconducting magnets are also pivotal to the magnetic resonance imaging of soft body tissue, research into nuclear fusion reactors, and the construction of magnetically levitated trains being developed in Japan.

By the end of this section, you should be able to:



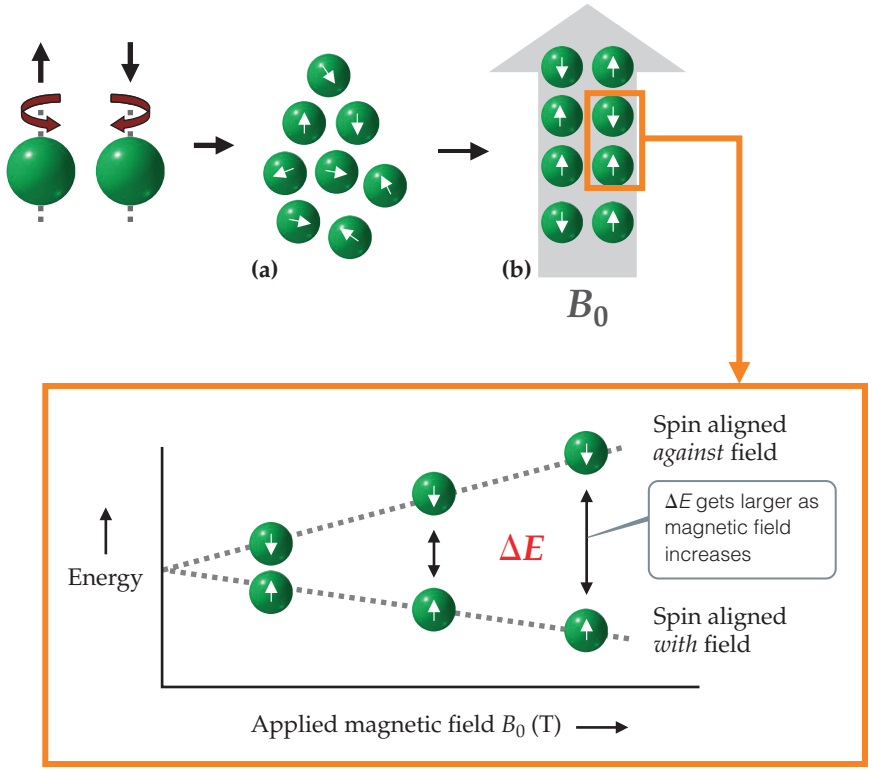
- Identify nuclei that can resonate in a magnetic field (i.e., are NMR active)
- Predict the NMR spectra of simple organic molecules
- Interpret an NMR spectrum to give structural information on a molecule

As a technique, **nuclear magnetic resonance (NMR) spectroscopy** is probably the most powerful tool in the organic chemist's research arsenal. It is a non-destructive technique that requires little sample (typically 2–10 mg for ^{1}H NMR and 20–40 mg for ^{13}C NMR spectroscopy). It has become a routine technique, due mainly to the advent of Fourier Transform NMR (FT-NMR), which provides for very rapid data acquisitions (typically 10 minutes), although more demanding experiments take longer (overnight). NMR gives us information about structure, so it is extremely useful for identifying unknown substances or confirming known structures. In the latter case, NMR spectroscopy is also useful for indicating the purity of a sample (to approximately 97%) and for observing the stability of a substance in solution. Even if you are do not intend to study chemistry in future years, the logical nature of the problem-solving skills developed by using this and the other techniques discussed in this chapter will be beneficial for your chosen science.

NMR spectroscopy is a technique that yields important structural information about a molecule by observing the interplay of the different nuclei, such as ^{1}H, ^{13}C, ^{15}N, ^{31}P, contained within it. The sensitivity of NMR spectroscopy allows us to also identify subtle differences in the same nuclei within a molecule based on their neighboring functional groups, whose influence over a strong magnetic field is measurable. This section concentrates on two forms of NMR spectroscopy: ^{1}H and ^{13}C NMR spectroscopy. Information about the number and different types of hydrogen environment within a compound, their connectivity and their relationships will be explored using ^{1}H NMR spectroscopy. Information on the different types of carbon environment present in a compound will be gained using ^{13}C NMR spectroscopy.

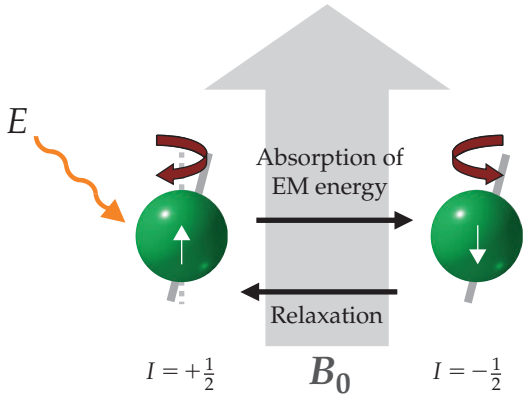
Let us begin our discussions on NMR spectroscopy by looking at a simple example. The ^{13}C NMR spectrum shown in **Figure 32.12** has three signals (or peaks), indicating that there are three different types of carbon environments within this compound, methyl acetate. The positions of these signals along the axis yields information about neighboring functional groups that allows us to assign each carbon environment to a signal with confidence. However, to understand the reasons why we can interpret the spectrum shown in Figure 32.12 the way we do, we need to gain an understanding of the background theory to NMR spectroscopy.

From Chapter 6, you should already be familiar with the concept that an electron has an associated magnetic field. Any atomic nucleus that has an odd number of protons or an odd number of neutrons will have a non-zero nuclear *spin* and resulting nuclear magnetic moment (μ). Like electron spin, nuclear spin is quantized. The allowed nuclear magnetic spin states are determined by the nuclear spin quantum number (I) of the nucleus.



◀ **Figure 32.12 ^{13}C NMR spectrum of methyl acetate.** The asterisk indicates signals due to $CDCl_3$ solvent.

A nucleus with a spin quantum number of I ($I = 0, \frac{1}{2}, 1, \frac{3}{2}, 2$, etc.) has $(2I + 1)$ spin states. If $I = \frac{1}{2}$, as for ^{1}H and ^{13}C, there are two allowed spin states with values of $+\frac{1}{2}$ and $-\frac{1}{2}$. This spinning charge creates an associated magnetic field that behaves as if it is a tiny bar magnet with a magnetic moment (μ).



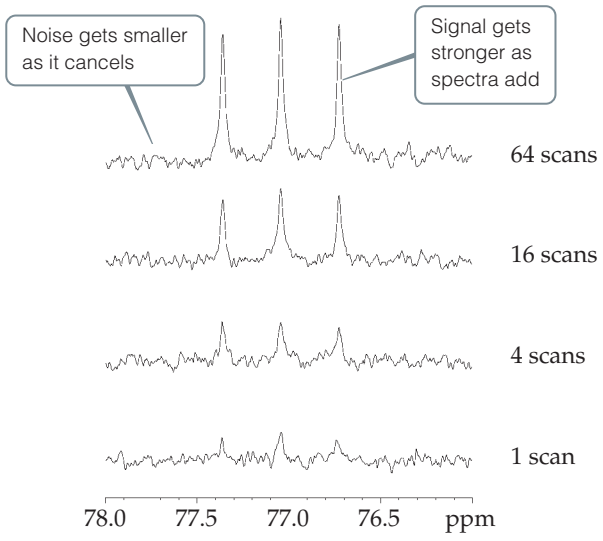
In the absence of external effects, such as an applied magnetic field, the two spin states have the same energy, as shown in **Figure 32.13(a)**, and completely random orientations. However, when the nuclei are placed in a strong external magnetic field, their spins can align parallel (with) or anti-parallel (against) to the field, giving rise to two energy

Go Figure Why would an increase in applied magnetic field strength increase the population differences between two spin states?

▲ **Figure 32.13 Nuclear spin.** Like electron spin, nuclear spin generates a small magnetic field and has two allowed values for ^{1}H and ^{13}C. In the absence of an external magnetic field (a), the two spin states have the same energy and a random orientation. If an external magnetic field is applied (b), the parallel alignment of the nuclear spin to the magnetic field is lower in energy than the anti-parallel alignment. The energy difference, ΔE, corresponds to the radiofrequency portion of the electromagnetic spectrum. The weaker the applied magnetic field, the smaller this difference is.

states. The parallel alignment is lower in energy than the anti-parallel one by an amount of energy ΔE, the size of which depends on the strength of the applied magnetic field (B_0) and the type of nucleus absorbing the radiation (Figure 32.13). For an applied field strength of 7.05 T (T = Tesla), which is readily available with modern-day superconducting electromagnets, the difference in energy between the two aligned spin states (with and against) is about 0.1 J/mol. This is a very small quantity on the chemical energy scale. NMR spectroscopy is considered a ground-state phenomenon.

▲ **Figure 32.14 Nuclear spin flip.** When Rf radiation of a frequency that corresponds to ΔE is applied, the parallelspin nuclei absorb this energy and their spins flip to an anti-parallel orientation. Although nuclei are described as aligning in a parallel or anti-parallel fashion, the axis of rotation is tilted, causing the nucleus to precess about its own axis of spin in a similar manner to a spinning top.



Nuclear Magnetic Resonance Frequencies

Based on your knowledge of thermodynamics, you would expect that the lower-energy state would have a higher population of nuclear spins aligned with the field compared with those aligned anti-parallel to the field (despite the small value of ΔE) because these aligned spins are lower in energy. If the nuclei being monitored by NMR spectroscopy are irradiated with electromagnetic radiation equal to the difference in energy between the two spin states in the applied magnetic field (ΔE), energy is absorbed and the spin of the nuclei can be "flipped"—that is, excited from a parallel to an anti-parallel alignment, as shown in **Figure 32.14**. The radiation used in ^{1}H NMR spectroscopic experiments is in the radiofrequency (Rf) range, typically 200–900 MHz. This radiofrequency is known as the spectrometer's **operating frequency**. The frequency at which the nuclei absorb energy is called the **Larmor frequency**. The absorption of this electromagnetic radiation, and the flip of its nuclear spin from a lower state to a higher state (and *vice versa*), is called **resonance**. Detection of the flipping of nuclei between the two spin states leads, after detection and mathematical manipulation (called Fourier Transform), to the NMR spectrum.

For NMR spectroscopy to be useful, the difference in population between the two aligned spin states needs to be significant. The greater the applied magnetic field, the greater the population difference between the two states (Figure 32.13). The more significant this difference is, the more *sensitive* the technique becomes. A greater sensitivity improves the spectrum acquisition time and lowers the amount of sample needed by providing a better *signal-to-noise ratio*. Acquiring and adding together multiple spectra of the same sample also increases the *signal-to-noise ratio* as shown in **Figure 32.15**. An increase in resolution allows us to gain more information on the connectivity of nuclei within a molecule. This is why chemists desire to have spectrometers with more powerful superconducting magnets (**Figure 32.16**).

From our discussions on NMR theory so far, you might expect that all ^{1}H or ^{13}C nuclei in a molecule would absorb energy at the same frequency. If this were the case, this technique would be of little use for structural determination. Luckily, the absorption frequency is not

▶ **Figure 32.15 75 MHz ^{13}C NMR spectrum of $CDCl_3$** showing improvement of the signal-to-noise ratio from one scan (bottom spectrum) to 64 scans (top spectrum).

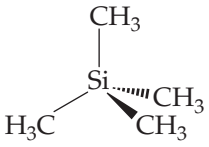
This 400 MHz NMR spectrometer shows (a) the superconducting magnet in the foreground with the return lines required to pump the liquid helium into the system to cool the magnet. In the background is the computer mainframe required for Fourier transformations. (b) The desktop computer, showing an initial free induction decay (FID) curve, is interfaced with the spectrometer for data manipulation.

the same for all ^{1}H or all ^{13}C nuclei because, in organic molecules, these nuclei are not isolated from each other or other atoms. Each nucleus is surrounded by electrons from other atoms, or groups of atoms, that can create local magnetic fields (B_{local}) that influence the applied field. This statement can be written in the following way:

$$B_{effective} = B_{applied} - B_{local} \qquad [32.4]$$

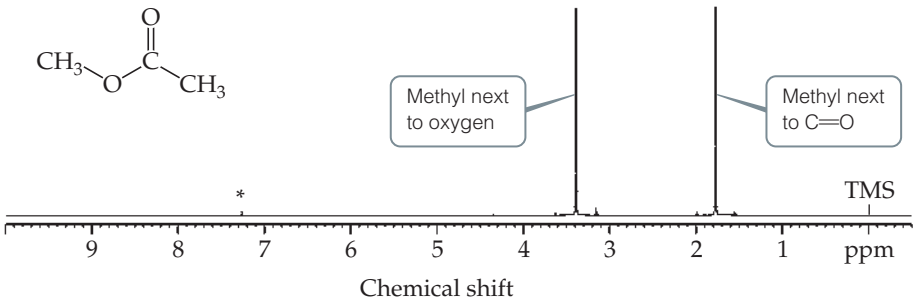
The result of the influence of these local magnetic fields is a **shielding** of the nuclei in question from the applied field by reducing its effect. In some instances, the local magnetic field of neighboring electrons can add to the applied field, **deshielding** the nuclei in question. The difference in resonance frequencies for various ^{1}H or ^{13}C nuclei within a molecule due to shielding or deshielding is generally very small but measurable. Such a difference leads the two nuclei in question to be *magnetically inequivalent*.



In fact, for a particular magnetic field B_0, the resonance frequencies of ^{1}H and ^{13}C are quite different. This is naturally advantageous when investigating either type of nuclei in isolation.

The Chemical Shift

Let us now consider the simplest case of a single ^{1}H nucleus within an applied magnetic field. Absorption of energy at the resonance frequency, which leads to the nuclear spin flip as shown in Figure 32.14, results in a detectable signal. However, because the resonance frequency depends on several factors, including the magnetic field strength (B_0) and the operating frequency of the spectrometer, chemists have developed a dimensionless quantity called the **chemical shift (δ)**, expressed in parts per million (ppm), to quantify the result. The chemical shift scale takes into account the shift in frequency of a particular nucleus from a standard (accepted universally to be tetramethylsilane, TMS), as well as the operating frequency of the spectrometer:



$$\delta = \frac{\text{Shift in resonance frequency from TMS (Hz)}}{\text{Operating frequency of the spectrometer (MHz)}} \qquad [32.5]$$

The chemical shift of an NMR absorption signal is constant, regardless of the operating frequency of the instrument. This is because the chemical shift scale is relative. Using δ allows a comparison between NMR spectra obtained on different spectrometers in different laboratories across the world.

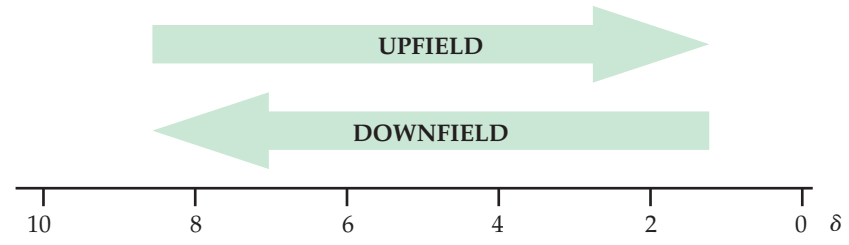
tetramethylsilane

The chemical shift of a ^{1}H nucleus that is strongly influenced by the electrons of an adjacent atom has a different chemical shift from a nucleus that is weakly influenced by neighboring electrons. This change in chemical shift is important and is diagnostic. Any competent organic chemist can use the information of functional group effects on

▶ **Figure 32.17 300 MHz ^{1}H NMR spectrum of methyl acetate** (inset) acquired in $CDCl_3$ solvent. The residual solvent is marked with an asterisk (*). Compare with the ^{13}C NMR spectrum of the same compound in Figure 32.12.

chemical shift to identify potential "leads". For example, the ^{1}H NMR spectrum of methyl acetate is shown in **Figure 32.17**. This compound has two "different" types of methyl groups: one adjacent to the carbonyl group and the other directly bonded to oxygen. The difference lies in the fact that the two methyl groups are *not* related by symmetry, that is, they are non-identical. Their effective magnetic fields, and hence δ, differ because the effects of the electrons associated with the neighboring carbonyl group and oxygen atom on the applied field are different—this is called *magnetic inequivalence*.

If a hydrogen is partially shielded from the applied field by local magnetic fields, the signal occurs *upfield* towards tetramethylsilane (TMS) (**Figure 32.18**). This is a shift to lower frequency. If the magnetic environment reinforces the applied field, the hydrogen is deshielded and the signal moves *downfield*, away from TMS. This is a shift to higher frequency. So, in the example of methyl acetate, the signal at δ3.39 is *downfield* of the signal at δ1.78.



Notice that the hydrogen atoms on each methyl group are equivalent to each other but different from the other methyl hydrogen atom set. Hence only two signals are seen, at 1.78 ppm and 3.39 ppm, in the ^{1}H NMR spectrum. The reason why the hydrogens of a methyl group form part of the same signal lies in the speed of rotation about the C—CH_3 or O—CH_3 bonds in methyl acetate. We mentioned in Chapter 24 that aliphatic alkanes are dynamic molecules, with free rotation about any single bond. This rotation is faster than the timescale of the NMR spectrometer at 300 K (which is the standard operating temperature of a spectrometer), so each hydrogen on the methyl group appears to be equivalent.

A spectrometer with an operating frequency of 400 MHz has a timescale of 400 000 000 times per second. Although several molecular dynamic events, such as rotation about a C—C bond, are faster than this, quite a few are slower—for example, hydrogen exchange rates and some conformational processes. These differences in timescale mean that NMR spectroscopy is a useful technique with which to study kinetic events.

Sample Preparation

Two other signals in the ^{1}H NMR spectrum of methyl acetate need to be accounted for. The first signal is arbitrarily assigned to 0.00 ppm and is a result of the 12 equivalent hydrogens of the reference compound, TMS, which is added to the NMR solvent. Historically, all other

Go Figure Is a methyl group resonance at 3.4 ppm shielded or deshielded compared with one at 1.8 ppm?

▲ **Figure 32.18 Chemical shift.** The term *downfield* refers to a higher chemical shift. Nuclei at high chemical shift are relatively *deshielded* by neighboring electron motions. A hydrogen resonance that is *upfield* resonates at a lower chemical shift value. These hydrogens are relatively *shielded* and are the furthest from the resonance of a bare hydrogen atom.

TABLE 32.2 Common solvents used for sample preparation in ^{1}H and ^{13}C NMR spectroscopy and the chemical shift of the residual solvent signal

Solvent	Residual solvent	δ_H (ppm)	δ_C (ppm)
$CDCl_3$	$CHCl_3$	7.26	77.16
CD_3OD	CHD_2OH	3.31	49.00
CD_3COCD_3	CHD_2COCD_3	2.05	29.84 206.26[a]
D_2O	HOD	4.79	—
CD_3CN	CHD_2CN	1.94	1.32 118.26[b]
$(CD_3)_2SO$	CHD_2SOCD_3	2.50	39.52

Data: H.E. Gottlieb, V. Kotlyar, A. Nudelman, *Journal of Organic Chemistry*, 1997, *62*, 7512.
[a] Value corresponds to carbonyl carbon.
[b] Value corresponds to nitrite carbon.

^{1}H signals are reported by their shift from TMS. Modern NMR spectroscopy, however, typically uses the *residual solvent signal* as the spectrum reference (see **Table 32.2**). There are two reasons for this. The addition of TMS (1% *v*/*v*) to a sample compromises the purity of the sample, even though it is usually removed easily by evaporation. Second, the sample needs to be in solution for this technique to be effective and, as there is usually some source of ^{1}H present in the solvent, a marker independent of the sample exists. This leads us to the last signal to be discussed from Figure 32.17, that of solvent.

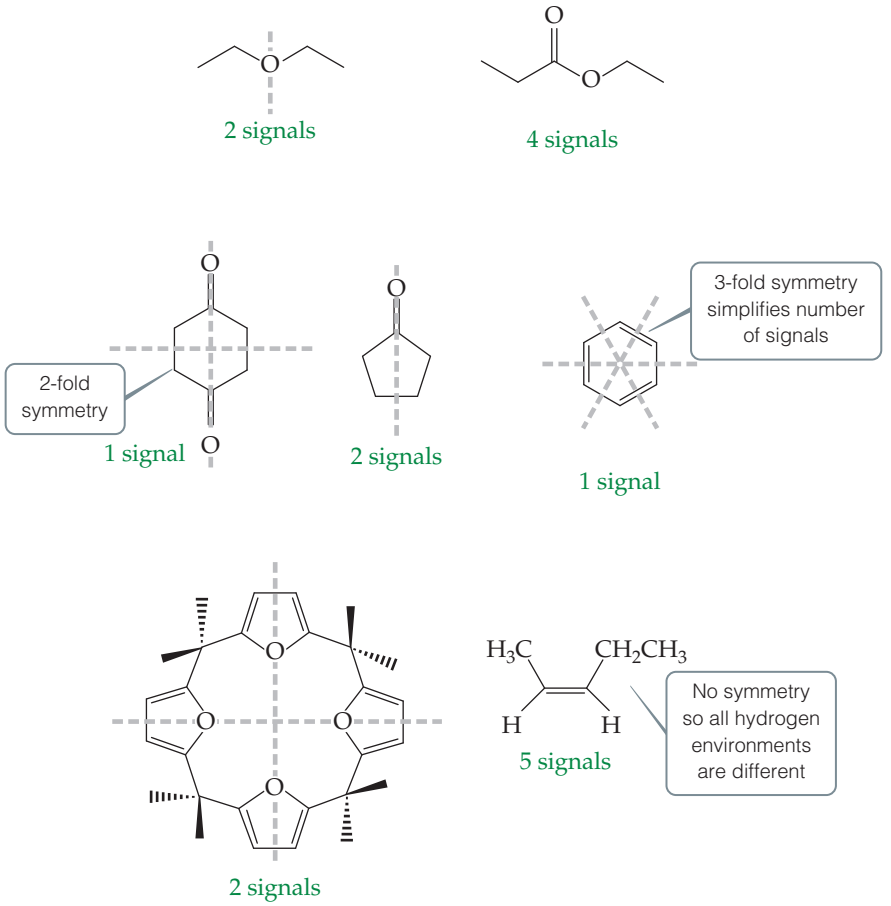
Recall from our initial discussion on the theory of NMR spectroscopy that any nuclei with a magnetic moment other than zero would produce an NMR spectrum. This means that ^{13}C produces an NMR signal while ^{12}C does not. Another way of saying this is that ^{12}C is *transparent* to the technique of NMR spectroscopy at the frequencies employed.

Typically, organic chemists use solvents to prepare an NMR sample, as a means of making the sample *homogeneous*. The type of solvent used is important because we need to distinguish between signals attributable to the sample and those from the solvent, especially when the solvent is in concentrations greater than 500 times that of the compound of interest in the preparation. This means that any solvent that contains hydrogens will also give rise to a ^{1}H NMR signal, which will be at least 500 times stronger than that of the sample. The effect is to "lose" the important sample signals.

To counter this problem, organic chemists use a range of ^{1}H NMR transparent (known as *deuterated*) solvents. Solvents such as deuterated chloroform ($CDCl_3$) or d_4-methanol (CD_3OD) become useful and common solvents in ^{1}H NMR spectroscopy because ^{2}H absorbs at a completely different frequency from ^{1}H, so does not interfere. However, although $CHCl_3$ or CH_3OH become unattractive in ^{1}H NMR spectroscopy for reasons described earlier, they are acceptable solvents in ^{13}C NMR spectroscopy. It is almost impossible (and certainly very expensive) to produce large quantities (liters) of 100% (v/v) pure deuterated solvents. Typically, an NMR spectroscopy laboratory would stock, for example, 99.8% $CDCl_3$ solvent. The extra 0.2% would contain protium rather than deuterium. This amount of $CHCl_3$ is still enough to produce a significant signal (known as the *residual solvent signal*) in the ^{1}H NMR spectrum of any sample (see Figure 32.17).

Interpreting NMR Spectra

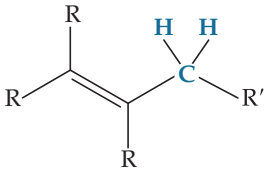
Three components of an NMR spectrum provide useful structural information about a molecule. They are:

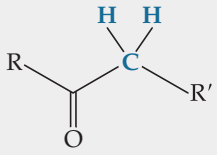


- *chemical shift* (δ)—gives evidence on neighboring functional groups;
- *integration* of the NMR signal—relative areas of signals in a ^{1}H NMR spectrum are proportional to the number of hydrogens giving rise to each signal;
- *coupling constant* (*J*)—measured in hertz (Hz), the coupling constant is extremely useful for determining the connectivity of nuclei within a molecule.

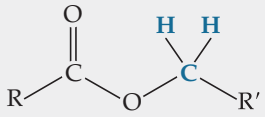
As you might expect, the result of an NMR spectroscopic experiment could become very complicated even with simple molecular structures. Luckily, molecular symmetry elements help to simplify matters. These symmetry elements occur in two ways. If the molecule has a plane of symmetry, then the two halves are identical and we need only concern ourselves with one-half of the molecule in order to work out its NMR spectrum. A few examples of the effects of symmetry on ^1H are shown in **Figure 32.19**.

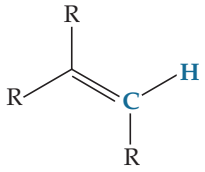
The second factor that simplifies a NMR spectrum was introduced in our earlier discussion on rotation about C—CH_3 bonds. In fact, this dynamic behaviour of rotation about C—C bonds usually leads to the two hydrogens on a methylene (CH_2) group being chemically and magnetically equivalent (Figure 32.19). This simplification using symmetry is a powerful way to differentiate between two constitutional isomers.

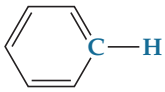


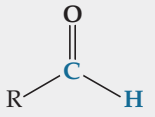


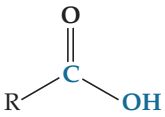
The typical ^1H and ^{13}C NMR chemical shifts for hydrogens and carbons with neighboring common functional groups are shown in **Table 32.3**. The ^1H signal associated with simple alkanes tends to resonate between 0.8 and 1.8 ppm, depending on their classification as primary, secondary or tertiary hydrogen atoms. The general trend for all other organic molecules is that δ depends on the electronegativity of nearby atoms and the hybridization of adjacent atoms. Thus the greater the electronegativity of a neighboring group (F > Cl > Br > I), the more deshielded the ^1H nucleus will be and the further downfield (higher δ) the ^1H NMR signal will lie. More than one electronegative group influences the signal even more, causing the ^1H signal to move further downfield (**Figure 32.20**).



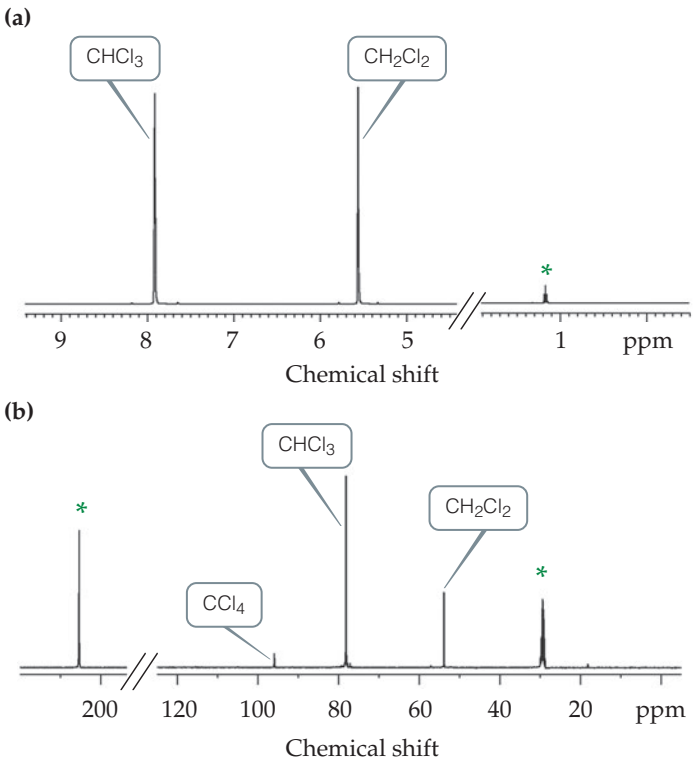








Go Figure How many signals would you expect in the ^{13}C NMR spectrum of the molecules shown in this figure?



▲ **Figure 32.19 Symmetry.** The number of NMR signals present in a spectrum depends on the symmetry of the compound in question. The higher the symmetry, the smaller the number of signals in the spectrum. Molecules with a single set of equivalent hydrogens will give rise to one ^1H NMR signal. Two or more sets of equivalent hydrogens will give different ^1H NMR signals for each set. Here, the number of signals seen in the ^1H NMR spectrum of each compound is indicated.

TABLE 32.3 Approximate chemical shift regions for ^1H and ^{13}C nuclei (colored) neighboring the most common functional groups

Type of neighboring group[a]	δ_H[b,c]	δ_C[c]
R**C**H_3, R**C**H_2R′, R_3**C**H	0.8–1.6	10–55
	1.5–2.5	40–80
	2.0–2.8	40–80

R—C≡C—**H**	2.0–3.0	65–85
R**C**H_2X (X=Cl, Br, I)	3.0–4.0	40–80
R**C**H_2OR′	3.0–4.0	40–80
R**C**N	n/a	110–130

Type of neighboring group[a]	δ_H[c]	δ_C[c]
	3.5–4.5	40–80
	4.5–6.0	100–150
RO**H**, RNH_2[d]	0.5–6.0	n/a
	6.5–8.5	110–160
	9.5–10.5	180–210
	10–13	175–185

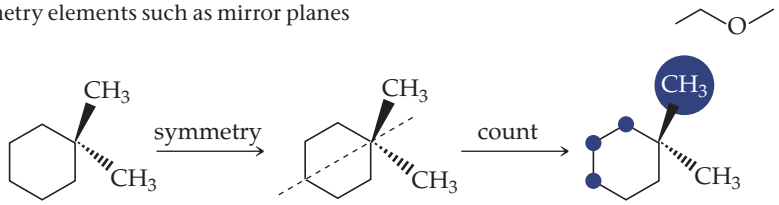
[a] R and R′ refer to simple aliphatic groups; Ar refers to an aromatic ring.
[b] Note that, when the symbol δ is used, there is no need to add ppm. Remember, chemical shift is dimensionless and ppm is not a dimension.
[c] Chemical shifts referenced to TMS.
[d] Both OH and NH NMR absorptions are typically broad as a result of the hydrogen exchange they exhibit with solvent and traces of water within the solvent.

◀ **Figure 32.20 Effect of electronegative atoms neighboring ^1H and ^{13}C nuclei on their chemical shift.** (a) 300 MHz ^1H NMR spectrum of $CHCl_3$ and CH_2Cl_2 in $(CD_3)_2CO$. (b) 75.5 MHz ^{13}C NMR spectrum of CCl_4, $CHCl_3$ and CH_2Cl_2 in $(CD_3)_2CO$. Asterisks indicate solvent or residual solvent signals.

Sample Exercise 32.2

Determining the number of NMR signals in a spectrum

How many absorptions would you expect in the ^{1}H NMR spectra of:
(a) 1,1-dimethylcyclohexane,
(b) ethyl methyl ether?



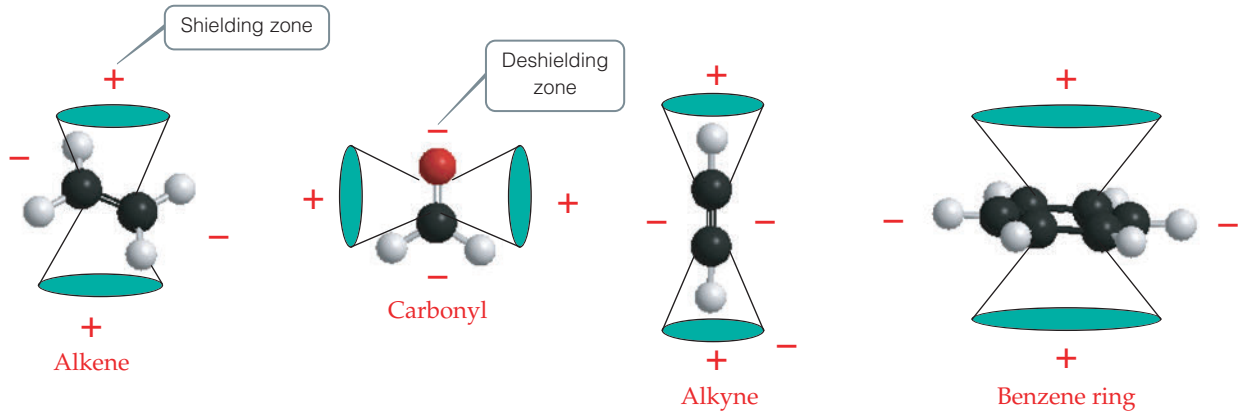
SOLUTION

Analyze We are asked to determine the number of "different" hydrogen environments in two molecules.

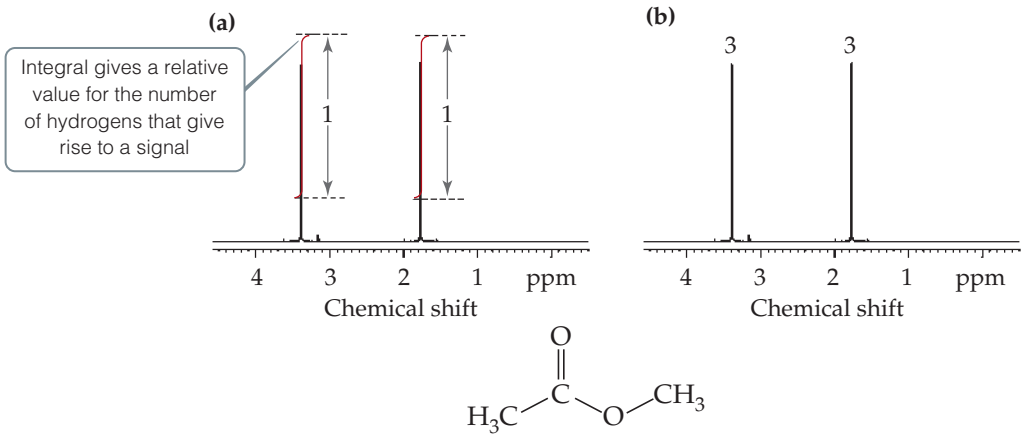
Plan We need to draw out the structure of each compound and look for symmetry. If no symmetry elements such as mirror planes exist, we then count up the number of *different* hydrogen atoms, remembering that hydrogens on the same carbon are equivalent in an alkane.

Solve

(a) The answer is four absorptions.
(b) The answer is three absorptions. In this case, there is no symmetry across the molecule.



Practice Exercise
How many absorptions would you expect in the ^{13}C NMR spectra of:
(a) cyclohexanone
(b) 2-methyl-2-butene?

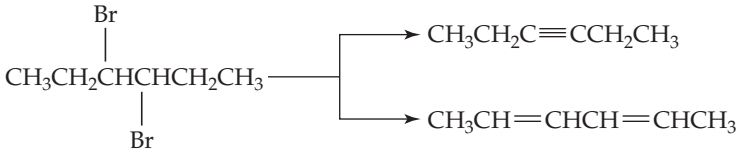


The chemical shift is also influenced by the hybridization of neighboring atoms (Figure 32.21). Generally, the more *p* character in a neighboring atom ($sp > sp^2 > sp^3$), the higher the chemical shift will be for the observed nucleus. This change in δ is due to the deshielding effect from the applied magnetic field produced by these bonds, as indicated in Figure 32.21. Note that orientation is an important factor in this generalization. The hydrogens on benzene are in a deshielding (−) zone, whereas those of ethyne, the carbons of which have more *p* character, are in a shielding (+) zone. In any case, the chemical shift of the signals attributable to either set of hydrogens is higher than that of a simple alkane.

Integration

Recall that in mathematical terms, **integration** refers to the area under a curve. The term *integration* in NMR is used to describe the area under each signal and is proportional to the number of equivalent nuclei that give rise to that signal. Integration is diagnostic in ^{1}H NMR experiments but used rarely in ^{13}C NMR experiments.

▲ **Figure 32.21** Deshielding effects in alkenes, carbonyls, alkynes and benzene. The magnetic fields associated with the π-electrons of the *sp* and sp^2 hybridized atoms cause regions of shielding (+) and deshielding (−) that influence the chemical shift of adjacent nuclei.



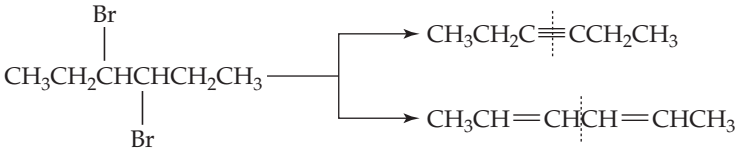
◀ **Figure 32.22 Integration.** (a) Integral lines indicate the area under the signal. This technique doesn't necessarily indicate how many hydrogens each signal accounts for, only their relative areas. (b) This method indicates the number of hydrogens associated with each signal. Both (a) and (b) yield the same information.

Two conventions describing the integration of a signal are used, as shown in **Figure 32.22**. The first method uses the height of the integral to give an area relative to other signals. For example, a ratio of areas that is 1 : 1 may in fact refer to a hydrogen ratio within the compound of 3 : 3, as for methyl acetate. An alternative method (and the one we use more often) does all the hard work for you. The numbers above the signals in Figure 32.22(b) equate to the numbers of protons that give rise to those signals. This result is based on the integration shown in Figure 32.22(a) and its application to the compound in question—methyl acetate in this example. Integration can help in structural analysis, particularly when determining symmetry.

Sample Exercise 32.3

Differentiating between products of a reaction

3,4-Dibromohexane can undergo base-induced double dehydrobromination to yield either 3-hexyne or 2,4-hexadiene. How could you use NMR spectroscopy to identify the product formed?

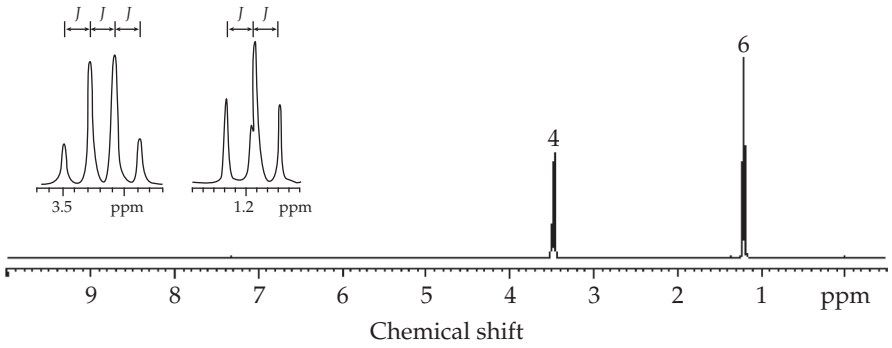


SOLUTION

Analyze We are asked to distinguish between the two possible products using NMR spectroscopy.

Plan As with all NMR questions of this kind, start with symmetry. Once identified, or not, count up the number of different carbon or hydrogen environments. Look for differences.

Solve Each potential product has a mirror plane, as shown here. Bearing this in mind, both products will exhibit three absorptions in their ^{13}C NMR spectrum.



However, the numbers of absorptions in the two ^{1}H NMR spectra are different. The alkyne will exhibit two absorptions while the diene exhibits three. Purely on this basis, the two potential products are distinguishable.

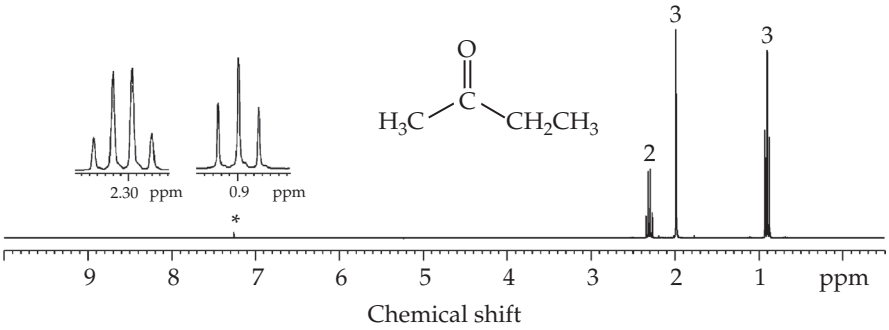
▶ Practice Exercise

Propene reacts with HBr potentially to produce two alkylbromides. Only one is formed, the outcome following Markovnikov's rule. How could you use NMR to determine which alkylbromide is the Markovnikov product?

Go Figure What does the very small signal at 7.3 ppm represent?

▲ **Figure 32.23 300 MHz ^{1}H NMR spectrum of diethyl ether in $CDCl_3$.** Inset: Expansions of the two signals showing the multiplicity of each signal.

singlet	1					
doublet	1	1				
triplet	1	2	1			
quartet	1	3	3	1		
quintet	1	4	6	4	1	
sextet	1	5	10	10	5	1



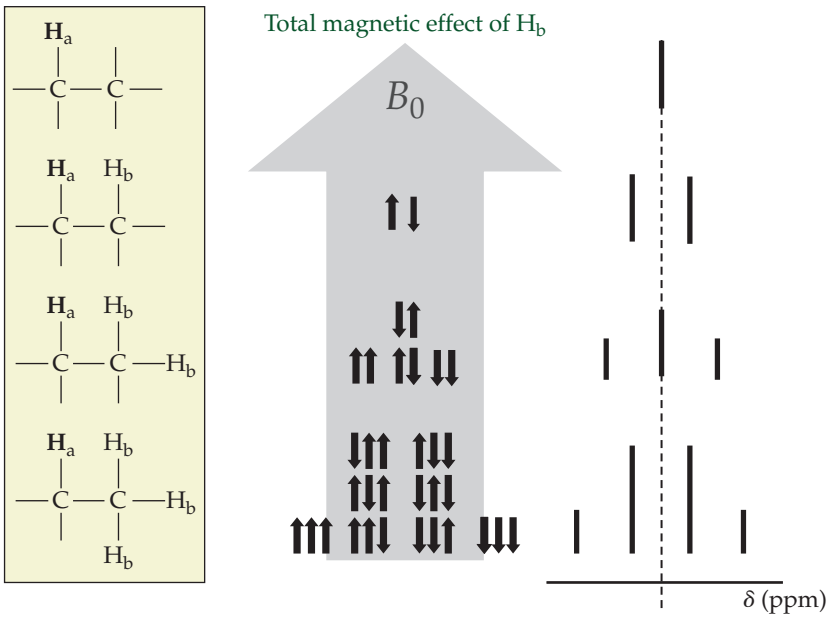
▲ **Figure 32.24 Multiplicity.** J is a quantitative measure of the magnetic interaction of coupled nuclei. The splitting pattern for nuclei with $I = \frac{1}{2}$ follows a binomial distribution. For example, if a signal is split into two peaks of equal intensity, that signal is called a doublet.

Spin–Spin Coupling

The last piece of NMR evidence we consider is probably the most powerful in determining structure. The concept is called **spin–spin coupling** or *J coupling*. So far we have looked at ^{1}H and ^{13}C nuclei in isolation. When two or more nuclei are close enough for their spins to interact or *couple*, the resulting signals split. This typically occurs if there are hydrogen atoms neigboring the nucleus that you are observing. The **splitting pattern** formed is characteristic of the coupling and yields more information about the nucleus's neighbor than it does about itself. For example, diethyl ether ($CH_3CH_2OCH_2CH_3$) has two sets of different hydrogens (as a result of symmetry), leading to two signals in the ^{1}H NMR spectrum (Figure 32.23). The chemical shift of these signals is influenced by the ether oxygen, with the hydrogens of the CH_2 being more deshielded. Closer inspection of the signals shows them to be complicated by very uniform patterns. This complicated pattern is a result of the *through-bond* communication between ^{1}H nuclei across the CH_2 and CH_3 groups. For any set of coupled hydrogens, the distance between peaks in each splitting pattern, termed the **coupling constant** (J), is identical. The magnitude of the coupling depends on the nature and number of intervening bonds between the two (or more) nuclei. The further away the coupling nuclei are from each other, the smaller the value for J. Therefore, a ^4J coupling (in which there are four intervening bonds) is smaller than a ^3J coupling (in which there are three intervening bonds). The pattern, or **multiplicity**, of the signals is derived from the number of identical nuclei that couple, and follows a binomial distribution, shown in Figure 32.24.

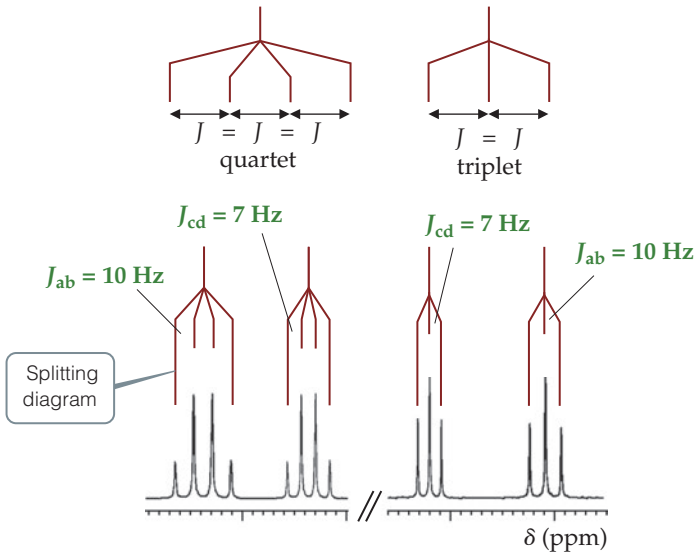
Hydrogen coupling does not usually proceed past a functional group within the carbon framework that doesn't contain ^{1}H. Figure 32.25 shows the ^{1}H NMR spectrum of 2-butanone to illustrate this point. The spectrum is dominated by three signals at 0.9, 2.0 and 2.3 ppm. An enlarged view of the resonance attributable to the methyl attached to the carbonyl group shows this signal to be a single sharp peak (or *singlet*), demonstrating

▶ **Figure 32.25 300 MHz ^{1}H NMR spectrum of butan-2-one in $CDCl_3$.** Despite the four intervening bonds linking ^{1}H nuclei, no ^4J coupling is observed at this operating frequency due to the carbonyl group. Residual solvent is marked with an asterisk (*).



that no coupling across the C═O group from the CH_2 group is seen. As with the ^1H NMR spectrum of diethyl ether (Figure 32.23), a characteristic splitting pattern is shown for the hydrogens of an ethyl group. Let's now take a more detailed look at this splitting pattern and why it occurs.

A nucleus coupled to n other equivalent nuclei (each with $I = \frac{1}{2}$) appears as a *multiplet* (Figure 32.24). The multiplicity attained for the signal of the coupled nuclei can be described as containing $(n + 1)$ peaks. The origin of this phenomenon, known as the **(n + 1) rule**, can be ideally described by considering two non-equivalent hydrogens, H_a and H_b, found on adjacent carbons. **Figure 32.26** illustrate the principle as well as the underlying reasoning. The chemical shift of H_a is influenced by H_b. In fact, this influence (and hence the multiplicity) is a result of the two possible spin orientations of H_b. The parallel orientation of nuclear spins adds to the applied field, causing the signal attributable to H_a to appear at a lower applied field (higher δ), whereas the anti-parallel orientation causes H_a to appear at a higher field (lower δ). These two signals (combined they are termed a *doublet*) occur on either side of the position H_a would occupy in the absence of the influence of H_b.

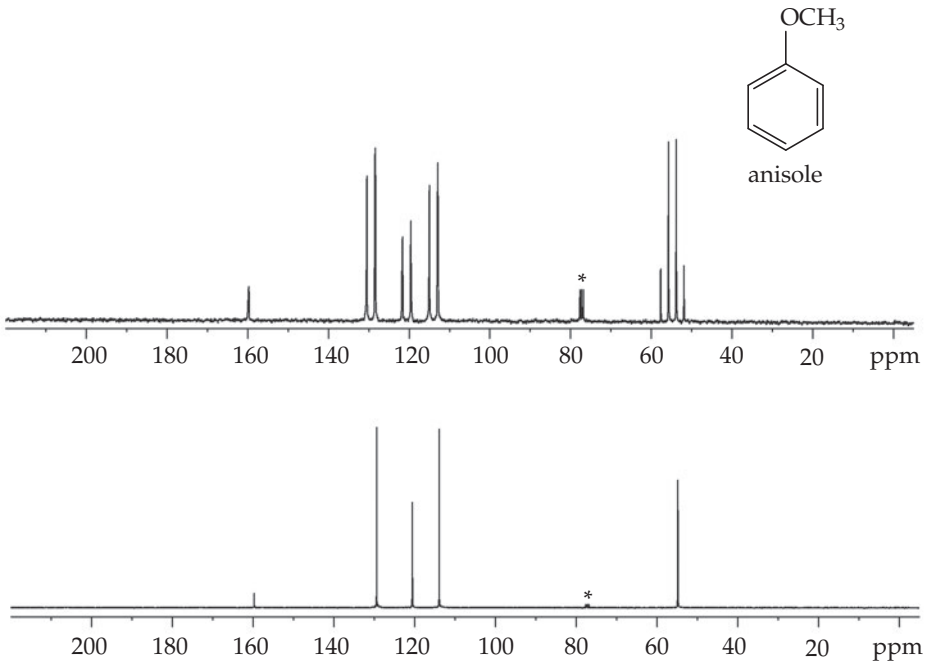


If we turn our attention back to the expanded region of the ^1H NMR spectrum of diethyl ether (Figure 32.23), we see that the CH_2 group is *coupled* to the three equivalent hydrogens of the methyl group. This coupling causes the signal attributable to the CH_2 hydrogens to split into four $(3 + 1)$ peaks with intensities in the ratio 1 : 3 : 3 : 1. This specific pattern is called a *quartet* (see Figure 32.24). Conversely, the methyl group couples

Go Figure

Determine the possible connectivity between hydrogen nuclei that show as a doublet and septet multiplicity with integration in the ratio 6 : 1, respectively, within the 1H NMR spectrum.

▲ **Figure 32.26 Origins of complex signal splitting.** The influence of the spin states of n neighboring H_b on the applied field causes the signal for H_a to split into 'n + 1' peaks. The splitting pattern and the relative peak heights are attributable to the additive and cancelling effect of H_b spins.



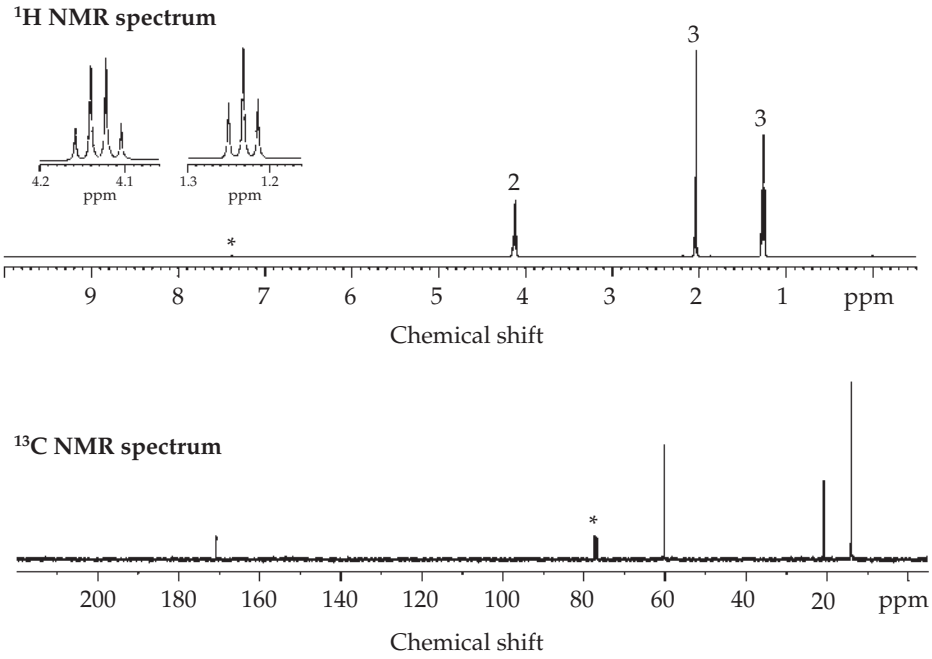
▶ **Figure 32.27 Coupling constants.** The spacing between each peak in a multiplet is called the coupling constant, *J*, expressed in hertz (Hz). Note that the *J* value between two mutually coupled nuclei is the same and different from that attained for other coupled pairs of nuclei. The coupling constant yields information on connectivity.

to the CH_2 group, splitting into three (2 + 1) signals in the ratio 1 : 2 : 1, with the distance between each signal in the *triplet* (known as the *J* value) being equivalent to those in the quartet. The permutations of nuclear spin "up" and "down" leading to the triplet and quartet are shown in Figure 32.26.

As organic chemists, we can use the information derived through individual *J* values to determine the connectivity of a carbon framework. **Figure 32.27** illustrates how the connectivity of two nuclei can be expressed by the magnitude of *J*. This spectrum contains two sets of triplets and two sets of quartets for an unknown compound. The triplet/quartet pattern is diagnostic of an ethyl group. So, intuitively, we might expect two sets of ethyl groups within the structure of the unknown. The difficulty lies in distinguishing between the two sets. Determination of the coupling constants, however, soon identifies which triplet is *coupled* to which quartet. We can use this information, together with the chemical shifts of the quartets, to determine the likely connectivity of the ethyl groups to other functional groups. Looking for sets of signals with the same *J* allows information to be extracted from very complex overlapping spectra. Because *J* values do not depend on the spectrometer, a spectrometer with a higher operating frequency will show the splitting of the signal compressed to a shorter distance on a δ scale, one more reason why higher operating frequencies are preferred for studying complex molecules.

^{13}C NMR Spectra

^{13}C NMR spectra are often used by chemists to indicate the number of different carbon atoms, as well as to provide some evidence on the nature of the functional groups contained within a molecule. In order to do this, ^{13}C NMR spectra often remove the multiplicity displayed by C–H coupling—a process called **decoupling**. As shown in **Figure 32.28** coupling of carbon to hydrogen complicates the spectrum to an unnecessary degree. By decoupling the ^{1}H and ^{13}C nuclei, all multiplicity is lost and the signals are simplified to singlets. This type of experiment is called a *heteronuclear decoupling* experiment because it decouples the effect of ^{1}H nuclei on ^{13}C nuclei. Note that the reverse is not necessary, that is, the need to decouple the effects of ^{13}C coupling on the ^{1}H NMR experiment. The reason is that ^{1}H is approximately 99% naturally abundant and ^{13}C is only 1% naturally abundant. Having such a low natural abundance means that, for the most part, the effect of ^{13}C nuclei contained within the sample is below the level of sensitivity for ^{1}H NMR spectroscopy. In ^{13}C NMR spectra, there are a number of factors that influence the intensity of the signal, not just the number of carbon atoms of a particular environment in the molecule. Consequently, integration is not usually performed on these signals.



◀ Figure 32.28 ^{13}C NMR spectra—when too much information complicates interpretation. Routinely, organic chemists undertake ^{13}C NMR experiments that involve decoupling the effect of ^{1}H to which it is attached. *Top spectrum*: Coupled ^{13}C NMR spectrum of anisole. *Bottom spectrum*: Decoupled ^{13}C NMR spectrum of anisole. Asterisks (*) denote $CDCl_3$ solvent.

Sample Exercise 32.4

Using NMR to Solve a Chemical Unknown

Compound A, with molecular formula $C_4H_8O_2$, has the following ^{1}H and ^{13}C NMR spectra. Deduce its structure using this information.

Note Numbers on top of signals represent integration values. Asterisk indicates signals due to solvent.

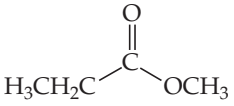
SOLUTION

Analyze We have been asked to use NMR spectra to deduce the molecular structure of a compound containing C, H and O.

Plan Based on chemical shift (δ) and splitting patterns in the ^{1}H NMR spectrum, we can deduce the structure of compound A. We will use the ^{13}C NMR spectrum to confirm the choice of structure.

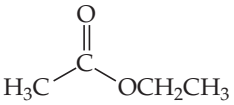
Solve The ^{1}H NMR spectrum contains three signals at about 1.2, 2.0 and 4.1 ppm, with integration in the ratio 3 : 3 : 2. This

Continued



integration totals the number of hydrogens in the molecular formula and so represents the molecule as a whole (no further symmetry).

Two of these hydrogen signals are split, forming a triplet and a quartet. This combined pattern is indicative of an ethyl group (CH_3CH_2) following the $n + 1$ rule, a deduction helped by the integration ratio.



The third signal is a three-hydrogen singlet, which means that the hydrogens on this methyl group (because it integrates for three hydrogens) do not couple. The chemical shift of this resonance implies that this methyl group is bonded to a carbonyl group, consistent with the lack of coupling within the signal (that is, a singlet).

At this stage we have accounted for all atoms in the molecule except for an oxygen atom. This must be linked between the ethyl and carbonyl groups in order to give rise to the chemical shift seen by the CH_2 group at 4.10 ppm.

Placing all this information together, suggests our unknown must be ethyl acetate.

Note the other ester

would have a chemical shift of 2.2 ppm for the CH_2 group, and a three-hydrogen singlet at 4.10 ppm.

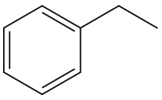
Check Our deduction is confirmed by the four signals within the ^{13}C NMR spectrum. The signal at 171 ppm indicates the presence of a carbonyl group. The signal at 60 ppm is indicative of a carbon attached to oxygen (in this case, as part of the ester group), with the two other signals at 13 ppm and 21 ppm consistent with the two methyl carbon atoms. Contrast this result with the spectrum of butan-2-one (Figure 32.25).

▶ Practice Exercise

A liquid sample has a band in the infrared spectrum at 1710 cm^{-1}. The NMR spectrum shows two ^1H resonances in the ratio of 3 : 2. The molecular formula of the unknown is $C_5H_{10}O$. Deduce its structure.

Self-Assessment Exercises

32.7 Which of the following nuclei will give an NMR spectrum: ^{16}O, ^{19}F, ^{31}P, and ^{32}S?



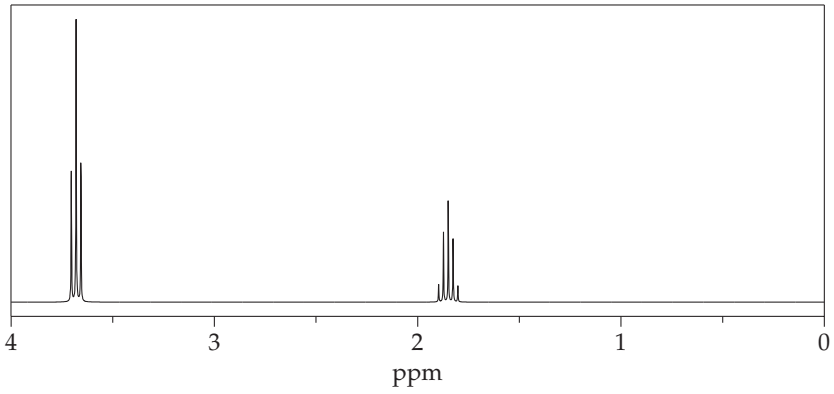
(a) ^{16}O and ^{19}F only

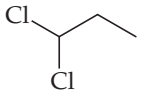
(b) ^{19}F and ^{31}P only

(c) ^{16}O and ^{32}S only

(d) ^{19}F and ^{31}P only

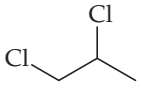
32.8 Consider ethylbenzene. How many signals do you predict would be in the ^1H NMR spectrum and what would be the relative sizes of the signals?





(a) Three signals in the ratio 2:2:1

(b) Five signals in the ratio 3:2:2:2:1



(c) Seven signals in the ratio 3:2:1:1:1:1:1

32.9 There are four constitutional isomers of dichloropropane, $C_3H_6C_{l2}$, shown here. Which one would have the ^1H NMR spectrum shown?

(a)

(b)

(c)

(d)

Exercises

32.10 Which of the following solvents could be used in ^{1}H NMR spectroscopy? Acetone (CH_3COCH_3), methanol-d_4 (CD_3OD), tetrachloromethane (CCl_4), water (H_2O), diethyl ether ($CH_3CH_2OCH_2CH_3$). Explain your choice.

32.11 Indicate the number of different absorptions and the relative intensities expected in the ^{1}H NMR spectra of:

(a) 2,2-dimethylbutane **(b)** ethanol

(c) acetone **(d)** 2-chloropropane

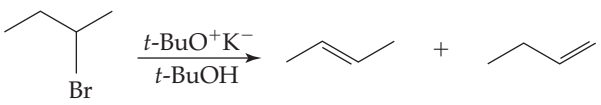
(e) cyclohexane **(f)** cyclohexanone

(g) ethyl methyl ether

32.12 Indicate the number of different absorptions expected in the ^{13}C NMR spectra of:

(a) 2,2-dimethylbutane **(b)** ethanol

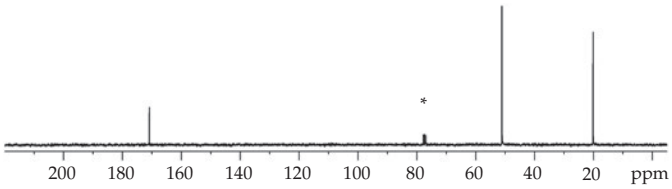
(c) acetone **(d)** 2-chloropropane



(e) cyclohexane **(f)** cyclohexanone

(g) ethyl methyl ether

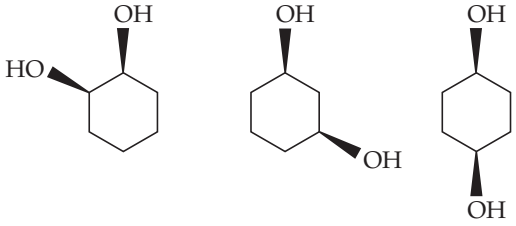
32.13 Predict the splitting pattern observed in the ^{1}H NMR spectrum for each of these compounds:



(a) CH_3CHBr_2 **(b)** $(CH_3)_2CHCl$ **(c)** $(CH_3)_3CBr$

32.14 2-Bromobutane undergoes a β-elimination reaction in the presence of potassium *tert*-butoxide to produce one of two isomeric alkenes.

How could you use NMR spectroscopy to determine which alkene is formed as the major product?

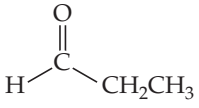


32.15 The reaction of an unknown with ethanol in the presence of a small amount of H_2SO_4 leads to a compound that smells distinctly like rum. The hydrogen-decoupled ^{13}C NMR spectrum of the product is shown here (* = solvent).

(a) What is the structure of the unknown?

(b) What other structure(s) would be consistent with this ^{13}C NMR spectrum?

32.16 Two bottles labelled *cis*-cyclohexandiol were found in a laboratory. Because of their differing melting points, the bottles clearly contained two different *cis*-cyclohexandiol isomers. To determine which isomer was in which bottle, the chemist decided to run ^{13}C NMR spectra on a sample of each. The three possible isomers were:



The two ^{13}C NMR hydrogen-decoupled spectra contained the following data:

- spectrum of sample in bottle A: 20.20, 62.55
- spectrum of sample in bottle B: 16.09, 29.52, 36.15, 63.08

Identify which isomer was present in each bottle.

32.17 The 200 MHz ^{1}H NMR spectrum of propanal (shown) has three distinctive resonances: δ9.5 (1H, singlet), 2.2 (2H, quartet), 1.0 (3H, triplet). Assign each resonance to the structure.

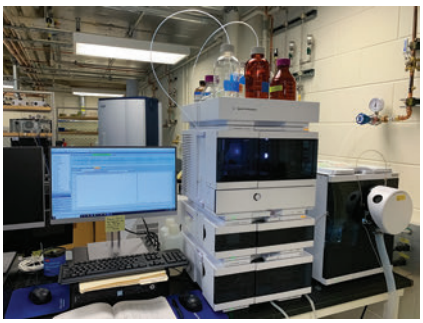
32.4 Mass Spectrometry

All international airports and many of the larger domestic airports require passengers to go through a security screening process. This generally involves two stages, the first being that all passengers pass through a metal detector while their hand luggage passes through an X-ray machine, both of which can detect metallic weapons. The second is a random check of a person's clothes and hand luggage using an explosive trace detector (ETD). Explosives are typically of rather few classes of compound, many of them containing nitro groups. These can be detected in minute quantities, well below that of visible particles. Mass spectrometry provides a fast and accurate means of identifying very small quantities of material. Now that compact 'bench-top' instruments are available, a mass spectrometer tuned to detect certain classes of compounds is a powerful ETD.



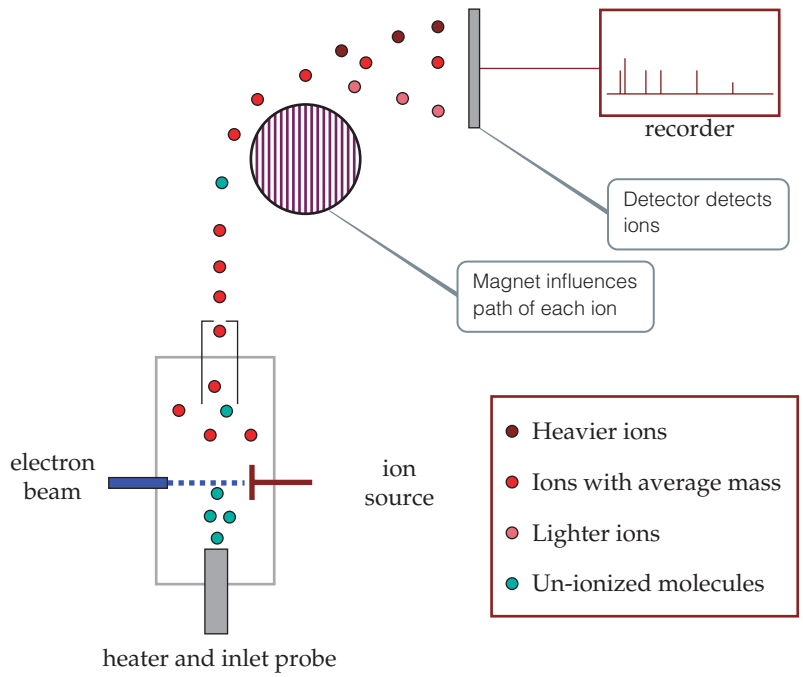
In this section, we examine how this technique can help identify unknown compounds. By the end of it, you should be able to:

- Understand the principle behind mass spectrometry
- Interpret simple spectra to provide some structural knowledge of a molecule

Mass spectrometry is distinctly different from the other characterization techniques introduced in this chapter. This technique does not depend on the absorption of electromagnetic radiation, but instead examines what happens when a molecule is bombarded with high-energy electrons. These electrons are used for two purposes. The molecule is *ionized* by the electrons and the electrons are used to break the molecule apart or **fragment** it, in a similar way to hitting a cricket ball through a pane of glass. The masses of the fragments are measured and brought together (in analysis) in order to reconstruct the molecule. Apart from determining the masses of the fragments, mass spectrometry can also indicate the mass of the *parent structure*, which in most instances, coincides with the signal of highest mass. This signal is called the **molecular ion**, or parent ion peak. Mass spectrometry is a technique used routinely to determine the molecular weight of a compound. The fragmentation pattern can give information on the functional groups present in molecules.

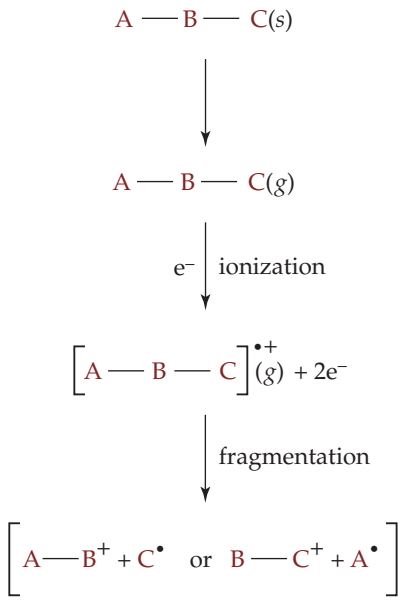
Mass spectrometry employs many different ionization techniques, including electron impact ionization (EI), chemical ionization (CI), fast atom bombardment (FAB) and more advanced techniques such as matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) and electrospray ionization (ESI) methods. Each of these different techniques has certain advantages, and the modern organic chemist uses more than one mass spectrometry technique to solve the structure of an unknown.

Mass spectrometry is also routinely employed in analytical laboratories as part of the identification of compounds in complex reaction mixtures, in the separation and identification of minute quantities of biologically active compounds, or in the identification of drugs in hair samples or trace explosives on luggage. **Figure 32.29** shows an ESI mass spectrometer (right) linked to a high-performance liquid chromatography (LC) unit (left), which is an instrument routinely used for separating complex mixtures. The combination, known as LCMS, is a powerful analytical technique.



▲ **Figure 32.29 A modern LCMS.** Mass spectrometry is often used in combination with other techniques, typically separation techniques such as liquid chromatography (LC) or gas-phase chromatography (GC). This LCMS is made up of three components: auto-sampler (left), liquid chromatography instrument (center) and electrospray mass spectrometer (right). As different compounds are separated from a mixture by LC, they are analyzed for their molecular mass.

Electron Impact Ionization Mass Spectrometry

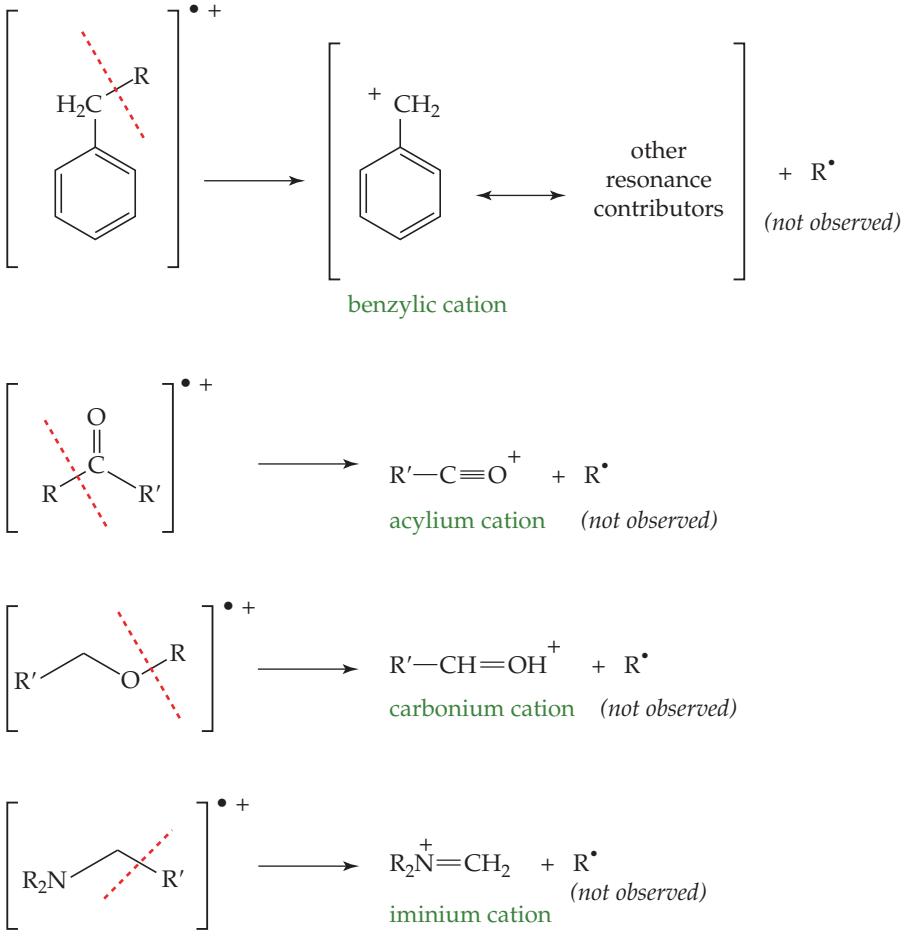


In this section, we concentrate on **electron impact ionization (EI) mass spectrometry (EIMS)** because it most clearly shows the principles of mass spectrometry, even though more complex methods are used more often today. Mass spectrometers using the EI technique operate by determining the *mass-to-charge ratio* (m/z) for ions in the gas phase. **Figure 32.30** illustrates how a result is obtained using an EI mass spectrometer. There are three principal components to EIMS: an ion source, which ionizes molecules in a high vacuum and accelerates them to form a beam; a strong magnet to deflect or separate the ions according to their masses; and a detector that records the masses of the ions generated. The intensity of each signal is then plotted as a function of the mass-to-charge ratio (m/z).

The sample to be analyzed by EIMS is vaporized by heating to the gas phase within the inlet probe. Ionization of the sample occurs when a beam of high-energy electrons (10–70 eV, 1 eV = 96 kJ/mol) collides with the sample. Energy is transferred as a result of that collision, removing an electron from the molecule and yielding a positive ion. In this case, we say that the organic molecule has been *ionized* by electron impact and the signal that results is called the molecular ion signal (M^+). This molecular ion has the same mass

Go Figure Why are neutral species not detected by this method?

▲ **Figure 32.30 The principle behind electron impact ionization mass spectrometry.** The technique relies on generating charged species (ions) by bombarding a gas-phase sample with high-energy electrons.



▲ **Figure 32.31** **Ionization and fragmentation.**

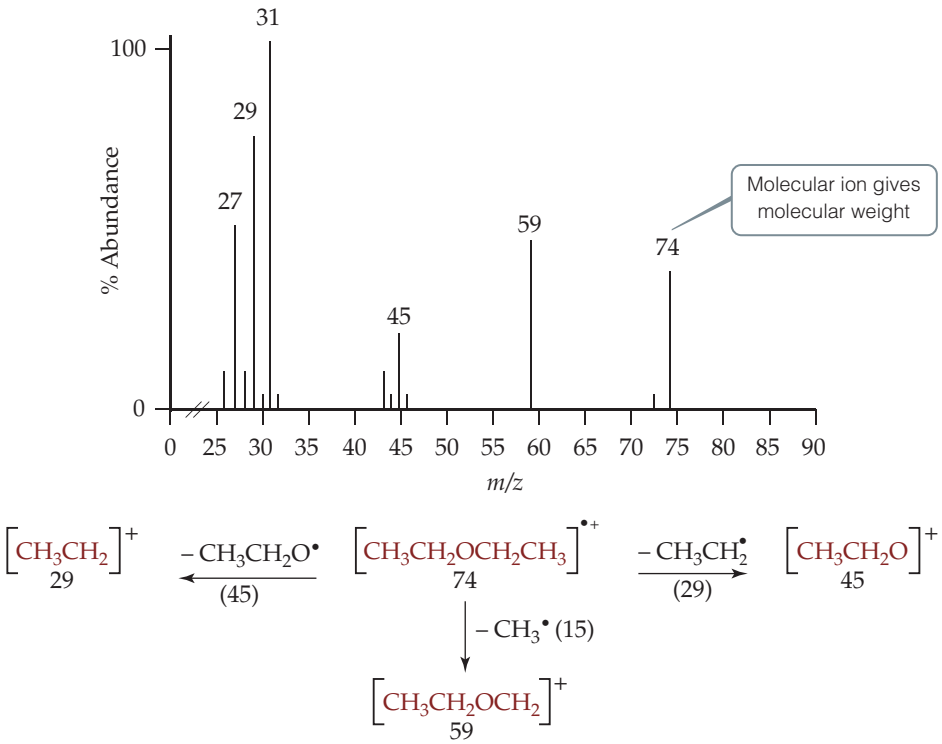
as the neutral molecule less the mass of a single electron, which is of course negligible compared with the mass of the molecule.

If the electron collides with the molecule at higher energy (that is, around 70 eV), it not only brings about the ionization of the molecule but also causes dissociation or *fragmentation* of the molecule, as shown in **Figure 32.31**. This fragmentation process gives a characteristic mixture of charged ions and uncharged radicals. The ions are detected easily, whereas the uncharged radicals are neither accelerated nor detected, but can be inferred by the difference in the mass between the molecular ion and the observed fragment. The type of cation (and radical) formed depends on the nature of the functional groups present, so fragmentation becomes diagnostic for functional group types. Those fragments able to stabilize the positive charge, such as allylic cations (derived from alkenes), benzylic cations ($C_6H_5CH_2^+$), acylium cations (derived from aldehydes and ketones), iminium cations (derived from amines) or oxonium cations (derived from alcohols and ethers), are always favored (**Figure 32.32**).

Once the ionization and fragmentation processes have occurred, the ions formed are separated and detected. Initially, the positively charged ions are attracted to a negatively charged accelerator plate that forms a narrow slit, allowing only a stream of ions to pass through. Once past the slit, the positive ion enters an evacuated tube where its flight path is perturbed by the poles of a large magnet. As the positive ion passes through the magnetic field, its path is bent. The degree of bending depends on the mass of the fragments but also on their charge. The detector then converts the signal it receives into a mass spectrum.

Go Figure Using resonance contributors, describe how a benzylic cation is able to be stabilized.

▲ **Figure 32.32** **Fragmentation of molecular ions.**



Interpreting Mass Spectra

Two aspects of a mass spectrum lead the chemical detective to the identity of a compound. The first, called the **mass-to-charge ratio,** is symbolized by m/z (see Figure 32.33), where m equals the mass of the ion (in u) and z is its charge. Typically, organic chemists use the term m/z as a dimensionless quantity. As the charges on ionized or fragmented molecules almost always equate to +1, the mass-to-charge ratio for a particular signal in the mass spectrum is equal to the mass of that ion. These signals are assigned as a percentage abundance with respect to the most intense signal in the spectrum, called the **base peak**. The base signal does not necessarily correspond to the mass of the molecular ion—it is simply the most intense signal in the spectrum. For example, the base peak in Figure 32.33 occurs at $m/z = 31$ and is the result of fragmentation leading to the cation CH_2OH^+. The molecular ion is found at $m/z = 74$. Figure 32.33 also illustrates the possible fragmentations leading to each of the signals within the mass spectrum. Note that only the positively charged fragments lead to the signals in the spectrum. All the neutral fragments are unaffected by the magnet and do not impact on the detector.

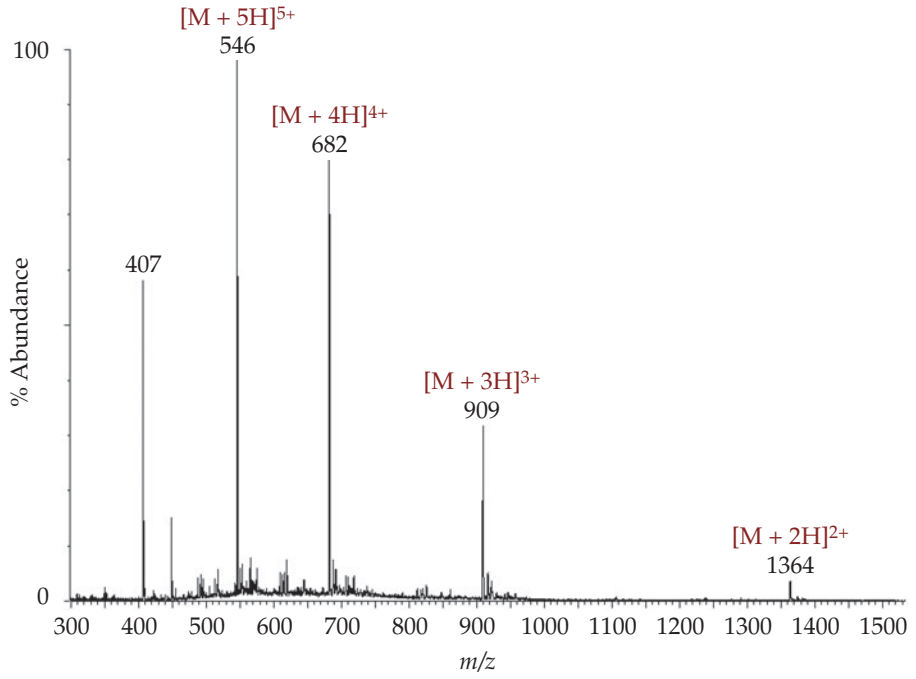


Figure 32.34 illustrates the principle of the mass-to-charge ratio by looking at species containing z values greater than 1. The signals at $m/z = 546, 682, 909$ and 1364 all equate to the same molecular weight, 2726 u. The non-unity charge is due to this molecule's ability to react with H^+ at multiple sites, leading to multiple-charged species. This effect is common in subtle techniques such as ESI rather than in the chemically harsher techniques of EI and CI.

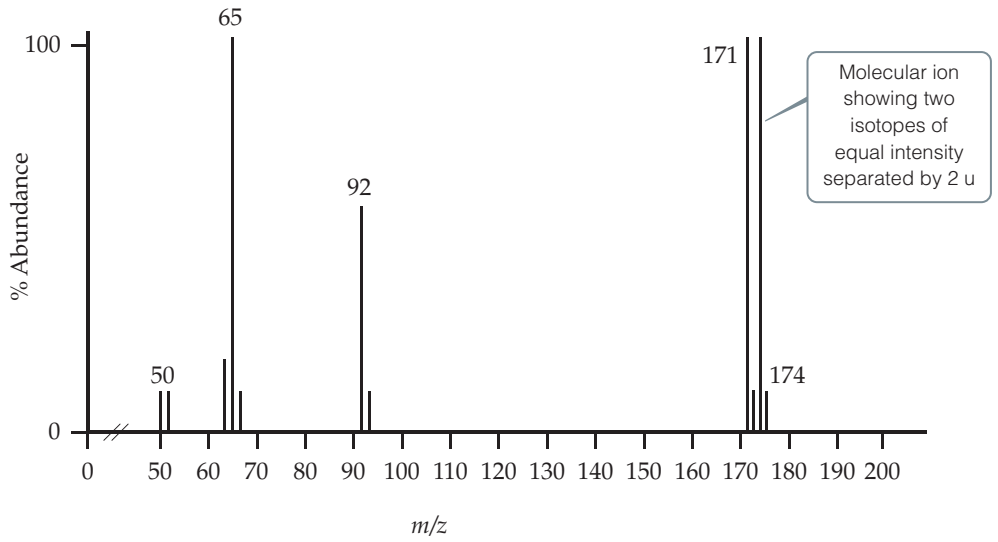
Routine mass spectrometry such as the type we have been describing is a low-resolution technique, meaning that the particle masses are rounded typically to a whole number. This means that carbon is taken as 12 u (^{12}C), oxygen as 16 u (^{16}O) and nitrogen as 14 u (^{14}N). However, most elements exist in more than one isotopic form. The heavier isotopes also give rise to small signals in the mass spectrum, higher than that of the molecular ion signal. These signals are sometimes called the $[M + 1]^+$ or $[M + 2]^+$ signals and can be very diagnostic in some instances. Table 32.4 gives the isotopic composition of some common elements, showing how they contribute to $[M + 1]^+$ or $[M + 2]^+$ signals. The isotopes for chlorine and bromine are highlighted as they show the most diagnostic abundance distributions.

For the most part, the $[M + 1]^+$ and $[M + 2]^+$ signals are significantly smaller (less than 1%) than the parent ion or molecular ion signal. However, chlorine exists as two

◀ **Figure 32.33 EI mass spectrum of diethyl ether**. The fragmentation pattern seen within the EI spectrum is also deduced, showing the loss of different radicals from the initially ionized diethyl ether. Remember, uncharged fragments such as $CH_3^•$ and $CH_3CH_2^•$ are not observed.



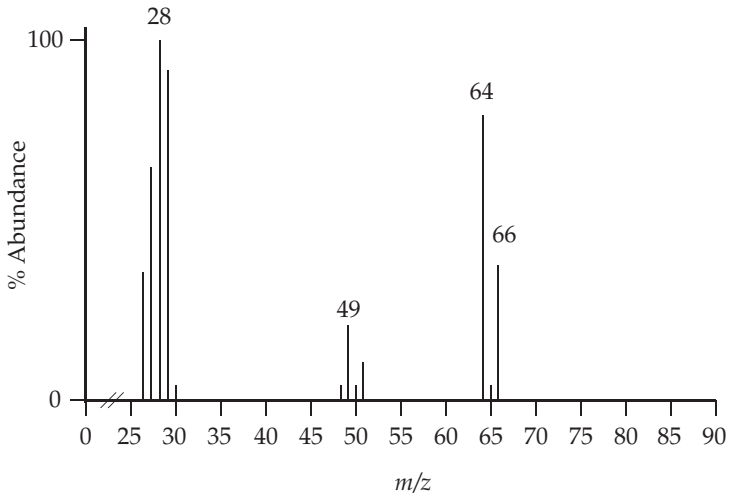
▶ **Figure 32.34 Mass-to-charge ratio.** Multiple charged fragments yield signals within the mass spectrum corresponding to greater masses. For example, a molecule with molecular mass *M* will yield a signal at *M*/2 when doubly charged. This electrospray spectrum is of a new type of therapeutic agent designed to interfere with the translation of the mRNA code to protein. Notice that this type of ionization leads to very little fragmentation, but does allow the sample molecules to accumulate protons, leading to multiple charged ions.

TABLE 32.4 Isotopic distributions for some common elements

Element	M	% Abundance	M + 1	% Abundance	M + 2	% Abundance
Hydrogen	^{1}H	100				
Carbon	^{12}C	98.9	^{13}C	1.1		
Nitrogen	^{14}N	99.6	^{15}N	0.4		
Oxygen	^{16}O	99.8			^{18}O	0.2
Sulfur	^{32}S	95.0	^{33}S	0.8	^{34}S	4.2
Chlorine	^{35}Cl	75.5			^{37}Cl	24.5
Bromine	^{79}Br	50.5			^{81}Br	49.5
Iodine	^{127}I	100				

isotopes, ^{35}Cl and ^{37}Cl, with respective isotope abundances of 75.5% and 24.5%. Bromine is the most easily recognized of the halogens. It has two signals, one for ^{79}Br and one for ^{81}Br, of near equal intensity (50.5% and 49.5%, respectively). What this means is that, if bromine is present in a molecule, the $[M + 2]^+$ ion has an intensity nearly equal to the molecular ion. This is illustrated in the EIMS spectrum of 4-bromoaniline, shown in **Figure 32.35**. Iodine is typically recognized by the presence of iodine cation (I^+) at *m/z* 127. This clue is also combined with a characteristic 127 separation in the mass spectrum between the molecular ion signal and the first fragmentation. If chlorine is present, the $[M + 2]^+$ signal is about one-third as large as the M^+ signal.

