macmillan learning™

Accessibility

Macmillan Learning is committed to the goal of providing equal access to all products regardless of an individual's age, ability, or situation and embraces the opportunity to develop services and information technologies that are accessible and usable by all individuals. Accessibility at Macmillan Learning is about extending the power of education to all users. In addition to addressing product compatibility with assistive technologies such as screen reader software, alternative keyboard devices, and voice recognition products, we are working to ensure that the content and platforms we provide are fully accessible.

Our E-books

Macmillan Learning became the first education solutions company to become Global Certified Accessible™, providing "born accessible" digital learning (e-book) options for students with disabilities. Books that are born accessible are developed to ensure that all students, no matter their ability, have the same access to information. This is increasingly important for students and instructors, as more than one out of every ten students who attends college has a disability.

To become Global Certified Accessible, Benetech evaluated Macmillan Learning's workflow for creating accessible books, as well as many samples of content across the disciplines they publish in, and certified conformance to the accessible EPUB creation guidelines, which are based on WCAG 2.0 AA+ standards put in place by the international standards organizations and the publishing community. Using a collaborative process, Benetech evaluated and

provided feedback on more than one hundred accessibility features. The certification applies to all books created using Macmillan Learning's updated process, which includes all e-books with a 2019 copyright and beyond.

Extended Descriptions

In this book, extended descriptions are present for complex images and graphs that may be helpful to understanding content. These extended descriptions can be accessed via a link on this icon:

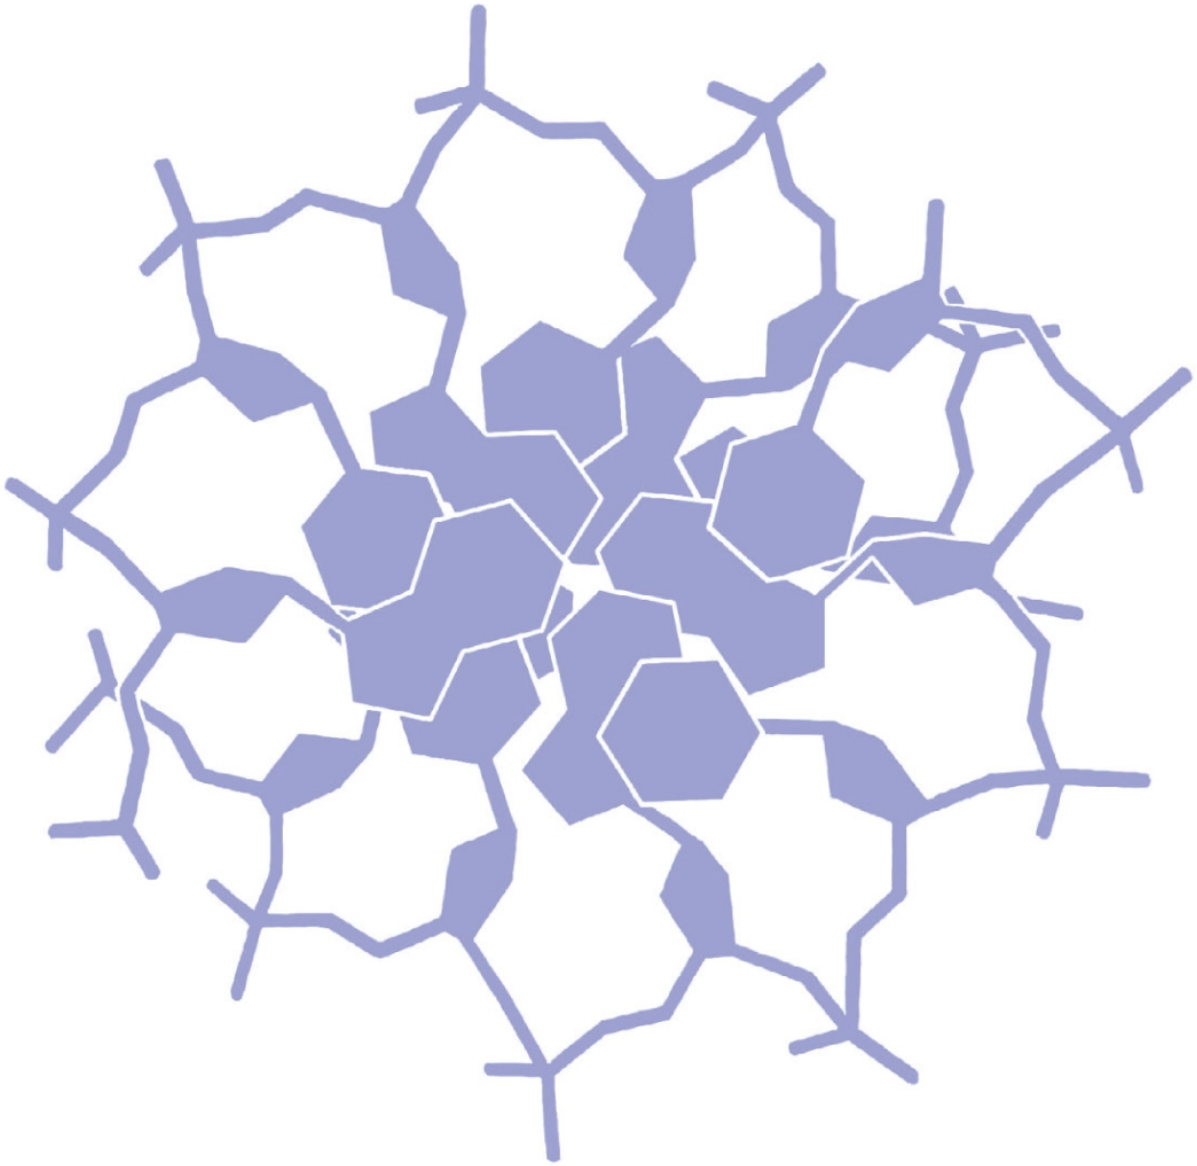
Alternative Text

When an image provides important pedagogical information, alternative text (which is also known as alt text) is provided for the image. This text is not visible on the page but can be accessed and read with screen reader technology and other assistive technologies. Our alt text is written and reviewed by subject matter experts.

Color Contrast

All of our book designs and illustrations are checked to ensure that they meet contrast requirements for WCAG 2.0 AA. Meeting these standards ensures ease of use for users with low vision and color

blindness, and can create a more supportive learning environment for users with learning disabilities.



Navigation

E-book navigation is designed to make it easy for users, with or without assistive technology, to discover and learn from content within the textbook. Text reflows when resized so there is no horizontal scrolling on the page, and page numbers are embedded in the book so that students can always find where they are compared to classmates using the print equivalent. Heading structures are clearly marked up so it's easy to see where you are within the book as you work your way through.

Accessibility Help

If you have any questions about the accessibility of this e-book or other Macmillan Learning e-books, please reach out to us at webaccessibility@macmillan.com. For student resources, visit our knowledge base.

In 1946, William Freeman founded W. H. Freeman and Company and published Linus Pauling's *General Chemistry*, which revolutionized the chemistry curriculum and established the prototype for a Freeman text. W. H. Freeman quickly became a publishing house where leading researchers can make significant contributions to mathematics and science. In

1996, W. H. Freeman joined Macmillan and we have since proudly continued the legacy of providing revolutionary, quality educational tools for teaching and learning in STEM.

To our teachers and our students,

including our late coauthor John Tymoczko,

whose devotion to his students was an inspiration

Brief Contents

1 Biochemistry in Space and Time
2 Protein Composition and Structure
3 Binding and Molecular Recognition
4 Protein Methods
5 Enzymes: Core Concepts and Kinetics
6 Enzyme Catalytic Strategies
7 Enzyme Regulatory Strategies
8 DNA, RNA, and the Flow of Genetic Information
9 Nucleic Acid Methods
10 Exploring Evolution and Bioinformatics
11 Carbohydrates and Glycoproteins
12 Lipids and Biological Membranes
13 Membrane Channels and Pumps
14 Signal-Transduction Pathways
15 Metabolism: Basic Concepts and Themes
16 Glycolysis and Gluconeogenesis
17 Pyruvate Dehydrogenase and the Citric Acid Cycle
18 Oxidative Phosphorylation
19 Phototrophy and the Light Reactions of Photosynthesis
20 The Calvin–Benson Cycle and the Pentose Phosphate Pathway
21 Glycogen Metabolism
22 Fatty Acid and Triacylglycerol Metabolism
23 Protein Turnover and Amino Acid Catabolism
24 Integration of Energy Metabolism
25 Biosynthesis of Amino Acids
26 Nucleotide Biosynthesis
27 Biosynthesis of Membrane Lipids and Steroids
28 DNA Replication, Repair, and Recombination
29 RNA Functions, Biosynthesis, and Processing
30 Protein Biosynthesis

31 Control of Gene Expression
32 Principles of Drug Discovery and Development

PREFACE
ACKNOWLEDGMENTS
ABOUT THE AUTHORS
CHAPTER 1
Biochemistry in Space and Time
- **1.1 Biochemical Unity Underlies Biological Diversity**
- **1.2 DNA Illustrates the Interplay Between Form and Function**
  - DNA is constructed from four building blocks
  - Two single strands of DNA combine to form a double helix
  - DNA structure explains heredity and the storage of information
- **1.3 Concepts from Chemistry Explain the Properties of Biological Molecules**
  - The formation of the DNA double helix is a key example
  - The double helix can form from its component strands
  - Atoms and molecules undergo random motions that help define the timescales for biochemical interactions
  - Covalent bonds and noncovalent interactions are important for the structure and stability of biological molecules
  - The formation of DNA's double helix is an expression of the rules of chemistry
  - The laws of thermodynamics govern the behavior of biochemical systems
  - By releasing heat, the formation of the double helix obeys the Second Law of Thermodynamics

Double-helix formation can be monitored one molecule at a time
Acid–base reactions are central in many biochemical processes
Acid–base reactions can disrupt the double helix
Buffers regulate pH in organisms and in the laboratory
EXAMPLE Applying the Henderson–Hasselbalch Equation
1.4 DNA Sequencing Is Transforming Biochemistry, Medicine, and Other Fields
Genome sequencing has become remarkably fast and inexpensive
Characterization of genetic variation between individuals is powerful for many applications
The most important function of genomic sequences is to encode proteins
Comparing genomes offers great insights into evolution
1.5 Biochemistry Is an Interconnected Human Endeavor
CHAPTER 2
Protein Composition and Structure
2.1 Several Properties of Protein Structure Are Key to Their Functional Versatility
2.2 Proteins Are Built from a Repertoire of 20 Amino Acids
The diversity of amino acids arises from the different side chains
Biochemists postulate several reasons why this set of amino acids is conserved across all species
2.3 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains
Proteins have unique amino acid sequences specified by genes
Polypeptide chains are flexible yet conformationally restricted

2.4 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures

The alpha helix is a coiled structure stabilized by intrachain hydrogen bonds
SCIENTIST PROFILE Herman Branson
Beta sheets are stabilized by hydrogen bonding between polypeptide strands
Polypeptide chains can change direction by making reverse turns and loops

2.5 Tertiary Structure: Proteins Can Fold into Globular or Fibrous Structures

Globular proteins form tightly packed structures
Fibrous proteins form extended structures that provide support for cells and tissues

2.6 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures

2.7 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

Amino acids have different propensities for forming α helices, β sheets, and turns
Protein folding is a highly cooperative process
Proteins fold by progressive stabilization of intermediates rather than by random search
Prediction of three-dimensional structure from sequence remains a great challenge

 Protein misfolding and aggregation are associated with some neurological diseases
Posttranslational modifications confer new capabilities to proteins

CHAPTER 3
Binding and Molecular Recognition

3.1 Binding Is a Fundamental Process in Biochemistry

Binding depends on the concentrations of the binding partners
Proteins can selectively bind certain small molecules
Binding is a dynamic process involving association and dissociation

3.2 Myoglobin Binds and Stores Oxygen

More myoglobin binds oxygen as the oxygen partial pressure is increased
A bond is formed between oxygen and iron in heme
The structure of myoglobin prevents the release of reactive oxygen species
Compared with model compounds, myoglobin discriminates between oxygen and carbon monoxide

3.3 Hemoglobin Is an Efficient Oxygen Carrier

Human hemoglobin is an assembly of four myoglobin-like subunits
Hemoglobin binds oxygen cooperatively
Oxygen binding markedly changes the quaternary structure of hemoglobin
Hemoglobin cooperativity can be potentially explained by several models
Structural changes at the heme groups are transmitted to the $\alpha_1\beta_1-\alpha_2\beta_2$ interface
2,3-Bisphosphoglycerate in red blood cells is crucial in determining the oxygen affinity of hemoglobin
Hydrogen ions and carbon dioxide promote the release of oxygen
Mutations in genes encoding hemoglobin subunits can result in disease

3.4 The Immune System Depends on Key Binding Proteins

The innate immune system recognizes molecules characteristic of pathogens

Antibodies bind specific molecules through specific hypervariable loops
Antibodies possess distinct antigen-binding and effector units
Recombination events equip the adaptive immune system with millions of unique antibodies
Major-histocompatibility-complex proteins present peptide antigens on cell surfaces for recognition by T-cell receptors
3.5 Quantitative Terms Can Describe Binding Propensity
Dissociation constants are useful in describing binding reactions quantitatively
SCIENTIST PROFILE Pamela Bjorkman
EXAMPLE Determining the Fraction of Bound Receptors
Specificity can be quantified by comparing dissociation constants
Kinetic parameters can also describe binding processes
CHAPTER 4
Protein Methods
4.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function
The assay: How do we recognize the protein we are looking for?
Proteins must be released from the cell to be purified
Proteins can be purified according to solubility, size, charge, and binding affinity
Proteins can be separated by gel electrophoresis and displayed
A protein purification scheme can be quantitatively evaluated
EXAMPLE Calculating the Effectiveness of Protein Purification
Ultracentrifugation is valuable for separating biomolecules and determining their masses

Recombinant DNA technology can make protein purification easier
4.2 Immunology Provides Important Techniques for Investigating Proteins
Antibodies to specific proteins can be generated
Monoclonal antibodies with virtually any desired specificity can be readily prepared
Proteins can be detected and quantified by using an enzyme-linked immunosorbent assay
Western blotting permits the detection of proteins separated by gel electrophoresis
Co-immunoprecipitation enables the identification of binding partners of a protein
Fluorescent markers make the visualization of proteins in the cell possible
4.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins
Peptides can be sequenced by mass spectrometry
Proteins can be specifically cleaved into small peptides to facilitate analysis
Genomic and proteomic methods are complementary approaches to deducing protein structure and function
The amino acid sequence of a protein provides valuable information
Individual proteins can be identified by mass spectrometry
The proteome is the functional representation of the genome
4.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods
4.5 Three-Dimensional Protein Structures Can Be Determined Experimentally
X-ray crystallography reveals three-dimensional structure in atomic detail

SCIENTIST PROFILE Rosalind Franklin
Nuclear magnetic resonance spectroscopy can reveal the structures of proteins in solution
Cryo-electron microscopy can be used to determine the structures of large proteins and macromolecular complexes
CHAPTER 5
Enzymes: Core Concepts and Kinetics
5.1 Enzymes Are Powerful and Highly Specific Catalysts
Most enzymes are classified by the types of reactions they catalyze
Many enzymes require cofactors for activity
Enzymes can transform energy from one form into another
5.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes
The free-energy change provides information about the spontaneity but not the rate of a reaction
The standard free-energy change of a reaction is related to the equilibrium constant
EXAMPLE Calculating and Comparing $\Delta G^{\circ\prime}$ and ΔG
Enzymes alter only the reaction rate and not the reaction equilibrium
5.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State
The formation of an enzyme–substrate complex is the first step in enzymatic catalysis
The active sites of enzymes have some common features
The binding energy between enzyme and substrate is important for catalysis
Because the transition state collapses randomly, the activation energies determine the accumulation of either product or substrate

5.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes

- Kinetics is the study of reaction rates
- The steady-state assumption aids a description of enzyme kinetics
- The Michaelis–Menten model explains many observations of enzyme kinetics
- The Michaelis–Menten equation describes the relationship between initial velocity and substrate concentration
- **SCIENTIST PROFILE** Maud Menten
- **EXAMPLE** Applying the Michaelis–Menten Equation
-  Variations in K_M can have physiological consequences
- K_M and V_{max} values can be determined by several means
- K_M and k_{cat} values are important enzyme characteristics
- k_{cat}/K_M is a measure of catalytic efficiency
- Most biochemical reactions include multiple substrates
- Allosteric enzymes often do not obey Michaelis–Menten kinetics
- Temperature affects enzymatic activity

5.5 Enzymes Can Be Studied One Molecule at a Time

- Single-molecule kinetics confirm results obtained from ensemble studies
- Single-molecule studies continue to reveal new information about enzyme molecular dynamics

5.6 Enzymes Can Be Inhibited by Specific Molecules

- The different types of reversible inhibitors are kinetically distinguishable
- Transition-state analogs are potent competitive inhibitors
- Irreversible inhibitors can be used to map the active site

EXAMPLE Determining Inhibitor Type from Data

 Penicillin irreversibly inactivates a key enzyme in bacterial cell-wall synthesis

CHAPTER 6

Enzyme Catalytic Strategies

6.1 Enzymes Use a Core Set of Catalytic Strategies

6.2 Proteases Facilitate a Fundamentally Difficult Reaction

Chymotrypsin possesses a highly reactive serine residue

Chymotrypsin action proceeds in two steps linked by a covalently bound intermediate

Serine is part of a catalytic triad that also includes histidine and aspartate

Catalytic triads are found in other hydrolytic enzymes

Scientists have dissected the catalytic triad using site-directed mutagenesis

Some proteases cleave peptides at other locations besides serine residues

 Protease inhibitors are important drugs

6.3 Carbonic Anhydrases Make a Fast Reaction Faster

Carbonic anhydrase contains a bound zinc ion essential for catalytic activity

Catalysis involves zinc activation of a water molecule

Rapid regeneration of the active form of carbonic anhydrase depends on proton availability

6.4 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions

Cleavage is by direct displacement of 3′-oxygen from phosphorus by magnesium-activated water

Restriction enzymes require magnesium for catalytic activity

The complete catalytic apparatus is assembled only within complexes of cognate DNA molecules, ensuring specificity
Host-cell DNA is protected by the addition of methyl groups to specific bases
6.5 Molecular Motor Proteins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work
ATP hydrolysis proceeds by the attack of water on the gamma phosphoryl group
Formation of the transition state for ATP hydrolysis is associated with a substantial conformational change
The altered conformation of myosin persists for a substantial period of time
Actin forms filaments along which myosin can move
CHAPTER 7
Enzyme Regulatory Strategies
7.1 Allosteric Regulation Enables Control of Metabolic Pathways
Many allosterically regulated enzymes do not follow Michaelis–Menten kinetics
ATCase consists of separable catalytic and regulatory subunits
Allosteric interactions in ATCase are mediated by large changes in quaternary structure
Allosteric regulators modulate the T-to-R equilibrium
7.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages
7.3 Covalent Modification Is a Means of Regulating Enzyme Activity
Kinases and phosphatases control the extent of protein phosphorylation
Phosphorylation is a highly effective means of regulating the activities of target proteins

Cyclic AMP activates protein kinase A by altering the quaternary structure
Mutations in protein kinase A can cause Cushing's syndrome
The phosphorylation states of the proteome can be measured
7.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage
Chymotrypsinogen is activated by specific cleavage of a single peptide bond
Proteolytic activation of chymotrypsinogen leads to the formation of a substrate-binding site
The generation of trypsin from trypsinogen leads to the activation of other zymogens
Some proteolytic enzymes have specific inhibitors
7.5 Enzymatic Cascades Allow Rapid Responses Such as Blood Clotting
Prothrombin must bind to Ca^{2+} to be converted to thrombin
Fibrinogen is converted by thrombin into a fibrin clot
Vitamin K is required for the formation of γ-carboxyglutamate
The clotting process must be precisely regulated
CHAPTER 8
DNA, RNA, and the Flow of Genetic Information
8.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar–Phosphate Backbone
RNA and DNA differ in the sugar component and one of the bases
Nucleotides are the monomeric units of nucleic acids
DNA molecules are very long and have directionality

8.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure
- The double helix is stabilized by hydrogen bonds and van der Waals interactions
- DNA can assume a variety of structural forms
- The major and minor grooves are lined by sequence-specific hydrogen-bonding groups
- Some DNA molecules are circular and supercoiled
- Single-stranded nucleic acids can adopt elaborate structures

8.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information
- Differences in DNA density established the validity of the semiconservative replication hypothesis
- The double helix can be reversibly melted

8.4 DNA Is Replicated by Polymerases That Take Instructions from Templates
- DNA polymerase catalyzes phosphodiester-bridge formation
- The genes of some viruses are made of RNA

8.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules
- Several kinds of RNA play key roles in gene expression
- All cellular RNA is synthesized by RNA polymerases
- RNA polymerases take instructions from DNA templates
- Transcription begins near promoter sites and ends at terminator sites
- Transfer RNAs are the adaptor molecules in protein synthesis

8.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point
- Major features of the genetic code
- **SCIENTIST PROFILE** Har Gobind Khorana

Messenger RNA contains start and stop signals for protein synthesis
The genetic code is nearly universal
8.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons
RNA processing generates mature RNA
Many exons encode protein domains
CHAPTER 9
Nucleic Acid Methods
9.1 The Exploration of Genes Relies on Key Tools
Restriction enzymes split DNA into specific fragments
Restriction fragments can be separated by gel electrophoresis and visualized
DNA can be sequenced by controlled termination of replication
DNA probes and genes can be synthesized by automated solid-phase methods
Selected DNA sequences can be greatly amplified by the polymerase chain reaction
PCR is a powerful technique in medical diagnostics, forensics, and studies of molecular evolution

The tools for recombinant DNA technology have been used to identify disease-causing mutations
9.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology
Restriction enzymes and DNA ligase are key tools in forming recombinant DNA molecules
Plasmids and λ phage are choice vectors for DNA cloning in bacteria
Specific genes can be cloned from digests of genomic DNA
Complementary DNA prepared from mRNA can be expressed in host cells

Proteins with new functions can be created through directed changes in DNA
9.3 Complete Genomes Have Been Sequenced and Analyzed
The genomes of organisms ranging from bacteria to multicellular eukaryotes have been sequenced
The sequence of the human genome has been completed
Next-generation sequencing methods enable the rapid determination of a complete genome sequence
Comparative genomics is a powerful research tool
9.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision
Gene-expression levels can be comprehensively examined
New genes inserted into eukaryotic cells can be efficiently expressed
Transgenic animals harbor and express genes introduced into their germ lines
Gene disruption and genome editing provide clues to gene function and opportunities for new therapies
RNA interference enables disruption of gene expression and presents new therapeutic opportunities
SCIENTIST PROFILE Emmanuelle Charpentier and Jennifer Doudna
Foreign DNA can be introduced into plants
CHAPTER 10
Exploring Evolution and Bioinformatics
10.1 Homologs Are Descended from a Common Ancestor and Can Be Detected by Sequence Alignments
Orthologs and paralogs are two different classes of homologous proteins
Statistical analysis of sequence alignments can detect homology

The statistical significance of alignments can be estimated by shuffling
Distant evolutionary relationships can be detected through the use of substitution matrices
Databases can be searched to identify homologous sequences
10.2 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships
Tertiary structure is more conserved than primary structure
Knowledge of three-dimensional structures can aid in the evaluation of sequence alignments
Repeated motifs can be detected by aligning sequences with themselves
Convergent evolution illustrates common solutions to biochemical challenges
Comparison of RNA sequences can be a source of insight into RNA secondary structures
EXAMPLE Interpreting an RNA Alignment
10.3 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information
Evolutionary trees can be calibrated using fossil record data
Horizontal gene transfer events may explain unexpected branches of the evolutionary tree
SCIENTIST PROFILE Russell Doolittle
10.4 Modern Techniques Make the Experimental Exploration of Evolution Possible
Ancient DNA can sometimes be amplified and sequenced
Molecular evolution can be examined experimentally
CHAPTER 11
Carbohydrates and Glycoproteins

11.1 Monosaccharides Are the Simplest Carbohydrates

There are many monosaccharides but they are structurally similar
Most monosaccharides exist as interchanging cyclic forms
Pyranose and furanose rings can assume different conformations
D-Glucose is an important fuel for most organisms
Glucose is a reducing sugar and reacts nonenzymatically with hemoglobin
Monosaccharides are joined to alcohols and amines through glycosidic linkages by specific enzymes
Phosphorylated sugars are key intermediates in metabolism

11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

Sucrose, lactose, and maltose are common disaccharides
 Maltase inhibitors can help to maintain blood glucose homeostasis
 Human milk oligosaccharides protect newborns from infection
Glycogen and starch are storage polysaccharides of glucose
Cellulose is the main structural polysaccharide of plants
Chitin is the main structural polysaccharide of fungi and arthropods
Chitin can be processed to a molecule with a variety of uses

11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins

Carbohydrates can be linked to proteins through asparagine (*N*-linked) or through serine or threonine (*O*-

linked) residues
 The glycoprotein erythropoietin is a vital hormone
Glycosylation functions in nutrient sensing
Proteoglycans have important structural roles
Proteoglycans are important components of cartilage
Mucins are glycoprotein components of mucus
Protein glycosylation takes place in the lumen of the endoplasmic reticulum and in the Golgi complex
Specific enzymes are responsible for oligosaccharide assembly
Blood groups are based on protein glycosylation patterns
 Errors in glycosylation can result in pathological conditions
Biochemists use several techniques to analyze the oligosaccharide components of glycoproteins
11.4 Lectins Are Specific Carbohydrate-Binding Proteins
Lectins promote interactions between cells and within cells
Lectins are organized into two large classes
Influenza virus binds to sialic acid residues
SCIENTIST PROFILE Carolyn Bertozzi
CHAPTER 12
Lipids and Biological Membranes
12.1 Fatty Acids Are Key Constituents of Lipids
Fatty acid names are based on their parent hydrocarbons
Chain length and degree of unsaturation affect fatty acid properties
12.2 Biological Membranes Are Composed of Three Common Types of Membrane Lipids
Phospholipids are the major class of membrane lipids
Glycolipids include carbohydrate moieties

Cholesterol is a lipid based on a steroid nucleus
SCIENTIST PROFILE Marie M. Daly
Archaeal membranes are built from ether lipids with branched chains
A membrane lipid is an amphipathic molecule containing a hydrophilic and a hydrophobic moiety
12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media
Lipid vesicles can be formed from phospholipids
Lipid bilayers are highly impermeable to ions and most polar molecules
12.4 Proteins Carry Out Most Membrane Processes
Proteins associate with the lipid bilayer in a variety of ways
Proteins interact with membranes in a variety of ways
Some proteins associate with membranes through covalently attached hydrophobic groups
Transmembrane helices can be accurately predicted from amino acid sequences
12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane
The fluid mosaic model allows lateral movement but not rotation through the membrane
Membrane fluidity is controlled by fatty acid composition and cholesterol content
Lipid rafts are highly dynamic complexes formed between cholesterol and specific lipids
All biological membranes are asymmetric
12.6 Prokaryotes and Eukaryotes Differ in Their Use of Biological Membranes
Eukaryotic cells contain compartments bounded by internal membranes
Membrane budding and fusion are highly controlled processes

CHAPTER 13
Membrane Channels and Pumps
13.1 The Transport of Molecules Across a Membrane May Be Active or Passive
Many molecules require protein transporters to cross membranes
Free energy stored in concentration gradients can be quantified
EXAMPLE Calculating the Energetic Cost of Ion Transport
13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Actively Transport Ions and Molecules Across Membranes
P-type ATPases couple phosphorylation and conformational changes to pump calcium ions across membranes
Digoxin specifically inhibits the Na^+-K^+ pump by blocking its dephosphorylation
P-type ATPases are evolutionarily conserved and play a wide range of roles
Multidrug resistance highlights a family of membrane pumps with ATP-binding cassette domains
13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another
13.4 Specific Channels Can Rapidly Transport Ions Across Membranes
Action potentials are mediated by transient changes in Na^+ and K^+ permeability
Patch-clamp conductance measurements reveal the activities of single channels

The structure of a potassium ion channel is an archetype for many ion-channel structures
SCIENTIST PROFILE Baldomero Olivera
The structure of the potassium ion channel reveals the basis of ion specificity
The structure of the potassium ion channel explains its rapid rate of transport
Voltage gating requires substantial conformational changes in specific ion-channel domains
A channel can be inactivated by occlusion of the pore: the ball-and-chain model
The acetylcholine receptor is an archetype for ligand-gated ion channels
Action potentials integrate the activities of several ion channels working in concert
EXAMPLE Calculating Equilibrium Potentials
Disruption of ion channels by mutations or chemicals can be potentially life-threatening
Hyperpolarization-activated ion channels enable pacemaker activity in the heart
13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells
13.6 Specific Channels Increase the Permeability of Some Membranes to Water
CHAPTER 14
Signal-Transduction Pathways
14.1 Many Signal-Transduction Pathways Share Common Themes
Signal transduction depends on molecular circuits
14.2 Epinephrine Signaling: Heterotrimeric G Proteins Transmit Signals and Reset Themselves
Ligand binding to 7TM receptors leads to the activation of heterotrimeric G proteins

Activated G proteins transmit signals by binding to other proteins
Cyclic AMP stimulates the phosphorylation of many target proteins by activating protein kinase A
G proteins spontaneously reset themselves through GTP hydrolysis
Some 7TM receptors activate the phosphoinositide cascade
Calcium ion is a widely used second messenger
Calcium ion often activates the regulatory protein calmodulin
Some receptors signal through G proteins that inhibit rather than stimulate adenylate cyclase
G-protein βγ-dimers can also directly participate in signaling
7TM receptors trigger signaling through G proteins in many other cell types
SCIENTIST PROFILE Eva Neer
14.3 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes
The insulin receptor is a protein kinase that is autoinhibited prior to insulin binding
Insulin binding results in the cross-phosphorylation and activation of the insulin receptor
The activated insulin-receptor kinase initiates a kinase cascade
Insulin signaling is terminated by the action of phosphatases
14.4 Epidermal Growth Factor: Receptor Dimerization Can Drive Signaling
The EGF receptor undergoes phosphorylation of its carboxyl-terminal tail
EGF signaling leads to the activation of Ras, a small G protein

Activated Ras initiates a protein kinase cascade
EGF signaling is terminated by protein phosphatases and the intrinsic GTPase activity of Ras

 **14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases**

Monoclonal antibodies can be used to inhibit signal-transduction pathways activated in tumors
Protein kinase inhibitors can be effective anticancer drugs

14.6 Sensory Systems Are Based on Specialized Signal-Transduction Pathways

A huge family of 7TM receptors detect a wide variety of organic compounds
Vision relies on a specialized 7TM receptor to signal in response to absorbed light
Light absorption induces a specific isomerization of bound 11-*cis*-retinal
Color vision is mediated by three cone receptors that are homologs of rhodopsin
Hearing depends on hair cells that use mechanosensitive ion channels to detect tiny motions
Comparison of different organisms yields insights into sensory system evolution

CHAPTER 15
Metabolism: Basic Concepts and Themes

15.1 Metabolism Is Composed of Many Interconnected Reactions

Metabolism consists of destructive and constructive reactions that typically yield or require energy
A thermodynamically unfavorable reaction can be driven by a favorable reaction

15.2 ATP Is the Universal Currency of Free Energy in Biological Systems

ATP hydrolysis is exergonic
ATP hydrolysis drives metabolism by shifting the equilibrium of coupled reactions
The high phosphoryl potential of ATP results from structural differences between ATP and its hydrolysis products
Phosphoryl-transfer potential is an important form of cellular energy transformation
EXAMPLE Calculating ΔG for a Coupled Reaction Under Real Conditions
15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy
Compounds with high phosphoryl-transfer potential can couple carbon oxidation to ATP synthesis
Ion gradients across membranes provide an important form of cellular energy that can be coupled to ATP synthesis
Phosphates play a prominent role in biochemical processes
Energy from food is extracted in three stages
15.4 Metabolic Pathways Contain Many Recurring Motifs
Activated carriers exemplify the modular structure and economy of metabolism
Many activated carriers are derived from vitamins
Key reactions are reiterated throughout metabolism
Metabolic processes are regulated in three principal ways
CHAPTER 16
Glycolysis and Gluconeogenesis
16.1 Glycolysis Is an Energy-Conversion Pathway in Most Organisms
Glucose is generated from dietary carbohydrates
A family of transporters enables glucose to enter and leave animal cells

16.2 Glycolysis Can Be Divided into Two Parts

- Stage 1 begins: Hexokinase traps glucose in the cell and begins glycolysis
- Fructose 1,6-bisphosphate is generated from glucose 6-phosphate
- The six-carbon sugar is cleaved into two three-carbon fragments
- Mechanism: Triose phosphate isomerase salvages a three-carbon fragment
- Stage 2 begins: The oxidation of an aldehyde powers the formation of a compound with high phosphoryl-transfer potential
- Mechanism: Phosphorylation is coupled to the oxidation of glyceraldehyde 3-phosphate by a thioester intermediate
- ATP is formed by phosphoryl transfer from 1,3-bisphosphoglycerate
- Additional ATP is generated with the formation of pyruvate
- Two ATP molecules are formed in the conversion of glucose into pyruvate
- NAD^+ is regenerated from the metabolism of pyruvate
- Fermentations provide usable energy in the absence of oxygen
- Fructose is converted into glycolytic intermediates by fructokinase
- Galactose is converted into glucose 6-phosphate
- Galactose can be highly toxic with a defective metabolic pathway
- Many adults worldwide are intolerant of milk because they are deficient in lactase

16.3 The Glycolytic Pathway Is Tightly Controlled

Glycolysis in muscle is regulated to meet the need for ATP
The regulation of glycolysis in the liver illustrates the biochemical versatility of the liver
The enzymes of glycolysis are physically associated with one another
 Aerobic glycolysis is a property of tumor cells and other rapidly growing cells
 Cancer and endurance training affect glycolysis in a similar fashion
16.4 Glucose Can Be Synthesized from Noncarbohydrate Precursors
Gluconeogenesis is not a reversal of glycolysis
The conversion of pyruvate into phosphoenolpyruvate begins with the formation of oxaloacetate
Oxaloacetate is shuttled into the cytoplasm and converted into phosphoenolpyruvate
The conversion of fructose 1,6-bisphosphate into fructose 6-phosphate and orthophosphate is an irreversible step
The generation of free glucose occurs only in some tissues and is an important control point
Six high-transfer-potential phosphoryl groups are spent in synthesizing glucose from pyruvate
16.5 Gluconeogenesis and Glycolysis Are Reciprocally Regulated
Glycolysis and gluconeogenesis are regulated by adenosine nucleotides and other metabolic intermediates
In mammals, glycolysis and gluconeogenesis in the liver are controlled by hormones sensitive to blood-glucose concentration

Substrate cycles amplify metabolic signals and produce heat
Lactate and alanine formed by contracting muscle and peripheral tissues are used by other organs
 Deficiencies in glycolytic or gluconeogenic enzymes are rare genetic disorders
SCIENTIST PROFILE Gerty Cori
Glycolysis and gluconeogenesis are evolutionarily intertwined
CHAPTER 17
Pyruvate Dehydrogenase and the Citric Acid Cycle
17.1 The Citric Acid Cycle Harvests High-Energy Electrons
17.2 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle
Mechanism: The synthesis of acetyl coenzyme A from pyruvate requires three enzymes and five coenzymes
Flexible linkages allow lipoamide to move between different active sites
17.3 The Citric Acid Cycle Oxidizes Two-Carbon Units
Citrate synthase forms citrate from oxaloacetate and the acetyl group from acetyl coenzyme A
Mechanism: The mechanism of citrate synthase prevents undesirable reactions
Citrate is isomerized into isocitrate
Isocitrate is oxidized and decarboxylated to alpha-ketoglutarate
Succinyl coenzyme A is formed by the oxidative decarboxylation of alpha-ketoglutarate
A compound with high phosphoryl-transfer potential is generated from succinyl coenzyme A
Mechanism: Succinyl coenzyme A synthetase transforms types of biochemical energy

Oxaloacetate is regenerated by the oxidation of succinate
SCIENTIST PROFILE Hans Krebs
The citric acid cycle produces high-transfer-potential electrons, ATP, and CO_2
17.4 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled
The pyruvate dehydrogenase complex is regulated allosterically and by reversible phosphorylation
 Diabetic neuropathy may be due to inhibition of the pyruvate dehydrogenase complex
The citric acid cycle is regulated at several points
17.5 The Citric Acid Cycle Is a Source of Biosynthetic Precursors
The citric acid cycle must be capable of being rapidly replenished
 The disruption of pyruvate metabolism is the cause of beriberi and poisoning by mercury and arsenic
The citric acid cycle likely evolved from preexisting pathways
17.6 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate
 Blocking the glyoxylate cycle may lead to new treatments for tuberculosis
CHAPTER 18
Oxidative Phosphorylation
18.1 Cellular Respiration Drives ATP Formation by Transferring Electrons to Molecular Oxygen
Eukaryotic oxidative phosphorylation takes place in mitochondria

Mitochondria are the result of an endosymbiotic event
SCIENTIST PROFILE Lynn Margulis
18.2 Oxidative Phosphorylation Depends on Electron Transfer
The electron-transfer potential of an electron is measured as redox potential
EXAMPLE Calculating the Standard Free Energy of a Reaction from Reduction Potentials
Electron flow from NADH to molecular oxygen powers the formation of a proton gradient
18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle
Iron–sulfur clusters are common components of the electron-transport chain
The high-potential energy electrons of NADH enter the respiratory chain at NADH-Q oxidoreductase
Ubiquinol is the entry point for electrons from $FADH_2$ of flavoproteins
Electrons flow from ubiquinol to cytochrome *c* through Q-cytochrome *c* oxidoreductase
The Q cycle funnels electrons from a two-electron carrier to a one-electron carrier while pumping protons
Cytochrome *c* oxidase catalyzes the reduction of molecular oxygen to water
Most of the electron-transport chain is organized into a larger complex called the respirasome
Toxic derivatives of molecular oxygen such as superoxide radicals are scavenged by protective enzymes
Electrons can be transferred between groups that are not in contact
18.4 A Proton Gradient Powers the Synthesis of ATP

The chemiosmotic hypothesis suggested that ATP formation is powered by a proton gradient
ATP synthase is composed of a proton-conducting unit and a catalytic unit
Proton flow through ATP synthase leads to the release of tightly bound ATP via the binding-change mechanism
Rotational catalysis is the world's smallest molecular motor
Proton flow around the c ring powers ATP synthesis
ATP synthase and G proteins have several common features

18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes

Electrons from cytoplasmic NADH enter mitochondria by shuttles
The entry of ADP into mitochondria is coupled to the exit of ATP by ATP-ADP translocase

18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

The complete oxidation of glucose yields about 30 molecules of ATP
The rate of oxidative phosphorylation is determined by the need for ATP
ATP synthase can be regulated
Regulated uncoupling leads to the generation of heat
Reintroduction of UCP-1 into pigs may be economically valuable
Oxidative phosphorylation can be inhibited at many stages
 New mitochondrial diseases are constantly being discovered
Mitochondria play a key role in apoptosis

18.7 Proton Gradients Generated by Respiratory Chains Drive Many Biochemical Processes

Proton flow through a rotary motor allows bacteria to swim

Power transmission by proton gradients is a central motif of bioenergetics

CHAPTER 19

Phototrophy and the Light Reactions of Photosynthesis

19.1 Phototrophy Converts Light Energy into Chemical Energy

Photosynthesis comprises light reactions and dark reactions

The same biochemical principles govern both respiration and photosynthesis

Two kinds of light reactions take place in the green plants

19.2 In Eukaryotes, Photosynthesis Takes Place in Chloroplasts

The primary events of photosynthesis take place in thylakoid membranes

Chloroplasts arose from an endosymbiotic event

19.3 Light Absorption by Chlorophyll Molecules Induces Electron Transfer

Transferring electrons allows energy to be captured instead of lost as heat

A “special pair” of chlorophylls initiate charge separation

A proton gradient across the membrane is established

Cyclic electron flow reduces the cytochrome of the reaction center

19.4 Two Photosystems Generate a Proton Gradient and Reducing Power in Cyanobacteria and Photosynthetic Eukaryotes

Photosystem II transfers electrons from water to plastoquinone and generates a proton gradient
Photosystem II is comparable to the purple bacterial reaction center
Cytochrome *bf* links photosystem II to photosystem I
Photosystem I uses light energy to generate reduced ferredoxin, a powerful reductant
Ferredoxin–$NADP^+$ reductase converts $NADP^+$ into NADPH
SCIENTIST PROFILE Peter Mitchell and André Jagendorf
19.5 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis
The ATP synthase of chloroplasts closely resembles those of mitochondria and prokaryotes
The activity of chloroplast ATP synthase is regulated
Cyclic electron flow through photosystem I leads to the production of ATP instead of NADPH
The absorption of eight photons yields one O_2, two NADPH, and three ATP molecules
19.6 Accessory Pigments Funnel Energy into Reaction Centers
Resonance energy transfer allows energy to move from the site of initial absorbance to the reaction center
Accessory pigments also protect plants from reactive oxygen
Increasing the efficiency of photosynthesis will increase crop yields
The components of photosynthesis are highly organized
Many herbicides inhibit the light reactions of photosynthesis
19.7 The Ability to Convert Light into Chemical Energy Is Ancient

Artificial photosynthetic systems may provide clean, renewable energy
 Photosensitive proteins are transforming other fields
CHAPTER 20
The Calvin–Benson Cycle and the Pentose Phosphate Pathway
20.1 The Calvin–Benson Cycle Synthesizes Hexoses from Carbon Dioxide and Water
Stage 1: Carbon dioxide reacts with ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate
SCIENTIST PROFILE Andrew Benson
Rubisco activity depends on magnesium and carbamate
Rubisco also catalyzes a wasteful oxygenase reaction
Stage 2: Hexose phosphates are made from phosphoglycerate
Stage 3: Ribulose 1,5-bisphosphate is regenerated
18 ATP and 12 NADPH molecules are used to bring six carbon dioxides to the level of a hexose
Starch and sucrose are the major carbohydrate stores in plants
Inspired by the Calvin–Benson cycle, scientists are developing new methods for fixing carbon dioxide
20.2 The Activity of the Calvin–Benson Cycle Depends on Environmental Conditions
Rubisco is activated by light-driven changes in proton and magnesium ion concentrations
Thioredoxin plays a key role in regulating the Calvin–Benson cycle
The C_4 pathway of tropical plants and grasses accelerates photosynthesis by concentrating carbon dioxide

Crassulacean acid metabolism permits growth in arid ecosystems
20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Pentoses
Two molecules of NADPH are generated in the conversion of glucose 6-phosphate into ribulose 5-phosphate
The pentose phosphate pathway and glycolysis are linked by transketolase and transaldolase
Transketolase and transaldolase stabilize carbanionic intermediates by different mechanisms
20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis
The rate of the oxidative phase of the pentose phosphate pathway is controlled by the level of $NADP^+$
The flow of glucose 6-phosphate depends on the need for NADPH, ribose 5-phosphate, and ATP
The pentose phosphate pathway is required for rapid cell growth
The Calvin–Benson cycle and the pentose phosphate pathway are essentially mirror images of one another
20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species
 Glucose 6-phosphate dehydrogenase deficiency causes a drug-induced hemolytic anemia
A deficiency of glucose 6-phosphate dehydrogenase can be protective against malaria
CHAPTER 21
Glycogen Metabolism
21.1 Glycogen Metabolism Is the Regulated Release and Storage of Glucose in Multiple Tissues

21.2 Glycogen Breakdown Requires the Interplay of Several Enzymes

- Phosphorylase catalyzes the phosphorolytic cleavage of glycogen to release glucose 1-phosphate
- Mechanism: Pyridoxal phosphate participates in the phosphorolytic cleavage of glycogen
- Debranching enzyme also is needed for the breakdown of glycogen
- Phosphoglucomutase converts glucose 1-phosphate into glucose 6-phosphate
- The liver contains glucose 6-phosphatase, a hydrolytic enzyme absent from muscle

21.3 Phosphorylase Is Regulated by Allosteric Interactions and Controlled by Reversible Phosphorylation

- Liver phosphorylase produces glucose for use by other tissues
- Muscle phosphorylase is regulated by changes in AMP and ATP concentrations
- Biochemical characteristics of muscle fiber types differ
- Phosphorylation promotes the conversion of phosphorylase *b* to phosphorylase *a*
- Phosphorylase kinase is activated by phosphorylation and calcium ions

21.4 Glucagon and Epinephrine Signal the Need for Glycogen Breakdown

- G proteins transmit the signal for the initiation of glycogen breakdown
- Glycogen breakdown must be rapidly turned off when necessary

21.5 Glycogen Synthesis Requires Several Enzymes and Uridine Diphosphate Glucose

- UDP-glucose is an activated form of glucose
- Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to growing chains

A branching enzyme forms α-1,6 linkages
Glycogen synthase is the key regulatory enzyme in glycogen synthesis
Glycogen is an efficient storage form of glucose
21.6 Glycogen Breakdown and Synthesis Are Reciprocally Controlled by Hormones
Protein phosphatase 1 reverses the effects of kinases on glycogen metabolism
Insulin stimulates glycogen synthesis by inactivating glycogen synthase kinase
Glycogen metabolism in the liver regulates the blood-glucose concentration
 Biochemists have uncovered the biochemical basis of multiple glycogen-storage diseases
CHAPTER 22
Fatty Acid and Triacylglycerol Metabolism
22.1 Triacylglycerols Are Highly Concentrated Energy Stores
Dietary lipids are digested by pancreatic lipases
Dietary lipids are transported in chylomicrons
22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing
Mobilization: Triacylglycerols are hydrolyzed by hormone-stimulated lipases
Mobilization continues: Free fatty acids and glycerol are released into the blood
Activation: Fatty acids are linked to coenzyme A before they are oxidized
Transport: Carnitine carries long-chain activated fatty acids into the mitochondrial matrix
Breakdown: Acetyl CoA, NADH, and $FADH_2$ are generated in each round of fatty acid oxidation

The complete oxidation of palmitate yields 106 molecules of ATP
22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation
An isomerase and a reductase are required for the oxidation of unsaturated fatty acids
Odd-chain fatty acids yield propionyl CoA in the final thiolysis step
Vitamin B_{12} contains a corrin ring and a cobalt atom
Mechanism: Methylmalonyl CoA mutase catalyzes a rearrangement to form succinyl CoA
SCIENTIST PROFILE Dorothy Hodgkin
Fatty acids are also oxidized in peroxisomes
Some fatty acids contribute to the development of pathological conditions
22.4 Ketone Bodies Are a Fuel Source Derived from Fats
Ketone bodies are a major fuel in some tissues
Diabetic ketoacidosis is a dangerous pathological condition caused by excessive ketone body formation
Animals cannot convert fatty acids into glucose
22.5 Fatty Acids Are Synthesized by Fatty Acid Synthase
Fatty acid degradation and synthesis mirror each other in their chemical reactions
Fatty acids are synthesized and degraded by different pathways
The formation of malonyl CoA is the committed step in fatty acid synthesis
Intermediates in fatty acid synthesis are attached to an acyl carrier protein
Fatty acid synthesis consists of a series of condensation, reduction, dehydration, and reduction reactions

Fatty acids are synthesized by a multifunctional enzyme complex in animals
The synthesis of palmitate requires 8 molecules of acetyl CoA, 14 molecules of NADPH, and 7 molecules of ATP
Citrate carries acetyl groups from mitochondria to the cytoplasm for fatty acid synthesis
Several sources supply NADPH for fatty acid synthesis
 Fatty acid metabolism is altered in tumor cells
Triacylglycerols may become an important renewable energy source
22.6 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems
Membrane-bound enzymes generate unsaturated fatty acids
Eicosanoid hormones are derived from polyunsaturated fatty acids
22.7 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism
Acetyl CoA carboxylase is regulated by conditions in the cell
Acetyl CoA carboxylase is controlled by a variety of hormones
AMP-activated protein kinase is a key regulator of metabolism
CHAPTER 23
Protein Turnover and Amino Acid Catabolism
23.1 Proteins Are Degraded to Amino Acids
The digestion of dietary proteins begins in the stomach and is completed in the intestine
Cellular proteins are degraded at different rates
23.2 Protein Turnover Is Tightly Regulated
Ubiquitin tags proteins for destruction
The proteasome digests the ubiquitin-tagged proteins

The ubiquitin pathway and the proteasome have prokaryotic counterparts
Protein degradation can be used to regulate biological function
23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen
Alpha-amino groups are converted into ammonium ions by the oxidative deamination of glutamate in the liver
SCIENTIST PROFILE Cecile Pickart
Mechanism: Pyridoxal phosphate forms Schiff-base intermediates in aminotransferases
Aspartate aminotransferase is an archetypal pyridoxal-dependent transaminase
 Blood levels of aminotransferases serve a diagnostic function
Pyridoxal phosphate enzymes catalyze a wide array of reactions
Serine and threonine can be directly deaminated
Peripheral tissues transport nitrogen to the liver
23.4 Ammonium Ions Are Converted into Urea in Most Terrestrial Vertebrates
The urea cycle begins with the formation of carbamoyl phosphate
Carbamoyl phosphate synthetase I is the key regulatory enzyme for urea synthesis
Carbamoyl phosphate reacts with ornithine to begin the urea cycle
The urea cycle is linked to gluconeogenesis
 Inherited defects of the urea cycle cause hyperammonemia and can lead to brain damage
Urea is not the only means of disposing of excess nitrogen

23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates

Pyruvate is an entry point into metabolism for a number of amino acids
Oxaloacetate is an entry point into metabolism for aspartate and asparagine
Alpha-ketoglutarate is an entry point into metabolism for amino acids with five-carbon chains
Succinyl coenzyme A is a point of entry for several amino acids
Methionine degradation requires the formation of a key methyl donor, *S*-adenosylmethionine
Threonine deaminase initiates the degradation of threonine
The branched-chain amino acids yield acetyl CoA, acetoacetate, or propionyl CoA
Oxygenases are required for the degradation of aromatic amino acids
Protein metabolism helps to power the flight of migratory birds
EXAMPLE Determining Metabolic Products of Amino Acid Degradation

23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

Branched-chain ketoaciduria is a serious disorder of branched-chain amino acid degradation
Phenylketonuria is one of the most common metabolic disorders

CHAPTER 24
Integration of Energy Metabolism

24.1 Caloric Homeostasis Is a Means of Regulating Body Weight

The brain plays a key role in caloric homeostasis

Short-term signals from the gastrointestinal tract induce feelings of satiety
Leptin and insulin regulate long-term control over caloric homeostasis
Leptin is one of several hormones secreted by adipose tissue
Leptin resistance may be a contributing factor to obesity
24.2 The Fasted–Fed Cycle Is a Response to Eating and Sleeping Behaviors
The postprandial state follows a meal
The postabsorptive state occurs at the beginning of a fast
The refed state occurs at the end of a long fast
 **24.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity**
Insulin initiates a complex signal-transduction pathway in muscle
Metabolic syndrome often precedes type 2 diabetes
Excess fatty acids in muscle modify metabolism
Insulin resistance in muscle facilitates pancreatic failure
Metabolic alterations in type 1 diabetes result from insulin insufficiency and glucagon excess
24.4 Exercise Beneficially Alters the Biochemistry of Cells
Fuel choice during exercise is determined by the intensity and duration of activity
 The perplexing symptoms of McArdle disease result from the distinct ways skeletal muscle produces ATP
Mitochondrial biogenesis is stimulated by muscular activity
Exercise alters muscle and whole-body metabolism

EXAMPLE Measuring the Impact of a Single Athletic Activity on Caloric Homeostasis
24.5 Starvation Induces Protein Wasting and Ketone Body Formation
The first priority during starvation is the maintenance of blood-glucose concentration
Metabolic adaptations in prolonged starvation minimize protein degradation
24.6 Ethanol Alters Energy Metabolism in the Liver
Ethanol metabolism leads to an excess of NADH
Ethanol metabolites cause liver damage
Excess ethanol consumption disrupts vitamin metabolism
 Ethanol and defects in central energy metabolism contribute to the development of cancer
CHAPTER 25
Biosynthesis of Amino Acids
25.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia
Biological nitrogen fixation is catalyzed by the nitrogenase complex
The iron–molybdenum cofactor of nitrogenase binds and reduces atmospheric nitrogen
Ammonium ion is assimilated into an amino acid through glutamate and glutamine
25.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways
Human beings can synthesize some amino acids but must obtain others from their diet
Aspartate, alanine, and glutamate are formed by the addition of an amino group to an alpha-ketoacid
SCIENTIST PROFILE Beverly Guirard

A common step determines the chirality of all amino acids
The formation of asparagine from aspartate requires an adenylated intermediate
Glutamate is the precursor of glutamine, proline, and arginine
3-Phosphoglycerate is the precursor of serine, cysteine, and glycine
Tetrahydrofolate carries activated one-carbon units at several oxidation levels
S-Adenosylmethionine is the major donor of methyl groups
Cysteine is synthesized from serine and homocysteine
 High homocysteine levels correlate with vascular disease
Shikimate and chorismate are intermediates in the biosynthesis of aromatic amino acids
Tryptophan synthase illustrates substrate channeling in enzymatic catalysis
25.3 Feedback Inhibition Regulates Amino Acid Biosynthesis
Branched pathways require sophisticated regulation
The sensitivity of glutamine synthetase to allosteric regulation is altered by covalent modification
25.4 Amino Acids Are Precursors of Many Biomolecules
Glutathione, a gamma-glutamyl peptide, serves as a sulfhydryl buffer and an antioxidant
Nitric oxide, a short-lived signal molecule, is formed from arginine
Amino acids are precursors for a number of neurotransmitters
Porphyrins are synthesized from glycine and succinyl coenzyme A

 Porphyrins accumulate in some inherited disorders of porphyrin metabolism
CHAPTER 26
Nucleotide Biosynthesis
26.1 Nucleotides Can Be Synthesized by de Novo or Salvage Pathways
26.2 The Pyrimidine Ring Is Assembled from CO_2, Ammonia, and Aspartate
Bicarbonate and other oxygenated carbon compounds are activated by phosphorylation
The side chain of glutamine can be hydrolyzed to generate ammonia
The pyrimidine ring is completed and coupled to ribose
Nucleotide mono-, di-, and triphosphates are interconvertible
CTP is formed by amination of UTP
Salvage pathways recycle pyrimidine bases
26.3 Purine Bases Can Be Synthesized from Glycine, Aspartate, and Other Components
The purine ring system is assembled on ribose phosphate
The purine ring is assembled by successive steps of activation by phosphorylation followed by displacement
AMP and GMP are formed from IMP
Enzymes of the purine biosynthesis pathway associate with one another
Salvage pathways economize intracellular resource consumption
An alternative to adenine is used by some viruses
26.4 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides
Ribonucleotide reduction occurs via a radical mechanism

Stable radicals are present in ribonucleotide reductases
SCIENTIST PROFILE JoAnne Stubbe
Thymidylate is formed by the methylation of deoxyuridylate
 Several valuable anticancer drugs block the synthesis of thymidylate
26.5 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition
Pyrimidine biosynthesis is regulated by aspartate transcarbamoylase
The synthesis of purine nucleotides is controlled by feedback inhibition at several sites
The synthesis of deoxyribonucleotides is controlled by the regulation of ribonucleotide reductase
26.6 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions
 The loss of adenosine deaminase activity results in severe combined immunodeficiency
 Gout is induced by high serum levels of urate
 Lesch–Nyhan syndrome is a dramatic consequence of mutations in a salvage-pathway enzyme
CHAPTER 27
Biosynthesis of Membrane Lipids and Steroids
27.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols
The synthesis of phospholipids requires an activated intermediate
Some phospholipids are synthesized from an activated alcohol

Phosphatidylcholine is an abundant phospholipid
Base-exchange reactions can generate phospholipids
Sphingolipids are synthesized from ceramide
Tay–Sachs disease results from the disruption of lipid metabolism
Phosphatidic acid phosphatase is a key regulatory enzyme in lipid metabolism
27.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages
Stage 1: The synthesis of mevalonate initiates the synthesis of cholesterol
Stage 2: Squalene (C_{30}) is synthesized from six molecules of isopentenyl pyrophosphate (C_5)
Stage 3: Squalene cyclizes to form cholesterol
27.3 The Regulation of Cholesterol Biosynthesis Takes Place at Several Levels
Lipoproteins transport cholesterol and triacylglycerols throughout the organism
Low-density lipoproteins play a central role in cholesterol metabolism
The absence of the LDL receptor leads to hypercholesterolemia and atherosclerosis
Mutations in the LDL receptor prevent LDL release and result in receptor destruction
Cycling of the LDL receptor is regulated
HDL appears to protect against atherosclerosis
The clinical management of cholesterol levels can be understood at the biochemical level

27.4 Important Biochemicals Are Synthesized from Cholesterol and Isoprene

Steroids are hydroxylated by cytochrome P450 monooxygenases that use NADPH and O_2

 Cytochrome P450s are widespread and perform many functions

SCIENTIST PROFILE Namandjé Bumpus

Pregnenolone is a precursor of many other steroids

Vitamin D is derived from cholesterol by the ring-splitting activity of light

Five-carbon units are joined to form a wide variety of biomolecules

Some isoprenoids have industrial applications

CHAPTER 28

DNA Replication, Repair, and Recombination

28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template

DNA polymerases require a template and a primer

DNA polymerases have common structural features

Bound metal ions participate in the polymerase reaction

The specificity of replication is dictated by complementarity of shape between bases

An RNA primer enables DNA synthesis to begin

SCIENTIST PROFILE Tsuneko and Reiji Okazaki

One strand of DNA is made continuously, whereas the other strand is synthesized in fragments

DNA ligase seals breaks in double-stranded DNA

The separation of DNA strands requires specific helicases and ATP hydrolysis

28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases

The linking number, a topological property, determines the degree of supercoiling

Topoisomerases prepare the double helix for unwinding
Type I topoisomerases relax supercoiled structures
Type II topoisomerases introduce negative supercoils through coupling to ATP hydrolysis
28.3 DNA Replication Is Highly Coordinated
DNA replication requires highly processive polymerases
The leading and lagging strands are synthesized in a coordinated fashion
DNA replication in *E. coli* begins at a unique site
DNA replication in eukaryotes is initiated at multiple sites
The eukaryotic cell cycle ensures coordination of DNA replication and cell division
Telomeres are protective structures at the ends of linear chromosomes
Telomeres are replicated by telomerase, a specialized polymerase that carries its own RNA template
28.4 Many Types of DNA Damage Can Be Repaired
Errors can arise in DNA replication
DNA can be damaged by oxidizing agents, alkylating agents, and light
DNA damage can be detected and repaired by a variety of systems
The presence of thymine instead of uracil in DNA permits the repair of deaminated cytosine
 Some genetic diseases are caused by the expansion of repeats of three nucleotides
Many cancers are initiated by the defective repair of DNA
Many potential carcinogens can be detected by their mutagenic action on bacteria
28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

RecA can initiate recombination by promoting strand invasion
Some recombination reactions proceed through Holliday-junction intermediates
CHAPTER 29
RNA Functions, Biosynthesis, and Processing
29.1 RNA Molecules Play Different Roles, Primarily in Gene Expression
RNAs play key roles in protein biosynthesis
Some RNAs can guide modifications of themselves or other RNAs
Some viruses have RNA genomes
 Messenger RNA vaccines provide protection against diseases
29.2 RNA Polymerases Catalyze Transcription
RNA synthesis comprises three stages: initiation, elongation, and termination
RNA polymerases catalyze the formation of a phosphodiester bond
RNA chains are formed de novo and grow in the $5'$-to-$3'$ direction
RNA polymerases backtrack and correct errors
RNA polymerase binds to promoter sites on the DNA template in bacteria to initiate transcription
Sigma subunits of RNA polymerase in bacteria recognize promoter sites
The template double helix must be unwound for transcription to take place
Elongation takes place at transcription bubbles that move along the DNA template
Sequences within the newly transcribed RNA signal termination

In bacteria, the rho protein helps to terminate the transcription of some genes
29.3 Transcription Is Highly Regulated
Alternative sigma subunits in bacteria control transcription in response to changes in conditions
Some messenger RNAs directly sense metabolite concentrations
Control of transcription in eukaryotes is highly complex
Eukaryotic DNA is organized into chromatin
Three types of RNA polymerase synthesize RNA in eukaryotic cells
Three common elements can be found in the RNA polymerase II promoter region
Regulatory cis-acting elements are recognized by different mechanisms
The TFIID protein complex initiates the assembly of the active transcription complex in eukaryotes
Enhancer sequences can stimulate transcription at start sites thousands of bases away
29.4 Some RNA Transcription Products Are Processed
Precursors of transfer and ribosomal RNA are cleaved and chemically modified after transcription
RNA polymerase I produces three ribosomal RNAs
RNA polymerase III produces transfer RNAs
The product of RNA polymerase II, the pre-mRNA transcript, acquires a $5'$ cap and a $3'$ poly(A) tail
Sequences at the ends of introns specify splice sites in mRNA precursors
Splicing consists of two sequential transesterification reactions
Small nuclear RNAs in spliceosomes catalyze the splicing of mRNA precursors

 Mutations that affect pre-mRNA splicing cause disease
Most human pre-mRNAs can be spliced in alternative ways to yield different proteins
Transcription and mRNA processing are coupled
Small regulatory RNAs are cleaved from larger precursors
RNA editing can lead to specific changes in mRNA
29.5 The Discovery of Catalytic RNA Revealed a Unique Splicing Mechanism
Some RNAs can promote their own splicing
RNA enzymes can promote many reactions, including RNA polymerization
SCIENTIST PROFILE Thomas Cech
CHAPTER 30
Protein Biosynthesis
30.1 Protein Biosynthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences
The biosynthesis of long proteins requires a low error frequency
Transfer RNA (tRNA) molecules have a common design
Some transfer RNA molecules recognize more than one codon because of wobble in base-pairing
30.2 Aminoacyl-tRNA Synthetases Establish the Genetic Code
Amino acids are first activated by adenylation
Aminoacyl-tRNA synthetases have highly discriminating amino acid activation sites
Proofreading by aminoacyl-tRNA synthetases increases the fidelity of protein biosynthesis
Kinetic proofreading increases the fidelity of protein biosynthesis

Synthetases recognize various features of transfer RNA molecules
Aminoacyl-tRNA synthetases are divided into two classes
30.3 The Ribosome Is the Site of Protein Biosynthesis
Ribosomal RNAs (5S, 16S, and 23S rRNA) play central roles in protein biosynthesis
Ribosomes have three transfer RNA-binding sites that bridge the 30S and 50S subunits
The start signal is usually AUG preceded by several bases that pair with 16S rRNA
Bacterial protein biosynthesis is initiated by *N*-formylmethionyl-transfer RNA
N-Formylmethionyl-$tRNA^{fMet}$ is placed in the P site of the ribosome in the formation of the 70S initiation complex
Elongation factors deliver aminoacyl-tRNAs to the ribosome
Peptidyl transferase catalyzes peptide-bond formation
GTP hydrolysis-driven translocation of tRNAs and mRNA follows peptide-bond formation
In bacteria, transcription and translation are coupled in space and time
Protein biosynthesis is terminated by release factors that read stop codons
Eukaryotic protein biosynthesis differs from bacterial protein biosynthesis primarily in translation initiation
Ribosomes selectively control gene expression
Scientists have manipulated protein biosynthesis pathways to incorporate unnatural amino acids in preselected positions
SCIENTIST PROFILE Ada Yonath
30.4 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

Protein biosynthesis begins on ribosomes that are free in the cytoplasm
Signal sequences mark proteins for translocation across the endoplasmic reticulum membrane
Transport vesicles carry cargo proteins to their final destinations
30.5 A Variety of Antibiotics and Toxins Inhibit Protein Biosynthesis
Some antibiotics inhibit protein biosynthesis
Diphtheria toxin blocks protein biosynthesis in eukaryotes by inhibiting translocation
Some toxins modify 28S ribosomal RNA
CHAPTER 31
Control of Gene Expression
31.1 Bacterial DNA-Binding Proteins Bind to Specific Regulatory Sites
Many DNA-binding proteins match the symmetry in their target DNA sequences
The helix-turn-helix motif is common to many bacterial DNA-binding proteins
31.2 In Bacteria, Genes Are Often Arranged into Clusters Under the Control of a Single Regulatory Sequence
An operon consists of regulatory elements and protein-encoding genes
The *lac* repressor protein can block transcription
Ligand binding can induce structural changes in regulatory proteins
The operon is a common regulatory unit in bacteria
Some DNA-binding proteins stimulate transcription
31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression
The λ repressor regulates its own expression

A circuit based on the λ repressor and Cro forms a genetic switch
31.4 Regulation of Gene Expression Is More Complex in Eukaryotes
A range of DNA-binding motifs are employed by eukaryotic DNA-binding proteins
Activation domains interact with other proteins
Multiple transcription factors interact with eukaryotic regulatory regions
31.5 The Control of Gene Expression in Eukaryotes Can Require Chromatin Remodeling
Chromatin remodeling and DNA methylation regulate access to DNA-binding sites
Epigenetic modifications influence gene expression
SCIENTIST PROFILE Sarah Stewart
Enhancers stimulate transcription by recruiting activator proteins that alter chromatin structure
Nuclear hormone receptors are transcription factors that cause changes in chromatin structure
Nuclear hormone receptors regulate transcription by recruiting coactivators to the transcription complex
Chromatin structure is modulated through covalent modifications of histone tails
Transcriptional repression can be achieved through histone deacetylation and other modifications
31.6 Gene Expression Can Be Controlled at the Posttranscriptional Level
Attenuation regulates transcription in bacteria through the modulation of nascent RNA secondary structure
Eukaryotes use different mechanisms to control gene expression at the posttranscriptional level
Genes associated with iron metabolism are translationally regulated in animals

Small RNAs are involved in posttranscriptional gene regulation in eukaryotes
CHAPTER 32
Principles of Drug Discovery and Development
32.1 Drug Discovery Begins with Target Identification and Validation
Drug targets must be validated and tractable
Serendipitous observations can drive drug development
32.2 Lead Molecules Can Be Discovered in Many Ways
Natural products are a valuable source of lead molecules
High-throughput screening expands the opportunity for lead identification
Screening libraries can be prepared using combinatorial chemistry
DNA-encoded libraries provide very large compound libraries for lead identification
Phenotypic screening provides an alternative to the target-centered approach
32.3 Compounds Must Meet Stringent Criteria to Be Developed into Drugs
Drugs must be potent and selective
EXAMPLE Determining the IC_{50} for an Inhibitor
Drugs must have suitable properties to reach their targets
Toxicity can limit drug effectiveness
Lead molecules can be optimized on the basis of three-dimensional structural information about their targets
32.4 Biologics Are a Growing Family of Drugs
The majority of biologics are recombinant proteins
Monoclonal antibodies are highly specific and potent recombinant protein biologics
SCIENTIST PROFILE Gertrude Elion
32.5 The Clinical Development of Medicines Proceeds Through Several Phases

Clinical trials are time-consuming and expensive
The evolution of drug resistance can limit the utility of drugs for infectious agents and cancer
CHEMISTRY REVIEW
ANSWERS TO SELF-CHECK QUESTIONS
ANSWERS TO PROBLEMS
INDEX

Preface

Fifty years ago, the first edition of *Biochemistry* hit the market and forever changed the way biochemistry is taught. In the tenth edition, we remain true to the hallmarks of Lubert Stryer's vision while presenting molecular structure and function, metabolism, regulation, and laboratory techniques in new ways that engage students actively in the process of learning biochemistry.

Thematic Threads

It has always been our goal to help students connect biochemistry to their own lives and the world around them. We use an evolutionary perspective to reveal the threads that bind organisms, clinical applications to show physiological relevance, and biotechnological and industrial applications to show how biochemistry is used to improve our lives. Pathways and processes are presented in a physiological context so students can see how biochemistry works in the body when it is at rest and during exercise, during health and disease, and under stress. Many of these examples are tagged with a caduceus symbol. (For a full list of these clinical applications, see p. xxxii.) New for this edition, we have highlighted the importance of time as a variable, linking the time scales associated with fundamental molecular processes, enzymatic reactions, physiological responses, and evolutionary change.

Several chapters provide the foundation for students' understanding of key aspects of biochemistry.

- Chapter 3 illustrates the remarkable abilities of biological molecules to interact specifically with one another, using as

examples the oxygen-binding proteins myoglobin and hemoglobin and key molecules from the immune system.

- Chapters 5 through 7 explain where enzymes derive the catalytic power, specificity, and control they have to drive chemical and energetic transformations.
- Chapter 15 introduces the basic concepts and design of metabolic pathways before students dive into the chapters on specific pathways.
- Chapter 24 integrates the concepts of energy metabolism by focusing on healthy caloric homeostasis and its dysfunctional extremes: obesity and starvation. The chapter also presents the biochemical basis for the many benefits of regular exercise and the pathology of diabetes.

Areas of Focus in the Tenth Edition

In developing the tenth edition of *Biochemistry*, we stayed true to the integrity of Lubert Stryer's original textbook while updating our approach to reflect today's biochemistry instructors and students. Within our main text, you will find our hallmark clear writing and straightforward illustrations, which together make the language of biochemistry accessible for students learning the subject for the first time. We present a logical flow of ideas, clearly written text, and informative figures to help students grasp and retain biochemical concepts and details.

The strengths of the tenth edition textbook are enhanced with videos, interactive figures, and more in our interactive e-book. The e-book is available within our Achieve platform and is downloadable through the VitalSource app, enabling students to read offline. Students can highlight, take notes, search by keyword, and even have the book

read aloud. The Achieve course further builds on the strengths of the tenth edition with interactive assessments, media, and abundant resources for use during class time or during study.

The tenth edition supports three organizing principles:

- Advances in biochemistry rely on diverse teams.
- Visualization is a critical teaching tool in biochemistry.
- Biochemistry requires conceptual understanding, critical thinking, effective problem solving, and practice.

Advances in Biochemistry Rely on Diverse Teams

In the tenth edition, we include short profiles of scientists, some very well-known and some less so, who have contributed to different aspects of biochemistry. In addition to introducing some fascinating people, the purpose of these profiles is to illustrate some of the wide range of training and career paths that different individuals have taken to allow them to make important contributions to biochemistry. Some profiles highlight how different life experiences have contributed to the selection of scientific problems or approaches. ▶

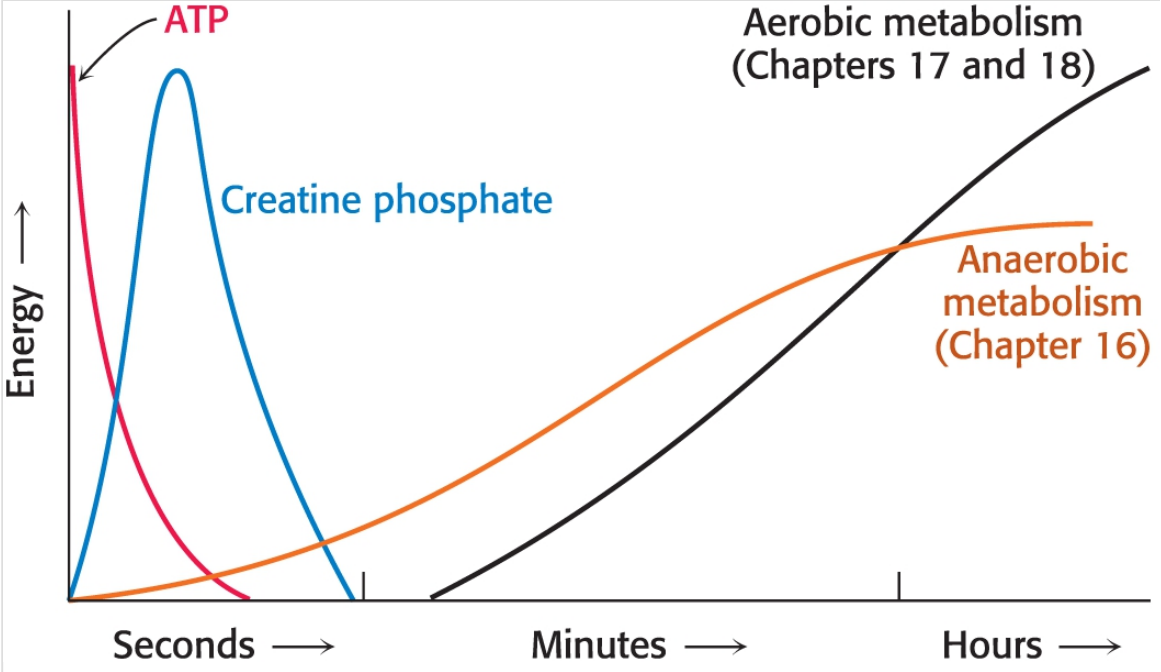

FIGURE 15.6 The sources of ATP change as exercise duration increases, even within the first few seconds. In the initial seconds of exertion, power is generated by existing high-phosphoryl-transfer compounds (ATP and creatine phosphate). Subsequently, the ATP must be regenerated by metabolic pathways.

Through these profiles, students may be able to apply their own experiences to understanding topics in biochemistry and other sciences. A list of all the profiles is on p. xxxiii.

Visualization Is a Critical Teaching Tool in Biochemistry

The ability to visualize concepts and how they are connected helps students gain a deeper conceptual understanding. Two innovations introduced in the first edition of *Biochemistry* were an open, uncluttered layout of text and figures that was easy on the eyes (and brain) and the presentation of one concept per figure. We continue these traditions in the tenth edition, while also presenting an updated art program that

enhances the power of figures to help students learn. Concise figures and ample margins are part of a layout that is well organized and easy to read.

- **One Idea at a Time.** Each figure illustrates a single concept, which helps students zoom in on the main points without the distraction of excess detail. **Figure captions** begin by identifying the concept in the figure.

- **Macromolecular Structures.** Beautifully rendered art depicting structures and structural models were prepared by authors Jeremy Berg and Gregory Gatto, based on the latest x-ray crystallographic, NMR, and cryo-electron microscopy data. For most molecular models, the **PDB number** at the end of the figure gives the student easy access to the file used in generating the structure (https://www.wwpdb.org).

JAMES TENSUAN/The New York Times/Redux

CAROLYN BERTOZZI Chemist Carolyn Bertozzi is a leader in developing the field of glycobiology and communicating its exciting possibilities. Initially planning to go to medical school, her interest in chemistry developed in college, and she went on to complete a PhD focused on synthesizing

In the tenth edition, chapter reading is enhanced with a variety of embedded multimedia tools in Achieve to enliven the narrative, while promoting strong visual understanding of the material. Each of these enhancements are available for stand-alone use in Achieve or within interactive questions and activities:

- **Interactive Figures.** Bring protein structures to life with interactive 3-D models using Jmol. Students can zoom and rotate structures and experiment with different display styles (space-filling, ball-and-stick, ribbon, and backbone) by means of a user-friendly interface. These interactive molecular structures can be launched within the e-book wherever you see the INTERACT callouts. ▼

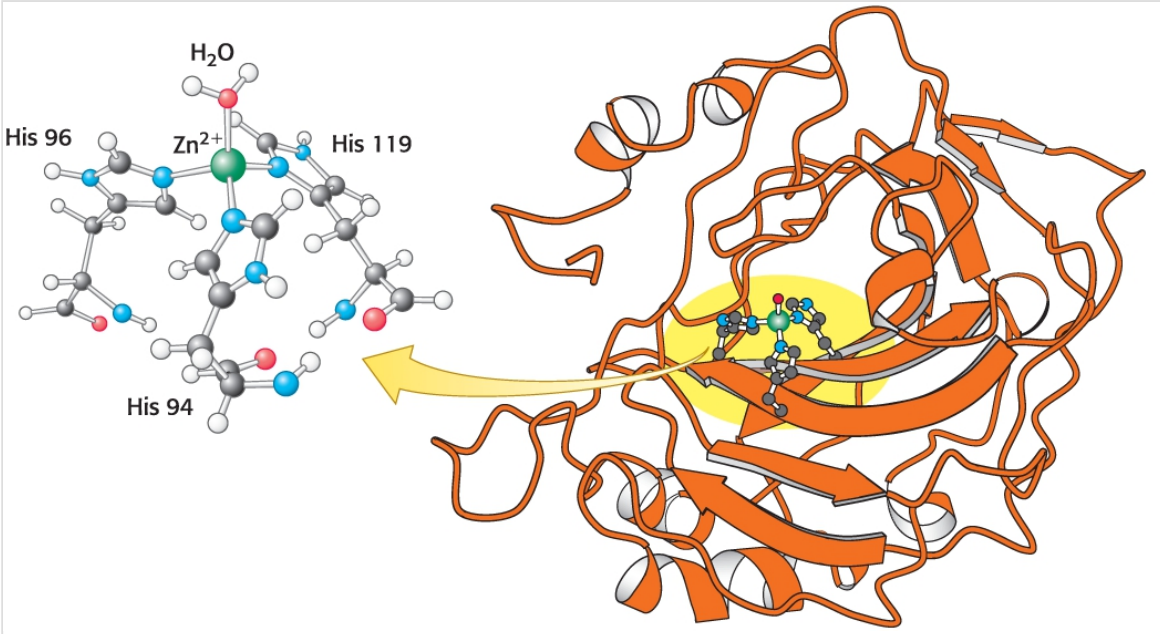

FIGURE 6.18 The active site of human carbonic anhydrase II includes a bound zincion. The active site includes a zinc ion that is bound to the imidazole rings of three histidine residues as well as to a water molecule in a cleft near the center of the enzyme.

[Drawn from 1CA2.pdb.]

INTERACT with this model in Achieve

- **Animated Mechanisms.** Watch the mechanisms of iconic enzymes as short animations.

- **Animated Technique Videos.** Reinforce understanding of laboratory techniques by watching animations that include an overview of protocol and then show what is happening at the

chemical level. Laboratory technique animations can be launched within the e-book wherever you see the VIEW callouts.

- **Interactive Metabolic Map.** EXPLORE callouts highlight metabolic processes that students can study in greater depth in 

. 

With this interactive tool, students can navigate and zoom between overviews and detailed views of the most commonly taught metabolic pathways. Embedded Tours take students through the pathways step by step. Such intimate interaction helps students visualize concepts in isolation as well as understand how concepts are interconnected. Metabolic Map Pathways include glycolysis, gluconeogenesis, the citric acid cycle, oxidative phosphorylation, the pentose phosphate pathway, glycogen metabolism, fatty acid synthesis, the urea cycle, and β oxidation.

Biochemistry Requires Conceptual Understanding, Critical Thinking, Effective Problem Solving, and Practice

Every chapter of *Biochemistry*, Tenth Edition, provides numerous opportunities for students to practice problem-solving skills and apply the concepts described in the text.

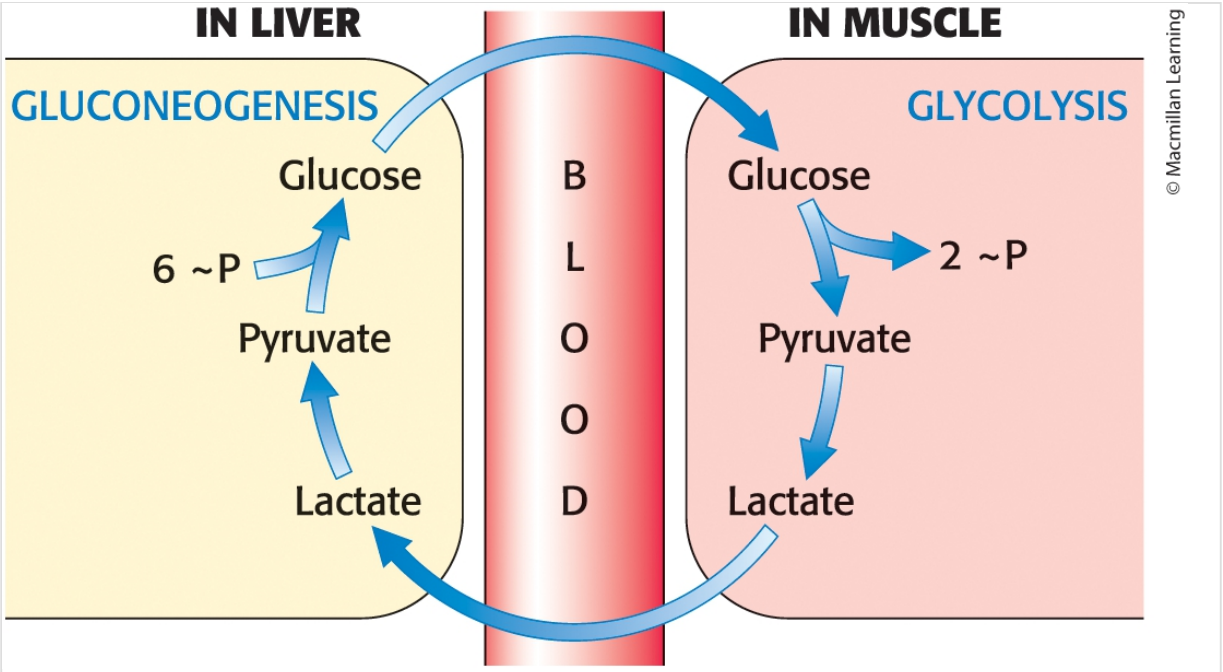

FIGURE 16.36 The Cori cycle allows the liver to better support other tissues, such as skeletal muscle. Lactate formed by active muscle is converted into glucose by the liver. This cycle shifts part of the metabolic burden of active muscle to the liver. The symbol, ~P represents nucleoside triphosphates.

EXPLORE this pathway further in the Metabolic Map in Achieve

- **NEW! Self-Check Questions.** New Self-Check questions provide periodic "speed bumps" in the chapter narrative to allow students to assess their comprehension and practice applying concepts they have just learned.

Self–Check Question

Recall our study of enzymes in previous chapters: Why do isolated F_1 subunits of ATP synthase catalyze ATP hydrolysis?

- **NEW! Examples.** The boxed examples (listed on p. xxxiii) provide point-of-use, worked-through examples of the types of quantitative and reasoning questions students will frequently encounter in biochemistry courses and in laboratory work. ▶

Example

Determining the Fraction of Bound Receptors

Problem:

What fraction of receptors are occupied with ligand at a ligand concentration of 5 μM, given that half of the receptors are occupied with ligand at a total ligand concentration of 20 μM?

Getting Started:

Equation 2 gives the relationship between the fraction of receptors occupied with ligands as a function of the total ligand concentration and the dissociation constant:

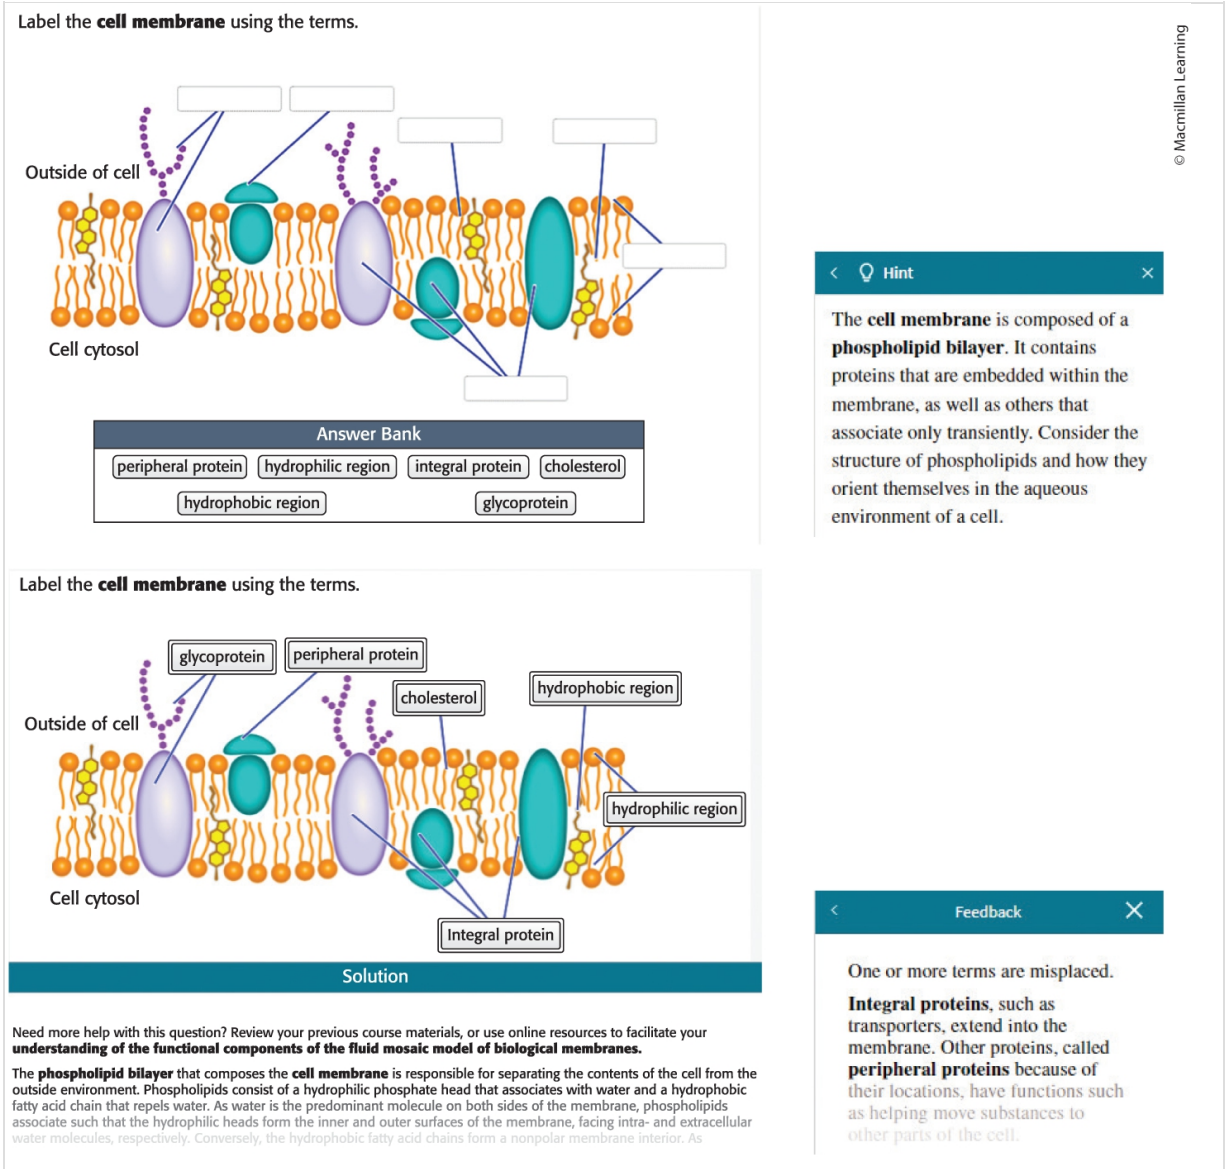
$$[RL]/R_{total} = L_{total}/(K_d + L_{total})$$

We are interested in what happens at a total ligand concentration of 5 μM. In order to use equation 2, we need to know the dissociation constant

Solve:

We showed that the half of the receptors are occupied with ligands when the total ligand concentration is equal to the dissociation constant. Since half of the receptors are occupied when the ligand concentration is 20 μM, we know that $K_d = 20\ nM$. Substituting this and $L_{total} = 5\ \mu M$ into equation 2, we find that

$$[RL]/R_{total} = 5\ \mu M/(20\ \mu M + 5\ \mu M) = 0.20$$



Reflect:

This result makes sense since the total ligand concentration is somewhat less than 20 μM, the ligand concentration at which half (0.50) of the receptors are occupied.

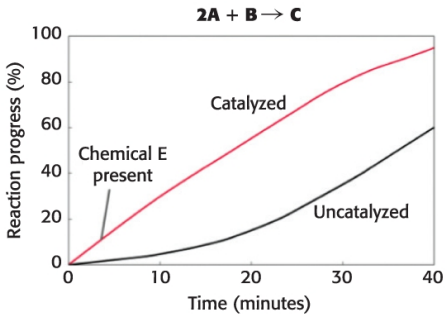
In Achieve, engagement is encouraged with adaptive quizzing, feedback-rich problem-solving practice, case study applications, and more.

- Achieve **Adaptive Quizzing.** This game-like activity motivates reading and provides individualized learning and feedback as students build towards a target score. All questions are tied back to the e-book to encourage students to explore the reading, figures, and interactive resources at hand. Adaptive quizzing includes a student dashboard with their progress and a personalized study plan. ▼

- **NEW! Every end-of-chapter problem from *Biochemistry*, Tenth Edition, is assignable in** Achieve**.** Raise comprehension and problem-solving skills with robust end-of-chapter questions, that are available as pencil-and-paper assignments or as autograded, feedback-rich online homework. The end-of-chapter problems in *Biochemistry*, Tenth Edition, vary in presentation and degree of difficulty; they include higher-level critical thinking questions that ask students to suggest or describe a chemical mechanism, draw conclusions from data taken from real research papers, and connect concepts across chapters.

- In Achieve, each autograded question delivers hints and immediate, individualized feedback so students get guidance targeted to the underlying misconception of each specific wrong answer. Upon completion of each question, students can see fully worked solutions that explain how to reason through and solve the question. ▼

- Achieve **Question Bank.** In addition to end-of-chapter problems, instructors can explore and assign thousands of additional interactive, autograded questions for more problem-solving practice. Questions in the question bank are frequently customizable and algorithmic so students working together see variations of the same problems. Achieve promotes student success through practice and targeted feedback, while saving instructors time and providing meaningful insights with assessment reports.



Most chemical reactions occur in a step-wise fashion, requiring more than one **elementary step** (or **elementary reaction**) to form the final products. During a step-wise reaction process, a later elementary step consumes the **intermediate** or intermediates formed by an earlier elementary step. Therefore, like catalysts, reaction intermediates do not appear in the overall schematic of a chemical reaction.

Uncatalyzed reaction

Step 1: $A + B \longrightarrow D$
Step 2: $A + D \longrightarrow C$
Overall: $2A + B \longrightarrow C$

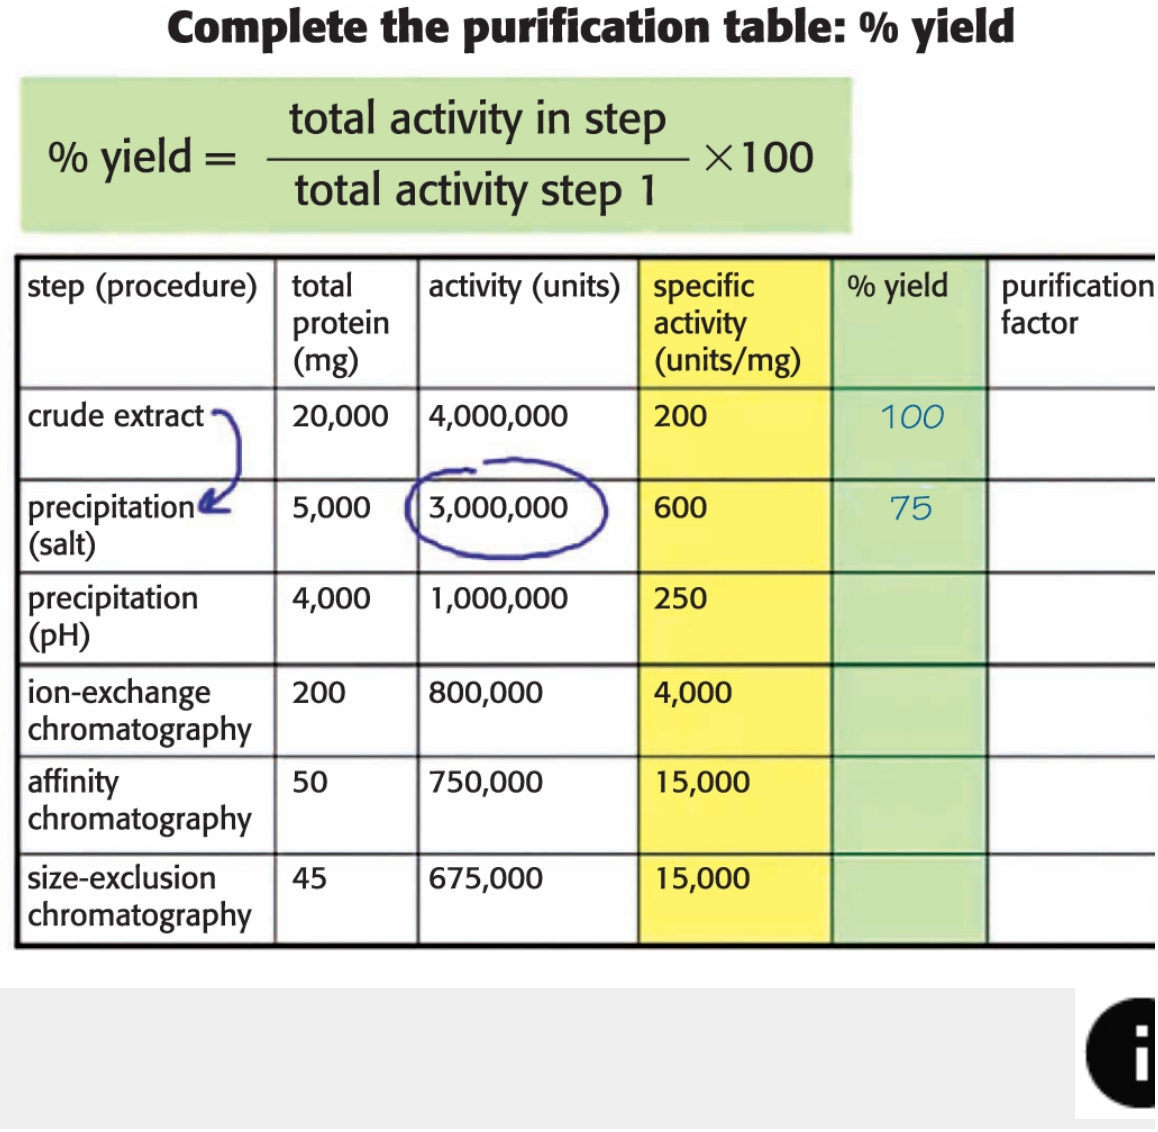
Catalyzed reaction

Step 1: $A + B + E \longrightarrow EAB$
Step 2: $A + EAB \longrightarrow C + E$
Overall: $2A + B \longrightarrow C$

Consider the given series of **elementary reactions** and their **overall reaction**.

reaction 1:	$A + B \longrightarrow AB$
reaction 2:	$AB + C \longrightarrow AC + B$
overall:	$A + C \longrightarrow AC$

© Macmillan Learning



Which species is an **intermediate** in the reaction?

- AC

- Achieve **NEW! Skills You Need Activities.** Each chapter includes a short activity that identifies one to three skills or concepts that students may have learned in prerequisite courses — such as general chemistry, organic chemistry, biology, and math — and will need to apply to the current biochemistry chapter. Developed with guidance from student reviewers, these activities provide short refreshers on the prerequisite content then allow students to assess their mastery of the content and provide helpful feedback and search terms they can apply through their preferred methods of study. ▶

-  **Readiness Activities.** Whereas Skills You Need activities are aligned with one chapter at a time, Readiness Activities are designed to get students ready for the course as a whole. Students can review the math, general chemistry, and organic chemistry skills they will need to use as biochemistry students, and each question provides hints, answer-specific feedback, and solutions.

-  **Problem-Solving Videos.** With diagrams, graphs, and narration, these videos walk students through problems on topics that typically prove difficult — such as data interpretation — helping students understand the right approach to the solution.

-  **Case Studies.** Each case study introduces students to a biochemical mystery and allows them to determine what investigations will solve it. Accompanying assessments ensure that students have fully completed and understood the case study, showing that they have applied their knowledge of the concepts. ▼ ▶

Case Study Topics

Biomolecules

- Observation Over Intuition: Thermodynamics of Protein Folding
- pH Peril: pH and Amino Acid Structure
- Profound Relevance: Hemoglobin Regulation (Bohr Effect)
- **NEW!** Mile High Stadium and Silent Killer: Hemoglobin Dysfunction
- **NEW!** Toxic Alcohols: Enzyme Function
- A Likely Story: Enzyme Inhibition

Signal Transduction/Metabolism

- **NEW!** Failure to Propagate: Signal Transduction
- **NEW!** Sudden Onset: Introduction to Metabolism
- An Unexplained Death: Carbohydrate Metabolism
- A Day at the Beach: Fatty Acid Metabolism
- **NEW!** The Narrow Window: Electron Transport Chain and Oxidative Phosphorylation
- Runner's Experiment: Integration of Energy Metabolism

Mile High Stadium and the Silent Killer
Case Study on Hemoglobin Regulation and Dysfunction
By Justin Hines, Lafayette College

Photo Credit: Zoonar /A. Kravchenko /AGE Fotostock

Act 1 - Trouble at Mile High Stadium

Gino had hemoglobin on the mind. He had been embarrassed earlier when he failed to remember how pH was related to oxygen transport in the human body.

As an undergraduate in his junior year who hoped to go to medical school, Gino's day job shadowing emergency room physician Dr. Rose Smith was otherwise going well. But the routine patient visits were interrupted when he saw a large crowd gathered just outside in the hospital lobby. Most had flowers, but some, strangely, were carrying footballs and wearing jerseys.

"Dr. Smith, what's that all about?" Gino pointed to the noisy crowd.

"Oh that... yes, we have a patient up on three recovering from a sickle cell attack."

"But why so many people?" asked Gino. "And why do some have footballs? Is it a child or something?"

"No, actually he's an NFL star... plays defensive end. Most of those people are just fans. He played a game last night here in Denver at the new Mile High Stadium. The combination of vigorous exercise from sprinting all over a 100-yard field and the fact that the game was here in Denver triggered a sickle cell crisis. He'll probably never play in Denver again."

"He has sickle cell anemia and plays in the NFL??!"

"Actually, he has sickle cell *trait*, meaning he is heterozygous for the sickle cell allele, HbS. Some people with sickle cell trait can be top athletes. But, the right conditions can still bring about a crisis."

Achieve: Your One-Stop-Shop For Instructional Resources

Integrated with the tenth edition are activities, media, and resources to support in-person, virtual, and hybrid teaching. The resources found in the Achieve platform include tools for class preparation, instruction, practice and assessment, and reporting and analytics:

Class Preparation

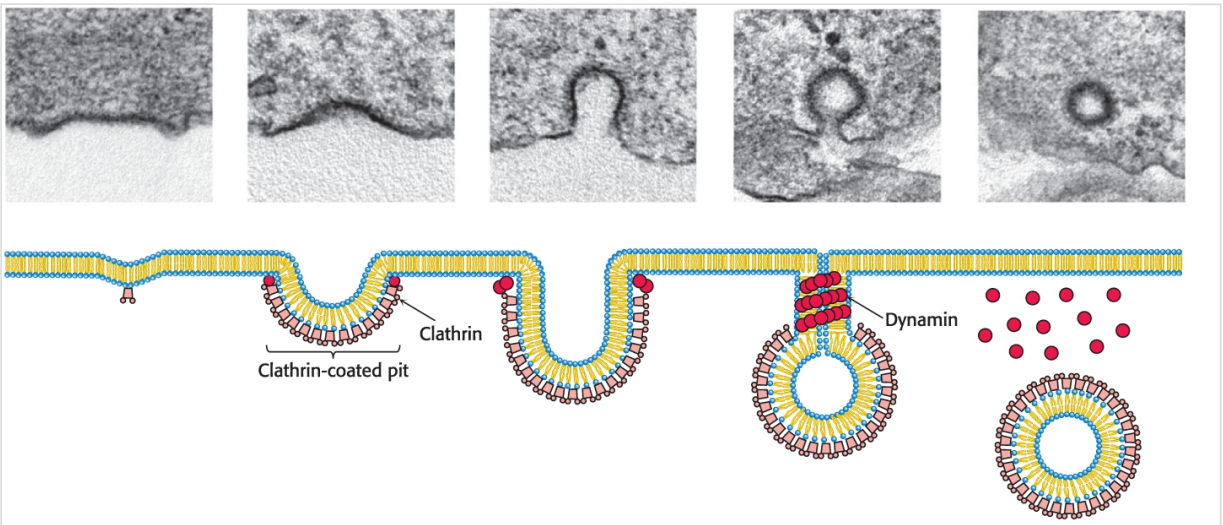
- **Transition Guide** for navigating the changes between editions
- **Goal-Setting and Reflection Surveys** to help students identify their goals, develop strategies to reach those goals, and realign their study habits throughout the course
- Assignable chapter-by-chapter **Skills You Need** and course-level **Readiness Activities** to refresh students on content from courses frequently taken as prerequisites
- **Interactive e-book** with assignable sections and chapters
- Assignable **LearningCurve Adaptive Quizzing** tasks to ensure reading comprehension

Instruction

- Editable all-in-one **Lecture Slides** that include content, images, iClicker questions, multimedia tools, and activities
- **Standalone Slide Decks** streamlined to just include content, images, and iClicker activities
- **Problem-Solving Activities** and other **In-Class Activities** with **Instructor Activity Guides** and student **Worksheets** that follow a consistent approach for solving biochemistry problems and include recommendations for use in face-to-face, virtual, and hybrid classes
- **Cloud-based iClicker**, an in-class response system with integrated Gradebook
- Presentation-ready media such as the **Interactive Metabolic Map**, **Animated Mechanisms**, **Animated Techniques**, **Problem-Solving**

Videos, **Living Figures**, and **Case Studies** integrated into **Lecture Slides**, **Problem-Solving Activities**, and other **In-Class Activities**; they are also available as stand-alone resources.

Practice and Assessment



- **Editable, curated, autograded homework assignments** that match the order and question in the text
- **Question Bank** with thousands of additional questions to create an assignment from scratch or add to a curated assignment
- **Abbreviated Solutions** and **Extended Solutions** for all end-of-chapter questions
- **Assignable Case Studies**
- **Test Banks** and accompanying software (located on Macmillan Learning's catalog page) to create tests outside of the Achieve environment

Reporting and Analytics

- **Learning Objectives** aligned with course content and resources
- **Insights** on student performance on top learning objectives and course data, such as time on task and other metrics
- **Detailed reporting** by class, by individual student, and by learning objective
- **Gradebook that syncs with iClicker** for an all-in-one gradebook
- **Integration** with most campus Learning Management Systems

Recent Advances and Discoveries Included in the New Edition

Biochemistry is an exciting and dynamic field of study. In the tenth edition of *Biochemistry*, we have updated examples and explanations to provide the latest and most interesting discoveries in biochemistry, along with material essential for understanding biochemical concepts. Some of these new topics are:

FIGURE 12.38 Many cells take up molecules by receptor-mediated endocytosis. Receptor binding on the surface of the cell induces the membrane to invaginate, with the assistance of specialized intracellular proteins such as clathrin and dynamin. The process results in the formation of a vesicle within the cell.

Discussion of SARS-CoV-2 and COVID-19 in multiple contexts (Chapter 1–4, 14, 29)
Discussion and illustration of binding phenomena at the single-molecule level (Chapter 1)

Expanded discussion of the interpretation of variations in genome sequences in terms of ancestry and evolutionary timescales (Chapter 1)
New section highlighting different career paths related to biochemistry, and the importance of diverse teams of people for advancing our field of knowledge (Chapter 1)
Updated discussion of protein structure prediction, including the development of AlphaFold (Chapter 2)
New chapter focused on molecular recognition, using the examples of steroid-hormone binding, oxygen transport by hemoglobin, and key proteins from the immune system (Chapter 3)
Expanded discussion of timescale and single-molecule kinetics, including new figures and equations (Chapter 5)
Expanded discussion of molecular motor proteins, particularly myosin (Chapter 6)
Updated discussion of anticoagulant medicines (Chapter 7)
Discussion of the major and minor grooves of double-stranded DNA (Chapter 8)
Expanded discussion of the methods for quantitation of gene expression to include RNA-seq (Chapter 9)
Updated presentation of carbohydrate structures and the role of glycoproteins in biology (Chapter 11)
Expanded discussion of lipid rafts (Chapter 12) ▲
Updated discussion of the ion channels responsible for cardiac pacemaker activity (Chapter 13)
Illustration of signal-transduction processes in the context of the “fight-or-flight” response (Chapter 14)
Discussion of signal-transduction processes involved in sensory systems, including sight, smell, and hearing (Chapter 14)
Updated information regarding the health effects of fructose consumption (Chapter 16)
Discussion of inborn errors of metabolism (Chapter 16)
Discussion of the role of the proton motive force in the flagellar motor (Chapter 18)
New emphasis on phototrophy versus photosynthesis, and autotrophy versus heterotrophy (Chapter 19)

Discussion of optogenetics, including bacteriorhodopsin and its relationship to rhodopsin and channelrhodopsin (Chapter 19)
Updated discussion of the evolution and enzymology of C_4 plants (Chapter 20)
Updated discussion of the UPS system, the role of degrons in regulation, and the alternative functions of ubiquitin (Chapter 23)
Updated discussion of the fasted-fed cycle, diabetes, and obesity (Chapter 24)
Discussion of McArdle glycogen storage disease and its effects on the fuel choices available to muscles (Chapter 24)
Discussion of metabolism and cancer (Chapter 24)
Discussion of some viruses that utilize an alternative nucleobase (Chapter 26)
Discussion of the involvement of 3-metal ions in catalysis by DNA polymerase (Chapter 28)
Added examples of RNA function (Chapter 29)
Discussion of the role of kinetic proofreading in increasing the fidelity of protein synthesis (Chapter 30)
Discussion of the manipulation of protein-synthesis pathways to incorporate unnatural amino acids in preselected positions (Chapter 30)
Discussion of how ribosomes selectively control gene expression (Chapter 30)
Updated and greatly revised discussion on drug discovery to emphasize target identification, validation, and tractability (Chapter 32)
Expanded discussion of the role of high-throughput screening in lead identification during drug discovery (Chapter 32)
Discussion of biologics (Chapter 32)

Clinical Applications

 This icon signals the start of a clinical application in the text.

Additional, briefer clinical correlations appear in the text as appropriate.

Osteogenesis imperfecta
Protein-misfolding diseases
2,3-BPG and fetal hemoglobin
Carbon monoxide poisoning
Sickle-cell anemia
Vaccines, including for SARS-CoV-2
Monoclonal antibodies
Aldehyde dehydrogenase deficiency
Competitive inhibitors as drugs
Action of penicillin
Toxins that modify reactive serine residues
Protease inhibitors as drugs
Protein kinase A mutations and Cushing's syndrome
Deficiency of α_1-antitrypsin and lung disease
Anticoagulant drugs
Identifying disease-causing mutations using recombinant DNA technology
Using RNAi to treat disease
Monitoring changes in glycosylated hemoglobin (A1C levels)
Using maltase inhibitors to control blood glucose
Human milk oligosaccharides and newborn protection
Erythropoietin (EPO)
Mucin overexpression and disease
Blood type O and cholera susceptibility
Errors in glycosylation and I-cell disease
Liposomes for drug delivery
Demyelinating diseases
Action of aspirin and ibuprofen
Gram staining to characterize bacterial infections
Digoxin and congestive heart failure
ATP-binding cassette domains and multidrug resistance
Drug side effects caused by interaction with the K^+ channel hERG

Signal-transduction pathways and cancer
COVID-19 effects on sense of smell
Vitamins

Effects of excessive fructose consumption
Galactosemia
Lactose intolerance
Glucokinase and type 2 diabetes
Aerobic glycolysis and cancer
Activation of transcription factor HIF1 by both cancer and endurance training
Effects of substrate cycles on health and disease
Deficiencies of glycolytic or gluconeogenic enzymes
Pyruvate dehydrogenase complex inhibition and diabetic neuropathy
Beriberi and mercury and arsenic poisoning
Blocking the glyoxylate cycle as potential tuberculosis treatment
Frataxin mutations and Friedreich's ataxia
Reactive oxygen species (ROS) and signal transduction
Mild uncouplers as drugs
Mitochondrial diseases
Photosensitive proteins and optogenetics
Glucose 6-phosphate dehydrogenase deficiency and drug-induced hemolytic anemia
Drugs for type 2 diabetes that target liver phosphorylase
Glycogen-storage diseases
Carnitine deficiency
Zellweger syndrome
Fatty acids and pathological conditions
Ketogenic diets as treatment for epilepsy
Diabetic ketosis
Fatty acid synthase inhibitors as drugs
Effects of aspirin on signaling pathways
Diseases resulting from defects in E3 proteins
Proteasome inhibitors and tuberculosis treatment
Blood levels of aminotransferases as indicators of liver damage
Inherited defects of the urea cycle and hyperammonemia
Phenylketonuria and other disorders of amino acid degradation
Causes of type 1 and type 2 diabetes
McArdle disease
Effects of ethanol on energy metabolism and link to cancer

High homocysteine levels and vascular disease
Inherited disorders of porphyrin metabolism
Herpes drug that targets viral thymidine kinase
Anticancer drugs that block the synthesis of thymidylate
Adenosine deaminase and severe combined immunodeficiency
Gout
Lesch–Nyhan syndrome
Cardiolipin and Parkinson's disease
Disruption of lipid metabolism and Tay–Sachs disease
Hypercholesterolemia and atherosclerosis
Mutations in the LDL receptor
Role of the protease PCSK9 in cardiovascular disease
Clinical management of cholesterol levels
Protective function of the cytochrome P450 system
Aromatase inhibitors in the treatment of breast and ovarian cancer
Rickets and vitamin D
Antibiotics that target DNA gyrase
Using DNA-repair mechanisms to study disease
Huntington's disease
mRNA vaccines
Burkitt lymphoma and B-cell leukemia
Diseases of defective RNA splicing
Diphtheria
Serendipitous discovery of penicillin
HMG-CoA reductase inhibitors
HIV protease inhibitors

Boxed Example Problems

The boxed Examples provide point-of-use, worked-through examples of the types of quantitative and reasoning questions students will frequently encounter in the course.

Applying the Henderson–Hasselbalch Equation

Determining the Fraction of Bound Receptors
Calculating the Effectiveness of Protein Purification
Calculating and Comparing $\Delta G^{\circ\prime}$ and $\Delta G^{\circ\prime}$
Applying the Michaelis–Menten Equation
Determining Inhibitor Type from Data
Interpreting an RNA Alignment
Calculating the Energetic Cost of Ion Transport
Calculating Equilibrium Potentials
Calculating ΔG for a Coupled Reaction Under Real Conditions
Calculating the Standard Free Energy of a Reaction from Reduction Potentials
Determining Metabolic Products of Amino Acid Degradation
Measuring the Impact of a Single Athletic Activity on Caloric Homeostasis
Determining the IC_{50} for an Inhibitor

Scientist Profiles

Scientist profiles throughout the book illustrate some of the wide range of training and career paths that different individuals have taken to allow them to make important contributions to biochemistry.

Acknowledgments

With the publication of this tenth edition of *Biochemistry*, we are reminded of the tremendous responsibility in continuing the tradition started by Lubert Stryer in 1975. Throughout our preparation and writing of this edition, we sought to reaffirm our commitment to the guiding principles that make this book special: clear and precise writing, simple and informative illustrations, and the awareness that our work would be consumed by clever and engaged students and their dedicated and meticulous teachers. It is an honor that we do not take lightly. We are grateful to all our colleagues who supported and advised us throughout this process, and to all the pioneering scientists whose discoveries and insights provide us with the subject material that inspires our passion for biochemistry.

It has been a joy to work with the Macmillan Learning team throughout the creative process. While the undertaking was invariably arduous, they continually kept our spirits up and our eyes focused on the ultimate goal by coaxing without nagging, and critiquing while supporting us. We have many people to thank for this experience, some of whom are first timers to *Biochemistry*. We were delighted to work with Senior Program Manager Liz Simmons for the first time. She was unfailing in her enthusiasm and tremendous leadership through an enormously tumultuous time during the pandemic. Senior Development Editor Jennifer Angel provided countless thoughtful suggestions to improve the book in every facet, from the writing to the page layout. Director of Development Debbie Hardin (and Barbara Yien in the final months of the project), provided support and encouragement throughout the project. A special word of thanks to our Senior Media Editor, Cassandra Korsvik,

who provided extraordinary support as we worked to synchronize our print and online assessments. Special thanks also to Assistant Editor Angelica Hernandez, who tirelessly juggled countless tasks in support of our team.

It is almost impossible to put into words the amount of coordination and effort required to shepherd a textbook project from authors' first draft to publication. We have many to thank for directing us through this complex process. Editorial Project Manager Jennifer Hart and Content Project Manager Peter Jacoby managed the flow of the entire project, from draft writing to copyediting to bound book, with amazing efficiency. Diana Blume, Director of Design, Content Management; Natasha Wolfe, Design Services Manager; and Maureen McCutcheon, Designer, produced a design and layout that makes the book uniquely attractive and modern, while still emphasizing its ties to past editions. Permissions Manager Christine Buese and Photo Researchers Richard Fox and Krystyna Borgen found many new photographs in addition to diligently tracking down classics from the published literature. Matthew McAdams, Art Manager, deftly directed the rendering of new illustrations and the conversion of legacy art for a new printing process. Paul Rohloff, Senior Workflow Project Manager, made sure that the significant difficulties of scheduling, composition, and manufacturing were smoothly overcome. Heather Southerland, Amy Thorne, Cassandra Korsvik, Kelsey Hughes, and Lily Huang did a wonderful job in their management of the media program. Maureen Rachford, Marketing Manager for the Physical Sciences, enthusiastically introduced this newest edition of *Biochemistry* to the academic world. We are deeply appreciative of Greg David and his sales staff for their support. Without their able and enthusiastic presentation of our text to the academic community, all of our efforts would be in vain.

Thanks also to our many colleagues at our own institutions as well as throughout the country who patiently answered our questions and

encouraged us on our quest. Finally, we owe a debt of gratitude to our families: our spouses — Wendie Berg, Megan Williams, Catherine Hines, and Mark Heller — and our children. Without their support, comfort, and understanding, this endeavor could never have been undertaken, let alone successfully completed.

We also especially thank those who served as reviewers for this tenth edition. Their thoughtful comments, suggestions, and encouragement have been of immense help to us in maintaining the excellence of the preceding editions. These reviewers are listed below.

About the Authors

Courtesy Jeremy Berg

JEREMY M. BERG received his BS and MS degrees in Chemistry from Stanford University (where he did research with Keith Hodgson and

Lubert Stryer) and his PhD in Chemistry from Harvard with Richard Holm. He then completed a postdoctoral fellowship with Carl Pabo in Biophysics at Johns Hopkins University School of Medicine. He was an Assistant Professor in the Department of Chemistry at Johns Hopkins from 1986 to 1990. He then moved to Johns Hopkins University School of Medicine as Professor and Director of the Department of Biophysics and Biophysical Chemistry, where he remained until 2003. He then became Director of the National Institute of General Medical Sciences at the National Institutes of Health. In 2011, he moved to the University of Pittsburgh, where he is now Professor of Computational and Systems Biology and Pittsburgh Foundation Chair and Director of the Institute for Personalized Medicine. He served as President of the American Society for Biochemistry and Molecular Biology from 2011 to 2013 and as Editor-in-Chief for *Science* magazine and the *Science* family of journals from 2016 to 2019. Dr. Berg has received numerous awards for his research, teaching, and public service. He is an elected member of the National Academy of Medicine and the American Academy of Arts and Sciences. He is coauthor, with Stephen J. Lippard, of the textbook *Principles of Bioinorganic Chemistry*. He greatly enjoys sharing his life with his wife, three grown children, and grandchildren.

Karpagam Aravindhan

GREGORY J. GATTO, JR., received his AB degree in Chemistry from Princeton University, where he worked with Martin F. Semmelhack and was awarded the Everett S. Wallis Prize in Organic Chemistry. In 2003, he received his MD and PhD degrees from the Johns Hopkins University School of Medicine, where he studied the structural biology of peroxisomal targeting signal recognition with Dr. Berg and received the Michael A. Shanoff Young Investigator Research Award. He completed a postdoctoral fellowship in 2006 with Christopher T.

Walsh at Harvard Medical School, where he studied the biosynthesis of the macrolide immunosuppressants. Dr. Gatto is currently a Scientific Director in the Novel Human Genetics Research Unit at GlaxoSmithKline. While he enjoys losing at board games, attempting but not completing crossword puzzles, and watching baseball games at every available opportunity, he treasures most the time he spends with his wife Megan and sons Timothy and Mark.

Clay Wegrzynowicz/Lafayette College Communications Dept

JUSTIN K. HINES is Professor of Chemistry at Lafayette College, where he teaches general chemistry and biochemistry courses and conducts education and NIH-funded laboratory research on protein misfolding with undergraduates. He received both his BS and PhD in Biochemistry from Iowa State University, where he studied the structure and regulation of the enzymes of central metabolism with Richard B. Honzatko and Herbert J. Fromm. He then completed a postdoctoral fellowship with Elizabeth A. Craig in Biochemistry at the University of Wisconsin–Madison. Professor Hines has won numerous awards for teaching and research, including being named a Cottrell Scholar by the Research Corporation for Science Advancement and a Henry-Dreyfus Teacher-Scholar by the Camille and Henry Dreyfus Foundation. He is also the author of the case-studies series for Macmillan's three biochemistry textbooks. He enjoys running, hiking, games of any kind, and spending time with his wife and children. He would like to dedicate his work on this book to his loving mother Kathryn, who passed away in 2021.

Jutta B. Heller

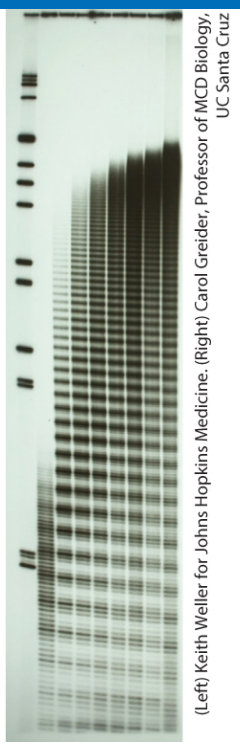
JUTTA BENEKEN HELLER is a Teaching Professor at the University of Washington Tacoma. She primarily teaches upper-division undergraduate courses in the Biomedical Sciences, with a focus on molecular biology. She also acts as a faculty mentor in an NSF-funded program that supports the academic success of undergraduate students with low-income or underrepresented backgrounds. Professor Heller's top priority is the academic and personal success

of her students as she strives to create a welcoming and equitable learning environment for everyone. She received her AB in Molecular Biology from Princeton University in 1995 and her PhD from Johns Hopkins University School of Medicine in 2001. Her PhD thesis work was completed in the lab of Dr. Daniel Leahy, where she determined the crystal structure of the Homer EVH1 domain in complex with a peptide ligand. She completed a postdoctoral fellowship at the University of Chicago and began her teaching career at Loyola University Chicago in 2004. She received the 2010 Edwin T. and Vivijeanne F. Sujack Award for Teaching Excellence at Loyola University. She enjoys exploring mountains, forests, and beaches with her husband Mark and their dog Ziggy.

Hai Ngo

JOHN L. TYMOCZKO was Towsley Professor of Biology Emeritus at Carleton College, where he taught from 1976 until his death in 2019. He taught a variety of courses, including Biochemistry, Biochemistry Laboratory, Oncogenes and the Molecular Biology of Cancer, and Exercise Biochemistry, and cotaught an introductory course, Energy Flow in Biological Systems. Professor Tymoczko received his BA from the University of Chicago in 1970 and his PhD in Biochemistry from the University of Chicago with Shutsung Liao at the Ben May Institute

for Cancer Research. He then had a postdoctoral position with Hewson Swift of the Department of Biology at the University of Chicago. The focus of his research was on steroid receptors, ribonucleoprotein particles, and proteolytic processing enzymes.



Saul Loeb/AFP/Getty Images

LUBERT STRYER is Winzer Professor of Cell Biology, Emeritus, in the School of Medicine and Professor of Neurobiology, Emeritus, at

Stanford University, where he has been on the faculty since 1976. He received his MD from Harvard Medical School. Professor Stryer has received many awards for his research on the interplay of light and life, including the Eli Lilly Award for Fundamental Research in Biological Chemistry, the Distinguished Inventors Award of the Intellectual Property Owners' Association, and election to the National Academy of Sciences and the American Philosophical Society. He was awarded the National Medal of Science in 2006. The publication of his first edition of *Biochemistry* in 1975 transformed the teaching of biochemistry.

Chapter 1
Biochemistry in Space and Time

(Left) Keith Weller for Johns Hopkins Medicine. (Right) Carol Greider, Professor of MCD Biology, UC Santa Cruz

Nobel Prize winners Peter Agre, MD, and Carol Greider, PhD, celebrated on the occasion of the announcement that Dr. Greider was sharing the Nobel Prize in Medicine or Physiology in 2009. Dr. Agre had won a Nobel in 2003. Dr. Greider was honored for determining a key aspect of how chromosomes are replicated faithfully. Some data from Dr. Greider's laboratory notebook (right) shows regularly spaced signals, indicating that she had found a biochemical process suspected to exist, but not previously discovered. This work not only helped Dr. Greider earn her PhD degree but was also cited when she shared the Nobel Prize.

Outline

1.1 Biochemical Unity Underlies Biological Diversity
1.2 DNA Illustrates the Interplay Between Form and Function

1.3 Concepts from Chemistry Explain the Properties of Biological Molecules
1.4 DNA Sequencing Is Transforming Biochemistry, Medicine, and Other Fields
1.5 Biochemistry Is an Interconnected Human Endeavor

Learning Goals

By the end of this chapter, you should be able to:

1. Provide examples of the unity of biology at the biochemical level.
2. Describe the double-helical structure of DNA including its formation from two component strands in the context of important atomic interactions: covalent bonds, ionic interactions, hydrogen bonds, van der Waals interactions, and the hydrophobic effect.
3. Discuss the first and second laws of thermodynamics and the concepts of entropy and enthalpy.
4. Discuss the importance of single-molecule experiments in terms of understanding reaction rates.
5. Explain the roles of buffers in stabilizing the pH of solutions.
6. Perform calculations using the definitions of pH and pK_a and the Henderson–Hasselbalch equation.
7. Briefly describe some discoveries enabled by advances in DNA sequencing technologies, including the concept of molecular clocks.

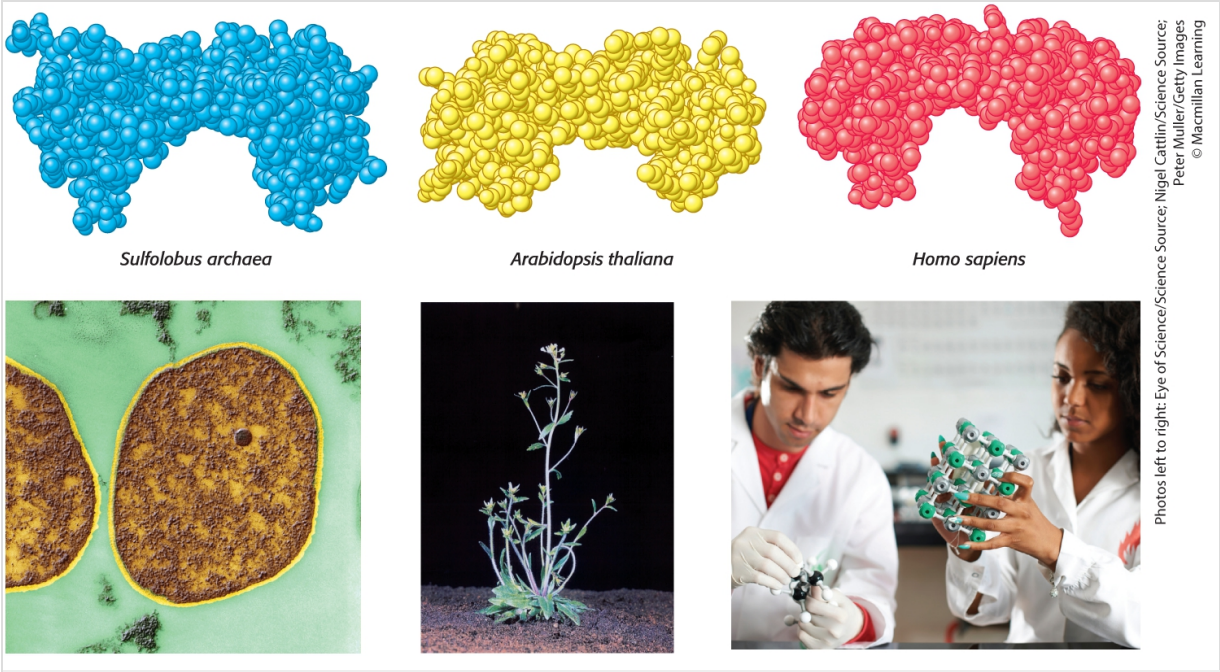
Biochemistry is the study of the chemistry of life processes. Scientists have explored the chemistry of life with great intensity for nearly two centuries. Many of the most fundamental mysteries of how living things function at a biochemical level have been solved. However, much remains to be investigated. As is often the case, each discovery raises at least as many new questions as it answers. We are now in an age of unprecedented opportunity for the application of this tremendous body of knowledge of biochemistry to problems in

medicine, agriculture, forensics, environmental sciences, and many other fields.

1.1 Biochemical Unity Underlies Biological Diversity

The biological world is magnificently diverse. Plant and animal species range from nearly microscopic insects to elephants, whales, and giant sequoias. This variability extends further when we descend into the microscopic world. A great diversity of organisms such as protozoa, yeast, and bacteria are found in water, in soil, and both on and within larger organisms. Some organisms can survive and even thrive in seemingly hostile environments such as hot springs, deep-sea vents, and glaciers.

The development of the microscope revealed a key unifying feature that underlies this diversity: large organisms are built up of **cells**, resembling, to some extent, single-celled microscopic organisms. The construction of animals, plants, and microorganisms from cells suggested that these diverse organisms might have more in common than is apparent from their outward appearance. With the development of biochemistry, this notion has been tremendously supported and expanded. At the biochemical level, all organisms have many common features (**Figure 1.1**).



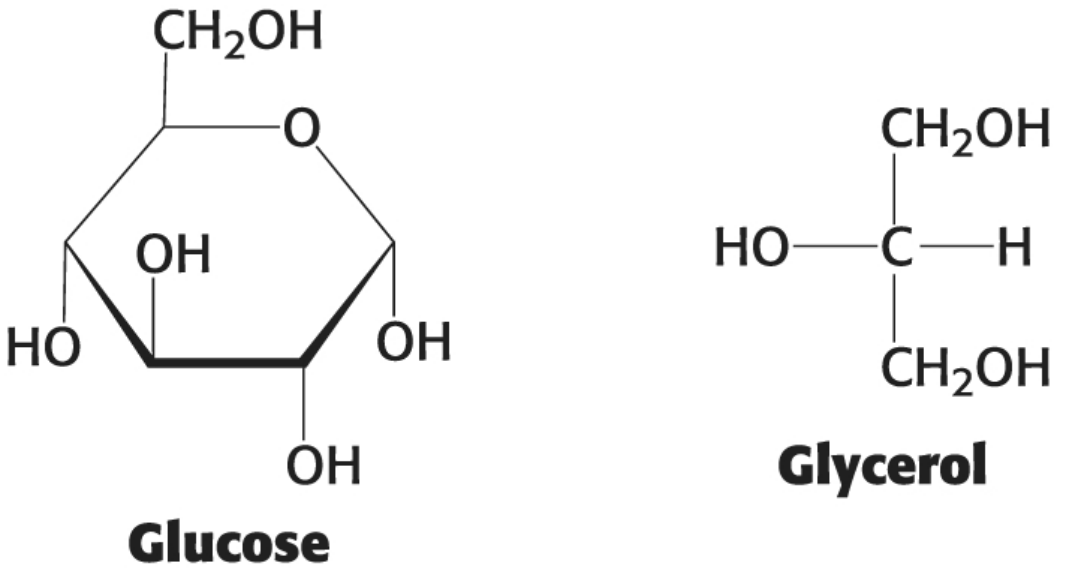


FIGURE 1.1 Despite tremendous biological diversity, there is remarkable similarity in the molecules that make up living organisms. The shape of a key molecule in gene regulation (the TATA-box-binding protein) is similar in three very different organisms that are separated from one another by billions of years of evolution.

Biochemical processes entail the interplay of two different classes of molecules: large molecules such as proteins and nucleic acids, referred to as **biological macromolecules**, and low-molecular-weight molecules such as glucose and glycerol, referred to as **metabolites**, that are chemically transformed in biological processes.

Examples of metabolites

Members of both these classes of molecules are common, with minor variations, to all living things. For example, **deoxyribonucleic acid (DNA)** stores genetic information in all cellular organisms. **Proteins**, macromolecules that are the key participants in most biological processes, are built from the same set of 20 building blocks in all organisms. Furthermore, proteins that play similar roles in different species often have very similar, or sometimes identical, three-dimensional structures (Figure 1.1).

Key metabolic processes also are common to many organisms. For example, the set of chemical transformations that converts glucose and oxygen into carbon dioxide and water is essentially identical in simple bacteria such as *Escherichia coli* (*E. coli*) and human beings. Even processes that appear to be quite distinct often have common features at the biochemical level. Remarkably, the biochemical processes by which plants capture light energy and convert it into

more-useful forms are strikingly similar to steps used in animals to capture energy released from the breakdown of glucose.

These observations overwhelmingly suggest that all living things on Earth have a **common ancestor** and that modern organisms have evolved from this ancestor into their present forms. Geological and biochemical findings support a timeline for this evolutionary path (**Figure 1.2**).

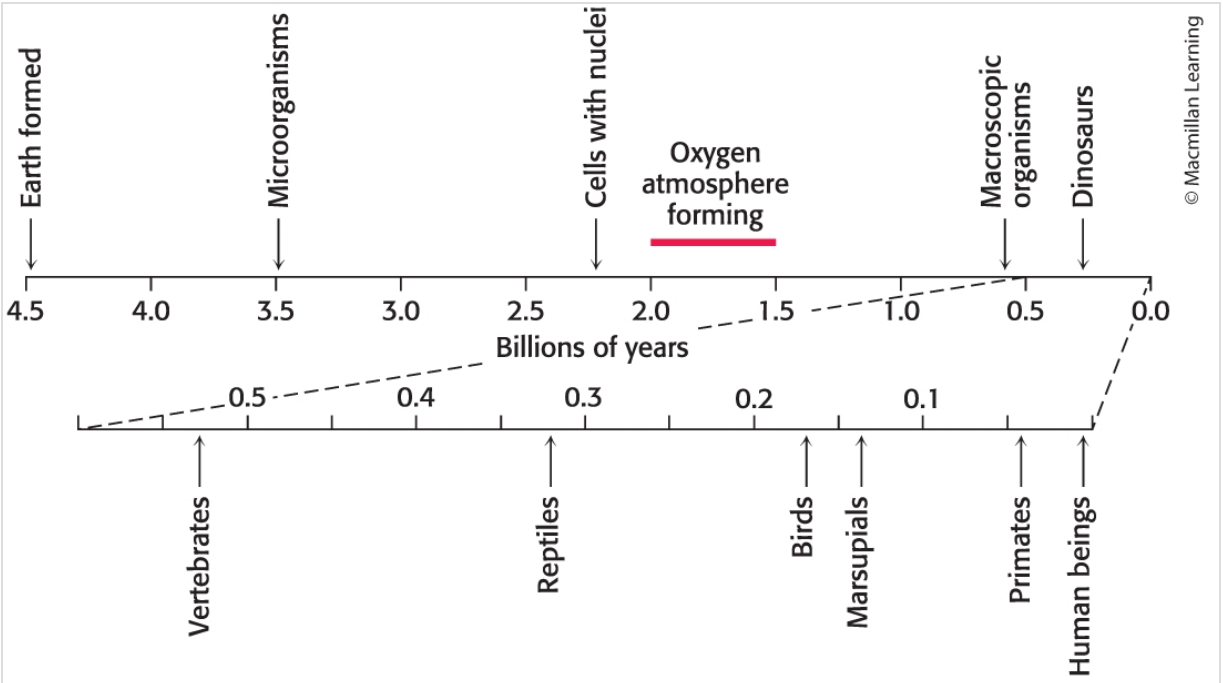

FIGURE 1.2 A possible timeline for biochemical evolution shows that life on Earth began approximately 3.5 billion years ago. Selected key events are indicated, including the relatively recent emergence of human beings. The times of emergence of classes of animals from the fossil record are shown below the main timeline.

On the basis of their biochemical characteristics, the diverse organisms of the modern world can be divided into three

fundamental groups called *domains:* Eukarya, Bacteria, and Archaea.

Domain **Eukarya** (also called **eukaryotes**) comprises all multicellular organisms, including all animals, plants, and human beings, as well as many microscopic unicellular organisms such as yeast. The defining characteristic of eukaryotes is the presence of a well-defined nucleus within each cell.

Unicellular organisms that lack a nucleus are referred to as **prokaryotes**. The prokaryotes were classified as two separate domains in response to Carl Woese's discovery in 1977 that certain unicellular organisms are biochemically quite distinct from previously characterized bacterial species. These organisms, now recognized as having diverged from the domain **Bacteria** early in evolution, make up the domain **Archaea**.

Evolutionary paths from a common ancestor to modern organisms can be deduced on the basis of biochemical information, with one possible such path shown in **Figure 1.3**. Much of this book will explore the chemical reactions and the associated biological macromolecules and metabolites that are found in biological processes common to all organisms. The unity of life at the biochemical level makes this approach possible. At the same time, different species have specific needs, depending on the particular biological niche in which they evolved and live. By comparing and contrasting details of particular biochemical pathways in different species, we can learn how biological challenges have been solved at the biochemical level. In most cases, these challenges are addressed by the adaptation of existing macromolecules to new roles rather than by the evolution of entirely new ones.

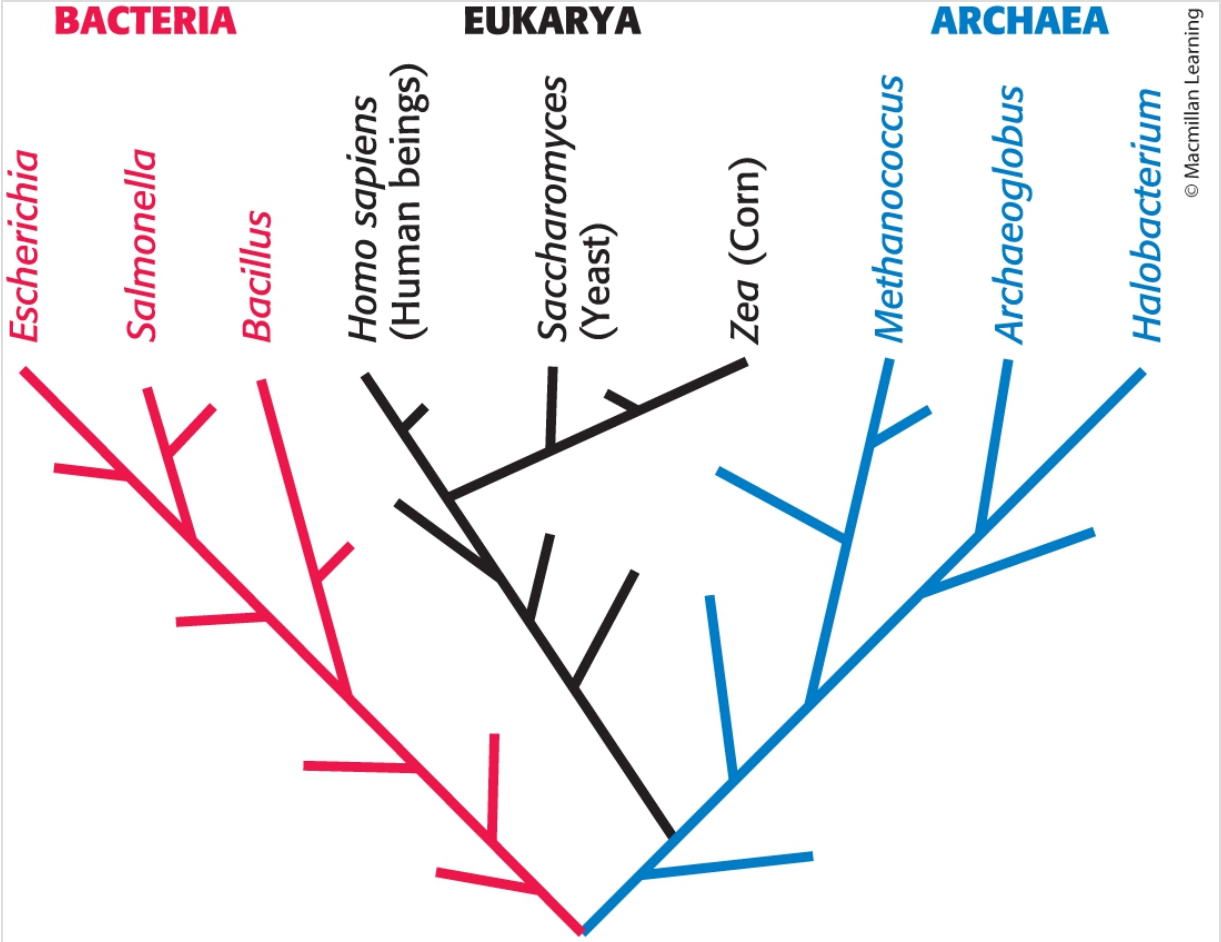

FIGURE 1.3 The relationships of all modern organisms can be displayed on a tree of life with just three major branches. A possible evolutionary path from a common ancestor is represented at the bottom of the tree, with organisms found in the modern world at the top.

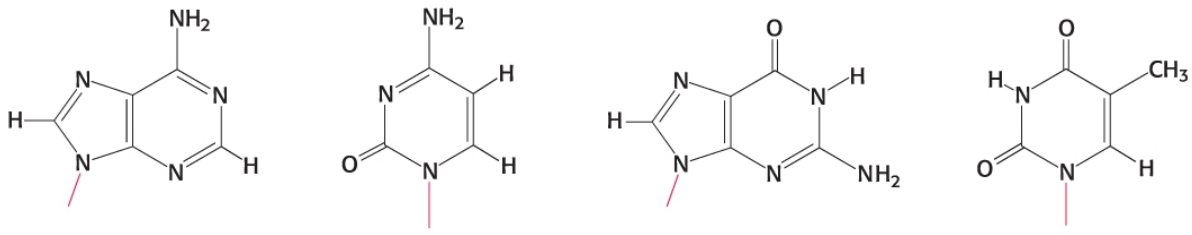
Biochemistry has been greatly enriched by our ability to examine the three-dimensional structures of biological macromolecules in exquisite detail. Some of these structures are simple and elegant, whereas others are incredibly complicated. In any case, these structures provide an essential framework for understanding function. We begin our exploration of the interplay between structure and function with the genetic material, DNA.



1.2 DNA Illustrates the Interplay Between Form and Function

A fundamental biochemical feature common to all cellular organisms is the use of DNA for the storage of genetic information. The discovery that DNA plays this central role was first made in studies of bacteria in the 1940s. A compelling proposal for the three-dimensional structure of DNA followed in 1953, setting the stage for many of the advances in biochemistry and numerous other fields, extending to the present.

The structure of DNA powerfully illustrates a basic principle common to all biological macromolecules: the intimate relationship between structure and function. The remarkable chemical properties of this substance allow it to function as an efficient and robust vehicle for storing information. We start with an examination of the covalent structure of DNA and its extension into three dimensions.

DNA is constructed from four building blocks

DNA is a linear polymer made up of four different types of monomers. It has a fixed backbone from which protrude variable substituents, referred to as **nitrogenous bases**, or simply, **bases** (**Figure 1.4**). The backbone is built of repeating sugar–phosphate units. The sugars are molecules of deoxyribose from which DNA receives its name. Each sugar is connected to two phosphate groups through different linkages. Moreover, each sugar is oriented in the same way, and so each DNA strand has directionality, with one end distinguishable from the other. This **polarity** is very important for many processes involving DNA. Joined to each deoxyribose is one of four possible nitrogenous bases: adenine (A), cytosine (C), guanine (G), and thymine (T).

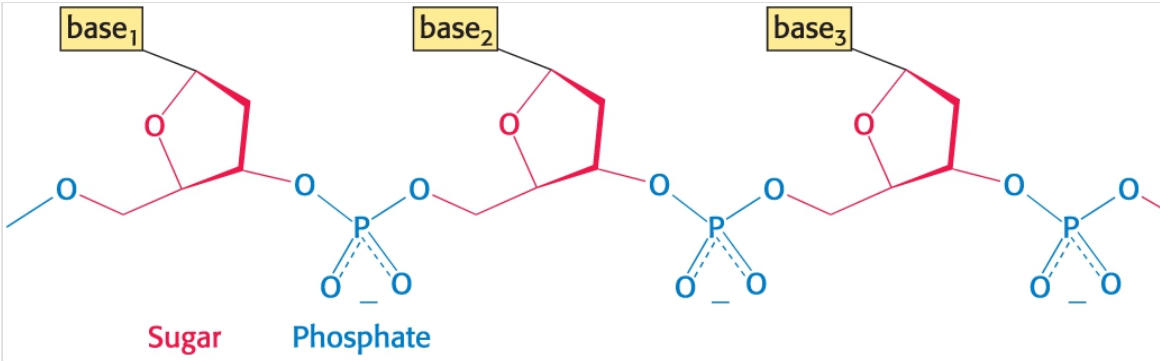


FIGURE 1.4 The covalent structure of DNA is a linear polymer of monomeric units. Each monomer is composed of a sugar (deoxyribose), a phosphate, and a variable nitrogenous base that protrudes from the sugar–phosphate backbone.

These bases are connected to the sugar components in the DNA backbone through the bonds shown in black in Figure 1.4. All four bases are planar but differ significantly in other respects. Thus, each monomer of DNA, called a *nucleotide*, consists of a sugar–phosphate unit and one of four bases attached to the sugar. These bases can be arranged in any order along a strand of DNA.

Two single strands of DNA combine to form a double helix

Most DNA molecules consist of not one but two strands (**Figure 1.5**). In 1953, James Watson and Francis Crick deduced the arrangement of these strands and proposed a three-dimensional structure for DNA molecules based, in part, on experimental data from Rosalind Franklin. This structure is a **double helix** composed of two intertwined strands arranged such that the sugar–phosphate backbone lies on the outside and the bases on the inside. The key to this structure is that the bases form specific **base pairs** held together by noncovalent interactions called *hydrogen bonds* (Section 1.3): adenine pairs with thymine (A–T) and guanine pairs with cytosine (G–C), as shown in **Figure 1.6**. Hydrogen bonds are much weaker than covalent bonds such as the carbon–carbon or carbon–nitrogen bonds that define the structures of the bases themselves. Such weak interactions are crucial to biochemical systems; they are weak enough to be reversibly broken in biochemical processes, yet they are strong enough, particularly when many form simultaneously, to help stabilize specific structures such as the double helix.

FIGURE 1.5 The double helix has two antiparallel strands. This representation of the double-helical structure of DNA proposed by Watson and Crick shows the sugar–phosphate backbones the two chains in red and blue, and the bases in green, purple, orange, and yellow. The two strands are antiparallel, running in opposite directions with respect to the axis of the double helix, as indicated by the arrows.

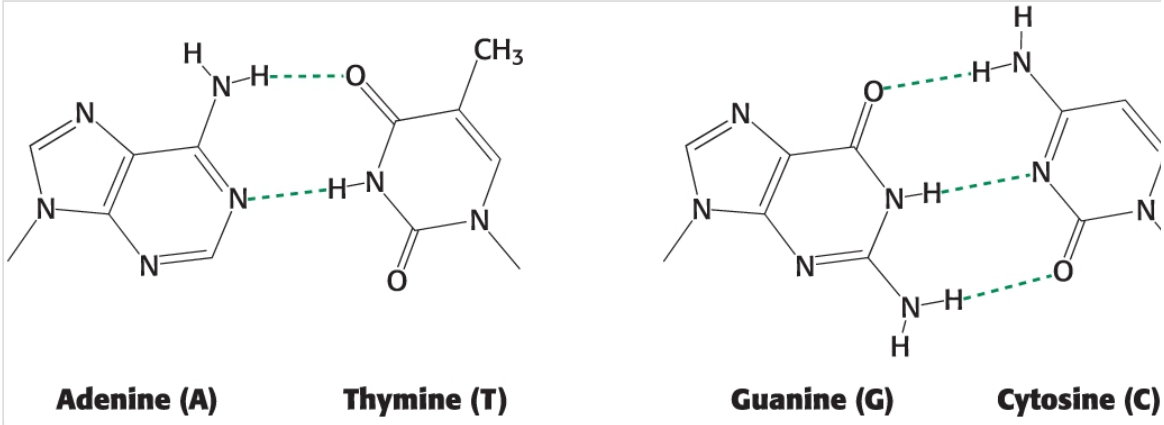

FIGURE 1.6 The nitrogenous bases in DNA form specific Watson–Crick base pairs. Adenine pai with thymine (A–T) and guanine with cytosine (G–C). The dashed green lines represent hydroge bonds.

DNA structure explains heredity and the storage of information

The structure proposed by Watson and Crick has two properties of central importance to the role of DNA as the hereditary material. First, the structure is compatible with any sequence of bases. While the bases are distinct in structure, the base pairs have essentially the same shape and thus fit equally well into the center of the double-helical structure of any sequence. Without any constraints, the sequence of bases along a DNA strand can act as an efficient means of encoding information. Indeed, the sequence of bases along DNA strands is how genetic information is stored. The DNA sequence determines the sequences of

the ribonucleic acid (RNA) and protein molecules that carry out most of the activities within cells.

Second, because of base pairing, the sequence of bases along one strand completely determines the sequence along the other strand. As Watson and Crick so coyly wrote: “It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.” Thus, if the DNA double helix is separated into two single strands, each strand can act as a template for the generation of its partner strand through specific base-pair formation (Figure 1.7). The three-dimensional structure of DNA beautifully illustrates the close connection between molecular form and function.

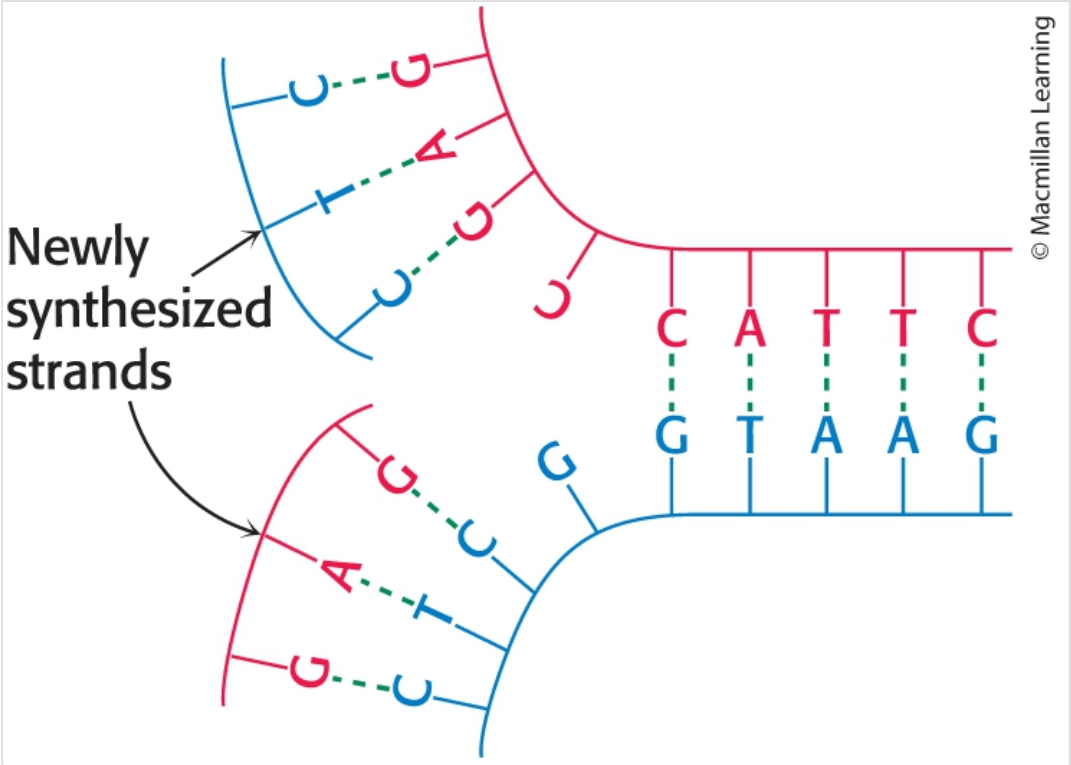

FIGURE 1.7 Once separated, each strand of the DNA double helix can act as a template for the generation of its partner strand.

1.3 Concepts from Chemistry Explain the Properties of Biological Molecules

We have seen how a chemical insight into the hydrogen-bonding capabilities of the bases of DNA led to a deep understanding of a fundamental biological process. To lay the groundwork for the rest of the book, we begin our study of biochemistry by examining selected concepts from chemistry and showing how these concepts apply to biological systems. The concepts include the types of chemical interactions; the structure of water, the solvent in which most biochemical processes take place; the First and Second Laws of Thermodynamics; and the principles of acid–base chemistry.

The formation of the DNA double helix is a key example

We will use these concepts to examine an archetypical biochemical process — the formation of a DNA double helix from its two component strands. The process is but one of many examples that could have been chosen to illustrate these topics. Keep in mind that, although the specific discussion is about DNA and double-helix formation, these concepts are quite general and will apply to many other classes of molecules and processes that will be discussed in the remainder of the book.

The double helix can form from its component strands

The discovery that DNA from natural sources exists in a double-helical form with Watson–Crick base pairs suggested, but did not prove, that such double helices would form spontaneously outside biological systems. Suppose that two short strands of DNA were chemically synthesized to have **complementary sequences** so that they could, in principle, form a double helix with Watson–Crick base pairs. Two such sequences are CGATTAAT and ATTAATCG. In this context, the term *complementary* refers to the fact that the two sequences can form Watson–Crick base pairs when the sequence of one of them is written in the reverse order.

The structures of these molecules in solution can be examined through a variety of techniques. In isolation, each sequence exists almost exclusively as a single-stranded molecule. However, when the two sequences are mixed, a double helix with Watson–Crick base pairs does form (**Figure 1.8**).

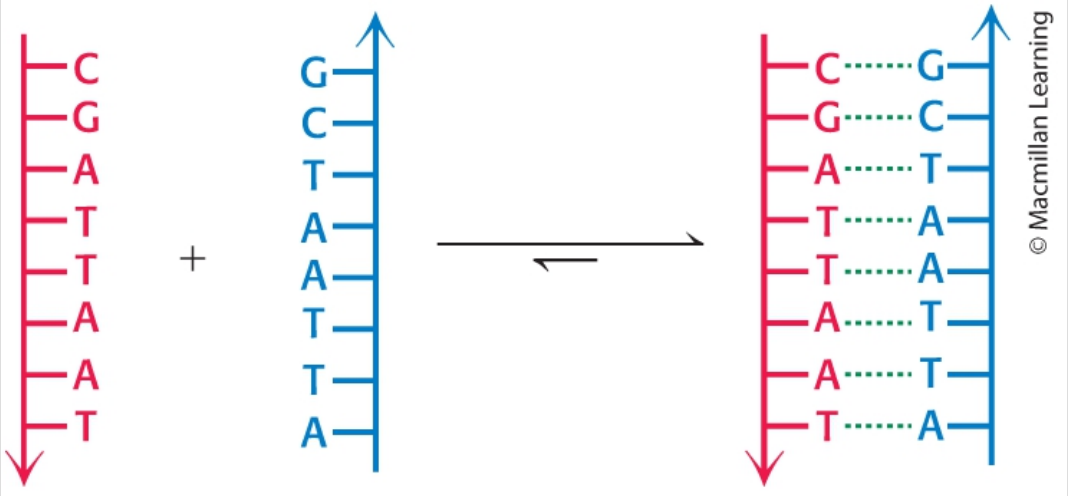

FIGURE 1.8 When two DNA strands with complementary sequences are mixed, they spontaneously assemble to form a double helix.

Self-Check Question

What DNA sequence can form a double helix with $5'-AGGTCCGATA-3'$?

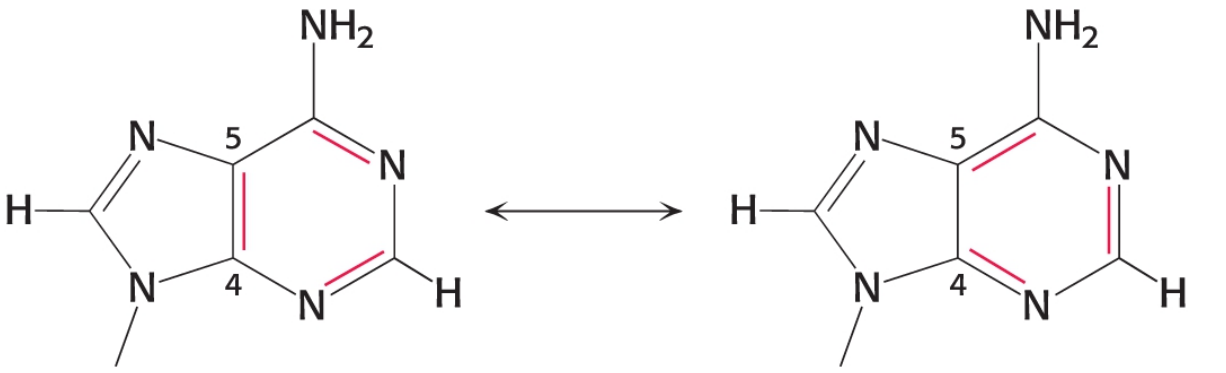
What forces cause the two strands of DNA to bind to each other? To analyze this binding process, we must consider several factors: the types of interactions and bonds in biochemical systems, the thermal motion of molecules, the energetic favorability of the process, and the influence of the solution conditions — in particular, the consequences of acid–base reactions. Remarkably, this process proceeds nearly to completion in less than a millisecond when the single strands are mixed at appropriate concentrations. How does this process occur so rapidly?

Atoms and molecules undergo random motions that help define the timescales for biochemical interactions

The atoms and molecules within and around us are in constant thermal motion: translating, vibrating, rotating, and colliding with one another very rapidly. How fast do these processes occur? One useful estimate to consider is that the gas molecules that make up the air you are breathing now are colliding with one another about 1 billion (10^9)

times per second, meaning the relevant timescale for these interactions is best measured in nanoseconds (10^{-9} s).

On a similar timescale to these gaseous molecular interactions are the biochemical interactions taking place in your cells. The timescale for biochemical interactions and processes are broadly on the order of picoseconds to microseconds (10^{-12}-10^{-6} s), which we shall refer to as the **biochemical timescale**. Consideration of this timescale can be quite illuminating in understanding biochemical phenomena. The rates of molecular interactions can be challenging to comprehend because, relative to them, human beings perceive time very slowly. Indeed, our perceptions are dependent on complex cascades of these very interactions. By carefully considering this timescale from the molecular perspective, we can improve our intuitions about the speed of chemical and biochemical events. For example, imagine a reaction that occurs once per millisecond (10^{-3} s), or 1000 times per second. Is this reaction occurring quickly or slowly? Our intuition about the passage of time might compel us to consider this a very fast reaction; this is, in fact, an imperceptibly short time for a human being. However, consider that molecules colliding one billion times per second will experience 1 million (10^{6}) unproductive collisions in this timeframe, on average, before a single reaction event occurs. From the perspective of a molecule undergoing these interactions, this reaction does not seem to be occurring particularly fast at all, but rather is the result of events that occur only rarely.



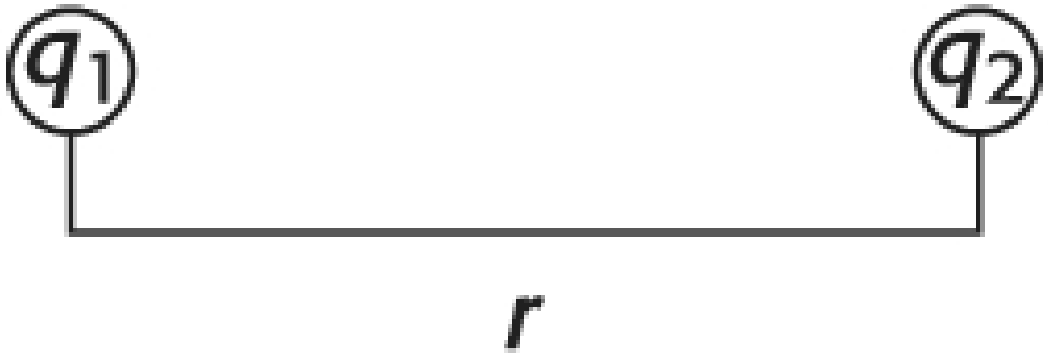
Many aspects of biochemistry depend on promoting specific processes and reactions so that they occur at biologically useful rates, harnessing the underlying rates of molecular interactions. In Chapters 5–7, we will focus explicitly on biochemical reaction rates and their control. In addition, we will visit the topic of biological timescale many times throughout the book as we explore molecular interactions in the context of biological systems.

Covalent bonds and noncovalent interactions are important for the structure and stability of biological molecules

Counteracting the chaos of thermal motion are attractive interactions that stabilize biological molecules. Atoms favorably interact with one another in several ways, including through the covalent bonds that define the structure of molecules, as well as a variety of noncovalent interactions that are of great importance to biochemistry. Among the strongest chemical interactions are **covalent bonds**, such as the bonds that hold the atoms together within DNA's individual bases. A covalent bond is formed by the sharing of a pair of electrons between adjacent atoms. A typical carbon–carbon ($C—C$) covalent bond has a bond length of $1.54\ Å$ — where $1\ Å$ (angstrom) is equivalent to one ten-billionth of a meter, or approximately 1/750,000th the width of a human hair — and a bond energy of $355\ kJ\ mol^{-1}$ ($85\ kcal\ mol^{-1}$). Because covalent bonds are so strong, considerable energy must be expended to break them. Recall that one joule (J) is the amount of energy required to move 1 meter against a force of 1 newton, and a kilojoule (kJ) is 1000 joules.

More than one electron pair can be shared between two atoms to form a multiple covalent bond. For example, three of the bases in Figure 1.6 include carbon–oxygen ($C=O$) double bonds. These bonds are shorter in length and even stronger than $C—C$ single bonds, with energies near $730\ kJ\ mol^{-1}$, or $175 kilocalories (kcal) mol^{-1}$.

For some molecules, more than one pattern of covalent bonding can be written; these alternative patterns are called **resonance structures**.



These adenine structures depict alternative arrangements of single and double bonds that are possible within the same structural framework, but the true structure of adenine is a composite of its two resonance structures. The composite structure has properties that are a blend of the two alternative states. For example, the observed length for the bond joining carbon atoms C-4 and C-5 is $1.40\ \text{Å}$, which is in between that expected for a $\text{C}-\text{C}$ single bond ($1.54\ \text{Å}$) and a $\text{C}=\text{C}$ double bond ($1.34\ \text{Å}$). A molecule that can be written as several resonance structures of approximately equal energies generally has greater stability than does a molecule without multiple resonance structures.

Noncovalent interactions are weaker than covalent bonds but are crucial for biochemical processes such as the formation of a double helix. Four fundamental noncovalent interaction types are ionic interactions, hydrogen bonds, van der Waals interactions, and hydrophobic interactions. They differ in geometry, strength, specificity, and physical origin. Furthermore, these interactions are affected in vastly different ways by the presence of water. Let us consider the characteristics of each type:

Ionic interactions

In an **ionic interaction**, a charged group on one molecule can attract an oppositely charged group on the same or another molecule. The energy of an ionic interaction (sometimes called an *electrostatic interaction*) is given by the Coulomb energy:

$$E = kq_1q_2 / Dr$$

where E is the energy, q_1 and q_2 are the charges on the two atoms (in units of the electronic charge), r is the distance between the two atoms (in angstroms), D is the dielectric constant (which decreases the Coulomb energy depending on the intervening solvent or medium), and k is a proportionality constant ($k = 1389$ for energies in units of kJ mol^{-1}, or 332 for energies in kcal mol^{-1}).

The ionic interaction between two ions bearing single opposite charges separated by $3\ \text{Å}$ in water (which has a dielectric constant of 80) has an energy of $5.8\ \text{kJ mol}^{-1}$ $(1.4\ \text{kcal mol}^{-1})$. Note the importance of the dielectric constant of the medium. For the same ions separated by $3\ \text{Å}$

in a solvent such as hexane (which has a dielectric constant of 2), the energy of this interaction is $232\ \text{kJ mol}^{-1}$ ($55\ \text{kcal mol}^{-1}$).

Thus far we have considered interactions between ions, atoms, or molecules that have one or more full electric charges. However, even molecules that have no overall charge can have regions where the electron distribution is uneven, such they are partially negatively or partially positively charged. This leads to **electric dipoles** (or simply **dipoles**) that can interact with ions or with other dipoles (**Figure 1.9**).

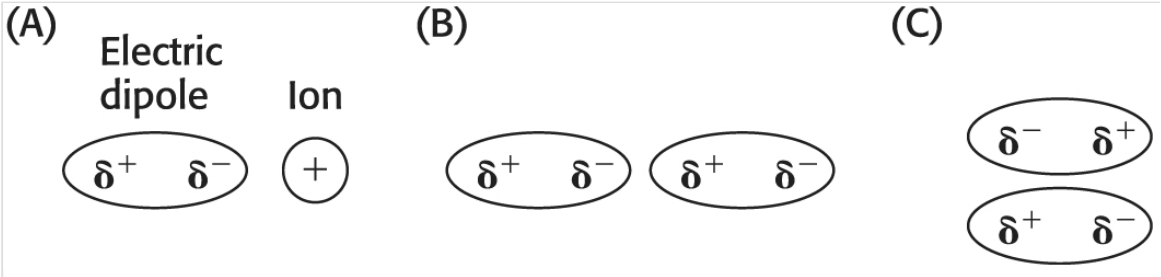


FIGURE 1.9 Electric dipoles can form a variety of noncovalent interactions. (A) An electric dipole can interact with an ion, with the negative end of the dipole pointing toward the positive charged ion. (B) Two dipoles can interact, with the negative end of one pointing toward to the positive end of the other. (C) Two dipoles position themselves so that both the positive and negative ends can favorably interact.

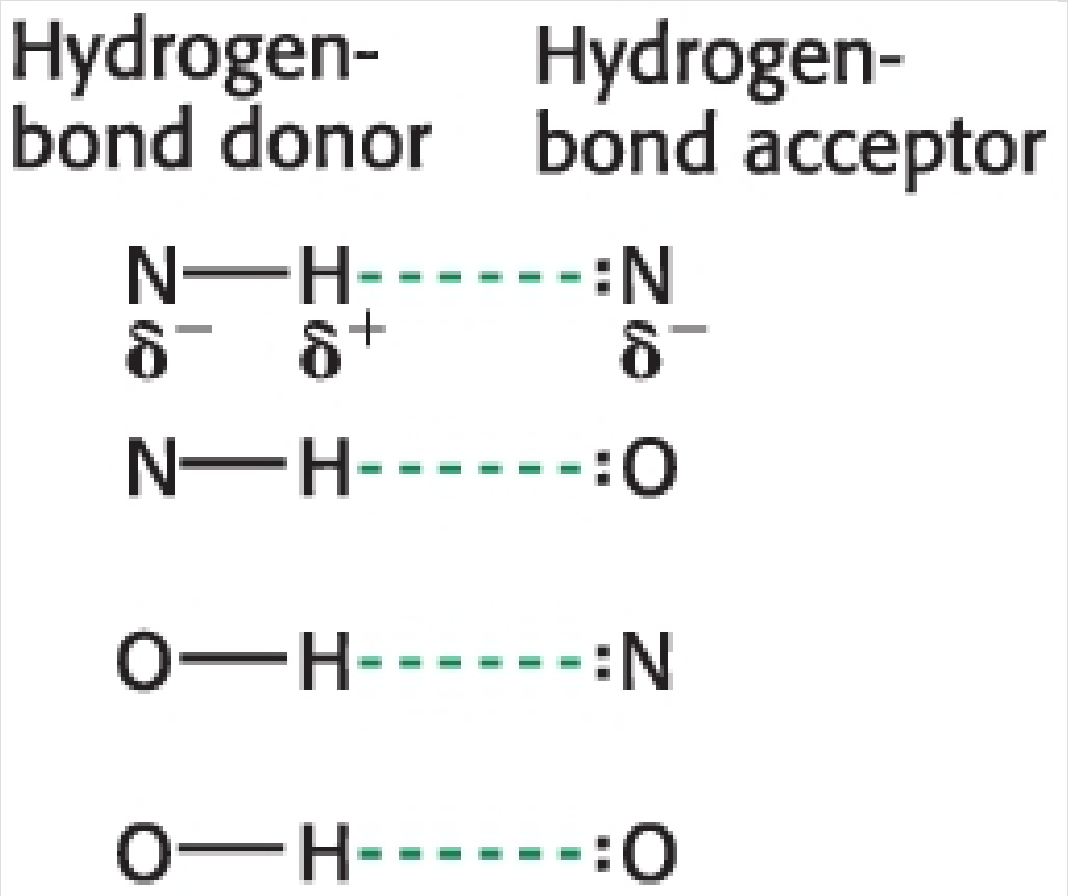
Hydrogen bonds

Hydrogen bonds are a specific type of dipole-dipole interactions that are so important in biochemistry that we single them out for a separate discussion. We already introduced hydrogen bonds in the context of their role in specific base-pair formation in the DNA double helix. In a **hydrogen bond**, an electropositive hydrogen atom is partially shared by two electronegative atoms such as nitrogen or oxygen. The **hydrogen-bond donor** is the group that includes both the atom to which the

hydrogen atom is covalently bonded and the hydrogen atom itself, whereas the **hydrogen-bond acceptor** is the lone pair of electrons that is on the atom less tightly linked to the hydrogen atom (Figure 1.10). The electronegative atom to which the hydrogen atom is covalently bonded pulls electron density away from the hydrogen atom, which thus develops a partial positive charge (δ^+). This hydrogen atom with a partial positive charge can interact with a lone pair of electrons on an atom having a partial negative charge (δ^-) through a dipole-dipole interaction.



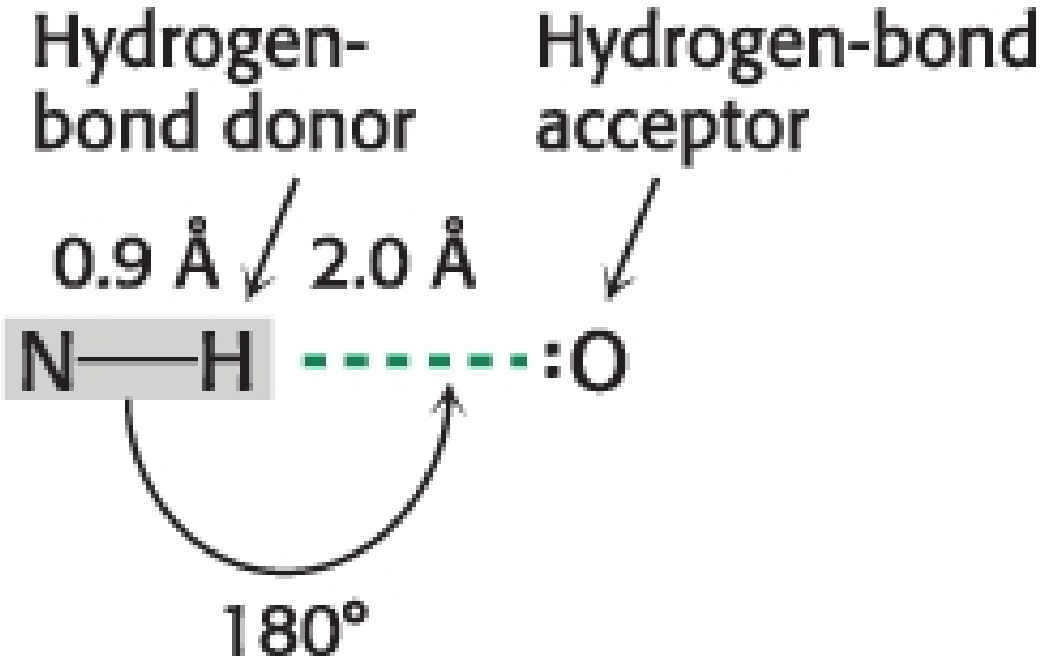


FIGURE 1.10 Hydrogen bonds are weak noncovalent interactions between specific hydrogen atoms and lone pairs of electrons. Hydrogen bonds are depicted as dashed green lines and the positions of the partial charges as δ^+ and δ^-.

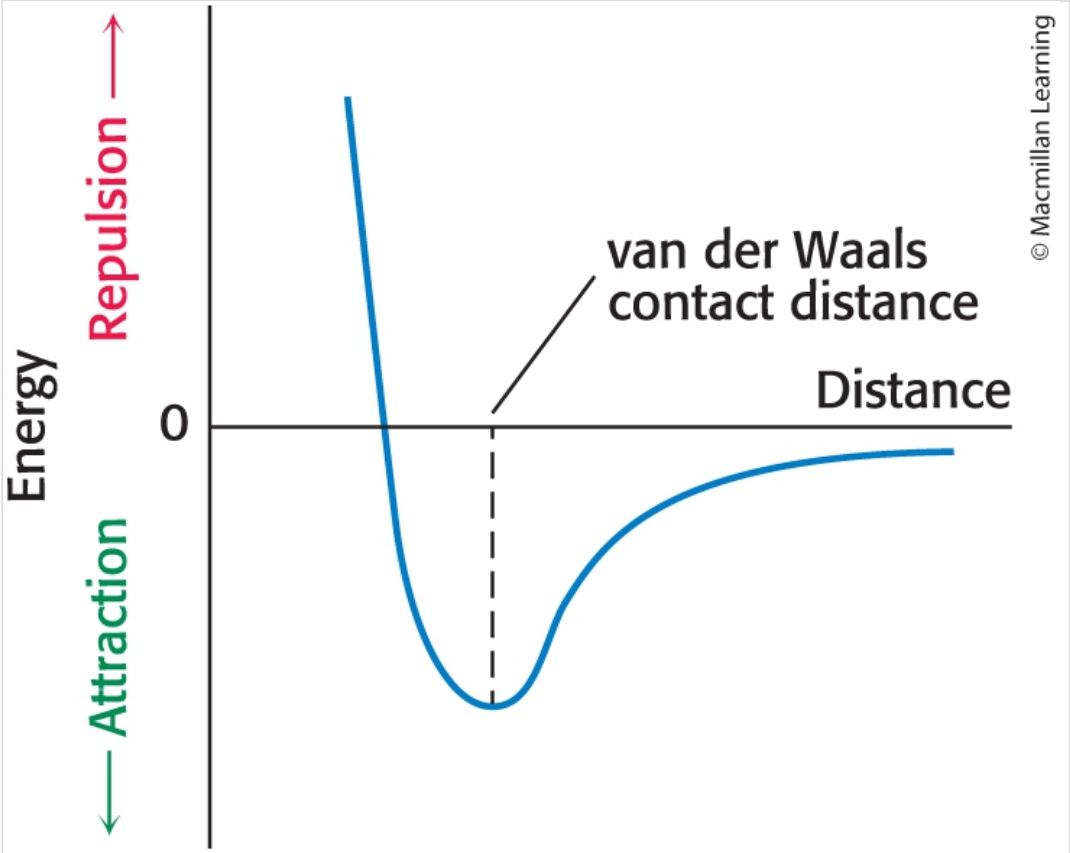
Hydrogen bonds are much weaker than covalent bonds. They have energies ranging from 4 to $20\ \text{kJ mol}^{-1}$ (from 1 to $5\ \text{kcal mol}^{-1}$). Accordingly, hydrogen bonds are also somewhat longer than covalent bonds; their bond lengths (measured from the hydrogen atom) range from $1.5\ \text{Å}$ to $2.6\ \text{Å}$. Hence, a distance ranging from $2.4\ \text{Å}$ to $3.5\ \text{Å}$ separates the two nonhydrogen atoms in a hydrogen bond.

Hydrogen bonds tend to be straight, such that the hydrogen-bond donor, the hydrogen atom, and the hydrogen-bond acceptor lie in a line. This tendency toward linearity can be important for orienting interacting molecules with respect to one another. Hydrogen-bonding interactions

are responsible for many of the properties of water that make it such an important solvent, as will be described shortly.

van der Waals interactions

The basis of a **van der Waals interaction** is that the distribution of electronic charge around an atom fluctuates with time. At any instant, the charge distribution is not perfectly symmetric, leading to a dipole. This dipole acts through dipole-dipole interactions to induce a complementary dipole in its neighboring molecules, causing an attraction between the molecules. This attraction increases as the two atoms come closer to each other, until they are separated by what is termed the **van der Waals contact distance** (**Figure 1.11**). At distances shorter than the van der Waals contact distance, very strong repulsive forces become dominant because the outer electron clouds of the two atoms overlap.



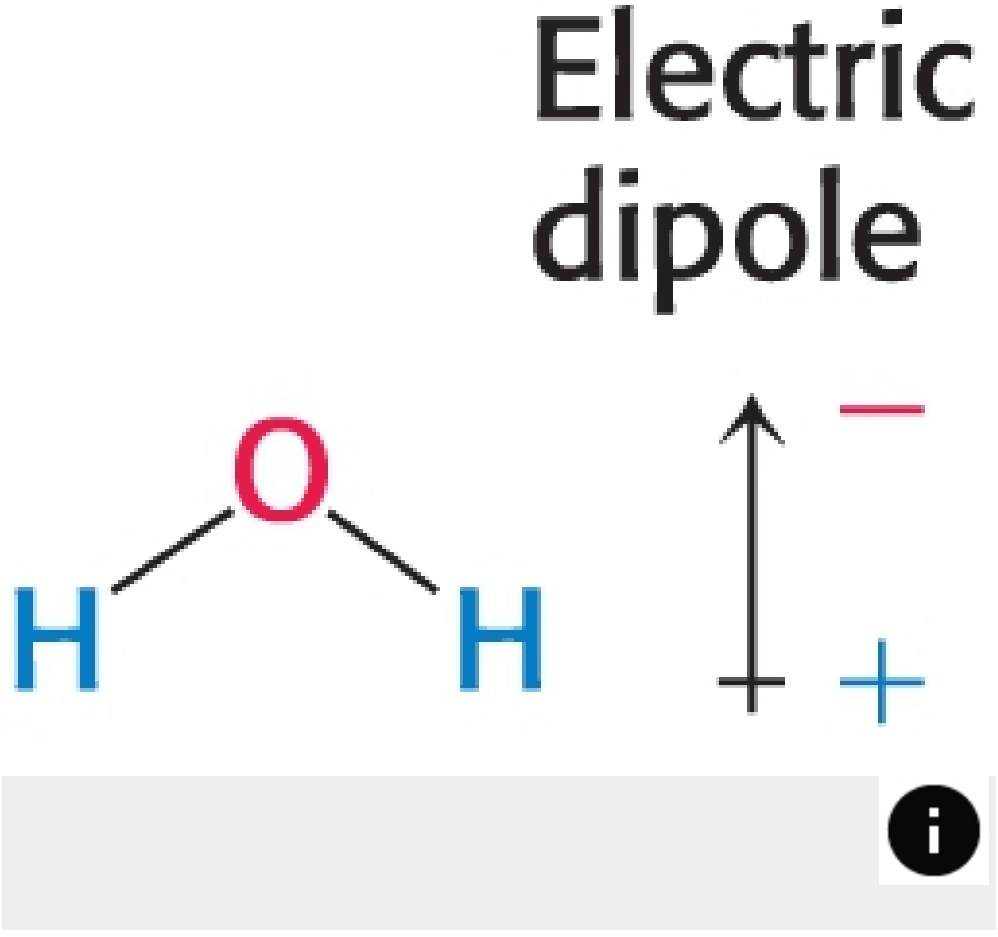


FIGURE 1.11 The energy of a van der Waals interaction varies and is most favorable at the van der Waals contact distance. Owing to electron–electron repulsion, the energy rises rapidly as the distance between the atoms becomes shorter than the contact distance.

Energies associated with van der Waals interactions are quite small; typical interactions contribute from 2 to $4\ \text{kJ mol}^{-1}$ (0.5 to $1\ \text{kcal mol}^{-1}$) per atom pair. When the surfaces of two large molecules come together, however, a large number of atoms are in van der Waals contact; the net effect, summed over many atom pairs, can be substantial.

The hydrophobic effect

Before we define the last noncovalent interaction, it's important to remember that water is the solvent in which most biochemical reactions take place; thus its properties are essential to the formation of macromolecular structures and the progress of chemical reactions. Two properties of water are especially relevant:

- *Water is a polar molecule*. The water molecule is bent, not linear, and so the distribution of charge is asymmetric. The oxygen nucleus draws electrons away from the two hydrogen nuclei, which leaves the region around each hydrogen atom with a net positive charge. The water molecule thus has a permanent electric dipole.

The polar nature of water is responsible for its high dielectric constant of 80. Molecules in aqueous solution interact with water molecules through the formation of hydrogen bonds and through ionic interactions. These interactions make water a versatile solvent, able to readily dissolve many species, especially polar and charged compounds that can participate in these interactions.

- *Water is highly cohesive*. Water molecules interact strongly with one another through hydrogen bonds. These interactions are apparent in the structure of ice (**Figure 1.12**). Networks of hydrogen bonds hold the structure together; similar interactions link molecules in liquid water and account for many of the properties of water. In the liquid state, approximately one in four of the hydrogen bonds present in ice is broken.

