For a comprehensive review, Gray (2000) provided a detailed analysis of voiding physiology. However, the body of evidence about the pathophysiology of UI continues to develop. Continence is a complex, multidimensional phenomenon influenced by anatomical, physiological, psychological, and cultural factors (Gray, 2000). Thus, continence requires intact lower urinary tract function, as well as cognitive and functional ability to recognize voiding signals and use a toilet or commode, the motivation to maintain continence, and an environment that facilitates the process (Barrie, 2016; Jirovec, Brink, & Wells, 1988). Physiologically, continence is a result of urethral pressure being equal to or greater than bladder pressure (C. P. Hodgkinson, 1965), of which angulation of the urethra, supported by pelvic muscles, plays a role (DeLancey, 1994, 2010). Using transperineal ultrasound, urethral changes were noted among women (mean age 60.4, range 19–89) with UI, but did not differentiate between subtypes of UI (Kupec et al., 2016). Continence also requires the ability to suppress autocontractility of the detrusor muscle (C. P. Hodgkinson, 1965). Micturition (urination) involves voluntary as well as reflexive control of the bladder, urethra, detrusor muscle, and urethral sphincter. When the bladder volume reaches approximately 400 mL, stretch receptors in the bladder wall send a message to the brain, and an impulse for voiding is sent back to the bladder. The detrusor muscle then contracts, and the urethral sphincter relaxes to allow urination (Gray, Rayome, & Moore, 1995). Normally, the micturition reflex can be voluntarily inhibited (at least for a time) until an individual desires to void or finds an appropriate place for voiding. UI occurs as the result of a disruption at any point during this process. Some evidence suggests that among older women with UI, the autonomic nervous system is impaired (Padilha et al., 2017). In addition, a study of 40 older women, with and without UI, noted morphometric differences in pelvic floor muscles among those with UI (Fradet, Morin, Kruger, & Dumoulin, 2018). Common age-associated changes, including a decrease in bladder capacity, benign prostatic hyperplasia (BPH), and menopausal loss of estrogen, can affect lower urinary tract function and predispose older individuals to UI (Bradway & Yetman, 2002). Despite these aging changes, UI is not considered a normal consequence of aging.

The two major types of UI are transient (or acute/reversible) and established (or chronic/persistent; Ermer-Seltun, 2006; Newman & Wein, 2009). Transient UI is characterized by the sudden onset of potentially reversible symptoms and typically has a duration of less than 6 months (Specht, 2005). There may be cases of acute UI that do not resolve, as in the case of acute UI caused by a spinal cord injury that then becomes an established UI. Causes of transient UI include delirium, infections (e.g., untreated UTI), decrease in mobility or function, excessive urine production, restricted mobility, and stool impaction or constipation (e.g., creates additional pressure on the bladder and can cause urinary urgency, frequency, and UI). Hospitalized older adults are at risk for developing transient UI. In the literature, these cases have been referred to as new-onset UI, hospital nosocomial, and hospital acquired (Ding & Jayaratnam, 1994; Kresevic, 1997; Paillard & Resnick, 1981; Palmer et al., 1997, 2002). Complicated by shorter hospital stays, older adults may also be at risk for being discharged without resolution of transient UI and, thus, urine leakage persists and may become established UI. However, transient UI is often preventable, or at least reversible (e.g., transient UI precipitated by a UTI that resolves with successful treatment, or acute UI related to diuretic therapy for heart failure exacerbation), if the underlying cause of the UI is identified and treated (Ding & Jayaratnam, 1994; Fantl et al., 1996; Palmer, 1996).

Established UI has either a sudden or a gradual onset; however, healthcare providers or family CGs may first

identify UI during the course of an acute illness, hospitalization, or abrupt change in environment or daily routine (Palmer, 1996). Types of established UI include stress, urge, mixed, overflow, and functional UI.

Stress UI is defined as an involuntary loss of urine associated with activities that increase intra-abdominal pressure. Symptomatically, individuals with stress UI usually present with complaints of small amounts of daytime urine loss that occurs during physical effort or exertion (e.g., position change, coughing, sneezing) that result in increased intra-abdominal pressure. Stress UI is more common in women; however, stress UI may also occur postprostatectomy (Abrams et al., 2003; Fantl et al., 1996; Hunter, Moore, Cody, & Glazener, 2004; Jayasekara, 2009).

Urge UI results from detrusor instability and is characterized by an involuntary urine loss associated with a strong desire to void (urgency; Haylen et al., 2010). Individuals with urge UI often complain of being unable to hold the urge to urinate and leak on the way to the bathroom. This history is most helpful to the identification of urge UI (Holroyd-Leduc, Tannenbaum, Thorpe, & Straus, 2008). In addition to urinary urgency, signs and symptoms of urge UI most often include urinary frequency, nocturia and enuresis, and UI of moderate to large amounts. Bladder changes common in aging make older adults particularly prone to this type of UI (Abrams et al., 2003; Fantl et al., 1996; Jayasekara, 2009). Individuals with overactive bladder (OAB) may complain of urgency, with or without UI, as well as urinary frequency and nocturia (Haylen et al., 2010). Assessment should focus on pathological or metabolic conditions that may explain these symptoms (Abrams et al., 2003).

Mixed UI is defined as involuntary urine loss as a result of both increased intra-abdominal pressure and detrusor instability (Fantl et al., 1996; Jayasekara, 2009). On history, individuals describe symptoms of stress UI in combination with symptoms of urge UI and OAB.

Overflow UI is an involuntary loss of urine associated with overdistention of the bladder, and may be caused by an underactive detrusor muscle or outlet obstruction leading to overdistention of the bladder and leakage of urine. Individuals with overflow UI often describe dribbling, urinary retention or hesitancy, urine loss without a recognizable urge, an uncomfortable sensation of fullness or pressure in the lower abdomen, and incomplete bladder emptying. Clinically, suprapubic palpation may reveal a distended or painful bladder as a result of urine retention, which may be acute or chronic. A common condition associated with this type of UI is BPH. Neurological conditions, such as multiple sclerosis and spinal cord injuries, or diabetes mellitus, which result in bladder muscle denervation, may also cause overflow UI (Abrams et al., 2003; Doughty, 2000; Fantl et al., 1996; Jayasekara, 2009).

Functional UI is caused by nongenitourinary factors, such as cognitive or physical impairments, that result in an inability of the individual to be independent in voiding. For example, acutely ill hospitalized individuals may be challenged by a combination of an acute illness and environmental changes. This, in turn, makes the voiding process even more complex, resulting in a functional type of UI (Fantl et al., 1996; B. Hodgkinson et al., 2008). In other settings, such as home settings, frail older adults may depend on others to avoid functional UI (Barrie, 2016). Home health nurses and rehabilitation therapists can be helpful in identifying barriers, such as fall hazards, and facilitators, such as bedside commodes and walking assistive devices to address functional UI.

ASSESSMENT PARAMETERS

It is essential to ask patients about the presence of UI because they may not offer this information or seek professional care (Hobdy, Huffaker & Bailey, 2018; Qaseem et al., 2014; Vethanayagam et al., 2017). Community-dwelling older women perceived UI as a normal part of aging that was not bothersome and lacked knowledge of curative strategies (Strickland, 2014); some evidence suggests that women who experience more daily episodes of UI are more likely to seek care than women with fewer daily episodes of UI (Jimenez-Cidre et al., 2014). Nurse continence experts suggested that entry-level nurses demonstrate the ability to collect and organize data surrounding urine control and implement nursing interventions that promote continence (Jirovec, Wyman, & Wells, 1998); yet, the extent to which this is actualized is not known.

Nurses play a critical role in the basic assessment and management of UI in older adults. Because UI is an interprofessional issue, collaboration with other members of the healthcare team is essential. It is not sufficient for nurses to only identify and document the presence of UI. Instead, the type of UI should be determined and documented based on a careful history and focused assessment; urodynamic tests are not required as part of the initial assessment of UI (DuBeau et al., 2010). Basic history and examination techniques are presented here to assist the nurse in identifying the type of UI along with a nursing standard-of-practice protocol (see Protocol 25.1 to guide UI assessment and management). Quality of care indicators for UI have been shown to be helpful in specialty and primary care settings and may also provide guidance for the standard of care for

patients with UI in other settings (Anger et al., 2016). Depending on the complexity of the case, interprofessional assessments that include gynecological, urological, gastroenterology, physiotherapy, and pharmacology specialties may be needed (Bonner & Boyle, 2017; Deeks, Naunton, & Nahon, 2017; Wright, Schorge, Kilcoyne, & Tambouret, 2017).

History

Nursing history should include questions to determine whether the individual has UI or risk factors for UI (Exhibit 25.1), while keeping in mind the shared relationship that UI has with other geriatric syndromes—delirium, falls, and insomnia—and assess for common risk factors,

EXHIBIT 25.1

Risk Factors Associated With Urinary Incontinence

- Age (da Silva et al., 2017; Erekson et al., 2016; B. Hodgkinson et al., 2008; Holroyd-Leduc et al., 2004; Jimenez-Cidre et al., 2014; Shamliyan et al., 2007)
- Caffeine intake (Holroyd-Leduc et al., 2004)
- Treatment of cervical and endometrial cancer, including radiation therapy and hysterectomy (Bernard et al., 2017; Donovan, Boyington, Judson, & Wyman, 2013)
- Immobility/functional limitations (Erekson et al., 2016; Fantl et al., 1996; Holroyd-Leduc & Straus, 2004; Kresevic, 1997; Offermans et al., 2009; Palmer et al., 2002; Parker-Autry et al., 2017; Shamliyan et al., 2007)
- Impaired cognition/confusion (Fantl et al., 1996; Palmer et al., 2002; Shamliyan et al., 2007)
- Medications (Fantl et al., 1996; Newman & Wein, 2009; Offermans et al., 2009)
- Overweight/Obesity (Erekson et al., 2016; Fantl et al., 1996; Parker-Autry et al., 2017; Subak et al., 2005; Subak, Richter, & Hunskaar, 2009; Suskind et al., 2017)
- Sedentary lifestyle (da Silva et al., 2017)
- Diuretics (Fantl et al., 1996)
- Smoking (Fantl et al., 1996)
- Constipation (Maeda et al., 2017); fecal impaction; fecal incontinence (Fantl et al., 1996; Offermans et al., 2009)
- Malnutrition (Kresevic, 1997)
- Depression/depressive symptoms (Erekson et al., 2016; Kresevic, 1997; Parker-Autry et al., 2017)
- Delirium (Fantl et al., 1996; Offermans et al., 2009)
- Pregnancy/vaginal delivery/episiotomy (DeLancey, 2010; Fantl et al., 1996; Holroyd-Leduc & Straus, 2004; Nygaard, 2006; Shamliyan et al., 2007)
- Large birth weight of baby (Bali, Mahalingam, & Bala, 2016)
- Treatment of prostate cancer, including radical prostatectomy and radiation therapy (Bernard et al., 2015; Hunter et al., 2004; Shamliyan et al., 2007)
- Hearing and/or visual impairment (Holroyd-Leduc & Straus, 2004)
- Heart failure (Meng et al., 2016)
- Low fluid intake (Fantl et al., 1996)
- Environmental barriers (Fantl et al., 1996; Offermans, Du Moulin, Hamers, Dassen, & Halfens, 2009)
- High-impact physical activities (Fantl et al., 1996)
- Multiple comorbidities (Erekson et al., 2016; Jimenez-Cidre et al., 2014)
- Diabetes mellitus (Fantl et al., 1996; Holroyd-Leduc & Straus, 2004; Shamliyan et al., 2007)
- Parkinson's disease (Buchman et al., 2016; Holroyd-Leduc & Straus, 2004; Nagaratnam et al., 2014; Vaughan et al., 2011)
- Stroke (Arkan et al., 2018; Fantl et al., 1996; Holroyd-Leduc & Straus, 2004; Meijer et al., 2003; Shamliyan et al., 2007; Thomas et al., 2005)
- Chronic obstructive pulmonary disease (Burge et al. 2017; Holroyd-Leduc & Straus, 2004)
- Estrogen depletion (Fantl et al., 1996; Holroyd-Leduc & Straus, 2004)
- Pelvic organ prolapse (Shamliyan et al., 2007)
- Pelvic muscle weakness (Bernard, Oullet, Moffet, Roy, & Dumoulin, 2015; DeLancey, 1994; Fantl et al., 1996; Fradet et al., 2018; Holroyd-Leduc & Straus, 2004; Kegel, 1956)
- Childhood nocturnal enuresis (Fantl et al., 1996)
- Race ([White] Erekson et al., 2016: Fantl et al., 1996; Holroyd-Leduc et al., 2004; Palmer et al., 2002 [Black]; Parker-Autry et al., 2017)
- Institutionalization prior to hospitalization (Palmer et al., 2002)
- Arthritis and/or back problems (Cassidy et al., 2017; Holroyd-Leduc & Straus, 2004)
- Menopause (da Silva et al., 2017)
- Gynecological surgery (da Silva et al., 2017)

such as age and decline in cognition and function (Luo et al., 2015; Vaughan et al., 2018). Because many patients affected by UI will not seek help, the nurse should include screening questions for all older adult patients, such as "Have you ever leaked urine? If yes, how much does it bother you?" (Vethanayagam et al., 2017). Although not validated in all settings, examples of screening instruments include the Urinary Distress Inventory-6 (UDI-6) and the Male Urinary Distress Inventory (MUDI). The UDI-6 is a self-report symptom inventory for UI that is reliable and valid for identifying the degree of bother and type of established UI in community-dwelling females (Lemack & Zimmern, 1999; Uebersax, Wyman, Shumaker, McClish, & Fantl, 1995). The MUDI is a valid and reliable measure of urinary symptoms in the male population (Robinson & Shea, 2002). Determining the degree of "bother" and the effect on HRQOL is important and appropriate and, with permission, may also include the perspective of lay CGs or significant others involved in caring for the person with UI. In addition, instruments for quantifying bother and HRQOL exist (Abrams et al., 2003; Bradway, 2003; Lobchuk & Rosenberg, 2014; Robinson & Shea, 2002; Shumaker et al., 1994).

Additional questions should focus on the characteristics of UI: time of onset, frequency, and severity of the problem. Questions also should review past health history and address possible precipitants of UI such as coughing, uncontrollable urinary urgency, functional decline, and acute illness (e.g., UTI, hip fracture). Nurses should inquire about lower urinary tract symptoms, such as nocturia, hematuria, and urinary hesitancy, as well as current management strategies for UI. The presence of and rationale for an indwelling urinary catheter should be documented (see Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection [CAUTI]).

A bladder diary or voiding record is recommended as a tool for obtaining objective information about the patient's voiding pattern, incontinent episodes, and UI severity (Haylen et al., 2010; Lau, 2009). There are numerous voiding records available; for an example, see Dowling-Castronovo, 2018). Although the 7-day voiding record is a validated, reliable research instrument for quantifying UI and identifying activities associated with unwanted urine loss (Jeyaseelan, Roe, & Oldham, 2000), a 3-day voiding record may be more feasible in community and long-term care settings (DuBeau et al., 2010; Fantl et al., 1996). A voiding record completed for even 1 day may help identify patients with bladder dysfunction or those requiring further referral; in one study, participants reported that self-recording in a small notepad was less "cumbersome" than the diaries (Gibson et al., 2018). Advanced practice nurses or urological and continence specialists can assist nursing staff with interpretation and offer suggestions regarding nursing interventions based on information from the voiding record.

COMPREHENSIVE PHYSICAL ASSESSMENT

A helpful mnemonic to guide the assessment for conditions that contribute to transient UI is TOILETED (see Box 25.1). A wide variety of medications can adversely affect continence. Diuretics are the most commonly known class of medications that contribute to UI caused by polyuria, frequency, and urgency. Medications with anticholinergic and antispasmodic properties may cause mental status changes, urinary retention with or without overflow incontinence, and stool impaction. Various psychotropic medications (e.g., tricyclic antidepressants, antipsychotics, sedative–hypnotics) have anticholinergic effects, contribute to immobility, and cause sedation and possibly delirium—each of which negatively affects bladder control. Alpha-adrenergic blockers may cause urethral relaxation, whereas alpha-adrenergic agonists may cause urinary retention. Calcium channel blockers also may cause urinary retention (Deeks et al., 2017; Newman & Wein, 2009).

Nurses should document all over-the-counter, herbal, and prescription medications during assessments. In addition, nurses must closely scrutinize new medications as possible causes if UI suddenly develops. Medications that may contribute to iatrogenic UI include diuretics and sedative–hypnotics. When a patient develops transient UI, it is important for the nurse to ask the question: Could a new medication be affecting this patient's bladder control?

If the answer is yes, then the nurse reviews this finding with the prescribing practitioner to learn whether the contributing medication may be discontinued or modified.

Important components of a comprehensive examination include abdominal, genital, rectal, and skin examinations. In particular, the abdominal examination should assess for suprapubic distention indicative of urinary retention. Inspection of the perineum and genitalia can be completed during bathing or as part of the skin assessment. In uncircumcised men, signs and symptoms of phimosis should prompt collaboration with a urological specialist (Gray, 2017). Signs and symptoms include the inability to retract tight foreskin, ballooning of the foreskin during urination due to the trapping of urine, and infections. In women, signs and symptoms of pelvic organ prolapse, such as vaginal bulging, pelvic pressure, and low backache (Haylen et al., 2010), should prompt a more thorough gynecological examination. Postmenopausal women are especially prone to atrophic vaginitis. Significant findings for atrophic vaginitis include perineal inflammation; tenderness (and, on occasion, trauma as a result of touch); and thin, pale genital tissues. During the genital examination, female patients should be instructed to cough or perform the Valsalva maneuver (sometimes referred to as a bladder stress test) to determine whether there is urine leakage caused by increased intra-abdominal pressure, which may be attributable to stress UI (Burns, 2000; Holroyd-Leduc et al., 2008).

Digital rectal and skin examinations are essential in identifying transient causes of UI such as constipation, fecal impaction, and the presence of fungal rashes. The "anal wink" (contraction of the external anal sphincter) indicates intact sacral nerve innervation and is assessed by lightly stroking the circumanal skin. Absence of the anal wink may suggest sphincter denervation (Burns, 2000) and risk of stress UI. In men, the prostate gland should be palpated during the rectal examination because BPH may contribute to urge or overflow UI. A normal prostate gland is symmetrically heart shaped, about the size of a large chestnut, and often described as "rubbery" or similar to the tip of the nose. When enlarged, as with BPH, the examiner may palpate symmetrical enlargement. Pain on palpation or asymmetrical borders may be indicative of prostatitis or prostate cancer, respectively (Gray & Haas, 2000).

In some cases, diagnostic testing may provide additional information. Initial diagnostic tests include urinalysis, urine culture and sensitivity, and postvoid residual (PVR) urine (DuBeau et al., 2010). Urinalysis and urine cultures are used to identify the presence of a UTI and bacterial agent responsible, which may contribute to acute UI. A measurement of PVR may reveal incomplete bladder emptying. Two methods for accurately evaluating PVR are bladder sonography and sterile catheter insertion after the patient has voided (Box 25.2). In addition, in some patients, it may be useful to determine optimal bladder volume, which in one study was defined as the sum of the voided volume plus the PVR (Iwatsubo, Suzuki, Igawa, & Homma, 2014). In comparison to the catheterization method, PVRs determined by sonograms do not carry the risk of CAUTI and should also be done during and after treatment for UI to determine response (Rosier et al., 2019).

BOX 25.2

Postvoid Residual

Instruct the patient to void. Post void (ideally within 15 minutes or less), measure the residual urine remaining in the bladder by either:

- Bladder sonography (scan): Noninvasive ultrasound of the suprapubic area identifies the residual amount of urine
- Sterile catheterization

A PVR of greater than 100 mL or 20% of the voided volume is considered abnormal and requires further evaluation by a urology specialist.

PVR, postvoid residual.

A simple pad test may provide additional information for the UI workup. To accomplish this, a perineal pad is weighed before and after a short time period, even as short as an hour, to determine the amount of urine loss (Krhut et al., 2014). Finally, a bedside cystometrogram urodynamic test, which provides information regarding detrusor activity, may be warranted in some cases (Burns, 2000; Lenherr & Clemens, 2013; Newman & Wein, 2009); however, owing to its invasive nature and potential for CAUTI, it should not be routinely done unless the benefits outweigh the risks (Rosier et al., 2019). Usually performed by an advanced practice nurse or physician, this test involves the following steps: (a) sterile urethral catheterization to empty the bladder (can be done to determine PVR), (b) maintaining the catheter in the bladder

and attaching a 50-mL syringe (without plunger) with the center of the syringe level with the symphysis pubis, (c) filling the bladder with sterile water, (d) monitoring the fluid level during filling for evidence of bladder contractions (evidenced by a fluctuation of the fluid level in the syringe), (e) documenting the volume at which bladder contractions occur, and (f) removal of the sterile urethral catheter (Homma et al., n.d.).

The International Consultation on Incontinence executive report recommends that patients who are not initially satisfied with their UI management based on symptom report and those with neurologic conditions that affect the lower urinary tract may benefit from complex urodynamic testing (Rosier et al., 2019). However, owing to the invasive nature of urodynamic testing, with tubes inserted into the bladder, clinicians need to determine the benefit, especially if considering for frail older adults. Therefore, more extensive testing, such as complex urodynamics and imaging studies, are typically initiated after consultation with a urological or urogynecological practice (Gray, 2017; Haylen et al., 2010).

Functional, environmental, psychosocial, and mental status assessments are essential components of the UI evaluation in older adults. The nurse should observe the patient voiding, assess mobility, note any use of assistive devices, and identify any obstacles that interfere with appropriate use of toilets or toilet substitutes, such as a bedside commode. Recent evidence suggests person-centered incontinence care has promise for improving UI and quality of life (Nazarko, 2015; Wijk et al., 2018). This care approach requires nursing staff to assess how UI affects their life-history. Cultural norms must also be considered when assessing the role UI plays in a person's life (Hamid et al., 2015; Park et al., 2017).

INTERVENTIONS AND CARE STRATEGIES

Evidence demonstrates that nurses in acute and long-term care settings lack the knowledge necessary for evidence-based care for UI, focusing more on containment strategies than on promoting continence (Cassells & Watt, 2003; Coffey, McCarthy, McCormack, Wright, & Slater, 2007; Colborne & Dahlke, 2017; Connor & Kooker, 1996). Although studies about the knowledge of community nurses have not been identified, it is reasonable to suggest that education of nurses is an essential component when implementing the UI protocol described in this chapter. For example, identifying nurses to serve as continence champions may facilitate incorporating evidence-based care of UI across care settings (Albertson, 2018; Hägglund & Olai, 2016; Hunter, 2016; Wijk et al., 2018). The Society of Urologic Nurses and Associates (SUNA) is a helpful resource for continence champions (www.suna.org). SUNA's Certification Board for Urologic Nurses also provides urological certifications, including the certified urologic registered nurse (CURN) and the certified urologic nurse practitioner (CUNP) for advanced practice registered nurses (SUNA, 2018). Additionally, wound, ostomy, and continence nurse (WOCN) certification is available to bachelor's prepared registered nurses to provide safe and evidence-based care to patients with conditions that affect continence (www.wocn.org). Nurses are likely to be the first to identify, and perhaps prevent, transient UI; however, more research is needed to understand the role nurses and other healthcare professionals play in preventing UI (Harlow et al., 2018; Sampselle, Palmer, Boyington, O'Dell, & Wooldridge, 2004).

Transient causes of UI should be identified and treated, and any individuals with a history of established UI who concurrently develop transient UI should have usual voiding routines and continence strategies immediately incorporated into the care plan, whenever possible. The use of indwelling urinary catheters should be avoided, and, if absolutely necessary, regular assessment of continued appropriateness should be included in the patient care plan to prevent prolonged use and negative sequelae (John et al., 2018).

The environment is vital in managing UI, particularly functional UI. Older adults who are incontinent often depend on adaptive devices (e.g., walker), family CGs, and formal CGs for assistance with voiding, making them "dependently continent." In institutional settings, call bells should be identified and within easy reach. If limited mobility is anticipated, nursing staff should consider using an elevated toilet or commode seat, male or female urinal, or bedpan. Nurses should obtain referrals to physical and occupational therapy for ambulation aids, gait training, further assessment of activities of daily living associated with continence, and improved overall muscle strength. Physical and chemical restraints should be avoided, including side rails (see Case Study 25.1). Patients should be encouraged and assisted to void before leaving the unit or traveling for tests or therapy (Fantl et al., 1996; Jirovec, 2000; Jirovec et al., 1988; Palmer, 1996). Incorporation of a general exercise program with support from physical therapists in nursing homes improved UI (Ouslander, Griffiths, McConnell, Riolo, & Schnelle, 2005). Moreover, a pilot study demonstrated that combining walking exercise with pelvic floor muscle exercises (PFMEs) improved UI for frail older women living in independent and assisted living (Talley, Wyman, Bronas, Olson-Kellogg, & McCarthy, 2017). In the hospital setting, patients described worrying

about having an "accident" in the therapy gym and requested "diapers" for fear of being sent back to the nursing unit if they "wet themselves" or having to ask the therapists for assistance to use the bathroom during a therapy session (Dowling-Castronovo, 2014).

Toileting programs (e.g., individualized, scheduled toileting programs, including timed voiding; prompted voiding) have varied success rates (Colling, Ouslander, Hadley, Eisch, & Campbell, 1992; Eustice, Roe, & Paterson, 2000; Gray, 2017; Ostaszkiewicz, Johnston, & Roe, 2004; Rathnayake, 2009c). In one study, acute care nurses reported preferring toileting programs over containment strategies, but this has not been explored further (Pfisterer, Johnson, Jenetzky, Hauer, & Oster, 2007). Timed voiding has been promoted as a strategy for managing UI in individuals who are not cognitively or physically able to participate in independent toileting (Rathnayake, 2009c; Thomas, Coupe, Cross, Tan, & Watkins, 2019). Stroke survivors reported that individualization of timed and prompted voiding was key to "getting back into the habit" (Gibson et al., 2018, p. 2046). In addition to its usefulness in the assessment of UI, a voiding record is essential for developing an individualized, scheduled toileting or timed voiding program, which mimics the patient's normal voiding patterns and requires continual assessment and reevaluation for successful outcomes. For example, if the initial scheduled toileting time is set for 8:00 a.m., yet at 6:30 a.m. the patient consistently attempts to independently void or is noted to be incontinent, then the toileting time should be adjusted to 6:00 a.m. Evidence is lacking in regard to the effectiveness of timed voiding as a primary management strategy for UI; however, it may be used based on the nurse's judgment of the clinical situation (Rathnayake, 2009c).

Prompted voiding requires someone (nurse or the family CG) to ask whether the patient needs to void, offer assistance, and then offer praise for successful voiding (Eustice et al., 2000; Jirovec, 2000; Ostaszkiewicz et al., 2004). Among nursing home residents with UI, prompted voiding may achieve short-term improvement in daytime UI and may be effective in reducing UI in cognitively intact older adults (B. Hodgkinson et al., 2008; Rathnayake, 2009b). Among hospitalized older adults in Japan, a prompted voiding program resulted in patients expressing a need to void, improvement in their ability to successfully void, and a decrease in the use of absorbent products (Iwatsubo et al., 2014).

The role of the family CG, such as spouses and children, needs to be explored in the acute care setting (Dowling-Castronovo, 2014). In the home care setting, evidence suggests that these CGs may provide better consistency strategies to manage UI than paid CGs (Egnatios, Dupree, & Williams, 2010). Moreover, a mutual learning process regarding management of UI (as well as other health problems) occurs when older adults with UI, their family CGs, nurses, and nursing aides interact (Jansen et al., 2013). Evidence supports improved coping of patients with UI who have strong social support and knowledge of the disease process (Szymona-Palkowka et al., 2016). In both home care and acute care settings, older adults attempt to build connections with nursing staff to meet their bladder needs (Dowling-Castronovo, 2014; Jansen et al., 2013). Therefore, from a practical and patient/family-centered approach, it is reasonable to suggest that both nurses and therapists "coach" (Frampton et al., 2008) patients and their family CGs in the skills needed to manage UI.

Healthy Bladder Behavior Skills

Traditionally, nursing interventions for UI focus on containment strategies by means of receptacles (e.g., bedpan, urinal, commode, indwelling urinary catheters) or by various absorbent products (e.g., sanitary napkin, adult brief, incontinent pad; Harmer & Henderson, 1955; Henderson & Nite, 1978; Palese et al., 2007). Various treatments beyond containment strategies require a multimodal approach (Gray, 2017; McClurg et al., 2016): dietary and fluid management, weight loss, PFMEs, pessaries, urge inhibition and bladder training (retraining) strategies, toileting programs (e.g., individualized, scheduled toileting programs/timed voiding, prompted voiding, habit training), constipation management, pharmacological therapy, and surgical options (Fantl et al., 1996; B. Hodgkinson et al., 2008; Qaseem et al., 2014). These treatments (excluding pharmacological and surgical options) are viewed as Health Bladder Behavior Skills (HBBS). Although the recommendation is to offer HBBS to all older adults with UI (Fantl et al., 1996; Teunissen, de Jonge, van Weel, & Lagro-Janseen, 2004), it is unclear how HBBS can be best incorporated in the care of older adults. Furthermore, despite the fact that contemporary nursing practice textbooks list and describe HBBS as nursing interventions (Kozier, Erb, Berman, & Snyder, 2004; Newman & Wein, 2009; Taylor, Lillis, & LeMone, 2005), many of these interventions have not been adequately examined across healthcare settings to understand how to best sustain their implementation. Nurses do not routinely implement these interventions (Bayliss, Salter, & Locke, 2003; Schnelle et al., 2003; Watson, Brink, Zimmer, & Mayer, 2003). Accurate assessment and identification of type of UI are needed before HBBS are initiated. Prior to instituting HBBS, the nurse needs to assess the motivation of the patient, family CG, and nursing staff because behavior modification

is a premise of HBBS (Palmer, 2004). It is also important to prioritize HBBS among competing interventions in a treatment care plan (Gibson et al., 2018) to empower individuals to better manage living by communicating in an open, compassionate manner to help empower patients to address their "incontinent body" (Hoogsteyns & van der Hoorst, 2015).

Examples of dietary management strategies include avoiding certain foods and beverages known to be bladder irritants such as caffeine, acidic foods or fluids, and aspartame (Gray & Haas, 2000; Vaughan et al., 2011). Women who are overweight or obese may benefit from a weight-loss program (Imamura, Williams, Wells, & McGrother, 2015; Subak et al., 2005, 2009; Wing et al., 2010). A weight loss of 5% to 10% significantly decreased UI episodes for some overweight and obese women with mean ages in the 50s (Subak et al., 2005). While these findings cannot be generalized to older adults, they do provide evidence that weight management is important to healthy aging. If not contraindicated, the nurse recommends adequate fluid intake, specifically water, and an increased intake of dietary fiber to maintain bowel regularity. It is important to work closely with older adults who fear that unwanted urine loss is a result of increased fluid intake. Education should focus on the adverse consequence of inadequate fluid intake, such as volume depletion or potential for dehydration, and that too little fluid intake may result in concentrated urine, which, in turn, may cause increased bladder contractions and increased feelings of urinary urgency. Finally, to manage and limit nocturia, patients may be advised to limit fluid intake a few hours before bedtime (Doughty, 2000; Fantl et al., 1996); however, this is questionable for older adults who do not have easy access to fluids or have diminished thirst sensation (DuBeau et al., 2010). One nursing intervention that may decrease nocturia involves assessing and tailoring diuretic doses to the needs of individual patients. For example, institutions may automatically schedule every-12-hour diuretic dose times at 10 a.m. and 10 p.m. For some patients, it will be extremely important that nurses navigate organizational processes to reschedule diuretic doses to an alternate time such as 6 a.m. and 6 p.m. or even 4 p.m. This simple strategy may decrease nocturia, which, in turn, may decrease the risk of falls. Research that examines which UI interventions best modify fall risk is needed (Wolf, Riolo, & Ouslander, 2000).

For community-dwelling, cognitively intact older adults, PFMEs are at least as effective as pharmacological therapies in treating stress and urge UI (B. Hodgkinson et al., 2008). There is sufficient evidence that for women, PFMEs effectively treat UI, may have long-term benefits, and are cost effective (Dumoulin, Cacciari, & Hay-Smith, 2018; Kegel, 1956; Qaseem et al., 2014; Vaughan et al., 2011). For men post prostatectomy, the evidence is inconclusive (Anderson et al., 2015). PFMEs also hold promise for the primary prevention of UI, but require additional research (Harlow et al., 2018; J. Hay-Smith, Herbison, & Mørkved, 2002). Recent evidence regarding the relationship among UI and other geriatric syndromes suggests that women who do not maintain active lifestyles and overall muscle strength are more likely than women who are active and have overall good muscle strength to develop UI (Parker-Autry et al., 2017).

Integrating PFMEs into the plan of care requires an assessment of the patient's baseline understanding of PFMEs to identify knowledge deficits. Ideally, PFMEs are taught during a vaginal or rectal examination, when the clinician manually assists the patient to identify the pelvic muscles by instructing the patient to squeeze around the gloved examination finger. This method allows for performance appraisal (J. Hay-Smith et al., 2002); together with weekly phone consults and monthly performance appraisal, this method is known to improve UI outcomes for community-dwelling individuals (Tsai & Liu, 2009). Alternately, PFMEs may be verbally taught by instructing the patient to gently squeeze or contract the rectal or vaginal muscles. Either teaching method includes instructions not to squeeze the stomach, buttocks, or thigh muscles (because this only increases intra-abdominal pressure), but to isolate the contraction of the pelvic muscles. Physical therapy specifically for UI has been shown to significantly improve UI severity and quality of life associated with UI in older adults (Neville, Beneciuk, Bishop, & Alappattu, 2016). For example, physical therapists specially trained in PFME therapy may offer complementary interventions, such as special stretching techniques, massage, and trigger point therapy (Hill, 2016).

Evidence suggests that supervised PFMEs, where a professional educates and coaches a client about how to correctly perform PFME, is key, although a standardized dose has not been identified (E. J. C. Hay-Smith, Herderschee, Dumoulin, & Herbison, 2011). Preferably, each exercise should consist of contracting for 10 seconds and relaxing for 10 seconds. Some patients may need to start with 3 or 5 seconds and then increase as their muscles become stronger. There is no set "exercise dose" (Du Moulin, Hamers, Paulus, Berendsen, & Halfens, 2005); one example is to recommend 15 PFMEs three times per day. For community-dwelling women with stress, urge, or mixed UI, PFMEs (at least 24 per day for at least 6 weeks) should be included in first-line conservative management programs (Choi, Palmer, & Park, 2007; Syah, 2010). Most

individuals notice improvement in 2 to 4 weeks, but not immediately. For community-dwelling older adults, a commercialized, evidence-based, PFME quality-improvement teaching program statistically improved UI outcomes (Albertson, 2018).

Adding biofeedback technology to clinician coaching for PFME may improve success for some individuals. For example, among older women without severe detrusor overactivity, mild to moderate urge UI predicted improvement occurred with two sessions of biofeedback combined with two clinician coaching sessions and home instruction (Resnick et al., 2013). In another study, improvement in UI frequency occurred even after only one session (Riley & Organist, 2014). In a study of community-dwelling older women, PFME instruction and reinforcement using biofeedback improved both UI outcomes and concurrent depressive symptoms (Tadic et al., 2007). A systematic review found that PFME coaching with biofeedback technology was more effective than provider feedback alone (Herderschee, Hay-Smith, Herbison, Roovers, & Heineman, 2011). However, the therapeutic relationship between providers and patients remains important (Wooldridge, 2017); individuals with UI will benefit from a referral to a continence nurse or other provider specializing in care of individuals with UI (e.g., urologist, gynecologist, urogynecologist).

Electrical stimulation (e-stim) and vaginal weights are additional strategies to consider for PFME training. Women with stress UI who have difficulty performing PFME, or who experience little improvement, may experience increased effectiveness by adding transcutaneous e-stim (via surface electrodes) of the nerves that innervate pelvic floor muscles (Stewart, Berghmans, Bø, & Glazener, 2017). For adults with OAB and mixed UI, e-stim has demonstrated benefit (Gray, 2017; Stewart, Gameiro, et al., 2017); however, men using e-stim post prostatectomy reported only short-term benefits, and some experienced pain or discomfort (Berghmans, Hendriks, Bernards, de Bie, & Omar, 2013).

For cognitively intact women with stress UI (and without severe pelvic organ prolapse), graduated vaginal weight training provides another option to enhance PFME training (Herbison & Dean, 2013). To accomplish this, a vaginal weight (usually in the form of a cone or ball) is inserted into the vagina, and the patient is instructed to retain the weight while walking or standing by contracting pelvic floor muscles around the weight. Weights are typically used for about 15 minutes once or twice per day. When the first weight is mastered (as evidenced by retention of the weight in the vaginal vault during walking or standing), a next higher weight is used.

For cognitively intact women with stress UI and pelvic organ prolapse that is not amenable to surgery, a pessary may be an option. A pessary is a support device typically made of medical grade silicone shaped like a ring, cube, or shelf. Women need to visit with a specially trained clinician, such as a physician, nurse, nurse practitioner, or physical therapist, to be evaluated and fitted with a pessary. The pessary supports the prolapsed organ and, in turn, may improve UI. For a comprehensive review, Atnip and O'Dell (2012) provide a detailed overview of appropriate assessment, fitting, and care of pessary support devices.

Urge inhibition and scheduled toileting times (also called bladder training, retraining, reeducation, or bladder drills) are other HBBS used to treat urge UI and OAB (DuBeau et al., 2010; Teunissen et al., 2004; Wallace, Roe, Williams, & Palmer, 2004). These techniques may be combined with functional incontinence training (FIT; DuBeau et al., 2010; Schnelle et al., 2003) and may be more effective if used in combination with PFMEs or anticholinergic drugs (Rathnayake, 2009a). Bladder training requires a baseline voiding record to assess the timing of voids and UI episodes.

If urinary frequency is assessed at baseline, the patient is instructed to lengthen the time between voids in an effort to retrain the bladder. When a strong urge to void occurs, the patient is instructed to use urge-inhibition techniques to suppress urinary urgency. Although the mechanism of how urge inhibition works is not well understood (Gray, 2005; Smith, 2000), urge inhibition includes distraction techniques (e.g., reciting a favorite poem or song), relaxation techniques, and several rapid pelvic floor muscle contractions, also called 'quick flicks' (Gray, 2005; Hill, 2016). The goal is to suppress the urge to void until desirable (Hill, 2016; Smith, 2000). Older women with urge UI have reported urge inhibition with quick flicks as being one of the most helpful HBBS (Riley & Organist, 2014); in contrast, patients after a stroke did not report benefit from this combination (Gibson et al., 2018). For individuals who rely on CGs, such as those who are cognitively impaired, bladder training was a challenge for family CGs to successfully implement (Ostaszkiewicz, Chestney, & Roe, 2009).

Preventing and treating constipation is important to address in patients with UI. Colonic massage, or abdominal massage, and using a stool for squatting during defecation are two methods to help manage constipation and improve UI (Hill, 2016; Hunter, 2016; McClurg et al., 2016; Vaughan et al., 2011). Additional first-line interventions for treating constipation include scheduled toileting (for bowel movements), increased fluid and dietary fiber intake, and increased physical activity, as tolerated

and with safety in mind (Mounsey, Raleigh, & Wilson, 2015; Schuster, Kosar, & Kamrul, 2015).

In some instances (e.g., for patients experiencing incomplete bladder emptying or overflow UI), patients and nursing staff can use Crede's maneuvers (i.e., deep suprapubic palpation) to facilitate bladder emptying. The Crede's maneuver is used with caution and requires manual compression over the suprapubic area during bladder emptying. The Crede's maneuver should be avoided if vesicoureteral reflux (i.e., abnormal flow of urine from the bladder back up the ureters) or overactive sphincter mechanisms are suspected because it may dangerously elevate pressure within the bladder (Doughty, 2000). Therefore, if the nurse suspects that UI is related to neurologic impairments, a urological specialist should be consulted before implementing this specific HBBS. In some cases, instructing patients to double void (i.e., after an initial void, instruct patients to stand or reposition for a second void) also facilitates bladder emptying.

Medication therapy for UI can be categorized by UI type. Antimuscarinic drugs (which target muscarinic receptors and, in turn, lead to detrusor relaxation) are FDA approved for the treatment of urge UI and OAB (Samuelsson et al., 2015); examples include oxybutynin, tolterodine, solifenacin, hyoscyamine, and darifenacin. An important consideration, especially in older persons, is side effects: dry mouth and constipation (McDonnell & Birder, 2017; Samuelsson et al., 2015). FDA-approved drugs to treat urge UI and OAB should be prescribed at the lowest possible dose and not used in combination (Deeks et al., 2017). Additionally, recent research suggests a link between cumulative use of antimuscarinic drugs with incident dementia and mood disorders, including depression, and, therefore, these drugs should be used with caution and in the lowest possible doses in older adults (McDonnell & Birder, 2017). Specifically, trospium, when included as part of a drug regimen of greater than seven total medications, carries a higher likelihood of side effects (Qaseem et al., 2014). A newer medication that has similar efficacy to the antimuscarinic class, but with increased tolerability, is mirabergron, a beta-3 agonist, FDA approved for treatment of urge UI and OAB (McDonnell & Birder, 2017). There are no FDA-approved drugs for the treatment of stress or overflow UI. For persons with mixed UI, a combination of behavioral strategies and pharmacological treatment of the urge UI and OAB may be beneficial (Wooldridge, 2017). Side effects of pharmacological therapies for UI, including dry mouth, constipation, and mood changes, must always be considered when caring for a patient with UI (American Geriatrics Society Beers Criteria® Update Expert Panel, 2019; Bardsley, 2015).

Additional Nursing Interventions

Maintaining skin integrity is a goal of nursing care. Decomposition of urinary urea by microorganisms releases ammonia and forms ammonium hydroxide, an alkali. This alkali makes the protective "acid mantle" of the skin vulnerable and jeopardizes skin integrity. If UI episodes persist despite management strategies, perineal skin care interventions should focus on maintaining the integrity of the protective acid mantle of the skin (Ersser, Getliffe, Voegeli, & Regan, 2005; see Chapter 28, Preventing Pressure Ulcers and Skin Tears) and specifically addressing incontinence-associated dermatitis (Gray, 2017). The use of evidence-based barrier creams and antifungals as indicated can be helpful in improving and maintaining skin integrity in individuals with UI (Callaghan, Hunt, Mohamud & Small, 2018; Gray, 2017).

Although many promising treatments for UI exist, when total cure is not achieved, containment strategies are an important component to consider for managing UI (Riemsma et al., 2017). Although absorbent products are commonly used for UI containment, there is little evidence available to guide product selection and no evidence of how absorbent products may interact with the acid mantle (Fader, Cottenden, & Getliffe, 2008). Community-dwelling women using products designed for light amount of urine loss reported important characteristics of absorbent pads, including the ability to hold and hide UI and ease of use (Getliffe, Fader, Cottenden, Jamieson, & Green, 2007). Yet those with heart failure and severe UI, defined as at least one episode of UI/day, were significantly more likely to seek care than those with less than severe UI because they believed the leakage could be improved (Meng et al., 2016). In an acute care setting, nursing staff reported problems with quality and availability of absorbent products (Clayman, Thompson, & Forth, 2005). Hospitalized patients fear "wetting the bed." Some gain a sense of control when able to contain and conceal UI with adult absorbent products; however, in one study, patients described a preference for brand name over the generic absorbent products provided by the hospital (Dowling-Castronovo, 2014).

In regard to reusable versus disposable absorbent products, there is no demonstrable risk of cross-infection with reusable absorbent products when appropriate laundering protocols are followed, and there are no clear cost savings associated with using one over the other. Reusable products have limited acceptability, especially among women, although men living at home preferred them at nighttime as a way to control costs (Fader, Cottenden, & Getliffe, 2007; Fader et al., 2008). Use of adult briefs

was significantly associated with an increased risk of infection (Zimakoff, Stickler, Pontoppidan, & Larsen, 1996). Although bed pads absorb urine, consumer satisfaction is questionable, and there are no studies on the use of chair pads. Although limited evidence suggests that disposable insert pads may be more effective for women with UI than other absorbent products (Rathnayake, 2009d), there is no clear evidence to suggest one absorbent product is superior to another. For men, penile sheaths and clamps are additional containment options but have risks for adverse events, such as skin and circulation impairment that require careful monitoring (Anderson et al., 2015; Nazarko, 2018). Post prostatectomy, men found a *Prostate Survivors' Toolkit* that included containment products, such as pads, to conceal UI helpful in managing UI (Weber & Roberts, 2015). Evidence supports pilot testing of absorbent products according to individual circumstances, including patient, family, and institutional preferences, and offering a choice of products to individuals with UI (Dunn, Kowanko, Paterson, & Pretty, 2002; Fader et al., 2007, 2008; Rathnayake, 2009d).

Trends to better understand and incorporate complementary modalities in the care of individuals with UI, such as acupuncture, reiki, guided imagery, yoga therapy, and naturopathic medicine, deserve consideration. Limited evidence exists for acupuncture, which may have a place in treating stress UI (Wang, Zhishun, Peng, Zhao, & Liu, 2013). Mindfulness-based stress reduction, which utilizes daily guided mindfulness meditation, is supported as a promising complementary modality alongside other HBBS methods (Baker, Costa, Guarino, & Nyagaard, 2014; Long, Khairat, Chmelo, & Palmer, 2018). Healthcare providers caring for persons with UI may consider referring patients to specialty practices or providers (such as Integrative Medicine) for assistance incorporating complementary modalities along with HBBS (Armstrong, Study, Zador, Peters, & Patricolo, 2019). In addition, innovative strategies to empower individuals to learn how to prevent and treat UI, such as nurse-led models in community fitness facilities (Cera, Twiss, & Struwe, 2019), are underway.

CASE STUDY 25.1

A student nurse received a report on A. G, an 86-year-old man with a history of Alzheimer's dementia (AD), who is hospitalized for delirium. The nurse was told that Mr. G was "pleasantly confused," required full assistance with personal care, and had spent a few hours in a bedside recliner. The student nurse performed an assessment that revealed the following:

- Patient sleeping in bed with all side rails up, call bell within reach, no urinal in sight
- Past health history: coronary artery disease, mild hypertension, mild osteoarthritis, AD
- Past surgical history: none
- Medications: enalapril (Vasotec) 5 mg by mouth every day for hypertension, multivitamin 1 tablet by mouth daily, donepezil (Aricept) 10 mg by mouth every day for AD
- Vital signs: 114/60, 72, 14, 98.0°F
- Alert and oriented to self; sleepy; no focal deficits
- Heart rate: regular
- Breath sounds clear, slightly decreased at the bases
- Abdomen: +BS (bowel sounds) in all quadrants, soft, nontender, no suprapubic tenderness; left quadrant slightly dull to percussion; no palpable masses
- Dry adult brief in place

The student nurse learns from the patient's wife (i.e., the primary CG at home) that the patient had experienced occasional urinary leaking in the past, but not to the extent of needing "diapers." He has a history of chronic constipation. With the nursing instructor's guidance, the student nurse assisted Mr. G to a dangling position at the side of the bed. After assessing and evaluating that the patient's muscular strength was strong, ambulation was attempted. The patient ambulated to the bathroom, the adult brief was removed, and Mr. G was prompted to void. He successfully voided and had a bowel movement. He proceeded to wash his hands and returned to the recliner. The adult brief was left off during the time the student nurse was there to assist him. During this time, Mr. G made one attempt to initiate voiding, successfully assisted by the student nurse.

Discussion

The importance of ongoing nursing assessment was stressed as being vital to quality of care. Had the student nurse just transferred the patient to the chair, he may not have effectively emptied his bowel and bladder. Mr. G's constipation was addressed by providing appropriate fluid and fiber intake and by continuing with an individualized toilet schedule as tolerated.

(*continued*)

CASE STUDY 25.1 (*continued*)

Evidence suggests that prompted voiding and individualized toileting schedules reduce the number of UI episodes (Eustice et al., 2000; Fink, Taylor, Tacklind, Rutks, & Wilt, 2008; Gray, 2017; Ostaszkiewicz et al., 2004; Thomas et al., 2019) and address constipation (Mounsey et al., 2015; Schuster, Kosar, & Kamrul, 2015). In addition, prompted voiding in cognitively impaired long-term care residents has demonstrated an increase in self-initiative toileting activities (Holroyd-Leduc & Straus, 2004). These strategies have not been extensively studied in the acute care setting; however, this case study demonstrates that nursing interventions used in other settings may also be beneficial for acutely hospitalized older adults. For example, one published case report highlights the importance of nurses working with older adults and their CGs to address UI during the transitional period from acute care to home (Bradway, Bixby, Hirschman, McCauley, & Naylor, 2013).

SUMMARY

UI is a significant health problem that should not be overlooked. Behavioral and supportive therapies and patient education should be initiated by nurses if the patient is cognitively, physically, and emotionally able to participate. Evidence from long-term care and community settings suggests that nurse continence experts play an essential role in improving the quality of continence care (Du Moulin et al., 2005; McDowell et al., 1999; Watson, 2004). An interprofessional approach including appropriate referral to specialists and follow-up is necessary to provide appropriate standard of care for patients with UI (Bonner & Boyle, 2017). Therefore, nurses that care for patients with UI, whether in acute, long-term, or community settings, have the responsibility to design a plan that includes referral to a continence nurse specialist or other continence expert for follow-up.

Other than identifying UI as a risk for falls, there are no requirements specific to UI from The Joint Commission (www.jointcommission.org), despite having evidence-based information for catheter-associated urinary tract infection (CAUTI); see Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection Nevertheless, it is recommended that a continuous quality-improvement (CQI) criterion should encompass critical elements in an effective and successful urinary continence program. For example, quality indicators for UI in the vulnerable older adult population include documentation of (a) the presence of UI, (b) the bothersome nature for the older adult and significant other, (c) focused history and physical examination, (d) documentation of urinalysis and/or culture, (e) PVR and, if elevated to more than 100 mL, consider referral for further evaluation; (f) type of UI; (g) discussion of HBBS; (h) interprofessional evaluation for urodynamic evaluation and pharmacological/surgical treatments; and (i) response to treatment (Fung, Spencer, Eslami, & Crandall, 2007). Institutional quality-improvement teams may use an if-then approach (Schnelle & Smith, 2001). For example, if an older adult experiences transient UI, then a focused assessment is performed to identify etiology.

Nurses have a significant role in improving the assessment and treatment of UI. It is recommended that nurses are particularly vigilant for persons who are "admitted dry and become wet" during a stay in a healthcare facility. These patients will particularly benefit from evidence-based assessment and management. Moreover, nurses can help to promote changes in attitudes toward UI and provide education on individual, facility-wide, community, and national levels.

NURSING STANDARD OF PRACTICE

Protocol 25.1: Urinary Incontinence in Older Adults

I. GOAL

A. Nursing staff will utilize comprehensive assessments and implement evidence-based management strategies for patients identified with UI.
B. Nursing staff will collaborate with interprofessional team members to identify and document type of UI.
C. Patients with UI will not have UI-associated complications.

II. OVERVIEW

Population studies from multiple countries reported UI prevalence between 5% and 70%, with most reporting between 25% and 45%. Prevalence increases with age, with more than 40% for the 70-year-old and older population (Milsom & Gyhagen, 2018). Of those receiving home care services, 40% have UI; and more than one third of short-term nursing home residents and close to 75% of long-term NH residents have UI (Gorina et al., 2014). Medications, constipation/fecal impaction, low fluid intake, environmental barriers, diabetes mellitus, stroke immobility, impaired cognition, malnutrition, and depression are factors specific to identifying older adults at risk of UI (Fantl et al., 1996; Holroyd-Leduc & Straus, 2004; Kresevic, 1997; Meijer et al., 2003; Offermans et al., 2009; Shamliyan et al., 2007; Thomas et al., 2005). Complications of UI include falls, skin irritation leading to pressure ulcers, social isolation, and depression (Bogner et al., 2002; Brown et al., 2000; Fantl et al., 1996; Goksin & Asiret, 2018; Hamid et al., 2015; Meng et al., 2016; Morris & Wagg, 2007). Nurses play a key role in the assessment and management of UI.

III. BACKGROUND

A. Definitions
   1. UI is defined as the complaint of involuntary urine loss (Abrams et al., 2003; Haylen et al., 2010) or involuntary loss of urine sufficient to be a problem (Fantl et al., 1996; National Association for Continence, 1998).
      a. *Transient UI* is characterized by the sudden onset of potentially reversible symptoms that typically have a duration of less than 6 months (Specht, 2005).
B. Types of *established UI* include the following:
   1. *Stress UI* is defined as an involuntary loss of urine associated with activities that increase intra-abdominal pressure; more common among women, but occurs in men after a prostatectomy (Abrams et al., 2003; Fantl et al., 1996; Hunter et al., 2004; Jayasekara, 2009).
   2. *Urge UI* is characterized by an involuntary urine loss associated with a strong desire to void (urgency; Abrams et al., 2003; Fantl et al., 1996). An individual with OAB may complain of urinary urgency, with or without UI (Abrams et al., 2003; Haylen et al., 2010).
   3. *Mixed UI* is defined as a combination of stress UI and urge UI (Fantl et al., 1996; Jayasekara, 2009).
   4. *Overflow UI* is an involuntary loss of urine associated with overdistention of the bladder and may be caused by an underactive detrusor muscle or outlet obstruction, leading to overdistention of the bladder and overflow of urine (Abrams et al., 2003; Doughty, 2000; Fantl et al., 1996; Jayasekara, 2009).
   5. *Functional UI* is caused by nongenitourinary factors, such as cognitive or physical impairments that result in an inability of the individual to void independently (Fantl et al., 1996; B. Hodgkinson et al., 2008); however, continence may be achieved with support of caregivers (Barrie, 2016).
C. Epidemiology
   1. In different healthcare settings across the globe, prevalence rates range between 5% and 70%, with most reporting between 25% and 45% (Milsom et al., 2014). In the United States, more than 33 million individuals report some type of UI or bladder condition (https://www.nafc.org/urinary-incontinence).
   2. UI studies specific to the acute care setting demonstrate that UI is present in 10% to 42% of older adults (Dowd & Campbell, 1995; Fantl et al., 1996; Kresevic, 1997; Palmer et al., 1992; Schultz et al., 1997); and prevalence of UI ranges from 8% to 46% among community-dwelling adult populations (Du Moulin et al.,

(*continued*)

Protocol 25.1: Urinary Incontinence in Older Adults (*continued*)

2008; Erekson et al., 2016; Kwong et al., 2010; Lee et al., 2009; Sims et al., 2011); 37% among those living in residential care facilities; 40% of those receiving home care services; and more than a third of short-term nursing home residents and close to 75% of long-term NH residents have UI (Gorina et al., 2014). Therefore, implementation of an evidence-based protocol to guide assessment and care planning is essential.

IV. PARAMETERS OF ASSESSMENT

A. Document the presence or absence of UI for all patients (DuBeau et al., 2010).
B. Document the presence or absence of an indwelling urinary catheter (John et al., 2018).
C. For patients with UI, the nurse collaborates with interprofessional team members to:
   1. Determine whether the UI is transient, established (stress/urge/mixed/overflow/functional), or both and document (DuBeau et al., 2010; Fantl et al., 1996; Jayasekara, 2009; Johnson, Bulechek, McCloskey-Dochterman, Maas, & Moorhead, 2001; Qaseem et al., 2014). The mnemonic TOILETED (see Box 25.1), the UDI-6, and the MUDI may be used to help guide nursing assessment (Dowling-Castronovo, 2018; Lemack & Zimmern, 1999; Robinson & Shea, 2002; Uebersax et al., 1995).
   2. Identify and document the possible etiologies of UI (DuBeau et al., 2010; Fantl et al., 1996).

V. NURSING CARE STRATEGIES

A. General principles that apply to prevention and management of all forms of UI
   1. Identify and treat causes of transient UI (DuBeau et al., 2010).
   2. Upon admission to a healthcare facility, identify and continue successful prefacility management strategies for established UI.
   3. Develop an individualized plan of care using data obtained from the history and physical examination and in collaboration with other team members. Implement toileting programs as needed (Gibson et al., 2018; Gray, 2017; Ostaszkiewicz et al., 2004; Rathnayake, 2009c; Thomas et al., 2019).
   4. Avoid medications that may contribute to UI (American Geriatrics Society Beers Criteria® Update Expert Panel, 2019; Newman & Wein, 2009).
   5. Avoid indwelling urinary catheters whenever possible to avoid the risk of CAUTI (Bouza, San Juan, Muñoz, Voss, & Kluytmans, 2001; Dowd & Campbell, 1995; Gould et al., 2009; Zimakoff et al., 1996).
   6. Monitor fluid intake and maintain an appropriate hydration schedule.
   7. Limit dietary bladder irritants (Gray & Haas, 2000; Vaughan et al., 2011).
   8. Consider adding weight management as a long-term goal in discharge planning to achieve a healthy BMI (Qaseem et al., 2014; Subak et al., 2005; Suskind et al., 2017).
   9. Modify the environment to facilitate continence (Fantl et al., 1996; Jirovec, 2000; Palmer, 1996).
   10. Provide patients with usual undergarments in expectation of continence, if possible.
   11. Prevent skin breakdown by providing immediate cleansing after an incontinent episode and utilizing barrier ointments (Callaghan et al., 2018; Ersser et al., 2005; Fader et al., 2007, 2008; Getliffe et al., 2007; Gray, 2017).
   12. Pilot test absorbent products to best meet patient, staff, and institutional preferences (Dunn et al., 2002), bearing in mind adult briefs have been associated with UTIs (Zimakoff et al., 1996).
   13. Assign exercise deemed safe and appropriate by healthcare providers (Ouslander et al., 2005; Talley et al., 2017).
   14. Perform constipation management (Fantl et al., 1996; Hill, 2016; B. Hodgkinson et al., 2008; Hunter, 2016; McClurg et al., 2016; Mounsey et al., 2015; Qaseem et al., 2014; Schuster et al., 2015; Vaughan et al., 2011).
B. Strategies for specific problems:
   1. Stress UI
      a. Teach PFMEs (DuBeau et al., 2010; B. Hodgkinson et al., 2008; Qaseem et al., 2014).
      b. Provide toileting assistance and bladder training as needed (DuBeau et al., 2010; Qaseem et al., 2014).
      c. Consider referral to other team members if pharmacological or surgical therapies are warranted (Bonner & Boyle, 2017; Deeks et al., 2017; Wright et al., 2017).

(*continued*)

Protocol 25.1: Urinary Incontinence in Older Adults (*continued*)

2. Urge UI and OAB
   a. Implement bladder training (retraining; DuBeau et al., 2010; Qaseem et al., 2014; Teunissen et al., 2004).
   b. If patient is cognitively intact and motivated, provide information on urge inhibition (Gray, 2005; Hill, 2016; Smith, 2000).
   c. Teach PFMEs to be used in conjunction with bladder training, and instruct in urge inhibition strategies (Flynn, Cell, & Luisi, 1994; Rathnayake, 2009a; Teunissen et al., 2004).
   d. Collaborate with prescribing team members if pharmacological therapy is warranted.
   e. Initiate referrals for those patients who do not respond to the aforementioned strategies.
3. Overflow UI
   a. Allow sufficient time for voiding.
   b. Discuss with interprofessional team the need for determining a PVR (Newman & Wein, 2009; Shinopulos, 2000; see Box 25.2).
   c. Instruct patients in double voiding and Crede's maneuver (Doughty, 2000).
   d. If catheterization is necessary, sterile intermittent catheterization is preferred over indwelling urinary catheterization (Saint et al., 2006; Terpenning et al., 1989; Warren, 1997).
   e. Initiate referrals to other team members for patients requiring pharmacological or surgical intervention.
4. Functional UI
   a. Provide individualized scheduled toileting, timed voiding, or prompted voiding (Eustice et al., 2000; Gibson et al., 2018; Jirovec, 2000; Lee et al., 2009; Ostaszkiewicz et al., 2004; Thomas et al., 2019).
   b. Provide adequate fluid intake.
   c. Refer for physical and occupational therapy as needed (Hill, 2016).
   d. Modify environment to maximize independence with continence (Fantl et al., 1996; Jirovec, 2000; Jirovec et al., 1988; Palmer, 1996).

VI. EVALUATION OF EXPECTED OUTCOMES

A. Patients will
   1. Have fewer or no episodes of UI or complications associated with UI.
B. Nurses will
   1. Document assessment of continence status. If UI is identified, document and determine type of UI.
   2. Use interprofessional expertise and interventions to assess and manage UI.
   3. Include UI in discharge planning needs and refer as needed.
C. Institutions will
   1. Set achievable goals for preventing, reducing, and resolving transient UI.
   2. Require assessment and documentation policies for continence status (Fung et al., 2007; Schnelle & Smith, 2001).
   3. Provide access to evidence-based guidelines for evaluation and management of UI.
   4. Instruct staff to receive administrative support and ongoing education regarding assessment and management of UI.

VII. FOLLOW-UP MONITORING OF CONDITION

A. Provide patient/CG discharge education and referral to specialists, as needed.
B. Incorporate CQI criteria into existing program (Anger et al., 2016; Fung et al., 2007), and measure quality indicators using an if-then approach (Schnelle & Smith, 2001).
C. Identify areas for improvement and enlist interprofessional collaboration in devising strategies for improvement (Bonner & Boyle, 2017; Deeks et al., 2017; Wright et al., 2017).

Prevention of Catheter-Associated Urinary Tract Infection*

26

Michelle Kidd and Mary Beth Flynn Makic

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Define catheter-associated urinary tract infection (CAUTI).
2. Describe the epidemiology of CAUTI.
3. Define indications for indwelling urinary catheters (IUC).
4. Identify evidence-based strategies and interventions for the prevention of CAUTI.
5. Describe key components of a nurse-driven protocol for IUC removal.
6. Understand how to engage an interdisciplinary team in the prevention and management of CAUTIs.

OVERVIEW

Healthcare-associated infections (HAIs) have received increasing scrutiny over the past two decades. It is now widely recognized that HAIs are often preventable adverse events related to medical care. CAUTIs are among the most common HAIs, accounting for more than 12% of infections reported by acute care adult inpatient units (Centers for Disease Control and Prevention [CDC], 2019; Lo et al., 2014), and are associated with significant morbidity and excess healthcare costs (Chenoweth & Saint, 2016; Lo et al., 2014). Catheter use and CAUTIs are disproportionately reported among older adults and patients in intensive care units (Chenoweth & Saint, 2016; Vincitorio et al., 2014). Efforts to reduce CAUTI have been a focus in acute care practice environments, and although there was a relative reduction of 6% in overall CAUTI rates (2006–2016), this effort fell short of the goal of 25% (CDC, 2019; Fakih, George, Edson, Goeschel, & Saint, 2013). Although once largely overlooked as being part of the price of doing business in hospitals, a significantly changed regulatory environment has continued to drive efforts to reduce HAIs, and CAUTIs in particular. Oversight for HAI reporting includes process and outcome measurement paired with financial incentives to improve measures. Since 2008, the Centers for Medicare & Medicaid Services (CMS) no longer reimburses for additional costs required to treat hospital-acquired urinary tract infections (UTIs; CMS, 2007). Long-term care facilities also follow CMS regulatory guidance and their federal regulations (F-315 Tag) mandate that indwelling urinary catheter (IUC) use must be medically justified and care rendered to reduce infection risk in all residents with or without an IUC (CMS, 2005). Enhanced public reporting and financial incentives figure prominently in the Patient Protection and Affordable Care Act of 2010; HAIs were singled out for inclusion in both of these initiatives (Patient Protection and Affordable Care Act, 2010). In related rulemaking, CAUTI is included as a measure for

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

HAI reduction programs and the value-based purchasing composite measure (PSI 90) for acute care hospitals (Agency for Healthcare Research and Quality [AHRQ], 2013a; CMS, 2007, 2008; CDC, 2015). Although progress is indeed being made, there remain opportunities to continue to develop strategies and interventions to reduce IUC use and duration to prevent CAUTIs, thus benefiting both clinical and financial outcomes.

This focus on reducing harm occurs even as the evidence base for the prevention and reporting of CAUTI continues to evolve (Hooten et al., 2010; Joanna Briggs Institute, 2017; Lo et al., 2014; Meddings et al., 2017). Also, the CDC's National Healthcare Safety Network (NHSN) significantly revised the surveillance definition for CAUTI several times, including a major revision in January 2015, with the cumulative effect of focusing surveillance efforts on only the most clinically important events (CDC, 2019). Despite this attention, CAUTI rates have decreased only slightly, with the greatest success seen in practice areas outside of the ICU. Evidence continues to suggest that CAUTIs remain a clinical problem, with the risk of infection increasing 3% to 7% each day, and IUC remains a part of patient care interventions. (CDC, 2019). However, a large national collaborative, the Comprehensive Unit-Based Safety Program (CUSP), developed a bladder bundle, or a group of actions, that when used together reduce CAUTI by pairing a technical bundle with a socioadaptive change model (AHRQ, 2013b, 2017).

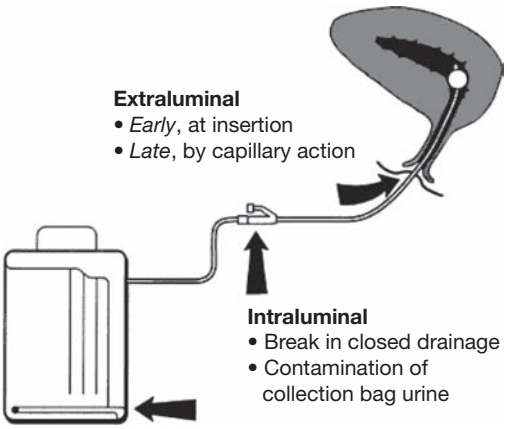
In light of these rapid changes in the field and the regulatory focus on CAUTI, the regular review of policies, procedures, practices, electronic record reminders, and products is imperative for all healthcare facilities. In this chapter, we review the rationale for CAUTI prevention strategies, suggest an approach to implementing a comprehensive CAUTI prevention program, and catalog the most important CAUTI prevention strategies.

BACKGROUND AND STATEMENT OF PROBLEM

Healthcare-associated UTIs are frequent and costly, resulting in increased morbidity and possible mortality in hospitalized adults. There are estimated to be more than 93,300 hospital-acquired UTIs in the United States annually (CDC, 2019). Although actual incidence rates are challenging to determine, data from NHSN in 2013 report 0.1 to 3.1 for adult inpatient floors and 1.2 to 5.3 for adult critical care units per 1,000 catheter days (Dudeck et al., 2015; Hollenbeak & Schilling, 2018; Shuman & Chenoweth, 2018). At an average cost of $13,793 ($5,019–$22,568), CAUTIs resulted in an estimated healthcare cost burden of $1.7 billion in 2016 (AHRQ, 2017; Hollenbeak & Schilling, 2018).

The majority of UTIs are associated with the ubiquitous IUC, also known as a Foley catheter, after urologist Frederick Foley, who developed the modern device. Urinary catheters are among the most widely used medical devices. Despite their utility in acutely ill patients, they have many downsides, including the CAUTI. Other complications include delirium (Inouye, 2006), accidental removal, gross hematuria, leakage, urethral injury, and restriction of mobility. Taken together, these complications of IUCs occur as frequently as CAUTI (Chenoweth & Saint, 2016; Hollingsworth et al., 2013). Therefore, the benefits of managing urinary output with an IUC must be weighed against the many risks.

Unfortunately, the indiscriminate use of IUCs is widespread. IUCs are used in up to 16% of adult hospital inpatients and are more commonly used in the older patient (Vincitorio et al., 2014). Female sex, older age (age greater than 50 years), diabetes mellitus, severe underlying illness, and serum creatinine greater than 2 mg/dL are host-level risk factors associated with CAUTIs (Shuman & Chenoweth, 2018; Vincitorio et al., 2014). According to the CDC, 12% to 16% of adult inpatients will have an IUC at some point during the acute care admission, and more than 50% of all IUCs are not medically indicated (CDC, 2019; Fakih et al., 2013; Hollenbeak & Schilling, 2018; Hooten et al., 2010). Thus, interventions aimed at evidence-based use of catheters are needed to reduce unnecessary use, overall catheter days, and ensure proper management of the IUC to prevent CAUTIs. To better understand the potential approaches to the prevention of CAUTIs, an understanding of CAUTI pathogenesis is essential.



CAUTI Pathogenesis

The urinary tract is normally a sterile body site; therefore, any positive urine culture can be considered abnormal. Asymptomatic bacteriuria is of questionable clinical significance; however, these infections are not typically treated except in pregnant patients or those undergoing urologic surgery (Nicolle, 2016).

When a patient has an IUC, microorganisms can gain access to the urinary tract on either the extraluminal surface of the IUC or the intraluminal surface through breaks in the catheter system (Figure 26.1). Extraluminal infection can occur early if bacteria are introduced during insertion, but, more commonly, extraluminal infection occurs later (Elkbuli et al, 2018; Tillekeratne et al., 2014). Once microorganisms gain access to the urinary tract, they

FIGURE 26.1

Routes of entry of uropathogens to catheterized urinary tract.

can thrive in a "biofilm" layer on either the extra- or intraluminal surface of the IUC. The biofilm, made up of bacteria, host proteins, and bacterial slime, is thought to be important in the development of late CAUTIs. Because the formation of a biofilm and colonization with bacteria take time, most CAUTI occurs after 48 hours of catheterization and increases approximately 5% per day (Bossa, Kline, Mdougald, Lee, & Rice, 2017; Schaeffer, 1986; Stamm, 1975).

The mechanisms described earlier provide the rationale for evidence-based care of IUCs and highlight four potential opportunities for intervention during the use of IUCs (Figure 26.2). The first opportunity is avoidance of catheters at the time of the decision for insertion, the second is evidence-based product selection and care practices regarding IUCs (including insertion and maintenance), and the third is minimizing duration through timely removal. A fourth set of additional strategies for CAUTI prevention include education of providers, surveillance of processes, and reporting practice outcomes and CAUTI rates. This set of strategies can be applied at any of the opportunities for intervention. A comprehensive program to eliminate CAUTIs includes elements of each of the aforementioned strategies.

FIGURE 26.2

Stages of catheter use and potential intervention strategies.

ASSESSMENT OF THE PROBLEM

Surveillance Definition of CAUTI

Although clinical diagnosis of CAUTI allows for clinical judgment, the NHSN has developed explicit surveillance criteria for CAUTI in acute care for use by infection control practitioners (CDC, 2019). The current definitions focus on symptomatic urinary tract infection (SUTI), asymptomatic bacteremic UTI (ABUTI), and urinary system infection (USI; see Table 26.1).

All elements of the definition must occur within a 7-day window (i.e., Infection Window Period [IWP]), and the DOE refers to the first time within the 7-day IWP that criteria are met for a HAI event. A CAUTI diagnosed within 48 hours of arrival to a healthcare facility or unit is attributed to the previous location.

Of note, the CDC's surveillance definition for UTI in long-term care facilities differs substantially from the acute care definition. Practitioners in long-term care facilities should acquaint themselves with that definition (Stone et al., 2012).

CAUTIs are generally reported as infections per 1,000 catheter days on a given patient care unit. More than half of all states require public reporting of HAIs, and among them many specify reporting of CAUTIs. Hospitals participating in the Medicare program must report all CAUTIs to the CDC's NHSN for the purposes of surveillance, public reporting on Hospital Compare, and incentive programs.

Additional important process measurement includes the catheter usage ratio reported as catheter days per patient days. Since October 2009, the Surgical Care Improvement Project (SCIP) has been collecting a measure of postoperative catheter removal on catheterization day 1 or 2 for all surgical patients (The Joint Commission, n.d.).

TABLE 26.1

National Healthcare Safety Network (NHSN) Surveillance Criteria for Catheter-Associated Urinary Tract Infections (CAUTI) in Acute Care

SUTI 1a CAUTI	Meets all Criteria 1. IUC in place ≥ 2 days in an inpatient location on the date of event and IUC present on day of event or removed the day before the event 2. Signs/symptoms (at least one present): fever >38°C in a patient that is ≤ 65 years of age; suprapubic tenderness; costovertebral angle pain or tenderness; urinary urgency, frequency, dysuria (catheter not in place). 3. Positive urine culture with no more than two species of organisms; one that is bacterium $\geq 10^5$ CFU/mL a. Urine culture with yeast can be included as long as there is at least one bacterium $\geq 10^5$ CFU/mL and not more than two organisms. b. Urine culture with > two organisms are considered contaminated; also mixed flora, perineal or vaginal flora cultures are considered contaminated.
SUTI 1b non-CAUTI	Meets all Criteria 1. Patient has had an IUC, but it has not been in place ≥2 days in an inpatient location on the date of event OR did not have an IUC on the date of or the day before the date of the event. 2. Signs/symptoms (at least one present): Fever >38°C in a patient that is ≤ 65 years of age; suprapubic tenderness; costovertebral angle pain or tenderness; urinary urgency, frequency, dysuria (catheter not in place). 3. Positive urine culture with no more than two species of organisms; one that is bacterium $\geq 10^5$ CFU/mL 4. Urine culture with yeast can be included as long as there is at least one bacterium $\geq 10^5$ CFU/mL and not more than two organisms. Urine culture with > two organisms is considered contaminated; also mixed flora, perineal or vaginal flora cultures are considered contaminated.
ABUTI	Meets all Criteria 1. Patient with or without an IUC has no signs of UTI (patient >65 years of age with a non-CAUTI may have a fever). 2. Positive urine culture with no more than two species of organisms; one that is bacterium $\geq 10^5$ CFU/mL 3. Organism identified from blood specimen with at least one matching bacterium identified in the urine specimen or meets LCBI criterion 2 (without fever) and matching common commensal(s) in the urine.

ABUTI, asymptomatic bacteremic urinary tract infection; CFU, colony-forming unit; IUC, indwellling urethral catheter; LCBI, laboratory confirmed bloodstream infection; SUTI, symptomatic urinary tract infection

Indications for IUC

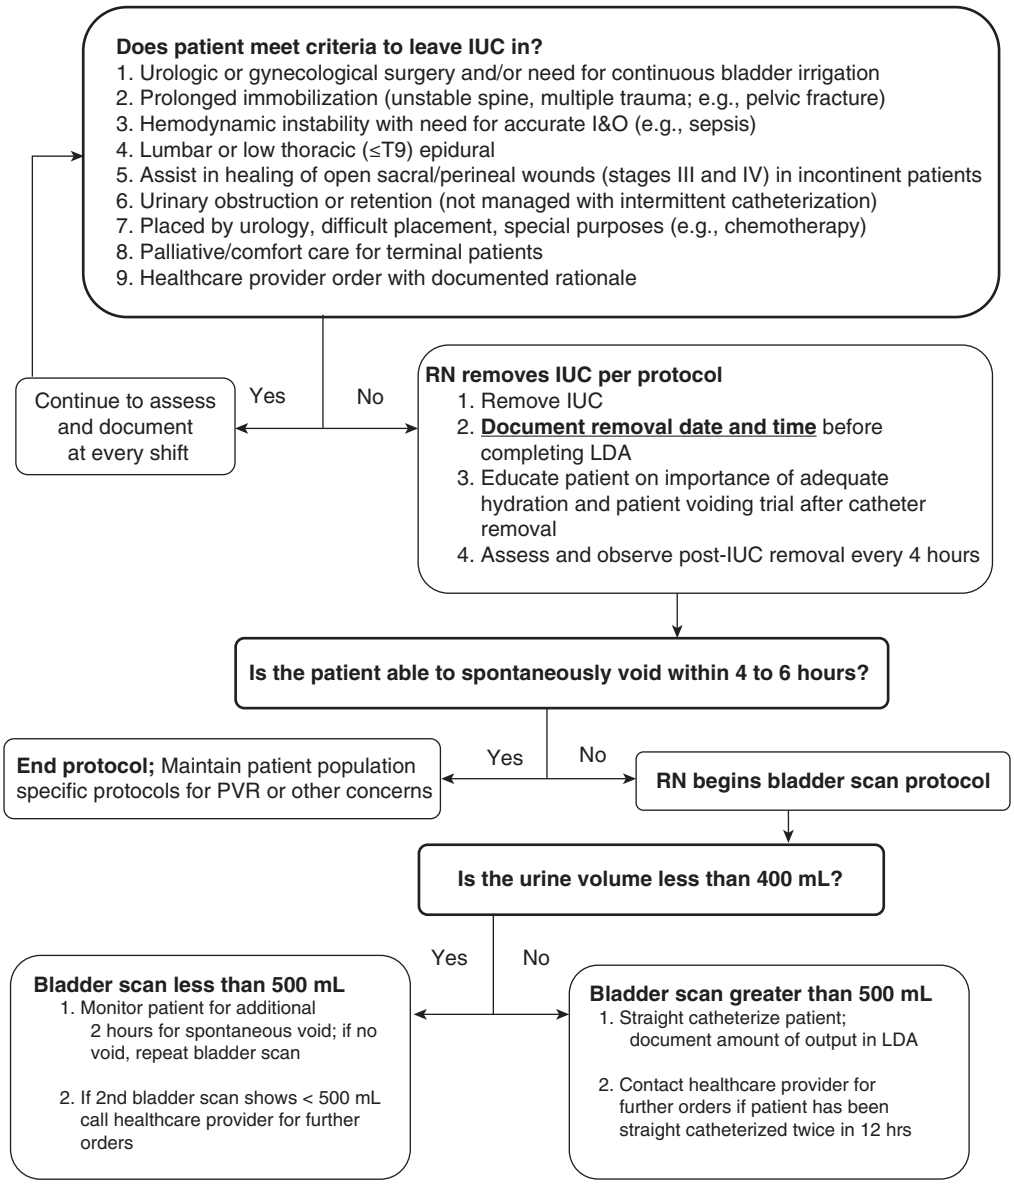
Avoidance of unnecessary IUCs may reduce CAUTI incidence and complications such as bloodstream infections. A decrease in IUC use is expected to result in decreases in length of stay and cost of hospitalization associated with treatment of CAUTI and bloodstream infections (Fakih et al., 2013; Lo et al., 2014; Meddings et al., 2014). Risk factors associated with the development of CAUTI in hospitalized patients can be divided into modifiable and nonmodifiable factors. Patient factors that increase risk of CAUTI include older age, female sex, underlying illness, diabetes mellitus, and renal disease; modifiable risk factors include duration of IUC, not maintaining a closed drainage system, improper provider training regarding insertion; insertion outside the operating room and after the sixth day of hospitalization (Lo et al., 2014; Shuman & Chenoweth, 2018). Explicit criteria for appropriate insertion may result in significant reductions in catheter duration and CAUTI prevalence. Criteria for appropriate insertion of IUCs in hospitalized patients based on evidence include perioperative use for specific surgical procedures; hourly assessment of urine output in critically ill patients; management of acute urinary retention; healing of open pressure injuries/wounds for patients with incontinence; and facilitating comfort at end of life (Chenoweth & Saint, 2016; Lo et al., 2014; Mori, 2014). It is important to ensure proper indications are well disseminated to nursing and physician staff through the integration of a nurse-driven protocol for IUC removal within the electronic health record (EHR; see Figure 26.3).

An IUC should not be used for routine care of patients who are incontinent, as a means to obtain urine culture or other diagnostic tests in a patient who can void, for prolonged postoperative duration without appropriate indications, or routinely in patients receiving epidural anesthesia/analgesia.

INTERVENTIONS AND CARE STRATEGIES

It is estimated that 12% to 16% of adult hospitalized patients will receive an IUC. For every day that a patient has an IUC, he or she has a 3% to 7% increased risk of receiving a CAUTI (CDC, 2019). Up to 70% of CAUTIs are considered preventable (Chenoweth & Saint, 2016; Gould et al., 2010; Sampathkumar, 2017). Specific interventions to prevent CAUTIs are summarized as follows and organized with regard to the four strategies illustrated in Figure 26.2. Many of these recommendations are supported by a growing body of evidence and expert opinion. Further study may impact these recommendations. A proposed approach to a comprehensive CAUTI intervention follows.

Strategy 1: Avoidance



To reduce the incidence of CAUTI, it is important to rethink practice and systems and examine the "why" behind the clinical indication for the IUC. Elimination options other than an IUC should be explored before insertion. Similarly, providing documentation of a clear indication for the IUC can reduce inappropriate device use (Lo et al., 2014; Uberoi et al., 2013). The use of explicit criteria (as in Figure 26.3) to guide the insertion decision may be of assistance. If an IUC is placed, an algorithm may be used to determine continued need for the device or promote prompt removal.

To avoid catheterizations, alternative strategies for managing urine output are necessary. Completing a systems evaluation of available equipment to provide alternatives to IUC for urinary elimination is an important first step in reducing use. Developing toileting schedules and providing assistance with toileting incorporated into frequent nursing staff rounding is another strategy that can be used to reduce urgency and incontinence episodes (Elkbuli et al., 2018; Lo et al., 2014; Uberoi et al., 2013). If the patient is mobile or has limited mobility, alternatives to an IUC include the use of a bedside commode with a toileting schedule (Elkbuli et al., 2018; Uberoi et al., 2013), condom catheters for male patients (Saint et al., 2013), exdwelling urine collection devices for females (Beeson & Davis, 2018), moisture-wicking incontinence pads, intermittent straight catheterization with the use of a bladder scanner to determine bladder urine volume (Elkbuli et al., 2018; Parry, Grant, & Sestovic, 2013; Saint et al., 2013), as well as urinals and bedpans. Careful consideration of products and how and where they are stocked is essential to success. For instance, commodes need to be available in multiple sizes and need to include bariatric commodes; urinals need to fit snugly on bedrails; bladder ultrasound needs to be readily available for assessment.

For less mobile male patients, the condom catheter is an effective alternative to an IUC, although there is still a small risk of infection with condom catheters (Saint et al., 2013). For female patients, use of an external urinary collection device is a possible alternative to manage urinary incontinence or replace an indwelling urinary catheter (Beeson & Davis, 2018). Other possible solutions for incontinence management include use of skin barrier creams for skin protection and high-absorbency pads (or briefs when mobile) that wick moisture away from the skin and long-term care or home environments (NAFC.org; AHRQ, 2015). For a full discussion of incontinence management, please refer to Chapter 25, Urinary Incontinence in the Older Adult.

Urinary retention post surgery or after initial IUC removal may pose clinical care challenges. To prevent IUC insertion or reinsertion, intermittent catheterization should be considered as an avoidance strategy. The bladder scanner, which uses ultrasound technology, is clinically beneficial in determining urinary retention, reducing unnecessary intermittent catheterizations, enhancing patient comfort, and saving costs associated with inappropriate catheterizations and possible CAUTIs (Saint et al., 2013; Sampathkumar, 2017).

Strategy 2: Evidence-Based Product Selection, Insertion, and Routine Care

If an IUC is determined to be clinically indicated, selection of the right catheter, proper aseptic technique during insertion of the device, hand hygiene prior to insertion or manipulation of IUC, and evidence-based ongoing care management are needed to reduce infection (Yokoe et al., 2014).

Catheter material remains an area of ongoing debate. Although antimicrobial catheter materials have been shown to reduce catheter-associated bacteriuria (Galiczewski, 2016; Lo et al., 2014), the impact of antimicrobial catheters on symptomatic CAUTIs remains unproven. Research syntheses have failed to conclusively demonstrate the effectiveness of silver-coated or antibiotic-impregnated catheters on prevention of CAUTIs for short-term catheterization of adult patients versus standard materials, necessitating further studies on the effects of antimicrobial and antiseptic-impregnated catheters in the reduction of symptomatic UTI (APIC Implementation Guide, 2014; Boev & Kiss, 2017; Lo et al., 2014; Meddings et al., 2014). There is also insufficient evidence to determine whether selection of a latex catheter, hydrogel-coated latex catheter, silicone-coated latex catheter, or all-silicone catheter influences CAUTI risk (Lo et al., 2014). The decision to use a silver-coated or antibiotic-impregnated catheter should be made with the understanding that it does not substitute for a comprehensive CAUTI prevention program.

Selecting the smallest IUC size, when possible, is an additional consideration to reduce the risk of infection. The selection of a smaller catheter (e.g., <18 French) reduces irritation and inflammation of the urethra and reduces infection risk (APIC Implementation Guide, 2014; Lo et al., 2014).

Placing an IUC is a fundamental skill for nurses; however, current evidence supporting sterile versus aseptic technique for the procedure is inconclusive (Lo et al., 2014). A strict sterile technique involves using a sterile gown, mask, prolonged handwashing (>4 minutes), opening and using a sterile insertion kit, donning sterile gloves, cleansing the urethral meatus and perineal area with an antiseptic solution, and inserting the catheter using a no-touch technique (APIC Implementation Guide, 2014; Lo et al., 2014). Current recommendations suggest an IUC insertion be placed under aseptic technique with sterile equipment (Elkbuli et al., 2018; Hooten et al., 2010; Joanna Briggs Institute, 2017; Lo et al., 2014; Sampathkumar, 2017).

Once an IUC is placed, optimal management includes care of the urethral meatus according to "routine hygiene" (e.g., daily cleansing of the meatal surface during bathing with soap and water and as needed following a bowel movement; Joanna Briggs Institute, 2017; Rhee, Phelps, Meyer, & Reed, 2016). Meatal cleansing with antiseptics, creams, lotions, or ointment has been found to irritate the meatus, possibly increasing the risk of infection (Joanna Briggs Institute, 2017; Lo et al., 2014; Sampathkumar, 2017).

Securing the IUC after placement to reduce friction from movement is an important element of catheter management supported by current guidelines, researchers, and expert opinion panels (Clarke et al., 2013). Maintaining a closed catheter system is also supported by current guidelines (Joanna Briggs Institute, 2017; Lo et al., 2014) to eliminate the introduction of microbes that occurs when breaking the prepackaged seals on the IUC. A systems analysis should be conducted to purchase and stock the most commonly needed IUC insertion and drainage-bag kits to optimize the maintenance of a closed system. Similarly, maintaining the urine collection bag below the level of the bladder minimizes reflux into the catheter itself, preventing retrograde flow of urine (Clarke et al., 2013; Joanna Briggs Institute, 2017). Establishing workflow protocols to routinely empty the drainage bag frequently and before transport is important in reducing urine reflux and opportunities for CAUTI.

Strategy 3: Timely Removal

Developing systems that prompt healthcare providers to review the need for the IUC and encourage early removal has been found to reduce IUC use and CAUTI rates (Alexaitis & Broome, 2014; American Nurses Association CAUTI Prevention Tool, 2015; American Urological Association, 2014; Carter, Reitmeier, & Goodloe, 2014; Meddings et al., 2014; Mori, 2014; Parry, Grant, & Sestovic, 2013; Purvis et al., 2014; Saint et al., 2013; Scott et al., 2014). Meddings et al. (2014) updated an earlier systematic review and meta-analysis and found that urinary catheter removal reminders and stop orders appeared to reduce CAUTI rates. Implementation of systems that provide physicians and nurses with routine reminders to evaluate the need for the IUC or automatic stop orders were found to reduce the CAUTI rate by 53% ($p \leq .0001$). In this study, automatic

stop orders were more effective than reminders in reducing catheter duration ($p < .0001$ and $p = .071$, respectively). Incorporating EHR reminders into bladder bundles has been found to encourage evaluation of the need for the IUC and remove devices no longer clinically indicated (Elkbuli et al., 2018; Sampathkumar, 2017; Shuman & Chenoweth, 2018; Spencer, Makic, & Shaw, 2019).

Other approaches to reducing catheter days include audit and feedback and reminders to recommend reevaluation of the need for the IUC (Jones, Meyrick, Bath, Dunham, & McNulty, 2018; Meddings et al., 2014; Parry et al., 2013; Purvis et al., 2014; Saint et al., 2013) and early removal (Alexaitis & Broome, 2014; American Nurses Association CAUTI Prevention Tool, 2015; Meddings et al., 2014; Mori, 2014; Parry et al., 2013; Saint et al., 2013). EHR icons (Purvis et al., 2014) or flags that calculate the number of days the IUC has been placed are effective forms of electronic reminders that can easily be incorporated into the EHR. Automatic stop orders or IUC orders that expire in a defined time frame have been shown to reduce both catheter usage and CAUTI (Saint et al., 2013). Daily nursing rounds (Alexaitis & Broome, 2014; Purvis et al., 2014) and the use of checklists or algorithms (Durant, 2017; Galiczewski, 2016; Lo et al., 2014) have also been shown to reduce catheter usage and CAUTI.

Nurse-driven catheter removal protocols are being developed and implemented successfully in many acute care settings (APIC Implementation Guide, 2014; Carter et al., 2014; Durant, 2017; Purvis et al., 2014; Saint et al., 2013; Scott et al., 2014). Protocols range in degree of nurse autonomy in catheter removal decision-making; some require a physician order; most allow the nurse to remove the catheter when there is no evidence-based indication for continuation. Protocols also differ in complexity, with some only addressing the IUC removal aspect of the protocol and others addressing follow-up bladder management strategies with bladder scanning guidelines (Alexaitis & Broome, 2014; American Nurses Association CAUTI Prevention Tool, 2015; Carter et al., 2014; Mori, 2014; Purvis et al., 2014; Saint et al., 2013). According to The Joint Commission, professional nurses have a tremendous impact on care and safety when granted the power to make timely decisions under protocol guidelines and subsequently reduce ICU days and infections. Conversely, the American Medical Association has expressed opposition to this practice, withholding the decision to physicians who are trained. Nevertheless, nurse-driven CAUTI prevention protocols are supported and recommended by many prominent quality healthcare agencies (Durant, 2017). Figure 26.3 is an example of a nurse-driven IUC removal protocol developed and implemented by one hospital.

If premature, early removal of IUCs poses the risk of unnecessary recatheterization. It is important to monitor the need for recatheterization to avoid unintended harm. In the meta-analysis conducted by Meddings et al. (2014), low recatheterization rates were noted in studies using reminders and automatic stop orders. Duration of IUC is the most well-known CAUTI risk factor. Several studies that implemented protocol or criteria-based reminders have shown that IUC duration of less than 7 days is linked with a significant decrease in CAUTI rates (Galiczewski, 2016).

Most of the implementation and quality-improvement research employs multiple interventions (or bundles), as CAUTI prevention is a multifaceted issue. These bundled approaches are also effective and are providing explicit criteria for catheter usage and structured approaches to CAUTI reduction (Galiczewski, 2016; Purvis et al., 2014).

It is well established that the duration of IUC increases CAUTI risk. The SCIP is a national quality partnership of organizations interested in improving surgical care by significantly reducing surgical complications (The Joint Commission, n.d.). One of the key performance measures in this program is CAUTI prevention, specifically, that IUCs be removed by postoperation day 2, also known as SCIP-inf-9. This SCIP performance measure has had a significant impact on decreasing catheter usage in surgical patients (CDC, 2020).

Keeping the IUC as long as thoracic epidural analgesia is maintained (higher than T9) may result in a higher incidence of CAUTI and increased hospital stay. IUC removal on the morning after surgery while the thoracic epidural catheter is still in place does not lead to increased incidence of urinary retention, infection, or higher rates of recatheterizations (Hu et al., 2014; Stubbs et al., 2013).

Strategy 4: Surveillance and Education

Ensuring that leadership of organizations and systems is in place to effectively evaluate and sustain practice change is essential to improving patient outcomes (AHRQ, 2015). In particular, surveillance is the cornerstone of CAUTI prevention but is resource intensive, typically relying on manual surveillance by trained infection prevention personnel (Wald, Bandle, & Richard, 2014). There is emerging evidence that electronic surveillance, using EHR algorithms, is effective in increasing the efficiency of CAUTI identification (Elkbuli et al., 2018; Sampathkumar, 2017; Shepard et al., 2014; Shuman & Chenoweth, 2018; Wald et al., 2014). Catheter usage data and CAUTI rates are key data elements to collect and trend. IUC usage is determined by the number of catheter days divided by the number of patient days and is expressed as a ratio.

CAUTI rate is determined by the number of CAUTIs divided by 1,000 catheter days. Both data elements can then be benchmarked against the NHSN pooled means to assess unit-level performance. However, the use of a catheter days denominator can produce unstable CAUTI rates when catheter usage is low (CDC, 2019). The standard infection ratio (SIR) may be used to adjust for hospital and patient factors that contribute to risks. SIR compares the actual number of CAUTI observed with the number of predicted infections determined by 2015 NHSN population data (CDC, 2019). An SIR greater than 1 indicates more CAUTI are observed, providing additional information to interpret CAUTI rates/10,000 catheter days.

Measurement must be accompanied by provision of knowledge and skills to frontline providers through appropriate education and training, which may be central to a multicomponent CAUTI intervention. Multiple studies and quality-improvement projects found that multifaceted educational interventions bundled with the use of algorithms/checklists, automated stop orders, physician EHR reminder prompts, and/or nurse-driven removal protocols are effective in decreasing CAUTIs and catheter usage (Alexaitis & Broome, 2014; Carter et al., 2014; Mori, 2014; Purvis et al., 2014). Ongoing system evaluation, nursing reeducation, practice reminders, and public reporting of unit-based CAUTI-rate data are strategies to inform the healthcare team of current practice outcomes and effectiveness of CAUTI prevention strategies. Developing a bladder bundle that incorporates elements to critically evaluate IUC indication, use, removal, and care can assist with efforts to reduce CAUTI (Elkbuli et al., 2018; Shuman & Chenwoeth, 2018). Implementing systems that encompass the whole healthcare team to question the need for the IUC and, when indicated, ensuring proper care and early removal can be pivotal in reducing CAUTI rates (AHRQ, 2015).

Approach to a Comprehensive CAUTI Intervention

Evidence-based practice (EBP) guidelines derived from valid, current research and other evidence sources can successfully improve patient outcomes and quality care. However, simply disseminating scientific evidence is often ineffective in changing clinical practice. Learning how to implement findings is critically important to promoting high-quality, safe care. How EBPs are adopted in practice depends on the type, complexity, and strength of the evidence and how the knowledge is communicated to clinicians (Buckwalter et al., 2017; Titler, 2011). There are a number of models that can guide the implementation of EBP, but there is not a single way to implement new findings into practice. What works in one setting may need modification to be successful in another context (Buckwalter et al., 2017; Titler, 2011). Understanding healthcare provider decisions, experiences, practice processes, and barriers is considered essential. These elements must be explored to successfully implement practice change based on best evidence.

The explicit use of a socioadaptive model has been employed in large-scale HAI prevention activities, including the AHRQ's Comprehensive Unit-based Safety Program (CUSP): STOP CAUTI initiative. Here, the technical interventions for CAUTI reduction were paired with the Core CUSP Toolkit for improving safety climate on clinical units (AHRQ, 2015).

At a minimum, the development of an interdisciplinary champion team and the creation of a multifaceted intervention to implement evidence-based procedures for IUC insertion and maintenance must be a priority in all practice settings. Once high-risk factors for CAUTI have been identified, intervention strategies can be tailored to reduce incidence on infection. The ultimate goals are to reduce routine catheter insertions, provide evidence-based catheter care, and ensure prompt early removal when possible, thus decreasing the risk of and prevention of CAUTI.

Nurses are not the only clinicians to interact with catheterized patients. A culture of safety for all disciplines is a crucial step in the implementation and sustenance of change. The new norm must be catheters for a select group of patients as an exception. Team review of catheters and catheter indications at huddles, interdisciplinary rounds, and other forums provides opportunities for coaching and discussion of alternatives to IUC. Engaging and educating patients and families on risk factors and early removal can also be a helpful strategy (Lo et al., 2014; Smith, 2015).

Physician and hospital executive support is crucial to the success of any CAUTI prevention initiative. Involving physician champions and chief medical officers has been successful among some programs (Lo et al., 2014; Quinn, 2015; Spencer et al., 2019).

Steps used for protocol development should explore the following items:

Protocol Development

1. Recruit an interdisciplinary champion team to include nurses (clinical, educators, operating room [OR] RNs, emergency department [ED] RNs); physicians [hospitalists, infectious disease, ED MDs, surgeons, anesthesiologists]); rehabilitation therapists and transport personnel; infection prevention specialists; and quality-improvement, central supply, and clinical informatics representatives.

2. Review CAUTI data for the organization and units with the greatest risk and rates to identify opportunities.
3. Examine and synthesize the evidence (search, review, critique, and hold journal clubs in various care areas to present the evidence).
4. Identify and understand product use, availability, and costs in your healthcare setting. Refine product use based on the best evidence and cost analysis. Examine
   - Urinary catheter materials, sizes, kits, drainage bags
   - Catheter securement device
   - Urinal and bedpan availability
   - Commodes (availability and size)
   - Bladder scanners
   - Alternatives (incontinence pads, condom catheters, female external collection device, etc.)
5. Identify barriers to optimal IUC care practices by surveying staff or holding focus groups throughout your healthcare setting.
6. Update your policy and procedures related to IUC insertion and care based on the evidence.
7. Consider dividing the project into manageable phases. Avoidance strategies may require a different approach than care or removal strategies. For instance, avoidance starts in the ED and operating room (OR); removal occurs on inpatient floors.
8. Develop and use algorithms, decision aids, and factoid posters displaying evidence-based caveats.
9. Development of a nurse-driven IUC removal protocol.
   - Recruit an interdisciplinary team to include nurses (clinical educators, physicians [hospitalists, infectious disease physicians, surgeons, anesthesiologists]) and clinical informatics representatives.
   - Examine and synthesize the evidence (search, review, critique) and protocol examples.
   - Develop protocol with interdisciplinary and key stakeholder (clinical nurses, charge nurses, educators, physicians [all specialties], midlevel providers, regulatory personnel) input and feedback.
   - Incorporate protocol into hospital policy/procedure.
   - Develop EHR interface.
   - Plan education and implementation procedures.
     a. Identify champions to assist with implementation: infection control champions, nurse educators, clinical nurse educators, and specialists.
     b. Journal club presentations, registered nurse (RN) tip sheets, provider tip sheets, EHR screenshot tip sheets, nursing unit posters/clings, PowerPoint presentations.
   - Plan evaluation strategies
     a. Verbal feedback from clinicians
     b. EHR reports on protocol usage/documentation
     c. Audits
10. Update patient and family educational materials on the importance of prompt and early removal of IUCs.
11. Educate staff (including radiology, transport, rehabilitation therapy staff [physical therapy, occupational therapy]) focusing on policy and procedure revision, insertion indication guidelines, insertion procedures, maintenance and care, catheter-bag placement, removal prompts or removal protocols, and bladder scanner use and procedures.
12. Work with infection prevention specialists and clinical informatics staff to audit and measure outcomes. Provide feedback to staff. Potential measurable outcomes include:
    - CAUTIs/1,000 catheter days
    - Catheter days/hospital days
    - Postoperative catheter days/patient
    - Proportion of catheterized/admitted patients from ED or
13. Continually evaluate and update practice changes based on new evidence.

CASE STUDY 26.1

Mrs. F is an 87-year-old woman with a history of Alzheimer's dementia, incontinence, and a recent fall at home. She presents to your hospital with failure to thrive, increased pain on movement, and a Stage II pressure ulcer on her coccyx. Mrs. F lives at home alone; her daughter frequently checks on her condition.

Mrs. F presents at your medical unit with an IUC that was placed in the ED. Given the patient's incontinence, fall risk, pain, and concern about pressure ulcer progression, the IUC is left in place. After stabilization of her pain (no fractures are present), Mrs. F is able to ambulate with assistance. Three days after admission, while awaiting placement in a skilled nursing facility (SNF), Mrs. F develops fever and delirium and is diagnosed with a UTI. This delays her transfer to the SNF.

Questions to Consider

1. Was the IUC placement medically indicated? If so, what were the indications?
2. What could have been used as alternatives to IUC placement?

(*continued*)

CASE STUDY 26.1 (*continued*)

3. Discuss various strategies that may have been used to remind the nursing team to remove the patient's IUC in a timely manner.

Discussion

As incontinence, fall risk, pain, and a Stage II pressure ulcer are not medically appropriate indications for an IUC, it should have been avoided in the ED or removed as soon as the patient arrived on the floor. Alternatives to indwelling catheterization in this patient would include a bedside commode with nursing assistance and/or moisture-wicking incontinence pads. Attentiveness to the appropriate medical indications for catheter use, familiarity with catheter alternatives, and recognition of the clinical and economic impacts may have prevented the infection and eased the placement of this patient. The use of a nurse-driven IUC removal protocol, automatic stop orders in the EHR, and daily nursing rounds on patients with IUCs may call attention to the unnecessary use of the IUC and encourage timely removal.

CASE STUDY 26.2

Mr. B is a 69-year-old alert man with a diagnosis of nonsmall cell lung cancer admitted for a thoracotomy. The patient is transferred from the postanesthesia care unit to the surgical ICU with an IUC that was placed in the OR and a thoracic epidural for pain management with morphine and bupivacaine infusion. Mr. B is doing well 48 hours postoperatively, experiencing little pain, and is able to cough and breathe deeply. He is transferred out of the ICU to the surgical floor with the urinary catheter and thoracic epidural still in place. When prompted by nursing staff to write an order for urinary catheter removal, the surgeon says he is waiting for the anesthesiology team to pull the epidural catheter before removing the urinary catheter.

Questions to Consider

1. Was the IUC placement surgically indicated?
2. When should the IUC be removed?
3. When the IUC is removed, what can be used as alternatives?
4. If the patient does not void after the IUC is removed, when is a bladder scanner indicated? What are the indications for recatheterization?

Discussion

The IUC was probably indicated because of the length of surgery (>2 hours) and need for accurate monitoring for intake and output. The misconception that the IUC needs to be in place as long as the thoracic epidural remains for pain management purposes needs clarification. Multiple studies have supported IUC removal on the morning after surgery to decrease CAUTI risk in the setting of a thoracic epidural higher than the T9 level (Stubbs et al., 2013). Early removal typically does not lead to urinary retention or higher rates of recatheterization. After IUC removal, toileting with assistance, use of a bedpan or urinal, placement of an incontinence pad, or use of a bladder scanner for postvoid residual volume assessment and use of straight catheterization if indicated are alternatives.

If the patient is unable to spontaneously void 4 to 6 hours post-IUC removal, a bladder scanning protocol should be instituted to determine the amount of urine in the bladder. If the bladder scan indicates less than 400 mL of urine, then Mr. B should be monitored for 2 additional hours post void. If he is still unable to void, the bladder scan is repeated. If the second bladder scan shows greater than 400 mL post void, the nurse needs to straight catheterize the patient, documenting the amount of output in the EHR. Additional orders will be necessary if Mr. B has been straight catheterized twice or more within 12 hours.

SUMMARY

A rapidly changing evidence base and regulatory environment necessitates a continued focus on the prevention of CAUTI, which is informed by an understanding of CAUTI pathogenesis and rational IUC use. Critical elements of a CAUTI prevention program include maximizing catheter avoidance, ensuring EBP and product use, and timely catheter removal. Additional strategies include staff education, continuing monitoring of CAUTI incidence, and catheter use. Multicomponent technical interventions have been used successfully in the prevention of CAUTIs when paired with a socioadaptive change strategy.

NURSING STANDARD OF PRACTICE

Protocol 26.1: Prevention of Catheter-Associated Urinary Tract Infection

I. GOAL

To ensure that nurses in acute care are able to

A. Define CAUTI.
B. Describe the epidemiology of CAUTI.
C. Define indications for IUC.
D. Identify evidence-based strategies and interventions for the prevention of CAUTI.
E. Describe key components of a nurse-driven protocol for IUC removal.
F. Understand how to engage an interdisciplinary team in the prevention and management of CAUTIs in the setting.

II. OVERVIEW

A. CAUTIs are the single most common HAI, accounting for 12% of all HAIs and associated with significant morbidity and excess healthcare costs.
B. Since 2008, the CMS no longer reimburses for additional costs required to treat nosocomial UTIs.
C. Multiple EBP strategies, recommendations, and/or guidelines for preventing CAUTI in hospitals and long-term care have been published.
D. In light of these rapid changes in the field, the review of policies, procedures, practices, and products is imperative for all healthcare facilities.

III. BACKGROUND/STATEMENT OF PROBLEM

A. Introduction
   1. The vast majority of UTIs are associated with the ubiquitous IUC, also known as a Foley catheter.
   2. Risk of CAUTI increases 3% to 7% each day the IUC remains in use.
   3. IUC use is disproportionately reported among older adults and patients in intensive care units.
B. Definitions
   1. *Symptomatic UTI:* A patient has at least one of the following signs or symptoms with no other recognized cause: Fever (>38°C), suprapubic tenderness, and a positive urine culture; urgency, frequency, and dysuria may or may not be catheter associated.
   2. *Asymptomatic bacteriuria:* A positive urine culture in a patient who does not have fever or symptoms referable to the urinary tract; may or may not be catheter associated.
   3. *CAUTI:* A symptomatic UTI that occurs while a patient has an IUC inserted for at least 2 days or within 24 hours of its removal.
C. Essential elements
   1. The urinary tract is normally a sterile body site. In the presence of an IUC, microorganisms can gain access to the urinary tract on either the extraluminal surface of the IUC or intraluminal surface through breaks in the catheter system.
   2. Once bacteria gain access to the urinary tract, microorganisms can thrive in a "biofilm" layer on either the extra- or intraluminal surface of the IUC.
   3. Because the formation of a biofilm and colonization with bacteria takes time, most CAUTI occurs after 48 hours of catheterization and increases approximately 3% to 7% per day.
   4. The mechanisms described earlier provide the rationale for evidence-based care of IUCs. Four potential opportunities for intervention are:
      a. Avoid the use of catheters
      b. Evidence-based care practices and product selection

(*continued*)

Protocol 26.1: Prevention of Catheter-Associated Urinary Tract Infection (*continued*)

c. Timely removal
d. Education and surveillance

IV. ASSESSMENT OF CAUTI

A. The CDC has developed explicit surveillance criteria for CAUTI. In brief, the patient must have:
   1. A positive urine culture sent more than 48 hours after admission to the healthcare facility
   2. An IUC at the time of or within 24 hours before the culture
   3. One of the following: suprapubic tenderness, costovertebral angle pain or tenderness, or a fever more than 38°C without another recognized cause; or a positive blood culture with the same organism as in the urine
B. Measures
   1. Outcomes
      a. CAUTIs/1,000 catheter days
   2. Processes
      a. Catheter days/hospital days
      b. Surgical patients with catheter removed on postoperative day 1 or 2 (unless surgically contra-indicated)
C. Indications for IUCs can be operationalized using algorithms or protocols.

V. NURSING CARE STRATEGIES

CAUTIs are preventable through the application of evidence-based care strategies.

A. Catheter avoidance
   1. Established insertion guidelines
   2. Alternative strategies to manage urine output available:
      a. Bedside commodes
      b. Exdwelling catheters
      c. Moisture-wicking incontinence pads
      d. Intermittent straight catheterization
      e. Bladder scanner for monitoring and assessment
      f. Bedpans and urinals that are functional
   3. Toileting schedules and frequent nursing rounds
B. Product selection and routine care
   1. Catheter material:
      a. Antimicrobial catheter materials have been shown to reduce catheter-associated bacteriuria (colonization), but impact on prevention of symptomatic CAUTIs during short-term insertions is unproven.
      b. There is insufficient evidence to determine whether selection of a latex catheter, hydrogel-coated latex catheter, silicone-coated latex catheter, or all-silicone catheter influences CAUTI risk.
   2. Select the smallest size possible (<18 French).
   3. Use aseptic technique and sterile product during catheter insertion.
   4. Cleanse urethral meatus with soap and water while having a bath and after bowel movement.
   5. Secure catheter to leg using a catheter securement device.
   6. Maintain a closed system at all times.
   7. Keep drainage bag below level of bladder.
   8. Empty the bag when two thirds full and before transport.
C. Timely removal
   1. Systems that prompt providers to review need for the catheter and encourage early removal. Examples include stop orders and reminder systems; audit/feedback, nurse-prompted reminders, nurse-driven removal protocols.
   2. Measure of removal: SCIP, SCIP-inf-9 measure; catheter removal on postoperative day 1 or 2.

(*continued*)

Protocol 26.1: Prevention of Catheter-Associated Urinary Tract Infection (*continued*)

D. Surveillance and education
   1. Measurement of processes and outcomes
   2. Ongoing system evaluation, nursing reeducation, practice reminders, and public reporting of unit-based CAUTI-rate data are strategies to inform the healthcare team of current practice outcomes and effectiveness of CAUTI prevention strategies.

VI. EVALUATION/EXPECTED OUTCOMES

A. Plan of care
   1. Assessment that patient meets established insertion criteria
   2. Adherence to prompts for early catheter removal
   3. Standardized catheter care guidelines followed
B. Documentation
   1. Dates of insertion and removal
   2. Type of catheter (new indwelling, chronic indwelling, reinsertion, change of device)
   3. Reason for catheter insertion
   4. Justification that catheter is still necessary
   5. Postvoid residual catheter removal if patient is unable to void in 4 to 6 hours; bladder volume; intervention
C. Catheter usage
   1. Monitor unit-specific CAUTI rates.
   2. Monitor average catheter duration (catheter days).
   3. Monitor SCIP postoperative catheter removal on catheterization day 1 or 2.
   4. Trend unit-specific IUC usage.

ABBREVIATIONS

CAUTI	Catheter-associated urinary tract infection
CMS	Centers for Medicare & Medicaid Services
EBP	Evidence-based practice
HAI	Healthcare-associated infection
IUC	Indwelling urinary catheters
SCIP	Surgical Care Improvement Project

Physical Restraints and Side Rails in Acute and Critical Care Settings*

27

Cheryl M. Bradas, Satinderpal K. Sandhu, and Lorraine C. Mion

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe the consequences of physical restraint use, including side rails, on older adults.
2. Describe the characteristics of an effective restraint reduction program.
3. Develop individualized care plan strategies that promote alternatives to restraint use through evidence-based care for falls, delirium, nutrition, medications, sleep, pain, and function.
4. Facilitate interprofessional team collaboration to ensure all aspects of restraint reduction programs are addressed.

OVERVIEW

The Centers for Medicare & Medicaid Services (CMS) defines *physical restraint* as "any manual method, physical or mechanical device, material, or equipment that immobilizes or reduces the ability of the patient to move his or her arms, legs, body or head freely" (U.S. Department of Health and Human Services [USHHS], 2006, p. 71383). Examples include wrist or leg restraints, Geri chairs, and, in certain situations, full side rails and reclining chairs. Many consider hand mitts a restraint only when wrist ties are used, but this is not universally agreed on; others consider hand mitts a type of restraint because they involuntarily limit the individual's ability to feed and groom himself or herself. Despite the federal regulations placed on hospitals since 1999, eliminating the use of physical restraints for the management of patients in acute nonpsychiatric settings has remained challenging. It is typical for healthcare professionals to use physical restraints and/or side rails to protect the patient or others (Evans & FitzGerald, 2002). However, the use of physical restraints or side rails for the involuntary immobilization of the patient may not only be an infringement of the patient's rights, but can also result in patient harm, including soft tissue injury, fractures, delirium, and even death (Burk, Grap, Munro, Schubert, & Sessler, 2014; Evans, Wood, & Lambert, 2003; Krexi, Georgiou, Krexi, & Sheppard, 2015; McPherson et al., 2013).

The standards from The Joint Commission (TJC) and regulations from CMS have raised concerns among hospital professionals about the feasibility and safety of eliminating the use of physical restraints and side rails in hospitals. The low to almost nonexistent use of physical restraint in other countries in comparable settings provides evidence that this can be achieved (De Jonghe et al., 2013; Elliott et al., 2013; Martin & Mathisen, 2005; O'Keeffe, Jack, & Lye, 1996). This chapter focuses on the issues of physical restraint in acute, nonpsychiatric hospital settings, paying particular attention to older adult patients.

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

BACKGROUND AND LEGAL ISSUES

U.S. Regulations and Accrediting Standards

In 1992, the U.S. Food and Drug Administration (FDA) issued a medical alert on the potential hazards of restraint devices (U.S. FDA, 2006a). Any harm that arises from the use of a restraining device, which now includes bedside rails, must be reported to the FDA. TJC hospital standards began to address the use of physical restraints in the early 1990s. In the ensuing years, the standards have become increasingly prescriptive.

In 1999, CMS established an interim rule for hospitals and, in December 2006, finalized the Patients' Rights Condition of Participation (USDHHS, 2006). These conditions establish the minimum protections of patients' rights and safety and may be superseded by state regulations or accrediting agencies. In brief, the use of physical restraint should be used as a last resort, only used when less restrictive mechanisms have been determined to be ineffective, the use of restraint must be in accordance with a written modification to the patient's plan of care, used in accordance with the order of a physician or licensed independent practitioner (LIP), and must never be written as an "as needed" order. Each order must be renewed every 24 hours for nonviolent behavior and every 4 hours for violent or self-destructive behavior. Orders must be renewed in accordance with hospital policy. Last, restraint must be discontinued at the earliest possible time.

Risks of Liability

A major obstacle in reducing clinicians' use of physical restraint or side rails is the fear of liability if restraints are not used and the patient incurs injury from falling or disrupting medical devices (e.g., see www.vanweylaw.com/whose-fault-patient-falls-hospital/). Case law has been mixed; hospitals have been found liable both for the use of physical restraints and for not using physical restraints (Kapp, 1994, 1996). Although hospitals have a clear duty to protect patients from harm, they do not have a duty to restrain patients. As the practice in hospitals becomes one of reduced restraints because of changing legal and accrediting standards, it will become easier for hospitals to justify nonuse of restraints in instances of patient injury in which use of nonrestraint interventions was clearly demonstrated (Kapp, 1999).

Professional Standards of Care

A number of organizations have established guidelines for the use of physical restraints in hospitals, including the American Nurses Association, the Society for Critical Care Medicine, and the Agency for Healthcare Research and Quality (Agency for Healthcare Research and Quality, 2018; American Nurses Association, 2012; Devlin et al., 2018; Maccioli et al., 2003). The National Quality Forum has designated physical restraint as a nursing-sensitive measure to be monitored in hospitals and nursing facilities. Last, as part of the condition for participation as a *Magnet® facility*, hospitals can examine the use of physical restraint in relation to nursing skill mix and hours. These guidelines have become the standard for customary practice and are used as an appropriate legal standard that defines the parameters of liability. Furthermore, these guidelines, in combination with TJC and CMS requirements, are used to establish hospital-based policies and procedures and quality of performance activities.

PREVALENCE AND RATIONALE OF STAFF

Extent of Use

These standards and guidelines have led to an overall decrease in physical restraint use in acute care and a change in practice patterns. In the 1980s, the overall prevalence rate of physical restraint use on general floors ranged from 6% to 13%, with higher rates (18%–22%) among older adult patients (Frengley & Mion, 1998). In the late 1990s, the overall hospital restraint prevalence decreased but varied as much as three-fold, with rates ranging from 39 restraint days/1,000 patient days to 82 restraint days/1,000 patient days (Minnick, Mion, Leipzig, Lamb, & Palmer, 1998; Mion et al., 2001). For the first time, restraint use was examined in critical care units and was noted to be as high as 500 restraint days/1,000 patient days. Intensive care unit (ICU) rates varied markedly among units in the same hospital setting as well as matched units among hospitals.

A U.S. national prevalence study, involving 434 units in 40 acute care hospitals selected at random from five geographical areas, was completed in 2005 (Minnick, Mion, Johnson, Catrambone, & Leipzig, 2007). Findings from this study revealed overall hospital prevalence of 50 restraint days/1,000 patient days but with a ten-fold variation among hospitals from a rate of 9 to 94 restraint days/1,000 patient days. The majority of use was accounted for in the ICUs. The pattern of differences by type of unit was again present (e.g., medical vs. surgical and adult vs. pediatric). However, even when controlling by type of unit, more than ten-fold variation existed among similar settings. For example, overall prevalence among the 41 general ICUs was 202.6 restraint days/1,000 patient days with a range of 9 to 351/1,000 patient days. Further, analyses revealed that variation in practice persisted even when controlling for size of hospital,

academic or nonacademic status, geographical region, type of hospital (e.g., nonprofit, profit, and government), staffing ratios, and nursing skill mix. Clearly, there are major practice differences *even when controlling for patient population*. Staggs and colleagues (Staggs, Olds, Cramer, & Shorr, 2017) conducted a longitudinal study from 2006 to 2010 of 3,101 medical, medical–surgical, and surgical units in the United States; they found that the prevalence of restraints decreased over time to a prevalence of 1.6% and was associated with the low unit skill mix. A Canadian study involving 51 ICUs revealed that (a) more than half of the patients were in restraints and (b) patient and hospital characteristics were *not* associated with restraint use of duration (Luk et al., 2014). Rather, treatment characteristics, such as use of sedative, analgesic, and antipsychotic drugs, were predictive of restraint use and duration.

Decision to Use Physical Restraint

Today's hospital nurses cite prevention of patient therapy disruption as the primary reason for restraint use followed by fall prevention (Benbenbishty, Adam, & Endacott, 2010; Choi & Song, 2003; Minnick et al., 2007; Staggs et al., 2017). Other less commonly voiced reasons included management of agitation or violent behavior, wandering, and positioning. Although most nurses cite patient care issues as the rationale for using physical restraint, a small proportion of nurses have cited insufficient staffing or legal concerns (Diercks de Casterle, Goethals, & Gastmans, 2015; Eskandari, Abdullah, Zainal, & Wong, 2017; Evans & FitzGerald, 2002).

The CMS regulations mandate that physicians or LIPs must order physical restraint. Similar to nurses, physicians vary in their decisions to order physical restraint (Mion et al., 2010; Sandhu et al., 2010). Factors associated with physicians' decisions to order restraint include (a) lack of knowledge of physical restraint and hospital policy, (b) higher appraisal of patient harm, (c) specialty (family practice or general surgery), (d) trusting the nurse, (e) patient behavior, and (f) presence of dementia. Given the variation in actual use of restraint, it appears that the decision to use physical restraint continues to be one based on individual judgment and beliefs rather than on scientifically validated guidelines or protocols.

ETHICAL ISSUES IN THE USE OF PHYSICAL RESTRAINT

The primary ethical dilemma resulting from physical restraint is the clinician's value of or emphasis on beneficence versus the patient's autonomy. (Clinicians believe that physical restraint maintains patient safety and prevents harm occurring from their behavior, such as falling or disrupting therapy; Via-Clavero et al., 2018.) The presence of a physical restraint, by its very nature, is applied against a patient's wishes and inevitably compromises the individual's dignity and diminishes respect for the person. Beneficence requires that at least no harm should arise from the use of physical restraint and that, optimally, a good outcome would result from use. The lack of beneficial results from the use of physical restraints has been well documented in many healthcare settings. Little is known, however, of the risk-to-benefit ratio of use or nonuse of physical restraint in patients who are critically ill (Devlin et al., 2018; Maccioli et al., 2003).

The discussion of physical restraints from an ethical viewpoint must also incorporate the sociocultural and political contexts. For example, clinicians have reported on low to nonexistent use of physical restraint in the United Kingdom, stemming perhaps from a legal mandate existing since the 1800s prohibiting their use. It has been suggested that in the United States, the domination of risk in geriatric assessment (e.g., prevent harm, prevent falls) shapes much of clinicians' understanding of old age (Kaufman, 1994). If one's primary focus is on the likelihood of patient risk resulting in harm, one is less likely to see self-esteem or dignity as the more important value or model to guide clinical decisions (Gastmans & Milisen, 2006; Slomka, Agich, Stagno, & Smith, 1998). Interestingly, Slomka and associates point to the contradictory nature of the frequent use of physical restraint in the United States—that is, a society that places a high value on autonomy yet is so willing to violate that autonomy in the interest of perceived patient benefit (Slomka et al., 1998).

The discussion of ethics in clinical practice must also acknowledge the realities of reduced resources and escalating costs (Minnick et al., 2007; Slomka et al., 1998). Decisions and protocols about the use of physical restraints and methods to reduce and/or eliminate restraints will be impacted by cost-containment efforts, and clinicians and administrators alike may be reluctant to minimize or eliminate restraints. If alternatives to physical restraints in acute care settings can be shown to contribute to quality outcomes (e.g., patient safety, patient dignity, or satisfaction) and to be within existing cost-containment efforts, then there is an increased likelihood of successfully implementing and maintaining practice guidelines. There is a chance, however, that if restraint reduction efforts are seen as too expensive (e.g., use of "sitters"), then the emphasis on cost constraint may trump other considerations (Slomka et al., 1998).

ADMINISTRATIVE RESPONSIBILITIES

Changing established practices and philosophies of care can be a daunting task. Although education and training are important, the most important factor in effecting a major shift in the present paradigm of care to one that is restraint-free care is the commitment by administrators and key clinical leaders (Enns, Rhemtulla, Ewa, Fruetel, & Holroyd-Leduc, 2014; Mion et al., 2001). Administrators, including nurse managers, set the tone for the practice on the unit. Reducing healthcare providers' reliance on physical restraint in managing confused or agitated patients, especially in the critical care units, is a major shift that leaves many staff uneasy. Clinical staff, especially the frontline care providers, must feel supported during the transition period. The goal set and supported by administration of a restraint-free environment would establish the presence of a physical restraint as an outlier that requires a full analysis as for a sentinel event. The outcome of such analyses may well lead to the recognition of system problems and organizational arrangements that can be improved, which, in turn, lead to even fewer restraints in use.

INTERVENTIONS AND CARE STRATEGIES

Studies of the prevalence of the use of physical restraints for nonpsychiatric purposes in hospitals have shown that there is great discrepancy among general medical and surgical units and ICUs in terms of the extent of use and rationale for it. Therefore, the use of physical restraints and approaches to possible alternatives can be considered separately for general hospital units and critical care units.

General Medical and Surgical Units

Rates of physical restraint use on general medical and surgical units have declined in the past 20 years, although variation exists (Staggs et al., 2017). It is apparent that there are units that demonstrate best practices but also that further efforts are needed to eliminate this practice as a national standard. Otherwise, significant numbers of patients will continue to be restrained.

Many hospitals provide care for acutely ill, frail older adults in settings that are not designed environmentally for the care of such older people (Catrambone, Johnson, Mion, & Minnick, 2009; Mion et al., 2007). Environmental structure can either facilitate or inhibit monitoring and surveillance, noise control, appropriate lighting, socialization, cognition, and function (Catrambone et al., 2009; Diercks de Casterle et al., 2015). Studies in long-term care settings have demonstrated that the use of environmental strategies can enhance function among those suffering from dementia; similar strategies need to be considered in acute care settings.

Besides environmental strategies, organizational factors, such as systems to determine staffing numbers and mix, models of care delivery, and transmission or communication of the plan of care among multiple disciplines and departments, are gaining increased recognition in the patient safety movement (Leape & Berwick, 2005). Many healthcare providers lack the knowledge, skills, and sensitivity in providing appropriate care to older adults. The TJC standard to ensure age-specific education and training is a step in the right direction, but further efforts are required.

No single approach to eliminating physical restraints on general medical and surgical units can be successful. Studies in a variety of settings have shown that the use of advanced practice nurses, comprehensive interprofessional approaches to enhance cognitive and physical function, staff education, organizational strategies, and environmental interventions can eliminate or reduce physical restraints in a cost-effective manner while promoting other patient outcomes such as reduced fall rates (Amato, Salter, & Mion, 2006; Enns et al., 2014; Mion et al., 2001).

Critical Care Units

The use of physical restraints now predominantly occurs within the ICUs to maintain needed life-sustaining therapies or life-maintaining therapies (Choi & Song, 2003; Devlin et al., 2018; Luk et al., 2014; Minnick et al., 2007). Strategies that have been used with success in long-term care settings, rehabilitation settings, and general hospital units are not as successful in critical care environments (Mion et al., 2001). The severity of illness of patients, the intensity and delivery of care, the pace of activity, and the consequences of interruptions, delays, or disruptions of therapeutic devices differ significantly between non-ICUs and ICUs. The thought of delirious patients dislodging external ventricular drains with subsequent brain damage, pulling out central lines with threat of hemorrhage, or self-extubation from mechanical ventilation with subsequent respiratory arrest is one that heavily influences critical care nurses' decisions to use physical restraints (Happ, 2000; Luk et al., 2014; Luk, Burry, Rezaie, Mehta, & Rose, 2015).

Efforts to limit physical restraint use in the ICU are hampered by lack of information regarding the extent of therapy disruption in these units or the resulting immediate and subsequent harm to patients (Devlin et al., 2018; Maccioli et al., 2003; Perez, Peters, Wilkes, & Murphy, 2019). A number of studies, mostly single site, have

examined self-extubation from mechanical ventilation (Kiekkas, Aretha, Panteli, Baltopoulos, & Filos, 2013). Rates have ranged from 0.3% to 14.3%, with higher rates in medical ICUs. Reintubation after self-extubation ranged from 11% to 76%. *It is important to note that 33% to 91% of those who self-extubated did so while physically restrained*. Mion and colleagues (Mion, Minnick, Leipzig, Catrambone, & Johnson, 2007) examined the prevalence of patient-initiated device removal, patient contexts, patient risk-adjusted factors, and consequences in 49 ICUs in 39 hospitals. Patients removed 1,623 devices on 1,097 occasions for an overall rate of 22.1 episodes/1,000 patient days. Similar to results on physical restraint prevalence, wide variation in rates was noted: from none to 102.4 episodes/1,000 patient days. Approximately half the episodes occurred on day shift, and 44% were in physical restraint at the time of the episode. Patient harm occurred in 250 (23%) events, mostly minor in nature. In 10 (0.9%) episodes, patients incurred major harm; no deaths occurred. The authors examined rates of reinsertion and found these varied by type of device. Devices that are easily applied, such as monitor lead or oxygen masks, had much higher reinsertion rates than devices that are more complex and difficult to insert (such as endotracheal tubes or surgical drains). It may be that devices are used too long, which could contribute to prolonged use of physical restraint. In turn, physical restraint may contribute to agitation and delirium (Burk et al., 2014; McPherson et al., 2013). Additional hospital resources (e.g., x-rays, laboratory tests) were used in slightly more than half the episodes, thus posing a potentially costly problem; others have reported similar findings (Fraser, Riker, Prato, & Wilkins, 2001; Kiekkas et al., 2013). Information gathered on staffing levels and mix showed little variation among these ICUs; hence, there was no association between staffing ratios and therapy disruptions. The authors found *no* association between a unit's restraint rate and rate of therapy disruption, a finding similar to some studies (Danielis, Chiaruttini, & Palese, 2018; Kapadia, Bajan, & Raje, 2000; Mion et al., 2001) but not others (Carrión et al., 2000).

Finally, the pattern of sedation and analgesia in these units was unclear, and 30% of the patients had received no analgesia or sedation in the 24 hours before the episode. Others have reported inconsistent sedation and analgesia practices in ICUs (Bair et al., 2000; Devlin et al., 2018; Egerod, Christensen, & Johansen, 2006; Mehta et al., 2006). In an earlier cohort study, the authors examined medical intensive care unit (MICU) patient outcomes after implementing sedation and analgesia guidelines and found that those cared for with the guidelines had less self-extubation events and less use of physical restraints (Bair et al., 2000). Examining appropriate strategies for sedation and analgesia in critically ill patients may well result in improved clinical outcomes while providing care in a more humane fashion (Devlin et al., 2018).

Attention to the environment of the ICU is as important as to any other setting. Indeed, the environment can affect more strongly persons whose personal competence is low and who are unable to exert control over the environment. Environmental features, such as noise, light, and unit design, have been shown to be associated with agitation, anxiety, and disorientation of ICU patients (Danielis et al., 2018; Devlin et al., 2018).

Lack of communication with ICU patients by care providers has been documented and results in distress, anxiety, and confusion (Dithole, Sibanda, Moleki, & Thupayagale-Tshweneagae, 2016). Attention to the physical environment; use of communication techniques with seemingly noncommunicative patients; encouragement of collaborative practice among ICU disciplines; and nonpharmacological approaches to relieve patient distress, anxiety, and agitation have been suggested (Devlin et al., 2018; Maccioli et al., 2003; Trotta, Hermann, Polomano, & Happ, 2019). A multipronged approach to optimize physical and cognitive function and address onset, as well as manage delirium and appropriate and adequate pain control, is likely to affect nurses' and physicians' reliance on physical restraint.

ALTERNATIVES TO PHYSICAL RESTRAINTS

This book has provided the reader with a number of protocols addressing care issues such as falls, delirium, sleep, nutrition, medications, and function. The reader is encouraged to review these protocols closely. Implementing best practices aimed at these areas will in itself reduce the use of physical restraints. A brief overview of an approach that the authors have found successful is presented herein.

Addressing the two major reasons for using physical restraints, to prevent therapy disruption and falls, requires comprehensive yet targeted approaches. The act of self-terminating therapy among hospitalized, acutely ill older adults is most likely a manifestation of delirium and less likely a desire to enact a clinical decision, as with advance directives. Both falls and delirium are well-known syndromes with significant morbidity and mortality among older adults. Both are complex syndromes with multiple underlying etiologies that require a combination of individual-, environmental-, and organization-specific strategies (Mudge et al., 2019). Inouye et al. (1999) have demonstrated a multicomponent approach to preventing delirium in a randomized controlled trial

that was subsequently implemented in a number of hospitals (Hshieh, Yang, Gartaganis, Yue, & Inouye, 2018). Fall prevention also requires a multicomponent approach (Barker et al., 2016; Cameron et al., 2018). Given the complexity of falls and delirium, it is unlikely that any single intervention will suffice as an alternative to physical restraint. Rather, attention to the environment and organization of the unit, as described in the two previous sections, combined with patient-specific approaches, provides the most successful way to eliminate restraint use (Amato et al., 2006; Enns et al., 2014; Mion et al., 2001).

Fall Prevention

Falls are common, serious events in hospitalized older patients. Although nurses perceive that physical restraint prevents falls from occurring, the reality is that physical restraints have not been shown to prevent falls and can actually contribute to fall injury (Frengley & Mion, 1998). The goal is to minimize the risk or probability of falling without compromising the older individual's mobility and functional independence. Using a systematic or standardized approach, the nurse and physician assess the patient for intrinsic (personal), extrinsic (environment), and situational (activity) factors. Common intrinsic risk factors include impaired gait or balance, sedating medications, vision and hearing impairments, and cognitive impairment, including impaired memory, impulsiveness, or poor judgment. Given the multiple potential causes of falls, no single intervention or combination of interventions has been found effective in preventing falls in hospital settings (Cameron et al., 2018; Hempel et al., 2013). A number of fall risk assessment guidelines are available (Oliver, Healey, & Haines, 2010). The reader is referred to Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care, for a more in-depth discussion. What is important to note is that the evaluation for intrinsic factors need not be complex or time consuming. For instance, the nurse can do a simple evaluation of gait and balance by simply observing the person's ability to transfer in and out of bed or chair and ability to walk to and from the bathroom. The nurse can quickly note any difficulty with steadiness, ability to stand up independently without using a rocking motion or use of upper extremities, ability to sit down without "plopping" onto the surface of the chair, and the ability to walk steadily to the bathroom without holding onto objects or the wall. At this time, notation can be made of lightheadedness or dizziness, presence of orthostatic hypotension, and use of sedating medications.

Extrinsic factors include clothing and footwear. Shoes or slippers should be nonskid, but rubber-soled footwear is not recommended because this material can "grip" the floor, causing the person to pitch forward. Furniture design, such as beds at a proper height and chairs with extended armrests for easier leverage, can facilitate mobility. Reclining chairs are helpful for those with poor trunk control and who slide out of chairs with a 90° seating angle. On the other hand, reclining chairs can act as a type of restraint if used for patients with general deconditioning or weakened states who subsequently struggle to rise out of the chair. Beds low to the floor assist with preventing fall injury because the distance from bed to floor is reduced (Bower, Lloyd, Lee, Powell-Cope, & Baptiste, 2008). Padded floor mats may be used in combination with the very low beds. However, caution must be exercised in determining which patients receive very low beds with or without the floor mats. There have been case reports of patient falls and injury from very low beds or floor mats (Bower et al., 2008; Doig & Morse, 2010). Falls can occur either because of difficulty rising to a standing position from a very low height and/or tripping on the mat. Thus, care must be taken in determining those patients most likely to benefit from these beds. We suggest use of these beds for patients who are identified at moderate to high risk for falls, unable to stand without assistance, and who forget or refuse to call for help (Bower et al., 2008; Capezuti et al., 2008; Doig & Morse, 2010; Tzeng & Yin, 2008). Use of these beds is no guarantee that falls or fall injuries will be reduced. Haines, Bell, and Varghese (2010) conducted a cluster randomized trial and found no effect on either falls or fall injury with the use of these beds. Similarly, another study found that bed and chair alarms have no effect on overall fall rates on general medical and surgical floors (Shorr et al., 2012). Last, hospital equipment can contribute to falls, such as legs collapsing on bedside commodes, wheelchairs tipping when a patient leans forward, or tubing from lower extremity intermittent-compression devices that may be left on when a patient stands up from bed. In determining equipment use, the nurse must weigh each patient's risk factors for the most effective and appropriate use.

The findings of either intrinsic or extrinsic factors should lead to targeted interventions. There are some fall-prevention strategies that one can consider "universal"—that is, to be implemented for all patients regardless of the risk level. For instance, all patients should have beds at appropriate heights for ease of exiting and entering, have call bells within reach, and have clear pathways. Depending on the type of unit, some units may elect to incorporate universal interventions that other floors would consider a targeted intervention. For example, an acute stroke unit may elect to automatically place all patients on a toileting schedule at the time of admission and reevaluate

continually whether this intervention is required, whereas the other units in the hospital would elect to use this as a targeted intervention only for those patients with cognitive impairment and incontinence. An important fall-prevention strategy in any setting is mobilization and exercise. Even in critical care settings, there is a growing body of literature that demonstrates the physiological and physical benefits of early mobilization and rehabilitation (Balas et al., 2018).