There is one last aspect of mass spectrometry that we should discuss. To do this, we consider the molecules propane, acetaldehyde and CO_2. Each one produces a molecular ion with a mass of 44 u. Under the low-resolution methods we have been applying to date, we would not be able to tell these molecules apart. If, however, we use a high-resolution approach by not considering the mass of atomic hydrogen (^{1}H) as 1 u but as 1.0078 u and ^{16}O as 15.9949, then the three molecules in question (with different molecular formulas) will correspond to different exact masses—C_3H_8, C_2H_4O and CO_2 have exact masses of 44.0626, 44.0262 and 43.9898 u. For this high-resolution technique to be useful, accurate masses are always quoted to four decimal places. Analysis requires a highly accurate measurement (± 1 part in 10^6). The result can then be compared with exact masses calculated for various element combinations. Note that, by definition, ^{12}C has an atomic weight of 12.0000 u.



◀ Figure 32.35 EI mass spectrum of 4-bromoaniline. Note the diagnostic M^+ and $[M + 2]^+$ signals of equal intensity and the spacing of 79 u between the molecular ion and first fragmentation. These clues all indicate that the molecule contains bromine.

Sample Exercise 32.5

Interpreting Mass Spectra

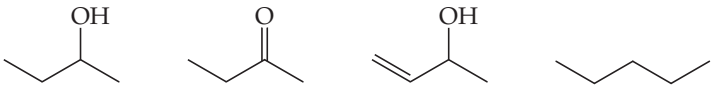
An EI mass spectrum of compound B, a simple haloalkane, is shown here. Deduce its structure.

SOLUTION

Analyze We are asked to deduce the structure and hence molecular formula based on the mass spectrum observed.

Plan Use the M^+ and $[M + 2]^+$ signals to deduce the halide present, as well as the molecular formula. Use the fragmentation patterns to confirm your deduction.

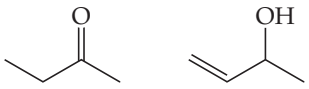
Solve The relative abundance of the M^+ and $[M + 2]^+$ signals suggests that chlorine is the likely halide, although the observed ratio of these two signals is slightly different from the expected 3 : 1 ratio. The presence of Cl within the structure is confirmed by the difference between the M^+ and the second fragmentation of 29 u (difference = 35). The position of this second fragmentation also coincides with the cation $CH_3CH_2^+$. Hence, the structure of our unknown must correspond to *chloroethane*.



Check The fragmentation signal at 49 u corresponds to the loss of a methyl radical (15 u) from M^+.

▶ Practice Exercise

The mass spectrum of compound C contains major peaks at m/z = 88, 73, 45, 43 and 29. Confirm that this fragmentation pattern is consistent with compound C being ethyl acetate.



Self-Assessment Exercises

32.18 Which molecule will have a molecular ion at $m/z = 74$ in its mass spectrum?

(a) **(b)** **(c)** **(d)**

32.19 A mass spectrum has signals at m/z = 72, 57, 43, 29, and15. Which molecule will give rise to this pattern?

$m/z = 72$ $m/z = 72$

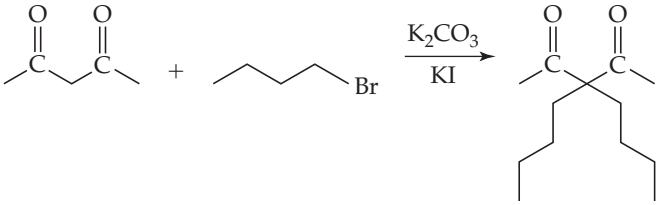
(a) **(b)**

Exercises

32.20 Carbon tetrabromide shows nine signals in the region $m/z = 328–337$ of the EI mass spectrum. Account for each of these signals.

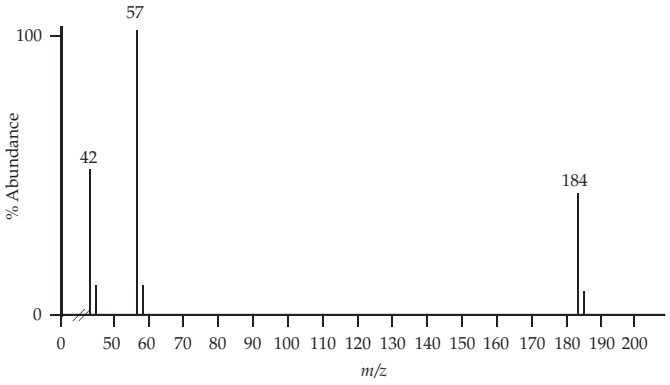
32.21 An aliphatic compound gives the following result from microanalysis: C, 66.6%; H, 11.2%. The mass spectrum reveals a molecular ion signal at $m/z = 72$. Determine the compound's molecular formula.

32.22 **(a)** What are the labels on the axes of a mass spectrum?



(b) In order to measure a mass spectrum of an atom or molecule, the atom or molecule must first lose (or gain) one or more electrons. Why is this so?

32.23 Illustrate the stability of the following cations by drawing any contributing resonance structures.



(a) acylium cation **(b)** carbonium cation

(c) iminium cation

32.24 Following a literature procedure, a student added butyl bromide (three equivalents) to 2,4-pentanedione in the presence of excess potassium carbonate and potassium iodide, as shown in the following reaction scheme:

As well as isolating the product, the student also isolated a clear oil which she promptly submitted for EIMS. The results are shown here. What is the structure of the by-product? [*Hint:* Look at the difference in mass between the molecular ion and the base peak.]

32.25 With the aid of a diagram, describe what the EI mass spectrum of 2-chloropropane might look like.

32.5 Compound Identification Using Spectra

Whether you are a police scientist in a forensic laboratory, a medical scientist in a pathology laboratory, or a research scientist in a synthesis laboratory, you will come across substances that need identifying. More often than not, a combination of techniques including chemical observations as well as instrumental analysis will be needed. Being able to pick the salient information from each bit of data and put it together to generate a structure based on evidence is a skill that takes practice to acquire. Often, an iterative process is useful. First, you "skim" the information to give a "first guess" at the substance. You then use this structure to see if it matches the information from the tests and analysis, refining the structure when the data is inconsistent with your first guess. Eventually, you refine the structure to a point when all the evidence you have is consistent with that structure.

In this section, we introduce this process and show how a combination of chemical tests and instrumental techniques may be used to solve a structure. By the end of this section, you should be able to:

- Identify simple substances based on chemical analysis and instrument data.

Deducing the Molecular Formula of an Organic Compound

To work out the empirical formula of an organic compound, an organic chemist subjects a small amount of sample to *microanalysis*. This destructive technique combusts the sample and analyses the amount and type of gas released. From these data, a percentage C, H, N is obtained based on weight. The remaining percentage is inferred as the content of O in the sample. Manipulation of these percentages, by taking into account the atomic masses of C, H, N and O leads to an empirical formula, from which a molecular formula can be determined, normally in conjunction with the value for the molecular ion signal in the mass spectrum.

In Chapters 24 and 26, we identified the general molecular formula of an alkane as C_nH_{2n+2}, a cycloalkane is C_nH_{2n} and the corresponding alkene also has the same general molecular formula, C_nH_{2n}. This difference in molecular formula between, for example, alkanes and alkenes actually yields important structural information. While the example

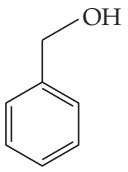
Sample Exercise 32.6

Microanalysis to Molecular Formula

The IR spectrum of a liquid aromatic compound has a broad band in the range 3000–3500 cm^{-1}. EIMS indicates a molecular ion signal at $m/z = 108$ and a sample of the unknown does not dissolve in 1 M NaOH. Microanalytical results for this unknown are: C, 78%; H, 7.4%. Deduce the molecular formula of this unknown.

SOLUTION

Analyze We are asked to use a set of analytical and chemical data for an unknown and asked to calculate its molecular formula.



Plan Work out the empirical formula and use the molecular ion result from EIMS to yield the molecular formula.

Solve The elements present are C = 78%, H = 7.4% and O = 14.6%. Taking into account their atomic weights:

$$\begin{aligned} C : H : O &= \frac{78}{12} : \frac{7.4}{1} : \frac{14.6}{16} \\ &= 6.5 : 7.4 : 0.91 \text{ (divide by smallest number)} \\ &= 7 : 8 : 1 \end{aligned}$$

Therefore the empirical formula is C_7H_8O. The empirical mass is equivalent to the molecular ion signal, so the molecular formula is also C_7H_8O.

Although this answers the question, let's use the extra information given to us to deduce a structure. We know that the molecule is aromatic (therefore it contains C_6) and contains an O—H stretching band in the IR spectrum (therefore it contains OH). Eliminating these fragments from the molecular formula leaves CH_7. Not being soluble in 1 M NaOH rules out that the unknown is a phenol. Using the remaining carbon atom to bridge the aromatic and OH groups yields benzyl alcohol as a likely suspect.

Practice Exercise

(a) An unknown liquid has an IR spectrum with a band at 3330 cm^{-1}. EIMS indicates a molecular ion signal at $m/z = 60$. Microanalytical results are: C, 60%; H, 13.4%. Deduce the molecular formula of the unknown.
(b) An unknown compound has a band at 1710 cm^{-1} in the IR spectrum. EIMS indicates a molecular ion signal at $m/z = 88$ and a base signal at $m/z = 43$. Microanalysis gives: C, 54.5%; H, 9.15%. Deduce the molecular formula of the unknown.

is trivial, knowing something about the **index of hydrogen deficiency (IHD)**, which is essentially the summation of all π-bonds and rings within a molecule, is useful when determining possible structures of compounds, especially alkenes, ketones and aldehydes, amines, alkyl halides and so on. The IHD quantity is determined by comparing the number of hydrogens in the molecular formula of an unknown with that of an *alkane* reference containing the same number of carbon atoms as the unknown. This last statement can be summarized in the following way:

$$\begin{aligned} \text{IHD} &= \text{Number double bond or ring equivalents} \\ &= \frac{\text{maximum number H possible per C} - \text{actual number H per C}}{2} \end{aligned} \qquad [32.6]$$

Let's investigate the molecular formula, $C_4H_8O_2$, used in Practice Exercise 32.6(b). The index of hydrogen deficiency is

$$\text{IHD} = \frac{\overbrace{(2n+2)}^{\text{maximum number of H atoms possible}} - \overbrace{8}^{\text{actual number}}}{2}$$

where $n = 4$

$$\begin{aligned} \text{IHD} &= \frac{(2 \times 4 + 2) - 8}{2} \\ &= 1 \end{aligned}$$

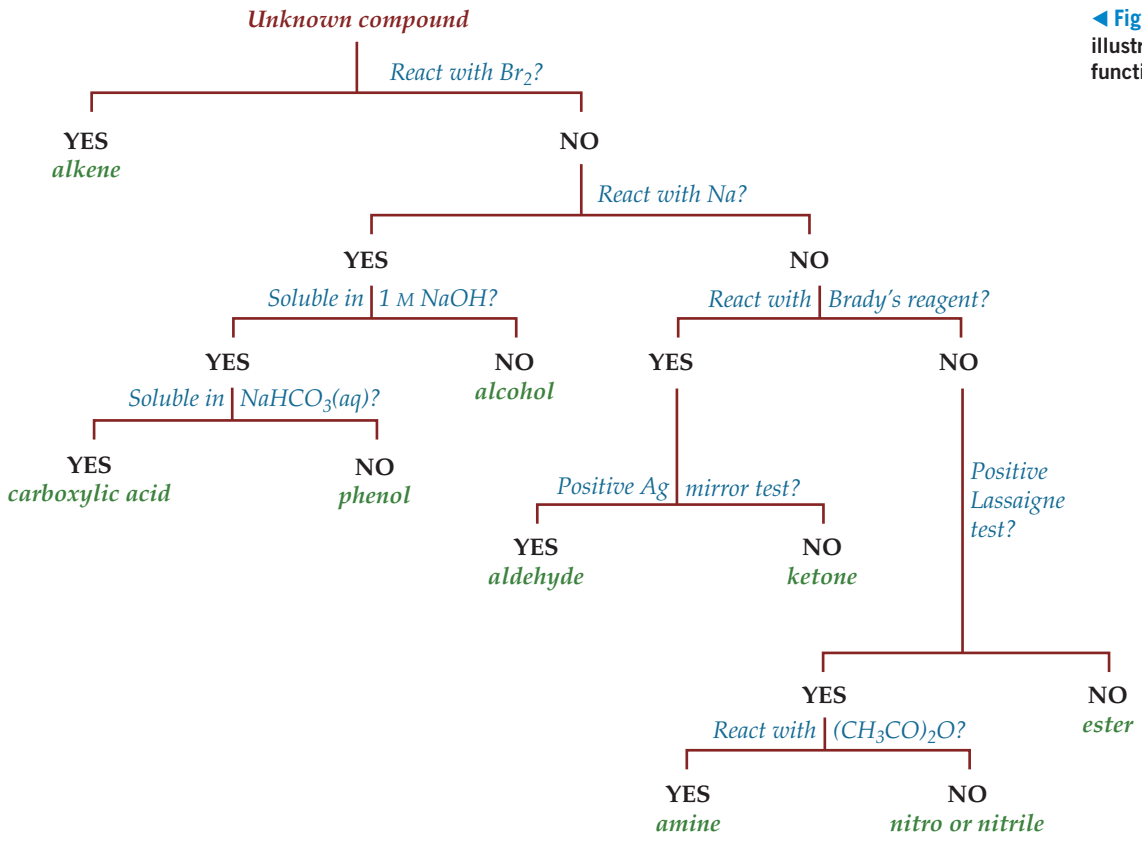
which means that one double bond (or a ring system) must exist within the molecule. This unknown is ethyl acetate. The presence of a C=O double bond in ethyl acetate supports our IHD calculations. While this calculation works for compounds containing C, H and O, other elements can complicate matters.

To help us, several guidelines have been devised to determine IHD.

1. Work out the molecular formula of the *reference alkane* based on the number of carbon atoms in the unknown's molecular formula.
2. For each halogen in the unknown's molecular formula, *subtract* one hydrogen off the reference's molecular formula.
3. For each nitrogen in the unknown's molecular formula, *add* one hydrogen to the reference's molecular formula.
4. Make no modifications for oxygen or sulfur in the formula.

Chemical Wet Testing: Tests for Functional Groups

As long as enough of an unknown compound is present, chemical wet tests are useful for providing clues to the types of functional groups present. These tests may be as simple as solubility in aqueous solution or as complex as two- or three-step processes in a micro-test tube. **Figure 32.36** illustrates the process of using functional group tests to offer clues to an unknown's structure. This flow diagram has a significant amount of chemistry, so we will briefly point out the requirements for a positive test for each functional group. Much of this chemistry has been dealt with in the preceding chapters.



Alkenes: The decolorization of a bromine solution when applied to an organic molecule usually indicates the presence of an alkene.

Alcohols: Alcohols of low molar mass, such as CH_3OH and CH_3CH_2OH, mix completely with water, but those with larger non-polar alkyl groups have low solubility. The addition of sodium metal to alcohols will evolve hydrogen gas (bubbles) generating the alkoxide.

$$2\ ROH + 2\ Na \longrightarrow 2\ RO^- + 2\ Na^+ + H_2(g) \qquad [32.7]$$

Alcohols do not react with aqueous hydroxide.

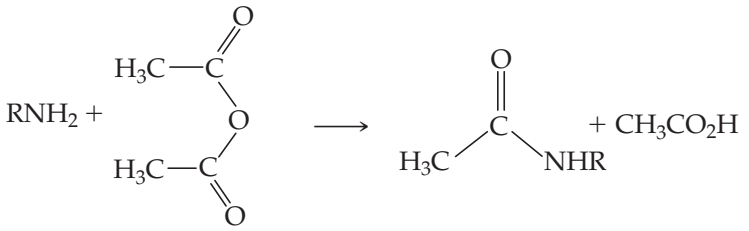
Phenols: Phenols behave as weak acids with pK_a about 10. As a result, they are soluble in 1 M NaOH but not soluble in saturated aqueous sodium bicarbonate solution.

◀ **Figure 32.36** **Flowchart illustrating some simple functional group tests.**

Carboxylic acids: Carboxylic acids react with saturated aqueous sodium bicarbonate solution, with the release of CO_2 from solution.

$$RCOOH + HCO_3^- (aq) \longrightarrow RCOO^- (aq) + H_2O + CO_2 (g) \quad [32.8]$$

Aldehydes and ketones: Both aldehydes and ketones react with 2,4-dinitrophenylhydrazine (DNP), also known as Brady's reagent, to form highly colored precipitates. A generalized equation for this reaction is:



$$R_2C{=}O + H_2NR' \longrightarrow R_2C{=}NR' + H_2O \quad [32.9]$$

To distinguish aldehydes from ketones, a silver mirror test is usually employed.

$$RCHO + 2\ Ag^+ (aq) + 3\ OH^- (aq) \longrightarrow RCOO^- (aq) + 2\ Ag(s) + 2H_2O \quad [32.10]$$

Nitrogen: The Lassaigne sodium fusion test is a dramatic test that requires the use of molten sodium metal and ferrous sulfate. The bright blue color of the product, $NaFe[Fe(CN)_6]$ (also known as Prussian blue), indicates a positive test. The nitrogen can be present in amines, nitro compounds, nitriles and amides.

Amines: Amines are soluble in 1 M HCl and give alkaline solutions when mixed with water. Primary aromatic amines yield bright red/orange-colored azo-dyes when mixed with nitrous acid and 2-naphthol. Amines form amides by reaction with acetic anhydride.

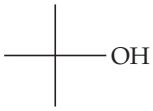
[32.11]

Using Analysis from Instrumental Techniques

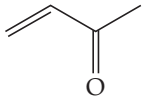
We are now ready to tackle an advanced problem as a chemical detective. To help you to become familiar with the process, here are some guidelines.

1. *Determine the molecular formula and index of hydrogen deficiency.* Calculate the empirical formula, determine the mass of the molecular ion (from the mass spectrum) and hence calculate the molecular formula and IHD.
2. *Check the IR spectrum.* Look for stretching bands indicative of functional groups O—H, N—H, C=O and so on.
3. *^{1}H NMR spectrum: number of signals and their positioning.* Determine the number of non-equivalent hydrogens by counting the number of signals present. Determine their chemical shift and relate this to potential neighboring functional groups—for example, CH_2—O at about 4 ppm, $CH_2C{=}O$ at about 2.5 ppm. Remember, this is only a guide.
4. *^{1}H NMR spectrum: integration.* Determine the relative number of equivalent hydrogens in each signal by measuring the area under each signal. Of course, this may already be done for you (Figure 32.22). The integral value could be exact in terms of the number of hydrogens or, based on extra symmetry within the molecule, may be a fraction of it.
5. *^{1}H NMR spectrum: splitting pattern.* Use your knowledge of splitting patterns and the $(n + 1)$ rule to determine the connectivity between groups of atoms. Learn to recognize ethyl groups by their characteristic splitting pattern.
6. *Deduce the structure.* Using all this information (including chemical tests), try to deduce the structure. Remember, it might not be the first one you draw.
7. *Check.* Use the ^{13}C NMR spectrum and any distinguishable fragmentation patterns in the mass spectrum to confirm your choice of structure. Use this information to distinguish isomers.

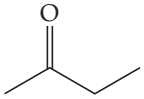
Self-Assessment Exercise



32.26 After a stocktake in a chemical store, two partially labelled bottles containing liquids with different odours remained. The label on both bottles was C_4H_xO where the value of x was unreadable. The bottles were marked A and B. The store's card index showed that there were five possibilities for A and B, numbered 1–5.



1



2

3

4

5

The ^{1}H NMR and IR spectra of A and B were recorded and are described here. For each bottle and its contents, suggest a possible conclusion for the information presented—for example, IR band at 2950 cm^{-1} indicates C—H present—and deduce the structures of A and B.

- *Bottle A:* Strong IR band near 1700 cm^{-1}, ^{1}H NMR spectrum: three signals in the ratio 3 : 3 : 2.
- *Bottle B:* Strong IR band near 3500 cm^{-1}, ^{1}H NMR spectrum: two signals in the ratio 9 : 1.

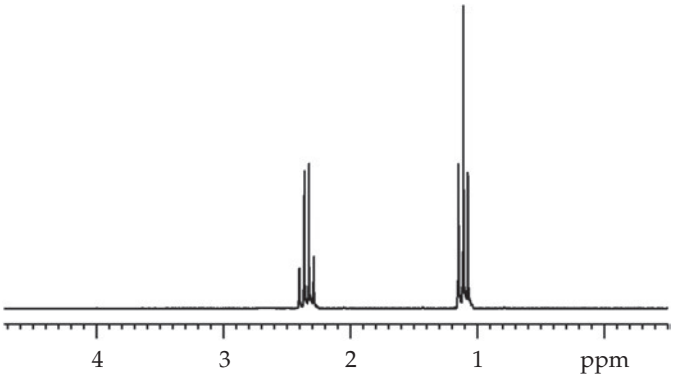
(a) Bottle A contains compound 4 and bottle B contains compound 2.

(b) Bottle A contains compound 1 and bottle B contains compound 3.

(c) Bottle A contains compound 3 and bottle B contains compound 5.

(d) Bottle A contains compound 5 and bottle B contains compound 3.

Exercises

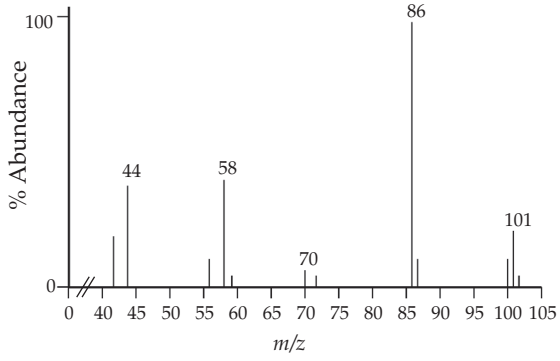


32.27 Calculate the IHD for the following compounds:

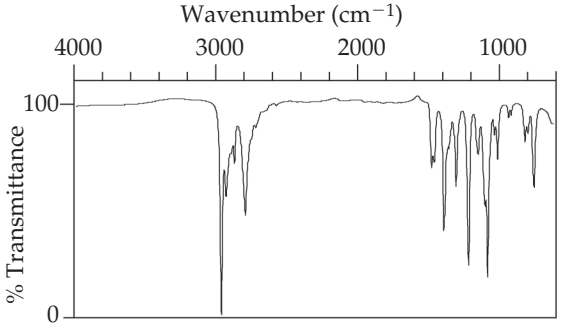
(a) cholesterol, $C_{27}H_{46}O$ **(b)** acetic acid, $C_2H_4O_2$

(c) aspirin, $C_9H_8O_4$ **(d)** naphthalene, $C_{10}H_8$

(e) ascorbic acid, $C_6H_8O_6$ **(f)** cocaine, $C_{17}H_{21}NO_4$



32.28 The product formed upon oxidation of an unknown organic compound with chromic acid has the molecular formula $C_5H_{10}O$. The ^{1}H NMR spectrum of the product is shown here and its IR spectrum has a strong band at 1700 cm^{-1}. Using this information, deduce the structure of the product and hence the structure of the unknown compound.



32.29 An acidic liquid has a broad band at 3300 cm^{-1} and a sharp band at 1710 cm^{-1} in the infrared spectrum. One mole of this unknown reacts with one mole of NaOH. The ^{1}H NMR spectrum shows three signals in the ratio 2: 2 : 1. Microanalysis gave C, 33.2%; H, 4.6%; Cl, 32.7%. Deduce the structure of the unknown.

32.30 This basic compound gives a positive result to the Lassaigne test. Microanalysis gave the following result: C, 71.22; H, 14.94; N, 13.84. Use this information and the accompanying spectra to deduce the structure of the unknown.

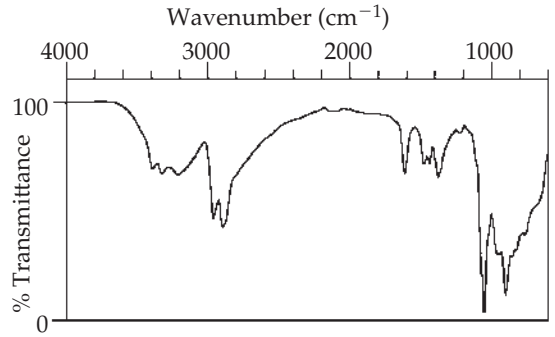
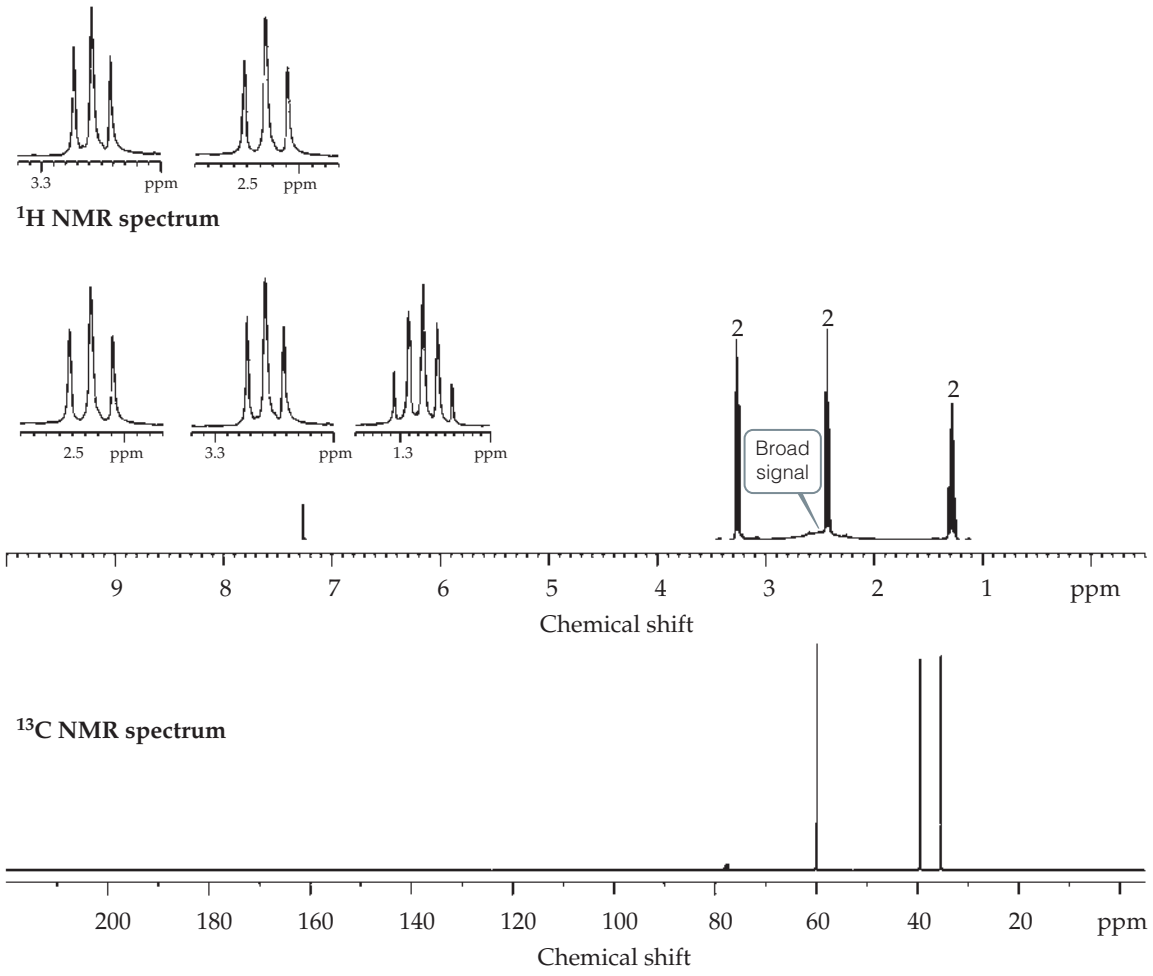
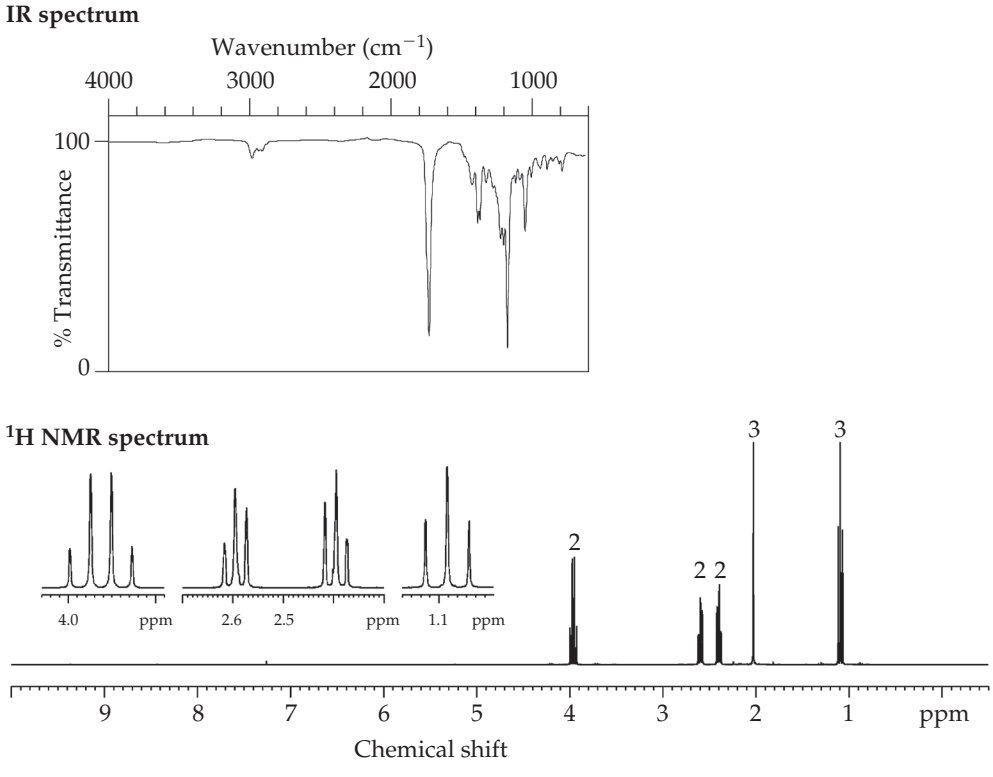
^{13}C NMR spectrum



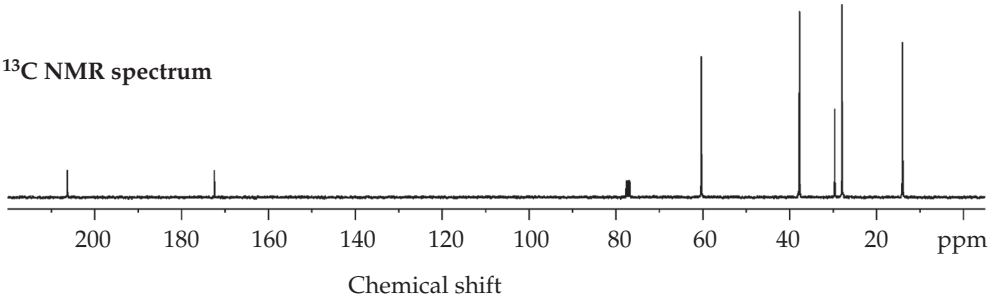


32.31 This unknown liquid is miscible with water, giving a mildly basic solution. Microanalysis gave the following result: C, 47.97; H, 12.08; N, 18.65. The broad, three-hydrogen signal within the ^{1}H NMR spectrum (indicated) disappears on the addition of D_2O. Use all the information available to deduce the structure of the unknown.

Mass spectrum



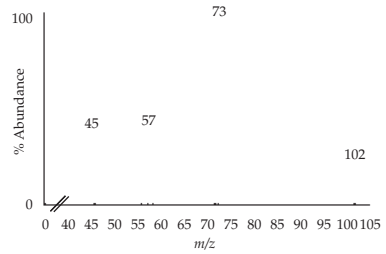
IR spectrum



32.32 This unknown liquid reacts with Brady's reagent to form a highly colored precipitate. The electrospray mass spectrum (not shown) has a signal at $m/z = 145$ corresponding to $[M + H]^+$. Microanalysis gave the following result: C, 58.32; H, 8.39. Use all the information available to deduce the structure of the unknown.

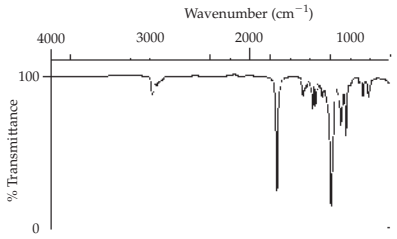
^{13}C NMR spectrum

Answers to Self-Assessment Exercise



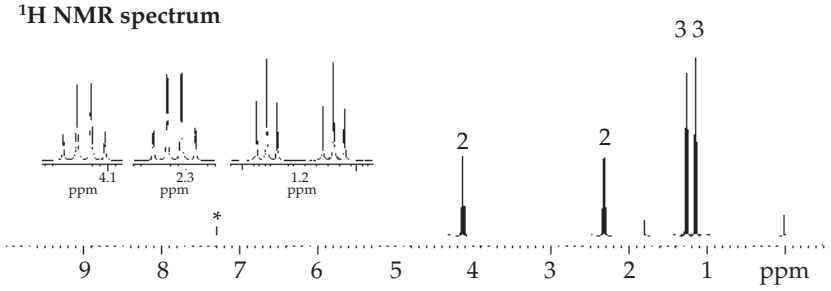
32.26 Bottle A contains butanone (compound 5); Bottle B contains 2-methylpropan-2-ol (compound 3).

Sample Integrative Exercise

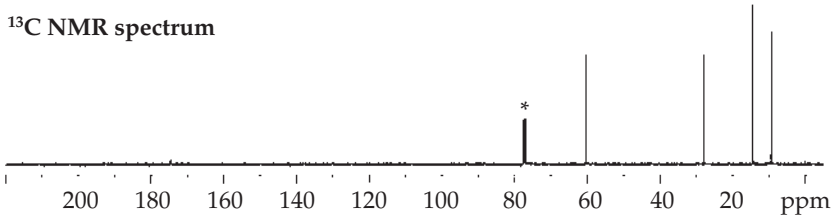


Putting Concepts Together

Unknown D is a sweet-smelling liquid. Microanalytical results for this unknown give C, 58.80%; H, 9.87%, and the characterization spectra acquired for this unknown are shown here. Use the information to deduce the structure of unknown D.



EI mass spectrum



IR spectrum

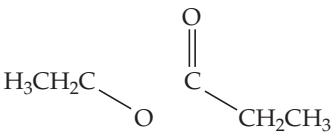
^{1}H NMR spectrum

^{13}C NMR spectrum

Asterisks denote solvent signals.

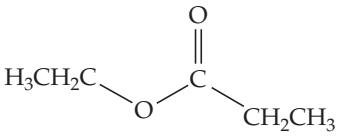
Analyze We are asked to use a set of analytical and chemical data for an unknown and asked to determine its structural formula.

Plan Use all the information given in the form of spectra and microanalytical data to deduce the structure of the unknown.



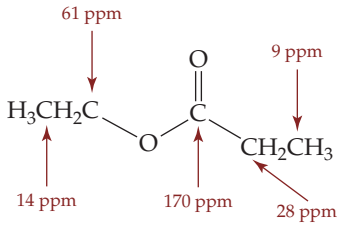
Solve The microanalytical data give an empirical formula of $C_5H_{10}O_2$, which has a mass equal to the molecular ion signal. Hence the molecular formula is also $C_5H_{10}O_2$. The IHD is 1, suggesting the presence of either a ring or double bond within the structure, but not both.

The IR spectrum shows a strong band at about 1750 cm^{-1}, attributable to a C=O stretching frequency. There is no O—H stretch, which means the extra oxygen atom in the molecular formula must be of ester or ether origin.



There are four signals in the ^1H NMR spectrum with integration in the ratio 2 : 2 : 3 : 3, which accounts for all the hydrogens in the molecular formula.

The chemical shifts of the two sets of quartets indicates that one set (approximately 4 ppm) neighbors oxygen and the other neighbors a carbonyl C=O group. Using the $(n + 1)$ rule, the hydrogens responsible for the quartet splitting patterns must be coupled to methyl groups. Hence, two different ethyl groups exist in this structure.



Putting together the clues to date, we have the following fragments:

These fragments make up the molecular formula of the unknown. Knowing that the unknown shows a positive test for esters (and is sweet-smelling) would confirm the choice in structure. Hence, our unknown is *ethyl propanoate*.

Check Use the ^{13}C NMR data to confirm the structure. The structure of ethyl propanoate has five different carbon atoms, the same number of signals as found in the ^{13}C NMR spectrum. In terms of chemical shift, the signals would be distributed as follows:

Practice Exercise
A number of these problems can be found in the end-of-chapter Exercises.

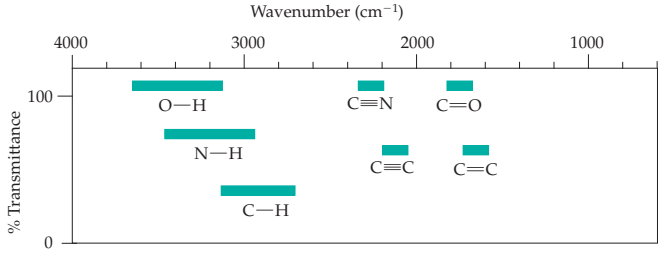
Chapter Summary and Key Terms

SECTION 32.1 All molecules absorb electromagnetic radiation to some degree and hence give rise to absorption spectra. The amount and type of absorption depends on the energy of radiation and the nature of the molecule, its bond types and its electronic structure. **Beer–Lambert's law** can be used to relate the amount of energy being absorbed to the concentration of the substance absorbing the energy in **UV-visible spectroscopy**.

SECTION 32.2 **Infrared spectroscopy** observes the vibrations of covalent bonds. The difference in vibration energy is a result of the stiffness of the covalent bond. This principle follows **Hooke's law** and provides useful evidence for the presence of functional groups in molecules. Compounds are measured either as solids, liquids or gases. An **infrared spectrum** is usually plotted as percentage **transmittance** (%T) versus **wavenumber** (cm^{-1}). The region below 1400 cm^{-1} is known as the **fingerprint region**.

SECTION 32.3 **Nuclear magnetic resonance (NMR) spectroscopy** is a method for observing nuclear spin transitions, giving information on the connectivity of nuclei (atoms). The technique relies on the difference in energy levels between nuclear spins of $I > 0$ ($I = \frac{1}{2}$ for ^1H and ^{13}C), within a strong magnetic field. The absorption of radiation at the **Larmor frequency**, which leads to an NMR spectrum, is termed **resonance**. The frequency of an NMR spectrometer is called its **operating frequency**.

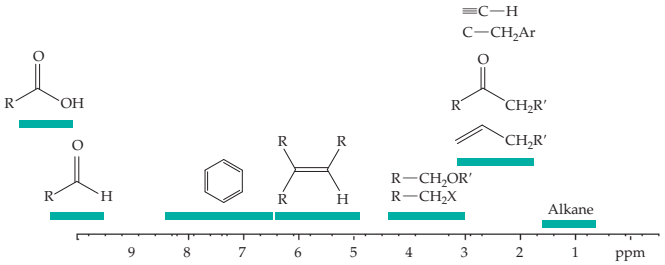
The electrons within these functional groups also have a spin that creates local magnetic fields that **shield** or **deshield** the neighboring nuclei from the applied magnetic field. Three aspects of an NMR spectrum are important: the **chemical shift** (δ) of a signal, the area under the signal (available by **integration**) and the **splitting pattern** of the signal all yield diagnostic information about the molecular structure. Equivalent hydrogens or carbons within a molecule by symmetry give rise to identical chemical shifts in ^1H or ^{13}C NMR spectra, respectively.



An NMR signal is split by the influence of adjacent atoms on the local magnetic field of the nucleus in question. This splitting is called **spin–spin coupling**. The splitting pattern that results follows the **$(n + 1)$ rule**. Splitting patterns are commonly described in terms of their **multiplicity**—for example, singlets, doublets, triplets, quartets, multiplets. Two (or more) coupled nuclei share the same **coupling constant** (J), which allows for easy tracing of the molecule's connectivity. ^{13}C NMR spectra are commonly devoid of coupling because they are recorded in a hydrogen-decoupled mode. **Decoupling** is used either to simplify a spectrum or to indicate coupled nuclei.

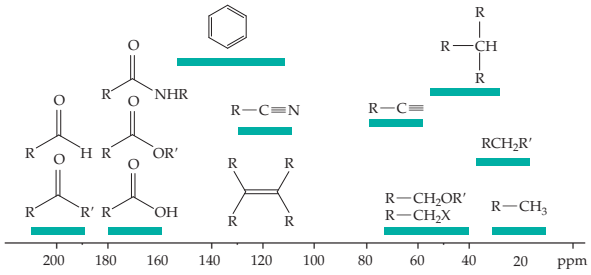
SECTION 32.4 **Electron impact ionization mass spectrometry (EIMS)** uses high-energy electrons to bombard a sample compound, causing it to *ionize* or **fragment**. The **molecularion** (M^+) formed upon ionization has a **mass-to-charge ratio** (m/z) equal in quantity to the molecular weight of the sample being tested. Signals with a mass spectrum are assigned a percentage abundance with respect to the **base peak**. Mass spectrometry often provides clues to the structure and functional groups contained within a molecule through either fragmentation or isotopic patterns.

SECTION 32.5 Using the **index of hydrogen deficiency (IHD)**, the chemist can determine the number of double bond or ring equivalents within a molecular formula.



Key Skills

- Understand how to use Beer–Lambert's law. (Section 32.1)
- Be able to identify O—H, C—H, C≡C, C═C, C═O stretches in IR spectra. (Section 32.2)



- Apply NMR chemical shifts to determine possible functional group types based on: (Section 32.3)

(a) ^{1}H NMR spectroscopy

(b) ^{13}C NMR spectroscopy

- Apply multiplicity and J in ^{1}H NMR to determine connectivity within organic molecules. (Section 32.3)
- Be able to identify the molecular ion signal and apply fragmentation patterns to determine functional groups and molecular weight. (Section 32.4)
- Be able to determine molecular formula from percentage composition and mass spectra. (Section 32.5)
- Calculate IHD based on a molecular formula. (Section 32.5)

Key Equations

- Beer–Lambert's law

$$A = \varepsilon c l \qquad [32.1]$$

- Transmittance

$$\text{Absorbance} = -\log_{10}(\text{transmittance})$$
$$\text{or}$$
$$A = -\log_{10} T \qquad [32.2]$$

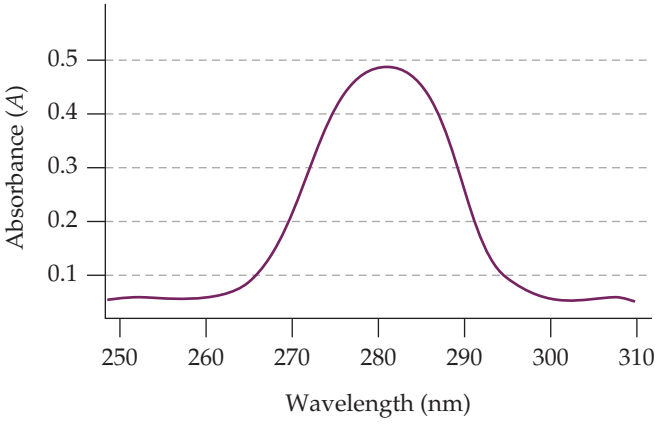
- IHD

IHD = Number double bond or ring equivalents

$$= \frac{\text{maximum number H possible per C} - \text{actual number H per C}}{2} \qquad [32.6]$$

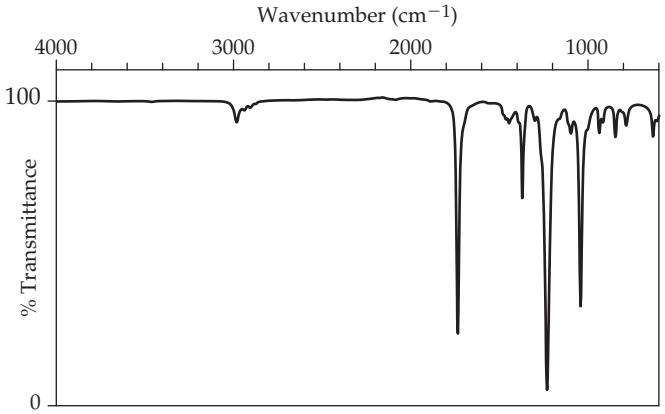
- Effective magnetic field

$$B_{\text{effective}} = B_{\text{applied}} - B_{\text{local}} \qquad [32.4]$$



- Chemical shift

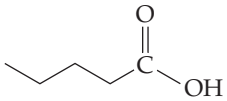
$$\delta = \frac{\text{Shift in resonance frequency from TMS (Hz)}}{\text{Operating frequency of the spectrometer (MHz)}} \qquad [32.5]$$



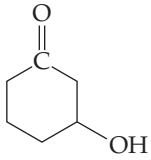
Exercises

Visualizing Concepts

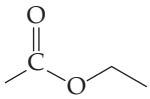
32.33 **(a)** An aqueous solution of 4-aminobenzoic acid gives a maximum absorbance of 0.21. What is the percentage transmittance? **(b)** The absorption spectrum of a solution of naphthalene ($\varepsilon = 300\ \text{dm}^3\ \text{mol}^{-1}\ \text{cm}^{-1}$) in hexane obtained through a path length of 1.0 cm is given here. What is the concentration of the sample? [*Hint:* You will need to estimate the absorbance value by reading off the graph.] [Section 32.1]



32.34 Determine which of the following compounds would be likely to give this IR spectrum. [Section 32.2]



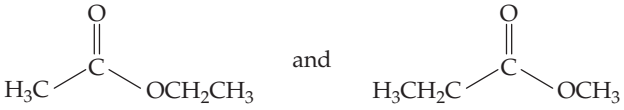
(a)



(b)

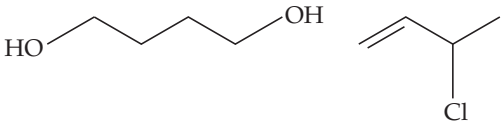
(c)

(d)



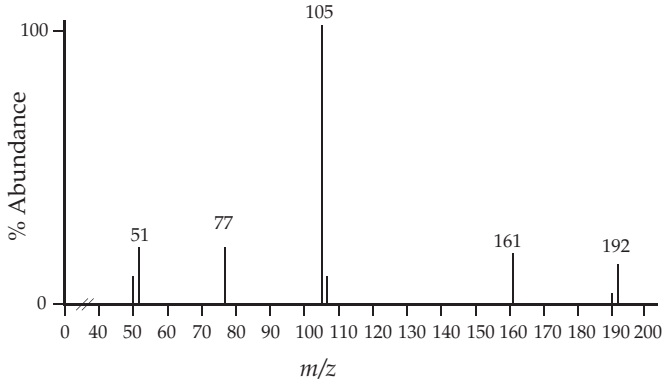
32.35 Magnetic Resonance Imaging is a medical equivalent to NMR spectroscopy. **(a)** Instruments for obtaining MRI data are typically labelled with a frequency, such as 600 MHz. Why do you suppose this label is relevant to the experiment? **(b)** In general, the stronger the magnetic field, the greater the information obtained from an NMR or MRI experiment. Why do you suppose this is the case? **(c)** What safety precautions do you think are relevant around superconducting magnets? [Section 32.3]

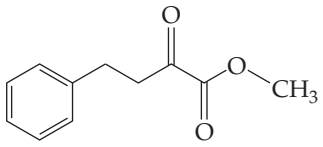
32.36 How could you use both ^{1}H and ^{13}C NMR to distinguish between these isomers? [*Hint:* Look for symmetry elements.] [Section 32.3]



(a) $CH_3CH_2OCH_2CH_3$ and $CH_3CH_2CH_2CH_2OH$

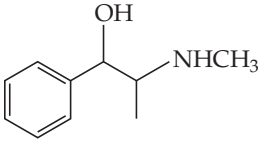
(b)



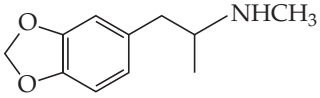


(c) $CH_3CH_2CH_2Br$ and $CH_3CHBrCH_3$

32.37 The two compounds shown here have a molecular ion signal at $m/z = 90$. Describe two ways, using mass spectrometry, of distinguishing between them. [Section 32.4]

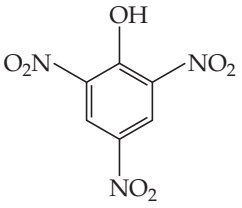


32.38 Confirm that the fragmentation pattern seen in the following EI mass spectrum is consistent with the structure shown here. What chemical wet test(s) could you perform to support the structure shown? [Sections 32.4 and 32.5]



Infrared Spectroscopy (Section 32.2)

32.39 Ephedrine is produced by a number of the *Ephedra* species of plants. Its medicinal properties have been related to respiratory conditions since 200 AD. Its structure was elucidated in 1923 and ephedrine began clinical trials in 1926 as a bronchodilator for asthma. In the late 1990s, a new recreational drug, ecstacy, became popular with people in their 20s. Its structure is similar to ephedrine, which also acts as a heart stimulant.



ephedrine

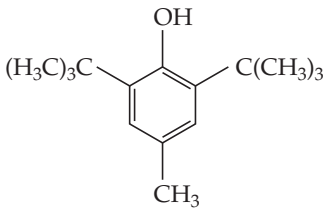
ecstacy

Could police and customs officials use IR spectroscopy to distinguish between the two compounds? Explain.

32.40 Picric acid is an aromatic compound used extensively before 1960 as an agent for co-crystallising liquid organic samples so that a melting point determination could be made. Picric acid is not a carboxylic acid but instead a phenol bearing nitro substituents at the 2,4, and 6 positions. How could you use IR spectroscopy to determine that picric acid was indeed a phenol and not a carboxylic acid?

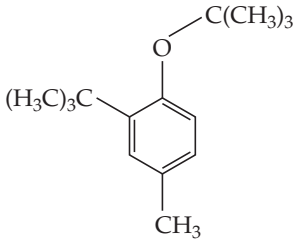
32.41 **(a)** Of the functional groups O—H, C=O, C≡N, which would be most diagnostic for bioimaging? Why? **(b)** Can you name another functional group that could be used for diagnostic purposes using the IR technique? What problems might arise?

NMR Spectroscopy (Section 32.3)



32.42 The ^{1}H NMR spectrum of acetone recorded on a spectrometer with an operating frequency of 200 MHz has a single resonance signal at 2.1 ppm.

(a) What is the difference in Hz between this signal and that of tetramethylsilane (TMS)?



(b) At what δ value does this signal lie if recorded using a 400 MHz spectrometer?

(c) How many Hz away from TMS does the absorption in the 400 MHz spectrum correspond to?

32.43 When the antioxidant BHT was first prepared, chemists were not sure of its structure. The chemical formula was determined by elemental analysis, but NMR, which would have instantaneously revealed the structure, had not yet been discovered. The problem arose because BHT failed the usual tests for phenols; for example, it was not soluble in dilute basic solution. Because of this, chemists thought the second 2-methylpropyl (*t*-butyl) group was linked to oxygen to form an ether. Of course, the reason BHT does not behave like other phenols is because the OH group is hindered by the two neighboring 2- methylpropyl groups, a protective quality that also allows this molecule to be used as a commercial antioxidant.

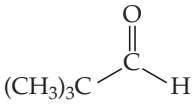
BHT

Supposed BHT

In terms of the number of equivalent hydrogens present, how could ^{1}H NMR spectroscopy be used to verify the correct structure for BHT?

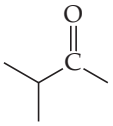
32.44 Two bottles labelled propanol were found in a laboratory. Because of their differing boiling points, the bottles clearly contained the two propanol constitutional isomers. To determine which propanol was in which bottle, a ^{1}H NMR spectrum was obtained on each sample. Draw the two possible isomers and describe how NMR might be used to distinguish between them.

32.45 Predict the splitting pattern observed in the hydrogen-coupled ^{13}C NMR spectrum for each of these compounds:



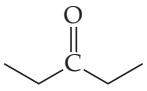
(a) CH_3CHBr_2 **(b)** $(CH_3)_2CHCl$ **(c)** $(CH_3)_3CBr$

32.46 The spin of an electron generates a magnetic field, with "spin-up" and "spin-down" electrons having opposite fields. In the absence of a magnetic field, a "spin-up" and a "spin-down" electron have the same energy. **(a)** Why do you think that the use of a magnet was important in the discovery of electron spin? **(b)** A phenomenon called electron spin resonance (ESR) is closely related to nuclear magnetic resonance. In ESR, a compound with an unpaired electron is placed in a magnetic field, causing the unpaired electron to have two different energy states similar to our discussion of nuclear spin (see Figure 32.13). ESR uses microwave radiation instead of radiofrequency radiation to excite the unpaired electron from one state to the other. Does an ESR experiment require photons of greater or lesser energy than an NMR experiment?

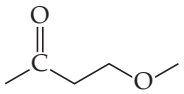


32.47 2-methylbut-2-ene contains signals at δ20.3, 22.5, 22.9, 110.3 and 111.5 in the ^{13}C NMR hydrogen-decoupled spectrum, whereas 2-methylbutane contains only four signals. Explain why this is so.

32.48 Predict the number of ^{1}H NMR signals and also the splitting pattern of each of these compounds in the ^{1}H NMR spectrum.

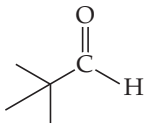


(a)

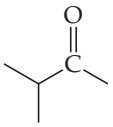


(b)

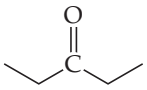
(c)



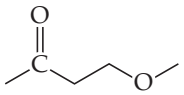
(d)



32.49 Predict the number of ^{13}C NMR signals in the hydrogen-decoupled spectrum of the following:

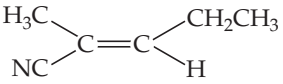


(a)



(b)

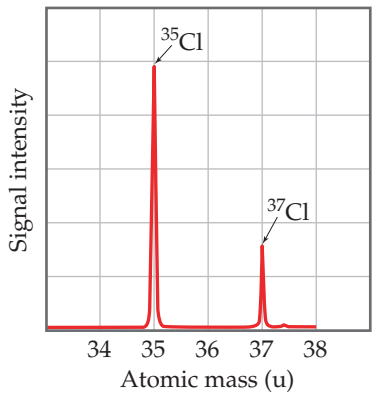
(c)



(d)

32.50 ^{31}P is NMR active ($I = \frac{1}{2}$) and is also the only naturally occurring phosphorus isotope. Describe the splitting you would see in both the ^{1}H NMR and ^{31}P NMR spectra of PH_2Cl.

32.51 The 200 MHz ^{1}H NMR spectrum of 2-cyanopent-2-ene has four distinctive resonances: δ5.3 (1H, singlet), 2.1 (2H, quartet), 1.9 (3H, singlet), 1.0 (3H, triplet). Assign each resonance to the structure.



Mass Spectrometry (Section 32.4)

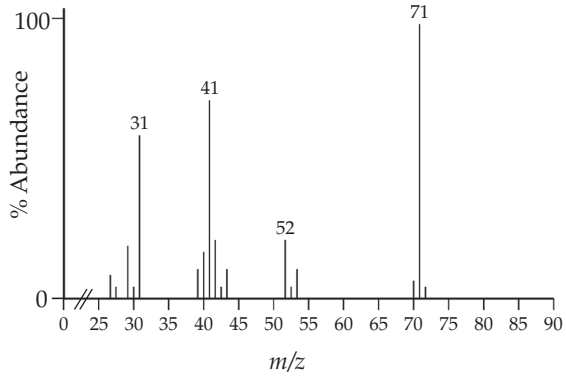
32.52 Triethylborane has two signals at *m/z* 97 and 98 in its EI mass spectrum. Account for the two signals.

32.53 An aliphatic compound contains C, 39.76%, and H, 7.34%, but doesn't contain oxygen. The EI mass spectrum shows a molecular ion at $m/z = 150$ and a second signal of equal intensity at $m/z = 152$. Determine this compound's molecular formula.

32.54 **(a)** The mass spectrometer in Figure 32.31 has a magnet as one of its components. What is the purpose of the magnet? **(b)** The atomic weight of Cl is 35.5 u. However, the mass spectrum of Cl, shown here, does not have a signal at this mass. Explain.

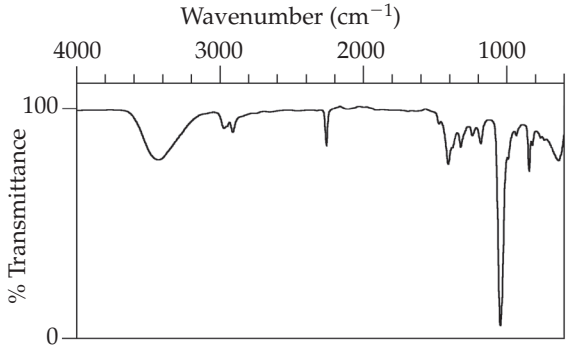
32.55 What is meant by these terms?

(a) M^+ **(b)** $[M+2]^+$ **(c)** base peak



(d) *m/z* **(e)** EIMS

Integrative Exercises



32.56 The guidelines for determining the IHD of a compound are listed on page 1488. Using examples as appropriate, discuss why, for each nitrogen in the unknown's molecular formula, one hydrogen needs to be added to the reference molecular formula, but for oxygen nothing is added.

32.57 This unknown evolves gas when a small amount of sodium metal is added. Microanalysis gave the following result: C, 50.69; H, 7.09; N, 19.71. Use all the information available to deduce the structure of the unknown.

Design an Experiment

The poison hemlock plant (*Conium maculatum*) is toxic to mammals and can be fatal. All parts of the plant are poisonous, and as few as about ten leaves can kill a human. You are asked to help investigate the sudden death of some cattle that are thought to have eaten hemlock, and the vet has provided you with a small sample of a substance taken from the dead animals for you to identify. You suspect the substance to be coniine, one of the active components of hemlock.

Coniine

What precautions would you take when handling this substance? What chemical tests would you perform, and what would you expect them to show? If an elemental analysis were carried out, what percent of C, H, and N would you expect for coniine? What instrumental method would you use to determine the molecular mass of the substance and what would you calculate it to be for coniine? You run an IR spectrum of the substance – which regions of the IR would give you information about what functional groups were, or were not, present in the sample? The ^{13}C NMR contains eight signals between 10 and 60 ppm. Is this consistent with the structure of coniine? The ^{1}H NMR spectrum contains many overlapping signals and is reproduced here. Does it help with your identification? If you are asked how confident you were with your identification, what would you say?

APPENDIX

A

MATHEMATICAL OPERATIONS

A.1 | Exponential Notation

The numbers used in chemistry are often either extremely large or extremely small. Such numbers are conveniently expressed in the form

$$N \times 10^n$$

where N is a number between 1 and 10, and n is the exponent. Some examples of this *exponential notation*, which is also called *scientific notation*, follow.

1,200,000 is 1.2×10^6	(read "one point two multi ten to the sixth power")
0.000604 is 6.04×10^{-4}	(read "six point zero four times ten to the negative fourth power")

A positive exponent, as in the first example, tells us how many times a number must be multiplied by 10 to give the long form of the number:

$$1.2 \times 10^6 = 1.2 \times 10 \times 10 \times 10 \times 10 \times 10 \times 10 \quad \text{(six tens)}$$
$$= 1{,}200{,}000$$

It is also convenient to think of the *positive exponent* as the number of places the decimal point must be moved to the *left* to obtain a number greater than 1 and less than 10. For example, if we begin with 3450 and move the decimal point three places to the left, we end up with 3.45×10^3.

In a related fashion, a negative exponent tells us how many times we must divide a number by 10 to give the long form of the number.

$$6.04 \times 10^{-4} = \frac{6.04}{10 \times 10 \times 10 \times 10} = 0.000604$$

It is convenient to think of the *negative exponent* as the number of places the decimal point must be moved to the *right* to obtain a number greater than 1 but less than 10. For example, if we begin with 0.0048 and move the decimal point three places to the right, we end up with 4.8×10^{-3}.

In the system of exponential notation, with each shift of the decimal point one place to the right, the exponent *decreases* by 1:

$$4.8 \times 10^{-3} = 48 \times 10^{-4}$$

Similarly, with each shift of the decimal point one place to the left, the exponent *increases* by 1:

$$4.8 \times 10^{-3} = 0.48 \times 10^{-2}$$

Many scientific calculators have a key labeled EXP or EE, which is used to enter numbers in exponential notation. To enter the number 5.8×10^3 on such a calculator, the key sequence is

$$\boxed{5}\ \boxed{\cdot}\ \boxed{8}\ \boxed{\text{EXP}}\ (\text{or}\ \boxed{\text{EE}})\ \boxed{3}$$

On some calculators the display will show 5.8, then a space, followed by 03, the exponent. On other calculators, a small 10 is shown with an exponent 3.

To enter a negative exponent, use the key labeled +/−. For example, to enter the number 8.6×10^{-5}, the key sequence is

$$\boxed{8}\ \boxed{\cdot}\ \boxed{6}\ \boxed{\text{EXP}}\ \boxed{+/-}\ \boxed{5}$$

When entering a number in exponential notation, do not key in the 10 if you use the EXP or EE button.

In working with exponents, it is important to recall that $10^0 = 1$. The following rules are useful for carrying exponents through calculations.

1. **Addition and Subtraction** In order to add or subtract numbers expressed in exponential notation, the powers of 10 must be the same.

$$\begin{aligned}(5.22 \times 10^4) + (3.21 \times 10^2) &= (522 \times 10^2) + (3.21 \times 10^2)\\ &= 525 \times 10^2 \quad (3 \text{ significant figures})\\ &= 5.25 \times 10^4\\ (6.25 \times 10^{-2}) - (5.77 \times 10^{-3}) &= (6.25 \times 10^{-2}) - (0.577 \times 10^{-2})\\ &= 5.67 \times 10^{-2} \quad (3 \text{ significant figures})\end{aligned}$$

When you use a calculator to add or subtract, you need not be concerned with having numbers with the same exponents because the calculator automatically takes care of this matter.

2. **Multiplication and Division** When numbers expressed in exponential notation are multiplied, the exponents are added; when numbers expressed in exponential notation are divided, the exponent of the denominator is subtracted from the exponent of the numerator.

$$\begin{aligned}(5.4 \times 10^2)(2.1 \times 10^3) &= (5.4)(2.1) \times 10^{2+3}\\ &= 11 \times 10^5\\ &= 1.1 \times 10^6\\ (1.2 \times 10^5)(3.22 \times 10^{-3}) &= (1.2)(3.22) \times 10^{5+(-3)} = 3.9 \times 10^2\\ \frac{3.2 \times 10^5}{6.5 \times 10^2} &= \frac{3.2}{6.5} \times 10^{5-2} = 0.49 \times 10^3 = 4.9 \times 10^2\\ \frac{5.7 \times 10^7}{8.5 \times 10^{-2}} &= \frac{5.7}{8.5} \times 10^{7-(-2)} = 0.67 \times 10^9 = 6.7 \times 10^8\end{aligned}$$

3. **Powers and Roots** When numbers expressed in exponential notation are raised to a power, the exponents are multiplied by the power. When the roots of numbers expressed in exponential notation are taken, the exponents are divided by the root.

$$\begin{aligned}(1.2 \times 10^5)^3 &= (1.2)^3 \times 10^{5\times 3}\\ &= 1.7 \times 10^{15}\\ \sqrt[3]{2.5 \times 10^6} &= \sqrt[3]{2.5} \times 10^{6/3}\\ &= 1.3 \times 10^2\end{aligned}$$

Scientific calculators usually have keys labeled x^2 and $\sqrt{x}$ for squaring and taking the square root of a number, respectively. To take higher powers or roots, many calculators have y^x and $\sqrt[x]{y}$ (or INV y^x) keys. For example, to perform the operation $\sqrt[3]{7.5 \times 10^{-4}}$ on such a calculator, you would key in 7.5×10^{-4}, press the $\sqrt[x]{y}$ key (or the INV and then the y^x keys), enter the root, 3, and finally press =. The result is 9.1×10^{-2}.

Sample Exercise 1

Using Exponential Notation

Perform each of the following operations, using your calculator where possible:
(**a**) Write the number 0.0054 in standard exponential notation. (**b**) $(5.0 \times 10^{-2}) + (4.7 \times 10^{-3})$ (**c**) $(5.98 \times 10^{12})(2.77 \times 10^{-5})$ (**d**) $\sqrt[4]{1.75 \times 10^{-12}}$

SOLUTION

(**a**) Because we move the decimal point three places to the right to convert 0.0054 to 5.4, the exponent is −3:

$$5.4 \times 10^{-3}$$

Scientific calculators are generally able to convert numbers to exponential notation using one or two keystrokes; frequently "SCI" for "scientific notation" will convert a number into exponential notation. Consult your instruction manual to see how this operation is accomplished on your calculator.

(**b**) To add these numbers longhand, we must convert them to the same exponent.

$$(5.0 \times 10^{-2}) + (0.47 \times 10^{-2}) = (5.0 + 0.47) \times 10^{-2} = 5.5 \times 10^{-2}$$

(**c**) Performing this operation longhand, we have

$$(5.98 \times 2.77) \times 10^{12-5} = 16.6 \times 10^{7} = 1.66 \times 10^{8}$$

(**d**) To perform this operation on a calculator, we enter the number, press the $\sqrt[x]{y}$ key (or the INV and y^x keys), enter 4, and press the = key. The result is 1.15×10^{-3}.

▶Practice Exercise

Perform the following operations:
(**a**) Write 67,000 in exponential notation, showing two significant figures.
(**b**) $(3.378 \times 10^{-3}) - (4.97 \times 10^{-5})$
(**c**) $(1.84 \times 10^{15})(7.45 \times 10^{-2})$
(**d**) $(6.67 \times 10^{-8})^3$

A.2 | Logarithms

Common Logarithms

The common, or base-10, logarithm (abbreviated log) of any number is the power to which 10 must be raised to equal the number. For example, the common logarithm of 1000 (written log 1000) is 3 because raising 10 to the third power gives 1000.

$$10^3 = 1000, \text{ therefore, } \log 1000 = 3$$

Further examples are

$$\log 10^5 = 5$$
$$\log 1 = 0 \quad \text{Remember that } 10^0 = 1$$
$$\log 10^{-2} = -2$$

In these examples the common logarithm can be obtained by inspection. However, it is not possible to obtain the logarithm of a number such as 31.25 by inspection. The logarithm of 31.25 is the number x that satisfies the following relationship:

$$10^x = 31.25$$

Most electronic calculators have a key labeled LOG that can be used to obtain logarithms. For example, on many calculators we obtain the value of log 31.25 by entering 31.25 and pressing the LOG key. We obtain the following result:

$$\log 31.25 = 1.4949$$

Notice that 31.25 is greater than 10 (10^1) and less than 100 (10^2). The value for log 31.25 is accordingly between log 10 and log 100, that is, between 1 and 2.

Significant Figures and Common Logarithms

For the common logarithm of a measured quantity, the number of digits after the decimal point equals the number of significant figures in the original number. For example, if 23.5 is a measured quantity (three significant figures), then log 23.5 = 1.371 (three significant figures after the decimal point).

Antilogarithms

The process of determining the number that corresponds to a certain logarithm is known as obtaining an *antilogarithm*. It is the reverse of taking a logarithm. For example, we saw previously that log 23.5 = 1.371. This means that the antilogarithm of 1.371 equals 23.5.

$$\log 23.5 = 1.371$$
$$\text{antilog } 1.371 = 23.5$$

The process of taking the antilog of a number is the same as raising 10 to a power equal to that number.

$$\text{antilog } 1.371 = 10^{1.371} = 23.5$$

Many calculators have a key labeled 10^x that allows you to obtain antilogs directly. On others, it will be necessary to press a key labeled INV (for *inverse*), followed by the LOG key.

Natural Logarithms

Logarithms based on the number e are called natural, or base e, logarithms (abbreviated ln). The natural log of a number is the power to which e (which has the value 2.71828...) must be raised to equal the number. For example, the natural log of 10 equals 2.303.

$$e^{2.303} = 10, \text{ therefore } \ln 10 = 2.303$$

Your calculator probably has a key labeled LN that allows you to obtain natural logarithms. For example, to obtain the natural log of 46.8, you enter 46.8 and press the LN key.

$$\ln 46.8 = 3.846$$

The natural antilog of a number is e raised to a power equal to that number. If your calculator can calculate natural logs, it will also be able to calculate natural antilogs. On some calculators there is a key labeled e^x that allows you to calculate natural antilogs directly; on others, it will be necessary to first press the INV key followed by the LN key. For example, the natural antilog of 1.679 is given by

$$\text{Natural antilog } 1.679 = e^{1.679} = 5.36$$

The relation between common and natural logarithms is as follows:

$$\ln a = 2.303 \log a$$

Notice that the factor relating the two, 2.303, is the natural log of 10, which we calculated earlier.

Mathematical Operations Using Logarithms

Because logarithms are exponents, mathematical operations involving logarithms follow the rules for the use of exponents. For example, the product of z^a and z^b (where z is any number) is given by

$$z^a \cdot z^b = z^{(a+b)}$$

Similarly, the logarithm (either common or natural) of a product equals the *sum* of the logs of the individual numbers.

$$\log ab = \log a + \log b \qquad \ln ab = \ln a + \ln b$$

For the log of a quotient,

$$\log(a/b) = \log a - \log b \qquad \ln(a/b) = \ln a - \ln b$$

Using the properties of exponents, we can also derive the rules for the logarithm of a number raised to a certain power.

$$\log a^n = n \log a \qquad \ln a^n = n \ln a$$

$$\log a^{1/n} = (1/n)\log a \qquad \ln a^{1/n} = (1/n)\ln a$$

pH Problems

One of the most frequent uses for common logarithms in general chemistry is in working pH problems. The pH is defined as $-\log[H^+]$, where $[H^+]$ is the hydrogen ion concentration of a solution. The following sample exercise illustrates this application.

Sample Exercise 2
Using Logarithms

(a) What is the pH of a solution whose hydrogen ion concentration is 0.015 *M*?
(b) If the pH of a solution is 3.80, what is its hydrogen ion concentration?

SOLUTION

(1) We are given the value of $[H^+]$. We use the LOG key of our calculator to calculate the value of $\log[H^+]$. The pH is obtained by changing the sign of the value obtained. (Be sure to change the sign *after* taking the logarithm.)

$$[H^+] = 0.015$$
$$\log[H^+] = -1.82 \quad (2 \text{ significant figures})$$
$$\text{pH} = -(-1.82) = 1.82$$

(2) To obtain the hydrogen ion concentration when given the pH, we must take the antilog of −pH.

$$\text{pH} = -\log[H^+] = 3.80$$
$$\log[H^+] = -3.80$$
$$[H^+] = \text{antilog}(-3.80) = 10^{-3.80} = 1.6 \times 10^{-4}\,M$$

Practice Exercise
Perform the following operations:
(**a**) $\log(2.5 \times 10^{-5})$
(**b**) ln 32.7
(**c**) antilog −3.47
(**d**) $e^{-1.89}$

A.3 | Quadratic Equations

An algebraic equation of the form $ax^2 + bx + c = 0$ is called a *quadratic equation*. The two solutions to such an equation are given by the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Many calculators today can calculate the solutions to a quadratic equation with one or two keystrokes. Most of the time, x corresponds to the concentration of a chemical species in solution. Only one of the solutions will be a positive number, and that is the one you should use; a "negative concentration" has no physical meaning.

Sample Exercise 3
Using the Quadratic Formula

Find the values of x that satisfy the equation $2x^2 + 4x = 1$.

SOLUTION

To solve the given equation for x, we must first put it in the form

$$ax^2 + bx + c = 0$$

and then use the quadratic formula. If

$$2x^2 + 4x = 1$$

then

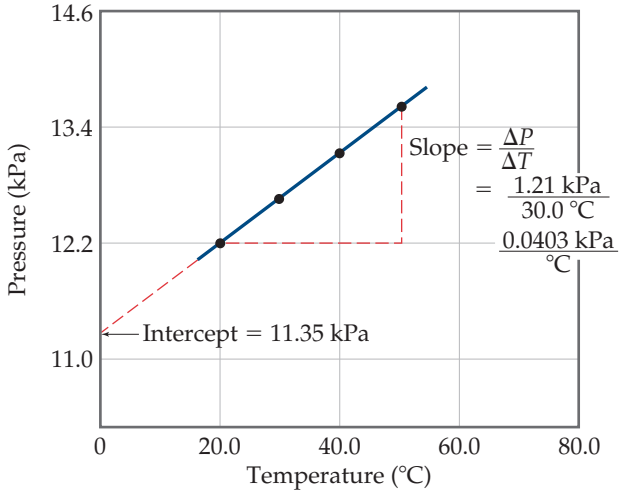
$$2x^2 + 4x - 1 = 0$$

Using the quadratic formula, where $a = 2, b = 4$, and $c = -1$, we have

$$x = \frac{-4 \pm \sqrt{4^2 - 4(2)(-1)}}{2(2)}$$
$$= \frac{-4 \pm \sqrt{16 + 8}}{4} = \frac{-4 \pm \sqrt{24}}{4} = \frac{-4 \pm 4.899}{4}$$

The two solutions are

$$x = \frac{0.899}{4} = 0.225 \quad \text{and} \quad x = \frac{-8.899}{4} = -2.225$$



If this was a problem in which x represented a concentration, we would say $x = 0.225$ (in the appropriate units), since a negative number for concentration has no physical meaning.

A.4 | Graphs

Often the clearest way to represent the interrelationship between two variables is to graph them. Usually, the variable that is being experimentally varied, called the *independent variable*, is shown along the horizontal axis (x-axis). The variable that responds to the change in the independent variable, called the *dependent variable*,

TABLE A.1 Interrelation between Pressure and Temperature

Temperature (°C)	Pressure (kPa)
20.0	12.16
30.0	12.56
40.0	12.97
50.0	13.37

▲ **Figure A.1** **A graph of pressure versus temperature yields a straight line for the data.**

is then shown along the vertical axis (y-axis). For example, consider an experiment in which we vary the temperature of an enclosed gas and measure its pressure. The independent variable is temperature and the dependent variable is pressure. The data shown in **Table A.1** can be obtained by means of this experiment. These data are shown graphically in **Figure A.1**. The relationship between temperature and pressure is linear. The equation for any straight-line graph has the form

$$y = mx + b$$

where m is the slope of the line and b is the intercept with the y-axis. In the case of Figure A.1, we could say that the relationship between temperature and pressure takes the form

$$P = mT + b$$

where P is pressure in kPa and T is temperature in °C. As shown in Figure A.1, the slope is 0.0403 kPa/°C, and the intercept—the point where the line crosses the y-axis—is 11.35 kPa. Therefore, the equation for the line is

$$P = (0.0403 \text{ kPa/°C})T + 11.35 \text{ kPa}$$

A.5 | Standard Deviation

The standard deviation from the mean, s, is a common method for describing precision in experimentally determined data. We define the standard deviation as

$$s = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \bar{x})^2}{N - 1}}$$

where N is the number of measurements, $\bar{x}$ is the average (also called the mean) of the measurements, and xi represent the individual measurements. Electronic calculators with built-in statistical functions can calculate s directly by inputting the individual measurements.

A smaller value of s indicates a higher precision, meaning that the data are more closely clustered around the average. The standard deviation has statistical significance. If a large number of measurements is made, 68% of the measured values is expected to be within one standard deviation of the average, assuming only random errors are associated with the measurements.

Sample Exercise 4

Calculating an Average and Standard Deviation

The percent carbon in a sugar is measured four times: 42.01%, 42.28%, 41.79%, and 42.25%. Calculate (**a**) the average and (**b**) the standard deviation for these measurements.

SOLUTION

(**a**) The average is found by adding the quantities and dividing by the number of measurements:

$$\bar{x} = \frac{42.01 + 42.28 + 41.79 + 42.25}{4} = \frac{168.33}{4} = 42.08$$

(**b**) The standard deviation is found using the preceding equation:

$$s = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \bar{x})^2}{N - 1}}$$

Let's tabulate the data so the calculation of $\sum_{i=1}^{N}(x_i - \bar{x})^2$ can be seen clearly.

Percent C	Difference between Measurement and Average, $(x_i - x)$	Square of Difference, $(x_i - x)^2$
42.01	$42.01 - 42.08 = -0.07$	$(-0.07)^2 = 0.005$
42.28	$42.28 - 42.08 = 0.20$	$(0.20)^2 = 0.040$
41.79	$41.79 - 42.08 = -0.29$	$(-0.29)^2 = 0.084$
42.25	$42.25 - 42.08 = 0.17$	$(0.17)^2 = 0.029$

The sum of the quantities in the last column is

$$\sum_{i=1}^{N}(x_i - \bar{x})^2 = 0.005 + 0.040 + 0.084 + 0.029 = 0.16$$

Thus, the standard deviation is

$$s = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \bar{x})^2}{N - 1}} = \sqrt{\frac{0.16}{4 - 1}} = \sqrt{\frac{0.16}{3}} = \sqrt{0.053} = 0.23$$

Based on these measurements, it would be appropriate to represent the measured percent carbon as 42.08 ± 0.23.