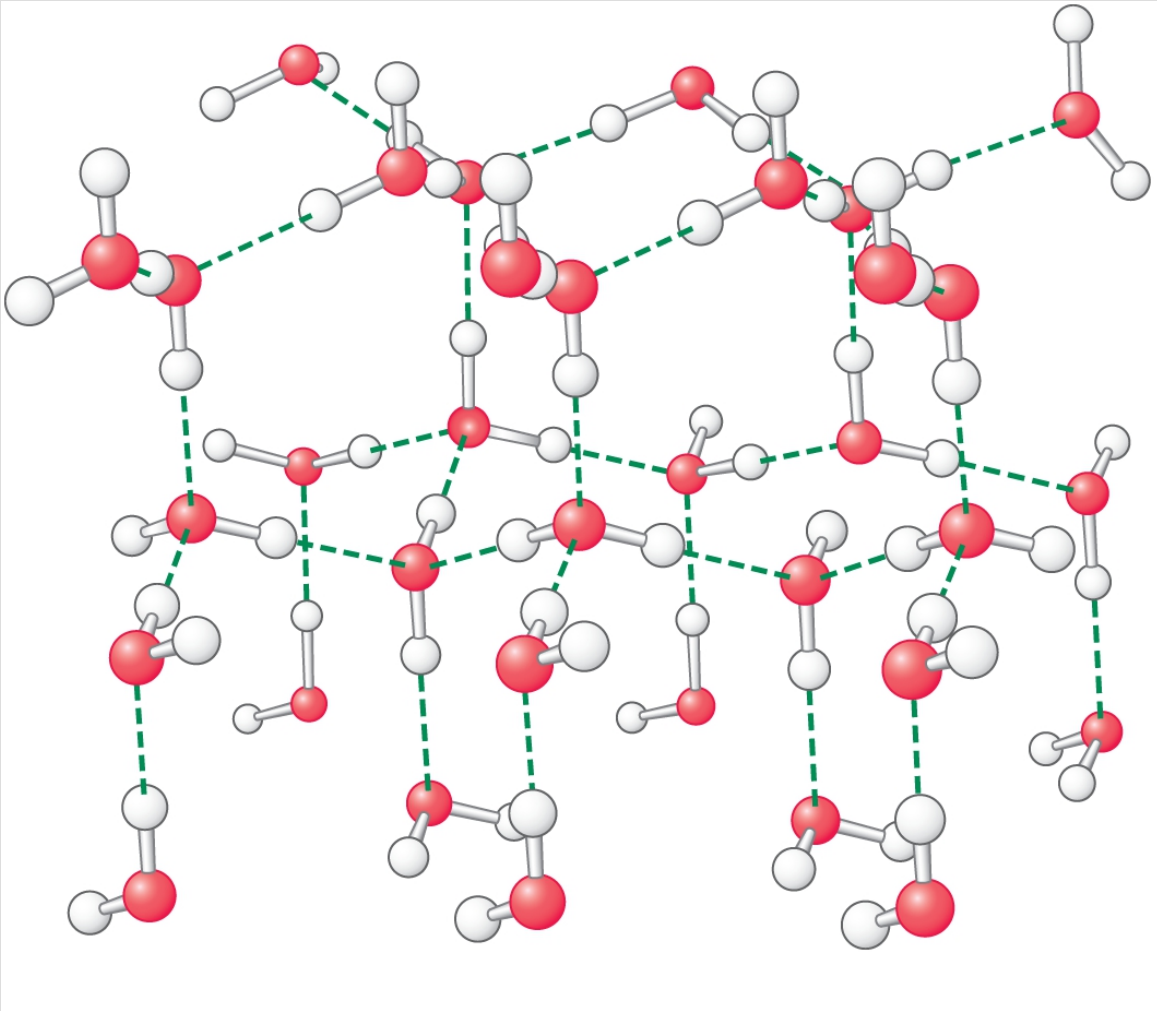

FIGURE 1.12 The structure of ice involves extensive hydrogen bonding. Hydrogen bonds (shown as dashed green lines) are formed between water molecules, producing a highly ordered and open structure.

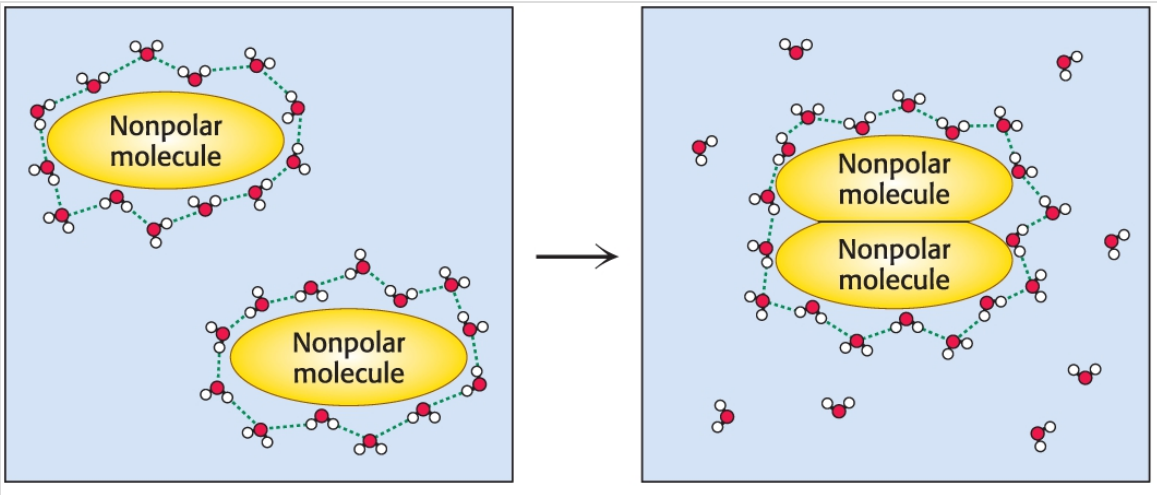
The **hydrophobic effect** is a manifestation of the properties of water just described: it is the increased tendency for nonpolar molecules to aggregate in water compared with other, less polar and less self-associating, solvents. Some molecules (termed **nonpolar molecules**) lack any dipoles and therefore cannot participate in hydrogen bonding or ionic interactions. Polar water molecules interact much more favorably with each other than they do with nonpolar molecules. In the presence of nonpolar molecules, water molecules form cage-like structures around them, becoming more ordered than water molecules free in solution. However, when two such nonpolar molecules come together, some of the water molecules that had been surrounding them are released from the "cage." The released water molecules interact freely with bulk water (**Figure 1.13**). Why the release of water from such cages is favorable will be considered shortly. The result is that nonpolar molecules show an increased tendency to associate with one another in water. This tendency is called the *hydrophobic effect*; the associated interactions are called *hydrophobic interactions*.



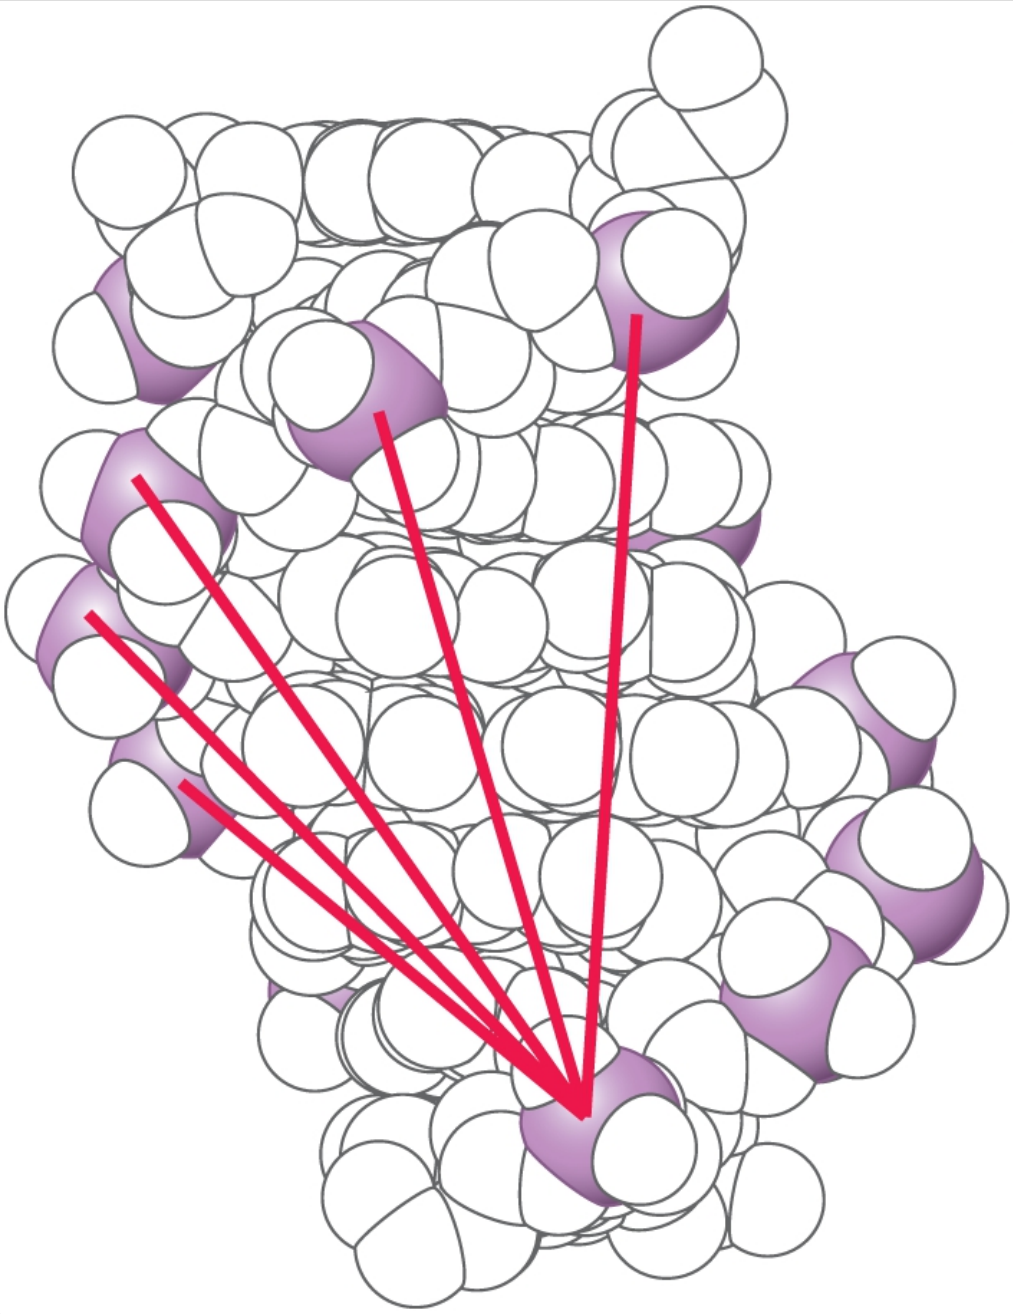


FIGURE 1.13 The hydrophobic effect is due to the behavior of water molecules. The aggregation of nonpolar groups in water leads to the release of water molecules, initially interacting with the nonpolar surface, into bulk water. The release of water molecules into solution makes the aggregation of nonpolar groups favorable.

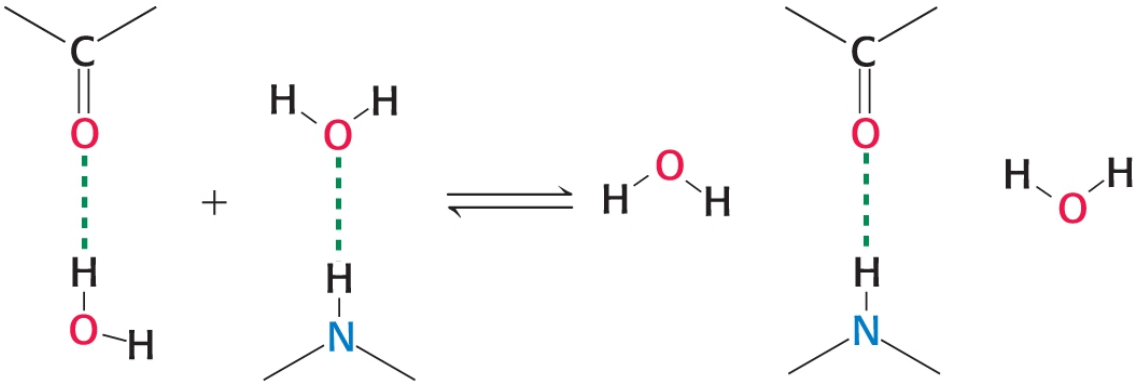
The formation of DNA's double helix is an expression of the rules of chemistry

Let us now explore how these noncovalent interactions work together to drive the association of two strands of DNA to form a double helix.



- *The aqueous environment surrounding DNA favors helix formation, overcoming the ionic repulsion between charged phosphate groups.* Each phosphate group in a DNA strand carries a negative charge and thus interacts unfavorably with other phosphate groups over distances. Even though the phosphate groups are far apart in the double helix, with distances greater than $10\ \text{Å}$, many such interactions take place (**Figure 1.14**). Thus, ionic interactions oppose the formation of the double helix. However, the strength of these repulsive ionic interactions is diminished by the high dielectric constant of water and the presence of ionic species such as Na^+ or Mg^{2+} ions in solution. These positively charged species interact with the phosphate groups and partly neutralize their negative charges.

© Macmillan Learning

FIGURE 1.14 Ionic interactions among phosphate groups oppose the formation of the DNA double helix. Each unit within the double helix includes a phosphate group (the phosphorus atom shown in purple) that bears a negative charge. The unfavorable (repulsive) interactions of one phosphate with several others are shown by red lines.

- *Hydrogen bonds help ensure the specificity of base-pairing.* The second type of noncovalent interactions to consider in the formation of the double helix are hydrogen bonds. In single-stranded DNA, the hydrogen-bond donors and acceptors are exposed to solution and can form hydrogen bonds with water molecules. When two single strands come together, these hydrogen bonds with water are broken and new hydrogen bonds between the bases are formed.

Because the number of hydrogen bonds that are broken is the same or greater than the number that are formed, these new hydrogen bonds do not contribute substantially to driving the overall process of double-helix formation. However, they do contribute greatly to the specificity of binding. Suppose two bases that cannot form Watson–Crick base pairs (adenine and cytosine, for example) are brought together. Hydrogen bonds with water must be broken as the bases come into contact, but because the bases are not complementary in structure, not all of the broken bonds can be simultaneously replaced by hydrogen bonds between the bases. Thus, the formation of a double helix between noncomplementary sequences is disfavored.

- *Within a double helix, van der Waals interactions encourage base stacking*. The base pairs are parallel and stacked nearly on top of one another, with a typical separation of $3.4\ \text{Å}$ between the planes of adjacent base pairs and approximately $3.6\ \text{Å}$ between the most closely approaching atoms. This separation distance corresponds nicely to the van der Waals contact distance (Figure 1.15). Bases tend to stack even in single-stranded DNA molecules. However, the base stacking and associated van der Waals interactions are nearly optimal in a double-helical structure.

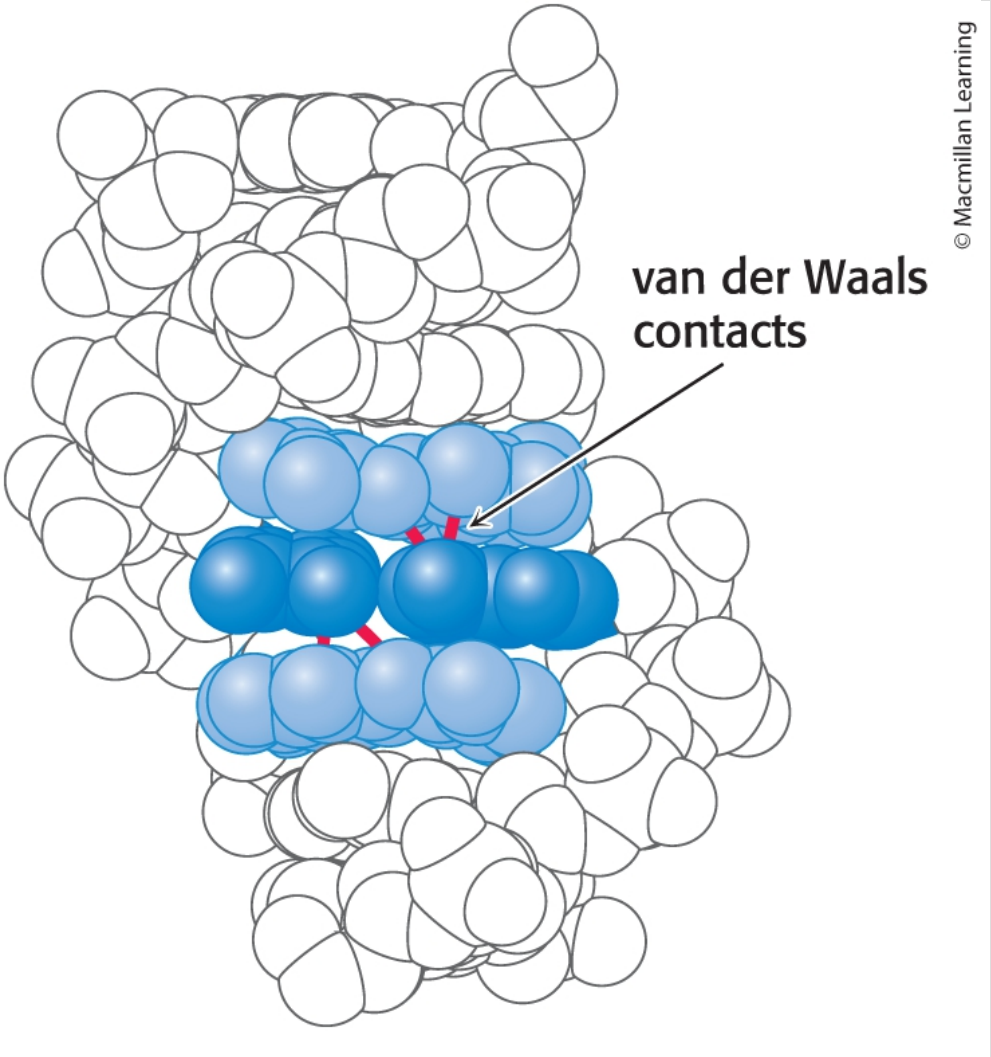


FIGURE 1.15 Optimal base stacking allows many weak, but favorable, van der Waals contacts that drive double-helix formation. In the DNA double

helix, adjacent base pairs are stacked nearly on top of one another, and so many atoms in each base pair are separated by their van der Waals contact distance. The central base pair is shown in dark blue and the two adjacent base pairs in light blue. Several van der Waals contacts are shown in red.

- *The hydrophobic effect also contributes to the favorability of base stacking.* More-complete base stacking moves the nonpolar surfaces of the bases away from water molecules and into contact with each other.

The principles of double-helix formation between two strands of DNA apply to many other biochemical processes. Many weak interactions contribute to the overall energetics of the process, some favorably and some unfavorably. Furthermore, **surface complementarity** is a key feature: when complementary surfaces meet, hydrogen-bond donors align with hydrogen-bond acceptors, and nonpolar surfaces come together to maximize van der Waals interactions and minimize nonpolar surface area exposed to the aqueous environment. The properties of water play a major role in determining the importance of these interactions. Interactions between complementary surfaces play central roles in a great many biochemical processes, and we will encounter them repeatedly throughout the book.

The laws of thermodynamics govern the behavior of biochemical systems

We can look at the formation of the double helix from a different perspective by examining the laws of thermodynamics, general principles that apply to all physical (and biological) processes. The laws distinguish between a system and its surroundings; a *system* refers to the

matter and energy within a defined region of space, and the matter and energy in the rest of the universe is called the *surroundings.*

The laws of thermodynamics are of great importance because they determine the conditions under which specific processes can or cannot take place. We will consider these laws from a general perspective first and then apply the principles that we have developed to the formation of the double helix.

- *The First Law of Thermodynamics states that the total energy of a system and its surroundings is constant.* In other words, the energy content of the universe is constant; energy can be neither created nor destroyed. Energy can take different forms, however. Heat, for example, is one form of energy. Heat is a manifestation of the *kinetic energy* associated with the random motion of molecules. Alternatively, energy can be present as *potential energy* — energy of position that will be released on the occurrence of some process. Consider, for example, a ball held at the top of a tower. In this position the ball has considerable gravitational potential energy because, when it is released, the ball will develop kinetic energy associated with its motion as it falls. Chemical potential energy is related to the plausible ways that atoms might react with one another. For instance, a mixture of gasoline and oxygen has a large potential energy because these molecules can react to form carbon dioxide and water and release energy as heat.

  Energy is always required to break chemical bonds and is released when new bonds form. The First Law requires that any energy released in the formation of chemical bonds must be used to break other bonds, released as heat or light, or stored in some other form.

- *The Second Law of Thermodynamics states that the total entropy of a system plus that of its surroundings always increases.* **Entropy** is a measure of the degree of randomness or disorder in a system. For example, the hydrophobic effect — the release of water from nonpolar surfaces — is favorable because water molecules that are

free in solution are more disordered than they are when they are associated with nonpolar surfaces.

At first glance, the Second Law appears to contradict much common experience, particularly about biological systems. Many biological processes, such as the generation of a leaf from carbon dioxide gas and other nutrients, clearly increase the level of order and hence decrease entropy. Entropy may be decreased locally in the formation of such ordered structures only if the entropy of other parts of the universe is increased by an equal or greater amount. The local decrease in entropy is usually accomplished by a release of heat, which increases the entropy of the surroundings.

We can analyze this process in quantitative terms. First, consider the system. The entropy (*S*) of the system may change in the course of a chemical reaction by an amount ΔS_{system}. If heat flows from the system to its surroundings, then the heat content, often referred to as the **enthalpy** (*H*), of the system will be reduced by an amount ΔH_{system}. To apply the Second Law, we must determine the change in entropy of the surroundings. If heat flows from the system to the surroundings, then the entropy of the surroundings will increase.

The precise change in the entropy of the surroundings depends on the temperature; the change in entropy is greater when heat is added to relatively cold surroundings than when heat is added to surroundings at high temperatures; these surroundings are already in a high degree of disorder. To be even more specific, the change in the entropy of the surroundings will be proportional to the amount of heat transferred from the system and inversely proportional to the temperature (*T*) of the surroundings. In biological systems, *T*, absolute temperature in kelvins (K), is usually assumed to be constant. Thus, a change in the entropy of the surroundings is given by

$$\Delta S_{surroundings} = -\Delta H_{system} / T$$

(1)

The total entropy change is given by the expression

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}}$$

(2)

Substituting equation 1 into equation 2 yields

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} - \Delta H_{\text{system}} / T$$

(3)

Multiplying by $-T$ gives

$$-T\Delta S_{\text{total}} = \Delta H_{\text{system}} - T\Delta S_{\text{system}}$$

The function $-T\Delta S$ has units of energy and is referred to as **free energy** or **Gibbs free energy**, after Josiah Willard Gibbs, who developed this function in 1878:

$$\Delta G = \Delta H_{\text{system}} - T\Delta S_{\text{system}}$$

The free-energy change, ΔG, will be used throughout this book to describe the energetics of biochemical reactions. The Gibbs free energy can also be considered the energy available to do useful work; it is essentially an accounting tool that keeps track of both the entropy of the system (directly) and the entropy of the surroundings (in the form of heat released from the system).

Recall that the Second Law of Thermodynamics states that, for a process to take place, the entropy of the universe must increase. Examination of equation 3 shows that the total entropy will increase if and only if

$$\Delta S_{\text{system}} > \Delta H_{\text{system}} / T$$

Rearranging gives $T\Delta S_{\text{system}} > \Delta H_{\text{system}}$ or, in other words, entropy will increase if and only if

$$\Delta G = \Delta H_{\text{system}} - T\Delta S_{\text{system}} < 0$$

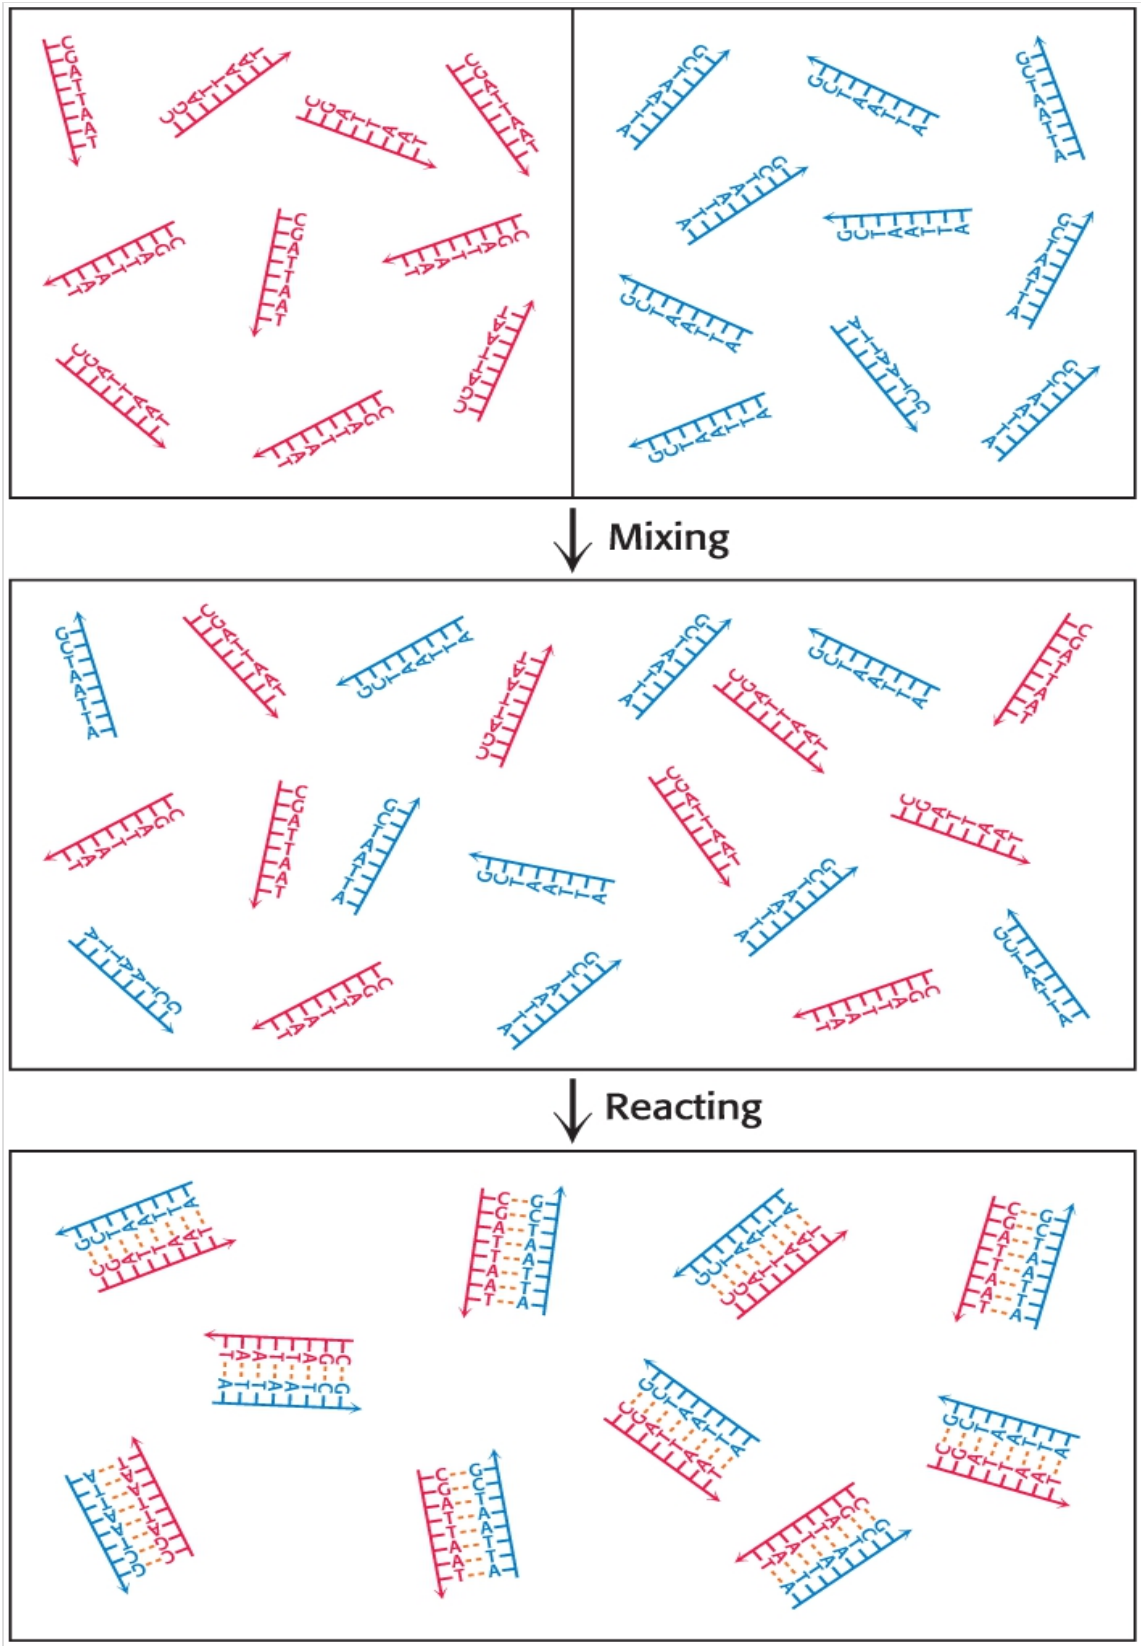
Thus, the free-energy change must be negative for a process to take place spontaneously. There is negative free-energy change when and only when the overall entropy of the universe is increased.

Self-Check Question

The free energy can be calculated based on the system only. Why don't the surroundings need to be considered separately?

By releasing heat, the formation of the double helix obeys the Second Law of Thermodynamics

Let's see how the principles of thermodynamics apply to the formation of the double helix (**Figure 1.16**). Suppose solutions containing each of the two single strands are mixed. Before the double helix forms, each of the single strands is free to translate (change position) and rotate in solution, whereas each matched pair of strands in the double helix must move together. Additionally, the free single strands exist in more conformations than possible when bound together in a double helix. Thus, the formation of a double helix from two single strands appears to result in a decrease rather than an increase in disorder, and therefore entropy, of the system.



Mixing
Reacting

FIGURE 1.16 Double-helix formation entails a loss of entropy. When solutions containing DNA strands with complementary sequences are mixed, the strands react to form double helices. Th process results in a loss of entropy from the system, indicating that heat must be released to th surroundings to prevent a violation of the Second Law of Thermodynamics.

On the basis of this analysis, we expect that the double helix cannot form without violating the Second Law of Thermodynamics unless heat is released to increase the entropy of the surroundings. Experimentally, we can measure the heat released by allowing the solutions containing the two single strands to come together within a water bath, which here corresponds to the surroundings. We then determine how much heat must be absorbed by the water bath or released from it to maintain it at a constant temperature.

This experiment establishes that a substantial amount of heat is released — namely, approximately $250\ \text{kJ mol}^{-1}$ ($60\ \text{kcal mol}^{-1}$) — consistent with our expectation that significant heat would have to be released to the surroundings for the process not to violate the Second Law. We see in quantitative terms how order within a system can be increased by releasing sufficient heat to the surroundings to ensure that the entropy of the universe increases. We will encounter this general theme throughout this book.

Double-helix formation can be monitored one molecule at a time

One of the most exciting advances in biochemistry in recent years has been the development of methods to monitor some types of biochemical reactions one molecule at a time. To see why this is such an astounding achievement, recall that chemistry typically deals in terms

of fractions of moles, and that a mole contains Avogadro's number (6.0×10^{23}) of molecules, a truly astronomical number. Being able to observe single molecules requires technological improvements to provide adequate signal to noise, as well as clever conceptions of experiments that often utilize other discoveries in biochemistry. We will discuss examples of these so-called *single-molecule methods* in some detail several times in this book. For now, we will examine the results when single molecules are monitored during the formation of double helices from single-stranded DNA molecules.

New methods allow one single-stranded DNA molecule to be exposed very abruptly to a solution containing a normal laboratory concentration, typically on the order of $1\ \mu M\ (10^{-6}\ moles/liter)$ of the complementary single-stranded DNA. Once exposed to the solution, the potential double-helix formation process is allowed to occur for a fixed period of time on the millisecond ($10^{-3}\ s$) timescale. At the completion of this period, the result of the process can be probed, to see if the exposed single-stranded molecule found and bound a partner to form a double helix (**Figure 1.17**).

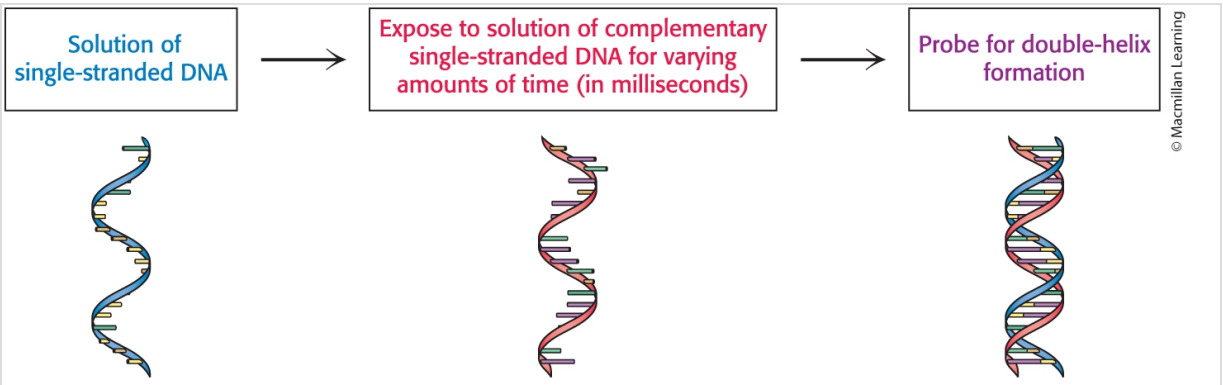


FIGURE 1.17 DNA double-helix formation can be probed at the single-molecule level. After one DNA single strand is exposed to a solution containing the complementary strand for a specific period of time, double-helix formation is probed. This experiment can be repeated many times with different individual DNA single strands.

Suppose that the first time we do the experiment, with an exposure time of 2.0 milliseconds, we observe that the double helix is formed. Perhaps surprisingly, however, when we repeat the identical experiment, no double helix is observed. We push on and repeat the experiment 800 times and observe that sometimes double-helix formation is observed, but usually it is not (Figure 1.18).

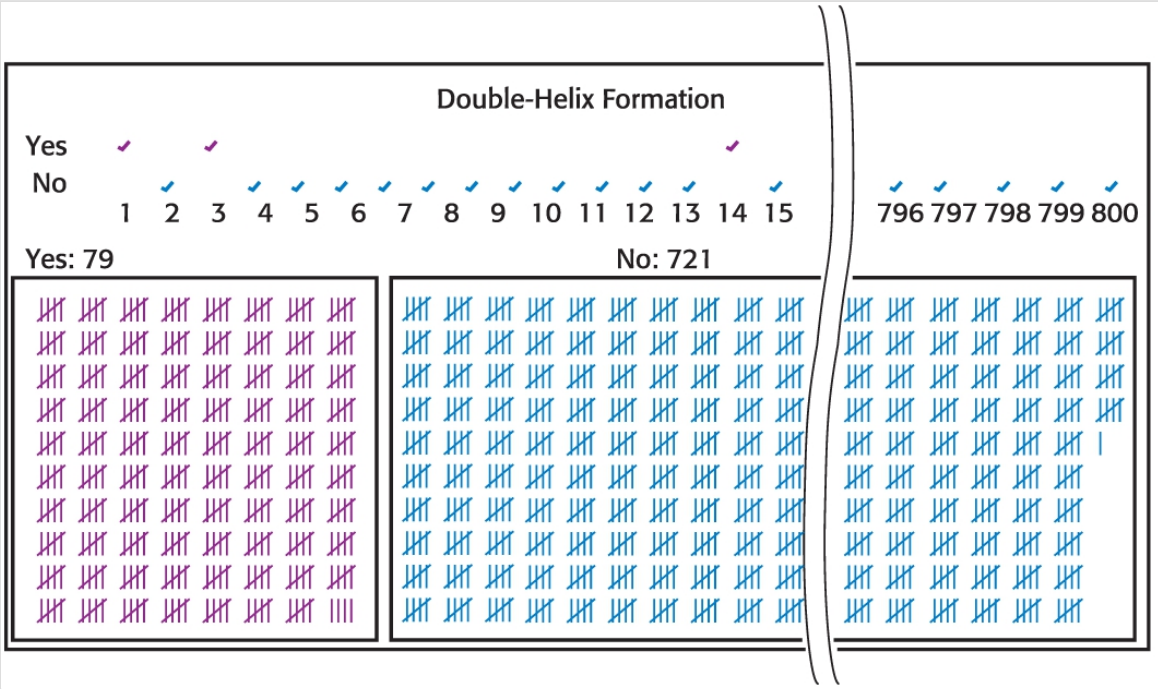

FIGURE 1.18 A tally sheet for repeating a single-molecule experiment shows the combined results of numerous individual trials. DNA double-helix formation was probed 800 times with a exposure time of 2.0 milliseconds, resulting in 79 times when a double helix was detected and 721 times where it was not.

Overall, the double-helix formation was observed in 9.9% (79/800) of the experiments. This value fluctuates somewhat as the number of experiments increases. For example, after 100 experimental runs were completed, 15 (or 15.0%) showed double-helix formation, whereas after 500 runs, 51 instances (or 10.2%) of double-helix formation were seen. A plot of the percentage showing double-helix formation as a function of the number of experimental runs reveals fluctuations prior to reaching a stable value (Figure 1.19).

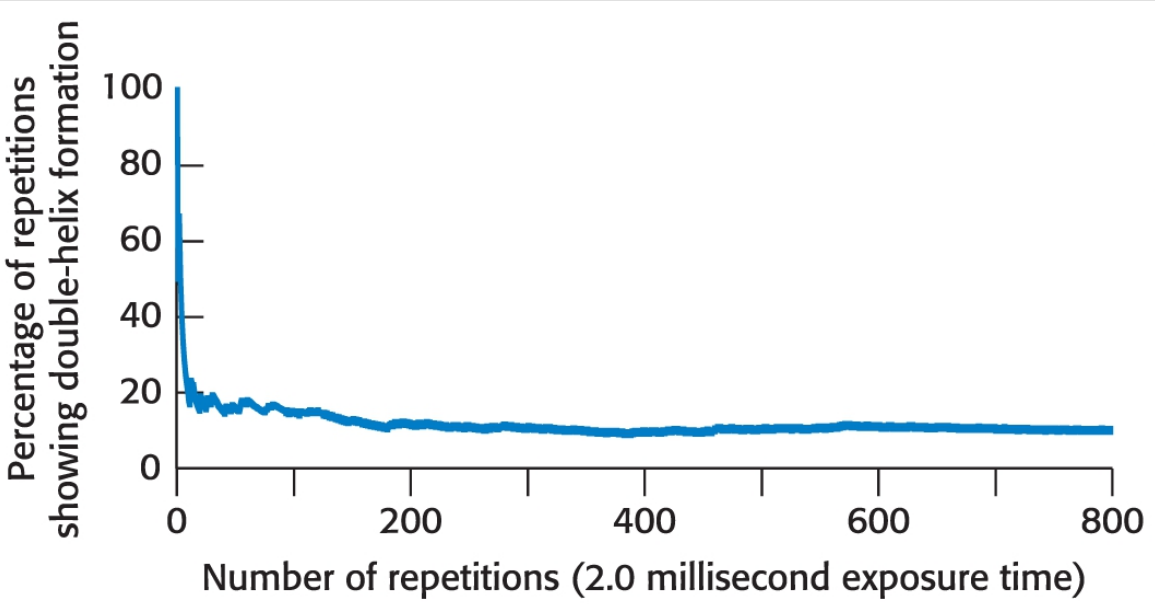

FIGURE 1.19 A plot of the running average of the number of experimental repetitions observing double-helix formation reveals eventual convergence on a stable value. For example, for the point at 500 repetitions, 51 had shown double-helix formation, for a percentag of $51/500 = 10.2\%$.

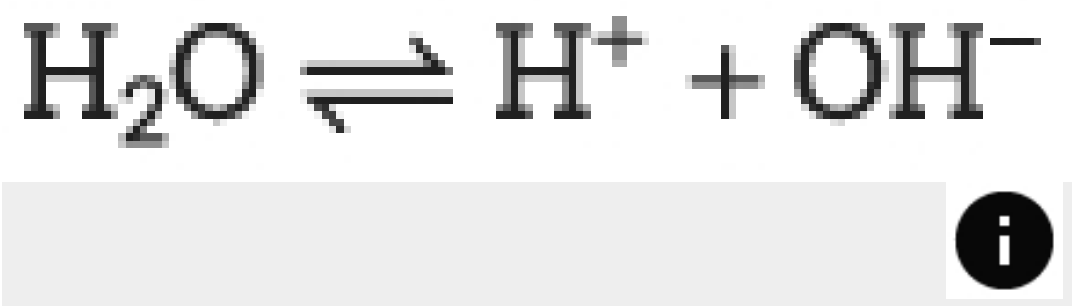
These results show that, at the single molecule level, the outcome of a particular attempt is not predictable — sometimes the double-helix forms, and sometimes it does not. Such processes are often referred to as **stochastic**. However, when averaged over hundreds of repetitions, the chance of double-helix formation converges to a well-defined

probability. Under most circumstances, we observe processes involving thousands, billions, or billions of billions of molecules, so that the variability at the single-molecule level is not apparent. However, it is best to keep in mind the reality of the variability at the level of single molecules; understanding this stochasticity is key to understanding some biochemical processes.

Acid–base reactions are central in many biochemical processes

Throughout our consideration of the formation of the double helix, we have dealt only with the noncovalent interactions that occur or are disrupted in this process. In addition, many biochemical processes entail the formation and cleavage of covalent bonds. A particularly important class of reactions prominent in biochemistry is **acid–base reactions**, in which hydrogen ions are added to molecules or removed from them. Throughout the book, we will encounter numerous processes in which the addition or removal of hydrogen ions is crucial.



A hydrogen ion, often written as H^+, corresponds to a proton. In fact, hydrogen ions exist in solution bound to water molecules, thus forming what are known as *hydronium ions*, H_3O^+. For simplicity, we will continue to write H^+, but we should keep in mind that H^+ is shorthand for the actual species (H_3O^+) that is present.

The concentration of hydrogen ions in solution is expressed as the pH Specifically, the **pH** of a solution is defined as

$$pH = -\log[H^+]$$

where $[H^+]$ is in units of molarity (M). Thus, pH 7.0 refers to a solution for which $-\log[H^+] = 7.0$, and so $\log[H^+] = -7.0$ and $[H^+] = 10^{\log[H^+]} = 10^{-7.0} = 1.0 \times 10^{-7}$ M.

The pH also indirectly expresses the concentration of hydroxide ions, $[OH^-]$, in solution. To see how, we must realize that water molecules can dissociate to form H^+ and OH^- ions in an equilibrium process:

The equilibrium constant (K) for the dissociation of water is defined as

$$K = [H^+][OH^-]/[H_2O]$$

and has a value of $K = 1.8 \times 10^{-16}$. Note that an equilibrium constant does not formally have units. Nonetheless, the value of the equilibrium constant given assumes that particular units are used for concentration (sometimes referred to as standard states); in this case and in many others, units of molarity (M) are assumed.

The concentration of water, $[H_2O]$, in pure water is 55.5 M, and this concentration is constant under most conditions. Thus, we can define a new constant, K_W:

$$\begin{aligned} K_W &= K[H_2O] = [H^+][OH^-] \\ K[H_2O] &= 1.8 \times 10^{-16} \times 55.5 \\ &= 1.0 \times 10^{-14} \end{aligned}$$

Because $K_W = [H^+][OH^-] = 1.0 \times 10^{-14}$, we can calculate

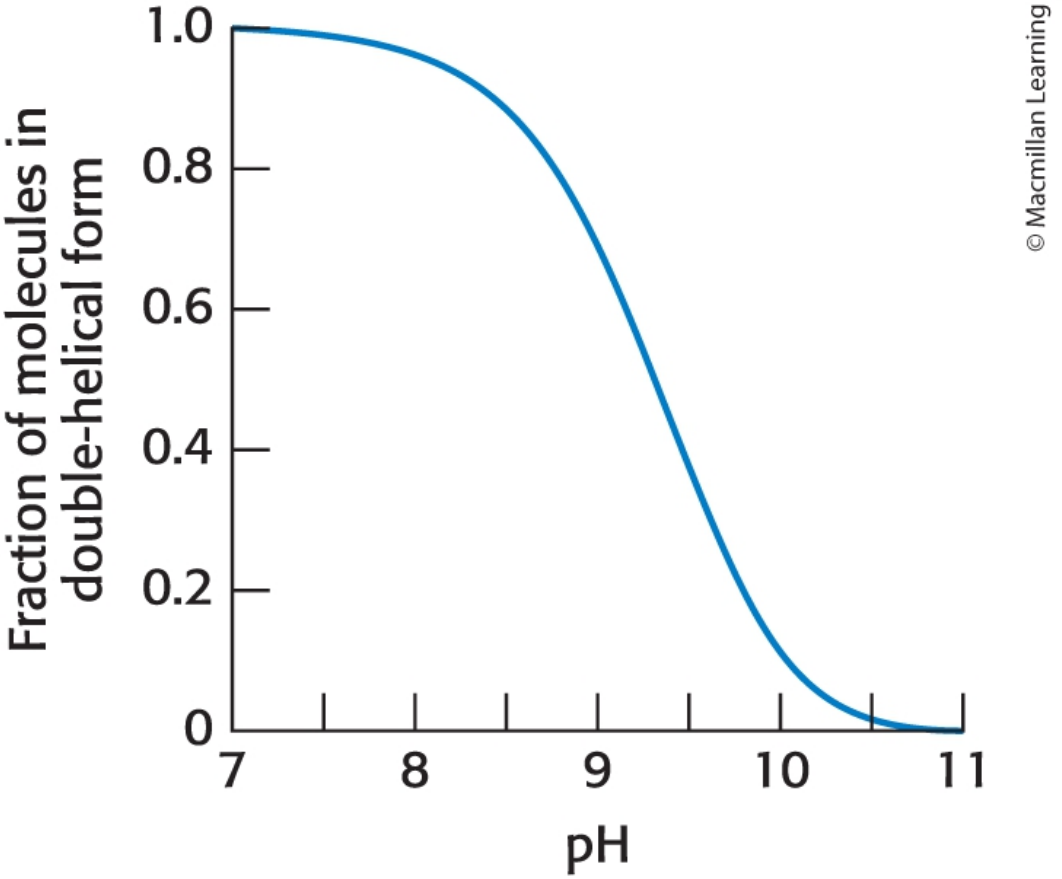
$$[OH^-] = 10^{-14}/[H^+] \text{ and } [H^+] = 10^{-14}/[OH^+]$$

With these relationships in hand, we can easily calculate the concentration of hydroxide ions in an aqueous solution, given the pH. For example, at $pH = 7.0$, we know that $[H^+] = 10^{-7}\ M$ and so $[OH^-] = 10^{-14}/10^{-7} = 10^{-7}\ M$. In acidic solutions, the concentration of hydrogen ions is higher than 10^{-7} and, hence, the pH is below 7. For example, in $0.1\ M\ HCl$, $[H^+] = 10^{-1}\ M$ and so $pH = 1.0$ and $[OH^-] = 10^{-14}/10^{-1} = 10^{-13}\ M$.

Acid–base reactions can disrupt the double helix

The formation process that we have been considering between two strands of DNA to form a double helix takes place readily at pH 7.0. Suppose that we take the solution containing the double-helical DNA and treat it with a solution of concentrated base (i.e., with a high concentration of OH^-). As the base is added, we monitor the pH and

the fraction of DNA in double-helical form (Figure 1.20). When the first additions of base are made, the pH rises, but the concentration of the double-helical DNA does not change significantly. However, as the pH approaches 9, the DNA double helix begins to dissociate into its component single strands. As the pH continues to rise from 9 to 10, this dissociation becomes essentially complete.



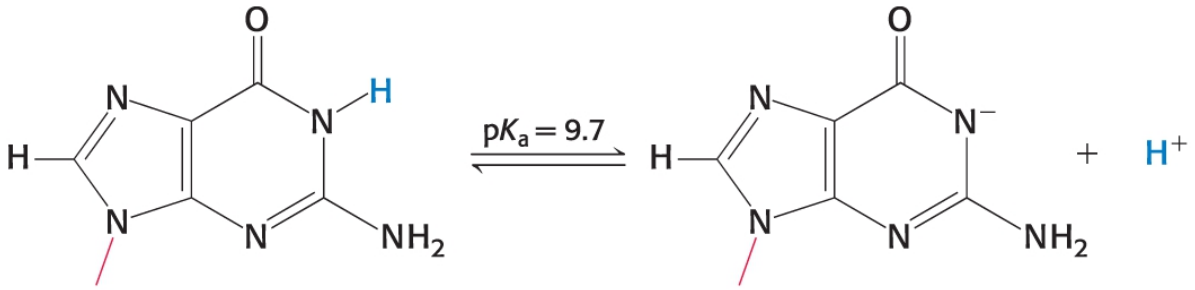


FIGURE 1.20 DNA strands are separated by the addition of a base. The addition of a base to a solution of double-helical DNA initially at pH 7 causes the double helix to separate into single strands. The process is half complete at slightly above pH 9.

Why do the two strands dissociate as pH increases? The hydroxide ions can react with nitrogenous bases in DNA base pairs to remove certain

protons. The most susceptible proton is the one bound to the N-1 nitrogen atom in a guanine base.

Guanine (G)

Proton dissociation for a substance HA (such as that bound to N-1 on guanine) has an equilibrium constant defined by the expression

$$K_a = [H^+][A^-]/[HA]$$

The susceptibility of a proton to removal by reaction with a base is often described by its **pK_a value**:

$$pK_a = -\log(K_a)$$

When the pH is equal to the pK_a, we have $pH = pK_a$

$$pH = pK_a$$

and so

$$-\log[H^+] = -\log([H^+][A^-]/[HA])$$

and

$$[H^+] = [H^+][A^-]/[HA]$$

Dividing by $[H^+]$ reveals that

$$1 = [A^-]/[HA]$$

and so

$$[A^-] = [HA]$$

So, when the pH equals the pK_a, the concentration of the deprotonated form of the group or molecule is equal to the concentration of the protonated form; the deprotonation process is halfway to completion. The pK_a for the proton on N-1 of guanine is typically 9.7. When the pH approaches this value, the proton on N-1 is lost (see Figure 1.20). Replacement of the partial positive change on the proton with a full negative charge substantially destabilizes the DNA double helix.

The DNA double helix is also destabilized by low pH. Below pH 5, some of the hydrogen-bond acceptors that participate in base-pairing become protonated. In their protonated forms, these bases can no longer form

these hydrogen bonds, and the double helix separates. So, acid–base reactions that either remove or donate protons at specific positions on the DNA bases can disrupt the double helix.

Buffers regulate pH in organisms and in the laboratory

These observations about DNA reveal that a significant change in pH can disrupt molecular structure. The same is true for many other biological macromolecules; changes in pH can protonate or deprotonate key groups, potentially disrupting structures and initiating harmful reactions. Thus, biological systems have evolved to mitigate changes in pH.

Solutions that resist changes in pH are called **buffers**. Specifically, when acid is added to an unbuffered aqueous solution, the pH drops in proportion to the amount of acid added. In contrast, when acid is added to a buffered solution, the pH drops more gradually. Buffers also mitigate the pH increase caused by the addition of base and changes in pH caused by dilution.

Compare the result (shown in **Figure 1.21**) of adding a 1 M solution of the strong acid HCl drop by drop to (1) pure water, versus (2) adding it to a solution containing 100 mM of the buffer sodium acetate ($Na^+CH_3COO^-$). The process of gradually adding known amounts of reagent to a solution with which the reagent reacts while monitoring the results is called a **titration**. For pure water, the pH drops from 7 to close to 2 on the addition of the first few drops of acid. However, for the sodium acetate solution, the pH first falls rapidly from its initial value near 10, then changes more gradually until the pH reaches 3.5, and then falls more rapidly again.

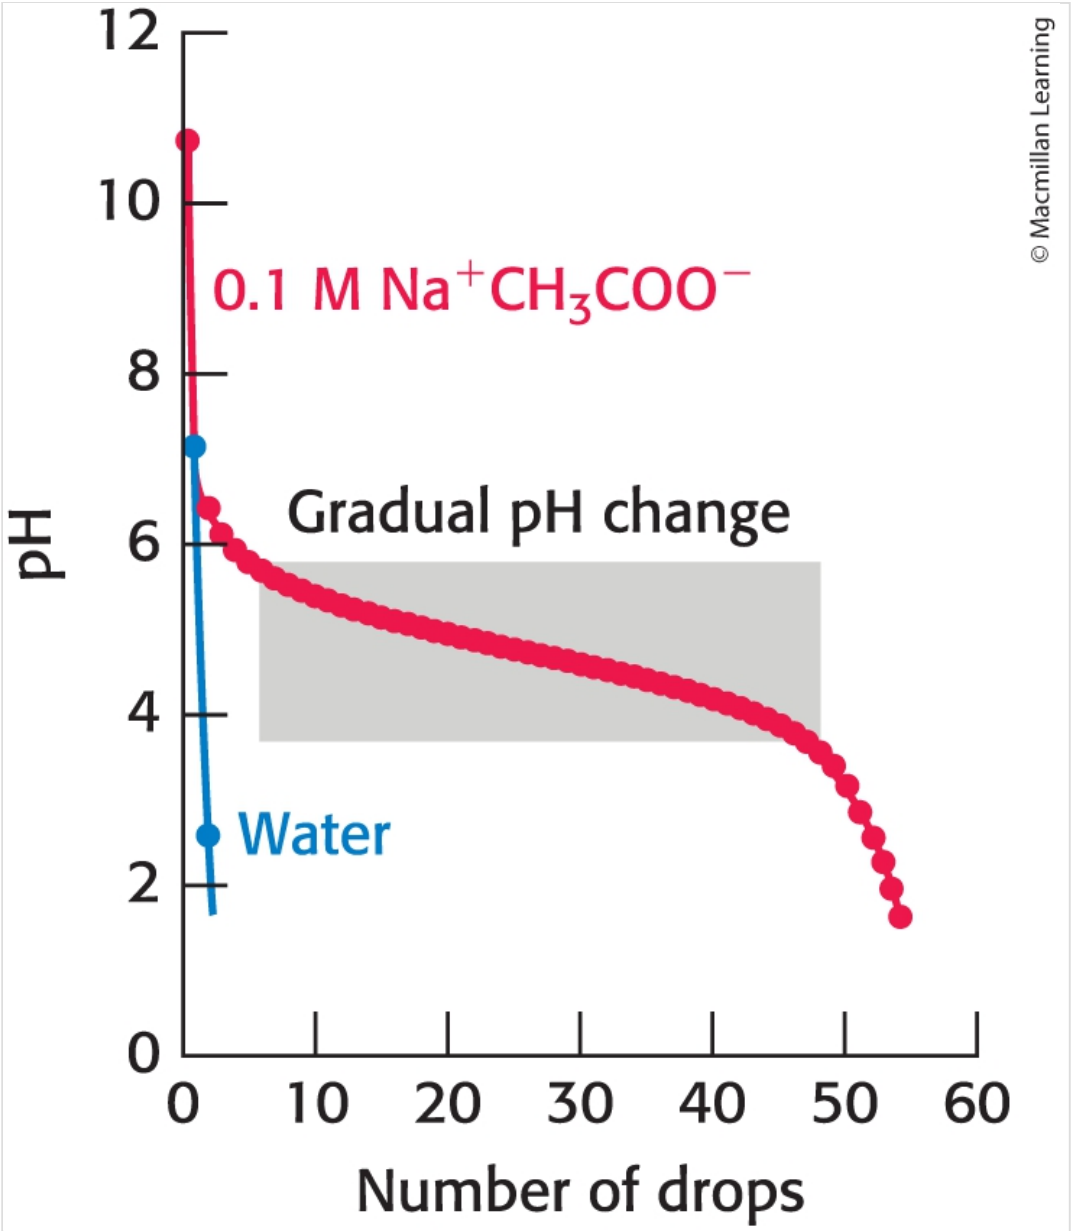

FIGURE 1.21 Buffers resist changes in pH over a narrow pH range. The addition of a strong acid, 1 M HCl, to pure water results in an immediate drop in pH to near 2. In contrast, the addition of the acid to a 0.1 M sodium acetate $(Na^+CH_3COO^-)$ solution results in a much more gradual change in pH until the pH drops below 3.5.

Why does the pH decrease so gradually in the middle of the titration? The answer is that when hydrogen ions are added to this solution, they react with acetate ions to form acetic acid. This reaction consumes some of the added hydrogen ions so that the pH does not drop. Hydrogen ions continue reacting with acetate ions until essentially all the acetate ion is converted into acetic acid. After this point, added protons remain free in solution and the pH begins to fall sharply again.

We can analyze the effect of the buffer in quantitative terms. The equilibrium constant for the deprotonation of an acid is

$$K_a = [H^+][A^-]/[HA]$$

Taking logarithms of both sides yields

$$\log(K_a) = \log([H^+]) + \log([A^-]/[HA])$$

Recalling the definitions of pK_a and pH and rearranging gives

$$pH = pK_a + \log([A^-]/[HA])$$

This expression is referred to as the **Henderson–Hasselbalch equation**.

We can apply the equation to our titration of sodium acetate. The pK_a of acetic acid is 4.75. We can calculate the ratio of the concentration of acetate ion to the concentration of acetic acid as a function of pH by slightly rearranging the Henderson–Hasselbalch equation:

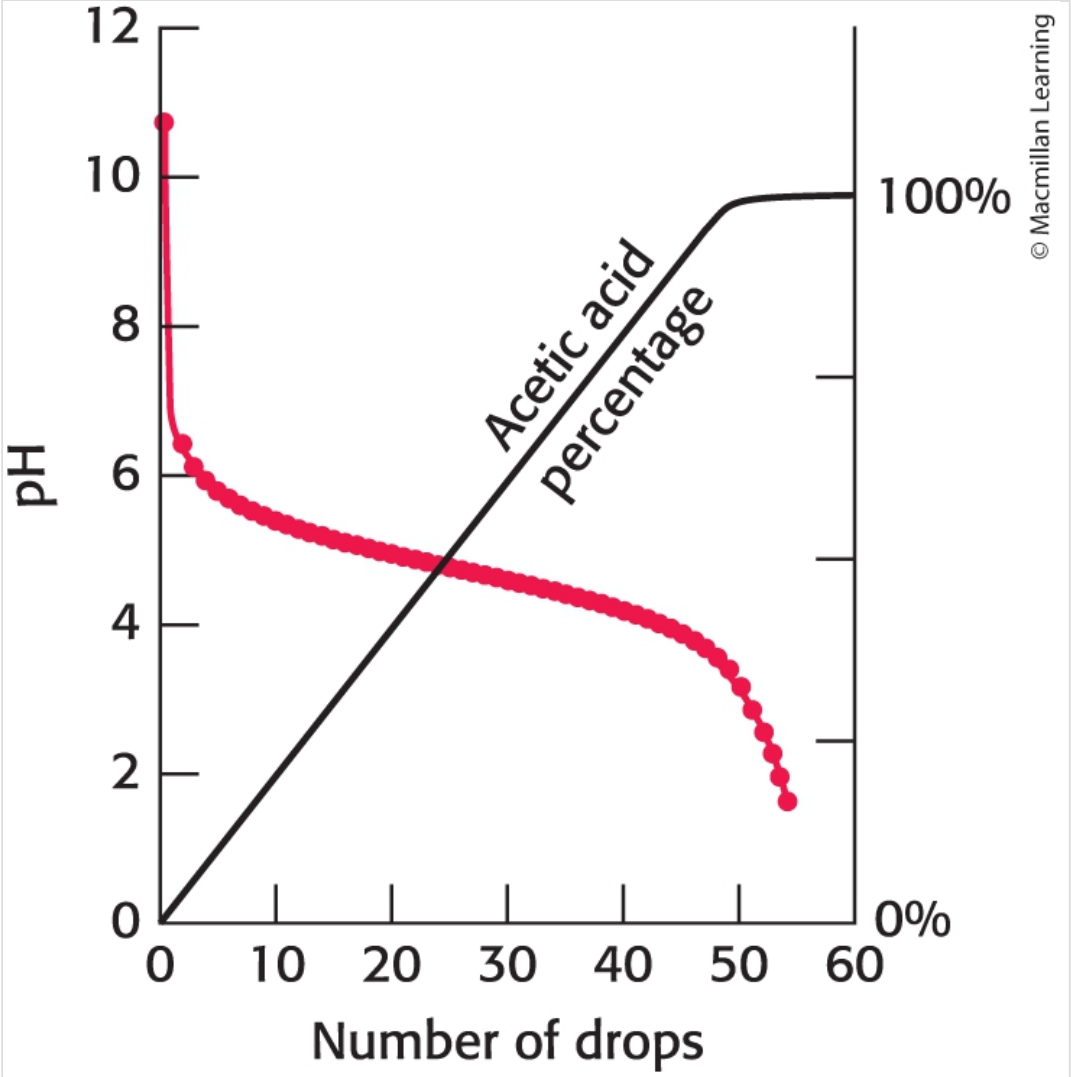
$$[\text{Acetate ion}]/[\text{Acetic acid}] = [A^-]/[HA] = 10^{pH - pK_a}$$

At pH 9, this ratio is $10^{9 - 4.75} = 10^{4.25} = 17{,}800$; very little acetic acid has been formed.

At pH 4.75 (when the pH equals the pK_a), the ratio is $10^{4.75 - 4.75} = 10^0 = 1$.

At pH 3, the ratio is $10^{3 - 4.75} = 10^{-1.25} = 0.02$; almost all the acetate ion has been converted into acetic acid.

We can follow the conversion of acetate ion into acetic acid over the entire titration (**Figure 1.22**). The graph shows that the region of relatively constant pH corresponds precisely to the region in which acetate ion is being protonated to form acetic acid.



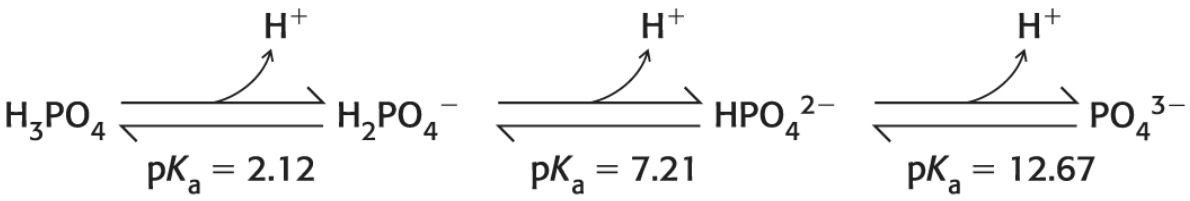


FIGURE 1.22 Added hydrogen ions protonate buffer components rather than remaining free. When acid is added to sodium acetate, the added hydrogen ions are used to convert acetate ion into acetic acid. Because the proton concentration does not increase significantly, the pH remains relatively constant until all the acetate has been converted into acetic acid.

From this discussion, we see that a buffer functions best close to the pK_a value of its acid component. Physiological pH is typically about 7.4.

An important buffer in biological systems is based on phosphoric acid (H_3PO_4). The acid can be deprotonated in three steps to form a phosphate ion.

At about pH 7.4, inorganic phosphate exists primarily as a nearly equal mixture of $H_2PO_4^-$ and HPO_4^{2-}. Thus, phosphate solutions function as effective buffers near $pH 7.4$. The concentration of inorganic phosphate in blood is typically approximately 1 mM, providing a useful buffer against processes that produce either acid or base.

Self-Check Question

Butyric acid ($CH_3CH_2CH_2COOH$) has a pK_a of 4.82. What is the ratio of butyrate ($CH_3CH_2CH_2COO^-$) to butyric acid at pH 6.0?

Example

Applying the Henderson—Hasselbalch Equation

Problem:

You need to prepare 2 liters of 0.100 M acetate buffer, pH 5.00 for acetic acid, sodium acetate, and water. How much acetic acid and sodium acetate do you use?

Getting Started:

The Henderson–Hasselbalch equation relates the pH to the ratio of ionized and unionized buffer components

$$pH = pK_a + \log([A^-]/[HA])$$

where $[A^-]$ is the concentration of acetate ion and [HA] is the concentration of acetic acid. We know that the pK_a of acetic acid is 4.75 and the buffer is supposed to have a pH of 5.00 with a total concentration of acetate-containing species of 0.100 M; that is, $[CH_3COO^-] + [CH_3COOH] = 0.100\ M$.

Solve:

Substituting into the Henderson–Hasselbalch equation, we find that

$$5.00 = 4.75 + \log([CH_3COO^-]/[CH_3COOH])$$

Solving for the ratio of species, we find that

$$\log([CH_3COO^-]/[CH_3COOH]) = 5.00 - 4.75 = 0.25$$

so that $[CH_3COO^-]/[CH_3COOH] = 10^{0.25} = 1.78$.

Thus, $[CH_3COO^-] = 1.78[CH_3COOH]$.

We can then substitute this expression into the expression for the total concentration of acetate-containing species,
$[CH_3COO^-] + [CH_3COOH] = 0.100\ M$

That is, $1.78[CH_3COOH] + [CH_3COOH] = 0.100\ M$

so that $(1.78 + 1.00)[CH_3COOH] = 2.78[CH_3COOH] = 0.100\ M$.

Thus, $[CH_3COOH] = (1/2.78)(0.100\ M) = 0.036\ M$ and
$[CH_3COO^-] = 1.78(0.036\ M) = 0.064\ M$.

We need to make 2 liters of buffer, so we need
$(2\ liters)(0.036\ M) = 0.072$ moles of acetic acid and
$(2\ liters)(0.064\ M) = 0.128$ moles of acetate ion, provided as sodium acetate.

The molecular weights of acetic acid and sodium acetate are
$60.052\ g/mol$ and $82.034\ g/mol$, respectively.

Thus, we need $(0.072\ moles)(60.052\ g/mol) = 4.32\ g$ of acetic acid

and $(0.128\ \text{moles})(82.034\ \text{g/mol}) = 10.50\ \text{g}$ of sodium acetate.

After weighing out these materials, we add water to make a total volume of 2 liters.

Reflect:

You can confirm the result by calculating the pH using the Henderson–Hasselbalch equation with the concentrations of acetic acid and acetate ion that you added.

1.4 DNA Sequencing Is Transforming Biochemistry, Medicine, and Other Fields

The discovery of the structure of DNA suggested the hypothesis that hereditary information is stored as a sequence of nitrogenous bases along long strands of DNA. This remarkable insight provided an entirely new way of thinking about biology. However, for years this hypothesis remained unconfirmed, and many features needed to be elucidated. How is the sequence information read and translated into action? What are the sequences of naturally occurring DNA molecules, and how can such sequences be experimentally determined?

Through advances in biochemistry and related sciences, we now have essentially complete answers to these questions. Indeed, in the past two decades, scientists have determined the complete genome sequences of thousands of different organisms, including simple microorganisms, plants, animals of varying degrees of complexity, and human beings. Comparisons of these genome sequences, with the use of methods discussed in Chapter 10, have provided many insights that have transformed biochemistry. In addition to its experimental and clinical aspects, biochemistry has now become an information science.

Genome sequencing has become remarkably fast and inexpensive

The sequencing of a human genome was a daunting task, because it contains approximately 3 billion (3×10^9) base pairs. We can look at a small section of the human genome to get a sense of its overall complexity. For example, the sequence

ACATTTGCTTCTGACACAACTGTGTTCACTAGCAACCTC
AAACAGACACCATGGTGCATCTGACTCCTGAGGAGAAGT
CTGCCGTTACTGCCCTGTGGGGCAAGGTGAACGTGGA...

is a part of one of the genes that encodes hemoglobin, the oxygen carrier in our blood, discussed in Chapter 3. This gene is found on the end of chromosome 9 of our 24 distinct chromosomes. If we were to include the complete sequence of our entire genome, this chapter would run to more than 500,000 pages. The sequencing of our genome is truly a landmark in human history. This sequence contains a vast amount of information, some of which we can now extract and interpret, but much of which we are only beginning to understand. For example, some human diseases have been linked to particular variations in genomic sequence. Sickle-cell anemia is caused by a single base change of an A (noted in boldface red type in the preceding sequence) to a T. In this course of this book, we will encounter many other examples of diseases that have been linked to specific DNA sequence changes.

Determining the first human genome sequences was a huge challenge. It required the efforts of large teams of geneticists, molecular biologists, biochemists, and computer scientists, as well as billions of dollars, because there was no previous framework for aligning the sequences of various DNA fragments: many methods had to be developed along the way. Fortunately, one human genome sequence can serve as a reference for others: the availability of reference sequences and modern techniques enables much more rapid characterization of partial or complete genomes from other individuals, as we will discuss in Chapter 9.

Methods for sequencing DNA have improved rapidly, resulting in dramatic increases in the sequencing rate and decreases in costs (**Figure 1.23**). The availability of such powerful sequencing technology is transforming many fields, including medicine, dentistry,

microbiology, pharmacology, and ecology, although a great deal remains to be done to improve the interpretation of these large data sets.

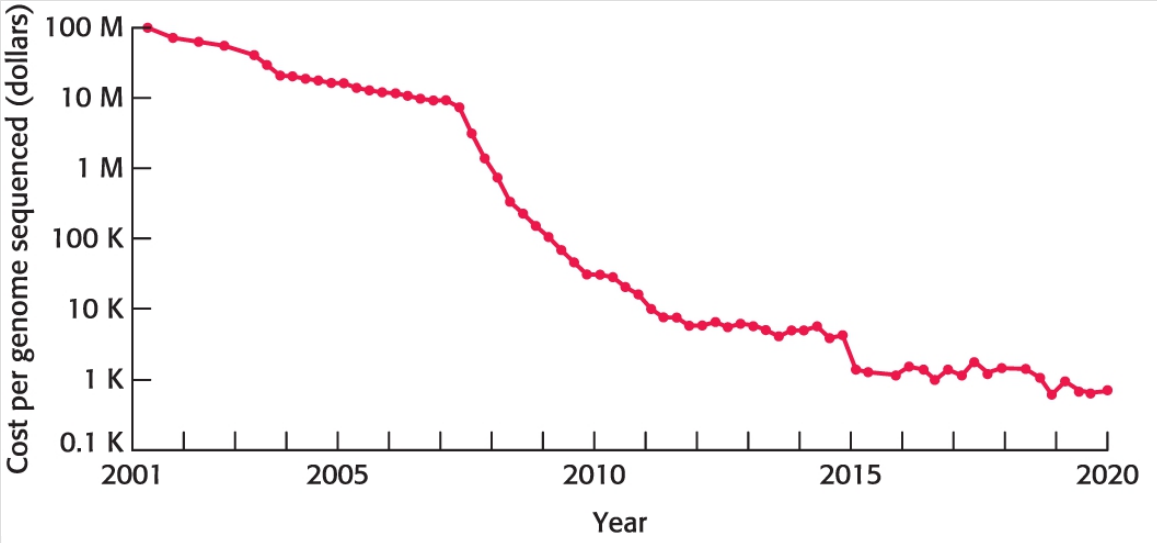

FIGURE 1.23 The cost to sequence a human genome has decreased dramatically over the pas two decades. Through the Human Genome Project, the costs of DNA sequencing dropped steadily due to new methods and are now under $1000 for a complete human genome sequenc

[National Human Genome Research Institute. https://www.genome.gov/about-genomics/fact-sheets/Sequencing-Human-Genome-cost]

Characterization of genetic variation between individuals is powerful for many applications

Each person has a unique sequence of DNA base pairs. How different are we from one another at the genomic level? Examination of the differences in our genomes reveals that, on average, each pair of individuals has a different base in one position per 200 bases; that is,

the difference is approximately 0.5%. This genomic variation between individuals who are not closely related is quite substantial compared with differences in populations. The average difference between two people within one population or ethnic group is greater than the difference between the averages of two different populations or ethnic groups (Figure 1.24).

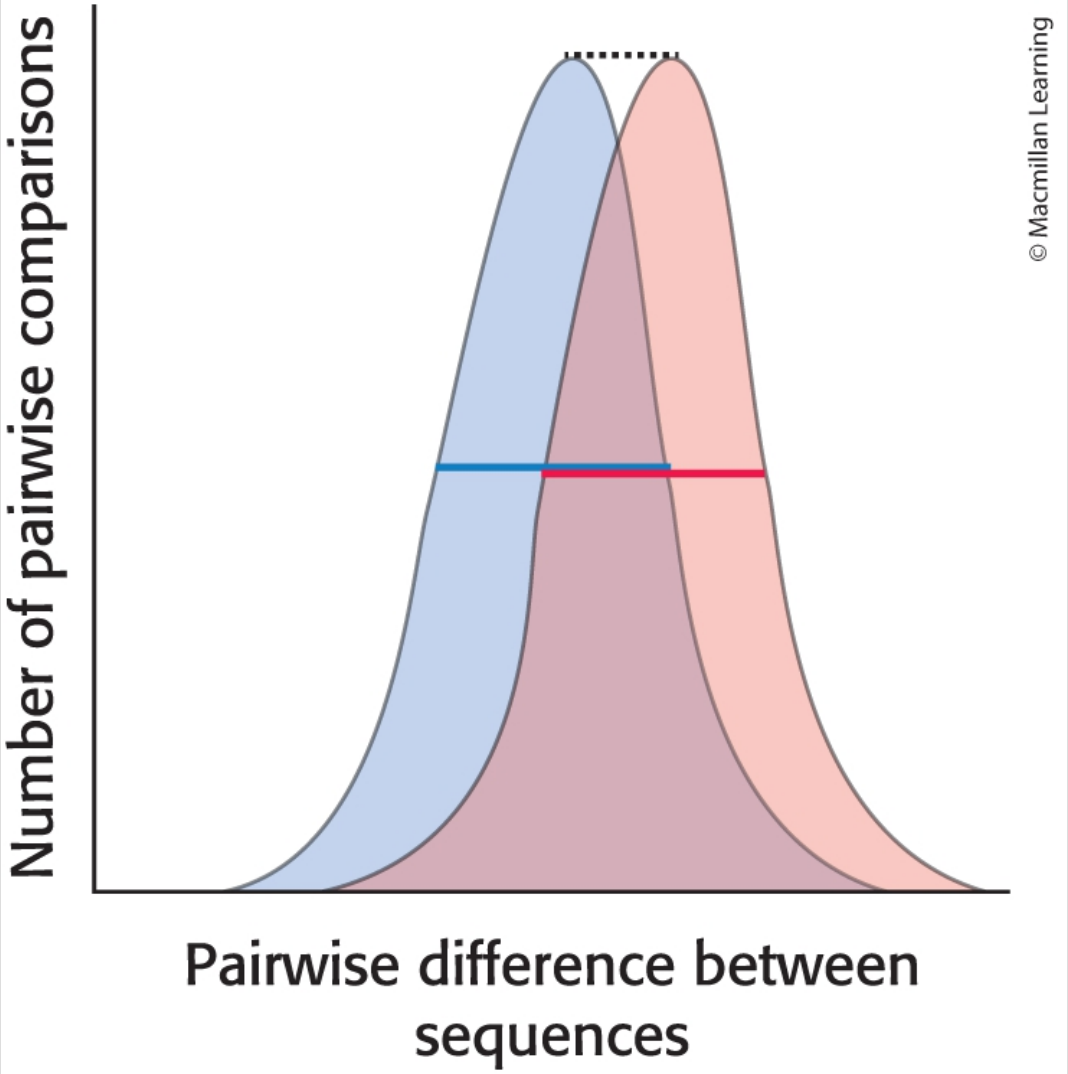

FIGURE 1.24 DNA sequences vary more within populations than they do between populations. The distribution of differences between pairs of individuals within two populations (from Europe and Sub-Saharan Africa) are shown in blue and red, respectively. The widths of these two distributions (shown by the blue and red lines) are larger than the average difference between the two populations (shown by the black dotted line).

[Adapted from Witherspoon *et al.* Genetic differences between and within human populations. *Genetics* **176,** 351–359 (2007).]

- *Providing insights into ancestry.* While average differences in DNA sequence between different human populations are relatively small, DNA analysis can be a powerful tool for providing information about ancestry. In a landmark study, DNA from more than 1300 individuals with known ancestry from different parts of Europe was analyzed. The study looked at more than 200,000 positions spanning the genome that were known to vary across populations and visualized the differences in two dimensions. Breathtakingly, this plot reflected a remarkably accurate map of Europe (**Figure 1.25**)! More recent studies of individuals from 50 ethnolinguistic groups across Africa have revealed greater genomic variation than is seen in European populations and have suggested migrations of groups of people across this continent that have occurred over the course of 2000 years.

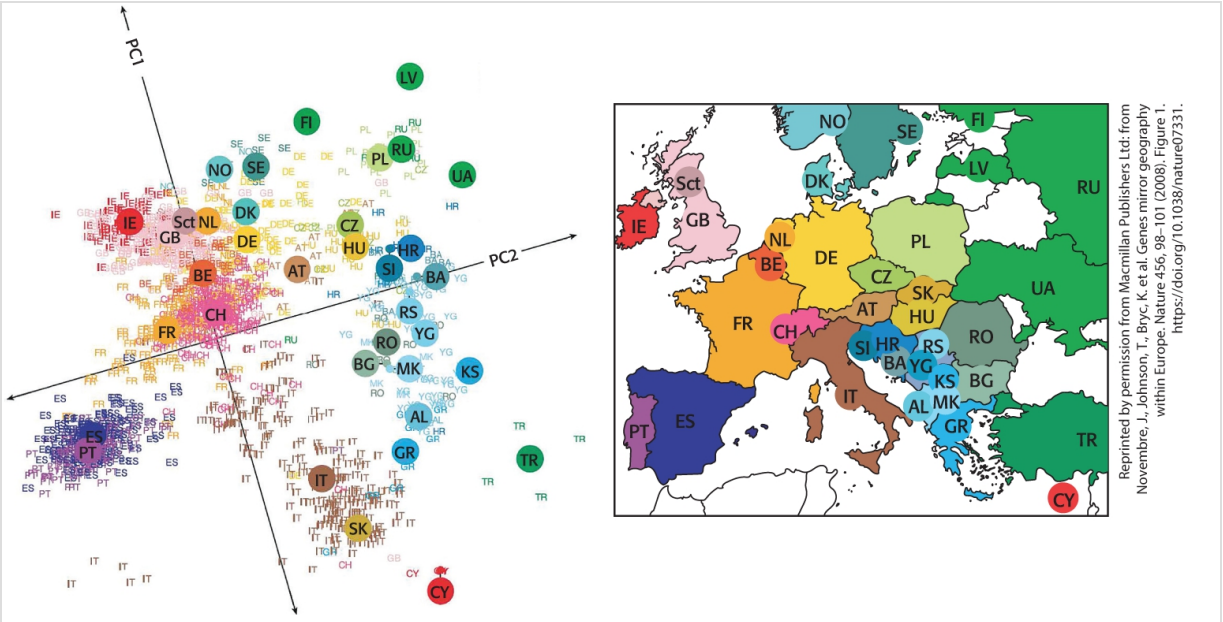

FIGURE 1.25 Genomic information can confirm locations of ancestry. Statistical analysis of the genomes of more than 1300 Europeans reproduced a map of Europe, providing a framework for inferring ancestry from genomic information.

- *Understanding the molecular basis of disease.* Scientists have identified the genetic variations associated with thousands of diseases, such as sickle-cell anemia, for which the cause can be traced to a single gene. For other diseases and traits, such as heart disease, we know that variation in many different genes contributes to disease in significant and often complex ways. Furthermore, in most cases, the presence of a particular variation or set of variations does not inevitably result in the onset of a disease but, instead, leads to a predisposition, or a heightened probability, for the development of the disease.

  The observation that genes alone do not determine disease outcomes is vividly illustrated through twin studies. Monozygotic (or "identical") twins share the same genome, whereas dizygotic (or "fraternal") twins share the same parents and typically develop in the same environment, but are not more genetically similar on average than any two siblings. By examining pairs of twins, scientists can begin to dissect the roles of genes versus environmental and other factors. For diseases like sickle-cell disease, monozygotic twins are always concordant; meaning, if one twin has the disease, so does the other. Most concordance rates, even for monozygotic twins, are well below 50%, indicating that environmental factors and chance are important in determining disease occurrence (**Table 1.1**). These often-modest levels of concordance reveal that environmental effects, and chance, can affect who gets any particular disease, revealing the complexity of biochemistry and biology that will be explored throughout the book.

- *Assessing the identity and role of our microbiome.* Our own genes are not the only ones that can contribute to our health and disease. Our bodies, including our skin, mouth, digestive tract, genitourinary

tract, respiratory tract, and other areas, contain a large number of microorganisms. These complex communities, collectively called the human **microbiome**, have been characterized through powerful methods that allow sequences from these biological samples to be examined without any previous knowledge of the organisms present.

Remarkably, we are outnumbered in our own bodies! Each of us contains more microbial cells than human cells, and these microbial cells collectively include many more genes than do our own genomes. These microbiomes differ between regions of the body, from one person to another, and in the same individual over time (**Figure 1.26**). They appear to play roles in health and in diseases such as obesity and dental caries.

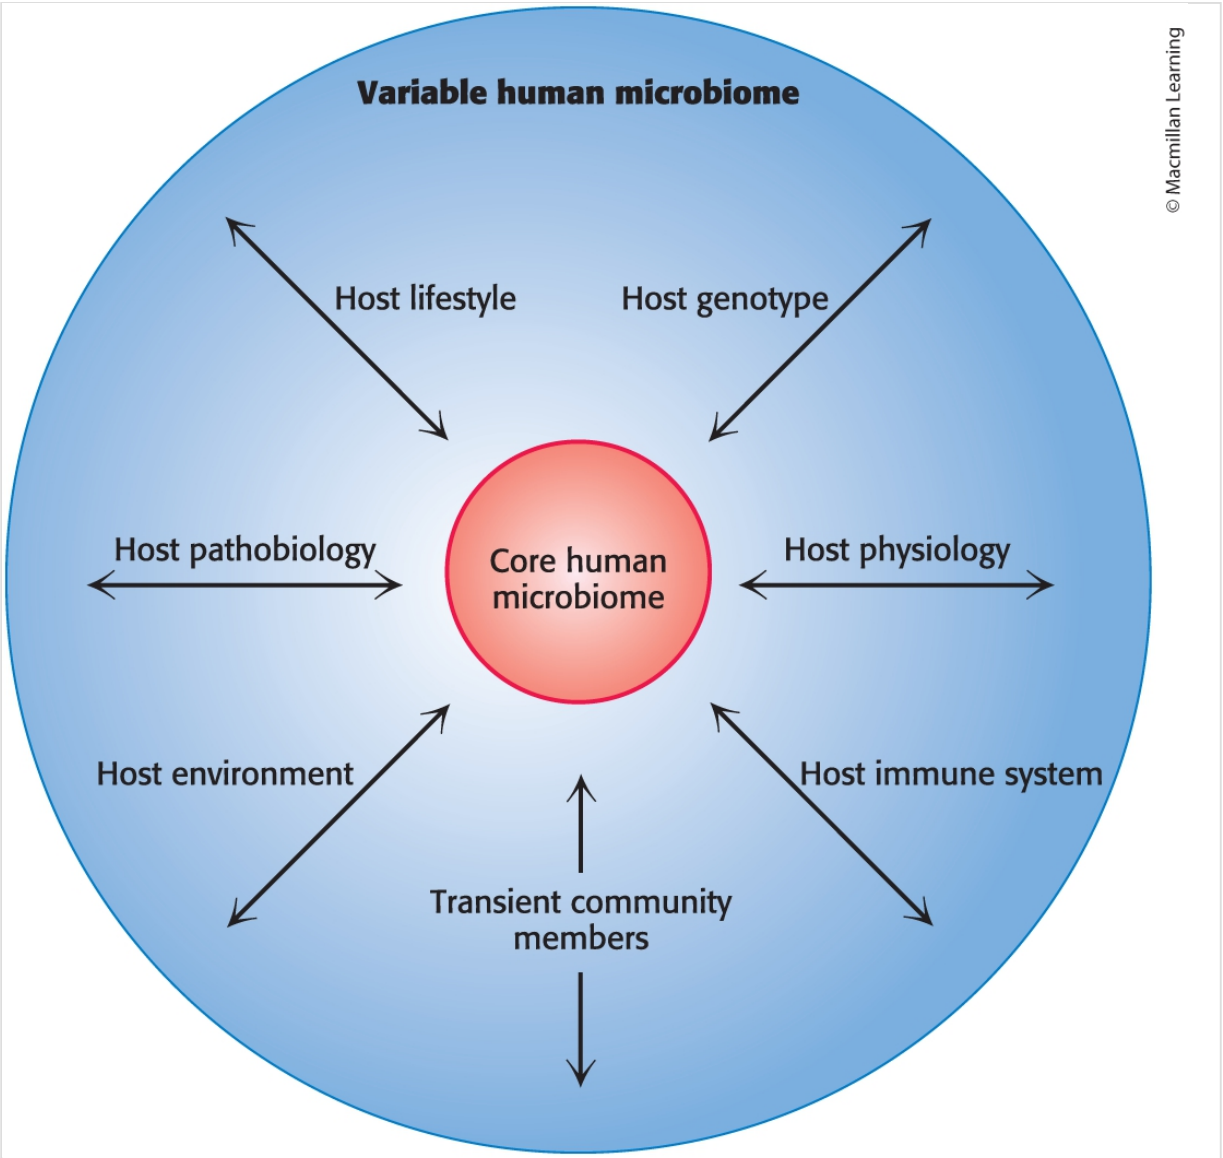

FIGURE 1.26 The human microbiome comprises many different bacterial and fungal species. The species composition varies greatly between individuals and within a given individual depending on a range of biological and environmental factors.

[From Turnbaugh, P., Ley, R., Hamady, M. *et al.* The human microbiome project. *Nature* **449,** 804–810 (2007). https://doi.org/10.1038/nature06244]

TABLE 1.1 Disease concordance rates in twins

	Monozygotic twins (%)	Dizygotic twins (%)
Diabetes (Type 1)	23	5
Diabetes (Type 2)	45	19
Breast cancer (Women)	17	11
Prostate cancer (Men)	33	15
Stroke	18	4
Amyotrophic lateral sclerosis	18	< 3
Alzheimer's disease	67	22

Note: Given one twin who has a disease, the percentage whose twin partner also has the disease is called the *concordance rate.*

The most important function of genomic sequences is to encode proteins

What kinds of information do DNA's base sequences store, and how is it expressed? The most fundamental role of DNA is to encode the sequences of proteins. Like DNA, proteins are linear polymers. However, proteins differ from DNA in two important ways. First, proteins are built from 20 building blocks, called **amino acids**, rather than just 4, as in DNA. The chemical complexity provided by this variety of building blocks enables proteins to perform a wide range of functions. Second, proteins spontaneously fold into elaborate three-dimensional structures, determined almost exclusively by their amino acid sequences (**Figure 1.27**). This enables the transition from a largely one-dimensional world of DNA sequences into a three-dimensional world of intricate, interacting objects with diverse properties that

characterize biochemistry. Proteins and protein folding will be discussed extensively in the next chapter. Interestingly, the human genome includes approximately 21,000 protein-coding genes, much smaller than earlier estimates of up to 100,000 or more.

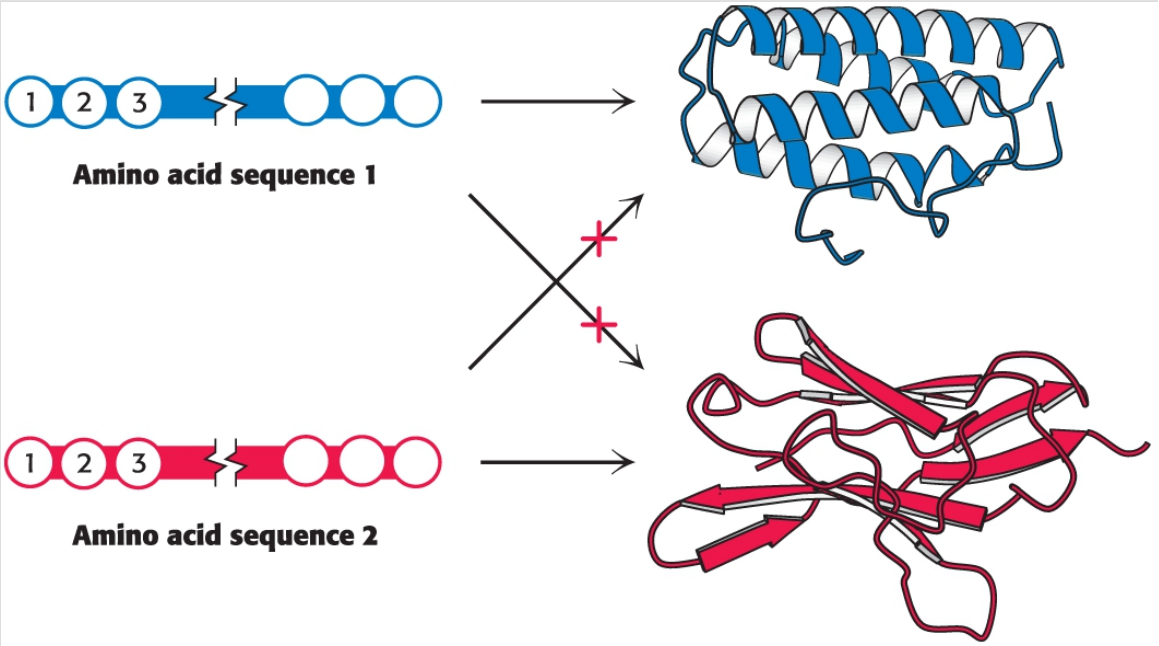

FIGURE 1.27 Protein folding is primarily dictated by the specific sequence of amino acids. Proteins are linear polymers of amino acids that fold into elaborate structures. The sequence of amino acids is the most important factor that determines the three-dimensional structure. Thus, amino acid sequence 1 gives rise only to a protein with the shape depicted in blue, not the shape depicted in red.

Comparing genomes offers great insights into evolution

Studies of comparative genomics, in which one organism's genome is compared with the genomes of other organisms, are confirming the tremendous unity that exists at the level of biochemistry. Comparative

genomics is also revealing key steps in the course of evolution. For example, many genes that are key to the function of the human brain and nervous system have evolutionary and functional relatives, even in the genomes of bacteria. Sequence comparisons can reveal a fascinating connection between biochemistry, evolution, and time.

The major mechanism for evolution involves the accumulation of small changes in DNA sequences. In rare cases, these changes (mutations) help the organism survive and reproduce under a particular set of conditions, leading to selection of organisms that carry these changes. More often, the changes are neutral, providing no advantage but causing no significant harm, and they accumulate because there is no reason or mechanism to remove them. Linus Pauling, a two-time Nobel Prize winner (for Chemistry and Peace) and his colleague followed this logic and suggested that the extent of sequence difference between the same protein from two organisms could be used as a measure of the time that had passed since these organisms had a common ancestor. This is called the **molecular clock hypothesis**.

To give one example of the sorts of conclusions we can reach from applying the molecular clock hypothesis, let us examine the number of sequence differences between one component of human hemoglobin and the same component from other species. The sequences of this hemoglobin subunit from human beings and our closest living relatives, chimpanzees, are identical, while those from human beings and a slightly more distant relative, gorillas, are 99.3% identical. In contrast, the sequences between human beings and chickens are only 70.4% identical. We can plot these differences and those from representatives from the classes of animals from Figure 1.2 versus the times for the emergence of these classes from the fossil record (**Figure 1.28**).

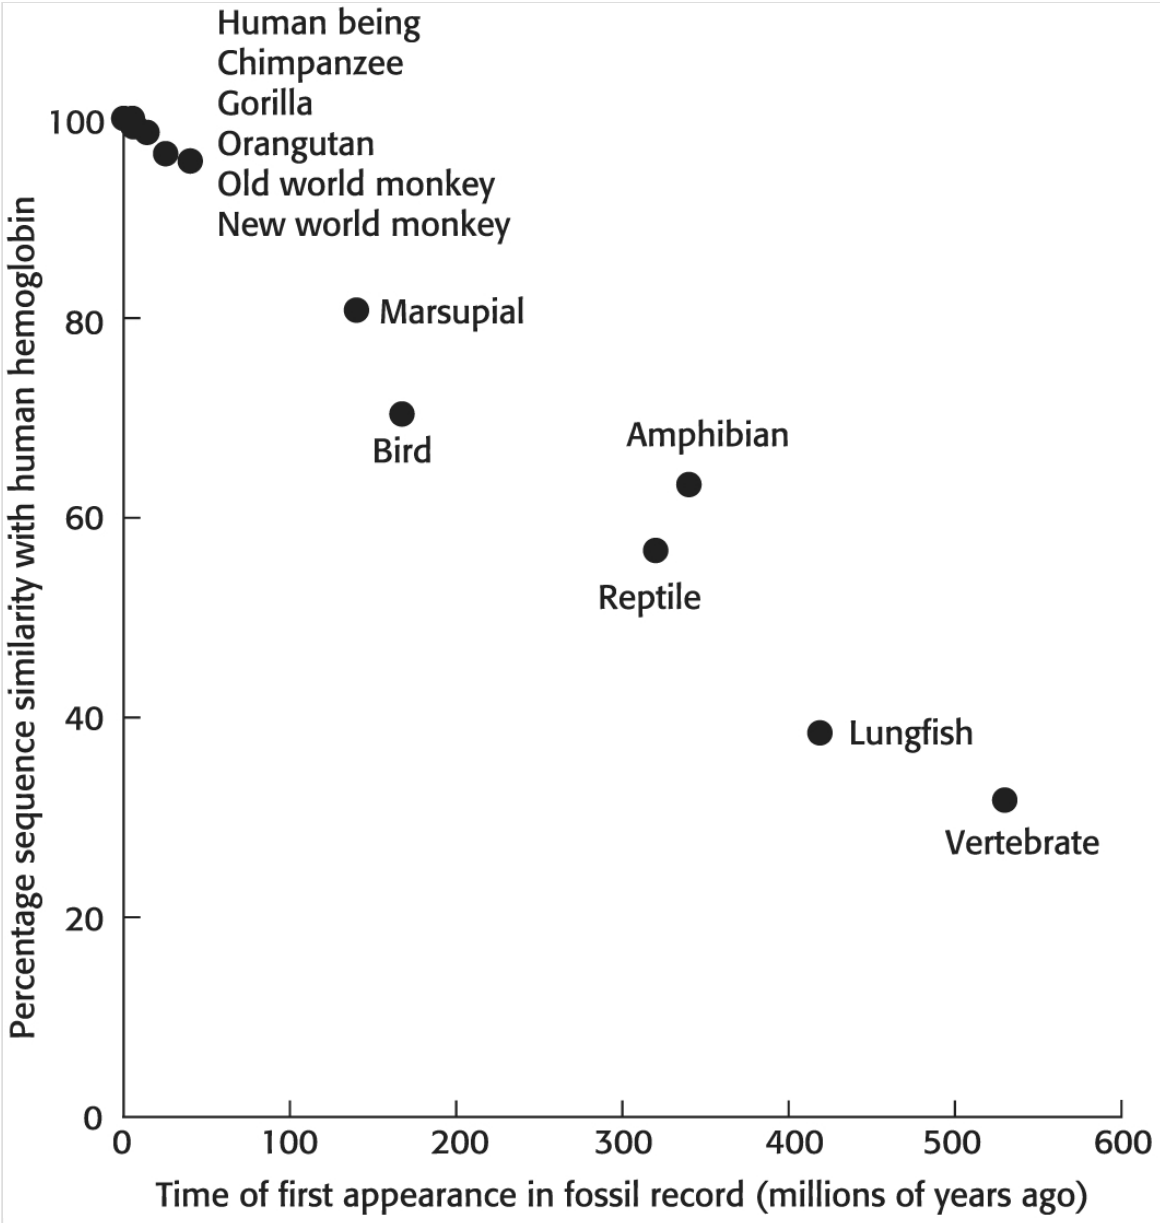

FIGURE 1.28 The similarities between hemoglobin sequences from different species provide evidence for a molecular clock. A comparison of the sequence identity between a component o the protein hemoglobin from human beings and those from representation of modern species from different classes of animals is shown. The nearly linear relationship between the sequence similarity and the time of emergence of the class of animals suggests that sequence similarity o this protein between two species can be used to measure evolutionary time since these species had a common ancestor.

Self-Check Question

The amino acid sequence of hemoglobin from an unknown species is found to be 83.5% identical to that from human beings. Could this be from a primate?

Different molecular clocks are also used for entities such as viruses that evolve very rapidly. In essence, a **virus** comprises a nucleic acid genome (DNA or the related molecule ribonucleic acid, abbreviated RNA) surrounded by a protein coat. Viruses are not alive in that they cannot grow or reproduce on their own, but instead infect specific cells and take advantage of the components of these cells to produce new virus particles by copying their genomes and synthesizing their protein coats and other components encoded by the viral genome. These virus particles then escape from these cells to go on and infect other cells. The sequence of a viral genome changes over time, even slightly every time the virus replicates.

Comparison of viral sequences allows the timing of key evolutionary events to be estimated. For example, both the virus that caused Severe Acute Respiratory Syndrome (SARS) in 2002–2004, termed SARS-CoV, and the virus that causes COVID-19, SARS-CoV-2, diverged over periods of a few years from viruses found in horseshoe bats. Sequence comparison also helps reveal the origins and spread of variant viruses across the human population.

Molecular clocks provide a framework that will be used throughout the book. Specifically, we can infer evolutionary relatedness from sequence comparison, with the simple rule of thumb that nearly identical sequences had a recent common evolutionary ancestor whereas more different versions of the same sequence have had more time to diverge.

1.5 Biochemistry Is an Interconnected Human Endeavor

Biochemical knowledge is generated through the research efforts of human beings, individually and in teams, at many different stages along a variety of career paths, some of which are outlined in **Figure 1.29**. To give some examples of the human journeys involved in establishing this knowledge, we will introduce you to a sampling of interconnected career paths and collegial partnerships.

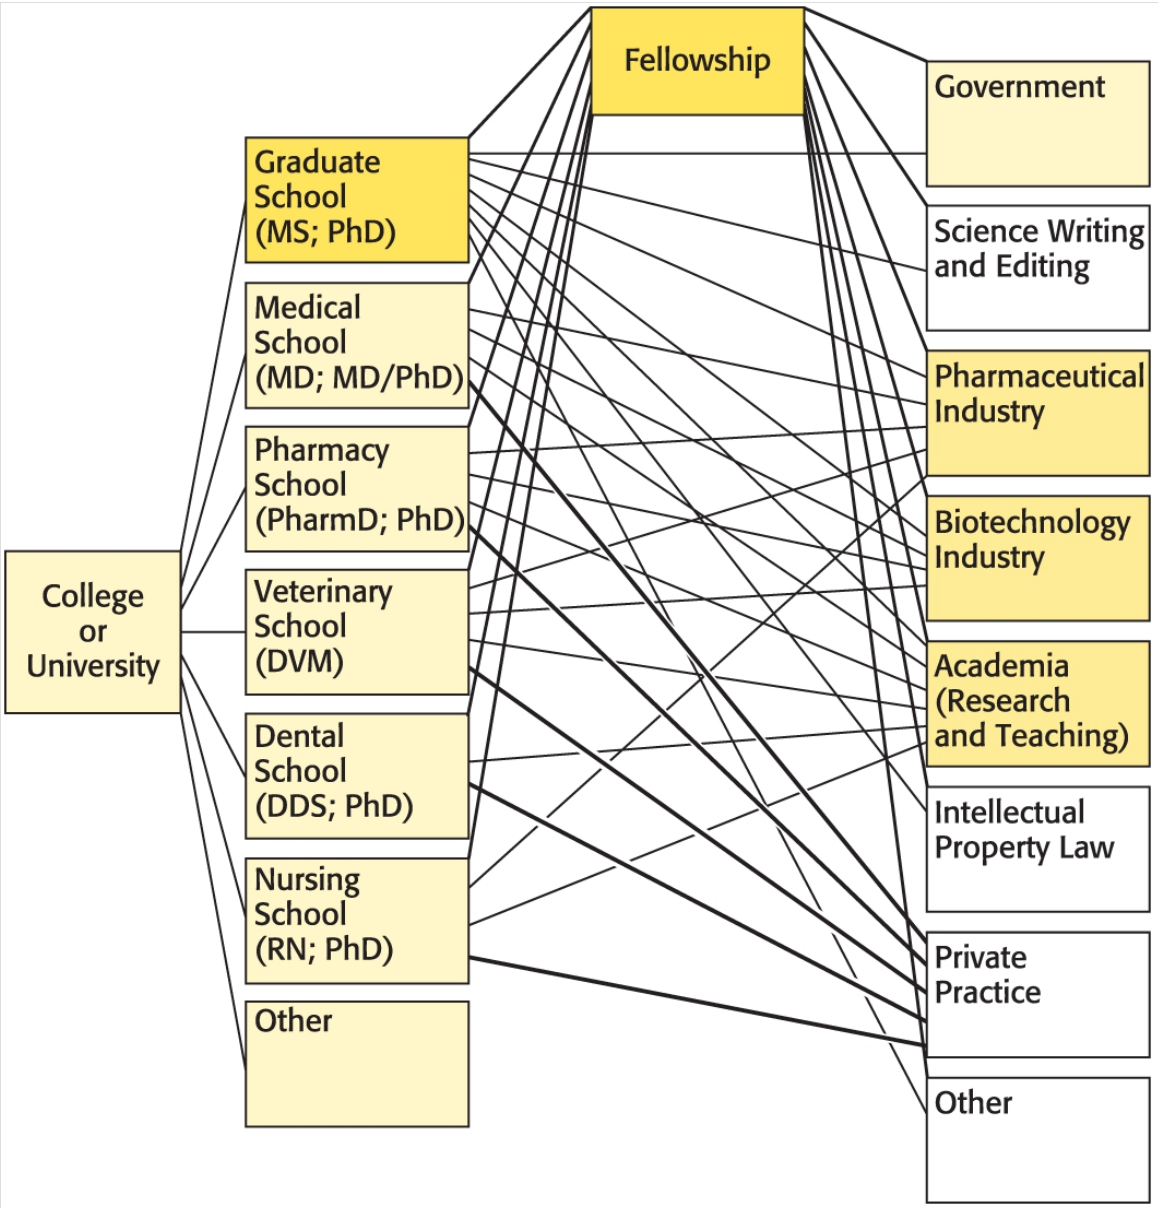

FIGURE 1.29 There are a variety of possible career paths for those involved in biochemical research. The intensity of the yellow shading corresponds to the intensity of the biochemical research activity in different positions and the lines highlight career paths that are commonly pursued.

This chapter opened with a photograph of Carol Greider, PhD, celebrating with Peter Agre, MD, on the occasion of her award of the

Nobel Prize in Medicine or Physiology in 2009 for research she started as a graduate student. Her discoveries, which were initially motivated by curiosity about fundamental biological process, have continued throughout her career, shedding light on both cancer and mechanisms of cellular aging. Her path to success was not always clear or easy, however. Although she was a strong student, she had struggled to get into college and graduate school because of relatively poor performance on standardized tests due to dyslexia.

Dr. Agre, shown with Dr. Greider in the photograph, had been awarded a Nobel Prize six years earlier. He was trained as a hematologist; his research was on Rh factor, a molecule important for blood compatibility for transfusions and in other contexts. In the course of this work, Dr. Agre and his coworkers discovered an abundant but uncharacterized component of red blood cells that turned out to be a long-hypothesized protein that allows red blood cells to take up and release water rapidly. For this discovery, Dr. Agre shared the Nobel in Chemistry, and he found this ironic, since he had temporarily withdrawn from high school because he received a “D” in chemistry.

One of the authors of this book, Jeremy Berg, PhD, was fortunate to have been colleagues with both Dr. Agre and Dr. Greider at Johns Hopkins University. Dr. Berg’s research experience began as an undergraduate in the laboratory of Lubert Stryer, MD. Based on this and other experiences, his interests focused on the roles of metal ions in biological systems. After completing a PhD in chemistry, his research changed directions as a postdoctoral fellow, focusing on the structures of proteins that bind DNA. He was able to combine these interests with the discovery that certain DNA- and RNA-binding proteins contained bound metal ions such as zinc. During his career in academia and in government, Dr. Berg worked with undergraduates, PhD and MD/PhD students, and postdoctoral fellows with a wide range of backgrounds, interests, and future career directions.

Science often involves friendly competitions between research teams working on the same problems. For Dr. Berg, one such team was led by Michael Summers, PhD, who also began in inorganic chemistry and expanded into the structures of biological molecules. Dr. Summers and his coworkers were the first to determine the three-dimensional structure of an RNA-binding protein from Human Immunodeficiency Virus (HIV) that contains zinc and is essential for this virus to incorporate its own genome into its protein coat. Summers is a co-leader of a nationally recognized program directed to providing substantial research experiences for undergraduate students. He and an ever-changing group of undergraduates, along with some PhD students, technicians, and postdoctoral fellows (**Figure 1.30**), have continued this research over many years, elucidating more details about how this protein performs its function and expanding into other areas of HIV research.

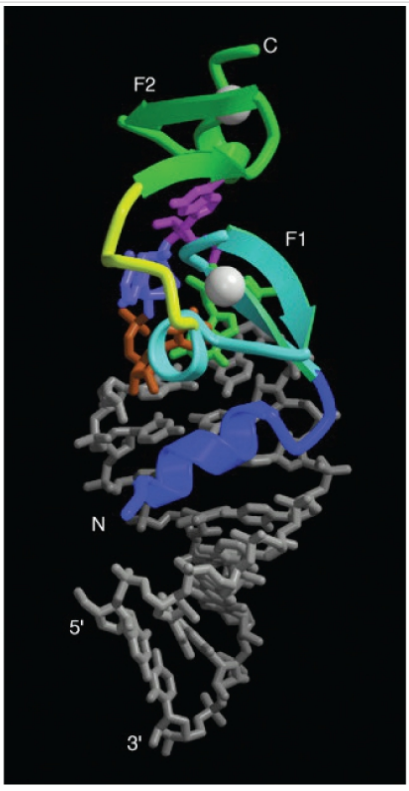

FIGURE 1.30 The research team of Professor Michael Summers at the University of Maryland, Baltimore County, is diverse in many dimensions. His team consists primarily of undergraduat

students, with some graduate students and postdoctoral fellows.

Among those who conducted research with Dr. Summers is Chelsea Pinnix, MD/PhD (Figure 1.31), who worked with Dr. Summers while she was an undergraduate student and contributed to the work that detailed the three-dimensional structure of the zinc-containing HIV protein bound to an RNA target. After graduating, she completed a combined MD/PhD program, earning her PhD in cell and molecular biology. She then completed additional medical training in radiation oncology and now uses her knowledge in all of these fields as a faculty member at an academic medical center.

Stalling, Lucia Pappalardo, Philip N. Borer, Michael F. Summers, "Structure of the HIV-1 Nucleocapsid Protein Bound to the SL3 Ψ-RNA Recognition Element." Science 16 Jan 1998: Vol. 279, Issue 5349, pp. 384–388, DOI: 10.1126/science.279.5349.384, Figure 4a. Permission conveyed through Copyright Clearance Center, Inc.

FIGURE 1.31 Chelsea Pinnix, MD/PhD, helped to determine the three-dimensional structure of an HIV zinc-containing protein bound to RNA.

Our knowledge of biochemistry is constantly expanding through the efforts of many individuals and teams working in universities and research institutes, and also in private industrial and government

laboratories. One of Dr. Berg's former students and coauthor of this book is Gregory Gatto, MD/PhD, who works on developing new drugs at a pharmaceutical company. Coauthor Justin Hines, PhD, began conducting research on protein structure and function as an undergraduate and now teaches and investigates protein misfolding with a research team made up solely of undergraduates. Coauthor Jutta Heller, PhD, studied protein structure in graduate school and now teaches molecular biology to undergraduates. Many students of biochemistry, however, pursue nonacademic careers, applying their biochemical knowledge to other aspects of human endeavor, such as medicine, intellectual property law, communication, and finance.

Biochemistry enriches many aspects of modern society. Throughout this book, we will continue to highlight individuals who have made important contributions to biochemistry while pursuing various career paths. We hope these profiles help you learn about some outstanding scientists and appreciate the varied paths available to students of biochemistry.

Chapter 1 Summary

1.1 Biochemical Unity Underlies Biological Diversity

- Many biochemical processes and pathways are quite similar even in organisms that appear quite different from one another.
- Organisms can be divided into three fundamental groups called domains.
- Eukarya (eukaryotes) includes all multicellular organisms, including all animals, plants, and human beings as well as some unicellular organisms, whereas Bacteria and Archaea represent two distinct groups of microscopic microorganisms (prokaryotes).

1.2 DNA Illustrates the Interplay Between Form and Function

- Each DNA strand consists of a phosphodiester backbone with four nitrogenous bases.
- Most DNA molecules consist of two strands that wind around a common axis to form a double helix with specific base pairs in the center.
- The double-helical structure of DNA can explain the role of DNA in storing hereditary information; the information is stored in the sequence of bases, and each strand can serve as a template for the synthesis of a new copy of the opposite strand.

1.3 Concepts from Chemistry Explain the Properties of Biological Molecules

- The DNA double helix serves as a useful example to illustrate how concepts from chemistry apply to essentially all other molecules in biochemistry.

- Most biochemical interactions take place on timescales from picoseconds to microseconds ($10^{-12}-10^{-6}$ s).
- Covalent bonds are strong bonds formed by the sharing of a pair of electrons between adjacent atoms.
- Noncovalent interactions are generally weaker than covalent bonds and include ionic interactions, hydrogen bonds, van der Waals interactions, and interactions associated with the hydrophobic effect.
- Most biochemical processes take place in water, which has a highly cohesive structure due to water molecules (H_2O) interacting with one another through hydrogen bonds.
- The hydrophobic effect refers to the tendency of nonpolar groups, those that lack the ability to participate in ionic interactions and hydrogen bonds, to come together, minimizing exposure to aqueous solution.
- A variety of methods have been developed to observe single molecules participating in different processes, revealing the underlying randomness of chemical processes.
- The laws of thermodynamics are general principles that apply to all physical and chemical processes: The First Law states that the total energy of a system and its surroundings is constant, and The Second Law states that the total entropy of a system plus that of its surroundings always increases.
- Acid–base reactions, which involve the addition or removal of hydrogen ions from molecules, are generally characterized by the equilibrium constant $K_a = [H^+][A^-]/[HA]$.
- Buffers are solutions that resist changes in pH due to the fact that they contain both a weak acid and the associated base.

1.4 DNA Sequencing Is Transforming Biochemistry, Medicine, and Other Fields

- DNA sequencing has become rapid and inexpensive and is transforming many fields, including biochemistry and medicine.
- On average, the genome sequences of two individual human beings differ by 0.5%; this difference is generally larger than the average difference between populations.
- While variations in genome sequences can be important in contributing to traits such as disease susceptibility, environmental factors and chance are also important.
- A major role of the genome sequence is to encode the amino acid sequences of proteins, the molecules that perform most of the functions within cells.
- Molecular clocks have been developed based on analyzing variations in DNA or protein sequences between different organisms to infer how long ago these organisms shared a common ancestor.

1.5 Biochemistry Is an Interconnected Human Endeavor

- Knowledge of biochemistry advances through the efforts of scientists generally working together in small teams.
- A wide variety of career paths is accessible to individuals who study biochemistry.

Problems

1. Identify the hydrogen-bond donors and acceptors in each of the four bases on page 4. 2

2. Draw a stable, uncharged resonance form for the structure shown. Be sure to include lone pairs of electrons. 2

3. What types of noncovalent interactions hold together the following solids? 2

a. Table salt (NaCl), which contains Na^+ and Cl^- ions.
b. Graphite (C), which consists of sheets of covalently bonded carbon atoms.

4. Given the following values for the changes in enthalpy (ΔH) and entropy (ΔS), which of the following processes can take place at 298 K without violating the Second Law of Thermodynamics? 3

a. $\Delta H = -84\ \text{kJ mol}^{-1}\ (-20\ \text{kcal mol}^{-1})$,

$\Delta S = +125\ \text{J mol}^{-1}\ \text{K}^{-1}\ (+30\ \text{cal mol}^{-1}\ \text{K}^{-1})$

b. $\Delta H = -84\ \text{kJ mol}^{-1}\ (-20\ \text{kcal mol}^{-1})$,

$\Delta S = -125\ \text{J mol}^{-1}\ \text{K}^{-1}\ (-30\ \text{cal mol}^{-1}\ \text{K}^{-1})$

c. $\Delta H = +84\ \text{kJ mol}^{-1}\ (+20\ \text{kcal mol}^{-1})$,

$\Delta S = +125\ \text{J mol}^{-1}\ \text{K}^{-1}\ (+30\ \text{cal mol}^{-1}\ \text{K}^{-1})$

d. $\Delta H = +84\ \text{kJ mol}^{-1}\ (+20\ \text{kcal mol}^{-1})$,

$$\Delta S = -125\ \text{J mol}^{-1}\ \text{K}^{-1}\ (-30\ \text{cal mol}^{-1}\ \text{K}^{-1})$$

5. For double-helix formation, ΔG can be measured to be $-54\ \text{kJ mol}^{-1}\ (-13\ \text{kcal mol}^{-1})$ at pH 7.0 in $1\ \text{M NaCl}$ at $25°\text{C}\ (298\ \text{K})$. The heat released indicates an enthalpy change of $-251\ \text{kJ mol}^{-1}\ (-60\ \text{kcal mol}^{-1})$. For this process, calculate the entropy change for the system and the entropy change for the surroundings. 3

6. Calculate the pH of a solution that is 0.153 M HCl. 6

7. Given a density of $1\ \text{g/ml}$ and a molecular weight of $18\ \text{g/mol}$, calculate the concentration of water in water.

8. A solution is prepared by adding $0.01\ \text{M}$ acetic acid $(pK_a = 4.75)$ and $0.01\ \text{M}$ ethylamine to water and adjusting the pH to 7.4. The pK_a of the ethylammonium ion $(CH_3CH_2NH_3^+)$ is 10.70. What is the ratio of acetate to acetic acid? What is the ratio of ethylamine to ethylammonium ion? 6

9. 100 mL of a solution of hydrochloric acid with pH 5.0 is diluted to 1 L. Similarly, $100\ \text{mL}$ of a 0.1 mM buffer solution made from acetic acid and sodium acetate with pH 5.0 is diluted to 1 L. What are the pH values of the two diluted solutions? 5

10. A dye that is an acid and that appears as different colors in its protonated and deprotonated forms can be used as a pH indicator. Suppose that you have a 0.001 M solution of a dye

with a pK_a of 7.2. From the color, the concentration of the protonated form is found to be 0.0002 M. Assume that the remainder of the dye is in the deprotonated form. What is the pH of the solution? 6

11. During exercise when the body lacks an adequate supply of oxygen to support energy production, a compound called pyruvate that is produced from the breakdown of glucose is converted into lactic acid.

The dissociation of lactic acid to lactate is shown in the reaction. Lactic acid has a pK_a of 3.86.

A solution containing a mixture of lactic acid and lactate was found to have a pH of 4.13. Calculate the ratio of the lactate concentration to the lactic acid concentration in this solution. 6

12. Through the use of nuclear magnetic resonance spectroscopy, it is possible to determine the ratio between the protonated and deprotonated forms of buffers. Use the Henderson–Hasselbalch equation for a propanoic acid solution ($CH_3CH_2CO_2H$, $pK_a = 4.87$) to calculate the quotient $[A^-]/[HA]$ at three different pH values:

a. $pH = 4.52$;
b. $pH = 4.87$;
c. $pH = 5.08$.

13. Given that phosphoric acid (H_3PO_4) can give up three protons with different pK_a values, sketch a plot of pH as a function of added drops of sodium hydroxide solution, starting with a solution of phosphoric acid at pH 1.0. 6

14. Your laboratory is out of materials to make phosphate buffer and you are considering using sulfate to make a buffer instead. The pK_a values for the two hydrogens in H_2SO_4 are -10 and 2.

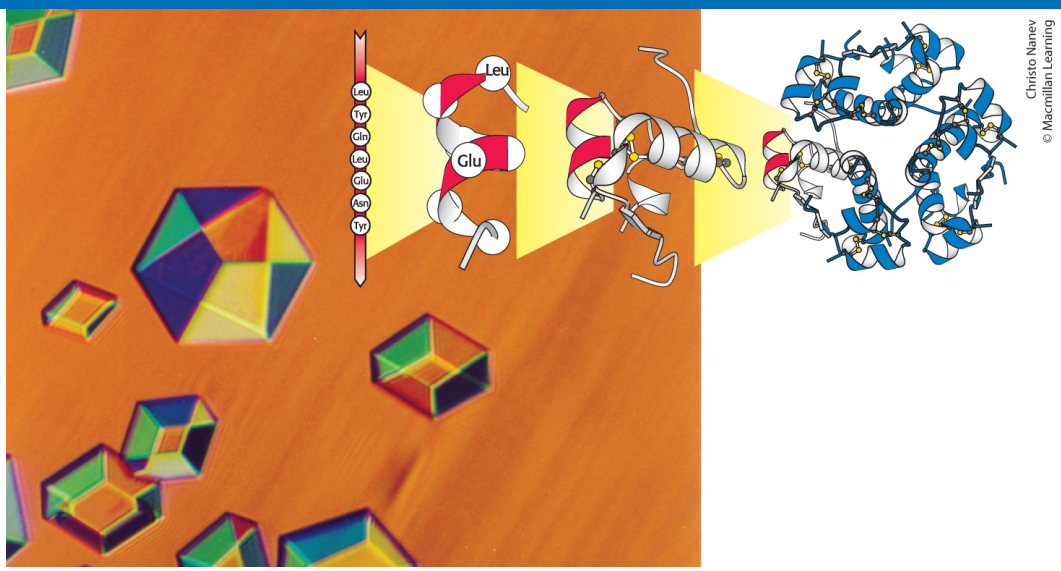
a. Will this approach work for making a buffer effective near pH 7?
b. Around what pH might a sulfate-based buffer be useful? 6

15. You wish to prepare a buffer consisting of acetic acid and sodium acetate with a total acetic acid plus acetate concentration of 250 mM and a pH of 5.0. What concentrations of acetic acid and sodium acetate should you use? Assuming you wish to make 2 liters of this buffer, how many moles of acetic acid and sodium acetate will you need? How many grams of each will you need (molecular weights: acetic acid $60.05\ g\ mol^{-1}$, sodium acetate, $82.03\ g\ mol^{-1}$)? 5

16. Norman Good and his colleagues developed a series of compounds that are useful buffers near neutral pH. Three of these buffers are abbreviated MES $(pK_a = 6.15)$, MOPS $(pK_a = 7.15)$, and HEPPS $(pK_a = 8.00)$.

a. Which of these buffers would be most effective near pH 7.0?
b. Near 6.0? 5

17. Would you expect the double helix in a short segment of DNA to be more stable in 100 sodium phosphate buffer at pH 7.0 or in pure water? Why? 2



18. Suppose two phosphate groups in DNA (each with a charge of -1) are separated by $12\ \text{Å}$. What is the energy of the ionic interaction between these two phosphates, assuming a dielectric constant of 80? Repeat the calculation, assuming a dielectric constant of 2. 2

19. Describe the noncovalent interactions that are primarily responsible for the fact that oil and water do not mix easily. 2

20. Hemoglobin from the Galapagos tortoise is 64% identical to that from human beings. In contrast, a protein called histone H2B is 98% identical in these two organisms. What level of identity would you expect for histone H2B for gorillas compared with human beings? Would histone H2B be as useful a molecular clock as hemoglobin? 7

21. Assume that 10% of the members of a population will get a particular disease over the course of their lifetime. Genomic studies reveal that 5% of the population have sequences in their genomes such that their probability of getting the disease over the course of their lifetimes is found to be 50%. What is the average lifetime risk of this disease for the remaining 95% of the population without these sequences? 7

Chapter 2
Protein Composition and Structure

Christo Nanev
© Macmillan Learning

A protein is defined by a specific sequence of amino acids, which uniquely determines its folded three-dimensional structure. For example, consider the protein insulin, a hormone that is crucial for maintaining blood sugar at appropriate levels. In this protein's chain of amino acids, the interactions of amino acids close to one another in the sequence produce spiraled chains (helices) that fold further into the precisely defined shape of a single insulin molecule. Complexes of six insulin molecules can be induced in the laboratory to form well-defined crystals (photograph at left), which allows the experimental determination of these structures at atomic-level resolution.

Outline

2.1 Several Properties of Protein Structure Are Key to Their Functional Versatility
2.2 Proteins Are Built from a Repertoire of 20 Amino Acids
2.3 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains
2.4 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures
2.5 Tertiary Structure: Proteins Can Fold into Globular or Fibrous Structures
2.6 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures
2.7 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

---

Learning Goals

By the end of this chapter, you should be able to:

1. Identify the 20 amino acids and their corresponding three-letter and one-letter abbreviations, and group them according to the chemical properties of their side chains.
2. Distinguish between primary, secondary, tertiary, and quaternary structures.
3. Describe the properties of the principal types of secondary structure, including the α helix, the β sheet, and the reverse turn.
4. Explain how the hydrophobic effect serves as the primary driving force for folding of polypeptide chains into globular proteins.
5. Describe the nucleation-condensation model of protein folding, and explain why it is preferable to a random sampling model.

Proteins are the most versatile macromolecules in living systems and serve crucial functions in essentially all biological processes. They function as catalysts, transport and store other molecules such

as oxygen, provide mechanical support and immune protection, generate movement, transmit nerve impulses, and control growth and differentiation. Indeed, much of this book will focus on understanding what proteins do and how they perform these functions. In order to fully appreciate this functional diversity, we must first understand the essential structural components shared by all proteins. For the biochemist, recognition of this architectural composition is critical and fundamental, akin to learning the alphabet of a new language.

2.1 Several Properties of Protein Structure Are Key to Their Functional Versatility

As we shall see throughout this text, proteins can adopt a breathtakingly wide variety of structures, which, in turn, enables them to participate in a broad range of functions. There are several key features of protein structure that allow for this remarkable diversity:

- *Proteins are linear polymers built of monomer units called amino acids, which are linked end to end*. The sequence of linked amino acids is called the primary structure. Remarkably, proteins spontaneously fold up into three-dimensional structures that are determined by the sequence of amino acids in the protein polymer. Three-dimensional structure formed by hydrogen bonds between amino acids near one another is called secondary structure, whereas tertiary structure is formed by long-range interactions between amino acids. Protein function depends directly on this three-dimensional structure (**Figure 2.1**). Thus, proteins are the embodiment of the transition from the one-dimensional world of sequences to the three-dimensional world of molecules capable of diverse activities. Many proteins also display quaternary structure, in which the functional protein is composed of several distinct polypeptide chains.

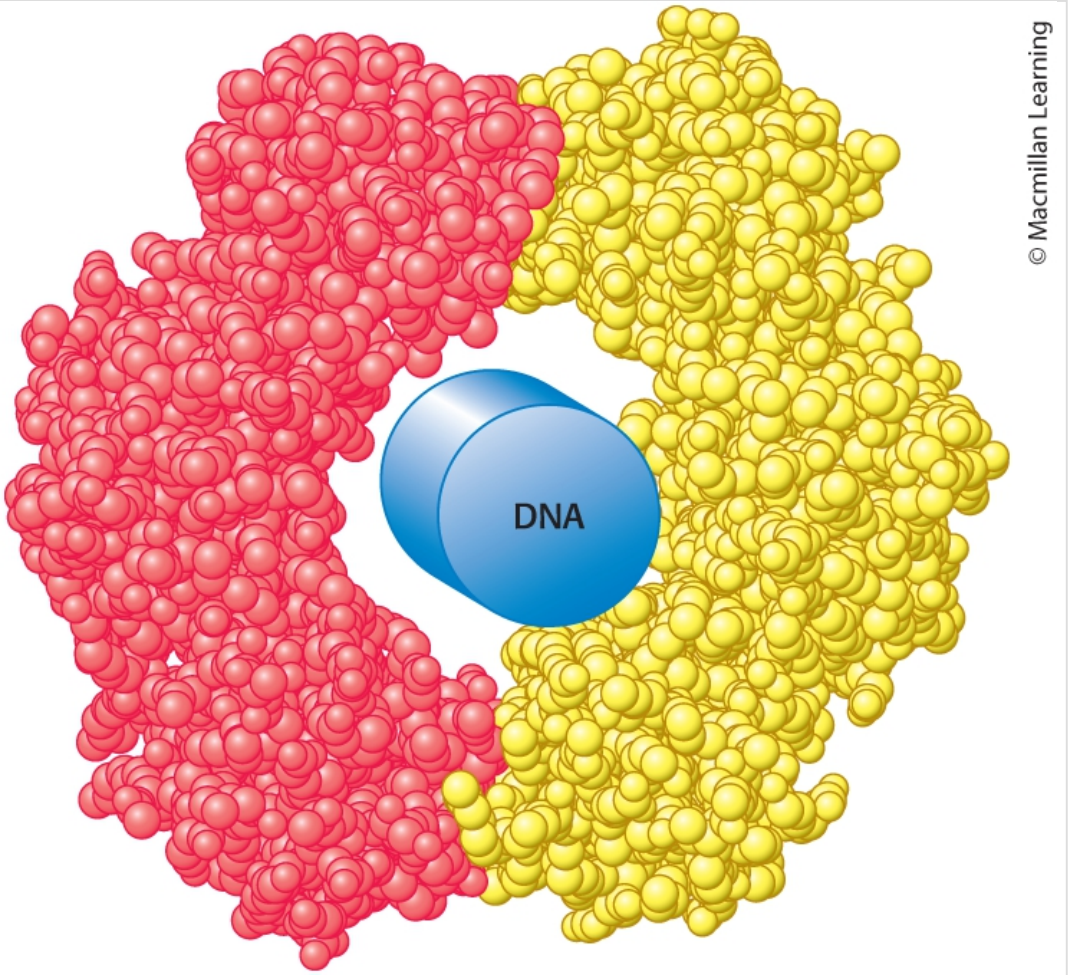


FIGURE 2.1 The structure of a protein determines its function. The protein component of the DNA replication machinery, which consists of two identical subunits (shown in red and yellow), acts as a clamp that allows large segments of DNA (depicted as a cylinder) to be copied without the replication machinery dissociating from the DNA.

[Drawn from 2POL.pdb.]

INTERACT with this model in Achieve

- *Proteins contain a wide range of functional groups*. These functional groups include alcohols, thiols, thioethers, carboxylic acids, carboxamides, and a variety of basic groups, such as amines. Most of these groups are chemically reactive. When combined in various

sequences, this array of functional groups accounts for the broad spectrum of protein function. For instance, their reactive properties are essential to the function of **enzymes** — the proteins that catalyze specific chemical reactions in biological systems (Chapters 5 through 7).

- *Proteins can interact with one another and with other biological macromolecules to form complex assemblies*. The proteins within these assemblies can act synergistically to generate capabilities that individual proteins may lack. Examples of these assemblies include macromolecular machines that replicate DNA, transmit signals within cells, and enable muscle cells to contract (**Figure 2.2**).

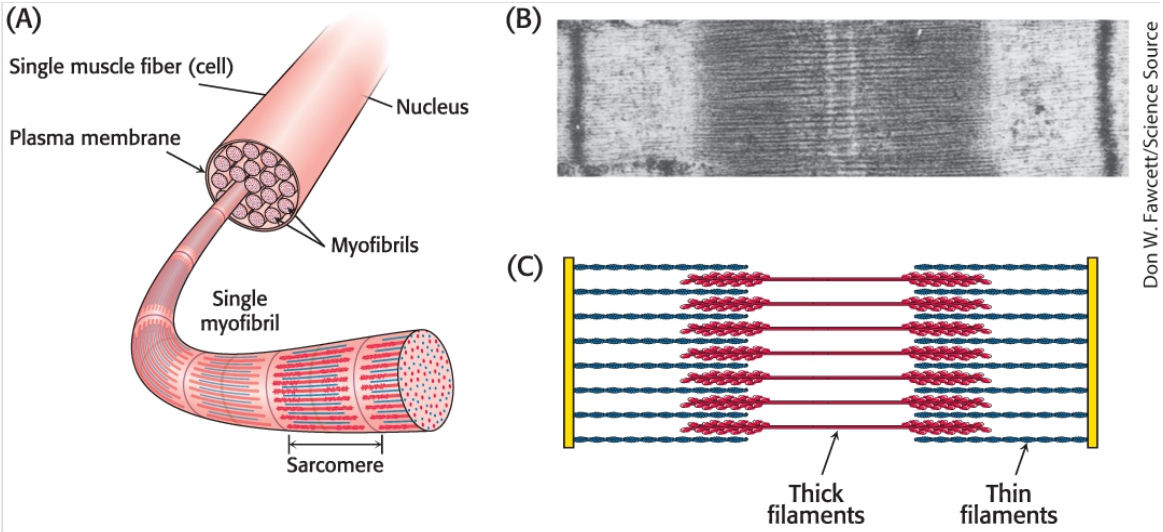

FIGURE 2.2 Some proteins form complex assemblies. (A) A single muscle cell contains multiple myofibrils, each of which is comprised of numerous repeats of a complex protein assembly known as the sarcomere. (B) The banding pattern of a sarcomere is evident by electron microscopy. (C) The banding is caused by the interdigitation of filaments made up of many individual proteins.

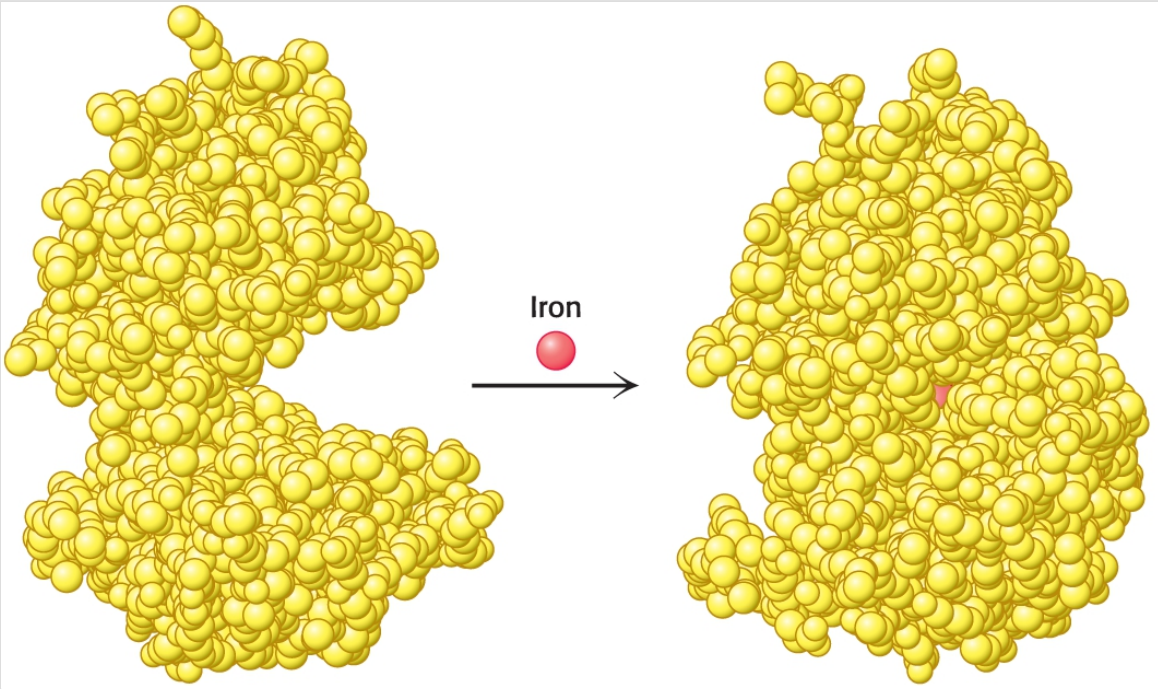
- *Some proteins are quite rigid, whereas others display considerable flexibility*. Rigid units can function as structural elements in the cytoskeleton (the internal scaffolding within cells) or in connective

tissue. Proteins with some flexibility may act as hinges, springs, or levers. In addition, conformational changes within proteins enable the regulated assembly of larger protein complexes as well as the transmission of information within and between cells (Figure 2.3).



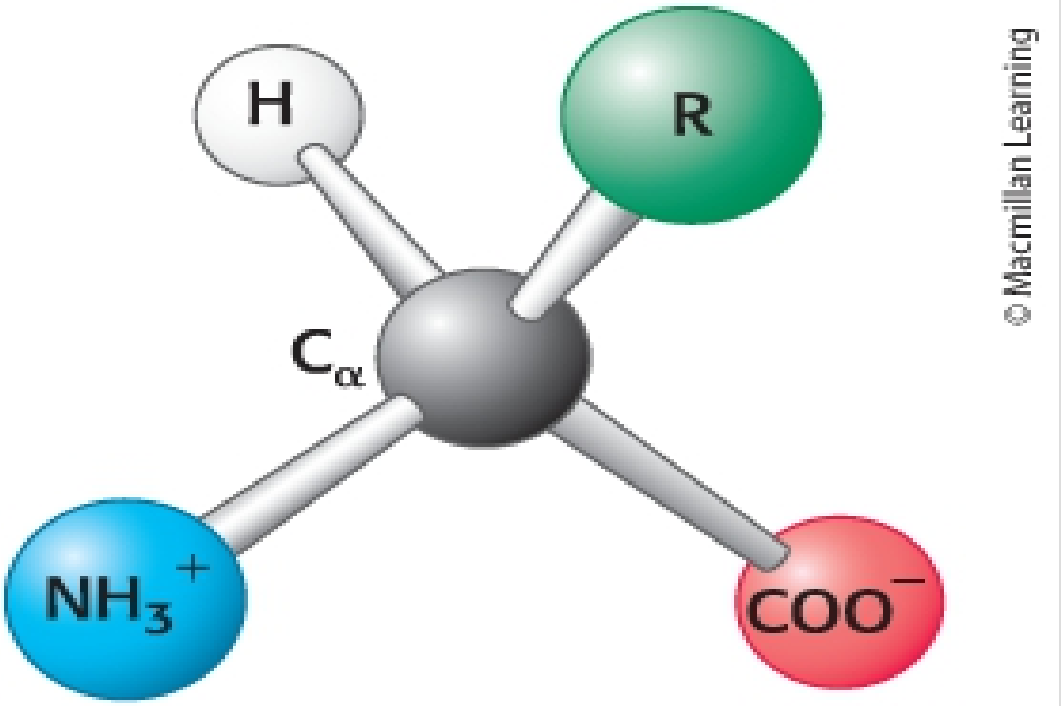


FIGURE 2.3 Conformational changes allow flexibility in protein function. On binding iron, the protein lactoferrin undergoes a substantial change in conformation that allows other molecules to distinguish between the iron-free and the iron-bound forms.

2.2 Proteins Are Built from a Repertoire of 20 Amino Acids

Amino acids are the building blocks of proteins. An α-amino acid consists of a central carbon atom, called the **α carbon**, linked to an amino group, a carboxylic acid group, a hydrogen atom, and a distinctive **R group** (also referred to as the **side chain**). With four different groups connected to the tetrahedral α-carbon atom, α-amino acids are **chiral**: they may exist in one or the other of two mirror-image forms, called the *L isomer* and the *D isomer* (**Figure 2.4**).

© Macmillan Learning

L isomer

D isomer

FIGURE 2.4 The L and D isomers of amino acids are mirror images of each other.
The letter R refers to the side chain. Only the L amino acids are found in proteins.

Only L isomers of amino acids (called *L amino acids*) are constituents of proteins. What is the basis for the preference for L amino acids? The answer has been lost to evolutionary history. It is possible that the preference for L over D amino acids was a consequence of a chance selection. However, there is evidence that L amino acids are slightly more soluble than a racemic mixture of D and L amino acids, which tend to form crystals. This small solubility difference could have been amplified over time so that the L isomer became dominant in solution.

Amino acids in solution at physiological pH (around 7.4) exist predominantly as **dipolar ions** (also called **zwitterions**). In the dipolar form, the amino group is protonated $(-NH_3^+)$ and the carboxyl group is deprotonated $(-COO^-)$. The ionization state of an amino acid varies with pH (**Figure 2.5**). In acid solution (e.g., pH 1), the amino group is protonated $(-NH_3^+)$ and the carboxyl group is not dissociated $(-COOH)$. As the pH is raised, the carboxylic acid is the first group to give up a proton, inasmuch as its pK_a is near 2. (The concept of pK_a was explained in Section 1.3.) The dipolar form persists until the pH approaches 9.5, when the protonated amino group loses a proton.

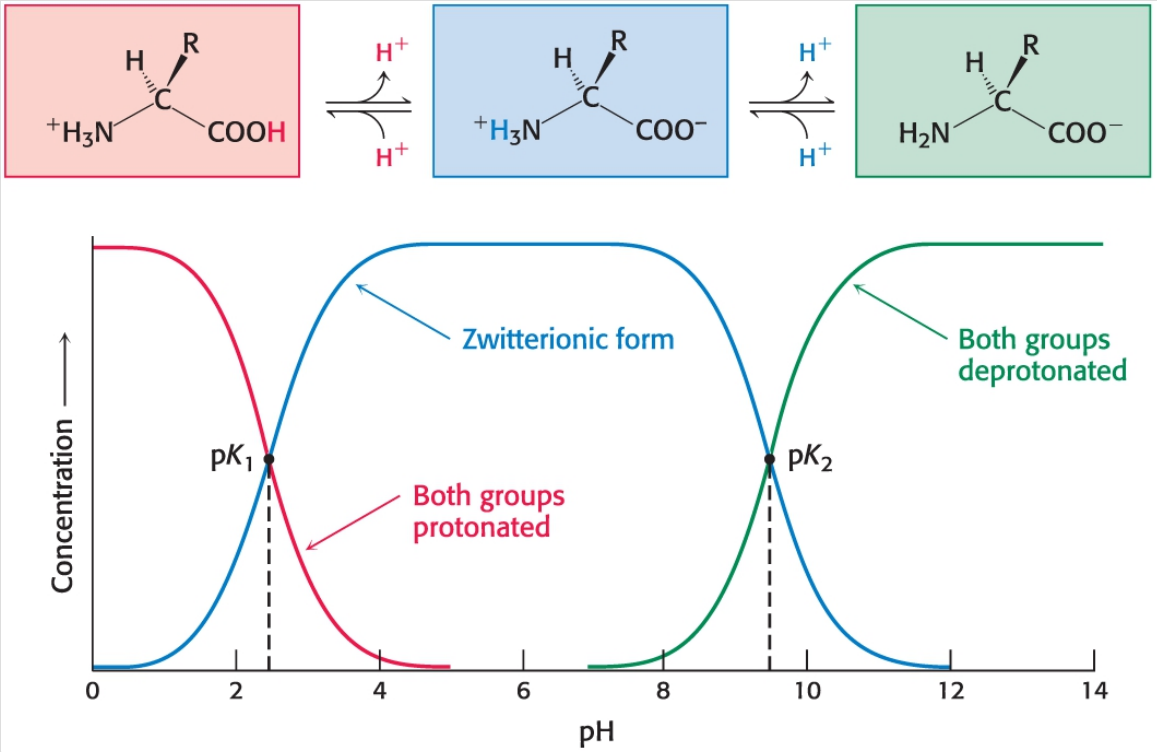

FIGURE 2.5 The ionization state of amino acids is altered by changes in pH. At low pH, near th pK_a for the carboxylic acid, pK_1, the $-COOH$ proton is lost from the fully protonated form. As the pH approaches physiological levels, the zwitterionic form predominates. At high pH near the pK_a for the amino group, pK_2, one of the $-NH_3^+$ protons is lost to form the ful deprotonated species.

The diversity of amino acids arises from the different side chains

Twenty kinds of side chains varying in size, shape, charge, hydrogen-bonding capacity, hydrophobic character, and chemical reactivity are commonly found in proteins. Indeed, all proteins in all species — bacterial, archaeal, and eukaryotic — are constructed from the same set of 20 amino acids with only a few exceptions. This fundamental

alphabet for the construction of proteins is several billion years old. The remarkable range of functions mediated by proteins results from the diversity and versatility of these 20 building blocks. Understanding how this alphabet is used to create the intricate three-dimensional structures that enable proteins to carry out so many biological processes is an exciting area of biochemistry, and one that we will return to in Section 2.7.

Although there are many ways to classify amino acids, we will sort these molecules into four groups, on the basis of the general chemical characteristics of their R groups:

1. Hydrophobic amino acids with nonpolar R groups
2. Polar amino acids with neutral R groups but the charge is not evenly distributed
3. Positively charged amino acids with R groups that have a positive charge at physiological pH
4. Negatively charged amino acids with R groups that have a negative charge at physiological pH

Hydrophobic amino acids

The simplest amino acid is glycine, which has a single hydrogen atom as its side chain. With two hydrogen atoms bonded to the α-carbon atom, glycine is unique in being achiral; that is, its mirror images are superimposable. Alanine, the next simplest amino acid, has a methyl group $(-CH_3)$ as its side chain (**Figure 2.6**).

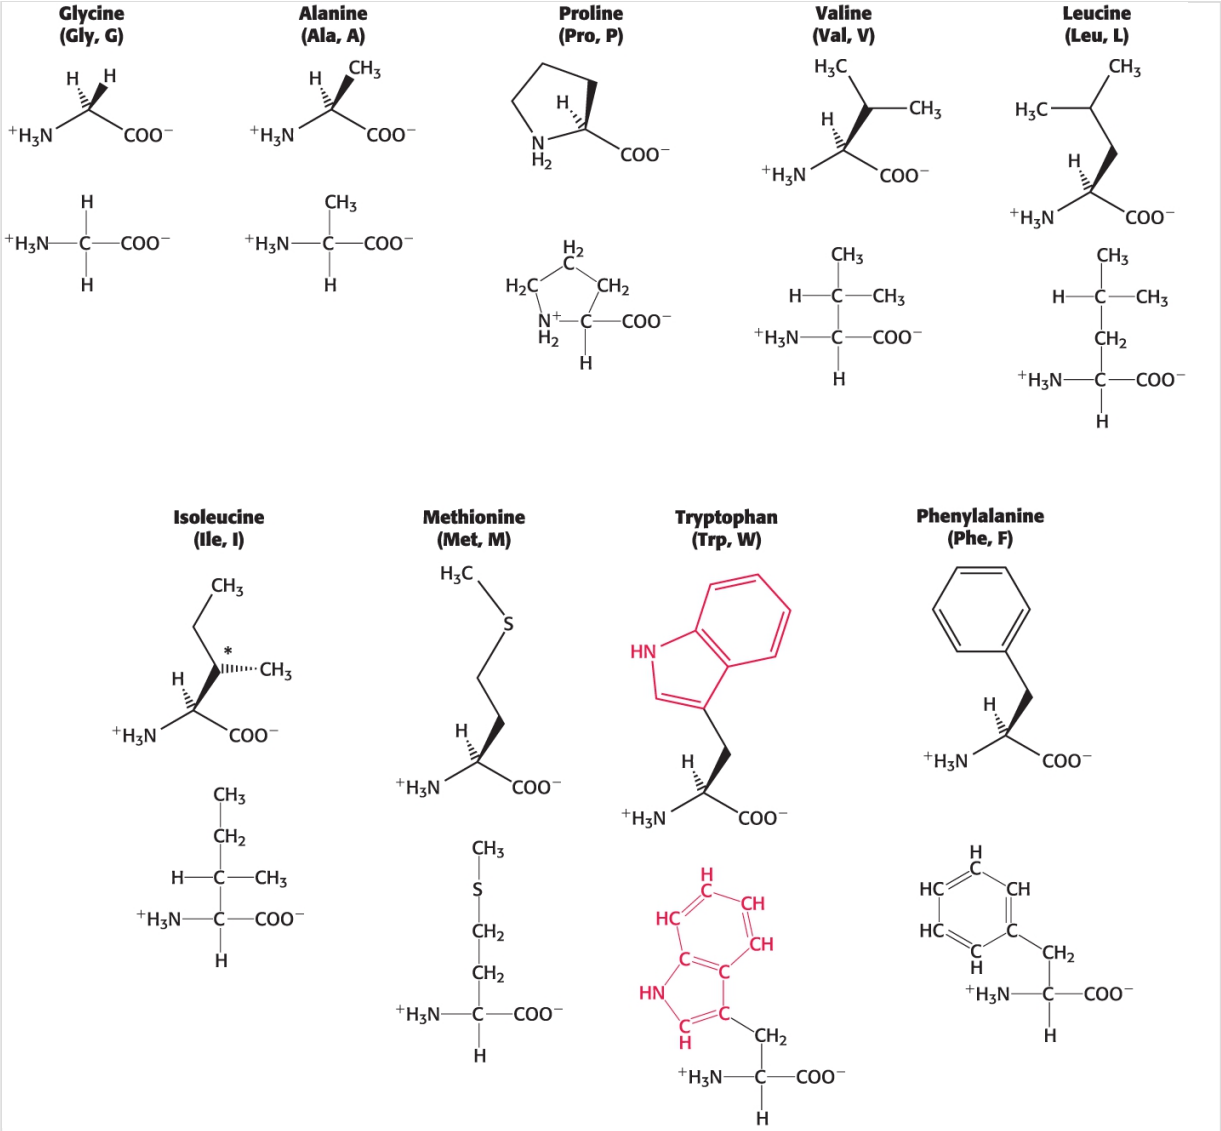

FIGURE 2.6 The hydrophobic amino acids have nonpolar R groups. For each amino acid, a stereochemically realistic formula (top) shows the geometric arrangement of bonds around atoms and a Fischer projection (bottom) shows all bonds as being perpendicular for a simplified representation. The additional chiral center in isoleucine is indicated by an asterisk. The indole group in the tryptophan side chain is shown in red.

Larger hydrocarbon side chains are found in valine, leucine, and isoleucine. Methionine contains a largely aliphatic side chain that includes a thioether (—S—) group. The side chain of isoleucine includes

an additional chiral center; only the isomer shown in Figure 2.6 is found in proteins. These aliphatic side chains are especially hydrophobic; that is, they tend to cluster together rather than contact water. The three-dimensional structures of water-soluble proteins are stabilized by this tendency of hydrophobic groups to come together (the hydrophobic effect, Section 1.3). The different sizes and shapes of these hydrocarbon side chains enable them to pack together to form compact structures with little empty space. Proline also has an aliphatic side chain, but it differs from other members of the set of 20 in that its side chain is bonded to both the nitrogen and the α-carbon atoms, yielding a pyrrolidine ring. Proline markedly influences protein architecture because its cyclic structure makes it more conformationally restricted than the other amino acids.

Two amino acids with relatively simple aromatic side chains are part of the fundamental repertoire. Phenylalanine, as its name indicates, contains a phenyl ring attached in place of one of the hydrogen atoms of alanine. Tryptophan has an indole group joined to a methylene $(-CH_2-)$ group; the indole group comprises two fused rings containing an NH group (Figure 2.6, shown in red). Phenylalanine is purely hydrophobic, whereas tryptophan is less so because of its side chain NH group.

Polar amino acids

Seven amino acids are polar but uncharged at physiological pH. Three amino acids, serine, threonine, and tyrosine, contain hydroxyl groups $(-OH)$ attached to a hydrophobic side chain (**Figure 2.7**). Serine can be thought of as a version of alanine with a hydroxyl group attached. Threonine resembles valine with a hydroxyl group in place of one of valine's methyl groups. Tyrosine is a version of phenylalanine with the hydroxyl group replacing a hydrogen atom on the aromatic ring. The hydroxyl group makes these amino acids much more hydrophilic (water

loving) and reactive than their hydrophobic analogs. Threonine, like isoleucine, contains an additional asymmetric center; again, only one isomer is present in proteins.

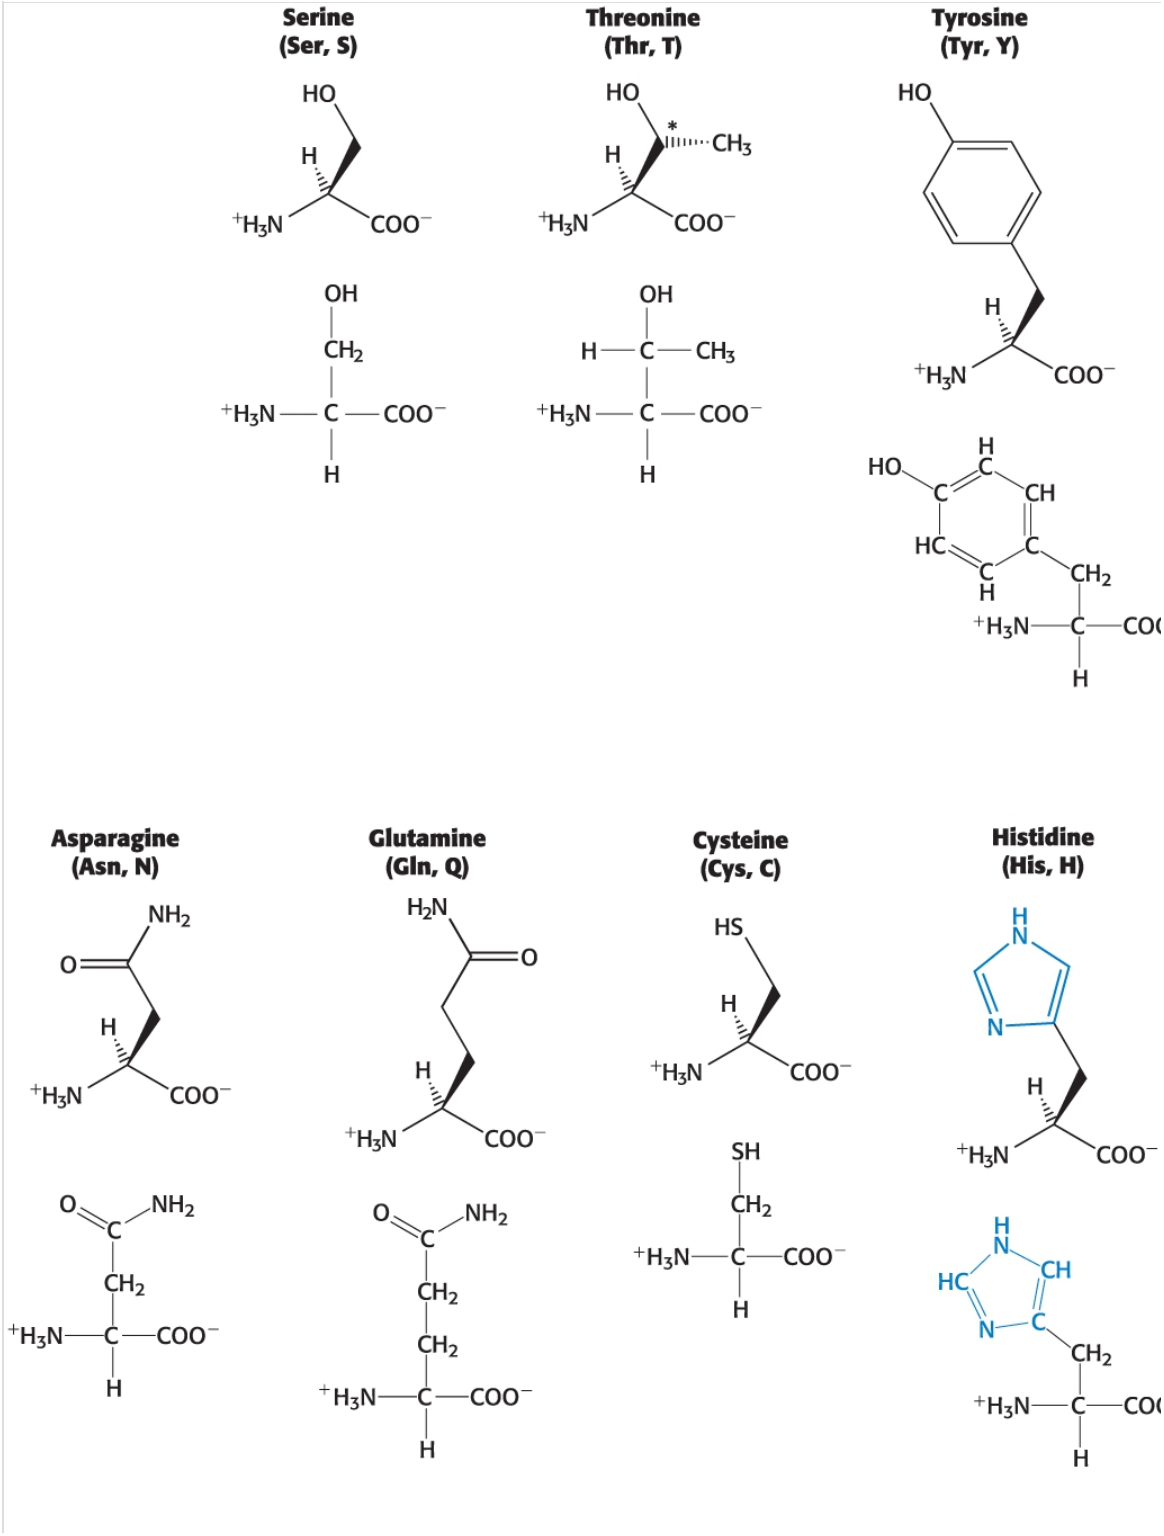

FIGURE 2.7 The polar amino acids have polar but uncharged R groups at physiological pH. Th additional chiral center in threonine is indicated by an asterisk. The carboxamide groups of asparagine and glutamine are shown in red. The imidazole group of histidine is shown in blue.

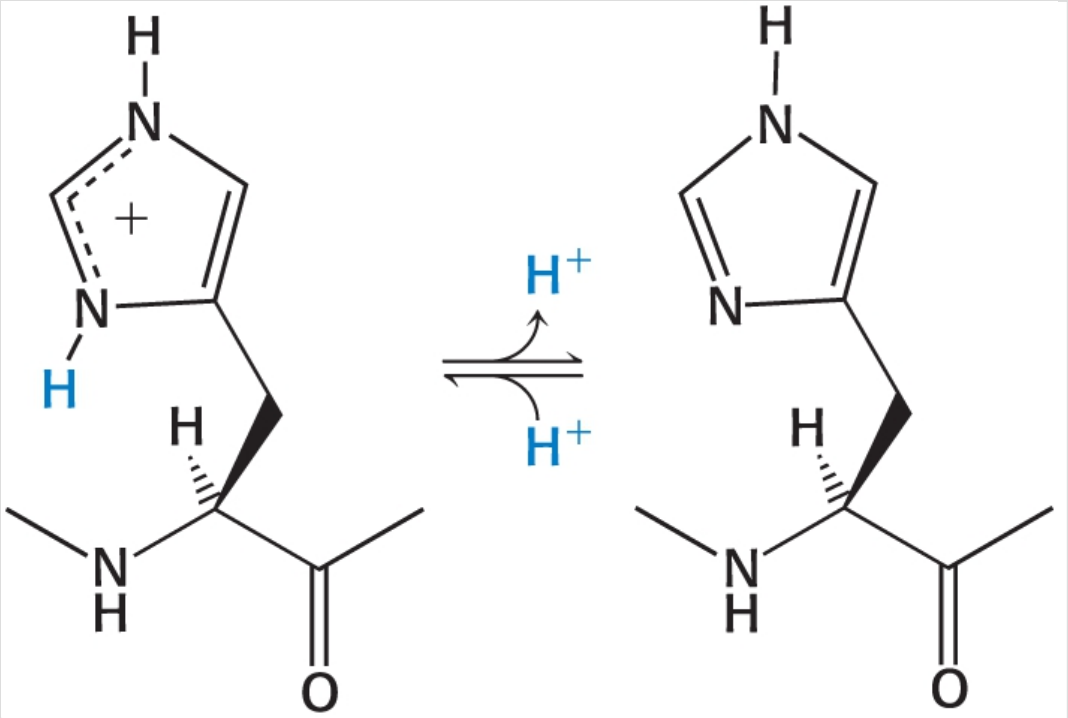
In addition, the set includes asparagine and glutamine, two amino acids that contain a terminal carboxamide, highlighted in red in Figure 2.7. The side chain of glutamine is one methylene group longer than that of asparagine.

Cysteine is structurally similar to serine but contains a sulfhydryl, or thiol $(-SH)$, group in place of the hydroxyl group. The sulfhydryl group is much more reactive. Pairs of sulfhydryl groups may come together to form disulfide bonds, which are particularly important in stabilizing some proteins, as will be discussed shortly.

Histidine contains an imidazole group, an aromatic ring that is uncharged at pH 7 (Figure 2.7, shown in blue). However, with a pK_a value near 6, the imidazole group can be uncharged or positively charged near neutral pH, depending on its local environment (**Figure 2.8**). Histidine is often found in the active sites of enzymes, where the imidazole ring can bind and release protons in the course of enzymatic reactions.



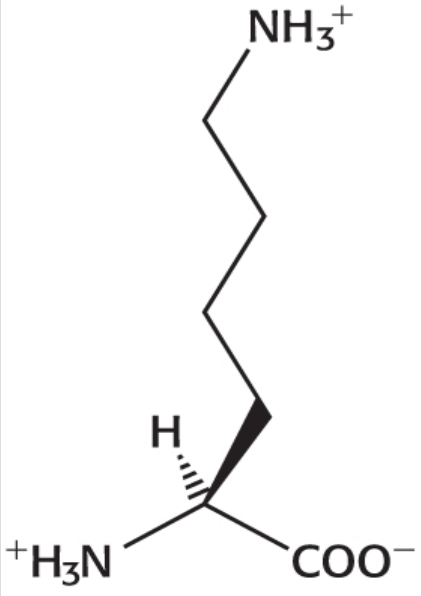


FIGURE 2.8 Histidine can bind or release protons near physiological pH.

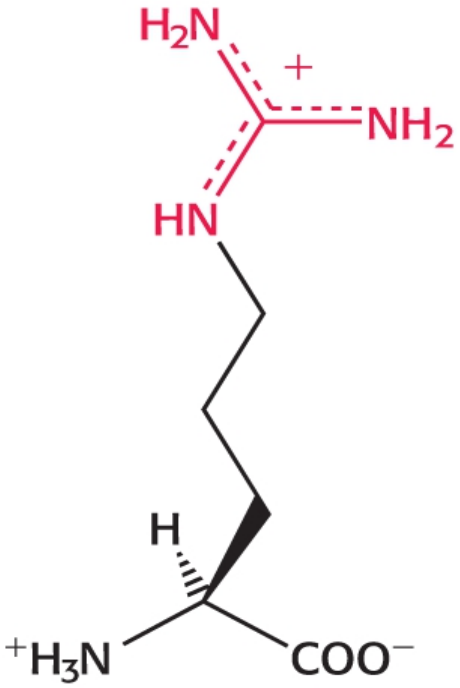
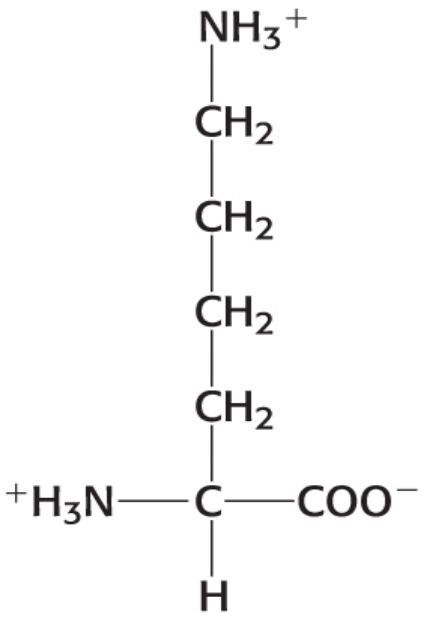


Positively charged amino acids



We turn now to amino acids with complete positive charges that render them highly hydrophilic (**Figure 2.9**). Lysine and arginine have long side chains that terminate with groups that are positively charged at neutral pH. Lysine is capped by a primary amino group and arginine by a guanidinium group (Figure 2.9, shown in red).

Lysine
(Lys, K)

Arginine
(Arg, R)

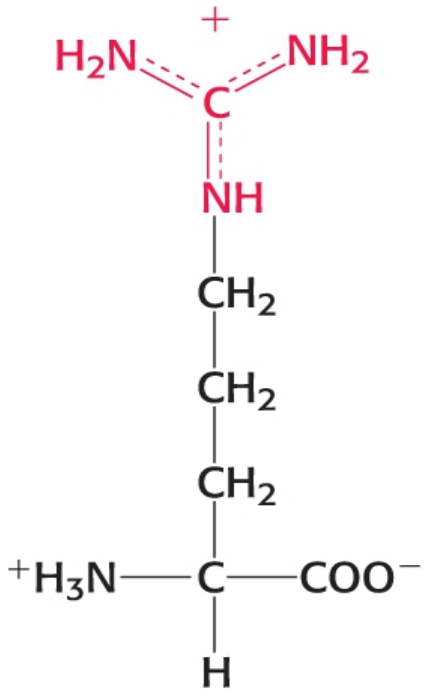


FIGURE 2.9 Two amino acids are positively charged at physiological pH. The guanidinium group in the arginine side chain is shown in red.

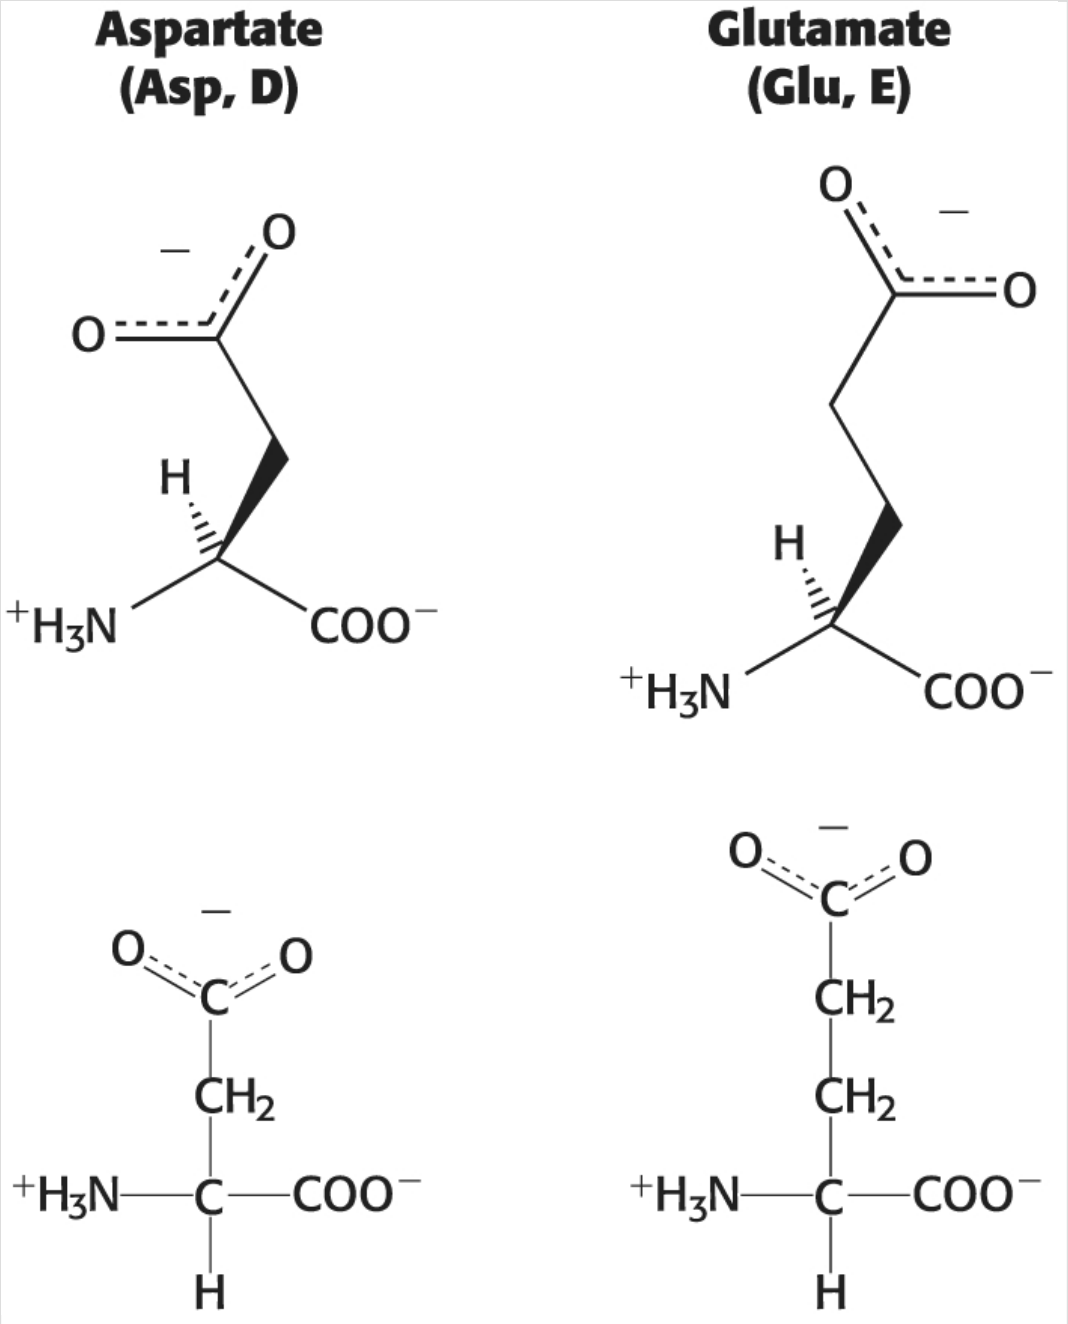
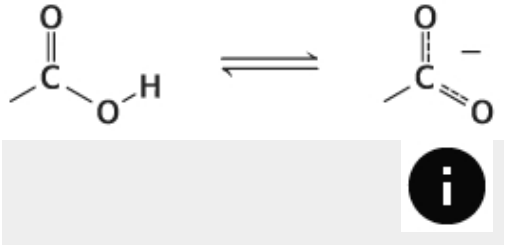
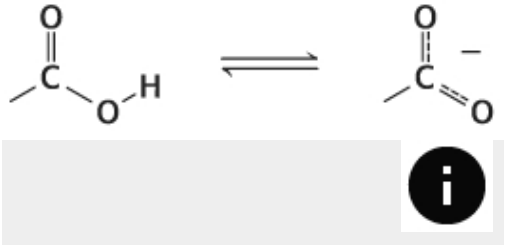
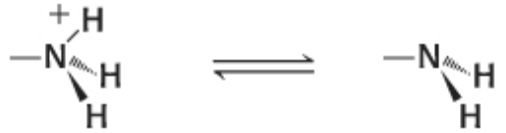
Negatively charged amino acids

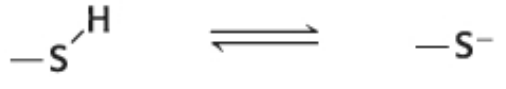
This set of amino acids contains two with acidic side chains: aspartic acid and glutamic acid (**Figure 2.10**). These amino acids are charged derivatives of asparagine and glutamine (Figure 2.7), with a carboxylic acid in place of a carboxamide. Aspartic acid and glutamic acid are often called *aspartate* and *glutamate* to emphasize that, at physiological pH, their side chains usually lack a proton that is present in the acid form and hence are negatively charged. Nonetheless, these side chains can accept protons in some proteins, often with functionally important consequences.

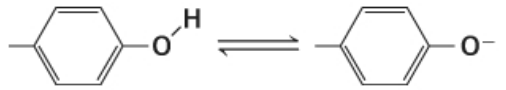












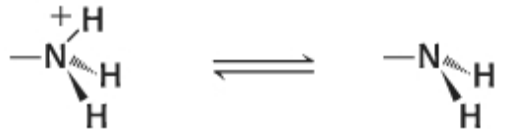


FIGURE 2.10 Two amino acids are negatively charged at physiological pH.

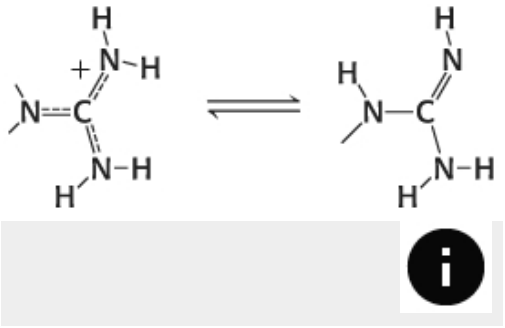
Seven of the 20 amino acids have readily ionizable side chains. These 7 amino acids are able to donate or accept protons to facilitate reactions



as well as to form ionic bonds. Table 2.1 gives equilibria and typical pK_a values for ionization of the side chains of tyrosine, cysteine, arginine, lysine, histidine, and aspartic and glutamic acids in proteins. Two other groups in proteins — the terminal α-amino group and the terminal α-carboxyl group — can be ionized, and typical pK_a values for these groups also are included in Table 2.1.

TABLE 2.1 Typical pK_a values of ionizable groups in proteins

Group	Acid ⇌ Base	Typical pK_a*
Terminal α-carboxyl group		3.1
Aspartic acid Glutamic acid		4.1
Histidine		6.0

Terminal α-amino group		8.0
Cysteine		8.3
Tyrosine		10.0
Lysine		10.4

Arginine	12.5

*pK_a values depend on temperature, ionic strength, and the microenvironment of the ionizable group

Amino acids are often designated by either a three-letter abbreviation or a one-letter symbol (Table 2.2). The abbreviations for amino acids are the first three letters of their names, except for asparagine (Asn), glutamine (Gln), isoleucine (Ile), and tryptophan (Trp). The symbols for many amino acids are the first letters of their names (e.g., G for glycine and L for leucine); the other symbols have been agreed on by convention. These abbreviations and symbols are an integral part of the vocabulary of biochemists.

TABLE 2.2 Abbreviations for amino acids

Amino acid	Three-letter abbreviation	One-letter abbreviation
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartic acid	Asp	D
Cysteine	Cys	C

Glutamine	Gln	Q
Glutamic acid	Glu	E
Glycine	Gly	G
Histidine	His	H
Isoleucine	Ile	I
Leucine	Leu	L
Lysine	Lys	K
Methionine	Met	M
Phenylalanine	Phe	F
Proline	Pro	P
Serine	Ser	S
Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V
Asparagine or aspartic acid	Asx	B
Glutamine or glutamic acid	Glx	Z

Biochemists postulate several reasons why this set of amino acids is conserved across all species

How did this particular set of amino acids become the building blocks of proteins? First, as a set, they are diverse: their structural and chemical properties span a wide range, endowing proteins with the versatility to assume many functional roles. Second, many of these amino acids were probably available from prebiotic reactions; that is, from reactions that took place before the origin of life. Finally, other possible amino acids may have simply been too reactive. For example, amino acids such as homoserine and homocysteine tend to form five-membered cyclic forms that limit their use in proteins (Figure 2.11); the alternative amino acids that are found in proteins — serine and cysteine — do not readily cyclize, because the rings in their cyclic forms are too small to be stable.

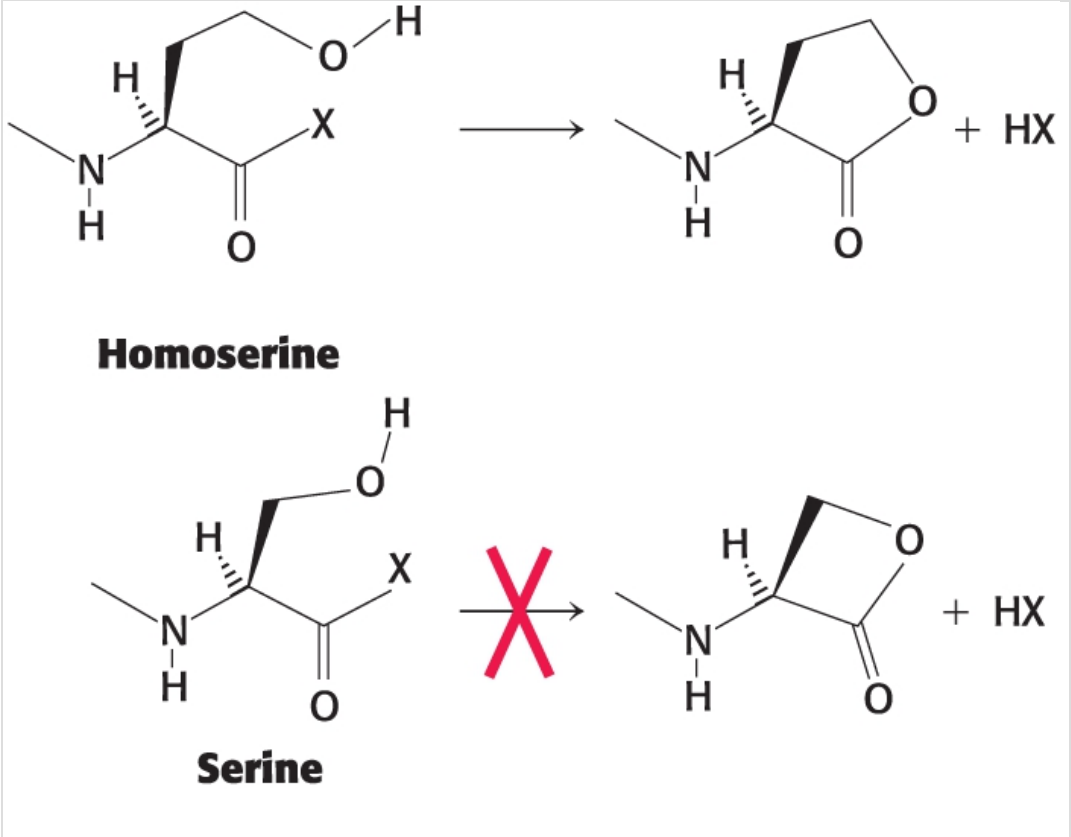


FIGURE 2.11 Some amino acids are not found in proteins because they are too reactive. Homoserine readily cyclizes to form a stable, five-membered ring, potentially resulting in peptide-bond cleavage. In contrast, serine cyclizes to a four-membered ring, which is significantly less stable.

Self-Check Question

Which two amino acids have additional chiral centers besides their α-carbon atoms?

2.3 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains

Proteins are linear polymers formed by linking the α-carboxyl group of one amino acid to the α-amino group of another amino acid. This type of linkage is called a **peptide bond** (or an **amide bond**). The formation of a dipeptide from two amino acids is accompanied by the loss of a water molecule (**Figure 2.12**). Under most conditions, the equilibrium of this reaction lies on the side of hydrolysis rather than synthesis. Hence, the biosynthesis of peptide bonds requires an input of free energy. Nonetheless, peptide bonds are quite stable kinetically because the rate of hydrolysis is extremely slow; the lifetime of a peptide bond in aqueous solution in the absence of a catalyst approaches 1000 years.

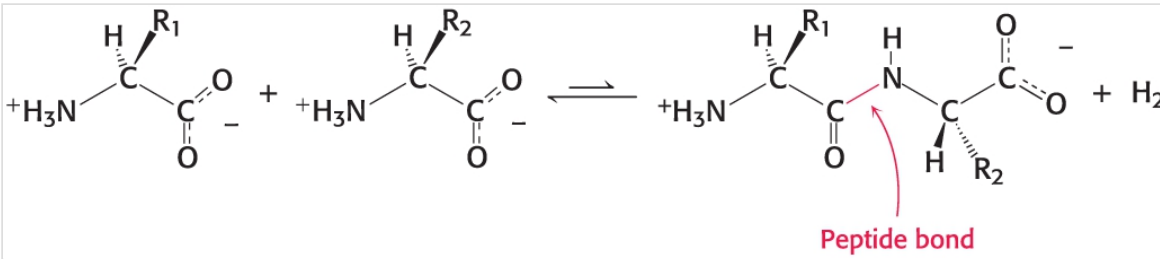

FIGURE 2.12 The formation of the peptide bond linking two amino acids is accompanied by t loss of a molecule of water.

A series of amino acids joined by peptide bonds forms a polypeptide chain, and each amino acid unit in a polypeptide is called a **residue**. A polypeptide chain has directionality because its ends are different: an α-amino group is present at one end and an α-carboxyl group at the other.

The amino end is taken to be the beginning of a polypeptide chain; by convention, the sequence of amino acids in a polypeptide chain is written starting with the amino-terminal residue. Thus, in the polypeptide Tyr-Gly-Gly-Phe-Leu (YGGFL), tyrosine is the amino-terminal (N-terminal) residue and leucine is the carboxyl-terminal (C-terminal) residue (Figure 2.13). Leu-Phe-Gly-Gly-Tyr (LFGGY) is a different polypeptide, with different chemical properties.