Protection of Medical Devices

Disruption of therapy or self-termination of devices can be dealt with by first identifying the underlying reason for the patient's attempts to terminate therapies. In many cases, the nurse will identify "confusion" as the underlying cause. As discussed in earlier chapters, the nurse needs to differentiate dementia, delirium, or delirium superimposed on dementia. Additionally, the interprofessional team must discern the underlying causes of delirium, including pain. A systematic approach to determine the cause of the behavior is necessary for treatment. For example, if an older adult is suffering from alcohol withdrawal, it is unlikely that interventions, such as increased surveillance or pain relief, will have much impact on the person's agitation and delirium. Refer to Chapter 9, Assessing Cognitive Function in the Older Adult; Chapter 21, Dementia: Assessment and Care Strategies; and Chapter 20, Delirium: Prevention, Early Recognition, and Treatment for further protocols to identify cognitive impairments and to prevent and manage delirium.

In the past, the options for managing agitation in the critical care unit have been sedation and/or physical restraint. The type and amount of sedation, however, may actually contribute to delirium and agitation (Devlin et al., 2018; Wunsch & Kress, 2009). Multiple studies suggest that limiting the use of benzodiazepines and use of an alternative medication, dexmedetomidine, can decrease ventilator time, length of stay, and long-term brain dysfunction (Wunsch & Kress, 2009). The use of physical restraint in critical care settings has been associated with delirium as well as posttraumatic stress disorder (Jones et al., 2007; McPherson et al., 2013; Micek, Anand, Laible, Shannon, & Kollef, 2005; Nirmalan, Dark, Nightingale, & Harris, 2004; Wallen, Chaboyer, Thalib, & Creedy, 2008).

As the healthcare team works to address the patient's behavior, nonpharmacological approaches to protecting the device from self-termination can be made. First, evaluate daily whether the device is absolutely necessary. Since the CMS designation of nonpayment of nosocomial catheter infections (e.g., urinary tract infections from indwelling catheters, ventilator-related pneumonia), many ICUs have implemented multidisciplinary daily mandatory checklists that incorporate assessment for compliance to infection control and timely discontinuation of devices (Byrnes et al., 2009; DuBose et al., 2010). Even in the critical care environment, major therapy devices may not be reinserted once a patient pulls it out. Thus, always question whether the device is absolutely necessary or whether a less noxious device or approach may be used instead. For example, if a nasogastric tube is used for nutrition, request the assessment of other disciplines, such as speech or occupational therapists (OTs), to determine whether oral feeding could be introduced. If long-term enteral feeding is required, an interprofessional team plan with the patient and family is warranted given the known deleterious effects of tube feedings with certain conditions.

Some therapeutic devices cannot be altered or discontinued, for example, use of endotracheal tubes, nasal cannula, or oxygen masks. A second approach is to use anchoring techniques to secure the device against the patient's attempts to dislodge the device or to use camouflage to "hide" the device from the patient. Proper anchoring addresses comfort as well as stabilization of the device(s). For example, it is not unusual for pressure ulcers to develop on the nares or behind the ears and neck because of undue pressure from the device; clearly, this creates a source of discomfort for the patient. Proper stabilization of the tube or device with secure anchoring can minimize accidental dislodgment as well as deter more purposeful removal. For instance, a nasogastric tube can be so placed as to avoid interfering with or interrupting the person's visual field. Seeing the tube dangling in front of one's eyes or pulling on one's nares is an obvious irritant. If a gastrostomy tube is determined to be appropriate in the person's plan of care, abdominal binders can aid in reducing the person's ability to pull it out. There are a number of commercial products available to secure various tubes, including nasogastric tubes, endotracheal tubes, intravenous (IV) lines, and indwelling bladder catheters. Although none of these devices is likely to prevent a determined person from pulling out a device, they do provide anchoring and stability of the device that is probably more secure than taping methods.

Side Rails

A discussion on physical restraints in hospitals would not be complete without mentioning side rails. Side rails, in and of themselves, are not considered a restraining device by either TJC or CMS. It is the nurse's intent of their use that determines whether side rails are a restraining device or a protective device. This has led to some confusion by nurses. Full

side rails to transfer patients in carts, during procedures (e.g., conscious sedation), or protect a sedated or lethargic patient from rolling out of the bed can be considered as protective devices. A number of specialty beds, such as ICU pulmonary beds or bariatric beds, require full side rails in use. Many bed manufacturers have bed controls and call systems embedded in the side rail frames, resulting in patients requesting the side rails be kept raised for ease of control. Hospital patients have also been observed to request partial to full side rails to be raised because of the narrowness of the beds or to facilitate movement (e.g., transfers, repositioning).

In ICU settings, full side rails are used, predominantly because of bed equipment specification (e.g., pulmonary beds) or because of procedural considerations (e.g., sedation protocols; Minnick, Mion, Johnson, Catrambone, & Leipzig, 2008). In non-ICUs, nurses may use full side rails primarily for fall prevention (46%), especially for older patients (Minnick et al., 2008). Full side rails used to keep patients in bed who *desire* to leave the bed are restraints. It does not matter what the cognitive level of the person is. If a severely demented patient wishes to leave the bed, full side rails are considered a restraint, even if the nurse believes that the side rails are for "patient safety." Side rails have been shown to increase fall injuries because patients either try to squeeze through rails or climb over the foot of the bed; hence, they are not recommended as a fall-prevention strategy for conscious patients, even in the presence of cognitive impairment (Braun & Capezuti, 2000). Rather, the use of side rails should be limited with patients who may inadvertently roll off the bed because of impaired levels of consciousness from sedation, anesthesia, or medical conditions. Indeed, the FDA has received reports of more than 400 deaths as a direct result of side rail entrapment from a variety of healthcare settings, including hospitals (U.S. FDA, 2006b). The reader is referred to Braun and Capezuti (2000) for an excellent review of the legal and medical aspects of side rail use.

SUMMARY

The pattern and rationale for physical restraint use has changed over the past two decades. Focusing on assessment and prevention of delirium and falls will likely minimize its use. Further work is needed in the ICU setting for best strategies to identify, prevent, and manage delirium that would include nonpharmacological as well as pharmacological approaches. To avoid the use of physical restraints, practical and cost-effective strategies need to be devised and tested. This would best be done in an interprofessional patient-centered fashion.

NURSING STANDARD OF PRACTICE

Protocol 27.1: Physical Restraints and Side Rails in Acute and Critical Care Settings

I. GOAL

To eliminate the use of physical restraints and side rails in acute and critical care settings

II. OVERVIEW

A. The use of physical restraints or side rails for the involuntary immobilization of the patient may not only be an infringement of the patient's rights, but can also result in patient harm, including soft tissue injury, fractures, delirium, and even death (Evans et al., 2003).
B. The primary ethical dilemma resulting from physical restraint is the clinician's value or emphasis of beneficence versus the patient's autonomy.
C. Physical restraint should be used as a last resort; that is, only when less restrictive mechanisms have been determined to be ineffective; the use of restraint must be in accordance with a written modification to the patient's plan of care, in accordance with the order of a physician or LIP, and must never be written as an "as needed" order. Each order must be renewed every 24 hours for nonviolent behavior and every 4 hours for violent or self-destructive behavior. Orders must be renewed in accordance with hospital policy. Last, restraint must be discontinued at the earliest possible time (USDHHS, 2007).

(*continued*)

Protocol 27.1: Physical Restraints and Side Rails in Acute and Critical Care Settings (*continued*)

III. BACKGROUND AND STATEMENT OF PROBLEM

A. Definition: The CMS defines physical restraint as "any manual method, physical or mechanical device, material, or equipment that immobilizes or reduces the ability of the patient to move his or her arms, legs, body or head freely" (USDHHS, 2006, p. 71383). Examples include wrist or leg restraints, Geri chairs, and, in certain situations, mitts, full side rails, and reclining chairs.
B. Etiology: Hospital nurses' reasons for use of physical restraint are prevention of patient disruption of medical devices and therapy (75%), confusion (25%), and fall prevention (20%) (Minnick et al., 2007; Perez et al., 2019).
C. Epidemiology
   1. Prevalence of physical restraint use on individual non-ICU rates has decreased significantly, with the overall rate on medical and surgical units being 1.6%. Variations exist across units (Minnick et al., 2007; Staggs et al., 2017).
   2. Individual ICU rates range from less than 20% to greater than 80% (Perez et al., 2019; Rose et al., 2016).

IV. PARAMETERS OF ASSESSMENT

A. Assess for underlying cause(s) of agitation and cognitive impairment leading to patient-initiated device removal (refer to Chapter 9, Assessing Cognitive Function in the Older Adult; Chapter 19, Late-Life Depression; Chapter 20, Delirium: Prevention, Early Recognition, and Treatment; and Chapter 21, Dementia: Assessment and Care Strategies).
   1. If abrupt change in perception, attention, or level of consciousness:
      a. Assess for life-threatening physiological impairments
      b. Review respiratory, neurological, fever and sepsis, hypoglycemia and hyperglycemia, alcohol or substance withdrawal, and fluid and electrolyte imbalance
      c. Notify physician of change in mental status and compromised physiological status
   2. Differential assessment (interprofessional)
      a. Obtain baseline or premorbid cognitive function from family and caregivers
      b. Establish whether the patient has history of dementia or depression
      c. Review medications to identify drug–drug interactions, adverse effects
      d. Review current laboratory values
B. Assess fall risk: intrinsic, extrinsic, and situational factors (refer to Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care)
C. Assess for medications that may cause drug–drug interactions and adverse drug effects (refer to Chapter 24, Reducing Adverse Drug Events in the Older Adult).

V. NURSING CARE STRATEGIES

A. Interventions to minimize or reduce patient-initiated device removal
   1. Disruption of any device
      a. Reassess daily to determine whether it is medically possible to discontinue device; try alternative mode of therapy (DuBose et al., 2010; Mion et al., 2001; Nirmalan et al., 2004).
      b. For mild to moderate cognitive impairment, explain device and allow patient to understand nurse's guidance.
   2. Attempted or actual disruption: ventilator
      a. Determine underlying cause of behavior for appropriate medical and/or pharmacological approach
      b. More secure anchoring
      c. Appropriate sedation and analgesia protocol
      d. Start with less restrictive means: mitts, elbow extenders
   3. Attempted or actual disruption: nasogastric tube
      a. If for feeding purposes, consult with nutritionist and speech or occupational therapist for swallow evaluation
      b. Consider gastrostomy tube for feeding as appropriate if other measures are ineffective

(*continued*)

Protocol 27.1: Physical Restraints and Side Rails in Acute and Critical Care Settings (*continued*)

   c. Anchoring of tube, either by taping techniques or commercial tube holder
   d. If restraints are needed, start with least restrictive: mitts, elbow extenders
4. Attempted or actual disruption: IV lines
   a. Commercial tube holder for anchoring
   b. Long-sleeved robes, commercial sleeves for arms
   c. Consider Hep-Lock and cover with skin sleeve. White gauze may also be used, but case reports exist in which patients focus on the white gauze and unravel it.
   d. Taping, securement of IV line under gown, sleeves
   e. Keep IV bag out of visual field
   f. Consider alternative therapy: oral fluids, drugs
5. Treatment (interprofessional)
   a. Treat underlying disorder(s)
   b. Judicious, low-dose use of medication if warranted for agitation
   c. Communication techniques: low voice, simple commands, reorientation
   d. Frequent reassurance and orientation
   e. Surveillance and observation: Determine whether family member(s) is willing to stay with patient, move patient closer to nurses' station, perform safety checks more frequently, redeploy staff to provide one-on-one observation if other measure is ineffective
6. Attempted or actual disruption: bladder catheter
   a. Consider intermittent catheterization if appropriate
   b. Proper securement, anchoring to leg; commercial tube holders available

B. Interventions to reduce fall risk
1. Patient-centered interventions
   a. Supervised, progressive ambulation even in ICUs (Devlin et al., 2018; Truong, Fan, Brower, & Needham, 2009)
   b. Physical therapist (PT)/Occupational therapist (OT) consultation: weakened or unsteady gait, trunk weakness, upper arm weakness
   c. Provide physical aids in hearing, vision, walking
   d. Modify clothing: skidproof slippers, slipper socks, robes no longer than ankle length
   e. Utilize bedside commode if impaired or weakened gait
   f. Postural hypotension: behavioral recommendations such as ankle pumps, hand clenching, reviewing medications, elevating head of bed
2. Organizational interventions (Mion et al., 2001)
   a. Examine pattern of falls on unit (e.g., time of day, day of week).
   b. Examine unit factors that can contribute to falls that can be ameliorated (e.g., report in staff room vs. walking rounds to improve surveillance during shift change).
   c. Restructure staff routines to increase number of available staff throughout the day.
   d. Set and maintain toilet schedules.
   e. Install electronic alarms for wanderers.
   f. Consider bed and chair alarms (note: no to little evidence on effectiveness; Shorr et al., 2012).
   g. Move patient closer to nurse station.
   h. Increase checks on high-risk patients.
   i. Perform video surveillance for high-risk patients.
3. Environmental interventions (Amato et al., 2006)
   a. Keep bed in low, locked position.
   b. Ensure safety features, such as grab bars, call bells, and bed alarms, are in good working order.
   c. Ensure bedside tables and dressers are within easy reach.
   d. Clear pathways of hazards.
   e. Bolster cushions to assist with posture; maintain seat in chair.

(*continued*)

Protocol 27.1: Physical Restraints and Side Rails in Acute and Critical Care Settings (*continued*)

f. Ensure adequate lighting, especially in bathroom at night.
g. Choose furniture to facilitate seating: reclining chairs (note: may be considered restraint in some instances), extended armrests, high back.

C. Review medications using Beers Criteria for potentially inappropriate medications.

VI. EVALUATION AND EXPECTED OUTCOMES

A. Patient will
   1. Remain free of restraints.
   2. Be put in physical restraints only as a last resort.
B. Nursing staff will
   1. Be able to accurately assess patients who are at risk for use of physical restraint.
   2. Only use physical restraints when less restrictive mechanisms have been determined to be ineffective.
   3. Have an increased use of nonrestraint, safety alternatives.
C. Organization will
   1. Have a decrease in incidence and/or prevalence of restraints.
   2. Not have an increase of falls, agitated behavior, and patient-initiated removal of medical devices.

VII. FOLLOW-UP MONITORING OF CONDITION

A. Monitor restraint incidence comparing benchmark rates over time by unit.
B. Document prevalence rate of restraint use on an ongoing basis.
C. Focus education on assessment and prevention of delirium and falls.
D. Consult with interprofessional members to identify additional safety alternatives.

VIII. RELEVANT PRACTICE GUIDELINES

A. American Nurses Association (2012)
B. Agency for Healthcare Research and Quality (2018)
C. Society of Critical Care Medicine (Devlin et al., 2018; Maccioli et al., 2003)

ABBREVIATIONS

CMS	Centers for Medicare & Medicaid Services
ICU	Intensive care unit
LIP	Licensed independent practitioner
OT	Occupational therapist
PT	Physical therapist
USDHHS	U.S. Department of Health and Human Services

Preventing Pressure Injuries and Skin Tears*

Reneeka Persaud-Jaimangal, Elizabeth A. Ayello, and R. Gary Sibbald

28

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Assess patients for pressure ulcer risk.
2. Classify pressure injuries using the correct staging definitions. (Check for applicability in your clinical care setting or country.)
3. Develop a comprehensive, holistic high-risk pressure injury prevention and treatment plan.
4. Identify high-risk individuals for skin tears (especially older adults).
5. Classify skin tears using the International Skin Tear Advisory Panel (ISTAP) classification system.
6. Develop a plan to prevent and treat skin tears.

OVERVIEW

The skin is the largest external organ, so preserving its integrity is an important aspect of nursing care. Performing a risk assessment and implementing a consistent prevention protocol may avoid disruption of the skin integrity, including the development of pressure injuries or skin tears. Although pressure ulcers, now referred to as pressure injuries as per the National Pressure Ulcer Advisory Panel 2016 guidelines (Edsberg et al., 2016), and skin tears may look similar, they are different types of skin injury. Skin tears are acute traumatic wounds, whereas pressure injuries are chronic wounds. It is important to assess the wound and to determine the correct etiology so that the proper individualized treatment plan can be implemented.

BACKGROUND AND STATEMENT OF PROBLEM

Pressure Injuries

Pressure injuries are a significant healthcare problem worldwide (Bolton, 2010) and have a significant impact on health-related quality of life (HRQL; Boyko, Longaker, & Yang, 2018; Gorecki et al., 2009). The word *friction* was first eliminated from the definition of a pressure ulcer in the 2009 joint pressure ulcer clinical guidelines written by the National Pressure Ulcer Advisory Panel and the European Pressure Ulcer Advisory Panel (EPUAP & NPUAP, 2019). See Box 28.1 for current NPUAP definitions. The NPUAP has upheld its position that friction is a superficial force that is not an important etiological factor for

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

BOX 28.1

National Pressure Ulcer Advisory Panel (NPUAP) Pressure Injury Stages

The NPUAP refined the definition of pressure injuries during the NPUAP 2016 Staging Consensus Conference that was held from April 8 to 9, 2016, in Rosemont, Chicago, Illinois, USA.

Pressure Injury

A pressure injury is localized damage to the skin and/or underlying soft tissue, usually over a bony prominence, or related to a medical or other device. The injury may present as intact skin or an open ulcer and may be painful. The injury occurs as a result of intense and/or prolonged pressure or pressure in combination with shear. The tolerance of softer tissue for pressure and shear may also be affected by microclimate, nutrition, perfusion, comorbidities and condition of the soft tissue.

Stage 1: Pressure Injury: Nonblanchable erythema of intact skin

Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.

Stage 2: Pressure Injury: Partial-thickness skin loss with exposed dermis

Partial-thickness skin loss with exposed dermis. The wound bed is viable, pink or red, and moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible, and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage (MASD), including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).

Stage 3: Pressure Injury: Full-thickness skin loss

Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges), is often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.

Stage 4: Pressure Injury: Full-thickness skin and tissue loss

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.

Unstageable Pressure Injury: Obscured full-thickness skin and tissue loss

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

Deep Tissue Pressure Injury: Persistent nonblanchable deep red, maroon, or purple discoloration

Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, purple discoloration, or epidermal separation revealing a dark wound bed or blood-filled blister. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone–muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full-thickness pressure injury (Unstageable, Stage 3, or Stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatological conditions.

Additional Pressure Injury Definitions

Medical Device-Related Pressure Injury

This describes an etiology. Medical device-related pressure injuries result from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury should be staged using the staging system.

(*continued*)

BOX 28.1 (*continued*)

Mucosal Membrane Pressure Injury

Mucosal membrane pressure injury is found on mucous membranes with a history of a medical device in use at the location of the injury. Due to the anatomy of the tissue, these ulcers cannot be staged.

pressure injuries (Brienza et al., 2015). Pressure injuries are believed to develop as a result of the tissues' internal mechanical deformation in response to external mechanical loading (NPUAP, EPUAP, & PanPacific Pressure Injury Alliance [PPPIA], 2014). The NPUAP 2016 guidelines also include nutrition, comorbidities, perfusion, microclimate, and condition of the soft tissue as factors that affect tolerance of pressure and shear forces (NPUAP, 2016). A case series by Berke (2015) can help clinicians differentiate friction injuries from pressure injuries, moisture-associated skin damage (MASD) such as incontinence-associated dermatitis (IAD), and other skin problems or injuries.

The exact combination of pressure, ischemia, muscle deformation, and reperfusion injury that leads to a pressure injury remains unclear (NPUAP, EPUAP, & PPPIA, 2014). In adults, most pressure injuries are found on the sacrum, with heels being the second most common site (VanGilder, Amlung, Harrison, & Meyer, 2009). In a study of hospitalized adults, a Hospital-Acquired Pressure Injury (HAPI) rate of 4.5% was identified, with the majority of HAPIs on the coccyx or sacrum (41%), heels (23%), and hip/buttock region (also 23%; Lyder et al., 2012). Across the United States, HAPI rates have decreased from 40.3 to 30.9 per 1,000 discharges between 2010 and 2014, because of the efforts from the Centers for Medicare and Medicaid Services (CMS), along with the Agency for Healthcare Research and Quality (2011; Rondinelli et al., 2018). A 2015 study included 210 U.S. academic medical centers with documented HAPI Stage 3 and 4 incidence rates decreasing from 11.8 cases per 1,000 patients in 2008 to 0.8 case per 1,000 patients in 2012 (Padula, Makic et al., 2015). A study published in 2018 reports the prevalence of pressure injuries to be 7.2% and facility-acquired prevalence to be 3.1% (Kayser, VanGilder, Ayello, & Lachenbruch, 2018).

Data in 2009 from 92,408 U.S. facilities reported an overall prevalence rate of 12.3%, with a facility-acquired rate of 5.0%, which lowers to 3.2% when Stage I injuries are excluded (VanGilder et al., 2009). This same study of 86,932 U.S. acute care facilities reported an overall prevalence rate of 11.9%, with a facility-acquired rate of 5.0%, which reduced to 3.1% when Stage I injuries were excluded (VanGilder et al., 2009).

A 2017 study by VanGilder et al. on a 10-year pressure injury prevalence survey (2006–2015) of 918,621 patients in the United States showed that there was a decrease in overall prevalence of pressure injuries in all facilities from 13.5% (2006) to 9.3% (2015). This study also corroborated findings from other studies documenting the decline in HAPI from 6.2% (2006) to 3.1% to 3.4% (2013–2015; VanGilder, Lachenbruch, Algrim-Boyle, & Meyer, 2017). The overall prevalence of acute care patients also showed a decline from 13.3% (2006) to 8.8%–9.3% (2012–2015).

In long-term care, facility-reported data from the Centers for Medicare & Medicaid Services (CMS) MDS 3.0 Section M, Skin Conditions documentation, minimum data set (MDS) section M: Skin Conditions, reports pressure injury prevalence was 8.24% in the first quarter of 2013 and 7.98% in the last quarter of 2016 (Ayello, 2017).

Table 28.1 summarizes the number of pressure injuries by stages in acute care (VanGilder et al., 2009).

TABLE 28.1

2009 Pressure Ulcer Prevalence by Stages in Acute Care

Type of Pressure Ulcer	Number of Pressure Injuries
Stage 1 or 2	4,985
Stage 3 or 4, eschar or unable to stage	876
DTI	642
Stage unspecified	86
Device-related (MDRPI)	1,631

DTI, deep tissue injury; MDRPI, medical device-related pressure injuries.

Source: Data from VanGilder, C., Amlung, S., Harrison, P., & Meyer, S. (2009). Results of the 2008–2009 International Pressure Ulcer Prevalence Survey and a 3-year, acute care, unit-specific analysis. *Ostomy/Wound Management, 55*(11), 39–45. Retrieved from https://www.o-wm.com/content/results-2008-%E2%80%93-2009-international-pressure-ulcer-prevalence%E2%84%A2-survey-and-a-3-year-acute-care-. *Evidence Level IV*.

The distribution of pressure injuries has changed over the years, with the number of Stage 1 injuries decreasing and the number of unstageable pressure injuries increasing to 15% and suspected deep tissue injury (sDTI) increasing to 9% (VanGilder, MacFarlane, Harrison, Lachenbruch, & Meyer, 2010). The most common site for deep tissue injury (DTI) is the heel (41%) followed by the sacrum (19%) and buttocks (13%; VanGilder et al., 2010).

In hospice patients, in addition to the usual sites on the sacrum and heels, elbows are a common site for injuries, with most injuries occurring within 2 weeks before death (Hanson et al., 1991). Pressure injuries and skin injuries in palliative care are known by various terminologies and concepts, including Kennedy terminal injuries, Skin Changes At Life's End (SCALE), Trombley-Brennan Terminal Tissue Injuries (TBTTI), and skin failure (Ayello et al., 2019). There has been controversy as to what term best describes these skin phenomena and whether these are or include pressure injuries (Ayello et al., 2019). In one hospital's 10-bed palliative care unit, 5% of their patients developed a terminal pressure injury (shaped like a pear, over the sacrum, bruise-like discoloration that is yellow and brown-black; Brennan & Trombley, 2010). When those authors extended their study to a larger sample of 80 patients, "[a]ll but 1 of the documented 80 patients in our study had wounds that remained intact to time of death, progressing only in surface area" (Trombley, Brennan, Thomas, & Kline, 2012). Unlike the Kennedy terminal ulcers (Kennedy, 1989), these authors reported no pear-shaped terminal ulcers. Rather, they reported that these terminal skin injuries were butterfly (48%), linear (40%), and white-centered (12%). Most were located on the sacrum (39%) or the buttocks (35%) and were less frequently seen on the leg (17.5%), back (2.5%), ischium (1%), arm (4%), or heel (1%; Trombley et al., 2012). Furthermore, they described this observed clinical phenomenon, which they called the TBTTIs, as evolving rapidly in skin areas not in areas of pressure and despite prevention strategies including turning or repositioning (Trombley et al., 2012).

Device-Related Pressure Injuries

As defined in Box 28.1, medical device-related pressure injuries (MDRPI) are not a stage but an etiology of a pressure injury. Early data of medical device-related pressure injuries (MDRPI) accounted for 9.1% of injuries, with ears being the most common location (VanGilder et al., 2009; see Table 28.2). Using 2016 IPUP data, 6.9% of all pressure injuries were from medical devices (804/11,651; Kayser et al., 2018), representing a decrease in MDRPI compared to the 2009 finding of 9.1% (1,631/17,91; VanGilder et al., 2009). Seventy-five percent of these device-related pressure injuries were facility acquired, with the most common anatomic locations being the ears (29%) and feet (12%, Kayser et al., 2018). MDRPI should be staged using the NPUAP classification/staging system unless they are located on the mucosa.

TABLE 28.2

Location of Device-Related Pressure Injuries—2016 International Pressure Ulcer Prevalence Survey

Location	Percentage (%)
Head	51
Ears	29
Nose	10
Lower extremities	24
Pelvic area	7.5
Upper extremities	3.0
Back	1.5
Others	10.0

Source: Data from Kayser, S. A., VanGilder, C. A., Ayello, E. A., & Lachenbruch, C. (2018). Prevalence and analysis of medical device-related pressure injuries: Results from the international pressure ulcer prevalence survey. *Advances in Skin and Wound Care, 31*(6), 276–285. doi:10.1097/01.ASW.0000532475.11971.aa. *Evidence Level IV*.

It is important to differentiate pressure injuries from device-related pressure injuries that are "found on mucous membranes with a history of a medical device in use at the location of the injury." Device-related pressure injuries on the mucosa are not staged using the NPUAP classification system, as mucosa does not keratinize, and, therefore, the staging definitions cannot be applied (Position paper on device-related pressure injuries; NPUAP, EPUAP, & PPPIA, 2014). Because of this ruling, the U.S. Centers for Medicare and Medicaid Services (CMS) has directed long-term care (LTC) facilities and long-term acute care hospitals (LTCHs) not to record mucosal device-related pressure injuries on the resident assessment instrument (RAI) of MDS under section M (pressure ulcer section of skin conditions; CMS, 2004; Thomas, 2006).

The NPUAP has four prevention best practice posters available free for download on their website (www.npuap.org). In addition, an educational enabler with two mnemonics (SORE© and DEVICE©) has been published to assist clinicians in raising awareness about MDRPI (Delmore & Ayello, 2017).

Pressure Injury Risk Factors

No single factor puts a patient at risk for pressure injury skin breakdown. The 2014 NPUAP/EPUAP/PPPIA pressure injury clinical guideline confirms the CMS requirement that pressure injury risk assessment should be comprehensive, including assessment of all patient-risk factors. The CMS directive applies to several facilities, including LTC facilities, LTCHs, and inpatient rehabilitation units. Clinicians need to go beyond just relying on validated pressure ulcer risk-assessment tools, including the Braden, Norton, or other scales (NPUAP, EPUAP, & PPPIA, 2014).

Nonnemacher et al. (2009) addressed the question of what combination of factors increases the pressure injury risk by exploring 12 factors that may have the most impact on predicting pressure ulcer risk. Historically, pressure injuries occur from a combination of intensity and duration of pressure as well as from tissue tolerance (Bergstrom, Braden, Laguzza, & Holman, 1987; Braden & Bergstrom, 1987, 1989). Some of the important identified pressure injury risk factors include: (a) immobility (as seen in bedbound or chair-bound patients, especially those unable to change body positions that can also lead to shear), in addition to (b) pressure damage, (c) undernourishment or malnutrition, (d) incontinence, (e) friable skin, (f) impaired cognitive ability, and (g) decreased ability to respond to one's environment (Braden, 1998).

True pressure injuries need to be distinguished from MASD or surface injury in the buttocks region caused by the contact irritation of local friction (Berke, 2015) and moisture factors (Gray et al., 2011). In a large study by Bergquist-Beringer and Gajewski (2011), immobility and incontinence were the two predictors of pressure injury development in older persons receiving home care. In a study by Gray and Giuliano (2018), the authors distinguished the prevalence of pressure injuries in continent patients at 4.1% from a higher prevalence for incontinent patients at 16.3%. They concluded that incontinence was a risk factor for developing a pressure injury (Gray & Giuliano, 2018).

A 20-hospital surgery wait time study revealed a higher incidence of pressure injuries for longer surgery waiting times or time in an intensive care unit (ICU; Baumgarten et al., 2003). Most pressure injuries, in another study of 84 surgical patients, occurred within the first three postoperative days (Karadag & Gümüskaya, 2006). An additional large study of more than 50,000 hospitalized Medicare beneficiaries reported that 4.5% developed at least one new pressure injury during their hospital stay. Pressure injury (PI) patients had higher mortality rates during their hospitalization or within 30 days of discharge and had longer hospital stays (Lyder et al., 2012). The following patient characteristics were found in those who developed hospital-acquired pressure ulcers (HAPUs): diagnoses of congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), cardiovascular disease (CVD), or diabetes mellitus (DM), and presence of obesity (Lyder et al., 2012). A 2015 study identified several independent risk factors for hospital-acquired heel pressure injuries, including immobility, diabetes mellitus, peripheral vascular disease, and a Braden Scale score of 18 or under (Delmore, Lebovits, Suggs, Rolnitzky, & Ayello, 2015).

Patients With Hip Fracture and Pressure Ulcer Risk

In a study of nine hospitals, the cumulative incidence of Stage 2 or higher pressure injuries in older adults with hip fractures was 36.1% (Baumgarten et al., 2009). The less time patients waited to go to the operating room (OR) for repair of the hip fracture, the fewer the associated Stage 4 pressure injuries (Hommel, Ulander, & Thorngren, 2003). The length of time on the OR table increased the risk of pressure injuries in patients with hip fracture (Houwing et al., 2004). Campbell, Woodbury, and Houghton (2010b) found that one third of their sample of patients with hip fracture developed Stage 2 or higher pressure injuries. Implementation of a Heel Pressure Ulcer Prevention Program (HPUPP) for orthopedic patients in Canada resulted in complete elimination of heel pressure injuries compared to the preimplementation level of 13.8% (Baumgarten et al., 2008).

Critically Ill, Intensive Care Unit Patients, and Pressure Ulcer Risk

Patients in ICUs are at a higher risk for developing pressure injuries due to multiple comorbidities and other life-saving interventions. The prevalence of pressure injuries in ICUs ranges from 8.8% to 23% (Krupp & Monfre, 2015). In a case-control study of medical patients in two hospitals, Baumgarten et al. (2008) concluded that the odds of developing a PI were twice as high for those having an ICU stay. In contrast, Shahin, Dassen, and Halfens (2009) found a low incidence of pressure injuries in their 121 ICU patients as a result of prevention measures, including foam and alternating air-pressure-reducing mattresses.

Acute Physiology and Chronic Health Evaluation II (APACHE II) scores, physiological criteria, and Glasgow Coma Scale (GCS) scores are used to predict ICU outcomes, with higher scores indicating poorer outcome;

scores were higher in patients who developed pressure injuries. In contrast, other researchers found no relationship between PI development and APACHE II scores (Kaitani, Tokunaga, Matsui, & Sanada, 2010). Shanks, Kleinhelter, and Baker (2008) found that despite the consistent implementation of PI prevention protocols in their critically ill patients, the patients who developed more hypotensive episodes were more likely to develop pressure injuries.

Several case series by multiple authors provide emerging support for the reduced incidence of pressure injuries, with polyurethane foam dressings applied prophylactically on the sacrum of critically ill, emergency department (ED) or medical–surgical (med–surg) patients (Brindle, 2010; Brindle & Wegelin, 2012; Chaiken, 2012; Cubit, NcNally, & Lopez, 2013; Keily, 2012; Ohura, Takahaski, & Ohura, 2008; Park, 2014; Philbin, Shaw, Walker, & Bishop, 2013; Santamaria et al., 2013; Torra I Bou et al., 2009; Walsh et al., 2012). Based on their review of the evidence, the 2014 NPUAP, EPUAP, PPPIA Pressure Ulcer Clinical Guideline has provided a recommendation at the B level of evidence to consider using polyurethane foam dressing prophylactically to prevent pressure injuries on bony prominences, including the heels or sacrum (NPUAP, EPUAP, & PPPIA, 2014, p. 18). It will be interesting to evaluate the updated preventive foam dressing recommendation from the updated NPUAP, EPUAP, PPPIA International Guideline expected to be released in November 2019.

Regulatory and Government Initiatives

Regulatory and government initiatives continuously support the importance of pressure ulcer prevention. Beginning October 1, 2008, CMS no longer reimbursed hospitals at a higher rate for pressure injuries acquired during hospitalization (CMS, 2019). Recording of location and stage of any Stage 3 and 4 pressure injuries present on admission (POA) now holds clinicians who are legally responsible for establishing the medical diagnosis accountable for documenting this information in the patient's medical record; otherwise, the hospital is not reimbursed for the PI diagnosis (Russo, Steiner, & Spector, 2008). Data from the Healthcare Cost and Utilization Project (HCUP) statistical review reveal that, over the past years, pressure injuries have increased in hospitalized patients by 80%, even though the number of hospitalizations during this period of 1993 to 2006 increased by only 15% (Russo et al., 2008). In the state of New Jersey, Stage 3 and 4 pressure injuries are now reportable in acute care (New Jersey Department of Health and Senior Services, 2008). Pressure injuries are one of the 12 targeted areas to reduce harm to hospitalized patients in the United States as part of the Institute for Healthcare Improvement's (IHI's) "5 Million Lives Campaign" launched in December 2006 (IHI, 2006). Therefore, at the beginning of the 21st century, appropriate risk assessment and preventive care take on even more important meanings.

Several successful initiatives to decrease PI incidence are reported in the literature (Anderson et al., 2015; Lyder & Ayello, 2009; McInerney, 2008; Pancorbo-Hidalgo, Garcia-Fernandez, Lopez-Medina, & Alvarez-Nieto, 2006). Nurses will find the Agency for Healthcare Research and Quality (AHRQ) toolkit (available at www.ahrq.gov/professionals/systems/hospital/pressureulcertoolkit) helpful in developing quality initiatives to decrease PI incidence. A summary of successful characteristics of pressure ulcer injury initiatives can be found in the literature (Niederhauser et al., 2012; Padula, Valuck, Makic, & Wald, 2015).

ASSESSMENT OF THE PROBLEM

When to Do an Assessment

The assessment of the relative PI risk is the first step of any individual patient or healthcare system plan for prevention. Some PI clinical guidelines recommend that patients are assessed for PI development on admission to a care facility, on discharge, whenever the patient's condition changes, and then reassessed based on the person's acuity (NPUAP, EPUAP, & PPPIA, 2014).

Pressure Injury Risk-Assessment Tools

Guidelines recommend that a comprehensive assessment for PI risk be structured and include evaluation of all relevant risk factors and avoid reliance on just one risk factor or assessment tool total score (NPUAP, EPUAP, & PPPIA, 2014). The assessment should include a history (comorbidities, previous PI, medications, and so forth) and physical examination, documenting skin inspection for skin status, and a PI risk assessment using a valid and reliable assessment tool, including subscale scores. Both the Braden (Braden & Bergstrom, 1989) and the Norton Scales (Norton, McLaren, & Exton-Smith, 1962; Norton, McLaren, & Exton-Smith, 1975) are considered reliable and valid. A study of 429 patients in acute care found the modified Braden Scale to be a better predictor than the Norton Scale (Kwong et al., 2005). Although Kottner and Dassen (2010) found that the Braden Scale was more valid and reliable than the Waterlow Scale, they do not recommend either of these scales for ICU patients. Research to create new scales specific to ICU patients continues (Suriadi, Sanada, Sugama, Thigpen, & Subuh, 2008).

The Braden Scale was created in 1987 (Bergstrom et al., 1987) as part of a research study. The scale has six factors and is the most widely used scale in the United States. The first three subscales, sensory/perception, mobility, and activity, address clinical situations that predispose the patient to intense and prolonged pressure. The last three subscales, moisture, nutrition, and friction/shear, address factors that alter tissue tolerance for pressure. Each of the six categories is ranked with a numerical score, with 1 representing the lowest possible subscore and indicating the greatest risk. The sum of the six subscores and the greatest risk is the final Braden Scale score, which can range from 6 to 23.

A low Braden Scale score indicates that a patient is at risk for pressure injuries. The original onset-of-risk score on the Braden Scale was 16 or less (Braden & Bergstrom, 1987). Further research on older adults (Bergstrom & Braden, 1992) and on persons with darkly pigmented skin (Lyder et al., 1998, 1999) supports a score of 18 or less. Research by E. Y. Chan, Tan, Lee, and Lee (2005) also determined that the total Braden Scale score was the only significant predictor of pressure injuries in hospitalized patients. In 2009, W. S. Chan, Pang, and Kwong (2009) applied a modified Braden Scale and calculated a cutoff score of 19 in a 107-bed orthopedic department of an acute care hospital in Hong Kong, with 9.1% of patients developing a PI. In a retrospective study of intensive care patients in Korea using a cutoff score of 13, the Braden Scale (without a more comprehensive approach to patient-risk assessment) had low to moderate positive predictive performance (Cho & Noh, 2010). Increased pressure injury–associated ICU risk development can be evaluated on the first day of hospitalization with combined low Braden and Glasgow Scale scores (Fernances & Caliri, 2008).

The NPUAP, EPUAP, and PPPIA 2014 clinical guidelines recommend that clinicians not only consider total Braden Scale scores but also address any low subscale scores (these indicate a higher risk) in planning PI prevention care. Once high risk is identified, either for overall score or in *any* low subscales (CMS, 2004), prevention interventions need to be implemented. However, one study determined that in a sample of 792 hospitalized patients with a high risk of PI development, only 51% of patients 65 years and older had a preventive device in place (Rich, Shardell, Margolis, & Baumgarten, 2009).

DOES RACE MAKE A DIFFERENCE?

When it comes to severity of pressure injuries, race may make a difference. Ayello and Lyder (2001) analyzed and summarized the existing data about pressure injuries across the skin pigmentation spectrum. Blacks have the lowest incidence (19%) of superficial tissue damage classified as Stage 1 pressure injuries, and Whites have the highest incidence at 46% (Barczak, Barnett, Childs, & Bosley, 1997). Despite the lower Stage 1 rate, the more severe tissue injury detected in Stages 2 to 4 pressure injuries is higher in persons with darkly pigmented skin (Barczak et al., 1997; Meehan, 1990, 1994). Three national surveys identified that Black-skinned individuals had higher incidence of Stage 2 pressure injuries compared to Caucasians: 39% (Barczak et al., 1997), 16% (Meehan, 1990), and 41% (Meehan, 1994). Subsequent studies by Lyder et al. (1998, 1999) continue to support a higher incidence of pressure injuries in persons with darkly pigmented skin. Fogerty, Guy, Barbul, Nanney, and Abumrad (2009) determined that not only was there a higher prevalence of pressure injuries, but also that they occurred at a younger age in African Americans as compared to Caucasians.

Inadequate detection of Stage 1 pressure injuries in persons with darkly pigmented skin may be a result of clinicians erroneously believing that dark skin tolerates pressure better than light skin (Bergstrom, Braden, Kemp, Champagne, & Ruby, 1996) or that only color changes that are more difficult to detect in black skin indicate a PI (Bennett, 1995; Henderson et al., 1997; Lyder, 1996; Lyder et al., 1998, 1999; Rich et al., 2009). Research has begun to validate these assessment characteristics in the Stage 1 definition. In 2001, Lyder et al. reported a higher diagnostic accuracy rate of 78% using the revised definition of Stage 1 pressure injuries compared with 58% with the original definition. Sprigle, Linden, McKenna, Davis, and Riordan (2001) evaluated changes in skin temperature, in particular, that warmth followed by coolness accompanied most Stage 1 pressure injuries.

Clinicians should pay careful attention to a variety of factors when assessing a patient with darkly pigmented skin for Stage 1 pressure injuries. Differences in skin over bony prominences (e.g., the sacrum and the heels) as compared with surrounding skin may be indicators of a Stage 1 PI. The skin should be assessed for alterations in pain or local sensation. In addition, a change of skin color should be noted; clinicians need to be familiar with the range of skin pigmentation that is normal for a particular patient (Bennett, 1995; Henderson et al., 1997).

INTERVENTIONS AND CARE STRATEGIES

Determining a patient's risk for developing a PI is only the first step in the provision of best practice care. Once risk is identified, it is essential to implement a consistent protocol to prevent the development of a PI. A nursing

standard-of-practice protocol for PI prevention is presented later in the chapter to facilitate proactive interventions to prevent pressure injuries (Protocol 28.1). A change in the attitudes of healthcare professionals may be required to facilitate prevention (Buss, Halfens, Abu-Saad, & Kok, 2004). Educating nursing students (Holst et al., 2010) and nurses in an ICU unit resulted in a decrease in pressure injuries (Uzun, Aylaz, & Karadag, 2009). Several clinical guidelines exist detailing PI prevention (NPUAP, EPUAP, & PPPIA, 2014; Wound, Ostomy, and Continence Nurses Society, 2010) with an updated international guideline due to be released in November 2019 by the NPUAP, EPUAP, and PPPIA. Components of a PI prevention protocol should minimally include interventions targeting the following: skin care (including addressing moisture and friction), pressure redistribution, repositioning, and nutrition.

Skin Care

Skin that is too dry or too wet has been associated with pressure injuries. Although there is limited research, dry skin is believed to predispose to ulcer formation (Allman, Goode, Patrick, Burst, & Bartolucci, 1995; Reddy, Gill, & Rochon, 2006). The type of cream used on the skin for different parts of the body may make a difference, as evidenced by a study of 79 patients treated with dimethyl sulfoxide cream, with an increase in pressure injuries when this cream was used on the heels as compared to the buttocks (Houwing, van der Zwet, van Asbeck, Halfens, & Arends, 2008). Other researchers (Stratton et al., 2005) found that a silicone-based dermal nourishing cream reduced the proportion of HAPUs to zero after 8 months. Each of these creams is lubricating, adding an external ointment layer preventing insensible losses. The stratum corneum has 10% moisture content maintained by a complex structure of a number of chemicals referred to as the natural moisturizing factor (NMF). When the NMF falls below a critical level, the skin integrity is lost, with defects occurring between the keratin layers (dry skin, winter itch, eczema craquelé). The second way to moisturize the skin is with humectants (urea, lactic acid, glycerin, ceramides) that actually bind water to the stratum corneum. These substances will sting or burn when applied to open skin because of their hydroscopic properties, but this does not indicate an allergy. Skin can also be too wet, causing a macerated stratum corneum, decreasing the cutaneous barrier and subjecting affected individuals to an increased risk of yeast and bacterial infections.

The use of a soft silicone dressing on the sacrum of critically ill patients resulted in zero pressure injuries in one ICU (Brindle, 2010). Other researchers have reported reduced pressure ulcer occurrence when polyurethane foam dressings are placed prophylactically on the heels or sacrum (Brindle & Wegelin, 2012; Chaiken, 2012; Cubit et al., 2013; Keily, 2012; Park, 2014; Philbin et al., 2013; Santamaria et al., 2013; Walsh et al., 2012). The prophylactic use of a sacral dressing in a critical care unit resulted in a reduced incidence of pressure injuries from 19.9 per 1,000 patient population to 0.84 per 1,000 patients in 2014 (Thorpe, 2016). Hydrocolloid dressings decreased pressure injuries from nasotracheal intubation (Huang, Tseng, Lee, Yeh, & Lai, 2009). When hydrocolloid or film dressings were applied to the skin under face masks, there were fewer device-related pressure injuries (Weng, 2008).

Repositioning and Pressure Redistribution

Because hospitalized patient immobility is a risk factor for the development of pressure injuries (Lindgren, Unosson, Fredrikson, & Ek, 2004), efforts must be made to address pressure. Although repositioning patients is a key intervention to pressure redistribution and prevention of pressure injuries, the best frequency for turning and repositioning, as well as determining which support surface to use, remains a challenge (Defloor, De Bacquer, & Grypdonck, 2005; Norton et al., 1975; Young, 2004). Patients on a particular support surface may not have to be repositioned every 2 hours, depending on their tolerance to pressure. There is no one repositioning timetable for all; the timing needs to be individualized (EPUAP & NPUAP, 2019). For patients who are hemodynamically unstable, a critical care consensus panel recommended slow, gradual turns at 15° to 30° initially. For those who cannot be turned 15°, reassessment of stability every 8 hours and shifting weight every 30 minutes were recommended (Brindle et al., 2013). The use of a wedge-shaped cushion rather than a pillow may be more effective in decreasing pressure injuries in some patients (Heyneman, Vanderwee, Grypdonck, & Defloor, 2009).

Redistributing pressure is a key PI prevention component. When compared to alternating pressure overlays, alternating pressure mattresses reduced length of stay for hospitalized patients, thus decreasing costs as well as having the added benefit of delaying the time at which a PI appeared (Iglesias et al., 2006; Nixon et al., 2006).

The incidence of heel pressure injuries decreased when the appropriate heel-suspending device was used to relieve pressure (Gilcreast et al., 2005). In 2010, a prospective 150-patient, 6-month study by Campbell, Woodbury, and Houghton (2010a) indicated PI incidence was being lowered significantly, by 16% ($p = .016$), for those

who received help with pressure relief interventions. No new pressure injuries developed in a single study of persons with a body mass index (BMI) greater than 35 who were placed on appropriately sized low air-loss equipment (Pemberton, Turner, & VanGilder, 2009). Clinicians may find the Wound, Ostomy, and Continence Nursing Society (WOCN) evidence-based algorithm for selecting a support surface to be a helpful tool in practice (McNichol, Watts, Mackey, Beitz, & Gray, 2015).

In Australia, where medical grade sheepskin (animal source, not synthetic) is available, one study with some questionable methodology demonstrated that hospitalized patients randomly assigned to the animal-source sheepskin mattress overlay had a 9.6% lower incidence of risk of pressure injuries compared to the control group, which had a risk of 16.6% (Jolley et al., 2004). The results were that 58 patients developed pressure injuries (sheepskin group, 21; referent group, 37). The cumulative incidence risk was 9.6% in the sheepskin group (95% CI, 6.1%–14.3%) versus 16.6% in the referent group (95% CI, 12.0%–22.1%). Patients in the sheepskin group developed new pressure injuries at a rate less than half that of referent patients (rate ratio, 0.42; 95% CI, 0.26–0.67).

Nutrition

There is lack of consensus about the best way to assess nutritional impairment, but, generally, consultation by a dietitian for nutritional status, determination of any unintended weight loss, and evaluation of laboratory values, including serum albumin or prealbumin, should be considered. Montalcini et al. (2015) concluded in a study that a serum albumin level of lower than 3.1 g/dL was a good predictor of PI formation and was associated with higher mortality. Cordeiro et al. (2005) found that the concentrations of ascorbic acid and alpha-tocopherol were significantly decreased in patients with pressure injuries or active infection. In a randomized double-blind study on the effect of a daily supplement with protein, arginine, zinc, and antioxidants versus a water-based placebo supplement in patients with hip fractures, there was a 9% difference in the incidence of Stage 2 pressure injuries between the nutritionally supplemented group and the placebo group (Houwing et al., 2003). Any new onset weight loss and unintentional weight loss (more than 5% reduction in body weight within 6–12 months) are important risk factors for mortality for elderly patients (Thomas, 2008). The Cochrane Database reviewed the role of nutrition in PI prevention and treatment. The analysis of the database was inconclusive because of the lack of high-quality trials (Langer, Schloemer, Knerr, Kuss, & Behrens, 2003). When and how patients should be nutritionally supplemented to prevent pressure injuries remains unclear (Houwing et al., 2003; Reddy et al., 2006; Stratton et al., 2005), with contradictions in the literature. The NPUAP nutritional recommendations (NPUAP, EPUAP, & PPPIA, 2014; Posthauer, Banks, Dorner, & Schols, 2015) for PI prevention are included in Protocol 28.1.

SKIN TEARS

Skin tears were originally conceptualized as traumatic wounds caused by shear and friction (O'Regan, 2002) when the epidermis is separated from the dermis (Malone, Rozario, Gavinski, & Goodwin, 1991). Extensive work of the International Skin Tear Advisory Panel (ISTAP, LeBlanc et al., 2018) has provided the following new skin tear definition:

> A skin tear is a traumatic wound caused by mechanical forces, including removal of adhesives. Severity may vary by depth (not extending through the subcutaneous layer).

The updated best practice recommendations for prevention and management of skin tears in the aged skin (LeBlanc et al., 2018) further added to the definition by adding removal of adhesives as a mechanical force that can cause a skin tear. Skin tears occur more frequently in the very young or very old, largely because of thinner and fragile skin that is more likely to be affected by shear, friction, and/or blunt forces (LeBlanc & Baranoski, 2011). Because of the thinner epidermis of aging skin, a flatter dermal–epidermal junction with partial loss of the rete pegs histologically, and decreased dermal collagen, older persons are more prone to skin injury from mechanical trauma (Baranoski, 2000; Payne & Martin, 1993; White, Karam, & Cowell, 1994). Therefore, skin tears are common in older adults, with more than 1.5 million occurring annually in institutionalized adults in the United States (Thomas, Goode, LaMaster, Tennyson, & Parnell, 1999), although the incidence in acute care is unknown. A 2015 systematic review by Pulido et al. reported the prevalence of skin tears in acute settings between 3.3% and 22% and in home care settings between 5.5% and 19.5% (Strazzieri-Pulido, Peres, Campanili, & Santos, 2015). In the United States, data from the CMS MDS section M skin conditions reports a low of 4.57% for the first quarter of 2017 to a higher percentage of 5.40% in the fourth quarter of 2014 (Ayello, 2017). Skin tears are frequently located at areas of age-related purpura (Malone et al., 1991; White et al., 1994). Certain skin characteristics, including ecchymosis, senile purpura, hematoma, photo aging, and signs

of a previous skin tear that has healed, are more prone to developing skin tears (Koyano et al., 2016; Newall et al., 2017; Rayner, Caville, Leslie, & Dhliwal, 2019).

Assessment of Skin Tears

Timely identification of people who are at high risk for developing a skin tear is a fundamental pillar in the prevention of skin tears (LeBlanc et al., 2018). A thorough skin assessment, with emphasis on the shins, face, dorsal aspect of hands, and plantar aspect of the foot, should be conducted (LeBlanc et al., 2018; Malone et al., 1991). In addition to older adults, others with thinning skin who are at risk for skin tears are patients on long-term steroid therapy, women with decreased hormone levels, persons with peripheral vascular disease or neuropathy (the decreased sensation making them more susceptible to injury), and those with inadequate nutritional intake (O'Regan, 2002).

The 2018 ISTAP guidelines outlined a Skin Tear Framework to determine the patient's risk of developing a skin tear based on three risk factor categories: general health, mobility and skin, and other considerations for skin tears risk assessment (LeBlanc et al., 2018):

General Health: comorbidities, malnutrition, medications, impaired cognitive faculties (e.g., auditory, visual, sensory), malnutrition

Mobility: impaired mobility, requires assistance for activities of daily living, history of falls, mechanical trauma

Skin: extremes of age (very young or very old), fragile, dry skin, history of previous skin tear or a current skin tear

Any patient that has any of these factors is considered at risk for developing a skin tear and should be evaluated. The ISTAP risk reduction programme checklist adapted from LeBlanc and Baranoski (2011) is a recommended tool (LeBlanc et al., 2018).

Several authors have suggested protocols to prevent skin tears (Baranoski, 2000; Battersby, 1990; LeBlanc, Baranoski, Christensen et al., 2013; Mason, 1997; O'Regan, 2002; White et al., 1994). Lacking research in acute care, some nursing home research supports the value of skin ulcer care protocols to reduce the incidence of skin tears (Bank, 2005; Birch & Coggins, 2003; Hanson, Anderson, Thompson, & Langemo, 2005). After changing from soap and water to a no-rinse, one-step bed product, skin tears declined from 23.5% to 3.5% in one nursing home (Birch & Coggins, 2003). Hanson et al. (2005) also found that skin tears could be reduced in two different nursing homes when staff were educated in appropriate skin cleaning and protection strategies. A reduction in monthly average of skin tears from 18 to 11 after using longer lasting moisturizer lotion, sleeves to protect the arms, and padded side rails was reported in yet another nursing home study (Bank, 2005). One study claims a decrease in skin tears when skin is treated with a moisturizing cream (Groom, Shannon, Chakravarthy, & Fleck, 2010).

Interventions for Skin Tears

If a skin tear does occur, it is important to correctly identify it and begin an appropriate plan of care. ISTAP (LeBlanc, Baranoski, Holloway et al., 2013) has suggested replacing the original three-category Payne–Martin classification system (Payne & Martin, 1993) with their newer and more simplified classification system of three types, as follows:

- Type 1: A skin tear with no skin loss
- Type 2: A skin tear with partial flap loss
- Type 3: A skin tear with total flap loss

The usual healing time for skin tears is 3 to 10 days (Krasner, 1991). Although skin tears are prevalent in the older adult patient, there is no consistent approach to managing these skin injuries (Baranoski, 2000; O'Regan, 2002). The extensive work of ISTAP has attempted to provide a research base for consistent care to prevent and treat skin tears worldwide (LeBlanc, Baranoski, Christensen et al., 2013, 2016; LeBlanc et al., 2018; LeBlanc, Baranoski, Holloway, Langemo, & Regan, 2014).

Research is just beginning to provide evidence on the best dressings for skin tears. One study (Edwards, Gaskill, & Nash, 1998) compared the use of four different types of dressings in treating skin tears in a nursing home: three occlusive (transparent film, hydrocolloid, and polyurethane foam) and one nonocclusive dressing of Steri-strips covered by a nonadhesive cellulose-polyester material. The nonocclusive dressing facilitated healing at a faster rate than the occlusive dressings. Another study by Thomas et al. (1999) evaluated older adult skin tears in three nursing homes and found a higher rate of complete healing with foam dressings compared to transparent films. ISTAP has published a skin tear product selection guide that directs clinicians to avoid adhesives, hydrocolloids, transparent films, and closure strips, and instead consider using lipocolloid mesh, silicone mesh, foam, impregnated gauze, hydrogel, calcium alginate, hydrofibers, or acrylic dressings (LeBlanc, Baranoski, Christensen et al., 2013).

Goals of care for skin tears include retaining the skin flap if present, providing a moist, nonadherent dressing, and protecting the site from further injury (LeBlanc, Baranoski, Christensen et al., 2013, 2018; O'Regan, 2002). A consensus protocol for treating skin tears based on suggested plans of care has been

developed by several authors (Baranoski, 2000; Baranoski & Ayello, 2008; Baranoski, LeBlanc, & Gloeckner, 2016; Edwards et al., 1998; LeBlanc, Baranoski, Christensen et al., 2013, 2018; O'Regan, 2002) as well as ISTAP and can be found in Protocol 28.2.

CASE STUDY 28.1

Mr. Randy Gonnagetawound, 70 years old, has diabetes mellitus with several microvascular and macrovascular complications. He was admitted to the hospital after a right-sided cerebral vascular accident. Past history includes retinal hemorrhages, a previous myocardial infarction, peripheral vascular disease, and a neuroischemic foot ulcer (healed after a left femoral popliteal bypass, intravenous antibiotics, and plantar pressure redistribution with deep-toed shoe and orthotic). He is incontinent of feces and urine and responds by nodding to verbal commands. His left arm and leg are paralyzed. He has a gag reflex but cannot swallow. His Braden Score is 10.

Current Data

Physical examination: There is an area of persistent erythema with bruising on the left buttock along with a number of superficial nonpalpable purpuric lesions on the arms and legs.

Physical Assessment and Pertinent Admission History

General: Responds to verbal questioning but he cannot move his left side. Over the past 3 days, he has been increasingly fatigued and completely bedridden. He can change position only with movement of the right side.

Vital signs
- Temperature: 39.2°C
- Respiration: 10 breaths/minute and regular
- Pulse: 88 and irregular
- Blood pressure: 162/94 mmHg
- Weight: 195 pounds
- Height: 5 feet, 9 inches
- Abdominal: Intake has been limited to half bowl of cereal twice a day and piece of toast and tea for lunch for the past 3 days. Last bowel movement was 3 days ago; + bowel sounds.
- Cardiovascular: Irregular heartbeat, no S_3S_4 at apex, +1 pedal edema, faintly palpable pedal pulses; capillary refill prolonged at 8 seconds.
- Respiratory: Crackles over right lower lobe, coughing periodically, nonproductive of mucus
- Renal: Episodes of urinary incontinence for the past 3 days before admission
- Integumentary: Skin is warm, dry, and translucent; tenting noted

Laboratory data: hemoglobin 10, hematocrit 28, red blood cells: 3.2, white blood cells: 11,000 shift to the left. Albumin 3.0 g/dL, potassium: 3.1, blood urea nitrogen (BUN): 32 mg/100 mL, glucose and/or HbA1c not available

Medical Orders

Dextrose 5% in water with equal parts normal saline and 10 mEq KCl at 100 mL/hr
- Colace 100 mg by mouth, three times a day
- Pulse oximetry monitoring continuously
- Metamucil one package every day
- Bed rest
- Multivitamin one tablet every day
- Daily weights
- Soft diet as tolerated

Discussion

Mr. Gonnagetawound is a prime candidate for developing a pressure injury (PI). His low numerical score on the Braden Scale (10), comorbidities, lack of movement, and other risk factors put him at high risk. Immediate strategies to prevent the occurrence of a PI are needed. Immobility is a leading risk factor for PI development, so a major part of his plan of care needs to first be directed to initiate moving as much as possible. A physiotherapy consult is needed to evaluate and recommend a plan of progressive exercise and activity. The plan should be to get him out of bed and moving within the constraints of his limitations from the stroke, as well as being in the chair rather than the bed. When in the chair, he should have a gel cushion for pressure redistribution. He will need to be repositioned every hour when in the chair. A Group 2, alternating low-air-loss mattress needs to be placed on his bed. For the limited time when he is in bed, he needs to be turned and positioned. His skin should be assessed every shift to evaluate signs for early skin injury.

A consult with a speech therapist is essential. A swallowing study is warranted to determine his ability to safely take an oral diet. A nutritional consult with a dietitian will address his needs for appropriate calories,

(*continued*)

CASE STUDY 28.1 (*continued*)

protein, and vitamins or minerals. A toileting regimen needs to be implemented to address the fecal and urinary incontinence. A discussion with the prescribing healthcare provider can explore whether he should continue on the Colace and Metamucil. His skin needs cleansing after each episode of incontinence. Use of a no-rinse bathing system is preferred here rather than soap and water. This vulnerable skin needs protection through use of one of the many skin barriers available on the market.

Both Mr. Gonnagetawound and his family need instruction on why it is so important to get him moving and why nutrition, skin care, turning, and repositioning are so critical to his skin health.

Considering his general health, low hemoglobin, possibility of sepsis, and increase in capillary refill must also be monitored and addressed. It would be beneficial to know the HbA1c to determine blood sugar control and prevent long-term complications.

CASE STUDY 28.2

Mrs. Keri Sight, 88 years old, is admitted to the hospital from an LTC facility with a primary diagnosis of pneumonia and secondary diagnosis of senile dementia of the Alzheimer's type with impaired communication skills. She has a history of congestive heart failure and osteoporosis. She spends most of the day in a wheelchair and needs two-person assistance for ambulation. Her skin is thin and dry, resembling an onion; each arm and leg has a purpura area. She weighs 15 pounds less than her ideal body weight and has difficulty swallowing. Laboratory values are as follows: total protein, 5.5 g/dL; albumin, 2.6 g/dL; and BUN, 28. She is verbally aggressive to the staff on which she depends for assistance for her activities of daily living (ADL).

Assessment of Mrs. Sight on admission for skin integrity as well as pressure ulcer risk needs to be done. Because she has four of the criteria from Group 2 of the skin tear risk-assessment tool developed by White et al. (1994; impaired decision-making skills caused by senile dementia, dependence for ADL, wheelchair or bed confined, unsteady gait), she is at risk for developing skin tears. Other factors that would put her at risk are her thin, dry skin with four purpura present and poor nutritional status (LeBlanc, Baranoski, Christensen et al., 2013). Her dependence on staff for ADL and assistance, coupled with her dementia, predispose her to skin injury during bathing and other ADL. A comprehensive pressure ulcer risk assessment, including her skin assessment, comorbidities, and Braden Scale score, puts her at very high risk for developing pressure injuries. A PI prevention protocol, such as in Protocol 28.1, is implemented. The rest of this case discussion focuses on her skin tear risk needs.

Discussion

A skin tear prevention protocol needs to be implemented for Mrs. Sight immediately. In order to achieve a safe environment for her, the staff must know how to approach her with her dementia. To address her nutrition and hydration risk factors, a dietary consultation should be performed. Her ability to safely swallow needs to be evaluated by a speech therapist. After the swallowing evaluation, a plan to encourage frequent fluids and assistance with eating should be implemented. To protect Mrs. Sight's skin from additional injury, avoid using hot water to bathe her and, instead, use one of the nonrinse, soapless bathing products. Her family can be asked to bring in a soft fleece jogging suit for her to wear. The purpura areas on her arms and legs should be covered with stockinet or some other soft nonadherent dressing or skin-protective barrier product to further protect these areas. Her bed rails, and the arms and legs of her wheelchair, should be padded. Staff should use the palms of their hands and a turn sheet when repositioning Mrs. Sight in bed. A moisturizer can be applied twice a day to her dry skin. Daily assessment of her skin, including the five minimal characteristics proposed by CMS, should be performed (Rich et al., 2009).

SUMMARY

The skin is the body's largest organ, so pay attention to it. Although the research into prevention strategies is limited, there is support for following the appropriate risk assessment and practice guidelines for these two types of skin injuries: pressure injuries (NPUAP, EPUAP, & PPPIA, 2014) and skin tears (LeBlanc et al., 2018). Make sure you correctly identify the type of skin injury so the proper plan of care can be implemented.

General skin assessment is important for early breakdown, protecting the skin by using appropriate bathing techniques, using products to minimize the effects of friction and shear on the skin, and paying attention to

nutritional status. In the case of pressure injuries, redistributing the pressure by turning and repositioning and appropriate use of support surfaces are also critical. Immediate initiation of prevention protocols after risk identification is key with correction of each major abnormal risk factor part of the treatment protocol. Following these suggestions can prevent and optimally treat skin integrity problems including skin tears and pressure injuries.

NURSING STANDARD OF PRACTICE

Protocol 28.1: Pressure Injury Prevention

I. GOAL

A. Prevention of PI
B. Early recognition of PI development and skin changes

II. BACKGROUND AND STATEMENT OF PROBLEM

A. Pressure injury 2009: Occurrence data reported for 2009 (VanGilder et al., 2009)
   1. All U.S. facilities
      a. Overall prevalence: 12.3%
      b. FA prevalence: 5.0%
      c. Prevalence excluding Stage 1: 9.0%
      d. FA prevalence excluding Stage 1: 3.2%
   2. Acute care
B. Etiology and/or epidemiology
   1. Risk factors (immobility, undernutrition or malnutrition, incontinence, friable skin, impaired cognitive ability)
   2. Higher incidence of Stage 2 and higher in persons with darkly pigmented skin

III. PARAMETERS OF ASSESSMENT

A. Perform a structured pressure ulcer risk assessment that includes complete skin assessment, consideration of all risk factors, and inclusion of subscores as well as total score when using a valid risk-assessment tool (NPUAP, EPUAP, & PPPIA, 2014).
   1. Inspect skin regularly for color changes such as redness in lightly pigmented persons and discoloration in darkly pigmented persons (EPUAP & NPUAP, 2019).
   2. Look at the skin located under any medical device (e.g., catheters, oxygen, airway or ventilator tubing, face masks, braces, and collars at least twice daily and more frequently in persons with fluid shifts or localized or generalized edema [NPUAP, EPUAP, & PPPIA, 2014]).
   3. Palpate skin for changes in temperature (warmth), edema, or hardness.
   4. Ask the patient whether he or she has any areas of pain or discomfort over bony prominences.
B. Assess for intrinsic and extrinsic risk factors.
C. Braden Scale risk score—18 or less for older adults and persons with darkly pigmented skin; pay attention to low subscale scores also.

IV. NURSING CARE STRATEGIES AND INTERVENTIONS

A. Risk-assessment documentation
   1. On admission to acute care

(*continued*)

Protocol 28.1: Pressure Injury Prevention (*continued*)

2. Reassess at intervals, taking into account the patient's acuity, any change in condition, and based on patient care setting:
   a. Based on patient acuity every 24 to 48 hours on general units
   b. Assess critically ill patients every 12 hours
3. Use a reliable and standardized tool as part of a risk assessment, such as the Braden Scale, as part of a comprehensive risk assessment (available at http://www.bradenscale.com/images/bradenscale.pdf). Do not rely only on a standardized tool for risk assessment!
4. Document risk-assessment scores and implement prevention protocols based on overall scores, low subscores, and the comprehensive assessment of other risk factors.
5. Assess risk of surgical patients for increased risk of PI, including the following factors: length of operation, number of hypotensive episodes, and/or low-core temperatures intraoperatively, as well as reduced mobility on first day postoperatively.

B. General care issues and interventions
1. Culturally sensitive early assessment for Stage 1 PI in patients with darkly pigmented skin.
   a. Use a halogen light to look for skin color changes—may be purple hues or other discoloration based on patient's skin tone.
   b. Compare skin over bony prominences to surrounding skin—may be boggy or stiff, warmer or cooler.
2. Prevention recommendations:
   a. Skin care (NPUAP, EPUAP, & PPPIA, 2014)
      i. Assess skin regularly.
      ii. Clean skin at time of soiling—avoid hot water and irritating cleaning agents.
      iii. Use emollients on dry skin.
      iv. Do not massage bony prominences as a pressure injury prevention strategy; do not vigorously rub skin at risk for PI.
      v. Protect skin from moisture-associated damage (e.g., urinary and/or fecal incontinence, perspiration, wound exudates) by using barrier products.
      vi. Use lubricants, protective dressings, and proper lifting techniques to avoid skin injury from friction and shear during transferring and turning of patients. Avoid drying out the patient's skin; use lotion after bathing.
      vii. Avoid hot water and soaps that are drying when bathing older adults. Use body wash and skin protectant (Hunter et al., 2003).
      viii. Teach patient, caregivers, and staff the prevention protocol.
      ix. Manage moisture by determining the cause; use absorbent pad that wicks moisture away from the skin.
      x. Consider protecting high-risk areas, such as elbows, heels, and sacrum, prophylactically from friction injury using foam dressing (NPUAP, EPUAP, & PPPIA, 2014).
   b. Repositioning and support surfaces
      i. Assess skin and other patient characteristics, as well as pressure injury risk, and consider using the WOCN evidence and consensus-based support surface algorithm (McNichol et al., 2015).
      ii. Keep patients off the reddened areas of skin.
      iii. Repositioning schedules should be individualized on the basis of the patient's condition, care goals, vulnerable skin areas, and type of support surface being used (NPUAP, EPUAP, & PPPIA, 2014).
      iv. Communicate the repositioning schedule to all the patient's caregivers.
      v. Raise heels of bedbound patients off the bed using either pillows or heel-protection devices; do not use donut-type devices (Gilcreast et al., 2005).
      vi. Use a 30° tilted, side-lying position; do not place patients directly in a 90° side-lying position on their trochanter.

(*continued*)

Protocol 28.1: Pressure Injury Prevention (*continued*)

vii. Keep head of the bed at lowest height possible.
viii. Use transfer and lifting devices (trapeze, bed linen) to move patients rather than dragging them in bed during transfers and position changes.
ix. Use pressure-reducing devices (static air, alternating air, gel, or water mattresses; Hampton & Collins, 2005; Iglesias et al., 2006). Use higher specification foam mattresses rather than standard hospital mattress for patients at risk for PI. If the patient cannot be frequently repositioned manually, use an active support surface (overlay or mattress).
x. Use high-specification reactive or alternating pressure support surfaces on the operating table for patients identified at risk for developing PI. Additional support surfaces, such as facial pads, are needed for patients in the prone position (NPUAP, EPUAP, & PPPIA, 2014).
xi. Reposition chair-bound or wheelchair-bound patients every hour. In addition, if patient is capable, have him or her do small weight shifts every 15 minutes.
xii. Use a pressure-reducing device (not a donut) for chair-bound patients.
xiii. Keep the patient as active as possible; encourage mobilization.
xiv. Avoid positioning the patient directly on his or her trochanter.
xv. Avoid using donut-shaped devices.
xvi. Offer a bedpan or urinal in conjunction with turning schedules.
xvii. Keep heels off the bed using heel suspension devices or other equipment that also avoids placing pressure on the Achilles tendon (NPUAP, EPUAP, & PPPIA, 2014).
xviii. Manage friction and shear:
a. Elevate the head of the bed no more than 30°.
b. Have the patient use a trapeze or other transfer devices to lift self up in bed.
c. Staff should use transfer devices, a lift sheet, or mechanical lifting device to move patient.

c. Nutrition
i. Assess nutritional status of patients at risk for PI.
ii. Assess and monitor weight status (NPUAP, EPUAP, & PPPIA, 2014).
iii. For at-risk patient, follow nutritional guidelines for hydration (1 mL/kcal of fluid/d), calories (30–35 kcal/kg of body weight/d), and protein (1.25–1.5 g/kg/d). Give high-protein supplements or tube feedings in addition to the usual diet in persons at nutritional and pressure ulcer risk (NPUAP, EPUAP, & PPPIA, 2014; Posthauer et al., 2015).
iv. Manage nutrition.
v. Consult a dietitian and correct nutritional deficiencies by increasing protein and calorie intake and A, C, or E vitamin supplements as needed (CMS, 2004; Houwing et al., 2003).
vi. Offer a glass of water with turning schedules to keep patient hydrated.

C. Interventions linked to Braden risk scores (Ayello & Braden, 2001)
Prevention protocols linked to Braden risk scores are as follows:
1. At risk: score of 15 to 18
a. Frequent repositioning, turning; use a written schedule
b. Maximize patient's mobility.
c. Protect patient's heels.
d. Use a pressure-reducing support surface if patient is bedbound or chair bound.
2. Moderate risk: score of 13 to 14
a. Same as cited, but provide foam wedges for 30° lateral position.
3. High risk: score of 10 to 12
a. Same as cited, but add the following (b and c).
b. Increase the turning frequency.
c. Do small shifts of position.

(*continued*)

Protocol 28.1: Pressure Injury Prevention (*continued*)

4. Very high risk: score of 9 or less
   a. Same as cited but use a pressure-relieving surface.
   b. Manage moisture, nutrition, and friction and shear.

V. EVALUATION AND EXPECTED OUTCOMES

A. Patient
   1. Skin will remain intact.
   2. Pressure ulcer will heal.
B. Provider or nurse will
   1. Accurately perform PI risk assessment using standardized tool.
   2. Implement PU prevention protocols for patients interpreted as at risk for PI.
   3. Perform a skin assessment for early detection of PI.
C. Institution will
   1. Reduce development of new PI.
   2. Increase number of risk assessments performed.
   3. Develop cost-effective prevention protocols.

VI. FOLLOW-UP MONITORING OF CONDITION

A. Monitor effectiveness of prevention interventions.
B. Monitor healing of any existing PU.

NURSING STANDARD OF PRACTICE

Protocol 28.2: Skin Tear Prevention

I. GOAL

A. Prevent skin tears in older adult patients (LeBlanc, Baranoski, Christensen et al., 2016; LeBlanc & Baranoski, 2017; LeBlanc et al., 2018)
B. Identify patients at risk for skin tears (Mason, 1997; LeBlanc, Baranoski, Christensen et al., 2016; LeBlanc & Baranoski, 2017; LeBlanc et al., 2018).
C. Foster healing of skin tears by:
   1. Retaining skin flap
   2. Providing a moist, nonadherent dressing (Edwards et al., 1998; LeBlanc, Baranoski, Christensen et al., 2013; 2016; Thomas et al., 1999)
   3. Protecting the site from further injury

(*continued*)

Protocol 28.2: Skin Tear Prevention (*continued*)

II. BACKGROUND AND STATEMENT OF THE PROBLEM

A. Traumatic wounds from mechanical injury of skin
B. Need to clearly differentiate etiology of skin tears from PU
C. Common in the older adult, especially over the areas of age-related purpura

III. PARAMETERS OF ASSESSMENT

A. Use either the three-group risk-assessment tool (White et al., 1994) or the ISTAP (LeBlanc, Baranoski, Christensen et al., 2013; LeBlanc et al., 2018) recommendations to assess for skin tear risk.
B. Use ISTAP-validated simplified classification system to classify skin tears (LeBlanc, Baranoski, Christensen et al., 2013; LeBlanc et al., 2018).
   1. Type 1: a skin tear with no skin loss
   2. Type 2: a skin tear with partial flap loss
   3. Type 3: a skin tear with total flap loss

IV. NURSING CARE STRATEGIES AND INTERVENTIONS

A. Preventing skin tears (Baranoski, 2000; Baranoski & Ayello, 2012; LeBlanc, Baranoski, Christensen et al., 2013, 2016; LeBlanc et al., 2018)
   1. Provide a safe environment:
      a. Do a risk assessment of older adult patients on admission.
      b. Implement prevention protocol for patients identified as at risk for skin tears.
      c. Have patients wear long sleeves or pants to protect their extremities (Bank, 2005).
      d. Have adequate light to reduce the risk of bumping into furniture or equipment.
      e. Provide a safe area for wandering.
   2. Educate staff or family caregivers in the correct way to handle patients to prevent skin tears. Maintain nutrition and hydration:
      a. Offer fluids between meals.
      b. Use lotion, especially on dry skin on arms and legs, twice daily (Hanson et al., 1991).
      c. Obtain a dietary consultation.
   3. Protect from self-injury or injury during routine care:
      a. Use a lift sheet to move and turn patients.
      b. Use transfer techniques that prevent friction or shear.
      c. Pad bed rails, wheelchair arms, and leg supports (Bank, 2005).
      d. Support dangling arms and legs with pillows or blankets.
      e. Use nonadherent dressings on frail skin.
         i. Apply skin-protective products (creams, ointments, liquid sealants, and so forth) or a nonadherent wound dressing, such as hydrogel dressing with gauze, as a secondary dressing, silicone, or Telfa-type dressings.
      f. Use gauze wraps, stockinettes, flexible netting, or other wraps to secure dressings rather than tape.
      g. Use no-rinse, soapless bathing products (Birch & Coggins, 2003; Mason, 1997).
      h. Keep skin from becoming dry; apply moisturizer (Bank, 2005; Hanson et al., 1991).
B. Treating skin tears (Baranoski & Ayello, 2012; LeBlanc, Baranoski, Christensen et al., 2013, 2016; LeBlanc et al., 2018)
   1. Gently clean the skin tear with normal saline.
   2. Let the area air dry or pat dry carefully.
   3. Approximate the skin tear flap.
   4. Use caution when removing dressings as skin damage can occur when removing dressings (LeBlanc, Baranoski, Christensen et al., 2016).

(*continued*)

Protocol 28.2: Skin Tear Prevention (*continued*)

5. Consider adding an arrow on the dressing to indicate the direction of the skin tear to minimize any further skin injury during dressing removal.
   a. Skin sealants, petroleum-based products, and other water-resistant products, such as protective barrier ointments or liquid barriers, may be used to protect the surrounding skin from wound drainage or dressing, or tape-removal trauma.
   b. Always assess the size of the skin tear; consider doing a wound tracing.
   c. Document assessment and treatment findings.

V. EVALUATION AND EXPECTED OUTCOMES

A. No skin tears will occur in at-risk patients.
B. Skin tears that do occur will heal.

VI. FOLLOW-UP MONITORING OF CONDITION

A. Continue to reassess for any new skin tears in older adults.

Optimizing Mealtimes for Persons Living With Dementia*

Melissa Batchelor

29

EDUCATIONAL OBJECTIVES

Upon completion of this chapter, the reader should be able to:

1. Assess the person with dementia for sensory, cognitive, and functional changes in dementia, as well as manage mealtime behaviors and environmental factors that impact meal intake.
2. Use a problem-solving framework to determine strategies that promote independence but adequately support and facilitate meal intake for a person with dementia.
3. Educate caregivers on how to deliver individualized assistance at mealtimes, using verbal and nonverbal cues and three Handfeeding techniques (sensorimotor cues).

OVERVIEW

Nearly 6 million people are living with Alzheimer's disease or a related dementia (dementia) in the United States today, and by 2050, this number is expected to triple (Alzheimer's Association, 2019). Of the top 10 leading causes of death in the United States, it stands alone as the only disease no one has survived. In fact, while death rates from heart disease and cancer have been steadily decreasing over the past decade, there has been a 145% increase in the number of deaths from dementia (Alzheimer's Association, 2019). While we wait for a cure for this burdensome disease, all caregivers need training to care for persons living with this disease. For family caregivers, managing mealtimes is among the most challenging of caregiving, from preparing food for special diets to helping the person to eat (Reinhard, Levine, & Samis, 2012). In the nursing home, mealtimes are the most time consuming of all of the activities of daily living (ADLs), and current training standards do not include content on Handfeeding techniques and/or managing mealtime behaviors (Batchelor-Murphy, Amelia, Zapka, Mueller, & Beck, 2015; Batchelor-Murphy et al., 2017). Mealtime behaviors in dementia are more complex than managing feeding behaviors. Caregivers must manage functional and cognitive challenges, trouble with swallowing (dysphagia), and elopement/wandering from the dining table to maximize meal intake effectively.

In the mid-1990s, feeding behaviors such as turning the head away and clamping the mouth shut were conceptualized as "aversive" behaviors. Caregivers typically interpreted these behaviors as "resistive" and stopped providing assistance (Pelletier, 2004, 2005; Watson, 1993; Watson & Green, 2006). The primary clinical instrument for "aversive" or "resistive" feeding behaviors is the Edinburgh Feeding Evaluation in Dementia (EdFED) Scale. Studies

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

using the EdFED aimed to decrease "aversive" feeding behaviors and increase meal intake.

Another line of inquiry for understanding behaviors in dementia involves conceptualizing behaviors in dementia as an attempt to communicate an "unmet" need (Algase et al., 1996; Batchelor-Murphy et al., 2015; Watson & Deary, 1994). Within this model, caregivers attempt to figure out what the behavior(s) mean and adapt the care provided through trial and error, and then the meal continues. Evidence that feeding behaviors are more likely a *form of communication*, and the *only form of control* a person with dementia has during a meal interaction, is emerging, with tremendous implications for clinical care (Batchelor-Murphy et al., 2015, 2017). For example, if a person with dementia doesn't open his or her mouth (rather than clamps the mouth shut), maybe the person is trying to communicate the need for a sip of his or her drink. Once the drink is offered, the meal resumes, increasing meal intake. Viewing these nonverbal feeding behaviors as communication of an "unmet" need is a paradigm shift for future research and clinical practice and creates the opportunity for caregivers and researchers to respond differently to the behaviors to improve nutritional outcomes (Algase et al., 1996; Batchelor-Murphy et al., 2015).

Malnutrition is a hidden epidemic among older adults across weight categories (underweight, normal, and obese/overweight) and across care settings (home, healthcare systems, and long-term care institutions). If an older adult is experiencing cognitive decline, the risk of malnutrition is greater. In the community setting, unintentional loss of body weight may be the first indicator of a cognitive issue for caregivers and providers (Batchelor-Aselage, Bales, Amella, & Rose, 2015). In the hospital setting, malnutrition is the biggest risk factor associated with readmission and mortality (The Gerontological Society of America, 2014); and in the nursing home setting, malnutrition is more prevalent than falls or pressure ulcers (Centers for Medicare and Medicaid Services, 2019a). Interventions to combat malnutrition fall into five major categories: nutritional supplements, training/education, environment/routine modification, feeding assistance, and mixed interventions (Wen, Jooyoung, & Thomas, 2014). The majority of interdisciplinary studies to date are descriptive and correlational studies, pointing to the need for research in the areas of eating ability, cognitive and behavioral function, and tailoring interventions according to level of dependence (Aselage, Amella, & Watson, 2011; Wen et al., 2014). Randomized controlled clinical trials are predominantly in the category of nutritional supplements and training/education (Aselage et al., 2011; Hanson, Ersek, Gilliam, & Carey, 2011; Wen et al., 2014). In spite of all efforts, current evidence demonstrates that specialized feeding interventions may not impact how long a person with dementia lives or improve function (Hanson et al., 2011). Given this, discussions among providers, caregivers, and the person living with dementia about the goals of care should be discussed shortly after dementia is diagnosed and continue throughout the disease trajectory. Issues related to managing meal intake will be a major factor at end-of-life. Advance directive discussions should include information related to Handfeeding or tube feeding until death early in the disease process. This allows caregivers, who will eventually be responsible for making the decisions at end-of-life, to be guided by the expressed wishes of the person with dementia and for these wishes to be documented and communicated to the healthcare team (Hickman, Keevern, & Hammes, 2015).

Several reviews have demonstrated that feeding tube placement in advanced dementia does not decrease negative outcomes such as aspiration pneumonia or pressure ulcers (Finucane, Christmas, & Travis, 1999; Mitchell, Buchanan, Littlehale, & Hamel, 2004). The reality for persons diagnosed with dementia and their caregivers is that dementia is a terminal illness; the person will die *from dementia* or *with dementia*, but not from "starving to death." Unfortunately, this reality is not well understood by the public. The "decision" to place a feeding tube or continue care with Handfeeding is an emotionally difficult one for a legally authorized representative. Skillful and educated clinicians must be available to provide the necessary emotional support for family caregivers as the disease reaches end stage and to explain that although there is no cure for dementia, there are care options—and Handfeeding until death is the preferred care option (American Geriatrics Society, 2014; Palecek et al., 2010; Sekerak & Stewart, 2014; Sherman, 2003). The purpose of this chapter is to present strategies caregivers can use throughout the disease trajectory to optimize nutritional intake, tailored to the ability of the person with dementia in the moment.

BACKGROUND AND STATEMENT OF PROBLEM

The ability to feed oneself is the first ADL mastered in childhood, and the last one lost in dementia (Katz, Downs, Cash, & Grotz, 1970; Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963). As the disease progresses, memory loss disrupts daily life and makes it difficult for the person living with dementia to complete familiar tasks such as eating. Changes in sensory perception alter self-care ability, and caregivers tend to focus on the *disability* rather than recognizing and supporting remaining *ability*. Reframing the caregiver focus to be on the ability of the person with dementia promotes dignity and sets the stage for meaningful

engagement during meals. The ability of a person with dementia to self-manage meals may vary from day to day and meal to meal. Adapting care to provide adequate support without taking over is critical, as is the need to use approaches that preserve dignity and promote quality of life.

Sensory Changes in Dementia

Alzheimer's disease and related dementias are neurodegenerative diseases that impact vision, taste, smell, hearing, and touch. These impairments do not typically occur in isolation. The complexity of concurrent sensory impairments and understanding how they impact cognition has been challenging; the relationship between and direction of causality for each is still a great unknown (Lin et al., 2014; Whitson et al., 2018). The degree of change in sensory ability varies from individual to individual, and caregivers must understand how these sensory changes drive behavior(s) in dementia.

Changes in Vision

Rates of impaired near and distance visual acuity increase with age. In normal aging, the most common changes are impaired visual processing, the ability to adapt to darkness and light, the ability to recognize patterns, and loss of peripheral vision (Beurskens & Bock, 2012; Whitson et al., 2018). In addition to normal age-related changes, as dementia progresses, peripheral vision is reduced significantly to binocular vision (top, bottom, and both sides of the visual field [Snow, 2018]). Reduced peripheral vision in dementia can be simulated as "binocular vision" by placing the fingers around your own eyes as if holding up a pair of binoculars. You would not be able to see a meal placed directly in front of you with this visual field; therefore, a person with dementia may not be able to see his or her food when placed directly in front of him or her. But what you can see is the food of your dining companions. This change in vision may be a reason a person with dementia will reach across the table to eat another person's food when his or her own tray is directly in front of him or her. As a caregiver, redirecting the individual back to his or her own plate may prove futile; therefore, a better strategy may be to move the dining companion and place the person with dementia's tray in that location, so the patient eats his or her own food. Other strategies to compensate for vision include using a high-contrast plate and place mat (white plate/black place mat), and organizing utensils and cups in locations one would typically look for them in a customary place setting—and replacing those items to correct locations if misplaced by the person with dementia after using.

Changes in Smell

The loss of ability to smell has been linked to neurodegenerative diseases as an early indicator of the disease and in later stages of Alzheimer's disease, Lewy body dementia, and vascular and frontotemporal dementias (Devanand, 2018; Doty, 2017; Woodward et al., 2018). The spectrum of loss ranges from mild to severe in dementia, but very few studies have been able to make clear distinctions between loss associated with normal aging compared to neurodegenerative changes (Doty, 2017; Woodward et al., 2018). Loss of smell is linked to taste, which impacts a person's ability to enjoy food and drink, but also poses a threat given the inability to smell spoiled food (Doty, 2017). Caregivers should be cautious to ensure food near expiration is removed and routinely check that smoke and carbon monoxide detectors are working.

Taste and Return of Suck Reflex

Although it is commonly known that taste and smell are linked, for those living with dementia, relatively little is known about the underlying mechanisms driving changes in the sense of taste (Sakai, Ikeda, Kazui, Shigenobu, & Nishikawa, 2016). Clinical observations of persons with Alzheimer's disease and related dementias indicate a common preference for sweet foods, particularly in frontotemporal dementia (Ahmed et al., 2017; Aiello, Silani, & Rumiati, 2016; Kai et al., 2015; Sakai et al., 2016). Food intake behaviors are linked to certain anatomical areas of the brain, but also driven by complex neurobiological pathways. Foods high in sugar and fat are potent rewards that promote food intake (Volkow, Wang, & Baler, 2011). As science delves deeper into how these complex systems interact, from a clinical perspective, caregivers that work with persons with dementia have already figured out that adding sugar to food does increase meal intake (Aselage, 2013). Adding sugar to meat loaf or carrots may not be typical in food preparation, and perhaps unconventional, but this strategy works in practice for increasing intake of real food. If food intake improves using sugar (or a sugar substitute), this intervention will likely reduce the need for expensive supplements or added snacks that are often not distributed in institutional settings. If the person with dementia has diabetes, the medical providers can adjust the medical regimen.

In Alzheimer's disease and related dementias, the suck reflex may also return (Damasceno et al., 2005; Schott & Rossor, 2003; Walker, 1990). For persons with dementia who exhibit this primitive reflex, offering drinks through a straw may be easier than drinking from a cup. To promote independence, a closed cup with a self-contained straw would be a better choice.

Hearing and Ability to Understand Language

Age-related hearing impairment affects nearly two thirds of adults over the age of 70 and is associated with accelerated cognitive decline (Lin et al., 2011). Additionally, comorbid occurrence of hearing loss and dementia results in compounded communication difficulties that can exacerbate dementia-related behaviors (Mamo et al., 2018). Hearing impairment is associated with brain atrophy in the temporal lobe, impacting language processing ability (Lin et al., 2014). As dementia progresses, a person loses the ability to use and understand language, significantly impairing verbal communication. This leaves nonverbal (behavior) cues as the primary form of communication. Caregivers should be aware that persons with dementia will automatically mimic their facial expressions and nonverbal behavior, and synchronize their emotional state to that of the caregiver (Sturm et al., 2013). In other words, when speaking to a person with dementia, our words may sound like those of Charlie Brown's teacher; but if coupled with a nonverbal cue (e.g., mimicking eating), this may increase understanding that it is mealtime. Whenever possible, caregivers should eat at the same time as the person with dementia to optimize the verbal and nonverbal cues that it is time to eat.

Touch and Return of Palmar Reflex

With the progression of neurodegeneration of the frontal lobe that occurs in Alzheimer's disease and related dementias, the palmar reflex returns (Damasceno et al., 2005; Schott & Rossor, 2003; Walker, 1990). The grasp reflex is elicited when a caregiver places his or her hand in the palm of a person with dementia; in other words, a traditional handshake will elicit the grasp reflex in a person with advanced dementia, and his or her grip is very strong. The person with dementia is not able to control the length of time before he or she releases the grip, and it can be a fairly painful experience for an unassuming caregiver. Persons with dementia retain strength much longer than fine motor skills. Therefore, the way to avoid a painful interaction is to greet persons with dementia using the Under Handshake (see Figure 29.1). When in the Under Handshake, the person with dementia can squeeze as hard as he or she would like, and it will not hurt the caregiver. The Under Handshake combined with a "palm pump" (gently squeezing and releasing the hand of the person with dementia in a rhythm similar to that of a heartbeat) can also be very soothing to the person with dementia.

APPROACH TO CARE

The amygdala controls our emotional response when we encounter a threatening situation and activates the sympathetic nervous system to reflexively respond with a fight, flight, or fright response. These areas of the brain remain intact with dementia. Caregivers should keep this in mind along with the sensory changes in hearing and vision. Be sure to call out to the person (verbal cue) and get into his or her field of vision from the front (visual cue, considering

FIGURE 29.1

Demonstration of the Under Handshake for use with persons with dementia.

loss of peripheral vision) before you touch the person (tactile cue). Imagine that you don't hear or see someone approaching you and he or she touches you first. When cues are not delivered in this order by unassuming caregivers, this sets off a fight, flight, or fright response in the person with dementia. A mnemonic to remember this approach is SHAKE Hands: Be sure the person **S**ees you and **H**ears you, **A**pproach slowly, **K**neel down, and **E**ngage with the Under Handshake. This order of cueing will minimize behavioral responses in the person with dementia that are often interpreted as "disruptive," when the caregiver may inadvertently have caused the behavior.

CARE STRATEGIES

Formal and informal caregivers should promote self-feeding as much as possible, for as long as possible, and only offer the least amount of support necessary to maximize meal intake. Assessing functional, cognitive, and sensory ability is a critical need when making decisions about how much assistance to provide to a person with dementia, and which handfeeding technique may be most appropriate for any given meal, bite of food, or drink. Observing all three daily meals, in their entirety, for multiple days and documenting the ability and challenges of the person with dementia may help caregivers identify patterns of better intake.

Meal Observation

As the meal begins, functional ability should be assessed by observing the ability of the person to scoop the proper amount of food and move the food into the mouth (each bite is a feeding cycle), ending in successful intake (or not.) Caregivers should observe the ability of the person with dementia to use his or her "skill fingers" (use of first two fingers and thumb to manipulate utensils; Figure 29.2), upper extremity range of motion, strength, endurance, and individual preference(s) (Batchelor-Murphy et al., 2017). Other functional and cognitive indicators to observe include the ability to begin a meal; use utensils; maintain attention and alertness during the meal; bite, chew, and swallow without choking; and end the meal (Edahiro et al., 2012; Lee & Song, 2015; Tully, Matrakas, Muir, & Musallam, 1997).

Self-Feeding

If the person with dementia has the functional, cognitive, and sensory ability needed to initiate, maintain, and end a meal with adequate intake, caregivers should promote self-feeding. Observing where difficulty occurs may require creative interventions, including finger foods if utensils are difficul to manage or a covered cup with a straw if drinking from a normal cup is challenging. If maintaining attention to the meal is difficult, caregivers can use person-centered verbal cues (e.g., redirecting attention to the meal, orienting to food items, expressing approval) and nonverbal cues (e.g., mimicking act of eating, positive gestures, and facial expressions) to promote self-feeding (Gilmore-Bykovskyi & Rogus-Pulia, 2018; Reimer & Keller, 2009). Monitoring the person during the entire meal is important as assistance may be required during part of or near the end of a meal to finish eating.

Handfeeding Assistance

For all three handfeeding techniques, the feeding assistant should first assess which hand is the dominant hand of the person with dementia. The feeding assistant should sit on the dominant side of the person with dementia and use the same hand to provide assistance (e.g., if the person with dementia is right-handed, the feeding assistant should sit on the right side and use his or her right hand to provide assistance). For each bite of food, assistance should be provided through the middle of the body, as that is the normal trajectory for moving food from a plate to the mouth in self-feeding. It is recommended that the person with dementia be in a chair during mealtimes as much as possible, as assistance is more challenging if the person with dementia is in bed.

The handfeeding techniques are identified according to where the caregiver (feeding assistant) places his or her hand in relation to the person who is being assisted. A Handfeeding demonstration video can be viewed at http://MelissaBPhD.com/NOSH to learn placement of the hands and available modifications for each technique. When first learning about these techniques, it is helpful to "role-play" with a partner. Each person can alternate being in the role of the feeding assistant and the person with dementia. Kinesthetically experiencing each technique oneself provides insight for the feeding assistant as to how the person with dementia may perceive that type of feeding assistance—these handfeeding techniques feel different, as though you have control over the movement or someone is forcing your hand toward your face. The handfeeding techniques may be used interchangeably during a meal. Decisions on which technique to use should consider the ability of the person with dementia and which technique(s) are preferred. Every person with dementia is an individual, and clinical judgment should be exercised by caregivers to promote safety, comfort, dignity, and quality of life during every meal interaction.

Over Hand. The Over Hand technique can be used when the person with dementia just needs a little help initiating, maintaining, or finishing a feeding cycle. The person possesses the "skill finger" ability necessary to hold the utensil, has the upper extremity range of motion and strength to move the utensil with food from the plate to the mouth, but just needs some physical guidance. To do so, the feeding assistant places his or her hand *over* the hand of the person being assisted with the meals. This technique may also be used to stabilize any hand tremor that results in spillage of food off the utensil. The feeding assistant may need to keep his or her hand over the hand of the person with dementia all the way through the feeding cycle, or just long enough to initiate the movement of the utensil to the mouth. If the person with dementia pushes away the feeding assistance, it may be because he or she is capable of performing the movement on his or her own and/or feels as though you are forcing his or her movement, so be mindful to provide this assistance gently at the other person's pace and not your own.

Under Hand. As dementia progresses, older adults will lose skill finger (fine motor) ability before they lose strength (gross motor ability), demonstrated with elicitation of the palmar reflex (Bottiggi & Harrison, 2008). The Under Hand technique can be used for a person with dementia who no longer has skill finger ability but is still able to engage in the act of eating. Caregivers should practice getting into the Under Handshake (detailed earlier) with one another, as this is the correct position for the Under Hand feeding technique. Once in the Under Handshake, the caregiver providing feeding assistance will have use of his or her skill fingers to support the loss of this ability in the person with dementia.

If the person with dementia has limited upper extremity range of motion, caregivers may need to modify the Under Hand technique to accommodate these functional limitations. If the person has partial range of motion, the caregiver can load the utensil with food and then continue the feeding cycle with the Under Hand technique. And if the person with dementia has a contracture in the upper extremity, the caregiver can slide a bowl of food under the person's arm and perform the Under Hand technique with shorter movements. The handfeeding demonstration video at http://MelissaBPhD.com/NOSH includes these limited range of motion modifications.

Direct Hand. In current practice, spoon-feeding is typically observed as the first (and only) type of assistance offered to a person with dementia. The problem with spoon-feeding is two-fold. The caregiver does not provide a tactile cue that he or she is present, and the spoon is moved from the plate to the person's mouth in more of a "swoop." This approach does not provide any cues before the food shows up in the person's mouth and may be spit out (feeding behavior) as a result of not expecting the food. Spoon-feeding needs to be adapted to Direct Hand feeding to include a tactile cue (hand on shoulder), and the spoon should be lifted until it is in the person's visual field (visual cue). The handfeeding demonstration video demonstrates these modifications for vision.

Rather than using Direct Hand as the first choice when providing feeding assistance, this Direct Hand technique should be reserved as the last resort when caregivers need to do all of the work for the person with dementia. Direct Hand assistance typically does not engage the person in the act of eating, making it a more passive experience. If used first, this can create excess disability. Therefore, this technique is most appropriate at the end stage of dementia, when the person is totally dependent for care. However, if the person with dementia is not used to caregivers using the Over Hand or Under Hand techniques, they may initially prefer the Direct Hand technique because it is what they are more familiar with. As caregivers use the Over and Under Hand techniques, the person with dementia will become more familiar, so allow some adjustment time. See Figures 29.2 and 29.3 for different feeding assistance techniques.

PROBLEM-SOLVING FRAMEWORK: THE C3P MODEL

The C3P Model is a problem-solving strategy that frames how licensed nurses can think through an identified mealtime difficulty: Change the Person, Change the People, and/or Change the Place (Amella & Batchelor-Aselage, 2014). The assessment and interventions for this chapter are framed around this model. The recommendations for assessment of mealtime difficulties and nutritional assessment will vary depending on the place of residence (community, long-term care, or acute care) of the person with dementia. Assessment is not a static event, especially when an older adult experiences the downward spiral of a life-limiting cognitive or physical illness. As an individual ages, the likelihood of functional impairment increases. With increased frailty, loss of function follows a predictable pattern, with the ability to feed oneself the last ADL to be lost (Katz et al., 1963; Katz et al., 1970).

Quite often, mealtime difficulties are first noticed by caregivers when the person with dementia has lost weight. In the nursing home setting, weight loss is quantified as a 5% loss in one month, or 10% loss in the past six months (Centers for Medicare and Medicaid Services, 2011). These parameters are a good "rule of thumb" for community-dwelling elders also. In early dementia, weight loss may be a sign of forgetting to prepare and eat meals. In moderate to advanced dementia, there may be issues more related to functional ability and/or deficits related to the disease process with apraxia, agnosia, and aphasia. As the disease progresses, if meal intake is affected, the general "rules" for dietary restrictions should be carefully weighed for risk versus benefit. Liberalizing diets may increase intake, especially when the goals of care are comfort, quality of life, and dignity (Sekerak & Stewart, 2014).

Change the Person

Physical Assessment and Daily Care Record Review

A head-to-toe physical assessment by licensed nursing personnel is vital. Investigation should focus on identifying any reversible, physical cause of weight loss. Potential factors at the individual level include, but are not limited to, pain, infection, medication interaction, abnormal lab values, food preferences, and/or sociocultural considerations. Along with the physical assessment, review any daily care documents available in the medical record. Looking back over several days (or weeks, if available) for patterns of daily intake through the meal intake record may provide information related to the onset of a reversible problem (e.g., urinary tract infection, constipation, new medication that causes a decrease in meal intake). Additionally, these patterns may provide insight into the best time of day to target meal intake. For example, if a person consumes 100% of breakfast and less over the course of the day, one strategy would be to double the breakfast portions to increase caloric intake at that time of day. Review of lab values for any abnormalities that may be easily remedied and/or new or unnecessary medications that could be eliminated are important components of a comprehensive geriatric assessment.

In addition to the physical exam and meal intake records, output records for "regular" bowel movements should be reviewed for regularity or changes in bowel habits. Teaching staff to correctly quantify bowel movement size is also a little known but critical assessment skill. Small bowel movements should be quantified as the size of a closed fist, medium bowel movements as half the length of the forearm, and large bowel movements as the full length of the forearm. The rationale for quantifying in this manner is that the full forearm is the same length as the colon. If a person is only outputting a series of small bowel movements every few days, he or she is not emptying the colon—increasing the risk of a major constipation episode or fecal impaction, which will impact any person's appetite.

Change the People

Successful completion of the meal is dependent on who assists or feeds the patient and the interpersonal process that the person uses to interact with the patient (Altus, Engelman, & Mathews, 2002; Amella, 2002). Caregivers who are able to let the patient set the tempo of the meal and allow others to make choices will be more effectual in increasing intake. These studies point to a need to use patient-centered approaches that individualize mealtimes for patients and suggest that the responsibility for ensuring this occurs rests with a sensitive and well-trained staff.

Several patient-centered factors have been identified as being critical to older adults: Each mealtime was seen as a unique process, and patients are central to the process through their actions not only at meals but also during the time surrounding meals, such as when socializing while waiting (Evans, Crogan, & Shultz, 2005; Gibbs-Ward & Keller, 2005). Encouraging the family to eat with the patient can be beneficial; this has been shown to be an effective strategy in nursing homes, increasing body weight and fine motor function in a randomized controlled trial (Altus et al., 2002; Nijs et al., 2006).

Change the Place

Because of the strong social and cultural components of eating, where one dines is sometimes as important as what one eats. Nurses should simply ask themselves, "Would I want to eat my next meal where this person is eating?" If the answer is no, then steps should be taken to improve the dining environment. Small changes in the dining environment may make large improvements in a patient's capacity and motivation to eat or be fed. Unfortunately, in institutions, the mealtime experience is often not focused on individual needs (Sydner & Fjellström, 2005). External factors such as decreased noise, increased lighting, and playing of relaxing music at meals positively influenced appetite (Hicks-Moore, 2005; McDaniel, Hunt, Hackes, & Pope, 2001). Using contrasting colors (foreground/background) in tableware and tablecloth and placing dishes in similar positions may help persons with low vision to be more independent (Ellexson, 2004). Proper positioning using the appropriate, supportive chair (instead of eating in bed or sitting on the bedside) promotes good eating posture (Rappl & Jones, 2000). Meals eaten in small groups—much like family dining—are considered an ideal method; however, this intervention had a greater effect on staff's perception of meals and willingness to spend time in the process of attending to meals (Kofod & Birkemose, 2004).

Role of Nutritional Supplements

Nutritional supplements include high-calorie supplements and appetite stimulants (Hanson et al., 2011). Although there is evidence that nutritional supplements improve body weight by 1 to 4 pounds in persons with dementia, there is less evidence that these supplements reduce risk of infections or promote wound healing (Hanson et al., 2011). In addition, these supplements have not demonstrated improvement in function or improved life expectancy (Hanson et al., 2011). Nutritional supplements are expensive, and between 55% and 65% of the time are not actually consumed by the person with dementia (Allen, Methven, & Gosney, 2014; Kayser-Jones et al., 1998). A recent randomized controlled clinical trial indicated that when offered the supplement in a glass/beaker rather than in a container with a straw inserted into it, persons with dementia did increase the amount of the supplements consumed (Allen et al., 2014). Even with this delivery modification, supplement consumption averaged 65%. Nutritional supplements given midmorning have also been associated with decreasing lunch intake (Young, Greenwood, van Reekum, & Binns, 2004).

The interdisciplinary team may have neglected to perform a thorough assessment of underlying issues prior to using nutritional supplements. Potentially reversible conditions such as adequate staffing and lack of supervision, poor oral health, or identifying other factors requiring intervention such as dysphagia should be investigated (Kayser-Jones et al., 1998). This in-depth assessment of the etiology of a mealtime difficulty should occur and results documented prior to using a nutritional supplement. Real food should be offered first, with deliberate attention to providing adequate support in order to achieve meal intake, based on individual preferences and functional ability, as outlined in this chapter.

CASE STUDY 29.1

Mr. Jones is an 85-year-old man admitted to the skilled nursing facility after a 3-day hospital stay after a fall. Prior to his hospitalization, Mr. Jones lived with his son's family in the community. The family's goal for discharge is for Mr. Jones to return home after rehabilitation. For his initial Minimum Data Set (MDS) assessment, the staff report fluctuations between needing assistance to being total care with meals.

(*continued*)

CASE STUDY 29.1 (*continued*)

On one particular midmorning round, the certified nursing assistant (CNA) enters Mr. Jones' room by first calling his name (auditory cue) and entering his visual field (visual cue) before finally touching his shoulder (tactile cue). The CNA spoon-feeds Mr. Jones, and he will occasionally clamp his mouth shut and turn his head away when offered his food. After several failed attempts to encourage eating, she consults the nurse about his "refusal" to eat.

The nurse uses the C3P Model and begins with *Change the Person*: She conducts a head-to-toe physical exam, medication reconciliation, meal intake review, and bowel review. The physical assessment is negative; no new medications have been added and all have a supporting diagnosis; his meal intake has been steady around 50% to 75% for all three meals; and he has been having regular, large bowel movements. Mr. Jones has (and is wearing) corrective eyeglasses, and he responds when his name is called.

Change the People: Next, the nurse uses the EdFED scale and observes several mealtimes over the course of the day. The nurse also observes the staff offering spoon-feeding assistance off and on while standing beside Mr. Jones at the table. When spoon-feeding assistance is provided, she observes Mr. Jones clamping his mouth shut and turning his head away when offered some food items. Some staff members offer him a sip of water with a straw when this behavior occurs, and the meal resumes; other staff interpret these behaviors as "refusing," and they walk away. If staff are not actively assisting him to eat, he does not sustain his attention to the meal, and verbal cues being used by staff in passing are ineffective. *Change the Place:* During the meal observations, the nurse also notes that several staff members enter and exit the room frequently. When a staff member catches Mr. Jones' attention, it takes additional time to get him refocused on his meal. The tables are set with contrasting place mats, and the noise level is kept to a minimum.

In addition to this assessment information, the nurse also consults the interdisciplinary team to decide what options would be available for improving Mr. Jones' meal intake. To assess his swallowing abilities, a speech and language pathologist conducts a bedside swallowing study. The study reveals no apparent pathology with his physiological swallowing function, but a mechanical soft diet is recommended because he is not able to cut his own food. Occupational therapy notes Mr. Jones has adequate upper extremity range of motion and moderate skill finger ability for self-feeding and recommends using adaptive equipment to help him independently hold his utensils owing to limited dexterity and fine motor control to hold a regular utensil. The dietary manager reviews food preferences with Mr. Jones' son, and adjustments are made to foods served to him to also include finger foods when possible.

With the *Change the Person* interventions recommended by the therapy departments in place (modified texture, adaptive equipment, food preferences), the nurse and CNA work collaboratively to provide meal assistance. *Change the People:* After initial attempts to verbally encourage independent feeding are not successful, the nurse and CNA begin trying the Handfeeding techniques to determine which would be most appropriate for Mr. Jones given his current ability. The CNA provides Mr. Jones with his adaptive utensil, which he is able to hold. Using the Over Hand technique, she begins to guide the utensil toward his face. During use of this technique, Mr. Jones begins to push the assistance away, but he is unable to complete the feeding cycle on his own and eat his food. In the next attempt to provide assistance, the CNA holds his utensil and uses the Under Hand feeding technique. Mr. Jones seems to like this technique and pulls the CNA's hand toward his mouth to eat his food. After a few cycles of Under Hand, Mr. Jones clamps his mouth shut and turns his head away. The nurse encourages the CNA to offer a sip of water at this point and notes this behavior occurs when he is offered carrots. Mr. Jones takes several sips of water. The CNA adds a little bit of sugar to the carrots and resumes providing assistance with the Under Hand feeding technique. When offered carrots again, Mr. Jones eats them. The CNA continues to respond to his feeding behaviors by offering some more food and then fluids, and Mr. Jones consumes 100% of his meal and fluids. *Change the Place:* A brief in-service is held with staff to praise use of contrasting place mats in the dining room and minimizing noise. Staff are encouraged to try to limit the traffic in and out of the dining room, as it is a distraction for the residents with dementia.

The effective strategies identified are added to his care plan. Over the next several weeks, Mr. Jones improves his meal intake to 75% to 100% consistently, and the staff are able to transition from Under Hand assistance to Over Hand assistance, and he regains the ability to self-feed part of his meal. As his nutritional status improves, he makes gains with his rehabilitation therapy. His functional and cognitive status return to baseline prior to the hospitalization for the fall. The social worker collaborates with the son and prior community support is available, and Mr. Jones returns home with his son.

SUMMARY

Mealtimes spent with family and friends are an integral part of life, and dementia can impact dignity and quality of life by slowly eroding the ability to eat independently. When caregivers understand some of the unique challenges this disease brings to the table, they are able to promote independence and tailor assistance to the individual. Caregivers who provide verbal, visual, and sensorimotor cues with the Handfeeding techniques will increase meal intake, allowing an opportunity for a person with dementia to understand our intentions as caregivers when language ability is lost. Given that what works during one meal may not work during another, the C3P Model provides a problem-solving framework to guide caregivers in adapting care strategies. Supportive Handfeeding offers a novel addition to the feeding assistance repertoire and allows caregivers to assist a person to eat in a way that promotes relationship, while optimizing food intake, quality of life, and dignity.

NURSING STANDARD OF PRACTICE

Protocol 29.1: Assessment and Management to Optimize Mealtimes in Dementia

I. GOAL

To maintain or improve nutritional intake during mealtimes and provide a quality mealtime experience that fosters dignity and maximum independence in eating, while respecting personal preferences and cultural/social aspects, for as long as possible.

II. OVERVIEW

Guiding Principles

A. Adequate intake of nutrients is necessary to maintain physical and emotional health.
B. Mealtimes are critical to socialization as well as maximizing nutritional intake; therefore, mealtime rituals, cultural norms, and food preferences will be observed to the extent possible.
C. Caregivers must be aware of sensory changes that occur in dementia and adapt care to include verbal, nonverbal (visual), and sensorimotor cues to optimize meal intake.
D. Persons should be encouraged to self-feed as long as possible, and level of support should be adjusted to compensate for the person's ability through Handfeeding techniques.
E. As persons require more assistance with eating, dignity will be maintained.
F. The quality of mealtime interactions is an indicator of quality of life and care provided to individuals.

III. BACKGROUND

A. Definitions

Basic

1. Feeding is "the process of getting the food from the plate to the mouth. It is a primitive sense without concern for social niceties" (Katz et al., 1970, p. 23).
2. Eating is "the ability to transfer food from plate to stomach through the mouth" (Katz et al., 1970, p. 23). Eating involves the ability to recognize food, the ability to transfer food to the mouth, and the phases of swallowing.
3. Dysphagia is "an abnormality in the transfer of a bolus from the mouth to the stomach" (Groher, 1997, p. 2).

Impact of dementia on independent meal management

(*continued*)

Protocol 29.1: Assessment and Management to Optimize Mealtimes in Dementia (*continued*)

Cognition

1. Attention and executive function are impaired. As it relates to eating, the person with dementia may have difficulty staying focused on the meal and initiating and maintaining self-feeding until the meal is consumed.
2. Agnosia is the inability to recognize familiar items when sensory cuing is limited. As it relates to feeding, a utensil (e.g., spoon or fork) is not recognized as an object for moving food from the plate to the person's mouth.
3. Aphasia is the inability to communicate effectively, and may be receptive or expressive. As it relates to feeding, spoken language may not be spoken or understood.

Function

4. Apraxia is an inability to carry out voluntary muscular activities related to neuromuscular damage. As it relates to eating and feeding, it involves loss of the voluntary stages of swallowing or the manipulation of eating utensils.
   a. "Skill fingers" ability: The person with dementia possesses the fine motor skill to use the first two fingers and thumb to hold and manipulate the utensil.

Handfeeding Techniques

For all techniques, the feeding assistant assesses the person with dementia for (a) skill finger ability and (b) upper extremity range of motion. Handfeeding technique use is in response to these abilities, which may fluctuate from meal to meal and day to day. Feeding assistants sit on the dominant side of the person with dementia, place their hand on the person's shoulder for touch cue, and provide feeding assistance through the middle of the person with dementia's body (self-feeding is naturally delivered through the body's midline).

NOTE: Direct Hand should be used last, and only when necessary. It is the least engaging technique for a person with dementia and can create excess disability if used when the person with dementia can still engage in the act of eating.

1. Over Hand: The person with dementia still possesses the fine motor skill needed to hold the utensil. The caregiver puts his/her hand *over* the hand of the person with dementia and guides it toward the individual's mouth. The person being assisted is active in the process, but may misinterpret the assistant as controlling and push assistance away (Batchelor-Aselage et al., 2015).
2. Under Hand: The person with dementia no longer possesses the fine motor skill needed to hold the utensil, so the caregiver holds the fork or spoon, and places his or her hand *under* the hand of the person with dementia. From the perspective of the person with dementia, this type of assistance may convey a feeling of control over the movement and provides fine motor assistance when it no longer exists (Batchelor-Aselage et al., 2015).
   a. Modify technique if person with dementia has limited upper extremity range of motion.
3. Direct Hand: The caregiver does all of the work: The caregiver holds the fork or spoon and moves food from plate to mouth; the person being assisted is passive in the interaction (Batchelor-Aselage et al., 2015).
   a. Modification: The caregiver using this technique should ensure visual cues are being received by the person with dementia through eye contact with food and/or the person opening his or her mouth before putting it in.

For a video demonstration depicting the three techniques and modifications, please visit the following website: http://melissabphd.com/nosh (Batchelor-Murphy, 2018)

B. Etiology

Mealtime difficulties Can have multiple causes from sensory, cognitive, functional, psychological, and iatrogenic origins. Health professionals need to consider multiple etiologies and not assume that difficulties are related only to increased confusion from a cognitive decline.

1. Sensory/Cognitive: Changes related to Alzheimer's disease and related dementia, including loss of peripheral vision, agnosia, and aphasia; Parkinson's disease; amyotrophic lateral sclerosis; stroke.
2. Functional: Changes related to Alzheimer's disease and related dementia, including apraxia; Parkinson's; stroke; deconditioning, including loss of upper extremity range of motion, strength, and/or endurance.
3. Psychological/Physiological: Depression, anxiety, constipation, infection.
4. Iatrogenic: Lack of adaptive equipment; use of physical restraints that limit the ability to move, position, or self-feed; improper chair or table surface, or discrepancy of chair to table height; use of wheelchair in lieu of table chair; being assisted to eat while lying in bed; use of disposable dinnerware, especially for patients with cognitive or neuromuscular impairments.

(*continued*)

Protocol 29.1: Assessment and Management to Optimize Mealtimes in Dementia (*continued*)

IV. PARAMETERS OF ASSESSMENT

A. Physical examination
   1. Look for reversible causes of low meal intake: Pain? Constipation? Infection?
   2. Psychological factors: Depression? Anxiety?

B. Meal observation
   1. Cognitive challenges: Able to initiate eating? Able to maintain attention to the meal? Behaviors that may indicate sensory deficit (e.g., reaching across table to eat another person's food may indicate decreased peripheral vision and inability to see meal/meal tray directly in front of them).
   2. Functional challenges: Self-feeding ability versus response to Handfeeding assistance? Trouble with utensils?
   3. Feeding behaviors: EdFED scale: Observe a few mealtimes at different times of the day using the EdFED scale to examine the presence of feeding behaviors and possible meaning of behavior (Watson, 1996):
      a. Turning head away, clamping mouth shut: Are these behaviors indicating a dislike of food offered, or desire for fluids at that moment? When choice is honored, does meal intake continue?
      b. Refusing to open mouth/not swallowing/allowing food to drop out of mouth: Does speech therapy need to evaluate swallowing problem? Dental consult?
      c. Spillage of food: Does person need stabilization of utensils with Over Hand or Under Hand feeding technique(s)?
      d. Spitting food out: Spits food into hand? Is it related to the food taste, temperature, or texture?
   4. Dysphagia: Coughing? Not swallowing food? Involve speech therapy, or observe for optimized cueing by feeding assistants.
   5. Wandering/Elopement from dining room: Timing of tray delivery? Finger food while walking, rather than making person sit at the table?

C. Care record review
   1. Medication reconciliation: Any new or missing medication? Medications given only for current medical diagnoses?
   2. Review recent lab values and urinalysis
   3. Patterns of intake and output:
      a. Meal intake record for patterns of increased or decreased intake. Clinical investigation should occur to determine underlying cause, as these patterns may indicate:
         i. Acute illness/onset of infection (e.g., meal intake decreased few days prior)
         ii. Daily patterns of meal intake (e.g., breakfast always 100%, dinner 25%).
      b. Review bowel movement records and auscultate for bowel sounds: look for patterns of 3 days with equivalent of a "large" bowel movement.
         i. Constipation will affect appetite. A "large" bowel movement is equivalent to the length of the lower arm, from elbow to fist (the length of the colon). Daily "small" bowel movements do not empty the colon, resulting in constipation.

V. NURSING INTERVENTIONS

A. Change the Person
   1. Allow time for rituals before meals (e.g., handwashing and toilet use); dressing for dinner; saying blessing of food or grace, if appropriate.
   2. Observation of religious rites or prohibitions observed in preparation of food or before meal begins (e.g., Muslim, Jewish, Seventh-Day Adventist; consult pastoral counselor or family as needed).
   3. Cultural or special cues: family history, special holiday occasions, especially rituals surrounding meals

(*continued*)

Protocol 29.1: Assessment and Management to Optimize Mealtimes in Dementia (*continued*)

4. Preferences about end-of-life decisions regarding withdrawal or administration of food/fluids in the face of incapacity, or request of designated healthcare proxy; ethicist or social worker may facilitate process.
5. Develop interdisciplinary care plan for any chronic, treatable conditions such as constipation, depression, or anxiety that may impact meal intake.

B. Change the People
1. Provide an adequate number of well-trained staff.
2. Deliver an individualized approach to meals, including choice of food and, tempo of assistance.
3. If meal patterns indicate one meal eaten better than other (100% breakfast intake, 25% dinner), provide double meal portions for the preferred meal.
4. Position of caregiver relative to older adult: caregiver seated beside older adult, on older adult's dominant side; eye contact; older adult able to see facial expressions and feeding behaviors emulated by the caregiver with visual cueing.
5. Self-feeding: Encouragement to self-feed with multiple methods based on functional ability; allow time for person to complete task, rather than provide assistance to minimize time.
6. Cueing:
   a. Verbal: Short statements of simple commands to direct meal behavior (e.g., here is your corn, open your mouth, swallow the food).
   b. Visual: Mimic behavior you want person to do (e.g., pretending to move food from plate to food to imitate eating).
   c. Sensorimotor: Using Handfeeding techniques with modifications based on person's cognitive, sensory, and functional abilities.
7. Mealtime rounds: Interdisciplinary team to examine multifaceted process of meal service, environment, and individual food preferences.

C. Change the Place
1. Odor: Food prepared in area adjacent to or in dining area. The smell and sounds of food being prepared can facilitate understanding of impending mealtime and stimulate appetite.
2. Adaptive equipment: Available, appropriate, and clean; caregivers and/or older adult knowledgeable in use; occupational therapist assists in evaluation.
3. Noise level: Environmental noise from music, caregivers, and television is minimal; personal conversation related between person and caregiver is encouraged.
4. Music: Pleasant, preferred by patient.
5. Light: Adequate and nonglaring versus dark, shadowy, or glaring.
6. Dining or patient room: Encourage the older adult to eat in the dining room to increase food intake, personalize the dining room; no treatments or other activities occurring during the mealtime; no distractions.
7. Tableware: Use of standard dinnerware (e.g., glasses, cups, saucers, flatware) versus disposable tableware and bibs.
8. Contrasting background/foreground: Use contrasting background and foreground colors with minimal design to aid person with decreased vision.
9. Furniture: Older adult seated in stable armchair; table of appropriate height versus eating in wheelchair or in bed.

VI. EVALUATION/EXPECTED OUTCOMES

A. Change the Person
1. Corrective and supportive strategies reflected in plan of care.
2. Quality-of-life issues emphasized in maintaining social aspects of dining.
3. Culture, personal preferences, and end-of-life decisions regarding nutrition respected.

(*continued*)

Protocol 29.1: Assessment and Management to Optimize Mealtimes in Dementia (*continued*)

B. Change the People
   1. System disruptions at mealtimes minimized.
   2. Family and staff informed and educated to patient's special needs to promote safe and effective meals.
   3. Maintenance of normal meals and adequate intake for the patient reflected in care plan.
   4. Competence in diet assessment; knowledge of and sensitivity to cultural norms and preferences for mealtimes reflected in care plan.

C. Change the Place
   1. Documentation of nutritional status and eating and feeding behavior meets expected standard.
   2. Alterations in nutritional status; eating and feeding behaviors assessed and addressed in a timely manner.
   3. Involvement of interdisciplinary team (geriatrician, advanced practice nurse, dietitian, speech therapist, dentist, occupational therapist, social worker, pastoral counselor, ethicist) appropriate and timely.
   4. Nutritional, eating, and/or feeding problems modified to respect individual preferences and cultural norms.
   5. Adequate number of well-trained staff who are committed to delivering knowledgeable and individualized care.

VII. FOLLOW-UP MONITORING

A. Providers' competency to monitor eating and feeding behaviors.
B. Documentation of eating and feeding behaviors.
C. Documentation of care strategies, and follow-up of alterations in nutritional status and eating and feeding behaviors.
D. Documentation of staffing and staff education; availability of supportive interdisciplinary team.

ABBREVIATION

EdFED Edinburgh Feeding Evaluation in Dementia

Disorders of Sleep in the Older Adult*

30

Jonna L. Morris, Lynn Baniak, Michelle L. Klimpt,
Eileen R. Chasens, and Grace E. Dean

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify common sleep disorders in the older adult.
2. Describe the signs, nighttime and daytime symptoms, and usual treatments for primary sleep disorders: obstructive sleep apnea (OSA), restless legs syndrome (RLS), insomnia.
3. Discuss the bidirectional relationships of chronic illness, medications, and acute hospitalization with sleep.
4. Provide nursing care that incorporates sleep-hygiene measures and consistent ongoing treatment for existing sleep disorders.
5. Educate patients and families about sleep disorders and sleep-hygiene measures.

OVERVIEW

Many factors can affect nighttime sleep and result in daytime sleepiness in older adults. These include psychological disorders, symptoms of chronic illnesses (e.g., pain), medication side effects, environmental factors, and lifestyle preferences. Problems with sleep can result from age-related changes in chronobiology and sleep disorders. In older adults, the most common primary sleep disorders are obstructive sleep apnea (OSA), restless legs syndrome (RLS), and insomnia. The extent to which changes in sleep patterns experienced by older adults are caused by normal physiological alterations, pathological events, sleep disorders, or poor sleep hygiene remains unclear. Hospitalization and institutionalization can also interfere with sleep quality or quantity. There are many effective treatments for sleep disorders, but the first step is to identify their cause and then to quantify and aggressively treat the condition in the older adult. This chapter outlines an overview of sleep pathophysiology, sleep disorders, and outcomes in older adults; describes how to assess them; and provides interventions to improve their sleep.

PHYSIOLOGICAL CHANGES IN SLEEP THAT ACCOMPANY AGING

Normal changes in sleep that occur as part of human development and lifestyle choices must be differentiated from pathological sleep conditions, which are common among older adults. The habitual sleep–wake pattern is mediated by the endogenous circadian pacemaker, located in the suprachiasmatic nucleus, along with exogenous environmental cues and a homeostatic need for sleep (Carskadon &

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

Dement, 2017). The propensity of older adults to get sleepy early in the evening and wake up earlier in the morning than in their younger years has been attributed to both an advanced phase circadian rhythm and an increased homeostatic sleep drive (Bliwise & Scullin, 2017). Although older adults require as much sleep as younger adults, older adults may divide their sleep between nighttime slumber and daytime naps, rather than a single consolidated period.

Additionally, alterations in *circadian activity rhythms* accompany aging and include changes in patterns for sleep–wake cycles, including decreases in amplitude, weakening of sleep–wake patterns, and decreased sensitivity to phase-resetting signals, such as light or sleep medications (Tranah, Stone, & Ancoli-Israel, 2017). Changes in *sleep architecture* associated with normal aging include increased difficulty in falling asleep, poorer sleep quality with decreased sleep efficiency (SE), more time awake after sleep onset, increased "light" sleep (stages 1 and 2 sleep), and decreased quantity and amplitude of restorative "deep" slow-wave sleep (stages 3 and 4; Bliwise & Scullin, 2017).

BACKGROUND AND STATEMENT OF THE PROBLEM

The Institute of Medicine has reported that 50 to 70 million Americans are affected by chronic disorders of sleep and wakefulness. Recent data from the Behavioral Risk Factor Surveillance System (BRFSS), conducted by the Centers for Disease Control and Prevention (CDC), found that among community-dwelling persons older than 65 years, over a quarter (26.3%) reported sleeping, on average, less than 7 hours in a 24-hour period (Liu et al., 2016). Data from the 2005 to 2008 National Health and Nutrition Examination Survey (NHANES) show that 32% of persons older than 60 years (n = 3,716) slept less than 7 hours per night on weekdays or workdays (CDC, 2011). Too short sleep duration (fewer than 6 hours) and too long sleep duration (more than 8 hours) in older adults are both associated with higher mortality risk (Ferrie et al., 2007). Rates of insomnia disorders in older adults are estimated at 5%, and apnea disorders are at 20% or higher (Gooneratne & Vitiello, 2014). Recently, problems of sleep duration and sleep disorders have been found to be associated with cognitive impairment in the older adult (Givens, Mezzacappa, Heeren, Yaffe, & Fredman, 2014). Further, some sleep disorders are more common in patients in acute and chronic care settings. Ancoli-Israel et al. (1991) and Ancoli-Israel, Kripke, and Mason (1987) studied only persons older than 65 years and found undiagnosed sleep apnea in 24% of those living independently in the community, in 33% of those in acute care settings, and in 42% of older adults in nursing home settings. Finally, older women report more subjective complaints of sleep disturbance than older men (Grandner et al., 2012).

CONSEQUENCES OF SLEEP DISORDERS

Excessive Daytime Sleepiness

Excessive daytime sleepiness in the older adult is not normal, and it results in decreased alertness, delayed reaction time, and reduced cognitive performance (Ohayon & Vecchierini, 2002). The Cardiovascular Health Study documented excessive sleepiness in 20% of subjects older than 65 years (n = 4,578; Whitney et al., 1998). Nevertheless, recent studies suggest that healthy adults from midlife to around 75 years of age are less likely to be sleepier than younger adults (Grandner et al., 2012). Although older adults may be more likely to nap, possibly because they have the opportunity to do so, no causal relationship between napping and excessive daily sleepiness has been established in this population (Grandner et al., 2012). Excessive daytime sleepiness is significantly associated with a higher likelihood of disability, increased risk of mortality, and substantially shorter disability-free life expectancy at age 60 and higher levels of depressive symptomatology (Anderson et al., 2014). It is also predictive of cognitive decline in the older adult (Jaussent et al., 2012). In one study, daytime sleepiness was the only sleep symptom associated with mortality, incident cardiovascular disease morbidity and mortality, myocardial infarction, and congestive heart failure, particularly among women (Newman et al., 2000).

Impaired Mood

Good sleep quality is a prerequisite for maintaining mental health, and research indicates that sleep disorders and poor sleep quality are often comorbidities of depression and impaired mood (Baglioni et al., 2016; Buysse, 2014). In addition, sleep quality has been identified to be a significant predictor of severe depression in a sample of elders (Rashid & Tahir, 2015). In older women, reports of poor sleep and objectively fragmented sleep at baseline indicated greater odds of worsening depressive symptoms 5 years later (Maglione et al., 2012). Healthcare practitioners should routinely screen for both sleep disorders and impaired mood and depression.

Falls

A significant association between sleep disturbances and falls in older adults exists, especially in individuals who have trouble staying asleep because of nocturia or

urinary urgency (Helbig et al., 2013). Although there is a well-documented relationship between nocturia and high risk of falls, past assumptions that "rushing to the bathroom" at night contributes to the risk of falls may not be correct. Instead, urge incontinence at night (as a symptom of nocturia) and risk of falls may instead be symptoms of both frailty and overall physical decline or cognitive impairment (Gibson et al., 2018). Thus, while nocturia has multiple causes, it may also be a symptom of frailty in the older patient and should not be overlooked as a simple nuisance. Two common fall risk assessment scales used in hospitals do not include questions on sleep disturbances (Hendrich, Bender, & Nyhuis, 2003; Morse, Black, Oberle, & Donahue, 1989), suggesting that frailty and nocturia may be missed as fall risk factors in acute care hospital patients.

PRIMARY SLEEP DISORDERS

Obstructive Sleep Apnea

OSA is a condition in which intermittent pharyngeal obstruction causes cessation of respiratory airflow (apneas) or reductions of airflow (hypopneas) that last for at least 10 seconds. This results in a microarousal that restores upper airway patency, permitting breathing and airflow to resume. According to the American Academy of Sleep Medicine (Fick et al., 2019) Task Force, OSA is diagnosed when these events occur at a rate of greater than 5 per hour of sleep and is accompanied by daytime sleepiness and impaired daytime functioning. It is common for patients with severe symptoms to experience multiple arousals during the night. These multiple arousals severely fragment sleep, preventing the deep sleep (stages 3 and 4) and rapid-eye movement (REM) sleep necessary for healthy mental and physical functioning (Yue, Bardwell, Ancoli-Israel, Loredo, & Dimsdale, 2009).

Age-related risk factors for OSA in older adults include an increased prevalence of overweight and obesity. Conversely, age-dependent risk factors include increased collapsibility of the upper airway, decreased lung capacity, altered ventilatory control, decreased muscular endurance, and altered sleep architecture (Edwards et al., 2014). Treatments for OSA depend on the contributing pathology and patient preference and include nocturnal positive airway pressure, surgical procedures designed to increase the posterior pharyngeal area, oral appliances, and weight reduction when obesity is a contributing factor. Nasal continuous positive airway pressure (CPAP) therapy, which is highly effective when individually titrated to eliminate apneas and hypopneas, is currently the gold standard for treating OSA (Freedman, 2017). Older adults tolerate CPAP therapy, with patterns of compliance similar to that of middle-aged adults (Weaver & Chasens, 2007). Although oral appliances offer a low-tech treatment option, they require a stable dentition that may be problematic for persons with extensive tooth loss or dentures.

OSA and Cardiovascular Disease

OSA is common in adults with cardiovascular disease and is associated with increased incidence and progression of coronary heart disease, heart failure, stroke, and atrial fibrillation, as well as with coronary and cerebrovascular morbidity and mortality. In recent years, trials have begun to examine the effect of CPAP on cardiovascular outcomes in older adults. Large-scale randomized controlled trials have demonstrated a beneficial effect from the treatment of OSA with CPAP therapy on excessive daytime sleepiness, quality of life, and mood, as well as intermediate cardiovascular end points such as systolic and diastolic blood pressure. Possibly because of low to modest levels of CPAP adherence, improvement in cardiovascular mortality has not been shown (McEvoy et al., 2016; McMillan et al., 2014).

Insomnia

Chronic Insomnia Disorder, defined as trouble initiating or maintaining sleep for at least three times per week for 3 months that is associated with daytime consequences despite adequate opportunity to sleep (Sateia, 2014), is one of the most common sleep disturbances in older adults (Carney et al., 2012). Clinical and population science studies have revealed U.S. prevalence rates of 5% to 31% for chronic insomnia disorder in older adults (Gooneratne & Vitiello, 2014; Mallon, Broman, & Hetta, 2000). Consequences of insomnia, if left untreated, include an increased risk for developing depression (Jaussent et al., 2011), heart disease (Laugsand, Vatten, Platou, & Janszky, 2011), diabetes (Gottlieb et al., 2005), metabolic syndrome (Troxel et al., 2010), prostate cancer (Sigurdardottir et al., 2013), and cognitive impairment (Yaffe, Falvey, & Hoang, 2014). Chronic insomnia can result in a conditioned response of anxiety and arousal at bedtime in anticipation of difficulty falling asleep; this may prompt the use of hypnotic medications, over-the-counter (OTC) drugs, or alcohol. Although the use of hypnotics may produce short-term relief, they also affect sleep architecture and consequently lead to deterioration of sleep quality. The cycle of dependency and substance abuse is a potential problem in this age group (see Chapter 24, Reducing Adverse Drug Events in the Older Adult). The 2019 Beers Criteria® recommend avoiding medications commonly prescribed for insomnia, such as benzodiazepines and other hypnotic medications, in view

of increased risk of falls and daytime confusion in the older adult (Fick et al., 2019).

Risk factors for insomnia include older adult age, female sex, comorbidities, and lower socioeconomic status, measured by education, employment, and income (Olfson, Wall, Liu, Morin, & Blanco, 2018). Both the cause and duration of insomnia should inform the choice of treatment. For example, insomnia associated with a psychological origin, such as depression or anxiety, is best treated from that perspective. If pain is affecting sleep, pain management should be addressed first, and strategies to promote sleep onset should be added secondarily. Short-term pharmacotherapy may be appropriate if insomnia is situational and of recent onset. When insomnia has been "learned" and the behavior becomes chronic, behavioral interventions are most appropriate. Behavioral treatments for insomnia include stimulus control, progressive muscle relaxation, paradoxical intention, sleep restriction, biofeedback, and multifaceted cognitive behavioral therapy (Morin, Colecchi, Stone, Sood, & Brink, 1999; Trauer, Qian, Doyle, Rajaratnam, & Cunnington, 2015; Zachariae, Lyby, Ritterband, & O'Toole, 2016). Data show that 70% to 80% of patients benefit from behavioral therapies and that improvement in sleep is often sustained for a minimum of 6 months after treatment.