AQUEOUS EQUILIBRIUM CONSTANTS

TABLE D.1 Dissociation Constants for Acids at 25 °C

Name	Formula	K_{a1}	K_{a2}	K_{a3}
Acetic acid	CH_3COOH (or $HC_2H_3O_2$)	1.8×10^{-5}		
Arsenic acid	H_3AsO_4	5.6×10^{-3}	1.0×10^{-7}	3.0×10^{-12}
Arsenous acid	H_3AsO_3	5.1×10^{-10}		
Ascorbic acid	$H_2C_6H_6O_6$	8.0×10^{-5}	1.6×10^{-12}	
Benzoic acid	C_6H_5COOH (or $HC_7H_5O_2$)	6.3×10^{-5}		
Boric acid	H_3BO_3	5.8×10^{-10}		
Butanoic acid	C_3H_7COOH (or $HC_4H_7O_2$)	1.5×10^{-5}		
Carbonic acid	H_2CO_3	4.3×10^{-7}	5.6×10^{-11}	
Chloroacetic acid	$CH_2ClCOOH$ (or $HC_2H_2O_2Cl$)	1.4×10^{-3}		
Chlorous acid	$HClO_2$	1.1×10^{-2}		
Citric acid	$HOOCC(OH)(CH_2COOH)_2$ (or $H_3C_6H_5O_7$)	7.4×10^{-4}	1.7×10^{-5}	4.0×10^{-7}
Cyanic acid	$HCNO$	3.5×10^{-4}		
Formic acid	$HCOOH$ (or $HCHO_2$)	1.8×10^{-4}		
Hydroazoic acid	HN_3	1.9×10^{-5}		
Hydrocyanic acid	HCN	4.9×10^{-10}		
Hydrofluoric acid	HF	6.8×10^{-4}		
Hydrogen chromate ion	$HCrO_4^-$	3.0×10^{-7}		
Hydrogen peroxide	H_2O_2	2.4×10^{-12}		
Hydrogen selenate ion	$HSeO_4^-$	2.2×10^{-2}		
Hydrogen sulfide	H_2S	9.5×10^{-8}	1×10^{-19}	
Hypobromous acid	$HBrO$	2.5×10^{-9}		
Hypochlorous acid	$HClO$	3.0×10^{-8}		
Hypoiodous acid	HIO	2.3×10^{-11}		
Iodic acid	HIO_3	1.7×10^{-1}		
Lactic acid	$CH_3CH(OH)COOH$ (or $HC_3H_5O_3$)	1.4×10^{-4}		
Malonic acid	$CH_2(COOH)_2$ (or $H_2C_3H_2O_4$)	1.5×10^{-3}	2.0×10^{-6}	
Nitrous acid	HNO_2	4.5×10^{-4}		
Oxalic acid	$(COOH)_2$ (or $H_2C_2O_4$)	5.9×10^{-2}	6.4×10^{-5}	
Paraperiodic acid	H_5IO_6	2.8×10^{-2}	5.3×10^{-9}	
Phenol	C_6H_5OH (or HC_6H_5O)	1.3×10^{-10}		
Phosphoric acid	H_3PO_4	7.5×10^{-3}	6.2×10^{-8}	4.2×10^{-13}
Propionic acid	C_2H_5COOH (or $HC_3H_5O_2$)	1.3×10^{-5}		
Pyrophosphoric acid	$H_4P_2O_7$	3.0×10^{-2}	4.4×10^{-3}	2.1×10^{-7}
Selenous acid	H_2SeO_3	2.3×10^{-3}	5.3×10^{-9}	
Sulfuric acid	H_2SO_4	Strong acid	1.2×10^{-2}	
Sulfurous acid	H_2SO_3	1.7×10^{-2}	6.4×10^{-8}	
Tartaric acid	$HOOC(CHOH)_2COOH$ (or $H_2C_4H_4O_6$)	1.0×10^{-3}		

TABLE D.2 Dissociation Constants for Bases at 25 °C

Name	Formula	K_b
Ammonia	NH_3	1.8×10^{-5}
Aniline	$C_6H_5NH_2$	4.3×10^{-10}
Dimethylamine	$(CH_3)_2NH$	5.4×10^{-4}
Ethylamine	$C_2H_5NH_2$	6.4×10^{-4}
Hydrazine	H_2NNH_2	1.3×10^{-6}
Hydroxylamine	$HONH_2$	1.1×10^{-8}
Methylamine	CH_3NH_2	4.4×10^{-4}
Pyridine	C_5H_5N	1.7×10^{-9}
Trimethylamine	$(CH_3)_3N$	6.4×10^{-5}

TABLE D.3 Solubility-Product Constants for Compounds at 25 °C

Name	Formula	K_{sp}	Name	Formula	K_{sp}
Barium carbonate	$BaCO_3$	5.0×10^{-9}	Lead(II) fluoride	PbF_2	3.6×10^{-8}
Barium chromate	$BaCrO_4$	2.1×10^{-10}	Lead(II) sulfate	$PbSO_4$	6.3×10^{-7}
Barium fluoride	BaF_2	1.7×10^{-6}	Lead(II) sulfide*	PbS	3×10^{-28}
Barium oxalate	BaC_2O_4	1.6×10^{-6}	Magnesium hydroxide	$Mg(OH)_2$	1.8×10^{-11}
Barium sulfate	$BaSO_4$	1.1×10^{-10}	Magnesium carbonate	$MgCO_3$	3.5×10^{-8}
Cadmium carbonate	$CdCO_3$	1.8×10^{-14}	Magnesium oxalate	MgC_2O_4	8.6×10^{-5}
Cadmium hydroxide	$Cd(OH)_2$	2.5×10^{-14}	Manganese(II) carbonate	$MnCO_3$	5.0×10^{-10}
Cadmium sulfide*	CdS	8×10^{-28}	Manganese(II) hydroxide	$Mn(OH)_2$	1.6×10^{-13}
Calcium carbonate (calcite)	$CaCO_3$	4.5×10^{-9}	Manganese(II) sulfide*	MnS	2×10^{-53}
Calcium chromate	$CaCrO_4$	4.5×10^{-9}	Mercury(I) chloride	Hg_2Cl_2	1.2×10^{-18}
Calcium fluoride	CaF_2	3.9×10^{-11}	Mercury(I) iodide	Hg_2I_2	$1.1 \times 10^{-1.1}$
Calcium hydroxide	$Ca(OH)_2$	6.5×10^{-6}	Mercury(II) sulfide*	HgS	2×10^{-53}
Calcium phosphate	$Ca_3(PO_4)_2$	2.0×10^{-29}	Nickel(II) carbonate	$NiCO_3$	1.3×10^{-7}
Calcium sulfate	$CaSO_4$	2.4×10^{-5}	Nickel(II) hydroxide	$Ni(OH)_2$	6.0×10^{-16}
Chromium(III) hydroxide	$Cr(OH)_3$	6.7×10^{-31}	Nickel(II) sulfide*	NiS	3×10^{-20}
Cobalt(II) carbonate	$CoCO_3$	1.0×10^{-10}	Silver bromate	$AgBrO_3$	5.5×10^{-13}
Cobalt(II) hydroxide	$Co(OH)_2$	1.3×10^{-15}	Silver bromide	AgBr	5.0×10^{-13}
Cobalt(II) sulfide*	CoS	5×10^{-22}	Silver carbonate	Ag_2CO_3	8.1×10^{-12}
Copper(I) bromide	CuBr	5.3×10^{-9}	Silver chloride	AgCl	1.8×10^{-10}
Copper(II) carbonate	$CuCO_3$	2.3×10^{-10}	Silver chromate	Ag_2CrO_4	1.2×10^{-12}
Copper(II) hydroxide	$Cu(OH)_2$	4.8×10^{-20}	Silver iodide	AgI	8.3×10^{-17}
Copper(II) sulfide*	CuS	6×10^{-37}	Silver sulfate	Ag_2SO_4	1.5×10^{-5}
Iron(II) carbonate	$FeCO_3$	2.1×10^{-11}	Silver sulfide*	Ag_2S	6×10^{-51}
Iron(II) hydroxide	$Fe(OH)_2$	7.9×10^{-16}	Strontium carbonate	$SrCO_3$	9.3×10^{-10}
Lanthanum fluoride	LaF_3	2×10^{-19}	Tin(II) sulfide*	SnS	1×10^{-26}
Lanthanum iodate	$La(IO_3)_3$	7.4×10^{-14}	Zinc carbonate	$ZnCO_3$	1.0×10^{-10}
Lead(II) carbonate	$PbCO_3$	7.4×10^{-14}	Zinc hydroxide	$Zn(OH)_2$	3.0×10^{-16}
Lead(II) chloride	$PbCl_2$	1.7×10^{-5}	Zinc oxalate	ZnC_2O_4	2.7×10^{-8}
Lead(II) chromate	$PbCrO_4$	2.8×10^{-13}	Zinc sulfide*	ZnS	2×10^{-25}

* For a solubility equilibrium of the type $MS(s) + H_2O(l) \rightleftharpoons M^{2+}(aq) + HS^-(aq) + OH^-(aq)$

ANSWERS TO SELECTED EXERCISES

Chapter 1

1.3 (**a**) Homogeneous mixture (**b**) homogeneous mixture (**c**) pure substance (**d**) homogeneous mixture. **1.4** (**a**) He (**b**) Pt (**c**) Co (**d**) Sn (**e**) Ag (**f**) antimony (**g**) lead (**h**) bromine (**i**) vanadium (**j**) mercury **1.5** C is a compound; it contains both carbon and oxygen. A is a compound; it contains at least carbon and oxygen. B is not defined by the data given; it is probably also a compound because few elements exist as white solids. **1.8** Physical properties: silvery white; lustrous; melting point = 649 °C, boiling point = 1105 °C; density at 20 °C = 1.738 g/cm^3; pounded into sheets; drawn into wires; good conductor. Chemical properties: burns in air; reacts with Cl_2. **1.9** (**a**) Physical (**b**) chemical (**c**) physical (**d**) chemical (**e**) chemical **1.10** Evaporation **1.12** (**a**) Kinetic energy (**b**) Potential energy decreases. **1.15** (**a**) 3×10^{12} m (**b**) 2.5×10^{-15} s (**c**) 5.7×10^{-5} m (**d**) 8.3×10^{3} kg **1.16** (**a**) 298 K (**b**) 383 K (**c**) 27 °C (**d**) 827 °C **1.17** (**a**) 1.62 g/mL. Tetrachloroethylene, 1.62 g/mL, is more dense than water, 1.00 g/mL; tetrachloroethylene will sink rather than float on water. (**b**) 11.7 g **1.18** (**a**) Calculated density = 0.86 g/mL. The substance is probably toluene, density = 0.866 g/mL. (**b**) 40.4 mL ethylene glycol (**c**) Yes, the graduated cylinder in Figure 1.21 will provide the appropriate level of accuracy. (**d**) 1.11×10^{3} g nickel **1.19** 4 Tg **1.21** Exact: (**b**), (**d**), and (**f**) **1.22** (**a**) 4 (**b**) 1 (**c**) 2 (**d**) 3 (**e**) 4 (**g**) 6 **1.23** (**a**) 2.04×10^{6} (**b**) 2.93×10^{-4} (**c**) -8.25×10^{4} (**d**) 9.42×10^{3} (**e**) -3.25×10^{-6} **1.24** (**a**) 43.052 (**b**) 879.30 (**c**) 2.14×10^{3} (**d**) 0.101 **1.25** 5 significant figures

1.27 (**a**) $\dfrac{2.54\text{ cm}}{1\text{ in}}$ (**b**) $\dfrac{1\text{ kg}}{2.2\text{ lb}} \times \dfrac{1\text{ g}}{1 \times 10^{-3}\text{ kg}}$

(**b**) The limiting reactant regulates the amount of products because it is completely used up during the reaction; no more product can be made when one of the reactants is unavailable. (**c**) Combining ratios are molecule and mole ratios. Since different molecules have different masses, comparing initial masses of reactants will not provide a comparison of numbers of molecules or moles. **3.55** (**a**) $2\,C_2H_5OH + 6\,O_2 \longrightarrow 4\,CO_2 + 6\,H_2O$ [This equation corresponds to the mixture of reactants in the box, but it does not have the simplest ratio of coefficients. Divide all coefficients by 2 to obtain $C_2H_5OH + 3\,O_2 \longrightarrow 2\,CO_2 + 3\,H_2O$] (**b**) C_2H_5OH limits (**c**) If the reaction goes to completion, there will be four molecules of CO_2, six molecules of H_2O, zero molecules of C_2H_5OH and one molecule of O_2. **3.56** NaOH is the limiting reactant; 0.925 mol Na_2CO_3 can be produced; 0.075 mol CO_2 remains. **3.57** (**a**) $NaHCO_3$ is the limiting reactant. (**b**) 0.524 g CO_2 (**c**) 0.238 g citric acid remains **3.58** 0.00 g $AgNO_3$ (limiting reactant), 1.94 g Na_2CO_3, 4.06 g Ag_2CO_3, 2.50 g $NaNO_3$ **3.59** (**a**) The theoretical yield is 60.3 g C_6H_5Br. (**b**) 70.1% yield **3.60** 28 g S_8 actual yield **3.61** Equation (**a**) best fits the diagram. **3.63** (**a**) NO_2 (**b**) No, because we have no way of knowing whether the empirical and molecular formulas are the same. NO_2 represents the simplest ratio of atoms in a molecule but not the only possible molecular formula. **3.65** (**a**) $C_2H_5NO_2$ (**b**) 75.0 g/mol (**c**) 1.332 mol glycine (**d**) Mass %N in glycine is 18.7%. **3.67** (**a**) $N_2 + 3H_2 \longrightarrow 2\,NH_3$. (**b**) H_2 is the limiting reactant. (**c**) 6 NH_3 molecules can be made. (**d**) One N_2 molecule is left over. **3.107** (**a**) $CH_3COCH_3(l) + 4\,O_2(g) \longrightarrow 3\,CO_2(g) + 3\,H_2O(l)$ (**b**) $Hg_2CO_3(s) \longrightarrow CO_2(g) + H_gO(s) + Hg(l)$
(**c**) $SO_2(g) + H_2O(l) \longrightarrow H_2SO_3(aq)$ **3.111** (**a**) 4.8×10^{-20} g CdSe (**b**) 150 Cd atoms (**c**) 8.4×10^{-19} g CdSe (**d**) 2.6×10^3 Cd atom **3.115** $C_8H_8O_3$ **3.119** (**a**) 1.19×10^{-5} mol NaI (**b**) 8.1×10^{-3} g NaI **3.123** 7.5 mol H_2 and 4.5 mol N_2 present initially **3.128** 6.46×10^{24} O atoms **3.132** (**a**) $2\,NO_2(g) \longrightarrow N_2(g) + 2\,O_2(g)$ (**b**) 3.95×10^1 g NO, 6.05×10^1 g NO_2

Chapter 4

4.2 (**a**) False. Electrolyte solutions conduct electricity because *ions* are moving through the solution. Because ions are mobile in solution, the added presence of uncharged molecules does not inhibit conductivity. **4.3** Statement (**b**) is most correct.
4.4 (**a**) $Li_2CO_3(aq) \longrightarrow 2\,Li^+(aq) + CO_3^{2-}(aq)$
(**b**) $(NH_4)_3PO_4(aq) \longrightarrow 3\,NH_4^+(aq) + PO_4^{3-}(aq)$
(**c**) $Na_2Cr_2O_7(aq) \longrightarrow 2\,Na^+(aq) + Cr_2O_7^{2-}(aq)$
(**d**) $NaPF_6(aq) \longrightarrow Na^+(aq) + PF_6^-(aq)$
4.5 H^+ and CO_3^{2-} ions; $H_2CO_3(aq) \rightleftharpoons 2\,H^+(aq) + CO_3^{2-}(aq)$
4.7 (**a**) Insoluble (**b**) soluble (**c**) soluble (**d**) soluble (**e**) insoluble
4.8 (**a**) $Ca(CH_3COO)_2(aq) + 2\,NaOH(aq) \longrightarrow Ca(OH)_2(s) + 2\,NaCH_3COO(aq)$ (**b**) No precipitate
(**c**) $3\,Na_2S(aq) + 2\,FeCl_3(aq) \longrightarrow Fe_2S_3(s) + 6\,NaCl(aq)$
4.10 Only Pb^{2+} could be present. **4.11** (**a**) True (**b**) false (**c**) false (**d**) true (**e**) false **4.13** (**a**) False. H_2SO_4 is a diprotic acid; it has two ionizable hydrogen atoms. (**b**) False. HCl is a strong acid. (**c**) False. CH_3OH is a molecular nonelectrolyte. **4.14** (**a**) Acid, mixture of ions and molecules (weak electrolyte) (**b**) none of the above, entirely molecules (nonelectrolyte) (**c**) salt, entirely ions (strong electrolyte) (**d**) base, entirely ions (strong electrolyte) **4.15** (**a**) HF, weak electrolyte (**b**) C_6H_5COOH, weak electrolyte (**c**) C_6H_6, nonelectrolyte (**d**) $CoCl_3$, strong electrolyte (**e**) $AgNO_3$, strong electrolyte
4.16 (**a**) $2\,HBr(aq) + Ca(OH)_2(aq) \longrightarrow CaBr(aq) + 2\,H_2O(l)$;
$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$;
(**b**) $Cu(OH)_2(s) + 2\,HClO_4(aq) \longrightarrow Cu(ClO_4)_2(aq) + 2\,H_2O(l)$;
$Cu(OH)_2(s) + 2\,H^+(aq) \longrightarrow 2\,H_2O(l) + Cu^{2+}(aq)$
(**c**) $Al(OH)_3(s) + 3\,HNO_3(aq) \longrightarrow Al(NO_3)_3(aq) + 3\,H_2O(l)$;
$Al(OH)_3(s) + 3\,H^+(aq) \longrightarrow 3\,H_2O(l) + Al^{3+}(aq)$
4.17 (**a**) $CdS(s) + H_2SO_4(aq) \longrightarrow CdSO_4(aq) + H_2S(g)$;
$CdS(s) + 2H^+(aq) \longrightarrow H_2S(g) + Cd^{2+}(aq)$

(**b**) $MgCO_3(s) + 2\,HClO_4(aq) \longrightarrow Mg(ClO_4)_2(aq) + H_2O(l) + CO_2(g)$; $MgCO_3(s) + 2\,H^+(aq) \longrightarrow H_2O(l) + CO_2(g) + Mg^{2+}(aq)$ **4.18** (**a**) $MgCO_3(s) + 2\,HCl(aq) \longrightarrow MgCl_2(aq) + H_2O(l) + CO_2(g)$; $MgCO_3(s) + 2\,H^+(aq) \longrightarrow Mg^{2+}(aq) + H_2O(l) + CO_2(g)$; $MgO(s) + 2\,HCl(aq) \longrightarrow MgCl_2(aq) + H_2O(l)$; $MgO(s) + 2\,H^+(aq) \longrightarrow Mg^{2+}(aq) + H_2O(l)$; $Mg(OH)_2(s) + 2\,H^+(aq) \longrightarrow Mg^{2+}(aq) + 2\,H_2O(l)$ (**b**) We can distinguish magnesium carbonate, $MgCO_3(s)$, because its reaction with acid produces $CO_2(g)$, which appears as bubbles. The other two compounds are indistinguishable, because the products of the two reactions are exactly the same. **4.20** Metals in region A are most easily oxidized. Nonmetals in region D are least easily oxidized. **4.22** (**a**) +6 (**b**) +4 (**c**) +5 (**d**) +5 (**e**) +4 (**f**) +2 **4.23** (**a**) $N_2 \longrightarrow 2\,NH_3$, N is reduced; $3\,H_2 \longrightarrow 2\,NH_3$, H is oxidized (**b**) $Fe^{2+} \longrightarrow Fe$, Fe is reduced; $Al \longrightarrow Al^{3+}$, Al is oxidized (**c**) $Cl_2 \longrightarrow 2\,Cl^-$, Cl is reduced; $2\,I^- \longrightarrow I_2$, I is oxidized (**d**) $S^{2-} \longrightarrow SO_4^{2-}$, S is oxidized; $H_2O_2 \longrightarrow H_2O$, O is reduced

4.24 (**a**) $Mn(s) + H_2SO_4(aq) \longrightarrow MnSO_4(aq) + H_2(g)$; $Mn(s) + 2\,H^+(aq) \longrightarrow Mn^{2+}(aq) + H_2(g)$ (**b**) $2\,Cr(s) + 6\,HBr(aq) \longrightarrow 2\,CrBr_3(aq) + 3\,H_2(g)$; $2\,Cr(s) + 6\,H^+(aq) \longrightarrow 2\,Cr^{3+}(aq) + 3\,H_2(g)$ (**c**) $Sn(s) + 2\,HCl(aq) \longrightarrow SnCl_2(aq) + H_2(g)$; $Sn(s) + 2\,H^+(aq) \longrightarrow Sn^{2+}(aq) + H_2(g)$ (**d**) $2\,Al(s) + 6\,HCOOH(aq) \longrightarrow 2\,Al(HCOO)_3(aq) + 3\,H_2(g)$; $2\,Al(s) + 6\,HCOOH(aq) \longrightarrow 2\,Al^{3+}(aq) + 6\,HCOO^-(aq) + 3\,H_2(g)$ **4.25** (**a**) $Fe(s) + Cu(NO_3)_2(aq) \longrightarrow Fe(NO_3)_2(aq) + Cu(s)$ (**b**) NR (**c**) $Sn(s) + 2\,HBr(aq) \longrightarrow SnBr_2(aq) + H_2(g)$ (**d**) NR (**e**) $2\,Al(s) + 3\,CoSO_4(aq) \longrightarrow Al_2(SO_4)_3(aq) + 3\,Co(s)$ **4.27** (**a**) 1.17 *M* $ZnCl_2$ (**b**) 0.158 mol H^+ (**c**) 58.3 mL of 6.00 *M* NaOH **4.28** 16 g $Na^+(aq)$ **4.29** BAC of 0.08 = 0.02 *M* CH_3CH_2OH (alcohol) **4.30** (**a**) 0.15 *M* Na_2CO_3 has the highest Na^+ concentration. (**b**) 20.0 mL of 0.15 *M* $NaHCO_3$ has more Na^+ ions. **4.31** (**a**) 1.05 *M* K^+, 0.35 *M* PO_4^{3-} (**b**) 5×10^{-4} *M* Cu^{2+}, 1×10^{-3} *M* Cl^- (**c**) 0.0184 *M* CH_3CH_2OH (**d**) 0.082 *M* Na^+, 0.041 *M* CO_3^{2-}, 0.236 *M* K^+, 0.118 *M* SO_4^{2-}

4.32 (**a**) 16.9 mL 14.8 *M* NH_3 (**b**) 0.296 *M* NH_3 **4.33** (**a**) The ratio of drug molecules to cancer cells is 4.5×10^6 **4.34** 1.398 *M* CH_3COOH **4.36** (**a**) 20.0 mL of 0.15 *M* HCl (**b**) 0.224 g KCl (**c**) The KCl reagent is virtually free relative to the HCl solution. The KCl analysis is more cost-effective. **4.37** (**a**) 38.0 mL of 0.115 *M* $HClO_4$ (**b**) 769 mL of 0.128 *M* HCl (**c**) 0.408 *M* $AgNO_3$ (**d**) 0.275 g KOH **4.38** 27 g $NaHCO_3$ **4.39** (**a**) Molar mass of metal hydroxide is 103 g/mol. (**b**) Rb^+

4.40 (**a**) $3\,NaOH(aq) + AlCl_3(aq) \longrightarrow Al(OH)_3(s) + 3\,NaCl(aq)$ (**b**) $Al(OH)_3$ (**c**) $AlCl_3$ is the limiting reagent. (**d**) 0.70 g $Al(OH)_3$ (**e**) 0.124 *M* Na^+, 0.106 *M* Cl^-, and 0.018 *M* OH^-.

4.41 91.39% $Mg(OH)_2$ **4.42** Diagram (**c**) represents Li_2SO_4

4.46 $BaCl_2$ **4.48** Platinum will neither be oxidized by nor dissolve in any of the three available solutions. Lead is oxidized by and will dissolve in the nitric acid solution, but not the nickel nitrate solution. Zinc is oxidized by and will dissolve in both nitric acid and nickel nitrate solutions. **4.50** The "water-splitting" reaction is (**c**), a redox reaction. **4.60** (**a**) K^+, SO_4^{2-} (**b**) Li^+, NO_3^- (**c**) NH_4^+, Cl^- **4.69** (**a**) False (**b**) false **4.75** (**a**) i. $Zn(s) + Cd^{2+}(aq) \longrightarrow Cd(s) + Zn^{2+}(aq)$; ii. $Cd(s) + Ni^{2+}(aq) \longrightarrow Ni(s) + Cd^{2+}(aq)$ (**b**) The elements chromium, iron, and cobalt more closely define the position of cadmium in the activity series. (**c**) Place an iron strip in $CdCl_2(aq)$. If Cd(s) is deposited, Cd is less active than Fe; if there is no reaction, Cd is more active than Fe. Do the same test with Co if Cd is less active than Fe or with Cr if Cd is more active than Fe. **4.77** (**a**) Extensive; it represents the amount of substances in a solution. The more the number of substances present in a solution, the larger the number of moles. (**b**) No. Concentration is an intensive property. It is the ratio of the amount of solute, in terms of number of moles, present in a certain quantity of solvent or solution. One cannot determine the number of moles of Zn^{2+} in a 0.1 *M* $ZnCl_2$ solution if the quantity of the solution is not given. **4.82** (**a**) 316 g ethanol (**b**) 401 mL ethanol **4.95** (**a**) $UO_2(s) + 4\,HF(aq) \longrightarrow UF_4(s) + H_2O$; $UF_4(s) + F_2(g) \longrightarrow UF_6(s)$ (**b**) Step 1 (**c**) Step 2 **4.99** (**a**) $Al(OH)_3(s) + 3\,H^+(aq) \longrightarrow Al^{3+}(aq) + 3\,H_2O(l)$ (**b**) $Mg(OH)_2(s) + 2\,H^+(aq) \longrightarrow Mg^{2+}(aq) + 2\,H_2O(l)$ (**c**) $MgCO_3(s) + 2\,H^+(aq) \longrightarrow Mg^{2+}(aq) + H_2O(l) + CO_2(g)$ (**d**) $NaAl(CO_3)(OH)_2(s) + 4\,H^+(aq) \longrightarrow Na^+(aq) + Al^{3+}(aq) + 3\,H_2O(l) + CO_2(g)$ (**e**) $CaCO_3(s) + 2\,H^+(aq) \longrightarrow Ca^{2+}(aq) + H_2O(l) + CO_2(g)$ [In (**c**), (**d**) and (**e**), one could also write the equation for formation of bicarbonate, e.g., $MgCO_3(s) + H^+(aq) \longrightarrow Mg^{2+} + HCO_3^-(aq)$.] **4.103** 415 mL H_3PO_4 **4.106** (**a**) 0.854 *M* CsOH (**b**) $CsOH(aq) + HI(aq) \longrightarrow CsI(aq) + H_2O(l)$ (**c**) 0.38 *M* HI **4.112** (**a**) $Zn(OH)_2(s) + H_2SO_4(aq) \longrightarrow 2\,H_2O(l) + ZnSO_4(aq)$ (**b**) $Zn(OH)_2$ is the limiting reactant. (**c**) 0 mol $Zn(OH)_2$, 0.026 mol of H_2SO_4, 0.0901 mol $ZnSO_4$ are present. **4.115** (**a**) +5 (**b**) silver arsenate (**c**) 5.22% As

Chapter 5

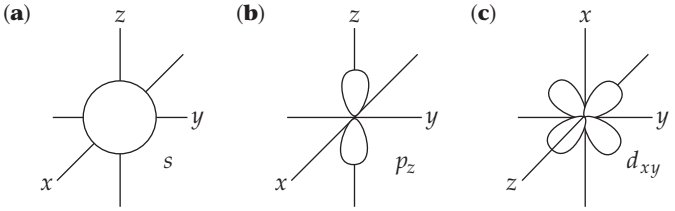
5.3 $w = 2.6 \times 10^{-18}$ J. **5.4** (**a**) Gravity; work is done because the force of gravity is opposed and the book is lifted. (**b**) Gas spring force; Work is done because the force of the pump is opposed as the gas is compressed into it. **5.6** (**a**) Matter cannot leave or enter a closed system. (**b**) Neither matter nor energy can leave or enter an isolated system. (**c**) Any part of the universe not part of the system is called the surroundings. **5.7** (**a**) According to the first law of thermodynamics, energy is conserved. (**b**) The *internal energy* (**E**) of a system is the sum of all the kinetic and potential energies of the system components. (**c**) The internal energy of a closed system increases when work is done on the system and when heat is transferred to the system. **5.8** (**a**) $\Delta E = -0.077$ kJ, endothermic (**b**) $\Delta E = -22.1$ kJ, exothermic **5.9** (**a**) Since no work is done by the system in case (2), the gas will absorb most of the energy as heat; the case (2) gas will have the higher temperature. (**b**) In case (1) energy will be used to do work on the surroundings ($-w$), but some will be absorbed as heat ($+q$). In case (2) $w = 0$ and q is (+). (**c**) ΔE is greater for case (2) because the entire 100 J increases the internal energy of the system rather than a part of the energy doing work on the surroundings. **5.10** (**a**) A *state function* is a property that depends only on the physical state (pressure, temperature, etc.) of the system, not on the route used to get to the current state. (**b**) Internal energy is a state function; heat is not a state function. (**c**) Volume is a state function. The volume of a system depends only on conditions (pressure, temperature, amount of substance), not the route or method used to establish that volume. **5.12** $w = 203$ J **5.13** (**a**) As $\Delta E = q + w$, measuring ΔE generally requires a means to measure both q and w. While, at constant pressure, the measured heat q_p is identical to the change in enthalpy ΔH. (**b**) E is a property of a thermodynamic system; it only depends on its conditions, e.g. its temperature and pressure. Heat q is not a property of a system, q describes energy transferred to or from the system. We can equate change in internal energy, ΔE, with heat only for the specific conditions of constant volume and no work. (**c**) The process is exothermic. **5.15** $\Delta E = 1.47$ kJ; $\Delta H = 0.824$ kJ **5.16**(**a**) $CH_4(g) + 2\,O_2(g) \longrightarrow CO_2(g) + 2H_2O(l)$; $\Delta H = -890$ kJ

(**b**)

$CH_4(g) + 2\,O_2(g)$

$\Delta H = -890$ kJ

$CO_2(g) + 2H_2O(l)$



5.17 (**a**) $\Delta H^0_{rxn} = -435.88$ kJ/mol (**b**) 2 H(g) has the higher enthalpy. **5.18** (**a**) Exothermic (**b**) −87.9 kJ heat transferred (**c**) 15.7 g MgO produced (**d**) 602 kJ heat absorbed **5.19** (**a**)−29.5 kJ (**b**) −4.11 kJ (**c**) 60.6 J **5.20** (**a**) $\Delta H = 726.5$ kJ (**b**) $\Delta H = -1453$ kJ (**c**) The exothermic forward reaction is more likely to be thermodynamically favored. (**d**) Vaporization is endothermic. If the product were $H_2O(g)$, the reaction would be more endothermic and would have a less negative ΔH. **5.22** (**a**) $C_m/C_s = MM$ (**b**) $C_m = 24.3$ J/mol-K (**c**) To calculate heat capacity from specific heat, the mass of the particular piece of aluminum component must be known. **5.23** (**a**) 4.184 J (**b**) 75.4 J (**c**) 1548 J/K (**d**) 452 kJ **5.24** (**a**) 2.66×10^3 J (**b**) It will require more heat to increase the temperature of one mole of octane, $C_8H_{18}(l)$, by a certain amount than to increase the temperature of one mole of water, $H_2O(l)$, by the same amount. **5.25** (**a**) $\Delta H = -19.024$ kJ (**b**) $\Delta H = -57.37$ kJ/mol **5.26** (**a**) $C_6H_4O_2(s) + 6O_2(g) \longrightarrow 2H_2O(l) + 6CO_2(g)$ (**b**) $\Delta H_{rxn} = -25.44$ kJ/g quinone or –2750 kJ/mol. **5.27** (**a**) Heat capacity of the complete calorimeter = 18.46 kJ/°C (**b**) 5.36 °C **5.30** $\Delta H = -1300.0$ kJ **5.31** $\Delta H = -2.49 \times 10^3$ kJ **5.33** (**a**) *Standard conditions* for enthalpy changes are $P = 1$ atm and some common temperature, usually 298 K. (**b**) *Enthalpy of formation* is the enthalpy change that occurs when a compound is formed from its component elements. (**c**) *Standard enthalpy of formation*, ΔH°_f, is the enthalpy change that accompanies formation of one mole of a substance from elements in their standard states.

5.34 (**a**) $\frac{1}{2}N_2(g) + O_2(g) \longrightarrow NO_2(g)$, $\Delta H^\circ_f = 33.84$ kJ
(**b**) $S(s) + \frac{3}{2}O_2(g) \longrightarrow SO_3(g)$, $\Delta H^\circ_f = -395.2$ kJ
(**c**) $Na(s) + \frac{1}{2}Br_2(l) \longrightarrow NaBr(s)$, $\Delta H^\circ_f = -361.4$ kJ
(**d**) $Pb(s) + N_2(g) + 3O_2(g) \longrightarrow Pb(NO_3)_2(s)$, $\Delta H^\circ_f = -451.9$ kJ
5.35 $\Delta H^\circ_{rxn} = -847.6$ kJ **5.36** (**a**) $\Delta H^\circ_{rxn} = -196.6$ kJ
(**b**) $\Delta H^\circ_{rxn} = 37.1$ kJ (**c**) $\Delta H^\circ_{rxn} = -976.94$ kJ (**d**) $\Delta H^\circ_{rxn} = -68.3$ kJ
5.37 $\Delta H^\circ_f = -248$ kJ
5.38 (**a**) $C_8H_{18}(l) + \frac{25}{2}O_2(g) \longrightarrow 8CO_2(g) + 9H_2O(g)$
(**b**) $\Delta H^\circ_f = -259.5$kJ
5.39 (**a**) $C_2H_5OH(l) + 3O_2(g) \longrightarrow 2CO_2(g) + 3H_2O(g)$
(**b**) $\Delta H^\circ_{rxn} = -1234.8$ kJ (**c**) 2.11×10^4 kJ/L heat produced
(**d**) 0.071284 g CO_2/kJ heat emitted **5.41** (**a**) $+\Delta H$ (**b**) $-\Delta H$ (**c**) $+\Delta H$ (**d**) $+\Delta H$ **5.42** (**a**) $\Delta H = -103$ kJ (**b**) $\Delta H = -1295$ kJ **5.43** (**a**) ΔH for the reaction is 192.9 kJ. D(Br—Br) = 193 kJ (**b**) The difference between the value calculated in part (**a**) and the value from Table 5.4 is zero, to three significant figures. **5.44** (**a**) ΔH for the reaction calculated using bond enthalpies is −485 kJ. (**b**) The estimate from part (**a**) is less negative or larger than the true reaction enthalpy. (**c**) ΔH for the reaction calculated using enthalpies of formation is −572 kJ. **5.45** (**a**) *Fuel value* is the amount of energy produced when 1 g of a substance (fuel) is combusted. (**b**) 5 g of fat (**c**) These products of metabolism are expelled as waste via the alimentary tract, $H_2O(l)$ primarily in urine and feces, and $CO_2(g)$ as gas when breathing. **5.46** (**a**) 228 cal/ serving (**b**) Potassium is not metabolized by the body, so it does not contribute to the calorie content of the food. **5.47** 59.7 Cal **5.48** (**a**) $\Delta H_{comb} = -1850$ kJ/mol C_3H_4, −1926 kJ/mol C_3H_6, −2044 kJ/mol C_3H_8 (**b**) $\Delta H_{comb} = -4.616 \times 10^4$ kJ/kg C_3H_4, -4.578×10^4 kJ/kg C_3H_6, -4.635×10^4 kJ/kg C_3H_8 (**c**) These three substances yield nearly identical quantities of heat per unit mass, but propane is marginally higher than the other two. **5.49** (**a**) $E_{el} = 1.8 \times 10^2$ J (**b**) If the spheres are released, they will move away from each other. (**c**) v = 19 m/s **5.52** (**a**) (iii) (**b**) none of them (**c**) all of them **5.55** (**a**) The sign of w is (+). (**b**) The sign of q is (−). (**c**) The sign of w is positive and the sign of q is negative, so we cannot absolutely determine the sign of ΔE. It is likely that the heat lost is much smaller than the work done on the system, so the sign of ΔE is probably positive. **5.58** (**a**) $N_2(g) + O_2(g) \longrightarrow 2NO(g)$. Since $\Delta V = 0$, $w = 0$. (**b**) $\Delta H = \Delta H_f = 90.37$ kJ. The definition of a formation reaction is one where elements combine to form one mole of a single product. The enthalpy change for such a reaction is the enthalpy of formation. **5.61** (**a**) $E_{el} = -1.0 \times 10^{-18}$ J (**b**) $\Delta E_{el} = 7.7 \times 10^{-19}$ J (**c**) The two objects carry opposite charges; they attract each other. As they move farther apart, their energy increases. **5.62** (**a**) $F_{el} = -4.4 \times 10^{-9}$ N (**b**) $F_g = 1.9 \times 10^{-48}$ N (**c**) The electrostatic force is 2.3×10^{39} times larger than the gravitational force. Both forces are attractive, that is, they point in the same direction. **5.73** (**a**) $w = 7.4$ kJ (**b**) $\Delta E = -476.2$ kJ (**c**) Since the value of Δn is negative, the quantity $(-P\Delta V)$ is positive. We add a positive quantity to ΔH to calculate ΔE, so ΔE must be larger. **5.87** Yes, because internal energy is a state function. **5.105** The spontaneous air bag reaction is probably exothermic, with $-\Delta H$ and thus $-q$. When the bag inflates, work is done by the system, so the sign of w is also negative. **5.108** $\Delta H = -11.73$ kJ; $\Delta E = -14.21$ kJ **5.110** 1.8×10^4 bricks **5.113** (**a**) $\Delta H^0_{rxn} = -11.73$ KJ (**b**) 39.7 g Fe needed **5.117** (**a**) $\Delta H^0_{rxn} = 82$ KJ/mol (**b**) 1-hexene has greater enthalpy than cyclohexane. (**c**) 1-hexene will have the larger combustion enthalpy. **5.120** If all work is used to increase the man's potential energy, the stair climbing uses 70 Cal and will not compensate for the extra order of 245 Cal fries. (More than 70 Cal will be required to climb the stairs because some energy is used to move limbs and some will be lost as heat.) **5.125** (**a**) 1.479×10^{-18} J/molecule (**b**) 1×10^{-15} J/photon. The X-ray has approximately 1000 times more energy than is produced by the combustion of 1 molecule of $CH_4(g)$. **5.127** (**a**) $\Delta H°$ for neutralization of the acids is: HNO_3, −55.8 kJ; HCl, −56.1 kJ; NH_4^+, −4.1 kJ. (**b**) $H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$ is the net ionic equation for the first two reactions. $NH_4^+(aq) + OH^-(aq) \longrightarrow NH_3(aq) + H_2O(l)$ (**c**) The $\Delta H°$ values for the first two reactions are nearly identical, −55.8 kJ and −56.1 kJ. Because spectator ions do not change during a reaction and these two reactions have the same net ionic equation, it is not surprising that they have the same $\Delta H°$. (**d**) Strong acids are more likely than weak acids to donate H^+. Neutralization of the two strong acids is energetically favorable, while the third reaction is barely so. NH_4^+ is likely a weak acid. **5.129** (**a**) $\Delta H° = -65.7$ kJ (**b**) $\Delta H°$ for the complete molecular equation will be the same as $\Delta H°$ for the net ionic equation. Since the overall enthalpy change is the enthalpy of products minus the enthalpy of reactants, the contributions of spectator ions cancel. (**c**) ΔH°_f for $AgNO_3(aq)$ is −100.4 kJ/mol.

Chapter 6

6.2 (**a**) True (**b**) False. Ultraviolet light has shorter wavelengths than visible light. (**c**) False. X-rays travel at the same speed as microwaves. (**d**) False. Electromagnetic radiation and sound waves travel at different speeds. **6.3** Wavelength of X-rays < ultraviolet < green light < red light < infrared < radio waves **6.4** (**a**) 10^7 1/cm (**b**) 2×10^4 1/cm (**c**) 10 1/cm **6.5** (**a**) 3.0×10^{13} s^{-1} (**b**) 5.45×10^{-7} m = 545 nm. (**c**) The radiation in (**b**) is visible; the radiation in (**a**) is not. (**d**) 1.50×10^4 m **6.6** 4.6×10^{14} s^{-1}; red. **6.8** (iv) **6.9** (**a**) 1.95×10^{-19} J (**b**) 4.81×10^{-19} J (**c**) 328 nm **6.10** (**a**) $\lambda = 3.0$ mm, $E = 6.6 \times 10^{-23}$ J, $\lambda = 3.0$ nm, $E = 6.6 \times 10^{-16}$ J (**b**) The 3.0 mm photon is in the microwave region and the 0.3 nm photon is in the x-ray region. The x-ray photon has the greater energy. **6.11** (**a**) 6.11×10^{-19} J/photon (**b**) 368 kJ/mol (**c**) 1.64×10^{15} photons (**d**) 368 kJ/mol **6.12** (**a**) The $\sim 1 \times 10^{-6}$ m radiation is in the infrared portion of the spectrum.
(**b**) 8.1×10^{16} photons/s **6.13** (**a**) $\nu = 1.09 \times 10^{15}$ 1/s
(**b**) $\lambda = 275$ nm (**c**) $E_{240} = 8.28 \times 10^{-19}$ J. The excess energy of the 240-nm photon is converted into the kinetic energy of the emitted electron. $\nu = 4.82 \times 10^5$ m/s. **6.15** When an electron in a hydrogen atom transitions from $n = 1$ to $n = 3$, the atom "expands". **6.16** (**a**) Emitted (**b**) emitted (**c**) emitted **6.17** (**a**) $E_3 = -2.42 \times 10^{-19}$ J; $E_6 = -6.06 \times 10^{-20}$ J; $\Delta E = -1.82 \times 10^{-19}$ J; $\lambda = 1090$ nm
(**b**) infrared **6.18** (**a**) (ii) (**b**) $n_i = 3$, $n_f = 2$; $\lambda = 6.56 \times 10^{-7}$ m; this is the red line at 656 nm. $n_i = 4$, $n_f = 2$; $\lambda = 4.86 \times 10^{-7}$ m; this is

the blue-green line at 486 nm. $n_i = 5$, $n_f = 2$; $\lambda = 4.34 \times 10^{-7}$ m; this is the blue-violet line at 434 nm. **6.19** (**a**) Ultraviolet region (**b**) $n_i = 5$, $n_f = 1$ **6.20** The order of decreasing energy of light absorbed is: $n = 1$ to $n = 3$; $n = 2$ to $n = 5$; $n = 3$ to $n = 7$; $n = 4$ to $n = 8$ **6.23** (**a**) $\lambda = 5.6 \times 10^{-37}$ m (**b**) $\lambda = 2.65 \times 10^{-34}$ m (**c**) $\lambda = 2.3 \times 10^{-13}$ m (**d**) $\lambda = 1.51 \times 10^{-11}$ m **6.24** 3.16×10^3 m/s **6.25** (**a**) $\Delta x \geq 4 \times 10^{-27}$ m (**b**) $\Delta x \geq 3 \times 10^{-10}$ m **6.27** (**a**) False (**b**) false **6.28** (**a**) $n = 4$, $l = 3, 2, 1, 0$ (**b**) $l = 2$, $m_l = -2, -1, 0, 1, 2$ (**c**) $m_l = 2$, $l \geq 2$ or $l = 2, 3$ or 4 **6.29** (**a**) 3*p*: $n = 3$, $l = 1$ (**b**) 2*s*: $n = 2$, $l = 0$ (**c**) 4*f*: $n = 4$, $l = 3$ (**d**) 5*d*: $n = 5$, $l = 2$ **6.30** (**a**) 3, 2, 1, 0, −1, −2, −3 (**b**) $\frac{1}{2}$, $-\frac{1}{2}$ **6.31** (**a**) Impossible, 1*p* (**b**) possible (**c**) possible (**d**) impossible, 2*d* **6.33**

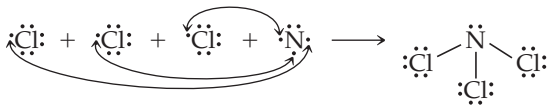
6.34 (**a**) The hydrogen atom 1*s* and 2*s* orbitals have the same overall spherical shape, but the 2*s* orbital has a larger radial extension and one more node than the 1*s* orbital. (**b**) A single 2*p* orbital is directional in that its electron density is concentrated along one of the three Cartesian axes of the atom. The $d_{x^2-y^2}$ orbital has electron density along both the *x*- and *y*-axes, while the p_x orbital has density only along the *x*-axis. (**c**) The average distance of an electron from the nucleus in a 3*s* orbital is greater than for an electron in a 2*s* orbital. (**d**) $1s < 2p < 3d < 4f < 6s$ **6.36** (**a**) For the He^+ ion, the 2*s* and 2*p* orbitals have the same energy. (**b**) Yes. In a helium atom, the 2*s* orbital is lower in energy than the 2*p* orbital. **6.37** (**a**) No. Both configurations follow the Pauli exclusion principle. (**b**) No. Both configurations follow Hund's rule. (**c**) No. In the absence of a magnetic field, we cannot say which configuration has the lower energy. **6.38** (**a**) 2 (**b**) 6 (**c**) 10 (**d**) 2 **6.40** (**a**) "Valence electrons" are those involved in chemical bonding. They are part or all of the outer-shell electrons listed after the core. (**b**) "Core electrons" are inner-shell electrons that have the electron configuration of the nearest noble-gas element. (**c**) Each box represents an orbital. (**d**) Each half-arrow in an orbital diagram represents an electron. The direction of the half-arrow represents electron spin. **6.41** (**a**) Cs, $[Xe]6s^1$ (**b**) Ni, $[Ar]4s^23d^8$ (**c**) Se, $[Ar]4s^23d^{10}4p^4$ (**d**) Cd, $[Kr]5s^24d^{10}$ (**e**) U, $[Rn]5f^36d^17s^2$ (**f**) Pb, $[Xe]6s^24f^{14}5d^{10}6p^2$ **6.42** (**a**) Be, 0 unpaired electrons (**b**) O, 2 unpaired electrons (**c**) Cr, 6 unpaired electrons (**d**) Te, 2 unpaired electrons **6.43** (**a**) The 4*s* subshell would fill before the 3*d*. (**b**) The *s* subshell can hold only 2 electrons. (**c**) The third electron would fill the 2*s* subshell before the 3*s*. **6.45** (**a**) 0.1 m or 10 cm (**b**) No. Visible radiation has wavelengths much shorter than 0.1 m. (**c**) Energy and wavelength are inversely proportional. Photons of the longer 0.1-m radiation have less energy than visible photons. (**d**) Radiation with $\lambda = 0.1$ m is in the low-energy portion of the microwave region. The appliance is probably a microwave oven. **6.48** (**a**) Increase (**b**) decrease **6.52** (**a**) $l = 1$ (**b**) $3p_y$ (**c**) (iii) **6.90** (**a**) $\lambda_A = 3.6 \times 10^{-8}$ m, $\lambda_B = 8.0 \times 10^{-8}$ m (**b**) $\nu_A = 8.4 \times 10^{15}$ s^{-1}, $\nu_B = 3.7 \times 10^{15}$ s^{-1} (**c**) A, ultraviolet; B, ultraviolet **6.93** 3.9 hr **6.95** 8.835×10^{19} photons **6.100** (**a**) Lines with $n_f = 1$ lie in the ultraviolet, lines with $n_f = 2$ lie in the visible and lines with $n_f = 3$ lie near the infrared. Lines with $n_f = 4$ will have smaller energy differences and longer wavelengths and lie in the infrared. (**b**) $n_i = 5$, $\Delta E = -4.905 \times 10^{-20}$ J; $\lambda = 4050$ nm; $n_i = 6$, $\Delta E = -7.569 \times 10^{-20}$ J, $\lambda = 2624$ nm; $n_i = 7$, $\Delta E = -9.176 \times 10^{-20}$ J, $\lambda = 2165$ nm **6.104** $\lambda = 12.3$ pm

6.108 (**a**) The nodal plane of the p_z orbital is the *xy*-plane. (**b**) The two nodal planes of the d_{xy} orbital are the ones where $x = 0$ and $y = 0$. These are the *yz*- and *xz*-planes. (**c**) The two nodal planes of the $d_{x^2-y^2}$ orbital are the ones that bisect the *x*- and *y*-axes and contain the *z*-axis. **6.110** (**a**) Cl:$[Ne]3s^2\,3p^5$, 1 unpaired electron (**b**) Al:$[Ne]3s^2\,3p^1$, 1 unpaired electron (**c**) Zr:$[Kr]5s^2\,4d^2$, 2 unpaired electrons (**d**) As:$[Ar]4s^2\,3d^{10}\,4p^3$, 3 unpaired electrons (**e**) Sb:$[Kr]5s^2\,4d^{10}\,5p^3$, 3 unpaired electrons (f) W:$[Xe]6s^2\,4f^{14}\,5d^4$, 4 unpaired electrons **6.113** (**a**) 1.7×10^{28} photons (**b**) 34 s **6.117** (**a**) Bohr's theory was based on the Rutherford nuclear model of the atom: a dense positive charge at the center and a diffuse negative charge surrounding it. Bohr's theory then specified the nature of the diffuse negative charge. The prevailing theory before the nuclear model was Thomson's plum pudding model: discrete electrons scattered about a diffuse positive charge cloud. Bohr's theory could not have been based on the Thomson model of the atom. (**b**) De Broglie's hypothesis is that electrons exhibit both particle and wave properties. Thomson's conclusion that electrons have mass is a particle property, while the nature of cathode rays is a wave property. De Broglie's hypothesis actually rationalizes these two seemingly contradictory observations about the properties of electrons.

Chapter 7

7.3 (**a**) Of the elements listed, only Fe was known before 1700. (**b**) The seven metals known in ancient times, Fe, Cu, Ag, Sn, Au, Hg, and Pb, are mostly near the bottom of the activity series, Table 4.5. **7.5** For elements N, O, P, and S, O and S have the largest effective nuclear charge; N and P have the smallest effective nuclear charge. **7.6** (**a**) For both Na and K, $Z_{eff} = 1$. (**b**) For both Na and K, $Z_{eff} = 2.2$. (**c**) Slater's rules give values closer to the detailed calculations: Na, 2.51; K, 3.49. (**d**) Both approximations give the same value of Z_{eff} for Na and K; neither accounts for the gradual increase in Z_{eff} moving down a group. (**e**) Following the trend from detailed calculations, we predict a Z_{eff} value of approximately 4.5. **7.7** The $n = 2$ electrons in F experience a greater effective nuclear charge and thus have a greater probability of being closer to the nucleus. **7.10** Quantity (**b**) must be measured to determine the bonding atomic radius of an atom. **7.11** (**a**) 137 pm (**b**) The distance between W atoms will decrease. **7.12** From the bonding atomic radii, P—Cl = 107 + 102 pm = 209 pm. It is very close to the experimental values of 204 pm in PCl_3. **7.13** (**a**) As > Kr > Ar (**b**) Rb > Cd > Te (**c**) Cu > Cl > C **7.14** (**a**) False (**b**) true (**c**) false **7.15** H^-: He, Ca^{2+}: Ar, In^{3+}: Pd, Pd ($[Kr]4d^{10}$, irregular), Ge^{2+}: Zn **7.16** (**a**) Na^+ (**b**) F^-, $Z_{eff} = 7$; Na^+, $Z_{eff} = 9$ (**c**) S = 4.15; F^-, $Z_{eff} = 4.85$; Na^+, $Z_{eff} = 6.85$ (**d**) For isoelectronic ions, as nuclear charge (*Z*) increases, effective nuclear charge (Z_{eff}) increases and ionic radius decreases. **7.18** $Cl(g) \longrightarrow Cl^+(g) + e^-$; $Cl^+(g) \longrightarrow Cl^{2+}(g) + e^-$; $Cl^{2+}(g) \longrightarrow Cl^{3+}(g) + e^-$. The process for the first ionization energy requires the least amount of energy. **7.19** Of these three elements, Li has the highest second ionization energy. Both Li^+ and K^+ have the stable electron configurations of noble gases, but the unshielded 1*s* electron of Li^+ is much closer to the nucleus and requires more energy to remove. **7.20** (**a**) The smaller the atom, the larger its first ionization energy. (**b**) Of the nonradioactive elements, He has the largest and Cs has the smallest first ionization energy. **7.21** (**a**) Br (**b**) Ca (**c**) Rb (**d**) Pb (**e**) Al **7.22** (**a**) Cu^{2+}: [Ar] $3d^9$ (**b**) Ca^{2+}: [Ar], noble gas configuration (**c**) N^{3-}: [Ne], noble gas configuration (**d**) Ru^{2+}: $[Kr]4d^6$ (**e**) H^-: [He], noble gas configuration **7.23** Zn^{2+}, $[Ar]3d^{10}$; Cd^{2+}, $[Kr]4d^{10}$; Hg^{2+}, $[Xe]4f^{14}6d^{10}$ **7.25** Second electron affinity of Cl: $Cl^- + 1e^- \longrightarrow Cl^{2-}(g)$. We predict that the second electron affinity of chlorine will be positive. It is probably not possible to directly measure this quantity, because a positive value indicates that Cl^{2-} ion is unstable and will not form.

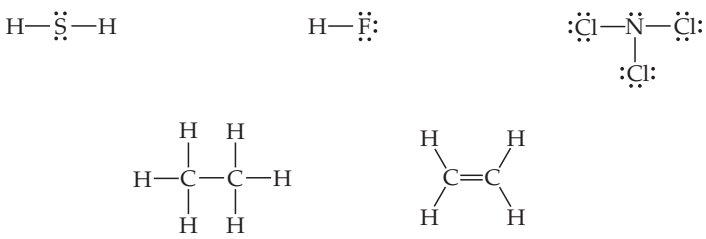
7.26 The electron affinity of I will be negative. The electron-electron repulsions created by adding an electron to an I^- ion causes the electron affinity of I^- to be a positive value. **7.27** (**a**) Ionization energy (I_1) of Ne: $Ne(g) \longrightarrow Ne^+(g) + 1\ e^-$; $[He]2s^22p^6 \longrightarrow [He]2s^22p^5$; electron affinity ($E_1$) of F: $F(g) + 1\ e^- \longrightarrow F^-(g)$; $[He]2s^22p^5 \longrightarrow [He]2s^22p^6$. (**b**) I_1 of Ne is positive; E_1 of F is negative. (**c**) One process is apparently the reverse of the other, with one important difference. Ne has a greater Z and Z_{eff}, so we expect I_1 for Ne to be somewhat greater in magnitude and opposite in sign to E_1 for F. **7.29** (**a**) Decrease (**b**) Increase (**c**) The smaller the first ionization energy of an element, the greater the metallic character of that element. The trends in (**a**) and (**b**) are the opposite of the trends in ionization energy. **7.30** Agree. When forming ions, all metals form cations. The only nonmetallic element that forms cations is the metalloid Sb, which is likely to have significant metallic character. **7.31** Ionic: ZnO, K_2O, TiO_2; molecular: SO_2, SiO_2, OF_2. Ionic compounds are formed by combining a metal and a nonmetal; molecular compounds are formed by two or more nonmetals. **7.32** ZrO will react more readily with $HCl(aq)$. **7.33** (**a**) Dichlorine heptoxide (**b**) $2\ Cl_2(g) + 7\ O_2(g) \longrightarrow 2\ Cl_2O_7(l)$ (**c**) Cl_2O_7 is an acidic oxide, so it will be more reactive to base, OH^-. (**d**) The oxidation state of Cl in Cl_2O_7 is +7; the corresponding electron configuration for Cl is $[He]2s^22p^6$ or [Ne]. **7.34** (**a**) $BCl_3(l) + 3\ H_2O(l) \longrightarrow B(OH)_3(aq) + 3\ HCl(aq)$ (**b**) $CoO\ (s) + 2\ HNO_3\ (aq) \longrightarrow Co(NO_3)_2\ (aq) + H_2O(l)$ (**c**) $P_4O_{10}(s) + 6H_2O(l) \longrightarrow 4H_3PO_4(aq)$
(**d**) $CO_2(g) + Ba(OH)_2(aq) \longrightarrow BaCO_3(s) + H_2O(l)$
7.36 (**a**) The first and second ionization energies of calcium are less than those of beryllium. (**b**) The first ionization energy of calcium is higher than that of rubidium. **7.37** (**a**) $2\ K(s) + Cl_2(g) \longrightarrow 2\ KCl(s)$
(**b**) $SrO(s) + H_2O(l) \longrightarrow Sr(OH)_2(aq)$
(**c**) $4\ Li(s) + O_2(g) \longrightarrow 2\ Li_2O(s)$ (**d**) $2\ Na(s) + S(l) \longrightarrow Na_2S(s)$
7.38 (**a**) The reactions of the alkali metals with hydrogen and with a halogen are redox reactions. Both hydrogen and the halogen gain electrons and are reduced. (The alkali metal loses electrons and is oxidized.) $Ca(s) + F_2(g) \longrightarrow CaF_2(s)$; $Ca(s) + H_2(g) \longrightarrow CaH_2(s)$.
(**b**) The oxidation number of Ca in both products is +2. The electron configuration is that of Ar, $[Ne]3s^23p^6$. **7.40** (**a**) Br, $[Ar]4s^24p^5$; Cl, $[Ne]3s^23p^5$ (**b**) Br and Cl are in the same group, and both adopt a 1− ionic charge. (**c**) The ionization energy of Br is smaller than that of Cl, because the 4*p* valence electrons in Br are farther from to the nucleus and less tightly held than the 3*p* electrons of Cl. (**d**) Both react slowly with water to form HX + HOX. (**e**) The electron affinity of Br is less negative than that of Cl, because the electron added to the 4*p* orbital in Br is farther from the nucleus and less tightly held than the electron added to the 3*p* orbital of Cl. (**f**) The atomic radius of Br is larger than that of Cl, because the 4*p* valence electrons in Br are farther from the nucleus and less tightly held than the 3*p* electrons of Cl. **7.41** (**a**) The term *inert* was dropped because it no longer described all the Group 18 elements. (**b**) In the 1960s, scientists discovered that Xe would react with substances having a strong tendency to remove electrons, such as F_2. Thus, Xe could not be categorized as an "inert" gas. (**c**) The group is now called the noble gases. **7.42** (**a**) $P_4(s) + 6\ Cl_2(g) \longrightarrow 4\ PCl_3(l)$ (**b**) $2Na(s) + 2H_2O(l) \longrightarrow H_2(g) + 2\ NaOH(aq)$ (**c**) $2HBr(g) + Cl_2(g) \longrightarrow 2HCl(g) + Br_2$
(**d**) $AlCl_3(s) + 3NaOH(aq) \longrightarrow Al(OH)_3(s) + 3NaCl(aq)$ **7.44** The largest brown sphere is Br^-, the intermediate blue one is Br, and the smallest red one is F. **7.47** (**a**) The bonding atomic radius of A, r_A, is $d_1/2$; $r_x = d_2 - (d_1/2)$. (**b**) The length of the X—X bond is $2r_x$ or $2d_2 - d_1$. **7.50** (**a**) $X + 2F_2 \longrightarrow XF_4$ (**b**) X in the diagram has about the same bonding radius as F, so it is likely to be a nonmetal. If X were a metal, the compound would be ionic and the charge on X would be 4+. The bonding (ionic) radius of X^{4+} would be much smaller than that of fluorine. **7.51** (**a**) The results are 2, 8, 18, 32. (**b**) The atomic numbers of the noble gases are 2, 10, 18, 36, 54, and 86. The differences between sequential pairs of these atomic numbers is 8, 8, 18, 18, and 32. These differences correspond to the results in (**a**). They represent the filling of new subshells when moving across the next row of the periodic chart. (**c**) The Pauli exclusion principle is the source of the "2". **7.63** (**a**) Cl < S < K (**b**) $K^+ < Cl^- < S^{2-}$ (**c**) The neutral K atom has the largest radius because the *n*-value of its outer electron is larger than the *n*-value of valence electrons in S and Cl. The K^+ ion is smallest because, in an isoelectronic series, the ion with the largest Z has the smallest ionic radius. **7.65** (**a**) Cl^- is larger than Ar because the two are isoelectronic and Ar has the larger Z and Z_{eff}. (**b**) P^{3-} is larger than S^{2-} because the two ions are isoelectronic and S^{2-} has the larger Z and Z_{eff}. (**c**) K^+ is larger than Na^+ because for particles with like charges, size increases going down a family. (**d**) F^- is larger than F because the increase in electron repulsions that accompany addition of an electron causes the electron cloud to expand. **7.88** Up to $Z = 82$, there are three instances where atomic weights are reversed relative to atomic numbers: Ar and K; Co and Ni; Te and I. **7.90** (**a**) 5+ (**b**) 4.8+ (**c**) Shielding is greater for 3*p* electrons, owing to penetration by 3*s* electrons, so Z_{eff} for 3*p* electrons is less than that for 3*s* electrons. (**d**) The first electron lost is a 3*p* electron because it has a smaller Z_{eff} and experiences less attraction for the nucleus than a 3*s* electron does. **7.94** (**a**) The P—Cl distance is 194 pm. (**b**) The predicted P—Cl bond length is 209 pm. **7.96** (**a**) Chalcogens, −2; halogens, −1. (**b**) The family with the larger value is: atomic radii, chalcogens; ionic radii of the most common oxidation state, chalcogens; first ionization energy, halogens; second ionization energy, halogens **7.100** *C*: $1s^22s^22p^2$. I_1 through I_4 represent loss of the 2*p* and 2*s* electrons in the outer shell of the atom. The values of I_1–I_4 increase as expected. I_5 and I_6 represent loss of the 1*s* core electrons. These 1*s* electrons are much closer to the nucleus and experience the full nuclear charge, so the values of I_5 and I_6 are significantly greater than I_1–I_4. **7.105** (**a**) Mg^{2+} (**b**) Cu^{2+} (**c**) Pb^{2+}
7.108 (**a**) For both H and the alkali metals, the added electron will complete an *ns* subshell, so shielding and repulsion effects will be similar. For the halogens, the electron is added to an *np* subshell, so the energy change is likely to be quite different. (**b**) True. The electron configuration of H is $1s^1$. The single 1*s* electron experiences no repulsion from other electrons and feels the full unshielded nuclear charge. The outer electrons of all other elements that form compounds are shielded by a spherical inner core of electrons and are less strongly attracted to the nucleus, resulting in larger bonding atomic radii. (**c**) Both H and the halogens have large ionization energies. The relatively large effective nuclear charge experienced by *np* electrons of the halogens is similar to the unshielded nuclear charge experienced by the H 1*s* electron. For the alkali metals, the *ns* electron being removed is effectively shielded by the core electrons, so ionization energies are low. (**d**) ionization energy of hydride, $H^-(g) \longrightarrow H(g) + 1e^-$ (**e**) electron affinity of hydrogen, $H(g) + 1\ e^- \longrightarrow H^-(g)$. The value for the ionization energy of hydride is equal in magnitude but opposite in sign to the electron affinity of hydrogen. **7.111** The most likely product is (**iii**). **7.116** Electron configuration, $[Rn]7s^25f^{14}6d^{10}7p^5$; first ionization energy, 805 kJ/mol; electron affinity, −235 kJ/mol; atomic size, 1.65 Å; common oxidation state, −1. **7.119** (**a**) Li, $[He]2s^1$; $Z_{eff} \approx 1+$ (**b**) $I_1 \approx 5.45 \times 10^{-19}$ J/atom ≈ 328 kJ/mol (**c**) The estimated value of 328 kJ/mol is less than the Table 7.4 value of 520 kJ/mol. Our estimate for Z_{eff} was a lower limit; the [He] core electrons do not perfectly shield the 2*s* electron from the nuclear charge. (**d**) Based on the experimental ionization energy, $Z_{eff} = 1.26$. This value is greater than the estimate from part (**a**) but agrees well with the "Slater" value of 1.3 and is consistent with the explanation in part (c). **7.122** (**a**) Mg_3N_2 (**b**) $Mg_3N_2(s) + 3\ H_2O(l) \longrightarrow 3\ MgO(s) + 2\ NH_3(g)$;



the driving force is the production of $NH_3(g)$. (**c**) 17% Mg_3N_2 (**d**) 3 $Mg(s)$ + 2 $NH_3(g)$ ⟶ $Mg_3N_2(s)$ + 3 $H_2(g)$. NH_3 is the limiting reactant and 0.46 g H_2 is formed. (**e**) $\Delta H^\circ_{rxn} = -368.70$ kJ

Chapter 8

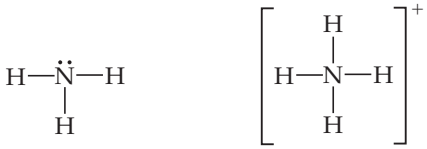
8.3 (**a**) $1s^2 2s^2 2p^6 3s^2 3p^5$ (**b**) seven (**c**) The 3*s* and 3*p* electrons are valence electrons. **8.4** (**a**)  (**b**)  (**c**)  (**d**) 



8.7 

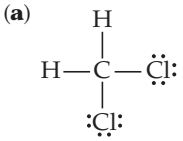
(**b**) one (**c**) K loses an electron. **8.8** (**a**) $AlCl_3$ (**b**) MgO (**c**) $ZnCl_2$ (**d**) Li_2O **8.9** (**a**) Be^{2+}: $1s^2$ = [He], noble-gas configuration (**b**) Mn^{2+}: [Ar] $3d^5$ (**c**) Cd^{2+}: [Kr] $4d^{10}$ (**d**) Fe^{3+}: [Ar] $3d^5$ (**e**) Tl^+: [Xe] $4f^{14}5d^{10}6s^2$ (**f**) At^-: [Xe] $4f^{14}5d^{10}6s^2 6p^6$ = [Rn], noble-gas configuration **8.10** (**a**) Endothermic (**b**) $NaCl(s) \longrightarrow Na^+(g) + Cl^-(g)$ (**c**) Salts like NaCl, that have singly charged ions, will have smaller lattice energies compared with salts like CaO, that have doubly charged ions. **8.11** (**a**) Na^+, 1+; Ca^{2+}, 2+ (**b**) F^-, 1−; O^{2-}, 2− (**c**) CaO will have the larger lattice energy. (**d**) We expect the lattice energy of ScN to be slightly less than 8.10×10^3 kJ **8.12** (**a**) K—F, 271 pm; Na—Cl, 283 pm; Na—Br, 298 pm; Li—Cl, 257 pm (**b**) LiCl > KF > NaCl > NaBr (**c**) From Table 8.2: LiCl, 1030 kJ; KF, 808 kJ; NaCl, 788 kJ; NaBr, 732 kJ. The predictions from ionic radii are correct. **8.13** Statement (**a**) is the best explanation. **8.15**

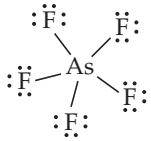
(**a**) 5 (**b**) 1 (**c**) 8 (**d**) 8 (**e**) 10 **8.16** (**a**)  (**b**) four bonding electrons (two bonding electron pairs) (**c**) An O═O double bond is shorter than an O—O single bond. The greater the number of shared electron pairs between two atoms, the shorter the distance between the atoms.

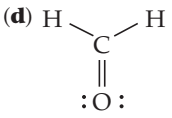


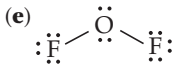
8.17

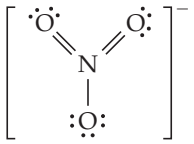
8.18



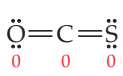






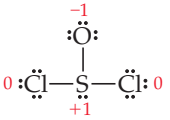


8.19



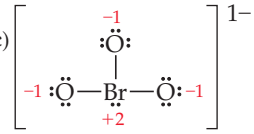
8.21 Statement (**b**) is false. **8.22** (**a**) Mg (**b**) S (**c**) C (**d**) As **8.23** The bonds in (**a**), (**b**) and (**d**) are polar. The more electronegative atom in each polar bond is: (**a**) O, (**b**) F (**d**) Cl. **8.24** (**a**) The calculated charge on H and Br is 0.12*e*. (**c**) $PbCl_4$, molecular (by contrast to the distinctly ionic RbCl), lead tetrachloride; RbCl, ionic, rubidium chloride

8.27



(**a**)  (**b**)  (**c**) 

(**d**)  (**e**)  (**f**) 

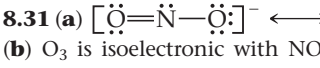


8.28 Statement (**b**) is most true. Keep in mind that when it is necessary to place more than an octet of electrons around an atom in order to minimize formal charge, there may not be a "best" Lewis structure. **8.29** Formal charges are shown on the Lewis structures; oxidation numbers are listed below each structure.

(**a**) 

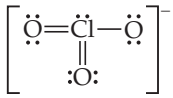
O, −2; C, +4; S, −2

(**b**) 

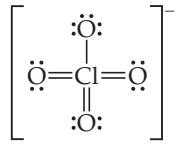


S, +4; Cl, −1; O, −2

(**c**) 



Br, +5; O, −2

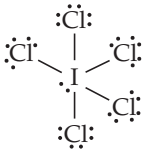


(**d**) 

Cl, +3; H, +1; O, −2

8.31 (**a**)  (**b**) O_3 is isoelectronic with NO_2^-; both have 18 valence electrons. (**c**) Since each N—O bond has partial double-bond character, the N—O bond length in NO_2^- should be shorter than an N—O single bond but longer than an N═O double bond. **8.34** Assume that the dominant structure is the one that minimizes formal charge. Following this guideline, only ClO^- obeys the octet rule. ClO, ClO_2^-, ClO_3^-, and ClO_4^- do not obey the octet rule.

ClO,  ClO^-, 

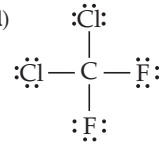


ClO_2^-,  ClO_3^-, 

ClO_4^-, 

8.35

(**a**) 



Does not obey the octet rule. H has 2 electrons.

(**b**) 

Does not obey the octet rule. Central I has 12 electrons.

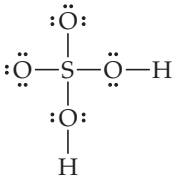
(**c**) 

Does not obey the octet rule. N has only 7 electrons.

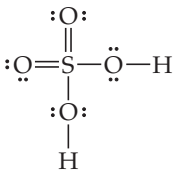
(d) 

(e) 

Does not obey the octet rule. Central I has 10 electrons.



8. 36 (a) 



This structure violates the octet rule.

(b) 

(c) Formal charges are minimized on the structure that violates the octet rule; this form is probably dominant.

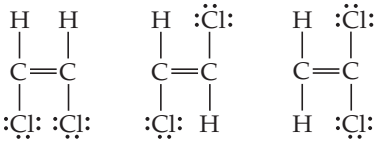
(a) 

(b) 

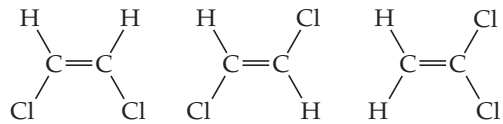
8.39 **(a)** $\Delta H = -304$ kJ **(b)** $\Delta H = -82$ kJ **(c)** $\Delta H = -467$ kJ **8.40** **(a)** False **(b)** false **(c)** false **(d)** false **(e)** false **8.41** The Ca—O bond will be stronger than the Na—Cl bond, because the ion charges are greater. **8.43** **(a)** Group 14 **(b)** Group 2 **(c)** Group 15 **8.46** **(a)** Ru **(b)** $[Kr]5s^24d^6$. **8.49** **(a)** Four **(b)** In order of increasing bond length: 3 < 1 < 2 **(c)** Bond 3 is the strongest C—C bond in the hydrocarbon molecule. For the same pair of bonded atoms, the greater the number of shared pairs of electrons, the shorter and stronger the bond. **8.61** The lattice energy of RbCl(*s*) is +692 kJ / mol. **8.74** The more electron pairs shared by the atoms, the shorter the bond. Thus, the bond length of O_2 is shorter than that of H_2O_2. **8.75** **(a)** AsF_5 is an exception to the octet rule. **(b)** BCl_3 is an exception to the octet rule. **8.83** **(a)** CH_2, 6 e^-, 3 e^- pr H—C—H 2 CH_2, → C_2H_4. **(b)** The product of this reaction, C_2H_4, contains a C—C double bond, with a typical bond length of 134 pm. **8.84** A double C—O bond **8.92** **(a)** B—O. The most polar bond will be formed by the two elements with the greatest difference in electronegativity. **(b)** As—I. These elements have the two largest covalent radii among this group of elements. **(c)** BCI_3. B has three valence electron and participates in three covalent bonds. The Octet rule is satisfied by all three chlorine atoms. **(d)** O. O has 6 valence electrons and it needs to participate in two covalent bonds in order to satisfy the octet rule. **8.97** **(a)** +1 **(b)** −1 **(c)** +1 (assuming the odd electron is on N) **(d)** 0 **(e)** +3 **8.100** **(a)** False. One possible example is ozone O_3. **(b)** False. O_3 does not have an odd electron. **8.103** **(a)** Ti^{2+}, $[Ar]3d^2$; Ca, $[Ar]4s^2$. **(b)** Ca has no unpaired electrons and Ti^{2+} has two. **(c)** In order to be isoelectronic with Ca^{2+}, Ti would have a 4+ charge. **8.109** **(a)** Potassium peroxide is K_2O_2. **(b)** 14 e^-, 7 e^- pairs **(c)**  **(d)** Based on the Lewis structure, it is a single bond in the peroxide ion, whereas a double bond for the oxygen molecule. Therefore, the O—O in peroxide ion is longer than that of the oxygen molecule.

8.114

(a) NH_3BF_3, 32 e^-, 16 e^- pr **(b)** $\overset{\delta+}{B}—\overset{\delta-}{N}$



(c) Chlorine is less electronegative and less electron withdrawing than fluorine. The B—N bond in NH_3BCl_3 is less polar than the B—N bond in NH_3BF_3.



Chapter 9

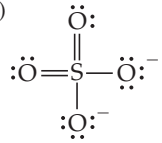
9.2 **(a)** 1 **(b)** 2 **(c)** 9 **(d)** 5 **9.3** **(a)** i, trigonal planar; ii, tetrahedral; iii, trigonal bipyramidal **(b)** i, 0; ii, 1; iii, 2 **(c)** N and P **(d)** Cl (or Br or I). This T-shaped molecular geometry arises from a trigonal-bipyramidal electron-domain geometry with 2 nonbonding domains. Assuming each F atom has 3 nonbonding domains and forms only single bonds with A, A must have 7 valence electrons and be in or below the third row of the periodic table to produce these electron-domain and molecular geometries. **9.4** **(a)** 1, less than 109.5°; 2, close to 120°; 3, less than 109.5° **(b)** 4, close to 120° **(c)** 5, close to 120°; 6, close to 180° **(d)** 7, less than 109.5°; 8, close to 120° **9.6** **(a)** In a linear AB_2 molecule, there can be either 0 or 3 nonbonding electron pairs. **(b)** three **(c)** yes **9.7** **(a)** Octahedral **(b)** octahedral **(c)** square planar **9.8** **(a)** No effect **(b)** no effect **(c)** 2 nonbonding pairs on the central O influence the molecular shape. **(d)** no effect **(e)** no effect **9.9** **(a)** Tetrahedral, tetrahedral **(b)** trigonal bipyramidal, T-shaped **(c)** octahedral, square pyramidal **(d)** octahedral, square planar **9.10** **(a)** Linear, linear **(b)** trigonal bipyramidal, trigonal bipyramidal **(c)** trigonal planar, bent **(d)** linear, linear **(e)** trigonal bipyridimal, seesaw **(f)** octahedral, square pyridimal **9.11** **(a)** NH_4^+ has zero nonbonding electron pairs on N and the largest bond angles. **(b)** NH_2^- has two nonbonding electron pairs on N and the smallest bond angles. **9.12** **(a)** Although both ions have 4 bonding electron domains, the 6 total domains around Br require octahedral domain geometry and square-planar molecular geometry, while the 4 total domains about B lead to tetrahedral domain and molecular geometry. **(b)** The angles will vary as $H_2O > H_2S > H_2Se$. The less electronegative the central atom, the larger the nonbonding electron domain, and the greater the effect of repulsive forces on adjacent bonding domains. The less electronegative the central atom, the greater the deviation from ideal tetrahedral angles. **9.15** **(a)** No. CS_2 does not have a dipole moment. **(b)** Yes. The net dipole moment vector points along the O—S—O angle bisector. **9.16** **(a)** Nonpolar. The polar B—F bonds are arranged in a symmetrical trigonal planar geometry. **(b)** No. The added nonbonding electron pair requires that the electron domain geometry is tetrahedral and the shape is a trigonal pyramid. **(c)** Yes. In BF_2Cl, the bond dipoles do not cancel. **9.17** **(a)** IF **(d)** PCl_3 and **(f)** IF_5 are polar.

9.18 **(a)** Lewis structures

Molecular geometries

Polar Nonpolar Polar

(b) The middle isomer has a zero net dipole moment. **(c)** C_2H_3Cl has only one isomer, and it has a dipole moment. **9.22** **(a)** False **(b)** true **(c)** false **(d)** false **9.23** **(a)** B, $[He]2s^22p^1$ **(b)** F, $[He]2s^22p^5$ **(c)** sp^2 **(d)** A single 2*p* orbital is unhybridized. It lies perpendicular to the trigonal plane of the sp^2 hybrid orbitals. **9.24** **(a)** sp^3 **(b)** sp^3d^2 **(c)** sp^3 **(d)** sp^2 **9.25** Left, no hybrid orbitals discussed in this chapter form angles



of 90° with each other; *p* atomic orbitals are perpendicular to each other; center, 109.5°, sp^3; right, 120°, sp^2

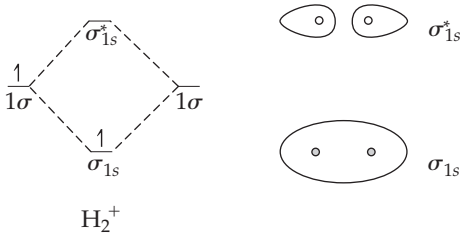
9.28 (**a**) 

(**b**) 

(**c**) A σ bond is generally stronger than a π bond because there is more extensive orbital overlap. (**d**) No. Overlap of two *s* orbitals results in electron density along the internuclear axis, while a π bond has none. **9.29** (**a**) 18 valence electrons (**b**) 10 valence electrons make σ bonds. (**c**) 2 valence electrons make π bonds. (**d**) 6 valence electrons are nonbonding. (**e**) Both carbon atoms in the molecule are sp^2 hybridized. **9.31** (**a**) In a localized π bond, the electron density is concentrated between the two atoms forming the bond. In a delocalized π bond, the electron density is spread over all the atoms that contribute *p* orbitals to the network. (**b**) The existence of more than one resonance form is a good indication that a molecule will have delocalized π bonding. (**c**) delocalized

9.32

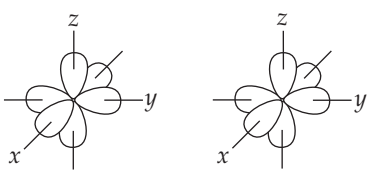
(**a**) 



(**b**) sp^3

(**c**) Yes, there are five equivalent resonance structures of the type shown in (a).

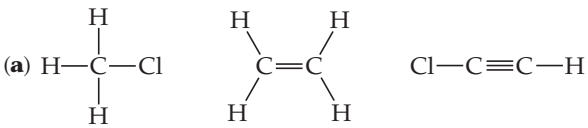
(**d**) There are four electrons in the π system of the molecule.



9.33 (**a**) Linear (**b**) The two central C atoms each have trigonal planar geometry with ~120° bond angles about them. The C and O atoms lie in a plane with the H atoms free to rotate in and out of this plane. (**c**) The molecule is planar with ~120° bond angles about the two N atoms. **9.35** (**a**) Hybrid orbitals are mixtures of atomic orbitals from a single atom and remain localized on that atom. Molecular orbitals are combinations of atomic orbitals from two or more atoms and are delocalized over at least two atoms. (**b**) Each MO can hold a maximum of two electrons. (**c**) Antibonding molecular orbitals can have electrons in them.

9.36

(**a**) 



(**b**) There is one electron in H_2^+. (**c**) $\sigma_{1s}{}^1$ (**d**) BO $= \frac{1}{2}$ (**e**) Fall apart. If the single electron in H_2^+ is excited to the σ^*_{1s} orbital, its energy is higher than the energy of an H 1*s* atomic orbital and H_2^+ will decompose into a hydrogen atom and a hydrogen ion. (**f**) Statement (**i**) is correct.

9.38

(**a**) 1 σ bond (**b**) 2 π bonds (**c**) 1 σ^* and 2 π^* **9.39** (**a**) When comparing the same two bonded atoms, as bond order increases, bond energy increases. As bond order increases, bond length decreases. When comparing different bonded nuclei, there are no simple relationships. (**b**) Be_2 is not expected to exist; it has a bond order of zero and is not energetically favored over isolated Be atoms. Be_2^+ has a bond order of 0.5 and is slightly lower in energy than isolated Be atoms. It will probably exist under special experimental conditions. **9.40** (**a**) Diamagnetic (**b**) F_2, O_2^{2+} **9.41** (**a**) B_2^+, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\pi_{2p}{}^1$, increase (**b**) Li_2^+, $\sigma_{1s}{}^2\sigma^*_{1s}{}^2\sigma_{2s}{}^1$, increase (**c**) N_2^+, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\pi_{2p}{}^4\sigma_{2p}{}^1$, increase (**d**) Ne_2^{2+}, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\sigma_{2p}{}^2\pi_{2p}{}^4\pi^*_{2p}{}^4$, decrease **9.42** CN, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\sigma_{2p}{}^2\pi_{2p}{}^3$, bond order $= 2.5$; CN^+, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\sigma_{2p}{}^2\pi_{2p}{}^2$, bond order $= 2.0$; CN^-, $\sigma_{2s}{}^2\sigma^*_{2s}{}^2\sigma_{2p}{}^2\pi_{2p}{}^4$, bond order $= 3.0$. (**a**) CN^- (**b**) CN, CN^+ **9.43** (**a**) 3*s*, $3p_x$, $3p_y$, $3p_z$ (**b**) π_{3p} (**c**) 2 (**d**) If the MO diagram for P_2 is similar to that of N_2, P_2 will have no unpaired electrons and be diamagnetic. **9.44** Removing an atom from the equatorial plane of the trigonal bipyramid in Figure 9.3 creates a seesaw shape. **9.46** (**a**) Two electron-domain geometries, linear and trigonal bipyramidal (**b**) one electron-domain geometry, trigonal bipyramidal (**c**) one electron-domain geometry, octahedral (**d**) one electron domain geometry, octahedral (**e**) one electron domain geometry, octahedral (**f**) one electron-domain geometry, trigonal bipyramidal (This triangular pyramid is an unusual molecular geometry not listed in Table 9.3. It could occur if the equatorial substituents on the trigonal bipyramid were extremely bulky, causing the nonbonding electron pair to occupy an axial position.) **9.48** (**a**) Zero. Moving from left to right along the x-axis of the plot, the distance between the Cl atoms increases. At very large separation, the potential energy of interaction approaches zero. (**b**) The Cl—Cl bond distance is approximately 200 pm. The Cl—Cl bond energy is approximately 240 kJ/mol. (**c**) Weaker. Under extreme pressure, the Cl—Cl bond gets shorter. The potential energy of the atom pair increases and the bond gets weaker. **9.54** (**a**) i, Two *s* atomic orbitals; ii, two *p* atomic orbitals overlapping end to end; iii, two *p* atomic orbitals overlapping side to side (**b**) i, σ-type MO; ii, σ-type MO; iii, π-type MO (**c**) i, antibonding; ii, bonding; iii, antibonding (**d**) i, the nodal plane is between the atom centers, perpendicular to the interatomic axis and equidistant from each atom. ii, there are two nodal planes; both are perpendicular to the interatomic axis. One is left of the left atom and the second is right of the right atom. iii, there are two nodal planes; one is between the atom centers, perpendicular to the interatomic axis and equidistant from each atom. The second contains the interatomic axis and is perpendicular to the first. **9.57** A molecule with tetrahedral molecular geometry has an atom at each vertex of the tetrahedron. A trigonal-pyramidal molecule has one vertex of the tetrahedron occupied by a nonbonding electron pair rather than an atom. **9.68** A bond dipole is the asymmetric charge distribution between two bonded atoms with unequal electronegativities. A molecular dipole moment is the three-dimensional sum of all the bond dipoles in a molecule. **9.73** (**a**) True (**b**) false (**c**) true (**d**) false (**e**) true

9.79

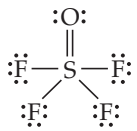
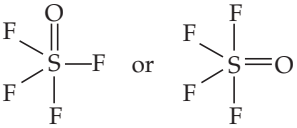
CH_4	Tetrahedral	sp^3	No
BH_3	Trigonal planar	sp^2	No
SF_4	Trigonal bipyramidal	Not applicable	Yes
SF_6	Octahedral	Not applicable	No
H_2CO	Trigonal planar	sp^2	Yes
PF_5	Trigonal bipyramidal	Not applicable	No
XeF_2	Trigonal bipyramidal	Not applicable	No



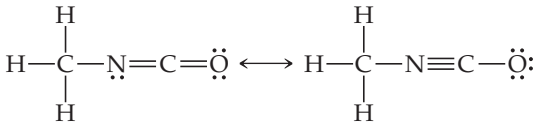
9.100 (**a**) 5 σ bonds (**b**) 2 σ bonds 2 π bonds (**c**) 3 σ bonds 3 π bonds (**d**) 2 σ bonds 1 π bond

9.107



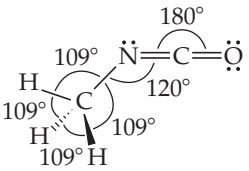
(**a**) The molecule is nonplanar. (**b**) Allene has no dipole moment. (**c**) The bonding in allene would not be described as delocalized. The π electron clouds of the two adjacent C=C are mutually perpendicular, so there is no overlap and no delocalization of π electrons. **9.110** (**a**) All O atoms have sp^2 hybridization. (**b**) The two σ bonds are formed by overlap of sp^2 hybrid orbitals, the π bond is formed by overlap of atomic p orbitals, one nonbonded pair is in a p atomic orbital and the other five nonbonded pairs are in sp^2 hybrid orbitals. (**c**) unhybridized p atomic orbitals (**d**) four, two from the π bond and two from the nonbonded pair in the p atomic orbital **9.113** (**a**) Ground state, $\sigma_{2s}^2\sigma^*_{2s}^2\pi_{2p}^4\sigma_{2p}^2$; excited state, $\sigma_{2s}^2\sigma^*_{2s}^2\pi_{2p}^4\sigma_{2s}^1\pi^*_{2p}^1$ (**b**) paramagnetic (**c**) σ_{2p} to π^*_{2p} (**d**) 7.0×10^2 kJ/mol (**e**) The bond order of the N—N bond in the first excited state is smaller and the bond is weaker than in the ground state. The silicon analogs would have the same hybridization as the C compounds. Silicon, which is in the row below C, has a larger bonding atomic radius and atomic orbitals than C. The close approach of Si atoms required to form strong, stable π bonds in Si_2H_4 and Si_2H_2 is not possible and these Si analogs do not readily form. **9.117** The yellow curcumin has the larger HOMO-LUMO gap because it absorbs visible violet light and appears yellow. **9.123** (**a**) $2\ SF_4(g) + O_2(g) \longrightarrow 2\ OSF_4(g)$

(**b**)



(**c**) $\Delta H = -551$ kJ, exothermic (**d**) The electron-domain geometry is trigonal bipyramidal. The O atom can be either equatorial or axial.

(**e**) In the structure on the left, there are 3 equatorial and 1 axial fluorine atoms. In the structure on the right, there are 2 equatorial and 2 axial fluorine atoms. **9.126** (**a**) 8462 kJ/mol (**b**) 8778 kJ/mol (**c**) Because the π electrons are delocalized, the molecule has a lower overall energy than that predicted for the presence of localized C—C and C=C bonds.



9.130

(**a**)

(The structure on the right does not minimize formal charges and will make a minor contribution to the true structure.)

(**b**)

Both resonance structures predict the same bond angles. (**c**) The two extreme Lewis structures predict different bond lengths. These bond length estimates assume that the structure minimizing formal charge makes a larger contribution to the true structure. C—O, 1.28 Å; C=N, 1.33 Å; C—N, 1.43 Å; C—H, 1.07 Å (**d**) The molecule will have a dipole moment. The C=N and C=O bond dipoles are opposite each other, but they are not equal. And, there are nonbonding electron pairs that are not directly opposite each other and will not cancel.

Chapter 10

10.2 Statement (**c**) is false. Gaseous molecules are so far apart that there is no barrier to mixing, regardless of the identity of the molecules. **10.10** The action in (**c**) would double the pressure **10.27** $X_{CO_2} = 0.000407$ **10.29** $P_{CO_2} = 91.0$ kPa **10.33** The root-mean-square speed of Rn is approximately 7.5 times slower than that of He. **10.36** Statements (**a**) and (**d**) are true. **10.40** (**a**) Non-ideal-gas behavior is observed at very high pressures and low temperatures. (**b**) The real volumes of gas molecules and attractive intermolecular forces between molecules cause gases to behave nonideally. **10.44** It would be much easier to drink from a straw on Mars. When a straw is placed in a glass of liquid, the atmosphere exerts equal pressure inside and outside the straw. When we drink through a straw, we withdraw air, thereby reducing the pressure on the liquid inside. If only 709 Pa is exerted on the liquid in the glass, a very small reduction in pressure inside the straw will cause the liquid to rise. **10.46** At the same temperature, volume and the lower pressure, the container would have half as many particles as at the higher pressure. **10.48** For a fixed amount of ideal gas at constant volume, if the pressure is doubled, the temperature also doubles. **10.50** (**a**) $P_{red} < P_{yellow} < P_{blue}$ (**b**) $P_{red} = 28.4$ kPa; $P_{yellow} = 42.6$ kPa; $P_{blue} = 71.0$ kPa **10.52** (**a**) Curve B is helium. (**b**) Curve B corresponds to the higher temperature. (**c**) The root mean square speed is highest. **10.54** The $NH_4Cl(s)$ ring will form at location a. **10.57** (**a**) 14.72 bar (**b**) 14.52 atm (**c**) 213.5 lb/in^2 **10.58** (**a**) 1.72 m (**b**) 1.96 atm **10.59** (**a**) 1.084 atm (**b**) 823.7 mm Hg (**c**) 1.098×10^5 Pa (**d**) 1.098 bar (**e**) 15.93 psi **10.60** (**i**) 0.31 atm (ii) 1.88 atm (iii) 0.136 atm **10.62** (**a**) Boyle's Law, $PV =$ constant or $P_1V_1 = P_2V_2$, at constant V, $P_1/P_2 = 1$; Charles' Law, $V/T =$ constant or $V_1/T_1 = V_2/T_2$, at constant V, $T_1/T_2 = 1$; then $P_1/T_1 = P_2/T_2$ or $P/T =$ constant. Amonton's law is that pressure and Kelvin temperature are directly proportional at constant volume. (**b**) 239.2 kPa **10.63** (**a**) STP stands for standard temperature, 0 °C (or 273 K), and standard pressure, 101.3 kPa. (**b**) 22.4 L (**c**) 24.5 L (**d**) 0.08315 L-bar/mol-K **10.65** Flask A contains the gas with a molar mass of 28 g/mol and flask B contains the gas with a molar mass of 56 g/mol.

10.66

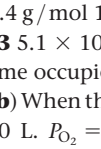
The order of increasing density is: NH^3 (17g/mol) < O_2(32g/mol) < HCl (36.5g/mol) Ar (40g/mol) **10.76** (**c**) Because the helium atoms are of lower mass than the average air molecule, the helium gas is less dense than air. The balloon thus weighs less than the air displaced by its volume. **10.78** molar mass = 89.4 g/mol **10.80** (**a**) 8.47 L CO_2 (**b**) 12.4 L O_2 **10.81** 0.0786 g Zn **10.83** 5.1×10^{-7} g Mg **10.84** (**a**) When the stopcock is opened, the volume occupied by $N_2(g)$ increases from 2.0 L to 5.0 L. $P_{N_2} = 40.53$ kPa (**b**) When the gases mix, the volume of $O_2(g)$ increases from 3.0 L to 5.0 L. $P_{O_2} = 121.6$ kPa (**c**) $P_t = 162.1$ kPa **10.85** (**a**) $P_t = 495.5$ kPa (**b**) $P_{H_2} = 49.6$ kPa, $P_{O_2} = 99.3$ kPa, $P_{N_2} = 346.5$ kPa **10.87** $P_{CO_2} = 45.04$ kPa, $P_t = 95.70$ kPa **10.89** $P_t = 250.27$ *kPa* **10.91** (**a**) Decrease (**b**) increase (**c**) decrease **10.93** (**a**) Average kinetic energy of the molecules increases. (**b**) Root mean square speed of the molecules increases. (**c**) Strength of an average impact with the container walls increases. (**d**) Total collisions of molecules with walls per second increases. **10.95** (**a**) In order of increasing speed and decreasing molar mass: Ar < HCl, < O_2 < CO < CH_4 (**b**) $u_{rms} = 515$ m/s (**c**) The most probable speed of an argon atom in the stratosphere is 337 m/s. **10.97** The order of increasing rate of effusion is $^2H^{37}Cl < {}^1H^{37}Cl < {}^2H^{35}Cl < {}^1H^{35}Cl$. **10.98** As_4S_6 **10.100** Statement (**b**) is true. **10.101** (**a**) $P = 495.48$ kPa (**b**) $P = 475.21$ kPa (**c**) Qualitatively, molecular attractions are more important as the amount of free space decreases and the number of molecular collisions increases. Molecular volume is a larger part of the total volume as the container volume decreases. **10.102** From the value of *b* for Xe, the nonbonding radius is 272 pm. From Figure 7.7, the bonding atomic radius of Xe is 140 pm. We expect the bonding radius of an atom to be smaller than its nonbonding radius, but our calculated value is nearly twice as large. **10.104** $V_f = 2.2$ mm^3 **10.106** $P = 74.7$ Pa **10.108** (**a**) 5.73 mol $C_3H_8(g)$ (**b**) 2.68×10^{2} mol $C_3H_8(l)$ (**c**) The ratio of moles liquid to moles gas is 47. Many more molecules and moles of liquid fit in a container of fixed volume because there is much less space between molecules in the liquid phase. **10.110** (**a**) Molar mass of the unknown gas is 100.4 g/mol (**b**) We assume that the gases behave ideally, and that *P, V* and *T* are constant. **10.112** (**a**) 0.00378 mol O_2 (**b**) 0.0345 g C_8H_{18} **10.114** 0.552 g H_2 **10.116** (**a**) Molar mass of the unknown gas is 50.46 g/mol (**b**) The ratio d/P varies with pressure because of the finite volumes of gas molecules and attractive intermolecular forces. **10.118** $T_2 = 687$ °C **10.120** (**a**) More significant (**b**) less significant **10.122** (**a**) At STP, argon atoms occupy 0.0359% of the total volume. (**b**) At 20.27 MPa pressure and 0 °C, argon atoms occupy 7.19% of the total volume. **10.124** (**a**) The molecular formula of cyclopropane is C_3H_6. (**b**) Although the molar masses of Ar and C_3H_6 are similar, we expect intermolecular attractions to be more significant for the more complex C_3H_6 molecules, and that C_3H_6 will deviate more from ideal behavior at the conditions listed. If the pressure is high enough for the volume correction in the van der Waals equation to dominate behavior, the larger C_3H_6 molecules definitely deviate more than Ar atoms from ideal behavior. (**c**) Cyclopropane would effuse through a pinhole slower than methane, because it has the greater molar mass. **10.126** (**a**) 44.58% C, 6.596% H, 16.44% Cl, 32.38% N (**b**) $C_8H_{14}N_5Cl$ (**c**) Molar mass of the compound is required in order to determine molecular formula when the empirical formula is known. **10.128** (**a**) $NH_3(g)$ remains after reaction. (**b**) 96.97 kPa (**c**) 7.33 g NH_4Cl

10.130



(**a**) 

(**b**) ClO_2 is very reactive because it is an odd-electron molecule. Adding an electron pairs the odd electron and completes the octet of Cl. ClO_2 has a strong tendency to gain an electron and be reduced.