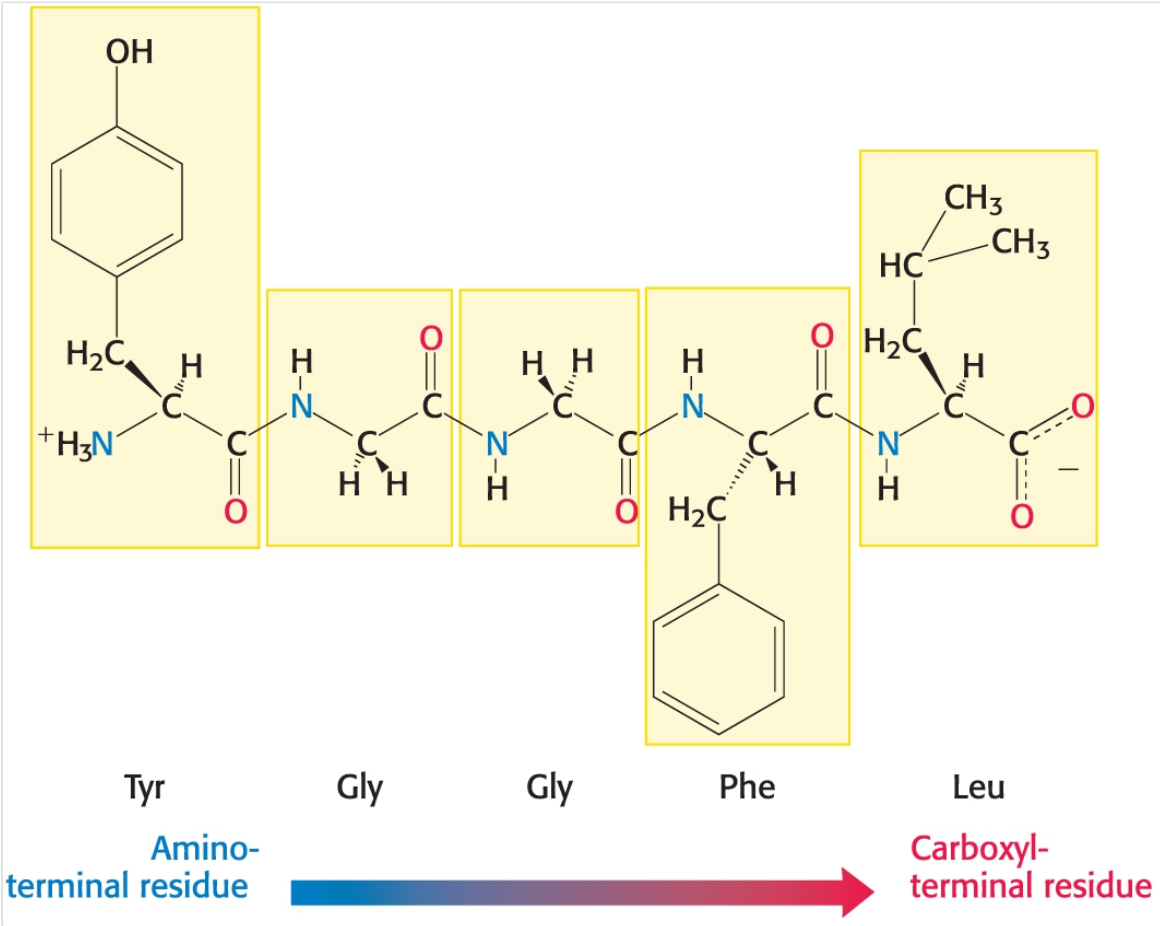

FIGURE 2.13 Amino acid sequences have direction. This illustration of the pentapeptide Tyr-Gl Gly-Phe-Leu (YGGFL) shows the sequence from the amino terminus to the carboxyl terminus. Th pentapeptide, Leu-enkephalin, is an opioid peptide that modulates the perception of pain. The reverse pentapeptide, Leu-Phe-Gly-Gly-Tyr (LFGGY), is a different molecule and has no such effects.

A polypeptide chain consists of a regularly repeating part, called the **main chain** (or **backbone**), and a variable part, comprising the distinctive side chains (**Figure 2.14**). The polypeptide backbone is rich in hydrogen-bonding potential. Each residue contains a carbonyl group (C=O), which is a good hydrogen-bond acceptor, and, with the exception of proline, an NH group, which is a good hydrogen-bond donor. These groups interact with each other and with functional groups from side chains to stabilize particular structures, as we will discuss shortly.

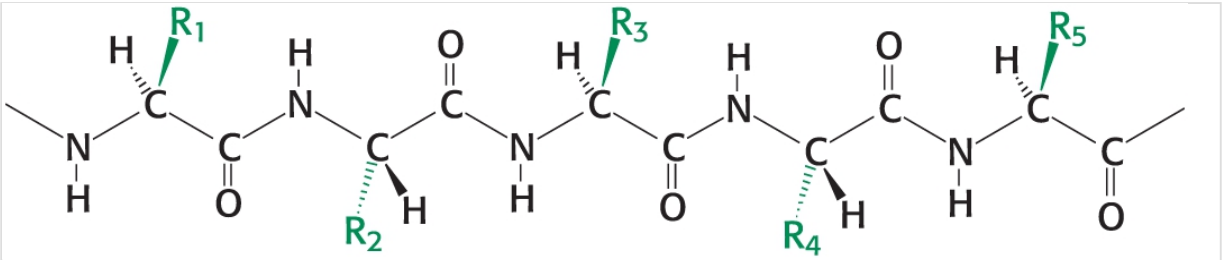

FIGURE 2.14 A polypeptide chain consists of a constant backbone and variable side chains. The side chains are shown in green.

Most natural polypeptide chains contain between 50 and 2000 amino acid residues and are commonly referred to as **proteins**. The largest single polypeptide known is the muscle protein titin, which consists of more than 27,000 amino acids. Polypeptide chains made of small numbers of amino acids are called **oligopeptides** (or, simply, **peptides**). The mean molecular weight of an amino acid residue is about $110\ \text{g mol}^{-1}$, and so the molecular weights of most proteins are between 5500 and $220{,}000\ \text{g mol}^{-1}$. We can also refer to the *molecular mass*, or the weight of a single molecule, of a protein in units of **daltons**; one dalton is equal to one atomic mass unit. A protein with a molecular weight of $50{,}000\ \text{g mol}^{-1}$ has a molecular mass of 50,000 daltons, or 50 kDa (kilodaltons).

In some proteins, the linear polypeptide chain is cross-linked. The most common cross-links are **disulfide bonds**, formed by the oxidation of a pair of cysteine residues (Figure 2.15). The resulting unit of two linked cysteines is called *cystine*. Extracellular proteins often have several disulfide bonds, whereas intracellular proteins usually lack them. Rarely, nondisulfide cross-links derived from other side chains are present in proteins. For example, collagen fibers in connective tissue are strengthened in this way, as are fibrin blood clots.

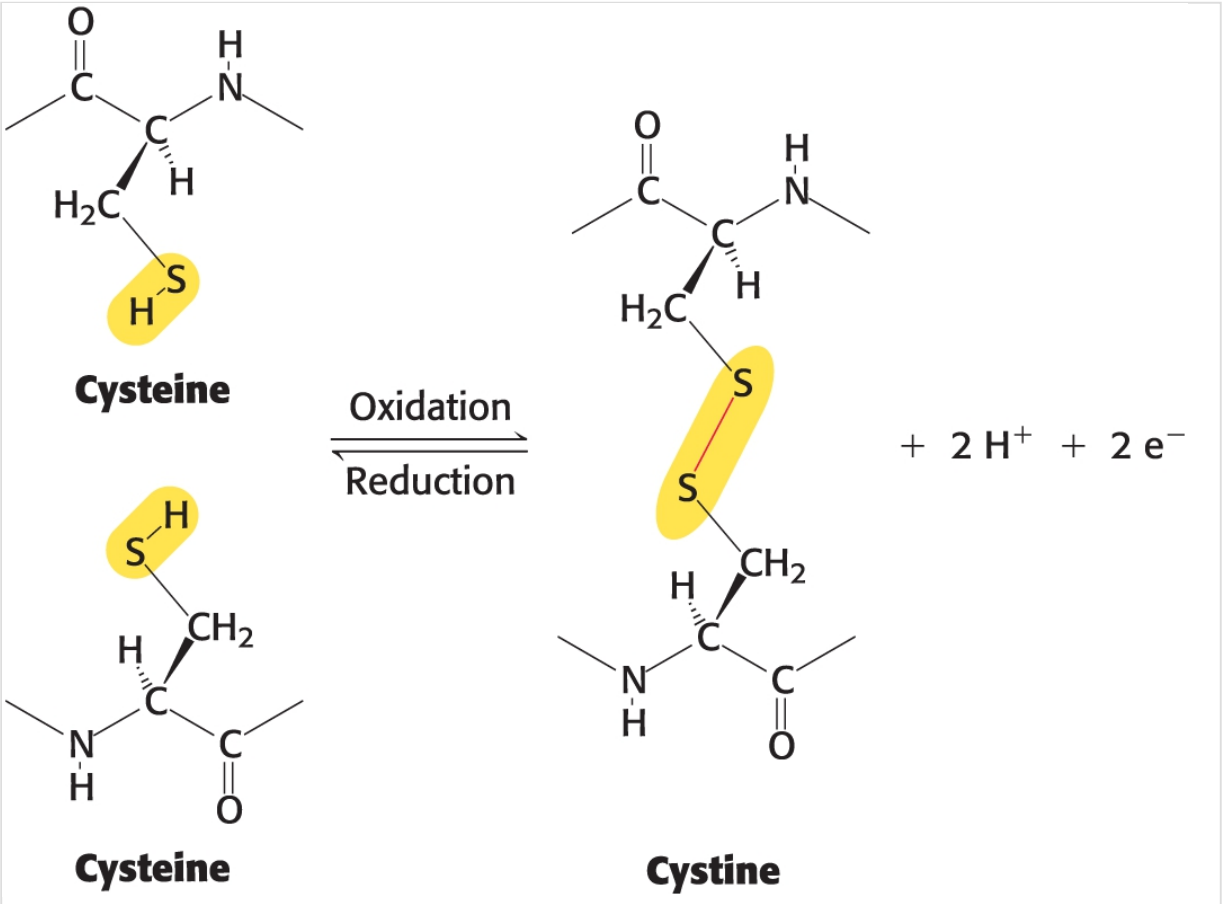

FIGURE 2.15 The formation of a disulfide bond from two cysteine residues is an oxidation reaction.

Proteins have unique amino acid sequences specified by genes

In 1953, Frederick Sanger determined the amino acid sequence of insulin, a protein hormone (**Figure 2.16**). This work is a landmark in biochemistry because it showed for the first time that a protein has a precisely defined amino acid sequence consisting only of L amino acids linked by peptide bonds. This accomplishment inspired other scientists to carry out sequence studies of a variety of proteins. Currently, the complete amino acid sequences of millions of proteins are known. The amino acid sequence of a protein is referred to as its **primary structure**.

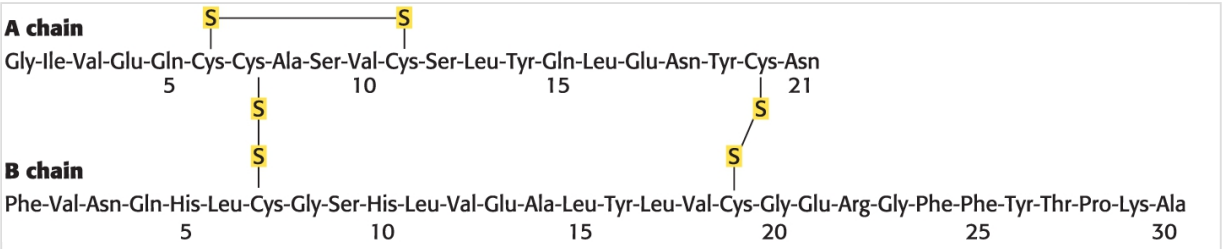

FIGURE 2.16 The primary structure of bovine insulin is its amino acid sequence. The cross links between the polypeptide chains, formed by disulfide bonds, are also shown.

A series of incisive studies in the late 1950s and early 1960s revealed that the amino acid sequences of proteins are determined by the nucleotide sequences of genes. The sequence of nucleotides in DNA specifies a complementary sequence of nucleotides in RNA, which in turn specifies the amino acid sequence of a protein. In particular, each of the 20 amino acids of the repertoire is encoded by one or more specific sequences of three nucleotides (Section 8.6).

Knowing amino acid sequences is important for several reasons:

- *Knowledge of the sequence of a protein is usually essential to elucidating its function (e.g., the catalytic mechanism of an enzyme)*. In fact, proteins with novel properties can be generated by varying the sequence of known proteins.

- *Amino acid sequences determine the three-dimensional structures of proteins*. The amino acid sequence is the link between the genetic message in DNA and the three-dimensional structure that performs a protein's biological function. Analyses of the relationships between amino acid sequences and three-dimensional structures of proteins are uncovering the rules that govern the folding of polypeptide chains.

- *Alterations in amino acid sequence can lead to abnormal protein function and disease*. Severe and sometimes fatal diseases, such as sickle-cell anemia and cystic fibrosis, can result from a change in a single amino acid within a protein.

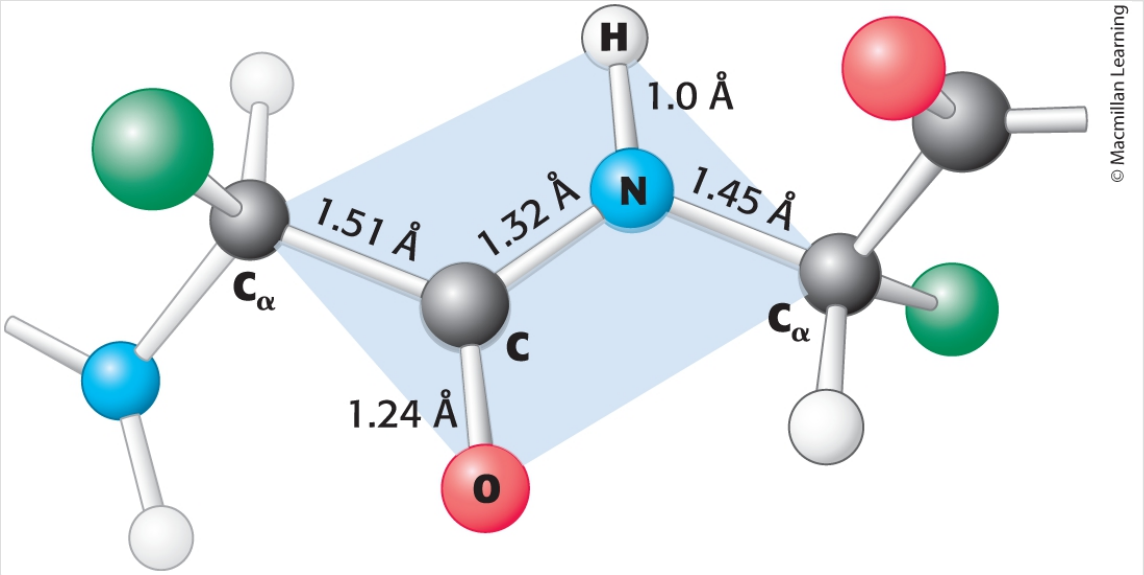
- *The sequence of a protein reveals much about its evolutionary history*. Proteins resemble one another in amino acid sequence only if they have a common ancestor. Consequently, molecular events in evolution can be traced from amino acid sequences; molecular paleontology is a flourishing area of research.

Polypeptide chains are flexible yet conformationally restricted

Examination of the geometry of the protein backbone reveals several important features:

- *The peptide bond is essentially planar* (**Figure 2.17**). Thus, for a pair of amino acids linked by a peptide bond, six atoms lie in the same plane: the α-carbon atom and CO group of the first amino acid and

the NH group and α-carbon atom of the second amino acid. The nature of the chemical bonding within a peptide accounts for the bond's planarity.



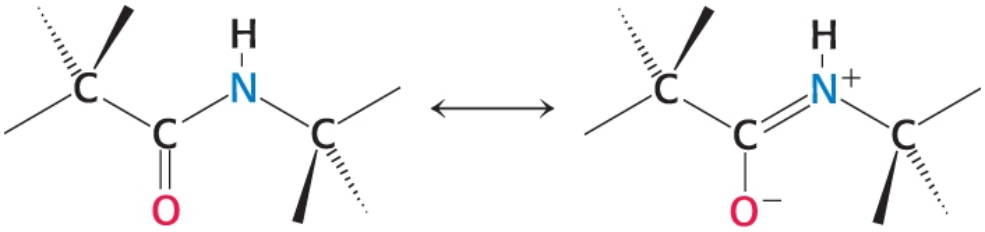


FIGURE 2.17 Peptide bonds are planar and have partial double-bond character. In a pair of linked amino acids, six atoms (C_α, C, O, N, H, and C_α) lie in a plane. Side chains are shown as green balls. The length of the peptide bond (1.32 Å) is between the expected values for a single bond and a double bond.

- *The peptide bond resonates between a single bond and a double bond.* Because of this partial double-bond character, rotation about this bond is prevented, and conformation of the peptide backbone is constrained.

Peptide-bond resonance structures

The partial double-bond character is also expressed in the length of the bond between the CO and the NH groups. As shown in Figure 2.17, the $C-N$ distance in a peptide bond is typically $1.32\ \text{Å}$, which is between the values expected for a $C-N$ single bond ($1.49\ \text{Å}$) and a $C=N$ double bond ($1.27\ \text{Å}$). Finally, the peptide bond is uncharged, allowing polymers of amino acids linked by peptide bonds to form tightly packed globular structures.

- *Almost all peptide bonds have a trans configuration*. In the trans configuration, the two α-carbon atoms are on opposite sides of the peptide bond. In the cis configuration, these groups are on the same side of the peptide bond. The preference for trans over cis can be explained by *steric repulsion*, the fact that two atoms will strongly oppose being brought together closer than their van der Waals contact distance (Section 1.3). Steric repulsion between groups attached to the α-carbon atoms hinders the formation of the cis configuration but does not arise in the trans configuration (**Figure 2.18**). By far the most common cis peptide bonds are found between proline and its preceding amino acid. Because the nitrogen of proline is bonded to two tetrahedral carbon atoms, the steric differences between the trans and cis forms are minimal, and both forms occur (**Figure 2.19**).

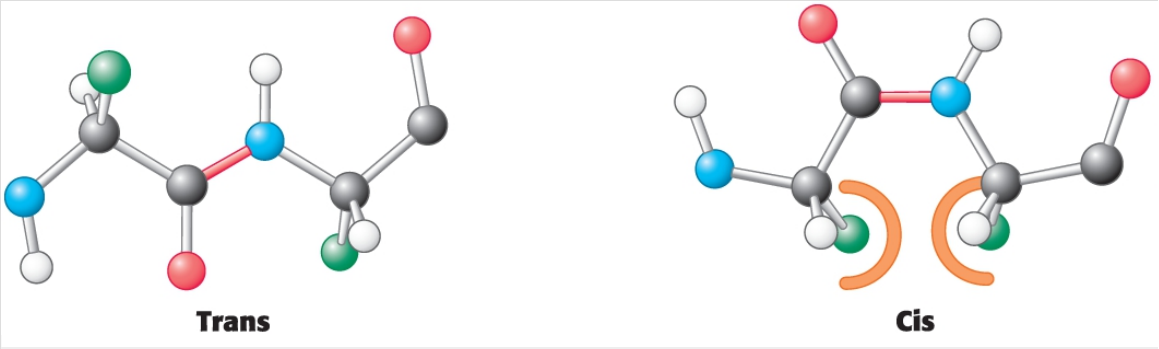

FIGURE 2.18 For most amino acids, the trans configuration of the peptide bond is strongly favored because of steric clashes that arise in the cis isomer. Steric clashes are indicated by orange semicircles. The exception to this rule is found in the next figure.

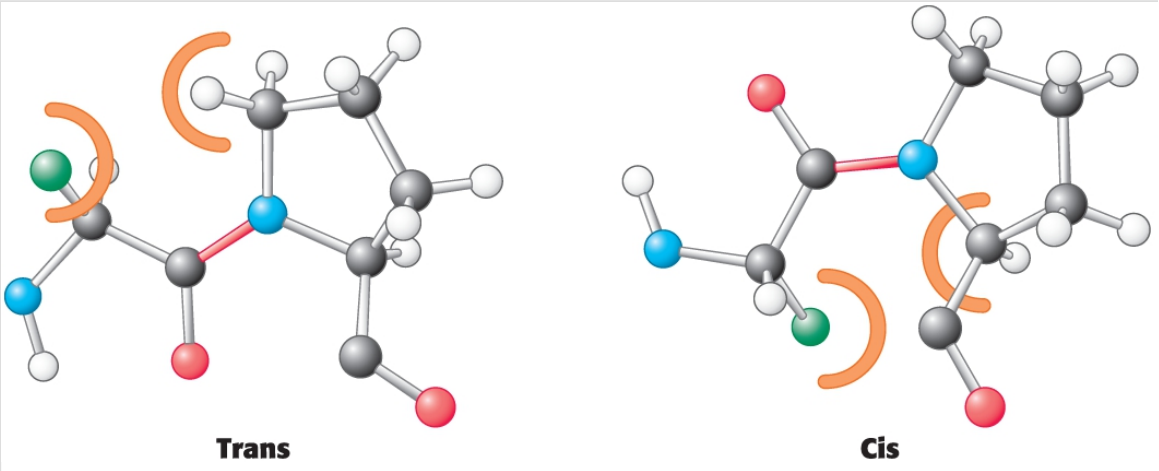

FIGURE 2.19 For peptide bonds between proline and its preceding residue, cis bonds are as likely as trans bonds. Neither configuration is favored because steric clashes exist for both the cis and trans forms.

- *The main chain bonds connected to the α carbon have rotational flexibility*. In contrast with the peptide bond, the bonds between the amino group and the α-carbon atom and between the α-carbon atom and the carbonyl group are pure single bonds. The two

adjacent rigid peptide units can rotate about these bonds, taking on various orientations. The freedom of rotation about these two bonds of each amino acid allows proteins to fold in many different conformations.

The rotations about these bonds can be specified by **torsion angles**, or **dihedral angles** (Figure 2.20). The angle of rotation about the bond between the nitrogen and the α-carbon atoms is called *phi* (ϕ). The angle of rotation about the bond between the α-carbon and the carbonyl carbon atoms is called *psi* (ψ). A clockwise rotation about either bond as viewed from the nitrogen atom toward the α-carbon atom or from the α-carbon atom toward the carbonyl group corresponds to a positive value. The ϕ and ψ angles determine the path of the polypeptide chain.

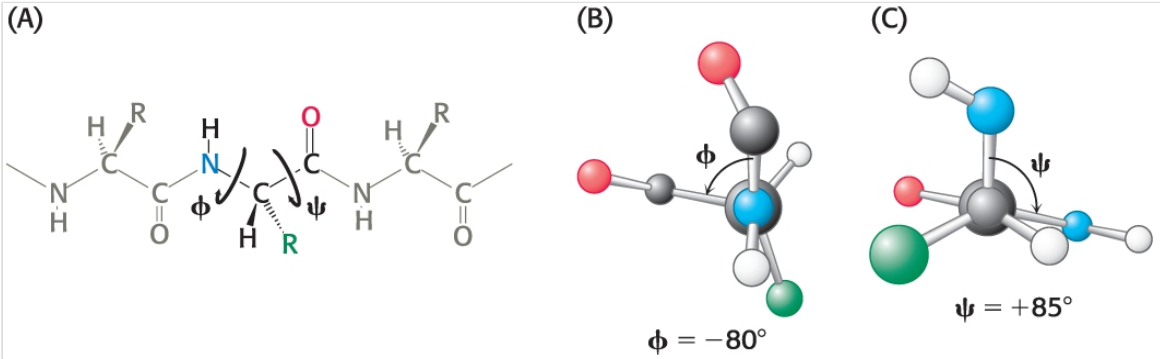

FIGURE 2.20 The structure of each amino acid in a polypeptide adjusts by rotation about two single bonds. (A) Phi (ϕ) is the angle of rotation about the bond between the nitrogen and the α carbon atoms, whereas psi (ψ) is the angle of rotation about the bond between the α-carbon ar the carbonyl carbon atoms. (B) A view down the bond between the nitrogen and the α-carbon atoms shows how φ is measured. (C) A view down the bond between the α-carbon and the carbonyl carbon atoms shows how ψ is measured.

Despite their rotational flexibility, not all values of ϕ and ψ are possible. In 1963, Gopalasamudram Ramachandran demonstrated that many combinations of ϕ and ψ are forbidden because of steric collisions between atoms. The allowed values can be visualized on a two-

dimensional plot called a **Ramachandran plot** (**Figure 2.21**). Three-quarters of the possible (ϕ, ψ) combinations are excluded simply by local steric clashes. Steric exclusion, the fact that two atoms cannot be in the same place at the same time, can be a powerful organizing principle.

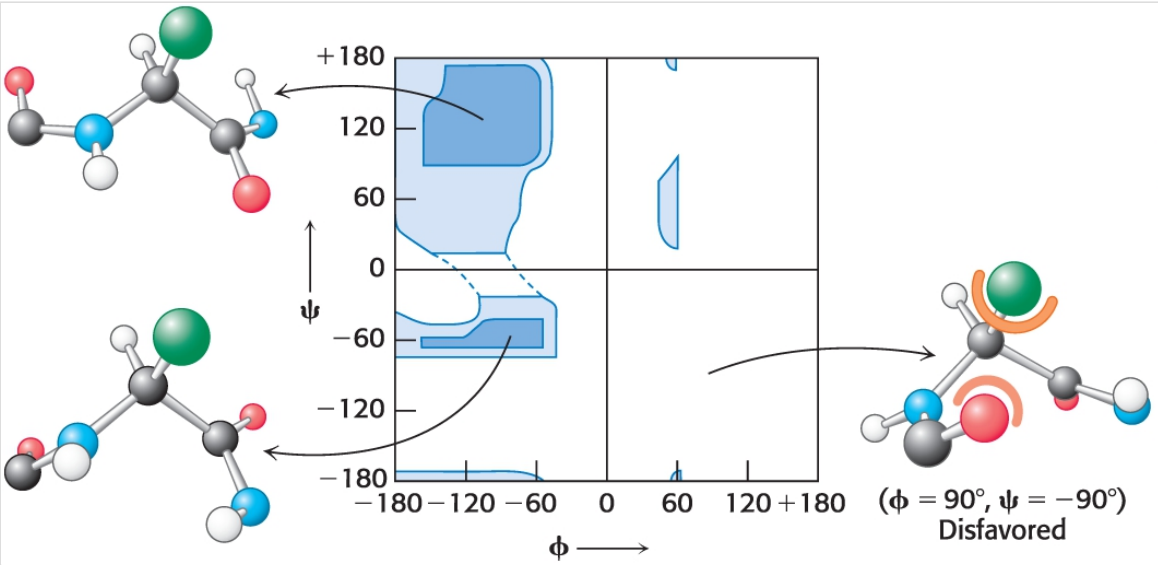

FIGURE 2.21 A Ramachandran plot shows that not all ϕ and ψ values are possible without collisions between atoms. The most favorable regions are shown in dark blue; borderline regions are shown in light blue. The structure on the right is disfavored because of steric clashes

The ability of biological polymers such as proteins to fold into well-defined structures is remarkable thermodynamically. An unfolded polymer exists as a random coil: each copy of an unfolded polymer will have a different conformation, yielding a mixture of many possible conformations. The favorable entropy associated with a mixture of many conformations opposes folding and must be overcome by interactions favoring the folded form. Thus, highly flexible polymers with a large number of possible conformations do not fold into unique structures. The rigidity of the peptide unit and the restricted set of

allowed ϕ and ψ angles limits the number of structures accessible to the unfolded form sufficiently to allow protein folding to take place.

Self-Check Question

Ramachandran plots of 18 amino acids exhibit allowed regions similar to those shown in Figure 2.21. However, the plots for two amino acids exhibit strikingly different patterns. Which two, and why?

2.4 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures

Ramachandran demonstrated that many conformations of a polypeptide backbone are disallowed on the basis of steric exclusion. Do the allowed conformations permit a polypeptide chain to fold into a regularly repeating structure? In 1951, Linus Pauling, Robert Corey, and Herman Branson defined two periodic structures, the α helix (alpha helix) and the β pleated sheet (beta pleated sheet). Subsequently, other structures such as the β turn and loop were identified. Although not periodic, these common turn or loop structures are well-defined and contribute with α helices and β sheets to form the final protein structure. Alpha helices, β strands, and turns are formed by a regular pattern of hydrogen bonds between the peptide $N-H$ and $C=O$ groups of amino acids that are near one another in the linear sequence. Such folded segments are called **secondary structure**.

The alpha helix is a coiled structure stabilized by intrachain hydrogen bonds

In evaluating potential structures, Pauling, Corey, and Branson considered which conformations of peptides were sterically allowed and which most fully exploited the hydrogen-bonding capacity of the backbone NH and CO groups. The first of their proposed structures, the **α helix**, is a rodlike structure (Figure 2.22). A tightly coiled backbone forms the inner part of the rod and the side chains extend outward in a helical array.

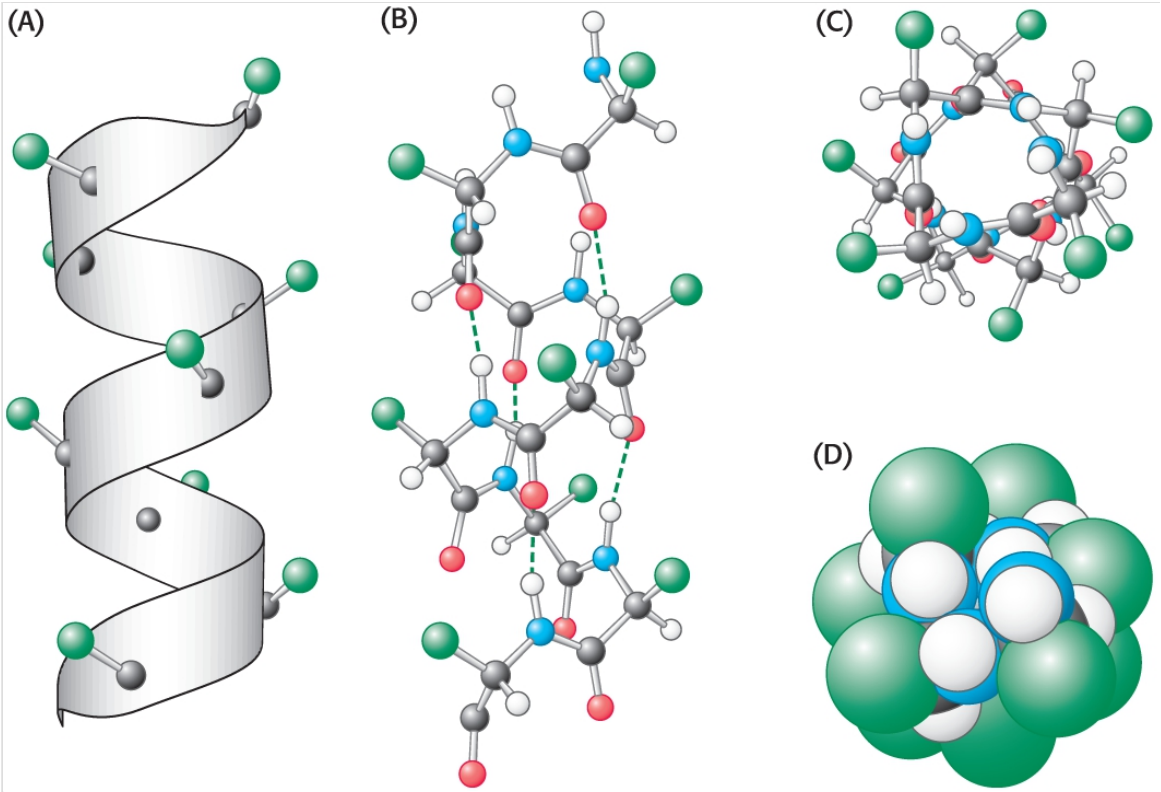

FIGURE 2.22 Various depictions of an α helix reveal several of its key features. (A) A ribbon depiction shows the α-carbon atoms and side chains (green). (B) A side view of a ball-and-stick version depicts the hydrogen bonds (dashed lines) between NH and CO groups. (C) An end view shows the coiled backbone as the inside of the helix and the side chains (green) projecting outward. (D) A space-filling view of part C shows the tightly packed interior core of the helix.

HERMAN BRANSON While Pauling and Corey often receive the most recognition for the discovery of the α helix, a third scientist, Herman Branson, also made key contributions to the discovery and was a coauthor on the seminal paper. Dr. Branson, a physics professor at Howard University who was a visiting scientist in Linus Pauling's lab at the California Institute of Technology in 1948, performed computational analysis using Pauling's x-ray measurements to narrow the possible structures down to the α helix and a looser structure called the gamma helix.

Following this work, his scientific career continued for two more decades, after which he served as the president at two historically Black universities, Central State University from 1968 to 1970, and Lincoln University from 1970 to 1985.

The α helix is stabilized by hydrogen bonds between the NH and CO groups of the main chain. In particular, the CO group of each amino acid forms a hydrogen bond with the NH group of the amino acid that is situated four residues ahead in the sequence (Figure 2.23). Thus, except for amino acids near the ends of an α helix, all the main-chain CO and NH groups are hydrogen bonded.

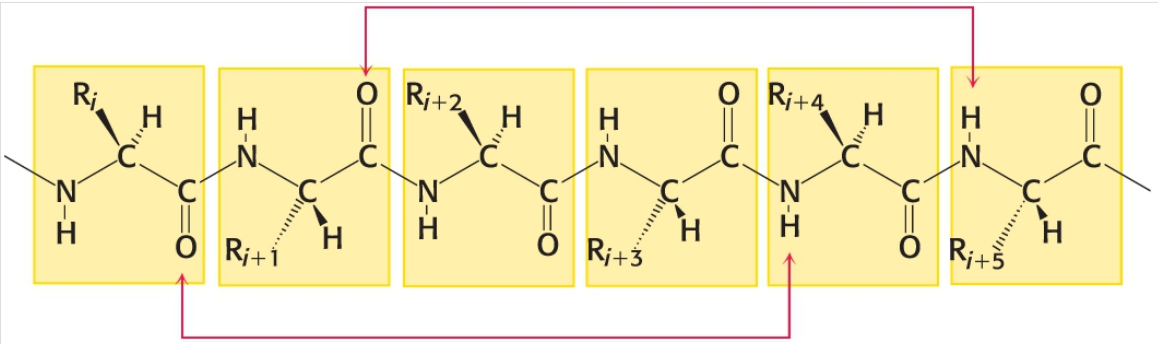

FIGURE 2.23 In an α helix, hydrogen bonds form between the CO group of residue *i* and the N group of residue $i + 4$.

Each residue in an α helix is related to the next one by a *rise* (or *translation*) of $1.5\ \text{Å}$ along the helix axis and a rotation of 100 degrees; this gives 3.6 amino acid residues per turn of the helix. Therefore, amino acids spaced three and four apart in the sequence are spatially quite close to one another in an α helix. In contrast, amino acids spaced two apart in the sequence are situated on opposite sides of the helix and so are unlikely to make contact. The *pitch* of the α helix is the length of one complete turn along the helix axis and is equal to the product of the rise ($1.5\ \text{Å}$) and the number of residues per turn (3.6), or $5.4\ \text{Å}$.

The direction of rotation about the axis of an α helix (called *screw sense*) can be right-handed (clockwise) or left-handed (counterclockwise). While the Ramachandran plot reveals that both the right-handed and the left-handed helices are among allowed conformations (Figure 2.24), essentially all α helices found in proteins are right-handed. Right-handed helices are energetically more favorable because there is less steric clash between the side chains and the backbone. In schematic representations of proteins, α helices are depicted as twisted ribbons or rods (Figure 2.25).

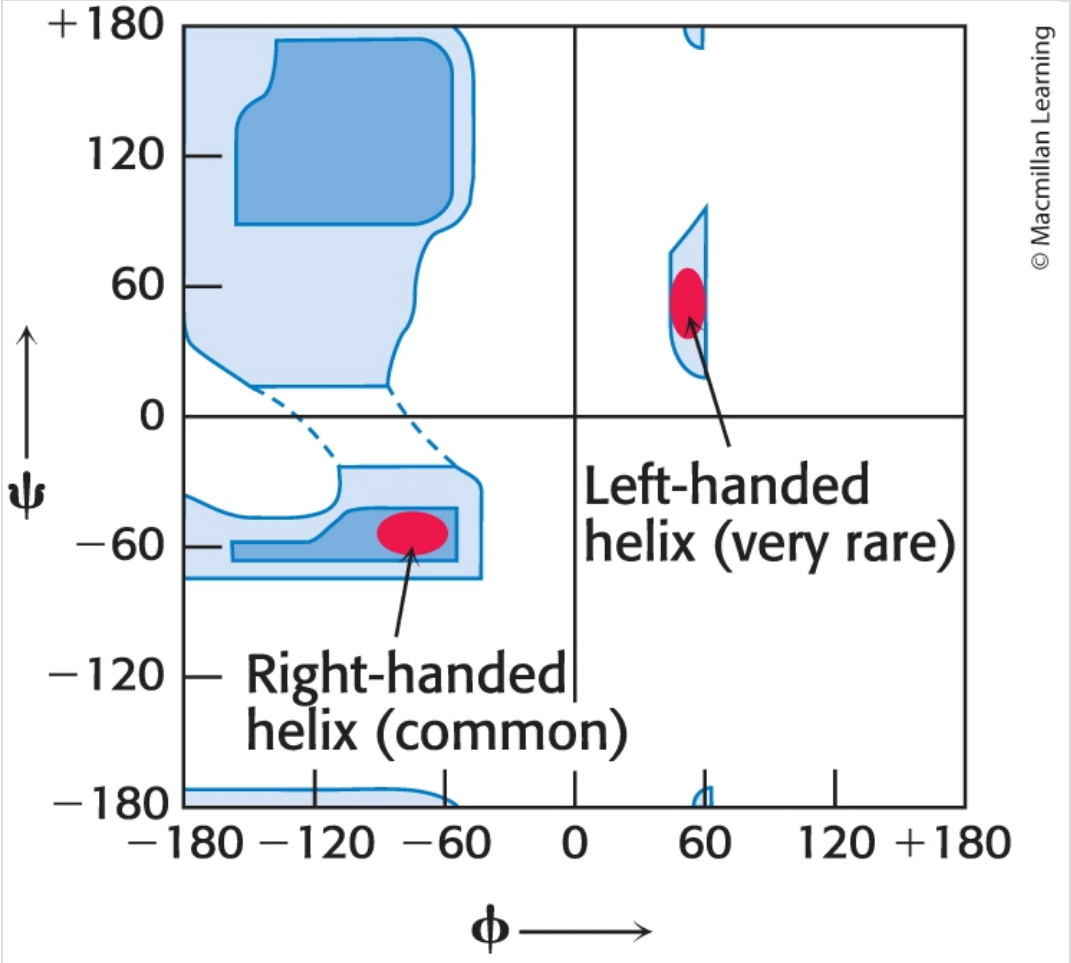

FIGURE 2.24 Both right- and left-handed helices lie in regions of allowed conformations in the Ramachandran plot. However, essentially all α helices in proteins are right-handed.

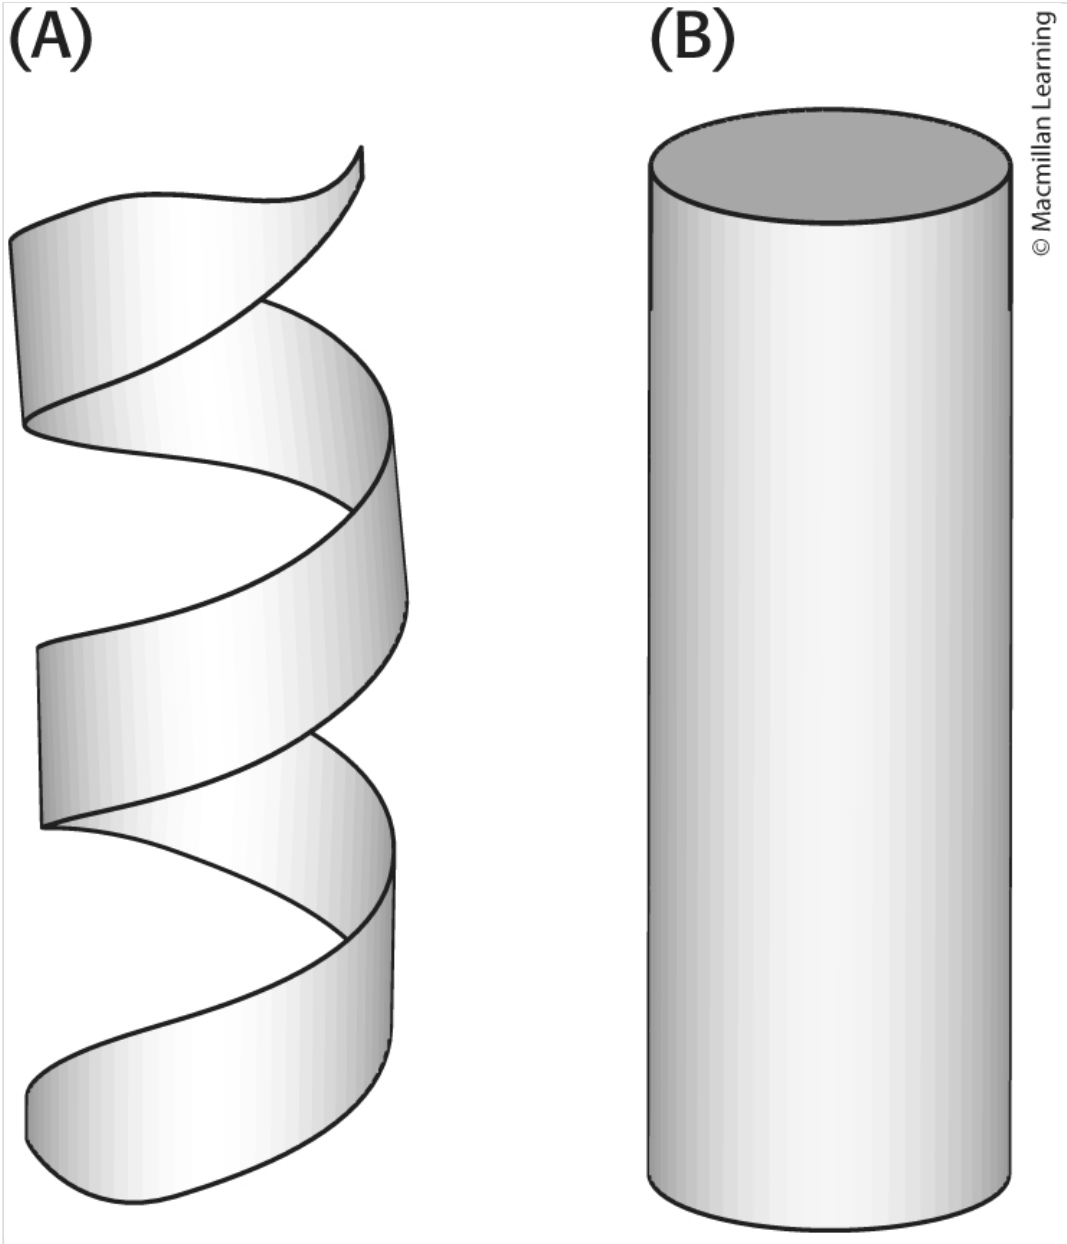

FIGURE 2.25 There are two common ways to draw α helices. (A) A ribbon depiction. (B) A cylindrical (rod) depiction.

Not all amino acids can be readily accommodated in an α helix. Branching at the β-carbon atom — the side chain carbon atom bonded to the α carbon — as in valine, threonine, and isoleucine, tends to destabilize α helices because of steric clashes. Serine, aspartate, and asparagine also tend to disrupt α helices because their side chains contain hydrogen-bond donors or acceptors in close proximity to the main chain, where they compete for main-chain NH and CO groups. Proline also is a helix breaker because it lacks an NH group and because its ring structure prevents it from assuming the Φ value to fit into an α helix.

The α-helical content of proteins ranges widely, from none to almost 100%. For example, about 75% of the residues in ferritin, a protein that helps store iron, are in α helices (Figure 2.26). Indeed, about 25% of all soluble proteins are composed of α helices connected by loops and turns of the polypeptide chain. Single α helices are usually less than 45 Å long. Many proteins that span biological membranes also contain α helices.

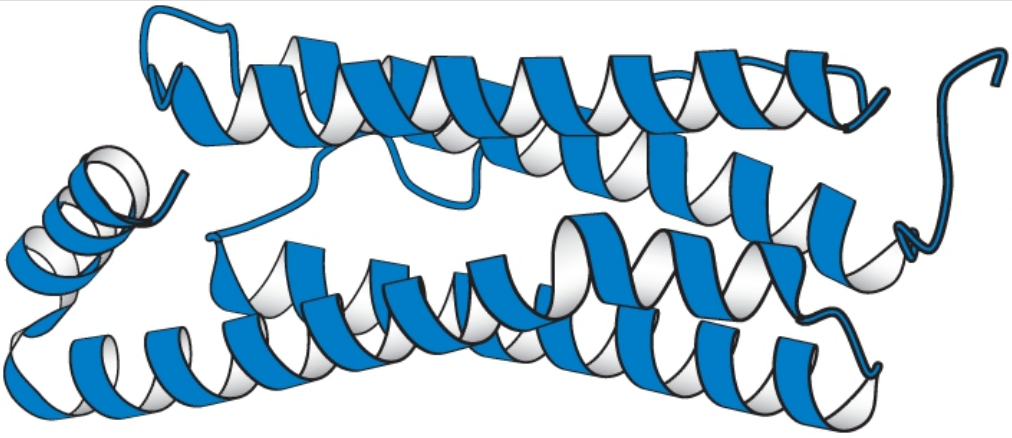

FIGURE 2.26 Ferritin, an iron-storage protein, is composed largely of α helices.

INTERACT with this model in Achieve

Beta sheets are stabilized by hydrogen bonding between polypeptide strands

Pauling and Corey proposed another periodic structural motif, which they named the **β pleated sheet** (β because it was the second structure they elucidated, the α helix having been the first). The β pleated sheet (or, more simply, the β sheet) differs markedly from the rodlike α helix. It is composed of two or more polypeptide chains called **β strands**. A β strand is almost fully extended rather than being tightly coiled as in the α helix. A range of extended structures are sterically allowed (Figure 2.27).

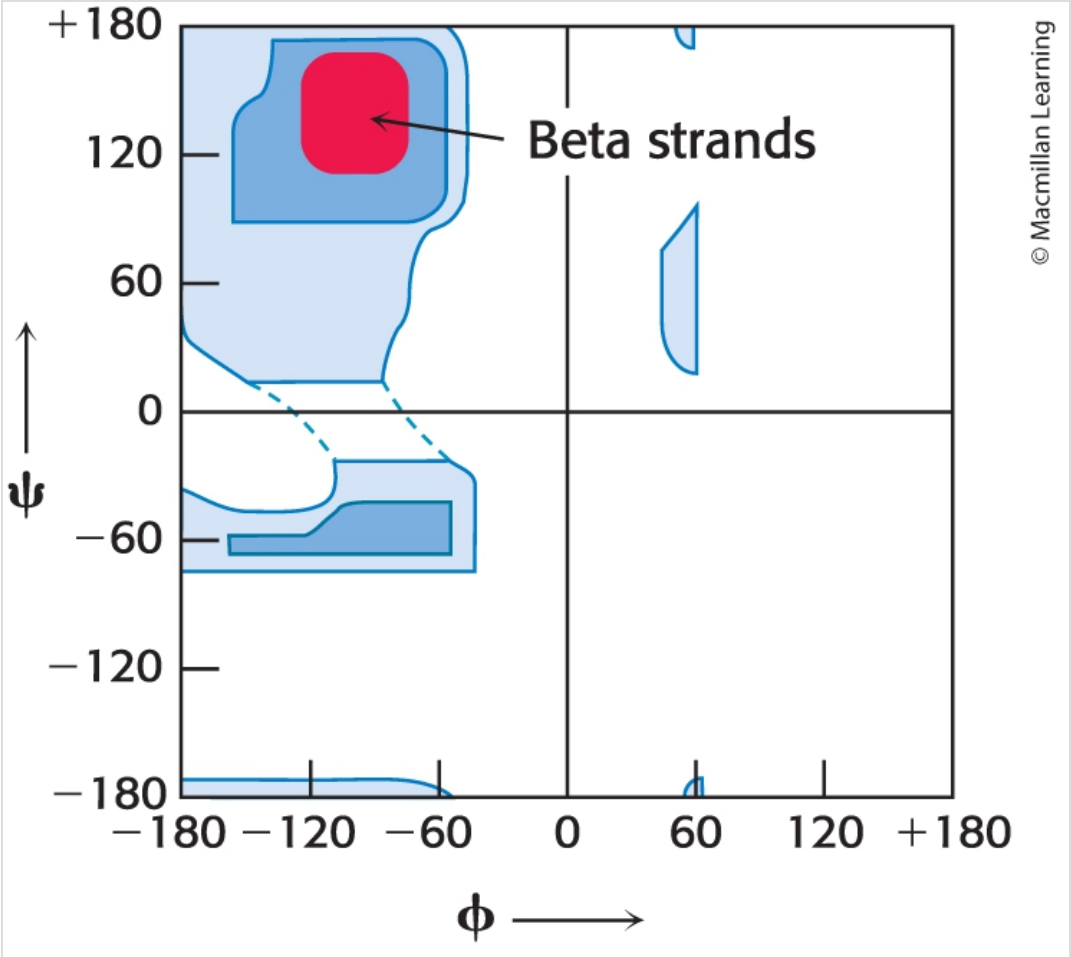

FIGURE 2.27 β strands occupy an allowed region of the Ramachandran plot.

The distance between adjacent amino acids along a β strand is approximately 3.5 Å, in contrast with a distance of 1.5 Å along an α helix. The side chains of adjacent amino acids point in opposite directions (Figure 2.28). A β sheet is formed by linking two or more β strands lying next to one another through hydrogen bonds. Adjacent strands in a β sheet can run in opposite directions (antiparallel β sheet) or in the same direction (parallel β sheet). In the antiparallel arrangement, the NH group and the CO group of each amino acid are respectively hydrogen bonded to the CO group and the NH group of a partner on the adjacent chain (Figure 2.29). In the parallel arrangement, the hydrogen-bonding scheme is slightly more complicated. For each amino acid, the NH group is hydrogen bonded to the CO group of one amino acid on the adjacent strand, whereas the CO group is hydrogen bonded to the NH group on the amino acid two residues farther along the chain (Figure 2.30). Many strands, typically 4 or 5 but as many as 10 or more, can come together in β sheets. Such β sheets can be purely antiparallel, purely parallel, or mixed (Figure 2.31).

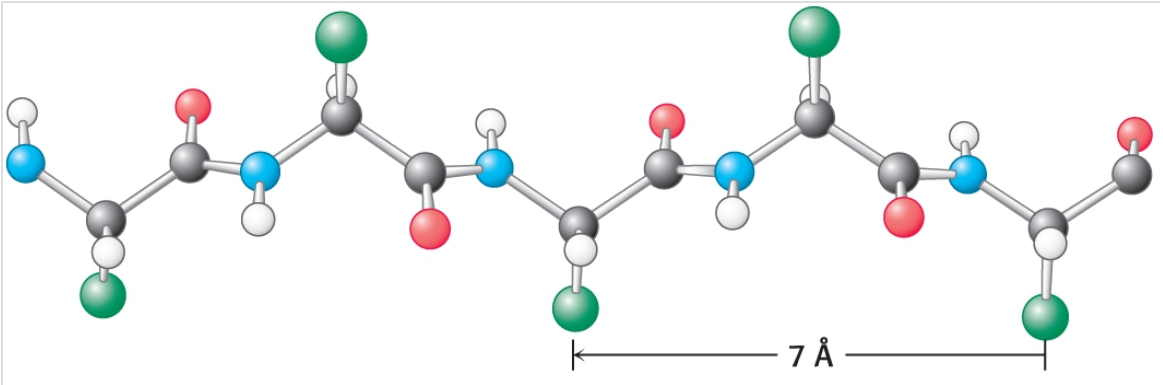

FIGURE 2.28 The side chains of a β strand project alternately above and below the plane of tl strand. In this extended conformation, the side chains (shown in green) on the same face of the strand are positioned about 7 Å apart.

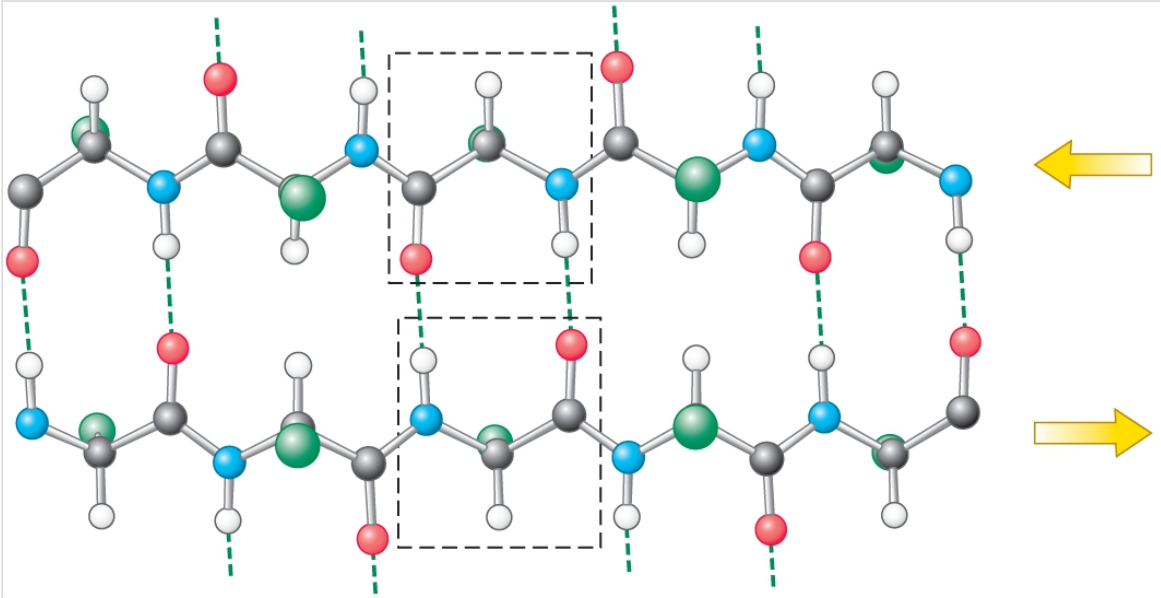

FIGURE 2.29 In an antiparallel β sheet, adjacent β strands run in opposite directions. Note th hydrogen bonds between NH and CO groups connect each amino acid to a single amino acid or an adjacent strand, stabilizing the structure.

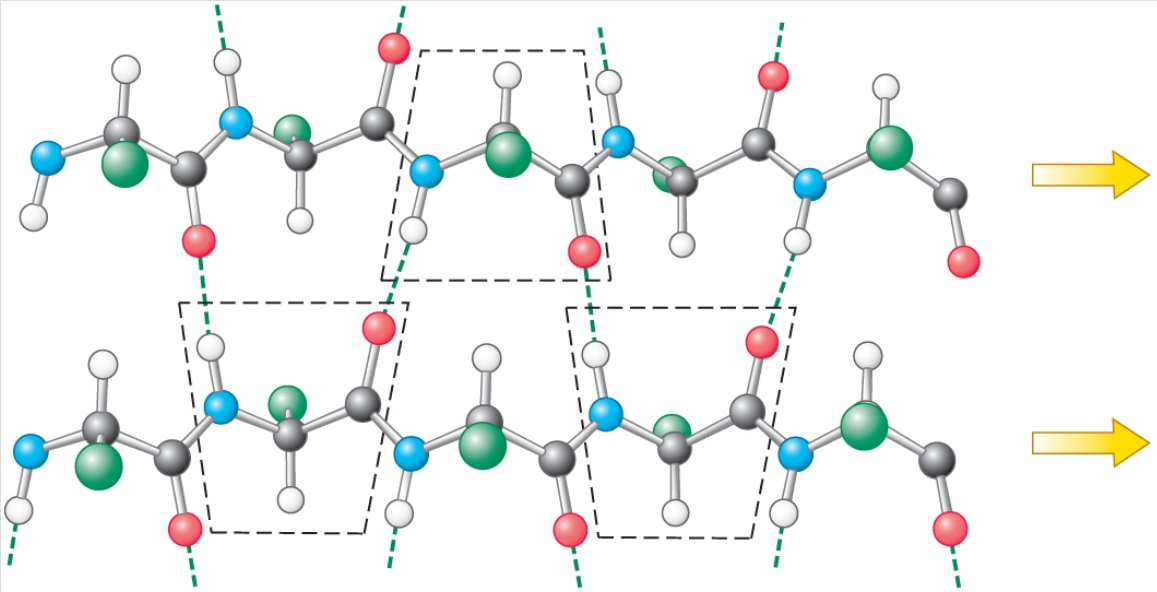

FIGURE 2.30 In a parallel β sheet, adjacent β strands run in the same direction. Note that hydrogen bonds connect each amino acid on one strand with two different amino acids on the adjacent strand.

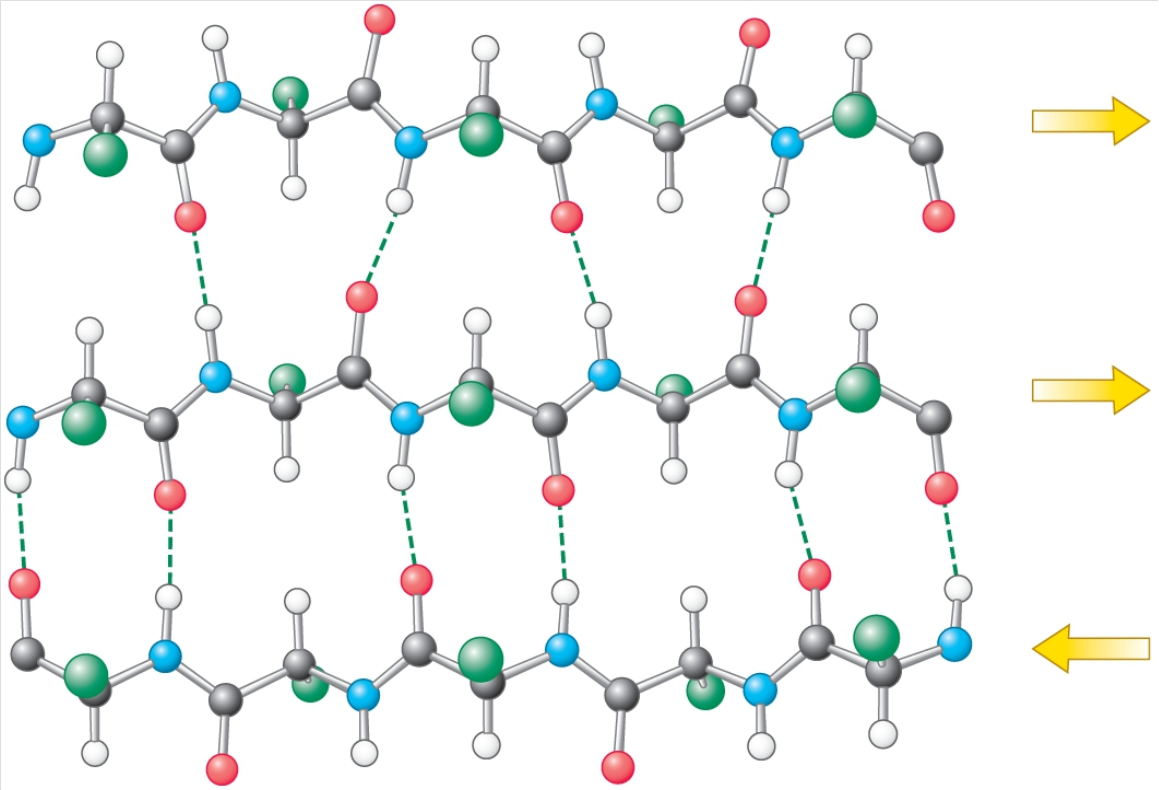

FIGURE 2.31 In a mixed β sheet, the β strands have a combination of parallel and antiparalle pairings.

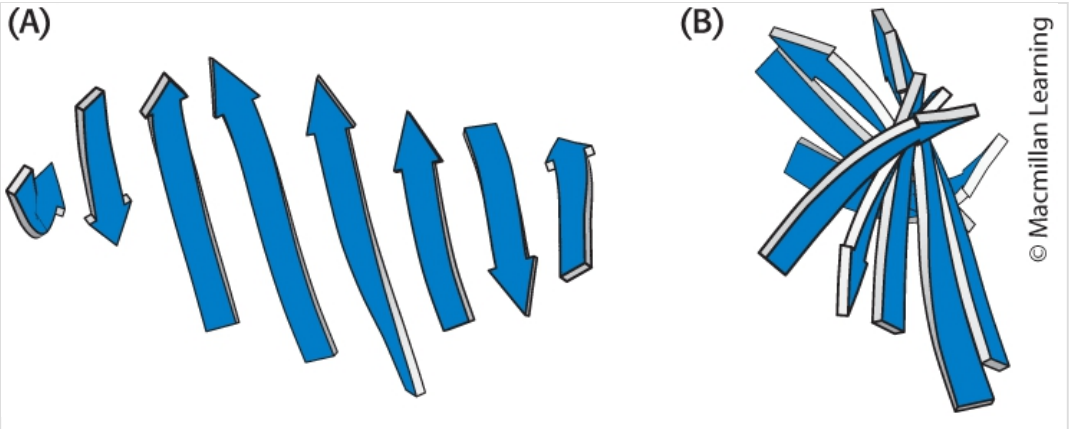
In schematic representations, β strands are usually depicted by broad arrows pointing in the direction of the carboxyl-terminal end to indicate the type of β sheet formed — parallel or antiparallel. More structurally diverse than α helices, β sheets can be almost flat, but most adopt a somewhat twisted shape (Figure 2.32). The β sheet is an important structural element in many proteins. For example, fatty acid-binding proteins, important for lipid metabolism, are built almost entirely from β sheets (Figure 2.33).



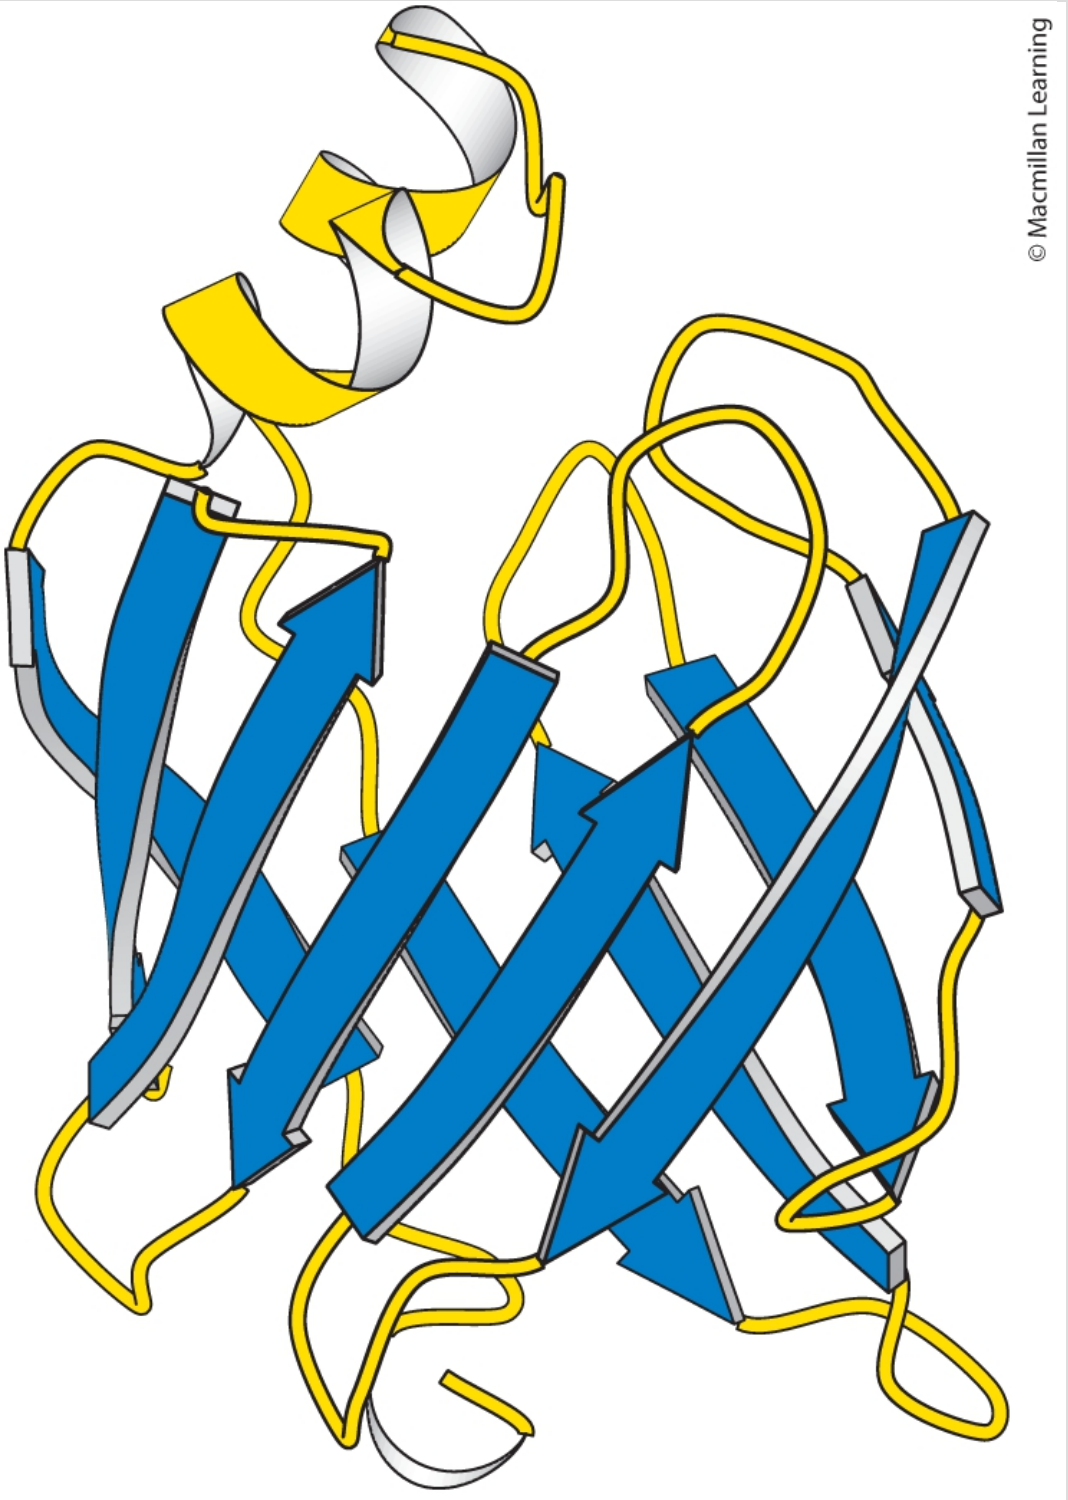


FIGURE 2.32 The twisted shape of some β sheets is more evident in a schematic depiction of β strands. (A) β strands are represented by broad arrows pointing towards their carboxy-terminal end. (B) When rotated by 90 degrees, the schematic view more clearly illustrates the twist in the β sheet.

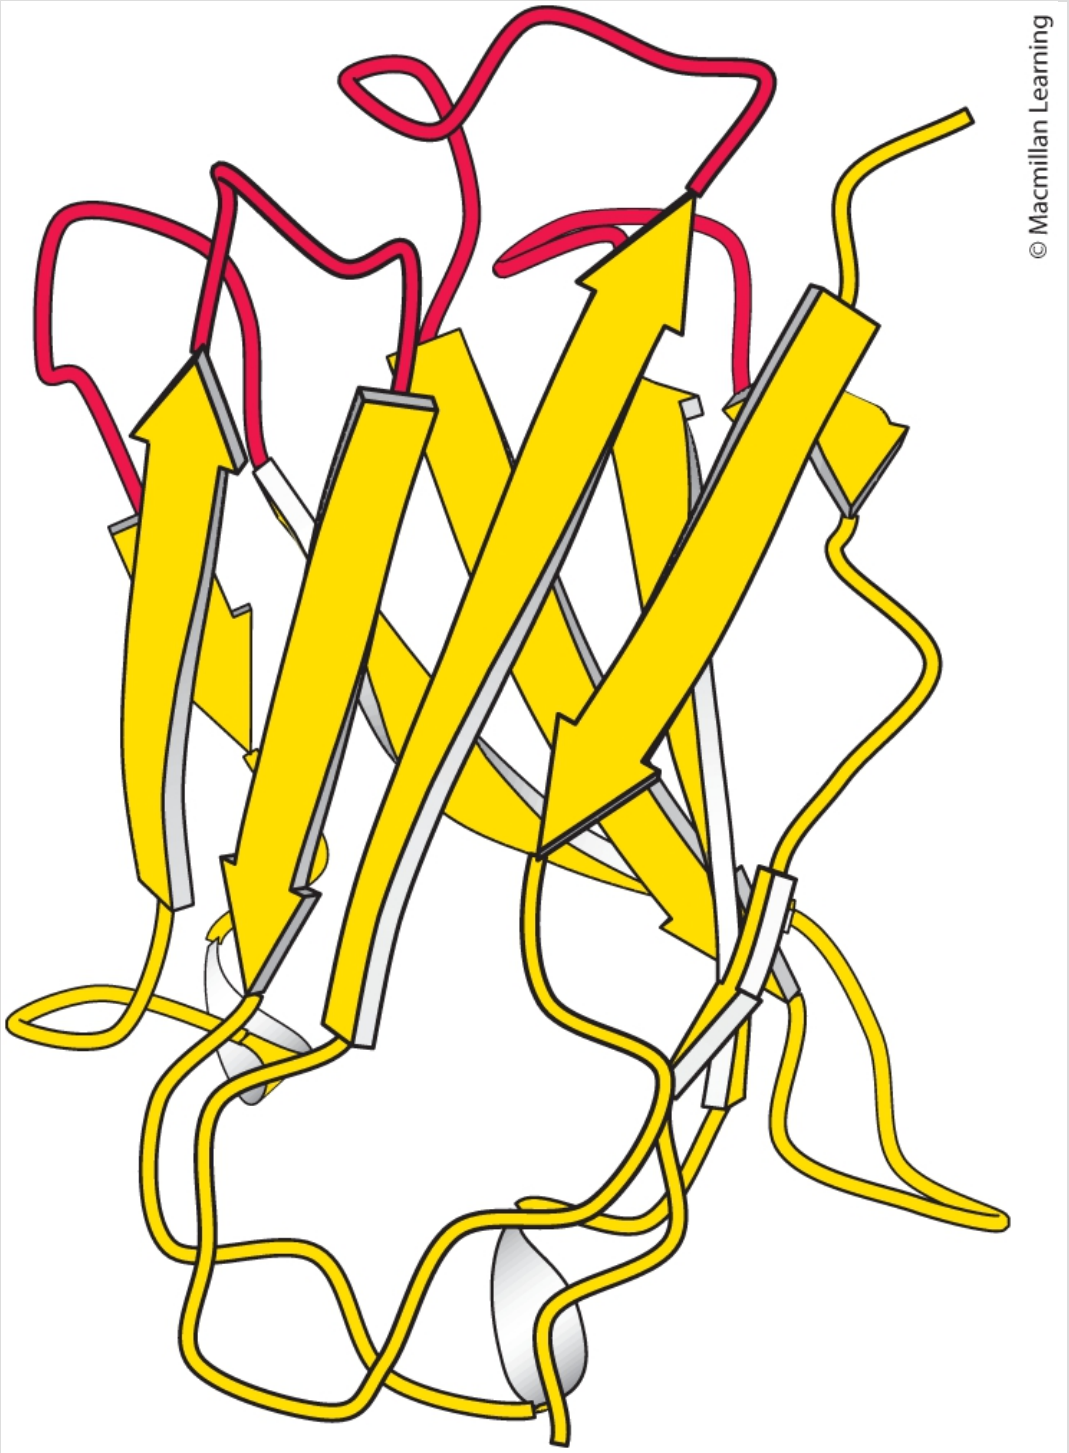
Self-Check Question

How far apart are residues that appear on the same face of an α helix? What about on a β strand?

Polypeptide chains can change direction by making reverse turns and loops



As we will explore in Section 2.5, most proteins have compact, globular shapes owing to reversals in the direction of their polypeptide chains. Many of these reversals are accomplished by a common structural element called the **reverse turn** (also known as the **β turn** or **hairpin turn**), illustrated in **Figure 2.34**. In many reverse turns, the CO group of residue *i* of a polypeptide is hydrogen bonded to the NH group of residue $i + 3$. This interaction stabilizes abrupt changes in direction of the polypeptide chain.

© Macmillan Learning

FIGURE 2.34 In a reverse turn, the CO group of residue *i* of the polypeptide chain is hydrogen bonded to the NH group of residue $i + 3$. This hydrogen bond stabilizes the turn.

In other cases, more-elaborate structures are responsible for chain reversals. These structures are called **loops**. Unlike α helices and β strands, loops do not have regular, periodic structures. Nonetheless, loop structures are often rigid and well-defined (Figure 2.35). Turns and loops invariably lie on the surfaces of proteins and often participate in interactions between proteins and other molecules.

2.5 Tertiary Structure: Proteins Can Fold into Globular or Fibrous Structures

Let us now examine how amino acids are grouped together in a complete protein. X-ray crystallographic, nuclear magnetic resonance (NMR), and cryo-electron microscopic (cryo-EM) studies (Section 4.5) have revealed the detailed three-dimensional structures of thousands of proteins. We begin here with an examination of myoglobin, the first protein to be seen in atomic detail, in work reported by John Kendrew and colleagues in 1958. Myoglobin, the oxygen storage protein in muscle, is a single polypeptide chain of 153 amino acids (Chapter 3) that forms an extremely compact molecule. Its overall dimensions are $45 \times 35 \times 25$ Å, an order of magnitude less than if it were fully stretched out (**Figure 2.36**). About 70% of the main chain is folded into eight α helices, and much of the rest of the chain forms turns and loops between helices.

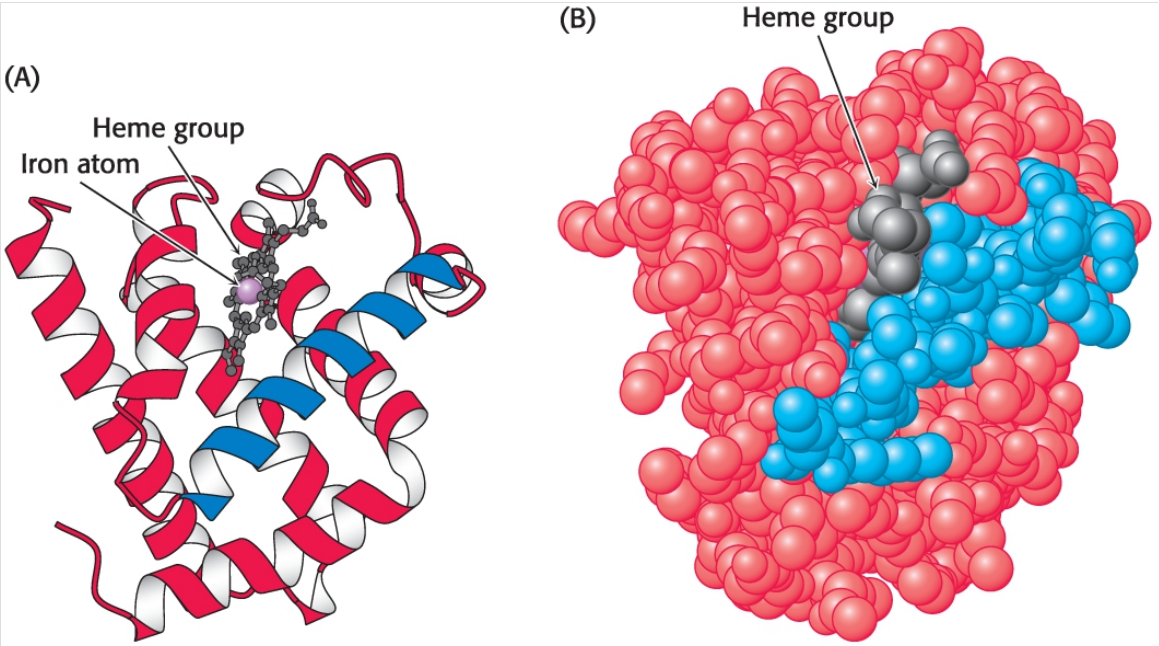

FIGURE 2.36 Myoglobin folds into a compact structure. (A) A ribbon diagram shows that the protein consists largely of α helices. (B) A space-filling model in the same orientation shows hov tightly packed the folded protein is. Notice that the heme group is nestled into a crevice in the compact protein with only an edge exposed. One helix is blue to allow comparison of the two structural depictions.

[Drawn from 1A6N.pdb.]

The folding of the main chain of myoglobin, like that of most other proteins, is complex and devoid of symmetry. The overall course of the polypeptide chain of a protein is referred to as its **tertiary structure**. A unifying principle emerges from the distribution of side chains. Strikingly, the interior consists almost entirely of nonpolar residues such as leucine, valine, methionine, and phenylalanine (Figure 2.37). Charged residues such as aspartate, glutamate, lysine, and arginine are absent from the inside of myoglobin. The only polar residues inside are two histidine residues, which play critical roles in binding iron and oxygen. The outside of myoglobin, on the other hand, consists of both polar and nonpolar residues. The space-filling model shows that there is very little empty space inside.

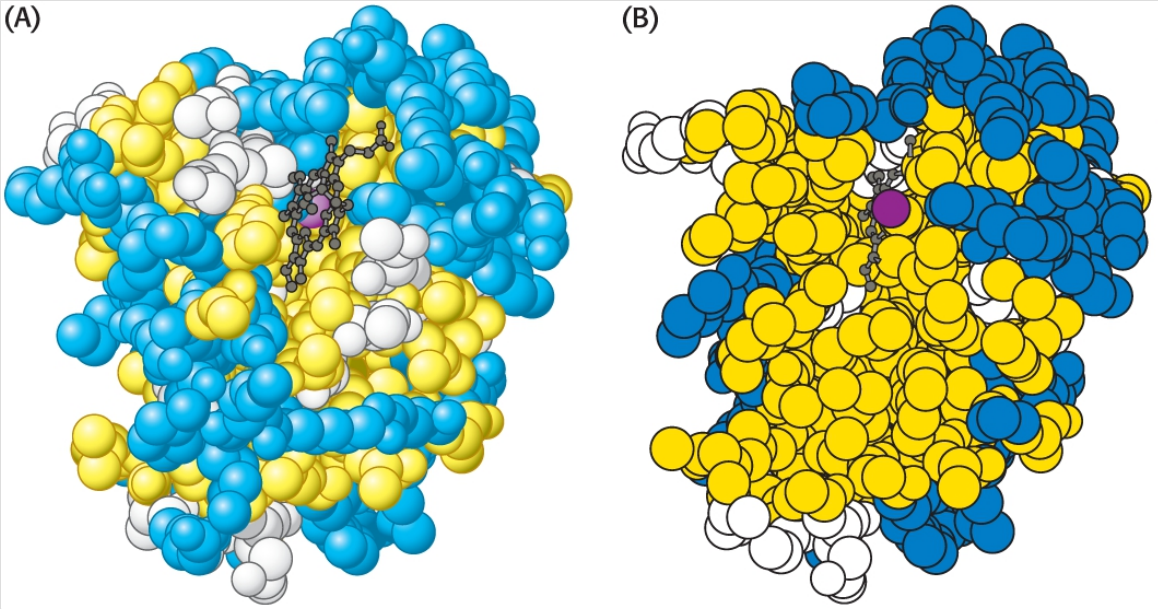

FIGURE 2.37 Hydrophobic amino acids are preferentially distributed in the interior of myoglobin. (A) A space-filling model of myoglobin with hydrophobic amino acids shown in yellow, charged amino acids shown in blue, and others shown in white. Notice that the surface of the molecule has many charged amino acids, as well as some hydrophobic amino acids. (B) In this cross-sectional view, notice that mostly hydrophobic amino acids are found on the inside of the structure, whereas the charged amino acids are found on the protein surface.

[Drawn from 1MBD.pdb.]

Globular proteins form tightly packed structures

The tight packing of myoglobin into a highly compact structure, its lack of symmetry, and its solubility in water are characteristics of **globular proteins** which perform a wide array of important functions, including regulatory, signaling, and enzymatic activities.

The contrasting distribution of polar and nonpolar residues reveals a key facet of protein architecture: in an aqueous environment, protein folding is driven by the strong tendency of hydrophobic residues to be

excluded from water. Recall that a system is more thermodynamically stable when hydrophobic groups are clustered rather than extended into the aqueous surroundings (the hydrophobic effect). The polypeptide chain therefore folds so that its hydrophobic side chains are buried and its polar, charged chains are on the surface.

Many α helices and β strands are amphipathic; that is, the α helix or β strand has a hydrophobic face, which points into the protein interior, and a more polar face, which points into solution. The fate of the main chain accompanying the hydrophobic side chains is important, too. An unpaired peptide NH or CO group markedly prefers water to a nonpolar milieu. The secret of burying a segment of main chain in a hydrophobic environment is to pair all the NH and CO groups by hydrogen bonding. This pairing is neatly accomplished in an α helix or β sheet.

Van der Waals interactions between tightly packed hydrocarbon side chains also contribute to the stability of proteins. We can now understand why the set of 20 amino acids contains several that differ subtly in size and shape. They provide a palette from which to choose to fill the interior of a protein neatly and thereby maximize van der Waals interactions, which require intimate contact.

Some proteins that span biological membranes are “the exceptions that prove the rule” because they have the reverse distribution of hydrophobic and hydrophilic amino acids. For example, consider porins — proteins found in the outer membranes of many bacteria (**Figure 2.38**). Membranes are built largely of hydrophobic chains. Thus, porins are covered on the outside largely with hydrophobic residues that interact with the neighboring alkane chains. In contrast, the center of the protein contains many charged and polar amino acids that surround a water-filled channel running through the middle of the protein. Because porins function in hydrophobic environments, they are “inside out” relative to proteins that function in aqueous solution.

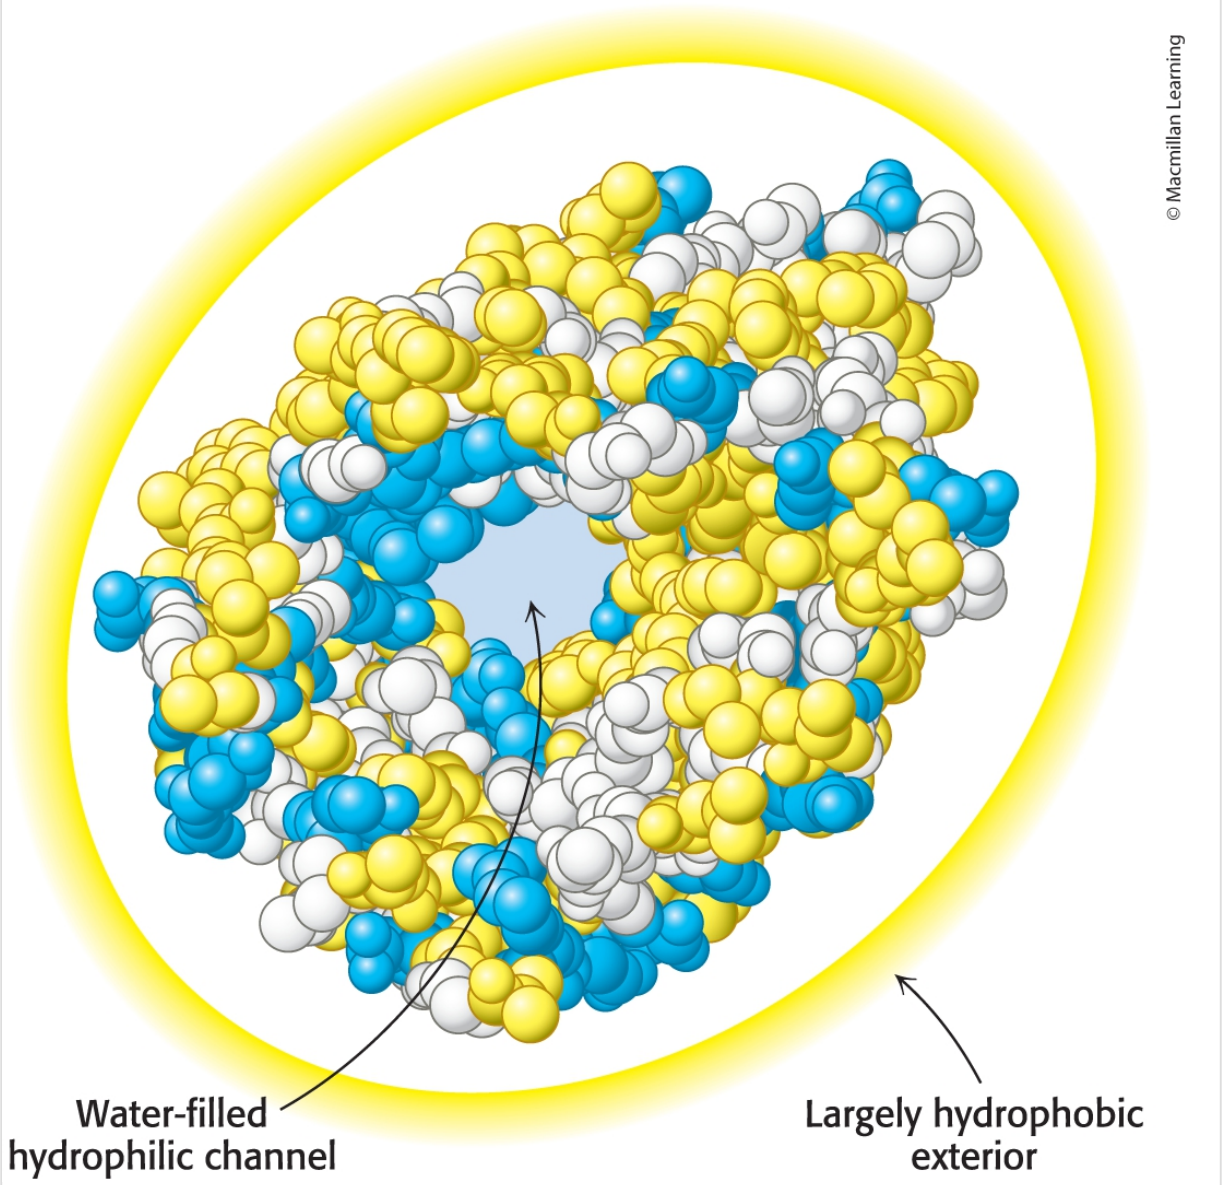

FIGURE 2.38 Porin, found in the hydrophobic environment of the membrane, exhibits an "inside out" amino acid distribution. The outside of porin (which contacts hydrophobic groups in membranes) is covered largely with hydrophobic residues, whereas the center includes a water-filled channel lined with charged and polar amino acids.

[Drawn from 1PRN.pdb.]

Certain combinations of secondary structure are present in many proteins and frequently exhibit similar functions. These combinations

are called **motifs** (or **supersecondary structures**). For example, an α helix separated from another α helix by a turn, called a *helix-turn-helix* motif, is found in many proteins that bind DNA (**Figure 2.39**).

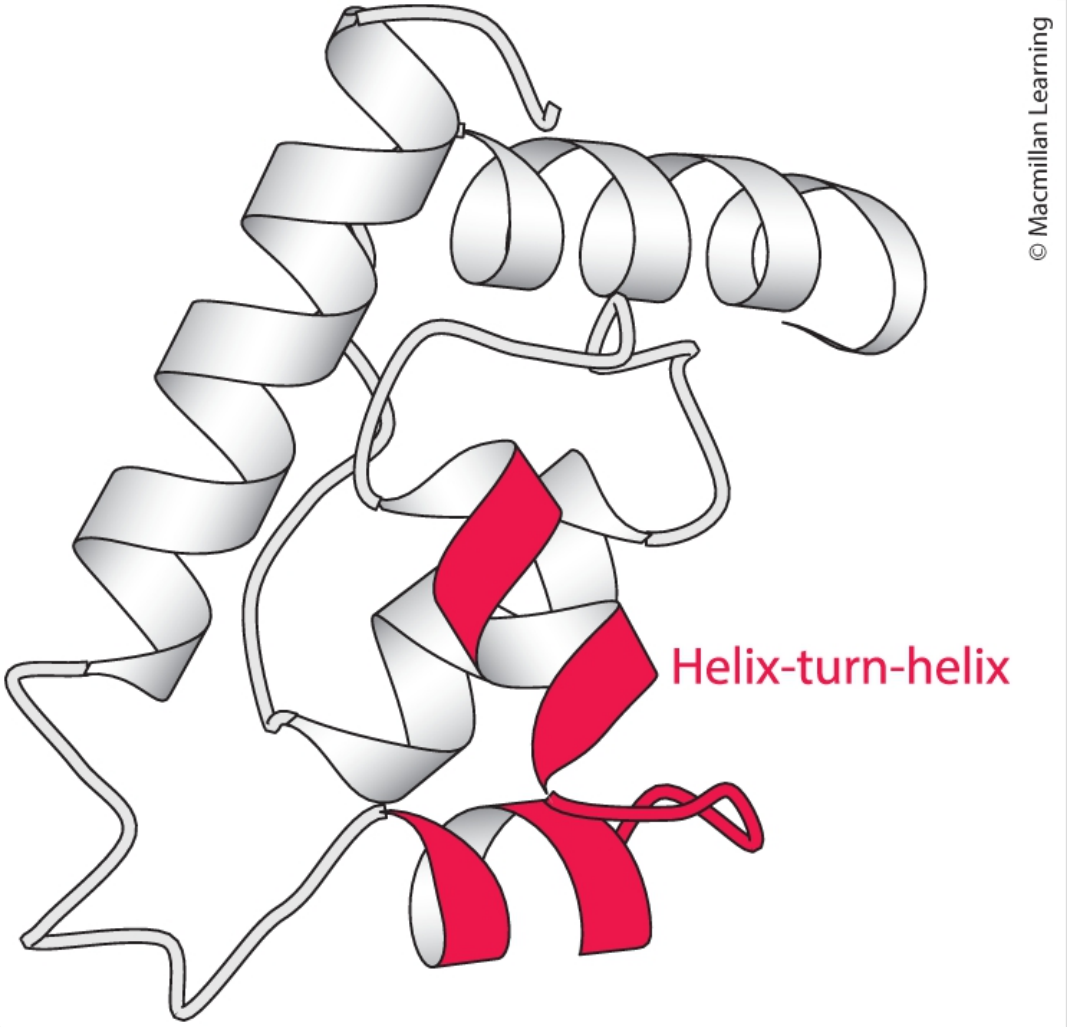

FIGURE 2.39 The helix-turn-helix motif is a supersecondary structural element found in many DNA-binding proteins.

[Drawn from 1LMB.pdb.]

Some polypeptide chains fold into two or more compact regions that may be connected by a flexible segment of polypeptide chain, rather

like pearls on a string. These compact globular units, called **domains**, range in size from about 30 to 400 amino acid residues. For example, the extracellular part of CD4, a protein on the surface of certain cells of the immune system, comprises four similar domains of approximately 100 amino acids each (**Figure 2.40**). Proteins may have domains in common even if their overall tertiary structures are different.

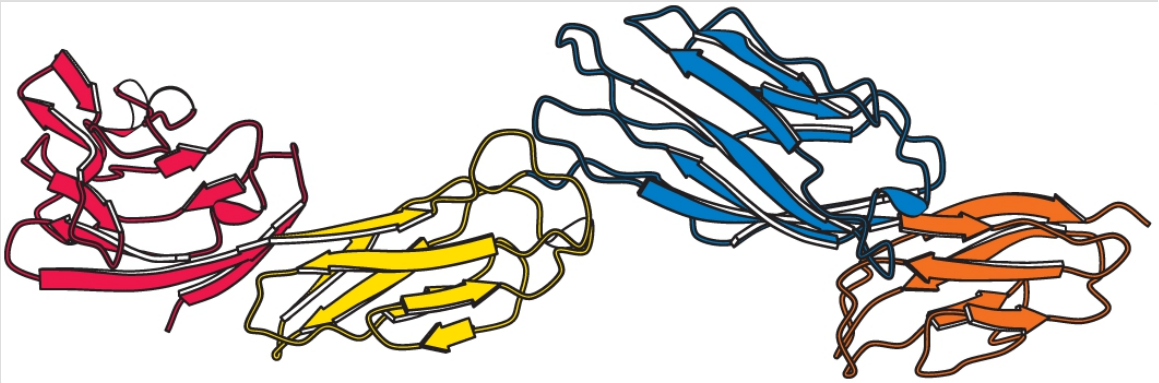

FIGURE 2.40 Domains are compact regions within proteins that are connected by flexible polypeptide segments. The cell-surface protein CD4 consists of four similar domains.

[Drawn from 1WIO.pdb.]

Self-Check Question

Proteins that span biological membranes often contain α helices. Given that the insides of membranes are highly hydrophobic, predict what type of amino acids would be in such an α helix. Why is an α helix particularly suited to existence in the hydrophobic environment of a membrane interior?

Fibrous proteins form extended structures that provide support for cells and tissues

In contrast to globular proteins, **fibrous proteins** form long, extended structures that feature repeated sequences. These proteins, such as α-keratin and collagen, use special types of helices that facilitate the formation of long fibers that serve a structural role.

α-Keratin, which is an essential component of wool, hair, and skin, consists of two right-handed α helices intertwined to form a type of left-handed superhelix called an α-*helical coiled coil*. α-Keratin is a member of a superfamily of proteins referred to as *coiled-coil proteins* (**Figure 2.41**). In these proteins, two or more α helices can entwine to form a very stable structure, which can have lengths of 1000 Å (100 nm, or 0.1 μm) or more. There are approximately 60 members of this family in humans, including intermediate filaments, proteins that contribute to the cell cytoskeleton (internal scaffolding in a cell), and the muscle proteins myosin and tropomyosin. Members of this family are characterized by a central region of 300 amino acids that contains imperfect repeats of a sequence of 7 amino acids called a *heptad repeat*.

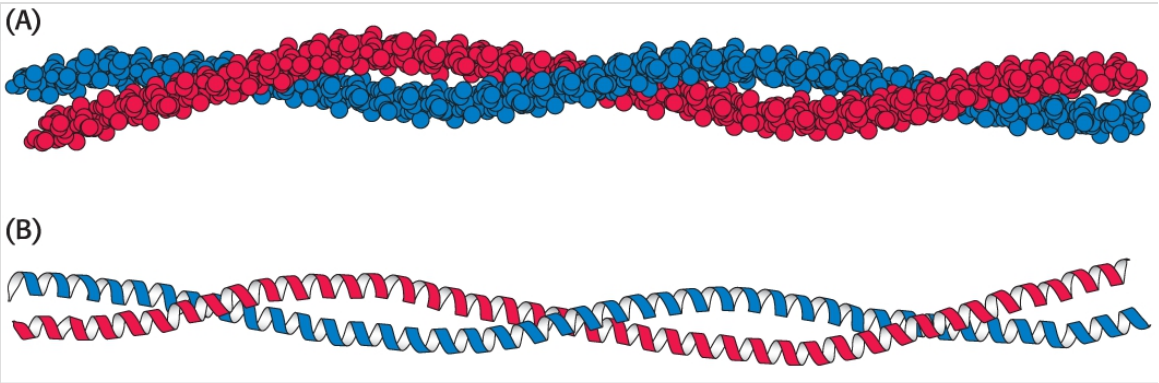

FIGURE 2.41 The α-helical coiled coil adopts an extended structure. (A) A space-filling model. (B) A ribbon diagram. The two helices wind around one another to form a superhelix. Such structures are found in many proteins, including keratin in hair, quills, claws, and horns.

[Drawn from 1C1G.pdb.]

The two helices in α-keratin associate with each other by weak interactions such as van der Waals forces and ionic interactions. The left-handed supercoil alters the two right-handed α helices such that there are 3.5 residues per turn instead of 3.6. As a result, the pattern of side-chain interactions can be repeated every seven residues, forming the heptad repeats. Two helices with such repeats are able to interact with one another if the repeats are complementary (Figure 2.42). For example, the repeating residues may be hydrophobic, allowing van der Waals interactions, or have opposite charge, allowing ionic interactions. In addition, the two helices may be linked by disulfide bonds formed by neighboring cysteine residues.

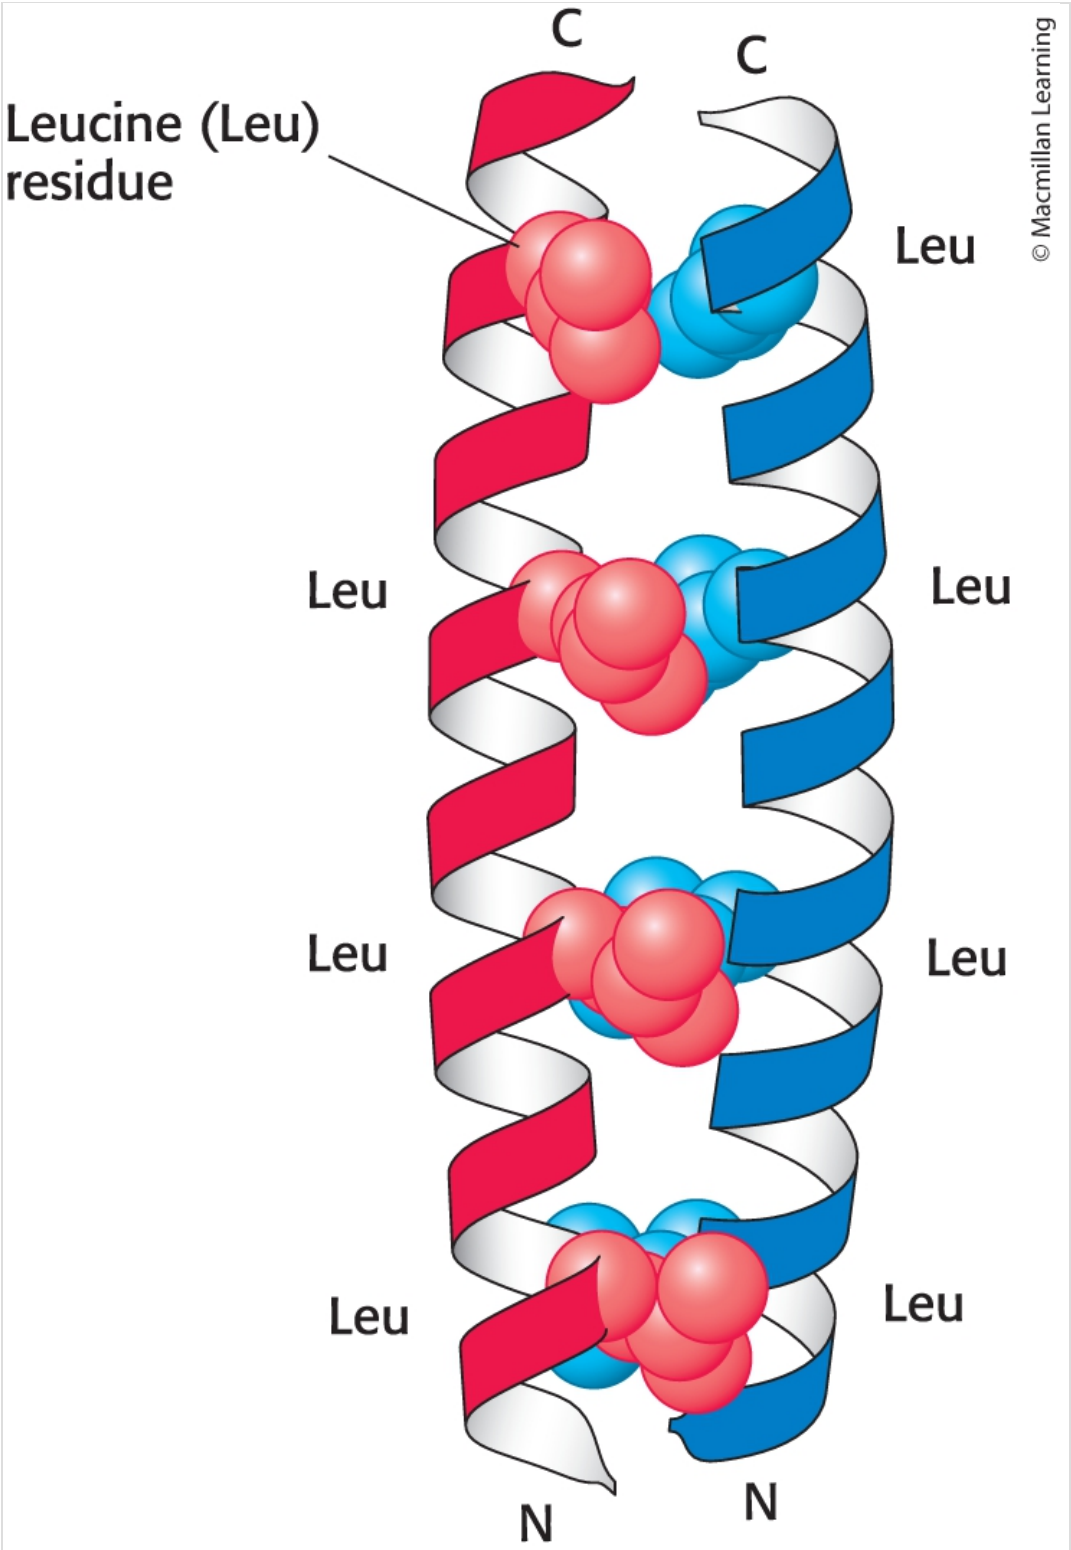

FIGURE 2.42 Heptad repeats from each helix in a coiled-coil protein interact with one another. Every seventh residue in each helix is leucine. The two helices are held together by van der Waals interactions primarily between the leucine residues.

[Drawn from 2ZTA.pdb.]

INTERACT with the models shown in Figure 2.33 and Figures 2.35–2.42 in Achieve

The bonding of the helices accounts for the physical properties of wool, an example of an α-keratin. Wool is extensible and can be stretched to nearly twice its length because the α helices stretch, breaking the weak interactions between neighboring helices. However, the covalent disulfide bonds resist breakage and return the fiber to its original state once the stretching force is released. The number of disulfide bond cross-links further defines the fiber's properties. Hair and wool, having fewer cross-links, are flexible. Horns, claws, and hooves, having more cross-links, are much harder.

A different type of helix is present in collagen, the most abundant protein of mammals. Collagen is the main fibrous component of skin, bone, tendon, cartilage, and teeth. This extracellular protein is a rod-shaped molecule, about $3000\ \text{Å}$ long and only $15\ \text{Å}$ in diameter. It contains three helical polypeptide chains, each nearly 1000 residues long. Glycine appears at every third residue in the amino acid sequence, and the sequence glycine-proline-hydroxyproline recurs frequently (**Figure 2.43**). Hydroxyproline is a derivative of proline that has a hydroxyl group in place of one of the hydrogen atoms on the pyrrolidine ring.

FIGURE 2.43 The amino acid sequence of a part of a collagen chain reveals that every third residue is a glycine. Proline and hydroxyproline (Hyp) also are abundant.

The collagen helix has properties different from those of the α helix. Hydrogen bonds within a strand are absent, and each strand adopts an extended conformation (Figure 2.44). The helix is stabilized by steric repulsion of the pyrrolidine rings of the proline and hydroxyproline residues. The pyrrolidine rings keep out of each other's way when the polypeptide chain assumes its helical form, which has about three residues per turn. Three strands wind around one another to form what is called a *superhelical cable*, a structure that is stabilized by hydrogen bonds between strands. The hydrogen bonds form between the peptide NH groups of glycine residues and the CO groups of residues on the other chains. The hydroxyl groups of hydroxyproline residues also participate in hydrogen bonding.

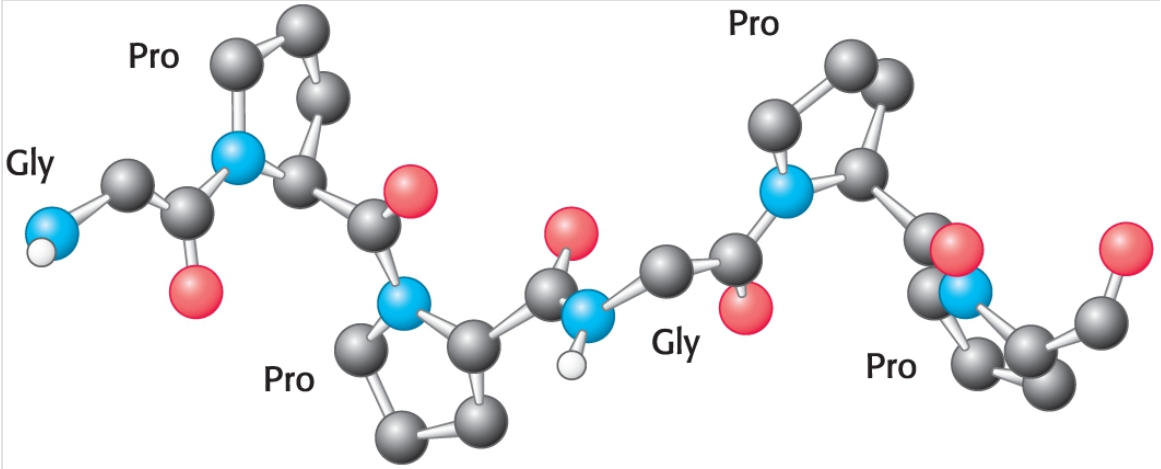

FIGURE 2.44 A single strand of a collagen triple helix adopts an extended conformation.

The inside of the triple-stranded helical cable is very crowded and accounts for the requirement that glycine be present at every third position on each strand (Figure 2.45A). The only residue that can fit in an interior position is glycine. The amino acid residue on either side of glycine is located on the outside of the cable, where there is room for the bulky rings of proline and hydroxyproline residues (Figure 2.45B).

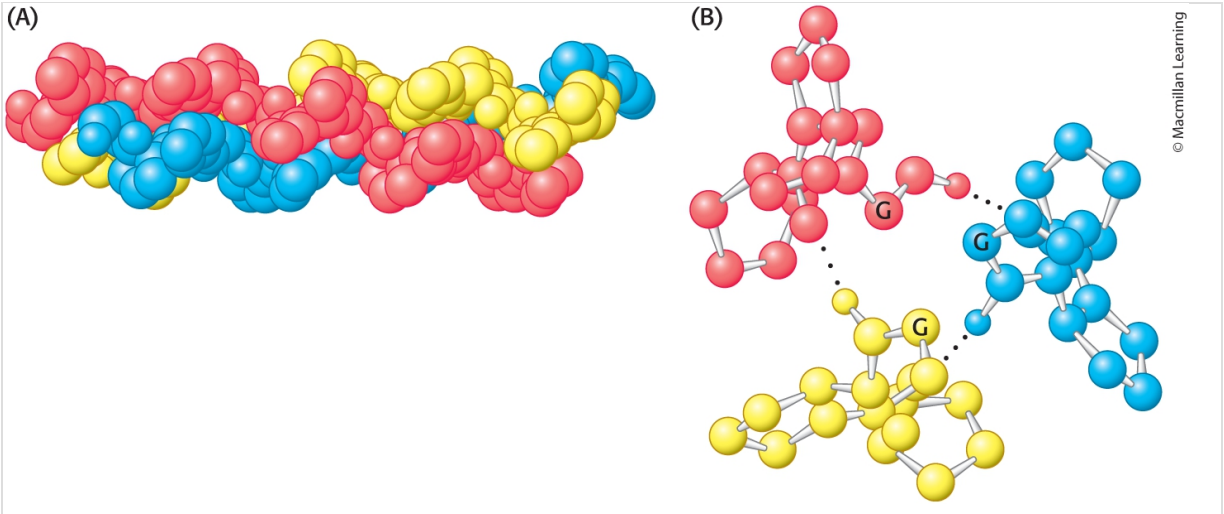

FIGURE 2.45 Glycine residues form the interior of the collagen triple helix. (A) In this space-filling model of collagen, each strand is shown in a different color. (B) In this cross section of a

model of collagen, each strand is hydrogen bonded to the other two strands. The α-carbon atom of a glycine residue is identified by the letter G. Every third residue must be glycine because there is no space in the center of the helix. Notice that the pyrrolidine rings of the proline residues are on the outside.

The importance of the positioning of glycine inside the triple helix is illustrated in the disorder osteogenesis imperfecta, also known as brittle bone disease. In this condition, which can vary from mild to very severe, other amino acids replace the internal glycine residue. This replacement leads to a delayed and improper folding of collagen. The most serious symptom is severe bone fragility. Defective collagen in the eyes causes the whites of the eyes, or *sclera*, to have a blue tint.

2.6 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures

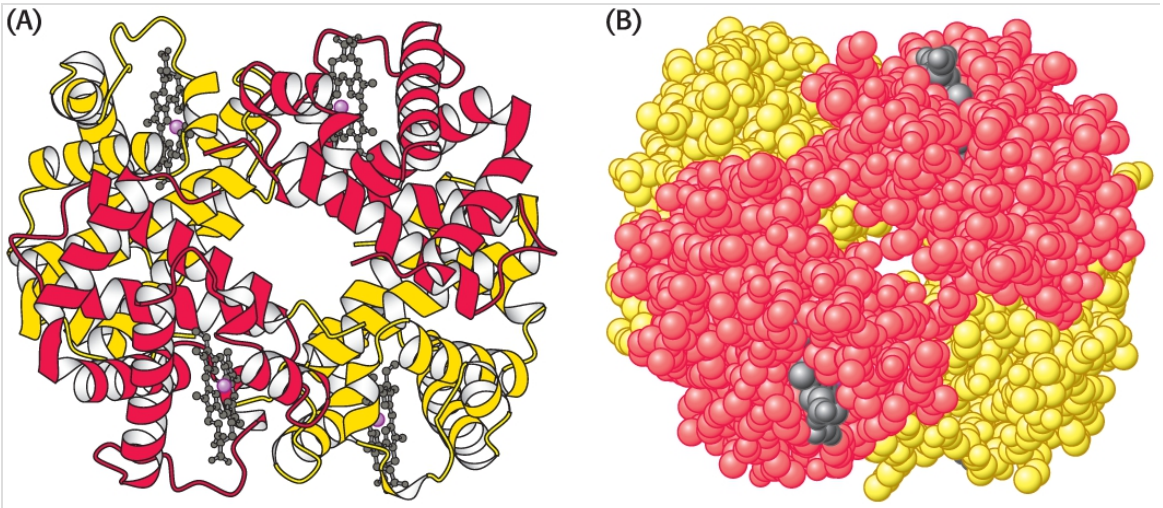
Four levels of structure are cited in discussions of protein architecture. So far, we have considered three: primary, secondary, and tertiary. We now turn to proteins containing more than one polypeptide chain. Such proteins exhibit a fourth level of structural organization. Each polypeptide chain in such a protein is called a **subunit**. The spatial arrangement of subunits and the nature of their interactions is called **quaternary structure**.

The simplest sort of quaternary structure is a **homodimer**, consisting of two identical subunits. For example, this organization is present in the DNA-binding protein Cro, found in a bacterial virus called *bacteriophage λ* (**Figure 2.46**). However, more-complicated quaternary structures are also common. More than one type of subunit can be present, often in variable numbers. For example, human hemoglobin, the oxygen-carrying protein in blood, consists of two subunits of one type (designated α) and two subunits of another type (designated β), as illustrated in **Figure 2.47**. Thus, the hemoglobin molecule exists as an $\alpha_2\beta_2$ tetramer. Subtle changes in the arrangement of subunits within the hemoglobin molecule allow it to carry oxygen from the lungs to tissues with great efficiency (Chapter 3).

FIGURE 2.46 Quaternary structure refers to the arrangement of multiple polypeptide chains. The Cro protein of bacteriophage λ adopts the simplest type of quaternary structure, a homodimer (two identical subunits).

[Drawn from 5CRO.pdb.]

INTERACT with the models shown in Figure 2.46 and 2.47 in Achieve



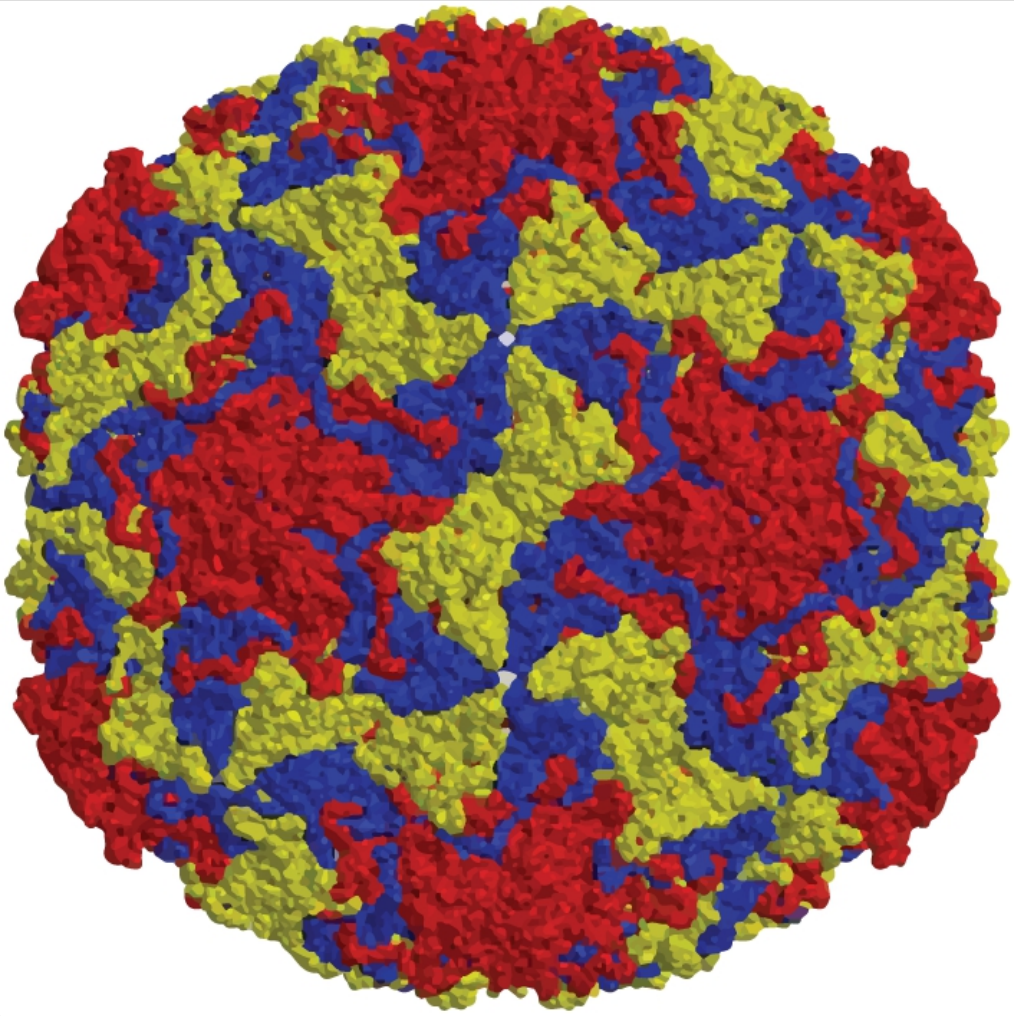


FIGURE 2.47 Human hemoglobin is composed of a $\alpha_2\beta_2$ tetramer. The structure of the two α subunits (red) is similar but not identical to that of the two β subunits (yellow). The molecule contains four heme groups (gray with the iron atom shown in purple). (A) The ribbon diagram highlights the similarity of the subunits and shows they are composed mainly of α helices. (B) The space-filling model illustrates how the heme groups occupy crevices in the protein.

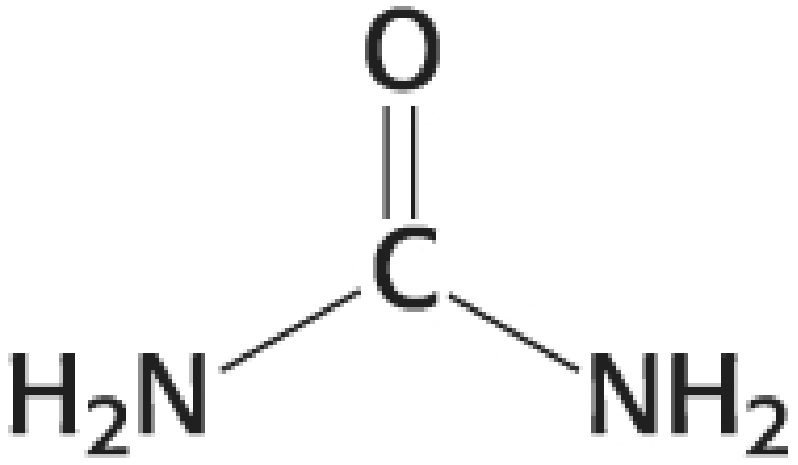
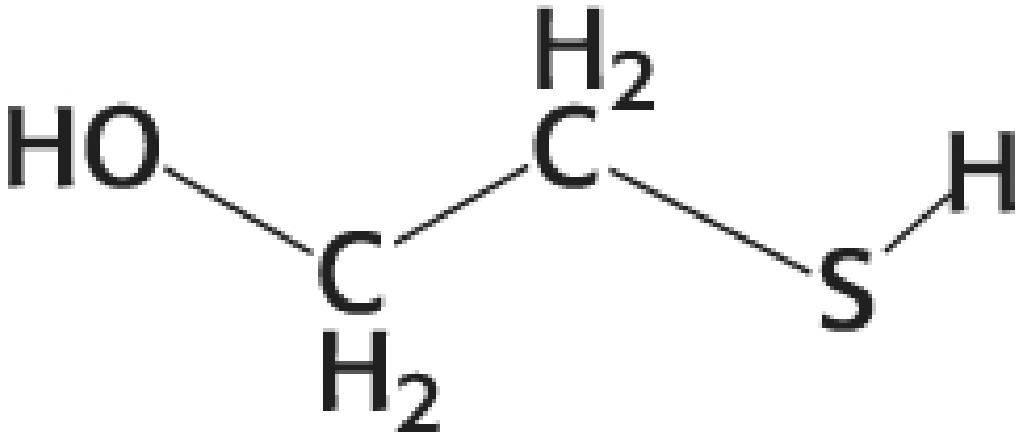
[Drawn from 1A3N.pdb.]

Viruses make the most of a limited amount of genetic information by forming coats that use the same kind of subunit repetitively in a symmetric array. For example, the coat of rhinovirus, the virus that causes the common cold, includes 60 copies of each of four subunits (**Figure 2.48**). The subunits come together to form a nearly spherical shell that encloses the viral genome. Although the rhinovirus coat ultimately requires 240 polypeptide chains, the symmetry achieved by its quaternary structure enables this structure to form from only four distinct sequences.



© Macmillan Learning

FIGURE 2.48 Viral coat proteins adopt complex quaternary structures with many copies of relatively few unique subunits. The coat of human rhinovirus, the cause of the common cold, comprises 240 individual polypeptide chains, 60 copies of each of four subunits. The three most prominent subunits are shown as different colors.



2.7 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

Thus far, we have seen that proteins can adopt a wide variety of structures, ranging from highly compact to fully extended. These structures reflect the broad diversity of protein functions and represent a theme we will encounter numerous times throughout this book. How polypeptide chains achieve these elaborate tertiary structures has been the focus of decades of research that still continues today.

The classic work of Christian Anfinsen in the 1950s on the enzyme ribonuclease revealed the relationship between the amino acid sequence of a protein and its conformation. Ribonuclease is a single polypeptide chain consisting of 124 amino acid residues cross-linked by four disulfide bonds (**Figure 2.49**). Anfinsen's plan was to destroy the three-dimensional structure of the enzyme and to then determine what conditions were required to restore the structure. In order to unfold ribonuclease, he used a high concentration (8 M) of urea, which effectively disrupts a protein's noncovalent interactions. Complete unfolding of ribonuclease also requires the cleavage, or reduction, of its four disulfide bonds (Figure 2.15). Using a large excess of β-mercaptoethanol, Anfinsen fully reduced the disulfides (cystines) into sulfhydryls (cysteines) (**Figure 2.50**).

Urea

β-Mercaptoethanol

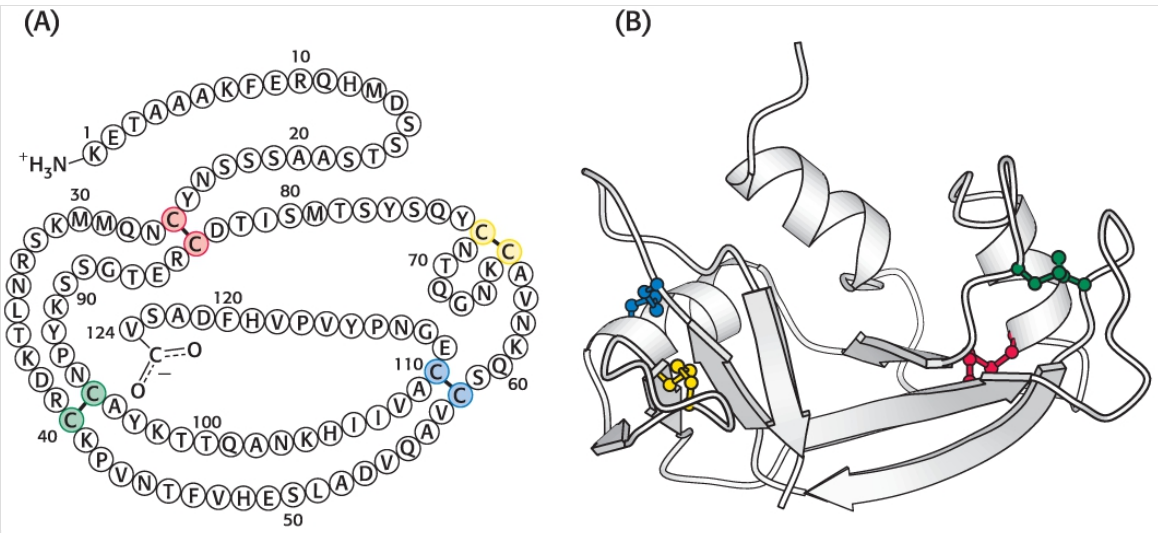


FIGURE 2.49 Bovine ribonuclease is a single polypeptide chain with four intramolecular disulfide bonds. (A) The primary structure of ribonuclease with the four disulfide bonds shown color. (B) Three-dimensional structure of ribonuclease with the same four disulfide bonds highlighted.

[(A) After C. H. W. Hirs, S. Moore, and W. H. Stein, *J. Biol. Chem*. 235:633–647, 1960; (B) Drawn from 1RBX.pdb.]

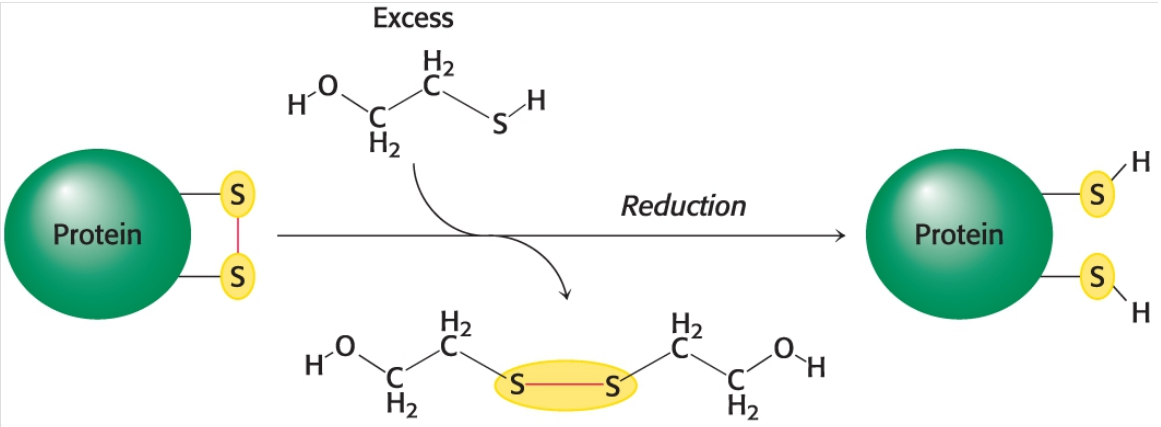

FIGURE 2.50 β-Mercaptoethanol disrupts disulfide bonds. Notice as the disulfides are disrupte (reduced), the β-mercaptoethanol is oxidized and forms dimers.

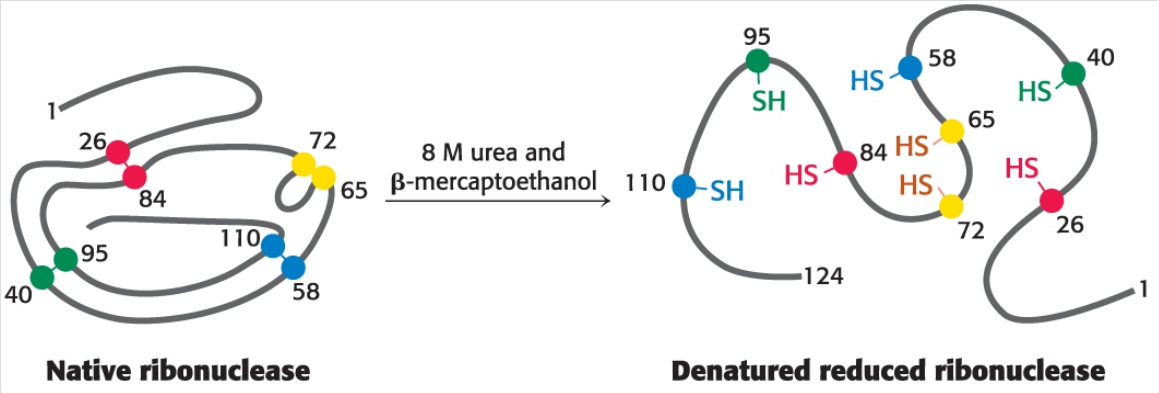
Most polypeptide chains devoid of cross-links assume a random-coil conformation in 8 M urea. When ribonuclease was treated with β-mercaptoethanol in 8 M urea, the product was a fully reduced, randomly coiled polypeptide chain devoid of enzymatic activity. When a protein is converted into a randomly coiled peptide without its normal activity, it is referred to as a **denatured protein** (**Figure 2.51**).



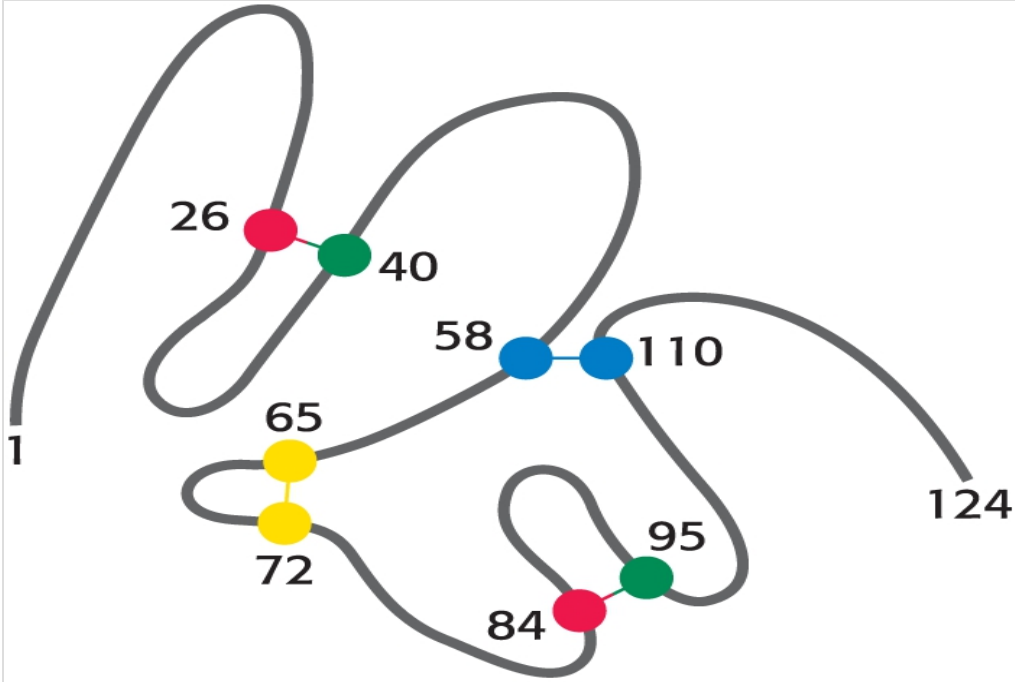


FIGURE 2.51 Ribonuclease is denatured with urea and β-mercaptoethanol.

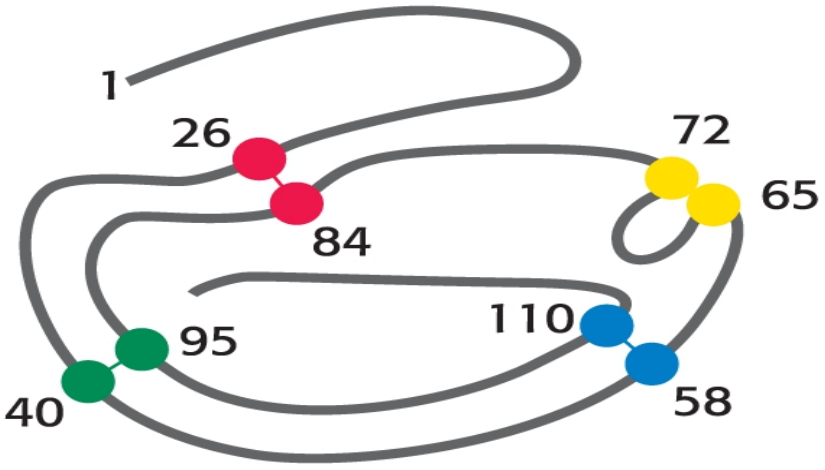
Anfinsen then made the critical observation that the denatured ribonuclease, introduced into a solution without urea and β-mercaptoethanol by a technique known as *dialysis* (Section 4.1), slowly regained enzymatic activity. He perceived the significance of this chance finding: the sulfhydryl groups of the denatured enzyme re-form disulfide bonds when exposed to air. Detailed studies then showed that nearly all the original enzymatic activity was regained if the disulfide bonds were oxidized under suitable conditions. All the measured physical and chemical properties of the refolded enzyme were virtually identical with those of the **native protein**; that is, the protein as it was originally isolated. These experiments showed that the information needed to specify the catalytically active structure of ribonuclease is contained in its amino acid sequence. Subsequent studies have



established the generality of this central principle of biochemistry: sequence specifies conformation.

A quite different result was obtained when ribonuclease was reoxidized while it was still in 8 M urea, followed by the removal of the urea. Ribonuclease treated in this way had only 1% of the enzymatic activity of the native protein. Why were the outcomes so different when reduced ribonuclease was reoxidized in the presence and absence of urea? The reason is that the wrong disulfides formed pairs in urea. There are 105 different ways of pairing eight cysteine molecules to form four disulfides; only one of these combinations is enzymatically active. The 104 wrong pairings have been picturesquely termed “scrambled” ribonuclease. Anfinsen found that scrambled ribonuclease spontaneously converted into fully active, native ribonuclease when trace amounts of β-mercaptoethanol were added to an aqueous solution of the protein (**Figure 2.52**). The added β-mercaptoethanol catalyzed the rearrangement of disulfide pairings until the native structure was regained in about 10 hours. This process was driven by the decrease in free energy as the scrambled conformations were converted into the stable, native conformation of the enzyme. The native disulfide pairings of ribonuclease thus contribute to the stabilization of the thermodynamically preferred structure.

Scrambled ribonuclease

Trace of
β-mercaptoethanol

Native ribonuclease

© Macmillan Learning

FIGURE 2.52 Native ribonuclease can be re-formed from scrambled ribonuclease in the presence of a trace of β-mercaptoethanol.

Similar refolding experiments have been performed on many other proteins. In many cases, the native structure can be generated under suitable conditions. For other proteins, however, refolding does not proceed efficiently. In these cases, the unfolded protein molecules usually become tangled up with one another to form aggregates. Inside cells, proteins called *chaperones* block such undesirable interactions. Additionally, it is now evident that some proteins do not assume a defined structure until they interact with molecular partners.

Self-Check Question

In his renaturation experiments, Anfinsen used a concentration of ribonuclease around $1\ \text{mg ml}^{-1}$. Inside a cell, the protein concentration is estimated to be around $100\ \text{mg ml}^{-1}$. Predict the outcome of Anfinsen's experiments had he used $100\ \text{mg ml}^{-1}$ ribonuclease.

Amino acids have different propensities for forming α helices, β sheets, and turns

How does the amino acid sequence of a protein specify its three-dimensional structure? How does an unfolded polypeptide chain acquire the form of the native protein? These fundamental questions in

biochemistry can be approached by first asking a simpler one: What determines whether a particular sequence in a protein forms an α helix, a β strand, or a turn? One source of insight is to examine the frequency of occurrence of particular amino acid residues in these secondary structures (Table 2.3). Residues such as alanine, glutamate, and leucine tend to be present in α helices, whereas valine and isoleucine tend to be present in β strands. Glycine, asparagine, and proline are more commonly observed in turns.

TABLE 2.3 Relative frequencies of amino acid residues in secondary structures

Amino acid	α helix	β sheet	Reverse turn
Glu	1.59	0.52	1.01
Ala	1.41	0.72	0.82
Leu	1.34	1.22	0.57
Met	1.30	1.14	0.52
Gln	1.27	0.98	0.84
Lys	1.23	0.69	1.07
Arg	1.21	0.84	0.90
His	1.05	0.80	0.81
Val	0.90	1.87	0.41
Ile	1.09	1.67	0.47

Tyr	0.74	1.45	0.76
Cys	0.66	1.40	0.54
Trp	1.02	1.35	0.65
Phe	1.16	1.33	0.59
Thr	0.76	1.17	0.96
Gly	0.43	0.58	1.77
Asn	0.76	0.48	1.34
Pro	0.34	0.31	1.32
Ser	0.57	0.96	1.22
Asp	0.99	0.39	1.24

Note: The amino acids are grouped according to their preference for α helices (top group), β sheets (middle group), or turns (bottom group).
Source: T. E. Creighton, *Proteins: Structures and Molecular Properties*, 2nd ed. (W. H. Freeman and Company, 1992), p. 256.

Studies of proteins and synthetic peptides have revealed some reasons for these preferences. Branching at the β-carbon atom, as in valine, threonine, and isoleucine, tends to destabilize α helices because of steric clashes. These residues are readily accommodated in β strands, where their side chains project out of the plane containing the main chain. Serine and asparagine tend to disrupt α helices because their side chains contain hydrogen-bond donors or acceptors in close proximity to the main chain, where they compete for main-chain NH and CO groups. Proline tends to disrupt both α helices and β strands because it lacks an NH group and because its ring structure restricts its φ value to near 60

degrees. Glycine readily fits into all structures, but its conformational flexibility renders it well-suited to reverse turns.

Can we predict the secondary structure of a protein by using this knowledge of the conformational preferences of amino acid residues? Accurate predictions of secondary structure adopted by even a short stretch of residues have proved to be difficult. Note that the conformational preferences of amino acid residues are not tipped all the way to one structure (Table 2.3). For example, glutamate, one of the strongest helix formers, prefers α helix to β strand by only a factor of three. The preference ratios of most other residues are smaller. Indeed, some penta- and hexapeptide sequences have been found to adopt one structure in one protein and an entirely different structure in another (**Figure 2.53**). Hence, some amino acid sequences do not uniquely determine secondary structure.

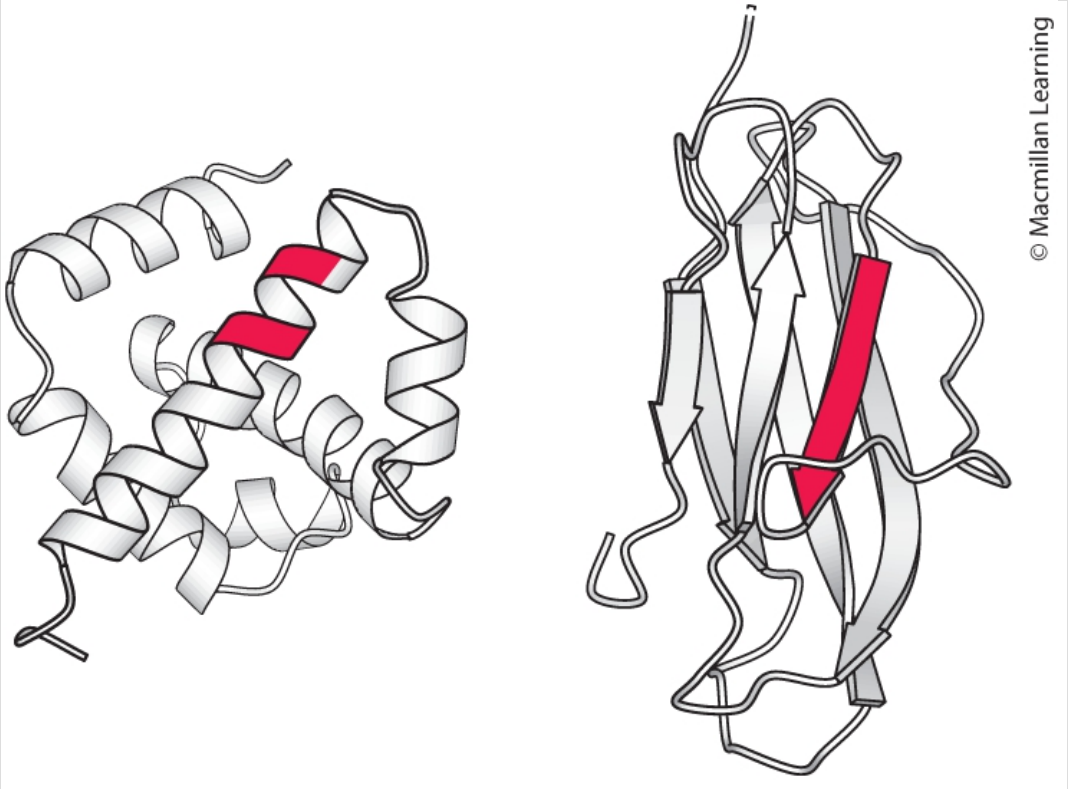


FIGURE 2.53 Many sequences can adopt alternative conformations in different proteins. Here the sequence VDLLKN shown in red assumes an α helix in one protein context (left) and a β strand in another (right).

[Drawn from (left) 3WRP.pdb and (right) 2HLA.pdb.]

Tertiary interactions — interactions between residues that are far apart in the sequence — may be decisive in specifying the secondary structure of some segments. Context is often crucial: the conformation of a protein has evolved to work in a particular environment. Nevertheless, substantial improvements in secondary structure prediction have been achieved by using families of related sequences, each of which adopts the same structure.

Protein folding is a highly cooperative process

Proteins can be denatured by any treatment that disrupts the weak bonds stabilizing tertiary structure, such as heating or chemical denaturants such as urea or guanidinium chloride. For many proteins, a comparison of the degree of unfolding as the concentration of denaturant increases reveals a sharp transition from the folded, or native, form to the unfolded, or denatured form, suggesting that only these two conformational states are present to any significant extent (Figure 2.54). A similar sharp transition is observed if denaturants are removed from unfolded proteins, allowing the proteins to refold.

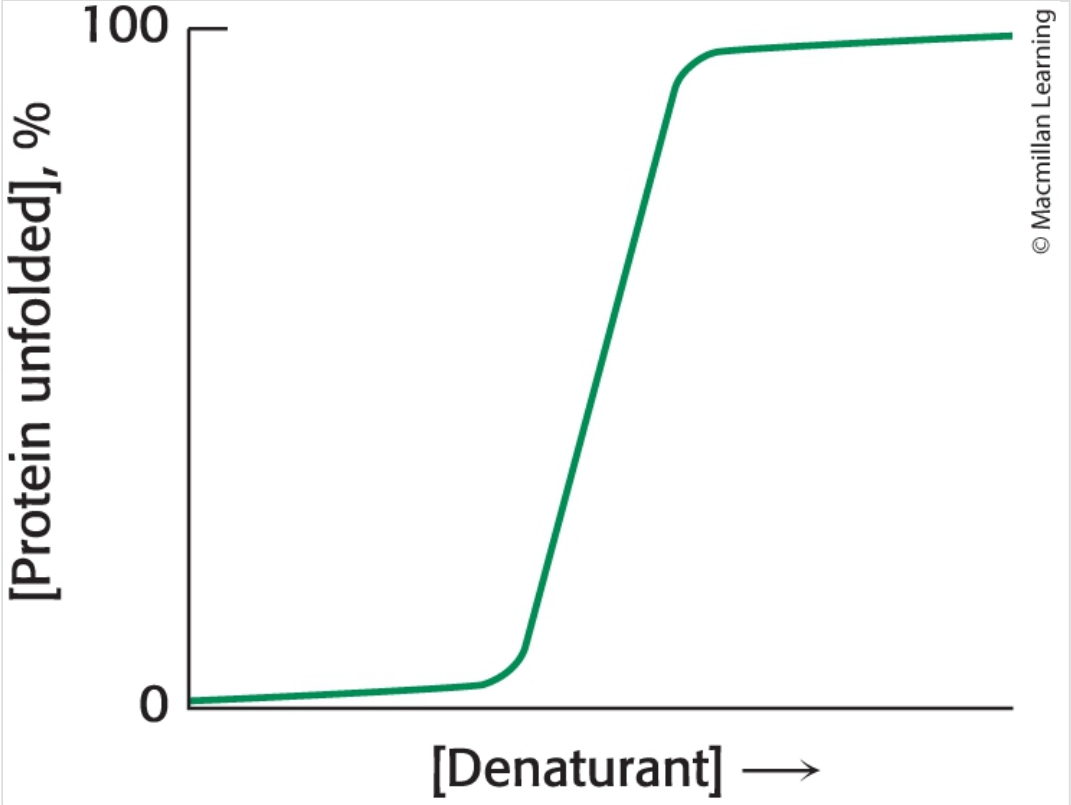

FIGURE 2.54 The transition from folded to unfolded state is abrupt. Most proteins show a sharp transition from the folded to the unfolded form on treatment with increasing concentrations of denaturants.

The sharp transition seen in Figure 2.54 suggests that protein folding and unfolding is an "all or none" process that results from a **cooperative transition**. Consider this example: suppose that a protein is placed in conditions under which some part of the protein structure is thermodynamically unstable. As this part of the folded structure is disrupted, the interactions between it and the remainder of the protein will be lost. The loss of these interactions, in turn, will destabilize the remainder of the structure. Thus, conditions that lead to the disruption of any part of a protein structure are likely to unravel the protein completely. The structural properties of proteins provide a clear rationale for the cooperative transition.

The consequences of cooperative folding can be illustrated by considering the contents of a protein solution under conditions corresponding to the middle of the transition between the folded and the unfolded forms. Under these conditions, the protein is "half folded." Yet the solution will appear to have no partly folded molecules but, instead, look as if it is a 50/50 mixture of fully folded and fully unfolded molecules (Figure 2.55). Although the protein may appear to behave as if it exists in only two states, this simple two-state existence is an impossibility at a molecular level. Even simple reactions go through reaction intermediates, and so a complex molecule such as a protein cannot simply switch from a completely unfolded state to the native state in one step. Unstable, transient intermediate structures must exist between the native and denatured state. Determining the nature of these intermediate structures is an area of intense biochemical research.

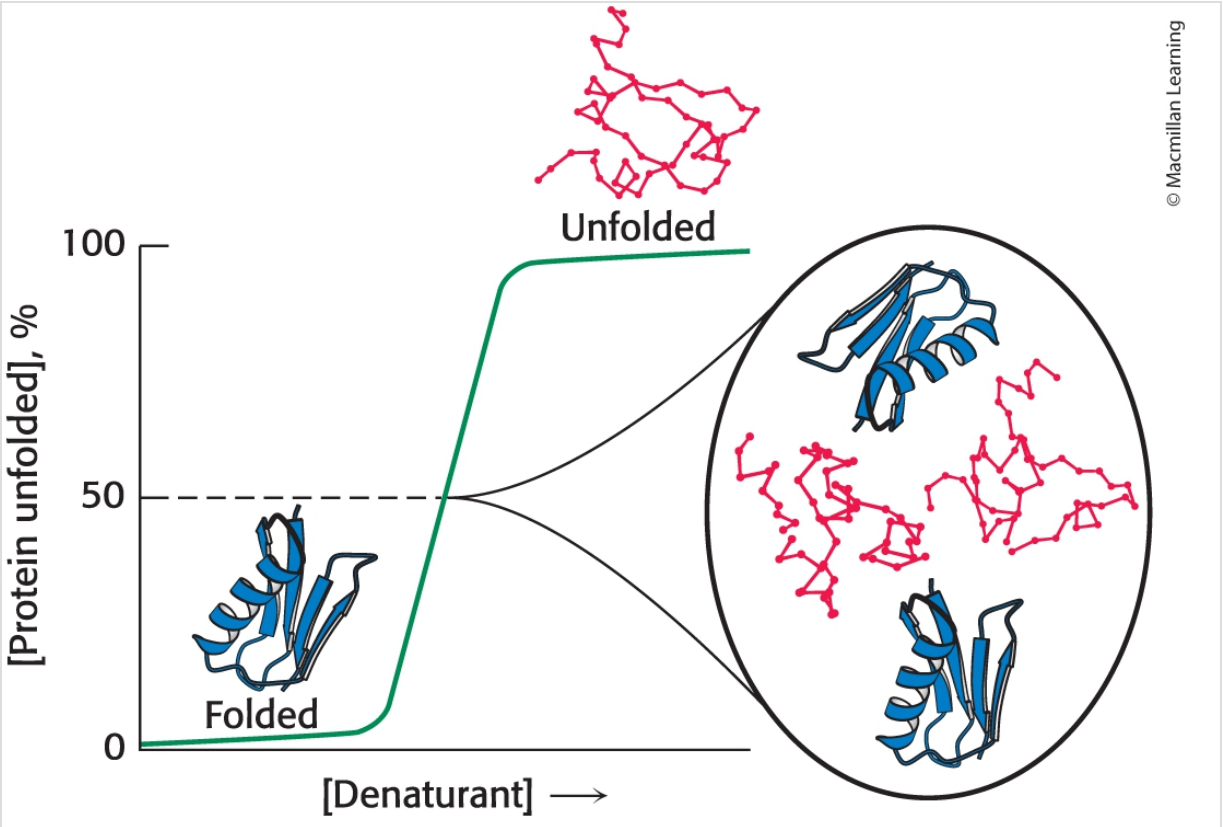

FIGURE 2.55 At the denaturation midpoint, half the molecules are fully folded and half are fully unfolded.

Proteins fold by progressive stabilization of intermediates rather than by random search

How does a protein make the transition from an unfolded structure to a unique conformation in the native form? One theoretical possibility would be that all possible conformations are sampled to find the energetically most favorable one. How long would such a random search take? Consider a small protein with 100 residues. In 1969, Cyrus Levinthal calculated that, if each residue can assume three different conformations, the total number of structures would be 3^{100}, which is equal to 5×10^{47}. If it takes 10^{-13} s to convert one structure into another, the total search time would be $5 \times 10^{47} \times 10^{-13}$ s, which is equal to 5×10^{34} s, or 1.6×10^{27} years. In reality, small proteins can fold in less than a second. Clearly, it would take much too long for even a small protein to fold properly by randomly trying out all possible conformations. The enormous difference between calculated and actual folding times is called *Levinthal's paradox*. This paradox clearly reveals that proteins do not fold by trying every possible conformation; instead, they must follow at least a partly defined folding pathway consisting of intermediates between the fully denatured protein and its native structure.

The way out of this paradox is to recognize the power of cumulative selection. Richard Dawkins, in *The Blind Watchmaker*, asked how long it would take a monkey poking randomly at a typewriter to reproduce Hamlet's remark to Polonius, "Methinks it is like a weasel" (**Figure 2.56**).

An astronomically large number of keystrokes, on the order of 10^{40}, would be required. However, suppose that we preserved each correct character and allowed the monkey to retype only the wrong ones. In this case, only a few thousand keystrokes, on average, would be needed. The crucial difference between these cases is that the first employs a completely random search, whereas, in the second, partly correct intermediates are retained.

FIGURE 2.56 In the analogy of the typing monkey, the desired result is achieved more rapidly if individual correct keystrokes are retained. In the two computer simulations shown, the cumulative number of keystrokes required to write a line from Shakespeare's *Hamlet* is given at the left of each line.

The essence of protein folding is the tendency to retain partly correct intermediates. However, the protein-folding problem is much more difficult than the one presented to our simian Shakespeare. First, the criterion of correctness is not a residue-by-residue scrutiny of conformation by an omniscient observer but rather the total free energy of the transient species. Second, proteins are only marginally stable. The free-energy difference between the folded and the unfolded states of a typical 100-residue protein is $42\ \text{kJ mol}^{-1}$ $(10\ \text{kcal mol}^{-1})$, and thus each residue contributes on average only $0.42\ \text{kJ mol}^{-1}$ $(0.1\ \text{kcal mol}^{-1})$ of energy to maintain the folded state. This amount is less than the amount of thermal energy, which is $2.5\ \text{kJ mol}^{-1}$ $(0.6\ \text{kcal mol}^{-1})$ at room temperature. This meager stabilization energy means that correct intermediates, especially those formed early in folding, can be lost. The analogy is that the monkey would be somewhat free to undo its correct keystrokes. Nonetheless, the interactions that lead to cooperative folding can stabilize intermediates as structure builds up. Thus, local regions that have significant structural preference, though not necessarily stable on their own, will tend to adopt their favored structures and, as they form, can interact with one other, leading to increasing stabilization. This conceptual framework is often referred to as the *nucleation-condensation model*.

A simulation of the folding of a protein, based on the nucleation-condensation model, is shown in **Figure 2.57**. This model suggests that certain pathways may be preferred. Although Figure 2.57 suggests a discrete pathway, each of the intermediates shown represents an

ensemble of similar structures, and thus a protein follows a general rather than a precise pathway in its transition from the unfolded to the native state. The energy surface for the overall process of protein folding can be visualized as a funnel (Figure 2.58). The wide rim of the funnel represents the wide range of structures accessible to the ensemble of denatured protein molecules. As the free energy of the population of protein molecules decreases, the proteins move down into narrower parts of the funnel, and fewer conformations are accessible. At the bottom of the funnel is the folded state with its well-defined conformation. Many paths can lead to this same energy minimum.

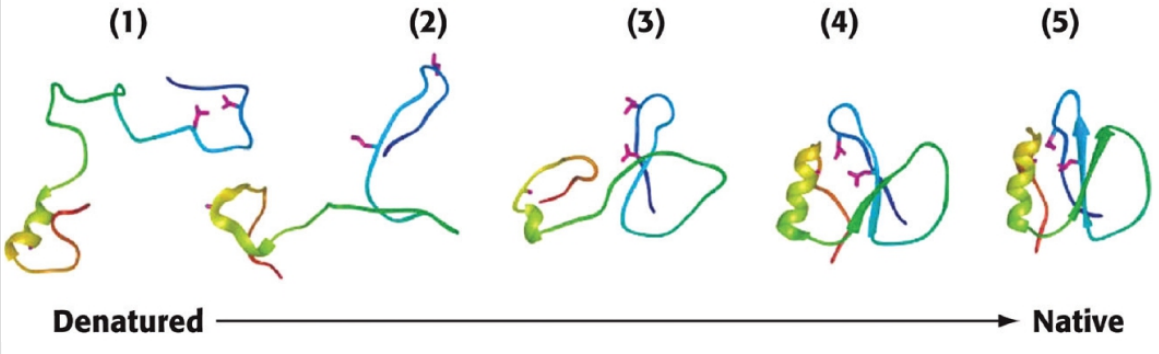

FIGURE 2.57 The proposed folding pathway of chymotrypsin inhibitor-2 demonstrates the nucleation-condensation model. Local regions with sufficient structural preference tend to adopt their favored structures initially (1). These structures come together to form a nucleus wi a nativelike, but still mobile, structure (4). This structure then fully condenses to form the native more rigid structure (5).

[From A. R. Fersht and V. Daggett. *Cell* 108:573–582, 2002; with permission from Elsevier.]

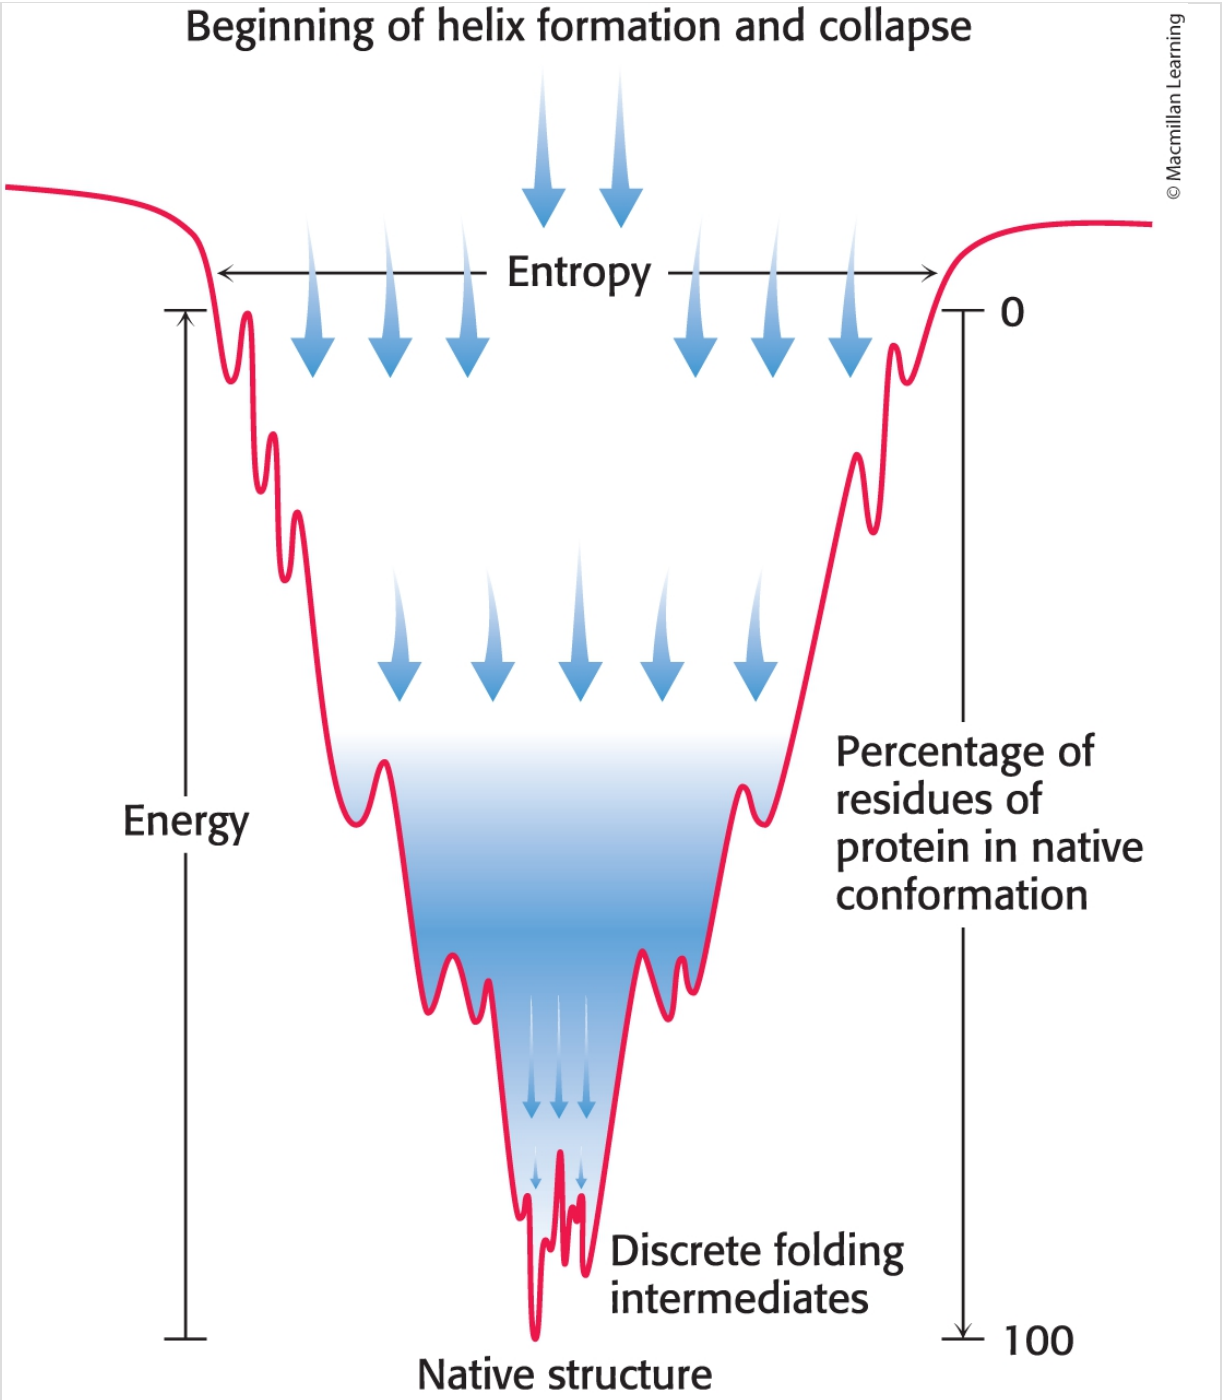

FIGURE 2.58 The folding funnel depicts the thermodynamics of protein folding. The top of the funnel represents all possible denatured conformations — that is, maximal conformational entropy. Depressions on the sides of the funnel represent semistable intermediates that can facilitate or hinder the formation of the native structure, depending on their depth. Secondary structures, such as helices, form and collapse onto one another to initiate folding.

[After D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2008), p. 143.]

Prediction of three-dimensional structure from sequence remains a great challenge

The prediction of three-dimensional structure from sequence has proved to be extremely difficult. The local sequence appears to determine only between 60% and 70% of the secondary structure; long-range interactions are required to stabilize the full secondary structure and the tertiary structure.

Investigators are exploring two fundamentally different approaches to predicting three-dimensional structure from amino acid sequence:

1. Ab initio *predictions attempt to predict the folding of an amino acid sequence without prior knowledge about similar sequences in known protein structures*. (*Ab initio*, from the Latin, means "from the beginning.") Computer-based calculations are employed that attempt to minimize the free energy of a structure with a given amino acid sequence or to simulate the folding process. The utility of these methods is limited by the vast number of possible conformations, the marginal stability of proteins, and the subtle energetics of weak interactions in aqueous solution.

2. *Knowledge-based methods take advantage of our growing knowledge of the three-dimensional structures of many proteins*. The amino acid sequence of unknown structure is examined for compatibility with known protein structures or fragments therefrom. If a significant match is detected, the known structure can be used as an initial model. Knowledge-based methods have been a source of many

insights into the three-dimensional conformation of proteins of known sequence but unknown structure.

The prediction of protein folding from sequence information is a formidable task, one that has compelled the scientific community to explore creative methods for achieving progress. In 1994, John Moult and Krzysztof Fidelis organized the first protein-structure prediction challenge called Critical Assessment of Structure Prediction (CASP). In this competition, contestants are provided with sequences of proteins whose structures had been recently solved but not yet published, and are asked to submit their structural predictions. The submissions are then graded based on how well their predictions match the experimentally determined structures. Importantly, the entire process is *blinded*: the entrants have no prior knowledge of the experimentally solved structures, and the judges have no information about the identity of the competitors and their prediction methods.

Since its inception, CASP competitions have been conducted every two years, with participation from over 200 groups in the most recent event in 2020. Highlighting the difficulty of the task, improvements in structure prediction have been modest, with the results largely reaching a plateau in the early 2010s. However, significant improvement has been achieved in the most recent two events, largely based on the advancement of artificial intelligence (AI) methods developed by the company DeepMind. Their algorithm, AlphaFold, recently achieved an average accuracy of nearly 90%, almost equivalent to what would be expected from experimental methods. For example, their best structural prediction of the protein ORF8 from the SARS-CoV-2 virus was 89% accurate, far exceeding the competition (**Figure 2.59**). Their success suggests that the accurate computational prediction of protein folding may very well be within reach. Additionally, these results serve as evidence of the achievements made possible through collaborative research.

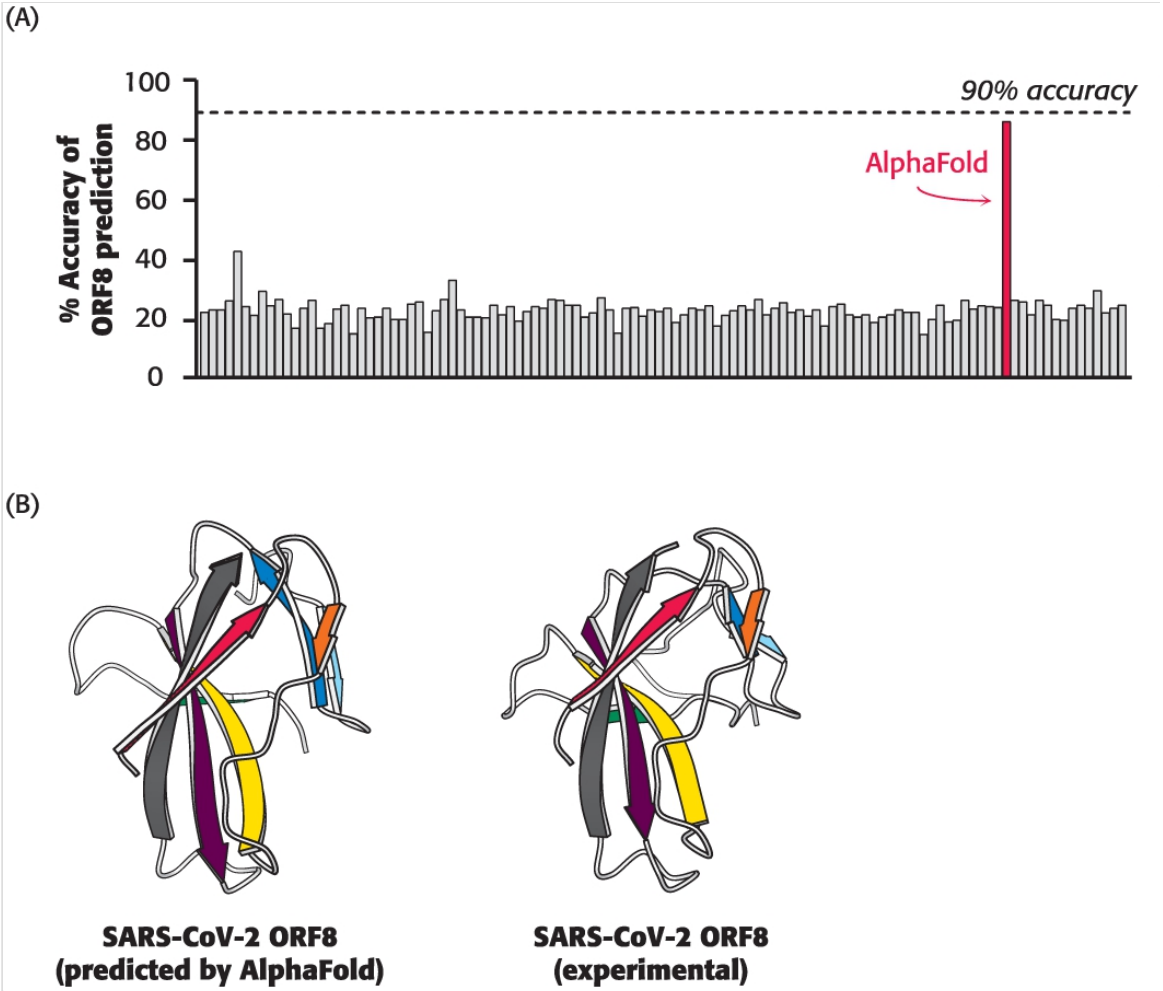

FIGURE 2.59 AlphaFold represents a significant step forward in protein folding prediction. On of the targets from the most recent CASP competition was the ORF8 protein from the SARS-CoV virus. (A) The AlphaFold algorithm (red bar) predicted the structure with nearly 90% accuracy (dashed line), far better than the other competitors (gray bars). (B) Comparison of the predicted structure with the experimentally determined structure shows the extensive similarity.

Protein misfolding and aggregation are associated with some neurological diseases

Understanding protein folding and misfolding is of more than academic interest. A host of neurological diseases, including Alzheimer disease, Parkinson disease, and Huntington disease are associated with improperly folded proteins. All of these diseases result in the deposition of protein aggregates, called **amyloid fibrils** or **amyloid plaques**. A common feature of such diseases is that normally soluble proteins are converted into insoluble fibrils rich in β sheets. The correctly folded protein is only marginally more stable than the incorrect form. But the incorrect form aggregates, pulling more correct forms into the incorrect form. For example, the brains of patients with Alzheimer disease contain amyloid plaques that consist primarily of a single polypeptide termed Aβ Polypeptide Aβ is prone to form insoluble aggregates. As expected, the structure is rich in β strands, which come together to form extended parallel β-sheet structures (**Figure 2.60**).

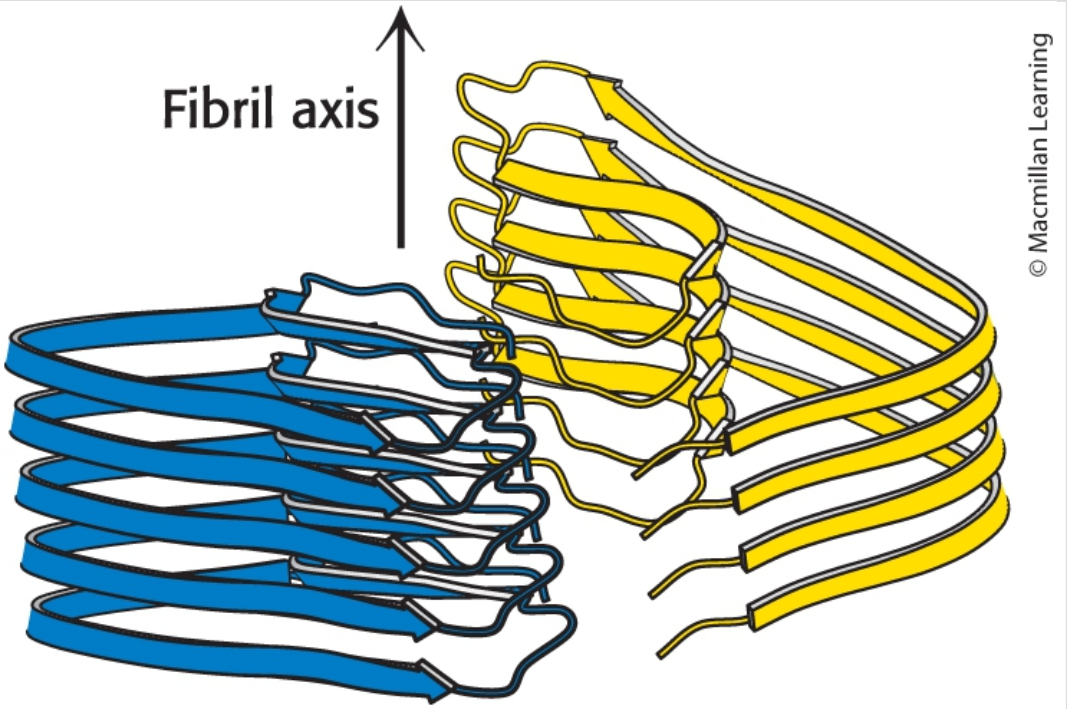

FIGURE 2.60 The structure of the Aβ amyloid fibril reveals its extensive β sheet network. The Aβ amyloid fibril structure shows that protein aggregation is due to the formation of large parallel β sheets. The black arrow indicates the long axis of the fibril.

[Drawn from 5OQV.pdb].

How do such aggregates lead to the death of the cells that harbor them? The answer is still controversial. One hypothesis is that the large aggregates themselves are not toxic but, instead, smaller aggregates of the same proteins may be the culprits, perhaps damaging cell membranes. Nevertheless, the amount of fibrillar Aβ deposited in the brain is correlated with the severity of disease. In fact, the extent of amyloid fibril accumulation can be measured in patients using a technique called *positron emission tomography* (PET) scanning. These images can be used to anticipate the progressive worsening of neurological function (**Figure 2.61**).

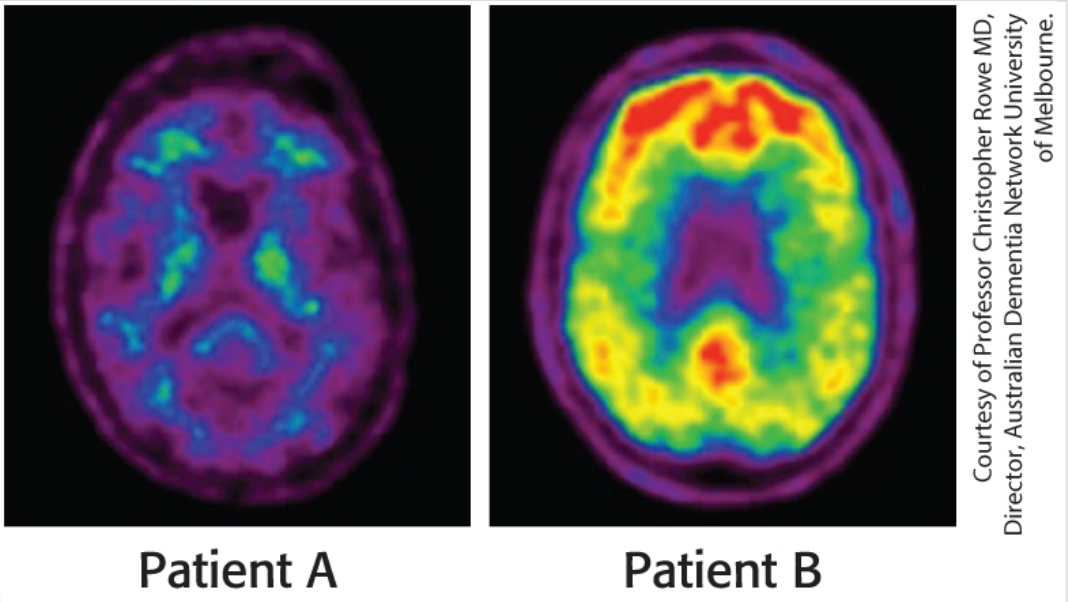

FIGURE 2.61 The extent of amyloid fibril aggregation in the brain can predict the progression of Alzheimer disease. With the aid of a molecule that binds Aβ fibrils, positron emission tomography scanning can measure the extent of amyloid aggregation in the brains of Alzheimer disease patients. The scan of Patient A (low) exhibited a relatively low signal, while the scan of Patient B (right) revealed a high degree of labeling throughout the brain. The mild impairment exhibited by Patient A remained stable for more than 4.5 years after the scan was taken, while Patient B progressed to dementia 3 years after the scan.

Posttranslational modifications confer new capabilities to proteins

Proteins are able to perform numerous functions that rely solely on the versatility of their 20 amino acids. This array of functions can be expanded even further by the incorporation of **posttranslational modifications**, alterations in the structure of a protein after its synthesis in the cell. These modifications may include the covalent attachment of groups to amino acid side chains (Figure 2.62) or the cleavage or modification of the polypeptide backbone.

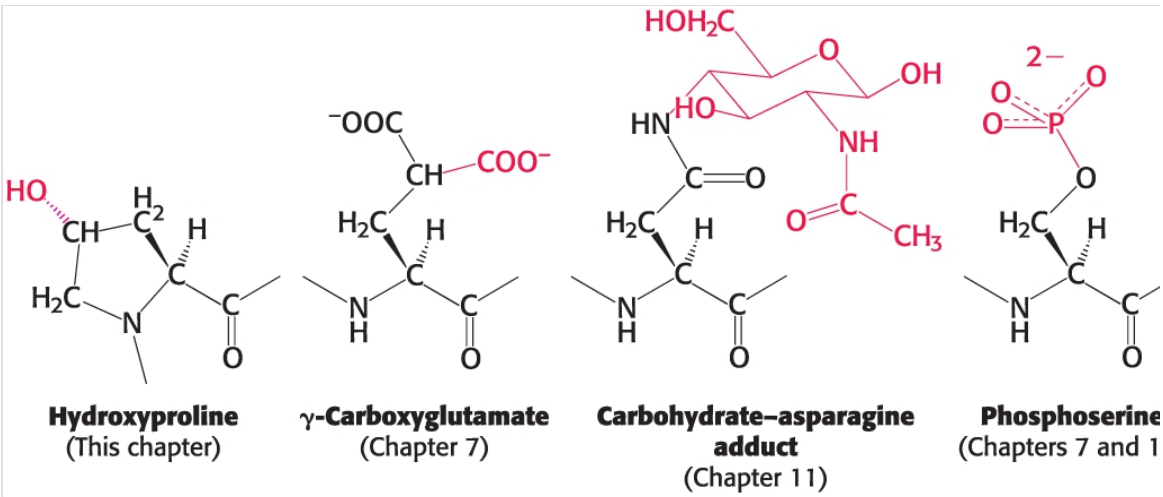

FIGURE 2.62 Posttranslational modifications to proteins include covalent attachments. Examples of common and important covalent modifications of amino acid side chains are show in red. These will be discussed in the indicated chapters.

One example of a posttranslational modification is hydroxylation. As discussed in Section 2.5, the addition of hydroxyl groups to many proline residues stabilizes fibers of newly synthesized collagen. The biological significance of this modification is evident in the disease scurvy: a deficiency of vitamin C results in insufficient hydroxylation of collagen, and the abnormal collagen fibers that result are unable to maintain normal tissue strength. Other covalent modifications shown in Figure 2.62 will be discussed in future chapters.

Other special groups are generated by chemical rearrangements of side chains and, sometimes, the peptide backbone. For example, the jellyfish *Aequorea victoria* produces green fluorescent protein (GFP), which emits green light when stimulated with blue light. The source of the fluorescence is a group formed by the spontaneous rearrangement and oxidation of the sequence Ser-Tyr-Gly within the center of the protein (**Figure 2.63A**). Since the discovery of GFP, a number of mutants have been engineered which absorb and emit light across the entire visible

spectrum (Figure 2.63B). These proteins are of great service to researchers as markers within cells (Figure 2.63C).

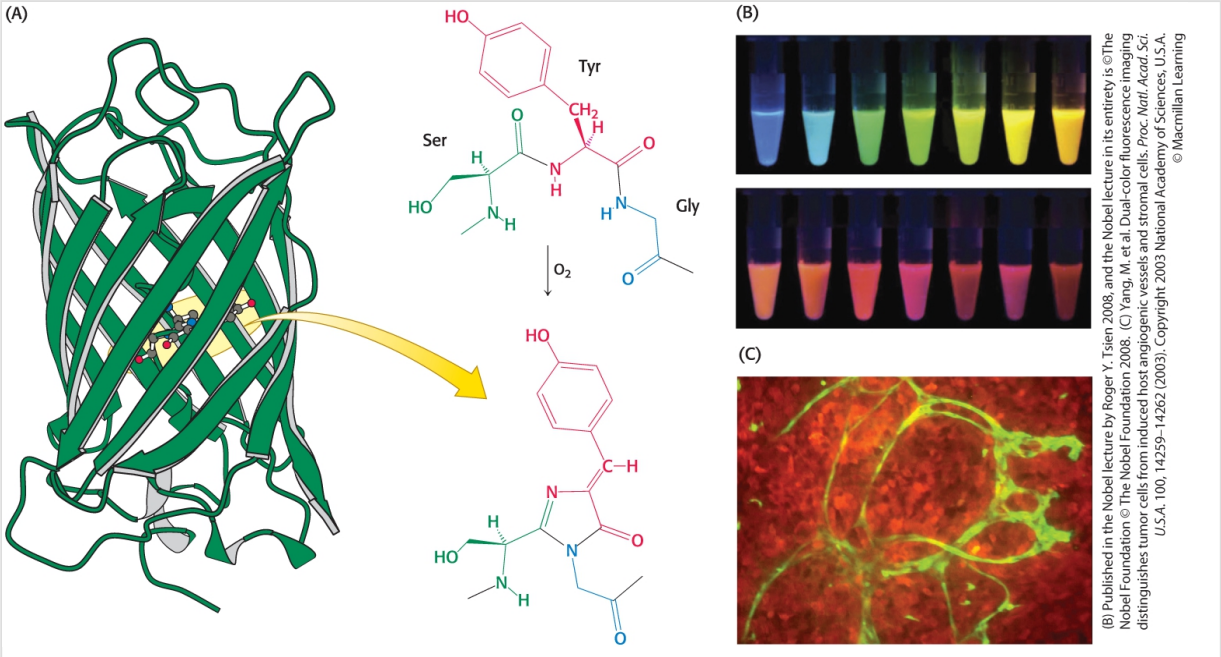

FIGURE 2.63 GFP is modified posttranslationally by the chemical rearrangement of three amino acids. (A) The rearrangement and oxidation of the sequence Ser-Tyr-Gly in green fluorescent protein (GFP) is the source of its fluorescence. (B) Mutants of GFP emit light across the visible spectrum. (C) A melanoma cell line engineered to express one of these GFP mutants, red fluorescent protein (RFP), was injected into a mouse whose blood vessels express GFP. In this fluorescence micrograph, the formation of new blood vessels (green) in the tumor (red) is readily apparent.

[(A) Drawn from 1GFL.pdb;]

Finally, many proteins are cleaved and trimmed after synthesis. For example, digestive enzymes are synthesized as inactive precursors that can be stored safely in the pancreas. After release into the intestine, these precursors become activated by peptide-bond cleavage (Section 7.4). In blood clotting, peptide-bond cleavage converts soluble fibrinogen into insoluble fibrin. A number of polypeptide hormones, such as adrenocorticotropic hormone, arise from the splitting of a single large precursor protein. Likewise, many viral proteins are

produced by the cleavage of large polyprotein precursors. We shall encounter many more examples of modification and cleavage as essential features of protein formation and function. Indeed, these finishing touches account for much of the versatility, precision, and elegance of protein action and regulation.

Chapter 2 Summary

2.1 Several Properties of Protein Structure Are Key to Their Functional Versatility

- Proteins are linear polymers built of amino acids.
- Proteins contain a wide range of functional groups.
- Proteins interact with each other to form assemblies.
- Proteins can vary from rigid to highly flexible.