Restless Legs Syndrome

RLS is a neurological condition that is characterized by the irresistible urge to move the legs. It is usually associated with disagreeable leg sensations that become worse during inactivity and often interferes with initiating and maintaining sleep (Rye & Trotti, 2012). As a secondary condition, this movement disorder can be caused by iron deficiency anemia, uremia, neurological lesions, diabetes, Parkinson's disease, or rheumatoid arthritis, or it can be a side effect of certain drugs (e.g., tricyclic antidepressants, serotonin reuptake inhibitors, lithium, dopamine blockers, xanthines). Periodic leg movement disorder (PLMD) is a similar condition (Rye & Trotti, 2012), but it is characterized by involuntary flexion of the leg and foot that produces microarousals or full arousals from sleep that interfere with achieving and maintaining restorative slow-wave sleep (stages 3 and 4). Although the etiology and associated mechanism of this specific movement disorder are not well defined, this condition has been linked to metabolic, vascular, and neurologic causes (Claman et al., 2013). Dopaminergic drugs are the most effective agents for treating RLS and PLMD as well as opioids, benzodiazepines, anticonvulsants, adrenergics, and iron supplements (Ancoli-Israel & Martin, 2006; Gamaldo & Earley, 2006). A study of adults with RLS (n = 78; mean age 43.79 ± 6.04) and matched (sex, BMI) normal controls (n = 123; 44.75 ± 9.59) found a significant association (p < .001) between vitamin D insufficiency and RLS severity (Wali et al., 2018). Vitamin D, recognized as important to reduce the risk of osteoporosis and fractures, is frequently low in older adults because of decreased sunlight and milk consumption (Mosekilde, 2005). Unfortunately, there is a lack of data to determine the association of vitamin D level and RLS symptoms in older adults or whether treatment of deficiency results in improved symptoms.

REM Behavior Disorder

REM Behavior Disorder (RBD) is a parasomnia that is characterized by a loss of muscle atonia during the REM stage of sleep. It is prevalent in approximately 0.5% of the population, usually men, beginning between ages 40 and 70 (Boeve, 2010). In this disorder, the sleeper may kick, punch, shout, jump, or act out any other scenarios of a dream and may cause injury to the bed partner (Boeve, 2010). The activity occurs during the REM stages of sleep, particularly in the hours just before wakening. People with narcolepsy, periodic limb movement disorder, and sleep apnea are at higher risk for the disease, and it is often associated with Parkinson's disease and other neurodegenerative disorders (Boeve, 2010). Certain medications such as selective serotonin reuptake inhibitors (SSRIs) and selective noradrenergic reuptake inhibitors (SNRIs) have also been implicated. RBD is diagnosed using polysomnography (PSG) with video monitoring (Boeve, 2010). Several questionnaires have been developed for use in situations when PSG is not available (You et al., 2017). In patients without OSA or cognitive impairment, medications such as clonazepam and melatonin have been found to be affective treatments. Until an effective medication is found for the patient, it is necessary to protect the bed partner. Various strategies can include oven mitts tied around the patient's hands, use of sleeping bags to keep the patient in a cocoon, and use of homemade barriers or even separate bedrooms (Boeve, 2010). Nurses working night shifts at the hospital should assess for these behaviors and plan to protect roommates or others accordingly.

SECONDARY CAUSES OF IMPAIRED SLEEP

Alzheimer's Disease or Other Neurological Disease

Sleep problems, such as changes in sleep architecture and an increased incidence of OSA, are prevalent among persons with Alzheimer's disease (Harper, 2010). A recent

meta-analysis found that persons with Alzheimer's disease have a five-fold increased risk of presenting with OSA compared to age-matched controls and that about 50% experience OSA after their initial Alzheimer's diagnosis (Emamian et al., 2016). The known relationship between sleep problems and reduced cognition is complex and dependent on multiple factors. Persons with Alzheimer's disease demonstrate a pattern of decreased slow-wave sleep similar to older adults with normal aging. However, patients with Alzheimer's disease also exhibit greatly reduced rapid-eye movement (REM) sleep and decreased stability of their circadian sleep–wake cycle that is not part of normal aging. Frequently, before the diagnosis of a permanent neurocognitive disorder, an evaluation of sleep is performed to rule out impaired cognitive functioning resulting from a potentially treatable sleep disorder. The link between sleep and cognitive and functional impairment is consistent with the 2005 to 2008 NHANES results, which demonstrated a greater rate of sleep-related problems with concentration, memory, and activities of daily living among women (CDC, 2011). Better sleep consolidation, thought to be protective, substantially reduced the negative impact of the ε4 allele on the incidence of Alzheimer's disease risk and has led investigators to conclude that interventions to enhance sleep consolidation should be studied as potential means to reduce the risk of Alzheimer's disease in APOE ε4+ individuals (Lim, Kowgier, Yu, Buchman, & Bennett, 2013).

Although OSA could be a consequence of events in the progression of Alzheimer's disease, alternatively, it may initiate Alzheimer's disease pathogenesis (Bubu et al., 2017; Lutsey et al., 2018). Studies evaluating Alzheimer's disease-specific cerebrospinal fluid biomarkers support OSA as a potential risk factor for Alzheimer's disease pathology (Liguori et al., 2017; Osorio et al., 2014; Sharma et al., 2018). A recent 2-year follow-up study of cognitively normal nondepressed community-dwelling adults between the ages of 55 and 90 investigated longitudinal associations between OSA and increased risk of Alzheimer's disease pathology (Sharma et al., 2018). The data showed that older people affected by OSA have higher levels of amyloid beta, the peptides involved in the brain plaque buildup that is a marker of Alzheimer's disease, and that the combination of sleep fragmentation and hypoxia as a result of OSA may be an underlying mechanism. Conversely, successfully treating OSA has been shown to delay the age of onset of mild cognitive impairment (Osorio et al., 2015) and to improve cognitive function in persons with Alzheimer's disease (Ancoli-Israel et al., 2008) and in those without (Kushida et al., 2012).

Polypharmacy

Painful chronic conditions, such as arthritis, or simply changing body position, may be painful enough to cause nighttime awakenings. Because older adults frequently have multiple medical conditions, they are also more likely to take OTC and prescription medications for symptom relief. However, many medications and nonprescription drugs (e.g., pseudoephedrine, alcohol, caffeine, and nicotine) interfere with sleep. Thus, healthcare providers must be acutely aware of which OTC medications and beverages can cause sleep problems. Symptom management must be balanced against preventing polypharmacy (Fick et al., 2019) in older adults to maintain sleep quality (Ancoli-Israel, 2005).

Nocturia

Nocturia, the need to void at night, is a common but burdensome problem for older adults. Seventy percent of adults over the age of 40 are estimated to void at least once per night, and approximately one third of these adults void two or more times per night (Madhu et al., 2015). While voiding once per night is commonly considered nonpathological, it is the increased frequency of nocturia, two or more nighttime voids, that results in sleep fragmentation, difficulty in returning to sleep, and may result in excessive daytime sleepiness or fatigue (Asplund, 2005; Cornu et al., 2012; Madhu et al., 2015). Factors associated with increased frequency of nocturia include reduced bladder capacity in women, enlarged prostate with urinary retention in men, use of diuretic medications, congestive heart failure, untreated OSA, and poor glycemic control in persons with diabetes (Madhu et al., 2015). It is often unclear whether the urge for urination causes the awakenings or whether some other cause of awakening led to the need for urination (Zeitzer, Bliwise, Hernandez, Friedman, & Yesavage, 2013). The nurse should always assess for nocturia in the older adult because it is an important risk factor for insomnia and reduced sleep quality and may be indicative of other serious medical disorders.

Sleep Disturbance During Hospitalization

As many as 22% to 61% of hospitalized patients experience impaired sleep (Redeker, 2000). Many older adults have primary sleep disorders (OSA, insomnia, RLS), and these conditions can become more pronounced or severe during acute illness and hospitalization. Sleep disorders may go unrecognized during a hospital stay, and thus patients may experience acute sleep deprivation concurrently with a medical crisis or surgical intervention. Additionally, sleep deprivation while hospitalized can also lead to poor

cardiovascular and metabolic effects, as well as delirium (Pilkington, 2013).

Protecting sleep and monitoring sleep quality should be routine elements of care in hospital settings (Young, Bourgeois, Hilty, & Hardin, 2008). There are three common environmental causes for sleep disruption in hospitals that are often overlooked by nursing staff: noise, light, and patient-care activities (Redeker, 2000). Further, anesthesia, cardiopulmonary disorders, and pain medications can inadvertently reduce the respiratory drive and lead to hypopneas and apneas. Pain medications typically administered postoperatively can affect alertness by causing excessive sedation, changes in sleep architecture, decreased REM sleep, nightmares, or insomnia. Pain and anxiety may also place older adult patients at increased risk for insomnia. Inadequate sleep impedes healing and recovery and may be associated with acute mental confusion in older adults (Young et al., 2008).

While sleep in hospitalized adults is a problem, it is generally recommended that nonpharmacological interventions should be the first line of therapy. Benzodiazepines as well as other hypnotic medications are on the Beers Criteria list identified by the AGS to avoid in older adults (Fick et al., 2019).

The sleep environment and the quality of patients' sleep can be improved in hospital settings if caregivers recognize the essential importance of sleep in illness and health. The American Academy of Nursing (2014) recommends that nurses should not wake patients for routine care unless the patient's condition necessitates it. As a standard practice, nurses should include a thorough sleep history (Exhibit 30.1) during admission to determine usual sleep patterns and/or symptoms of sleep disorders. Patients with OSA who use CPAP at home should be instructed to bring their machines with them to the hospital. Anticipatory and preventive pain management is also an important element of care to promote adequate sleep in the hospital setting (Young, Bourgeois, Hilty, & Hardin, 2009). Sleep-hygiene measures should be incorporated into nursing care routines during evening and night hours and also into care plans on every nursing unit. This includes simple practices, such as reducing light intensity, maintaining a quiet environment, and efficient delivery of patient care, to minimize sleep disruption. Enhancing the sleep environment in the hospitalized older adult may lead to better health outcomes.

ASSESSMENT OF SLEEP PROBLEMS

It is important to utilize appropriate screening tools to diagnose sleep disorders in older adults who do not present with symptoms. Although some sleep disorders are more common in older patients in both acute and chronic care settings, older adults may be vulnerable to disparities in the clinical evaluation for sleep disorders such as sleep apnea. In a nationally representative sample of adults 65 years and older (N = 1,052), a majority (56%) were found to be at risk for OSA, but only 8% of those individuals had been evaluated for OSA (Braley et al., 2018). Although OSA can only be diagnosed with a sleep study, the risk of OSA is frequently evaluated in adults using the Berlin questionnaire (Netzer, Stoohs, Netzer, Clark, & Strohl, 1999) or the Snore, Tired, Observed, Pressure, Body Mass Index, Age, Neck, Gender (STOP-Bang) Questionnaire (Chung et al., 2008). However, a study of older adults (n = 643; mean age of 65.6 years) found that the Berlin questionnaire was unable to accurately identify OSA in older adults (Sforza et al., 2011). The STOP-Bang, first developed to screen for OSA in persons scheduled for anesthesia, consists of eight questions and has sensitivity from 76% to 96%. The STOP-Bang may underestimate OSA in older women because men are automatically scored one point higher than women. The Insomnia in the Elderly Scale (IES) has been validated in persons aged 65 years and older. With only nine questions to be scored, it can easily be completed in less than 5 minutes and takes only a minute or 2 to assess (Navarro et al., 2013). The Functional Outcomes of Sleep Questionnaire (Weaver et al., 1997) is used to evaluate the impact of sleepiness on functional status, and the Pittsburgh Sleep Quality Index (Buysse et al., 1989) quantifies sleep quality over the past month. Many sleep clinicians use the Epworth Sleepiness Scale (ESS) to screen for sleepiness and track symptoms over the previous week during common activities such as sitting and reading, watching TV, or riding in a car. It is easy to administer and includes a scoring parameter to indicate the need for a medical evaluation (Johns, 1991), but recent research questions the validity of the ESS in older adults (Onen et al., 2013). Results of a study of independently living older adults (n = 104; age > 65 years) who affirmatively answered the question "Do you feel excessively sleepy during the day recently?" found that over half the participants could not answer at least one of the questions on the ESS and that only 25% had an abnormal ESS score. Therefore, although subjective questionnaires should be used to assist in the evaluation of sleep disorders in the older adult, the nurse needs to recognize that older adults may not be as aware of impaired sleep. The diagnosis of sleep disorders requires both an in-depth history (Exhibit 30.1) and an objective sleep evaluation in both younger and older adults.

EXHIBIT 30.1

Sleep History

Basic Sleep History Questions	Follow-Up Questions	Sleep Disorders to Consider
■ Do you have any difficulty falling asleep? ■ Are you having any difficulty sleeping until morning? ■ Are you having difficulty sleeping throughout the night? ■ Have you or anyone else ever noticed that you snore loudly or stop breathing in your sleep? ■ Do you find yourself falling asleep during the day when you do not want to?	■ What time do you usually go to bed? ■ What time do you fall asleep? ■ What prevents you from falling asleep? ■ Review intake of alcohol, nicotine, caffeine, all medications ■ Review of depressive symptoms: weight loss, sadness, or recent losses ■ How often do you waken? ■ How long are you awake? ■ Do you have any pain, discomfort, or shortness of breath during the night? ■ How many times do you void during the night? ■ What prevents you from falling back to sleep? ■ Are you sleepy or tired during the day? ■ Review risk factors (e.g., obesity, arthritis, poorly controlled illnesses) ■ Do your legs kick or jump around while you sleep? ■ Do you stay outdoors in natural daylight on most days?	■ Shift work/sleep schedule disorders ■ Psychophysiological insomnia ■ RLS ■ Psychiatric disorders ■ Substance/medications-related disorders ■ Depression ■ Insomnia ■ Medical causes of sleep disturbance ■ Obstructive sleep apnea ■ Functional impairment resulting from sleep disorder ■ PLMDs

PLMDs, periodic leg movement disorders; RLS, restless legs syndrome.

Polysomnography

In a sleep-laboratory setting, a complete evaluation of sleep is conducted using PSG that includes electroencephalogram (EEG), electromyogram (EMG), electrooculogram, respiratory effort, oxygen saturation, and electrophysiological cardiac aspects of sleep. Additional electrophysiological tests, such as the Multiple Sleep Latency Test, used to test for narcolepsy, are also used to quantify daytime sleepiness.

Actigraphy/Fitbit

Discordance between subjectively measured and objectively measured sleep outcomes are common. As such, actigraphy provides an objective assessment of sleep disorders such as insomnia (Dzierzewski et al., 2019; Kay, Buysse, Germain, Hall, & Monk, 2015). The AASM developed recommendations for the use of actigraphy to evaluate adults with sleep disorders using FDA-approved devices. These recommendations include using actigraphy to assess adults with insomnia, circadian rhythm disorders, in conjunction with sleep apnea test devices at home to estimate total sleep time. Additionally, the use of actigraphy is suggested to assess for suspected hypersomnolence disorders and suspected insufficient sleep syndrome (Smith et al., 2018). Although more people of all ages are utilizing multisensory wristbands for many purposes, it is important to note that although they do show promise in detecting sleep–wake states, more research to assess and evaluate sleep disorders in different scenarios (at home, for multiple nights, etc.) and specific populations (elderly) is needed (de Zambotti, Goldstone, Claudatos, Colrain, & Baker, 2018).

Sleep History for Nurses to Use With Hospitalized Patients

Hospitalization may represent a missed opportunity to screen patients for and identify underlying sleep disorders that may, in turn, be associated with poor health outcomes (Stewart & Arora, 2018). Although no particular sleep questionnaires have been validated for use in hospital settings, it is recommended that nurses assess all hospitalized patients for sleep disorders, and a brief sleep history can be obtained by using the questionnaire in Exhibit 30.1.

SLEEP HYGIENE

The best way to ensure good sleep quality is a lifestyle that promotes and ensures adequate sleep and rest. By maintaining a daily routine, sleep quality can be maximized and daytime fatigue and sleepiness minimized. Characteristics of a routine that have been found to be helpful are timing, frequency, and duration of activities (Zisberg, Gur-Yaish, & Shochat, 2010). Although humans have a natural drive to sleep, environment and habituation play an important behavioral role in sleep. Sleep hygiene, those practices that permit and promote sleep onset and sleep maintenance, have many behavioral aspects that require regular reinforcement to maintain good quality of sleep. Regardless of health status, sleep-hygiene practices and routines are as important for older adults as they are for children, adolescents, and other adults. Most important in the assessment of sleepiness is an evaluation of the patient's knowledge and application of sleep-hygiene measures (Box 30.1) that are also effective behavioral strategies to maximize, promote, and protect sleep.

BOX 30.1

Sleep-Hygiene Measures

- Use the bed only for sleeping or sex.
- Develop consistent and rest-promoting bedtime routines.
- Allow for adequate time in bed to obtain 7 to 8 hours of sleep.
- Maintain the same bedtime and waking time every day.
- Exposure to bright sunlight is desirable on awakening.
- On awakening, get out of bed slowly, no matter what time it is, to prevent postural hypotension.
- If awakened during the night, avoid looking at the clock; frequent time checks may heighten anxiety and hinder sleep onset.
- Avoid naps if they negatively affect nighttime sleep. Limit naps to 30 minutes' duration and time early in the afternoon.
- Sleep in a cool, quiet environment.
- If you cannot fall asleep after 15 or 20 minutes in bed, get up and go into another room, read, or do a quiet activity, using dim lighting, until you are sleepy again.
- Before bedtime, avoid the following:
  - Caffeine and nicotine after noon
  - Alcohol intake (more than three drinks)
  - Large meals or exercise 3 to 4 hours before bedtime
  - Emotional upset or emotionally charged activities, including television programs that are troubling

CBTI

Cognitive behavioral therapy for insomnia (CBTI), the recommended treatment for insomnia, improves sleep by restricting sleep to sleep needs and reestablishing positive associations while breaking negative ones between the sleep setting and sleep (Qaseem, Kansagara, Forciea, Cooke, & Denberg, 2016). CBTI components (e.g., sleep restriction, stimulus control, relaxation, cognitive restructuring, and sleep hygiene) are employed to reduce physiological and cognitive arousals (Schwartz & Carney, 2012). CBTI results in clinically significant, reliable, and durable improvements in sleep (e.g., sleep latency, nocturnal wake after sleep onset, early morning awakenings) in older adults (McCurry, Logsdon, Teri, & Vitiello, 2007). The comparative efficacy of Behavior Therapy, Cognitive Therapy, and CBTI in 188 individuals with chronic insomnia revealed that all treatment groups had significant improvements on measures of insomnia severity, nighttime sleep disturbances, and daytime functioning and that these improvements were generally sustained at 6-month follow-up (Harvey et al., 2014). Although effective, traditional CBTI has disadvantages, including the need for a trained therapist and significant time commitment on the part of the patient. Currently, a manualized version of brief behavioral treatment for insomnia is available for clinical use (Troxel, Germain, & Buysse, 2012).

Napping

Napping is common in older adults, and it is unclear whether it is beneficial for older adults or whether it is indicative of worse health and outcomes. Several studies with older adults found an association between napping behavior and increased weight gain, risk for diabetes, hypertension, and dementia (Han et al., 2016; Kowall et al., 2016; Leng et al., 2016). A cross-sectional study of community-dwelling older adults examined the independent association between nighttime sleep and daytime napping for all-cause mortality for 19 years from baseline. Increased mortality was associated in women sleeping more than 9 hours per night and in men napping 30 minutes or more during the day (Jung, Song, Ancoli-Israel, & Barrett-Connor, 2013). These results are akin to a recent systematic review and meta-analysis, which examined napping and all-cause mortality, finding that daytime napping of 30 minutes or more was associated with a significantly increased risk for all-cause mortality (RR 1.27; 95% CI 1.08–1.49; da Silva et al., 2016). However, data from a study by Devine and Wolf (2016) suggest that negative health outcomes may be associated with persons who nap and have poor nighttime sleep, whereas persons who had

infrequent naps or those with frequent naps but good nighttime sleep did not exhibit negative health consequences. In addition, a study of 2,974 persons 65 years and older found "moderate" nappers had better cognitive function compared to non-, short, or extended nappers (Li et al., 2017).

All of these studies were observational, and therefore causality or directionality between naps and health outcomes cannot be inferred. These conflicting findings suggest that healthcare providers need to personalize their recommendations about napping. While napping behavior in older adults with comorbid diseases may predict worse outcomes, naps may be required by an individual in order to function when excessively sleepy or fatigued to improve functional outcomes. Napping behavior may be discouraged in older adults who describe difficulty in initiating sleep so as to increase the sleep drive and improve their ability to fall asleep. Finally, napping behavior in the generally healthy person with good nighttime sleep may be a positive part of his or her health behavior and should be encouraged.

CASE STUDY 30.1

Ms. K stopped attending her weekly bingo night with her girlfriends, saying, "I just don't have the energy." Usually the ringleader, she had become more withdrawn from her friends and family. Work had also become a struggle for Ms. K, but she blamed it on poor sleep. Her daughter suggested that she may need professional help and encouraged her to make an appointment with her primary care provider.

Ms. K is a 67-year-old African American woman who is overweight (height, 62 inches; weight, 140 lbs; body mass index [BMI] 25.6). She is a lung cancer survivor. She is hypertensive and takes a variety of medications. She has a 53-pack-year history of smoking and currently smokes approximately three to 12 cigarettes per day because she is bored and lonely. She lives alone in a second-story apartment with a cat, although she states that she is a dog person. She reports that she stopped going to bingo night at the local fire station about 2 months ago. She said that she loved hanging out with her girlfriends but feels like it is such an effort now. She is a self-employed aide working in the home care setting.

Fatigue, irritability, and the inability to get going in the morning are her major complaints because they interfere with her ability to work and socialize. Ms. K worries when she goes out whether she will make it back home under her own power. She would like to stop smoking, but because of her poor energy level, she stays home and smokes. She can only work 4 hours per day and must take frequent rest periods because she becomes short of breath easily. She takes long naps and then cannot fall asleep at night. Her cat wakes her up frequently, too. She also becomes short of breath when climbing the stairs to her apartment.

Ms. K has severe fatigue and worries about her lack of nighttime sleep, which may be the result of comorbid insomnia related to her diagnosis of lung cancer and poor sleep hygiene. Ms. K often falls asleep watching TV with the cat, and then the cat wakes her up in the middle of the night and she cannot get back to sleep, tossing and turning, worrying about her poor sleep. She will then have a cigarette because she is bored. Although Ms. K has no bed partner, her daughter has stayed overnight and never reported to Ms. K about any loud snoring, gasping for breath, or breath holding. She also denies the occurrence of morning headaches. Because her sleep problem is interfering with her daytime functioning (e.g., ability to work), Ms. K warrants a referral to a sleep specialist. The self-limiting of her socialization and reports of boredom and loneliness suggest a need for depression screening.

The sleep specialist ordered an overnight portable screening for sleep apnea (e.g., ApneaLink) to rule out OSA, which is a common cause of daytime sleepiness. The results demonstrated that Ms. K does not have OSA (Table 30.1). A 14-day sleep-diary screening for insomnia revealed the following: SE = 62% (slept 240 minutes; in bed 390 minutes); sleep latency (SL) = 33 minutes; wake after sleep onset (WASO) = 117 minutes; naps = 84 minutes; ESS = 9.

TABLE 30.1
Results of Overnight Apnea Link to Rule Out OSA

Total recording time	274 minutes	Apnea/ Hypopnea Index	1.9/hours of sleep
Lowest O2 saturation	88%	Saturation less than or equal to 90%	10 minutes

Normal Sleep Values

SE greater than 85%; SL lower than 30; WASO lower than 30; ESS lower than 11; naps lower than 30

Ms. K was also referred for CBT for her insomnia. CBT for insomnia (CBTI) is now accepted as the standard of care for patients with insomnia regardless of etiology. CBTI consists of sleep restriction, stimulus control, relaxation, sleep–hygiene education, and cognitive therapy that focuses on dysfunctional sleep-related thoughts and unhelpful sleep behaviors that may exacerbate insomnia.

Ms. K returned to her primary care provider, who diagnosed her as having a major depressive episode and discussed further treatment options. Her insomnia is being managed with CBTI; it is improving, but not yet resolved. Therefore, an antidepressant medication with sedating side effects was indicated. Celexa, Lexapro, Paxil, and Zoloft were considered. Zoloft was eventually chosen, but knowing that there were other alternatives was appealing to Ms. K.

Diagnosis

Comorbid insomnia with major depressive episode

Treatment

CBTI—individual therapy

6-Month Follow-Up

While working with the CBTI therapist, who just happened to be a nurse practitioner, Ms. K's 14-day sleep-diary data improved: SE = 86% (slept 360 minutes; in bed 420 minutes); SL = 15 minutes; WASO = 45; naps = 36 minutes; ESS = 8. Although she is still taking naps, she is not taking them every day, and she is taking them earlier so that they do not interfere with her ability to fall asleep at bedtime. The cat is out of the bedroom, and she has started to volunteer at her local library and has rejoined her friends at bingo. She is still smoking but is now down to only three to five cigarettes per day. The nurse practitioner discussed how smoking is a stimulant that may increase insomnia and the importance of smoking-cessation programs. Ms. K declines to stop smoking completely at this time; she states she is "working at it on her own," but agrees to give up her bedtime cigarette. The nurse practitioner plans to continue to encourage sleep hygiene and smoking cessation on follow-up visits.

SUMMARY

No other group of healthcare providers watch more people sleep than nurses, and sleep disorders can affect all aspects of health and illness. Nurses must be able to identify, screen, and refer patients either at risk for or with symptoms of sleep disorders. Sleep medicine is a relatively new specialty, and many healthcare providers have had little preparation in the science of sleep. Nurses must also incorporate sleep-hygiene measures and actively address existing sleep disorders in care plans of older adults to ensure adequate sleep in all settings: acute care, primary care, long-term care, and at home. Failing to identify, diagnose, or treat excessive sleepiness and its underlying cause(s) can adversely affect the health and longevity of older adults.

NURSING STANDARD OF PRACTICE

Protocol 30.1: Disorders of Sleep in the Older Adult

I. GOAL

Older adults will maintain an optimal state of alertness while awake and optimal quality and quantity of sleep during their preferred sleep period.

II. OVERVIEW

Although normal aging is accompanied by decreased "deep sleep," sleep efficiency, and increased time awake after sleep onset, these changes should not result in excessive daytime sleepiness, increased risk of falls, or insomnia. Impaired sleep results in decreased health and functional outcomes in the older adult.

III. BACKGROUND

A. Definition
   1. Sleep disorders involve problems with the quality, timing, and amount of sleep, which cause problems with functioning and distress during the daytime.
   2. Sleep disorders can affect overall health, safety, and quality of life. In the older adult, OSA, insomnia, restless legs syndrome, and REBD are common. These disorders result in excessive daytime sleepiness, cognitive dysfunction, nocturia, high risk of falls, and increased morbidity and mortality.

B. Etiology and epidemiology
   1. There are many types of sleep diagnoses, and the most common disorders reported by older adults are OSA, insomnia, and RLS.
   2. Approximately 5% to 31% of older adults have insomnia, 18% have obstructive sleep apnea (Punjabi, 2008), and 9.4% to 15% of adults older than 40 report RLS (Ohayon, O'Hara, & Vitiello, 2012).

IV. PARAMETERS OF ASSESSMENT

A. A sleep history (see Exhibit 30.1) should include information from both the patient and the family members. People who share living and sleeping spaces can provide important information about sleep behavior that the patient may not be able to convey.

B. The Epworth Sleepiness Scale (Johns, 1991) is a brief instrument to screen for severity of daytime sleepiness in the community setting. It can also be found under "Resources" at consultgerirn.org/resources.

C. The Pittsburgh Sleep Quality Index (Buysse et al., 1989) is useful to screen for sleep problems in the home environment and to monitor changes in sleep quality. This instrument can be found under "Resources" at consultgerirn.org/resources.

D. Insomnia Severity Index (Bastien, 2001) is a seven-item self-report questionnaire used to screen for insomnia severity. This single measure allows a clinician the ability to assess the mismatch between sleep opportunities and sleep ability, and the effects of treatment.

V. NURSING CARE STRATEGIES

A. Vigilance by nursing staff in observing patients for snoring, apneas during sleep, excessive leg movements during sleep, and difficulty staying awake during normal daytime activities (Ancoli-Israel & Martin, 2006; Avidan, 2005)

B. Management of medical conditions, psychological disorders, and symptoms that interfere with sleep, such as depression, pain, hot flashes, anemia, or uremia (Ancoli-Israel & Martin, 2006; Avidan, 2005)

C. For patients with a current diagnosis of a sleep disorder, ongoing treatments, such as CPAP should be documented, maintained, and reinforced through patient and family education (Avidan, 2005). Nursing staff should reinforce patient instruction in cleaning and maintaining positive airway pressure equipment and masks.

D. Instructions for patients and families regarding sleep-hygiene techniques to protect and promote sleep among all family members (see Box 30.1; Avidan, 2005)

(*continued*)

Protocol 30.1: Disorders of Sleep in the Older Adult (*continued*)

E. Review and, if necessary, adjust medications that interact with one another or whose side effects include drowsiness or sleep impairment (Ancoli-Israel & Martin, 2006), referring also to the Beers Criteria for potentially inappropriate medications for older adults (Fick et al., 2019; Ancoli-Israel & Martin, 2006).
F. Referral to a sleep specialist for moderate or severe sleepiness or a clinical profile consistent with major sleep disorders such as OSA or RLS (Avidan, 2005)
G. Aggressive planning, monitoring, and management of patients with OSA when sedative medications or anesthesia are given (Avidan, 2005)
H. Ongoing assessment of adherence to prescriptions for sleep hygiene, medications, and devices to support respiration during sleep (Avidan, 2005)
I. Hospital staff should avoid waking a patient for routine care, such as baths, vital signs, and routine blood tests (American Academy of Nursing, 2014).

VI. EVALUATION AND EXPECTED OUTCOMES

A. Quality-assurance actions
   1. Provide staff education on the major causes of sleep disorders (i.e., OSA, insomnia, RLS).
   2. Provide staff with in-services on how to use and monitor CPAP equipment.
   3. Have individual nursing units conduct environmental surveys regarding noise level during the night hours, and then develop strategies to reduce sleep disruption caused by noise and care patterns.
   4. Add sleep as a parameter of the admission assessment for patients, and provide written instructions for patients using CPAP at home to always bring the equipment with them to the hospital. Include sleep quality (e.g., see PSQI tool; www.hartfordign.org) in the assessment.
   5. Use posthospital surveys of patient satisfaction with sleep while in the hospital, and provide feedback for nursing staff (see www.hartfordign.org, Sleep topic).
B. Quality outcomes
   1. Improved quality of sleep during normal sleep intervals as reported by patients and staff.
   2. Improved quantity of sleep during normal sleep intervals as reported by patients and staff.

VII. FOLLOW-UP MONITORING

A. Depending on the diagnosis, follow-up may include long-term reinforcement of the original interventions along with support for adhering to treatments prescribed by a sleep specialist. For example, patient compliance with CPAP therapy for OSA is critical to its efficacy and should be assessed during the first week of treatment (Weaver et al., 2012). All patients benefit from positive reinforcement while trying to acclimate to nightly use of a positive airway pressure device.
B. CPAP masks may require minor adjustments or refitting to find the most comfortable fit. Most such changes are needed during the acclimation period, but patients should be encouraged to seek assistance if mask problems develop (Weaver et al., 2012). In the acute care setting, respiratory care technicians are valuable in-house resources when staff from a sleep center are not readily available.
C. During the initial treatment phase of insomnia, sleep deprivation may cause rebound sleepiness, which should subside over time. Follow-up should include ongoing assessment of napping habits and sleepiness to track treatment effectiveness (Avidan, 2005).
D. If obesity has been a complicating health factor, weight loss is a desirable long-term goal. Treatment of sleep disorders should include planning for strategic changes in lifestyle that include weight loss and regular exercise, which is also consistent with cardiovascular health and long-term diabetes control (Ancoli-Israel & Ayalon, 2006).

ABBREVIATIONS

CPAP	Continuous positive airway pressure
OSA	Obstructive sleep apnea
PSQI	Pittsburgh Sleep Quality Index
RLS	Restless legs syndrome

RESOURCES

American Academy of Sleep Medicine (AASM)

This organization for sleep professionals is also a great source of information for the public and for practice guidelines for professionals.
http://www.aasmnet.org

Basics of Sleep Guide

This Sleep Research Society publication is designed for students, sleep researchers, and nonsleep professionals interested in studying sleep across the life cycle, sleep deprivation or restriction, and sleep physiology. Information about this publication and how to order it can be found on the *Sleep Research Society* website: https://my.sleepresearchsociety.org/SRS_Product?id=a1341000004QTb0AAG

National Institutes of Health, National Center on Sleep Disorders Research

This site includes brochures that may be downloaded or printed for distribution to patients or for the education of other healthcare providers.
For healthcare professionals: http://www.nhlbi.nih.gov/health/prof/sleep/index.htm
For patients and the general public: http://www.nhlbi.nih.gov/health/resources/sleep

Sleep Research Society

This professional organization fosters scientific investigation, professional education, and career development in sleep research and academic sleep medicine. It is an excellent resource for nurses who are interested in studying issues of sleep and circadian processes.
http://www.sleepresearchsociety.org

Willis-Ekbom Disease Foundation (formerly Restless Legs Syndrome Foundation)

This organization is dedicated to improving the lives of those living with this often devastating disease. The organization's goals are to increase awareness of WED/RLS, to improve treatments, and to find a cure through research.

The Frail Hospitalized Older Adult*

Stewart M. Bond

31

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:
1. Describe frailty in hospitalized older adults.
2. List complications associated with frailty in hospitalized older adults.
3. Discuss the importance of early recognition of frailty.
4. Develop a patient-centered plan for frail hospitalized older adults.

OVERVIEW

Frailty is a multidimensional geriatric syndrome characterized by multisystem dysregulation and decreased physiological reserve. The interaction of these biological abnormalities (including inflammation) results in an increased vulnerability to stressors and adverse health outcomes (Clegg, Young, Iliffe, Rikkert, & Rockwood, 2013; Song, Mitnitski, & Rockwood, 2010). Frailty is characterized by diminished strength, endurance, and reduced physiological function that increases an individual's risk of dependence on caregivers and/or death. Frailty is a risk factor for hospitalization, and hospitalization often results in new or worsening frailty (Hogan et al., 2017). A longitudinal study conducted among community-dwelling older adults found that the course of disability closely mirrored the prevalence of hospital admission, indicating that aggressive measures are needed to prevent complications in frail older adults during hospitalization (Gill, Gahbauer, Han, & Allore, 2015). Nurses play a central role in the detection of frailty and in providing timely interventions to prevent complications in those who are frail, both during hospitalization and the transition to the postacute setting.

BACKGROUND AND STATEMENT OF PROBLEM

Presentation and Prevalence

While different definitions exist, frailty is generally understood as a multidimensional concept characterized by physical components such as low physical activity, decreased muscle strength, and unintentional weight loss, as well as cognitive, emotional, social, and spiritual aspects (Dent, Kowal, & Hoogendijk, 2016; Hogan, 2018; Turner & Clegg, 2014). In a systematic review, although the reported prevalence of frailty in community-dwelling older adults varied widely (range 4.0%–59.1%), the overall weighted prevalence was 10.7% (Collard, Boter, Schoevers, & Oude Voshaar, 2012). Frailty increases with increasing age. It is estimated that 25% to 50% of people older than 85 years are frail (Song et al., 2010). Declines in physiological reserves and resilience are the essence of being frail (Fedarko, 2011).

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

The development of frailty involves declines in energy production, energy usage, and repair systems in the body, resulting in declines in the function of many different physiological systems (Bandeen-Roche et al., 2006). This decline in multiple systems affects the normal, complex adaptive behavior that is essential to health (Fried et al., 2009). Frail individuals are significantly more likely to have cognitive decline, memory decline, and sarcopenia than nonfrail older adults (Nishiguchi et al., 2014).

Primary frailty occurs in the absence of significant overt disease, whereas *secondary* frailty is associated with known advanced disease. Although many frail older adults have chronic medical conditions and may have disability when frailty is detected, in the Cardiovascular Health Study (CHS), 63% of frail patients had no impairment in activities of daily living (ADL), and 32% had none or only one of nine chronic diseases (Fried et al., 2001). Persons with secondary frailty may have worse prognoses than those with primary frailty, as suggested by a study in which patients with diabetes, cancer, heart failure, and lung disease showed worse 4-year survival independent of features such as low weight and decreased walking (S. J. Lee, Lindquist, Segal, & Covinsky, 2006). Frailty can potentially be prevented or treated with specific modalities, such as exercise, protein-calorie supplementation, vitamin D, and reduction of polypharmacy (Morley et al., 2013). In the hospitalized older adult, the clinical presentation of frailty often includes nonspecific symptoms (e.g., extreme fatigue, unexplained weight loss, and frequent infections) and gait and balance impairment with potential falls, delirium, and functional abilities that vary from day to day (Parker, Fadayevatan, & Lee, 2006).

Etiology and Epidemiology

A number of risk factors have been identified for frailty, including (a) chronic diseases, such as cardiovascular disease, diabetes, chronic kidney disease, depression, and cognitive impairment (Fried, Ferrucci, Darer, Williamson, & Anderson, 2004); (b) physiological impairments, such as activation of inflammation and coagulation systems (Walston et al., 2002); (c) anemia (Chaves et al., 2005; Roy, 2011); (d) atherosclerosis (Chaves et al., 2008); (e) autonomic dysfunction, (Varadhan et al., 2009); (f) hormonal abnormalities (Cappola, Xue, & Fried, 2009); (g) obesity (Blaum, Xue, Michelon, Semba, & Fried, 2005); (h) hypovitaminosis D in men (Shardell et al., 2009); and (i) environmental factors within the living space and the neighborhood (Xue, Fried, Glass, Laffan, & Chaves, 2008). The occurrence of frailty increases incrementally with advancing age and is more common in older women than men and among those of lower socioeconomic status (Fried et al., 2004).

Pathophysiology

The pathophysiology of frailty is multifaceted. In addition to sarcopenia (Ferrucci, Penninx, & Volpato, 2002), a proinflammatory state that is present in cardiovascular disease, diabetes mellitus, renal insufficiency, and other diseases (Walston et al., 2002) are believed to contribute to frailty. Anemia (Chaves et al., 2005; Roy, 2011), deficiencies in anabolic hormones (e.g., androgens and growth hormone; Cappola et al., 2009), excess exposure to cortisol (Varadhan et al., 2008), insulin resistance (Barzilay et al., 2007), compromised altered immune function (Wang et al., 2010; Yao, Li, & Leng, 2011), micronutrient deficiencies, and oxidative stress (Semba et al., 2007) are also each individually associated with a higher likelihood of frailty. Thus, frailty is a consequence of cumulative decline in many physiological systems during a lifetime rather than the presence of a measurable disease state.

Outcomes Associated With Frailty

Frail older adults are at high risk for major adverse health outcomes, including disability, falls, institutionalization, hospitalization, and mortality (Fried et al., 2001; Lahousse et al., 2014). Frailty, cognitive impairment, and functional status were markers of perceived risk for negative outcomes (e.g., institutionalization, hospitalization, and death) in frail older adults (O'Caoimh et al., 2014). In older surgical patients, frailty independently predicts postoperative complications, length of stay, discharge to a skilled or assisted-living facility, and mortality (Afilalo et al., 2010; D. H. Lee, Buth, Martin, Yip, & Hirsch, 2010; Makary et al., 2010; Sundermann et al., 2011). A systematic review conducted by Sepehri et al. (2014) examined the relationship between objective frailty assessments and postoperative outcomes. Frailty, defined using multiple criteria, had a strong positive relationship with the risk of major adverse cardiac and cerebrovascular events (MACCE; odds ratio, 4.89; 95% CI [1.64, 14.60]). The authors concluded that further study is needed to determine which components of frailty are most predictive of negative postoperative outcomes before integration in risk prediction scores (Sepehri et al., 2014). In a study of older adults admitted to a Geriatric Evaluation and Management Unit (GEMU) in Australia, Dent, Chapman, Howell, Piantadosi, and Visvanathan (2014) found that psychosocial factors modify the association of frailty with adverse outcomes. Frail patients had an increased likelihood of 12-month mortality, discharge to a higher level of care, longer length of stay, and 1-month emergency rehospitalization. Psychosocial factors that increased the likelihood of adverse outcomes included

anxiety and low ratings for well-being, sense of control, social activities, and home/neighborhood satisfaction.

Frailty Models

Frailty models are underpinned by biological principles of causality and are offered to predict the clinical course and response to treatment (Bell, 2010). The two main emerging models of frailty are the phenotype model (Fried et al., 2001) and the cumulative deficit model (Rockwood et al., 2005).

The frailty phenotype proposed by Fried et al. (2001) includes five dimensions: unintentional weight loss, exhaustion, muscle weakness, slowness while walking, and low levels of activity (Table 31.1). A criticism of this model is that cognitive impairment, a highly prevalent condition associated with functional decline and disability, is not included as part of the phenotype (Rothman, Leo-Summers, & Gill, 2008). In addition, it may be difficult to use this model in hospitalized older adults whose clinical presentation may be altered by the acute illness or injury.

The cumulative deficit model views frailty as the combined effect of individual symptoms (e.g., low mood), signs (e.g., tremor), abnormal laboratory values, disease states, and disabilities (collectively referred to as deficits). This model supports the idea of reduced homeostatic reserve, as no single deficit causes frailty; rather, it is the accumulation of deficits that contribute to risk. Frailty, then, is viewed as a gradable syndrome (Rockwood & Mitnitski, 2007).

TABLE 31.1

The Phenotype Model: Indicators of Frailty and Measures

Indicators	Measures
Unintentional weight loss	Self-reported weight loss of 10 lb or recorded weight loss of 5% or more per year
Exhaustion	Self-reported exhaustion on U.S. Center for Epidemiological Studies Depression Scale (3–4 days/week or most of the time)
Slow gait speed	Standardized cutoff times to walk 15 feet, stratified by sex and height
Muscle weakness	Grip strength, stratified by sex and body mass index
Low activity levels	Energy expenditure less than 383 kcal/week (men) or less than 270 kcal/week (women)

Source: Data from Fried, L. P., Tangen, C. M., Walston, J., Newman, A. B., Hirsch, C., Gottdiener, J., … McBurnie, M. A. (2001). Frailty in older adults: Evidence for a phenotype. *Journals of Gerontology: Series A, 56*(3), M146–M156. doi:10.1093/gerona/56.3.m146

ASSESSMENT OF THE PROBLEM

The International Frailty Consensus Group recommends that all individuals with significant weight loss (≥5%) resulting from chronic disease should be screened for frailty (Morley et al., 2013). Although many methods have been proposed in academic trials, a universally accepted screening tool for frailty in acute admissions does not exist.

Single Markers of Frailty

Grip strength and walking speed are commonly used single measures of frailty. Grip strength is evaluated as the maximum of three attempts of the dominant hand using a handheld dynamometer: low grip strength is less than 18 kg in women and less than 30 kg in men (Fairhall et al., 2008). Walking speed is measured over 6 m, with or without the use of a walking aid. Slow walking speed is defined as an inability to walk 6 m in less than or equal to 30 seconds (Smith, 1994).

Phenotypic Frailty Indices

The frailty phenotype (Fried et al., 2001), with its five indicators described earlier, is commonly used to identify frailty. Older adults with three or more of the five factors are considered to be frail, those with one or two factors as prefrail, and those without any factors as robust or not frail. Table 31.1 describes the measures associated with each indicator.

The SOF (Study of Osteoporotic Fractures) Index defines frailty as two or more of the following: weight loss (5% loss either intentional or unintentional over the past year), self-report of low energy, and low mobility (unable to rise from chair five times; Ensrud et al., 2008). The CHS Index defines *frailty* as three or more of the following: shrinking (unintentional weight loss of 4.5 kg or more in the past year), weakness (low grip strength), exhaustion (self-report), slowness, and low physical activity (low walking speed, defined as unable to walk 6 m in 30 seconds; Fried et al., 2001).

Multidimensional Indices

Frailty, conceptualized as an accumulation of deficits, can be assessed using a frailty index (Rockwood & Mitnitski, 2007). A frailty index allows one to quantify frailty or vulnerability resulting from multiple, interacting health-related problems (i.e., individuals with more accumulated deficits

are more likely to be frail). A frailty index demonstrated greater discriminatory ability for people with moderate and severe frailty than that shown by the categorical phenotype model—a finding that has been validated independently (Kulminski et al., 2008).

A frailty index can be constructed using different numbers and types of health deficits (Searle, Mitnitski, Gahbauer, Gill, & Rockwood, 2008). It is recommended that a frailty index include at least 30 to 40 deficits to enhance its precision. Typically, the index includes information that is gathered in routine health assessments or health surveys. To score the frailty index, the deficits that are present are summed and divided by the total number of deficits on the index. Kulminski et al. (2008) created a Cumulative Deficit Index (DI) based on a set of 48 deficits, including multiple chronic medical conditions, health attitudes, symptoms, functional impairments, ADL, depression and other mental health problems, eyesight/hearing difficulties, and social support. Hubbard et al. (2011) used a frailty index based on a comprehensive geriatric assessment (FI-CGA) in conjunction with balance and mobility to assess illness and recovery in older hospitalized patients. The FI-CGA comprised 52 items covering the following: cognition, mood, motivation, health attitude, communication, strength, mobility, continence, nutrition, instrumental and basic ADL, sleep, medical problems, and medications. Similarly, Dent et al. (2014) developed and used the Frailty Index of Cumulative Deficits (FI-CD) to predict outcomes in patients admitted to a GEMU. The FI-CD included 50 multidimensional health-related deficits that were largely obtained from patients' CGAs.

SHERPA (Score Hospitalier d'Evaluation du Risque de Perte d'Autonomie) dimensions include age, falls in the previous year before hospitalization, Mini-Mental State Exam (first 21 questions), perception of health, and instrumental activities of daily living (IADL). Scores are summed and frailty is defined as scores greater than 6 out of 11.5, consistent with the category of high risk for functional decline during hospitalization (Cornette et al., 2006).

The Multidimensional Prognostic Index (MPI) is based on a CGA and includes the following components: ADL, IADL, mental status, comorbidity, nutrition, pressure ulcer risk assessment, medication number, and living status. Problems for each component are classified as: major (1 point), minor (0.5 point), and none (0 point). Scores were summed and divided by eight, and scores greater than 0.66 are graded as frailty (Pilotto et al., 2008).

Two tools are efficient for use in the busy acute care setting. The nine-point Clinical Frailty Scale is easy to use and classifies frailty status on a range from very fit to terminally ill (Dalhouse University, n.d.). The scale has been shown to be valid and reliable and highly correlated ($r = 0.80$) with the frailty index (Rockwood et al., 2005). The five-item FRAIL scale (Fatigue, Resistance, Ambulation, Illnesses, & Loss of Weight) is another tool used to screen for frailty and the risk of disability (Abellan van Kan et al., 2008). The tool inquires about whether patients are fatigued, are unable to climb a flight of stairs or walk one block, have more than five illnesses, and lost more than 5% of body weight in the past year. Three or more positive items indicate frailty.

CARE OF THE HOSPITALIZED FRAIL OLDER ADULT

The older adult who demonstrates characteristics of frailty requires a multifaceted approach to address the potential for or actual presence of the hazards of hospitalization. In addition to the increased predisposition to deep vein thrombosis and adverse medication effects, frail individuals are at increased risk for worsening functional status, delirium, falls, nosocomial infections, malnutrition, dehydration, immobilization, and decubitus ulcers while in the hospital (Boockvar & Meier, 2006).

Nutritional supplements, including fortified foods and essential vitamins and minerals, may be necessary (Torpy, Lynm, & Glass, 2006). Randomized controlled trials showed oral nutritional supplements during acute illness, and recovery was associated with reduced nonelective hospital readmissions (Bergstrom, 2007) and, in patients recovering from hip fracture, a decreased hospital length of stay (Myint et al., 2013). Ongoing oral assessment and adequate oral hygiene are standard care.

Increased exercise and physical activity during hospitalization have demonstrated significant positive benefits, including decreased fatigue, pain, delirium, urinary tract infections, deep vein thromboses, pneumonia, anxiety, and depression, as well as decreased length of stay, decreased costs, decreased mortality, increased functional recovery, increased independence, increased quality of life, and an increased likelihood of being discharged to home (de Morton, Keating, & Jeffs, 2007; Hartley, Adamson, Cunningham, Embleton, & Romero-Ortuno, 2016; Kalish, Lee, & Dabney, 2014; Martinez-Velilla, Cadore, Casas-Herrero, Idoate-Saralegui, & Izquierdo, 2016). Strategies to mitigate fall risk should be implemented without restricting physical activity. Multidisciplinary and nursing care models and processes such as comprehensive geriatric assessment (CGA; Ellis et al., 2017; Turner & Clegg, 2014), function-focused care (Boltz, Chippendale, Resnick, & Galvin, 2015; Boltz, Resnick, Chippendale, & Galvin, 2014; Resnick & Boltz, 2019; Resnick et al., 2016), and the Acute Care

for Elders model (Fox et al., 2012, 2013) may potentially benefit frail older adults, particularly those with dementia or those at high risk for delirium and other geriatric syndromes. These proactive, coordinated, patient/family-centered, multifaceted approaches emphasize the promotion of physical and cognitive activity, the maintenance of adequate nutrition and hydration, the use of nonpharmacological strategies for sleep and behavioral manifestations of distress, the avoidance of both physical restraint and the use of indwelling urinary catheters, the use of appropriate assistive devices, and ongoing assessment of patient responses. It is critical to mobilize these interventions in tandem to address the clinical complexity of the frail older adult. Multidisciplinary collaboration with physicians, dietitians, rehabilitation therapists, and social workers will facilitate these interventions. Evidence-based approaches to prevent, detect, and manage the syndromes associated with frailty are described in detail in various chapters throughout this book.

Discussions of goals of care, treatment preferences and intensity, and advance care planning are routinely indicated when the frail older person is hospitalized (Boockvar & Meier, 2006). For patients with advanced frailty, palliative care focused on relief of discomfort and enhancement of quality of life is highly appropriate and beneficial (Pal & Manning, 2014; Stow, Spiers, Matthews, & Hanratty, 2019). Studies suggest that patients with serious end-stage conditions, such as cancer, end-stage kidney disease, or neurodegenerative disease, have the following priorities for treatment: symptom management, measures to optimize quality of life, sense of control, minimized burden on family, and promoting relationships with loved ones (Singer, Martin, & Kelner, 1999; Steinhauser et al., 2000).

Current evidence indicates that hospital discharge planning for frail older people can be improved if interventions address family inclusion and education, communication between healthcare workers and family, interdisciplinary communication, and ongoing support after discharge (Bauer, Fitzgerald, Haesler, & Manfrin, 2009). Interventions that combine discharge planning and discharge support (i.e., postacute health monitoring and teaching) tend to have the greatest effects (Mistiaen, Francke, & Poot, 2007). In addition to the traditional approaches that include coordination and teaching related to the management and follow-up of the acute admitting problem, discharge planning of the frail older adult requires attention to preventing future disability (Clegg et al., 2013; Parker et al., 2006). Transitional planning requires additional foci: (a) exercise, including resistance, strength, physical movement (gait and balance) training, and lingual exercise; (b) nutritional maintenance and/or supplementation; (c) maintenance of oral health; (d) environmental modifications; and (e) family and professional caregiver education (Benefield & Higbee, 2013).

Referral to postacute services is warranted to address rehabilitative needs, dental care, assistive support, and social engagement. Alerting the postacute provider to the degree and nature of the older adult's frailty status is critical to promote a smooth transition and prepare for care in the postacute setting. An important priority is modifying the living environment to enhance opportunities for independence and self-reliance. These interventions include grab bars; walk-in showers with shower seats; counter and cabinet height adjustments; wide doors and hallways; contrasting colors of counters, floors, walls, and dishes; nonslip surfaces; ramps; proper lighting; and emergency call systems (Crews & Zavotka, 2006). Physical therapy should include both resistance and aerobic exercise training (Carr, Flood, Steger-May, Schechtman, & Binder, 2006). Resistance training involves weight-lifting or weight-bearing exercises of the large skeletal muscle groups to increase lean body mass and improve strength, exercise tolerance, and walking speed (Fiatarone et al., 1994). After the older adult's condition stabilizes, a recommendation for tai chi may be considered. Tai chi is a slow and gentle exercise regimen that involves both physical movement and meditation to improve balance and gait (Adler & Roberts, 2006). Additionally, lingual exercises (i.e., isometric exercises compressing an air-filled bulb between the tongue and hard palate) may help to enhance swallowing (Robbins et al., 2005).

When a frail older adult is transferred to the nursing home, details of the treatment of the acute problem as well as supportive measures to promote functional recovery need to be communicated. Family and caregiver education are needed to address the need for use of medications, nutritional approaches, oral health, promotion of socialization, and engagement in physical activity.

CASE STUDY 31.1

Ms. T is an 88-year-old woman who was admitted to the medical unit after being brought to the emergency department from the assisted-living facility, where she resides. Her admitting diagnosis is acute change in mental status. Her other medical problems include Alzheimer's disease, a history of falls, and atrial fibrillation. The emergency department reports that Ms. T has a low-grade fever and an area of consolidation in the right lower lobe. Her lab values indicate dehydration

(*continued*)

CASE STUDY 31.1 (*continued*)

and an elevated international normalized ratio (INR). Her medications before admission included donepezil hydrochloride/Aricept, Coumadin, and Risperdal. After spending 6 hours in the emergency department because of high patient volume and demands there, Ms. T is restless and irritable on transfer to the medical unit. Her daughter, who has her power of attorney, reports that Ms. T was admitted to the assisted-living facility 6 months ago after she lost 20 lb over several months and began to require assistance with medications, bathing, and dressing.

Ms. T's physical examination reveals a small, disheveled woman with an anxious appearance. An intravenous (IV) line is running; she is receiving hydration and antibiotics. The IV site is "camouflaged" and secured for comfort. Her oral mucosa is dry and dentition is fair (a few missing teeth). Ms. T is oriented to person and place but has difficulty with the Clock Draw test and can recall only one of three words. She is able to respond to a two-step verbal command. Her heart rate is 80, with an irregularly, irregular rhythm. She is able to rise from the chair very slowly with maximum help and states she is "too tired" and "too weak" to walk. Ms. T's balance is poor, as she sways back onto the bed, when assisted to stand. Her motor strength is diminished in all extremities; range of motion is intact. Her body mass index is 18. Ms. T's unintended weight loss, exhaustion, muscle weakness, and low activity levels are consistent with a frailty state.

The initial plan of care developed with the input of Ms. T and her daughter includes:

- Evaluation with the geriatric consultation service with a plan to secure physical therapy consultation, nutritional evaluation, and discussion of treatment goals and advance directives
- A fall-prevention plan, including an adjustable height low bed and a room close to the nurses' station
- Careful monitoring of her INR is warranted, especially with the addition of new medications
- Diligent oral care
- Careful monitoring of food and fluid intake; follow-up with the dietitian to provide dietary supplements and address food preferences
- Ongoing monitoring for delirium and implementation of nonpharmacological delirium prevention strategies
- Avoiding physical and chemical restraints
- Encouraging her daughter to bring in a few familiar items from home
- A plan for family visits/frequent presence at the bedside
- Assistance to a chair for meals and a commode for elimination. Range of motion and self-care during bathing are encouraged. Follow-up needed with physical therapy to develop a plan for ambulation, including the assistive device, as soon as possible
- Discuss with the assisted-living facility staff the supports and resources available at discharge, including the need for postacute rehabilitation, nutritional support and monitoring, and therapeutic activities that provide social engagement, cognitive stimulation, and physical activity

(*continued*)

SUMMARY

Frailty has been conceptualized as a diminished capacity to withstand stress that places individuals at risk for adverse health outcomes (Boockvar & Meier, 2006). The acute care stay creates further risk for disability and other complications for the frail older adult. A multifaceted, nurse-led approach provided by a multidisciplinary team that engages family caregivers is warranted to prevent hospital-acquired complications. Hospitalization also provides an opportunity to initiate measures to promote maximum function, health, and quality of life while acknowledging the patient's unique circumstances and preferences.

NURSING STANDARD OF PRACTICE

Protocol 31.1: Frailty in the Hospitalized Older Adult

I. GOALS

To ensure that nurses in acute care are able to

A. Describe frailty in hospitalized older adults.
B. List complications associated with frailty in hospitalized older adults.
C. Discuss the importance of early recognition of frailty.
D. Develop a patient-centered plan for frail hospitalized older adults.

II. OVERVIEW

A. Frailty is a multidimensional geriatric syndrome characterized by multisystem dysregulation and decreased physiological reserve.
B. Frailty is associated with increased vulnerability to stressors.
C. Frailty is characterized by diminished strength, endurance, and reduced physiological function that increases an individual's vulnerability for developing increased dependency and/or death.
D. Hospitalization increases the risk of disability in frail older adults.
E. Nurses play a central role in the detection of frailty, timely interventions to both prevent frailty and prevent complications in those who are frail, both during hospitalization and during the transition to the postacute setting.

III. BACKGROUND/STATEMENT OF PROBLEM

A. Presentation and prevalence
    1. Frailty is characterized by physical factors such as low physical activity, decreased muscle strength, and unintentional weight loss, as well as cognitive, emotional, social, and spiritual aspects.
    2. Between 25% and 50% of people older than 85 years are estimated to be frail with an estimate of 10.7% reported in noninstitutionalized, community-dwelling older adults.
    3. Decline in multiple systems affects the normal complex adaptive behavior that is essential to health.
    4. Primary frailty occurs in the absence of significant overt disease, whereas secondary frailty is associated with known advanced disease.
    5. Frailty can potentially be prevented or treated with specific modalities, such as exercise, protein-calorie supplementation, vitamin D, and reduction of polypharmacy.
    6. In the hospitalized older adult, the clinical presentation of frailty often includes nonspecific symptoms, and gait and balance impairment with potential falls, delirium, and functional abilities that vary from day to day.
B. Etiology and epidemiology
    1. Risk factors include (a) chronic diseases; (b) physiological impairments, such as activation of inflammation and coagulation systems; (c) anemia; (d) atherosclerosis; (e) autonomic dysfunction; (f) hormonal abnormalities; (g) obesity; (h) hypovitaminosis D in men; and (i) environmental characteristics.
    2. The occurrence of frailty increases incrementally with advancing age and is more common in older women than men and among those of lower socioeconomic status.
C. Pathophysiology
    1. The pathophysiology of frailty is considered to be multifaceted, and it reflects a consequence of cumulative decline in many physiological systems during a lifetime.
    2. Contributors to frailty include sarcopenia, a proinflammatory state, anemia, deficiencies in anabolic hormones, excess exposure to cortisol, insulin resistance, compromised or altered immune function, micronutrient deficiencies, and oxidative stress.
D. Outcomes of frailty
    1. Frail older adults are at high risk for disability, falls, institutionalization, hospitalization, and mortality.
    2. Frailty increases risk of MACCE.

(*continued*)

Protocol 31.1: Frailty in the Hospitalized Older Adult (*continued*)

3. Frailty independently predicts postoperative complications, length of stay, discharge to a skilled or assisted-living facility in older surgical patients, and mortality.
4. Psychosocial factors that increase the likelihood of adverse outcomes include anxiety, as well as low sense of well-being, sense of control, social activities, and home/neighborhood satisfaction.

E. Frailty models
1. The frailty phenotype proposed by Fried et al. includes five dimensions: unintentional weight loss, exhaustion, muscle weakness, slowness while walking, and low levels of activity.
2. The cumulative deficit model views frailty as the combined effect of individual symptoms (e.g., low mood); signs (e.g., tremor); and abnormal laboratory values, disease states, and disabilities (collectively referred to as deficits).

IV. ASSESSMENT OF FRAILTY

A. Single markers of frailty
1. Grip strength is evaluated as the maximum of three attempts of the dominant hand using a handheld dynamometer: low grip strength is less than 18 kg (women), less than 30 kg (men).
2. Walking speed is measured over 6 m, with or without the use of a walking aid. Slow walking speed is defined as unable to walk 6 m in 30 seconds.

B. Phenotypic frailty indices
1. The frailty phenotype, with its five indicators, is commonly used to identify frailty. Those with three or more of the five factors are considered as frail, those with one or two factors as prefrail, and those with no factors as not frail or robust older adults.
2. The SOF Index (Study of Osteoporotic Fractures frailty scale) defines *frailty* as two or more of weight loss (5% loss either intentional or unintentional over the past year) and self-report of low energy and low mobility (unable to rise from a chair five times).
3. The FRAIL Index classifies frailty as three or more of fatigue (self-report), resistance (unable to rise from a chair five times), ambulation (slow walking speed), illnesses (greater than or equal to five illnesses on CCI), and loss of weight of 5% or more in the past year.
4. The CHS Index defines frailty as three or more of shrinking (unintentional weight loss of 4.5 kg or more in the last year), weakness (low grip strength), exhaustion (self-report), slowness, and low physical activity (low walking speed, defined as unable to walk 6 m in 30 seconds).

C. Multidimensional indices
1. A frailty index can be constructed using different numbers and types of health deficits.
2. The DI is based on a set of 48 deficits, including multiple chronic medical conditions, health attitudes, symptoms, functional impairments, ADL, depression and other mental health problems, eyesight/hearing difficulties, and social support.
3. The FI-CGA comprises 52 items covering the following: cognition, mood, motivation, health attitude, communication, strength, mobility, continence, nutrition, instrumental and basic ADL, sleep, medical problems, and medications.
4. The FI-CD includes 50 multidimensional health-related deficits largely obtained from patients' CGAs.
5. SHERPA dimensions include age, falls in the previous year before hospitalization, Mini-Mental State Exam (first 21 questions), perception of health, and IADL.
6. The MPI components include ADL, IADL, mental status, nutrition, pressure ulcer risk assessment, number of medications, and living status.
7. The nine-point Clinical Frailty Scale is easy to use and classifies frailty status on a range from very fit to terminally ill. The scale has been shown to be valid and reliable, highly correlated ($r = 0.80$) with the frailty index.
8. The five-item FRAIL scale is another tool used to screen for frailty and the risk for disability.

(*continued*)

Protocol 31.1: Frailty in the Hospitalized Older Adult (*continued*)

V. CARE OF THE HOSPITALIZED FRAIL OLDER ADULT

A. Multifaceted plans of care: require multidisciplinary collaboration
   1. Evaluate need for nutritional supplements, including fortified food and supplements of essential vitamins and minerals mass.
   2. Ensure oral assessment and adequate oral hygiene.
   3. Promote self-care, continence, mobility, and cognitive stimulation; avoid restraints.
   4. Avoid indwelling urinary catheters.
   5. Implement strategies to decrease fall risk.

B. Involvement of patient and family in decision-making
   1. Establish clear goals of care based on patient preferences and needs.
   2. For patients with advanced frailty, offer palliative care focused on relief of discomfort and enhancement of quality of life.
   3. Whenever possible, combine discharge planning and discharge support (postacute follow-up).
   4. Plan to prevent future disability: (a) exercise, including resistance, strength, physical movement (gait and balance) training, and lingual exercise; (b) nutritional maintenance and/or supplement; (c) maintenance of oral health; (d) environmental modifications; and (e) family and professional caregiver education.

C. Referral to postacute services is warranted to address rehabilitative needs, dental care, assistive services, social engagement, and environmental home safety.

D. Communication to the postacute provider details the treatment of acute problems as well as supportive measures to promote functional recovery.

E. Family and caregiver education is needed to address the need for use of medications, nutritional approaches, oral health, promotion of socialization, and engagement in physical activity.

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient outcomes
   1. Improved functional and nutritional outcomes
   2. Delirium detection, avoidance, and abatement
   3. Prevention of complications: falls, delirium, pressure ulcers, adverse drug events
   4. Less hospital readmissions and decreased length of stay

B. Clinician outcomes
   1. Assessment, identification, and management of older adults susceptible to or experiencing frailty
   2. Documentation and communication of the patient's functional and cognitive capacity, interventions used, and outcomes
   3. Competence in preventive and restorative strategies for preserving independence and function
   4. Educate older adult and family caregiver(s) on intervention strategies to preserve function and reduce task demand in the preferred home or care setting.

C. Organizational outcomes
   1. Assessment of frailty as indicated
   2. Prompt and accurate referral for evaluation of frailty
   3. Increase in prevalence of patients who leave the hospital care facility or professional home care with baseline or improved functional status
   4. Support of institutional policies and programs that promote function, for example, caregiver educational efforts and walking programs
   5. Evidence of continued interdisciplinary assessments and evaluation of care
   6. Environmental approaches that support function and comfort

HIV Prevention and Care for the Older Adult*

Rosanna F. DeMarco and Simon Manga

32

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe HIV prevalence, burden, population at risk, and risk behavior.
2. Discuss HIV prevention in the older adult.
3. Describe community-based care and acute care services for the older adult living with HIV.
4. Identify strategies to promote successful aging in the older adult living with HIV infection.
5. Discuss the case to support palliative care in HIV and aging.

OVERVIEW

At the beginning of the HIV pandemic, the most affected population was that of younger adults, especially those aged 15 to 24 (HIV/AIDS and Work, 2006). With the emergence of antiretroviral therapy (ART), people living with HIV infection (PLWH) are now living longer. As such, there are more and more PLWH who are aging, and the number is predicted to rise in the ensuing years (Karpiak & Havlik, 2017). Because of this increase in prevalence rates, there is a great need to understand more about the pattern in which people age with HIV. To date, HIV has not been sufficiently studied in this emerging group of aging individuals (Karpiak & Havlik, 2017). At the same time, there is a dramatic decrease in HIV incidence (new infections), yielding a paradigm shift of the population of PLWH from younger adults to older adults. Older adults, that is, those over 50, will soon disproportionately represent the future experiences of the HIV pandemic (Beaulaurier, Fortuna, Lind, & Emlet, 2014). The rate at which people age varies from one part of the world to another, probably because of differences in culture, living standards, and genetic makeup. Therefore, the number of older PLWH also varies by region as well as by the relative risk of contracting the infection and disease (Joint United National Programme on HIV/AIDS [UNAIDS], 2013).

Africa is the continent most affected by the HIV pandemic. The current prevalence ranges from 0.1% in Northern Africa to 26.5% in Swaziland. Over 70% of PLWH globally are in Sub-Saharan Africa (SSA; UNAIDS, 2013). It has been difficult to understand the demographics of aging in SSA because of the absence of vital registration/identification data systems (Sprague & Brown, 2017). There has been a significant change in the size and age distribution of SSA as a result of increased mortality related to HIV (Velkoff & Kowal, 2007). Since the availability of ARTs, the life expectancy in SSA has been on the rise. For

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

instance, in South Africa, life expectancy has recently risen to 60 years from 56.5 years thanks to the role of ARTs (Bradshaw, Dorrington, & Laubscher, 2012).

According to the Concerted Action on SeroConversion to AIDS and Death in Europe (CASCADE), there is an increase in the median age of HIV infection in Europe from 26.2 years prior to 1986 to 33.2 years between 2006 and 2010. The North America AIDS Cohort Collaboration on Research and Design (NA-ACCORD) reveals an increase in the number of older adults aged 50 and over who are newly enrolled into HIV care and treatment from 8.5% to 19.1% in men and from 6.6% to 19.5% in women between 1993 and 2012. The NA-ACCORD also indicated that in North America, the proportion of adults aged 50 and above presenting for HIV care and treatment from 1997 to 2007 increased from 17% to 27% (Althoff et al., 2010).

Men who have sex with men (MSM) carry a high risk for contracting HIV. In the United States, MSM was the group with the highest increase in HIV prevalence between 2007 and 2010, from 28,077 to 30,573, and male-to-male sexual intercourse accounted for up to 65% of HIV incidence in the United States in 2011. In 2016, the number had risen from 30,573 to 154,730 (CDC, 2019). The prevalence among Black MSM is even higher than among their White counterparts (Millet et al., 2012). In 2016, there were 272,527 Black MSM in the US compared to 262,510 of their White counterparts (CDC, 2019). In addition, Black MSM are more likely to be ignorant of their HIV status, have lower rates of HIV care and treatment, have poor adherence to ART, and are less likely to achieve viral load suppression (Cohen et al., 2014). Prevention of HIV transmission among MSM has had limited achievement (Sullivan et al., 2012).

One of the lowest worldwide HIV prevalence rates is in the Eastern Mediterranean region. This low rate of the total number of PLWH in a cross-section of time who are aging could be attributable to cultural and social norms that discourage premarital and extramarital sexual encounters. In 2012, the HIV prevalence was as low as 0.2%, and the most affected individuals were sex workers, MSM, and injecting drug users (World Health Organization [WHO], 2010). Even though the prevalence in this region seems to be rising in recent times, there are insufficient data to capture the exact situation and to identify those most at risk. The region has the lowest HIV care and treatment coverage rate worldwide, particularly in Sudan, South Sudan, Iran, Somalia, and Pakistan, with a coverage rate of only 10% (WHO & UNAIDS, 2013). In the Eastern Mediterranean, HIV care and treatment is free, but the major barrier to treatment coverage is stigma, discrimination, frequent ART stockout, and shortage of health personnel (WHO, 2010). Data on HIV available in this region cover mostly the 15 to 49 age group; there are little to no data on older adults (WHO & UNAIDS, 2013).

The South East Asia Region (SEAR) has the second highest burden of HIV after SSA, with 3.4 million PLWH and an HIV care and treatment coverage rate of 32% (WHO-SEAR, 2013). Although India has a very low HIV prevalence of 0.26%, because of its huge overall population of 1.2 billion people, the absolute number of PLWH is high, at over 2,500,000 people (National AIDS Control Organization, 2013). The country with the highest HIV prevalence in this region is Thailand, with a prevalence of 1.1% (WHO-SEAR, 2012). Stigma and discrimination are a major barrier to HIV testing and treatment within the region. Data on PLWH over 50 are poor.

In the Western Pacific Region (WPR), the HIV prevalence is less than 1% (WHO-WPR, 2012). The region has a strong HIV surveillance system but lacks comprehensive data on older PLWH (Yu, Wi, & Calleja, 2011). The most affected countries in this region are Cambodia, China, Malaysia, Papua, New Guinea, and Vietnam, with a prevalence of 5% (WHO-WPRO, 2014). China is the most populated country in the region, and the most common mode of transmission in adults is injecting drugs and sexual intercourse (WHO-WPRO, 2014). In Nanning, China's second largest city of PLWH, the prevalence of older adults with HIV increased from 16.5% in 2007 to 42.7% in 2011 (Zhang, Fuller-Thomson, Mitchell, & Zhang, 2013). In Australia, the prevalence of PLWH aged 50 to 64 has increased from 6.1% in 2006 to 10.6% in 2009 (Kirbi Institute, 2015).

In summary, this historical and international review highlights the variation in HIV prevalence, burden, population at risk, and risk behavior from one part of the world to another. Because the HIV pandemic started as a problem of young people, very little focus has been placed on older adults with HIV in most parts of the world. With the rapid paradigm shift of the population affected by HIV from younger to older adults, more research is needed to study the phenomenon of HIV and aging in order to better respond to the needs of older PLWH.

PREVENTION IN THE OLDER ADULT

The modes of transmission of HIV have been well documented since the 1980s. These include unprotected penetrative anal or vaginal intercourse; blood transmission, including infected injecting needles; and vertical transmission, that is, during pregnancy, delivery, and/or breastfeeding (Evans & Dukes, 2018). Among these

modes of transmission, the sexual route is the most common route of transmission. Sexuality is a vital aspect of life and health across all ages (WHO, 2002), even though sexual activities decline in older adults with increasing age with men experiencing erectile dysfunction and women experiencing problems with vaginal lubrication (Lindau et al., 2007). However, some authors have argued that older adults remain sexually active, and perhaps even more so when pregnancy may not be an issue after women reach menopause (Eden & Kevan, 2009). In some cases, sexual activity in older age might increase (Grossman, 1995). In one study, 40% to 65% of persons between 60 and 71 admitted being sexually active (Whipple & Scura, 1996). In another study, 75% of older adults between 57 and 64, over 50% of older adults between 65 and 74, and over 25% of older adults above 75 years of age were sexually active (Kuehn, 2008). In South Africa, 50% of adults over 50 have sexual intercourse one to five times a month (Negin et al., 2012). In China, heterosexual contact is the principal mode of HIV transmission among older adults (Liu et al., 2012). Nearly 58% of all cases of HIV in adults over 50 admit that sexual intercourse is the primary risk factor for HIV infection (CDC, 1999). Considering that sexual intercourse is the principal mode of HIV transmission among adults aged 50 and over reaffirms the likelihood of the need to address sexual risk behaviors in prevention efforts among older adults (Chiao, Ries, & Sande, 1999). However, very few studies have been completed on sexuality in older adults as it relates to HIV risk (Cahill & Valadez, 2013). HIV prevention among older adults must take sexual transmission strongly into account.

Disease prevention generally consists of three levels: primary prevention, secondary prevention, and tertiary prevention. Primary prevention involves stopping the disease from happening among those who do not yet have the disease. Secondary prevention involves stopping the progression of the disease among those who already have it. Tertiary prevention involves decreasing the impact of the disease among those in whom the disease is already advanced (WHO, 2014). In the case of HIV prevention in adults, primary prevention involves lifestyle modifications aimed at avoiding infection with the virus such as sexual abstinence, fidelity to sexual partner, or proper use of condoms. Secondary HIV prevention involves screening to identify early nonsymptomatic infections in order to begin early treatment. HIV prevention programs in adults usually focuses on primary and secondary prevention.

Adults over 50 are less likely to be engaged in HIV risk behaviors compared to younger persons (Costagliola, 2014) as well as being less likely to use condoms, that is, a low-cost and easily accessible method to decrease transmission if used properly (UNAIDS, 2014). The rate of newly acquired HIV infections among older adults seems to be higher than formerly thought. However, there is very little information about the sexual behaviors and practices, as well as HIV incidence among older adults (Negin et al., 2016). Older adults tend to have less knowledge of risk factors for HIV transmission compared to younger persons (Negin et al., 2012). Among individuals at an older age, the assumption is that HIV and other sexually transmitted infections are phenomena for the younger generation.

Because of the lack of awareness of the risk of acquiring HIV, as described previously, older adults often do not consider the key secondary prevention method of screening for HIV as part of routine care even if they are sexually active. They often consider HIV testing very late in the acute phase of the infection because of this belief compared to younger persons (Negin et al., 2012). This leads to delay in diagnosis, and course of treatment, and often addressing care and treatment when the immune system has been substantially damaged, yielding a diagnosis of AIDs (CD4 counts so low that there is no defense for opportunistic infections; Costagliola, 2014). Even in Europe and America, older adults have been diagnosed with HIV very late after manifestations of AIDS-defining illness (el-Sadr & Gettler, 1995). A study in Europe indicated that older age is associated with late diagnosis and delayed initiation of ART (Costagliola, 2014). Persons over 50 years old who acquire HIV usually have persistently low CD4 counts (little immunity strength) and thus poor response to treatment compared to younger persons (Costagliola, 2014; McDonald, Elliott, & Saugeres, 2013). Even when older adults have initiated treatment for HIV, they maintain a lower CD4 count for a sustained period before any improvement is noticed, putting them at higher risk for disease progression and death (Costagliola, 2014). This could be why HIV-related mortality is higher among older PLWH than among their younger counterparts (Greig, Casas, O'Brien, Mills, & Ford, 2012). All of these differences in diagnosis time and physiological response in older PLWH affect the general health and survival time of this group. In the context of prevention, these insights highlight the importance of both primary and secondary HIV prevention among older adults, that is, getting "lead time" to diagnose and treat for a better trajectory of health and wellness. Consequently, efforts should be directed toward making HIV testing and treatment programs available, sensitive, and responsive to the needs of older adults (Negin et al., 2016). More studies are needed on HIV attitudes, awareness, testing, and prevention among older adults (Sprague & Brown, 2017).

COMMUNITY-BASED CARE AND ACUTE CARE CONSIDERATIONS

HIV has no effective cure, but with coordinated acute and community-based care, it can be managed and controlled from a public health perspective. If accessible, ART taken right after diagnosis and as directed can dramatically prolong the lives of many PLWH, keep them healthy, and greatly lower their chance of infecting others. Despite the increasing availability of ART, accessibility and acceptability are still a major concern in some areas. In Ethiopia, PLWH who failed to disclose their HIV status to their relatives had difficulties in adhering to ART in attempts to conceal their HIV status (Yakob & Ncama, 2016). In an antenatal clinic in Ethiopia practicing Option B plus, 14.8% of the pregnant women living with HIV did not adhere to ART because of forgetfulness and challenges in adopting a time schedule (Tesfaye et al., 2019). In Uganda, adolescents living with HIV reported a number of barriers. These included keeping and taking the ART pills while at school, because taking pills in school frequently among classmates and friends could create difficulties in preserving confidentiality, and those whose HIV-positive parents had died, while struggling to deal with the loss, also have to face a frequent change in guardianship, contributing to problems with adherence to ART (MacCarthy et al., 2018).

Before the introduction of ART in the mid-1990s, PLWH could progress to AIDS, the most severe form of the virus, where the immune system is severely damaged, in just a few years. Today, someone diagnosed with HIV and treated before the disease is far advanced can live nearly as long as someone who does not have HIV. As such, acute and community-based care for those PLWH parallel the chronic care trajectory of most persons who are aging in a context of varying comorbidities.

Community services constitute a vital part of a nation's response to HIV (Beck, Fasawe, Ongpin, Avilla, & De Lay, 2013). For example, a U.S. federally funded, state-administered community service called AIDS drug assistance program (ADAP) provides access to ART to over 110,000 PLWH annually who lack suitable health insurance. The aim of the ADAP is to provide adequate ART coverage to PLWH who lack Medicaid or other forms of insurance (Pinkerton, Kibicho, & Galletly, 2013). Such community programs can bridge the gap between the privileged and the underprivileged in terms of ART access.

Persons living with HIV infection can experience three stages of illness if they are not treated with ART or do not have access to quality and cost-effective primary, acute, and community-based care. HIV advances in stages by overwhelming the immune system and getting worse over time without treatment. The three stages of HIV infection are: (a) acute HIV infection, (b) clinical latency, and (c) AIDS (Ginaldi et al., 1997). PLWH may progress through these stages at different rates, depending on a variety of factors, including their genetic makeup, how healthy they were before they were infected, how much virus they were exposed to and its genetic characteristics, how soon after infection they are diagnosed and linked to care and treatment, whether they see their healthcare provider regularly and take their HIV medications as directed, and different health-related choices they make, such as decisions to eat a healthy diet, exercise, and not smoke. Of course, the interaction or the ecology of aging cannot be studied without consideration of other systemic effects of HIV or the evolving knowledge of physiological aging, which may be different in onset and severity than those of PLWH. In a 1-year prospective study among PLWH in Mexico, over 50% of the participants developed an increase in cardiovascular risk factors at the end of 1 year (Cibrián-Ponce et al., 2018). In a study aimed at evaluating the renal function of PLWH on a tenofovir disoproxil fumarate–based regimen, renal dysfunction was found in 25.4% of the participants and PLWH over age 50 were more likely to develop renal dysfunction (Yazie, Orjino, & Degu, 2019). Care must include what we know and what we are discovering over time about the needs of those now living longer and longer toward successful aging with HIV.

CARE FOR THE OLDER ADULT AND AGING SUCCESSFULLY WITH HIV INFECTION

Vance, McGuinness, Musgrove, Orel, and Fazeli (2011) adapted a model by Baltes and Baltes (1998) to categorize eight areas of successful aging for those living with HIV infection: (a) length of life, (b) mental health, (c) cognitive efficiency, (d) social competence, (e) biological health, (f) productivity, (g) personal control, and (h) life satisfaction. Vance and colleagues (2011) chose this model to understand and guide care of aging HIV-infected adults for the following reasons: (a) the extensive use of the model's guide points in gerontology, (b) specific benchmarks that are specifically identified to describe aging as a process that met selection, optimization, and compensation (SOC) of abilities that would guide successful aging, and (c) the understanding that all eight categories of successful aging interact with each other and, therefore, create an "ecology of an aging" experience within the confines of living with a life-threatening and chronic illness. The following sections use the derivation of the Baltes and Baltes (1998) model updated recently in Vance and colleagues

(2019) to organize and identify how care needs to be addressed for those aging with HIV infection locally and globally in terms of community-based care and acute care considerations.

Although acute care experiences occur across a trajectory of chronic care with PLWH, the most significant difference over the last 30 years in acute and subacute settings for those living with HIV infection is notably the widespread use of universal infectious disease precautions for all people, including those not living with HIV infection. Initially, many of those living with HIV infection experienced acute care in hospitals and other settings as traumatic experiences, including the overuse of infection control devices and care worker protections as well as physical and emotional isolation based on the fear of transmission (Janssen et al., 1992). Although science is still building an understanding of the interaction of aging and HIV infection, comorbidities of aging are treated in the same way for those living with HIV infection and those that are not living with HIV infection (Guaraldi et al., 2011; Schouten et al., 2014). As such, the key focus in this chapter is community-based care of those living with HIV because most live within a trajectory of chronic care in the context of their family and community life over time. Included in this presentation is the need to consider palliation during all acute phases of illness directly related to or correlated with HIV.

Length of Life

Length of life is a very important indicator of successful aging (Vance et al., 2019). The advent of ART provided PLWH with the chance to live longer, much like their HIV-uninfected counterparts (Harrison, Song, & Zhang, 2010). The number of PLWH entering into older age has been rising steadily, creating a new challenge in healthcare because the needs of older adults living with HIV infection appear to be different than those of younger PLWH or even different than those of the same age without HIV infection. In the United States, it is estimated that over 50% of PLWH are over the age of 50 (CDC, 2019; Effros et al., 2008), and the proportion is higher in SSA (Bendavid, Ford, & Mills, 2012). Unfortunately, care of older adults living with HIV infection has not been studied sufficiently, and HIV in adults over age 50 has different manifestations in terms of predisposition to multimorbidity and side effects of drugs compared to younger PLWH (Negin & Cumming, 2010), giving rise to the need for community-based care and acute care considerations. For example, aging is independently associated with multimorbidity (Guaraldi et al., 2011; Schouten et al., 2014), cognitive declines (Barter & Foster, 2018), stigma (Levy & Macdonald, 2016), and lack of productivity (Rueda et al., 2011). When aging is accompanied by positive HIV status, these conditions might become more pronounced.

Life expectancy has become similar between PLWH and those who are HIV negative (Samji et al., 2013). However, PLWH engaged in risky behaviors such as smoking, physical inactivity, substance abuse, and poor social networking may have reduced life expectancy. Comparing life expectancy between PLWH who smoke to those who do not, Helleberg et al. (2013) found a difference of approximately 15.8 years. That is, PLWH who are smokers have a life expectancy that is about 15 years less than that of their HIV-infected counterparts who are nonsmokers. Therefore, community-based programs should be designed to discourage smoking among PLWH. In a randomized controlled trial in the United States, using video-call intervention and voice-call intervention for smoking cessation among women living with HIV, researchers found that participants in the video group were significantly more likely to abstain from smoking than those in the voice group (log rank chi(2) = 4.02, $p < .05$). However, the voice call was more feasible than the video calls among poorer women (Kim, Darwish, Lee, Sprague, & DeMarco, 2018).

Mental Health and Cognitive Efficiency

Older adults with HIV face a lot of challenges, including physiological declines that are associated with aging, deteriorating health status, and loss of partner(s), friends, and relatives (Wallach & Brotman, 2013). Also, such individuals, especially those with multiple health problems, may develop poorer self-esteem when they see themselves as different from the healthy population and may thus develop the tendency to withdraw socially (Kara & Mirici, 2004). On the other hand, relatives and friends may want to withdraw from them to avoid the psychological distress of being around a loved one who is always sick (Miller, 1985). A study found that 39% of older adults with HIV over age 50 were socially isolated as opposed to only 25% of younger PLWH (Charles, 2006). Social isolation therefore has to be addressed when considering community-based programs for older PLWH. For example, support groups for PLWH over age 50 can help in preventing social isolation. However, PLWH of more advanced age, such as those over 90, may have difficulties in participating in such support group activities, such as riding, without additional support from friends/family members. In a qualitative study of a support group of older PLWH aged over 50 in Helsinki, Finland, the majority of the research participants reported having most of their social support from their HIV-positive peers. They

also noted that formal support came principally from the HIV support group (Ribeiro, Jari, Tapio, & Marco, 2016). In another qualitative study in Baltimore, United States, researchers found that older PLWH are able to employ active and meaningful coping mechanisms through support group activities, including accessing support and assisting peers. This enables them to engage in productive or better quality of life despite the HIV infection and multimorbidity as well as their related stressors (DeGrezia, 2012).

These challenges easily give rise to mental instability and depression. Older adults with HIV have been found to exhibit worse depression than their HIV-negative counterparts and younger persons (Pantalone, Czajkowski, & Taylor, 2017). Depression in older adults with HIV has been strongly associated with loneliness, social withdrawal, and stigma (Arseniou, Arvatini, & Samakouri, 2014). Cognitive problems such as dementia are also an issue with older adults with HIV. However, the prevalence of dementia has reduced drastically with the advent of more effective ARTs (Vance et al., 2019). Persons living with HIV infection have been found to have significant aging of the brain cells of approximately 2.15 years compared to their HIV-negative counterparts (Horvath & Levine, 2015). Providers caring for older adults with HIV must include mental health in their package of care. This should take into consideration the substantial impact of sociodemographic variables that interlace to affect mental well-being among older PLWH such as class, gender, race, and sexual orientation (Furlotte & Schwartz, 2017).

Social Competence

Social competence, which is the ability to construct and maintain social interactions to enhance physical and emotional well-being (Vance et al., 2011), is a challenge among older adults with HIV. Social competence/support, in addition to medical support, must be considered when dealing with older adults with HIV (Brennan-Ing, Seidel, & Karpiak, 2017). When individuals are no longer socially competent, community-based support becomes their hope.

Community-based care can be formal or informal. Informal community-based care is that which is usually offered by relatives and friends of the affected person mostly on a voluntary basis, that is, without a salary (Cantor & Brennan, 2000). The informal caregivers usually perform tasks like rides to the hospital for appointments, as well as housekeeping, including cooking, laundry, and cleaning. Formal community-based care, on the other hand, is provided by professionals, and they do it as part of their means of earning a living. They usually carry out tasks of personal care such as bathing and counseling. Such professionals may be nurses, psychologists, or social workers. In some cases, the informal and formal caregivers work together as a team. Social workers can assist older PLWH in addressing their most urgent needs and linking them to ongoing medical care. The objective of the community-based caregiving team is to help the patient be independent as much as possible and to remain at home. The team usually coordinates services such as adherence to medication, medical care, counseling, nutritional support, and mental health (Brennan-Ing et al., 2017). In the United States, it was noted that anticipating the needs of the patients is crucial in constructing relationships between community-based workers and the patients as well as with their families (Vanderboom, Holland, Targonski, & Madigan, 2013), leading to better understanding of the patient and his or her needs.

Formal community-based care also involves outreach services. Outreach workers assist patients with HIV in making and adhering to their medical appointments, understanding the importance of adhering to their medications as prescribed, and accessing other support services (Bradford, Coleman, & Cunningham, 2007; Shippy & Karpiak, 2005). Outreach referrals are done to patients who have defaulted appointments, missed laboratory tests, or need any form of medical support. Outreach services also target persons with HIV who have never been linked to care. Outreach activities include principally phone calls and home visits (Cox & Brennan-Ing, 2017). Putting aside older adults who have aged with HIV, there are older adults who acquire HIV in their old age. Those who acquire the virus at an older age have a different set of challenges. For example, older age is associated with late diagnosis (Costagliola, 2014) because older adults do not do HIV testing frequently (Negin et al., 2012). New HIV infection in older age is usually associated with persistent lower CD4 counts and poor response to treatment (Stall & Catania, 1994). Therefore, outreach services could be helpful in tracking older adults with new HIV infection and navigating them to care as soon as possible. Even though it has been demonstrated that community-based outreach services can improve linkage to care in SSA (Hatcher et al., 2012), outreach services are not well established in most of SSA (Bogart et al., 2017). In England, outreach care, including waiting times, patient satisfaction, patient convenience, and follow-up, was better in outreach than in regular stationary hospitals. The authors also found that 60% (81) of the outreach clients had shorter distances compared to 28% (22) of stationary hospitals (X2:49.96; 1 df; $p < .0001$; Bowling, Stramer, Dickinson, Windsor, & Bond, 1997). In rural Zambia, on the other hand, both caregivers and healthcare providers reported lower quality of services at the outreach clinics compared to those at the

regular stationary hospitals (van Dijk, Moss, Hamangaba, Munsanje, & Sutcliffe, 2014).

In the United States, some social support services are provided through assistance from governmental and community-based organizations. Older adults living with HIV also do benefit from these social supportive services. Some of these services include transportation support, support groups of PLWH, recreational support, personal and environmental hygiene, financial assistance, housing assistance, and nutritional assistance, including food vouchers and food pantries. These services usually augment the services provided by the informal caregivers (Cantor & Mayer, 1978). Without such external assistance, the burden might be quite high for the informal caregiver, and he or she may suffer from economic hardship related to increased expenditure and absenteeism from work. For example, in the United States, the Ryan White Care Act is a source of federal public funding for HIV care that ensures that HIV services are accessible and delivered according to conventional HIV treatment protocol at the community level. In 1998, an evaluation showed that patients in the Ryan White–supported sites had better quality of care than patients in the non–Ryan White-supported sites (Sullivan, Denniston, Mokotoff, Buskin, & Broyles, 2008). With the advent of the Affordable Care Act (ACA), some policy makers questioned the continued importance of the Ryan White HIV/AIDS Program. Nevertheless, research has found that the Ryan White Program is still vital in facilitating quality care for PLWH in the United States in the ACA era (Sood, Juday, Vanderpuye-Orgle, Rosenblatt, & Romley, 2014). However, this external assistance is not available in most resource constraint settings such as SSA. Thus, the informal caregivers have to bear all the cost, leading to deepening financial hardship and sufferings.

Studies have shown that social support increases the well-being of older adults with HIV. One study showed that availability and adequacy of social support among older adults with HIV resulted in better adaptability to the disease as well as psychological stability (Brennan, 2004). In another study, the level of psychological distress was found to be lower among older adults with HIV (Chesney, Chambers, Taylor, & Johnson, 2003). In addition, older lesbian, gay, bisexual, and transgender (LGBT) individuals living with HIV were found to experience better quality of life when offered social support.

Biological Health

Both HIV and aging are chronic conditions. Multimorbidity, a situation in which a person suffers from a combination of morbid conditions or illnesses, usually noncommunicable diseases, increases with increasing age (Guaraldi et al., 2011; Schouten et al., 2014). Some of these noncommunicable diseases include cardiovascular disease (CVD) and diabetes mellitus in addition to general organ degeneration with its associated complications. These conditions tend to further increase in older adults living with HIV. According to the U.S. Medicaid data from 2003 to 2013, increasing prevalence of noncommunicable diseases was noted among older adults with HIV as follows: CVD, 3% to 7%; diabetes mellitus, 9% to 19%; renal impairment, 5% to 11%; and osteoporosis, 4% to 6% (Meyer, Gallant, Hsue, & Song, 2015). Multimorbidity of chronic conditions is generally common in the general population of all ethnic groups, and the frequency increases with increase in age. In addition to the age factor, multimorbidity of chronic conditions is higher among those with lower socioeconomic status and among those with concomitant mental disorders. In the population of PLWH, the burden of multimorbidity is higher than expected with regard to age alone (Brown & Guaraldi, 2017).

A combination of factors contributes to multimorbidity in older adults with HIV. First, HIV itself is a chronic inflammatory condition. The longer one lives with HIV, the higher the likelihood that he or she suffers from the chronic inflammatory response. With the advent of ART, PLWH are now living longer to reasonable old age (WHO, 2013), thus giving room for prolonged HIV inflammatory response. Chronic HIV inflammation is associated with CDV (Shaked et al., 2014), diabetes mellitus (Brown, Tassiopoulos, Bosch, Shikuma, & McComsey, 2010), psychiatric problems (Lake et al., 2015), osteoporosis (Yin et al., 2010), and renal impairment (Abraham et al., 2015). Co-infection with other viral infections, especially hepatitis C virus (HCV), further enhances systemic inflammation. Chronic HCV alone can lead to multimorbidity, including CVD, osteoporosis, psychiatric impairment, and renal impairment (Soriano & Berenguer, 2015). These conditions will therefore be exaggerated if the person is infected with both HCV and HIV at the same time. Even though considerable progress has been made in the development of ARTs with lesser metabolic toxicities in recent years, prolonged use of ART is still associated with the risk of multimorbidity. For example, one of the most widely used nucleoside reverse transcriptase inhibitors (NRTIs), tenofovir disoproxil fumarate, is associated with toxicities of the kidney and bone (Cooper et al., 2010). Another widely used NRTI, Abacavir, has been found to be associated with CVD in some studies (Brown et al., 2015; Ofotokun et al., 2015). All these further increase the risk of multimorbidity among PLWH. The third factor is behavioral influences such as smoking and substance abuse.

This tends to be higher among the population of PLWH than in the general population (Hasse et al., 2011). In a Swiss study, CVD, renal, and hepatic diseases were more prevalent among PLWH who smoked (Hasse et al., 2015). The prevalence of illicit drug use such as cocaine and heroin, which are associated with CVD, is higher among the HIV-infected population (Dettmeyer, Friedrich, Schmidt, & Madea, 2009). Physical inactivity, which increases with increasing age, is associated with CVD, diabetes mellitus, and psychiatric impairment (Schouten et al., 2014). Older adults with HIV are even more prone to physical inactivity because of the likelihood of multimorbidity.

In addition to the foregoing noncommunicable diseases, some types of cancers, such as Kaposi's sarcoma, have been strongly associated with HIV disease. Some of these cancers are infection-causing cancers, for example, non–Hodgkin's lymphoma, cervical and anal cancers, and liver cancer (Ball, 2014). Cervical cancer is particularly a problem for women living with HIV because they have an over five-fold increased risk of developing the disease than their HIV-negative counterparts (Denslow et al., 2017). In SSA, where cervical cancer rates are the highest, the rates are further increased among HIV-infected women. This is because ART is causing the women to live longer, and then they end up developing cervical cancer at older age (Harris, 2017).

Generally, multimorbidity is associated with polypharmacy, or the need for more than five different drugs within a given time (Gleason, Luque, & Shah, 2013). The various health conditions that emerge with aging require drug management (Wastesson, Canudas-Romo, Lindahl-Jacobsen, & Johnell, 2016). Thus, an older adult with multimorbidity will have to deal with the problems of polypharmacy. The burden of polypharmacy will be even higher in the case of older adults living with HIV, who are more likely to suffer from serious multimorbidity. In addition, they are equally expected to remain on their ARTs. One major concern of polypharmacy is secondary effects and drug interactions. Older age is independently associated with increased risk of secondary effects (Brooks, Buchacz, Gebo, & Mermin, 2012). Adherence to medications as prescribed can also be a burden with polypharmacy. It has been shown that the greater the number of drugs to be taken per day, the lesser the adherence (Clay, 2014). Some drugs, especially anti-infectious agents, require strict adherence for optimal benefit.

The combination of the complications of multimorbidity and polypharmacy in older adults with HIV can give rise to acute conditions. In the past decades, PLWH were more likely to suffer from acute conditions arising from opportunistic infections (Brooks et al., 2012). Since the advent of ARTs, these opportunistic infections have reduced dramatically. Hence, acute conditions in elderly PLWH are likely to occur from those associated with multimorbidity and polypharmacy. Acute care of older adults with HIV requires a multidisciplinary approach, which can be composed of an acute care specialist, a geriatrician, an infectious disease/HIV specialist, a cardiologist, a pharmacologist, and so on. When providing acute care to older adults, the acute care team must guard against falls and pressure ulcers (Krall et al., 2012). Having acute care units for the older adults only has been found to produce better results than caring for older adults in acute care units for the general population (Krall et al., 2012).

Productivity

Productivity is centered on meeting one's needs or enjoying a good quality of life by an individual through his or her efforts such as employment and contributions to development of the society (Rueda et al., 2011). Productivity can be affected by ageism. Ageism is a natural life process that involves breakdown of the different body systems (Shorthill & DeMarco, 2017). It is associated with a decrease in physical and behavioral health as well as an increase in frailty (DeMarco, Brennan-Ing, Brown, & Sprague, 2017). Therefore, as the individual ages and these traits become pronounced, he or she loses his or her productivity on an increasing basis. Such individuals find it increasingly difficult to work and take care of themselves. So they tend to be dependent on others for their immediate or daily needs. As already noted, ageism is more accelerated or pronounced in PLWH. Therefore, older adults with HIV or persons aging with HIV have lesser productivity as compared to their HIV-negative counterparts of the same age group, thus requiring more community-based care.

Ageism is associated with stigma (Levy & Macdonald, 2016). Considering that HIV is also associated with stigma, older adults with HIV have double stigma to deal with, and consequently further decreases in their productivity. Older adults with HIV who are LGBTs or sexual minorities have an additional stigma to handle because they are stigmatized on the basis of age, HIV status, and sexual orientation (Wight, LeBlanc, Meyer, & Harig, 2015), thus experiencing increased psychological distress and a consequential decrease in productivity.

Personal Control

Persons living with HIV are sometimes tempted to feel that they lack personal control over their health or social issues (Solomon, O'Brien, Wilkins, & Gervais, 2014). This

is probably because of the fear of imminent breakdown of the immune system with consequential multimorbidity and polypharmacy. It has been shown that improvements in personal control are associated with improvements in psychological indicators. Improvements in personal control are dependent on preliminary control level. For example, patients who start with very high control levels show subsequent improvements, whereas those who start with very low control levels show subsequent decline (Zhu, Schroevers, van der Lee, Garssen, & Stewart, 2015). To improve personal control, McVey, Madill, and Fielding (2001) recommended that (a) there should be improvements in provider–patient communication in order for the provider to become more aware of the psychological needs of the patient, and (b) providers should be trained in identifying patients with very low personal control as well as delayed psychological adaptation.

Life Satisfaction

Life satisfaction deals with the state of well-being of an individual, that is, how an individual is contented with his or her life (Vance et al., 2019). Life satisfaction is nonstatic, that is, it changes from time to time with changes in situation. For example, having a diagnosis of a chronic illness like HIV and irreversible life processes such as aging can affect a person's life satisfaction. Therefore, it is likely that older adults with HIV do experience altered life satisfaction and need support from community-based programs.

THE CASE TO SUPPORT PALLIATIVE CARE IN HIV AND AGING

Palliative care is care aimed at preventing and relieving sufferings of patients afflicted with chronic or life-threatening diseases in order to improve their quality of life. Palliation should be considered an important aspect of care when considering older PLWH (WHO, 2015). It is a vital component of HIV care from diagnosis to end of life (WHO, 2015). Even with the advent of effective ARTs, palliative care continues to have an essential role in HIV/AIDS care because over time the treatment might become less effective or harmful to some patients (Shorthill & DeMarco, 2017). In the past, palliative care was primarily used in the context of terminal diseases such as cancers and end-of-life care, but currently it is being integrated into all areas of healthcare (Weissman, 2012). Owing to the success of ARTs, HIV is no longer regarded as a life-threatening illness, so the ties between HIV and end-of-life care are no longer as strong as they were at the beginning of the pandemic. However, in some developing countries where some of the very effective ARTs are neither available nor affordable, HIV care is still strongly integrated with end-of-life care to address the burden of multimorbidity, opportunistic infections, and physical and psychological distress (Huang, 2013).

Ideally, patients with HIV are supposed to be enrolled in palliative care as soon as they are diagnosed. Unfortunately, they are often enrolled late, when other options have failed. Some patients have died shortly after being enrolled in palliative care despite the fact that they lived with the infection for a long time (Weissman & Meier, 2011). These patients failed to get the benefits of the palliative care services. Palliative care was the mainstay of HIV care before the availability of ARTs, especially in reducing anxiety related to the uncertainty of dealing with an incurable illness (Lowther et al., 2012), and it still has a role in modern practice.

In relation to older PLWH, the following recommendations are of significant importance: (a) increase community awareness on the importance of palliative care for older PLWH through sharing of best practices (Shorthill & DeMarco, 2017); (b) make members of the community recognize the value of a higher quality of life among older PLWH that can be attained through palliative care (Kovacs, Bellin, & Fauri, 2006); (c) establish more opportunities for interdisciplinary studies that focus on older PLWH (Harkness & DeMarco, 2016); and (d) promote comprehensive follow-up care of older PLWH in the community (Greene et al., 2015).

CASE STUDY 32.1 (PANTON, 2017)

Stephen (Note: This is a pseudonym.) tested positive for HIV some 30 years ago; at that time, he had a history of periodic intravenous drug use for 8 years. For 10 years, he was nonadherent to HIV care, and during this time he had a baby. The relationship with his partner broke down, but he remained close to his baby, and this is what motivated him to start and continue ART. For the past 20 years, he has been adherent to his ART, and for the most part, he has maintained an undetectable viral load. His family is supportive, and he has a great relationship with his HIV community mental health nurse, who makes home visits to him regularly. For several years, he has not taken intravenous drugs, and he is maintained on 100 mL of daily methadone. He uses diazepam, as prescribed, and smokes huge quantities of cannabis. He was reviewed in the hospital

(*continued*)

CASE STUDY 32.1 (*continued*)

last year, and he was on ART. His viral load was still undetectable, even though he said he does not take his ART frequently. His mental health nurse and HIV clinical nurse specialist made a home visit to him 5 months afterward because he defaulted care. He had problems of memory and general instability and weight loss. He had lost value for life and admitted defaulting ART for 4 months. Meanwhile, he had stopped taking his antidepressant medications. He was admitted, detained, and cared for under the Adults with Incapacity Act 2006. During his admission, the staff noticed that he was suffering from disorientation to time, person, and place. He demonstrated a suicidal tendency and admitted having planned this previously. He had body weight loss of 13%. He had an ECG that revealed a prolonged QTc interval, so his dose of methadone and other drugs had to be reduced. He had cerebral atrophy higher for his age on CT brain scan. After admission, his mood got better, and the suicidal tendency abated. He expressed willingness to recommence ART and wanted to try a dosette box. His mental health nurse has been following up with him. He felt all his drugs were being stopped rather than reduced, so he was unhappy. This was in line with his periodic confusion because of a combination of drug misuse, being off ART, and depression. He accepted from a social worker a referral to a caregiver for provision of daily help. Even though he misses his dog, his family members have decided that he is no longer capable of caring for it. He recently had a mental health evaluation; he remains unhappy about the dose reduction of his trazadone, methadone, and diazepam because he thinks no one has the legitimacy to interfere with his drugs, since he has been doing well with the drugs for several years. He is still on daily heavy consumption of cannabis and has no plans of reducing it. He gets bored and admits getting upset and emotional about simple issues. He continues taking his antidepressants but does not want to continue on ART.

Discussion

This case study highlights some of the challenges faced when caring for older adults with HIV. Though Stephen's age is not given, it is most plausible that he was over age 50, considering that he has been living with HIV for 30 years. For several years, he was adherent to his ART and was stable. As he got older, he became nonadherent to ART but adherent to his other non-ART medications and would not even want to resume his ART after counseling. The reason why he prefers his non-ART medications to the ART is not understood. His mental status deteriorated when he stopped his ART. However, it is not clear whether it is the stopping of the ART that has caused deterioration of his mental state or the deterioration of his mental state that has caused him to stop his ART. This reaffirms that a lot still needs to be understood about aging with HIV.

The brain CT revealed cerebral atrophy higher for his age. It has been discovered that PLWH have significant aging of the brain cells of approximately 2.15 years compared to their HIV-negative counterparts (Horvath & Levine, 2015). This highlights the importance of integrating mental health in the care of older PLWH.

When Stephen defaulted his appointments, his mental health nurse and his HIV specialist nurse went out to his home to look for him and refer him for acute care. Had these nurses not made this home visit, Stephen's condition could have continued to deteriorate, and he would have died at home or committed suicide. Community care including home visits is a very important component of care when dealing with older PLWH (Cox & Brennan-Ing, 2017).

SUMMARY

There is a gradual shift in HIV incidence and prevalence from younger adults to older adults. Persons aging with HIV face a number of challenges, including multimorbidity, polypharmacy, depression, and stigma. Also, individuals who acquire HIV at older age have a different set of challenges, including rapid destruction of the immune system, persistently low CD4 count, and poor response to ART. Unfortunately, the literature on HIV and aging is scanty across most parts of the world. Research programs need to be developed to better understand the phenomenon of HIV and aging in order to design interventions that will respond to the challenges surrounding older PLWH.

NURSING STANDARD OF PRACTICE

Protocol 32.1: HIV Prevention and Care for Older Adults

I. GOAL

Determine strategies for preventing HIV transmission among older adults and caring for older adults living with HIV.

II. OVERVIEW

Older adults remain sexually active but are less likely to use condoms for HIV prevention. They are equally less likely to be involved in HIV risk reduction behaviors as well as in carrying out routine HIV testing. As such, they are usually diagnosed at late stages of the disease. Older adults who acquire HIV are likely to have persistent low CD4 count and poor response to ART, and, of course, higher morbidity and mortality. Therefore, HIV prevention among older adults ought to be taken seriously.

More than 50% of PLWH in the United States are over age 50. Because of the advent of ARTs, PLWH are living longer, and life expectancy between HIV-infected and HIV-uninfected persons has become very similar. So a lot of people are now aging with HIV, and this number will continue to rise in ensuing years. These persons aging with HIV have a number of additional challenges to deal with, including multimorbidity, polypharmacy, physical inactivity, nonproductivity, social isolation, and dementia. Care of older adults with HIV has not been sufficiently studied. Therefore, more research is needed to explore how care of older adults with HIV can be ameliorated.

III. BACKGROUND/STATEMENT OF THE PROBLEM

Preventing HIV Transmission Among Older Adults

1. Acquisition of HIV is possible in all age groups, including older adults. Sexual transmission remains the most common method of transmission among young and older adults. Older adults remain sexually active, and perhaps even more so when pregnancy may not be an issue after women reach menopause (Eden & Kevan, 2009).
2. About 58% of all cases of HIV in adults over 50 are acquired through sexual intercourse (CDC, 1999).
3. Adults over 50 are less likely to be engaged in HIV risk behaviors compared to younger persons (Costagliola, 2014) as well as being less likely to use condoms, that is, a low-cost and easily accessible method to decrease transmission if used properly (UNAIDS, 2014).
4. Considering that sexual intercourse is the principal mode of HIV transmission among adults aged 50 and over reaffirms the likelihood of the need to address sexual risk behaviors in prevention efforts among older adults (Chiao et al., 1999).
5. Older adults often usually consider HIV testing very late in the acute phase of the infection compared to younger persons (Negin et al., 2012).
6. Persons who acquire HIV who are over 50 years old usually have persistently low CD4 counts (little immunity strength) and thus poor response to treatment compared to younger persons (Costagliola, 2014; McDonald et al., 2013).
7. Even when older adults have initiated treatment for HIV, they maintain a lower CD4 count for a sustained period of time before any improvement is noticed, putting them at higher risk for disease progression and death (Costagliola, 2014).

Caring for Older Adults Living With HIV

1. In the population of PLWH, the burden of multimorbidity is higher than expected with regards to age alone (Brown & Guaraldi, 2017).
2. The longer one lives with HIV, the higher the likelihood that he/she suffers from the chronic inflammatory response.

(*continued*)

Protocol 32.1: HIV Prevention and Care for Older Adults (*continued*)

3. With the advent of ART, PLWH are now living longer to reasonable old age (WHO Regional Office for South-East Asia, 2013), thus, giving room for prolonged HIV inflammatory response.
4. Multimorbidity is associated with polypharmacy, which is the need for more than five different drugs within a given time (Gleason et al., 2013).

IV. NURSING STRATEGIES

1. HIV prevention among older adults must take sexual transmission into strong consideration because it is the major mode of transmission in this age group.
2. More studies are needed on HIV attitudes, awareness, testing, and prevention among older adults (Sprague & Brown, 2017).
3. Nurses caring for older adults with HIV must include mental health to their package of care. This should take into consideration the substantial impact of sociodemographic variables which interlace to affect mental well-being among older PLWH such as class, gender, race, and sexual orientation (Furlotte & Schwartz, 2017).
4. Having acute care units for the older adults only has been found to produce better results than caring for older adults in acute care units for the general population (Krall et al., 2012).
5. To improve personal control among older adults with HIV: (a) there should be improvements in nurse-patient communication in order for the nurse to become more aware of the psychological needs of the patient; and (b) Nurses should be trained on identifying patients with very low personal control as well as delayed psychological adaptation (McVey, Madill, & Fielding, 2001).
6. Increase community awareness on the importance of palliative care for older PLWH through sharing of best practices (Shorthill & DeMarco, 2017).
7. Make members of the community recognize the value of higher quality of life among older PLWH, which can be attained through palliative care (Kovacs et al., 2006).
8. Establish more opportunities for interdisciplinary studies with focus on older PLWH (Harkness & DeMarco, 2016).
9. Promote comprehensive follow-up care of older PLWH in the community (Greene et al., 2015).

ABBREVIATIONS

ART	Antiretroviral therapy
CDC	Centers for Disease Control and Prevention

LGBTQ Perspectives for Older Adult Care*

Janejira J. Chaiyasit and Anthony R. Lutz

33

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Develop a welcoming lesbian, gay, bisexual, transgender, and queer (LGBTQ) practice environment through the use of correct terminology, preferred pronouns, and gender-affirming language.
2. Identify the various barriers to access to care within the LGBTQ community.
3. Identify appropriate screening guidelines for the LGBTQ population for preventive care.
4. Understand hormone therapy (HT) and the risks of HT in the transgender community to best provide comprehensive care.
5. Address psychosocial needs of the aging geriatric LGBTQ population.

OVERVIEW

Members of the lesbian, gay, bisexual, transgender, and queer/questioning (LGBTQ) community will reach over 1.6 million by 2020, according to *Healthy People 2020*. In a more recent survey in 2017, Gallup estimates that 4.5% of Americans identify as LGBTQ and that about a fifth of this population are over the age of 50 (Newport, 2018). With the population aging, there will be a considerable number of LGBT elders who will need to access health services. This community spans all races, socioeconomic classes, ages, and ethnicities in the United States (National LGBT Health Education Center, n.d.). According to the National Academy of Medicine, almost 30% of LGBT adults do not seek health services because of health disparities, marginalization, and socioeconomic determinants that affect access and approach to healthcare.

In particular, the elder LGBT community has lived through the hardships of historical events, including the Stonewall riots, the AIDS epidemic, and, at one point, the view that homosexuality was a mental illness, potentially punishable by law. They have faced direct discrimination that has prevented many from coming "out" because of stigma and fear of breaking the law and being labeled. Those affected have been forced to selectively disclose their personal health to professionals, despite the possibility of not receiving appropriate and much needed care. This contributes to major distrust in the health field, which may carry on as they age. Elder LGBTQ members are less likely to reach out to a provider or utilize community and social services such as meal services and elder care services, even though they have higher rates of depression, anxiety, substance abuse, and physical health needs (Foglia &

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

Fredriksen-Goldsen, 2015). Nurses can be valuable resources to elder LGBT members by creating a welcoming environment and providing culturally sensitive care.

CREATING A CULTURALLY SENSITIVE ENVIRONMENT

Creating a culturally sensitive environment in the healthcare setting is imperative to provide care for any cultural group, especially the LGBT community. Past and present history of public discrimination within the legal, health, and social settings have led a majority of these patients to be untrusting of healthcare providers owing to fear of stigma (Lim, Brown, & Kim, 2014). Developing a perceived safe environment free from judgment and discrimination allows patients to feel comfortable to discuss their medical history, which in turn improves the health outcomes of this population (Fredriksen-Goldsen et al., 2014). To achieve this, one of the first steps would be using welcoming terminology and language, both verbal and nonverbal, allowing the patients to feel confident that the nurse is experienced with their specific population. This can promote a trusting patient–provider relationship (Dean et al., 2000). Appropriate language focuses on the sexual identity, orientation, activity, and aura with which patients associate themselves. Use of such terminology displays awareness and compassion of the LGBT hardships and builds trust (Whitehead, Shaver, & Stephenson, 2016).

Expression of self-identity through sexual orientation and gender identity is very important among the community, and nurses can acknowledge this by utilizing preferred terms. Sexual orientation refers to how a person characterizes his or her sexual, emotional, and physical attraction to others. Common terms that describe sexual orientation include heterosexual, gay, lesbian, and bisexual. However, some persons may describe their sexual orientation on the basis of their sexual behavior such as men who have sex with men (MSM) or women who have sex with women (WSW), or same sex attracted, owing to the fear of negative reaction to more commonly used terms (Ard & Makadon, 2012).

Gender identity is a person's sense of being a woman/female, man/male, both, neither, or another gender. Most people have a gender identity that corresponds to the sex they were born with, an identity known as "cisgender." Transgender is the term used to describe an individual whose gender identity does not correspond to the sex that individual was assigned at birth. A transgender male is someone who was assigned female sex organs at birth but who identifies as a man. Conversely, a transgender woman is someone born with male sex organs but who identifies as a woman. There are others who have a gender identity that falls outside the gender of male or female. Some may identify as both male and female or neither, or it may evolve over time. Other terms to describe such are genderqueer, gender fluid, and gender nonbinary. These more expansive terms are typically more common in younger generations. It is also important to ask the patient if his or her preferred pronoun is he, she, or they, because it should not be assumed given the individual's physical appearance (Gay & Lesbian Medical Association, n.d.). It is also key to recognize the fluidity and diversity of expression when communicating with LGBTQ patients in a community that may not accept these identities and will thus want to use alternative terms (Ard & Makadon, 2012).

OBTAINING A SEXUAL HISTORY

Sexual history is important to understand the social and societal behaviors and risks among the LGBTQ community. Obtaining a thorough sexual history helps nurses to identify these factors, especially when appropriate. It is important to get a sexual history when appropriate as it pertains to the patient's current status—whether the individual is being seen for a routine exam or whether the sexual history may be related to why the individual is seeking healthcare. Older adults are still sexually active and should be questioned as appropriate (Gay & Lesbian Medical Association, n.d.).

Obtaining a thorough sexual history can give a wealth of information that helps to identify risk factors when appropriate. Other than just asking if a patient is sexually active, it is important to learn the sex of the partner(s), noting it may be more than just one sex and what type of intercourse the individual participated in. Inquiring in a nonjudgmental manner further develops a trusting relationship, in which the patient will feel comfortable divulging his or her personal information. Some ways to ask personal questions are by using language that does not assume an answer—are you sexually active with men/women, both, or all genders? What type of sexual activity do you partake in? Do you engage in anoreceptive or anoinsertive intercourse? Any recent oral sex? Have there been any new sexual partners in the last 6 months? Do you use a protective barrier of some sort, or are you or your partner on a contraceptive method? Questions like these allow nurses to obtain more detailed information that can play a part in assessing the patient's medical and social needs.

PREVENTIVE SCREENINGS

Preventive screening for cancer, infectious disease, and sexually transmitted disease follows guidelines from

accredited national organizations recommended for the general population. The LGBTQ population does generally follow these guidelines as they fit; however, there are some conditions that disproportionately affect the LGBTQ community and that do not have explicit recommendations; nurses should be aware of them (Quinn et al., 2015).

Screening should follow the general rule of "screen what you have" for transgender patients because these patients may or may not have had gender-affirming surgical procedures to align with their gender identity. Also, transgender adults may or may not have been on hormone therapy (HT), which is associated with increased health risks as well and will be further discussed later in this chapter. When assessing a transgender patient, getting a thorough surgical and medication history can assist with identifying risks.

Gender reassignment surgery provides transgender patients with physical characteristics of their gender identity, but does not give new physiologic sexual organs. Transgender women who have undergone surgery still have a prostate gland and should be screened for prostate cancer according to recommended guidelines. Transgender males who have had surgery should still be screened for breast cancer per guidelines, although they are not at increased risk for breast cancer (Meads & Moore, 2013). Keep in mind that some patients may still have their ovaries unless they underwent an oophorectomy.

Lesbian women were once considered at a higher risk for breast cancer because of higher prevalence of some risk factors, such as alcohol use, cigarette smoking, obesity, nulliparity, and lower rates of breast cancer screening (Institute of Medicine [IOM], 2011). However, a recent systematic review of breast cancer incidence and prevalence in lesbian and bisexual women found no reliable published data that suggest elevated breast cancer cases among lesbian women (Meads & Moore, 2013). Nurses should always inquire about recent breast cancer screening and educate their patients on the basis of known increased risk factors. It was once thought that lesbian women were at lower risk of cervical cancer because they were less likely to have sexual contact with males. However, lesbian women are at increased risk for cervical cancer and HPV exposure due to history of sexual contact with women and men previously and because they are less likely to be screened regularly (Gorgos & Marrazzo, 2011). Lesbian women should follow the Pap smear schedule according to their history as occurs with their heterosexual peers.

Anal cancers are rare, but MSM are at increased risk for this cancer through exposure to the HPV virus because of anal intercourse (Chin-Hong et al., 2004). Risk factors associated with increased risk of anal cancer include multiple sexual partners, presence of other sexually transmitted infections, cigarette smoking, and MSM. Vaccination against HPV would be instrumental in prevention. Anal Pap smears and anoscopy are good screening tools to detect the presence of HPV. National guidelines are not yet available to suggest a screening schedule for those at risk, keeping in mind that older MSM males may have not had access to or have been offered the HPV vaccine due to current recommendations. Nurses should be aware that screening tools do exist for suspected anal cancers.

Screening for sexually transmitted infections should be done routinely based on the patient's risk factors and recent sexual activity. Screenings should not only be done for traditional routes of intercourse but should also include extragenital sites such as anorectal and oral swabs for gonorrhea and chlamydia. Assessments can be made about the need for frequency and need for screening based on a detailed sexual history.

Members of the LGBT community have higher rates of mental health diagnoses such as depression, anxiety, bipolar disorder, and substance abuse (IOM, 2011). Therefore, all members should be screened at every encounter. Older LGBT adults face higher rates of depression and anxiety due to isolation, and they are less likely to have children and good relationships with family to help care for them. Older LGBT adults tend to seek social networks and social resources as a source of support rather than professional assistance (Foglia & Fredriksen-Goldsen, 2015). They should be screened at least annually and referred to appropriate resources.

HORMONE THERAPY

While it can be difficult to accurately assess how many people in the population are transgender because of multiple barriers to visibility and access to care, current surveys estimate that anywhere from 0.3% to 0.5% of people in the United States are transgender (Unger, 2016). As transgender visibility increases and barriers to care decrease, nurses in all settings will likely see increased numbers of transgender patients. Thus, it is imperative that nurses in hospitals, long-term care facilities, and community settings are familiar with the unique healthcare considerations of this population.

For transgender patients who elect to utilize medical treatments to aid in their transition (while not all transgender patients do), available options include HT, surgical intervention, or both (Webb & Safer, 2019). The prevalence of transgender patients desiring HT is increasing with time (Unger, 2016). However, one study of primary care providers in a large healthcare system in the Midwest

revealed that only about 50% of primary care providers would be willing to continue HT for transgender patients, due to providers' own biases or perceived capability (Shires, Stroumsa, Jaffee, & Woodford, 2018). A familiarity with the current options for hormonal therapies will help nurses in all settings be more prepared to manage potential side effects and comorbidities for transgender patients.

Male-to-Female (Transgender Women) Hormone Therapy

The main goal of HT for male-to-female (MTF)/transgender women is to help develop more feminine-appearing features, including reducing male pattern hair growth, altering the way body fat is distributed, increasing breast size, and reducing characteristically male muscle mass (Shatzel, Connelly, & DeLoughery, 2017). This is typically accomplished by a combination of two hormonal therapies: an exogenous estrogen combined with an antiandrogen (Randolph, 2018).

Multiple formulations of exogenous estrogen are available. As nurses, when taking a detailed health history, it is important to identify the formulation of estrogen used by the patient, because different formulations can cause different degrees of side-effect risks. Exogenous estrogen can come in oral, parenteral (either subcutaneous or intramuscular injections), or transdermal formulations, and are all commonly referred to by the generic name estradiol (Unger, 2016).

The most significant risk associated with exogenous estrogen is a potential increase in venous thromboembolic events (VTE), and various studies have estimated the incidence of VTE to range from as low as 1% to as high as 6% to 8% of populations studied (Weinand & Safer, 2015). One particular oral formulation of estrogen, called ethinyl estradiol, is no longer commonly used because it carries the highest risk for VTE (Arnold, Sarkodie, Coleman, & Goldstein, 2016). VTE is typically more likely to occur during the first year of starting exogenous estrogen, and VTE is generally a higher risk with the oral formulations of estradiol and a lower risk with the transdermal and parental formulations (Shatzel et al., 2017). MTF transgender patients considering estradiol are at even increased risk for VTE if they are current smokers, are obese, have a history of prior VTE, or have a thrombophilia/hypercoagulable disorder, so it is important to ask about these risk factors when taking a health history (Shatzel et al., 2017).

Another potentially common, but less emergent, risk associated with exogenous estrogen is an increase in triglycerides, so it is recommended to monitor serum lipid panels while on any formulation of estradiol (Fernandez & Tannock, 2016). There is also a potential risk of cardiovascular disease and stroke to consider with exogenous estrogen (Defreyne, Van de Bruaene, Rietzschel, Van Schuylenbergh, & T'Sjoen, 2019), so nurses in any setting working with MTF patients on estradiol can help manage these risks by monitoring blood pressure, watching for any signs/symptoms of stroke, and observing for signs of DVT in postoperative patients (Shatzel et al., 2017). Additionally, although there can be increased oncologic risk for certain hormonally influenced cancers in cisgender women who take estradiol, there is no increased oncologic risk for transgender MTF patients who take estradiol (Weinand & Safer, 2015).

The addition of an antiandrogen therapy to treatment with exogenous estrogen helps to both decrease overall testosterone and lower the dose or amount of exogenous estrogen needed to achieve the desired lower testosterone levels and change in secondary sex characteristics (Webb & Safer, 2019). There are several different options for antiandrogen therapy, but the most commonly utilized option is a potassium-sparing diuretic called spironolactone (Randolph, 2018). The most common potential side effect of spironolactone to monitor for in the transgender population is hyperkalemia, which becomes a higher risk as the patient gets older (Randolph, 2018). Other options for antiandrogens include finasteride, which carries the risk of liver toxicity (Unger, 2016), and gonadotropin-releasing hormone agonists like leuprolide, which can be very expensive (Unger, 2016) and carry the risks of decreased bone mass/osteopenia and decreased libido (Weinand & Safer, 2015).

Female-to-Male (Transgender Men) Hormone Therapy

The main goal of HT for female-to-male (FTM)/transgender men is to help develop more masculine-appearing features, including increased male pattern hair growth, increased muscle development, cessation of menstrual bleeding, and enlargement of the clitoris (Webb & Safer, 2019). The main hormonal therapy for FTM transgender men is testosterone supplementation, with the goal of increasing the serum testosterone level to the standard reference range for men (Irwig, 2017). The different available formulations of testosterone are the same options utilized to treat hypogonadism in cisgender men, including transdermal, parenteral (either subcutaneous or intramuscular injections), subcutaneous implant, or an oral formulation that is not currently available in the United States (Unger, 2016).

The most common side effects of testosterone therapy in FTM transgender men, similarly to cisgender men who utilize testosterone therapy, include an increase in serum hemoglobin and hematocrit, a possible decrease in HDL

cholesterol, and a possible increase in serum triglycerides (Irwig, 2017). An increase in body mass index (BMI) is also a likely possibility for FTM transgender men on testosterone therapy (Fernandez & Tannock, 2016). However, there is no increased risk for VTE in FTM patients on testosterone therapy (Shatzel et al., 2017) and no known increased risk of cardiovascular or oncologic events in FTM patients on testosterone therapy (Gooren & T'Sjoen, 2018).

PSYCHOSOCIAL NEEDS OF THE AGING LGBT POPULATION

In addition to the unique clinical needs of older LGBT adults, there are also unique psychosocial needs in this population that have a significant impact on quality of life, health, and survival. Many of today's LGBT older adults lived through decades of discrimination and mistreatment by a society and healthcare system that rejected them, attempted to "cure" them of who they are, and shamed them during the HIV/AIDS epidemic (Marsack & Stephenson, 2018). Although great strides have been made in LGBT visibility and acceptance over the last several decades, not all attitudes have changed, and many older LGBT adults remain fearful of discrimination by their heterosexual peers and the healthcare practitioners they depend on as they age (Jablonski, Vance, & Beattie, 2013).

These fears, stemming from past experiences of rejection and/or abuse, cause many LGBT adults over 55 years old to remain closeted (Zelle & Arms, 2015) or to hide their identity and return to the closet when they enter a long-term care facility or nursing facility (Jablonski et al., 2013). Many LGBT older adults who return to the closet when in a nursing facility are afraid that the nursing/healthcare staff will have their own personal biases that are not accepting of the LGBT identity, and thus the staff may neglect, abuse, or persecute them (Serafin, Smith, & Keltz, 2013). These fears are not present solely in the United States; a survey of LGBT older adults in Ireland revealed that less than half of the respondents felt that healthcare providers, in general, respected them as a person of LGBT identity and that about one third of respondents felt that healthcare providers had an adequate understanding of issues important to LGBT patients (Sharek, McCann, Sheerin, Glacken, & Higgins, 2015).

Patients may also fear mistreatment or bias from their heterosexual peers with whom they cohabitate within a long-term care facility, particularly if they are assigned a roommate (Jablonski et al., 2013). Patients may choose to hide their identity and present as heterosexual, and partners who enter a long-term care facility together may choose to describe themselves just as best friends or close friends, when they previously had lived openly as partners (Serafin et al., 2013). Transgender older adults, especially, may be afraid that they would be assigned a room based on the gender of their birth rather than the gender they identify with, especially if they have not had a surgical transition (Jablonski et al., 2013).

One survey of fears that may cause patients to conceal their true identities and return to the closet found that older LGBT adults worried about being dependent on healthcare practitioners, being mistreated by staff or peers, being isolated and alone, and developing dementia (Putney, Keary, Hebert, Krinsky, & Halmo, 2018). In addition to hiding their true identities, these patients may be so affected by these fears that they could develop psychologic distress and/or suicidal ideation (Putney et al., 2018).

Social Support

Another psychosocial issue facing many older LGBT adults is the nature and size of their social support network. The main support network for many heterosexual older adults is their family; however, for many older LGBT adults, their main support network is their friend group (McParland & Camic, 2016). This idea that the friend group is the patient's "chosen family" became crucial for many LGBT people who were rejected or ostracized by their biologic family—however, caregivers should not assume that all LGBT patients have strained family relations, because many have improved with the improvement in overall LGBT visibility (Cloyes, Hull, & Davis, 2018).

Many older LGBT adults do struggle with the lack of biologic family support and are fearful of social isolation. LGBT adults are more likely not to have children, and a majority live alone and are at risk for self-neglect (McParland & Camic, 2016). One survey found that more than half of LGBT older adults lack companionship and feel isolated and/or excluded (Yang, Chu, & Salmon, 2018). Social isolation can have a significantly negative impact on the physical health of an older adult and has been found to potentially contribute to worsening cognitive function, coronary artery disease, stroke risk, depression, and/or suicidal ideation (Yang et al., 2018).

However, in response to both LGBT-related discrimination and agism, many LGBT older adults have also been noted to have developed a strong sense of resilience that may help them to advocate for their needs, adapt to new situations, and manage crises well as they age (Hash & Rogers, 2013). There still remain significant psychosocial issues to address for older LGBT adults, including for the

partners/spouses of older LGBT patients. During times of health crisis or incapacity, there can be challenges to the idea of a patient's "chosen family" or significant other if this is not documented in medical or legal paperwork or if the documentation has not yet been obtained (Marsack & Stephenson, 2018). There are also concerns that an older LGBT patient's spouse or partner may experience devalued bereavement after a loss if that relationship is not valued or respected in the same manner socially as a heterosexual relationship, even if that marriage or relationship has equal legal standing under the law (Hayman & Wilkes, 2016).

End-of-Life Perspectives

Characteristics of "perceived successful aging" for LGBT older adults includes not only a large network of social support, but also the confidence that healthcare providers will treat them respectfully and with dignity at the end of life (Walker, Powers, & Witten, 2017). End-of-life issues and fears impact LGBT older adults especially significantly, as LGBT patients are more likely to be without children or a partner toward the end of life and have been described to be more likely to have fears of dying in pain or alone (de Vries & Gutman, 2016). Some gay and bisexual men who lived through the HIV/AIDS epidemic and lost friends at a young age have also expressed the fear of reliving the losses of multiple friends again in older age (de Vries & Gutman, 2016).

The difficult hospice experiences that these gay and bisexual men had during the HIV/AIDS epidemic also give rise to a potential fear of recurrent discrimination in palliative and hospice care services in older age, particularly in organizations that are faith-based or religious (Griebling, 2016). Nurses and healthcare workers can help to alleviate these fears in hospice and palliative care settings by providing culturally sensitive and competent care, helping to discuss and formalize the patient's wishes for surrogate decision-making and visitation, and educating other clinicians (Maingi, Bagabag, & O'Mahony, 2018). Education for everyone is crucial, as one survey of LGBT persons revealed that only about one quarter of participants could correctly identify the legal decision-maker in a scenario describing a car accident involving a same-sex couple (Hughes & Cartwright, 2014). It is also important not to make assumptions during palliative care and end-of-life discussions and not to neglect the option that many LGBT older adults may want/request spiritual care and counsel during difficult and emotional times (Cloyes et al., 2018).

CASE STUDY 33.1

Ms. C is a 68-year-old transgender female recently transferred from the PACU to the medical–surgical unit for postoperative monitoring and recovery after a partial nephrectomy for a renal tumor. The surgical course was uncomplicated. The nurse on the medical–surgical unit begins the assessment for the admission. The patient is awake and alert, and her pain is well controlled. She is obese, with a BMI of 32.4 kg/m^2, and smokes five to six cigarettes per day. Aside from her recently diagnosed renal tumor, her medical history is notable only for hypertension. Her medications include an antihypertensive, oral estradiol (17-beta-estradiol), and spironolactone. Her only other surgery, aside from the recent partial nephrectomy, was an appendectomy for appendicitis at age 23.

Nursing considerations for this transgender patient in the postoperative setting include:

- Identifying/asking the patient his or her preferred pronoun(s) at initial assessment
- Confirming the patient's preferences for next of kin and visitors, and ensuring appropriate documentation of those preferences is completed in the patient's chart
- A detailed medication history
- A detailed surgical history
- A detailed social history
- Monitoring blood pressure closely along with other vital signs
- Encouraging ambulation
- Assessing for signs/symptoms of DVT/VTE
- Ensuring DVT/VTE prophylaxis is appropriately ordered by the surgical team and administered
- Encouraging smoking cessation

While performing the assessment, the medical–surgical nurse confirmed that Ms. C's preferred pronouns are "she" and "her" and documented this appropriately in the chart. While confirming the patient's preferences for next of kin and visitors, the nurse learned that Ms. C has a partner of 1 year, whom she designated as her surrogate decision-maker, and is on the way to the unit from the family waiting area. Ms. C mentioned they are talking about marriage, but are not currently married, and the nurse confirmed any documentation regarding surrogate decision-making was signed and in the chart. Ms. C told the nurse

(*continued*)

CASE STUDY 33.1 (*continued*)

she appreciated this, as there has been some strain in her family relationships since coming out as transgender 5 years ago and starting hormonal therapy about 2 years ago. Ms. C mentioned that she is divorced and has two children from her previous marriage who are supportive and will likely come to visit her. Because of the accepting environment that the nurse provided, Ms. C shared that she had been afraid to come out until only a few years ago as she was afraid of the social stigmas and the possibility of rejection from her family and friends.

Later that evening, while giving the handoff to the nurse on the night shift, the nurse made sure she communicated to the oncoming nurse several key points to ensure continuity of optimal care for this patient:

- The patient's preferred pronouns
- The patient's surrogate decision-maker's wishes and documentation
- The patient's multiple risks for DVT/VTE in the postoperative setting, including estrogen therapy, obesity, smoking, and recent surgery
- The plan for ambulation and DVT/VTE prophylaxis

SUMMARY

The LGBTQ population is a diverse community, including people of all ages, ethnicities, and socioeconomic classes. As the overall population ages, the number and visibility of LGBTQ elders will also continue to increase. The healthcare-related needs and disparities of this population are a unique fusion of medical and psychosocial, and are rooted in a history of rejection of their identity and distrust in the healthcare system. Thus, it is essential that nurses understand this unique combination of needs in order to overcome current barriers to care and provide comprehensive care to this growing population.

Nurses can make a valuable impact on the care of LGBT elders by creating a culturally sensitive and welcoming environment. This starts with understanding the difference between gender identity and sexual orientation and being comfortable and consistent in asking patients their preferred pronouns. Creating a comfortable environment will also make it easier to obtain a thorough sexual health history and age-appropriately screen for health conditions. Understanding the options for hormonal treatments for transgender elders will allow nurses to assess for age-specific risks and side effects and more comprehensively manage long-term health for these patients. And familiarity with the history and psychosocial concerns of the aging LGBTQ community will help nurses lead in addressing the unique holistic needs of LGBTQ elders and their caregivers.