(**c**) 

(**d**) The bond angle is less than 109°. (**e**) 11.2 g ClO_2

10.132 (**a**) $P_{IF_3} = 52.18$ kPa (**b**) $X_{IF_5} = 0.544$

(**c**) 

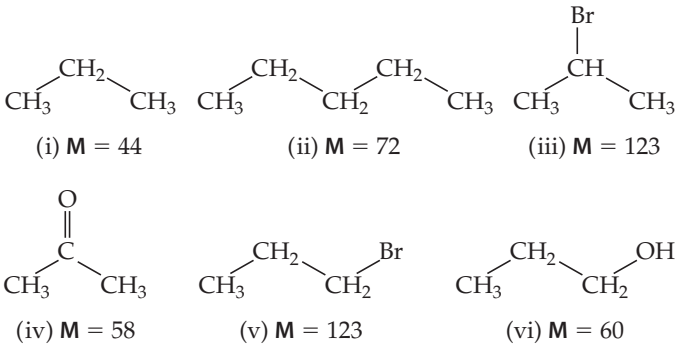
(**d**) Total mass in the flask is 20.00 g; mass is conserved.

Chapter 11

11.4 (**a**) The molar volumes of Cl_2 and NH_3 are nearly the same because they are both gases. (**b**) On cooling to 160 K, both compounds condense from the gas phase to the solid-state, so we expect a significant decrease in the molar volume. (**c**) The molar volumes are 0.0351 L/mol Cl_2 and 0.0203 L/mol NH_3 (**d**) Solid-state molar volumes are not as similar as those in the gaseous state, because most of the empty space is gone and molecular characteristics determine properties. $Cl_2(s)$ is heavier, has a longer bond distance and weaker intermolecular forces, so it has a significantly larger molar volume than $NH_3(s)$. (**e**) There is little empty space between molecules in the liquid state, so we expect their molar volumes to be closer to those in the solid state than those in the gaseous state. **11.10** (**a**) A molecule must contain H atoms, bound to either N, O, or F atoms, in order to participate in hydrogen bonding with like molecules. (**b**) CH_3NH_2 and CH_3OH **11.22** (**a**) 14.3 kJ (**b**) 25.1 kJ **11.23** (**a**) False (**b**) true (**c**) false (**d**) true **11.30** (**a**) The critical point is the temperature and pressure beyond which the gas and liquid phases are indistinguishable. (**b**) The line that separates the gas and liquid phases ends at the critical point because at conditions beyond the critical temperature and pressure, there is no distinction between gas and liquid. In experimental terms a gas cannot be liquefied at temperatures higher than the critical temperature, regardless of pressure. At conditions beyond the critical point, a substance is known as a supercritical fluid. **11.32** (**a**) 24 K (**b**) Neon sublimes at pressures less than the triple point pressure, approximately 50.7 kPa. (**c**) No **11.35** In a nematic liquid crystalline phase, molecules are aligned along their long axes, but the molecular ends are not aligned. Molecules are free to translate in all dimensions, but they cannot tumble or rotate out of the molecular plane, or the order of the nematic phase is lost and the sample becomes an ordinary liquid. In an ordinary liquid, molecules are randomly oriented and free to move in any direction. No **11.39** (**a**) The diagram best describes a liquid. (**b**) In the diagram, particles are close together, mostly touching, but there is no regular arrangement or order. This rules out a gaseous sample, where the particles are far apart, and a crystalline solid, which has a regular repeating structure in all three directions. **11.42** In its final state, methane is a gas at 185 °C. **11.44**

(**a**) Propanol can engage in hydrogen bonding. (**b**) While both molecules are somewhat polar, we expect propanol to have a larger dipole moment because of its O–H bond. (**c**) Propanol boils at 97.2 °C, while ethyl methyl ether boils at 10.8 °C. The stronger intermolecular forces in propanol cause it to have the higher boiling point. **11.47** (**a**) Solid < liquid < gas (**b**) gas < liquid < solid (**c**) Matter in the gaseous state is most easily compressed because particles are far apart and there is much empty space. **11.48** (**a**) It increases. Kinetic energy is the energy of motion. As melting occurs, the motion of atoms relative to each other increases. (**b**) It increases somewhat. The density of liquid lead is less than the density of solid lead. The smaller density means a greater sample volume and greater average distance between atoms in three dimensions. **11.50** (**a**) London dispersion forces (**b**) dipole–dipole forces (**c**) hydrogen bonding **11.51** (**a**) SO_2, London dispersion forces (**b**) NH_3, London dispersion, dipole–dipole, and hydrogen-bonding (N—H bonds) forces (**c**) BCl_3, non-polar covalent molecule **11.52** (**a**) In order of increasing polarizability: $CH_4 < SiH_4 < SiCl_4 < GeCl_4 < GeBr_4$ (**b**) The magnitudes of London dispersion forces and thus the boiling points of molecules increase as polarizability increases. The order of increasing boiling points is the order of increasing polarizability given in (a). **11.53** (**a**) CH_3CH_2OH (**b**) $N(CH_3)_3$ (**c**) CH_2Br_2 **11.54** Both rodlike butane molecules and spherical 2-methylpropane molecules experience dispersion forces. The larger contact surface between butane molecules facilitates stronger forces and produces a higher boiling point. **11.57** (**a**) Replacing a hydroxyl hydrogen with a CH_3 group eliminates hydrogen bonding in that part of the molecule. This reduces the strength of intermolecular forces and leads to a lower boiling point. (**b**) $CH_3OCH_2CH_2OCH_3$ is a larger, more polarizable molecule with stronger London dispersion forces and thus a higher boiling point.

11.58



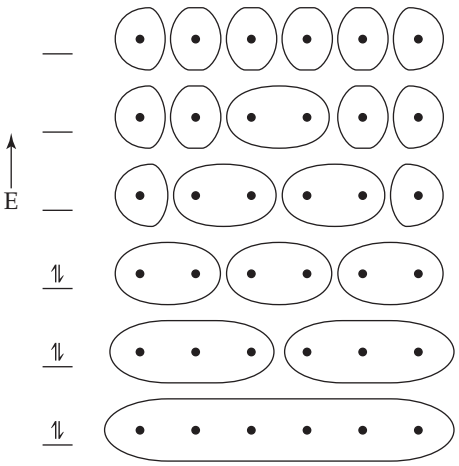
Physical Property	H_2O	H_2S
Normal boiling point, °C	100.00	−60.7
Normal melting point, °C	0.00	−85.5

(**a**) Based on its much higher normal melting point and boiling point, H_2O has much stronger intermolecular forces. (**b**) H_2O has hydrogen bonding, while H_2S has dipole–dipole forces. Both molecules have London dispersion forces. **11.59** SO_4^{2-} has a greater negative charge than BF_4^-, so ion–ion electrostatic attractions are greater in sulfate salts and they are less likely to form liquids. **11.60** (**a**) As temperature increases, surface tension decreases; they are inversely related. (**b**) As temperature increases, viscosity decreases; they are inversely related. (**c**) The same attractive forces that cause surface molecules to be difficult to separate (high surface tension) cause molecules elsewhere in the sample to resist movement relative to each other (high viscosity). **11.61** (**a**) Diagram (ii) shows stronger adhesive forces between the surface and the liquid. (**b**) Diagram (**i**) represents water on a nonpolar surface. (**c**) Diagram (ii) represents water on a polar surface. **11.62** (**a**) The three molecules have similar structures and experience the same types of intermolecular forces. As molar mass increases, the strength of dispersion forces increases and the boiling points, surface tension, and viscosities all increase. (**b**) Ethylene glycol has an —OH group at both ends of the molecule. This greatly increases the possibilities for hydrogen bonding; the overall intermolecular attractive forces are greater and the viscosity of ethylene glycol is much greater. (**c**) Water has the highest surface tension but lowest viscosity because it is the smallest molecule in the series. There is no hydrocarbon chain to inhibit their strong attraction to molecules in the interior of the drop, resulting in high surface tension. The absence of an alkyl chain also means the molecules can move around each other easily, resulting in the low viscosity. **11.63** (**a**) Fusion, endothermic (**b**) vaporization, endotermic (**c**) condensation exothermic (**d**) condensation exothermic **11.64** (**a**) vaporization (l) → (g) (**b**) endothermic (**c**) Same numerical value. **11.65** 2.3×10^3 g H_2O **11.68** Properties (**c**) intermolecular attractive forces, (**d**) temperature and (**e**) density of the liquid affect vapor pressure of a liquid.

11.69 (**a**) $CBr_4 < CHBr_3 < CH_2Br_2 < CH_2Cl_2 < CH_3Cl < CH_4$. (**b**) $CH_4 < CH_3Cl < CH_2Cl_2 < CH_2Br_2 < CHBr_3 < CBr_4$ (**c**) By analogy to attractive forces in HCl, the trend will be dominated by dispersion forces, even though four of the molecules are polar. The order of increasing boiling point is the order of increasing molar mass and increasing strength of dispersion forces. **11.70** (**a**) The temperature of the water in the two pans is the same. (**b**) Vapor pressure does not depend on either volume or surface area of the liquid. At the same temperature, the vapor pressures of water in the two containers are the same. **11.71** (**a**) Approximately 40 °C (**b**) approximately 7 kPa (**c**) approximately 50 °C (**d**) approximately 51 kPa **11.73** (**a**) $H_2O(g)$ will condense to $H_2O(s)$ at approximately 530 Pa; at a higher pressure, perhaps 500 kPa or so, $H_2O(s)$ will melt to form $H_2O(l)$. (**b**) At 100 °C and 50.7 kPa, water is in the vapor phase. As it cools, water vapor condenses to the liquid at approximately 82 °C, the temperature where the vapor pressure of liquid water is 50.7 kPa. Further cooling results in freezing at approximately 0 °C. The freezing point of water increases with decreasing pressure, so at 50.7 kPa the freezing temperature is very slightly above 0 °C. **11.75** (**a**) Methane on the surface of Titan is likely to exist in both solid and liquid forms. (**b**) As pressure decreases upon moving away from the surface of Titan, $CH_4(l)$ (at −178 °C) will vaporize to $CH_4(g)$, and $CH_4(s)$ (at temperatures below −180 °C) will sublime to $CH_4(g)$. **11.77** (**a**) True (**b**) false (**c**) true (**d**) false (**e**) false (**f**) true **11.78** Because order is maintained in at least one dimension, the molecules in a liquid-crystalline phase are not totally free to change orientation. This makes the liquid-crystalline phase more resistant to flow, more viscous, than the isotropic liquid. **11.79** Melting provides kinetic energy sufficient to disrupt molecular alignment in one dimension in the solid, producing a smectic phase with ordering in two dimensions. Additional heating of the smectic phase provides kinetic energy sufficient to disrupt alignment in another dimension, producing a nematic phase with one-dimensional order. **11.80** (**a**) Decrease (**b**) increase (**c**) increase (**d**) increase (**e**) increase (**f**) increase (**g**) increase **11.83** (**a**) The *trans* isomer will have stronger intermolecular hydrogen bonding, but the *cis* isomer will have stronger intramolecular hydrogen bonding. (**b**) The *trans* isomer melts at 287 °C and the *cis* isomer melts at 135 °C. **11.85** (**a**) All of these compounds exhibit dispersion interactions. (**b**)) All of these compounds are polar and exhibit dipole–dipole interactions. (**c**) Only methanoic acid and ethanoic acid exhibit hydrogen bonding. (**d**) Methanoic acid and ethanoic acid both exhibit hydrogen bonding, but ethanoic acid has a higher molecular weight. Thus, it has a higher total intermolecular force resulting in a higher boiling point. (**e**) Ethanal does not exhibit hydrogen bonding and it has the lowest molecular weight. Therefore, it has the lowest boiling point. **11.88** A plot of number of carbon atoms versus boiling point indicates that the boiling point of C_8H_{18} is approximately 130 °C. The more carbon atoms in the hydrocarbon, the longer the chain, the more polarizable the electron cloud, the higher the boiling point. **11.90** (**a**) Evaporation is an endothermic process. The heat required to vaporize sweat is absorbed from your body, helping to keep it cool. (**b**) The vacuum pump reduces the pressure of the atmosphere above the water until atmospheric pressure equals the vapor pressure of water and the water boils. Boiling is an endothermic process, and the temperature drops if the system is not able to absorb heat from the surroundings fast enough. As the temperature of the water decreases, the water freezes. **11.95** At low Antarctic temperatures,

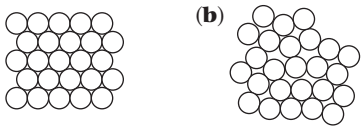
molecules in the liquid crystalline phase have less kinetic energy due to temperature, and the applied voltage may not be sufficient to overcome orienting forces among the ends of molecules. If some or all of the molecules do not rotate when the voltage is applied, the display will not function properly.

11.99



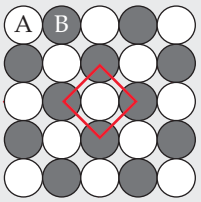
(**a**) Molar mass: Compounds (**i**) and (ii) have similar rodlike structures. The longer chain in (ii) leads to greater molar mass, stronger London dispersion forces, and higher heat of vaporization. (**b**) Molecular shape: Compounds (iii) and (v) have the same chemical formula and molar mass but different molecular shapes. The more rodlike shape of (v) leads to more contact between molecules, stronger dispersion forces, and higher heat of vaporization. (**c**) Molecular polarity: Compound (iv) has a smaller molar mass than (ii) but a larger heat of vaporization, which must be due to the presence of dipole–dipole forces. (**d**) Hydrogen bonding interactions: Molecules (v) and (vi) have similar structures. Even though (v) has larger molar mass and dispersion forces, hydrogen bonding causes (vi) to have the higher heat of vaporization. **11.103** P(hexane vapor) = 25,278 Pa

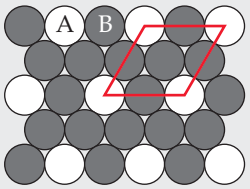
Chapter 12



12.14 Copper. A body-centered cubic structure has more empty space than a face-centered cubic one. The more empty space, the less dense the solid. We expect the element with the highest density, copper, to adopt the face-centered cubic structure.

12.20





(**a**) Six AOs require six MOs (**b**) zero nodes in the lowest energy orbital (**c**) five nodes in highest energy orbital (**d**) two nodes in the HOMO (**e**) three nodes in the LUMO (**f**) The HOMO-LUMO energy gap for the six-atom diagram is smaller than the one for the four-atom diagram. In general, the more atoms in the chain, the smaller the HOMO-LUMO energy gap. **12.21** (**a**) Ag is more ductile. Cr has stronger metallic bonding, a stiffer lattice, and is less susceptible to distortion. (**b**) Zn is more ductile. Ge is a metalloid semi-conductor solid with a stiffer lattice than metallic Zn. **12.46** 2.47×10^5 Au atoms **12.48** The red-orange compound is more likely to be a semiconductor and the white one an insulator. The red-orange compound absorbs light in the visible spectrum (red-orange is reflected, so blue-green is absorbed), while the white compound does not. This indicates that the red-orange compound has a lower energy electron transition than the white one. Semiconductors have lower energy electron transitions than insulators. **12.52** (**a**) The structure is hexagonal close-packed. (**b**) The coordination number, CN, is twelve. (**c**) CN(1) = 9, CN(2) = 6. **12.54** Fragment (**b**) is more likely to give rise to electrical conductivity. Arrangement (**b**) has a delocalized π system, in which electrons are free to move. Mobile electrons are required for electrical conductivity. **12.56** We expect linear polymer (**a**), with ordered regions, to be more crystalline and to have a higher melting point than branched polymer (**b**). **12.57** Statement (**b**) is the best explanation. **12.58** (**a**) Hydrogen bonding, dipole–dipole forces, London dispersion forces (**b**) covalent chemical bonds (**c**) ionic bonds (**d**) metallic bonds **12.59** (**a**) Covalent-network (**b**) metallic (**c**) ionic (**d**) molecular (**e**) molecular (**f**) ionic **12.61** Metallic, because of its melting point, conductivity, and insolubility in water

12.62 (**a**) (**b**)

12.65 Tetragonal **12.66** (**e**) Triclinic and rhombohedral **12.67** (**b**) 2 **12.68** (**a**) Primitive hexagonal unit cell (**b**) NiAs **12.70** (**a**) Structure types A and C have equally dense packing and are more densely packed than structure type B. (**b**) Structure type B is least densely packed. **12.72** (**a**) The radius of an Rh atom is 135 pm. (**b**) The density of Rh is 12.4 g/cm^3. **12.73** (**a**) The radius of a Ca atom is 197.6 pm. (**b**) The density of Ca is 1.526 g/cm^3 **12.75** (**a**) 4 Al atoms per unit cell (**b**) coordination number = 12 (**c**) $a = 4.04 \times 10^{-8}$ cm (**d**) density = 2.71 g/cm^3 **12.77** Statement (**b**) is false. **12.78** (**a**) Interstitial alloy (**b**) substitutional alloy (**c**) intermetallic compound **12.79** (**a**) True (**b**) false (**c**) false **12.80** (**a**) Nickel or palladium, substitutional alloy (**b**) copper, substitutional alloy (**c**) silver, substitutional alloy **12.82** (**a**) True (**b**) false (**c**) false (**d**) false**12.84** The order of increasing melting points is La < Hf < Ta < W. Moving from La to W, the number of valence electrons, occupancy of the bonding band, and strength of

metallic bonding increase. Stronger metallic bonding requires more energy to break bonds and mobilize atoms, resulting in higher melting points from La to W. **12.86** (**a**) $SrTiO_3$ (**b**) Six (**c**) Each Sr atom is coordinated to a total of twelve O atoms in the eight unit cells that contain the Sr atom. **12.87** The density of PbS is 7.60 g/cm^3. **12.88** (**a**) 2.90 g/cm^3 (**b**) We expect As^{3-} to have a larger ionic radius than P^{3-}, so BAs will occupy a larger volume and the unit cell edge will be longer. (**c**) The density of BAs is 5.21 g/cm^3. The greater mass of As accounts for the greater density of BAs. **12.89** (**a**) Cs^+ and I^- have the most similar radii and will adopt the CsCl-type structure. The radii of Na^+ and I^- are somewhat different; NaI will adopt the NaCl-type structure. The radii of Cu^+ and I^- are very different; CuI has the ZnS-type structure. (**b**) CsI, 8; NaI, 6; CuI, 4 **12.90** (**a**) 6 (**b**) 3 (**c**) 6 **12.91** (**a**) False (**b**) true **12.92** (**a**) Ionic solids are much more likely to dissolve in water. (**b**) Covalent-network solids can become considerably better conductors of electricity via chemical substitution. **12.93** (**a**) CdS (**b**) GaN (**c**) GaAs **12.94** Ge or Si (Ge is closer to Ga in bonding atomic radius.) **12.95** (**a**) A 1.1 eV photon corresponds to a wavelength of 1.1×10^{-6} *M* (**b**) According to the figure, Si can absorb all wavelengths in the visible portion of the solar spectrum. (**c**) Si absorbs wavelengths less than 1100 nm. This corresponds to approximately 80–90% of the total area under the curve. **12.96** The emitted light has a wavelength of 365 nm. This is radiation in the ultraviolet region of the electromagnetic spectrum. **12.97** The band gap is approximately 2.09 eV, which corresponds to a wavelength of 593 nm. **12.99** (**a**) A monomer is a small molecule with low molecular mass that can be joined with other monomers to form a polymer. They are the repeating units of a polymer. (**b**) ethene (also known as ethylene) **12.100** Reasonable values for a polymer's molecular weight are 10,000 u, 100,000 u, and 1,000,000 u.

12.101

12.102

12.104 (**a**) Flexibility of the molecular chains causes flexibility of the bulk polymer. Flexibility is enhanced by molecular features that inhibit order, such as branching, and diminished by features that encourage order, such as cross-linking or delocalized π electron density. (**b**) Less flexible **12.105** Low degree of crystallinity **12.106** If a solid has nanoscale dimensions of 1–10 nm, there may not be enough atoms contributing atomic orbitals to produce continuous energy bands of molecular orbitals. **12.107** (**a**) False. As particle size decreases, the band gap increases. (**b**) False. As particle size decreases, wavelength decreases. **12.109** Statement (**b**) is correct. **12.116** 3 Ni atoms, 1 Al atom; 6 Nb atoms, 2 Sn atoms; 1 Sm atom, 5 Co atoms. In each case, the atom ratio matches the empirical formula given in the exercise. **12.118** The wavelength that corresponds to a photon with this energy is 477 nm. **12.120** (**a**) Zinc sulfide, ZnS (**b**) covalent (**c**) In the solid, each Si is bound to four C atoms in a tetrahedral arrangement, and each C is bound to four Si atoms in a tetrahedral arrangement, producing an extended three-dimensional network. SiC is high-melting because melting requires breaking covalent Si—C bonds, which takes a huge amount of thermal energy. It is hard because the three-dimensional lattice resists any deformation that would weaken the Si—C bonding network. **12.127** The distance between planes in crystalline silicon is 313 pm. **12.133** (**a**) 109° (**b**) 120° (**c**) atomic *p* orbitals **12.137** (**a**) 2.50×10^{22} Si atoms (To 1 sig fig, the result is 2×10^{22} Si atoms.) (**b**) 1.29×10^{-3} mg P (1.29 μg P) **12.139** 63 Si atoms

Chapter 13

13.4 Very soluble (**b**) ΔH_{mix} will be the largest negative number. In order for ΔH_{soln} to be negative, the magnitude of ΔH_{mix} must be greater than the magnitude of ($\Delta H_{solute} + \Delta H_{solvent}$). **13.6** (**a**) ΔH_{soln} is nearly zero. Because the solute and solvent in this case experience very similar London dispersion forces, the energy required to separate them individually and the energy released when they are mixed are approximately equal. $\Delta H_{mix} \approx -(\Delta H_{solute} + \Delta H_{solvent})$. (**b**) The entropy of the system increases when benzene and toluene form a solution. The change involves taking two pure liquids and forming a (homogeneous) mixture. The result is an increase in randomness or disorder. From part (**a**), the enthalpy of mixing is nearly zero, so the increase in entropy is the driving force for mixing in all proportions. **13.12** Toluene, $C_6H_5CH_3$, is the best solvent for nonpolar solutes. Without polar groups or nonbonding electron pairs, it forms only dispersion interactions with itself and other molecules. **13.16** $S_{H_2} = 2.0 \times 10^{-3}$ *M*, $S_{Ar} = 3.5 \times 10^{-3}$ *M* **13.30** (**a**) $X_{Eth} = 0.2812$ (**b**) $P_{soln} = 31.7$ kPa (**c**) X_{Eth} in vapor = 0.472 **13.34** Molar mass of lysozyme = 1.39×10^4 g **13.40** (**a**) < (**b**) < (**c**) **13.42** (**a**) No (**b**) The ionic solid with the smaller lattice energy will be more soluble in water. **13.46** Vitamin B_6 is more water soluble. Vitamin E is more fat soluble. **13.48** (**a**) Yes, the *molarity* changes with a change in temperature. (**b**) No, *molality* does not change with change in temperature. **13.50** The volume inside the balloon will be 0.5 L, assuming perfect osmosis across the semipermeable membrane. **13.52** (**a**) False (**b**) false (**c**) true **13.53** (**a**) Dispersion (**b**) hydrogen bonding (**c**) ion–dipole (**d**) dipole–dipole **13.55** (**a**) ΔH_{solute} (**b**) ΔH_{mix} **13.57** (**a**) Supersaturated (**b**) The bits of glass scraped from the vessel act as a seed crystal, which provides a nucleus of already aligned molecules, so that ordering of the dissolved particles is more facile. The excess alum is crystallizing out. (**c**) 86 g alum form **13.58** (**a**) Saturated (**b**) unsaturated (**c**) saturated (**d**) unsaturated **13.59** (**a**) We expect the liquids water and glycerol to be miscible in all proportions. (**b**) Hydrogen bonding, dipole-dipole forces, London dispersion forces **13.61** (**a**) Carbon tetrachloride (**b**) water **13.62** (**a**) CCl_4 is more soluble because dispersion forces among nonpolar CCl_4 molecules are similar to dispersion forces in hexane. (**b**) C_6H_6 is a nonpolar hydrocarbon and will be more soluble in the similarly nonpolar hexane. (**c**) The long, rodlike hydrocarbon chain of octanoic acid forms strong dispersion interactions and causes it to be more soluble in hexane. **13.63** (**a**) False (**b**) true (**c**) false (**d**) true **13.65** (**a**) 1.60% of $NaNO_3$ (**b**) 28.6 ppm **13.66**(**a**) $X_{C_2H_5OH} = 0.0192$ (**b**) 4.76% C_2H_5OH by mass (**c**) 1.09 *m* C_2H_5OH **13.67** (**a**) 8.63×10^{-3} *M* $Mg(NO_3)_2$ (**b**) 1.25 M $LiClO_4 \cdot 3H_2O$ (**c**) 0.375 *M* HNO_3 **13.68** (**a**) 2.56 *m* C_6H_6 (**b**) 0.858 *m* NaCl **13.69** (**a**) 50.01% H_2SO_4 by mass (**b**) $X_{H_2SO_4} = 0.155$ (**c**) 10.20 *m* H_2SO_4 (**d**) 7.112 *M* H_2SO_4 **13.70** (**a**) $X_{CH_3OH} = 0.244$ (**b**) 7.85 *m* CH_3OH (**c**) 4.94 *M* CH_3OH **13.72** (**a**) 0.0900 mol $SrBr_2$ (**b**) 1.40×10^{-2} mol KCl (**c**) 8.63 g $C_6H_{12}O_6$ **13.73** (**a**) Weigh out 1.3 g KBr, dissolve in water, dilute with stirring to 0.75 L. (**b**) Weigh out 2.62 g KBr, dissolve it in 122.38 g H_2O to make exactly 125 g of 0.180 *m* solution. (**c**) Dissolve 244 g KBr in water, dilute with stirring to 1.85 L. (**d**) Weigh 10.1 g KBr, dissolve it in a small amount of water, and dilute to 0.568 L. **13.75** 21% HNO_3 by mass **13.76** (**a**) 8.23 *m* Zn (**b**) 45.3 *M* Zn **13.77** (**a**) 4.66 kPa (**b**) 1.8×10^{-3} *M* CO_2 **13.78** (**a**) False (**b**) true (**c**) true (**d**) false **13.79** The vapor pressure of the first solution, $C_6H_{12}O_6$ (*aq*), is 3.10 kPa. The vapor

pressure of the second solution, $C_{12}H_{22}O_{11}$ (*aq*), is 3.14 kPa. Generally, the less concentrated solution, the one with fewer moles of solute per kilogram of solvent, will have the higher vapor pressure. **13.81** (**a**) P_{H_2O} = 24.85 kPa (**b**) 78.9 g $C_3H_8O_2$ **13.83** (**a**) Because KCl is a strong electrolyte, one mole of KCl produces twice as many dissolved particles as one mole of the molecular solute urea. Freezing-point depression is directly related to total moles of dissolved particles. The 0.10 *m* KCl has more dissolved particles so its freezing point is lower than that of 0.10 *m* $CO(NH_2)_2$. (b) In solutions of strong electrolytes like KCl, ion pairing reduces the effective number of particles in solution, decreasing the change in freezing point. The actual freezing point is then higher than the calculated freezing point for a 0.10 *m* solution. (**b**) In solutions of strong electrolytes like NaCl, ion pairing reduces the effective number of particles in solution, decreasing the change in boiling point. The actual boiling point is then lower than the calculated boiling point for a 0.10 *m* solution. **13.85** 0.130 *m* urea < 0.080 *m* KBr < 0.070 *m* $Mg(NO_2)_2$ **13.86** (**a**) $T_f = -115.0\,°C$, $T_b = 78.7\,°C$ (**b**) $T_f = -67.3\,°C$, $T_b = 64.2\,°C$ (**c**) $T_f = -0.4\,°C$, $T_b = 100.1\,°C$ (**d**) $T_f = -0.6\,°C$, $T_b = 100.2\,°C$ **13.87** 667 g $C_2H_6O_2$ **13.89** Π = 7.15 kPa **13.90** The approximate molar mass of adrenaline is 1.8×10^2 g. **13.93** $i = 2.8$ **13.94** (**a**) No. In the gaseous state, particles are far apart and intermolecular attractive forces are small. When two gases combine, all terms in Equation 13.1 are essentially zero and the mixture is always homogeneous. (**b**) To determine whether Faraday's dispersion is a true solution or a colloid, shine a beam of light on it. If light is scattered, the dispersion is a colloid. **13.95** Choice (**d**), $CH_3(CH_2)_{11}COONa$, is the best emulsifying agent. The long hydrocarbon chain will interact with the hydrophobic component, while the ionic end will interact with the hydrophilic component, as well as stabilize the colloid. **13.96** (**a**) No. The hydrophobic or hydrophilic nature of the protein will determine which electrolyte at which concentration will be the most effective precipitating agent. (**b**) Stronger. If a protein has been "salted out", protein-protein interactions are stronger than protein-solvent interactions and solid protein forms. (**c**) The first hypothesis seems plausible, since ion-dipole interactions among electrolytes and water molecules are stronger than dipole–dipole and hydrogen bonding interactions between water and protein molecules. But, we also know that ions adsorb on the surface of a hydrophobic colloid; the second hypothesis also seems plausible. If we could measure the charge and adsorbed water content of protein molecules as a function of salt concentration, then we could distinguish between these two hypotheses. **13.97** (**a**) Hydrochloride (**b**) free base (**c**) 0.492 *M* free base (**d**) 7.36 *M* hydrochloride (**e**) 275 mL of 12.0 *M* HCl **13.100** (**a**) $k_{Rn} = 7.17 \times 10^{-3}$mol/L-kPa (**b**) P_{Rn} = 23 Pa; $S_{Rn} = 1.6 \times 10^{-6}\,M$ **13.103** (**a**) 2.69 *m* LiBr (**b**) $X_{LiBr} = 0.0994$ (**c**) 81.1% LiBr by mass **13.105** $X_{H_2O} = 0.95$; 0.0263 mol ions; 0.0132 mol NaCl; 0.769 g NaCl **13.108** (**a**) − 0.6 °C (**b**) −0.4 °C **13.111** (**a**), CF_4, 1.7×10^{-4} *m*; $CClF_3$, 9×10^{-4} *m*; CCl_2F_2, 2.3×10^{-2} *m*; $CHClF_2$, 3.5×10^{-2} *m* (**b**) dipole moment (**c**) 3.9×10^{-4} mol O_2 **13.114** (**a**) The central atom and the number of electron-pair domains about it are: (**i**) Cl, 4; (ii) B, 4; (iii) P, 6; (iv) Al, 4; (v) B, 4 (**b**) tetrahedral (**c**) The central P atom in anion (iii) has an expanded octet. As drawn, the central Cl atom in anion (**i**) also has an expanded octet. Note that multiple resonance structures for ClO_4^- can be drawn, including one where Cl obeys the octet rule. The structure shown in this exercise is one that minimizes formal charge. (**d**) BARF **13.118** (**a**) P_t = 56.34 kPa (**b**) Endothermic. Repulsive forces lead to an overall lowering of the energy of the system. $\Delta H_{soln} > 0$.

Chapter 14

14.2 (**a**) *Reaction rate* is the change in the amount of products or reactants in a given amount of time. (**b**) Rates depend on concentration of reactants, surface area of reactants, temperature, and activation energy/presence of catalyst. (**c**) No. The stoichiometry of the reaction (mole ratios of reactants and products) must be known to relate rate of disappearance of reactants to rate of appearance of products.**14.12** (**a**) Rate = $k[N_2O_5]$ (**b**) Rate = $2.06 \times 10^{-4}\,M/s$ (**c**) When the concentration of N_2O_5 triples,the rate of the reaction triples. (**d**) When the concentration of N_2O_5 is reduced by 10 %, the rate of the reaction is reduced by 10%. **14.19** (**a**) A graph of ln[A] versus time yields a straight line for a first-order reaction. (**b**) On a graph of ln[A] versus time, the rate constant is the (–slope) of the straight line. **14.20**(**a**) $k = 3.2 \times 10^{-6}s^{-1}(0.28\,d^{-1})$ (**b**) $t_{1/2} = 2.2 \times 10^2$ s (3.7 min) **14.21** (**a**) P = 4 kPa (**b**) t = 51 s **14.26** (**a**) The energy of the collision and the orientation of the molecules when they collide determine whether a reaction will occur. (**b**) The rate constant usually increases with an increase in reaction temperature. (**c**) The fraction of molecules with energy greater than the activation energy changes most dramatically with temperature. Frequency of collision and the orientation factor are lumped into the frequency factor, A, which is considered to be constant with temperature. **14.47** The rate of the combustion reaction in the cylinder depends on the surface area of the droplets in the spray. The smaller the droplets, the greater the surface area exposed to oxygen, the faster the combustion reaction. In the case of a clogged injector, larger droplets lead to slower combustion. Uneven combustion in the various cylinders can cause the engine to run roughly and decrease fuel economy. **14.49** Equation (iv) (**b**) rate = $-\Delta[B]/\Delta t = \frac{1}{2}\Delta[A]/\Delta t$ **14.55** (1) Total potential energy of the reactants (2) E_a, activation energy of the reaction (3) ΔE, net energy change for the reaction (4) total potential energy of the products **14.58** (**a**) $NO_2 + F_2 \longrightarrow NO_2F + F$; $NO_2 + F \longrightarrow NO_2F$ (**b**) $2NO_2 + F_2 \longrightarrow 2NO_2F$ (**c**) F (atomic fluorine) is the intermediate (**d**) rate = $k[NO_2][F_2]$ **14. 61** (**a**) Net reaction: $AB + AC \longrightarrow BA_2 + C$ (**b**) A is the intermediate. (**c**) A_2 is the catalyst.

14.64

Time (min)	Mol A	(a) Mol B	[A] (mol/L)	Δ[A] (mol/L)	(b) Rate (M/s)
0	0.065	0.000	0.65		
10	0.051	0.014	0.51	−0.14	2.3×10^{-4}
20	0.042	0.023	0.42	−0.09	1.5×10^{-4}

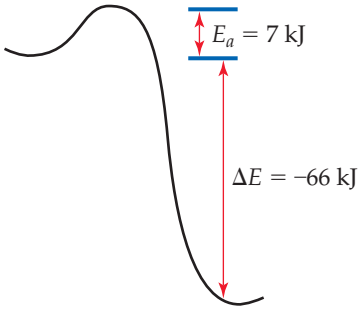
40	0.031	0.034	0.31	−0.05	0.8×10^{-4}

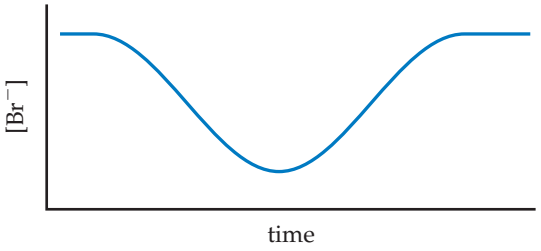
(**c**) $\Delta[B]_{avg}/\Delta t = 1.3 \times 10^{-4}\,M/s$



14.65
(**a**)

Time (s)	Time Interval (s)	Concentration (M)	Δ*M*	Rate (M/s)
0		0.0165		
2,000	2,000	0.0110	−0.0055	28×10^{-7}
5,000	3,000	0.00591	−0.0051	17×10^{-7}
8,000	3,000	0.00314	−0.00277	9.3×10^{-7}
12,000	4,000	0.00137	−0.00177	4.43×10^{-7}
15,000	3,000	0.00074	−0.00063	2.1×10^{-7}

(**b**) The average rate of reaction is $1.05 \times 10^{-6}\,M/s$ (**c**) The average rate between t = 2000 and t = 12,000 s ($9.63 \times 10^{-7}M/s$) is greater than the average rate between t = 8,000 and t = 15,000 s

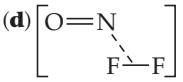


$(3.43 \times 10^{-7} M/s)$. (**d**) From the slopes of the tangents to the graph, the rates are $12 \times 10^{-7} M/s$ at 5000 s, $5.8 \times 10^{-7} M/s$ at 8000 s. **14.66** (**a**) $-\Delta[CO]/\Delta t = \Delta[CO_2]/\Delta t = \Delta[H_2]/\Delta t$; $-\Delta[H_2O]/\Delta t = \Delta[CO_2]/\Delta t = \Delta[H_2]\Delta t$ (**b**) $-\Delta[NO]/\Delta t = \Delta[NOCl]/\Delta t$; $-\Delta[Cl_2]/\Delta t = \Delta[NOCl]/2\,\Delta t$ (**c**) $-\Delta[CO_4]/\Delta t = \Delta[CO_2]/\Delta t = \Delta[H_2O]/2\,\Delta t$; $-\Delta[O_2]/\Delta t = 2\Delta[CO_2]/\Delta t = \Delta[H_2O]/\Delta t$ (**d**) $-\Delta[N_2O_4]/\Delta t = \Delta[NO_2]/\Delta t$ **14.67** (**a**) $-\Delta[O_2]/\Delta t = 0.25$ mol/s; $\Delta[H_2O]/\Delta t = 0.5$ mol/s (**b**) P_{total} decreases by 30 kPa/min. **14.68** (**a**) If [B] doubles, there is no change in the rate or the rate constant. (**b**) The reaction is third order in A, zero order in B, and third order overall. (**c**) units of $k = M^{-2}s^{-1}$ **14.70** (**a**) $5.2 \times 10^2 M^{-1}s^{-1}$ (**b**) If $[OH^-]$ is cut in half, the rate decreases by a factor of ½. (**c**) If both $[OH^-]$ and $[C_2H_5Cl]$ are cut in half, the rate decreases by a factor of ¼. **14.71** (**a**) Rate $= k[OCl^-][I^-]$ (**b**) $k = 60\,M^{-1}s^{-1}$. (**c**) Rate $= 6.0 \times 10^{-5}\,M/s$ **14.72** (**a**) Rate $= k[BF_3][NH_3]$ (**b**) The reaction is second order overall. (**c**) $k_{avg} = 3.41\,M^{-1}s^{-1}$ (**d**) $0.170\,M/s$ **14.73** (**a**) Rate $= k[NO]^2[Br_2]$ (**b**) $k_{avg} = 1.2 \times 10^4\,M^{-2}s^{-1}$ (**c**) $\frac{1}{2}\Delta[NOBr]/\Delta t = -\Delta[Br_2]/\Delta t$ (**d**) $-\Delta[Br_2]/\Delta t = 8.4\,M/s$ **14.77** Plot $(\ln P_{SO_2Cl_2})$ versus time, $k = -\text{slope} = 2.19 \times 10^{-5}s^{-1}$ **14.78** (**a**) The plot of $1/[A]$ versus time is linear, the reaction is second order in [A]. (**b**) 281 seconds (**c**) $t_{1/2} = 38$ min **14.79** (**a**) The plot of $1/[NO_2]$ versus time is linear, so the reaction is second order in NO_2. (**b**) $k = \text{slope} = 10\,M^{-1}s^{-1}$ (**c**) rate at $0.200\,M = 0.400\,M/s$, rate at $0.100\,M = 0.100\,M/s$; rate at $0.050\,M = 0.025\,M/s$ **14.81** $f = 1.81 \times 10^{-2}$. At 300 K, approximately 2 out of 100 molecules have this kinetic energy.

14.82 (**a**)

(**b**) E_a(reverse) = 73 kJ **14.83** (**a**) False (**b**) false (**c**) true **14.84** The order of slowest reaction to fastest reaction is: rate (**b**) < rate (**c**) < rate (**a**) **14.85** (**a**) $k = 1.1\ s^{-1}$ (**b**) $k = 13\ s^{-1}$ (**c**) The method in parts (**a**) and (**b**) assumes that the collision model and thus the Arrhenius equation describe the kinetics of the reactions. That is, activation energy is constant over the temperature range under consideration. **14.86** A plot of ln k versus $1/T$ has a slope of -5.64×10^3; $E_a = -R(\text{slope}) = 47.5$ kJ/mol **14.87** (**a**) An *elementary reaction* is a process that occurs as a single event; the order is given by the coefficients in the balanced equation for the reaction. (**b**) A *unimolecular* elementary reaction involves only one reactant molecule; a *bimolecular* elementary reaction involves two reactant molecules. (**c**) A *reaction mechanism* is a series of elementary reactions that describes how an overall reaction occurs and explains the experimentally determined rate law. (**d**) A *rate-determining step* is the slow step in a reaction mechanism. It limits the overall reaction rate. **14.88** (**a**) Bimolecular, rate $= k[H_2O][CN^-]$ (**b**) bimolecular, rate $= k[CH_3Cl][OH^-]$ (**c**) unimolecular, rate $= k[N_2O_4]$ **14.89** (**a**) Two intermediates, B and C. (**b**) three transition states (**c**) C ⟶ D is fastest. (**d**) ΔE is positive. **14.90** (**a**) $H_2(g) + 2\,ICl(g) \rightarrow I_2(g) + 2\,HCl(g)$ (**b**) HI is the intermediate. (**c**) If the first step is slow, the observed rate law is rate $= k[H_2][ICI]$. **14.91** (**a**) The two-step mechanism is consistent with the data, assuming that the second step is rate determining. (**b**) No. The linear plot guarantees that the overall rate law will include $[NO]^2$. Since the data were obtained at constant $[Cl_2]$, we have no information about reaction order with respect to $[Cl_2]$. **14.92** (**a**) A catalyst is a substance that changes (usually increases) the speed of a chemical reaction without undergoing a permanent chemical change itself. (**b**) A homogeneous catalyst is in the same phase as the reactants, while a hetereogeneous catalyst is in a different phase. (**c**) A catalyst has no effect on the overall enthalpy change for a reaction, but it does affect activation energy. It can also affect the frequency factor.

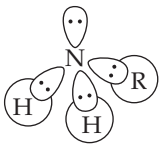
14.93



14.94 (**a**) Multiply the coefficients in the first reaction by 2 and sum. (**b**) NO_2(**g**) is a catalyst. (**c**) NO(**g**) is an intermediate. (**d**) This is a homogeneous catalysis. **14.95** (**a**) Use of chemically stable supports makes it possible to obtain very large surface areas per unit mass of the precious metal catalyst because the metal can be deposited in a very thin, even monomolecular, layer on the surface of the support. (**b**) The greater the surface area of the catalyst, the more reaction sites, the greater the rate of the catalyzed reaction. **14.96** To put two D atoms on a single carbon, it is necessary that one of the already existing C—H bonds in ethylene be broken while the molecule is adsorbed, so that the H atom moves off as an adsorbed atom and is replaced by a D atom. This requires a larger activation energy than simply adsorbing C_2H_4 and adding one D atom to each carbon. **14.97** The enzyme lowers the activation energy of the reaction by 44 kJ/mol. **14.98** (**a**) The catalyzed reaction is approximately 10,000,000 times faster at 25 °C (**b**) The catalyzed reaction is 180,000 times faster at 125 °C. **14.101** (**a**) Rate $= 4.7 \times 10^{-5}\,M/s$ (b, c) $k = 0.84\,M^{-2}s^{-1}$ (**d**) If the [NO] is increased by a factor of 1.8, the rate would increase by a factor of 3.2. **14.105** (**a**) The reaction is second order in C_2F_4. (**b**) 889 seconds **14.109** (**a**) The half-life of cobalt-60 is 5.29 years, that of iron-59 is 44.7 days. (**b**) Iron-59 decays at a faster rate. (**c**) 0.13 mg remains after three half-lives. (**d**) 0.925 mg remains after five days. **14.113** (**a**) The plot of $1/[C_5H_6]$ versus time is linear and the reaction is second order. (**b**) $k = 0.167\,M^{-1}\,s^{-1}$ **14.116** (**a**) When the two elementary reactions are added, $N_2O_2(g)$ appears on both sides and cancels, resulting in the overall reaction. $2\,NO(g) + H_2(g) \longrightarrow N_2O(g) + H_2O(g)$ (**b**) First reaction, $-[NO]/\Delta t = k[NO]^2$, second reaction, $-[H_2]/\Delta t = k[H_2][N_2O_2]$ (**c**) N_2O_2 is the intermediate. (**d**) Because $[H_2]$ appears in the rate law, the second step must be slow relative to the first. **14.119** (**a**) $Cl_2(g) + CHCl_3(g) \longrightarrow HCl(g) + CCl_4(g)$ (**b**) Cl(**g**), CCl_3(**g**) (**c**) reaction 1, unimolecular; reaction 2, bimolecular; reaction 3, bimolecular (**d**) Reaction 2 is rate determining. (**e**) Rate $= k[CHCl_3][Cl_2]^{1/2}$. **14.124** The enzyme must lower the activation energy by 22 kJ in order to make it useful. **14.129** (**a**) $k = 8 \times 10^7\,M^{-1}s^{-1}$

(**b**) :Ṅ═Ö:

:Ö═Ṅ—F̈: ⟷ (:Ö̇—N═F̈)



(**c**) NOF is bent with a bond angle of approximately 120°

(**d**)

(**e**) The electron-deficient NO molecule is attracted to electron-rich F_2 so the driving force for formation of the transition state is greater than simple random collisions.

14.132 (**a**)

(**b**) A reactant that is attracted to the lone pair of electrons on nitrogen will produce a tetrahedral intermediate. This can be a moiety with a full, partial, or even transient positive charge.

Chapter 15

15.2 (**a**) $K = 0.1$ (**b**) At equilibrium, the partial pressure of A is greater than the partial pressure of B. **15.17** $K_c = 10.5$ **15.18** (**a**) $[NO] = 0.050$, $[N_2] = 0.010$, $[H_2O] = 0.150$ (**b**) $K_c = 9.0 \times 10^2$ **15.32** (**a**) Endothermic (**b**) The equilibrium constant increases. (**c**) The forward rate constant increases by a larger amount than the reverse rate constant. **15.33** (**a**) $k_f > k_r$ (**b**) The equilibrium constant is greater than one. **15.35** K is greater than one. **15.37** $A(g) + B(g) \rightleftharpoons AB(g)$ has the larger equilibrium constant. **15.38** From the smallest to the largest equilibrium constant, (**c**) < (**b**) < (**a**). **15.39** Statement (**b**) is true. **15.41** Two B atoms should be added to the diagram. **15.43** K_c decreases as T increases, so the reaction is exothermic. **15.46** (**a**) $K_c = [I^2]/[I_2]$; homogeneous (**b**) $K_c = [SO_3]^2/[SO_2]^2[O_2]$; homogeneous (**c**) $K_c = [CO]^2/[CO]$; heterogeneous (**d**) $K_c = [CO_2][H_2]/[H_2O][CO]$; homogeneous (**e**) $K_c = [HCO_3^-][H^+]/[CO_2]$; homogeneous (**f**) $K_c = [Zn^{2+}][Fe^{2+}]$; heterogeneous (**g**) $K_c = [Ca^{2+}][CO_3^{2-}]$; heterogeneous **15.47** (**a**) Mostly products (**b**) at low total pressure, mostly reactants **15.48** (**a**) True (**b**) false (**c**) false **15.49** $K_p = 1.6 \times 10^{-9}$ **15.50** (**a**) The equilibrium favors NO and Br_2 at this temperature. (**b**) $Q = 3.0 \times 10^{-11}$, the reaction will proceed to the right. (**c**) $Q = 5.18 \times 10^{-9}$, the reaction will proceed to the left. **15.63** $P_{Cl_2} = 395$ kPa
15.65 $[Br_2] = 0.00939\,M$, $[Br] = 0.00312\,M$, 0.250 g Br(g)
15.67 $[I] = 4.73 \times 10^{-5}M$, $[I_2] = 7.2 \times 10^{-5}M$, 0.092 g I_2
15.68 $[NO] = 0.003\,M$, $[N_2] = [O_2] = 0.12\,M$
15.69 The equilibrium pressure of $Br_2(g)$ is 205 kPa.
15.71 (**a**) $[Ca^{2+}] = [SO_4^{2-}] = 4.9 \times 10^{-3}\,M$ (**b**) A bit more than 1.0 g $CaSO_4$ is needed in order to have some undissolved $CaSO_4$ (s) in equilibrium with 1.4 L of saturated solution.
15.72 $[IBr] = 0.180\,M$, $[I_2] = [Br_2] = 0.0102\,M$
15.74 (**a**) $P_{CH_3I} = P_{HI} = 130$ Pa, $P_{CH_4} = 13.2$ kPa, $P_{I_2} = 6.5$ kPa
15.76 (**a**) No effect (**b**) shift equilibrium to the left (**c**) shift equilibrium to the right (**d**) shift equilibrium to the left (**e**) shift equilibrium to the left (**f**) no effect **15.77** (**a**) No effect (**b**) no effect (**c**) increase K_P (**d**) no effect (**e**) decrease K_P **15.78** (**a**) $\Delta H° = -155.7$ kJ (**b**) The reaction is exothermic, so the equilibrium constant will decrease with increasing temperature. (**c**) Δn does not equal zero, so a change in volume at constant temperature will affect the fraction of products in the equilibrium mixture. **15.79** An increase in pressure favors formation of ozone. **15.83** $K_p = 2.5 \times 10^5$; $K_c = 3.67 \times 10^{-3}$ **15.86** (**a**) $P_{Br_2} = 16.3$ kPa $P_{NO} = 63.6$ kPa, $P_{NOBr} = 18.1$ kPa; $K_c = 0.0643$ (**b**) $P_t = 98.1$ kPa, (**c**) 10.49 g NOBr

15.90 $[CO_2] = [H_2] = 0.264\,M$, $[CO] = [H_2O] = 0.236\,M$ **15.98** $Q = 8 \times 10^{-6}$. $Q > K_p$, so the system is not at equilibrium; it will shift left to attain equilibrium. A catalyst that speeds up the reaction and thereby promotes the attainment of equilibrium would decrease the CO concentration in the exhaust. **15.100** At equilibrium, $[H_4IO_6^-] = 0.0015\,M$

Chapter 16

16.37 (**a**) $C_6H_5OH(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + C_6H_5O^-(aq)$
(**b**) $K_b = 7.7 \times 10^{-5}$ (**c**) Phenol is a stronger acid than water.
16.47 $NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$. Ammonia, NH_3, acts as an Arrhenius base because it increases the concentration of hydroxide ion, OH^-, in aqueous solution. It acts like a Brønsted-Lowry base because it is a proton, H^+, acceptor. It acts like a Lewis base because it is an electron pair donor. **16.50** (**a**) HCl, the H^+ donor, is the Brønsted–Lowry acid. NH_3, the H^+ acceptor, is the Brønsted–Lowry base. (**b**) HCl, the electron pair acceptor, is the Lewis acid. NH_3, the electron pair donor, is the Lewis base. **16.54** (**a**) HY is a strong acid. There are no neutral HY molecules in solution, only H^+ cations and Y^- anions. (**b**) HX has the smallest K_a value. It has most neutral acid molecules and fewest ions. (**c**) HX has fewest H^+ and highest pH. **16.60** (**a**) Molecule (**b**) is more acidic because its conjugate base is resonance-stabilized and the ionization equilibrium favors the more stable products. (**b**) Increasing the electronegativity of X increases the strength of both acids. As X becomes more electronegative and attracts more electron density, the O—H bond becomes weaker, more polar, and more likely to be ionized. An electronegative X group also stabilizes the anionic conjugate bases by delocalizing the negative charge. The equilibria favor products and the values of K_a increase. **16.62** HCl is the Brønsted–Lowry acid; NH_3 is the Brønsted–Lowry base. **16.63** (**a**) (i) HPO_4^{2-} (ii) Br^- (**b**) (i) HCN (ii) H_2SO_4

16.64

Acid +	Base ⇌	Conjugate Acid +	Conjugate Base
(**a**) $NH_4^+(aq)$	$CN^-(aq)$	HCN(aq)	$NH_3(aq)$
(**b**) $H_2O(l)$	$(CH_3)_3N(aq)$	$(CH_3)_3NH^+(aq)$	$OH^-(aq)$
(**c**) HCOOH(aq)	$PO_4^{3-}(aq)$	$HPO_4^{2-}(aq)$	$HCOO^-(aq)$

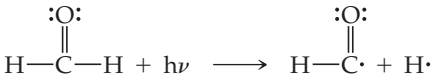
16.65 (**a**) Acid: $HCO_3^-(aq) + H_2O(l) \longrightarrow H_3O^+(aq) + CO_3^{2-}(aq)$, Base: $HCO_3^-(aq) + H_2O(l) \longrightarrow OH^-(aq) + H_2CO_3(aq)$ (**b**) H_2CO_3 is the conjugate acid of HCO_3^-. CO_3^{2-} is the conjugate base of HCO_3^-. **16.66** (**a**) F^-, weak base; HF, weak acid (**b**) HBr, strong acid; Br^-, negligible base (**c**) HS^-, strong base; H_2S, weak acid (**d**) ClO_4^-, negligible base; $HClO_4$, strong acid (**e**) $HCOO^-$, weak base; HCOOH, weak acid **16.67** (**a**) HBr (**b**) F^- **16.68** (**a**) $OH^-(aq) + OH^-(aq)$, the equilibrium lies to the right. (**b**) $H_2S(aq) + CH_3COO^-(aq)$, the equilibrium lies to the right. (**c**) $HNO_3(aq) + OH^-(aq)$, the equilibrium lies to the left. **16.69** Statement (ii) is correct. **16.70** (**a**) $[H^+] = 1.4 \times 10^{-5}\,M$, acidic (**b**) $[H^+] = 6.7 \times 10^{-13}\,M$, basic (**c**) $[H^+] = 3.16 \times 10^{-7}\,M$, acidic **16.71** $[H^+] = [OH^-] = 7.5 \times 10^{-7}\,M$ **16.72** (**a**) $[H^+]$ changes by a factor of 1000. (**b**) $[H^+]$ changes by a factor of 2.

16.73

$[H^+]$	$[OH^-]$	pH	pOH	Acidic or Basic
$5.7 \times 10^{-3}M$	$1.8 \times 10^{-12}M$	2.24	11.76	acidic
$1.6 \times 10^{-5}M$	$6.3 \times 10^{-10}M$	4.80	9.20	acidic
$1.1 \times 10^{-10}M$	$8.9 \times 10^{-5}M$	9.95	4.05	basic
$1.6 \times 10^{-10}M$	$6.3 \times 10^{-5}M$	9.80	4.20	basic

16.74 $[H^+] = 4.0 \times 10^{-8}\,M$, $[OH^-] = 6.0 \times 10^{-7}\,M$, pOH = 6.22
16.75 (**a**) Acidic (**b**) The range of possible integer pH values for the solution is 4-6. (**c**) Methyl red would help determine the pH of the solution more precisely. **16.76** (**a**) True (**b**) true (**c**) false
16.77 (**a**) $[H^+] = 8.3 \times 10^{-4}\,M$; pH = 3.08
(**b**) $[H^+] = 0.0381\,M$, pH = 1.42
(**c**) $[H^+] = 0.0125\,M$, pH = 1.903
(**d**) $[H^+] = 0.150\,M$, pH = 0.823
16.78 (**a**) $[OH^-] = 3.0 \times 10^{-3}\,M$, pH = 11.48
(**b**) $[OH^-] = 0.3758\,M$, pH = 13.5750
(**c**) $[OH^-] = 8.75 \times 10^{-5}\,M$, pH = 9.942
(**d**) $[OH^-] = 0.17\,M$, pH = 13.23 **16.79** 0.050 *M* NaOH
16.80 (**a**) $HNO_2(aq) \rightleftharpoons H^+(aq) + NO_2^-(aq)$,
$K_a = [H^+][NO_2^-]/[HNO_2]$;
$HNO_2(aq) + H_2O \rightleftharpoons H_3O^+(aq) + NO_2^-(aq)$,
$K_a = [H_3O^+][NO_2^-]/HNO_2$
(**b**) $ClH_2CCOOH(aq) \rightleftharpoons H^+(aq) + ClH_2CCOOH^-(aq)$,
$K_a = [H^+][ClH_2CCOO^-]/[ClH_2CCOOH]$;
$ClH_2CCOOH(aq) + H_2O \rightleftharpoons H_3O^+(aq) + ClH_2CCOO^-(aq)$,
$K_a = [H_3O^+][ClH_2CCOO^-]/[ClH_2CCOOH]$
16.81 $K_a = 1.4 \times 10^{-4}$ **16.82** $[H^+] = [CNO^-] = 5.9 \times 10^{-3}\,M$, $[HCNO] = 9.4 \times 10^{-2}\,M$, $K_a = 3.7 \times 10^{-4}$ **16.83** 2.2 *M* CH_3COOH **16.85** $[H^+] = [C_6H_5COO^-] = 2.5 \times 10^{-3}\,M$, $[C_6H_5COOH] = 0.098\,M$ **16.86** $[H^+] = 3.2 \times 10^{-2}\,M$, pH = 1.49
16.87 (**a**) $[H^+] = 2.8 \times 10^{-3}\,M$, 0.69% ionization
(**b**) $[H^+] = 1.4 \times 10^{-3}\,M$, 1.4% ionization
(**c**) $[H^+] = 8.7 \times 10^{-4}\,M$, 2.2% ionization
16.88 (**a**) $[H^+] = 5.1 \times 10^{-3}\,M$, pH = 2.30. (**b**) Yes. We started the calculation by assuming that only the first step made a significant contribution to $[H^+]$ and pH. Calculation proved this assumption to be true. Next we assumed $[H^+]$ from the first ionization was small relative to 0.040 *M* citric acid; this assumption was not valid. Finally we assumed that additional ionization of $[H_2C_6H_5O_7^{2-}]$ was small, which was true. (**c**) $[C_6H_5O_7^{3-}]$ is much less than $[H^+]$. **16.89** (**a**) $HONH_3^+$ (**b**) When hydroxylamine acts as a base, the nitrogen atom accepts a proton. (**c**) In hydroxylamine, O and N are the atoms with nonbonding electron pairs; in the neutral molecule both have zero formal charges. Nitrogen is less electronegative than oxygen and more likely to share a lone pair of electrons with an incoming (and electron-deficient) H^+. The resulting cation with the +1 formal charge on N is more stable than the one with the +1 formal charge on O.
16.90 (**a**) $(CH_3)_3N(aq) + H_2O(l) \rightleftharpoons (CH_3)_3NH^+(aq) + OH^-(aq)$;
$K_b = [(CH_3)_3NH^+][OH^-]/[(CH_3)_3N]$
(**b**) $SO_3^{2-}(aq) + H_2O(l) \rightleftharpoons HSO_3^-(aq) + OH^-(aq)$;
$K_b = [HSO_3^-][OH^-]/[SO_3^{2-}]$
(**c**) $CN^-(aq) + H_2O(l) \rightleftharpoons HCN(aq) + OH^-(aq)$;
$K_b = [HCN][OH^-]/[CN^-]$
16.91 From the quadratic formula, $[OH^-] = 5.4 \times 10^{-3}\,M$, pH = 11.73 **16.92** (**a**) $[C_{10}H_{15}ON] = 0.033\,M$, $[C_{10}H_{15}ONH^+] = [OH^+] = 2.1 \times 10^{-3}\,M$ (**b**) $K_b = 1.4 \times 10^{-4}$
16.94 (**a**) Hydrofluoric acid is stronger. (**b**) Cyanate ion is the stronger base. (**c**) For NCO^-, $K_b = 2.9 \times 10^{-11}$; for F^-, $K_b = 1.5 \times 10^{-11}$
16.95 (**a**) $[OH^-] = 5.7 \times 10^{-4}\,M$, pH = 10.75
(**b**) $[OH^-] = 1.3 \times 10^{-4}\,M$, pH = 10.10
(**c**) $[OH^-] = 3.5 \times 10^{-6}\,M$, pH = 8.54 **16.97** 0.11 *M* KCH_3COO
16.99 (**a**) Acidic (**b**) acidic (**c**) basic (**d**) neutral (**e**) acidic **16.100** K_b for the anion of the unknown salt is 1.4×10^{-11}; K_b for F^- is 1.5×10^{-11}; The unknown salt is NaF. **16.101** (**a**) HNO_3 is a stronger acid than HNO_2 (**b**) H_2S is a stronger acid than H_2O. (**c**) H_2SO_4 is a stronger acid than H_2SeO_4. (**d**) CCl_3COOH is stronger than CH_3COOH **16.102** (**a**) BrO^- (**b**) BrO^- (**c**) HPO_4^{2-} **16.103** (**a**) True (**b**) False. In a series of acids that have the same central atom, acid strength increases with the number of nonprotonated oxygen atoms bonded to the central atom. (**c**) False. H_2Te is a stronger acid than H_2S because the H—Te bond is longer, weaker, and more easily ionized than the H—S bond. **16.105** (**a**) Acid, $Fe(ClO_4)_3$ or Fe^{3+}, base, H_2O (**b**) Acid, H_2O; base, CN^- (**c**) Acid, BF_3; base, $(CH_3)_3N$ (**d**) Acid, HIO; base, NH_2^- **16.106** (**a**) Cu^{2+}, higher cation charge (**b**) Fe^{3+}, higher cation charge (**c**) Al^{3+}, smaller cation radius, same charge **16.107** (**a**) $[H^+] = 1.3 \times 10^{-3}\,M$, pH = 2.85
(**b**) $[H^+] = 2.7 \times 10^{-4}\,M$, pH = 3.56
(**c**) $[OH^-] = 3.6 \times 10^{-5}\,M$, pH = 9.55 **16.111** $K = 3.3 \times 10^7$
16.116 pH = 7.03 (not 6.1, from the typical calculation, which does not make sense). Usually we assume that $[H^+]$ and $[OH^-]$ from the autoprotolysis of water do not contribute to the overall $[H^+]$ and $[OH^-]$. However, for acid or base solute concentrations less than $1.0 \times 10^{-6}\,M$, the autoprotolysis of water produces significant $[H^+]$ and $[OH^-]$ and we must consider it when calculating pH. **16.119** (**a**) $pK_a = 4.84$ (**b**) pH = 2.98 (**c**) pH = 8.86 **16.123** Nicotine, protonated; caffeine, neutral base; strychnine, protonated; quinine, protonated **16.126** 6.0×10^{13} H^+ ions **16.129** (**a**) To the precision of the reported data, the pH of rainwater 40 years ago was 5.4, no different from the pH today. With extra significant figures, $[H^+] = 3.61 \times 10^{-6}\,M$, pH = 5.443 (**b**) A 20.0-L bucket of today's rainwater contains 0.02 L (with extra significant figures, 0.0200 L) of dissolved CO_2. **16.133** Rx 1, $\Delta H = 104$ kJ; Rx 2, $\Delta H = -32$ kJ. Reaction 2 is exothermic while reaction 1 is endothermic. For binary acids with heavy atoms (X) in the same family, the longer and weaker the H—X bond, the stronger the acid (and the more exothermic the ionization reaction). **16.136** (**a**) K(i) = 5.6×10^3, K(ii) = 10 (**b**) Both (**i**) and (ii) have $K > 1$, so both could be written with a single arrow.

Chapter 17

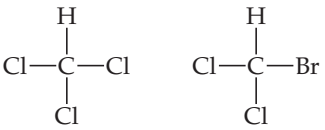


17.17 (**a**) Curve B (**b**) pH at the approximate equivalence point of curve A = 8.0, pH at the approximate equivalence point of curve B = 7.0 (**c**) For equal volumes of A and B, the concentration of acid B is greater, since it requires a larger volume of base to reach the equivalence point. (**d**) The pK_a value of the weak acid is approximately 4.5 **17.35** More soluble in acid: (**b**) CuS (**c**) $Cd(OH)_2$ (**d**) PbF_2 **17.45** (**a**) Base is required to increase $[PO_4^{3-}]$ so that the solubility product of the metal phosphates of interest is exceeded and the phosphate salts precipitate. (**b**) K_{sp} for the cations in group 3 is much larger; to exceed K_{sp}, a higher $[S^{2-}]$ is required. (**c**) They should all redissolve in strongly acidic solution.
17.46 The middle box has the highest pH. For equal amounts of acid HX, the greater the amount of conjugate base X^-, the smaller the amount of H^+ and the higher the pH. **17.52** (**a**) The red curve corresponds to the more concentrated acid solution. (**b**) On the titration curve of a weak acid, pH = pK_a at the volume halfway to the equivalence point. Reading the pK_a values from the two curves, the red curve has the smaller pK_a and the larger K_a. **17.54** (**a**) The right-most diagram represents the solubility of $BaCO_3$ as HNO_3 is added. (**b**) The left-most diagram represents the solubility of $BaCO_3$ as Na_2CO_3 is added. (**c**) The center diagram represents the solubility of $BaCO_3$ as $NaNO_3$ is added. **17.58** Statement (**a**) is most correct. **17.59** (**a**) $[H^+] = 1.58 \times 10^{-5}\,M$, pH = 4.80 (**b**) $[OH^-] = 5.44 \times 10^{-5}\,M$, pH = 9.74 (**c**) $[H^+] = 1.44 \times 10^{-5}\,M$, pH = 4.84 **17.60** (**a**) 4.2% ionization (**b**) 0.020 % ionization **17.61** Only solution (**b**) is a buffer
17.62 (**a**) pH = 3.76 (**b**) pH = 3.28 **17.63** (**a**) pH = 5.31
(**b**) $Na^+(aq) + CH_3COO^-(aq) + H^+(aq) + NO_3^-(aq) \longrightarrow CH_3COOH(aq) + Na^+(aq) + NO_3^-(aq)$
(**c**) $CH_3COOH(aq) + K^+(aq) + OH^-(aq) \longrightarrow CH_3COO^-(aq) + K^+(aq) + H_2O(l)$ **17.64** (**a**) pH = 1.65 (**b**) 10 g NaF
17.65 (**a**) pH = 4.84 (**b**) pH = 5.05 (**c**) pH = 4.65

17.66 (**a**) $[HCO_3^-]/[H_2CO_3] = 11$ (**b**) $[HCO_3^-]/[H_2CO_3] = 5.4$
17.67 1.41 L of 0.2 *M* KH_2PO_4, 0.59 L of 0.2 *M* H_3PO_4
17.69 (**a**) False (**b**) true (**c**) true **17.70** (**a**) Above pH 7 (**b**) below pH 7 (**c**) at pH 7 **17.71** The second color change of thymol blue is in the correct pH range to show the equivalence point of the titration of a weak acid with a strong base. **17.72** (**a**) 36.0 mL KOH soln (**b**) 45.0 mL KOH soln (**c**) 24.7 mL KOH soln **17.73** (**a**) pH = 1.54 (**b**) pH = 3.30 (**c**) pH = 7.00 (**d**) pH = 10.69 (**e**) pH = 12.74
17.74 (**a**) pH = 2.67 (**b**) pH = 4.74 (**c**) pH = 6.43 (**d**) pH = 8.80 (**e**) pH = 11.15 (**f**) pH = 12.10 **17.75** (**a**) pH = 7.00 (**b**) $[HONH_3^+] = 0.100\,M$, pH = 3.52 (**c**) $[C_6H_5NH_3^+] = 0.100\,M$, pH = 2.82 **17.76** (**a**) True (**b**) false (**c**) false (**d**) true
17.77 $K_{sp} = [Ba^{2+}][CrO_4^{2-}]$; $K_{sp} = [Cu^{2+}][S^{2-}]$; $K_{sp} = [Pb^{2+}][Cl^-]^2$; $K_{sp} = [La^{3+}][F^-]^3$ **17.78** (**a**) $K_{sp} = 7.63 \times 10^{-9}$ (**b**) $K_{sp} = 2.7 \times 10^{-9}$ (**c**) 5.3×10^{-4} mol $Ba(IO_3)_2$/L
17.79 $K_{sp} = 2.3 \times 10^{-10}$ **17.80** (**a**) 9.1×10^{-9} mol AgI/L (**b**) 5.5×10^{-16} mol AgI/L (**c**) 1.7×10^{-15} mol AgI/L **17.81** (**a**) The amount of $CaF_2(s)$ on the bottom of the beaker increases. (**b**) The $[Ca^{2+}]$ in solution increases. (**c**) The $[F^-]$ in solution decreases.
17.82 (**a**) 1.4×10^3 g $Mn(OH)_2$/L (**b**) 0.014 g/L (**c**) 3.6×10^{-7} g/L
17.84 $[Cu^{2+}] = 7 \times 10^{-11}\,M$, $[Cu(NH_3)_4^{2+}] = 3.72 \times 10^{-2}\,M$
17.85 (**a**) 9.1×10^{-9} mol AgI per L pure water (**b**) $K = K_{sp} \times K_f = 8 \times 10^4$ (**c**) 0.0500 mol AgI per L 0.100 *M* NaCN
17.86 (**a**) $Q < K_{sp}$; no $Ca(OH)_2$ precipitates (**b**) $Q < K_{sp}$; no Ag_2SO_4 precipitates **17.87** pH = 11.5 **17.88** LaF_3 will precipitate first, at $[F^-] = 1 \times 10^{-5}\,M$. **17.89** AgCl will precipitate first. **17.90** Ag^+ (Group 1) and Mg^{2+} (Group 4) are definitely absent. Al^{3+} (Group 3) is definitely present and Na^+ (Group 5) is possibly present. **17.91** (**a**) Make the solution acidic with 0.2 *M* HCl; saturate with H_2S. CdS will precipitate; ZnS will not. (**b**) Add excess base; $Fe(OH_3)(s)$ precipitates, but Cr^{3+} forms the soluble complex $Cr(OH)_4^-$. (**c**) Add $(NH_4)_2HPO_4$; Mg^{2+} precipitates as $MgNH_4PO_4$; K^+ remains soluble. (**d**) Add 6 *M* HCl; precipitate Ag^+ as $AgCl(s)$; Mn^{2+} remains soluble.
17.93 $pOH = pK_b + \log\{[BH^-]/[B]\}$ **17.99** (**a**) 6.5 mL glacial acetic acid, 5.25 g CH_3COONa **17.101** (**a**) The molar mass of the acid is 121 g/mol. (**b**) $K_a = 6.3 \times 10^{-5}$ **17.107** (**a**) $[Pb^{2+}] = 2.7 \times 10^{-7}\,M$ (**b**) 56 ppb Pb^{2+} (**c**) The solubility of $PbCO_3$ increases as pH is lowered. (**d**) A saturated solution of lead carbonate, with a lead concentration of 56 ppb, exceeds the EPA acceptable lead level of 15 ppb. **17.112** The solubility of $Fe(OH)_2$ in 0.50 *M* NH_4Cl is 5.34×10^{-3} mol/L
17.118 $[OH^-] \geq 1.0 \times 10^{-2}\,M$ or pH ≥ 12.02 **17.121** (**a**) The molar mass of the acid is 94.5 g/mol. (**b**) $K_a = 1.3 \times 10^{-5}$ (**c**) From Appendix D, butanoic acid is the closest match for K_a and molar mass, but the agreement is not exact. **17.123** (**a**) At the conditions given for the stomach, 99.7% of the aspirin is present as neutral molecules.
17.127 (**a**) $[Ag^+]$ from AgCl is 1.4×10^3 ppb or 1.4 ppm. (**b**) $[Ag^+]$ from AgBr is 76 ppb. (**c**) $[Ag^+]$ from AgI is 0.98 ppb. AgBr would maintain $[Ag^+]$ in the correct range.

Chapter 18

18.5 (**a**) The partial pressure of O_3 is 8.5×10^{-3} Pa. (**b**) 2.0×10^{15} O_3 molecules/1.0 L air **18.13** (**a**) A chlorofluorocarbon is a compound that contains chlorine, fluorine, and carbon, while a hydrofluorocarbon is a compound that contains hydrogen, fluorine, and carbon. An HFC contains hydrogen in place of the chlorine present in a CFC. (**b**) HFCs are potentially less harmful to the ozone layer than CFCs because their photodissociation does not produce Cl atoms, which catalyze the destruction of ozone. **18.33** (**a**) A volume greater than 22.4 L (**b**) No. The relative volumes of one mole of an ideal gas at 50 km and 85 km depend on the temperature and pressure at the two altitudes. From Figure 18.1, the gas will occupy a much larger volume at 85 km than at 50 km. (**c**) We expect gases to behave most ideally in the thermosphere, around the stratopause and in the troposphere at low altitude. **18.35** (**a**) A = troposphere, 0–10 km; B = stratosphere, 12–50 km; C = mesosphere, 50–85 km (**b**) Ozone is a pollutant in the troposphere and filters UV radiation in the stratosphere. (**c**) The troposphere (**d**) Only region C in the diagram is involved in an aurora borealis, assuming a narrow "boundary" between the stratosphere and mesosphere at 50 km. (**e**) The concentration of water vapor is greatest near Earth's surface in region A and decreases with altitude. Water's single bonds are susceptible to photodissociation in regions B and C, so its concentration is likely to be very low in these regions. The relative concentration of CO_2, with strong double bonds, increases in regions B and C, because it is less susceptible to photodissociation.
18.37 The Sun **18.39** $CO_2(g)$ dissolves in seawater to form $H_2CO_3(aq)$. The basic pH of the ocean encourages ionization of $H_2CO_3(aq)$ to form $HCO_3^-(aq)$ and $CO_3^{2-}(aq)$. Under the correct conditions, carbon is removed from the ocean as $CaCO_3(s)$ (sea shells, coral, chalk cliffs). As carbon is removed, more $CO_2(g)$ dissolves to maintain the balance of complex and interacting acid-base and precipitation equilibria. **18.41** Above ground, evaporation of petroleum gases and hydrogen sulfide at the well head, evaporation of volatile petroleum products and organic compounds from waste ponds, as well as leakage and overflow from the ponds are potential sources of contamination. Below ground, petroleum gases and fracking liquid can migrate into groundwater, both deep and shallow aquifers. **18.43** (**a**) Its temperature profile (**b**) troposphere, 0 to 12 km; stratosphere, 12 to 50 km; mesosphere, 50 to 85 km; thermosphere, 85 to 110 km **18.45** 7.3×10^{16} CO molecules/1.0 L air **18.46** (**a**) 499 nm (**b**) visible electromagnetic radiation **18.47** (**a**) *Photodissociation* is cleavage of a bond such that two neutral species are produced. *Photoionization* is absorption of a photon with sufficient energy to eject an electron, producing an ion and the ejected electron. (**b**) Photoionization of O_2 requires 1205 kJ/mol. Photodissociation requires only 495 kJ/mol. At lower elevations, high-energy short-wavelength solar radiation has already been absorbed. Below 90 km, the increased concentration of O_2 and the availability of longer-wavelength radiation cause the photodissociation process to dominate. **18.48** (**a**) 127 nm (**b**) A wavelength of 127 nm is in the ultraviolet portion of the electromagnetic spectrum. The energy is not enough energy to photoionize N_2. **18.49** Ozone depletion reactions, which involve only O_3, O_2, or O (oxidation state = 0), do not involve a change in oxidation state for oxygen atoms. Reactions involving ClO and one of the oxygen species with a zero oxidation state do involve a change in the oxidation state of oxygen atoms. **18.51** (**a**) The maximum wavelength of a single photon that will break a C—C bond is 344 nm. The maximum wavelength of a single photon that will break a C—H bond is 291 nm. (**b**) The photodissociation of both C—C bonds and C—H bonds will be significant. **18.52** $2\,NO_2(g) + H_2O(l) \rightleftharpoons HNO_2 + HNO_3(aq)$; $2\,NO(g) + O_2 + H_2O(l) \rightleftharpoons HNO_2(aq) + HNO_3$
18.53 (**a**) $H_2SO_4(aq) + Fe(s) \longrightarrow FeSO_4(aq) + H_2(g)$ (**b**) As copper is a much more noble metal than iron, acid alone cannot attack copper. But the combination of acid and oxygen is a very corrosive medium, that can dissolve copper: $H_2SO_4(aq) + \frac{1}{2}O_2(g) + Cu(s) \longrightarrow CuSO_4(aq) + H_2O(l)$ **18.54** (**a**) Ultraviolet (**b**) 357 kJ/mol (**c**) The average C—H bond energy from Table 8.3 is 413 kJ/mol. The C—H bond energy in CH_2O, 357 kJ/mol, is less than the "average" C—H bond energy.



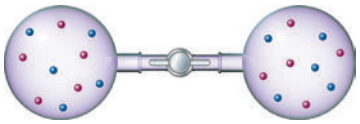
(**d**)

18.55 (**a**) 235 W/m^2. (**b**) Four sources, surface radiation, evapotranspiration, incoming solar radiation and convective heating, transfer energy to the atmosphere. Surface radiation makes the

largest contribution and convective heating the smallest. (**c**) Of the 519 W/m^2 absorbed by the atmosphere, 324 W/m^2 are radiated back to the surface. The percentage is 62.4%. **18.56** 0.445 *M* **18.57** (**a**) 3.22×10^3 gH_2O (**b**) The final temperature is 43.4 °C. **18.58** 961.4 kg CaO **18.59** (**a**) The total cation charge is 5.866 = 5.9 C; the total anion charge is 5.847 = 5.8 C. The two numbers vary in the third significant figure. This is not surprising, because the molarities of the various ions are given to two significant figures. **18.60** The minimum pressure required to initiate reverse osmosis is greater than 599 kPa. **18.61** (**a**) $CO_2(g)$, HCO_3^-, $H_2O(l)$, SO_4^{2-}, NO_3^-, HPO_4^{2-}, $H_2PO_4^-$ (**b**) $CH_4(g)$, $H_2S(g)$, $NH_3(g)$, $PH_3(g)$, **18.62** 8.1 g O_2 **18.63** $5\ Ca^{2+}(aq) + 4\ OH^-(aq) + 3\ HPO_4^{2-}(aq) \longrightarrow Ca_5(OH)(PO_4)_3(s) + 3\ H_2O(l)$ **18.64** (**a**) *Trihalomethanes* are the by-products of water chlorination; they contain one central carbon atom bound to one hydrogen and three halogen atoms.

(**b**)

18.65 The fewer steps in a process, the less waste is generated. Processes with fewer steps require less energy at the site of the process and for subsequent cleanup or disposal of waste. **18.66** (**a**) H_2O (**b**) It is better to prevent waste than to treat it. Atom economy. Less hazardous chemical synthesis and inherently safer for accident prevention. Catalysis and design for energy efficiency. Raw materials should be renewable. **18.67** (**a**) Vegetable oil as a raw material, by criteria 5, 7, and 12. (**b**) Water as a solvent, by criteria 5, 7, and 12. (**c**) Catalyzed reaction, by criteria 6, 9 and 12. **18.71** Multiply equations 18.7 and 18.9 by a factor of 2. Add these two equations to a third equation, $O(g) + O(g) \longrightarrow O_2(g)$. 2 $Cl(g)$ and 2 $ClO(g)$ cancel from each side of the resulting equation to produce equation 18.10. **18.74** (**a**) A CFC has C—Cl bonds and C—F bonds. In an HFC, the C—Cl bonds are replaced by C—H bonds. (**b**) Stratospheric lifetime is significant because, the longer a halogen-containing molecule exists in the stratosphere, the greater the likelihood that it will encounter light with energy sufficient to dissociate a carbon-halogen bond. Free halogen atoms are the bad actors in ozone destruction. (**c**) HFCs have replaced CFCs because it is infrequent that light with energy sufficient to dissociate a C—F bond will reach an HFC molecule. F atoms are much less likely than Cl atoms to be produced by photodissociation in the stratosphere. (**d**) The main disadvantage of HFCs as replacements for CFCs is that they are potent greenhouse gases. **18.76** (**a**) $C_3H_8(l) + 5\ O_2(g) \longrightarrow 3\ CO_2(g) + 4\ H_2O(g)$ (**b**) $C_3H_8(l) + \frac{7}{2}\ O_2(g) \longrightarrow 3\ CO(g) + 4\ H_2O(g)$ (**c**) 66 L of dry air **18.80** 20 m^2 **18.82** (**a**) $CO_3^{2-}(aq) + H_2O(l) \longrightarrow HCO_3^-(aq) + OH^-(aq)$; $Mg^{2+}(aq) + 2\ OH^-(aq) \longrightarrow Mg(OH)_2(s)$ (**b**) At these ion concentrations, Q > K_{sp} and $Mg(OH)_2$ will precipitate.

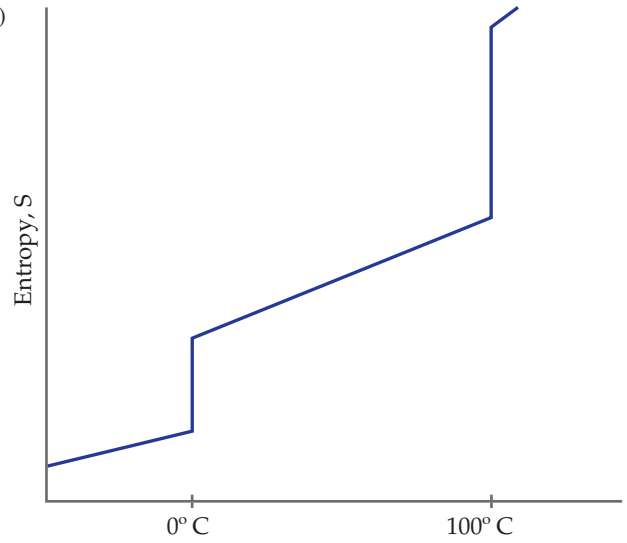


18.85 (**a**) 4.2×10^6 ton CO_2, 8.6×10^4 ton SO_2 (**b**) 8.0×10^4 ton $CaSO_3$

18.88 (**a**) H—Ö—H ⟶ H· + ·Ö—H (**b**) 258 nm (**c**) The overall reaction is $O_3(g) + O(g) \longrightarrow 2O_2(g)$. $OH(g)$ is the catalyst in the overall reaction because it is consumed and then reproduced. **18.90** The enthalpy change for the first step is −141 kJ, for the second step, −249 kJ, for the overall reaction, −390 kJ. **18.93** (**a**) Rate = $k[O_3][H]$ (**b**) $k_{avg} = 1.11 \times 10^{44} M^{-1}s^{-1}$ **18.97** (**a**) Process (**i**) is greener because it involves neither the toxic reactant phosgene nor the by-product HCl. (**b**) Reaction (**i**): C in CO_2 is linear with *sp* hybridization; C in R—N=C=O is linear with *sp* hybridization; C in the urethane monomer is trigonal planar with sp^2 hybridization. Reaction (ii): C in $COCl_2$ is trigonal planar with sp^2 hybridization; C in R—N=C=O is linear with *sp* hybridization; C in the urethane monomer is trigonal planar with sp^2 hybridization. (**c**) The greenest way to promote formation of the isocyanate is to remove by-product, either water or HCl, from the reaction mixture.

Chapter 19

19.24 (**a**) $C_4H_{10}(g)$ (**b**) $C_4H_{10}(g)$ **19.30** (**a**) Yes. $\Delta G = \Delta H - T\Delta S$ (**b**) No. If ΔG is positive, the process is nonspontaneous. (**c**) No. There is no relationship between ΔG and rate of reaction. **19.36** (**a**) The forward reaction is spontaneous at low temperatures but becomes nonspontaneous at higher temperatures. (**b**) The reaction is nonspontaneous in the forward direction at all temperatures. (**c**) The forward reaction is nonspontaneous at low temperatures but becomes spontaneous at higher temperatures.