2.2 Proteins Are Built from a Repertoire of 20 Amino Acids

- Proteins are polymers of L amino acids which can be classified on the properties of their side chains.
- Hydrophobic amino acids with nonpolar R groups include: glycine, alanine, valine, leucine, isoleucine, methionine, proline, phenylalanine, and tryptophan.
- Polar amino acids include: serine, threonine, tyrosine, asparagine, glutamine, cysteine, and histidine.
- Positively charged amino acids include: lysine and arginine.
- Negatively charged amino acids include: aspartate and glutamate.

2.3 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains

- Amino acids are linked together into polypeptides by peptide bonds.
- The sequence of amino acids in a protein is called its primary structure.
- Polypeptide chains are directional, in that the ends of the chain are different: by convention, polypeptide sequences are written

from the amino-terminal residue to the carboxyl-terminal residue.
- Each protein has its own unique primary structure.
- Peptide bonds have a planar geometry due to their partial double-bond character.
- The main chain bonds preceding and following the α carbon have rotational flexibility, which can be depicted in a Ramachandran plot.

2.4 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures

- Secondary structure refers to the formation of regular structures near one another in the protein sequence.
- The α helix is a tightly packed rod where the CO group from one amino acid is hydrogen bonded to the NH group four residues further along the chain.
- The β sheet features a series of fully extended polypeptide chains (β strands) hydrogen-bonded to each other.
- Turns and loops are shorter, less-regular secondary structures that enable the polypeptide chain to change direction.

2.5 Tertiary Structure: Proteins Can Fold into Globular or Fibrous Structures

- Tertiary structure refers to the fully folded structure of a single polypeptide chain.
- The formation of tertiary structure in water-soluble proteins is largely driven by packing hydrophobic residues in the interior of the protein and exposing hydrophilic resides on the surface.
- Proteins can fold into highly compact and asymmetric globular proteins or fully extended fibrous proteins.

2.6 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures

- Quaternary structure refers to the organization of multiple polypeptide chains (subunits) into an organized complex.
- These assemblies can range from simple dimers to highly complicated viral coats with hundreds of subunits.
- Quaternary structures are held together by numerous noncovalent bonds.

2.7 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

- The amino acid sequence determines the three-dimensional structure and, hence, all other properties of a protein.
- Protein folding does not occur by random searching, but by progressive stabilization of intermediate structural elements.
- Protein folding is a highly cooperative process; structural intermediates between the unfolded and folded forms do not accumulate.
- The versatility of proteins is further increased by posttranslational modifications, including the chemical modification or rearrangement of side chains and the cleavage of the peptide backbone.

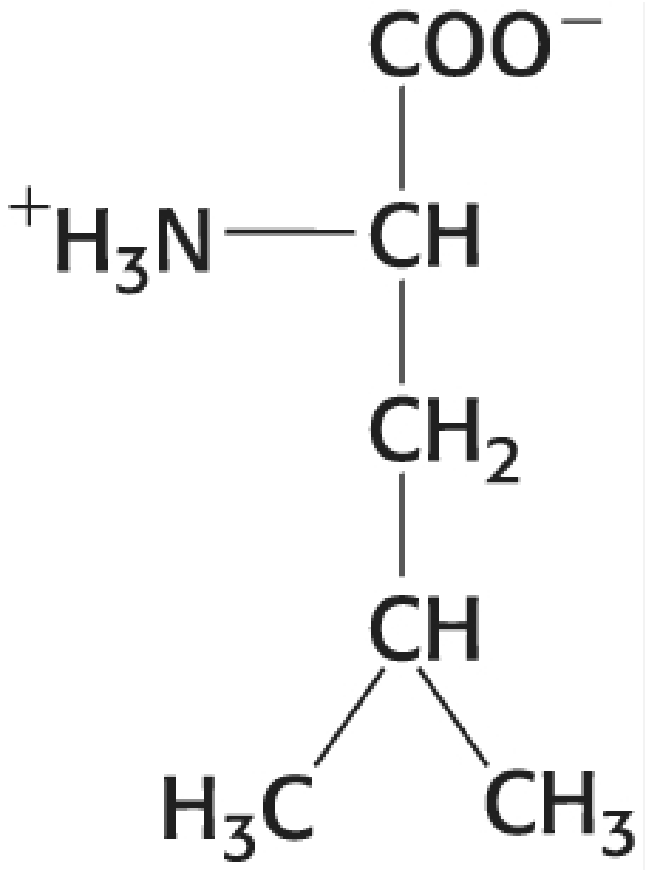
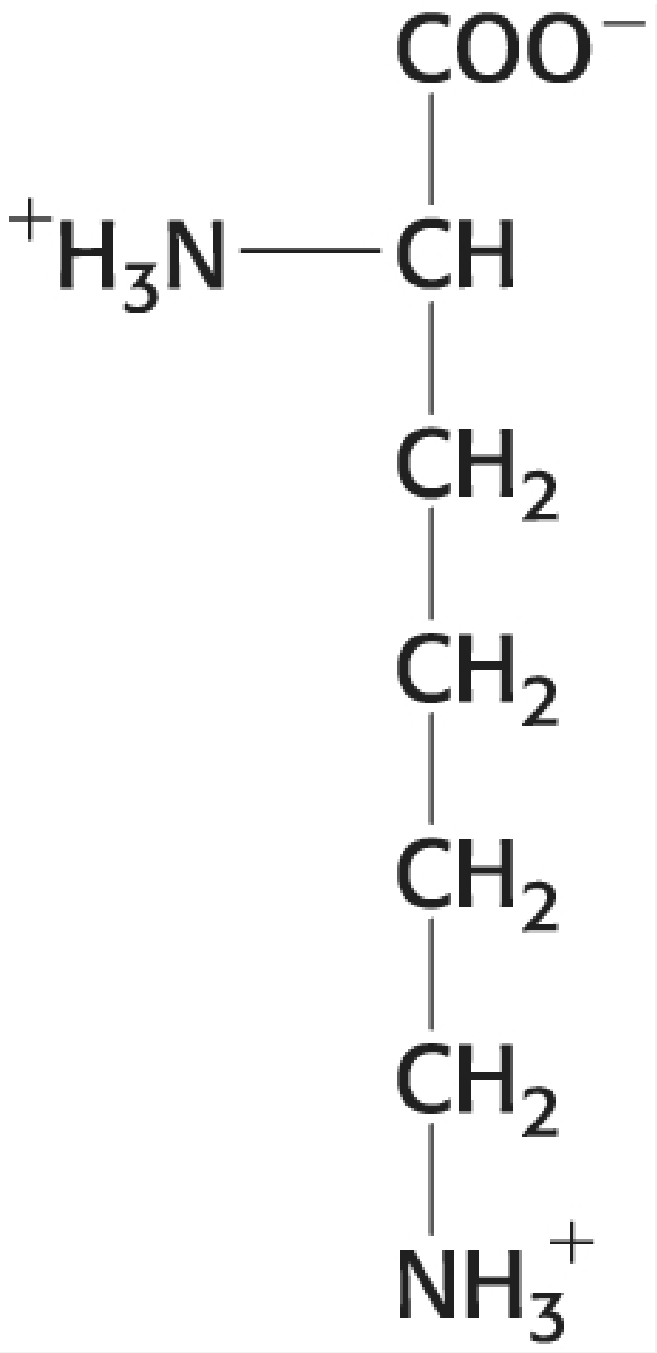
Problems

1. Examine the following four amino acids (A–D):



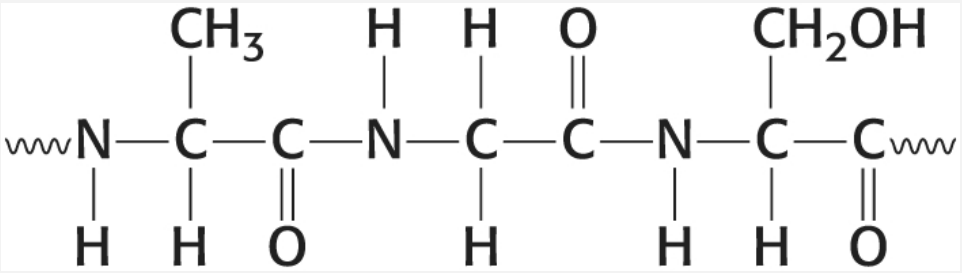
A.



B.

C.

D.

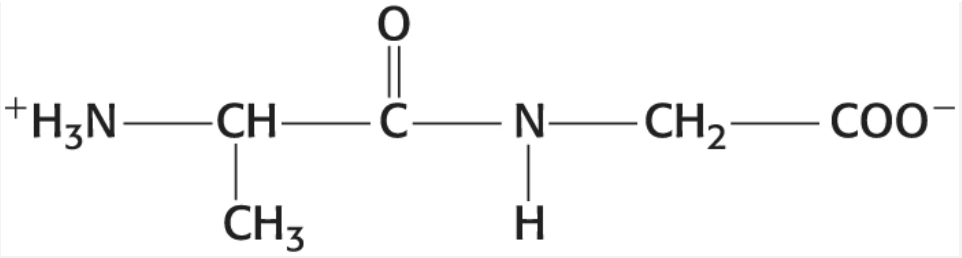


What are their names, three-letter abbreviations, and one-letter symbols? 1

2. Sort the amino acids shown in problem 1 according to the category in which it fits. 1

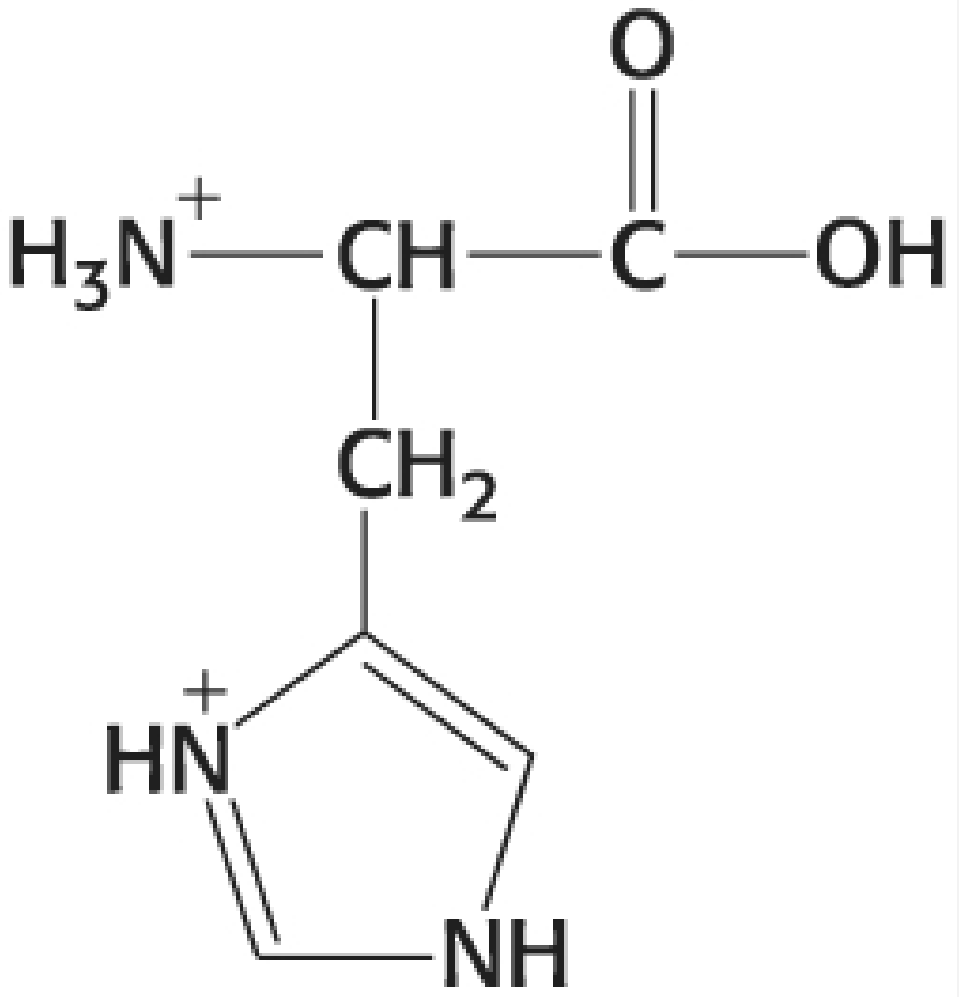
a. Basic side chain _____
b. Acidic side chain _____
c. Neutral polar side chain _____
d. Hydrophobic side chain _____

3. Which of the following amino acids have R groups that have hydrogen-bonding potential? Ala, Gly, Ser, Phe, Glu, Tyr, Ile, and Thr. 1



4. Examine the segment of a protein shown here.

a. What three amino acids are present?
b. Of the three, which is the N-terminal amino acid?
c. How many peptide bonds are explicitly shown in this peptide?



5. Draw the structure of the dipeptide Gly-His. What is the charge on the peptide at pH 5.5? pH 7.5? 1

6. Draw the resonance structure for the peptide bond shown in the image.

7. On Figure 2.5, indicate the pH value at which a solution of this amino acid would have no net charge.

8. All amino acids have two ionizable functional groups: an α-amino group (typical pK_a of 8.0) and an α-carboxylic acid group (typical pK_a of 3.1). Histidine also has an ionizable side chain (R group) with a pK_a of about 6.0. One of the possible ionization states of histidine is shown in the image.

a. At what pH would the structure be the predominant ionization state? Consider the ionization state of all three of the functional groups.

pH 11.6 pH 8.4 pH 7.0 pH 6.0 pH 3.1 pH 1.5

b. The protonated form of the R group of histidine is shown in the structure. The ratio of the charged

(protonated) form to the deprotonated form depends on the pK_a of the R group and the pH of the solution. At which of these pH values would the charged form of the R group predominate?

pH 3.0 pH 4.9 pH 6.0 pH 11.1

9.

a. Tropomyosin, a 70-kDa muscle protein, is a two-stranded α-helical coiled coil. Estimate the length of the molecule.
b. Suppose that a 40-residue segment of a protein folds into a two-stranded antiparallel β structure with a 4-residue hairpin turn. What is the longest dimension of this motif? 3

10. Poly-L-leucine in an organic solvent such as dioxane is α helical, whereas poly-L-isoleucine is not. Why do these amino acids with the same number and kinds of atoms have different helix-forming tendencies? 3

11. An enzyme that catalyzes disulfide–sulfhydryl exchange reactions, called protein disulfide isomerase (PDI), has been isolated. PDI rapidly converts inactive scrambled ribonuclease into enzymatically active ribonuclease. In contrast, insulin is rapidly inactivated by PDI. What does this important observation imply about the relationship between the amino acid sequence of insulin and its three-dimensional structure?

12. What is the length of a 12 kDa single-stranded α-helical protein segment? Assume a mean residue mass of 110 daltons. 3

13. Which of these four peptides is most likely to form a β sheet?

a. Lys-Thr-Val-Ile-Trp-Pro-Phe-Tyr-Ile-Gln-Ile-Gly
b. Met-Leu-Lys-Ala-Ser-Ala-Leu-Glu-Lys-Leu-Ser-Glu
c. Arg-Ser-Tyr-Glu-Gly-Leu-Lys-Arg-Ile-Ala-Glu-Ser
d. Ala-Glu-Met-Leu-Gln-Lys-Arg-Gly-Cys-Gly-Asp-Glu

14. Consider the Ramachandran plots in Figures 2.21, 2.24, and 2.27.

a. Which observation most likely describes part of an observed α helix? (choose one) 3
   1. $\varphi = -60^\circ$; $\psi = -47^\circ$; many Ala residues
   2. $\varphi = -140^\circ$; $\psi = +130^\circ$; many Val residues
   3. $\varphi = -59^\circ$; $\psi = +150^\circ$; many Ser residues
   4. $\varphi = +60^\circ$; $\psi = +40^\circ$; many Gly residues
   5. $\varphi = -57^\circ$; $\psi = -47^\circ$; many Pro residues

b. Which observations would not likely occur in a β sheet? (may be more than one)
   1. $\varphi = -57^\circ$; $\psi = -49^\circ$; many Ala residues
   2. $\varphi = +60^\circ$; $\psi = +60^\circ$; many Gly residues
   3. $\varphi = -51^\circ$; $\psi = +153^\circ$; many Gly and Pro residues
   4. $\varphi = -139^\circ$; $\psi = +135^\circ$; many Val residues
   5. $\varphi = -120^\circ$; $\psi = +120^\circ$; many Tyr residues

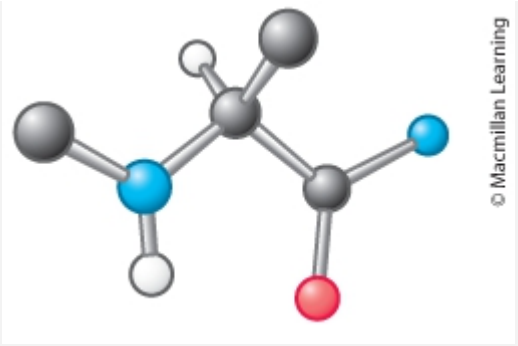
15. Classify each phrase as a description of α helices, β sheets, reverse turns, or all: 3

a. Contains —NH hydrogen bonded to C=O

b. Successive R groups point in opposite directions
c. All —NH groups point in the same direction
d. First residue hydrogen bonded to fourth residue (i.e., residue *i* is H-bonded to residue $i + 3$)
e. First residue hydrogen bonded to fifth residue (i.e., residue *i* is H-bonded to residue $i + 4$)

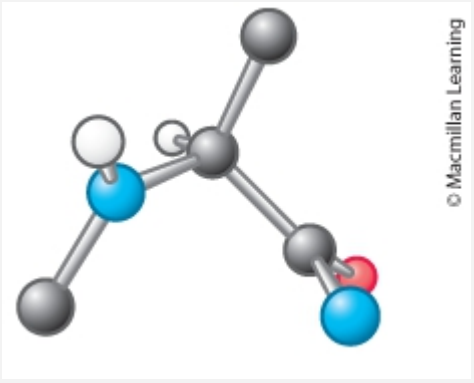
16. The α and β subunits of hemoglobin bear a remarkable structural similarity to myoglobin. However, certain residues that are hydrophilic in myoglobin are hydrophobic in the subunits of hemoglobin. Why might this be the case?

17. For an amino acid such as alanine, the major species in solution at pH 7 is the zwitterionic form. Assume a pK_a value of 8 for the amino group and a pK_a value of 3 for the carboxylic acid. Estimate the ratio of the concentration of the neutral amino acid species (with the carboxylic acid protonated and the amino group neutral) to that of the zwitterionic species at pH 7 (Section 1.3).



18. Translate the following amino acid sequence into one-letter code: Glu-Leu-Val-Ile-Ser-Ile-Ser-Leu-Ile-Val-Ile-Asn-Gly-Ile-Asn-Leu-Ala-Ser-Val-Glu-Gly-Ala-Ser. 1

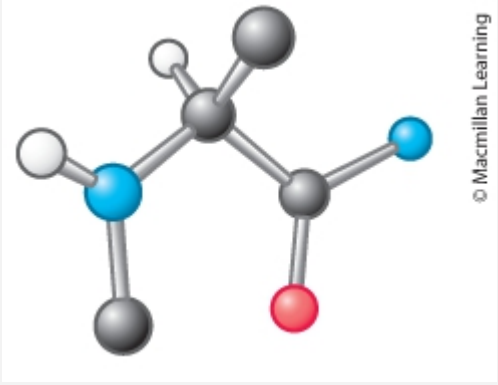
19. Would you expect Pro—X peptide bonds to tend to have cis conformations like those of X—Pro bonds? Why or why not?



20. For each of the amino acid derivatives shown here (A–E), find the matching set of ϕ and ψ values (a–e).

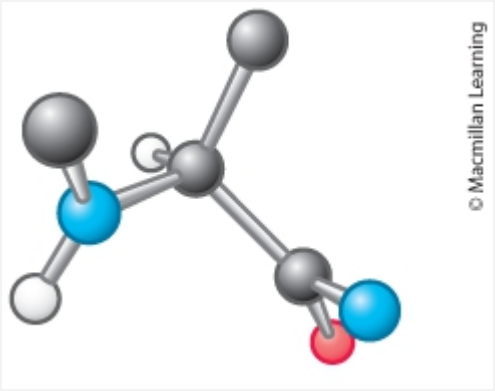
(A)

(a)
$\phi = 120$,
$\psi = 120$



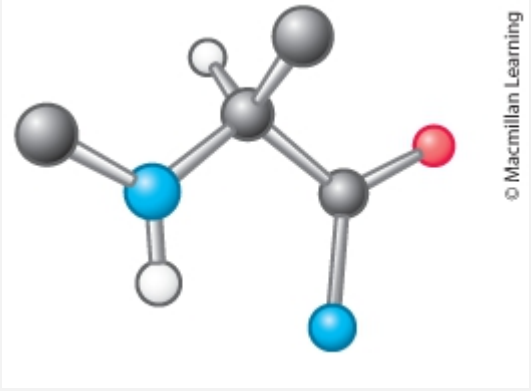
(B)

(b)
$\phi = 180$,
$\psi = 0$



(C)

(c)
$\phi = 180$,
$\psi = 180$



(D)

(d)
$\phi = 0$,
$\psi = 180$

(E)

(e)
$\phi = -60$,
$\psi = -40$

21. In the 1950s, Christian Anfinsen demonstrated the renaturation of the protein ribonuclease *in vitro*. After reduction and the addition of urea, the protein was in an unfolded state. After removing the urea and then the reducing agent, the protein oxidized and refolded, with greater than 90% activity. If reducing agent removal occurs before removing the urea, the protein showed less than 5% activity. Why does ribonuclease refold incorrectly if the reducing agent is removed before urea removal?

Chapter 3
Binding and Molecular Recognition

Stefan Christmann/naturepl.com
© Macmillan Learning

Penguins can recognize and find their mates even in a crowd of quite similar-looking and sounding birds. At the level of molecules, recognition plays a hugely important role in biochemical interactions. The complex shown above involves a protein that recognizes and binds extended amino acid sequences on other proteins and helps target them to the proper cellular compartment. The receptor protein can readily distinguish even minor differences in its target, such as the substitution of an isoleucine for a leucine.

Outline

3.1 Binding Is a Fundamental Process in Biochemistry
3.2 Myoglobin Binds and Stores Oxygen
3.3 Hemoglobin Is an Efficient Oxygen Carrier
3.4 The Immune System Depends on Key Binding Proteins

3.5 Quantitative Terms Can Describe Binding Propensity

Learning Goals

By the end of this chapter, you should be able to:

1. Explain in qualitative terms how the interaction between a receptor and a ligand that it binds depends on the concentration of the ligand.
2. Describe the key principles for the binding of oxygen by myoglobin and hemoglobin.
3. Discuss the concept of binding cooperativity and how it applies to hemoglobin, and how cooperativity enhances the ability of hemoglobin to function as a highly effective oxygen carrier.
4. Describe some key binding proteins in the immune system, including toll-like receptors, immunoglobulins, and major histocompatibility complex proteins, and how binding reactions involving these proteins function in the immune system.
5. Calculate parameters of binding reactions using the concentrations of the reactants and the characteristics such as the dissociation constant and kinetic rate constants.

Organisms and cells are packed with different kinds of small molecules, including building blocks and metabolites, as well as macromolecules including proteins and nucleic acids, all bustling around due to thermal motion. Yet, out of this chaos, order emerges with intricately organized assemblies on a range of scales and specific biochemical pathways that are the subject of much of this book. The key process that enables this organization is specific molecular binding. The ability of many biological macromolecules to bind a specific set of molecules out of extremely complicated mixtures is very unusual compared to the capacity of non-biological molecules and can seem astounding, but it is the consequence of chemical principles and the selective power of molecular evolution.

3.1 Binding Is a Fundamental Process in Biochemistry

Sets of molecules stick together so that they spend much more time together than they would without this binding, and this occurs despite the fact that there are many other potential binding partners around them. This ability for certain molecules to bind to one another in the face of many alternatives is often referred to as **molecular recognition**. Furthermore, this binding is specific in another way: the structures of the complexes formed have particular three-dimensional shapes. This enables the complexes to have well-defined properties including participating in other binding events and, in some cases, playing key roles in processes such as the transmission of information within and between cells.

In this chapter, we will focus primarily on two examples, likely familiar in some aspects of everyday life, to illustrate these principles. These are the oxygen storage and carrier proteins myoglobin and hemoglobin, and important proteins from the immune system, including antibodies. **Myoglobin** binds oxygen and stores it for use when muscles expend energy and need to convert molecules from food into useable forms. Myoglobin, by virtue of bound **heme**, is responsible for the color of red meat. **Hemoglobin** is a related heme-containing protein found in blood that acts as oxygen carrier, transporting oxygen that it binds in the lungs to tissues throughout the body. Hemoglobin is remarkably efficient in fulfilling this role. It binds and releases oxygen in a manner that is quite sensitive to the amount of available oxygen in its environment and also to pH and the presence of carbon dioxide. These binding properties allow hemoglobin to deliver oxygen specifically to tissues where it is most needed due to ongoing metabolic activity.

Our immune systems must respond to pathogens such as viruses and bacteria, even those to which we have never previously been exposed. Remarkably, our immune systems can generate proteins called *antibodies* that bind specifically to components of these pathogens. Each antibody has a set of polypeptide loops on its surface that are selected to facilitate binding to a particular pathogen component. The ability to generate an essentially infinite set of binding proteins by combining a limited set of component loops has kept members of our and other species protected in the face of an ever-evolving set of potentially deadly pathogens.

We begin with a discussion of some of the general characteristics of binding processes. For this, we will use examples related to the estrogen receptor, a key protein that functions physiologically by binding certain steroid hormones and is also the target of some important drugs and environmental pollutants.

Binding depends on the concentrations of the binding partners

Suppose we start with a receptor R, typically a protein, and add a potential binding partner, often referred to as a **ligand**, L. These might come together to form a complex, RL.

$$\mathrm{R} + \mathrm{L} \rightleftharpoons \mathrm{RL} \tag{1}$$

If R and L have a very strong tendency to bind to one another, then every molecule of L that is added will combine with a molecule of R, if one is available, to form a complex. As we add more L, this will continue until all of the R molecules are now in the RL form. On the other hand, if R and L have little tendency to combine, then, even if R and L collide, no complex will form as thermal motions will dominate. In between

these two limiting cases, some of the added L will combine with R to form RL while the remainder remains free. These cases are summarized in Figure 3.1.

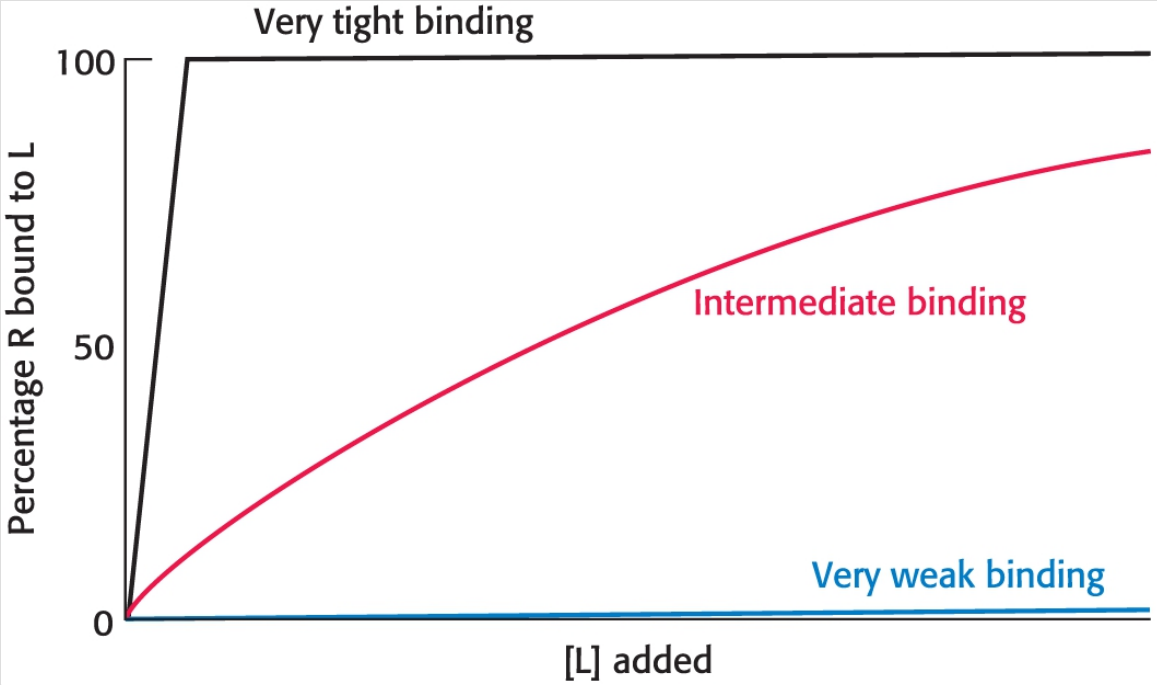


FIGURE 3.1 Comparing the percentage of receptor R bound to ligand L with the concentration of added L reveals how tightly R binds L.

Let us examine the case of intermediate binding in more detail. As more L is added, the probability that a given receptor molecule is bound to L gradually increases. A parameter that is useful for characterizing such curves is the concentration of L at which half of the receptor is bound to L and half is free. This is designated as $L_{1/2}$ in Figure 3.2. This parameter is useful because it reveals the concentration range of L around which the receptor makes the transition from being mostly free to mostly bound. We will explore these curves in more quantitative terms later in this chapter.

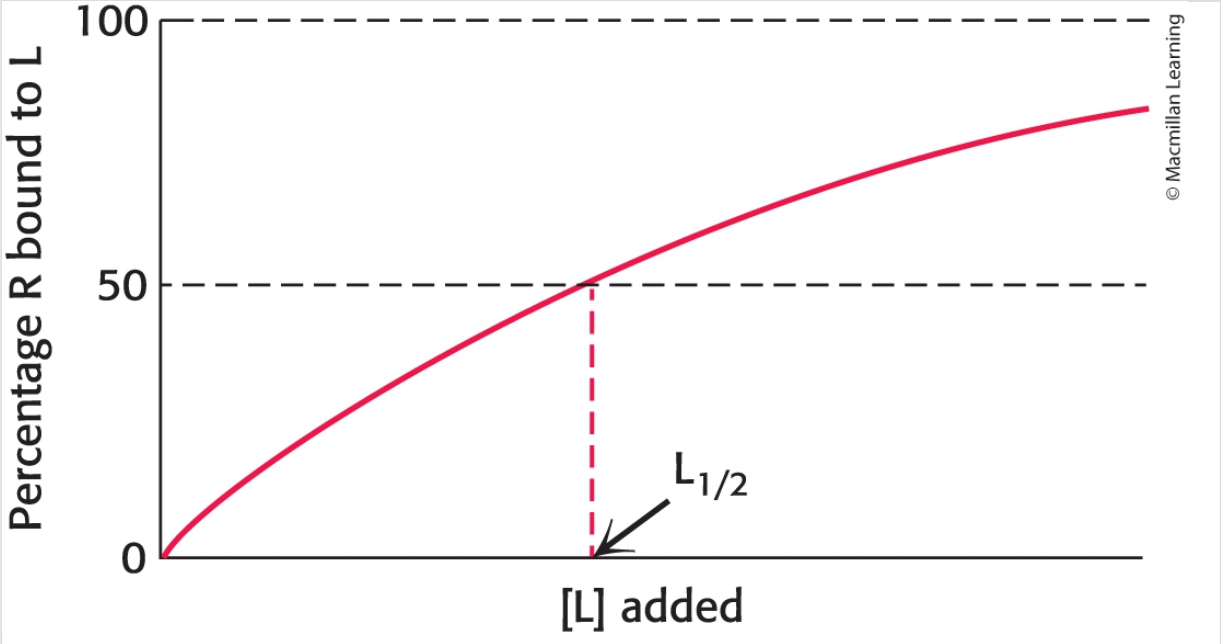

FIGURE 3.2 The binding of L to R can be characterized by $L_{1/2}$. The parameter $L_{1/2}$ is the concentration of L at which half (50%) of the total amount of R is bound to L.

Proteins can selectively bind certain small molecules

To put the importance of binding within biochemical systems in context, let us consider the estrogen receptor and its ligands. Estrogens are steroid hormones that play primary roles in the development of the female reproductive system and secondary sex characteristics. The most prevalent estrogen is β-estradiol or, more simply, estradiol (Figure 3.3). The first step in estrogen exerting its biological activity is binding to estrogen receptors. These receptors are present in tissues such as mammary glands and the endometrium. Estradiol binds to these receptors with an $L_{1/2}$ of approximately $1\ \text{nM}\ (10^{-9}\ \text{M})$. The amount of

estradiol in blood serum varies with age and time within the menstrual cycle, but on average it is around 1.1 nM, just in the range likely to trigger substantial receptor occupancy and activity.

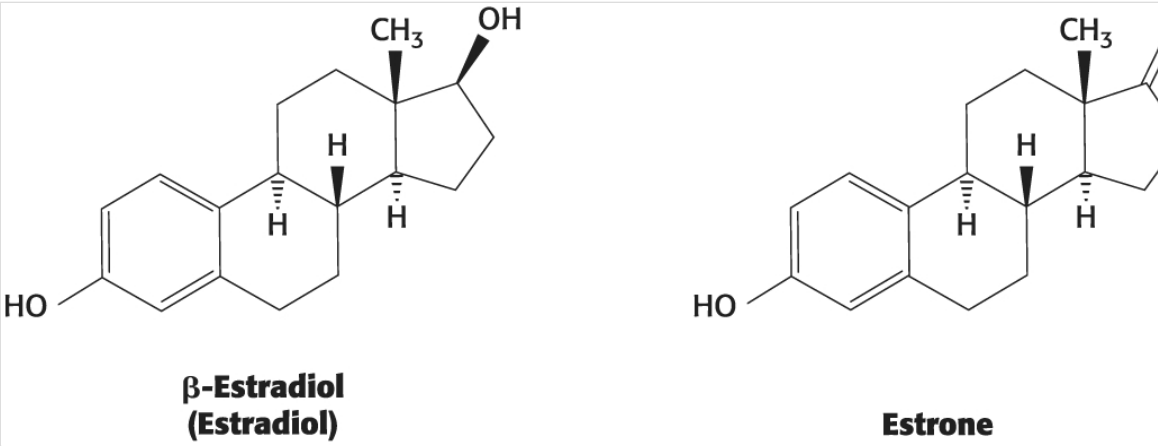

FIGURE 3.3 Estrogens are hormones that are bound by estrogen receptors. β-Estradiol is the most prevalent and potent estrogen, and estrone is one of a number of other estrogens that pla somewhat different biological roles.

This binding occurs despite the fact that serum contains thousands of different small molecules, many of which are present at concentrations higher than that for estradiol. For example, testosterone, a steroid hormone associated with the development of the male reproductive system and secondary sex characteristics, is present at concentrations comparable to or even higher than those for estradiol, even in women. However, the binding of testosterone to the estrogen receptor is very weak with $L_{1/2} > 1\mu M$, more than 1000 times larger than that for estradiol.

The ability of the estrogen receptor to recognize estradiol, that is, to discriminate between estradiol and testosterone, is impressive given the similarities in their structures (**Figure 3.4**). Both structures are based on the same four-ring framework characteristic of steroids. However, one six-membered ring (the A ring shown in Figure 3.4) in estrogens such as

estradiol is aromatic and, therefore, planar, whereas the corresponding ring in testosterone is not aromatic and is bonded to an additional methyl group absent in estrogens. Examination of the three-dimensional structure of the estrogen receptor bound to estradiol reveals that this protein has a narrow binding pocket lined with hydrophobic residues such as leucine and phenylalanine that fits neatly around the ligand but would likely sterically clash with thicker ligands such as testosterone. Moreover, the pocket includes groups that recognize both the oxygen and the hydrogen of the hydroxyl group in estradiol (Figure 3.5).

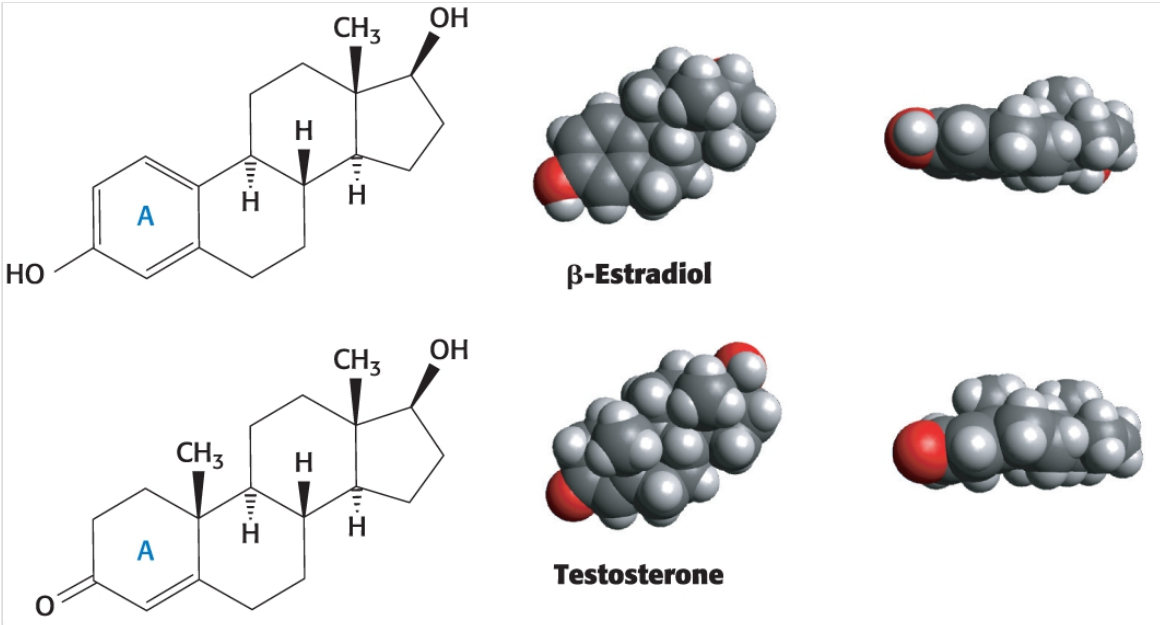

FIGURE 3.4 The steroid hormones β-estradiol and testosterone appear quite similar, yet receptors recognize the molecules as distinct. Their chemical structures are shown together with space-filling depictions from two orientations. The side views on the right reveal key differences in thickness that aid molecular recognition. The ring marked "A" is aromatic (and therefore planar) in β-estradiol, but not in testosterone.

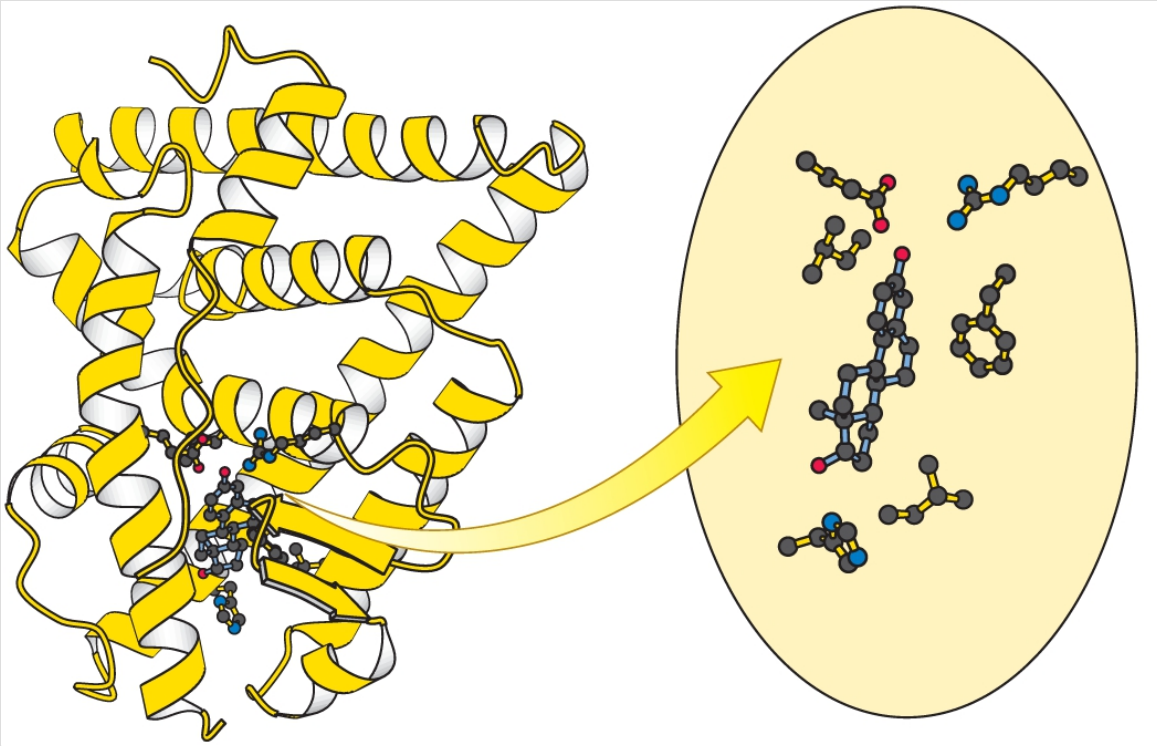

FIGURE 3.5 Proteins such as estrogen receptors include binding pockets that are complementary to the shapes of specific ligands. This enables the proteins to bind these ligands while rejecting ligands with even subtly different shapes. In the case of estrogen receptors, and some but not all proteins, some conformational changes occur upon ligand binding.

This ability of proteins such as the estrogen receptor to bind ligands selectively has been probed further through the use of synthetic compounds that share some characteristics with estrogens. For example, the two compounds in **Figure 3.6** are mirror images of each other by virtue of the orientation of a single methyl group. Despite this relatively small change in structure, these compounds are bound by the estrogen receptor with $\downarrow_{1/2}$ values that differ from one another by a factor of more than 20.

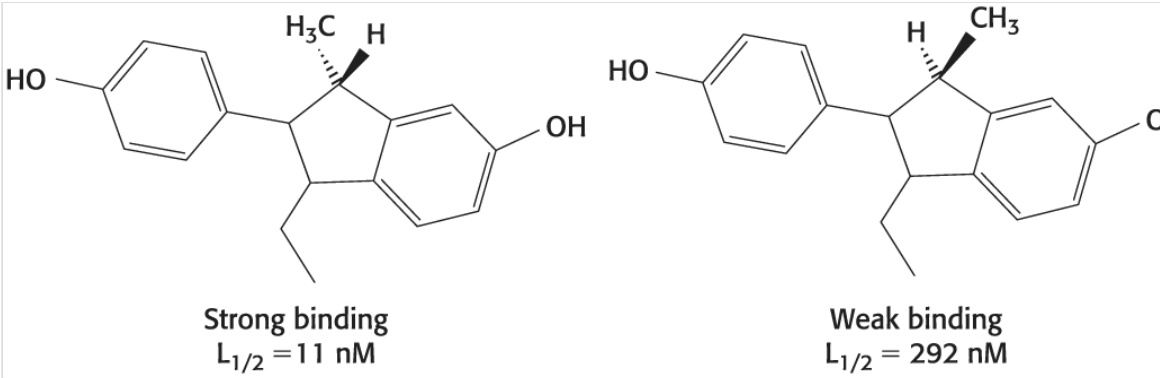

FIGURE 3.6 Even subtle features of ligands can be recognized. These two synthetic ligands for estrogen receptors are mirror images of one another, differing in the orientation of a single methyl group, yet they show substantial differences in how tightly they are bound by estrogen receptors.

This example of ligand binding by the estrogen receptor is typical of a great many proteins that we will encounter throughout this book. The ability to bind small molecules with selectivity allows proteins to pick particular molecules out of complicated mixtures to facilitate sensing of the presence of these molecules and, in some cases, to use the bound molecules for other purposes.

Self-Check Question

Human growth hormone is a protein with a molecular weight of approximately 22,000 grams/mol and a concentration in the bloodstreams of children in the range of 50 nanograms/ml. What is its molar concentration? What range would you anticipate for its $L_{1/2}$ value for the growth hormone receptor?

Binding is a dynamic process involving association and dissociation

At a given ligand concentration at equilibrium, the concentrations of receptor and receptor-ligand complex are constant. For example, when the ligand concentration is $L_{1/2}$, the concentrations of the receptor and the receptor-ligand complex are equal to one another and, therefore, equal to half of the total receptor concentration. Yet, each receptor is constantly releasing one ligand molecule and, subsequently, rebinding another (Figure 3.7). Thus, at equilibrium where the concentrations of all species are constant, underlying processes of association and dissociation occur.

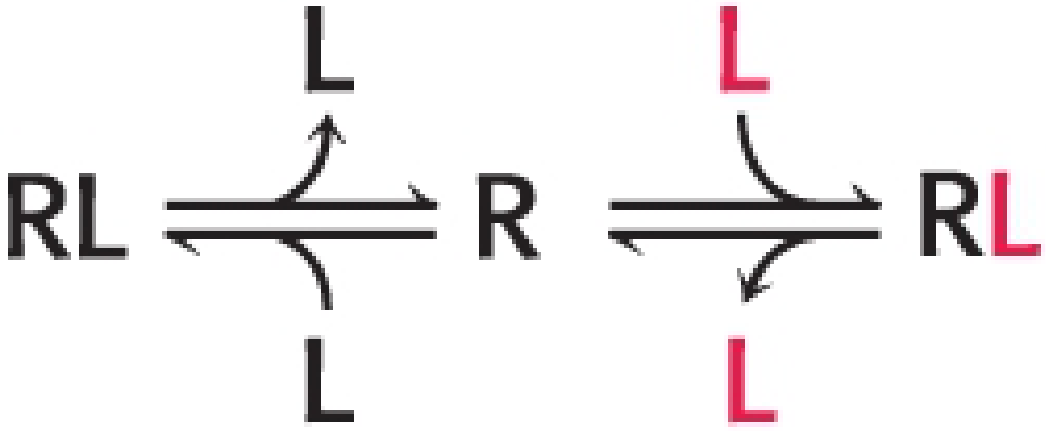

FIGURE 3.7 Dissociation and association are constantly occurring, even at equilibrium where the concentrations of all species are constant.

Returning to the estrogen receptor, experiments reveal that each receptor-estradiol complex releases its ligand on average once every 10 minutes. This relatively slow dissociation rate is related to the tight binding of estradiol to its receptor. At equilibrium, the dissociation and association rates must balance. Thus, if the estradiol concentration is

$1\ nM\ (L_{1/2})$, the rate of association between an unoccupied receptor and an estradiol molecule is also once every 10 minutes.

Self-Check Question

A testosterone derivative has been found to bind to the estrogen receptor with an $L_{1/2}$ of approximately $5\ \mu M$. When this compound is present at this concentration, the association rate with the estrogen receptor is estimated to be $5\ s^{-1}$. What is the expected dissociation rate?

3.2 Myoglobin Binds and Stores Oxygen

Myoglobin is a fairly abundant protein representing about 0.5% by weight in our muscles, and up to nearly 10% by weight in species such as sperm whales. This protein functions to bind and store oxygen, picking it up from the bloodstream and storing in muscle for use when needed. The abundance of myoglobin in sperm whale muscles is one of the adaptations that allows these marvelous creatures to dive very deep and to stay under water for up to two hours.

More myoglobin binds oxygen as the oxygen partial pressure is increased

We can characterize the oxygen-binding properties of myoglobin by observing its oxygen-binding curve, a plot of the fractional saturation versus the concentration of oxygen. The **fractional saturation** (Y) is defined as the fraction of possible binding sites that contain bound oxygen. The value of Y can range from 0 (all sites empty) to 1 (all sites filled). The concentration of oxygen is most conveniently measured by its partial pressure, pO_2. For myoglobin, a binding curve indicating a simple chemical equilibrium is observed (**Figure 3.8**). Notice that the curve rises sharply as pO_2 increases and then levels off. Half-saturation of the binding sites, referred to as P_{50} (analogous to $L_{1/2}$ introduced previously) occurs at approximately 2 torr (mm Hg) for human myoglobin. For context, the partial pressure of oxygen at sea level is around 150 torr. Thus, a P_{50} value of 2 torr reveals that myoglobin binds oxygen with high affinity.

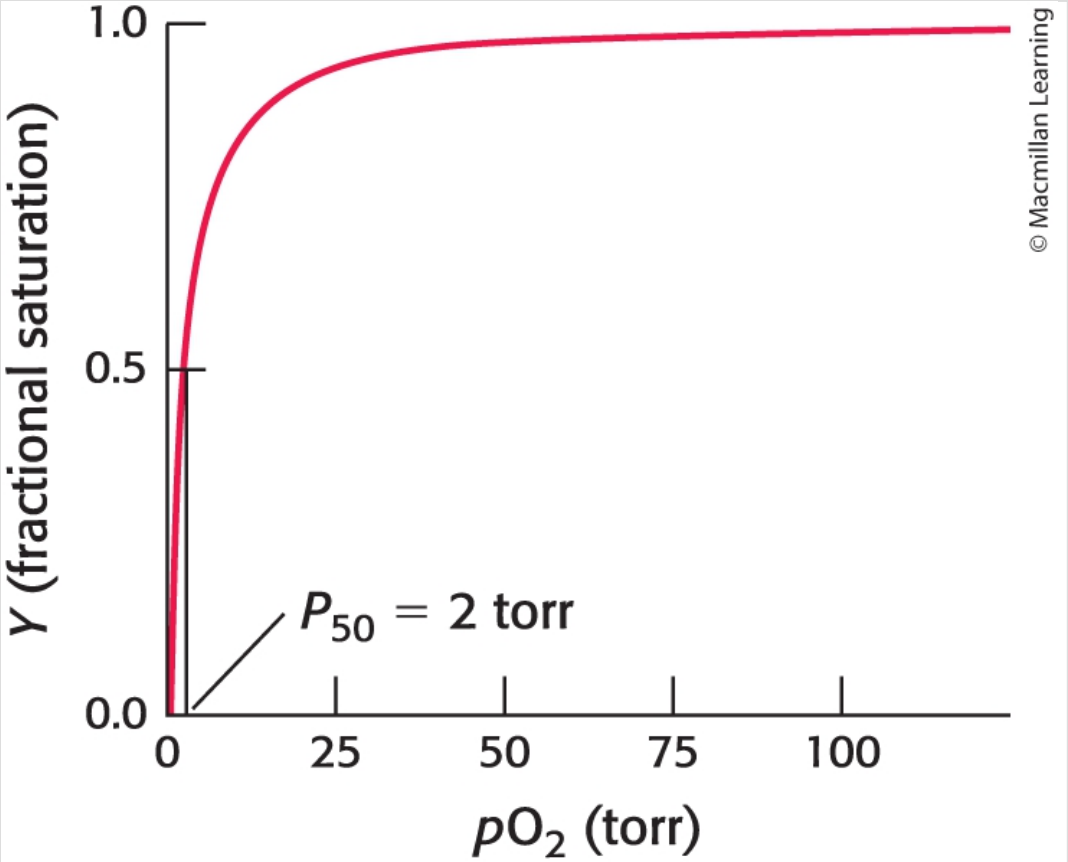

FIGURE 3.8 Half saturation of human myoglobin occurs when the partial pressure of oxygen is 2 torr. This point is revealed by plotting the fraction of myoglobin molecules that have oxygen bound (fractional saturation) as a function of the partial pressure of oxygen (pO_2).

A bond is formed between oxygen and iron in heme

Sperm whale myoglobin was the first protein for which the three-dimensional structure was determined (Figure 3.9). Myoglobin consists largely of α helices that are linked to one another by turns to form a globular structure. The ability of myoglobin to bind oxygen depends on

the presence of a *heme* molecule (Figure 3.10). The heme group consists of an organic component and a central iron atom. The organic component, called protoporphyrin IX, is made up of four linked pyrrole rings. The iron atom lies in the center of the protoporphyrin, bonded to the four pyrrole nitrogen atoms. The iron ion in myoglobin can form two additional bonds, one on each side of the heme plane. These binding sites are referred to as the fifth and sixth coordination sites. The fifth coordination site is occupied by the imidazole ring of a histidine residue from the protein, known as the **proximal histidine**.

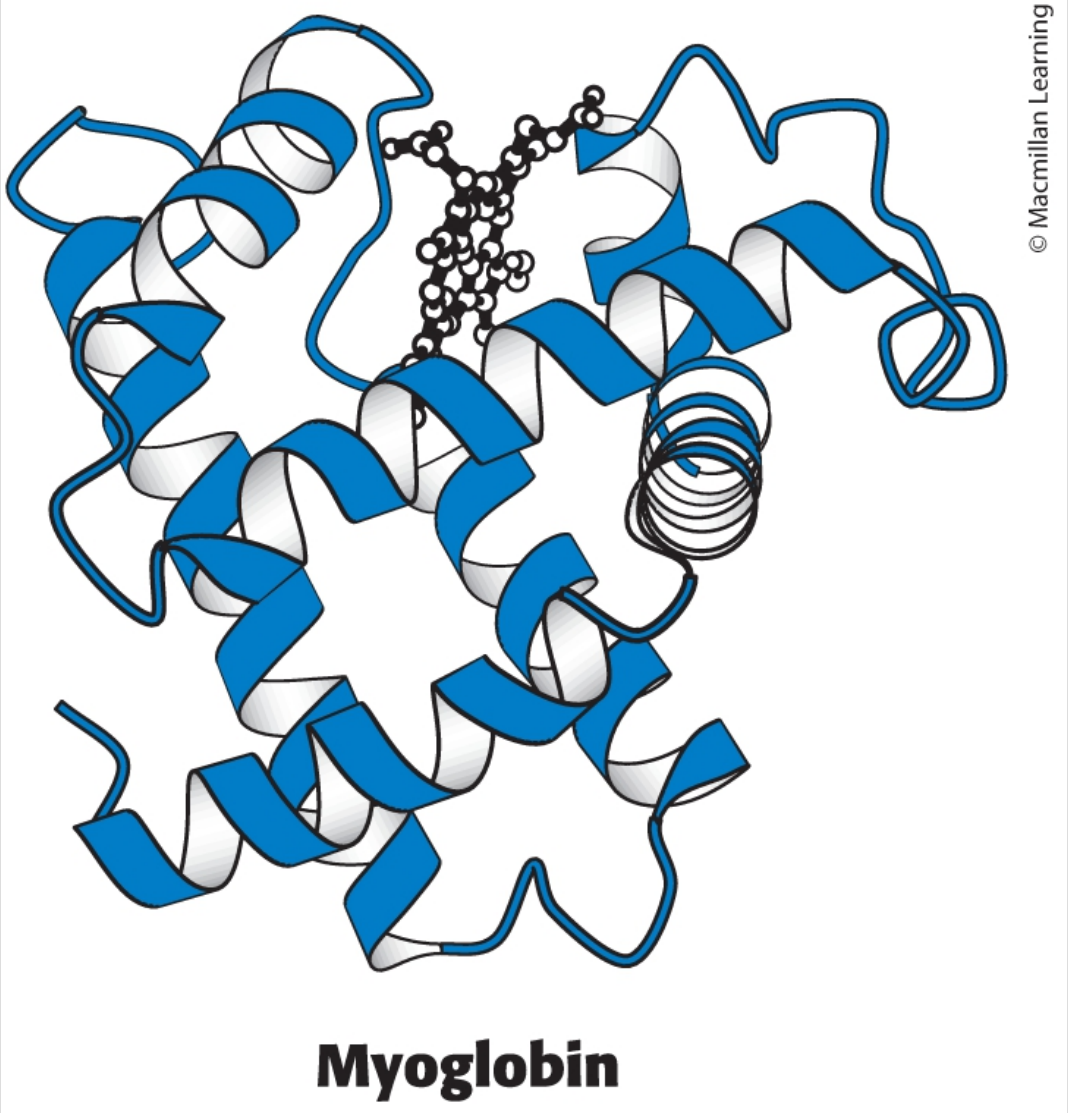

FIGURE 3.9 The structure of myoglobin consists primarily of α helices surrounding a heme molecule. The heme molecule functions as the oxygen-binding site.

INTERACT with this model in Achieve

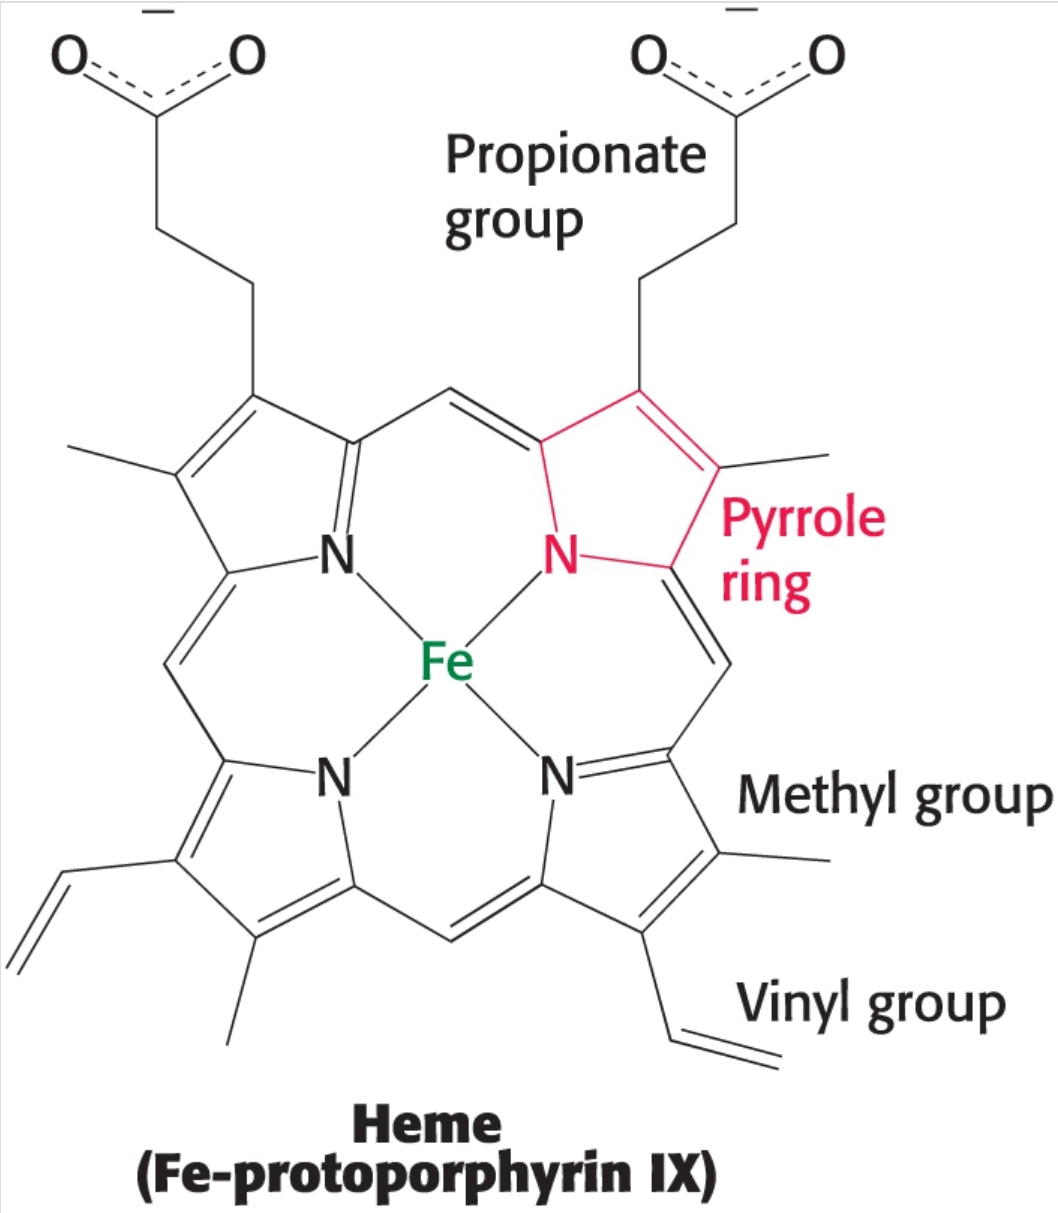

FIGURE 3.10 The structure of heme comprises four pyrrole rings that use their nitrogen atoms to bind to a central iron atom. Four methyl groups, two vinyl groups, and two propionate side chains are attached to the central tetrapyrrole.

Myoglobin can exist in an oxygen-free form called **deoxymyoglobin** or in a form with an oxygen molecule bound called **oxymyoglobin**. In deoxymyoglobin, the iron is in the ferrous (Fe^{2+}) oxidation state, and the sixth site remains unoccupied. The ferrous iron ion is slightly too large to fit into the well-defined hole within the porphyrin ring; it lies approximately $0.4\ \text{Å}$ outside the porphyrin plane (**Figure 3.11**).

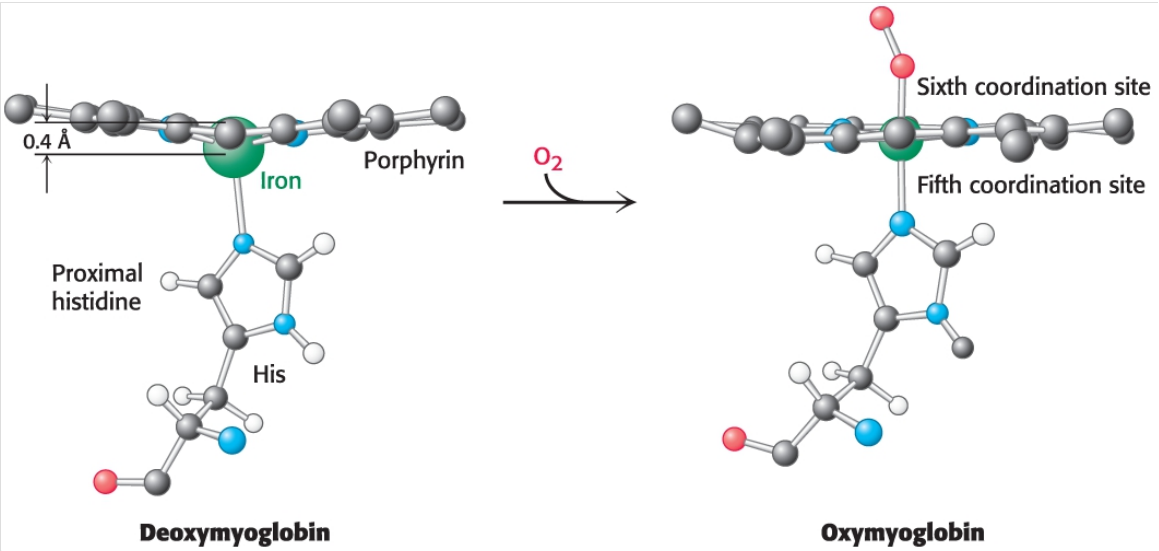

FIGURE 3.11 Oxygen binding changes the position of the heme iron ion. In deoxymyoglobin, t iron ion lies slightly outside the plane of the porphyrin and moves into the plane of the porphyr upon oxygen binding.

Oxymyoglobin forms when oxygen binding occurs at the sixth coordination site. This oxygen binding substantially rearranges the electrons within the iron so that the ion becomes effectively smaller, allowing it to move into the plane of the porphyrin (Figure 3.11, above).

Oxygen binding to iron in heme is accompanied by the partial transfer of an electron from the ferrous ion to oxygen. In many ways, the structure is best described as a complex between ferric ion (Fe^{3+}) and superoxide anion O_2^- (Figure 3.12).

FIGURE 3.12 The complex between iron and oxygen in myoglobin can be described by two resonance structures. One resonance structure has Fe^{2+} bound to dioxygen, and the other has Fe^{3+} bound to superoxide ion.

The structure of myoglobin prevents the release of reactive oxygen species

It is crucial that oxygen, when it is released, leaves as dioxygen rather than superoxide ion, for two important reasons. First, superoxide ion and other species generated from it are reactive oxygen species that can be damaging to many biological materials. Second, release of superoxide would leave the iron ion in the ferric state, producing a species, termed *metmyoglobin*, that does not bind oxygen. Thus, potential oxygen-storage capacity would be lost.

Features of myoglobin stabilize the oxygen complex such that superoxide is less likely to be released. In particular, the binding pocket

of myoglobin includes an additional histidine residue (termed the **distal histidine**) that donates a hydrogen bond from its imidazole group to the bound oxygen molecule (**Figure 3.13**).

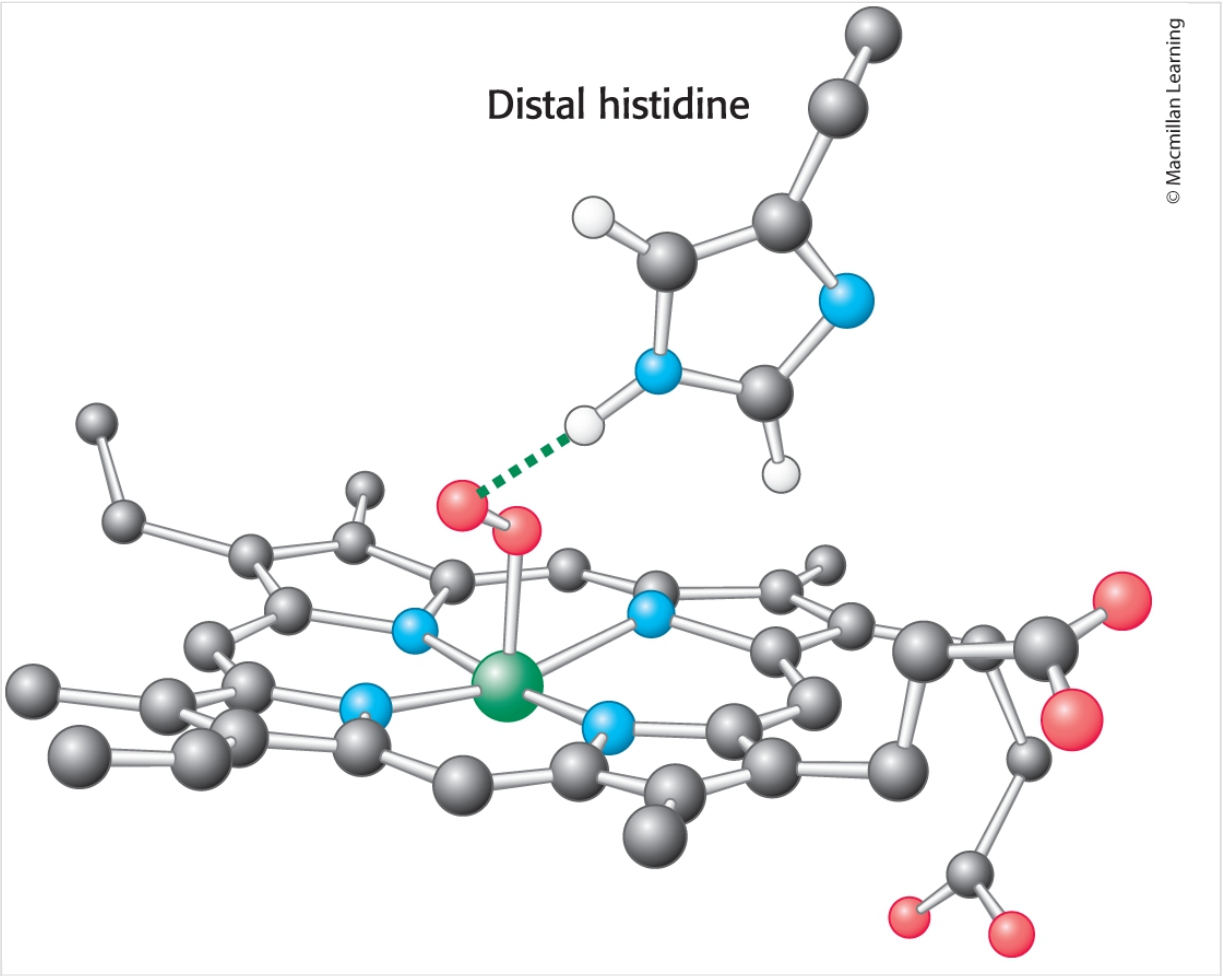

FIGURE 3.13 Bound oxygen is stabilized through a hydrogen bond between the distal histidine and one of the oxygen atoms. The hydrogen bond is shown as a dotted green line. The superoxide character of the bound oxygen species strengthens this interaction. Thus, the protein component of myoglobin controls the intrinsic reactivity of heme, making it more suitable for reversible oxygen binding.

Compared with model compounds, myoglobin discriminates between oxygen and carbon monoxide

While the available site on deoxymyoglobin allows oxygen binding, it also has the potential to enable combination with other molecules of similar size and binding characteristics. In particular, **carbon monoxide** (CO) is a potential competitor for this site. Indeed, this odorless gas can be deadly due to its ability to bind myoglobin and hemoglobin. Binding studies indicate that deoxymyoglobin binds CO very tightly, with a P_{50} of approximately 0.02 torr, a hundredfold tighter than oxygen (**Figure 3.14**). This is a potential problem, since oxygen cannot bind if CO is occupying the site. Environmental exposure to CO can result in blocking and inactivating both myoglobin and hemoglobin, the oxygen-carrying protein in the blood to be discussed shortly. In addition, some CO is produced by the body, ironically during the breakdown of heme, and this, too, can compete for oxygen-binding sites.

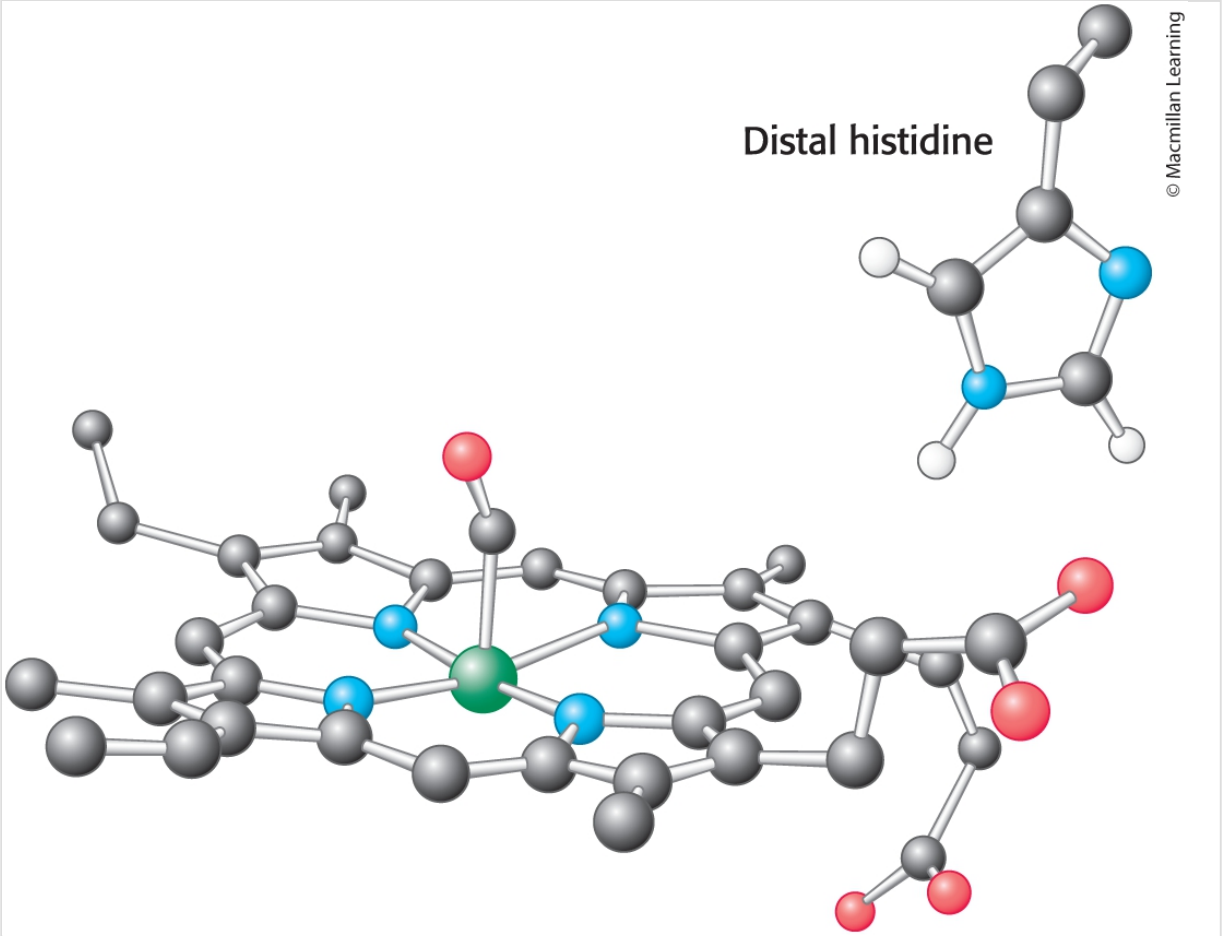

FIGURE 3.14 Carbon monoxide can bind to the iron ion in myoglobin, blocking the oxygen-binding site.

It may seem surprising that myoglobin does not discriminate better against CO given the potential risks of CO poisoning. Scientists have probed the chemical basis underlying this phenomenon using synthetic heme model compounds that mimic the essential characteristics of the myoglobin ligand-binding site. Some of these model compounds have affinities for oxygen similar to that for myoglobin, with a P_{50} of 0.6 torr. However, these model compounds bind CO with a P_{50} of 0.00002 torr; their affinity for CO is 30,000 times higher than that for oxygen. This suggests that myoglobin has evolved to show enhanced recognition of

oxygen versus CO but is limited by the much higher intrinsic affinity of iron for CO.

Site-directed mutagenesis studies of sperm whale myoglobin support this conclusion and highlight an important role of the distal histidine. Removal of the imidazole group by the replacement of histidine with glycine results in a protein that binds oxygen approximately 13 times less tightly than does the wide-type protein but binds CO five times more tightly. This combination decreases the recognition of oxygen over CO by a factor of 65. Other substitutions can increase this factor further. These results reveal a major mechanism by which myoglobin has evolved to improve recognition of a key ligand.

3.3 Hemoglobin Is an Efficient Oxygen Carrier

As we have seen, myoglobin functions as an oxygen storage protein. Hemoglobin serves a more complicated role as an oxygen carrier. This role requires considerable sophistication, as this protein must bind oxygen in the lungs and then release as much oxygen as possible to tissues, particularly where it is most needed. We shall see that the oxygen-binding properties of hemoglobin differ from those of simpler proteins like myoglobin, and how additional ligands including carbon dioxide and hydrogen ions can influence these binding properties. Hemoglobin serves as an archetype for many other proteins with complicated properties that we will encounter throughout the book.

Human hemoglobin is an assembly of four myoglobin-like subunits

The three-dimensional structure of hemoglobin from horse heart was solved by Max Perutz and colleagues shortly after the determination of myoglobin's structure. Since then, the structures of hemoglobins from other species, including humans, have been determined. Hemoglobin consists of four polypeptide chains, two identical α chains, and two identical β chains (**Figure 3.15**). Each of the subunits consists of a set of α helices in the same arrangement as the α helices in myoglobin. The recurring structural motif is called a globin fold.

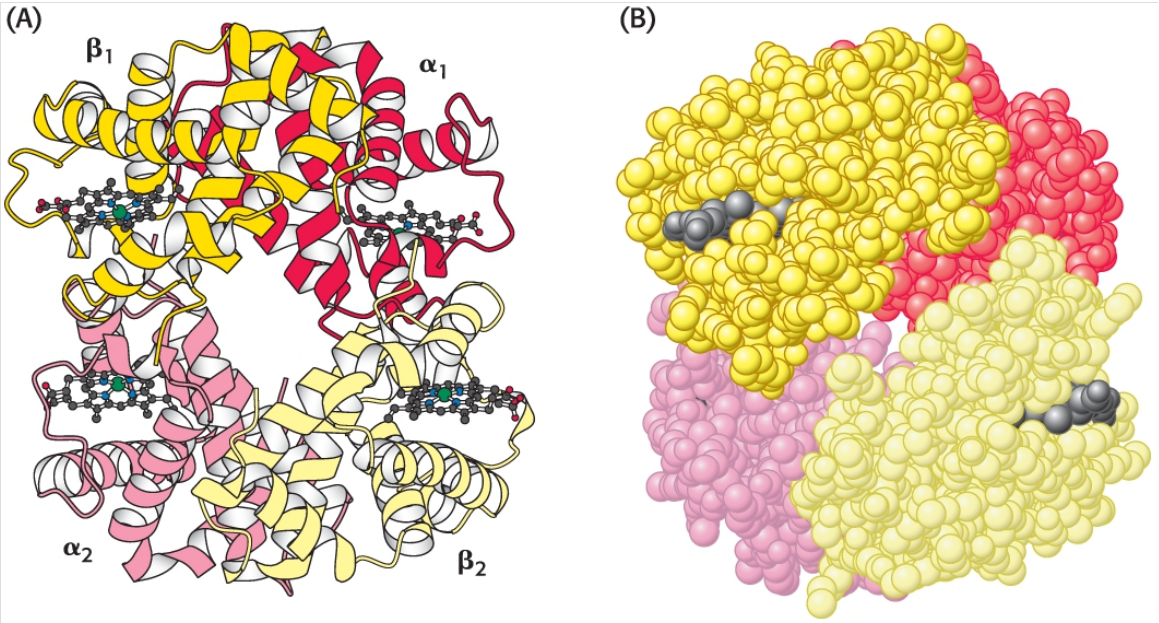

FIGURE 3.15 Hemoglobin is an assembly of four subunits, each of which is very similar to myoglobin. There are two α subunits and two β subunits that come together to form two αβ dimers. (A) A ribbon diagram. (B) A space-filling model.

INTERACT with this model in Achieve

The hemoglobin tetramer, referred to as hemoglobin A (HbA), is best described as a homodimer of heterodimers, that is, a pair of identical αβ dimers ($\alpha_1\beta_1$ and $\alpha_2\beta_2$) that associate to form the tetramer. In deoxyhemoglobin, these αβ dimers are linked by an extensive interface, which includes the carboxyl terminus of each chain. The heme groups are well separated in the tetramer by iron–iron distances ranging from 24 to 40 Å.

Hemoglobin binds oxygen cooperatively

The oxygen-binding curve for hemoglobin in red blood cells shows some remarkable features (Figure 3.16). It does not look like a simple binding curve such as that for myoglobin; instead, it resembles an "S." Such curves are described as **sigmoid** for their S-like shape. In addition, oxygen binding for hemoglobin $(P_{50} = 26\ \text{torr})$ is significantly weaker than that for myoglobin. Note that this binding curve is derived from hemoglobin in red blood cells.

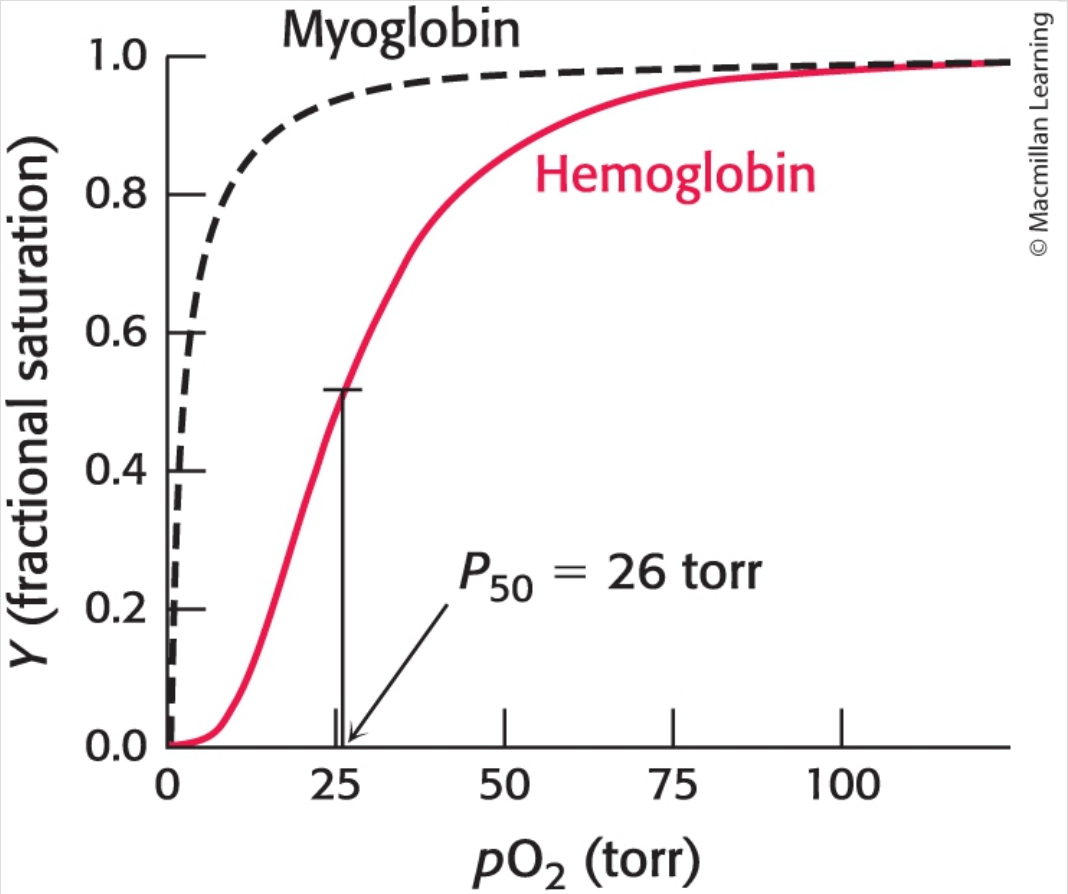

FIGURE 3.16 The oxygen-binding curve for hemoglobin, with its sigmoid (S-like) shape, is markedly different from that for myoglobin. The P_{50} value for hemoglobin is 26 torr compared with 2 torr for myoglobin.

A sigmoid binding curve indicates that a protein exhibits a particular binding behavior. For hemoglobin, the sigmoid shape suggests that the binding of oxygen at one site within the hemoglobin tetramer increases the likelihood that oxygen binds at the remaining unoccupied sites. Conversely, the unloading of oxygen at one heme facilitates the unloading of oxygen at the others. This sort of binding behavior is referred to as *cooperative*, because the binding reactions at individual sites in each hemoglobin molecule are not independent of one another. We have seen cooperativity in a different context, protein folding, where folding of one part of a protein is not independent of the folding of other parts. We will return to the mechanism of oxygen-binding cooperativity shortly.

What is the physiological significance of the cooperative binding of oxygen by hemoglobin?

- *Cooperative binding leads to efficient oxygen transport*. Oxygen must be transported in the blood from the lungs, where the partial pressure of oxygen is relatively high (approximately 100 torr), to the actively metabolizing tissues, where the partial pressure of oxygen is much lower (typically, 20 torr). Let us consider how the cooperative behavior indicated by the sigmoid curve leads to efficient oxygen transport (**Figure 3.17**). In the lungs, hemoglobin becomes nearly saturated with oxygen such that 98% of the oxygen-binding sites are occupied. When hemoglobin moves to the tissues and releases oxygen, the saturation level drops to 32%. Thus, a total of 66% (98% − 32%) of the potential oxygen-binding sites contribute to oxygen transport.

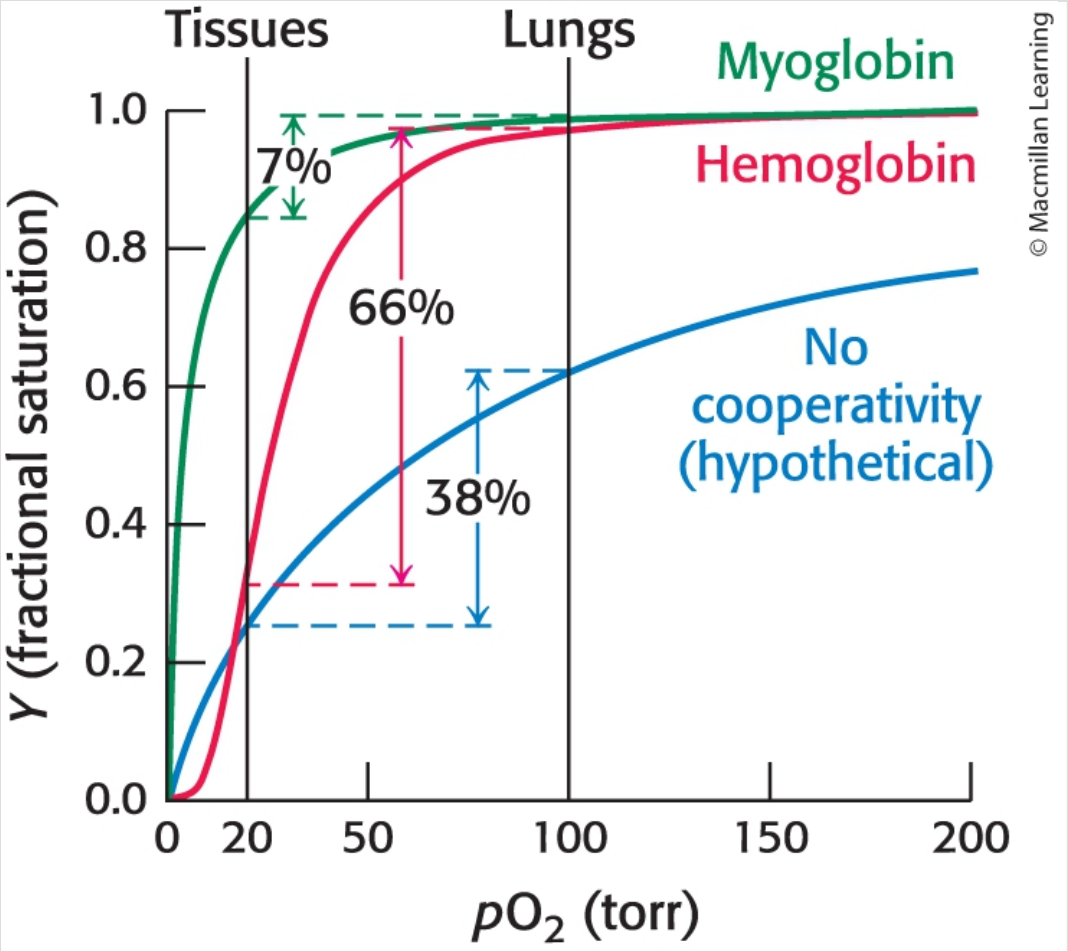

FIGURE 3.17 Cooperativity enhances oxygen delivery by hemoglobin. Because of cooperativity between oxygen-binding sites, hemoglobin delivers more oxygen to actively metabolizing tissues than would myoglobin or, indeed, any noncooperative protein, even with an optimized oxygen affinity.

- *Cooperative release of oxygen favors more complete delivery to tissues.* The cooperative release of oxygen favors a more complete unloading of oxygen in the tissues. If myoglobin were employed for oxygen transport, it would be 98% saturated in the lungs but would remain 91% saturated in the tissues, and so only 7% of the sites would contribute to oxygen transport; myoglobin binds oxygen too tightly to be useful in oxygen transport. Nature might have solved this problem by weakening the affinity of myoglobin for oxygen to

maximize the difference in saturation between 20 and 100 torr. However, for such a protein, the most oxygen that could be transported from a region in which pO_2 is 100 torr to one in which it is 20 torr is 38% (63% − 25%), as indicated by the blue curve in Figure 3.17. Thus, the cooperative binding and release of oxygen by hemoglobin enables it to deliver nearly 10 times as much oxygen as could be delivered by myoglobin and more than 1.7 times as much as could be delivered by an optimized noncooperative protein.

- *Oxygen is delivered to tissues where it is most needed.* Closer examination of oxygen concentrations in tissues at rest and during exercise underscores the effectiveness of hemoglobin as an oxygen carrier (**Figure 3.18**). Under resting conditions, the oxygen concentration in muscle is approximately 40 torr, but during exercise the concentration is reduced to 20 torr. In the decrease from 100 torr in the lungs to 40 torr in resting muscle, the oxygen saturation of hemoglobin is reduced from 98% to 77%, and so 21% of the oxygen is released over a drop of 60 torr. In a decrease from 40 torr to 20 torr, the oxygen saturation is reduced from 77% to 32%, corresponding to an oxygen release of 45% over a drop of 20 torr. Thus, because the change in oxygen concentration from rest to exercise corresponds to the steepest part of the oxygen-binding curve, oxygen is effectively delivered to tissues where it is most needed. Later, we shall examine other properties of hemoglobin that enhance its physiological responsiveness.

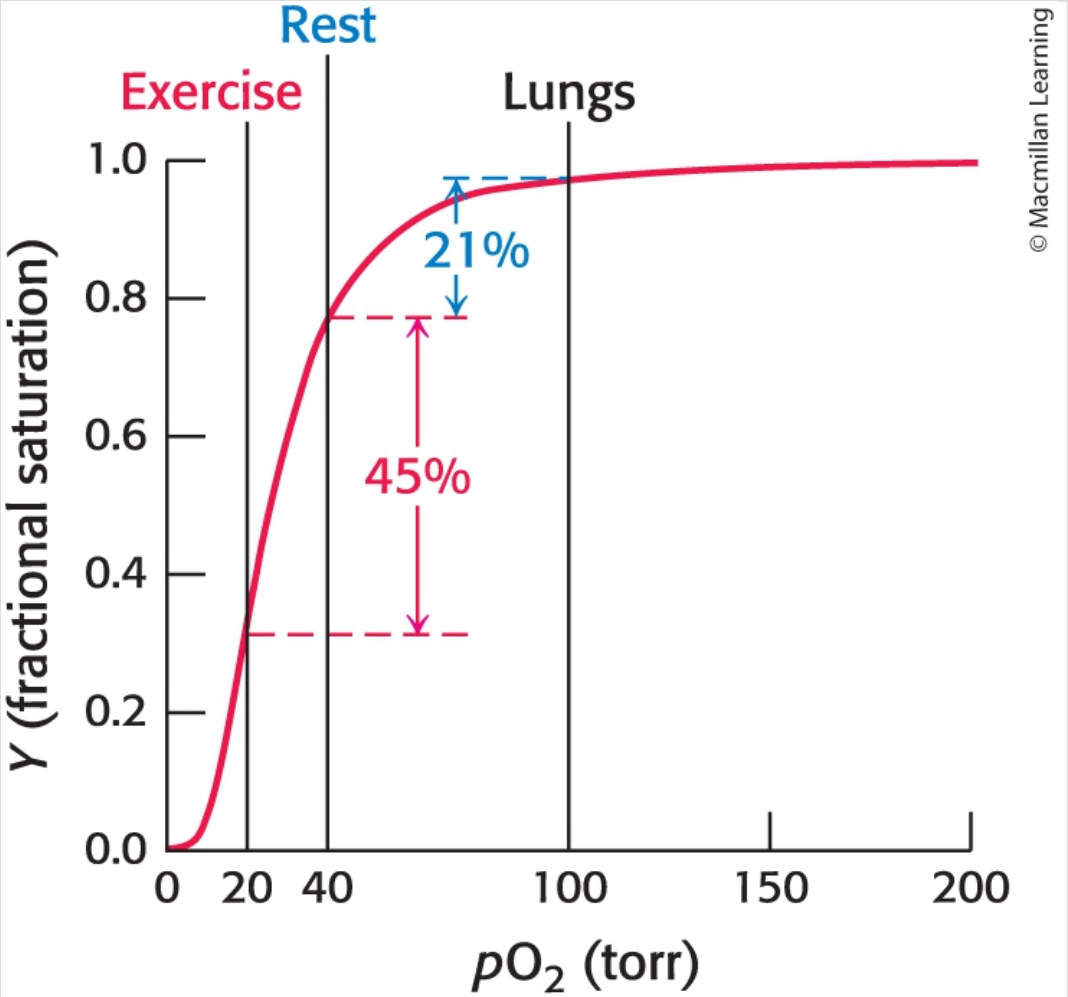

FIGURE 3.18 Oxygen delivery by hemoglobin responds to exercise. The drop in oxygen concentration from 40 torr in resting tissues to 20 torr in exercising tissues corresponds to the steepest part of the oxygen-binding curve. This allows a substantial quantity of oxygen to be released to exercising tissues.

Oxygen binding markedly changes the quaternary structure of hemoglobin

The cooperative binding of oxygen by hemoglobin requires that the binding of oxygen at one site in the hemoglobin tetramer influences the

oxygen-binding properties at the other sites. Given the large separation between the iron sites, direct interactions are not possible. Thus, indirect mechanisms for coupling the sites must be at work. These mechanisms are intimately related to the quaternary structure of hemoglobin.

Hemoglobin undergoes substantial changes in quaternary structure on oxygen binding: the $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers rotate approximately 15 degrees with respect to one another (Figure 3.19). The dimers themselves are relatively unchanged, although there are localized conformational shifts. Thus, the interface between the $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers is most affected by this structural transition. In particular, the $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers are more free to move with respect to one another in the oxygenated state than they are in the deoxygenated state.

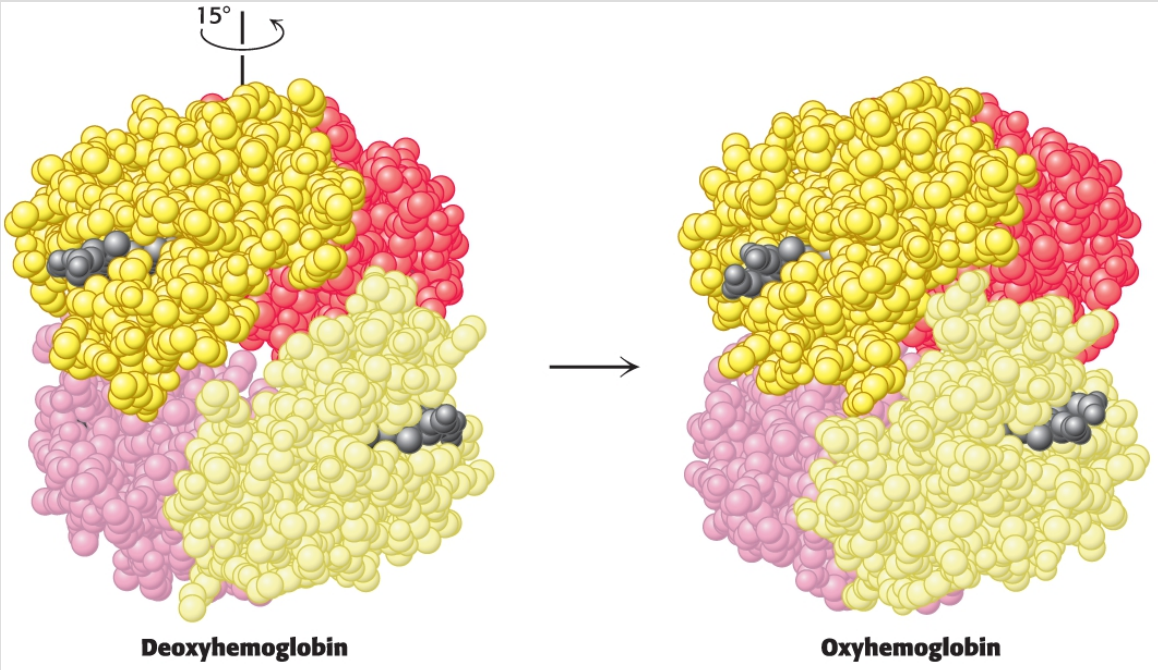

FIGURE 3.19 Substantial quaternary structural changes occur in hemoglobin upon oxygen binding. Comparing the structures of deoxyhemoglobin and oxyhemoglobin reveals that one α
dimer has rotated by 15 degrees relative to the other.

INTERACT with this model in Achieve

The quaternary structure observed in the deoxy form of hemoglobin, **deoxyhemoglobin**, is often referred to as the **T state** (T for *tense*), because it is quite constrained by subunit–subunit interactions. In contrast, the quaternary structure of the fully oxygenated form, **oxyhemoglobin**, is referred to as the **R state** (R for *relaxed*). In light of the observation that the R form of hemoglobin is less constrained, the tense and relaxed designations seem particularly apt. Importantly, in the R state, the oxygen-binding sites are free of strain and are capable of binding oxygen with higher affinity than are the sites in the T state. By triggering the shift of the hemoglobin tetramer from the T state to the R state, the binding of oxygen to one site increases the binding affinity of other sites.

Hemoglobin cooperativity can be potentially explained by several models

Two limiting models have been developed to explain the cooperative binding of ligands to a multisubunit assembly such as hemoglobin. In the **concerted model**, also known as the MWC model after Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux, who first proposed it, the overall assembly can exist only in two forms: the T state and the R state. The binding of ligands simply shifts the equilibrium between these two states (**Figure 3.20**). Thus, as a hemoglobin tetramer binds each oxygen molecule, the probability that the tetramer is in the R state increases. Deoxyhemoglobin tetramers are almost exclusively in the T state. However, the binding of oxygen to one site in the molecule shifts the equilibrium toward the R state. If a molecule assumes the R quaternary structure, the oxygen affinity of its sites increases.

Additional oxygen molecules are now more likely to bind to the three unoccupied sites. Thus, the binding curve for hemoglobin can be seen as a combination of the binding curves that would be observed if all molecules remained in the T state or if all of the molecules were in the R state. As oxygen molecules bind, the hemoglobin tetramers convert from the T state into the R state, yielding the sigmoid binding curve so important for efficient oxygen transport (Figure 3.21).

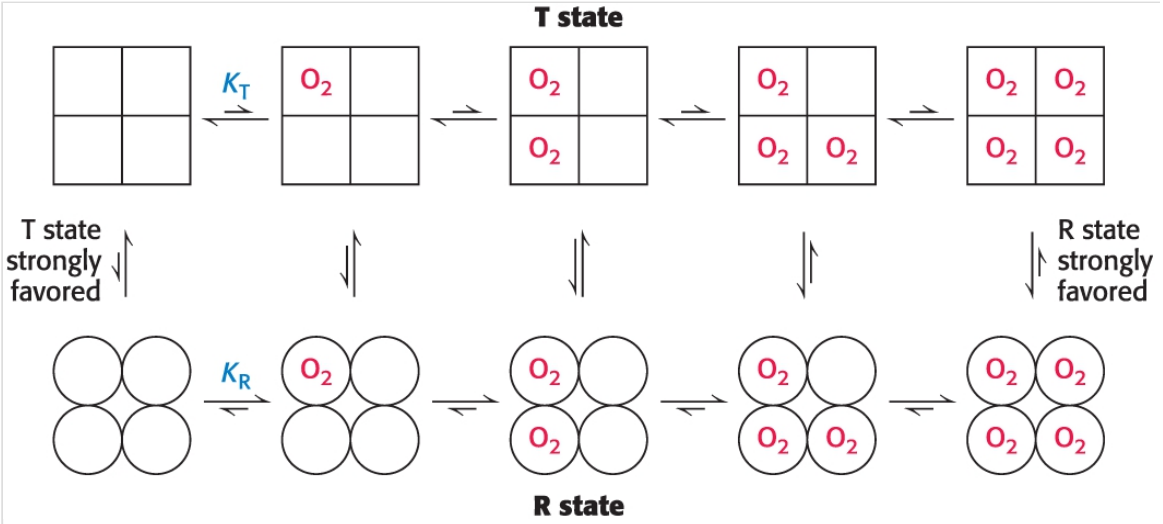

FIGURE 3.20 A concerted model can explain cooperative oxygen binding by hemoglobin. The hemoglobin tetramer can exist in the T state or the R state. With no oxygen bound, the equilibrium between these states strongly favors the T state. As each oxygen binds, the equilibrium shifts so that when all four sites have oxygen bound, the equilibrium strongly favors the R state. Binding sites in the R state have a higher affinity for oxygen than those in the T state

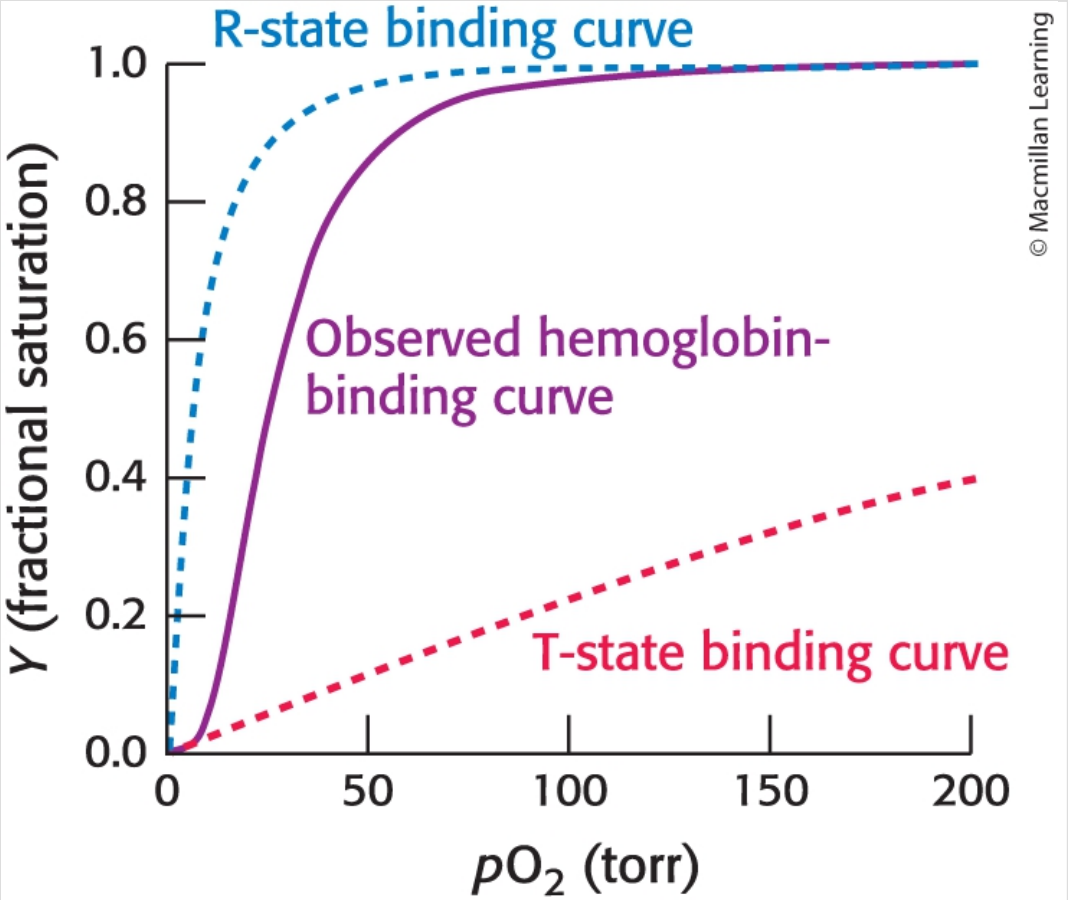

FIGURE 3.21 The sigmoid oxygen-binding curve of hemoglobin can be seen as a combination of the T state binding curve and the R state binding curve. As oxygen binds, more hemoglobin tetramers are converted from the T state to the R state, increasing the oxygen affinity of the available binding sites.

In the concerted model, each tetramer can exist in only two states—the T state and the R state. In an alternative model, the **sequential model**, the binding of a ligand to one site in an assembly increases the binding affinity of neighboring sites without inducing a full conversion from the T into the R state (**Figure 3.22**).

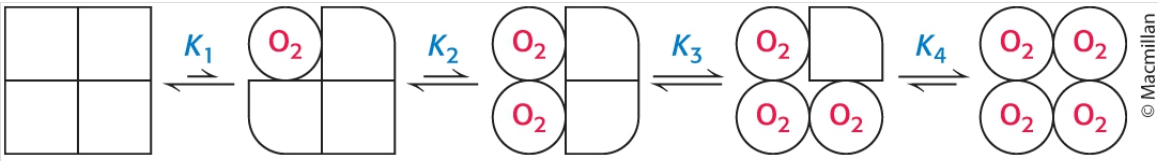

FIGURE 3.22 A sequential model can account for oxygen-binding cooperativity. As each oxyge molecule binds to one site in the hemoglobin tetramer, the affinities of the remaining sites increase, resulting in a sigmoidal binding curve.

Is the cooperative binding of oxygen by hemoglobin better described by the concerted or the sequential model? Neither model in its pure form fully accounts for all of the behavior of hemoglobin. Instead, a combined model is required. Hemoglobin behavior is concerted in that the tetramer with three sites occupied by oxygen is almost always in the quaternary structure associated with the R state. The remaining open binding site has an affinity for oxygen more than 20-fold greater than that of fully deoxygenated hemoglobin binding its first oxygen. However, the behavior is not fully concerted, because hemoglobin with oxygen bound to only one of four sites remains primarily in the T-state quaternary structure. Yet, this molecule binds oxygen three times as strongly as does fully deoxygenated hemoglobin, an observation consistent only with a sequential model. These results highlight the fact that the concerted and sequential models represent idealized limiting cases, which real systems may approach but rarely attain.

Self-Check Question

Which is higher: (a) the affinity of a deoxyhemoglobin molecule for its first oxygen, or (b) the affinity of a hemoglobin molecule with three bound oxygens for its last oxygen?

Structural changes at the heme groups are transmitted to the $\alpha_1\beta_1$-$\alpha_2\beta_2$ interface

We will now examine how oxygen binding at one site is able to shift the equilibrium between the T and R states of the entire hemoglobin tetramer. As in myoglobin, oxygen binding causes each iron atom in hemoglobin to move from outside the plane of the porphyrin into the plane. When the iron atom moves, the proximal histidine residue moves with it. This histidine residue is part of an α helix, which also moves (Figure 3.23). The carboxyl terminal end of this α helix lies in the interface between the two αβ dimers. The change in position of the carboxyl terminal end of the helix favors the T-to-R transition. Consequently, the structural transition at the iron ion in one subunit is directly transmitted to the other subunits. The rearrangement of the dimer interface provides a pathway for communication between subunits, enabling the cooperative binding of oxygen.

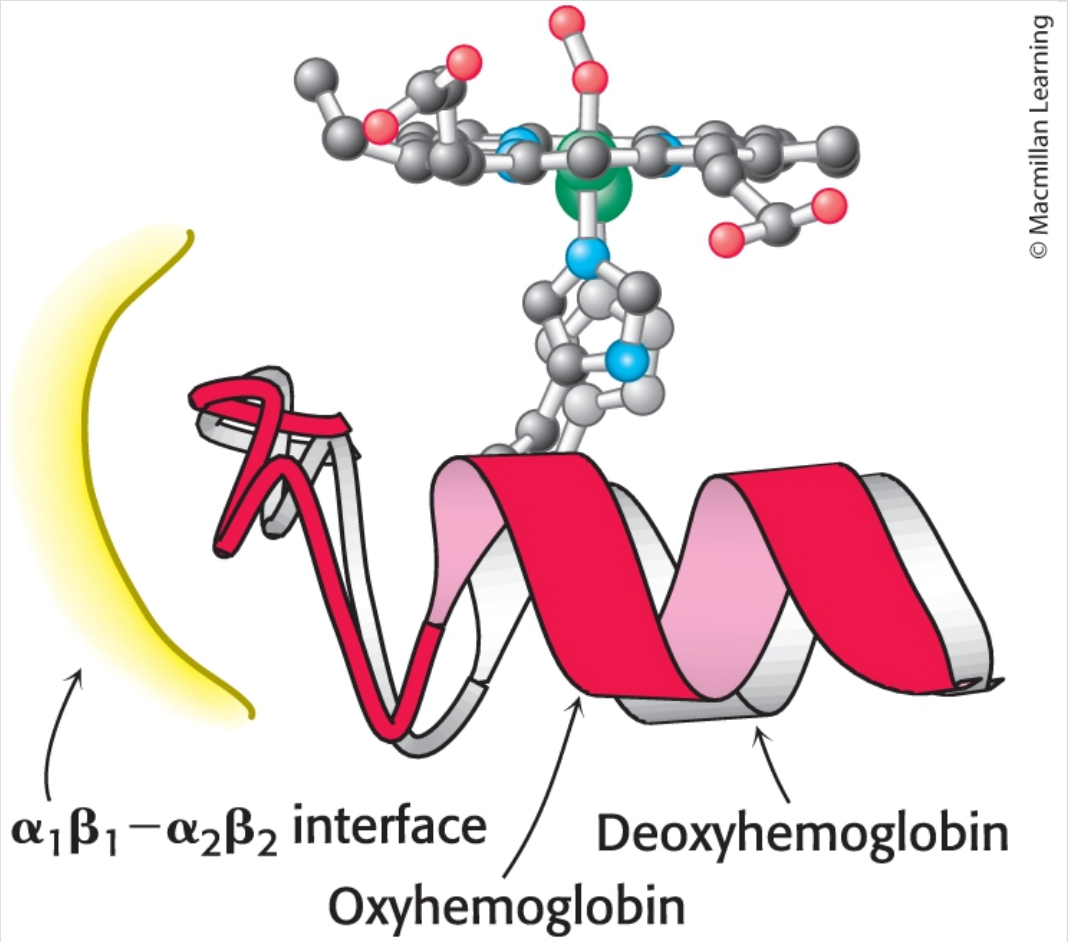

FIGURE 3.23 Oxygen binding causes the iron to move into the porphyrin. The motion of the iron pulls the proximal histidine and the associated helix, transmitting the structure change to the $\alpha_1\beta_1-\alpha_2\beta_2$ interface. The structure of oxyhemoglobin is shown in red on top of that for deoxyhemoglobin, in gray.

This mechanism predicts that if the bonds connecting the proximal histidines to the α helices were to be severed, then the resulting hemoglobin molecules would bind oxygen with relatively high affinity, retain the T quaternary structure even upon oxygen binding, and show no or substantially less cooperativity. This thought experiment has actually been realized by replacing the proximal histidines with glycines and adding free imidazole, which binds to the iron ion in place of the histidine side chain (Figure 3.24). Such binding studies, along with

structural studies, have confirmed this prediction, although some cooperativity remains, indicating that some other pathways for inter-subunit communication must be present.

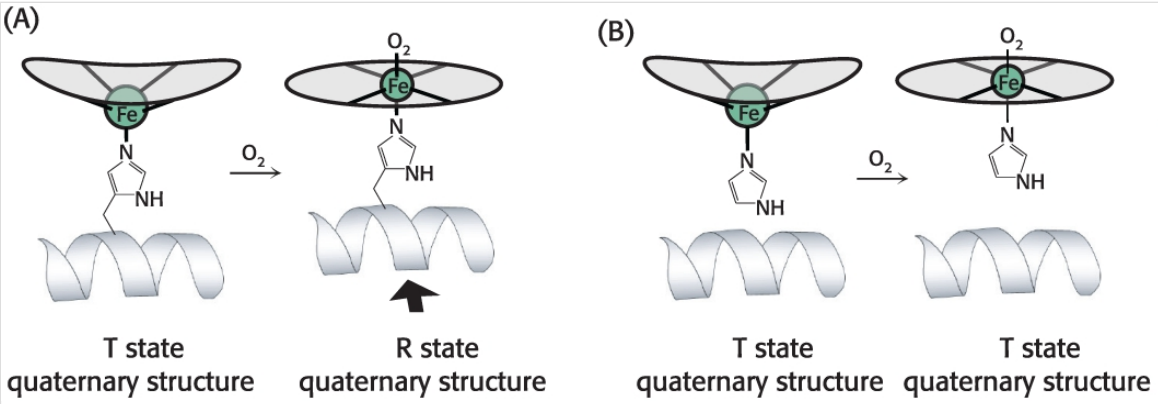

FIGURE 3.24 The movement of the proximal histidine and its associated α helix upon oxygen binding drives cooperativity. (A) In normal hemoglobin, the structural changes at iron upon oxygen binding in normal hemoglobin result in motion of the α helix that includes the proximal histidine, indicated by the arrow. (B) In hemoglobin, with the proximal histidine replaced with glycine with added imidazole bound to iron, oxygen binding results in the same changes at iron but the motion of the α helix does not occur.

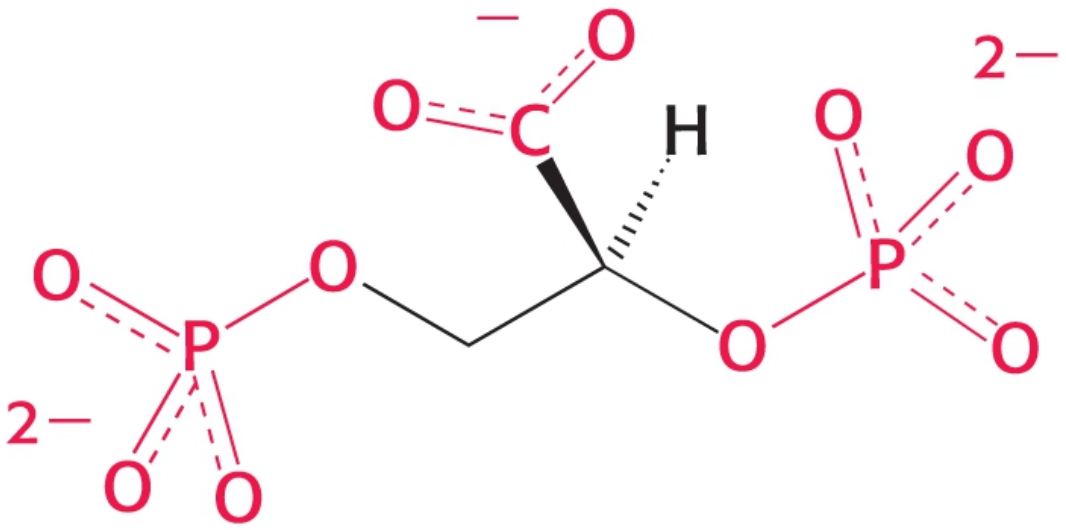

Self-Check Question

Why is the oxygen affinity of the hemoglobin variant with the proximal histidines detached (as shown in Figure 3.24) relatively high?

2,3-Bisphosphoglycerate in red blood cells is crucial in determining the oxygen affinity of

hemoglobin

The oxygen-binding curves for hemoglobin shown up to this point have been for hemoglobin in red blood cells. Surprisingly, highly purified hemoglobin binds oxygen much more tightly than does hemoglobin in red blood cells (Figure 3.25). This dramatic difference is due to the presence within red blood cells of 2,3-bisphosphoglycerate (2,3-BPG).

2,3-Bisphosphoglycerate (2,3-BPG)

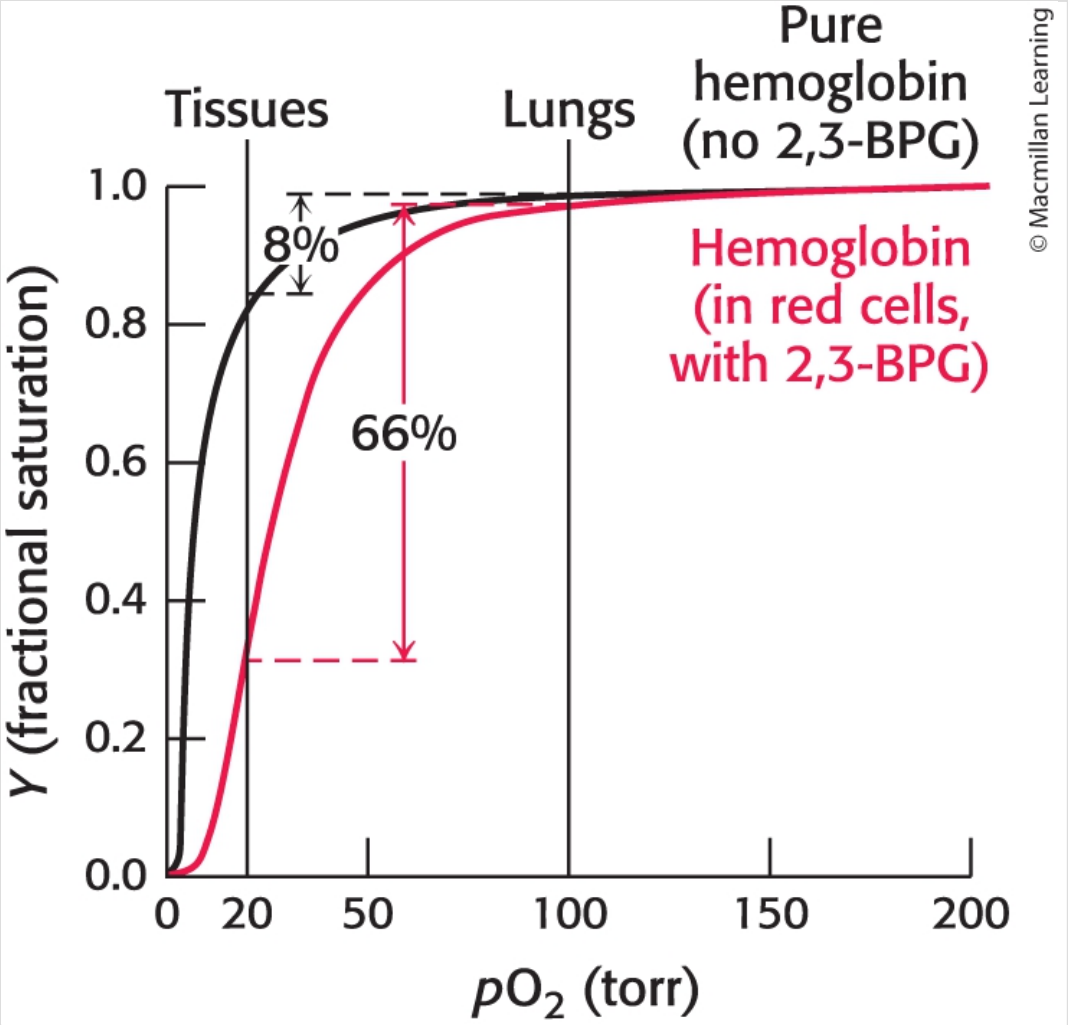

FIGURE 3.25 The oxygen-binding curves for pure hemoglobin and hemoglobin in red blood are markedly different. Hemoglobin in red blood cells shows a lower oxygen affinity than does pure hemoglobin due to the presence of 2,3-bisphosphoglycerate in red blood cells.

This highly anionic compound is present in red blood cells at approximately the same concentration as that of hemoglobin (~2 mM). Without 2,3-BPG, hemoglobin would be an extremely inefficient oxygen transporter, releasing only 8% of its cargo in the tissues.

How does 2,3-BPG lower the oxygen affinity of hemoglobin so significantly? Examination of the crystal structure of deoxyhemoglobin in the presence of 2,3-BPG reveals that a single molecule of 2,3-BPG binds in the center of the tetramer, in a pocket present only in the T state (Figure 3.26). During the T-to-R transition, this pocket collapses, and 2,3-BPG is released. Thus, in order for the structural transition from T to R to take place, the interactions between hemoglobin and 2,3-BPG must be disrupted. In the presence of 2,3-BPG, more oxygen-binding sites within the hemoglobin tetramer must be occupied in order to induce the T-to-R transition, and so hemoglobin remains in the lower-affinity T state until higher oxygen concentrations are reached.

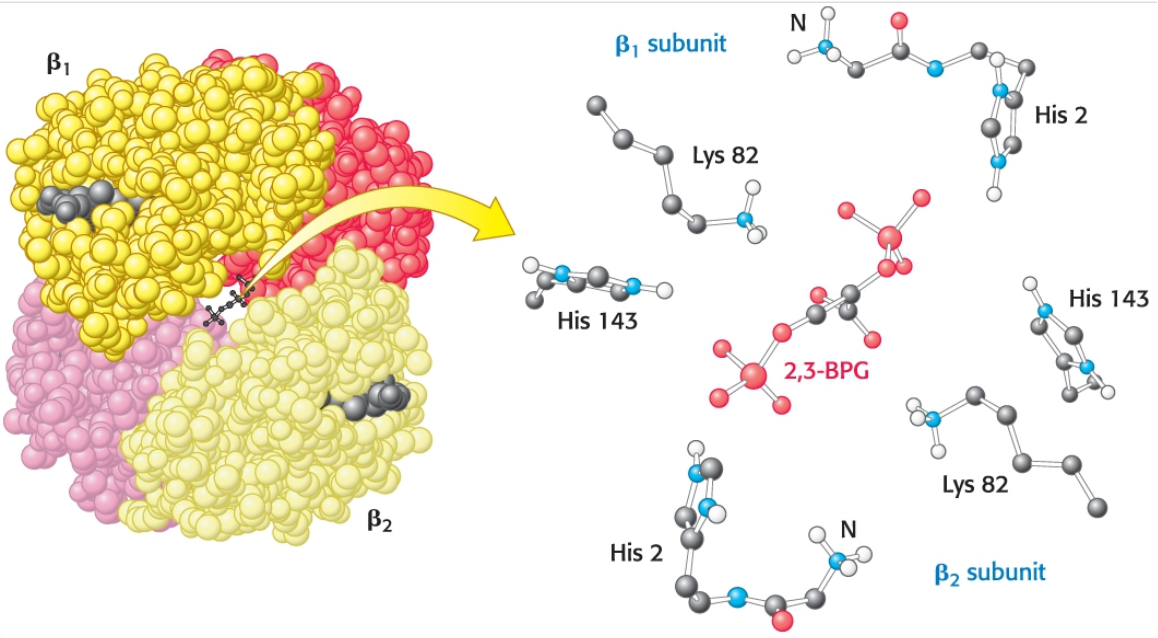

FIGURE 3.26 2,3-Bisphosphoglycerate binds in the central cavity within deoxyhemoglobin. Within the cavity, the negatively charged molecule interacts with three positively charged side chains from each β chain.

INTERACT with this model in Achieve

This mechanism of regulation is remarkable because 2,3-BPG does not in any way resemble oxygen, the molecule on which hemoglobin carries out its primary function. 2,3-BPG is referred to as an **allosteric effector** (from the Greek *allos*, "other," and *stereos*, "structure"), a molecule that affects the binding of another molecule from a distance. Because they bind in sites other than the active site, allosteric effector molecules can have structures that are completely different from the other molecules to which a protein binds. We will encounter allosteric effectors again when we consider enzyme regulation in Chapter 5. The binding of 2,3-BPG by deoxyhemoglobin but not by oxyhemoglobin is another illustration of the utility of molecular recognition.

The binding of 2,3-BPG to hemoglobin has other crucial physiological consequences. For example, the hemoglobin produced by human fetuses is different from that produced by adults. The differences are relatively subtle, but one of their consequences is that fetal hemoglobin has a lower affinity for 2,3-BPG than does adult hemoglobin. Consequently, the oxygen affinity of fetal red blood cells is higher than that for maternal (adult) red blood cells (**Figure 3.27**). This difference in oxygen affinity allows oxygen to be effectively transferred from maternal to fetal red blood cells, helping to ensure that the fetus receives an adequate oxygen supply.

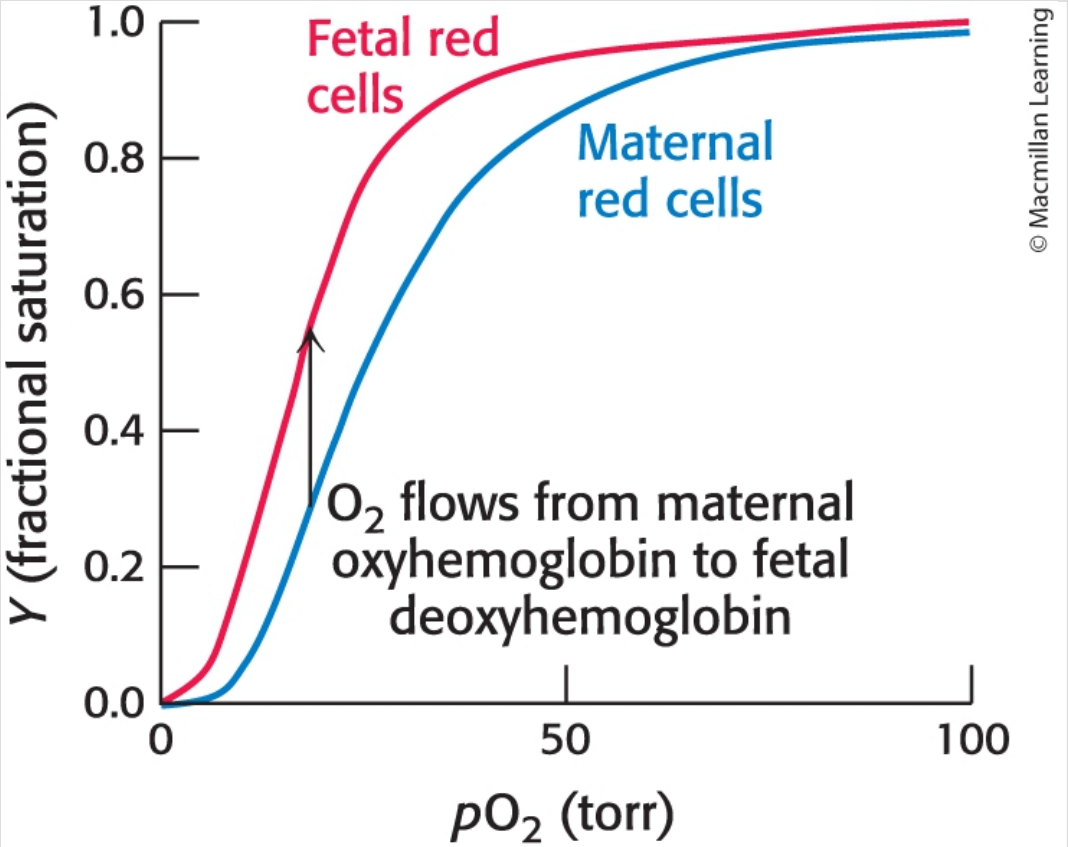

FIGURE 3.27 Fetal red blood cells obtain oxygen from maternal red blood cells by virtue of fetal hemoglobin's lower affinity for 2,3-BPG. This results in fetal hemoglobin having a higher affinity for oxygen.

Hydrogen ions and carbon dioxide promote the release of oxygen

We have seen how cooperative release of oxygen from hemoglobin helps deliver oxygen to where it is most needed: tissues exhibiting low oxygen partial pressures. This ability is enhanced by the facility of hemoglobin to respond to other cues in its physiological environment that signal the need for oxygen. For example, consider rapidly metabolizing tissues, such as contracting muscle, which generate large

amounts of hydrogen ions and carbon dioxide. To release oxygen where the need is greatest, hemoglobin has evolved to respond to higher levels of these substances. Like 2,3-BPG, hydrogen ions and carbon dioxide are allosteric effectors of hemoglobin that bind to sites on the molecule that are distinct from the oxygen-binding sites. The regulation of oxygen binding by hydrogen ions and carbon dioxide is called the **Bohr effect** after Christian Bohr, who described this phenomenon in 1904.

The effect of hydrogen ions

The oxygen affinity of hemoglobin decreases as pH decreases from a value of 7.4 (**Figure 3.28**). Consequently, as hemoglobin moves into a region of lower pH, its tendency to release oxygen increases. For example, transport from the lungs, with pH 7.4 and an oxygen partial pressure of 100 torr, to active muscle, with a pH of 7.2 and an oxygen partial pressure of 20 torr, results in a release of oxygen amounting to 77% of total carrying capacity. Only 66% of the oxygen would be released in the absence of any change in pH.

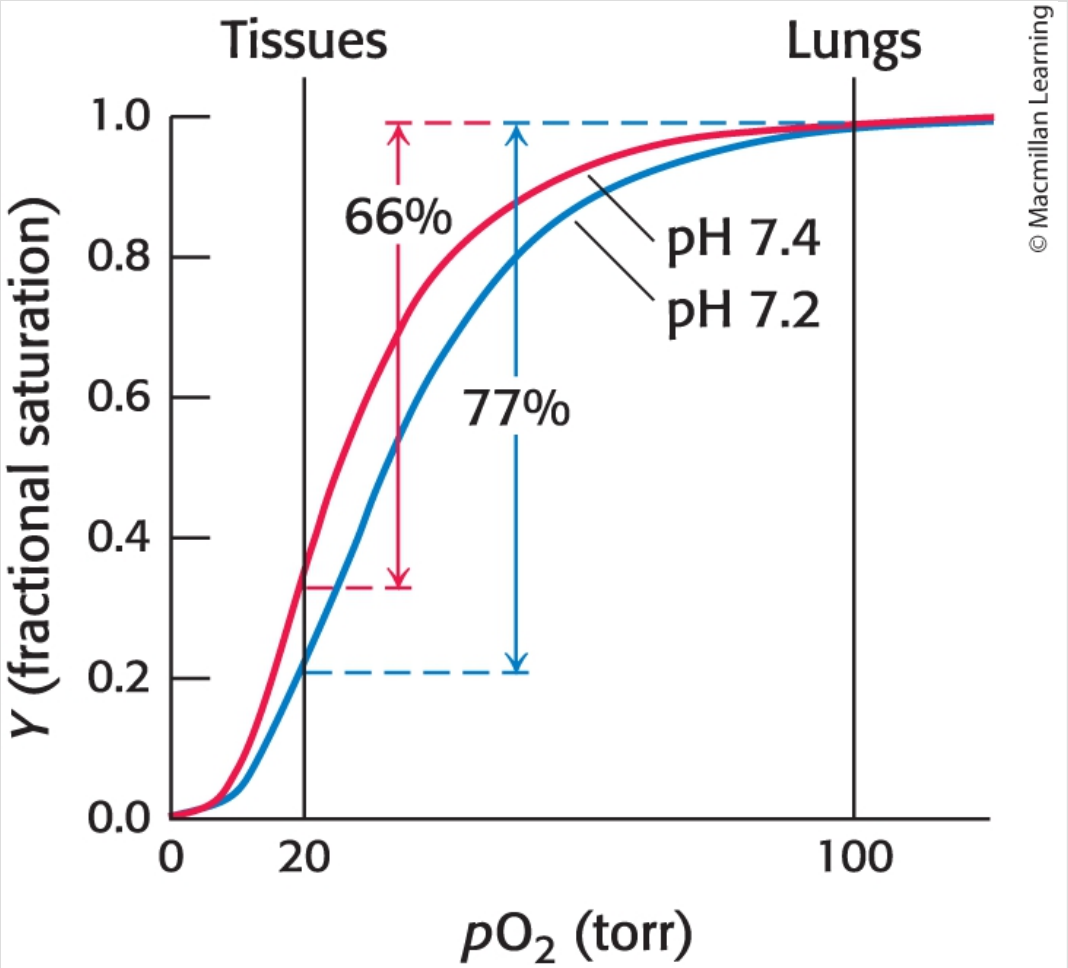

FIGURE 3.28 Lowering the pH decreases the oxygen affinity of hemoglobin and facilitates the release of oxygen into metabolically active tissues. The oxygen-binding curve at pH 7.2 (blue curve) is compared with that at pH 7.4 (red curve).

Structural and chemical studies have revealed much about the chemical basis of the Bohr effect. Several chemical groups within the hemoglobin tetramer are important for sensing changes in pH; all of these have pK_a values near pH 7. Consider histidine $\beta 146$, the residue at the C terminus of the β chain. In its protonated form, the histidine sidechain participates in an ionic interaction with the negatively charged aspartate $\beta 94$ in the same chain. This interaction locks the terminal

carboxylate group of β^{146} in a position where it can interact electrostatically with a lysine residue from the α subunit of the other αβ dimer in the T-state conformation (Figure 3.29).

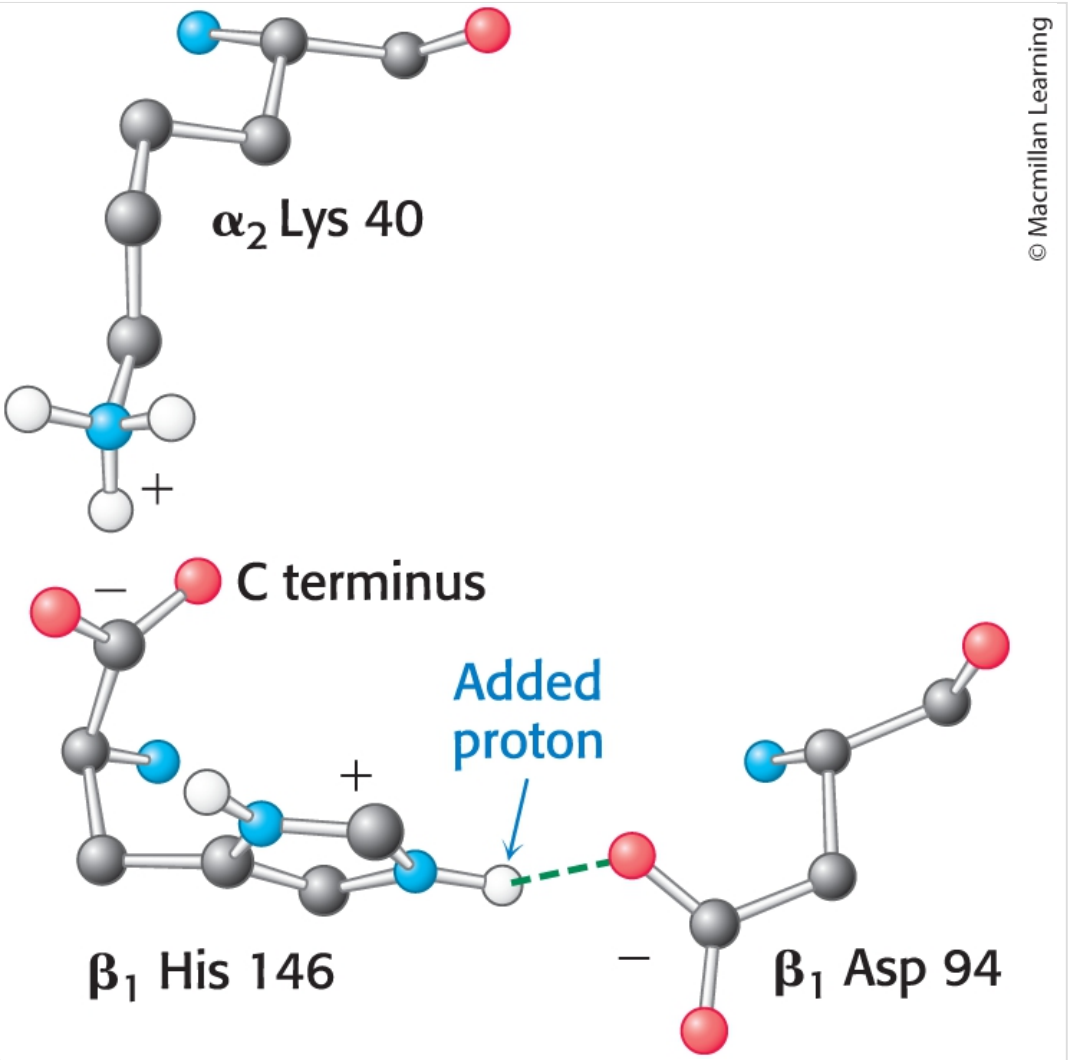

FIGURE 3.29 Ionic interactions involving the β chain C-terminal histidine are responsible for some of the pH sensitivity of hemoglobin oxygen affinity. As the pH decreases, the likelihood that the imidazole side chain of His β^{146} is protonated increases. This promotes an ionic interaction between the terminal carboxylate and a lysine side chain from the other αβ dimer, stabilizing the T state.

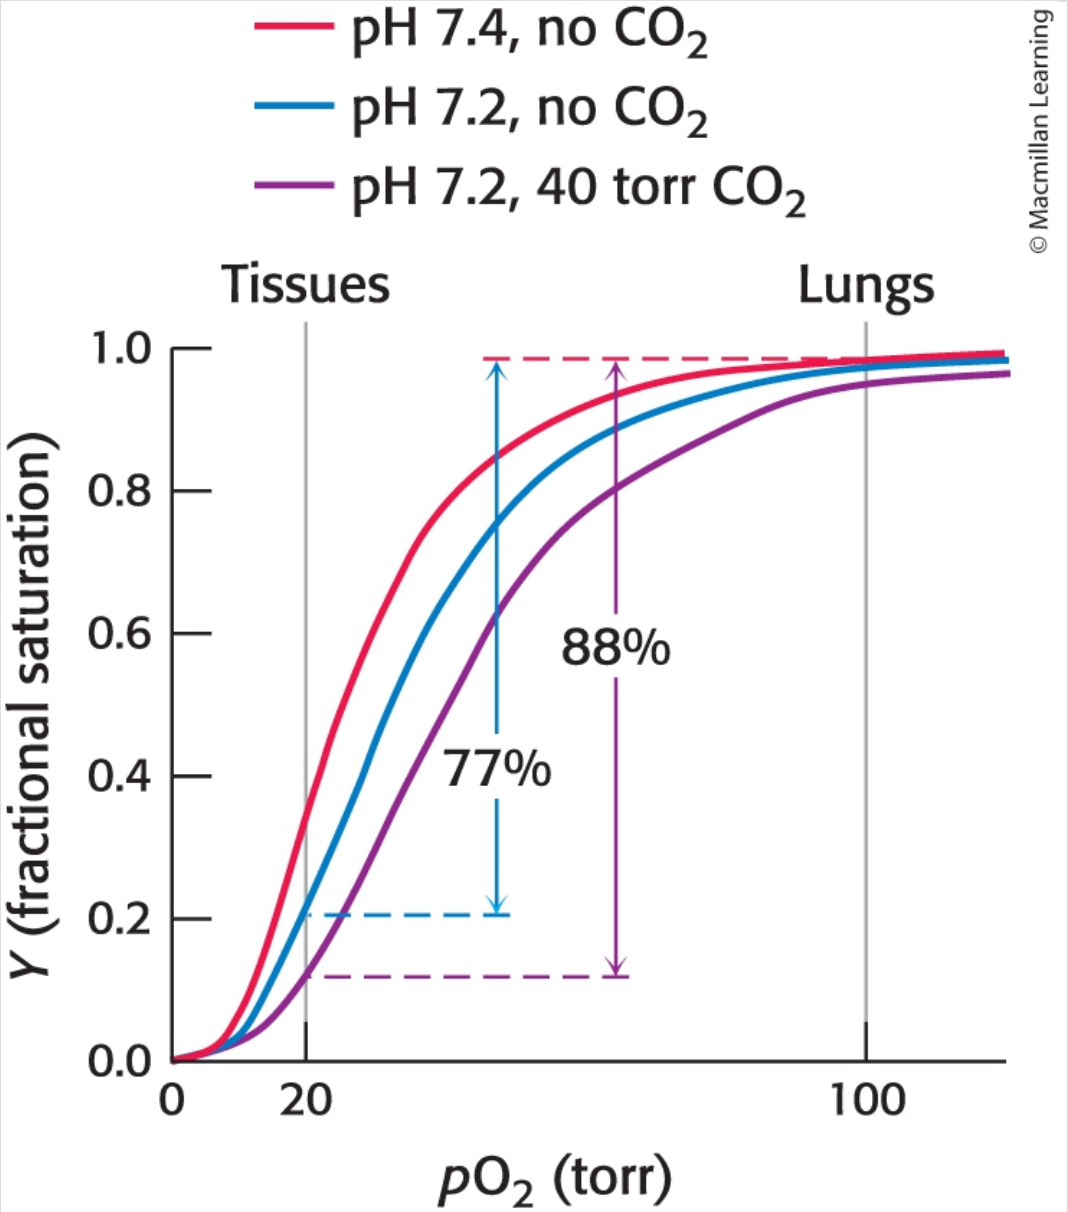
In addition to His $\beta 146$, the α-amino groups at the amino termini of the α chains and the side chain of histidine $\alpha 122$ also participate in ionic interactions in the T state. The formation of these ionic interactions stabilizes the T state, leading to a greater tendency for oxygen to be released.

The effect of carbon dioxide

Carbon dioxide stimulates oxygen release by two mechanisms. First, carbon dioxide reacts with water to form to form bicarbonate ion, HCO_3^- and H^+, resulting in a drop in pH that stabilizes the T state by the mechanism discussed previously. Second, a direct chemical interaction between carbon dioxide and hemoglobin stimulates oxygen release.

The effect of carbon dioxide on oxygen affinity can be seen by comparing oxygen-binding curves in the absence and in the presence of carbon dioxide at a constant pH (**Figure 3.30**). In the presence of carbon dioxide at a partial pressure of 40 torr at pH 7.2, the amount of oxygen released increases to 88% of the maximum carrying capacity.



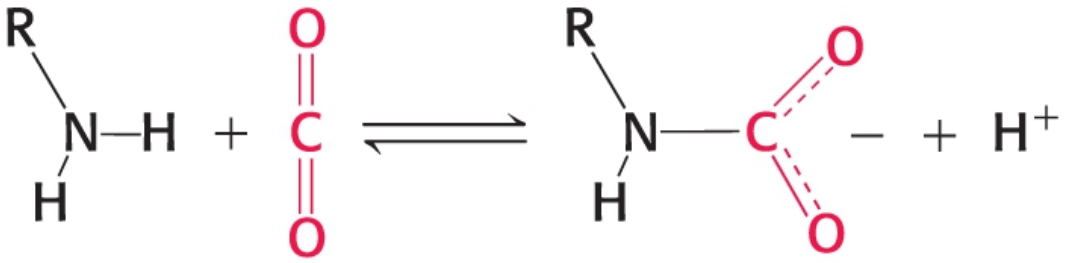


FIGURE 3.30 The presence of carbon dioxide decreases the oxygen affinity of hemoglobin, even beyond the effect due to a decrease in pH. At a constant pH 7.2, the presence of CO_2 at a level of 40 torr decreases the oxygen affinity of hemoglobin and increases the amount of oxygen delivered from 77% to 88%.

Carbon dioxide stabilizes deoxyhemoglobin by reacting with the terminal amino groups to form carbamate groups, which are negatively

charged, in contrast with the neutral or positive charges on the free amino groups.

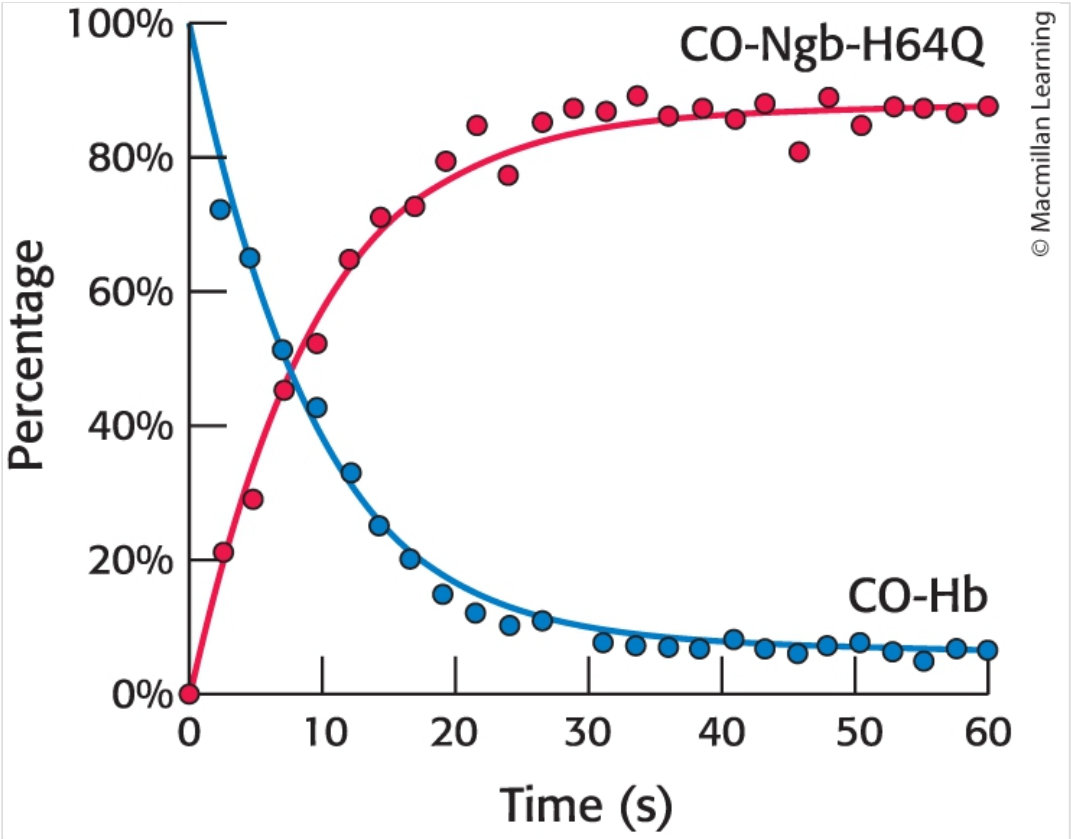
Carbamate

The amino termini lie at the interface between the αβ dimers, and these negatively charged carbamate groups participate in ionic interactions that stabilize the T state, favoring the release of oxygen. The binding of hydrogen ions and carbon dioxide by hemoglobin illustrate another example of molecular recognition based on chemical reactivity.

The binding mode of carbon dioxide is very different from the binding mode for carbon monoxide. Just as for myoglobin, carbon monoxide binds to the heme irons in hemoglobin and competes with oxygen for binding. Carbon monoxide poisoning from burning materials with inadequate ventilation is a frequent cause of emergency department visits and deaths in many countries.

A variant of neuroglobin, a monomeric protein evolutionarily and structurally related to myoglobin and hemoglobin, is being developed as a potential treatment for carbon monoxide that could be administered by first responders. In the course of studying neuroglobin, scientists replaced the distal histidine with glutamine. This substitution resulted in a protein with an extremely high affinity for oxygen and, most importantly, for carbon monoxide. With three additional changes to

improve the solubility, a protein termed Ngb-H64Q was generated which binds carbon monoxide 500 times more tightly that does hemoglobin. When carboxyhemoglobin was mixed with free Ngb-H64Q, CO transfer was very rapid, with almost complete conversion in less than one minute (Figure 3.31)! The discovery of this mutant neuroglobin revealed an exciting potential therapeutic option for the treatment of carbon monoxide poisoning, which has since been directly tested in animal studies.



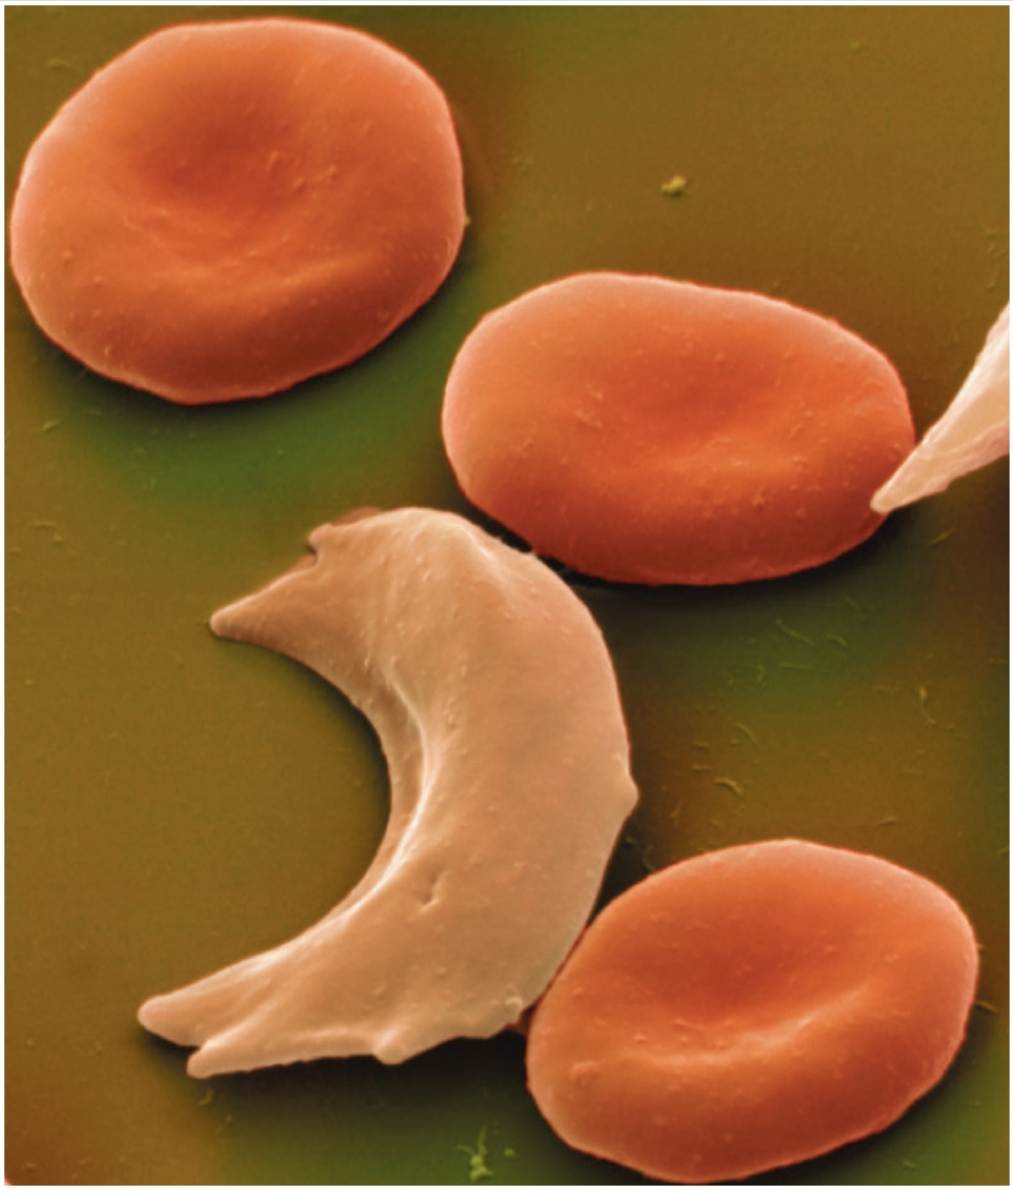


FIGURE 3.31 Carbon monoxide is rapidly transferred from carboxyhemoglobin to Ngb-H64Q. When carboxyhemoglobin (CO-Hb) is mixed with ligand-free Ngb-H64Q, CO is rapidly transferred away from hemoglobin, with exchange complete in less than one minute.

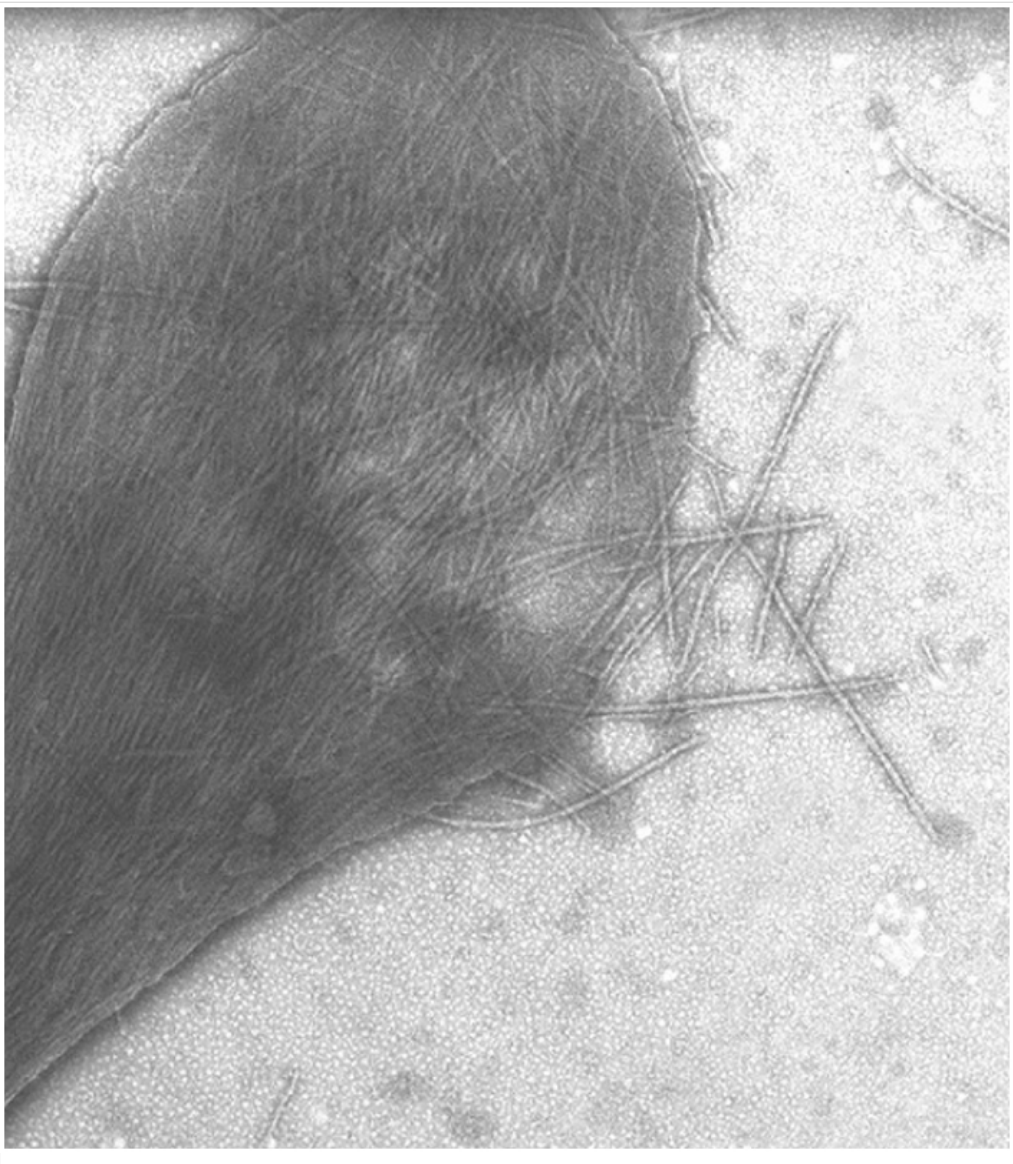
Mutations in genes encoding hemoglobin subunits can result in disease

In modern times, particularly after the sequencing of the human genome, it is routine to think of genetically encoded variations in protein sequence as a factor in specific diseases. But this was not always the case. In 1949, four years prior to the proposal of the structure of the DNA double helix, the notion that diseases might be caused by molecular defects was proposed by Linus Pauling, Harvey Itano, and colleagues to explain the blood disease **sickle-cell anemia**. The name of the disorder comes from the abnormal sickle shape of red blood cells deprived of oxygen in people suffering from this disease (**Figure 3.32**). Based on experimental studies, they proposed that sickle-cell anemia might be caused by a specific variation in the amino acid sequence of one hemoglobin chain. Today, we know that this bold hypothesis is correct.



Eye of Science/Science Source

FIGURE 3.32 Red blood cells in patients with sickle-cell anemia adopt a sickle shape when oxygen levels are low. The micrograph shows a sickled red blood cell adjacent to normally shaped red blood cells

People with sickled red blood cells experience a number of dangerous symptoms. Examination of the contents of these cells reveals that the hemoglobin molecules have formed large fibrous aggregates (Figure 3.33). These fibers extend across the red blood cells, distorting them so that they clog small capillaries and impair blood flow. In addition, red blood cells from sickle-cell patients adhere more readily to the walls of

blood vessels than those from normal individuals, prolonging the opportunity to block capillaries. The results may be painful swelling of the extremities and a higher risk of stroke or bacterial infection, due to poor circulation. The sickled red blood cells also do not remain in circulation as long as normal cells do, in part because even a single event when sickling occurs can increase the tendency of the cells to break open, or lyse, leading to anemia.

Courtesy of Robert Josephs and Thomas E. Wellems, University of Chicago.

FIGURE 3.33 Hemoglobin in individuals with sickle-cell disease forms long fibers. An electron micrograph depicting a ruptured sickled red blood cell is shown with fibers of sickle-cell hemoglobin emerging.

What is the molecular defect associated with sickle-cell anemia? Vernon Ingram and coworkers demonstrated in 1956 that a single amino acid substitution in the β chain of hemoglobin is responsible—namely, the replacement of a glutamate residue with valine in position 6. The mutated form is referred to as hemoglobin S (HbS). In people with sickle-cell anemia, both alleles (one from the mother and one from the father) of the hemoglobin β-chain gene are mutated. The HbS substitution substantially decreases the solubility of deoxyhemoglobin, although it does not markedly alter the properties of oxyhemoglobin.

Examination of the structure of hemoglobin S reveals that the new valine residue lies on the surface of the T-state molecule (**Figure 3.34**). This new hydrophobic patch interacts with another hydrophobic patch formed by Phe 85 and Leu 88 of the β chain of a neighboring molecule to initiate the aggregation process. Why do these aggregates not form when hemoglobin S is oxygenated? When oxyhemoglobin S is in the R state, residues Phe 85 and Leu 88 on the β chain are largely buried inside the hemoglobin assembly. In the absence of a partner with which to interact, the surface Val residue in position 6 is benign. While these interactions are generally not very specific, hemoglobin S fibers illustrate how many such interactions can work together to form a specific oligomeric structure.

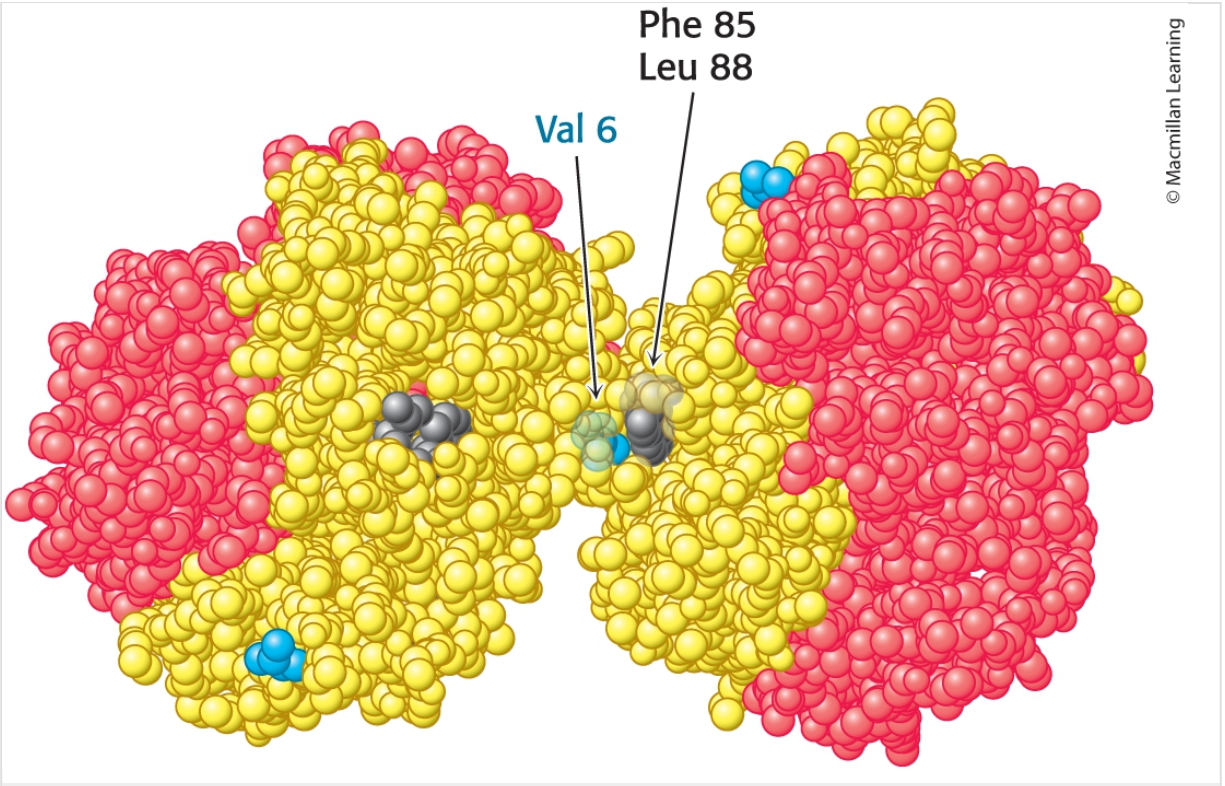


FIGURE 3.34 Two molecules of hemoglobin S interact through hydrophobic patches. These patches involve the Val $\beta 6$ residue characteristic of hemoglobin S, and Phe $\beta 85$ and Leu $\beta 88$ on an adjacent hemoglobin tetramer. This interaction drives the formation of hemoglobin S fibers.

3.4 The Immune System Depends on Key Binding Proteins

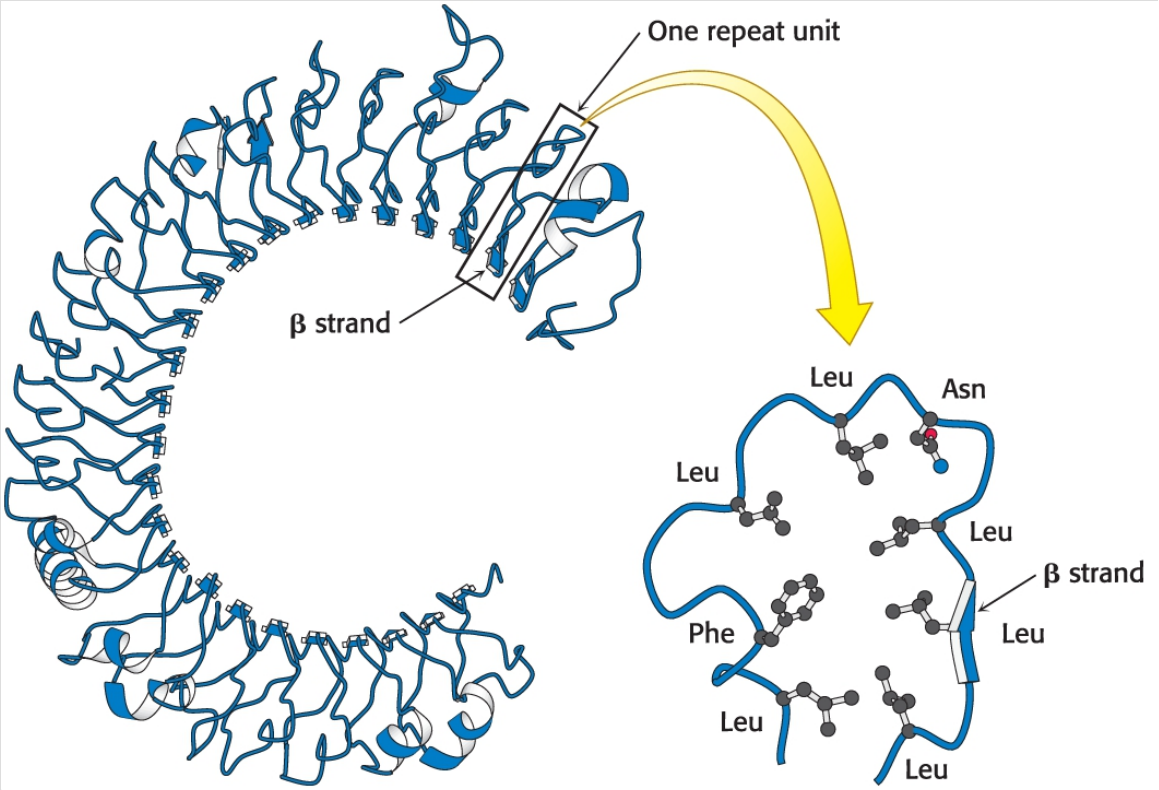
The immune system faces a daunting challenge in molecular recognition, namely the ability to identify and respond to signs of invading foreign pathogens such as bacteria and viruses in the presence of vast numbers of highly similar molecules from normal cells. Several elaborate and elegant systems have evolved that address the problem of recognition of non-self in the context of self. Here, the term "non-self" can refer to pathogens such as viruses and bacteria but also to tissue from another individual in the case of organ transplantation.

The **innate immune system** is an evolutionarily ancient defense system found, at least in some form, in all multicellular plants and animals. The innate immune system represents a first line of defense against foreign pathogens. It relies on the recognition of classes of molecules common to invading organisms to identify and eliminate these threats.

Because intracellular pathogens do not leave markings on the exteriors of infected cells, vertebrates have evolved mechanisms to display components of interior contents, both self and foreign, on the cell surface. Some internal proteins are broken into peptides, which are then bound to proteins encoded by the **major histocompatibility complex (MHC)**. T cells continually scan the bound peptides to find and kill cells that display foreign motifs on their surfaces. In all of these systems, molecular recognition processes are fundamental, facilitating the detection of components of foreign pathogens and then elimination of the invaders.

The innate immune system recognizes molecules characteristic of pathogens

Perhaps the most important components of the innate immune system are members of a family of receptors that can recognize specific classes of molecules present in many pathogens but normally absent in the host. The best-understood of these receptors are the Toll-like receptors (TLRs). The name "Toll-like" is derived from a receptor known as Toll encoded in the genome of the fruit fly *Drosophila melanogaster*. The TLRs, which are present on the outer surfaces of cells, have a common C-shaped three-dimensional structure (**Figure 3.35**). Each receptor consists of a large domain that sits on the outside of cells and is built primarily from imperfectly repeated amino acid sequences termed leucine-rich repeats (LRRs). Each LRR typically contains 20–30 residues, including 6 that are usually leucine. The human TLRs have from 18 to 27 LRR repeats. In addition to the LRR domains, each TLR has additional domains that anchor the protein to the cell surface and participate in signaling processes inside the cell.



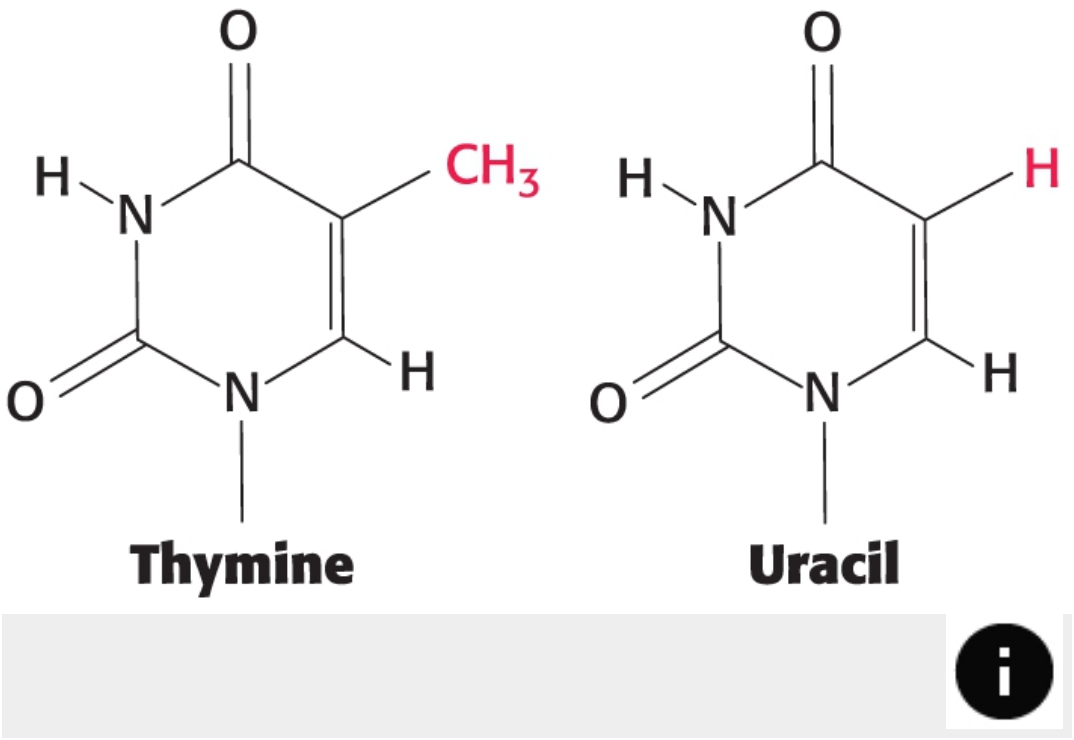


FIGURE 3.35 The structure of the LRR domain from TLR3 reveals how many LRR units come together to form a structure with binding surfaces for potential partners. Each LRR has a sing β strand and included leucine residues that come together to form a hydrophobic core. The interior and the two sides of the C-like structure are surfaces that recognize potential partners.

Each TLR targets a specific molecular class, often called a *pathogen-associated molecular pattern (PAMP)*, found primarily on invading organisms. Typically, a PAMP is a critical and widespread component of the pathogen. Examples include certain key molecules found on bacterial cell surfaces and certain classes of nucleic acids, including double-stranded RNAs. RNA is a relative of DNA that has an additional hydroxyl group on each backbone sugar unit and has uracil instead of thymine, present in DNA. Uracil lacks the methyl group in thymine.

RNA molecules are present inside normal cells in single-stranded forms. However, many viruses utilize RNA as their genomes; RNAs outside cells are therefore markers of infections or cellular damage. The difference between uracil and thymine as well as differences in the backbone conformation due to the additional hydroxyl group present opportunities for recognition of RNA versus DNA.

How do TLRs recognize PAMPs? The hook-like structures from the extracellular domains of TLRs have surfaces that are capable of recognizing a variety of a ligands in a wide array of binding modes. For example, the PAMPs for TLR3 are double-stranded RNA molecules of appropriate lengths which fit in the cavity between two monomers (Figure 3.36). As might be anticipated from this structure, RNA molecules that are much shorter than 46 base pairs are bound less tightly, as they cannot interact with the two TLR3 molecules optimally at the same time. In addition, studies show that more than 1000 times the concentration of double-stranded DNA molecules are required to achieve the same level of binding as for double-stranded RNA. This can be explained by the fact that double-stranded RNA molecules have a

somewhat different double-helical structure from those of double-stranded DNA molecules.

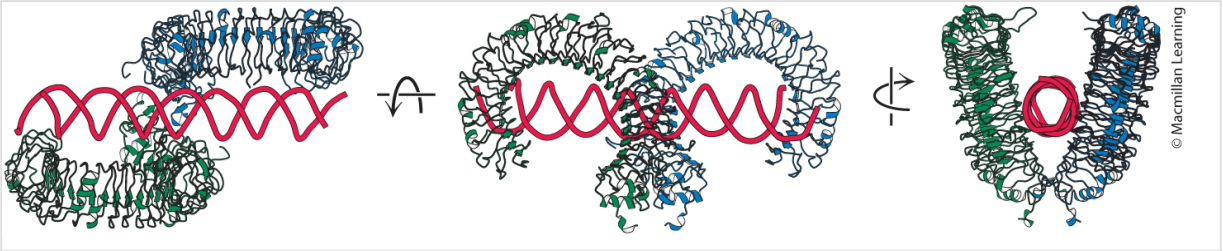

FIGURE 3.36 The innate immunity component TLR3 recognizes its PAMP, a double-stranded RNA. The structure of the complex between two molecules of the extracellular domain of TLR3 and a 46-base-pair double-stranded RNA molecule is shown from three perspectives showing how the receptor recognizes the structure and length of the RNA molecule.

Because the TLRs and other components of the innate immune system are always present on the surfaces of appropriate cells, they provide the host organism with a rapid response to resist attack by pathogens. However, many pathogens have evolved the ability to escape detection by the innate immune system. How does the host defend itself in these instances?

Antibodies bind specific molecules through specific hypervariable loops

For protection against novel pathogens, the host relies on the **adaptive immune system**, which is able to target specific pathogens, even those that it has never encountered in the course of evolution. The adaptive immune system comprises two parallel but interrelated responses: humoral and cellular immune responses. In the humoral immune response, soluble proteins called **antibodies** (or **immunoglobulins**) function to recognize foreign molecules and mark them, signaling

foreign invasion. In the cellular immune response, cells called **cytotoxic T lymphocytes** (also commonly called **killer T cells**) destroy cells that have been invaded by a pathogen.

How does a system capable of recognizing essentially any foreign molecule function? A clue emerged from comparison of the amino acid sequences of a large number of antibodies of a type referred to as *immunoglobulin G* (IgG). For most proteins, the amino acid sequences from many different individuals, and even across species such as human beings and mice, show only minor variations. However, for portions of these IgG molecules, especially three stretches of approximately 7 to 12 amino acids within each chain, these sequences are highly variable (**Figure 3.37**). These segments are referred to as the *hypervariable regions*.

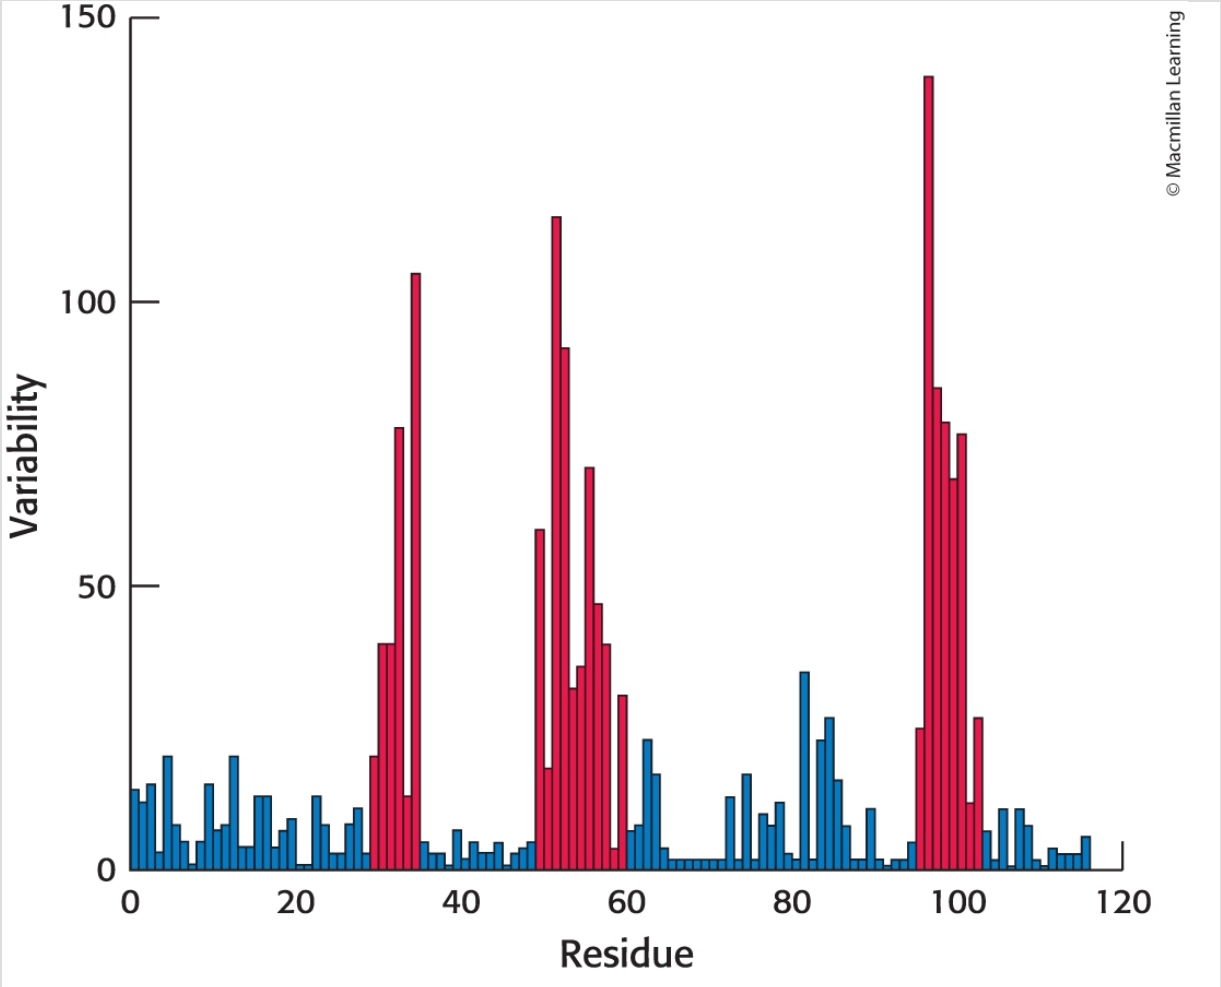

FIGURE 3.37 Immunoglobulin sequences include regions of extensive sequence variability. A plot of sequence variability in a portion of immunoglobulins as a function of position reveals three regions (red) with much greater variability than the rest of the sequence (blue). Sequence variability is measured by the number of different amino acids that were observed within a set of immunoglobulin sequences.

[After R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 91.]

Based on this observation, one could envisage a process involving a vast collection of potential binding proteins, each of which is constructed with a relatively constant scaffold with other regions that vary substantially from one member of the collection to another. If the collection is large and varied enough, then the odds are that one or more members of the collection have a surface that will recognize any foreign molecule. Molecules that induce immune responses are referred to as **antigens**. The challenge is to find the "needle in the haystack" for the given antigen and then produce the antibody at adequate levels to be of use. This is, indeed, the principle by which the adaptive immune system operates.

Let us look carefully at the structure of IgG to examine this adaptive ability in more detail. An IgG molecule consists of 12 structural domains. These domains have many sequence features in common and adopt a common structure, the **immunoglobulin fold** (**Figure 3.38**). The immunoglobulin fold consists of a pair of β sheets, each built of antiparallel β strands, that surround a central hydrophobic core. A single disulfide bond bridges the two sheets. Two aspects of this structure are particularly important for its function. First, three loops at one end of the structure that contain hypervariable regions form a potential binding surface. These loops are referred to as **hypervariable loops** or **complementarity-determining regions (CDRs)**. Second, the amino terminus and the carboxyl terminus are at opposite ends of the

structure, which allows structural domains to be strung together to form chains.