NURSING STANDARD OF PRACTICE

Protocol 33.1: LGBTQ-Sensitive Care for Older Adult Patients

I. GOAL

Improve nursing care for older LGBTQ adults.

II. OVERVIEW

Older LGBTQ adults are less likely to seek healthcare owing to distrust but continue to have health needs that require medical attention and intervention.

III. BACKGROUND

Older LGBTQ adults have less access to care owing to fear of stigma of their sexual orientation and therefore often have a lapse in general healthcare needs and are more prone to depression, anxiety, and substance abuse than non-LGBTQ adults. Nurses should assist in creating a welcoming environment free of judgment and stigma to ensure that the LGBTQ adults are comfortable to discuss their needs.

(*continued*)

Protocol 33.1: LGBTQ-Sensitive Care for Older Adult Patients (*continued*)

IV. PRINCIPLES OF CARING FOR OLDER LGBTQ ADULTS

A. Create LGBT-friendly environment by using appropriate language.
   1. Inquire about sexual identity (Gay & Lesbian Medical Association, n.d.)
   2. Discuss sexual orientation (Gay & Lesbian Medical Association, n.d.)
   3. Ask about preferred pronouns (Gay & Lesbian Medical Association, n.d.)

B. Assess risk factors for chronic medical conditions as appropriate.
   1. Obtain a thorough sexual history (Gay & Lesbian Medical Association, n.d.).
      a. Discuss sexual preferences, partner preferences, and routes of intercourse.
      b. Assess barrier methods used.
      c. Discuss addition of new sexual partners.
   2. Assess social behaviors.
      a. Inquire about smoking, alcohol, and recreational drug use.
      b. Discuss current exercise regimen, diet.
   3. Determine if patient is up to date with screening guidelines.
      a. Follow nationally accredited guidelines as recommended according to risk factors (Meads & Moore, 2013; Quinn et al., 2015).
      b. Assess for risk of anal cancer (Quinn et al., 2015).

C. Assess for hormone therapy use in transgender patients and monitor for side effects.
   1. Exogenous estrogen for transgender females
      a. Estrogen formulations include oral, parenteral (either subcutaneous or intramuscular injections), or transdermal formulations (Unger, 2016).
      b. Most significant risk is increase in venous thromboembolic events (VTE), so monitor for symptoms of VTE (Weinand & Safer, 2015).
      c. Avoid ethinyl estradiol formulation, which carries the highest risk for VTE (Arnold et al., 2016).
      d. Further increased risk for VTE exists if on estrogen and smoking, obese, have a history of prior VTE, or have a thrombophilia/hypercoagulable disorder, so ask about these risk factors when taking a health history (Shatzel et al., 2017).
      e. Risk for elevation in triglycerides exists, so monitor serum lipid panels (Fernandez & Tannock, 2016).
      f. Potential risk of cardiovascular disease and stroke exists, so monitor blood pressure and assess for symptoms of stroke (Defreyne et al., 2019).
      g. No increased oncologic risk (Weinand & Safer, 2015).
   2. Antiandrogens for transgender females
      a. Addition of antiandrogen (when also on estrogen) decreases testosterone and lowers the dose of estrogen needed (Webb & Safer, 2019).
      b. Most common option is spironolactone (Randolph, 2018).
      c. Spironolactone is a potassium-sparing diuretic, so monitor for hyperkalemia, which increases in risk with age (Randolph, 2018).
      d. Finasteride is another option; its main risk is liver toxicity (Unger, 2016).
      e. Leuprolide, a gonadotropin-releasing hormone agonist, is another option but can be very expensive (Unger, 2016).
      f. Leuprolide also carries risks of osteopenia and decreased libido (Weinand & Safer, 2015).
   3. Exogenous testosterone for transgender males
      a. Testosterone formulations available in the United States include transdermal, parenteral (either subcutaneous or intramuscular injections), or subcutaneous implant (Unger, 2016).
      b. Risk for increase in serum hemoglobin and hematocrit (Irwig, 2017)
      c. Risk for possible decrease in HDL cholesterol (Irwig, 2017)
      d. Possibility for increase in serum triglycerides (Irwig, 2017)
      e. Likely to increase BMI (Fernandez & Tannock, 2016)

(*continued*)

Protocol 33.1: LGBTQ-Sensitive Care for Older Adult Patients (*continued*)

   f. No increased risk for VTE (Shatzel et al., 2017)
   g. No known increased risk of cardiovascular or oncologic events (Gooren & T'Sjoen, 2018)

D. Assess for psychosocial needs
   1. Fears/history of discrimination
      a. Many older LGBT adults are fearful of discrimination by their heterosexual peers and the healthcare practitioners they depend on as they age (Jablonski et al., 2013).
      b. Past experiences of rejection and/or abuse cause many LGBT adults over 55 years old to remain closeted (Zelle & Arms, 2015).
      c. LGBT older adults may return to the closet in a nursing facility and may be afraid that the nursing/healthcare staff will have their own personal biases that are not accepting of the LGBT identity and thus that the staff may neglect, abuse, or persecute them (Serafin et al., 2013).
      d. Patients may hide their identity and present as heterosexual owing to fears of discrimination by heterosexual roommates or cohabitants in a long-term care facility (Serafin et al., 2013).
      e. Transgender older adults may be afraid that they would be assigned a room based on the gender of their birth rather than the gender they identify with, especially if they have not had a surgical transition (Jablonski et al., 2013).
      f. These fears and isolation are risks for psychologic distress and/or suicidal ideation (Putney et al., 2018).
   2. Social support
      a. For many older LGBT adults, their main support network is their friend group, or "chosen family" (McParland & Camic, 2016).
      b. LGBT adults are more likely not to have children, and a majority live alone and are at risk for self-neglect (McParland & Camic, 2016).
      c. Social isolation can contribute to worsening cognitive function, coronary artery disease, stroke risk, depression, and/or suicidal ideation (Yang et al., 2018).
      d. It is important to ensure documentation of a surrogate decision-maker if that person is "chosen family" or an unmarried partner (Marsack & Stephenson, 2018).
      e. It is important to recognize an older LGBT patient's spouse or partner during a time of loss, to avoid devalued bereavement, which can occur if that relationship is not valued or respected in the same manner socially (Hayman & Wilkes, 2016).
   3. End of life
      a. "Perceived successful aging" for LGBT older adults includes not only a large network of social support, but also the confidence that healthcare providers will treat them respectfully and with dignity at the end of life (Walker et al., 2017).
      b. LGBT patients are more likely to be without children or a partner toward the end of life and have been described to be more likely to have fears of dying in pain or alone (de Vries & Gutman, 2016).
      c. Some gay and bisexual men who lived through the HIV/AIDS epidemic may express the fear of reliving the losses of multiple friends again in older age (de Vries & Gutman, 2016).
      d. Providing culturally sensitive and competent care can help to alleviate fears of recurrent discrimination in the hospice setting, which includes helping to discuss and formalize the patient's wishes for surrogate decision-making and visitation (Maingi et al., 2018).
      e. Avoid assumptions during palliative/end-of-life discussions, as LGBT older adults may want/request spiritual care during difficult times (Cloyes et al., 2018).
      f. Promote team education of LGBT-sensitive care, as it is important to understand the legalities of surrogate decision-making (Hughes & Cartwright, 2014).

E. Access appropriate resources specific to patient needs.

Substance Misuse and Alcohol Use Disorder in the Older Adult*

34

Donna E. McCabe, Michelle M. Knapp, and Madeline A. Naegle

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:
1. Describe common patterns of substance use in older adults.
2. Recognize common substance use disorders (SUDs) diagnosed in older adults.
3. Outline steps for screening for SUDs in older adults.
4. Discuss the stepwise assessment and rationale for identifying a SUD.
5. Analyze intervention strategies for SUDs in older adults.
6. List potential resources on SUDs for older adults and their families.

OVERVIEW

Evidence of alcohol and drug use by persons aged 50 years and older is increasing as more people live longer, continue community living, and persist in substance use habits established in youth and middle adulthood. Approximately 65 million persons aged 65 years and older now live in the United States, and this number is projected to grow to more than 90 million by 2060 (Mather, Jacobsen, & Pollard, 2015). Population growth and increases in alcohol and drug use predict greater numbers of older adults will experience substance-related problems, perhaps as many as 5.7 million by 2020. Nurses should be prepared to identify and intervene with substance-using behaviors, which place the older adult at risk for health problems (Eden, Maslow, Le, & Blazer, 2012). The estimated one fourth of the older population who are minority group members will also grow. Although drug and alcohol use in minorities have been understudied, new data suggest that the minority women are drinking alcohol at growing rates and that there is a high prevalence of smoking among Asian-Pacific men (Grant et al., 2017). Nursing interventions with these groups of older adults should be culturally competent and tailored to their substance use patterns.

BACKGROUND AND STATEMENT OF PROBLEM

Events of the past decade have highlighted high levels of substance use from adolescence to older adulthood. Substance use disorders (SUDs) have been declared a national public health emergency (Lehmann & Fingerhood, 2018; U.S. Department of Health and Human Services, Office of the Surgeon General, 2018). Deaths from prescription and illicit drug overdoses among all ages reached over 70,000 in 2017, and older adults are especially vulnerable due to chronic illness and associated pain syndromes (Hedegaard, Miniño, & Warner, 2018). Health problems

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

linked to SUDs and excess alcohol consumption are costly to society with direct and indirect economic costs of hundreds of billions of dollars (Gryczynski et al., 2016). The burden of prescription drug misuse alone is estimated to be 78.5 annually (Florence, Luo, Xu, & Zhou, 2016). Older adults use one third of all medications prescribed in the United States (National Institute on Drug Abuse [NIDA], 2015), and it is estimated that 25.4% of all opioid prescriptions extending over 90 days are written for older adults (Mojtabai, 2018). High rates of chronic pain among older adults may account for the high opioid use; however, opioid misuse has increased for those ages 60 to 64 years despite an overall reduction in other populations (Chang & Compton, 2016).

The use of substances by older adults is a health concern. While cigarette smoking has declined in recent years, about 8 out of 100 people, or 9%, aged 65 years or older report smoking (Wang et al., 2018). Marijuana use among older adults is increasing, with a past year prevalence rate of 1.3% to 2.0% among those aged 65 years and older, the highest increase in use across populations (Han & Palamar, 2018).

Patterns of substance use vary in subpopulations, and some differences among groups are noteworthy. For example, the success of antiretroviral therapies has extended life for those living with HIV. In 2015, 47% of those living with HIV were over 50 years of age, 7% were over 65 years of age, and 17% of all new cases were in persons over age 50 (Centers for Disease Control and Prevention [CDC], 2018). This population has disparately high rates of substance use, estimated to be as high as 50%. Older people living with HIV are particularly susceptible to the hazards of substance use and misuse (Deren et al., 2019).

Variations related to race and substance-using patterns differ with age. Although Caucasian adult drinkers outnumber African American adult drinkers, African American males, especially those over 50 years, have the highest risk for alcoholism and related legal and social problems (Zapolski, Pedersen, McCarthy, & Smith, 2014).

Mental health and substance use problems are highly stigmatized in older populations, and this, coupled with a general reluctance to seek medical help, means that access to such care is limited. The dearth of geropsychiatric nurses and physicians and other geriatric behavioral health specialists has been recognized as an increasingly serious problem. Proposed solutions to the lack of specialty providers include incorporating training on screening and basic interventions for SUDs for professionals in all healthcare settings (Eden et al., 2012). Psychiatric disorders often co-occur with alcohol use and misuse in older adults, with prevalence rates ranging from 12% to 30% (Oslin, 2005), and depression can occur independently or accompany excess drinking. Older adults are among those with the highest suicide rates. People entering late middle age, ages 45 to 54, commit suicide at rates of 20.2%, and those over 85 at 20.1% (American Foundation for Suicide Prevention, 2017).

The metabolic and organ changes of aging linked with drug or alcohol use contribute to high morbidity in advancing age. Decreased total body water and lower rates of alcohol metabolism in the gastrointestinal tract increase sensitivity to alcohol, resulting in decreasing tolerance with age (U.S. Department of Health and Human Services [USDHHS], 2004a). With functional and neurological changes, tolerance to alcohol decreases, and behavioral changes are more evident (USDHHS, 2004a). More dramatic behavioral changes occur at lower drug doses, and adverse physical responses result in morbidity or mortality and may curtail intake. Most alcohol consumers drink less with age, and only 4.1% of those 65 to 75 and 1.6% of those 75+ years report a lifetime alcohol use disorder (AUD; Wu & Blazer, 2014). Social and legal problems occur more frequently and are more pronounced than in younger people, especially for older women (Blow & Barry, 2003). Because criteria for the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*; American Psychiatric Association [APA], 2013) may be less applicable to older adults, these must be interpreted and applied in age-appropriate ways. Even when persons older than 65 years do not meet the *DSM-5* criteria for a moderate or severe use disorder, alcohol consumption at levels greater than seven drinks weekly or more than three drinks on any single day warrants teaching about potential consequences for health.

Alcohol

The drug most commonly used by older adults remains alcohol, with approximately 16.2 million adults over age 65 years, nearly 24%, reporting drinking alcohol in the past month (Mattson, Lipari, Hays, & Van Horn, 2017). Research findings have suggested that moderate alcohol use by adults has been associated with the decreased risk for cardiovascular heart disease and improved cognitive function; findings, however, have been inconsistent. Excess alcohol use compromises health by interfering with the absorption and utilization of prescribed drugs and nutrients and may place the older individual at risk for falls, self-neglect, and diminished cognitive capacity. Long-term excess alcohol use is linked to common medical problems such as sleep disorders, restlessness and agitation, abnormalities in liver function, pneumonia, pancreatitis, gastrointestinal

bleeding, and trauma as well as chronic diseases, particularly neuropsychiatric and digestive disorders, diabetes, cardiovascular disease, and pancreatic or head and neck cancer (Kuerbis, Moore, Sacco, & Zanjani, 2017).

The WHO (World Health Organization) Global Burden of Disease study recommends that alcohol intake be zero in order to minimize disease (Griswold et al., 2018). Evidence of association between alcohol use and disease burden, which is highest for cancer, supports experts' advice against health professionals' recommendations of moderate alcohol for cardiovascular disease protection or other health benefit (Mialon & McCambridge, 2018). Older adults treated for AUDs earlier remain at risk if they return to drinking. Harmful or "risky" drinking is use that does not meet criteria for an AUD but that places the individual at risk for health problems including AUD (Kuerbis, Sacco, Blazer, & Moore, 2014). American Geriatric Society and National Institute for Alcohol Abuse and Alcoholism guidelines specify that no more than three standard (two for women) drinks a day, and no more than seven a week, may reduce health risks for older adults. Alcohol use by those using prescribed medications and who have chronic disease should be modified further. It is estimated that 16% of older men and 10% of older women drink at levels potentially harmful to health. Recent data indicate that "binge drinking," defined as more than four standard drinks on one occasion, is on the rise in older adults, with rates of 14.4% of persons over 50 reporting binge drinking in the last month (Han & Palamar, 2018). These patterns can result in high personal and medical costs at all ages, but more so for older adults. Because alcohol-attributable conditions often go unrecognized and, therefore, unreported, rates are underestimated. Alcohol use by older adults is associated with falls and unintentional injury, more frequent hospitalization, more depressive symptoms, and increased adverse medication–alcohol interactions (Lehmann & Fingerhood, 2018).

Tobacco and Nicotine

The global burden of disease linked to tabacco use is heaviest among older individuals. Age at initiation of smoking and time spent smoking are predictors of mortality for people aged 70 years and older (Nash, Liao, Harris, & Freedman, 2017). In 2017, 16.5% of those aged 45 to 64 years and 8.2% of individuals over the age of 65 reported daily cigarette use (Wang et al., 2018). The development and marketing of alternative tobacco and nicotine delivery products has dramatically increased use. Marketed as safer alternatives to combustible cigarettes, these devices deliver nicotine, known to be addictive and have deleterious health effects in any form. E-cigarette use prevalence rates in adults over 18 years of age was 4.5% in 2016. While rates of e-cigarette use are lower among older adults as compared to younger adults, high use by younger adults may predict significant health issues with age (Weaver, Kemp, Heath, Pechacek, & Eriksen, 2017).

Illicit Drugs

People often continue drug use patterns from young adulthood to older age, and recent data suggest that the "baby boomer" generation is continuing greater use of recreational, generally illicit, drugs than previous generations. A Substance Abuse and Mental Health Services Administration (SAMHSA) survey found that adults aged 50 to 64 who used illicit substances increased from 2.7% in 2002 to 6% in 2013. Marijuana has been legalized in 13 states for medical and recreational use but is still considered illicit, and the past year prevalence of marijuana use by those 50 and older increased by 71.4% from 2006 to 2013 (Han & Palamar, 2018). A combination of factors, including recommendations to treat pain more effectively, deception regarding addictive potential of synthetic opioids, and overprescribing by health professionals (Kolodny, Courtwright, Hwang, Clark, & Alexander, 2015), contributed to an epidemic of opioid addiction in the United States, which peaked in 2009. Increases in the use of synthetic opioid analgesics, while less prevalent in older adults, is linked to higher mortality rates for drugs like oxycodone, fentanyl, oxymorphone, and tramadol. The higher rates of opioid use among this population is often the result of high rates of chronic pain, more common in older adults than any other age group. The drugs most commonly used in this group are prescription anxiolytics, sedatives–hypnotics, and opioids (West, Severtson, Green, & Dart, 2015).

ASSESSMENT OF SUBSTANCE USE DISORDERS

SUDs occur on a continuum ranging from mild to severe (*DSM-5*; APA, 2013). Treatment interventions range from harm reduction to techniques that promote abstinence. Many people are ambivalent about changing patterns of alcohol and nicotine use and may opt to "cut back" rather than abstain, a change that has been found ineffective with smoking but more effective with alcohol use. Binge drinking is the most common form of problematic alcohol consumption among young adults and may indicate the continuation of maladaptive use patterns formed at a younger age when people are more likely to develop SUDs. Social use of alcohol may change

to "at-risk" drinking or prescription drug use to drug misuse with stressful life situations like loss of a spouse, partner, or job; estrangement from family; or diagnosis with a serious illness. Risks for excess use rise with these circumstances. Comprehensive assessment, including social and mental status assessments, extracts such patient-specific information that is basic to patient-centered treatment planning.

SUDs are categorized as mild, moderate, or severe for 10 classes of drugs of abuse and are in accord with the number of symptoms described in 11 diagnostic criteria. New-onset SUDs in older adults may be the result of negative, physical, and psychological symptoms. "Late-onset alcoholism" and patterns of prescription drug abuse, marked by increased use and/or overreliance on either, can emerge secondary to losses, chronic illness, and psychological traumas. Misuse of prescription opioids, which are at high rates for all ages, may be related to the increase in opioid prescriptions among older adults and comes with consequences; there was a 35% increase in opioid-related hospital admissions in this population from 2000 to 2015 (Agency for Healthcare Research and Quality, 2018). Pathological patterns of use, including negative social and health consequences, can be linked to the amount and frequency of the substance used, the length of time of use (a 12-month period or more), and the specific substance.

Alcohol Use Disorders

The most common SUDs diagnosed in older adults are AUDs, including interactions of alcohol with prescription and over-the-counter (OTC) drugs (SAMHSA, 2018; Wu & Blazer, 2014). A SUD is diagnosed when a maladaptive pattern of use is evidenced by 11 criteria occurring over a 12-month period (modified from APA, 2013). Behaviors indicate impaired control over use of a substance (Criteria 1–4), with an inability to cut down on use, and persistent failures to control use (Criterion 2), and recovery from use occupying significant periods of time (Criterion 3), with the result that other role obligations are neglected (Criterion 5). Craving or an intense desire to use a drug may occur (Criterion 4), and use persists despite social, health, and interpersonal problems worsened by use (Criterion 6); there is a growing tendency to withdraw from work or recreational activities (Criterion 7).

"At-risk" drinking is a pattern that may not appear to be linked with problems, but, with this continued pattern, can result in harmful consequences. Individuals over the age of 60 are more likely to experience medical complications associated with alcohol use, even when drinking amounts similar to those in prior years (Kuerbis et al., 2014). Women are at an even higher risk for negative consequences related to other psychological and physiological changes (e.g., menopause; Lal & Pattanayak, 2017). Outcomes are determined by the individual's response to alcohol, the use of prescription drugs (alcohol interacts with at least 50% of prescription drugs), and co-occurrence of other chronic medical or psychiatric disorders. Similarly, a decline in visual, auditory, or other perceptual capacities makes alcohol consumption hazardous.

Severe SUDs are chronic, recurring illnesses. Recovery can be achieved with medication, self-help, and psychotherapy. Periods of abstinence or decreased consumption may be interrupted by brief "slips," after which the individual returns to action toward recovery. Severe SUDs have two components—first, physiological dependence induced by certain drugs, such as alcohol, tobacco, benzodiazepines, barbiturates, amphetamines, and opioids, which is evidenced in "tolerance"; the need for increasing amounts of a substance to achieve the desired effect; and "withdrawal," a characteristic pattern of symptoms when use of a substance is suddenly stopped. Second, craving accompanies withdrawal, so there is also psychological dependence, the perceived need to use the drug. Psychological dependence is evidenced in moderate and severe substance disorder and is more difficult to resolve than physiological dependence, requiring ongoing efforts in behavioral change.

Illicit Drug Use

Illicit drug use in older adults has historically been far less prevalent than excess alcohol use until recently (see earlier discussion). Although there have been steady increases in unhealthy alcohol use by older adults, data suggest that the proportion of older adults seeking treatment for illicit substance use is rising, whereas treatment for AUDs is declining (Chhatre, Cook, Mallik, & Jayadevappa, 2017). These data highlight the chronicity of substance use and SUDs. About 90% of adults aged 50 to 59 first used illicit substances before age 30. Of illicit substances used, marijuana use is the highest and is more prevalent among older adults than adolescents (SAMHSA, 2018) are. The growing number of states legalizing marijuana may play a role in the uptake of marijuana use. Medical marijuana laws have been associated with decreased opioid prescriptions for older adults, which could decrease risks associated with opioid use; however, there are long-term complications and medication interactions associated with marijuana use by older adults (Bradford, Bradford, Abraham, & Adams, 2018; Han & Moore, 2018). In addition, marijuana users have higher rates

of AUD, nicotine dependence, cocaine use, and misuse of prescription opioids, without perceived risk (Han & Palamar, 2018). Opioid misuse among older adults is also concerning given the risks associated with the number of prescription drugs that older adults take. There is also a national increase in the use of benzodiazepines by older adults, which can have serious complications (including death and overdose; Maust, Blow, Wiechers, Kales, & Marcus, 2017). The failure to identify substance-related problems in older adults has been linked to the failure to inquire about alcohol and drug use, including misuse of prescribed drugs. Assessment should include questions on the type, amount, and frequency of use of all substances, including food supplements and vitamins.

Recovery From Severe Substance Use Disorders

The term *recovery* has different meanings. The components of recovery have been described by the Betty Ford Institute Consensus Panel (2007). *Recovery* is defined as a lifestyle voluntarily maintained by an individual that includes sobriety, varying levels of personal health, and citizenship. Many older adults are "in recovery" or have established long-term abstinence from the use of alcohol, cocaine, heroin, or other drugs. Those active in Alcoholics Anonymous or NarAnon consider "sobriety" to be about moral character. Other individuals consider reduction of substance use to be recovery. Adverse circumstances and life stressors may contribute to an abstinent individual's relapse to alcohol or drug use. Transitions that come with aging, increasing numbers of losses, and the onset of illness may all be "triggers" to return to prior patterns of problematic substance use, posing threats to recovery and risks for a return to regular, maladaptive patterns of use (relapse). While not widely known, rates of substance use treatment completion, which are important in the recovery process, are higher in persons over 65 than in any other age group (Sahker, Schultz, & Arndt, 2015). Nursing interventions include support of the patient's attendance at self-help group meetings, continued involvement in treatment such as methadone or buprenorphine maintenance, active community and family involvement, and/or group or individual psychotherapy.

In this chapter, the term *drug* applies to herbs, OTC medications, and prescription medications taken as prescribed. *Substance* refers to the 10 types of substances listed by *DSM-5* category (which may also include illicit use of prescribed medications). Please refer to www.drugabuse.gov for a full listing of drugs of abuse and their chemical properties.

Psychoactive Drug Misuse and Abuse

Drug misuse, defined as use of a drug for reasons other than those for which it was intended, is a risk for the older adult. Prescriptions for multiple medications and cognitive changes, including early signs of dementia, can lead to medication misuse. Common outcomes of drug misuse include overdose; synergistic and cumulative effects; adverse reactions to drugs; or drug interactions, especially with alcohol. Older adults account for 30% of national expenditures on all prescription drugs, and nonmedical use of prescription drugs increases in persons older than 60 years (NIDA, 2015). In addition to higher rates of mortality from opioid misuse, the accessibility of heroin and synthetic opioids are increasingly factors in suicide in older adults (West et al., 2015).

Regular use of multiple drugs for more than one medical condition (i.e., polypharmacy) is complicated by the older adult's use of alcohol or illicit drugs (Letizia & Reinbolz, 2005). In persons aged 18 to 70 years treated for falls, 40% of men and 8% of women tested positive for alcohol and/or benzodiazepines (9% and 3%, respectively), or both (A. R. Boyle & Davis, 2006).

Abuse of psychoactive drugs is increasingly a health problem for older adults. Few evidence-based findings on factors contributing to the problem exist, but those identified include isolation, history of substance-related or mental health disorder, bereavement, chronic medical disorders, female gender, and exposure to prescription drugs with abuse potential. Few older adults are lifetime illicit drug users (Wu & Blazer, 2014), other than marijuana users. However, substance abuse by older adults, one in four of whom receives prescriptions for drugs with abuse potential, is becoming more common. The most commonly misused drugs, other than nicotine or tobacco, are benzodiazepines, sedative hypnotics, and opioid analgesics (Wu & Blazer, 2014).

Smoking and Nicotine Dependence

Today's older Americans have smoked at rates among the highest of any U.S. generation (American Lung Association [ALA], 2010), resulting in many health problems and contributing to the estimated 438,000 American deaths annually caused by smoking. Nearly 20 of every 100 American adults aged 45 to 64 years (19.9%) and nearly 9 of every 100 adults aged 65+ years (8.8%) are current smokers (CDC, 2015).

Although these rates in older adults have decreased in recent years, vulnerability to the effects of smoking is evident. The risk of dying of a heart attack for men aged

65 years and older is twice that for women smokers and 60% higher than for nonsmoking men of the same age. Smokers also have significantly higher risks than nonsmokers for Alzheimer's disease and other types of dementia, and smoking plays a role in heart and lung disease, cancer, osteoporosis, diabetes, erectile dysfunction, and visual disorders like macular degeneration and nuclear cataracts (Whitmer, Sidney, Selby, Johnston, & Yaffe, 2005).

Polysubstance Abuse

Polysubstance abuse, the misuse, abuse, or regular use of three or more drugs, is common in older adults and, depending on the class of drug, can induce dependence. Older problem drinkers, as well, report more severe pain, greater disruption of activities caused by pain, and frequent use of alcohol to manage pain (Brennan, Schutte, & Moos, 2005). These findings underscore the importance of monitoring drinking and medication use in patients who present with complaints of pain, especially those with histories of any heavy drug use or SUDs, including alcohol and nicotine.

ASSESSMENT OF SUBSTANCE USE

The nurse should review the most recent nursing and medical histories and the most recent physical examination. The Mental Status Examination (MSE) is of particular relevance to assessing the acuity and chronicity of a SUD. The MSE should include queries on self-harm, history of suicide attempts, and current suicidal ideation. The use of substances is linked with suicide, and older adults are among Americans with the highest suicide rates (SAMHSA, 2018; West et al., 2015).

When patients are using alcohol, there may be deviations in standard liver function tests (LFTs) and elevations in gamma-glutamyl transferase (GGT) and carbohydrate-deficient transferrin (CDT) levels; 50% to 70% of heavy drinkers will have percentages of CDT greater than 2.6 (Miller, Cluver, & Anton, 2009). Physical signs, such as ecchymosis, spider angiomas, flushing, palmar erythema, or sarcopenia, may be evidence of heavy use. The patient may have an altered level of consciousness, changes in mental status or mood, poor coordination, tremor, increased deep tendon reflexes, or a positive Romberg sign. Increased lacrimal secretions, nystagmus, and sluggish pupil reactivity may also be noted on examination (Letizia & Reinbolz, 2005). Patients who report use of marijuana and/or other drugs should have toxicology tests to establish baseline use level. Findings can be effectively used in a motivational interview and brief interventions and/or counseling.

Nurses need to assess and document frequent changes in drug-using habits and record these in substance use histories, dating from first use to current use. It is recommended that the nurse ask whether the individual ever experienced problems related to drug or alcohol use, spontaneously stopped using a drug or alcohol, or is in recovery and participating in self-help programs such as Alcoholics Anonymous or Narcotics Anonymous.

In taking the patient history, the nurse should ask about a history of smoking, alcohol use in the form of number of standard drinks, OTC medications, prescription and recreational drugs, herbal supplements, and food and drink supplements. This information can be recorded using the Quantity Frequency (QF) Index (Khavari & Farber, 1978). Another helpful technique in assessing drug use is the "brown bag" technique. The client is asked to bring in a brown bag containing all the prescribed OTC, food supplements, and other legal or illicit drugs that he or she consumes weekly. These are used to develop the history and to open a discussion about the implications of drug use with the patient. It is important to ask the client about the intended use of the drug (e.g., relief of pain, feelings of loneliness, anxiety, or comfort).

Screening, brief intervention, and referral to treatment (SBIRT) has been found to be effective with adults and older adults for smoking, illicit drug and prescription drug abuse, and alcohol use, and should be part of the nursing evaluation (Schonfeld et al., 2010). Despite federal agency guidelines supporting its use, it is rarely used with older adults. SBIRT has demonstrated efficacy and feasibility in reducing patients' alcohol consumption, decreasing dependence symptoms (Babor et al., 2007; SAMHSA, 2018), and improving general and mental health (Madras et al., 2009) following its use by nurses and nurse practitioners.

Using SBIRT

SBIRT begins with *screening* an individual using a valid and age-appropriate screening tool to identify alcohol use behaviors that may place the individual at risk for health problems. Short, well-tested questionnaires that identify risk include the Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST), the Short Michigan Alcohol Screening Test-Geriatric version (SMAST-G), the Alcohol Use Disorders Identification Test (AUDIT), and AUDIT-C (Consumption), and abbreviated AUDIT tool.

Although screening can often be self-administered by paper and pencil, older adults may respond to administration by the nurse or trained personnel. A positive score on the screening tool for excess alcohol use or for smoking can be determined by a brief 3- to 5-minute session, including advice to cut down. SBIRT is not effective with individuals with severe SUDs and physiological dependence on alcohol.

Blow, Bartels, Brockmann, and Van Citters (2005) recommend modifying the *brief intervention* for older adults to include the following points:

1. Help the individual identify future goals for health, activities, and relationships.
2. Give feedback that is customized to the individual's patterns of substance use, health habits, and emotional and cognitive function.
3. Discuss norms of drinking habits. Define drinking patterns (light, moderate, and heavy).
4. Help the client weigh the pros and cons of drinking.
5. Explore the consequences of heavy drinking.
6. Explore the reasons to cut down on or quit drinking.
7. Help the client to set a sensible drinking standard using strategies to cut down or quit.
8. Help the client anticipate and plan for coping in risky situations (Blow et al., 2005).

If the patient declines change at this time, the discussion is dropped. The topic of possible change, however, should be raised at the next visit. When the screening instrument (AUDIT, SMAST-G) score indicates dependence on alcohol or nicotine, *referral* to specialty treatment and information needed to access a provider or a specialty healthcare agency are in order.

Depending on the healthcare setting, between 1% and 10% of patients may need some level of *treatment*—to ensure safe withdrawal and reinforce decreased intake or cessation.

Despite the U.S. Preventive Services Task Force recommendation to screen older adults for excess alcohol use, screening is inconsistently implemented. Health providers, family members, and friends may overlook excess use because the drug use is not linked to the usual disruptions in work or function that are more evident in early life. Other reasons for not taking action are beliefs that indulging in such activity is deserved, and that older people cannot change long-standing behaviors. Evidence suggests that many health professionals continue to view alcohol and other drug use with pessimism and negativity (van Boekel, Brouwers, van Weeghel, & Garretsen, 2013). Some healthcare providers may lack knowledge of the association of drug use, smoking, or excessive alcohol use with health problems like chronic obstructive pulmonary disease (COPD), stroke, or depression.

SUDs are now recognized as chronic conditions, characterized by slips and relapses, and conditions that respond to treatment (McLellan, Lewis, O'Brien, & Kleber, 2000). Interventions and treatment should be matched to stages of the disease (acute phases, exacerbations, and stages of recovery) to improve outcomes.

Screening Tools for Alcohol and Drug Use

Screening for alcohol and other drug use should be implemented in community and hospital settings, and even a few questions can suggest or rule out a disorder. A Q/F Index, such as the Khavari Alcohol Test (KAT), asks (a) usual frequency of alcohol use, (b) usual amount consumed per occasion, (c) maximum amount consumed on any one occasion, and (d) frequency of consumption of the maximum amount (Allen & Wilson, 2003). The KAT consists of the four questions noted previously that are asked for each type of beverage (beer, wine, spirits, and liqueurs) and can be administered in 6 to 8 minutes (Khavari & Farber, 1978). The amounts are then compared with National Institute on Alcohol Abuse and Alcoholism (NIAAA) guidelines for persons older than 65 years. Additional inquiries such as (a) "Did you ever feel you had a problem related to alcohol or other drug use?" and (b) "Have you ever been treated for an alcohol or drug problem?" will yield important additional information.

Short Michigan Alcohol Screening Test-Geriatric Version

The SMAST-G is an effective tool for screening older adults in all settings. The complete drug use history can be obtained in the comprehensive assessment. The original instrument from which this version was derived has a sensitivity of 93.9% and a specificity of 78.1% (Blow et al., 1992). The SMAST-G is composed of 10 questions and is quickly administered. Each positive response counts as 1 point.

Alcohol Use Disorders Identification Test (AUDIT)

This 10-item questionnaire has good validity in ethnically diverse groups, and scores classify alcohol use as hazardous, harmful, or dependent; administration: 2 minutes (Saunders, Aasland, Babor, de la Fuente, & Grant, 1993). The

AUDIT has been found to have high specificity in adults older than 65 years (Babor, Higgins-Biddle, Saunders, & Monteiro, 2001).

AUDIT-C

The AUDIT-C, a modification of the 10-item AUDIT, is only three questions, making administration simple. It is used to identify people who are risky drinkers or those with frank AUD and has a sensitivity when used with men of 0.95/specificity of 0.60, and when used with women a sensitivity of 0.66/specificity of 0.94 (see AUD-C, WHO).

Fagerström Test for Nicotine Dependence-Revised

This six-question scale provides an indicator of the severity of nicotine use disorder: less than 4 (*low to moderate dependence*), 4 to 6 (*moderate dependence*), and 7 to 10 (*highly dependent on nicotine*). The questions ask about first use early in the day, amount and frequency, inability to refrain, and smoking despite illness. This instrument has good internal consistency and reliability in culturally diverse, mixed-gender samples (Pomerleau, Carton, Lutzke, Flessland, & Pomerleau, 1994).

INTERVENTION AND CARE

Interdisciplinary collaboration is essential to providing the range of treatment modalities for SUDs and related problems because SUDs have physical, mental, spiritual, and emotional components. Primary care providers, psychologists, dentists, nurses, and social workers should be equipped to screen for and refer a problem, and treatment and aftercare should address all dimensions of the disorder. The least intensive treatment approaches should be implemented first and should be flexible, individualized/patient centered, and implemented over time. Older adults are reluctant to seek or continue care with mental health/addictions specialists. Brief interventions and motivational interviewing have been found effective in producing short-term reduction in alcohol consumption for older persons. Some findings suggest that motivational interviewing is more effective with smoking than brief advice (Ballesteros, González-Pinto, Querejeta, & Ariño, 2004; Wutzke, Conigrave, Saunders, & Hall, 2002). Research findings also suggest that once enrolled in treatment for an SUD, older people treated for alcohol or opioid dependence with medications, such as naltrexone, methadone, or buprenorphine, and individualized, supportive, and medically based psychosocial interventions have better outcomes than younger people (Satre, Mertens, Arean, & Weisner, 2004).

Inpatient Hospitalization

All older adults should be screened for alcohol use on admission to any care facility (Nicholas & Hall, 2011). A small but important percentage will be at risk for the development of acute alcohol withdrawal syndrome (AWS) on sudden cessation of drinking. Patients at highest risk have (a) a history of consuming large amounts of alcohol, (b) coexisting acute illness, (c) previous episodes of AWS or seizure activity, (d) a history of detoxification, and (e) intense cravings for alcohol (Letizia & Reinbolz, 2005). Symptoms of withdrawal are intense and of greater duration than in younger persons, with onset of withdrawal as early as 4 to 8 hours after the last drink and persisting up to 72 hours. The clinical symptoms determine the need for detoxification and determine medical and nursing decisions. Two instruments assist in managing symptoms of withdrawal: CIWA (Clinical Institute Withdrawal Assessment for Alcohol) and COWS (Clinical Opiate Withdrawal Scale). The COWS is an 11-item scale that quantifies the severity of opiate withdrawal by rating symptoms from mild to severe. It should be administered and scored by a clinician. Scores range from 5 to 36 (Wesson & Ling, 2003). The CIWA queries 10 symptoms of alcohol withdrawal and rates them numerically. Scores are ranged from 10 to 15 (mild), 16 to 20 (moderate), and 21 to 67 (severe; Stuppaeck et al., 1994).

A 10- to 28-day period of acute care hospitalization in a mental health or alcohol and drug treatment center is indicated for the older person addicted to alcohol, benzodiazepines, heroin, amphetamines, or cocaine when (a) living situations and access to the drug make abstinence unlikely; (b) there is a likelihood of severe withdrawal symptoms; (c) comorbid physical or psychiatric diagnoses, such as depression and accompanying suicidal ideation or a chronic physical illness, are present; (d) daily ingestion of alcohol or a sedative hypnotic has been higher than recommended doses for 4 weeks or more; and (e) there is mixed addiction, that is, alcohol and benzodiazepines or cocaine and alcohol. It is helpful if programs specifically designed to meet the needs of older persons are available (USDHHS, 2004a).

Ambulatory Care

Persons dependent on alcohol, tobacco, and heroin can be successfully withdrawn from high levels of drugs in community-based care through the collaboration of a medical doctor or nurse practitioner and with the support and oversight of family members and friends. Specialists in addiction should oversee the process. Older persons drinking at risky levels or regularly using alcohol or other drugs

are generally treated in the community. Tobacco-cessation protocols are now available directly to consumers as well as to primary care providers and mental health professionals.

Residential Treatment

Residential treatment is available in specialty care centers, therapeutic communities, and some long-term care facilities. Programs designed specifically for the older person are beneficial in their focus on the specific healthcare needs and challenges to abstinence faced by older people. These long-standing habits of use, a diminished social network, risks of social isolation, and health implications of heavy alcohol and prescription drug use make behavioral change particularly challenging.

Therapeutic Communities

Therapeutic communities provide long-term (up to 18 months) treatment and are abstinence-oriented programs. They use the 12-step Alcoholics Anonymous model of individual and group counseling, as well as participation in a social community, to address drug-related problems. For the isolated, older drug user with a history of frequent relapse, these are good treatment options.

Pharmacological Treatment

There are several FDA-approved medications available to treat opioid, alcohol, and tobacco use disorders. Considerations include use patterns, treatment goals, and any contraindications for use that are often related to the metabolic changes associated with aging. The best outcomes of pharmacological interventions are achieved by the combination of medication with individual and/or group counseling. Attendance at structured self-help groups such as 12-step programs or SMART Recovery also supports adherence to treatment regimens.

Severe Alcohol Use Disorder and Medication-Assisted Treatment

There is strong evidence for both naltrexone and acamprosate to help individuals with risky or dangerous alcohol use patterns to decrease alcohol consumption (Kim, Hack, Ahn, & Kim, 2018; Maisel, Blodgett, Wilbourne, Humphreys, & Finney, 2013). Naltrexone is an FDA-approved medication that comes in oral and once-monthly injectable formulations. Although the long-acting injectable (Vivitrol) form lasts 28 days and may improve adherence, both medications have been shown to lengthen periods of abstinence, reduce the number of drinking days, and increase overall treatment retention (Maisel et al., 2013; Rösner et al., 2010). Naltrexone is a Mu opioid antagonist and is an option for an individual who has a concomitant opioid use disorder and wishes to be abstinent from all opioids. Evidence suggests that naltrexone is well tolerated by older people (Caputo et al., 2012). Contraindications for its use include renal problems, acute hepatitis, or liver failure. Psychosocial interventions can help to enhance adherence to pharmacological interventions for AUDs.

Acamprosate calcium (Campral) has been shown to help chronic, heavy alcohol consumers achieve abstinence (Jonas et al., 2014). Disulfiram (Antabuse) is used to deter alcohol consumption and thus is intended for the person who wishes to achieve abstinence. The medication interferes with alcohol metabolism; therefore, an elevation in vital signs and severe gastrointestinal symptoms can occur if alcohol is ingested. This medication is metabolized in the renal system and may be ideal for persons with hepatic disease. Given its side-effect profile and metabolism, the medication may be poorly tolerated by individuals older than 55 years (Caputo et al., 2012). In addition, it should be taken every day to achieve the greatest aversive effects on consumption. The best outcomes with this medication occur when working with the patient's family members and support persons.

Opioid Use Disorder

The proportion of older adults who misuse opioids is low compared to the case of younger adults. There is concern for older adults as opioid misuse rates are growing and as misuse for younger adults has declined (SAMHSA, 2017). Older adults, particular those with chronic health conditions, are more likely to be prescribed opioids than younger adults (CDC, 2017). The number of opioid-related emergency department visits for older adults increased 74.2% between 2010 and 2015 (Fingar et al., 2018). These data highlight older adults as at risk for developing opioid use disorders. There are physiological changes with aging, in addition to an increase in other prescribed and nonprescribed sedative use (benzodiazepines and other sedative hypnotics) in this population, which puts them at high risk for physiological complications, including overdose (Hwang et al., 2016; Maust et al., 2017). The use of opioid-based treatments and abstinence-based approaches that assist the person with an opioid use disorder to focus on psychological and life problems is highly underutilized in the older adult (Chhatre et al., 2017). Methadone is a full opioid agonist that can be obtained from a specialty clinic setting. The drug buprenorphine—both an opioid

antagonist and a partial agonist—also helps a person to stop using opioids and may be of particular benefit for persons who have a high risk of overdose or who have a cocaine and/or heroin use disorder. Buprenorphine can be prescribed from an outpatient setting by a provider with a special waiver obtained after training. Both medications can be used safely and effectively in individuals with moderate to severe opioid use disorder (Mattick, Breen, Kimber, & Davoli, 2014). The long-acting form of naltrexone (a Mu opioid antagonist) also shows success in motivated individuals at 6 months and may have benefit for the older adult who has difficulty with maintaining a complex medication regimen (Lee et al., 2018). Evidence supports added benefit of psychosocial treatment for patient adherence to pharmacological treatment, particularly in the case of methadone treatment (Dugosh et al., 2016).

Smoking

Varenicline (Chantix) is a prescription medication that safely helps individuals achieve nicotine abstinence (Anthenelli et al., 2016). Bupropion is an antidepressant also approved to treat tobacco use disorders. Both medications have been shown to be helpful when started between 1 and 2 weeks before the smoker intends to quit. Nicorette transdermal patches, nicotine gum, and nicotine lozenges are available OTC, and there is research support for their pharmacological contribution to smoking cessation, particularly when combined with bupropion (Stapleton et al., 2013). The dosage of transdermal patches is determined by the number of cigarettes smoked (level of SUD). Overall, smoking cessation shows good efficacy with combination therapies resulting from a combination of individual or group psychosocial support and medication (CDC, 2014; Patnode et al., 2015).

Models of Care

Individualized care plans should be developed for older adults at risk for SUDs in accordance with the classes of drugs used and the mild, moderate, or severe nature of the disorder. Individualizing care allows flexibility for patient and nurse. Evidence is emerging, however, on models of care for older adults with complex health problems, including comorbid other psychiatric diagnoses. In one study, the integration of mental health into primary care increased access to mental health and substance abuse treatment for both Black and White older adult patients who are offered both enhanced specialist services and mental health services at the primary care site (Ayalon, Areán, Linkins, Lynch, & Estes, 2007). Case management has also demonstrated effective outcomes with older adults with multiple social, mental health, and physical needs with problems accessing community services, including substance abuse (Hesse, Vanderplasschen, Rapp, Broekaert, & Fridell, 2007). Guidelines for all interventions should include the following:

- A nonjudgmental, health-oriented approach to substance-related problems. Drug and alcohol use and abuse are highly stigmatized in American society, particularly in minority communities, leading to denial and/or rejection by family members. Understanding addiction as a disease helps nurses and other providers adopt attitudes and approaches similar to care required for other chronic illnesses.
- A supportive, encouraging approach to changing use habits must be fostered. The patient or client is taught that change occurs in stages and that support and assistance are available at each stage.
- Patient and family education on the risks associated with drug misuse. Because older persons use so many medications, the potential health consequences of medication misuse and drug abuse may be minimized in the eyes of family members and caretakers.
- Assessment of substance use in association with lifestyle, existing chronic illnesses, nutritional patterns, sleep, exercise, sexual patterns, and recreation is needed. Also of importance is counseling the patient and/or family about the effects of substances used on these areas of the patient's life.
- Setting the goal of "harm reduction" in the form of decreased use and supervised use if abstinence is not imperative or achievable.
- Monitoring substance use patterns at each encounter; documenting changes and providing reinforcement of positive changes and/or movement toward treatment.
- Enhancing the involvement of members of the patient's support system, including family and friends identified by the patient, community-based groups, support groups, appropriate clergy, or organizational groups such as senior centers.
- Supporting the development of coping mechanisms and supporting modifications in social, housing, and recreational environments, to minimize associations with settings and groups in which substance use and abuse are common (USDHHS, 2004a).

Counseling and Psychotherapy

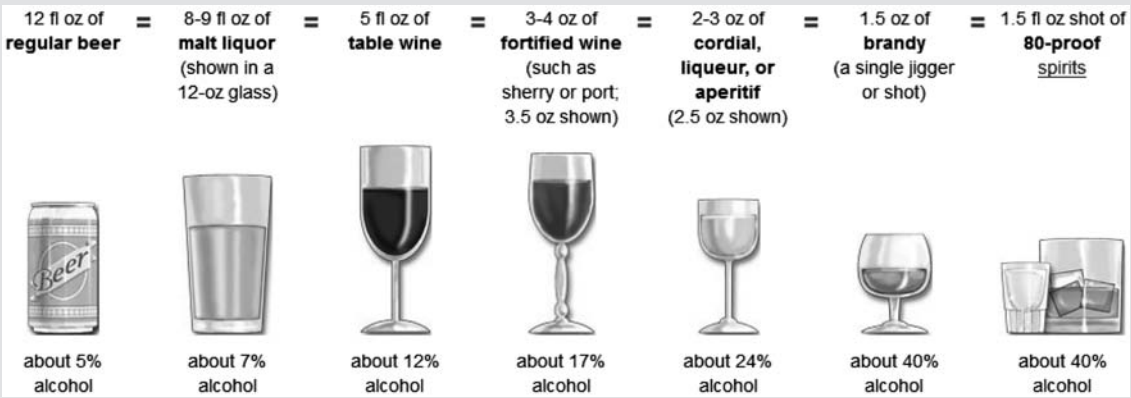
Older persons tend to seek care from their primary care, medical specialist, or nurse/nurse practitioner provider for mental health and substance-related problems. This

practice derives from long-held beliefs that mental health problems like depression or anxiety indicate weakness or lack of character.

Older persons, more than others, stigmatize the excess use of alcohol or use of an illicit drug and problems with prescription drugs. Counseling done by the nurse using SBIRT is likely to be more readily accepted by older patients than referral to mental health or substance abuse clinics.

Optimal treatment involves short-term psychotherapy by a practitioner with education about abuse and addiction. Following the model of cognitive behavioral therapy, in particular, has demonstrated good outcomes with excessive drinking and marijuana use (Magill & Ray, 2009). These approaches help the older adult to modify behavior and to deal with negative feelings and/or chronic pain that often motivate use.

Treatment Outcomes



Healthcare providers and older persons may be pessimistic about the possibilities of changing substance use habits. Health providers often do not intervene because they believe that older people do not change. Treatment outcomes for older persons with substance use problems, however, have been shown to be as good as or better than those for younger people (USDHHS, 2004b). Good treatment outcomes, however, can be compromised by inconsistency of follow-up and limited access to aftercare for community-dwelling older adults.

CASE STUDY 34.1

Joseph and Mary P, both 71 years old, reside in a small, rural community, where Mr. P owns the only pharmacy. Retired for 5 years, Mr. P is in good health except for osteoarthritis, and Mrs. P has heart failure, which is usually well managed when she adheres to her diet and medication regimen. She is also being treated for depression and generalized anxiety disorder, for which she has been prescribed paroxetine (Paxil). The couple enjoys a nightly cocktail hour, at which Mr. P consumes two scotch whiskies and Mrs. P has "wine." Recently, the visiting nurse who has been monitoring Mrs. P's recovery from an episode of congestive heart failure received a phone call from the couple's daughter who stated that on her last three evening phone calls to her parents, Mrs. P sounded somewhat confused and her speech was slurred. She also reports that her father had a fall in the evening last week. When the daughter questioned her parents about their drinking, Mr. P became irritable and defensive.

FIGURE 34.1

Standard drink.

The percentage of "pure" alcohol, expressed here as alcohol by volume (alc/vol), varies by beverage.

Source: U.S. Department of Health and Human Services: National Institute on Alcohol Abuse and Alcoholism. (n.d.). *Rethinking drinking: What's a "standard" drink?* Retrieved from https://www.rethinkingdrinking.niaaa.nih.gov/How-much-is-too-much/What-counts-as-a-drink/Whats-A-Standard-Drink.aspx

(*continued*)

CASE STUDY 34.1 (*continued*)

The nurse was concerned that the Ps were at risk related to their alcohol use. She made it a point to visit the Ps in the early evening on her way home. She found them enjoying their cocktails and took the opportunity to conduct a drug and alcohol use screen using the SMAST-G. This indicated a problem with alcohol use and potential for associated negative health outcomes. She conducted a brief intervention, giving them information about their respective chronic diseases, including the benefits of reducing their drinking. The nurse discussed how decreasing alcohol intake can reduce the gastric distress Mr. P experiences and the benefits of improving depression symptoms and effectiveness of paroxetine hydrochloride (Paxil). The nurse taught them (building on autonomy and responsibility) about the relationship between physical changes and the effects of alcohol on their sleep patterns, mood, balance, and fall risk. She also pointed out that both were consuming alcohol more than one daily drink and recommended that they cut down to one standard drink (Figure 34.1) a day (1.5 oz. spirits, 4–5 oz. wine, or 12 oz. of beer). At first, they seemed unhappy about the recommendation, but both committed to attempting to reduce their intake for the sake of their overall health. When the nurse visited 2 weeks later, they had begun to journal their drinking, and both were recording consistent declines in the amount of alcohol consumed. Thus, this is a successful example of the SBIRT intervention.

SUMMARY

Two current trends are predicted to result in an increase in the already significant number of men and women older than 55 years who experience various SUDs: the growing numbers of older persons in America and the continuation of tobacco, drug, and alcohol use patterns established earlier in life. Although most people decrease the amount of alcohol and use of recreational drugs with age, anywhere from 10% to 24% of older persons do not (USDHHS, 2004a). The most common of SUDs is heavy drinking, especially by Caucasian men older than 65 years and living alone (USDHHS, 2004a). The prevalence of heavy drinking is often linked with smoking, which causes the highest number of premature deaths among older people (Han & Palamar, 2018). The high numbers of prescription drugs used by older adults pose serious problems related to misuse and drug interactions. Health professionals are disinclined to query older adults about substance use, but the substance use problems emerge with the diagnosis and treatment of other medical disorders. Nurses in daily contact with institutionalized and community-dwelling older adults must be skilled in screening and counseling on the use of nicotine and alcohol, as well as prescription, illicit, and OTC drugs. Educating the patient and family about health risks and referring patients to specialists and community resources are essential "best practices."

NURSING STANDARD OF PRACTICE

Protocol 34.1: Substance Misuse and Alcohol Use Disorders

I. GOAL

To implement best nursing practices in older persons with drug, alcohol, tobacco, or other drug use disorders

II. OVERVIEW

A. Several factors increase the risks associated with alcohol and drug use for the older individual; continuing drug use patterns that were commonplace earlier in life can be potentially harmful. Constitutional risk factors include changes in body composition such as decreased muscle mass, decreased organ efficiency (especially kidney and liver), and increased vulnerability of the central nervous system (CNS).

B. Alcohol use in combination with other drugs or used excessively may result in falls, impaired cognition, malnourishment, and decreased resistance to disease, as well as interpersonal and legal problems.

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

C. At-risk drinking (more than one drink per day or more than three drinks on one occasion) by older adults increases the likelihood of negative health consequences.
D. Any smoking is considered drug abuse and places the person at risk for negative health consequences; advancing age increases the likelihood of respiratory and cardiovascular illnesses.

III. BACKGROUND AND STATEMENT OF THE PROBLEM

A. The use of alcohol, tobacco, illicit drugs, and the misuse of prescription drugs can result in SUDs. These are classified on a continuum of mild, moderate, and severe based on the number of symptoms associated with drug use.
   1. Symptoms include mental or physical health problems; impairment in the performance of social, family, work, and civil role relationships because of excessive and frequent use of a substance or multiple substances. For 25% of the U.S. population, *at-risk drinking*—defined as more than one drink per day, 7 days a week, or more than three drinks on any one occasion for persons 65 years and older—is an example of drug use that results in short- and long-term health problems. For older adults, at-risk drinking increases the likelihood of negative health consequences, including depression, falls, impaired motor function, and interactions with prescription drugs.
   2. The frequency and quantity of the drug used generally determines the extent of a SUD. For example, heavy drinking—five or more drinks (four for women) every day for more than 5 days in the past 30 days—can result in health, safety, and social problems. In addition, some drugs, including alcohol, opioids, nicotine, benzodiazepines, and barbiturates, induce *tolerance*, defined as
      a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect
      b. A markedly diminished effect with continued use of the same amount of the drug
   3. Tolerance drives the need to increase amounts of a drug in an effort to achieve the "high" experienced on early use and is indicative of physiological dependence.
   4. When physiological dependence has developed, sudden cessation of use of the drug precipitates *withdrawal*, characteristic signs and symptoms derived from the chemical properties of the drug. The continuous use of alcohol, opioids, and sedating drugs results in CNS depression, and withdrawal symptoms can be nausea, agitation (mild) to seizure, and fluid and electrolyte disorder (severe).
   5. Untreated withdrawal from depressant drugs can be life threatening. Older adults, especially those with comorbid conditions, must be monitored closely and appropriately medicated.
   6. Decreased metabolic capacity for any drug places older adults at risk for *intoxication* and interaction or potentiation of other prescription or illicit drugs. Intoxication is evidenced in signs such as drowsiness, slurred speech, and uneven gait following consumption of sedative drugs such as opioids, alcohol, or barbiturates or agitation, anxiety, and mania associated with the use of cocaine or other stimulants. The symptoms derive from the effects of the drug properties. Of note, women develop more pathology from lower levels of alcohol consumption than do men of the same age as a function of their physiological vulnerability. Intoxication will have an earlier onset even with tolerance, and withdrawal can be more severe. An aging metabolism complicates these constitutional traits.
   7. *Drug misuse* is a common practice among older adults but is not limited to this population. Drug misuse is defined as taking a drug for purposes other than that for which the drug was prescribed or intended to achieve a desired effect. Because older adults are often prescribed five or more drugs as common practice in the treatment of chronic illness and common health problems, reliance on pharmacotherapy to address pain, sleep disorders, depression, and general malaise is not uncommon. A comprehensive history of drug use (including tobacco and alcohol) is important in identifying this problem as well as *polysubstance-related disorder*, defined as misuse, abuse, or dependence on three or more drugs that have psychotropic effects. For older adults, this is often a combination of illicit and prescription drugs and often includes nicotine and/or alcohol.
   8. Older adults, once engaged in treatment for an SUD, have good rates of recovery. Recovery means learning and maintaining a lifestyle of sobriety at various levels of personal health and the capacity to engage productively with society. Early recovery spans a first year, and, beyond 1 year, recovery is referred to as "sustained." *Relapse*,

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

or returning to regular use of a substance in a maladaptive pattern, is a lifetime concern, which is why persons often self-refer as "recovering." SUDs are chronic illnesses that require ongoing monitoring and self-care and may include medication.

B. Etiology and/or epidemiology: Of persons older than 50 years, 16.7% reported drinking two or more drinks per day (risky drinking), and 19.6% reported binge drinking on occasion. Among primary care patients older than 60 years, 15% of men and 12% of women regularly drank in excess of the NIAAA-recommended levels (one drink per day and no more than three drinks on any one occasion).
   1. The drugs used and misused most frequently by older adults are nicotine, alcohol, and prescription drugs, particularly analgesics and benzodiazepines.
   2. Excessive drinking by individuals of all ethnic groups ages 65 years and older is approximately 7%, down from 12% in persons aged 55 to 64 years.
   3. Five hundred thousand persons aged 55 years and older reported monthly use of illicit drugs in the National Household Survey on Drug Use, NIDA.
   4. Approximately 11% of women older than 59 years misuse psychoactive drugs.

C. Risk factors (USDHHS, 2004a)
   1. Family history of dependence on alcohol, tobacco, prescription, or illicit drugs
   2. Co-occurring moderate to severe SUD of another substance (i.e., alcohol and tobacco)
   3. Lifelong pattern of substance use, including heavy drinking
   4. Male gender
   5. Social isolation
   6. Recent and multiple losses
   7. Chronic pain
   8. Co-occurrence with depression
   9. Unpartnered and/or living alone

IV. PARAMETERS OF ASSESSMENT

A. Screening for alcohol, tobacco, and other drug use is recommended for all community-dwelling and hospitalized older adults. It is essential that the nurse:
   1. State the purpose of questions about substances used and link them to health and safety.
   2. Be empathic and nonjudgmental; avoid stigmatic terms such as *alcoholic.*
   3. Ask the questions when the patient is alcohol and drug free.
   4. Inquire about the patient's understanding of the question (Aalto, Pekuri, & Seppä, 2003).

B. Assessment and screening tools
   1. The QF Index (Khavari & Farber, 1978): *Review all classes* of drugs, alcohol, nicotine, illicit drugs, prescription drugs, OTC drugs, and vitamin supplements, for each drug used. *Record the types* of drugs, including the kinds of beverages. *Note the frequency*: The number of occasions on which the drug is consumed (daily, weekly, and monthly). *Record the amount of drug consumed* on each occasion over the past 30 days. The psychological function, what the drugs do for the individual, is also important to identify. The QF Index tool should be part of the intake nursing history. The brown bag approach is also useful. Ask the patient to bring all drugs and supplements he or she uses in a brown bag to the interview.
   2. SMAST-G: Highly valid and reliable, this is a 10-item tool that can be used in all settings. Between 2 and 3 minutes are needed for administration. This instrument is derived from the SMAST-G with a sensitivity of 93.6% and a positive predictive value of 87.2% (Blow et al., 1992).
   3. The AUDIT: This 10-item questionnaire has good validity in ethnically mixed groups, and scores classify alcohol use as hazardous, harmful, or dependent; administration: 2 minutes. Sensitivity scores range from 0.74% to 0.84% and specificity around 0.90% in groups of mixed age and ethnicity (Allen, Litten, Fertig, & Babor, 1997). This instrument is highly effective for use with older adults (Roberts, Marshall, & Macdonald, 2005).

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

Its derivative, the AUDIT-C, is composed of three questions that have proved equally valid in detecting an alcohol-related problem.

4. Fagerström Test for Nicotine Dependence (Pomerleau et al., 1994): This six-question scale provides an indicator of the severity of nicotine dependence: scores of less than 4 (*very low*), 4 to 6 (*moderate*), and 7 to 10 (*very high*). The questions inquire about first use early in the day, amount and frequency, inability to refrain, and smoking despite illness. This instrument has good internal consistency and reliability in culturally diverse, mixed-gender samples (Pomerleau et al., 1994).

C. Atypical presentation
   1. Men and women older than 65 years may have substance-related disorder problems even though the signs and symptoms may be less numerous than those listed in the *DSM-5* (APA, 2013).

D. Signs of CNS intoxication (i.e., slurred speech, drowsiness, unsteady gait, decreased reaction time, impaired judgment, disinhibition, ataxia)
   1. Assess by individual or collateral (speaking with family members) data collection; detail the consumption of amount and type of depressant medications, including alcohol, sedatives, hypnotics, and opioid or synthetic opioid analgesics.
   2. Obtain a blood alcohol level. Marked intoxication occurs at 0.3% to 0.4%, toxic effects occur at 0.4% to 0.5%, and coma and death occur at 0.5% or higher.
   3. Assess vital signs and determine respiratory, cardiac, or neurological depression.
   4. Assess for existing medical conditions, including depression.
   5. Arrange for emergency department or hospitalization treatment as necessary.
   6. Obtain urine for toxicology, if possible.
   7. Assess for delirium, which can be confused with intoxication and withdrawal in the older adult.

E. At-risk drinking is regular consumption of alcohol in excess of one drink per day for 7 days a week or more than three drinks on any one occasion.
   1. Assess for readiness to change behavior using SBIRT.
   2. Is the drinker concerned about the amount or consequences of the drinking? Has he or she contemplated cutting down?
   3. Does he or she have a plan for cutting down or stopping consumption?
   4. Has he or she previously stopped but then resumed risky drinking?
   5. Personalized feedback and education on "at-risk drinking" results in a reduction in at-risk drinking among older primary care patients.

F. Treatment of acute AWS (guidelines are modified for other CNS-depressant drugs such as barbiturates, heroin, sedative hypnotics)
   1. Assess for risk factors: (a) previous episodes of detoxification; (b) recent heavy drinking; (c) medical comorbidities, including liver disease, pneumonia, and anemia; and (d) previous history of seizures or delirium (Wetterling, Weber, Depfenhart, Schneider, & Junghanns, 2006).
   2. Assess for extreme CNS stimulation and a minor withdrawal syndrome evidenced in tremors, disorientation, tachycardia, irritability, anxiety, insomnia, and moderate diaphoresis. When these signs are not detected, life-threatening situations for older adults often result. Withdrawal, occurring 24 to 72 hours after the last drink, can progress to seizures, hallucinosis, withdrawal delirium, extreme hypertension, and profuse diarrhea from 4 to 8 hours and for up to 72 hours following cessation of alcohol intake (DTs).
   3. Assess neurological signs, using the CIWA-Ar. The CIWA-Ar is a 10-item rating scale that delineates symptoms of gastric distress, perceptual distortions, cognitive impairment, anxiety, agitation, and headache (Sullivan, Sykora, Schneiderman, Naranjo, & Sellers, 1989).
   4. Medicate with a short-acting benzodiazepine (lorazepam or oxazepam) in doses titrated to the patient's score on the CIWA-Ar, patient's age, and weight; use one third to one half the recommended dose (Amato, Minozzi, Vecchi, & Davoli, 2010). Continue CIWA-Ar to monitor treatment response.

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

5. Provide emotional support and frequent reorientation in a cool, low-stimulation setting; monitor hydration and nutritional intake. Give therapeutic dose of thiamine and multivitamins.

G. Report sleep disturbance, anxiety, depression, and problems with attention and concentration (acute care)
   1. Assess for neuropsychiatric conditions using the mental status exam, Geriatric Depression Scale, or Hamilton Anxiety Scale.
   2. Obtain sleep history because drugs disrupt sleep patterns in older persons.
   3. Assess intake of all drugs, including alcohol, OTC, prescription, herbal and food supplements, and nicotine. Use the "brown bag" strategy.
   4. If positive for alcohol use, assess for last time of use and amount used.
   5. Assess for alcohol or sedative drug withdrawal as indicated.

H. Smoking cigarettes, e-cigarettes, hookah, or using smokeless tobacco
   1. Assess for level of dependence using the Fagerström Test (see "Screening Tools for Alcohol and Drug Use" section).

V. NURSING CARE STRATEGIES

A. At-risk drinking (consumption of alcohol in excess of one drink per day for 7 days a week or more than three drinks on any one occasion) or excess alcohol consumption (more than three to four drinks on frequent occasions):
   1. Conduct screening, brief intervention, and, as indicated, referral to treatment: (SAMHSA, 2018)
      a. Screen using the AUDIT-C, AUDIT, or SMAST-G.
      b. Provide feedback information to the client about current health problems or potential problems associated with the level of alcohol or other drug consumption.
      c. Stress client's responsible choice about actions in response to the information provided.
      d. Advice must be clear about reducing his or her amount of drinking or total consumption.
      e. Recommend drinking according to NIAAA levels for older adults.
      f. Provide a menu of choices to the patient or client regarding future drinking behaviors.
      g. Offer information based on scientific evidence, acknowledge the difficulty of change, and avoid confrontation. Empathy is essential to the exchange.

B. Support self-efficacy. Help client explore options for change.
   1. Assist client in identifying options to solve the identified problem.
   2. Review the pros and cons of behavior change options presented.
   3. Help client weigh potential decisions by considering outcomes.

C. Smoking cigars, cigarettes, e-cigarettes, or using smokeless tobacco
   1. Apply the five A's intervention (Agency for Healthcare Research and Quality [formerly the Agency for Healthcare Policy and Research] Guidelines)
      a. Ask: Identify and document all tobacco use.
      b. Advise: Urge the user to quit in a strong personalized manner.
      c. Assess: Is the tobacco user willing to make a quit attempt at this time?
      d. Assist: If user is willing to attempt, refer for individual or group counseling and pharmacotherapy. Refer to telephone "quit lines" in region or state.
      e. Arrange referrals to providers, agencies, and self-help groups. Monitor pharmacotherapy once quit date is established. The U.S. FDA-approved pharmacotherapies for smoking cessation are the following:
         i. Bupropion SR (Zyban) and nicotine replacement products, such as nicotine gum, nicotine inhalers, nicotine nasal spray, and nicotine patch. Nurse-initiated education about these medications is essential.
         ii. Zyban, for example, should not be combined with alcohol. Nurses working with inpatients in a case management model were found to produce outcomes in smoking cessation (Smith, Reilly, Houston Miller, DeBusk, & Taylor, 2002).
         iii. Show caring, concern, and provide ongoing support.

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

2. Communicate care and concern
   a. Encourage moderate-intensity exercise to reduce cravings for nicotine because 5 minutes of such exercise is associated with short-term reduction in the desire to smoke and in tobacco withdrawal symptoms (Daniel, Cropley, Ussher, & West, 2004).
   b. Schedule follow-up contact in person or by telephone within 1 week after planned quit date. Continue telephone counseling, especially with those using medications and nicotine patches (R. G. Boyle et al., 2005; Cooper et al., 2004).

D. Alcohol dependence
   1. Assess the patient for psychological dependence.
   2. Assess the patient for (a) physiological dependence and (b) "tolerance." Psychological dependence occurs with both abuse and dependence and is more difficult to resolve.
   3. Assess need for medical detoxification (see alcohol withdrawal in "Inpatient Hospitalization" section).
   4. Refer patient and family to addictions or mental health nurse practitioner or physician.
   5. Evaluate patient and family capacity to implement referral.
   6. On successful detoxification, monitor use of medications, interpersonal therapies, and participation in self-help groups.

E. Marijuana dependence: Little research on effective intervention for psychological dependence on marijuana is available. Some guidance can be found for smoking cessation and self-help approaches.
   1. Refer to steps for smoking cessation (see section C of Nursing Care Strategies).
   2. Refer patient to addiction specialist for counseling for psychological dependence and/or treatment with cognitive behavioral therapy.
   3. Refer to community-based self-help groups such as Narcotics Anonymous, Alcoholics Anonymous, or Al-Anon.
   4. Encourage development or expansion of patient's social support system.

F. Heroin or opioid dependence
   1. Older long-term opioid users may continue use, relapse, and seek treatment. Methadone or buprenorphine are current pharmacological treatment options that are effective in conjunction with self-help programs and/or psychosocial interventions.
   2. Treatment with methadone, a synthetic narcotic agonist, suppresses withdrawal symptoms and drug cravings associated with opioid dependence but requires daily dosing of 60 mg, minimum. It is dispensed only in state-licensed clinics.
   3. Treatment with buprenorphine (Subutex or Suboxone): Treatment occurs in office practice by trained physicians, with this opioid partial agonist–antagonist. Alone and in combination with naloxone (Suboxone), it can prevent withdrawal when someone ceases use of an opioid drug and then be used for long-term treatment. Naloxone is an opioid antagonist used to reverse depressant symptoms in opiate overdose and at different dosages to treat dependence (Center for Substance Abuse Treatment [CSAT], 2010).
      a. Close collaboration with the prescriber is required because these drugs should not be abruptly terminated or used with antidepressants, and they interact negatively with many prescription medications.
   4. Naltrexone, a long-acting opioid antagonist, blocks opioid effects and is most effective with those who are no longer opioid dependent but are at high risk for relapse (Srisurapanont & Jarusuraisin, 2005).
   5. Treatment of the older patient who has become addicted to Oxycontin or other opioids should be done in consultation with an addictions specialist nurse or physician.
      a. It is recommended that prescribers avoid opioids and synthetic opioids (Demerol, Dilaudid, and Oxycontin). Opioids have high potential for addiction, and Demerol has been associated with delirium in older adults (CSAT, 2010).
      b. Barbiturates should be avoided as hypnotics, and the use of benzodiazepines for anxiety should be limited to 4 months (USDHHS, 2004a).

(*continued*)

Protocol 34.1: Substance Misuse and Alcohol Use Disorders (*continued*)

G. Treatment and relapse prevention
   1. Monitor pharmacological treatment. The benefits of this treatment are dependent on adherence, and psychosocial treatment should accompany its use (World Health Organization, 2000). Methadone or buprenorphine should be used for long-term treatment of opioid dependence.
   2. In limited studies using a cognitive behavioral approach, group psychotherapy has produced good outcomes with older adults (Payne & Marcus, 2008).
   3. Refer to community-based groups, such as Alcoholics Anonymous, Narcotics Anonymous, Al-Anon groups, and encourage attendance.
   4. Educate family and patient regarding signs of risky use or relapse to heavy drinking or alcohol-dependent behavior.
   5. Counsel patient to reduce drug use (harm reduction), and engage in relationship healing or building, to engage in community or intellectually rewarding activities, spiritual growth, and so on, that increase valued nondrinking rewards.
   6. Counsel in the development of coping skills.
      a. Anticipate and avoid temptation.
      b. Learn cognitive strategies to avoid negative moods.
      c. Make lifestyle changes to reduce stress, improve the quality of life, and increase pleasure.
      d. Learn cognitive and behavioral activities to cope with cravings and urges to use.
      e. Encourage development or expansion of patient's social support system.

VI. EVALUATION AND EXPECTED OUTCOMES

A. Patient will have:
   1. Improved physical health and function
   2. Improved quality of life, sense of well-being, and mental health
   3. More satisfying interpersonal relationships
   4. Enhanced productivity and mental alertness
   5. Decreased likelihood of falls and other accidents
B. Nurses will demonstrate:
   1. Increased accuracy in detecting patient problems related to use or misuse of substances
   2. More evidence-based interventions resulting in better outcomes
C. Institution will have:
   1. Increased number of referrals to ambulatory substance abuse and mental health treatment programs
   2. Improved links with community-based organizations engaged in prevention, education, and treatment of older adults with substance-related disorders

VII. FOLLOW-UP MONITORING OF CONDITION

A. Evaluate for increase in substance use or misuse associated with growing numbers of aging adults.
B. Increase outreach to targeted vulnerable populations.
C. Document chronic care needs of older adults diagnosed with substance-related disorders.
D. Monitor alcohol use among older adults with chronic pain.
E. Communicate findings to all members of the caregiver team.

VIII. GUIDELINES

The National Quality Forum has published *Evidence-Based Practices to Treat Substance Use Disorders*. These guidelines are inclusive of primary care, the settings in which older adults seek treatment (National Quality Forum, 2007).

Comprehensive Assessment and Management of the Critically Ill Older Adult*

Michele C. Balas, Lee Cordell, Paige Donahue, and Mary Beth Happ

35

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify factors that influence older adults' ability to survive and effectively recover from a serious or life-threatening illness.
2. Choose valid and reliable instruments to measure critically ill older adults' symptom experience and physical, functional, and cognitive ability.
3. Describe evidence-based, nurse-led, interprofessional intensive care unit interventions that decrease critically ill older adults' risk for adverse events and poor short- and long-term outcomes.

OVERVIEW

Fostering effective ICU survivorship for patients experiencing a serious or life-threatening illness is an emerging and significant societal challenge. Over five million patients receive cutting-edge medical and nursing interventions in the U.S. ICUs annually (Barrett, Smith, Elixhauser, Honigman, & Pines, 2014; Wunsch et al., 2011, 2013). On average, Americans are admitted to an ICU twice in their life, and nearly 1 in 5 will die in this high-paced and technologically complex setting (Angus et al., 2004; Angus et al., 2006). This number is expected to rise to unprecedented levels as the number of adults with complex comorbidities grows, our population ages, and the incidence of acute respiratory and heart failure increases (Carson, Cox, Holmes, Howard, & Carey, 2006; Mehta, Syeda, Soylemez Wiener, & Walkey, 2015). Although recent advances in critical care medicine have improved overall ICU survival rates (Iwashyna, Cooke, Wunsch, & Kahn, 2012), for some older adults and their family members, this survival comes with heavy personal and financial costs.

Many ICU survivors experience profound physical, cognitive, and/or mental health impairments that often persist for months or years after hospitalization (D. Elliott et al., 2014; Needham et al., 2012). The constellation of these impairments is now referred to as post-intensive care syndrome (PICS; D. Elliott et al., 2014; Needham et al., 2012). Although the exact etiology of PICS remains unclear, its incidence and severity are likely related to both preexisting risk factors (e.g., senescence, comorbidities, disease pathology) and commonly acquired ICU symptoms/syndromes (e.g., pain, oversedation, delirium) that are initiated or exacerbated by antiquated sedation, mechanical ventilation (MV), and mobility practices (Ely, 2017; Morandi, Brummel, & Ely, 2011; Pandharipande, Banerjee, McGrane, & Ely, 2010; Vasilevskis et al., 2010). Given the substantial burden PICS imposes on older adults, their family caregivers, and society, ICU

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

survivorship will likely remain a key challenge of critical care into the 21st century and beyond (Iwashyna, 2010).

Improving the lives of the growing number of older adults who experience critical illness will require not only the consistent application of timely, evidence-based, interprofessional ICU interventions, but also several modifications to the overall critical care environment. To optimize outcomes and reduce disability in this population, ICU providers need to consider how age-related alterations in homeostatic mechanisms affect disease progression, symptom manifestation, and appropriate medication selection (Brummel et al., 2015). An accurate assessment of the critically ill older adults' preadmission health status, treatment preferences, and social support systems is also essential for care and discharge planning purposes. Finally, it is essential that critically ill older adults and their family members are actively engaged and empowered to participate actively throughout their ICU stay.

BACKGROUND AND STATEMENT OF PROBLEM

Currently, the median age of critically ill patients approaches 65 years globally (Flaatten et al., 2017). The proportion of critically ill patients 80 years of age and older is predicted to increase faster than any other ICU cohort (Flaatten et al., 2017). Although critically ill older adults are an extremely heterogeneous group, they share some age-related characteristics and are susceptible to a variety of geriatric syndromes and complications that may influence both ICU treatments and outcomes. In addition to high ICU, hospital, and long-term mortality rates, the 1.4 million older adults who survive critical illness each year in the United States (Wunsch et al., 2010) are at increased risk for substantial physical, functional, and neurocognitive impairment; psychological distress; sleep disturbances; and postdischarge institutional care (Balas, Happ, Yang, Chelluri, & Richmond, 2009; Balas et al., 2011; Barnato et al., 2011; Boumendil et al., 2004; Broslawski, Elkins, & Algus 1995; Brummel et al., 2014; Chelluri et al., 1993; Daubin et al., 2011; de Rooij et al., 2008; Ehlenbach et al., 2010; Esteban et al., 2004; Ford, Thomas, Cook, Whitley, & Peden, 2007; Guerra, Linde-Zwirble, & Wunsch, 2012; Hennessy, Juzwishin, Yergens, Noseworthy, & Doig, 2005; Hopkins & Jackson, 2006; Ip, Leung, Ip, & Mak, 1999; Kaarlola, Tallgren, & Pettile, 2006; Kass, Castriotta, & Makakoff, 1992; Mahul et al., 1991; Montuclard et al., 2000; Pandharipande et al., 2013; Parno, Teres, Lemeshow, Brown, & Avrunin, 1984; Pavoni et al., 2012; Rockwood et al., 1993; Sacanella et al., 2011; Somme et al., 2010; Udekwu, Gurkin, Oller, Lapio, & Bourbina, 2001; Wunsch et al., 2010). Older age is also one of the factors that may lead to physician bias in refusing ICU admission (Joynt et al., 2001; Mick & Ackerman, 2004); the decision to withhold MV, surgery, or dialysis (Hamel et al., 1999); and an increased frequency of do-not-resuscitate orders (Hakim et al., 1996). Despite these findings, most critically ill older adults demonstrate resiliency, report being satisfied with their quality of life (QOL) after discharge, and, if needed, would reaccept ICU care and MV (Guentner et al., 2006; Hennessy et al., 2005; Kleinpell & Ferrans, 2002). Given their knowledge and expertise, nurses will continue to play a key role in facilitating older adults' ability to survive and successfully rehabilitate from a catastrophic illness.

Decades of research demonstrate that chronological age *alone* is not an acceptable or accurate predictor of poor outcomes after critical illness (Devlin et al., 2018; D. Elliott et al., 2014; Milbrandt, Eldadah, Nayfield, Hadley, & Angus, 2010; Needham et al., 2012; Vasilevskis et al., 2010). Factors influencing an older adult's ability to survive a critical illness are multifactorial and include severity of illness, nature and extent of comorbidities, medical diagnosis, MV use, complications, preexisting frailty, malnutrition, and patient preference (Baldwin et al., 2014; de Rooij, Abu-Hanna, Levi, & de Jonge, 2005; Marik, 2006; Wunsch et al., 2010). Other, less well investigated variables include senescence, vasoactive drug use, ageism, decreased social support, and the critical care environment (Ford et al., 2007; Mick & Ackerman, 2004; Tullmann & Dracup, 2000). The onset of new geriatric syndromes for an older hospitalized adult, such as delirium, urinary incontinence, infection, or falls, is also a harbinger of decline that can often be prevented with appropriate and timely ICU nursing interventions (for more information visit https://consultgeri.org/tools/try-this-series). Finally, there is a much greater appreciation for the role ICU symptoms play in critically ill older adults' recovery (Devlin et al., 2018). This chapter presents strategies and rationale for the comprehensive assessment and management of critically ill older adults.

ASSESSMENT OF PROBLEM AND NURSING CARE STRATEGIES

Baseline Assessments

The performance of a comprehensive assessment of a critically ill older adult's preadmission cognitive and functional ability, medication regimen, and social support systems helps nurses identify the multiple risk factors that make older adults susceptible to a variety of life-threatening conditions, complications, and frequently encountered geriatric syndromes. Nurses can use these initial assessments to develop an evidence-based, holistic, and individualized plan of care that meets both the elder's and her/his family's needs and the goals of care throughout hospitalization. This baseline assessment is also useful to other members of the interdisciplinary ICU team as they develop their own profession-specific plans of care.

Preexisting Cognitive Impairment

Several anatomic and physiological changes occur in the aged central nervous system (Table 35.1). When these age-related changes are combined with the stress of acute pathology, multiple comorbidities, and polypharmacy, critically ill older adults are particularly vulnerable to a number of commonly encountered ICU syndromes such as pain, oversedation, and delirium (Balas et al., 2007; Barr et al., 2013; Devlin et al., 2018; McNicoll et al., 2003; Pisani, Murphy, Van Ness, Araujo, & Inouye, 2007). High rates of preexisting cognitive impairment (31%–42%) have been previously reported in older adults admitted to both medical and surgical ICUs (Balas et al., 2007; Pisani, Redlich, McNicoll, Ely, & Inouye, 2003). Unfortunately, this cognitive impairment is often unrecognized by both the older adults' family and healthcare providers (Balas et al., 2007; Pisani et al., 2003). Dementia, a progressive terminal illness, is commonly seen in the ICU setting, with one study finding that nearly one in 10 nursing home residents with advanced cognitive impairment and severe functional impairment had an ICU stay before death (Fulton, Gozalo, Mitchell, Mor, & Teno, 2014).

A recent review highlighted the frequency and burden of newly acquired cognitive impairment and dementia following critical illness (Brummel et al., 2015). Of the studies included in this review that assessed preillness cognitive

TABLE 35.1

Age-Associated Changes and Atypical Presentations by Body System in the Older ICU Patient

System	Age-Associated Changes
Respiratory	**Decrease in:** chest wall compliance, rib mobility, lung size/elasticity, ventilatory response to hypoxia and hypercapnia, strength of respiratory muscles, PaO_2 level, mucociliary clearance, cilia, total lung capacity (minimal), forced vital capacity, forced inspiratory and expiratory volume, peak and maximal expiratory flow rate, tidal volume (slight), diffusing capacity, maximal inspiratory and expiratory pressure **Increase in:** residual volume, closing volume, ventilation/perfusion (VQ) imbalance, chest wall stiffness **Physical assessment findings:** Possible kyphosis and an increased anteroposterior diameter of the chest; on auscultation, a few bibasilar crackles that clear with deep breathing and coughing **Atypical presentations:** Hallmark symptoms of infection (e.g., fever, chills) and pneumonia (e.g., fever, cough, and sputum production) may be absent or not as dramatic. Older patients with sepsis or pneumonia may present with rather vague symptomatology, including acute confusion, tachypnea, and tachycardia.
Gastrointestinal	**Decrease in:** number of mucus-secreting cells, mucosal prostaglandin concentrations, bicarbonate secretion, transit time of feces, pepsin and acid secretion, gastric emptying and thinning of smooth muscle in gastric mucosa, decrease in the number and velocity of peristaltic contractions in esophagus, enteric nervous system neurons, capacity to repair gastric mucosa, calcium absorption, lean muscle mass and strength, daily energy expenditure, intracellular water, number of hepatocytes and overall weight and size of liver (compensatory increase in cell size and proliferation of bile ducts), hepatic blood flow, metabolism of and sensitivity to drugs **Increase in:** body fat, changes to interstitial tissue (predisposing to soft tissue injury and increasing the time and course for mobilization of extracellular water) Atypical presentations: Age may blunt the manifestations of acute abdominal disease. For example, pain may be less severe, fever less pronounced or absent, and signs of peritoneal inflammation such as muscle guarding and rebound tenderness may be diminished or absent.
Genitourinary	**Increase in:** proportion of sclerotic nephrons/glomeruli, functional unit hypertrophy, afferent and efferent arteriole atrophy, collagen in the bladder, benign prostatic hypertrophy (men), hypertrophy of bladder muscle, thickening of the bladder **Decline in:** number of functioning nephrons; glomerular filtration rate; renal tubular cell function and number; renal blood flow and creatinine clearance; ability to conserve sodium and excrete hydrogen ions; ability to excrete salt and water loads, ammonia, and certain drugs in the activity of the renin–angiotensin system and end-organ responsiveness to antidiuretic hormone; tone of sphincters; alterations in estrogen cause further changes in urethral sphincter of women **Atypical presentations:** Signs of dehydration, such as loss of skin turgor, should be considered an unreliable sign in an older adult related to loss of subcutaneous tissue.
Skin	**Decrease in:** surface area between dermis and epidermis, subcutaneous and connective tissue; number of eccrine and sebaceous glands; sebum amount; vascular supply to dermis; epidermal turnover; skin turgor; moisture content, dermal thickness **Physical assessment findings:** thin, fragile, wrinkled, loose or transparent, dry, flaky, rough, and often itchy skin

(*continued*)

TABLE 35.1

Age-Associated Changes and Atypical Presentations by Body System in the Older ICU Patient (*continued*)

System	Age-Associated Changes
Neurological	**Decrease in:** size of brain/brain weight; number of neurons and dendrites; length of dendrite spines; cerebral blood flow; neurotransmitters or their binding sites in dopaminergic function, visual acuity and depth perception (secondary to anatomic and functional changes to the auditory and vestibular apparatus) and proprioception; balance and postural control and tactile and vibratory sensation **Increase in:** neuritic plaques, neurofibrillary bodies, ventricle size, sulci widening **Physical assessment findings:** decreased papillary response to penlight, decrease in near and peripheral vision, loss of visual acuity to dim light, evidence of muscle wasting and atrophy, presentation of a benign essential tumor, slower and less agile movement as compared to younger adults, diminished peripheral reflexes, a decreased vibratory sense in the feet and ankles **Atypical presentations:** Acute mental status changes in older adults often represent an atypical presentation of an acute illness such as an infection, electrolyte imbalance, or a drug toxicity.
Cardiovascular	**Decrease in:** number of myocytes/pacemaker cells, ventricular compliance, rate of relaxation, baroreceptor sensitivity, vein elasticity, compliance of arteries, response of myocardium to catecholamine stimulation, resting heart rate, heart rate with stress, cardiac reserve **Increase in:** myocardial collagen content, amyloid deposits, myocardial irritability, stiffening of the outflow tract and great vessels (causing resistance to vascular emptying), ventricular hypertrophy (slight), pulse wave velocity, time required to complete the cycle of diastolic filling and systolic emptying, vein dilation, valvular stiffening **Physical assessment findings:** On auscultation, many healthy older adults display a fourth heart sound (S_4), an aortic systolic murmur, higher systolic blood pressure with a widening pulse pressure, and a slower resting heart rate. **Atypical presentations:** Symptoms of myocardial infarction and congestive heart failure may be blunted and require the need to monitor for nonspecific and atypical presentations in older adults, including shortness of breath, acute confusion, and syncope. Worsening of clinical status or difficulty with MV liberation should prompt the ICU team to investigate the possibility of myocardial ischemia in this population
Immune/ hematopoietic	Change in T-cell populations, products, and response to stimuli; defects in B-cell function; change in mix of immunoglobulins (i.e., IgM decreases, IGG and IGA increase), and decline in neutrophil function **Atypical presentations:** Older adults' ability to mount a febrile response to infection diminishes with age. Thus, an older adult may be septic without the warning of a fever and instead may exhibit only a decline in mental status.

ICU, intensive care unit; IGA, immunoglobulin A; IGG, immunoglobulin G; IGM, immunoglobulin M; MV, mechanical ventilation; SATS, spontaneous awakening trials; SBTs, spontaneous breathing trials.

functioning in older adults, newly developed (incident dementia) was present in 12% to 18% of patients who were assessed between 1 year and 8 years after critical illness (Ehlenbach et al., 2010; Guerra et al., 2012; Herridge et al., 2011). Prevalent dementia (i.e., unknown preillness dementia status) was reported in 15% of patients at hospital discharge and in 10% at 1-year follow-up (Sacanella et al., 2011). This review also reported that newly acquired

mild to moderate cognitive impairment was present in 56% of patients—yielding an overall proportion of cognitive impairment plus dementia of 73% of patients 4 years after critical illness (de Rooij et al., 2008).

Given these collective findings, it is recommended that relatives or other caregivers be asked for baseline information about an older adults' memory, executive function (problem-solving, planning, organization of information), and overall cognitive ability before the critical care admission (Kane, Ouslander, & Abrass, 2004; see Chapter 9, Assessing Cognitive Function in the Older Adult). Because knowledge of an older adult's preadmission cognitive ability may also assist in treatment decisions, ICU clinicians should consider familiarizing themselves with dementia screening tools, such as the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE), specifically designed for proxy administration (Jorm, 1994), and/or the Mini-Cog (Borson, Scanlan, Brush, Vitaliano, & Dokmak, 2000).

Preexisting Functional Ability and Frailty

Assessing preadmission frailty and functional ability is essential when caring for critically ill older adults because multiple studies report them to be important prognostic indicators in this vulnerable population (Baldwin et al., 2014; Daubin et al., 2011; Ferrante et al., 2018; Fronczek et al., 2018; Hamidi et al., 2019; Magnette et al., 2015; Pietiläinen et al., 2018). Moreover, given the high levels of disability in activities of daily living (ADLs), instrumental activities of daily living (IADLs), and mobility older adults experience after a critical illness (Brummel et al., 2015), knowledge of preadmission frailty and functional ability can, hopefully, enhance the discharge planning process. The Katz Index of Activities of Daily Living (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963), Functional Independence Measure (Kidd et al., 1995), Barthel Index (Mahoney & Barthel, 1965), Lawton Index (Lawton & Brody, 1969), and Fried's Frailty Index (Fried et al., 2001) have been previously used with an older critically ill population (see Chapter 10, Assessment of Physical Function in the Older Adult). On admission to the ICU, we further suggest nurses investigate whether the older adult uses glasses, hearing aids, or assistive devices to perform his or her ADLs. Having these assistive devices available to the older adult while he or she is in the ICU is important to enhance communication, cognition, and rehabilitation efforts.

Preadmission Medication Use

Polypharmacy disproportionally affects the critically ill older adult population (Garpestad & Devlin, 2017). In fact, one study noted that older adults take an average of 12 different prescription medications at the time of ICU admission (Bell et al., 2011). Thus, it is essential that a thorough medication history be performed at the time of ICU admission. In addition to the medical record, family members can often provide important information regarding older adults' medication history. Moreover, because adverse drug events account for more than 30% of all hospital admissions and specific drug-related causes are a common reason for entry to the ICU for older adults, pharmacists are ideally suited to lead an assessment of preadmission medication history and aid in the decision to discontinue medications that may increase risk for morbidity and mortality (Budnitz et al., 2005; Jolivot et al., 2014).

Psychosocial Factors and Social Support Systems

Critical illness often renders older adults physically unable to effectively communicate with the healthcare team. The inability to communicate may stem from multiple factors, including physiological instability, tracheal intubation, and/or sedative and narcotic use (Happ, 2000, 2001). Family members or significant others are therefore a crucial source for obtaining important preadmission information such as the older adult's past medical and surgical history, drug and alcohol use, nutritional status, home environment, infectious disease exposure, religious preference, and social support systems. Further, the lack of presence of family or a significant other threatens the nurse's ability to obtain accurate data about the person, which is often needed to make important care management decisions and conduct end-of-life discussions (see Chapter 7, Healthcare Decision-Making).

Physical Assessment of the Critically Ill Older Adult

Although a full discussion of the physiological changes that accompany normal aging is beyond the scope of this chapter, we believe ICU clinicians should appreciate the role they play during the course of a serious or life-threatening illness. These changes affect nearly every body system and may influence important treatment decisions. Moreover, age-related changes often manifest on physical examination and may be responsible for some of the atypical presentations and complications critically ill older adults experience throughout their hospital stay. Table 35.1 presents readers with a summary of these special considerations.

ICU-Acquired Conditions That Disproportionally Affect Critically Ill Older Adults

In 2013, the Society of Critical Care Medicine updated their "Clinical Practice Guidelines for the Management

of Pain, Agitation, and Delirium in Adult Patients in the ICU" (PAD Guidelines; Barr et al., 2013). Version 3 of the PAD guidelines was released in 2018 and included two additional topics particularly relevant to the care of critically ill older adults—immobility and sleep. Both guideline versions highlight the importance, high incidence, and substantial physical, psychological, and cognitive toll various symptoms play during and after critical illness (Devlin et al., 2018). Pain, occurring in more than 70% of ICU patients (Gélinas, 2007; Puntillo, 1990), is one of the most prevalent, distressing, and undertreated physical symptoms experienced by the critically ill. Pain occurs both at rest and with routine clinical activities, such as wound care, tracheal suctioning, and turning (Puntillo et al., 2001). Air hunger, being dependent on health professionals, and not being able to effectively communicate needs cause many ICU patients to feel anxiety, fear, and loneliness. These feelings seem to depend on the ability of ICU providers and family members to be physically "present" with the patient (Baumgarten & Poulsen, 2015). Delirium, occurring in up to 80% of patients requiring MV (Ely et al., 2001a, 2001b), is recognized as a significant prognostic indicator. A recent meta-analysis found delirious patients were six times more likely to experience nosocomial complications, 2.5 times more likely to be discharged to skilled placement, had longer ICU and hospital length of stay (LOS), and spent an average of 7 days longer on MV (Zhang, Pan, & Ni, 2013). Lastly, the ICU-acquired muscle weakness often caused by ICU medications and prolonged bed rest can be present in 25% to 50% of critically ill patients (Denehy, Lanphere, & Needham, 2017; Fan et al., 2014; Needham et al., 2014). The impact of ICU-acquired pain, anxiety, delirium, and weakness extends well beyond hospitalization. ICU pain and anxiety are associated with insufficient sleep (J. Jones, Hoggart, Withey, Donaghue, & Ellis, 1979), posttraumatic stress disorder (Granja et al., 2008; Schelling et al., 1998), chronic pain (Barr et al., 2013), depression (Castillo, Cooke, Macfarlane, & Aitken, 2016), and lower health-related QOL (Schelling et al., 1998) post hospitalization. Patients with ICU delirium and weakness experience substantial functional decline (Balas et al., 2009; Herridge et al., 2003, 2011), elevated mortality risk (Ely et al., 2004; Pisani, Kong, et al., 2009), and severe long-term neurocognitive impairment (Girard et al., 2010; Jackson, Gordon, Hart, Hopkins, & Ely, 2004; Pandharipande et al., 2013; Wolters et al., 2017). Collectively, these findings suggest that ICU-acquired pain, anxiety, delirium, and weakness are precursors to poor short- and long-term outcomes for critically ill older adults.

Evidence-Based ICU Sedation, Mechanical Ventilation, and Mobility Interventions

The PAD (Barr et al., 2013) and Pain, Agitation/sedation, Delirium, Immobility, and Sleep disruption (PADIS) Guidelines (Devlin et al., 2018) recommend a number of strategies to improve the care and outcomes of critically ill adults. These interventions include: (a) the routine monitoring of pain, agitation/sedation, and delirium using valid and reliable tools; (b) maintaining critically ill patients at "light" levels of sedation; (c) using daily spontaneous awakening trials (SATs) or a light "target level" of sedation; and (d) performing early mobilization whenever feasible. Sedation strategies recommend nonbenzodiazepine sedatives (i.e., propofol or dexmedetomidine) versus benzodiazepines (i.e., midazolam orlorazepam). Additional patient benefit accrues when SATs are coordinated with daily MV discontinuation protocols that include spontaneous breathing trials (SBTs; Girard et al., 2008). In well-designed studies, these symptom-focused interventions were associated with reduced ICU and hospital LOS, time spent on MV, tracheostomy placement rates, delirium and coma, functional decline, and risk of death (Balzer et al., 2015; Ely et al., 1996; Girard et al., 2008; Kollef et al., 1998; Kress, Pohlman, O'Connor, & Hall, 2000; Pandharipande et al., 2006, 2007; Pandharipande, Sanders, et al., 2010; Riker et al., 2009; Schweickert et al., 2009; Shehabi et al., 2012; Tanaka et al., 2014).

Despite their known clinical benefit, widespread adoption of the evidence-based interventions contained in the PAD and PADIS guidelines remains poor. Routine monitoring of pain, delirium, and sedation levels during an ICU stay remains inconsistent (Chawla et al., 2014; R. Elliott, McKinley, & Aitken, 2006; D. Elliott et al., 2013; Payen et al., 2007; Spronk, Riekerk, Hofhuis, & Rommes, 2009; van Eijk et al., 2009). Benzodiazepines and other potentially harmful sedative medications continue to be routinely administered (Chawla et al., 2014), elevating patients' risk for delirium and complicating ICU providers' ability to mobilize patients (Pandharipande et al., 2006; Pisani, Murphy, et al., 2009). Patients remain on sedation and MV longer than needed, and resistance remains high on the part of clinicians to maintain patients at a light level of sedation, use a protocolized MV discontinuation approach, and get patients out of bed during their ICU stay (Baggs et al., 1999; Bakhru, McWilliams, Wiebe, Spuhler & Schweickert, 2016; Balas et al., 2013; Berney et al., 2013; Carrothers et al., 2013; Chawla et al., 2014; Connolly, O'Neill, Salisbury & Blackwood, 2016; Dubb et al., 2016; Jolley et al., 2017; Kahn, Brake, & Steinberg, 2007; Luetz et al.,

2014; M. A. Miller, Govindan, Watson, Hyzy, & Iwashyna, 2015; Nydahl et al., 2014). Furthermore, despite the broad consensus that liberalization of visiting hours in the ICU improves the care and experience of patients and families (Davidson et al., 2017), few critical care units are open for family visits 24 hours per day (Garrouste-Orgeas, Vinatier, Tabah, Misset, & Timsit, 2016; Morandi et al., 2017; Ramos, Fumis, de Azevedo, & Schettino, 2014). Clearly, there remains an important and significant gap between the discovery of and the consistent use of proven-effective ICU interventions that can equip ICU providers with the knowledge, skills, and tools necessary to adopt and sustain these interventions in everyday practice.

The ABCDEF Bundle

To facilitate adoption of the PAD and PADIS guidelines into everyday ICU care, an evidence-based, multicomponent, and interprofessional team-management framework, known at the ABCDEF bundle, was developed (Balas et al., 2012, 2013, 2016; Barnes-Daly et al., 2018; Ely, 2017; Marra, 2017; Morandi et al., 2011; Pandharipande, Banerjee, et al., 2010; Vasilevskis et al., 2010). The ABCDEF bundle is described in Table 35.2. Based on dozens of research studies published in high-impact journals (Barr et al., 2013), the ABCDEF bundle elements are intentionally interdependent and specifically designed to improve collaboration among ICU team members, standardize care processes, and break the cycle of oversedation, prolonged MV, and immobility (Vasilevskis et al., 2010). These changes in care come about through daily use of: (a) the assessment tools recommended in the PAD guidelines, (b) both SATs and SBTs, (c) select sedative medications, (d) standardized exercise/mobility activities, and (e) engaging and empowering family members as active participants in ICU care.

The bundle differs from other evidence-based, multicomponent ICU interventions in a number of important ways. First, it is applicable to every ICU patient every day, regardless of MV status or admitting diagnosis (i.e., the patient receives every evidence-based intervention for which she/he is eligible). Second, because it focuses on "symptom" versus "disease" assessment, prevention, and management, it is particularly relevant early in the course of critical illness and is suitable for use in conjunction with other life-sustaining therapies. Finally, the ultimate goal is to produce patients who are more awake, cognitively engaged, and

TABLE 35.2

ABCDEF Bundle Components and Suggested Measurement Tools

Component	Tools
A—Assess, prevent, and manage pain	Numeric Pain Scale, Critical Care Pain Observation Tool (CPOT), Behavioral Pain Scale (BPS)
B—Both spontaneous awakening trials and spontaneous breathing trials	
C—Choice of analgesic and sedative medications	Richmond Agitation and Sedation Scale (RASS), Sedation-Agitation Scale (SAS)
D—Delirium-assess, prevent, and manage	Confusion Assessment Method Intensive Care Unit (CAM-ICU), Intensive Care Delirium Screening Checklist (ICDSC)
E—Early mobility and exercise	
F—Family engagement and empowerment

physically active. This ultimately serves to facilitate patient autonomy; improve the ability to express unmet physical, emotional, and spiritual needs; and empower ICU patients and their families to be active participants in care.

A number of studies and quality improvement (QI) projects have demonstrated the benefits of incorporating earlier versions of the ABCDEF bundle into everyday clinical care. In a single-center, before/after study (Balas et al., 2014), bundle implementation was associated with a 3-day improvement in ventilator-free days. After adjusting for age, sex, severity of illness, comorbidity, and MV status, patients managed with the bundle experienced a near halving of the odds of delirium and increased odds of mobilizing out of bed at least once during an ICU stay. Both ICU and hospital mortality rates were lower in the group treated with the bundle. In a study sponsored by the Centers for Disease Control and Prevention (Klompas et al., 2015), which included 20 ICUs and 5,164 consecutive ventilator days, coordinated use of SATs and SBTs resulted in 37% fewer ventilator-associated events and 65% fewer infection-related ventilator-associated complications. Another single-system, multisite QI project, which included over 6,000 patient days, found a "dose–response" relationship to bundle implementation. After adjusting for age, severity of illness, and MV status, multivariable analysis showed that, for every 10% increase in bundle compliance, patients had 15% higher odds of hospital survival (Barnes-Daly, Phillips, & Ely, 2017). Patients also experienced more days alive and free of delirium and coma with increased bundle compliance. Finally, in a more recent prospective, multicenter, cohort study from a national QI collaborative, involving 68 academic, community, and federal ICUs and over 15,000 patients, complete ABCDEF bundle performance was associated with a lower likelihood of seven outcomes (Pun et al., 2019). These outcomes included hospital death within 7 days, next-day MV, coma, delirium, physical restraint use, ICU readmission, and discharge to a facility other than home. Importantly, there was a consistent dose–response relationship between higher proportional bundle performance and improvements in each of the aforementioned clinical outcomes. In other words, the more components of the ABCDEF bundle patients receive, the more clinical benefit obtained. Given these improvements, the ABCDEF bundle is now considered an ICU best practice.

Other Evidence-Based ICU Interventions and Considerations

Impaired Communication. In addition to the physical barriers to speech imposed by MV, older adults are at greater risk for impaired communication than their younger counterparts because of preexisting vision and hearing impairments and cognitive or language impairments (Bartlett, Blais, Tamblyn, Clermont, & MacGibbon, 2008; Happ et al., 2015; Happ, Tate, & Garrett, 2006; Patak et al., 2009). Accurate interpretation of patient messages, including pain and symptom descriptions, may be difficult and frustrating for patients and care providers. Partnering with speech–language pathologists on tools and techniques to facilitate patient comprehension and communication can improve this process (Altschuler & Happ, 2019; Happ et al., 2006, 2010; Radtke, Baumann, Garrett, & Happ, 2011).

A multilevel communication intervention, composed of nurse training, algorithm-guided assessment and communication tool selection, and the provision of communication tools to the ICU, demonstrated improved frequency of communication, successful communication about pain and other symptoms, and less patient-reported difficulty with communication (Happ et al., 2014). Age and delirium status affected communication performance and content. When patients tested positive for delirium, communication exchanges with their nurses were less successful. Delirium was also associated with the identification of fewer patient symptoms and more complaints of dry mouth (Tate et al., 2013). Older age was associated with more symptom complaints of pain, drowsiness, and feeling cold.

Family Engagement. Interactions with family members can be therapeutic for critically ill patients (Black, Boore, & Parahoo, 2011) and help them to make sense of the experience (Davidson, Daly, Agan, Brady, & Higgins, 2010). They may also ameliorate the stress and trauma experienced by patients and family during and after ICU hospitalization (Bergbom & Askwall, 2000; C. Jones et al., 2010). Family members support patients' psychological well-being by providing reassurance, hope, information, a sense of normality, and distraction from the ICU environment and illness experience (Black et al., 2011; Happ, Swigart, Tate, Hoffman, & Arnold, 2007b; Karlsson, Forsberg, & Bergbom, 2010; Morse & Pooler, 2002; Riggio, Singer, Hartman, & Sneider, 1982; Williams, 2005). They also provide reorientation, detect signs of delirium, and serve as proxy or shared decision-makers (Black et al., 2011; Happ, 2000; Happ et al., 2007a, 2007b; White, Braddock, Bereknyei, & Curtis, 2007; White et al., 2012; Williams, 2005). Family presence has also been associated with significantly greater tolerance of MV weaning trials (Happ et al., 2007a). Family interventions in the ICU have focused on providing basic information about the environment, patient condition and treatment (Azoulay et al., 2002; Black et al., 2011; Medland & Ferrans, 1998), advice and coaching on family presence or caregiving (Black et al., 2011; Daly et al., 2010; Davidson et al., 2010), and decision-making support (Curtis et al., 2011; Daly et al., 2010; Lautrette, Ciroldi,

Ksibi, & Azoulay, 2006; White et al., 2007) with mixed results on patient–family anxiety, depression, and posttraumatic stress disorder (PTSD). For example, an information leaflet improved family members' comprehension of the ICU patient's diagnosis and prognosis but did not affect anxiety or depression (Azoulay et al., 2002).

Black et al. (2011) tested the effect of a family psychological support intervention facilitated by nurses on patient delirium and psychological recovery. Intervention group patients showed less delirium than usual care (29%–77%) and had significantly lower Sickness Impact Profile scores at 4, 8, and 12 weeks after the intervention (*p* lower than .001). The use of diaries written by health providers and family visitors to help patients to make sense of the memories and ICU experience following discharge were associated with a decrease in new onset of PTSD in patients (C. Jones et al., 2010); however, the impact on family caregivers' anxiety has been equivocal (Kloos & Daly, 2008; Ullman et al., 2015). To date, there is insufficient evidence from randomized controlled trials of the benefits or harms of patient diaries for patients and their caregivers (Ullman et al., 2015). Davidson tested the feasibility and acceptability of a family visiting kit and supportive coaching intervention with family members of mechanically ventilated patients in an ICU (Davidson et al., 2010). Families found the kit materials (workbook, cognitive recovery tools, personal care items, and information on available services) helpful. The toolkit did not, however, meet their communication needs; the effect on patient or family outcomes was not tested.

Family members are commonly required to act as decisional surrogates for older adult patients in the ICU. This role is known to confer emotional stress, burden, and psychological sequelae (depression, anxiety, PTSD) for some family caregivers, particularly for those family members involved in decisions to limit or withdraw life-sustaining treatments (Gries et al., 2010; McAdam, Fontaine, White, Dracup, & Puntillo, 2012). Nurses play a crucial role in integrating palliative care in the ICU and improving end-of-life care, communication, and support for critically ill older adults and their family members (Krimshtein et al., 2011; Nelson et al., 2010; Seaman, Arnold, Scheunemann, & White, 2017; Seaman, Barnato, Sereika, Happ, & Erlen, 2017; White et al., 2012). In a study of 1,440 adult ICU patients with 2 or more days of MV, only 9.7% of patients at high risk for dying received palliative care consultations in ICU (Seaman, Barnato, et al., 2017). Older age and longer ICU stay were associated with higher likelihood of palliative care consultation services. Skills-training programs and resources for nurses include the End-of-Life Nursing Education Consortium (ELNEC-Critical Care and ELNEC Geriatric), Improving Palliative Care in the ICU (IPAL-ICU), and the American Association of Critical-Care Nurses E-learning program on Palliative and End-of-Life Care.

Given the increasing evidence of the significant impact that critical illness has on family members of the critically ill, guidelines for family-centered care in the ICU have been recently published (Davidson et al., 2017). These guidelines are particularly relevant for family members of critically ill older adults who are often left caring for a loved one with substantial physical and cognitive impairment and are aging themselves, given the level of post-ICU impairment (Serrano et al., 2019). These guidelines offer a number of important recommendations, including the need for open or flexible family presence at the ICU bedside and family education programs, offering family members the option of participating in interdisciplinary team rounds and being present during resuscitation efforts, and the use of specific consultations (e.g., palliative care, ethics) and ICU team members (e.g., social workers, psychologists).

Other Interprofessional Interventions. There are a number of other important evidence-based ICU interventions nurses should consider using when caring for the critically ill older adult (Box 35.1). It is important to note that successful implementation of these interventions requires

BOX 35.1

Evidence-Based Intensive Care Unit Interventions to Consider When Caring for Critically Ill Older Adults

Use of noninvasive positive pressure ventilation whenever feasible
Ventilator-Associated Pneumonia protocols
Aspiration precautions
Elevation of head of bed (30°–45°)
Daily sedation interruption and assessment of readiness to extubate
Use of subglottic secretion drainage
Avoidance of scheduled ventilator circuit changes
Deep breathing and coughing to aid movement and expand lungs
Oral care protocols
Careful monitoring of hemodynamic and fluid status (e.g., maintain adequate stroke volume; avoid overhydration)
Avoid physical restraint use
Mobilize early and often
Diagnostic tests to identify infectious agent
Timely and appropriate antibiotic administration
Eliminate infectious sources, remove invasive lines and tubes as early as possible

(*continued*)

BOX 35.1 (*continued*)

Early fluid resuscitation and vasopressor support as needed in patients with sepsis
Glycemic control and enteral feedings
Deep vein thromboses prophylaxis
Stress ulcer prevention with low-molecular-weight heparin and proton pump inhibitors or H2 blockers if indicated
Careful monitoring for transition from sepsis to severe sepsis to septic shock
Daily medication profile review
Discontinue redundant drugs
Administer all drugs at their lowest effective dose
Avoid polypharmacy and ensure that all medications are dosed appropriately
Consider medication withdrawal effects (particularly benzodiazepines)
Avoid anticholinergic and benzodiazepine medications
Avoid use of nonbenzodiazepine sleep aids when possible
Avoid metoclopramide when possible
Reassess need for continued antibiotic therapy
Monitor diuretic therapy for signs of dehydration and/or electrolyte abnormalities
Every time it is possible, ask the patient and his or her family about his/her care wishes
Assess communication function and apply assistive communication techniques
Mobilize geriatric expertise, if possible, especially during the discharge process
Provide vaccinations on recovery

CASE STUDY 35.1

Jack Robbins was a 69-year-old man with a previous medical history of chronic obstructive pulmonary disease, hypertension, hearing impairment, and tobacco abuse (40 pack-year history, current smoker). He presents to the emergency department with complaints of dyspnea, productive sputum, and persistent cough that had worsened over the last several days. He reported taking his short-acting bronchodilator and antihypertensive medications as prescribed and denied any recent travel or sick contacts. On exam, Mr. Robbins was found to be tachypneic, tachycardic, and hypertensive, as well as hypoxic and hypercapnic. A CT angiography of the chest was performed and showed no evidence of pneumonia or pulmonary embolism. Mr. Robbins was diagnosed with acute respiratory failure secondary to chronic obstructive pulmonary disorder (COPD) exacerbation and admitted to the ICU for evaluation and treatment.

Several hours after his admission to the ICU, Mr. Robbins' respiratory status declined, and he developed altered mental status and somnolence. He was intubated, placed on MV, and started on midazolam and fentanyl for sedation and pain control, respectively. On day 3 of hospitalization, Mr. Robbins was noted to be delirious, as evidenced by positive CAM-ICU testing as well as agitation despite sedation.

To address Mr. Robbins' delirium, a treatment plan was developed using the ABCDEF bundle and included the following interventions:

Assess, Prevent, and Manage Pain (A):

Given his agitation, Mr. Robbins' nurse determined that an assessment of his current pain level was warranted. The nurse decided to use a 0 to 10 visually enlarged horizontal Numeric Rating Scale (NRS) to perform this assessment. After his wrist restraints were released, Mr. Robbins was able to indicate (via pointing) that his current pain level was a three. Because he

(*continued*)

CASE STUDY 35.1 (*continued*)

was now physical restraint free, he was also able to communicate to his nurse by pointing to message icons on a communication board that the pain was mainly in his throat (likely from the endotracheal tube) and back. Importantly, he also wrote that he felt as though he was "laying on something". Mr. Robbins' nurse assisted him with turning to his side and discovered he was lying on blood pressure cuff tubing and that this was causing an indentation and redness. She removed the blood pressure cuff tubing and assisted him in finding a comfortable position. The nurse instructed Mr. Robbins that he still needed the ventilator to help him breathe and that it was very important for him not to remove the endotracheal tube by himself because this could cause significant problems for him. She asked him if he understood this, and he nodded his head in agreement. She then asked him if he would like his physical restraints removed, and he again indicated yes. The nurse provided Mr. Robbins his call bell, pen, pencil, and a set of picture-message communication boards and asked him if he would like more pain medicine. Mr. Robbins, who now had a Richmond Agitation and Sedation Scale (RASS) score of 0, said he was "OK" for now and did not need the additional medicine. Frequent pain assessments continued throughout his ICU stay.

Both Spontaneous Awakening Trials (SATs) and Spontaneous Breathing Trials (SBTs) (B):

Each morning, nurses performed a SAT safety screen to determine whether Mr. Robbins was able to have his continuous sedation interrupted. Mr. Robbins failed the SAT on days 2, 3, and 4 of his hospital course owing to respirations lower than 35/min for over 5 minutes. On day 5, he passed the SAT and immediately had an SBT safety screen performed by the respiratory therapist. On day 6 of hospitalization, Mr. Robbins passed the SBT safety screen but failed his SBT because of signs of respiratory distress. Mr. Robbins passed his SBT on day 7 and was extubated that day.

Choice of Analgesia/Sedation (C):

On day 2 of hospitalization, the nursing staff advocated a change from the use of midazolam to that of a nonbenzodiazepine for sedation. Mr. Robbins was therefore transitioned to a continuous infusion of propofol, and his fentanyl infusion was changed to as needed bolus dosing.

Assess, Prevent, and Manage Delirium (D):

Throughout Mr. Robbins' hospitalization, the nursing staff routinely assessed him for signs of delirium using the CAM-ICU assessment. The RASS score was documented every 4 hours along with vital signs, and sedation was titrated to maintain a RASS score of –1 to +1. The nursing staff reported the CAM-ICU and RASS score findings to the treatment team during daily rounds to aid in the formulation of Mr. Robbins' treatment plan. As described earlier, Mr. Robbins was also transitioned off all benzodiazepines owing to their effect of the development of delirium. The nurses also provided frequent reorientation to Mr. Robbins and ensured his hearing aids were worn and functioning properly during his hospitalization. Lastly, the nursing staff advocated the prescription of a nicotine patch to prevent agitation due to nicotine withdrawal. ICU pharmacists ensured all medications Mr. Robbins received were appropriate and dosed with geriatric considerations in mind.

Early Mobility (E):

Nurses caring for Mr. Robbins were responsible for ensuring that he was physiologically stable enough to engage in mobility activities by performing daily early mobility safety screens. Once these screens were passed (Day 3), physical therapy and nursing staff collaborated and assisted Mr. Robbins with progressive activities that included sitting on the edge of the bed, to transferring to chair, and then ultimately walking him. The nurses also ensured that Mr. Robbins assisted with frequent turning to prevent skin breakdown.

Family Engagement and Empowerment (F):

Throughout Mr. Robbins' admission to the ICU, his wife and two daughters were frequently at the bedside. On admission, they provided the care team with information regarding the patient's cognitive and functional status prior to his illness, as well as his medical and surgical history, including medications. The patient's family was encouraged to participate in Mr. Robbins' care, including joining daily bedside interdisciplinary rounds and helping provide reorientation and calming measures whenever Mr. Robbins became agitated. The nurses called Mr. Robbins' wife at mutually agreed upon times whenever she was unable to be at the bedside to provide her with updates on her husband's progress. On day 9 of hospitalization, Mr. Robbins had clinically improved enough for transfer to the medical–surgical floor. The ICU nurse

(*continued*)

CASE STUDY 35.1 (*continued*)

ensured that family information was communicated to the floor nurse so that Mr. Robbins' family could remain involved in his care after transfer from the ICU.

Once Mr. Robbins was transferred to the medical–surgical floor, the nurses continued to implement the ABCDEF bundle as applicable, including minimizing sedating medications and promoting mobility. The patient and his family were highly encouraged to participate in the discharge planning process, including working with the social work team to choose a homecare agency to provide postdischarge care for Mr. Robbins. The team ensured that Mr. Robbins' family understood the discharge plan fully, including the patient's medication schedule and when to call his provider or return to the emergency department. Mr. Robbins was discharged to home on day 12 of hospitalization and showed no signs of PICS at 6-month follow-up with his primary care provider.

effective interdisciplinary communication, collaboration, and teamwork. Evidence implementation will also require significant leadership buy-in and support.

SUMMARY

Nurses in the acute care setting must recognize and respond to the many factors that influence a critically ill older adult's ability to survive and rehabilitate from a catastrophic illness. In order to identify some of these risk factors, it is essential that the nurse perform a comprehensive assessment of each older adult's preadmission health status, functional and cognitive ability, and social support systems. It is equally important that the nurse understand the implications of common aging changes, comorbidities, and acute pathology that interacts with and heightens the risk for adverse and often preventable medical outcomes. The application of evidence-based interventions like the ABCDEF bundle aimed at restoring physiological stability, preventing complications, maintaining comfort and safety, preserving preillness functional and cognitive ability, and enhancing overall QOL are crucial components of caring for this extremely vulnerable population.

NURSING STANDARD OF PRACTICE

Protocol 35.1: Comprehensive Assessment and Management of the Critically Ill

I. GOAL

To restore physiological stability, prevent complications, maintain comfort and safety, and preserve preillness functional ability, cognitive ability, and quality of life (QOL) in older adults admitted to critical care units

II. OVERVIEW

Caring for an older adult who is experiencing a serious or life-threatening illness often poses significant challenges for critical care nurses. Although older adults are an extremely heterogeneous group, they share some age-related characteristics that leave them susceptible to a variety of geriatric syndromes and diseases. This vulnerability may influence both their ICU utilization rates and outcomes. Critical care nurses caring for this population must not only recognize the importance of performing ongoing, comprehensive physical, functional, and psychosocial assessments tailored to the older ICU patient, but also must be able to identify and implement evidence-based interventions designed to improve the care of this extremely vulnerable population.

III. BACKGROUND

A. Definition

A critically ill older adult is a person, aged 65 years or older, who is currently experiencing, or at risk for, some form of physiological instability or alteration warranting urgent or emergent, advanced, nursing/medical interventions and monitoring.

B. Etiology/epidemiology

1. More than one half (55.8%) of all ICU days are incurred by patients older than 65 years (Angus et al., 2006).

(*continued*)

Protocol 35.1: Comprehensive Assessment and Management of the Critically Ill (*continued*)

2. Older adults are living longer, are more racially and ethnically diverse, often have multiple chronic conditions, and more than one quarter report difficulty performing one or more ADL. These factors may affect both the course and outcome of critical illness.
3. Once hospitalized for a life-threatening illness, older adults often:
   a. Experience high ICU, hospital, and long-term crude mortality rates and are at risk for deterioration in functional ability and postdischarge institutional care (Balas et al., 2009, 2011; Brummel et al., 2014; de Rooij et al., 2008; Esteban et al., 2004; Ford et al., 2007; Hennessy et al., 2005; Hopkins & Jackson, 2006; Kaarlola et al., 2006; Pandharipande et al., 2013; Wunsch et al., 2010)
   b. Older age is also a factor that may lead to:
      i. Physician bias in refusing ICU admission (Joynt et al., 2001; Mick & Ackerman, 2004)
      ii. The decision to withhold MV, surgery, or dialysis (Hamel et al., 1999)
      iii. An increased likelihood of an established resuscitation directive (Hakim et al., 1996)
   c. Most critically ill older adults:
      i. Demonstrate resiliency
      ii. Report being satisfied with their postdischarge QOL
      iii. Would reaccept ICU care and MV if needed (Guentner et al., 2006; Hennessy et al., 2005; Kleinpell & Ferrans, 2002)
   d. Chronological age *alone* is not an acceptable, or accurate, predictor of poor outcomes after critical illness (D. Elliott et al., 2014; Milbrandt et al., 2010; Nagappan & Parkin, 2003).
   e. Factors that may influence an older adult's ability to survive a catastrophic illness include (de Rooij et al., 2005; Ford et al., 2007; Marik, 2006; Mick & Ackerman, 2004; Wunsch et al., 2010):
      i. Severity of illness
      ii. Nature and extent of comorbidities
      iii. Diagnosis, reason for/duration of mechanical ventilation
      iv. Complications
      v. Others
         a. Prehospitalization functional ability
         b. Vasoactive drug use
         c. Preexisting cognitive impairment
         d. Senescence
         e. Ageism
         f. Decreased social support
         g. The critical care environment
         h. Patient preference
   f. Dementia is a common development in older adults after admission to ICU for critical illness.
      i. Newly developed (incident) dementia is present in 12% to 18% of patients at 1 year to 8 years post critical illness (Brummel et al., 2014; Ehlenbach et al., 2010; Guerra et al., 2012; Herridge et al., 2011).
      ii. Prevalent (unknown preillness status) dementia is reported in 15% of patients post discharge, and in 10% of patients at 1 year follow-up (Sacanella et al., 2011).
      iii. Newly acquired mild or moderate cognitive impairment is reported in 56% of patients at 4 years post critical illness (de Rooji et al., 2008).

IV. PARAMETERS OF ASSESSMENT

A. On admission to the ICU, the nurse should ask relatives or other caregivers for baseline information about the older adults'
   1. Memory, executive function (e.g., fine motor coordination, planning, organization of information, etc.), and overall cognitive ability (Kane et al., 2004)
      a. Behavior on a typical day, how the patient interacts with others; his or her responsiveness to stimuli, how able he or she is to communicate (reading level, writing, and speech); and his or her memory, orientation, and perceptual patterns before the illness (Milisen & DeGeest, 2001).

(*continued*)

Protocol 35.1: Comprehensive Assessment and Management of the Critically Ill (*continued*)

2. Medication history to assess for potential withdrawal syndromes and adverse drug events (Broyles, Colbert, Tate, Swigart, & Happ, 2008; Bunditz et al., 2006).
3. Preadmission functional ability, frailty, and nutritional status—limited preadmission functional ability, frailty, and poor nutritional status are associated with many negative outcomes for critically ill older adults (Fronczek et al., 2018; Hamidi et al., 2019). Therefore, the nurse should assess the following:
   a. Did the elder suffer any limitations in the ability to perform his or her ADL preadmission? If so, what were these limitations?
   b. Does the elder use any assistive devices to perform ADL? If so, what type?
   c. Where did the patient live before admission? Did he or she live alone or with others? What was the elder's physical environment like (i.e., house, apartment, stairs, multiple levels, etc.)?
   d. What was the older adult's nutritional status like before admission? Does he or she have enough money to buy food? Does he or she need assistance with making meals/obtaining food? Does he or she have any particular food restrictions/preferences? Was he or she using supplements/vitamins on a regular basis? Does he or she have any signs of malnutrition, including recent weight loss/gain, muscle wasting, hair loss, skin breakdown?
4. Psychosocial factors—Critical illness can render older adults unable to communicate effectively with the healthcare team, often related to physiological instability, technology that leaves them voiceless, and sedative and narcotic use (Happ, 2000, 2001). Family members are therefore often a crucial source for obtaining important preadmission information.
   a. What is the elder's past medical, surgical, and psychiatric history? How did the elder communicate prior to the critical illness? What medication was the older adult taking before coming to the ICU? Does the elder use illicit drugs, tobacco, or alcohol regularly? Does he or she have a history of falls, physical abuse, or confusion?
   b. What is the older adult's marital status? Who is the patient's significant other? Will this person be the one responsible for making decisions for the elder if he or she is unable to do so? Does the elder have an advance directive for healthcare? Is the elder a primary caregiver to an aging spouse, child, grandchild, or other person?
   c. How would the elder describe his or her ethnicity? Does he or she practice a particular religion or have spiritual needs that should be addressed? What was his or her QOL like before becoming ill?

B. During ICU stay—There are many anatomic/physiological changes that occur with aging (see Table 35.1). The interaction of these changes with the acute pathology of a critical illness, comorbidities, and the ICU environment not only leads to atypical presentation of some of the most commonly encountered ICU diagnoses, but may also elevate the older adults' risk for complications. The older adult must be systematically assessed for the following:
   1. ICU/Environmental factors—Deconditioning, poor oral hygiene, sleep deprivation, pain, immobility, nutritional status, MV, hemodynamic monitoring devices, polypharmacy, high-risk medications (e.g., narcotics, sedatives, hypnotics, nephrotoxins, vasopressors), lack of assistive devices (e.g., glasses, hearing aids, dentures), noise, tubes that bypass the oropharyngeal airway, poorly regulated glucose control, Foley catheter use, stress, invasive procedures, shear/friction, intravenous catheters
   2. Atypical presentations of illness are commonly seen in older adults experiencing the following:
      a. Myocardial infarction
      b. Acute abdomen
      c. Systemic infection
      d. Hypoxia

V. NURSING CARE STRATEGIES

A. Preadmission: Based on the individual's preadmission assessment findings, the nurse should consider:
   1. Obtaining appropriate consults (i.e., dietitian, physical/occupational/speech therapist)
   2. Implementing safety precautions
   3. Using pressure-relieving devices

(*continued*)

Protocol 35.1: Comprehensive Assessment and Management of the Critically Ill (*continued*)

4. Organizing family meetings
5. Providing the older adult with a consistent primary nurse
6. Screening for risk factors placing the patient at increased likelihood of developing PICS
   a. Preexisting risk factors: Senescence, comorbid illnesses, disease pathology
   b. ICU syndromes/conditions: Pain, delirium, and oversedation

B. During ICU admission, the nurse should attempt to:
1. Continue to screen for ICU conditions using appropriate tools such as the RASS, CAM-ICU, and Intensive Care Delirium Screening Checklist (ICDSC; Bergeron, Dubois, Dumont, Dial, & Skrobik, 2001; Ely et al., 2001a, 2001b; Riker, Picard, & Frasier, 1999; Sessler et al., 2002).
2. Prevent development of ICU conditions by implementing ABCDEF bundle (see Table 35.2).
   a. Assess, prevent, and manage pain using verified pain scale such as Critical Care Pain Observation Tool (CPOT) or Behavioral Pain Scale (BPS; Gélinas, Fillion, Puntillo, Viens, & Fortier, 2006; Payen et al., 2001).
   b. Coordinate SAT and SBT to assess need for sedation and ventilation concurrently.
   c. Ensure choices of analgesic and sedative medications are appropriate for the patient condition.
   d. Assess, prevent, and manage delirium.
   e. Encourage early mobility and exercise.
   f. Increase family engagement and empowerment.
3. Foster patient communication strategies
   a. Consider use of algorithm-guided assessment and communication tool selection (Happ et al., 2014)
   b. Consider consulting speech therapist to facilitate communication (Happ et al., 2010; Altschuler & Happ, 2019)
4. Consider other appropriate interventions (see Box 35.1)

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient
1. Preadmission functional ability will be maintained/optimized.
2. ICU syndromes such as pain, anxiety, immobility, and delirium will be minimized.
3. Communication between the patient, family, and the healthcare team will be improved.

B. Provider
1. Employ consistent and accurate documentation of assessment relevant to the older ICU patient.
2. Provide consistent, accurate, and timely care in response to deviations identified through ongoing monitoring and assessment of the older ICU patient.
3. Provide patient/caregiver with information and teaching related to his or her illness as well as news of transfer of care and/or discharge.

C. Institution—include QA/QI
1. Evaluate staff competence in the assessment of older critically ill patients.
2. Use unit-specific, hospital-specific, and national standards of care to evaluate existing practice.
3. Identify areas for improvement, and work collaboratively across disciplines to develop strategies for improving critical care to older adults.

VII. RELEVANT PRACTICE GUIDELINES

Clinical practice guidelines for the prevention and management of pain, agitation/sedation, delirium, immobility, and sleep disruption in adult patients in the intensive care unit. *Critical Care Medicine, 46*(9), e826–e873. doi:10.1097/CCM.0000000000003299

(*continued*)

Protocol 35.1: Comprehensive Assessment and Management of the Critically Ill (*continued*)

ABBREVIATIONS

ADL	Activities of daily living
ICU	Intensive care unit
MV	Mechanical ventilation
PICS	Post-intensive care syndrome
QA	Quality assurance
QI	Quality improvement
QOL	Quality of life
SAT	Spontaneous awakening trial
SBT	Spontaneous breathing trial

NOTE

This chapter was adapted from the American Association of Colleges of Nursing "Preparing Nursing Students to Care for Older Adults: Enhancing Gerontology in Senior-Level Undergraduate Courses" curriculum module, Assessment and Management of Older Adults With Complex Illness in the Critical Care Unit, prepared by Michele C. Balas, Colleen M. Casey, and Mary Beth Happ.

ACKNOWLEDGMENTS

The authors would like to acknowledge the continued support and commitment to improving nursing care of older adults provided by the John A. Hartford Foundation.

Fluid Overload: Identifying and Managing Heart Failure Patients at Risk for Hospital Readmission*

Ameera Chakravarthy and Joan Davenport

36

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe the older adult with heart failure (HF) who is at risk for hospital readmission.
2. Conduct a comprehensive cardiac history.
3. Identify three physical findings that may be associated with fluid overload in the older adult patient with HF.
4. Name three key symptoms associated with fluid overload in the older adult patient with HF.
5. Define cardiovascular stability in relation to the five key indicators.
6. Plan monitoring strategies to reduce fluid overload in the older adult with HF.

OVERVIEW

Heart failure (HF) is the most common cause of hospital admission in the older adult, increasing substantially after age 60 and accounting for 1 million hospitalizations annually in the United States (Benjamin et al., 2017; Centers for Disease Control and Prevention [CDC], 2019; Schocken et al., 2008; Yancy et al., 2013). Older adults with HF are at high risk for readmission with 30-day readmission rates of approximately 25%, 50% by 6 months, and 67.4% in 12 months (Benjamin et al., 2017; Dharmarajan et al., 2015). The evidence-based literature demonstrates that as many as half of these admissions are readmissions and are preventable (Feltner et al., 2014; Ziaeian & Fonarow, 2016; Zsilinszka et al., 2017). The epidemic in HF prevalence is commensurate with an aging population and has stimulated a focus of research to identify those patients at high risk for hospitalization and readmission. Early identification of patients at risk for rehospitalization during the hospital stay provides opportunity for interventions to impact the readmission rate. Symptoms of HF compel patients to seek medical aid; however, evidence to date has shown that HF patients postpone seeking medical assistance 2 hours to 14 days before recognition of these changes as harmful to bodily functioning (Evangelista, Dracup, & Doering, 2000; Jurgens, Hoke, Byrnes, & Riegel, 2009; Sethares, Chin, & Jurgens, 2015; Sethares, Sosa, Fisher, & Riegel, 2014). The delay causes further deterioration in cardiac status, requiring acute hospitalization. This chapter presents the complex nature and pathophysiology of HF symptoms, along with nursing management strategies to reduce hospital readmission rates. A detailed protocol for nursing practice of the aging population is presented, highlighting the nursing assessment and management of HF.

BACKGROUND AND STATEMENT OF PROBLEM

HF is a public health problem affecting an estimated 5.8 million Americans yearly (CDC, 2019). Cardiovascular disease (CVD), which includes hypertension (HTN),

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

HF, valvular heart disease, and arrhythmias, along with the atherosclerotic disease that causes coronary heart disease (CHD), stroke, and peripheral vascular disease (PVD), is the major contributor to mortality and comorbidity in older adults. CVD accounted for 840,678 deaths in the United States in 2016, approximately one of every three deaths. In adults aged 75 to 85 years, it accounts for 40% of all deaths, and 48% of all deaths in those 85 years and older (Benjamin et al., 2017; Lloyd-Jones et al., 2010). Acute or chronic HF is the leading cause of hospital admission in patients older than 65 years, and readmission rates to acute care facilities, which averaged 17.2% nationally in 1996, increased to 23.6% in 2010, and are currently at 25% (Dharmarajan et al., 2013; Fleg, 2018; Gupta et al., 2018). Risk of readmission has been shown to be four times higher in older adults aged 80 years and older, higher in ethnicities other than Whites, and higher with lower economic status (Mirkin, Enomoto, Caputo, & Hollenbeak, 2017). In addition, there is evidence to show that risk factors such as noncardiovascular comorbidities, poor physical condition, history of admission, and failure to use evidence-based medication are more strongly associated with 90-day readmission or death than standard risks in patients with HF (Saito, Negishi, & Marwick, 2016).

The prevalence of HF increases with age, and more than 75% of those affected are older than 65 years old. Development of HF is higher with the male sex, lower level of education, low levels of physical activity, cigarette smoking, overweight, diabetes mellitus (DM), HTN, valvular heart disease, left ventricular hypertrophy (LVH), and atherosclerosis of the coronary arteries (CHD). HTN is a precursor in 75% of individuals diagnosed with HF (Messerli, Rimoldi, & Bangalore, 2017). Both the incidence and the prevalence of HF continue to increase as the population ages.

Risk Factors for Developing HF in Older Adults

The primary clinical risk factors for developing HF are advancing age, male sex, HTN, myocardial infarction (MI), DM, valvular heart disease, and obesity (Bui, Horwich, & Fonarow, 2011). HTN is the most common cause of HF in patients without CHD, accounting for 24% of the cases of HF (Ahmad et al., 2016; Messerli et al., 2017). HTN is also extremely common in type 2 DM, as it occurs in more than 50% of older adults with type 2 DM (Lastra, Syed, Kurukulasuriya, Manrique, & Sowers, 2014). Women with DM are at extremely high risk for developing HTN and HF (Lastra et al., 2014). Individuals with HTN and DM often develop HF with preserved left ventricular (LV) systolic function (heart failure with a preserved ejection fraction [HFpEF]) or so-called diastolic HF, rather than LV systolic dysfunction (Bell & Goncalves, 2019). Having DM is associated with an adjusted two-fold increase in cardiovascular death or hospitalization for HF and an 80% increase in the hazard of all-cause mortality (MacDonald et al., 2008). HFpEF is a clinical syndrome in which LV filling pressures are elevated, the LV ejection fraction (LVEF) is normal, and yet the heart is unable to satisfy the systemic oxygen needs of an individual.