19.47 (**a**)

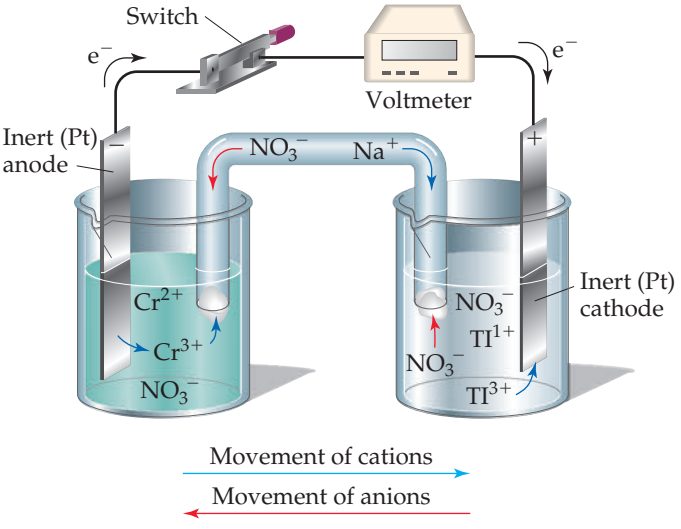
(**b**) $\Delta H = 0$ for mixing ideal gases. ΔS is positive because the disorder of the system increases. (**c**) The process is spontaneous and therefore irreversible. (**d**) Since $\Delta H = 0$, the process does not affect the entropy of the surroundings. **19.50** Both ΔH and ΔS are positive. The net change in the chemical reaction is the breaking of five blue-blue bonds. Enthalpies for bond breaking are always positive. There are twice as many molecules of gas in the products, so ΔS is positive for this reaction. **19.53** (**a**) At 300 K, $\Delta G = 0$, and the system is at equilibrium. (**b**) The reaction is spontaneous at temperatures above 300 K. **19.56** (**a**) True (**b**) false (**c**) false (**d**) false (**e**) true **19.57** Spontaneous: a, d; nonspontaneous: b, c, e **19.58** (**a**) True, assuming that the forward and reverse processes occur at the same conditions. (**b**) false (**c**) false (**d**) true (**e**) false **19.59** (**a**) Endothermic (**b**) above 0 °C (**c**) below 0 °C (**d**) at 0 °C **19.60** (**a**) No. An isothermal process occurs at constant temperature. (**b**) No. Temperature is a state function, so a change in temperature does not depend on pathway. (**c**) No. ΔE is a state function. **19.62** (**a**) An ice cube can melt reversibly at the conditions of temperature and pressure where the solid and liquid are in equilibrium. (**b**) No. We know that ΔH is a state function, and that melting is endothermic. Whether the ice cube melts reversibly or irreversibly, ΔH for the process is not zero. **19.63** (**a**) False (**b**) true (**c**) true (**d**) false **19.64** (**a**) Entropy increases (**b**) 188 J/K **19.65** (**a**) True (**b**) false (**c**) false **19.66** (**a**) Positive ΔS (**b**) $\Delta S = 1.02$ J/K (**c**) Temperature need not be specified to calculate ΔS, as long as the expansion is isothermal. **19.67** (**a**) $T_b = 57$ °C (**b**) From the *Handbook of Chemistry and Physics*, 74th Edition, $T_b = 58.8$ °C. The values are remarkably close; the small difference is primarily due to the fact that we used thermodynamic data at 25 °C for our calculation. **19.68** (**a**) Yes, the expansion is spontaneous. (**b**) As the ideal gas expands into the vacuum, there is nothing for it to "push back," so no work is done. Mathematically, $w = -P_{ext}\Delta V$. Since the gas expands into a vacuum, $P_{ext} = 0$ and $w = 0$. (**c**) The "driving force" for the expansion of the gas is the increase in entropy. **19.69** (**a**) An increase in temperature produces more available microstates for a system. (**b**) A decrease in volume produces fewer available microstates for a system. (**c**) Going from liquid to gas, the number of available microstates increases. **19.70** (**a**) ΔS is negative. (**b**) S of the system increases in 19.11 (a), (b) and (c). **19.71** S increases in (**a**) and (**c**); S decreases in (**b**). **19.72** (**a**) False (**b**) true (**c**) false (**d**) true **19. 73** (**a**) $I_2(g)$ (**b**) $O_2(g)$ at 50.7 kPa pressure (**c**) 1 mol of N_2 in 44.8 L (**d**) $CH_3OH(l)$ **19.74** (**a**) $\Delta S < 0$ (**b**) $\Delta S < 0$ (**c**) $\Delta S > 0$ (**d**) $\Delta S < 0$

19.75

(**a**)

(**b**) Boiling water, at 100 °C, has a much larger entropy change than melting ice at 0 °C. **19.77** (**a**) $HNO_3(g)$ will have the higher standard entropy at 25 °C. $HNO_3(g)$, 266.4 J/mol K; $HNO_3(aq)$, 146 J/mol K (**b**) $PCl_3(g)$ will have the higher standard entropy at 25 °C. $PCl_3(l)$, 217 J/mol K; $PCl_3(g)$, 311.7 J/mol K (**c**) $Fe_3O_4(s)$ will have the higher standard entropy at 25 °C. $Fe_2O_3(s)$, 89.96 J/mol K; $Fe_3O_4(s)$, 146.4 J/mol K. (**d**) Li(*g*) will have the higher standard entropy at 25 °C. Li(*s*), 29.09 J/mol K; Li(*g*), 138.8 J/mol K. **19.78** For elements with similar structures, the heavier the atoms, the lower the vibrational frequencies at a given temperature. This means that more vibrations can be accessed at a particular temperature, resulting in greater absolute entropy for the heavier elements. **19.79** (**a**) $\Delta S° = +75.3$ J/K. $\Delta S°$ is positive because the product contains more total particles with more motional freedom. (**b**) $\Delta S° = +221.46$ J/K. $\Delta S°$ is positive because there are more moles of gas in the products. (**c**) $\Delta S° = 5.04$ J/K. $\Delta S°$ is almost zero, as there are equal moles of gas in the products and in the reactants. (**d**) $\Delta S° = 242.88$ J/K. $\Delta S°$ is negative because there are fewer moles of gas in the products. **19.81** (**a**) $\Delta S°$ is negative; the reaction leads to a decrease in disorder of the system. (**b**) $\Delta H°$ is negative; the reaction leads to an increase in disorder of the surroundings. (**c**) $\Delta G° = +4.7$kJ (**d**) If all reactants and products are present in their standard states, the reaction is nonspontaneous in the forward direction at this temperature.

19.82 (**a**) $\Delta H° = -804.2$ kJ, $\Delta S° = -254.8$ J/K, $\Delta G° = -728.1$ kJ, $\Delta G° = \Delta H° - T\Delta G° = -728.3$ kJ
(**b**) $\Delta H° = -56.1$ kJ, $\Delta S° = 79.1$ J/K, $\Delta G° = -79.7$ kJ, $\Delta G° = \Delta H° - T\Delta G° = -79.7$ kJ
(**c**) $\Delta H° = -394.5$ kJ, $\Delta S° = 176.3$ J/K, $\Delta G° = -447.7$ kJ, $\Delta G° = \Delta H° - T\Delta G° = -447.1$ kJ (**d**) $\Delta H° = -27.6$ kJ, $\Delta S° = 269.5$ J/K, $\Delta G° = -107.6$ kJ, $\Delta G° = \Delta H° - T\Delta G° = -107.9$ kJ. The discrepancy in $\Delta G°$ values is due to experimental uncertainties in the tabulated thermodynamic data. **19.83** (**a**) $\Delta G° = -636.4$ kJ, spontaneous (**b**) $\Delta G° = 856.3$ kJ, nonspontaneous (**c**) $\Delta G° = 44.2$ kJ, nonspontaneous (**d**) $\Delta G° = 159.2$ kJ, nonspontaneous



19.84 (**a**) $C_{31}H_{64}(s) + 47\ O_2(g) \rightarrow 31\ CO_2(g) + 32\ H_2O(g)$ (**b**) Because $\Delta S°$ is positive, $\Delta G°$ is more negative than $\Delta H°$. **19.86** $\Delta S > 47.5$ J/K **19.87** (**a**) $T = 333$ K (**b**) spontaneous **19.88** (**a**) $\Delta H° = 155.7$ kJ, $\Delta S° = 171.4$ kJ. Since $\Delta S°$ is positive, $\Delta G°$ becomes more negative with increasing temperature. (**b**) $\Delta G° = 19$ kJ. The reaction is not spontaneous under standard conditions at 800 K (**c**) $\Delta G° = -15.7$ kJ. The reaction is spontaneous under standard conditions at 1000 K.

19.90 (**a**) $C_2H_2(g) + \frac{5}{2}\ O_2(g) \longrightarrow 2\ CO_2(g) + H_2O(l)$
(**b**) −1299.5 kJ of heat produced / mol C_2H_2 burned
(**c**) $w_{max} = -1235.1$ kJ / mol C_2H_2 **19.91** (**a**) ΔG increases; it becomes more positive. (**b**) ΔG decreases; it becomes more negative. (**c**) ΔG increases; it becomes more positive. **19.92** (**a**) $\Delta G° = -69.74$ kJ (**b**) $\Delta G = -67$ kJ **19.93** (**a**) $\Delta G° = -16.77$ kJ, $K = 870$
(**b**) $\Delta G° = 8.0$ kJ, $K = 0.039$ (**c**) $\Delta G° = -497.9$ kJ, $K = 2 \times 10^{87}$
19.94 $\Delta H° = 269.3$ kJ, $\Delta S° = 0.1719$ kJ / K (**a**) $P_{CO_2} = 6.1 \times 10^{-37}$ kPa (**b**) $P_{CO_2} = 1.6 \times 10^{-2}$ kPa
19.95 (**a**) $HNO_2(aq) \rightleftharpoons H^+(aq) + NO_2^-(aq)$ (**b**) $\Delta G° = 19.1$ kJ
(**c**) $\Delta G = 0$ at equilibrium (**d**) $\Delta G = -2.7$ kJ **19.96** (**a**) The thermodynamic quantities *P*, *H* and *G* are state functions (**b**) $w_{rev} < w_{irrev}$ (**c**) $q_{rev} > q_{irrev}$ (**d**) $\Delta H = q_{rev} + w_{rev} + p\Delta V$, $\Delta G = w_{rev} + p\Delta V$
19.105 (**a**) $C(s) + 2\ H_2(g) \rightarrow CH_4(g)$; $Na(s) + \frac{1}{2}Cl_2(g) \rightarrow NaCl(s)$
(**b**) In both reactions, ΔG_f^0 will be more positive (less negative) than ΔH_f^0. (**c**) Condition (iii), when ΔS_f^0 is negative. **19.110** (**a**) For the oxidation of glucose in the body, $\Delta G° = -2878.8$ kJ, $K = 5 \times 10^{504}$; for the anaerobic decomposition of glucose, $\Delta G° = -228.0$ kJ, $K = 9 \times 10^{39}$
(**b**) A greater maximum amount of work at standard conditions can be obtained from the oxidation of glucose in the body, because ΔG° is much more negative. **19.114** (**a**) Acetone, $\Delta S°_{vap} = 88.4$ J/mol K; dimethyl ether, $\Delta S°_{vap} = 86.6$ J/mol K; ethanol, $\Delta S°_{vap} = 110$ J/mol K; octane, $\Delta S°_{vap} = 86.3$ J/mol K; pyridine, $\Delta S°_{vap} = 90.4$ J/mol K. Ethanol does not obey Trouton's rule. (**b**) Hydrogen bonding (in ethanol and other liquids) leads to more ordering in the liquid state and a greater than usual increase in entropy upon vaporization. Liquids that experience hydrogen bonding are probably exceptions to Trouton's rule. (**c**) Owing to strong hydrogen bonding interactions, water probably does not obey Trouton's rule. $\Delta S°_{vap} = 109.0$ J/mol K. (**d**) ΔH_{vap} for $C_6H_5Cl \approx 36$ kJ/mol **19.121** (**a**) 682 K or 409 °C (**b**) 782 K or 509 °C

Chapter 20

20.42 (**a**) anode: $Fe(s) \longrightarrow Fe^{2+}(aq) + 2\ e^-$; cathode: $O_2(g) + 4\ H^+(aq) + 4\ e^- \longrightarrow 2\ H_2O(l)$ (**b**) $2\ Fe^{2+}(aq) + 3\ H_2O(l) + 3\ H_2O(l) \longrightarrow Fe_2O_3 \cdot 3\ H_2O(s) + 6\ H^+(aq) + 2\ e^-$; $O_2(g) + 4\ H^+(aq) + 4\ e^- \longrightarrow 2\ H_2O(l)$ **20.50** In this analogy, the electron is analogous to the proton (H^+). Redox reactions can be viewed as electron-transfer reactions, just as acid-base reactions can be viewed as proton-transfer reactions. Oxidizing agents are themselves reduced; they gain electrons. A strong oxidizing agent would be analogous to a strong base. **20.52** (**a**) The process represents oxidation. (**b**) The electrode is the anode. (**c**) When a neutral atom loses a valence electron, the radius of the resulting cation is smaller than the radius of the neutral atom. **20.56** (**a**) The sign of $\Delta G°$ is positive. (**b**) The equilibrium constant is less than one. (**c**) No. An electrochemical cell based on this reaction cannot accomplish work on its surroundings. **20.59** (**a**) Zinc is the anode. (**b**) The energy density of the silver oxide battery is most similar to the nickel-cadmium battery. The molar masses of the electrode materials and the cell potentials for these two batteries are most similar. **20.62** (**a**) *Oxidation* is the loss of electrons. (**b**) Electrons appear on the products' side (right side). (**c**) The *oxidant* is the reactant that is reduced. (**d**) An *oxidizing agent* is the substance that promotes oxidation; it is the oxidant. **20.63** (**a**) True (**b**) false (**c**) true
20.64 (**a**) (i) Reactants: H, +1; Mn, +2; Na, +1; Bi, +5; O, −2. Products: H, +1; O, −2; Mn, +7; Bi, +3, Na, +1 (ii) The total number of electrons transferred is 10. (**b**) Reactants: K, +1; Mn, +7; O, −2; Na, +1; S, +4; O, −2; H, +1. Products: Mn, +4; O, −2; Na, +1; S, +6, K, +1; H, +1 (ii) The total number of electrons transferred is 6. (**c**) (i) Reactants: Cu, 0; Ag, +1; N, +5; O, −2. Products: Ag, 0; Cu, +2; N, +5; O, −2. (ii) The total number of electrons transferred is 2.

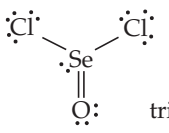
20.65 (**a**) Nitrogen is oxidized from +4 to +5; oxygen is reduced from −1 to −2. (**b**) no oxidation-reduction (**c**) Iron is oxidized from 0 to +2; nitrogen is reduced from +5 to +4. **20.66** (**a**) $SiCl_4(g) + 2\,H_2(g) \rightarrow Si(s) + 4\,HCl(g)$ (**b**) $H_2(g)$ is oxidized; $SiCl_4(g)$ is reduced. (**c**) $H_2(g)$ is the reductant; $SiCl_4(g)$ is the oxidant. **20.67** (**a**) $14\,H^+(aq) + Cr_2O_7^{2-}(aq) + 6\,e^- \rightarrow 2\,Cr^{3+}(aq) + 7\,H_2O(l)$, reduction (**b**) $4\,H_2O(l) + Mn^{2+}(aq) \rightarrow MnO_4^-(aq) + 8\,H^+(aq) + 5\,e^-$, oxidation (**c**) $I_2(s) + 6\,H_2O(l) \rightarrow 2\,IO_3^-(aq) + 12\,H^+(aq) + 10\,e^-$, oxidation (**d**) $S(s) + 2\,H^+(aq) + 2\,e^- \rightarrow H_2S(g)$, reduction (**e**) $H_2O(l) + 2\,e^- + NO_3^-(aq) \rightarrow NO_2^-(aq) + 2\,OH^-(aq)$ reduction (**f**) $H_2O_2(aq) + 2\,e^- \rightarrow 2\,OH^-(aq)$, reduction **20.68** (**a**) $Cr_2O_7^{2-}(aq) + I^-(aq) + 8\,H^+(aq) \longrightarrow 2\,Cr^{3+}(aq) + IO_3^-(aq) + 4\,H_2O(l)$; oxidizing agent, $Cr_2O_7^{2-}$; reducing agent, I^- (**b**) $4\,MnO_4^-(aq) + 5\,CH_3OH(aq) + 12\,H^+(aq) \longrightarrow 4\,Mn^{2+}(aq) + 5\,HCOOH(aq) + 12\,H_2O(aq)$; oxidizing agent, MnO_4^-; reducing agent, CH_3OH (**c**) $I_2(s) + 5\,OCl^-(aq) + H_2O(l) \longrightarrow 2\,IO_3^-(aq) + 5\,Cl^-(aq) + 2\,H^+(aq)$; oxidizing agent, OCl^-; reducing agent, I_2 (**d**) $As_2O_3(s) + 2\,NO_3^-(aq) + 2\,H_2O(l) + 2\,H^+(aq) \longrightarrow 2\,H_3AsO_4(aq) + N_2O_3(aq)$; oxidizing agent, NO_3^-; reducing agent, As_2O_3 (**e**) $2\,MnO_4^-(aq) + Br^-(aq) + H_2O(l) \longrightarrow 2MnO_2(s) + BrO_3^-(aq) + 2\,OH^-(aq)$; oxidizing agent, MnO_4^-; reducing agent, Br^- (**f**) $Pb(OH)_4^{2-}(aq) + ClO^-(aq) \longrightarrow PbO_2(s) + Cl^-(aq) + 2\,OH^-(aq) + H_2O(l)$; oxidizing agent, $ClO^-(aq)$; reducing agent, $Pb(OH)_4^{2-}$ **20.69** (**a**) False (**b**) true (**c**) true **20.70** (**a**) Mg is oxidized, Ni^{2+} is reduced. (**b**) $Mg(s) \rightarrow Mg^{2+}(aq) + 2\,e^-$; $Ni^{2+}(aq) + 2\,e^- \rightarrow Ni(s)$ (**c**) Mg is the anode, Ni is the cathode. (**d**) Mg(*s*) is negative; Ni(*s*) is positive. (**e**) Electrons flow from the Mg electrode (–) toward the Ni electrode (+). (**f**) Anions migrate toward the Mg(*s*) anode; cations migrate towards the Ni(*s*) cathode. **20.71** (**a**) One *volt* is the potential energy difference required to impart 1 J of energy to a charge of 1 coulomb. (**b**) Yes. All voltaic cells involve spontaneous redox reactions that produce positive cell potentials or emfs. **20.72** (**a**) $O_2(g) + 4\,H^+(aq) + 4\,e^- \rightarrow 2\,H_2O(l)$ (**b**) $2\,H_2O(l) \rightarrow O_2(g) + 4\,H^+(aq) + 4\,e^-$ (**c**) A *standard* oxygen electrode is an oxygen electrode where the components are at standard conditions, 1 *M* $H^+(aq)$ and $O_2(g)$ at 101.3 kPa, such that $E° = 1.23$ V. **20.74** (**a**) $Cr^{2+}(aq) \longrightarrow Cr^{3+}(aq) + e^-$; $Tl^{3+}(aq) + 2\,e^- \longrightarrow Tl^+(aq)$ (**b**) $E°_{red} = 0.78\ V$ (**c**)

20.75 (**a**) $E° = 0.82$ V (**b**) $E° = 1.89$ V (**c**) $E° = 1.21$ V (**d**) $E° = 0.62$ V **20.76** (**a**) $Fe(s) + 2\,Ag^+(aq) \rightarrow 2\,Ag(s) + 2\,Fe^{2+}(aq)$, $E^0_{cell} = 1.239$ V (**b**) $Fe(s) + Cd^{2+}(aq) \rightarrow Cd(s) + 2\,Fe^{2+}(aq)$, $E^0_{cell} = 0.037$ V

20.77 (**a**) Anode, Cu(*s*); cathode, Ag(*s*). (**b**) The silver electrode gains mass as Ag is plated out, and the Cu electrode loses mass as Cu is oxidized. (**c**) $Cu(s) + 2\,Ag^+(aq) \rightarrow 2\,Ag(s) + 2\,Cu^{2+}(aq)$ (**d**) $E^0_{cell} = 0.462$ V **20.78** (**a**) Mg(*s*) (**b**) Fe(*s*) (**c**) Sn(*s*) (**d**) $I^-(aq)$ **20.79** (**a**) $H_2(g)$, basic, reductant (**b**) $Cr_2O_7^{2-}(aq)$, acidic, oxidant (**c**) $F_2(g)$, oxidant (**d**) Li(*s*), reductant **20.80** (**a**) $HSO_4^-(aq) < O_2(g) < MnO_4^-(aq) < HClO(aq) < O_3(g)$ (**b**) $Cr(OH)_3(s) < Fe(s) < H_2(g) < Mn(s) < Ca(s)$ **20.82** Al and $H_2C_2O_4$ **20.83** (**a**) $2\,Fe^{2+}(aq) + S_2O_6^{2-}(aq) + 4\,H^+(aq) \longrightarrow 2\,Fe^{3+}(aq) + 2\,H_2SO_3(aq)$; $2\,Fe^{2+}(aq) + N_2O(aq) + 2\,H^+(aq) \longrightarrow 2\,Fe^{3+}(aq) + N_2(g) + H_2O(l)$; $Fe^{2+}(aq) + VO_2^+(aq) + 2\,H^+(aq) \longrightarrow Fe^{3+}(aq) + VO^{2+}(aq) + H_2O(l)$ (**b**) $E° = -0.17$ V, $\Delta G° = 33$ kJ; $E° = -2.54$ V, $\Delta G° = 4.90 \times 10^2$ kJ; $E° = 0.23$ V, $\Delta G° = -22$ kJ (**c**) $K = 1.8 \times 10^{-6} = 10^{-6}$; $K = 1.2 \times 10^{-86} = 10^{-86}$; $K = 7.8 \times 10^3 = 8 \times 10^3$ **20.84** $\Delta G° = 27$ kJ, $E^0_{cell} = -0.28$ V **20.85** (**a**) $E° = 0.16$ V, $K = 2.54 \times 10^5 = 3 \times 10^5$ (**b**) $E° = 0.28$ V, $K = 2.93 \times 10^9 = 3 \times 10^9$ (**c**) $E° = 0.44$ V, $K = 2.40 \times 10^{74} = 10^{74}$ **20.86** (**a**) $K = 2.2 \times 10^4$ (**b**) $K = 4.9 \times 10^8$ (**c**) $K = 1.1 \times 10^{13}$ **20.87** $w_{max} = 1.3 \times 10^2$ kJ/mol Sn; 8.3×10^4 J/75.0 g Sn **20.88** (**a**) In the Nernst equation, $Q = 1$ if all reactants and products are at standard conditions. (**b**) Yes. The Nernst equation is applicable to cell emf at nonstandard conditions, so it must be applicable at temperatures other than 298 K. Values of $E°$ at temperatures other than 298 K are required. And, there is a variable for T in the second term. If the short-hand form of the equation, Equation 20.18, is used, a coefficient other than 0.0592 is required. **20.89** (**a**) *E* decreases (**b**) *E* increases (**c**) no effect (**d**) *E* decreases **20.90** (**a**) $E° = 0.48$ V (**b**) $E = 0.52$ V (**c**) $E = 0.46$ V **20.91** (**a**) $E° = 0.46$ V (**b**) $E = 0.37$ V **20.92** (**a**) The compartment with $[Cu^{2+}] = 0.100\,M$ is the cathode. (**b**) $E° = 0$ (**c**) $E = 0.0888$ V (**d**) In the anode compartment $[Cu^{2+}]$ increases; in the cathode compartment $[Cu^{2+}]$ decreases. **20.93** $E° = 0.76$ V, pH = 2.2 **20.94** (**a**) 260 g Pb (**b**) 2.42×10^5 C **20.95** (**a**) The anode (**b**) $E° = 3.50$ V (**c**) The emf of the battery, 3.5 V, is exactly the standard cell potential calculated in part (**b**). (**d**) At ambient conditions, $E \approx E°$, so $\log Q \approx 1$. Assuming that the value of $E°$ is relatively constant with temperature, the value of the second term in the Nernst equation is approximately zero at 37 °C, and $E \approx 3.5$ V. **20.96** (**a**) The cell emf will have a smaller value. (**b**) NiMH batteries use an alloy such as $ZrNi_2$ as the anode material. This eliminates the use and disposal problems associated with Cd, a toxic heavy metal. **20.97** (**a**) When the battery is fully charged, the mole ratio of the elements in the cathode is: 0.5 mol Li^+ to 0.5 mol Co^{3+} to 0.5 mol Co^{4+} to 2 mol O^{2-}. The material is $LiCo_2O_4$ (**b**) 4.9×10^3 C of electricity delivered on full discharge of a fully charged battery **20.98** (**a**) The spontaneous reaction in the hydrogen fuel cell is hydrogen gas plus oxygen gas makes water. (**b**) $E° = 1.23$ V **20.100** (**a**) Al is called a "sacrificial anode" because it has a more negative E^0_{red} than the pipeline metal and is preferentially oxidized when the two are coupled. It is sacrificed to preserve the pipeline. (**b**) E^0_{red} for Al^{3+} is −1.66 V, more negative than most metals present in pipelines, including Fe and Zn. **20.101** (**a**) +3 (**b**) +8/3 or +2.67 (**c**) 2 Fe(III) and 1 Fe(II) **20.102** (**a**) *Electrolysis* is an electrochemical process driven by an outside energy source. (**b**) By definition, electrolysis reactions are nonspontaneous. (**c**) $2\,Cl^-(l) \longrightarrow Cl_2(g) + 2\,e^-$ (**d**) When an aqueous solution of NaCl undergoes electrolysis, sodium metal is not formed because H_2O is preferentially reduced to form $H_2(g)$ **20.103** (**a**) 236 g Cr(*s*) (**b**) 2.51 A **20.104** (**a**) 4.0×10^5 g Li (**b**) The minimum voltage required to drive the electrolysis is +4.41 V. **20.105** Gold is less active than copper and thus more difficult to oxidize. When a mixture of copper and gold is refined by electrolysis, Cu is oxidized from the anode, but any metallic gold present in the mixture is not oxidized, so it accumulates near the anode, available for collection.

20.106 (**a**) $3\ Fe^{2+}(aq) \rightarrow Fe(s) + 2\ Fe^{3+}(aq)$
(**b**) $3\ Br_2(l) + 3\ H_2O(l) \rightarrow 6\ H^+(aq) + 5\ Br^-(aq) + BrO_3^-(aq)$
(**c**) $4\ Cr^{3+}(aq) + 7\ H_2O(l) \rightarrow 14\ H^+(aq) + Cr_2O_7^{2-}(aq) + 2\ Cr(s)$
(**d**) $5\ NO_2^-(aq) + 2\ H^+(aq) \rightarrow H_2O(l) + N_2(g) + 3\ NO_3^-(aq)$
20.108 (**a**) $E° = 0.226$ V, spontaneous (**b**) $E° = -0.44$ V, nonspontaneous (**c**) $E° = -0.144$ V, nonspontaneous (**d**) $E° = -0.434$ V, nonspontaneous **20.112** $K = 1.22 \times 10^{-41}$ **20.115** (**a**) By analogy to O in hydroxide (OH^-) and in alcohol (R−OH), the oxidation state of S in a thiol (R−SH) is −2. (**b**) By analogy to O in peroxide (−O−O−), the oxidation state of S in a disulfide (−S−S−) is −1. (**c**) The oxidation number of S becomes more positive and the thiols are oxidized. (**d**) Converting a disulfide to two thiols is the reverse of the process described in part (**c**). In order to reduce the disulfide, a reducing agent must be added to the solution. (**e**) When two thiols (R−SH) react to form a disulfide (R−S−S−R), the H atoms are probably removed by base before the oxidizing agent does its work. **20.118** 1.5×10^4 kWh required **20.123** (**a**) $E° = 0.728$ V, (**b**) cathode: $Br_2(l) + 2\ e^- \rightarrow 2\ Br^-(aq)$; anode: $Cu(s) \rightarrow Cu^{2+}(aq) + 2\ e^-$
(**c**) $\Delta S° = -123.78$ J. Because $\Delta S°$ is negative, $\Delta G°$ will become more positive and $E°$ will become more negative as temperature is increased. **20.126** K_{sp} for AgCl is 1.8×10^{-10}.

Chapter 21



21.24 (**a**) NaI is a good source of iodine because iodine is a large percentage of its mass; it is completely dissociated into ions in aqueous solution, and iodine in the form of $I^-(aq)$ is mobile and immediately available for biouptake. (**b**) A Geiger counter placed near the thyroid immediately after ingestion will register background, then gradually increase in signal until the concentration of iodine in the thyroid reaches a maximum. Over time, iodine-131 decays, and the signal decreases. (**c**) The radioactive iodine will decay to 0.01% of the original amount in approximately 107 days. **21.29** (**a**) 1.71×10^5 kg/d (**b**) 2.1×10^8 g ^{235}U **21.30** ^{55}Mn is likely to have the largest mass defect per nucleon. **21.36** Hydrogen abstraction: $RCOOH + {\bullet}OH^- \longrightarrow RCOO{\bullet} + H_2O$; deprotonation: $RCOOH + OH^- \longrightarrow RCOO^- + H_2O$. Hydroxyl radical is more toxic to living systems because it produces other radicals when it reacts with molecules in the organism. Hydroxide ion, OH^-, on the other hand, will be readily neutralized in the buffered cell environment. The acid–base reactions of OH^- are usually much less disruptive to the organism than the chain of redox reactions initiated by OH radical. **21.38** (**a**) ^{24}Ne; outside; reduce neutron-to-proton ratio via β decay (**b**) ^{32}Cl; outside; increase neutron-to-proton ratio via positron emission or orbital electron capture (**c**) ^{108}Sn; outside; increase neutron-to-proton ratio via positron emission or orbital electron capture (**d**) ^{216}Po; outside; nuclei with $Z \geq 84$ usually decay via α emission. **21.43** (**a**) 7 min (**b**) 0.1 min^{-1} (**c**) 30% (3/10) of the sample remains after 12 min. 23.79

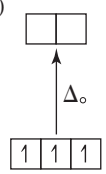
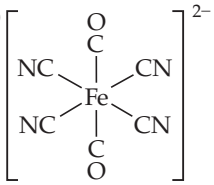
Both dmpe and en are bidentate ligands, binding through P and N, respectively. Because phosphorus is less electronegative than N, dmpe is a stronger electron pair donor and Lewis base than en. Dmpe creates a stronger ligand field and is higher on the spectrochemical series. Structurally, dmpe occupies a larger volume than en. M–P bonds are longer than M—N bonds and the two $-CH_3$ groups on each P atom in dmpe create more steric hindrance than the H atoms on N in en. (**b**) The oxidation state of Mo is zero. (**c**) The symbol $\widehat{PP}$ represents the bidentate dmpe ligand.



optical isomers

23.82 (**a**) Iron (**b**) magnesium (**c**) iron (**d**) copper **23.84** (**a**) Pentacarbonyliron(0) (**b**) The oxidation state of iron must be zero. (**c**) Two. One isomer has CN in an axial position and the other has it in an equatorial position.

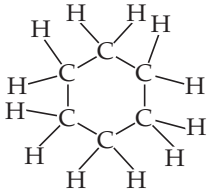
23.86



(**a**)

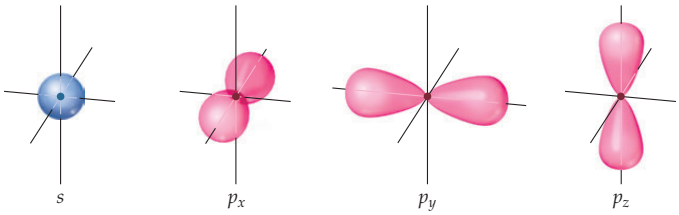
(**b**) These complexes are colored because the crystal-field splitting energy, Δ, is in the visible portion of the electromagnetic spectrum. Visible light with $\lambda = hc/\Delta$ is absorbed, promoting one of the

d-electrons into a higher energy *d*-orbital. The remaining wavelengths of visible light are reflected or transmitted; the combination of these wavelengths is the color we see. (**c**) $[Cr(NH_3)_6]^{3+}$ will absorb light with higher energy. NH_3 is in the middle of the spectrochemical series, and causes a larger Δ than Br^-, a weak-field ligand. Because Δ and λ are inversely related, larger Δ corresponds to higher energy and shorter λ. **23.88** $[Co(NH_3)_6]^{3+}$, yellow; $[Co(H_2O)_6]^{2+}$, pink; $[CoCl_4]^{2-}$, blue



23.89 (**a**)

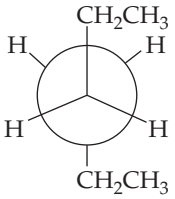
(**b**) sodium dicarbonyltetracyanoferrate(II) (**c**) +2, 6 *d*-electrons (**d**) We expect the complex to be low spin. Cyanide (and carbonyl) are high on the spectrochemical series, which means the complex will have a large Δ splitting, characteristic of low-spin complexes. **23.99** (**a**) Yes, the oxidation state of Co is +3 in both complexes. (**b**) Compound A has SO_4^{2-} outside the coordination sphere and coordinated Br^-, so it forms a precipitate with $BaCl_2(aq)$ but not $AgNO_3(aq)$. Compound B has Br^- outside the coordination sphere and coordinated SO_4^{2-} so it forms a precipitate with $AgNO_3(aq)$ but not $BaCl_2(aq)$. (**c**) Compounds A and B are coordination sphere isomers. (**d**) Both compounds are strong electrolytes. **23.102** The chemical formula is $[Pt(NH_3)_2Cl_2]$. This should be a neutral square-planar complex of Pt(II), a nonelectrolyte. Because it has a net dipole moment, we can infer that it must be the cis isomer. **23.104** 47.3 mg Mg^{2+}/L, 53.4 mg Ca^{2+}/L **23.106** $\Delta E = 3.30 \times 10^{-19}$ J/photon, $\lambda = 602$ nm. The complex will absorb in the visible around 600 nm and appear blue.



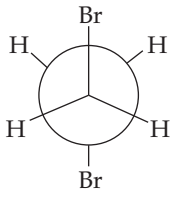
Chapter 24

24.3 The bond enthalpies in kJ mol^{-1} are: C—H, 413; C—C, 348; C—O, 358; C—CI, 328. The bond enthalpies indicate that C—H bonds are most difficult to break and C—CI bonds least difficult. However, they do not explain the reactivity of C—O bonds, or stability of C—C bonds. The reactivity of molecules containing C—O and C—CI bonds is a result of their unequal charge distribution, which attracts reactants that are either electron deficient (electrophilic) or electron rich (nucleophilic). **24.6** An empirical formula shows the simplest mole ratio of elements in a compound. For example, an empirical formula of CH_2 implies that the molecule contains only carbon and hydrogen and that they are present in a 1:2 ratio. A molecular formula shows the exact number and kinds of atoms in a molecule. For example, C_6H_{12} ($(CH_2)_6$) tells us the number of carbons and hydrogens actually found within a molecule of the compound. A structural formula shows the bonding of atoms within a molecule. In this instance, it shows that the hydrocarbon is cyclic.

24.7 (**a**) A compound that contains only hydrogen and carbon atoms. (**b**) Yes. (**c**) $CH_3CH_2CH_3$ (**d**) butane: $CH_3CH_2CH_2CH_3$, molecular formula = C_4H_{10}, empirical formula = C_2H_5. **24.9** Ethanol < hexane < palmitic acid



24.12



The drawings represent the probability of an electron occupying a given space. The blending (hybridisation) of all these orbitals leads to one sp^3 hybrid orbital. **24.13** Five: $CH_3CH_2CH_2CH_2CH_2CH_3$; $CH_3CH(CH_3)CH_2CH_2CH_3$; $CH_3CH_2CH(CH_3)CH_2CH_3$; $CH_3CH(CH_3)CH(CH_3)CH_3$; $CH_3C(CH_3)_2CH_2CH_3$. **24.14** Constitutional isomers have the same molecular formula but a different connectivity for the atoms. Constitutional isomers are not interconvertable without the breaking or formation of a C—C bond. For example, butane and 2-methylpropane are constitutional isomers. Conformational isomers are isomers that differ only in their three-dimensional arrangement in space by rotation about a single C—C bond; for example, the eclipsed and staggered forms of butane.

24.16

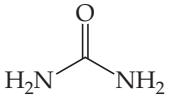
24.39

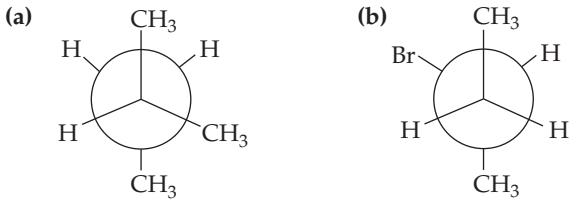
24.41 (**a**) Greater than 2:1 (cyclohexane:chlorine)
(**b**) The carbons (and hydrogens) in cyclohexane are all chemically equivalent (and secondary) and lead to the same product. Hexane has two types of secondary carbons which lead to two regioisomers formed. Some reaction at primary carbons also complicates matters.
24.42 (**c**) and (**d**) are the same **24.44** The end-on overlap of the atomic orbitals would form a σ-bond.

24.46



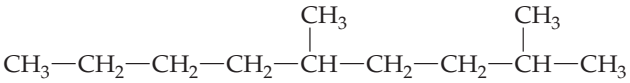
24.48

$CH_3—CHBr—CH_2—CH_2—CH_3$



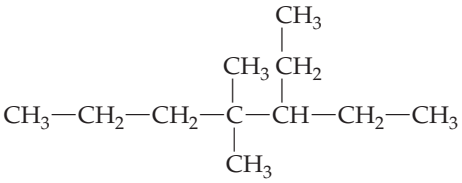
24.50 (**a**) Ether (O single bonded to two C) and two alkene groups (double bonded carbons). (**b**) Ester and five alcohols (OH groups). (**c**) Alcohol, alkene (double bonded carbons) and ketone (O double bonded to a C). (**d**) Ether, two alcohols, alkene and a tertiary amine (N bonded to three C). (Note that the ring of six carbons with three double bonds, although not covered in this chapter, is an aromatic ring, and is sometimes considered a functional group.) (**e**) Ester, two alcohols and chloroalkane.

24.52

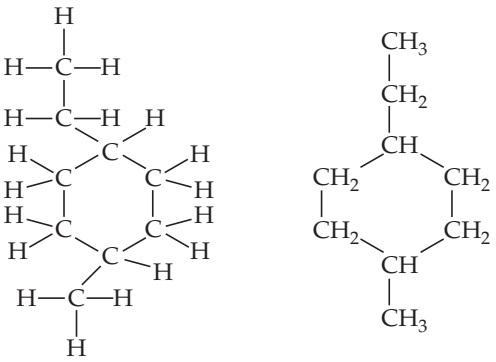


Urea would be considered an organic molecule because it is a carbon attached to two nitrogen atoms and double bonded to an oxygen atom. Thus it is a molecule containing carbon that created four bonds.

24.58

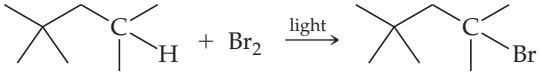


24.61 The polymer shown here is an alkane. Since molecules are more soluble in 'like' solvents, we would expect polyethylene to be more soluble in organic solvents such as hexane. **24.62** (**a**) 3,3,5-trimethylheptane (**b**) 3,4,4-trimethylheptane



(**c**)

(**d**)



(**e**)

24.63 (**a**) 2,4-dimethylpentane (**b**) 3,5-dimethylheptane (**c**) 4-ethyl-2,4-dimethylhexane (**d**) 3-ethyl-2-methylpentane **24.64** 2,3,3-trimethylpentane **24.65** Butane and 2-methylpropane are constitutional isomers. Butane molecules are able to maximise their London dispersive forces when compared with 2-methylpropane which is more globular. The energy associated with this stabilising interaction needs to be overcome for butane to boil. The higher boiling point of butane equates to this extra energy. **24.66** ΔH_{comb}/mol CH_2 for cyclopropane = −2089/3 = 696.3 kJ, for cyclopentane = −3317/5 663.4 kJ. $\Delta H_{comb}/CH_2$ group for cyclopropane is greater because C_3H_6 contains a significantly more strained ring than C_5H_{10}. When combustion occurs, the strain is relieved and the stored energy is released. **24.68** (**a**) OH axial, Cl equatorial (**b**) all equatorial (**c**) OH and CH_3 axial (**d**) clockwise from OH - axial OH, equatorial Cl, axial CH_3, equatorial CH_3 **24.70** Cycloalkanes are able to have geometric isomerism due to the restricted (in fact, impossible) rotation about any C–C bond within the cyclic framework. Alkanes are able to rotate freely about C–C bonds and so are able to interconvert freely. Such isomers are known as conformational isomers. **24.73** (**a**) A functional group is a site of reactivity in an organic molecule (**b**) Functional groups are important because they not only provide a description of the molecule but also controls how the molecule will behave or function given certain conditions **24.76** (**a**) In a substitution reaction one atom or group of atoms replaces another atom. An oxidation reaction typically occurs with the loss of electrons within a chemical reaction. In terms of alkanes, combustion is classed as an oxidation reaction.

(**b**) The reaction is:

This substitution reaction is classed as regiospecific because it occurs preferentially at one carbon, namely the tertiary carbon.

(**c**) The reaction is:

$$C_5H_{12} + 8\,O_2 \longrightarrow 5\,CO_2 + 6\,H_2O$$

24.78 (**a**) Then reaction is $C_6H_{12} + 9\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$. Nine moles of oxygen are required for each mole of cyclohexane. Moles of cyclohexane = 70 g / 84 g mol^{-1} = 0.83 mol Moles of $O_2 = 9 \times 0.83 = 7.5$ mol g $O_2 = 32$ g $mol^{-1} \times 7.5$ mol = 240 g (**b**) Six moles of carbon dioxide are produced for each mole of cyclohexane. Moles of $CO_2 = 6 \times 0.83 = 5.0$ mol g $CO_2 = 44$ g $mol^{-1} \times 5.0$ mol = 220 g

24.79 (**a**) Propagation

$$^{\bullet}Cl + CH_4 \longrightarrow HCl + {}^{\bullet}CH_3$$

$$^{\bullet}CH_3 + Cl_2 \longrightarrow CH_3Cl + Cl^{\bullet}$$

$$CH_3Cl + Cl^{\bullet} \longrightarrow HCl + {}^{\bullet}CH_2Cl$$

$$^{\bullet}CH_2Cl + Cl_2 \longrightarrow CH_2Cl_2 + Cl^{\bullet}$$

(**b**) Termination (for example)

$$^{\bullet}CH_3 + {}^{\bullet}CH_2Cl \longrightarrow CH_3CH_2Cl$$

$$^{\bullet}CH_3 + {}^{\bullet}CH_3 \longrightarrow CH_3CH_3$$

24.81 (**d**) >> (**c**),(**a**) > (**b**) (**d**) would be formed from a tertiary carbon, (**c**) and (**a**) from a secondary carbon, and (**b**) from a primary carbon. **24.84** *Analyse/Plan:* We are asked the number of structural isomers for two specified carbon chain lengths and a certain number of double bonds. Structural isomers have different connectivity. Since the chain length is specified, we can ignore structural isomers created by branching. We are not asked about geometrical isomers, so we can ignore those as well. The resulting question is: How many ways are there to place the specified number of double bonds along the specified C chain?

5 C chain with one double bond: 2 structural isomers

C═C—C—C—C C—C═C—C—C

6 C chain with two double bonds: 6 structural isomers

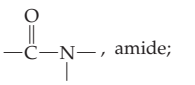
C═C—C═C—C—C C═C—C—C═C—C C═C—C—C—C═C

C—C═C—C═C—C C═C═C—C—C—C C—C═C═C—C—C

24.86 The suffix –ene signifies an alkene, –one a ketone. The molecule has alkene and ketone functional groups.

24.88

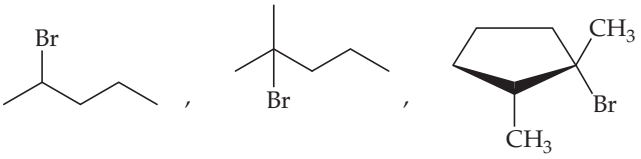
(a)  , aldehyde; , *trans*-alkene; , *cis*-alkene



(b) —O— , ether; —OH , alcohol; C═C , alkene;

 , amine (two of these, one aliphatic and one aromatic);

 , aromatic (phenyl) ring



(c)  , ketone (2 of these);  , amine (2 of these)

 , aromatic (phenyl) ring (2 of these)

(d)  , amide; , aromatic (phenyl) ring;

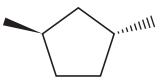
—OH , alcohol (aromatic alcohol, phenol)

24.90 (**a**) Pentane and 2-methylbutane are constitutional isomers. More specifically they are non-superimposable mirror images of each other, which makes them enantiomers. (**b**) The two molecules shown are mirror images of each other. (**c**) 1,2-dimethylcyclopentane (**d**) The most likely point(s) for bromination will be the places where the most stable radicals are found. Thus we would expect bromination to occur most readily at a tertiary carbon if available, then secondary, and then primary. This leads to then following most likely products from bromination of pentane, 2-methylbutane, and 1,2-dimethylcyclopentane:

24.92 Determine the empirical formula, molar mass, and thus molecular formula of the compound. Confirm with physical data:

$$85.7\ \text{g C} \times \frac{1\ \text{mol}}{12.01\ \text{g}} = 7.136\ \text{mol C};\ 7.136/7.136 = 1$$

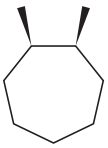
$$14.2\ \text{g H} \times \frac{1\ \text{mol}}{1.008\ \text{g}} = 14.19\ \text{mol H};\ 14.19/7.136 = 2$$



The empirical formula is CH_2. Use the relationship between molecular mass and the gas constant:

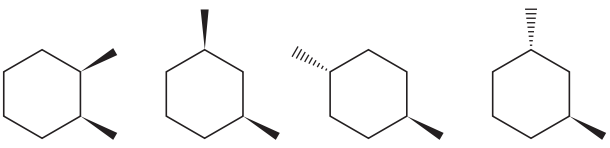
$$\frac{(2.21\ \text{g dm}^{-3})\ (0.08206\ \text{dm}^3\ \text{torr mol}^{-1}\ \text{K})\ (373\ \text{K})}{(735/760)\ \text{torr}} = 69.9\ \text{g mol}^{-1}$$

The molecular formula is this C_5H_{10}. The absence of reaction with bromine indicates the compound is not an alkene, so the compound is most likely a cycloalkane, likely cyclopentane. Physical properties such as the boiling point of cyclopentane (49° at 1 bar) can be used to confirm this deduction.



Chapter 25

25.4



trans-1,3-dimethylcyclopentane

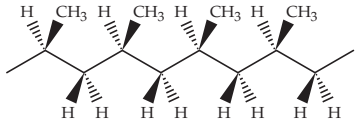
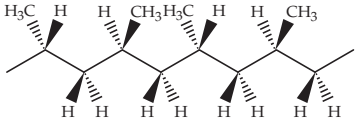
(a)

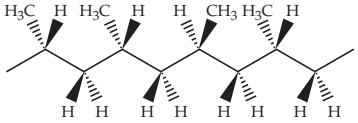


(b)



26.39 Most of a polymer backbone is composed of σ bonds. The geometry around individual atoms is tetrahedral with bond angles of 109°, so the polymer is not flat, and there is relatively free rotation around the σ-bonds. The flexibility of the molecular chains causes flexibility of the bulk material. Flexibility is enhanced by molecular features that inhibit order, such as branching, and diminished by features that encourage order, such as cross-linking or delocalised π-electron density. Cross-linking is the formation of chemical bonds between polymer chains. It reduces flexibility of the molecular chains and increases the hardness of the material. Cross-linked polymers are less chemically reactive because of the links. **26.40** (**a**) The orbitals at each carbon atom are sp^3 hybridised. The angles between the bonds are expected to be 109.5°.

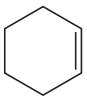
(**b**)



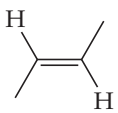
(i)

(ii)

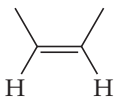
(iii)



The isotactic polymer is the most crystalline and has the highest melting point (approx 175°C), as the regular arrangement of the methyl groups on the same side of the chain allows for closer packing of polymer chains. Because of the high degree of order, Van der Waals interactions also contribute to the high crystalline nature of the isotactic polymer. The syndiotactic polymer also exhibits crystallinity with a melting temperature of approximately 145°C. Due to the random arrangement of the methyl groups along the polymer chain the atactic polymer has the lowest melting point and is amorphous. (**c**) Cotton has many –OH groups along the molecular chain and as such can form hydrogen bonds with water. Polypropylene is a polymer containing only carbon and hydrogen. As such polypropylene is non-polar and does not interact with water. Hence, cotton materials absorb water while polypropylene materials repel water. **26.42** As the percentage of sulfur increases, the rubber becomes harder and less flexible. **26.43** (**c**) and (**d**) **26.45** Molecule (**c**)

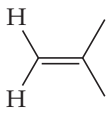


26.47

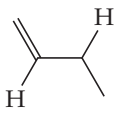


26.48 A cycloalkene is a cyclic hydrocarbon containing at least one double bond. For each double bond or ring the number of hydrogens required decreases by 2. Hence the general formula for a cycloalkene would be given by: C_nH_{2n-2}. This is the same general formula as an alkyne. Use an example to help understand what is happening:

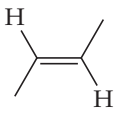
The structure above has molecular formula: C_6H_{10}. This follows the general formula: C_nH_{2n-2} **26.50** (**a**) *trans*-hex-2-ene or (*E*)-hex-2-ene (**b**) *trans*-1-chloro-2-fluorocyclohexane (**c**) *cis*-pent-2-ene or (*Z*)-2-pentene **26.51** (**a**) Geometric (*cis/trans*) isomers: Same atoms involved in bonding, but different non-interchangeable orientations in space.



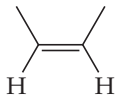
trans-but-2-ene



cis-2-butene



Structural (constitutional) isomers: Same molecular formula, but different bonding between atoms.



2-methylprop-1-ene

but-1-ene

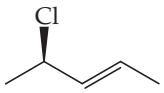
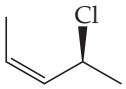
(*Z*)-but-2-ene



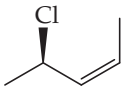
cyclobutane

(**b**) 4-chloropent-2-ene



(*S,E*)-4-chloropent-2-ene

1

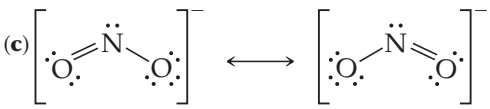


(*R,E*)-4-chloropent-2-ene

2

(*S,Z*)-4-chloropent-2-ene

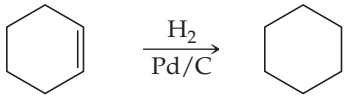
3



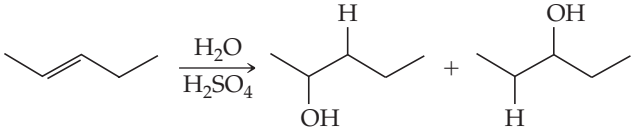
(*R,Z*)-4-chloropent-2-ene

4

The pairs 1 & 3 and 2 & 4 are geometric (*cis/trans*) isomers. The pairs 1 & 2 and 3 & 4 are enantiomers. The four isomers arise because the position of the double bond allows for *cis/trans* isomerism and the presence of a stereocentre at C4 gives R,S stereoisomerism. **26.54** (**a**) In a localised π bond, the electron density is concentrated strictly between the two atoms forming the bond. In a delocalised π bond, parallel *p* orbitals on more than two adjacent atoms overlap and the electron density is spread over all the atoms that contribute *p* orbitals to the network. There are still two regions of overlap, above and below the σ framework of the molecule. (b) The existence of more than one resonance form is a good indication that a molecule will have delocalised π bonding.

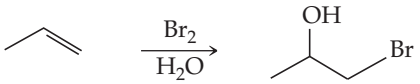


(**c**)

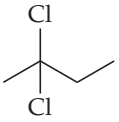


The existence of more than one resonance form for NO_2 indicates that the π bond is delocalised. From an orbital perspective, the electron-domain geometry around N is trigonal planar, so the hybridisation at N is sp^2. This leaves a *p* orbital on N and one on each O atom perpendicular to the trigonal plane of the molecule, in the correct orientation for delocalised π overlap. Physically, the two N–O bond lengths are equal, indicating that the two N–O bonds are equivalent, rather than one longer single bond and one shorter double bond.

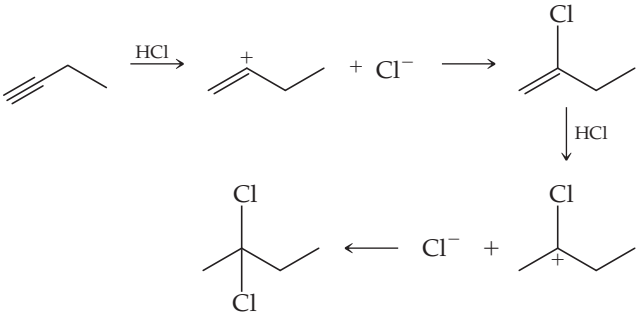
26.55



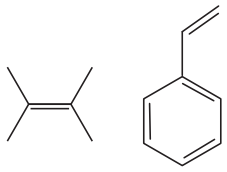
(a)



(b)



(c)



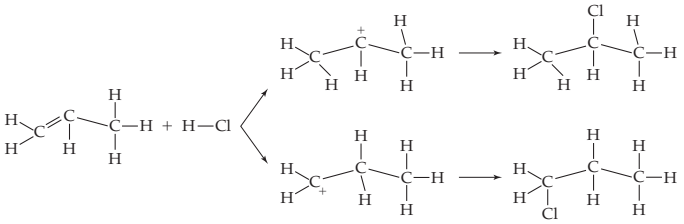
26.58 (**a**)

(**b**) One could imagine a sequence of steps as follows:

At each step, the introduction of the chlorine substituent is determined by addition of H^+ to form the most stable carbocation. **26.60** (**a**) H_2, Pd/C (**b**) Concentrated H_2SO_4/H_2O (**c**) H_2 (1 mol equivalent), Pd/C will allow formation of the alkene, but further reaction to the alkane is inevitable. A better method employs the use of a deactivated catalyst such as Lindlar's catalyst (Pd/C poisoned with $Pb(OAc)_2$ and quinoline) which allows for hydrogenation of the more reactive alkyne to the alkene, but does not allow further reduction of the alkene to the alkyne. (**d**) Excess Br_2 (**e**) Br_2 in methanol (CH_3OH) **26.63** Monomers are molecules of low molecular weight that are used as a repeating unit to construct a polymer. Some examples are:

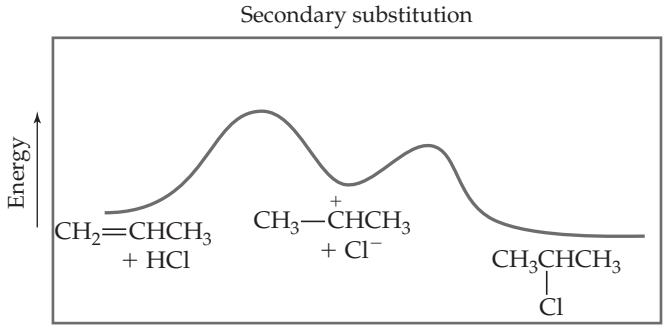
$F_2C{=}CF_2$

Ethylene Styrene tetrafluoroethylene

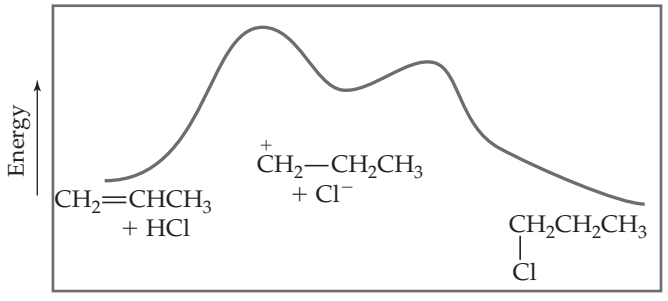


26.66 The function of the material (polymer) determines whether high molecular mass and high degree of crystallinity are desirable properties. If the material will be formed into containers or pipes, the rigidity and structural strength associated with high molecular mass are required. If the polymer will be used as a flexible wrapping or as a garment material, rigidity is an undesirable property. The viscosity of a polymer depends on its molecular weight, so it might be undesirable to have high molecular weight in a polymer adhesive solution that needs to be squeezed out of a tube, for example. **26.67** (**a**) sp^2 (**b**) The π-bond will be destroyed half way through the rotation because the two p orbitals that create it will no longer line up. (**c**) It can be assumed that the strength of the single π-bond would be the enthalpy of a carbon-carbon double bond (614 kJ mol^{-1}) minus the enthalpy of a carbon-carbon single bond (348 kJ mol^{-1}). 614 – 348 = 266 kJ mol^{-1} Since this is per mole, we would divide this value by Avogadro's number resulting in 4.419×10^{-22} kJ per bond.
(**d**)

$$\lambda = hc/E = 6.626 \times 10^{-34}\,\text{J s} \times 2.998 \times 10^{8}\,\text{m s}^{-1} \times \frac{1}{4.419 \times 10^{-19}\,\text{J}}$$



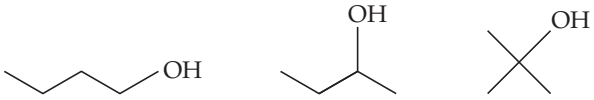
$$= 4.50 \times 10^{-7}\,\text{m} = 450\,\text{nm}$$



(**e**) 450 nm metres is in the visible spectrum. This is important as the visible spectrum is the portion of the electromagnetic spectrum that reacts with the rods and cones of the eye.

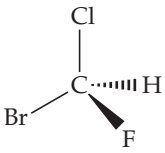
26.69 (**a**)

(**b**)



The carbocation in the secondary substitution is more stable. (**c**) If the temperature were increased, this would leave more stability to the primary carbocation, resulting in a higher proportion to the primary halogenated propane than at the previous temperature **26.71** (**a**) 3 $C_2H_2 \rightarrow C_6H_6$ (**b**) $\Delta H = \Sigma(\Delta H$ products) – $\Sigma(\Delta H$ reactants) However, since the heat of formation was given for acetylene, then sign of that value must be reversed. Thus we have the following equation: $\Delta H = 83 - 3(-227) = 764$ kJ mol^{-1}

Chapter 27



27.4 The solubility would be lower when the OH group is replaced by an OCH_3 group, because the solute can no longer act as a hydrogen-bonding donor to the water.

27.8

27.14 Ethanol is able to form intermolecular hydrogen bonds, while dimethyl ether is unable to form hydrogen bonds and therefore has the lower boiling point. CH_2F_2 has an overall net dipole, which allows for intermolecular dipole-dipole interactions, while CF_4 has no net dipole because its bond dipoles cancel, so the only intermolecular interactions are weak dispersion forces, giving it a much lower boiling point than CH_2F_2.

27.16

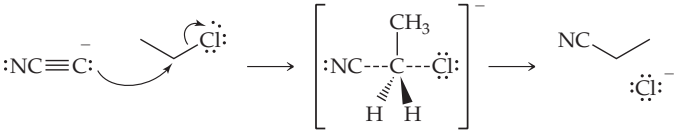
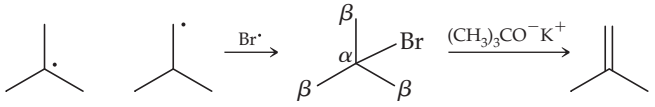
(e)



27.29

1-methoxy-2,2-dimethylcyclopentane

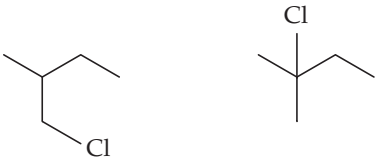
27.30



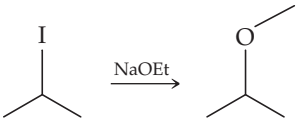
27.31 When OH^- acts as a base it is in a proton transfer reaction:
e.g. $CH_3COOH + OH^- \rightarrow CH_3COO^- + H_2O$
When OH^- acts as a nucleophile it is in, for example, a substitution reaction:
$CH_3I + OH^- \rightarrow CH_3OH + I$

27.32 $CH_3OH + HBr \rightarrow CH_3Br + H_2O$ and $CH_3OH + Na \rightarrow CH_3O^- + Na^+$ Combining the two products: $CH_3Br + CH_3O^- \rightarrow CH_3OCH_3 + Br^-$

27.34 2-Bromo-2-methylpentane **27.35** Either 2-chlorodecane or 3-chlorodecane could be used; however, 3-chlorodecane would form approximately equal amounts of dec-2-ene and dec-3-ene, while 2-chlorodecane would form predominately dec-2-ene. **27.36** This is a difficult one! The norbornane ring system is heavily strained as a result of the bridging CH_2 group. Having a double bond at the base of the bridge as shown below (Zaitsev product = most substituted double bond) would increase the strain even further. The geometry at the carbon found at the base of the bridge could not be trigonal planar.

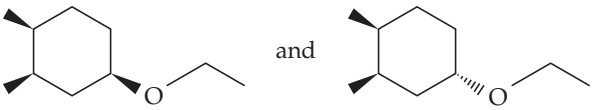


27.37 In the first step the free-radical bromination of 2-methyl propane will preferentially add the Br to the most substituted carbon (regioselective) as this comes from the most stable carbon radical (3° versus 1°).



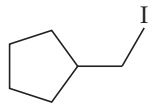
more stable radical only product

27.41

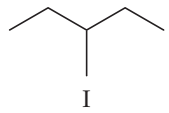


A **B**

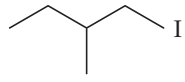
Compound B gives the slowest S_N2 reaction. The tertiary carbon bearing the chloride is less accessible to the incoming nucleophile than the primary carbon in compound A. **27.42** (**a**) Methoxide is the stronger nucleophile because nucleophilicity is related to the rate of addition. In the gas phase, t-butoxide is a stronger base, but because it is highly sterically hindered it reacts more slowly and is not as good a nucleophile. (**b**)



27.43 (**a**) The products will be a racemic mixture of

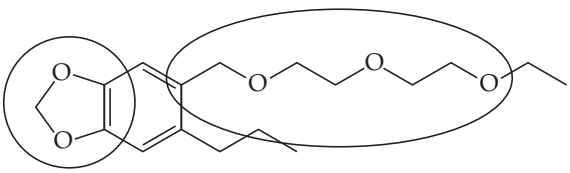


(**b**) The reaction most likely follows a S_N1 mechanism, because the reactants are a secondary haloalkane and a weak nucleophile. **27.45** The best substrate for the E2 reaction will be where the halogen is a good leaving group and where the adjacent carbon is easily accessible for deprotonation by the nucleophile. Iodide is a better leaving group than bromide which is a better leaving group than chloride, and the 2-haloalkanes provide the most accessibility at the adjacent carbons. Thus: (**a**) B is the most reactive in an E2 reaction. (**b**) D is the least reactive in an E2 reaction. **27.46** Iodine is shown in the results below, but Br or Cl would also give valid haloalkanes.

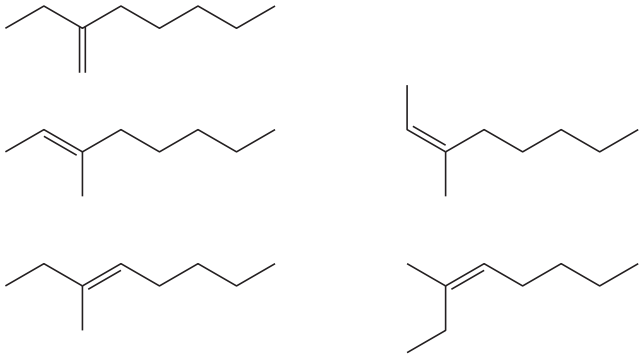


(i)

(ii)



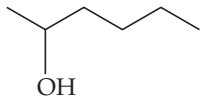
(iii)



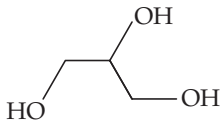
27.47 Less hindered hydrogen bonding interactions and maximisation of London dispersion forces in propan-1-ol lead to a higher boiling point.

27.49

cyclic ether acyclic polyether



27.51 There are five possible alkene products.



27.52 One oxygen-containing compound could be an alcohol that could participate in hydrogen bonding and so would have a higher boiling point than the corresponding ether, which is unable to participate in hydrogen bonding.

27.53

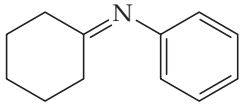
cyclohexene
Conditions: $O_3/(CH_3)_2S$



28.35 To act as a non-ionic detergent the molecule needs to contain both polar (e.g. OH) and non-polar (e.g. C_8H_{15}) groups. *n*-Octoglucoside has the properties of a surfactant; the long alkyl chain (non-polar) can bind hydrophobic portions of the protein whilst the glucoside group (polar) will facilitate water solubility of the protein-*n*-octoglucoside complex.

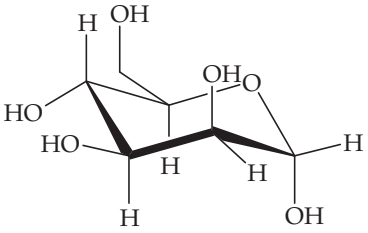
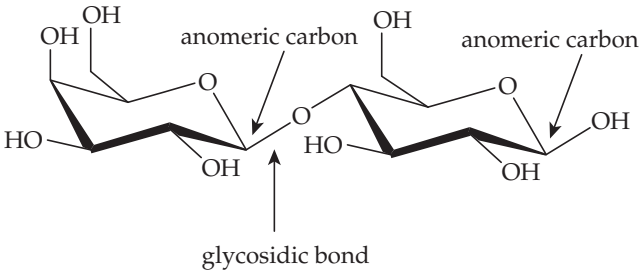
(**d**)

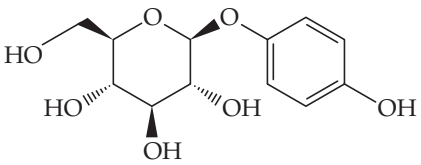


28.50



28.52 (**a**) four

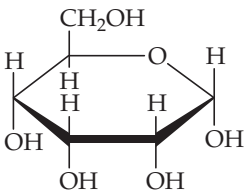
(**b**)



28.53 (**a**) Starch: glucose units are all in α-form, can exist in both branched and unbranched forms. Glycogen: similar to starch with greater branching. Cellulose: glucose units are in the β-form. (**b**) The α-1,4-glycosidic linkages in starch cause it to form a left handed helix. This formation is conducive to the formation of H-bonds with water, increasing its water solubility. The β-linkages found in cellulose promote the formation of intramolecular H-bonds. Cellulose polymers tend to form large aggregates which are insoluble in water. **28.54** (**a**) Disaccharide and a glycoside.

(**b**)

(**c**) 1,4-linkage



28.55

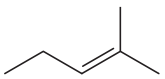
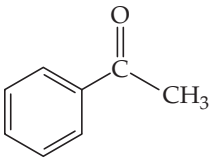
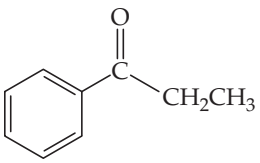
(**b**)

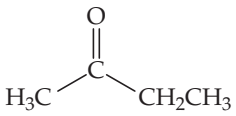


(**c**)



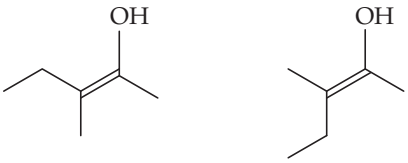
(**d**)





28.57

28.58

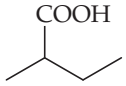


28.60 (**a**) There are two stereoisomers. Their configurations will be RR, SS, RS, and SR. Any confirmations that produce mirror images will be enantiomers and non-mirror images will be diastereoisomers. (**b**) $C_6H_{14}O + H_2Cr_2O_7 \rightarrow C_6H_{12}O_2$. The reaction converts the alcohol into a ketone. (**c**) The reaction destroys one of the stereocentres and thus the product only has two stereoisomers.

(**d**)

(**e**) The ketone products destroy one of the chiral centres. In addition the ketones are in equilibrium with their achiral enol forms. When the ketone reforms, a proton can be added to the chiral centre from either side leading to a more racemic mixture. Optical rotation will therefore eventually be reduced to zero. **28.62** To determine which molecule would release the most energy per gram, divide the energy released per mole by the molecular weight.

$-2803/180.16 = 15.56$ kJ g^{-1} glucose



$-5640/342.30 = 16.48$ kJ g^{-1} sucrose

Chapter 29

29.3 (**a**) methanoic acid (**b**) butanoic acid (**c**) 3-methylpentanoic acid. **29.5** (**a**) The presence of both OH and C=O groups in pure acetic acid leads us to expect that it will be a strongly hydrogen-bonded substance. (**b**) That the melting and boiling points of pure acetic acid (m.p. 16, 6 °C; b.p. 117.9 °C) are both higher than those of water, a substance we know to be strongly hydrogen-bonded, supports this conclusion. **29.6** The carboxylic acid will react with the bicarbonate solution, resulting in the evolution of CO_2 (bubbles). The ester will not. **29.7** Acid A is most acidic. The trifluoromethane group is inductive, making the O–H bond weaker and compound A more acidic than compound B. Although the benzene ring has a stabilising effect on the conjugate base of Acid C, it is not as great as the inductive effect of the fluorines in Acid A.

Conditions: $K_2Cr_2O_7/H_2SO_4$

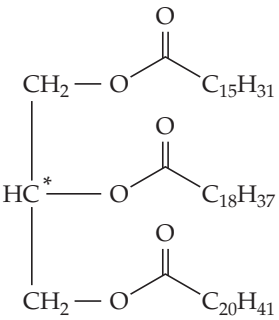
29.40 Arachidic acid would form better micelles and hence be a better soap because molecules of arachidic acid can pack more tightly and interact more strongly due to their regular shape. **29.45** The general Lewis structures for these acids and their conjugate bases are shown below.

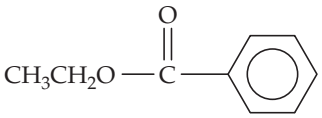
where X = H or Cl Replacement of H on the acid by the more electronegative chlorine atoms causes the central carbon to become more positively charged, thus withdrawing more electrons from the attached COOH group, in turn causing the O–H bond to be more polar, so that H^+ is more readily ionised. For the conjugate base (two resonance structures), the electronegative X atoms delocalise negative charge and stabilise these forms relative to the unsubstituted anions. This favours products in the ionisation equilibrium and increases the value of K_a. To calculate pH proceed as usual, except that the full quadratic formula



$$\frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

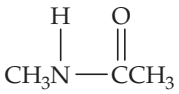
must be used for all but acetic acid. ($[H^+]$ =, where a = 1, b = K_a and c = $-0.01 \times K_a$.)

Acid	pH
acetic	3.37
chloroacetic	2.51
dichloroacetic	2.09
trichloroacetic	2.0



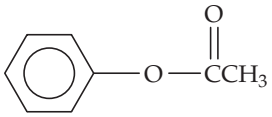
29.47 (**a**) Oxidation with chromic acid (CrO_3/H_2SO_4) (**b**) Oxidation with chromic acid (CrO_3/H_2SO_4) (**c**) Saponification with KOH followed by acidic workup (**d**) Addition of water

29.52 The chiral centre is marked with an asterisk.



29.55

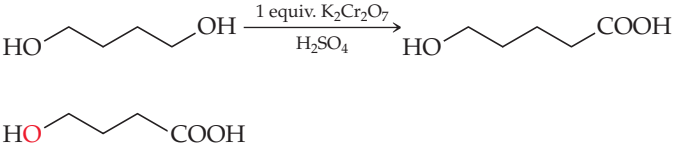
(a)



ethyl benzoate

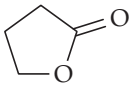
(b)

N-methylethanamide or *N*-methylacetamide



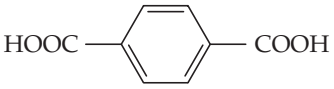
(c)

phenyl acetate



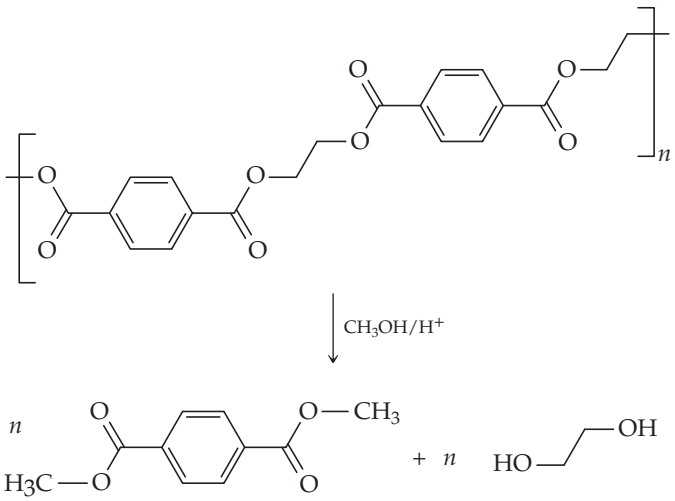
29.56 (**a**)

(a)

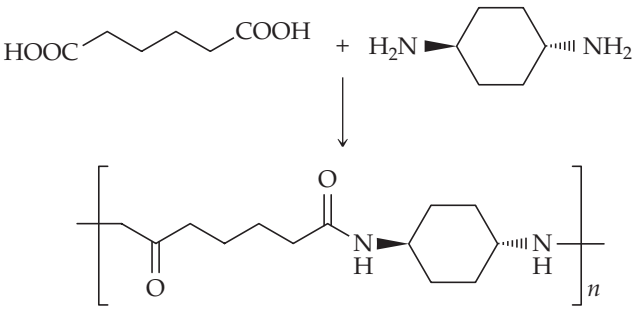


The compromise with this synthesis is that there will be some dicarboxylic butanoic acid formed as a by-product. This could be minimised by adding the oxidising agent slowly to a stirred solution of the 1,4-butanediol so as to keep the alcohol in excess.

(b)

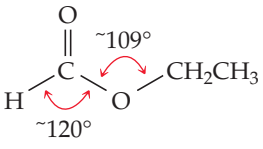


29.58



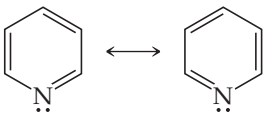
29.60 Failure to start with 1:1 stoichiometry of functional groups in condensation polymerisation so will lead to incomplete condensation between monomers and smaller polymeric (oligomeric) species.

29.62

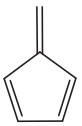


29.63 (**a**)

(**b**) The shape of the polymer would be quite different and it would have different mechanical and thermal properties. It might be expected that the cis-1,4-cyclohexanediamine would be more likely to introduce 'kinks' in the polymer, similar to cis double bonds in lipid side chains, to make a less rigid product. **29.64** Poly(phenylene ether) is more rigid, due to the phenyl rings. If used in a composite with nylon, it would confer rigidity and ensures that the nylon retained its shape.



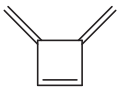
29.66 (**a**) Ethyl methanoate



(**b**) Dispersion forces (**c**) Dispersion forces and dipole-dipole forces are present in esters. They are also present in carboxylic acids and alcohols from which esters are derived. In addition carboxylic acids and alcohols.

Chapter 30

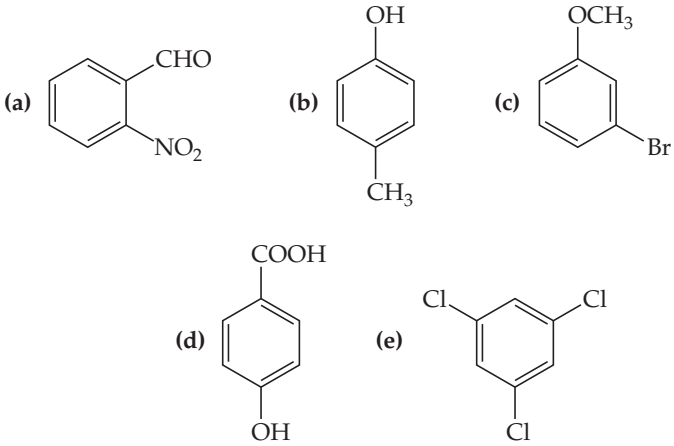
30.2 (**a**) Yes
(**b**)



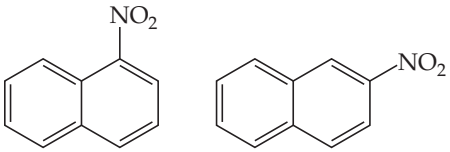
(**c**) The lone pair is in the plane of the ring and pointing away from the centre. It is not involved with the delocalised π-system.
30.4 The empirical formula of benzene is CH. Acetylene, C_2H_2, is the simplest compound with this empirical formula. Some compounds with the same molecular formula as benzene are:

methylenecyclopentadiene

Dewar benzene

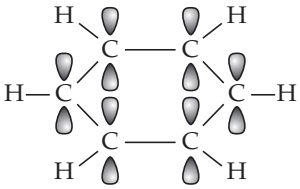


3,4-dimethylenecyclubutene



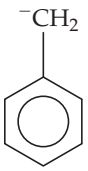
2,4-dimethylenebicyclo[1,1,0]butane

30.6

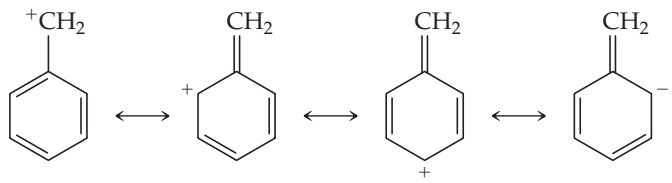


(**a**) 2-nitrobenzaldehyde (**b**) 4-methylphenol (common name: *para*-cresol) (**c**) 3-bromoanisole (**d**) 4-hydroxybenzoic acid (**e**) 1,3,5-trichlorobenzene

30.7

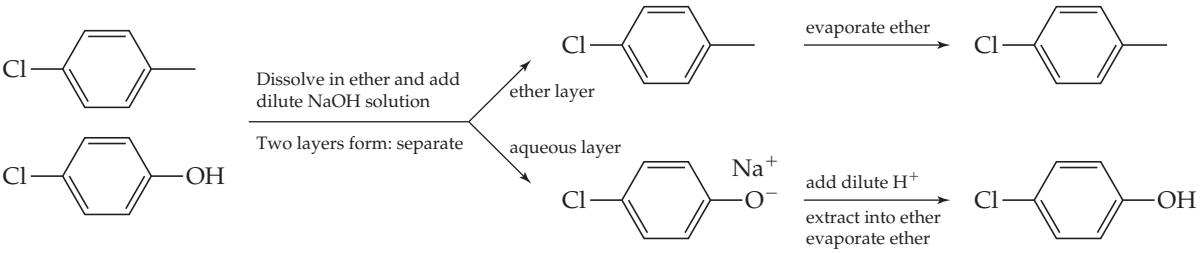


30.10 (**a**) The hydrogenation of benzene is much less energetically favourable than we would predict for a six-membered ring with three double bonds if we extrapolate from the enthalpy change associated with hydrogenation of cyclohexene and 1,4-cyclohexadiene – this suggests that benzene has some extra stability. Cyclohexene and 1,4 cyclodihexene also react readily by an addition mechanism- e.g., by bromination- while it is very difficult to carry out addition reactions on benzene; bromine reacts by substitution, not addition. This also suggests that the double bonds in benzene are unusually stable. (**b**) Aromatic systems have a delocalised p-bonding system in which each *p*-orbital connects to form a 'super π-way'. This is explained in the following diagram:

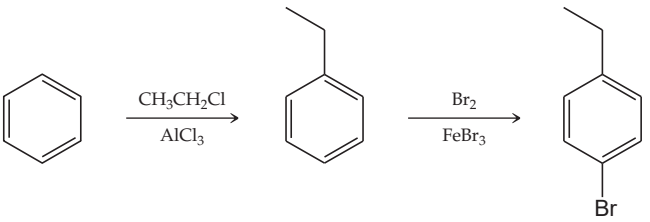


30.12

(a)

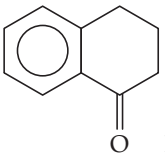


(b)



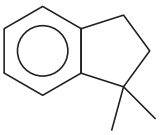
The benzylic cation is stabilized by resonance since the positive charge is delocalized over the benzene ring. This resonance stabilisation is unavailable to the methylcyclohexane primary carbocation. **30.14** (**a**) $4n+2$ (**b**) The compound has 8 π-electrons and would not be planar, so it does not fit the criteria stated in the solution to Problem 30.24. It is not aromatic. **30.16** An alkoxide will be a stronger base than a phenoxide as the anion of an alkoxide is not stabilized, unlike that of a phenoxide. **30.17** The chloro group acts as an electron withdrawing group, increasing the acidity of the phenol. This inductive effect is greatest if the interacting groups are close together and decreases as the number of bonds separating the groups increases.

30.18



30.22

30.24 (**a**) $CH_3Cl/AlCl_3$ (**b**) $(CH_3)_2CHCl/AlCl_3$ (**c**) $Cl_2/FeCl_3$ (**d**) $CH_3COCl/AlCl_3$.



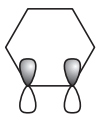
30.26

(a)

Friedel-Crafts acylation

(b)

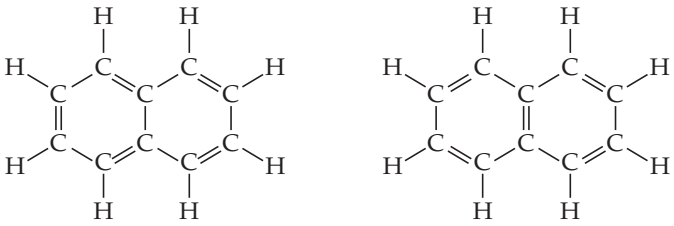
Friedel-Crafts alkylation



30.27 All of the functional groups activate the benzene ring towards electrophilic aromatic substitution. Therefore, benzene alone, (**e**), with no functional groups, will be the most deactivating. Of the rest, the ethyl group is the weakest activating group. The other three groups (methoxy, phenol and acetamide) all have the ability to stabilise the intermediate carbocation through resonance.

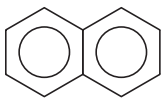
30.28

(a)



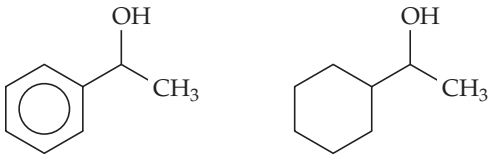
(b)

30.30 Compound (ii) is most likely to exhibit liquid crystalline behaviour as it has a long-chain alkane component greater than 5 carbons long linked to an aromatic ring. **30.32** (**a**) Not aromatic. Compound has 8 π-electrons therefore it does not satisfy the $[4n+2]$ rule and is not planar. (**b**) Aromatic. Compound is planar and satisfies the $[4n+2]$ rule ($n=3$). All atoms in ring have an unhybridised p orbital. (**c**) Not aromatic. Compound has 8π electrons therefore does not satisfy the $[4n+2]$ rule. Looks conjugated, but this compound is not planar. (**d**) Not aromatic. Compound satisfies the $[4n+2]$ rule but is not planar. One of the carbons in the ring does not have an unhybridised p orbital so therefore the molecule is not conjugated. **30.34** The change in visual appearance of the phase, from milky to clear, upon repeated heating and cooling. **30.36** The hydrogens of benzene are more acidic than those of cyclohexane because the resulting anion from benzene (the conjugate base) is stabilised by resonance.



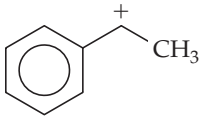
30.37

(a)

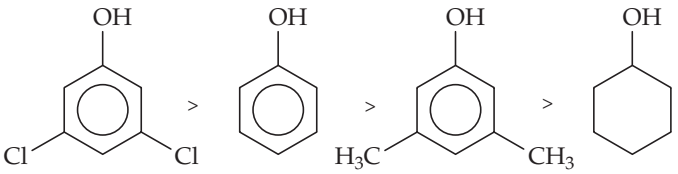


(**b**) This is because of the influence of the two canonical structures. Each C–C bond is neither a single nor a double bond, but is best represented as something in between; for example, as a '1.5' bond.

(c)



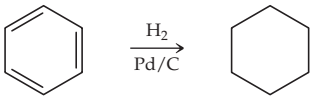
30.40



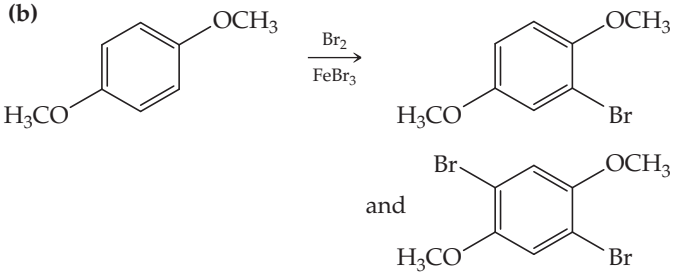
A **B**

Compound A undergoes dehydration more rapidly than compound B because the resulting intermediate carbocation, shown below, is stabilised by resonance.

30.42 Acidity depends on the stability of the conjugate base: i.e. HA $\rightleftharpoons A^- + H^+$ The more stable the conjugate base ($A^- = RO^-$ or ArO^- in this case) the more the equilibrium will be shifted to the right hand side and the greater will be the availability of the proton. So all we have to do is arrange the compounds in decreasing order of stability of RO^- or ArO^-. The compound on the left below (3,5-dichlorophenol) would form the most stable conjugate base because the chlorine atoms are electron withdrawing and would stabilise the anion. 3,5-Dimethylphenol

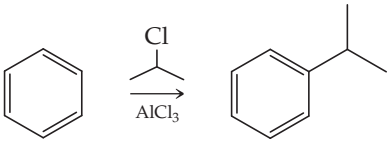


would form a less-stable conjugate base than phenol itself because the methyl groups are electron donating and would destabilise the anion. The compound on the right (cyclohexanol) would form the least stable conjugate base because it does not have an aromatic ring to help delocalise the negative charge.

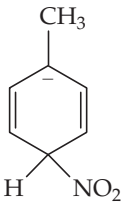


30.44 (**a**) The periphery of the BHT molecule is mostly non-polar groups, such as -CH_3. The one –OH group is rather buried inside and probably does little to enhance solubility in water. Thus, BHT is more likely to be soluble in the non-polar hydrocarbon hexane, C_6H_{14}, than in polar water. (**b**) BHT could be produced by reacting 4-methylphenol with $(CH_3)_3CCl/AlCl_3$.