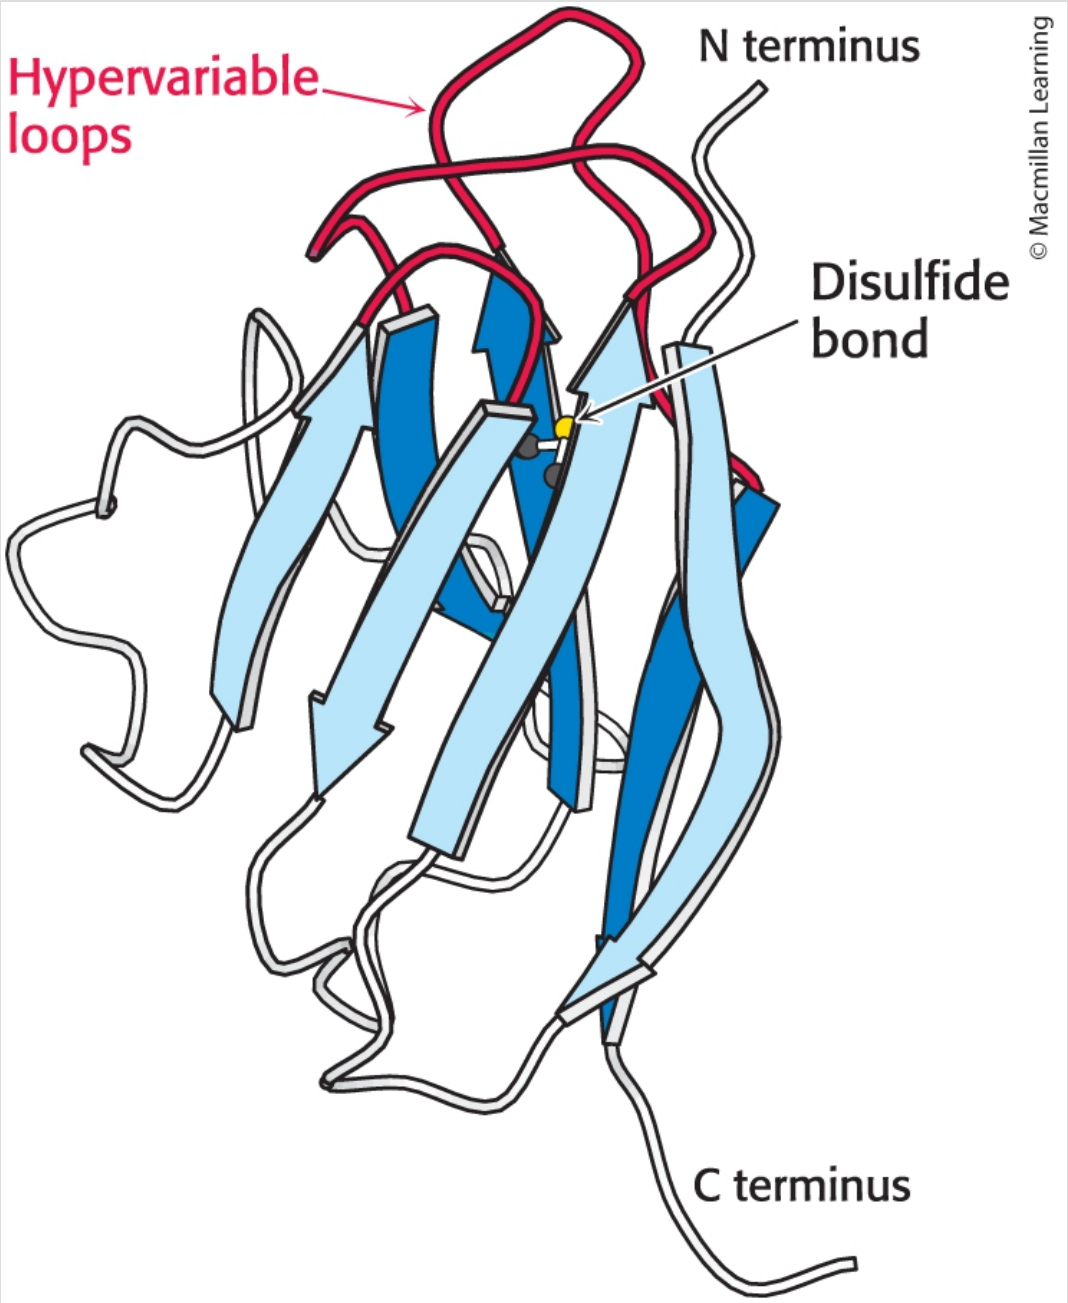

FIGURE 3.38 The immunoglobulin fold consists of a pair of β sheets linked by a disulfide bond. Hydrophobic interactions occur with three hypervariable loops at one end of the structure.

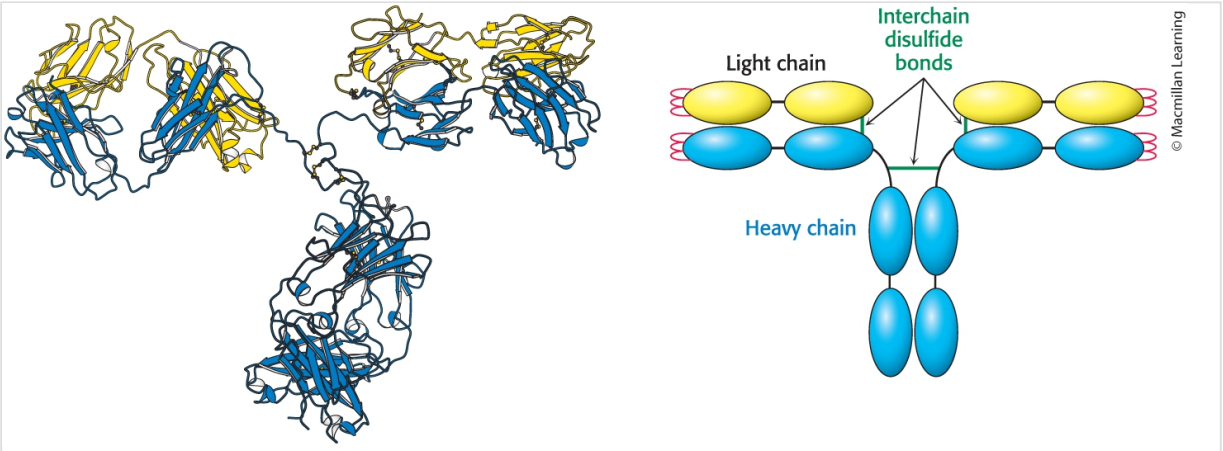
INTERACT with this model in Achieve

The 12 immunoglobulin fold domains in an IgG molecule are arranged to form a Y-shaped structure (Figure 3.39). Each IgG molecule consists of four chains: two so-called *heavy chains*, each of which has four immunoglobulin domains; and two *light chains*, each of which has two immunoglobulin domains. The two heavy chains are linked together by a disulfide bond, and each heavy chain is also linked to one light chain by an additional disulfide bond. The positions of the CDRs are striking. These hypervariable sequences, present in three loops of each domain, come together so that all six loops come together at the end of each arm.



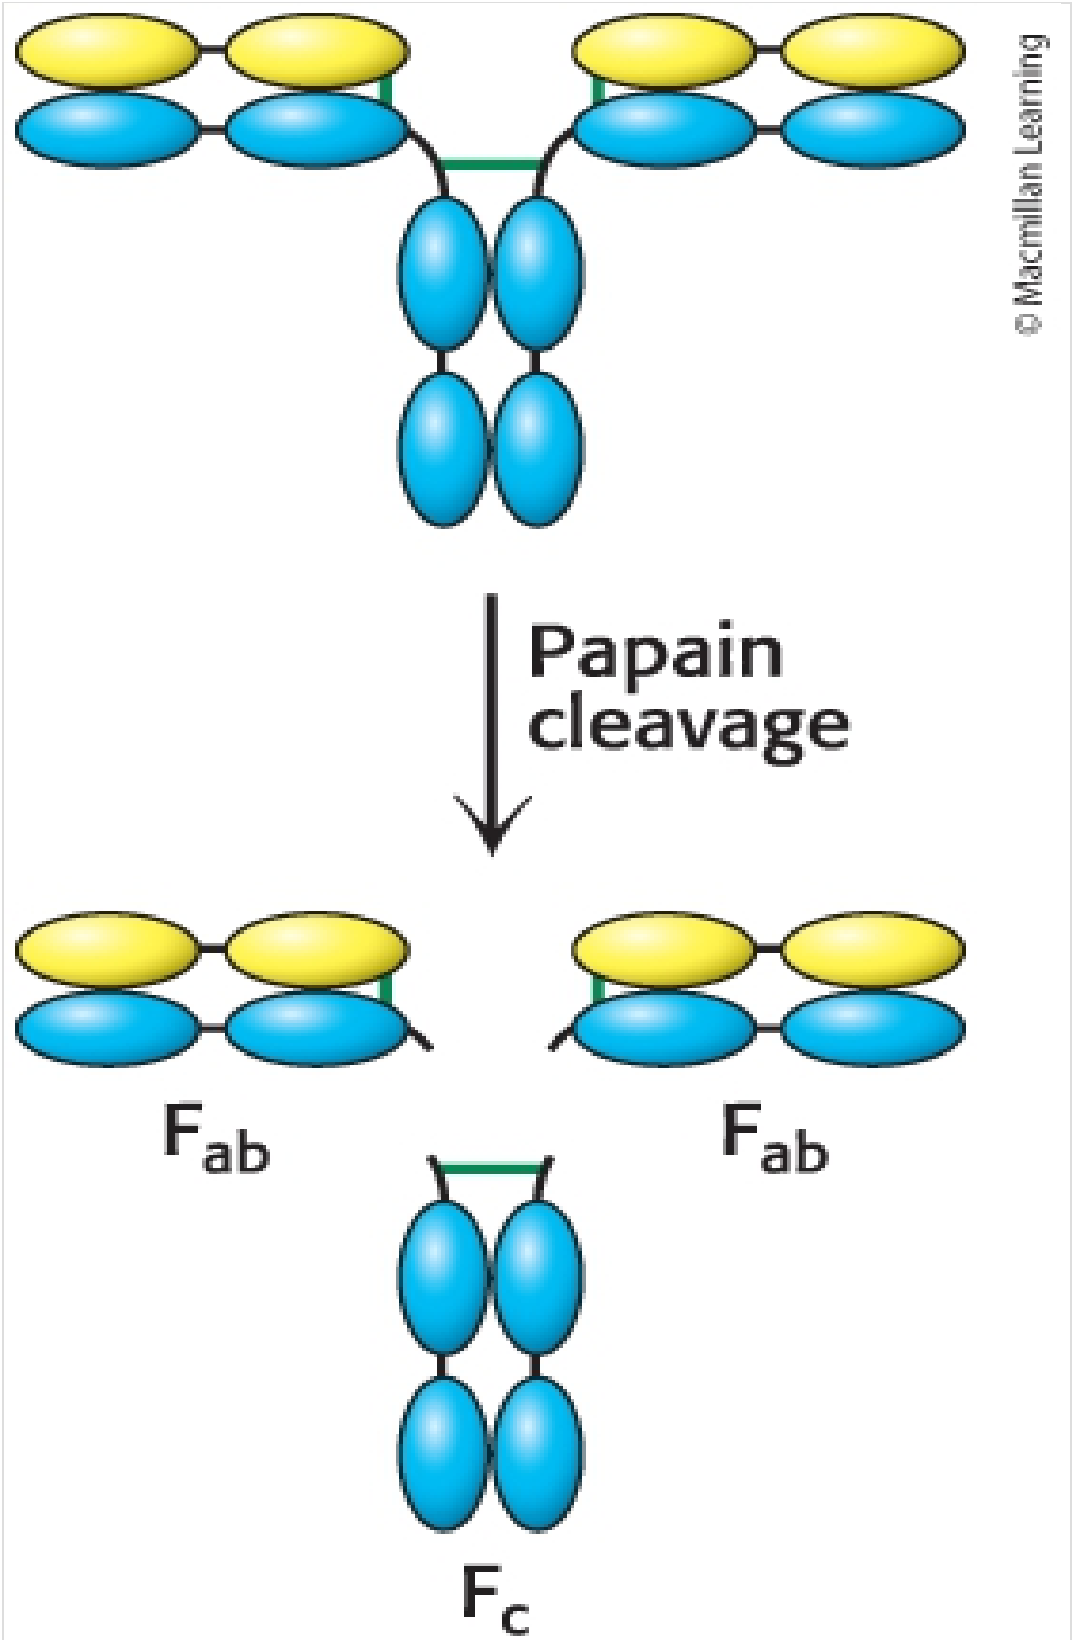


FIGURE 3.39 An IgG molecule has a Y-shaped structure comprising two identical arms with hypervariable regions at the end. The heavy chains are shown in blue, the light chains in yellow, and the hypervariable loops at the end of the two arms in red. The positions of intrachain disulfide bonds are indicated.

INTERACT with this model in Achieve

Biochemists have dissected IgG using a protein called papain, isolated from papaya fruit (**Figure 3.40**). Papain catalyzes the cleavage of certain exposed peptide binds; treatment of an IgG molecule with papain results in two products in a 2:1 ratio. The first products are F_{ab} fragments, which comprise a light chain as well as a portion of the heavy chain; the second product, termed F_c, comprises two disulfide-linked portions of the heavy chain. This dissection allows the binding and structural properties of IgG molecules to be studied more easily; the three-dimensional structure of an F_{ab} fragment shows how the CDRs come together to form a binding surface (**Figure 3.41**).

© Macmillan Learning

FIGURE 3.40 Immunoglobulin G molecules can be cleaved into two F_{ab} fragments and one F_c fragment by treatment with papain. The F_{ab} fragments include the antigen binding sites.

FIGURE 3.41 The structure of an F_{ab} fragment reveals how the six hypervariable loops come together to form a binding surface. (A) Side view. (B) End view looking down on the binding surface.

Let us now examine in detail the interactions in one representative complex between an antibody F_{ab} fragment and a typical protein: lysozyme from egg whites. This antibody binds two polypeptide segments of lysozyme that are widely separated in the primary structure. All six CDRs of the antibody participate directly in molecular recognition. The region of contact is quite extensive (about 30×20 Å), and the apposed surfaces are rather flat. The only exception is the side chain of glutamine 121 of lysozyme, which penetrates deeply into the antibody's binding site, where it forms a hydrogen bond with a main-chain carbonyl oxygen atom and is surrounded by three aromatic side chains (Figure 3.42).

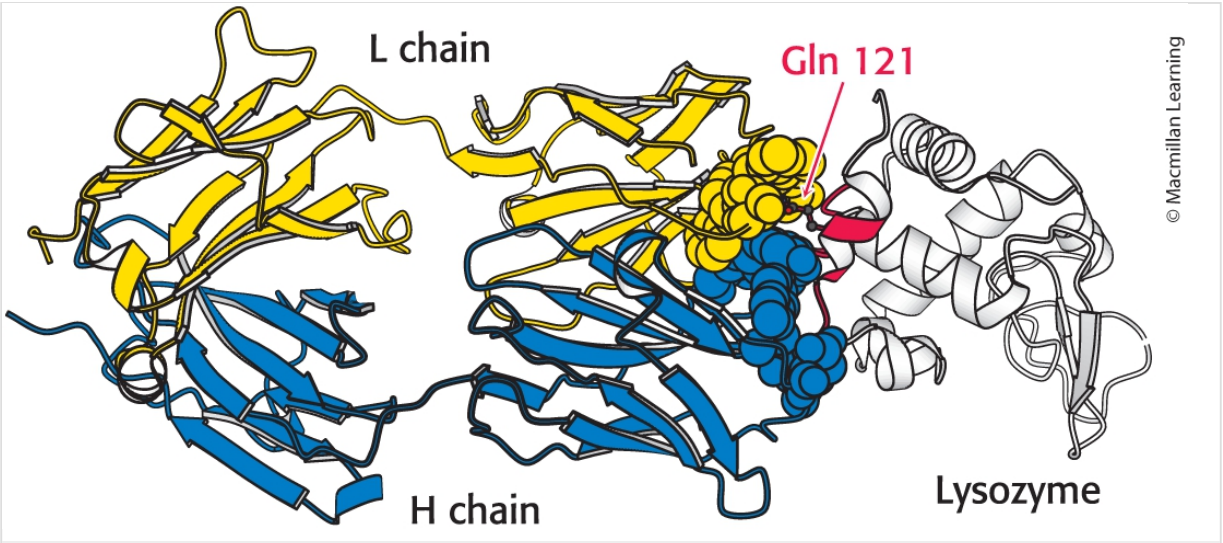

FIGURE 3.42 The structure of a complex between lysozyme and a specific F_{ab} fragment reveals how the binding surface on the F_{ab} interacts with the antigen. The hypervariable loops are shown as space-filling models. A single residue from lysozyme, glutamine 121, penetrates relatively deeply into the antibody.

INTERACT with this model in Achieve

The formation of 12 hydrogen bonds and numerous van der Waals interactions contributes to the high affinity ($L_{1/2} = 20$ nM) of this antibody–antigen interaction. Examination of the F_{ab} molecule without bound protein reveals that the structures of the immunoglobulin domains change little on binding, although they slide 1 Å apart to allow more intimate contact with lysozyme.

Studies of thousands of large and small antigens bound to F_{ab} molecules have been sources of much insight into the structural basis of molecular recognition by antibodies. The interaction between complementary shapes results in numerous contacts between amino acids at the binding surfaces of both molecules. Many hydrogen bonds, ionic

interactions, and van der Waals interactions, reinforced by hydrophobic interactions, combine to give specific and strong binding.

Self-Check Question

How many total hypervariable loops does an immunoglobulin G molecule have? Not counting duplicates more than once, how many unique loops does it have?

Antibodies possess distinct antigen-binding and effector units

The major antibody in the serum is immunoglobulin G. As noted previously, IgG molecules have Y-shaped structures with two F_{ab} arms that participate in antigen binding and one F_c arm (Figure 3.39). The F_c arm is not merely a scaffold but is a target for molecular recognition itself, as it is recognized by specific proteins on the surfaces of certain cells. This allows the IgG molecule to act as an adaptor, linking an antigen bound by the F_{ab} arms to cells expressing the F_c receptor, initiating other steps that can help destroy the pathogen.

Why does an IgG have more than one F_{ab} arm? Many invaders such as viruses and bacteria have surfaces with repeating structures. Having two F_{ab} arms joined by a flexible hinge allows the IgG to bind to such a surface, with each F_{ab} binding to a different instance of the structural repeat. This allows the IgG to stick more avidly to the surface with a longer dissociation time. The polyvalent interactions are analogous to Velcro®, in which many hooks and loops interact relatively weakly but together can produce a strong interaction.

Recall that an IgG protein is a heterotetramer with two heavy chains and two light chains. Five different classes of antibody—IgG, IgM, IgA, IgD, and IgE—differ in their heavy chains and, hence, in their effector functions (Figure 3.43). By virtue of their different effector domains and, hence, different interaction partners, each of these classes can participate in different physiological processes. For example, IgM has a noteworthy pentameric structure with ten potential antigen-binding sites. IgMs are the first class of antibody produced after an infection; in general, each IgM antigen-binding site has a relatively modest affinity for antigen, but the overall affinity is higher due to the large number of connected potential binding sites.

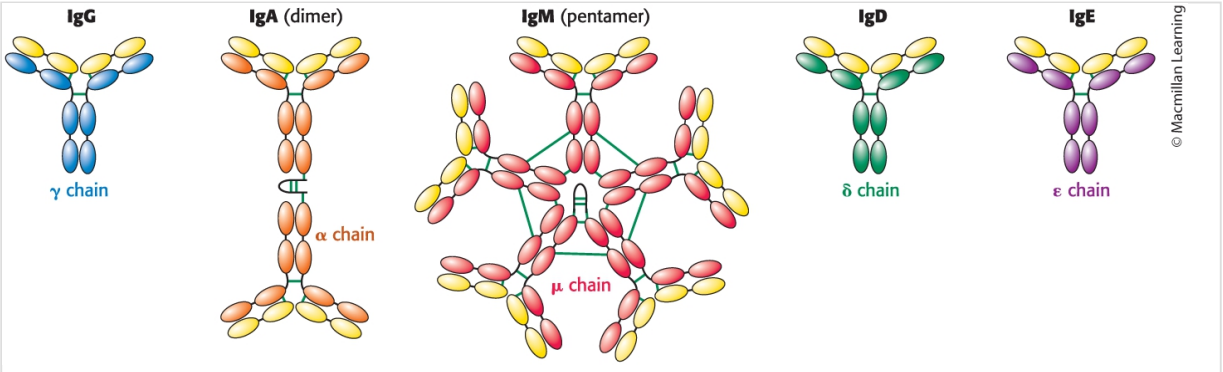

FIGURE 3.43 Five classes of immunoglobulin have the same light chain combined with a different heavy chain (γ, α, μ, δ, or ε). The light chains are shown in yellow, and disulfide bonds are indicated by green lines.

Recombination events equip the adaptive immune system with millions of unique antibodies

The genes that encode immunoglobulin light and heavy chains undergo fascinating recombination events that introduce different combinations

of CDRs, resulting in more than 300 possible light chains and more than 8000 possible IgG heavy chains. As each light chain can come together with each heavy chain, this produces more than $300 \times 8000 = 2{,}400{,}000$ potential antibodies. This explains how the adaptive immune system can respond to unknown invaders; it is prepared with many potential molecular recognition templates, some of which will adequately match any new threat.

 Through the use of vaccines, the adaptive immune system can be primed for agents known to be potential threats. Vaccines, which expose the immune system to molecules associated with a potential infection without causing serious disease, are perhaps the most powerful public health measures ever developed. Vaccines can be complete bacteria or viruses that have been rendered relatively harmless by various means, or they may be molecular components that trigger protective immune responses. The development of several vaccines against the so-called “spike” protein found on the surface of SARS-CoV-2, the virus that causes COVID-19, were hugely important advances. The vaccines can induce antibodies that bind to the spike protein and block its ability to bind to and infect cells (**Figure 3.44**).

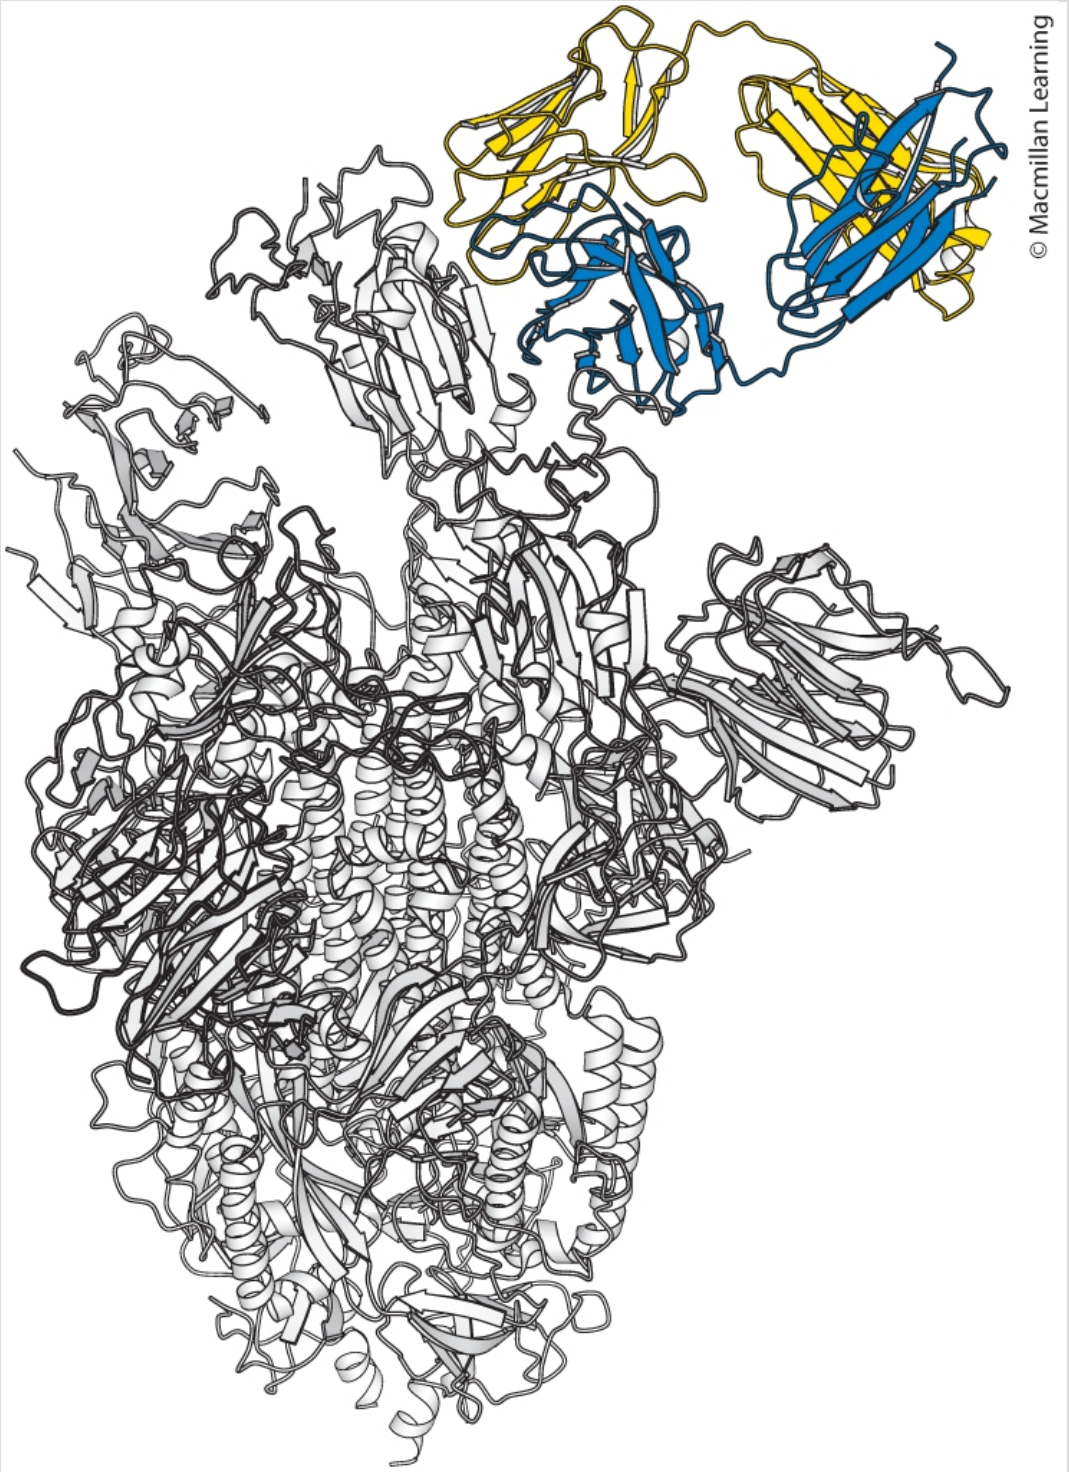

FIGURE 3.44 Antibodies elicited against the spike protein of SARS-CoV-2 can bind to this protein and block the ability of the virus to infect cells. The structure shows the trimeric spike protein targeted by an F_{ab} fragment from one specific antibody.

Major-histocompatibility-complex proteins present peptide antigens on cell surfaces for recognition by T-cell receptors

Soluble antibodies are highly effective against extracellular pathogens, but they confer little protection against microorganisms that are predominantly intracellular, such as some viruses and mycobacteria (which cause tuberculosis and leprosy). These pathogens are shielded from antibodies by the host-cell membrane. A different and more subtle strategy, **cell-mediated immunity**, evolved in response to the damaging properties of intracellular pathogens. The task is not simple; intracellular microorganisms are not so obliging as to leave telltale traces on the cell surfaces of their host without assistance. Quite the contrary, successful pathogens are masters of the art of camouflage. However, vertebrates use an elaborate mechanism—cut and display—to reveal the presence of stealthy intruders. The process starts in the cytoplasm with the cutting step; self-proteins as well as those of pathogens are cleaved into short peptides. Nearly all vertebrate cells exhibit on their surfaces a sample of peptides derived from the digestion of proteins in their cytoplasm. These peptides are then displayed by proteins embedded in the cell membrane that are encoded by the major histocompatibility complex (MHC); they are called **class I MHC proteins**. These cell-surface proteins tightly grip their bound peptides, which are then touched and scrutinized by other cells.

The three-dimensional structure of a large extracellular fragment of a human MHC class I protein termed HLA-A2, solved in 1987 by Don Wiley, Pamela Bjorkman, and colleagues, reveals a deep groove that

serves as the binding site for the presentation of peptides (**Figure 3.45**). The groove can be filled by a peptide from 8 to 10 residues long in an extended conformation (**Figure 3.46**). An individual typically has six distinct MHC class I proteins with different peptide specificities, and these vary from individual to individual across the population.

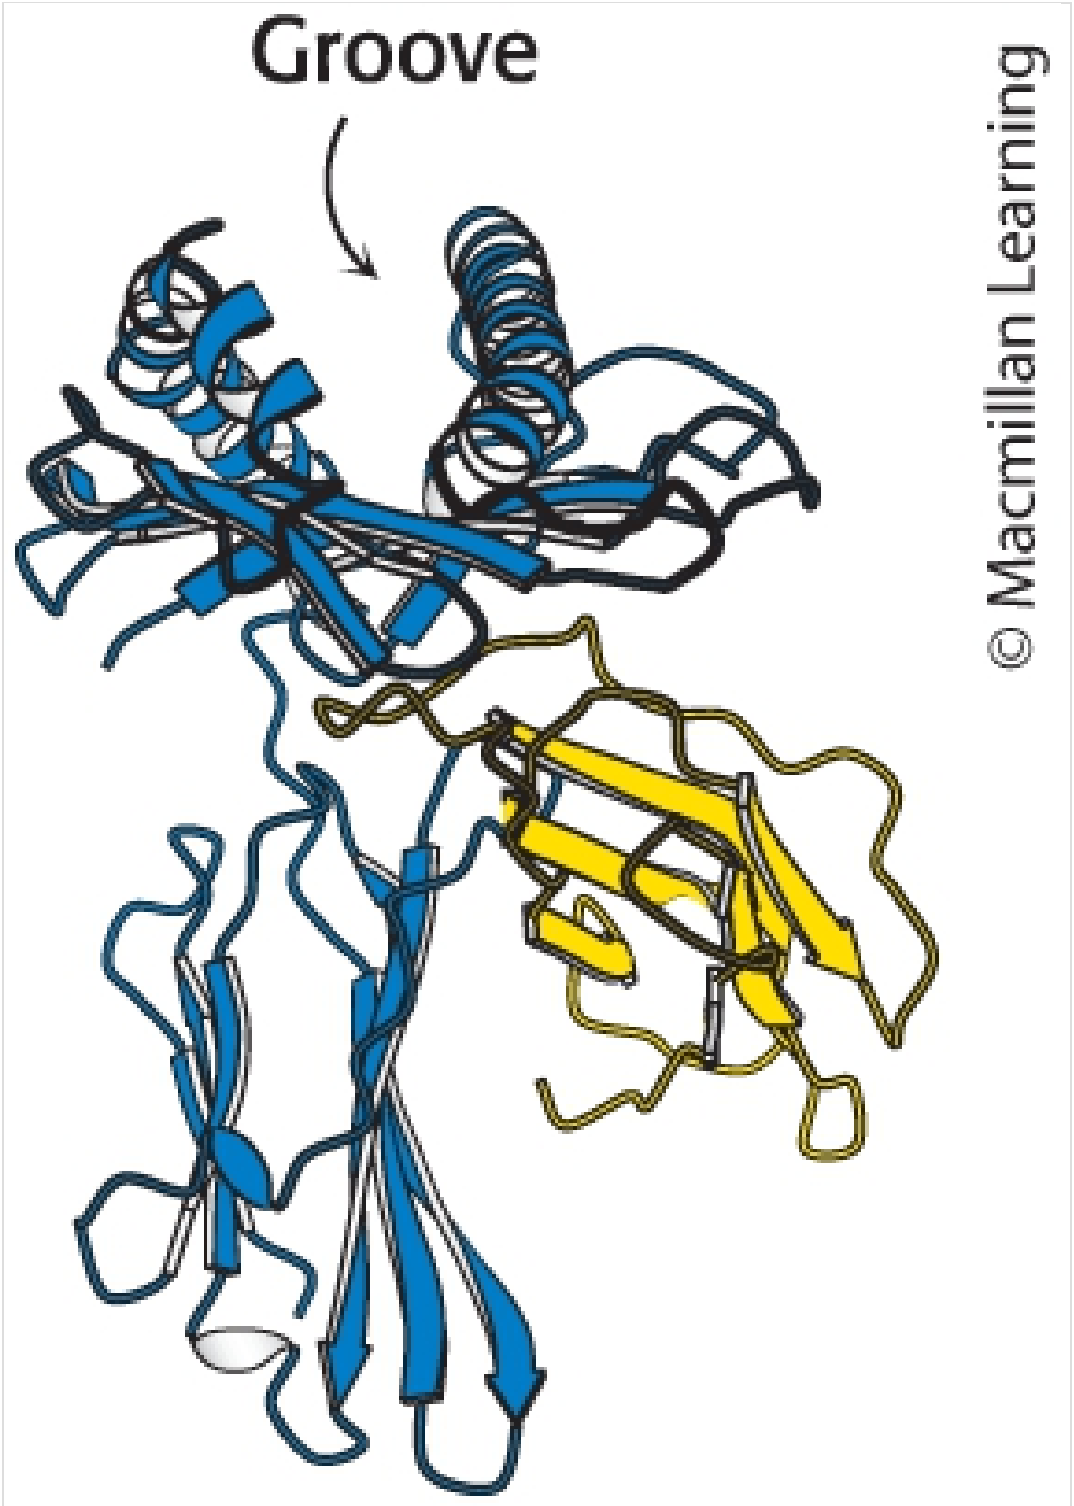

FIGURE 3.45 The structure of the extracellular domain of a class I MHC protein reveals a deep groove. The domain is a complex between two different polypeptide chains, shown in blue and yellow.

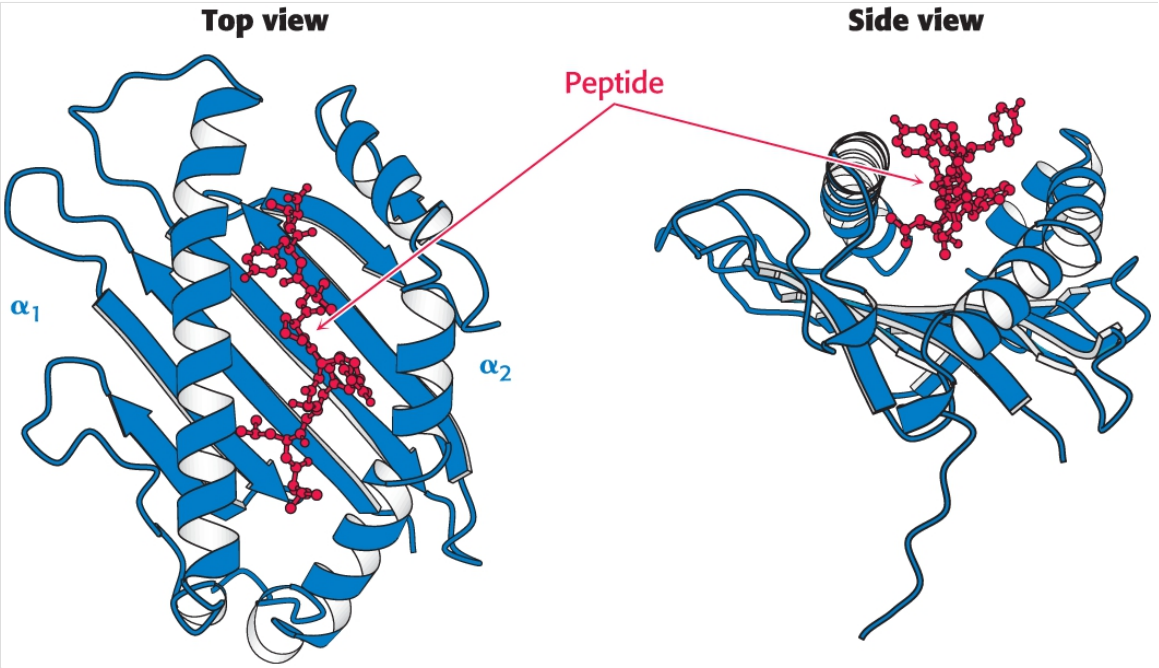

FIGURE 3.46 In class I MHC proteins, peptides can bind in the groove. The peptide (shown in red) binds in a relatively extended conformation.

The first class I MHC protein to have its structure determined binds peptides that almost always have leucine in the second position and valine in the last position (Figure 3.47). Side chains from the MHC molecule interact with the amino and carboxyl termini and with amino acids in these two key positions. These two residues are often referred to as the *anchor residues*. The other residues are highly variable. Thus, many millions of different peptides can be presented by this particular class I MHC protein; the identities of only two of the nine residues are crucial for binding to the MHC protein. Each different MHC molecule

recognizes a unique set of anchor residues, so a tremendous range of peptides can be presented by these molecules.

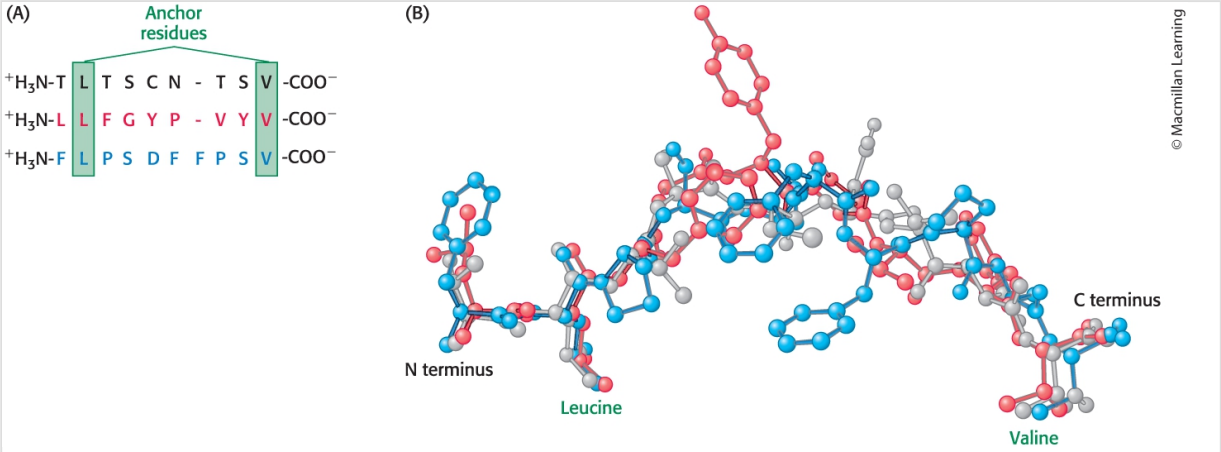

FIGURE 3.47 Each MHC class I protein presents peptides with some recurring features. (A) The amino acid sequences of three peptides that bind to the class I MHC protein HLA-A2 are shown. Each of these peptides has leucine in the second position and valine in the carboxyl-terminal position. (B) Comparison of the structures of these peptides reveals that the amino and carboxyl termini, as well as the side chains of the leucine and valine residues, are in essentially the same positions in each peptide, whereas the remainder of the structures are quite different.

One face of the bound peptide is exposed to solution, where it can be examined by other molecules, particularly receptors on the surfaces of T cells. These T-cell receptors have a structure that is closely related to the F_{ab} portion of an antibody, comprising two chains with immunoglobulin folds and hypervariable loops. Each T-cell receptor is, in principle, capable of recognizing an MHC-peptide complex by forming a structure analogous to an antibody–antigen complex (Figure 3.48).

FIGURE 3.48 The T-cell receptor recognizes specific class I MHC complexes, contacting both the MHC protein and the bound peptide. The bound peptide is shown in red.

INTERACT with the models shown in Figures 3.45, 3.46, and 3.48 in Achieve

Neither the foreign peptide alone nor the MHC protein alone forms a complex with the T-cell receptor. Molecular recognition depends on the complete structure identifying fragments of an intracellular pathogen, after they are presented in a context that allows their detection and an appropriate response. An assembly consisting of the foreign peptide-MHC complex, the T-cell receptor, and some additional proteins triggers a cascade that induces death of the infected cell.

We close this section by considering an essential biological aspect of molecular recognition in the immune system; namely, the ability to distinguish between self and non-self. How is this achieved? There is no special molecular characteristic of self-proteins that pathogen proteins lack. Instead, the answer lies in developmental biology: antibody-producing cells and T cells that react to self-proteins are identified and blocked before they are released into the circulation, preventing dangerous immune responses to normal tissues. This process can fail, however, as revealed by the occurrence of autoimmune diseases such as type 1 diabetes, rheumatoid arthritis, and dozens of other conditions.

Lance Hayashida/Caltech

PAMELA BJORKMAN Soon after entering graduate school with a strong background in chemistry, Pamela Bjorkman was intrigued by a presentation by Assistant Professor Don Wiley, who was trying to determine the three-dimensional structures of an important viral protein. She also learned that another graduate student in Professor Jack Strominger's laboratory had painstakingly purified substantial amounts of an MHC protein. She convinced the two professors that she should try to solve the MHC structure for her PhD dissertation project. She was stymied in solving the structure by what turned out to be unexpected peptides bound in the groove, but she completed the structure as a postdoctoral fellow. The elucidation of this MHC-

peptide structure represents a key milestone in immunology. Dr. Bjorkman has gone on to an extremely productive career at the California Institute of Technology, where she works with students, fellows, and staff to reveal other important structures of the immune system, with an aim to developing interventions that improve human health.

3.5 Quantitative Terms Can Describe Binding Propensity

Molecular recognition is not a “yes or no” process. The tendency of a receptor to bind a particular ligand depends on the ligand concentration. We have thus far used parameters such as $L_{1/2}$ and P_{50} to capture this concentration dependence. In order to describe binding propensity in more quantitative terms, we will now apply concepts from chemical equilibrium for ligand-binding reactions.

Dissociation constants are useful in describing binding reactions quantitatively

Recall the ligand-binding reaction (equation 1)

$$\mathrm{R} + \mathrm{L} \rightleftharpoons \mathrm{RL}$$

The equilibrium constant for this reaction is

$$K = \{\mathrm{RL}\}/\{\mathrm{R}\}\{\mathrm{L}\}$$

where {X} is the thermodynamic activity for component X. These activities are ratios of the concentrations of the components relative to standard states; they are unitless quantities and, therefore, so is *K*. The standard states are usually defined as concentrations of 1 M. With certain assumptions, the equilibrium constant can be written in terms of concentration as

$$K = [RL]/[R][L]$$

where [X] is the concentration of component X in molarity. Since each concentration has units of molarity, the equilibrium constant has units of M^{-1}; the appearance of units of molarity reflects the choice of standard states.

The equilibrium constant for this reaction is often written as K_a, where the subscript "a" refers to the fact this this is an association reaction. (This K_a should not be confused with K_a related to acidity and pH.) An equivalent but generally more useful quantity is the equilibrium constant for the reaction written as a dissociation process:

$$RL \rightleftharpoons R + L$$

$$K_d = [R][L]/[RL]$$

K_d has units of concentration (in molarity with standard states of 1 M). These units are easier to understand intuitively than are units of inverse concentration.

Suppose that $[L] = L_{1/2}$. Recall that under these conditions, half of the receptor is bound and half is unbound, therefore, $[R] = [RL]$. Making these two substitutions for [L] and [R] in the equation for K_d above gives us:

$$K_d = [RL][L_{1/2}]/[RL] \text{ or } K_d = L_{1/2}$$

In many experiments, the concentration of the receptor-ligand complex, RL, is measured as the concentration of added L is increased. In general, the concentrations of free R and free L are not measured, but rather the total concentrations of R and L are known. We can use these parameters in the equilibrium constant expression:

$$R_{total} = [R] + [RL] \text{ so } [R] = R_{total} - [RL]$$

$$\text{and } L_{total} = [L] + [RL] \text{ so } [L] = L_{total} - [RL]$$

$$\text{Thus, } K_d = (R_{total} - [RL])(L_{total} - [RL])/[RL]$$

Except for ligands that are bound very tightly, the concentration of [RL] is usually much lower than the total concentration of L added, that is, $L_{total} - [RL] \approx L_{total}$.

Then, $K_d = (R_{total} - [RL])(L_{total} - [RL])/[RL] \approx (R_{total} - [RL])(L_{total})/[RL]$

$$= R_{total}L_{total}/[RL] - L_{total}$$

Rearranging, we find that $K_d + L_{total} = R_{total}L_{total}/[RL]$ so that

$$[RL]/R_{total} = L_{total}/(K_d + L_{total})$$

(2)

Now, suppose that the total added ligand concentration is equal to K_d.

$$[RL]/R_{total} = L_{total}/(K_d + L_{total}) = L_{total}/(L_{total} + L_{total}) = 1/2$$

At this point, the one half of the total receptor concentration is bound to L. Therefore, the dissociation constant K_d is equivalent to $L_{1/2}$. Also notice that $[RL]/R_{total}$ is the fraction of the total receptor bound to a ligand; thus, the degree of saturation of the receptor with a ligand can be found from equation 2 once the K_d value is known (**Figure 3.49**).

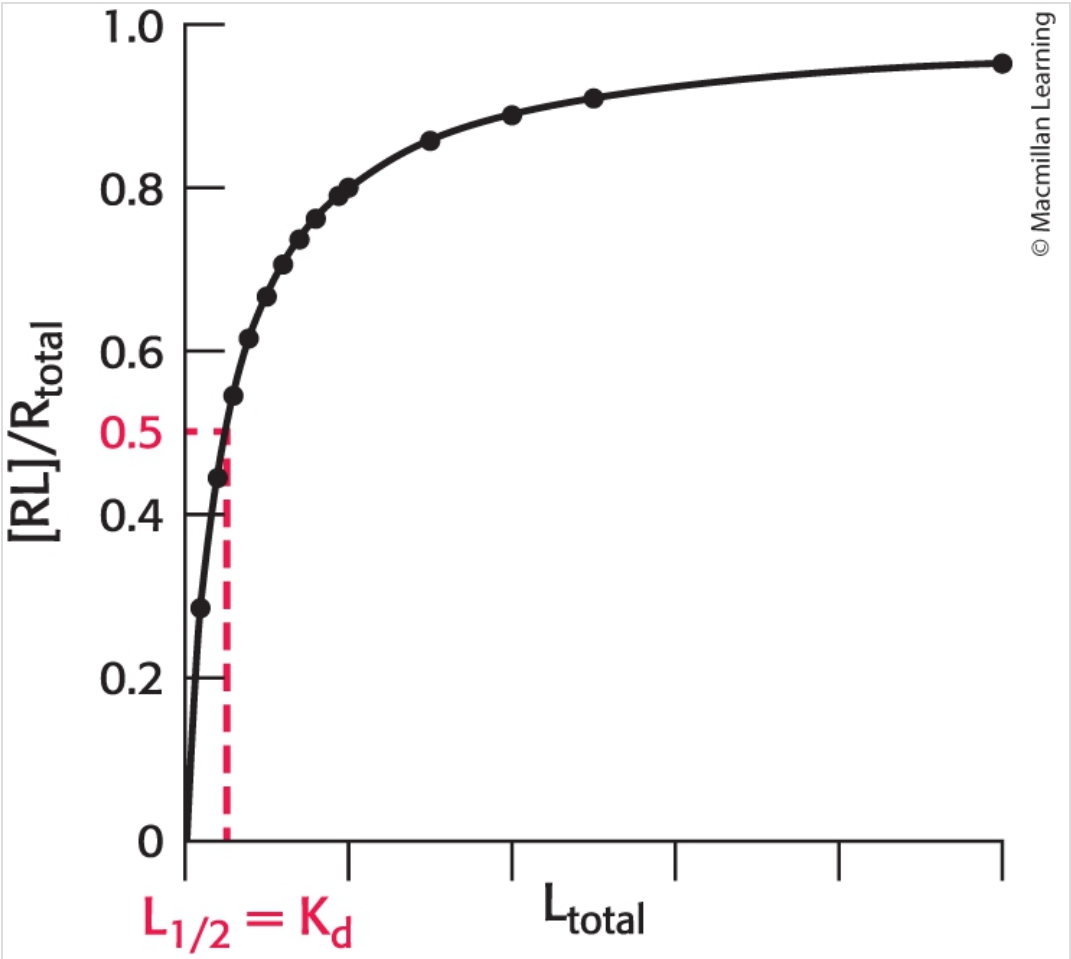

FIGURE 3.49 Binding can be monitored by measuring the fraction of receptors with ligand bound as a function of the amount of ligand added. The data curve is characterized by the value of K_d, which is the same as $L_{1/2}$.

Example

Determining the Fraction of Bound Receptors

Problem:

What fraction of receptors are occupied with ligand at a ligand concentration of $5\ \mu M$, given that half of the receptors are occupied with ligand at a total ligand concentration of $20\ \mu M$?

Getting Started:

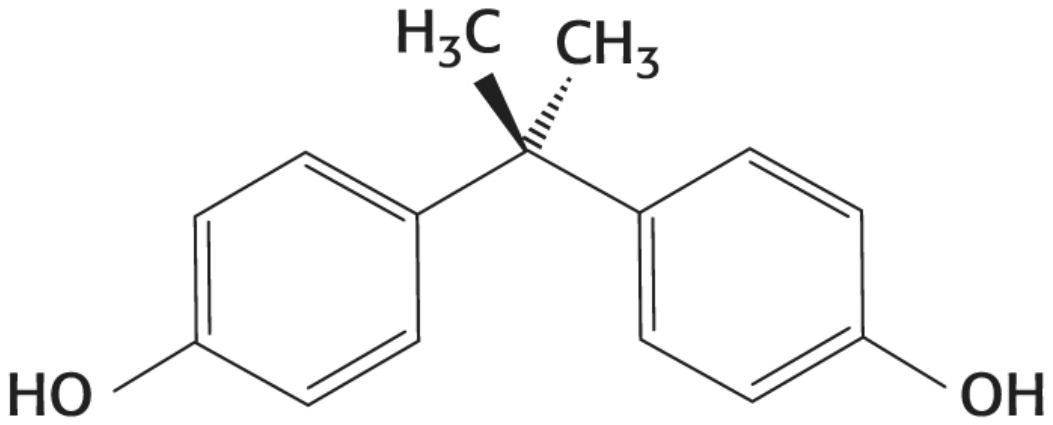
Equation 2 gives the relationship between the fraction of receptors occupied with ligands as a function of the total ligand concentration and the dissociation constant:

$$[RL]/R_{total} = L_{total}/(K_d + L_{total})$$

We are interested in what happens at a total ligand concentration of $5\ \mu M$. In order to use equation 2, we need to know the dissociation constant.

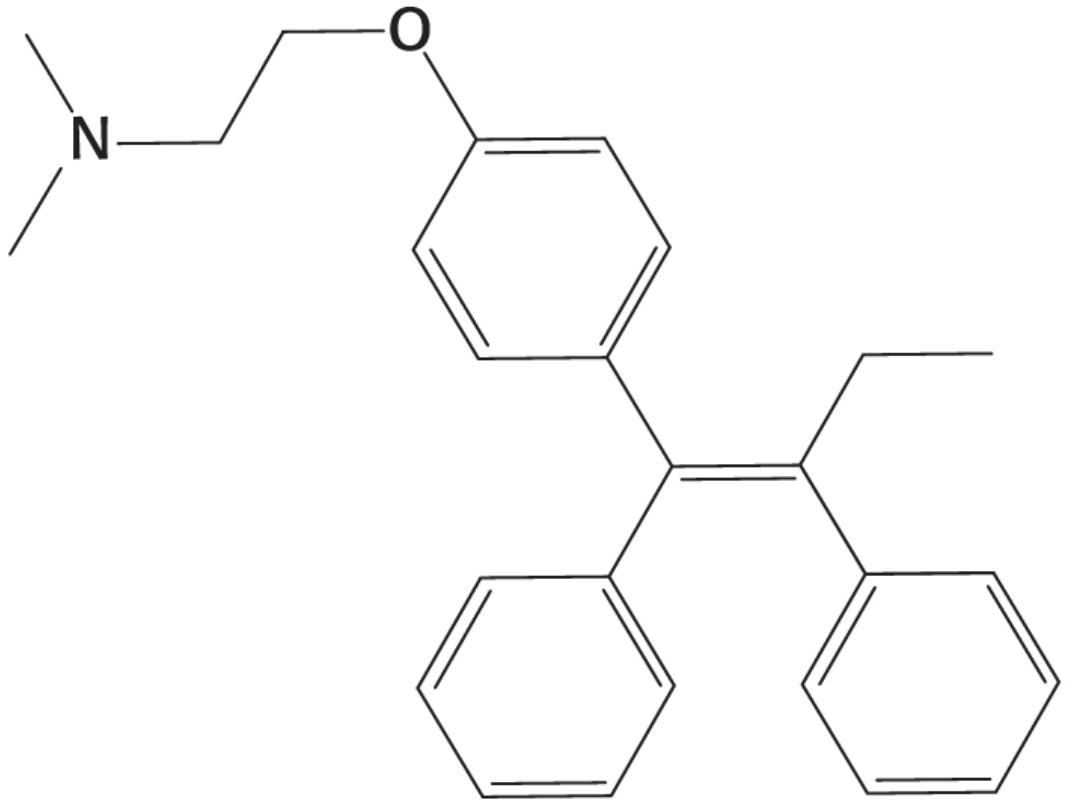
Solve:

We showed that the half of the receptors are occupied with ligands when the total ligand concentration is equal to the dissociation constant. Since half of the receptors are occupied when the ligand concentration is $20\ \mu M$, we know that $K_d = 20\ nM$. Substituting this and $L_{total} = 5\ \mu M$ into equation 2, we find that



$$[RL]/R_{total} = 5\ \mu M/(20\ \mu M + 5\ \mu M) = 0.20$$

Reflect:



This result makes sense since the total ligand concentration is somewhat less than $20\ \mu M$, the ligand concentration at which half (0.50) of the receptors are occupied.

Specificity can be quantified by comparing dissociation constants

Molecular recognition is reflected not just in the affinity of a protein for its preferred ligands, but also in the affinities of the protein for other potentially competitor ligands. For example, estrogen receptors can bind ligands such as estradiol but also competitor ligands such as bisphenol A (BPA), a precursor used in the manufacture of some types of plastics, and tamoxifen, a cancer drug that is bound without receptor activation.

Bisphenol A (BPA)

Tamoxifen

For estradiol, the $L_{1/2}$, which we now know is equal to the dissociation constant K_d, is 1 nM. Thus, if the estradiol concentration is 1 nM, the fraction of receptors that will be occupied by estradiol is 0.5. For BPA, $L_{1/2} = K_d = 200\ \text{nM}$. If we assume that BPA is present at a concentration of 1 nM, we can apply equation 2 to find that the fraction of receptors occupied is $1\ \text{nM} / (200\ \text{nM} + 1\ \text{nM}) = 0.005$. The concentration of BPA must be increased to 200 nM in order for the fraction of receptors to be occupied with BPA to reach 0.5.

Suppose we have estrogen receptors in the presence of 1 nM estradiol and then add $1\ \mu\text{M}$ BPA (**Figure 3.50**). We cannot simply use equation 2 for each ligand, because this equation was derived assuming that $R_{total} = [R] + [RL]$ without any other species present. But with two ligands, say L_1 and L_2, R_{total} must be replaced with $[R] + [RL_1] + [RL_2]$, since the receptor can be unoccupied or bound to either ligand. Using this expression, we can derive the concentrations of RL_1 and RL_2 as a function of the concentrations of L_1 and L_2, although we will not go through this derivation here. With 1 nM estradiol and $1\ \mu\text{M}$ BPA, we find that the fraction of receptors occupied with estradiol is 0.14 and the fraction of receptors occupied with BPA is 0.71. Thus, the fraction of receptors bound to estradiol drops due to the addition of substantial concentrations of BPA. Conceptually, we can understand this in the following way. Initially, half of the receptors are bound to estradiol and half are unoccupied. As the concentration of BPA increases, BPA will bind to the free receptors. This will drive the equilibrium

$$\text{Receptor} + \text{estradiol} \rightleftharpoons \text{Receptor-estradiol}$$

away from the receptor-estradiol complex as the occupied receptor concentration drops.

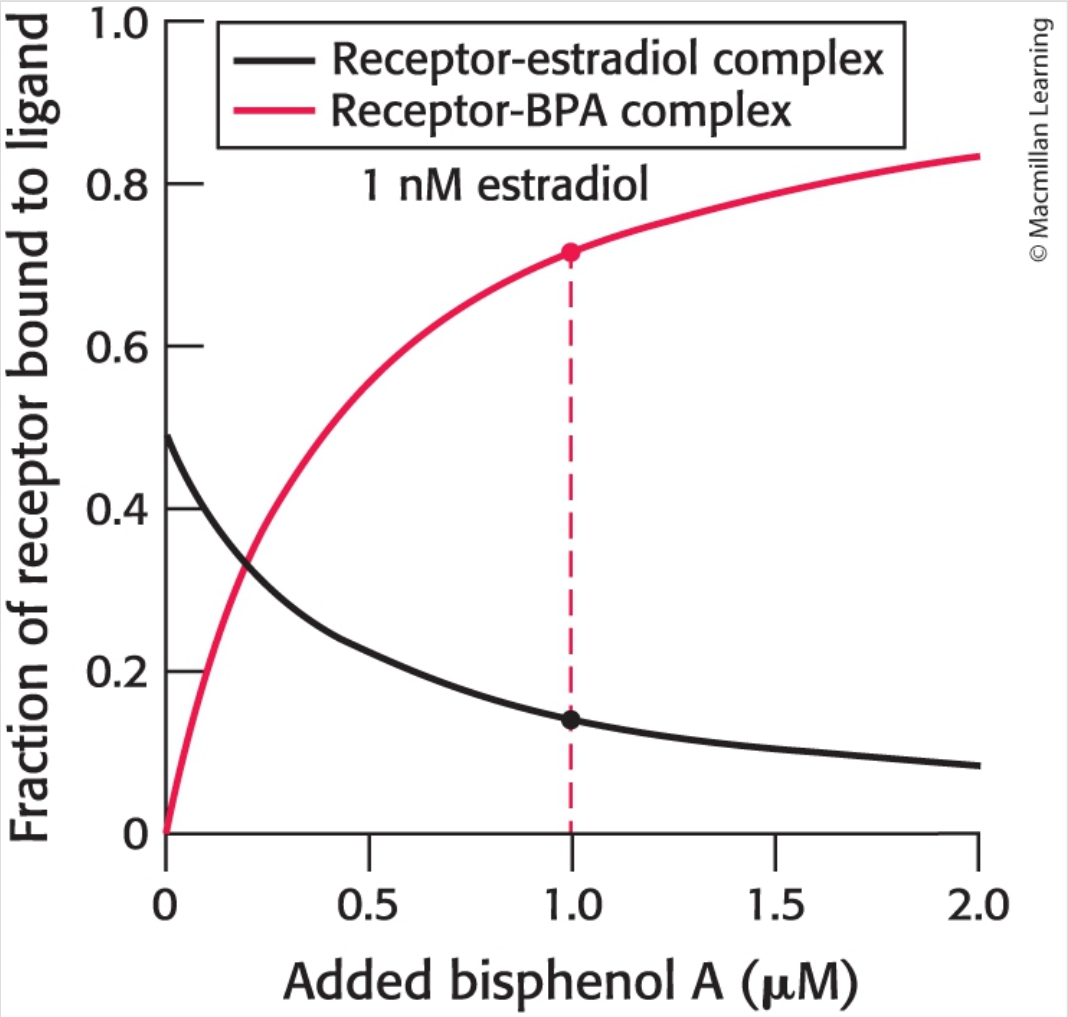


FIGURE 3.50 At high enough concentrations, ligands with lower affinity for a receptor can compete for binding with high-affinity ligands. The curves show the concentrations of an estrogen receptor-estradiol complex (black) and an estrogen receptor-BPA complex (red) as a function of increasing concentrations of BPA. At a BPA concentration of $1\ \mu M$, the fraction of estrogen receptor bound to estradiol is reduced from 0.5 to 0.14.

This analysis provides a quantitative measure of how well estrogen receptors recognize estradiol compared with BPA as an alternative ligand based on their different K_d values; if the two ligands are present at the same concentration, then a much larger fraction of receptors will bind estradiol; a much higher concentration of BPA is required for BPA to successfully compete with estradiol for the receptor-binding sites.

Kinetic parameters can also describe binding processes

Equilibria can also be viewed from the perspective of the rates of forward and reverse reactions.

$$R + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RL$$

The forward reaction, the association of R and L to form RL, is a second-order reaction, meaning that its rate depends on the concentrations of two species, R and L. The rate of the forward reaction is given by

$$\text{Rate}_{\text{forward}} = k_1[R][L]$$

The forward rate constant, k_1, has units $M^{-1}s^{-1}$. The reverse reaction, the dissociation of RL, is a first-order reaction, depending only on the concentration of RL. The rate of the reverse reaction is given by

$$\text{Rate}_{\text{revserse}} = k_{-1}[RL]$$

The reverse rate constant, k_{-1}, has units s^{-1}.

At equilibrium, the concentrations of all species are unchanging. The rates of the forward and reverse reactions must be the same even though both reactions are still continuing (Figure 3.51). $\text{Rate}_{\text{forward}} = \text{Rate}_{\text{reverse}}$, so that $k_1[R][L] = k_{-1}[RL]$; therefore, $k_{-1}/k_1 = [R][L]/[RL] = K_d$. Thus, we can also determine the dissociation constant of a complex, K_d, by examining the ratio of the reverse rate constant to the forward rate constant.

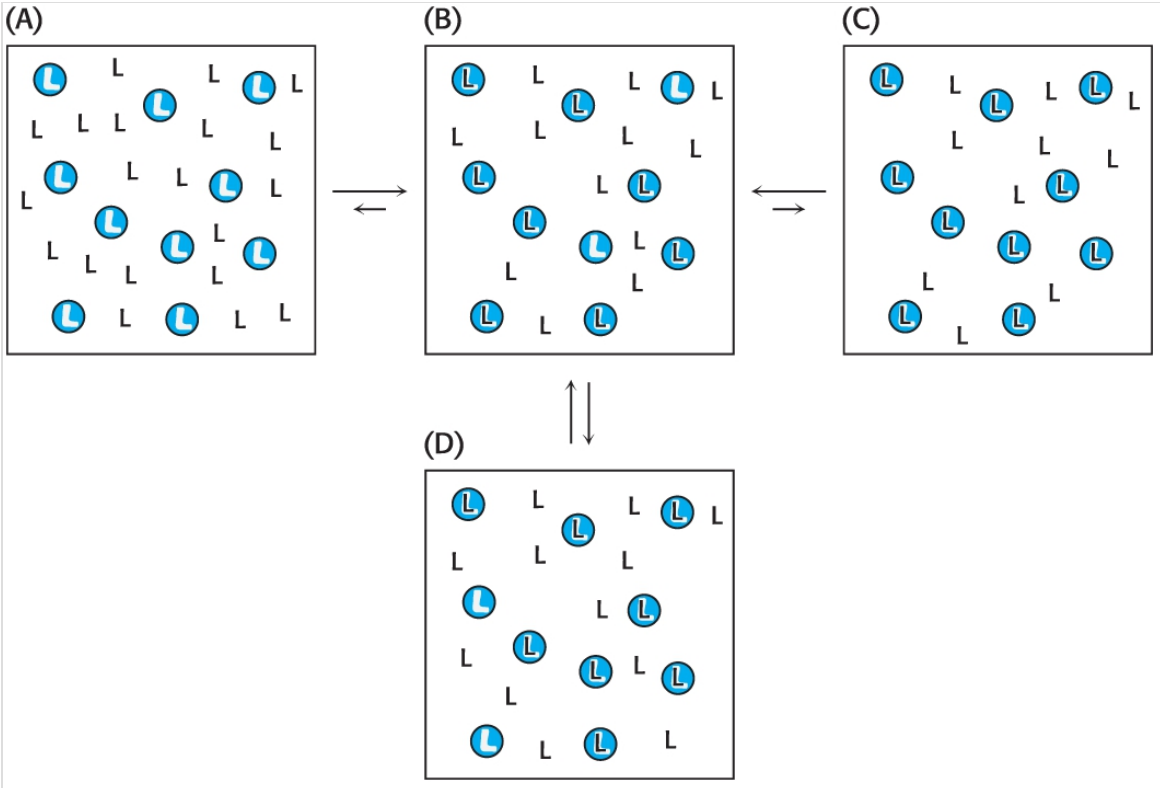

FIGURE 3.51 At equilibrium, the rates of the forward and reverse reactions are the same. A ligand-binding reaction is shown. In (A), no ligands are bound and the forward reaction will proceed faster than the reverse reaction to reach the equilibrium distribution in (B). In (C), all receptor sites are filled and the reverse reaction will proceed faster to reach (B). At equilibrium,

the forward and reverse reactions can proceed at the same rates to interconvert the distributio
in (B) and (D), which have the same fraction of receptors filled.

Self-Check Question

A receptor binds a ligand L with a rate of $10^4\ s^{-1}$ when the ligand concentration is 1 mM. The dissociation rate is $50\ s^{-1}$. What is the dissociation constant for the receptor-ligand complex?

Let us consider again the complex between the estrogen receptor and estradiol. The forward rate constant is found to be approximately $1.2 \times 10^6\ M^{-1}s^{-1}$, and the reverse rate constant is found to be $1.2 \times 10^{-3}\ s^{-1}$, consistent with $K_d = (1.2 \times 10^{-3}\ s^{-1})/(1.2 \times 10^6\ M^{-1}s^{-1}) = 10^{-9}\ M = 1\ nM$. For comparison, for BPA, the forward rate constant is found to be approximately $1.3 \times 10^6\ M^{-1}s^{-1}$ and the reverse rate constant is $2.7 \times 10^{-1}\ s^{-1}$, consistent with $K_d = (2.7 \times 10^{-1}\ s^{-1})/(1.3 \times 10^6\ M^{-1}s^{-1}) = 2 \times 10^{-7}\ M = 210\ nM$.

Notice that the forward rate constants are quite similar to one another, at approximately $1 \times 10^6\ M^{-1}s^{-1}$. There is a limit for such forward rate constants, as two molecules cannot form a complex any faster than they can diffuse together and collide. The rate constants for such

diffusion processes for proteins and small molecules in solution are approximately $10^9\,M^{-1}s^{-1}$. Of course, not all collisions result in complex formation. The ratio of the observed rate constant to the diffusion limit of $10^6\,M^{-1}s^{-1}/10^9\,M^{-1}s^{-1} = 0.001$ indicates that approximately 1 in 1000 collisions is productive.

Empirically, many forward rate constants for biochemical binding reactions are found to fall in the $10^6 - 10^7\,M^{-1}s^{-1}$ range, providing a useful tool for estimating such rate constants in the absence of other information, although there are exceptions. For example, the drug tamoxifen binds to the estrogen receptor with a forward rate constant of only $4.5 \times 10^3\,M^{-1}s^{-1}$. However, the reverse rate constant for the estrogen-tamoxifen complex is $1.0 \times 10^{-3}\,s^{-1}$, consistent with $K_d = (1.0 \times 10^{-3}\,s^{-1})/(4.5 \times 10^3\,M^{-1}s^{-1}) = 22 \times 10^{-7}\,M = 220\,nM$. The strikingly low forward rate constant indicates that only a small number of collusions result in complex formation, consistent with a substantial conformational change being necessary for binding.

We close the chapter with a reminder that rate constants are ensemble properties and, as such, represent the average behavior of the single molecules within the ensemble. For instance, for the estrogen receptor-tamoxifen complex the dissociation rate constant is $1.0 \times 10^{-3}\,s^{-1}$, but if we were to examine such complexes at the single molecule level, we would see a distribution of dissociation times (**Figure 3.52**). The histogram of these dissociation times can be fit to an exponential equation of the form

$$RL(t) = RL_0 e^{-k_{-1}t}$$

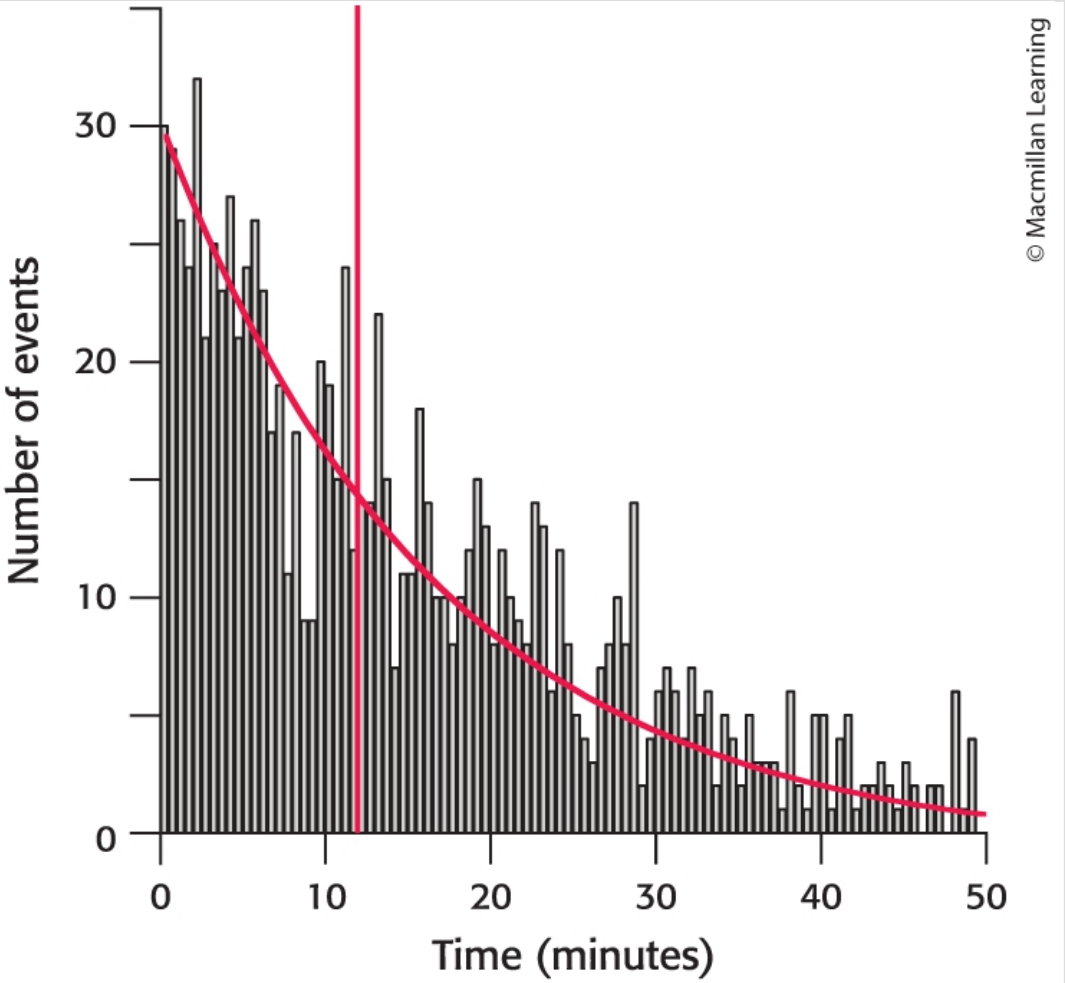

FIGURE 3.52 A rate constant reflects the distribution of reaction times at the single molecule level. The results of a simulation with 1000 events of dissociation times for an estrogen receptor–tamoxifen complex are shown, with dissociation times ranging from nearly zero to more than 50 minutes, with an average of 12 minutes. The rate constant of $1.0 \times 10^{-3}\ s^{-1}$ characterizes the exponential decline in this distribution, shown in red.

The average dissociation time in this distribution is approximately 12 minutes, a duration that is quite long in the context of the biochemical timescale. This may be important for the role of tamoxifen as a drug since, once bound, it remains bound to the receptor and blocks estradiol binding for a substantial period of time.

Chapter 3 Summary

3.1 Binding Is a Fundamental Process in Biochemistry

- Many biochemical macromolecules form specific complexes with other macromolecules or metabolites, and these molecular recognition processes facilitate the organization and specificity of binding.
- The tendency of molecules to form complexes increases as the concentration of the partners rises, with the key concentrations required for substantial complex formation varying greatly from one complex to another.
- The concentrations of many biomolecules fall in the range required to drive substantial complex formation.

3.2 Myoglobin Binds and Stores Oxygen

- The muscle protein myoglobin binds oxygen via a bound heme group with a central iron atom.
- Myoglobin binds oxygen via a simple binding reaction; myoglobin is half-saturated with oxygen at a partial pressure of 2 torr, corresponding to a high oxygen affinity.

3.3 Hemoglobin Is an Efficient Oxygen Carrier

- Human hemoglobin consists of four myoglobin-like subunits of two types, forming a homodimer of heterodimeric structures.
- Hemoglobin binds oxygen cooperatively, with relatively low affinity when no oxygen is bound, but higher affinity as each hemoglobin tetramer has already bound an increasing number of oxygen molecules.
- This cooperativity together with changes in the oxygen affinity in response to pH and the presence of carbon dioxide make

hemoglobin quite efficient in delivering oxygen to tissues where it is most needed.
- Sickle-cell disease illustrates how the change of a single amino acid in a large protein can lead to disease through the formation of an unusual macromolecular complex.

3.4 The Immune System Depends on Key Binding Proteins

- The immune system includes two components: an innate system that stands ready to respond immediately to signs of pathogens; and an adaptive system that develops specific components tailored to new pathogens encountered by the host.
- Antibodies, also known as immunoglobulins, have structures comprising a conserved framework with hypervariable loops that form binding surfaces able to recognize almost any foreign antigen.
- Class I major compatibility complex proteins include a deep binding groove that presents peptides from foreign proteins on surfaces where they can be sensed by T-cell receptors, leading to an immune response.

3.5 Quantitative Terms Can Describe Binding Propensity

- Binding reactions are chemical equilibria that can be described in quantitative terms, allowing the calculation of the concentrations of various species based on a small number of parameters, including the dissociation constant and kinetic rate constants.
- Different molecules (ligands) can compete for binding to the same receptor site; the relative occupancies depend on the binding affinities and concentrations of these ligands.

Problems

1. What fraction of estrogen receptors is expected to be free in the presence of an estradiol concentration of 1 nM assuming no other ligands are present? 1

2. The molecular weight of sperm whale myoglobin is 17.8 kDa. The myoglobin content of sperm whale muscle is about $80.0\ g \cdot kg^{-1}$. In contrast, the myoglobin content of some human muscles is about $8.00\ g \cdot kg^{-1}$.

a. Compare the amounts of O_2 bound to myoglobin in human muscle and in sperm whale muscle. Assume that the myoglobin is saturated with O_2, and that the molecular weights of human and sperm whale myoglobin are the same. 2
b. The amount of oxygen dissolved in tissue water at 37°C is about $3.5 \times 10^{-5}\ M$. What is the ratio of myoglobin–bound oxygen to dissolved oxygen in the tissue water of sperm whale muscle?

3. Suppose myoglobin is prepared with Zn^{2+} in the place of Fe^{2+} in the porphyrin. Would you expect this modified myoglobin to bind oxygen? 2

4. Does myoglobin exhibit a Bohr effect? Why or why not? 3

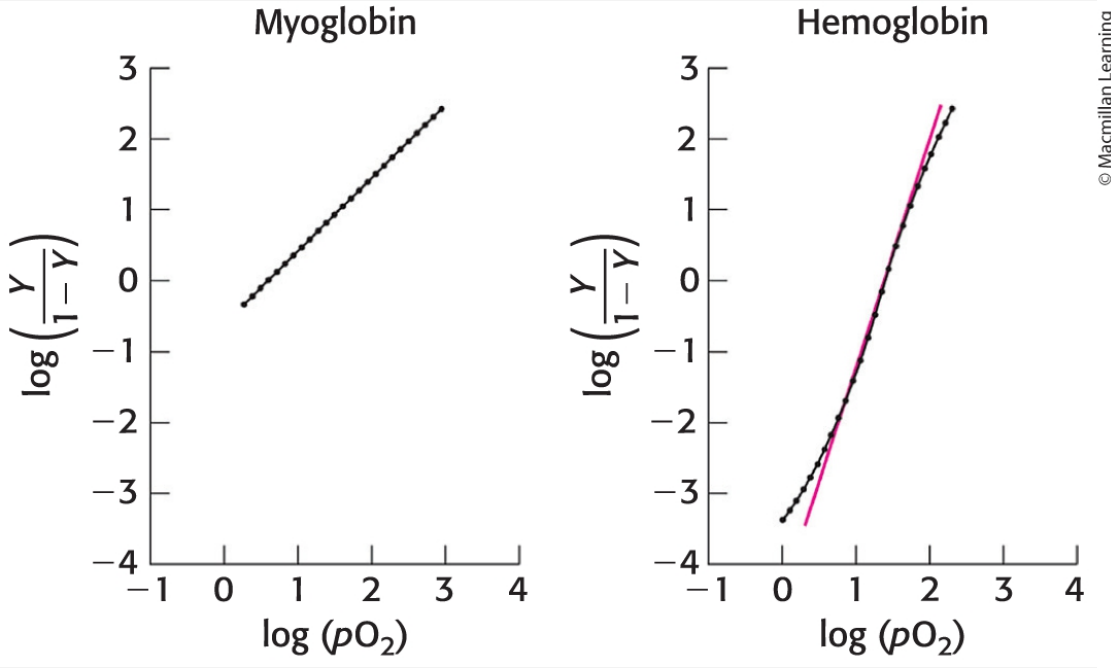
5. Alkyl isocyanides, R-NC, are bound by myoglobin and hemoglobin.

Would you expect that n-hexyl isocyanide would be bound more or less tightly than methyl isocyanide? Briefly explain. 2

6. The pK_a of an acid depends partly on its environment. Predict the effect of each of the following environmental changes on the pK_a of a glutamic acid side chain. 3

a. If a lysine side chain is brought into proximity, the pK_a of the glutamic acid chain is _____.
b. If the terminal carboxyl group of the protein is brought into proximity to the glutamic acid side chain, the pK_a of the side chain is _____.
c. If the glutamic acid side chain is shifted from the outside of the protein to a nonpolar site inside of the protein, the pK_a is _____.

7. In 1913, Archibald Hill described an alternative formulation for cooperative processes such as the binding of oxygen by hemoglobin by considering the hypothetical equilibrium



$$Hb + nO_2 \rightleftharpoons Hb(O_2)_n$$

Analysis leads to the Hill equation:

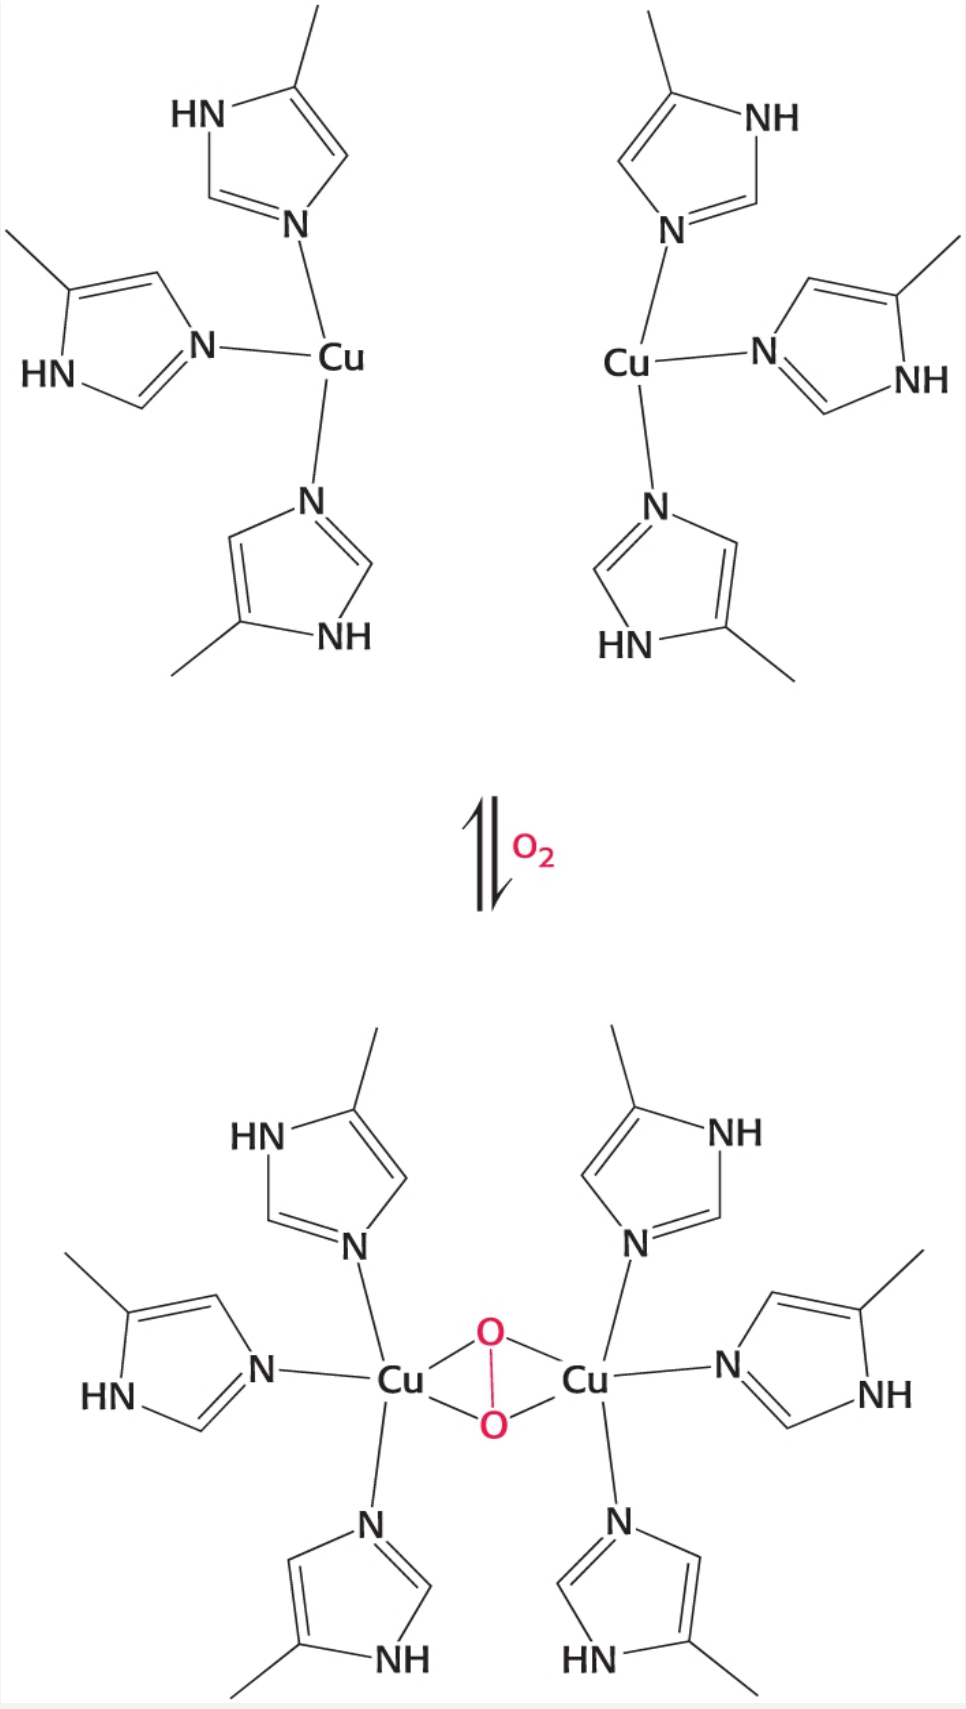
$$\log(Y/1-Y) = \log(pO_2{}^n / P_{50}{}^n) = n\log(pO_2) - n\log(P_{50})$$

where Y is the fractional saturation. This equation suggests that a plot of $\log(Y/1-Y)$ versus $\log(pO_2)$ should yield a line with slope n.

Plots for myoglobin and hemoglobin are shown below:

© Macmillan Learning

a. Estimate the apparent slope of the plot for myoglobin and comment on the value.
b. Estimate the apparent slope in the center of the plot for hemoglobin and comment on the value. 3

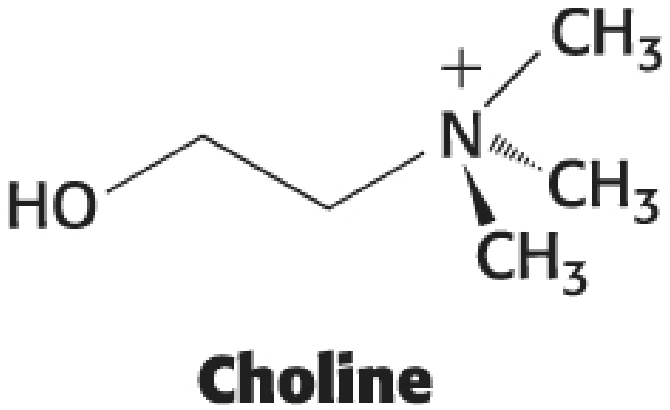


8. Suppose Gina climbs a high mountain where the oxygen partial pressure in the air decreases to 70 torr. Assume that the pH of her tissues and lungs is 7.4 and the oxygen concentration in her tissues is 20 torr. The P_{50} of hemoglobin is 26 torr. The degree of cooperativity of hemoglobin (n) based on the Hill equation in problem 7 is 2.8.

a. Estimate the percentage of the oxygen–carrying capacity that she utilizes. Calculate your answer to one decimal place.

After Gina spends a day at the mountaintop, where the oxygen partial pressure is 70 torr, the concentration of 2,3–bisphosphoglycerate (2,3–BPG) in her red blood cells increases.

b. Why does increasing the concentration of 2,3–BPG in Gina's blood cells help her function well at high altitudes?
 3



9. Arthropods such as lobsters have oxygen carriers quite different from those of hemoglobin. The oxygen-binding sites do not contain heme but, instead, are based on two copper (Cu) ions. The structural changes that accompany oxygen binding are shown below.

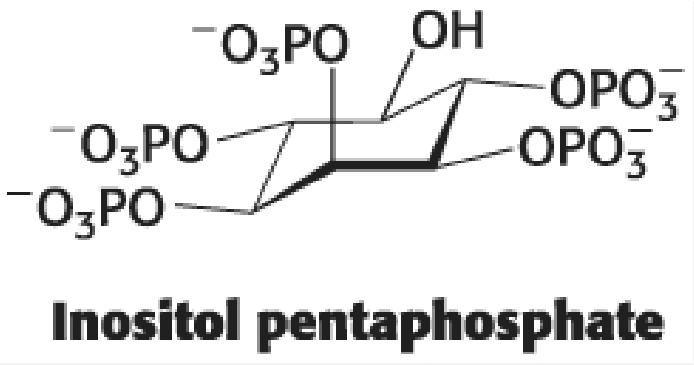
How might these changes be used to facilitate cooperative oxygen binding? 3

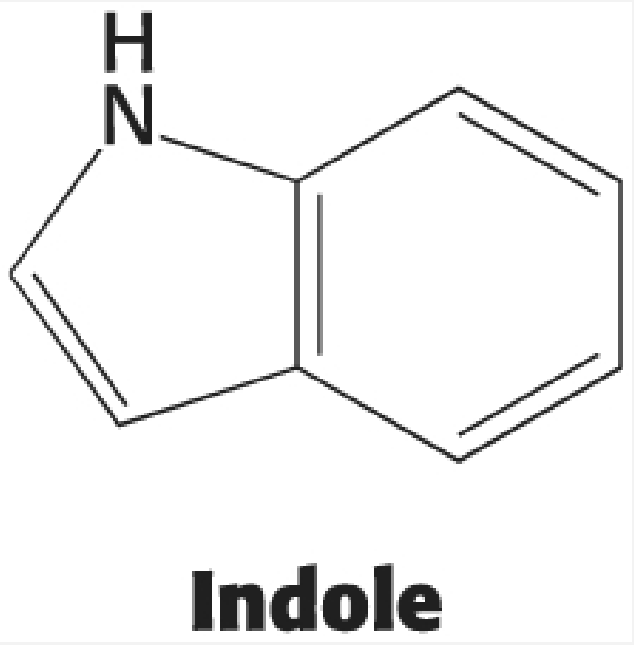
10. Blood cells from some birds do not contain 2,3-bisphosphoglycerate but, instead, contain one of the compounds shown below, which plays an analogous functional role. Which compound do you think is most likely to play this role? Explain briefly. 3

a.



Choline

b.



Spermine

c.

Inositol pentaphosphate

d.

Indole

11. Some Toll-like receptors bind nucleic acids that contain uracil, but not thymine or similar bases. What is the biological rationale for this binding preference? 4

12. Some of the first vaccines against COVID-19 are based on RNA molecules that lead to the production of the SARS-CoV-2 spike protein. The RNA molecules are modified so that one base is replaced with an alternative. What base is most likely to need to be replaced? 4

13. Addition of an IgG molecule specific for hemoglobin to a solution of hemoglobin results in the formation of a red precipitate. In contrast, addition of the F_{ab} fragments from this antibody to myoglobin results in no such precipitate. Propose an explanation. 4

14. The amino acid sequence of a small protein is MSRLASKNLIRSDHAGGLLQATYSAVSSIKNTMSFGAWSNAALNDS RDA. Which peptide would most likely be presented by the class I MHC molecule HLA–A2? 4

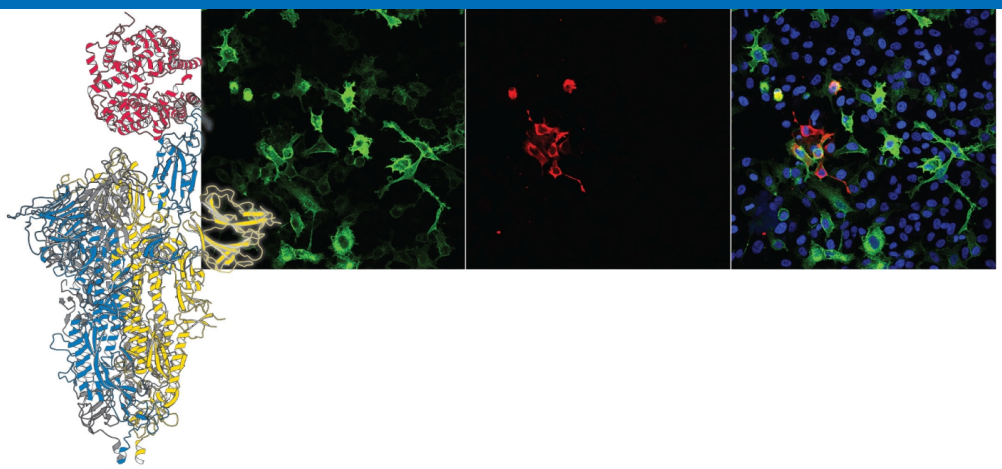
a. LLQATYSAV
b. MSRLASKNLIRSD
c. NLIRS
d. SSIKNTMSF

15. A receptor-ligand complex has a dissociation constant of $5\ \mu M$. What is the ratio of the receptor-ligand complex to total receptor when the total receptor concentration is 10 nM with total added ligand concentrations of $1\ \mu M$, $10\ \mu M$, $100\ \mu M$, and 1 mM. 5

16. Recall that when we calculated that estrogen receptors with 1 nM estradiol and $1\ \mu M$ BPA, the fraction of receptors occupied with estradiol was 0.14 and the fraction of receptors occupied with BPA was 0.71.

a. Calculate the concentration of free receptor in terms of the total concentration of receptor, R_{total}.

b. Calculate the concentration of free estradiol in terms of the total concentration of receptor, R_{total}.
c. Calculate the concentration of free BPA in terms of the total concentration of receptor, R_{total}.
d. Confirm the approximate values for the dissociation constants for the estrogen receptor-estradiol and estrogen receptor-BPA complexes. 5



17. A receptor-ligand complex has a dissociation constant of $K_d = 20\ nM$. The rate of receptor-ligand complex formation with an added ligand concentration of $10\ \mu M$ is $5 \times 10^3\ s^{-1}$. What is the value of the reverse rate constant, k_{-1}? 5

18. An F_{ab} fragment binds to lysozyme with a dissociation constant of $K_D = 10^{-11}\ M$. A $1\ nM\ (10^{-9}\ M)$ solution of lysozyme is treated with increasing concentrations of the F_{ab} fragment. At what concentration of added F_{ab} will half of the lysozyme be bound to F_{ab}? 5

19. A different F_{ab} fragment binds to lysozyme with a dissociation constant of $K_D = 10^{-6}$ M. A 1 nM solution of lysozyme is treated with increasing concentrations of this F_{ab} fragment. At what concentration of added F_{ab} will half of the lysozyme be bound to this F_{ab}? 5

20. Deoxyhemoglobin is treated with a 1:1 mixture of oxygen and carbon monoxide under conditions where essentially all of the iron atoms in hemoglobin are bound to a ligand. Approximately what percentage of the irons will be bound to oxygen? 2, 5

In 2019, researchers in China identified a new strain of coronavirus that caused acute respiratory syndrome in several thousand individuals in the city of Wuhan. Using antibodies labeled with fluorescent tags, they showed that the virus (center, labeled red) preferentially infected cells that expressed angiotensin-converting enzyme 2 (ACE2, left, labeled green). Note that the signals overlap in the combined image (right; cell nuclei are stained in blue). These data suggested that ACE2 served as the target for the virus particles. Less than a year later, the structure of the SARS-CoV-2 spike protein bound to ACE2 (shown at left) was solved by cryo-electron microscopy. These experiments were critical in understanding how the virus functions and developing effective vaccines.

Outline

4.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function
4.2 Immunology Provides Important Techniques for Investigating Proteins
4.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins
4.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods
4.5 Three-Dimensional Protein Structures Can Be Determined Experimentally

Learning Goals

By the end of this chapter, you should be able to:

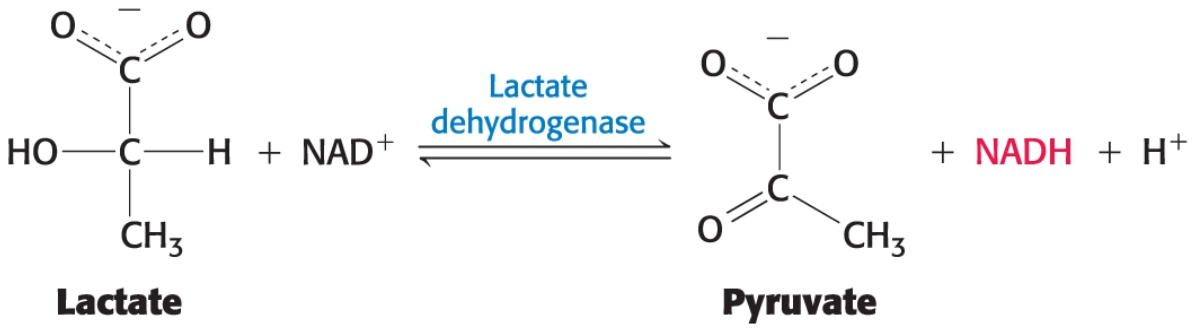
1. Explain the importance of protein purification and how it can be quantified.
2. Describe the different types of chromatography used to purify proteins.
3. Describe the different methods available for determining the mass of a protein.
4. Explain how antibodies can be used as tools for protein identification, purification, and quantitation.
5. Describe how proteins are sequenced, and explain why sequence determination is important.
6. Distinguish between the commonly used methods for protein structure determination, and describe the advantages and disadvantages of each.

A major goal of the biochemist is to understand how individual proteins adopt their unique structures and perform their functions. The first step in these experiments is usually the purification of the protein of interest so as to avoid confounding effects from contaminants. Once purified, a protein's molecular mass and amino acid sequence can be precisely determined. Many protein sequences are now available in vast sequence databases. Such a protein might

be identified by matching its mass to those deduced for proteins in these databases.

After a protein has been purified and its identity confirmed, the challenge remains to determine its function and its three-dimensional structure within a physiologically relevant context. Throughout this chapter, we will discuss some of the more commonly used — and still rapidly improving — methods to achieve the purification, functional evaluation, and structural determination of a given protein. The exploration of proteins by this array of physical and chemical techniques has greatly enriched our understanding of the molecular basis of life. These techniques make it possible to tackle some of the most challenging questions of biology in molecular terms.

4.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function



An adage of biochemistry is "never waste pure thoughts on an impure protein." Starting from pure proteins, we can determine amino acid sequences and investigate biochemical functions. From the amino acid sequences, we can map evolutionary relationships between proteins in diverse organisms (Chapter 10). By using crystals grown from pure protein, we can obtain x-ray data that will provide us with a picture of the protein's tertiary structure — the shape that determines function.

The assay: How do we recognize the protein we are looking for?

Purification should yield a sample containing only one type of molecule — the protein in which the biochemist is interested. This protein sample may be only a fraction of 1% of the starting material, whether that starting material consists of one type of cell in culture or a particular organ from a plant or animal. How is the biochemist able to isolate a particular protein from a complex mixture of proteins?

A protein can be purified by subjecting the impure mixture of the starting material to a series of separations based on physical properties such as size and charge. To monitor the success of this purification, the biochemist needs a test, called an **assay**, for some unique identifying property of the protein. A positive result on the assay indicates that the protein is present.

Although assay development can be a challenging task, the more specific the assay, the more effective the purification. For enzymes, the assay usually measures catalytic activity — that is, the ability of the enzyme to promote a particular chemical reaction. This activity is often measured indirectly. Consider the enzyme lactate dehydrogenase, which catalyzes the following reaction in the synthesis of glucose:

Reduced nicotinamide adenine dinucleotide (NADH, Section 15.4) absorbs light at 340 nm, whereas oxidized nicotinamide adenine dinucleotide (NAD^+) does not. Consequently, we can follow the progress of the reaction by examining how much light-absorbing ability is developed by a sample in a given period of time — for instance, within 1 minute after the addition of the enzyme. Our assay for enzyme activity during the purification of lactate dehydrogenase is thus the increase in the absorbance of light at 340 nm observed in 1 minute.

To analyze how our purification scheme is working, we need one additional piece of information — the amount of total protein present in the mixture being assayed. There are various rapid and reasonably accurate means of determining protein concentration. With these two experimentally determined numbers — enzyme activity and protein concentration — we then calculate the **specific activity**, the ratio of enzyme activity to the amount of protein in the mixture. Ideally, the specific activity will rise as the purification proceeds, and the protein

mixture will contain the protein of interest to a greater extent. For a pure enzyme, the specific activity will have a constant value. In essence, the overall goal of the purification is to maximize the specific activity.

Proteins must be released from the cell to be purified

Having found an assay and chosen a source of protein, we now fractionate the cell into components and determine which component is enriched in the protein of interest. In the first step, a **homogenate** is formed by disrupting the cell membrane, and the mixture is fractionated by centrifugation, yielding a dense pellet of heavy material at the bottom of the centrifuge tube and a lighter supernatant above (**Figure 4.1**). The supernatant is again centrifuged at a greater force to yield yet another pellet and supernatant. This procedure, called *differential centrifugation*, yields several fractions of decreasing density, each still containing hundreds of different proteins. The fractions are each separately assayed for the desired activity. Usually, one fraction will be enriched for such activity, and it then serves as the source of material to which more-discriminating purification techniques are applied.

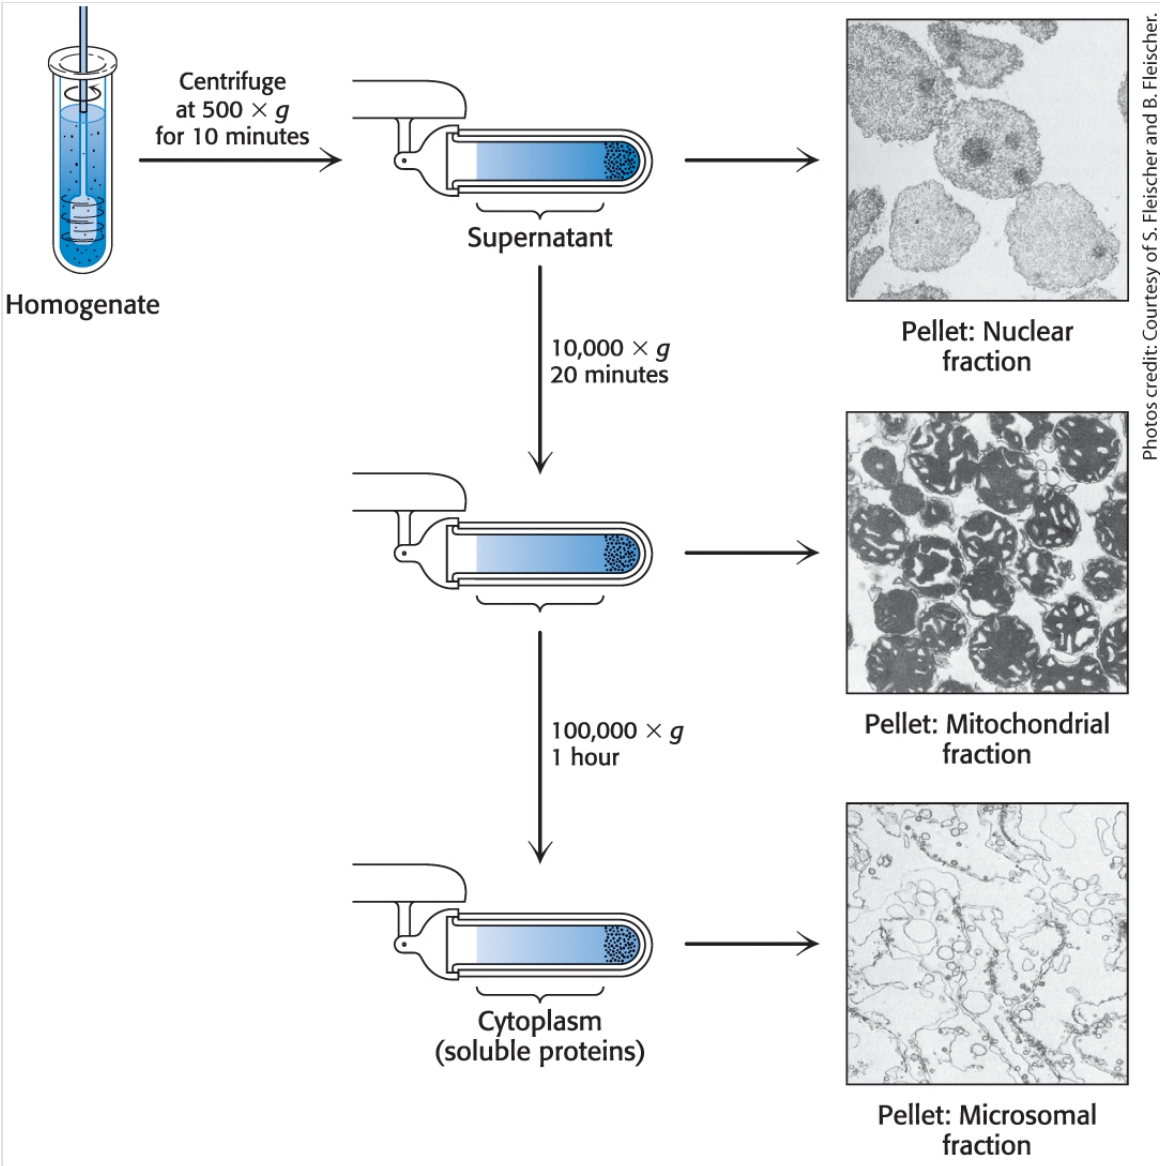


FIGURE 4.1 Differential centrifugation separates the contents of cells based on their density. Cells are disrupted in a homogenizer and the resulting mixture is centrifuged in a step-by-step fashion of increasing centrifugal force. Centrifugal forces are represented as multipliers of *g*, the force of gravity. The denser material will form a pellet at lower centrifugal force than will the less dense material. The isolated fractions can be used for further purification.

Proteins can be purified according to solubility, size, charge, and binding affinity

Thousands of proteins have been purified in active form on the basis of such characteristics as solubility, size, charge, and binding affinity. Usually, protein mixtures are subjected to a series of separations, each based on a different property. At each step in the purification, the preparation is assayed and its specific activity is determined. A variety of purification techniques are available.

Salting out

Most proteins are less soluble at high salt concentrations, an effect called *salting out*. The salt concentration at which a protein falls out of solution, or precipitates, differs from one protein to another. Hence, salting out can be used to fractionate proteins. For example, 0.8 M ammonium sulfate precipitates fibrinogen, a blood-clotting protein, whereas a concentration of 2.4 M is needed to precipitate serum albumin. Salting out is also useful for concentrating dilute solutions of proteins, including active fractions obtained from other purification steps. Dialysis can be used to remove the salt, if necessary.

Dialysis

Proteins can be separated from small molecules such as salt by **dialysis** through a semipermeable membrane, such as a cellulose membrane with pores (**Figure 4.2**). The protein mixture is placed inside the dialysis bag, which is then submerged in a buffer solution that is devoid of the small molecules to be separated away. Molecules having dimensions significantly greater than the pore diameter remain inside the dialysis bag. Smaller molecules and ions capable of passing through the pores of the membrane diffuse down their concentration gradients and emerge in the solution outside the bag. This technique is useful for removing a

salt or other small molecule from a cell fractionate, but it does not distinguish between proteins effectively.

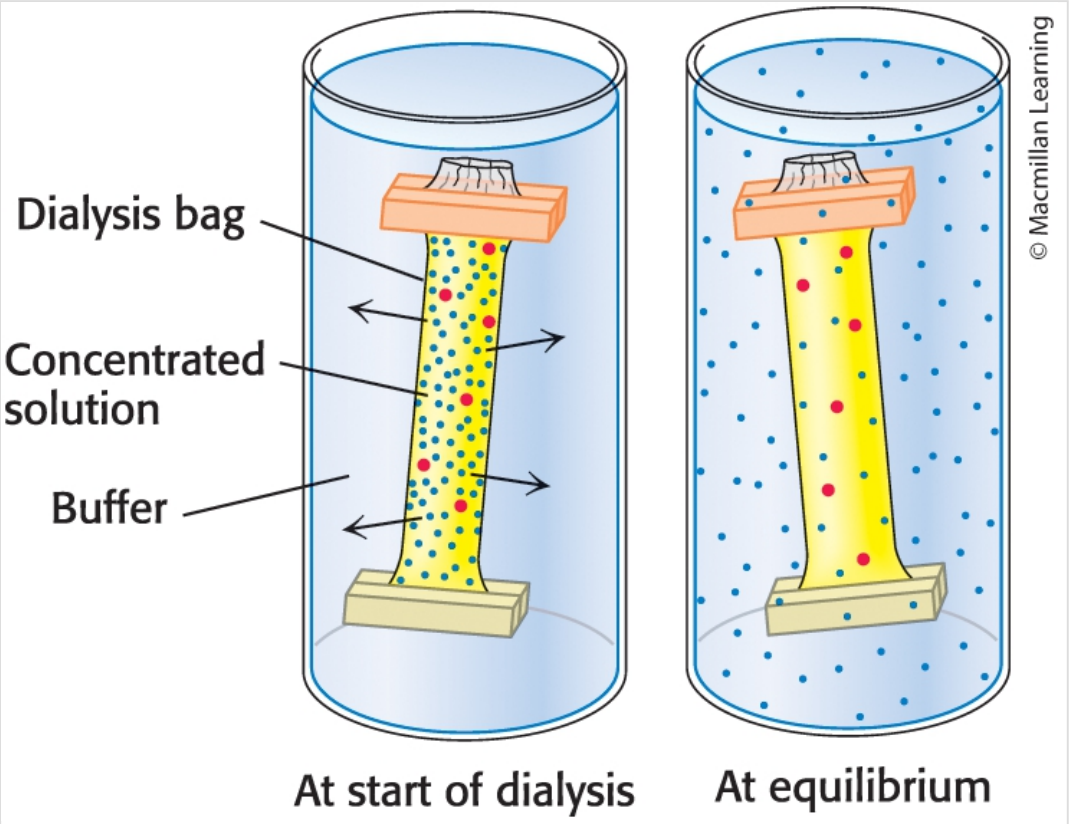

FIGURE 4.2 Dialysis separates proteins from smaller molecules. Protein molecules (red) are retained within the dialysis bag, whereas small molecules (blue) diffuse down their concentration gradient into the surrounding medium.

Gel-filtration chromatography

More precise separations on the basis of size can be achieved by the technique of **gel-filtration chromatography**, also known as molecular exclusion chromatography (Figure 4.3). The sample is applied to the top of a column consisting of porous beads made of an insoluble but highly hydrated polymer such as dextran or agarose (carbohydrates) or

polyacrylamide. Sephadex, Sepharose, and Biogel are commonly used commercial preparations of these beads, which are typically 100 μm (0.1 mm) in diameter. Small molecules can enter these beads; large ones cannot.

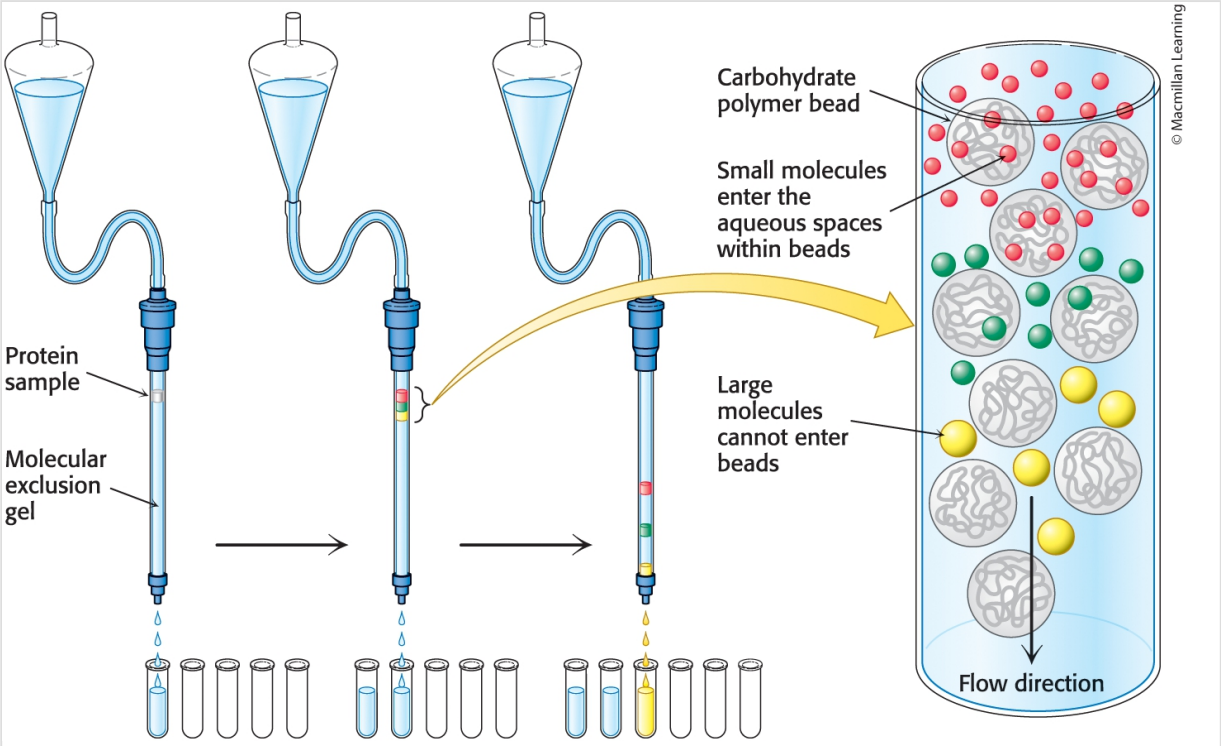

FIGURE 4.3 Gel-filtration chromatography separates proteins based on size. A mixture of proteins in a small volume is applied to a column filled with porous beads. Because large proteins cannot enter the internal volume of the beads, they emerge sooner than do small ones.

VIEW an animation of this technique in Achieve

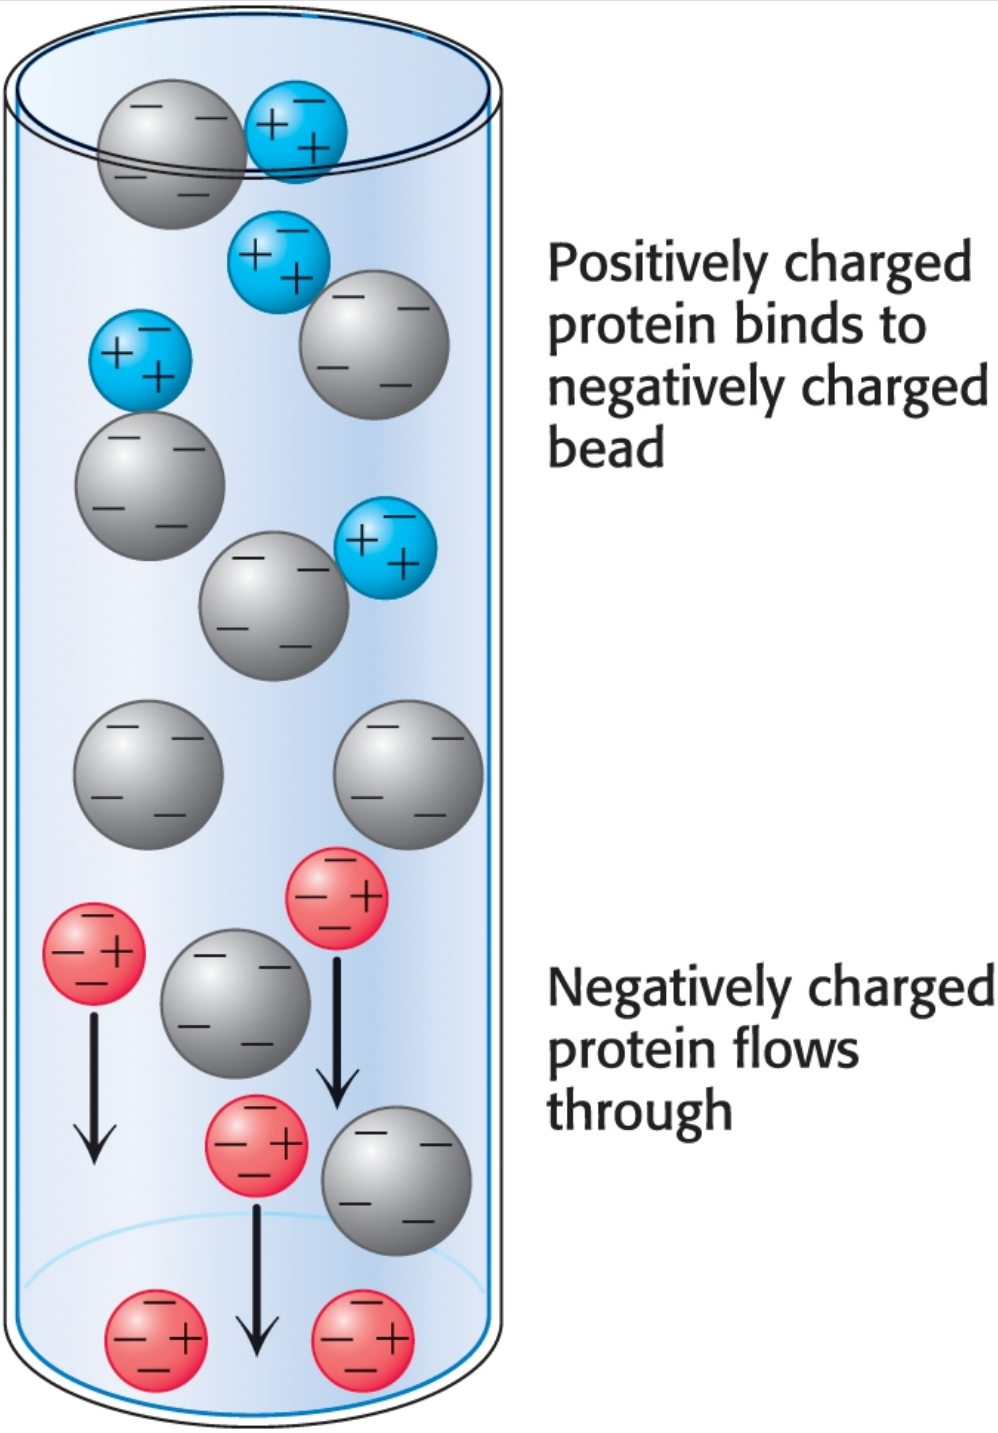
The result is that small molecules are distributed in the aqueous solution both inside the beads and between them, whereas large molecules are located only in the solution between the beads. Large molecules flow more rapidly through this column and emerge first because a smaller volume is accessible to them. Molecules of medium size occasionally enter the beads and will flow from the column at an

intermediate position, while small molecules, which take a longer path through the beads, will exit last.

Ion-exchange chromatography

To obtain a protein of high purity, one chromatography step is usually not sufficient. For example, other proteins in the crude mixture of similar size as the desired protein will likely pass through the column together during a separation using gel filtration chromatography. Additional purity can be achieved by performing sequential separations based on distinct molecular properties.

For example, in addition to size, proteins can be separated on the basis of their net charge by **ion-exchange chromatography**. If a protein has a net positive charge at pH 7, it will usually bind to a column of beads containing carboxylate groups, whereas a negatively charged protein will not (**Figure 4.4**). The bound protein can then be eluted, or released, from the column by increasing the concentration of sodium chloride or another salt in the eluting buffer; sodium ions compete with positively charged groups on the protein for binding to the column. Proteins that have a low density of net positive charge will tend to emerge first, followed by those having a higher charge density.



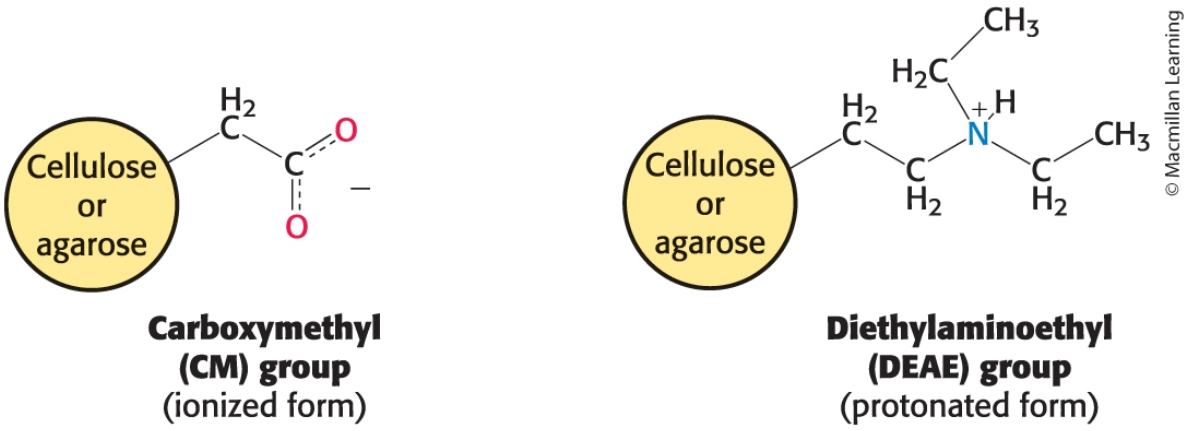


FIGURE 4.4 Ion-exchange chromatography separates proteins based on their net charge. As shown here, proteins with a net positive charge will bind to a column in which the beads are coated with negatively charged groups. Proteins with a net negative charge will pass through much more quickly. This is an example of cation exchange.

This procedure is also referred to as **cation exchange** to indicate that positively charged groups will bind to the anionic beads. Positively charged proteins (cationic proteins) can be separated by chromatography on negatively charged carboxymethylcellulose (CM-cellulose) columns. Conversely, negatively charged proteins (anionic proteins) can be separated by **anion exchange** on positively charged diethylaminoethylcellulose (DEAE-cellulose) columns.

Affinity chromatography

Another powerful means of purifying proteins that is highly selective for the protein of interest is **affinity chromatography**. This technique takes advantage of the high affinity of many proteins for specific molecules, called *ligands*. For example, the plant protein concanavalin A is a carbohydrate-binding protein that has affinity for glucose. When a crude extract is passed through a column of beads containing covalently attached glucose residues, concanavalin A binds to the beads, whereas

most other proteins do not (Figure 4.5). The bound concanavalin A can then be eluted from the column by adding a concentrated solution of glucose. At a high concentration, the added glucose will replace the bead-bound glucose as the ligand for concanavalin A, releasing it from the column.

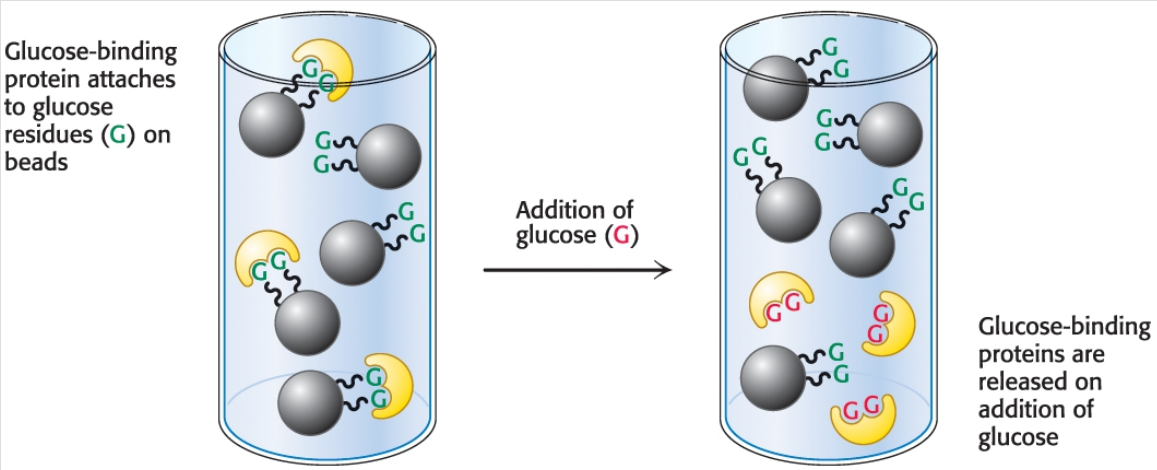

FIGURE 4.5 Affinity chromatography enables the separation of proteins that can bind to a specific ligand. In this example, concanavalin A (shown in yellow), a glucose-binding protein, ca be retained on a column composed of beads with covalently attached glucose residues (G). Afte washing away proteins that cannot bind the ligand, concanavalin can be eluted by adding a concentrated solution of glucose.

Affinity chromatography is a powerful means of isolating transcription factors — proteins that regulate gene expression by binding to specific DNA sequences. A protein mixture is passed through a column containing specific DNA sequences attached to a matrix; proteins with a high affinity for the sequence will bind and be retained. In this instance, the transcription factor is released by washing with a solution containing a high concentration of salt.

In general, affinity chromatography can be effectively used to isolate a protein that recognizes a particular ligand X by (1) covalently attaching X or a derivative of it to a column; (2) adding a mixture of proteins to

this column, which is then washed with buffer to remove unbound proteins; and (3) eluting the desired protein by adding a high concentration of a soluble form of X or altering the conditions to decrease binding affinity. Affinity chromatography is most effective when the interaction between the protein and its ligand is highly specific.

Affinity chromatography can also be applied to proteins that do not have an identified ligand using the power of recombinant DNA technology (Section 9.2). Simply put, the desired protein is attached to a polypeptide that can bind to a highly specific, known ligand. For example, repeats of the amino acid histidine may be added such that the expressed protein has a string of histidine residues (called a *His tag*) on one end. The tagged proteins are then passed through a column of beads containing covalently attached, immobilized nickel(II). The His tag binds tightly to the immobilized metal ion, capturing the desired protein, while other proteins flow through the column. The tagged protein can then be eluted from the column by the addition of imidazole that binds to the metal ions and displaces the protein.

High-performance liquid chromatography

A technique called **high-performance liquid chromatography (HPLC)** is an enhanced version of the column techniques already discussed. The solid beads within the column have a much smaller diameter, and, as a consequence, possess a greater surface area that yields more interaction sites. With this increase in surface area, HPLC results in greater resolving power. Because the column is made of finer material, pressure must be applied to the column to obtain adequate flow rates. The net result is both sharper separations between proteins and a more rapid separation.

In a typical HPLC setup, the presence of protein emerging from the column is measured in real time. Since the peptide bond absorbs light at

a wavelength of 220 nm, a detector that monitors light absorbance at this wavelength is placed immediately after the column. In the sample HPLC elution profile shown in **Figure 4.6**, proteins emerging from the column are readily noted by the presence of sharp peaks measured by the detector. In a short span of 10 minutes, a number of individual proteins can be readily identified.

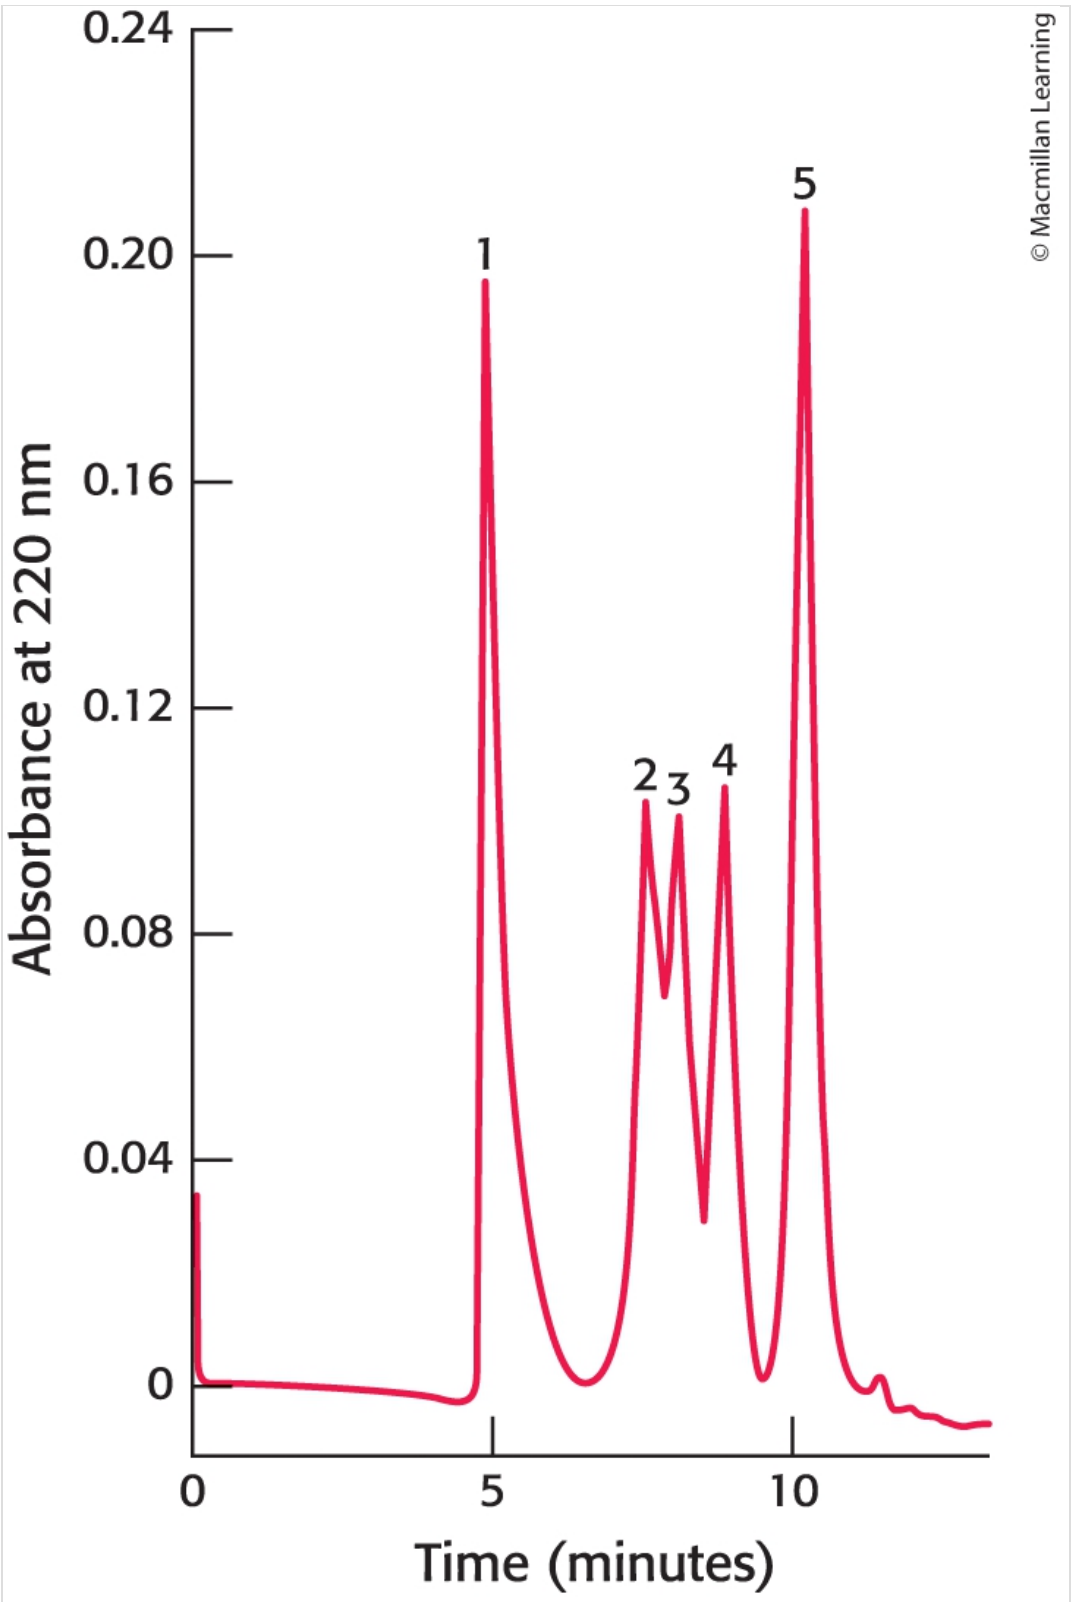

FIGURE 4.6 High-performance liquid chromatography (HPLC) can separate proteins with high resolving power over short elution times. Gel filtration by HPLC

clearly defines the individual proteins because of its greater resolving power: (1) thyroglobulin (669 kDa), (2) catalase (232 kDa), (3) bovine serum albumin (67 kDa), (4) ovalbumin (43 kDa), and (5) ribonuclease (13.4 kDa).

[Data from K. J. Wilson and T. D. Schlabach. In *Current Protocols in Molecular Biology*, vol. 2, suppl. 41, F. M. Ausubel, R. Brent, R. E. Kingston, D. D. Moore, J. G. Seidman, J. A. Smith, and K. Struhl, Eds. (Wiley, 1998), p. 10.14.1.]

Proteins can be separated by gel electrophoresis and displayed

How can we tell that a purification scheme is effective? One way is to ascertain that the specific activity rises with each purification step. Another is to determine that the number of different proteins in each sample declines at each step. The technique of electrophoresis makes the latter method possible.

Gel electrophoresis

A molecule with a net charge, such as a protein or a nucleic acid, will move in an electric field. This phenomenon, termed *electrophoresis*, offers a powerful means of separating mixtures of proteins or nucleic acids. Electrophoretic separations are nearly always carried out in porous gels (or on solid supports such as paper) because the gel serves as a molecular sieve that enhances separation (**Figure 4.7**). Molecules that are small compared with the pores in the gel readily move through the gel, whereas molecules much larger than the pores are almost immobile. Intermediate-size molecules move through the gel with various degrees of facility. The electric field is applied such that proteins migrate from the negative to the positive electrodes, typically from top to bottom. **Gel electrophoresis** is performed in a thin, vertical slab of a

gel composed of the polymer polyacrylamide (Figure 4.8). Polyacrylamide gels are choice supporting media for electrophoresis because they are chemically inert and readily formed by the polymerization of acrylamide with a small amount of a cross-linking agent to make a three-dimensional mesh.

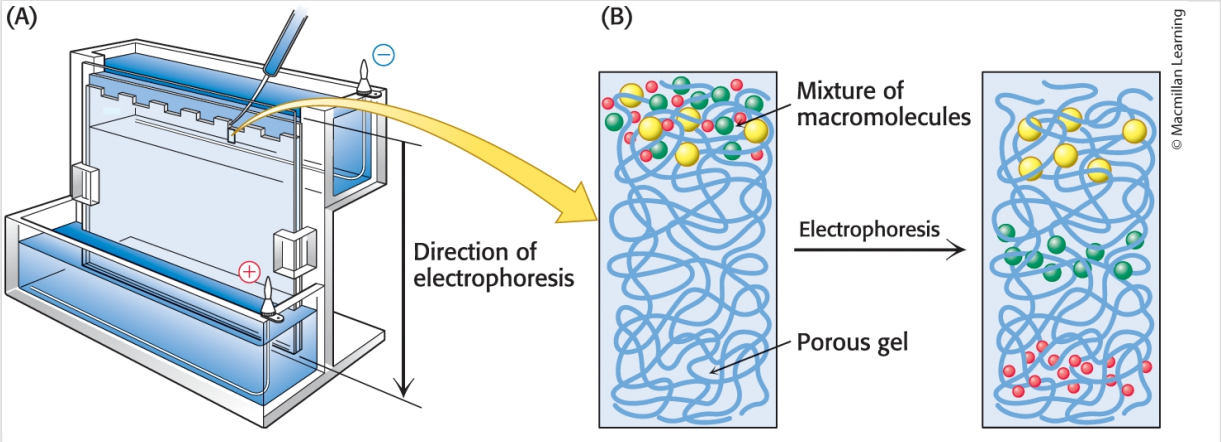

FIGURE 4.7 Polyacrylamide gel electrophoresis can be used to separate and visualize mixtures of proteins. (A) A microliter pipette is used to place solutions of proteins in the wells of the slab. A cover is then placed over the gel chamber and voltage is applied. The negatively charged SDS (sodium dodecyl sulfate)–protein complexes migrate in the direction of the anode, at the bottom of the gel. (B) The sieving action of a porous gel separates proteins according to size, with the smallest moving most rapidly.

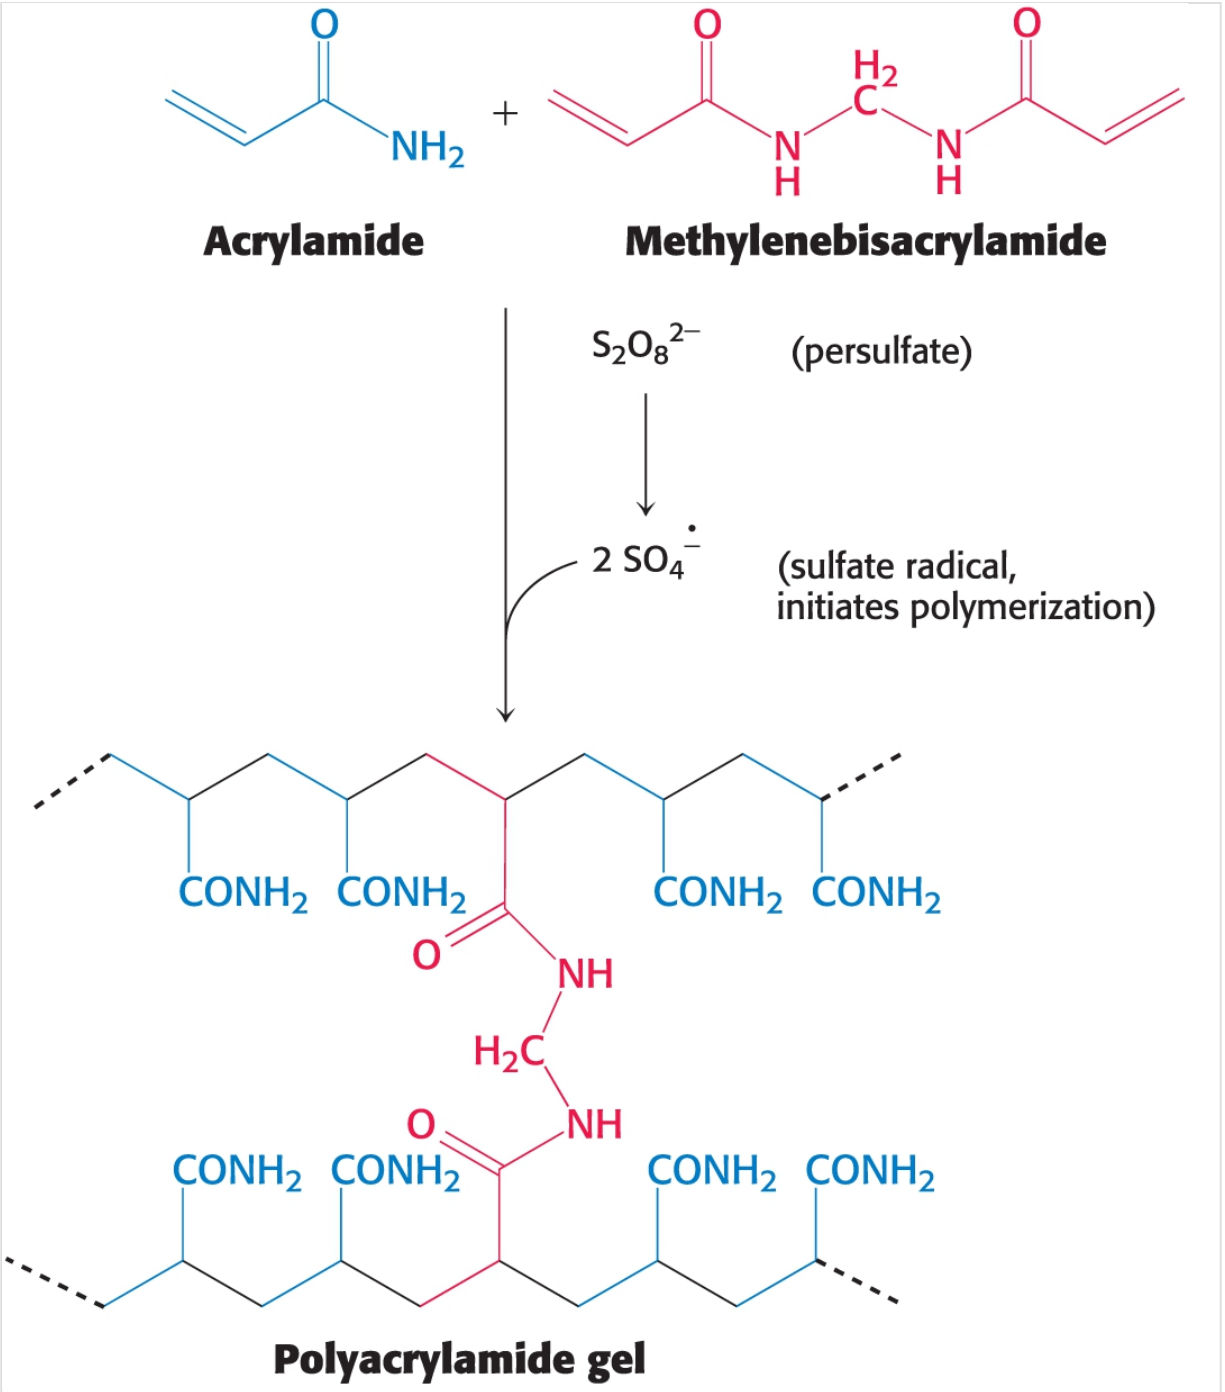
VIEW animations of the techniques shown in Figure 4.5 and Figure 4.7 in Achieve



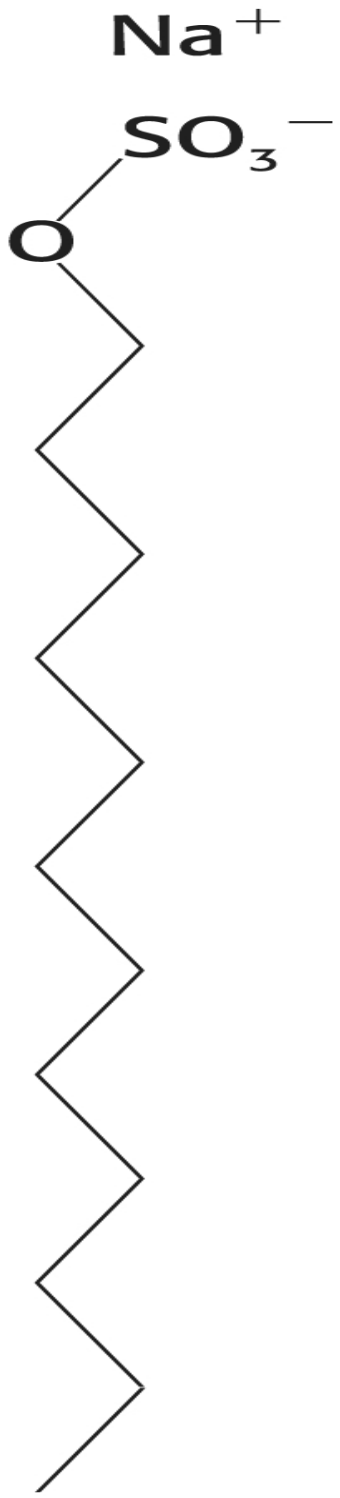


FIGURE 4.8 A polyacrylamide gel is a highly cross-linked three-dimensional mesh. The gel is formed by polymers of acrylamide with intermittently spaced cross-linker (red).

Proteins can be separated largely on the basis of mass by electrophoresis in a polyacrylamide gel under denaturing conditions. The mixture of proteins is first dissolved in a solution of sodium dodecyl sulfate (SDS), an anionic detergent that disrupts nearly all noncovalent interactions in native proteins. Then, β-mercaptoethanol (2-thioethanol) or dithiothreitol is added to reduce disulfide bonds. Anions of SDS bind to main chains at a ratio of about one SDS anion for every two amino acid residues. The negative charge acquired on binding SDS is usually much greater than the charge on the native protein; the contribution of the protein to the total charge of the SDS–protein complex is thus rendered insignificant. As a result, this complex of SDS with a denatured protein has a large net negative charge roughly proportional to the mass of the protein.

Sodium dodecyl sulfate (SDS)

The SDS–protein complexes are then subjected to electrophoresis. When the electrophoresis is complete, the proteins in the gel can be visualized by staining them with silver nitrate or a dye such as Coomassie blue, which reveals a series of bands (Figure 4.9). Small proteins move rapidly through the gel, whereas large proteins stay at the top, near the point of application of the mixture. The mobility of most polypeptide chains under these conditions is linearly proportional to the logarithm of their mass (Figure 4.10). Some carbohydrate-rich proteins and membrane proteins do not obey this empirical relation, however.

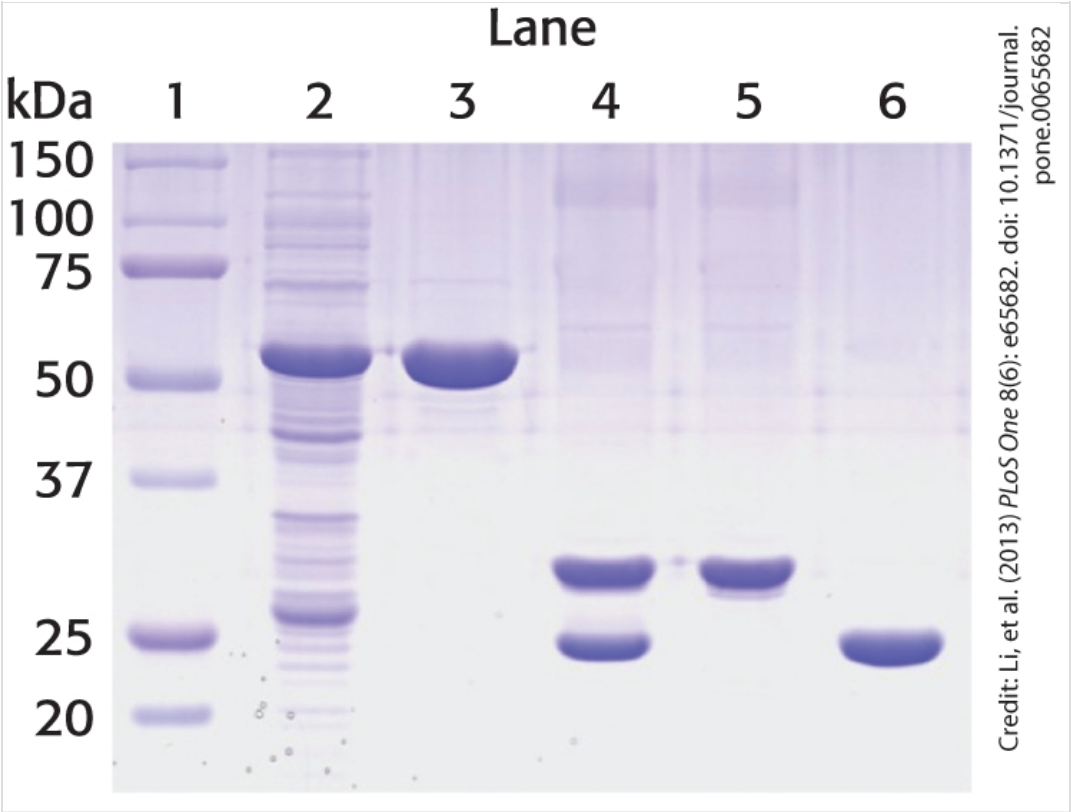

FIGURE 4.9 Staining of the polyacrylamide after electrophoresis enables visualization of the protein bands. Mixtures of proteins subjected to electrophoresis on an SDS–polyacrylamide gel can be visualized by staining with Coomassie blue. The first lane contains a mixture of proteins of known molecular weights, which can be used to estimate the sizes of the bands in the samples.

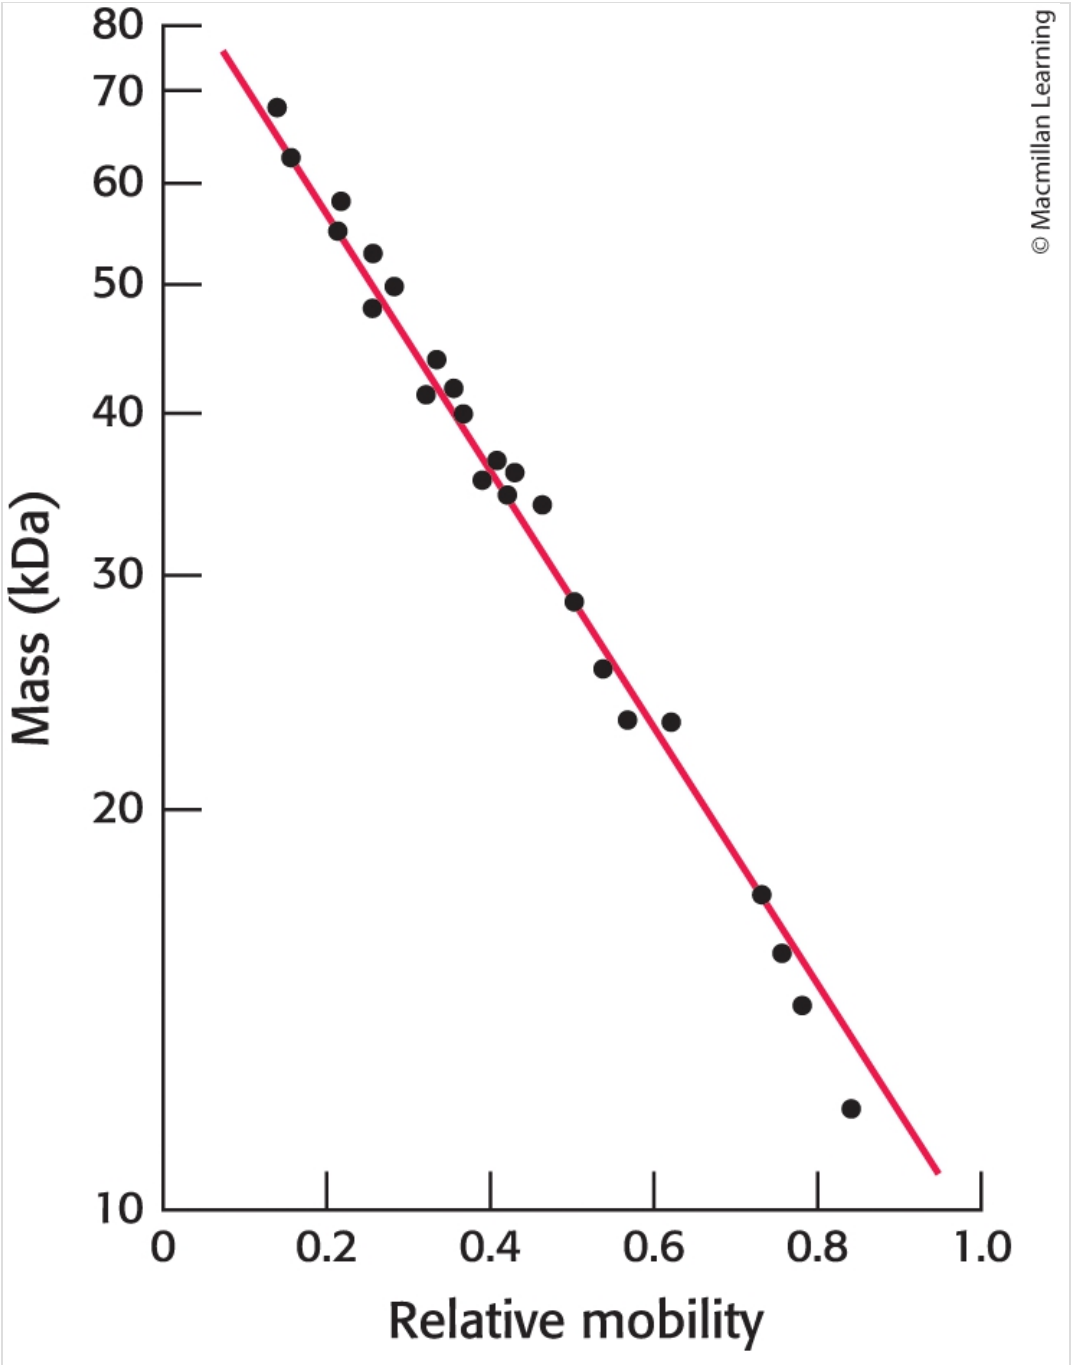

FIGURE 4.10 Electrophoresis can determine the mass of a protein. The electrophoretic mobility of many proteins in SDS–polyacrylamide gels is inversely proportional to the logarithm of their mass.

[Data from K. Weber and M. Osborn, *The Proteins*, vol. 1, 3rd ed. (Academic Press, 1975), p. 179.]

This technique, **SDS–polyacrylamide gel electrophoresis** (often referred to as SDS-PAGE), is rapid, sensitive, and capable of a high degree of resolution. As little as $0.1\ \mu g\ (\sim 2\ pmol)$ of a protein gives a distinct band when stained with Coomassie blue, and even less $(\sim 0.02\ \mu g)$ can be detected with a silver stain. Proteins that differ in mass by about 2% (e.g., 50 and 51 kDa, arising from a difference of about 10 amino acids) can usually be distinguished with SDS-PAGE.

We can examine the efficacy of a purification scheme by analyzing a part of each fraction by SDS-PAGE. The initial fractions will display dozens to hundreds of proteins. As the purification progresses, the number of bands will diminish, and the prominence of one of the bands should increase (**Figure 4.11**). This band should correspond to the protein of interest.

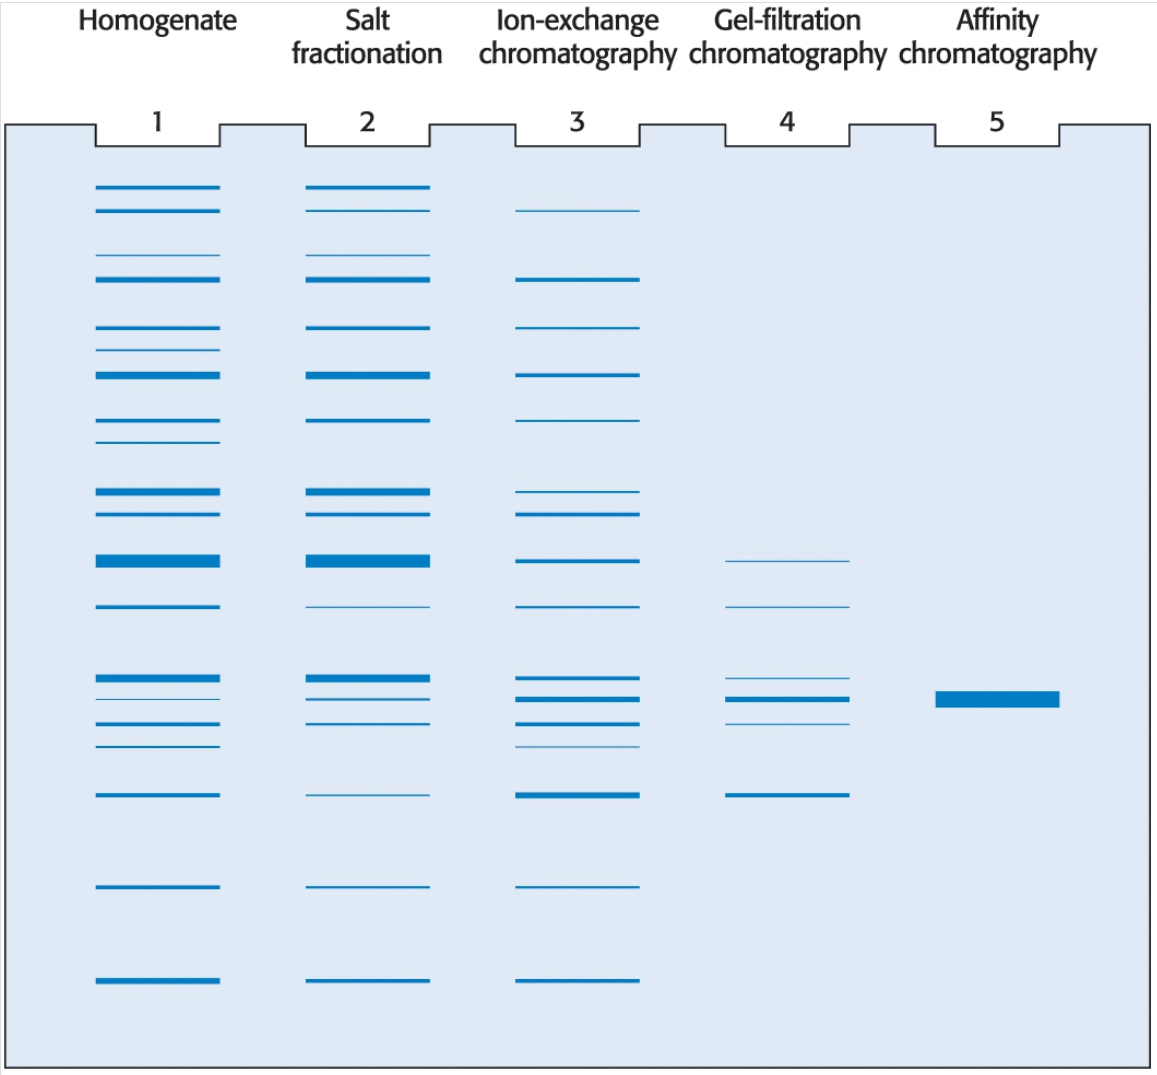

FIGURE 4.11 Electrophoretic analysis can be used to monitor the progress of protein purification. At each step of a protein purification scheme, the sample was analyzed by SDS-PAGE. Each lane contained 50 µg of sample. The effectiveness of the purification can be seen as the band for the protein of interest becomes more prominent relative to other bands.

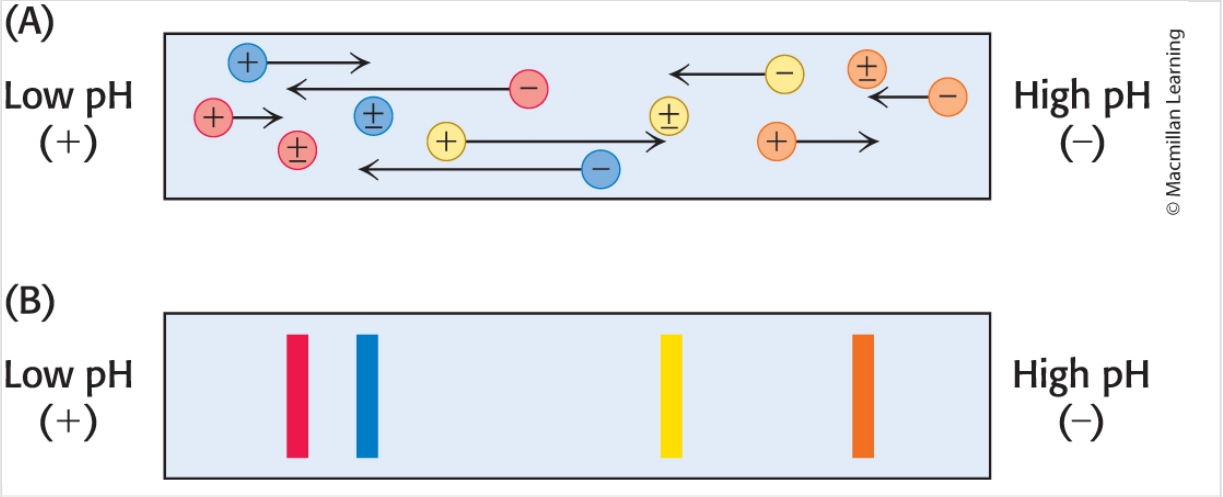


Self-Check Question

The relative electrophoretic mobilities of a 30-kDa protein and a 92-kDa protein used as standards on an SDS–polyacrylamide gel are 0.80 and 0.41, respectively. What is the apparent mass of a protein having a mobility of 0.62 on this gel?

Isoelectric focusing

Proteins can also be separated electrophoretically on the basis of their relative contents of acidic and basic residues. The **isoelectric point** (pI) of a protein is the pH at which its net charge is zero. At this pH, its electrophoretic mobility is zero. For example, the pI of cytochrome *c*, a highly basic electron-transport protein found primarily in mitochondria, is 10.6, whereas that of serum albumin, an acidic protein in blood, is 4.8.

Suppose that a mixture of proteins undergoes electrophoresis in a pH gradient in a gel in the absence of SDS. Each protein will move until it reaches a position in the gel at which the pH is equal to the pI of the protein. This method of separating proteins according to their isoelectric point is called **isoelectric focusing**. The pH gradient in the gel is formed first by subjecting a mixture of small multicharged polymers having many different pI values to electrophoresis. Isoelectric focusing can readily resolve proteins that differ in pI by as little as 0.01, which means that proteins differing by one net charge can be separated (**Figure 4.12**).

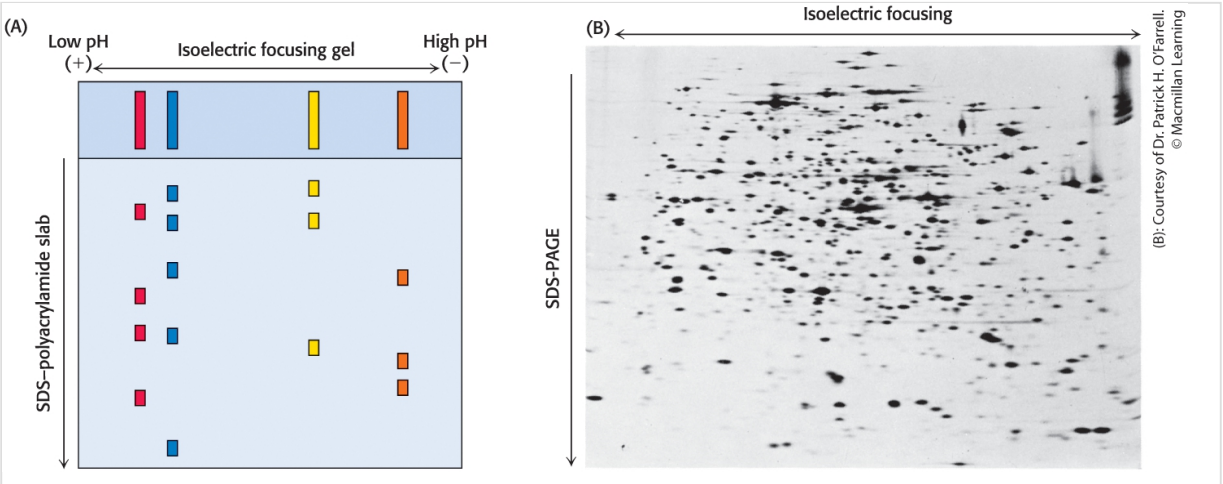
© Macmillan Learning

FIGURE 4.12 Isoelectric focusing separates proteins based on their isoelectric point (pI). A pH gradient is established in a gel before loading the sample. (A) Each protein, represented by the different-colored circles, will possess a net positive charge in the regions of the gel where the pH is lower than its respective pI value and a net negative charge where the pH is greater than its pI. When voltage is applied to the gel, each protein will migrate to its pI, the location at which it has no net charge. (B) The proteins form bands that can be excised and used for further experimentation.

Two-dimensional electrophoresis

Isoelectric focusing can be combined with SDS-PAGE to obtain very high-resolution separations by **two-dimensional electrophoresis**. A single sample is first subjected to isoelectric focusing. This single-lane gel is then placed horizontally across the top of an SDS–polyacrylamide slab. The proteins are thus spread across the top of the polyacrylamide gel according to how far they migrated during isoelectric focusing. They then undergo electrophoresis again in a perpendicular direction (vertically) to yield a two-dimensional pattern of spots (**Figure 4.13A**). In such a gel, proteins have been separated in the horizontal direction on the basis of isoelectric point and in the vertical direction on the basis of mass. Remarkably, more than a thousand different proteins in the

bacterium *Escherichia coli* can be resolved in a single experiment by two-dimensional electrophoresis (**Figure 4.13B**).



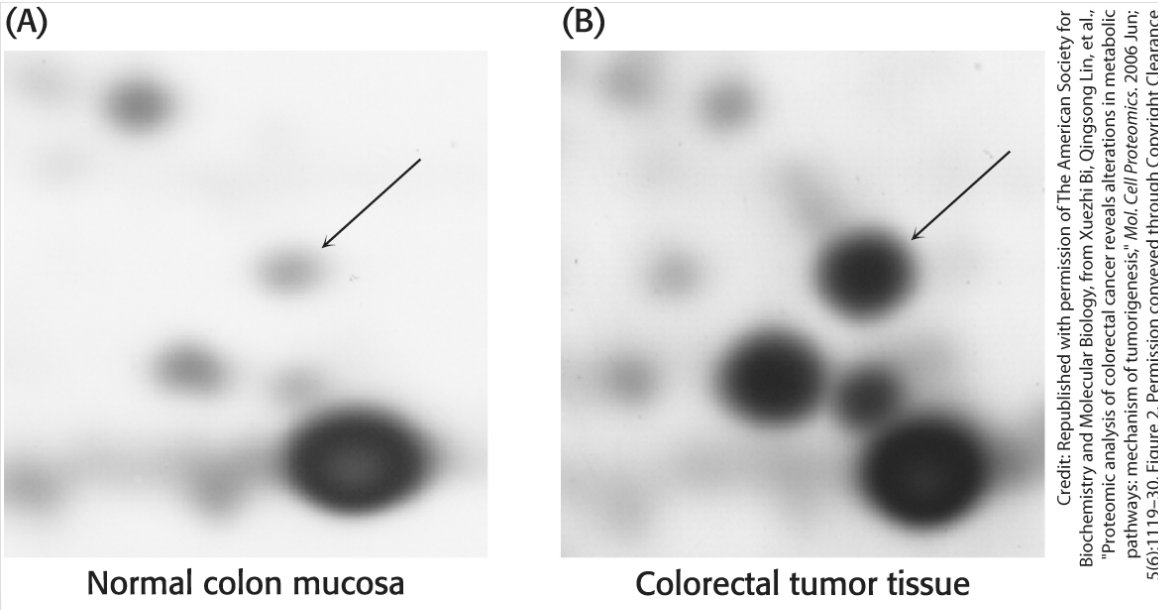


FIGURE 4.13 Two-dimensional electrophoresis uses isoelectric focusing and polyacrylamide gel electrophoresis to separate complex mixtures of proteins. (A) A protein sample is initially fractionated in one dimension by isoelectric focusing as described in Figure 4.12. The isoelectric focusing gel is then attached to an SDS–polyacrylamide gel, and electrophoresis is performed in the second dimension, perpendicular to the original separation. Proteins with the same pI are now separated on the basis of mass. (B) Proteins from *E. coli* were separated by two-dimensional gel electrophoresis, resolving more than a thousand different proteins.

VIEW animations of the techniques shown in Figure 4.12 and Figure 4.13 in Achieve

Two-dimensional electrophoresis can be used to resolve proteins isolated from cells under different physiological conditions. The intensities of individual spots on the gels can then be compared, with any differences indicating that the concentrations of specific proteins have changed in response to the physiological state (**Figure 4.14**). How can we discover the identity of a protein that is showing such responses? Although many proteins are displayed on a two-dimensional gel, they are not identified. We will examine how it is possible to identify proteins by coupling two-dimensional gel electrophoresis with mass spectrometric techniques (Section 4.3).

Cell Proteomics*. 2006 Jun; 5(6):1119–30. Figure 2. Permission conveyed through Copyright Clearance

FIGURE 4.14 Alterations in protein levels under differing cellular conditions can be detected b two-dimensional gel electrophoresis. Samples of (A) normal colon mucosa and (B) colorectal tumor tissue from the same person were analyzed by two-dimensional gel electrophoresis. In th gel section shown, changes in the intensity of several spots are evident, including a dramatic increase in levels of the protein indicated by the arrow, corresponding to the enzyme glyceraldehyde-3-phosphate dehydrogenase.

A protein purification scheme can be quantitatively evaluated

To determine the success of a protein purification scheme, we monitor each step of the procedure by determining the specific activity of the protein mixture and by subjecting it to SDS-PAGE analysis. Consider the results for the purification of a fictitious enzyme, summarized in **Table 4.1** and Figure 4.11. At each step, the following parameters are measured:

- *Total Protein.* The quantity of protein present in a fraction is obtained by determining the protein concentration of a part of each fraction and multiplying by the fraction's total volume.
- *Total Activity.* The total activity for the fraction is obtained by measuring the enzyme activity in the volume of fraction used in the assay and multiplying by the fraction's total volume.
- *Specific Activity.* This parameter is obtained by dividing total activity by total protein.
- *Yield.* This parameter is a measure of the activity retained after each purification step as a percentage of the activity in the crude extract. The amount of activity in the initial extract is taken to be 100%.
- *Purification Level.* This parameter is a measure of the increase in purity and is obtained by dividing the specific activity, calculated after each purification step, by the specific activity of the initial extract.

TABLE 4.1 Quantification of a purification protocol for a fictitious enzyme

Step	Total protein (mg)	Total activity (units)	Specific activity (units mg^{-1})	Yield (%)	Purification level
Homogenization	15,000	150,000	10	100	1
Salt fractionation	4600	138,000	30	92	3
Ion-exchange chromatography	1278	115,500	90	77	9

Gel-filtration chromatography	68.8	75,000	1100	50	110
Affinity chromatography	1.75	52,500	30,000	35	3000

As we see in Table 4.1, the first purification step, salt fractionation, leads to an increase in purity of only 3-fold, but we recover nearly all the target protein in the original extract, given that the yield is 92%. After dialysis to lower the high concentration of salt remaining from the salt fractionation, the fraction is passed through an ion-exchange column. The purification now increases to 9-fold compared with the original extract, whereas the yield falls to 77%. Gel-filtration chromatography brings the level of purification to 110-fold, but the yield is now at 50%. The final step is affinity chromatography with the use of a ligand specific for the target enzyme. This step, the most powerful of these purification procedures, results in a purification level of 3000-fold but lowers the yield to 35%. The SDS-PAGE analysis in Figure 4.11 shows that, if we load a constant amount of protein onto each lane after each step, the number of bands decreases in proportion to the level of purification, and the amount of protein of interest increases as a proportion of the total protein present.

A good purification scheme takes into account both purification levels and yield. A high degree of purification and a poor yield leave little protein with which to experiment. A high yield with low purification leaves many contaminants (proteins other than the one of interest) in the fraction and complicates the interpretation of subsequent experiments.

Example

Calculating the Effectiveness of Protein Purification

Problem:

In the final column chromatography step of a protein purification sequence, the total protein drops from 50 mg to 11 mg, and the total activity goes from 11,000 units to 1040 units. Was this final purification step effective?

Getting Started:

The problem provides us with the data for only one purification step within a scheme, the total protein and the total activity before and after the column. Recall that the goal of protein purification is to maximize specific activity. How do we calculate specific activity given the values provided?

Solve:

The specific activity of a protein sample is simply the activity (usually in units) divided by the total amount of protein present. Before the column, the specific activity of the sample was:

$$\text{Specific activity} = \frac{11{,}000 \text{ units}}{50 \text{ mg}} = 220 \text{ units mg}^{-1}$$

After the purification step, the specific activity is now:

$$\text{Specific activity} = \frac{1040 \text{ units}}{11 \text{ mg}} = 94.5 \text{ units mg}^{-1}$$

Another helpful equation for assessing efficacy is the purification level. Usually, this is determined by dividing the specific activity of the current sample with the specific activity of the crude extract. The problem does not provide any data about the crude extract, but we can measure the purification level for this particular step:

$$\text{Purification level} = \frac{94.5 \text{ units mg}^{-1}}{220 \text{ units mg}^{-1}} = 0.43$$

Reflect:

What is the significance of this result? In a single purification step, the amount of total protein has decreased, but this is always the case (notice, for example, that in Table 4.1, the amount of total protein drops with each step). More importantly, however, the specific activity of the sample has *decreased* after this column step, resulting in a purification level of less than one. Clearly, this final chromatography step was not effective in the purification of our protein.

Ultracentrifugation is valuable for separating biomolecules and determining their masses

We have already seen that centrifugation is a powerful and generally applicable method for separating a crude mixture of cell components. At higher velocities, this technique, referred to as **ultracentrifugation**, is also valuable for the analysis of the physical properties of biomolecules. Using ultracentrifugation, we can determine such parameters as mass and density, learn about the shape of a molecule, and investigate the interactions between molecules.

A particle will move through a liquid medium when subjected to a centrifugal force. A convenient means of quantifying the rate of movement is the sedimentation coefficient of a particle. Sedimentation coefficients are usually expressed in Svedberg units (S). The smaller the S value, the more slowly a molecule moves in a centrifugal field. The S values for a number of biomolecules are listed in **Table 4.2**. In general, a more massive particle sediments more rapidly than does a less-massive particle of the same shape and density. Also, elongated particles sediment more slowly than do spherical ones of the same mass.

TABLE 4.2 S values and molecular weights of sample proteins

Protein	S value (Svedberg units)	Molecular weight
Pancreatic trypsin inhibitor	1	6520
Cytochrome *c*	1.83	12,310
Ribonuclease A	1.78	13,690
Myoglobin	1.97	17,800

Trypsin	2.5	23,200
Carbonic anhydrase	3.23	28,800
Concanavalin A	3.8	51,260
Malate dehydrogenase	5.76	74,900
Lactate dehydrogenase	7.54	146,200

Source: T. Creighton, *Proteins*, 2nd ed. (W. H. Freeman and Company, 1993), Table 7.1.

The mass of a protein can be directly determined by sedimentation equilibrium, in which a sample is centrifuged at low speed such that a concentration gradient of the sample is formed. However, this sedimentation is counterbalanced by the diffusion of the sample from regions of high to low concentration. When equilibrium has been achieved, the shape of the final gradient depends solely on the mass of the sample.

The sedimentation-equilibrium technique for determining mass is very accurate and can be applied without denaturing the protein. Thus, the native quaternary structure of multimeric proteins is preserved. In contrast, SDS–polyacrylamide gel electrophoresis provides only an estimate of the mass of dissociated polypeptide chains under denaturing conditions. Note that, if we know the mass of the dissociated components of a multimeric protein as determined by SDS–polyacrylamide analysis and the mass of the intact multimer as determined by sedimentation-equilibrium analysis, we can determine the number of copies of each polypeptide chain present in the protein complex.

Recombinant DNA technology can make protein purification easier

In Chapter 9, we shall consider the widespread effect of recombinant DNA technology on all areas of biochemistry and molecular biology. The application of recombinant methods to the overproduction of proteins has enabled dramatic advances in our understanding of their structure and function. Before the advent of this technology, proteins were isolated solely from their native sources, often requiring a large amount of tissue to obtain a sufficient amount of protein for analytical study. For example, the purification of bovine deoxyribonuclease in 1946 required nearly ten pounds of beef pancreas to yield one gram of protein. As a result, biochemical studies on purified material were often limited to abundant proteins.

Recombinant DNA technology affords a number of advantages in the production and purification of proteins:

- *Proteins can be expressed in large quantities.* For recombinant systems, a host organism that is amenable to genetic manipulation, such as the bacterium *E. coli* or the yeast *Pichia pastoris*, is utilized to express a protein of interest. The biochemist can exploit the short doubling times and ease of genetic manipulation of such organisms to produce large amounts of protein from manageable amounts of culture. As a result, purification can begin with a homogenate that is often highly enriched with the desired molecule. Moreover, a protein can be easily obtained regardless of its natural abundance or its species of origin.

- *Affinity tags can be fused to proteins.* As described above, affinity chromatography can be a highly selective step within a protein purification scheme. Recombinant DNA technology enables the attachment of any one of a number of possible affinity tags to a protein (such as the “His tag” mentioned earlier). Hence, the benefits of affinity chromatography can be realized even for those

proteins for which a binding partner is unknown or not easily determined.

- *Proteins with modified primary structures can be readily generated.* Recombinant DNA technology gives biochemists the ability to manipulate genes to generate variants of a native protein sequence. Recall from Section 2.5 that many proteins consist of compact domains connected by flexible linker regions. With the use of recombinant DNA technology, fragments of a protein that encompass single domains can be generated, an advantageous approach when expression of the entire protein is limited by its size or solubility. Additionally, amino acid substitutions can be introduced into a protein to precisely probe the significance of these residues.

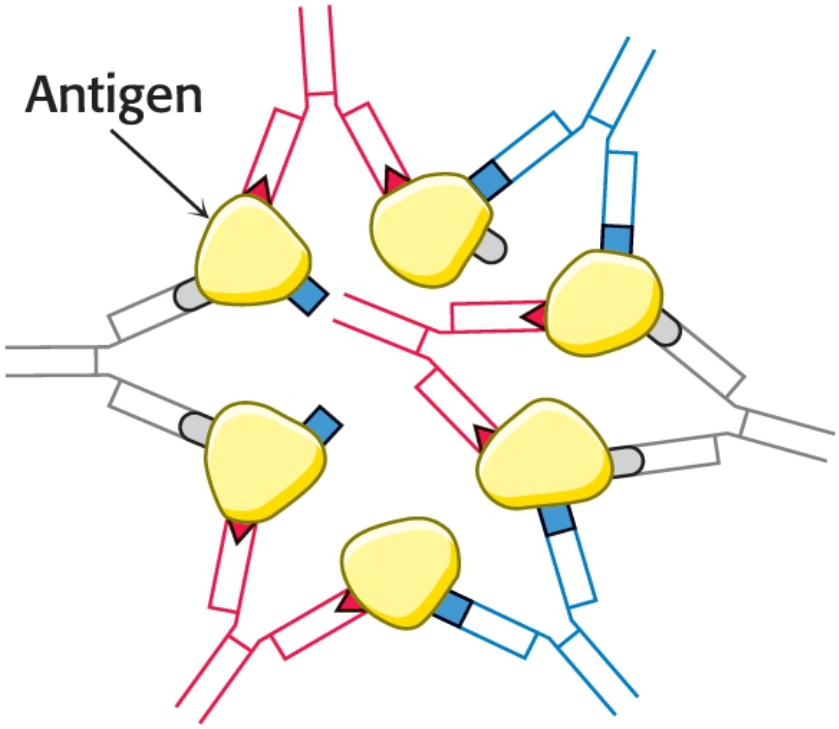
4.2 Immunology Provides Important Techniques for Investigating Proteins

The purification of a protein enables the biochemist to explore its function and structure within a precisely controlled environment. However, the isolation of a protein removes it from its native context within the cell, where its activity is most physiologically relevant. Advances in the field of immunology have enabled the use of antibodies as critical reagents for exploring the functions of proteins within the cell. The exquisite specificity of antibodies for their target proteins provides a means to tag a specific protein so that it can be isolated, quantified, or visualized.

Antibodies to specific proteins can be generated

Immunological techniques begin with the generation of antibodies to a particular protein. Recall from Section 3.4 that antibodies have specific and high affinity for the antigens — foreign proteins, polysaccharides, and nucleic acids — that stimulated their production. Small foreign molecules, such as synthetic peptides, also can elicit antibodies, provided that the small molecule is attached to a macromolecular carrier. An antibody recognizes a specific group or cluster of amino acids on the target molecule called an **antigenic determinant** or **epitope**.

Animals have a very large repertoire of antibody-producing cells, each producing an antibody that contains a unique surface for antigen recognition. When an antigen is introduced into an animal, it is recognized by a select few cells from this population, stimulating the



proliferation of these cells. This process ensures that more antibodies of the appropriate specificity are produced.

Immunological techniques depend on the ability to generate antibodies to a specific antigen. To obtain antibodies that recognize a particular protein, a biochemist injects the protein into a rabbit or other lab mammal. The injected protein acts as an antigen, stimulating the reproduction of cells producing antibodies that recognize it. Blood is drawn from the immunized rabbit several weeks later and centrifuged to separate blood cells from the supernatant. This supernatant contains antibodies to all antigens to which the rabbit has been exposed, and is therefore called *antiserum*.

Only some of the antibodies in the antiserum will react with the injected protein. Moreover, antibodies that recognize a particular antigen are not a single molecular species. For instance, when 2,4-dinitrophenol (DNP) is used as an antigen to generate antibodies, the dissociation constants of individual anti-DNP antibodies range from about 0.1 nM to $1\ \mu M$. Correspondingly, a large number of bands are evident when the anti-DNP antibody mixture is subjected to isoelectric focusing.