Other related clinical risk factors of HF include smoking, dyslipidemia of genetic and dietary etiology, sleep-disordered breathing or obstructive sleep apnea (OSA), chronic kidney disease, albuminuria, sedentary lifestyle, low socioeconomic status, and psychological stress. Toxic substances, such as chemotherapeutic agents (anthracyclines, cyclophosphamide, 5-FU, trastuzumab), illicit drugs (amphetamines, cocaine), and medications (nonsteroidal anti-inflammatory drugs [NSAIDs], thiazolidinediones [TZDs], alcohol), can precipitate HF (Schocken et al., 2008).

DM is a CVD equivalent and, as such, is an important contributor to HF (Bell & Goncalves, 2019; Tousoulis, Oikonomou, Siasos, & Stefanadis, 2014). Women and those individuals treated with insulin are at the greatest risk for ischemic etiology of both reduced ejection fraction (HFrEf) and HFpEF. In a sample of older Medicare patients with type 2 DM, 22% had a diagnosis of HF, and this prevalence increased with advancing age (Bertoni et al., 2004). In addition, the presence of type 2 DM is associated with higher HF-related morbidity and mortality. After MI or coronary revascularization procedures, individuals with type 2 DM also have a high morbidity and mortality, which is largely caused by the development of HF (von Bibra & St John Sutton, 2011). An earlier analysis of outcomes in Medicare patients 1 year after an MI revealed that 11% of patients without DM had HF, whereas 17% of patients with DM on oral agents and 25% of those treated with insulin were admitted for HF exacerbation (Chyun, Vaccarino, Murillo, Young, & Krumholz, 2002).

The initial diagnosis of HF is most often an acute index event requiring hospitalization. Patients at risk of readmission after initial diagnosis of HF include the following (Bertoni et al., 2004; Chyun et al., 2002):

- Age 65 years and older, and even more so for age 80 years and older
- Male gender, black race (Mirkin et al., 2017)
- Newly diagnosed HF with hospitalization (Arora et al., 2017)
- Hypotension or low output states
- Obstructive sleep apnea and/or chronic obstructive pulmonary disease (COPD; Arora et al., 2017)

- Renal failure or electrolyte imbalance (Arora et al., 2017; Mirkin et al., 2017)
- Rheumatoid arthritis (Davis et al., 2008; Nicola et al., 2005)
- Cardiovascular and vascular comorbid conditions such as MI, PVD, cerebrovascular disease, HTN, hyperlipidemia, and arrhythmias (Manemann et al., 2016; Mirkin et al., 2017)
- Hospitalizations for any reason in the past 5 years (Kossovsky et al., 2000)
- Social isolation (Cené et al., 2012)
- HF related to acute MI
- History of alcohol or illicit drug abuse (Marin et al., 2017; Whitman et al., 2017)
- HF with acute infection
- Anemia with hemoglobin of less than 12 (Young et al., 2008)
- History of depression or anxiety (Rustad, Stern, Hebert, & Musselman, 2013)
- Nonadherence to diet, fluid intake, respiratory treatments or medications

Pathophysiology of HF

Understanding the pathophysiology of HF provides insight into the rationale for treatment. HF is defined as the inability of the heart to pump blood sufficient to meet the metabolic needs of the body or the inability to do so without significantly elevated filling pressures (Harjola et al., 2017). The inability of the left ventricle to eject blood sufficiently represents LV systolic HF or HFrEF and is diagnosed with a measurement of EF less than 50%. Diastolic dysfunction and failure result in high LV filling pressures, yet inadequate ability of LV to deliver oxygenated blood to fulfill the body's needs. Diastolic HF is also more descriptively named HF with preserved systolic function or HFpEF because the EF is essentially normal: approximately 60%. The symptoms of HF are directly related to impairment in the filling and ejecting of the blood in the left ventricle.

All of the risk factors and disease entities listed previously can cause direct damage to the myocardium, as in MI and toxic exposure, or subject it to an increased level of wall stress, as in HTN or valvular lesions. Such an insult initiates compensatory actions by the heart that are mediated by the neurohormones of the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS), which are active, both systemically and directly, in the myocardium. Rather than offering benefit, the SNS (epinephrine and norepinephrine) and RAAS (angiotensin II, vasopressin, aldosterone) hormones promote cardiac remodeling and hypertrophy, causing dilatation of the ventricle and buildup of fibrous tissue that weakens the cardiomyocytes. These changes occur during compensated (asymptomatic) as well as decompensated (symptomatic) failure. The overexpression of neurohormones causes salt and water retention and vasoconstriction, which in turn produces increased hemodynamic stress on the left ventricle. These factors are cyclical unless treated. Untreated, there is further disruption of left ventricle architecture and performance (Kemp & Conte, 2012).

Because this process begins without symptoms, for patients at risk, it is essential to identify factors that are a hazard to cardiovascular health and initiate treatment before significant damage to the myocardium occurs. The American College of Cardiology Foundation/American Heart Association Task Force (ACCF/AHA) developed guidelines to classify HF in four stages (Yancy et al., 2013, 2017) based on the structural changes and damage to the heart:

Stage A is considered a pre-HF stage or an "at-risk" stage without structural heart disease or symptoms of HF. It includes patients with HTN, atherosclerotic disease, DM, obesity, metabolic syndrome, those using cardiotoxic substances, or those with a family history of cardiomyopathy.

Stage B includes asymptomatic individuals with structural heart disease but without signs or symptoms of HF, for example those with previous MI, LVH, decreased EF, and asymptomatic valvular disease.

Stage C includes individuals with known structural heart disease and symptoms of HF—shortness of breath, fatigue, and reduced exercise tolerance—or those who, after treatment, are now asymptomatic for their heart disease.

Stage D includes individuals with refractory HF requiring the use of specialized interventions and includes patients with marked symptoms at rest despite maximal medical therapy.

Atherosclerosis and ischemia in CHD are the most common etiology of HF in the United States, followed closely by HTN alone and valvular disease. Thyroid dysfunction and excessive alcohol intake may also lead to HF. In the absence of known CVD, systolic function of the heart remains relatively unchanged in older adults, as does exercise tolerance. Diastolic dysfunction, however, is predominantly a disease of older adults and may be present even in the absence of HTN or cardiomyopathy, which are also known to contribute to diastolic failure (A. Shah, Gandhi, Srivastava, Shah, & Mansukhani, 2017). The prevalence of HFpEF is increasing as the population of those older than 65 years grows along with the burden of

lifestyle risk factors of diabetes and obesity (Chrysant & Chrysant, 2019; Kristensen et al., 2017; Vasan & Levy, 2000). The archetypical patient presenting with diastolic HF is 70 to 80 years of age, female, obese, diabetic, and often has atrial fibrillation (Coats, 2001). Diastolic dysfunction is characterized by an exaggerated HR with activity, which is often one of the first clinical findings. The severity of symptoms varies among patients and may not correlate with LVEF as exercise capacity and quality of life are similarly reduced in HFrEF and HFpEF (Aziz, Tk, Enweluzo, Dutta, & Zaeem, 2013).

HTN, CHD, and hypertrophic cardiomyopathy are all abnormalities that are exacerbated by tachycardia, underscoring the importance of avoiding a high HR in all older individuals. Diastolic abnormalities caused by HTN, aortic stenosis, hypertrophic cardiomyopathy, or CHD may precipitate HF. Patients with either systolic or diastolic HF are at risk of fluid overload. Although discussed as two separate entities, many older adults have components of both systolic and diastolic dysfunction in addition to geriatric syndromes such as frailty, delirium, and falls (Iyngkaran et al., 2018).

TABLE 36.1

New York Heart Association Functional Capacity Classification

Class I	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or angina.
Class II	Slight limitation of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
Class III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.
Class IV	Unable to carry on any physical activity without discomfort. Symptoms present at rest. With any physical activity, symptoms increase.

ASSESSMENT OF THE PROBLEM

For older adults diagnosed with HF, the health history and physical assessment are directed at monitoring symptoms and assessing cardiovascular function. For the nurse assessing and managing the patient with HF, it is important to note that the recognition of fluid overload is not always straightforward. The assessment of symptoms of fluid overload for acute and chronic HF can be a challenge for the nurse to assess. There are multiple factors that account for the accumulation and redistribution of body fluid. This fluid increases over time, ultimately leading to refractory volume overload and organ congestion. Monitoring parameters must be established, in which the patient and nurse actively identify subtle changes and seek intervention as early as possible (Miller, 2017; Tuy & Than, 2013).

The Health History

HF has both symptomatic and nonsymptomatic phases. When symptoms occur, they are related to intravascular and interstitial fluid overload and inadequate tissue perfusion. Symptoms become evident with exertion, and in severe HF, even at rest. The New York Heart Association (NYHA) functional capacity is an important standardized classification of the HF patient according to how much activity patients are able to accomplish without symptoms (Table 36.1). Classifying patients according to their physical symptoms offers evidence of the extent of volume overload and limitation caused by symptoms, which then leads the nurse to recognize the severity of the disease. Patients, with proper treatment, can improve their functional status and classification as their symptoms improve from a NYHA class III to class II or even class I; however, once identified at an advanced stage, C or D, earlier stages are not reclaimed. For example, a stage C patient does not return to stage B. Although current therapies are shown in studies to improve mortality, success in returning diseased myocardium to health has not yet been achieved.

Both patients and providers frequently attribute symptoms of fluid overload to aging. When symptoms occur during exertion, senior patients may simply decrease their activities to prevent symptoms, yet when asked, they report activity from a memory of months earlier. Because of inaccurate reporting of activity, HF in older adults is often difficult to recognize and, therefore, goes untreated. Thus, the nurse should routinely ask questions related to activity-limiting dyspnea. A key indicator in establishing a baseline for functional capacity is to ask the patient what his or her maximal asymptomatic activity is now, what it was 6 months ago, and what it was 1 year ago. Other important questions include "How far can you walk without getting short of breath?" The answer to a question, such as "How far is the bathroom from your bed?", can elicit information about symptoms in walking, sleep habits, and nocturia. "What is the activity that commonly produces shortness of breath?" Try to avoid questions that can be

answered "Yes" or "No" (e.g., "Do you experience shortness of breath when simply sitting?" "Do you wake at night feeling short of breath?"). Rather, say, "Tell me about what you do during a typical day." Repeating these questions in subsequent interviews will help monitor changes in activity associated with treatment or with suspected fluid gain. The goal is to identify whether the patient is physically capable of performing activities of daily living (ADL).

HFrEF is a pathophysiological process in which LV dysfunction occurs independent of symptom development (Tromp et al., 2018). Symptom expression is dependent on compensatory mechanisms and the length of time HF has been present. Patients with acute HF, as seen with MI, may be more symptomatic because their compensatory mechanisms have not fully developed. In comparison, the patient with long-standing HF may have severe dysfunction but may not become symptomatic until consuming a high-sodium meal or experiencing physical stress. Fluid overload can then occur rapidly, oftentimes overnight. In this case, compensatory mechanisms are now exhausted and, as a result, fail. The window of opportunity to successfully intervene is narrow, as is the margin of error. Treatment for fluid overload in this case must be swift and brisk but gentle enough to maintain BP (Yancy et al., 2018). Nurses need to be aware of the importance of both early recognition and early intervention in the patient with fluid overload. A few hours' delay in providing treatment can mean the difference between successful management at home or need for hospital admission with variable outcomes.

Knowledge of past medical history will help to anticipate problems related to other conditions because their presence may complicate assessment and management of HF. Cardiac risk factors; levels of physical activity; and control of lipids, HTN, obesity, DM, and smoking need to be determined. Additionally, it is important to consider that older adult responses to HF medications and treatment are variable. Other drugs commonly used in this age group, such as over-the-counter NSAIDs, can actually exacerbate fluid overload by increasing sodium retention. Previous questions related to cardiovascular functional capacity may have already provided some information, but additional information on musculoskeletal and neurological function can add needed insight.

Assessment for additional symptoms will assist in identifying the patient with HF. *Orthopnea* is the most sensitive and specific symptom of elevated filling pressures, and it tends to reliably parallel filling pressures in patients with this symptom (Anker et al., 2003; Stevenson & Perloff, 1989). Nocturnal or exertional cough is often a dyspnea equivalent and should not be confused with the cough from an angiotensin-converting enzyme (ACE) inhibitor, which is not associated with activity or position. Individual patients generally exhibit patterns of fluid overload that reoccur in subsequent exacerbations. These should be documented, made available to all on the care team, and used in patient education for self-monitoring and for early recognition by the healthcare team. Questions related to symptoms and function should be part not only of the initial assessment, but also of subsequent visits as a means of surveillance (Miller, 2017; Stevenson & Perloff, 1989).

The clinical presentation of HF may include a variety of symptoms reflective of pulmonary congestion and decreased cardiac output. The questions related to health history are important to include and/or observe during the health encounter. Although the presence of any one major symptom is sufficient to warrant consideration of HF, symptoms occurring with other physical findings of orthopnea, paroxysmal nocturnal dyspnea, and progressive dyspnea on exertion are virtually diagnostic of fluid overload. The Framingham criteria (Margolis, Gillum, Feinleib, Brasch, & Fabsitz, 1974) are validated and are most often used to identify congestive HF or HF exacerbation. If two major criteria or one major with two minor criteria are present, the professional can have reasonable certainty that the patient has HF. These criteria are listed as follows.

Major:

- Paroxysmal nocturnal dyspnea
- Neck vein distention
- Rales
- Enlarged heart on chest x-ray
- Acute pulmonary edema
- S3 gallop
- Increased central venous pressure
- Hepatojugular reflux
- Weight loss greater than or equal to 4.5 kg (10 pounds) in response to treatment

Minor:

- Bilateral ankle edema
- Nocturnal cough
- Dyspnea on ordinary exertion
- Hepatomegaly
- Pleural effusion
- Tachycardia greater than or equal to 120 beats/min

The presence of other comorbidities, such as DM, renal dysfunction, and liver disease, along with systemic physiological changes associated with aging, further

complicates the assessment and management of HF in the older adult. Comorbidities should also be carefully assessed by reviewing laboratory data. DM may necessitate monitoring of blood glucose because wide variations in glucose can affect the ischemic threshold. Renal dysfunction and liver disease may affect the pharmacodynamics of drugs used to treat HF. Inclusion of the pharmacist on the healthcare team or at least a consultation with the pharmacist will assist in ensuring the efficacy and safety of medications in the aging population. Anemia, a common medical condition in older adults, affects oxygenation, activity tolerance, and subsequent fluid balance (Lanier, Park, & Callahan, 2018). The presence of COPD, as well as other comorbidities, may necessitate special precautions when assessing and managing oxygen therapy and beta-blockers (Arora et al., 2017).

As overuse of salt in the diet may precipitate fluid overload, a comprehensive dietary history is absolutely essential. The nurse should include specific questions about what the patient eats for meals and who prepares those meals, recognizing that it may be more important to discuss food preparation and sodium restriction with the patient's primary caregiver. Additionally, does the patient use the salt-shaker or salt substitutes at the table or in cooking? How often does the patient eat out at a restaurant or order in food? A review of foods high in sodium on a printed list often reveals foods the patient is eating that he or she previously did not admit to. For instance, important dietary questions related to use of canned products or deli meats, which contain higher amounts of sodium, should be included. A list of the sodium and the potassium content of a variety of foods, including fruits and vegetables, can be helpful in providing the information necessary for the patient to make appropriate daily choices. Because assessment of nutritional status is critical to elicit accurate fluid and sodium intake, it is prudent in the acute care setting for the older adult to have a dietician consultation. Additionally, as cachexia is a harbinger of a downward spiral in patients with HF, questions need to be included on the health history related to appetite and weight loss (Abshire et al., 2015; Colin-Ramirez, Arcand, & Ezekowitz, 2015; Colin-Ramirez, McAlister, Zheng, Sharma, & Ezekowitz, 2016).

Current prescription and over-the-counter medication use should be assessed, along with any alternative or herbal therapies. Many older adults who are eligible for aspirin, beta-blockers, and ACE inhibitors (ACEIs) do not receive these medications despite the important role that these agents have in reducing CHD-related morbidity and mortality (Ruppar, Cooper, Mehr, Delgado, & Dunbar-Jacob, 2016; Schocken et al., 2008; Yancy et al., 2018).

Included in the health history should be questions related to medication adherence and the patient's decision to either take or not take medications (Ferdinand et al., 2017; Unverzagt et al., 2016). Understanding a patient's rationale to selectively not take certain medications at certain times will help reveal ways for the nurse to intervene. Patients may wish to adjust their diuretic dose so that they can function socially during the day. This is not an adherence issue but a sound decision based on the patient's rationale as to how to fit the medication regimen into his or her lifestyle. The interview can reveal whether "non-adherence" has such a rationale. If a cause is not found, other issues need to be explored, such as cost, number of medications, and/or the frequency of the doses. Ways to simplify the drug regimen should be explored as the older adult can become overwhelmed because of cognitive impairment, lack of health literacy with poor understanding of medication importance, and when symptomatic, for example, simply unable to do more than breathe.

Psychosocial factors and personal beliefs and behaviors, along with cultural and environmental influences, all contribute to management of chronic disease. The importance of depression and social support has been well documented in the older adult; therefore, all of these factors need to be assessed (Cené et al., 2012; Rustad et al., 2013). The nursing assessment in individuals with HF should identify the individual's response to treatment, which can then be used to assist the individual in subsequent management of symptoms and the underlying condition, health-promotion and disease prevention activities, and chronic disease management. Awareness of the patient's own perception of why he or she sought medical care and a detailed analysis of the symptoms will help in assessing the individual's or caregiver's ability to identify symptoms, his or her knowledge regarding the condition, its prognosis, and general health beliefs, along with the prior ability to manage this or other medical conditions.

Physical Assessment of the Older Adult With Fluid Overload

Physical assessment of the patient with suspected fluid overload includes inspection; palpation; and auscultation of the peripheral vasculature, heart, lungs, abdomen, and extremities. Orientation, functional limitations, and mental clarity are observed during examination of vital signs, which include height, weight, and waist circumference.

A patient's height and baseline weight are important indicators of both nutritional and fluid status. Patients may know their ideal weight or "dry weight." Ascertain this when obtaining the health history to establish initial

goals in diuretic treatment. Hospitalized patients with HF should have a weight measurement each day. The importance of daily weights should be emphasized with each weight in the hospital setting to reinforce the need to continue this practice at home. At home, family involvement is important, and weights should be taken daily, typically the first thing in the morning on arising, before breakfast, and with no clothes or wearing light clothing to avoid false fluctuations (Clark et al., 2014; Grady et al., 2000; Riegel et al., 2009; Riegel, Naylor, Stewart, McMurray, & Rich, 2004). This provides the best baseline for consistency. A 2-pounds weight gain overnight or a 3-pounds weight gain in a week is an indication that medical management must change. Measurement of a senior's waist circumference is also important to determine at baseline, because often, this is the location for fluid accumulation (Grady et al., 2000). Once height and weight are measured, a body mass index (BMI) should be calculated. Research has shown that higher BMIs indicating mild to moderate obesity (30–39.9 kg/m^2) are associated with longer survival, known as the obesity paradox in HF (Horwich, Fonarow, & Clark, 2018; Oga & Eseyin, 2016).

A thorough and accurate evaluation of the BP should be performed. A variety of environmental factors can influence BP determination; therefore, the room should be at a comfortable temperature, the patient as relaxed as possible, and a 5-minute rest allowed before taking the first reading. Clothing that covers the area where the cuff will be placed should be removed, the stethoscope bell placed over the brachial artery and not under the cuff, and the individual seated comfortably, with legs uncrossed, with the back and arm supported; the middle of the cuff on the upper arm should be at the level of the right atrium (Pickering et al., 2005; Rabbia et al., 2013). The initial BP reading should be taken in both arms. Proper cuff size is critical to obtaining an accurate measurement. Obese individuals with large arm circumference need to have the appropriate cuff size for accuracy. Conversely, thin, cachectic patients will also have inaccurate readings with a standard cuff. The bladder length should be 80% of the arm circumference, and width at least 40%. The midline of the bladder should be placed above the brachial artery, 2 to 3 cm above the antecubital fossa, where the artery should have first been palpated. When using the auscultatory method, which remains the "gold standard" for BP measurement, palpating the radial pulse first while inflating the cuff will identify the point at which the pulse disappears. For the subsequent auscultatory measurement, the cuff should then be inflated to at least 30 mmHg above this point. The rate of deflation is also extremely important, with a rate of 2 to 3 mmHg/sec recommended. The first and last audible sounds are the systolic blood pressure (SBP) and diastolic blood pressure (DBP), respectively. Two readings, taken 5 minutes apart, should be averaged, and if there is greater than 5 mmHg difference, additional readings should be obtained (Pickering et al., 2005).

Pseudohypertension is a rare phenomenon, resulting from noncompressibility of thickened arteries and will result in the recording of falsely high BP when indirect methods are used (Spence, Sibbald, & Cape, 1978). A high BP over time without any indication of end-organ damage and treatment of the BP creating symptoms of hypotension, such as dizziness, confusion, and decreased urine output, point to a diagnosis of pseudohypertension. This tendency for peripheral arteries to become rigid with aging may result in a need to increase cuff pressure in order to compress the artery. If suspected, an intra-arterial reading has been suggested to avoid overmedication with antihypertensives; however, this is an extreme measure and is rarely done (Dai, Wang, & Fang, 2017). Most providers who treat HTN in older adults consider 160/90 mmHg as a hypertensive BP and will treat gently with appropriate antihypertensives and pull back on treatment if symptoms of hypotension or orthostasis occur. Isolated systolic HTN is also common in the older adult and is defined by an SBP greater than 140 mmHg and a DBP less than 90 mmHg. Care must be taken not to overtreat in this population, especially if aortic stenosis or other valvular disease is present. Older adults are also more likely to exhibit white-coat HTN, in which the BP may be elevated more than 140/90 mmHg in the presence of a healthcare worker and an actual reading at home is usually 135/85 mmHg or less. Therefore, assessment of the BP requires not only careful attention to technique but also consideration of the physiological abnormalities associated with aging. Home BP monitoring has been suggested as a means for patients to partner with their providers to provide care. For those patients who are unable, for whatever reason, 24-hour ambulatory BP monitoring is available to more accurately assess BP fluctuations during the day (Tseng, 2006; Turner, Viera, & Shimbo, 2015).

In addition, the standing BP should be assessed because older adults have a tendency for postural hypotension. Orthostatic hypotension is diagnosed when the SBP falls by at least 20 mmHg or the DBP by 10 mmHg within 3 minutes. The presence of orthostatic hypotension may also reveal early dehydration in a patient who is usually otherwise stable (Ricci, De Caterina, & Fedorowski, 2015). Because dehydration is the second most common admission for the older adult with HF, with falls following closely behind, standing BPs should be part of the routine assessment. In addition, patients should be assessed for

dehydration during diuresis and whenever a condition exists in which fluid loss could occur. This includes not only with vomiting or diarrhea but also with diaphoresis caused by extremes in temperature and humidity.

Inspection is the first step of the physical assessment. General inspection of the periphery includes the following:

- Observing color of the skin and mucous membranes
- Inspecting the patient's nails, including nail beds, and the angle between the base of the nail and the skin of the cuticle (normally less than 160°). An angle of 180° is called *clubbing*; the distal phalanx appears rounded. Clubbing is associated with chronic hemoglobin desaturation.
- If cachexic, check dependent areas for decubiti.
- Evaluate hair on distal extremities (indication of adequate arterial perfusion)

Palpation of the extremities occurs following inspection of the skin color for temperature and turgor as well as the color of the nail beds. Capillary refill of the nail should be assessed by compressing the nail for 2 to 3 seconds and then releasing. Note the time elapsed until the original color returns. Normally, the nail bed is pink; capillary refill occurs within 2 to 3 seconds. A pale or cyanotic nail with delayed capillary refill may indicate decreased peripheral perfusion. The peripheral pulses should be palpated bilaterally, including radial, femoral, pedal, and posterior tibial pulse. Note pulse rate, rhythm, and symmetry.

Respiratory rate and effort should be assessed before auscultation of the lungs. If possible, oxygen saturation during rest and activity should be recorded. Patients whose oxygen level desaturates during activity to 86% or lower may require oxygen support at home. In addition, surveillance of oxygen saturation during sleep may be required if the patient or family reports difficulty with sleep at night. Sleep apnea can be the etiology of HF in patients with HF and, if untreated or treated ineffectively, can be the cause of exacerbation and decompensation in HF (Kasai & Bradley, 2011; Khattak et al., 2018). Use the diaphragm of the stethoscope to assess the lungs. Listen in all the lobes for diminished sounds, crackles, wheezes, or rhonchi. Lung sounds are an important part of the assessment, particularly in patients with a history of HF.

The cardiovascular assessment begins by locating the apex and apical pulse by feeling for the point of maximal impulse (PMI). In systolic HF, the PMI is displaced laterally and indicates the heart is dilated. Assessment of apical pulse rate and regularity, with attention to fullness and amplitude, are also important. Heart sounds should be ascertained with both the diaphragm and the bell of the stethoscope. Note the presence of S1 and S2 and of extra sounds, S3 gallop, S4 murmurs, clicks, or rubs. If extra heart sounds are present, also examine the carotid arteries by listening on both sides of the neck with the bell. Bruits sound like murmurs, so it is important to differentiate between the two. Some aortic murmurs will radiate into the neck and may even be audible when auscultating the lungs posteriorly. Always listen to the heart before listening for extra sounds in the neck. Carotids should be palpated unilaterally, never simultaneous bilaterally, to avoid occlusion of blood flow to the brain.

Jugular veins are assessed best with the patient in semi-Fowler's position, but, if the patient is severely dyspneic, Fowler's position may be necessary. With the patient's head in straight alignment, observe the jugular neck veins for the presence of jugular venous distention (JVD). Turning the head slightly to the left and shining a penlight angularly on the vein allows for easier visualization of JVD and "a" and "v" waves, particularly in obese patients with thick necks. The jugular venous pulse waves will vary with respiration and decrease during inspiration. The jugular vein is compressible and varies with the angle of the neck. In the absence of pathology, venous distention is not present. JVD is the most sensitive sign of elevated filling pressures and is present with fluid overload, cor pulmonale, or high venous pressure (Chiaco, Parikh, & Fergusson, 2013; Stevenson & Perloff, 1989).

The abdomen should then be examined. First, auscultate for bowel sounds in a distended abdomen to assess for other pathology-causing distention. Next, palpate to determine whether the abdomen is soft and nontender. A protuberant abdomen with bulging flanks suggests the possibility of ascites. Because ascitic fluid characteristically sinks with gravity, whereas gas-filled loops of bowel float to the top, percussion gives a dull note in dependent areas of the abdomen. Look for such a pattern by percussing outward in several directions from the central area of tympany. Map the area between tympany and dullness. To palpate the liver, place your hand behind the patient, parallel to and supporting the right 11th and 12th ribs and adjacent soft tissues below. Remind the patient to relax. By pressing your left hand forward, the patient's liver may be felt more easily by the other hand. Patients who are sensitive to palpation can rest their hand on your palpating hand. Note any tenderness. If at all palpable, the edge of the liver is soft, sharp, and regular. The liver can be enlarged in HF because of congestion. To further assess for volume excess, place the patient in semi-Fowler's position at the highest level at which the jugular neck pulsations remain visible. Firmly apply pressure with the palmar surface of the hand over the right upper quadrant of the patient's abdomen for 1 minute. A 1-cm rise in the jugular distention, called

hepatojugular reflux, confirms the presence of fluid overload. Hepatojugular reflux may be associated with or without tenderness. Patients may also complain of a feeling of fullness.

The presence of *peripheral edema*, a symptom that can be related to fluid overload from cardiac renal disease or PVD, should be evaluated. Edema can also occur in response to medications such as calcium channel blockers. Dependent parts of the body, such as the feet, the ankles, and the sacrum, are the most likely locations to find edema. The presence and location of edema, and whether it is pitting or nonpitting, should be assessed. Depress an edematous area over a bony prominence for 5 to 15 seconds, then release. The grading scale for edema is as follows:

0 = *No pitting*
1+ = *Trace or mild, 2 mm depression that disappears rapidly*
2+ = *Moderate, 4 mm depression that disappears in 10 to 15 seconds*
3+ = *Moderate severe pitting, 6 mm depression that may last more than 1 minute*
4+ = *Severe pitting, 8 mm depression that can last more than 2 minutes*

The neurological assessment cannot be overlooked because changes in HR and rhythm, a decrease in cardiac output, and side effects of cardiac medications may cause significant changes in mental status. The nurse can observe and assess the patient's mood, thought processes, thought content, abnormal perceptions, insight, judgment, memory, and retention throughout the examination from intake of history and throughout treatment. Because depression is common among both the older adult and the chronically ill, signs of depression should be assessed (Cené et al., 2012; Rustad et al., 2013). Examples of signs of depression include feelings of hopelessness and sadness (also see Chapter 19, Late-Life Depression). The time, the day, and the year, as well as orientation to place, should be included. Memory of hospitalization, teaching that occurred while hospitalized, and subsequent events post discharge can be addressed depending on whether the patient is hospitalized or is being seen as an outpatient (Clark et al., 2014; Grady et al., 2000).

To summarize, the physical examination findings consistent with HF include the following:

- JVD
- Basilar crackles, bronchospasm, and wheezing
- Displaced apical impulse
- Presence of S3 or S4; heart murmur
- Elevated HR and BP
- Hepatomegaly/splenomegaly
- Hepatojugular reflux
- Elevated HR and BP
- Temperature of extremities, warm versus cool

Laboratory and Diagnostic Studies

The initial laboratory evaluation of patients presenting with symptoms of HF should include complete blood count; serum electrolytes, including calcium and magnesium; blood urea nitrogen (BUN); serum creatinine; fasting blood glucose; glycosylated hemoglobin A1c (HbA1c); lipid profile; liver function tests; thyroid-stimulating hormone; and urinalysis.

B-type natriuretic peptide (BNP) is useful in the evaluation of symptomatic patients presenting in the urgent care setting in whom the clinical diagnosis of HF is uncertain (Yancy et al., 2017). A baseline BNP in the patient with a confirmed diagnosis of HF in the compensated state can provide a comparison measurement when the presence of fluid overload is suspected. A BNP level below 100 indicates a very low probability of HFrEF; however, a symptomatic patient may have diastolic HF or HFpEF. A level between 100 and 400 pg/mL should begin to raise suspicion of either HFrEf or HFpEF or right ventricular systolic dysfunction. Levels greater than 400 pg/mL have a 95% probability of HF and congestion caused by volume overload. Admission BNP values for acute HF decompensation with BNP levels 1,730 pg/mL or greater were associated with a 2.23-fold increase in in-hospital mortality compared with BNP levels under 430 pg/mL (Balion et al., 2013; Fonarow, Peacock, Phillips, Givertz, & Lopatin, 2007; Hunt et al., 2005; Yancy et al., 2017).

Electrolyte abnormalities are common in the older adult, particularly in individuals on chronic diuretic therapy. The serum potassium level should be monitored and supplemented so that it does not drop below 3.8 mmol/L. Renal function, as well as electrolyte levels, should remain current and test repeated whenever a patient has to increase diuretic therapy for longer than 3 days because of fluid overload. Anemia is frequently observed, especially in renal insufficiency and poor nutritional status and may contribute to hypoxia, myocardial ischemia, and fluid overload.

The index episode or first acute HF is most often ischemic in etiology. Cardiac enzymes assist in determining the presence of acute MI when an acute fluid overload event occurs (Manemann et al., 2016; Mirkin et al., 2017). Older adults may have an MI in the total absence of symptoms or with atypical symptoms. It is also

important to know that patients who are congested may leak troponin at low levels and not be acutely ischemic. All of these factors make a review of diagnostic test results very important.

A 12-lead electrocardiogram (EKG) and chest x-ray (posterioranterior [PA] and lateral) should be performed initially in all patients presenting with symptoms of HF. A baseline EKG is vital so that ST and T waves; axis changes; and prolongation in PR, QRS, and QT intervals can be assessed for indication of ongoing ischemia and response to medications. A new-onset arrhythmia heralded by an episode of fluid overload is not uncommon. The excess volume in HF can cause a stretch of the atrium, which, in turn, can precipitate atrial fibrillation, a common arrhythmia in patients with chronic HF. Two-dimensional echocardiography with Doppler should be performed during the initial evaluation to assess LVEF, LV size, wall thickness, and valve function. Radionucleotide ventriculography (multigated acquisition [MUGA] scan) can be performed to assess ventricular volumes, LVEF, and myocardial perfusion abnormalities although the current advanced technology of echocardiography makes the radionucleotide method of MUGA unnecessary. Cardiac catheterization should be performed on patients presenting with symptoms of HF who have angina or significant ischemia or who have known, suspected, or are at high risk for CHD, unless the patient is not eligible for revascularization of any kind.

Holter monitoring may be considered in patients presenting with HF who have a history of MI and/or syncope and are being considered for an electrophysiology study to document an inducible ventricular tachycardia. In addition, other candidates for electrophysiology referral include those with an LVEF of 30% or less with a QRS complex duration that exceeds 130 msec. Patients who meet this criteria should receive a biventricular pacemaker in combination with an automatic implantable defibrillator in order to prevent sudden death from ventricular arrhythmia and delay disease progression through ventricular remodeling, as well as improve cardiac output (Bardy et al., 2005; Breithardt, 2009).

INTERVENTIONS AND CARE STRATEGIES

Initial goals in the acute management of HF are to alleviate symptoms and improve oxygenation, improve circulation, and correct the underlying causes of the HF. Longer-term goals are to improve exercise tolerance and functional capacity, and through treatment improve ventricular function. Guideline-directed medical therapies (GDMT) are evidence-based therapies (EBT) that demonstrate reductions in the morbidity and mortality in HF and, as such, are recommended in the guidelines for managing HF. Effective treatment with EBT can also assist in reducing admission and readmission rates. The management of HF follows standard ACC/AHA Task Force expert consensus recommendations, including intensive treatment of coexistent HTN, CHD, and renal disease (Miller, 2017). It is important to note that optimal treatment of HTN is critical to both the prevention and treatment of HF. Although the level at which medication should be started is often still debated, the treatment goal in HTN for those older than 60 years, according to the Eighth Joint National Committee (JNC-8), is 150/90 mmHg (Baruch et al., 2004; James et al., 2014). There is compelling evidence for patients with coronary disease to continue to treat to the lower targets recommended in the previous commission, JNC-7 (Bangalore, Gong, Cooper-DeHoff, Pepine, & Messerli, 2014; Dinicolantonio et al., 2013).

Key prognostic indicators of 4-year mortality for older adults diagnosed with HF include renal dysfunction, pulmonary disease, a BMI of less than 25 kg/m^2, diabetes, HTN, and cancer. Patients who continue to smoke have a greater risk of mortality. Those individuals with a functional deficit in ADL, such as difficulty bathing, managing finances, walking several blocks, or pushing or pulling heavy objects, combined with one or more of the earlier mentioned factors are at greater risk not only for mortality but, additionally, the need for hospitalization (Collamati et al., 2016; Saitoh, Ebner, von Haehling, Anker, & Springer, 2018; Springer, Springer, & Anker, 2017). A chart review and history during hospitalization should include the standard accepted cardiac risk factors and the key indicators as listed previously. Detecting these additional prognostic indicators can aid in developing interventions that can affect quality of life and survival. Goals for therapy should include reaching goals for fasting blood sugar and HbA1c, BP, cholesterol, and HF therapy through the use of evidence-based standards of care.

In *stage A*, HF, HTN, and lipid disorders are treated with lifestyle modification and medication as indicated to achieve guideline-recommended goals for BP and cholesterol. Smoking-cessation assistance, in the form of counseling and medication, is offered at every interaction with a patient who smokes. A goal of increasing activity or exercise should be mutually established with patients. For some, this may be as little as standing and sitting during television commercials, whereas for others, it may mean a walk before or after dinner. The control of metabolic syndrome is achieved through lifestyle modification. Alcohol is a simple sugar, and in excess it contributes to the development of insulin resistance and diabetes, increasing

cardiovascular risk. Illicit drug use must be identified, with treatment offered and encouraged. Both ACEIs and angiotensin-receptor blockers (ARBs; A. Shah et al., 2017) treat HTN and HFrEF, but it is important to note that they have been shown to prevent cardiovascular events, cerebrovascular events, and progression of renal disease in stage A. Their use is especially important in patients with vascular disease or in those with DM.

In *stage B*, these same cited measures are used with ACEIs, ARBs, and beta-blockers in certain patients. All ACEIs are indicated in HFrEF; however, there are only two ARBs with evidence strong enough to be GDMT in HFrEF. Valsartan and candesartan, both ARBs, obtained recognition for benefit in HFrEF in their respective studies (Cohn, 1999; Cohn & Tognoni, 2001; Ostergren, 2006; Packer, 1998; Packer, Bristow, et al., 1996; Packer, Colucci, et al., 1996; R. V. Shah, Desai, & Givertz, 2010).

In *stage C*, dietary sodium restriction is added to this regimen, and at a symptomatic stage, diuretics need to be added to treat the fluid retention that causes symptoms, along with ACEIs or ARBs and beta-blockers. Carvedilol and metoprolol, in the extended-release form of metoprolol succinate, are the two drugs in the beta-blocker category that are evidence based and guideline recommended in the treatment of HFrEF (Colucci et al., 1996, 2007; Goldstein & Hjalmarson, 1999; Hjalmarson & Fagerberg, 2000; Hjalmarson et al., 2000). Aldosterone antagonists are also GDMT in HFrEF, with some evidence of benefit in HFpEF as well. In certain patients, digitalis can also be effective (Ambrosy et al., 2014; Baruch et al., 2004; Gheorghiade, van Veldhuisen, & Colucci, 2006; Nagarajan, Chamsi-Pasha, & Tang, 2012). Hydralazine in combination with isordil or other nitrates is beneficial and GDMT in the African American population (Yancy & Feldman, 2009). Many of the *stage C* patients qualify for a biventricular pacemaker and/or implantable defibrillators to treat life-threatening arrhythmias.

In *stage D*, patients younger than 70 years without significant comorbidities may be offered advanced therapy options, such as cardiac transplant or LV assist device (LVAD; ventricular assist device [VAD]). A trial of inotropic therapy, such as milrinone or dobutamine, may serve as a temporary boost to end-stage patients but also may be treatment as palliative therapy, offering patients at end of life an improved quality and ability to be with their family. Palliative care offers the end-stage patient comfort that affords the patient a quality of life in an environment where the patient can be at ease rather than enduring the frequent and recurrent hospital visits on an emergent basis. Although the LVAD first was designed as a bridge to transplant, VADs are now offered as a bridge to decision about transplant. Additionally, the LVAD as destination therapy is a palliative measure, again offering the patients a quality of life their heart is unable to give. Hospice care is also offered to the end-stage HF patient who is not a candidate for any further therapy. The nurse has an important role in assisting the individual and his or her caregivers in understanding the disease process and treatment options, including end-of-life care (Chmielinski & Koons, 2017; O'Connor, Moyer, & Kirkpatrick, 2016).

Open and honest discussion regarding the chronic, progressive nature of HF must begin early in the disease process as the natural history of HF involves declining physical as well as psychological functioning. Although depression is commonly seen in the older adult, as well as individuals with CVD, there are few studies that have addressed this important problem (Mbakwem, Aina, & Amadi, 2016). One in five patients with HF have depression, and among these adults, 48% will have significant depression with a higher prevalence compared with the general population (Celano, Villegas, Albanese, Gaggin, & Huffman, 2018; Mbakwem et al., 2016; Rutledge, Reis, Linke, Greenberg, & Mills, 2006). Because pharmacotherapy and behavioral interventions have demonstrated effectiveness, all older individuals should be screened for depression and treated appropriately. Early discussions related to the goals of care and advance directives with frequent revisiting of patient understanding of the disease course and patient preferences as the illness progresses ensure patient and care partner participation in decision-making. A multidisciplinary team, including a spiritual and/or a psychological representative, should be developed to offer support for all involved: the patient, family, and all caregivers.

The benefits of the multidisciplinary team providing care to HF patients have been discussed for the past several years. In most cases, this has been related to the use of the team approach to help keep patients stable in order to prevent hospital readmissions (Naylor, 2006; Naylor & Keating, 2008; Naylor et al., 2004). Comprehensive multidisciplinary transitional care interventions have been shown not only to reduce costs and cardiac outcomes, but also to have a beneficial effect on hospitalization for comorbid conditions (Chan, Lin, & Wong, 2016; Chriss, Sheposh, Carlson, & Riegel, 2004; Coviello, Hricz-Borges, & Masulli, 2002; Riegel et al., 2004). A scientific statement made by the AHA on recommendations to improve the effectiveness of transitional care interventions for HF included routine assessment of high-risk characteristics associated with poor postdischarge outcomes, assessment of nurse knowledge, and comfort in delivering patient education and using health informatics to assist with program

sustainability (Albert et al., 2015). In the case of the patient in end-stage HF, a multidisciplinary team—either for inpatient or outpatient management—can provide cost-effective service for patients with care in the environment of choice (Grady et al., 2000; Naylor & Keating, 2008; Riegel et al., 2016).

Once the initial history and physical assessment have been completed, an individualized care plan to monitor and treat fluid overload should be implemented. The care plan should include teaching that begins early in the hospital stay while the patient's memory of a decompensated state is fresh. The teaching of principles of HF self-care relies on the patient's ability to learn to recognize the beginnings of decompensation. It is crucial to begin techniques to prevent a congested state and manage self-care to maintain euvolemia as early as possible, with increased caution given to depressed patients to apply self-management strategies (Jonkman et al., 2016). A 3-pound weight gain in 1 to 2 days or a 5-pound weight gain in the course of the week is a reason to alter diuretic dosage for up to 3 days. If the patient returns to baseline weight before the 3-day period, he or she may reduce the dose back to the standard daily dose (Grady et al., 2000; Riegel et al., 2009; Toukhsati, Driscoll, & Hare, 2015). Patients can be taught how to regulate their diuretic doses based on their symptoms and weight. The nurse and the patient can construct a self-care algorithm that gives them a sound "recipe" to follow if fluid overload occurs. The important factor here is early recognition and swift, brief action. Clear guidelines as to when to contact caregivers, if they are not living with the patient, should also be provided. Consideration should be given to the patient's baseline functional capacity, as well as renal function. Diuretics are used in both systolic and diastolic HF to relieve congestive symptoms by promoting the excretion of sodium and water and by decreasing cardiac filling pressures, thereby decreasing preload. They should be used effectively but cautiously in the older adult with diastolic dysfunction, when maintaining an adequate cardiac output is required in order to avoid syncope, falls, or confusion.

A doubled dose of oral diuretics for up to 3 days is usually well tolerated in congested patients with systolic or diastolic HF. When diuretics are used, serum potassium levels should be monitored because of an increased risk of hypokalemia with loop diuretics and of hyperkalemia with potassium-sparing agents, especially if renal impairment exists. Patients should be forewarned about signs of hypokalemia such as profound weakness. Loop diuretics may be useful for patients who are volume sensitive or who have a tendency to retain fluid because of renal impairment. Aldosterone antagonists are potassium-sparing diuretics, which abate some degree of hypokalemia seen with loop diuretics; however, serum potassium levels should be monitored. In some patients, ACEIs can cause hyperkalemia; in combination with aldosterone inhibitors, this may be exacerbated. Recent evidence suggests that many individuals, particularly African Americans, may still require potassium supplementation (Chen et al., 2017; Gonseth, Guallar-Castillón, Banegas, & Rodríguez-Artalejo, 2004; Suh et al., 2004). In addition, dehydration is an important problem in older adults taking diuretics and appears to be an even greater concern in African Americans (Lancaster, Smiciklas-Wright, Heller, Ahern, & Jensen, 2003), making assessment of hydration status an important nursing concern.

Use of diuretic agents increases the risk of sudden loss of urinary control (urinary incontinence) in older adults. This is a very common, potentially reversible geriatric syndrome (see Chapter 25 Urinary Incontinence in the Older Adult). The older adult population requires frequent monitoring and detection of symptoms related to the onset of urinary incontinence, which is often signaled by symptoms of urinary frequency, urgency, or nocturia. These symptoms may actually be present in the older adult from other coexisting comorbidities. Nocturia is particularly evident in patients with heart disease because the supine position increases vascular return and precipitates frequent rising at night to urinate. Nighttime falls in the older adult often occur when the patient wakes to advance to the bathroom. Preexisting comorbidities, such as visual impairment or osteoarthritis of the hip and/or knees, as well as prostate hypertrophy in men, make safety strategies a priority in urgent bathroom requirements. Overall, management considerations for the older adult with heart disease and a new development of urinary incontinence or falls include reevaluation of medication regimen, activity considerations, and the use of additional adaptive aids to assist in avoidance of preventable events. Use of a nighttime bedpan, urinal, or commode with frequent toileting rounds and reduction of nighttime fluids are all possible and worthwhile solutions. Furosemide, as the most commonly used diuretic, has a half-life of 6 hours. In patients who are at a falling risk, timing the completion of diuresis before bedtime can decrease nocturia.

Beta-blockers are useful in the management of diastolic HF because of their inhibition of the SNS and resultant negative chronotropic effect, which decreases HR and increases time for diastolic filling. Beta-blockers are beneficial in the treatment of systolic HFrEF and are initiated in a euvolemic state after symptoms have resolved (Cohn, 1999; Colucci et al., 1996, 2007; Goldstein & Hjalmarson, 1999; Hjalmarson & Fagerberg, 2000; Ostergren, 2006; Packer, 1998; Packer, Bristow, et al., 1996; Packer,

Colucci, et al., 1996; A. Shah et al., 2017; R. V. Shah et al., 2010). These agents should be initiated at low doses and titrated up to an optimal tolerated dose. Use of beta-blockers in combination with ACEIs has demonstrated an improvement in both LVEF and functional capacity once optimized. Although beta-blockers may potentially worsen insulin resistance, mask hypoglycemia, or aggravate orthostatic hypotension in older individuals with DM, these agents have been shown to contribute to improved outcomes. Therefore, careful monitoring for adverse effects is required with beta-blocker treatment to realize the beneficial effects of this important medication.

Digoxin increases contractility and decreases HR. It is not routinely indicated; however, it may be useful in those patients with persistent symptoms despite diuretic and ACEI therapy and in those patients who also have atrial fibrillation. Blood levels of digoxin should be monitored for toxicity and interactions with other medications such as amiodarone, verapamil, and vasodilators. Quinidine is no longer indicated or used therapeutically. It is extremely important to monitor the narrow therapeutic range for potassium in order to prevent hypokalemia, which can precipitate arrhythmias in older adult patients with HF who are predisposed to both atrial and ventricular arrhythmias. Other medications that have a positive inotropic effect are dopamine and dobutamine. Both of these drugs can improve contractility and subsequent cardiac output; however, they also increase myocardial oxygen demand. *Milrinone* is a phosphodiesterase inhibitor that has been shown to be beneficial in the management of the hospitalized patient with HF, providing a positive inotropic effect, as well as a vasodilation (see Chapter 24, Reducing Adverse Drug Events in the Older Adult, for potential sequelae to several CV medications).

Vasodilators are also useful in the treatment of systolic and diastolic failure through reduction in preload. As with diuretics, they should be used cautiously in those with diastolic HF. Hydralazine and isosorbide reduce both preload and afterload, relieving symptoms and improving exercise tolerance. This combination is commonly used when patients do not tolerate ACE therapy. African Americans, in particular, had reduction in morbidity and mortality with a hydralazine/nitrate combination (Yancy & Feldman, 2009). Morphine sulfate, often used in an emergent situation, also has a peripheral vasodilating effect and is useful with pulmonary edema or in patients with breathlessness at end of life.

With appropriate titration of these medications, an improvement in both LV function and functional capacity can be achieved. Medications to treat HTN and lipid abnormalities may not be well tolerated, and the potential for side effects and drug interactions is increased in the setting of polypharmacy. An antihypertensive agent should be used in the lowest dose to bring about the desired goal for BP treatment. Lipid-lowering agents should be offered as they were found to be effective in studies; however, patients may not be able to tolerate high doses. Use the highest dose that the patient can tolerate to achieve cholesterol lowering.

Patients and caregivers need to understand the warning signs of HF decompensation and recurrent MI such as chest pain, pressure, shortness of breath, indigestion, nausea, dizziness, palpitations, confusion, weakness, and weight gain. A clear plan for obtaining immediate medical attention should be developed. This is especially important if the older person lives alone; some type of "medical alert" system may be needed. Telemonitoring may be an option for some patients to consider. Understanding and ability to follow the medication regimen is paramount. A thorough assessment of the patient and his or her caregivers is therefore vital. The older individual may be on multiple medications, and the schedule may be confusing. The need to maintain cardiac medications must be stressed, and the risk of the patient abruptly discontinuing beta-blocker, nitrates, and antiarrhythmics must be assessed. All medications should be reviewed with the patient and caregivers, stressing desired effects, common side effects, and possible interactions with over-the-counter medications. The nurse should also review what to do if medications are accidentally omitted or become too costly to maintain.

Long-term management of HF requires a multidisciplinary team approach, and disease management programs have been effective in reducing readmission rates (Riegel et al., 2016). Furthermore, even though many of these individuals are debilitated, exercise training has been shown to improve muscle mass, strength, and functional ability (Collamati et al., 2016; Saitoh et al., 2018; Springer et al., 2017). Referral to inpatient cardiac rehabilitation is an important stepping stone to reconditioning patients so they can better function at home when discharged.

Optimization of the medication for HF, coupled with activity progression, can enhance the patient's capacity for ADL and quality of life. An active patient may notice early signs of fluid overload when unable to accomplish standard activities done the previous week. Therefore, questions related to activity tolerance can provide insight for the nurse who monitors the patient. The patient with gradual fluid gain will first notice a change in his or her level of fatigue, which will translate into a change in daily routine. Previous experience with fluid overload will also reveal to the nurse the patient's own unique signs and symptoms because not every patient has the same indicators. It is important to not only assess these factors directly

with the patient during the interview but to also reinforce that these symptoms are important for the patient to monitor as well (Grady et al., 2000; Riegel et al., 2009). In addition to changes in weight, deviation from the baseline functional ability is an early clue, even before peripheral edema or lung congestion is present.

The prevention and treatment of HF in patients with DM requires optimal management of coexistent HTN, CHD, and LV dysfunction. Additionally, control of hyperglycemia is an important issue because the presence of HF affects the choice of medications used to treat type 2 DM. Although insulin and insulin secretagogues are considered safe for use in individuals with HF, TZDs are contraindicated, and metformin should be used only cautiously with careful monitoring of renal function (Tousoulis et al., 2014). Decreased clearance of metformin in individuals with HF caused by hypoperfusion or renal insufficiency can lead to potentially dangerous lactic acidosis. TZDs are associated with fluid retention, pedal edema, and weight gain, particularly when used in conjunction with insulin, and contribute to HF (Rosano, Vitale, & Seferovic, 2017). Careful clinical assessment and ongoing monitoring should be implemented in the presence of known structural heart disease or a prior history of HF.

Adequate control of BP is also essential in the management of HF. Treatment of older persons with HTN has been shown to reduce CVD morbidity and mortality (Ahmad et al., 2016; James et al., 2014). An important nursing consideration is to monitor for adverse effects of medications used to manage HF, as well as HTN, along with patient and caregiver education. ACEIs are important in the management of systolic HF and may also be helpful in diastolic failure. In the Heart Outcomes Prevention Evaluation Study (Wing et al., 2003), ACEIs prevented cardiac events in high-risk patients without HF or known low EFs (Collamati et al., 2016). In addition, ACEIs have a renal protective benefit that is extremely important in preventing the development or worsening of HF, especially in patients with DM. Recent evidence suggests that use of ACEIs is associated with a larger lower extremity muscle mass, which may have benefit in wasting syndromes (e.g., sarcopenia) and prevention of disability and that they are particularly efficacious in older adults. ARBs are also used widely for the prevention and treatment of HFrEF, particularly when patients are unable to use ACEIs because of the development of cough (James et al., 2014; A. Shah et al., 2017; Yancy et al., 2017, 2018). Renal function and hyperkalemia should be assessed when using both classes of agents, especially in the presence of underlying renal dysfunction.

CASE STUDY 36.1

CTG is a 72-year-old woman with a history of diet-controlled glucose intolerance and HFrEF of 38% with normal renal function. She is seen in the geriatric clinic with a 3-day history of poor appetite, nausea, and occasional vomiting. She complains of a constant feeling of fullness. She was last hospitalized 3 months ago because of fluid overload related to newly diagnosed HF. Her diuretic was increased 6 weeks ago for mild ankle swelling. She denies recent lower extremity swelling, orthopnea, or paroxysmal nocturnal dyspnea. Her blood sugars have been well controlled in the 90-to-130 range without hypoglycemic episodes. She denies fever, chills, cough, or urinary symptoms. She says she never misses her medications. Until 5 days ago, she was able to walk 30 minutes a day without difficulty. She has noticed a gradual increase in fatigue over the last 10 days and has found herself too tired to attend several social and church events in the evening. When asked what her daily weights have been, she confessed that since she had been feeling so good she had abandoned this as a daily practice. Concerned, however, about her recent symptoms, she weighed herself this morning and found that she had gained 6 pounds since she last weighed herself 2 weeks ago despite being compliant with her medications for HF, which include the following:

Coreg 6.25 mg twice a day
Altace 5 mg daily
Aldactone 12.5 mg daily
Lasix 20 mg daily
Imdur 15 mg daily

She has not taken a double dose of Lasix with the additional weight gain, as shown in her self-care action plan. She had been unaware of that weight gain because she had not been weighing herself. In addition, she had attended two social events two weekends ago that included eating out. Her self-care action plan had shown that she should increase her diuretic for 1 day following eating out the day before.

On physical examination, her BP is 132/86 mmHg with an HR of 88 beats/min. She is afebrile. She has fine crackles in the lower bases bilaterally. There is 1+ lower extremity edema. Heart sounds demonstrate S1, S2, and S3. Her apical impulse is displaced to the left. There is jugular neck vein distention. Her abdominal girth has increased 2 inches since her last visit.

(*continued*)

CASE STUDY 36.1 (*continued*)

Lasix was increased to 40 mg for a maximum of 3 days. If at any point during the 3 days her weight returned to baseline, she was instructed to return to her usual dose of Lasix. She was advised of the importance of daily weights in order to maintain her baseline weight. She was referred back to her self-care action plan for changes in diuretic, depending on her daily weight and the maintenance of her low-sodium diet in light of her social schedule. She will return to the clinic in 1 week.

Discussion

This patient exemplifies the need for educational reinforcement in a newly diagnosed patient with HF, who is just learning how to incorporate a self-care action plan. Like many patients who have had to take antibiotics in the past, compliance can wane when the patient feels well. Assessment of self-care knowledge and ability should be ongoing throughout the hospital stay but is critical at the time of discharge in order to provide appropriate focus in outpatient care and support.

The use of a tool to quantify knowledge and ability of self-care, such as the Self-Care in Heart Failure Index, is useful to identify patients who have a continued need for assistance after discharge (Riegel et al., 2009). It is important to make contact with a newly diagnosed patient with HF fairly frequently in order to address questions that might influence the self-care decision-making of the patient.

SUMMARY

Hospital admissions can be reduced in older adults with HF:

1. When care is taken in identifying the patients' own unique signs and symptoms of fluid overload
2. By creating monitoring parameters for the nurse in the form of history and physical assessment
3. By creating monitoring parameters for the patient in the form of a self-care algorithm with clear guidelines for self-care action
4. By achieving goals for clinical stability

NURSING STANDARD OF PRACTICE

Protocol 36.1: Heart Failure: Early Recognition and Treatment of the Patient at Risk of Hospital Readmission

I. GOAL

To reduce the incidence of hospital readmission of older adult patients with HF

II. OVERVIEW

A. HF is the most common cause of hospitalization of adults older than 65 years (Schocken et al., 2008) and is the cause of functional impairment and ultimate morbidity and mortality as well as significant hospital costs (Messerli et al., 2017).
B. Hospitalization can be prevented by identifying the high-risk HF patient, early recognition of signs and symptoms of decompensation, and timely initiation or regulation of medical therapy (Evangelista et al., 2000; Jurgens et al., 2009; Sethares et al., 2015).
C. Recognition of risk factors and routine monitoring for potential HF decompensation should be part of the comprehensive nursing care of older adults (Ahmad et al., 2016; Bui et al., 2011; Messerli et al., 2017).

(*continued*)

Protocol 36.1: Heart Failure: Early Recognition and Treatment of the Patient at Risk of Hospital Readmission (*continued*)

III. BACKGROUND AND STATEMENT OF PROBLEM

A. Definition

HF is the inability of the heart to pump blood sufficient to meet the metabolic needs of the body or it cannot do so without significantly elevated filling pressures (Miller & Piña, 2009). Acute HF can develop swiftly or over the preceding weeks as the primary initial event. Acute decompensated HF is the result of chronic HF (Harjola et al., 2017).

B. Etiology and epidemiology

1. *Prevalence and incidence:* There are more than 5.8 million individuals with HF in the United States, and approximately half a million new cases develop every year ("Heart Failure Fact Sheet|Data & Statistics|DHDSP|CDC," 2019).
2. *Etiology:* Deficiency in myocardial pump function as a result of nonischemic progressive cardiomyopathy or more prevalent ischemic causes, such as coronary heart disease and MI with a resulting development of signs and symptoms, such as edema, dyspnea, and orthopnea (Harjola et al., 2017; Kemp & Conte, 2012).
3. *Risk factors*
   a. *Predisposing* age (65 years and older); severity of illness; comorbidities, such as HTN, coronary artery disease, diabetes, valvular heart disease, and obesity. Additionally, cognitive impairment, depression, sensory impairment, fluid and electrolyte disturbances, and polypharmacy also impose an increased risk (Ahmad et al., 2016; Bell & Goncalves, 2019; Bui et al., 2011; Lastra et al., 2014; Messerli et al., 2017)
   b. *Precipitating:* High-sodium diet; excess fluid intake; sleep-disordered breathing; chronic kidney disease; anemia; cardiotoxins, such as chemotherapeutic agents, NSAIDs, illicit drugs, or alcohol (Schocken et al., 2008)
   c. *Environmental factors:* Low socioeconomic status, psychological stress, and inadequate social support (Schocken et al., 2008)
4. *Outcomes:* HF has a downward trajectory that through preventative measures can be delayed; however, not without considerable impact on quality of life (Grady et al., 2000).

IV. PARAMETERS OF ASSESSMENT

A. Assess at initial encounter and every shift

1. *Baseline:* Health history NYHA classification of functional status and stage of HF, cognitive and psychosocial support systems (Miller, 2017; Tuy & Than, 2013)
2. *Symptoms:* Dyspnea, orthopnea, cough, edema; vital signs: BP, HR, and RR (Pickering et al., 2005); physical assessment with signs: rales or "crackles"; peripheral edema, ascites, or pulmonary vascular congestion of chest x-ray (Stevenson & Perloff, 1989)
3. *Medications review:* Optimal medical regimen according to ACC/AHA/HFSA guideline unless contraindicated (Riegel et al., 2009; Wing et al., 2003)
4. *Electrocardiogram/telemetry review:* HR, rhythm, QRS duration, QT interval (Bertoni et al., 2004; Chyun et al., 2002)
5. Review echocardiography, cardiac angiogram, MUGA scan, cardiac CT or MRI for left ventricle and valve function: LVEF (Bertoni et al., 2004; Chyun et al., 2002; Lewis et al., 2003)
6. Laboratory value review (Yancy et al., 2018)

   Metabolic evaluation: Electrolytes (hyponatremia, hypokalemia), thyroid function, liver function, kidney function

   Hematology: Evaluation for anemia: Hemoglobin, hematocrit, iron, iron-binding capacity, and B12 folic acid

Evaluation for infection (fever, WBCs with differential, cultures)

7. *Impaired mobility/deconditioned status:* Physical therapy or structured cardiac rehabilitation inpatient or outpatient

(*continued*)

Protocol 36.1: Heart Failure: Early Recognition and Treatment of the Patient at Risk of Hospital Readmission (*continued*)

B. Sensory impairment—vision, hearing—limitations in ability for self-care (Ferdinand et al., 2017; Jonkman et al., 2016)
C. Signs and symptoms—assess for changes in mental status every shift (Ferdinand et al., 2017; Jonkman et al., 2016)

V. NURSING CARE STRATEGIES

A. Obtain HF/cardiology and geriatric consultation (Naylor, 2006; Naylor et al., 2004; Naylor & Keating, 2008; Rich & Kitzman, 2005).
B. Eliminate or minimize risk factors.
   1. Administer medications according to guidelines and patient assessment (Brenner et al., 2001; Riegel et al., 2009; Wing et al., 2003).
   2. Avoid continuous intravenous infusion, especially of saline (Lancaster et al., 2003; Riegel et al., 2009).
   3. Maintain euvolemia once fluid overload is treated. Prevent/promptly treat fluid overload, dehydration, and electrolyte disturbances. Maximize oxygen delivery supplemental oxygen, blood, and BP support as needed (Lancaster et al., 2003; Riegel et al., 2009).
   4. Ensure daily weights accurately charted (Grady et al., 2000; Riegel et al., 2004, 2009).
   5. Provide adequate nutrition with a 2-g/d sodium diet (see Chapter 13, Nutrition in the Older Adult).
   6. Provide adequate pain control (see Chapter 22, Pain Management in the Older Adult).
   7. Use sensory aids as appropriate.
   8. Regulate bowel/bladder function.
C. Provide self-care education with maintenance and management strategies (Ferdinand et al., 2017; Jonkman et al., 2016; Naylor, 2006; Pickering et al., 2005).
   1. Encourage activity recommendation as appropriate to functional status. Assess for safety in ambulation hourly rounds with encouragement to toilet.
   2. Facilitate rest with schedule of diuretic medications for limited nocturia.
   3. Maximize mobility: involve occupational therapy and physical therapy and limit use of urinary catheters.
   4. Communicate clearly; provide explanations.
   5. Emphasize purpose and importance of daily weights.
   6. Arrange dietician referral for educational needs regarding sodium.
D. Identify primary care partner. Reassure and educate.
   1. Foster care support of family/friends.
   2. Assess willingness and ability of care partner to assist with self-care: Dietary needs of sodium restriction, daily weight logging, symptom recognition, and medical follow-up.

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient
   1. Absence of symptoms of congestion
   2. Hemodynamic status remains stable
   3. Functional status returned to baseline (before acute decompensation)
   4. Improved adherence to medical and self-care regimen
   5. Discharged to same destination as prehospitalization
B. Healthcare provider
   1. Regular use of self-care HF index screening tool
   2. Increased detection of symptoms of acute decompensation
   3. Implementation of appropriate interventions to prevent/treat volume overload
   4. Improved nurse awareness of patient/caregiver self-care confidence and ability
   5. Increased management using guideline-directed therapy

(*continued*)

Protocol 36.1: Heart Failure: Early Recognition and Treatment of the Patient at Risk of Hospital Readmission (*continued*)

C. Institution
   1. Staff education and interprofessional care planning
   2. Implementation of HF specific treatments
   3. Decreased overall cost
   4. Decreased preventable readmission and length of hospital stay
   5. Decreased morbidity and mortality
   6. Increased referrals and consultation to previously specified specialists
   7. Improved satisfaction of patients, families, and nursing staff

VII. FOLLOW-UP MONITORING OF CONDITION

A. Decreased frequency of readmission as a measure of quality care
B. Incidence of decompensated HF to decrease
C. Patient days with symptoms of congestion to decrease
D. Staff competence in prevention, recognition, and treatment of HF
E. Documentation of a variety of interventions for HF

ABBREVIATIONS

ACC/AHA/HFSA	American College of Cardiology/American Heart Association Task Force/Heart Failure Society of America
BP	Blood pressure
BUN/Cr	Blood urea nitrogen/creatinine ratio
HF	Heart failure
Hgb/Hct	Hemoglobin and hematocrit
HR	Heart rate
HTN	Hypertension

Cancer Assessment and Intervention Strategies in the Older Adult*

Janine Overcash

37

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Recognize the incidence and prevalence of U.S. statistics of malignancy in the older adult.
2. Identify three common malignancies in the older adult.
3. Recognize three common comorbidities in the older adult with cancer.
4. Identify three common cancer-related emergencies in the older adult.
5. Identify three assessment instruments useful in the assessment of the older person.
6. Identify three important elements of a health history specific to the older cancer patient.
7. Identify three important elements of a physical examination specific to the older cancer patient.
8. Define clinical parameters of frailty of an older adult with cancer.

OVERVIEW

The probability of developing a malignancy increases with age. In the years between 2012 and 2016, the National Cancer Institute Surveillance, Epidemiology, and End Results Program (SEER, 2014) found that the mean age of a cancer diagnosis is 66 years (Howlader et al., 2018). Cancer of any site is most often diagnosed among people aged 65 to 74 years (Howlader et al., 2018). Rates of cardiovascular and heart disease have declined since 2011; however, the rates of cancer mortality have remained stable (Sidney et al., 2016). Based on data from the years 2011 to 2016, 39% of men and women living in the United States will be diagnosed with cancer (Howlader et al., 2018).

Older people diagnosed with cancer are often resilient; however, problems associated with comorbid conditions and poor general health status can result in less aggressive cancer treatment options (Inwald, Kowalski, Wesselmann, Ferencz, & Ortmann, 2019; Williams et al., 2015). Treatment decisions of older cancer patients depend on life expectancy, comorbidity, and health status and not on chronological age (Bhatt, 2019; Droz, Boyle, Albrand, Mottet, & Puts, 2017; Hurria, 2013; K. H. Kim et al., 2019). Many older people tolerate chemotherapy as compared with younger people, depending on their level of fitness and general health status (K. W. Lee et al., 2017; Sastre, Puente, García-Saenz, & Díaz-Rubio, 2008). The same is true for surgery (S. H. Kim et al., 2018; Volkel et al., 2019; Wildiers et al., 2007) and radiation therapy (Gomez-Millan, 2009).

Acute care nurses must appreciate that cancer is common in older adult patients and be aware of management

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

strategies and potential emergencies associated with the diagnosis and treatment of a malignancy. This chapter presents aspects of health that should be considered when caring for a hospitalized older cancer patient. Geriatric assessment instruments that can be used in an acute care setting and potential medical emergencies associated with the cancer disease process are addressed.

ASSESSMENT OF THE OLDER HOSPITALIZED PATIENT

Comorbid Conditions

A diagnosis of cancer may be one of several diagnoses, and it is important to understand how the malignant and nonmalignant conditions affect the health of the older person. Often, nonmalignant conditions can present more risk of mortality as compared with a cancer diagnosis. Breast cancer patients undergoing treatment with chemotherapy or radiation are likely to die of nonmalignant diagnoses (Ording et al., 2015). In early-stage breast cancer, rates of non–cancer-related disease death in patients aged 80 years and over are higher compared with those in people aged 65 to 69 years (Sakurai et al., 2015). In patients with lung cancer, cardiovascular comorbidities have a considerable impact on survival (Kravchenko et al., 2015).

For every chronic comorbid condition, life expectancy decreases 1.8 years (DuGoff, Canudas-Romo, Buttorff, Leff, & Anderson, 2014). The timing of a nonmalignant diagnosis between 18 and 6 months before a diagnosis of colorectal cancer has been associated with lower 1-year survival (Shack, Rachet, Williams, Northover, & Coleman, 2010). The more severe the degree of comorbidity, the lower the probability of survival at 1 year and 5 years after a diagnosis of cancer (Iversen, Nørgaard, Jacobsen, Laurberg, & Sørensen, 2009). For patients who are diagnosed with diabetes, the risk of recurrence or development of a new breast cancer is twofold compared with that in the case of people who do not have diabetes (Patterson et al., 2010). Recognition, management, and severity of comorbid conditions are the principal aspects of the acute nursing assessment. Unmanaged or uncontrolled comorbid conditions have the potential to modify cancer treatment and outcomes. For patients who have managed comorbidity, nonmetastatic prostate cancer patients receiving treatment, 10-year life expectancy was not impacted by comorbid conditions or age (Boehm et al., 2017).

Comprehensive Geriatric Assessment

The Society for International Oncology in Geriatrics (SIOG) recommends a comprehensive geriatric assessment (CGA) be administered to older patients who are receiving cancer care (Mohile et al., 2015). The CGA has been used to identify people who may not benefit from cancer treatment (Lundqvist et al., 2018), risk of postoperative complications (Fukuse, Satoda, Hijiya, & Fujinaga, 2005; Kristjansson et al., 2010), and toxicity to cancer chemotherapy treatment (Aaldriks et al., 2011; Freyer et al., 2005; Hurria & Lichtman, 2007; Soto-Perez-de-Celis, Li, Yuan, Lau, & Hurria, 2018) and also provides information to avoid over- and undertreatment of cancer (Schiphorst et al., 2016). The CGA is also helpful in identifying older cancer patients who are most likely to benefit from more aggressive chemotherapy (Tucci et al., 2009) and from various surgical oncology procedures (Xue, Cheng, Wu, & Zhang, 2018). Postsurgical cognitive changes can be predicted using CGA (Liang et al., 2015).

CGA used in oncology has been found to influence cancer treatment decisions in terms of dosing and delaying treatments (Chaïbi et al., 2011; Schiphorst et al., 2016; Wildiers et al., 2014). Presurgical CGA can identify greater risk for mortality, postdischarge long-term care placement, inpatient adverse events, and increased length of hospital stay (K. I. Kim, Park, Koo, Han, & Kim, 2013).

The CGA can be a predictor of mortality (Avelino-Silva et al., 2014; Pilotto et al., 2007) and a 3-year predictor of survival (Stotter, Reed, Gray, Moore, & Robinson, 2015) in older patients. Impairment on various components of the CGA, such as nutrition, functional status, and cognition, is predictive of in-hospital mortality (Avelino-Silva et al., 2014). Older patients receiving acute care can benefit from the CGA by revealing health concerns and potential readmissions to an acute care setting (W. J. Lee, Chou, et al., 2014).

No single definition of a CGA exists. A CGA can be developed to include screening instruments necessary to meet the needs of a particular older patient population (American Geriatrics Society [AGS] and the British Geriatrics Society, 2010; Wildiers et al., 2014). The instruments that commonly make up the CGA and that guide screening practices in many healthcare domains are all found on www.consultgerirn.org and chapters in this text. Although a CGA may be relevant to primary care settings, understanding such issues as medication history and polypharmacy, caregiver situation, and emotional condition is also important to an acute assessment.

A CGA can include various laboratory tests in addition to self-report and performance evaluations. Laboratory data, such as C-reactive protein, are able to predict morbidity or mortality and help identify individual risk factors (Chundadze et al., 2010; Pal, Katheria, & Hurria, 2010). Serum 25-hydroxyvitamin D (25OHD) will assess vitamin D levels to determine whether falls or muscle

weakness can be a risk factor. People with lower concentrations of 25OHD have a high probability of falling (Annweiler & Beauchet, 2015). In patients with colorectal cancer, higher levels of 25OHD are related to better survival (Wesa et al., 2015). Serum albumin levels at 3.3 mg/dL on admission, serum creatinine levels at 1.3 mg/dL or higher, history of heart failure, immobility, and advanced age are all predictors of inpatient mortality (T. J. Silva, Jerussalmy, Farfel, Curiati, & Jacob-Filho, 2009). Other mortality risk factors in older hospitalized patients are red blood cell and platelet transfusions, which increase the opportunity for venous and arterial thrombotic events (Khorana et al., 2008).

Determining caregiver availability in the home following hospital discharge is another important element of the CGA. For many older cancer patients, lack of a caregiver can be a problem and can impact health and medical treatment. Breast cancer patients who live alone or are unmarried have an increased risk of mortality (Osborne, Ostir, Du, Peek, & Goodwin, 2005). Conversely, older cancer patients who are married tend to live longer than those who are not married (Franke & Kulu, 2018; Patel et al., 2010). In general, people who are married report higher perceived health status (Joutsenniemi et al., 2006). It is important for the nurse to determine whether the patient lives with someone and the extent to which that person is able to assist. Of note, often the patient is the caregiver to the spouse or others (Overcash, 2004), and it is important to discuss the caregiver situation before discharge.

Assessment of the older patient should occur on admission to the hospital and before discharge to understand trends in health, as well as in functional and behavioral ability. Discharge planning should include interventions based on the CGA findings, and communication is vital with outpatient providers to continue to address the limitations that may affect the health, quality of life, and independence of the older person with cancer.

DEVELOPING A COMPREHENSIVE GERIATRIC ASSESSMENT FOR HOSPITALIZED PATIENTS

The following are instruments that can identify functional, physical, emotional, and medication history and cognitive impairment in the acute care patient and are generally included in a CGA.

A. Assess for depression and/or emotional distress
    1. The Geriatric Depression Scale (Yesavage et al., 1982)
    2. The SF-12 Tool (Ware, Kosinski, & Keller, 1996): The SF-12 is a general health-related quality-of-life instrument that is widely used in research and clinical assessment. Two summary scores are the culmination of the measures from the mental health aspect and the physical health domain. The SF-12 is simple to administer and provides the clinician with a measure of emotional health and physical health.
B. Assessment for cognitive limitations. The Mini-Cog is used in the assessment of cognition (Borson, Scanlan, Brush, Vitaliano, & Dokmak, 2000; Borson, Scanlan, Chen, & Ganguli, 2003). The instrument comprises the Clock Draw test and recall. For more information on cognitive assessment, see Chapter 9, Assessing Cognitive Function in the Older Adult.
C. Assess the number and indications of medications. Look for medications with the same indications and potential harmful interactions, and consider any difficulty with cancer treatment agents. For more information on polypharmacy see Chapter 24, Reducing Adverse Drug Events in the Older Adult.
D. Assess for geriatric syndromes (such as depression, falls, urinary incontinence). For more information, see Chapter 19, Late-Life Depression; Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care; and Chapter 25, Urinary Incontinence in the Older Adult.
E. Assess functional status and potential for falls
    1. Ask the patient whether a fall had been experienced within the past year.
    2. The Physical Performance Test battery (Simmonds, 2002) has age-related norms and is a valid and reliable tool used with cancer patients.
    3. The 6-minute walk assesses the speed and ability to ambulate for the entire time (Enright et al., 2003).
    4. The Timed Get Up and Go test considers rising from a chair, walking 3 m, and returning to the chair in a sitting position (Podsiadlo & Richardson, 1991).
    5. Assessment of physical status can take place on observation of gait using the Gait Assessment Scale (Tinetti, 1986; Tinetti, Mendes de Leon, Doucette, & Baker, 1994).
    6. Berg Balance Scale (BBS) is a 14-item scale developed for use in a clinical setting (Berg, Wood-Dauphinee, Williams, & Maki, 1992). The BBS can be helpful in predicting falls and functional-status problems.
F. Assess the ability to perform self-care activities
    1. Activities of Daily Living Scale (Katz, Downs, Cash, & Grotz, 1970)
    2. Instrumental Activities of Daily Living Scale (Lawton & Brody, 1969)

Health History

The subjective information obtained from the older adult is a critical factor in the development of the plan of care. Respect and confidence are not only prudent, but also standard practice for the acute care nurse and can set the stage for a productive health-centered dialogue. The nurse should assess the reason(s) for seeking care (chief complaint) and include the family and support person(s). The following are issues that should be considered when conducting a health history of the older adult with cancer:

A. Assess history of present illness in regard to cancer diagnosis, cancer stage at diagnosis, current cancer stage, and cancer treatment (surgical, chemotherapy, radiation therapy, and hormonal therapy).
B. Assess past medical history as related to a diagnosis of cancer (include dates of diagnosis and treatments and regular oncological assessment continued).
C. Assess family medical history of malignancy and ages on diagnosis (some families have strong familial histories of malignancy, and perhaps younger generations should consider genetic counseling).
D. Assess regular cancer screening examinations.
E. Assess for common geriatric syndromes (issues, such as incontinence or falls, that have many predisposing factors).

Physical Examination

Conducting a physical examination of an older adult must incorporate an understanding of normative aging changes and knowledge of pathology. The physical examination is also an opportunity to teach about the importance of self-examination (breast and skin exams) and provide relevant health information. The physical exam is not only an empirical evaluation, but also an opportunity to determine current health status and trends over time.

Evaluation of functional status should be performed with the physical examination of the older patient. Understanding level of fitness (healthy, vulnerable, frail, or terminally ill; Balducci, 2013) can help identify appropriate cancer treatment options (Droz et al., 2014). Physical examination and functional-status assessment can help reveal a clinical presentation of frailty. According to a classic study by Fried et al. (2001), frailty is characterized in part, as:

1. Age greater than 85 years
2. Dependence in one or more activities of daily living (ADL)
3. The presence of one or more geriatric syndromes

Determining whether a person is "frail" in the primary care setting can help guide important decisions before a patient is admitted to an acute care unit (L. Lee, Heckman, & Molnar, 2015). When frailty is considered in the physical examination, discussions concerning advance directives, palliative versus curative treatment, and many other critical conversations can occur before an acute situation is realized (Sanchis et al., 2014).

MEDICAL EMERGENCIES ASSOCIATED WITH CANCER AND CANCER TREATMENT

A diagnosis of cancer can lead to medical emergencies, such as electrolyte imbalances, unstable fractures, and neutropenia leading to infection. It is important to obtain cancer-related history and physical information concerning the type of treatment and the exact diagnosis with metastasis (spread of the malignancy from the original site). It is also important for the acute care nurse to know the chemotherapy administration schedule, the dosage, and when it was last administered. Often, chemotherapy, such as doxorubicin and cyclophosphamide, is administered four times, 3 weeks apart. As the chemotherapy proceeds, various issues, such as nausea and vomiting, low white cell counts (neutropenia), and mouth sores, may occur and be present on acute evaluation. The following are considered oncological emergencies and require acute care.

Hypercalcemia

A common cause of hypercalcemia is malignancy (Reagan, Pani, & Rosner, 2014), and it is generally found in 3% to 5% of emergency admission patients (C. T. Lee et al., 2006). Hypercalcemia is a reasonably common complication associated with multiple myeloma, as well as breast and lung cancers. In primary hypercalcemia, hyperparathyroidism is the most common cause (Ahmad, Kuraganti, & Steenkamp, 2015). Survival can be markedly improved with early recognition in the emergency department (Royer, Maclellan, Stanley, Willingham, & Giles, 2014).

Hypercalcemia is defined as calcium concentration greater than 10.2 mg/dL (C. T. Lee et al., 2006). Signs and symptoms of hypercalcemia are often not evident in patients with mild or moderate hypercalcemia (calcium levels of 10.3–14.0 mg/dL). Gastrointestinal discomfort, changes in level of consciousness, and general nonspecific discomfort can be experienced in cases of moderate hypercalcemia (Reagan et al., 2014). Other signs and symptoms are lethargy, confusion, anorexia, nausea, constipation, polyuria, and polydipsia (Halfdanarson, Hogan, & Moynihan, 2006).

Treatment of hypercalcemia depends on the severity. Thiazide diuretics should be discontinued. Hydration must be maintained to diminish the risk of exacerbation of hypercalcemia. Severe hypercalcemia should be considered a medical emergency. Intravenous normal saline and loop diuretics should be implemented but will last only as long as the treatments are infusing. Bisphosphonates can help reduce bone reabsorption resulting in low serum calcium levels (Fallah-Rad & Morton, 2013). Calcitonin can also be administered subcutaneously or intramuscularly and can also reduce calcium levels (Halfdanarson et al., 2006). 25OHD levels and vitamin D supplementation may also reduce the risk of hypercalcemia (Fallah-Rad & Morton, 2013).

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is caused when a tumor breaks down rapidly as a result of treatment or decompensation, leading to massive cell death (Dubbs, 2018; Wagner & Arora, 2014). TLS is often detected in hematological malignancies (Rasool et al., 2014) and can be associated with high proliferation rate, bulky tumor (Mughal, Ejaz, Foringer, & Coiffier, 2010), high tumor burden, and sensitivity to chemotherapy (Rasool et al., 2014). TLS causes hyperkalemia, hyperuricemia, and hyperphosphatemia, which can enhance the risk of renal failure, reduced cardiac function, and mortality (Cantril & Haylock, 2004; Dubbs, 2018; Mughal et al., 2010; Shah, 2014). As chemotherapy agents become more effective, the risks increase for TLS.

Hyperphosphatemia and hypocalcemia can occur about 24 to 48 hours following the first chemotherapy administration. Signs and symptoms, such as muscle cramps, anxiety, depression, confusion, hallucinations, cardiac arrhythmia, and seizures, can result (Cantril & Haylock, 2004; Strauss, Hamlin, & Dang, 2017). The use of biomarkers (superoxide dismutase, malondialdehyde, glutathione, and catalase) may help one to recognize TLS so that treatment can be started (Rasool et al., 2014).

Other issues associated with TLS include hyperkalemia, which is created by a release of potassium from the debilitation of the tumor cells. High serum potassium levels can cause severe arrhythmias and sudden death (Cairo & Bishop, 2004; Criscuolo, Fianchi, Dragonetti, & Pagano, 2016). Hyperuricemia (uric acid greater than 10 mg/dL) can result in acute obstruction uropathy and cause hematuria, flank pain, hypertension, edema, lethargy, and restlessness (Cairo & Bishop, 2004; Cantril & Haylock, 2004) and is caused by underexcretion (Oka et al., 2014). Hydration, administration of allopurinol, and diuresis are generally the first-line treatment (Ahmad et al., 2015; Cantril & Haylock, 2004). Treatment with rasburicase has been found to be effective in the treatment by lowering plasma uric acid levels (Dinnel, Moore, Skiver, & Bose, 2015). The signs and symptoms associated with TLS include decreased urine output, seizures, and arrhythmias. Electrolytes must be assessed to determine the presence of hyperkalemia, hyperuricemia, and hyperphosphatemia. Electrocardiograms should be obtained to assess for arrhythmia.

Spinal Cord Compression

Spinal cord compression (SCC) is not uncommon and can occur when metastasis spreads to the vertebral bodies and invades the spinal cord. Spinal metastasis of three or more vertebra are more likely to develop SCC (G. T. Silva, Bergmann, & Thuler, 2015). Malignant SCC is related to a poor prognosis and a mean survival of less than 3 months following diagnosis (Campillo-Recio et al., 2019). The spinal column in the thoracic area is the most common location for this and must be recognized immediately to prevent critical, irreversible damage (Halfdanarson et al., 2006). SCC can lead to long-term neurological deficits and is often detected in solid tumors such as prostate, lung, breast, and kidney cancers (Savage et al., 2014).

Signs and symptoms are numbness, tingling and weakness in the extremities, sensory changes, and upper thorax and back pain (Bowers, 2015; Lowey, 2006; Tsukada et al., 2015). Pain can radiate or localize and may seem chronic, which may disguise the emergent SCC and delay critical treatment. Bowel and bladder dysfunction can also occur. For patients who are experiencing SCC, the inability to walk into the clinic or emergency department often results in a delay of care (Tsukada et al., 2015), and it is important to recognize that the ability to ambulate does not exclude the existence of SCC.

Diagnosis is often made with MRI and CT and sometimes plain radiographic films of the affected area. Treatment is often initiated with glucocorticoids, followed by either radiation therapy or surgery, and in some cases both. For people who are ambulatory, radiation therapy can be considered. Patients with paraplegia, nonradiosensitive tumors, and a predicted survival of more than 3 months may benefit from surgery to decompress the spine (George et al., 2008). In some cases, combination therapy of surgery and radiation therapy can be beneficial to preserving ambulatory status and survival (C. H. Lee, Kwon, et al., 2014).

Neutropenic Fever

Neutropenic fever is an oncological medical emergency, which is caused by the diminishment of neutrophils by

chemotherapeutic agents. Neutropenia is defined by an oral temperature of 101°F and an absolute neutrophil count (ANC) of less than 1,500 cells/μL. An ANC of less than 500 cells/μL is considered severe (Freifeld et al., 2011). Neutropenia can be the motivator for a severe infection, and timely treatment is essential (Villafuerte-Gutierrez, Villalon, Losa, & Henriquez-Camacho, 2014). Generally, fever is the presenting sign; however, skin rashes and mucositis may also be present. For some patients, neutropenic fever can occur after the first cycle of chemotherapy, and patients who have undergone aggressive surgery with bowel resections are at enhanced risk (Sharma, Rezai, Driscoll, Odunsi, & Lele, 2006).

Myelosuppression is associated with many chemotherapies, and growth factors, such as granulocyte-colony stimulating factor (G-CSF), work to elevate white blood cell counts necessary in fighting infection (Miller & Steinbach, 2014). A great amount of nursing literature exists on the definition, prevention, and management of neutropenic fever. Prevention of neutropenia and neutropenic fever should be proactive in the administration of G-CSFs in patients who are considered to be at high risk (Aapro et al., 2011; Dale, 2016). An older cancer patient receiving myelotoxic chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisolone) is considered high risk and should receive prophylactic G-CSF administration (Aapro et al., 2011; Repetto et al., 2003), yet many patients are not treated with growth factors despite the potential positive outcomes (Lugtenburg et al., 2012).

CASE STUDY 37.1

A 76-year-old woman presents to the emergency department with delirium and trauma to her left hip. The patient's daughter reports that the patient fell in the bathroom several hours earlier. She has a diagnosis of breast cancer and is currently undergoing chemotherapy and has received four cycles of Adriamycin and cyclophosphamide. She also has a history of osteoarthritis, hypertension, and gastric reflux disease. Presenting signs and symptoms are delirium, cracked mucous membranes, low blood pressure, at 88/42 mmHg, and tachycardia.

Situations such as dehydration are not uncommon in an older person undergoing chemotherapy. Patients may have vomiting or diarrhea and become dehydrated as a result. Seniors have less functional reserve and are therefore more likely to suffer from complications of cancer treatment (Balducci, 2006). Older adults require careful examination and intervention in order to maintain and enhance health and independence.

1. In this clinical scenario, which geriatric syndromes are present?
   Answer: Falls, delirium, pain associated with trauma, functional-status limitations, and ambulatory difficulty.
   Rationale: This patient has multiple geriatric syndromes and is at risk for further deconditioning. It is important to recognize the geriatric syndromes present and anticipate any additional injuries. Ensure caregiver support and help facilitate a plan for care while at home.
2. In this clinical scenario, which oncological emergency is this patient at greatest risk to develop?
   Answer: This clinical scenario is not written for an oncological emergency. Let us give the patient bone metastasis in her thoracic spine. Then she can be at risk for SCC.
   Rationale: Based on the signs and symptoms of dehydration, hypercalcemia is of concern. Hydrate to prevent hypercalcemia and to reduce signs and symptoms of dementia. Falls are also of concern because the risk of future falls is associated with prior falls. Dehydration in an older adult cancer patient can be associated with many problematic health and functional limitations.

(*continued*)

SUMMARY

Acute care of the older patient requires nurses' health assessment skills to be proactive in detecting and addressing limitations that can result from a cancer diagnosis and treatment. Nonmalignant comorbidities and geriatric syndromes play a role in the diagnosis and treatment of cancer and should be assimilated into the critical thinking involved in developing the nursing plan of care. Careful health assessment and evaluation are critical to the acute care nurse in understanding the disease progress, treatment tolerance, and the presence of oncological emergencies. Nurses working in acute settings must be acquainted with the principles of geriatric care, which should be applied to patients with any type of diagnosis and not limited to malignancy. Understanding normative aging changes versus pathology can help facilitate a specialized plan of care with enhanced health and independence as the intended patient outcomes.

NURSING STANDARD OF PRACTICE

Protocol 37.1: Cancer Assessment and Interventions

I. GOAL

Improve the care of the older person diagnosed with cancer

II. OVERVIEW

Older adults have an increased risk of malignancy (Howlader et al., 2018). Seniors often tolerate cancer treatment as well as younger people, depending on functional and general health status (Droz et al., 2017; Gomez-Millan, 2009; Sastre et al. 2008, Wildiers et al., 2007).

III. BACKGROUND

Cancer is most often diagnosed in people aged 65 years and over (Howlader et al., 2018). Nurses must be aware of management options and some potential emergencies associated with the diagnosis and treatment of a malignancy.

IV. PRINCIPLES OF CANCER CARE IN THE OLDER PERSON

A. Assessment of comorbid conditions
   1. Cancer may be one of several chronic conditions.
   2. The more severe the comorbidity, the lower the probability of survival after a diagnosis of cancer (Iversen et al., 2009). The absence of severe comorbidity and good general health allows older people to be considered for more aggressive types of cancer treatments (Banysch et al., 2018; Vitale et al., 2019).

B. Assess the patient using a comprehensive geriatric assessment.
   1. The CGA is a battery of clinical measures used to assess functional, emotional, and cognitive status; falls; medications; and general health status (Overcash, 2018; Wildiers et al., 2014).
   2. Functional status can be measured using an Activity of Daily Living Scale (Katz et al., 1970), Instrumental Activities of Daily Living Scale (Lawton & Brody, 1969), Gait Assessment Scale (Tinetti, 1986), or Berg Balance Scale (Berg et al., 1992).
   3. Risk of falls can be assessed using the Timed Up and Go Test (Podsiadlo & Richardson, 1991).
   4. Emotional status is often assessed using the Geriatric Depression Scale (Yesavage et al., 1982).
   5. Cognitive status is assessed using the Mini-Cog (Borson et al., 2000).
   6. General health status is assessed with a complete history and physical exam.
   7. Medication is evaluated using the Beers Medication Screen (AGS, 2019).

C. Assessment of medical emergencies associated with cancer
   1. Hypercalcemia
      a. Defined as calcium concentrations greater than 10.2 mg/mL (C. T. Lee et al., 2006)
      b. Signs and symptoms are not often noticeable.
      c. Gastrointestinal discomfort, lethargy, confusion, anorexia, nausea, constipation, polyuria, and polydipsia are symptoms (Halfdanarson et al., 2006).
      d. Treatment depends on severity.
      e. Thiazide diuretics should be discontinued.
      f. Hydration with intravenous normal saline is recommended.
      g. Bisphosphonates are an option (Fallah-Rad & Morton, 2013).
   2. Tumor lysis syndrome (TLS)
      a. Caused when a tumor breaks down rapidly (Wagner & Arora, 2014).
      b. Causes hyperkalemia, hyperuricemia, and hyperphosphatemia, which can cause renal failure and reduced cardiac function.

(*continued*)

Protocol 37.1: Cancer Assessment and Interventions (*continued*)

c. Signs and symptoms are muscle cramps, anxiety, depression, confusion, hallucinations, cardiac arrhythmia, and seizures (Cantril & Haylock, 2004; Dubbs, 2018).
d. Treatment with hydration, administration of allopurinol, and diuresis are generally the first line of treatment (Cantril & Haylock, 2004).
e. Treatment with rasburicase has been found to be effective in the treatment and prevention of hyperuricemia and TLS (Dinnel et al., 2015).

3. Spinal cord compression
   a. Occurs when metastasis spreads to the vertebral bodies and invades the spinal cord (Campillo-Recio et al., 2019; Halfdanarson et al., 2006).
   b. Signs and symptoms are numbness, tingling, and weakness in the extremities; sensory changes; upper thorax and back pain (Lowey, 2006; Tsukada et al., 2015).
   c. Pain can radiate or localize and may seem chronic, which may disguise the emergent spinal cord compression and delay critical treatment.
   d. Bowel and bladder dysfunction can also occur (Tsukada et al., 2015).
   e. Treatment is often initiated with glucocorticoids, followed by radiation therapy and/or surgery (George et al., 2008).
4. Neutropenia fever
   a. Caused by the diminishment of neutrophils by chemotherapeutic agents
   b. Neutropenia is defined by an oral temperature of 101°F and an ANC of less than1,500 cells/μL. An ANC of less than 500 cells/μL is considered severe (Freifeld et al., 2011).
   c. Generally, fever is the presenting sign; however, skin rashes and mucositis may also be present.
   d. Prevention of neutropenia and neutropenic fever should be proactive in the administration of G-CSFs in patients who are considered to be at high risk (Aapro et al., 2011; Dale, 2016).
   e. Treatment of neutropenia is to stop chemotherapy until white counts elevate.

V. PARAMETERS OF ASSESSMENT

A. Older patients with cancer require comprehensive geriatric assessment and monitoring during diagnosis and treatment of malignancy.

ABBREVIATIONS

ANC	Absolute neutrophil count
CGA	Comprehensive geriatric assessment
G-CSF	Granulocyte-colony stimulating factor

Perioperative Care of the Older Adult*

Fidelindo Lim and Larry Z. Slater

38

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify unique multifactorial challenges affecting the older adult perioperative patient.
2. Synthesize current best practices from related geriatric themes in the assessment and management of the older adult perioperative patient.
3. Describe geriatric-specific, evidence-based, and interprofessional interventions to improve outcomes among older adult perioperative patients.

OVERVIEW

The confluence of advancing age, geriatric syndromes, regulatory changes, and advances in medical technology has made perioperative care scenarios of older adults more complex. Surgical procedures performed on older adults are expected to rise. About 27% of adults aged 65 and older had two or more hospital stays in 2016 (Centers for Disease Control and Prevention [CDC], 2018). In 2015, the 10 most commonly performed operative procedures among persons between 65 and 74 years old were (Agency for Healthcare Research and Quality [AHRQ], 2019):

1. Knee arthroplasty
2. Hip replacement (total and partial)
3. Percutaneous transluminal coronary angioplasty (PTCA)
4. Spinal fusion
5. Laminectomy and excision intervertebral disc
6. Other procedures on vessels other than head and neck
7. Partial excision of bone
8. Other therapeutic procedures (hemic and lymphatic system)
9. Colorectal resection
10. Coronary artery bypass graft (CABG)

A 9% decrease in the rate of hospitalizations for adults aged 85 and over was noted from 2000 to 2010. The same age group comprised 2% of the U.S. population, but accounted for 9% of hospital discharges (Levant, Chari, & DeFrances, 2015). Factors such as polypharmacy, diabetes mellitus, presurgical cognitive status, use of general anesthesia, and an increasing number of procedures done in ambulatory care settings will continue to impact perioperative outcomes, particularly the development of postoperative delirium, a significant determinant of poor outcomes (American Geriatrics Society [AGS], 2012).

Perioperative nursing is defined as the "delivery of comprehensive care within preoperative, intraoperative

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

and postoperative periods of the patient's experience during operative and other invasive procedures" (Steelman, 2015, p. 1). The high-stake demands of perioperative patient care, the increasing number of older adults undergoing surgery, and the unique vulnerabilities of this population require the translation of science-based interprofessional collaboration. The use of the nursing process, critical thinking, and evidence-based practice models will ensure patient safety and quality for older adult patients and their families.

The discussion about perioperative care of older adults comes at an opportune time, when there is growing recognition that the educational background of nursing staff directly impacts the mortality of surgical patients. Aiken et al. (2014) found that a 10% increase in the proportion of staff nurses holding a bachelor's degree is associated with a 7% decrease in the risk of death among patients following common surgeries in an acute care setting. This finding supports earlier evidence of lower mortality among surgical patients when there is a higher proportion of bachelor's-prepared nurses on staff (Aiken, Clarke, Cheung, Sloane, & Silber, 2003). Lower rates of postoperative deep vein thrombosis (DVT) or pulmonary embolism (PE) and shorter length of stay have also been found in hospitals with a higher percentage of registered nurses (RNs) with baccalaureate or higher degrees (Blegen, Goode, Park, Vaughn, & Spetz, 2013).

The improvement of care outcomes in older adult perioperative patients will draw from an array of evidence not only from clinical studies but also from research in nursing policy, management, and health professions education. Specific safety and quality benchmarks for the general surgical care of older adults are described in Chapter 39, General Surgical Care of the Older Adult. The inevitable aging of the population will result in greater demand for surgical care. Comprehensive geriatric assessment that takes into account patient's participation is an established clinical approach in optimizing positive outcomes for the perioperative older adult patient (Partridge, Harari, Martin, & Dhesi, 2014).

BACKGROUND AND STATEMENT OF PROBLEM

The number and type of surgical procedures performed in the past decade vary according to the body systems involved. In 2014, 10.1 million inpatient hospital stays involved operating room (OR) procedures (a total of 14.2 million OR procedures) with an aggregate hospital cost of $187.1 billion (McDermont, Elixhauser, & Sun, 2017). Of these, adults older than 65 comprised 32.6% (3,292,300 patients) of hospital stays involving one or more surgeries (McDermont et al., 2017). Of the 1.8 million Medicare beneficiaries 65 years of age and older who died in 2008, 31.9% had undergone an inpatient surgical procedure during the year before death, 18.3% had undergone a procedure in their last month of life, and 8% had undergone a procedure during their last week of life. For those between the ages of 80 and 90 years, the percentage of surgical procedures in the last year of life decreased by 33% (Kwok et al., 2011). A 2017 report on OR procedures requiring inpatient stays in 2014 included the following data:

- Although just over one quarter (28.6%) of all stays involved OR procedures, these stays accounted for nearly half (48.4%) of aggregate hospital costs.
- Compared with stays without OR procedures, hospital stays involving OR procedures were longer on average (5.1 vs. 4.4 days) and had higher average costs ($18,500 vs. $7,900).
- 36.7% of stays that were privately insured involved OR procedures compared with 23% to 25% of stays among other types of payers.
- Three musculoskeletal procedures (hip replacement, knee arthroplasty, and spinal fusion) accounted for 12.2% of all OR procedures and 19.6% of aggregate costs for all inpatient stays with a first-listed OR procedure.

Ambulatory surgeries continue to increase because of medical and technological advancements and the development and expansion of minimally invasive and noninvasive surgeries. Estimates of surgical and nonsurgical ambulatory procedures performed in hospitals and ambulatory surgery centers (ASCs) in the United States in 2010 include these highlights (Hall, Schwartzman, Zhang, & Liu, 2017):

- 28.6 million ambulatory surgery visits to hospitals and ASCs occurred.
- 48.3 million surgical and nonsurgical procedures were performed.
- 25.7 million (53%) ambulatory surgery procedures were performed in hospitals, and 22.5 million (47%) were performed in ASCs.
- 51% of the visits for ambulatory surgery were paid for by private insurance. Medicare payment was expected for 31%, and Medicaid for 8%; only 4% were self-pay; 4% were listed as other and 2% listed as unknown in their source of payment.
- 95% of the visits with a specified discharge disposition had a routine discharge to the patient's home. Patients who were admitted to the hospital as inpatients accounted for 2% of these visits.
- 19% of procedures were performed on those aged 65 to 74, with about 14% performed on those aged 75 and over.

Going for surgery, whether an outpatient or inpatient procedure, emergent or elective, marks an important healthcare transition, particularly among vulnerable older adults, because of the increased morbidity and mortality risks. A study involving 24,216 patients reported that failures-to-rescue were more than two times higher in patients older than 75 years compared with those younger than 75 years (26.0% vs. 10.3% at high-mortality hospitals, *p* less than .001; Sheetz et al., 2014). It is interesting to note that a higher nurse–patient ratio (odds ratio [OR]: 0.99, 95% confidence interval [CI; 0.98–1.00]) did not influence failure-to-rescue (Sheetz et al., 2014).

Overall mortality among older adults presenting with trauma is higher among those older than 74 years than in younger geriatric cohorts (Hashmi et al., 2014). Furthermore, severe and extremely severe injuries and systolic hypotension at presentation are associated with significant mortality risks (Hashmi et al., 2014). Higher mortality trends have also been noted among older adults who had cardiac surgery (Sepehri et al., 2014), kidney transplant (Knoll, 2013), hip-fracture surgery (Carpintero et al., 2014), and colectomy (Visser, Keegan, Martin, & Wren, 2009), as well as among surgical oncology patients (Korc-Grodzicki et al., 2014). Among cardiac surgical patients, age more than 75 years is an independent risk factor for intensive care unit (ICU) mortality, and these patients have a higher risk of multiorgan dysfunction syndrome (MODS; Curiel-Balsera et al., 2013).

In general, high surgical mortality among older adults is closely linked with increased risk of falls, prolonged hospitalization, and frailty (Green et al., 2012; Sepehri et al., 2014). However, advanced age alone does not correlate or predict higher mortality postsurgery (Green et al., 2012). Similar findings have been noted among patients in critical care settings (Balas et al., 2012). This is important for nurses to consider in their assessment, and they should be aware of personal or professional biases (e.g., ageism) that might impact the overall quality of care provided among older adult perioperative patients. Consideration of the overall health scenario, including the typical age-related physiologic changes, baseline health status, severity of present illness, and potential risks of perioperative complications, rather than age alone, should guide the realistic care decisions for perioperative older adult patients (Oresanya, Lyons, & Finlayson, 2014).

The Surgery Standing Committee of the National Quality Forum (NQF) endorses measures for surgical procedures. As a result, there have been numerous collaborative safety initiatives, from both governmental and nonregulatory agencies, in the past decade to meet these measures. The 15 measures endorsed by NQF are (NQF, 2017):

1. Beta Blockade at Discharge
2. Preoperative Beta Blockade
3. Use of Internal Mammary Artery (IMA) in Coronary Artery Bypass Graft (CABG)
4. Risk Adjusted Case Mix Adjusted Elderly Surgery Outcomes Measure
5. Risk Adjusted Colon Surgery Outcome Measure
6. Statin Therapy at Discharge After Lower Extremity Bypass (LEB)
7. Rate of Open Repair of Abdominal Aortic Aneurysms (AAA) Where Patients Are Discharged Alive
8. In-Hospital Mortality Following Elective Endovascular Aneurysm Repair (EVAR) of AAAs
9. Postoperative Stroke or Death in Asymptomatic Patients Undergoing Carotid Endarterectomy
10. Postoperative Stroke or Death in Asymptomatic Patients Undergoing Carotid Artery Stenting (CAS)
11. Hospital-Level Risk-Standardized Complication Rate (RSCR) Following Elective Primary Total Hip Arthroplasty (THA) and/or Total Knee Arthroplasty (TKA)
12. Hospital-Level 30-Day, All-Cause Risk-Standardized Readmission Rate (RSRR) Following Elective Primary Total Hip Arthroplasty (THA) and/or Total Knee Arthroplasty (TKA)
13. The Society of Thoracic Surgeons (STS) Individual Surgeon Composite Measure for Adult Cardiac Surgery
14. STS Mitral Valve Repair/Replacement (MVRR) Composite Score
15. STS Mitral Valve Repair/Replacement (MVRR) and Coronary Artery Bypass Graft (CABG) Composite Score

It is expected that these measures inform and align with the nurse-sensitive outcomes set forth by the National Database of Nursing Quality Indicators (NDNQI). Examples of NDNQI indicators that may particularly impact older adult perioperative patients include falls, pressure injury, restraint prevalence, and hospital-acquired infections such as urinary tract infections and central line–associated bloodstream infections (Montalvo, 2007).

ASSESSMENT OF PROBLEM AND NURSING CARE STRATEGIES

Preoperative Considerations

Successful perioperative care of the older adult begins at the time surgery has been determined to be a safe option. What distinguishes older adults from their younger

counterparts is the former's loss of functional reserve and a general decline in organ function (Khan, Singer, & Vaughan, 2017). Older patients may present with a host of comorbidities involving any organ system, and these must be evaluated and optimized before surgery to improve the postoperative outcome. This highlights the crucial roles played by anesthetists, geriatricians, and nurses in the preoperative management of this challenging patient population. Functional and cognitive impairment, malnutrition, facility residence, and frailty have been associated with adverse surgical outcomes (Oresanya et al., 2014).

As part of the comprehensive preoperative assessment of older patients, "it is useful to determine whether a patient is physiologically 'young' (i.e., exhibiting only changes associated with normal aging) or 'old' (i.e., exhibiting aging effects due to comorbidities in addition to normal aging)" (White et al., 2012, p. 1191). Throughout the perioperative period, the team should reinforce the patient's psychological preparation. This intervention has been shown to be beneficial for the outcomes related to postoperative pain, behavioral recovery, negative affect, and length of stay (Powell et al., 2016).

Consent for Surgery

Determining the patient's capacity to consent for surgery is another challenge for the provider. Age alone does not predict incapacity to consent for surgery (Oresanya et al., 2014). It is important to view capacity within a continuum. It can be evanescent and can be optimized with careful consideration of situational, psychosocial, medical, psychiatric, and neurologic factors (Sessums, Zembrzuska, & Jackson, 2011). Patients with cognitive impairment will have limited participation in the informed consent process. Reliable capacity assessment can also be influenced by problematic relationships between patients and providers, as well as cultural, linguistic, and educational barriers (Ivashkov & Van Norman, 2009). From a legal and medical standpoint, competence to consent to treatment may require the following criteria (Appelbaum & Grisso, 1995; Welie & Welie, 2001):

- Ability to appreciate the nature of one's situation and the consequences of one's choices
- Ability to understand the relevant information
- Ability to reason about the risks and benefits of potential options
- Ability to communicate a choice

The use of validated tools, such as the Standardized Mini-Mental State Examination (SMMSE) or the Mini-Cog, must be used to evaluate the medical decision-making capacity of the patient (see Chapter 7, Healthcare Decision-Making, and Chapter 9, Assessing Cognitive Function in the Older Adult). A review of 43 prospective studies to determine the prevalence of incapacity and assessment accuracy in adult medical patients without severe mental illnesses found that only 2.8% of healthy older adult control subjects lacked decision-making capacity, compared with 20% in those with mild cognitive impairment and 54% among persons with Alzheimer's disease (Sessums et al., 2011). The authors also noted that SMMSE scores of less than 20 are associated with increased likelihood of incapacity. Other validated tools that can be used to assess capacity are the Aid to Capacity Evaluation (ACE) tool, the Hopkins Competency Assessment Test, and the Understanding Treatment Disclosure (Sessums et al., 2011). Competency to use any assessment tools is paramount. Therefore, clinicians must have sufficient training and ongoing validation on how to use these tools. An algorithm can be used to assess decision-making capacity using a stepwise series of questions (Jones & Holden, 2004).

Preoperative Optimization

It is ideal if the process of obtaining an informed consent includes a discussion of treatment goals, risks, and benefits, with full participation of the patient, family, and other caregivers. If surgery is unlikely to satisfy the patient's goals and preferences, nonoperative treatments may be pursued (Oresanya et al., 2014). A comprehensive geriatric assessment is called for not only for its benefits in reducing adverse postoperative outcomes, but also to aid clinicians in optimizing function before surgery (Kumar, Salzman, & Colburn, 2018; Partridge et al., 2014). Experts recommend the following four domains as the focus of preoperative optimization: cognition, functional status, nutrition, and frailty (Oresanya et al., 2014). Evidence suggests that poor functional status (e.g., inability to climb two flights of stairs or walk four blocks) is associated with an increased risk of postoperative cardiopulmonary complications after major noncardiac surgery (Girish, Trayner, Dammann, Pinto-Plata, & Celli, 2001).

For older adults with hip fractures, optimization requires estimating perioperative risks and performing the surgery early, as well as focusing on intravascular volume restoration, pain management, and prevention of perioperative hypotension (Nicholas, 2014b). Advanced preoperative cardiac testing (e.g., echocardiography and stress testing) does not seem to improve outcomes and may inappropriately delay surgical repair (Nicholas, 2014a). Regardless of the surgery needed, older adults with active cardiac

conditions, such as unstable coronary syndromes, decompensated heart failure, significant arrhythmia, and severe valvular disease, require evaluation and treatment before nonurgent or noncardiac surgery (Fleisher et al., 2014).

The Perioperative Optimization of Senior Health (POSH) Initiative

The POSH program is an innovative care redesign that utilized geriatrics experts throughout the perioperative period for the care of patients older than 65 who underwent elective surgeries. Interventions were focused on management of comorbidities, reduction of polypharmacy, enhancement of mobility and nutrition, and delirium risk mitigation. Primary outcomes were length of stay (LOS), readmission rates (7-day and 30-day, all-cause inpatient readmission), and discharge disposition (home with self-care vs. need for ongoing health services, including home health, skilled nursing facility, or hospice). Despite higher mean age and morbidity burden, older adults in the intervention group had fewer complications, shorter hospitalizations, more frequent discharge to home, and fewer readmissions than a comparison group (McDonald et al., 2018).

Admission

Unless the patient is coming in for an elective or ambulatory surgery, inpatient surgeries usually necessitate a visit to the emergency department (ED), partly because of the nature of clinical scenarios requiring surgical interventions (e.g., hip fracture, gastrointestinal bleeding, subdural hematoma, etc.). The time spent in the ED, particularly among vulnerable older adults, is an important consideration because of its positive correlation with negative patient-oriented outcomes, from worse patient satisfaction to higher inpatient mortality rates (Singer, Thode, Viccellio, & Pines, 2011).

A retrospective cohort study (N = 41,256, with 37% of subjects older than 65 years) reported higher mortality correlates with increased ED boarding time (2.5% inpatients boarded less than 2 hours; 4.5% inpatients boarded 12 hours or more [p less than .001; Singer et al., 2011]). The authors also noted longer hospital stay correlates with longer boarding time in the ED. On average, those who stayed in the ED for less than 2 hours had 5.6 days of hospitalization (SD ±11.4) compared with 8.7 days (SD ± 16.3 days) for those who boarded for more than 24 hours (Singer et al., 2011). Similar negative findings have been reported in ED nursing case studies of older adult patients (Donatelli, Gregorowicz, & Somes, 2013). Among orthopedic patients, surgical delay is associated with a significant increase in the risk of death and pressure injuries (Moja et al., 2012)—both are nursing-sensitive indicators. Clinical and administrative nursing personnel play a pivotal role in expediting patient transfer from the ED to the surgical unit or the OR and in facilitating timely performance of diagnostic procedures and other inpatient preoperative screening to minimize unwanted delays.

Assessment of Surgical Risk

Comprehensive preoperative assessment of older adults needs to consider calculating surgical risks in order for the patient and his or her family and the provider to come up with an informed decision to operate. Although there are currently no validated tools specific to the older adult population, various available surgical-risk calculators may be applied, particularly in evaluating cardiac risk before noncardiac surgery (Bilimoria et al., 2013). The *Assessment of an Older Patient With a Condition Potentially Amenable to Surgery* is an algorithm intended to guide the surgeon and the patient in determining the appropriateness of surgery (Oresanya et al., 2014). Table 38.1 shows examples of surgical-risk assessment tools and their descriptions.

Based on the synthesis of existing evidence, the following clinical factors have been associated with increased perioperative risk of a cardiovascular event (Fleisher et al., 2014): history of ischemic heart disease, heart failure, cerebrovascular disease, insulin-dependent diabetes mellitus, preoperative serum creatinine greater than 1.5 mg/dL, increasing age, American Society of Anesthesiologists (ASA) physical status classification, and preoperative functional status. Emergency surgery is associated with higher risk, as cardiac complications are two to five times more likely than with elective procedures (Fleisher et al., 2014). Frailty and resiliency are two vital concepts to consider in the comprehensive assessment of older surgical patients. Use of a validated frailty scoring tool can be used in preoperative assessment where applicable (Chow, Rosenthal, Merkow, Ko, & Esnaola, 2012).

Intraoperative Considerations

Anesthesia

The physiologic changes that accompany aging may put the older adult surgical patient at risk for adverse effects of anesthetics. Loss of skeletal muscle mass, decrease in total body water, and increased adipose tissue, especially in women, can lead to an expansion of the lipid reservoir for centrally active anesthetic drugs (e.g., benzodiazepines, volatile agents, opioid analgesics, and sedative-hypnotics), contributing to delayed elimination and increased duration of action of these drugs (White et al., 2012). Among

TABLE 38.1

Examples of Surgical-Risk Assessment Tools

Surgical-Risk Assessment Tool	Description
Revised Goldman Cardiac Risk Index (RCRI; Devereaux et al., 2005; Lee et al., 1999)	Referred to as the Lee Index, the tool offers significant predictive value for cardiac complications and mortality after major noncardiac surgery in various populations and settings, except for abdominal aortic aneurysm surgery.
Vascular Study Group of New England (VSGNE; Bertges et al., 2010)	The risk index predicts in-hospital cardiac events after vascular surgeries such as nonemergent carotid endarterectomy, lower extremity bypass, endovascular abdominal aortic aneurysm repair, and open infrarenal abdominal aortic aneurysm repair.
American College of Surgeons—National Surgery Quality Improvement Program (ACS-NSQIP) Universal Surgical Risk Calculator (Bilimoria et al., 2013)	A universal decision-support tool based on 21 preoperative factors. It is used as a morbidity and mortality risk calculator for patients undergoing surgery and includes several geriatric variables, such as age, functional health status, albumin level, type of procedure, demographics, and comorbidities. The tool can be used to estimate risks for postoperative complications.
Gupta MICA (myocardial infarction or cardiac arrest) NSQIP Database Risk Model (Gupta et al., 2011)	This cardiac risk calculator provides a risk estimate of intraoperative or postoperative MICA. Five factors identified as predictors of MICA are type of surgery, dependent functional status, abnormal creatinine, American Society of Anesthesiologists class, and increased age.

malnourished older adults with hypoalbuminemia, there is a higher risk of toxicity for albumin-bound anesthetic agents, such as propofol and diazepam, because of increased free-drug concentrations, contributing to increased sensitivity to these drugs (Aymanns, Keller, Maus, Hartmann, & Czock, 2010). Anesthetic agents are also known to decrease cardiac output, arterial pressure, and microvascular perfusion (Bentov & Reed, 2014), which can further strain the patient's limited physiologic reserve.

To assess postoperative risks, the ASA Classification of Physical Health remains the most common tool used in appraising preoperative health of surgical patients. The patient's preoperative health is categorized into five classes (I–V). An "E" for emergency surgery is placed after the Roman numeral (Dripps, 1963):

I. Patient is a completely healthy, fit patient.
II. Patient has mild systemic disease.
III. Patient has severe systemic disease that is not incapacitating.
IV. Patient has incapacitating disease that is a constant threat to life.
V. A moribund patient who is not expected to live 24 hours with or without surgery.

An ASA score of VI is designated for patients who are declared brain dead and coming to the OR for organ procurement. An ASA score of III or higher is a predictor of greater blood loss and need for transfusion in total hip replacement patients (Grosflam, Wright, Cleary, & Katz, 1995). The ASA score has been shown to have a predictive value in long-term mortality after a hip fracture (Bjorgul, Novicoff, & Saleh, 2010). In a prospective study of 1,635 patients with hip fracture, survival for those rated with ASA I was 8.5 years versus only 1.6 years for those rated as ASA IV (Bjorgul et al., 2010). A prospective study of 168 hip-fracture patients (age range: 50–98 years) reported that an ASA score of III or higher is a predictive factor of postoperative delirium (Zakriya et al., 2002).

Although this grading system is widely used, there has been notable criticism of its value. Variations of the classification systems are available. Perioperative nurses need to inform themselves of what system is used in their facility. Use of the ASA classification to predict postoperative mortality risk can be further enhanced by complementing it with the Short Potable Mental Status Questionnaire (SPMSQ) for assessing cognitive function. Söderqvist et al. (2009), in a prospective cohort study of 1,944 patients aged 66 years or older, reported that the combination of ASA score and SPMSQ provides greater information about survival times compared with the ASA score alone. Nurses are encouraged to be active participants in evaluating the patient's surgical risk and in communicating with the provider any changes in the patient's condition that may impact the use of anesthetics. In order to safely monitor patients, nurses need to have an up-to-date knowledge of pharmacokinetics and pharmacodynamics of the common anesthetic agents used and the unique precautions related to older adults.

Oxygen Supplementation

A systematic review indicated that use fraction of inspired oxygen (FiO_2) of 60% or higher is associated with a greater risk of adverse events, including mortality. Evidence is

insufficient to support the routine use of FiO_2 of 60% or higher during anesthesia and surgery (Wetterslev et al., 2015). Clinicians must rely on objective proof of the patient's need for higher FiO_2 such as arterial blood gas (ABG) results.

Intraoperative Medication Safety

Although the exact number of medication errors taking place throughout the perioperative continuum cannot be fully known, medication safety continues to be a challenge (Treiber & Jones, 2012). A prospective observational study to assess the rates of perioperative medication errors (MEs) and adverse drug events (ADEs) found that 1 in 20 perioperative medication administrations included an ME and/or ADE. More than one third of the MEs led to observed ADEs, and the remaining two thirds had the potential for harm (Nanji, Patel, Shaikh, Seger, & Bates, 2016). A Pennsylvania Patient Safety Authority study found 1,137 medication error events associated with the perioperative settings in 1 year. More than half (54.6%) of the reported events reached the patient. Nearly three quarters (74.9%) of events were attributed to a breakdown in communication during transitions of care or handoff procedures (Cierniak, Gaunt, & Grissinger, 2018). Perioperative medication prescribing and administration often bypasses standard safety checks, such as electronic provider order entry with decision support, pharmacy verification, and multiple nursing checks at the time of medication administration. Other potential factors for MEs include medications in unlabeled containers or removed from their original containers and placed into unlabeled containers (The Joint Commission [TJC], 2019b). In one qualitative study, preoperative MEs were the most frequently reported perioperative medication error (Treiber & Jones, 2012).

Antibiotic Prophylaxis

In 2013, 19% fewer surgical site infections (SSI) were observed than predicted on the basis of 2006 to 2008 baseline data (NQF, 2017). Among the many strategies to prevent SSI is the use of antibiotic prophylaxis. The current guidelines are an interprofessional collaboration supported by the American Society of Health-System Pharmacists (ASHP), the Infectious Diseases Society of America (IDSA), the Surgical Infection Society (SIS), and the Society for Healthcare Epidemiology of America (SHEA). The guidelines include specific recommendations for various surgeries (e.g., neurosurgery, cardiac, thoracic, gastroduodenal, bowel, and biliary) that disproportionately affect older adults. The key recommendation is to administer intraoperative antibiotic within 60 minutes before surgical incision. Antibiotics requiring longer infusion times, such as fluoroquinolones and vancomycin, should begin within 120 minutes before surgical incision (Bratzler et al., 2013).

Time Out/Universal Protocol

From 2005 to 2018, the TJC reported 1,501 sentinel events related to wrong-patient, wrong-site, wrong-procedure events (TJC, 2019a). Seen within the overall number of surgeries done annually (14.2 million OR procedures performed in 2014; McDermont et al., 2017), these incidences are considered rare, although they have very serious consequences. Older adults can be seen as having high vulnerability for such events because of a higher prevalence of cognitive or memory impairment, which might affect their full participation in the Time Out procedure.

A Cochrane Review that evaluated the effectiveness of organizational and professional interventions for reducing wrong-site surgery reported that preoperative verification using Universal Protocol, site marking, Time Out, and targeted educational interventions has been demonstrated to reduce the incidence of wrong-site surgery events (Algie et al., 2015). Recognizing the complexities of the work processes involved in Universal Protocol, TJC offers some guidelines for its implementation (see Protocol 38.1 for details). Patients with cognitive decline have an impaired ability to participate in the surgical site identification and verification processes; therefore, this requires an added layer of safety checks.

POSTANESTHESIA CARE UNIT CONSIDERATIONS

Perioperative Delirium

Delirium is a high-impact, high-volume complication of surgery among older adults that is associated with a host of negative outcomes (Pallaria, Panebianco, & Kamienski, 2018). Underlying cognitive impairment predisposes the patient to postoperative delirium, which cascades to a host of adverse care trajectories such as longer hospitalization and ICU stay, higher costs, increased mortality, greater use of continuous sedation and physical restraints, increased unintended removal of catheters and self-extubation, functional decline, new institutionalization, and new onset of cognitive impairment (Balas et al., 2012). A narrative review of 54 studies of surgical patients older than 60 years reported an adjusted OR of 17 (CI [1.2–239.8]; *p* less than .05), associating preoperative cognitive impairment with postoperative delirium (Oresanya et al., 2014).

Current best practice guidelines recommend the use of validated clinical protocols to assist in preventing episodes of delirium. Because of its significant impact, preoperative discussions among patients, their families, and providers may include the use of preoperative delirium prophylaxis. Findings from a meta-analysis suggest that perioperative use of prophylactic antipsychotics may effectively reduce the overall risk of postoperative delirium in the elderly (Teslyar et al., 2013). See Chapter 20, Delirium: Prevention, Early Recognition, and Treatment, for more detailed discussion and current guidelines.

Pain Management

There is evidence that pain management of older adults is inadequate, particularly among the cognitively impaired and those with altered mental states, in spite of the availability of validated tools for pain assessment and management (Schofield, 2014). High compliance with implementation of assessment tools will result in increased identification of postoperative pain as well as delirium (Pallaria et al., 2018). The American Society of PeriAnesthesia Nurses (ASPAN) has issued guidelines on how to manage pain and promote comfort (ASPAN, 2003). Please refer to Chapter 22, Pain Management in the Older Adult, for a detailed discussion of pain in older adults.

Medication Reconciliation and Perioperative Beta-Blocker

Medication reconciliation of perioperative older adults should pay close attention to making sure that beta-blockers are part of the patient's ongoing medications. The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults (AGS, 2015) should be used as a guide in reviewing medications during medication reconciliation and bedside rounds. The continuation of beta-blocker therapy perioperatively decreases the risk of in-hospital death among high-risk, but not low-risk, patients undergoing major noncardiac surgery (Fleisher et al., 2014). A systematic review has shown that use of perioperative beta-blockers prevents postop supraventricular and ventricular arrhythmias among cardiac surgery patients. In noncardiac surgery, evidence shows an association of beta-blockers with increased all-cause mortality (Blessberger et al., 2018). For patients who cannot take oral beta-blockers, the intravenous equivalent needs to be given. Beta-blockers' effect on mortality, acute myocardial infarction (MI), stroke, heart failure, hypotension, and bradycardia in the cardiac surgery setting remains unclear (Blessberger et al., 2018).

Postoperative and Postdischarge Nausea and Vomiting

The ASPAN published practice guidelines on how to manage the common perioperative complication of nausea and vomiting. Potential trajectories of postoperative nausea and vomiting (PONV) and postdischarge nausea and vomiting (PDNV) include aspiration, wound dehiscence, prolonged postoperative hospital stays, unanticipated hospital admission after outpatient surgery, delayed return of a patient's functional ability in the 24-hour period after surgery, and lost time from work for patients and care providers at home (ASPAN, 2006). A weblink to the ASPAN guidelines is provided in Protocol 38.1 practice guideline section.

GENERAL PERIOPERATIVE CONSIDERATIONS

A Culture of Safety

Maintaining safety and quality patient care in a high-stress environment, such as the perioperative unit, enables the unit to flourish in a culture of safety based on nonpunitive principles. The use of an evidence-based teamwork system to improve communication and collaborative skills (e.g., TeamSTEPPS) will empower staff to self-advocate for safety (AHRQ, n.d.). Nurse-led initiatives, such as unit practice councils and appointing "champions" for specific perioperative core measures, are essential in this process (Institute for Healthcare Improvement [IHI], n.d.). Hardwiring a culture of safety would require a concerted systematic approach across all levels of care.

Handoff Communication

The transition between preoperative (preop) to postoperative (postop) is a high-stake event that might require multiple location changes (from the admitting area to the holding area, from the OR to the postanesthesia care unit [PACU], from the PACU to the surgical ward or specialty care units, from the surgical inpatient unit to a rehabilitation unit and other transitions). Essential to safe transition is high-quality handoff. This is defined as "the process of transferring primary authority and responsibility for providing clinical care to a patient from one departing caregiver to one oncoming caregiver" (Patterson & Wears, 2010, p. 53). Handoff communication has now become a proxy measure of the overall communication quality among providers (Riesenberg, Leisch, & Cunningham, 2010).

The Joint Commission accreditation evaluates the effectiveness of communication among caregivers as part of its National Patient Safety Goals (TJC, 2019b). Root-cause analysis of perioperative sentinel event (e.g., resulting in

death or permanent loss of function) data from 2005 to 2018 reveals communication failure and human factors are among the leading causes of errors in wrong-patient, wrong-site, and wrong-procedure; patient falls, delays in treatment, and unintended retention of foreign object events (TJC, 2019a). Communication skills have been measured as the worst aspect of teamwork behavior in the OR (Wahr et al., 2013).

Although handoff varies according to unique institution process (e.g., use of electronic health record), it is imperative to use a standardized form or checklist coupled with preoperative and postoperative debriefings (Wahr et al., 2013). The Association of periOperative Registered Nurses (AORN) website has extensive resources and tools to guide design and implementation of quality handoff (AORN, 2012). For guidance on how to implement quality-improvement projects in handoff, the Handoff Communications Targeted Solutions Tool by TJC is an excellent starting point (see the "Resources" section for the website).

SSI Prevention

Patients' risk of having a healthcare-associated infection was 16% lower in 2015 than in 2011. A 2015 study found that SSI is the third most common healthcare-associated infection (HAI) in U.S. hospitals (Magill et al., 2018). HAI is estimated to affect 2% to 5% of inpatient surgery, with 3% mortality, while increasing the risk of death 2 to 11 times compared to those who did not acquire an SSI (Anderson et al., 2014). *Staphylococcus aureus* is the most common pathogen causing SSIs, accounting for 30% of SSIs in the United States (Bratzler et al., 2013). Standards and guidelines to prevent SSI have been recommended by the Surgical Care Improvement Project (SCIP) supported by key stakeholders. Comprehensive SSI prevention strategies include well-established measures, such as surgical hand asepsis, and other collaborative measures, such as antibiotic prophylaxis, glycemic control, maintaining normothermia, and skin and bowel prep (Fry, 2008). A comprehensive policy on SSI prevention includes environmental and engineering policies such as keeping the OR doors closed during surgery except as needed for passage of equipment, personnel, and the patient (Berríos-Torres, 2009). The CDC standard and transmission-based precautions should be followed where applicable. See Protocol 38.1 for SSI practice guidelines.

Deep Vein Thrombosis Prophylaxis

Venous thromboembolism (VTE) is defined as having either a DVT and/or a PE (He et al., 2014). The rate of postoperative VTE after hip-fracture surgery is low, estimated at 1.34%, 95% (CI [1.04–1.64]), with PE actuarial rate of 0.25% at 3 months; however, the overall mortality is 14.7% (Rosencher, Vielpeau, Emmerich, Fagnani, & Samama, 2005). Indeed, hip-fracture patients belong to a vulnerable group of old people with comorbid diseases that put them at high risk for postoperative VTE morbidity and mortality. Residents in long-term care (LTC) facilities and hospitals account for about 60% of diagnosed VTE events (Heit et al., 2002).

Well-known risk factors for VTE include advanced age; obesity; trauma; hypertension; those with a diagnosis of cancer, congestive heart failure, chronic obstructive pulmonary disease, or chronic kidney disease, especially nephrotic syndrome; trauma; and those undergoing major surgery, including laparoscopic surgery (Buesing, Mullapudi, & Flowers, 2015). Appropriate screening using evidence-based clinical decision rules (CDRs) is warranted among perioperative older adults (Siccama et al., 2011) in the light of the 2008 Surgeon General's office call to action to prevent the estimated 350,000 to 600,000 annual VTE cases in the United States (Leavitt, 2008). To maintain the safety and reduce harm, nurses need to observe TJC's guidelines related to the use of anticoagulants (TJC, 2019b). VTE prophylaxis should be initiated 24 hours before surgery and continued thereafter as clinically indicated (Cataife, Weinberg, Wong, & Kahn, 2014; TJC, 2019b).

Special Population: Bariatric Surgery

Current U.S. estimates indicate approximately one third of persons older than 65 years are obese (Fakhouri et al., 2012). As a result, there is a consequent rise of bariatric surgery among this age group. Although there has been some debate on the safety of bariatric surgery among older adults, a systematic review and meta-analysis declared the procedure to be safe for those aged 55 years and older (Giordano & Viktorzon, 2015). Implementation of early mobility protocol, VTE prophylaxis, use of incentive spirometer, and optimized pain management will enhance positive outcomes for this high-risk procedure.

Preoperative Fasting Guidelines

The traditional practice of not letting patients eat or drink after midnight ("NPO after midnight") before general anesthesia aims to reduce the volume and acidity of stomach contents during surgery, thus reducing the risk of regurgitation or aspiration. Prolonged fasting has been associated with adverse physical and psychological perioperative complications such as irritability, headache, dehydration, emesis, hypotension, hypovolemia, and hypoglycemia (Brady, Kinn, & Stuart, 2003).

Current guidelines recommend fasting of 2 hours for clear liquid and 6 hours for a light meal (ASA, 2011). Nurses should be familiar with institutional fasting procedures and be proactive in evaluating outdated policies that might impact the well-being of older adult patients. Another important consideration is determining which medications (e.g., beta-blockers) the patient should continue taking in spite of fasting requirements. The administration of oral carbohydrate drinks 2 hours before surgery (also known as carbohydrate loading) is shown to attenuate insulin resistance, minimize protein losses, reduce hospital stays, and improve patient comfort without adversely affecting gastric emptying (Bilku, Dennison, Hall, Metcalfe, & Garcea, 2014).

Surgery and Do-Not-Resuscitate Orders

Although information on advance directives, such as a healthcare proxy, is now routinely collected during patient interviews, the discussion on do-not-resuscitate (DNR) orders remains a sensitive topic. This highlights the importance of clear communication among the patient or designated surrogate and the provider. The suspension of DNR orders during the perioperative period is determined by hospital policy.

The nursing staff provides high-quality care regardless of the patient's DNR status. Nurses need to communicate advance directive information during handoff and care transitions. In patient teaching, nurses may interpret for the patient and designated surrogate unfamiliar language of advance directives and related institutional policies. It is important to uphold the patient's autonomy and right to self-determination.

CASE STUDY 38.1

Mr. P is an 85-year-old male patient who was brought in by ambulance after falling in his apartment, where he lives alone. He reported to have slipped while getting out of bed. He remained conscious but felt pain on his right hip. He denied headache, loss of consciousness, chest pain, palpitation, and dizziness. After he managed to get up from the floor, he called his son on the phone, who, in turn, called the emergency medical service (EMS). Mr. P's past medical history includes coronary artery disease (CAD), coronary artery bypass graft in 2005, atrial fibrillation (on warfarin), permanent pacemaker, peripheral vascular disease, end-stage renal disease (ESRD; on hemodialysis on Mondays, Wednesdays, and Fridays), and anemia of chronic disease. He has an allergy to sulfa drugs (rash). Mr. P is a resident of an assisted living facility.

On arrival in the ED, he was awake, alert, and oriented to self and place, but not to time. His right arm and forehead have multiple bruises and abrasions. Up until very recently, he has been mostly independent in performing his activities of daily living (ADL) and can ambulate using a walker. He gets physical therapy at home five times a week, and his last hospitalization was 6 months ago for pneumonia.

In the ED, his vital signs were as follows: blood pressure (BP): 124/76 mmHg, heart rate (HR): 60/min (paced rhythm), respiratory rate (RR): 17 regular, temperature: 36.9°C, and his oxygen saturation was 97% on room air. His current body mass index (BMI) is 25. His physical examination was unremarkable other than an external rotation and abduction of his right leg and exertional pain on the right hip area (6/10) as well as bruising on the hip area. An x-ray of the right hip revealed a comminuted intertrochanteric fracture with mild displacement of bone fragments. The head CT scan showed no evidence of acute intracranial trauma. Mr. P has a right brachial arteriovenous fistula for dialysis. His baseline lab values are shown in Exhibit 38.1.

EXHIBIT 38.1
Mr. P's Current Lab Results

Na: 139 mEq/L	WBC: 6.9 × 10^3/μL	Albumin: 3.6 g/dL
K: 4.6 mEq/L	Hemoglobin: 11.1 g/dL	Calcium: 10 mg/dL
Cl: 98 mEq/L	Hematocrit: 34.1%	Magnesium: 2.0 mEq/L
CO_2: 25 mEq/L	Platelets: 140 × 10^9/L	Phosphorus: 4.0 mg/dL
BUN: 40 mg/dL	Prothrombin time: 25.4 seconds	Troponin: 0.2 μg/L
Creatinine: 4.0 mg/dL	INR: 2.2	

BUN, blood urea nitrogen; Cl, chlorine; CO_2, carbon dioxide; INR, international normalized ratio; K, potassium; Na, sodium; WBC, white blood cells.

(*continued*)

CASE STUDY 38.1 (*continued*)

Mr. P's current home medications include warfarin, sevelamer carbonate, cetirizine, baby aspirin, docusate sodium, senna, and multivitamins. He denied alcohol or other chemical dependency issues. His son, who is named in the patient's healthcare proxy, lives nearby and is actively involved in his care.

Discussion

1. What are the priority assessments and interventions for Mr. P in the ED?

Given that Mr. P was not in acute distress and his vital signs were stable when he arrived in the ED, the care team would conduct a comprehensive geriatric assessment and request consult with an orthopedic surgeon as soon as possible. If available within the facility, a call for a geriatric consult (MD or APRN [advanced practice registered nurse]) should also be arranged. Assessment and evaluation of his right hip pain should be performed. The choice of pain medication needs to take into consideration his ESRD. For mild to moderate pain, acetaminophen may be prescribed. Drugs, such as meperidine and ketorolac, are best avoided in treating pain in older adult patients. Nonpharmacologic interventions for pain should also be explored. Because of Mr. P's elevated international normalized ratio (INR), his warfarin should be stopped, and he should be monitored for bleeding and changes in neurologic status. In anticipation of surgery, his aspirin should also be held.

Preoperative Optimization

2. Describe the best practices for preoperative optimization for Mr. P.

Maintaining patient safety is a priority for Mr. P. Once a hospital bed has been assigned, he should be transferred as soon as possible. Stabilizing his fracture might require the use of an abduction pillow. A bedside discussion with his son and the orthopedic surgeon determined that a closed reduction and intramedullary nailing will be performed once the INR is less than 1.5 and a cardiology clearance is obtained. Mr. P expressed optimism and understanding of the operative procedure, and he signed the consent himself.