30.45

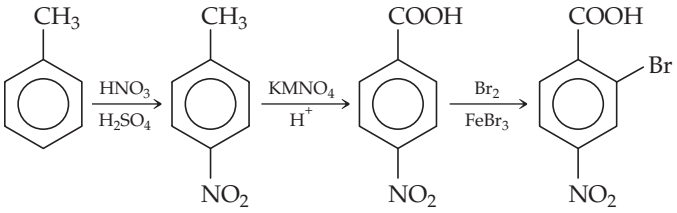


(a)

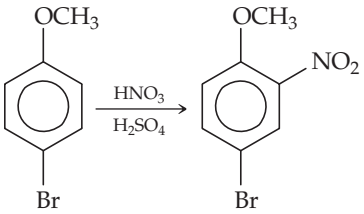


(b)

(c)



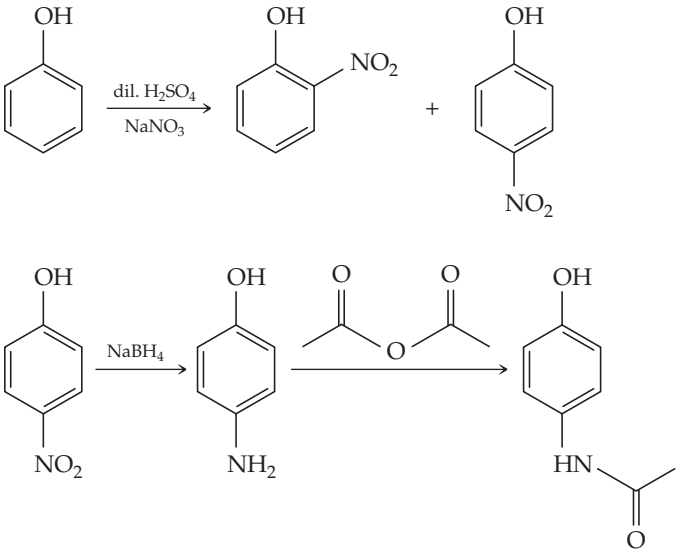
30.49



This is the only tertiary carbocation resonance structure, so should be most stable. **30.51** (**a**) A chloro substituent weakly deactivates the aromatic ring and directs the electrophile towards the *ortho* and *para* positions. (**b**) A nitro substituent strongly deactivates the aromatic ring and directs the electrophile towards the *meta* position. **30.53** The nitro group acts as a strong deactivator in nitrobenzene and makes it unreactive towards electrophilic aromatic substitution to such an extent that it can be used as a solvent for a Friedel-Crafts alkylation of a more reactive aromatic compound.

30.56

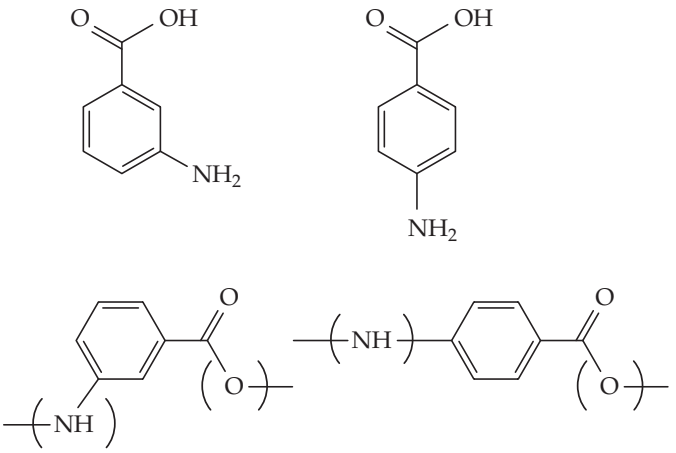
(In the last step, while both COOH and NO_2 are meta directing, the nitrogen group is a strong deactivator).



30.58

(The methoxy group is a much more strongly *ortho* directing than the bromo group).

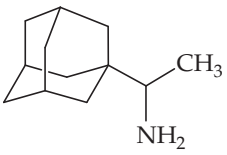
30.60



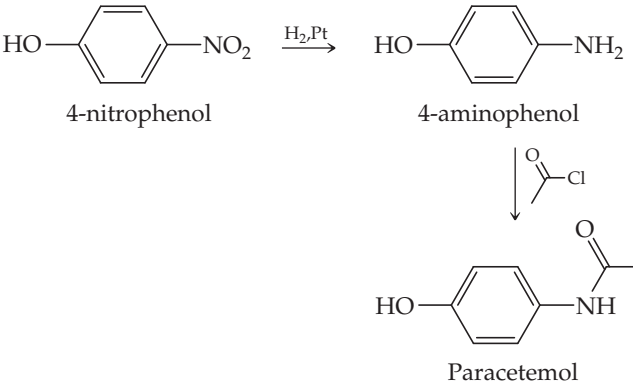
(a)

(**b**) The name 'paracetamol' suggests that the structure will be a benzene ring with two functional groups in the *para*-positions. **30.62** (1) Combustion of decahydronaphthalene: $C_{10}H_{18} + 14.5O_2 \rightarrow 10CO_2 + 9H_2O$, −6286 kJ mol^{-1} (2) Combustion of naphthalene: $C_{10}H_8 + 12\ O_2 \rightarrow 10CO_2 + 4H_2O$, -5157 kJ mol^{-1} (3) Formation of water: $H_2 + ½\ O_2 \rightarrow H_2O$ (l), −285.83 kJ mol^{-1} (4) Using Hess's Law, reaction (1) + (2): $C_{10}H_8 + 5H_2O \rightarrow C_{10}H_{18} + 2.5O_2$, +1129 kJ mol^{-1} (5) And again, reaction (3) × 5 + (4): $C_{10}H_8 + 5H_2 \rightarrow C_{10}H_{18\ 2}$, +1129 −1429.15 kJ mol^{-1} Heat of hydrogenation = −300 kJ mol^{-1} Yes, the value obtained for the heat of hydrogenation of naphthalene does provide evidence for aromatic character. The heat of hydrogenation of a double bond is roughly −116 kJ mol^{-1}. If naphthalene was treated as possessing 5 isolated double bonds, then we would expect it to have a heat of hydrogenation of approximately 5 × −116 kJ mol^{-1} = −580 kJ mol^{-1}. The difference between the 'expected' heat of hydrogenation (–580 kJ mol^{-1}) and the observed heat of hydrogenation (–300.15 kJ mol^{-1})

is due to stabilisation of the π-electrons through delocalisation. The difference of 280 kJ mol^{-1} is known as the 'resonance energy'. **30.64** The order for the synthesis of 4-aminobenzoic acid is as follows. The order for the synthesis of 3-aminobenzoic acid is as follows. 1. Oxidisation of the aromatic alkyl group with acidified potassium permanganate; 2.Nitration using concentrated nitric acid and concentrated sulfuric acid; 3. Reduction of a nitro group using hydrogen gas and palladium catalyst. (**a**) Structural isomers

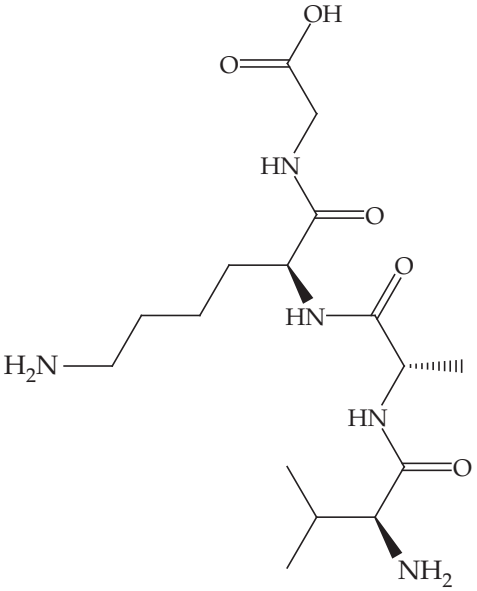


(b)



(**c**) 1. Nitration using concentrated nitric acid and concentrated sulfuric acid 2. Oxidisation of the aromatic alkyl group with acidified potassium permanganate 3. Reduction of a nitro group using hydrogen gas and palladium catalyst. **30.66** (**a**) Ketones, benzene ring, amines and alkene groups. (**b**) All carbon in indigo is sp^2 hybridised. (**c**) The reason indigo is planar is because it is only comprised of sp^2 hybridised orbital which have a trigonal planar shape. (**d**) 613 nm, which is orange light, corresponds to 3.24×10^{-19} J.

Chapter 31



31.9

31.11

31.14 α-alanine and β-alanine both share the same molecular formula and have the same functional groups. They are structural isomers (also known as constitutional isomers). **31.16** (**a**) Both amino and carboxyl groups in acidic form. (**b**) Carboxyl group in basic form, amino group in acidic form. (**c**) pI = 3.22 (Halfway between the first two pK_a values). **31.19** A has an overall neutral charge. B is negatively charged. C is positively charged. The 2nd electrophoresis result (from the left) is expected. **31.26** Glu-Cys-Gly

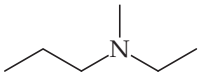
(d)

2-methylcyclohexylamine

(e)

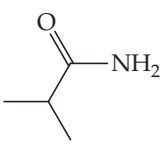
2-methyl-3-ethylpyrrole

31.47 (**a**)



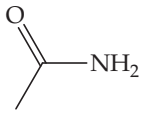
Primary amine:

Secondary amine:



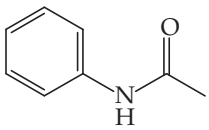
Tertiary amine:

All three amines are constitutional isomers. (**b**) The boiling point of an amine will depend on the strength of intermolecular interactions, *i.e.*, H-bonding, dipole-dipole and Van der Waals dispersion forces. For primary, secondary and tertiary amines with the same molecular formula: tertiary amines do not have a hydrogen attached to the nitrogen atom hence tertiary amines are not able to form H-bonds with each other. Their boiling point is normally much lower than secondary and primary amines. The primary amine has two hydrogen bond donor atoms and one hydrogen bond acceptor atom, while the secondary amine has one atom that can act as a hydrogen bond donor and one that can act as an acceptor. The primary amine will form the strongest intermolecular bonds and hence have a higher boiling point. (**c**) Both propylamine and triethylamine can form H-bonds with water. Propylamine can act as both a hydrogen bond donor and acceptor, while triethylamine can only act as a hydrogen bond acceptor through the lone pair on nitrogen. Triethylamine is therefore slightly less soluble than propylamine. Isobutane cannot form H-bonds and is far less soluble in water. **31.48** For a cyclic structure to be classed as aromatic it must have an odd number of pairs of π electrons. The lone pair on N has a low K_b indicating that these electrons form part of the aromatic π-system. The nitrogen will only be weakly basic - the lone pair is not concentrated on N, decreasing its ability to accept protons. Indole can be considered aromatic only if N contributes a lone pair to the delocalised π system.



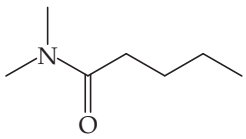
31.50

(a)



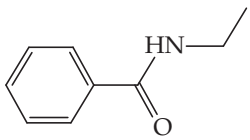
2-methylpropanamide

(b)



acetamide

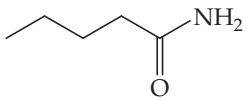
(c)



N-phenylacetamide

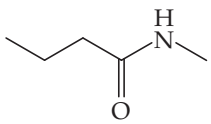
(d)

N,N-dimethylpentanamide



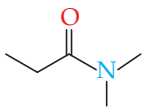
(e)

N-ethylbenzamide



31.51

Primary amide:

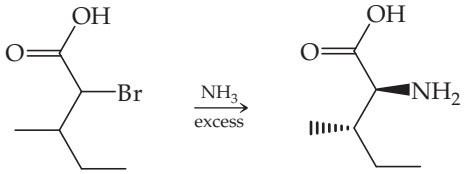


Chemical Formula: $C_5H_{11}NO$

Secondary amide:

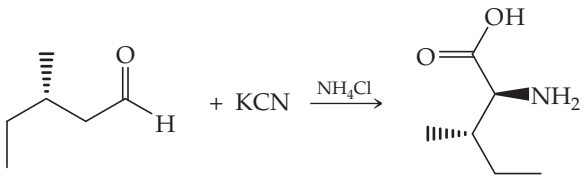
Chemical Formula: $C_5H_{11}NO$

Tertiary amide:



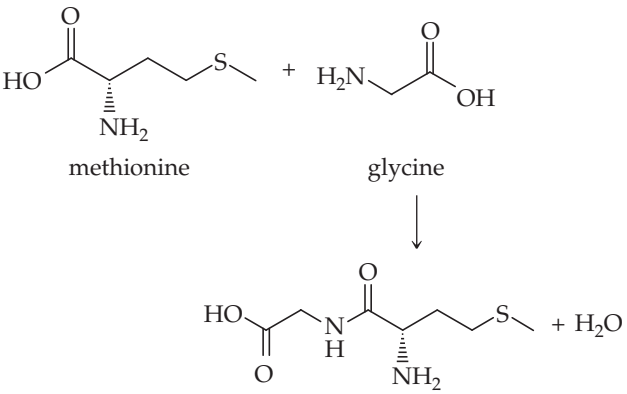
All three molecules are constitutional isomers. **31.54** The charge, basicity, acidity, shape, specific functionality and hydrophobic/hydrophilic character of the amino acid side chain can have a profound affect on the structure and function of proteins in which they are incorporated. For example, aspartic acid and lysine both have side chains that can form charged species under biological conditions, so they will tend to be on the exposed parts of proteins. Aspartic acid, as its name suggests, is an acid, while lysine is a base, and hence they will tend to react with different substrates. Proline, as the only cyclic member of the 20 amino acids in the genetic code, introduces a 'kink' in

a protein chain, so cannot be incorporated into most of the ordered motifs (secondary structure) in proteins; and glycine, with the smallest side chain, is required to be every third amino acid along the collagen chain because it is the only one small enough to fit this structure. Only cysteine can give rise to the disulfide bonds which provide covalent links between and within protein chains, making very large structural proteins like keratin possible. Hydrophobic amino acids, like isoleucine, are commonly found in the interior of proteins, far from water. **31.56** pK_a 2-3: carboxyl group pK_a 3-4: side chain pK_a 9-10: amino group (**a**) +0.97 (rounded) (**b**) 0 (**c**) −0.06



31.60

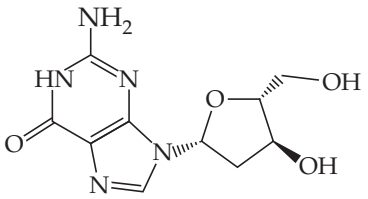
(a)



2-bromo-3-methylpentanoic acid isoleucine

(b)

31.61 (**a**)

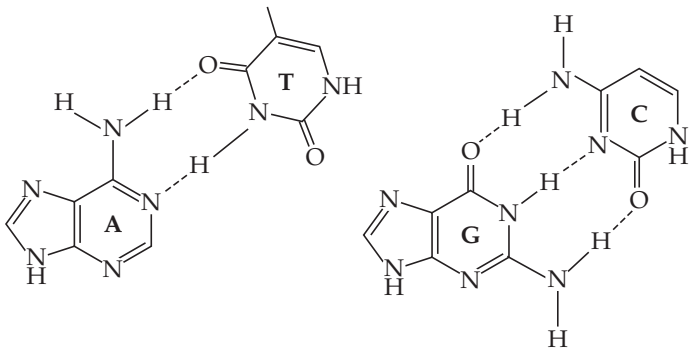


methionine glycine

methionyl glycine

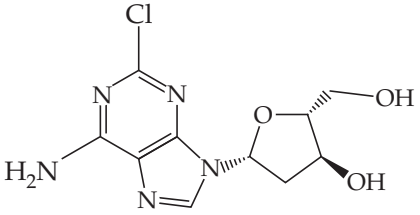
(**b**) 4 **31.62** (**a**) Valine, serine and glutamate. (**b**) 6: Val-Ser-Glu VSE Val-Glu-Ser VES Ser-Val-Glu SVE Ser-Glu-Val SEV Glu-Ser-Val ESV Glu-Val-Ser EVS **31.63** (**a**) H-bonds form between amino acids four residues apart in an α-helix. This stabilises the alpha-helical structure. (**b**) Proline forms a secondary rather than primary amide. It cannot participate in hydrogen bonding therefore destabilises the alpha-helix. Proline is more rigid than other amino acids because of its cyclic nature and cannot adopt the ideal bond angles required for an alpha helix when it is incorporated in a protein. This would also distort the structure of the helix. **31.67** (**a**) The native form of the protein has a lower free energy. (**b**) The entropy change in going from the denatured to the folded form will be negative for the protein. (**c**) The disulfide bridges will decrease the free energy and the entropy of the system. (**d**) The protein is likely to unfold without the disulfide bridges to maintain its structure.

31.68



dexyguanosine

31.71 Use pH = pK_a + log([base]/[acid]) 7.4 = 7.21 + log([base]/[acid]) 0.19 = log([base]/[acid]) [base]/[acid] = $10^{0.19}$ = 1.55 The ratio of AMP-OH$^-$ (acid) to AMP-O^{2-} (conjugate base) will be approximately 2 to 3.

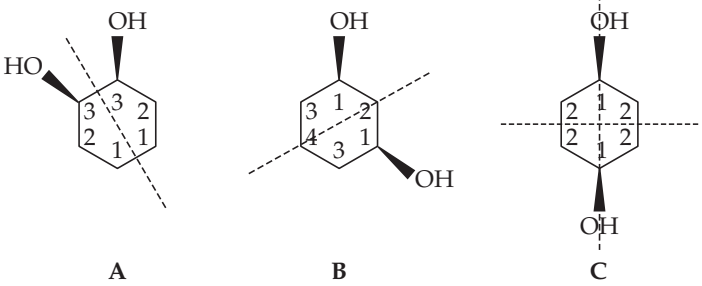


31.72

(a) **(b)**

Guanine does not base pair with thymine because guanine has two hydrogen bond donor groups and one hydrogen bond acceptor group, while thymine has one of each. This imbalance in the number of hydrogen bonds each base can form and their differing sizes means they do not base-pair in DNA.

31.74

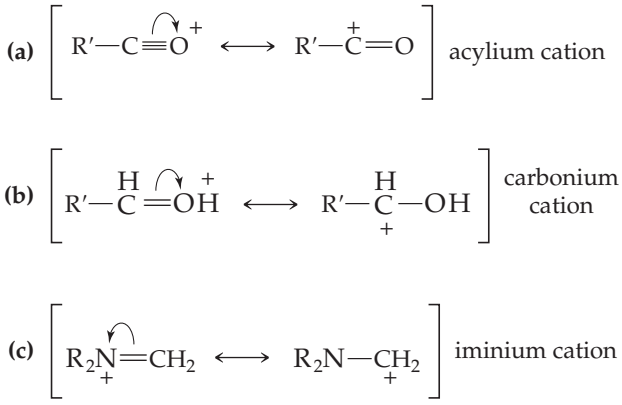


2-chloro-2′-dexyadenosine

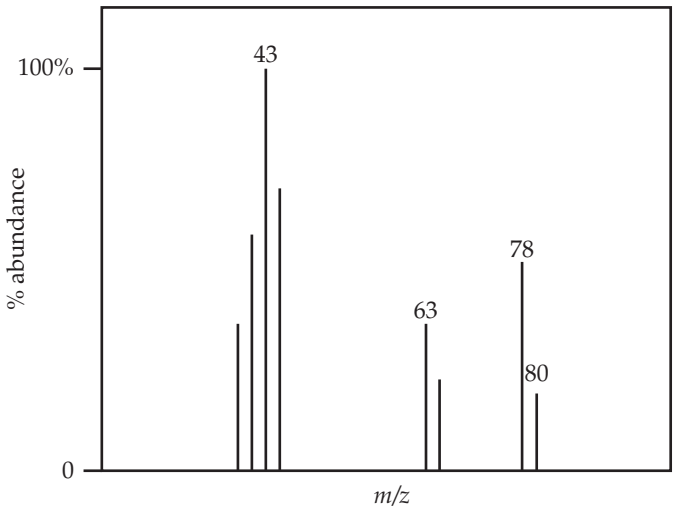
31.75 (**a**) Arg-Thr-Ala-Ser-Gln (**b**) UCC UGA CGU AGC GUU **31.77** (**a**) seven (**b**) *N*-glycoside (**c**) furanose form **31.79** (**a**) Quinine is a basic amine and not very soluble in water. Salts of amines are usually more stable and water soluble than their corresponding amines and therefore easier to administer as medicine. (**b**) With a pK_a of 4.32 quinine hydrochloride counts as weak acid. Therefore, the pH can be calculated as follows: pH = ½ (pK_a – log[c_0]) pH = ½ (4.32 – log 0.053) pH = 2.8

Chapter 32

32.3 (**a**) OH (**b**) C=O (**c**) C=C (**d**) COOH (**e**) primary or secondary amide, $CONH_2$ or CONH **32.5** (**a**) OH stretch present for $CH_3CH_2CH_2CH_2OH$ (**b**) OH stretch present for CH_2=$CHCH_2OH$ (**c**) C=O stretch present for pyridone (**d**) C=C stretch present for CH_3CH=$CHCH_2CH_3$ (**e**) N–H stretch present for $CH_3CH_2NHCH_3$ **32.10** CD_3OD and CCl_4 are suitable solvents for use in ^{1}H NMR spectroscopy as they do not contain any ^{1}H nuclei, which would mask the signal from the analyte.

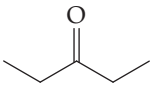


32.12 (**a**) 4 (**b**) 2 (**c**) 2 (**d**) 2 (**e**) 1 (**f**) 4 (**g**) 3 **32.16** Each product below has a different ^{13}C NMR spectrum, and they all have an element of symmetry, which simplifies spectra. Compound C is the most symmetric and has only two different carbons, which means there are two signals in its spectrum. Compound A and B have 3 and 4 signals respectively. *dotted lines indicate lines of symmetry



A **B** **C**

It can therefore be inferred that bottle A contains compound C and bottle B contains compound B.



32.23

32.25

The spectrum for chloropropane has an M^+ peak at 78 and an $[M+2]^+$ peak at 80. The relative abundance of these two peaks is expected to be 3:1 respectively, due to the relative abundance of ^{35}Cl to ^{37}Cl. The fragmentation peaks at 63 and 65 amu corresponds to the mass of a methyl radical (15 amu) from M^+ and $[M+2]^+$. The loss of Cl from the structure results in the base peak at 43 amu. **32.28** The product of the oxidation (using chromic acid) can be a ketone or aldehyde (which can react further to a carboxylic acid). Because there are only 2 signals in the ^1H NMR spectrum, it can be inferred that the molecule is symmetric with only two different 'environments' for the hygrogens. The presence of a triplet and quartet with same coupling indicates a $-CH_2CH_3$ (ethyl) group. The quartet at 2.35 ppm is more downfield than the triplet, which indicates that it is close to an electron withdrawing group – in this case, a carbonyl. The functionality must therefore be a ketone, as aldehydes and carboxylic acids are terminal. The structure of the molecule is shown below, and consists of the ketone and two ethyl groups.

3-pentanone

32.30 Chemical Evidence:

The Lassaigne test is used to detect the presence of nitrogen, sulfur and halogens in organic compounds. From the empirical formula, it is known that there is nitrogen in the compound. In this case the Lassaigne test is positive for nitrogen.

Microanalysis:

	C	H	N
% composition	71.22	14.94	13.84
relative atomic mass	12.01	1.01	14.01
Divide by relative atomic mass	5.89	14.79	0.99
Divide by	0.99	0.99	0.99
Ratio of atoms	5.95	14.94	1
Round to nearest whole number	6	15	1

Empirical formula = $C_6H_{15}N$

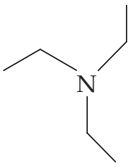
Mass spectrum:

From the mass spectrum the molecular ion peak appears at *m/z* 101. Peak at 86 represents a loss of 15 mass units ($-CH_3$). Mass of empirical formula: $C_6H_{15}N$ = 101 g mol^{-1}. Therefore molecular formula is $C_6H_{15}N$.

IR spectrum:

No signal for N–H, so there must be a tertiary amine present.

^{1}H NMR



There are only two signals in the proton NMR, which indicates some symmetry in the molecule. The presence of a triplet and quartet with same coupling indicates a $-CH_2CH_3$ (ethyl) group. The quartet at 2.5 ppm is more downfield than the triplet, which indicates that it is close to an electron withdrawing group (the nitrogen). In addition to this, there are only 5 hydrogens accounted for in the spectrum, which means that the triplet and quartet actually integrate for 9 and 6 hydrogens (*i.e.,* three ethyl groups).

^{13}C NMR

There are two signals, which indicate two different types of carbons in the molecule. The signal at 16 ppm is that of the $-CH_3$ groups, and the more downfield signal (at 47 ppm, due to neighboring N atom) is of the $-CH_2$ groups

Putting it all together:

The likely structure of the unknown is:

Triethylamine

32.32 Chemical Evidence:

Reaction with Brady's reagent forming a highly coloured compound suggests the presence of a ketone or aldehyde in the molecule.

Microanalysis:

	C	H	O
% composition	58.32	8.39	33.29
Atomic mass	12.01	1.01	16.00
Divide by relative atomic mass	4.86	8.31	2.08
Divide by	2.08	2.08	2.08
Ratio of atoms	2.33	3.99	1
Whole number ratio of atoms	7	12	3

Empirical formula = $C_7H_{12}O_3$

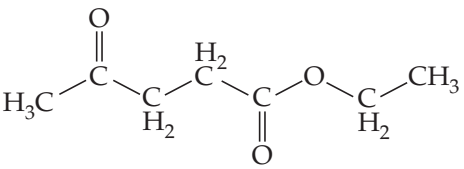
Mass spectrum:

From the mass spectrum the $[M + H]^+$ peak appears at m/z 145. Mass of empirical formula: $C_7H_{12}O_3$ = 144 g/mol. Therefore molecular formula is $C_7H_{12}O_3$.

IR spectrum:

Strong peak at 1700 cm^{-1}: C = O

^{1}H NMR



The presence of a triplet and quartet with same coupling indicates a $-CH_2CH_3$ group. The $-CH_2$ appears as a quartet since it is next to a $-CH_3$ group. Since the quartet for the $-CH_2$ group appears at 3.97 ppm, this indicates it is bonded next to an oxygen. The two triplets around 2.5 ppm have the same coupling, which implies that they are next to each other and also as they have similar chemical shifts, it is expected that they are in a similar chemical environment. The signal at 2.0 ppm integrating for three protons is not in close proximity to other hydrogens, so is a singlet.

^{13}C NMR

The signals at 208 and 172 ppm are both indicative of –C=O carbons, suggesting two such groups are present. The downfield carbonyl signal is consistent with an ester (due to the electronegativity of the adjoining oxygen).

Putting it all together:

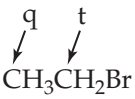
The likely structure of the unknown is:

Ethyl 4-oxopentanoate

32.33 (**a**) $A = -\log_{10}T = 0.21$ $T = 10^{-0.21} = 0.617$ %T = 61.7% (**b**) $A = \varepsilon \times c \times l$ 0.48 = 300 $dm^3\ mol^{-1}\ cm^{-1} \times c \times 1.0$ cm c = 0.48 / (300 × 1.0) mol dm^{-3} 1.6×10^{-3} M **32.35** (**a**) The label of 600 MHz indicates radio frequency (RF) radiation or operating frequency. The higher this number the better the spatial resolution and image that the instrument can obtain. This number is important for calculating chemical shift. (**b**) The stronger the applied magnetic field the greater the population difference between the two spin states (parallel and anti-parallel) of the ^{1}H nucleus. Increasing this difference leads to greater sensitivity, increased resolution, decreased acquisition time and a better signal-to-noise ratio. (**c**) Superconducting magnets emit a magnetic field. Implants and other foreign bodies made of ferromagnetic materials (those that are magnetic or respond to a magnetic field) can move or heat up if such a strong field is applied to the body. As such many implants are made from titanium that do not exhibit ferromagnetism. The strong magnetic field required for MRI is known to interfere with artificial pacemakers and hence the technique can not be used on a person that has had one implanted. Other safety concerns relate to potential projectiles in the room and the use of cryogens. Current superconducting magnets require cooling to very low temperatures to be able to superconduct. The cold liquids used (liquid He and liquid N_2) possess their own safety concerns, one of which is the risk of asphyxiation. **32.37** These two compounds can be distinguished using mass spectrometry by: i) The distinct isotopic pattern of Cl in a mass spectrum ($[M]^+$: $[M+2]^+$ peaks with a ratio of 3:1. ii) By studying the fragmentation peaks and looking for characteristic mass losses of 35 and 37 atomic mass units (amu) for Cl. **32.40** If picric acid were a carboxylic acid it would contain stretches at around 1700 cm^{-1} and 3500 cm^{-1}. As a phenol, it contains an absorption at 3500 cm^{-1}. **32.41** (**a**) Bioimaging using the functional group would allow the mapping of water in the body, distinguishing between different sorts of tissues. For bioimaging of molecules other than water, the C=O group would probably be most useful because it occurs in all proteins, while water would mask the O–H signal of other molecules containing this functional group and C≡N is rare in biological systems. (**b**) The amide and amine functional groups are widely distributed in biological systems so bioimaging based on N–H might be useful. Because of the similarity between the O–H and N–H functional groups behaviour in the infrared, a bioimaging technique based on infrared using N–H would probably run into problems with masking of signal by water.

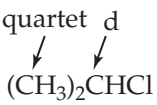
32.44 (**a**)

2-propanol 1-propanol



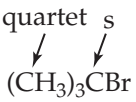
(**b**) The ^{1}H NMR for 2-propanol should give three signals with integration 1:6:1:

1. A broad singlet for the –OH
2. A doublet for the 6 $-CH_3$ protons
3. A septet for the 1H on the central carbon



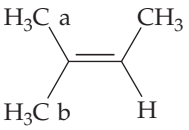
The ^{1}H NMR for 1-propanol should give four signals with integration 1:2:2:3:

1. A broad singlet for the –OH
2. A triplet for the 2 $-CH_2-O$ protons
3. A multiplet for the 2 $C-CH_2-C$ protons
4. A triplet for the 3 $-CH_3$ protons

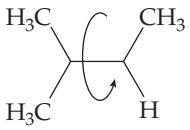


32.45 (**a**) s = singlet, d = doublet, t = triplet, q = quartet

(**b**)



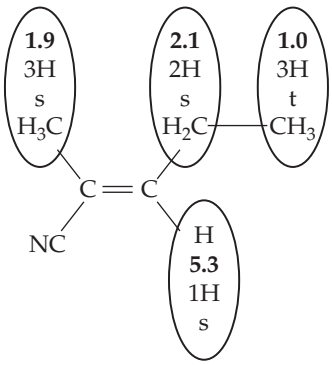
(**c**)



32.46 (**a**) The direction of electron spin does not affect the energy of the electron unless it is in a strong applied magnetic field. Hence strong magnets were needed to discover electron spin as they produced a small, but measurable, change in electron energy. The

detection of two different energy states in a magnetic field led to the formulation of the electron spin concept. (**b**) An ESR experiment requires greater energy than an NMR experiment. Microwave radiation is at a higher frequency than radio frequency radiation and photon energy is directly proportional to frequency: E=hν.

32.47



2-methyl-2-butene

2-methylbutane

Due to the inability to rotate around the C=C double bond, the two –CH_3 groups in 2-methyl-2-butene labelled 'a' and 'b' are in different magnetic environments. As such they each produce a distinct ^{13}C signal, as do all the other carbons in the compound, leading to 5 signals being observed. When the double bond is broken to form the alkane, free rotation about the C–C single bond makes the two –CH_3 groups magnetically and chemically equivalent and hence only one signal is observed for the two carbons. **32.49** (**a**) 3 (**b**) 4 (**c**) 3 (**d**) 5 **32.50** Spin ½ nuclei such as ^{31}P and ^{1}H couple to each other and cause splitting according to the n+1 rule. Hence for PH_2Cl we have two magnetically and chemically equivalent H that will not couple to each other. We would expect the following: ^{1}H NMR: A doublet integrating for 2 protons ^{31}P NMR: A triplet integrating for 1 phosphorus

32.51

32.52 Boron occurs naturally as two isotopes ^{10}B (19.9%) and ^{11}B (80.1%). Triethylborane [$(CH_3CH_2)_3B$] has a mass of (6×12)+(15×1)+10 = 97 amu or (6×12)+(15×1)+11 = 98 amu depending on which isotope of boron is present in the molecule. **32.53** Microanalysis determines the empirical formula, which then needs to be multiplied by a factor to get the correct molecular weight to give the molecular formula. In this case, the molecular and empirical formulas are the same. From TABLE 32.4, it can be seen that chlorine and bromine both exist as two isotopes ($[M]^+$ and $[M+2]^+$, each of which are of significant abundance). The two isotopes of bromine however, are almost of equal abundance so by calculating the extra 52.90% of the elemental analysis as bromine of average atomic weight 80 and following the procedure of 32.38, the following is found: Empirical formula = $C_5H_{11}Br$ From the mass spectrum the molecular ion peak appears at m/z 150, and the $[M+2]^+$ peak appears at m/z 152 Mass of empirical formula: $C_5H_{11}{}^{79}Br$ = 150 amu. Mass of empirical formula: $C_5H_{11}{}^{81}Br$ = 152 amu. Therefore, molecular formula is $C_5H_{11}Br$. **32.55** (**a**) Molecular ion peak (**b**) Molecular ion peak plus 2 mass units (**c**) The peak in the mass spectrum that has the greatest intensity (**d**) Mass to charge ratio (**e**) Electron impact mass spectrometry **32.56** If we study the compounds below we notice that oxygen does not change the ratio of C:H as it requires two bonds. This means effectively it inserts between a C–C bond or C–H bond without changing the ratio. Nitrogen atoms require 3 bonds so incorporating into a C–C bond or C–H bond requires the addition of an extra H to complete the valence of nitrogen.

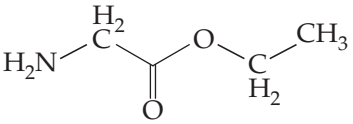
$H_3C—CH_3$	$H_3C—CH_2—OH$	$H_3C—O—CH_3$	$H_3C—CH_2—NH_2$
C_nH_{2n+2}	C_nH_{2n+2}	C_nH_{2n+2}	C_nH_{2n+3}

32.58 Chemical Evidence:
Amino acids contain oxygen and nitrogen atoms, so the missing atom in the elemental analysis is oxygen.

Microanalysis:

	C	H	N	O
% composition	46.59	8.80	13.58	31.03
relative atomic mass	12.01	1.01	14.01	16.00
Divide by relative atomic mass	3.88	8.71	0.97	1.94
Divide by	0.97	0.97	0.97	0.97
Ratio of atoms rounded to nearest whole number	4	9	1	2

Empirical formula = $C_4H_9NO_2$



Mass spectrum:
From the mass spectrum the molecular ion peak appears at m/z 103. Peak at 74 represents a loss of 29 mass units (–CH_2CH_3). Mass of empirical formula: $C_4H_9NO_2$ = 103 g mol^{-1}. Therefore molecular formula is $C_4H_9NO_2$.

IR spectrum:
Strong peak at 1700 cm^{-1}: C = O Broad peak from 3000–3100 cm^{-1}: N–H

^{1}H NMR
The presence of a triplet and quartet with same coupling indicates a –CH_2CH_3 (ethyl) group. The –CH_2 appears as a quartet since it is next to a –CH_3 group. Since the quartet for the –CH_2 group appears at 4.16 ppm, this indicates it is bonded next to an oxygen group. The broad singlet at 3.4 ppm indicated an –NH_2 group, while the singlet at 2.15 ppm is indicative of the –CH_2 group next to the amine.

^{13}C NMR
The signal at 175 ppm is indicative of a carbonyl carbon, while the signal at 61 ppm for the –CH_2 group next to the amine. The –CH_2 and –CH_3 groups of the ethyl groups have signals at 43 and 15 ppm respectively. The –CH_2 signal is more downfield because it is in close proximity to the oxygen.

Putting it all together:
The likely structure of the unknown is:

Ethyl 2-aminoacetate or glycine ethyl ester

32.60 Chemical Evidence:
Reaction with aqueous sodium bicarbonate indicates that the organic unknown possesses a carboxylic acid.

Microanalysis:

	C	H	O
% composition	48.64	8.16	43.2
Divide by relative atomic mass	12.01	1.01	16.00
	4.04	8.08	2.7
Divide by lowest	2.7	2.7	2.7
Ratio of atoms	1.5	3	1
Multiply by 2	3	6	2

Empirical formula = $C_3H_6O_2$

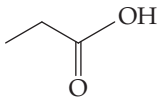
Mass spectrum:

From the mass spectrum the molecular ion peak appears at *m/z* 74. Peak at 57 represents a loss of 17 mass units (–OH). Mass of empirical formula: $C_3H_6O_2 = 74$ g mol^{-1}. Therefore molecular formula is $C_3H_6O_2$.

IR spectrum:

Strong peak at 1700 cm^{-1}: C = O Broad peak from 3000–3200 cm^{-1}: O–H

^{1}H NMR



The presence of a triplet and quartet with same coupling indicates a $-CH_2CH_3$ group. The $-CH_2$ appears as a quartet since it is next to a $-CH_3$ group. Since the quartet for the $-CH_2$ group appears at 2.3 ppm, this indicates it is bonded next to a –C=O group.

^{13}C NMR

There are three peaks indicating the presence of 3 different types of carbon atoms. The peak at approximately 182 ppm is indicative of a –C=O carbon.

Putting it all together:

The likely structure of the unknown is:

CH_3CH_2COOH

Propionic acid

ANSWERS TO GO FIGURE

Chapter 1

Figure 1.1 Aspirin. It contains 9 carbon atoms. ***Figure 1.4*** Vapor (gas) ***Figure 1.5*** Molecules of a compound are composed of more than one type of atom, and molecules of an element are composed of only one type of atom. ***Figure 1.6*** It would get larger because hydrogen atoms are lighter than the atoms of any other element. ***Figure 1.7*** (**c**) Each water molecule contains one oxygen atom and two hydrogen atoms. ***Figure 1.14*** The separations are due to physical processes of adsorption of the materials onto the column ***Figure 1.18*** True ***Figure 1.19*** 1000 ***Figure 1.23*** The darts would be scattered widely (poor precision) but their average position would be at the center (good accuracy).

Chapter 2

Figure 2.2 Cathode rays would still be generated but without the fluorescent screen you would not be able to see them. ***Figure 2.3*** The electron beam would be deflected downward because of repulsion by the upper negative plate and attraction toward the positive plate. ***Figure 2.4*** No, the electrons are of negligible mass compared with an oil drop. ***Figure 2.6*** Beta rays are equivalent to electrons. (**a**) They are lighter. ***Figure 2.8*** The beam consists of alpha particles, which carry a +2 charge. They are repelled from the positively charged gold nuclei. ***Figure 2.9*** 10^{-2} pm ***Figure 2.12*** Based on the periodic trend, we expect that elements that precede a nonreactive gas, as F does, will also be reactive nonmetals. The elements fitting this pattern are H and Cl. ***Figure 2.14*** All of the metals shown here are solids, that exhibit varying degrees of luster to their appearance. In contrast, bromine is a liquid and none of the nonmetals shown here are lustrous. ***Figure 2.16*** The ball-and-stick model. ***Figure 2.17*** The elements are in the following groups: Ag^+ is 11, Zn^{2+} is 12, and Sc^{3+} is 3. Only Sc^{3+} has the same number of electrons as a noble gas, Ar (element 18). ***Figure 2.18*** No it is not, ionic solids like NaCl do not contain discrete molecules. ***Figure 2.21*** Removing one O atom from the perbromate ion gives the bromate ion, BrO_3^-.

Chapter 3

Figure 3.3 There are two CH_4 and four O_2 molecules on the reactant side, which contain 2 C atoms, 8 H atoms and 8 O atoms. The number of each type of atom remains the same on the product side as it must. ***Figure 3.7*** The flame gives off heat and therefore the reaction must release heat. ***Figure 3.8*** Avogadro's number ***Figure 3.10*** g/mol and mol^{-1} ***Figure 3.16*** If the amount of H_2 is doubled then O_2 becomes the limiting reactant. In that case $(7\ mol\ O_2) \times (2\ mol\ H_2O/1\ mol\ O_2) =$ 14 mol H_2O would be produced.

Chapter 4

Figure 4.2 NaCl(*aq*) ***Figure 4.3*** K^+ and NO_3^- ***Figure 4.7*** Mg$(NO_3)_2$ and water ***Figure 4.10*** Two. Each O atom becomes an O^{2-} ion. ***Figure 4.11*** One, based on the reaction stoichiometry. ***Figure 4.12*** Because the Cu(II) ion produces a blue color in aqueous solution. ***Figure 4.16*** The volume needed to reach the end point if $Ba(OH)_2(aq)$ were used would be one-half the volume needed for titration with NaOH(*aq*), because there are two hydroxide ions for every barium ion.

Chapter 5

Figure 5.2 The electrostatic potential energy of two oppositely charged particles is negative (Equation 5.2). As the particles become closer, the electrostatic potential energy becomes even more negative—that is, it decreases. ***Figure 5.3*** Attractions between oppositely charged ions would cause the ions to move closer together reducing the potential energy of the system. The lost potential energy is converted to kinetic energy needed to move the ions. ***Figure 5.4*** The number of molecules will change because three reactant molecules (2 H_2 and 1 O_2) are needed to make two product (H_2O) molecules. However, in a closed system like this one the total mass will not change. ***Figure 5.5*** If $E_{final} = E_{initial}$, then $\Delta E = 0$. ***Figure 5.6***

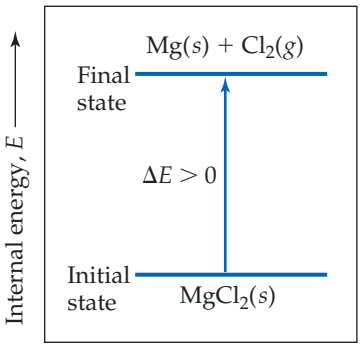


Figure 5.7 $\Delta E = 50\ J + (-85\ J) = -35\ J$ ***Figure 5.10*** The battery is doing work on the surroundings, so $w < 0$. ***Figure 5.11*** The system does work on the surroundings to move the piston upward, so $w < 0$. ***Figure 5.17*** Endothermic—heat is being added to the system to raise the temperature of the water. ***Figure 5.18*** Two cups provide more thermal insulation so less heat will escape the system. ***Figure 5.19*** In a calorimeter the system is defined as the reactants and products, so the water inside the calorimeter is part of the surroundings. ***Figure 5.21*** The condensation of 2 $H_2O(g)$ to 2 $H_2O(l)$ ***Figure 5.22*** Yes, ΔH_3 would remain the same as it is the enthalpy change for the process $CO(g) + \frac{1}{2}O_2(g) \longrightarrow CO_2(g)$. ***Figure 5.24*** Exothermic, because the enthalpy of the products is lower than that of the reactants. ***Figure 5.25*** Grams of fat

Chapter 6

Figure 6.3 Wavelength = 1.0 m, frequency = 3.0×10^8 cycles/s. ***Figure 6.4*** Longer by 3 to 5 orders of magnitude (depending on what part of the microwave spectrum is considered). ***Figure 6.5*** The part of the nail glowing yellow is hotter than the part glowing red. ***Figure 6.7*** As the frequency of the incoming light is increased the photon energy will increase and the kinetic energy of the ejected electrons will increase. ***Figure 6.11*** The $n = 2$ to $n = 1$ transition involves a larger energy change than the $n = 3$ to $n = 2$ transition. (Compare the lengths of the arrows connecting the states in the figure.) If the $n = 3$ to $n = 2$ transition produces visible light, the $n = 2$ to $n = 1$ transition must produce radiation of greater energy. Of the two choices only ultraviolet radiation has higher frequency and greater energy than visible light. ***Figure 6.12*** The $n = 4$ to $n = 3$ transition involves a smaller energy difference and will therefore emit light of longer wavelength. ***Figure 6.16*** The region of highest electron density is where the density of dots

is highest, which is near the nucleus. ***Figure 6.17*** For a single electron atom like hydrogen the energies of the orbitals are the same as the energies of the orbits in the Bohr model. ***Figure 6.18*** There would be four maxima and three nodes. ***Figure 6.22*** The p_x orbital. ***Figure 6.23*** There are two nodal planes for each of the *d*-orbitals. For the d_{xy} orbital the nodal planes are the *xz* and *yz* planes. ***Figure 6.24*** The 4*d* and 4*f* subshells are not shown. ***Figure 6.30*** Osmium

Chapter 7

Figure 7.1 These three metals do not readily react with other elements, especially oxygen, so they are often found in nature in the elemental form as metals (such as gold nuggets) ***Figure 7.4*** Because of the peak near the nucleus in the 2*s* curve there is a higher probability of finding a 2*s* within 50 pm of the nucleus. In a multielectron atom an electron in a 2*s* orbital will have a lower energy than one in a 2*p* orbital. ***Figure 7.7*** Bottom and left ***Figure 7.8*** They get larger, just like the atoms do. ***Figure 7.10*** 900 kJ/mol ***Figure 7.11*** There is more electron–electron repulsion in the case of oxygen because two electrons have to occupy the same orbital. ***Figure 7.12*** The added electron for the Group 14 elements leads to a half-filled np^3 configuration. For the Group 15 elements, the added electron leads to an np^4 configuration, so the electron must be added to an orbital that already has one electron in it, and thus experiences more electron-electron repulsion. ***Figure 7.13*** They are opposite: As ionization energy increases, metallic character decreases, and vice versa. ***Figure 7.15*** Anions are above and to the right of the line; cations are below and to the left of the line. ***Figure 7.16*** No. The Na^+ and NO_3^- ions will simply be spectator ions. The H^+ ions of an acid are needed in order to dissolve NiO. ***Figure 7.17*** No. As seen in the photo, sulfur crumbles as it is hit with a hammer, typical of a solid nonmetal. ***Figure 7.21*** Because Rb is below K in the periodic table, and has a lower first ionization energy we expect Rb to be more reactive with water than K. ***Figure 7.23*** Lilac (see ***Figure 7.22***). ***Figure 7.25*** The bubbles are due to $H_2(g)$. This could be confirmed by carefully testing the bubbles with a flame—there should be popping as the hydrogen gas ignites. ***Figure 7.26*** A regular octagon. ***Figure 7.27*** I_2 is a solid whereas Cl_2 is a gas. Molecules are more closely packed together in a solid than they are in a gas, as will be discussed in detail in Chapter 11.

Chapter 8

Figure 8.1 We would draw the chemical structure of sugar molecules (which have no charges and have covalent bonding between atoms in each molecule) and indicate weak intermolecular forces (especially hydrogen bonding) between sugar molecules. ***Figure 8.3*** Yes. ***Figure 8.4*** Cations have a smaller radius than their neutral atoms and anions have a larger radius. Because Na and Cl are in the same row of the periodic table, we would expect Na^+ to have a smaller radius than Cl^-, so we would infer that the larger green spheres represent the chloride ions and the smaller purple spheres represent the sodium ions. ***Figure 8.5*** The distance between ions in KF should be larger than that in NaF and smaller than that in KCl. We would thus expect the lattice energy of KF to be between 701 and 910 kJ/mol. ***Figure 8.7*** The repulsions between the nuclei would decrease, the attractions between the nuclei and the electrons would decrease, and the repulsions between the electrons would be unaffected. ***Figure 8.8*** The electronegativity decreases with increasing atomic number. ***Figure 8.10*** μ will decrease. ***Figure 8.11*** The bonds are not polar enough to cause enough excess electron density on the halogen atom to lead to a red shading. ***Figure 8.13*** The lengths of the bonds of the outer O atoms to the inner O atom are the same. ***Figure 8.14*** Yes. The electron densities on the left and right parts of the molecule are the same, indicating that resonance has made the two O — O bonds equivalent to one another. ***Figure 8.15*** It should be halfway between the values for single and double bonds, which we can estimate to be about 280 kJ/mol from the graph.

Chapter 9

Figure 9.1 The radii of the atoms involved (see Section 7.3). ***Figure 9.2*** NF_3 ***Figure 9.3*** Octahedral. ***Figure 9.4*** No. We will get the same bent-shaped geometry regardless of which two atoms we remove. ***Figure 9.8*** 90°. ***Figure 9.9*** The C — O — H bond involving the right O because of the greater repulsions due to the nonbonding electron domains. The angle should be less than the ideal value of 109.5°. ***Figure 9.10*** Zero. Because they are equal in magnitude but opposite in sign, the vectors cancel upon addition. ***Figure 9.13*** 74 pm is the bond length, 436 kJ/mol is the bond strength. ***Figure 9.16*** 120° ***Figure 9.17*** The p_z orbital. ***Figure 9.18*** No. All four hybrids are equivalent and the angles between them are all the same, so we can use any of the two to hold the nonbonding pairs. ***Figure 9.19*** Because the P 3*p* orbitals are larger than the N 2*p* orbitals, we would expect somewhat larger lobes on the hybrid orbitals in the right-most drawing. Other than that, the molecules are entirely analogous. ***Figure 9.22*** They have to lie in the same plane in order to allow the overlap of the π orbitals to be effective in forming the π bond. ***Figure 9.23*** Acetylene should have the higher carbon-carbon bond energy because it has a triple bond as compared to the double bond in ethylene. ***Figure 9.25*** It has six C — C σ and six C — H σ bonds. ***Figure 9.31*** σ_{1s}^2, $\sigma^*_{1s}{}^1$. ***Figure 9.32*** σ^*_{1s} and σ^*_{2s}. ***Figure 9.33*** The end-on overlap in the σ_{2p} MO is greater than the sideways overlap in the π_{2p}. ***Figure 9.39*** The σ_{2p} and π_{2p} MOs have switched order. ***Figure 9.40*** O_2 and F_2 ***Figure 9.42*** N_2 is diamagnetic so it would not be attracted to the magnetic field. The liquid nitrogen would simply pour through the poles of the magnet without "sticking." ***Figure 9.43*** 11. All the electrons in the $n = 2$ level are valenceshell electrons.

Chapter 10

Figure 10.2 It will increase. ***Figure 10.5*** Decreases ***Figure 10.6*** 1520 torr or 203 kPa ***Figure 10.9*** One ***Figure 10.10*** Chlorine, Cl_2. ***Figure 10.12*** About one-sixth ***Figure 10.13*** O_2 has the largest molar mass, 32 g/mol, and H_2 has the smallest, 2.0 g/mol. ***Figure 10.16*** *n*, moles of gas ***Figure 10.20*** True ***Figure 10.22*** It would increase.

Chapter 11

Figure 11.1 The density in a liquid is much closer to a solid than it is to a gas. ***Figure 11.3*** The distance within the molecule (the covalent bond distance) represented by the solid black line is smaller than the intermolecular distance represented by the red dotted line. ***Figure 11.5*** The halogens are diatomic molecules and have much greater size and mass, and therefore greater polarizability, than the noble gases, which are monatomic. ***Figure 11.8*** They stay roughly the same because the molecules have roughly the same molecular weights. Thus, the change in boiling point moving left to right is due mainly to the increasing dipole-dipole attractions. ***Figure 11.9*** Both compounds are nonpolar and incapable of forming hydrogen bonds. Therefore, the boiling point is determined by the dispersion forces, which are stronger for the larger,

heavier AsH_3. ***Figure 11.10*** The non-hydrogen atom must possess a nonbonding electron pair. ***Figure 11.11*** There are four electron pairs surrounding oxygen in a water molecule. Two of the electron pairs are used to make covalent bonds to hydrogen within the H_2O molecule, while the other two are available to make hydrogen bonds to neighboring molecules. Because the electron-pair geometry is tetrahedral (four electron domains around the central atom), the H — O · · · H bond angle is approximately 109°. ***Figure 11.13*** The O atom is the negative end of the polar H_2O molecule; the negative end of the dipole is attracted to the positive ion. ***Figure 11.14*** Yes, although not likely. ***Figure 11.19*** Wax is a hydrocarbon that cannot form hydrogen bonds. Therefore, coating the inside of tube with wax will dramatically decrease the adhesive forces between water and the tube and change the shape of the water meniscus to an inverted U-shape. Neither wax nor glass can form metallic bonds with mercury so the shape of the mercury meniscus will be qualitatively the same, an inverted U-shape. ***Figure 11.20*** Because energy is a state function, the energy to convert a gas to a solid is the same regardless of whether the process occurs in one or two steps. Thus, the energy of deposition equals the energy of condensation plus the energy of freezing. ***Figure 11.21*** Because water has stronger intermolecular interactions. ***Figure 11.22*** The temperature of the liquid water is increasing. ***Figure 11.24*** Increases, because the molecules have more kinetic energy as the temperature increases and can escape more easily ***Figure 11.25*** All liquids including ethylene glycol reach their normal boiling point when their vapor pressure is equal to atmospheric pressure, 101.3 kPa. ***Figure 11.27*** It must be lower than the temperature at the triple point.

Chapter 12

Figure 12.5 There is not a centered square lattice, because if you tile squares and put lattice points on the corners and the center of each square it would be possible to draw a smaller square (rotated by 45°) that only has lattice points on the corners. Hence a "centered square lattice" would be indistinguishable from a primitive square lattice with a smaller unit cell. ***Figure 12.12*** Face-centered cubic, assuming similar size spheres and cell edge lengths, since there are more atoms per volume for this unit cell compared to the other two. ***Figure 12.13*** A hexagonal lattice ***Figure 12.15*** The solvent is the majority component and the solute the minority component. Therefore, there will be more solvent atoms than solute atoms. ***Figure 12.17*** The samarium atoms sit on the corners of the unit cell so there is only $8 \times (1/8) = 1$ Sm atom per unit cell. Eight of the nine cobalt atoms sit on faces of the unit cell, and the other sits in the middle of the unit cell so there are $8 \times (1/2) + 1 = 5$ Co atoms per unit cell. ***Figure 12.19*** P_4, S_8, and Cl_2 are all molecules, because they have strong chemical bonds between atoms and have well-defined numbers of atoms per molecule. ***Figure 12.21*** In the fourth period, vanadium and chromium have very similar melting points. Molybdenum and tungsten have the highest melting points in the fifth and sixth periods, respectively. All of these elements are located near the middle of the period where the bonding orbitals are mostly filled and the antibonding orbitals mostly empty. ***Figure 12.22*** The molecular orbitals become more closely spaced in energy. ***Figure 12.23*** Potassium has only one valence electron per atom ($4s^1$). Therefore we expect the 4*s* band to be approximately half full. If we fill the 4*s* band halfway a small amount of electron density might leak over and start to fill the 3*d* orbitals as well. The 4*p* orbitals should be empty. ***Figure 12.24*** Ionic substances cleave because the nearest neighbor interactions switch from attractive to repulsive if the atoms slide so that ions of like charge (cation–cation and anion–anion) touch each other. Metals don't cleave because the atoms are attracted to all other atoms in the crystal through metallic bonding. ***Figure 12.25*** No, ions of like charge do not touch in an ionic compound because they are repelled from one another. In an ionic compound the cations touch the anions. ***Figure 12.27*** In NaF there are four Na^+ ions ($12 \times 1/4$) and four F^- ions ($8 \times 1/8 + 6 \times 1/2$) per unit cell. In MgF_2 there are two Mg^{2+} ions ($8 \times 1/8 + 1$) and four F^- ions ($4 \times 1/2 + 2$) per unit cell. In ScF_3 there is one Sc^{3+} ion ($8 \times 1/8$) and three F^- ions ($12 \times 1/4$) per unit cell. ***Figure 12.28*** The intermolecular forces are stronger in toluene, as shown by its higher boiling point. The molecules pack more efficiently in benzene, which explains its higher melting point, even though the intermolecular forces are weaker. ***Figure 12.30*** The band gap for an insulator would be larger than the one for a semiconductor. ***Figure 12.31*** If you doubled the amount of doping in panel (**b**), the amount of blue shading the conduction band would also double. ***Figure 12.44*** Decrease. As the quantum dots get smaller, the band gap increases and the emitted light shifts to shorter wavelength. ***Figure 12.48*** Each carbon atom in C_{60} is bonded to three neighboring carbon atoms through covalent bonds. Thus, the bonding is more like graphite, where carbon atoms also bond to three neighbors, than diamond, where carbon atoms bond to four neighbors.

Chapter 13

Figure 13.1 Gas molecules move in constant random motion. ***Figure 13.2*** Opposite charges attract. The electron-rich O atom of the H_2O molecule, which is the negative end of the dipole, is attracted to the positive Na^+ ion. ***Figure 13.4*** For exothermic solution processes the magnitude of ΔH_{mix} will be larger than the magnitude of $\Delta H_{solute} + \Delta H_{solvent}$ ***Figure 13.6*** 46 g. ***Figure 13.11*** If the partial pressure of a gas over a solution is doubled, the concentration of gas in the solution would double. ***Figure 13.12*** The highest. ***Figure 13.14*** Looking at where the solubility curves for KCl and NaCl intersect the 80 °C line, we see that the solubility of KCl is about 51 g/100 g H_2O, whereas NaCl has a solubility of about 39 g/100 g H_2O. Thus, KCl is more soluble than NaCl at this temperature. ***Figure 13.15*** N_2 has the same molecular weight as CO but is nonpolar, so we can predict that its curve will be just below that of CO. ***Figure 13.21*** The water will move through the semipermeable membrane toward the more concentrated solution. Thus, the liquid level in the left arm will increase. ***Figure 13.22*** Water will move toward the more concentrated solute solution, which is inside the red blood cells, causing them to undergo hemolysis. ***Figure 13.25*** The negatively charged groups both have the composition $—CO_2^-$. ***Figure 13.27*** Recall the rule that likes dissolve likes. The oil drop is composed of nonpolar molecules, which interact with the nonpolar part of the stearate ion via dispersion forces.

Chapter 14

Figure 14.1 No. The surface area of a steel nail is much smaller than that for the same mass of steel wool, so the reaction with O_2 would not be as vigorous. Depending on how hot it is, it might not burn at all. ***Figure 14.2*** Our first guess might be half way between the values at 20 s and 40 s, namely 0.42 mol A. However, we also see that the change in the number of moles of A between 0 s and 20 s is greater than that between 20 s and 40 s—in other words, the rate of

conversion gets smaller as the amount of A decreases. So we would guess that the change from 20 s to 30 s is greater than the change from 30 s to 40 s, and we would estimate that the number of moles of A is between 0.42 and 0.30 mol. ***Figure 14.3*** The instantaneous rate decreases as the reaction proceeds. ***Figure 14.7*** The reaction is first order. ***Figure 14.9*** At the beginning of the reaction when both plots are linear or nearly so. ***Figure 14.13*** No, it will not turn down. The rate constant increases monotonically with increasing temperature because the kinetic energy of the colliding molecules continues to increase. ***Figure 14.15*** The difference in height between the ball and the top of the barrier. ***Figure 14.16*** As shown, the magnitude of energy needed to overcome the energy barrier is greater than the magnitude of the energy change in the reaction. ***Figure 14.17*** It would be more spread out, the maximum of the curve would be lower and to the right of the maximum of the red curve, and a greater fraction of molecules would have kinetic energy greater than E_a than for the red curve. ***Figure 14.19*** The rate of converting intermediates to products will be faster, because this reaction has a lower barrier than the reaction that converts intermediates back to reactants. ***Figure 14.20*** No, because the bottleneck, or rate determining step, is passing through toll plaza A. ***Figure 14.21*** The color is characteristic of molecular bromine, Br_2, which is an intermediate in this reaction. ***Figure 14.22*** There is one valley corresponding to the formation of intermediates, so the reaction has a total of two steps. ***Figure 14.25*** Grinding increases the surface area, exposing more of the catalase to react with the hydrogen peroxide. ***Figure 14.26*** Substrates must be held more tightly so that they can undergo the desired reaction. Products are released from the active site.

Chapter 15

Figure 15.1 The same because once the system reaches equilibrium the concentrations of NO_2 and N_2O_4 stop changing. ***Figure 15.2*** Because the concentration of reactants is decreasing, which reduces the frequency of collisions and hence the rate of the forward reaction. ***Figure 15.3*** Yes. The reaction stoichiometry dictates that H_2 disappears at three times the rate that N_2 disappears. ***Figure 15.5*** Experiment 4 ***Figure 15.6*** The boxes would be approximately the same size. ***Figure 15.7*** It would decrease. To reestablish equilibrium the concentration of $CO_2(g)$ would need to return to its previous value. The only way to do that would be for more $CaCO_3$ to decompose to produce enough $CO_2(g)$ to replace what was lost. ***Figure 15.9*** High pressure and low temperature, 500 atm and 400 °C in this figure. ***Figure 15.10*** Nitrogen must react with some of the added hydrogen to create ammonia and restore equilibrium. ***Figure 15.15*** (**a**) the energy difference between the initial state and the transition state. ***Figure 15.16*** About 5×10^{-4}

Chapter 16

Figure 16.1 Hydrogen bonds. ***Figure 16.3*** $O^{2-}(aq) + H_2O(l) \longrightarrow 2\,OH^-(aq)$. ***Figure 16.4*** Basic. The mixture of the two solutions will still have $[H^+] < [OH^-]$. ***Figure 16.5*** Lemon juice. It has a pH of about 2 whereas black coffee has a pH of about 5. The lower the pH, the more acidic the solution. ***Figure 16.7*** Phenolphthalein changes from colorless, for pH values less than 8, to pink for pH values greater than 10. A pink color indicates pH $>$ 10. ***Figure 16.8*** Bromthymol blue would be most suitable because it changes pH over a range that brackets pH $=$ 7. Methyl red is not sensitive to pH changes when pH $>$ 6, while phenolphthalein is not sensitive to pH changes when pH $<$ 8, so neither changes color at pH $=$ 7. ***Figure 16.12*** Yes. The equilibrium of interest is $H_3CCOOH \rightleftharpoons H^+ + H_3CCOO^-$. If the percent dissociation remained constant as the acid concentration increased, the concentration of all three species would increase at the same rate. However, because there are two products and only one reactant, the product of the concentrations of products would increase faster than the concentration of the reactant. Because the equilibrium constant is constant, the percent dissociation decreases as the acid concentration increases. ***Figure 16.13*** 3. ***Figure 16.15*** The nitrogen atom in hydroxylamine accepts a proton to form NH_3OH^+. As a general rule, nonbonding electron pairs on nitrogen atoms are more basic than nonbonding electron pairs on oxygen atoms. ***Figure 16.17*** The range of pH values is so large that we can't show the effects using a single indicator (see Figure 16.8). ***Figure 16.20*** The HOY molecule on the left because it is a weak acid. Most of the HOY molecules remain undissociated.

Chapter 17

Figure 17.6 The pH will increase upon addition of the base. ***Figure 17.7*** 25.00 mL. The number of moles of added base needed to reach the equivalence point remains the same. Therefore, by doubling the concentration of added base the volume needed to reach the equivalence point is halved. ***Figure 17.9*** The volume of base needed to reach the equivalence point would not change because this quantity does not depend on the strength of the acid. However, the pH at the equivalence point, which is greater than 7 for a weak acid–strong base titration, would decrease to 7 because hydrochloric acid is a strong acid. ***Figure 17.11*** The pH at the equivalence point increases (becomes more basic) as the acid becomes weaker. The volume of added base needed to reach the equivalence point remains unchanged. ***Figure 17.12*** No; it would change color by pH 6 and miss pH 7. ***Figure 17.15*** $H_2PO_3^-$ at first equivalence point, HPO_3^{2-} at the second. ***Figure 17.22*** Because the solution is basic. ***Figure 17.23*** Yes. CuS would precipitate in step 2 on addition of H_2S to an acidic solution, while the Zn^{2+} ions remained in solution.

Chapter 18

Figure 18.1 About 85 km, at the mesopause. ***Figure 18.3*** The atmosphere absorbs a significant fraction of solar radiation. ***Figure 18.4*** (**c**) UV ***Figure 18.5*** The peak value is about 5×10^{12} molecules per cm^3. If we use Avogradro's number to convert molecules to moles, and the conversion factor of $1000\ cm^3 = 1000\ mL = 1\ L$, we find that the concentration of ozone at the peak is 8×10^{-9} mol/L. ***Figure 18.8*** $CaSO_3(s)$ ***Figure 18.10*** The Earth's surface absorbs 492 W/m^2. Of that amount 390 W/m^2 or 79% is radiated back toward the atmosphere. ***Figure 18.12*** The increasing slope corresponds to an increasing *rate* of addition of CO_2 to the atmosphere, probably as a result of ever-increasing burning of fossil fuels worldwide. ***Figure 18.14*** Evaporation from sea water, evaporation from freshwater; evaporation and transpiration from land. ***Figure 18.15*** As the temperature of water goes down its density increases. Therefore, density increases as depth increases (note the pressure also increases which also results in an increase in density). ***Figure 18.19*** To reduce concentrations of dissolved iron and manganese, remove H_2S and NH_3, and reduce bacterial levels.

Chapter 19

Figure 19.1 Yes, the potential energy of the eggs decreases as they fall. ***Figure 19.3*** To be truly reversible, the temperature change δT must be infinitesimally small. ***Figure 19.5*** Because the final volume would be less than twice the volume of Flask A, the final pressure would be greater than 50.7 kPa. ***Figure 19.8*** There are two other independent rotational motions of the H_2O molecule:

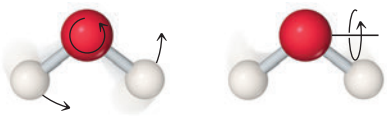

Figure 19.9 Ice, because it is the phase in which the molecules are held most rigidly ***Figure 19.11*** The decrease in the number of molecules due to the formation of new bonds. ***Figure 19.12*** During a phase change, the temperature remains constant but the entropy change can be large as molecules increase their degrees of freedom and motion. ***Figure 19.13*** Based on the three molecules shown, the addition of each C increases $S°$ by 40–45 J/mol K. Based on this observation, we would predict that $S°(C_4H_{10})$ would 310–315 J/mol K. Appendix C confirms that this is a good prediction: $S°(C_4H_{10}) = 310.0\,J/mol\,K$. ***Figure 19.14*** Spontaneous ***Figure 19.15*** If we plot progress of the reaction versus free energy, equilibrium is at a minimum point in free energy, as shown in the figure. In that sense, the reaction runs "downhill" until it reaches that minimum point.

Chapter 20

Figure 20.1 Exothermic. ***Figure 20.2*** The permanganate ion, MnO_4^-, is reduced, as the half-reactions in the text show. The oxalate ion, $C_2O_4^{2-}$, acts as the reducing agent. ***Figure 20.3*** The blue color is due to $Cu^{2+}(aq)$. As this ion is reduced, forming $Cu(s)$, its concentration decreases and the blue color fades. ***Figure 20.4*** The Zn is oxidized and, therefore, serves as the anode of the cell. ***Figure 20.5*** The electrical balance is maintained in two ways: Anions migrate into the half-cell, and cations migrate out via the salt bridge. ***Figure 20.9*** As the cell operates, H^+ is reduced to H_2 in the cathode half-cell. As H^+ is depleted, the positive Na^+ ions are drawn into the half-cell to maintain electrical balance in the solution. ***Figure 20.11*** Yes. ***Figure 20.13*** The variable n is the number of moles of electrons transferred in the process. ***Figure 20.14*** The cathode. ***Figure 20.19*** The cathode consists of $PbO_2(s)$. Because each oxygen has an oxidation state of −2, lead must have an oxidation state of +4 in this compound. ***Figure 20.20*** Zn ***Figure 20.21*** Co^{3+}. The oxidation number increases as the battery charges. ***Figure 20.24*** $O_2(g) + 4\,H^+ + 4\,e^- \longrightarrow 2\,H_2O(g)$ ***Figure 20.25*** The oxidizing agent of $O_2(g)$ from the air. ***Figure 20.29*** 0 V

Chapter 21

Figure 21.1 From Figure 21.1 we see that the belt of stability for a nucleus containing 70 protons lies at approximately 102 neutrons. ***Figure 21.2*** $^{234}_{90}Th \longrightarrow {}^{234}_{91}Pa + {}^{0}_{-1}e$ ***Figure 21.3*** Only three of the elements with an even number of protons have fewer than three isotopes: He, Be, and C. Note that these three elements are the lightest elements that have an even atomic number. Because they are so light, any change in the number of neutrons will change the neutron/proton ratio significantly. This helps to explain why they do not have more stable isotopes. None of the elements in Figure 21.3 that have an odd number of protons have more than two stable isotopes. ***Figure 21.6*** 6.25 g. After one half-life, the amount of the radioactive material will have dropped to 25.0 g. After two half-lives, it will have dropped to 12.5 g. After three half-lives, it will have dropped to 6.25 g. ***Figure 21.7*** Plants convert $^{14}CO_2$ to ^{14}C-containing sugars via photosynthesis. When mammals eat the plants, they metabolize the sugars, thereby incorporating ^{14}C in their bodies. ***Figure 21.8*** Gamma rays. Both X rays and gamma rays consist of high-energy electromagnetic radiation, whereas alpha and beta rays are streams of particles. ***Figure 21.9*** Ionization energy. Detection depends on the ability of the radiation to cause ionization of the gas atoms. ***Figure 21.14*** The mass numbers are equal on both sides. Remember that this does not mean that mass is conserved—mass is lost during the reaction, which appears as energy released. ***Figure 21.15*** 16. Each of the eight neutrons would split another uranium-235 nucleus, releasing two more neutrons. ***Figure 21.16*** Critical without being supercritical so that the release of energy is controlled. ***Figure 21.23*** Alpha rays are less dangerous when outside the body because they cannot penetrate the skin. However, once inside the body they can do great harm to any cells that are nearby.

Chapter 22

Figure 22.5 Beaker on the right is warmer. ***Figure 22.6*** HF is the most stable, SbH_3 the least stable. ***Figure 22.8*** More soluble in CCl_4 — the colors are deeper. ***Figure 22.9*** CF_2 ***Figure 22.12*** No ***Figure 22.14*** Based on this structure—yes, it would have a dipole moment. In fact, if you look it up, hydrogen peroxide's dipole moment is larger than water's! ***Figure 22.19*** Formally they could both be +2. If we consider that the central sulfur is like SO_4^{2-}, however, then the central sulfur would be +6, like SO_4^{2-}, and the terminal sulfur would be −2. ***Figure 22.21*** Nitrite ***Figure 22.22*** Longer. (There is a triple bond in N_2.) ***Figure 22.24*** The NO double bond ***Figure 22.26*** In both compounds the electron domains around the P atoms are tetrahedral. In P_4O_{10} all the electron domains around the P atoms are bonding. In P_4O_6 one of the electron domains about each P atom is nonbonding. ***Figure 22.30*** The minimum temperature should be the melting point of silicon; the temperature of the heating coil should not be so high that the silicon rod starts to melt outside the zone of the heating coil.

Chapter 23

Figure 23.3 No. The radius decreases first and then flattens out before increasing on moving past group 8B, while the effective nuclear charge increases steadily on moving left to right across the transition metal series. ***Figure 23.4*** Zn^{2+}. ***Figure 23.5*** The 4*s* orbitals are always empty in transition metal ions, so all of the ions shown in this table have empty 4*s* orbitals. The 3*d* orbitals are only empty for those ions that have lost all of their valence electrons: Sc^{3+}, Ti^{4+}, V^{5+}, Cr^{6+}, and Mn^{7+}. ***Figure 23.6*** The electron spins would tend to align with the direction of the magnetic field. ***Figure 23.8*** No. If you start with a chloride ion on one vertex of the octahedron and then generate structures by placing the second chloride ion on any of the other five vertices you will get one complex that is the *trans* isomer and four complexes that are equivalent to the *cis* isomer shown in this figure. ***Figure 23.9*** Neither the coordination number nor the oxidation state of iron change in this reaction. ***Figure 23.10*** The solid wedge represents a bond coming out of the plane of the page. The dashed wedge

represents a bond that is going into the plane of the page. ***Figure 23.13*** There are 20 carbon atoms in porphine, all of which have sp^2 hybridization. ***Figure 23.15*** The coordination number is 6. The blue atoms in the heme are nitrogen atoms. ***Figure 23.16*** The peak at 660 nm. ***Figure 23.20*** $[Fe(NH_3)_5(NO_2)]^{2+}$ and pentaammi-nenitroiron(III) ion for the complex on the left. $[Fe(NH_3)_5(ONO)]^{2+}$ and pentaamminenitritoiron(III) ion for the complex on the right. ***Figure 23.21*** The *cis* isomer. ***Figure 23.24*** Larger, since ammonia can displace water. ***Figure 23.26*** The peak would stay in the same position in terms of wavelength, but its absorbance would decrease. ***Figure 23.28*** $d_{x^2-y^2}$ and d_{z^2}. ***Figure 23.29*** Convert the wavelength of light, 495 nm, into energy in joules using the relationship $E = hc/\lambda$. ***Figure 23.30*** The absorption peak would shift to shorter wavelengths absorbing green light and the color of the complex ion would become red. An even larger shift would move the absorption peak into the blue region of the spectrum and the color would become orange. ***Figure 23.34*** Only the $d_{x^2-y^2}$ orbital points directly at the ligands.

Chapter 24

Figure 24.5 Four. ***Figure 24.12*** Staggered = chair, eclipsed = boat.

Chapter 25

Figure 25.1 No, there are no other ways of positioning three C–C bonds. ***Figure 25.12*** There is one that appears at the sharp end of the wedge.

Chapter 26

Figure 26.5 To achieve maximum overlap of the unhybridised orbitals thereby creating a π-bond. ***Figure 26.6*** Acetylene, since it has a triple bond. ***Figure 26.11*** None. ***Figure 26.14*** Z. ***Figure 26.20*** Exothermic.

Chapter 27

Figure 27.3 Three, one from the hydrogen attached to the oxygen and two involving the lone pairs on the oxygen. ***Figure 27.7*** Butan-2-ol is chiral. It has one stereocentre and so can exist as *R* or *S* stereoisomers. ***Figure 27.17*** The distributed alkenes; the 1,1-disubstituted alkene is a constitutional isomer of the 1,2-disubstituted alkenes and the two 1,2-disubstituted alkenes are stereoisomers (geometric isomers) of one another.

Chapter 28

Figure 28.1 O=C=O. ***Figure 28.2*** Propanoic acid, propanone. ***Figure 28.5*** Being a salt, $NaBH_4$ would not be very soluble in common organic solvents. It is slightly soluble in polar solvents like methanol where ion pairing can be disrupted. ***Figure 28.6*** Benzaldehyde. ***Figure 28.7*** Three. ***Figure 28.8*** Because of a plane of symmetry. ***Figure 28.13*** Four. There are four hydroxyl groups attached directly to the ring, all of which are in an equatorial position.

Chapter 29

Figure 29.1 Lactic acid and citric acid. ***Figure 29.2*** Non-polar solvents as polar solvents compete for hydrogen bonding. ***Figure 29.6*** Long-chain fatty acids. ***Figure 29.13*** They are nucleophiles. ***Figure 29.14*** It acts to cross-link the polymers.

Chapter 30

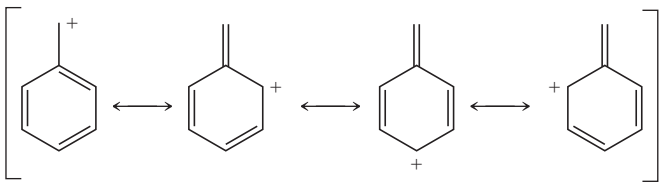

Figure 30.1 Apart from each having six carbons and both being hydrocarbons, there are no similarities. Their shape, electronic characteristics and reactivity are very different. ***Figure 30.4*** Vanillin: aldehyde, phenol, ether; styrene: alkene; asprin: carboxylic acid, ester; terephthalic acid: carboxylic acid; BHT: phenol; benzoic acid: carboxylic acid. ***Figure 30.9*** Two *ortho,* two *meta* and one *para*. ***Figure 30.14*** The nitro groups are converted to the very stable N_2 upon reaching the activation energy barrier, thereby releasing heat due to the exothermic nature of the reaction.

Chapter 31

Figure 31.1 The number of C–N bonds. ***Figure 31.2*** The pyridine N is 3°, the aliphatic amine is 1°. ***Figure 31.5*** The lone pair in cyclohexylamine cannot be redistributed and so is concentrated on the nitrogen. ***Figure 31.11*** All but glycine. ***Figure 31.18*** At pH 5.66, tyrosine has no net overall charge and will not move in an electrophoresis experiment. At pH 9, tyrosine will be deprotonated and attracted to the positive electrode. ***Figure 31.25*** A molecule of specific shape is required to unlock the activity the enzyme, similar to a specific key needed to unlock a lock. ***Figure 31.28*** Negatively charged. ***Figure 31.30*** G–C. There are three hydrogen bonds holding this base pair together and there are two hydrogen bonds binding adenine to thymine.

Chapter 32

Figure 32.2 Dark-coloured cars absorb electromagnetic radiation within the visible region while light-coloured cars reflect it. ***Figure 32.5*** Lower. ***Figure 32.13*** An applied magnetic field increases the energy difference between spin-aligned and spin-not-aligned nuclei. Thermodynamically, most nuclei would like to minimise their energy and so would populate the lower energy state. ***Figure 32.18*** Deshielded. ***Figure 32.19*** Top to bottom, left to right: 2, 5, 2, 3, 1, 4, 5 signals. ***Figure 32.23*** The solvent. There is a small amount of $CHCl_3$ in the $CDCl_3$ solvent. ***Figure 32.26*** $(CH_3)_2CH$–. ***Figure 32.30*** The magnetic field only influences charged particles and so it is only the charged particles that are bent towards the detector. ***Figure 32.32***

ANSWERS TO SELECTED PRACTICE EXERCISES

Chapter 1

Sample Exercise 1.1
Practice Exercise: It is a compound because it has constant composition and can be separated into several elements.

Sample Exercise 1.2
Practice Exercise: (**a**) 10^{12} pm, (**b**) 6.0 km, (**c**) 4.22×10^{-3} g, (**d**) 0.00422 g.

Sample Exercise 1.3
Practice Exercise: (**c**) selenium, Se

Sample Exercise 1.4
Practice Exercise: (**a**) 8.96 g/cm^3, (**b**) 19.0 mL, (**c**) 340 g.

Sample Exercise 1.5
Practice Exercise: (**a**) a 500-kg motorcycle moving at 100 km/h

Sample Exercise 1.6
Practice Exercise: No. The number of cm^3 in a liter is a defined quantity and is therefore exact, but the volume represented by one cm^3 is not exact, although it is known to high accuracy.

Sample Exercise 1.7
Practice Exercise: (**c**) 4

Sample Exercise 1.8
Practice Exercise: 9.52 m/s (three significant figures).

Sample Exercise 1.9
Practice Exercise: (**e**) 2.9×10^2 g

Sample Exercise 1.10
Practice Exercise: 1.496×10^8 km

Sample Exercise 1.11
Practice Exercise: 12 km/L.

Sample Exercise 1.12
Practice Exercise: $2.24/gal

Chapter 2

Sample Exercise 2.1
Practice Exercise: (**a**) 154 pm, (**b**) 1.3×10^6 C atoms

Sample Exercise 2.2
Practice Exercise: (**d**) ^{162}Ho, (**e**) ^{159}Gd

Sample Exercise 2.3
Practice Exercise: $^{208}_{82}$Pb

Sample Exercise 2.4
Practice Exercise: 28.09 u

Sample Exercise 2.5
Practice Exercise: Na, atomic number 11, is a metal; Br, atomic number 35, is a nonmetal.

Sample Exercise 2.6
Practice Exercise: (**d**) C_4O_2, C_2O

Sample Exercise 2.7
Practice Exercise: (**b**) P^{3-}, (**d**) Se^{2-}

Sample Exercise 2.8
Practice Exercise: (**a**) Ti^{4+}, (**d**) Te^{2-}

Sample Exercise 2.9
Practice Exercise: (**a**) Rb is from Group 1, and readily loses one electron to attain the electron configuration of the nearest noble gas element, Kr. (**b**) Nitrogen and the halogens are all nonmetallic elements, which form molecular compounds with one another. (**c**) Krypton, Kr, is a noble gas element and is chemically inactive except under special conditions. (**d**) Na and K are both from Group 1 and adjacent to one another in the periodic table. They would be expected to behave very similarly. (**e**) Calcium is an active metal and readily loses two electrons to attain the noble gas configuration of Ar.

Sample Exercise 2.10
Practice Exercise: (**d**) N

Sample Exercise 2.11
Practice Exercise: (**a**) ClO^{2-}, chlorate

Sample Exercise 2.12
Practice Exercise: (**c**) Fe_2O_3, diiron oxide

Sample Exercise 2.13
Practice Exercise: (**b**) nitrous acid, (**d**) iodic acid

Sample Exercise 2.14
Practice Exercise: (**a**) carbon disulfide (**b**) carbon monoxide (**c**) tricarbon dioxide (**d**) carbon tetrabromide (**e**) carbon monofluoride.

Sample Exercise 2.15
Practice Exercise: (**a**) C_6H_{14}, (**b**) hexanol, C–6H_{14}O

Chapter 3

Sample Exercise 3.1
Practice Exercise: (**d**) 6

Sample Exercise 3.2
Practice Exercise: (**a**) 4, 3, 2; (**b**) 2, 6, 2, 3; (**c**) 1, 2, 1, 1, 1

Sample Exercise 3.3
Practice Exercise: (**d**) $2\,Ag_2O(s) \longrightarrow 4\,Ag(s) + O_2(g)$

Sample Exercise 3.4
Practice Exercise: (**b**) $2\,C_2H_4(OH)_2(l) + 5\,O_2(g) \longrightarrow 4\,CO_2(g) + 6\,H_2O(g)$

Sample Exercise 3.5
Practice Exercise: (**a**) 78.0 u, (**b**) 32.0 u, (**c**) 211.0 u

Sample Exercise 3.6
Practice Exercise: (**b**) 17.1%

Sample Exercise 3.7
Practice Exercise: (**c**) 50 g sodium chloride

Sample Exercise 3.8
Practice Exercise: (**a**) 9.0×10^{23}, (**b**) 2.71×10^{24}

Sample Exercise 3.9
Practice Exercise: (**b**) 2+

Sample Exercise 3.10
Practice Exercise: 6.05 mol

Sample Exercise 3.11
Practice Exercise: 532 g

Sample Exercise 3.12
Practice Exercise: (**c**) 1.91×10^{23}

Sample Exercise 3.13
Practice Exercise: (**b**) $COCl_2$

Sample Exercise 3.14
Practice Exercise: (**d**) C_6H_{12}

Sample Exercise 3.15
Practice Exercise: (**d**) $C_4H_8O_2$

Sample Exercise 3.16
Practice Exercise: (**a**) 3.18 g

Sample Exercise 3.17
Practice Exercise: (**d**) 3.63 g

Sample Exercise 3.18
Practice Exercise: (**a**) Al, (**b**) 1.50 mol, (**c**) 0.75 mol Cl_2

Sample Exercise 3.19
Practice Exercise: (**a**) 1.20 g As

Sample Exercise 3.20
Practice Exercise: (**b**) 96%

Chapter 4

Sample Exercise 4.1
Practice Exercise: (**a**) 6, (**b**) 12, (**c**) 2, (**d**) 9

Sample Exercise 4.2
Practice Exercise: (**b**) $CaCO_3$

Sample Exercise 4.3
Practice Exercise: (**a**) $Fe(OH)_3$,
(**b**) $Fe_2(SO_4)_3(aq) + 6\,LiOH(aq) \longrightarrow 2\,Fe(OH)_3(s) + 3\,Li_2SO_4(aq)$

Sample Exercise 4.4
Practice Exercise: $3\,Ag^+(aq) + PO_4^{3-}(aq) \longrightarrow Ag_3PO_4(s)$

Sample Exercise 4.5
Practice Exercise: (**d**) both chloric acid and hydrobromic acid

Sample Exercise 4.6
Practice Exercise: (**d**) sodium nitrate

Sample Exercise 4.7
Practice Exercise: (**d**) $NH_3(aq) + H^+(aq) \longrightarrow NH_4^+(aq)$

Sample Exercise 4.8
Practice Exercise: (**d**) H_2O_2

Sample Exercise 4.9
Practice Exercise: (**b**) Zinc is reduced, and copper ion is oxidized.

Sample Exercise 4.10
Practice Exercise: (**d**) sodium

Sample Exercise 4.11
Practice Exercise: (**c**) $3.91 \times 10^{-2}\,M$

Sample Exercise 4.12
Practice Exercise: (**e**) 2:1

Sample Exercise 4.13
Practice Exercise: (**a**) 1.1 g, (**b**) 76 mL

Sample Exercise 4.14
Practice Exercise: (**b**) 8.75 mL

Sample Exercise 4.15
Practice Exercise: (**b**) 19.5 mg

Sample Exercise 4.16
Practice Exercise: (**c**) 0.163 *M*

Sample Exercise 4.17
Practice Exercise: (**e**) 81.0%

Chapter 5

Sample Exercise 5.1
Practice Exercise: (**c**) $q < 0, w > 0$, the sign of ΔE cannot be determined from the information given

Sample Exercise 5.2
Practice Exercise: 70 J

Sample Exercise 5.3
Practice Exercise: (**d**) exothermic, negative

Sample Exercise 5.4
Practice Exercise: −14.4 kJ

Sample Exercise 5.5
Practice Exercise: (**a**) 4.9×10^5 J,
(**b**) 11 K decrease = 11 °C decrease

Sample Exercise 5.6
Practice Exercise: −68,000 J/mol = −68 kJ/mol

Sample Exercise 5.7
Practice Exercise: (**a**) −15.2 kJ/g, (**b**) −1370 kJ/mol

Sample Exercise 5.8
Practice Exercise: (**d**) −171.0 kJ

Sample Exercise 5.9
Practice Exercise: −304.1 kJ

Sample Exercise 5.10
Practice Exercise: $C(graphite) + 2\,Cl_2(g) \longrightarrow CCl_4(l)$;
$\Delta H_f^\circ = -106.7$ kJ/mol.