These results indicate that cells are producing many different antibodies, each recognizing a different surface feature of the same antigen. These antibodies are termed **polyclonal antibodies**, referring to the fact that they are derived from multiple antibody-producing cell populations (**Figure 4.15**). The heterogeneity of polyclonal antibodies can be advantageous for certain applications, such as the detection of a protein of low abundance, because each protein molecule can be bound by more than one antibody at multiple distinct antigenic sites.

Polyclonal antibodies

© Macmillan Learning

Monoclonal antibodies

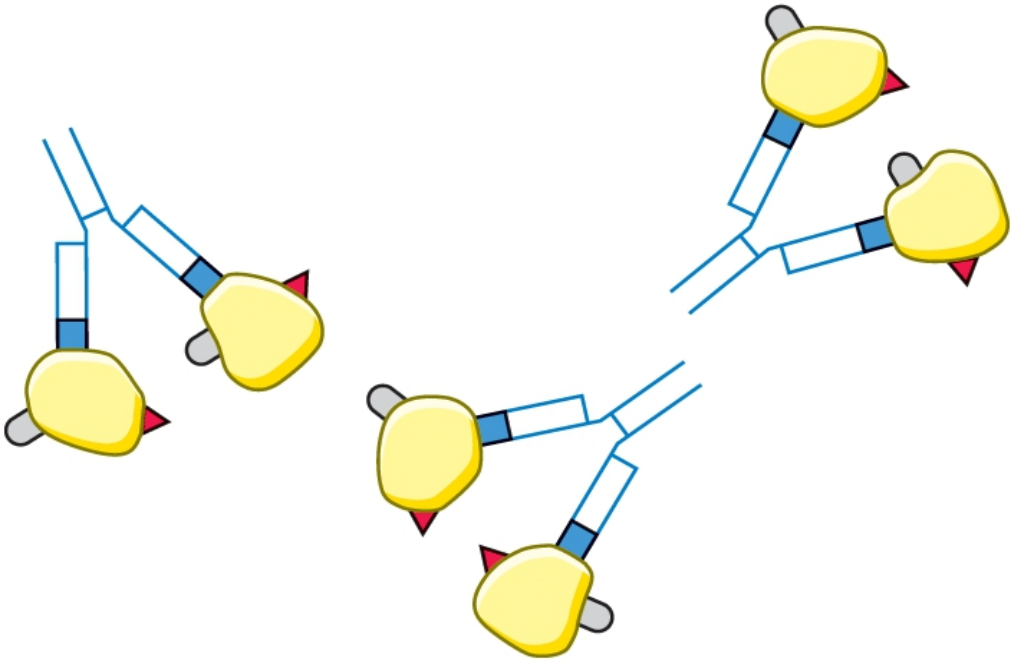


FIGURE 4.15 Polyclonal and monoclonal antibodies differ in the number of epitopes they recognize. Most antigens have several epitopes. Polyclonal antibodies are heterogeneous mixtures of antibodies, each specific for one of the various epitopes on an antigen. Monoclonal antibodies are all identical, produced by clones of a single antibody-producing cell. They recognize one specific epitope.

[Information from R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 154.]

Monoclonal antibodies with virtually any desired specificity can be readily prepared

The discovery of a means of producing **monoclonal antibodies** of virtually any desired specificity was a major breakthrough that intensified the power of immunological approaches. As when working with impure proteins, working with a mixture of different antibodies makes it difficult to interpret data. Ideally, biochemists would isolate a clone of cells producing a single, identical antibody. The problem is that antibody-producing cells isolated from an organism have short life spans.

Immortal cell lines that produce monoclonal antibodies do exist. These cell lines are derived from a type of cancer called *multiple myeloma*, which is a malignant disorder of antibody-producing cells. In this cancer, a single transformed plasma cell (a type of white blood cell) divides uncontrollably, generating a very large number of cells of a single kind. Such a group of cells is called a *clone* because the cells are descended from the same cell and have identical properties. The identical cells of the myeloma secrete large amounts of a single immunoglobulin generation after generation. While these antibodies have proven useful for elucidating antibody structure, nothing is known

about their specificity. Hence, they have little utility for the immunological methods described in the next pages.

César Milstein and Georges Köhler discovered that large amounts of antibodies of nearly any desired specificity can be obtained by fusing a short-lived antibody-producing cell with an immortal myeloma cell. An antigen is injected into a mouse, and its spleen is removed several weeks later (**Figure 4.16**). A mixture of plasma cells from this spleen is then fused in vitro with myeloma cells. Each of the resulting hybrid cells, called **hybridoma** cells, indefinitely produces the identical antibody specified by the parent cell from the spleen. Hybridoma cells can then be screened by a specific assay for the antigen–antibody interaction to determine which ones produce antibodies of the preferred specificity. Collections of cells shown to produce the desired antibody are subdivided and assayed again. This process is repeated until a pure cell line, a clone producing a single antibody, is isolated. These positive cells can be grown in culture medium or injected into mice to induce myelomas. Alternatively, the cells can be frozen and stored for long periods.

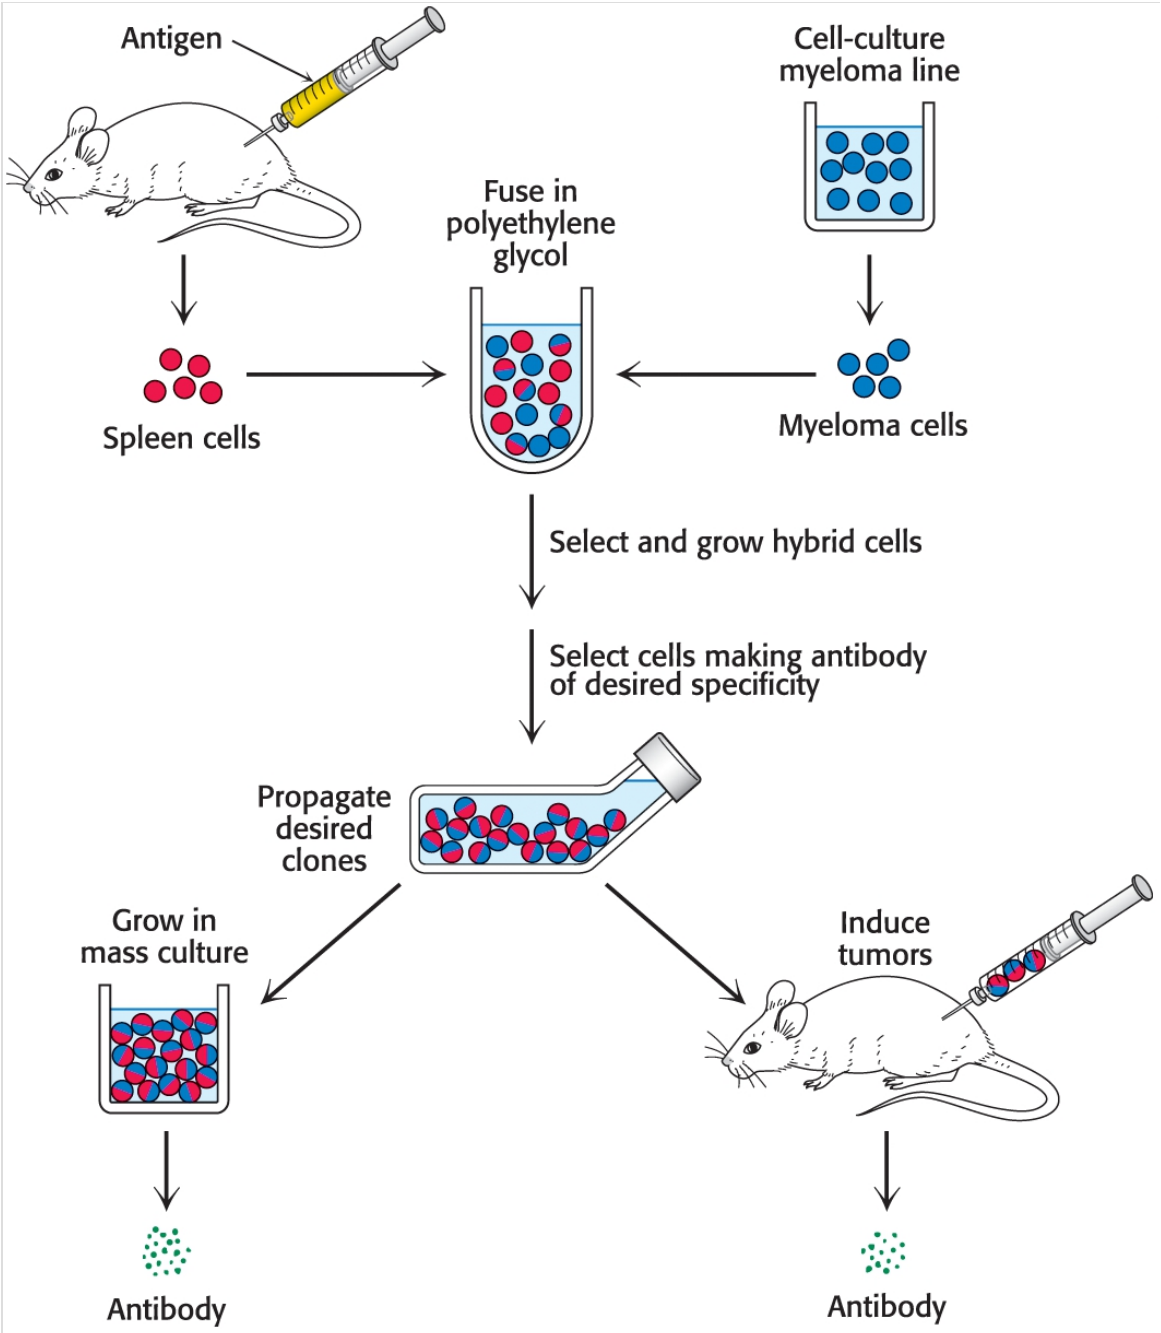

FIGURE 4.16 Monoclonal antibodies are produced by hybridoma cells formed by the fusion o antibody-producing cells and myeloma cells. The hybrid cells are allowed to proliferate by growing them in selective medium. They are then screened to determine which ones produce antibody of the desired specificity.

[Information from C. Milstein. Monoclonal antibodies. Copyright © 1980 by Scientific American, Inc. All rights reserved.]

The hybridoma method of producing monoclonal antibodies has had a dramatic impact on biology and medicine. Biochemists can now readily prepare large amounts of identical antibodies with tailor-made specificities and use them to gather insight into the relationship between antibody structure and specificity. Monoclonal antibodies attached to solid supports can be used as affinity columns to purify scarce proteins. For example, this method has been used to purify interferon (an antiviral protein) 5000-fold from a crude mixture. Moreover, as we shall see below, biologists can use monoclonal antibodies as precise analytical and preparative reagents.

 Clinical laboratories use monoclonal antibodies in many assays. For example, the detection in blood of proteins that are normally localized in the heart points to a heart attack. Blood transfusions have been made safer by antibody screening of donor blood for viruses that cause AIDS (acquired immune deficiency syndrome), hepatitis, and other infectious diseases. Monoclonal antibodies can also be used as therapeutic agents (Chapter 32). For example, trastuzumab (Herceptin) is a monoclonal antibody useful for treating some forms of breast cancer.

Proteins can be detected and quantified by using an enzyme-linked immunosorbent assay

Antibodies can be used as exquisitely specific analytic reagents to quantify the amount of a protein or other antigen present in a biological

sample. The **enzyme-linked immunosorbent assay (ELISA)** makes use of an enzyme, such as horseradish peroxidase or alkaline phosphatase, that reacts with a colorless substrate to produce a colored product. The enzyme is covalently linked to a specific antibody that recognizes a target antigen. If the antigen is present, the antibody–enzyme complex will bind to it and, on addition of the substrate, the enzyme will catalyze the reaction, generating the colored product. Thus, the presence of the colored product indicates the presence of the antigen. Rapid and convenient, ELISAs can detect less than a nanogram $(10^{-9}\ g)$ of a specific protein. ELISAs can be performed with either polyclonal or monoclonal antibodies, but the use of monoclonal antibodies yields more-reliable results.

Of the several types of ELISA that exist, we will further examine two types:

- *The indirect ELISA is used to detect the presence of antibodies.* This method is the basis of the test for HIV infection. The HIV test detects the presence of antibodies that recognize viral core protein antigens. Viral core proteins are coated on the bottom of a well. Antibodies from the person being tested are then added to the coated well. Only someone infected with HIV will have antibodies that bind to the antigen. Finally, enzyme-linked antibodies to human antibodies (e.g., enzyme-linked goat antibodies that recognize human antibodies) are allowed to react in the well, and unbound antibodies are removed by washing. Substrate is then applied. An enzyme reaction yielding a colored product suggests that the enzyme-linked antibodies were bound to human antibodies, which in turn implies that the patient has antibodies to the viral antigen (**Figure 4.17A**). This assay is quantitative: the rate of the color-formation reaction is proportional to the amount of antibody originally present.

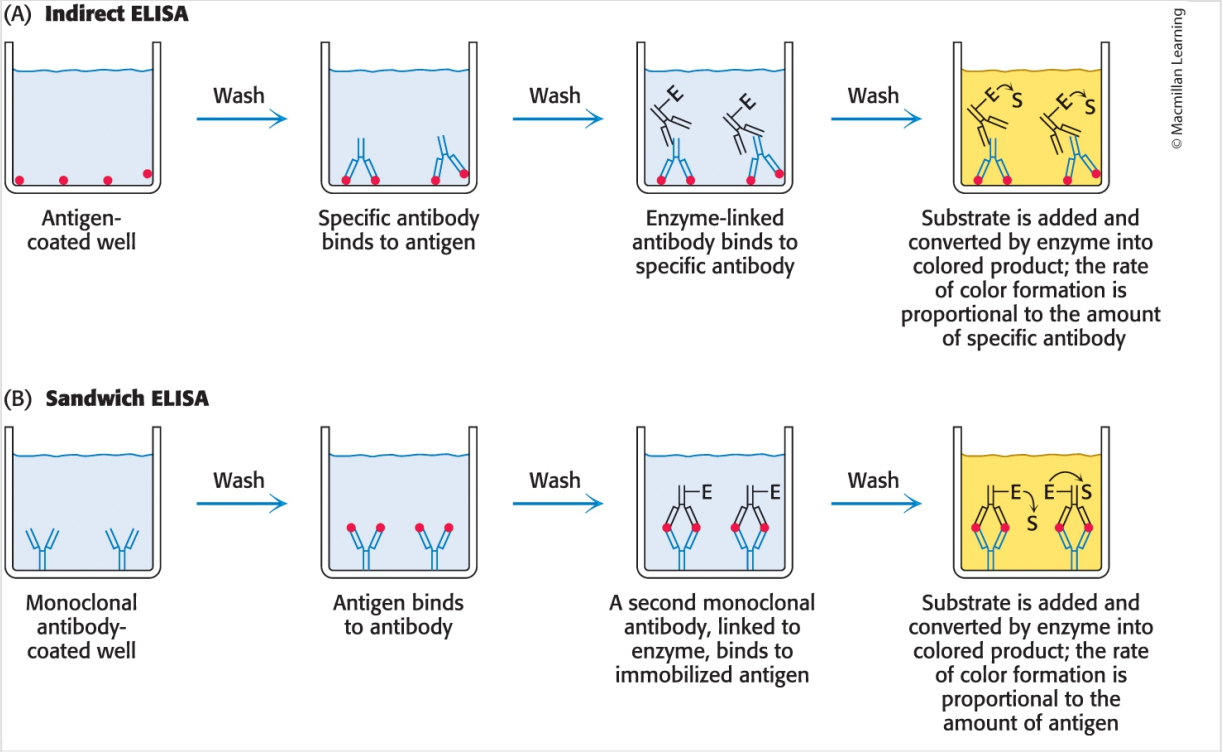

FIGURE 4.17 Indirect ELISA and sandwich ELISA are sensitive methods for detecting the presence of antigen or antibody in a sample. (A) In indirect ELISA, the production of color indicates the amount of an antibody to a specific antigen. (B) In sandwich ELISA, the production of color indicates the quantity of antigen.

[Information from R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 162.]

- *The sandwich ELISA is used to detect an antigen rather than an antibody*. An antibody to a particular antigen — the capture antibody — is first coated on the bottom of a well. Next, solution containing the antigen (such as blood or urine, in medical diagnostic tests) is added to the well and binds to the antibody. Finally, a second antibody — the detection antibody — that also recognizes the antigen is added. Importantly, this antibody binds to the antigen in a region distinct from, and thus does not displace, the first antibody. This antibody is enzyme-linked and is processed as described for indirect ELISA. In this case, the rate of color formation is directly proportional to the amount of antigen present.

Consequently, it permits the measurement of small quantities of antigen (Figure 4.17B).

Self-Check Question

Suppose in a sandwich ELISA experiment, the antibody coated on the bottom of the well recognized the same epitope as the antibody used for antigen detection. Will this experiment work? Why or why not?

Western blotting permits the detection of proteins separated by gel electrophoresis

Very small quantities of a protein of interest in a cell or in body fluid can be detected by an immunoassay technique called **western blotting** (Figure 4.18). A sample is subjected to electrophoresis on an SDS–polyacrylamide gel. A polymer sheet is pressed against the gel, transferring the resolved proteins on the gel to the sheet, which makes the proteins more accessible for reaction. An antibody that is specific for the protein of interest, called the *primary antibody*, is added to the sheet and reacts with the antigen. The antibody–antigen complex on the sheet can then be detected by rinsing the sheet with a second antibody, called the *secondary antibody*, that is specific for the primary antibody (e.g., a goat antibody that recognizes mouse antibodies). Typically, the secondary antibody is fused to an enzyme that produces a chemiluminescent or colored product or contains a fluorescent tag, enabling the identification and quantitation of the protein of interest.

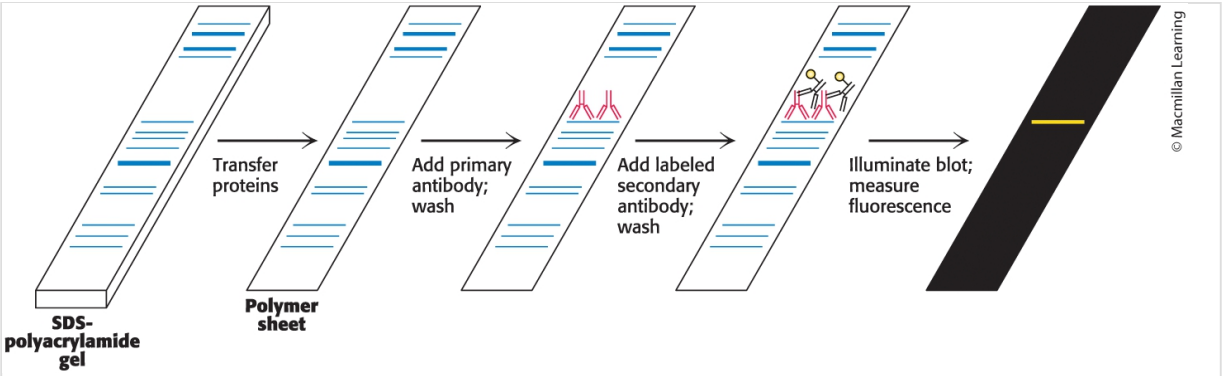

FIGURE 4.18 Western blotting uses antibodies to detect specific proteins after gel electrophoresis. Proteins on an SDS–polyacrylamide gel are transferred to a polymer sheet. The sheet is first treated with a primary antibody, which is specific for the protein of interest, and then washed to remove unbound antibody. Next, the sheet is treated with a secondary antibody, which recognizes the primary antibody, and washed again. Since the secondary antibody is labeled (here, with a fluorescent tag indicated by the yellow circle), the band containing the protein of interest can be identified.

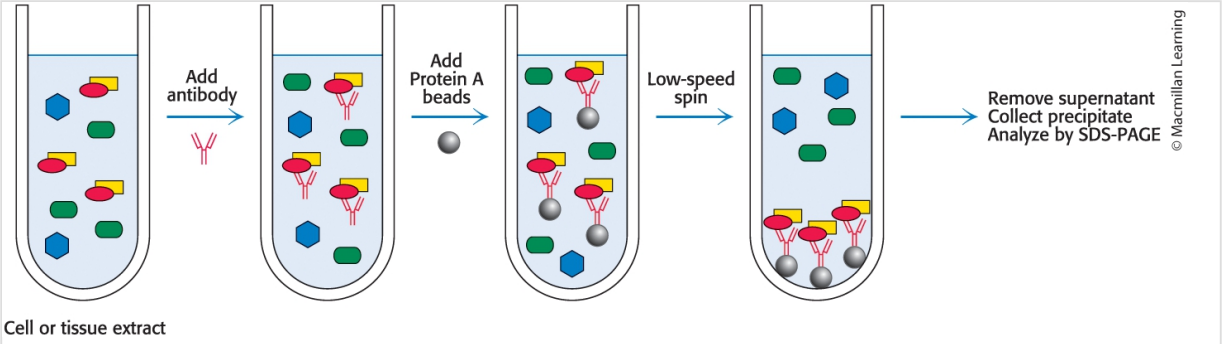
VIEW an animation of this technique in Achieve

Western blotting makes it possible to find a protein in a complex mixture, the proverbial needle in a haystack. It is the basis for the test for infection by hepatitis C, where it is used to detect a core protein of the virus. This technique is also very useful in monitoring protein purification and in the cloning of genes.

Co-immunoprecipitation enables the identification of binding partners of a protein

With a monoclonal antibody against a specific protein, it is also possible to determine the binding partners of that protein under a specific set of conditions. In this technique, known as co-immunoprecipitation, the

sample of interest — an extract prepared from cultured cells or isolated tissue, for example — is incubated with the specific antibody. Then, agarose beads coated with an antibody-binding protein (such as Protein A from the bacterium *Staphylococcus aureus*) are added to the mixture. Protein A recognizes a portion of the antibody that is separate from the antigen-binding region (e.g., the F_c domain, Figure 3.40), and thus does not disrupt the protein-antibody complex. After centrifugation at low speed, the antibody, now bound to the beads, aggregates at the bottom of the tube. Under optimal buffer conditions, the antibody-protein complex will also precipitate any additional proteins that are bound to the original protein (**Figure 4.19**). Subsequent analysis of the precipitate by SDS-PAGE, followed by either western blot or mass spectrometric fingerprinting (Section 4.3), enables the identification of the binding partners.



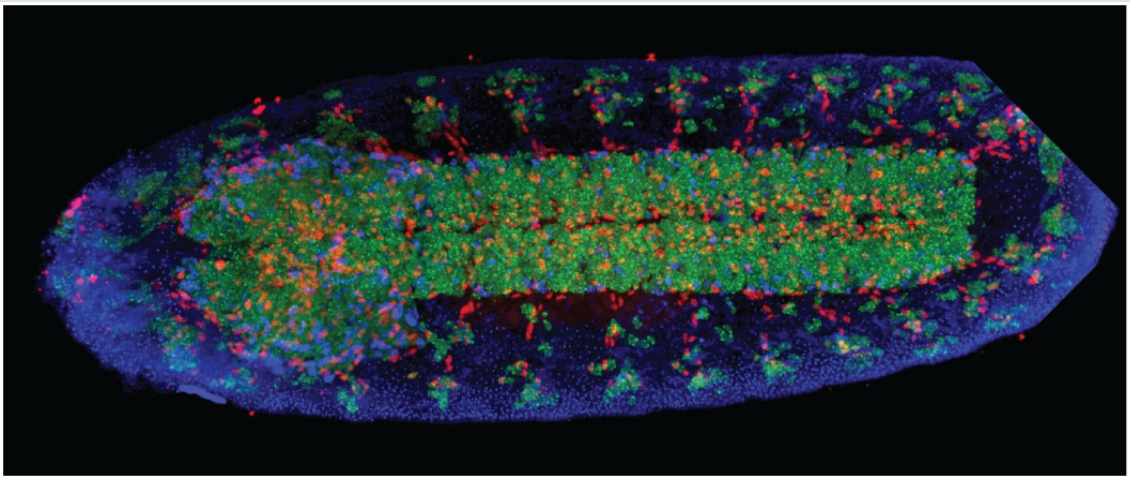


FIGURE 4.19 Co-immunoprecipitation can identify binding partners to a specific protein. An antibody specific for a particular protein (here, the red oval) is added to an extract isolated from cells or tissue. After an incubation period, agarose beads coated with Protein A are added, and the mixture is subjected to low-speed centrifugation. The beads bind to the antibody-protein complex and precipitate. Any additional proteins that interact with the target protein (here, the yellow rectangle) will also precipitate and can be identified by SDS-PAGE followed by western blotting or mass spectrometry.

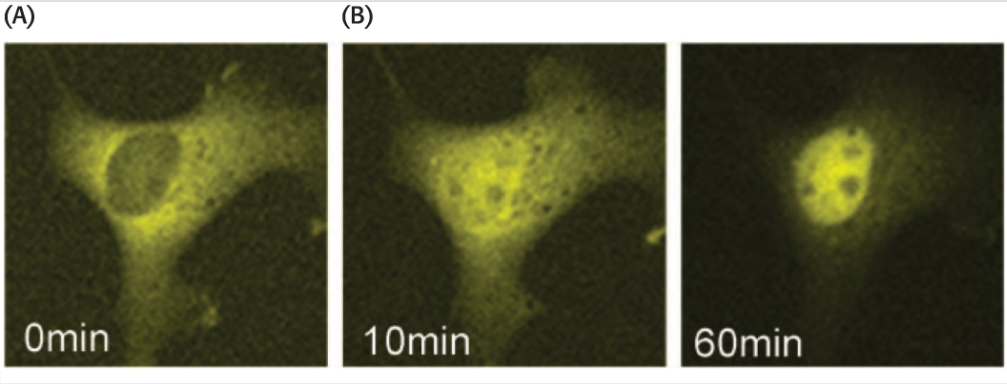
Fluorescent markers make the visualization of proteins in the cell possible

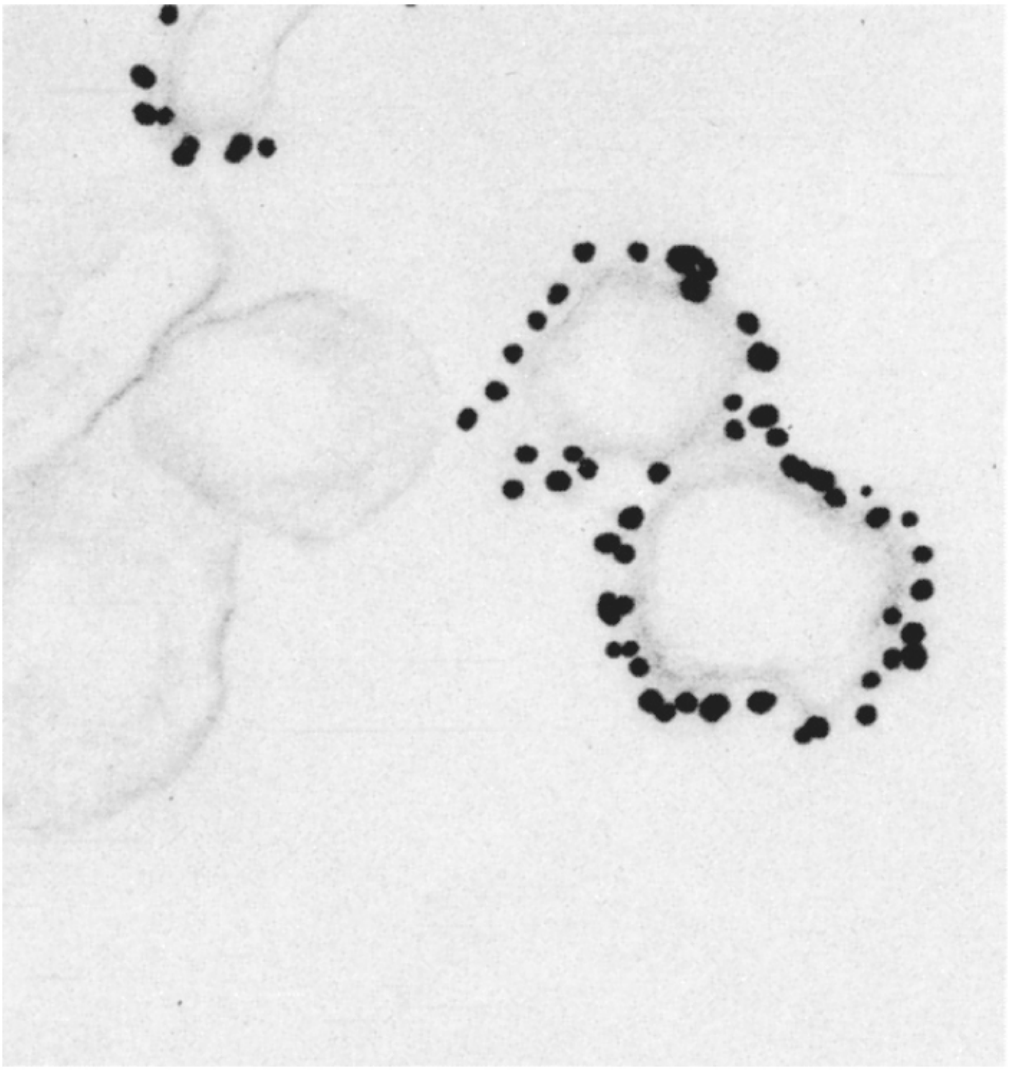
Fluorescent markers provide a powerful means of examining proteins in their biological context. Cells can be stained with fluorescence-labeled antibodies and examined by **fluorescence microscopy** to reveal the location of a protein of interest. For example, proteins that play key roles in embryonic development have been identified with the use of monoclonal antibodies as tags (**Figure 4.20**).



Credit: Laurina Manning, Chris Doe Lab, HHMI at University of Oregon.

FIGURE 4.20 Fluorescence-labeled monoclonal antibodies can detect proteins in a multicellular embryo imaged by microscopy. Here, a developing *Drosophila* embryo was stained with three different fluorescence-labeled monoclonal antibodies (red, green, and blue), each directed against a different protein important for gene regulation.

By tracking protein location, fluorescent markers also provide clues to protein function. For instance, the mineralocorticoid receptor protein binds to steroid hormones, including cortisol. The receptor was linked to a yellow variant of green fluorescent protein (GFP), a naturally fluorescent protein isolated from the jellyfish *Aequorea victoria* (Section 2.7). Fluorescence microscopy revealed that, in the absence of the hormone, the receptor is located in the cytoplasm (**Figure 4.21A**). On addition of the steroid, the receptor is translocated to the nucleus, where it binds to DNA (**Figure 4.21B**). These results indicate that the



mineralocorticoid receptor protein is a transcription factor that controls gene expression.

Permission conveyed through Copyright Clearance Center, Inc.

FIGURE 4.21 Fluorescence microscopy can detect changes in protein localization within the cell. (A) The mineralocorticoid receptor, made visible by attachment to a yellow variant of GFP, is located predominantly in the cytoplasm of the cultured cell. (B) Subsequent to the addition of corticosterone (a glucocorticoid steroid that also binds to the mineralocorticoid receptor), the receptor moves into the nucleus.

The highest resolution of fluorescence microscopy is about $0.2\ \mu m$ (200 nm, or $2000\ Å$), the wavelength of visible light. Finer spatial resolution can be achieved by electron microscopy if the antibodies are tagged with electron-dense markers. For example, antibodies attached to clusters of gold or to ferritin (which has an electron-dense core rich in iron) are highly visible under the electron microscope. This technique, called *immunoelectron microscopy*, can define the position of antigens to a resolution of 10 nm $(100\ Å)$ or finer (**Figure 4.22**).

FIGURE 4.22 Immunoelectron microscopy can detect proteins at very high spatial resolution. The opaque particles (150–Å, or 15-nm, diameter) in this electron micrograph are clusters of gold atoms bound to antibody molecules. A gold-labeled antibody against a channel protein (Section 13.1) identifies membrane vesicles at the termini of neurons that contain this protein.

4.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins

In several of the techniques described in the previous section, identification of the proteins present in the sample is often critical. For example, we may use co-immunoprecipitation to discover an unexpected protein that interacts with our sample protein. The identity of this unknown protein must be determined to advance our understanding of how our protein works. Antibody-based techniques, such as ELISA, can be very helpful toward this goal. However, these techniques are limited to the detection of proteins for which an antibody is already available.

Mass spectrometry enables the highly precise and sensitive measurement of the atomic composition of a particular molecule, or *analyte*, without prior knowledge of its identity. Originally, this method was relegated to the study of the chemical composition and molecular mass of gases or volatile liquids. However, technological advances have dramatically expanded the utility of mass spectrometry to the study of proteins, even those found at very low concentrations within highly complex mixtures, such as the contents of a particular cell type.

Mass spectrometers operate by converting analyte molecules into gaseous, charged forms (called *gas-phase ions*). Through the application of electrostatic potentials, the ratio of the mass of each ion to its charge (termed the *mass-to-charge ratio*, or m/z) can be measured. Although a wide variety of techniques employed by mass spectrometers are used in current practice, each of them comprises three essential components: the ion source, the mass analyzer, and the detector. Let us consider the

first two in greater detail, because improvements in them have contributed most significantly to the analysis of biological samples:

1. *The ion source achieves the first critical step in mass spectrometric analysis: ionization, or the conversion of the analyte into gas-phase ions.* Proteins are difficult to ionize efficiently because of their high molecular weights and low volatility. However, the development of two techniques in particular has enabled the clearing of this significant hurdle.

    - In **matrix-assisted laser desorption/ionization (MALDI)**, the analyte is evaporated to dryness in the presence of a volatile, aromatic compound (the matrix) that can absorb light at specific wavelengths. A laser pulse tuned to one of these wavelengths excites and vaporizes the matrix, converting some of the analyte into the gas phase. Subsequent gaseous collisions enable the intermolecular transfer of charge, ionizing the analyte.

    - In **electrospray ionization (ESI)**, a solution of the analyte is passed through an electrically charged nozzle. Droplets of the analyte, now charged, emerge from the nozzle into a chamber of very low pressure, evaporating the solvent and ultimately yielding the ionized analyte.

2. *In the second step, the newly formed analyte ions then enter the mass analyzer, where they are distinguished on the basis of their mass-to-charge ratios.* There are a number of different types of mass analyzers. For this discussion, we will consider one of the simplest, the **time-of-flight (TOF) mass analyzer**, in which ions are accelerated through an elongated chamber under a fixed electrostatic potential. Given two ions of identical net charge, the smaller ion will require less time to traverse the chamber than will the larger ion. The mass of each ion can be determined by measuring the time required for each ion to pass through the chamber.

The sequential action of the ion source and the mass analyzer enables the highly sensitive measurement of the mass-to-charge ratios of very large ions, such as the charged forms of proteins. Consider an example of a MALDI ion source coupled to a TOF mass analyzer: the MALDI-TOF mass spectrometer (Figure 4.23). Gas-phase ions generated by the MALDI ion source pass directly into the TOF analyzer, where the mass-to-charge ratios are recorded. In Figure 4.24, the MALDI-TOF mass spectrum of a mixture of 5 pmol (5×10^{-12} mol) each of insulin and lactoglobulin is shown. The masses determined by MALDI-TOF are 5733.9 and 18,364, respectively. A comparison with the calculated values of 5733.5 and 18,388 reveals that MALDI-TOF is clearly an accurate means of determining protein mass.

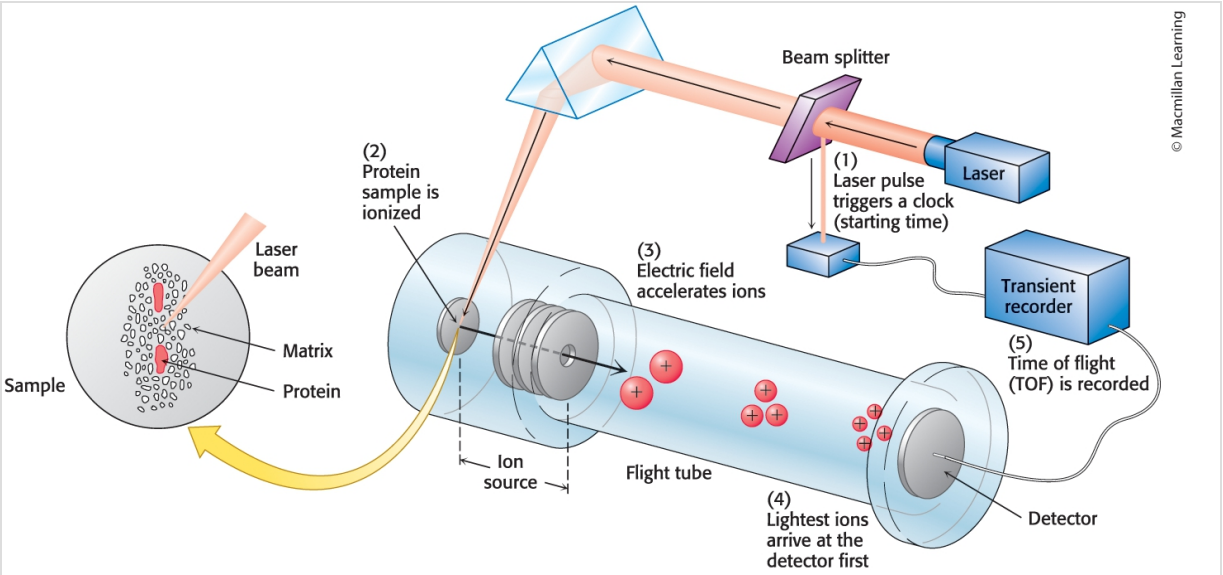

FIGURE 4.23 The MALDI-TOF mass spectrometer measures ionized samples based on their mass-to-charge ratio. (1) A laser pulse simultaneously starts a clock and is directed toward the sample. (2) The protein sample, embedded in an appropriate matrix, is ionized by the application of the laser pulse. (3) An electric field accelerates the ions through the flight tube toward the detector. (4) The lightest ions arrive first. (5) Based on the clock reading initiated in Step 1, the time of flight (TOF) for the ions can be measured.

[Information from J. T. Watson, *Introduction to Mass Spectrometry*, 3rd ed. (Lippincott-Raven, 1997), p. 279.]

VIEW an animation of this technique in Achieve

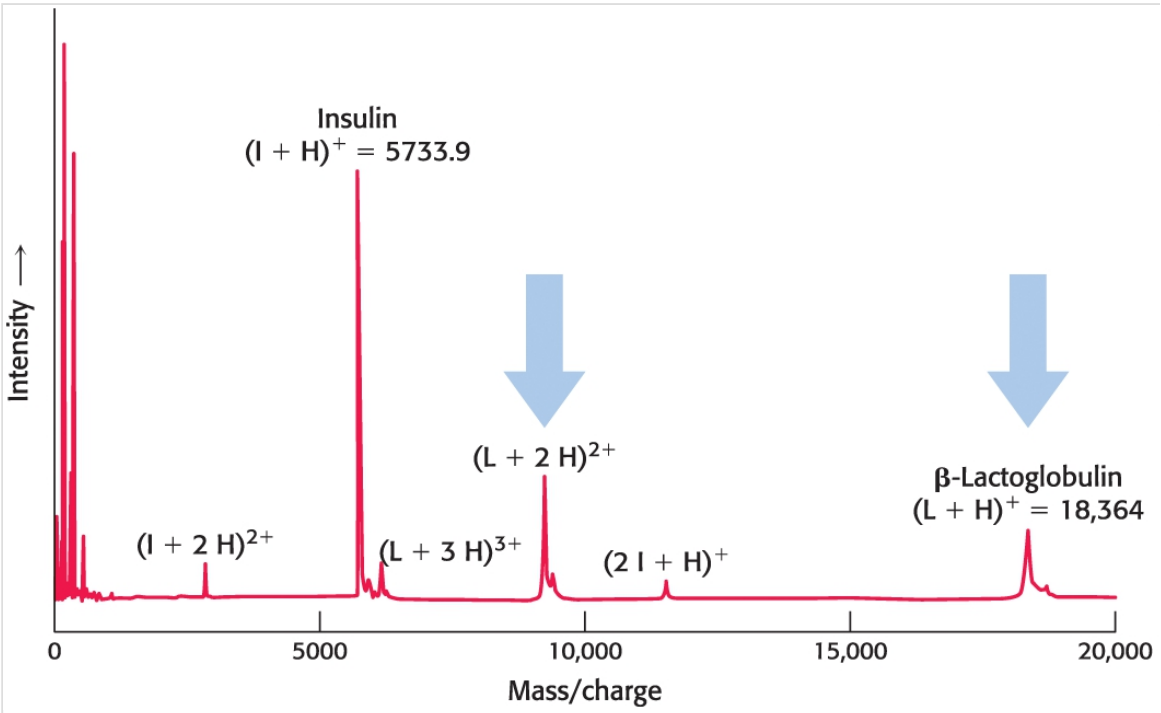

FIGURE 4.24 MALDI-TOF mass spectrometry can detect molecular masses with a high degree sensitivity and accuracy. A mixture of 5 pmol each of insulin (I) and β-lactoglobulin (L) was ionized by MALDI, which produces predominantly singly charged molecular ions from peptides and proteins — the insulin ion $(I+H)^+$ and the lactoglobulin ion $(L+H)^+$. Peaks corresponding to β-lactoglobulin but carrying different total net charges are indicated by the blue arrows, as well as small quantities of a singly charged dimer of insulin $(2\,I+H)^+$ also ar produced.

[Data from J. T. Watson, *Introduction to Mass Spectrometry*, 3rd ed. (Lippincott-Raven, 1997), p. 282.]

In the ionization process, a family of ions, each of the same mass but carrying different total net charges, is formed from a single analyte. Because the mass spectrometer detects ions on the basis of their mass-

to-charge ratio, these ions will appear as separate peaks in the mass spectrum. For example, in the mass spectrum of β-lactoglobulin shown in Figure 4.24, peaks near $m/z = 18{,}364$ (corresponding to the $+1$ charged ion) and $m/z = 9183$ (corresponding to the $+2$ charged ion) are visible (indicated by the blue arrows). Although multiple peaks for the same ion may appear to be a nuisance, they enable the spectrometrist to measure the mass of an analyte ion more than once in a single experiment, improving the overall precision of the calculated result.

Peptides can be sequenced by mass spectrometry

For many years, chemical methods were the primary means for peptide sequencing. In the most common of these methods, called *Edman degradation*, the N-terminal amino acid of a polypeptide is labeled with phenyl isothiocyanate. Subsequent cleavage yields the phenylthiohydantoin (PTH)-amino acid derivative, which can be identified by chromatographic methods, and the polypeptide chain, now shortened by one residue (**Figure 4.25**). This procedure can then be repeated on the shortened peptide, yielding another PTH–amino acid, which can again be identified by chromatography.

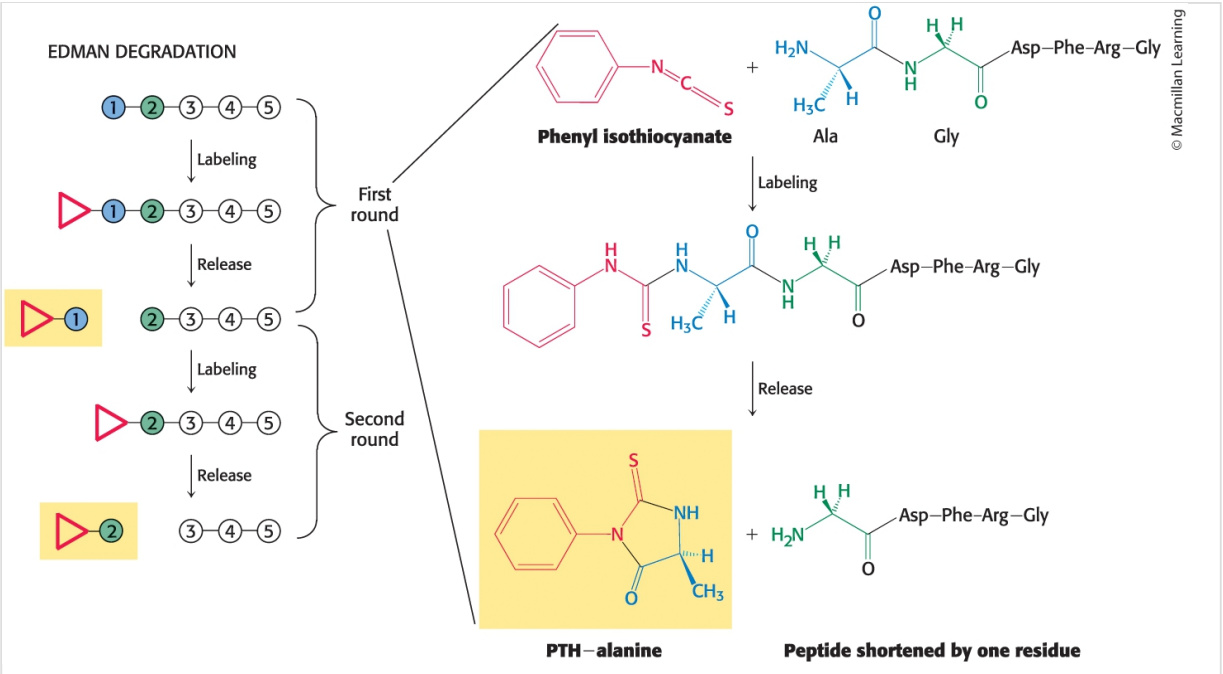

FIGURE 4.25 The Edman degradation is a chemical method for peptide sequencing. The labeled amino-terminal residue (PTH–alanine in the first round) can be released without hydrolyzing the rest of the peptide. Hence, the amino-terminal residue of the shortened peptide (Gly-Asp-Phe-Arg-Gly) can be determined in the second round. Three more rounds of the Edman degradation reveal the complete sequence of the original peptide.

While technological advancements have improved the speed and sensitivity of the Edman degradation, these parameters have largely been surpassed by the application of mass spectrometric methods. The use of mass spectrometry for protein sequencing takes advantage of the fact that ions of proteins that have been analyzed by a mass spectrometer, called *precursor ions*, can be broken into smaller peptide chains by bombardment with atoms of an inert gas such as helium or argon. These new fragments, called *product ions*, can be passed through a second mass analyzer for further mass characterization.

Using two mass analyzers arranged in this manner is referred to as **tandem mass spectrometry**. Importantly, the product-ion fragments are formed in chemically predictable ways that can provide clues to the

amino acid sequence of the precursor ion. For polypeptide analytes, disruption of individual peptide bonds will yield two smaller peptide ions, containing the sequences before and after the cleavage site. Hence, a family of ions can be detected; each ion represents a fragment of the original peptide with one or more amino acids removed from one end (**Figure 4.26A**). For simplicity, only the carboxyl-terminal peptide fragments are shown in Figure 4.26A. **Figure 4.26B** depicts a representative mass spectrum from a fragmented peptide. The mass differences between the peaks in this fragmentation experiment indicate the amino acid sequence of the precursor peptide ion.

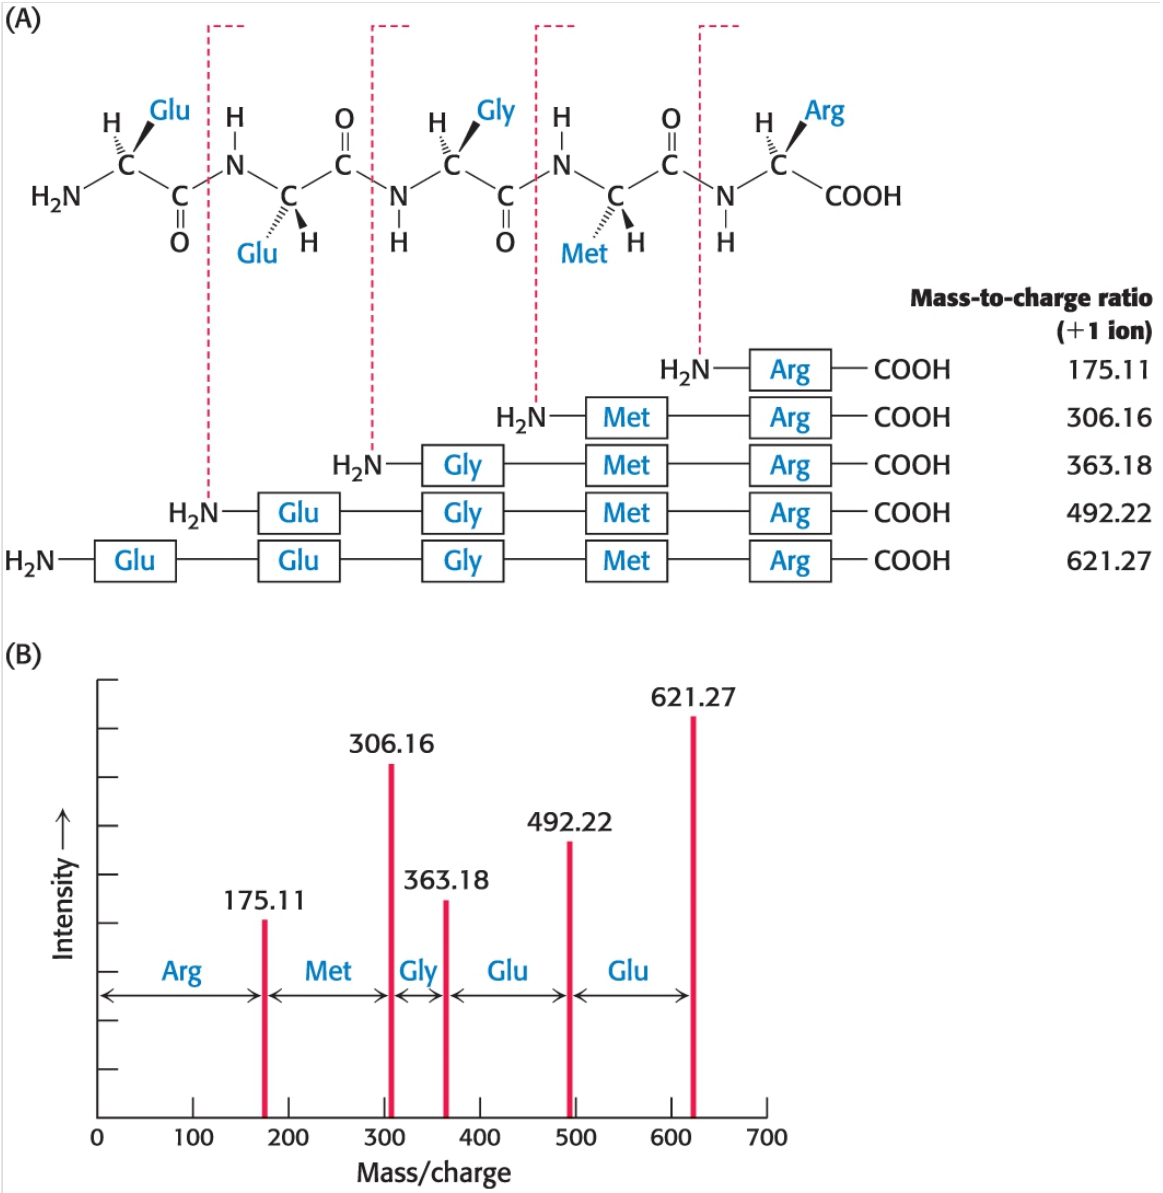

FIGURE 4.26 Peptides can be sequenced by tandem mass spectrometry. (A) Within the mass spectrometer, peptides can be fragmented by bombardment with inert gaseous ions to generat a family of product ions in which individual amino acids have been removed from one end. In th example, the carboxyl fragment of the cleaved peptide bond is ionized. (B) The product ions are detected in the second mass analyzer. The mass differences between the peaks indicate the sequence of amino acids in the precursor ion.

Self-Check Question

Which two amino acids are indistinguishable by tandem mass spectrometry as described above, and why?

Proteins can be specifically cleaved into small peptides to facilitate analysis

In principle, it should be possible to sequence an entire protein using the Edman degradation or mass spectrometric methods. In practice, the Edman degradation is limited to peptides of 50 residues, because not all peptides in the reaction mixture release the amino acid derivative at each step. For instance, if the efficiency of release for each round were 98%, the proportion of "correct" amino acid released after 60 rounds would be (0.98^{60}), or 0.3 — a hopelessly impure mix.

Similarly, sequencing of long peptides by mass spectrometry yields a mass spectrum that can be complex and difficult to interpret. This obstacle can be overcome by cutting the protein into smaller peptides that can be sequenced. **Table 4.3** lists several ways of cleaving polypeptide chains, with either chemical reagents or proteolytic (protein-breaking) enzymes. Note that these methods are sequence specific: they disrupt the protein backbone at particular amino acid residues in a predictable manner. The peptides obtained by these methods are separated by some type of chromatography. The sequence of each purified peptide can then be more easily determined. At this point, the amino acid sequences of segments of the protein are known, but the order of these segments is not yet defined.

TABLE 4.3 Specific cleavage of polypeptides

Reagent	Cleavage site
Chemical cleavage	
Cyanogen bromide	Carboxyl side of methionine residues
O-Iodosobenzoate	Carboxyl side of tryptophan residues
Hydroxylamine	Asparagine–glycine bonds
2-Nitro-5-thiocyanobenzoate	Amino side of cysteine residues
Enzymatic cleavage	
Trypsin	Carboxyl side of lysine and arginine residues
Clostripain	Carboxyl side of arginine residues
Staphylococcal protease	Carboxyl side of aspartate and glutamate residues (glutamate only under certain conditions)
Thrombin	Carboxyl side of arginine
Chymotrypsin	Carboxyl side of tyrosine, tryptophan, phenylalanine, leucine, and methionine
Carboxypeptidase A	Amino side of C-terminal amino acid (not arginine, lysine, or proline)

How can we order the peptides to obtain the primary structure of the original protein? The necessary additional information is obtained from **overlap peptides** (Figure 4.27). A second enzyme is used to split the polypeptide chain at different linkages. For example, chymotrypsin

cleaves preferentially on the carboxyl side of aromatic and some other bulky nonpolar residues, while trypsin cleaves on the carboxyl side of positively charged residues (Table 4.3). Because these chymotryptic peptides overlap two or more tryptic peptides, they can be used to establish the order of the peptides. The entire amino acid sequence of the polypeptide chain is then known.

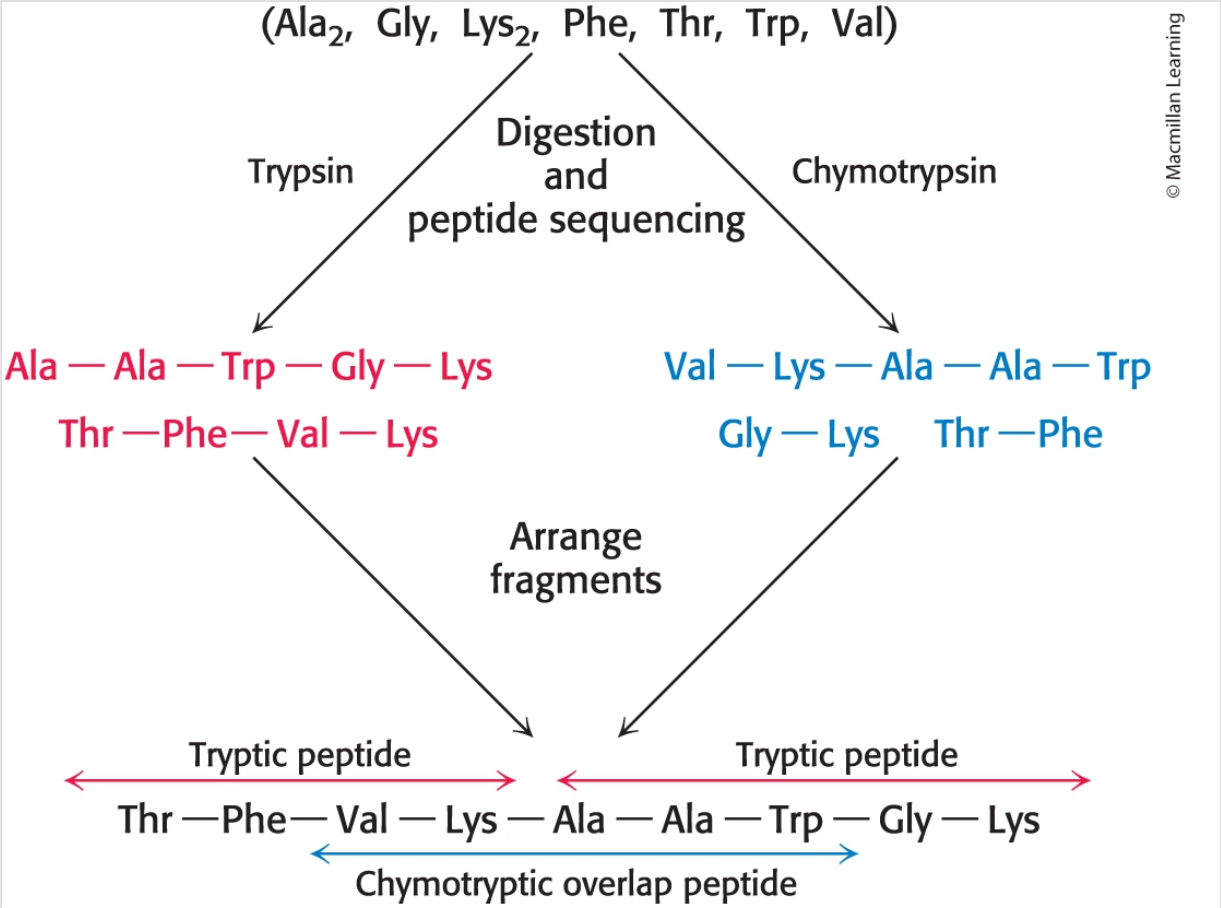

FIGURE 4.27 Overlap peptides are used to establish the order of sequenced peptides. The peptide obtained by chymotryptic digestion overlaps two tryptic peptides, establishing their order.

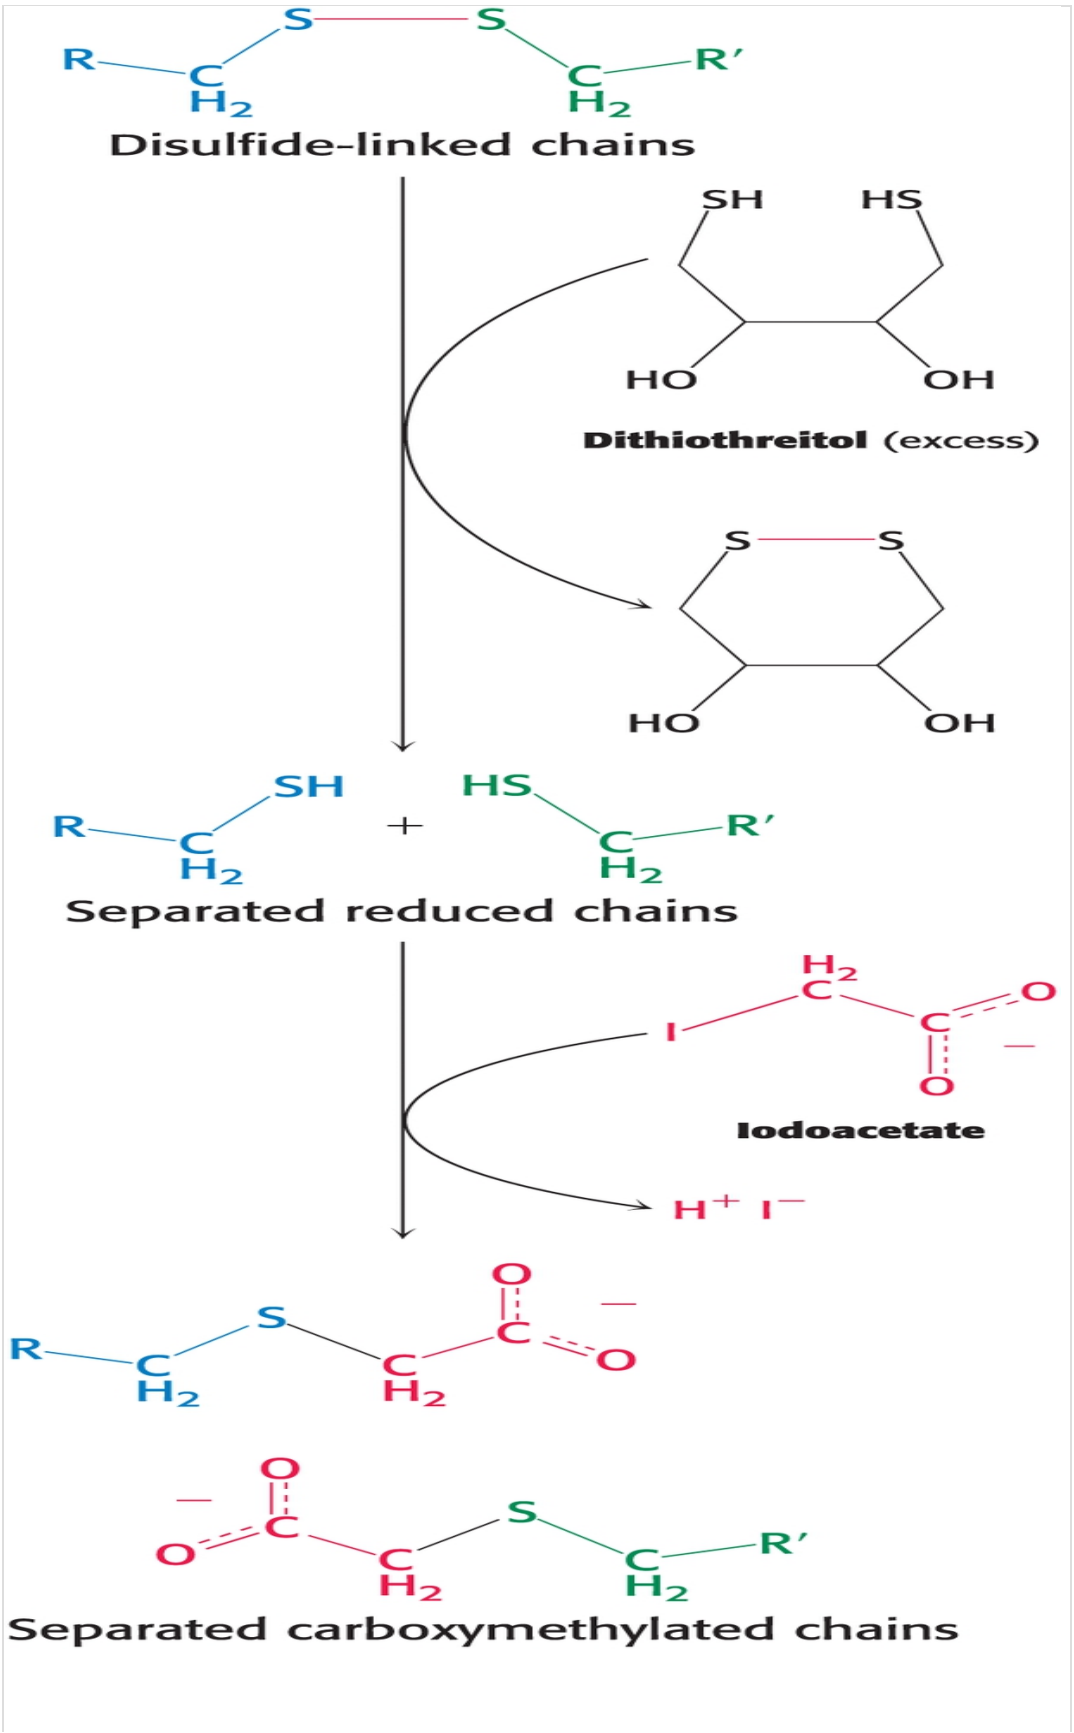
Additional steps are necessary if the initial protein sample is actually several polypeptide chains. SDS-PAGE under reducing conditions should

display the number of chains. Alternatively, the number of distinct N-terminal amino acids could be determined. After a protein has been identified as being made up of two or more polypeptide chains, the chains must be separated from one another first. Denaturing agents, such as urea or guanidine hydrochloride, are used to dissociate chains held together by noncovalent interactions; polypeptide chains linked by covalent disulfide bonds are separated by reduction with thiols such as β-mercaptoethanol or dithiothreitol. To prevent the cysteine residues from recombining, they are alkylated with iodoacetate to form stable *S*-carboxymethyl derivatives (**Figure 4.28**).



Disulfide-linked chains
Dithiothreitol (excess)
Separated reduced chains
Iodoacetate
Separated carboxymethylated chains

FIGURE 4.28 Reduction and alkylation are used to separate disulfide-linked polypeptides prior to sequencing. Polypeptides linked by disulfide bonds can be separated by reduction with dithiothreitol followed by alkylation to prevent them from re-forming.

Genomic and proteomic methods are complementary approaches to deducing protein structure and function

Despite the technological advancements in both chemical and mass spectrometric methods of peptide sequencing, heroic effort is required to elucidate the sequence of large proteins, those with more than 1000 residues. For sequencing such proteins, a complementary experimental approach based on recombinant DNA technology is often more efficient. As will be discussed in Chapter 9, long stretches of DNA can be cloned and sequenced, and the nucleotide sequence can be translated to reveal the amino acid sequence of the protein encoded by the gene. Recombinant DNA technology has generated a wealth of amino acid sequence information at a remarkable rate.

Even with the use of the DNA base sequence to determine primary structure, however, there is still a need to work with isolated proteins. The amino acid sequence deduced by reading the DNA sequence is that of the nascent protein, the direct product of the translational machinery. However, many proteins undergo posttranslational modifications after their syntheses (Section 2.7). Some have their ends trimmed, and others arise by cleavage of a larger initial polypeptide chain. Cysteine residues in some proteins are oxidized to form disulfide links, connecting either parts within a chain or separate polypeptide chains. Specific side chains of some proteins are altered. Amino acid

sequences derived from DNA sequences are rich in information, but they do not disclose these modifications. Chemical analyses of proteins in their mature form are needed to delineate the nature of these changes, which are critical for the biological activities of most proteins.

The amino acid sequence of a protein provides valuable information

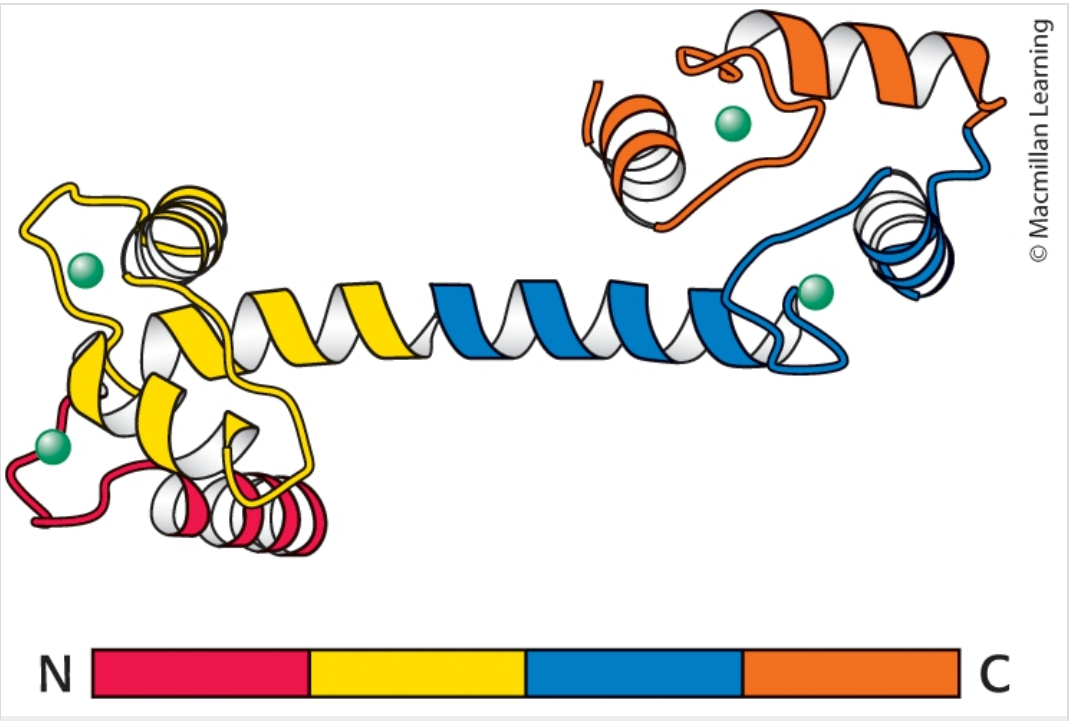
Regardless of the method used for its determination, the amino acid sequence of a protein provides the biochemist with a wealth of information as to the protein's structure, function, and history.

- *The sequence of a protein of interest can be compared with all other known sequences to determine whether significant similarities exist.* A search for kinship between a newly sequenced protein and the millions of previously sequenced ones takes only a few seconds on a personal computer (Chapter 10). If the newly isolated protein is a member of an established class of protein, we can begin to infer information about the protein's structure and function. For instance, chymotrypsin and trypsin are members of the serine protease family, a clan of proteolytic enzymes that have a common catalytic mechanism based on a reactive serine residue (Chapter 6). If the sequence of the newly isolated protein shows sequence similarity with trypsin or chymotrypsin, the result suggests that it, too, may be a serine protease.

- *Comparison of sequences of the same protein in different species yields information about evolutionary pathways.* Evolutionary relationships between species can be inferred from sequence differences between their proteins. If we assume that the random mutation rate of proteins over time is constant, then careful sequence comparison of related proteins between two organisms can provide an estimate for when these two evolutionary lines diverged. For

example, a comparison of serum albumins found in primates indicates that human beings and African apes diverged 5 million years ago, not 30 million years ago as was once thought. Sequence analyses have opened a new perspective on the fossil record and the pathway of human evolution.

- *Amino acid sequences can be searched for the presence of internal repeats*. Such internal repeats can reveal the history of an individual protein itself. Many proteins apparently have arisen by duplication of primordial genes followed by their diversification. For example, calmodulin, a ubiquitous eukaryotic calcium sensor, contains four similar calcium-binding modules that arose by gene duplication (**Figure 4.29**).



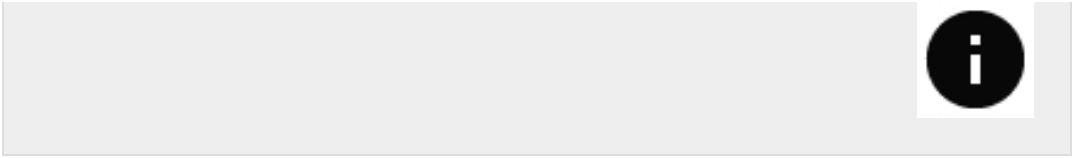


FIGURE 4.29 Many proteins contain internal repeats within their sequences. Calmodulin, a calcium sensor, contains four similar units (shown in red, yellow, blue, and orange) in a single polypeptide chain. Each unit binds a calcium ion (shown in green).

[Drawn from 1CLL.pdb.]

INTERACT with this model in Achieve

- *Many proteins contain amino acid sequences that serve as signals designating their destinations or controlling their processing*. For example, a protein destined for export from a cell or for location in a membrane contains a signal sequence — a stretch of about 20 hydrophobic residues near the amino terminus that directs the protein to the appropriate membrane. Another protein may contain a stretch of amino acids that functions as a nuclear localization signal, directing the protein to the nucleus. Identification of these sequences within a protein provides clues to its function within the cell.

- *Sequence data provide a basis for preparing antibodies specific for a protein of interest*. One or more parts of the amino acid sequence of a protein will elicit an antibody when injected into a mouse or rabbit. These specific antibodies can be very useful in determining the amount of a protein present in solution or in the blood, ascertaining its distribution within a cell, or cloning its gene (Section 4.2).

- *Amino acid sequences are valuable for making DNA probes that are specific for the genes encoding the corresponding proteins*. Knowledge of a protein's primary structure means that DNA sequences corresponding to a part of the amino acid sequence can be constructed on the basis of the genetic code. These DNA sequences can be used as probes to isolate the gene encoding the protein so that the entire sequence of the protein can be determined. The gene in turn can provide valuable information about the physiological regulation of the protein. Protein sequencing is an integral part of molecular genetics, just as DNA cloning is central to the analysis of protein structure and function. We will revisit some of these topics in more detail in Chapter 9.

Individual proteins can be identified by mass spectrometry

The combination of mass spectrometry with chromatographic and peptide-cleavage techniques enables highly sensitive protein identification in complex biological mixtures. When a protein is cleaved by chemical or enzymatic methods (Table 4.3), a specific and predictable family of peptide fragments is formed. We learned in Chapter 2 that each protein has a unique, precisely defined amino acid sequence. Hence, the identity of the individual peptides formed from this cleavage reaction — and, importantly, their corresponding masses — is a distinctive signature for that particular protein. Protein cleavage, followed by chromatographic separation and mass spectrometry, enables rapid identification and quantitation of these signatures, even if they are present at very low concentrations. This technique for protein identification is referred to as **peptide mass fingerprinting**.

The speed and sensitivity of mass spectrometry has made this technology critical for the study of proteomics. Let us consider the analysis of the nuclear pore complex from yeast, which facilitates the transport of large molecules into and out of the nucleus. This huge macromolecular complex — around 100,000 kDa! — was purified from yeast cells, then fractionated by HPLC followed by gel electrophoresis. Individual bands from the gel were isolated, cleaved with trypsin, and analyzed by MALDI-TOF mass spectrometry. The fragments produced were compared with amino acid sequences deduced from the DNA sequence of the yeast genome, as shown in **Figure 4.30**. A total of 174 nuclear pore proteins were identified in this manner.

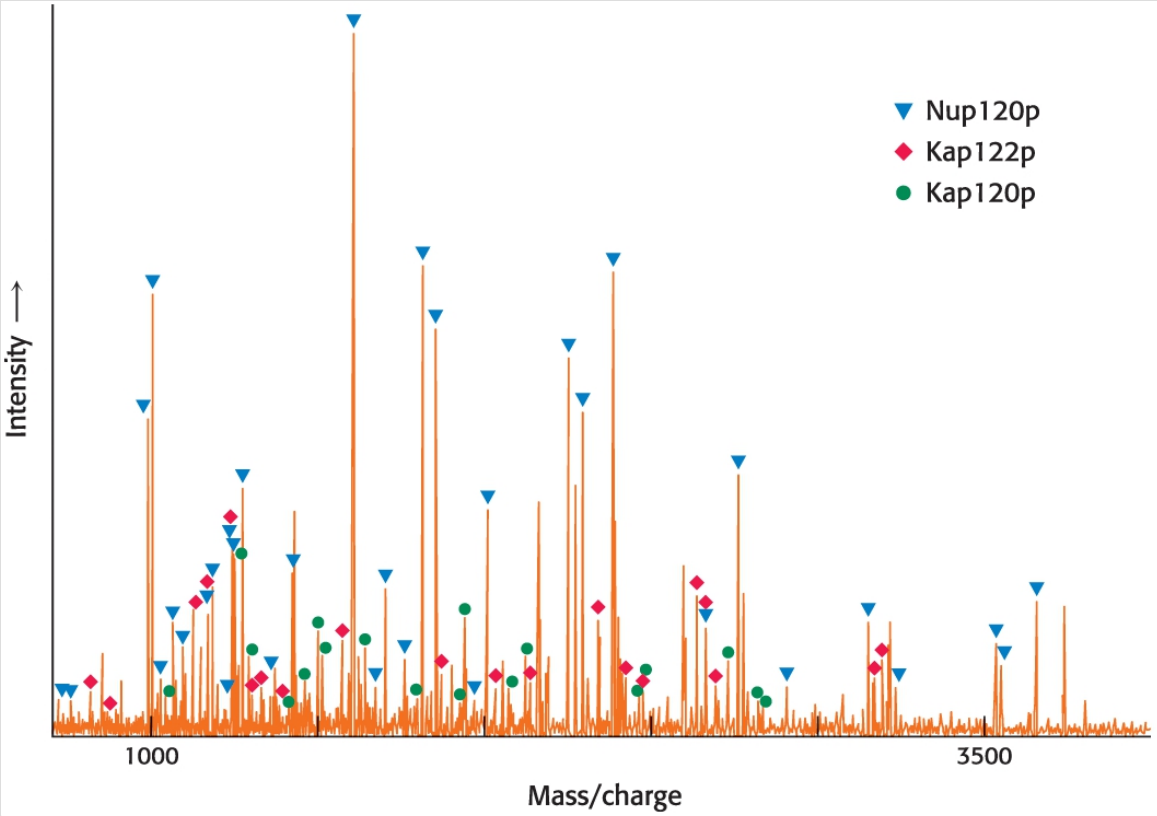

FIGURE 4.30 Peptide mass fingerprinting can identify individual proteins within complex mixtures. This mass spectrum was obtained by analyzing a trypsin-treated band in a gel derive from a yeast nuclear-pore sample. Many of the peaks were found to match the masses predicte for peptide fragments from three proteins (Nup120p, Kap122p, and Kap120p) within the yeast genome.

[Data from M. P. Rout, J. D. Aitchison, A. Suprapto, K. Hjertaas, Y. Zhao, and B. T. Chait, *J. Cell Biol*. 148:635–651, 200

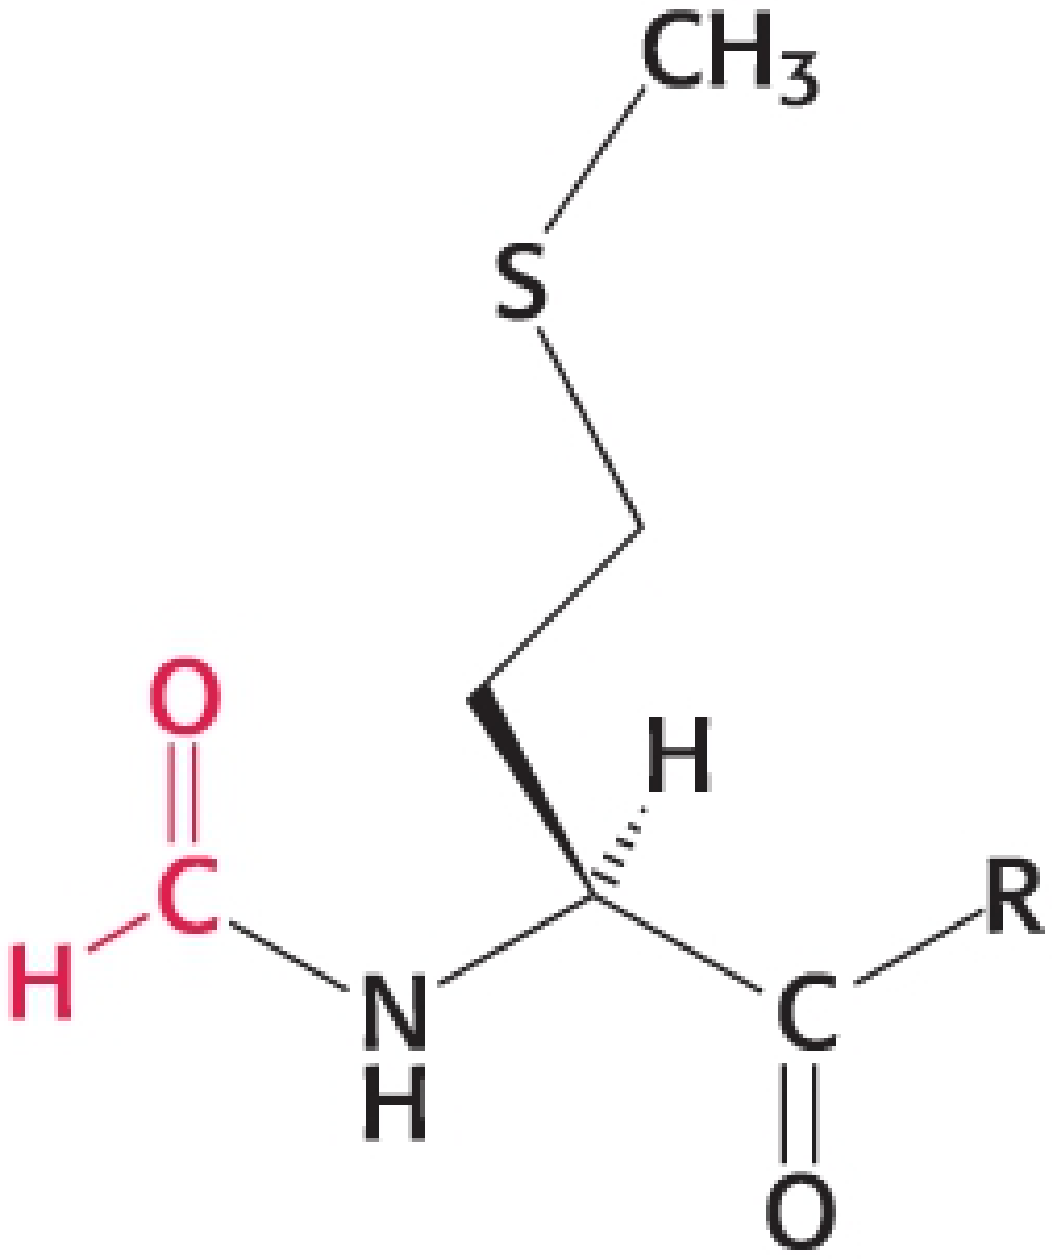
Many of the proteins found in this experiment had not previously been identified as being associated with the nuclear pore despite years of study. Furthermore, mass spectrometric methods are sensitive enough to detect essentially all components of the pore if they are present in the samples used. Thus, a complete list of the components constituting this macromolecular complex could be obtained in a straightforward manner.

The proteome is the functional representation of the genome

Thus far, we have discussed several techniques, including two-dimensional electrophoresis and peptide mass fingerprinting, which allow for the rapid and scalable detection and quantitation of large numbers of proteins in a single experiment. These methods can be used to (1) explore the compete catalog of proteins expressed in a cell under a specific set of conditions, and (2) investigate how this inventory changes when these conditions are altered. These studies, referred to as *proteomics*, can be very powerful in understanding the mechanisms by which cells adapt to changing environments.

As will be discussed in Chapter 9, the complete DNA base sequences, or genomes, of many organisms are now available. For example, the roundworm *Caenorhabditis elegans* has a genome of 97 million bases and about 19,000 protein-encoding genes, whereas that of the fruit fly *Drosophila melanogaster* contains 180 million bases and about 14,000 genes. The completely sequenced human genome contains 3 billion bases and about 23,000 genes. However, these genomes are simply inventories of the genes that could be expressed within a cell under specific conditions. Only a subset of the proteins encoded by these genes will actually be present in a given biological context. The **proteome** — derived from proteins expressed by the genome — of an organism signifies a more complex level of information content, encompassing the types, functions, and interactions of proteins within its biological environment.

The proteome is not a fixed characteristic of the cell. Because it represents the functional expression of information, it varies with cell type, developmental stage, and environmental conditions. The proteome is much larger than the genome because almost all gene products are proteins that can be chemically modified in a variety of ways. Furthermore, these proteins do not exist in isolation; they often



interact with one another to form complexes with specific functional properties. Whereas the genome is “hard wired,” the proteome is highly dynamic. The techniques we have described in this section enable the understanding of the proteome by providing a means of investigating, characterizing, and cataloging proteins.

4.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods

Peptides of defined sequence can be synthesized to assist in biochemical analysis. These peptides are valuable tools for several purposes.

- *Synthetic peptides can serve as antigens to stimulate the formation of specific antibodies*. Suppose we want to isolate the protein expressed by a specific gene. Peptides can be synthesized that match the translation of part of the gene's nucleic acid sequence, and antibodies can be generated that target these peptides. These antibodies can then be used to isolate the intact protein or localize it within the cell.

- *Synthetic peptides can be used to isolate receptors for many hormones and other signal molecules*. For example, white blood cells are attracted to bacteria by formylmethionyl (fMet) peptides released in the breakdown of bacterial proteins. Synthetic formylmethionyl peptides have been useful in identifying the cell-surface receptor for this class of peptide. Moreover, synthetic peptides can be attached to agarose beads to prepare affinity chromatography columns for the purification of receptor proteins that specifically recognize the peptides.

fMet peptide

- *Synthetic peptides enable the study of the effects of nonproteinogenic amino acids on protein structure and function.* Recall from Section 2.2 that proteins synthesized within the cell are composed from a repertoire of 20 natural, or *proteinogenic*, amino acids. Chemical synthesis of peptides provides a convenient method for inserting *nonproteinogenic* amino acids — that is, those not directly coded into the genome — into peptides. Examples of nonproteinogenic amino acids include the D isomers of the proteinogenic amino acids (e.g., D-alanine) and amino acids that contain posttranslational modifications (Section 2.7), such as hydroxyproline. Peptides containing these amino acids are valuable tools in the study of protein structure and function.

- *Synthetic peptides can serve as drugs.* Vasopressin is a peptide hormone that stimulates the reabsorption of water in the kidney, leading to the formation of more-concentrated urine. Patients with diabetes insipidus are deficient in vasopressin (also called *antidiuretic hormone*), and so they excrete large volumes of dilute urine (more than 5 liters per day) and are continually thirsty. This defect can be treated by administering 1-desamino-8-D-arginine vasopressin (also called desmopressin), a synthetic analog of the missing hormone (**Figure 4.31**). This synthetic peptide is degraded in the body much more slowly than vasopressin and does not increase blood pressure.

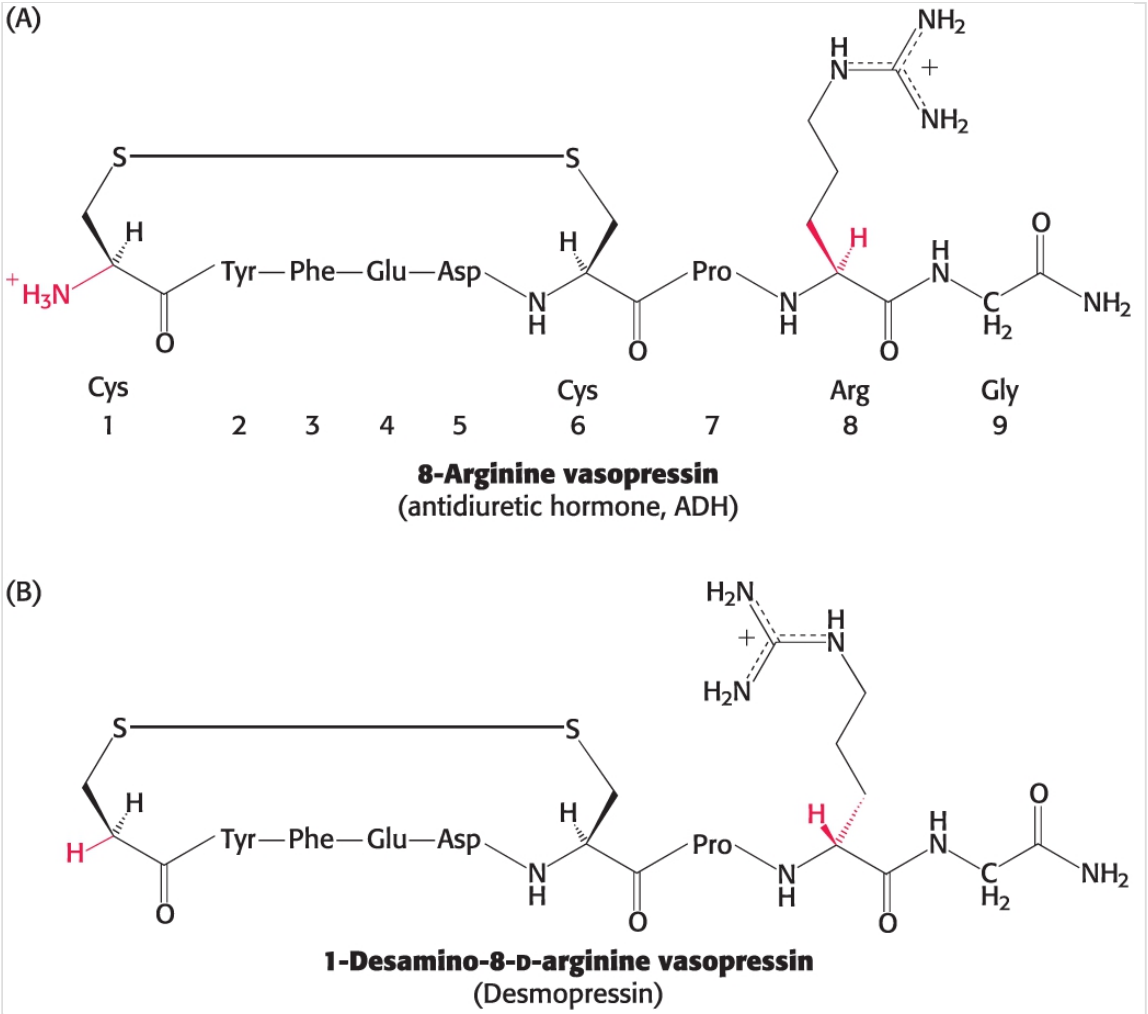


FIGURE 4.31 Desmopressin, a synthetic vasopressin analog, can be used to treat patients deficient in vasopressin. Structural formulas of (A) vasopressin, a peptide hormone that stimulates water resorption, and (B) 1-desamino-8-D-arginine vasopressin (desmopressin), a more stable synthetic analog of this antidiuretic hormone.

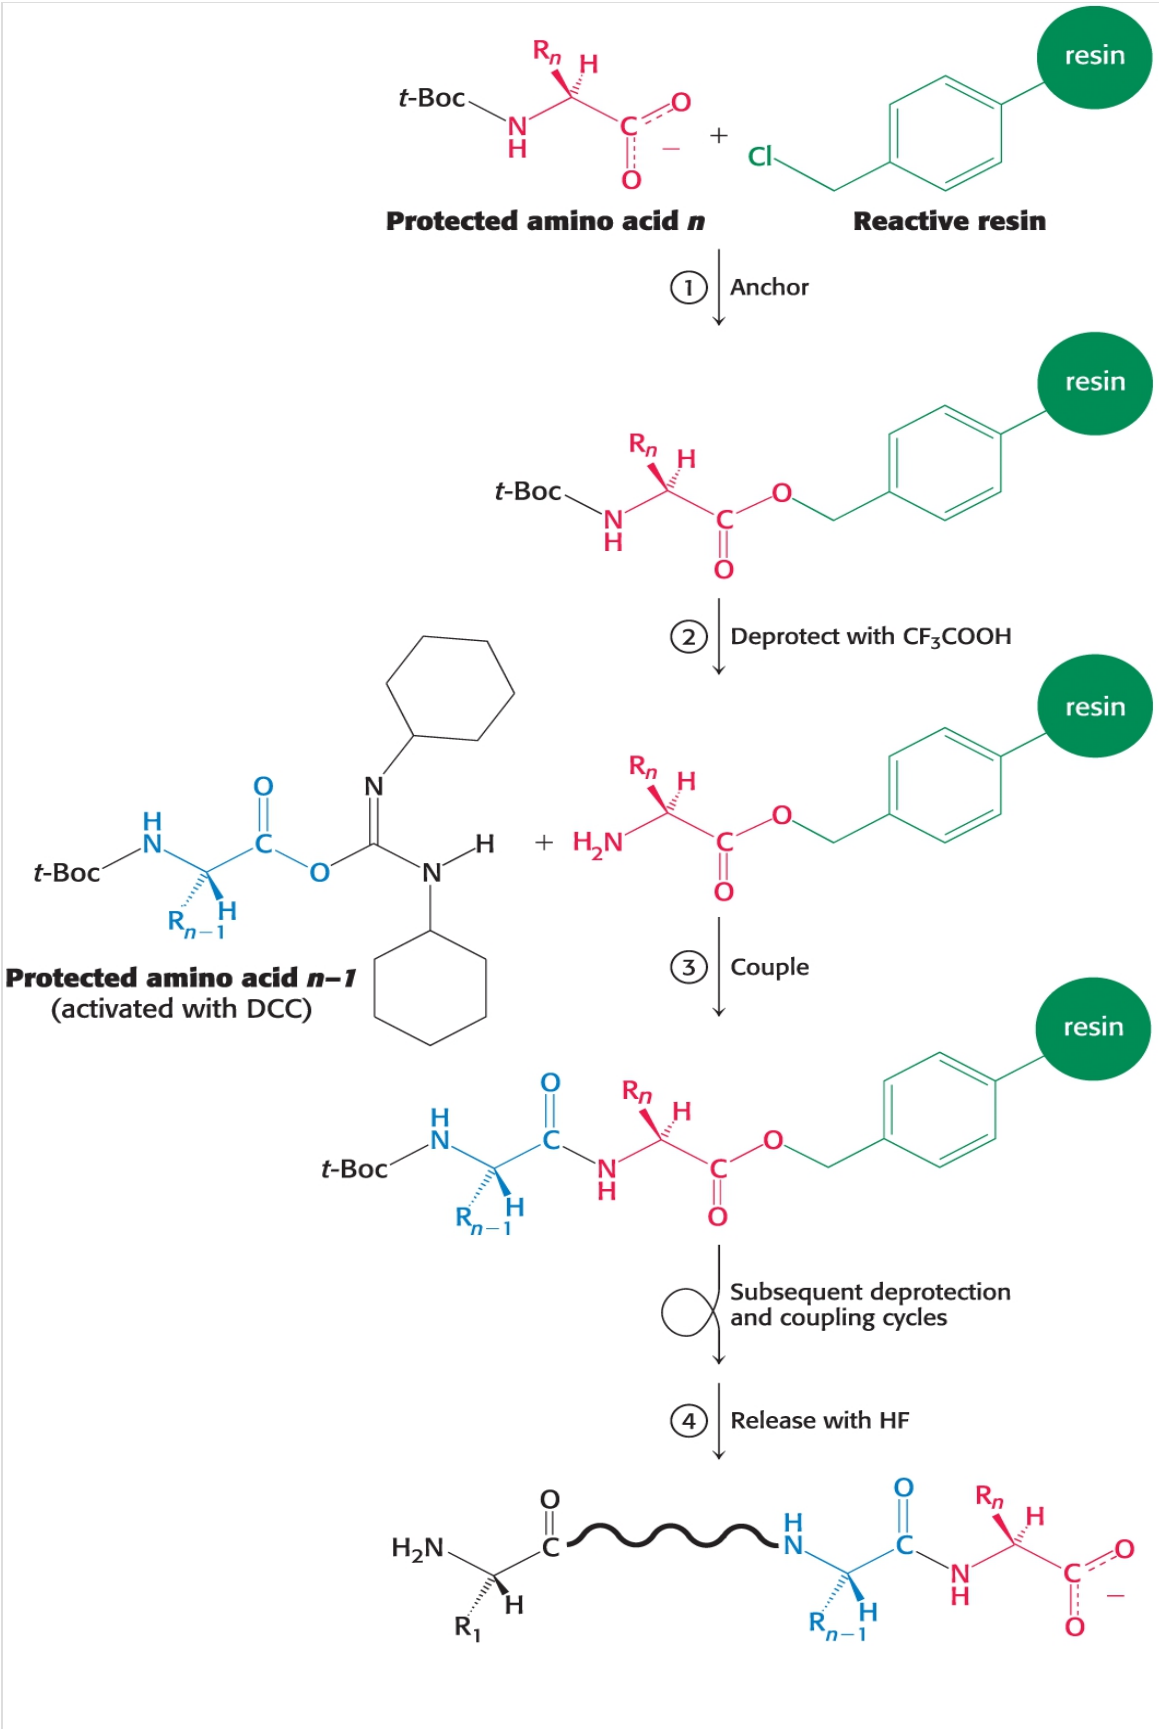
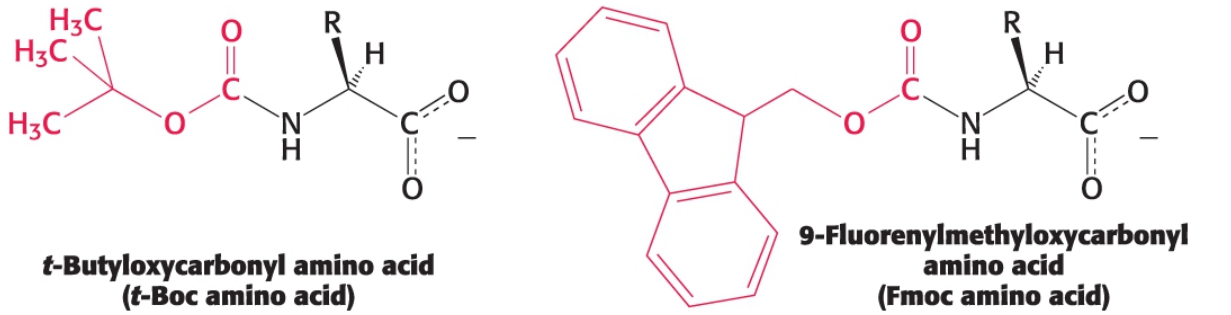
- *Studying synthetic peptides can help define the rules governing the three-dimensional structure of proteins.* We can ask whether a particular sequence by itself tends to fold into an α helix, a β strand, or a hairpin turn, or behaves as a random coil (Section 2.4). The peptides created for such studies can incorporate amino acids not

normally found in proteins, allowing greater variation in chemical structure than is possible with the use of only 20 amino acids.

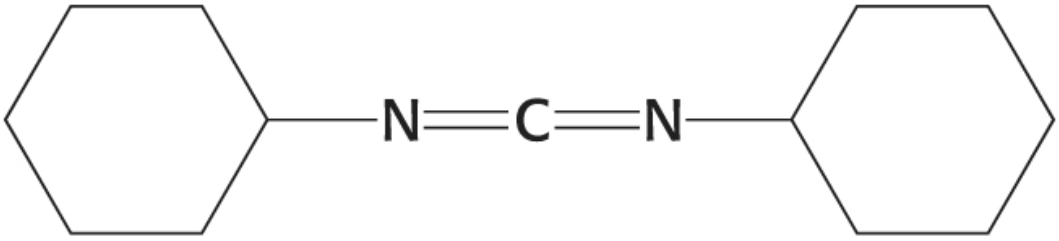
How are these peptides constructed? The **solid-phase method**, first developed by R. Bruce Merrifield, provides a highly efficient approach to the synthesis of polypeptides (**Figure 4.32**). Recall that the amino group of one amino acid can link to the carboxyl group of any another. However, a unique product will form if only a single amino group and a single carboxyl group are available for reaction. To achieve this, it is necessary to block some groups and to activate others to prevent unwanted reactions:





t-Boc
Protected amino acid n
Cl
resin
Reactive resin
1 Anchor
2 Deprotect with CF3COOH
Protected amino acid n–1
(activated with DCC)
3 Couple
Subsequent deprotection
and coupling cycles
4 Release with HF

FIGURE 4.32 Solid-phase peptide synthesis is achieved by repeated coupling and deprotectic steps. The sequence of steps in solid-phase synthesis is: (1) anchoring of the *t*-Boc-protected C-terminal amino acid to a solid resin, (2) deprotection of the amino terminus, and (3) coupling of the free amino terminus with the DCC-activated carboxyl group of the next *t*-Boc-protected amino acid. Steps 2 and 3 are repeated for each added amino acid. Finally, in step 4, the completed peptide is released from the resin.



1. First, the carboxyl-terminal amino acid (shown in red in Figure 4.32) is anchored to an insoluble resin, usually beads, by its carboxyl group, effectively protecting it from further peptide-bond-forming reactions. The α-amino group of this amino acid is blocked with a protecting group such as the *tert*-butyloxycarbonyl (*t*-Boc) or the 9-fluorenylmethyloxycarboyl (Fmoc) group. In this example, we will use the *t*-Boc protecting groups.

2. The *t*-Boc protecting group of this amino acid is then removed with trifluoroacetic acid, freeing the α-amino group for the next coupling reaction.

3. The next amino acid (in the protected *t*-Boc form, shown in blue in Figure 4.32) and dicyclohexylcarbodiimide (DCC) are added together. At this stage, only the carboxyl group of the incoming amino acid and the amino group of the resin-bound amino acid are

free to form a peptide bond. DCC reacts with the carboxyl group of the incoming amino acid, activating it for the peptide-bond-forming reaction. After the peptide bond has formed, excess reagents are washed away, leaving the desired dipeptide product attached to the beads. Additional amino acids are linked by repeating Steps 2 and 3.

Dicyclohexylcarbodiimide (DCC)

4. At the end of the synthesis, the peptide is released from the beads by the addition of hydrofluoric acid (HF), which cleaves the carboxyl ester anchor without disrupting peptide bonds. Protecting groups on potentially reactive side chains, such as that of lysine, also are removed at this time.

A major advantage of the solid-phase method is that the desired product at each stage is bound to beads that can be rapidly filtered and washed. Hence, there is no need to purify intermediates. Additionally, all reactions are carried out in a single vessel, eliminating losses caused by repeated transfers of products, and the cycle of reactions can be readily automated, which makes it feasible to routinely synthesize peptides containing about 50 residues in good yield and purity.

Even larger peptides can be synthesized using a technique called *native chemical ligation*. In this approach, two synthetic peptide fragments can

be linked together provided the C-terminus of one peptide features a thioester and the N-terminal residue of the other peptide is a cysteine residue (Figure 4.33). In the first step, a trans-thioesterification reaction occurs, where the side-chain sulfur of the cysteine residue displaces the thiol group of the incoming thioester. This is followed by the rapid, irreversible rearrangement of the new thioester, yielding a new peptide bond. Native chemical ligation can be used to link together multiple peptide fragments, allowing for the synthesis of fully active proteins over 100 residues in length.

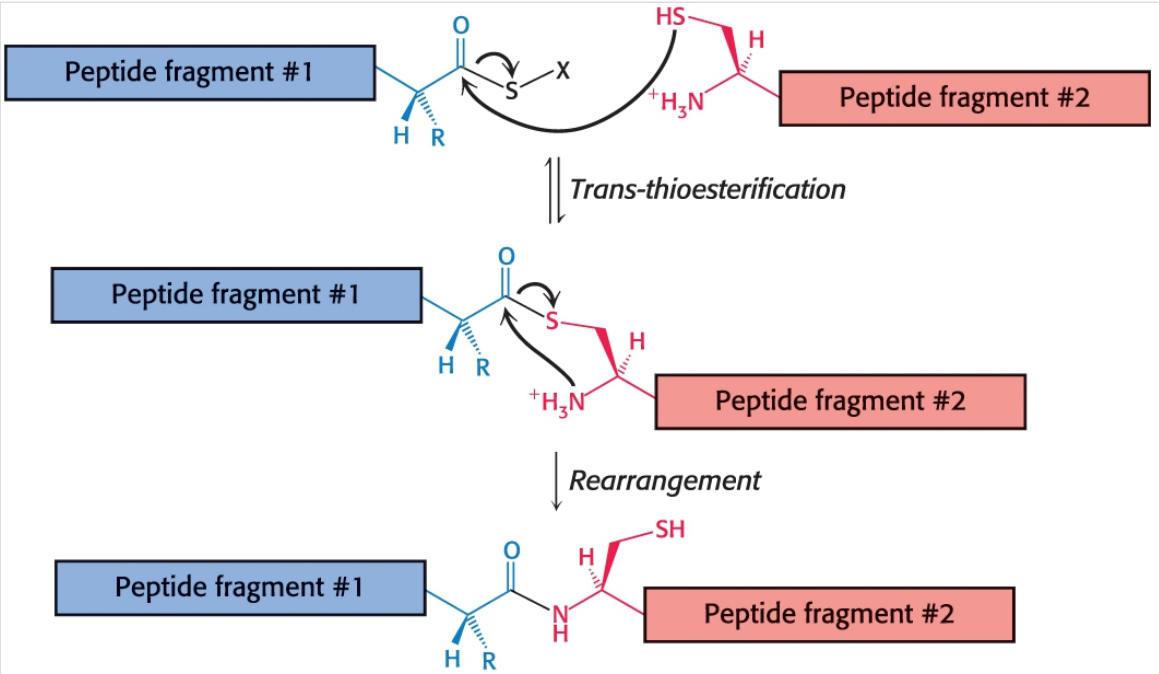


FIGURE 4.33 Native chemical ligation can be used to link two synthetic peptides. The sulfur atom of the N-terminal cysteine of one synthetic peptide ("Peptide fragment #2") undergoes a trans-thioesterification reaction with the C-terminal thioester of the other peptide ("Peptide fragment #1"). A rapid, irreversible rearrangement leads to the formation of a peptide bond between the two fragments.

4.5 Three-Dimensional Protein Structures Can Be Determined Experimentally

Elucidating the three-dimensional structure of a protein can provide a tremendous amount of insight into its corresponding function. For example, the precise atomic arrangements within active sites and binding sites provide clues to their specificities. Knowing a protein's structure enables the biochemist to predict its mechanism of action, the effects of mutations on its function, and the desired features of drugs that may inhibit or augment its activity. X-ray crystallography, nuclear magnetic resonance spectroscopy, and cryo-electron microscopy are the most important techniques for elucidating the conformation of proteins.

Universal Images Group Editorial/Getty Images

ROSALIND FRANKLIN Today, Rosalind Franklin is known as the x-ray crystallographer who generated clear diffraction patterns for DNA. Her data were used by James Watson and Francis Crick to develop their proposed structural model of the DNA double helix. However, the importance of her contributions to this landmark achievement were not fully appreciated or acknowledged at the time. Dr. Franklin had completed her PhD in physical chemistry, studying the density and porosity of coal, and she then learned x-ray crystallography to examine structural changes in carbon upon heating. She was a very skilled experimentalist and began to apply x-ray crystallographic techniques to the structure of DNA two years before the structural proposal by Watson and Crick. She subsequently did outstanding work on the structures of viruses. Her structural analysis of the polio virus was abruptly cut short by her untimely death from ovarian cancer at the age of 37. The subsequent

publication of the polio virus structure by John Finch and Aaron Klug was dedicated to her memory.

X-ray crystallography reveals three-dimensional structure in atomic detail

The first method developed to determine protein structure in atomic detail was **x-ray crystallography**. This technique provides the clearest visualization of the precise three-dimensional positions of most atoms within a protein. Of all forms of radiation, x-rays provide the best resolution for the determination of molecular structures because their wavelength approximately corresponds to the length of a covalent bond. While the details of crystallography can be technically challenging, there are several fundamental steps required in an x-ray crystallographic experiment (**Figure 4.34**):

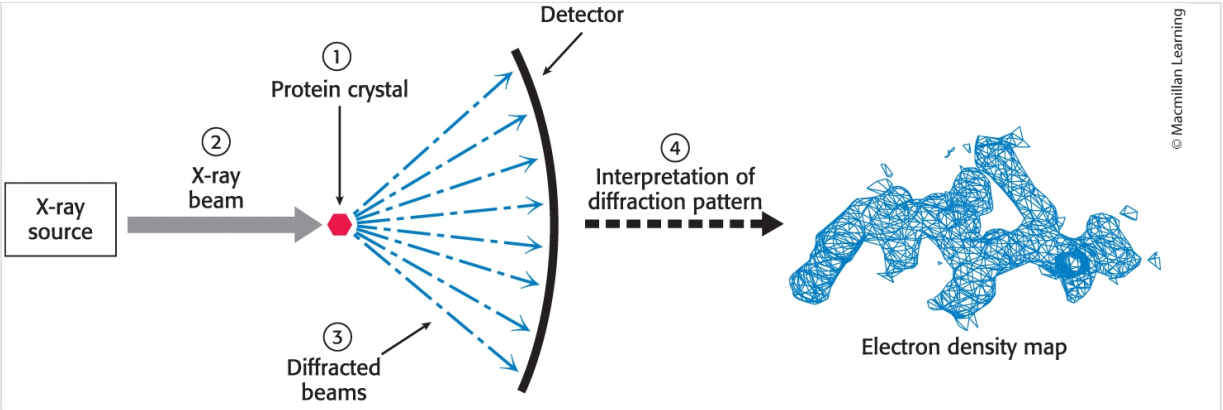

FIGURE 4.34 An x-ray crystallographic experiment is composed of several fundamental steps. (1) A crystal of the protein is prepared, then (2) placed within the path of an x-ray beam. (3) The crystal diffracts the beam, and the resulting pattern is collected on a detector. (4) The diffraction pattern is interpreted using computational methods to generate an electron density map, which enables the determination of the atomic positions of the protein.

VIEW an animation of this technique in Achieve

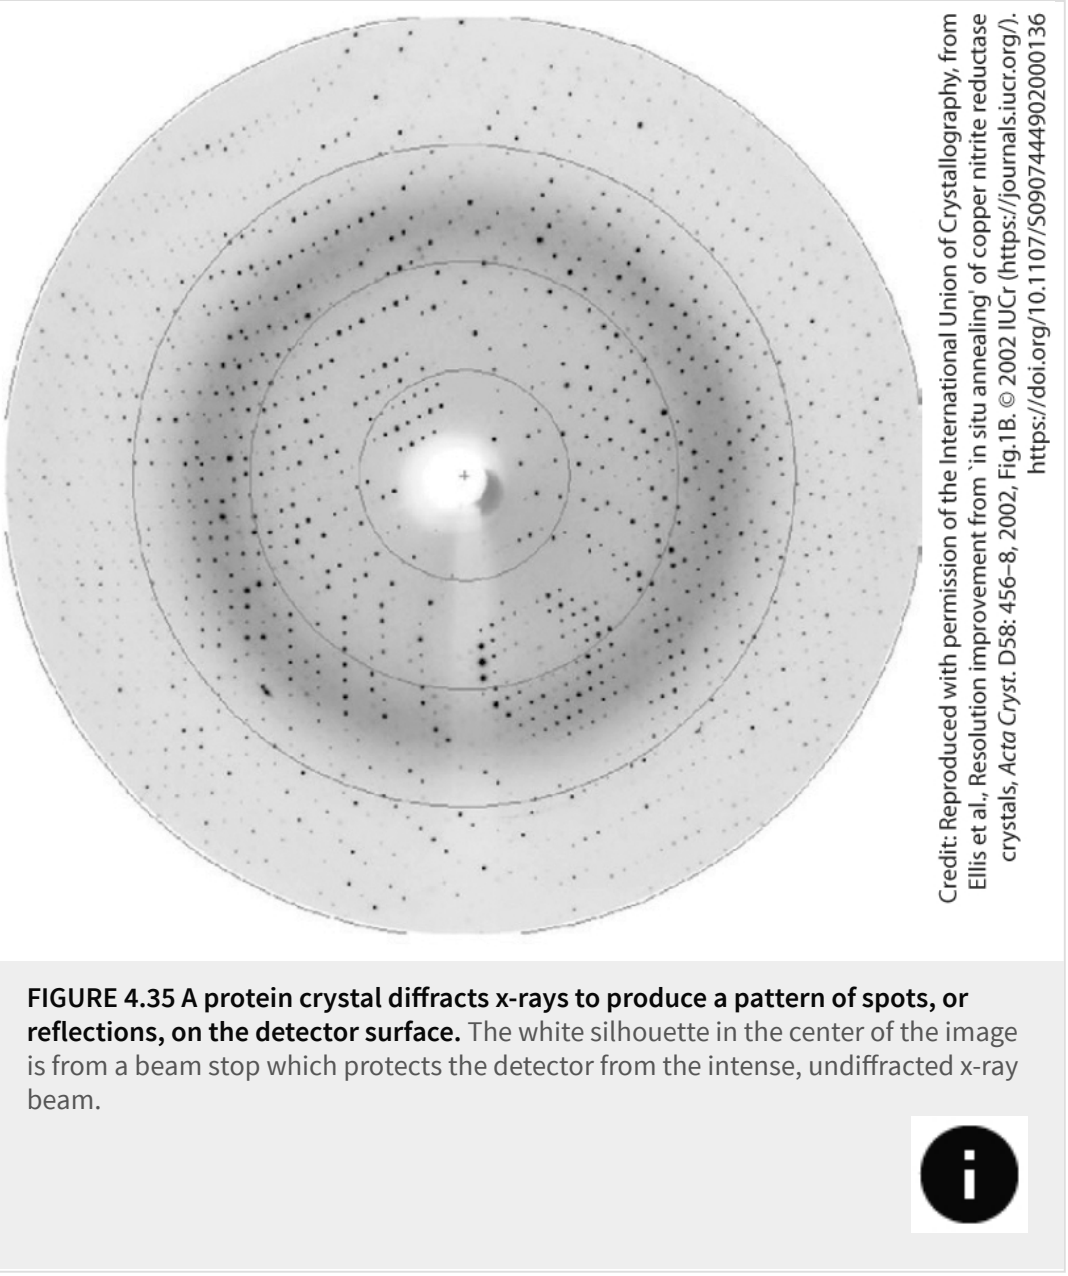
1. *Preparing a protein crystal.* X-ray crystallography first requires the preparation of a protein or protein complex in crystal form, in which all protein molecules are oriented in a fixed, repeated arrangement with respect to one another. Slowly adding ammonium sulfate or another salt to a concentrated solution of protein to reduce its solubility favors the formation of highly ordered crystals — the process of salting out discussed in Section 4.1.

   Protein crystallization can be challenging: a concentrated solution of highly pure material is required, and it is often difficult to predict which experimental conditions will yield the most-effective crystals. Typically, hundreds of conditions must be tested to obtain crystals fully suitable for crystallographic studies. Nevertheless, increasingly large and complex proteins have been crystallized. For example, poliovirus, an 8500-kDa assembly of 240 protein subunits surrounding an RNA core, has been crystallized and its structure solved by x-ray methods. Crucially, proteins frequently crystallize in their biologically active configuration, and thus enzyme crystals may display catalytic activity if the crystals are suffused with substrate.

2. *Exposing the crystal to a source of x-rays.* After a suitably pure crystal of protein has been obtained, a source of x-rays is required. A beam of x-rays of wavelength 1.54 Å is produced by accelerating electrons against a copper target. Alternatively, x-rays can be produced by the acceleration of electrons in circular orbits at speeds close to the speed of light, a phenomenon referred to as *synchrotron radiation*. Synchrotron-generated x-ray beams are much more intense than those generated by electrons hitting copper. The higher intensity allows high-quality data to be gathered from smaller crystals over a shorter exposure time. There are around 100 facilities across the world that generate synchrotron radiation.

3. *Detecting the diffraction of the x-ray by the crystal.* When a narrow beam of x-rays is directed at the protein crystal, most of the beam

passes directly through the crystal while a small part is scattered in various directions. These scattered, or diffracted, x-rays can be detected by x-ray film or by a solid-state electronic detector.



The scattering pattern produced by the diffracted x-rays provides abundant information about protein structure. The basic physical principles underlying the technique are:

- *Electrons scatter x-rays*. The amplitude of the wave scattered by an atom is proportional to its number of electrons. Thus, a carbon atom scatters six times as strongly as a hydrogen atom does.

- *The scattered waves recombine*. Each diffracted beam comprises waves scattered by each atom in the crystal. The scattered waves reinforce one another at the film or detector if they are in phase — that is, they are aligned — and they cancel one another if they are out of phase.

- *The way in which the scattered waves recombine depends only on the atomic arrangement*. The protein crystal is mounted and positioned in a precise orientation with respect to the x-ray beam and the film. The crystal is rotated so that the beam can strike the crystal from many directions. This rotational motion results in an x-ray photograph consisting of a regular array of spots called *reflections*.

The intensities and positions of these reflections are the basic experimental data of an x-ray crystallographic analysis. The x-ray photograph shown in **Figure 4.35** is a two-dimensional section through a three-dimensional array of tens of thousands of reflections. Each reflection is formed from a wave with an amplitude proportional to the square root of the observed intensity of the spot. Each wave also has a phase — that is, the timing of its crests and troughs relative to those of other waves. Additional experiments or calculations must be performed to determine the phases corresponding to each reflection.

FIGURE 4.35 A protein crystal diffracts x-rays to produce a pattern of spots, or reflections, on the detector surface. The white silhouette in the center of the image is from a beam stop which protects the detector from the intense, undiffracted x-ray beam.

4. *Interpreting the diffraction pattern into an electron density map.* The next step is to reconstruct an image of the protein from the observed reflections. In light microscopy or electron microscopy, the diffracted beams are focused by lenses to directly form an image. However, appropriate lenses for focusing x-rays do not exist. Instead, the image is formed by applying a mathematical calculation called a *Fourier transform* to the measured amplitudes and calculated phases of every observed reflection. The image

obtained is referred to as the **electron-density map**. This map is a three-dimensional graphic representation of where the electrons are most densely localized and it is used to determine the positions of the atoms in the crystallized molecule (Figure 4.36).

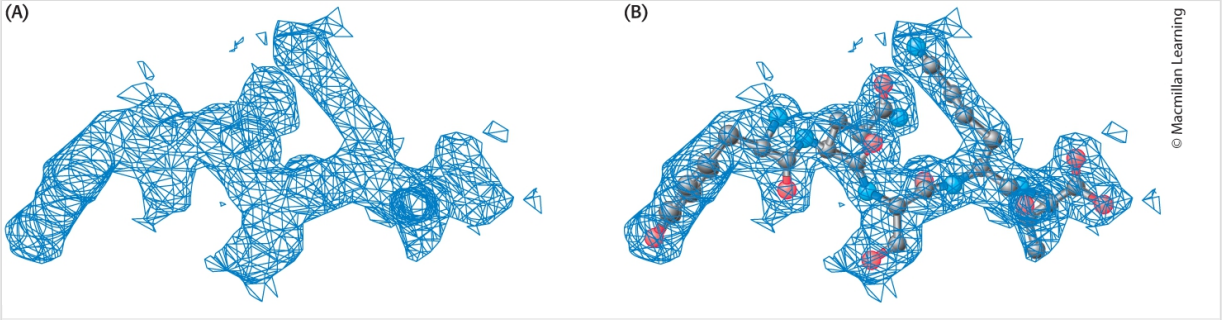

FIGURE 4.36 The electron-density map enables the determination of atomic positions of the crystallized protein. (A) A segment of an electron-density map is drawn as a three-dimensional contour plot, in which the regions inside the "cage" represent the regions of highest electron density. (B) A model of the protein is built into this map so as to maximize the placement of atoms within this density.

[Drawn from 1FCH.pdb.]

Critical to the interpretation of the electron-density map is its resolution, which is established by the number of scattered intensities used in the Fourier transform. The fidelity of the image depends on this resolution. A resolution of $6\ \text{Å}$ reveals the course of the polypeptide chain but few other structural details. The reason is that polypeptide chains pack together so that their centers are between $5\ \text{Å}$ and $10\ \text{Å}$ apart. Maps at higher resolution are needed to delineate groups of atoms, which lie between $2.8\ \text{Å}$ and $4.0\ \text{Å}$ apart, and individual atoms, which are between $1.0\ \text{Å}$ and $1.5\ \text{Å}$ apart (Figure 4.37). The ultimate resolution of an x-ray analysis is determined by the degree of perfection

of the crystal. For proteins, this limiting resolution is often about $2\ \text{Å}$; however, in exceptional cases, resolutions of $1.0\ \text{Å}$ have been obtained.

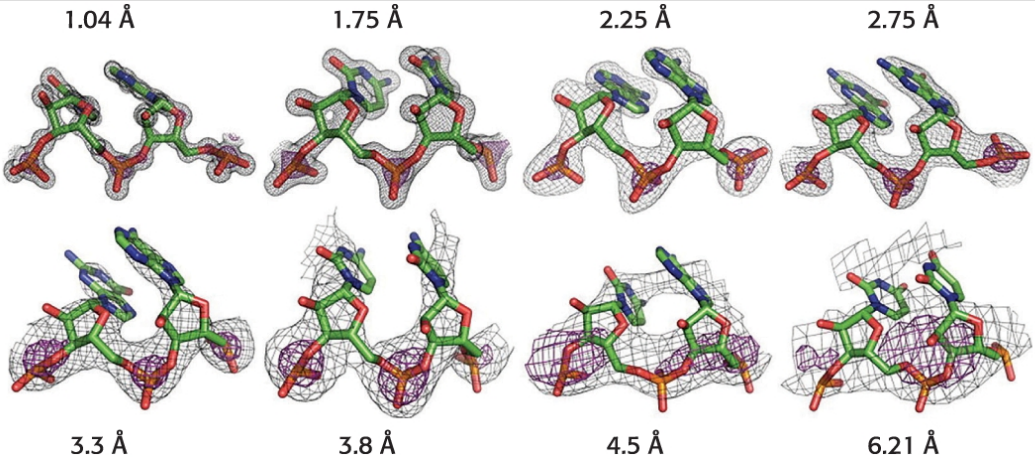

FIGURE 4.37 Resolution affects the quality of the electron density map. Electron density maps at six different resolution levels are shown. At the low resolution levels ($4.5\ \text{Å}$ and $6.21\ \text{Å}$) only a poorly defined area of density is visible, whereas at the higher resolutions, individual atoms are distinguishable.

Self-Check Question

Structures of proteins comprising domains separated by flexible linker regions can be quite difficult to solve by x-ray crystallographic methods. Why might this be the case?

Nuclear magnetic resonance spectroscopy can reveal the structures of proteins in solution

While x-ray crystallography is a powerful method for determining protein structures, some proteins do not readily crystallize. Furthermore, nonphysiological conditions (such as pH and added salts) are often required for successful crystallization. In addition, crystallized proteins adopt conformations that may be influenced by constraints imposed by the crystalline environment. However, since most proteins function not in crystalline form but in solution under physiological conditions, greater insight into protein function may be gained by other methods.

Nuclear magnetic resonance (NMR) spectroscopy is unique in being able to reveal the atomic structure of macromolecules in solution, provided that highly concentrated solutions ($\sim 1\ \text{mM}$, or $15\ \text{mg ml}^{-1}$ for a 15-kDa protein) can be obtained. This technique depends on the fact that certain atomic nuclei are intrinsically magnetic. Only a limited number of isotopes display this property, called *spin*; Table 4.4 lists those most important to biochemistry.

TABLE 4.4 Biologically important nuclei giving NMR signals

Nucleus	Natural abundance (% by weight of the element)
^{1}H	99.984
^{2}H	0.016
^{13}C	1.108

^{14}N	99.635
^{15}N	0.365
^{17}O	0.037
^{23}Na	100.0
^{25}Mg	10.05
^{31}P	100.0
^{35}Cl	75.4
^{39}K	93.1

The simplest example of an isotope with spin is the hydrogen nucleus (^{1}H), which is a proton. The spinning of a proton generates a property called a *magnetic moment*. This moment can take either of two orientations, called *spin states* (α and β), when an external magnetic field is applied (**Figure 4.38**). The energy difference between these states is proportional to the strength of the imposed magnetic field. The α state has a slightly lower energy because it is aligned with this applied field. Hence, in a given population of nuclei, slightly more will occupy the α state (by a factor of the order of 1.00001 in a typical experiment). A spinning proton in an α state can be raised to an excited state (β state) by applying a pulse of electromagnetic radiation (a radio-frequency, or RF, pulse), provided that the frequency corresponds to the energy difference between the α and the β states. In these circumstances, the

spin will change from α to β; in other words, resonance will be obtained.

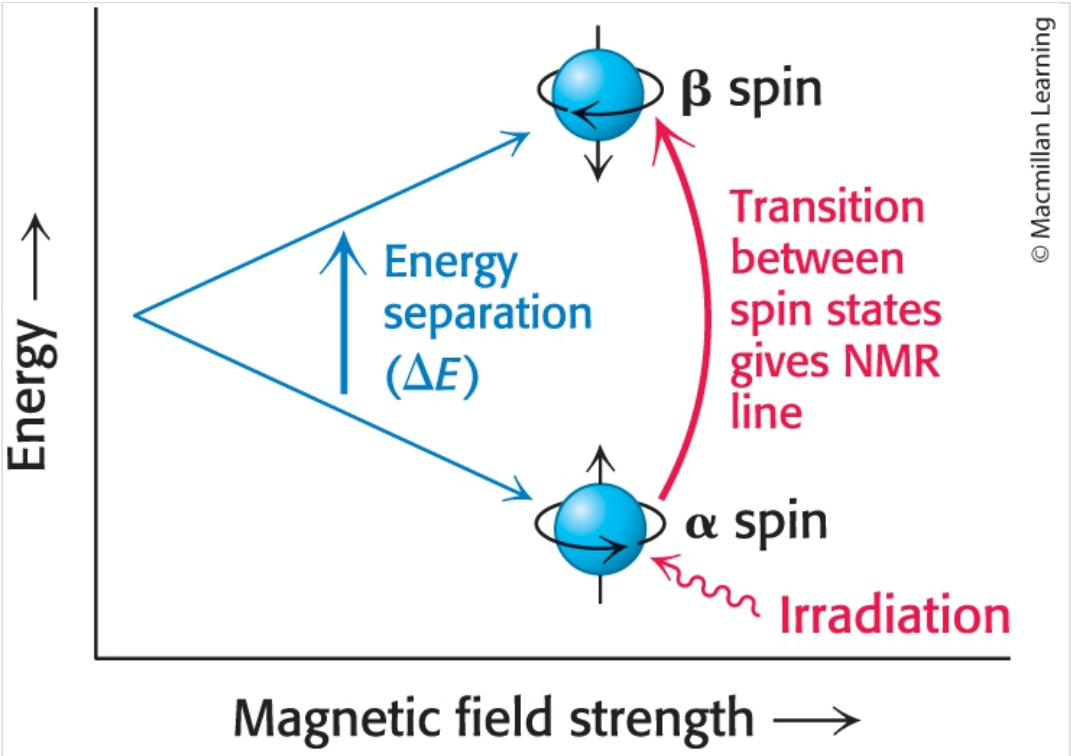

FIGURE 4.38 The transition between spin states forms the basis of NMR spectroscopy. The energies of the two orientations of an intrinsically magnetic nucleus depend on the strength of the applied magnetic field. Absorption of electromagnetic radiation of appropriate frequency induces a transition from the lower to the upper level.

VIEW an animation of NMR spectroscopy in Achieve

These properties can be used to examine the chemical surroundings of the hydrogen nucleus. The flow of electrons around a magnetic nucleus generates a small, local magnetic field that opposes the applied field. The degree of such shielding depends on the surrounding electron density. Consequently, nuclei in different environments will change states, or resonate, at slightly different field strengths or radiation frequencies.

One-dimensional NMR

Most protons in many proteins can be resolved by using a technique called *one-dimensional NMR*, in which a resonance spectrum for a molecule is obtained by keeping the magnetic field constant and varying the frequency of the electromagnetic radiation. The nuclei of the perturbed sample absorb electromagnetic radiation at a measurable frequency. The different frequencies, termed **chemical shifts**, are expressed in fractional units δ (parts per million, or ppm) relative to the shifts of a standard compound, such as a water-soluble derivative of tetramethylsilane, that is added with the sample. For example, a $-CH_3$ proton typically exhibits a chemical shift (δ) of 1 ppm, compared with a chemical shift of 7 ppm for an aromatic proton. The chemical shifts of most protons in protein molecules fall between 0 and 9 ppm (**Figure 4.39**). With this information, we can then deduce changes to a particular chemical group under different conditions, such as the conformational change of a protein from a disordered structure to an α helix in response to a change in pH.

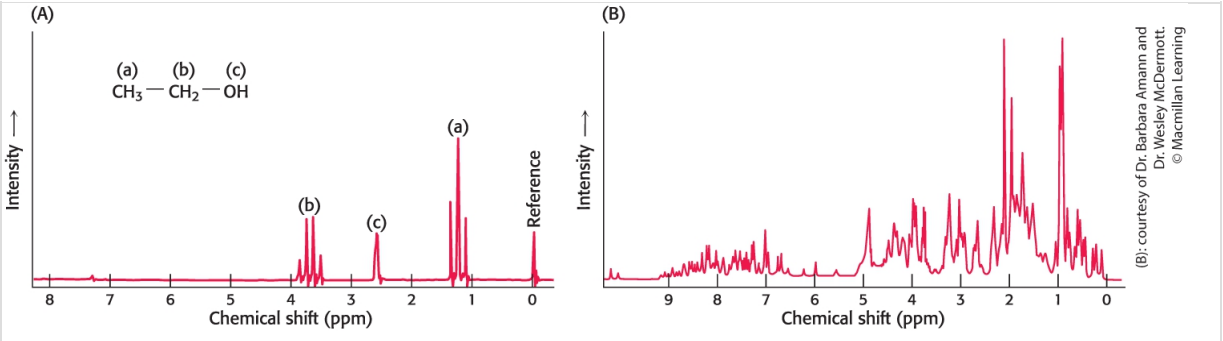

FIGURE 4.39 One-dimensional ^1H NMR spectra reveal the chemical shifts of protons within the sample. (A) ^1H-NMR spectrum of ethanol (CH_3CH_2OH) shows that the chemical shifts for the hydrogen are clearly resolved. (B) ^1H-NMR spectrum of a 55 amino acid fragment of a protein having a role in RNA splicing shows a greater degree of complexity. A large number of peaks are present, and many overlap.

[(A) Data from C. Branden and J. Tooze, *Introduction to Protein Structure* (Garland, 1991), p. 280.]

Two-dimensional NMR

We can garner even more information by examining how the spins on different protons affect their neighbors. Through the application of a radio-frequency pulse to briefly induce magnetization in the sample, we can alter the spin on one nucleus and examine the effect on the spin of a neighboring nucleus. Especially revealing is a two-dimensional spectrum obtained by nuclear Overhauser enhancement spectroscopy (NOESY), which graphically displays pairs of protons that are in close proximity, even if they are not close together in the primary structure. The basis for this technique is the **nuclear Overhauser effect**, an interaction between nuclei that is proportional to the inverse sixth power of the distance between them. Magnetization is transferred from an excited nucleus to an unexcited one if the two nuclei are less than about 5 Å apart (**Figure 4.40A**).

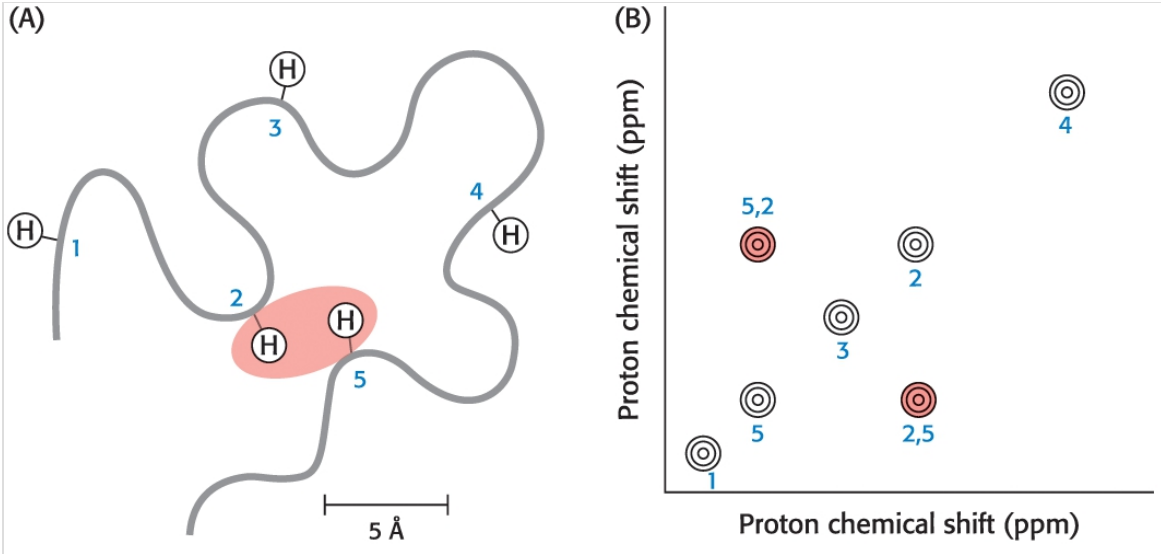

FIGURE 4.40 The nuclear Overhauser effect identifies pairs of protons that are in close proximity. (A) Schematic representation of a polypeptide chain highlighting five particular

protons. Protons 2 and 5 are in close proximity (~ 4 Å apart), whereas other pairs are farther apart. (B) A highly simplified NOESY spectrum. The diagonal shows five peaks corresponding to the five protons in part A. The peak above the diagonal and the symmetrically related one belo reveal that proton 2 is close to proton 5.

In other words, the nuclear Overhauser effect provides a means of detecting the location of atoms relative to one another in the three-dimensional structure of the protein. The peaks that lie along the diagonal of a NOESY spectrum (shown in white in **Figure 4.40B**) correspond to those present in a one-dimensional NMR experiment. The peaks apart from the diagonal (shown in red in Figure 4.40B), referred to as *off-diagonal peaks* or *cross-peaks*, provide crucial new information: they identify pairs of protons that are less than 5 Å apart.

A two-dimensional NOESY spectrum for a protein comprising 55 amino acids is shown in **Figure 4.41**. The large number of off-diagonal peaks reveals short proton–proton distances. The three-dimensional structure of a protein can be reconstructed with the use of such proximity relationships. Structures are calculated such that proton pairs identified by NOESY cross-peaks must be separated by less than 5 Å in the three-dimensional structure (**Figure 4.42**). If a sufficient number of distance constraints are applied, the three-dimensional structure can nearly be determined uniquely.

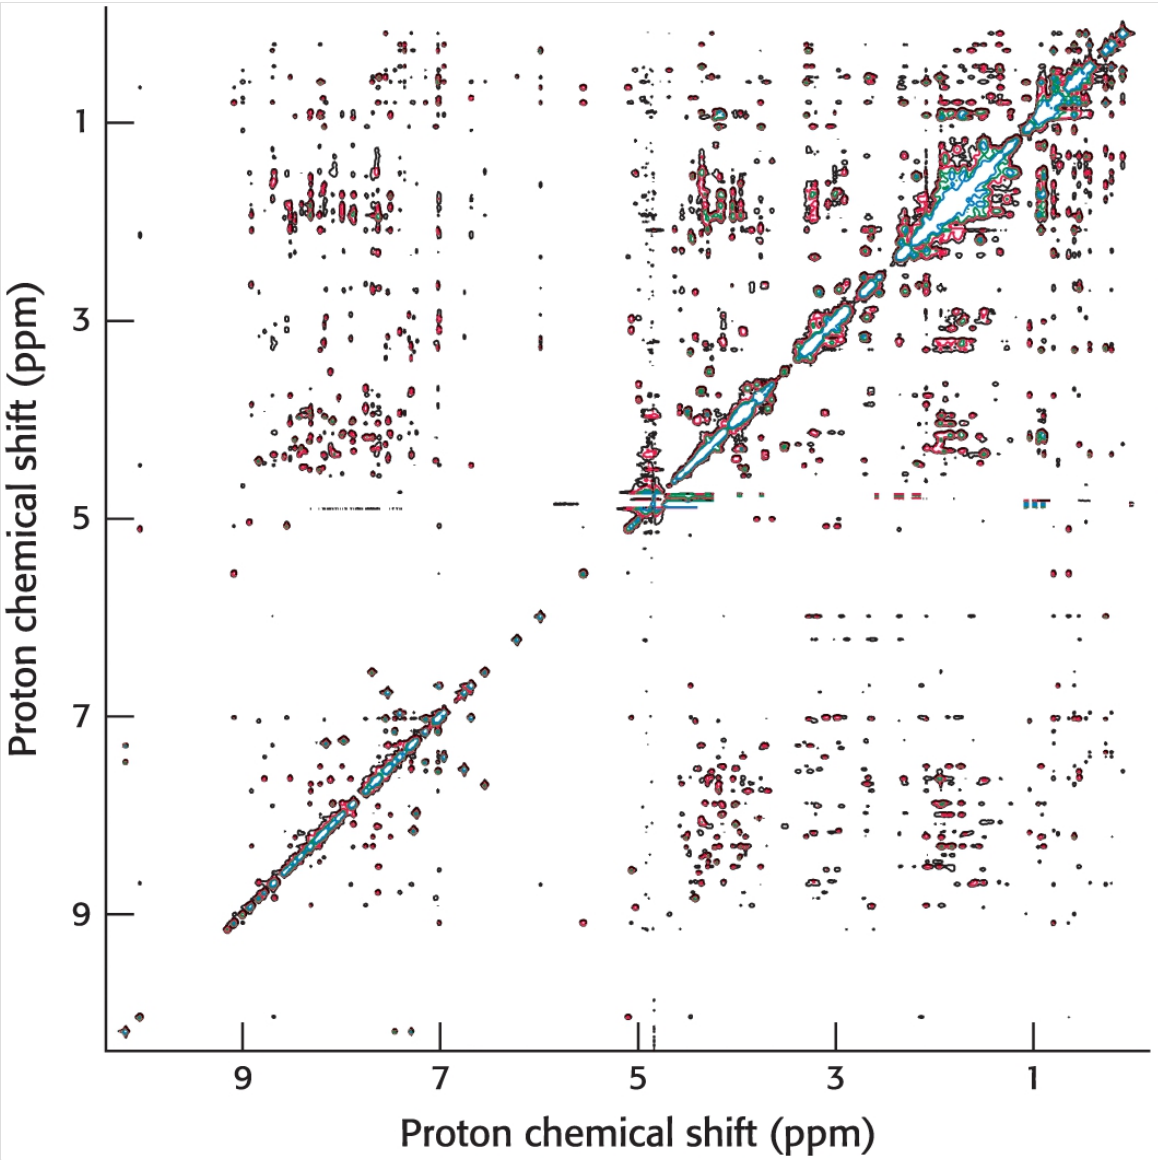

FIGURE 4.41 The NOESY spectrum for a protein reveals many short proton–proton distances. Each off-diagonal peak corresponds to a short proton–proton separation. This spectrum, obtained from a 55-amino-acid protein domain, reveals hundreds of such short proton–proton distances, which can be used to determine the three-dimensional structure of this domain.

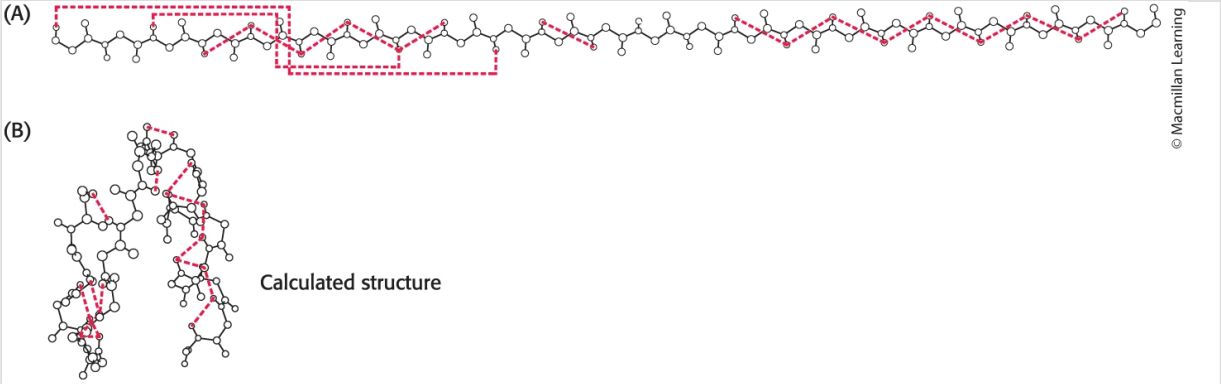

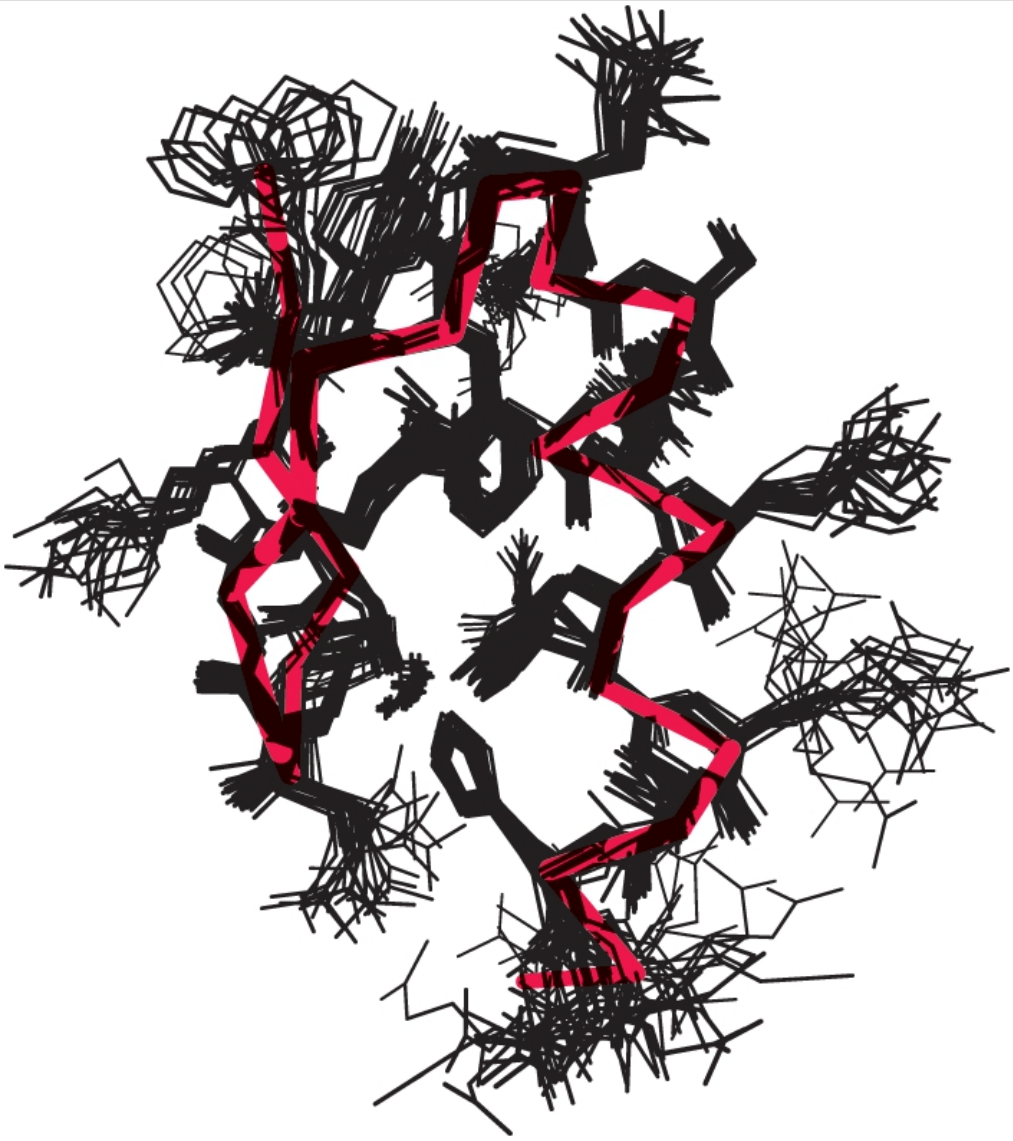

FIGURE 4.42 Structures are calculated on the basis of NMR constraints. (A) NOESY observations show that protons (connected by dotted red lines) are close to one another in space. (B) A three-dimensional structure calculated with these proton pairs constrained to be close together.

In practice, a family of related structures is generated by two-dimensional NMR spectroscopy for three reasons (Figure 4.43). First, not enough constraints may be experimentally accessible to fully specify the structure. Second, the distances obtained from analysis of the NOESY spectrum are only approximate. Finally, the experimental observations are made not on single molecules but on a large number of molecules in solution that may have slightly different structures at any given moment. Thus, the family of structures generated from NMR structure analysis indicates the range of conformations for the protein in solution. With the ability of recombinant DNA technology to produce proteins labeled uniformly or at specific sites with ^{13}C, ^{15}N, and ^{2}H, structural determination by NMR spectroscopy can be applied to proteins up to 50 kDa. While solving the structure of proteins above this limit remains challenging, creative approaches have allowed NMR spectroscopy to address many important questions relating to very large proteins.

Courtesy of Dr. Barbara Amann

FIGURE 4.43 NMR spectroscopy generates a family of related structures. A set of 25 structures placed on top of each other for a 28-amino-acid domain from a DNA-binding protein. The red line traces the average course of the protein backbone. Each of these structures is consistent with hundreds of constraints derived from NMR experiments. The differences between the individual structures are due to a combination of imperfections in the experimental data and the dynamic nature of proteins in solution.

Cryo-electron microscopy can be used to determine the structures of large proteins and macromolecular complexes

As we shall see throughout this book, the structures determined by x-ray crystallography and NMR spectroscopy have illuminated much of our understanding of protein function. However, certain proteins, especially those that form large macromolecular complexes or are embedded within lipid membranes, represent a unique challenge. While crystallographic methods have been developed to enable structure determination of such proteins, these techniques can be quite complex and are not always reliable. An additional method for protein structure determination, **cryo-electron microscopy (cryo-EM)**, has emerged as a viable alternative.

In order to perform cryo-EM, a thin layer of the protein solution is prepared in a fine grid and then frozen very quickly, trapping the molecules in an ensemble of orientations. The sample is then placed in a transmission electron microscope under vacuum conditions and exposed to an incident electron beam. Each protein interacts with the beam to produce a two-dimensional projection on the image capture device, or detector. Many projections are detected, each capturing a molecule in a different orientation (**Figure 4.44A**). Using a process called *single-particle analysis*, these projections are assembled to build a three-dimensional representation of the protein (**Figure 4.44B**).

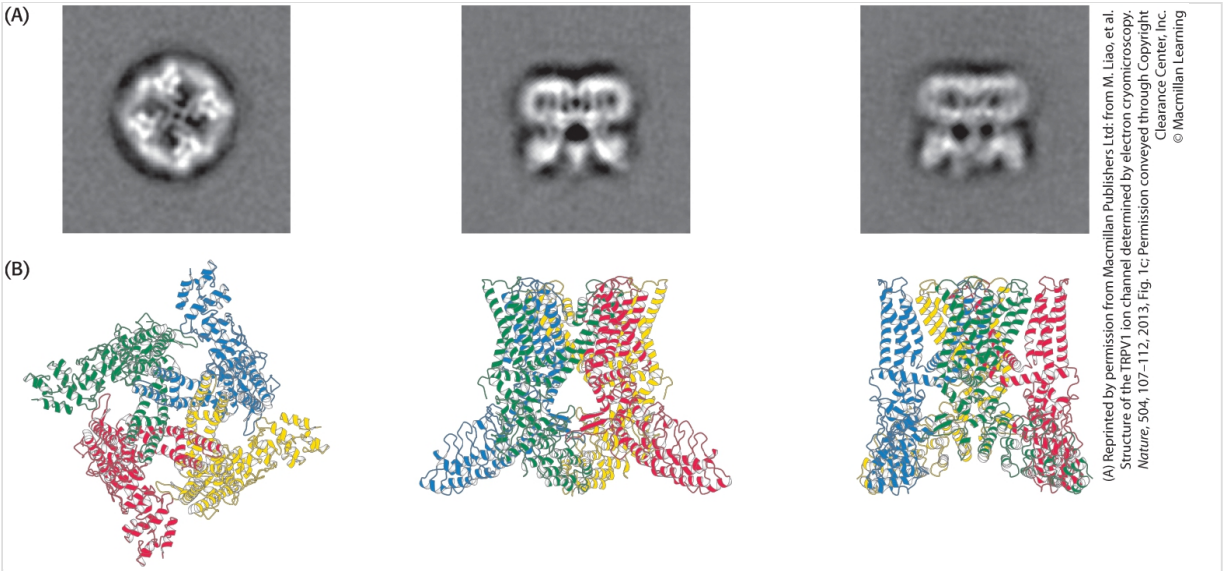

FIGURE 4.44 Cryo-EM captures numerous projections of a protein complex. The projections detected in a cryo-EM experiment represent two-dimensional images of the protein trapped in various orientations. Three such projections of the tetrameric protein TRPV1 are shown in (A). Collection of many such projections enables the reconstruction of a three-dimensional model of the protein, as depicted in (B).

[(B) Drawn from 3J5P.pdb.]

With improvements in image quality and sample preparation, cryo-EM is delivering structures at resolutions approaching $3\ \text{Å}$ or better. At this level, details of atomic groups emerge. For example, cryo-EM studies were able to identify the location and structure of small molecules within the structure of TRPV1, the tetrameric protein present in the plasma membranes of pain-sensing neurons and depicted in Figure 4.44. At this resolution, cryo-EM can be used to aid the discovery and optimization of drug molecules (Chapter 32).

In addition, cryo-EM enables the visualization of very large molecular complexes. Consider the spliceosome, a complex of 4 oligonucleotide chains and over 30 protein subunits that plays an important role in the processing of eukaryotic messenger RNA (Chapter 29). While x-ray

crystallographic methods have been unable to determine the structure of this massive complex, it has been solved to nearly $3.5\ \text{Å}$ resolution by cryo-EM.

By the end of 2020, x-ray crystallography, NMR spectroscopy, and cryo-EM had revealed the structures of over 170,000 proteins. Several new structures are now determined each day. The coordinates are collected at the Protein Data Bank (www.pdb.org), and the structures can be accessed for visualization and analysis. Knowledge of the detailed molecular architecture of proteins has provided insight into how proteins recognize and bind other molecules, how they function as enzymes, how they fold, and how they have evolved. This extraordinarily rich harvest is continuing at a rapid pace and is greatly influencing the entire field of biochemistry as well as other biological and physical sciences.

Chapter 4 Summary

4.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function

- Effective protein purification relies on the development of an assay, used to determine the specific activity of a sample.
- The starting point for protein purification is the homogenate, in which the cellular membranes have been disrupted.
- Chromatography can separate proteins on the basis of size (gel-filtration chromatography), charge (ion-exchange chromatography), and specific binding to a ligand (affinity chromatography).
- Proteins can be separated and easily visualized by gel electrophoresis.
- Isoelectric focusing separates proteins on the basis of their isoelectric points.
- Two-dimensional electrophoresis combines isoelectric focusing and gel electrophoresis to separate complex mixtures of proteins.

4.2 Immunology Provides Important Techniques for Investigating Proteins

- Antibodies against a specific protein can be generated by injecting the protein, or a fragment of the protein, into an animal and collecting the antiserum.
- Monoclonal antibodies can be obtained by the hybridoma method.
- Using antibodies, proteins can be sensitively detected using enzyme-linked immunosorbent assays and western blotting.
- Labeled antibodies can be used to visualize proteins within cells and tissues.

4.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins

- Tandem mass spectrometry enables the rapid and highly accurate sequencing of peptides.
- Knowledge of a sequence provides valuable clues to the conformation, function, and evolutionary history of a protein.
- Peptide mass fingerprinting can be used to identify proteins, even in complex mixtures and at very low concentrations.
- Mass spectrometric techniques are central to proteomics because they make it possible to analyze the constituents of large macromolecular assemblies or other collections of proteins.

4.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods

- Synthetic peptides have many important applications, including as antigens for the generation of antibodies.
- In the solid phase method, repeated cycles of peptide coupling and deprotection of a growing peptide attached to resin enables rapid synthesis without isolation of intermediates.

4.5 Three-Dimensional Protein Structures Can Be Determined Experimentally

- X-ray crystallography uses diffracted x-rays from a protein crystal to generate an electron density map, which indicates the atomic positions of the protein.
- Nuclear magnetic resonance spectroscopy reveals the structure and dynamics of proteins in solution by identifying protons in close proximity to one another.
- Cryo-electron microscopy is a rapidly developing method that can elucidate the structures of large multimeric complexes at increasingly higher resolutions.

- The three-dimensional structures of over 170,000 proteins are now known in atomic detail.

Problems

1. Which of the following statements about SDS-PAGE under reducing conditions is true? Select all that apply. 3

a. Smaller proteins migrate faster through the polyacrylamide gel.
b. Protein-SDS complexes migrate toward the negative electrode.
c. Proteins are separated in a polyacrylamide gel matrix.
d. Protein-SDS complexes have similar mass-to-charge ratios; therefore, separation is by size.
e. Proteins are visualized using a dye that binds to the gel matrix, but not to proteins.
f. Sodium dodecyl sulfate binds proteins, resulting in protein-SDS complexes that are similar in size.

2. Complete the following table. 1

Purification procedure	Total protein (mg)	Total activity (units)	Specific activity (units mg^{-1})	Purification level	Yield (%)
Crude extract	20,000	4,000,000		1	100
$(NH_4)_2SO_4$ precipitation	5000	3,000,000			
DEAE-cellulose chromatography	1500	1,000,000			
Gel-filtration chromatography	500	750,000			
Affinity chromatography	45	675,000			

3.

a. A purified protein is in a buffer solution at pH 7 with 800 mM NaCl. A 1 mL sample of the protein solution is placed in a dialysis membrane and dialyzed against 2.0 L of the same buffer with 0 mM NaCl. Small molecules and ions, such as Na, Cl, and the buffer, can diffuse across the membrane, but the protein cannot. Once the dialysis has come to equilibrium, what is the concentration of NaCl in the protein sample (assuming no change in volume inside the membrane)?
b. If the original 1 mL sample were dialyzed twice, successively, against 200 mL of the same buffer in 0 mM

NaCl, what would be the final NaCl concentration in the sample?

4. Fluorescence-activated cell sorting (FACS) is a powerful technique for separating cells according to their content of particular molecules. For example, a fluorescence-labeled antibody specific for a cell-surface protein can be used to detect cells containing such a molecule. Suppose that you want to isolate cells that possess a receptor enabling them to detect bacterial degradation products. However, you do not yet have an antibody directed against this receptor. Which fluorescence-labeled molecule would you prepare to identify such cells?

5.

a. The octapeptide AVGWRVKS was digested with the enzyme trypsin. Which method would be most appropriate for separating the products: ion-exchange or gel-filtration chromatography? Explain.
b. Suppose that the peptide was digested with chymotrypsin. What would be the optimal separation technique? Explain.  2

6. Your frustrated colleague hands you a mixture of four proteins with the following properties:

	Isoelectric point (pI)	Molecular weight (in kDa)
Protein A	4.1	80
Protein B	9.0	81
Protein C	8.8	37

Protein D	3.9	172

a. Propose a method for the isolation of Protein B from the other proteins.
b. If Protein B also carried a His tag at its N-terminus, how could you revise your method? 2

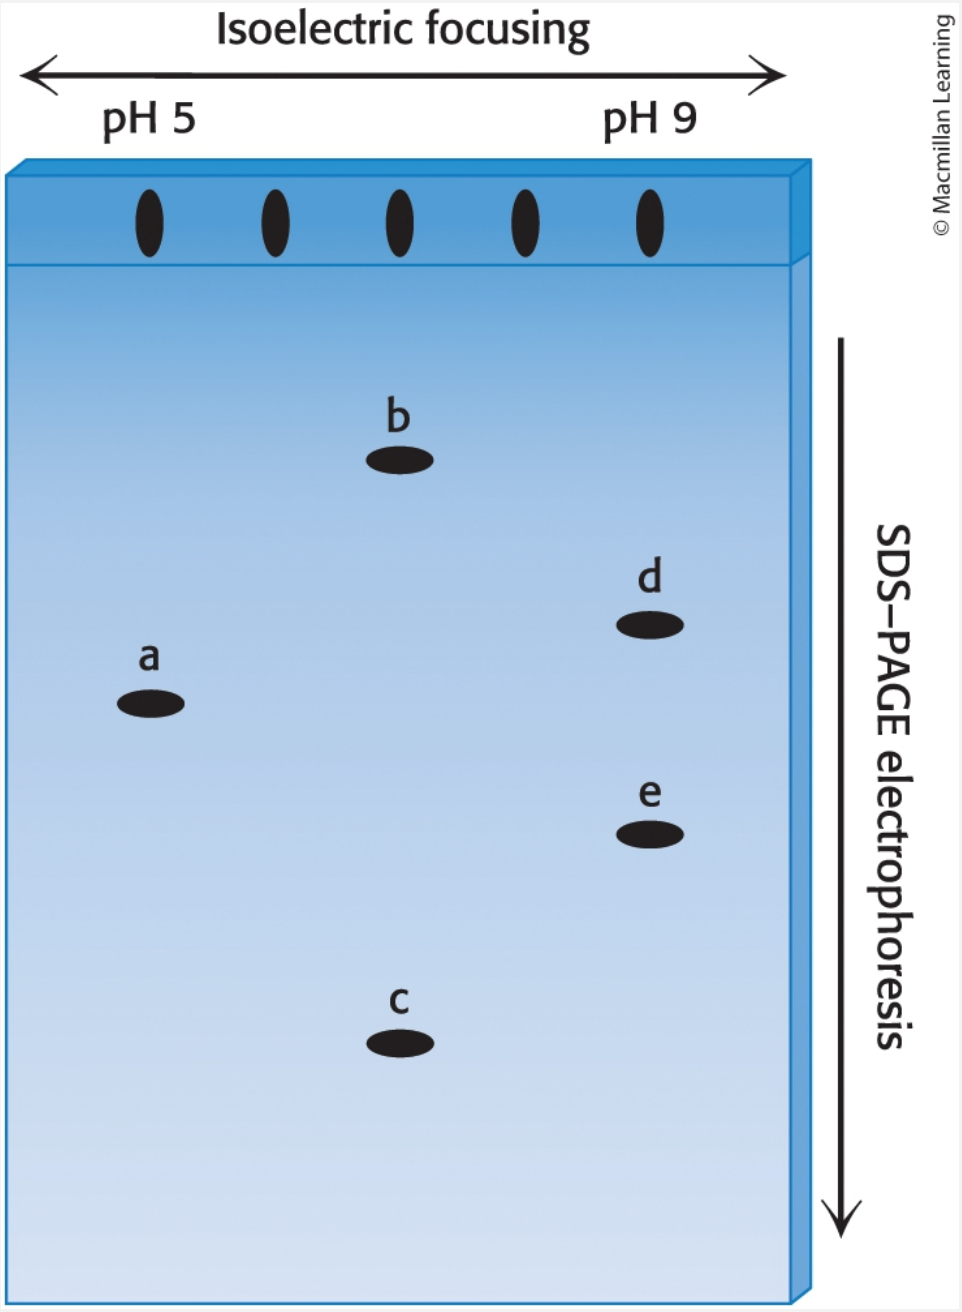
7. The amide hydrogen atoms of peptide bonds within proteins can exchange with protons in the solvent. In general, amide hydrogen atoms in buried regions of proteins and protein complexes exchange more slowly than those on the solvent-accessible surface do. Determination of these rates can be used to explore the protein-folding reaction, probe the tertiary structure of proteins, and identify the regions of protein–protein interfaces. These exchange reactions can be followed by studying the behavior of the protein in solvent that has been labeled with deuterium (^2H), a stable isotope of hydrogen. What two methods described in this chapter could be readily applied to the study of hydrogen–deuterium exchange rates in proteins?

8. In this chapter, we described co-immunoprecipitation as a method for identifying binding partners to a protein of interest. A simpler variation of this method can also be used to isolate proteins of low abundance in a complex mixture. Arrange the steps in sequential order to use this technique for this purpose: 4

a. The antibody-protein complexes become insoluble.
b. Protein A beads are added to the mixture.
c. An antibody against the protein of interest is added to the mixture.

d. The protein mixture is centrifuged, the supernatant is removed, and the pellet is washed.
e. The antibody binds to the protein of interest.

9. You have isolated a protein from the bacterium *E. coli* and seek to confirm its identity by trypsin digestion and mass spectrometry. Determination of the masses of several peptide fragments has enabled you to deduce the identity of the protein. However, there is a discrepancy with one of the peptide fragments, which you believe should have the sequence MLNSFK and an $(M + H)^+$ value of 739.38. In your experiments, you repeatedly obtain an $(M + H)^+$ value of 767.38. What is the cause of this discrepancy, and what does it tell you about the region of the protein from which this peptide is derived? 5

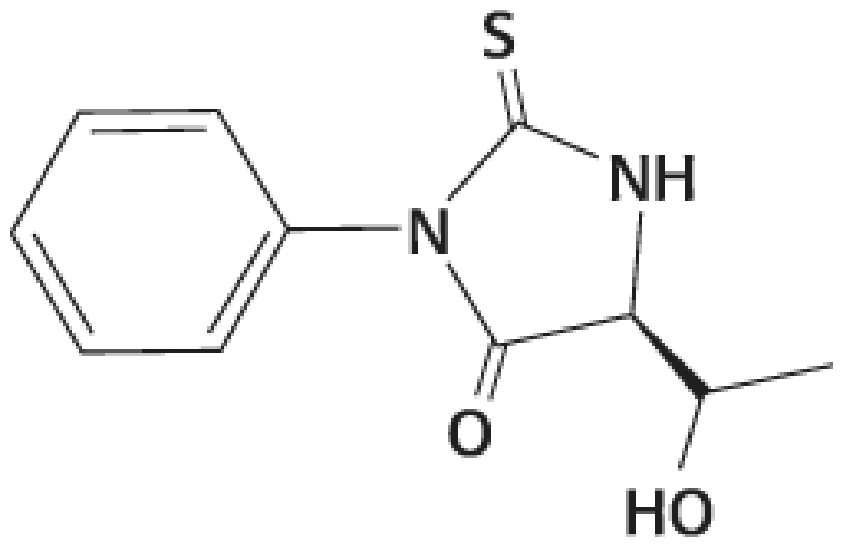


10. Which solution conditions would be best used for eluting a transcription factor from a DNA affinity column? 2

a. High imidazole concentration
b. High salt concentration
c. High glucose concentration
d. A mixture of free DNA nucleotides

11. A peptide has the sequence Gly-Ser-Lys-Ala-Gly-Arg-Ser-Arg.

a. How many fragments would result from cleaving the sequence with trypsin? What is the sequence of the smallest fragment?
b. How many fragments result from chymotrypsin cleavage? What is the sequence of the largest fragment?



12. The results of a separation using two-dimensional electrophoresis are:

a. Which protein(s) have the highest pI value?
b. Which protein has the highest molecular weight? 3

13. A protein has been isolated, but now one needs to determine its amino acid sequence. The results are shown:

- After one cycle of Edman degradation, the following phenylthiohydantoin (PTH) derivative was produced:

- Treatment with cyanogen bromide gave the fragments: KPAM, PD, LICWM, and TRM.
- One of the fragments produced after treatment with chymotrypsin was MPD.

What is the sequence of the peptide? 5

14. Determine the sequence of decapeptide on the basis of the following data.

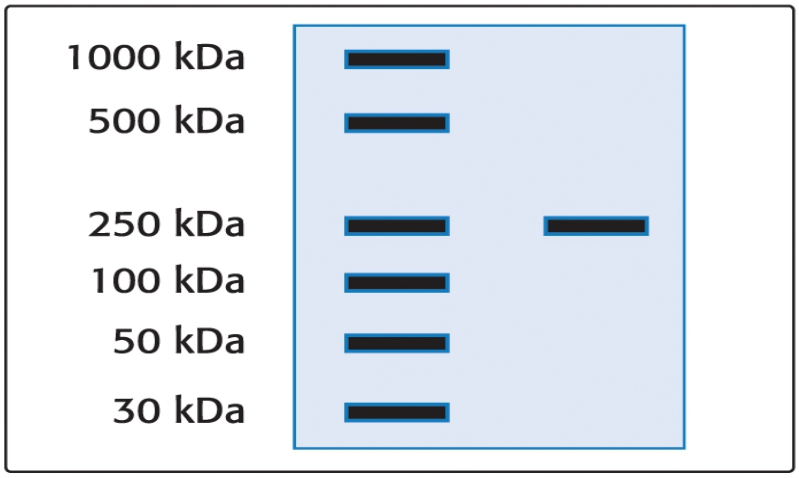
Trysin digestion gave two fragments with multiple residues (not in order):

T1: Ala, Arg, Phe, Gly, Thr, Trp, Tyr
T2: Lys, Met, Val

Chymotrypsin digestion gave four fragments with multiple residues (not in order):

CT1: Ala, Phe
CT2: Thr, Trp
CT3: Lys, Met, Tyr, Val
CT4: Arg, Gly

Treatment with cyanogen bromide yielded a single amino acid, methionine, and a nonapeptide.



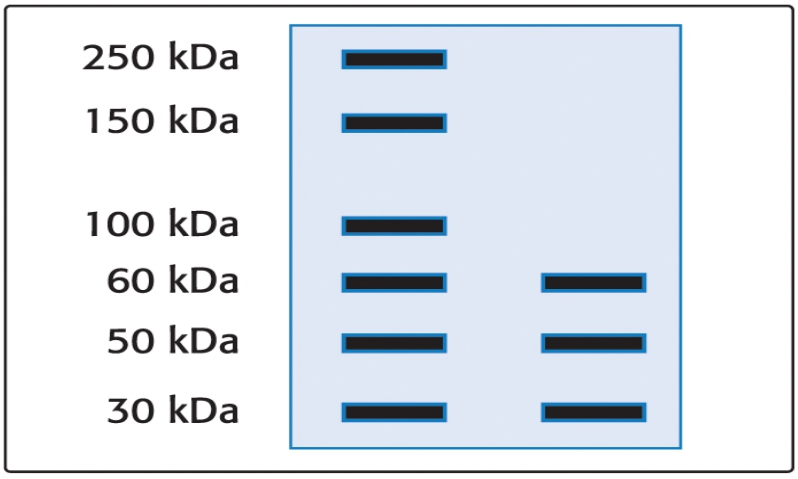
What is the sequence of this decapeptide? 5

15. Polyacrylamide gel electrophoresis experiments can be run under different sample preparation conditions, with informative results. Native PAGE does not include SDS. Reducing SDS-PAGE uses both SDS and a reducing agent, such as β-mercaptoethanol. Nonreducing SDS-PAGE uses SDS, but no reducing agent.

a. A protein sample complex consists of two proteins, a smaller protein X, and a larger protein Y. Protein X is composed of two polypeptide chains lined by disulfide bonds. Protein Y is composed of three polypeptide chains linked by disulfide bonds.

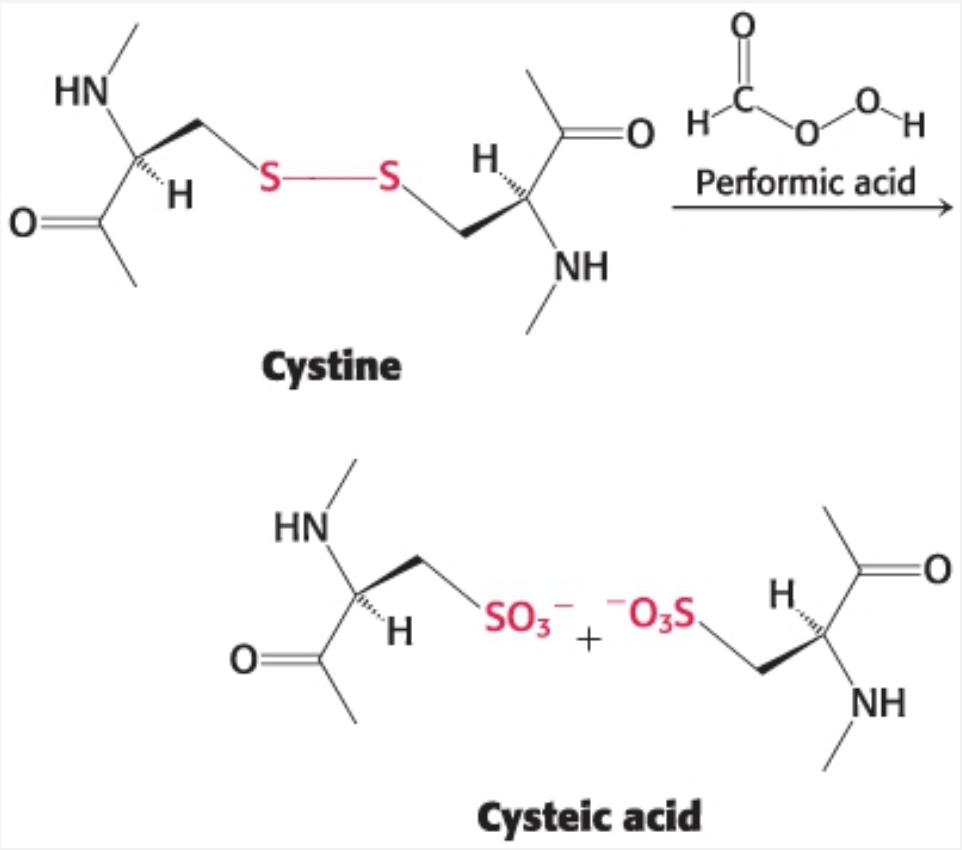
   Which type of PAGE was used to generate the each of the gels below?

(A)



© Macmillan Learning

(B)



(C)

b. What are the molecular weights of the protein X polypeptides?
c. What are the molecular weights of the protein Y polypeptides? 3

16. Performic acid cleaves the disulfide linkage of cystine and converts the sulfhydryl groups into cysteic acid residues, which are then no longer capable of disulfide-bond formation.

Consider the following experiment: You suspect that a protein containing three cysteine residues has a single disulfide bond. You digest the protein with trypsin and subject the mixture to electrophoresis along one end of a sheet of paper. After treating the paper with performic acid, you subject the sheet to electrophoresis in the perpendicular direction and stain it with a reagent that detects proteins. How would the paper appear if the protein did not contain any disulfide bonds? If the protein contained a single disulfide bond? Propose an experiment to identify which cysteine residues form the disulfide bond.

17. If the proteins listed in the following table were subjected to SDS-PAGE, give the order of migration from the top (where the proteins are applied to the gel) to the bottom.

Protein	Isoelectric point (pI)	Molecular weight (daltons)
(a) Aldolase	10.1	40,000
(b) Cytochrome *c*	9.2	14,000
(c) Lactate dehydrogenase	8.5	18,000
(d) Ornithine decarboxylase	4.1	75,000
(e) Phosphoenolpyruvate carboxylase	5.0	74,000
(f) Pyruvate kinase	6.0	62,000

18. If the same proteins listed in Problem 17 were separated by isoelectric focusing, indicate their distribution in the gradient

from low pH to high pH.

Chapter 5
Enzymes: Core Concepts and Kinetics

John Lamb/Getty Images
© Macmillan Learning

Much of life is motion, whether at the macroscopic level of our daily life or at the molecular level of a cell. Stop-motion photography captures the motion of this dancer in frames separated by only about a quarter of a second. In biochemistry, kinetics (derived from the Greek *kinesis*, meaning "movement") is used to measure the extremely fast dynamics of enzyme activity. The enzyme carbonic anhydrase, one of the fastest known, can catalyze 250,000 reactions in the time elapsed between each frame shown in the image of the dancer.

Outline

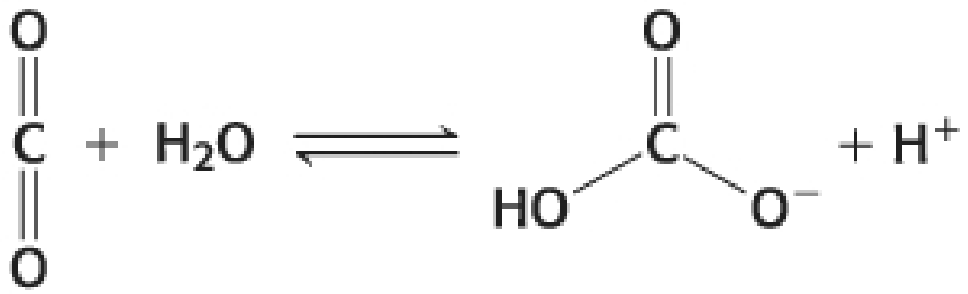
5.1 Enzymes Are Powerful and Highly Specific Catalysts
5.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes
5.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State

5.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes
5.5 Enzymes Can Be Studied One Molecule at a Time
5.6 Enzymes Can Be Inhibited by Specific Molecules

Learning Goals

By the end of this chapter, you should be able to:

1. Explain the thermodynamics of catalyzed and uncatalyzed reactions using Gibbs free energy diagrams.
2. Describe the central role of the formation of the transition state in enzyme catalysis.
3. Explain how reaction velocity is determined and used to characterize enzyme activity in terms of the fundamental kinetic parameters of an enzyme, K_M and k_{cat}.
4. Differentiate between types of reversible and irreversible inhibitors by mechanisms of action and using kinetics data.



Enzymes like carbonic anhydrase are biological catalysts that determine the patterns of chemical transformations and mediate the transformation of one form of energy into another. Enzymes are also the target of many drugs; in fact, the majority of all pharmaceuticals ever created have been molecules that reduce enzyme function. For instance, a host of drugs used to manage pain, inflammation, and fever are inhibitors of a class of enzymes called cyclooxygenases. One of the most widely used medications in the world, acetylsalicylic acid, commonly known as aspirin, is among this group. About a quarter of the genes in the human genome encode enzymes, a testament to their importance to life. In this chapter, you will learn how enzymes accelerate reactions, how the

speed of their effects is measured, and how their action can be inhibited.

5.1 Enzymes Are Powerful and Highly Specific Catalysts

Agents called **catalysts** speed up chemical reactions without being consumed by them. **Enzymes** are powerful biological catalysts — made by all living organisms — that dramatically enhance and control the rates of chemical reactions. Almost all enzymes are proteins, which are highly effective catalysts for an enormous diversity of chemical reactions because of their capacity to specifically bind a very wide range of molecules. Using the full repertoire of intermolecular forces, enzymes optimally orient reactant molecules to make and break chemical bonds. However, proteins do not have an absolute monopoly on catalysis; the discovery of catalytically active RNA molecules, called **ribozymes**, provides compelling evidence that RNA was a biocatalyst early in evolution. Two remarkable properties of enzymes to consider from the start are their speed and their specificity.

- *Speed*. Enzymes can accelerate reactions by factors of a billion or more (**Table 5.1**). Indeed, most reactions in biological systems do not take place at perceptible rates in the absence of enzymes. Even a reaction as simple as the hydration of carbon dioxide is catalyzed by an enzyme — namely, carbonic anhydrase.

The transfer of CO_2 from the tissues to the blood and then to the air in the alveolae of the lungs would be less complete in the absence of this enzyme. In fact, carbonic anhydrase is one of the fastest enzymes known. Each enzyme molecule can hydrate 10^6 molecules of CO_2 per second. This catalyzed reaction is 10^7 times as fast as the uncatalyzed one. We will consider the mechanism of carbonic anhydrase catalysis in Chapter 6.

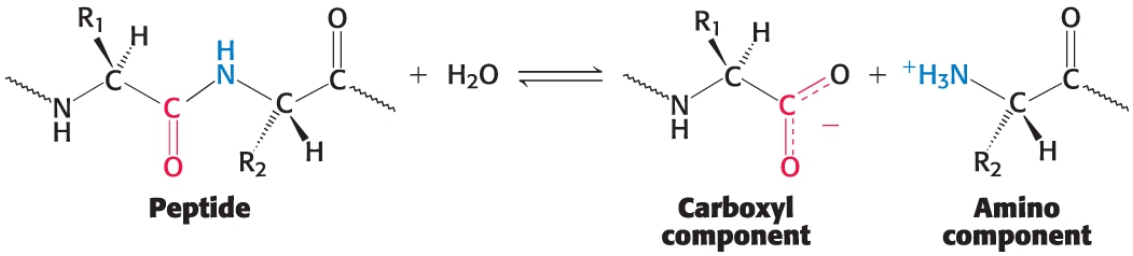


TABLE 5.1 Rate enhancement by selected enzymes

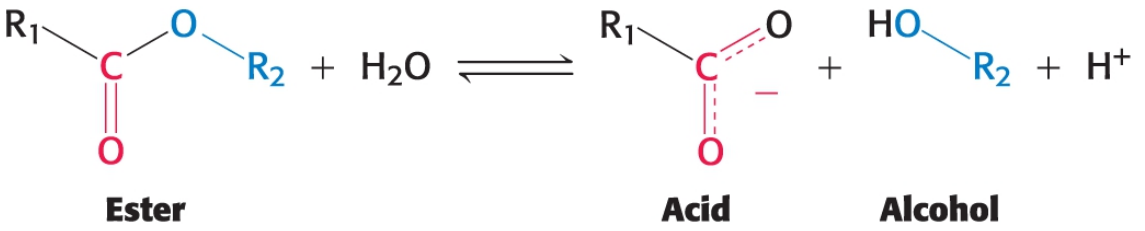
Enzyme	Nonenzymatic half-life	Uncatalyzed rate $(k_{un}s^{-1})$	Catalyzed rate $(k_{cat}s^{-1})$	Rate enhancement $(k_{cat}s^{-1}/k_{un}s^{-1})$
OMP decarboxylase	78,000,000 years	2.8×10^{-16}	39	1.4×10^{17}
Staphylococcal nuclease	130,000 years	1.7×10^{-13}	95	5.6×10^{14}
AMP nucleosidase	69,000 years	1.0×10^{-11}	60	6.0×10^{12}
Carboxypeptidase A	7.3 years	3.0×10^{-9}	578	1.9×10^{11}
Ketosteroid isomerase	7 weeks	1.7×10^{-7}	66,000	3.9×10^{11}



Triose phosphate isomerase	1.9 days	4.3×10^{-6}	4300	1.0×10^{9}
Chorismate mutase	7.4 hours	2.6×10^{-5}	50	1.9×10^{6}
Carbonic anhydrase	5 seconds	1.3×10^{-1}	1×10^{6}	7.7×10^{6}

Abbreviations: OMP, orotidine monophosphate; AMP, adenosine monophosphate.
Source: After A. Radzicka and R. Wolfenden, *Science* 267:90–93, 1995.

- *Specificity*. Enzymes are highly specific both in the reactions that they catalyze and in the reactants they bind, which are called **substrates**. An enzyme usually catalyzes a single chemical reaction or a set of closely related reactions. For example, enzymes known as **proteases** catalyze proteolysis, the hydrolysis of a peptide bond.

Most proteolytic enzymes also catalyze a different but related reaction in vitro — namely, the hydrolysis of an ester bond. Such reactions are more easily monitored than is proteolysis and are useful in experimental investigations of these enzymes.

Proteolytic enzymes differ markedly in their degree of substrate specificity. Papain, which is found in papaya plants, is quite undiscriminating: it will cleave any peptide bond with little regard to the identity of the adjacent side chains. The digestive enzyme trypsin, on the other hand, is quite specific and catalyzes the splitting of peptide bonds only on the carboxyl side of lysine and arginine residues (**Figure 5.1A**). Thrombin, an enzyme that participates in blood clotting (Section 10.4), is even more specific than trypsin. It catalyzes the hydrolysis of Arg–Gly bonds in particular peptide sequences only (**Figure 5.1B**). The specificity of an enzyme is due to the precise interaction of the substrate with the enzyme, which is a result of the intricate three-dimensional structure of the enzyme.