A comprehensive preoperative workup should include assessment of Mr. P's cognitive status (using the Mini-Cog tool), depression screening, and identifying risk factors for developing postoperative delirium. The cardiology consult would entail obtaining a 12-lead EKG, serial Troponin, an echocardiogram, and a chest x-ray. Mr. P's telemetry reading shows a paced rhythm. Routine blood tests would include a complete blood count, renal profile, and coagulation profile. In anticipation of possible fresh frozen plasma (FFP) transfusion, a blood type and screen would be needed. A urinalysis is not recommended because Mr. P is anuric and has no risk of urinary tract infection. Mr. P's current lab values are consistent with his ESRD diagnosis, with no critical levels requiring immediate intervention.

Initial medication reconciliation revealed Mr. P takes metoprolol 25 mg twice a day, though this was not reflected in his original list of medications. Metoprolol is added to his current medication orders. A physical therapy consult determined a plan for postop bedside therapy. As a result of increased risk of VTE, pneumatic sequential compression sleeves were applied. Because of his ESRD, heparin 5,000 units every 12 hours, instead of low-molecular-weight heparin, was ordered for VTE prophylaxis.

Bedside hemodialysis was scheduled and a renal/cardiac diet was ordered. To optimize and to prevent further reduction of physiologic reserve, it is essential that Mr. P consumes enough calories and adequate hydration within the context of his ESRD. A nutrition consultation recommended two cans per day of high-calorie supplemental drink for renal patients and multivitamins. It is important that the nursing staff assist and encourage Mr. P to eat. Nursing handoff should include findings on how well Mr. P is meeting caloric requirements as well as intake and output balance. Taking all the relevant clinical data, a frailty score can be calculated for Mr. P, and this information should be shared during interprofessional rounds.

Intraoperative Considerations

Five days after admission, Mr. P was scheduled for a 9 a.m. closed reduction and intramedullary nailing under general anesthesia. Hemodialysis was done in the late afternoon before surgery. His latest INR was 1.4. He did not require any FFP transfusion, and his vital signs reflected baseline patterns. He remained alert and

(*continued*)

CASE STUDY 38.1 (*continued*)

oriented to self, place, and time. Morphine 2 mg intravenous (IV) push every 4 hours as needed was ordered for pain, although Mr. P hardly requested medication for pain. The nursing staff continued to perform turning every 2 hours to prevent pressure injuries.

3. Describe safety and quality benchmarks for the care of older adults within the intraoperative continuum.

A standardized electronic preoperative checklist was used to ensure that key assessment parameters were met. A copy of the consent was kept in the chart. The nursing staff verified that Mr. P had the correct name and allergy bands. On the evening before the surgery, patient education using teach-back was reinforced to verify Mr. P's comprehension of the procedure. This is also an opportunity to reinforce postoperative teaching topics, such as using the incentive spirometer, and to provide reassurance to the patient and family. Mr. P was informed that he could continue to drink and eat a light meal after midnight if desired. He was notified that in the morning he could take his metoprolol with a sip of water. Parameters for withholding the metoprolol dose have been included in the medication order.

The nursing care focus was to allow Mr. P a restful night, continue VTE prophylaxis using the pneumatic sleeves, discontinue heparin the day before surgery, and continue delirium surveillance. The nurse anesthetist and orthopedic surgeon examined Mr. P and reviewed his latest lab values. Based on the nature of the procedure, hair removal was not indicated. A gauge-22 IV needle was placed on his left arm for intermittent or emergency use. The patient care technician assisted Mr. P with his bedbath.

An RN-to-RN handoff report using a standardized form took place before Mr. P was picked up for the OR. His son and grandson accompanied him to the OR entrance and were notified where to wait until Mr. P's return from the PACU. During the bedside handoff, the plan of care was communicated using the electronic health record.

Within 60 minutes before the surgical incision, Mr. P received an IV infusion of cefazolin (adjusted renal dose based on his latest glomerular filtration rate [GFR]) with no untoward reactions. Throughout his stay in the OR, his temperature was kept within normal limits through the use of warm blankets and a head covering. The circulating nurse made sure that the SCIP core measures were followed at all times.

Immediate Postoperative Considerations

4. Discuss key parameters of assessment and intervention of older adults in PACU.

When the surgery was completed, an RN-to-RN handoff report took place using a standardized form. On arrival in the PACU, the priority focus was to maintain a patent airway and adequate oxygenation because Mr. P had just been extubated. Mr. P's vital signs, telemetry rhythm, and pain were assessed, followed by a comprehensive head-to-toe examination, focusing on the surgical site and signs of delirium. A warming blanket was used to maintain Mr. P's temperature at greater than or equal to 96.8°F. Pneumatic sequential compression devices for both legs were continued. The RN reviewed Mr. P's current medication orders, particularly focusing on starting the patient-controlled analgesia (PCA) morphine and continuation of beta-blockers. Cefazolin 1 g IV piggyback once daily was to be continued for another 24 hours. During his stay in the PACU, Mr. P was monitored for signs of pain, agitation, and delirium using validated tools such as the confusion assessment method for the ICU (CAM-ICU). The PACU nurse notified Mr. P's family of his current status and his expected return to his surgical room.

SUMMARY

The perioperative period is a highly vulnerable time for older adults. Safe, quality patient care requires meaningful implementation of various evidence-based guidelines discussed in this chapter. The benefits of high-quality interprofessional team collaboration cannot be overemphasized. Regardless of the type of surgery, a comprehensive plan of care that takes into account the patient's values and preferences is desirable. Meeting the various perioperative core measures unique to the older adult population will rely on a seamless, albeit challenging, synthesis of various specialty practice recommendations, models of care, and understanding of geriatric syndromes, as well as clinical judgment and provider expertise.

NURSING STANDARD OF PRACTICE

Protocol 38.1: Perioperative Care of the Older Adult

I. GOAL

To restore physiologic stability, prevent complications, maintain comfort and safety, and preserve pre-illness functional ability and QOL in older adults throughout the perioperative continuum

II. OVERVIEW

A. From 2003 to 2012, the most frequently performed OR procedures for persons over 65 were knee arthroplasty, percutaneous coronary angioplasty (PTCA), hip replacement, laminectomy, spinal fusion, and colorectal resection (Fingar, Stocks, Weiss, & Steiner, 2014).
B. A 10% increase in the proportion of staff nurses holding a bachelor's degree is associated with a 7% decrease in the risk of death among patients following common surgeries in an acute care setting (Aiken et al., 2014).
C. Lower rates of postoperative VTE and shorter length of stay have also been found in hospitals with a higher percentage of RNs with baccalaureate or higher degrees (Blegen et al., 2013).
D. Comprehensive preoperative geriatric assessment correlates with positive postoperative outcomes in older patients (Partridge et al., 2014).

III. BACKGROUND

A. Definition
   1. *Perioperative nursing* is defined as the "delivery of comprehensive care within preoperative, intraoperative and postoperative periods of the patient's experience during operative and other invasive procedure" (Steelman, 2015, p. 1). The high-stake demands of perioperative patient care, the increasing number of older adults undergoing surgery, and the unique vulnerabilities of this population require the translation of science-based interprofessional collaboration. The use of the nursing process, critical thinking, and evidence-based practice models will ensure patient safety and quality for older adult patients and their families.
B. Etiology/epidemiology
   1. The demand for surgical procedures is expected to rise with the aging population.
   2. In 2014, 10.1 million inpatient hospital stays involved operating room (OR) procedures, with a total of 14.2 million OR procedures (McDermont et al., 2017).
   3. Procedures that place the patient at the most risk include those that involve general anesthesia or deep sedation (TJC, 2019b).
   4. Failure-to-rescue was more than two times higher in patients older than 75 years compared with those younger than 75 years (26.0% vs. 10.3% at high-mortality hospitals, *p* less than 001; Sheetz et al., 2014).
   5. Death (failure-to-rescue) among surgical inpatients with treatable serious complications and the percentage of major surgical inpatients who experience hospital-acquired complications (e.g., sepsis, pneumonia, gastrointestinal bleeding, shock/cardiac arrest, VTE) are nursing-sensitive measures and publicly reportable events (NQF, 2017).
   6. A 10% increase in the proportion of staff nurses with a bachelor's degree is associated with a 7% decrease in the risk of death among patients following common surgeries in an acute care setting (Aiken et al., 2014).
   7. Lower postoperative VTE and shorter length of stay are associated with higher percentage of RNs with baccalaureate or higher degrees (Blegen et al., 2013).
   8. Perioperative beta-blocker therapy is associated with a reduced risk of in-hospital death among high-risk, but not low-risk, patients undergoing major noncardiac surgery. Patient safety may be enhanced by increasing the use of beta-blockers in high-risk patients (Lindenauer et al., 2005).

(*continued*)

Protocol 38.1: Perioperative Care of the Older Adult (*continued*)

IV. PARAMETERS OF ASSESSMENT

A. The ACS-NSQIP and the AGS's *Best Practices Guidelines for Optimal Preoperative Assessment of the Geriatric Surgical Patient* recommend the following preoperative assessment parameters (Chow et al., 2012):
   1. Assess the patient's cognitive ability and capacity to understand the anticipated surgery.
   2. Screen the patient for depression.
   3. Identify the patient's risk factors for developing postoperative delirium.
   4. Screen for alcohol and other substance abuse/dependence.
   5. Perform a preoperative cardiac evaluation according to the ACC/AHA algorithm for patients undergoing noncardiac surgery.
   6. Identify the patient's risk factors for postoperative pulmonary complications and implement appropriate strategies for prevention.
   7. Document functional status and history of falls.
   8. Determine baseline frailty score.
   9. Assess the patient's nutritional status and consider preoperative interventions if the patient is at severe nutritional risk.
   10. Take an accurate and detailed medication history, and consider appropriate perioperative adjustments. Monitor for polypharmacy.
   11. Determine the patient's treatment goals and expectations in the context of the possible treatment outcomes.
   12. Determine the patient's family and social support system.
   13. Order appropriate preoperative diagnostic tests based on unique clinical scenarios of elderly patients.

B. For comprehensive preoperative evaluation, the provider should inquire about symptoms, such as angina, dyspnea, syncope, and palpitations, as well as history of heart disease, including ischemic, valvular, or myopathic disease; and history of hypertension, diabetes, chronic kidney disease, and cerebrovascular or peripheral artery disease (Bilimoria et al., 2013).

C. For geriatric fracture patients, recommended preoperative optimization focus includes (Nicholas, 2014b):
   1. Assurance of adequate intravascular volume
   2. Medication adjustment in anticipation of intraoperative hypotension
   3. Judicious continuation of beta-blockers and other antiarrhythmic chronotropic drugs for selected patients
   4. Pain management
   5. Prevention of polypharmacy and excessive laboratory testing

D. Orthopedic surgery services should ensure that patients are operated on within 1 or 2 days of admission when cleared for surgery (Moja et al., 2012).

E. In patients assessed to be at intermediate or high cardiovascular risk, a referral to a cardiologist for further evaluation is recommended (Fleisher et al., 2014).

F. Adjust dose of medications according to renal function using GFR parameters.

G. Implement the 2014 SCIP Core Measure Set (TJC, 2014).
   1. Prophylactic antibiotic received within 1 hour before surgical incision
   2. Prophylactic antibiotics discontinued within 24 hours after surgery end time
   3. Cardiac surgery patients with controlled postoperative blood glucose
   4. Surgery patients with appropriate hair removal
   5. Urinary catheter removed on POD 1 or 2 with day of surgery being day 0
   6. Perioperative temperature management
   7. Those who were under beta-blocker therapy before arrival received a beta-blocker during the perioperative period.
   8. Received appropriate VTE prophylaxis within 24 hours before surgery to 24 hours after surgery

(*continued*)

Protocol 38.1: Perioperative Care of the Older Adult (*continued*)

H. Improve medication safety within the perioperative settings through the following measures: (TJC, 2019b)
   1. Label all medications, medication containers, and other solutions on and off the sterile field in perioperative and other procedural settings.
   2. Label medications and solutions that are not immediately administered. This applies even if there is only one medication being used.
   3. Label any medication or solution transferred from the original packaging to another container.
   4. Verify all medication or solution labels both verbally and visually.
   5. Label each medication or solution as soon as it is prepared, unless it is immediately administered.
   6. Discard immediately any medication found unlabeled.
   7. Remove all labeled containers on the sterile field, and discard their contents at the conclusion of the procedure.
   8. Review all medications and solutions both on and off the sterile field.

I. Implement SSI prevention guidelines (TJC, 2019b)
   1. Educate staff and licensed independent practitioners involved in surgical procedures about SSIs and the importance of prevention.
   2. Educate patients who are undergoing a surgical procedure and their families about SSI prevention as needed.
   3. Implement policies and practices aimed at reducing the risk of SSI.
   4. Conduct periodic risk assessments for SSI.
   5. Select SSI measures using best practices or evidence-based guidelines.
   6. Monitor compliance with best practices or evidence-based guidelines.
   7. Evaluate the effectiveness of prevention efforts.

J. Consistently implement TJC's Time Out and Universal Protocol guidelines that include the following (TJC, 2019b):
   1. Implement a preprocedure process to verify the correct procedure, for the correct patient, at the correct site. Involve the patient in the verification process when possible.
   2. Identify the items that must be available for the procedure, and use a standardized list to verify their availability.
   3. Match the items that are to be available in the procedure area to the patient.
   4. Identify those procedures that require marking of the incision or insertion site. At a minimum, sites are marked when there is more than one possible location for the procedure and when performing the procedure in a different location would negatively affect quality or safety.
   5. Mark the procedure site before the procedure is performed and, if possible, with the patient involved.

V. NURSING CARE STRATEGIES

Synthesis of perioperative best practices guidelines (AORN, 2006; Bratzler et al., 2013; Chow et al., 2012; Fleisher et al., 2014; TJC, 2019b) provides collaborative nursing opportunities across the perioperative continuum.

A. Preoperative
   1. Perform a comprehensive assessment: History and physical examination, cognitive and functional assessment, medication reconciliation, nutrition, advance directives, and so on, using validated tools and checklists (Chow et al., 2012).
   2. Collect nursing-sensitive data during interview with patient and family.
   3. Review, document, and interpret pertinent laboratory and diagnostic findings, specific to patient's clinical scenario.
   4. Assess, review, and document vital signs, including glucose finger stick (e.g., blood sugar goal) and other disease-specific lab values as appropriate.
   5. Educate patient and family using teach-back method on routine (e.g., consent, fasting requirement [2 hours for clear liquid and 6 hours for light meal], patient escort) and special topics (e.g., bowel preparation or withholding specific drugs, such as metformin, after an angiogram).

(*continued*)

Protocol 38.1: Perioperative Care of the Older Adult (*continued*)

6. Conduct medication reconciliation (TJC, 2019b), focusing on Beers Criteria for potentially inappropriate medication use in older adults (AGS, 2015).
7. Evaluate use of cardiac drugs throughout perioperative continuum. In particular, the guidelines for perioperative use of beta-blockers recommend to (Fleisher et al., 2014):
   a. Continue beta-blockers, particularly those with independent cardiac indications such as arrhythmia or history of myocardial infarction.
   b. Continue beta-blockers in patients undergoing intermediate risk or vascular surgery with known coronary artery disease or with multiple clinical risk factors for ischemic heart disease.
   c. Titrate to a heart rate of 60 to 80 beats/min in the absence of hypotension.
   d. Titrated rate control with beta-blockers should continue during the intraoperative and postoperative periods.
   e. Beta-blockers should be tapered off slowly to minimize risk of withdrawal.
8. Inform patient or caregiver to bring all home medications on the day of procedure, especially for outpatient same-day surgery.
9. Reinforce appropriate VTE prophylaxis within 24 hours before surgery (Cataife et al., 2014; TJC, 2019b).
10. Facilitate appropriate hair removal before surgery (TJC, 2019b).
11. Implement POSH interventions for elective surgery patients (McDonald et al., 2018).
12. Provide carbohydrate loading as per hospital protocol (Bilku et al., 2014).
13. Calculate risk using the Surgical-Risk Calculator (http://riskcalculator.facs.org/RiskCalculator/PatientInfo.jsp; Bilimoria et al., 2013).

B. Intraoperative
1. Participate in high-quality interprofessional Time Out and handoff procedure (TJC, 2019b).
2. Safely administer antibiotics within 60 minutes before surgical incision. For some agents that require longer administration time, such as fluoroquinolones and vancomycin, infusion can begin 120 minutes before incision. Redosing of antibiotic is recommended if the procedure exceeds two half-lives of the drug or if there is excessive blood loss during surgery (Bratzler et al., 2013).
3. Safely administer beta-blocker during the perioperative period if applicable (Blessberger et al., 2018).
4. Assess and manage patient temperature intraoperatively (e.g., active warming to maintain greater than or equal to 96.8°F 30 minutes before anesthesia or 15 minutes post anesthesia end time).
5. Maintain asepsis and sterility of the operative field.
6. Keep OR doors closed during surgery except as needed for passage of equipment, personnel, and the patient (Berríos-Torres, 2009).
7. Monitor intraoperative systems processes throughout the procedure.
8. Follow procedure and policy related to prevention on unintended retention of foreign objects intraoperatively.
9. Follow CDC infection control guidelines in handling infectious materials (e.g., specimen, equipment).
10. Use supplemental oxygen judiciously during the perioperative period (Wetterslev et al., 2015).
11. Implement pressure injury prevention measures (Spruce, 2017).

C. Postoperative
1. Perform high-quality handoff during care transitions (e.g., between the OR and PACU using standardized forms or checklists; TJC, 2019b).
2. Maintain patient safety during transfer and handoff.
3. Monitor vital signs per institution protocol, including hemodynamic profile and glucose finger stick, if applicable.
4. Assess and document pain, including pharmacologic and nonpharmacologic interventions.
5. Maintain patient temperature at greater than or equal to 96.8°F.
6. Monitor blood sugar as clinically applicable (e.g., SCIP measure for cardiac surgery patients is to keep serum glucose greater than or equal to 200 mg/dL 18 to 24 hours postoperation; Fry, 2008).

(*continued*)

Protocol 38.1: Perioperative Care of the Older Adult (*continued*)

7. Monitor patient's GFR, assess patient's urine output and weight, and follow protocol/procedures in administering nephrotoxic medications.
8. Coordinate medication reconciliation, with special attention to beta-blockers (TJC, 2019b) and antidiabetic medications.
9. Implement safe VTE prophylaxis within 24 hours before surgery or 24 hours postoperation (e.g., compression stockings or pneumatic compression devices, heparin, low-dose heparin; Buesing et al., 2015; TJC, 2019b).
10. Protect primary closure incisions with sterile dressing for 24 to 48 hours post operation (Fry, 2008).
11. Discontinue antibiotics within 24 hours after surgery end time (48 hours for cardiac surgery; Fry, 2008).
12. Provide timely and accurate information to patient and family members.
13. Resume diet as clinically appropriate.
14. Avoid medications that induce delirium postoperatively (e.g., anticholinergics, sedative-hypnotics, diphenhydramine; American Geriatrics Society [AGS], 2012).
15. Use validated delirium screening instruments (AGS, 2014).
16. Implement early mobility protocol (Goldfarb, Afilalo, Chan, Herscovici, & Cercek, 2018).
17. Implement nonpharmacologic interventions to improve sleep (Tamrat, Huynh-Le, & Goyal, 2014).
18. Coach patient to use incentive spirometer.

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient outcomes
   1. Maintain patient safety across the perioperative continuum.
   2. Assess patient decision-making capacity, and honor patient and family care decision choices.
   3. Receive a comprehensive preoperative screening, including, but not limited to, the following domains: Cognitive and behavioral, cardiopulmonary, functional status, nutrition, medication, and frailty.
   4. Undergo clinically relevant preoperative testing (e.g., blood, urine, radiologic, EKG, etc.) based on best practice evidence (see ACS-NSQIP/AGS Best Practice Guidelines Optimal Preoperative Assessment of the Geriatric Surgical Patient).
   5. Optimize function across the perioperative continuum.
   6. Receive timely and accurate information related to plan of care, including transitional care and long-term follow-up.
   7. Patient will not develop postoperative complications such as SSI, DVT, cardiopulmonary adverse events, falls, and pressure injuries.
   8. Patient will be free from adverse events such as medication errors, wrong site-procedure events, anesthesia-related events, and issues.

B. Provider outcomes
   1. Receive education and ongoing training on best practices in the care of the geriatric surgical patient.
   2. Assess patient's decision-making capacity and obtain informed consent.
   3. Implement latest guidelines for antimicrobial prophylaxis in surgery (e.g., receive antibiotics within 60 minutes before surgical incision).
   4. Participate in high-quality interprofessional collaboration across the perioperative continuum, including rounding, handoff, Time Out/Universal Protocol, pain management, SSI prevention, early mobility, nutrition, medication reconciliation, and transitional care.
   5. Use an evidence-based teamwork system to improve communication and teamwork skills (e.g., TeamSTEPPS) for patient safety (AHRQ, n.d.).
   6. Apply teach-back method in all patient education encounters that are culturally competent and patient-centered.
   7. Employ consistent and accurate documentation of care throughout the perioperative continuum.
   8. Provide patient and caregivers with timely and accurate information of patient's condition and plan of care, including care transitions.

(*continued*)

Protocol 38.1: Perioperative Care of the Older Adult (*continued*)

9. Perioperative nurses achieve a minimum of bachelor's degree and obtain practice-specific certification (e.g., gerontological nursing, CNOR).
10. Organize and participate in unit-based practice and quality-improvement councils.

C. Systems outcomes
1. Uphold patient safety and quality in the care of older adults through policy and social statements (e.g., safety language in hospital's mission).
2. Review and align existing institutional policies and procedures with latest national standards (see "Practice Guidelines" section).
3. Facilitate and sustain interprofessional geriatrics care teams.
4. Monitor, evaluate, and disseminate hospital performance in perioperative benchmarks such as Time Out/Universal Protocol, antibiotic prophylaxis, DVT prophylaxis, and other site-specific parameters.
5. Establish a system of reporting patient safety issues (e.g., falls, medication errors, unintended retention of foreign object, wrong-patient, wrong-site, wrong-procedure, etc.) across the perioperative continuum to identify opportunities for improvement.
6. Adopt specific patient safety initiatives for older adults that include use of informatics, algorithms, checklists, and personnel oversight.
7. Develop ongoing quality-improvement initiatives consistent with SCIP core measures and other practice guidelines.
8. Facilitate clinical rotation for nursing students across the perioperative units to promote experiential learning for prelicensure students.
9. Enforce SSI prevention policies and conduct SSI surveillance based on CDC and TJC guidelines.
10. Organize and support interprofessional unit-based practice and quality-improvement councils (IHI, n.d.).
11. Demonstrate a commitment to culture of safety based on openness and mutual trust (e.g., patient safety leadership walk rounds; IHI, n.d.).
12. Monitor hospital-acquired perioperative pressure injuries.

General Surgical Care of the Older Adult*

Fidelindo Lim and Larry Z. Slater

39

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify the unique challenges associated with the care of older adults following surgery.
2. Integrate preoperative and perioperative assessment and plans into the postoperative care plan for older adults following surgery.
3. Synthesize current best practices in the assessment and interdisciplinary management of the older adult surgical patient.
4. Describe evidence-based nursing and interprofessional interventions to improve outcomes among older adult surgical patients.

OVERVIEW

Older adult surgical patients offer unique challenges for the multidisciplinary team from the postoperative period to discharge. Physiological changes of aging (e.g., decreased cardiac and respiratory reserve, impaired kidney and liver function, and loss of muscle mass) can significantly affect the recovery time of older adult surgical patients and put them at greater risk for postoperative complications (Lixie, Edgeworth, & Shamir, 2015; Makary et al., 2010). In addition, older adults often present for elective and nonelective or emergent surgeries with a number of medical comorbidities that place them at further risk of postoperative morbidity and mortality (Dasgupta, Rolfson, Stolee, Borrie, & Speechley, 2009). The risk of complications and mortality continues to increase with advancing age, with those aged 90 years and older experiencing twice the rate of mortality at less than 48 hours post surgery as compared to those younger than 65 years (Deiner, Westlake, & Dutton, 2014).

As the number of surgeries for older adults continues to rise, with adults aged 65 years and older currently accounting for 34% of all surgeries (Deiner et al., 2014), it is imperative that nurses in intensive care, step-down, and medical–surgical units develop competencies in working with a multidisciplinary team to provide patient-centered care for older adult surgical patients. Such care can help maximize recovery, facilitate a return to baseline functioning, and decrease the time to discharge. Longer lengths of stay have been consistently linked to increased postoperative adverse outcomes (Makary et al., 2010). Blegen, Goode, Park, Vaughn, and Spetz (2013) found that surgical patients at hospitals with a higher percentage of

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

nurses with a baccalaureate or higher degree experienced shorter lengths of stay and less postoperative complications. Similarly, Aiken et al. (2014) demonstrated that a higher education level for nursing staff decreased mortality risk among surgical patients. These studies underscore the importance of nurses receiving initial and ongoing education and training in providing evidence-based care to older adult surgical patients.

BACKGROUND AND STATEMENT OF PROBLEM

In spite of its common use as a descriptor of a population subset, there is no universal criterion for what defines older adults. The use of 65 years as a cutoff age is being questioned based on the notion that physiological age is more clinically relevant than chronological age (White et al., 2012). In the developed world, the syndromes most relevant to geriatricians (e.g., dementia, frailty) are most common after age 80. In other areas, such as sub-Saharan Africa, older people may be defined as over age 50 (Shenkin, Harrison, Wilkinson, Dodds, & Ioannidis, 2017). By 2030, all baby boomers will be older than age 65, and older adults are projected to outnumber children for the first time in history (United States Census Bureau, 2018).

In 2010, older adults (aged 65 years and older) had a total of 19.2 million operative procedures performed in acute care settings (Centers for Disease Control and Prevention [CDC], 2010). In addition, they accounted for more than 37% of all procedures and 45% of total hospital days of care (CDC, 2010). As the population continues to age, the number of operative procedures and hospital stays for older adults will only increase. Hospital stays that involve surgical procedures have been shown to be more costly, require longer lengths of stay, and result in higher morbidity and mortality (Weiss & Elixhauser, 2014), so it is imperative that nurses address the specific needs of older adult surgical patients.

The American Geriatrics Society (AGS, 2007) developed quality indicators related to care of vulnerable elders (Assessing Care of Vulnerable Elders [ACOVE]), which include sections on hospital care, surgery, and perioperative care. The indicators address several key areas that fall under the purview of nurses providing general surgical care of the older adult: Venous thromboembolism (VTE) prophylaxis, infection prevention, delirium screening and prevention, mobilization, fall prevention, and discharge assessment (AGS, 2007). An expert panel, with funding from the National Institute on Aging (NIA), also developed a list of process-based quality indicators for older adult surgical patients, applicable across disciplines, to improve surgical care and outcomes (McGory et al., 2009). The panel rated 91 indicators as valid for surgical management of the older adult, which direct the assessment and management of critical areas in order to prevent postoperative complications, decrease lengths of stay, and facilitate discharge transitions (McGory et al., 2009). The report highlighted the need for comprehensive baseline status assessment and the use of an interdisciplinary team with surgical and geriatric expertise to follow the patient from preop to discharge, facilitating as quick a return as possible to presurgery functioning (McGory et al., 2009). The indicators were similar to the ACOVE indicators: Nutrition, hydration, pain management, delirium, respiratory function, infection prevention, mobility/ambulation, functional status, fall prevention, skin integrity, and restraint use (McGory et al., 2009).

This chapter provides the latest evidence and guidelines for the management of the stable older surgical patient in each of these key areas outlined by the ACOVE (AGS, 2007) and NIA Expert Panel (McGory et al., 2009) quality indicators. In addition, the nurse's responsibilities related to discharge planning will be highlighted. The discussion also provides, where applicable, the identification of applicable Joint Commission (TJC) National Patient Safety Goals (TJC, 2019) and National Quality Forum (NQF) National Database of Nursing Quality Indicators (NDNQI; Montalvo, 2007). For a discussion on the comprehensive management of critically ill, older patients, please refer to Chapter 35, Comprehensive Assessment and Management of the Critically Ill Older Adult.

ASSESSMENT OF THE PROBLEM AND NURSING CARE STRATEGIES

Enhanced Recovery After Surgery

Enhanced recovery after surgery (ERAS) is an evidence-based, multidisciplinary approach to the care of the surgical patient that has been shown to improve patient outcomes while decreasing length of stay and overall cost (Ljungqvist, Scott, & Fearon, 2017). ERAS programs address care from preadmission through the perioperative phase and into postdischarge. ERAS guidelines currently exist for a number of surgeries, including hip and knee replacement, the most common operative procedures for older adults, as well as for anesthesia protocols. For those undergoing hip and knee arthroplasty, a systematic review and meta-analysis by Zhu, Qian, Jiang, Ye, and Chen (2017) showed that ERAS significantly reduced length of stay and better pain management and led to fewer complications; however, there was no significant reduction in 30-day readmission rates.

Patient Safety Indicators

The Patient Safety Indicators (PSIs) recommended by the Agency for Healthcare Research and Quality (AHRQ) guide assessment and screening for adverse events that patients experience as a result of exposure to the healthcare system (AHRQ, 2014). PSIs that are directly related to postsurgical care include (Weiss & Elixhauser, 2014):

- Death among surgical inpatients
- Central venous catheter (CVC)–related bloodstream infection
- Postoperative hemorrhage or hematoma rate, physiological and metabolic derangements, respiratory failure, pulmonary embolism or deep vein thrombosis (DVT), sepsis, and wound dehiscence
- Transfusion reaction

These high-risk and high-impact events are deemed amenable to prevention by changes at the system or provider level (AHRQ, 2014). Nurses play a pivotal role in the prevention and management of these events. In the next section, specific care topics directly or indirectly related to the PSIs are explored.

Postoperative Delirium and Cognitive and Sensory Function

Postoperative delirium can occur in up to 50% of high-risk older adult surgical patients, leading to prolonged and more costly hospitalizations, functional decline, and death (AGS, 2014). Older adult surgical patients are at a high risk for delirium for a number of causes, including medication side effects; immobility; infection; inadequate pain management; and cardiac, renal, and respiratory complications (Hughes, Leary, Zweizig, & Cain, 2013). In addition, routine hospital care may contribute to delirium resulting from effects on the patient's sleep–wake cycle and sleep deprivation, often related to routine procedures and hospital noise, and inattention to visual and hearing deficits, including lack of appropriate corrective lenses and hearing aids (Hughes et al., 2013).

The management of postoperative delirium begins before surgery. The ACOVE and NIA Expert Panel recommend that this assessment be performed 8 weeks before surgery (AGS, 2007; McGory et al., 2009). The AGS Expert Panel on Postoperative Delirium in Older Adults (2014) emphasizes the assessment of risk factors for postoperative delirium, with the presence of two or more factors placing the patient at greater risk for delirium after surgery. Moreover, patients should receive a comprehensive evaluation of cognitive and sensory (vision/hearing) function 8 weeks before surgery (McGory et al., 2009). Chapter 9, Assessing Cognitive Function in the Older Adult, discusses the assessment of cognitive function and Chapter 8, Sensory Changes in the Older Adult, outlines sensory changes in older adults. For more on preoperative (as well as intraoperative) management of delirium in surgical patients, see Chapter 38, Perioperative Care of the Older Adult.

Postoperatively, healthcare professionals with adequate training in the assessment and diagnosis of delirium should screen patients using validated screening instruments, at least daily or as clinically indicated, to diagnose postoperative delirium and institute early interventions (AGS, 2014). ACOVE recommends screening to occur for at least the first 3 days after surgery (AGS, 2007). Table 39.1 provides more specific medical evaluations,

TABLE 39.1

Evaluation of Precipitating Factors for Postoperative Delirium

Precipitating Factors	Evaluation
Environmental factors	
■ Inadequate pain control	Physical examination Pain assessment
■ Sleep deprivation ■ Use of restraints ■ Urinary catheterization ■ Poor vision/hearing	Review of records, nursing notes
Infection	
■ Urinary tract infection	Physical examination Urinalysis with white blood cell count
■ Pneumonia	Chest x-ray
■ Central-line and bloodstream infections	Blood, sputum, and urine cultures
■ Surgical site infection	Surgical site imaging, as needed Medication reconciliation
Delirium-inducing medications	Medication reconciliation
Metabolic derangement	
■ Hypoxia and acidosis	Vital signs and pulse oximetry
■ Electrolyte imbalances ■ Hypoglycemia ■ Dehydration ■ Anemia ■ Hypotension and shock	Laboratory evaluation, including electrolytes, creatinine, blood urea nitrogen, glucose, hematocrit, and blood gas analysis

(*continued*)

TABLE 39.1

Evaluation of Precipitating Factors for Postoperative Delirium (*continued*)

Precipitating Factors	Evaluation
Substance withdrawal	
■ Alcohol	Physical examination
■ Benzodiazepines	Social history
■ Illicit drugs	Preadmission medication reconciliation

Source: Data from the American Geriatrics Society. (2014). Clinical practice guideline for postoperative delirium in older adults. Retrieved from http://geriatricscareonline.org/ProductAbstract/american-geriatrics-society-clinical-practice-guideline-for-postoperative-delirium-in-older-adults/CL018. *Evidence Level I*.

which include both nursing and collaborative assessments, as listed by the AGS Expert Panel on Postoperative Delirium. These evaluations are also highlighted in the National Institute for Health and Care Excellence (2019) and the NIA Expert Panel quality indicators (McGory et al., 2009) for older surgical patients. Lagoo-Deenadayalan, Newell, and Pofahl (2011) also provide a useful mnemonic, *I'm Confused*, to summarize etiologies of delirium in surgical older adult patients. A variation of this mnemonic is shown in Box 39.1.

Chapter 20, Delirium: Prevention, Early Recognition, and Treatment, outlines in greater detail the prevention, recognition, and treatment of delirium in the older adult population. For the older surgical patient, however, there are some specific management dos and don'ts that need to be highlighted here. Given the breadth of factors that may lead to postoperative delirium, adequate nursing care, as emphasized in the rest of this chapter, that addresses the general surgical care of the older adult may help prevent delirium; it will also be essential in the management of delirium, should it occur. Although evidence has not demonstrated that specific units designed for older adult surgical patients or those with delirium improve patient outcomes, environmental adjustments remain an important component of care (AGS, 2014). These may include continuity of care (familiar residents, nurses, and care technicians), continuous environmental and personal orientation, availability of working hearing and vision aids, minimization of noise and interruptions to promote adequate sleep, and involvement of family and caregivers (BGS, 2006). In addition, the AGS (2014) and BGS (2006) emphasize the following pharmacological and nonpharmacological interventions.

BOX 39.1

Mnemonic for Potential Causes of Postoperative Delirium in Older Adult Surgical Patients

C	Cognitive impairment and dementia
O	Older (more than 70 years), overmedication (polypharmacy)
N	Nutritional deficiency
S	Stress, sleep deprivation
I	Infection, immobility, impaired vision and hearing
D	Depression, dehydration
E	Electrolyte abnormalities
R	Renal insufficiency
A	Acid–base disturbances
T	Toxins (alcohol withdrawal)
I	Inappropriate medications (anticholinergics, benzodiazepines, psychotropic meds)
O	Oxygen (hypoxia)
N	Noxious stimuli (pain, inflammation)

Pharmacological

- Adequate pain management, preferably with nonopioid pain medications
- Avoidance of delirium-inducing medications such as benzodiazepines, anticholinergics, diphenhydramine, histamine2-receptor antagonists, sedative–hypnotics, and meperidine (see also the AGS Beers Criteria; AGS, 2012)
- Avoidance of routine sedation or prophylactic antipsychotics

Nonpharmacological

- Use of nonpharmacological pain management strategies
- Adequate fluid and nutrition intake
- Promotion of early ambulation/mobility, physical, and occupational therapy
- Initiation of plans to prevent pressure injury, falls, and infection
- Prevention of complications (respiratory, cardiac, gastrointestinal [GI], and renal)
- Avoidance of unnecessary catheterization and restraint use

Pain Management

A large majority of hospitalized older adults experience pain or discomfort, but they are consistently less likely to receive adequate pain management than their younger counterparts (Schofield, 2014). Pain may be postoperative, but could also include the patient's chronic pain issues, which may be exacerbated as a result of the stress of surgery and/or hospitalization. A study in the United Kingdom found that although 81% of older adults were being treated in a hospital that had an acute pain service, only a small minority of them actually had a pain assessment chart (National Confidential Enquiry into Perioperative Deaths [NCEPOD], 1999). One reason may be the misconception that older adults have a higher pain threshold (Doerflinger, 2009). This may be compounded by the fact that older adults may be more hesitant to report pain, feeling that it is just a fact of life or possibly not wanting to be a bother to the nursing staff (Panprese & Johnson, 2014), or they may be concerned about becoming dependent on pain medications (Hughes et al., 2013). Pain management is further complicated if the older adult has cognitive or communication issues.

Adequate assessment and management of pain are the nurse's imperative for the older surgical patient, because a lack of pain control can lead to a host of complications, including delirium, depression, fluid imbalances, atelectasis, and fatigue (AGS, 2014; Bashaw & Scott, 2012). Pain assessments should be performed with each set of vital signs, at a minimum (McGory et al., 2009; Schofield, 2014), but are most effective when performed as part of hourly rounding. Assessments should include a rating of intensity (using numeric, verbal, or visual scales), a pain description (to address sensory and affective dimensions as well as the impact of pain on function), and observations of signs of pain, which are especially important for patients with cognitive or communication issues (Royal College of Physicians, British Geriatrics Society, & British Pain Society, 2007). For patients with dementia, a rating scale, such as Patient Assessment in Advanced Dementia (PAINAD), may be used to systematically gather pain data (Warden, Hurley, & Volicer, 2003). In addition, a family member or caregiver may be able to assist in identifying signs of pain in the person with dementia because he or she is often more experienced in recognizing subtle clues (Hughes et al., 2013).

Although pain assessment is an ongoing critical component of TJC Hospital Accreditation Standards (TJC, 2019), and pain has been assessed as the fifth vital sign since the Veterans Health Administration launched its initiative in 1999, there has been little improvement in the overall quality of pain management (Mularski et al., 2006). The NIA Expert Panel recommends that a comprehensive pain management plan should be offered to any patient with a pain score greater than 5 (McGory et al., 2009). However, it is best to set pain management plans and goals according to the individualized needs of the patient, and the plans must take into account any chronic pain-related conditions that already exist. ACOVE states that for complaints of moderate to severe pain, an intervention should be performed, reassessment of pain should occur within 4 hours, and documentation of the intervention and reassessment should be placed in the medical chart (AGS, 2007). In practice, pain reassessment often occurs within 15 minutes for intravenous (IV) medications and 1 hour for oral (PO) medications.

Chapter 22, Pain Management in the Older Adult, provides specific protocols for management of pain in older adult populations. When applying these protocols to the surgical patient, the nurse must also take into account medication side effects that can contribute to postoperative complications (e.g., morphine and constipation). ACOVE specifically recommends interventions to address constipation when the older adult surgical patient is on opioid therapy (AGS, 2007). These are described in greater detail in the following section on Nutrition and Gastrointestinal Complications. TJC (2014) provided a clarification to their pain management standard to express the many nonpharmacological strategies, such as massage, acupuncture, and cognitive behavioral therapy, which may be used as part of the pain management arsenal. These methods may be preferred over the use of nonsteroidal anti-inflammatory drugs (NSAIDs) because of the potential GI and renal complications associated with these medications (Griffiths et al., 2014).

Nutrition and Gastrointestinal Complications

Poor preoperative nutritional status can put the older adult surgical client at risk of serious postoperative complications, including impaired skin integrity, delayed wound healing, wound or other infections, sepsis, and death (Lagoo-Deenadayalan et al., 2011; Scandrett, Zuckerbraun, & Peitzman, 2015). As older adults may have several factors that put them at risk for malnutrition, such as financial constraints, social isolation, poor oral health, depression, alcohol use, or difficulties with meal preparation (Volkert, 2002), nutritional screening before surgery is of vital importance. In the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) and AGS *Best Practice Guidelines* on preoperative assessment, Chow, Rosenthal, Merkow, Ko, and Esnaola (2012)

list a body mass index (BMI) less than 18.5 kg/m^2, a serum albumin less than 3.0 g/dL, and unintentional weight loss greater than 10% to 15% within 6 months as placing the surgical patient at severe nutritional risk; they advise that a comprehensive nutritional plan be developed to address deficits through the postoperative period. As approximately 86% of older hospitalized adults are malnourished or are at risk of malnutrition (Kaiser et al., 2010), early nutritional intervention is imperative in preventing complications, decreasing length of stay, and promoting a quick return to baseline functioning.

Chapter 13, Nutrition in the Older Adult, provides a detailed discussion of nutrition assessment and nursing care strategies for older adults, and Chapter 29, Optimizing Mealtimes for Persons Living With Dementia, discusses mealtime difficulties. Nutritional care requires collaboration with the multidisciplinary healthcare team, including the nurse, surgical resident, and dietitian, as well as the speech therapist and occupational therapist. The goal is to provide early and adequate nutritional intake, preferably by mouth, which may be enhanced through the use of nutritional supplements (e.g., Ensure®). If oral intake is not possible, the team may consider the use of other forms of enteral nutrition (e.g., percutaneous endoscopic gastrostomy [PEG] tube and Dobhoff tube) or parenteral nutrition. Although parenteral nutrition may temporarily be the only option for some postsurgical older adults, especially those with a prolonged postoperative ileus (POI), it is important to note that enteral nutrition offers better outcomes than parenteral, as the former is associated with shorter hospital stays, lower incidence of infection, and lower severity of complications (Wheble, Knight, & Khan, 2012).

Several issues could possibly prevent early postsurgical nutrition intake, including postoperative nausea and vomiting (PONV) and dysphagia. PONV affects about one third of surgical patients (Apfel, Kranke, & Eberhart, 2004). Not only does PONV affect nutritional status, but it can also lead to further complications for the older surgical patient, including aspiration, wound dehiscence, and prolonged length of stay (American Society of PeriAnesthesia Nurses [ASPAN], 2006). The risk of PONV increases with age and duration of surgery (ASPAN, 2006). PONV should be continually monitored, especially within the first 24 hours of arrival in the unit. If PONV is present, it should be quantified using a descriptive or visual scale, and then rescue interventions should be implemented, including the administration of antiemetic agents, verification of adequate hydration, and use of aromatherapy (ASPAN, 2006). For older adults, however, it is important to steer clear of metoclopramide, which can lead to extrapyramidal effects (AGS, 2012).

Older adults may experience age-related decreases in swallowing function (Scandrett et al., 2015). Additionally, swallowing difficulties take longer to resolve following extubation for older adults, particularly after long surgeries (El Solh, Okada, Bhat, & Peitrantoni, 2003), predisposing the older adult patient to postoperative dysphagia. Hence, swallowing ability should be assessed early to address the need for fluid and caloric intake and to lower the risk of aspiration and debilitating aspiration pneumonia (Lagoo-Deenadayalan et al., 2011). If the swallowing assessment shows signs of aspiration, modification of the diet, including alterations in food consistency, upright positioning during and up to 1 hour after feeding, speech therapy, and aggressive oral care should be implemented to improve intake (Marik & Kaplan, 2003; McGory et al., 2009). For patients who may need to receive tube feedings because of swallowing difficulties or other postoperative complications, a documented plan to reduce the risk of aspiration should be incorporated into the medical record (AGS, 2007).

Constipation or diarrhea can also complicate postsurgical nutritional interventions and may signify more serious complications. Constipation can occur postoperatively as a result of immobility, altered (or lack of) diet, and excessive use of opioid pain medications (Doerflinger, 2009). In addition, the use of anticholinergics, particularly first-generation antihistamines (e.g., diphenhydramine), may initiate or exacerbate constipation and should be avoided in the older postsurgical patient (AGS, 2012). Preventive methods for constipation should be instituted for older adult surgical patients on opioid pain management regimens. This typically includes the use of bowel stimulants (senna and bisacodyl) and osmotic agents (polyethylene glycol); however, bulk-forming agents (psyllium) should be avoided because they are ineffective and may worsen symptoms, especially in a patient without adequate fluid intake (AGS, 2007; Malec & Shega, 2015). Quick transitioning from opioid medications to acetaminophen for mild to moderate pain may help reduce the risk of constipation.

The presence of diarrhea might trigger assessment for fecal impaction (following unaddressed constipation) or a more serious complication, such as *Clostridium difficile* infection (Doerflinger, 2009). A study by Zerey et al. (2007) showed that *C. difficile* infection occurs in about 1% of older adults undergoing a general surgical procedure. The occurrence of *C. difficile* infection can increase length of stay by 16 days and triple the mortality risk (Zerey et al., 2007). Universal precautions and proper handwashing are essential in reducing the risk of *C. difficile* infection. If *C. difficile* infection is suspected, then stool samples should

be taken and prompt treatment initiated if samples test positive (Doerflinger, 2009).

Special Consideration: POI Following Gastrointestinal Surgery

Older adult surgical patients have a higher incidence of POI following surgeries involving manipulation of the bowel (Hamel, Henderson, Khuri, & Daley, 2005). Prolonged POI (lasting more than 5 days) occurs in 40% of patients and leads to prolonged hospital stays and increased medical costs (Delaney, 2004; Schuster, Grewal, Greaney, & Waxman, 2006). Management for POI has routinely included bowel rest and bowel decompression (through placement of a nasogastric [NG] tube; Lagoo-Deenadayalan et al., 2011). However, evidence has shown that early enteral feeding is often well tolerated and may decrease POI, whereas NG decompression has not been shown to reduce incidence of POI and may actually place the patient at risk of aspiration and other postoperative pulmonary complications (Lubawski & Saclarides, 2008). In addition to early return to feeding, early mobilization and avoidance of unnecessary use of opioids can reduce the incidence of prolonged POI (Lagoo-Deenadayalan et al., 2011, Lubawski & Saclarides, 2008).

Hydration and Renal Complications

Older adults are at greater risk for fluid and electrolyte imbalances caused by physiological changes that lead to decreased total body water and poorer kidney function (lower glomerular filtration rate [GFR] and decreased ability to concentrate urine; Luckey & Parsa, 2003). Older adults are more susceptible to experiencing dehydration resulting from changes in thirst response, functional disability leading to decreased intake, and polypharmacy, including the overuse of diuretics (El-Sharkaway, Sahota, Maughan, & Lobo, 2014). However, surgical stress and excessive fluid resuscitation during the perioperative period could have the opposite effect, leading to water, sodium, and chloride excess, all of which have been shown to be independent risk factors for mortality, postoperative renal injury, and increased lengths of stay (El-Sharkaway et al., 2014).

Given this dichotomy, fluid management during the perioperative period is of vital importance. However, fluid orders are often delegated to the most junior member of the medical team who may lack an understanding of the importance of maintaining fluid balance for the older adult surgical patient (El-Sharkaway et al., 2014). In a report by the NCEPOD in the United Kingdom (1999), the authors noted that fluid management in older adult surgical patients was poor and contributed to serious postoperative morbidity and mortality. After conducting chart reviews, the report cited both doctors and nurses as being remiss in providing accurate documentation in fluid balance charts and recommended that working practices be developed, including elevating fluid management to the same importance as drug prescribing, to address the problem (NCEPOD, 1999).

During the postoperative period, the older adult is most at risk for dehydration and acute renal failure. Gajdos et al. (2013) reported that approximately 1.5% of adults older than 60 years undergoing nonemergent surgery developed postoperative renal insufficiency and that, of those, the mortality rate was more than 31%. The nurse plays a vital role in the assessment of fluid status, monitoring for signs and symptoms of fluid volume deficit and providing accurate documentation of fluid balance. The NIA Expert Panel recommends that fluid status be monitored for at least the first 5 days after surgery using daily weights and/or daily intake and output (McGory et al., 2009). However, Sullivan (2011) notes that because fluid volume shifts may take up to twice as long to resolve in the older surgical patient, urine output alone may not be enough to determine whether the patient has low blood volume leading to poor perfusion. The nurse should also be on the lookout for drops in blood pressure, changes in mental status, and new-onset atrial fibrillation, all of which could signify poor perfusion (Sullivan, 2011). Hughes et al. (2013) stress the importance of routine screening of serum electrolytes, urea nitrogen, and creatinine, although in older adults creatinine levels may not change even with significant drops in GFR.

As with nutrition, oral hydration should begin as soon as feasibly possible. Similarly, PONV and dysphagia must be addressed in order for the postoperative older adult to maintain adequate fluid balance. Chapter 12, Managing Oral Hydration in the Older Adult, addresses the management of oral hydration in the older adult, much of which is applicable to the older postsurgical patient. However, if the patient is unable to maintain adequate oral intake, IV fluids or adequate hydration through tube feeding may be required (with appropriate aspiration precautions instituted).

Respiratory Complications

Age-related changes in respiratory function include weakened swallowing and cough responses, chest wall stiffness, a weakened diaphragm, and decreased vital capacity and forced expiratory volume in 1 second (Bashaw & Scott, 2012; Hughes et al., 2013). These changes predispose the older adult surgical patient to respiratory complications.

For patients with preexisting respiratory conditions, such as chronic obstructive pulmonary disease or asthma, or for those who are smokers, the risk of complications is even greater (Lagoo-Deenadayalan et al., 2011). Preoperative assessment of pulmonary function is vital to delineating postoperative risk, and the promotion of preoperative smoking cessation, even just 24 to 48 hours before surgery, may help lessen postoperative sequelae (AGS, 2007; Hughes et al., 2013).

Pulmonary complications occur in approximately 10% of older adult surgical patients and account for up to 40% of postoperative complications and nearly 20% of preventable deaths (Lagoo-Deenadayalan et al., 2011). Magill et al. (2014) estimated that there were approximately 157,500 cases of hospital-acquired pneumonia (HAP) in the United States in 2011, of which 39% were ventilator-associated pneumonia (VAP). Gajdos et al. (2013) found that pulmonary complications, including pneumonia, failure to wean from a ventilator, and unplanned intubation, occurred in 7% of patients aged 60 years and older undergoing nonemergent surgery, with a mortality rate of 23% among those that had such complications.

Nursing interventions are essential in the prevention of respiratory complications through implementation of an aggressive pulmonary toilet regimen (Lagoo-Deenadayalan et al., 2011). In order to promote lung expansion and prevent postoperative atelectasis, the nurse should promote the use of an incentive spirometer (with adequate education and reinforcement on use) at least 10 times/hr; turning, coughing, and deep breathing every 2 hours; and chest percussion or other chest physiotherapy as needed (Doerflinger, 2009; McGory et al., 2009). Early ambulation should also be encouraged, as should proper positioning when in bed with the head of the bed elevated (Bashaw & Scott, 2012; Doerflinger, 2009). Adequate pain control is imperative because pain may reduce respiratory effort and may limit coughing to clear secretions (Lagoo-Deenadayalan et al., 2011). The healthcare team should also avoid the excessive use of narcotics and sedatives that could lead to respiratory depression (Lagoo-Deenadayalan et al., 2011).

VAP is a key nursing-sensitive indicator listed by the NDQNI and also endorsed by the NQF because the nurse plays a pivotal role in its prevention (Montalvo, 2007). For patients who are mechanically ventilated, evidence-based strategies to prevent VAP in acute care hospitals include selective oral or digestive decontamination, interrupt sedation daily, assess readiness to extubate daily, perform spontaneous breathing trials with sedatives turned off, facilitate early mobility, and change the ventilator circuit only if visibly soiled or malfunctioning (Klompas et al., 2014).

Despite the evidence, Munaco, Dumas, and Edlund (2014) noted that lack of staff education and limitations of the electronic medical record (EMR) affected overall compliance with a VAP bundle. AGS (2007) emphasizes the need for a documented care plan to reduce VAP. Therefore, facilities must address EMR limitations and provide ongoing education and training of nurses and nursing assistants to adequately implement VAP prevention.

Infection Prevention

Older adults are at increased infection risk post surgery because of immune system changes and delayed wound healing (Panprese & Johnson, 2014). In 2011, it was estimated that approximately 4% of hospitalized patients had at least one hospital-acquired infection (HAI; Magill et al., 2014). In addition to pneumonia (22% of HAI) and GI infection (17%), the remaining common HAI included surgical site infection (SSI; 22%), urinary tract infection (UTI; 13%), and primary bloodstream infection (10%; Magill et al., 2014). Older age and increased length of stay were related to increased risk of HAI (Magill et al., 2014). One of the most consistently cited ways to reduce HAI is through improving hand hygiene in the hospital setting.

A localized infection could potentially become systemic, putting the patient at risk for increased morbidity/mortality resulting from sepsis, which can occur in up to 2% of postoperative older adults (Lagoo-Deenadayalan et al., 2011). The NIA Expert Panel on quality indicators for older adult surgical patients recommends the following for any patient who has a fever greater than 38.0°C after postoperative (postop) day 2: Urinalysis and urine culture, examination of wound, blood culture from central venous line (if one is in place), peripheral vein blood culture, and chest radiograph (McGory et al., 2009). Older adults, however, may not necessarily mount a febrile response to systemic infection (Norman, 2000). Therefore, it is also important to monitor for other manifestations of sepsis, including altered mental status, agitation, respiratory distress, tachycardia, and hypotension (Lee, Chen, Chang, Chen, & Wu, 2007). If the older adult does have a significant febrile response, it often indicates severe infection with increased morbidity and mortality (Norman, 2000).

The Centers for Medicare & Medicaid Services (CMS) list several HAI as hospital-acquired conditions for which hospitals will receive no reimbursement (CMS, 2014). The HAI include SSIs following coronary artery bypass graft, bariatric surgery, and orthopedic procedures; catheter-associated urinary tract infections (CAUTI); and vascular catheter–associated infections (CMS, 2014). Because reimbursement will not be provided for HAI, it is

imperative that the multidisciplinary healthcare team works to prevent HAI from occurring in the hospital.

Zingg et al. (2015) performed a comprehensive systematic literature review and identified 10 key components that can impact HAI prevention. Some of the components addressed system issues, such as availability and ease of access to equipment (poorer access is related to higher risk); bed occupancy, staffing, and workload (high occupancy, low staffing levels, and high workload correlated with increased risk); and modeling a culture of infection control at the organizational level (Zingg et al., 2015). The study group also noted that adequate education and training on the appropriate use of guidelines, as well as proper auditing, surveillance, and feedback, reduced HAI risk (Zingg et al., 2015). In reviewing HAI programs from a national collaborative, Welsh, Flanagan, Hoke, Doebbeling, and Herwaldt (2012) had similar findings. They highlighted the importance of engaging frontline staff by involving them in projects and enlisting champions to further complement the education, surveillance, and feedback required to succeed in reducing HAI (Welsh et al., 2012). In sum, a system-wide, multidisciplinary, collaborative effort is required to reduce HAI and thus reduce morbidity and mortality in older adult surgical patients.

Surgical Site Infection

Approximately 2% to 5% of surgical patients develop an SSI (Anderson et al., 2014). Among older surgical patients (aged 60 years and older), SSI occurred in 8%, with a 7% mortality rate for those developing an SSI (Gajdos et al., 2013). The occurrence of an SSI, of which approximately 60% are preventable, can lead to an additional 11 days of postoperative hospital days and two to 11 times the mortality rate of those who do not acquire an SSI (Anderson et al., 2014). SSI, which are typically defined as those that occur within 30 days of surgery but may occur up to 90 days after, are classified into three categories: superficial incisional SSI, which affects only the skin or subcutaneous tissue; deep incisional SSI, which involves deep soft tissues such as fascia or muscle; and organ/space SSI, which involves any other part of the body that was manipulated during surgery (Anderson et al., 2014).

The Surgical Care Improvement Project (SCIP) was developed to decrease SSI and develop performance measures to improve outcomes (Fry, 2008). SCIP built on previous work by the Surgical Infection Prevention Project (SIP) that identified three quality-performance measures, which related to use of prophylactic antibiotics (Fry, 2008). SCIP added three additional measures: Glucose control in cardiac patients, proper hair removal before incision, and maintenance of normothermia in colorectal surgery patients (Fry, 2008). The ACOVE quality indicators also identified prophylactic antibiotics for the prevention of SSI (AGS, 2007). These measures relate more specifically to the perioperative phase, which is discussed in Chapter 32, HIV Prevention and Care for the Older Adult.

Although there is insufficient evidence to support strict glycemic control versus conventional management (maintenance of glucose less than 200 mg/dL) for the prevention of SSIs in the perioperative setting (Kao, Meeks, Moyer, & Lally, 2009), institutions implement specific protocols for target serum glucose in the immediate postop period. No trials were found that evaluated strict glycemic control in the immediate preoperative period or outside the setting of an intensive care unit. Additionally, compliance with appropriate antibiotic selection and administration within 60 minutes of time of incision has been associated with a lower SSI rate (Cataife, Weinberg, Wong, & Kahn, 2014).

A majority of TJC (2019) National Patient Safety Goals for SSI, as well as the TJC (2013) Implementation Guide for SSI, relate to implementation of education and training of healthcare providers and patients/families on SSI and how to prevent them, as well as ongoing monitoring and reporting of SSI occurrences. However, other than hand hygiene, TJC provides no clear postoperative procedures for prevention of SSI. For hand hygiene, the World Health Organization (WHO) identified five key moments that require adequate hand hygiene: (a) before touching a patient, (b) before clean and aseptic procedures (which would include clean and sterile dressing changes), (c) after contact with bodily fluids, (d) after touching a patient, and (e) after touching a patient's surroundings (Tsai & Caterson, 2014). Hand hygiene should include hand rubbing with alcohol-based products or, if hands are visibly soiled, then scrubbing with soap and water (Tsai & Caterson, 2014).

For incisional care, the CDC recommends that closed incisions, those with approximated edges after surgery, be covered with a sterile dressing for 24 to 48 hours and that dressing changes be done using a sterile technique (Mangram, Horan, Pearson, Silver, & Jarvis, 1999). Beyond 48 hours, the CDC did not provide any guidance on continued use of sterile dressings or the effects of bathing/showering (Mangram et al., 1999). For open surgical incisions, the CDC recommended that the wound should be packed with sterile moist gauze and covered with a sterile dressing (Mangram et al., 1999). Some conventional wound care regimens have specified dressing changes up to 7 days postoperatively, which could also require patient

education if the patient were discharged before that time (Akagi et al., 2012). In a study by Akagi et al. (2012), the authors found that the CDC recommendation of dressing changes up to 48 hours showed no increased risk of SSI compared with a standard 7-day regimen. A Cochrane Review also found no difference in SSI risk for early dressing removal (48 hours) when compared with delayed removal (after 48 hours; Toon, Ramamoorthy, Davidson, & Gurusamy, 2013). Furthermore, early removal could result in shorter hospital stays and decreased costs (Akagi et al., 2012; Toon et al., 2013).

In addition to wound care and dressing changes, the nurse must be vigilant in assessing for signs of infection, including redness around the wound edges, warmth, tenderness to palpation, and purulent drainage from the site (Lagoo-Deenadayalan et al., 2011). If an SSI occurs, treatment may include reopening of the incision to allow for drainage and frequent monitoring for signs of systemic infection; antibiotic use is typically discouraged unless the infection becomes systemic (Lagoo-Deenadayalan et al., 2011). A wound culture will identify any infection with multidrug-resistant organisms (MDRO). If an MDRO is the infectious agent, contact isolation precautions will be instituted along with adequate cleaning and disinfecting of equipment and the patient's environment (TJC, 2019).

Catheter-Associated Urinary Tract Infections

Up to 25% of all hospitalized patients receive urinary catheterization (Institute for Healthcare Improvement [IHI], 2011a). However, studies have shown that approximately 21% of patients with urinary catheters lacked a proper indication for insertion and up to 58% of catheters that were in place were subsequently found to be unnecessary (IHI, 2011a). The risk of developing a CAUTI increases as the length of catheterization increases, with a daily UTI risk of 5% (Bhardwaj, Pickard, Carrick-Sen, & Brittain, 2012; IHI, 2011a). Magill et al. (2014) noted that 68% of all UTIs in 2011 were CAUTI. In a survey of postoperative complications following nonemergent surgery, Gajdos et al. (2013) found that UTI occurred in 4% of adults aged 60 years and older, with a 5% mortality rate for those experiencing a UTI. The occurrence of a postoperative CAUTI can result in longer lengths of stay, increased hospital costs, and increased morbidity/mortality for the older adult surgical patient (Gajdos et al., 2013; Lagoo-Deenadayalan et al., 2011). CAUTI is listed as a nursing-sensitive indicator by NDNQI (Montalvo, 2007) and is a target for TJC National Patient Safety Goals (2019).

The IHI (2011a) provides four components of care to prevent or reduce the risk of CAUTI. They are (a) avoidance of unnecessary catheterizations, (b) insertion of catheters using an aseptic technique, (c) maintenance of catheters based on recommended guidelines, and (d) daily review of catheter necessity and prompt removal. TJC's National Patient Safety Goals (2019) address these same components. Hospitals should have specific protocols outlining the criteria for appropriate catheter insertion. For the older adult surgical client, catheterization will most likely occur in the perioperative period. However, catheters should be removed as soon as possible post surgery to prevent infection risk. IHI (2011a) recommends developing protocols that allow nurses to remove catheters if criteria for necessity are no longer met and if there are no contraindications to removal. Additionally, automatic stop orders can be used in the EMR to promote removal within 48 to 72 hours after surgery (IHI, 2011a). The NIA Expert Panel also specified that the catheter should be removed by postop day 3 (McGory et al., 2009). If the catheter remains in place, documentation should be provided to indicate the need for continued catheterization (IHI, 2011a). ACOVE quality indicators recommend documentation at least every 3 days, indicating the continued need for use until the catheter is removed (AGS, 2007).

Involving the patient in catheter-related decision-making could also lead to decreased length of catheterization. Bhardwaj et al. (2012) found that patients who underwent short-term catheterization for surgery lacked knowledge about the reason for catheterization, often did not provide consent, and were not included in the decision to remove the catheter. Patients also felt that their catheter remained in longer than was necessary because of a lack of easily accessible toileting options, even though they would have preferred to use a bedpan or bedside commode over continued catheterization (Bhardwaj et al., 2012). Therefore, the nurse should advocate for patient participation in the decision-making process for catheter removal as part of CAUTI-prevention practices.

Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection, provides further protocols on the prevention of CAUTI in older adults. The chapter discusses proper insertion using an aseptic technique as well as evidence-based maintenance of catheters that are in place. Guidelines for proper insertion include adequate hand hygiene, use of sterile equipment and an aseptic technique, and use of as small a catheter as possible that still allows for proper drainage (IHI, 2011a). Routine maintenance should include, at a minimum, maintaining a closed, sterile drainage system; properly securing the catheter and collection bag, which should be below the level of the bladder at all times; maintaining unobstructed urine flow; and emptying the collection bag regularly, using a separate

container for each patient and not allowing the nozzle to touch the collection device (IHI, 2011a).

Central Line–Associated Bloodstream Infections

Approximately 84% of the estimated 72,000 primary bloodstream infections in the United States in 2011 were central line–associated bloodstream infections (CLABSI; Magill et al., 2014). For older adults, CLABSI is associated with more than twice the mortality risk, longer lengths of stay (up to 10 additional hospital days), and increased healthcare costs (Kaye et al., 2014). Most CVC days, approximately 15 million in the United States, occur in the intensive care setting (CDC, 2011). However, some older adult surgical patients on step-down or medical–surgical floors may have peripherally inserted central catheters (PICC) or other tunneled lines that can also place them at risk for CLABSI. As with other HAI, nurses play an integral role in the prevention of CLABSI, which is listed as an NDNQI nursing-sensitive indicator (Montalvo, 2007) and specified as a National Patient Safety Goal by TJC (2019).

The IHI (2012a) describes five key components of its central line bundle aimed at preventing CLABSI. The components are: (a) hand hygiene; (b) maximal barrier precautions, which include sterile operator procedures and equipment and sterile patient draping from head to toe; (c) chlorhexidine skin antisepsis before insertion; (d) optimal catheter site selection, avoiding the use of the femoral vein; and (e) daily review of line necessity and prompt removal when indicated. The CDC, in its 2011 guidelines, also recommended implementing bundle strategies, which incorporate hand hygiene and aseptic, appropriate catheter and site selection, and maximum barrier precautions. The guidelines also highlight the need for adequate education, training, and staffing in the prevention of CLABSI. The ACOVE quality indicators for vulnerable elders include documentation in the EMR of the use of maximal barrier protection.

For nursing care, the CDC (2011) specifies dressing-change regimens, which include the following:

- Use sterile gauze (if patient is diaphoretic or the site is bleeding or oozing) and a transparent, semipermeable dressing to cover the site.
- Replace dressing if it becomes damp, loosened, or visibly soiled.
- Replace gauze dressings every 2 days and transparent dressings every 7 days for short-term sites.
- Use chlorhexidine-impregnated sponge dressing for temporary catheters if basic prevention measures are not working.

The nurse should also replace IV administration sets at the appropriate intervals: no less than 96-hour intervals but at least every 7 days for continuous or secondary infusion tubing; within 24 hours for tubing involving blood, blood products, or fat emulsions; or every 6 to 12 hours for propofol infusion tubing (CDC, 2011). When accessing catheter hubs, needleless injectors, and injection ports, the nurse should disinfect (scrub) using an appropriate antiseptic and access the site using only sterile devices/equipment (CDC, 2011).

Other important nursing functions are to ensure that the patient is not showering or submerging the CVC site in water (adequate patient education and monitoring) and to palpate the site through an intact dressing regularly to assess for tenderness (CDC, 2011). If tenderness is noted, the dressing should be removed for full visual inspection and, if indicated, provider notification made to address possible CLABSI (CDC, 2011). ACOVE indicators specify daily documentation of examination of the site for signs of infection as well as documentation of the continued need for use (AGS, 2007). The NIA Expert Panel offers the same quality indicators as ACOVE, but also adds daily examination for swelling in the extremity on the side of line placement (McGory et al., 2009).

Mobility, Function, and Frailty

Older adults experience loss of muscle mass, muscle strength, and bone mass as they age (Bashaw & Scott, 2012). Further deconditioning can occur following periods of inactivity, such as prolonged immobility during surgical procedures and bed rest during the immediate postoperative period (Lagoo-Deenadayalan et al., 2011). Postsurgical deconditioning can slow recovery in older adults, including restoration of activities of daily living (ADLs), and put the patient at increased risk for DVT, delirium, incontinence, constipation, pressure injury, and falls (Lagoo-Deenadayalan et al., 2011). Early mobilization has been shown to combat deconditioning, decrease length of stay, and increase discharges to home (Engel, Tatebe, Alonzo, Mustille, & Rivera, 2013).

Frailty is defined as having decreased physiological and functional reserve (Scandrett et al., 2015). Frailty has been shown to be an independent risk factor for postoperative complications, increased length of hospital stay, and discharge to a skilled or assisted-living facility after previously living at home (Dasgupta et al., 2009; Makary et al., 2010). Chapter 31, The Frail Hospitalized Older Adult, provides a more thorough discussion of frailty in older adult populations.

To address postoperative risks for issues with mobility and functional decline, it is imperative to develop a preoperative baseline assessment. The ACS NSQIP/AGS *Best Practice Guidelines* specifically address assessment of functional/performance status and frailty risk (Chow et al., 2012). If the patient is unable to perform any ADL, a full screening of ADL and instrumental ADL (IADL) should be performed (Chow et al., 2012). Performance is assessed using the Timed Up and Go Test (TUGT) and also includes inquiring about a history of falls (see the following section on Fall Prevention; Chow et al., 2012). The TUGT is performed by the patient using normal walking aids and without any assistance in the following manner (Chow et al., 2012). The patient:

1. Rises from a chair, if possible without using armrests
2. Walks 10 feet down a line on the floor
3. Turns
4. Returns to the chair and
5. Sits down again

If the patient takes longer than 15 seconds to complete the exercise, the patient is considered to have a high risk of falls, and a more detailed gait assessment should be completed (Chow et al., 2012).

Frailty can be measured using a number of validated tools. ACS NSQIP/AGS (Chow et al., 2012) recommend the use of the Frailty Phenotype, which assesses five domains: weight loss, weakness, exhaustion, low physical activity, and slowness (Makary et al., 2010). Each domain is scored 0 to 1, and then scores are totaled; scores of 2 to 3 indicate prefrailty and 4 to 5 indicate frailty (Chow et al., 2012). Panprese and Johnson (2014) recommend using the Braden Scale because, although it is typically used for pressure injury risk, its six domains of sensory perception, moisture, mobility, nutrition, activity, and skin friction and shearing characterize frailty vulnerabilities. Another reason for its use is that nurses are familiar with the tool, and it is already incorporated into many EMR systems (Panprese & Johnson, 2014).

The NAI Expert Panel recommends that function and mobility screening be performed 8 weeks before surgery (McGory et al., 2009). The assessment should include the TUGT with a comprehensive assessment of mobility if it is abnormal, and assessment of hearing/visual impairment, ADL, and IADL (McGory et al., 2009). For any abnormalities, including with the TUGT, the panel recommends that a written plan be developed for postoperative care before surgery (McGory et al., 2009). Chapter 10, Assessment of Physical Function in the Older Adult, provides further discussion about the assessment of physical function in older adults.

Re-enablement after surgery describes the process of returning the patient to presurgery functioning (Griffiths et al., 2014). During the postoperative period, the nurse participates with a multidisciplinary team to prevent functional decline and the development of frailty and allow for re-enablement before discharge. The team includes the nurse, nursing assistant, physician resident, physical therapist, and occupational therapist. It is imperative that each member of the team understand his or her role in patient re-enablement, as confusion has been shown to be a significant barrier to mobility and activity program implementation (Markey & Brown, 2002). Other potential caregiver and patient barriers must also be addressed. Some patient barriers include dependent behavior and daytime sleepiness; the nurse and nursing assistant as well as family members should encourage independence and discourage daytime sleeping (Markey & Brown, 2002). For further information on excessive sleepiness in older adults, refer to Chapter 30, Disorders of Sleep in the Older Adult. Caregiver barriers include scheduling conflicts and the use of equipment (i.e., IV poles and tubing, urinary catheters, and sequential compression devices [SCDs]) that make ambulation and mobility activities more complex (Markey & Brown, 2002).

A physical therapy consult should provide an early assessment of the patient to develop a mobility and strengthening plan, including the potential need for assistive devices (Hughes et al., 2013). ACOVE and the NIA Expert Panel stress that ambulation should occur by postop day 2 and, if not, documentation should be provided in the EMR about why ambulation could not occur (AGS, 2007; McGory et al., 2009). The NIA Expert Panel further specifies that if the patient cannot ambulate, mobilization (e.g., range-of-motion [ROM] exercises) should be performed by postop day 2 and, if not, documentation should be provided about why it could not be done (McGory et al., 2009).

The nurse, nursing assistant, and occupational therapist will address the patient's ADL and IADL. Independent performance of ADL should be encouraged, but if the patient needs assistance, the level of assistance should be documented, relayed to the occupational therapist, and communicated during handoff (Markey & Brown, 2002). If the level of assistance indicates a change from baseline functioning, a plan should be developed and documented in the EMR to facilitate re-enablement (McGory et al., 2009). A final assessment of ambulation, mobility, ADL, and IADL should also be completed and documented at discharge, with appropriate documentation provided to the skilled or assisted-living facility, home health agency, or family/caregivers, depending on the discharge destination

(McGory et al., 2009). Chapter 18, Preventing Functional Decline in the Acute Care Setting, provides further information on preventing functional decline in the acute care setting.

Fall Prevention

In the acute care setting, up to 20% of patients fall at least once over the course of their hospitalization (IHI, 2012b). Falls are the most frequently reported adverse event in hospitals, reaching approximately 1 million per year, with 90,000 serious injuries and 11,000 deaths occurring as a result (Currie, 2008). Falls can lead to head injuries, hip fracture, reduced mobility (caused by pain or added fear of falling), longer length of stay, unplanned discharge to assisted-living facilities, and increased medical costs (IHI, 201b). Studies have consistently identified unsteady gait, confusion, increased need for toileting, use of sedative–hypnotics, and history of falling as key risk factors for falling in an acute care setting (Currie, 2008). Although it is inconclusive whether older age is a risk factor for falls, it does place the surgical patient at greater risk of injury from a fall (Currie, 2008). NQF (2011) placed falls resulting in serious injury on its list of serious reportable events (SRE). NDNQI lists falls and falls with injury as key nursing-sensitive indicators (Montalvo, 2007). CMS (2014) lists trauma related to falls as a nonreimbursable hospital-acquired condition.

Similar to mobility and function, preoperative fall-risk assessment is critical to identifying those who may be at risk for falls and developing a multidisciplinary plan to prevent falls postoperatively. The NIA Expert Panel specifies that an assessment should be performed 8 weeks before surgery on an older adult and that if the patient has reported two or more falls in the past year or one fall with injury, referral should be made for a comprehensive preoperative fall evaluation as well as inpatient physical therapy (McGory et al., 2009). There are a number of tools that have been developed to assess fall risk, including the Morse Falls Risk Assessment Tool, the Hendrich Falls Risk Model II, or the STRATIFY instrument (Currie, 2008). Although research has demonstrated that the Hendrich Falls Risk Model II may be more robust, it is more important that assessment remain consistent from preoperative screening through discharge (Currie, 2008).

Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care, provides a comprehensive discussion on preventing falls in acute care settings. A number of intervention strategies have been examined, including staff education, armband identification, bed alarms, exercise and toileting regimens, and vitamin D supplementation (Cameron et al., 2012). Although some have shown to be effective, multifaceted prevention strategies have been shown to be more effective (Cameron et al., 2012). IHI (2012b) highlights six key areas to address in its guide on preventing falls: fall risk screening on admission, injury and injury risk factors screening on admission, in-depth admission screening for any positive findings, communication and education about the patient's fall risk, standardized interventions for those at risk for falls, and customized interventions for those at highest risk. The final three areas address postoperative care and may incorporate such interventions as signage to identify those at risk; teach-back education to patients and family members about fall risk; and rounding every hour or 2 to address the patient's need for pain relief, toileting, and positioning (IHI, 2012b). TJC and the AHRQ have similar guidelines and also provide educational and training materials for preventing falls on their websites. If a fall does occur, ACOVE recommends that an inpatient fall evaluation should occur within 24 hours to include the presence or absence of any signs/symptoms of injury and a review of medications that could potentially contribute to a fall.

Skin Integrity

With advancing age, older adults experience thinning of the dermis, loss of collagen and adipose tissue, and decreased skin elasticity (Bashaw & Scott, 2012). As the skin becomes more friable, older adults are at increased risk for bruising, tearing, shearing, and infection, especially over bony prominences (Panprese & Johnson, 2014). If the older adult is malnourished or dehydrated, the risk of skin breakdown and pressure injury development increases (Bashaw & Scott, 2012). Because of the nurse's specific role in assessing and maintaining skin integrity, pressure injuries are listed by NDQNI as a nursing-sensitive quality indicator (Montalvo, 2007). Additionally, CMS (2014) lists stages 3 and 4 pressure injuries as nonreimbursable hospital-acquired conditions.

The IHI (2011b) identifies six essential elements for pressure injury prevention: (a) pressure injury admission assessment, (b) daily reassessment of pressure injury risk, (c) daily skin inspection, (d) moisture management, (e) adequate nutrition and hydration, and (f) minimization of pressure. The NIA Expert Panel dictates admission screening for pressure injury risk using the Braden or Norton Scales (McGory et al., 2009). This is in line with admission assessments as recommended by TJC and NQF (IHI, 2011b). The remaining five elements fall under the nurse's purview during postoperative care. Chapter 28, Preventing Pressure Ulcers and Skin Tears, outlines nursing protocols for preventing pressure injuries and skin

tears in older adults. Daily risk assessment should be completed using the same tool as was used on admission and should be documented in the EMR along with the visual skin inspection (IHI, 2011b). Some other key interventions include the following (IHI, 2011b):

- *Management of moisture:* (a) skin cleaning routinely and at times of soiling with mild cleansing agents; (b) use of skin moisturizes for dry skin; (c) use of absorbent underpads for excessive incontinence, perspiration, or wound drainage
- *Pressure relief:* (a) turn/reposition the patient every 2 hours; (b) use mattresses and cushions to redistribute pressure

Additional care should be focused on pressure caused by medical devices as well as caution when removing dressings, pads, tape, or leads in order to prevent skin tears (Bashaw & Scott, 2012).

The NIA Expert Panel recommends daily screening and repositioning/pressure reduction at least until the patient is ambulatory (McGory et al., 2009). Additionally, if the surgical patient has an existing stage 2, stage 3, or stage 4 pressure injury, a treatment plan should be outlined and documented before surgery (McGory et al., 2009). For patients undergoing cardiac surgery, it is recommended to continue skin assessment and interventions up until the postop day 5 (Pokorny, Koldjeski, & Swanson, 2003).

Prevention of VTE

Older adult surgical patients may have many factors, including age, that place them at risk for VTE, including obesity, prolonged immobility, lengthy surgery (longer than 2 hours), presence of varicose veins, and smoking history (Bashaw & Scott, 2012). VTE occurs in approximately 1 million patients each year (Dobesh, 2009). In a study of nonemergent surgeries, Gajdos et al. (2013) found that 2% of adults aged 60 years and older experienced VTE and that 10% of those with VTE died. The occurrence of VTE leads to increased length and cost of stay and also puts the patient at risk for other potentially life-threatening complications (Dobesh, 2009). In addition, there may be significant long-term complications and related costs, often caused by recurrent VTE, postthrombotic syndrome, or pulmonary hypertension (Dobesh, 2009). According to the CMS (2014), the occurrence of VTE following certain orthopedic surgeries (e.g., total knee replacement and hip replacement) is a nonreimbursable hospital-acquired condition.

The AHRQ (2012) guidelines for VTE prophylaxis list four interventions and practices to consider: (a) assessment of VTE risk factors, (b) patient education and early ambulation, (c) mechanical prophylaxis, and (d) pharmacological prophylaxis (AHRQ, 2012). The guidelines also address special situations, such as prophylaxis for patients with hip/knee arthroplasty and hip fracture (see Chapter 40, Care of the Older Adult With Fragility Hip Fracture). For VTE screening of surgical patients, AHRQ (2012) recommends the use of the Caprini Risk Assessment Model. The Caprini Model uses a checklist of factors scored as 1 point (e.g., swollen legs and acute myocardial infarction), 2 points (e.g., age 61–74 years and central venous access), 3 points (e.g., age 75 years or more and history of DVT), or 5 points (e.g., stroke within the past month); the scores for the checked boxes are then summed for an overall Caprini score (Caprini, 2010).

Mechanical prophylaxis measures include early ambulation and the use of SCDs (AHRQ, 2012). Compression stockings have been shown to reduce VTE risk when used effectively, but are not necessarily recommended because tight fit can impair circulation and lead to additional complications (Bashaw & Scott, 2012). The BGS cautions against the use of compression stockings in older adults, but if they are used, skin integrity needs to be regularly and carefully monitored (Donald, 2019). ROM exercises can also be effective if the patient is unable to ambulate (Bashaw & Scott, 2012). Inferior vena cava (IVC) filters may be placed in critically ill adults to prevent pulmonary embolism related to DVT; however, AHRQ (2012) does not recommend their use. Pharmacological prophylaxis measures include the use of low-molecular-weight heparin (LMWH) or low-dose unfractionated heparin (LDUH). However, the BGS purports that major bleeding risk may outweigh VTE risk in older adults, and thus use of LMWH or LDUH may not be the best choice for prophylaxis (Donald, 2019).

The AHRQ (2012) stratifies mechanical and pharmacological prophylaxis based on the Caprini Risk score and a comprehensive assessment of bleeding risk. Table 39.2 provides the measures based on score and bleeding risk for patients undergoing nonorthopedic surgery. The ACOVE quality indicators also emphasize the use of SCDs and pharmacological prophylaxis in vulnerable elders at high risk for VTE (AGS, 2007).

Restraint Use

Restraints are often used in an acute care setting to prevent falls and patient interference with therapy (Minnick, Mion, Johnson, Catrambone, & Leipzig, 2007).

TABLE 39.2
VTE Prophylaxis

VTE Risk Category	Low Bleeding Risk	High Risk for Major Bleeding
Very low risk		
(Caprini score 0)	Early ambulation	Early ambulation
Low risk		
(Caprini score 1–2)	SCDs	SCDs
Moderate risk		
(Caprini score 3–4)	LMWH/LDUH or SCDs	SCDs
High risk		
(Caprini score greater than or equal to 5)	LMWH/LUDH *and* SCDs	SCDs until bleeding risk diminishes, then addition of LMWH/LUDH

LDUH, low-dose unfractionated heparin; LMWH, low-molecular-weight heparin; SCD, sequential compression device; VTE, venous thromboembolism.

Source: Agency for Healthcare Research and Quality. (2012). Venous thromboembolism prophylaxis (Guideline NGC-9541). Bloomington, MN: Institute for Clinical Systems Improvement. *Evidence Level I*.

Restraints may also be used on patients who are confused or agitated, wander, or are perceived to have behavioral problems (Evans & Fitzgerald, 2002). Use may also be a result of inadequate staffing (Evans & Fitzgerald, 2002). Although rates of restraint use among older and younger adults in intensive care settings are similar, older adults represent much higher rates on medical units than their younger counterparts (Minnick et al., 2007). The use of restraints has been shown to increase the risk of falls, pressure injuries, and delirium in older adult surgical patients, which could lead to increased morbidity, mortality, and length of stay (Baumgarten et al., 2008; Inouye et al., 2007; Shorr et al., 2002). Restraint use is a key NDNQI nursing-sensitive indicator endorsed by the NQF (Montalvo, 2007).

If restraints are used, the NIA Expert Panel quality indicators specify that the target behavioral or safety issue must be addressed with the patient or legal guardian and documented in the chart, along with methods other than restraints implemented as part of the plan of care (McGory et al., 2009). In order to prevent or lessen restraint use, the healthcare provider should certify the continued need for invasive lines because removal of unnecessary lines may eliminate the need for restraints. In addition, the NIA Expert Panel advises implementation of the following care measures (McGory et al., 2009):

- Release from restraints and repositioning at least every 2 hours
- Face-to-face reassessment by the nurse at least every 4 hours and by the physician before renewal of the restraint order
- 15-minute observations; more if the patient's condition warrants more frequent assessment
- Nurse-related interventions every 2 hours to address nutrition, hydration, toileting, personal hygiene, and ROM

Additional information on the use of restraints in the acute care setting is provided in Chapter 27, Physical Restraints and Side Rails in Acute and Critical Care Settings.

Discharge Planning

Adequate discharge planning begins before surgery, including assessment of the need for social support or home health expected after discharge (McGory et al., 2009). Comprehensive discharge planning involves the multidisciplinary team to address patient status before discharge as well as follow-up care after discharge (Palmer, 2009). ACOVE quality indicators specify that an assessment of cognition and function should be performed and compared with preoperative levels and that the level of independence, along with the need for home health services, be documented in the EMR (AGS, 2007). The NIA Expert Panel includes assessment of nutrition, cognition, ambulation, and ADL in its discharge planning criteria (McGory et al., 2009).

A comprehensive medication reconciliation addressing chronic medications as well as new prescriptions will help facilitate discharge and, along with adequate care transition planning and communication with outpatient providers, can help reduce rehospitalizations and emergency department visits (Legrain et al., 2011). For new medications, the nurse will facilitate patient education with regard to the purpose of the drug, how to take it, and expected side effects, as well as possible adverse effects (McGory et al., 2009). Medication education is just one of many patient and family education tasks of the nurse. Others include a detailed explanation of the plan of care, which may include home health visits, physical or occupational therapy appointments, follow-up appointments, education on the use of new equipment or devices, or demonstration on the performance of activities such as dressing changes and wound care. Effective nursing education using teach-back and return demonstration has been

shown to increase patient and family confidence and decrease nonscheduled healthcare visits post discharge (Henderson & Zernike, 2001; Williams, 2008). For further information on discharge planning, refer to Chapter 42 Transitional Care.

CASE STUDY 39.1

ADMISSION AND PREOPERATIVE COURSE

KL is a 72-year-old Asian woman admitted from home because of intermittent vomiting and poor oral intake. No other associated symptoms were reported. The history was obtained from the patient's daughter via an interpreter. KL has no known drug allergies and is full-code status. The remainder of her admission history includes:

- *Home medications:* Aspirin, ascorbic acid, docusate sodium, folic acid, multivitamins, ferrous sulfate, pantoprazole, senna, metoprolol, and lisinopril
- *Past medical history:* Anemia, constipation, hypertension, chronic kidney disease (CKD), non-ST-segment elevation myocardial infarction (NSTEMI)
- *Past surgical history:* "Bowel surgery many years ago" (unknown date)
- *Psychosocial history:* KL is widowed. She lives with her daughter in a single-family house. She has no history of tobacco or alcohol use and was independent with ADL until this admission.

General overview revealed a frail-looking, non–English-speaking female who looks her stated age. Her general physical examination is mostly unremarkable except for a distended and tympanic abdomen with hypoactive bowel sounds. An episode of vomiting of bilious liquid was noted in the emergency department (ED), for which she was given metoclopramide 10-mg IV push. A Salem sump tube attached to low continuous intermittent suction (LCS) was draining yellow-greenish liquid. Normal saline at 100 mL/hr was started via a left peripheral IV line, and an indwelling urinary catheter was inserted.

KL was oriented to self and place but not to time. She denied any abdominal pain but referred to feeling bloated and nauseated. Her vital signs were blood pressure = 141/71 mmHg, heart rate = 7,090/min, respiratory rate = 18–20/min, temperature = 98.2°F, and a 96% oxygen saturation on room air. Her latest lab results are shown in Exhibit 39.1.

A 12-lead EKG revealed sinus rhythm. KL's chest x-ray showed an enlarged cardiac silhouette but no signs of consolidation or infiltrates. The abdominal CT scan findings reported marked gaseous distention of stomach; small and large bowels without definite transition point identified; and mild colonic stool retention within the rectosigmoid up to 4.2 cm in transverse diameter. After a 6-hour stay in the ED, KL was moved to the surgical ward. She was kept at nothing-by-mouth status, continued on normal saline at 100 mL/hr, and the Salem sump to LCS. VTE prophylaxis with pneumatic compressions was initiated. Routine lab work, including urinalysis, blood type, and screening, were ordered for the following morning. Once cleared by cardiology, KL was scheduled for exploratory laparotomy.

EXHIBIT 39.1
KL's Latest Lab Results

Na = 145 mEq/L	WBC = 16,100 × 10^3/μL	Albumin = 3.9 g/dL
K = 4.4 mEq/L	Hemoglobin = 9.6 g/dL	Calcium = 9.0 mg/dL
Cl = 103 mEq/L	Hematocrit = 31.3%	Magnesium = 2.5 mEq/L
CO_2 = 24 mEq/L	Platelets = 360 × 10^9/L	Phosphorus = 4.2 mg/dL
BUN = 33 mg/dL	Prothrombin time = 16.1 seconds	Troponin = 0.0 μg/L
Creatinine = 2.0 mg/dL	International normalized ratio (INR) = 1.2	Creatinine clearance (CrCl) = 23.2

BUN, blood urea nitrogen; Cl, chlorine; CO_2, carbon dioxide; K, potassium; Na, sodium; WBC, white blood cells.

Intraoperative Course

After routine universal protocol procedure, KL had an uneventful induction and administration of general anesthesia. No adverse events were noted intraoperatively. The surgery performed was small bowel resection with anastomosis and lysis of adhesion. After extubation, she was transported to the postanesthesia care unit (PACU) for 4 hours and subsequently transferred to the surgical step-down unit.

Postoperative Course

KL's postop orders include oxygen 4 L via nasal cannula; lactated Ringer's at 100 mL/hr for 24 hours; Salem sump to LCS; SCD to both legs; bedside telemetry; Foley to side drainage; patient-controlled

(*continued*)

CASE STUDY 39.1 (*continued*)

analgesia (PCA) morphine 1-mg continuous dose, 1-mg demand dose, 6-minute lock out, and 20 mg 4-hour limit; metoprolol 5 mg IV piggy back (IVPB) every 6 hours; famotidine 20 mg IVPB once daily; metoclopramide 10 mg IVPB every 6 hours as needed for nausea and vomiting; Benadryl 25 mg IVPB every 12 hours as needed for itchiness; out-of-bed to chair in a.m.; and physical therapy and nutrition consults.

1. Describe the application of best practice guidelines for KL's transition from PACU to the surgical unit.

Patient safety is an utmost consideration.

Transitions between the various operative units should be marked by high-quality handoff between providers using standardized forms, both in paper and electronically. Bedside safety checks are best done with both the giving and receiving providers present using a checklist. Specific institutional procedures and protocols should be followed (e.g., who should accompany the patient during transport).

2. Describe key assessment parameters for KL's postsurgical care.

When KL arrives on the surgical unit, a priority is to ensure she has a patent airway and is hemodynamically stable. A thorough head-to-toe assessment is essential, giving special attention to abdominal and operative wound assessment and ensuring that KL's vital signs are within baseline. It is important to ensure that the Salem sump tube is attached to suction and that VTE prophylaxis is maintained (SCD). As KL has baseline CKD, a close monitoring of her urine output and implementation of the CAUTI bundle are important considerations.

3. Describe the importance of medication reconciliation in postop older adult patients.

Medication reconciliation should be performed during every transition in order to prevent inadvertent omission of essential medications (e.g., beta-blockers) and use of inappropriate medications. In KL's case, it is important to raise clinical concern regarding the order of metoclopramide for postop nausea and vomiting. It is best avoided among older adults as it can cause extrapyramidal effects, including tardive dyskinesia (AGS, 2012). The use of diphenhydramine, chlorpromazine, and H2-receptor antagonist is also considered inappropriate in older adults because of increased risk of confusion/delirium (AGS, 2012). In KL's case, famotidine can be replaced with pantoprazole and metoclopramide with ondansetron. If KL develops itchiness as a result of the morphine, nonpharmacological interventions should be tried first (e.g., applying lotion to her skin). For mild to moderate pain, acetaminophen can be ordered for KL.

4. Describe ongoing best practices for postop older adult patients.

The postop period is a vulnerable time that can set back the older patient from major gains such as overcoming general anesthesia. Essential to achieving positive outcomes is hardwired interprofessional collaboration across all disciplines. In addition to focused assessments, purposeful hourly rounding (e.g., addressing pain, positioning, elimination, and comfort needs) will enable the staff to address the patient's routine needs and avert potentially high-risk events such as a fall. Fall-risk assessment and interventions need to be reviewed as per hospital protocol. The removal of catheters or other nonessential invasive devices will reduce the overall risk for infection. Key postop complications that require special attention are listed in the following.

A. *Postop ileus*—Preventing postop ileus can be a challenge for KL because of the use of morphine. Using the lowest dose and transitioning from PCA to "as needed" status might be considered. Early mobilization and active range-of-motion exercises will be beneficial in promoting peristalsis, preventing VTE, and improving general well-being. The nurse needs to continue focused GI surveillance for signs of ileus. When listening for bowel sounds, KL's Salem sump tube should be disconnected from the LCS in order not to confuse the negative pressure from the suction as bowel sounds.

B. *Postop atelectasis*—The nature of abdominal surgeries puts the patient at greater risk for atelectasis. Although KL has no pulmonary comorbidities, she should be encouraged and coached to use the incentive spirometer (e.g., 10 times every hour while awake). Nursing measures to improve compliance with breathing and coughing exercises include splinting wound with a binder, premedicating with pain relievers, and empowering the patient.

C. *Postop VTE*—KL's abdominal surgery and her comorbidities make her vulnerable to VTE. Early mobilization, adequate hydration, and the use of SCD and pharmacological prophylaxis (e.g., heparin) will help reduce the risk.

(*continued*)

CASE STUDY 39.1 (*continued*)

D. *Surgical site infection*—The implementation of evidence-based practices listed in this chapter will eliminate the risk of SSI. The operative wound should have a sterile dressing for 24 to 48 hours postop. Monitoring and reporting changes in KL's mental status that might signal an infection are essential. The trend of KL's white blood cell count and wound appearance should be monitored. Hand hygiene remains the most cost-effective and most effective way to prevent the transmission of infection.

5. Describe best practices in patient/family education for postop patients.

Patients' active participation in their care is now recognized as an essential element for positive health outcomes. For surgical patients, physical (e.g., wound) and psychological healing continues on discharge. This endeavor requires high-quality patient education using proven methods such as the teach-back approach. KL and her daughter should be provided easy-to-understand handouts on wound care, nutrition, and exercise at home. Providing KL and her daughter a script from the National Patient Safety Foundation (e.g., What is my main problem? What do I need to do? Why is it important for me to do this?) for use when they visit the surgical provider will help them feel empowered and improve follow-up care. For best practices in transitional care, please refer to Chapter 36, Fluid Overload: Identifying and Managing Heart Failure Patients at Risk of Hospital Readmission.

SUMMARY

Older adult surgical patients are at higher risk for morbidity and mortality following surgery due to age-related changes that lead to limited physiological reserve as well as a potential number of medical comorbidities that may further complicate recovery. As such, the nurse must work diligently with the interprofessional team to develop a comprehensive plan of care post surgery. Frequent assessment and early intervention are necessary to prevent debilitating complications, including postoperative delirium, functional decline, HAIs, pressure injuries, and falls. Pain management, early ambulation, and adequate nutrition and hydration can help prevent complications or lessen the intensity or duration of their effects. With an appropriate plan of care, the older adult surgical patient will experience shorter lengths of stay, be discharged with baseline cognitive and physical functioning, and transition to the location from which he or she was admitted.

NURSING STANDARD OF PRACTICE

Protocol 39.1: General Surgical Care of the Older Adult

I. GOAL

To restore physiological stability, prevent complications, maintain safety and comfort, and preserve presurgical functional ability and QOL in older adult surgical patients

II. OVERVIEW

A. Physiological changes of aging can significantly affect the recovery time of older adult surgical patients and put them at greater risk for postoperative complications (Makary et al., 2010).
B. Older adults often present for elective and nonelective or emergent surgeries with a number of medical comorbidities that place them at further risk for postoperative morbidity and mortality (Dasgupta et al., 2009).
C. The risk of complications and mortality increases with advancing age, with those aged 90 years and older experiencing twice the rate of mortality at less than 48 hours post surgery as compared with those younger than 65 years (Deiner et al., 2014).
D. Longer lengths of stay have been consistently linked to increased postoperative adverse outcomes (Makary et al., 2010).

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

E. Surgical patients at hospitals with a higher percentage of nurses with a baccalaureate or higher degree experienced shorter lengths of stay and fewer postoperative complications (Blegen et al., 2013).
F. A proportionate increase in staff nurses with bachelor's degrees decreases the risk of death among patients following common surgeries in acute care settings (Aiken et al., 2014).

III. BACKGROUND

A. Definition
   1. The patient is discharged from the PACU following an established protocol, such as the Aldrete Score, a post-anesthesia recovery score. Patients with scores of 9 or 10 may be discharged to the surgical or equivalent units, those with eight require further observation, and those with 7 or less require admission to the ICU (Aldrete & Kroulik, 1970). Another tool in use is the PADSS (Chung, Chan, & Ong, 1995). No matter which tool is used, collaborative ongoing assessment and clinical judgment are required.
   2. Nursing priorities when the patient arrives from the PACU to the surgical unit include high-quality handoff; focus on airway, breathing and circulation; assessment of vital signs based on specific protocol; monitoring of complications; and discharge readiness (Odom-Forren, 2015).
B. Etiology/epidemiology
   1. In 2010, 19.2 million operative procedures were performed among older adults in acute care settings. These accounted for more than 37% of all procedures and 45% of total hospital days of care (CDC, 2010).
   2. Hospital stays that involve surgical procedures have been shown to be more costly, required longer lengths of stay, and resulted in higher morbidity and mortality (Weiss & Elixhauser, 2014).
   3. The need for comprehensive baseline status assessment and the use of an interdisciplinary team with surgical and geriatric expertise to follow the patient from preop to discharge are essential for achieving positive outcomes (McGory et al., 2009).
   4. Postoperative delirium can occur in up to 50% of high-risk older adult surgical patients, leading to prolonged and more costly hospitalizations, functional decline, and death (AGS, 2014).
   5. Older adult surgical patients are at higher risk for delirium resulting from medication side effects; immobility; infection; inadequate pain management; and cardiac, renal, and respiratory complications (Hughes et al., 2013).
   6. Hospitalized older adults are consistently less likely to receive adequate pain control compared with younger adult patients (Schofield, 2014).
   7. A lack of pain control for the older surgical patient can lead to delirium, depression, fluid imbalances, atelectasis, and fatigue (AGS, 2014; Bashaw & Scott, 2012).
   8. A large majority of hospitalized older adults are malnourished or at risk of malnutrition, placing them at risk of impaired skin integrity, wound or other infections, sepsis, and death (Kaiser et al., 2010; Lagoo-Deenadayalan et al., 2011; Scandrett et al., 2015).
   9. Approximately 1.5% of older surgical patients develop postoperative renal insufficiency, with a mortality rate of greater than 31% (Gajdos et al., 2013).
   10. Postoperative pulmonary complications occur in about 10% of older adult surgical patients, accounting for 40% of postoperative complications and 20% of preventable deaths (Lagoo-Deenadayalan et al., 2011).
   11. Among older surgical patients, SSI occurred in 8%, with a 7% mortality rate for those developing an SSI (Gajdos et al., 2013).
   12. Approximately 60% of SSIs are preventable. Developing an SSI can lead to an additional 11 postoperative hospital days and a two- to 11-fold increase in mortality risks (Anderson et al., 2014).
   13. The risk of developing CAUTI increases by 5% per day of catheterization (Bhardwaj et al., 2012; IHI, 2011a).
   14. CLABSI has been shown to double mortality risk, add up to 10 additional hospital days, and increase healthcare costs (Kaye et al., 2014).

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

15. Postsurgical deconditioning can slow recovery, delay in restoring independence with ADL, and increase risk for VTE, delirium, incontinence, constipation, pressure injuries, and falls (Lagoo-Deenadayalan et al., 2011).
16. The postsurgical period is a vulnerable time for increased risk of falls (Currie, 2008).
17. Approximately 15% of hospitalized patients in hospitals at any given time have pressure injuries, with 60,000 dying per year (IHI, 2011b).
18. The postsurgical older adult is at increased risk of VTE, which occurs in about 1 million patients each year (Bashaw & Scott, 2012; Dobesh, 2009).
19. Restraint use increases the risk of falls, pressure injuries, and delirium, leading to increased morbidity, mortality, and length of stay (Baumgarten et al., 2008; Inouye et al., 2007; Shorr et al., 2002).

IV. PARAMETERS OF ASSESSMENT

A. The PSIs are the key drivers of assessment and screening of surgical older adult patients. PSIs that are relevant to surgical patients include (AHRQ, 2014):
   1. Death among surgical inpatients
   2. CVC-related bloodstream infection
   3. Postoperative hemorrhage or hematoma, physiological and metabolic derangements, respiratory failure, pulmonary embolism or DVT, sepsis, and wound dehiscence
   4. Transfusion reaction

B. A seamless synthesis of various practice guidelines, such as those recommended in the Assessing Care of Vulnerable Elders-3 (ACOVE) Quality Indicators (AGS, 2007), Beers Criteria for Potentially Inappropriate Medication Use in Older Adults (AGS, 2014), and Clinical Practice Guideline for Postoperative Delirium in Older Adults (AGS, 2014), will be essential in achieving positive outcomes. All older adult postsurgical patients must be assessed and screened for:
   1. Falls (AGS, 2007)
   2. Frailty (AGS, 2007)
   3. Inappropriate medication use (AGS, 2012)
   4. Postoperative atelectasis (AGS, 2007)
   5. Postoperative delirium (AGS, 2007, 2014)
   6. Postoperative ileus (AGS, 2007)
   7. PONV (ASPAN, 2006)
   8. Postoperative pain (AGS, 2007, 2014)
   9. Pressure injuries (AGS, 2007)
   10. SSI (TJC, 2019)
   11. VTE (AGS, 2007; AHRQ, 2012)
   12. Restraint use (McGory et al., 2009)

C. Other epidemiologically significant assessment parameters, depending on the specific patient scenario, would include screening patients for CAUTI, CLABSI, and VAP. The nurse is encouraged to be familiar with the current best practices related to these HAIs.

V. NURSING CARE STRATEGIES

A. Unit admission
   1. Provide for high-quality handoff to include the following information:
      a. Preoperative assessment of cognitive and functional status
      b. List of comorbidities and preoperative home medications
      c. Preoperative assessment for falls and pressure injuries

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

d. Course of surgery, including any surgical complications and interventions for such, blood loss, blood transfusions, and intraoperative fluid use
e. Description of surgical sites, including dressings and instructions for care
f. Identification of invasive lines, including arterial and/or venous catheters, urinary catheters, GI tubes, chest tubes, and any other drainage devices (e.g., Jackson–Pratt, t-tube)
g. Patient's respiratory, cardiovascular, and cognitive status before transfer
h. Patient's current pain level and description of pharmacological and nonpharmacological interventions (used since surgery) before transfer

2. Perform comprehensive admission assessment to include:
   a. Airway, breathing, circulation, and cognitive status
   b. Pain and/or PONV, with immediate intervention if necessary
   c. Surgical site or surgical dressing if in place and intact
   d. Invasive lines, including line patency and visual inspection of site and dressing
   e. Thorough skin examination, particularly on bony prominences that may have been damaged during surgery
   f. ROM, mobility, and functional status
3. Discuss plan of care with patient and caregivers, addressing pain management, mobility, nutrition, hydration, and functional status.
4. Advocate for older adult patients who are unable to fully engage in their own care and for their designated caregiver.

B. Duration of stay—comprehensive management to prevent postoperative complications and sentinel events
   1. Postoperative delirium/cognitive and sensory function
      a. Use a validated tool to assess for delirium at least once per shift for up to 3 days postop.
      b. Provide for continuity of care (familiar residents, nurses, and care technicians).
      c. Provide continuous environmental and personal orientation.
      d. Adequately manage pain (see Pain Management in subsequent discussion).
      e. Avoid delirium-inducing medications such as benzodiazepines and anticholinergics (see also the AGS Beers Criteria; AGS, 2012).
      f. Avoid use of routine sedation.
      g. Provide for adequate fluid and nutrition intake (see Nutrition and Hydration in the following text).
      h. Avoid use of restraints (see Restraints).
      i. Avoid urinary catheterization or ensure prompt removal if in place (see HAIs in the following discussion).
      j. Promote adequate sleep, including involving family and caregivers in managing daytime sleepiness.
      k. Promote appropriate use of glasses, hearing aids, and other assistive devices.
      l. Provide for adequate communication as necessary, including the use of pen/paper, nonverbal communication, or translators.
      m. Minimize noise and patient care activities, as much as possible, during nighttime hours.
   2. Pain management
      a. Perform comprehensive pain assessment during hourly rounding or, at a minimum, with each set of vital signs.
         i. Rating of intensity (numeric, verbal, or visual scales)
         ii. Pain description to include location, characteristics, and impact of pain on function
         iii. Observation of signs of pain
         iv. Use appropriate scales (e.g., PAINAD) for patients with dementia
      b. For pain scores greater than 5, initiate comprehensive pain management plan.
         i. Pharmacological strategies
            a. Preferable use of nonopioid pain medications
            b. Address medication side effects, as necessary (e.g., morphine and constipation)
            c. Avoid NSAIDs, if possible

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

ii. Nonpharmacological strategies (e.g., massage, acupuncture, cognitive behavioral therapy, and distraction)
iii. See Chapter 18, Preventing Functional Decline in the Acute Care Setting, for specific protocols on the management of pain in older adults

c. Reassess pain post intervention.
i. At 15 minutes, for IV medication interventions
ii. At 1 hour for by-mouth medication interventions
iii. Within 4 hours, at a minimum, for other interventions

3. Nutrition and gastrointestinal complications
a. Assess for postoperative dysphagia.
i. Assessment by speech therapist if patient is at high risk for aspiration
ii. Modification of diet as necessary (e.g., alteration in food consistency)
b. Assess for and aggressively manage PONV.
c. Implement a comprehensive nutrition plan.
i. Assessment by a registered dietitian specializing in geriatric care
ii. Include adequate nutritional intake with supplementation as necessary
d. Implement a collaborative feeding plan, involving care technicians, family, and caregivers.
i. Maintain upright position while feeding and for at least 1 hour after.
ii. Provide comprehensive oral care.
iii. See Chapter 10, Assessment of Physical Function in the Older Adult and Chapter 25, Urinary Incontinence in the Older Adult for further discussion on nutrition and mealtime difficulties in older adults, respectively.
e. Assess for and manage constipation.
i. Avoid excessive use of anticholinergics and opioid medications, with quick transition to acetaminophen for mild to moderate pain.
ii. Administer bowel stimulants (e.g., senna and bisacodyl) and osmotic agents (e.g., polyethylene glycol) as needed.
iii. Provide adequate hydration (see Hydration).
iv. Promote early ambulation and mobilization (see Mobility).
f. Assess for and manage diarrhea.
i. Maintain adequate hydration (see Hydration) and nutritional intake.
ii. Collect stool samples, as ordered, to assess for *C. difficile* infection.
iii. Provide prompt treatment if positive for *C. difficile*, including implementation of contact precautions and maintenance of adequate hand-hygiene regimens.
g. Manage postoperative ileus for GI surgery patients.
i. Promote early feeding and mobilization.
ii. If NG decompression is used, continuously monitor for aspiration and postoperative pulmonary complications.

4. Hydration and renal complications
a. Initiate oral hydration as soon as feasibly possible.
i. Promptly manage PONV.
ii. Provide adequate hydration through IV fluids or tube feedings if oral hydration is not possible.
iii. Provide comprehensive oral care.
b. Monitor fluid status at least once per shift for the first 5 days postop.
i. Weigh patient daily.

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

ii. Accurately assess and document intake and output.
iii. Assess for changes in blood pressure, mental status, and new-onset atrial fibrillation that could indicate dehydration.
c. Perform routine screening of serum electrolytes, urea nitrogen, and creatinine.

5. Respiratory complications
   a. Implement an aggressive pulmonary toilet regimen.
      i. Promote use of incentive spirometer 10 times/hr.
      ii. Perform turn, cough, and deep-breathing exercises every 2 hours.
      iii. Provide chest percussion or chest physiotherapy as needed.
      iv. Promote early mobilization and ambulation (see Mobility).
      v. Maintain head of bed in an elevated position.
      vi. Adequately manage pain (see earlier section on Pain Management).
      vii. Avoid excessive use of narcotics and sedatives.
   b. Prevent VAP for intubated patients.
      i. Implement a VAP bundle, including:
         a. Elevation of the head of the bed between 30° and 45°
         b. Daily sedative interruptions and assessment of readiness to extubate
         c. Peptic ulcer disease prophylaxis
         d. DVT prophylaxis
         e. Daily oral care with chlorhexidine
6. Infection prevention
   a. Implement unit-wide HAI prevention programs.
      i. Continuing education on the appropriate use of guidelines for HAI prevention
      ii. Enforce universal precaution and contact precaution protocols
      iii. Hand-hygiene protocols, including hand rubbing with alcohol-based products or scrubbing with soap and water if hands are visibly soiled:
         a. Before touching the patient
         b. Before clean and aseptic procedures
         c. After contact with body fluids
         d. After touching a patient
         e. After touching a patient's surroundings
   b. Assess for signs/symptoms of infection.
      i. Local signs/symptoms, including redness, tenderness, swelling, and warmth
      ii. Systemic signs/symptoms, including:
         a. Fever greater than 38.0°C after postop day 2
         b. Altered mental status, agitation, respiratory distress, tachycardia, and hypotension
         c. Elevated white blood cell count
   c. SSI
      i. Perioperative prevention protocols, including prophylactic antibiotics and proper hair removal before incision (see Chapter 32, HIV Prevention and Care for the Older Adult on the perioperative care of older adult surgical patients)
      ii. For closed surgical incisions
         a. Maintain sterile dressing for closed surgical incisions up to 48 hours.
         b. Perform dressing changes using sterile technique.
         c. Remove dressing after 48 hours, unless instructed otherwise.

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

iii. For open surgical incisions
   a. Pack wound with sterile gauze and cover with sterile dressing.
   b. Consult with wound ostomy continence nurse for dressing-change regimen, which may continue post discharge.
iv. Continue to assess for local and systemic signs/symptoms of infection
v. Aggressively treat SSI
   a. Reopening and drainage of incision
   b. Wound culture
   c. Antibiotic treatment of infection if it becomes systemic
   d. Contact precautions and adequate cleaning and disinfecting of equipment/environment if infectious agent is an MDRO

d. CAUTI
   i. Implement CAUTI bundle.
      a. Avoid unnecessary catheterizations.
      b. Insert catheters using an aseptic technique, using the smallest possible catheter.
      c. Review catheter necessity daily and remove promptly if use is no longer indicated.
   ii. Remove catheters placed during surgery by postop day 3. If not removed, provide documentation of the need for continued use.
   iii. Provide bedpan, urinal, bedside commode, and/or ambulation to the bathroom as an alternative to catheterization.
   iv. Involve the patient, family, and caregivers in catheter plan of care.
   v. Continue to assess for local and systemic signs/symptoms of infection.
   vi. See Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection, for further information on the prevention of CAUTI.

e. CLABSI
   i. Implement a CLABSI bundle.
      a. Maintain adequate hand-hygiene regimens.
      b. Provide maximal barrier precautions when inserting lines.
      c. Use chlorhexidine skin antiseptic before insertion.
      d. Optimize site selection, avoiding the use of the femoral vein.
      e. Review necessity of line daily and provide for prompt removal if no longer indicated.
   ii. Institute appropriate dressing-change regimens.
      a. Use sterile gauze and a transparent, semipermeable dressing to cover the site.
      b. Replace dressing if it becomes damp, loosened, or visibly soiled.
      c. Replace gauze dressings every 2 days and transparent dressings every 7 days for short-term sites.
      d. Use chlorhexidine-impregnated sponge dressing for temporary catheters if other measures are not working.
   iii. Replace administration sets at appropriate intervals.
      a. At least every 7 days (but not less than 96 hours) for continuous or secondary infusion tubing
      b. Within 24 hours for tubing involving blood, blood products, or fat emulsions
      c. Every 6 to 12 hours for propofol infusion tubing
   iv. Disinfect (scrub) using an appropriate antiseptic when accessing catheter hubs, needleless injectors, and injection ports, using only sterile devices/equipment.
   v. Educate the patient and monitor to prevent submersion of CVC sites in water during showering or bathing.
   vi. Continue to assess for local and systemic signs/symptoms of infection.

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

7. Mobility, function, and frailty
   a. Work with interprofessional team to develop a plan for re-enablement after surgery.
   b. Incorporate the patient, family, and caregivers in the development of the plan of care for re-enablement.
   c. Address barriers to plan, including lack of understanding of roles among healthcare team members, patient dependence and daytime sleepiness, scheduling conflicts, and patient care equipment (e.g., IV tubing, catheters, and SCDs).
   d. Ensure physical therapy provides early assessment of the patient postsurgery and develops a mobility and strengthening plan, including the need for assistive devices.
   e. Provide ambulation by postop day 2.
      i. If ambulation is not possible, then documentation should be provided as to why ambulation did not occur.
      ii. Provide ROM exercises for patients unable to ambulate.
      iii. If ROM exercises cannot be performed, then documentation should be provided as to why they did not occur.
   f. Assist patient with ADL and IADL, while allowing for as much independence as possible.
8. Fall prevention
   a. Routine screening of fall risk, at least once per shift, using validated assessment tools
   b. Use a multipronged approach to address falls, including:
      i. Fall-risk screening on admission
      ii. Injury and injury risk-factors screening on admission
      iii. In-depth admission screening for any positive findings
      iv. Communication and education about the patient's fall risk
      v. Standardized interventions (e.g., armband identification, bed alarms, exercise and toileting regimens, pain relief) for any positive findings
      vi. Customized interventions for those at highest risk
   c. If a fall occurs, perform a comprehensive fall evaluation within 24 hours to include the presence or absence of any signs/symptoms of injury and a review of medications that may have contributed to the fall.
   d. See Chapter 19, Late-Life Depression, for a more detailed discussion on fall prevention in the older adult.
9. Skin integrity
   a. Address pressure injury prevention from admission to discharge, including:
      i. Perform a comprehensive skin assessment and adequately document findings on admission to the unit.
      ii. Complete a pressure injury risk assessment at least daily using a validated assessment tool (e.g., Braden Scale).
      iii. Daily comprehensive assessment of skin integrity
      iv. Moisture management
         a. Skin cleaning routinely and at times of soiling with mild cleansing agents
         b. Use of skin moisturizers for dry skin
         c. Use of absorbent underpads for excessive incontinence, perspiration, or wound drainage
      v. Maintenance of adequate nutrition and hydration (see earlier sections Nutrition and Hydration)
      vi. Minimize pressure on skin and bony prominences
         a. Turn and reposition the patient every 2 hours.
         b. Use mattresses and cushions to redistribute pressure.
         c. Address pressure from medical devices.
      vii. Use care when removing dressings, pads, tape, or leads in order to prevent skin tears.
   b. See Chapter 28, Preventing Pressure Injuries and Skin Tears, for further information on the prevention of pressure injuries in older adults.

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

10. VTE prevention
    a. Institute VTE prophylaxis, including:
        i. Assessment of VTE risk factors using validated measures (e.g., Caprini Risk Score)
        ii. Patient education about VTE risk
        iii. Early ambulation (see earlier section, Mobility)
        iv. Mechanical prophylaxis
            a. Use of SCDs
            b. Caution when using compression stockings as tight fit may impair circulation and lead to complications
            c. ROM exercises for patients unable to ambulate
        v. Pharmacological prophylaxis
            a. Use of LMWH or LDUH, as indicated
            b. Monitor for signs/symptoms of bleeding
11. Restraint use
    a. Restraint use should be avoided if at all possible.
    b. If restraints must be used, address the target behavioral or safety issue with the patient and caregivers and document in the chart.
    c. Use and document methods other than restraints that can be used as part of the plan of care.
    d. Seek early removal of devices or lines that will allow for the discontinuation of restraint use.
    e. Implement a care plan for the management of the patient in restraints.
        i. Release from restraints and reposition every 2 hours.
        ii. Perform face-to-face assessment at least every 4 hours (with physician assessment before renewal of restraint order).
        iii. Provide 15-minute observations, more frequently if warranted by the patient's condition.
        iv. Perform nurse-related interventions every 2 hours to address nutrition, hydration, toileting, personal hygiene, and ROM.
    f. See Chapter 27, Physical Restraints and Side Rails in Acute Care and Critical Care Settings, for further information on the use of restraints in the hospitalized older adult.

C. Discharge
1. Assess the need for social support or home healthcare expected after discharge.
2. Perform comprehensive discharge assessment of cognition and function (mobility, ADL, IADL) and compare with preoperative levels.
3. Assess nutritional status before discharge.
4. Perform comprehensive medication reconciliation.
    a. Address both prior-use and new medications.
    b. Facilitate education for new medications, including purpose of the drug, how to take it, expected side effects, and adverse side effects.
5. Provide detailed explanation to patient, family, and caregivers about the plan of care, including:
    a. Home health visits
    b. Physical or occupational therapy appointments
    c. Follow-up appointments
    d. Education on the use of new equipment or devices, and activity
    e. Education using teach-back strategies on performance of activities such as dressing changes, wound care, and medication administration

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient outcomes
   1. Maintain patient safety across the postoperative continuum.
   2. Assess patient decision-making capacity and honor patient and family care decision choices.
   3. Receive a comprehensive unit admission screening and ongoing assessment, including, but not limited to, the following domains: cognitive and behavioral, cardiopulmonary, functional status, nutrition, medication, and frailty.
   4. Receive adequate pain control through implementation of a patient-centered pain management plan.
   5. Restore mobility and functioning to preoperative levels before discharge.
   6. Receive timely and accurate information related to plan of care, including transitional care and long-term follow-up.
   7. Patient will not develop postop complications such as delirium, HAI, VTE, cardiopulmonary adverse events, GI or renal complications, and pressure injuries.
   8. Patient will be free from adverse events such as medication errors and falls.
   9. Comprehensive discharge planning, including discharge assessment of cognitive, functional, and nutritional status; medication reconciliation; discharge location; and home health or other follow-up care.

B. Provider outcomes
   1. Receive education and ongoing training on best practices in the care of the geriatric surgical patient.
   2. Assess patient's and family's decision-making capacity and involve the patient and family in the development of the plan of care.
   3. Provide patient and caregivers with timely and accurate information of patient's condition and plan of care, including transitions.
   4. Participate in high-quality interprofessional collaboration throughout the postoperative stay, including rounding, handoff, pain management, early mobility, nutrition and hydration, medication reconciliation, and transitional care.
   5. Use an evidence-based teamwork system to improve communication and teamwork skills (e.g., TeamSTEPPS) for patient safety (AHRQ, n.d.).
   6. Employ consistent and accurate documentation throughout the postoperative stay.
   7. Apply teach-back method in all patient and family education encounters that are culturally competent and patient centered.
   8. Staff nurses achieve a minimum of a bachelor's degree and obtain practice-specific certification (e.g., gerontological nursing).
   9. Organize and participate in unit-based practice and quality-improvement councils.
   10. Receive education and undergo competency verification that addresses the specialized knowledge and skills related to the care of older adults (AORN, 2015).

C. Systems outcomes
   1. Uphold patient safety and quality in the care of older adults through policy and social statements (e.g., safety language in hospital's mission).
   2. Review and align existing institutional policies and procedures with the latest national standards (see Relevant Practice Guidelines section).
   3. Facilitate and sustain interprofessional geriatric care teams.
   4. Establish a system of reporting patient safety issues (e.g., falls, medication errors, HAI, restraint use, etc.) across the postoperative continuum to identify opportunities for improvement.
   5. Adopt specific patient safety initiatives for older adults that include use of informatics, algorithms, checklists, and personnel oversight.
   6. Develop ongoing quality-improvement initiatives consistent with practice guidelines.

(*continued*)

Protocol 39.1: General Surgical Care of the Older Adult (*continued*)

7. Facilitate clinical rotations for nursing students across postoperative units to promote experiential learning for prelicensure students.
8. Enforce SSI, CAUTI, CLABSI, and VAP prevention policies, and conduct SSI surveillance based on CDC and TJC guidelines.
9. Organize and support interprofessional unit-based practice and quality-improvement councils (IHI, n.d.).
10. Demonstrate a commitment to culture of safety based on openness and mutual trust (e.g., patient safety leadership walk rounds; IHI, n.d.).

Care of the Older Adult With Fragility Hip Fracture*

Anita J. Meehan, Ann Butler Maher, Valerie MacDonald, Karen Hertz, and Ami Hommel

40

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the impact of fragility hip fracture on global healthcare systems.
2. Describe methods to assess bone health and fracture risk.
3. Identify common complications associated with care of older adults with fragility hip fracture.
4. Articulate specific nursing management strategies to address common complications.
5. Discuss fracture liaison service as a process for secondary fracture prevention.

OVERVIEW

The global incidence of fragility hip fractures continues to rise on an annual basis, making it one of the most common causes of hospital admission following trauma for older adults. In 1990, the global incidence of hip fracture was approximately 1.26 million; conservative estimates indicate that this number will burgeon to between 4.5 and 6.3 million by 2050 (Gullberg, Johnell, & Kanis, 1997). Although regional costs of hip fracture differ, it is a significant economic burden globally (Williamson et al., 2017). The annual cost of treating fragility fractures in the United States in 2005 was $17 billion, with hip fractures accounting for 72% of these expenses (Burge et al., 2007); these costs will increase with the growing aging population. Rehabilitation is not always successful. A study by Bertram, Norman, Kemp, and Vos (2011) found that 1 year after fragility hip fracture, 29% of patients did not achieve their prefracture level of function for activities of daily living (ADL).

Age-standardized incidence of hip fracture is falling in many countries, but this is far outweighed by overall population aging (Veronese & Maggi, 2018). Globally, the number of high-risk individuals is expected to double over the next 40 years (Odén, McCloskey, Kanis, Harvey, & Johansson, 2015), and the actual number of hip fractures is increasing. In the United States, although an analysis of Medicare claims data (2002–2015) showed a plateau in the age-adjusted hip-fracture incidence, this plateau featured 11,000 more hip fractures in women than previously estimated (Michael Lewiecki et al., 2018).

Despite advances in anesthesia, nursing care, and surgical techniques, this injury can be overwhelming for both patient and family, often resulting in permanent disability and increased reliance on others. Evidence-based interventions to reduce common complications and prevent secondary fractures are crucial to maximize recovery for individuals as well as decrease mortality and contain healthcare costs. Nurses are in an optimal position to make

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

a significant difference for patients who suffer a fragility fracture.

BACKGROUND AND STATEMENT OF PROBLEM

Hip fracture is the most devastating of all fragility fractures with risk of long-lasting disability and significant morbidity and mortality (Flikweert et al., 2018; Katsoulis et al., 2017). Although the vast majority of people who suffer a hip fracture are older females, the number of men suffering from fragility hip fracture is increasing, with almost 30% of all hip fractures occurring in men (Khosla, Amin, & Orwoll, 2008). As the age of patients with these injuries continues to trend upward and include more of the very old (older than 90 years), the incidence of coexisting medical problems and subsequent complications will increase (Bergstrom et al., 2009). Studies show that many of those who survive do not regain their prefracture level of independence (Bentler et al., 2009; Bertram et al., 2011). Many people recovering from hip fracture experience ongoing limitations in mobility, basic ADL, self-care, and quality of life (Dyer et al., 2016).

Mortality rates after hip fracture are significant as well; rates in the first year after fracture range from 18% to 33% (Abrahamsen, van Staa, Ariely, Olson, & Cooper, 2009; Pugely et al., 2014). von Friesendorff and colleagues (2016) followed 1,013 fracture patients and 2,026 matched community controls for 22 years; excess mortality remained high in postfracture patients of both sexes—up to 10 years in women and up to 20 years in men. The CHANCES Project that included over 120,000 patients from Europe and the United States found that hip fracture was associated with excess short- and long-term all-causes mortality in both men and women (Katsoulis et al., 2017).

Functional decline and subsequent death are attributable to the complex interplay of surgical stress, comorbidity, prefracture frailty, and level of physical and cognitive function. Although the fracture itself is responsible for less than half of the deaths (Parker & Johansen, 2006), families often identify the hip fracture as playing a central role in the patient's decline.

Decades of research shows that half of those who sustain fragility hip fracture have had a previous fragility fracture (Edwards, Bunta, Simonelli, Bolander, & Fitzpatrick, 2007; Gallagher, Melton, Riggs, & Bergstrath, 1980). Despite evidence demonstrating benefits of early detection of osteoporosis and implementation of strategies to reduce fracture risk (Akesson et al., 2013, Greene & Dell, 2010; Newman, Ayoub, Starkey, Diehl, & Wood, 2003), studies reveal that these recommendations are not being applied in practice (Ellanti et al., 2014; P. J. Mitchell, 2013; Sobolev, Sheehan, Kuramoto, & Guy, 2015).

Nurses are ideally positioned to play a pivotal role in preventing or mitigating the effects of common complications associated with fragility hip fracture, such as pain, delirium, venous thromboembolism (VTE), malnutrition, pressure ulcers, infections, fluid and electrolyte imbalances, and functional decline, and to manage programs focused on secondary fracture prevention.

DEFINITION OF FRAGILITY HIP FRACTURE

A fragility fracture is defined as a break in the bone resulting from low-impact trauma, such as falling from a standing height or less, or one that occurs in the absence of significant trauma. *Hip fracture* is a collective term for different types of fractures in the proximal end of the femur. The type and location of the fracture will determine how the fracture is repaired, specific postoperative restrictions, and how quickly healing will progress. Hip fracture location can be broadly categorized into two areas: intracapsular and extracapsular. Intracapsular fractures occur within the capsule that forms the hip joint and involve the head and neck of the femur. Fractures outside the capsule are further described as trochanteric or subtrochanteric fractures.

The most common location for a fragility hip fracture is the femoral neck (45%–53%), followed by intertrochanteric fractures (38%–49%) and, less often, subtrochanteric fractures (5%–15%; Marks, Allegrante, Ronald MacKenzie, & Lane, 2003; see Figure 40.1). A large prospective study of more than 220,000 persons found that people who suffered fractures around the trochanters tended to be older, with poorer health status, longer hospital stays, and poorer functional recovery (Fox, Magaziner, Hebel, Kenzora, & Kashner, 1999).

SURGICAL REPAIR OF HIP FRACTURE

When the bone breaks, the broken pieces may remain in their original position, and the fracture is said to be nondisplaced. A displaced fracture occurs if the broken pieces move out of alignment. Surgical treatment approaches depend on a variety of factors, including quality of the bone and postsurgical rehabilitation potential. A nondisplaced fracture may be stabilized using percutaneously inserted pins (Figure 40.2). If the fracture is displaced, or out of alignment, the blood supply to the area is often compromised, and patients will generally do better if some of the components of the hip are replaced. If both the ball and the socket, or acetabulum, are replaced, the procedure is referred to as a total hip replacement (Figure 40.2). If only the head of the femur is replaced, the procedure is referred to as a hemiarthroplasty (Figure 40.3). A nondisplaced fracture around the trochanters may be repaired with a large screw that slides within

FIGURE 40.1

Common sites of hip fracture.

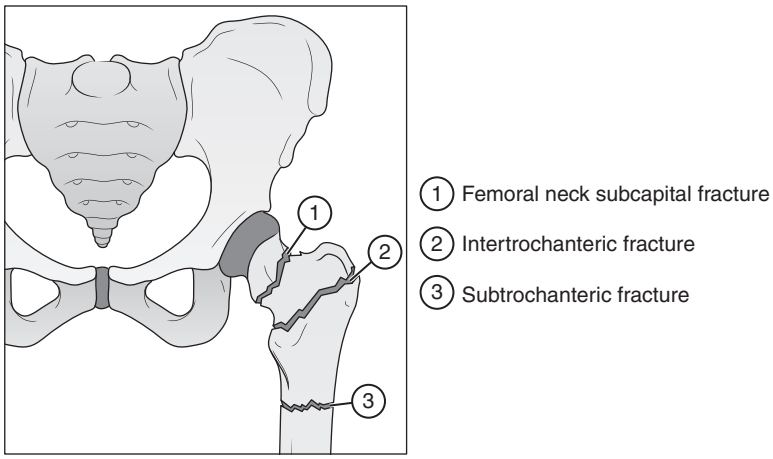

FIGURE 40.2

Total hip replacement (right hip) and cannulated screws (left hip).

the barrel of a plate that is screwed to the side of the femur. This type of fixation will stabilize the fracture over time by impacting the broken area on itself, thus stimulating new bone growth and is called a dynamic or compression hip screw (Figure 40.4). A subtrochanteric fracture distal to the trochanters is commonly fixed with an intermedullary rod and stabilized with a large screw (Figure 40.5). Regardless of the type of fixation, the goal postoperatively is to advance the patient to maximum weight-bearing status as quickly as possible. The type of surgical fixation and quality of the bone will determine weight-bearing limitations and/or postoperative positioning restrictions.

Fracture Repair as a Palliative Measure

The 1-year mortality rate after hip fracture is approximately 30% (Pugely et al., 2014). Those most likely to die have advanced age, severe comorbidities, poor ambulation abilities, severe dementia, and reside in a facility (Hu, Jiang, Shen, Tang, & Wang, 2012; Pugely et al., 2014; Wiles, Moran, Sahota, & Moppett, 2011). The fall and hip fracture may be precipitated by a cardiorespiratory, metastatic, or neurological condition. For patients with advanced age, severe comorbid illness, and high dependency needs, the hip-fracture surgery may be viewed as a palliative intervention performed with the goal of reducing pain and improving the quality of life (Ko & Morrison, 2014; Koso, Sheets, Richardson, & Galanos, 2018; Leland, Teno, Gozalo, Bynum, & Mor, 2012). For more detailed information, see Chapter 43 Palliative Care Models.

PATHOPHYSIOLOGY

Fragility hip fracture is a painful sequela of poor bone quality and a traumatic event, often involving a fall. In adults, small amounts of bone mineral are lost as osteoclast cells clean up old bone, in a process known as resorption. These bone minerals are replaced by bone-building cells called osteoblasts in a process known as remodeling. With aging, the loss of bone occurs progressively and asymptomatically,

accelerating in women after menopause. When the balance tips toward excessive resorption, bones weaken (osteopenia) and can become brittle and prone to fracture (osteoporosis) over time. Based on a number of factors, men develop greater bone strength as they mature and lose bone strength more slowly, in part because of a more gradual loss in sex hormone levels with aging (Willson, Nelson, Newbold, Nelson, & LaFleur, 2015).

A fracture is often the first indication of diminished bone health. Approximately 10 million people in the United States have osteoporosis, and as the population continues to age, an increasing number of people will be affected by this disease (Wright et al., 2014).

Risk Factors for Fragility Hip Fracture

Falling is the leading cause of hip fracture in older adults. Determination of the circumstances precipitating a fall and fracture is essential to illuminate underlying issues that

need to be addressed in addition to the fracture. Intrinsic factors, such as acute medical conditions, exacerbation of chronic conditions, and visual or balance problems, as well as extrinsic factors, including environmental factors and lifestyle, contribute to increasing the risk of falling.

Intrinsic Fall Risk Factors

Normal age-related changes affecting vision, hearing loss, balance, and/or gait disturbances coupled with a slowed reaction time are factors that contribute to increased fall risk in older adults. In addition, many older adults have underlying chronic conditions or an acute event that may result in a fall. A neurological event, cardiac condition, dehydration, urge incontinence, or underlying infection may contribute to increasing the risk of falling and subsequent fracture. Medications may have anticholinergic side effects that increase fall/fracture risk, for example, dizziness or blurred vision.

Sarcopenia is an age-related decline in muscle bulk and quality that may escalate the risk of fracture, especially if associated with diminished functional mobility, reduced lower quadriceps strength, and poor balance or body sway. Sarcopenia and osteoporosis are linked from a biological and functional perspective and increase fracture risk in older adults. The elevated fracture risk from sarcopenia and osteoporosis is a result of the decline of muscle mass and strength, the decrease in bone mineral density (BMD), and limited mobility (Tarantino et al., 2015).

Extrinsic Fall Risk Factors

Environmental tripping hazards, for example, small pets, clutter, or poor fitting footwear, may contribute to increasing fall risk. Alcohol or drug use may impair balance and/or cause drowsiness or delirium. Another concern in this population is potential elder abuse. The admitting head-to-toe assessment is critical to determine whether the circumstances of the fall are consistent with the pattern of injury. (For more detailed information, see Chapter 16, Elder Mistreatment Detection; Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care; and Chapter 34, "Substance Misuse and Alcohol Use Disorder in the Older Adult.)

Diminished Bone Strength

The other risk factor that contributes to increasing the risk of fragility fracture is bone loss associated with aging. There are several factors that increase the risk of bone loss.

- *Age.* Bones weaken as we age. Eighty percent of patients hospitalized for hip fracture are of age 65 years and older (Hall, DeFrances, Williams, Golosinskiy, & Schwartzman, 2010).
- *Gender.* The drop in estrogen levels that occurs with menopause accelerates bone loss in women. The majority of hip fractures occur in women.
- *Nutrition.* Poor nutrition and a diet low in calcium and vitamin D contribute to increasing risk of hip fracture.
- *Heredity.* A family history of osteoporosis or broken bones after age 50 years and people with a low body mass index are at greater risk for fragility fracture.
- *Lifestyle.* Smoking and drinking more than two alcoholic beverages per day can interfere with normal processes of bone remodeling, resulting in bone loss. Inactivity can weaken bones.
- *Medications.* Long-term corticosteroid use can weaken bones. Side effects of medications can affect balance and eyesight, which increases fall risk.
- *Medical conditions.* Endocrine disorders, such as hyperparathyroidism, and intestinal disorders, such as Crohn's disease, may reduce absorption of calcium and vitamin D, which negatively impacts bone health.

Frailty and Sarcopenia

Two complex geriatric syndromes, frailty and sarcopenia, are now recognized as significant risk factors for fragility fracture. They often coexist (Carmeli, 2017), but while sarcopenia is considered a component of frailty, frailty is not considered a component of sarcopenia (Wilson, Jackson, Sapey, & Lord, 2017). So while frail older individuals will exhibit some degree of sarcopenia, not all sarcopenic individuals are frail.

Frailty

Although a consensus definition remains elusive, frailty is characterized by an older person's increased vulnerability and diminished resistance to stressors that increase risk of adverse health outcomes (Morley et al., 2013; Rodríguez-Mañas et al., 2013). Frailty occurs on a continuum (Sieber, 2017) that is dynamic and can improve or worsen over time. It can incorporate physical and/or psychological aspects and is influenced by a range of factors that are treatable (medical diagnoses, social issues such as isolation and food insecurity) and those that are more difficult to manage (dementia, depression, catabolic disorders; Marques & Quierós, 2018). Frailty can be objectively measured, although only a few frailty measures seem to be valid and have good predictive ability (Apóstolo et al., 2017). Frailty is closely linked to musculoskeletal health (McGuigan, Bartosch, & Åkesson, 2017). It contributes to functional disability and osteoporosis development (Rosen & Klibanski, 2009) as well as increasing fall risk in

community dwelling older adults (Cheng & Chang, 2017; Kojima, 2015). In a representative profile of U.S. elders using data from the National Health and Aging Trends Study, over half of the individuals identified as frail had suffered a fall in the previous year (Bandeen-Roche et al., 2015). For more information on frailty, see Chapter 31, The Frail Hospitalized Older Adult.