Sample Exercise 5.11
Practice Exercise: (**b**) −196.0 kJ

Sample Exercise 5.12
Practice Exercise: (**c**) $2\Delta H_f^\circ[SO_3] = \Delta H_{rxn}^\circ + 2\Delta H_f^\circ[SO_2]$

Sample Exercise 5.13
Practice Exercise: −1255 kJ

Sample Exercise 5.14
Practice Exercise: (**a**) 15 kJ/g, (**b**) 100 min

Chapter 6

Sample Exercise 6.1
Practice Exercise: 34.5 μm

Sample Exercise 6.2
Practice Exercise: (**a**) $1.43 \times 10^{14}\,s^{-1}$, (**b**) 2.899 m

Sample Exercise 6.3
Practice Exercise: (**e**) $E = N_A \frac{hc}{\lambda}$

Sample Exercise 6.4
Practice Exercise: (**a**) 3

Sample Exercise 6.5
Practice Exercise: (**a**) i < iii < ii

Sample Exercise 6.6
Practice Exercise: (**a**) $5p$; (**b**) 3; (**c**) 1, 0, −1

Sample Exercise 6.7
Practice Exercise: (**a**) $1s^2 2s^2 2p^6 3s^2 3p^2$, (**b**) two

Practice Exercise: Group 14

Sample Exercise 6.9
Practice Exercise: (**b**) Te

Chapter 7

Sample Exercise 7.1
Practice Exercise: P−Br

Sample Exercise 7.2
Practice Exercise: C < Be < Ca < K

Sample Exercise 7.3
Practice Exercise: (**b**) F < Cl < S^{2-} < Se^{2-}

Sample Exercise 7.4
Practice Exercise: (**a**) $Sr^{2+} < Rb^+ < Br^- < Se^{2-} < Te^{2-}$

Sample Exercise 7.5
Practice Exercise: (**e**) $Br^{2+}(g) \longrightarrow Br^{3+}(g) + e^-$

Sample Exercise 7.6
Practice Exercise: (**d**) Statements (ii) and (iii) are true.

Sample Exercise 7.7
Practice Exercise: (**a**) $[Kr]4d^4$

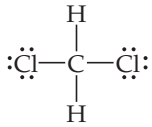
Sample Exercise 7.8
Practice Exercise: (**e**) $M(OH)_3(aq)$

Sample Exercise 7.9
Practice Exercise: (**c**) 3

Sample Exercise 7.10
Practice Exercise: (**e**) All three statements are true.

Chapter 8

Sample Exercise 8.1
Practice Exercise: (**b**) ScN > MgO > NaCl > CsI



Sample Exercise 8.2
Practice Exercise: Mg^{2+} and N^{3-}

Sample Exercise 8.3
Practice Exercise: (**b**) H_2S

Sample Exercise 8.4
Practice Exercise: (**a**) H—F

Sample Exercise 8.5
Practice Exercise: (**a**) F, (**b**) 0.11−

Sample Exercise 8.6
Practice Exercise: (**a**) 20, (**b**)

Sample Exercise 8.7
Practice Exercise: (**a**) zero

Sample Exercise 8.8
Practice Exercise: (**b**) 6

Sample Exercise 8.10
Practice Exercise: (**d**) The cyanide ion has only one dominant resonance structure.

Sample Exercise 8.11
Practice Exercise: (**a**) C, (**b**)

Chapter 9

Sample Exercise 9.1
Practice Exercise: (**a**) tetrahedral, bent; (**b**) trigonal planar, trigonal planar

Sample Exercise 9.2
Practice Exercise: (**d**) Statements (ii) and (iii) are true.

Sample Exercise 9.3
Practice Exercise: (**a**) 109.5° and 109.5°

Sample Exercise 9.4
Practice Exercise: (**b**) Trigonal planar

Sample Exercise 9.5
Practice Exercise: (**c**) O_3

Sample Exercise 9.6
Practice Exercise: (**e**) All three statements are true.

Sample Exercise 9.7
Practice Exercise: (**b**) 4

Sample Exercise 9.8
Practice Exercise: (**c**) 2

Sample Exercise 9.9
Practice Exercise: (**e**) $F_2^- < C_2^{2+} < O_2^- < N_2^-$

Chapter 10

Sample Exercise 10.1
Practice Exercise: (**d**) 10.3 m

Sample Exercise 10.2
Practice Exercise: 107.6 kPa

Sample Exercise 10.3
Practice Exercise: 5.30×10^3 L

Sample Exercise 10.4
Practice Exercise: 202.65 kPa

Sample Exercise 10.5
Practice Exercise: $3.83 \times 10^3\ m^3$

Sample Exercise 10.6
Practice Exercise: 27 °C

Sample Exercise 10.7
Practice Exercise: 5.9 g/L

Sample Exercise 10.8
Practice Exercise: (**c**) 44.1 g/mol

Sample Exercise 10.9
Practice Exercise: 14.8 L

Sample Exercise 10.10
Practice Exercise: 289.8 kPa

Sample Exercise 10.11
Practice Exercise: (**b**) 0.33

Sample Exercise 10.12
Practice Exercise: (**b**) The C_3H_8 and CH_4 molecules have the same average kinetic energy

Sample Exercise 10.13
Practice Exercise: (**a**) four, will not change

Sample Exercise 10.14
Practice Exercise: $r_{N_2}/r_{O_2} = 1.07$

Sample Exercise 10.15
Practice Exercise: (**a**) 756.6 kPa, (**b**) 727.1 kPa

Chapter 11

Sample Exercise 11.1
Practice Exercise: (**d**) hydrogen peroxide, H_2O_2

Sample Exercise 11.2
Practice Exercise: (**d**) $CH_3COOH < Cl_2 < Ar < CH_4$

Sample Exercise 11.3
Practice Exercise: (**d**) heat of vaporization and specific heat of $H_2O(l)$

Sample Exercise 11.4
Practice Exercise: about 45 kPa

Sample Exercise 11.5
Practice Exercise: (**a**) −162 °C; (**b**) It sublimes whenever the pressure is less than 10 kPa; (**c**) The highest temperature at which a liquid can exist is defined by the critical temperature. So we do not expect to find liquid methane when the temperature is higher than −80 °C.

Sample Exercise 11.6
Practice Exercise: (**e**) rod-shaped molecules

Chapter 12

Sample Exercise 12.1
Practice Exercise: (**e**) 78.5%

Sample Exercise 12.2
Practice Exercise: $a = 402$ pm and density $= 4.31\ g/cm^3$

Sample Exercise 12.3
Practice Exercise: smaller.

Sample Exercise 12.4
Practice Exercise: A Group 15 element could be used to replace Se.

Chapter 13

Sample Exercise 13.2
Practice Exercise: (**d**) There are twice as many gas molecules in the liquid.

Sample Exercise 13.3
Practice Exercise: (**d**) 2.91%

Sample Exercise 13.4
Practice Exercise: (**c**) It is unchanged.

Sample Exercise 13.5
Practice Exercise: (**b**) 1.80×10^{-5}

Sample Exercise 13.6
Practice Exercise: (**a**) 10.9 *m*, (**b**) $X_{C_3H_8O_3} = 0.163$, (**c**) 5.97 *M*

Sample Exercise 13.7
Practice Exercise: 0.290

Sample Exercise 13.8
Practice Exercise: (**b**) 0.15 *m* NaCl

Sample Exercise 13.9
Practice Exercise: (**d**) increasing the temperature

Sample Exercise 13.10
Practice Exercise: (**d**) norfenefrine

Sample Exercise 13.11
Practice Exercise: 4.20×10^4 g/mol

Chapter 14

Sample Exercise 14.1
Practice Exercise: (**e**) All three statements are true.

Sample Exercise 14.2
Practice Exercise: (**d**) $2.7 \times 10^{-5}\ M/s$

Sample Exercise 14.3
Practice Exercise: (**c**) $2\ A \longrightarrow B + 3\ C$

Sample Exercise 14.4
Practice Exercise: (**e**) $3 < 1 < 2$

Sample Exercise 14.5
Practice Exercise: (**a**) $M^{-1/2}s^{-1}$

Sample Exercise 14.7
Practice Exercise:

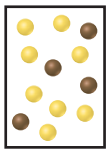
Sample Exercise 14.8
Practice Exercise: (**b**) Statements (i) and (ii) are true.

Sample Exercise 14.9
Practice Exercise: (**a**) 0.478 yr = 1.51×10^7 s, (**b**) it takes two half-lives, 2(0.478 yr) = 0.956 yr

Sample Exercise 14.10
Practice Exercise: (**a**) Only one—(i), or (ii), or (iii)—increases the reaction rate.

Sample Exercise 14.12
Practice Exercise: (**c**) Statements (i) and (iii) are true.

Sample Exercise 14.13
Practice Exercise: (**e**) $A + B \longrightarrow X + Z$



Sample Exercise 14.15
Practice Exercise: (**c**) Rate $= k[P]^2[Q]$

Chapter 15

Sample Exercise 15.1
Practice Exercise: (**c**) $K_c = \dfrac{[SO_3]^2}{[SO_2]^2[O_2]}$

Sample Exercise 15.2
Practice Exercise: (**c**) $Ni(CO)_4(g) \rightleftharpoons Ni(s) + 4\,CO(g)$

Sample Exercise 15.3
Practice Exercise:

(b)

Sample Exercise 15.4
Practice Exercise: (**d**) 1.8×10^2

Sample Exercise 15.5
Practice Exercise: (**e**) neither $[Ag^+]$ nor $[Cl^-]$ will change

Sample Exercise 15.6
Practice Exercise: (**d**) Increasing the volume of the vessel

Sample Exercise 15.7
Practice Exercise: 1.79×10^{-5}

Sample Exercise 15.8
Practice Exercise: (**d**) 1.4

Sample Exercise 15.9
Practice Exercise: (**c**) The direction of this reaction does not depend on the volume of the container.

Sample Exercise 15.10
Practice Exercise: 127.5 kPa

Sample Exercise 15.11
Practice Exercise: $P_{PCl_5} = 97.94$ kPa, $P_{PCl_3} = P_{Cl_2} = 70.26$ kPa

Sample Exercise 15.12
Practice Exercise: (**a**) right, (**b**) left, (**c**) right, (**d**) left

Chapter 16

Sample Exercise 16.1
Practice Exercise: (**b**) HSO_4^- and H_2O

Sample Exercise 16.2
Practice Exercise: (**c**) i and iii

Sample Exercise 16.3
Practice Exercise: (**e**) iii < ii < i

Sample Exercise 16.4
Practice Exercise: (**a**) $1.0 \times 10^{-8}\,M$

Sample Exercise 16.5
Practice Exercise: (**c**) $2.5 \times 10^{-7}\,M$

Sample Exercise 16.6
Practice Exercise: (**d**) 11.83

Sample Exercise 16.7
Practice Exercise: (**e**) All three statements are true.

Sample Exercise 16.8
Practice Exercise: (**c**) iii < i < ii

Sample Exercise 16.9
Practice Exercise: (**e**) iii < ii < i

Sample Exercise 16.10
Practice Exercise: (**c**) 6.6×10^{-5}

Sample Exercise 16.11
Practice Exercise: (**e**) 9.0%

Sample Exercise 16.12
Practice Exercise: (**a**) 2.30

Sample Exercise 16.13
Practice Exercise: (**e**) 2.64

Sample Exercise 16.14
Practice Exercise: (**b**) 2.32

Sample Exercise 16.15
Practice Exercise: (**c**) 9.52

Sample Exercise 16.16
Practice Exercise: (**a**) 0.38

Sample Exercise 16.17
Practice Exercise: (**d**) ii < iii < i

Sample Exercise 16.18
Practice Exercise: (**e**) iii < ii < i

Sample Exercise 16.19
Practice Exercise: (**c**) 2

Sample Exercise 16.20
Practice Exercise: (**b**) $HOI < HIO_2 < HBrO_2 < HClO_2 < HClO_3$

Chapter 17

Sample Exercise 17.1
Practice Exercise: (**d**) If you add the soluble salt KA to a solution of HA that is at equilibrium, the pH would increase.

Sample Exercise 17.2
Practice Exercise: (**e**) $1.73 \times 10^{-4}\,M$

Sample Exercise 17.3
Practice Exercise: (**c**) The acid and base concentrations must be equal.

Sample Exercise 17.4
Practice Exercise: (**b**) 0.174

Sample Exercise 17.5
Practice Exercise: (**a**) 60.7 g

Sample Exercise 17.6
Practice Exercise: (**e**) In order to do calculations in which a strong acid or base is added to a buffer, you need to calculate the amounts of substances from the neutralization reaction and then equilibrate.

Sample Exercise 17.7
Practice Exercise: (**e**) At the equivalence point, the OH^- concentration in the solution is $3.67 \times 10^{-3}\,M$.

Sample Exercise 17.8
Practice Exercise: (**b**) Halfway to the equivalence point, $pH = pK_a$.

Sample Exercise 17.9
Practice Exercise: (**d**) The conjugate base that is formed at the equivalence point reacts with water.

Sample Exercise 17.10
Practice Exercise: (**c**) $[Ag^+]^3[PO_4^{3-}]$

Sample Exercise 17.11
Practice Exercise: (**e**) 1.40×10^{-37}

Sample Exercise 17.12
Practice Exercise: (**b**) cobalt(II) hydroxide, $K_{sp} = 1.3 \times 10^{-15}$

Sample Exercise 17.13
Practice Exercise: (**d**) Raising the temperature of the solution.

Sample Exercise 17.14
Practice Exercise: (**e**) none of these

Sample Exercise 17.15
Practice Exercise: (**c**) The precipitate was chromium hydroxide, which then reacted with more hydroxide to produce a soluble complex ion, $Cr(OH)_4^-(aq)$.

Sample Exercise 17.16
Practice Exercise: (**a**) Yes

Sample Exercise 17.17
Practice Exercise: (**c**) when Q exceeds K_{sp}

Chapter 18

Sample Exercise 18.1
Practice Exercise: 4.0×10^{-4} kPa

Sample Exercise 18.2
Practice Exercise: (**a**) 620 nm

Sample Exercise 18.3
1.5×10^4 g CO_2 or 15 kg CO_2

Chapter 19

Sample Exercise 19.1
Practice Exercise: (**d**) Equilibrium is achieved in a closed system when the rate of iron oxidation is equal to the rate of iron(III) oxide reduction.

Sample Exercise 19.2
Practice Exercise: (**a**) Yes, because the heat transferred from the system has a negative sign.

Sample Exercise 19.3
Practice Exercise: (**a**) $CO_2(s) \longrightarrow CO_2(g)$

Sample Exercise 19.4
Practice Exercise: (**a**) 1 mol of $SO_2(g)$ at STP, (**b**) 2 mol of $NO_2(g)$ at STP

Sample Exercise 19.5
Practice Exercise: (**a**) 326.3 J/K

Sample Exercise 19.6
Practice Exercise: (**d**) All spontaneous reactions have a negative free-energy change

Sample Exercise 19.7
Practice Exercise: (**b**) $\Delta G_1^\circ = 2\,\Delta G_2^\circ$

Sample Exercise 19.8
Practice Exercise: (**b**) The reaction is nonspontaneous at all temperatures

Sample Exercise 19.9
Practice Exercise: (**d**) 193 °C

Sample Exercise 19.10
Practice Exercise: (**c**) +34,000 J

Sample Exercise 19.11
Practice Exercise: (**e**) If $Q > 1$, $\Delta G > \Delta G^\circ$.

Sample Exercise 19.12
Practice Exercise: (**e**) +265 kJ/mol

Chapter 20

Sample Exercise 20.1
Practice Exercise: (**a**) $Br^-(aq)$

Sample Exercise 20.2
Practice Exercise: (**d**) Seven on the product side

Sample Exercise 20.3
Practice Exercise: (**a**) One on the reactant side

Sample Exercise 20.4
Practice Exercise: (**b**) The electrode is gaining mass and cations from the salt bridge are flowing into the half-cell.

Sample Exercise 20.5
Practice Exercise: (**a**) −0.35 V

Sample Exercise 20.6
Practice Exercise: (**e**) +0.80 V

Sample Exercise 20.7
Practice Exercise: (**d**) Cells 1 and 2

Sample Exercise 20.8
Practice Exercise: (**b**) $Cl_2(g)$

Sample Exercise 20.9
Practice Exercise: **d**) Cl_2 and Br_2

Sample Exercise 20.10
Practice Exercise: (**d**) −0.13 V

Sample Exercise 20.11
Practice Exercise:(**b**) 0.56 V

Sample Exercise 20.12
Practice Exercise: (**e**) $7.6 \times 10^{-3}\,M$

Sample Exercise 20.13
Practice Exercise: (**a**) The anode is the half-cell in which $[Zn^{2+}] = 3.75 \times 10^{-4}\,M$. (**b**) The emf is 0.105 V.

Sample Exercise 20.14
Practice Exercise: (**c**) 62 min

Chapter 21

Sample Exercise 21.1
Practice Exercise: (**b**) Uranium-234

Sample Exercise 21.2
Practice Exercise: (**a**) Alpha decay followed by beta emission

Sample Exercise 21.3
Practice Exercise: (**d**) iodine-131

Sample Exercise 21.4
Practice Exercise: (**e**) $^{239}_{93}Np$

Sample Exercise 21.5
Practice Exercise: (**b**) 6.0 h

Sample Exercise 21.6
Practice Exercise: (**d**) 45.5 yr

Sample Exercise 21.7
Practice Exercise: (**e**) 178 yr

Sample Exercise 21.8
Practice Exercise: -3.19×10^{-3} g

Chapter 22

Sample Exercise 22.1
Practice Exercise: (**d**) Oxygen is better able to form π bonds than sulfur.

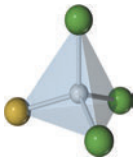
Sample Exercise 22.2
Practice Exercise: (**d**) C_2H_2

Sample Exercise 22.3
Practice Exercise: (**c**) trigonal bipyramidal, T shaped

Sample Exercise 22.4
Practice Exercise: (**a**) F_2

Sample Exercise 22.5
Practice Exercise: $N_2H_4(aq) + O_2 \longrightarrow N_2(g)_2 + H_2O(l)$

Sample Exercise 22.6
Practice Exercise: (**d**) $BeAl_2Si_6O_{15}$?



Chapter 23

Sample Exercise 23.1
Practice Exercise: (**b**) $[Rh(NH_3)_4Cl_2]Cl$

Sample Exercise 23.2
Practice Exercise: (**c**) $Rb_3[MoO_3F_3]$

Sample Exercise 23.3
Practice Exercise: (**c**) Tetraamminedichloridorhodium(III) chloride

Sample Exercise 23.4
Practice Exercise:

$[MX_3Y]$
(a)

Sample Exercise 23.5
Practice Exercise: (**d**) Tetrahedral $[Co(NH_3)BrClI]^-$

Sample Exercise 23.6
Practice Exercise: (**d**) orange

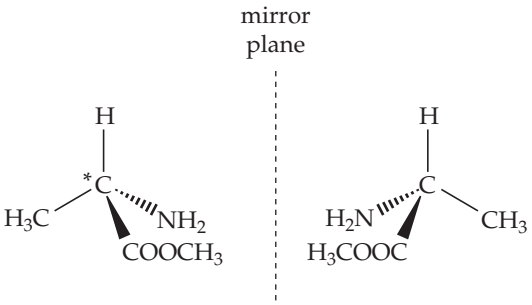
Sample Exercise 23.7
Practice Exercise: (**d**) $[RhCl_6]^{3-}$

Sample Exercise 23.8
Practice Exercise: (**e**) 5

Chapter 24

Sample Exercise 24.1
Practice Exercise: 2,4-dimethylpentane

Sample Exercise 24.2
Practice Exercise:



$CH_3CH(CH_3)CH(CH_3)CH_2CH_2CH_3$ or $CH_3CH(CH_3)CH(CH_3)CH_2CH_2CH_3$

Sample Exercise 24.3
Practice Exercise: $2\ C_6H_{14}(g) + 19\ O_2(g)$: $12\ CO_2(g) + 14\ H_2O(l)$

Chapter 25

Sample Exercise 25.1
Practice Exercise: *trans*-1,3-dimethylcyclopentanes

Sample Exercise 25.2
Practice Exercise:

Sample Exercise 25.3
Practice Exercise: $[\alpha]_D = +30°$. This value is lower than that listed in Table 25.1; hence the sample contains a small amount of the other enantiomer.

Sample Exercise 25.4
Practice Exercise: (**a**) *R*, (**b**) *S*

Chapter 26

Sample Exercise 26.1
Practice Exercise: (**a**) Approximately 109° around the left C and 180° on the right C; (**b**) sp^3, sp; (**c**) five σ-bonds and two π-bonds

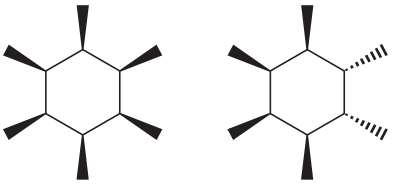
Sample Exercise 26.2
Practice Exercise: (**a**) The molecule has $2 \times sp$, $2 \times sp^2$ and $1 \times sp^3$ hybridised carbon atoms. (**b**) The molecule has $5 \times sp^3$ and $1 \times sp^2$ hybridised carbon atoms.

Sample Exercise 26.3
Practice Exercise: Five (hex-1-ene, *cis*-hex-2-ene, *trans*-hex-2-ene, *cis*-hex-3-ene, *trans*-hex-3-ene)

Sample Exercise 26.4
Practice Exercise:

$CH_3—C{\equiv}C—CH(CH_3)—CH_3$

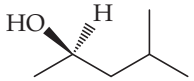
Sample Exercise 26.5
Practice Exercise: SO_3^{2-} and O_3, as indicated by the presence of two or more resonance structures involving π-bonding for each of these molecules.



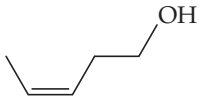
Sample Exercise 26.6
Practice Exercise: 3-methylbut-1-ene

Sample Exercise 26.7
Practice Exercise:

major minor

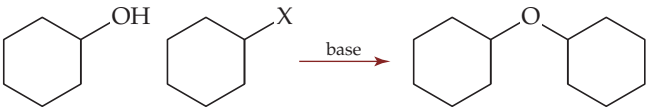


Sample Exercise 26.8
Practice Exercise: There are two products which, as line drawings, are:



Chapter 27

Sample Exercise 27.1
Practice Exercise: $C_5H_{12} < C_5H_{11}Cl < C_5H_{11}OH < C_5H_{10}(OH)_2$ (in order of increasing polarity and hydrogen-bonding ability)

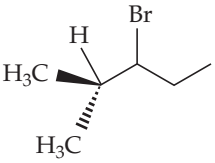


Sample Exercise 27.2
Practice Exercise:

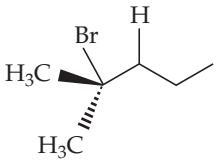
(a) 

(b) 

Sample Exercise 27.3
Practice Exercise: There are four 2° and one 3° OH groups (around the ring), and one 1° OH group.



Sample Exercise 27.4
Practice Exercise: There are two parts to answering this question. Disconnection of the ether leads to the following reaction:



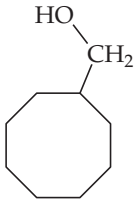
X = Cl, Br, I

The haloalkane can be synthesised from cyclohexanol by treatment with a haloacid (HCl, HBr, HI, respectively) or use of $SOCl_2$ in the case where X = Cl.

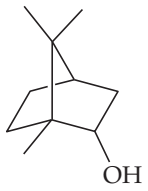
Sample Exercise 27.5
Practice Exercise: There are two answers but only one is realistic. Both these haloalkanes will yield the desired product:

III

IV



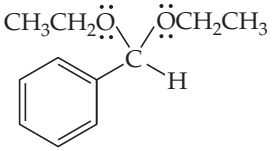
However, in the case of III, the *β*-hydrogen that leads to the product is sterically hindered by the two methyl groups on one carbon atom and the bromine atom and ethyl group on the adjacent carbon atom. This steric concern is further enhanced by the use of potassium *tert*-butoxide which is also very bulky. Compound IV is not hindered as much and so is the better choice of haloalkane.



Sample Exercise 27.6
Practice Exercise: 2-methylpropene

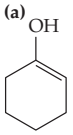
Chapter 28

Sample Exercise 28.1
Practice Exercise: (**a**) (*S*)-2-methylcyclohexanone, (**b**) (*S*)-4-hydroxypentan-2-one

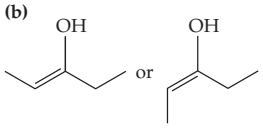


Sample Exercise 28.2
Practice Exercise:

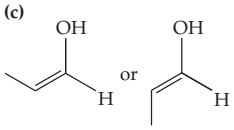
(a) 



(b) 



Sample Exercise 28.3
Practice Exercise: (**a**) Mg in diethyl ether, (**b**) formaldehyde

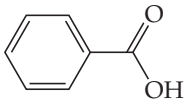


Sample Exercise 28.4
Practice Exercise:

Sample Exercise 28.5
Practice Exercise:

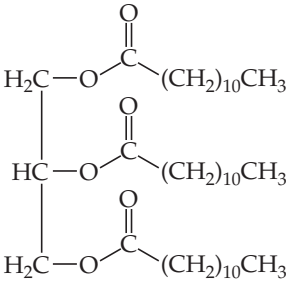
(a) 

(b) 



(c) 

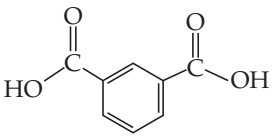
Sample Exercise 28.6
Practice Exercise: (**a**) L-aldopentose, (**b**) L-ketopentose, (**c**) D-aldohexose

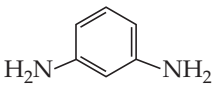


Chapter 29

Sample Exercise 29.1
Practice Exercise: a < e < b < c < d

Sample Exercise 29.2
Practice Exercise:





Sample Exercise 29.4
Practice Exercise:

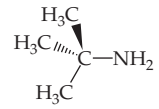
Sample Exercise 29.5
Practice Exercise: In both cases a hydrophobic tail and polar head group are present. The difference lies in both the nature of the head group (negatively or positively charged) and in its functionality.

Sample Exercise 29.6
Practice Exercise: This is a polyamide, a step-growth polymer. The monomers that are used to prepare it are:

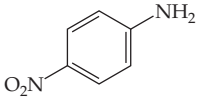
Chapter 30

Sample Exercise 30.1
Practice Exercise: phenol < 2,4-dichlorophenol < 4-nitro- 2-chlorophenol < 2,6-dinitrophenol

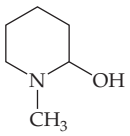
Sample Exercise 30.2
Practice Exercise: chlorobenzene



Sample Exercise 30.3
Practice Exercise: (**a**) Being an alkyl group, the *tert*-butyl group would be activating. In this case the rate is ~15 times faster than that for benzene. (**b**) The *para* position is favoured for nitration. Being an alkyl group means the *tert*-butyl group is *o, p*-directing. However, because of its bulk, *para* substitution is more likely.

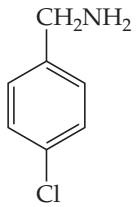


Sample Exercise 30.4
Practice Exercise: anisole

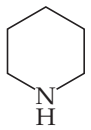


Chapter 31

Sample Exercise 31.1
Practice Exercise: Spermine contains primary and secondary amines. The primary amines occupy positions at the end of the chain. The secondary amines appear within the chain.

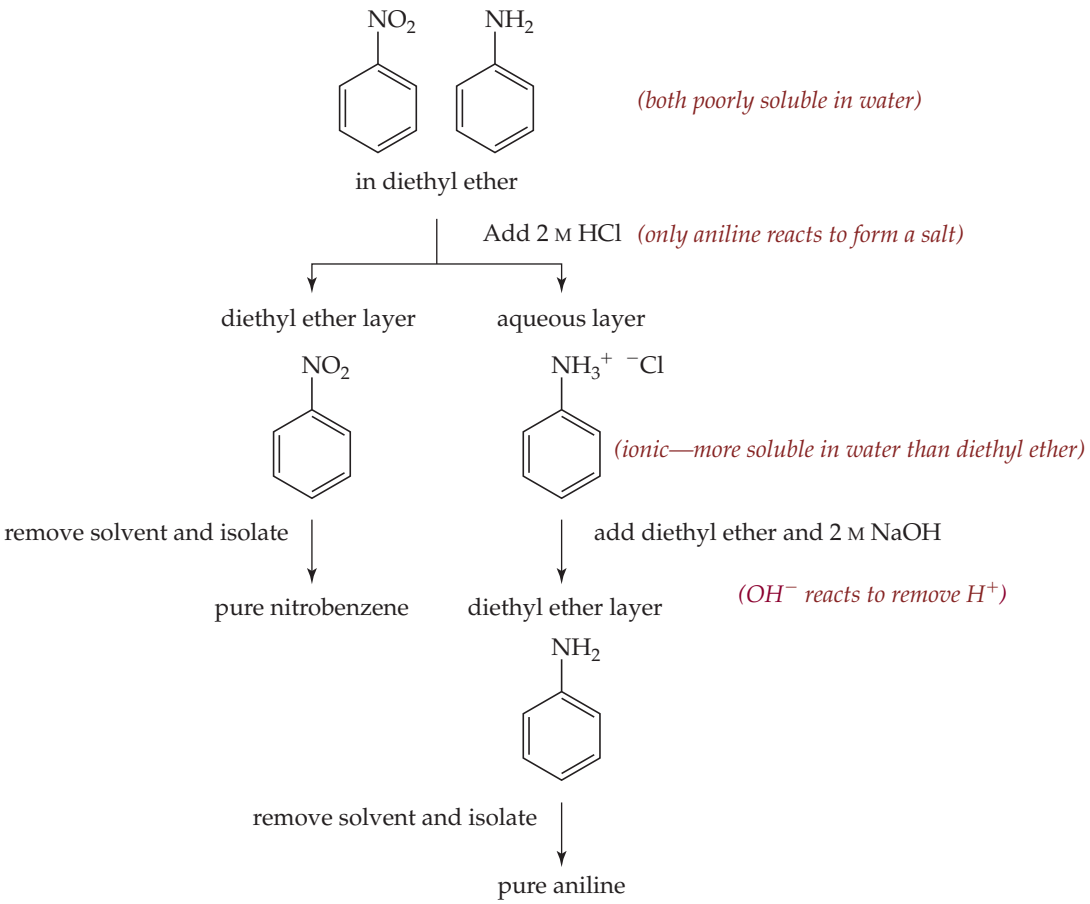


Sample Exercise 31.2
Practice Exercise:



(a)

(b)



(c)

Sample Exercise 31.3
Practice Exercise:

(a)

(b)

Sample Exercise 31.4
Practice Exercise: The easiest way to achieve the separation is to take advantage of the basicity of aniline and the solubility of the resultant ammonium salt (**Comment:** This method is quite general. Any basic organic compound can be separated from a non-basic one in this way).

Sample Exercise 31.5
Practice Exercise:

At pH 2 $^{+}H_3NCHRCO_2H$

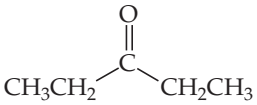
At pH 7 $^{+}H_3NCHRCO_2^{-}$

At pH 10 $H_2NCHRCO_2^{-}$

R = CH_2OH

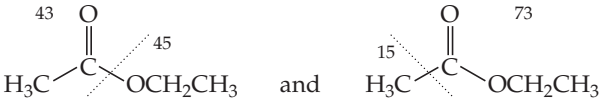
Sample Exercise 31.7
Practice Exercise: Serylaspartic acid: Ser-Asp, SD

Sample Exercise 31.8
Practice Exercise: Gly-Ala-Phe-Tyr-His-Glu



Chapter 32

Sample Exercise 32.1
Practice Exercise: (**a**) Cyclohexene shows a weak but characteristic C=C stretching absorption at 1600–1680 cm–1. (**b**) Both show an N–H absorption, but acetamide (being an amide) has a C=O absorption at 1600–1680 cm-1.



Sample Exercise 32.2
Practice Exercise: (**a**) 4, (**b**) 5

Sample Exercise 32.3
Practice Exercise: Draw the two possibilities. The Markovnikov product is symmetrical, which leads to only two absorptions in either the ^{1}H or ^{13}C NMR spectrum.

Sample Exercise 32.4
Practice Exercise: Check for symmetry by comparing the integration with the number of hydrogens in the molecular formula. The structure is

Sample Exercise 32.5
Practice Exercise: Fragmentation around the carbonyl group yielding acylium cations is extremely likely. For example:

Sample Exercise 32.6
Practice Exercise: (**a**) C_3H_8O, (**b**) $C_4H_8O_2$

GLOSSARY

absolute configuration The configuration of a molecule defined unambiguously using the Cahn–Ingold–Prelog rules. (Section 25.5)

absolute zero The temperature at which all thermal motion ceases: 0 K on the Kelvin scale and −273.15 °C on the Celsius scale. (Section 1.5)

absorption spectrum A pattern of variation in the amount of light absorbed by a sample as a function of wavelength. (Section 23.5)

accuracy A measure of how closely individual measurements agree with the correct, or "true," value. (Section 1.6)

acetals The product formed by the reaction of an aldehyde or ketone with two moles of an alcohol. (Section 28.3)

achiral A term used to describe molecules with a plane of symmetry that is superimposable on its mirror image. (Section 25.3)

acid A substance that is able to donate a H^+ ion (a proton) and, hence, increases the concentration of $H^+(aq)$ when it dissolves in water. (Section 4.3)

acid anhydrides An organic compound that has two carbonyl groups linked by a single oxygen. (Section 29.5)

acid halides A compound with molecular formula RCOX, where R = alkyl, aryl and X = halogen substituent. (Section 29.5)

activated (Section 30.5)

activating group A substituent that increases the reactivity of an aromatic ring. (Section 30.5)

active site Specific site on a heterogeneous catalyst or an enzyme where catalysis occurs. (Section 31.3)

acyl groups The group R—C(=O)—, where R = alkyl, aryl. (Section 29.5)

acid-dissociation constant (K_a) An equilibrium constant that expresses the extent to which an acid transfers a proton to solvent water. (Section 16.5)

acidic anhydride (acidic oxide) An oxide that forms an acid when added to water; soluble nonmetal oxides are acidic anhydrides. (Section 22.5)

acidic oxide (acidic anhydride) An oxide that reacts either with a base to form a salt or with water to form an acid. (Section 22.5)

acid rain Rainwater that has become excessively acidic because of absorption of pollutant oxides, notably SO_3, produced by human activities. (Section 18.2)

actinide element Element in which the 5*f* orbitals are only partially occupied. (Section 6.8)

activated complex (transition state) The particular arrangement of atoms found at the top of the potential-energy barrier as a reaction proceeds from reactants to products. (Section 14.5)

activation energy (E_a) The minimum energy needed for reaction; the height of the energy barrier to formation of products. (Section 14.5)

active site Specific site on a heterogeneous catalyst or an enzyme where catalysis occurs. (Section 14.7)

activity The decay rate of a radioactive material, generally expressed as the number of disintegrations per unit time. (Section 21.3)

activity series A list of metals in order of decreasing ease of oxidation. (Section 4.4)

addition polymerization Polymerization in which monomers are coupled through their multiple bonds. (Section 12.5)

addition polymerizations Polymerisation that occurs through coupling of monomers with one another, with no other products formed in the reaction. (Section 26.6)

addition polymer A polymer formed from alkenes by a free-radical process. (Section 26.6)

addition reaction A reaction in which a reagent adds to the two carbon atoms of a carbon–carbon multiple bond. (Section 24.3)

addition reactions A reaction in which a reagent adds to the two carbon atoms of a carbon–carbon multiple bond. (Section 26.4)

adsorption The binding of molecules to a surface. (Section 14.7)

alcohols An organic compound obtained by substituting a hydroxyl group (—OH) for a hydrogen on a hydrocarbon. (Sections 2.9, 24.4, 24.6 and 27.1)

aldehyde An organic compound that contains a carbonyl group (C=O) to which at least one hydrogen atom is attached. (Section 24.4)

aldehyde An organic compound that contains a carbonyl group to which at least one hydrogen atom is attached. (Section 28.1)

aldoses A carbohydrate that contains an aldehyde group when in its open-chain form. (Section 28.4)

aliphatic amines An amine in which alkyl chains are bonded to nitrogen. (Section 31.1)

alkali metals Members of group 1 in the periodic table. (Section 7.7)

alkaloids A large class of naturally occurring compounds with biological activity. Alkaloids are cyclic amines derived from plant material and contain a basic nitrogen atom. (Section 31.1)

alkaline earth metals Members of group 2 in the periodic table. (Section 7.7)

alkanes Compounds of carbon and hydrogen containing only carbon–carbon single bonds. (Sections 2.9 and 24.2)

alkenes Hydrocarbons containing one or more carbon–carbon double bonds. (Section 26.1)

alkoxide The conjugate base of an alcohol. (Section 27.4)

alkoxy (–OR) **group** A group of the form –OR, where R is generally alkyl or aryl. (Section 27.3)

alkyl ammonium salt An ionic class of molecule containing four groups around nitrogen, of which one is an alkyl group; for example, R_3NH^+, $R_2NH_2^+$, RNH_3^+, where R = alkyl group. (Section 27.5 and 31.1)

alkyl group A group that is formed by removing a hydrogen atom from an alkane. (Section 24.2)

alkynes Hydrocarbons containing one or more carbon–carbon triple bonds. (Section 24.2)

alloy A substance that has the characteristic properties of a metal and contains more than one element. Often there is one principal metallic component, with other elements present in smaller amounts. Alloys may be homogeneous or heterogeneous. (Section 12.2)

alpha emission A type of radioactive decay in which an atomic nucleus emits an alpha particle and thereby transforms (or "decays") into an atom with a mass number 4 less and atomic number 2 less. (Section 21.1)

alpha (α) helix A protein structure in which the protein is coiled in the form of a helix with hydrogen bonds between C=O and N—H groups on adjacent turns. (Section 24.7)

alpha particles Particles that are identical to helium-4 nuclei, consisting of two protons and two neutrons, symbol ^4_2He or $^4_2\alpha$. (Section 21.1)

amide An organic compound that has an NR_2 group attached to a carbonyl. (Section 29.5)

amides An organic compound that has an NR_2 group attached to a carbonyl, where R may be H or a hydrocarbon group. (Section 24.4)

amines A compound that has the general formula R_3N, where R may be H or a hydrocarbon group. (Section 16.6, 27.5 and 30.1)

amino acid A carboxylic acid that contains an amino (—NH_2) group attached to the carbon atom adjacent to the carboxylic acid (—COOH) functional group. (Section 24.7 and Section 31.2)

α-amino acid An amino acid in which the carboxylic acid and amine groups are bonded through the same carbon atom. (Section 31.2)

amino group A nitrogen-containing group of the type –NH_2, –NHR or –NR_2. (Section 31.1)

amorphous solid A solid whose molecular arrangement lacks the order (regularly repeating long-range pattern) of a crystal. (Section 12.1)

amphiprotic Refers to the capacity of a substance to either add or lose a proton (H^+). (Section 16.1)

amphiprotic Refers to the capacity of a substance to either lose or gain a proton; that is, to act as an acid or a base. (Section 31.2)

amphoteric oxides and hydroxides Oxides and hydroxides that are only slightly soluble in water but that dissolve in either acidic or basic solutions. (Section 17.5)

amylopectins A branched derivative of starch, a polysaccharide. (Section 28.4)

amyloses An unbranched derivative of starch, a polysaccharide. (Section 28.4)

angstrom A common non-SI unit of length, denoted Å, that is used to measure atomic dimensions: $1Å = 10^{-10}$ m. (Section 2.3)

anion A negatively charged ion. (Section 2.7)

anode An electrode at which oxidation occurs. (Section 20.3)

anomeric carbon The new stereocentre formed in a monosaccharide as a result of intramolecular hemiacetal formation. (Section 28.4)

anomers Diastereoisomers that are formed about the anomeric carbon upon hemiacetal formation. The two forms are α and β anomers. (Section 28.4)

antibonding molecular orbital A molecular orbital in which electron density is concentrated outside the region between the two nuclei of bonded atoms. Such orbitals, designated as σ^* or π^*, are less stable (of higher energy) than bonding molecular orbitals. (Section 9.7)

antiferromagnetism A form of magnetism in which unpaired electron spins on adjacent sites point in opposite directions and cancel each other's effects. (Section 23.1)

antioxidants Compounds able to terminate the harmful effects of naturally occurring free radicals. (Section 24.7)

aqueous solution A solution in which water is the solvent. (Section 4.1)

arene Hydrocarbon compounds that contain a planar, cyclic arrangement of carbon atoms linked by both σ-bonds and delocalised π-bonds. (Section 30.1)

aromatic amines An amine in which at least one aryl group is bonded to nitrogen, or the nitrogen forms part of the aromatic unit, as in pyridine. (Section 31.1)

aromatic hydrocarbons Hydrocarbon compounds that contain a planar, cyclic arrangement of carbon atoms linked by both σ and delocalized π bonds. (Section 24.2)

aromatic hydrocarbon Hydrocarbon compounds that contain a planar, cyclic arrangement of carbon atoms linked by both σ-bonds and delocalised π-bonds. (Section 30.1)

Arrhenius equation An equation that relates the rate constant for a reaction to the frequency factor, A, the activation energy, E_a, and the temperature, T: $k = Ae^{-E_a/RT}$. In its logarithmic form it is written $\ln k = -E_a/RT + \ln A$. (Section 14.5)

atmosphere (atm) A unit of pressure equal to 760 torr; 1 atm = 101.325 kPa. (Section 10.2)

atom The smallest representative particle of an element. The almost infinitesimally small building blocks of matter. (Sections 1.1 and 2.1)

atomic mass unit (amu) A unit based on the value of exactly 12 amu for the mass of the isotope of carbon that has six protons and six neutrons in the nucleus; 1 amu = 1.66054×10^{-24} g. (Sections 2.3 and 2.4)

atomic number The number of protons in the nucleus of an atom of an element. (Section 2.3)

atomic radius An estimate of the size of an atom. See bonding atomic radius. (Section 7.3)

atomic weight The average mass of the atoms of an element in atomic mass units (amu); it is numerically equal to the mass in grams of one mole of the element. (Section 2.4)

autoionization The process whereby water spontaneously forms low concentrations of $H^+(aq)$ and $OH^-(aq)$ ions by proton transfer from one water molecule to another. (Section 16.2)

Avogadro's hypothesis A statement that equal volumes of gases at the same temperature and pressure contain equal numbers of molecules. (Section 10.3)

Avogadro's law A statement that the volume of a gas maintained at constant temperature and pressure is directly proportional to the number of moles of the gas. (Section 10.3)

Avogadro's number (N_A) The number of ^{12}C atoms in exactly 12 g of ^{12}C; it equals $6.022 \times 10^{23}\ mol^{-1}$. (Section 3.4)

axial hydrogens Those hydrogens on a chair conformation that extend perpendicular to the rough plane of the ring. (Section 24.5)

ball-and-stick model Model that depicts atoms as spheres and bonds as sticks. (Section 2.6)

band An array of closely spaced molecular orbitals occupying a continuous range of energy. (Section 12.2)

band gap The energy gap between a fully occupied valence band and an empty conduction band. (Section 12.4)

band structure The electronic structure of a bulk solid. (Section 12.2)

bar A unit of pressure equal to 10^5 Pa. (Section 10.2)

base A substance that is an H^+ acceptor; a base produces an excess of $OH^-(aq)$ ions when it dissolves in water. (Section 4.3)

base-dissociation constant (K_b) An equilibrium constant that expresses the extent to which a base reacts with solvent water, accepting a proton and forming $OH^-(aq)$. (Section 16.6)

basic anhydride (basic oxide) An oxide that forms a base when added to water; soluble metal oxides are basic anhydrides. (Section 22.5)

basic oxide (basic anhydride) An oxide that either reacts with water to form a base or reacts with an acid to form a salt and water. (Section 22.5)

base peak The peak within the mass spectrum that has 100% relative intensity. This does not necessarily correspond to the molecular ion. (Section 32.4)

battery A portable, self-contained electrochemical power source that contains one or more voltaic cells. (Section 20.7)

becquerel The SI unit of radioactivity. It corresponds to one nuclear disintegration per second. (Section 21.3)

Beer's law The light absorbed by a substance (A) equals the product of its extinction coefficient (ε), the path length through which the light passes (b), and the molar concentration of the substance (c): $A = \varepsilon bc$. (Section 14.3)

Beer–Lambert's law The light absorbed by a substance (A) equals the product of its molar absorption coefficient (ε), the path length through which the light passes (l) and the molar concentration of the substance (c): $A = \varepsilon \times c \times l$. (Section 32.1)

benzyl group A hydrocarbon group with formula $C_6H_5CH_2$. (Section 30.2)

beta emission A nuclear decay process where a beta particle is emitted from the nucleus; also called beta decay. (Section 21.1)

beta particles Energetic electrons emitted from the nucleus, symbol $^0_{-1}e$ or β^-. (Section 21.1)

beta sheet A structural form of protein in which sheets are made of two or more strands of peptides that hydrogen-bond from an amide H in one strand to a carbonyl O in the other strand. (Section 24.7)

bidentate ligand A ligand in which two linked coordinating atoms are bound to a metal. (Section 23.3)

bimolecular reaction An elementary reaction that involves two molecules. (Section 14.6)

biochemistry The study of the chemistry of living systems. (Section 24.1)

biodegradable Organic material that bacteria are able to oxidize. (Section 18.4)

biopolymers Three broad categories of polymers: proteins, polysaccharides (carbohydrates), and nucleic acids. (Section 24.6)

boat conformation The least stable conformation of a cyclohexane ring. (Section 24.5)

body-centered lattice A crystal lattice in which the lattice points are located at the center and corners of each unit cell. (Section 12.1)

bomb calorimeter A device for measuring the heat evolved in the combustion of a substance under constant-volume conditions. (Section 5.5)

bond angles The angles made by the lines joining the nuclei of the atoms in a molecule. (Section 9.1)

bond dipole The dipole moment that is due only to unequal electron sharing between two atoms in a covalent bond. (Section 9.3)

bond enthalpy The enthalpy change, ΔH, required to break a particular bond when the substance is in the gas phase. (Section 5.8)

bonding atomic radius The radius of an atom as defined by the distances separating it from other atoms to which it is chemically bonded. (Section 7.3)

bonding molecular orbital A molecular orbital in which the electron density is concentrated in the internuclear region. The energy of a bonding molecular orbital is lower than the energy of the separate atomic orbitals from which it forms. (Section 9.7)

bonding pair In a Lewis structure, a pair of electrons that is shared by two atoms. (Section 8.3)

bond length The distance between the centers of two bonded atoms. (Section 8.3)

bond order The number of bonding electron pairs shared between two atoms, minus the number of antibonding electron pairs: bond order = (number of bonding electrons − number of antibonding electrons)/2. (Section 9.7)

bond polarity A measure of the degree to which the electrons are shared unequally between two atoms in a chemical bond. (Section 8.4)

boranes Molecules containing only boron and hydrogen; covalent hydrides of boron. (Section 22.11)

Born–Haber cycle A thermodynamic cycle based on Hess's law that relates the lattice energy of an ionic substance to its enthalpy of formation and to other measurable quantities. (Section 8.2)

Boyle's law A law stating that at constant temperature, the product of the volume and pressure of a given amount of gas is a constant. (Section 10.3)

Brønsted–Lowry acid A substance (molecule or ion) that acts as a proton donor. (Section 16.1)

Brønsted–Lowry base A substance (molecule or ion) that acts as a proton acceptor. (Section 16.1)

Brownian motion The random motion of colloidal particles in solution due to collisions with solvent molecules. (Section 13.6)

buffer capacity The amount of acid or base a buffer can neutralize before the pH begins to change appreciably. (Section 17.2)

buffered solution (buffer) A solution that undergoes a limited change in pH upon addition of a small amount of acid or base. (Section 17.2)

Cahn–Ingold–Prelog *R,S* notation Use of *R,S* notation to describe the configuration of a stereocentre as defined by a set of sequence priority rules. (Section 25.5)

calorie A unit of energy; it is the amount of energy needed to raise the temperature of 1 g of water by 1 °C from 14.5 °C to 15.5 °C. A related unit is the joule: 1 cal = 4.184 J. (Section 1.5)

calorimeter An apparatus that measures the heat released or absorbed in a chemical or physical process. (Section 5.5)

calorimetry The experimental measurement of heat produced in chemical and physical processes. (Section 5.5)

capillary action The process by which a liquid rises in a tube because of a combination of adhesion to the walls of the tube and cohesion between liquid particles. (Section 11.3)

carbanions A species containing a carbon atom that bears a negative charge. (Section 28.3)

carbide A binary compound of carbon with a metal or metalloid. (Section 22.9)

carbocations A species containing a carbon atom that bears a positive charge. (Section 26.4)

carbohydrates A class of substances formed from polyhydroxy aldehydes or ketones. (Section 24.8)

carbohydrate A class of substances formed from polyhydroxy aldehydes or ketones, typically with a molecular formula in the form $Cr(H_2O)_m$. (Section 28.4)

carbon black An amorphous form of carbon. (Section 22.9)

carbonyl group The C=O double bond, a characteristic feature of several organic functional groups, such as ketones and aldehydes. (Section 24.4)

carbonyl group The C=O double bond, a characteristic feature of several organic functional groups, such as ketones and aldehydes. (Section 28.1)

carboxylic acid An acid that contains the —COOH functional group. (Sections 16.8 and 24.4)

carboxylic acids A compound that contains the —COOH functional group. (Section 29.1)

carboxylate anion The conjugate base of a carboxylic acid. (Section 29.1)

catalyst A substance that changes the speed of a chemical reaction without itself undergoing a permanent chemical change in the process. (Section 14.7)

catalytic hydrogenation A reaction used to add molecular hydrogen to a molecule in the presence of a catalyst. Most commonly used for the conversion of unsaturated hydrocarbons to saturated hydrocarbons. (Section 26.5)

cathode An electrode at which reduction occurs. (Section 20.3)

cathode rays Streams of electrons that are produced when a high voltage is applied to electrodes in an evacuated tube. (Section 2.2)

cathodic protection A means of protecting a metal against corrosion by making it the cathode in a voltaic cell. This can be achieved by attaching a more easily oxidized metal, which serves as an anode, to the metal to be protected. (Section 20.8)

cation A positively charged ion. (Section 2.7)

cell potential The potential difference between the cathode and anode in an electrochemical cell; it is measured in volts: 1 V = 1 J/C. Also called electromotive force. (Section 20.4)

cellulose A polysaccharide of glucose; it is the major structural element in plant matter. (Section 24.8)

cellulose polysaccharide of glucose; it is the major structural element in plant matter. (Section 28.4)

Celsius scale A temperature scale on which water freezes at 0° and boils at 100° at sea level. (Section 1.5)

chain reaction A series of reactions in which one reaction initiates the next. (Section 21.5)

changes of state Physical changes of matter from one state to a different one, for example, from a gas to a liquid. (Section 1.3)

chair conformation The most stable conformation of a cyclohexane ring. (Section 24.5)

charcoal An amorphous form of carbon produced when wood is heated strongly in a deficiency of air. (Section 22.9)

Charles's law A law stating that at constant pressure, the volume of a given quantity of gas is proportional to absolute temperature. (Section 10.3)

chelate effect The generally larger formation constants for bidentate and polydentate ligands as compared with the corresponding *monodentate* ligands. (Section 23.3)

chelating agent Bidentate and polydentate ligands capable of occupying two or more sites in the coordination sphere. (Section 23.3)

chemical bond A strong attractive force that exists between atoms in a molecule. (Section 8.1)

chemical changes Processes in which a substance is transformed into a chemically different substance; also called chemical reactions. (Section 1.3)

chemical equation A representation of a chemical reaction using the chemical formulas of the reactants and products; a balanced chemical equation contains equal numbers of atoms of each element on both sides of the equation. (Section 3.1)

chemical equilibrium A state of dynamic balance in which the rate of formation of the products of a reaction from the reactants equals the rate of formation of the reactants from the products; at equilibrium the concentrations of the reactants and products remain constant. (Section 4.1; Section 15.1)

chemical formula A notation that uses chemical symbols with numerical subscripts to convey the relative proportions of atoms of the different elements in a substance. (Section 2.6)

chemical kinetics The area of chemistry concerned with the speeds, or rates, at which chemical reactions occur. (Section 14.1)

chemical nomenclature The rules used in naming substances. (Section 2.8)

chemical properties Properties that describe the way a substance may change, or *react*, to form other substances. (Section 1.3)

chemical reactions Processes in which a substance is transformed into a chemically different substance; also called chemical changes. (Section 1.3)

chemical shift (δ) The frequency of a signal, expressed in parts per million (ppm), from tetramethylsilane divided by the operating frequency of the spectrometer. (Section 32.3)

chemistry The scientific discipline that studies matter, its properties, and the changes that matter undergoes. (Section 1.1)

chiral A term describing a molecule or an ion that cannot be superimposed on its mirror image. (Section 25.3)

chiral center A tetrahedral atom, usually carbon, bearing four different substituents. (Section 25.3)

chlorofluorocarbons Ozone-damaging substances, principally $CFCl_3$ and CF_2Cl_2, that were once widely used as propellants in spray cans. They do not occur in nature. (Section 18.2)

chlorophyll A plant pigment that plays a major role in conversion of solar energy to chemical energy in photosynthesis. (Section 23.3)

cholesteric liquid crystal A liquid crystal having molecules arranged in layers, with their long axes parallel to the other molecules within the same layer. Moving from one layer to the next, the orientation of the molecules rotates by a fixed angle, resulting in a spiral pattern. (Section 11.7)

cis A geometric isomer in which two substituents attached to a cyclic compound are orientated on different sides of the plane of the ring. (Section 25.2)

coal A naturally occurring solid containing hydrocarbons of high molecular weight, as well as compounds containing sulfur, oxygen, and nitrogen. (Section 5.9)

codon The sets of three successive nucleotides in mRNA that are encoded for amino acids. Used in translation. (Section 31.4)

colligative property A property of a solvent (vapor-pressure lowering, freezing-point lowering, boiling-point elevation, osmotic pressure) that depends on the total concentration of solute particles present. (Section 13.5)

collision model A model of reaction rates based on the idea that molecules must collide to react; it explains the factors influencing reaction rates in terms of the frequency of collisions, the number of collisions with energies exceeding the activation energy, and the probability that the collisions occur with suitable orientations. (Section 14.5)

colloids (colloidal dispersions) Mixtures containing particles larger than normal solutes but small enough to remain suspended in the dispersing medium. (Section 13.6)

combination reaction A chemical reaction in which two or more substances combine to form a single product. (Section 3.2)

combustion A chemical reaction that proceeds with evolution of heat and usually also a flame; most combustion involves reaction with oxygen, as in the burning of a match. (Section 24.7)

combustion reaction A chemical reaction that proceeds with evolution of heat and usually also a flame; most combustion involves reaction with oxygen, as in the burning of a match. (Section 3.2)

common-ion effect A shift of an equilibrium induced by an ion common to the equilibrium. Whenever a weak electrolyte and a strong electrolyte containing a common ion are together in solution, the weak electrolyte ionizes less than it would if it were alone in solution. (Section 17.1)

complementary colors Colors that, when mixed in proper proportions, appear white or colorless. For example, orange and blue are complementary colors that form white light when mixed; when blue is removed, the light looks orange. (Section 23.5)

complete ionic equation A chemical equation in which dissolved strong electrolytes (such as dissolved ionic compounds) are written as separate ions. (Section 4.2)

complex ion (complex) An assembly of a metal ion and the Lewis bases bonded to it. (Section 17.5)

compound A substance composed of two or more elements united chemically in definite proportions. (Section 1.2)

complex lipids Lipids that can be broken down into smaller constituents, usually by hydrolysis. (Section 29.4)

concentration The quantity of solute present in a given quantity of solvent or solution. (Section 4.5)

concentration cell A voltaic cell containing the same electrolyte and the same electrode materials in both the anode and cathode compartments. The emf of the cell is derived from a difference in the concentrations of the same electrolyte solutions in the compartments. (Section 20.6)

condensation polymerization Polymerization in which two molecules are joined to form a larger molecule by elimination of a small molecule, such as H_2O. (Section 12.5)

condensation polymerization Polymerisation in which molecules are joined together through condensation reactions. (Section 29.5)

condensation reaction A reaction in which two molecules are joined to form a larger molecule by elimination of a small molecule, such as H_2O. (Section 12.8)

conduction band A band of unoccupied antibonding molecular orbitals lying higher in energy than the occupied valence band and distinctly separated from it. (Section 12.4)

conformation (Section 24.3)

conformational isomers Isomers which are differentiated by their three-dimensional shape at any instance by rotation about a C–C bond. (Section 24.3)

conjugate acid A substance formed by addition of a proton to a Brønsted–Lowry base. (Section 16.1)

conjugate acid–base pair An acid and a base, such as H_2O and OH^-, that differ only in the presence or absence of a proton. (Section 16.1)

conjugate base A substance formed by the loss of a proton from a Brønsted–Lowry acid. (Section 16.1)

conjugated proteins A protein that yields compounds, such as carbohydrates, lipids, metal complexes and so on, as well as amino acids on hydrolysis. (Section 31.3)

continuous spectrum A spectrum that contains radiation distributed over all wavelengths. (Section 6.3)

conversion factor A fraction whose numerator and denominator are the same quantity expressed in different units. (Section 1.7)

coordination compound A compound containing a complex. (Section 23.2)

coordination number The number of adjacent atoms in a crystal structure to which an atom is directly bonded. In a complex, the coordination number of the metal ion is the number of atoms bonded to the metal ion. (Sections 12.2 and 23.2)

coordination sphere The central metal ion and its surrounding ligands. (Section 23.2)

coordination-sphere isomers Structural isomers that differ in which species in the complex are ligands and which are outside the coordination sphere in the solid. (Section 23.4)

copolymer A complex polymer resulting from the polymerization of two or more chemically different monomers. (Section 12.5)

copolymers A complex polymer resulting from the polymerisation of two or more chemically different monomers. (Section 29.5)

core electrons The electrons that are not in the outermost shell of an atom. (Section 6.8)

corrosion Spontaneous redox reactions in which a metal is attacked by some substance in its environment and converted to an unwanted compound. (Section 20.8)

coupling constant A measure of the spin–spin interactions between two coupled nuclei. (Section 32.3)

covalent bond A bond formed between two or more atoms by a sharing of electrons. (Section 8.1)

covalent-network solids Solids that are held together by an extended network of covalent bonds. (Sections 12.1 and 12.4)

critical mass The amount of fissionable material necessary to maintain a nuclear chain reaction. (Section 21.5)

critical point The temperature and pressure beyond which the liquid and gas phases are indistinguishable from each other. (Section 11.6)

critical pressure The pressure at which a gas at its critical temperature is converted to a liquid state. (Section 11.4)

critical temperature The highest temperature at which a distinct liquid phase can form. The critical temperature increases with an increase in the magnitude of intermolecular forces. (Section 11.4)

cross-linking A method of stiffening polymers by introducing chemical bonds between chains. (Section 12.5)

crown ethers Cyclic compounds containing three or more ether linkages. (Section 27.3)

crystal-field theory A theory that accounts for the colors and the magnetic and other properties of transition-metal complexes in terms of the splitting of the energies of metal ion *d* orbitals by the electrostatic interaction with the ligands. (Section 23.6)

crystal lattice The geometrical pattern of points on which the unit cells are arranged; in effect, an abstract (that is, not real) scaffolding for the crystal structure. (Section 12.1)

crystalline solid (crystal) A solid whose internal arrangement of atoms, molecules, or ions possesses a regularly repeating pattern in any direction through the solid. (Section 12.1)

crystallinity A measure of the extent of short-range ordering in a polymer where chains line up in regular arrays. (Section 12.5)

crystallinity A measure of the extent of crystalline character (order) in a polymer. (Section 26.6)

crystallization The process in which molecules, ions, or atoms come together to form a crystalline solid. The opposite of the solution process. (Section 13.2)

cross-linking The formation of bonds between polymer chains. (Section 26.6)

cubic close packing A crystal structure where the atoms are packed together as close as possible, and the close-packed layers of atoms adopt a three-layer repeating pattern that leads to a face-centered cubic unit cell. (Section 12.2)

curie A measure of radioactivity: $1\text{ curie} = 3.7 \times 10^{10}$ nuclear disintegrations per second. (Section 21.3)

cyanohydrins Compounds containing both a hydroxy (OH) and nitrile (CN) group typically on the same carbon atom. (Section 28.3)

cyclic amines A cycloalkane in which at least one of the carbons within the ring is replaced by nitrogen. A heterocyclic compound. (Section 31.1)

cyclic polyethers A cyclic compound containing more than one ether group within the ring. (Section 27.3)

cycloalkanes Saturated hydrocarbons of general formula C_nH_{2n} in which the carbon atoms form a closed ring. (Section 24.5)

Dalton's law of partial pressures A law stating that the total pressure of a mixture of gases is the sum of the pressures that each gas would exert if it were present alone. (Section 10.5)

***d–d* transition** The transition of an electron in a transition-metal compound from a lower-energy *d* orbital to a higher-energy *d* orbital. (Section 23.6)

deactivating group A substituent that makes the functional group to which it is attached less reactive. Often applied to substituents on aromatic rings undergoing an electrophilic aromatic substitution reaction. (Section 30.5)

decomposition reaction A chemical reaction in which a single compound reacts to give two or more products. (Section 3.2)

decoupling An experiment where information on coupling between two nuclei is lost by saturation. (Section 32.3)

deoxyribonucleic acids (DNA) A polynucleotide in which the sugar component is deoxyribose. (Section 31.4)

degenerate A situation in which two or more orbitals have the same energy. (Section 6.7)

delocalized electrons Electrons that are spread over a number of atoms in a molecule or a crystal rather than localized on a single atom or a pair of atoms. (Section 9.6)

density The amount of mass in a unit volume of a substance. (Section 1.5)

dextrorotatory A term used to label a chiral molecule that rotates the plane of polarisation of plane-polarised light to the right (clockwise). (Section 25.4)

deoxyribonucleic acid (DNA) A polynucleotide in which the sugar component is deoxyribose. (Section 24.10)

derived unit An SI unit obtained by multiplication or division of one or more of the SI base units. (Section 1.5)

desalination The removal of salts from seawater, brine, or brackish water to make it fit for human consumption. (Section 18.4)

deuterium The isotope of hydrogen whose nucleus contains a proton and a neutron: ${}^{2}_{1}\text{H}$. (Section 22.2)

dextrorotatory, or merely dextro or *d* A term used to label a chiral molecule that rotates the plane of polarization of plane-polarized light to the right (clockwise). (Section 23.4)

diamagnetism A type of magnetism that causes a substance with no unpaired electrons to be weakly repelled from a magnetic field. (Section 9.8)

diatomic molecule A molecule composed of only two atoms. (Section 2.6)

1,3-diaxial interactions Interactions between two groups in an axial position on the same side of a chair conformation of a cyclohexane ring separated by three carbon atoms. (Section 24.5)

diffusion The spreading of one substance throughout a space or throughout a second substance. (Section 10.7)

dilution The process of preparing a less concentrated solution from a more concentrated one by adding solvent. (Section 4.5)

dimensional analysis A method of problem solving in which units are multiplied together or divided into each other along with the numerical values. Dimensional analysis ensures that the final answer of a calculation has the desired units. (Section 1.7)

dipole A molecule with one end having a partial negative charge and the other end having a partial positive charge; a polar molecule. (Section 8.4)

dipole–dipole interactions A force that becomes significant when polar molecules come in close contact with one another. The force is attractive when the positive end of one polar molecule approaches the negative end of another. (Section 11.2)

dipole moment A measure of the separation and magnitude of the positive and negative charges in polar molecules. (Section 8.4)

disaccharide Two monosaccharide units linked together by a condensation reaction. (Section 24.8)

diastereomers Stereoisomers that have a non-mirror-image relationship. (Sections 25.1 and 25.6)

dispersion forces Intermolecular forces resulting from attractions between induced dipoles. Also called London dispersion forces. (Section 11.2)

displacement reaction A reaction in which an ion in solution is displaced (replaced) through oxidation of an element. (Section 4.4)

disproportionation reaction A reaction in which an element is simultaneously oxidized and reduced. (Section 22.5)

distillation A separation process that depends on the different abilities of substances to form gases. (Section 1.3)

donor atom The atom of a ligand that bonds to the central metal ion in a coordination complex. (Section 23.3)

doping The process of adding controlled amounts of impurity atoms to a material. For example, incorporation of P into Si. (Section 12.4)

double bond A covalent bond involving two electron pairs. (Section 8.3)

double helix The structure for DNA that involves the winding of two DNA polynucleotide chains together in a helical arrangement. The two strands of the double helix are complementary in that the organic bases on the two strands are paired for optimal hydrogen bond interaction. (Section 24.10)

double helix The structure for DNA that involves the winding of two DNA polynucleotide chains together in a helical arrangement. The two strands of the double helix are complementary in that the organic bases on the two strands are paired for optimal hydrogen bond interaction. (Section 31.4)

dynamic equilibrium A state of balance in which opposing processes occur at the same rate. (Section 11.5)

E1 An elimination reaction displaying second order kinetics. (Section 27.7)

E2 An elimination reaction displaying second order kinetics. (Section 27.6)

***E, Z* system** A system used to distinguish between geometrical isomers in alkenes. The term *E* for *entgegen* means opposite. The term *Z* for *zusammen* means together (or same side). (Section 26.2)

eclipsed A conformation in which all groups around a C–C single bond are as close as possible. This arrangement results in the bonds about a C–C single bond being behind each other when viewed as a Newman projection. (Section 24.3)

Edman degradation A systematic process designed to cleave and identify one amino acid at a time from the *N*-terminus of the peptide chain. (Section 31.3)

effective nuclear charge The net positive charge experienced by an electron in a many-electron atom; this charge is not the full nuclear charge because there is some shielding of the nucleus by the other electrons in the atom. (Section 7.2)

effusion The escape of a gas through an orifice or hole. (Section 10.7)

elastomer A material that can undergo a substantial change in shape via stretching, bending, or compression and return to its original shape upon release of the distorting force. (Section 12.5)

electrochemistry The branch of chemistry that deals with the relationships between electricity and chemical reactions. (Section 20.1)

electrolysis reaction A reaction in which a nonspontaneous redox reaction is brought about by the passage of current under a sufficient external electrical potential. The devices in which electrolysis reactions occur are called electrolytic cells. (Section 20.9)

electrolyte A solute that produces ions in solution; an electrolytic solution conducts an electric current. (Section 4.1)

electrolytic cell A device in which a nonspontaneous oxidation–reduction reaction is caused to occur by passage of current under a sufficient external electrical potential. (Section 20.9)

electron-withdrawing groups A group that has an attraction for electrons that it shares in a chemical bond with other atoms. (Section 30.4)

electron impact ionization (EI) mass spectrometry (EIMS) A popular technique used to determine the molecular weight of a compound through bombardment with high-energy electrons. (Section 32.4)

electromagnetic radiation (radiant energy) A form of energy that has wave characteristics and that propagates through a vacuum at the characteristic speed of 3.00×10^8 m/s. (Section 6.1)

electrometallurgy The use of electrolysis to reduce or refine metals. (Section 20.9)

electromotive force (emf) A measure of the driving force, or *electrical pressure*, for the completion of an electrochemical reaction. Electromotive force is measured in volts: $1\text{ V} = 1\text{ J/C}$. Also called the cell potential. (Section 20.4)

electron A negatively charged subatomic particle found outside the atomic nucleus; it is a part of all atoms. (Section 2.2)

electron affinity The energy change that occurs when an electron is added to a gaseous atom or ion. (Section 7.5)

electron capture A mode of radioactive decay in which an inner-shell orbital electron is captured by the nucleus. (Section 21.1)

electrophilic aromatic substitution (EAS) The mechanism by which benzene and its derivatives react to form more highly substituted compounds. (Section 30.5)

electrophoresis A method for separating compounds based on their electric charge at a given pH. (Section 31.2)

electron configuration The arrangement of electrons in the orbitals of an atom or molecule (Section 6.8)

electron density The probability of finding an electron at any particular point in an atom; this probability is equal to ψ^2, the square of the wave function. Also called the probability density. (Section 6.5)

electron domain In the VSEPR model, a region about a central atom in which an electron pair is concentrated. (Section 9.2)

electron-domain geometry The three-dimensional arrangement of the electron domains around an atom according to the VSEPR model. (Section 9.2)

electronegativity A measure of the ability of an atom that is bonded to another atom to attract electrons to itself. (Section 8.4)

electronic charge The negative charge carried by an electron; it has a magnitude of 1.602×10^{-19} C. (Section 2.3)

electronic structure The arrangement of electrons in an atom or molecule. (Section 6.1)

electron-sea model A model for the behavior of electrons in metals. (Section 12.2)

electron shell A collection of orbitals that have the same value of n. For example, the orbitals with $n = 3$ (the 3*s*, 3*p*, and 3*d* orbitals) comprise the third shell. (Section 6.5)

electron spin A property of the electron that makes it behave as though it were a tiny magnet. The electron behaves as if it were spinning on its axis; electron spin is quantized. (Section 6.7)

electrophiles Any atom, molecule or ion that accepts a pair of electrons from a nucleophile to form a new covalent bond. (Section 26.4)

element A substance that cannot be decomposed into simpler substances. (Sections 1.1 and 1.2)

elemental composition The percentage composition of an element in a substance. (Section 3.3)

elementary reaction A process in a chemical reaction that occurs in a single step. An overall chemical reaction consists of one or more elementary reactions or steps. (Section 14.6)

***β*-elimination reaction** A reaction that produces an unsaturated hydrocarbon by the loss of atoms from adjacent carbons in a molecule. (Section 27.6)

elimination reaction A reaction that proceeds by the loss of atoms or groups of atoms, resulting in the formation of multiple bonds. (Section 27.6)

empirical formula A chemical formula that shows the kinds of atoms and their relative numbers in a substance in the smallest possible whole-number ratios. (Section 2.6)

enantiomers Two mirror-image molecules of a chiral substance. The enantiomers are non-superimposable. (Section 25.1)

enantiomerically pure A term used to describe a sample containing 100% of a single enantiomer. (Section 25.4)

endothermic process A process in which a system absorbs heat from its surroundings. (Section 5.2)

energy The capacity to do work or to transfer heat. (Section 1.4)

energy-level diagram A diagram that shows the energies of molecular orbitals relative to the atomic orbitals from which they are derived. Also called a **molecular-orbital diagram**. (Section 9.7)

enthalpy A quantity defined by the relationship $H = E + PV$; the enthalpy change, ΔH, for a reaction that occurs at constant pressure is the heat evolved or absorbed in the reaction: $\Delta H = q_p$. (Section 5.3)

enthalpy of formation The enthalpy change that accompanies the formation of a substance from the most stable forms of its component elements. (Section 5.7)

enthalpy of reaction The enthalpy change associated with a chemical reaction. (Section 5.4)

entropy A measure of the tendency for energy to spread or disperse, thereby reducing its ability to accomplish work. In a general sense, it reflects the degree of *randomness* or *disorder* associated with the particles that carry the energy. (Section 19.2)

enzyme A protein molecule that acts to catalyze specific biochemical reactions. (Section 14.7)

enzymes A protein molecule that acts to catalyse specific biochemical reactions. (Section 31.3)

equatorial hydrogens Those hydrogens on a chair conformation that radiate out in the rough plane of the ring. (Section 24.5)

equilibrium constant The numerical value of the equilibrium-constant expression for a system at equilibrium. The equilibrium constant is most usually denoted by K_p for gas-phase systems or K_c for solution-phase systems. (Section 15.2)

equilibrium-constant expression The expression that describes the relationship among the concentrations (or partial pressures) of the substances present in a system at equilibrium. The numerator is obtained by multiplying the concentrations of the substances on the product side of the equation, each raised to a power equal to its coefficient in the chemical equation. The denominator similarly contains the concentrations of the substances on the reactant side of the equation. (Section 15.2)

equivalence point The point in a titration at which the added solute reacts completely with the solute present in the solution. (Section 4.6)

ester An organic compound that has an OR group attached to a carbonyl; it is the product of a reaction between a carboxylic acid and an alcohol. (Section 24.4)

ethers A compound in which two hydrocarbon groups are bonded to one oxygen. (Section 24.4 and 27.3)

esters An organic compound that has an –OR group attached to a carbonyl; it is the product of a reaction between a carboxylic acid and an alcohol. (Section 29.3)

exchange (metathesis) reaction A reaction between compounds that when written as a molecular equation appears to involve the exchange of ions between the two reactants. (Section 4.2)

excited state A higher energy state than the ground state. (Section 6.3)

exothermic process A process in which a system releases heat to its surroundings. (Section 5.2)

extensive property A property that depends on the amount of sample considered; for example, mass or volume. (Section 1.3)

face-centered lattice A crystal lattice in which the lattice points are located at the faces and corners of each unit cell. (Section 12.1)

Faraday constant (*F*) The magnitude of charge of one mole of electrons: 96,500 C/mol. (Section 20.5)

fats Triglycerides that are solids or semi-solids at room temperature. They are usually rich in saturated fatty acids. (Section 26.5 and 29.4)

fatty acids Carboxylic acids with > C12 alkyl chains. (Section 29.4)

***f*-block metals** Lanthanide and actinide elements in which the 4*f* or 5*f* orbitals are partially occupied. (Section 6.9)

ferrimagnetism A substance that has both ferromagnetic and antiferromagnetic characteristics. A form of magnetism in which unpaired electron spins on different-type ions point in opposite directions but do not fully cancel out. (Section 23.1)

ferromagnetism A form of magnetism in which unpaired electron spins align parallel to one another. (Section 23.1)

fibrous proteins Proteins that are arranged like filaments or fibres, for example collagen. (Section 31.3)

fingerprint region Usually defined as the most complex region of the IR spectrum (300–1400 cm^{-1}). (Section 32.2)

first law of thermodynamics A statement that energy is conserved in any process. One way to express the law is that the change in internal energy, ΔE, of a system in any process is equal to the heat, q, added to the system, plus the work, w, done on the system by its surroundings: $\Delta E = q + w$. (Section 5.2)

first-order reaction A reaction in which the reaction rate is proportional to the concentration of a single reactant, raised to the first power. (Section 14.4)

fission The splitting of a large nucleus into two smaller ones. (Section 21.5)

Fischer projections A convention for representing the configuration of a stereocentre in two dimensions. (Section 28.4)

folding The process by which a protein adopts its biologically active shape. (Section 24.7)

folding The process by which a protein adopts the biologically active form. (Section 31.3)

force A push or a pull. (Section 1.4)

formal charge The charge an atom (in a molecule) would have if each bonding electron pair in the molecule were shared equally between its two atoms. (Section 8.5)

formation constant For a metal ion complex, the equilibrium constant for formation of the complex from the metal ion and base species present in solution. It is a measure of the tendency of the complex to form. (Section 17.5)

formula weight The sum of the atomic weights (AW) of the atoms in the chemical formula of the substance. For example, the formula weight of NO_2 (46.0 amu) is the sum of the masses of one nitrogen atom and two oxygen atoms. (Section 3.3)

fossil fuels Coal, oil, and natural gas, which are presently our major sources of energy. (Section 5.9)

fracking The practice in which water laden with sand and other materials is pumped at high pressure into rock formations to release natural gas and other petroleum materials. (Section 18.4)

fragment A chemical species produced by the cleavage of a covalent bond. Usually associated with mass spectrometry. (Section 32.4)

free energy (Gibbs free energy, *G*) A thermodynamic state function that gives a criterion for spontaneous change in terms of enthalpy and entropy: $G = H - TS$. (Section 19.5)

free radical A substance with one or more unpaired electrons. (Section 21.6)

free radicals A substance with one or more unpaired electrons. (Section 24.7)

frequency The number of times per second that one complete wavelength passes a given point. (Section 6.1)

frequency factor (*A*) A term in the Arrhenius equation that is related to the frequency of collision and the probability that the collisions are favorably oriented for reaction. (Section 14.5)

fuel cell A voltaic cell that utilizes the oxidation of a conventional fuel, such as H_2 or CH_4, in the cell reaction. (Section 20.7)

fuel value The energy released when 1 g of a substance is combusted. (Section 5.9)

functional group An atom or group of atoms that imparts characteristic chemical properties to an organic compound. (Section 24.1 and 24.6)

fusion The joining of two light nuclei to form a more massive one. (Section 21.5)

galvanic cell See **voltaic (galvanic) cell**. (Section 20.3)

gamma radiation Energetic electromagnetic radiation emanating from the nucleus of a radioactive atom. (Section 21.1)

gas Matter that has no fixed volume or shape; it uniformly fills its container. (Section 1.2)

gas constant (*R*) The constant of proportionality in the ideal-gas equation. (Section 10.4)

geometric isomerism A form of isomerism in which compounds with the same type and number of atoms and the same chemical bonds have different spatial arrangements of these atoms and bonds. (Sections 23.4 and 24.3)

geometric isomers Compounds with the same type and number of atoms and the same chemical bonds but different spatial arrangements of these atoms and bonds. (Section 25.1)

Gibbs free energy A thermodynamic state function that combines enthalpy and entropy, in the form $G = H - TS$. For a change occurring at constant temperature and pressure, the change in free energy is $\Delta G = \Delta H - T\Delta S$. (Section 19.5)

glass An amorphous solid formed by fusion of SiO_2, CaO, and Na_2O. Other oxides may also be used to form glasses with differing characteristics. (Section 22.10)

globular proteins Tightly bundled proteins, so named because of their globular or spherical shape. (Section 31.3)

glucose A polyhydroxy aldehyde whose formula is $CH_2OH(CHOH)_4CHO$; it is the most important of the monosaccharides. (Section 24.8)

glucose A polyhydroxy aldehyde whose formula is $CH_2OH(CHOH)_4CHO$; it is the most important of the monosaccharides. (Section 28.4)

glycogen The general name given to a group of polysaccharides of glucose that are synthesized in mammals and used to store energy from carbohydrates. (Section 24.8)

glycoside A carbohydrate derivative in which the hydroxy group (–OH) located at the anomeric carbon is replaced by another group, typically an alkoxy group (–OR) or amine. (Section 28.4)

glycogen The general name given to a group of polysaccharides of glucose that are synthesised in mammals and used to store energy from carbohydrates. (Section 28.4)

glycosidic bond The bond from the anomeric carbon to the OR group in a glycoside. (Section 28.4)

Graham's law A law stating that the rate of effusion of a gas is inversely proportional to the square root of its molecular weight. (Section 10.7)

gray (Gy) The SI unit for radiation dose corresponding to the absorption of 1 J of energy per kilogram of biological material; 1 Gy = 100 rads. (Section 21.6)

green chemistry Chemistry that promotes the design and application of chemical products and processes that are compatible with human health and that preserve the environment. (Section 18.5)

greenhouse gases Gases in an atmosphere that absorb and emit infrared radiation (radiant heat), "trapping" heat in the atmosphere. (Section 18.2)

Grignard Reagent A class of reagent with general formula RMgX, where R = alkyl, aryl and X = halide. (Section 28.3)

ground state The lowest-energy, or most stable, state. (Section 6.3)

group Elements that are in the same column of the periodic table; elements within the same group or family exhibit similarities in their chemical behavior. (Section 2.5)

Haber process The catalyst system and conditions of temperature and pressure developed by Fritz Haber and coworkers for the formation of NH_3 from H_2 and N_2. (Section 15.2)

half-life The time required for the concentration of a reactant substance to decrease to half its initial value; the time required for half of a sample of a particular radioisotope to decay. (Sections 14.4 and 21.3)

half-reaction An equation for either an oxidation or a reduction that explicitly shows the electrons involved, for example, $Zn^{2+}(aq) + 2\,e^- \longrightarrow Zn(s)$. (Section 20.2)

halogens Members of group 17 in the periodic table. (Section 7.8)

halogenation A reaction in which at least one halide is added. In the case of addition reactions to alkenes, two halogen atoms are added across the double bond. (Section 24.7 and 26.4)

haloalkanes Of general formula R–X, where X = F, Cl, Br, I. A haloalkane is any hydrocarbon containing one or more halo groups. (Section 27.2)

haloforms Compounds of the form CHX_3, for example chloroform.(Section 27.1)

hardening A term used to describe the conversion of oils to fats by hydrogenation of unsaturated triglycerides. (Section 26.5 and 29.4)

Haworth projection A convention for representing the configuration of functional groups around a furanose or pyranose ring. (Section 28.4)

heat The energy that causes the temperature of an object to increase. The flow of energy from a body at higher temperature to one at lower temperature when they are placed in thermal contact. (Sections 1.4 and 1.5)

heat capacity The quantity of heat required to raise the temperature of a sample of matter by 1 °C (or 1 K). (Section 5.5)

heat of fusion The enthalpy change, ΔH, for melting a solid. (Section 11.4)

heat of sublimation The enthalpy change, ΔH, for vaporization of a solid. (Section 11.4)

heat of vaporization The enthalpy change, ΔH, for vaporization of a liquid. (Section 11.4)

α-helix A protein structure in which the protein is coiled in the form of a helix, with hydrogen bonds between C=O and N–H groups on adjacent turns. (Section 31.3)

hemiacetals The product formed by the reaction of an aldehyde or ketone with one mole of alcohol. (Section 28.3)

Henderson–Hasselbalch equation The relationship among the pH, pK_a, and the concentrations of acid and conjugate base in an aqueous solution: $pH = pK_a + \log\frac{[base]}{[acid]}$. (Section 17.2)

Henry's law A law stating that the concentration of a gas in a solution, S_g, is proportional to the pressure of gas over the solution: $S_g = kP_g$. (Section 13.3)

Hess's law If a reaction is carried out in a series of steps, ΔH for the overall reaction equals the sum of the enthalpy changes for the individual steps. (Section 5.6)

Heteroatom An atom other than carbon or hydrogen used to form functional groups in organic compounds. (Section 24.6)

heterocyclic compounds A cyclic compound in which one or more carbon atoms within the ring are replaced by heteroatoms. (Section 27.3)

heterogeneous alloy An alloy in which the components are not distributed uniformly; instead, two or more distinct phases with characteristic compositions are present. (Section 12.2)

heterogeneous catalyst A catalyst that is in a different phase from that of the reactant substances. (Section 14.7)

heterogeneous equilibrium The equilibrium established between substances in two or more different phases, for example, between a gas and a solid or between a solid and a liquid. (Section 15.3)

heteroatoms An atom other than carbon or hydrogen used to form functional groups in organic compounds. (Section 30.2)

heterocyclic compounds A cyclic compound in which one or more carbon atoms within the ring are replaced by heteroatoms. (Section 30.2)

hexagonal close packing A crystal structure where the atoms are packed together as closely as possible. The close-packed layers adopt a two-layer repeating pattern, which leads to a primitive hexagonal unit cell. (Section 12.2)

high-spin complex A complex whose electrons are arranged to give the maximum number of unpaired electrons. (Section 23.6)

hole A vacancy in the valence band of a semiconductor, created by doping. (Section 12.4)

homogeneous catalyst A catalyst that is in the same phase as the reactant substances. (Section 14.7)

homogeneous equilibrium The equilibrium established between reactant and product substances that are all in the same phase. (Section 15.3)

homologous series A series of compounds that differ only by the number of methane ($-CH_2-$) units. (Section 24.2)

homolytic bond cleavage Symmetrical breaking of a covalent bond to yield two radicals. (Section 24.7)

Hooke's law States that the elongation of a spring is proportional to the load applied. Mathematically: $F_s = -kx$. (Section 32.2)