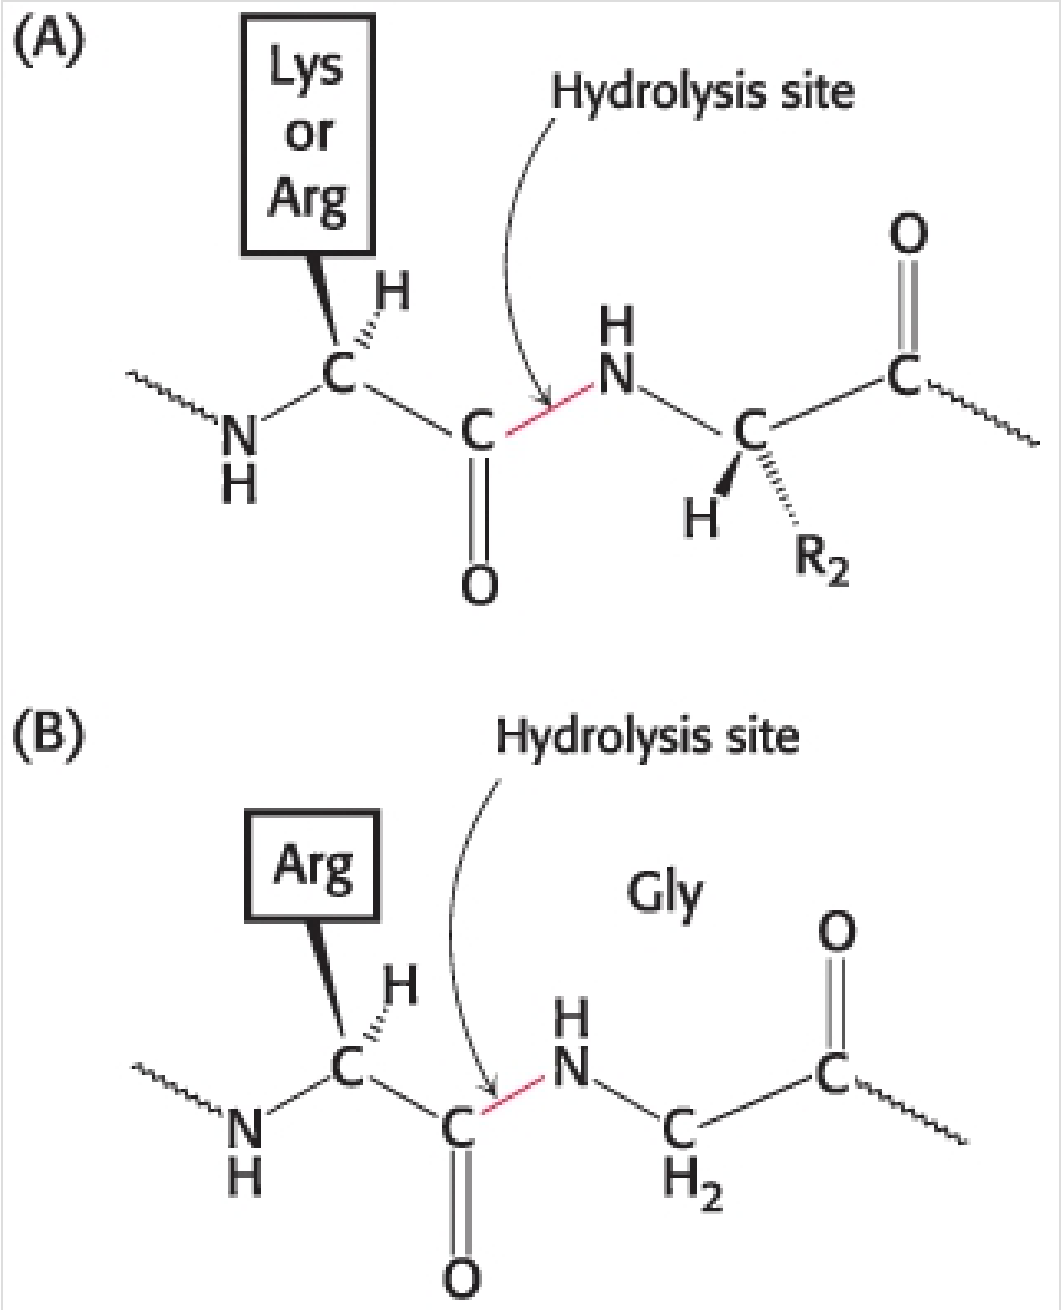


FIGURE 5.1 Enzymes are highly specific to particular substrates and chemical reactions. (A) Trypsin cleaves on the carboxyl side of arginine and lysine residues, whereas (B) thrombin cleaves Arg–Gly bonds in particular sequences only.

Most enzymes are classified by the types of reactions they catalyze

While some enzymes have common names — like papain, trypsin, and thrombin — that provide little information regarding their function, most enzymes are named for one of their substrates and for the reactions that they catalyze, with the suffix "-ase" added. Thus, a peptide hydrolase is an enzyme that hydrolyzes peptide bonds, whereas ATP synthase is an enzyme that synthesizes ATP. It is important to note, however, that enzymes catalyze chemical reactions in both the forward and reverse directions, yet only one direction of the reaction is typically denoted in the name.

To bring some consistency to enzyme nomenclature, a classification system for enzymes — developed by the International Union of Biochemistry — divides reactions into seven major groups (**Table 5.2**). These groups are further subdivided so that a four-number code preceded by the letters *EC* could precisely identify all enzymes. Consider as an example nucleoside monophosphate (NMP) kinase, an enzyme that we will examine in detail in Section 9.4. It catalyzes the following reaction:

$$\text{ATP} + \text{NMP} \rightleftharpoons \text{ADP} + \text{NDP}$$

NMP kinase transfers a phosphoryl group from ATP to any NMP to form a nucleoside diphosphate (NDP) and ADP. Consequently, it is a transferase, or member of group 2. Transferases that shift a phosphoryl group are designated 2.7. If a phosphate is the acceptor,

the transferase is designated 2.7.4, and most precisely EC 2.7.4.4 if a nucleoside monophosphate is the acceptor. Although the common names are used routinely, the classification number is used when the precise identity of the enzyme is not clear from the common name alone.

TABLE 5.2 Seven major classes of enzymes

Class	Type of reaction	Example	Chapter
1. Oxidoreductases	Oxidation–reduction	Lactate dehydrogenase	16
2. Transferases	Group transfer	Nucleoside monophosphate kinase (NMP kinase)	6
3. Hydrolases	Hydrolysis reactions (transfer of functional groups to water)	Chymotrypsin	6
4. Lyases	Addition or removal of groups to form double bonds	Fumarase	17
5. Isomerases	Isomerization (intramolecular group transfer)	Triose phosphate isomerase	16
6. Ligases	Ligation of two substrates at the expense of ATP hydrolysis	Aminoacyl-tRNA synthetase	30
7. Translocases	Movement of ions or molecules across membranes	Na^+–K^+ATPase	12

	or within membranes

Many enzymes require cofactors for activity

The catalytic activity of many enzymes depends on the presence of small molecules termed **cofactors**, although the precise role varies with the cofactor and the enzyme. Generally, these cofactors are able to execute chemical reactions that cannot be performed by the standard set of twenty amino acids. An enzyme without its cofactor is referred to as an **apoenzyme**; the complete, catalytically active enzyme is called a **holoenzyme**.

$$\text{apoenzyme} + \text{cofactor} = \text{holoenzyme}$$

Cofactors can be subdivided into two groups: (1) metals, whose importance to enzymatic activity we will explore in Chapter 6, and (2) small organic molecules called **coenzymes** (**Table 5.3**). Often derived from vitamins, coenzymes either can be tightly or loosely bound to the enzyme.

TABLE 5.3 Enzyme cofactors

Cofactor	Enzyme
Coenzyme	
Thiamine pyrophosphate	Pyruvate dehydrogenase

Flavin adenine nucleotide	Monoamine oxidase
Nicotinamide adenine dinucleotide	Lactate dehydrogenase
Pyridoxal phosphate	Glycogen phosphorylase
Coenzyme A (CoA)	Acetyl CoA carboxylase
Biotin	Pyruvate carboxylase
$5'$-Deoxyadenosylcobalamin	Methylmalonyl mutase
Tetrahydrofolate	Thymidylate synthase
Metal	
Zn^{2+}	Carbonic anhydrase
Zn^{2+}	Carboxypeptidase
Mg^{2+}	*Eco*RV
Mg^{2+}	Hexokinase
Ni^{2+}	Urease
Mo	Nitrogenase
Se	Glutathione peroxidase

Mn	Superoxide dismutase
K^+	Acetyl CoA thiolase

Tightly bound coenzymes are called **prosthetic groups**. Prosthetic groups are catalytic in that they are unchanged in the overall chemical reaction. In contrast, loosely associated coenzymes often behave more like second substrates (cosubstrates) because they bind to the enzyme, are changed by it, and then are released from it. Thus, these are also sometimes called *stoichiometric coenzymes* because they must be present in stoichiometric ratios with other substrates. The use of the same loosely associated coenzyme by a variety of enzymes sets these coenzymes apart from normal substrates, however, as does their source in vitamins (Table 5.3 and Section 15.4). Enzymes that use the same coenzyme usually perform catalysis by similar mechanisms. Throughout the book, we will see how coenzymes and their enzyme partners operate in their biochemical context.

Self-Check Question

Which terms (cofactor, coenzyme, and/or prosthetic group) correctly describe the heme from cytochrome c oxidase, which doesn't dissociate from the protein?

Enzymes can transform energy from one form into another

A key activity in all living systems is the conversion of one form of energy into another. For example, in photosynthesis, light energy is converted into chemical potential energy. In cellular respiration, which takes place in mitochondria, the free energy contained in small molecules derived from food is converted first into the free energy of an ion gradient and then into a different currency — the free energy of adenosine triphosphate. Given their centrality to life, it should come as no surprise that enzymes play vital roles in energy transformation.

After enzymes perform fundamental roles in photosynthesis and cellular respiration, other enzymes can then use the chemical potential energy of ATP in diverse ways. For instance, the enzyme myosin converts the energy of ATP into the mechanical energy of contracting muscles (Section 6.5). Pumps in the membranes of cells and organelles, which can be thought of as enzymes that move substrates rather than chemically alter them, use the energy of ATP to transport molecules and ions across the membrane (Chapter 13). The chemical and electrical gradients resulting from the unequal distribution of these molecules and ions are themselves forms of potential energy that can be used for a variety of purposes, such as sending nerve impulses (Section 13.4).

Recent developments show that the power of enzymes may be harnessed to generate energy for entire communities, as well as reducing landfill. Unsorted municipal waste can be treated with a cocktail of enzymes that includes an array of proteases as well as carbohydrate- and lipid-degrading enzymes, turning much of the waste into a bioliquid of sugars, amino acids, and other biomolecules. The bioliquid can then be used to fuel the growth of

methane-producing bacteria, and the methane harvested and burned to generate electricity. Any waste not degraded by the enzyme cocktail is recycled or incinerated to produce electricity.

5.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes

Enzymes speed up the rate of chemical reactions, but the properties of the reaction — whether it can take place at all and the degree to which the enzyme accelerates the reaction — depend on energy differences between reactants (the initial state) and products (the final state). Gibbs free energy (G), which was discussed in Section 1.3, is a thermodynamic property that is a measure of useful energy, or the energy that is capable of doing work. To understand how enzymes operate, we need to consider only two thermodynamic properties of the reaction: (1) the free-energy difference (ΔG) between the products and reactants; and (2) the energy required to initiate the conversion of reactants into products. The former determines whether the reaction will take place spontaneously, whereas the latter determines the rate of the reaction. Enzymes affect only the rate.

The free-energy change provides information about the spontaneity but not the rate of a reaction

The free-energy change of a reaction (ΔG) tells us if the reaction can take place spontaneously:

- *A reaction can take place spontaneously only if* ΔG *is negative*. Such reactions are said to be *exergonic*.
- *A system is at equilibrium and no net change can take place if* ΔG *is zero*.
- *A reaction cannot take place spontaneously if* ΔG *is positive*. An input of free energy is required to drive such a reaction. These reactions are termed *endergonic*.
- *The* ΔG *of a reaction depends only on the free energy of the products minus the free energy of the reactants*. The ΔG of a reaction is independent of the molecular mechanism of the transformation. For example, the ΔG for the oxidation of glucose to CO_2 and H_2O is the same whether it takes place by combustion or by a series of enzyme-catalyzed steps in a cell.
- *The* ΔG *provides no information about the rate of a reaction*. A negative ΔG indicates that a reaction can take place spontaneously, but it does not signify whether it will proceed at a perceptible rate.

The standard free-energy change of a reaction is related to the equilibrium constant

As for any reaction, we need to be able to determine ΔG for an enzyme-catalyzed reaction to know whether the reaction is spontaneous or requires an input of energy, measured in kilojoules (kJ) or kilocalories (kcal); one kilojoule is equivalent to 0.239

kilocalories. To determine this important thermodynamic parameter, we need to take into account the nature of both the reactants and the products as well as their concentrations.

Consider the reaction

$$A + B \rightleftharpoons C + D$$

The ΔG of this reaction is given by

$$\Delta G = \Delta G^\circ + RT \ln \frac{[C][D]}{[A][B]} \quad \textbf{(1)}$$

in which ΔG° is the standard free-energy change, R is the gas constant, T is the absolute temperature, and [A], [B], [C], and [D] are the molar concentrations (more precisely, the activities) of the reactants. ΔG° is the free-energy change for this reaction under standard conditions — that is, when each of the reactants A, B, C, and D is present at a concentration of 1.0 M (for a gas, the standard state is usually chosen to be 1 bar, which is very close to 1 atmosphere). Thus, the ΔG of a reaction depends on the nature of the reactants (expressed in the ΔG° term of equation 1) and on their concentrations (expressed in the logarithmic term of equation 1).

A convention has been adopted to simplify free-energy calculations for biochemical reactions, in which the standard state is defined as having a pH of 7. Consequently, when H^+ is a reactant, its activity has the value 1 (corresponding to a pH of 7) in equations 1 and 2. The activity of water also is taken to be 1 in these equations. The standard free-energy change at pH 7, denoted by the symbol $\Delta G^{\circ\prime}$, will be used throughout this book. A simple way to determine $\Delta G^{\circ\prime}$ is to measure the concentrations of reactants and products when the reaction has reached equilibrium. At equilibrium, there is no net change in reactants and products; in essence, the reaction has stopped and $\Delta G = 0$. At equilibrium, equation 1 then becomes

$$0 = \Delta G^{\circ\prime} + RT \ln \frac{[C]_{eq}[D]_{eq}}{[A]_{eq}[B]_{eq}}$$

and so

$$\Delta G^{\circ\prime} = -RT \ln \frac{[C]_{eq}[D]_{eq}}{[A]_{eq}[B]_{eq}} \quad \textbf{(2)}$$

The equilibrium constant under standard conditions, K'_{eq}, is defined as

$$K'_{eq} = \frac{[C]_{eq}[D]_{eq}}{[A]_{eq}[B]_{eq}}$$

(3)

Substituting equation 3 into equation 2 gives

$$\Delta G^{\circ\prime} = -RT \ln K'_{eq}$$

(4)

which can be rearranged to give

$$K'_{eq} = e^{-\Delta G^{\circ\prime}/RT}$$

Substituting $R = 8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{K}^{-1}$ and $T = 298\ \text{K}$ (corresponding to 25°C) gives

$$K'_{eq} = e^{-\Delta G^{\circ\prime}/2.48}$$

(5)

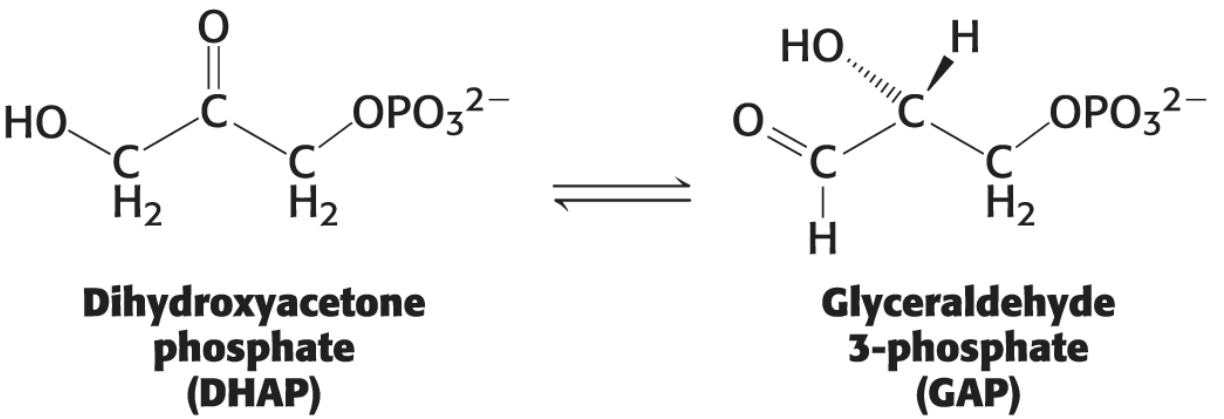
where $\Delta G^{\circ\prime}$ is here expressed in kilojoules per mole because of the choice of the units for *R* in equation 4. Thus, the standard free energy and the equilibrium constant of a reaction are related by a simple expression. For example, an equilibrium constant of 10 gives

a standard free-energy change of $-5.69\ \text{kJ mol}^{-1}$ or $-1.36\ \text{kcal mol}^{-1}$ at 25°C (Table 5.4). Note that, for each 10-fold change in the equilibrium constant, the $\Delta G^{\circ\prime}$ changes by $5.69\ \text{kJ mol}^{-1}$ or $1.36\ \text{kcal mol}^{-1}$.

TABLE 5.4 Relationship between $\Delta G^{\circ\prime}$ and K'_{eq} (at 25°C)

	$\Delta G^{\circ\prime}$	
K'_{eq}	kJ mol^{-1}	kcal mol^{-1}
10^{-5}	28.53	6.82
10^{-4}	22.84	5.46
10^{-3}	17.11	4.09
10^{-2}	11.42	2.73
10^{-1}	5.69	1.36
1	0.00	0.00
10	−5.69	−1.36
10^{2}	−11.42	−2.73

10^3	−17.11	−4.09
10^4	−22.84	−5.46
10^5	−28.53	−6.82



It is important to stress that whether the ΔG for a reaction is larger, smaller, or the same as $\Delta G^{\circ\prime}$ depends on the concentrations of the reactants and products. The criterion of spontaneity for a reaction under real conditions is ΔG, not $\Delta G^{\circ\prime}$. This point is important because reactions that are not spontaneous based on $\Delta G^{\circ\prime}$ can be made spontaneous by adjusting the concentrations of reactants and products. This principle is commonly observed in enzyme-catalyzed reactions in metabolic pathways (Chapter 15).

Example

Calculating and Comparing $\Delta G^{\circ\prime}$ and ΔG

Problem:

Calculate $\Delta G^{\circ\prime}$ and ΔG for a specific reaction that occurs during glucose metabolism:

Dihydroxyacetone phosphate (DHAP)

Glyceraldehyde 3-phosphate (GAP)

At equilibrium, the ratio of GAP to DHAP is 0.0475 at 25°C (298 K) and pH 7; hence, $K'_{eq} = 0.0475$. Typical concentrations in the cell are $2 \times 10^{-4}\ \text{M}$ for DHAP and $3 \times 10^{-6}\ \text{M}$ for GAP.

Getting Started:

Locate the equations used to calculate $\Delta G^{\circ\prime}$ and ΔG (equations 1 and 4). Besides the values given in the problem, is there anything else we need to know to solve these equations? Recall that the gas constant, *R*, is $8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{K}^{-1}$

Calculate:

Let's begin by calculating $\Delta G^{\circ\prime}$, the standard free-energy change for this reaction, using equation 4 and substituting in the values for

R, the temperature in Kelvin, and the value of K'_{eq}:

$$\begin{aligned}\Delta G^{\circ\prime} &= -RT \ln K'_{eq} \\ &= -8.315 \times 10^{-3} \times 298 \times \ln (0.0475) \\ &= +7.53 \text{ kJ mol}^{-1} \text{or} +1.80 \text{ kcal mol}^{-1}\end{aligned}$$

What does $\Delta G^{\circ\prime}$ tell us? We can see from this result that under standard conditions the reaction is endergonic and DHAP will not spontaneously convert into GAP. However, this pertains only to standard conditions, not actual physiological conditions. For those we need to calculate ΔG, by substituting the real cellular concentrations into the equation for ΔG (equation 1):

$$\begin{aligned}\Delta G &= 7.53 \text{ kJ mol}^{-1} - RT \ln \frac{3 \times 10^{-6} \text{ M}}{2 \times 10^{-4} \text{ M}} \\ &= 7.53 \text{ kJ mol}^{-1} - (10.42 \text{ kJ mol}^{-1}) \\ &= -2.89 \text{ kJ mol}^{-1} \text{ or } -0.69 \text{ kcal mol}^{-1}\end{aligned}$$

Reflect:

What is the significance of the difference between ΔG and $\Delta G^{\circ\prime}$? Note that ΔG for this reaction is negative, even though $\Delta G^{\circ\prime}$ is positive. The negative value for ΔG indicates that the conversion of

DHAP to GAP is exergonic and can take place spontaneously when these species are present at the concentrations given.

Enzymes alter only the reaction rate and not the reaction equilibrium

We have established that enzymes are excellent catalysts, but it is equally important to understand what they cannot do: an enzyme cannot alter the laws of thermodynamics and consequently cannot alter the equilibrium of a chemical reaction. Consider an enzyme-catalyzed reaction, the conversion of substrate, S, into product, P. **Figure 5.2** shows the rate of product formation with time in the presence and absence of enzyme. Note that the amount of product formed is the same whether or not the enzyme is present but, in the current example, the amount of product formed in seconds when the enzyme is present might take hours (or centuries; see Table 5.1) to form if the enzyme were absent.

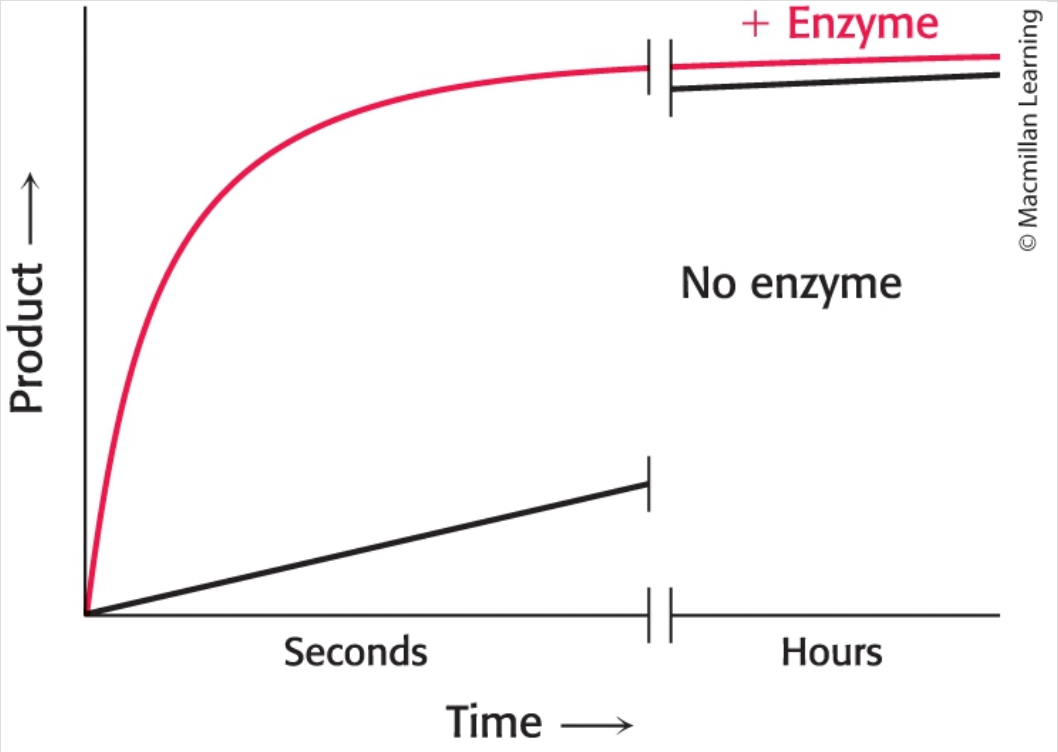


FIGURE 5.2 Enzymes do not affect thermodynamics and therefore do not change the equilibrium point. The same equilibrium point is reached much more quickly in the presence of an enzyme.

Why does the rate of product formation level off with time? The reaction has reached equilibrium. Substrate S is still being converted into product P, but P is being converted into S at a rate such that the amount of P present stays the same.

Let us examine the equilibrium in a more quantitative way. Suppose that, in the absence of enzyme, the forward rate constant (k_F) for the conversion of S into P is $10^{-4}\ s^{-1}$ and the reverse rate constant (k_R) for the conversion of P into S is $10^{-6}\ s^{-1}$. Remember: enzymes accelerate the rate of both the forward and reverse reactions. So,

also suppose that in the presence of an enzyme these values are $10^5\ s^{-1}$ and $10^3\ s^{-1}$ for k_F and k_R, respectively. The equilibrium constant *K* is given by the ratio of these rate constants in either case:

$$S \underset{10^{-6}\,s^{-1}}{\overset{10^{-4}\,s^{-1}}{\rightleftharpoons}} P \qquad S \underset{10^{3}\,s^{-1}}{\overset{10^{5}\,s^{-1}}{\rightleftharpoons}} P$$

$$K_{Uncatalyzed} = \frac{[P]}{[S]} = \frac{k_F}{k_R} = \frac{10^{-4}}{10^{-6}} = 100 \qquad K_{Catalyzed} = \frac{[P]}{[S]} = \frac{k_F}{k_R} = \frac{10^{5}}{10^{3}} = 100$$

Notice that the equilibrium concentration of P is 100 times that of S, whether or not enzyme is present. However, it might take a very long time to approach this equilibrium without enzyme, whereas equilibrium would be attained rapidly in the presence of a suitable enzyme (Table 5.1).

By catalyzing both the forward and reverse directions of reactions, enzymes accelerate the attainment of equilibria but do not shift their positions. The equilibrium position is a function only of the free-energy difference between reactants and products.

5.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State

The free-energy difference between reactants and products accounts for the equilibrium of the reaction, but enzymes accelerate how quickly this equilibrium is attained. How can we explain the rate enhancement in terms of thermodynamics? To do so, we have to consider not the end points of the reaction, but the chemical pathway between the end points.

A chemical reaction of substrate S to form product P goes through a **transition state** $X^{\ddagger}$ that has a higher free energy than does either S or P.

$$S \rightarrow X^{\ddagger} \rightarrow P$$

The double dagger $(\ ^{\ddagger})$ denotes the transition state. The transition state is a transitory molecular structure that is no longer the substrate but is not yet the product. The transition state is the least-stable and most-seldom-occupied species along the reaction pathway because it is the one with the highest free energy. The difference in free energy between the transition state and the substrate is called the **Gibbs free energy of activation** or simply the **activation energy**, symbolized by $\Delta G^{\ddagger}$ (**Figure 5.3**).

$$\Delta G^{\ddagger} = G_{X}{}^{\ddagger} - G_{S}$$

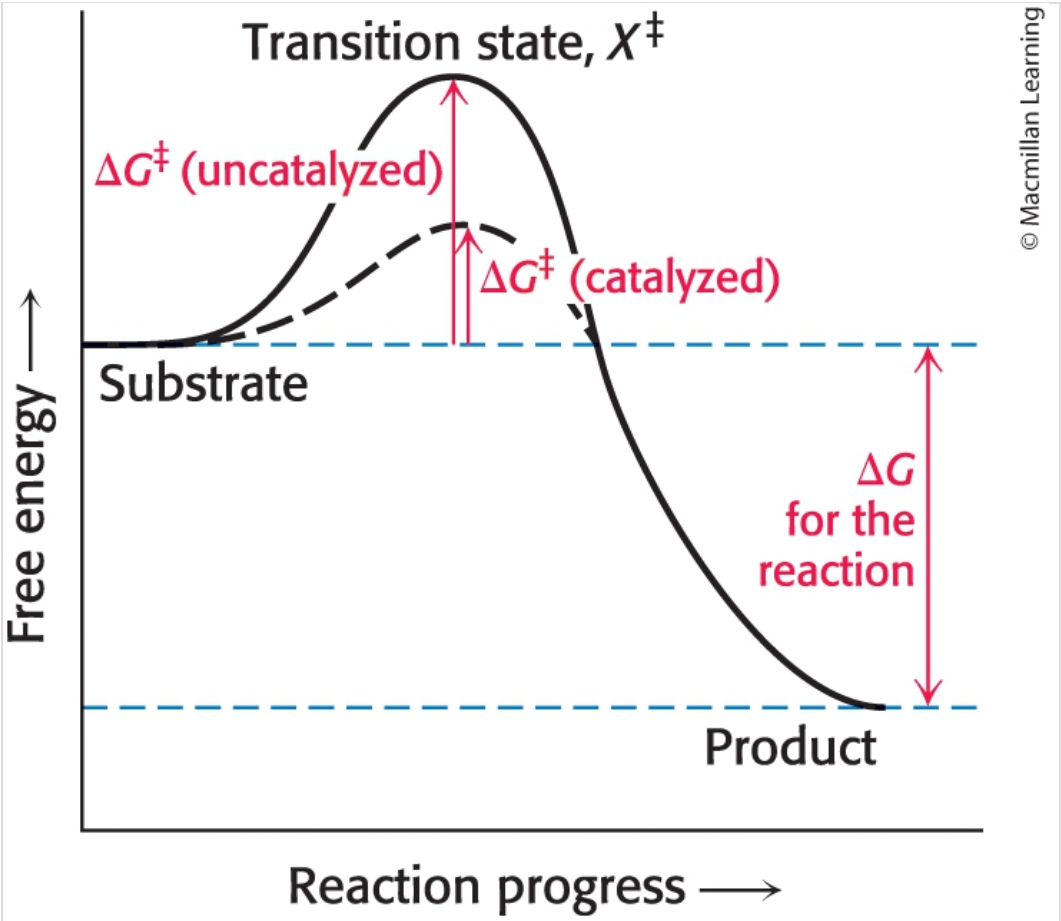

FIGURE 5.3 Enzymes accelerate reactions by decreasing $\Delta G^{\ddagger}$, the free energy of activation.

Note that $\Delta G^{\ddagger}$ does not enter into the final ΔG calculation for the reaction, because the energy required to generate the transition state is released when the transition state forms the product. This is also true when we consider the reaction from the reverse direction.

The activation-energy barrier immediately suggests how an enzyme enhances the reaction rates in both directions without altering ΔG of the reaction: enzymes accelerate reactions by decreasing $\Delta G^{\ddagger}$, the activation energy, thus facilitating the formation of the transition state from either substrate or product.

The combination of substrate and enzyme creates a reaction pathway whose transition-state energy is lower than that of the reaction in the absence of enzyme (Figure 5.3). Because the activation energy is lower, more molecules have the energy required to reach the transition state. Decreasing the activation barrier is analogous to lowering the height of a high-jump bar; more athletes will be able to clear the bar.

The formation of an enzyme–substrate complex is the first step in enzymatic catalysis

Much of the catalytic power of enzymes comes from their binding to and then altering the structure of the substrate to promote the formation of the transition state. Thus, the first step in catalysis is the formation of an enzyme–substrate (ES) complex. Substrates bind to a specific region of the enzyme called the **active site**. Most enzymes are highly selective in the substrates that they bind. Indeed, the catalytic specificity of enzymes depends in part on the specificity of binding.

What is the evidence for the existence of an enzyme–substrate complex?

- The first clue was the observation that, at a constant concentration of enzyme, the reaction rate increases with increasing substrate concentration until a maximal velocity is reached (Figure 5.4), suggesting that a discrete ES complex has formed. In contrast, uncatalyzed reactions do not show this saturation effect. At a sufficiently high substrate concentration, all the catalytic sites are filled, or saturated, and so the reaction rate cannot increase. Although indirect, the ability to saturate an enzyme with substrate is the most general evidence for the existence of ES complexes.

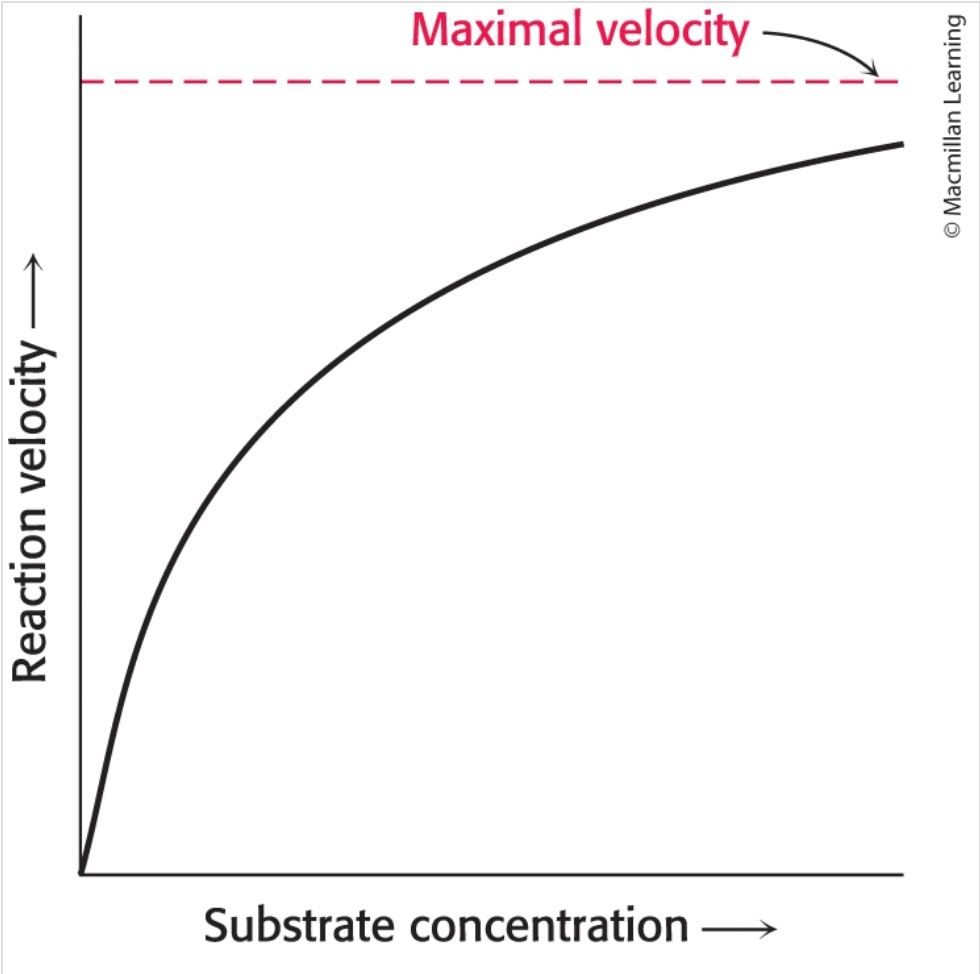

FIGURE 5.4 As substrate concentration increases, an enzyme-catalyzed reaction asymptotically approaches a maximal velocity.

- The spectroscopic characteristics of many enzymes and substrates change on the formation of an ES complex. These changes are particularly striking if the enzyme contains a colored prosthetic group.
- X-ray crystallography has provided high-resolution images of substrates and substrate analogs bound to the active sites of many enzymes (**Figure 5.5**). In Chapter 6, we will take a close look at several of these complexes.

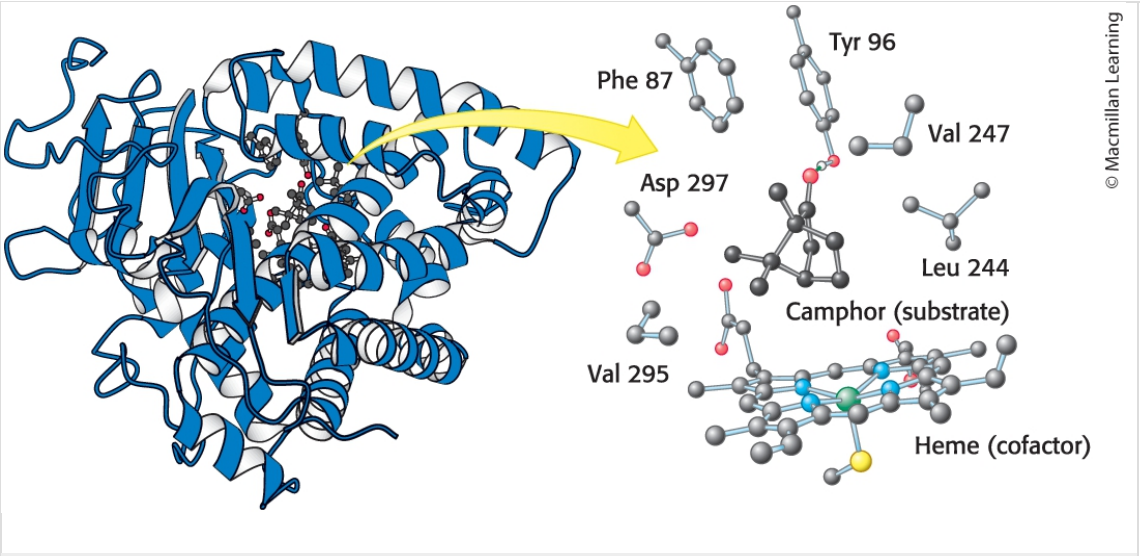

FIGURE 5.5 In the active site, substrates are surrounded by enzyme residues and sometimes cofactors. (Left) The structure of the complex between the enzyme cytochrome P450 and its substrate camphor. (Right) The substrate sits in the active site, which is a cavity formed by residues from the enzyme and the heme prosthetic group.

INTERACT with this model in Achieve

The active sites of enzymes have some common features

Recall from Chapter 2 that proteins are not rigid structures, but are flexible and exist in an array of conformations. Thus, the interaction of the enzyme and substrate at the active site and the formation of the transition state is a dynamic process. Although enzymes differ widely in structure, specificity, and mode of catalysis, at least five generalizations can be made concerning their active sites:

1. *The active site is a three-dimensional cleft, or crevice, formed by groups that come from different parts of the amino acid sequence*. Indeed, residues far apart in the amino acid sequence may interact more strongly than adjacent residues in the sequence, which may be sterically constrained from interacting with one another. For example, in the enzyme lysozyme, the residues that contribute important groups to the active site are numbered 35, 52, 62, 63, 101, and 108 in the sequence of 129 amino acids (**Figure 5.6**). Lysozyme, found in a variety of organisms and tissues, including human tears, degrades the cell walls of some bacteria.

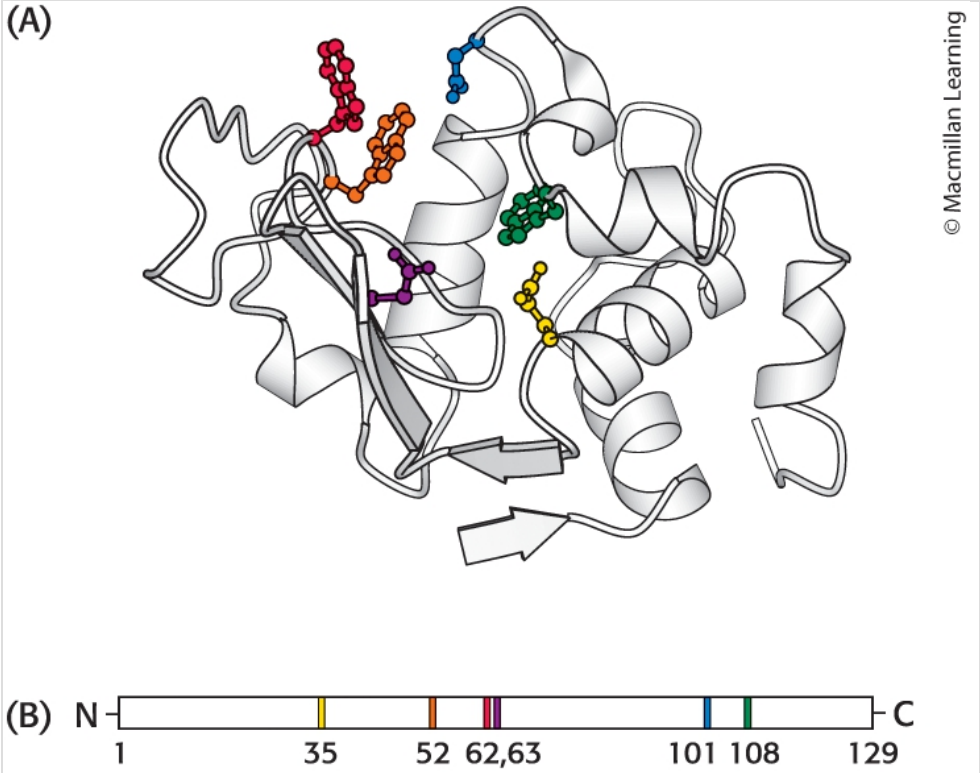

FIGURE 5.6 Amino acids that are far apart in sequence can be close together in the active site of the folded protein. (A) A ribbon diagram of the enzyme lysozyme with several components of the active site shown in color. (B) A schematic representation of the primary structure of lysozyme shows that the active site is composed of residues that come from different parts of the polypeptide chain.

[Drawn from 6LYZ.pdb.]

INTERACT with this model in Achieve

2. *The active site takes up a small part of the total volume of an enzyme*. Although residues in an enzyme are not in contact with the substrate, the cooperative motions of the entire enzyme help to correctly position the catalytic residues at the active site. Experimental attempts to reduce the size of a catalytically active enzyme show that the minimum size requires about 100

residues. In fact, nearly all enzymes are larger than this, which gives them a mass normally greater than 10 kDa and a diameter of more than $25\ \text{Å}$, suggesting that all residues in a protein, not just those at the active site, are ultimately required to form a functional enzyme.

3. *Active sites are unique microenvironments*. Water is usually excluded from the active site cleft unless it is a reactant. Often a nonpolar microenvironment in the cleft enhances the binding of substrates as well as catalysis. The cleft may also contain polar residues, some of which may acquire special properties essential for substrate binding or catalysis. The internal positions of these polar residues are biologically crucial exceptions to the general rule that polar residues are located on the surface of proteins, exposed to water.

4. *Substrates are bound to enzymes by multiple weak attractions*. The noncovalent interactions in ES complexes are much weaker than covalent bonds, which have energies between -210 and $-460\ \text{kJ mol}^{-1}$ (between -50 and $-110\ \text{kcal mol}^{-1}$). In contrast, ES complexes usually have equilibrium constants that range from 10^{-2} to $10^{-8}\ \text{M}$ corresponding to free energies of interaction ranging from about -13 to $-50\ \text{kJ mol}^{-1}$ (from -3 to $-12\ \text{kcal mol}^{-1}$). As discussed in Section 1.3, these weak reversible contacts are mediated by ionic interactions, hydrogen bonds, van der Waals forces, and the hydrophobic effect. Van der Waals forces become significant in binding only when numerous substrate and enzyme atoms simultaneously come into close contact. Hence, the enzyme and substrate should have complementary shapes. The directional character of hydrogen bonds between enzyme and substrate often

enforces a high degree of specificity, as seen in the RNA-degrading enzyme ribonuclease (Figure 5.7).

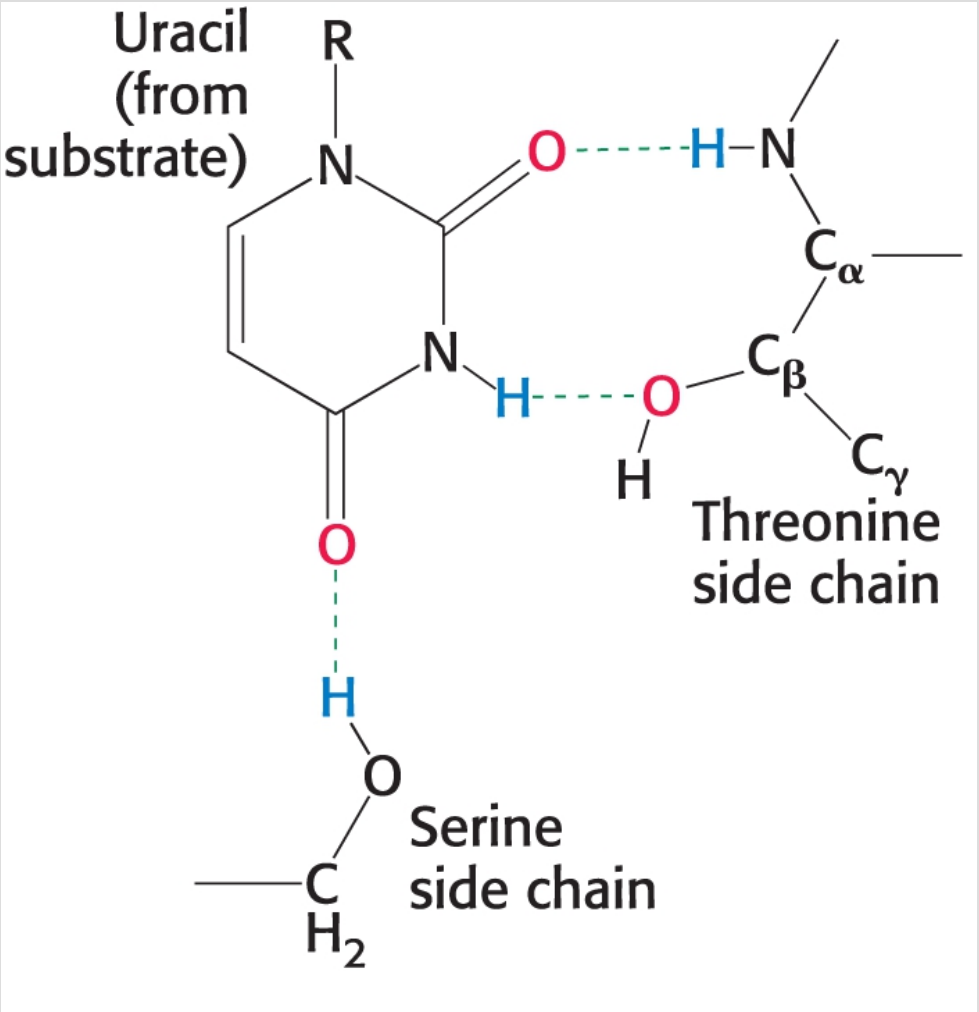

FIGURE 5.7 The geometry of hydrogen bonds often creates specificity between an enzyme and its substrate. The enzyme ribonuclease forms hydrogen bonds with the uridine component of the substrate.

[Information from F. M. Richards, H. W. Wyckoff, and N. Allewell, In *The Neurosciences: Second Study Program*, F. O. Schmidt, Ed. (Rockefeller University Press, 1970), p. 970.]

5. *The specificity of binding depends on the precisely defined arrangement of atoms in an active site*. Because the enzyme and

the substrate interact by means of short-range forces that require close contact, a substrate must have a matching shape to fit into the site. Emil Fischer proposed the lock-and-key analogy in 1890, which was the model for enzyme–substrate interaction for several decades (**Figure 5.8A**). We now know that enzymes are flexible and that the shapes of the active sites can be markedly modified by the binding of substrate, a process of dynamic recognition called **induced fit** (**Figure 5.8B**). Moreover, the substrate may bind to only certain conformations of the enzyme, in what is called *conformation selection*. Thus, the mechanism of catalysis is dynamic, involving structural changes in both the substrates and the enzyme until the substrate reaches the transition state.

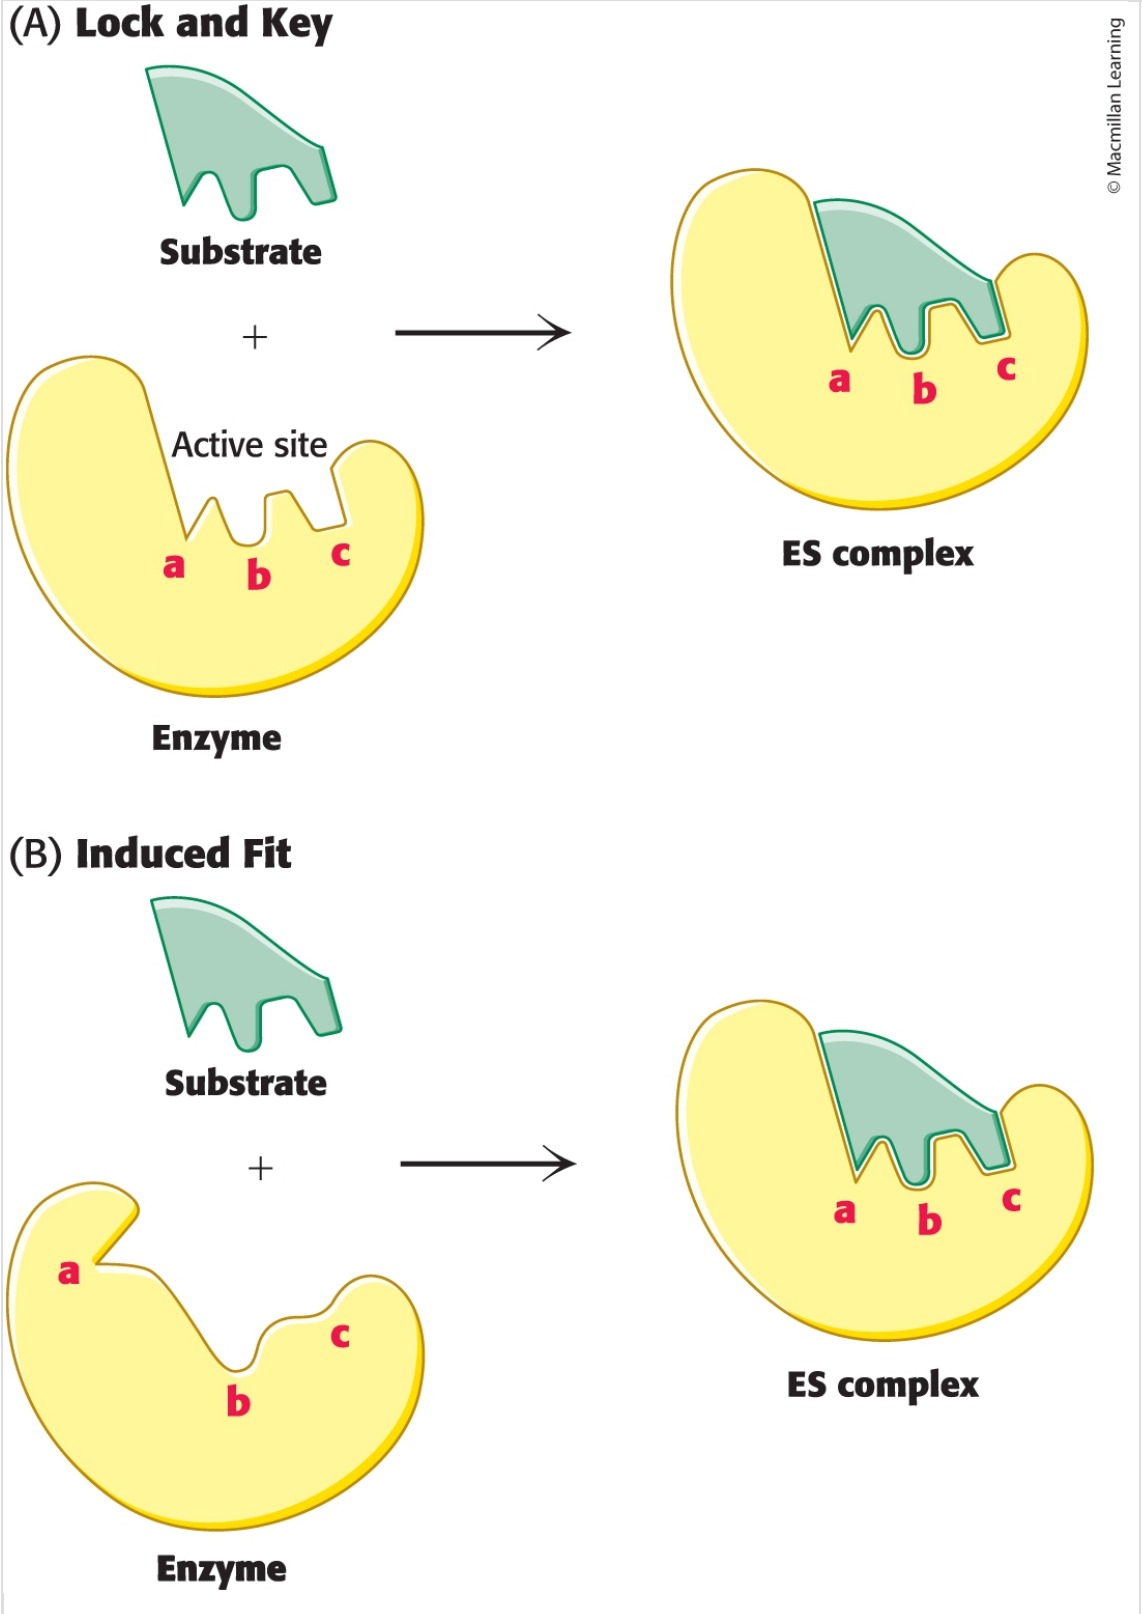

FIGURE 5.8 The old lock-and-key model of enzyme binding has been replaced by an induced-fit model. (A) In the lock-and-key model of enzyme–substrate binding, the

active site of the unbound enzyme was proposed to be complementary in shape to the substrate, whereas in (B) the current induced-fit model of enzyme–substrate binding, the enzyme changes shape on substrate binding, with the active site forming a shape complementary to the substrate only after the substrate has been bound. The enzyme then continues to change shape as it induces changes in the substrate, converting it into the transition state.

The binding energy between enzyme and substrate is important for catalysis

Enzymes lower the activation energy, but where does the energy to lower the activation energy come from? Free energy is released by the formation of a large number of weak interactions between a complementary enzyme and its substrate. The free energy released on binding is called the **binding energy**. Only the correct substrate can participate in most or all of the interactions with the enzyme and thus maximize binding energy, accounting for the exquisite substrate specificity exhibited by many enzymes. Furthermore, the full complement of such interactions is formed — and the maximal binding energy is released — only when the substrate is converted into the transition state. The energy released by the interaction between the enzyme and the substrate can be thought of as lowering the activation energy.

Because the transition state collapses randomly, the activation energies

determine the accumulation of either product or substrate

Molecular movements resulting in the optimal alignment of functional groups at the active site occur fleetingly. The transition state is too unstable to exist for long, collapsing randomly to either substrate or product. A consideration of the biochemical timescale, in which molecule motion is occurring on the order of microseconds to nanoseconds, is once again illuminating: a substrate may reach the transition state and collapse back to substrate again many times in a single active site within a fraction of a second before collapsing to product.

Whether substrate or product ultimately accumulates is determined only by the energy difference between the substrate and the product — that is, by the ΔG of the reaction, but why? If the direction of the collapse from the transition state is random, then the accumulation of either product or substrate can be explained by the activation energy in either direction because it dictates how frequently substrates or products reach the transition state. By lowering this activation energy, enzymes accelerate reactions in both directions by increasing the rate at which both products and substrates reach the transition state.

5.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes

The study of the rates of chemical reactions is called *kinetics*, and the study of the rates of enzyme-catalyzed reactions is called *enzyme kinetics*. A kinetic description of enzyme activity will help us understand how enzymes function.

Kinetics is the study of reaction rates

What do we mean when we say the "rate" of a chemical reaction? Consider a simple reaction:

$$A \rightarrow P$$

The rate V is the quantity of A that disappears in a specified unit of time. It is equal to the rate of the appearance of P, or the quantity of P that appears in a specified unit of time.

$$V = -d[A]/dt = d[P]/dt$$

If A is yellow and P is colorless, we can follow the decrease in the concentration of A by measuring the decrease in the intensity of yellow color with time. Consider only the change in the

concentration of A for now. The rate of the reaction is directly related to the concentration of A by a proportionality constant, *k*, called the *rate constant*.

$$V = k[A]$$

Reactions that are directly proportional to the reactant concentration are first-order reactions. First-order rate constants have the units of s^{-1}.

Many important biochemical reactions include two reactants. For example,

$$2A \rightarrow P$$

or

$$A + B \rightarrow P$$

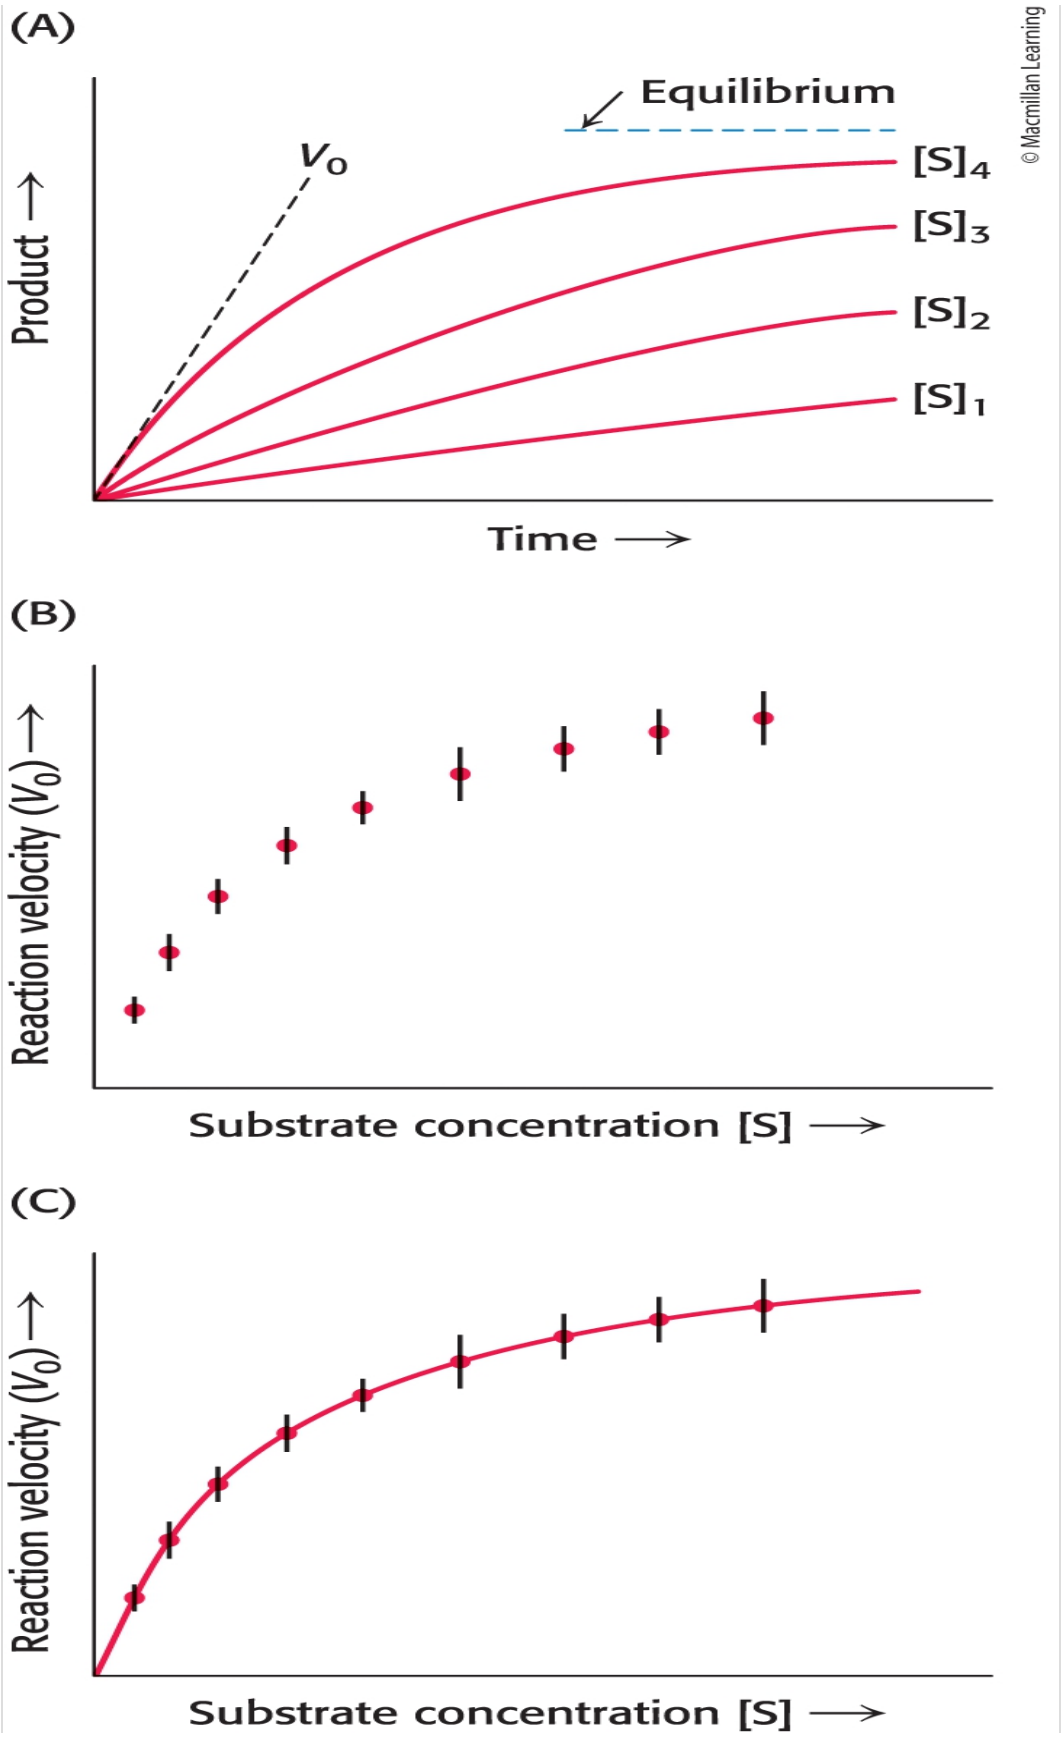
They are called *bimolecular reactions*, and the corresponding rate equations often take the form

$$V = k[A]^2$$

and

$$V = k[A][B] \quad \textbf{(6)}$$

The rate constants, called second-order rate constants, have the units $M^{-1}\,s^{-1}$.



Sometimes, second-order reactions can appear to be first-order reactions. For instance, in the reaction described by equation 6, if B is present in excess and A is present at low concentrations, the reaction rate will be first order with respect to A and will not appear to depend on the concentration of B. These reactions are called *pseudo-first-order reactions*, and we will see them a number of times in our study of biochemistry.

Interestingly, under some conditions, a reaction can be zero order. In these cases the rate is independent of reactant concentrations. Enzyme-catalyzed reactions can approximate zero-order reactions under some circumstances, as we will soon see.

The steady-state assumption aids a description of enzyme kinetics

The simplest way to investigate the reaction rate is to follow the increase in reaction product as a function of time. First, the extent of product formation is determined as a function of time for a series of substrate concentrations (**Figure 5.9A**). As expected, in each case, the amount of product formed increases with time, although eventually a time is reached when there is no net change in the concentration of S or P. The enzyme is still actively converting

substrate into product and vice versa, but the reaction equilibrium has been attained.

© Macmillan Learning

FIGURE 5.9 The relation between initial velocity and substrate concentration can be determined by a series of assays. (A) The amount of product formed at different substrate concentrations is plotted as a function of time. The initial velocity (V_0) for each substrate concentration is determined from the slope of the curve at the beginning of a reaction, when the reverse reaction is insignificant. (B) The values for initial velocity determined in part A are then plotted, with error bars, against substrate concentration. (C) The data points are connected to clearly reveal the relationship of initial velocity to substrate concentration.

However, enzyme kinetics is more readily comprehended if we consider only the forward reaction, which is most closely described by the initial rates of the reaction. Note that the rate of the reaction (the slope of the tangent line in Figure 5.9A) decreases over time. Additionally, only at the beginning of the reaction is the exact concentration of the substrate known because it is being converted to product as the reaction progresses. For these two reasons, it is often most useful to focus on initial rate enzyme kinetics. We can define the rate of catalysis V_0, or the initial rate of catalysis, as the number of moles of product formed per second when the reaction is just beginning — that is, when $t \approx 0$ and $[P] \approx 0$, so the rate of the reverse reaction is negligible (Figure 5.9A). These experiments are repeated three to five times with each substrate concentration to ensure the accuracy of and assess the variability of the values attained.

Next, we plot V_0 versus the initial substrate concentration used in each experiment, [S], assuming a constant amount of enzyme and showing the data points with error bars (**Figure 5.9B**). Finally, the data points are connected, yielding the results shown in **Figure 5.9C**. The rate of catalysis rises linearly as substrate concentration increases and then begins to level off and approach a maximum at

higher substrate concentrations. For convenience, we will show idealized data without error bars throughout the text, but it is important to keep in mind that in reality, all experiments are repeated multiple times.

The Michaelis–Menten model explains many observations of enzyme kinetics

In 1913, Leonor Michaelis and Maud Menten proposed a simple model to account for these kinetic characteristics. The critical feature in their treatment is that a specific ES complex is a necessary intermediate in catalysis. The model they proposed is

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E + P$$

An enzyme E (here representing the “free enzyme”) combines with substrate S (“free substrate”) to form an ES complex, with a rate constant k_1.

The ES complex has two possible fates. It can dissociate to E and S, with a rate constant k_{-1}, or it can proceed to form product P, with a rate constant k_2. The ES complex can also be reformed from E and P by the reverse reaction with a rate constant k_{-2}. However, as before, we can simplify these reactions by considering the rate of

reaction at times close to zero (hence, V_0) when there is negligible product formation and thus no back reaction $(k_{-2}[E][P] \approx 0)$.

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

(7)

Thus, for the graph in **Figure 5.10**, V_0 is determined for each substrate concentration by measuring the rate of product formation at early times before P accumulates (Figure 5.9A).

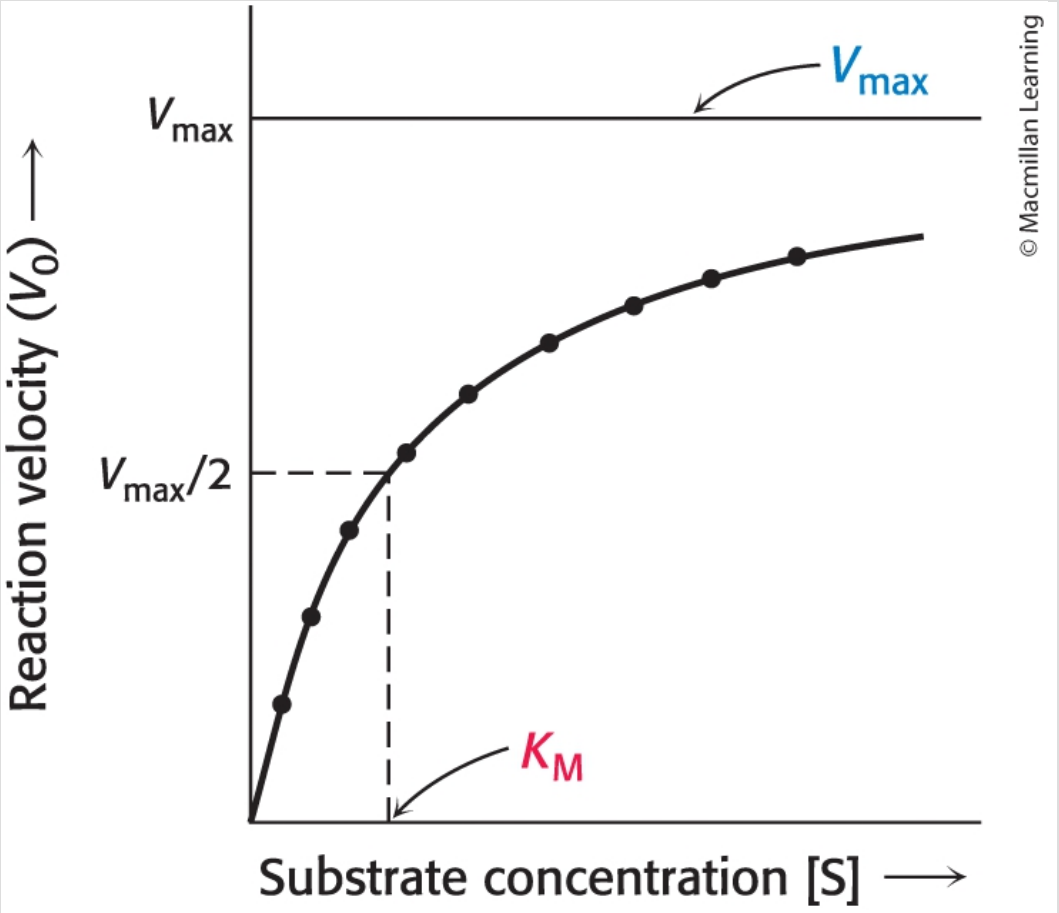


FIGURE 5.10 Michaelis–Menten kinetics are marked by a hyperbolic relationship between initial velocity and substrate concentration. A plot of the reaction velocity (V_0) as a function of the substrate concentration [S] for an enzyme that obeys Michaelis–Menten kinetics shows that the maximal velocity (V_{max}) is approached asymptotically, which is to say, V_{max} will be attained only at an infinite substrate concentration. The Michaelis constant (K_M) is the substrate concentration yielding a velocity of $V_{max}/2$.

The Michaelis–Menten equation describes the relationship between initial velocity and substrate concentration

We want an expression that relates the rate of catalysis to the concentrations of substrate and enzyme and the rates of the individual steps. For any chemical reaction, the overall reaction rate is determined only by the slowest, or rate-determining step. Thus, our starting point is the assumption that catalysis, resulting from the ES complex, is slow relative to the rate of substrate binding, i.e., the formation of the ES complex. Thus, the overall reaction rate can be expressed solely as the rate of this one step, which is the product of the concentration of the ES complex and k_2.

$$V_0 = k_2[\mathrm{ES}]$$

(8)

Now we need to express [ES] in terms of known quantities. The rates of formation and breakdown of ES are given by

$$\text{Rate of formation of ES} = k_1[\mathrm{E}][\mathrm{S}]$$

(9)

$$\text{Rate of breakdown of ES} = (k_{-1} + k_2)[\mathrm{ES}]$$

(10)

We will use what biochemists term the *steady-state assumption* to simplify matters. In a steady-state system, the concentrations of intermediates — in this case, [ES] — stay the same even though the concentrations of starting materials and products are changing and the system is not in equilibrium. An analogy is a sink filled with water that has the tap open just enough to match the loss of water down the drain: the level of the water in the sink never changes even though water is constantly flowing from the faucet through the sink and out through the drain. This steady state is reached when the rates of formation and breakdown of the ES complex are equal. Setting the right-hand sides of equations 9 and 10 equal gives

$$k_1[E][S] = (k_{-1} + k_2)[ES]$$

(11)

By rearranging equation 11, we obtain

$$[E][S]/[ES] = (k_{-1} + k_2)/k_1$$

(12)

Equation 12 can be simplified by defining a new constant, K_M, called the **Michaelis constant**:

$$K_M = \frac{k_{-1} + k_2}{k_1}$$

(13)

Note that K_M has the units of concentration and is independent of enzyme and substrate concentrations. As will be explained, K_M is an important characteristic of enzyme–substrate interactions.

Inserting equation 13 into equation 12 and solving for [ES] yields

$$[ES] = \frac{[E][S]}{K_M} \tag{14}$$

Now let us examine the numerator of equation 14. Because the substrate is usually present at a much higher concentration than that of the enzyme, the concentration of uncombined (free) substrate [S] is very nearly equal to the total substrate concentration. The concentration of uncombined (free) enzyme [E] is equal to the total enzyme concentration $[E]_T$ minus the concentration of the ES complex:

$$[E] = [E]_T - [ES]$$

Substituting this expression for [E] in equation 14 gives

$$[ES] = \frac{([E]_T - [ES])[S]}{K_M}$$

Solving the above equation for [ES] gives

$$[ES] = \frac{[E]_T[S]/K_M}{1 + [S]/K_M}$$

or

$$[ES] = [E]_T \frac{[S]}{[S] + K_M}$$

By substituting this expression for [ES] into equation 8, we obtain

$$V_0 = k_2[E]_T \frac{[S]}{[S] + K_M}$$

(15)

The **maximal rate**, V_{max}, is attained when the catalytic sites on the enzyme are saturated with substrate — that is, when $[ES] = [E]_T$. Thus,

$$V_{max} = k_2[E]_T$$

(16)

Substituting equation 16 into equation 15 yields the **Michaelis–Menten equation**:

$$V_0 = V_{max} \frac{[S]}{[S] + K_M}$$

(17)

This equation accounts for the kinetic data given in Figure 5.10. At very low substrate concentration, when [S] is much less than K_M, $V_0 = (V_{max} / K_M)[S]$; that is, the reaction is first order with the rate directly proportional to the substrate concentration. At high substrate concentration, when [S] is much greater than K_M, $V_0 = V_{max}$; that is, the rate is maximal. The reaction is zero order, independent of substrate concentration.

Notice that because V_0 is a function of [S], then if the K_M value is known, the equation gives the velocity as a fraction of V_{max} at any concentration of substrate. Thus, the velocity can be calculated at any [S], using the Michaelis–Menten equation, and expressed either in real units (if V_{max} is known) or as a fraction of V_{max}. Likewise, if the fraction of V_{max} is known, then the relationship between [S] and K_M can be calculated.

The significance of K_M is clear when we set $[S] = K_M$ in equation 17. When $[S] = K_M$, then $V_0 = V_{max}/2$. Thus, K_M is equal to the substrate concentration at which the reaction rate is half its maximal value. As we will see, K_M is an important characteristic of an enzyme-catalyzed reaction and is significant for its biological function.

Smithsonian Institution Archives, Accession 90-105, Science Service Records, Image No. SIA2008-5999

MAUD MENTEN Paving new career paths for women at the dawn of the 20th century, Maud Menten was among the first Canadian women to obtain an MD degree, in 1911; she then earned a PhD in 1916. Although she is most famous for her groundbreaking work on enzyme kinetics as a graduate student, she had a long and productive scientific career at the University of Pittsburgh and the British Columbia Medical Research Institute, teaching and publishing over 70 papers on a variety of subjects. She invented a still-used histochemical assay for

alkaline phosphatase, characterized bacterial toxins and early vitamin C deficiency, and pioneered the use of electrophoresis for the study of proteins.

Example

Applying the Michaelis–Menten Equation

Problem:

Assume that the initial velocity of an enzyme is 80% of V_{max}. What is the ratio of [S] to K_M under these conditions?

Getting Started:

The Michaelis–Menten equation relates the three terms discussed in the problem, so let's begin with it:

$$V_0 = V_{max} \frac{[S]}{[S] + K_M}$$

What do we already know? The question states the $V_0 = 80\%\ V_{max}$. This is the only value we are provided, so we should be able to solve the problem with that value and the equation.

SOLVE:

First, for convenience, let's convert 80% to 0.8 and substitute the $0.8\ V_{max}$ for V_0 in the equation:

$$0.8V_{max} = V_{max}\frac{[S]}{[S] + K_M}$$

Now we see that we can divide both sides of the equation by V_{max}, which yields

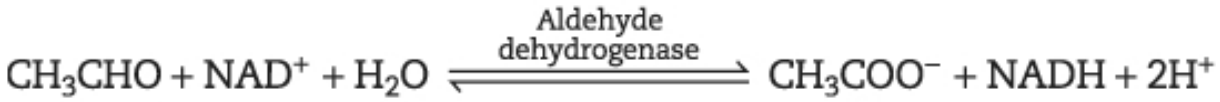
$$0.8 = \frac{[S]}{[S] + K_M}$$

Now we can solve the equation for $[S]/K_M$.

$$\begin{aligned} 0.8[S] + 0.8K_M &= [S] \\ 0.8K_M &= [S] - 0.8[S] \\ 0.8K_M &= 0.2[S] \\ 4 &= \frac{[S]}{K_M} \end{aligned}$$

Thus, when [S] is fourfold greater than K_M, $V_0 = 0.8\ V_{max} = 80\%\ V_{max}$.

Reflect:



You can confirm this answer by solving the Michaelis–Menten equation using $[S] = 4K_M$ and solving for V_0 as a fraction of V_{max}.

Variations in K_M can have physiological consequences

The physiological consequence of K_M is illustrated by the sensitivity of some persons to ethanol. Such persons exhibit facial flushing and rapid heart rate (tachycardia) after ingesting even small amounts of alcohol. In the liver, alcohol dehydrogenase converts ethanol (CH_3CH_2OH) into acetaldehyde (CH_3CHO).

$$CH_3CH_2OH + NAD^+ \underset{}{\overset{\text{Alcohol dehydrogenase}}{\rightleftharpoons}} CH_3CHO + NADH + H^+$$

Normally, the acetaldehyde, which is the cause of the symptoms when present at high concentrations, is processed to acetate by aldehyde dehydrogenase.

Most people have two forms of the aldehyde dehydrogenase, a low K_M mitochondrial form and a high K_M cytoplasmic form. In susceptible persons, the mitochondrial enzyme is less active owing to the substitution of a single amino acid, and acetaldehyde is processed only by the cytoplasmic enzyme. Because this enzyme has a high K_M, it achieves a high rate of catalysis only at very high concentrations of acetaldehyde. Consequently, less acetaldehyde is converted into acetate; excess acetaldehyde escapes into the blood and accounts for the physiological effects.

K_M and V_{max} values can be determined by several means

K_M is equal to the substrate concentration that yields $V_{max}/2$; however, like perfection, V_{max} is approached but never attained. How, then, can we experimentally determine K_M and V_{max}, and how do these parameters enhance our understanding of enzyme-catalyzed reactions? The Michaelis constant, K_M, and the maximal rate, V_{max}, can be readily derived from rates of catalysis measured at a variety of substrate concentrations if an enzyme operates according to the simple scheme given in equation 17. The derivation of K_M and V_{max} is most commonly achieved with the use of curve-fitting programs on a computer. However, an older method,

although rarely used because the data points at high and low concentrations are weighted differently and thus sensitive to errors, is a source of further insight into the meaning of K_M and V_{max}.

Before the availability of computers, the determination of K_M and V_{max} values required algebraic manipulation of the Michaelis–Menten equation. The Michaelis–Menten equation is transformed into one that gives a straight-line plot that yields values for V_{max} and K_M. Taking the reciprocal of both sides of equation 17 gives

$$\frac{1}{V_0} = \frac{K_M}{V_{max}} \times \frac{1}{[S]} + \frac{1}{V_{max}} \quad \textbf{(18)}$$

A plot of $1/V_0$ versus $1/[S]$, called a **Lineweaver–Burk plot** or sometimes just called a *double-reciprocal plot*, yields a straight line with a *y*-intercept of $1/V_{max}$ and a slope of K_M/V_{max} (**Figure 5.11**). The intercept on the *x*-axis is $-1/K_M$.

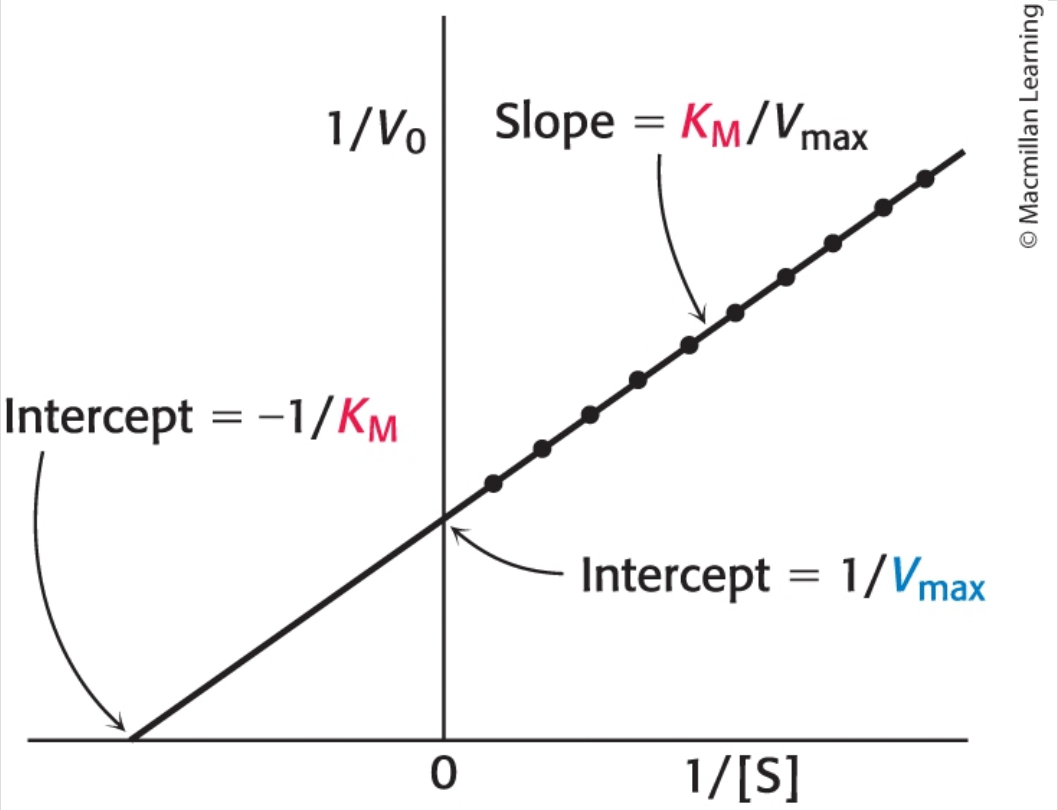


FIGURE 5.11 A Lineweaver–Burk plot shows $1/V_0$ as a function of $1/[S]$. The slope is K_M/V_{max}, the intercept on the vertical axis is $1/V_{max}$, and the intercept on the horizontal axis is $-1/K_M$.

K_M and k_{cat} values are important enzyme characteristics

The K_M values of enzymes range widely (Table 5.5). For most enzymes, K_M lies between 10^{-1} and 10^{-7} M. The K_M value for an enzyme depends on the particular substrate and on environmental

conditions such as pH, temperature, and ionic strength. The Michaelis constant, being equal to the concentration of substrate at which half the active sites are filled, thus provides a measure of the substrate concentration required for significant catalysis to take place.

TABLE 5.5 K_M values of some enzymes

Enzyme	Substrate	K_M (μM)
Chymotrypsin	Acetyl-L-tryptophanamide	5000
Lysozyme	Hexa-*N*-acetylglucosamine	6
β-Galactosidase	Lactose	4000
Threonine deaminase	Threonine	5000
Carbonic anhydrase	CO_2	8000
Penicillinase	Benzylpenicillin	50
Pyruvate carboxylase	Pyruvate	400
	HCO_3^-	1000
	ATP	60
Arginine-tRNA synthetase	Arginine	3
	tRNA	0.4

For many enzymes, experimental evidence suggests that the K_M value provides an approximation of the substrate concentration in vivo, which in turn suggests that most enzymes evolved to have a K_M approximately equal to the substrate concentration commonly available. Why might it be beneficial to have a K_M value approximately equal to the commonly available substrate concentration? If the normal concentration of substrate is near K_M, the enzyme will display significant activity, and yet the activity will be sensitive to changes in environmental conditions — that is, changes in substrate concentration. This property is known as **elasticity**. At values below K_M, enzymes are very sensitive to changes in substrate concentration — in other words, they are elastic — but display little activity. At substrate values well above K_M, enzymes have greater catalytic activity but are insensitive — or inelastic — to changes in substrate concentration. Thus, with the normal substrate concentration being approximately K_M, the enzymes have significant activity ($1/2\ V_{max}$) but are still elastic to changes in substrate concentration.

Under certain circumstances, K_M reflects the strength of the enzyme–substrate interaction. In equation 13, K_M is defined as $(k_{-1} + k_2)/k_1$. Consider a case in which k_{-1} is much greater than k_2. Under such circumstances, the ES complex dissociates to E and S much more rapidly than product is formed. Under these conditions, ($k_{-1} \gg k_2$)

$$K_M \approx \frac{k_{-1}}{k_1}$$

(19)

Equation 19 describes the dissociation constant, K_d (Chapter 3), of the ES complex.

$$K_{ES} = \frac{[E][S]}{[ES]} = \frac{k_{-1}}{k_1}$$

In other words, K_M is equal to the dissociation constant (K_d) of the ES complex if k_2 is much smaller than k_{-1}. When this condition is met, K_M is a measure of the strength of the ES complex: a high K_M indicates weak binding; a low K_M indicates strong binding. It must be stressed that K_M indicates the affinity of the ES complex only when k_{-1} is much greater than k_2.

The maximal rate, V_{max}, reveals the **turnover number** of an enzyme, which is the number of substrate molecules converted into product by an enzyme molecule in a unit time when the enzyme is fully saturated with substrate. For a single active site, it is equal to the rate constant k_2, which is also called k_{cat}. The maximal rate, V_{max}, reveals the turnover number of an enzyme if the concentration of active sites $[E]_T$ is known, because

$$V_{max} = k_{cat}[E]_T$$

and thus

$$k_{cat} = V_{max} / [E]_T \tag{20}$$

For example, a 10^{-6} M solution of carbonic anhydrase catalyzes the formation of 0.6 M H_2CO_3 per second when the enzyme is fully saturated with substrate. Hence, k_{cat} is 6×10^5 s^{-1}. This turnover number is one of the largest known. Each catalyzed reaction takes place in a time equal to, on average, $1/k_{cat}$, which is 1.7 μs for carbonic anhydrase. The turnover numbers of most enzymes with their physiological substrates range from 1 to 10^6 per second (Table 5.6).

TABLE 5.6 Turnover numbers of some enzymes

Enzyme	Turnover number (per second)
Carbonic anhydrase	600,000
3-Ketosteroid isomerase	280,000
Acetylcholinesterase	25,000
Penicillinase	2000
Lactate dehydrogenase	1000
Chymotrypsin	100

DNA polymerase I	15
Tryptophan synthetase	2
Lysozyme	0.5

K_M and V_{max} also permit the determination of f_{ES}, the fraction of active sites filled. This relation of f_{ES} to K_M and V_{max} is given by the following equation:

$$f_{ES} = \frac{V_0}{V_{max}} = \frac{[S]}{[S] + K_M}$$

(21)

Self-Check Question

Explain why K_M is an intrinsic property of an enzyme while V_{max} is not?

k_{cat}/K_M is a measure of catalytic efficiency

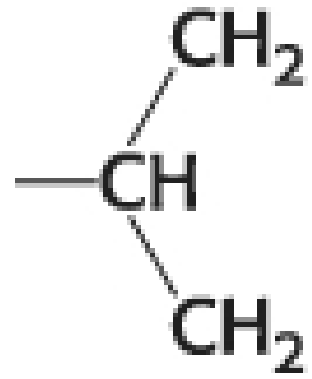
Recall that when the substrate concentration is much greater than K_M, the rate of catalysis is equal to V_{max}, which is a function of k_{cat}, the turnover number. However, most enzymes are not normally

saturated with substrate. Under physiological conditions, the $[S]/K_M$ ratio is typically between 0.01 and 1.0. When $[S] = K_M$, the enzymatic rate is much less than k_{cat} because most of the active sites are unoccupied.

Is there a number that characterizes the kinetics of an enzyme under these more typical cellular conditions? Indeed there is, as can be shown by combining equations 8 and 14 to give

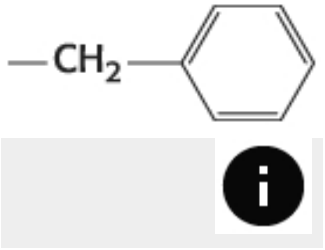
$$V_0 = \frac{k_{cat}}{K_M}[E][S]$$

When $[S] \ll K_M$, the concentration of free enzyme [E], is nearly equal to the total concentration of enzyme $[E]_T$; so



$$V_0 = \frac{k_{cat}}{K_M}[S][E]_T$$

Thus, when $[S] \ll K_M$, the enzymatic velocity depends on the values of k_{cat}/K_M, [S], and $[E]_T$. Under these conditions, k_{cat}/K_M is the rate constant for the interaction of S and E.



The rate constant $\boldsymbol{k_{cat}/K_M}$, called the **specificity constant**, is a measure of catalytic efficiency because it takes into account both the rate of catalysis with a particular substrate (k_{cat}) and the nature of the enzyme–substrate interaction (K_M). For instance, by using

k_{cat}/K_M values, we can compare an enzyme's preference for different substrates. Table 5.7 shows the k_{cat}, K_M, and k_{cat}/K_M values for several different substrates of chymotrypsin. Chymotrypsin clearly has a preference for cleaving next to bulky, hydrophobic side chains.

TABLE 5.7 Substrate preferences of chymotrypsin

Amino acid in ester	Amino acid side chain	k_{cat}/K_M ($s^{-1}\,M^{-1}$)
Glycine	—H	1.3×10^{-1}
Valine		2.0
Norvaline	$-CH_2CH_2CH_3$	3.6×10^{2}
Norleucine	$-CH_2CH_2CH_2CH_3$	3.0×10^{3}

Phenylalanine	1.0×10^5

How efficient can an enzyme be? We can approach this question by determining whether there are any physical limits on the value of k_{cat}/K_M. Note that the k_{cat}/K_M ratio depends on k_1, k_{-1}, and k_{cat}, as can be shown by substituting for K_M.

$$k_{cat}/K_M = \frac{k_{cat}k_1}{k_{-1}+k_{cat}} = \left(\frac{k_{cat}}{k_{-1}+k_{cat}}\right)k_1 < k_1$$

Note that the value of k_{cat}/K_M is always less than k_1. Suppose that the rate of formation of product (k_{cat}) is much faster than the rate of dissociation of the ES complex (k_{-1}). The value of k_{cat}/K_M then approaches k_1. Thus, the ultimate limit on the value of k_{cat}/K_M is set by k_1, the rate of formation of the ES complex, which is limited by the diffusion-controlled encounter of an enzyme and its substrate. Because diffusion limits the value of k_1, it cannot be higher than between 10^8 and $10^9\ s^{-1}M^{-1}$.

Enzymes that have k_{cat}/K_M ratios in the range of these upper limits, such as superoxide dismutase, acetylcholinesterase, and triose phosphate isomerase, have attained what is called *kinetic perfection*. Their catalytic velocity is restricted only by the rate at which they encounter substrate in the solution (Table 5.8). Any further gain in catalytic rate can come only by decreasing the time for diffusion of the substrate into the enzyme's immediate environment.

TABLE 5.8 Enzymes with k_{cat}/K_M near the diffusion-controlled limit

Enzyme	k_{cat}/K_M ($s^{-1}\,M^{-1}$)
Acetylcholinesterase	1.6×10^8
Carbonic anhydrase	8.3×10^7
Catalase	4×10^7
Crotonase	2.8×10^8
Fumarase	1.6×10^8
Triose phosphate isomerase	2.4×10^8
β-Lactamase	1×10^8
Superoxide dismutase	7×10^9

Source: Information from A. Fersht, *Structure and Mechanism in Protein Science: A Guide to Enzyme Catalysis and Protein Folding* (W. H. Freeman and Company, 1999), Table 4.5.

Remember that the active site is only a small part of the total enzyme structure. Yet, for catalytically perfect enzymes, every encounter between enzyme and substrate is productive. In these cases, there may be attractive electrostatic forces on the enzyme that entice the substrate to the active site. These forces are sometimes referred to poetically as *Circe effects*, named for the figure from Greek mythology known for her powers of seduction and transformation.

The diffusion of a substrate throughout a solution can also be partly overcome by confining substrates and products in the limited volume of a multienzyme complex, such that the product of one enzyme is very rapidly found by the next enzyme. In effect, products are channeled from one enzyme to the next, much as in an assembly line.

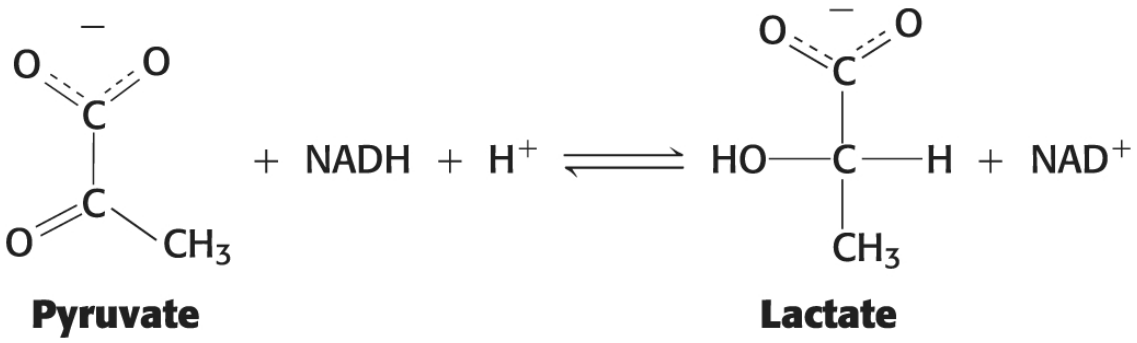
Self-Check Question

If a mutation occurs in the gene encoding an enzyme which decreases k_{cat} for a specific substrate by a factor of 2 and decreases K_M for that substrate by a factor of 3, did the mutation make the enzyme a more or less efficient catalyst with respect to that substrate?

Most biochemical reactions include multiple substrates

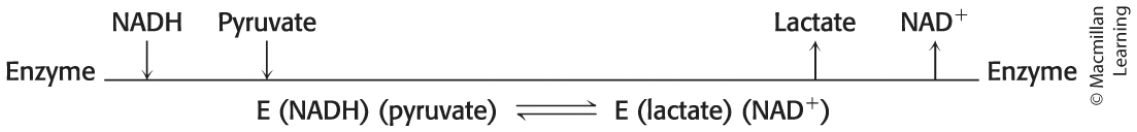
Most reactions in biological systems are bisubstrate reactions, which start with two substrates and yield two products, represented by:

$$A + B \rightleftharpoons P + Q$$



Many bisubstrate reactions transfer a functional group, such as a phosphoryl or an ammonium group, from one substrate to the other. Those that are oxidation–reduction reactions transfer electrons between substrates. Multiple substrate reactions can be divided into two classes: sequential reactions and double-displacement reactions.

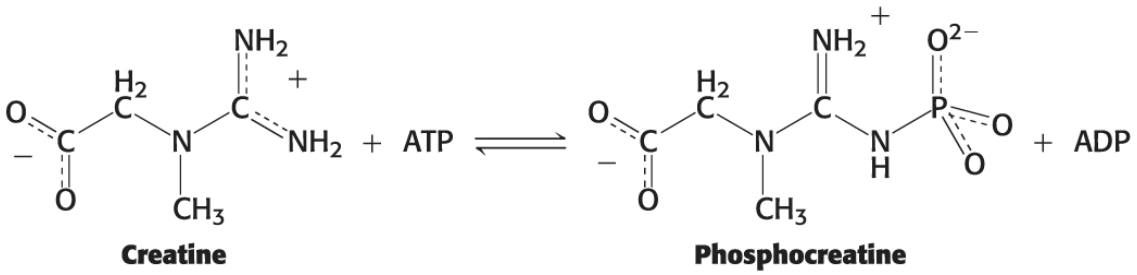
Sequential reactions



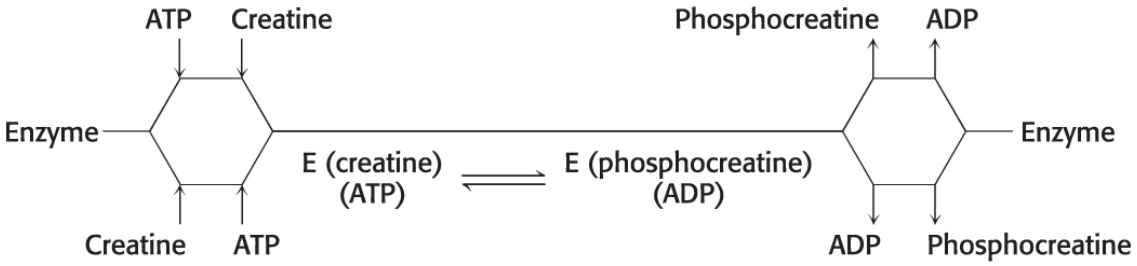
In **sequential reactions**, all substrates must bind to the enzyme before any product is released. Specifically, in a bisubstrate reaction, a ternary complex — composed of the enzyme and both substrates — forms.

- *In ordered sequential mechanisms, the substrates bind the enzyme in a defined sequence*. For example, many enzymes that have NAD^+ or NADH as a substrate exhibit the ordered sequential mechanism. Consider lactate dehydrogenase, an important

enzyme in glucose metabolism (Section 16.1). This enzyme reduces pyruvate to lactate while oxidizing NADH to NAD^+.



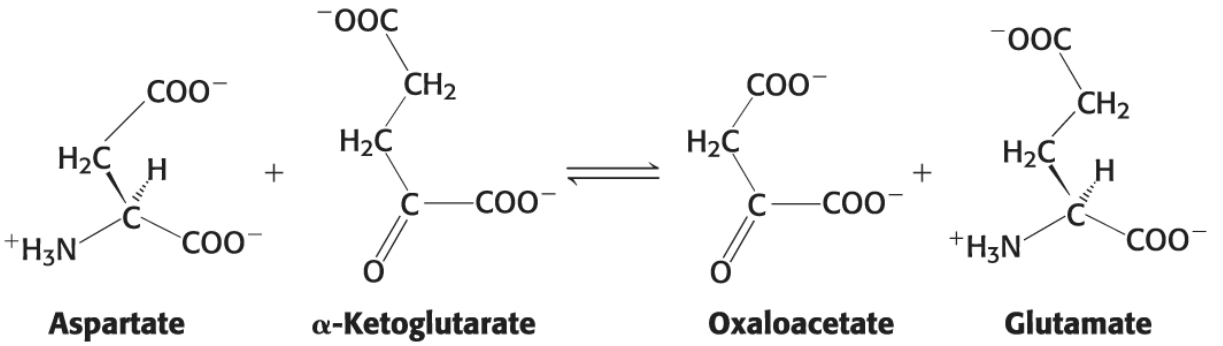
In the ordered sequential mechanism, the coenzyme always binds first, and the lactate is always released first. This sequence can be represented by using a notation developed by W. Wallace Cleland:



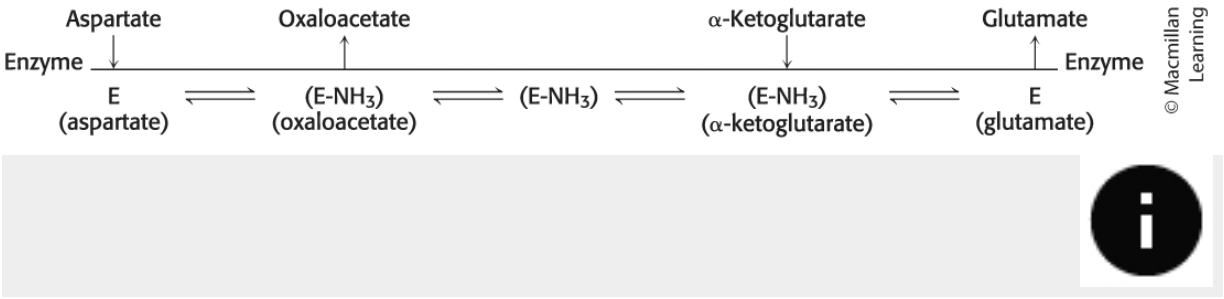
The enzyme exists as a ternary complex consisting of, first, the enzyme and substrates and, after catalysis, the enzyme and products.

- *In the random sequential mechanism, the order of the addition of substrates and the release of products is arbitrary*. An example of a random sequential reaction is the formation of phosphocreatine and ADP from creatine and ATP which is catalyzed by creatine kinase (Section 15.2).

Either creatine or ATP may bind first, and either phosphocreatine or ADP may be released first. Phosphocreatine is an important energy source in muscle. Random sequential reactions also can be depicted in the Cleland notation.



Although the order of certain events is random, the reaction still passes through the ternary complexes, including the substrates first and then the products.



Double-displacement reactions

In **double-displacement reactions** (also called **Ping-Pong reactions**), one or more products are released before all substrates bind the enzyme. The defining feature of double-displacement reactions is the existence of an enzyme intermediate in which the enzyme is temporarily modified.

Reactions that shuttle amino groups between amino acids and α-ketoacids are classic examples of double-displacement mechanisms. The enzyme aspartate aminotransferase catalyzes the transfer of an amino group from aspartate to α-ketoglutarate.

The sequence of events can be portrayed as the following Cleland notation:

After aspartate binds to the enzyme, the enzyme accepts aspartate's amino group to form the substituted enzyme intermediate. The first product, oxaloacetate, subsequently departs. The second substrate, α-ketoglutarate, binds to the enzyme, accepts the amino group from the modified enzyme, and is then released as the final product, glutamate. In the Cleland notation, the substrates appear to bounce on and off the enzyme much as a Ping-Pong ball bounces on a table. Note that for double-displacement reactions, substrate binding order is always fixed (ordered) and never random.

Allosteric enzymes often do not obey Michaelis–Menten kinetics

The Michaelis–Menten model has greatly assisted the development of enzymology. Its virtues are simplicity and broad applicability. However, the Michaelis–Menten model cannot account for the kinetic properties of many enzymes. An important group of enzymes that often do not obey Michaelis–Menten kinetics are **allosteric enzymes**, which consist of multiple subunits and multiple active sites. The binding of substrate to one active site can alter the properties of other active sites in the same enzyme molecule (an effect known as *allostery*, Chapter 3). Allosteric enzymes often display sigmoidal plots of the reaction velocity V_0 versus substrate

concentration [S] (**Figure 5.12**), rather than the hyperbolic plots predicted by the Michaelis–Menten equation (see Figure 5.10).

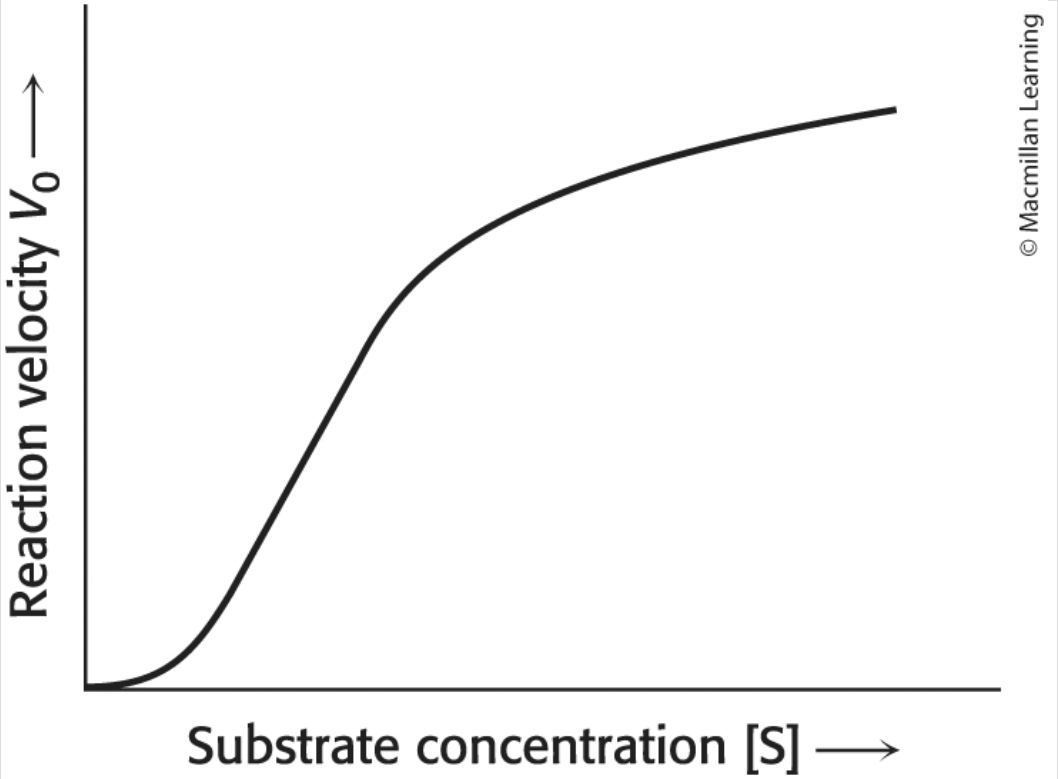


FIGURE 5.12 Allosteric enzymes often display a sigmoidal dependence of reaction velocity on substrate concentration. Shown are the kinetics for an allosteric enzyme exhibiting positive cooperativity.

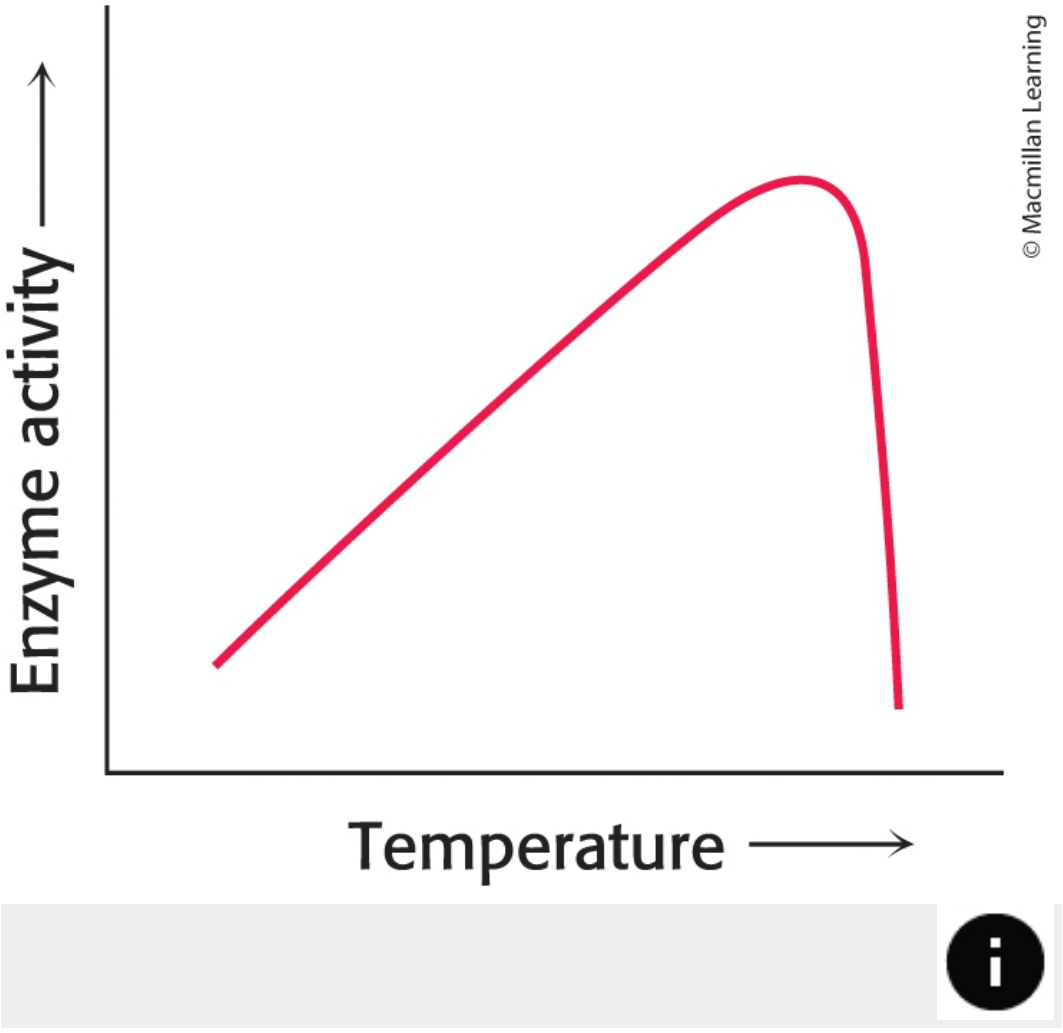


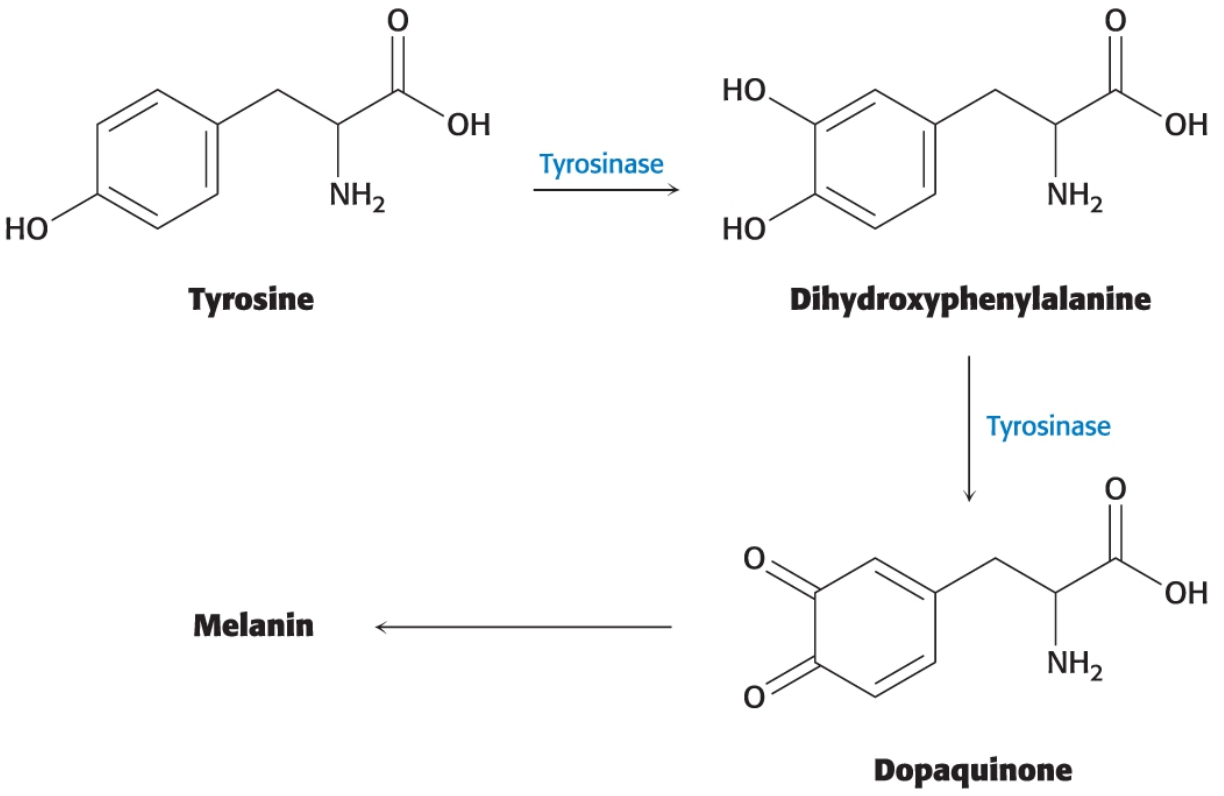
The interaction between an allosteric enzyme's multiple subunits can exhibit positive cooperativity. In other words, the binding of substrate to one active site facilitates the binding of substrate to the other active sites, akin to the behavior of oxygen binding to the multiple subunits of the allosteric protein hemoglobin (see Section 3.3). Such positive cooperativity results in a sigmoidal plot of V_0 versus [S]. In addition, the activity of an allosteric enzyme may be altered by regulatory molecules that reversibly bind to specific sites

other than the catalytic sites. Furthermore, the enzymes themselves can often interconvert between more- or less-active quaternary states, typically denoted as “R” and “T,” respectively, by the conventions established for hemoglobin.

The complexities of allosteric enzymes often require more-elaborate models than the Michaelis–Menten model to account for multiple active sites and quaternary state transitions. The catalytic properties of allosteric enzymes make them key regulators of metabolic pathways in ways we will explore more fully in Chapter 7.

Temperature affects enzymatic activity

As the temperature rises, the rate of most reactions, including enzyme-catalyzed reactions, increases. For most enzymes, there is a temperature at which the increase in catalytic activity ceases and there is a precipitous loss of activity.



What is the basis of this loss of activity? Recall from Chapter 2 that proteins have a complex three-dimensional structure that is held together by weak interactions. When the temperature increases beyond a certain point, the favorable interactions maintaining the three-dimensional structure are not strong enough to withstand the polypeptide chain's thermal jostling, and the protein loses the structure required for activity. The protein is said to be *denatured* (Section 2.7).

In endotherms, organisms such as ourselves that maintain a constant body temperature, the effect of outside temperature on enzyme activity is minimized. However, in ectotherms, organisms

that assume the temperature of their environment, temperature is an important regulator of biochemical and, indeed, biological activity. Lizards, for instance, are most active in warmer temperatures — a behavioral manifestation of biochemical activity.

Although endotherms are not as sensitive to ambient temperature as ectotherms, slight tissue temperature alterations are sometimes important and can even have dramatic effects. For example, the characteristic coloration of Siamese cats can be explained by variation in enzyme sensitivity due to temperature. Their fur color is due to the presence of the pigment melanin, the same pigment that is responsible for human skin color. The first steps in the synthesis of melanin are catalyzed by the enzyme tyrosinase:

Most Siamese cats are born with very little coloration; sometimes they are even white. As they mature, their extremities — tips of the ears, snout, paws, and end of the tail — darken to black. A hint to understanding this phenomenon comes from the knowledge that a cat's skin temperature is coolest at the extremities. Biochemists have established that there is a mutation in the Siamese tyrosinase that results in a loss of activity above 37-39°C. The temperature of a Siamese kitten is too warm for the enzyme to be active, but as the kitten grows, the temperature at its extremities cools enough to allow the enzyme to become active and pigment to form. The core of the cat's body remains above the threshold temperature, however, and thus remains pale in color.

5.5 Enzymes Can Be Studied One Molecule at a Time

Most experiments performed to determine an enzyme's characteristics use an enzyme preparation in a buffered solution. Even a few microliters of such a solution will contain millions of enzyme molecules. Experiments on this scale, called *ensemble studies*, make the basic assumption that all of the enzyme molecules are the same or very similar. For example, when we determine an enzymatic property such as the value of K_M in ensemble studies, we assume that value is an average value of all of the enzyme molecules present.

Keep in mind, however, that individual enzyme molecules behave stochastically, as we saw for DNA double helix formation in Chapter 1. New methods, dubbed *single-molecule experiments*, now allow one individual molecule to be examined at a time, yielding a great deal of new information but with a potential pitfall: how can we be certain that the molecule is representative and not an outlier? We can overcome this challenge by studying enough individuals to satisfy statistical analysis for validity.

Let us consider a biochemical situation. **Figure 5.13A** shows a hypothetical enzyme that displays molecular heterogeneity, with three active forms that catalyze the same reaction but at different rates. These forms have slightly different stabilities, but thermal motion is sufficient to interconvert them. Each form is present as a fraction of the total enzyme population, as indicated. If we were to perform an ensemble method experiment to determine enzyme activity under a particular set of conditions, we would get a single

value, which would represent the average of the heterogeneous assembly (Figure 5.13B). However, were we to perform a sufficient number of single-molecule experiments, we would discover that the enzyme has three different molecular forms with very different activities (Figure 5.13C). Moreover, these different forms would most likely correspond to important biochemical differences.

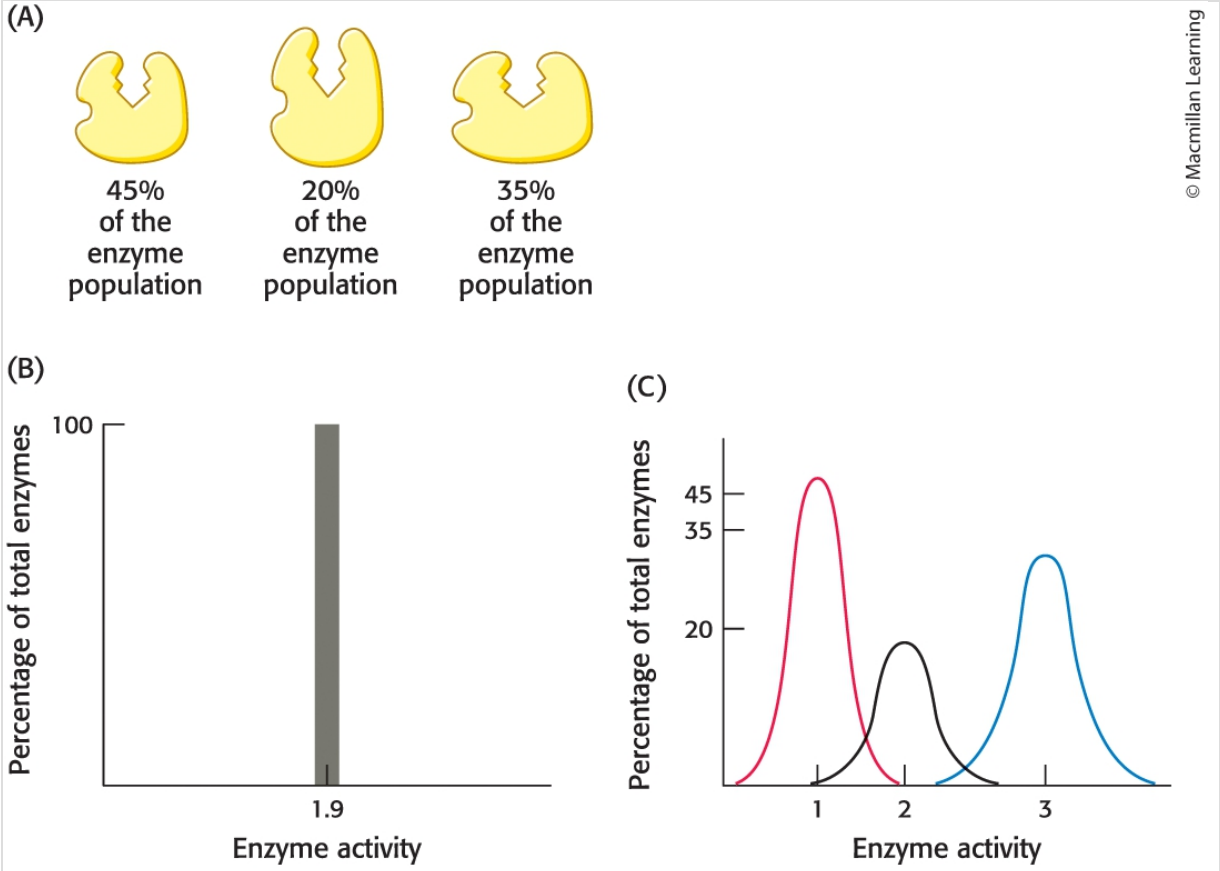


FIGURE 5.13 Single-molecule studies can reveal molecular heterogeneity. (A) Complex biomolecules, such as enzymes, display molecular heterogeneity. (B) When measuring an enzyme property using ensemble methods, an average value of all of the enzymes present can be obtained. (C) Single-enzyme studies reveal molecular heterogeneity, with the various forms showing different properties.

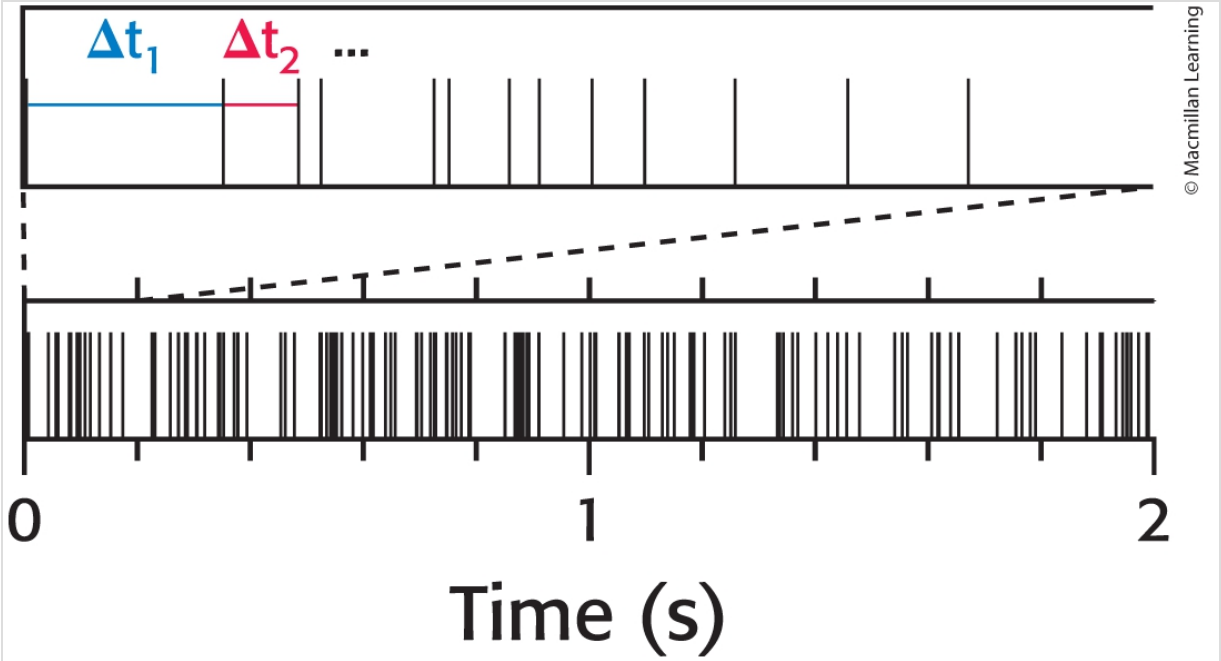
Single-molecule kinetics confirm results obtained from ensemble studies

Now suppose that we watch an individual enzyme molecule in action, monitoring every time it produces a molecule of product. **Figure 5.14** illustrates what we would expect to see, with each line representing a single reaction event. Because individual enzyme molecules behave stochastically, the time between consecutive reaction events appears to vary randomly. However, if we watch an individual enzyme molecule turn over many thousands of times, we find a pattern in the distribution of the time intervals separating consecutive events that allows us to state the anticipated relationship between the average time increments at different substrate concentrations as

$$1/(\text{Time increment})_{\text{average}} = k_2[S]/([S] + K_M)$$

The output from this equation, called the *single-molecule Michaelis–Menten equation*, reveals the same saturation behavior for reaction rates that we observe for ensemble studies of enzymes. In fact, plotting the reciprocal of the average time increment at different substrate concentrations produces a Michaelis–Menten saturation curve, which can also be visualized as a Lineweaver–Burk plot, as we will see shortly. This illustrates a reassuring finding of single-molecule methods: they often reaffirm observations made by ensemble methods.



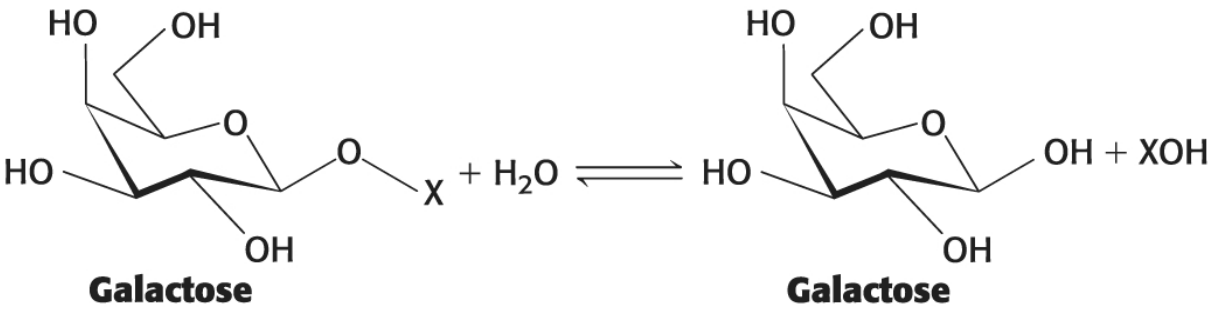


FIGURE 5.14 An anticipated time course for a single-enzyme molecule reveals stochastic behavior. Each line represents an enzyme molecule turning a substrate molecule into product. These events occur stochastically, with variable time increments between consecutive events.

Up to this point, we have discussed monitoring hypothetical enzymes. We now turn to a real example, the enzyme β-galactosidase from *E. coli*, which allows this bacterium to utilize certain sugars. Studies of this enzyme played a central role in elucidating fundamental mechanisms in gene regulation, to be discussed in Chapter 31. This enzyme catalyzes reactions of the form

While the enzyme is quite specific for the carbohydrate galactose (to be discussed in Chapter 11), substantial variations in the other half of the substrate can be accommodated, permitting the binding of probe substrates such as Substrate G-R (**Figure 5.15**). Cleavage of this substrate by β-galactosidase releases a fluorescent product.

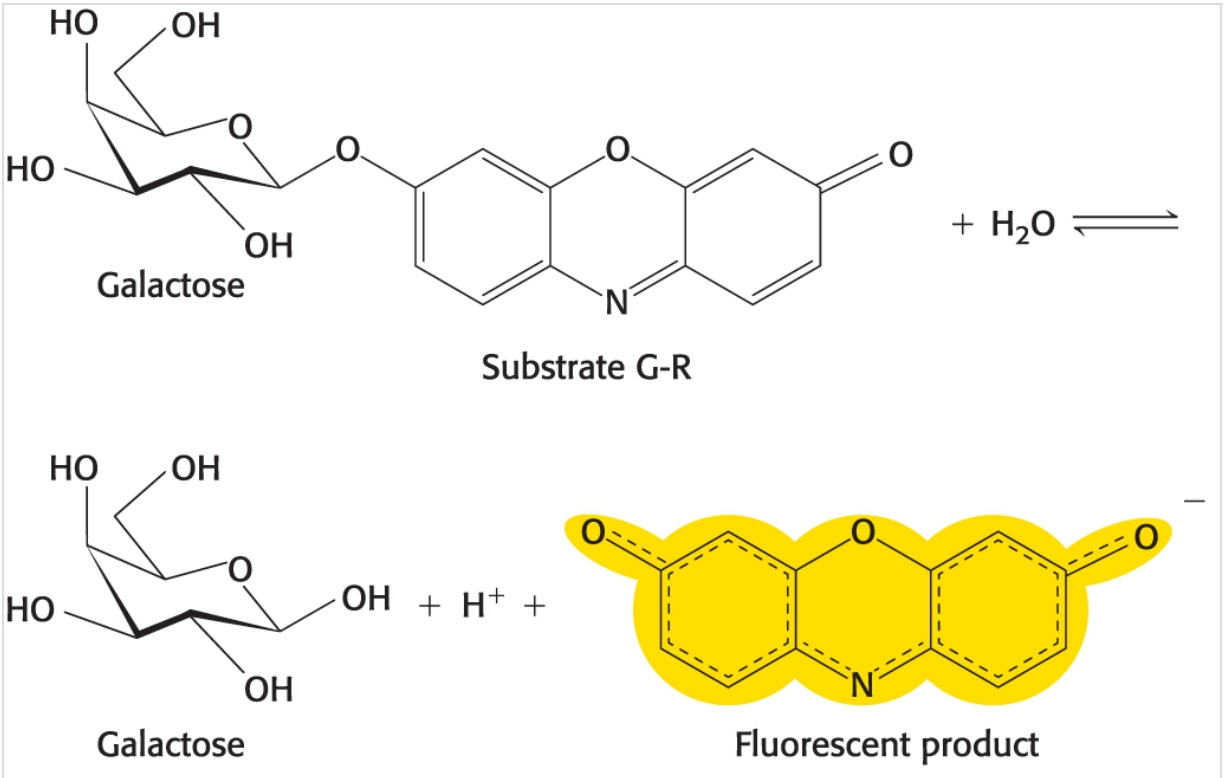

FIGURE 5.15 Upon reaction with β-galactosidase, Substrate G-R produces a highly fluorescent product. The formation of individual molecules of this product can be detected,

allowing for the observation of single-enzyme turnovers to be tracked.

Using immobilized enzyme molecules and a fluorescence microscope, product release (and, hence, enzyme activity) can be monitored directly at the single-molecule level. With this system, experiments were performed at a range of substrate concentrations and the results compared with those obtained from ensemble studies using the same enzyme and substrate (**Figure 5.16**).

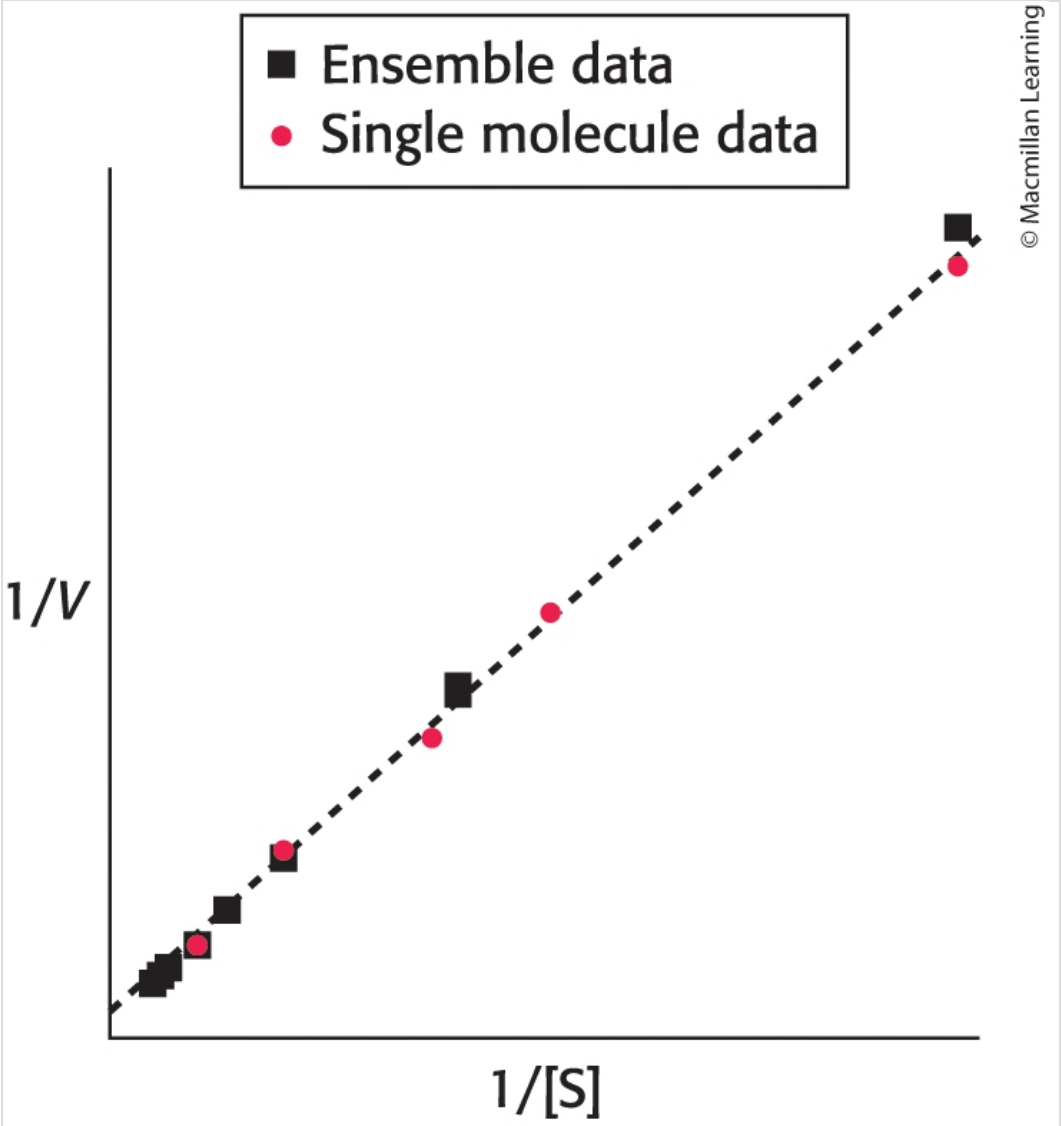

FIGURE 5.16 Lineweaver–Burk plots of single-molecule data compare favorably to those from ensemble studies. The results from single-molecule kinetic studies of β-galactosidase (red) are nearly indistinguishable from those from ensemble studies of the same enzyme at the same substrate concentration (black).

[Adapted from B. P. English et al., *Nature Chemical Biology* 2:87–94, 2006.]

Single-molecule studies continue to reveal new information about enzyme molecular dynamics

While it is quite reassuring to see in a real example that the results of technically challenging single-molecule studies agree so well with those of ensemble studies, the single-molecule results don't tell us anything new about enzyme behavior. However, depicting the distribution of time increments on a log plot does reveal an important new insight (**Figure 5.17**). At a low substrate concentration of $10\ \mu M$, this plot is relatively linear. However, at a higher concentration of $100\ \mu M$, this plot is decidedly nonlinear, changing from a relatively steep slope at short time increments to a more gradual slope at longer time increments.

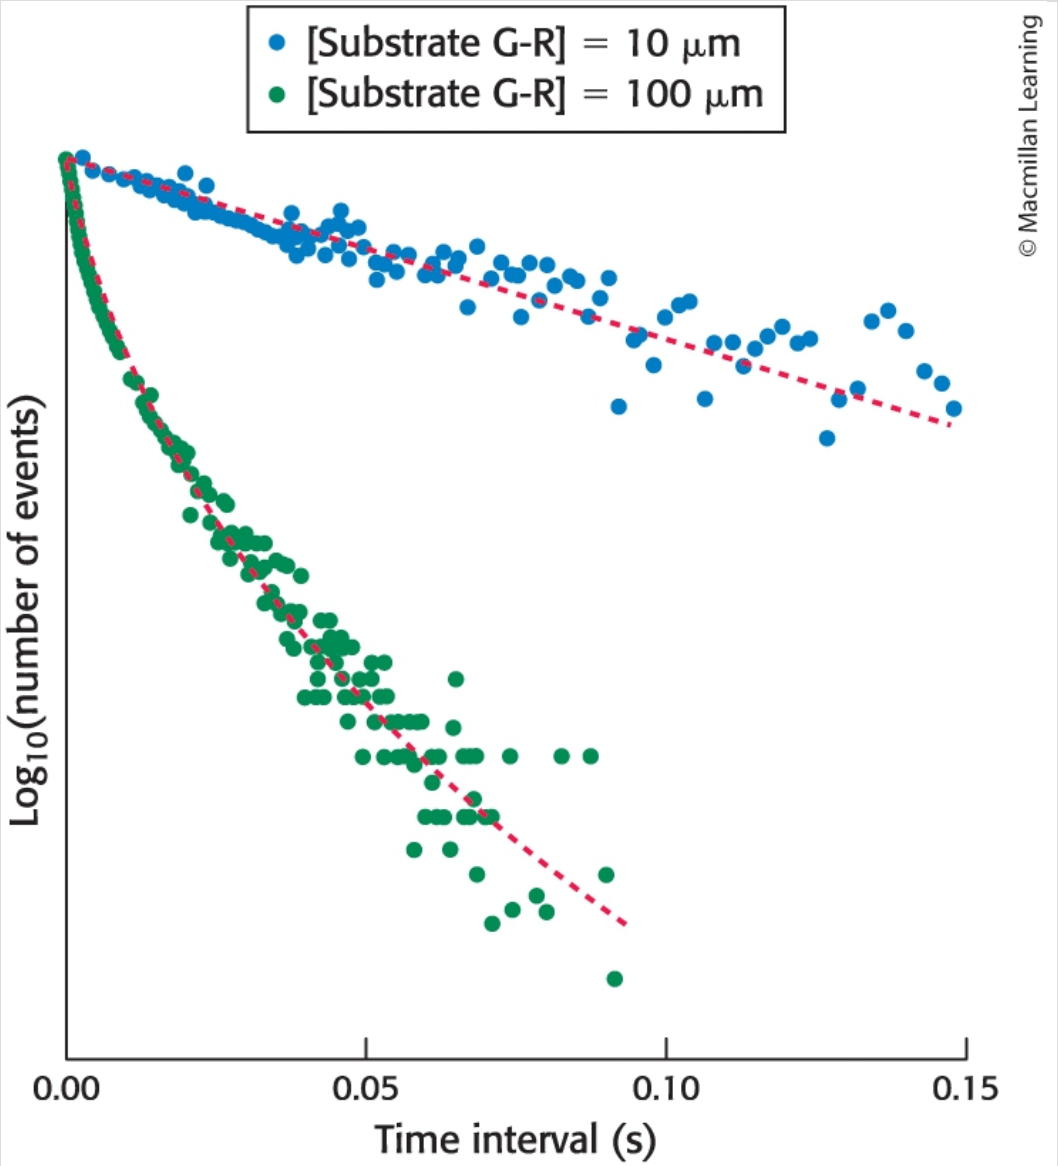

FIGURE 5.17 Details of single-molecule time increment distributions for β-galactosidase indicate heterogeneity at the molecular level. At a relatively high substrate concentration (100 μM), a plot of the logarithm of the number of events in each time interval is not linear, indicated by the distribution not following a simple exponential fall off. This observation reveals that the enzyme cannot be modeled as a single species at the single-molecule level.

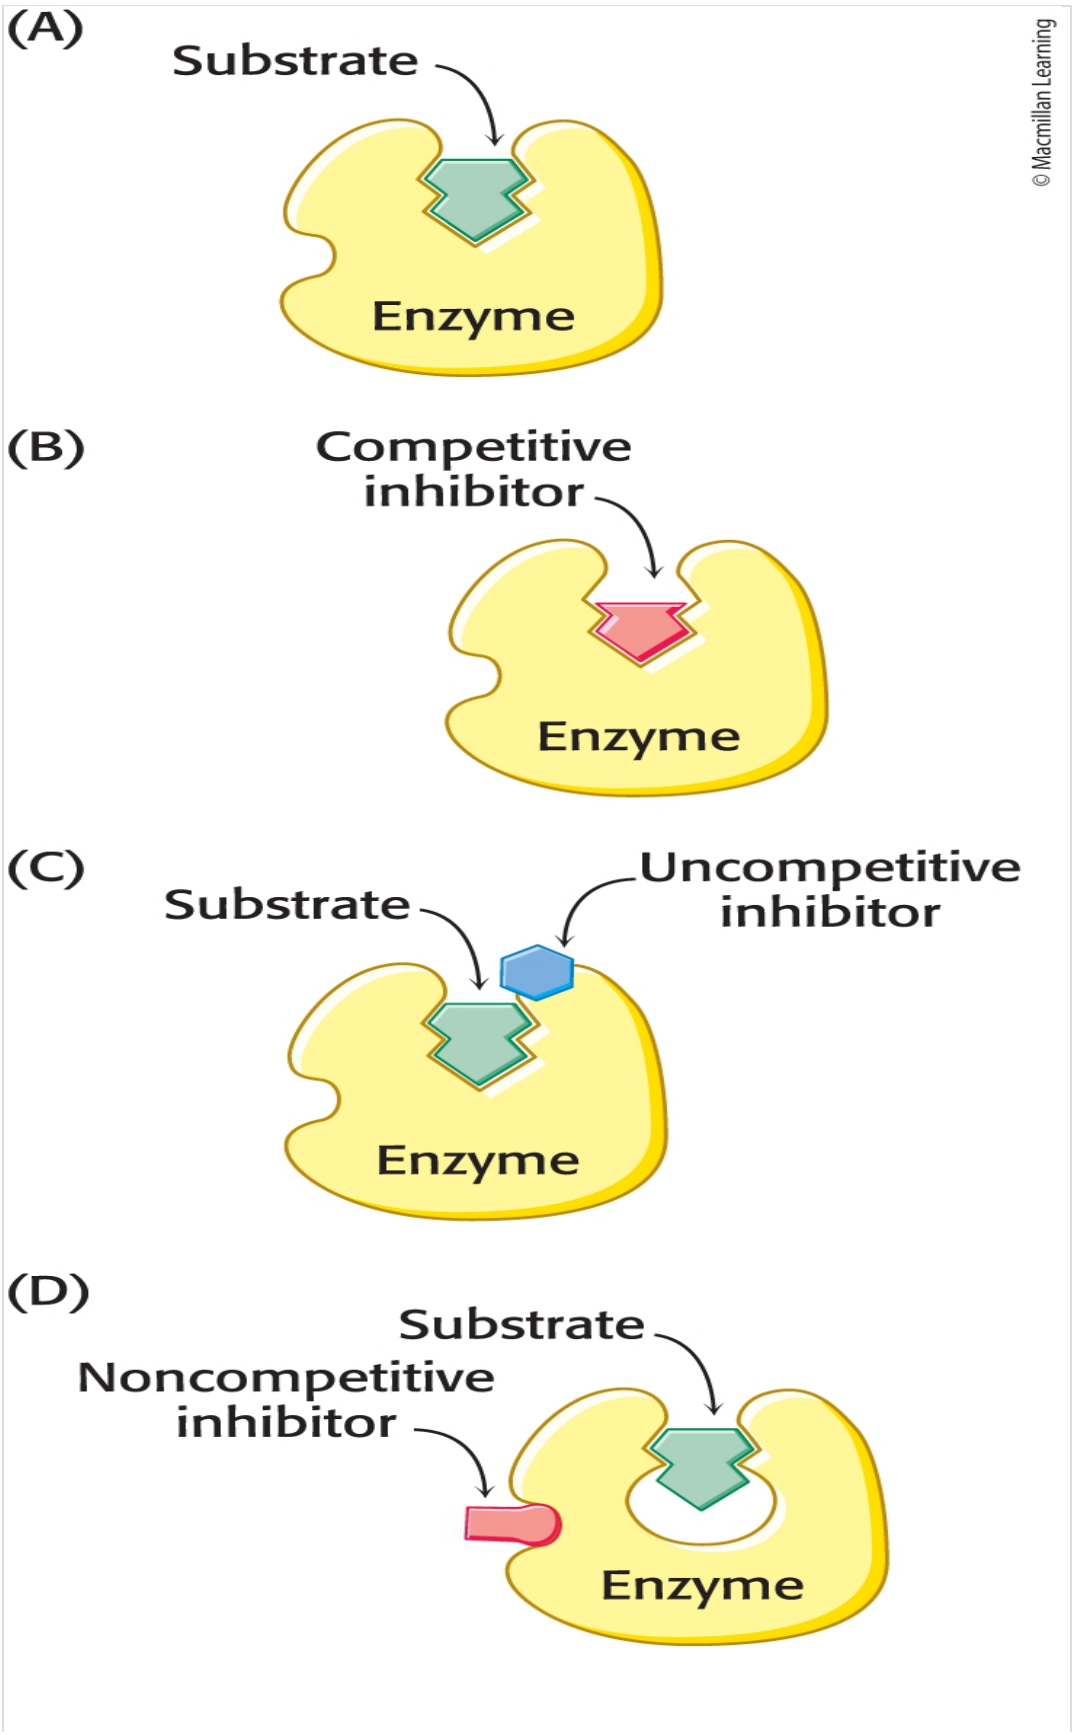
[Adapted from B. P. English et al., *Nature Chemical Biology* 2:87–94, 2006.]

We can explain this observation in terms of the dynamic nature of individual enzyme molecules. Each molecule can exist and convert between multiple conformational states, as we envisioned hypothetically in Figure 5.13, each conformation having distinct catalytic properties. The structural differences of these conformational states could be as simple as the orientations of particular side chains or as complex as large, interdomain movements. Further studies are required to gain such structural information, but regardless of the structural details, single-molecule experiments provide direct evidence for a critical aspect of enzymes: their dynamic nature.

Using the many powerful single-molecule techniques that now exist, we can observe events at a molecular level to reveal rare or transient structures and fleeting events in a reaction sequence, as well as to measure mechanical forces affecting or generated by an enzyme. Single-molecule studies open a new vista on the function of enzymes in particular and all large biomolecules in general. We will examine additional single-molecule studies in future chapters.

5.6 Enzymes Can Be Inhibited by Specific Molecules



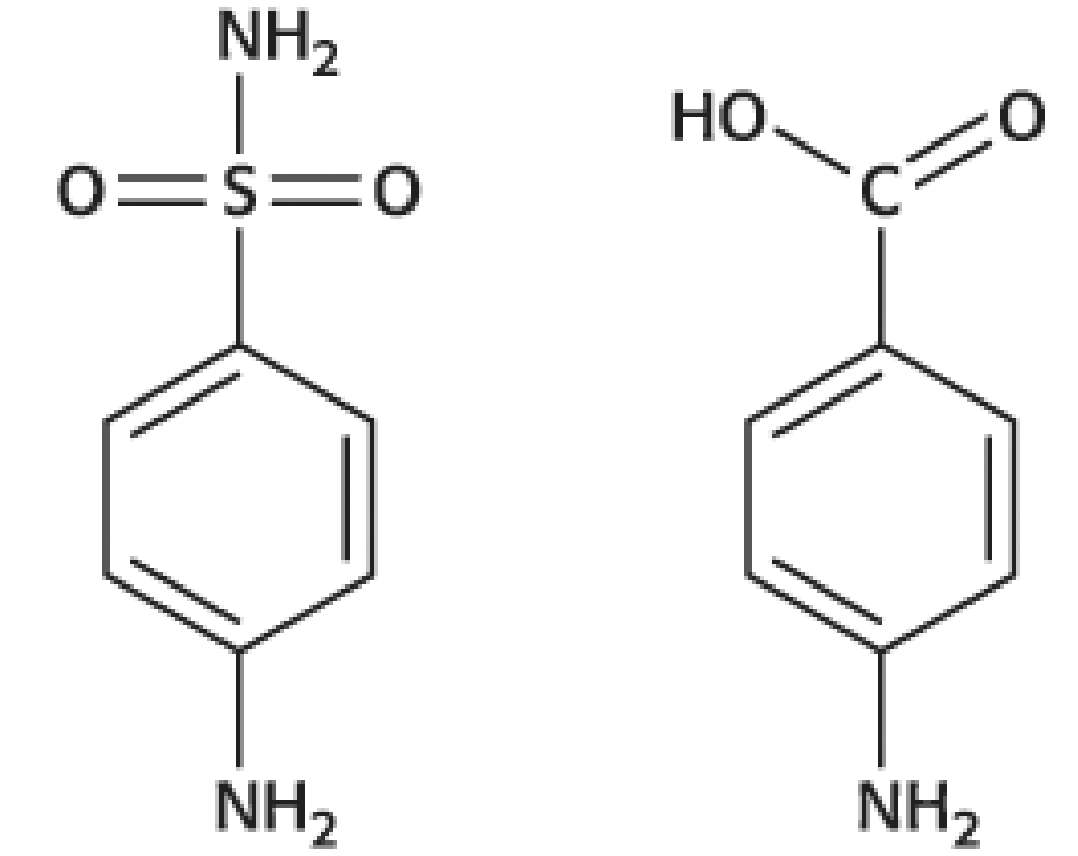
The activity of many enzymes can be inhibited by the binding of specific small molecules and ions. Enzyme inhibition serves as a major control mechanism in biological systems, especially by regulating the activity of allosteric enzymes. In addition, many drugs and toxic agents act by inhibiting enzymes (Chapter 32). These inhibitors are often designed by scientists or result from a chance discovery of an inhibitory molecule. Examining inhibition can give insight into the mechanism of enzyme action; for example, specific inhibitors are often used to identify residues critical for catalysis. Enzyme inhibition can be either irreversible or reversible.

- *An irreversible inhibitor covalently bonds to its target enzyme and thus does not dissociate at any appreciable rate*. The mode of action of some important drugs is irreversible inhibition. For example, as we will discuss shortly, penicillin acts by covalently modifying the enzyme transpeptidase, thereby preventing the synthesis of bacterial cell walls and thus killing the bacteria. Aspirin acts by covalently modifying the enzyme cyclooxygenase, reducing the synthesis of signaling molecules in inflammation.

- *Reversible inhibition is characterized by the dissociation of the enzyme–inhibitor complex, which is formed by noncovalent interactions*. Depending on their target and their effect, reversible inhibitors are classified as competitive, uncompetitive, or noncompetitive.

In **competitive inhibition**, the inhibitor competes with the substrate for binding to the enzyme and thus reduces the proportion of enzyme molecules bound to substrate. The enzyme can bind the substrate (**Figure 5.18A**) or an inhibitor (**Figure 5.18B**), but not both at the same time. Competitive inhibitors can bind anywhere on the enzyme, but

they most often resemble the substrate and bind to the active site. The substrate is thereby prevented from binding to the same active site. At any given inhibitor concentration, competitive inhibition can be relieved by increasing the substrate concentration. Under these conditions, the substrate successfully competes with the inhibitor for the enzyme.



© Macmillan Learning

FIGURE 5.18 Reversible inhibitors can be distinguished by whether they bind to the enzyme with or without the substrate present. (A) An enzyme–substrate complex; (B) competitive inhibitors prevent the substrate from binding, usually by themselves binding at the active site; (C) an uncompetitive inhibitor binds only to the enzyme–substrate complex; (D) a pure noncompetitive inhibitor does not affect the binding of substrate.

Many competitive inhibitors are useful drugs. Drugs such as ibuprofen are competitive inhibitors of enzymes that participate in signaling pathways in the inflammatory response. Statins are drugs that reduce high cholesterol levels by competitively inhibiting a key enzyme in cholesterol biosynthesis (Section 26.3). One of the earliest examples was the use of sulfanilamide as an antibiotic. Sulfanilamide is an example of a sulfa drug, a sulfur-containing antibiotic. Structurally, sulfanilamide mimics *p*-aminobenzoic acid (PABA), a metabolite required by bacteria for the synthesis of the coenzyme folic acid. Sulfanilamide binds to the enzyme that normally metabolizes PABA and competitively inhibits it, preventing folic acid synthesis. Human beings, unlike bacteria, absorb folic acid from the diet and are thus unaffected by the sulfa drug.

In **uncompetitive inhibition**, the inhibitor binds not to the enzyme itself but to the enzyme–substrate complex; it is therefore substrate-dependent. The binding site of an uncompetitive inhibitor is created only on interaction of the enzyme and substrate (**Figure 5.18C**). Uncompetitive inhibitors inhibit catalysis, rather than prevent substrate binding, and cannot be overcome by the addition of more substrate. The herbicide glyphosate, also known as Roundup, is an uncompetitive inhibitor of an enzyme in the biosynthetic pathway for aromatic amino acids.

In **pure noncompetitive inhibition**, the inhibitor and substrate can bind simultaneously to an enzyme molecule at two different binding sites (**Figure 5.18D**). Unlike competitive or uncompetitive inhibition, a noncompetitive inhibitor can bind free enzyme or the enzyme–substrate complex, but in either case it decreases the rate catalysis.

Noncompetitive inhibitors can be either pure or mixed. A pure noncompetitive inhibitor binds equally well to the enzyme with or without substrate bound, and the effect is that only turnover number is decreased. Thus, pure noncompetitive inhibitors act by decreasing the concentration of functional enzyme rather than by altering the proportion of enzyme molecules that are bound to substrate. Noncompetitive inhibition, like uncompetitive inhibition, cannot be overcome by increasing the substrate concentration. **Mixed noncompetitive inhibition** is more complex in that the inhibitor binds preferentially to either the free enzyme or the enzyme–substrate complex, resulting in a pattern of inhibition that alters both substrate binding and turnover number simultaneously. The commonly prescribed antibiotic doxycycline, which is used to treat periodontal disease, functions at low concentrations as a noncompetitive inhibitor of a proteolytic enzyme (collagenase).

The different types of reversible inhibitors are kinetically distinguishable

How can we determine whether a reversible inhibitor acts by competitive, uncompetitive, or noncompetitive inhibition? Considering only enzymes that exhibit Michaelis–Menten kinetics, we can use measurements of the rates of catalysis at different concentrations of substrate and inhibitor and Lineweaver–Burk plots as clues to which type of reversible inhibition is occurring.

Competitive inhibition

In competitive inhibition, where the inhibitor competes with the substrate for the enzyme, the dissociation constant for the inhibitor is given by

$$K_i = [E][I]/[EI]$$

The smaller the K_i, the more potent the inhibition. The hallmark of competitive inhibition is that it can be overcome by a sufficiently high concentration of substrate (**Figure 5.19**). The effect of a competitive inhibitor is to increase the apparent value of K_M, meaning that more substrate is needed to obtain the same reaction rate. This new apparent value of K_M, called K_M^{app}, is numerically equal to

$$K_M^{app} = K_M(1 + [I]/K_i)$$

where [I] is the concentration of inhibitor and K_i is the dissociation constant for the enzyme–inhibitor complex. In the presence of a competitive inhibitor, an enzyme will have the same V_{max} as in the absence of an inhibitor. At a sufficiently high concentration, virtually all the active sites are filled with substrate, and the enzyme is fully operative.

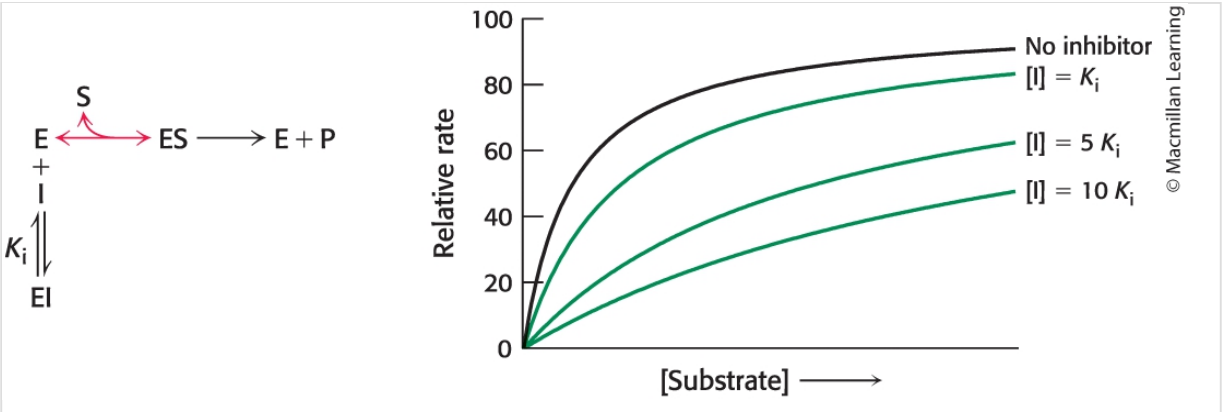


FIGURE 5.19 Michaelis–Menten plots of a competitive inhibitor reveal changes in the apparent K_M but not V_{max}. As the concentration of a competitive inhibitor increases, higher concentrations of substrate are required to attain a particular reaction velocity. The reaction pathway suggests how sufficiently high concentrations of substrate can completely relieve competitive inhibition resulting in the same V_{max} value at infinite substrate concentration.

A Lineweaver–Burk plot can also reveal competitive inhibition. In competitive inhibition, the intercept on the *y*-axis of the plot of $1/V_0$ versus $1/[S]$ is the same in the presence and in the absence of inhibitor, although the slope is increased (Figure 5.20).

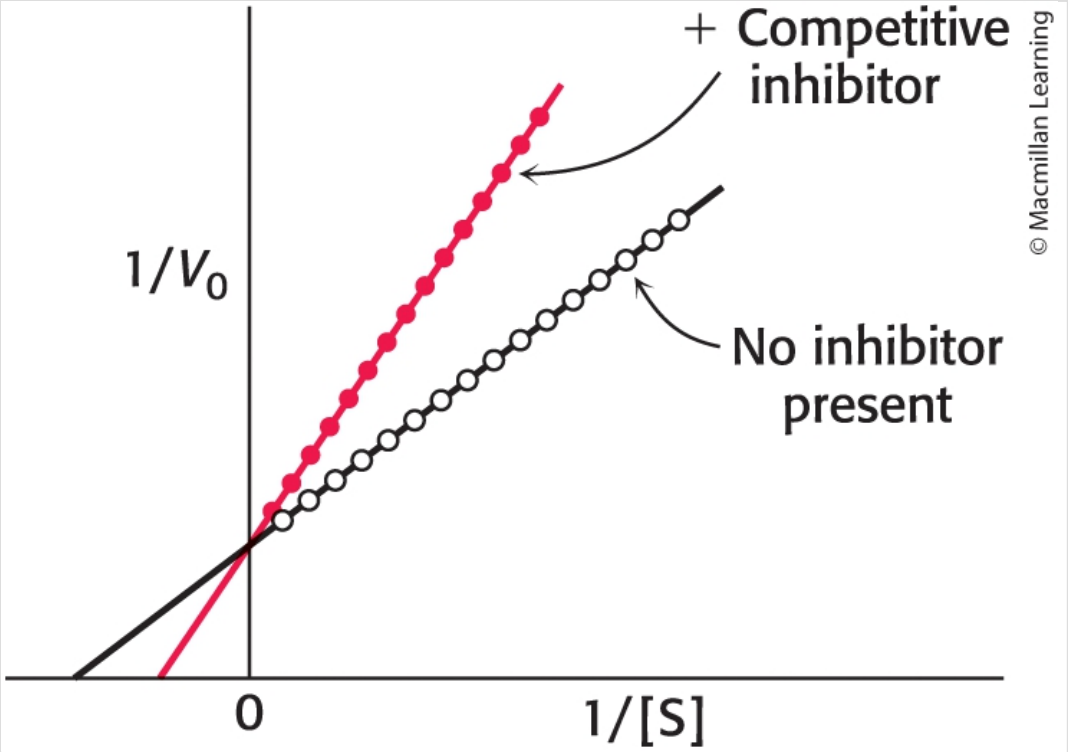

FIGURE 5.20 Competitive inhibition is easily recognized using a Lineweaver–Burk plot. A Lineweaver–Burk plot of enzyme kinetics in the presence and absence of a competitive inhibitor illustrates that the inhibitor has no effect on V_{max} but increases the apparent K_M.

The intercept is unchanged because a competitive inhibitor does not alter V_{max}. The increase in the slope of the $1/V_0$ versus $1/[S]$ plot indicates the strength of binding of a competitive inhibitor. In the presence of a competitive inhibitor, equation 18 is replaced by

$$\frac{1}{V_0} = \frac{1}{V_{max}} + \frac{K_M}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)\left(\frac{1}{[S]}\right) \quad \textbf{(22)}$$

In other words, the slope of the plot is increased by the factor $(1 + [I]/K_i)$ in the presence of a competitive inhibitor. Consider an enzyme with a K_M of 10^{-4} M. In the absence of inhibitor, when $V_0 = V_{max}/2$, $[S] = 10^{-4}$ M. In the presence of a 2×10^{-3} M competitive inhibitor that is bound to the enzyme with a K_i of 10^{-3} M, the apparent K_M (K_M^{app}) will be equal to $K_M(1 + [I]/K_i)$, or 3×10^{-4} M. Substitution of these values into equation 22 gives $V_0 = V_{max}/4$, when $[S] = 10^{-4}$ M. Thus, the presence of the competitive inhibitor cuts the reaction rate in half at this substrate concentration.

Uncompetitive inhibition

In uncompetitive inhibition, where the inhibitor binds only to the ES complex, the resulting enzyme–substrate–inhibitor (ESI) complex does not go on to form any product. Because some unproductive ESI complex will always be present, V_{max} will be lower in the presence of inhibitor than in its absence (**Figure 5.21**). The uncompetitive inhibitor lowers the apparent value of K_M because the inhibitor binds to ES to form ESI, depleting ES. To maintain the equilibrium between E and ES, more S binds to E, increasing the apparent value of k_1 and thereby reducing the apparent value of K_M (see equation 13). Thus, a lower concentration of S is required to form half of the maximal concentration of ES.

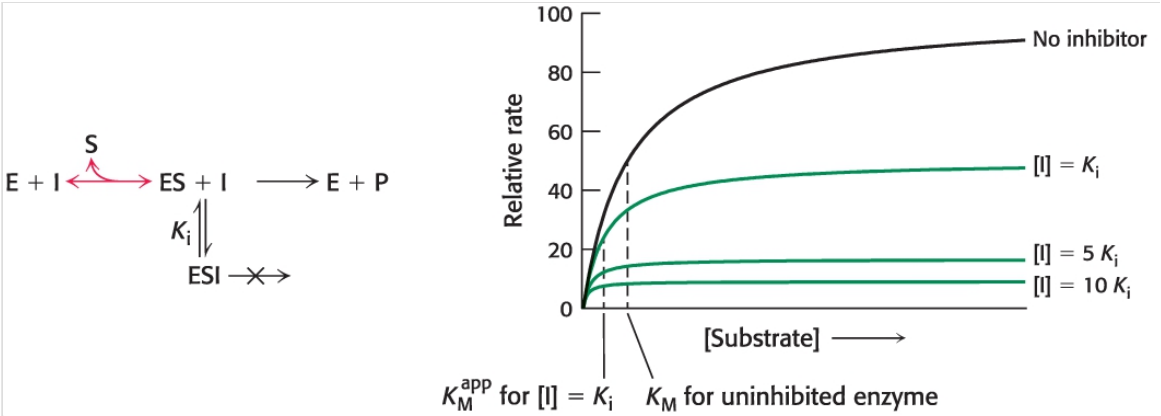

FIGURE 5.21 Michaelis–Menten plots of an uncompetitive inhibitor reveal decreases in both the apparent K_M and V_{max}. The reaction pathway shows that the inhibitor binds only to the enzyme–substrate complex. Consequently, V_{max} cannot be attained, even at high substrate concentrations. The apparent value for K_M is lowered, becoming smaller as more inhibitor is added.

The equation that describes the Lineweaver–Burk plot for an uncompetitive inhibitor is

$$\frac{1}{V_0} = \frac{K_M}{V_{max}}\left(\frac{1}{[S]}\right) + \frac{1}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)$$

The slope of the line, K_M / V_{max}, is the same as that for the uninhibited enzyme, but the intercept on the *y*-axis will be increased by $1 + [I]/K_i$. Consequently, the lines in Lineweaver–Burk plots will be parallel (Figure 5.22).

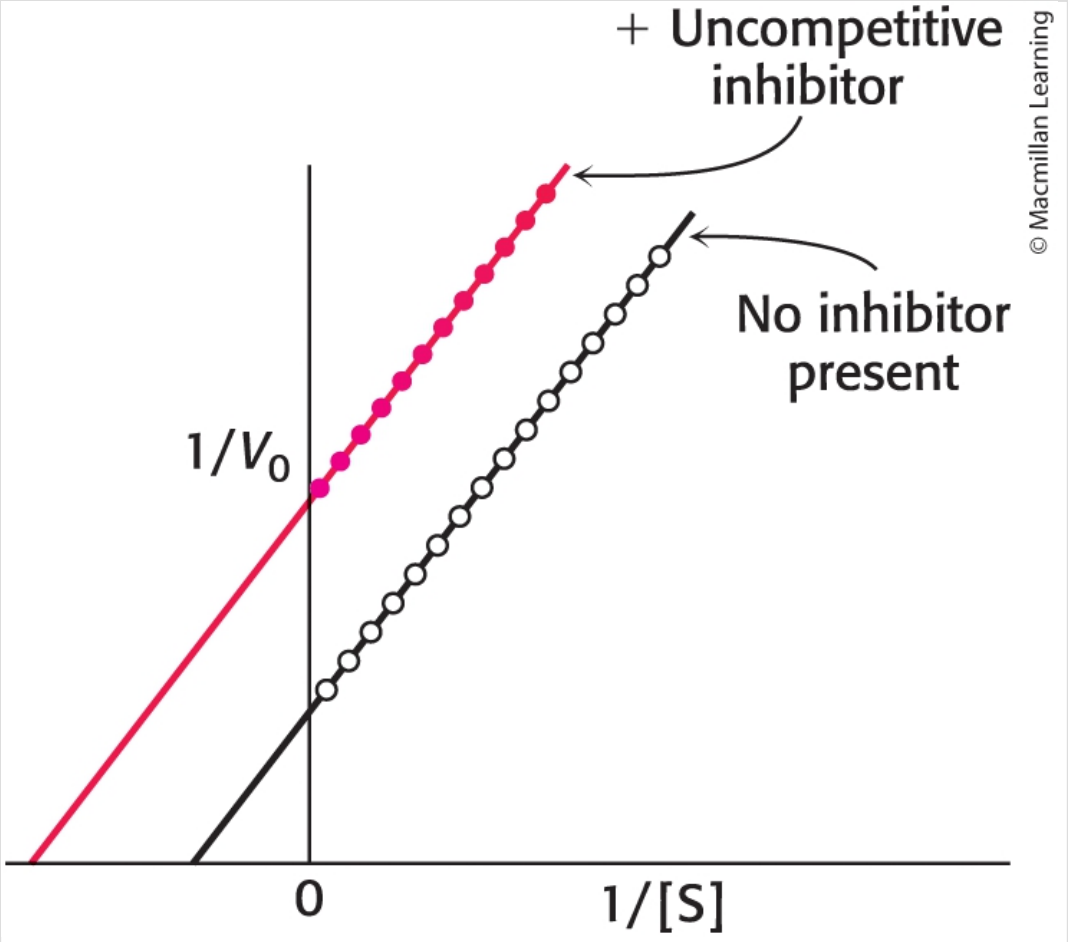

FIGURE 5.22 Uncompetitive inhibition is easily distinguished by parallel lines in a Lineweaver–Burk plot. An uncompetitive inhibitor does not affect the slope of the Lineweaver–Burk plot. V_{max} and K_M are reduced by equivalent amounts.

Noncompetitive inhibition

Recall that in noncompetitive inhibition, the inhibitor can bind at a different site from the substrate either the enzyme or the enzyme–substrate complex; in either case, the enzyme–inhibitor–substrate complex does not proceed to form product. In pure noncompetitive

inhibition, the K_i for the inhibitor binding to E is the same as for binding to ES complex (Figure 5.23).

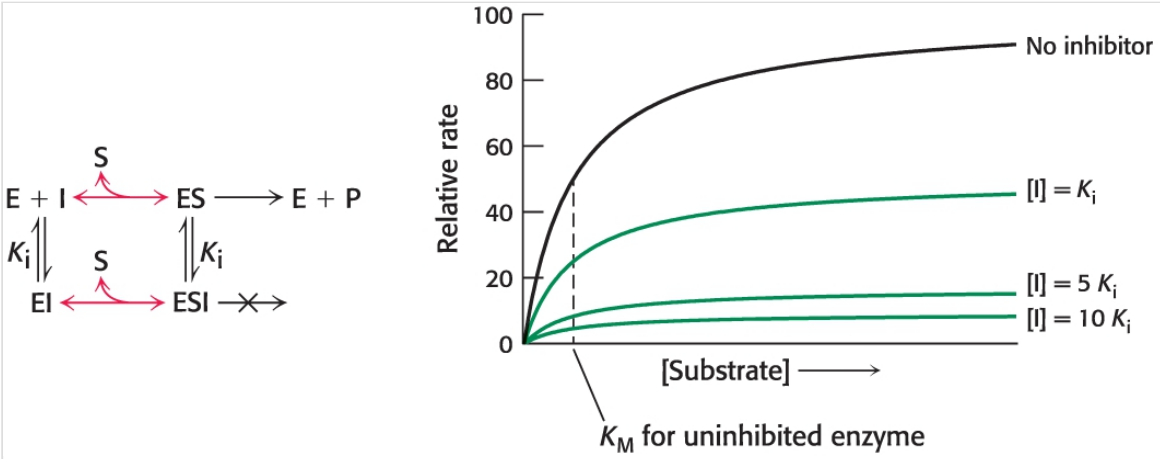

FIGURE 5.23 Michaelis–Menten plots of a pure noncompetitive inhibitor reveal a decrease in V_{max}, while K_M remains unchanged. The reaction pathway shows that the inhibitor binds both to free enzyme and to an enzyme–substrate complex. Consequently, as with uncompetitiv inhibition, V_{max} cannot be attained. In pure noncompetitive inhibition, K_M remains unchanged, and so the reaction rate increases more slowly at low substrate concentrations tha is the case for uncompetitive competition.

The apparent value of V_{max} is decreased to a new value called V_{max}^{app}, whereas the value of K_M is unchanged. The maximal velocity in the presence of a pure noncompetitive inhibitor, V_{max}^{app}, is given by

$$V_{max}^{app} = \frac{V_{max}}{1 + [I]/K_i} \quad (23)$$

Why is V_{max} lowered though K_M remains unchanged? In essence, the inhibitor simply lowers the concentration of functional enzyme because some quantity of enzyme is always bound to the inhibitor and inactive at any given moment, regardless of the substrate concentration. Because the inhibitor and the substrate do not affect the binding of one another, pure noncompetitive inhibition cannot be overcome by increasing the substrate concentration.

In the Lineweaver–Burk plot for pure noncompetitive inhibition (**Figure 5.24**), the value of V_{max} is decreased to the new value V_{max}^{app}, and so the intercept on the vertical axis is increased (equation 23). The new slope, which is equal to K_M / V_{max}^{app}, is larger by the same factor. In contrast with V_{max}, K_M is not affected by pure noncompetitive inhibition.

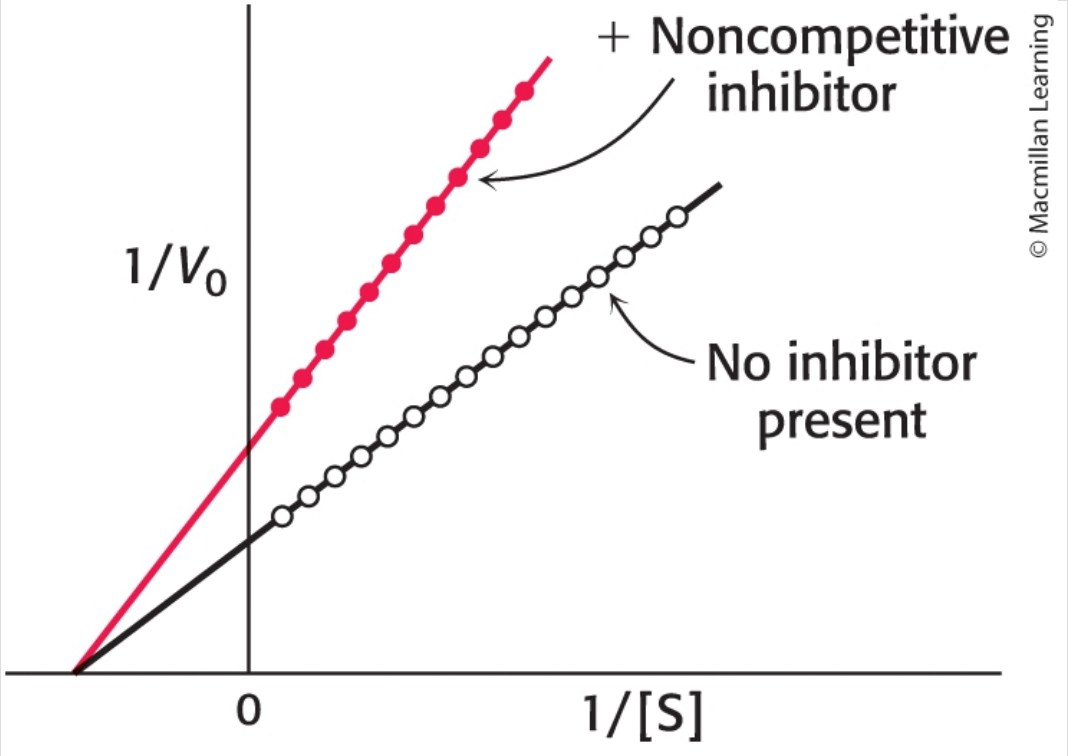

FIGURE 5.24 Pure noncompetitive inhibition can be distinguished on a Lineweaver–Burk plot by lines converging at the *x*-axis. A Lineweaver–Burk plot of enzyme kinetics in the presence and absence of a pure noncompetitive inhibitor shows that K_M is unaltered and V_{max} is decreased.

Finally, in mixed noncompetitive inhibition, the inhibitor binds preferentially to either E or ES, but still binds both, and thus behaves as a blend of a noncompetitive inhibitor and either a competitive or an uncompetitive inhibitor, depending upon the binding preference. Thus, for a mixed noncompetitive inhibitor V_{max} always decreases but the apparent value of K_M can either increase or decrease; the Lineweaver–Burk plot resembles that of a pure noncompetitive inhibitor but with lines converging either above or below the *x*-axis.

Transition-state analogs are potent competitive inhibitors

We turn now to compounds that provide the most intimate views of the catalytic process itself. Linus Pauling proposed in 1948 that compounds resembling the transition state of a catalyzed reaction should be very effective inhibitors of enzymes. These mimics are called **transition-state analogs**.

The inhibition of proline racemase is an instructive example. The racemization of proline proceeds through a transition state in which the tetrahedral α-carbon atom has become trigonal (**Figure 5.25**). In the trigonal form, all three bonds are in the same plane; C_α also carries a net negative charge. This symmetric carbanion can be reprotonated on one side to give the L isomer or on the other side to give the D isomer. Pauling's hypothesis was supported by the finding that the inhibitor pyrrole 2-carboxylate binds to the racemase active site 160 times as

tightly as does proline. The α-carbon atom of this inhibitor, like that of the transition state, is trigonal.

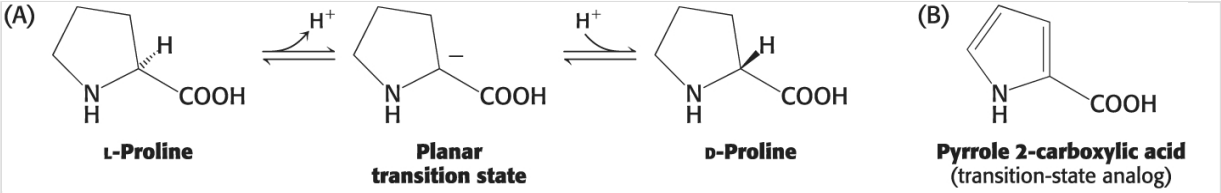

FIGURE 5.25 Transition-state analogs are potent competitive inhibitors because they structurally resemble the transition state of a catalyzed reaction. (A) The isomerization of L-proline to D-proline by proline racemase proceeds through a planar transition state in which the α-carbon atom is trigonal rather than tetrahedral. (B) Pyrrole 2-carboxylic acid, a transition-state analog because of its trigonal geometry, is a potent competitive inhibitor of proline racemase. An analog that also carries a negative charge on C_α would be expected to bind even more tightly.

In general, highly potent and specific competitive inhibitors of enzymes can be produced by synthesizing compounds that more closely resemble the transition state than the substrate itself. Because only molecules that are structurally similar to the real transition state will bind tightly to the active site, potent competitive inhibition — or its absence — by these molecules can be used to support or refute hypotheses regarding the structure of the transition state for a given enzyme-catalyzed reaction, providing evidence for particular chemical mechanisms. The inhibitory power of transition-state analogs underscores the essence of enzyme catalysis: catalysis is accomplished by selective binding of the transition state structure by the active site.

Self-Check Question

An inhibitor binds noncovalently to an allosteric site and induces a change in protein structure such that the enzyme can no longer bind substrate in the active site. Conversely,

when the substrate is bound in the active site, the allosteric site for the inhibitor is closed such that the inhibitor cannot bind. What type of inhibition is being described here?

Irreversible inhibitors can be used to map the active site

The first step in obtaining the chemical mechanism of an enzyme is to determine what functional groups are required for enzyme activity. How can we ascertain what these functional groups are? X-ray crystallography of the enzyme bound to its substrate or substrate analog provides one approach. Irreversible inhibitors that covalently bond to the enzyme provide an alternative and often complementary approach: the inhibitors modify the functional groups, which can then be identified. Irreversible inhibitors can be divided into three categories: group-specific reagents, affinity labels, and suicide inhibitors.

- **Group-specific reagents** inhibit enzymes by reacting with specific side chains of the enzyme's amino acids. An example of a group-specific reagent is diisopropylphosphofluoridate (DIPF). DIPF modifies only 1 of the 28 serine residues in the proteolytic enzyme chymotrypsin and yet inhibits the enzyme, implying that this serine residue is especially reactive. We will see in Chapter 6 that this serine residue is indeed located at the active site. DIPF also revealed a reactive serine residue in acetylcholinesterase, an enzyme important in the transmission of nerve impulses (**Figure 5.26**). Thus, DIPF and similar compounds that bind and inactivate acetylcholinesterase are potent nerve gases. Most group-specific reagents do not display the exquisite specificity shown by DIPF. Consequently, more specific means of modifying the active site are required.

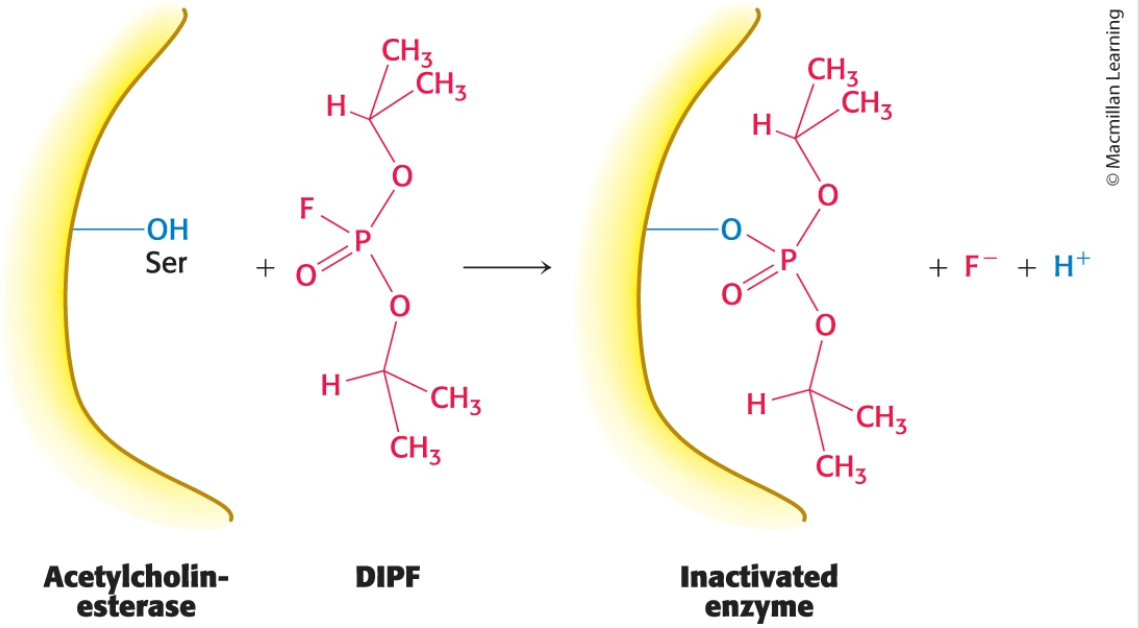

FIGURE 5.26 A group-specific reagent irreversibly inhibits enzymes by reacting with specific side chains. For example, DIPF can inhibit an enzyme by covalently modifying a crucial serine residue.