Sarcopenia

Primary sarcopenia is an age-related, progressive, and generalized decline in muscle mass and strength along with low physical performance that negatively impacts ADL (Carmeli, 2017; Cruz-Jentoft et al., 2010). The decline in muscle mass begins around age 30 and significantly accelerates after age 5 with a concomitant decrease in muscle strength (Curcio et al., 2016). In 2018, the European Working Group on Sarcopenia in Older People (EWGSOP2) updated their guidelines, which now define sarcopenia as a muscle disease and emphasize that "practitioners have ever-increasing possibilities for preventing, delaying, treating, and sometimes even reversing sarcopenia by way of early and effective interventions" (Cruz-Jentoft et al., 2019, p. 17).

Sarcopenia increases fracture risk due to decline in muscle mass and strength (a critical component of walking), which in turn increases the risk for gait and balance deficits as well as falls (Beaudart, Zaaria, Pasleau, Reginster, & Bruyère, 2017; Carmeli, 2017; Dhillon & Hasni, 2017; Wong et al., 2019). In a meta-analysis that included 10,073 subjects, Zhang et al. (in press) found that sarcopenia is a risk factor for falls among community older people but not among nursing home residents.

Clinically, muscle strength is evaluated by handgrip strength, whereas physical performance can be measured by gait speed and/or the Short Physical Performance Battery and "timed up and go" from a chair (Liguori et al., 2018). Muscle mass evaluation remains a diagnostic issue (Curcio et al., 2016), with whole body DXA and CT/MRI scans being the most commonly used (Lee et al., 2019), while CT/MRI remains the gold standard. There is ongoing research about determining clinically meaningful cutoff values for muscle mass and strength (see, e.g., Chiles Shaffer, Ferrucci, Shardell, Simonsick, & Studenski, 2017) as well as appropriate values across diverse populations (Cruz-Jentoft et al., 2019).

Our understanding of sarcopenia continues to expand and evolve (Marzetti et al., 2017). Interventions can mitigate some of the functional decline it causes. These include aerobic and resistance exercise; nutritional interventions (e.g., increased protein to counteract changes in protein metabolism as well as higher catabolic rates associated with chronic illness, vitamin supplements); and pharmaceutical agents currently under investigation (testosterone, selective androgen receptor modulators, ghrelin and ghrelin receptor agonists, and angiotensin-converting inhibitors, among others.) For more detailed information, see Cruz-Jentoft et al. (2019); Cruz-Jentoft, Kiesswetter, Drey, & Sieber, (2017); Carmeli (2017); and Liguori et al. (2018).

Assessment of Fracture Risk and Bone Health

There are two widely used measures to determine fracture risk and bone health. The World Health Organization (WHO) developed the Fracture Risk Assessment Tool (FRAX) in 2008 (Kanis, Johnell, Oden, Johansson, & McCloskey, 2008). The FRAX is a major achievement in helping to determine those patients who may suffer a fragility fracture (Vernon & King, 2011) as well as those who may be candidates for pharmacological therapy for osteoporosis (Watts, 2011). The FRAX contains 12 variables used to calculate risks, such as BMD, including age, low body mass index, previous fragility fracture, parental history of fracture, glucocorticoid treatment, current smoking status, rheumatoid arthritis history, alcohol intake, and other secondary causes of osteoporosis. The FRAX takes approximately 20 minutes to complete and provides a qualitative estimate of 10-year fracture risk. Its intended use is for those not currently being treated for osteoporosis. The FRAX is commonly administered in conjunction with dual-energy x-ray absorptiometry (DEXA scan; www.shef.ac.uk/FRAX/tool.jsp).

The DEXA scan is the most widely used method to evaluate BMD. The WHO uses BMD measured by the DEXA to define osteoporosis. A DEXA scan measures the density of bone at two areas, the proximal femur and the lumbar spine. The results are reported as a T-and a Z-score. The standard measure T-score is 0.0, representing bone density of a young healthy individual at peak bone health. According to WHO criteria (Kanis et al., 2008), a T-score higher than −0.1 is considered normal bone density, a T-score between −1.0 and −2.5 is considered osteopenia, and a T-score below −2.5 is considered osteoporosis. The Z-score is a comparative measure of persons of the same age and gender as the patient and can be used to evaluate men, children, and premenopausal women. A Z-score measure of −2.0 is considered low bone mass for chronological age, and a Z-score of above −2.0 is considered within the expected range for age (National Osteoporosis Foundation [NOF], 2010).

Although BMD using the DEXA is considered the gold standard surrogate marker of bone health, and

assessment of fracture risk is completed using the FRAX, there are newer measures being reported in the literature that hold promise as measures of bone health and treatment monitoring (Fitton, Astroth, & Wilson, 2015). Bone turnover markers (BTM) are measures of by-products of protein secreted by bone-forming osteoblasts, measured in serum, and bone-resorbing osteoclasts, measured in urine. Unlike the DEXA, which evaluates specific skeletal sites, these markers reflect global skeletal activity and have the potential to be used to monitor effectiveness of treatment (Kleerekoper, 2001). Another approach under investigation is the use of MRI to evaluate bone marrow adipose tissue (BMAT). A study conducted by Li et al. (2014) found that women with osteopenia and osteoporosis had a higher marrow fat content compared to those with normal BMD. There is growing attention to the use of BTM and BMAT as biomarkers for bone quality (Burch et al., 2014; Li et al., 2014; Tang et al., 2010).

COMMON COMPLICATIONS AND EVIDENCE-BASED NURSING CARE STRATEGIES

Although in most cases surgical repair is crucial, optimal outcome depends on an interprofessional approach to care, often referred to as orthogeriatrics (Wallace et al., 2019). Advanced age, chronic conditions, and diminished physical and cognitive reserves expose older adults with fragility hip fracture to increased risk of developing specific geriatric syndromes. It is of crucial importance that nursing care include evidence-based strategies to engage both patient and family in learning about risk factors, prevention, and management of complications such as delirium, pressure ulcers, VTE, malnutrition, constipation, fluid and electrolyte imbalances, functional decline, infections, and prevention of secondary fractures (Meehan et al., 2019).

Although hospitalized older adults experience many of these complications and most are discussed elsewhere in this book, they coalesce in the hip-fracture patient population to increase morbidity and mortality and significantly reduce the individual's prospects for maximum functional recovery. Nurses play a vital role in ameliorating these risk factors and ensuring optimal outcomes.

PAIN: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

A fall, hip fracture, and surgical repair are painful assaults injuring the skin, muscle, and bone. Older patients with hip fractures are at high risk for unmanaged pain with higher rates of delirium, impaired mobility, and long-term functional impairment as a result (Bjorkelund, Hommel, Thorngren, Lundberg, & Larsson, 2011; Peeters et al., 2016). Unmanaged pain disturbs sleep, diminishes appetite, and may also increase the risk of delirium (American Geriatrics Society [AGS] Panel on the Pharmacological Management of Persistent Pain in Older Persons, 2009). Painful conditions, such as osteoarthritis, osteoporotic fractures, degenerative spine disease, cancer, and neuralgias, increase in prevalence with age and may add to the pain experience for patients with hip fracture (Reid, Eccleston, & Pillemer, 2015).

Nursing Management Strategies to Address Pain

There is a paucity of evidence on pain management for patients with hip fractures. Studies often exclude those with delirium, dementia, and/or severe comorbid illness, approximately 40% of the population, because of challenges with communication and obtaining consent. Therefore, expert opinion supplements the evidence for this section.

As functional mobility is the key to recovery, a balanced approach to pain management is required to achieve both mobility and comfort. Frequent evidence-based pain assessment is the foundation for effective pain management. This begins with an evidence-based pain history tool and screening health records. Information on preexisting painful conditions and prior pain treatments serve to illuminate potential sources of discomfort and types of pain to incorporate into the treatment plan. Assessing and recording pain intensity using a valid scale with vital signs make the pain assessment visible and help ensure that pain is assessed on a regular basis (Purser, Warfield, & Richardson, 2014). The specific pain scale used would be based on the patient's comprehension and preference (Herr & Titler, 2009). For patients with severe cognitive impairment, one should use a validated pain behavior scale such as the Pain Assessment in Advanced Dementia (PAINAD) Scale, created for those with dementia (Herr, Coyne, McCaffery, Manworren, & Merkel, 2011; Warden, Hurley, & Volicer, 2003). For information on specific pain assessment tools, see Chapter 22, Pain Management in the Older Adult.

A multimodal approach to analgesia helps maximize the synergistic effect of analgesics while decreasing the dose requirement of any one medication, thereby limiting their adverse effects (Kang et al., 2013; Roberts & Brox, 2015). Preoperative regional anesthesia is recommended (Amin, West, Farmer, & Basmajian, 2017; Peeters et al., 2016). A combination of a geriatric-appropriate opioid together with acetaminophen and regional analgesia (e.g., nerve block) may manage pain while reducing side effects such as sedation and delirium (Kang et al., 2013). Nonpharmacological strategies, such as relaxation exercises, physiotherapy, and application of heat or cold, may reduce opioid requirements and improve comfort (Abou-Setta

et al., 2011). Nonsteroidal anti-inflammatory medications are usually not recommended because of their higher rates of adverse effects, such as bleeding, cardiovascular complications, and acute kidney impairment, in older patients (AGS Panel on the Pharmacological Management of Persistent Pain in Older Persons, 2012; AGS Beers Criteria Update Expert Panel, 2019).

Minimizing sedation while maximizing pain control is a goal to facilitate mobility. It is important to identify the time of the peak effect of the specific analgesic and route of administration and administer the analgesic when peak effect will coincide with physiotherapy or ambulation. Strategic timing of analgesics can help alleviate the increased pain of mobilization and reduce the need for additional opioid doses.

Regional blocks (e.g., femoral and fascia iliaca compartment block) are effective in relieving the acute pain of hip fracture compared with standard care (Amin et al., 2017; Peeters et al., 2016; Steenberg & Møller, 2018). The block is typically administered before surgery and provides substantial perioperative pain relief, reducing the need for opioid analgesia and the risk of delirium (Peeters et al., 2016). Nurse-initiated fascia iliaca blocks have improved pain management effectiveness and safety (Dochez et al., 2014).

Managing moderate to severe pain after hip fracture may involve the administration of opioids. Older adults are more susceptible to the adverse effects of opioids, and a "start low/go slow" approach to opioid administration is advised. This approach is not appropriate if the patient was on opioid therapy before admission because a higher dose may be required. An individualized approach considering the patient's opioid use history with careful monitoring and titration of analgesic to achieve an acceptable pain level is essential.

Strategies to Manage Adverse Effects of Analgesics

Oversedation is a serious adverse effect of opioid therapy that could lead to respiratory failure. According to Pasero (2009), the level of sedation increases gradually and is a warning sign requiring a prompt reduction in opioid use with more frequent monitoring. The first 24 hours of opioid therapy are the riskiest time, and sedation assessment using a validated tool every hour is recommended, with reduction to every 4 hours thereafter if the patient is stable (Pasero, 2009). The Pasero Sedation Scale is recommended as a validated tool that defines levels of sedation as well as actions to take for patient comfort and safety.

Constipation is highly likely to occur and increases the risk of abdominal and rectal pain, delirium, agitation, and bowel obstruction (Neighbour, 2014). Although individual bowel habits vary, in general, the goal is that the patient has a moderate to large bowel movement (BM; e.g., at least 8 ounces) every 48 hours (Auron-Gomez & Michota, 2008), and daily monitoring of BMs is required. The preemptive use of a laxative, a high-fiber diet, and fluids is recommended (Neighbour, 2014).

Other practice recommendations include:

- Avoid prolonged fasting and delays to surgery.
- Encourage a minimum of 6 cups of oral fluid daily unless otherwise restricted.
- Mobilize frequently, for example, walk to the toilet while awake.
- Avoid the use of bedpans; use a toilet or bedside commode. Ensure privacy for patient dignity.

Nausea and vomiting are potential adverse effects of opioids and are typically managed with antiemetic medication. However, medications with anticholinergic properties should be avoided, because they can cause delirium (AGS Beers Criteria Update Expert Panel, 2019). Delirium can also be an adverse effect of analgesics; however, delirium is also associated with unmanaged pain. Assessing and adjusting the medication or reducing the dose of analgesics are interventions that may reduce the analgesic contribution to delirium (Meehan et al., 2019).

DELIRIUM: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Delirium is the most common complication associated with hip fracture. Rates of delirium in this population have been reported to be as high as 62% (J. J. White, Khan, & Smitham, 2011). Findings from multiple studies confirm that delirium is independently associated with a variety of adverse outcomes, including pressure injuries, functional decline, institutionalization, dementia, and death (Arshi et al., 2018; Krogseth, Wyller, Engedal, & Juliebø, 2014; Malik, Quatman, Phieffer, Ly, & Khan, 2019; Morandi et al., 2019).

One of the strongest predictors of postoperative delirium is preoperative cognitive dysfunction (Oh et al., 2015). Cognitive impairment is common in the hip-fracture population. Griffiths et al. (2012) report that approximately 25% of hip-fracture patients have a moderate cognitive impairment. A systematic review and meta-analysis of 32 studies involving 6,704 patients with hip fracture found that those with dementia were six times more likely to develop postoperative delirium (Smith et al., 2017). Lundstrom, Stenvall, and Olofsson (2012) studied 129 patients with hip fracture who developed postoperative delirium and found that patients with delirium

superimposed on dementia (54%) displayed hyperactive symptoms, whereas those without baseline dementia more commonly displayed symptoms of hypoactive delirium.

Patients with hypoactive delirium are 2.9 times more likely to die within 1-year post fracture than those whose delirium resolves (Kiely et al., 2009). Bellelli, Mazzola, et al. (2014) reported that for each day of postoperative delirium in patients with hip fracture, the risk of dying at 6 months increases by 17%. Postoperative delirium is also a prognostic indicator for dementia. A prospective study of 106 hip-fracture patients found that those who developed delirium, when compared to those who did not, were at increased risk for dementia at 6 months post op (36% vs. 7%; Krogseth, Wyller, Engedal, & Juliebø, 2011). The patient's primary care provider should be alert to test for cognitive changes post hip fracture.

The ability to differentiate between dementia and delirium is important because, unlike dementia, the cognitive changes in delirium are potentially preventable, and likely reversible. Despite its prevalence, significant cost, and negative outcomes, nurses and physicians often fail to recognize delirium, especially when dementia or the hypoactive form of delirium is present (Lemiengre et al., 2006; Steis & Fick, 2008). Nurses are ideally suited to assess for risk factors and initiate prevention strategies and interventions to address delirium in this vulnerable population.

Nursing Management Strategies for Delirium

Early identification of risk and timely initiation of preventive interventions is the most effective approach to manage delirium (Oberai et al., 2018). Studies suggest that this approach may prevent up to 40% of the cases of delirium (Inouye et al., 1999; Marcantonio, Flacker, Wright, & Resnick, 2001). The Delirium Elderly At Risk (DEAR) is a tool created to identify risk for pre- and postoperative delirium in the hip-fracture population (Freter, Dunbar, Koller, MacKnight, & Rockwood, 2015). For those identified as being at high risk, further and continued daily assessment for delirium should be performed using a validated measure such as the brief version of the confusion assessment method (bCAM) or the 4 A's test (4AT; Bellelli, Morandi, et al., 2014). Vigilant assessment and documentation of cognitive status in the medical record will increase the likelihood that delirium is detected and underlying causes identified and addressed.

Determination of baseline cognition is essential in the assessment for delirium. One of the highest predictors of delirium is having a history of delirium, so it is important to inquire about a previous episode. It is also important to ask about alcohol or other drug use in order to avoid withdrawal symptoms during hospitalization. Often family is the best source of this information. While delirium cannot be prevented in every instance, optimal results are achieved by clinicians who are knowledgeable of the risk factors and initiate preventive strategies. Martinez, Tobar, and Hill (2015) conducted a systematic review of nonpharmacological, multicomponent interventions for delirium. They found that strategies such as ensuring access to sensory aids, providing a restful environment, ensuring adequate hydration and nutrition, and adequate and appropriate pain control were effective in reducing incident delirium. Hip fracture is a painful event, and the management of postoperative pain can be especially challenging in the delirious patient. It is not uncommon for analgesia to be withdrawn or reduced as a way to reduce agitation associated with acute confusion. However, as Morrison et al. (2003) demonstrated, inadequate pain control may also contribute to delirium.

Delirium is a frightening experience for the patient and family, and distressing for staff. Conversations should be initiated with families on admission to educate them on risks for delirium and reinforce the vital role families and friends play in providing a sense of familiarity, comfort, and reassurance (AGS Expert Panel on Postoperative Delirium in Older Adults, 2015; Meehan et al., 2019; for more detailed information, see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment).

MALNUTRITION: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

It is estimated that as many as 63% of patients with fragility hip fracture are malnourished at the time of admission (Wyers et al., 2010). Circumstances prior to and surrounding the fall and fracture coupled with processes of care, such as prolonged restriction of solid food while awaiting surgery, combine to increase the risk of malnutrition. The stress of the acute injury and surgical intervention results in postoperative nutritional intake that routinely fails to meet energy and protein requirements, contributing to further deterioration in nutritional status (Bell, Bauer, Capra, & Pulle, 2013). Surveys of dietary intake of patients recovering from hip fracture reveal a less-than-optimal dietary intake (Lumbers, New, Gibson, & Murphy, 2001).

Lack of adequate nutrition leads to lowered cognitive function, lean muscle wasting, weakness, and impaired cardiac function, all of which contribute to impaired mobility and an increased risk for developing postoperative complications (Wyers et al., 2010). Duration of preoperative fasting is also a precipitating and modifiable risk factor for postoperative delirium (Radtke et al., 2010). A descriptive cohort study of 428 older adults with hip

TABLE 40.1
Complications Associated With Malnutrition

Complication	Odds Ratio of Developing If Malnourished
Pressure ulcers	3.8
Postop pneumonia	2.8
Catheter-associated urinary tract infections	5.1
Surgical site infections	2.5

Source: Data from Fry, D. E., Pine, M., Jones, B. L., & Meimban, R. J. (2010). Patient characteristics and the occurrence of never events. *Archives of Surgery, 145*(2), 148–151. doi:10.1001/archsurg.2009.277. *Evidence Level IV.*

fractures revealed that preoperative fasting of 12 hours or longer was a risk factor for development of delirium and an increased risk for mortality at 4 months postoperatively (Bjorkelund et al., 2011). Fry, Pine, Jones, and Meimban (2010) reviewed the records of more than 800,000 surgical patients from more than 13,000 hospitals and found malnutrition was an independent risk factor for developing a number of hospital-acquired infections (Table 40.1).

Although common preoperative fasting time in the United States remains "NPO (nothing by mouth) after midnight," a growing number of organizations have endorsed liberalizing food and fluid restrictions (American Society of Anesthesiologists Committee, 1999; Braga et al., 2009). Evidence indicates that patients with no specific risk of aspiration may drink clear fluids up to 2 hours before anesthesia and have solid foods up to 6 hours before surgery. The maximum period of oral fasting should be no greater than 12 hours under any circumstances (Shiga, Wajima, & Ohe, 2008).

In addition to liberalizing fasting restrictions, several studies have reported on the benefits of prescribing, in select patients, a clear carbohydrate-rich beverage, either apple juice or a commercially prepared formula, to be consumed 2 to 3 hours before surgery. Carbohydrate loading may reduce the negative consequences of preoperative fasting, which includes postoperative nausea and vomiting, loss of muscle strength, and postoperative insulin resistance (Melis et al., 2006; Nygren, Thorell, & Ljungqvist, 2015; Yagci et al., 2008).

The American Academy of Orthopaedic Surgeons (AAOS) guidelines for management of hip fractures in the older adult (Roberts & Brox, 2015), the European Pressure Ulcer Advisory Panel (EPUAP), and National Pressure Ulcer Advisory Panel (NPUAP, 2014) support the practice of offering a high-protein oral nutritional supplement (ONS) in addition to regular diet for patients at nutritional risk caused by chronic or acute illness following surgery. A systematic review of nutritional interventions provided to older adults recovering from hip-fracture surgery endorsed the benefits of pre- and postsurgical protein and energy supplements in preventing complications 6 months after surgery; however, more robust studies are needed (Avenell, Smith, Curtain, Mak, & Myint, 2016).

Nursing Management Strategies for Malnutrition

Nutritional screening is suggested for all hospitalized patients (Mueller, Compher, & Ellen, 2011). Biochemical indicators should no longer be used to identify malnutrition. Albumin and prealbumin in the presence of inflammation are depressed. Thus, a low albumin or low prealbumin may indicate illness and inflammation rather than reflect nutritional status (Anthony, 2008; White, Guenter, Jensen, Malone, & Schofield, 2012). Screening for malnutrition should be performed using a validated tool.

While there is no "gold standard" screening tool for malnutrition, the Mini Nutritional Assessment (MNA) tool was developed specifically for screening malnutrition in the geriatric population. The MNA and a shortened version, the MNA-SF, have been used internationally; both are available in 30 languages and are free to download (www.mna-elderly.com). Several studies have tested nutrition risk assessment measures in the hip-fracture population and found MNA-SF optimal in identifying functional decline during the postop period (Inoue, Misu, Tanaka, Kakehi, & Ono, 2019; Koren-Hakim et al., 2017). Prompt referral to a registered dietitian for at-risk patients should be a nursing priority and is essential in order to curtail the negative consequences associated with malnutrition (Jefferies, Johnson, & Ravens, 2011).

Nurses should be aware of the potential for swallowing problems in older adults with hip fracture. A prospective cohort study of 181 patients after hip-fracture surgery found that 34% presented with oropharyngeal dysphasia within 72 hours after surgery. Common factors in those with swallowing problems included preexisting dementia, postoperative delirium, and preexisting respiratory problems (Love, Cornwell, & Whitehouse, 2013). Early identification and referral to speech therapy for a more comprehensive swallow evaluation are essential to avoid aspiration pneumonia.

Implementation of protocols that liberalize preoperative fasting in accordance with existing guidelines should be advocated for patients who have no specific risk of aspiration, for example, gastroparesis. Evidence-based

protocols should include orders to advance the diet as tolerated after surgery (Association of Anaesthetists of Great Britain & Ireland, 2014). In all care settings, nursing staff should monitor dietary intake and notify a dietitian if a consistent pattern of consuming less than 50% of meals is observed. For patients who are malnourished, incorporating a high-protein ONS as part of the daily medication distribution is an effective strategy to enhance the likelihood of consumption and embed a nutritional intervention into the routine process of care (Breedveld-Peters et al., 2012; Dillabough, Mammel, & Yee, 2011; Meehan et al., 2015). Incorporating dietitian recommendations in discharge handoff information is essential in order to continue interventions aimed at addressing or preventing malnutrition in this vulnerable population.

For more detailed information, see Chapter 13, Nutrition in the Older Adult.

FLUID AND ELECTROLYTE IMBALANCE: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Patients admitted for hip fracture are at risk for dehydration, electrolyte disturbances, fluid overload, and heart failure because of advanced age and comorbid conditions (Bukata et al., 2011). Optimized perioperative fluid management helps to manage the frequent incidence of dehydration in hip-fracture patients while avoiding volume overload, which is crucial because many of these patients have coexisting cardiac disease (Gerber et al., 2013). Strict fluid balance monitoring that begins in the emergency department and continues throughout the acute hospitalization is essential.

Dehydration

Older adults admitted with hip fracture often present with dehydration for a variety of reasons. These include preexisting restricted fluid intake, diminished thirst reflex with subsequent diminished fluid intake, and prolonged time from injury to discovery and initiation of care. Many patients who suffer from incontinence or frequency self-regulate fluid intake to reduce the risk of incontinence, or they may have difficulty accessing toilet facilities. Diuretic use is high in this patient group and may be partly responsible for altered fluid balance. Because dehydration diminishes perfusion to both organs and tissues, it is implicated in the development of a range of conditions and complications prevalent in the hip-fracture population, such as delirium, acute kidney injury (AKI), pressure ulcers, falls, VTE, and urinary tract infections.

Fluid Overload/Heart Failure

Preexisting heart failure or renal conditions that increase fluid load will worsen with the stress of the injury and subsequent surgery. This diminished cardiac and renal function renders the frail older adult more susceptible to fluid overload. For a detailed discussion, see Chapter 36, Fluid Overload: Identifying and Managing Heart Failure Patients at Risk of Hospital Readmission.

Electrolyte Imbalance/Acute Kidney Injury

Electrolyte imbalances such as hyponatremia and hypokalemia are prevalent in patients admitted with hip fracture and are associated with increased risk of 30-day mortality (Madsen, Jantzen, Lauritzen, Abrahamsen, & Jorgensen, 2016). Diuretics and inappropriate maintenance of intravenous fluids may exacerbate these problems. Limited renal reserve is reflected in the high risk of AKI in hip-fracture patients, which is estimated to be 16% (Bennet, Berry, Goddard, & Keating, 2010) and is associated with prolonged hospital stay, increased morbidity and mortality, and poor outcome (Ulucay et al., 2012).

Older patients admitted to the hospital for emergency surgery are at increased risk for AKI and its associated pre- and postoperative complications. Risk factors include preexisting comorbid conditions; age; complex polypharmacy; and use of diuretics, nephrotoxic medications such as angiotensin-converting enzyme (ACE) inhibitors used in the management of hypertension and heart failure, and nonsteroidal anti-inflammatory drugs (NSAIDs) used for pain relief. Time spent down before patient discovery after injury as well as immobility before surgery also increases the risk of rhabdomyolysis. The most significant complication of rhabdomyolysis is AKI (Torres, Helmstetter, Kaye, & Kaye, 2015).

Nursing Management Strategies: Fluid and Electrolyte Imbalances

Dehydration

Factors that add to the normal risk of dehydration in this population include preoperative fasting and surgical blood loss. A short period of preoperative fasting supported by intravenous fluids with early resumption of oral intake in the postoperative period is optimal. Environmental factors, such as limited access to fluids, visual impairments, and drinking containers that are difficult to handle, may compound the problem. Hourly rounding that includes proactive offering of fluids as well as mouth care are two important nursing interventions.

Fluid Overload

Recommended nursing interventions include ensuring that regular diuretics are administered as prescribed, monitoring vital signs, maintaining accurate documentation of fluid balance, and promptly reporting alterations in the patient's clinical and cognitive status. The stress of surgery leads to an increased secretion of the antidiuretic hormone (ADH), which impairs the ability to excrete sodium and water. Symptoms to monitor include urinary output less than 30 mL/hr, increasing blood pressure, shortness of breath, moist breath sounds, and dependent edema.

Electrolyte Imbalance/AKI

AKI, previously referred to as acute renal failure, is an abrupt change in kidney function signaled by a rise in serum creatinine and a reduction in urine output (Pakula & Skinner, 2016). This type of injury usually occurs within 48 hours of one or more precipitating events, such as a hip fracture. Baseline renal function is an independent predictor for AKI (Ulucay et al., 2012), but establishment of this may be difficult in hip-fracture patients, because they may be acutely dehydrated on admission with or without the presence of some chronic renal dysfunction. However, vigilance is necessary, as Porter and colleagues (2017) found in their study that AKI occurred in 24% of over 2,000 individuals with hip fracture and was associated with longer length of stay and worse outcomes.

Close monitoring of fluid balance, particularly decreasing urine output and rising serum creatinine, is essential to early identification of this significant clinical problem. AKI is managed with renal replacement therapy, a topic that is beyond the scope of this chapter. For more information, see, for example, Bagshaw and Wald (2017); Romagnoli, Clark, Ricci, and Ronco (2017).

PRESSURE INJURY: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Older adults undergoing surgical repair of a fragility hip fracture constitute a high-risk population for developing pressure injury (PI). Findings from several studies indicate that long periods of immobility before, during, and after surgery are a major factor for increasing risk for PI in this population. A meta-analysis (Simunovic et al., 2010) revealed that earlier surgery was associated with a lower risk of death and lower rates of postoperative complications, such as pneumonia and pressure ulcers, among older patients with hip fracture. Rai, Varma, & Wani (2018) showed that it is beneficial to undergo surgical treatment as early as possible because surgery within 24 hours definitively improves outcome and reduces morbidity, PI, infection, and the length of hospital stay in this population. Furthermore, a study by Magny et al. (2017) showed that pressure injuries are associated with 6-month mortality in older patients with fragility hip fracture. Patients with fragility hip fracture are an important group to target for assessment of risk factors and implementation of prevention strategies to reduce the risk of developing these debilitating wounds.

Nursing Strategies to Avoid Pressure Injury

A head-to-toe skin assessment on admission with examination of pressure points every shift is an important strategy to proactively avoid development of pressure ulcers. Prior to surgery, it is important to ensure that the heels are offloaded and free from pressure. Patients should be cared for on pressure-relieving mattresses throughout the continuum of care, including the ED, the perioperative area, and the nursing unit. Interoperative padding of bony prominences and avoidance of friction and shearing forces are also imperative to avoid skin tears. Patients with fragility fracture will often require assistance with repositioning, especially before surgery. Adequate pain relief, both before and after surgery, is crucial to reduce fear of repositioning. These patients often have poor nutritional status and are fasting prior to surgery, thus increasing the risk of developing pressure-related skin breakdown. Strategies to reduce this risk include introducing an evidence-based pathway that includes early surgery and optimizing fluid and nutritional balance, which are clinical imperatives for these vulnerable patients (Hommel, Bjorkelund, Thorngren, & Ulander, 2007).

PI prevention must be an organizational priority. Protocols that reflect the importance of vigilant skin assessment, commencing on admission and continuing throughout the hospital stay, coupled with timely initiation of prevention interventions, should be considered standard of care (Hommel, Gunningberg, Idvall, & Bååth, 2017; Meehan et al., 2019). Prevention protocols should include use of pressure redistributing/relieving surfaces for high-risk patients across the care continuum: on nursing units, in the operating theater, and in the emergency department (Beckett, 2010; Pham et al., 2011; Meehan et al., 2019). For a more detailed discussion, see Chapter 28, Preventing Pressure Injuries and Skin Tears.

VENOUS THROMBOEMBOLISM (VTE): SIGNIFICANCE IN HIP-FRACTURE PATIENTS

VTE is a serious, potentially fatal, surgical complication in patients operated on for hip fracture and one of the principal causes of perioperative morbidity and mortality

(Carpintero et al., 2014). It is, therefore, no surprise that prophylaxis is recommended in evidence-based clinical practice guidelines (AAOS, 2014; Falck-Ytter et al., 2012; National Institute for Health and Clinical Excellence [NICE], 2018) and has long been a part of standard treatment protocols. A Cochrane review by Kakkos and colleagues (Kakkos et al., 2016) agreed with current guidelines recommendations supporting the use of combined modalities in hospitalized trauma and surgical patients at risk for developing VTE.

Patients sustaining hip fracture are at increased risk for VTE resulting from advanced age, delay to surgery, blood vessel damage secondary to the fracture as well as the operative repair (Prisco, Cenci, Silvestri, Emmi, & Ciucciarelli, 2014), cardiac and respiratory comorbidities (Falck-Ytter et al., 2012), and delay to postoperative mobilization. Patients with orthopedic trauma are also more vulnerable to coagulation activation from tissue and bone injury as well as reduced venous emptying perioperatively (Cionac Florescu, Anastase, Munteanu, Stoica, & Antonescu, 2013). Unlike in other hip surgeries, the risk of VTE increases immediately after injury (Shin, Lee, & Suh, 2017), and this excess risk persists for up to 1 year following the fracture (Pedersen, Ehrenstein, Szépligeti, & Sørensen, 2017).

Nursing Strategies to Avoid VTE

Mobilization

Prevention of VTE is the key. Early mobilization and adequate hydration are essential components of VTE prevention. Encourage patients to mobilize as soon as practical after surgery and to undertake leg exercises as instructed in order to get the calf muscles pumping and limit blood stasis. Request that family provide sturdy footwear with a closed heel and toe and ensure that an individually fitted walker is available at the bedside. Offer and encourage fluid intake in accordance with any limitations.

Pharmacological Prophylaxis

There is no way to predict which patients will develop VTE (Cionac Florescu et al., 2013), and, therefore, pharmacological prophylaxis must be administered to all patients with hip fractures unless contraindicated (Marsland, Mears, & Kates, 2010). In patients with acquired coagulopathies and other conditions at risk for bleeding, Prisco and colleagues (Prisco et al., 2014) note that the risk/benefit ratio for treatment must be accurately assessed as soon as the hemorrhagic risk is under control, and pharmacological prophylaxis should be started if the thrombotic risk persists. Current treatment with aspirin or clopidogrel is not a contraindication for pharmacological prophylaxis (AAOS, 2014).

Pharmacological agents recommended for VTE prophylaxis include primarily low-molecular-weight heparin (LMWH) or fondaparinux (Falck-Ytter et al., 2012; NICE, 2018; Prisco et al., 2014). LMWH interrupts the clotting cascade at various levels, whereas fondaparinux is a specific Factor Xa inhibitor. LMWH is an option for preventing preoperative VTE because of its fast onset of action and short elimination half-life (Shin et al., 2017). Agents, such as unfractionated heparin and aspirin, among others, may be used depending on individual patient circumstances. Nursing strategies include administering medications within the prescribed time schedule and monitoring the patient for adverse effects, primarily bleeding. Other complications include liver function abnormalities, skin rashes, and bruising.

Mechanical Prophylaxis

The most important intervention for VTE prevention is the mechanism of walking. Establish mobility goals and stress the importance of mobility in healing and restoring functional recovery as well as VTE prevention. Until such time as the patient is ambulatory or when resting in bed, mechanical prophylaxis may also include intermittent (or sequential) compression devices and graduated compression stockings (GCS). The magnitude of individual benefit from these mechanical treatment methods is unclear because they are usually combined with pharmacological methods (Cionac Florescu et al., 2013).

Intermittent pneumatic compression devices (IPCD) provide a good alternative to anticoagulation and may be used alone for VTE prophylaxis in patients at high risk for bleeding (Koo, Choi, Ahn, Kwon, & Cho, 2014). IPCD are appropriate for thromboprophylaxis in postoperative surgical patients when used within current clinical guidelines, although the current evidence base for specific device or type of device is limited (Pavon et al., 2016). Moderate quality evidence suggests that combining IPC and pharmacological prophylaxis, compared with IPC or pharmacological prophylaxis alone, decreases the incidence of deep venous thrombosis (DVT) when compared to compression and PE (pulmonary embolism) incidence when compared to anticoagulation (Kakkos et al., 2016).

However, many IPC units are large and bulky, making correct application difficult for patients after discharge and increasing fall risk. Smaller portable, battery-powered units are an alternative. Foot compression requires higher pressures than calf compression, so patient cooperation with therapy may be problematic. When part of a patient's

treatment plan, ensure correct application and continuous use for the recommended time period daily.

A recent Cochrane review (Sachdeva, Dalton, & Lees, 2018) concluded that there is high-quality evidence that GCS/antiembolic stockings are effective in reducing risk of DVT in hospitalized patients following orthopedic surgery with or without other methods of background prophylaxis. The review found moderate quality evidence that GCS reduces the risk of proximal DVT and low-quality evidence to assess their effectiveness in diminishing risk of PE.

Compression stockings can be difficult and painful for patients and caregivers to apply correctly, and thus compliance with their appropriate use is a concern. Most commonly cited adverse effects are skin irritation and skin breakdown. To prevent the development of a PI from compression stockings, Bukata et al. (2011) suggest stockings be removed while the patient is in bed. Although rare, pain and numbness could be early warning signs of compartment syndrome or peroneal nerve injury, which have been described in the literature as complications (Guzelkucuk, Skempes, & Kumnerddee, 2014; Hinderland, Ng, Paden, & Stone, 2011). It is recommended that stockings be removed at least once daily for hygienic purposes and to inspect skin condition because this is the most notable complication associated with their use. Stockings should be discontinued if there is marking, blistering, or discoloration of skin, particularly over heels and bony prominences, or if the patient has associated pain, numbness, or discomfort. The nurse is advised to use caution and clinical judgment when applying antiembolism stockings over wounds. If edema or postoperative swelling develops, legs are remeasured and stockings refitted. GCS are contraindicated in patients with diagnoses such as arterial disease, peripheral arterial bypass graft, peripheral neuropathy, leg deformities, and certain skin conditions and cardiac failure (NICE, 2018).

Patient Education

VTE prophylaxis usually continues past the acute care period. In preparation for discharge, patients and/or their families and care providers require both verbal and written information addressing:

- The signs and symptoms of VTE and PE
- The proper technique for administering injectable medication
- The importance of taking the medication at the appropriate time and for the prescribed duration
- Mobilization as instructed and to maintain adequate hydration (Copanitsanou, 2018)
- The signs and symptoms of adverse reactions related to VTE prophylaxis and the importance of seeking medical help as well as whom to contact; and for those patients who are discharged with antiembolism stockings or intermittent compression devices, their use and whom to contact for questions
- For patients who are discharged with antiembolism stockings or intermittent compression devices, instruction on their use and whom to contact for questions about their use

CATHETER-ASSOCIATED URINARY TRACT INFECTION: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Older adults with fragility hip fracture are at increased risk for developing a urinary tract infection. There is no good-quality evidence to support routine catheterization in this population, although indwelling urinary catheters (IUCs) are commonly inserted on admission to the ED. The clinical indication for the catheter is to avoid movement at the fracture site before surgical repair, which is in compliance with Centers for Disease Control and Prevention (CDC) criteria. The Joint Commission (TJC) and Centers for Medicare & Medicaid Services (CMS) Surgical Care Improvement Project (SCIP) have developed and implemented standards (core measures) aimed at encouraging early discontinuation of these devices in surgical patients. The SCIP core measure related to IUCs states that IUCs are to be removed on postoperative day 1 or 2, with day 0 defined as the day of surgery (TJC, 2015).

It is important to remember that these devices are not innocuous. IUCs are known to be a contributing factor to the development of urinary tract infection and delirium, and they are considered a one-point restraint impacting ease of mobility (Saint, Lipsky, & Goold, 2002). A study of 402 surgically treated older hip-fracture patients concluded that those who developed a CAUTI (catheter-associated urinary tract infection) seemed to be at risk for inferior functional outcomes (Bliemel et al., 2017).

Nursing Management Strategies to Avoid Catheter-Associated Urinary Tract Infection

The criteria for avoiding the development of a CAUTI include ensuring that insertion is clinically necessary and reflects CDC and Society for Healthcare Epidemiology of America (SHEA)/Infectious Disease Society of America (IDSA) criteria, use of aseptic technique when inserting the device, good/routine perineal hygiene, and removal of the device as soon as no longer needed (Gould et al., 2010; Lo

et al., 2014). Nurse-initiated protocols for the management of IUCs have proven beneficial in reducing dwell time and thus reducing the risk of infection (Alexaitis & Broome, 2014; Mori, 2014). For more detailed information, see Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection.

FUNCTIONAL DECLINE: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Fragility hip fracture in old age is a condition recognized as a major cause of functional decline and disability (Dyer et al., 2016). The devastating effect on long-term function is described in a review by Bertram et al. (2011), who found that 29% of the patients with hip fracture did not regain their prefracture level of ADL function. Furthermore, at 1 year postoperatively, more than 40% had not regained their prefracture level of function, and 47% reported pain. More than one third were unable to walk independently as a result of the fracture. Decreased mobility and pain contribute to functional decline and may lead to frailty. These findings suggest that a significant proportion of the patients experience disability post fracture, with many becoming dependent on community and home care services. They are also at increased risk for falling and future fracture (Milte & Crotty, 2014). A randomized controlled study of patients that received early rehabilitation in the home setting showed improved balance, confidence, independence, and physical activity in the group participating in the program (Ziden, Kreuter, & Frandin, 2010).

Nursing Management Strategies to Avoid Functional Decline

The goal of rehabilitation is that the patient will regain as much of his or her prefracture level of function and health-related quality of life as he or she had before the fracture (Rasmussen & Uhrenfeldt, 2016). A nursing strategy to achieve that goal is to adopt a function-focused approach to care, encouraging and supporting hospitalized patients to be active participants in their self-care activities (Boltz, Resnick, Capezuti, Shuluk, & Secic, 2012). Early mobility, transferring in and out of bed, dressing, grooming and walking to the toilet, and being out of bed for meals are essential. Nurses should ensure patients have their sensory aids in place and that pain is managed in anticipation of ambulation. Effective interventions also include nutritional therapy and resistance training (Morley et al., 2013). Continued rehabilitation after the patient returns home is also important (see Chapter 18, Preventing Functional Decline in the Acute Care Setting).

LOSS, GRIEF, DEPRESSION: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Patients vary greatly in the speed and extent of their recovery. For some patients and families, the hip fracture is a catastrophic event that results in diminished function, a loss of independence, and a high risk of death within 1 year. Patients may lose hope for the future and experience loss, grief, and depression. A quality of life survey of women aged 75 and older at risk for hip fracture reported 80% feared the disability associated with hip fracture more than they feared dying (Salkeld et al., 2000).

The rate of depression in hip-fracture patients in a review of eight U.S. and U.K. studies ranged from 9% to 47% (Holmes & House, 2000). Hip-fracture patients with depression are less likely to regain function and are prone to longer stays in hospital (Atay, Aslan, Burç, Demirci, & Atay, 2016; Lenze et al., 2004). A qualitative study of patients' perceptions of their capacity to regain function post hip fracture found the culture in the acute care setting fostered dependence that tended to erode initial feelings of self-confidence toward recovery (Gesar, Hommel, Hedin, & Bååth, 2017). A positive attitude, social supports, and active participation/movement were findings across two qualitative studies that identified themes reported by patients as important in their recovery (Schiller et al., 2015; Young & Resnick, 2009).

Nursing Strategies to Address Grief, Loss, and Depression

Nurses can support and foster a positive attitude and hope by informing patients and families that most patients survive and can regain some or all of their prefracture function through participation in rehabilitation. Nurses play a key role in assessing the patient's and family's emotional well-being. Maintaining a heightened awareness of the prevalence of depression in this population combined with screening for depression and ensuring referrals are sent to medical or psychiatric clinicians if warranted is essential. For more detailed information, see Chapter 19, Late-Life Depression.

CARE TRANSITIONS: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

Care transition is a term used to describe a patient's movement from one healthcare setting to the next (Coleman & Berenson, 2004). Leaving the hospital to go home is a perilous time for patients with hip fractures. Without

a coordinated plan and clear communication, medication adverse events, complications, emergency department visits, and unnecessary readmissions to the hospital can occur (Forster, Murff, Peterson, Gandhi, & Bates, 2003; Glenny, Stolee, Sheiban, & Jaglal, 2013). Although deemed ready for discharge by the healthcare team, some patients and families feel unprepared to manage independently at home. Interviews of family care providers reveal that they are often confused and distressed about the fracture and surgery, feel uninformed about their medications, and may become overwhelmed with the challenges of coping at home (Sims-Gould, Byrne, Hicks, Khan, & Stolee, 2012). Older adults report extreme vulnerability following a hip fracture, with the first 12 weeks being particularly turbulent (Ziden et al., 2010).

The readmission rate for hip-fracture patients was determined to be 11.9% in a university-affiliated trauma center (Kates, Behrend, Mendelson, Cram, & Friedman, 2015). The 1-year mortality rate for readmitted patients was 56.2% versus 21.8% for those not readmitted. Readmission was attributed to medical causes for 81.4% of patients and surgical causes for 18.6%. It was concluded that 17% of these readmissions were preventable through interventions.

Coleman's Care Transitions Intervention (Coleman & Berenson, 2004; Coleman, Parry, Chalmers, & Min, 2006) is a proven model shown to improve the safety and experience for patients and family. In this model, patient and family caregivers engage with the healthcare team to prevent and address risks by focusing on (a) medication adherence strategies; (b) postdischarge follow-ups, for example, for bone health and medication reviews; (c) detecting and addressing "red flags," indicative of complications or medical deterioration; and (d) keeping a personal health record to aid communication.

Hip fracture represents a major traumatic life change for many patients and families. They may be anxious and distressed and may require emotional support and counseling around loss and grief (Lenze et al., 2007; Ziden et al., 2010). The following guidelines are derived from the Fresh Start Toolkit: Hip Fracture Recovery Guide for Patients and Families, an evidence-based tool developed collaboratively by patients and the interprofessional team (BC Hip Fracture Redesign Committee Centre for Hip Health and Mobility, 2015). Involvement of the interprofessional team is required to address the patient's needs through the following activity:

1. Apply principles of teaching appropriate to older adults, provide both verbal and written instruction, and begin early in the hospital stay; see Chapter 42, Transitional Care.
2. Include information on the surgical procedure/activity restrictions, the importance of frequent ambulation, healthy diet, sleep strategies, and pain management at home.
3. Educate patients on early warning signs of "red flags" and what to do (e.g., VTE, delirium, infection, dislocation, and constipation).
4. Determine home-assistance requirements for ADL, housekeeping, shopping, and banking. Assist patients to arrange the aforementioned.
5. Assess medication management skills, and develop a plan for medication review and safety at home.
6. As falls remain a significant risk for these patients, conduct a fall risk assessment and develop an individualized plan.
7. Evaluate need for home modifications to improve home safety and convenience, for example, a bath or shower bench, grab bars installed for the toilet and bath, setting the bed to knee height, solid handrails on stairs, removing tripping hazards, and good lighting. Specialized equipment, such as a walker, raised toilet seat, and a reacher, may also be required. Assess the individual's needs, and facilitate arrangements to procure and install as appropriate.
8. Because so many patients feel overwhelmed at home, a follow-up phone call or home visit from a healthcare professional is recommended for support, teaching, and problem-solving.

SECONDARY PREVENTION: SIGNIFICANCE IN HIP-FRACTURE PATIENTS

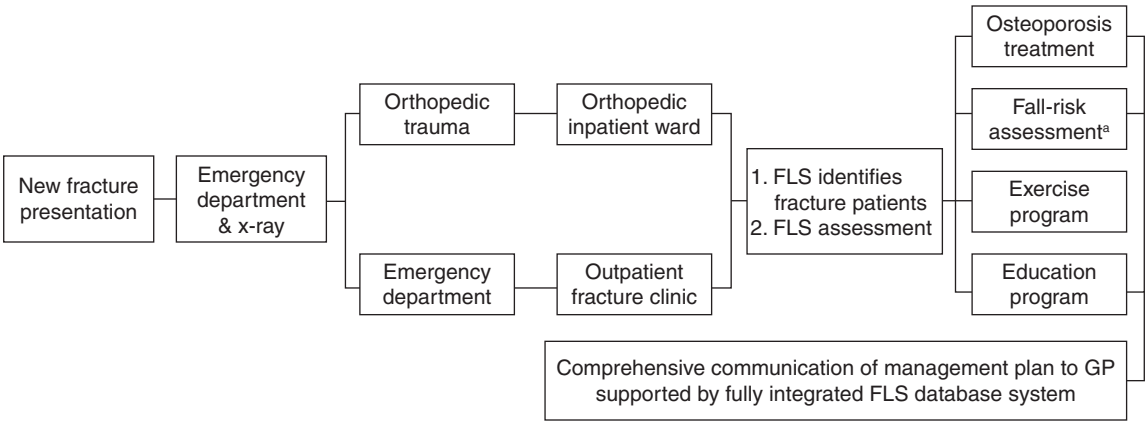
It is well known that one of the highest risk factors for sustaining a fragility fracture is the history of a previous fracture (Cooper, Mitchell, & Kanis, 2011). The highest risk period is in the first year following a fracture, but the risk persists for at least 10 years (Sobolev et al., 2015). It has been known for decades that half of all patients who suffer a fragility hip fracture experienced a prior fracture (Edwards et al., 2007; Gallagher et al., 1980; Port et al., 2003). The first fragility fracture should serve as a signal alerting clinicians to the need to evaluate the patient for underlying osteoporosis and, if confirmed, to initiate interventions to prevent the occurrence of future fracture (Port et al., 2003). Although effective treatments and care models have been available for many years, a review of current practice suggests that care gaps continue (P. J. Mitchell & Chem, 2013). This gap in secondary care

needs to be addressed in order to minimize both the debilitating consequences of subsequent fractures for patients and the associated economic burden to healthcare systems (Marsh et al., 2011).

Sobolev et al. (2015) reviewed more than 38,000 records of patients aged 60 years or older discharged after hip fracture and found that less than 20% were screened for osteoporosis. An observational cohort study of 51,346 Medicare patients admitted to 318 hospitals in the United States with a diagnosis of osteoporosis found that despite proven therapies for osteoporosis, hip-fracture patients who sustain hip fractures remain grossly undertreated and that only 2% were provided ideal therapy (Jennings et al., 2010).

One of the most commonly used and most effective approaches to fracture management is a fracture liaison service (FLS). This approach has been developed and successfully implemented, both nationally and internationally, with the most mature programs in the United Kingdom. FLS programs center on the use of a dedicated coordinator to identify patients with fragility fracture. Marsh et al. (2011) conducted a systematic review of fracture-management programs and found that 65% included a dedicated coordinator. The role of the coordinator, often an advanced practice nurse, is to identify patients with fragility fracture, and following evidence-based protocols, facilitate BMD testing, provide osteoporosis education, evaluate and address fall risks, initiate osteoporosis treatment, and monitor adherence to therapy. A review of best practices (P. J. Mitchell, 2013) and findings of a task force commissioned by the Society of Bone and Mineral Research (Eisman et al., 2012) reports that the most effective tool for change and the optimal approach to fracture management is a program that uses a dedicated fracture liaison coordinator.

Several FLSs have been established in the United States. Kaiser Permanente, a California-based health maintenance organization, established a "Healthy Bones Program" in 2002. Within this fracture-management program, advanced practice nurses identify, stratify risk, treat, and track patients with osteoporosis as well as individuals who have had or are at risk for a fragility fracture. Since its inception, it is estimated that the Healthy Bones Program has reduced the incidence of hip fractures by more than 40% (Dell, 2011; Greene & Dell, 2010). The Geisinger Health System, serving a large population in rural central Pennsylvania, developed an osteoporosis disease management program and, using a cost–benefit model, projected a $7.8 million cost savings over the 5-year period from 1996 to 2000 (Newman et al., 2003). The success of these programs is aided by having integrated electronic medical record systems, which enhance the ability to share information and monitor patients.



The International Osteoporosis Foundation (IOF) launched a Capture the Fracture program in 2012 with the goal of promoting coordinator-based FLSs globally (Akesson et al., 2013). In 2012, the National Bone Health Alliance (NBHA) and Kaiser Permanente unveiled their 20/20 vision for reducing hip fractures by 20% by the year 2020. They are lobbying the federal government to establish reimbursement criteria within the Medicare system that would support the development of secondary fracture-prevention services for Medicare recipients (NBHA, 2012). In addition, the NBHA has developed an online education program for nurses interested in being certified as a fracture liaison nurse. The growing emphasis on quality improvement for reimbursement and accreditation may heighten interest in expanding the number of fragility-fracture management services in other institutions (Aizer & Bolster, 2014).

The ultimate goal of a fracture-management program is to capture 100% of fragility-fracture sufferers and prevent a second fragility fracture. Core objectives include:

1. Inclusive case finding
2. Evidence-based assessment to:
   a. Stratify risk
   b. Identify secondary causes of osteoporosis
   c. Evaluate fall risk
3. Initiate individualized treatment plan in accordance with relevant evidence-based guidelines
4. Improve long-term adherence to treatment plan. These programs ensure that all patients presenting with fragility fractures receive fracture risk assessment, education, and treatment appropriately. The fracture-management program can be based in secondary or primary care healthcare settings and requires support from a medically qualified practitioner, commonly an advanced practice nurse, with expertise in fragility-fracture prevention or a primary care physician with a specialist interest. An example of the structure of a hospital-based fracture-management service is provided in Figure 40.6.

FIGURE 40.6

Hospital-based fracture liaison service algorithm.

[a] Older patients, where appropriate, are identified and referred for falls assessment.

FLS, fracture liaison service; GP, general practitioner.

Capture the Fracture: A Best Practice Framework and global campaign to break the fragility fracture cycle. *Osteoporosis International, 24*(8), 2135–2152. doi:10.1007/s00198-013-2348-z. *Evidence Level V.* With permission from Springer Nature.For more information on secondary prevention and fracture-management programs, visit the IOF Capture the Fracture website (http://share.iofbonehealth.org/WOD/2012/report/WOD12-Report.pdf), the National Bone Health Alliance website (http://nbha.org/projects/secondary-fracture-prevention-initiative), and the Fragility Fracture Network website (http://fragilityfracturenetwork.org).

CASE STUDY 40.1

Mrs. W is an 84-year-old widow and a retired schoolteacher who lives in a senior apartment complex. Her 80-year-old sister lives in a nearby apartment. Mrs. W is independent in her ADL; she cooks meals and sorts her medications; however, her daughter provides help with bill paying and transportation because Mrs. W voluntarily gave up driving 2 years ago as a result of limited motion in her neck. She wears glasses for reading and distance and uses a cane for walking outside her apartment. Her medical history includes hypertension, osteoarthritis, and gastroesophageal reflux disease (GERD). She has urge incontinence and chronic pain caused by osteoarthritis, which sometimes interferes with her sleep. Her family will tell you that she has some "occasional forgetfulness." Her medications include a multivitamin, antihypertensive, a proton pump inhibitor, and extra-strength acetaminophen for her arthritic pain, which she takes as needed. Past surgical history includes hysterectomy for fibroids (age 48 years) and a nondisplaced distal radius fracture that was treated with a cast (age 58 years), and 6 years ago she had a total left hip replacement for degenerative joint disease.

The night of her fall, Mrs. W recalls taking two acetaminophen PM tablets before going to bed. She remembers waking during the night needing to toilet and falling on her way to the bathroom. Unable to get up or summon help, she remained on the floor until discovered in the morning by her sister. She presents in the ED complaining of pain in her right hip. Her sister accompanies her in the ambulance to the ED, and her daughter is on the way. She arrives at your hospital, which has a geriatric section in the ED and protocols based on best practice to care for older adults with hip fracture.

Nursing concerns in the ED will include:

- Medication history
- Review of circumstances surrounding fall/fracture and pattern of injury
- Assessment and treatment for acute pain and chronic pain
  - Regional pain block would reduce opioid use.
- Sensory devices and family at bedside
- Monitoring of fluid balance
- Monitoring of oxygenation/avoidance of hypoxia
- Establishing baseline cognition

(*continued*)

CASE STUDY 40.1 (*continued*)

- Awareness of increased risk of delirium
- Skin assessment; pressure ulcer prevention
- Evaluation of need for indwelling catheter before insertion
  - Catheter inserted because of fracture instability and related immobility
- Protocol for fast tracking through ED to the orthopedic unit

An x-ray of Mrs. W's hip confirms a displaced neck of the femur fracture. She is transferred to the orthopedic unit within 4 hours of arrival. Nursing strategies on the *admitting unit* include:

- Monitoring of adequate and appropriate pain relief
- VTE prophylaxis as ordered
- Delirium assessment every 12 hours; more frequent if changes in mentation
- Sensory aids in place
- Inviting family involvement/providing information on potential risk of delirium
- Pressure-relieving mattress/position changes
- Nutritional assessment, dietary consults
- High-protein oral nutritional supplement with medications
- Protocol in place that liberalizes presurgical fasting restrictions consistent with patient's fluid balance
  - High-carbohydrate drink, such as apple juice, up to 2 hours before surgery
- Avoiding overstimulating environment/preserving sleep–wake cycle

Mrs. W is scheduled for surgery within 48 hours of arrival. She is transferred to the *perioperative* area, where her fracture is repaired with hemiarthroplasty. She spends a total of 4 hours in the *preoperative, surgery, and postoperative* units. Nursing management strategies include:

- Pressure-relieving surfaces in the perioperative area
- Padding of pressure points
- Monitoring of oxygenation
- Administration of ordered antibiotics
- Monitoring of fluid balance/blood loss

Mrs. W returns to the nursing unit after surgery. *Postoperative* nursing management strategies include:

- Continuation of adequate and appropriate pain relief, both acute and chronic
- Sensory aids in place, family involvement
- Nursing begins mobilization day of surgery/physical therapy (PT) and occupational therapy (OT) consulted
- Continuation of VTE prophylaxis
- Removal of IUC postoperative day 1
- Awareness of increased risk and assessment for delirium and depression
- Pressure-point assessment; pressure-relieving seat cushion when in chair
- Advance diet as tolerated per protocol; continuation of oral nutritional supplements with medications
- Monitoring of fluids and electrolytes
- Monitoring of bowel function

Proactive care strategies designed to avoid risk factors associated with common complications of hip fracture ensured an uneventful course during hospitalization. PT and OT recommend discharge to a rehabilitation facility before returning home with assistance. As part of the care transition process, nursing management strategies include the following:

- With Mrs. W's permission, arrange a meeting with her daughter and her sister to help them prepare for Mrs. W's eventual homecoming.
- Provide both verbal and written instructions on the surgical procedure, activity restrictions, and importance of frequent ambulation and early warning signs of "red flags" and what to do if they develop (e.g., VTE, delirium, infection, constipation, and dislocation).
- PT and OT assess Mrs. W's home-equipment needs and provide further information on where to obtain additional items. Review home safety instructions to reduce fall risk.
- Before transfer to rehab unit, a consultation with FLS is initiated for evaluation and ongoing fracture risk management.
- Follow up with orthopedic surgeon and family nurse practitioner needed in 6 weeks.

SUMMARY

A hip fracture is a serious injury with a significant impact on the patient, family, and healthcare system. Healthcare resources will be strained as the proportion of older adults in the population steadily increases and the incidence of hip fracture reaches unprecedented numbers. Although there is a high rate of mortality and disability post fracture, an interprofessional approach that incorporates best

practices can significantly improve the experience and outcomes for these patients.

The risks that lead to death and disability post fracture are foreseeable and, in many cases, preventable. People with fragility hip fractures, with few exceptions, are older than 65 years with comorbid conditions and thus highly susceptible to the stress of the injury, surgery, and immobility. Timely surgery, good pain management, early and frequent mobility, prevention of infection, and fluid balance are associated with improved outcomes. Providing support for loss and grief, goal setting for recovery, and screening and referral for depression when warranted will aid in longer-term recovery. Going home is a precarious time, and patients are at high risk for readmissions resulting from medical concerns, falls, and subsequent fractures. Patients and families require education and support to prepare their home environments, caregivers, and follow-ups for medical concerns and bone health. Nurses who provide evidence-based care focused on the patient and family ensure the best possible outcomes for patients with fragility hip fractures.

NURSING STANDARD OF PRACTICE

Protocol 40.1: Managing Patients With Hip Fracture

I. GOALS

Patients with hip fracture are susceptible to foreseeable and potentially avoidable complications. An interprofessional team approach to care that uses evidence-based strategies for prevention, early detection, and proactive care to avoid complications are the key to optimal patient outcomes.

II. EMERGENCY ROOM

The majority of these patients will enter the hospital via the emergency department. Consideration must be given to provide an environment that is sensitive to the care needs of this vulnerable population. Increasingly, hospitals are providing spaces in their emergency departments designed to accommodate the needs of older adults and avoid the negative consequences associated with an overstimulating environment. Early implementation of multifactorial interventions aimed at reducing complications in this vulnerable population, starting in the emergency department, has proven beneficial (Arshi, Rezzadeh, Stavrakis, Bukata, & Zeegen, 2019; Bjorkelund et al., 2011; see Chapter 44, Care of the Older Adult in the Emergency Department).

III. TIMELY SURGERY

Delays to surgery greater than 24 to 48 hours increase the risk of complications, delirium, and mortality. Hommel et al. (2008) found higher mortality at 4 months among medically fit patients with administrative delay to surgery compared to patients with no delay and longer hospital stays for those with delays greater than 24 hours. In a study of 38,020 patients with hip fractures, Daugaard et al. (2012) concluded that avoiding surgical delay is the most important factor in reducing mortality for hip-fracture patients. A systematic review seeking to answer the questions of the effect of early hip-fracture surgery on patients 60 years or older on all-cause mortality and postop complications found early surgery reduced the incidence of pressure injury, postoperative pneumonia, and mortality (Simunovic et al., 2010). A retrospective review of American College of Surgeons National Quality Database from 2006 to 2013 of 17,459 patients who sustained hip fracture found delay to surgery prolonged length of stay; however, there was no reported difference in postoperative readmission, postoperative infection, or mortality. Interestingly, 74% of the patients reviewed in this study underwent surgery within 48 hours (S. M. Mitchell et al., 2018). Nurses can play an important role in advocating for timely access to surgery.

IV. DELIRIUM

A. Determine patient's preadmission cognitive status and cognitive presentation on admission using a standardized tool and information from family.
B. Screen for delirium every 12 hours using an evidence-based tool.

(*continued*)

Protocol 40.1: Managing Patients With Hip Fracture (*continued*)

C. Educate patient and family on the increased risk of delirium with hip fracture and how they can help prevent and cope with it.
D. Prevent/address the factors that may contribute to delirium, for example, pain, urine retention, infection, constipation, sensory impairment, sleep, metabolic disturbances, medications, alcohol withdrawal, dehydration, and environmental over-/understimulation.
E. Reassess cognitive status before care transition.

V. MALNUTRITION

A. Assess for malnutrition on admission using a standardized screening tool.
B. Consult registered dietitian for comprehensive assessment if malnourished or if the patient is unable to tolerate the diet.
C. Screen for dysphagia and refer to a speech or occupational therapist if dysphagia is suspected.
D. Adopt protocols that minimize fasting before surgery. Evidence supports the benefits of:
   1. Solid food up to 8 hours before surgery
   2. Clear fluids up to 2 to 4 hours before surgery
   3. Clear fluid high-carbohydrate drink 2 to 4 hours before surgery, for example, clear juice
E. Postsurgery nutrition
   1. Provide a regular diet as tolerated the day of surgery.
   2. Monitor nutritional intake. Inform dietitian or physician if intake is consistently less than 50% of the diet provided.
   3. Provide scheduled administration of high-protein, high-calorie nutritional supplements in addition to ordered diet.

VI. PAIN

A. Assume your patient has moderate to severe pain. Recognize that unmanaged pain increases complications, impedes recovery, and increases mortality.
B. Assess pain and pain history on admission using a comprehensive validated tool.
C. Consider any painful comorbid conditions and prehospital analgesic use in the pain management plan, for example, arthritic joint pain exacerbated by immobility.
D. Assess valid pain scale with vital signs; differentiate between acute and chronic pain.
E. Assess using a validated sedation scale every hour for 24 hours and then every 4 hours thereafter. Adjust analgesic dosing according to the scale.
F. Time the administration of analgesics such that their peak effect coincides with physiotherapy and mobility.
G. Use a pharmacological and nonpharmacological multimodal approach to reduce the need for opioids.
H. Advocate for regional blocks (nerve/compartment).
I. Ensure that geriatric-appropriate analgesics/doses are prescribed and administered.
J. Use regularly scheduled doses of analgesics while pain persists.

VII. CONSTIPATION

A. Assess prehospital bowel habits and management.
B. Assess for BM daily, including size, consistency, and color.
C. Assume your patient will be constipated as a result of immobility, analgesics, and pain.
D. Use a standardized geriatric-appropriate bowel protocol.
E. Administer prophylactic laxatives as ordered unless contraindicated, for example, diarrhea, multiple daily moderate to large BMs.

(*continued*)

Boltz88144_PTR_CH40_755-786_02-25-20.indd 775 AL GRAWANY 25/02/20 12:56 PM

Protocol 40.1: Managing Patients With Hip Fracture (*continued*)

F. Ensure adequate fluid intake and a high-fiber diet where appropriate, for example, bran, prunes, applesauce, and dates.
G. Encourage ambulation to promote bowel function. Avoid bedpans; ambulate to the toilet.

VIII. CATHETER-ASSOCIATED URINARY TRACT INFECTION

A. Avoid indwelling catheters. Use an indwelling catheter only if evidence-based criteria are met, for example, Centers for Disease Control and Prevention (CDC) criteria (Gould et al., 2010).
B. Reassess the need for the catheter each shift and remove as soon as possible, within 36 hours after surgery.
C. Use an evidence-based nursing protocol to guide insertion, hygiene, and management of the catheter and drainage system.

IX. PRESSURE ULCER PREVENTION

A. Conduct a head-to-toe pressure-point assessment on admission and then each shift.
B. Use an evidence-based pressure ulcer risk-screening tool (i.e., Braden Scale) to identify areas to be monitored and addressed.
C. Implement a written care plan to address any underlying risk factors as indicated (e.g., immobility, nutrition, moisture, etc.).
D. Consider using pressure reduction mattresses and chair surfaces routinely for hip-fracture patients.
E. Ensure that patients are repositioned every 2 hours (some patients may do this independently).
F. Mobilize and assess toileting needs every 2 to 3 hours while awake.
G. Ensure nutrition and hydration are monitored and needs are met.
H. Implement a written care plan to address any skin injury or breakdown as per evidence-based clinical guidelines.

X. VENOUS THROMBOEMBOLISM

A. Recognize that hip-fracture patients are at high risk for VTE.
B. Advocate for evidence-based treatment.
C. Ensure that treatment is initiated as prescribed.
D. Monitor for adverse events, for example, bleeding, bruising, or rashes with chemoprophylaxis or skin breakdown and circulatory impairment with compression stockings or pneumatic compression sleeves.
E. Encourage leg exercises and early, frequent mobilization.
F. Encourage fluid intake of six cups minimum daily unless contraindicated.
G. Educate patients and families on detection and prevention of VTE at home and actions to take if VTE is suspected.

XI. FLUID AND ELECTROLYTE IMBALANCE

A. Monitor fluid balance after surgery.
B. Review lab values and report abnormalities to medical practitioner as indicated.
C. Ensure adequate fluid intake, minimum 6 cups per day or as per fluid restrictions.
D. Assess for clinical signs of dehydration (hypotension, headache, dry mouth, oliguria, and skin turgor) or overload (edema, cough, and coarse breath sounds). Follow up with medical practitioner as indicated.

XII. MOBILITY

The nurse is responsible for ensuring timely and consistent postoperative mobility.

A. Request that family provide sturdy footwear with a closed heel and toe.
B. Ensure that an individually fitted walker is available at the bedside.

(*continued*)

Protocol 40.1: Managing Patients With Hip Fracture (*continued*)

C. Teach bed exercises: Buttock tightening, foot circles, dorsal and plantar flexion of both feet. Remind patient to do exercises every hour while awake.
D. Teach the importance of mobility in healing and restoring function.
E. Establish mobility goals with patient.
F. Assist patient to:
   1. Sit at the bedside, stand, and/or walk on the day of surgery.
   2. Get up in a chair for at least two meals each day beginning the day after surgery.
   3. Walk every day after surgery at least three times with increasing distances.

XIII. TRANSITIONS FROM HOSPITAL TO HOME

A. Both verbal and written instructions on preparing to go to the next level of care should begin early in the hospital stay (see Chapter 36, Fluid Overload: Identifying and Managing Heart Failure Patients at Risk of Hospital Readmission).
B. For those going to a rehabilitation facility, handoff should include information on surgical procedure/activity restrictions and cognitive status, including delirium assessment results, diet/appetite, sleep strategies, and pain management.
C. For those going directly home, determine home-assistance requirements and assist patients to make arrangements. Stress the importance of frequent ambulation, healthy diet, adequate sleep, pain management, and follow up to ensure adequate bone health.
D. Educate patients on early warning signs of "red flags" and what to do (e.g., VTE, delirium, infection, dislocation, and constipation).
E. Assess medication management skills, and develop a plan for medication review and safety at home.
F. Consult with occupational or physical therapists to assess and address the need for home modifications and equipment.
G. Arrange a home follow-up phone call or home visit from a healthcare professional for support, teaching, and problem-solving.
H. Provide information for follow-up with orthopedic surgeon.

Include information on the surgical procedure/activity restrictions, the importance of frequent ambulation, healthy diet, sleep strategies, bone health, and pain management.

XIV. SECONDARY FRACTURE PREVENTION

A. Ensure consultation with fracture liaison service before discharge.
   1. Evaluation of bone health and fracture risk
   2. Evaluate for referral to fall prevention program
   3. Ongoing osteoporosis management

ABBREVIATIONS

BM	Bowel movement
VTE	Venous thromboembolism

ACKNOWLEDGMENTS

The authors wish to thank Judy Knight, MLS, AHIP, Health Services Librarian, for her generosity, support, and expertise.

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify the objectives common to all geriatric acute care models.
2. Describe the various types of models employed in North American hospitals.
3. Understand the evidence to support implementation of geriatric acute care models.

OVERVIEW

Advances in geriatric science, coupled with the increasing older adult patient population, have led to the development of several geriatric models of care across all healthcare settings. Acute care models addressing the unique needs of older hospitalized patients began with the comprehensive geriatric assessment (CGA) programs first developed in the 1970s (Palmer, 2018a, 2018b).

Geriatric acute care models aim to facilitate improved overall outcomes by promoting a rehabilitative approach while preventing adverse events that occur more commonly in older patients. Also known as geriatric syndromes, these are clinical conditions in older persons that do not fit into discrete disease categories (Palmer, 2018a, 2018b) and include functional decline, pressure ulcers, fall-related injury, undernutrition or malnutrition, urinary tract infection, and delirium (see Part III, Clinical Interventions). These syndromes or complications contribute to prolonged hospital stays as well as increased likelihood for rehospitalization, institutionalization, ED usage, and postacute rehabilitation therapy services. These complications rarely occur alone; the interrelationships among these various syndromes during hospitalization are well documented (Flood, Booth, Danto-Nocton, Kresevic, & Palmer, 2015; Inouye, Studenski, Tinetti, & Kuchel, 2007; Koroukian et al., 2016; Palmer, 2014).

Acute care models attend to the age-specific vulnerabilities (i.e., frailty, comorbidities, and cognitive impairment) of older hospitalized patients. These models also address the role of institutional factors that determine staff practices and the physical environment that can contribute to iatrogenic complications. Thus, the overall goals of acute geriatric models of care are (a) prevention of complications that occur more commonly in older adults and (b) address hospital factors that contribute to complications (Capezuti, Boltz, Tejada, & Malone, 2018). This chapter provides an overview of care delivery issues that are addressed by acute models of care for older adults and a description of the most commonly employed hospital models.

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

OBJECTIVES OF GERIATRIC ACUTE CARE MODELS

There are several geriatric acute care models, each with its own approach to prevent complications and address institutional/staff practices that can contribute to complications. All of these models, however, share a common set of general objectives (Bell et al., 2016; Hickman, Newton, Halcomb, Chang, & Davidson, 2007; Hickman, Rolley, & Davidson, 2010). The general objectives of geriatric acute care models are discussed herein.

Employ Geriatric Specialists

The expert knowledge of clinicians with specific geriatric preparation such as geriatricians, geriatric psychiatrists, geriatric advanced practice nurses, social workers, pharmacists, and others (some disciplines only provide continuing education without recognized specialty expertise) are needed to facilitate integration of geriatric care principles into practice (Conley et al., 2012a, 2012b; Maxwell, Mion, & Minnick, 2013).

Educate Healthcare Providers in Core Geriatric Principles

Many healthcare providers have not received the core geriatric care principles, such as recognition of age-specific factors that increase the risk of complications, in their basic or continuing education (Miller & Rosenthal, 2017; Nunnelee et al., 2015). All acute care models require a coordinator with advanced geriatric education; however, successful implementation depends on direct-care staff with the knowledge and competencies to deliver evidence-based care to older patients. Thus, the coordinator or a clinician with geriatric specialization will facilitate staff learning via individual patient consultation, in-service group education, unit rounds, journal clubs, web-based discussion groups, conferences, and other internal institutional educational venues (Conley et al., 2012a, 2012b; Fletcher, Hawkes, Williams-Rosenthal, Mariscal, & Cox, 2007).

Promote Interprofessional Communication

The management of geriatric syndromes is not limited to medical intervention but requires other disciplines, such as nursing, pharmacy, social work, and physical and occupational therapy, to address the complex interaction of medical, functional, psychological, and social issues leading to these complications. Communication of the various disciplines' input, facilitated by geriatric care models, is essential.

Target Risk Factors for Complications

The ideal method to prevent complications is timely screening of potential geriatric syndromes, early identification, and subsequent reduction of risk factors. Some of the models focus on a particular syndrome; however, because of the interrelationship of shared risk factors, reduction of one complication will affect the prevention of other geriatric syndromes. Standardized assessment tools are recommended to properly identify individuals who are at an increased risk of geriatric syndromes. The Portal of Geriatrics Online Education (www.pogoe.org) and the Hartford Institute for Geriatric Nursing (www.hartfordign.org) websites provide assessment instruments. At the institutional level, incorporating these risk-assessment tools into the workflow of everyday practice requires hospital policies, procedures, and protocols that will promote usage such as embedding these tools within the electronic health record.

Embed Geriatric Care Principles Within the Organization

The high proportion of complications in older hospitalized patients is partly attributed to the lack of evidence-based geriatric care practices, including CGA of those screened as vulnerable to such complications. In several systematic reviews and meta-analyses, CGA in the acute care setting has demonstrated positive patient outcomes (Conroy et al., 2019; Ellis et al., 2017; Pilotto et al., 2017).

There is tremendous variability, however, in the adoption of geriatric protocols (Neuman, Speck, Karlawish, Schwartz, & Shea, 2010). Issues with overuse or inappropriate medications (e.g., overuse of psychoactive drugs), unnecessary restraints, inadequate detection of cognitive or affective changes (e.g., delirium and depression), and poor pain control are examples of hospital factors that can lead to adverse outcomes. Geriatric acute care models promote the use of standardized evidence-based protocols such as those described in this book.

Thus, to be effective, geriatric models of care cannot be limited to a few individuals or a team but most work within institutional committees to embed evidence-based geriatric care processes within the organizational structure of the health system. For example, this may include incorporating these geriatric-specific screening tools in the electronic medical record (Khan, Malone, Pagel, Vollbrecht, & Baumgardner, 2012) as well as in-hospital policies, procedures, and protocols (Capezuti et al., 2012; 2013).

Incorporate Patient or Family Choices and Treatment Goals

Informed patient's choices are essential whether they are decisions about activity level and medication use to more complex issues such as advance directives. Family members of patients who can no longer participate in decision-making must often deal with the complicated balance between quality-of-life considerations and potential length of life (Reinhard, Capezuti, Bricoli, & Choula, 2017). The decision to employ life-sustaining treatments consistent with patients' preferences is often only considered when the patient is hospitalized (You et al., 2015). For this reason, many geriatric models work collaboratively or in conjunction with palliative care programs (see Chapter 43, Palliative Care Models).

Support a Senior-Friendly Physical Environment

The built environment is meant to reduce physical obstacles for transferring and ambulating, as well as promote cognitive orientation and socialization (Boltz, Capezuti, Shabbat, & Hall, 2010; Fox et al., 2013; Palmer, Landefeld, Kresevic, & Kowal, 1994). Physical modifications in the typical hospital setting include grab bars, furniture (chairs and bed) that adjusts height to facilitate mobility, carpeted flooring, clocks, and calendars (Fox et al., 2013). Most of these are now considered universal design elements to promote patient safety. Other environmental interventions are not typically used (Parke et al., 2016) such as a communal dining space to reduce isolation that can promote intake (Singh, Subhan, Krishnan, Edwards, & Okeke, 2016). Others include shock-absorbing flooring (Latimer, Dixon, Drahota, & Severs, 2013) and therapeutic use of lighting to reduce agitation (Barrick et al., 2010) and promote night-time sleep (Patel, Baldwin, Bunting, & Laha, 2014).

Emphasize Proactive Discharge Planning

Older hospitalized patients are more likely to experience delays in discharge, greater emergency service use, hospital readmission, and rehabilitation in an institution or at home (Coleman, Min, Chomiak, & Kramer, 2004). Hospital readmission for older patients is most likely associated with medical errors in medication continuity (Coleman, Smith, Raha, & Min, 2005; Foust, Naylor, Boling, & Cappuzzo, 2005; Parekh, Ali, Page, Roper, & Rajkumar, 2018), diagnostic workup, or test follow-up (Forster, Murff, Peterson, Gandhi, & Bates, 2003). Geriatric acute care models address the posthospital care environment and the care transition following hospital discharge by promoting coordination among healthcare providers, facilitating medication reconciliation, preparing patients and their caregivers to carry out discharge instructions, and making appropriate home care referrals (Bowles, Naylor, & Foust, 2002; Flacker, Park, & Sims, 2007; Le Berre, Maimon, Sourial, Guériton, & Vedel, 2017). Two of the models consider care transition as the primary focus of their programs.

TYPES OF ACUTE CARE MODELS

Although there are several types of geriatric acute care models that are used in U.S. hospitals, all address both common health problems and care delivery issues. Most consider all geriatric syndromes, whereas others target specific syndromes such as delirium. The models are implemented in various degrees from a hospital-wide to a unit-based approach, whereas others focus on specific processes of hospitalization such as discharge planning.

Geriatric Consultation Service

The consultants in a geriatric service may include a geriatrician, a geropsychiatrist, a geriatric advanced practice nurse (GAPN), or an interprofessional team of geriatric healthcare providers who conduct a CGA or evaluate a specific condition (older adult mistreatment), symptom (wandering), or situation (adequacy of spouse to care for patient at home). Geriatrics consultation programs have been successfully implemented in community hospitals, academic medical centers, and in Veterans Affairs hospitals. A unique trend at some sites is integrating nurse practicioners as the primary expert leading the consultation. Some hospitals will require that all patients who are screened as high risk for geriatric-related complications or are admitted from a homebound program or a nursing home will receive a geriatric consult, whereas most are requested by another primary service for an individual patient (Hung, Tejada, Soryal, Akbar, & Bowman, 2015). A systematic review/meta-analysis of randomized and nonrandomized studies did not find a statistically significant reduction in functional decline, readmissions, or length of stay but did report fewer consult patients dying at 6 and 8 months following discharge (Deschodt, Flamaing, Haentijens, Boonen, & Millisen, 2013). A more recent study found significant reductions in daily charges, ICU days, potentially inappropriate medication use, and use of physical restraints and increased end of life planning while reducing costs (Bernstein, Graven, Drago, Dobbertin, & Eckstrom, 2018). It is difficult to evaluate any consultation

service because their recommendations may not be followed or the hospital may not have the resources or staff to adequately implement the recommendations (C. M. Allen et al., 1986). Further, rural hospitals in North America seldom have access to geriatric consultation programs, even though a large proportion of their patients are older adults (Howe & Kramer, 2019).

Acute Care for Elders Units

These discrete geriatric units provide CGA delivered by a multidisciplinary team with a focus on the rehabilitative needs of older patients. Team rounds and patient-centered team conferences are considered essential. The core team includes a geriatrician, GAPN, and social worker, as well as specialists from other disciplines providing consultation—occupational and physical therapy, nutrition, pharmacy, audiology, and psychology. In the last 20 years, hospitalists have become the physician provider for most of the patients and hence are an essential member of the team. Geriatric evaluation and management (GEM) units developed in the U.S. Department of Veterans Affairs (VA) system have documented significant reductions in functional decline and suboptimal medication use as well as return to home postdischarge and, more recent, decreased rate of nursing home placement among hospitalized veterans on GEM units compared with general medical units (Flood et al., 2018; Phibbs et al., 2006).

Since the 1990s, acute care for the elderly (ACE) units have been implemented in non-VA hospitals. An interprofessional team consisting of staff with geriatric expertise works collaboratively using strategies such as team rounds and family conferences. Most ACE units have made physical environment adaptations to address age-related changes (e.g., flooring to reduce glare), support orientation (white boards indicating staff names and discharge goals), and promote staff observation (e.g., alarmed exit doors and communal space for meals). Led by geriatricians and/or GAPNs, the interprofessional team facilitates care coordination and identification of modifiable risk factors for geriatric syndromes and prevents avoidable discharge delay (Flood et al., 2015; Fox et al., 2013; Malone, Capezuti, & Palmer, 2014).

Compared with other medical units, patients hospitalized on ACE units have maintained prehospital or demonstrated improved functional status at discharge without increases in hospital or postdischarge costs and are less likely to be discharged to nursing homes (Fox et al., 2012; Landefeld, Palmer, Kresevic, Fortinsky, & Kowal, 1995). Other important positive outcomes associated with ACE units include improved drug prescribing (Spinewine et al., 2007), fewer falls (Fox et al., 2012), less delirium (Bo et al., 2009; Fox et al., 2012), and reduced mortality (Saltvedt, Mo, Fayers, Kaasa, & Sletvold, 2002). In addition, reduced costs have been reported in those on ACE units as a result of shorter hospital stays (Barnes et al., 2012; Fox et al., 2012) and fewer 30-day readmissions (Flood et al., 2013).

These positive outcomes are attributed to processes of care more likely found in ACE units: less restraint use, early mobilization, fewer days to discharge planning, and less use of high-risk medications (Counsell et al., 2000). A 2013 systematic review suggested that the best outcomes from ACE programs were those that included patient-centered care, medical review, and early mobilization (Fox et al., 2012). In a recent shift, more hospitals are using ACE units for those at the highest risk of age-related complications with ACE staff also providing consultation, while exporting ACE principles, throughout the health system to reach a greater number of older hospitalized patients. These "virtual" and/or "ACE without walls" consult teams work similarly to a geriatric consultation service except for the fact that there is also an inpatient ACE unit within the hospital or health system. In another variant, the Mobile Acute Care for Elders (MACE) service, an outpatient geriatric team (attending geriatrician hospitalist, geriatric medicine fellow, social worker, and clinical nurse specialist), also provides primary care to its patients when hospitalized (Hung, Ross, Farber, & Siu, 2013; Farber, Korc Grodzicki, Du, Leipzig, & Siu, 2011). An evaluation of this model in one hospital reported that MACE service patients experienced fewer adverse events (catheter-associated urinary tract infection, pressure ulcers, restraint use, and falls) and had shorter hospital stays when compared with similar older patients cared for on medical units (Hung et al., 2013).

Nurses Improving Care for Healthsystem Elders

A national program aimed at system improvement to achieve positive outcomes for hospitalized older adults, Nurses Improving Care for Healthsystem Elders (NICHE), seeks to improve the quality of care provided to older patients and improve nurse competence by modifying the nurse practice environment with the infusion of geriatric-specific (a) core values into the mission statement of the institution; (b) special equipment, supplies, and other resources; and (c) protocols and techniques that promote interprofessional collaboration (Boltz et al., 2008b; Bub, Boltz, Malsch, & Fletcher, 2015; Capezuti, Bricoli, & Boltz, 2013; Capezuti et al., 2012). NICHE includes several approaches that promote dissemination of

evidence-based geriatric best practices into hospital care. The system-level approach of NICHE provides a structure for nurses to collaborate with other disciplines and to actively participate in or coordinate other geriatric acute care models. A NICHE coordinator acts in a leadership role by facilitating, teaching, and mentoring others and changing systems of care (Fletcher et al., 2007). In some hospitals, a GAPN functions in this role as well as providing direct clinical consultation for evaluating and managing patients. The geriatric resource nurse (GRN) model is foundational to NICHE; it is an educational intervention whereby the NICHE coordinator or the GAPN prepares staff nurses to be the clinical resource person on geriatric issues to other nurses on the unit (Capezuti et al., 2012; Lee, Fletcher, Westley, & Fankhauser, 2004). The GRN model provides staff nurses, via education and role modeling (e.g., nursing bedside rounds) by a GAPN or NICHE coordinator, with content focusing on care management for geriatric syndromes. Application of evidence-based practice at the bedside is facilitated by organizational strategies such as incorporation of institution-wide clinical protocols as provided in this book.

The GRN model fosters professional development and enhanced work satisfaction for nurses who feel that they have institutional support in providing quality care. These supports include geriatric-specific resources (continuing education, equipment, and specialty services); interprofessional collaboration; and patient, family, and nurse involvement in treatment-related decision-making. Evaluation in NICHE hospitals has reported improved clinical outcomes, rate of compliance with geriatric institutional protocols, cost-related outcomes, and improved nurse knowledge (Boltz et al., 2013; Bub et al., 2015; Capezuti et al., 2013; Hendrix, Matters, West, Stewart, & McConnell, 2011; Pfaff, 2002; Swauger & Tomlin, 2002; Turner, Lee, Fletcher, Hudson, & Barton, 2001; Wald, Bandle, Richard, Min, & Capezuti, 2014a, 2014b). The GRN model is associated with positive outcomes such as reduced delirium in a NICHE orthopedic unit (Guthrie, Schumacher, & Edinger, 2006) and reduced complications among hospitalized older adults with dementia (J. Allen & Close, 2010). In studies aggregating results from several NICHE hospitals, NICHE implementation is associated with improved processes of care as well as higher nurse-perceived quality of care (Boltz et al., 2008a).

NICHE also promotes implementation of the ACE model. The ACE model, as promoted by NICHE, emphasizes nurse-driven protocols and geriatric continuing education of all nursing staff. Similar to other ACE units, study of a NICHE–ACE unit found lower fall and pressure ulcer rates and lower length of stay when compared with overall hospital rates (LaReau & Raphelson, 2005). Similarly, a geriatric nurse consultant-led CGA program implemented in three medical units of a large, academic NICHE medical center was found to uncover clinically actionable findings (Trotta, Rao, Hermann, & Boltz, 2018).

The Hospital Elder Life Program

The Hospital Elder Life Program (HELP), developed in 1993, is a multicomponent intervention that utilizes an interdisciplinary assessment, trained volunteers, and protocols to prevent cognitive and functional decline in hospitalized older adults. The primary goals of HELP are to maintain physical and cognitive functioning during hospitalization, maximize independence, assist with transition to home, and prevent unplanned hospital readmission (Inouye et al., 1999).

Standardized protocols incorporate interventions tailored to the patient's preferences and abilities may include cognitive stimulation/orientation, therapeutic activities, early mobilization, vision and hearing adaptations, hydration and feeding assistance, and sleep enhancement (Inouye, Bogardus, Baker, Leo-Summers, & Cooney, 2000). Hospital volunteers are well trained and closely supervised to deploy patient care interventions (Bradley, Webster, Schlesinger, Baker, & Inouye, 2006b) that are coordinated by elder life nurse specialists. The elder life nurse specialist typically has advanced geriatric nursing education and will supervise the implementation of nursing-related assessments and tracking of delirium risk-factor-protocol adherence.

In 2013, HELP protocols were adapted to ensure compliance with the National Institute for Health and Care Excellence (NICE) guidelines (Yue, Kshieh, & Inouye, 2015). Interventions added based on the NICE guidelines include prevention of infection and management of constipation, pain, and hypoxia. HELP clinical protocols are often supplemented with operational enhancements including geriatric nursing assessment and intervention, interdisciplinary rounds, ongoing staff educational programs, postdischarge community linkages, and telephone follow-up (Inouye, Baker, Fugal, Bradley; the HELP Dissemination Project, 2006; Yue et al., 2015).

HELP has been disseminated to more than 200 hospitals worldwide, implemented in multiple types of hospital units (medical, medical subspecialty, neurological, surgical, surgical subspecialty, mixed medical-surgical, orthopedic, palliative care, intensive care, rehabilitation, and emergency department). A systematic review of 44 HELP studies and a meta-analysis (Hshieh, Yang, Gartaganis, Yue, & Inouye, 2018) demonstrated that, in the 14 studies examined for effectiveness, all 14 demonstrated

significant reductions in delirium incidence (OR 0.47, 95% CI 0.37–0.59). The rate of falls was reduced by 42% among intervention patients in three comparative studies (OR 0.58, 95% CI 0.35–0.95). The meta-analysis indicated that in the nine studies that examined length of stay, the mean difference was −0.24 days, favoring the intervention group (95% CI −0.95 to 0.48), but this did not achieve statistical significance, and heterogeneity was high (I^2 = 71%). In the four studies of HELP models that reported outcomes related to institutionalization after hospital discharge, the meta-analysis showed that the odds of being institutionalized was not significantly different (OR 1.00, 95% CI 0.72–1.27, I^2 = 0%) among intervention subjects. In nine studies of cost-effectiveness, the program saved US$1,600 to US$3,800 per patient in hospital costs and over US$16,000 per person-year in long-term care costs in the year following delirium. One of the studies demonstrated that modifying the HELP program to include only three key interventions was cost-effective and effective for surgical patients (Chen et al., 2017). These components included orienting communication, oral care and nutritional assistance, and early mobilization.

The impact of HELP upon additional outcomes is beginning to be explored. A secondary data analysis of administrative data and electronic health records at an academic community hospital in which HELP was implemented indicated that HELP intervention participants, compared to pre-intervention patients, were less likely to receive inappropriate treatment for asymptomatic bacteriuria (3.0% vs. 6.7%, adjusted odds ratio = 0.46, 95% confidence interval = 0.26–0.79, p = .005). HELP was associated with a reduction in the treatment of asymptomatic bacteriuria (O'Donnell, Walsh, Tang, & Weinberg, 2019).

A modified version of HELP has been implemented in a long-term care facility ("HELP-LTC") by Boockvar, Teresi, and Inouye (2016) with mobile certified nursing assistant (CNA) collaborating with the resident's primary medical and nursing team and a geriatrician program director. Delirium-prevention components were provided to individuals with moderate-to-severe physical and cognitive impairment and at the time of onset of acute illness by case-finding and referral. The mobile CNAs provided daily visits targeting delirium risk factors, notably cognition, mobility, hydration, and nutrition. Although the preliminary study was limited by lack of a comparison group, study findings suggest that HELP-LTC is feasible, decreased delirium severity, and resulted in individuals returning to baseline cognitive function after acute illness (Boockvar et al., 2016).

Transitional Care Models

Transitional care models address the needs of older adult patients with complex medical and social needs and their caregivers as they move from hospital to postacute care. Two models with demonstrated positive outcomes are the advanced practice nurse (APN) transitional care model (Naylor & Keating, 2008) and the care transitions coaching or care transitions intervention (Coleman, Parry, Chalmers, & Min, 2006; Coleman, Smith, et al., 2004). (These are described in more detail in Chapter 42, Transitional Care.)

COLLABORATIVE APPROACHES

Hospitalists

Considering that hospitalists provide care for an increasing number of older acutely ill Medicare patients, some hospitals have initiated a proactive geriatrics consultation service implemented in collaboration with hospitalists (Sennour, Counsell, Jones, & Weiner, 2009). After 4 years and more than 1,500 consults, this service reported a high level of satisfaction by hospitalists while resulting in a shorter hospital stay and less hospital costs in patients receiving a geriatrics consultation (Sennour et al., 2009). Others have employed collaborative learning experiences to "geriatricize" hospitalists (Gillespie et al., 2014; Sinvani et al., 2018). A program in which hospitalists are trained to lead transitional care teams (BOOST—Better Outcomes for Older adults through Safer Transitions) has shown preliminary evidence to suggest prevention of post-discharge complications and readmissions within 30 days and increased confidence in self-management (Dedhia et al., 2009). In an analysis of the initial hospitals participating in the quality-improvement program, BOOST was associated with a modest but significant reduction in 30-day hospital readmissions from 14.7% at baseline to 12.7% after the intervention (Hansen et al., 2013). Administered by the Society of Hospital Medicine, the BOOST program provides technical support to optimize the hospital discharge process and diminish discontinuity and fragmentation of care (Williams & Coleman, 2009), including a risk stratification tool to predict 30 day readmissions (Sieck, Adams & Burkhart, 2019).

E-Approaches

The availability of geriatric clinicians is essential to implementing any model; however, there is a significant shortage of fellowship-trained geriatricians, geriatric psychiatrists, and master's-prepared geriatric nurse specialists, as well as specialists in other disciplines (Committee on the Future

Health Care Workforce for Older Americans, 2008). This is especially true for hospitals located in rural areas as well as small hospitals without the financial capacity to employ geriatric specialists (Howe & Kramer, 2019). Some hospitals are working with other hospitals in their health system or in their region to create learning collaboratives or "knowledge networks" by using web-based and other long-distance communication strategies. Thus, a geriatrician (Malone et al., 2010) or a GAPN (Capezuti, 2010) can participate in "virtual" rounds with staff in another location (Friedman, Mendelson, Kates, & McCann, 2008; Pallawala & Lun, 2001) to foster communication; that is, the e-Geriatrician or e-APN has access to a system-wide electronic health record such as the ACE Tracker and the TeleGeriatric system (Pallawala & Lun, 2001) or similar web-based assessment tool (Booth et al., 2019; Gray & Wootton, 2008; Martin-Khan et al., 2012; Meyer, 2011; Vollbrecht et al., 2015). In this way, collaboration and mentoring of professional colleagues are facilitated while enhancing the care provided to older adults. The e-approaches require health system leadership buy-in and payment systems which support geriatrics care provided to populations of patients, compared to fee-for-service payment models which reimburse care for individuals.

COMBINATION/SPECIALTY GERIATRIC MODELS

In some hospitals, a combination of geriatric models is implemented such as a geriatric consultation team and transitional care (Arbaje et al., 2010), inpatient geriatric assessment and intensive home care (Buurman, Parlevliet, van Deelen, de Haan, & de Rooij, 2010), CGA with NICHE (Borenstein et al., 2016), or an ACE unit incorporating NICHE and HELP (Sinha, Bennett, Ramsden, Bon, & Chalk, 2018). In others, a core geriatric interprofessional team provides direct consultation as well as screens patients for other related services, such as palliative care, rehabilitative services, or pain management programs. Some hospitals have developed dual-function units, such as merging an ACE unit with a palliative care (Gelfman, Meier, & Morrison, 2008; Tomasovic, 2005), stroke (K. R. Allen et al., 2003), or oncology (Flood, Brown, Carroll, & Locher, 2011) unit, as well as incorporating a "delirium room" within an ACE unit (Flaherty et al., 2003), whereas others have developed programs that incorporate geriatric comanagement with other specialties such as rehabilitation, orthopedics, trauma, and oncology (K. R. Allen et al., 2003; Gelfman et al., 2008; Kammerlander et al., 2010; Mendelson & Friedman, 2014). These programs have demonstrated increased detection of and reduced incidence of delirium, as well as reduced length of stay, readmission rates, morbidity, and mortality (Flaherty et al., 2003; Flood et al., 2011; Kates, 2014; Milisen et al., 2001; Pareja et al., 2009).

Senior ED Care Models

Organizational models have emerged to address the specialized needs of older adults using the ED, and their families. Core components of these models include interprofessional collaboration, the use of evidence-based clinical interventions, and the central role of the nurse in coordinating care. Interprofessional teams (geriatrician, nurse practitioner, rehabilitation therapists, and social worker) evaluate high-risk patients in the ED (and follow them throughout the hospital stay; Gold & Bergman, 1997). A prospective, randomized controlled trial conducted in a medical school–affiliated urban public hospital in Sydney, Australia, found that older adults sent home from the ED who received a CGA demonstrated positive outcomes. Although there was no difference in admission to nursing homes or mortality, patients randomized to the intervention group maintained a greater degree of physical and mental function (Caplan, Williams, Daly, & Abraham, 2004). In the randomized controlled trial of SIGNET (Systematic Interventions for a Geriatric Network of Evaluation and Treatment), an intervention (CGA) conducted in the ED by an APN resulted in very modest reductions in the risk of 90-day admission of elderly patients to a nursing home and in the mean number of hospital days among high-risk patients who received the intervention (Mion et al., 2003).

Mobile interprofessional teams in the ED conduct a brief geriatric assessment and develop a comprehensive plan. Two types of recommendations have been made: (a) medical recommendations for diagnosis and treatment of the presenting illnesses, and other geriatrics syndromes; and (b) gerontological recommendations for social and home needs. Outcomes reported include shortened hospital stay and early discharge from the ED (Launay, Decker, Hureaux-Huynh, Annweiler, & Beauchet, 2012).

GEM nurses provide targeted geriatric assessment and intervention for older adult patients (aged 65+ years) in the ED. At-risk patients are identified through the Triage Risk Factor Screening Tool (TRST) and the Identification of Seniors at Risk (ISAR) tool. Interventions include support for staff to implement geriatric care strategies in the ED, linkage to community support services, referral for specialized geriatric services, and collaboration with the family physician. GEM nurses have provided timely development of care plans and initiation of needed referrals (Asomaning, Loftus, & Ramsden, 2012; Rogers, 2009); however, there has been limited demonstrated impact upon clinical outcomes. A

systematic review of geriatric focused nurse assessment and intervention included seven randomized controlled trials and two prospective pre/post-intervention designed studies. Consistencies in assessment and interventions were apparent between studies. The interventions did not have a statistical impact on hospitalization, readmissions, length of hospital stay, and ED revisits. An increase in ED visits in the intervention group at 30 days post-intervention was noted (Malik, Moore, Patton, O'Connor, & Nugent, 2018).

In Australia, the Geriatric Emergency Department Intervention (GEDI) model, a nurse-led, physician-championed intervention, reduced ED length of stay, hospital admission, and, if admitted, hospital length of stay and cost without increasing mortality or same cause re-presentation in adults over the age of 70. The nurses, working 2.4 full-time equivalent 7 days from 07:00 to 17:30 hours (15:30 hours on weekends), had gerontology experience and education and provided targeted geriatric assessment and streamlining of care (Wallis et al., 2018).

The first senior-friendly ED, a self-contained unit within a larger ED, was created by Holy Cross Hospital in Maryland in 2008. The physical environment is adapted to age-related changes (warm colors with select use of color contrast; thick mattresses; indirect light; glare-free floors; large, easy-to-use call light/TV remotes, telephones, and clocks; and documents with larger print). Dedicated, gerontologically prepared nursing staff, nurse practitioners, and social workers staff the unit and volunteers provide comfort measures. Evidence-based clinical protocols are used. A geriatric pharmacist reviews the medications of seniors who receive seven or more medications. The staff provides follow-up calls or home visits after discharge from the ED and care coordination is provided as indicated.

The trend of senior-friendly EDs is growing, although research is needed to evaluate their clinical and organizational effectiveness (Hwang & Morrison, 2007). A senior ED in a large community hospital screened patients aged 65 years and older for fall risk, depression, alcoholism, delirium, and cognitive and functional impairments, and at-risk patients are provided with additional resources. Additionally, pharmacists and social workers were included in assessment and clinical management. The senior ED was not associated with reduced ED recidivism or hospital length of stay, but was associated with decreased rate of admission in a large community hospital (Keyes, Singal, Kropf, & Fisk, 2014).

The elder-friendly hospital conceptual framework offered by Parke and Brand (2004) provides guidance in efforts to develop a senior-friendly ED. This framework includes four major components to consider when developing a senior-friendly ED, and is described in Box 41.1.

BOX 41.1

Dimensions of a Senior-Friendly Hospital

Social climate: Evident in the treatment of older people in the hospital and the degree of conflict and stress experienced in the ED environment.

Policies and procedures: Expressed in the conduct of hospital staff, which is influenced by the explicit and implicit bureaucratic rules and regulations.

Care systems and processes: The organization of clinical ED care and how work is completed in the provision of services; access to best practice.

Physical design: The observable built environment and all its architectural features, including equipment, furnishings, and decor, that together enable or disable an older person's independent functioning.

Source: Parke, B., & Brand, P. (2004). An elder-friendly hospital: Translating a dream into reality. *Nursing Leadership, 17*, 62–76. doi:10.12927/cjnl.2004.16344

Additionally, the Geriatric Emergency Department Guidelines Task Force (2014), developed by the Emergency Nurses Association, American College of Emergency Physicians, American Geriatrics Society, and Society for Academic Emergency Medicine, create a template for staffing (including management roles), equipment, education, policies and procedures, follow-up care, and performance improvement measures. Chapter 44, Care of the Older Adult in the Emergency Department, provides more information on senior EDS and clinical care.

Surgical Specialty Models

Although most geriatric care models target medical patients, there are now many surgical programs that consult or integrate geriatrics. Integration means geriatric comanagement programs in both general surgery and other surgical specialties (urology, vascular surgery, cardiothoracic surgery, and neurosurgery). For example, a VA hospital with these multiple comanagement surgical units reported higher rates of discharge back to the community (Walke et al., 2014). A urology comanagement program with a geriatrician-led unit rounds resulted in reduced inpatient stay and total postoperative complications (Braude et al., 2017).

Orthogeriatric Models

The American College of Surgeons TQIP (Trauma Quality Improvement Program) Geriatric Trauma specialized geriatric surgical care including criteria for early geriatric

consultation and geriatric expertise on the multidisciplinary trauma care team. During the last 30 years orthopedic programs have emerged that incorporate geriatric input into hip surgery care. The goal is to reduce the incidence of iatrogenic complications and streamline flow though in-hospital care including early discharge that will improve survival, clinical, and cost outcomes (Giusti et al., 2015).

The organization of ortho-geriatrics programs vary considerably but generally fit within one of these three types: (a) A geriatrician and/or geriatric interdisciplinary team that consistently consults older patients admitted to an orthopedic hospital unit; (b) a geriatric or ACE unit with the orthopedic surgeon providing consultation; or (c) comanagement in which the responsibility for care of the older patient on an orthopedic unit is shared between the surgeon and the geriatrician/geriatric team (Grigoryan, Javedan, & Rudolph, 2014). The latter has become the more frequently employed approach.

The components of care including the outcome criteria also differ considerably among orthogeriatric programs (Grigoryan et al., 2014). Some focus on minimizing time to surgery and employment of standardized orders and protocols (Friedman et al., 2008) while some deliver daily geriatrics recommendations for older patients who were receiving care for hip fracture. The latter demonstrated reduction of delirium by over one-third, severe delirium by over one-half, as well as decreased predicted length of stay, readmission rates, complication rates, and mortality (Marcantonio, Flacker, Wright, & Resnick, 2001). Another approach is having a geriatrician and GAPN evaluate all older trauma patients and share recommendations in weekly multidisciplinary rounds and performance improvement meetings of the trauma service. Fallon et al. (2006) reported that nearly all (91%) geriatric recommendations were followed and included: advanced care planning, disposition decisions to promote function, decreased inappropriate medications, and pain management (Fallon et al., 2006).

The difference among orthogeriatric programs in terms of overall organization, personnel, and interventions employed makes it challenging to compare outcomes among these programs. A systematic review and meta-analysis of 18 orthogeriatric programs (Grigoryan et al., 2014) reported that the 10 programs utilizing routine geriatric consultation resulted in significant decreases in long-term mortality, in-hospital mortality, and time to surgery, compared to controls receiving usual orthopedic care. There were only three studies examining the geriatric unit approach but it was not possible to report conclusions due to low quality methodology and sample size. The five studies of orthogeriatric comanagement found patients experienced shortened length of stay compared to controls. Other positive outcomes among the 18 studies in this review included reduced postoperative complications such as decreased incidence of delirium and functional decline.

Since 2012, three other reviews of co-managed care have reported reductions in in-hospital complications (Giusti et al., 2015; Martinez-Reig, Ahmad, & Duque, 2012; Van Grootven et al., 2017) while two demonstrate decreased occurrence of short- and long-term mortality (Giusti et al., 2015; Martinez-Reig et al., 2012). In particular, two well-executed, randomized controlled trials have shown that orthogeriatric care is positively associated with improved mobility at 4 months post surgery compared to controls (Prestmo et al., 2015; Watne et al., 2014).

The increased utilization of orthogeriatric comanagement demonstrates the feasibility of easily integrating this care. There has been considerable evidence collected about these programs that supports the idea that consistent geriatric input embedded into the orthopedic service is ideal since "as needed" geriatric consultation is often too late to prevent common complications of older patients (Giusti et al., 2015). The outcome reporting, however, needs to be consistent. In response, the AO trauma network of Europe recommends that the following should be collected at admission: quality of life, pain, satisfaction, function, falls, medication use, and place of residence. At discharge, the following should also be collected: mortality, length of stay, time to surgery, complications (medical and surgical), and costs (Liem et al., 2013). Depending on the type of surgery, readmission rates should also be collected 30 days, 90 days, and 1-year post surgery.

Surgical Onco-Geriatrics

Most (60%) persons with cancer are over 65 years of age and older cancer patients account for 70% of annual cancer deaths. The high complication rate, such as delirium (Korc-Grodzicki et al., 2015) with oncologic treatment, has prompted the integration of geriatric assessment into standard oncology practice in cancer centers (McEvoy & Cope, 2012) and oncology units of general hospitals (Burhenn, Perrin, & McCarthy, 2016; Lynch, DeDonato, & Kutney-Lee, 2016). Functional status, comorbidity, and frailty are the most predictive factors associated with post-oncology surgery complications according to a systematic review of nine systematic reviews (Huisman et al., 2017). Moreover, older oncology patients, in general, have more complex medical and social needs than adult oncology patients. This has spurred the development of onco-geriatric consultation teams or geriatric–oncology units, some of

which are part of an existing ACE unit to address prevention or reduction of these complications (Flood et al., 2006; Flood et al., 2011; Retornaz, Seux, Pauly, & Soubeyrand, 2008; Retornaz et al., 2007).

Medical Gero-Oncology

Due to the complexity of nursing care for older cancer patients, many cancer centers are educating nurses in comprehensive geriatric screening and assessments (Burhenn et al., 2016; Lynch et al., 2016). These efforts are often led by APNs (Morgan & Tarbi, 2016) and many are part of the hospital's NICHE implementation. This is also being integrated in medical oncology (Magnuson et al., 2016).

THE AGE-FRIENDLY HOSPITAL

In 2016, the John A. Hartford Foundation, under the leadership of foundation president Dr. Terry Fulmer, spearheaded a new initiative to accelerate geriatric quality acute care via the Age-Friendly Health Systems initiative (John A. Hartford Foundation, 2018). The focus is not one discipline or area of the hospital; rather, it supports integration of services across the care continuum (Fulmer, Mate, & Berman, 2018). This initiative is administered by the Institute for Healthcare Improvement (IHI, n.d.), well-known for their Triple Aim framework for "improving the patient experience of care, improving the health of populations, and reducing the per capita cost of health" (para. 2). IHI's track record in optimizing healthcare across U.S. healthcare systems makes them an ideal facilitator for meeting the aims of age-friendly health systems.

The John A. Hartford Foundation and IHI, together with five major U.S. health systems (Ascension, Trinity Health, Anne Arundel Medical Center, Providence St. Joseph, Kaiser Permanente) known for their quality geriatric care, as well as with other experts and organizations (e.g., American Hospital Association and the Catholic Health Association of the United States), identified and operationalized four essentials of geriatric care. These essentials address the major reasons for complications during hospitalization and following discharge, including knowing and acting on what *m*atters to the older person, *m*edication, *m*obility, and *m*entation (Fulmer & Li, 2018). These essentials or "4Ms" are when clinicians fail to systematically assess and manage cognitive changes (mentation), reconcile medications and evaluate for potentially inappropriate medications, and employ a function-focused approach (mobility).

A systems-level approach to implementation of the 4Ms consistently across all settings (hospitals, home care, postacute rehabilitation, primary care, nursing homes, and assisted living) was developed in each of the five health systems (Fulmer & Berman, 2016). Since September 2018, 100 health systems began their participation in a 7-month intensive training program. By 2020, the initiative expects to enroll 20% of all U.S. healthcare systems in the program that will likely compel all U.S. health systems to be age friendly (Fulmer & Berman, 2016; Fulmer & Li, 2018; Mate, Berman, Laderman, Kabcenell, & Fulmer, 2017).

SUMMARY

Despite differences in approaches or foci, all models share common goals. The model employed in a hospital or health system is based on the unique needs of that hospital's patient population, the resources available (geriatric clinicians, bed size, volunteers, etc.), and especially the senior administrator's commitment to geriatric programming. Because there is currently no direct reimbursement for many components of these models, administrators are motivated by the model's alignment to the institution's strategic plan or mission, consumer or community satisfaction, and costs savings (such as reduced costly and nonreimbursable complications; Adunsky et al., 2005; Boult et al., 2009; Bradley, Webster, Schlesinger, Baker, & Inouye, 2006a; Capezuti, Bricoli et al., 2013; Hart, Frank, Hoffman, Dickey, & Kristjansson, 2006; Kammerlander et al., 2010; Leff et al., 2012; Siu, Spragens, Inouye, Morrison, & Leff, 2009).

Although all of the models have demonstrated positive outcomes, only a small number (approximately 750) have been implemented in U.S. acute care facilities. Most are located in academic or teaching hospitals. For example, although slightly less than half of Americans admitted to the hospital due to traumatic injury are 65 or older, only 7% of trauma centers incorporate the acute care models of NICHE or HELP (Maxwell et al., 2013).

Implementing and monitoring these acute care models can be seen as a continuous quality-improvement process. Geriatric nurses and geriatricians play a key role in leading these system-based programs to bring best-practice strategies to populations of older individuals. Expansion to more than 3,000 hospitals that serve a high proportion of older adults may depend on advancing the unique contributions of each within an integrated model such as the Age-Friendly Hospital initiative that will enhance the entire hospital experience of the older patient (Capezuti & Brush, 2018).

Transitional Care*

Fidelindo Lim and Janice B. Foust

42

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe various transitional care models (TCMs) and hospital discharge redesign.
2. Identify potential for nurse-led and advanced practice nurse (APN)-led transitional care.
3. Identify essential elements of successful transitional care.

OVERVIEW

Persons with continuous complex care needs frequently require care in multiple settings. *Transitional care* is defined as "a set of actions designed to ensure the coordination and continuity of healthcare as patients transfer between different locations or different levels of care within the same location" (Coleman, 2003, p. 549). Representative locations include (but are not limited to) hospitals, subacute and postacute nursing facilities, the patient's home, primary and specialty care offices, and long-term care facilities (Coleman, 2003). During transitions between settings, older adults are particularly vulnerable to experiencing poor care quality and problems of care fragmentation. An estimated 3.3 million adult 30-day, all-cause hospital readmissions in the United States were reported in 2011, costing $41.3 billion (Hines, Barrett, Jiang, & Steiner, 2014). For Medicare patients, the three conditions with the largest number of 30-day all-cause readmissions were heart failure, septicemia, and pneumonia. One in four heart failure patients is readmitted within 30 days of discharge (Suter et al., 2014). For patients aged 65 and older, the readmission rate is 16.2% for 30-day all-cause readmissions in 2013 (Barrett, Weir, Jiang, & Steiner, 2015). Despite how common these readmissions and transitions have become, the challenges of improving care transitions have received little attention from policy makers, clinicians, and quality-improvement entities (Coleman, 2003), until recently.

With hospital readmission now heralded as a quality indicator, there is more of an incentive to address transition-related problems. As part of the Affordable Care Act (Obamacare), Medicare created the Hospital Readmissions Reduction Program (HRRP) in 2012. HRRP is a value-based purchasing program that lowers payments to Inpatient Prospective Payment System (IPPS) hospitals with too many readmissions (Centers for Medicare and Medicaid Services [CMS], 2019a). It financially penalizes hospitals whose 30-day readmission rates for six targeted conditions—heart attack, heart failure, pneumonia, chronic obstructive pulmonary disease (COPD), elective

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

hip and knee replacement, and coronary artery bypass graft (CABG)—are high relative to other facilities (CMS, 2019a). Acute myocardial infarction (AMI), heart failure (HF), COPD, and pneumonia are the four high-volume conditions resulting in approximately 500,000 readmissions in 2013, costing $7 billion (Fingar & Washington, 2015). Reducing 30-day hospital readmissions is a major impetus in designing and adopting evidence-based transitional care models (TCMs; Jack et al., 2009).

Many factors contribute to gaps in care during critical transitions. Poor communication, incomplete transfer of information, inadequate education of older adults and their family caregivers, limited access to essential services, and the absence of a single point person to ensure continuity of care all contribute to transition-associated problems (Naylor & Keating, 2008). The practice of nursing is closely tied to health illness transitions in a person's lifetime. The quality of the outcomes during these transitional events is determined largely by the degree of care coordination among healthcare environments and proactive involvement of the patient and their families in the process, wherein a nurse plays a pivotal role. Success in implementing evidence-based transition-care strategies will help curtail preventable rehospitalizations and save healthcare dollars.

This chapter reviews issues and trends associated with transitional care mainly from the acute care setting and presents evidence-based TCMs, redesigned hospital discharge models, and strategies to enhance outcome performance.

BACKGROUND AND STATEMENT OF PROBLEM

In 2017, an estimated 51.7 million U.S. residents (15.6% of the U.S. population) were older than 65 years (United States Census Bureau, 2017). All baby boomers will be older than age 65 in 2030. It is projected that by 2035, there will be 78 million people 65 years and older compared to 76.7 million under the age of 18 (United States Census Bureau, 2018). This population subset remains the core consumer of healthcare resources. There were approximately 137.8 million ED visits in 2014 (a 14.8% increase from 2006). Of these, 18.1%, or about 25 million patients, were 65 years and older (Moore, Stocks, & Owens, 2017). The number of ED visits resulting in hospital admission among persons over 65 years dropped from 42% to 33.6% from 2006 to 2015 (Sun, Karaca, & Wong, 2018). However, patients aged 65 years and older with Medicare and private insurance accounted for 95% to 96% of all ED visits from 2006 to 2015 (Sun, Karaca, & Wong, 2018). The likelihood of older adults being in a state of transition between care environments is very high, with a steep price tag. In 2013, aggregate inpatient hospital costs for all hospital stays totaled $381.4 billion (Torio & Moore, 2016).

Current trends indicated a decrease in hospitalization rates from 2005 through 2014 for those aged 75 years and older by 11.8%. However, for those between 65 and 74 years old, the number of hospital stays did not change substantially during the 10-year period (McDermont, Elixhauser, & Sun, 2017). An estimated 13.5 million discharges (38.7% of total discharges) from short-stay hospitals among this age group were reported in 2010 (U.S. Department of Health and Human Services, 2012). This cohort is also reported to have the highest mean hospitalization cost ($14,300 per episode in 2014 dollars; McDermont et al., 2017). Although adults aged 85 and older accounted for only 2% of the U.S. population in 2010, 9% of hospital discharges belonged to this age group (Levant, Chari, & DeFrances, 2015).

In 2015, the 10 most common diagnoses for inpatient stays among patients between 65 and 74 years of age are septicemia, HF, dysrhythmias, COPD and bronchiectasis, pneumonia, AMI, complication of device (implant or graft), acute cerebrovascular disease, and spondylosis (intervertebral disc disorders and other back problems; Agency for Healthcare Research and Quality [AHRQ], 2017). This is notable because evidence-based TCMs have targeted these high-volume, high-risk conditions (Naylor et al., 2013).

Transitions are considered high-stress events for patients, their families, and care providers alike. Evidence suggests that transitions are particularly vulnerable to breakdowns in care and that there is thus a need for transitional care services (Naylor et al., 2013). Two especially problematic areas are medication discrepancies and poor posthospital follow-up with primary care providers. Forster, Murff, Peterson, Gandhi, and Bates (2003) found that nearly 20% of recently discharged medical patients experienced an adverse event during the first several weeks at home. Of these, 66% involved medications and were the most common type of adverse event (Forster et al., 2003). In a study on home medication discrepancies, Corbett, Setter, Daratha, Neumiller, and Wood (2010) found that the problems were astoundingly widespread, with 94% of the participants having at least one discrepancy. The average number of medication discrepancies identified was 3.3 per patient during hospital-to-home transition (Corbett et al., 2010). Similarly, 71% of the hospital discharge records of older adults with HF had at least one type of medication reconciliation problem (i.e., discrepancies, partial discharge instructions, or incomplete discharge summaries; Foust, Naylor, Bixby, & Ratcliffe, 2012). Another major area of breakdown is

patient follow-up visits after discharge. For example, one study reported that among Medicare patients rehospitalized within 30 days, up to 50% did not have documentation of physician follow-up visits post discharge (Jencks, Williams, & Coleman, 2009). Standardizing handoff processes and developing metrics for transfers of care have been shown to improve transition care to and from the ED (Kessler, Williams, Moustoukas, & Pappas, 2013).

Patients and their caregivers are often unprepared for transitions and are overwhelmed by discharge information. Poor preparation of the patient and his or her informal caregivers for the next level-of-care interface, be it the home or another facility, compromises overall patient safety (Coleman, Parry, Chalmers, & Min, 2006). Follow-up visits after discharges provide opportunities to reinforce discharge education and monitor for changes in conditions. Three important patient and caregiver outcomes related to transitions were (a) feeling cared for and cared about, (b) clear accountability, and (c) feeling prepared and capable to implement the posthospital care (Mitchell et al., 2018). The authors also described strategies to improve outcomes, which included empathic communication, anticipatory guidance regarding home care needs, collaborative discharge planning, clear information, and limiting handoffs with continued care.

At an increasing rate, patients are being discharged home or to other healthcare environments with both complex and complicated treatment plans with limited timely follow-through by professionals, causing undue stress to the patient and his or her informal caregivers once they leave the hospital. Levine, Halper, Peist, and Gould (2010) have described informal caregivers' essential role and called for more proactive involvement of caregivers as partners during transitions, especially when they could be the major source of continuity for the patient. The stress of caregiving is likely to be exacerbated during episodes of acute illness (Naylor & Keating, 2008), readmissions, and transfers to various healthcare environments.

Healthcare disparities and lack of or inadequate access to transition-care resources will be more pronounced in the disenfranchised segment of older adults, namely, those who are living alone, have multiple comorbidities, are undomiciled, are suffering from mental illness, are victims of elder abuse and neglect, are uninsured, and are lacking in legal status. Notable disparities related to transitions of care include (AHRQ, 2018):

- Percentage of hospitalized adult patients with HF who were given complete written discharge instructions was lower for American Indians and Alaska Natives than for Whites.
- Black and Asian patients were less likely than White patients to receive good communication about discharge information.
- Black, American Indian or Alaska Native, and multiple-race patients were more likely than White patients to strongly disagree or disagree that they understood how to manage their health after discharge.
- Black, Native Hawaiian or other Pacific Islander, American Indian or Alaska Native, and multiple-race patients were more likely than White patients to strongly disagree or disagree that staff took their preferences and those of their families and caregiver into account when deciding what the patient's discharge healthcare would be.

Inadequate health literacy is a significant risk factor for adverse outcomes such as preventable readmissions among hospitalized patients (Boyle et al., 2017). This underscores the importance of comprehensive assessment that includes the use of a validated health literacy assessment tool and meaningful implementation of the teach-back method in patient education.

ASSESSMENT OF THE PROBLEM

Several studies have delineated the problems that patients encounter during transitions. Coleman, Min, Chomiak, and Kramer (2004) identified four major content areas that patients and caregivers who recently underwent posthospital care transitions expressed as most essential and most needed: medication self-management, a patient-centered health record, primary care and specialist follow-up, and knowledge of "red-flag" warning symptoms or signs indicative of a worsening condition. Similarly, Miller, Piacentine, and Weiss (2008) identified posthospital difficulties faced by adults during the first 3 weeks at home. Among those patients who had difficulty coping, pain was the most frequent stressor, followed by managing complications and recovery challenges. These recently discharged patients also described relying on family or friends for emotional support and were concerned about being a burden. A lack of written detail and accessibility of hospital discharge instructions were significant problems described by patients, informal caregivers, and home healthcare clinicians when patients returned home from the hospital (Foust, Vuckovic, & Henriquez, 2012). The enactment of the Caregiver Advise, Record, Enable (CARE) Act in most states is designed to educate caregivers about the medical tasks they will need to perform for the patient at home (American Association of Retired Persons, n.d.).

A study that compared the referral decisions of hospital clinicians with those of nurses with expertise in discharge planning and transitional care found that transitional care nurses (TCNs) judged that 96 of 99 of the control-group patients discharged without home care had unmet discharge needs that may have benefited from a postdischarge referral (Bowles, Naylor, & Foust, 2002). Some nurse researchers have developed standardized discharge planning assessment tools (Holland & Bowles, 2012) and predictors of discharge readiness (Weiss et al., 2007).

A prospective observational cohort study to evaluate the quality of discharge practices at an academic medical center (N = 395) found that, although the majority of patients (95.6%) reported understanding the reason for their hospitalization, fewer patients (59.6%) were able to accurately describe their diagnosis in postdischarge interviews (Horwitz et al., 2013). Other key findings include deficiencies in follow-up appointments and advance discharge planning, and patient understanding of key aspects of postdischarge care (Horwitz et al., 2013). The impetus to implement high-quality discharge instructions stems from the CMS and The Joint Commission's (TJC) Core Measures to meet accreditation and public reporting requirements.

A retrospective cohort study of age and other risk factors for medication discrepancies reported that 96% of all hospitalized patients have at least one medication or dosage change compared with their home medication regimens (Unroe et al., 2010). Only 44% of them were notified of the changes at hospital discharge. A study of older Chinese Americans, who transitioned from hospital to home care, reported that 24.3% of participants were prescribed at least one potentially inappropriate medication (PIM) at hospital discharge, whereas 67.1% experienced at least one medication discrepancy. A positive correlation was found between the occurrence of PIM and medication discrepancy (Hu, Capezuti, Foust, Boltz, & Kim, 2012). It is imperative that during discharge medication reconciliation and instructions, a standard guideline, such as the Beers Criteria for PIM use in older adults, be hardwired in the transition process (Hu, Foust, Boltz, & Capezuti, 2014). Another medication-related concern is posthospitalization adverse drug events (Kanaan et al., 2013). Among 1,000 hospital discharges, 19% of them involved an adverse drug event within 45 days among older adults discharged home from the hospital (Kanaan et al., 2013). More than half of these events occurred within 2 weeks of discharge. This highlights the importance of medication reconciliation in care transitions (TJC, 2019). The current Joint Commission National Patient Safety Goals (TJC, 2019) now focus on the safe use of medicines. The goals include patient education, steps on obtaining an accurate list of medications from patients, and encouraging patients to bring a current medication list to physician or provider visits (TJC, 2019).

A review of literature noted that direct communication between hospital and community physicians was relatively rare (3%–20%), and available discharge summaries at the first primary care visit were low (12%–34%; Kripalani et al., 2007). Additionally, discharge summaries did not always have essential information (i.e., medications and diagnostic results) when available. The most common example of communication breakdown is when systems of care fail to ensure that the essential elements of the patient's care plan that were developed in one setting are communicated to the next team of clinicians (i.e., preparation for the goals of care delivered in the next setting, arrangements for follow-up appointments and laboratory testing, and reviewing the current medication regimen; Coleman, 2003). Language and health literacy issues and cultural differences exacerbate the communication breakdowns encountered in healthcare transition (Hu et al., 2014; Naylor & Keating, 2008). The use of pictographs in discharge instructions for older adults with low-literacy skills has been demonstrated to be effective (Choi, 2011).

INTERVENTIONS AND CARE STRATEGIES

Various TCMs have been described in the literature, and several randomized controlled trials (RCTs) have tested interventions. Key outcome variables from these RCTs include rehospitalization rate, cost reduction, patient satisfaction, and quality of care. Specific features of the two well-known evidence-based models are summarized in Table 42.1.

The Two Leading Examples of Transitional Care Interventions

The Advanced Practice Nurses TCM

The TCM was developed at the University of Pennsylvania. It provides a comprehensive in-hospital planning and home follow-up for chronically ill, high-risk older adults hospitalized for common medical and surgical conditions (Naylor & Keating, 2008). The central facilitator of the model is an advanced practice TCN, who follows patients from the hospital into their homes and provides services designed to streamline plans of care, interrupt patterns of frequent acute hospital and ED use, and prevent health status decline. Although the TCM is nurse led, it is a multidisciplinary model that includes the physician, other nurses, social workers,

TABLE 42.1

Transition Care—Strategies for Implementation

Model	Transition Interface	Target Population	Implementation	Primary Provider	Duration of Follow-Up
Transitional care model (TCM; Bradway et al., 2012; Naylor, 2002; Naylor & Sochalski, 2010; Naylor et al., 2004, 2009, 2013, 2014, 2017, 2018; Toles, Colon-Emeric, Naylor, Barosso, & Anderson, 2016)	Hospital to home and home to hospital	Sixty-five years or older, high-risk, adults with a variety of medical and surgical conditions (i.e., CHF and comorbidities)	Initial APN visit within 24 hours of hospital admission. APN visits at least daily at index hospitalization. APN home visits (one within 24 hours of discharge), weekly visits during the first month (with one of these visits coinciding with the initial follow-up visit to the patient's physician). Bimonthly visits during the second and third months. Additional APN visits based on patients' needs and APN telephone availability 7 d/wk. If a patient was rehospitalized for any reason during the intervention period, the APN resumed daily hospital visits to facilitate the transition from hospital to home. Use of care management strategies foundational to the quality-cost model of APN transitional care model, including identification of patients' and caregivers' goals and individualized and collaborative plan of care Implementation of an evidence-based protocol, guided by national heart failure guidelines	APN in a "manager coordinator" role	From admission to 3 months post discharge
Care transitions intervention (CTI; Coleman, Mahoney, & Parry, 2005; Coleman et al., 2006; Gardner et al., 2014; Hung & Leidig, 2015, Li, Guo, Suga-Nakagawa, Takahashi, & Renaud, 2015)	Hospital to home and hospital to skilled nursing facility	Sixty-five years or older with at least one of the following diagnoses: stroke, congestive heart failure, coronary artery disease, cardiac arrhythmias, COPD, diabetes mellitus, spinal stenosis, hip fracture, peripheral vascular disease, deep venous thrombosis, and pulmonary embolism	The transition coach first met with the patient in the hospital before discharge. Arrange a home visit, ideally within 48–72 hours after hospital discharge. For those patients transferred to a skilled nursing facility, the transition coach telephoned or visited at least weekly. The home visit involved the transition coach, the patient, and the caregiver. The primary goal of the home visit is to reconcile all of the patient's medication regimens (i.e., prehospitalization and posthospitalization medications). Transition coach imparted skills on how to effectively communicate care needs during subsequent encounters with healthcare professionals. The patient and transition coach rehearsed or role-played effective communication strategies. The transition coach reviewed with the patient any red flags that indicated a condition was worsening and provided education about the initial steps to take to manage the red flags and when to contact the appropriate healthcare professional. Following the home visit, the transition coach maintained continuity with the patient and caregiver by telephoning three times during a 28-day posthospitalization discharge period. The first telephone call generally focused on determining whether the patient had received appropriate services (i.e., whether new medications had been obtained or durable medical equipment had been delivered). In the two subsequent telephone calls, the transition coach reviewed the patient's progress toward goals established during the home visit, discussed any encounters that took place with other healthcare professionals, reinforced the importance of maintaining and sharing the personal health record, and supported the patient's role in chronic illness self-management.	Nurse "transition coach" in a supportive role (social workers and occupational therapists may also serve as a transition coach)	From admission to 28 days post discharge

APN, advanced practice nurses; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.

discharge planners, pharmacists, and other members of the healthcare team, all of whom implement tested protocols uniquely focused on increasing the ability of patients and their caregivers to manage their care (Naylor et al., 2009).

This model involves advanced practice nurses (APNs) who assume a primary role in managing patients and coordinating the transition from hospital to home and vice versa. APNs implement a comprehensive discharge planning and home follow-up protocol. A qualitative analysis highlighted the barriers and facilitators faced by advanced practice TCNs and emphasized how individualized approaches, providing care that exceeds the type of care typically staffed and reimbursed by insurers, and advanced clinical judgment influenced positive outcomes in the implementation of TCM (Bradway et al., 2012). When compared with the control group, members of the intervention group had improved physical function, quality of life, and satisfaction with care. People in the intervention group had fewer rehospitalizations during the year after discharge, resulting in a mean savings in total healthcare costs of $5,000 per patient (Naylor & Keating, 2008). An RCT using the TCM for older adults hospitalized with HF showed an increase in the length of time between hospital discharge and readmission or death, reduced the total number of rehospitalizations, and decreased healthcare costs (Naylor et al., 2004). A systematic review reported that transition interventions carried out by a HF trained nurse who conducts at least one home visit and follows the patient at least weekly for a minimum of 30 days post discharge with either additional home visits or telephone contact resulted in reduced readmissions (Slyer, Concert, Eusebio, Rogers, & Singleton, 2011).

Among cognitively impaired older adults, a comparative effectiveness of RCT among three models (Augmented Standard Care [ASC], Resource Nurse Care [RNC], and TCM) has demonstrated a statistically significant decrease in mean 30-day rehospitalization per patient using TCM, with similar effects 90 days after the index hospitalization (Naylor et al., 2014). The TCM had significantly lower costs than the ASC group at 30 (p <.001) and 180 days (p = 0.030) and significantly lower costs than RNC at 30 days (p = 0.02; Pauly et al., 2018).

The Care Transitions Intervention Model

Coleman et al. (2006) developed the Care Transitions Intervention Model through the Division of Health Care Policy and Research at the University of Colorado Health Sciences Center in Denver. This model involves a nurse (social workers and occupational therapists may also serve as a coach) functioning as a "transition coach," who teaches patients self-management skills and ensures their needs are met during a transition between healthcare settings. The transition coach helps the patients achieve the positive outcomes outlined in the four pillars of care transitions intervention (CTI): medication self-management, dynamic patient-centered health record keeping, follow-up care with primary physician, and learning how to recognize and respond to red flags that indicate the condition is worsening.

Providing patients with support and tools to participate in their transitional care using this model has been shown to reduce hospital readmissions and associated costs (Coleman et al., 2006). An RCT found that patients who received this intervention had lower all-cause rehospitalization rates through 90 and 180 days after discharge compared with control patients. At 6 months, mean hospital costs were approximately $500 less for patients in the intervention group compared with controls (Coleman et al., 2006).

A self-care model of the CTI has been demonstrated to improve outcomes in a Medicare fee-for-service population. There were significantly fewer hospital readmissions at 30, 90, and 180 days in the intervention group as compared with those who did not receive the CTI (Parry, Min, Chugh, Chalmers, & Coleman, 2009). When compared with matched internal controls (N = 321), patients who received the CTI had significantly lower utilization in the 6 months post discharge and lower mean total healthcare costs ($14,729 vs. $18,779, p = .03). The cost savings per patient receiving the CTI were $3,752 (Gardner et al., 2014). The CTI has been adopted by more than 900 healthcare organizations in 44 states (The Care Transitions Program, 2014). The CTI's website reports that an anticipated net cost savings for a typical Transitions Coach® panel of 350 chronically ill adults with an initial hospitalization over 12 months is conservatively estimated at $365,000 and a 20% to 50% reduction in hospital readmissions (The Care Transitions Program, n.d.).

A qualitative exploration of the value of CTI has demonstrated that patient-centered coaching interventions improved care transitions in chronically ill older adults, particularly because it fostered the perception of a caring relationship, leading to greater patient investment in the program (Parry, Kramer, & Coleman, 2006). A study aimed at understanding the barriers and facilitators for successful implementation of the CTI has been described in the literature (Hung & Leidig, 2015). Several studies have been conducted to explore quality-improvement processes in CTI implementation, particularly its dissemination and sustainability (Bennett, Coleman, Parry, Bodenheimer, & Chen, 2010; Coleman, Rosenbek, & Roman, 2013; Parrish, O'Malley, Adams, Adams, & Coleman, 2009).

Key Components of Transitional Care

The Patient-Centered Outcomes Research Institute (PCORI) sponsored Project ACHIEVE (Achieving patient-centered Care and optimized Health In care transitions by Evaluating the Value of Evidence) lists the components of comprehensive and effective transitional care. These are (Naylor et al., 2017):

- Patient engagement
- Caregiver engagement
- Complexity and medication management
- Patient education
- Caregiver education
- Patient and caregiver well-being
- Care continuity
- Accountability

These key elements can be used as a guide for program planning and implementation. The success of the TCM was tied to the comprehensive assessment of an individual's health goals and preferences; physical, emotional, cognitive, and functional capacities and needs; and social and environmental considerations. Coordinated services during and following the hospitalization by a healthcare professional with special preparation in the care of chronically ill people, preferably a master's-prepared nurse, is a desired feature of the TCM (Naylor & Keating, 2008). Until very recently, sustained transitional care programs outside of funded RCTs were lacking largely because of limited third-party reimbursement of transitional care services (Naylor & Keating, 2008). Medicare currently pays for transition-care management services for medical and psychosocial problems (CMS, 2019b). It is anticipated that reimbursement will continue to expand as part of valued-based patient initiatives.

Hospital Discharge Redesign

Randomized trials have demonstrated the benefits of redesigned hospital discharge processes to strengthen timeliness of primary care visits and/or reduce hospital readmissions or emergency department use (Balaban, Weissman, Samuel, & Woolhandler, 2008; Jack et al., 2009). The interventions included redesigned discharge forms or individualized information sent to primary care providers, medications with specific forms or having a clinical pharmacist call patients after discharge, and arranging patients' primary care visits and facilitating communication with the outpatient offices (i.e., sharing discharge forms). Redesigned discharge processes led to comparatively lower hospital use, especially for those with prior hospitalizations (Jack et al., 2009) and more patients following up with their primary care providers within 21 days (Balaban et al., 2008).