Hund's rule A rule stating that electrons occupy degenerate orbitals in such a way as to maximize the number of electrons with the same spin. In other words, each orbital has one electron placed in it before pairing of electrons in orbitals occurs. (Section 6.8)

hybridization The mathematical mixing of different types of atomic orbitals to produce a set of equivalent hybrid orbitals. (Section 9.5)

hybrid orbital An orbital that results from the mixing of different kinds of atomic orbitals on the same atom. For example, an sp^3 hybrid results from the mixing, or hybridizing, of one s orbital and three *p* orbitals. (Section 9.5)

hydration Solvation when the solvent is water. (Section 26.4)

hydride ion An ion formed by the addition of an electron to a hydrogen atom: H^-. (Section 7.7)

hydrocarbons Compounds composed of only carbon and hydrogen. (Section 24.2)

hydrogen bonding Bonding that results from intermolecular attractions between molecules containing hydrogen bonded to an electronegative element. The most important examples involve OH, NH, and HF. (Section 11.2)

hydrohalogenation A reaction that adds HX across a C=C double bond (X is typically Cl, Br, I). (Section 26.4)

hydrolysis A reaction with water. When a cation or anion reacts with water, it changes the pH. (Sections 16.7 and 24.4)

hydronium ion (H_3O^+) The predominant form of the proton in aqueous solution. (Section 16.1)

hydrophilic Water attracting. The term is often used to describe a type of colloid. (Section 13.6)

hydrophobic Water repelling. The term is often used to describe a type of colloid. (Section 13.6)

hypervalent A compound with more than an octet of electrons around the central atom. (Section 9.5)

hypothesis A model or tentative explanation of a series of observations. (Section 1.5)

ideal gas A hypothetical gas whose pressure, volume, and temperature behavior is completely described by the ideal-gas equation. (Section 10.4)

ideal-gas equation An equation of state for gases that embodies Boyle's law, Charles's law, and Avogadro's hypothesis in the form $PV = nRT$. (Section 10.4)

ideal solution A solution that obeys Raoult's law. (Section 13.5)

immiscible liquids Liquids that do not dissolve in one another to a significant extent. (Section 13.3)

imines The product formed by the condensation of an aldehyde or ketone with a primary amine. (Section 28.3)

index of hydrogen deficiency (IHD) A summation of all π-bonds and rings within a molecule. The index of hydrogen deficiency quantity is determined by comparing the number of hydrogens in the molecular formula of an unknown with that of an *alkane* reference that contains the same number of carbon atoms as the unknown. (Section 32.5)

indicator A substance added to a solution that changes color when the added solute has reacted with all the solute present in solution. The most common type of indicator is an acid–base indicator whose color changes as a function of pH. (Section 4.6)

inductive effects An electronic effect transmitted through bonds by a more electronegative neighboring atom. (Section 30.4)

infrared spectroscopy An analytical technique used to characterise functional groups that is based on the absorption of energy by a molecule as it vibrates by stretching and bending. (Section 32.2)

initiation The first step in a chain reaction. (Section 26.6)

instantaneous rate The reaction rate at a particular time as opposed to the average rate over an interval of time. (Section 14.2)

insulators Materials that do not conduct electricity. (Section 12.7)

integration The area under a signal within a ^1H NMR spectrum. The area is proportional to the number of equivalent protons that gives rise to that signal. (Section 32.3)

intensive property A property that does not depend on the amount of sample being examined, for example, density. (Section 1.3)

interhalogens Compounds formed between two different halogen elements. Examples include IBr and BrF_3. (Section 22.4)

intermediate A substance formed in one elementary step of a multistep mechanism and consumed in another; it is neither a reactant nor an ultimate product of the overall reaction. (Section 14.6)

intermetallic compound A homogeneous alloy with definite properties and a fixed composition. (Section 12.2)

intermolecular forces Forces that exist between molecules. (Section 11.1)

internal energy The sum of all the kinetic and potential energies of the components of the system. When a system undergoes a change, the change in internal energy, ΔE, is defined as the heat, q, added to the system, plus the work, w, done on the system by its surroundings: $\Delta E = q + w$. (Section 5.2)

interstitial alloy An alloy formed when solute atoms occupy interstitial positions in the "holes" between solvent atoms. (Section 12.2)

ion Electrically charged atom or group of atoms (polyatomic ion); ions can be positively or negatively charged, depending on whether electrons are lost (positive) or gained (negative) by the atoms. (Section 2.7)

ion–dipole force The force that exists between an ion and a polar molecule that possesses a permanent dipole moment. (Section 11.2)

ionic bond A bond formed by the electrostatic attractions between oppositely charged ions. The ions are formed from atoms by transfer of one or more electrons. (Section 8.1)

ionic compound A compound composed of cations and anions. (Section 2.7)

ionic hydrides Compounds formed when hydrogen reacts with alkali metals and also the heavier alkaline earths (Ca, Sr, and Ba); these compounds contain the hydride ion, H^-. (Section 22.2)

ionic solids Solids that are held together by the mutual electrostatic attraction between cations and anions. (Sections 12.1 and 12.5)

ionization energy The minimum energy required to remove an electron from the ground state of an isolated gaseous atom or ion. (Section 7.4)

ionizing radiation Radiation that has sufficient energy to remove an electron from a molecule, thereby ionizing it. (Section 21.6)

ion-product constant For water, K_w is the product of the aquated hydrogen ion and hydroxide ion concentrations: $[H^+][OH^-] = K_w = 1.0 \times 10^{-14}$ at 25 °C. (Section 16.2)

irreversible process A process that leaves the surroundings somehow changed when the system is restored to its original state. (Section 19.1)

isoelectronic series A series of atoms, ions, or molecules having the same number of electrons. (Section 7.3)

isoelectric point The pH at which the maximum number of molecules of a compound in aqueous solution contain both positively and negatively charged regions. That is, the pH at which the zwitterion form is maximised. (Section 31.2)

isomers Compounds whose molecules have the same overall composition but different structures. (Sections 2.9 and 23.4)

isothermal process A process that occurs at constant temperature. (Section 19.1)

isotopes Atoms of the same element containing different numbers of neutrons and therefore having different masses. (Section 2.3)

joule (J) The SI unit of energy, $1\ kg\text{-}m^2/s^2$. A related unit is the calorie: $4.184\ J = 1\ cal$. (Section 1.5)

Kelvin scale The SI temperature scale; the SI unit for temperature is the kelvin. Zero on the Kelvin scale corresponds to −273.15 °C. (Section 1.5)

ketone A compound in which the carbonyl group (C=O) occurs at the interior of a carbon chain and is therefore flanked by carbon atoms. (Section 24.4)

ketones A compound in which the carbonyl group occurs at the interior of a carbon chain and is therefore flanked by carbon atoms. (Section 28.2)

ketoses A carbohydrate that contains a ketone group when in its open-chain form. (Section 28.4)

kinetic energy The energy that an object possesses by virtue of its motion. (Section 1.4)

kinetic-molecular theory of gases A set of assumptions about the nature of gases. These assumptions, when translated into mathematical form, yield the ideal-gas equation. (Section 10.6)

lactams A cyclic amide in which the amide bond forms part of the ring. (Section 31.1)

Larmor frequency The frequency at which a nucleus absorbs energy. This frequency is a function of the strength of the applied field B_0. (Section 32.3)

lanthanide contraction The gradual decrease in atomic and ionic radii with increasing atomic number among the lanthanide elements, atomic numbers 57 through 70. The decrease arises because of a gradual increase in effective nuclear charge through the lanthanide series. (Section 23.1)

lanthanide (rare earth) element Element in which the 4*f* subshell is only partially occupied. (Sections 6.8 and 6.9)

lattice energy The energy required to separate completely the ions in an ionic solid into its gaseous ions. (Section 8.2)

lattice points Points in a crystal, all of which have identical environments. (Section 12.1)

lattice vectors The vectors $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ that define each lattice point in a crystal lattice. Beginning from any lattice point, it is possible to move to any other lattice point by adding together whole-number multiples of the two lattice vectors. (Section 12.1)

law of conservation of mass The total mass of materials present after a chemical reaction is the same as the total mass present before the reaction. (Section 2.1)

law of constant composition A law that states that the elemental composition of a compound is always the same; also called the **law of definite proportions**. (Section 1.2)

law of definite proportions A law that states that the elemental composition of a substance is always the same; also called the **law of constant composition**. (Section 1.2)

law of mass action The rules by which the equilibrium constant is expressed in terms of the concentrations of reactants and products, in accordance with the balanced chemical equation for the reaction. (Section 15.2)

law of multiple proportions If two elements A and B combine to form more than one compound, the masses of B that can combine with a given mass of A are in the ratio of small whole numbers. (Section 2.1)

Le Châtelier's principle A principle stating that when we disturb a system at chemical equilibrium, the relative concentrations of reactants and products shift so as to partially undo the effects of the disturbance. (Section 15.5)

levorotatory, or merely levo or *l* A term used to label a chiral molecule that rotates the plane of polarization of plane-polarized light to the left (counterclockwise). (Section 23.4)

levorotatory A term used to label a chiral molecule that rotates the plane of polarisation of plane-polarised light to the left (anticlockwise). (Section 25.4)

Lewis acid An electron-pair acceptor. (Section 16.8)

Lewis base An electron-pair donor. (Section 16.8)

Lewis structure A representation of covalent bonding in a molecule that is drawn using Lewis symbols. Shared electron pairs are shown as lines, and unshared electron pairs are shown as pairs of dots. Only the valence-shell electrons are shown. (Section 8.3)

Lewis symbol (electron-dot symbol) The chemical symbol for an element, with a dot for each valence electron. (Section 8.1)

ligand An ion or molecule that coordinates to a metal atom or to a metal ion to form a complex. (Section 23.2)

limiting reactant (limiting reagent) The reactant that is completely consumed in a reaction; the amount of product that can form is limited by the complete consumption of the limiting reactant. (Section 3.7)

line spectrum A spectrum that contains radiation at only certain specific wavelengths. (Section 6.3)

linkage isomers Structural isomers of coordination compounds in which a ligand is capable of coordinating to a metal in two ways. (Section 23.4)

lipid A nonpolar biological molecule used by organisms for long-term energy storage or as a structural component. (Section 24.9)

lipids A heterogeneous class of naturally occurring organic compounds that are more soluble in aprotic organic solvents but not soluble in water. (Section 29.4)

liquid Matter that has a distinct volume independent of its container. (Section 1.2)

liquid crystal A substance that exhibits a viscous, milky state between the liquid and solid states. (Section 11.7)

lock-and-key model A model of enzyme action in which the substrate molecule is pictured as fitting rather specifically into the active site on the enzyme. It is assumed that in being bound to the active site, the substrate is somehow activated for reaction. (Section 14.7)

lock-and-key model A model of enzyme action in which the substrate molecule is pictured as fitting rather specifically into the active site on the enzyme. It is assumed that, in being bound to the active site, the substrate is somehow activated for reaction. (Section 31.3)

lone pair A pair of electrons that do not participate in covalent bonding in neutral molecules. (Section 27.1)

low-spin complex A metal complex in which the electrons are paired in lower-energy orbitals. (Section 23.6)

macroporous Solids having pores that are visible to the naked eye. (Section 12.6)

magic numbers Numbers of protons and neutrons that result in very stable nuclei. (Section 21.2)

main-group elements Elements in the *s* and *p* blocks of the periodic table. (Section 6.9)

Markovnikov's rule A rule stating that, for the addition of HX to an alkene, the hydrogen of HX adds to the carbon of the double bond with the most hydrogens already attached to it. In essence, the most stable carbocation is formed in preference. (Section 26.4)

mass A measure of the amount of material in an object. In SI units, mass is measured in kilograms. (Section 1.5)

mass defect The difference between the mass of a nucleus and the total masses of the individual nucleons that it contains. (Section 21.5)

mass-to-charge ratio Defined as m/z, where m = mass of the ionised species and z = charge on that species. Organic chemists use the term m/z as a dimensionless quantity. (Section 32.4)

mass number The sum of the number of protons and neutrons in the nucleus of a particular atom. (Section 2.3)

mass percentage The number of grams of solute in each 100 g of solution. (Section 13.4)

mass spectrometer An instrument used to measure the precise masses and relative amounts of atomic and molecular ions. (Section 2.4)

matter Anything that occupies space and has mass; the physical material of the universe. (Section 1.1)

matter waves The term used to describe the wave characteristics of a moving particle. (Section 6.4)

mean free path The average distance traveled by a gas molecule between collisions. (Section 10.7)

***meso* compound** An achiral compound containing two or more stereocentres. (Section 25.6)

mesoporous Solids having pore sizes in the range 2 to 50 nm. (Section 12.6)

metal complex Species that are assemblies of a central transition-metal ion bonded to a group of surrounding molecules or ions, such as $[Ag(NH_3)_2]^+$ and $[Fe(H_2O)_6]^{3+}$. (Section 23.2)

***meta*-director** A substituent on an aromatic compound that preferentially directs an incoming substituent in an electrophillic aromatic substitution to the *meta* position. (Section 30.5)

metal hydrides A compound containing a metal-to-hydrogen bond. Typically used as a source of hydride H^- in organic chemistry. (Section 28.3)

metallic bond Bonding, usually in solid metals, in which the bonding electrons are relatively free to move throughout the three-dimensional structure. (Section 8.1)

metallic character The extent to which an element exhibits the physical and chemical properties characteristic of metals, for example, luster, malleability, ductility, and good thermal and electrical conductivity. (Section 7.6)

metallic elements (metals) Elements that are usually solids at room temperature, exhibit high electrical and heat conductivity, and appear lustrous. Most of the elements in the periodic table are metals. (Sections 2.5 and 12.1)

metallic hydrides Compounds formed when hydrogen reacts with transition metals; these compounds contain the hydride ion, H^-. (Section 22.2)

metallic solids Solids that are composed of metal atoms held together by a delocalized "sea" of collectively shared valence electrons. (Sections 12.1 and 12.2)

metalloids Elements that lie along the diagonal line separating the metals from the nonmetals in the periodic table; the properties of metalloids are intermediate between those of metals and nonmetals. (Section 2.5)

metallurgy The science of extracting metals from their natural sources by a combination of chemical and physical processes. It is also concerned with the properties and structures of metals and alloys. (Section 23.1)

metathesis (exchange) reaction A reaction in which two substances react through an exchange of their component ions: $AX + BY \longrightarrow AY + BX$. Precipitation and acid–base neutralization reactions are examples of metathesis reactions. (Section 4.2)

metric system A system of measurement used in science and in most countries. The meter and the gram are examples of metric units. (Section 1.5)

micelles A spherical aggregate of molecules such as the sodium or potassium salts of fatty acids, oriented in such a way that they have a hydrophilic (charged) surface and a hydrophobic core. (Section 29.4)

microporous Refers to solids that have pores up to 2 nm in size. (Section 12.6)

microstate A single possible arrangement of the positions and kinetic energies of the molecules when the molecules are in a specific thermodynamic state. (Section 19.3)

mineral A solid, inorganic substance occurring in nature, such as calcium carbonate, which occurs as calcite. (Section 23.1)

miscible liquids Liquids that mix in all proportions. (Section 13.3)

mixture A combination of two or more substances in which each substance retains its own chemical identity. (Section 1.2)

molal boiling-point-elevation constant (K_b) A constant characteristic of a particular solvent that gives the increase in boiling point as a function of solution molality: $\Delta T_b = iK_b m$. (Section 13.5)

molal freezing-point-depression constant (K_f) A constant characteristic of a particular solvent that gives the decrease in freezing point as a function of solution molality: $\Delta T_f = -iK_f m$. (Section 13.5)

molality The concentration of a solution expressed as moles of solute per kilogram of solvent; abbreviated *m*. (Section 13.4)

molar heat capacity The heat required to raise the temperature of one mole of a substance by 1 °C. (Section 5.5)

molarity The concentration of a solution expressed as moles of solute per liter of solution; abbreviated *M*. (Section 4.5)

molar mass The mass of one mole of a substance in grams; it is numerically equal to the formula weight in atomic mass units. (Section 3.4)

mole A collection of Avogadro's number (6.022×10^{23}) of objects; for example, a mole of H_2O is 6.022×10^{23} H_2O molecules. (Section 3.4)

molecular compound A compound that consists of molecules. (Section 2.6)

molecular equation A chemical equation in which the formula for each substance is written without regard for whether it is an electrolyte or a nonelectrolyte. (Section 4.2)

molecular formula A chemical formula that indicates the actual number of atoms of each element in one molecule of a substance. (Section 2.6)

molecular geometry The arrangement in space of the atoms of a molecule. (Section 9.2)

molecular hydrides Compounds formed when hydrogen reacts with nonmetals and metalloids. (Section 22.2)

molecularity The number of molecules that participate as reactants in an elementary reaction. (Section 14.6)

molecular orbital (MO) An allowed state for an electron in a molecule. According to molecular-orbital theory, a molecular orbital is entirely analogous to an atomic orbital, which is an allowed state for an electron in an atom. Most bonding molecular orbitals can be classified as σ or π, depending on the disposition of electron density with respect to the internuclear axis. (Section 9.7)

molecular-orbital diagram A diagram that shows the energies of molecular orbitals relative to the atomic orbitals from which they are derived; also called an **energy-level diagram**. (Section 9.7)

molecular-orbital theory A theory that accounts for the allowed states for electrons in molecules by using specific wave functions. (Section 9.7)

molecular ion Typically, the species formed by the loss of an electron from a molecule. (Section 32.4)

molecular solids Solids that are composed of molecules held together by their intermolecular forces. (Sections 12.1 and 12.4)

molecular weight The sum of the atomic weights (AW) of the atoms represented by their chemical formula for a molecule. (Section 3.3)

molecule A chemical combination of two or more atoms. (Sections 1.1 and 2.6)

mole fraction The ratio of the number of moles of one component of a mixture to the total moles of all components; abbreviated *X*, with a subscript to identify the component. (Section 10.5)

momentum The product of the mass, *m*, and velocity, *v*, of an object. (Section 6.4)

monodentate ligand A ligand that binds to the metal ion via a single donor atom. It occupies one position in the coordination sphere. (Section 23.3)

monomers Molecules with low molecular weights which can be joined together (polymerised) to form a polymer. (Section 26.6)

monosaccharide A simple sugar, most commonly containing six carbon atoms. The joining together of monosaccharide units by condensation reactions results in formation of polysaccharides. (Section 24.8)

monosaccharides A simple sugar, most commonly containing six carbon atoms. The joining together of monosaccharide units by condensation reactions results in formation of polysaccharides. (Section 28.4)

motif In a crystal, the group of atoms associated with each lattice point. (Section 12.1)

multiplicity The number of peaks an NMR signal is split into due to spin–spin coupling. (Section 32.3)

mutarotation The change in optical rotation that occurs upon the equilibration of α and β anomers from a single anomer. (Section 28.4)

nanomaterial A solid whose dimensions range from 1 to 100 nm and whose properties differ from those of a bulk material with the same composition. (Sections 12.1 and 12.6)

natural gas A naturally occurring mixture of gaseous hydrocarbon compounds composed of hydrogen and carbon. (Section 5.9)

nematic liquid crystalline phase A liquid crystal in which the molecules are aligned in the same general direction, along their long axes, but in which the ends of the molecules are not aligned. (Section 11.7)

Nernst equation An equation that relates the cell emf, E, to the standard emf, E°, and the reaction quotient, Q: $E = E^\circ - (RT/nF) \ln Q$. (Section 20.6)

net ionic equation A chemical equation for a solution reaction in which soluble strong electrolytes are written as ions and spectator ions are omitted. (Section 4.2)

neutralization reaction A reaction in which an acid and a base react in stoichiometrically equivalent amounts; the neutralization reaction between an acid and a metal hydroxide produces water and a salt. (Section 4.3)

neutron An electrically neutral particle found in the nucleus of an atom; it has approximately the same mass as a proton. (Section 2.2)

Newman projection A representation of a molecule's spatial arrangement looking along a C–C single bond. (Section 24.3)

nitriles Any hydrocarbon containing the C≡N group. (Section 27.5 and 28.3)

noble gases Members of group 18 in the periodic table. (Section 7.8)

nodal plane In an antibonding orbital, the plane in the region between the nuclei where the electron density is zero. (Section 9.7)

node Points in an atom at which the electron density is zero. For example, the node in a 2s orbital is a spherical surface. (Section 6.6)

nomenclature The systematic naming of a compound. (Section 24.4)

nonbonding pair In a Lewis structure a pair of electrons assigned completely to one atom; also called a lone pair. (Section 8.3)

nonelectrolyte A substance that does not ionize in water and consequently gives a nonconducting solution. (Section 4.1)

nonionizing radiation Radiation that does not have sufficient energy to remove an electron from a molecule. (Section 21.6)

nonmetallic elements (nonmetals) Elements in the upper right corner of the periodic table; nonmetals differ from metals in their physical and chemical properties. (Section 2.5)

nonpolar covalent bond A covalent bond in which the electrons are shared equally. (Section 8.4)

normal boiling point The boiling point at 1 atm pressure. (Section 11.5)

normal melting point The melting point at 1 atm pressure. (Section 11.6)

nuclear binding energy The energy required to decompose an atomic nucleus into its component protons and neutrons. (Section 21.5)

nuclear disintegration series A series of nuclear reactions that begins with an unstable nucleus and terminates with a stable one; also called a radioactive series. (Section 21.2)

nuclear magnetic resonance (NMR) spectroscopy A non-destructive technique able to provide information on the types and relative number of atoms, atom connectivity and spatial relationships. This technique observes nuclear spin transitions within a strong magnetic field. (Section 32.3)

nuclear model Model of the atom with a very small and extremely dense nucleus containing most of the mass (protons and neutrons) and with electrons in the space outside the nucleus. (Section 2.2)

nuclear reaction Reaction in which transformations of atomic nuclei occur. (Section 21.1)

nuclear transmutation A conversion of one kind of nucleus to another. (Section 21.2)

nucleophilic acyl substitution The mechanism by which one carboxylic acid derivative is converted into a less reactive one. (Section 29.5)

nucleic acids Polymers of high molecular weight that carry genetic information and control protein synthesis. (Section 24.10 and 31.4)

nucleon Particles found in the nucleus of an atom; protons and neutrons. (Section 21.1)

nucleophile Any atom, molecule or ion that donates a pair of electrons to an electrophile to form a new covalent bond. (Section 26.4)

nucleophilic addition A reaction that involves the addition of a nucleophile to a reagent, usually a carbonyl compound. (Section 28.3)

nucleosides Compounds containing a five-carbon sugar and a nitrogen-containing organic base. (Section 31.4)

nucleotides Compounds formed from a molecule of phosphoric acid, a sugar molecule and an organic nitrogen base. Nucleotides form linear polymers called DNA and RNA, which are involved in protein synthesis and cell reproduction. (Section 31.4)

***N*-glycosides** Formed particularly when a monosaccharide is reacted with an amine in the presence of acid. Nucleosides are also *N*-glycosides. (Section 31.4)

nucleophilic substitution (SN) reaction Any reaction in which one nucleophile is substituted by another. (Section 27.4)

nucleotide Monomers of nucleic acids formed from a five-carbon sugar, a nitrogen-containing organic base, and a phosphate group. Nucleotides form linear polymers called DNA and RNA, which are involved in protein synthesis and cell reproduction. (Section 24.10)

nucleus The very small, very dense, positively charged portion of an atom; it is composed of protons and neutrons. (Section 2.2)

octet rule A rule stating that atoms tend to gain, lose, or share electrons until they are surrounded by eight valence electrons. (Section 8.1)

oils Triglycerides that are liquids at room temperature. They are usually rich in unsaturated fatty acids. (Section 29.4)

operating frequency The frequency at which a NMR spectrometer operates to observe a given nucleus, usually 1H. (Section 32.3)

optical isomers Stereoisomers in which the two forms of the compound are nonsuperimposable mirror images. (Section 25.3)

optical isomerism A form of isomerism in which the two forms of a compound (stereoisomers) are nonsuperimposable mirror images. Also called **enantiomers**. (Section 23.4)

optically active Possessing the ability to rotate the plane of polarized light. (Section 23.4)

orbital An allowed energy state of an electron in the quantum-mechanical model of the atom; the term *orbital* is also used to describe the spatial distribution of the electron. An orbital is defined by the values of three quantum numbers: n, l, and m_l (Section 6.5)

orbital diagram A representation of an atomic orbital drawn as a box with one or two half-arrows inside representing electrons. (Section 6.8)

organic chemistry The study of carbon-containing compounds, typically containing carbon–carbon bonds. (Section 2.9; Section 24.1)

organometallic compounds A compound containing a carbon-to-metal bond. (Section 28.3)

***ortho*, *para*-director** A substituent on an aromatic compound that directs an incoming substituent in an electrophilic aromatic sub-stitution, to the *ortho* and *para* positions in preference. (Section 30.5)

osmosis The net movement of solvent through a semipermeable membrane toward the solution with greater solute concentration. (Section 13.5)

osmotic pressure The pressure that must be applied to a solution to stop osmosis from pure solvent into the solution. (Section 13.5)

Ostwald process An industrial process used to make nitric acid from ammonia. The NH_3 is catalytically oxidized by O_2 to form NO; NO in air is oxidized to NO_2; HNO_3 is formed in a disproportionation reaction when NO_2 dissolves in water. (Section 22.7)

overall reaction order The sum of the reaction orders of all the reactants appearing in the rate expression when the rate can be expressed as $\text{rate} = k[A]^a[B]^b\ldots$. (Section 14.3)

overlap The extent to which atomic orbitals on different atoms share the same region of space. When the overlap between two orbitals is large, a strong bond may be formed. (Section 9.4)

oxidation A process in which a substance loses one or more electrons. (Section 24.7)

oxidation number (oxidation state) A positive or negative whole number assigned to an element in a molecule or ion on the basis of a set of formal rules; to some degree it reflects the positive or negative character of that atom. (Section 4.4)

oxidation–reduction (redox) reaction A reaction in which electrons are transferred from one reactant to another and the oxidation states of these atoms change. (Section 4.4; Section 20.1)

oxidizing agent, or oxidant The substance that is reduced and thereby causes the oxidation of some other substance in an oxidation–reduction reaction. (Section 20.1)

oxyacid A compound in which one or more OH groups, and possibly additional oxygen atoms, are bonded to a central atom. (Section 16.8)

oxyanion A polyatomic anion that contains one or more oxygen atoms. (Section 2.8)

ozone The name given to O_3, an allotrope of oxygen. (Section 7.8)

ozonolysis A synthetically useful way of generating aldehydes and ketones. (Section 28.2)

paramagnetism A property that a substance possesses if it contains one or more unpaired electrons. A paramagnetic substance is drawn into a magnetic field. (Section 9.8)

partial pressure The pressure exerted by a particular gas in a mixture. (Section 10.5)

particle accelerator A device that uses strong magnetic and electrostatic fields to accelerate charged particles. (Section 21.2)

parts per billion (ppb) The concentration of a solution in grams of solute per 10^9 (billion) grams of solution; equals micrograms of solute per liter of solution for aqueous solutions. (Section 13.4)

parts per million (ppm) The concentration of a solution in grams of solute per 10^6 (million) grams of solution; equals milligrams of solute per liter of solution for aqueous solutions. (Section 13.4)

pascal (Pa) The SI unit of pressure: $1\ \text{Pa} = 1\ \text{N/m}^2$. (Section 10.2)

Pauli exclusion principle A rule stating that no two electrons in an atom may have the same four quantum numbers (n, l, m_l, and m_s).

As a reflection of this principle, there can be no more than two electrons in any one atomic orbital. (Section 6.7)

penicillins A lactam with antibiotic activity. (Section 31.1)

peptide The name given to a short polymer (oligomer) of amino acids joined by amide bonds, usually without significant tertiary structure. (Section 31.3)

peptide bond An amide group formed by amino acids. A bond formed between two amino acids. (Section 24.7)

peptide bond A bond formed between two amino acids. (Section 31.3)

percent ionization The percent of a substance that undergoes ionization on dissolution in water. The term applies to solutions of weak acids and bases. (Section 16.5)

percent yield The ratio of the actual (experimental) yield of a product to its theoretical (calculated) yield, multiplied by 100. (Section 3.7)

period The row of elements that lie in a horizontal row in the periodic table. (Section 2.5)

periodic table The arrangement of elements in order of increasing atomic number, with elements having similar properties placed in vertical columns. (Section 2.5)

perspective drawing A model that uses wedges and dashed lines to depict bonds that are not in the plane of the paper. (Section 2.6)

petroleum A naturally occurring combustible liquid composed of hundreds of hydrocarbons and other organic compounds. (Section 5.9)

pH The negative log in base 10 of the aquated hydrogen ion concentration: $pH = -\log[H^+]$. (Section 16.3)

pH titration curve A graph of pH as a function of added titrant. (Section 17.3)

phase change The conversion of a substance from one state of matter to another. The phase changes we consider are melting and freezing (solid $\rightleftharpoons$ liquid), sublimation and deposition, and vaporization and condensation (liquid $\rightleftharpoons$ gas). (Section 11.4)

phase diagram A graphic representation of the equilibria among the solid, liquid, and gaseous phases of a substance as a function of temperature and pressure. (Section 11.6)

phenyl group A hydrocarbon group with formula C_6H_5. (Section 30.2)

phenols A compound with molecular formula C_6H_5OH. (Section 30.2)

phospholipid A form of lipid molecule that contains charged phosphate groups. (Section 24.9)

photochemical smog A complex mixture of undesirable substances produced by the action of sunlight on an urban atmosphere polluted with automobile emissions. The major starting ingredients are nitrogen oxides and organic substances. (Section 18.2)

photodissociation The rupture of a chemical bond resulting from absorption of a photon by a molecule. (Section 18.1)

photoelectric effect The emission of electrons from a metal surface induced by light. (Section 6.2)

photoionization The removal of an electron from an atom or molecule by absorption of light. (Section 18.1)

photon The smallest increment (a quantum) of radiant energy; a photon of light with frequency ν has an energy equal to $h\nu$. (Section 6.2)

photosynthesis The process that occurs in plant leaves by which light energy is used to convert carbon dioxide and water to carbohydrates and oxygen. (Section 23.3)

physical changes Changes in physical appearance (such as a phase change) that occur with no change in chemical composition. (Section 1.3)

physical properties Properties that can be measured without changing the composition of a substance, for example, color and freezing point. (Section 1.3)

pi (π) bond A covalent bond in which electron density is concentrated above and below the internuclear axis; produced by the sideways overlap of *p* orbitals. (Section 9.6)

pi (π)-bond A covalent bond in which electron density is concentrated above and below the line joining the bonded atoms. (Section 26.1)

pi (π) molecular orbital A molecular orbital that concentrates the electron density on opposite sides of an imaginary line that passes through the nuclei. (Section 9.8)

Planck constant (*h*) The constant that relates the energy and frequency of a photon, $E = h\nu$. Its value is 6.626×10^{-34} J-s. (Section 6.2)

plastic A polymeric solid that can be formed into particular shapes by application of heat and pressure. (Section 12.5)

plastics A material that can be formed into particular shapes by application of heat and pressure. (Section 26.6)

β-pleated sheet A form of protein secondary structure characterised by an intermolecular hydrogen bonding arrangement with another peptide chain. (Section 31.3)

polar covalent bond A covalent bond in which the electrons are not shared equally. (Section 8.4)

polarimeter An instrument used to measure the rotation of plane-polarised light. (Section 25.4)

polarizability The ease with which the electron cloud of an atom or a molecule is distorted by an outside influence, thereby inducing a dipole moment. (Section 11.2)

polar molecule A molecule in which the centers of positive and negative charge do not coincide; a molecule that possesses a nonzero dipole moment. (Section 8.4)

polyatomic ion An electrically charged group of two or more atoms. (Section 2.7)

polypeptides A polymer of amino acids that has a molecular weight of less than 10000. (Section 31.3)

polyesters Polymers in which the repeating structural units are joined together by ester bonds. Usually formed by the condensation of dicarboxylic acids and their derivatives with diols. (Section 29.5)

polyamides Polymers in which the repeating structural units are joined together by amide bonds. Usually formed by the condensation of dicarboxylic acids and their derivatives with diamines. (Section 29.5)

polydentate ligand A ligand in which two, three, or more donor atoms can coordinate to the same metal ion. (Section 23.3)

polymer Large molecules with long chains of atoms (usually carbon), where the atoms within a given chain are connected by covalent bonds and adjacent chains are held to one another largely by weaker intermolecular forces. (Sections 12.1 and 12.5)

polymer A large molecule of high molecular mass, formed by the joining together, or polymerisation, of a large number of molecules of low molecular mass. The individual molecules forming the polymer are called monomers. (Section 26.6)

polypeptide A polymer of amino acids formed when a large number of amino acids (>30) are linked together by peptide bonds. (Section 24.7)

polyprotic acid A substance capable of dissociating more than one proton in water; H_2SO_4 is an example. (Section 16.5)

polysaccharide A substance made up of many monosaccharide units joined together. (Section 24.8)

polysaccharides A substance made up of several monosaccharide units joined together. (Section 28.4)

porphyrin A complex derived from the porphine molecule. (Section 23.3)

positron A particle with the same mass as an electron but with a positive charge, ${}^{0}_{+1}e$, or β^+. (Section 21.1)

positron emission A nuclear decay process where a positron, a particle with the same mass as an electron but with a positive charge, symbol ${}^{0}_{+1}e$, or β^+, is emitted from the nucleus. (Section 21.1)

potential energy The energy that an object possesses as a result of its position with respect to another object. (Section 1.4)

precipitate An insoluble substance that forms in, and separates from, a solution. (Section 4.2)

precipitation reaction A reaction that occurs between substances in solution in which one of the products is insoluble. (Section 4.2)

precision The closeness of agreement among several measurements of the same quantity. (Section 1.6)

pressure A measure of the force exerted on a unit area. In chemistry, pressure is often expressed in units of atmospheres (atm) or torr: 760 torr = 1 atm; in SI units pressure is expressed in pascals (Pa). (Section 10.2)

pressure–volume (*PV*) work Work performed by expansion of a gas against a resisting pressure. (Section 5.3)

primary cell A voltaic cell that cannot be recharged. (Section 20.7)

primary structure The sequence of amino acids along a protein chain. (Section 24.7)

primary structure The sequence of amino acids along a protein chain. (Section 31.3)

primitive lattice A crystal lattice in which the lattice points are located only at the corners of each unit cell. (Section 12.1)

principal quantum number The integer, n, associated with orbits and energy levels in the Bohr atom. (Section 6.3)

probability density (ψ^2) A value that represents the probability that an electron will be found at a given point in space. Also called **electron density**. (Section 6.5)

product A substance produced in a chemical reaction; it appears to the right of the arrow in a chemical equation. (Section 3.1)

propagation Fundamental steps in a freeradical polymerisation that are repeated over and over again in a chain reaction. (Section 26.6)

property Any characteristic that allows us to recognize a particular type of matter and to distinguish it from other types. (Section 1.1)

protein Macromolecules present in all living cells; a biopolymer formed from amino acids. (Section 24.7)

proteins A biopolymer formed from amino acids. (Section 31.3)

protium The most common isotope of hydrogen. (Section 22.2)

proton A positively charged subatomic particle found in the nucleus of an atom. (Section 2.2)

pyrimidine A nitrogen-containing sixmembered heterocyclic compound used as an organic base for genetic information storage within DNA. (Section 31.4)

purine A nitrogen-containing heterocyclic compound comprising fused five- and six-membered rings. Used as an organic base for genetic information storage within DNA. (Section 31.4)

pure substance Matter that has a fixed composition and distinct properties. (Section 1.2)

qualitative analysis The determination of the presence or absence of a particular substance in a mixture. (Section 17.6)

quantitative analysis The determination of the amount of a given substance that is present in a sample. (Section 17.6)

quantum The smallest increment of radiant energy that may be absorbed or emitted; the magnitude of radiant energy is $h\nu$. (Section 6.2)

quaternary structure The structure of a protein resulting from the clustering of several individual protein chains into a final specific shape. (Section 24.7)

quaternary structure The aggregation of two or more proteins into a larger macromolecular assembly. (Section 31.3)

racemic mixture A mixture of equal amounts of the dextrorotatory and levorotatory forms of a chiral molecule. A racemic mixture will not rotate the plane of polarized light. (Section 23.4)

rad A measure of the energy absorbed from radiation by tissue or other biological material; 1 rad = transfer of 1×10^{-2} J of energy per kilogram of material. (Section 21.6)

radial probability function The probability that the electron will be found at a certain distance from the nucleus. (Section 6.6)

radioactive Possessing radioactivity, the spontaneous disintegration of an unstable atomic nucleus with accompanying emission of radiation. (Section 2.2; Section 21.1)

radioactive decay chain A series of nuclear reactions that begins with an unstable nucleus and terminates with a stable one. Also called **nuclear disintegration series**. (Section 21.2)

radioisotope An isotope that is radioactive; that is, it is undergoing nuclear changes with emission of radiation. (Section 21.1)

radionuclide A radioactive nuclide. (Section 21.1)

radiotracer A radioisotope that can be used to trace the path of an element in a chemical system. (Section 21.4)

Raoult's law A law stating that the partial pressure exerted by solvent vapor above the solution, $P_{solution}$, equals the product of the mole fraction of the solvent, $X_{solvent}$, and the vapor pressure of the pure solvent, $P^{\circ}_{solvent}$. $P_{solution} = X_{solvent}P^{\circ}_{solvent}$. (Section 13.5)

racemic mixture A mixture of equal amounts of the dextrorotatory and levorotatory forms of a chiral molecule. A racemic mixture will not rotate polarised light. Also called a racemate. (Section 25.4)

rare earth element See **lanthanide (rare earth) element**. (Sections 6.8 and 6.9)

rate constant A constant of proportionality between the reaction rate and the concentrations of reactants that appear in the rate law. (Section 14.3)

rate-determining step The slowest elementary step in a reaction mechanism. (Section 14.6)

rate law An equation that relates the reaction rate to the concentrations of reactants (and sometimes of products also). (Section 14.3)

reactant A starting substance in a chemical reaction; it appears to the left of the arrow in a chemical equation. (Section 3.1)

reaction mechanism A detailed picture, or model, of how the reaction occurs; that is, the order in which bonds are broken and formed and the changes in relative positions of the atoms as the reaction proceeds. (Section 14.6)

reaction order The power to which the concentration of a reactant is raised in a rate law. (Section 14.3)

reaction quotient (*Q*) The value that is obtained when concentrations of reactants and products are inserted into the equilibrium expression. If the concentrations are equilibrium concentrations, $Q = K$; otherwise, $Q \neq K$. (Section 15.4)

reaction rate The speed at which a chemical reaction occurs; a measure of the decrease in concentration of a reactant or the increase in concentration of a product with time. (Section 14.1 and Section 14.2)

redox (oxidation–reduction) reaction A reaction in which certain atoms undergo changes in oxidation states. The substance increasing in oxidation state is oxidized; the substance decreasing in oxidation state is reduced. (Section 4.4; Section 20.1)

reducing agent, or reductant The substance that is oxidized and thereby causes the reduction of some other substance in an oxidation–reduction reaction. (Section 20.1)

reduction A process in which a substance gains one or more electrons. (Section 4.4)

reductive amination A reaction between an aldehyde or ketone and primary amine, or ammonia, that occurs in the presence of a reducing agent, leading to the formation of a new amine. (Section 31.1)

rem A measure of the biological damage caused by radiation; rems = rads × RBE. (Section 21.6)

renewable energy sources Energy such as solar energy, wind energy, and hydroelectric energy derived from essentially inexhaustible sources. (Section 5.9)

representative (main-group) element An element from within the *s* and *p* blocks of the periodic table (Figure 6.30). (Section 6.9)

resonance structures (resonance forms) Individual Lewis structures in cases where two or more Lewis structures are equally good descriptions of a single molecule. The resonance structures in such an instance are "averaged" to give a more accurate description of the real molecule. (Section 8.6)

resolution The act of separating a racemic mixture into its constituent enantiomers. (Section 25.6)

resonance 1. The term given to the absorption of electromagnetic radiation at the Larmor frequency, which leads to the flip of its nuclear spin from a lower state to a higher state (and *vice versa*). 2. The way electron delocalisation is shown using Lewis structures. (Section 30.3 and 32.3)

resonance structures (resonance forms) Individual Lewis structures in cases where two or more Lewis structures are equally good descriptions of a single molecule. The resonance structures in such an instance are 'averaged' to give a more accurate description of the real molecule. (Section 30.2)

resonance energy The difference in energy between a resonance hybrid and the most stable contributing structure in which the bonds are localised. (Section 30.2)

resonance-stabilized The stabilisation given to any molecule in which its electrons can be delocalised over three or more atoms. (Section 30.4)

reverse osmosis The process by which water molecules move under high pressure through a semipermeable membrane from the more concentrated to the less concentrated solution. (Section 18.4)

reversible process A process in which the system can be restored to its original condition with no change to the surroundings. (Section 19.1)

ribonucleic acid (RNA) A polynucleotide in which ribose is the sugar component. (Section 24.10)

ribonucleic acids (RNA) A polynucleotide in which ribose is the sugar component. (Section 31.4)

root-mean-square (rms) speed (μ_{rms}) The square root of the average of the squared speeds of the gas molecules in a gas sample. (Section 10.6)

rotational motion Movement of a molecule as it spins about an axis. (Section 19.3)

saponification Hydrolysis of an ester in the presence of a base. (Section 29.3)

salinity A measure of the salt content of seawater, brine, or brackish water. It is equal to the mass in grams of dissolved salts present in 1 kg of seawater. (Section 18.3)

salt Any ionic compound whose cation comes from a base (for example, Na^+ from NaOH) and whose anion comes from an acid (for example, Cl^- from HCl). (Section 4.3)

saponification Hydrolysis of an ester in the presence of a base. (Section 24.4)

saturated solution A solution in which undissolved solute and dissolved solute are in equilibrium. (Section 24.2)

scientific law A statement of what is always observed to happen, to the best of our knowledge. (Section 1.5)

scientific method The general process of advancing scientific knowledge by making experimental observations and by formulating hypotheses, theories, and laws. (Figure 1.17)

secondary cell A voltaic cell that can be recharged. (Section 20.7)

secondary structure Refers to how segments of the protein chain are oriented in a regular pattern. (Section 24.7)

secondary structure The manner in which a protein is coiled or stretched. (Section 31.3)

second law of thermodynamics A statement of our experience that there is a direction to the way events occur in nature. When a process occurs spontaneously in one direction, it is nonspontaneous in the reverse direction. It is possible to state the second law in many different forms, but they all relate back to the same idea about spontaneity. One of the most common statements found in chemical contexts is that in any spontaneous process the entropy of the universe increases. (Section 19.2)

second-order reaction A reaction in which the rate depends either on a reactant concentration raised to the second power or on the concentrations of two reactants each raised to the first power. (Section 14.4)

semiconductor A material that has electrical conductivity between that of a metal and that of an insulator. (Section 12.4)

sequence priority rules A process of determining priority based on the atomic weights of atoms connected to a stereocentre. (Section 25.5)

shielding/deshielding Any effect that causes a nucleus to come into resonance at a higher/lower field, respectively. (Section 32.3)

side chain That part of an α-amino acid that distinguishes it from other α-amino acids. (Section 31.2)

sigma (σ) bond A covalent bond in which electron density is concentrated along the internuclear axis. (Section 26.1)

sigma (σ) molecular orbital A molecular orbital that centers the electron density about an imaginary line passing through two nuclei. (Section 9.7)

significant figures The digits that indicate the precision with which a measurement is made; all digits of a measured quantity are significant, including the last digit, which is uncertain. (Section 1.6)

silica Common name for silicon dioxide. (Section 22.4)

silicates Compounds containing silicon and oxygen, structurally based on SiO_4 tetrahedra. (Section 22.10)

simple proteins A protein that yields only amino acids upon hydrolysis. (Section 31.3)

single bond A covalent bond involving one electron pair. (Section 8.3)

SI units The preferred metric units for use in science. (Section 1.5)

smectic A and smectic C liquid crystals Liquid crystals in which the molecules maintain the long-axis alignment seen in nematic crystals, but in addition pack into layers. (Section 11.7)

solid Matter that has both a definite shape and a definite volume. (Section 1.2)

solubility The amount of a substance that dissolves in a given quantity of solvent at a given temperature to form a saturated solution. (Sections 4.2 and 13.2)

solubility-product constant (solubility product) (K_{sp}) An equilibrium constant related to the equilibrium between a solid salt and its ions in solution. It provides a quantitative measure of the solubility of a slightly soluble salt. (Section 17.4)

solute A substance dissolved in a solvent to form a solution; it is normally the component of a solution present in the smaller amount. (Section 4.1)

solution A mixture of substances that has a uniform composition; a homogeneous mixture. (Section 1.2)

solvation The clustering of solvent molecules around a solute particle. (Section 13.1)

solvent The dissolving medium of a solution; it is normally the component of a solution present in the greater amount. (Section 4.1)

space-filling model Model that shows relative sizes of the atoms. (Section 2.6)

specific heat (C_s) The heat capacity of 1 g of a substance; the heat required to raise the temperature of 1 g of a substance by 1 °C. (Section 5.5)

specific rotation The amount an optically active compound of concentration 1.0 g per 100 cm^{-3} rotates plane-polarised light through a 1-dm-long cell at 25 °C. (Section 25.4)

spectator ions Ions that go through a reaction unchanged and that appear on both sides of the complete ionic equation. (Section 4.2)

spectrochemical series A list of ligands arranged in order of their abilities to increase the crystal-field splitting energy. (Section 23.6)

spectrum The distribution among various wavelengths of the radiant energy emitted or absorbed by an object. (Section 6.3)

spin magnetic quantum number (m_s) A quantum number associated with the electron spin; it may have values of $+\frac{1}{2}$ or $-\frac{1}{2}$. (Section 6.7)

spin-pairing energy The difference between the energy required to pair an electron in an occupied orbital and the energy required to place that electron in an empty orbital. (Section 23.6)

spin–spin coupling The communication of nuclear spin information between nuclei expressed in an NMR spectrum by multiplicity. (Section 32.3)

splitting pattern The output of spin–spin coupling within a spectrum. (Section 32.3)

spontaneous process A process that is capable of proceeding in a given direction, as written or described, without needing to be driven by an outside source of energy. A process may be spontaneous even though it is very slow. (Section 19.1)

Staggered A conformation in which all groups around a C–C single bond are separated as far as possible. (Section 24.3)

standard atmospheric pressure Defined as 760 torr or, in SI units, 101.325 kPa. (Section 10.2)

standard emf, also called the standard cell potential ($E°$) The emf of a cell when all reagents are at standard conditions. (Section 20.4)

standard enthalpy change ($\Delta H°$) The change in enthalpy in a process when all reactants and products are in their stable forms at 1 atm pressure and a specified temperature, commonly 25 °C. (Section 5.7)

standard enthalpy of formation (ΔH_f°) The change in enthalpy that accompanies the formation of one mole of a substance from its elements, with all substances in their standard states. (Section 5.7)

standard free energy of formation (ΔG_f°) The change in free energy associated with the formation of a substance from its elements under standard conditions. (Section 19.5)

standard hydrogen electrode (SHE) An electrode based on the half-reaction $2\,H^+(1\,M) + 2\,e^- \longrightarrow H_2(1\,atm)$. The standard electrode potential of the standard hydrogen electrode is defined as 0 V. (Section 20.4)

standard molar entropy ($S°$) The entropy value for a mole of a substance in its standard state. (Section 19.4)

standard reduction potential ($E°_{red}$) The potential of a reduction half-reaction under standard conditions, measured relative to the standard hydrogen electrode. A standard reduction potential is also called a standard electrode potential. (Section 20.4)

standard solution A solution of known concentration. (Section 4.6)

standard temperature and pressure (STP) Defined as 0 °C and 1 atm pressure; frequently used as reference conditions for a gas. (Section 10.4)

starch The general name given to a group of polysaccharides that acts as energy-storage substances in plants. (Section 24.8)

starch The general name given to a group of polysaccharides that act as energy storage substances in plants. (Section 28.4)

state function A property of a system that is determined by its state or condition and not by how it got to that state; its value is fixed when temperature, pressure, composition, and physical form are specified; P, V, T, E, and H are state functions. (Section 5.2)

states of matter The three forms that matter can assume: solid, liquid, and gas. (Section 1.2)

stereoisomers Compounds possessing the same formula and bonding arrangement but differing in the spatial arrangements of the atoms. (Section 23.4)

stereocenter See **chiral centre**. (Section 25.3)

stereogenic center See **chiral centre**. (Section 25.3)

stereoselective reaction A reaction in which one stereoisomer is formed (or destroyed) in preference to all other possible stereoisomers. (Section 26.4)

Steric An effect due to the size of an atom, or groups of atoms. (Section 24.3)

Strecker synthesis A method of synthesising α-amino acids from aldehydes. (Section 31.2)

structural or constitutional isomers Compounds possessing the same formula but differing in the bonding arrangements of the atoms. Also often called **constitutional isomers**. (Section 24.3)

stoichiometry The relationships among the quantities of reactants and products involved in chemical reactions. (Section 3.1)

stratosphere The region of Earth's atmosphere from 10 km to 50 km above the surface. (Section 18.1)

strong acid An acid that ionizes completely in water. (Section 4.3)

strong base A base that ionizes completely in water. (Section 4.3)

strong electrolyte A substance (strong acids, strong bases, and most salts) that is completely ionized in solution. (Section 4.1)

structural formula A formula that shows not only the number and kinds of atoms in the molecule but also the arrangement (connections) of the atoms. (Section 2.6)

structural isomers Compounds possessing the same formula but differing in the bonding arrangements of the atoms. (Sections 23.4 and 24.2)

subatomic particles Particles such as protons, neutrons, and electrons that are smaller than an atom. (Section 2.2)

subshell One or more orbitals with the same set of quantum numbers n and l. For example, we speak of the $2p$ subshell $(n = 2, l = 1)$, which is composed of three orbitals ($2p_x$, $2p_y$, and $2p_z$). (Section 6.5)

substrates A substance that undergoes a reaction at the active site in an enzyme. (Section 31.3)

substitutional alloy An alloy formed when atoms of the solute in a solid solution occupy positions normally occupied by a solvent atom. (Section 12.2)

substitution reaction Reactions in which one atom (or group of atoms) replaces another atom (or group) within a molecule; substitution reactions are typical for alkanes and aromatic hydrocarbons. (Section 24.7)

substitution reactions Reactions in which one atom (or group of atoms) replaces another atom (or group) within a molecule; substitution reactions are typical for alkanes and aromatic hydrocarbons. (Section 24.3)

substrate A substance that undergoes a reaction at the active site in an enzyme. (Section 14.7)

supercritical fluid The state that exists when liquid and gas phases are indistinguishable from each other as the temperature exceeds the critical temperature and the pressure exceeds the critical pressure. (Section 11.4)

supercritical mass An amount of fissionable material larger than the critical mass. (Section 21.5)

supersaturated solution A solution containing more solute than an equivalent saturated solution. (Section 13.2)

surface tension The energy required to increase the surface area of a liquid by a unit amount. (Section 11.3)

surroundings In thermodynamics, everything that lies outside the system that we study. (Section 5.2)

system In thermodynamics, the portion of the universe that we single out for study. We must be careful to state exactly what the system contains and what transfers of energy it may have with its surroundings. (Section 5.2)

synthetic detergents A substance that cleans by forming micelles but is not made by the hydrolysis of fats. A synthetic analogue of a soap. (Section 29.4)

tautomerism The interconversion of equilibrating isomers that differ in the location of their bonding electrons, usually accompanying a proton movement. (Section 28.3)

termination The final step in a chain reaction that stops further reaction. (Section 26.6)

tertiary structure The overall shape of a large protein, specifically the manner in which sections of the protein fold back upon themselves or intertwine. (Section 31.3)

temperature A measure of the hotness or coldness of an object; a physical property that determines the direction of heat flow. (Section 1.5)

termolecular reaction An elementary reaction that involves three molecules. Termolecular reactions are rare. (Section 14.6)

tertiary structure The overall shape of a large protein, specifically, the manner in which sections of the protein fold back upon themselves or intertwine. (Section 24.7)

theoretical yield The quantity of product that is calculated to form when all of the limiting reagent reacts. (Section 3.7)

theory A tested model or explanation that has predictive powers and that accounts for all available observations. (Section 1.5)

thermochemistry The relationship between chemical reactions and energy changes. (Section 5.1)

thermodynamics The study of energy and its transformation. (Section 5.1)

thermonuclear reaction Another name for fusion reactions; reactions in which two light nuclei are joined to form a more massive one. (Section 21.5)

thermoplastic A polymeric material that can be readily reshaped by application of heat and pressure. (Section 26.6)

thermosetting plastic A plastic that is formed by irreversible chemical processes and therefore is not readily reshaped by application of heat and pressure. (Section 26.6)

thermosetting plastic A plastic that, once formed in a particular mould, is not readily reshaped by application of heat and pressure. (Section 26.6)

third law of thermodynamics A law stating that the entropy of a pure, crystalline solid at absolute zero temperature is zero: $S(0\,\mathrm{K}) = 0$. (Section 19.3)

titration The process of reacting a solution of unknown concentration with one of known concentration (a standard solution). (Section 4.6)

torr A unit of pressure $(1\ \mathrm{torr} = 1\ \mathrm{mm\ Hg})$. (Section 10.2)

trans A geometric isomer in which two substituents attached to a cyclic compound are orientated on different sides of the plane of the ring. (Section 25.2)

transition elements (transition metals) Elements in which the *d* orbitals are partially occupied. (Section 6.8)

transition state (activated complex) The particular arrangement of reactant and product molecules at the point of maximum energy in the rate-determining step of a reaction. (Section 14.5)

transmittance Expressed by the ratio $I/I0$, where I = intensity of light through the sample and $I0$ = intensity of light used for the measurement. The value of transmittance always lies between 0 and 1. (Section 32.2)

translational motion Movement in which an entire molecule moves in a definite direction. (Section 19.3)

transuranium elements Elements that follow uranium in the periodic table. (Section 21.2)

triglycerides Triesters of glycerol, including common fats and oils. (Section 26.5)

triglycerides Triesters of glycerol, including common fats and oils. (Section 29.4)

triple bond A covalent bond involving three electron pairs. (Section 8.3)

triple point The temperature at which solid, liquid, and gas phases coexist in equilibrium. (Section 11.6)

tritium The isotope of hydrogen whose nucleus contains a proton and two neutrons. (Section 22.2)

troposphere The region of Earth's atmosphere extending from the surface to about 10 km altitude. (Section 18.1)

Tyndall effect The scattering of a beam of visible light by the particles in a colloidal dispersion. (Section 13.6)

uncertainty principle A principle stating there is an inherent uncertainty in the precision with which we can simultaneously specify the position and momentum of a particle. This uncertainty is significant only for particles of extremely small mass, such as electrons. (Section 6.4)

unimolecular reaction An elementary reaction that involves a single molecule. (Section 14.6)

unit cell The smallest portion of a crystal that reproduces the structure of the entire crystal when repeated in different directions in space. It is the repeating unit or building block of the crystal lattice. (Section 12.1)

unsaturated solution A solution containing less solute than a saturated solution. (Section 13.2)

UV-visible spectroscopy An analytical technique based on the transitions between electronic energy states within a molecule. (Section 32.1)

valence band A band of closely spaced bonding molecular orbitals that is essentially fully occupied by electrons. (Section 12.4)

valence-bond theory A model of chemical bonding in which an electron-pair bond is formed between two atoms by the overlap of orbitals on the two atoms. (Section 9.4)

valence electrons The outermost electrons of an atom; those that occupy orbitals not occupied in the nearest noble-gas element of lower atomic number. The valence electrons are the ones the atom uses in bonding. (Section 6.8)

valence orbitals Orbitals that contain the outer-shell electrons of an atom. (Section 7.1)

valence-shell electron-pair repulsion (VSEPR) model A model that accounts for the geometric arrangements of shared and unshared electron pairs around a central atom in terms of the repulsions between electron pairs. (Sections 9.1 and 9.2)

van der Waals equation An equation of state for nonideal gases that is based on adding corrections to the ideal-gas equation. The correction terms account for intermolecular forces of attraction and for the volumes occupied by the gas molecules themselves. (Section 10.8)

van't Hoff factor The number of fragments that a solute breaks into for a particular solvent. (Section 13.5)

vapor Gaseous state of any substance that normally exists as a liquid or solid. (Section 10.1)

vapor pressure The pressure exerted by a vapor in equilibrium with its liquid or solid phase. (Section 11.5)

vibrational motion Movement of the atoms within a molecule in which they move periodically toward and away from one another. (Section 19.3)

viscosity A measure of the resistance of fluids to flow. (Section 11.3)

volatile Refers to liquids that evaporate readily. (Section 11.5)

voltaic (galvanic) cell A device in which a spontaneous oxidation–reduction reaction occurs with the passage of electrons through an external circuit. (Section 20.3)

vulcanization The process of cross-linking polymer chains in rubber. (Section 12.5)

vulcanisation The process of cross-linking polymer chains in rubber. (Section 26.6)

watt A unit of power; $1\,W = 1\,J/s$. (Section 20.5)

Watson–Crick pairing The selective pairing by hydrogen bonding of purine and pyrimidine bases that gives rise to the DNA double helix. (Section 31.4)

wave function A mathematical description of an allowed energy state (an orbital) for an electron in the quantum-mechanical model of the atom; it is usually symbolized by the Greek letter ψ. (Section 6.5)

wavelength The distance between identical points (such as two adjacent peaks or two adjacent troughs) on successive waves. (Section 6.1)

wavenumber A conventional unit in IR spectroscopy expressed in reciprocal centimetres (cm^{-1}). (Section 32.2)

waxes Single esters made from fatty acids and long-chain alcohols. (Section 29.4)

weak acid An acid that only partly ionizes in water. (Section 4.3)

weak base A base that only partly ionizes in water. (Section 4.3)

weak electrolyte A substance that only partly ionizes in solution. (Section 4.1)

work The energy transferred when a force exerted on an object causes a displacement of that object. (Section 1.4)

Zaitsev's rule A rule stating that when a mixture of isomeric alkenes is formed through an elimination reaction, the more substituted alkene will generally predominate. (Section 27.6)

zeolite A class of aluminosilicates that occur naturally and can also be synthesized. (Section 12.6)

zero-order reaction A reaction in which the rate of disappearance of A is independent of [A]. (Section 14.4)

zwitterion A neutral molecule containing both positive and negative charges by virtue of internal proton exchange. (Section 31.2)

Adipic acid, 593, 595*f*, 1360
ADP (adenosine diphosphate), 939, 939*f*
Adrenaline, 1404–1405
Adsorption, defined, 646, 697
Advanced burning, 1039, 1039*f*
Air bags, 141
-al (suffix), 1170*t*
Alanine, 801–802, 1416–1418, 1424–1425
Albuterol, 1199
Alcohol(s), 125, 1169, 1254. *See also specific Alcohol*
  acetal formation from, 1304–1306, 1322
  acidity of, 1382–1385
  versus alkanes, 1254
  bond-stretching frequencies, 1461
  chemical wet testing for, 1489
  classification of, 1259–1261
  common, 1257
  condensation reactions, 1342–1343
  ethers, 1266
  functional groups, 1170*t*, 1257, 1268
  in Grignard reactions, 1302–1303
  isomeric, 1259*f*
  nomenclature, 1254, 1257–1260
  oxidation of, 1298–1299, 1339
  properties of, 1254
  reactions of, 1268–1271
    alkoxides, 1269, 1280–1281
    basicity of, 1269
    dehydration, 1231, 1270–1271
    haloalkane conversion, 1269, 1272–1275
  solubility of, 621–623, 621*f*, 622*ft*, 623*f*, 1255, 1256*t*
  structure of, 1254
  unsaturated, 1259
Aldehydes, 1293. *See also specific Compound*
  bond-stretching frequencies, 1459
  chemical wet testing for, 1490
  functional groups in, 1170*t*, 1293–1295
  nomenclature, 1293–1296
  preparation of, 1297–1299
  reactions of, 1300–1311
    carbon nucleophile addition, 1301–1304, 1357
    with cyanide, 1424
    cyanohydrins, 1307–1309
    halogenation, 1310–1311
    oxidation, 1339
    reduction, 1306–1307
    tautomerism, 1309–1310
Aldohexose, 1314
Aldoses, 1314
Aliphatic aldehydes, 1294
Aliphatic alkanes, 1153, 1159, 1468
Aliphatic amines, 1403, 1405, 1407
Aliphatic carboxylic acids, 1334
Alizarin yellow R, 771*f*
Alkali metals. *See also specific Metal*

ocean acidity, 882–884, 883*f*
properties and uses, 1088
Carbonic acid–bicarbonate buffer system, 825, 825*f*
Carbon monoxide (CO)
in atmosphere, 865–867, 866*t*, 867*t*
hemoglobin and, 1117–1120, 1117*f*, 1118*f*
properties of, 1087
Carbon nanotubes, 1380
Carbon tetrachloride, 638*t*
Carbonylation, 1339
Carbonyl group, 1293–1296
deshielding effects in, 1472
IR frequency, 1459
nucleophilic substitution reaction at, 1356–1358
Carborundum, 1088
Carboxylate anions, 1335–1336, 1336*f*
Carboxyl group, 1258, 1333–1334, 1416–1417
Carboxylic acid group, 125
polymerization reaction and, 593–595, 594*f*
Carboxylic acids, 801, 1333
acidity of, 1335–1337
applications of, 1359
bond-stretching frequencies, 1459–1460
chemical wet testing for, 1489
Carothers, Wallace, 1360
Car(s)
engine knocking in, 1156
plastic, 1361
radiation coolant, 1257
Carvone, 1192, 1192*f*, 1216, 1294
Catalase, 1432
Catalysts
catalytic converters, 699, 699*f*
defined, 696
in electrophilic aromatic substitution, 1386
enzymes, 699–700, 699*f*, 700*f*
heterogeneous, 1237
heterogeneous catalysis, 697–698, 698*f*
homogeneous catalysis, 696–697, 697*f*, 698*f*
Le Châtelier's principle and, 745–746, 745*f*, 746*f*
nitric oxide emissions, controlling, 748, 748*f*
reaction rates and, 658–659, 659*f*
Catalytic converters, 877
Catalytic hydrogenation, 1237–1239, 1306, 1349, 1410
Catechin, 1379
Catechol, 1379
Cathode rays, 92–94, 93*f*, 94*f*

Coulomb (C), 93*n*
Coulomb's law, 99
Counterion exchange, 1350
Couple, 1474–1476
Coupling constant (*J*), 1469, 1474, 1476, 1476*f*
Coupling reactions, 939, 939*f*
Covalent bonds
  bond order, 448
  comparing with ionic bonds, 387
  defined, 370
  Lewis structures, 379–380, 379*f*
  Lewis structures, drawing of, 388–393, 393*f*
  molecular orbital theory, 445–449, 446*f*, 447*f*
  orbital overlap and, 429–431, 430*f*
  overview of, 378–381, 379*f*
  spring model of, 1456–1458
  strength and length of, 401–402, 401*t*, 402*t*
Covalent carbides, 1088
Covalent-network solids
  classification of, 560–565, 561*f*
  properties of, 586, 586*f*
  semiconductors, 586–589, 587*f*, 588*t*, 589*f*, 590*f*, 591*f*
Cracked lips, 1436
Cracking, 1059, 1156
Cram, Donald, 1267
Cresols, 1379, 1384*t*
Crick, Francis, 1442*f*
Critical mass, 1034, 1035*f*
Critical point, phase diagrams, 542–546, 543*f*, 544*f*, 545*f*
Critical pressure, 536–538, 538*t*
Critical temperature, 536–538, 538*t*
Cross-linking, 1245, 1246
Cross-linking, polymers, 596
Crown ethers, 1266, 1285
Crutzen, Paul, 873, 1262
Crystal(s)
  liquid, 1376
Crystal-field theory, 1131–1139, 1131*f*, 1132*f*, 1133*f*, 1134*f*, 1135*f*, 1136*f*, 1137*f*
Crystal lattices, 562–564, 562*f*, 563*f*, 564*f*
  ionic solids, structures of, 580–583, 581*f*, 582*f*
  metallic structures, 568, 568*f*, 569*f*
  metallic structures, close packing, 568–572, 569*ft*, 570*f*, 571*f*
  polymers, crystallinity of, 596–597, 596*f*, 597*f*
  transition metals, 1104*t*
  X-ray diffraction, 565, 565*f*
Crystalline amino acids, 1417
Crystalline solids, 562, 562*f*
Crystallinity, 1243, 1244
Crystallinity, defined, 596
Crystallization, 619–620, 620*f*
Crystallography, X-ray, 565, 565*f*
Crystals, giant gypsum, 372, 372*f*
Cubic close packing, 568–572, 569*ft*, 570*f*, 571*f*
Cubic lattice, 563*f*
  ionic solids, 580–581, 581*f*
  metallic solids, 568, 568*f*, 569*f*
Cumene, 1377*f*
Cupric ion, 118*t*
Curie (Ci), 1023
Curie, Marie Sklodwska, 94–95, 94*f*
Curie temperature (T_c), 1107
Curl, Robert, 601
Curved arrow notation, 1222–1225
Cyanide (CN), 120*t*, 1115*t*, 1121–1122, 1122*t*, 1274, 1424
Cyanocobalamine (vitamin B_{12}), 1436

Cyanogen bromide, 1435*t*
Cyanohydrins, 1307–1309
Cyclic amides (lactams), 1414
Cyclic amines, 1403
Cyclic carbohydrates, 1317–1320
Cyclic ethers, 1265–1266, 1285
Cyclic polyethers, 1266, 1266*f*
Cycloalkanes, 1165–1167, 1188–1189, 1487
Cycloalkenes, 1218
Cyclobutane, 1166
Cyclodextrins, 1321
Cyclodextrin glucanotransferase (CGTase), 1321
Cyclohexane, 1166, 1258, 1381
Cyclohexanol, 1383
Cyclohexatriene, 1381
Cyclohexene, 1235, 1381
Cyclohexoxide, 1384
Cyclopentane, 1166
Cyclopentyl propyl ether (propoxycyclopentane), 1266
Cyclopropane, 1166
Cyclotron, 1017–1018, 1018*f*
Cysteine, 1418
Cytidine, 1439
Cytoplasm, 1439
Cytosine, 1440–1442

D

Dacron®, 1359
Dalton, John, 90
Dalton's law of partial pressures, 492
Dashed wedge (symbol), 1188
D (configuration), 1315–1317, 1315*f*
d-d transition, 1133, 1133*f*
de Broglie, Louis, 288–289
Deactivating group, 1389, 1393–1394
Decane, 1154
Decay constant (*k*), 1023
Decimal places, significant figures, 72–75
Decomposition reactions, 140–141, 140*f,* 141*ft*, 250, 251*f*
Decoupling, 1476
Degenerate, orbital energy, 301, 301*f*
Dehydration
  of alcohols, 1231, 1269, 1270–1271
  of carboxylic acid, 1355
Dehydrohalogenation, 1277
Delocalized molecular bonds, 442–443, 442*f*, 443*f*
Delocalised pi (p) bonds, 1373, 1373*f*, 1380, 1386, 1388
delta (Δ) symbol, chemical equations, 136
Dementia, 1436
Density
  calculations using volume and mass, 68
  conversion factors, calculations with, 79–80
  hydrogen isotopes and, 1057
  SI units, 67, 67*t*
Dental materials, 1362–1363
Deoxyadenine monophosphate, 1439
Deoxyribonucleic acid (DNA), 1285, 1439
  replication, 1442–1443, 1443*f*
  structure of, 1440–1441, 1441*f*
Deoxyribonucleotide, 1440
Deoxyribose, 1439
Depression, 1436
Derivatization, 1203
Derived units, 65–66
Dermatitis, 1436
Desalination, 886, 886*f*
Deshielding, 1467–1468, 1472
Detergents, 1350–1352
  synthetic, 1351
Deterministic theories, 293
Deuteration, 1057, 1469
Deuterium, 1057
Dextrorotatory, 1125–1126, 1126*f*, 1195
D-fructose, 1320
D-galactosamine, 1318
D-galactose, 1320–1321
Diacid, 593–594, 594*f*
Diamine, 593–594, 594*f*
Diamond, 343, 586, 586*f*, 1054, 1086
Diarrhoea, 1436
Diastereomers, 1186, 1201, 1202
Diatomic molecules, 108, 108*f*, 450–460, 451*f*–460*f*
1,3-Diaxial interactions, 1167
Diborane, 1093–1094, 1094*f*
2,3-Dibromobutane, 1201, 1202*f*
1,2-Dicarboxylic acids, 1355
Dichloromethane (methylene chloride), 1232, 1263, 1298
Dichromate ion, 120*t*
-diene (suffix), 1218
Diethylenetriamine, 1115*t*
Diethyl ether, 1264–1266, 1474, 1483*f*
Diffraction, 565, 565*f*
Diffusion, molecular, 498–502, 499*f*, 500*f*, 501*f*
Digestion, colloids and, 647
Digestive system, 1325
Dihydroxyacetone, 1314–1315
Dilutions, 204–205, 205*f*
Dimagnetic substances, 1106–1107, 1107*f*
Dimagnetism, 456, 456*f*, 458*f*
Dimensional analysis, 76–81
1,2-Dimethylcyclohexane, 1188
Dimeric proteins, 1430–1432
Dimerisation, 1334*f*
Dimethyl ether (methoxymethane), 1170
2,2-Dimethylpropane (neopentane), 1160*t*
Dinitrobenzene, 1378
2,4-Dinitrophenol, 1384*t*
2,4-Dinitrophenylhydrazine (DNP), 1490
Diols, 1260, 1359
1,4-Dioxane, 1265*f*
Dioxygen, 356
Dipeptide, 1427
Dipole, defined, 385
Dipole-dipole interactions, 523–524, 524*f*, 527–528, 528*f*, 585, 585*f*
Dipole moments, 384–387, 385*f*, 386*t*, 386*f*
  dispersion force, 522–523, 522*f*, 523*f*
  oxidation number and charge, 392, 393*f*
  solute–solvent interactions, 621–623, 621*t*, 622*f*, 623*f*
  vibrational frequency and, 1457–1458
Diprotic acids, 186, 773
Directing groups, 1389–1395
Disaccharides, 1320–1321
Disilicate ions, 1091–1092, 1091*f*
d-(+)-isomer, 1194–1196
Dispersion forces, 522–523, 522*f*, 523*f*, 527–528, 528*f*, 585, 585*f*, 1154
Displacement reactions, 196–199, 196*f*, 198*t*, 199*f*
Disproportionation reaction, 1071, 1071*f*
Dissociation energy, 868–869, 1176
Dissolution, solution process, 613–618, 613*f*, 614*f*, 615*f*, 616*f,* 617*f,* 618*f*
Dissolution in water, 177–178, 177*f*
Distillation, 58, 58*f,* 59*f*, 886
  fractional, 1156*f*
Disulfide bonds, 1074, 1075*f*
2,6,-Di-*tert*-butyl-4-methylphenol (BHT), 1374*f*
D-mannosamine, 1318
DMSO, 1236
DNP (2,4-dinitrophenylhydrazine), 1490
Dolomite, 1088
Donor atoms, ligands, 1115, 1116*f*
Dopants, 348
Doping, semiconductors, 589–590, 589*f*
d orbitals, 293–294, 294*f*, 299, 299*f*

crystal-field theory, 1131*f*, 1132–1139, 1137*f*, 1138*f*, 1139*f*, 1140*f*, 1141*f*, 1142*f*
energetics of ionic bond formation, 376–377
metals, electronic band structure, 576–578, 577*f*
periodic table and electron configuration, 307–312, 309*ft*, 312*f*, 313*f*
phases in, 453–455, 453*f*, 454*f*, 455*f*
transition elements, 1104*t*, 1105–1106, 1106*f*
Double bonds
Lewis structure, 380–381
sigma and pi bonds, 438–445, 438*f*, 439*f*, 440*f*, 441*f*, 442*f*, 443*f*, 444*f*
strength and length of bonds, 401–402, 401*t*, 402*t*
Double helix, 1440, 1442
Doublet, 1475
Downfield, 1468
Drugs
amines as, 1403–1405, 1406
benzene-based, 1372
chiral, 1199
limulus amoebocyte lysate (LAL), 1103
lithium and, 352
solubility of, 1258
Dry ice, 488, 488*f*, 1087, 1340
Du Pont, 1246, 1359, 1360
Ductile, defined, 567
Dyes
for amino acid detection, 1424, 1434
organic, 1301, 1388, 1404
Dynamic equilibrium, 540–541, 540*f*, 541*f*
saturated solutions, 619–620, 619*f*, 620*f*

E

Earth
acid rain, 874–875, 874*t*, 875*f*
atmosphere, components, 864–867, 864*f*, 866*ft*, 867*t*
atmosphere, ozone in, 870–874, 870*f*, 871*f*, 873*f*
atmosphere, photochemical reactions in, 868–870, 868*f*, 870*t*
crust, components of, 52, 52*f*
greenhouse gases, 877–880, 877*f*, 878*f*, 879*f*, 880*f*
smog, 875–877, 876*f*
water on, 881–884, 882*f*, 883*ft*
water quality, 885–890, 886*f*, 887*f*, 888*f*, 889*f*
EAS (electrophilic aromatic substitution), 1386–1395
e-caprolactam, 1360
Eclipsed conformations, 1158, 1158*f*
Edman, Pehr, 1435
Edman degradation, 1435
EDTA (ethylenediaminetetraacetate ion), 1115, 1115*t*, 1116*f*
Effective nuclear charge, 326–329, 327*f*, 328*f*
Effusion, molecular, 498–502, 499*f*, 500*f*, 501*f*
Einstein, Albert, 63–64, 279–280, 293, 647, 1035
EIMS (electron impact ionization mass spectrometry), 1481–1482, 1484
Elastomers, 592–593, 592*ft*, 593*f*, 1363. *See also* Polymers
Electrical charge. *See also* Electrochemistry

Haber process, 719–720, 719*f*, 740–743, 741*f*, 742*f*, 746, 746*ft*
nitrogen, properties and uses, 1077–1080, 1077*ft*, 1078*f*, 1079*f*
phosgene, 725–726, 725*f*
phosphorus oxy compounds, 1083–1084, 1083*f*
water quality and, 886, 886*f*
Fibres
polymer, 1360–1361
Fibrous proteins, 1427
Filtration, 58–59, 59*f*
Fingerprint region, 1457
First law of thermodynamics, 223–229, 224*f*, 225*f*, 226*f*, 227*ft*, 229*f*
First-order reactions, 674–676, 676*f*
Fischer, Emil, 1342
Fischer esterification, 1342
Fischer projections, 1314, 1315*f*
Fishhook arrows, 1241
Fission, 1033–1038, 1033*f*, 1034*f*, 1035*f*, 1037*f*
Flavoproteins, 1436
Flavours, 1294, 1344
Flint, Michigan water, 849, 849*f*
Fluoresce, defined, 92
Fluoridation, tooth decay and, 845
Fluorine (F), 1236
common anions, 120*t*
electron configurations, 305
ligands, 1115*t*, 1122, 1122*t*
oxidizing and reducing agent strength, 968–971, 970*f*
properties of, 356–358, 358*t*, 357*f*, 1064–1067, 1065*ft*, 1066*f*, 1067*t*
radiotracers in medicine, 1028, 1028*t*
in seawater, 883*t*
standard reduction potential, 967*t*
uses for, 1066
van der Waals constant, 506*t*

Fluoro-(prefix), 1262
Fluorocarbons, 1066
Folding, 1431, 1432
Food
  as vitamin D source, 1256
Food, fuel value and, 259–263, 259*t*, 261*t*, 262*f*
f orbital, 293–294, 294*ft*, 299–300, 299*f*
Force. *See also* Intermolecular forces
  defined, 60
  electromagnetic force, 99
  gravitational force, 99
  strong and weak nuclear forces, 99
Formal charge, 390–393, 393*f*
Formaldehyde, 1215, 1293, 1302
Formation constant (K_f), 846–847, 846*f*, 847*t*
Formic acid, 1335–1336
Formulas, empirical formula calculation, 152–157, 155*f*
Formula weight (FW), 143–145
  molar mass and, 147–149, 148*ft*
Fossil fuels, 261–263, 261*t*, 746
  acid rain and, 874–875, 874*t*, 875*f*
  fracking, 888, 889*f*
  gasoline, 1060*f*
  greenhouse gases and, 877–880, 877*f*, 878*f*, 879*f*, 880*f*
Fourier Transform NMR (FT-NMR), 1464, 1466
Fraction(s), 1156
Fractional distillation, 1090, 1091*f*, 1156*f*
Fragment, 1480
Fragmentation, 1480–1482
Free energy. *See* Gibbs free energy

Lewis structures, drawing of, 388–393, 393*f*
Octyl acetate, 1343
Odours, 1186, 1192, 1294, 1343–1344, 1406
Oenology, 1254
-Oic acid (suffix), 1170, 1334, 1336, 1355, 1356
Oil(s), 1347–1351, 1350*f*
hardening, 1239, 1239, 1349
polyunsaturated, 1239, 1349
-Ol (suffix), 1170
Oleic acid, 1348
Oligosaccharides, 1320–1327
-One (suffix), 1171, 1294
Open-chain carbohydrates, 1317–1320
Open systems, 223–224, 224*f*
Operating frequency, 1466, 1467
Opium, 1404
Opsin, 438–439, 439*f*
Optical activity, 1194
measurement of, 1195–1196
substitution reactions and, 1282–1283
Optical isomers, 1124–1126, 1125*f*, 1126*f*
Optically active molecules, 1125–1126, 1126*f*
Oranges (fruit), 1186, 1216
Orbitals, atomic, 291–294, 292*f*, 294*ft*
alkali metals, 349–352, 349*t*, 350*f*, 351*f*
alkaline earth metals, 353, 353*ft*
covalent bonding and orbital overlap, 429–431, 430*f*
crystal-field theory, 1131–1138, 1131*f*, 1132*f*, 1133*f*, 1134*f*, 1135*f*, 1137*f*
effective nuclear charge, 326–329, 327*f*, 328*f*
electron affinity, 341–342, 342*f*
electron configuration, 303–305
electron configurations and periodic table, 306–313, 307*f*, 309*ft*, 310*f*, 312*f*, 313*f*
electronic band structure, 576–578, 577*f*
energy and, 460, 460*f*
halogens, Group 7A, 356–358, 357*ft*
Hund's rule, 305–306
hybrid orbitals, 431–437, 433*f*, 434*f*, 435*f*, 436*t*, 437*f*
hypervalent molecules, 434–435, 435*f*, 436*t*
ionization energy, 336–340, 337*t*, 338*f*, 339*f*
magnetism and, 456–458, 457*f*, 458*f*
many-electron atoms, orbital energies, 301–302, 301*f*
metalloids, 348–349
metals, 344–346, 344*f*, 345*f*
molecular orbital theory, 446–448, 446, 447*f*, 448*f*
multiple bonds, sigma and pi, 438–444, 439*f*, 440*f*, 441*f*, 442*f*, 443*f*, 444*f*
noble gases, 358, 358*t*
nonmetals, 346–348, 347*f*, 1053–1055, 1054*f*, 1055*f*
orbital diagrams, 304–306, 305*t*
oxygen group, Group 6A, 355–356, 355*t*
Period 2, diatomic molecule bonds, 450–461, 450*f*–461*f*
phases in, 453–455, 453*f*, 454*f*, 455*f*
p orbital, 298–300, 299*f*
s orbitals, 296–298, 297*f*, 298*f*
spin-pairing energy, 1135–1136, 1135*f*
transition elements, 1104*t*, 1105–1107, 1106*f*, 1107*f*
Ores, 1103–1104
Organic chemistry, 1150
alcohols in, 1268–1269
amino acids, 801–802
analytical techniques in 1455. *See also specific Technique*
generalisations of, 1171*f*
green chemistry, overview of, 892–895
iron in living systems, 1119–1120, 1119*f*
living systems, metals and chelates in, 1116–1120, 1117*f*, 1118*f*, 1119*f*
nucleic acids, 1111*f*, 1112*f*, 1113*f*
organic compounds, defined, 124
resonance structures, 395–396
solubility of compounds, 621–623, 622*ft*, 623*f*
Organic compounds. *See also specific Compound*
chirality in, 1190–1192, 1203, 1337, 1417
formulae
determination of, 1487–1489, 1490
heterocyclic, 1266, 1382, 1407
homologous series, 1154
microanalysis of, 1487–1489
optical activity, 1194–1196, 1283
solubility of, 1256–1257
stabilities of, 1150–1151
structures of, 1150
Organic dyes, 1388, 1403
Organomagnesium, 1301
Organometallic compounds, 1301
Ornithine, 1419
Ortho isomers
of benzene, 1377–1378, 1393–1394
of toluene, 1389–1391
Ortho, para-director, 1389, 1392
Ortho-phenanthroline, 1115*t*
Orthorhombic lattice, 563*f*
Osmosis, 639–640, 639*f*, 640*f*
reverse osmosis, 886, 886*f*
Osmotic pressure, 639
Osteoarthritis, 1318
Ostwald process, 1079, 1079*f*
Overall reaction order, 669
Oxalate ion, 1115*t*
Oxalic acid, 783*t*, 1333
Oxidant, defined, 952. *See also* Oxidation–reduction reactions
Oxidation, 1174
of alcohols, 1297–1299, 1339
of aldehydes, 1339
of alkanes, 1174
Oxidation number, 194–195

  hard water, 1088
  heating curve, 535–536, 536*f*
  heavy water, 1057
  hydration, 616
  hydrogen, reactions in, 354–355
  hydrogen bonds, state changes and, 525–527, 526*f*
  hydronium ion, 758, 758*f*
  ion-product constant for (K_w), 790
  lead contamination, drinking water, 849, 849*f*
  Lewis acids and bases, 802–803, 803*f*
  as ligand, 1115*t*
  metal–ligand bonds, 1112
  molarity and molality calculations, 629–630
  ocean acidification, 890, 890*f*
  osmosis, 639–640, 639*f*, 640*f*
  phase changes, 535–538, 535*f*, 536*f*, 538*t*, 911
  properties of, 54*t*, 637, 637*f*, 638*t*
  purification, municipal treatment, 887–889, 887*f*, 888*f*
  salt solutions, properties of, 792–796, 794*ft*
  salt water, Earth, 882–884, 883*ft*
  solubilities of gases in, 621*t*, 626–627, 626*f*
  solute–solvent interactions, 621–623, 621*ft*, 622*ft*, 623*f*
  standard reduction potential, 967*t*
  van der Waals constant, 506*t*
Water cycle, 882, 882*f*
Water fearing (hydrophobic)
  cyclodextrins, 1321
  soaps, 1350, 1351*f*
Water gas, 1058
Water loving (hydrophilic)
  cyclodextrins, 1321
Water-soluble vitamins, 623, 623*f*
Watson, James, 1442
Watson–Crick pairing, 1442
Watt (W), 976
Wave functions, 291

Common Ions

Positive Ions (Cations)

1+

ammonium (NH_4^+)
cesium (Cs^+)
copper(I) or cuprous (Cu^+)
hydrogen (H^+)
lithium (Li^+)
potassium (K^+)
silver (Ag^+)
sodium (Na^+)

2+

barium (Ba^{2+})
cadmium (Cd^{2+})
calcium (Ca^{2+})
chromium(II) or chromous (Cr^{2+})
cobalt(II) or cobaltous (Co^{2+})
copper(II) or cupric (Cu^{2+})
iron(II) or ferrous (Fe^{2+})
lead(II) or plumbous (Pb^{2+})
magnesium (Mg^{2+})
manganese(II) or manganous (Mn^{2+})
mercury(I) or mercurous (Hg_2^{2+})
mercury(II) or mercuric (Hg^{2+})
strontium (Sr^{2+})
nickel(II) (Ni^{2+})
tin(II) or stannous (Sn^{2+})
zinc (Zn^{2+})

3+

aluminum (Al^{3+})
chromium(III) or chromic (Cr^{3+})
iron(III) or ferric (Fe^{3+})

Negative Ions (Anions)

1−

acetate (CH_3COO^- or $C_2H_3O_2^-$)
bromide (Br^-)
chlorate (ClO_3^-)
chloride (Cl^-)
cyanide (CN^-)
dihydrogen phosphate ($H_2PO_4^-$)
fluoride (F^-)
hydride (H^-)
hydrogen carbonate or bicarbonate (HCO_3^-)
hydrogen sulfite or bisulfite (HSO_3^-)
hydroxide (OH^-)
iodide (I^-)
nitrate (NO_3^-)
nitrite (NO_2^-)
perchlorate (ClO_4^-)
permanganate (MnO_4^-)
thiocyanate (SCN^-)

2−

carbonate (CO_3^{2-})
chromate (CrO_4^{2-})
dichromate ($Cr_2O_7^{2-}$)
hydrogen phosphate (HPO_4^{2-})
oxide (O^{2-})
peroxide (O_2^{2-})
sulfate (SO_4^{2-})
sulfide (S^{2-})
sulfite (SO_3^{2-})

3−

arsenate (AsO_4^{3-})
phosphate (PO_4^{3-})

Fundamental Constants*

Atomic mass constant	1 u	$= 1.660539040 \times 10^{-27}$ kg
	1 g	$= 6.022140859 \times 10^{23}$ amu
Avogadro's number†	N_A	$= 6.022140857 \times 10^{23}$/mol
Boltzmann Constant	k	$= 1.3806485 \times 10^{-23}$ J/K
Electron charge	e	$= 1.6021766208 \times 10^{-19}$ C
Faraday constant	F	$= 9.648533289 \times 10^{4}$ C/mol
Gas constant	R	$= 0.0820582$ L-atm/mol-K
		$= 8.3144598$ J/mol-K
Mass of electron	m_e	$= 5.4857990946 \times 10^{-4}$ u
		$= 9.10938356 \times 10^{-31}$ kg
Mass of neutron	m_n	$= 1.008664916$ u
		$= 1.674927471 \times 10^{-27}$ kg
Mass of proton	m_p	$= 1.007276466$ u
		$= 1.672621898 \times 10^{-27}$ kg
Pi	π	$= 3.1415926535$
Planck constant	h	$= 6.626070040 \times 10^{-34}$ J-s
Speed of light in vacuum	c	$= 2.99792458 \times 10^{8}$ m/s

*Fundamental constants are listed at the National Institute of Standards and Technology (NIST) Web site: http://physics.nist.gov/cuu/Constants/index.html

†Avogadro's number is also referred to as the Avogadro constant. The latter term is the name adopted by agencies such as the International Union of Pure and Applied Chemistry (IUPAC) and the National Institute of Standards and Technology (NIST), but "Avogadro's number" remains in widespread usage and is used in most places in this book.

Useful Conversion Factors and Relationships

Length

SI unit: meter (m)

$1\ \text{km} = 0.62137\ \text{mi}$
$1\ \text{mi} = 5280\ \text{ft}$
$= 1.6093\ \text{km}$
$1\ \text{m} = 1.0936\ \text{yd}$
$1\ \text{in.} = 2.54\ \text{cm (exactly)}$
$1\ \text{cm} = 0.39370\ \text{in.}$
$1\ \text{Å} = 10^{-10}\ \text{m}$

Mass

SI unit: kilogram (kg)

$1\ \text{kg} = 2.2046\ \text{lb}$
$1\ \text{lb} = 453.59\ \text{g}$
$= 16\ \text{oz}$
$1\ \text{u} = 1.660538921 \times 10^{-27}\ \text{kg}$

Temperature

SI unit: Kelvin (K)

$0\ \text{K} = -273.15\ ^\circ\text{C}$
$= -459.67\ ^\circ\text{F}$
$\text{K} = {}^\circ\text{C} + 273.15$
$^\circ\text{C} = \frac{5}{9}(^\circ\text{F} - 32^\circ)$
$^\circ\text{F} = \frac{9}{5}\,^\circ\text{C} + 32^\circ$

Energy (derived)

SI unit: Joule (J)

$1\ \text{J} = 1\ \text{kg-m}^2/\text{s}^2$
$= 0.2390\ \text{cal}$
$= 1\text{C-V}$
$1\ \text{cal} = 4.184\ \text{J}$
$1\ \text{eV} = 1.602 \times 10^{-19}\ \text{J}$

Pressure (derived)

SI unit: Pascal (Pa)

$1\ \text{Pa} = 1\ \text{N/m}^2$
$= 1\ \text{kg/m-s}^2$
$1\ \text{atm} = 1.01325 \times 10^5\ \text{Pa}$
$= 760\ \text{torr}$
$= 14.70\ \text{lb/in}^2$
$1\ \text{bar} = 10^5\ \text{Pa}$
$1\ \text{torr} = 1\ \text{mm Hg}$

Volume (derived)

SI unit: cubic meter (m^3)

$1\ \text{L} = 10^{-3}\ \text{m}^3$
$= 1\ \text{dm}^3$
$= 10^3\ \text{cm}^3$
$= 1.0567\ \text{qt}$
$1\ \text{gal} = 4\ \text{qt}$
$= 3.7854\ \text{L}$
$1\ \text{cm}^3 = 1\ \text{mL}$
$1\ \text{in}^3 = 16.4\ \text{cm}^3$

Color Chart for Common Elements