Other transition models that have been described in the literature include the following:

- Guided Care Model—Developed at Johns Hopkins University. It is described as an enhancement to primary care, including access to community resources and policies, and self-management (http://www.guidedcare.org).
- The Bridge Model—Developed by the Illinois Transitional Care Consortium (ITCC). The model emphasizes addressing social determinants of health, biopsychosocial factors, community-specific focus, and hospital–community collaboration (www.transitionalcare.org/the-bridge-model).
- Better Outcomes for Older Adults through Safe Transitions (BOOST)—A project funded by a grant from the John A. Hartford Foundation that provides face-to-face training and a year of expert mentoring and coaching to customize and implement BOOST interventions based on the TCM and CTI (The Society of Hospital Medicine, n.d.; www.hospitalmedicine.org/clinical-topics/care-transitions).
- Geriatric Resources for Assessment and Care of Elders (GRACE)—A model of primary care for low-income seniors and their primary care physicians (PCPs) aimed at improving the quality of geriatric care, optimizing health and functional status, decreasing excess healthcare use, and preventing long-term nursing home placement (graceteamcare.indiana.edu/home.html).
- Project RED (Re-Engineered Discharge)—Supported by grants from the Agency for Healthcare Research and Quality (AHRQ) and the National Institutes of Health's (NIH) National Heart, Lung and Blood Institute (NHBLI), Project RED is a research group at Boston University Medical Center that develops and tests strategies to improve the hospital discharge process and reduce rehospitalization rates (www.bu.edu/fammed/projectred/index.html).
- Interventions to reduce acute care transfers (INTERACT)—This is a quality-improvement program to improve early identification, assessment, documentation, and communication about changes in the status of residents in skilled nursing facilities (www.pathway-interact.com/).
- Connet-Home—A four-step process to address the unique transitional care needs of residents of a skilled nursing facility (SNF) who are returning home (www.lutheranservices.org/sites/default/files/media_room/C-H%20Outreach%20Brief%202-26-19.pdf)

Whichever model is adopted by the institution and stakeholders, staff training is of vital importance. Competency in cross-site collaboration is critical to the management of patients with complex acute and chronic illnesses.

CASE STUDY 42.1

Lin Kwon Ying is a 70-year-old widower who lives alone in an apartment in Chinatown. He was mostly independent up until 5 months ago when he started to develop shortness of breath, increasing fatigue, and cough. He has had three admissions for HF exacerbation. His medical–surgical history includes hypertension (HTN), arthritis, peptic ulcer disease, and gastrointestinal (GI) bleeding. He is back in the hospital for another HF exacerbation, a small left pleural effusion, and a left leg deep venous thrombosis (DVT). Although cognitively intact, Mr. Ying does not speak English, and his family is very much involved in his care. A relative is present during most of the day and evening while he is in the hospital. Most of his relatives have very limited English proficiency. Mr. Ying is scheduled for discharge home the next day after being in the hospital for 6 days. His current medications have been satisfactorily reconciled, with the addition of enoxaparin (low-molecular-weight heparin) injection for 7 days and to check with his primary care provider for possible oral anticoagulation. He is to continue taking prehospitalization medications: metoprolol, esomeprazole, multivitamins, and furosemide. The family reports that Mr. Ying uses Chinese liniment to ease his joint pains. He is described by his family as an obedient patient who will do whatever his doctor recommends, although he has received little advice or "teachings" during his previous HF admissions. He cannot recall being informed what lifestyle changes are required of him.

Factors, such as Mr. Ying's rehospitalization, a diagnosis of HF, language barrier, family involvement, being cognitively intact, and a complex plan of care (i.e., self-injection of enoxaparin), indicate that he is an ideal candidate to receive dedicated transitional care services. If transitional care service were available in the current institution, he would have been referred for a consult on admission. An assessment would have been made by an advanced practice TCN or "coach," preferably in the presence of the informal caregiver and a staff translator. From this transitional care evaluation, a multidisciplinary plan of care with emphasis on applying best practices, on family involvement, and patient teaching by the staff nurses would be drawn up. The handoff report would mention Mr. Ying's status as a transition-care patient, and a disease-specific clinical pathway (in his case HF) would be implemented and followed through during rounds and discharge planning.

To meet TJC standards, all his medication should have been reconciled within 24 hours of his admission and the record placed in a prominent location in his chart. The challenge is to create a medication reconciliation record written in Mr. Ying's own language (Mandarin) that he can take with him on discharge.

At the bedside level, the nurses (mostly bilingual Chinese) provided random or "ambush" teachings when they saw Mr. Ying consuming Chinese food brought from home that they considered high in sodium. No dedicated patient teachings were conducted, and no printed materials in the patient's language were provided. How best to standardize patient teachings in acute care transitions is an ongoing challenge. Staff often report not having the time to teach patients and their families. Patient education must be held as an essential and independent nursing intervention. The facility must provide adequate training, not only for the licensed providers (nurses, APNs, physicians, and social workers), but also for the auxiliary staff such as patient-care technicians and other staff members with direct patient contact. Repetition and reinforcement with the use of traditional printed media can easily be achieved. Numerous online patient teaching materials are now available. The institution could translate these materials into various languages based on local needs. In Mr. Ying's case, his ability to self-inject enoxaparin should be assessed, reinforced, and documented. During the handoff, the nurse would include the patient's teaching needs and the follow-up needed, focusing on health-promotion content, follow-up appointments, telephone numbers to call for questions, or to report changes in condition.

Depending on the TCM applied, Mr. Ying would receive a home visit from the nurse TCM coordinator or nurse "coach" within 24 hours post discharge with an individualized and explicit plan of care, including following up on medications, availability of equipment, and self-report of any "red-flag" signs for HF exacerbation or pulmonary embolism. On his first visit to his primary care provider, he would be accompanied by his transitional care coordinator/coach. In this visit and in future encounters with healthcare providers, Mr. Ying would be encouraged and provided with the

(*continued*)

CASE STUDY 42.1 (*continued*)

skills necessary for self-advocacy and self-management of his condition. Success would depend on various factors such as patient readiness, literacy, and longitudinal follow-up. From the evidence-based models mentioned in this chapter, follow-up varies from day 1 of hospitalization to up to 3 months post discharge. Patient follow-up must also address patients' and informal caregivers' satisfaction with the care received. Additionally, the postacute transition-care nurse could also coordinate referrals to relevant local community organizations to provide greater continuity and long-term social support.

SUMMARY

High-quality transitional care is especially important for older adults with multiple chronic conditions and complex therapeutic regimens, as well as for their family caregivers (Naylor & Keating, 2008). Nurses must recognize their critical role in safe transitions. Breakdown in communication is often cited as one of the major causes of poor-quality transitions that may lead to untimely rehospitalization, injury, and poor patient satisfaction. Clinicians and institutions must actively collaborate and communicate to ensure an appropriate exchange of information and coordination of care across healthcare settings among multiple providers.

The evidence supports the effectiveness of transitional care models to decrease readmissions and reduce costs. These models are now expanding beyond the traditional hospital-to-home model to include postacute home visits and hold promise to improve transitions from SNF to home (Naylor et al., 2018). In addition, evidence supports the need for close follow-up post-hospitalization, including home visits, telephone calls, and timely primary care provider visits. This provides opportunities to reinforce previous patient and family education, especially medications, and monitoring of condition changes (Coleman et al., 2006; Naylor et al., 2004; Rich et al., 1995).

As more evidence on the value of transitional care programs in improving health outcomes emerges, we hope that nurse-sensitive quality indicators of transitional healthcare delivery will emerge as well as sustainable adaptation of these models. Stakeholders in education, practice, research, and health policy will continue to assess the value of evidence-based transitional care interventions for the ever-growing older adult population.

NURSING STANDARD OF PRACTICE

Protocol 42.1: Transitional Care

I. GOAL

To facilitate the implementation of comprehensive and evidence-based transitional care services as patients transfer between different locations or different levels of care within the same location

II. OVERVIEW

A. Evidence that both quality and patient safety are jeopardized for patients undergoing transitions across care settings continues to expand (Coleman et al., 2005).
B. Care transitions are clinically dangerous times for older adults with complex health problems (Corbett et al., 2010).
C. Problems encountered with poor transition process can lead to unplanned readmission and ED visits (Jacob & Poletick, 2008).
D. Transitions are particularly vulnerable to breakdowns in care and, thus, have the greatest need for transitional care services (Coleman et al., 2006; Naylor & Keating, 2008).
E. Family caregivers play a major—and perhaps the most important—role in supporting older adults during hospitalization, especially after discharge (Naylor & Keating, 2008).

(*continued*)

Protocol 42.1: Transitional Care (*continued*)

III. BACKGROUND AND STATEMENT OF PROBLEM

A. Definition

Transitional care: The American Geriatrics Society defines *transitional care* as "a set of actions designed to ensure the coordination and continuity of healthcare as patients transfer between different locations or different levels of care within the same location. Representative locations include (but are not limited to) hospitals, subacute and postacute nursing facilities, the patient's home, primary and specialty care offices, and long-term care facilities. Transitional care, which encompasses both the sending and the receiving aspects of the transfer, is based on a comprehensive plan of care and includes logistical arrangements, education of the patient and family, and coordination among the health professionals involved in the transition" (Coleman & Boult, 2003, p. 549).

Transitional care encompasses a broad range of services and environments designed to promote the safe and timely passage of patients between levels of healthcare and across care settings (Naylor & Keating, 2008).

B. Etiology and/or epidemiology
   1. Situations likely to result in failed transitions include poor social support, discharge during times when ancillary services are unavailable, uncertain medication reconciliation, depression, and patients' cognitive limitations (Cumbler, Carter, & Kutner, 2008).
   2. Medication errors related to medication reconciliation typically occur at the "interfaces of care"—when a patient is admitted to, transferred within, or discharged from a healthcare facility (TJC, 2012).
   3. Hospital discharge practices are placing an increasing burden of care on the family caregiver (Bauer, Fitzgerald, Haesler, & Manfrin, 2009).
   4. RCTs of transitional care interventions have been shown to reduce hospital readmissions and healthcare costs (Arbaje et al., 2010; Coleman et al., 2006; Naylor et al., 2004).
   5. APN interventions in transition care have consistently resulted in improved patient outcomes and reduced healthcare costs (Naylor, 2002).

IV. PARAMETERS OF ASSESSMENT

A. The patient population that is most likely to benefit from transitional care interventions includes those who are diagnosed with one or more of the following diseases: CHF, cognitive impairment (dementia), chronic obstructive pulmonary disease, coronary artery disease, diabetes, stroke, medical and surgical back conditions (spinal stenosis), hip fracture, peripheral vascular disease, cardiac arrhythmias, DVT, and pulmonary embolism (Coleman, Smith, et al., 2004).

B. On admission to an acute care setting, starting at the ED, patient evaluation must include referral of vulnerable older adults for transitional care services.

C. Compliance with TJC standards in medication reconciliation will be used as one of the quality indicators and predictors in overall patient safety.

V. NURSING CARE STRATEGIES

A. A synthesis of best practice guidelines based on existing transitional care models recommends the following key features of a fully developed transition of care (TJC, 2012):
   1. Multidisciplinary communication, collaboration, and coordination, including patient/caregiver education, from admission through transition
   2. Clinician involvement and shared accountability during all points of transition
   3. Comprehensive planning and risk assessment throughout the hospital stay
   4. Standardized transition plans, procedures, and forms
   5. Standardized training of every care provider involved
   6. If a patient is readmitted within 30 days, gain an understanding of the factors associated with the admission
   7. Evaluation of transitions of care measures

(*continued*)

Protocol 42.1: Transitional Care (*continued*)

B. Successful and safe transitions demand active patient and informal caregiver involvement. To improve patient advocacy and safety, the nurse can:
   1. Use the teach-back method in all patient education encounters (AHRQ, 2015).
   2. Promote the "Speak Up" initiative by the TJC (2018). The brochure "Planning Your Follow-Up Care" lists patient-centered and safety-focused questions to be asked by the patients of their healthcare provider before they are discharged from the hospital.
   3. Encourage family involvement and direct them to the "Next Steps in Care" website (see "Resources" section).
   4. Provide the patient with a complete and updated medication reconciliation record. The record should include medications the patient was taking before admission, medications prescribed during hospitalization, and medications to be continued on discharge (TJC, 2019).
   5. Implement evidence-based interventions to reduce transition-related medication discrepancies (Corbett et al., 2010).
   6. Encourage the patients to carry a medication list (i.e., a copy of recent medication reconciliation from a recent hospital admission) and to share the list with any providers of care, including primary care and specialist physicians, nurses, pharmacists, and so forth (TJC, 2019).

C. Critical elements of successful transitions
   1. The Society of Hospital Medicine (n.d.), recommends the 8P Screening Tool to identify patients at risk for adverse events post hospital discharge (www.hospitalmedicine.org/globalassets/clinical-topics/clinical-pdf/8ps_riskassess-1.pdf).
   2. Team approach and preferably nurse led (APN or specialized nurse; Coleman et al., 2006; Naylor & Keating, 2008)
   3. Active and early family involvement across transitions (Almborg, Ulander, Thulin, & Berg, 2009; Bauer et al., 2009; Naylor & Keating, 2008)
   4. Proactive patient roles and self-advocacy (Coleman et al., 2006)
   5. High-quality and individualized patient and family discharge instructions (Clark et al., 2005)
   6. Apply interventions for improving comprehension among patients with low health literacy and impaired cognitive function (Chugh, Williams, Grigsby, & Coleman, 2009), such as the National Patient Safety Foundation's "Ask Me 3" campaign. Retrieved from http://www.ihi.org/resources/Pages/Tools/Ask-Me-3-Good-Questions-for-Your-Good-Health.aspx
   7. Patient and informal caregiver empowerment through education
   8. Commence interventions well before discharge (Bauer et al., 2009)
   9. Elements identified for effective and successful transitions (Coleman, 2003):
      a. Communication between the sending and receiving clinicians regarding a common plan of care
      b. A summary of care provided by the sending institution (to the next care interface providers)
      c. The patient's goals and preferences (including advance directives)
      d. An updated list of problems, baseline physical and cognitive functional status, medications, and allergies
      e. Contact information for the patient's caregiver(s) and primary care practitioner
      f. Preparation of the patient and caregiver for what to expect at the next site of care
      g. Reconciliation of the patient's prescribed medications before the initial transfer with the current regimen and communication of changes to the patient and family
      h. A follow-up plan for how outstanding tests and follow-up appointments will be completed
      i. An explicit discussion with the patient and caregiver regarding warning symptoms or signs to monitor that may indicate that the condition has worsened and the name and phone number of whom to contact if this occurs

D. Barriers to successful transitions (barriers to effective care transitions have been identified at three levels: the delivery system, the clinician, and the patient; Coleman, 2003).
   1. The delivery system barriers

(*continued*)

Protocol 42.1: Transitional Care (*continued*)

a. The lack of formal relationships between care settings represents a barrier to cross-site communication and collaboration.
b. Lack of financial incentives promoting transitional care and accountability in fee-for-service Medicare; although such incentives exist in Medicare-managed care, most plans do not fully address care integration.
c. The different financing and contractual relationships that facilities have with various pharmaceutical companies impede effective transitions. As patients are transferred across settings, each facility has incentives to prescribe or substitute medications according to its own medication formulary. This constant changing of medications creates confusion for the patient, caregiver, and receiving clinicians.
d. Neither fee-for-service nor Medicare-managed care has implemented quality or performance indicators designed to assess the effectiveness of transitional care.
e. There is a lack of information systems designed to facilitate the timely transfer of essential information.
f. There is a lack of interoperability of electronic health information.

2. The clinician barriers
   a. The growing reliance on designated institution-based physicians (i.e., hospitalists) and productivity pressures have made it difficult for primary care physicians to follow their patients when they require hospitalization or short-term rehabilitation.
   b. Nursing staff shortages have forced an increasing number of acute care hospitals to divert patients to other facilities, where a completely new set of clinicians, who often do not have timely access to the patients' prior medical records, manages them. SNF staff are also overwhelmed and do not have the time or initiative to request necessary information.
   c. Clinicians do not verbally communicate patient information to one another across care settings.
   d. Clinicians are not familiar with other clinical sites (e.g., sending or receiving).
3. The patient barriers
   a. There is a lack of advocacy or outcry from patients for improving transitional care until they or a family member are confronted with the problem firsthand.
   b. Older patients and their caregivers often are not well prepared or equipped to optimize the care they will receive in the next setting.
   c. Patients may have unrealistic expectations about the content or duration of the next phase of care and may not feel empowered to express their preferences or provide input for their care plan.
   d. Patients may not feel comfortable expressing their concern that the primary factor that led to their disease exacerbation was not adequately addressed.

E. Evaluation/Expected outcomes
1. Clinician outcomes
   a. Increase nurse involvement in leading transition-care teams.
   b. Enhance staff training of transitional care by a multidisciplinary team.
   c. Include patient's transitional care needs during in-hospital handoff.
   d. Improve medication reconciliation throughout all transition interfaces.
2. Patient outcomes
   a. Improve patient satisfaction, and increase involvement in their care during hospitalization and transitions across healthcare settings.
   b. Increase feeling of empowerment in making healthcare decisions.
   c. Reduce rehospitalization and ED visits because of primary disease and comorbidities.
   d. Increase timeliness of making follow-up appointments after hospital discharge.
3. Informal caregiver outcomes
   a. Improve informal caregiver satisfaction and exercise proactive roles during transitions across healthcare settings.
   b. Increase informal caregiver participation in all transition interfaces.

(*continued*)

Protocol 42.1: Transitional Care (*continued*)

4. Institutional outcomes
   a. Adopt evidence-based TCMs and provide logistic support.
   b. Provide orientation and ongoing education on transitional care strategies.
   c. Introduce transitional care content into nursing core curriculum, at both baccalaureate and graduate levels.
   d. Assess transition-care interventions as part of hospital accreditation by TJC and CMS.

VI. FOLLOW-UP MONITORING

A. Institute comprehensive and multidisciplinary transition-care planning as soon as the patient is admitted, and sustain throughout hospitalization.
B. Identify transition-care team members and perform periodic role reassessment, including roles of informal caregivers.
C. Incorporate continuous quality-improvement criteria into transition-care programs such as monitoring for rehospitalization of targeted older adults, quality of discharge instruction, and medication reconciliation.
D. Develop ongoing transitional care educational programs for both formal and informal caregivers, using high-tech and traditional media.
E. Provide orientation and ongoing education on procedures for reconciling medications to all healthcare providers, including ongoing monitoring (TJC, 2019).
F. Perform periodic debriefing of high-risk discharges as a quality-improvement strategy.
G. Improve recognition of condition changes or adverse events caused by medications.
H. Increase patients' and caregivers' knowledge concerning actions to take if condition worsens, including contact information.
I. Consistently transmit hospital discharge summary with all the relevant information to primary care providers (Burton, 2012).
J. Use the Assessing Care of Vulnerable Elders-3 Quality Indicators as a guide in assessing, monitoring, and evaluating care of specific conditions (American Geriatrics Society, 2007).
K. Use a decision support algorithm for referrals to post-acute care (Bowles et al., 2018).
L. Gauge hospital performance in the HRRP. Measure the hospital's relative performance and the ratio of predicted-to-expected readmissions (CMS, 2019a).

VII. RELEVANT PRACTICE GUIDELINES

A. Ongoing chart and medical records review of patients being considered for discharge or awaiting transition should reflect the QI outlined in the ACOVE under the Continuity and Coordination of Care QI heading (Askari et al., 2011).
B. Adopt NPSGs most relevant to transitions of care such as the domains of improving staff communication and using medicines safely (TJC, 2019). The elements of performance include:
   1. Obtain information on the medications the patient is currently taking when he or she is admitted to the hospital or is seen in an outpatient setting. This information is documented in a list or other format that is useful to those who manage medications.
      a. Current medications include those taken at scheduled times and those taken on an as-needed basis.
      b. It is often difficult to obtain complete information on current medication from a patient. A good-faith effort to obtain this information from the patient and/or other sources will be considered as meeting the intent of the EP.
   2. Define the types of medication information to be collected in non–24-hour settings and different patient circumstances.
      a. Examples of non-24-hour settings include the ED, primary care, outpatient radiology, ambulatory surgery, and diagnostic settings.
      b. Examples of medication information that may be collected include name, dose, route, frequency, and purpose.

(*continued*)

Protocol 42.1: Transitional Care (*continued*)

3. Compare the medication information the patient brought to the hospital with the medications ordered for the patient by the hospital to identify and resolve discrepancies.
   a. Discrepancies include omissions, duplications, contraindications, unclear information, and changes. A qualified individual, identified by the hospital, does the comparison.
4. Provide the patient (or family as needed) with written information on the medications the patient should be taking when he or she is discharged from the hospital or at the end of an outpatient encounter (i.e., name, dose, route, frequency, and purpose).
   a. When the only additional medications prescribed are for a short duration, the medication information the hospital provides may include only those medications.
5. Explain the importance of managing medication information to the patient when he or she is discharged from the hospital or at the end of an outpatient encounter.
   a. Examples include instructing the patient to give a list to his or her primary care physician; to update the information when medications are discontinued, doses are changed, or new medications (including over-the-counter products) are added; and to carry medication information at all times in the event of emergency situations.

C. The Position Statement of the American Geriatrics Society Health Care Systems Committee on Improving the Quality of Transitional Care for Persons With Complex Care Needs must be considered in developing practice guidelines (Coleman, 2003).

D. Implement policies and procedures related to the Caregiver Advise, Record, Enable (CARE) Act such as educating the caregiver with education and instruction of the medical tasks he or she will need to perform for the patient at home (American Association of Retired Persons, n.d.).

Palliative Care Models*

Constance Dahlin

43

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Define palliative care and how it differs from hospice.
2. Describe how palliative care promotes quality healthcare.
3. Discuss the metrics that support the role of palliative care in reducing healthcare costs.
4. Delineate models of palliative care in the United States based on venue.

OVERVIEW

The U.S. federal government defines *palliative care* as patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness involves addressing physical, intellectual, emotional, social, and spiritual needs and to facilitate patient autonomy, access to information, and choice (Centers for Medicare & Medicaid Services, 2012).

There are specific characteristics that underpin palliative care: (a) services are appropriate at any stage of illness for a person with a serious illness based on the needs and not on prognosis; (b) care provision is holistic and provided by an interdisciplinary team; (c) the circle of care includes patients, families, and palliative and nonpalliative health providers who collaborate and communicate about care needs; (d) services are available in conjunction with or independent of curative or life-prolonging therapies; (e) goals of care for patients and families are supported and congruency is assured throughout the course of illness, during the dying process, and after death (National Consensus Project for Quality Palliative Care [NCP, 2018]).

Palliative care is especially synergistic with nursing (Lynch, Dahlin, Hultman, & Coakley, 2011). The aims of nursing actions are to protect, promote, and optimize health; prevent illness and injury; and alleviate suffering (American Nurses Association, 2015). Nurses have been in the forefront of efforts to improve quality of life for patients and families throughout the experience of illness (Benoliel, 2010). Indeed, the establishment of palliative care in the United States occurred during the late 1970s. Dr. Florence Wald, the dean of Yale School of Nursing, visited Dame Cicely Saunders, founder of the modern hospice movement in England (Dahlin & Mazanec, 2011; Yale Bulletin and Calendar, 2001). Dr. Wald stated that, "hospice care was the epitome of good nursing care, as it enables the patient to get through the end of life on their own terms. It is a holistic approach, looking at the patient

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

as an individual, a human being. The spiritual role nurses play in the end-of-life process is essential to both patients and families" (Yale Bulletin and Calendar, 2001). On return to Yale University, Dr. Wald developed a comprehensive nursing curriculum of the essential nursing skills necessary in the care of dying patients, including communication, as well as pain and symptom management (Adams, 2010). This was the beginning of the specialty of hospice and palliative nursing.

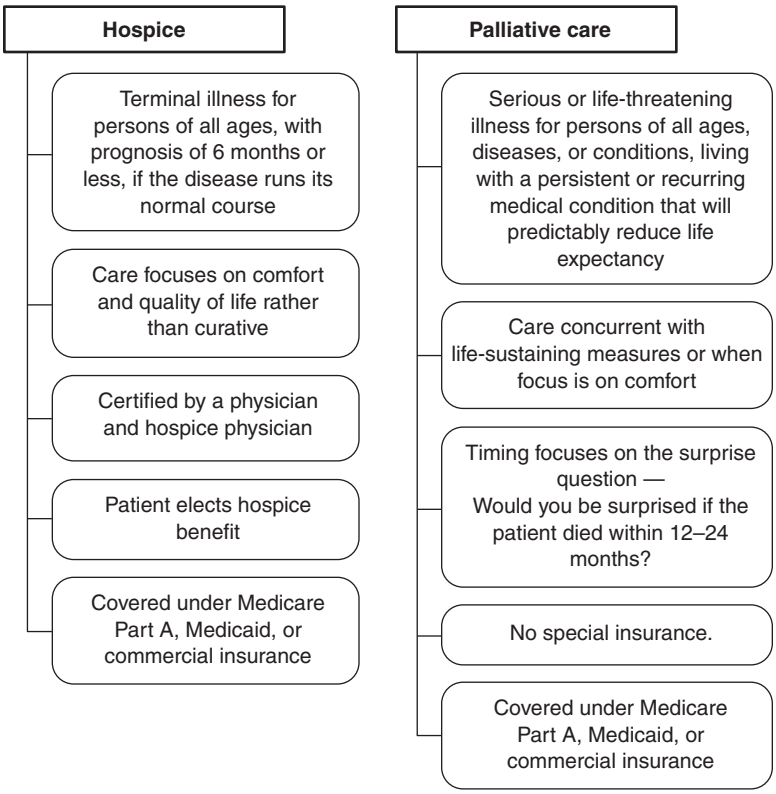
This stimulated national interest in hospice care. The comprehensive care model, inclusive of physical, psychological, spiritual, and emotional aspects of care in the context of culturally appropriate care, involved a cultural shift to the more technological type of healthcare in which death and dying were ignored. Reaction to this resulted in the creation of the Centers for Medicare & Medicaid Services (CMS) demonstration project of eight hospice sites across the country. In 1982, the Medicare Hospice Benefit was enacted as part of healthcare, offering benefits to patients with terminal illness. At the time, the payment structure was progressive because its fee structure was a capitated rate of a specific rate per day. It became the gold standard by which to measure care of patients with life-limiting illnesses.

To promote consistency and quality, the hospice conditions of participation (CoPs) were created, which specified required services and characteristics for hospice development and care delivery (CMS, 2008). Eligibility for hospice is determined by meeting three criteria: a life-limiting diagnosis, a prognosis of 6 months or less, and the desire to forgo curative treatment. It should be noted that patients may start on home health before moving to hospice. However, the home health CoPs are more directed toward reversible conditions and nurses may lack the expertise to provide specialty care to patients with serious illness (CMS, 2017). Four categories of hospice care are available: home care, continuous care, inpatient care, and respite care. Patients and families receive a range of services such as medications, equipment, and interdisciplinary care. In programs across the United States, the majority of hospice care centers on care delivery by nurses visiting the patient's home. These nurses represent all levels of practice from nursing assistant to licensed practical or vocational nurse, registered nurse, and APRN. Patients receive care during the benefit period in which attestations are made to the patient's continued eligibility.

CURRENT STATE OF PALLIATIVE CARE

Forty years later, the basic structure of the Medicare Hospice Benefit remains relatively intact. Eligibility criteria are unchanged, but are more tightly monitored. However, benefit periods have been redefined and recertification processes have been added. Revisions have occurred in reimbursement rates, and in the broader expansion of provider roles. Finally, the Affordable Care Act brought the Medicare Hospice Benefit care into the fold of quality-measurement and reporting, similar to all other healthcare delivery providers (Patient Protection and Affordable Care Act [PPACA], 2010).

Hospice remains a wonderful model of care for patients with end-stage illness and who want to forgo curative treatment. The challenge is what to do for patients with serious illness, diagnosed with life-limiting illnesses, who do not qualify for hospice, want to pursue curative therapies, or for whom hospice means "giving up" (Casarett & Quill, 2007). The answer is palliative care. Palliative care was developed for patients diagnosed with serious illness for whom cure is not possible. However, the illness could have a trajectory of years to days, and so the "dosing" of palliative care may vary depending on the illness and the stage of severity.



Palliative care focuses on quality of life and can be provided concurrently with life-sustaining therapies. In the 1990s, a Canadian physician, Balfour Mount, coined the term *palliative care* when he brought hospice concepts of caring for patients with life-limiting illness into the academic hospital setting. The focus was on care for patients with serious illness at diagnosis with the potential for care to occur over longer periods. In the United States, this meant more time than possible under the hospice benefit. More specifically, care was moved upstream to diagnosis to provide care that was consistent with patients' values, preferences, and belief throughout the disease trajectory. Figure 43.1 provides a comparison of hospice and palliative care.

This focus on patient wishes was mandated by the *Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment* (SUPPORT), the 1995 landmark study that demonstrated a failure to honor patients' preferences (SUPPORT Principal Investigators, 1995). It revealed continued lack of communication between patients and their healthcare providers about end of life, high levels of pain reported by the seriously ill and dying, and that in spite of expressed patient preferences that suggested otherwise, aggressive care continued (SUPPORT Principal Investigators, 1995).

Other important documents about the process of dying in America indicated the demand for palliative care. In 1997, the Institute of Medicine (IOM) published *Approaching Death*, which set the groundwork for subsequent review and analysis (Field & Cassel, 1997). This

FIGURE 43.1

Comparison of hospice and palliative care.

report recommended specialty palliative care, endorsed appropriate utilization of medications for pain and symptom management, supported financial investment in palliative care, and called for healthcare provider education with the inclusion of palliative care principles and practice in both training programs and curriculum textbooks (Field & Cassel, 1997). The 2001 IOM published *When Children Die* and *Crossing the Quality Chasm*, which called for significant changes in care of dying children and quality in healthcare (Field & Behrman, 2002; IOM, 2001). These commentaries focused on the need for better care of dying children similar to adults and for better quality measurement in healthcare. In 2002, Last Acts—a Robert Wood Johnson Foundation supported entity—published a state-by-state report card of end-of-life care in America, which captured a fairly bleak picture of palliative care in the United States (Last Acts, 2002). Clearly, there was work to be done.

A monograph by the National Hospice Work Group (NHWG) and the Hastings Center, in association with the National Hospice and Palliative Care Organization (NHPCO), titled *Access to Hospice Care: Expanding Boundaries, Overcoming Barriers,* argued for significant changes in access to palliative care, including all ages, all health settings, and all progressive chronic or serious life-threatening illness and injuries (Jennings, Ryndes, D'Onofrio, & Baily, 2003).

In 2013, the IOM published *Delivering High-Quality Cancer Care: Charting a New Course for a System in Crisis* (Levit, Balogh, Nass, & Ganz, 2013). There were two palliative care-specific recommendations. The first was that the cancer care team should provide patients and their families with understandable information on cancer prognosis, treatment benefits and harms, palliative care, psychosocial support, and estimates of the total and out-of-pocket costs of cancer care. The second was that in the setting of advanced cancer, the cancer care team should provide patients with end-of-life care consistent with their needs, values, and preferences.

In 2014, the IOM released *Dying in America—Improving Quality and Honoring Individual Preferences Near End of Life* (IOM, 2014). The report provided five areas for quality palliative care in achieving healthcare improvement and moving care upstream to patients with serious illness, rather than focusing on end of life: (a) delivery of person-centered and family-focused palliative care; (b) clinician–patient communication and advance care planning; (c) professional education in palliative care; (d) policies and payment for palliative care; and (e) public education and engagement in palliative care (IOM, 2014). Currently, over 75% of hospitals with over 300 beds have palliative care services and 33% of counties in the United States have palliative care in their communities (Center to Advance Palliative Care, 2018). In just over 25 years, the field of palliative care has emerged as a specialty and has matured so that it is now available at diagnosis of a serious illness across all settings, populations, and ages.

QUALITY AND PALLIATIVE CARE

Quality is and has been an essential component of palliative care. Within hospice, there are guidelines and standards for care. From the outset of the hospice benefit, CMS created the CoPs, as previously described. Most recently updated in 2011, the CoPs articulate essential components of hospice care, such as the eligibility criteria, core services, hospice care planning, benefit periods, and coverage. The NHPCO (2011) created 10 quality and practice standards: (a) patient- and family-centered care, (b) ethical behavior and consumer rights, (c) clinical excellence and safety, (d) inclusion and access, (e) organizational excellence, (f) workforce excellence, (g) standards, (h) compliance with laws and regulations, (i) stewardship and accountability, and (j) performance measurement.

Although hospice had standards of care, palliative care did not. This need for quality, consistency, and access was the backdrop to a national discussion regarding national guidelines for palliative care. In 2001, an interdisciplinary meeting of palliative, hospice, and end-of-life leaders convened to create national palliative care standards. This meeting served as the inception of the National Consensus Project (NCP) for quality palliative care. With representation from the national palliative care organizations in the United States, this consortium created the *Clinical Practice Guidelines for Quality Palliative Care*, which was first published in 2004 (NCP, 2004). The guidelines have been updated three times to ensure that they reflected the ongoing maturity of the field, healthcare reform, and the growing literature within the field (NCP, 2009, 2013, 2018). The most recent edition focuses on palliative care in the community, and again all populations from neonates to very old adults.

BOX 43.1

Eight Domains of Palliative Care

Domain 1: Structure and Processes of Care
Domain 2: Physical Aspects of Care
Domain 3: Psychological and Psychiatric Aspects of Care
Domain 4: Social Aspects of Care
Domain 5: Spiritual, Religious, and Existential Aspects of Care
Domain 6: Cultural Aspects of Care
Domain 7: Care of the Patient Nearing the End of Life*
Domain 8: Ethical and Legal Aspects of Care

*Note this domain title has changed three times.

Source: National Consensus Project for Quality Palliative Care. (2018). *Clinical practice guidelines for quality palliative care* (4th ed.). Richmond, VA: National Hospice and Palliative Care Coalition. Retrieved from https://www.nationalcoalitionhpc.org/wp-content/uploads/2018/10/NCHPC-NCPGuidelines_4thED_web_FINAL.pdf.

The document delineates eight domains of palliative care (Box 43.1) and encapsulates the palliative care–related research (NCP, 2018). From its outset, the aim of the *Clinical Practice Guidelines* was as follows: (a) promote quality and consistency, thereby reducing variation in new and existing programs; (b) develop and encourage continuity of care across settings; and (c) facilitate collaborative partnerships among palliative care programs and community hospices, as well as a wide range of other healthcare delivery settings (NCP, 2004, 2009, 2013). Rather than setting minimally acceptable practices, ideal practices and goals for quality palliative care service delivery are offered. The *Clinical Practice Guidelines* offer a framework for the future of palliative care in serving as a manual or blueprint to create new programs, guide developing programs, and set high expectations for excellence for existing programs.

In 2006, the National Quality Forum (NQF, 2006) adopted the *Clinical Practice Guidelines for Quality Palliative Care* within the document—*A National Framework and Preferred Practice for Palliative and Hospice Care Quality*. The NQF is a private, nonprofit, membership organization created to develop and implement a national strategy for healthcare quality improvement. Its mission is to improve American healthcare through the endorsement of consensus-based national standards for measurement and public reporting of healthcare performance data (NQF, 2019a, 2019b). Because the NQF is recognized as the national leader in healthcare quality improvement and representative of the broadest possible array of practice areas and topics,

it offered palliative care both legitimacy and recognition within a broad healthcare focus to policy makers and payers.

The NQF had not previously addressed the topic of hospice and palliative care. Given the consensus-based process of the guideline development, it was consistent with the NQF goals. The NCP requested the NQF to review and endorse the guidelines. The NQF appointed a technical expert panel to review the guidelines and propose preferred practices. The result was the *Framework* document, which formulated palliative care standards and preferred practices with implications for reimbursement, internal and external quality measurements, regulation, and accreditation (NQF, 2006). With important recognition of the federal government as the basis for reimbursement, regulation, and accreditation, the significance of this endorsement cannot be overstated. See Appendix 43.1for the correspondence between the NCP *Clinical Practice Guidelines* and the NQF Preferred Practices.

The NQF has continued to recognize the importance of quality palliative care. In 2008, the National Priorities Partnership (NPP)—a consortium of U.S. healthcare organizations working with NQF—identified palliative care as one of six top priorities for improving the U.S. health system (NPP, 2008). They developed a National Priority Partners Palliative and End-of-Life work group to consider the next steps. NPP released the report *National Priorities & Goals—Aligning Our Efforts to Transform America's Healthcare*. It identified palliative care and end-of-life care as one of the six national priorities that, if addressed, would significantly improve the quality of care delivered to Americans (NPP, 2008). In 2010, the NPP convened a palliative and end-of-life meeting to develop strategies to promote palliative care, including quality improvement stakeholders, insurers, consumer groups, certification groups, professional groups, and education institutions (NPP, 2010). In 2018, the NQF initiated a new Serious Illness Care Initiative funded by the Moore Foundation to examine quality in palliative care. Their work includes identification of existing measures and recommendation of approaches to address measure gaps that exist within serious illness. A summit report to disseminate findings has been released.

Within the federal reporting structures of healthcare reporting, palliative measure development remains a priority. In 2011, as required by the Affordable Care Act, the NQF established the Measure Applications Partnership (MAP) as a public–private partnership entity that reports directly to the U.S. Department of Health and Human Services secretary and advises on quality measures for public reporting across all healthcare settings and performance-based payment programs (NQF, 2019a). They evaluate measures for CMS for public reporting and reimbursement. There is palliative representation on all these groups, which promotes and supports palliative-related measures.

A Palliative Care and End-of-Life Care Endorsement Maintenance Measures Project was established in 2011. Over the course of a year, it evaluated 22 measures that addressed assessment and management of conditions and symptoms in patients, including pain, dyspnea, weight loss, weakness, nausea, serious bowel problems, delirium, and depression; patient- and family-centered palliative and hospice care focused on psychosocial needs and care transitions; as well as patient, caregiver, and family experiences of care (NQF, 2012b). In February 2012, the NQF (2012a, 2012b) endorsed 14 quality measures for palliative and hospice care. The goal of these measures is to ensure the provision of high-quality palliative care and end-of-life care. The measures, some of which are applicable to all clinical settings and provider types, will help hospice and palliative care providers to improve quality of care and generate ideas for future research.

One of the MAP workgroups, the Post-Acute Care/Long-Term Care (PAC/LTC) workgroup, is responsible for reviewing and advising on hospice and palliative care measures. However, there are measures that occur within the Clinician Workgroup and the Hospital Workgroup. The June 2012 MAP Final Report on Performance Measurement Coordination Strategy for Hospice and Palliative Care states that, "while measurement in this area is new, MAP suggests a phased approach that emphasizes clinically-focused measures at first, but quickly expands to more measures that follow the patient and their full set of experiences rather than the setting or fragments of a patient's care (often referred to in this report as 'cross-cutting')" (NQF, 2012a, p. 3). The MAP report also addresses quality reporting in palliative care, by stating "while there is not a formal quality reporting program for palliative care, settings in which palliative care is provided (e.g., hospitals, home health) are required to participate in federal quality initiatives" (NQF, 2012a, p. 4). Each year, they provide a summary of metrics reflecting palliative care and care of individuals with serious illness.

Another project on quality is the joint program between the American Academy of Hospice and Palliative Medicine (AAHPM) and the Hospice and Palliative Nurses Association (HPNA), *Measuring What Matters* (Dy et al., 2015). As the population ages and the demand for this type of care grows, the ability to assess quality throughout the country and across care settings is increasingly important. This project promotes the use of validated indicators in order to ensure consistent quality measures that can ultimately be used for benchmarking, comparison, and quality improvement (Dy et al., 2015). They have identified 10 measures that range from

a complete assessment (including physical, psychological, social, spiritual, and functional needs) to a plan for managing pain and shortness of breath to having patients' treatment preferences followed. Currently, there are two joint HPNA–AAHPM working groups to promote further measurement in the field: Technical Specifications for electronic Clinical Quality Measures (eCQMs) Working Group and the Quality Improvement (QI) Education and Strategies Working Group (AAHPM, 2019a).

Finally, in terms of quality, specialty palliative care designation for both healthcare programs and providers demonstrates quality to the public and insurers. Specialty certification is now possible in each of the core services—chaplaincy, medicine, nursing, and social work, as well as hospital-based programs (AAHPM, 2019b; Advanced Palliative Hospice Social Worker Certification Board, 2018; Board of Chaplaincy, 2019; Hospice and Palliative Credentialing Center, 2015; National Association of Catholic Chaplains, 2019; National Association of Social Workers, 2015). Different discipline-specific organizations are responsible for certification, which occurs either by examination or meeting standards of practice. See Table

TABLE 43.1

Health Disciplines With Palliative Care Specialty Certification

Discipline	Organization	Certification Process	Credential	Eligibility
Chaplaincy	Collaboration of: Association of Professional Chaplaincy National Council of Catholic Chaplains	Application	BCC-PCHAC	■ Board certification as a chaplain for 1 year ■ Clinical experience in hospice/palliative care spanning over 3 years at minimum of 520 hours a year ■ Completion of course in hospice and palliative care equivalent to three (3) credit hours (45 hours)
Medicine	American Academy of Hospice and Palliative Medicine	Examination		■ 1-year fellowship
Nursing	Hospice and Palliative Credentialing Center	Examination	CHPN	■ RN ■ 500 hours in 1 year or 1,000 hours in 2 years of specialty palliative nursing practice
			ACHPN	■ APRN ■ 500 hours in 1 year or 1,000 hours in 2 years of specialty palliative nursing practice
Social work	SWHPN—Advanced Palliative Hospice Social Worker Certification Board	Examination	APHSW-C	■ BSW ■ 3 years postdegree supervised experience in hospice and palliative care ■ 3 years postdegree experience within the past 5 years ■ MSW ■ 2 years postdegree supervised experience in hospice and palliative care
Social work	National Association of Social Work and the National Hospice and Palliative Care Organization	Application	CHP-SW	■ BSW—A bachelor's degree in social work from an accredited university ■ 3 years of practice ■ 20 CEUs in hospice or palliative care
			ACHP-SW	■ MSW—Master's degree in social work from an accredited college or university program is required ■ 3,000 hours of post-MSW practice ■ 20 CEUs in H&P care ■ Reference review of advanced SW palliative competencies

ACHPN, advanced certified hospice and palliative nurse; ACHP-SW, advanced certified hospice and palliative social worker; APHSW-C, advanced palliative hospice social worker-certified; BCC-PCHAC, board certified chaplain-palliative care and hospice advanced certified; BSW, bachelor's in social work; CE, continuing education; CEU, continuing-education units; CHPLN, certified hospice and palliative licensed practical/vocational nurse; CHPN, certified hospice and palliative nurse; CHP-SW, certified hospice and palliative social worker; H&P, hospice and palliative; RN, registered nurse; MSW, master's in social work; SW, social work.

43.1 for a list of disciplines with the association responsible and the eligibility for certification.

In 2011, The Joint Commission (TJC) created the first voluntary specialty palliative care designation for hospital palliative care teams followed by designation for community-based home health agencies and hospices in 2016 (TJC, 2016). Today, there are several other organizations that offer designation for specialty community-based palliative programs and hospital-based palliative care programs, including Accreditation Commission for Health Care (ACHC), DNV-GL (DNV), and Community Health Accreditation Partner (CHAP; ACHC, 2017; CHAP, 2019; DNV-GL, 2019). Although all the organizations' survey standards and indicators are steeped with the NCP Guidelines, they vary in eligibility criteria, duration of designation, and cost. For hospitals, both TJC and DNV offer specialty palliative care designation; however, TJC requires the organization to hold TJC primary certification. In the community, both TJC and ACHC offer palliative care designation to home health agencies and hospice and private duty agencies for palliative care delivery who are TJC- and ACHC-certified. CHAP offers a specialty palliative care designation to any eligible care delivery model in the community that meets its requirements, such as clinics, physician/provider groups, or programs in a long-term care setting. See Table 43.2 for a comparison of program specialty palliative care designation.

TABLE 43.2

Program Specialty Palliative Care Designation

Organization/Year Initiated	Designation	Length/Eligibility	Requirements	Survey Criteria
Hospital-Based Palliative Care				
TJC (2011) https://www.jointcommission.org/certification/palliative_care.aspx	Advanced Certification for Palliative Care	Valid for 2 years. Hospital must be TJC-certified. Any hospital eligible—long-term care, children's hospitals, acute care.	Provide the full range of palliative care services to hospitalized patients 24 hours/day, 7 days/week. Programs must have team members available to answer phone calls during nights/weekend and the ability to come to the hospital to see patients 24/7 when necessary to meet patient/family needs. Programs must commit to long-term evaluation of process and clinical measurement.	39 standards within six categories Foundation 1. TJC prior accreditation 2. NCP Guidelines
DNV-GL (2019) https://www.dnvgl.us/assurance/healthcare/PalliativeCare.html	Palliative Care Program Certification	Valid for 1 year. No requirements about prior certification.		37 standards within 11 categories Foundation: 1. CMS hospital CoPs 2. NCP Guidelines
Community-Based Palliative Care				
ACHC (2017) https://www.achc.org/achc-distinctions.html	Distinction in Palliative Care	Valid for 3 years. Organization must have prior ACHC Home Health, Hospice, or Private Duty accreditation. This may include home health agencies, hospices, clinics, group practices, and the like.		

(*continued*)

TABLE 43.2

Program Specialty Palliative Care Designation (*continued*)

Organization/Year Initiated	Designation	Length/Eligibility	Requirements	Survey Criteria
TJC (2011)	Community-Based Palliative Care (CBPC) Certification	Valid for 3 years. Organization must be TJC-certified. Patients may live at home, in a skilled facility, in assisted living, or another domiciliary setting receiving services under the home health or hospice benefit.	Provide the full range of palliative care services to patients 24 hours/day, 7 days/week. Programs must commit to long-term evaluation of process and clinical measurement.	48 standards within eight categories Foundation: 1. TJC prior accreditation 2. NCP Guidelines
CHAP (2019) https://education.chaplinq.org/chap-standards-of-excellence	Palliative Care Certification	Valid for 3 years. No prior certification. Any organization (home health agency, hospice, assisted living, skilled nursing facility, physician/clinician practice. palliative care program in the home, clinic/office, long-term care setting) can apply based on their ability to meet the standards.	Focus is on delivery of services, rather than a particular organization. If program CHAP accredited for home health, or private duty, they do not have to re-create the QI process.	56 standards within 86 categories Foundation: 1. NCP Guidelines

ACHC, Accreditation Commission for Health Care; CHAP, Community Health Accreditation Partner; CMS, Centers for Medicare & Medicaid Services; CoP, conditions of participation; NCP, National Consensus Project for Quality Palliative Care; TJC, The Joint Commission.

Lastly, to promote quality, there have been various initiatives to assure quality palliative care education for all disciplines. Within nursing, the American Nurses Association and the HPNA released *A Call for Action: Nurses Lead and Transform Palliative Care*, which stated that all nurses should receive End-of-Life Nursing Education Consortium (ELNEC) training (ANA & HPNA, 2017). To accomplish this, competencies for nurses to achieve in both undergraduate and graduate nurses education have been established. There was a major revision to the nursing end-of-life competencies to reflect serious illness care. In 2016, Competencies and Recommendations for Educating Undergraduate Nursing Students was developed to be integrated into undergraduate nursing programs (AACN, 2016). In 2019, Graduate Competencies and Recommendations for Educating Nursing Students was developed to be integrated into graduate nursing programs at the master's and doctorate levels (AACN, 2019).

OUTCOMES

Over the past 15 years, research has demonstrated the quality of palliative care (Evans, Ison, & Ellis-Smith, 2019). For years, many hospice and palliative providers have intuitively known that they promoted quality of life. However, there were no studies to support these claims. The seminal studies to demonstrate the positive aspects of palliative care, specifically quality of life and survival in patients with the involvement of palliative care, occurred between 2009 and 2010 (Bakitas et al., 2009; Temel et al., 2010). Other studies in patients with noncancer diagnoses in outpatient settings have also demonstrated more comprehensive care, higher satisfaction rates, and deaths at home (Brumley et al., 2007; Rabow, Hauser, & Adams, 2004; Rabow, Schanche, Petersen, Dibble, & McPhee, 2003). More recent studies have demonstrated cost savings and better care for patients, across age groups, site of care, and diseases (Cassel, Kerr, Kalman, & Smith, 2016, May, Garrido, Aldridge, et al. 2017; May, Garrido, Cassel et al., 2017).

MODELS ACROSS HEALTHCARE VENUES

As the definition of palliative care has broadened to patients with serious illness, the potential to affect a range of populations is apparent. The NCP *Clinical Practice Guidelines* describe how a serious or life-threatening illness is assumed to encompass populations of patients at all ages within the broad range of diagnostic categories, living with a persistent or recurring medical condition that adversely affects their daily functioning or will predictably reduce life expectancy. Moreover, palliative care crosses all settings. In the

community, patients may live in a residence, a group home or shelter, or in long-term care settings such as a skilled facility, assisted living facility, continuing care retirement community, or chronic care facility. They may receive care from office-based practices such as palliative care clinics or disease-specific clinics, outpatient practices, or the like. In the hospital, there may be practices in rural, community, and urban hospitals as well as academic medical centers.

Palliative care focuses on expert assessment and management of physical and psychological symptoms, assessment of caregiver needs, and support and coordination of care. Hence, it is appropriate at any time of a serious illness, provided in an interdisciplinary manner over time, and offered across settings in a manner consistent with goals of the patient (NCP, 2018). As a model, palliative care has several tenets set forth by the NCP (Box 43.2). Both clinical and service delivery models have been identified (Luckett et al., 2014). Clinically, they range from case management to liaison, integrated care, and consultative models. Service delivery ranges from clinical networks to managed care networks, and collaboration among community providers (Luckett et al., 2014). Service delivery models have complex considerations and financial implications and are beyond the scope of this chapter. Clinical models range from models in the hospital, home, office, and long-term care setting and are discussed as follows.

Every palliative model provides comprehensive assessment in all domains (physical, spiritual, emotional, and social) related to quality of life. There is simultaneous evaluation and reevaluation of initiation of interventions to manage any of these aspects of care (Partridge et al., 2014). Specifically, palliative care addresses pain and symptoms, psychosocial distress, quality of life, and care preferences. This may look different depending on the diagnosis (American Colleges of Surgeons, 2012; Braun et al., 2016; Ferrell et al., 2017; Holloway et al., 2014; Smith et al., 2012). The National Comprehensive Cancer Network suggests the following criteria for palliative care: (a) uncontrolled symptoms, (b) moderate to severe distress related to diagnosis and treatment, (c) serious comorbid physical and psychosocial conditions, (d) life expectancy less than 6 months, and (e) patient concerns about the course of disease and/or his or her treatment options, including when these are expressed by the family (Levy et al., 2014; National Comprehensive Cancer Network, 2012).

Palliative care is an essential aspect of healthcare, and it occurs across a variety of settings. The venue will determine the model of care and the financial aspects of program development. Venues can be based on a health system, a hospital, an office, a long-term care setting, a hospice organization, a home health agency, and in the community. With all the models, there is the overarching principle of giving the right care, to the right patients, in the right settings.

BOX 43.2

Tenets of Palliative Care

1. Palliative care is patient- and family-centered care.
2. There is comprehensive palliative care with continuity across health settings.
3. Early introduction of primary palliative care concepts should begin at diagnosis of a serious or life-threatening illness by the primary team.
4. The goal of palliative care is the relief of physical, psychological, emotional, and spiritual suffering of patients and families. If provided early, it allows patients to achieve quality of life while living with serious illness.
5. Palliative care may be offered concurrent with or independent of curative or life-prolonging care. Patient and family hopes for quality of life are supported throughout the course of illness. At advanced illness and end of life, peace and dignity are preserved during the dying process, and after death.
6. Palliative care team members have clinical and communication expertise achieved through education, training, and specialty palliative care certification.
7. Palliative care is interdisciplinary and collaborative. Communication between patients, families, palliative care specialists, and other healthcare providers is essential to provide patient-centered care and assure quality throughout care transitions.
8. Equitable access to quality requires a commitment to building primary palliative care skills across all disciplines and settings as well as building the interdisciplinary workforce of specialty palliative care providers.

Source: Adapted from the National Consensus Project for Quality Palliative Care. (2013). *Clinical practice guidelines for quality palliative care* (3rd ed.). Pittsburgh, PA: Author; National Consensus Project for Quality Palliative Care. (2018). *Clinical practice guidelines for quality palliative care* (4th ed.). Richmond, VA: National Hospice and Palliative Care Coalition.

Although hospice is considered the gold standard of care, it is a subset of palliative care. First of all, it focuses on end-of-life care as a result of the eligibility requirements of a prognosis of 6 months or less without curative measures. Patients must sign onto the benefit. Patients can receive care in the home, nursing home, hospice unit, or residential setting with different levels of intensity depending on the pain and symptom management. Palliative care programs can vary because there are no restrictions of prognosis, treatment direction, election of benefit, or necessity of specific interventions (Table 43.3).

TABLE 43.3

Palliative Care Models

Model	Payment Structure	Clinical Responsibility	Team Composition	Referral/Duration/Limitation
Hospital-Based Palliative Care				
Hospital-based (academic medical center, community hospital, rural hospital, critical or essential access hospital)	Medicare B Medicaid Commercial	Consultative, comanagement, or primary care role	Medicine, nursing, social work, and chaplaincy	■ By referral of primary attending (APRN, DO, MD, PA), other disciplines, or self-referral ■ Length of hospital stay ■ May not cross to other settings
Community-Based Palliative Care				
Office-based (independent clinic, outpatient clinic, ambulatory clinic)	Medicare B Medicaid Commercial	Consultative, comanagement, or primary care role	Medicine, nursing, social work, and chaplaincy	■ By referral of primary attending provider (APRN, DO, MD, PA), other disciplines, or self-referral ■ Duration of disease/condition ■ May move easily cross-settings
Home-based (home, rest home, group home, senior housing, shelter)	Medicare B Medicaid Commercial	Comanagement or primary care role	Medicine and nursing	■ By referral of primary attending (APRN, DO, MD, PA), other disciplines, service organizations, or self-referral ■ Duration of disease/condition ■ Center of care coordination
Palliative Care in Long-Term Care Settings				
Skilled nursing facility (skilled facility, long-term acute care, nursing home)	Medicare B Medicaid Commercial	Consultative comanagement	Medicine and nursing	■ By referral of primary attending (APRN, DO, MD, PA), other disciplines, service organizations, or self-referral ■ Duration of disease/condition ■ Center of care coordination
Assisted living facility	Medicare B Medicaid Commercial	Comanagement and/or primary care role	Medicine and nursing	■ By referral of primary attending (APRN, DO, MD, PA), other disciplines, service organizations, or self-referral ■ Duration of disease/condition ■ Center of care coordination

APRN, advanced practice registered nurse; DO, doctor of osteopathy; MD, medical doctor; PA, physician assistant.

There are positive and negative aspects to various hospice and palliative care models (Wiencek & Coyne, 2014). Hospital-based models are the most defined. Indeed, over the past 15 years, the focus has been on inpatient palliative care. These are inpatient consultative services that consist of an interdisciplinary team. They vary in resources and acuity by academic medical center, community hospital, rural hospital, and critical or essential access hospital. These programs must have interdisciplinary teams; in particular, a team for each of the core service disciplines. These programs may be led by any one of the team members, but are often led by physicians or APRNs.

There can be a range of clinical responsibilities after consultation. This includes consultation only in which recommendations of pharmacological and nonpharmacological interventions are offered; comanagement of a specific pain or symptom in which the team writes orders and prescriptions; assuming the role of a primary care provider responsible for all the care, not just the serious diagnosis; or a mix of all clinical responsibilities. Currently, the most common financial structure is based on billing and reimbursement through Medicare, Medicaid, and other commercial payers, as well as hospital support. However, within healthcare reform, there may be alternative payment models that pay either per-member-per-month or by incentives of care delivered. The palliative care team may see a range of patients all over a hospital, or have specific beds or even a unit.

Hospital-based palliative care models are often the easiest to implement as they usually build off of current hospital structures. They are, by nature, crisis-oriented and close to 24/7 access. They demand, however, the

collaboration of an interdisciplinary team, which may or may not be under the auspices of a palliative care department. The benefits may be lower costs, earlier discharge, higher satisfaction, and better pain management (Casarett et al., 2008, Cassel et al., 2016).

Office-based palliative care may offer more continuity to longer-term issues. Models include outpatient or ambulatory care clinics as well as independent clinics in the community or clinics run by a hospice, home health agency, or a collaborative effort. These practices may be imbedded in another specialty clinic such as oncology, heart failure, amyotrophic lateral sclerosis, liver failure, kidney failure, or gerontology. There are also stand-alone or free-standing palliative care clinics. The nature of these programs is care over a longer period of time with care coordination. The focus is on continuity and relationship building to promote and avoid both emergency visits and hospitalizations. Clinical responsibility of the palliative care team is most often comanagement of pain and symptoms as well as assuming primary care roles or a mix of comanagement and primary care. To be considered as a specialty palliative care service, the clinics must be either interdisciplinary or multidisciplinary teams depending on the structure. Very often, however, office-based practices lack the full scope of an interdisciplinary team, delineating them more as a palliative provider than interdisciplinary.

Many office-based programs developed from hospital teams. However, many are growing in the community that are separate from hospital teams. Office-based models necessitate different resources depending on the type of practice and ownership—outpatient clinic as part of a hospital, ambulatory clinic as part of a health system, or independent clinic as part of a hospice or palliative care provider. Resources depend on the financial structure of the clinic, in particular whether it is hospital or system-owned, independent, or supported philanthropically. Often, the primary providers are physicians and advanced practice providers because their visits are reimbursable under Medicare, Medicaid, and commercial insurance. The benefits of palliative care are reduction in emergency department admissions, hospital admissions, and better patient satisfaction (Bakitas et al., 2009; Brumley et al., 2007; Cassel et al., 2016; Kerr & Cassel 2014; May, Garrido, Aldridge, et al., 2017; May, Garrido, Cassel, et al, 2017; Temel et al., 2010).

Home-based palliative care models are growing. The focus is coordinating care from service agencies and delivering clinical care in the home. These programs work well for geriatric patients who have avoided the clinic or hospital for any care, but also for patients who are too sick to travel to appointments. It is essential for these programs to coordinate with service agencies such as Councils on Aging, Meals on Wheels, Parish Nurses, and so on. Some programs have clinicians who visit patients whom they have seen in the hospital. Other programs enroll patients from the community who lack primary care providers. Clinical responsibility is most often held by primary providers, although there may be comanagement of pain and symptoms as well. These teams are multidisciplinary in nature, depending on workforce availability and financial structure. Reimbursement occurs through Medicare, Medicaid, and commercial payers.

There is wide variability in home-based models differentiated by structure and services. Their benefit is keeping people in their homes and community. However, because of reimbursement and revenue streams, home-based models may not encompass a full interdisciplinary team. In addition, depending on the geography of the area covered, there may be issues in the number of patients seen or financial implications of transportation. However, there is research to suggest that home-based palliative care decreases healthcare costs, reduces 30-day hospital readmission rates, and increases patient satisfaction (Brumley et al., 2007; Cassel et al., 2016; Enguidanos, Vesper, & Lorenz, 2012; Kerr & Cassel, 2014).

Palliative care in the long-term care setting is less developed and not well-delineated (Ersek & Carpenter, 2013). Broadly, it includes consultation to patients in the skilled nursing facility, assisted living facility, nursing home, or chronic and acute rehabilitation settings. Although there is research about pain and symptom management for this population as well as advance care planning, there are few commentaries on models (Ersek & Carpenter, 2013). It has been suggested that outside of hospice, there are two models—external consultative teams and internal consultative teams (Ersek & Stevenson, 2013). Either model includes a variety of interdisciplinary team members to provide consultation to these complex populations. However, palliative care initiatives in nursing homes are beset with the challenges of high staff turnover, staff shortages of qualified individuals, regulatory requirements, reimbursement, and various health policies (Strumpf, Tuch, Stillman, Parrish, & Morrison, 2004).

Within a health system, such as an accountable care organization (ACO) or Patient-Centered Medical Home (PCMH), care is focused on keeping the patient out of the hospital. This palliative care model focuses on primary palliative care in which there is a strong communication and care coordination across the system. In particular, there is a major presence of nurse case management with a focus on advance care planning. There is constant assessment of the

TABLE 43.4

Current Palliative Care Delivery Under Medicare and Medicaid Hospice and Home Health Benefits

Hospice	Medicare A—Hospice Benefit Medicaid Hospice Benefit varies by state	Mostly primary care role	Mandated by conditions of participation Medicine, nursing, social work, and chaplaincy	Limited by 6-month eligibility
Hospice Benefit–based palliative care	Medicare A—limited palliative care under the Hospice Benefit Medicaid—may be included in Hospice Benefit	Consultative or comanagement	Physician and/or APRN	Medicare Hospice Benefit allows three visits
Home Health Benefit–based palliative care	Medicare B—under home care Medicaid—may be included in Home Health Benefit	Consultative or comanagement	Nurse	Must be homebound, defined as leaving the home is difficult

APRN, advanced practice registered nurse.

needs of the patient and the right services. Here, quality care for patients with serious illness may include hospital-, office-, and home-based palliative care. However, the model for palliative care will emanate from primary care practices.

Finally, there are palliative care models that occur broadly under Medicare programs such as under the Hospice or Home Health Benefit (Table 43.4). However, there are limitations because of Medicare regulations. First, under the Medicare Hospice or Home Health Benefit, palliative care may lack interdisciplinary care because nurses most often provide the care alone. Palliative care under the Medicare Hospice Benefit is time-limited to only a few consultation visits. Palliative care under Home Health is limited by the necessity that the patient qualify for homebound status. Moreover, hospices and home health agencies must attend to antitrust issues. Therefore, palliative care programs under Hospice and Home Health Benefits are restricted in their breadth and scope.

CASE STUDY 43.1

Sophie Jones, ACNOPC-BC, ACHPN, is a palliative nurse practitioner who works in a healthcare system that has a hospital, a clinic, and a home-based program. She performs palliative care consultations for patients with serious illness in a community palliative care clinic 3 days a week. She then sees patients in the home 2 days a week. She receives referrals from all eligible licensed professionals (physicians, physician assistants, nurse practitioners, and clinical nurse specialists).

As part of her evaluation, she initiates advance care planning by eliciting a patient's and family's goals of care, and, if they are ready, complete the appropriate paper work, including the delegation of a surrogate decision-maker, advance directive/living will, and out-of-hospital orders for life-sustaining treatment (commonly known as Provider/Physician/Medical Orders for Life-Sustaining Treatment or POLST/MOLST forms). Sophie performs the Edmonton Symptom Assessment System on each patient to determine his or her symptoms and distress. She orders diagnostics as necessary to create a differential diagnosis. In order to implement a care plan, she collaborates with the patient's primary care providers. As part of her comanagement role, she writes orders and prescriptions for pain and symptom management when she makes recommendations and develops a palliative care plan. She records consultation documentation for new patients as well as follow-ups in the electronic health record (EHR).

Her clinical responsibilities include both a consultative role in the clinic, when she collaborates with other providers, and a primary care role in the home, when she assumes responsibility for the patient. She offers 24/7 coverage during the week. On the weekends, the covering provider for primary care covers both her clinic patients and her home patients.

She bills for her services under Medicare Part B professional billing for a palliative care encounter, as well as symptoms, and a primary diagnosis. She also bills for advance care planning (ACP). There are occasions in which she visits a hospitalized patient to provide continuity in terms of goals of care. The health system tracks her visits and her patient satisfaction scores are the highest in the system. Her patient satisfaction scores demonstrate better quality of life and better communication with her care plan. Her symptom

(*continued*)

CASE STUDY 43.1 (*continued*)

assessment data demonstrates that on average her patients' symptoms are managed within 48 hours.

She is able to recoup 40% of her salary in billing and reimbursement. Additionally, her care offers the ACO savings of around US$400,000 per year. This is achieved by her ability to prevent 30-day readmission hospitalizations and emergency department visits as well as prevent transfers to the intensive care unit for her patients. She is also able to promote earlier admissions to hospice and assure goal concordant care consistent with the patients' wishes.

SUMMARY

Palliative care is an important model of care. It promotes quality patient- and family-centered care that incorporates patient and family values and preferences of care in the settings where patients and families prefer to receive care. As healthcare reform continues, palliative care is essential in promoting patient-centered and family-focused care in accordance with patient preferences. Palliative care promulgates the foundational principle of healthcare by advocating for the four Rs—the right care, for the right patient, at the right time, in the right place. It has been demonstrated that palliative care increases patients' quality of life, satisfaction, improves pain and symptom management, and reduces cost of care. Although no one model of palliative care fits every setting, palliative care is being established for all ages in all types of hospitals (i.e., rural and community, not just urban or academic medical centers), offices (i.e., specialty adult or pediatric palliative care clinics or embedded in other specialties such as geriatrics, oncology, heart failure, pulmonology, or neurology), the home (i.e., the residence where the patient lives), and in long-term care settings. Nurses have a prominent role in all palliative care models as the largest segment of healthcare providers who are most often at the forefront of clinical care. There are many opportunities for developing competencies and skills in serious illness care. They can also demonstrate their skills through certification. Nurses must implement new initiatives, which build their skills, education, and training to practice to the full extent of their scope of practice (IOM, 2011). They have the capacity to lead and transform care in serious illness and beyond with creating new models. In this way, nurses will assure access to quality palliative care.

APPENDIX 43.1

Mapping the National Consensus Project Domains and the National Quality Forum Preferred Practices

2018 NCP Domains	2006 NQF Preferred Practices
Domain 1—Structure and Processes of Care	Preferred Practice 1 ■ Provide palliative and hospice care by an interdisciplinary team of skilled palliative care professionals, including physicians, nurses, social workers, pharmacists, spiritual care counselors, and others who collaborate with primary healthcare professional(s). Preferred Practice 2 ■ Provide access to palliative and hospice care that is responsive to the patient and family 24 hours a day, 7 days a week. Preferred Practice 3 ■ Provide continuing education to all healthcare professionals on the domains of palliative care and hospice care. Preferred Practice 4 ■ Provide adequate training and clinical support to assure that professional staff are confident in their ability to provide palliative care for patients. Preferred Practice 5 ■ Hospice care and specialized palliative care professionals should be appropriately trained, credentialed, and/or certified in their area of expertise. Preferred Practice 6 ■ Formulate, utilize, and regularly review a timely care plan based on a comprehensive interdisciplinary assessment of the values, preferences, goals, and needs of the patient and family and, to the extent that existing privacy laws permit, ensure that the plan is broadly disseminated, both internally and externally, to all professionals involved in the patient's care. Preferred Practice 7 ■ Ensure that on transfer between healthcare settings, there is timely and thorough communication of the patient's goals, preferences, values, and clinical information so that continuity of care and seamless follow-up are assured. Preferred Practice 8 ■ Healthcare professionals should present hospice as an option to all patients and families when death within a year would not be surprising, and reintroduce the hospice option as the patient declines. Preferred Practice 9 ■ Patients and caregivers should be asked by palliative and hospice care programs to assess physicians' or healthcare professionals' ability to discuss hospice as an option. Preferred Practice 10 ■ Enable patients to make informed decisions about their care by educating them on the process of their disease, prognosis, and the benefits and burdens of potential interventions. Preferred Practice 11 ■ Provide education and support to families and unlicensed caregivers based on the patient's individualized care plan to assure safe and appropriate care for the patient.
Domain 2—Physical Aspects of Care	Preferred Practice 12 ■ Measure and document pain, dyspnea, constipation, and other symptoms using available standardized scales. Preferred Practice 13 ■ Assess and manage symptoms and side effects in a timely, safe, and effective manner to a level acceptable to the patient and family.

(*continued*)

APPENDIX 43.1

Mapping the National Consensus Project Domains and the National Quality Forum Preferred Practices (*continued*)

2018 NCP Domains	2006 NQF Preferred Practices
Domain 3—Psychological and Psychiatric Aspects of Care	Preferred Practice 14 ■ Measure and document anxiety, depression, delirium, behavioral disturbances, and other common psychological symptoms using available standardized scales. Preferred Practice 15 ■ Manage anxiety, depression, delirium, behavioral disturbances, and other common psychological symptoms in a timely, safe, and effective manner to a level acceptable to the patient and family. Preferred Practice 16 ■ Assess and manage psychological reactions of patients and families to address emotional and functional impairment and loss, including stress, anticipatory grief, and coping, in a regular ongoing fashion. Preferred Practice 17 ■ Develop and offer a grief and bereavement care plan to provide services to patients and families before and for at least 13 months after the death of the patient.
Domain 4—Social Aspects of Care	Preferred Practice 18 ■ Conduct regular patient and family care conferences with physicians and other appropriate members of the interdisciplinary team to provide information; discuss goals of care, disease prognosis, and advance care planning; and offer support. Preferred Practice 19 ■ Develop and implement a comprehensive social care plan, which addresses the social, practical, and legal needs of the patient and caregivers, including but not limited to relationships, communication, existing social and cultural networks, decision-making, work and school settings, finances, sexuality/intimacy, caregiver availability/stress, and access to medicines and equipment.
Domain 5—Spiritual, Religious, and Existential Aspects of Care	Preferred Practice 20 ■ Develop and document a plan based on assessment of religious, spiritual, and existential concerns using a structured instrument and integrate the information obtained from the assessment into the palliative care plan. Preferred Practice 21 ■ Provide information about the availability of spiritual care services and make spiritual care available either through organizational spiritual counseling or through the patient's own clergy relationships. Preferred Practice 22 ■ Specialized palliative and hospice care teams should include spiritual care professionals appropriately trained and certified in palliative care. Preferred Practice 23 ■ Specialized palliative and hospice spiritual care professionals should build partnerships with community clergy and provide education and counseling related to end-of-life care.
Domain 6—Cultural Aspects of Care	Preferred Practice 24 ■ Incorporate cultural assessment as a component of comprehensive palliative and hospice care assessment, including, but not limited to, locus of decision-making, preferences regarding disclosure of information, truth-telling and decision-making, dietary preferences, language, family communication, desire for support measures such as palliative therapies and complementary and alternative medicine, perspectives on death, suffering and grieving, and funeral/burial rituals. Preferred Practice 25 ■ Provide professional interpreter services and culturally sensitive materials in the patient's and family's preferred language.

(*continued*)

APPENDIX 43.1

Mapping the National Consensus Project Domains and the National Quality Forum Preferred Practices (*continued*)

2018 NCP Domains	2006 NQF Preferred Practices
Domain 7—Care of Patient Nearing the End of Life	Preferred Practice 26 ■ Recognize and document the transition to the active dying phase and communicate to the patient, family, and staff the expectation of imminent death. Preferred Practice 27 ■ The family is educated on a timely basis regarding the signs and symptoms of imminent death in a developmentally, age-, and culturally appropriate manner. Preferred Practice 28 ■ As part of the ongoing care-planning process, routinely ascertain and document patient and family wishes about the care setting for site of death and fulfill patient and family preferences when possible. Preferred Practice 29 ■ Provide adequate dosage of analgesics and sedatives as appropriate to achieve patient comfort during the active dying phase and address concerns and fears about using narcotics and using analgesics to hasten death. Preferred Practice 30 ■ After death, treat the body with respect according to the cultural and religious practices of the family and in accordance with local law. Preferred Practice 31 ■ Facilitate effective grieving by implementing a bereavement care plan in a timely manner after the patient's death when the family remains the focus of care.
Domain 8—Ethical and Legal Aspects of Care	Preferred Practice 32 ■ Document the designated surrogate/decision-maker in accordance with state law for every patient in primary, acute, and long-term care and in palliative and hospice care. Preferred Practice 33 ■ Document the patient/surrogate preferences for goals of care, treatment options, and setting of care at first assessment and at frequent intervals as conditions change. Preferred Practice 34 ■ Convert the patient treatment goals into medical orders and ensure that the information is transferable and applicable across care settings, including long-term care, emergency medical services, and hospitals, such as the Physician Orders for Life-Sustaining Treatments (POLST) Program. Preferred Practice 35 ■ Make advance directives and surrogacy designations *available* across care settings, while protecting patient privacy and adherence to Health Insurance Portability and Accountability Act (HIPAA) regulations, for example, by Internet-based registries or electronic personal health records. Preferred Practice 36 ■ Develop healthcare and community collaborations to promote advance care planning and completion of advance directives for all individuals, for example, Respecting Choices, Community Conversations on Compassionate Care. Preferred Practice 37 ■ Establish or have access to ethics committees or ethics consultation across care settings to address ethical conflicts at the end of life. Preferred Practice 38 ■ For minors with decision-making capacity, document the child's views and preferences for medical care, including assent for treatment, and give appropriate weight in decision-making. Make appropriate professional staff members available to both the child and the adult decision-maker for consultation and intervention when the child's wishes differ from those of the adult decision-maker.

Care of the Older Adult in the Emergency Department*

Rachel Arendacs and Marie Boltz

44

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify evidence-based approaches and tools to assess the older adult in the ED.
2. Describe interventions to prevent and manage geriatric syndromes in the ED.
3. Discuss approaches to support effective transitions from the ED.

OVERVIEW

Older adults aged 65 years and older use more ED services than any other age group, comprising approximately 21% to 40% of all consumers who use the ED (Niska, Bhuiya, & Xu, 2010). One in five patients aged 65 to 74 years and one in four patients aged 75 years and older visit the ED each year; the percentage of ED visits made by nursing home (NH) residents, patients arriving by ambulance, and patients admitted to the hospital increases with age (Albert, McCaig, & Ashman, 2013). Approximately 42% of ED visits of patients 65 years and older result in hospitalization. ED use increased 25% for adults aged 65 and older from 2001 to 2009, outpacing the 21% population growth in older adults in general (Pines, Mullins, Cooper, Feng, & Roth, 2013).

The ED plays a critical role in the healthcare system for older adults, acknowledged by the American College of Emergency Physicians which has developed a geriatric ED accreditation process. The recommended interventions include geriatric-friendly equipment, geriatric-specialized staff, and more routine screenings for geriatric vulnerabilities (Huff, 2018). The most common role of the ED is related to its position in the crossroads of inpatient and outpatient care (Carpenter & Platts-Mills, 2013; Lutz et al., 2017). The higher prevalence of chronic disease and exacerbations of these conditions is one reason for high utilization of ED (McCelland & Sorrell, 2015; Perry, Macias, & Melady, 2018). In other cases, older adults transition from the ED to other settings such as long-term care or mental health facilities. Finally, others receive care for crises such as mistreatment or displacement. The ED may be used for the performance of complex diagnostic workups, overflow, and off-hours medical care; for some older adults, the ED is the only source of healthcare evaluation and treatment (Gonzalez Morganti et al., 2013; Stefanacci & Riddle, 2018). This chapter describes the evidence-based approaches to assessing the older adult presenting to the ED, as well as interventions to prevent and manage common geriatric syndromes that occur before or during the

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

ED admission. Transitions from the ED and organizational approaches to senior-friendly ED care are also discussed.

BACKGROUND AND STATEMENT OF PROBLEM

Older adults present to the ED with serious complaints such as injury, dyspnea, chest pain, and abdominal pain, as well as nonspecific complaints associated with atypical presentation, including weakness, fatigue, and dizziness, which may indicate serious disease (Theou, Campbell, Malone, & Rockwood, 2018). When compared to younger people, older adults have more diagnostic tests, longer stays in the ED, and are more likely to be admitted to the hospital (Banerjee, Dehnadi, & Mbamalu, 2011; Kreindler, Cui, Metge, & Raynard, 2015). Those older adults who are discharged from the ED are more likely to be readmitted; they also risk functional loss and higher rates of mortality (McCusker et al., 2007; Niska et al., 2010; Sklar et al., 2007).

Although they represent a cohort of frequent ED users, it has been argued that older adults typically do not receive specialized care. When compared to younger persons, older adults are more likely to experience missed or incorrect diagnoses (Theou et al., 2018), inadequate pain management (Hwang, Richardson, Harris, & Morrison, 2010; Iyer, 2011), and less information (Boltz, Parke, Shuluk, Capezuti, & Galvin, 2013; George, Jell, & Todd, 2006). There is international consensus that care of older adults in the ED warrants close attention and systemic approaches that support uptake of evidence-based care (Gruneir, Silver, & Rochon, 2011; Hwang et al., 2013; Parke & McCusker, 2008).

ASSESSMENT OF THE OLDER ADULT IN THE ED

The complex presentation of disease and illness in older adults, along with complicated polypharmacy, functional impairment (Schnitker, Martin-Khan, Beattie, & Gray, 2011; Wilber, Blanda, & Gerson, 2006), communication problems, and cognitive impairment (Press et al., 2009; Salvi et al., 2007), presents a challenge to the ED nurse. Therefore, assessment of older adults encompasses a comprehensive evaluation to detect critical health issues hidden within a complex clinical and social presentation. Whenever possible, and with the permission of the older adult, the emergency nurse should include the patient's significant other, family, and support person in the assessment process (Boltz et al., 2013). The three major components of assessment are triage, risk assessment to prevent adverse outcomes, and general assessment.

Triage/Primary Assessment

Accurate triage of elder patients is a key component of providing effective emergency care for this vulnerable population. The large number of ED visits by older adults, the growing problem of ED crowding, and the longer time it takes to evaluate older adults often result in delays at the point of triage (Brouns et al., 2015; Platts-Mills et al., 2010). Delays in triage are associated with increased waiting time, anxiety, and discomfort for older adults (Miró et al., 1999). Moreover, the resulting delay in treatment increases the risk for mortality, especially in older trauma patients (Perdue, Watts, Kaufmann, & Trask, 1998). Thus, there is a need for triage that promotes timely treatment.

The three widely used emergency patient triage methods are the Canadian Triage and Acuity Scale (CTAS), the Emergency Severity Index (ESI), and the Manchester Triage System (MTS). The performance of the MTS appears inferior in older patients than younger patients, illustrated by a worse predictive ability of the MTS for in-hospital mortality in older patients (Brouns et al., 2015). The ESI includes a comprehensive algorithm that describes symptoms, physiological indicators, and the resources anticipated to be used (Gilboy, Tanabe, Travers, & Rosenau, 2012). However, there has been reported under-triage in older adults when the ESI guidelines are not precisely followed (Platts-Mills et al., 2010). The CTAS has demonstrated high validity for older adults and it is an especially useful tool for categorizing severity and for recognizing older adults who require immediate life-saving intervention (Bullard, Unger, Spence, & Grafstein, 2008; Lee et al., 2011). See Table 44.1 for the CTAS levels and associated descriptions, examples of conditions, and recommended time to be seen by a physician in an ED.

Airway–Breathing–Circulation

The goal of the primary assessment is to identify and immediately treat the patient for all life-threatening conditions, incorporating prearrival information from emergency medical services (EMSs). During the assessment of *airway* patency, the emergency clinician considers the physiological changes with age that may alter patency of the airway. Dentures can occlude the airway if dislodged; additionally, dentures can cause difficulty with bag-valve mask ventilation of the airway. Kyphosis and other changes in spinal alignment may cause alterations in positioning of a cervical collar or spinal backboard, which may inhibit appropriate airway patency. Cervical rigidity may present challenges to establishing a definitive airway (Aresco & Stein, 2010). The quality of *breathing* and ventilation is evaluated. While

TABLE 44.1

Canadian Triage and Acuity Scale (CTAS) Used in an ED

Evidence Level	Description: Conditions That	Examples	Time to Be Seen by a Physician
1. Resuscitation	Pose threats to life or limb (or imminent risk for deterioration), requiring immediate aggressive interventions	Cardiac/respiratory arrest, major trauma, shock states, unconscious patients, severe respiratory distress, severe dehydration	Immediately 98% of the time
2. Emergent	Pose potential threat to life, limb, or function, requiring rapid medical intervention or delegated acts	Altered mental states, head injury, severe trauma, MI, overdose, and CVA	Less than or equal to 15 minutes 95% of the time
3. Urgent	Could potentially progress to a serious problem requiring emergency intervention. May be associated with significant discomfort or affect ability to function at work or activities of daily living.	Moderate trauma, asthma, GI bleeds, acute psychosis and/or suicidal thoughts, and acute pain	Less than or equal to 30 minutes 90% of the time
4. Less urgent/ semi-urgent	Are related to patient age, distress, or potential for deterioration or complications that would benefit from intervention or reassurance within 1–2 hours	Headache, corneal foreign body, and chronic back pain	Less than or equal to 1 hour 85% of the time
5. Nonurgent	May be acute but nonurgent as well as conditions that may be part of a chronic problem with or without evidence of deterioration	Sore throat, URI, mild abdominal pain (chronic or recurring), with normal vital signs, vomiting alone, and diarrhea alone	120 minutes 80% of the time

CVA, cerebrovascular accident; GI, gastrointestinal; MI, myocardial infarction; URI, upper respiratory infection.

assessing the volume of lung expansion and effectiveness of breathing, it is important to consider that pulmonary vascular tissue and parenchyma tissue may become stiff and cause decreased compliance as well as an increase in pulmonary vascular resistance. Lung capacity is diminished by alveolar changes in depth and width. Older adults are at risk for decreased respiratory reserve and arterial blood oxygenation, which can lead to decompensation sooner than their younger counterparts (Blumenthal, Plummer, & Gambert, 2010). Assessment of *circulation* may also be affected by physiological changes with increased age. Patients with cardiac history may be consuming antihypertensive medications or rate-control medications that may inhibit or alter the physiological responses. Additionally, hypertension in the patient may mask the signs of a lowered blood pressure caused by hypovolemic shock (Criddle, 2013).

Patients older than age 65 years are more likely to present with dysrhythmias. During the assessment phase, other causes of abnormal cardiac function should be evaluated, such as electrolyte imbalances, hypoxia, cardiac injury, or hypovolemia (McQuillan, Makic, & Whalen, 2009). Vague and, in some cases, nondramatic presentations indicate serious, life-threatening problems in older adults. Box 44.1 shows the common atypical presentation of geriatric emergencies. Additionally, "red flags" during triage that should be evaluated closely include acute change in mental status and/or physical function, dyspnea, fatigue, self-neglect, apathy, and falls (Gabayan et al., 2016).

Screening for Risk for Adverse Outcomes

Two commonly used tools, the Identification of Seniors at Risk (ISAR) and the Triage Risk Screening Tool (TRST), evaluate the presence or absence of risk factors for adverse outcomes. These tools are useful in guiding a plan to prevent avoidable complications during the ED stay, if admitted during hospitalization, and after an ED visit, when transitioning to home or another setting. The TRST (Box 44.2) is considered positive when an older adult has cognitive impairment or has two or more of the remaining risk factors and the screening has been found to be predictive of subsequent ED use, hospitalization, and NH admission (Meldon et al., 2003). The ISAR tool (Box 44.3) is positive when the score is greater than or equal to 2 and is a predictor of increased risk for death, institutionalization, functional decline, and both repeat ED visit and hospital admission in the following 6 months after an ED visit (McCusker et al., 1999). ISAR or TRST is administered

BOX 44.1

Atypical Presentation of Common Geriatric Emergencies

- Acute abdomen with constipation and decreased appetite, rather than severe pain
- Pneumonia with vague chest pain and dry cough, rather than fever
- Depression with agitation, rather than dysphoria
- Infection with falls, rather than fever or elevated white count
- Sepsis with functional decline and generalized weakness, rather than fever
- Myocardial infarction with dyspnea and confusion, rather than chest pain
- Heart failure with fatigue, rather than dyspnea

A brief risk-stratification tool to predict repeat emergency department visits and hospitalizations in older patients discharged from the emergency department. *Academic Emergency Medicine, 10*(3), 224–232. doi:10.1197/aemj.10.3.224. *Evidence Level IV.*

by a nurse just after triage, to identify high-risk patients more likely to benefit from a comprehensive geriatric evaluation and follow-up, a longer observation time (or access to observation units), and appropriate referrals (primary physician, geriatric evaluation and management unit, and/or social service). Furthermore, all patients noted to be at risk who are admitted to the hospital are referred to case management; those who are discharged from the hospital can be followed up the following day, either through a home visit or telephone consultation (Salvi et al., 2012).

BOX 44.3

Identification of Seniors at Risk Tool

- Before the injury or illness, did you need someone to help you on a regular basis?
- Since the injury or illness, have you needed more help than usual?
- Have you been hospitalized for one or more nights in the past 6 months?
- In general, do you see well?
- In general, do you have serious problems with your memory?
- Do you take more than three medications daily?

Detection of older people at increased risk of adverse health outcomes after an emergency visit: The ISAR screening tool. *Journal of the American Geriatrics Society, 47*(10), 1229–1237. doi:10.1111/j.1532-5415.1999.tb05204.x. *Evidence Level IV.*

General Assessment

At a minimum, the social history should address the person's living situation, marital status, work status, and advance directives. A social assessment also focuses on supports within the family and in the community. A way to assess this is to ask, "If something bad happened, who would you call?" Stressors related to loss, grief, relationship changes, and environmental factors are often antecedents to acute onset or exacerbation of illness and should be ascertained (Graf, Zekry, Giannelli, Michel, & Chevalley, 2011; Malik, Moore, Patton, O'Connor, & Nugent, 2018). In addition to the past medical/surgical history, medication use, and allergies, weight loss/changes in oral intake and details on recent changes in diagnosis or medication regimes are standard data. When evaluating the reason for coming to the ED, the nurse should elicit a comparison between the older adult's condition before the acute illness and new or exacerbated symptoms. Information about baseline cognition, mood, and physical function is essential because changes within these dimensions can be early and sensitive indicators of physiological dysfunction (Ellis, Marshall, & Ritchie, 2014; Hare, Wynaden, McGowan, & Speed, 2008).

Cognition and Mood

It is estimated that one-fourth of all older adults who present to the ED show impaired mental status associated with delirium, dementia, or both (Hustey & Meldon, 2002; Hustey, Meldon, Smith, & Lex, 2003). Although

common in older ED patients, cognitive impairment is often undetected (Hustey & Meldon, 2002; Lewis, Miller, Morley, Nork, & Lasater, 1995). The Geriatric Emergency Medicine Task Force recommends a mental status evaluation for all older adults presenting to the ED (Wilber, Lofgren, et al., 2005). The Six-Item Screener (immediate recall of three words; orientation to year, month, day of the week; recall of three words) is short and easy to use and detects cognitive impairment with a sensitivity of 94% and a specificity of 86% in the ED setting (Callahan, Unverzagt, Hui, Perkins, & Hendrie, 2002). If cognitive impairment is detected, the family or formal caregiver should be questioned regarding the baseline cognition; abrupt onset suggests delirium.

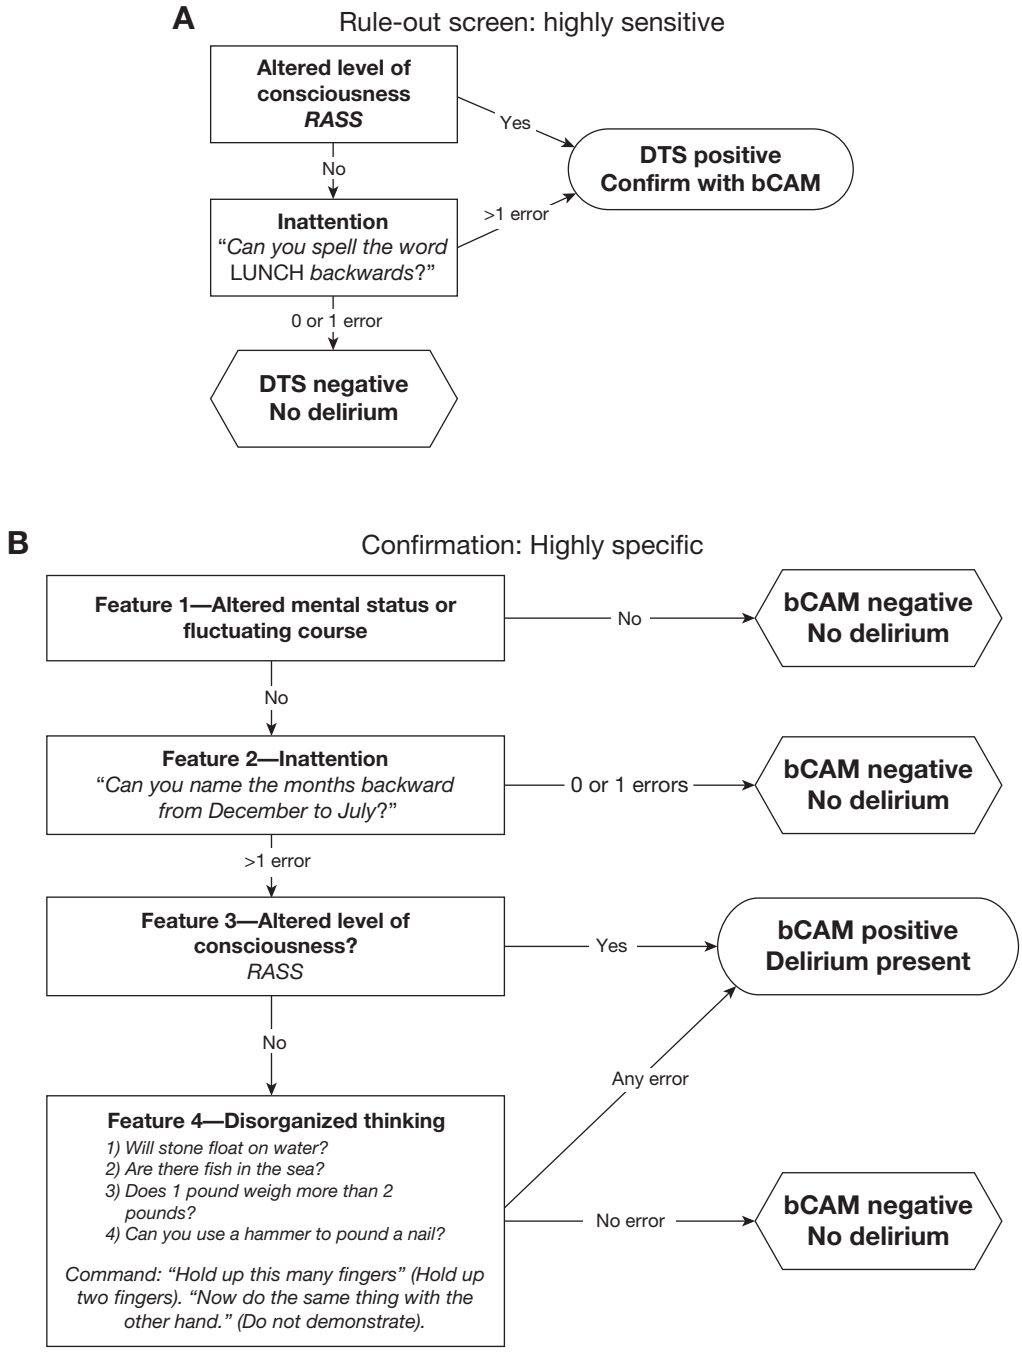
The Geriatric Emergency Department Guidelines (2014), developed by the Emergency Nurses Association, American College of Emergency Physicians, American Geriatrics Society, and Society for Academic Emergency Medicine, recommend a two-step process to assess for delirium. Step 1 (Figure 44.1) is the highly sensitive delirium triage screen (DTS). Step 2 is the highly specific Brief Confusion Assessment Method (bCAM; Han et al., 2013).

The DTS is comprised of two parts: (a) level of consciousness as measured by the Richmond Agitation Sedation Scale (RASS) and (b) inattention by spelling the word "LUNCH" backwards. If the patient has an RASS other than 0 (0 = alert and calm; Ely et al., 2003) or makes more than one error on the "LUNCH" backward spelling test, then the DTS is considered positive. The bCAM is then used to rule in delirium.

A variety of ED-appropriate dementia and mild cognitive impairment screening instruments have been validated; they are useful to reduce the probability of nondelirium cognitive impairment (dementia or mild cognitive impairment) rather than to rule in the diagnosis. During diagnosis of delirium, attention is paid to identify the underlying cause, which can be infection, medications, dehydration, electrolyte imbalance, alcohol/drug use or withdrawal, depression, stroke, or other neurological problems (Elie, Cole, Primeau, & Bellavance, 1998). Additionally, the following should be evaluated as risk factors for the development of delirium: decreased vision or hearing, decreased cognitive ability, severe illness, and dehydration/prerenal azotemia (Geriatric Emergency Department Guidelines Task Force, 2014).

Depression may interfere with the clinical presentation of acute medical disorders and results in a larger number of ED visits (Fabacher, Raccio-Robak, McErlean, Milano, & Verdile, 2002). Approximately one-third of older ED patients present with depression (Meldon et al., 2003; Sanders, 2001). The Emergency Department Depression Screening Instrument (ED-DSI) is appropriate for the detection of depression in the ED; it is brief, consisting of three questions (Do you often feel [a] sad and depressed? [b] helpless? [c] downhearted and blue?). The ED-DSI has a sensitivity of 79% and a specificity of 66% when compared with the longer Geriatric Depression Scale (Fabacher et al., 2002).

Physical Function



Physical function is an important metric of health in older adults, as described in Chapter 10, Assessment of Physical Function in the Older Adult. A recent loss of function often precedes a visit to the ED and can signify underlying illness (Wilber et al., 2006). Additional information on function is used to benchmark response to treatment as the patient transitions among various settings. Finally, the degree of services, including rehabilitation therapy, is largely guided by an assessment of functional status. Basic activities of daily living (ADLs) and instrumental activities of daily living (IADLs) function should be assessed for each patient, including capacity for dressing, eating, transferring, toileting, hygiene, ambulation, and medication adherence. Measurement needs to capture baseline function (before the acute admitting problem, typically 2 weeks before admission) as well as current functional performance. Physical function is appraised using a valid measure of basic function such as the Katz ADL Index (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963) or Barthel Index (Mahoney & Barthel, 1965) and IADLs using the Lawton IADL Scale (Lawton & Brody, 1969).

Medication Evaluation

A national surveillance study of adverse drug events (ADEs) and a national outpatient survey estimated that Americans aged 65 years or older have more than 175,000 ED visits for ADE yearly. One-third of ADE-related visits were attributed to three commonly prescribed drugs: warfarin, insulin, and digoxin (Budnitz, Shehab, Kegler, & Richards, 2007). Furthermore, older adults who are more frequent ED users have a greater number of potentially inappropriate medications (PIMs); they also tend to experience significant delay between hospital discharge and primary care follow-up (Wong, Marr, Kwan, Meiyappan, & Adcock, 2014). In addition to following established medication reconciliation processes, the emergency nurse has a pivotal role in facilitating systematic screening for polypharmacy and use of PIMs as well as detecting ADE in the ED (Samaras, Chevalley, Samaras, & Gold, 2010). For those patients who demonstrate polypharmacy, PIMs, and/or ADEs, and are admitted, a referral to the pharmacist and interdisciplinary

team will enable collaborating with the attending physician to correct the medication problem (Geriatric Emergency Department Guidelines Task Force, 2014).

Fall Assessment

According to the Centers for Disease Control and Prevention (CDC, 2016), falls are the number one cause of nonfatal injuries treated in people older than age 65 treated in hospital ED. Furthermore, almost one-third of adults aged 65 years and older who fell in a bathroom were diagnosed with a fracture, and among adults aged 85 years and older, 38% were hospitalized as a result of their injuries (CDC, 2016).

The appropriate ED evaluation of an older adult who has fallen includes three components: (a) a thorough assessment for traumatic injuries, (b) an assessment of the cause of the fall, and (c) an estimation of future fall risk. Evaluation of the patient for injury should include a complete head-to-toe evaluation for all patients, including those presenting with seemingly isolated injuries. An EKG; complete blood count; standard electrolyte panel; evaluation of medications, including measurable levels; and appropriate imaging should be secured. For those older adults who present to the ED after a fall, traumatic injuries may be occult, presenting without classic signs or symptoms (Geriatric Emergency Department Guidelines Task Force, 2014). High-risk injuries, such as blunt head trauma, spinal fractures, and hip fractures, warrant a higher degree of suspicion and extensive workups (Sterling, O'Connor, & Bonadies, 2001). For example, hip fractures can present as isolated knee pain and can be underdetected on x-ray (Dominguez, Liu, Roberts, Mandell, & Richman, 2005; Guss, 1997). Older adults who have sustained head trauma, even when perceived by the patient to be slight, require neurological assessment and observation (Rathlev et al., 2006). Altered mental state, focal neurologic deficits, headache, and falls may indicate the presence of a chronic subdural hematoma (Adhiyaman, Asghar, Ganeshram, & Bhowmick, 2002).

A targeted interview with the patient and the family member should address previous falls as well as the location, activity, potential environmental factors, and symptoms preceding the actual fall. This description helps identify a fall as a result of an underlying pathology or general frailty. Falls may be the chief symptom of orthostatic hypotension, cardiovascular syncope, or carotid sinus syndrome (Mitchell, Richardson, Davies, Bexton, & Kenny, 2002). Other responsible pathologies may include acute myocardial infarction, infection, medications (side effects, interactions, and toxicity), metabolic disturbances, neurological event or conditions (e.g., seizure and transient ischemic attack), acute abdominal pathology, or elder abuse (Sanders, 1999). Finally, environmental factors, including physical hazards and unfamiliar surroundings, are common culprits.

A systematic review revealed the paucity of evidence in the literature regarding ED-based screening for risk for future falls among older adults (Carpenter et al., 2014). Six fall predictors were identified in more than one study (past falls, living alone, use of walking aid, depression, cognitive deficit, and more than six medications), with a self-report of depression associated with the highest likelihood of falling. Additionally, the assessment of the etiology of a fall will help determine if a patient will continue to be at risk for a fall at the time of discharge and the potential risk factors (Carpenter, Scheatzle, D'Antonio, Ricci, & Coben, 2009). This may include involving home health services (nursing, physical, or occupational therapies) to schedule a home safety evaluation. A home evaluation typically involves an assessment to determine if home modifications/hazard removal is needed as well as if use of assistive devices and proper footwear, medication management, and so forth, will decrease fall risk. Depending on hospital protocol, a physical therapy evaluation in the ED should be considered to ensure a safe discharge home, and is indicated for all patients admitted to the hospital after a fall (Aschkenasy & Rothenhaus, 2006). Communicating the details of the fall event and evaluation is critical during handoff to ensure mobilization of fall-prevention measures (see Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care).

Substance Misuse

The ED may be the portal to treatment for older adults dealing with substance misuse. Alcohol is the drug that is most commonly misused by older adults, followed by tobacco and psychoactive prescription drugs, with trends indicating an increase in the numbers of older individuals using marijuana (Moore et al., 2009). *Misuse* is defined as the use of a drug for purposes other than that for which it was intended. Alcohol abuse is present in 6% to 11% of older persons admitted to the hospital, and 14% of older adults presenting to the ED have diagnosable alcoholism (Ferreira & Weems, 2008). Validated screening instruments for older adults, including the Alcohol Use Screening and Assessment for Older Adults, have shown to have good-to-excellent sensitivity and specificity (Ong-Flaherty, 2012). Other simple questions can also uncover a substance abuse problem. For example, the CAGE questionnaire, originally developed for alcohol (Ewing, 1984), has been modified to ascertain drug use and has been tested in older adults with some success. CAGE is an acronym for the four basic questions:

1. Have you felt you ought to *cut* down on your drinking or drug use?
2. Have people *annoyed* you by criticizing your drinking or drug use?
3. Have you felt bad or *guilty* about your drinking or drug use?
4. Have you ever had a drink or used drugs first thing in the morning to steady your nerves, get rid of a hangover, or get the day started (as an *eye-opener*)?

A complete social evaluation is vital given that social risk factors play a role in substance misuse. It is important to evaluate the patient's social network and identify which members are supportive of treatment and which are potentially hazardous to the patient. Harmful network members include active substance abusers; those who "enable" the patient's misuse; and those who abuse the patient physically, sexually, or emotionally. In addition, the evaluation should make sure the patient has adequate housing and access to food, adequate transportation, and medical care. The patient's mood, cognition, sleep patterns, and mental health history, including past treatment, should also be ascertained (Ross, 2005).

When there is evidence of substance misuse, nursing interventions focus on (a) monitoring for withdrawal; (b) providing an environment that is safe from potential harm to the patient; and (c) collaborating with the patient, family, physician, and social worker to secure a mental health evaluation and program directed to the substance abuse needs and support. If the patient is admitted to the hospital, careful handoff should include the communication of the patient's history and clinical findings as well as safety issues, including fall risk and the presence of delirium (Center for Substance Abuse Treatment, 1998).

Elder Mistreatment

EDs are often the first point of contact for elder mistreatment (EM) victims (Fulmer, Paveza, Abraham, & Fairchild, 2000). EM includes physical, verbal, sexual, and psychological abuse, as well as abandonment, exploitation, and neglect (Acierno et al., 2010). The ED nurse needs to be vigilant to recognize the clinical features of EM and to know the organization's policies for reporting suspected EM, as required by The Joint Commission on Accreditation and state mandatory reporting requirements (Dong, 2012; Falk, Baigis, & Kopac, 2012). The clinician should look for red flags of mistreatment—delays in seeking treatment, signs of withholding or giving too much medication, missed appointments, use of several hospitals, driving to a hospital farther away from home, description of an event that does not fit the injury sustained, and repetitive injuries (Heath & Phair, 2009). Signs of caregiver indifference, berating or threatening comments, hypervigilant/possessive behavior, or excessive concerns over finances warrant suspicion of EM (Bond & Butler, 2013; Stiegel, Klem, & Turner, 2007).

When EM is suspected, it is recommended to separate the older adult from the caregiver and obtain a detailed history and physical assessment; interviewing the patient about his or her feelings of safety is important (Bond & Butler, 2013). Care needs to be taken by clinicians to secure a careful medical history, including baseline conditions, and conduct a comprehensive physical examination. Physical examination cues may include poor hydration; poor hygiene; suspicious injuries in unusual locations and bruises in various stages of healing; and unexplained abrasions and/or markings on skin, including human bite marks, skin tears, pressure ulcers, or genital complaints, including infections or injury (Dong, 2017; Stiegel et al., 2007). Additional information on EM can be found in Chapter 16, Elder Mistreatment Detection.

NURSING INTERVENTIONS

Delirium and Dementia

In addition to collaborating with the physician to detect cognitive impairment, including delirium or delirium superimposed on dementia, the nurse provides key interventions to prevent delirium and promote comfort and safety. Strategies include controlling the environment: (a) supporting the family/familiar person (or volunteer) present with the patient; (b) providing sensory aides (glasses and hearing aids and offering hearing amplifiers and magnifiers as indicated); (c) controlling noise; (d) avoiding excessively bright lights when possible; and (e) providing comfort measures, including fluids and a warm blanket. Additional nursing interventions include promoting mobility and addressing need for pain management, toileting, rest/sleep, and fluid/hydration (Hshieh et al., 2015; Rivosecchi, Smithburger, Svec, Campbell, & Kane-Gill, 2015). Invasive procedures should be avoided as much as possible. Alternatives to physical restraints should be employed, such as camouflaging dressings and securing intravenous and other lines to promote comfort. Adapting communication to cognitive loss through the use of verbal and physical cues, brief and clear instructions, and inclusion of family in the sharing of information and decision-making will promote a sense of security for the patient and promote effective collaboration with family (Boltz, Chippendale, Resnick, & Galvin, 2015; Boltz, Resnick, Chippendale, & Galvin, 2014).

When delirium is detected, interventions are aimed at reversing the cause (which may include the use of supplemental oxygen, hydration, etc.) while continuing to provide supportive preventive measures. The use of physical and chemical restraints should be avoided (American Association of Critical Care Nurses, 2011). For more information on restraints, see Chapter 27 Physical Restraints and Side Rails in Acute and Critical Care Settings. Education about the etiology of delirium and planned interventions will reassure anxious family members and help enlist their involvement in promoting safety and comfort for the patient (Boltz et al., 2014, 2015).

Prevention of Falls and Related Injuries

The aforementioned interventions will also mitigate the risk for falls and injuries. In addition to addressing modifiable fall risk factors, such as offending medications or dehydration, attention to the patient's safety is paramount (Christopher, Carpenter, Cameron, Ganz, & Liu, 2019). Patients often fall when trying to get out of bed unsupervised or unassisted; bedrails do not reduce the amount of falls and may increase the severity of the fall (Capezuti, Maislin, Strumpf, & Evans, 2002). For the person who is at risk for injury as a result of cognitive impairment, weakness, and low mobility, and who is nonambulatory and at risk for leaving the bed unsafely, low beds should be considered with bedside mats. Close oversight is essential (Capezuti et al., 2002). Encouraging physical activity (e.g., range of motion) and helping the older adult to walk to the bathroom when possible or use of a commode is helpful to prevent early deconditioning and thereby to mitigate fall risk (Alexander, Kinsley, & Waszinski, 2013; Capezuti et al., 2002).

The Geriatric Emergency Department Guidelines recommend that EDs make an effort to align their physical and personnel resources with the physical needs of the older adult patient. Equipment to prevent falls in the ED should include: (a) rubber or nonskid flood surfaces/mats; (b) even floor surfaces; (c) handrails on walls and hallways; (d) aisle lighting; (e) bedside commodes and grab bars in restrooms; (f) bedrails properly positioned and functioning (avoid use of full rails); and (g) patient gown and hospital clothing that minimize fall risk (long, baggy, loose tie strings, etc.). The guidelines also recommend expedited outpatient follow-up for those patients discharged from the ED/hospital to address fall risk factors (Patterson et al., 2018), conduct home safety assessments, and provide walkers and other gait assistance devices as needed on discharge (Geriatric Emergency Department Guidelines Task Force, 2014).

Prevention of Pressure Ulcers

The use of pressure-redistributing foam mattresses has shown to be a cost-effective approach to prevent ED-acquired pressure ulcers (Pham et al., 2011). The use of reclining chairs in the ED instead of ED gurney beds has been shown to reduce pain and improve patient satisfaction (Wilber, Burger, Gerson, & Blanda, 2005). Evidence-based guidelines to prevent and manage pressure ulcers (as described in Chapter 28, Preventing Pressure Injuries and Skin Tears) should be followed, including skin assessment, pressure relief/off-loading, prevention/treatment of infection, pain control, and nutritional evaluation and management (Ayello, 2011; Reddy, Gill, & Rochon, 2006).

Prevention of Catheter-Associated Urinary Tract Infection

A catheter-associated urinary tract infection (CAUTI) is a urinary tract infection (UTI) that occurs while a patient has an indwelling urinary catheter (IUC) or within 48 hours of its removal. The use of preventive practices is associated with a lower incidence of CAUTIs. These practices include avoiding unnecessary urinary catheter use, removal prompts and nurse-initiated urinary catheter discontinuation protocols, alternatives to indwelling urinary catheterization, portable bladder ultrasound monitoring, and insertion care and maintenance (Oman et al., 2012; Saint et al., 2013). For more information on CAUTI, see Chapter 26, Prevention of Catheter-Associated Urinary Tract Infection.

In the ED, the identification of appropriate patients for urinary catheter insertion is an essential component of a protocol to prevent CAUTIs. According to the Infectious Disease Society of America and other expert opinion (Apisarnthanarak et al., 2007; Fink et al., 2012; Saint et al., 2013), these indications are as follows: (a) urinary retention/obstruction; (b) need for very close monitoring of urine output and patient unable to use urinal or bedpan; (c) open wound in sacral or perineal area with urinary incontinence; (d) patient too ill, fatigued, or incapacitated to use alternative urine collection method; (e) patient status after recent surgery, hip fracture, emergency pelvic ultrasound, neurogenic bladder, and other urologic problems; and (f) hospice/palliative care. After receiving a physician order with the appropriate indications documented, the nurse should insert the indwelling catheter as per protocol, using the smallest size catheter and sterile technique (Fink et al., 2012; Hooton et al., 2010). There should be a plan for the earliest removal, which is communicated during the handoff to the nurse on the transferred unit. Daily catheter rounds guide decision-making for continued use or removal of indwelling catheters (Wald & Kramer, 2011).

TRANSITIONS FROM THE ED

In a 12-state survey study of a combined 65.5 million ED visits from 2006 to 2007, carried out with patients older than 65 years, approximately 40% had medication errors after a hospital discharge, and 18% of Medicare patients discharged from a hospital were readmitted within 30 days (Steiner, Barrett, & Hunter, 2010). Older ED patients have identified misinformation, a factor associated with ED readmissions, as a primary source of dissatisfaction with ED care. Factors associated with misinformation include underrecognition of cognitive dysfunction, lower health literacy, and financial impediments for prescriptions and recommended outpatient follow-up (Baraff et al., 1992; Carpenter et al., 2009; Han et al., 2011).

ED-based interventions that emphasize patient education and care coordination have demonstrated mixed results on the rate of ED readmissions and the prevention of complications (Basic & Conforti, 2005; Corbett, Lim, Davis, & Elkins, 2005; Hegney et al., 2006). Experts agree, however, that the transition from the ED to other settings includes four systematic processes: discharge planning, patient/family education, handoff, and follow-up (Geriatric Emergency Department Guidelines Task Force, 2014).

Discharge Planning

Discharge planning from the ED is a multidisciplinary process that includes the family or significant others. The process is tailored to the individual needs of the older adult patient according to his or her discharge diagnosis and the destination setting. Components of discharge planning include (a) evaluation of the clinical status related to the admitting problem, (b) assessment of physical and psychosocial functional status (including fall/safety risk), (c) risk assessment for subsequent functional decline (e.g., ISAR or TRST), (d) assessment of caregiver availability and ability, (e) an appraisal of the patient/family readiness and ability to learn, (f) medication review, (g) review of advance directives, and (h) referrals with follow-up arrangements (Centers for Medicare & Medicaid Services [CMS], 2019). If the assessment by the nurse, physician, and other relevant disciplines determines that post-ED care is indicated, active engagement of patients and families and offering a range of options will support the patient's preferences and goals (Popejoy, 2011). The CMS (2014) recommends that the EDs maintain a complete and accurate file of appropriate community-based services, supports, and facilities to which the patient can be referred.

Patient/Family Education

Older adults often rely on the support of family and friends in the ED. ED patients frequently do not understand their discharge instructions (Crane, 1997; Jolly, Scott, Feied, & Sanford, 1993; Zavala & Shaffer, 2011). Education and information should be communicated in a concise manner, using the teach-back method. In a study of patient and caregiver understanding of discharge instructions, the investigators assessed patient and caregiver understanding of discharge instruction in four domains: (a) diagnosis and cause, (b) ED care, (c) post-ED care, and (d) return instructions. Seventy-eight percent of participants demonstrated deficient comprehension in at least one domain. Greater than one-third of the deficiencies involved understanding of post-ED care (Engel et al., 2009). Within the emergency medicine literature, commonly cited challenges to patient/caregiver understanding are limited literacy and numeracy (Ginde, Clark, Goldstein, & Camargo, 2008; Ginde, Weiner, Pallin, & Camargo, 2008). Adding to the problem, print discharge instructions are often not written at appropriate reading levels (Jolly et al., 1993; Williams, Counselman, & Caggiano, 1996).

To address these challenges, written instructions should be at the sixth-grade level (established using a literacy calculator). It is recommended that nurses use plain language, focusing on "need-to-know" information and limiting the documents to essential content to avoid information overload (McCarthy et al., 2012). Also, information and educational material should be provided in large font suitable for older adults. The use of the teach-back method has demonstrated a positive impact on recall of discharge instructions in the ED regardless of age and education (Slater, Dalawari, & Huang, 2013). This teaching method assesses the effectiveness of teaching by having the person explain and/or demonstrate back to the nurse what he or she has just been taught, ensuring that the patient is actively involved in the teaching process (Schillinger et al., 2003).

The nurse may use a standardized tool that assesses older adults' ability to self-administer their medication such as the Drug Regimen Unassisted Grading Scale (DRUGS), which takes approximately 5 minutes to complete. This tool requires subjects to perform the following four tasks with each of their medications: (a) identify the appropriate medication, (b) open the container, (c) select the correct dose, and (d) report the appropriate timing of doses (Edelberg, Shallenberger, Hausdorff, & Wei, 2000; Kripalani et al., 2006).

Handoff

Communication with primary care providers regarding an ED visit is considered to be a necessary process, particularly for vulnerable elders (ACOVE-3 Investigators, 2007). In an effort to improve continuity of care between the ED and other settings, the Geriatric Emergency Department Guidelines Task Force (2014) recommends standardized information be provided to the patient/family and outpatient care providers, including NHs and primary care providers (Box 44.4). Structured focus group interviews with NH staff, ED staff, and a county-wide EMS system identified the following additional approaches to support handoffs between EDs and NHs: (a) a verbal report from ED nurses provided to the NH as well as written documentation, (b) an emergency form in NH residents' charts that contains predocumented information with an area to write in the reason for transfer, and (c) brief NH-to-ED and ED-to-NH transfer forms that are accepted and used by local NHs and EDs (Terrell & Miller, 2006). Additionally, streamlined, structured data-sharing between healthcare systems, hospitals, clinics, and the SNFs is also an emerging systems-based priority to promote safe and effective transitions (Vollbrecht, Biese, Hastings, Ko, & Previll, 2018).

Interventions to Reduce Acute Care Transfers (INTERACT) is a publicly available quality improvement program that focuses on improving the identification, evaluation, and management of acute changes in condition of NH residents (J. G. Ouslander, Bonner, Herndon, & Shutes, 2014). One INTERACT objective is to improve communication between the ED and the NH (J. F. Ouslander, Scnelle, & Han, 2015). INTERACT tools include a checklist of key transfer documents, lists of critical data for interfacility communication at the time of transfers, and a medication reconciliation form. The "Nursing Home to Hospital Transfer Form" has information for ED clinicians to make informed decisions about evaluation and management of the transferred resident. When transferring an NH resident back to the NH, the ED may use the "Hospital to Post-Acute Care Transfer Form," which provides critical time-sensitive information essential to provide care in the first 48 to 72 hours after transfer (J. G. Ouslander et al., 2014).

Follow-Up

Telephone follow-up is recommended for patients discharged from the ED; home visits are ideally provided to high-risk individuals. Telemedicine alternatives hold promise for effective follow-up and should be considered, especially in rural areas (Kessler, Williams, Moustoukas, & Pappas, 2013).

BOX 44.4

Standardized Discharge Information

- Presenting complaints
- Test results and interpretation
- ED therapy and clinical response
- Consultation notes (in person or via telephone) in ED
- Working discharge diagnosis
- ED physician note or copy of dictation
- Patient condition (including fall risk and functional and cognitive status)
- New prescriptions and alterations with long-term medications
- Discharge recommendations: physical activity, diet, and resources/services
- Support systems
- Advance directives
- Follow-up plan

Source: Geriatric Emergency Department Guidelines Task Force. (2014). The geriatric emergency department guidelines. *Annals of Emergency Medicine, 63*(5), e7–25. doi:10.1016/j.annemergmed.2014.02.008. *Evidence Level VI.*

CASE STUDY 44.1

EMS transported an 86-year-old woman to the ED from a nearby assisted living facility (ALF). She was evaluated 3 days ago in the ED for UTI presenting with increased lethargy and a fall without injury. She was started on antibiotic therapy and returned to the ALF. Forty-eight hours later, a nurse from the ALF contacted the on-call physician to report continued confusion, poor oral intake, and declining functional status. She was sent back to the ED; her daughter is alarmed by her confusion and inability to respond to questions coherently, stating, "She is normally as clear as a bell." Transfer records indicate new-onset urinary and fecal incontinence in addition to the mental status changes. As the triage nurse identifies the emergent nature of the patient's condition because of the change in mental status, she is evaluated by the physician within 15 minutes of arrival. Before this, the ED nurse determines her past medical history (positive for hypertension, depression, and gastroesophageal reflux disease [GERD]), baseline cognition of being oriented times three with no apparent problems with recall and managing her daily routine at the ALF, and requiring assistance getting in and out of the bathtub. The Six-Item

(*continued*)

CASE STUDY 44.1 (*continued*)

Screener indicates impaired recall and orientation and the bCAM is positive for delirium.

The patient's medications include verapamil SR = 360 mg daily, donapezil = 10 mg daily, levofloxacin = 500 mg daily, ranitidine = 150 mg daily, hydrochlorothiazide (HTCZ) = 12.5 mg daily, and paroxetine 20 = mg daily. The labs are remarkable for a blood urea nitrogen (BUN) of 42 and creatinine of 2.6, and urinalysis with 15 to 20 red blood cells (RBCs) per high-power field, 0 to 2 white blood cells (WBCs) per high-power field, +1 protein, and +2 leukocyte esterase.

The ED nurse ascertains that a UTI is a likely cause of delirium. Additionally, the patient's medications may be contributing to her altered cognition. Ranitidine and paroxetine (unlike most other selective serotonin reuptake inhibitors [SSRIs]) exhibit anticholinergic activity and sedation as a side effect. Verapamil can cause constipation, which can contribute to UTI and delirium. Quinolone antibiotics cause delirium in a small percentage of older adults. A medication review is conducted with the physician and pharmacist to eliminate offending agents.

Important nursing interventions focus on safety, comfort, and preventing complications. The nurse encourages the daughter to stay with the patient, and advises her to let the staff know when she needs to leave, in which case a volunteer will cover. The patient is located in a quiet area, with gentle lighting and warming blankets. A pressure-relieving mattress and repositioning are provided to prevent ED-acquired pressure ulcers. The intravenous line is camouflaged and secured to minimize discomfort, as an alternative to a physical restraint. The nurse provides education to the daughter about delirium, including the plan to correct the probable causes, as well as interventions to support comfort and recovery (including familiar presence, calm approach, early mobility, and adequate food/fluids). The case manager covering the ED and the receiving nurse on the medical floor are notified of the patient's risk for functional decline, NH placement, and subsequent readmission, based on her TRST findings (cognitive impairment, use of five or more medications, recent fall, recent ED admission, and need for ADL support). During the handoff to the medical floor, the following are communicated: the patient's health and social history; details of ED admission, including findings; baseline and current cognitive status; fall and pressure ulcer risk; and daughter's involvement in her care. The daughter is present during the handoff.

SUMMARY

The nurse has the opportunity to positively influence the experience and outcomes of the older adult admitted to the ED. Careful assessment and planning as well as considering age-related changes and the interaction of the acute illness with comorbid conditions are critical to prevent complications and promote resolution of the admitting problem. Clear and comprehensive communication during transitions and engaging family in care delivery and decision-making support effectiveness and patient comfort. The nurse also plays a critical role in leading an interdisciplinary review of the national GED Guidelines and systematically addressing the specific education needs of their own staff regarding older adult ED patients (Schumacher, Hirshon, Magidson, Chrisman, & Hogan, 2018).

NURSING STANDARD OF PRACTICE

Protocol 44.1: Care of the Older Adult in the Emergency Department

I. GOALS

To ensure nurses in acute care are able to:

A. Identify evidence-based approaches and tools to assess the older adult in the ED
B. Describe interventions to prevent and manage geriatric syndromes in the ED
C. Discuss approaches to support effective transitions from the ED

(*continued*)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

II. OVERVIEW

A. One in five patients aged 65 to 74 years and one in four patients aged 75 years and older visit the ED each year (Albert et al., 2013).
B. The ED is:
   1. The portal to other settings, including the hospital, long-term care, and mental health facilities (Samaras et al., 2010)
   2. Used for the performance of complex diagnostic workups, overflow, and off-hour medical care
   3. For some older adults, the only source of healthcare evaluation and treatment (Gonzalez Morganti et al., 2013; Stefanacci & Riddle, 2018)

III. BACKGROUND AND STATEMENT OF THE PROBLEM

A. As compared to younger people, older adults:
   1. Have more diagnostic tests, longer stays in the ED, and are more likely to be admitted to the hospital (Banerjee et al., 2011)
   2. Are more likely to be readmitted on discharge from the ED; they also risk functional loss and higher rates of mortality (McCusker et al., 2007; Niska et al., 2010; Sklar et al., 2007)
   3. Are more likely to experience missed or incorrect diagnoses (Salvi et al., 2007), inadequate pain management (Hwang et al., 2010; Iyer, 2011), and less information (Baillie, 2005; George et al., 2006)

IV. ASSESSMENT OF THE OLDER ADULT IN THE ED

A. Triage/primary assessment
   1. Delays in triage for older adults are associated with increased waiting time, anxiety, and discomfort (Miró et al., 1999), and increased risk for mortality (Perdue et al., 1998).
   2. Tools
      a. The CTAS demonstrated high validity for older adults, which is especially useful for categorizing severity and for recognizing older adults who require immediate life-saving intervention (Bullard et al., 2008; Lee et al., 2011).
      b. The ESI includes a comprehensive algorithm that describes symptoms and physiological indicators as well as the resources anticipated to be used (Gilboy et al., 2012). There are reports of under-triage using this tool when guidelines are not precisely followed (Platts-Mills et al., 2010).
   3. A–B–C: identify and treat life-threatening conditions
      a. Airway: challenges to establishing an airway include the presence of dentures, kyphosis, and cervical rigidity (Aresco & Stein, 2010).
      b. Breathing and ventilation: consider age-related changes, including decreased pulmonary compliance, respiratory reserve, and arterial oxygenation (Blumenthal et al., 2010).
      c. Circulation: use of antihypertensive medication may inhibit physiological response and/or mask signs of hypovolemic shock (Criddle, 2013).
   4. Consider atypical presentation and "red flags" (acute change on mental status and/or physical function, dyspnea, fatigue, self-neglect, apathy, and falls; Fletcher, 2004).
B. Screen for risk for adverse outcomes: useful in guiding a plan to prevent avoidable complications during the ED stay, if admitted during hospitalization, and after an ED visit when transitioning to home or another setting
   1. TRST: is predictive of subsequent ED use, hospitalization, and NH admission (Meldon et al., 2003)
   2. ISAR: is predictive of increased risk for death, institutionalization, functional decline, and both repeat ED visit and hospital admission in the following 6 months after an ED visit (McCusker et al., 1999)
C. General assessment
   1. History
      a. Social history: living situation, marital status, work status, advance directives, supports within family and community, and stressors (Graf et al., 2011)

(continued)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

   b. Past medical/surgical history: medication use, allergies, weight loss/changes in oral intake, and recent changes in diagnosis or medication regimens
   c. Baseline cognition, mood, and physical function: early and sensitive indicators of physiological dysfunction (Ellis et al., 2014; Hare et al., 2008)
2. Cognition and mood
   a. Cognitive impairment: Geriatric Emergency Medicine Task Force recommends a mental status examination for older adults presenting to ED (Wilber et al., 2005).
      i. Six-Item screener (Callahan et al., 2002)
   b. Delirium: suggested by abrupt onset of cognitive impairment
      i. Two-step process included in the Geriatric Emergency Department Guidelines Task Force (2014): delirium triage screen followed by the Brief Confusion Assessment Method (Han et al., 2013)
   c. Depression: may interfere with clinical presentation and may be associated with greater number of ED visits (Meldon et al., 2003; Sanders, 2001)
      i. ED-DSI: three-question screener (Fabacher et al., 2002)
3. Physical function: recent loss often precedes the visit to the ED and can signify underlying illness (Wilber et al., 2006).
   a. Basic ADL: Katz ADL index (Katz et al., 1963) or Barthel index (Mahoney & Barthel, 1965)
   b. IADL: Lawton IADL Scale (Lawton & Brody, 1969)
4. Medications:
   a. ADEs: one-third are related to one of the following: warfarin, insulin, or digoxin (Budnitz et al., 2007).
   b. PIMs: greater number is associated with frequent ED use (Wong et al., 2014).
   c. Geriatric Emergency Department Guidelines Task Force (2014) recommendations:
      i. Medication reconciliation
      ii. Screening for polypharmacy, PIMs, ADEs; collaborate with pharmacist and interdisciplinary team as indicated, and attending physician to correct.
5. Falls: number one cause of nonfatal injuries in people older than 65 years treated in hospital EDs. (CDC, 2016)
   a. ED evaluation
      i. Assess for injury (consider occult presentation): complete physical examination; EKG; complete blood count; electrolytes; medication evaluation, including measurable levels; and appropriate imaging (Adhiyaman et al., 2002; Dominguez et al., 2005; Rathlev et al., 2006; Sterling et al., 2001)
      ii. Assess the cause of the fall (Mitchell et al., 2002; Sanders, 1999).
   b. Targeted interview with patient and family: previous falls, location, activity, potential environmental factors, and symptoms preceding the fall
   c. Comprehensive history and physical examination
      i. Estimation of future fall risk: guided largely by determination of reasons for past falls (Carpenter et al., 2009)
6. Substance misuse
   a. Misuse defined: use of a drug for purposes other than that for which it was intended
   b. Alcohol abuse: present in 14% of older adults presenting to the ED
      i. Screening tool: Alcohol Use Screen and Assessment in Older Adult has been shown to have good-to-excellent sensitivity and specificity (Ong-Flaherty, 2012).
   c. Evaluation (Center for Substance Abuse Treatment, 1998)
      i. Patient's social network: identify which members are supportive of treatment and which members are potentially hazardous to the patient. Harmful network members include active substance abusers; those who "enable" the patient's misuse; and those who abuse the patient physically, sexually, or emotionally.
      ii. Patient's mood, cognition, sleep patterns, and mental health history, including past treatment, should also be ascertained.

(*continued*)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

iii. It should also be verified that the patient has adequate housing and access to food, adequate transportation, and medical care (Ross, 2005).
iv. When there is evidence of substance misuse, nursing interventions focus on (a) monitoring for withdrawal; (b) providing an environment that is safe from potential harms to patient; (c) collaborating with the patient, family, physician, and social worker to secure a mental health evaluation and program directed to the substance abuse needs and support.
v. Careful handoff should include the communication of the patient's history and clinical findings as well as safety issues, including fall risk and the presence of delirium.

7. EM
   a. Definition: physical, verbal, sexual, and psychological abuse, as well as abandonment, exploitation, and neglect (Acierno et al., 2010)
   b. Nurse is expected to know the organization's policies for reporting suspected EM, as required by The Joint Commission on Accreditation and state mandatory reporting requirements (Dong, 2012; Falk et al., 2012).
   c. Red flags of EM: delays in seeking treatment; signs of withholding or giving too much medication; missed appointments; use of several hospitals; driving to a hospital farther away from home; description of an event that does not fit the injury sustained; repetitive injuries (Heath & Phair, 2009); and signs of caregiver indifference, berating or threatening comments, hypervigilant/possessive behavior, or excessive concerns over finances warrant suspicion of EM (Bond & Butler, 2013; Stiegel et al., 2007)
   d. When EM is suspected:
      i. Separate the older adult from the caregiver and obtain a detailed history and physical assessment; interviewing the patient about his or her feelings of safety is an important screening question (Bond & Butler, 2013).
      ii. Conduct a careful medical history, including baseline conditions, and a comprehensive physical examination.
         a) Physical examination cues may include poor hydration; poor hygiene; suspicious injuries in unusual locations and bruises in various stages of healing; and unexplained abrasions and/or markings on skin, including human bite marks, skin tears, pressure ulcers, or genital complaints, including infections or injury (Stiegel et al., 2007).
         b) Follow mandatory reporting procedures.

V. NURSING CARE STRATEGIES

A. Delirium and dementia
   1. Preventing delirium
      a. Control the environment:
         i. Support the family/familiar person (or volunteer) present with the patient.
         ii. Provide sensory aids (glasses and hearing aids, and offer hearing amplifiers and magnifiers as indicated).
         iii. Control noise.
         iv. Avoid excessively bright lights when possible.
         v. Provide comfort measures, including fluids and a warm blanket.
      b. Additional nursing interventions include promoting mobility and addressing the need for pain management, toileting, rest/sleep, and fluid/hydration (Hshieh et al., 2015; Rivosecchi et al., 2015).
   2. Managing delirium: in addition to interventions aimed at reversing the cause:
      a. Continue to provide aforementioned supportive measures.
      b. Avoid physical and chemical restraints (American Association of Critical Care Nurses, 2011).
      c. Educate patient/family about the etiology of delirium and interventions.
      d. Involve family in promoting safety and comfort for the patient (Boltz et al., 2014, 2015).

(*continued*)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

B. Prevention of falls and related injuries
   1. Collaborate with the interdisciplinary team to modify fall risk (e.g., correct orthostasis, remove offending medications, etc.; Alexander et al., 2013).
   2. Provide close oversight (Capezuti et al., 2002).
   3. Encourage physical activity (e.g., range of motion).
   4. Pay attention to toileting (Alexander et al., 2013; Capezuti et al., 2002).
   5. For the person who is at risk for injury caused by cognitive impairment, weakness, and low mobility, provide low beds with bedside mats (Capezuti et al., 2002).

C. Prevention of pressure ulcers
   1. The use of pressure-redistributing foam mattresses has shown to be a cost-effective approach to prevent ED-acquired pressure ulcers (Pham et al., 2011).
   2. The use of reclining chairs in the ED instead of ED gurney beds has been shown to reduce pain and improve patient satisfaction (Wilber, Burger, et al., 2005).
   3. Evidence-based guidelines to prevent and manage pressure ulcers should be followed, including skin assessment, pressure relief/off-loading, prevention/treatment of infection, pain control, and nutritional evaluation and management (Ayello, 2011; Reddy et al., 2006).

D. Prevention of CAUTI
   1. Definition: a UTI that occurs while a patient has an IUC or within 48 hours of its removal.
   2. Preventive practices
      a. Avoid unnecessary urinary catheter use (Apisarnthanarak et al., 2007; Fink et al., 2012; Hooton et al., 2010; Saint et al., 2013).
      b. Consider removal prompts and nurse-initiated urinary catheter discontinuation protocols (Fink et al., 2012).
      c. Use an aseptic technique and sterile products during catheter insertion; maintain cleanliness (Oman et al., 2012; Saint et al., 2013).
      d. Handoff: communicate plan/need for surveillance and for the earliest removal (Wald & Kramer, 2011).

VI. TRANSITIONS FROM THE ED

A. Problem: misinformation (Steiner et al., 2010)
   1. Primary source of older adults' dissatisfaction with ED care
   2. Contributes to readmission

B. Factors associated with misinformation include underrecognition of cognitive dysfunction, lower health literacy, and financial impediments for prescriptions and recommended outpatient follow-up (Baraff et al., 1992; Carpenter et al., 2014; Han et al., 2011).
   1. Three systematic processes to ensure appropriate transfer of information to patient/family and providers (Geriatric Emergency Department Guidelines Task Force, 2014):
      a. Discharge planning
         i. Components: (a) evaluation of the clinical status related to the admitting problem, (b) assessment of physical and psychosocial functional status (including fall/safety risk), (c) risk assessment for subsequent functional decline (e.g., ISAR or TRST), (d) assessment of caregiver availability and ability, (e) an appraisal of the patient/family readiness and ability to learn, (f) medication review, (g) review of advance directives, and (h) referrals with follow-up arrangements (AHRQ, 2009; CMS, 2014)
         ii. Patients and families prefer active engagement and a range of options will support the patient's preferences and goals (Popejoy, 2011).
         iii. CMS (2014) recommends that EDs maintain a file of appropriate community-based services, supports, and facilities to which the patient can be referred.

(*continued*)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

b. Patient/family education
   i. Challenges to patient/caregiver understanding are limited literacy and numeracy (Ginde, Clark, et al., 2008; Ginde, Weiner, et al., 2008).
   ii. Print discharge instructions are often not written at appropriate reading levels (Jolly et al., 1993; Williams et al., 1996).
   iii. To address challenges (Geriatric Emergency Department Guidelines Task Force, 2014):
      a) Written instructions should be at the appropriate grade level (established using a literacy calculator).
      b) Use plain language, focusing on "need-to-know" information, limiting the documents to essential content in order to avoid information overload (McCarthy et al., 2012).
      c) Information and educational material should be provided in large font suitable for older adults
      d) Use the teach-back method (Schillinger et al., 2003; Slater et al., 2013).
      e) Use a standardized tool that assesses older adults' ability to self-administer medication such as the DRUGS. This tool requires subjects to perform the following four tasks with each of their medications: (a) identify the appropriate medication, (b) open the container, (c) select the correct dose, and (d) report the appropriate timing of doses (Edelberg et al., 2000; Kripalani et al., 2006)

c. Handoff
   i. Recommended standardized information (Geriatric Emergency Department Guidelines Task Force, 2014) to provide cross-settings:
      a) Presenting complaints
      b) Test results and interpretation
      c) ED therapy and clinical response
      d) Consultation notes (in person or via telephone) in ED
      e) Working discharge diagnosis
      f) ED physician note, or copy of dictation
      g) Patient condition (including fall risk, functional and cognitive status)
      h) New prescriptions and alterations with long-term medications
      i) Discharge recommendations: physical activity, diet, resources/services
      j) Support systems
      k) Advance directives
      l) Follow-up plan
   ii. Additional approaches: (a) a verbal report from ED nurses provided to the NH as well as written documentation; (b) an emergency form in NH residents' charts that contains predocumented information with an area to write in the reason for transfer; (c) brief NH-to-ED and ED-to-NH transfer forms that are accepted and used by local NHs and EDs (Terrell & Miller, 2006); (d) structured data-sharing (Vollbrecht et al., 2018); and (e) INTERACT tools: checklist of key transfer documents, lists of critical data for interfacility communication at the time of transfers, a medication reconciliation form, and transfer forms (J. G. Ouslander et al., 2014).

d. Follow-up (Kessler et al., 2013)
   i. Telephone follow-up for patients discharged from the ED
   ii. Home visits provided to high-risk individuals
   iii. Telemedicine alternatives when indicated, especially in rural areas

VII. EVALUATION AND EXPECTED OUTCOME(S) FOR CARE OF OLDER ADULTS IN ED

A. Improved patient/family satisfaction and experience
B. Processes:
   1. Adherence to evidence-based practice and guidelines
   2. Throughput and waiting times
C. Better clinical outcomes, such as fewer falls, pressure ulcers, and hospital-acquired infections, as well as improved diagnostic accuracy

(*continued*)

Protocol 44.1: Care of the Older Adult in the Emergency Department (*continued*)

D. Improved organizational outcomes: readmission rates (ED and hospital) and cost
E. Enhanced staff competencies and satisfaction