- **Affinity labels (reactive substrate analogs)** inhibit enzymes by being structurally similar to the substrate and covalently bonding to active-site residues. They are thus more specific for the enzyme's active site than are group-specific reagents. Tosyl-L-phenylalanine chloromethyl ketone (TPCK) is a substrate analog for chymotrypsin (Figure 5.27). TPCK binds at the active site and then reacts irreversibly with a histidine residue at that site, inhibiting the enzyme.

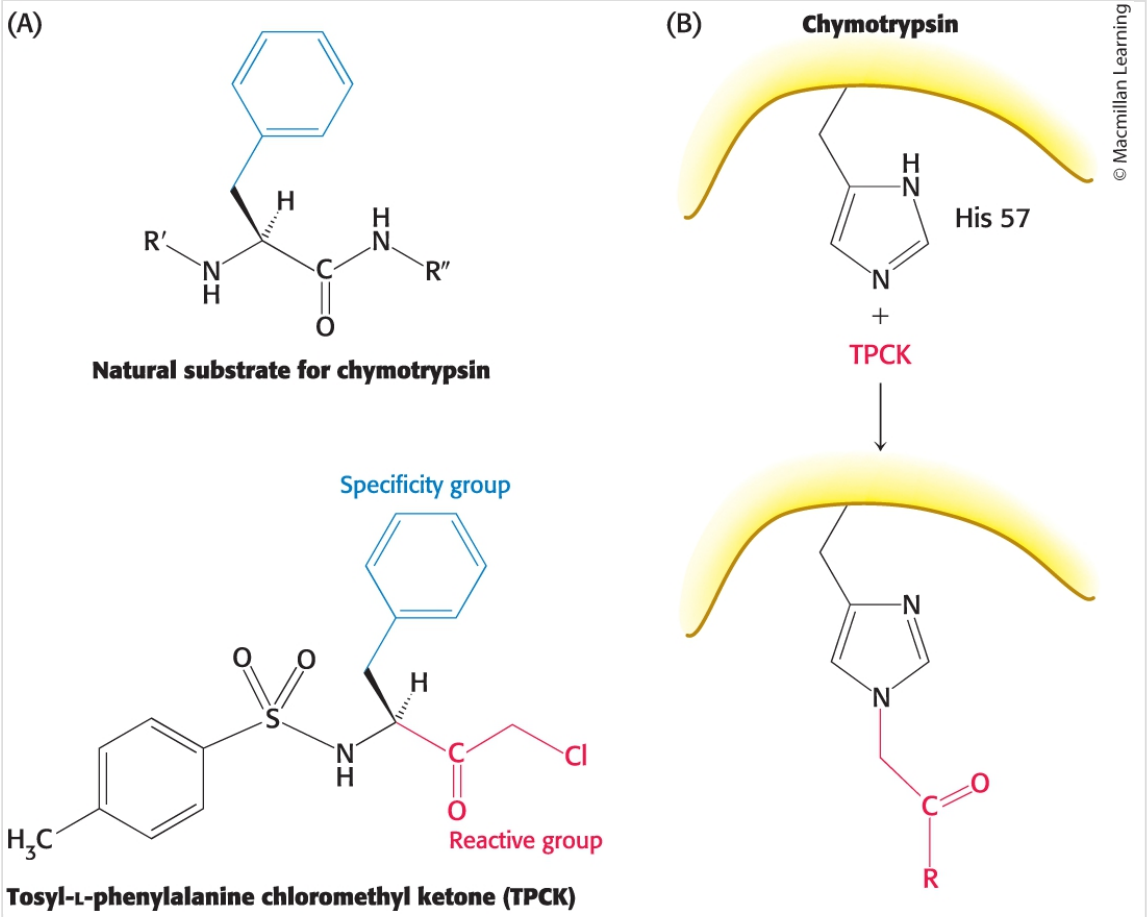

FIGURE 5.27 Affinity labels are highly specific irreversible inhibitors because they are structurally similar to the enzyme substrate. (A) Tosyl-L-phenylalanine chloromethyl ketone (TPCK) is a reactive analog of the normal substrate for the enzyme chymotrypsin. (B) TPCK binds at the active site of chymotrypsin and modifies an essential histidine residue.

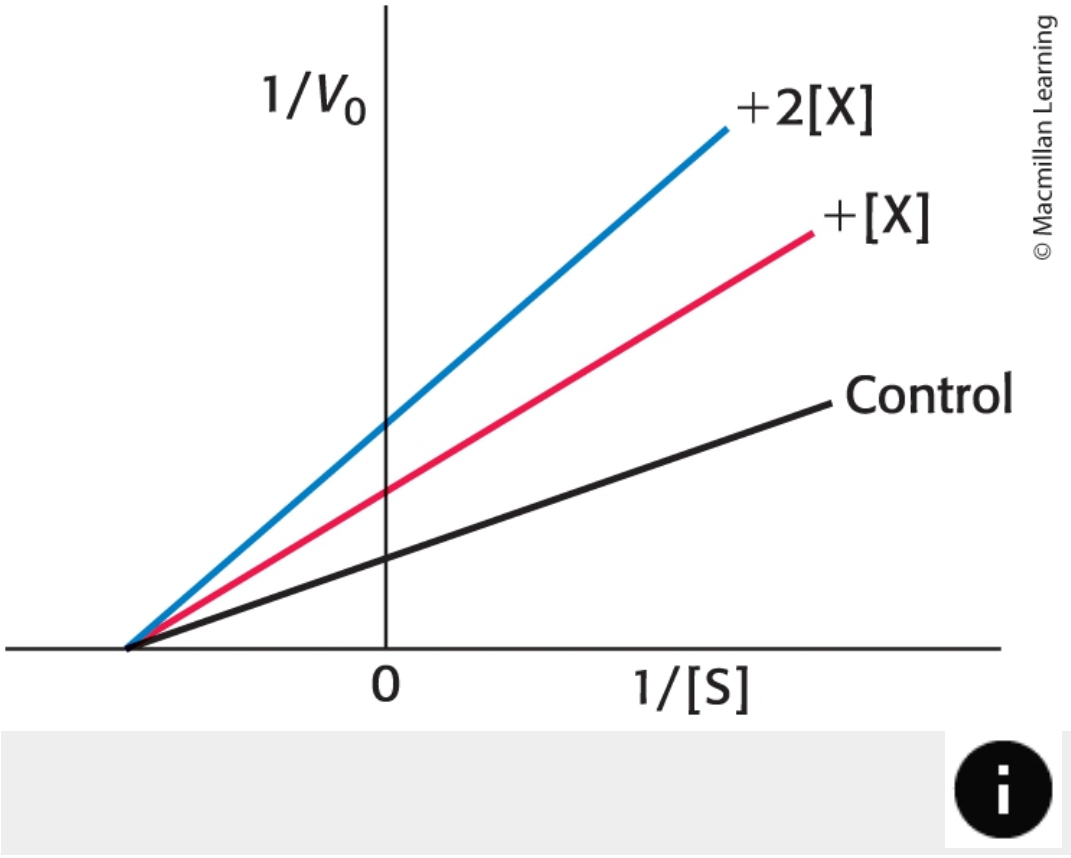
- **Mechanism-based (suicide) inhibitors** are modified substrates that provide the most specific means for modifying an enzyme's active site. The inhibitor binds to the enzyme as a substrate and is initially processed by the normal catalytic mechanism. The mechanism of catalysis then generates a chemically reactive intermediate that inactivates the enzyme through covalent modification. The fact that

the enzyme participates in its own irreversible inhibition strongly suggests that the covalently modified group on the enzyme is vital for catalysis.



How would a molecule like TPCK — or other types of irreversible inhibitors, for that matter — affect the kinetic parameters V_{max} and K_M that we have discussed throughout this chapter? We will address that question in the context of all the inhibitors discussed in this chapter in the example below.

Example

Determining Inhibitor Type from Data

Problem:

The graph shows the effect of two different concentrations of a molecule X on an enzyme. What kind of molecule is X, and how is it affecting enzyme activity?

Getting Started:

What kind of plot is this? The first step is to examine the axes: the *x*-axis shows 1/[S], while the *y*-axis displays $1/V_0$. Note that these are two reciprocal values, so this is a double reciprocal plot, specifically a Lineweaver–Burk plot. Next, consider what we know about these plots: they can reveal how molecules affect the apparent values of the kinetic parameters K_M and V_{max} based on where the line crosses the two axes. Recall that the point where the line crosses the *y*-axis is $1/V_{max}$, while the intersection with the *x*-axis is $-1/K_M$.

Analyze:

How is the molecule affecting the enzyme? If we first consider the *x*-axis, we see that all of the lines converge there. Therefore, the apparent K_M is not altered in the presence of X. However, when X is present, the lines cross the *y*-axis at increasing values, indicating that $1/V_{max}$ increases with increasing amounts of X. If $1/V_{max}$ increases in the presence of X, then the apparent V_{max} must be decreasing.

Let's summarize these effects and then consider the possibilities. The apparent K_M is unchanged, but the apparent V_{max} is reduced. This latter observation means that X must be some type of an inhibitor of the enzyme. Let's consider some possibilities: competitive inhibitors, including transition-state analogs, alter the apparent K_M but don't affect V_{max}. Uncompetitive inhibitors decrease both the apparent values of K_M and V_{max}. Finally, mixed noncompetitive inhibitors may raise or lower the apparent value of K_M but do not leave it unchanged. None of these descriptions fit the data. The only type of reversible inhibitor that affects an enzyme this way is a pure noncompetitive inhibitor. Recall that pure noncompetitive inhibitors lower the apparent V_{max} without altering K_M.

However, this is not the end of the problem! One more possibility exists that we have not considered: irreversible inhibitors. Because irreversible inhibitors permanently inactivate enzyme molecules, essentially removing a stoichiometric amount of them from pool of active enzyme molecules involved in the observed reaction, the effect is the same as if there were less enzyme originally added to the reaction mixture. That is, the apparent V_{max} is lowered because there are fewer active enzyme molecules, but the K_M is unaffected because those excess enzyme molecules which do not react with the inhibitor are completely unaffected by it.

Reflect:

All irreversible inhibitors give rise to the same pattern as a pure noncompetitive inhibitor with respect to the observed changes to the apparent values of K_M and V_{max}; so, in this case, additional information is required to distinguish whether molecule X is an irreversible or a pure noncompetitive inhibitor. The effects of various types of inhibitors are summarized in Table 5.9.

Table 5.9 Summary of effects of enzyme inhibitors on kinetic parameters

Type of inhibition	K_M	V_{max}
Competitive	Increased	Unchanged
Uncompetitive	Decreased	Decreased
Pure noncompetitive	Unchanged	Decreased
Mixed noncompetitive	Increased or decreased	Decreased
Irreversible	Unchanged	Decreased

Penicillin irreversibly inactivates a key enzyme in bacterial cell-wall synthesis

Penicillin, the first antibiotic ever discovered, is a clinically useful suicide inhibitor. Penicillin consists of a thiazolidine ring fused to a β-*lactam* ring to which a variable R group is attached by a peptide bond (Figure 5.28A). In benzylpenicillin, for example, R is a benzyl group (Figure 5.28B). The β-lactam ring is very labile due to significant strain in the four-membered ring; this instability is closely tied to the antibiotic action of penicillin.

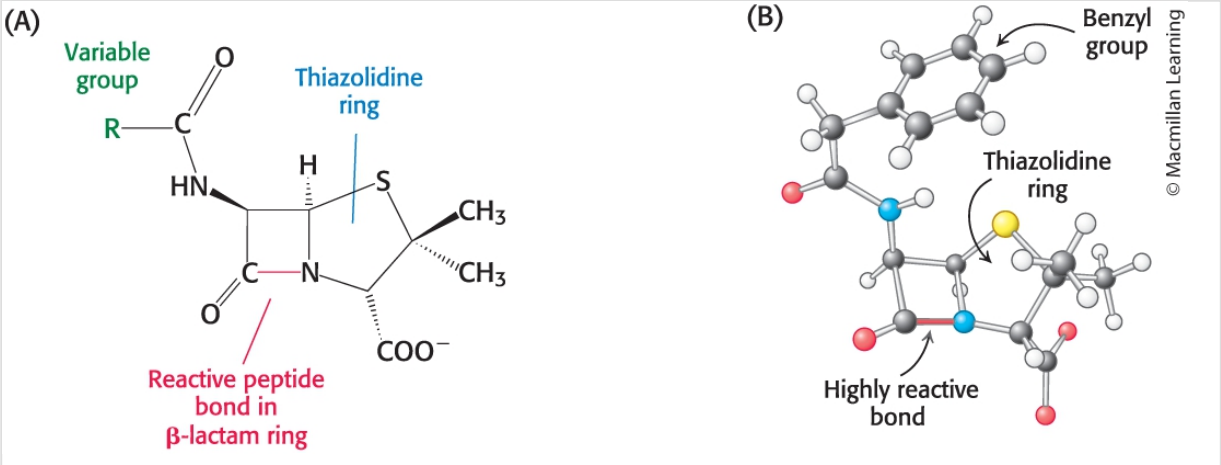


FIGURE 5.28 The reactive site of penicillin is the peptide bond of its β-lactam ring. (A) Structural formula of penicillin. (B) Representation of benzylpenicillin.

How does penicillin inhibit bacterial growth? Let us consider *Staphylococcus aureus*, the most common cause of staph infections. Like the vast majority of all bacteria, the cell wall of *S. aureus* is made up of a macromolecule, called *peptidoglycan* (Figure 5.29), which consists of linear polysaccharide chains that are cross-linked by short peptides. The enormous peptidoglycan molecule provides a continuous, covalently linked mesh that confers mechanical support and prevents bacteria from bursting in response to their high internal osmotic pressure. Glycopeptide transpeptidase catalyzes the formation of the cross-links that make the peptidoglycan so stable. Note that bacterial

cell walls are distinctive in containing D amino acids, which form cross-links by a mechanism different from that used to synthesize proteins.

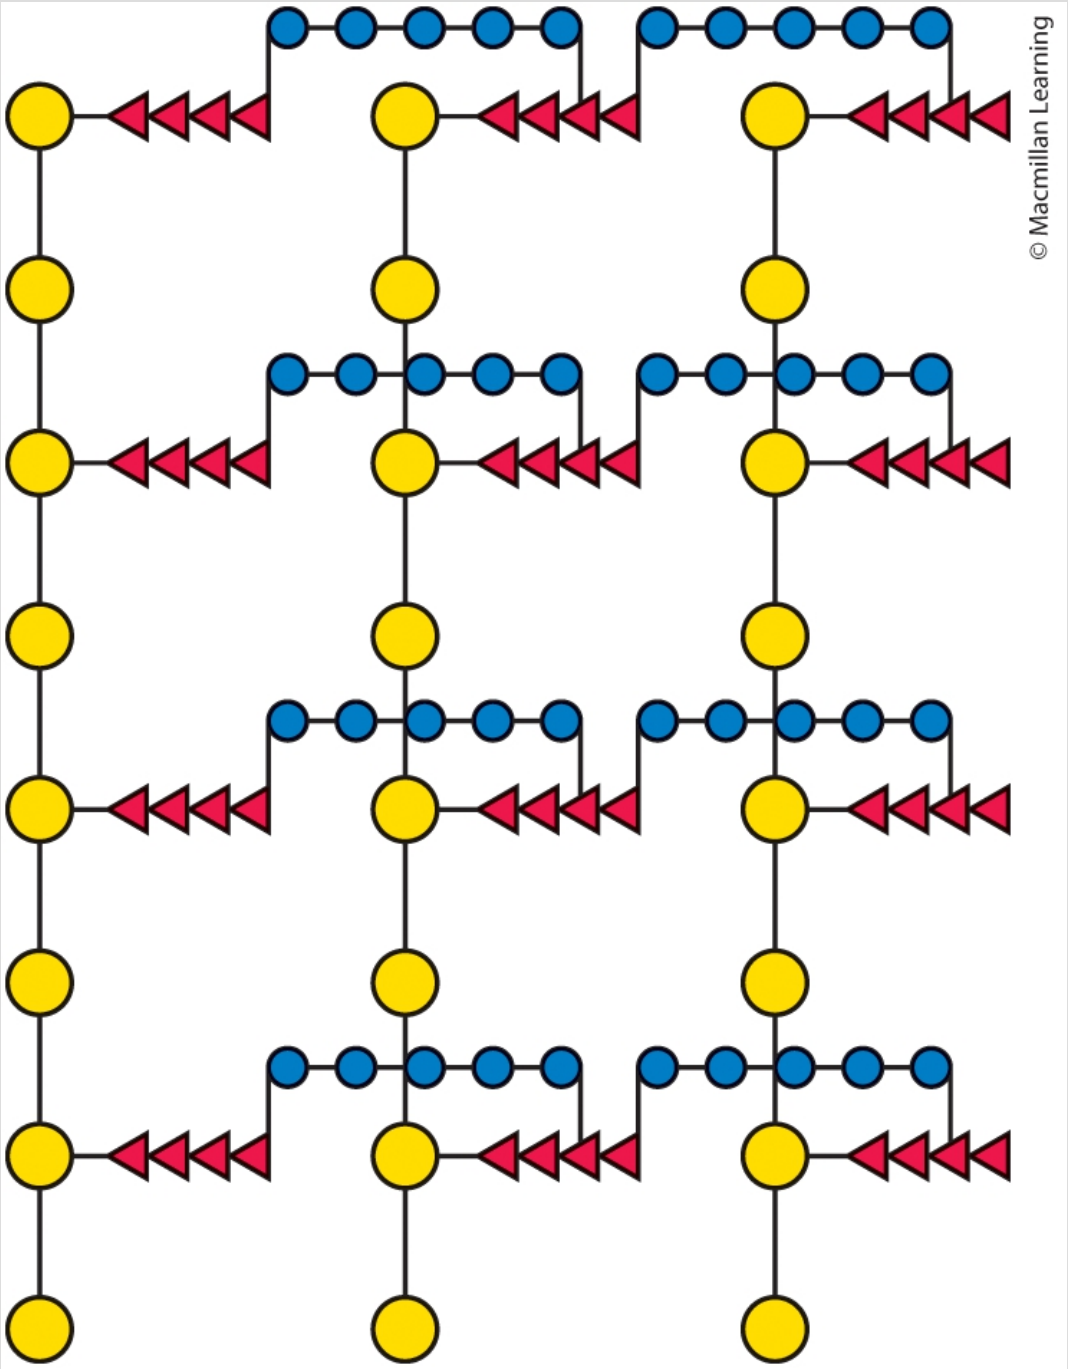

FIGURE 5.29 A schematic representation of a peptidoglycan section in *S. aureus* shows the crosslinking between sugar fibers. The sugars are shown in yellow, the tetrapeptides in red, and the pentaglycine bridges in blue. Only a small section is represented; the cell wall is a single, enormous, bag-shaped macromolecule because of extensive crosslinking.

Penicillin is an effective antibiotic because it interferes with the synthesis of the bacterial cell wall by irreversibly inhibiting the cross-linking transpeptidase. The transpeptidase normally forms an acyl intermediate with the penultimate D-alanine residue of the D-Ala-D-Ala peptide, which then reacts with the amino group of the terminal glycine in another peptide to form the cross-link. But penicillin can be accepted into the active site of the transpeptidase instead, because it mimics the D-Ala-D-Ala moiety of the normal substrate (Figure 5.30). Bound penicillin then forms a covalent bond with an active-site serine, permanently inactivating the enzyme and preventing the completion of cell-wall synthesis.

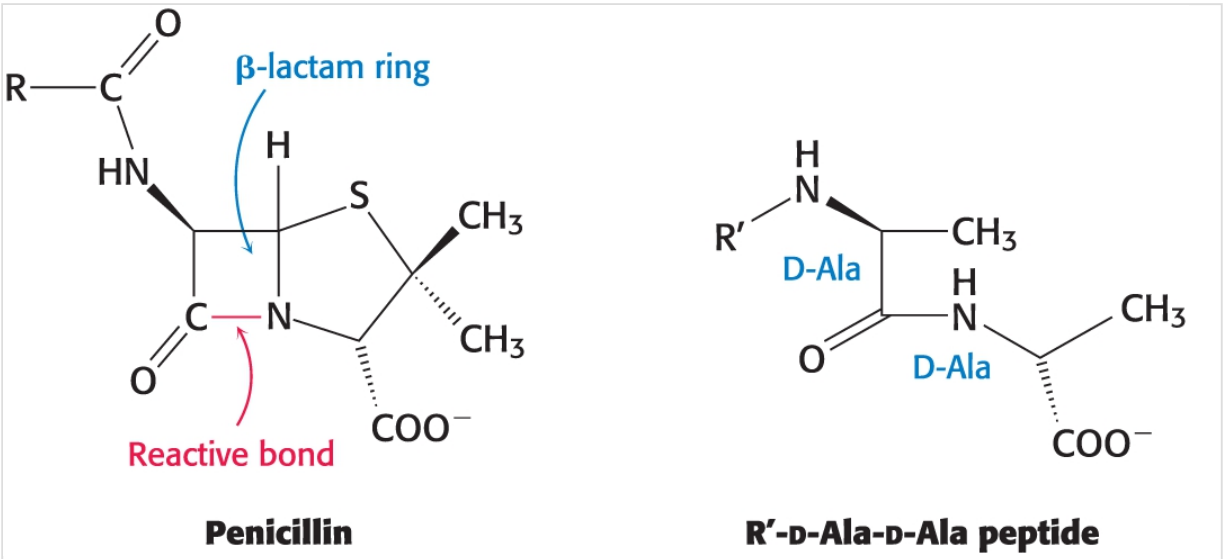

FIGURE 5.30 Penicillin resembles the transition state of the transpeptidase reaction. In the vicinity of its reactive peptide bond, the conformation of penicillin resembles the postulated conformation of the transition state of R'-D-Ala-D-Ala in the transpeptidation reaction.

[Information from B. Lee, *J. Mol. Biol.* 61:463–469, 1971.]

Why is penicillin such an effective inhibitor of the transpeptidase? The highly strained, four-membered β-lactam ring of penicillin makes it especially reactive. On binding to the transpeptidase, the serine residue at the active site attacks the carbonyl carbon atom of the lactam ring to form the penicilloyl-serine derivative (Figure 5.31). Because the peptidase participates in its own inactivation, penicillin acts as a suicide inhibitor.

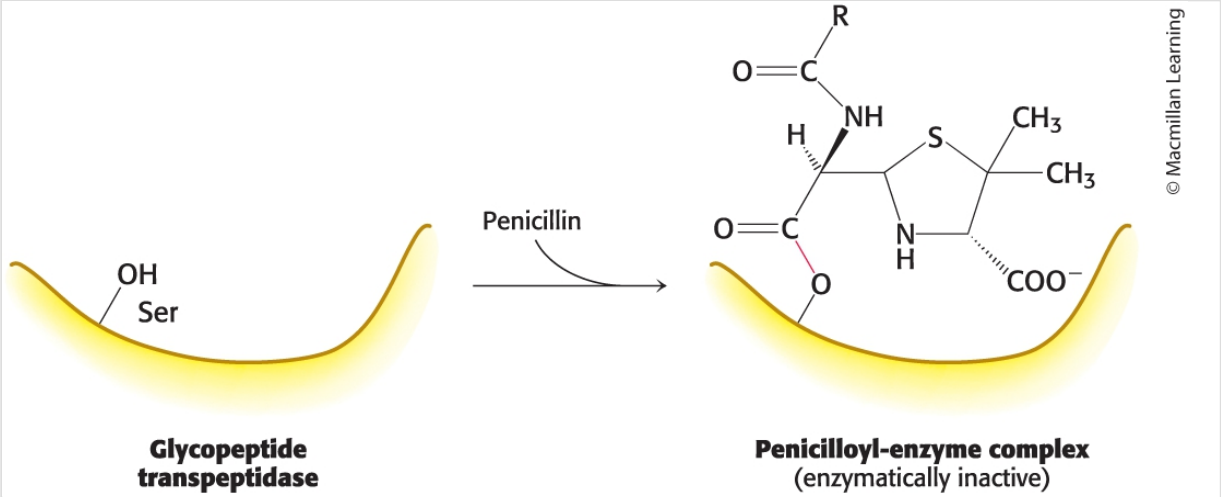

FIGURE 5.31 The formation of a penicilloyl-enzyme derivative is irreversible. Penicillin reacts irreversibly with the transpeptidase to inactivate the enzyme.

Chapter 5 Summary

5.1 Enzymes Are Powerful and Highly Specific Catalysts

- Enzymes are biological catalysts, most of which are proteins.
- Enzymes are highly specific and can enhance reaction rates by factors as great as 10^{17}.
- Many enzymes require cofactors for activity which can be metal ions or small, vitamin-derived organic molecules called coenzymes.

5.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes

- A reaction can take place spontaneously only if the change in free energy (ΔG) is negative.
- The free-energy change of a reaction under standard conditions is called the standard free-energy change (ΔG°) while biochemists use $\Delta G^{\circ\prime}$, the standard free-energy change at pH 7.
- Enzymes do not alter reaction equilibria; rather, they increase the rate at which equilibrium is attained.

5.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State

- Enzymes decrease the free energy of activation of a chemical reaction by providing a reaction pathway in which the transition state (the highest-energy species) has a lower free energy and hence is more rapidly formed than in the uncatalyzed reaction; the result is that the reaction is accelerated in both directions.
- The first step in catalysis is the formation of an enzyme–substrate complex in which substrates are bound at active-site

clefts from which water is largely excluded.
- The specificity of enzyme–substrate interactions arises mainly from weak reversible contacts mediated by ionic interactions, hydrogen bonds, and van der Waals forces, and from the shape of the active site, which rejects molecules that do not have a sufficiently complementary shape and charge.
- Enzymes facilitate formation of the transition state by a dynamic process in which the substrate binds to specific conformations of the enzyme, accompanied by conformational changes at active sites that result in catalysis.

5.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes

- The kinetic properties of many enzymes are described by the Michaelis–Menten model in which an enzyme (E) combines with a substrate (S) to form an enzyme–substrate (ES) complex, which can proceed to form a product (P) or to dissociate into E and S.

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

- The rate of formation of product V_0 is given by the Michaelis–Menten equation:

$$V_0 = V_{max} \frac{[S]}{[S] + K_M}$$

in which V_{max} is the reaction rate when the enzyme is fully saturated with substrate and K_M, the Michaelis constant, is the

substrate concentration at which the reaction rate is half maximal.
- The kinetic constant k_{cat}, called the turnover number, is the number of substrate molecules converted into product per unit time at a single catalytic site when the enzyme is fully saturated with substrate. The ratio of k_{cat}/K_M provides a measure of enzyme efficiency and specificity.
- Allosteric enzymes constitute an important class of enzymes whose catalytic activity can be regulated. These enzymes have multiple active sites which often display cooperativity, as evidenced by a sigmoidal dependence of reaction velocity on substrate concentration.

5.5 Enzymes Can Be Studied One Molecule at a Time

- Single-molecule methods reaffirm the key findings from ensemble studies but also reveal a distribution of enzyme characteristics rather than an average value.

5.6 Enzymes Can Be Inhibited by Specific Molecules

- Irreversible inhibitors bind covalently to enzymes and can provide a means of mapping the enzyme's active site, while reversible inhibition is characterized by a more rapid and less stable interaction between enzyme and inhibitor.
- Competitive inhibitors prevent the substrate from binding to the active site and thereby reduce the reaction velocity by diminishing the proportion of enzyme molecules that are bound to substrate. Competitive inhibition can be overcome by raising the substrate concentration.
- Uncompetitive inhibitors bind only to the enzyme–substrate complex, decreasing both the turnover number and the apparent K_M.
- Pure noncompetitive inhibitors decrease only the turnover number, while mixed noncompetitive inhibitors can have a

variety of effects.
- Transition-state analogs are stable compounds that mimic key features of the transition state and are potent and specific competitive inhibitors of enzymes.

Key Terms

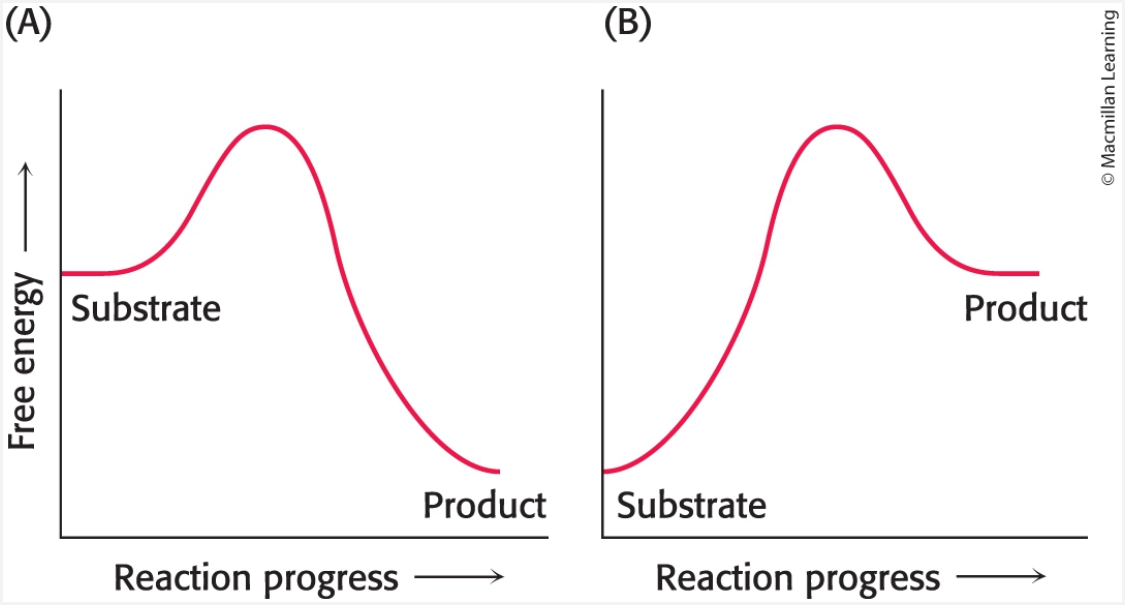
catalyst
enzyme
ribozyme
substrate
protease
cofactor
apoenzyme
holoenzyme
coenzyme
prosthetic group
transition state
Gibbs free energy of activation (activation energy)
active site
induced fit
binding energy
K_M (Michaelis constant)
V_{max} (maximal rate)
Michaelis–Menten equation
Lineweaver–Burk plot
elasticity
turnover number
k_{cat}/K_M (specificity constant)
sequential reaction
double-displacement (Ping-Pong) reaction
allosteric enzyme

competitive inhibition
uncompetitive inhibition
pure noncompetitive inhibition
mixed noncompetitive inhibition
transition-state analog
group-specific reagent
affinity label (reactive substrate analog)
mechanism-based (suicide) inhibitor

Problems

1. What does an apoenzyme require to become a holoenzyme?

2. Consider the reaction: $S \rightleftharpoons P$. Which of the following



effects are produced by an enzyme on the general reaction?
1, 2

a. The reaction equilibrium is shifted away from the products.
b. The concentration of the products is increased.
c. ΔG for the reaction increases.
d. The activation energy for the reaction is lowered.
e. The formation of the transition state is promoted.
f. The rate constant for the forward reaction increases.

3. Why does the activation energy of a reaction not appear in the final ΔG of the reaction? 1

4. The illustrations below show the reaction-progress curves for two different reactions. Indicate the activation energy as well as

the ΔG for each reaction. Which reaction is endergonic? Exergonic? 1

5. Suppose that, in the absence of enzyme, the forward rate constant (k_F) for the conversion of S into P is $10^{-4}\ s^{-1}$ and the reverse rate constant (k_R) for the conversion of P into S is $10^{-6}\ s^{-1}$. 1, 2

$$S \underset{10^{-6}\ s^{-1}}{\overset{10^{-4}\ s^{-1}}{\rightleftharpoons}} P$$

a. What is the equilibrium for the reaction? What is the $\Delta G^{\circ\prime}$?

b. Suppose an enzyme enhances the rate of the reaction 100-fold. What are the rate constants for the enzyme-catalyzed reaction? What is the equilibrium constant? The $\Delta G^{\circ\prime}$?

6. What would be the result of an enzyme having a greater binding energy for the substrate than for the transition state?

2

7. Match the K'_{eq} values with the appropriate $\Delta G^{\circ\prime}$ values.

1

K'_{eq}	$\Delta G^{\circ\prime}$ (kJ mol^{-1})
1. 1	28.53
2. 10^{-5}	−11.42
3. 10^{4}	5.69
4. 10^{2}	0

-22.84

5. 10^{-1}

---

8. Assume that you have a solution of 0.1 M glucose 6-phosphate (G 6-P). To this solution, you add the enzyme phosphoglucomutase, which catalyzes the following reaction:

$$\text{G 6-P} \underset{}{\overset{\text{Phosphoglucomutase}}{\rightleftharpoons}} \text{G 1-P}$$

The $\Delta G^{\circ\prime}$ for the reaction is $+7.5\ \text{kJ mol}^{-1}\ (+1.8\ \text{kcal mol}^{-1})$. 1

a. Does the reaction proceed as written? If so, what are the final concentrations of G 6-P and G 1-P?
b. Under what cellular conditions could you produce G 1-P at a high rate?

9. Consider the following reaction:

$$\text{G 6-P} \underset{}{\overset{\text{Phosphoglucomutase}}{\rightleftharpoons}} \text{G 1-P}$$

After reactant and product were mixed and allowed to reach equilibrium at 25°C, the concentration of each compound was measured:

$$[\text{Glucose 1-phosphate}]_{eq} = 0.01\ \text{M}$$
$$[\text{Glucose 6-phosphate}]_{eq} = 0.19\ \text{M}$$

Calculate K_{eq} and $\Delta G^{\circ\prime}$. 1

10. The affinity between a protein and a molecule that binds to the protein is frequently expressed in terms of a dissociation constant K_d. 3

$$\text{Protein} + \text{small molecule} \rightleftharpoons \text{Protein} - \text{small molecule complex}$$

$$K_d = \frac{[\text{protein}][\text{small molecule}]}{[\text{protein} - \text{small molecule complex}]}$$

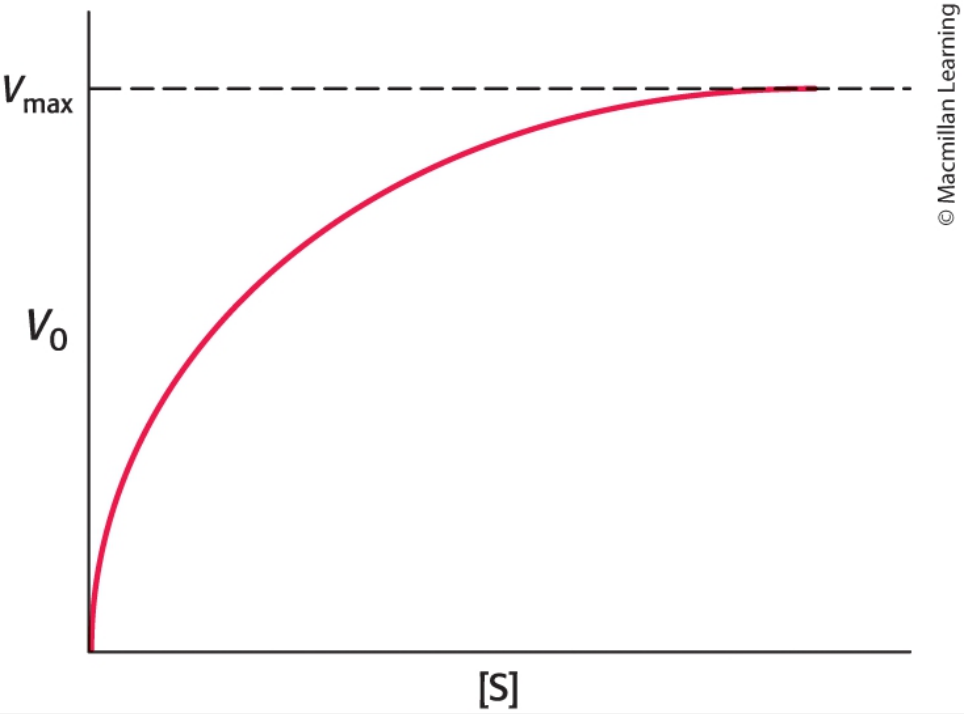
Does K_M measure the affinity of the enzyme complex? Under what circumstances might K_M approximately equal K_d?

11. Match the term with the description or compound. 3, 4

1. Competitive inhibition _____
2. Uncompetitive inhibition _____
3. Noncompetitive inhibition _____

1. Inhibitor and substrate can bind simultaneously
2. V_{max} remains the same but the K_M^{app} increases
3. Sulfanilamide
4. Binds to the enzyme–substrate complex only
5. Lowers V_{max} and K_M^{app}

6. Roundup



7. K_M remains unchanged but V_{max} is lower

8. Doxycycline

9. Prevents S from binding to the active site

---

12. Many biochemists go bananas, and justifiably, when they see a Michaelis–Menten plot like the one shown below. To see why, determine the V_0 as a fraction of V_{max} when the substrate concentration is equal to 10 K_M and 20 K_M. Please control your outrage. 3

13. The hydrolysis of pyrophosphate to orthophosphate is important in driving forward biosynthetic reactions such as the synthesis of DNA. This hydrolytic reaction is catalyzed in *E. coli* by a pyrophosphatase that has a mass of 120 kDa and consists of six identical subunits. For this enzyme, a unit of activity is defined as the amount of enzyme that hydrolyzes 10 μmol of pyrophosphate in 15 minutes at 37°C under standard assay conditions. The purified enzyme has a V_{max} of 2800 units per milligram of enzyme. 3

a. How many moles of substrate are hydrolyzed per second per milligram of enzyme when the substrate concentration is much greater than K_M?
b. How many moles of active sites are there in 1 mg of enzyme? Assume that each subunit has one active site.
c. What is the turnover number of the enzyme? Compare this value with others mentioned in this chapter.

14. Penicillin is hydrolyzed and thereby rendered inactive by penicillinase (also known as β-lactamase), an enzyme present in some penicillin-resistant bacteria. The mass of this enzyme in *Staphylococcus aureus* is 29.6 kDa. The amount of penicillin hydrolyzed in 1 minute in a 10-ml solution containing 10^{-9} g of purified penicillinase was measured as a function of the concentration of penicillin. Assume that the concentration of penicillin does not change appreciably during the assay. 3

[Penicillin] μM	Amount hydrolyzed (nmol)

1	0.11
3	0.25
5	0.34
10	0.45
30	0.58
50	0.61

a. Plot V_0 versus [S] and $1/V_0$ versus 1/[S] for these data. Does penicillinase appear to obey Michaelis–Menten kinetics? If so, what is the value of K_M?
b. What is the value of V_{max}?
c. What is the turnover number of penicillinase under these experimental conditions? Assume one active site per enzyme molecule.

15. The kinetics of an enzyme is measured as a function of substrate concentration in the presence and absence of $100\ \mu M$ inhibitor. 3, 4

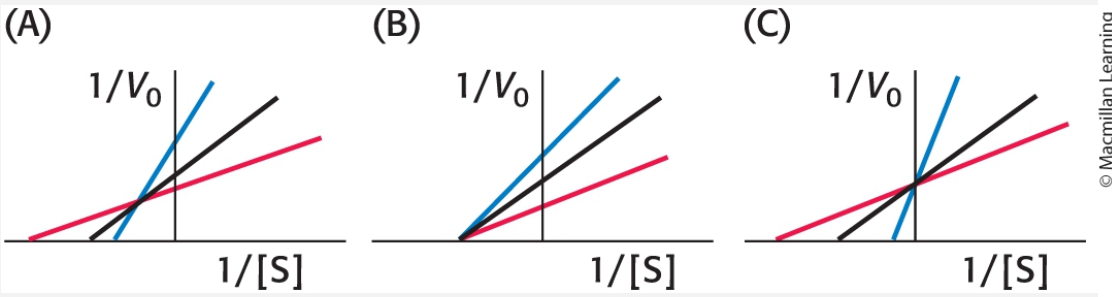
	Velocity $(\mu mol\ minute^{-1})$	
[S] (μM)	**No inhibitor**	**Inhibitor**
3	10.4	2.1

5	14.5	2.9
10	22.5	4.5
30	33.8	6.8
90	40.5	8.1

a. What are the values of V_{max} and K_M in the presence of this inhibitor?
b. What type of inhibition is it?
c. What is the dissociation constant of this inhibitor?
d. If $[S] = 30\ \mu M$, what fraction of the enzyme molecules has a bound substrate in the presence and in the absence of $100\ \mu M$ inhibitor?

16. The plot of $1/V_0$ versus 1/[S] is sometimes called a Lineweaver–Burk plot. Another way of expressing the kinetic data is to plot V_0 versus $V_0/[S]$, which is known as an Eadie–Hofstee plot. 3, 4

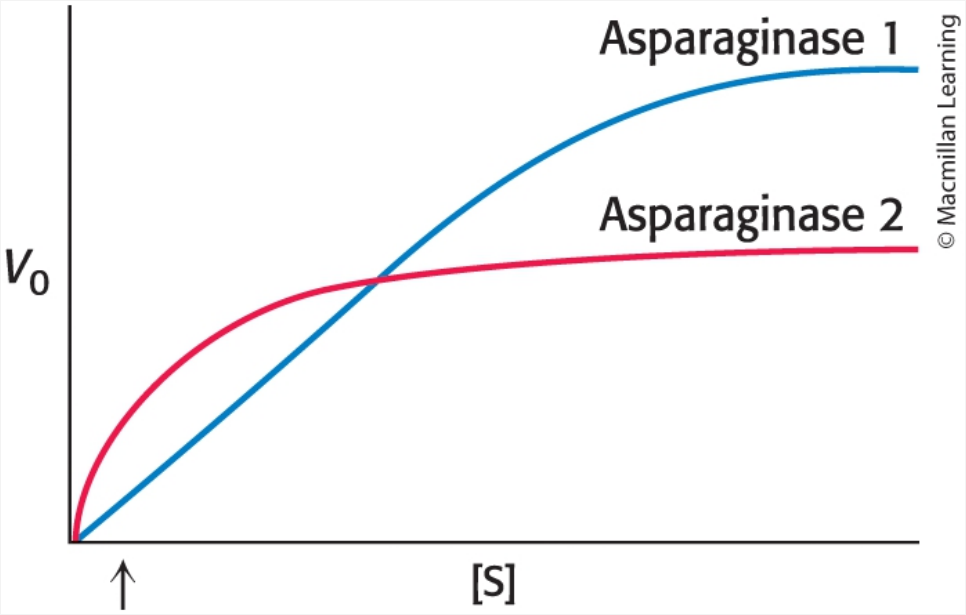
a. Rearrange the Michaelis–Menten equation to give V_0 as a function of $V_0/[S]$.
b. What is the significance of the slope, the *y*-intercept, and the *x*-intercept in a plot of V_0 versus $V_0/[S]$?
c. Sketch a plot of V_0 versus $V_0/[S]$ in the absence of an inhibitor, in the presence of a competitive inhibitor, and in the presence of a noncompetitive inhibitor.



17. What is the defining characteristic for an enzyme catalyzing a sequential reaction? A double-displacement reaction?

18. You have isolated two versions of the same enzyme, a wild type and a mutant differing from the wild type at a single amino acid. Working carefully but expeditiously, you then establish the following kinetic characteristics of the enzymes. 1, 3

	Maximum velocity	K_M
Wild type	100 μmol/min	10 mM
Mutant	1 μmol/min	0.1 mM



a. With the assumption that the reaction occurs in two steps in which k_{-1} is much larger than k_2, which enzyme has the higher affinity for substrate?
b. What is the initial velocity of the reaction catalyzed by the wild-type enzyme when the substrate concentration is 10 mM?
c. Which enzyme alters the equilibrium more in the direction of product?

19. For a one-substrate, enzyme-catalyzed reaction, double-reciprocal plots were determined for three different enzyme concentrations. Which of the following three families of curve would you expect to be obtained? Explain. 3

© Macmillan Learning

20. The amino acid asparagine is required by cancer cells to proliferate. Treating patients with the enzyme asparaginase is sometimes used as a chemotherapy treatment. Asparaginase hydrolyzes asparagine to aspartate and ammonia. The below illustration shows the Michaelis–Menten curves for two asparaginases from different sources, as well as the concentration of asparagine in the environment (indicated by the arrow). Which enzyme would make a better chemotherapeutic agent? 3

21. Picture in your mind the velocity-versus-substrate concentration curve for a typical Michaelis–Menten enzyme.

Now, imagine that the experimental conditions are altered as described below. For each of the conditions described, fill in the table indicating precisely (when possible) the effect on V_{max} and K_M of the imagined Michaelis–Menten enzyme. 3, 4

Experimental condition	V_{max}	K_M
1. Twice as much enzyme is used.		
2. Half as much enzyme is used.		
3. A competitive inhibitor is present.		
4. An uncompetitive inhibitor is present.		
5. A pure noncompetitive inhibitor is present.		

---

22. In the conversion of A into D in the following biochemical pathway, enzymes E_A, E_B, and E_C have the K_M values indicated under each enzyme. If all of the substrates and products are present at a concentration of 10^{-4} M and the enzymes have approximately the same V_{max}, which step will be rate limiting and why? 3

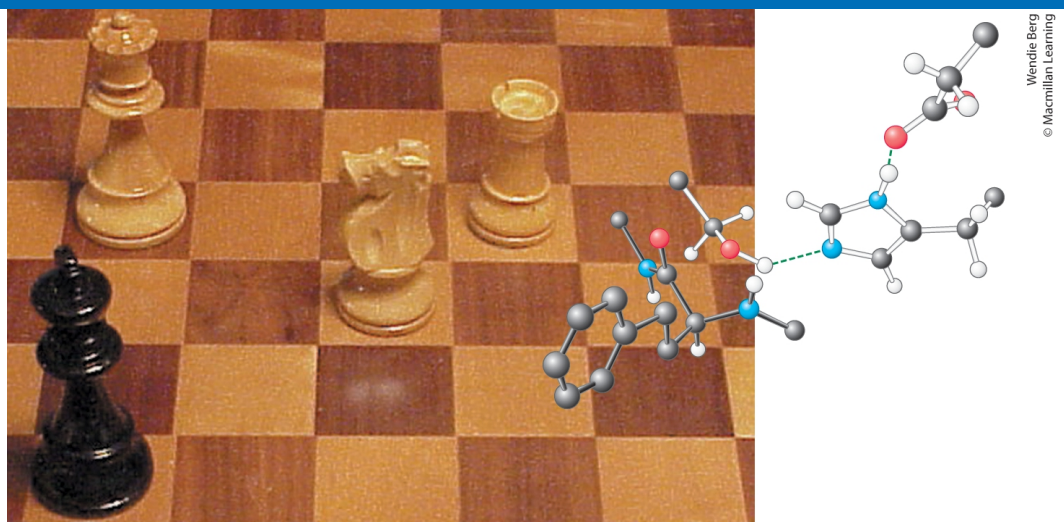
$$A \underset{E_A}{\rightleftharpoons} B \underset{E_B}{\rightleftharpoons} C \underset{E_C}{\rightleftharpoons} D$$

$K_M =$ 10^{-2} M 10^{-4} M 10^{-6} M

23. Proteins are thermodynamically unstable. The ΔG of the hydrolysis of proteins is quite negative, yet proteins can be quite

stable. Explain this apparent paradox. What does it tell you about protein synthesis? 1

24. Transition-state analogs, which can be used as enzyme inhibitors and to generate catalytic antibodies, are often difficult to synthesize. Suggest a reason. 2



25. What is the biochemical advantage of having a K_M approximately equal to the substrate concentration normally available to an enzyme? 3

26. Succinylcholine is a fast-acting, short-duration muscle relaxant that is used when a tube is inserted into a patient's trachea or when a bronchoscope is used to examine the trachea and bronchi for signs of cancer. Within seconds of the administration of succinylcholine, the patient experiences muscle paralysis and is placed on a respirator while the examination proceeds. Succinylcholine is a competitive inhibitor of acetylcholinesterase, a nervous system enzyme, and this inhibition causes paralysis. However, succinylcholine is hydrolyzed by blood-serum cholinesterase, which shows a broader substrate specificity than does the nervous system enzyme. Paralysis lasts until the succinylcholine is hydrolyzed by the serum cholinesterase, usually several minutes later. 3

a. As a safety measure, serum cholinesterase is measured before the examination takes place. Explain why this measurement is good idea.
b. What would happen to the patient if the serum cholinesterase activity were only 10 units of activity per liter rather than the normal activity of about 80 units?
c. Some patients have a mutant form of the serum cholinesterase that displays a K_M of 10 mM, rather than

the normal 1.4 mM. What will be the effect of this mutation on the patient?

Chapter 6
Enzyme Catalytic Strategies

Chess and enzymes have in common the use of strategy, consciously thought out in the game of chess and selected by evolution for the action of an enzyme. The three amino acid residues at the right, denoted by the white bonds, represent a particular chemical strategy for catalyzing a reaction that is normally very slow. This strategy relies on the properties of the different amino acids, much as chess strategy relies on different rules for moving each type of piece.

Outline

6.1 Enzymes Use a Core Set of Catalytic Strategies
6.2 Proteases Facilitate a Fundamentally Difficult Reaction
6.3 Carbonic Anhydrases Make a Fast Reaction Faster

6.4 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions
6.5 Molecular Motor Proteins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

Learning Goals

By the end of this chapter, you should be able to:

1. Discuss four general strategies used by enzymes to accelerate particular reactions.
2. Give examples of specific chemical features of enzyme active sites that facilitate increasing the rates of specific reactions.
3. Give an example of when high absolute rate acceleration is physiologically important and how an enzyme achieves this acceleration.
4. Understand when high specificity is important for an enzyme and how this specificity is achieved.
5. Describe an example of when large conformational changes that occur during an enzymatic reaction cycle are used to drive other processes.
6. Discuss some of the experimental approaches biochemists use to elucidate enzymatic mechanisms.

What are the sources of the catalytic power and specificity of enzymes? This chapter presents the catalytic strategies used by four classes of enzymes, each of which catalyze reactions that involve the addition of water to a substrate. Scientists have revealed the mechanisms of these enzymes using incisive experimental probes, including protein structure determination, site-directed mutagenesis, detailed kinetic studies, and the use of isotope labels.

Each of the four classes of enzymes addresses a different challenge. Serine proteases promote a reaction that is almost immeasurably slow at neutral pH in the absence of a catalyst; carbonic anhydrases

achieve a high absolute rate of reaction, suitable for integration with other rapid physiological processes; and restriction enzymes attain a high degree of specificity. Finally, molecular motor proteins such as myosin harness the free energy associated with the hydrolysis of ATP to drive other processes.

6.1 Enzymes Use a Core Set of Catalytic Strategies

In Chapter 5, we learned that enzymatic catalysis begins with substrate binding. The **binding energy** is the free energy released in the formation of a large number of weak interactions between the enzyme and the substrate. The use of this binding energy is the first common strategy used by enzymes. This binding energy serves two purposes: it establishes substrate specificity and increases catalytic efficiency. Often only the correct substrate can participate in most or all of the interactions with the enzyme and thus optimize binding energy, accounting for the exquisite substrate specificity exhibited by many enzymes.

Furthermore, the full complement of such interactions is formed only when the combination of enzyme and substrate is in the transition state. Thus, interactions between the enzyme and the substrate stabilize the transition state, thereby lowering the free energy of activation. The binding energy can also promote structural changes in both the enzyme and the substrate that facilitate catalysis, a process referred to as **induced fit**.

In addition to the first strategy involving binding energy, enzymes commonly employ one or more of the following four additional strategies to catalyze specific reactions:

1. *Covalent catalysis*. In **covalent catalysis**, the active site contains a reactive group that becomes temporarily covalently attached to a part of the substrate in the course of catalysis. The proteolytic enzyme chymotrypsin provides an excellent example of this strategy (Section 6.2).

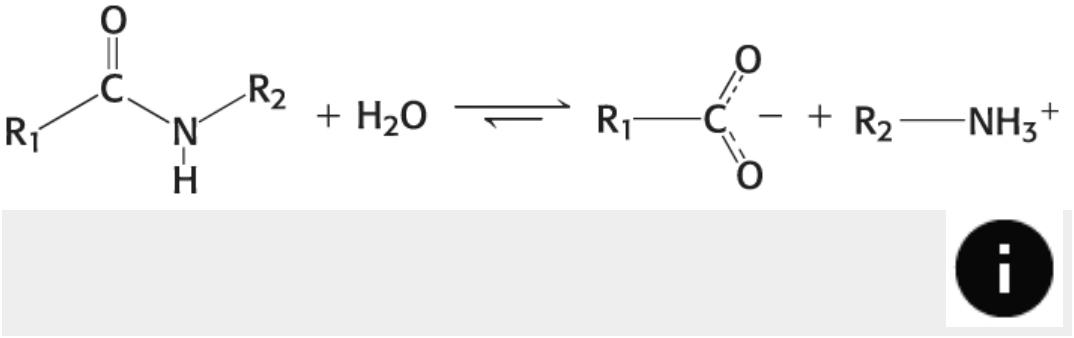
2. *General acid–base catalysis*. In **general acid–base catalysis**, a molecule other than water plays the role of a proton donor or acceptor. These include histidine residues in chymotrypsin and carbonic anhydrase, an aspartate residue in EcoRV, and a phosphate group of the ATP substrate for myosin and kinesin.

3. *Catalysis by approximation*. Many reactions have two distinct substrates, including all four classes of hydrolases considered in detail in this chapter. In such cases, the reaction rate may be considerably enhanced by bringing the two substrates together along a single binding surface on an enzyme, a process called **catalysis by approximation**. For example, carbonic anhydrase binds carbon dioxide and water in adjacent sites to facilitate their reaction.

4. *Metal ion catalysis*. In **metal ion catalysis**, metal ions function catalytically in several ways. For instance, a metal ion may facilitate the formation of reactive species such as hydroxide ion by direct coordination. A zinc(II) ion serves this purpose in catalysis by carbonic anhydrase. Alternatively, a metal ion may serve to stabilize a negative charge on a reaction intermediate, a role played by magnesium(II) ion in EcoRV. Finally, a metal ion may serve as a bridge between enzyme and substrate, increasing the binding energy and holding the substrate in a conformation appropriate for catalysis. This strategy is used by myosin and kinesin and, indeed, by essentially all enzymes that use ATP as a substrate.

Although we shall not consider catalytic RNA molecules explicitly in this chapter, the principles described for protein enzymes also apply to these catalysts.

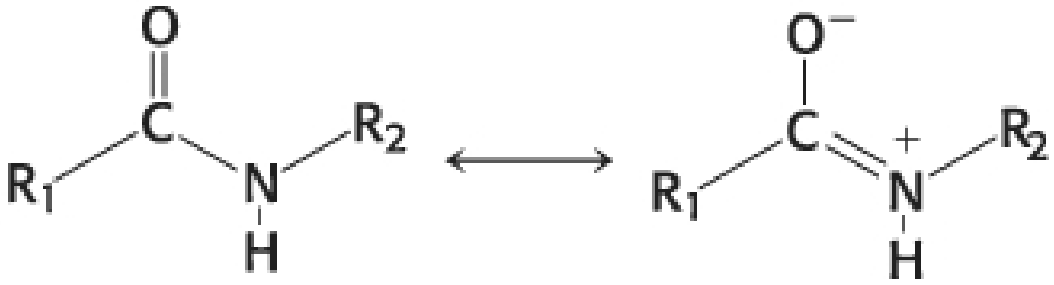
Self-Check Question



The enzyme adenylate kinase can convert two molecules of ADP to one molecule of AMP and one molecule of ATP. Suggest at least one catalytic strategy likely used by this enzyme.

6.2 Proteases Facilitate a Fundamentally Difficult Reaction

Peptide bond hydrolysis is an important process in living systems. Proteins that have served their purpose must be degraded so that their constituent amino acids can be recycled for the synthesis of new proteins; for example, proteins ingested in the diet must be broken down into small peptides and amino acids for absorption in the gut. Furthermore, as described in detail in Chapter 7, proteolytic reactions are important in regulating the activity of certain enzymes and other proteins.



Proteases cleave proteins by a hydrolysis reaction — the addition of a molecule of water to a peptide bond:

Although the hydrolysis of peptide bonds is thermodynamically favorable, such reactions are extremely slow. In the absence of a catalyst, the half-life for the hydrolysis of a typical peptide at neutral pH is estimated to be between 10 and 1000 years. Yet, peptide bonds must be hydrolyzed within milliseconds in some biochemical processes.

The chemical nature of peptide bonds is responsible for their kinetic stability. Specifically, the resonance structure that accounts for the

planarity of peptide bonds also makes them resistant to hydrolysis. This resonance structure endows them with partial double-bond character:

The carbon–nitrogen bond is strengthened by its double-bond character. More importantly, the carbonyl carbon atom is less **electrophilic** and less susceptible to **nucleophilic** attack than are the carbonyl carbon atoms in more reactive compounds such as carboxylate esters. Consequently, to promote peptide-bond cleavage, an enzyme must facilitate nucleophilic attack at a normally unreactive carbonyl group.

Chymotrypsin possesses a highly reactive serine residue

A number of proteolytic enzymes participate in the breakdown of proteins in the digestive systems of mammals and other organisms. One such enzyme, chymotrypsin, cleaves peptide bonds selectively on the carboxyl-terminal side of the large hydrophobic amino acids such as tryptophan, tyrosine, phenylalanine, and methionine (**Figure 6.1**). Chymotrypsin is a good example of the use of covalent catalysis. The enzyme employs a powerful nucleophile to attack the unreactive carbonyl carbon atom of the substrate. This nucleophile becomes covalently attached to the substrate transiently in the course of catalysis.

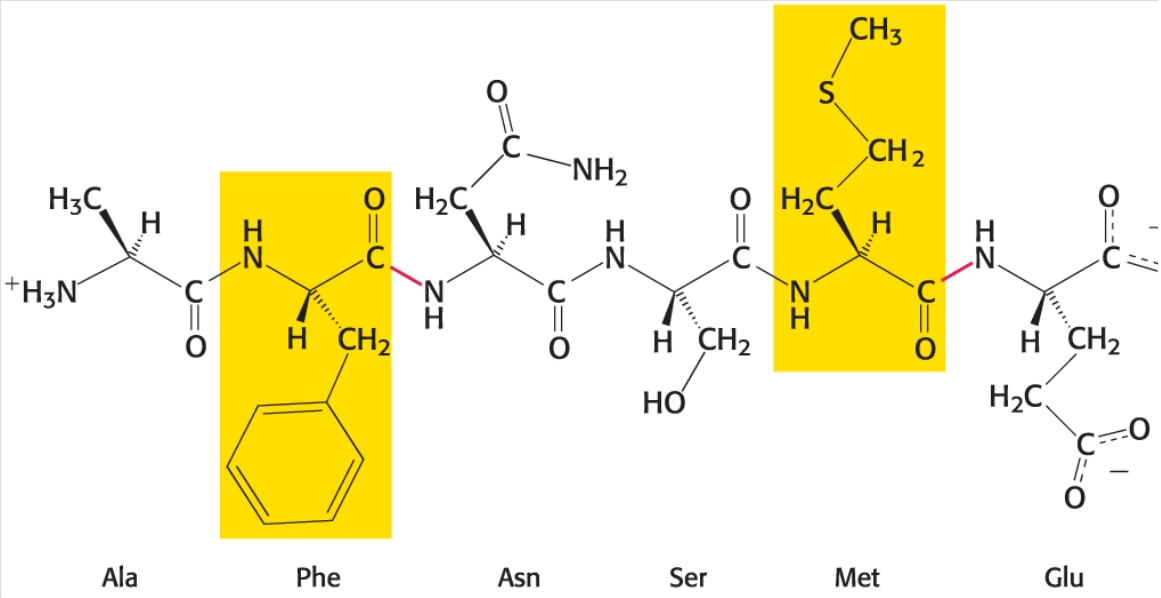


FIGURE 6.1 Chymotrypsin cleaves proteins specifically on the carboxyl side of aromatic or large hydrophobic amino acids. The targeted amino acids are highlighted, and the bonds cleaved by chymotrypsin are indicated in red.

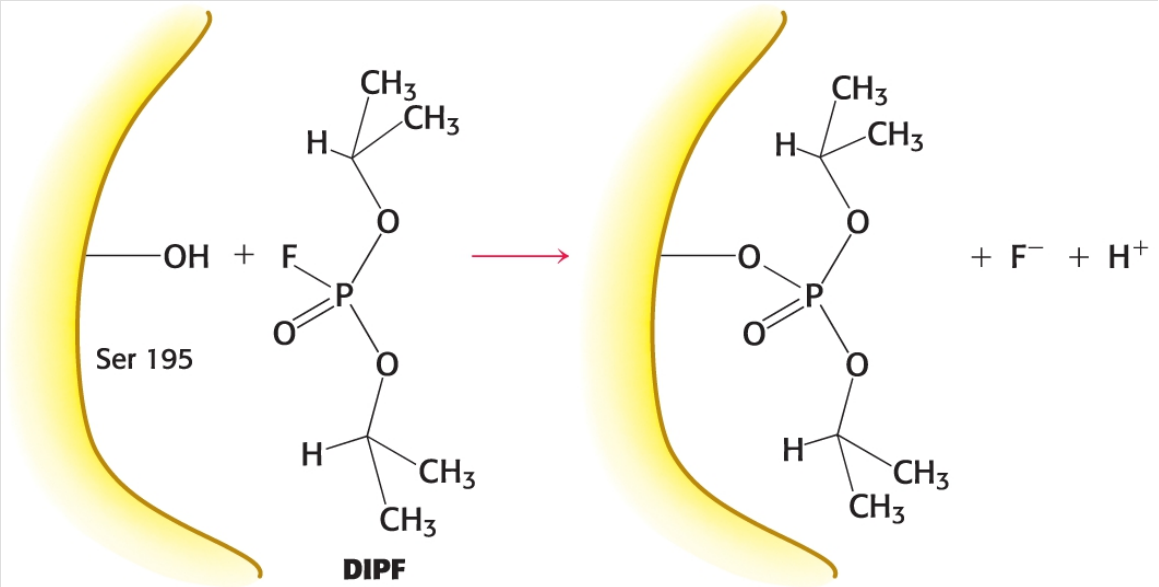
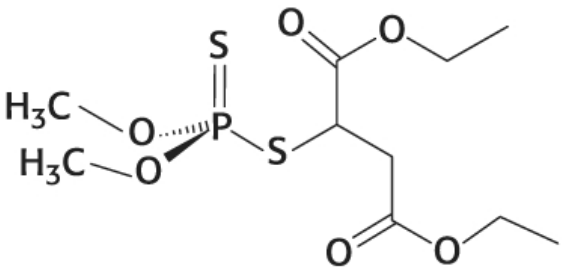
What is the nucleophile that chymotrypsin employs to attack the substrate carbonyl carbon atom? A clue comes from the fact that chymotrypsin contains an extraordinarily reactive serine residue. Chymotrypsin molecules treated with organofluorophosphates such as diisopropylphosphofluoridate (DIPF) lose all activity irreversibly (Figure 6.2). Only a single residue, serine 195, is modified. This chemical modification reaction suggests that this unusually reactive serine residue plays a central role in the catalytic mechanism of chymotrypsin.





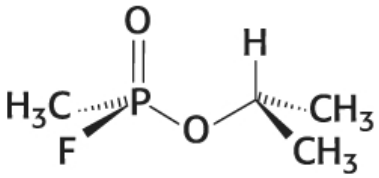


FIGURE 6.2 Chymotrypsin is inactivated by treatment with diisopropylphosphofluoridate (DIPF). DIPF reacts only with one serine among 28 possible serine residues, revealing the unusu reactivity of serine 195.

Phosphorus-based agents that modify reactive serine residues can be potent toxins. Compounds such as malathion, used to kill pest insects, and nerve agents such as sarin, developed as a chemical weapon, each modify a reactive serine residue in a key enzyme in the nervous system and disrupt nerve function.

Malathion

Sarin

Chymotrypsin action proceeds in two steps linked by a covalently bound intermediate

A study of the kinetics of chymotrypsin provides a second clue to its catalytic mechanism. Enzyme kinetics is often monitored by having the enzyme act on a substrate analog, called a **chromogenic substrate**, that forms a colored product. For chymotrypsin, one such substrate is *N*-acetyl-L-phenylalanine *p*-nitrophenyl ester. You might notice that this substrate is an ester rather than an amide, but many proteases will also hydrolyze esters. One of the products formed cleavage of this substrate by chymotrypsin is *p*-nitrophenolate, which has a yellow color (**Figure 6.3**). Measurements of the absorbance of light reveal the amount of *p*-nitrophenolate being produced.

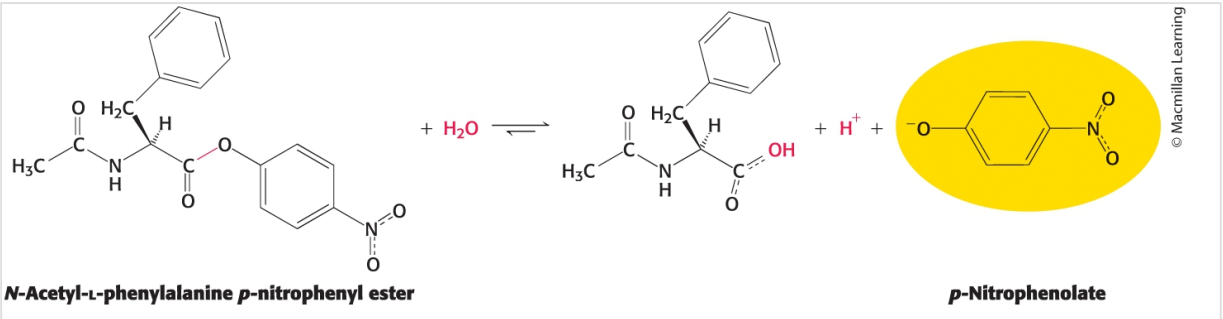

FIGURE 6.3 The action of chymotrypsin can be monitored by using a substrate that forms a colored product. The substrate *N*-Acetyl-L-phenylalanine *p*-nitrophenyl ester is cleaved to produce a yellow-colored product, *p*-nitrophenolate. *p*-Nitrophenolate forms by deprotonation of *p*-nitrophenol at pH 7.

Under steady-state conditions, the cleavage of this substrate obeys Michaelis–Menten kinetics with K_M of $20\ \mu M$ and k_{cat} of $77\ s^{-1}$. More insight into the mechanism can be gained by monitoring the initial phase of the reaction by using the stopped-flow method, which makes it possible to mix enzyme and substrate and monitor the results within a millisecond. This method reveals an initial rapid burst of colored product, followed by its slower formation as the reaction reached the steady state (Figure 6.4), confirming that hydrolysis proceeds in two phases. In the first reaction cycle that takes place on each enzyme molecule immediately after mixing, only the first phase must take place before the colored product is released. In subsequent reaction cycles, both phases must take place. Note that the burst is observed because the first phase is substantially more rapid than the second phase for this substrate.

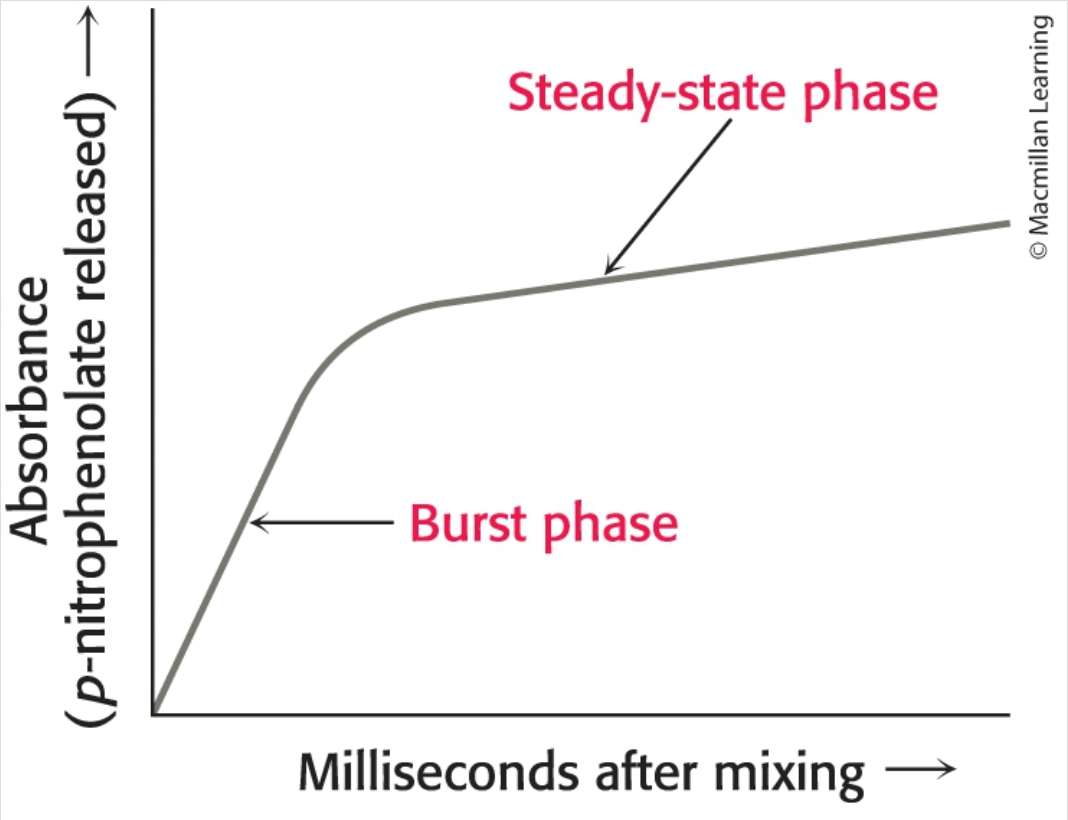

FIGURE 6.4 Two kinetic phases are evident by monitoring the initial action of chymotrypsin. When chymotrypsin is rapidly mixed with a solution of *N*-acetyl-L-phenylalanine *p*-nitrophenyl ester, a rapid burst phase of colored product is

observed followed by a steady-state phase. This observation provides insight into the chymotrypsin mechanism.

The two phases are explained by the formation of a covalent enzyme–substrate intermediate (Figure 6.5). First, the acyl group of the substrate becomes covalently attached to the enzyme as *p*-nitrophenolate (or an amine if the substrate is an amide rather than an ester) is released. The enzyme–acyl group complex is called the acyl-enzyme intermediate. Second, the acyl-enzyme intermediate is hydrolyzed to release the carboxylic acid component of the substrate and regenerate the free enzyme. Thus, one molecule of *p*-nitrophenolate is produced rapidly from each enzyme molecule as the acyl-enzyme intermediate is formed. However, it takes longer for the enzyme to be reset by the hydrolysis of the acyl-enzyme intermediate, and both phases are required for enzyme turnover.

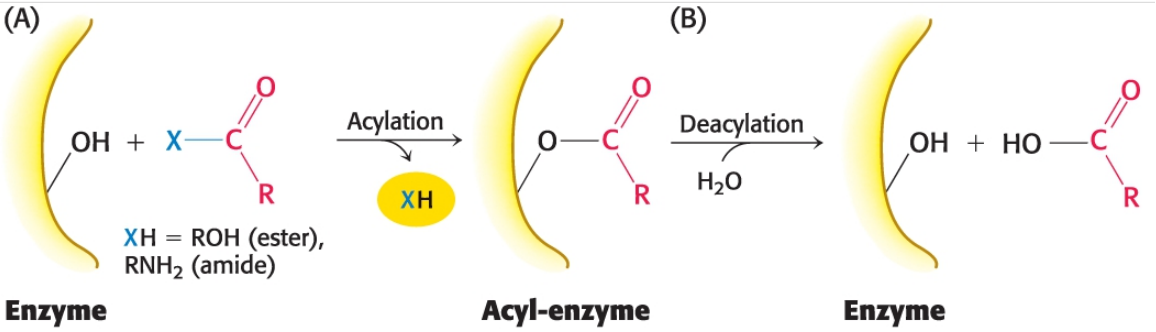

FIGURE 6.5 Hydrolysis by chymotrypsin involves covalent catalysis. In step (A), the enzyme is covalently modified to form an acyl-enzyme intermediate. In step (B), the enzyme is freed by deacylation.

Serine is part of a catalytic triad that also includes histidine and aspartate

The three-dimensional structure of chymotrypsin reveals that this enzyme is roughly spherical and comprises three polypeptide chains, linked by disulfide bonds (Figure 6.6). Note that the active site of chymotrypsin, marked by serine 195, lies in a cleft on the surface of the enzyme. The structure of the active site explains the special reactivity of serine 195 (Figure 6.7). The side chain of serine 195 is hydrogen bonded to the imidazole ring of histidine 57. The —NH group of this imidazole ring is, in turn, hydrogen bonded to the carboxylate group of aspartate 102. This constellation of residues is referred to as the **catalytic triad**.

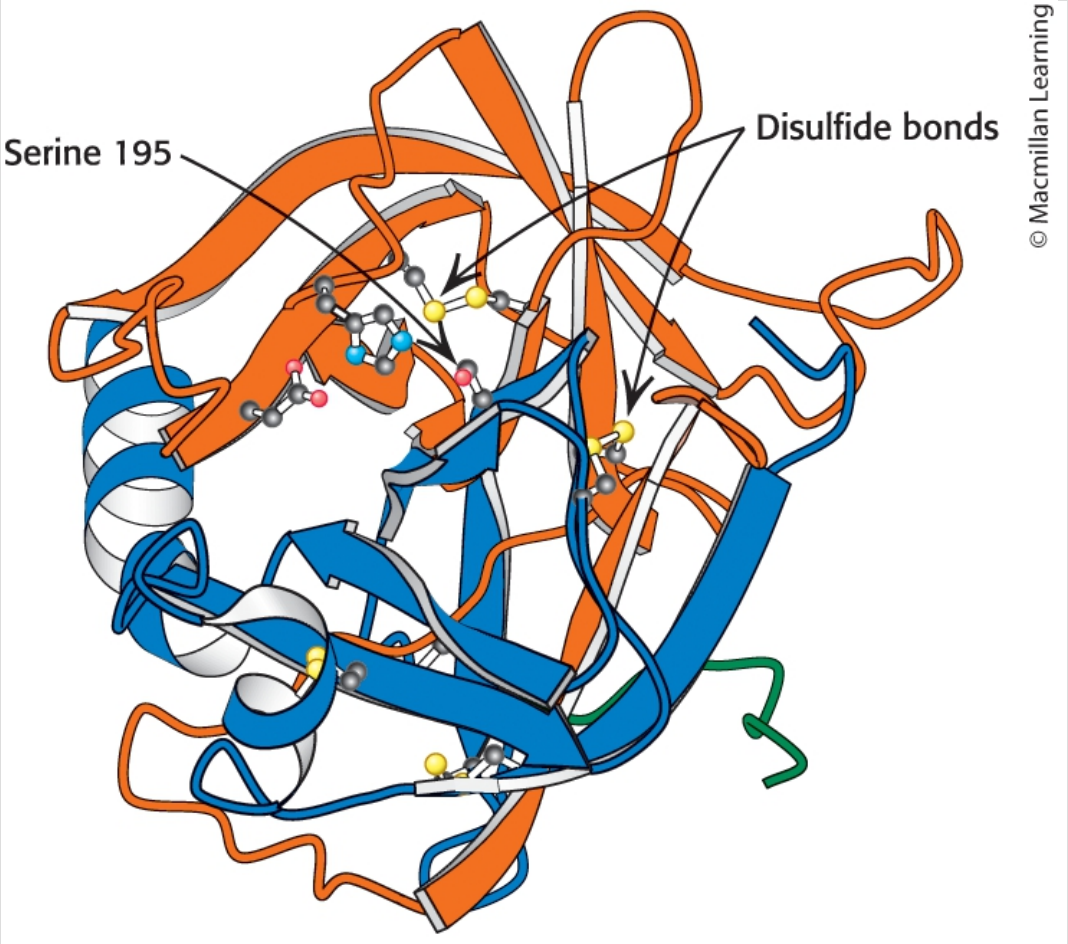

FIGURE 6.6 The active site serine 195 sits in a cleft on the surface of chymotrypsin. In the ribbon diagram shown here, chymotrypsin's three chains are indicated in

orange, blue, and green. Two intrastrand and two interstrand disulfide bonds are also shown.

[Drawn from 1GCT.pdb.]

INTERACT with this model in Achieve

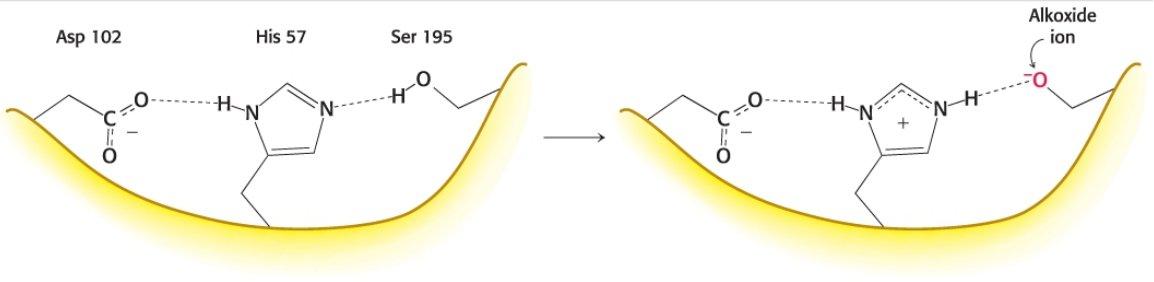

FIGURE 6.7 The catalytic triad increases the reactivity of serine 195. The catalytic triad poises this residue for formation of an alkoxide ion, a much stronger nucleophile than a hydroxyl grou

How does this arrangement of residues lead to the high reactivity of serine 195? The histidine residue serves to position the serine side chain and to polarize its hydroxyl group so that it is poised for deprotonation. In the presence of the substrate, the histidine residue accepts the proton from the serine 195 hydroxyl group. In doing so, the histidine acts as a general base catalyst. The withdrawal of the proton from the hydroxyl group generates an alkoxide ion, which is a much more powerful nucleophile than is an alcohol. The aspartate residue helps orient the histidine residue and make it a better proton acceptor through hydrogen bonding and electrostatic effects.

These observations suggest a mechanism for peptide hydrolysis (Figure 6.8). After substrate binding (step 1), the reaction begins with the oxygen atom of the side chain of serine 195 making a nucleophilic attack on the carbonyl carbon atom of the target peptide bond (step 2).

There are now four atoms bonded to the carbonyl carbon, arranged as a tetrahedron, instead of three atoms in a planar arrangement. This inherently unstable tetrahedral intermediate bears a formal negative charge on the oxygen atom derived from the carbonyl group. This charge is stabilized by interactions with NH groups from the protein in a site termed the **oxyanion hole** (**Figure 6.9**). These interactions also help stabilize the transition state that precedes the formation of the tetrahedral intermediate. This tetrahedral intermediate collapses to generate the acyl-enzyme (step 3), facilitated by the transfer of the proton being held by the positively charged histidine residue to the amino group formed by cleavage of the peptide bond. The amine component is now free to depart from the enzyme (step 4), completing the first stage of the hydrolytic reaction — acylation of the enzyme. Such acyl-enzyme intermediates have been observed using x-ray crystallography by trapping them through adjustment of conditions such as the nature of the substrate, pH, or temperature.

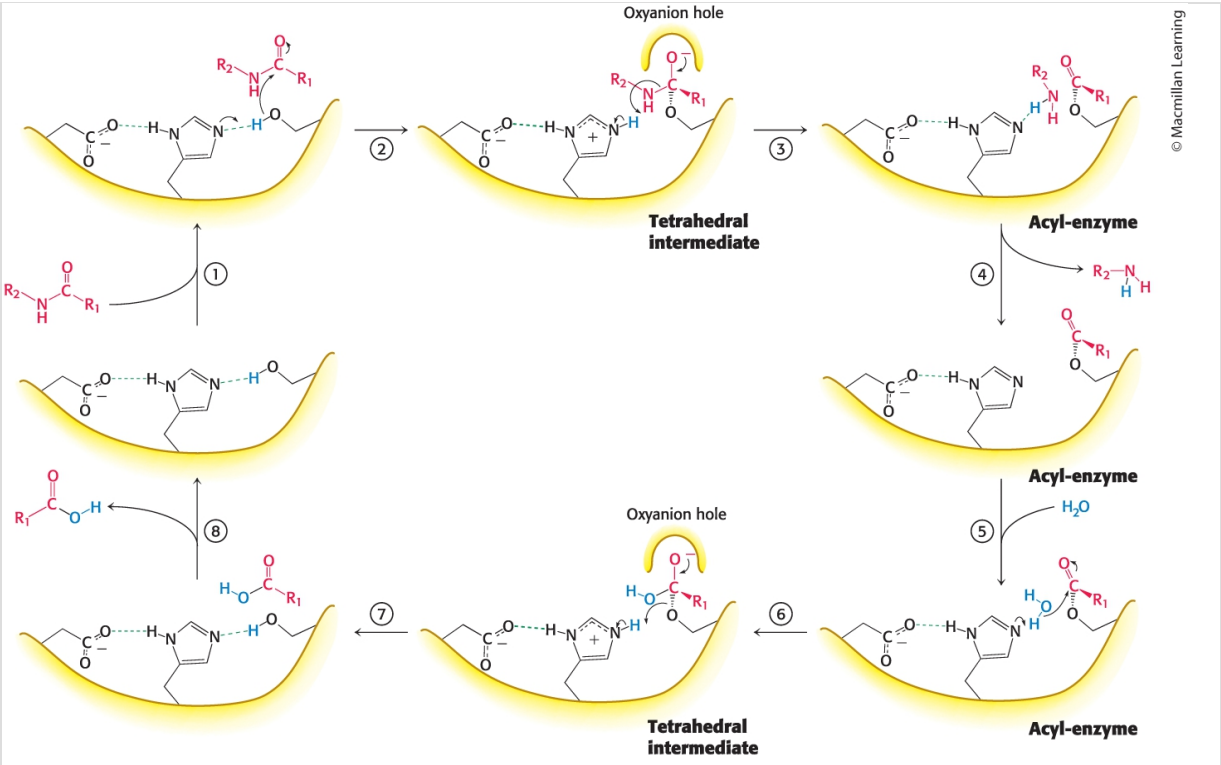

FIGURE 6.8 The mechanism of peptide hydrolysis illustrates the principles of covalent and acid–base catalysis. The mechanism proceeds in eight steps: (1) substrate binding, (2) nucleophilic attack of serine on the peptide carbonyl group, (3) collapse of the tetrahedral

intermediate, (4) release of the amine component, (5) water binding, (6) nucleophilic attack of water on the acyl-enzyme intermediate, (7) collapse of the tetrahedral intermediate, and (8) release of the carboxylic acid component. The dashed green lines represent hydrogen bonds.

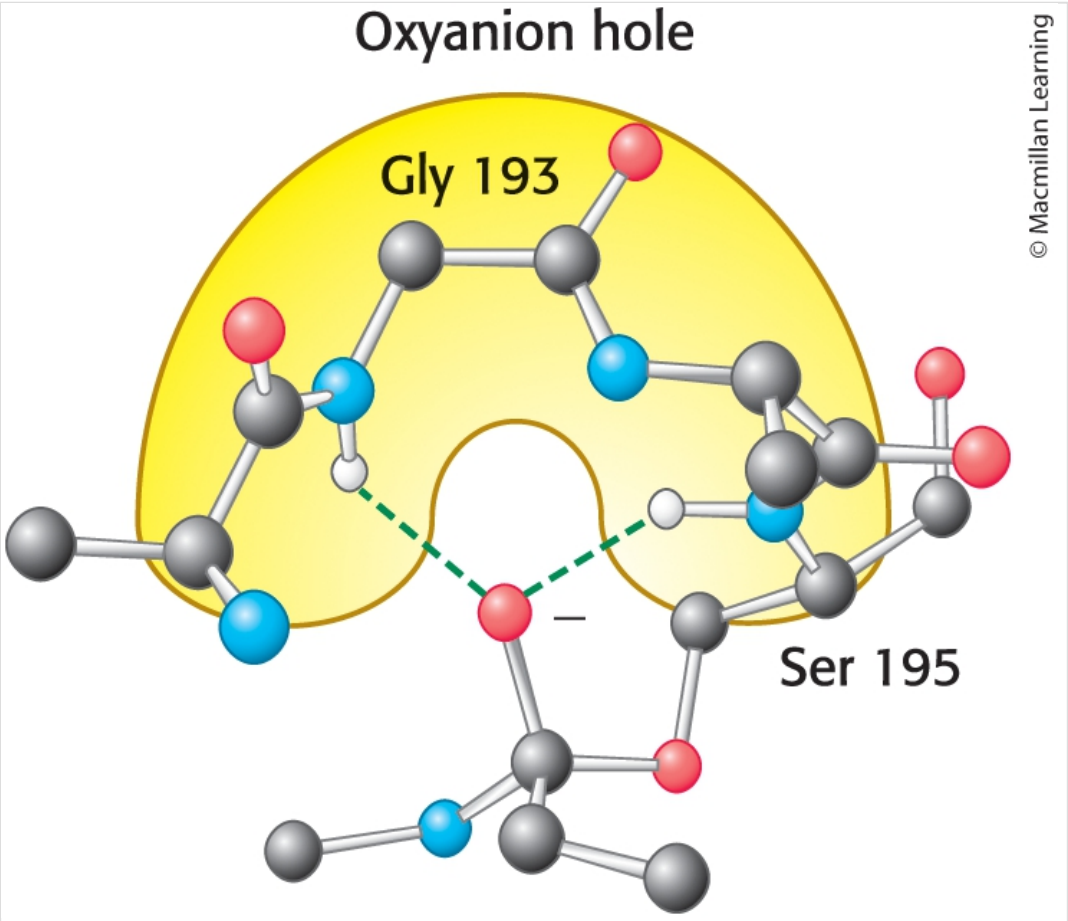

FIGURE 6.9 The oxyanion hole stabilizes the tetrahedral intermediates that occur during the chymotrypsin reaction. Note the hydrogen bonds (shown in green) that link peptide NH groups and the negatively charged oxygen atom of the intermediate.

The next stage — deacylation — begins when a water molecule takes the place occupied earlier by the amine component of the substrate (step 5).

The ester group of the acyl-enzyme is now hydrolyzed by a process that essentially repeats steps 2 through 4. Again acting as a general base catalyst, histidine 57 draws a proton away from the water molecule. The resulting OH^- ion attacks the carbonyl carbon atom of the acyl group, forming a tetrahedral intermediate (step 6). This structure breaks down to form the carboxylic acid product (step 7). Finally, the release of the carboxylic acid product (step 8) readies the enzyme for another round of catalysis.

This mechanism accounts for all characteristics of chymotrypsin action except the observed preference for cleaving the peptide bonds just past residues with large, hydrophobic side chains. Examination of the three-dimensional structure of chymotrypsin with substrate analogs and enzyme inhibitors reveals the presence of a deep hydrophobic pocket, called the S_1 pocket, into which the long, uncharged side chains of residues such as phenylalanine and tryptophan can fit. The binding of an appropriate side chain into this pocket positions the adjacent peptide bond into the active site for cleavage (**Figure 6.10**). The bond to be cleaved is called the **scissile bond**.

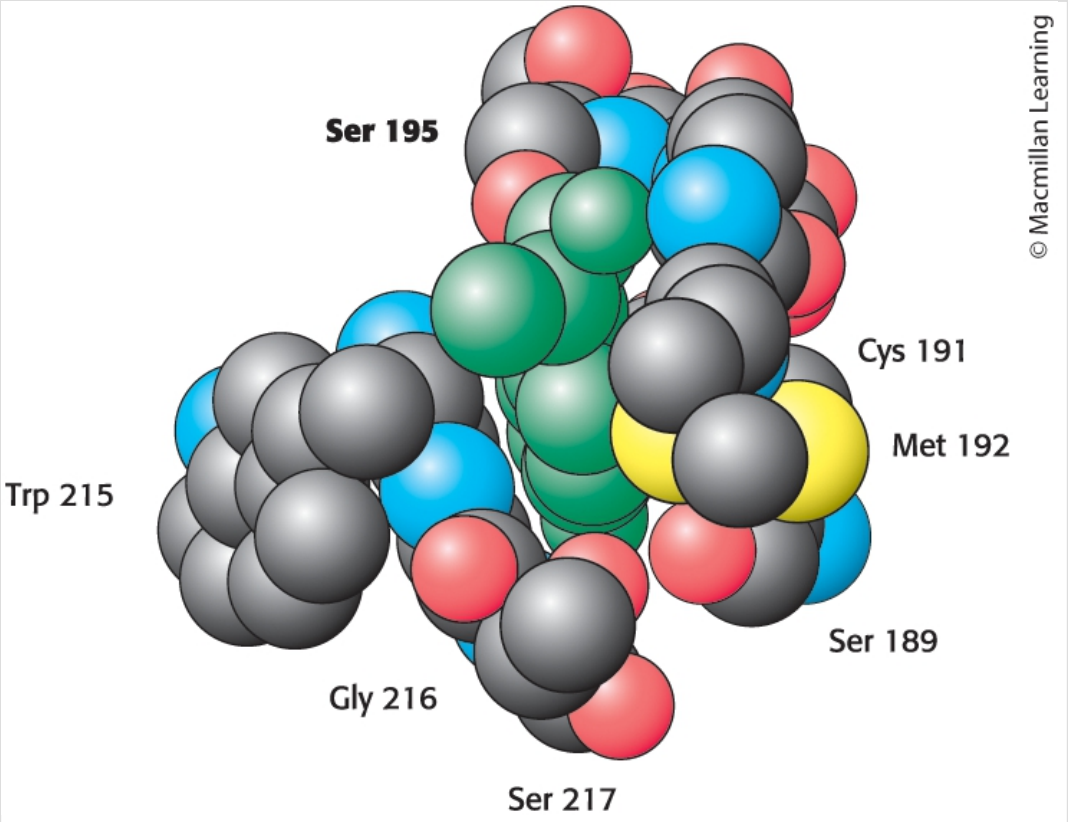

FIGURE 6.10 The specificity pocket of chymotrypsin favors the binding of residues with long hydrophobic side chains. The pocket is deep and lined with hydrophobic residues, with active-site serine residue (serine 195) positioned to cleave the peptide backbone between the residue bound in the pocket (in this case, phenylalanine, shown in green) and the next residue in the sequence.

The specificity of chymotrypsin depends almost entirely on which amino acid is directly on the amino-terminal side of the peptide bond to be cleaved, but other proteases have more-complex specificity patterns. Such enzymes have additional pockets on their surfaces for the recognition of other residues in the substrate. Figure 6.11 shows a generic example of the nomenclature used in diagramming protease-substrate interactions. Residues on the amino-terminal side of the scissile bond are labeled P_1, P_2, P_3, and so forth, heading away from the scissile bond. Likewise, residues on the carboxyl side of the scissile

bond are labeled P_1', P_2', P_3', and so forth. The corresponding sites on the enzyme are referred to as S_1, S_2 or S_1', S_2', and so forth.

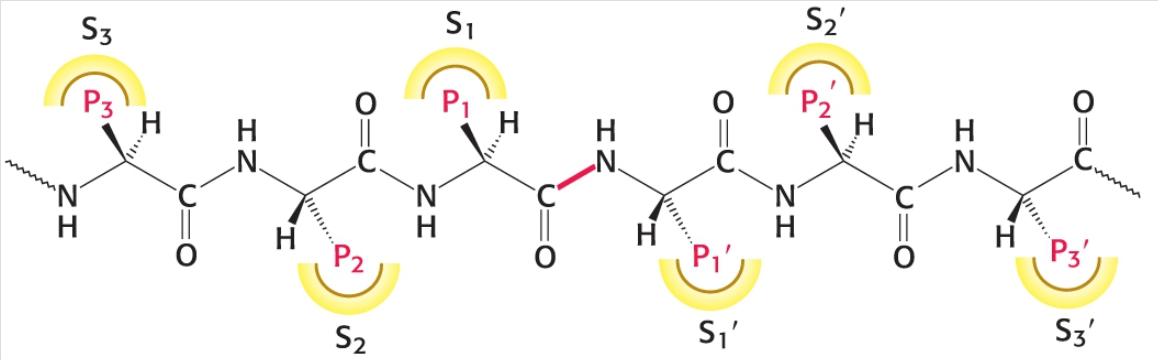

FIGURE 6.11 The specificity nomenclature for protease–substrate interactions shows the potential sites of interaction. The protease site is designated P, and the corresponding binding sites on the enzyme are designated S. The scissile bond (shown in red) is the reference point.

Catalytic triads are found in other hydrolytic enzymes

Many other peptide-cleaving proteins have subsequently been found to contain catalytic triads similar to that discovered in chymotrypsin. Some, such as trypsin and elastase, are obvious homologs of chymotrypsin; that is, they clearly evolved from a common ancestor. The sequences of these proteins are approximately 40% identical with that of chymotrypsin, and their overall structures are quite similar (Figure 6.12). These proteins operate by mechanisms identical with that of chymotrypsin. However, the three enzymes differ markedly in substrate specificity. Chymotrypsin cleaves at the peptide bond after residues with an aromatic or long, nonpolar side chain. Trypsin cleaves at the peptide bond after residues with long, positively charged side

chains — namely, arginine and lysine. Elastase cleaves at the peptide bond after amino acids with small side chains — such as alanine and serine.

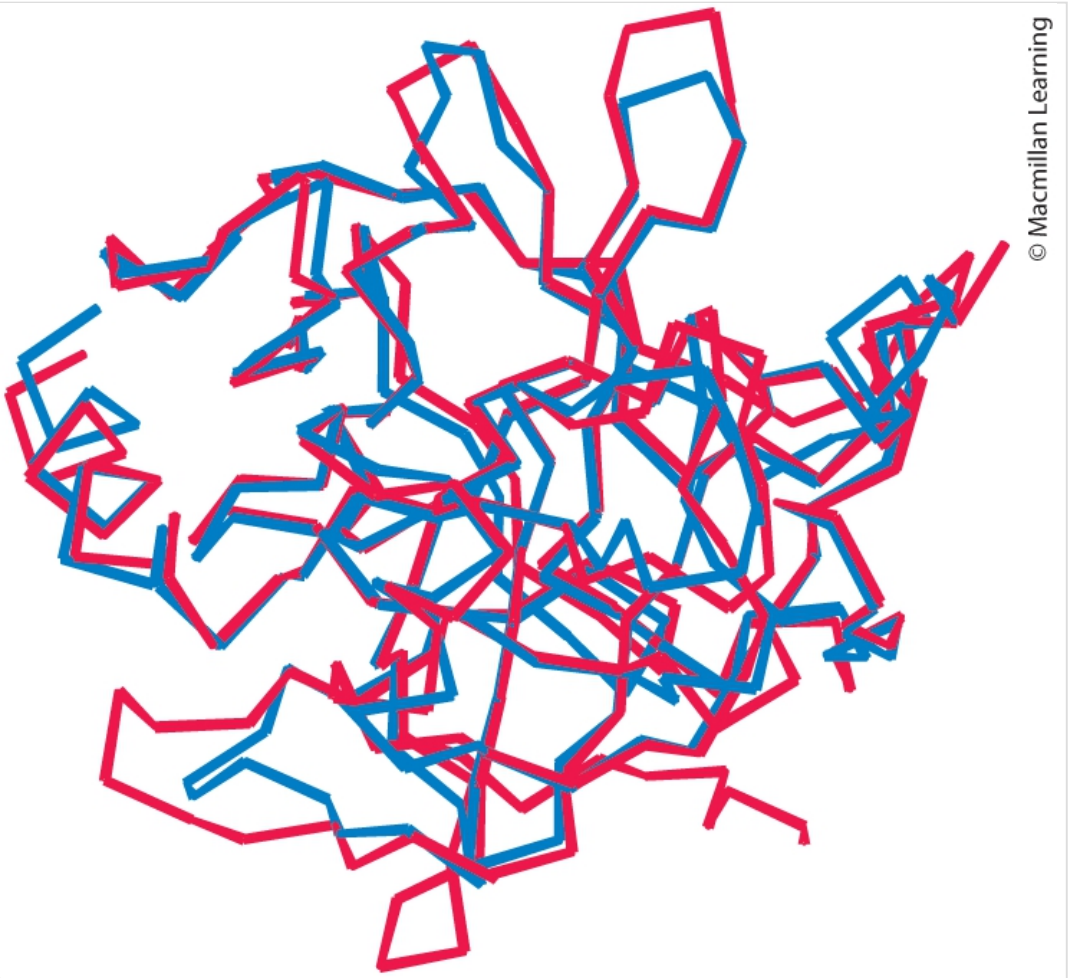

FIGURE 6.12 Chymotrypsin and trypsin are structurally similar. This similarity is revealed by overlaying the structures of chymotrypsin (red) and trypsin (blue). Only α-carbon-atom positions are shown. The mean deviation in position between corresponding α-carbon atoms is quite small, only 1.7 Å.

[Drawn from 5PTP.pdb and 1GCT.pdb.]

INTERACT with this model in Achieve

Comparison of the S_1 pockets of these enzymes reveals that these different specificities are due to small structural differences. In trypsin, an aspartate residue (Asp 189) is present at the bottom of the S_1 pocket in place of a serine residue in chymotrypsin. The aspartate residue attracts and stabilizes a positively charged arginine or lysine residue in the substrate. In elastase, two residues at the top of the pocket in chymotrypsin and trypsin are replaced by much bulkier valine residues (Val 190 and Val 216). These residues close off the mouth of the pocket so that only small side chains can enter (Figure 6.13).

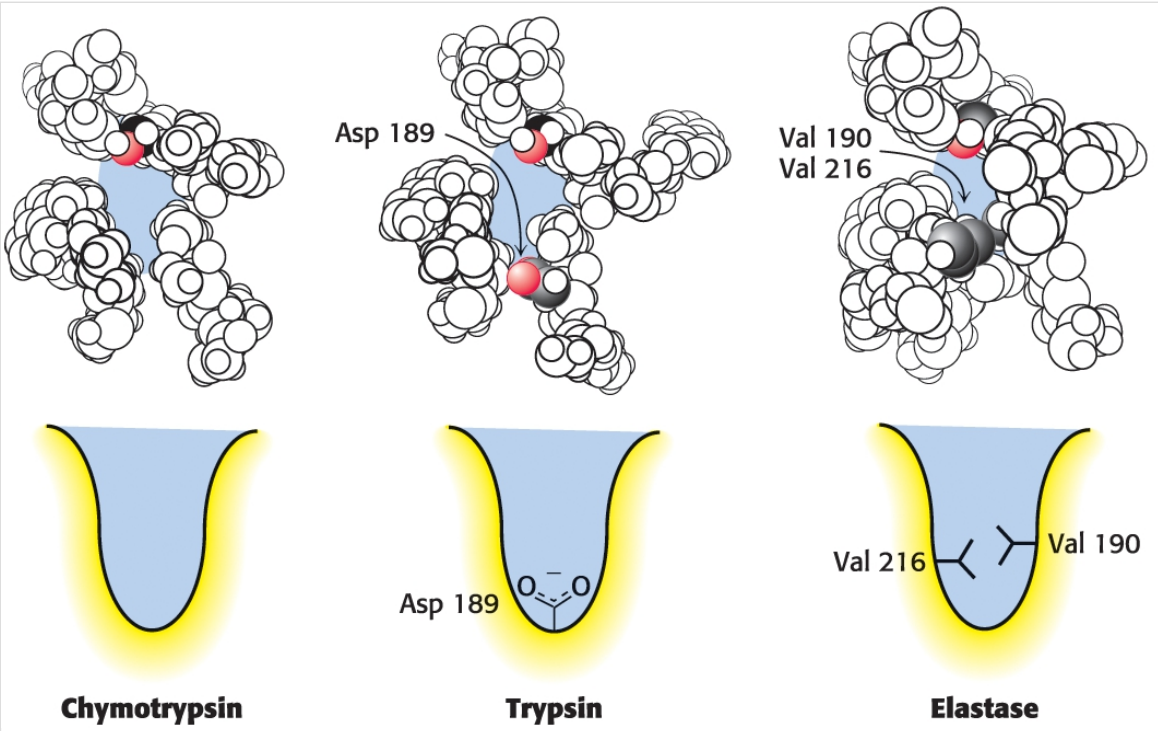

FIGURE 6.13 The S_1 pockets of chymotrypsin, trypsin, and elastase show the residues that play key roles in determining enzyme specificity. The side chains of these residues, as well as those of the active-site serine residues, are shown in color, and schematic depictions are shown below.

Other members of the chymotrypsin family include a collection of proteins that take part in blood clotting, to be discussed in Chapter 7, as well as the tumor marker protein prostate-specific antigen (PSA). In addition, a wide range of proteases found in bacteria, viruses, and plants belong to this clan.

Other enzymes that are not homologs of chymotrypsin have been found to contain very similar active sites to that of chymotrypsin, not because of a shared common ancestor, but because a similar active evolved independently. Subtilisin, a protease in bacteria such as *Bacillus amyloliquefaciens*, is a particularly well-characterized example. The active site of this enzyme includes both the catalytic triad and the oxyanion hole. However, one of the NH groups that forms the oxyanion hole comes from the side chain of an asparagine residue rather than from the peptide backbone (**Figure 6.14**). Subtilisin is the founding member of another large family of proteases. Still other proteases have been discovered that contain an active-site serine or threonine residue that is activated not by a histidine–aspartate pair but by a primary amino group from the side chain of lysine or by the N-terminal amino group of the polypeptide chain.

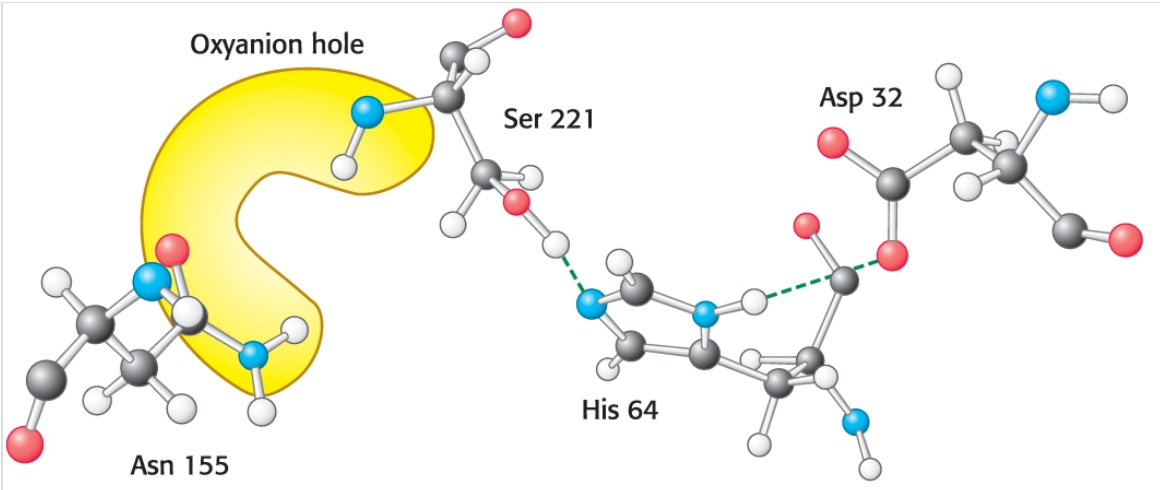

FIGURE 6.14 The catalytic triad and oxyanion hole of subtilisin includes two NH groups, one from the backbone and one from the side chain of Asn 155. The NH groups will stabilize a negative charge that develops on the peptide bond attacked by nucleophilic serine 221 of the catalytic triad.

The catalytic triad in proteases has clearly emerged several times in the course of evolution. We can conclude that this catalytic strategy must be an especially effective approach to the hydrolysis of peptides and related bonds.

Scientists have dissected the catalytic triad using site-directed mutagenesis

How can we test the validity of the mechanism proposed for the catalytic triad? One way is to test the contribution of individual amino acid residues to the catalytic power of a protease by using site-directed mutagenesis. Subtilisin has been extensively studied by this method. Each of the residues within the catalytic triad, consisting of aspartic acid 32, histidine 64, and serine 221, has been individually converted into alanine, and the ability of each mutant enzyme to cleave a model substrate has been examined (**Figure 6.15**).

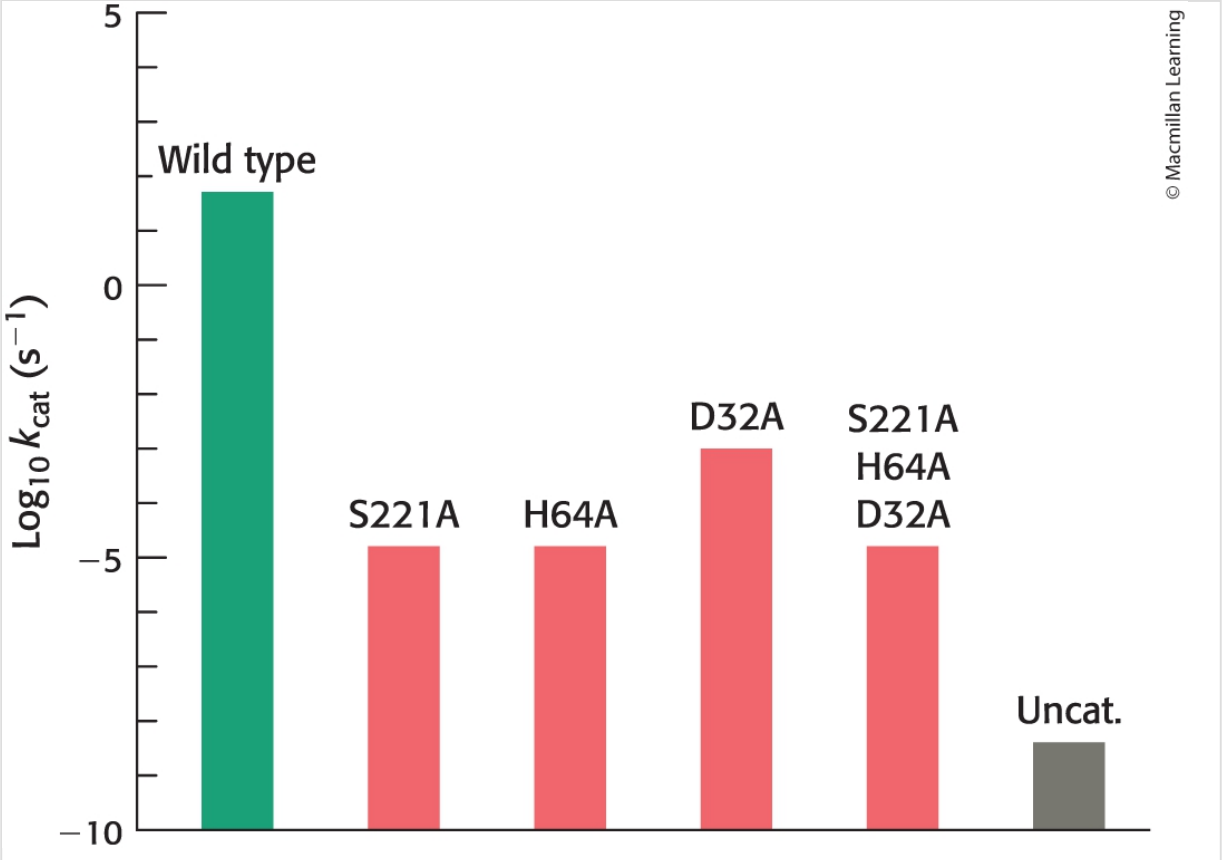

FIGURE 6.15 Mutating the residues of the catalytic triad to alanine allows the importance of each residue for catalytic activity to be quantified. Note that the activities are displayed on a logarithmic scale. The mutations are identified as follows: the first letter is the one-letter abbreviation for the amino acid being altered; the number identifies the position of the residue in the primary structure; and the second letter is the one-letter abbreviation for the amino acid replacing the original one. *Uncat.* refers to the estimated rate for the uncatalyzed reaction.

As expected, the conversion of active-site serine 221 into alanine dramatically reduces catalytic power; the value of k_{cat} falls to less than one millionth of its value for the wild-type enzyme. The value of K_M is essentially unchanged; its increase by no more than a factor of two indicates that substrate continues to bind normally. The mutation of histidine 64 to alanine reduces catalytic power to a similar degree. The conversion of aspartate 32 into alanine reduces catalytic power by less, although the value of k_{cat} still falls to less than 0.005% of its wild-type

value. The simultaneous conversion of all three residues into alanine is no more deleterious than the conversion of serine or histidine alone. These observations support the notion that the catalytic triad and, particularly, the serine–histidine pair act together to generate a nucleophile of sufficient power to attack the carbonyl carbon atom of a peptide bond. Despite the reduction in their catalytic power, the mutated enzymes still hydrolyze peptides a thousand times as fast as buffer at pH 8.6.

Site-directed mutagenesis also offers a way to probe the importance of the oxyanion hole for catalysis. The mutation of asparagine 155 to glycine eliminates the side-chain NH group from the oxyanion hole of subtilisin. The elimination of the NH group reduces the value of k_{cat} to 0.2% of its wild-type value but increases the value of K_M by only a factor of two. These observations demonstrate that the NH group of the asparagine residue plays a significant role in stabilizing the tetrahedral intermediate and the transition state leading to it.

Some proteases cleave peptides at other locations besides serine residues

Not all proteases use strategies based on activated serine residues. Classes of proteins have been discovered that employ three alternative approaches to peptide-bond hydrolysis. In each case, the strategy is to generate a nucleophile that attacks the peptide carbonyl group (**Figure 6.16**).

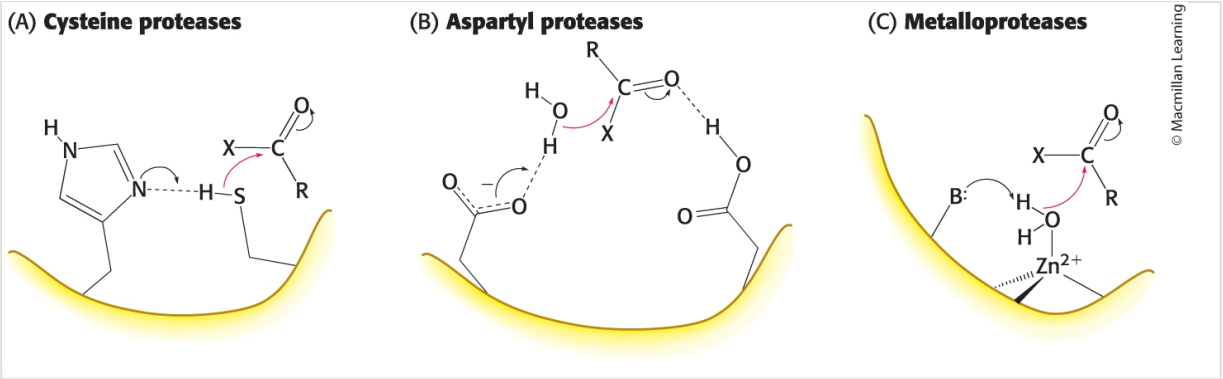

FIGURE 6.16 The key steps employed by the three classes of proteases reveal three different catalytic strategies. The peptide carbonyl group is attacked by (A) a histidine-activated cysteine in the cysteine proteases, (B) an aspartate-activated water molecule in the aspartyl proteases, and (C) a metal-activated water molecule in the metalloproteases. For the metalloproteases, the letter B represents a base (often glutamate) that helps deprotonate the metal-bound water.

Cysteine proteases

The strategy used by the cysteine proteases is most similar to that used by the chymotrypsin family. In these enzymes, a cysteine residue, activated by a histidine residue, plays the role of the nucleophile that attacks the peptide bond in a manner quite analogous to that of the serine residue in serine proteases (Figure 6.16). Because the sulfur atom in cysteine is inherently a better nucleophile than is the oxygen atom in serine, cysteine proteases appear to require only this histidine residue in addition to cysteine and not the full catalytic triad.

Aspartyl proteases

The central feature of the active sites in aspartyl proteases is a pair of aspartic acid residues that act together to allow a water molecule to attack the peptide bond. One aspartic acid residue (in its deprotonated form) activates the attacking water molecule by poising it for deprotonation. The other aspartic acid residue (in its protonated form)

polarizes the peptide carbonyl group so that it is more susceptible to attack (Figure 6.16).

Metalloproteases

The active site of a metalloprotease contains a bound metal ion, most often zinc, that activates a water molecule to act as a nucleophile to attack the peptide carbonyl group. In each of these three classes of enzymes, the active site includes features that act to (1) activate a water molecule or another nucleophile, (2) polarize the peptide carbonyl group, and (3) stabilize a tetrahedral intermediate (Figure 6.16).

Self-Check Question

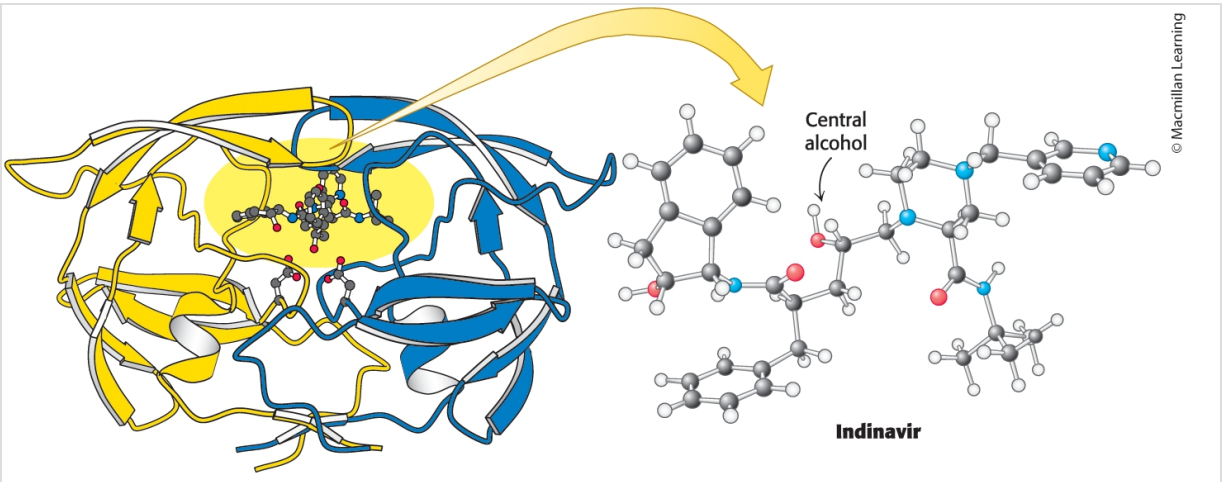
Write out a mechanism for a cysteine protease analogous with that for chymotrypsin.

Protease inhibitors are important drugs

Because of the fundamental biological roles of proteases, these enzymes are important drug targets. Drugs that block protease activity are called **protease inhibitors**. For example, captopril, a drug used to regulate blood pressure, is one of many inhibitors of the angiotensin-converting enzyme (ACE), a metalloprotease. Indinavir (Crixivan), retrovir, and many other compounds used in the treatment of AIDS are inhibitors of HIV protease, an aspartyl protease. HIV protease cleaves multidomain

viral proteins into their active forms; blocking this process completely prevents the virus from being infectious. HIV protease inhibitors, in combination with inhibitors of other key HIV enzymes, have dramatically reduced deaths due to AIDS, assuming that the cost of the treatment could be covered. In many cases, these drugs have converted AIDS from a death sentence to a treatable chronic disease.

Indinavir, one of the first HIV protease inhibitors developed but not one that is widely used at present, reveals an important strategy for developing enzyme inhibitors. Indinavir was designed to resemble a peptide substrate of the enzyme. X-ray crystallographic studies revealed that indinavir adopts a confirmation that approximates the twofold symmetry of the enzyme (Figure 6.17). The active site of HIV protease is covered by two flexible flaps that fold down on top of the bound inhibitor. The OH group of the central alcohol interacts with the two aspartate residues of the active site and was intended to mimic a water molecule observed in crystal structures of HIV protease but generally absent in cellular aspartyl proteases. This OH group was intended to contribute to the specificity of indinavir for HIV protease. To prevent side effects, enzyme inhibitors used as drugs should be relatively specific for one enzyme, minimally inhibiting other similar enzymes within the body.



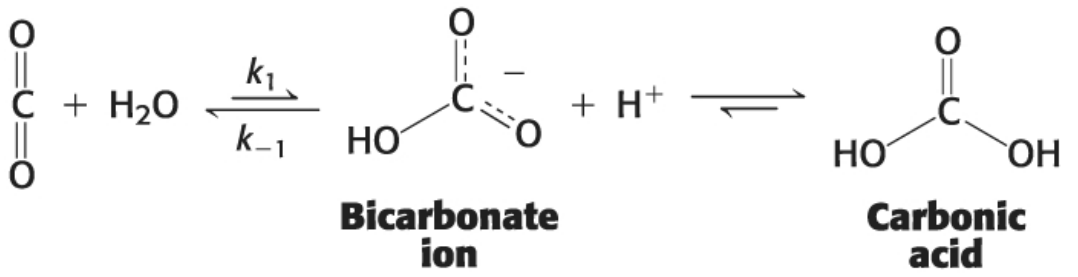


FIGURE 6.17 HIV protease has twofold symmetry. (Left) The three-dimensional structure of HIV protease is shown with the inhibitor indinavir bound in the active site. (Right) The drug has been rotated to reveal its approximately twofold symmetric conformation.

6.3 Carbonic Anhydrases Make a Fast Reaction Faster

Carbon dioxide is a major end product of aerobic metabolism. In mammals, this carbon dioxide is released into the blood and transported to the lungs for exhalation. While in the red blood cells, carbon dioxide reacts with water. The products of this reaction are bicarbonate ion (HCO_3^-) and a proton. These are a form of carbonic acid, H_2CO_3, a moderately strong acid, with $pK_a = 3.5$.

Even in the absence of a catalyst, this hydration reaction proceeds at a moderately fast pace. At 37°C near neutral pH, the second-order rate constant k_1 is $0.0027\ M^{-1}\ s^{-1}$. This value corresponds to an effective first-order rate constant of $0.15\ s^{-1}$ in water $([H_2O] = 55.5\ M)$. The reverse reaction, the dehydration of HCO_3^-, is even more rapid, with a rate constant of $k_{-1} = 50\ s^{-1}$. These rate constants correspond to an equilibrium constant of $K_1 = 5.4 \times 10^{-5}$ and a ratio of $[CO_2]$ to $[H_2CO_3]$ of 340:1 at equilibrium.

Carbon dioxide hydration and HCO_3^- dehydration are often coupled to rapid processes, particularly transport processes. Thus, almost all organisms contain enzymes, referred to as **carbonic anhydrases**, that increase the rate of reaction beyond the already relatively high spontaneous rate. For example, carbonic anhydrases dehydrate HCO_3^- in the blood to form CO_2 for exhalation as the blood passes through the lungs. Conversely, they convert CO_2 into HCO_3^- to generate the aqueous humor of the eye and other secretions. For this reason, one of the drugs used for treating glaucoma, a condition associated with too much pressure inside the eye, acts by inhibiting carbonic anhydrase. Furthermore, both CO_2 and HCO_3^- are substrates and products for a variety of enzymes, and the rapid interconversion of these species may be necessary to ensure appropriate substrate levels.

Carbonic anhydrases accelerate CO_2 hydration dramatically. The most-active enzymes hydrate CO_2 at rates as high as $k_{cat} = 10^6\ s^{-1}$, or a million times a second per enzyme molecule. Fundamental physical processes such as diffusion and proton transfer ordinarily limit the rate of hydration, and so the enzymes employ special strategies to attain such high rates.

Carbonic anhydrase contains a bound zinc ion essential for catalytic activity

Less than 10 years after the discovery of carbonic anhydrase in 1932, this enzyme was found to contain a bound zinc ion. Moreover, the zinc ion appeared to be necessary for catalytic activity. This discovery, remarkable at the time, made carbonic anhydrase the first known zinc-containing enzyme. At present, thousands of enzymes are known to contain zinc. In fact, more than one-third of all enzymes either contain bound metal ions or require the addition of such ions for activity.

Metal ions have several properties that increase chemical reactivity: their positive charges, their ability to form strong yet kinetically labile bonds, and, in some cases, their capacity to be stable in more than one oxidation state. The chemical reactivity of metal ions explains why catalytic strategies that employ metal ions have been adopted throughout evolution.

X-ray crystallographic studies have supplied the most detailed and direct information about the zinc site in carbonic anhydrase. At least seven carbonic anhydrases, each with its own gene, are present in human beings. They are all clearly homologous, as revealed by substantial sequence identity. Carbonic anhydrase II, a major protein component of red blood cells, has been the most extensively studied (Figure 6.18). It is also one of the most active carbonic anhydrases.

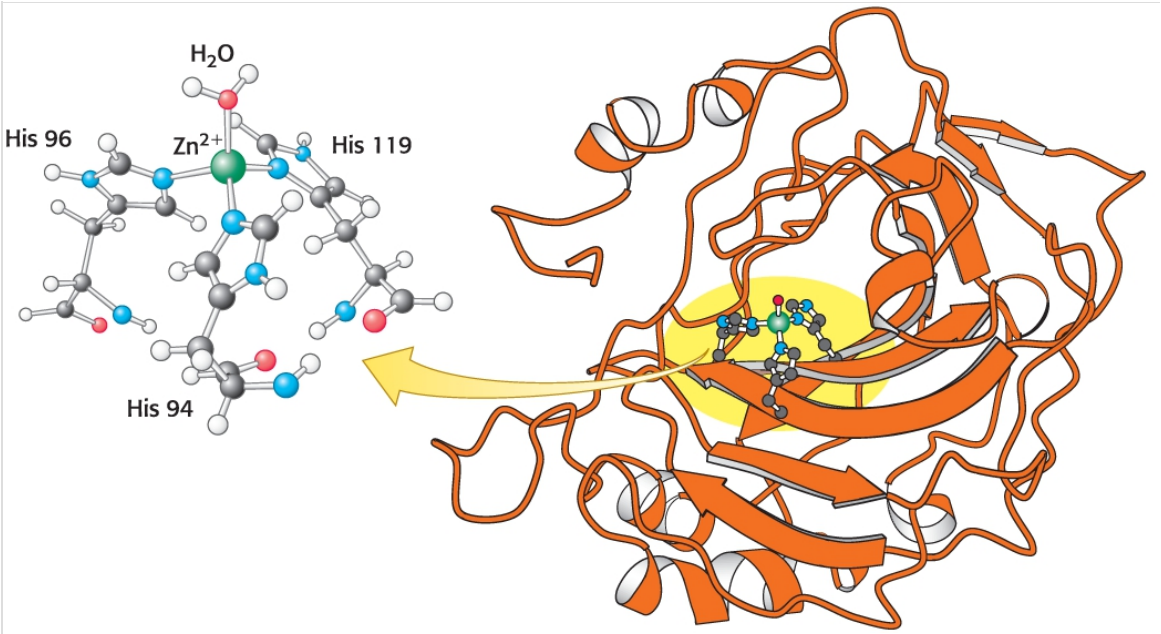

FIGURE 6.18 The active site of human carbonic anhydrase II includes a bound zinc ion. The active site includes a zinc ion that is bound to the imidazole rings of three histidine residues as well as to a water molecule in a cleft near the center of the enzyme.

[Drawn from 1CA2.pdb.]

INTERACT with this model in Achieve

Zinc is found only in the $^{+2}$ state in biological systems. A zinc atom is essentially always bound to four or more specific molecules or groups, called **ligands**. In carbonic anhydrase, three coordination sites are occupied by nitrogen ligands from the imidazole rings of three histidine residues, and an additional coordination site is occupied by a water molecule (or a hydroxide ion, depending on pH). Because the ligands occupying the coordination sites are neutral, the overall charge on the $Zn(His)_3$ unit remains $^{+2}$.

Catalysis involves zinc activation of a water molecule

How does this zinc complex facilitate carbon dioxide hydration? A major clue comes from the pH profile of enzymatically catalyzed carbon dioxide hydration (**Figure 6.19**). At pH 8, the reaction proceeds near its maximal rate. As the pH decreases, the rate of the reaction drops. The midpoint of this transition is near pH 7, suggesting that a group that loses a proton at pH 7 $(pK_a = 7)$ plays an important role in the activity of carbonic anhydrase. Moreover, the curve suggests that the deprotonated (high pH) form of this group participates more effectively in catalysis. Although some amino acids, notably histidine, have pK_a values near 7, a variety of evidence suggests that the group responsible for this transition is not an amino acid but is the zinc-bound water molecule.

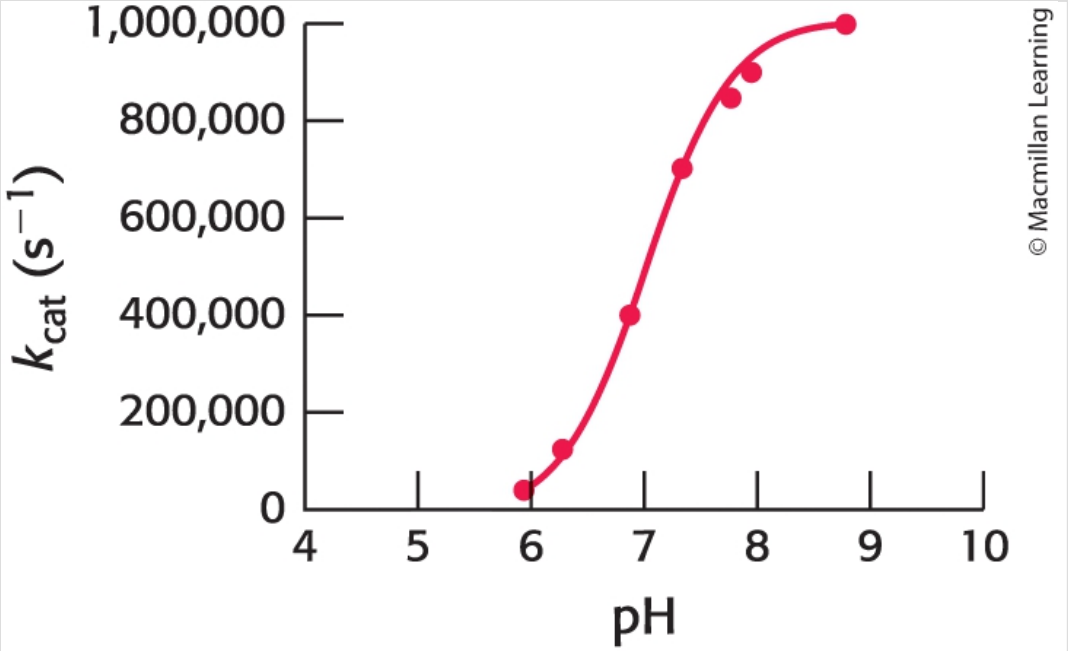

FIGURE 6.19 The activity of carbonic anhydrase varies with pH. The enzyme is maximally active at pH values near 9.

The binding of a water molecule to the positively charged zinc center reduces the pK_a of the water molecule from 15.7 to 7 (Figure 6.20). With the pK_a lowered, the water molecule can more easily lose a proton at neutral pH, generating a substantial concentration of hydroxide ion (bound to the zinc atom). A zinc-bound hydroxide ion (OH^-) is a potent nucleophile able to attack carbon dioxide much more readily than water does. Adjacent to the zinc site, carbonic anhydrase also possesses a hydrophobic patch that serves as a binding site for carbon dioxide (Figure 6.21). Based on these observations, a simple mechanism for carbon dioxide hydration can be proposed (Figure 6.22):

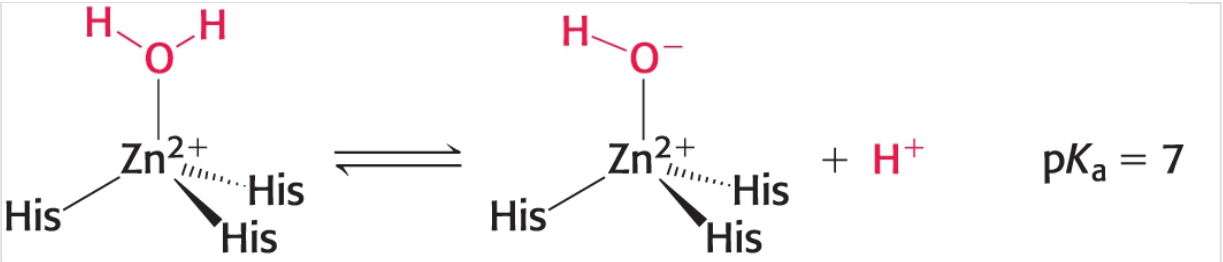

FIGURE 6.20 Upon binding to zinc in carbonic anhydrase, the pK_a of water decreases from 15.7 to approximately 7.

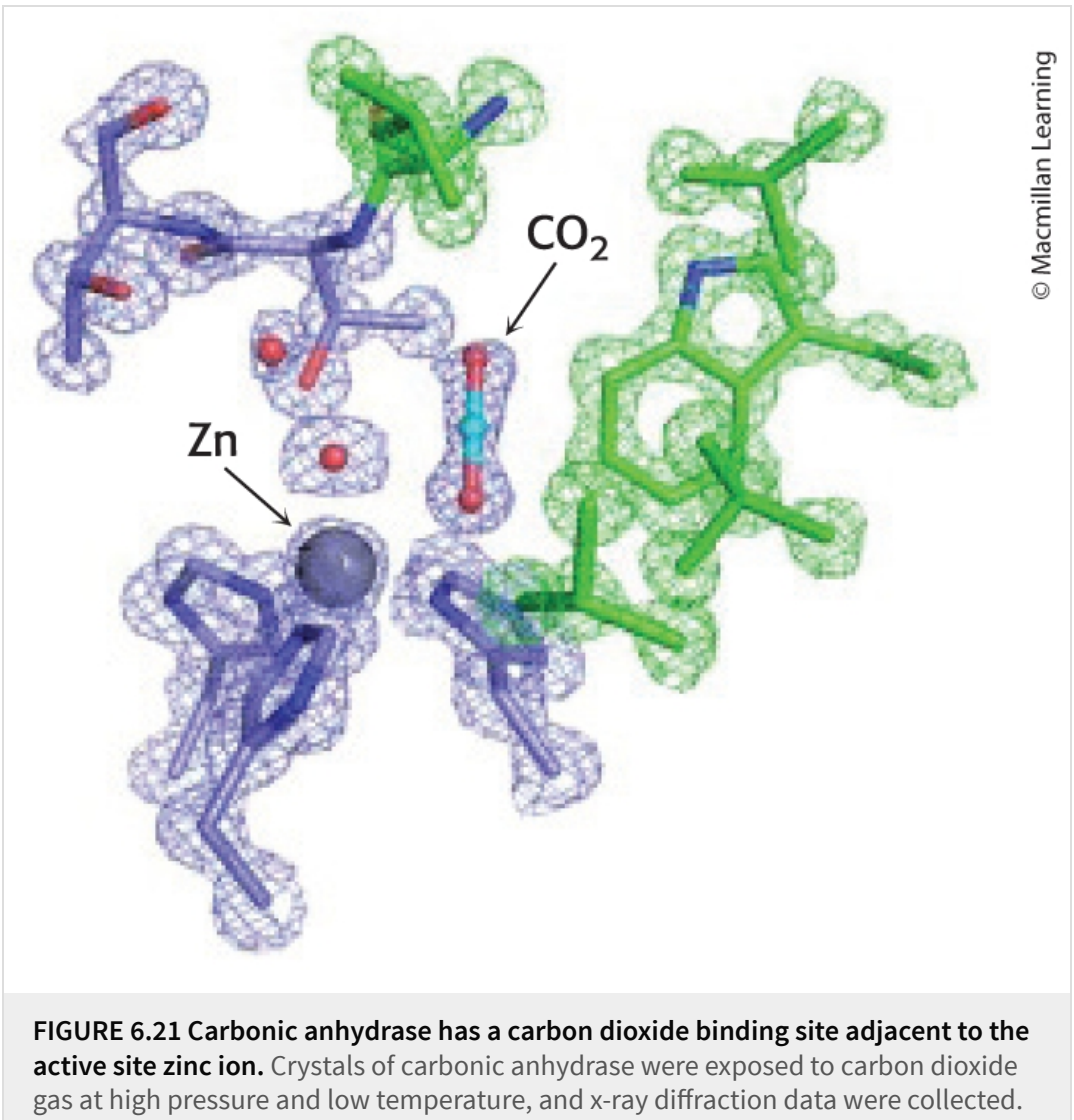

FIGURE 6.21 Carbonic anhydrase has a carbon dioxide binding site adjacent to the active site zinc ion. Crystals of carbonic anhydrase were exposed to carbon dioxide gas at high pressure and low temperature, and x-ray diffraction data were collected.

The electron density (shown as cages) for carbon dioxide, clearly visible adjacent to the zinc and its bound water, reveals the carbon dioxide binding site. Hydrophobic amino acids are shaded green, and the purple ones are hydrophilic.

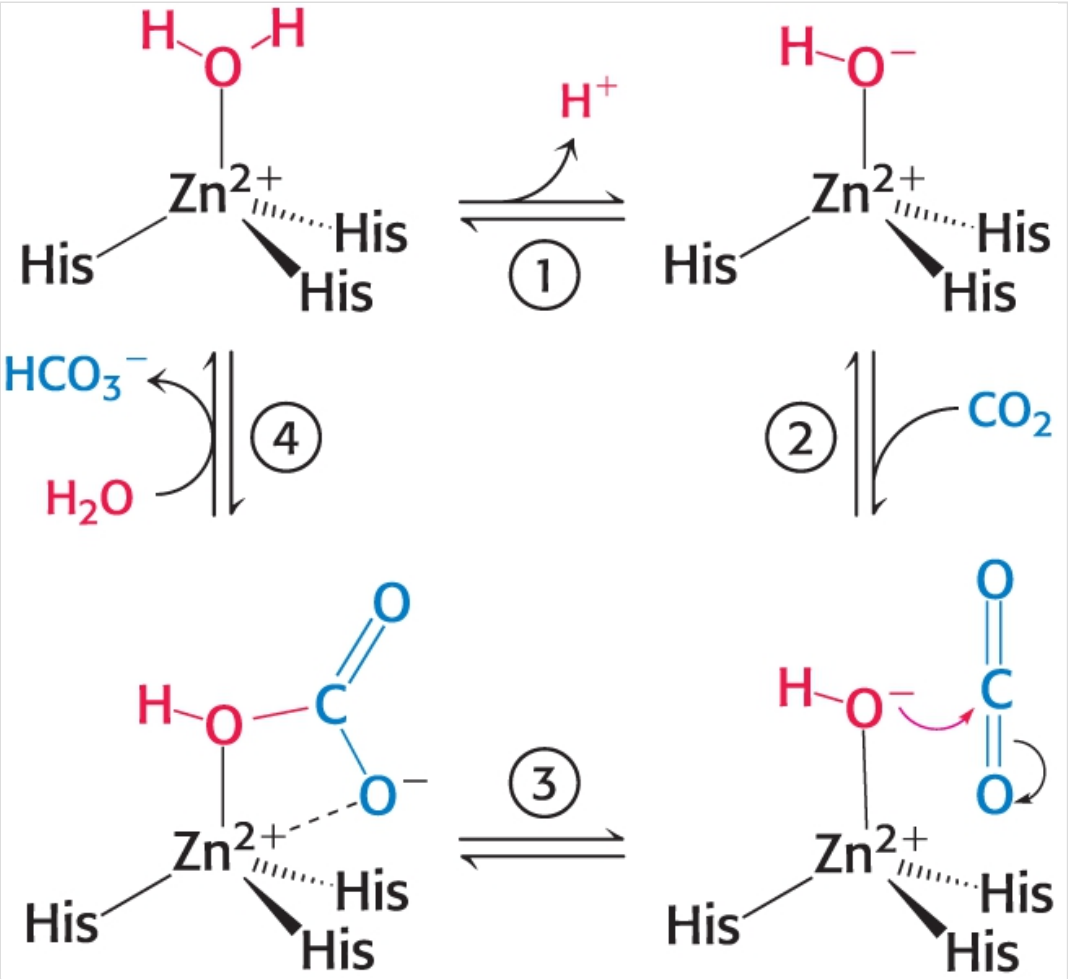

FIGURE 6.22 The zinc-bound hydroxide mechanism for the hydration of carbon dioxide proceeds in four steps. These are (1) water deprotonation, (2) carbon dioxide binding, (3) nucleophilic attack by hydroxide on carbon dioxide, and (4) displacement of bicarbonate ion by water. This mechanism provides a good example of one type of metal ion catalysis.

1. The zinc ion facilitates the release of a proton from a water molecule, which generates a hydroxide ion.
2. The carbon dioxide substrate binds to the enzyme's active site and is positioned to react with the hydroxide ion.
3. The hydroxide ion attacks the carbon dioxide, converting it into bicarbonate ion, HCO_3^-.
4. The catalytic site is regenerated with the release of HCO_3^- and the binding of another molecule of water.

Thus, the binding of a water molecule to the zinc ion favors the formation of the transition state by facilitating proton release and by positioning the water molecule to be in close proximity to the other reactant.

Rapid regeneration of the active form of carbonic anhydrase depends on proton availability

In the first step of a carbon dioxide hydration reaction, the zinc-bound water molecule must lose a proton to regenerate the active form of the enzyme (Figure 6.23). Let use consider this in detail:

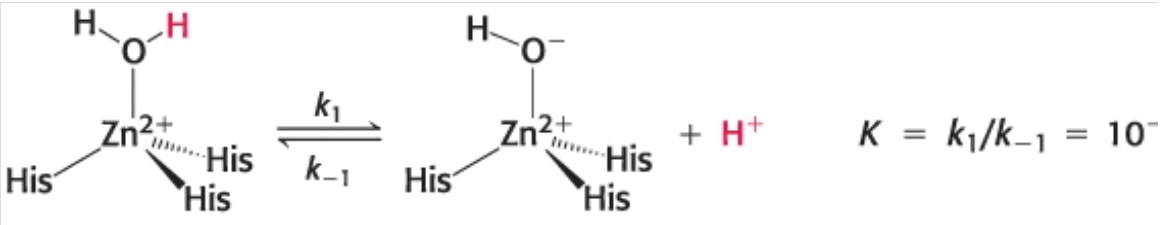

FIGURE 6.23 The ratio of the rate constant for water deprotonation to that for hydroxide protonation must equal 10^{-7}. This is true since the pK_a of this water molecule in carbonic anhydrase is 7.

- The equilibrium constant for this process is $K = 10^{-7}\ \mathrm{M}$ (since $\mathrm{p}K_a = 7$) and $K = k_1 / k_{-1}$.
- The rate of the reverse reaction, the protonation of the zinc-bound hydroxide ion, is limited by the rate of proton diffusion. Protons diffuse very rapidly with second-order rate constants near $10^{11}\ \mathrm{M}^{-1}\,\mathrm{s}^{-1}$.
- The forward rate constant is given by $k_1 = K \times k_{-1}$. Since $k_{-1} \leq 10^{11}\ \mathrm{M}^{-1}\,\mathrm{s}^{-1}$, k_1 must be less than or equal to $10^4\ \mathrm{s}^{-1}$.

As noted earlier, some carbonic anhydrases can hydrate carbon dioxide at rates as high as a million times a second $(10^6\ \mathrm{s}^{-1})$. This rate is so high that it seems to violate the analysis above. If carbon dioxide is hydrated at a rate of $10^6\ \mathrm{s}^{-1}$, then every step in the mechanism (Figure 6.22) must take place at least this fast. How is this apparent paradox resolved?

The role of buffers

The answer became clear with the observation that the highest rates of carbon dioxide hydration require the presence of buffer, suggesting that the buffer components participate in the reaction. The buffer can bind or release protons. The advantage is that, whereas the concentrations of protons and hydroxide ions are limited to $10^{-7}\ \mathrm{M}$ at neutral pH, the concentration of buffer components can be much higher, of the order of several millimolar. Let us consider the role of buffer components in more detail:

- If the buffer component BH^+ has a pK_a of 7 (matching that for the zinc-bound water molecule), then the equilibrium constant for the reaction in Figure 6.24 is 1.

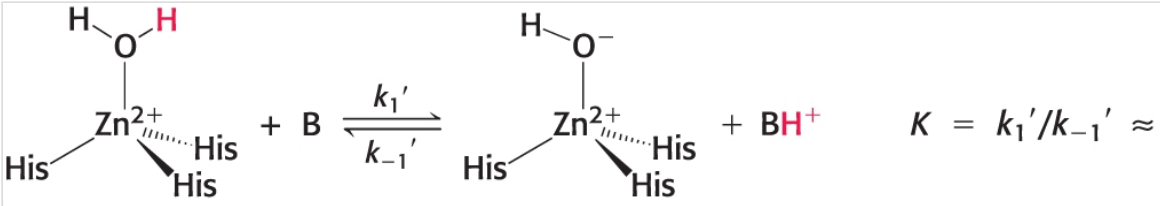

FIGURE 6.24 The deprotonation of the zinc-bound water molecule in carbonic anhydrase can be aided by buffer component B. This is optimized if the pK_a of the buffer is near 7 and if the buffer is present at a sufficiently high concentration.

- The second-order rate constants k_1' and k_{-1}' will be limited by buffer diffusion to values less than approximately $10^9\ M^{-1}\ s^{-1}$.
- The rate of proton abstraction is given by $k_1' \times [B]$.
- If buffer concentrations greater than $[B] = 10^{-3}\ M$ (or 1 mM) are used, then carbon dioxide hydration rates $\geq 10^6\ M^{-1}\ s^{-1}$ may be possible because

$$k_1' \times [B] = (10^9\ M^{-1}\ s^{-1}) \times (10^{-3}\ M) = 10^6\ s^{-1}$$

The prediction that the rate increases with increasing buffer concentration has been confirmed experimentally (Figure 6.25).

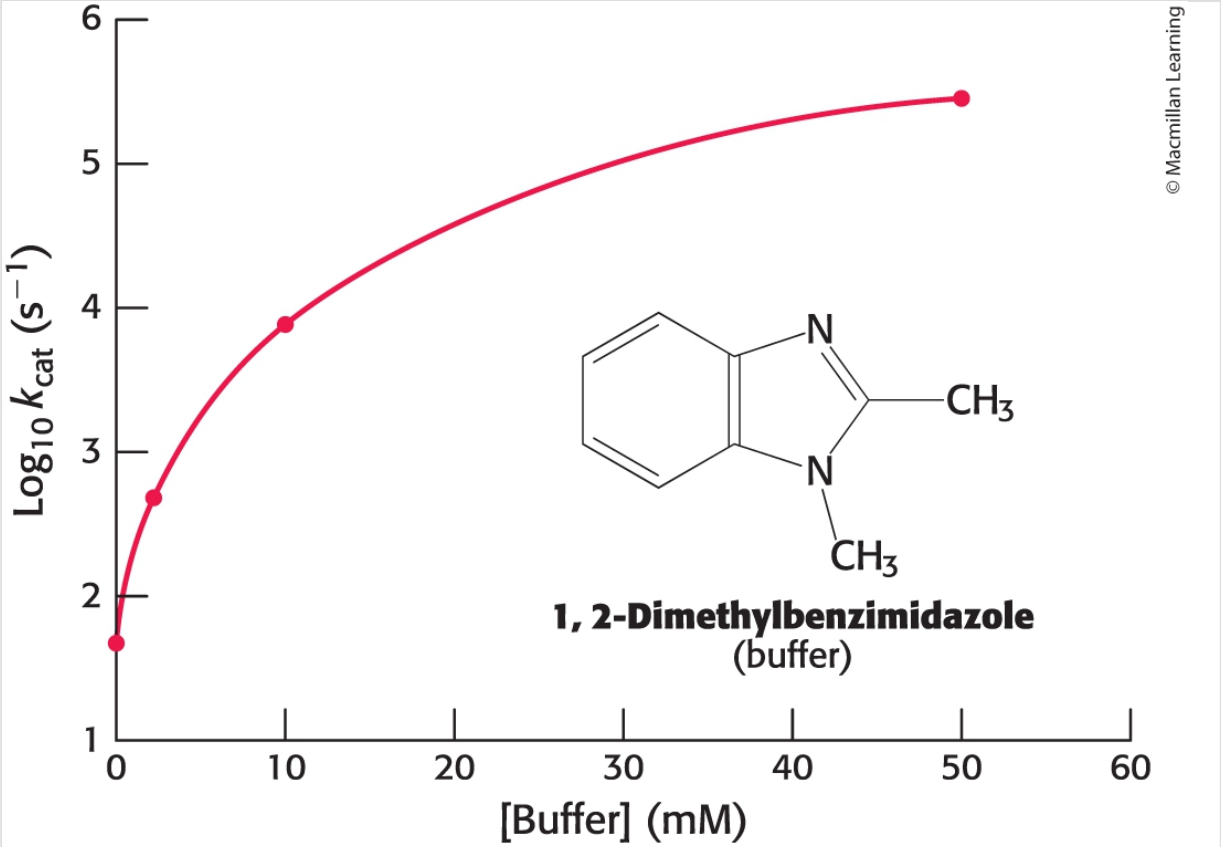

FIGURE 6.25 The rate of carbon dioxide hydration by carbonic anhydrase increases with the concentration of the buffer 1,2-dimethylbenzimidazole. If present at high enough concentrations, such buffers enable the enzyme to achieve its highest catalytic rates.

Self-Check Question

Suppose that the rate of CO_2 hydration is measured in 1 mM buffer at pH 7.0. What is the maximum expected rate?

A “proton shuttle” for large buffers

The molecular components of many buffers are too large to reach the active site of carbonic anhydrase. Carbonic anhydrase II has evolved a **proton shuttle** to allow buffer components to participate in the reaction from solution. The primary component of this shuttle is histidine 64. This residue transfers protons from the zinc-bound water molecule to the protein surface and then to the buffer (Figure 6.26). Thus, catalytic function has been enhanced through the evolution of an apparatus for controlling proton transfer from and to the active site. Because protons participate in many biochemical reactions, the manipulation of the proton inventory within active sites is crucial to the function of many enzymes and explains the prominence of acid–base catalysis.

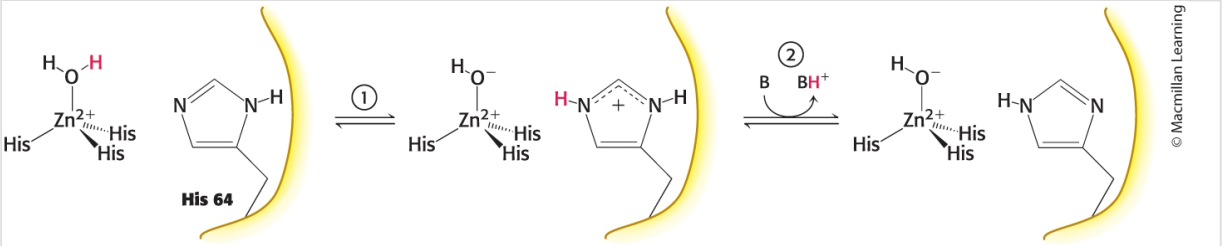

FIGURE 6.26 Histidine 64 acts as a proton shuttle. Histidine 64 (1) removes a proton from the zinc-bound water molecule and (2) transfers the proton to buffer molecules in solution.

6.4 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions

We next consider a hydrolytic reaction that results in the cleavage of DNA. Bacteria and archaea have evolved mechanisms to protect themselves from viral infections. Many viruses inject their DNA genomes into cells; once inside, the viral DNA hijacks the cell's machinery to drive the production of viral proteins and, eventually, of progeny virus. Often, a viral infection results in the death of the host cell.

A major protective strategy for the host is to use **restriction enzymes** (also called **restriction endonucleases**) to degrade the viral DNA on its introduction into a cell. These enzymes recognize particular base sequences, called **recognition sequences** or recognition sites, in DNA molecules and cleave such molecules (hereafter referred to as *cognate DNA*) at defined positions. Restriction enzymes are best known because they are powerful tools for characterizing and manipulating DNA molecules, and their discovery was a key step that led to a revolution in molecular biology and genetic engineering. The most well-studied class of restriction enzymes comprises the type II restriction enzymes, which cleave DNA within their recognition sequences. Other types of restriction enzymes cleave DNA at positions somewhat distant from their recognition sites.

Restriction enzymes must show tremendous specificity at two levels:

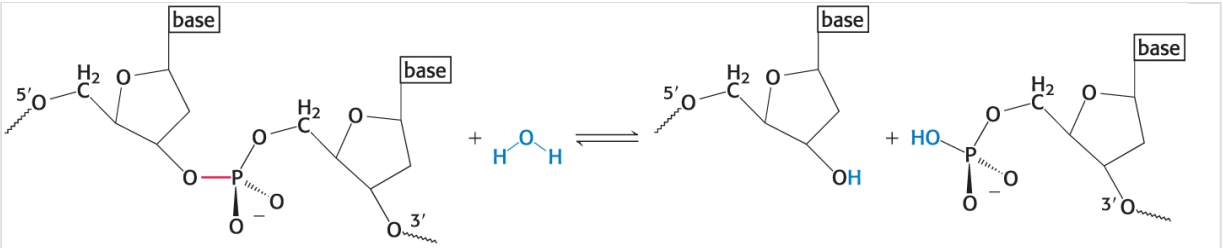
1. *Restriction enzymes must cleave only DNA molecules that contain recognition sites, without cleaving DNA molecules that lack these sites.* Suppose that a recognition sequence is six base-pairs long. Because

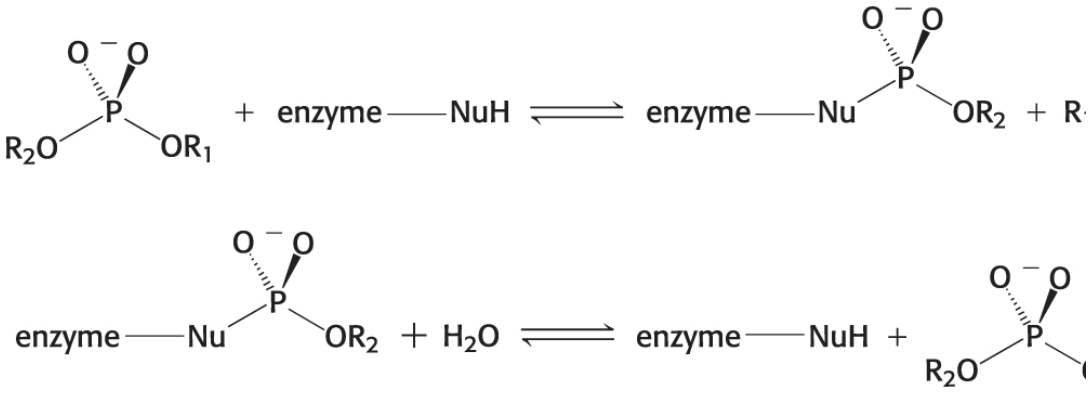
there are 4^6, or 4096, sequences having six base pairs, the concentration of sites that must not be cleaved will be approximately 4000-fold higher than the concentration of sites that should be cleaved. Thus, to keep from damaging host DNA, restriction enzymes must cleave cognate DNA molecules much more than 4000 times as efficiently as they cleave nonspecific sites. We shall return to the mechanism used to achieve the necessary high specificity after considering the chemistry of the cleavage process.

2. *Restriction enzymes must not degrade host DNA containing the recognition sequences.* How do these enzymes manage to degrade viral DNA while sparing their own? In *E. coli*, the restriction endonuclease EcoRV cleaves double-stranded viral DNA molecules that contain the sequence $5'-GATATC-3'$, but it leaves intact host DNA containing hundreds of such sequences. We shall return to the strategy by which host cells protect their own DNA at the end of this section.

Cleavage is by direct displacement of $3'$-oxygen from phosphorus by magnesium-activated water

A restriction enzyme catalyzes the hydrolysis of the phosphodiester backbone of DNA. Specifically, the bond between the $3'$-oxygen atom and the phosphorus atom is broken. The products of this reaction are DNA strands with a free $3'$-hydroxyl group and a $5'$-phosphoryl group at the cleavage site (**Figure 6.27**). This reaction proceeds by nucleophilic attack at the phosphorus atom. We will consider two alternative mechanisms, suggested by analogy with the proteases.





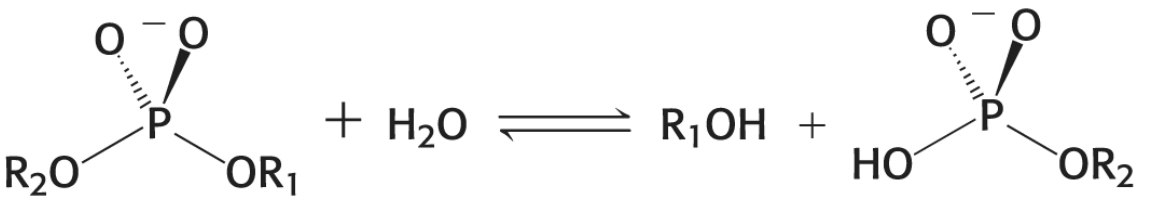


FIGURE 6.27 Restriction enzymes catalyze the hydrolysis of DNA phosphodiester bonds. The reaction leaves a hydroxyl group at the 3′ end of one product fragment and a phosphoryl group attached to the 5′ end of the other. The bond that is cleaved is shown in red.

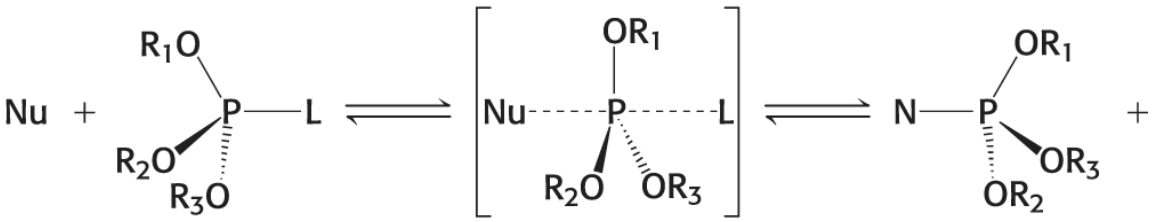

1. The restriction enzyme might cleave DNA through a covalent intermediate, employing a potent nucleophile (Nu):
   Mechanism 1 (covalent intermediate)

2. Alternatively, the restriction enzyme might cleave DNA through direct hydrolysis:
   Mechanism 2 (direct hydrolysis)

Each mechanism postulates a different nucleophile to attack the phosphorus atom. In either case, each reaction takes place by in-line displacement, in which the incoming nucleophile attacks the phosphorus atom, and a pentacoordinate transition state is formed:

The transition state has a trigonal bipyramidal geometry centered at the phosphorus atom, with the incoming nucleophile at one apex of the two pyramids and the group that is displaced (the leaving group, L) at the other apex. Note that the displacement inverts the stereochemical conformation at the tetrahedral phosphorous atom, analogous to the interconversion of stereoisomers around a tetrahedral carbon center.

The two mechanisms differ in the number of times that the displacement takes place in the course of the reaction:

1. In the first type of mechanism, a nucleophile in the enzyme (analogous to serine 195 in chymotrypsin) attacks the phosphate

group to form a covalent intermediate. Next, this intermediate is hydrolyzed to produce the final products. In this case, two displacement reactions take place at the phosphorus atom. Consequently, the stereochemical configuration at the phosphorus atom would be inverted and then inverted again, and the overall configuration would be retained.

2. In the second type of mechanism, analogous to that used by the aspartyl- and metalloproteases, an activated water molecule attacks the phosphorus atom directly. In this mechanism, a single displacement reaction takes place at the phosphorus atom. Hence, the stereochemical configuration at the phosphorus atom is inverted after cleavage.

One approach to determine which mechanism is correct involves examining potential changes in the stereochemistry at the phosphorus atom over the course of cleavage. However, this stereochemical change is not easily observed, because two of the groups bound to the phosphorus atom are simply oxygen atoms, identical with each other. This challenge can be overcome by replacing one oxygen atom with sulfur (producing a species called a phosphorothioate).

Let us consider EcoRV endonuclease. This enzyme cleaves the phosphodiester bond between the T and the A at the center of the recognition sequence $5'-GATATC-3'$. The first step is to synthesize an appropriate substrate for EcoRV containing phosphorothioates at the sites of cleavage (**Figure 6.28**). The reaction is then performed in water that has been greatly enriched in ^{18}O to allow the incoming oxygen atom to be tagged. The location of the ^{18}O label with respect to the sulfur atom indicates whether the reaction proceeds with inversion or retention of stereochemistry. This experiment reveals that the stereochemical configuration at the phosphorus atom is inverted only once with cleavage. This result is consistent with a direct attack by

water at the phosphorus atom and rules out the formation of any covalently bound intermediate (Figure 6.29).

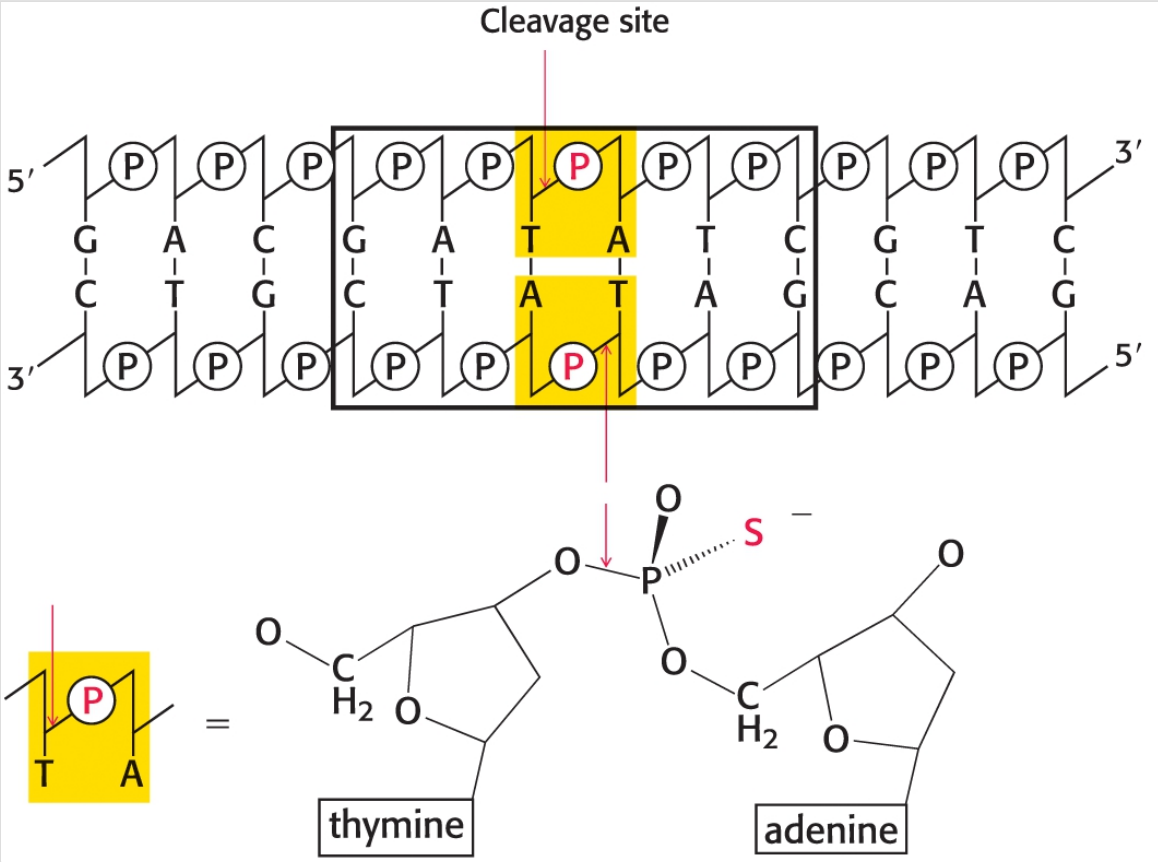

FIGURE 6.28 Phosphorothioate groups can be used to determine the overall stereochemical course of a displacement reaction. A phosphorothioate group has one of the nonbridging oxygen atoms replaced by a sulfur atom. Here, a phosphorothioate is placed at sites of cleavage by EcoRV endonuclease.

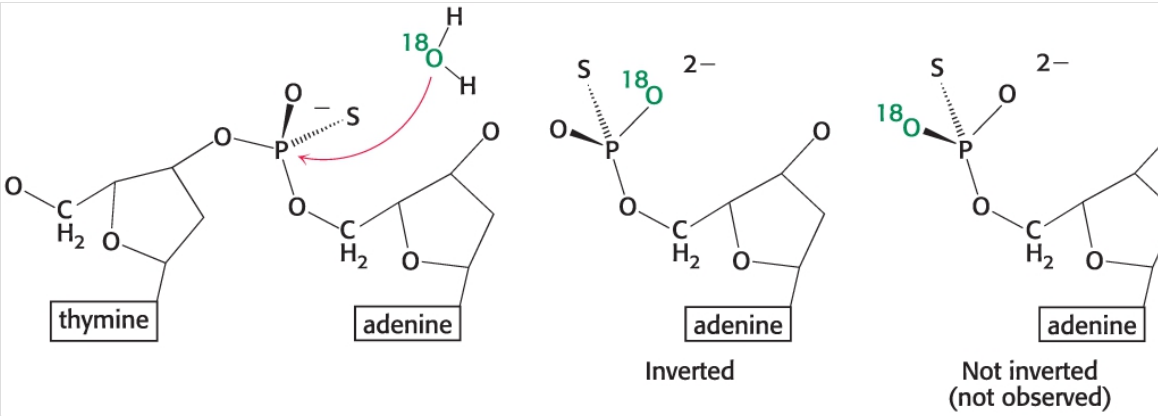

FIGURE 6.29 Cleavage of DNA by EcoRV endonuclease results in overall inversion of the stereochemical configuration at the phosphorus atom. This is indicated by the stereochemistr of the phosphorus atom bound to one bridging oxygen atom, one ^{16}O, one ^{18}O, and one sulfur atom. Two possible products are shown, only one of which is observed, indicating direct attack of water at the phosphorous atom.

Restriction enzymes require magnesium for catalytic activity

Many enzymes that act on phosphate-containing substrates require Mg^{2+} or some other similar divalent cation for activity. One or more Mg^{2+} (or similar) cations are essential to the function of restriction endonucleases. What are the functions of these metal ions?

Direct visualization of the complex between EcoRV endonuclease and cognate DNA molecules in the presence of Mg^{2+} by crystallization has been challenging, because the enzyme cleaves the substrate under these circumstances. Nonetheless, metal ion complexes can be visualized through several approaches. In one approach, crystals of

EcoRV endonuclease are prepared bound to oligonucleotides that contain the enzyme's recognition sequence. These crystals are grown in the absence of magnesium to prevent cleavage; after their preparation, the crystals are soaked in solutions containing the metal ion. Alternatively, crystals have been grown with the use of a mutated form of the enzyme that is less active. Finally, Mg^{2+} can be replaced by metal ions such as Ca^{2+} that bind but do not result in much catalytic activity. In all cases, no cleavage takes place, and so the locations of the metal ion-binding sites are readily determined.

As many as three metal ions per active site have been found. One ion-binding site is occupied in essentially all structures. This metal ion is coordinated to the protein through two aspartate residues and to one of the phosphate-group oxygen atoms at the site of cleavage. This metal ion binds the water molecule that attacks the phosphorus atom, helping to position and activate the water molecule in a manner similar to that for the Zn^{2+} ion of carbonic anhydrase (**Figure 6.30**).

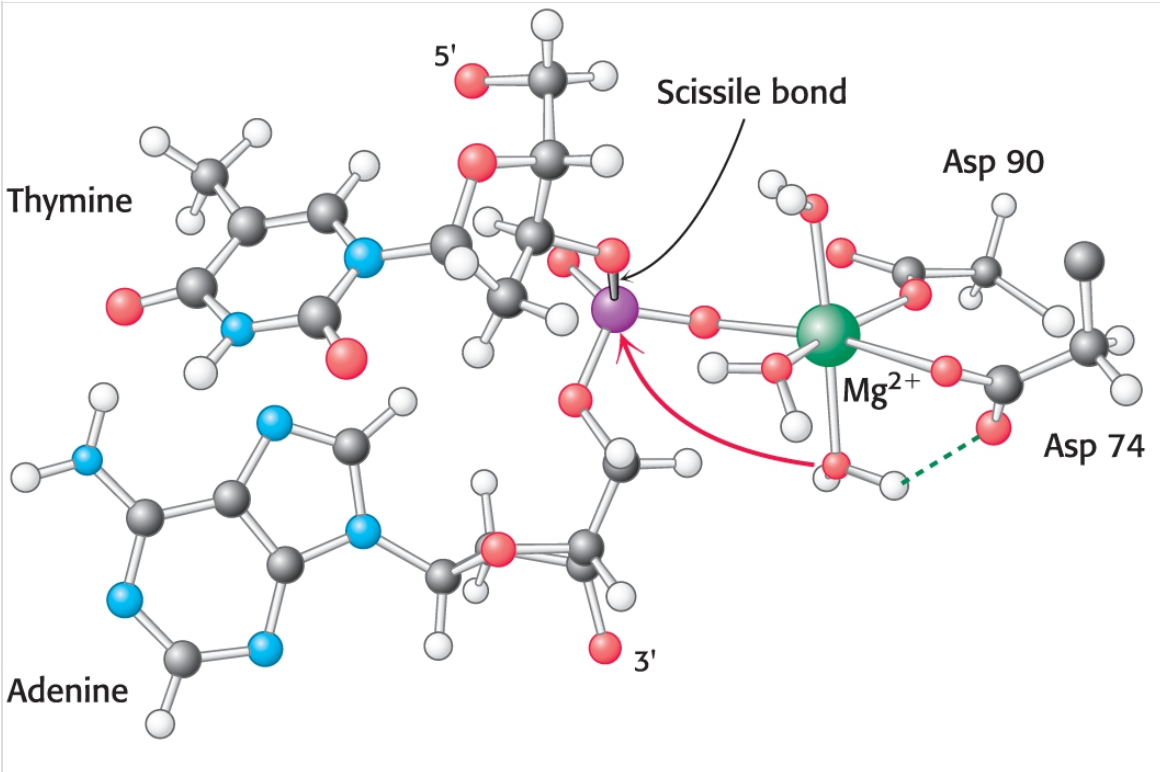

FIGURE 6.30 A magnesium ion forms a bridge between the enzyme and the DNA substrate. In this position, the ion helps activate a water molecule and position it so that it can attack the phosphorus atom at the cleavage site.

The complete catalytic apparatus is assembled only within complexes of cognate DNA molecules, ensuring specificity

We now return to the question of cleavage site-specificity, the defining feature of restriction enzymes.

The recognition sequences for most restriction enzymes are inverted repeats, giving the three-dimensional structure of the recognition site a twofold rotational symmetry, meaning that the structure is the same if rotated by $360^\circ/2 = 180^\circ$ (Figure 6.31). The restriction enzymes display a corresponding symmetry: they are dimers whose two subunits are related by an appropriate 180° rotation. The matching symmetry of the recognition sequence and the enzyme facilitates the recognition of cognate DNA by the enzyme. This similarity in structure has been confirmed by the determination of the structure of the complex between EcoRV endonuclease and DNA fragments containing its recognition sequence (Figure 6.32). The enzyme surrounds the DNA in a tight embrace.

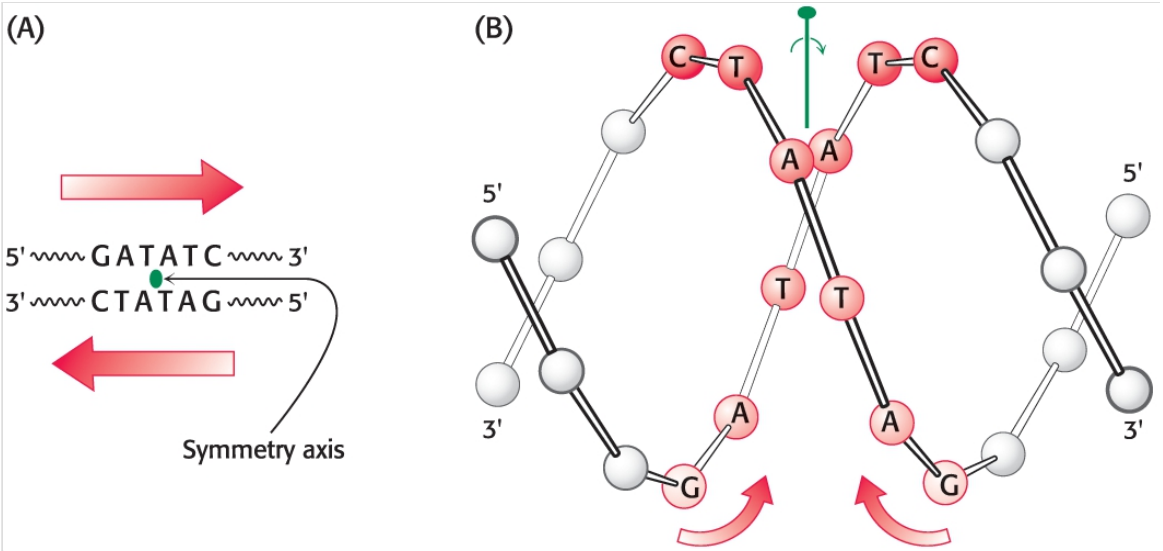

FIGURE 6.31 The recognition site for EcoRV displays twofold rotational symmetry. (A) The sequence of the recognition site, which is symmetric around the axis of rotation designated in green. (B) The inverted repeat within the recognition sequence of EcoRV (and most other restriction endonucleases) endows the DNA site with twofold rotational symmetry.

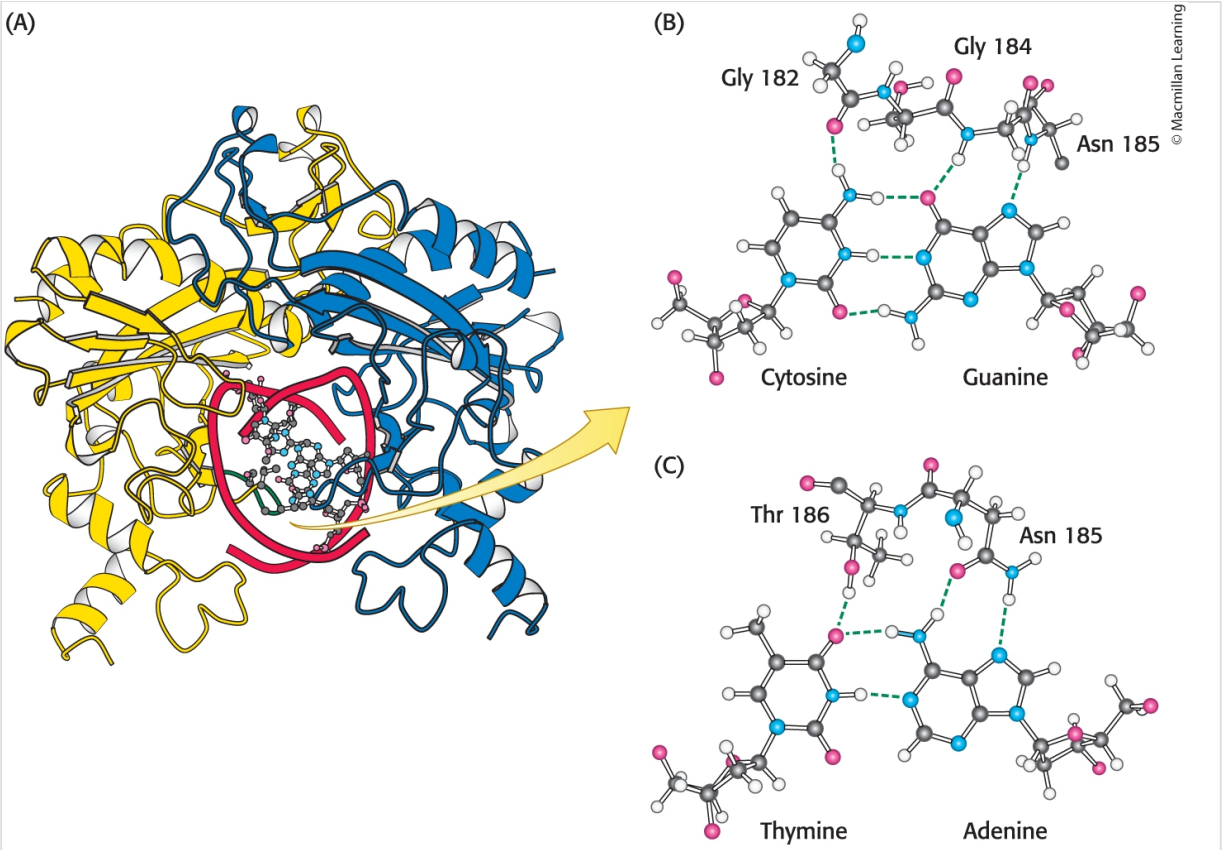

FIGURE 6.32 The three-dimensional structure of the complex between EcoRV and a cognate DNA molecule reveals interactions responsible for the sequence specificity. (A) This view of the structure of EcoRV endonuclease bound to a cognate DNA fragment is down the helical axis of the DNA. The two protein subunits are in yellow and blue, and the DNA backbone is in red. One of the DNA-binding loops of EcoRV endonuclease is shown interacting with the base pairs of its cognate DNA-binding site. Key amino acid residues are shown hydrogen-bonding with (B) a CG base pair and (C) an AT base pair.

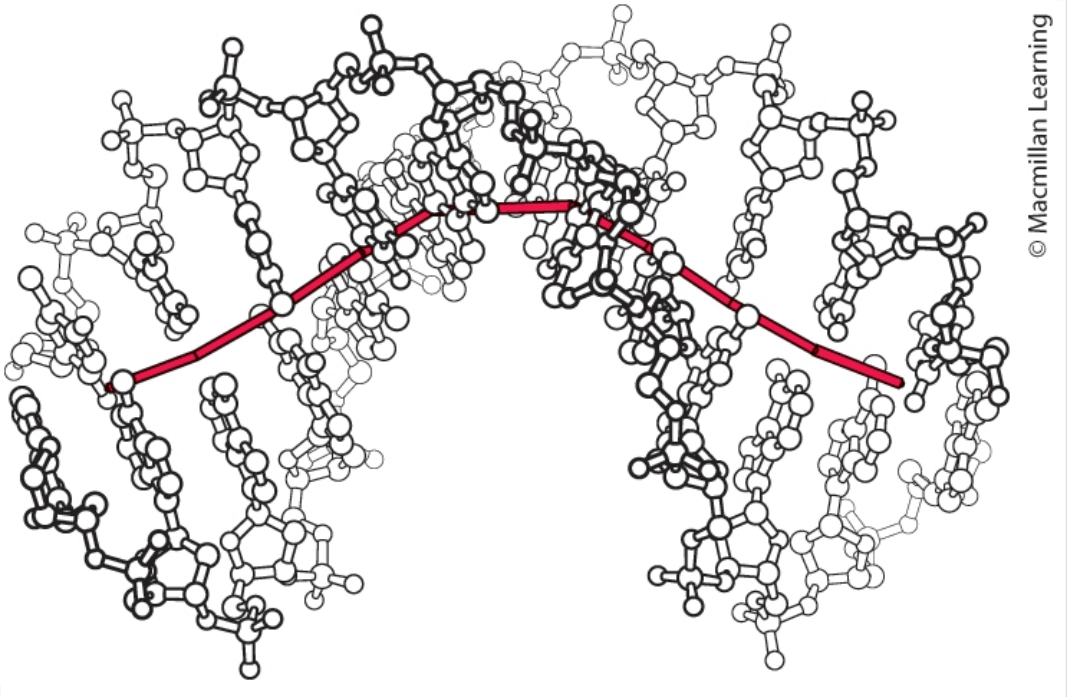
[Drawn from 1RVB.pdb.]

INTERACT with this model in Achieve

Surprisingly, binding studies performed in the absence of magnesium have demonstrated that the EcoRV endonuclease binds to all sequences, both cognate and noncognate, with approximately equal affinity. Why, then, does the enzyme cleave only cognate sequences? The answer lies in a unique set of interactions between the enzyme and a cognate DNA

sequence. Within the $5'-GATATC-3'$ sequence, the G and A bases at the $5'$ end of each strand (and their Watson–Crick partners) directly contact the enzyme via hydrogen bonds with residues that are located in two loops, one projecting from the surface of each enzyme subunit (Figure 6.32). The most striking feature of this complex is the distortion of the DNA, which is substantially kinked in the center (**Figure 6.33**), whereas double-stranded DNA is normally straight. The central two TA base pairs in the recognition sequence play a key role in allowing the kink. They do not make contact with the enzyme but appear to be required because of their ease of distortion. The $5'-TA-3'$ sequence is known to be among the most easily deformed base-pair steps.



© Macmillan Learning

FIGURE 6.33 The cognate DNA from the EcoRV complex is substantially bent. The DNA is represented as a ball-and-stick model. The path of the DNA helical axis, shown in red, is substantially distorted on binding to the enzyme. For B form DNA, the axis is normally straight (not shown).

The structures of complexes formed with noncognate DNA fragments are strikingly different from those formed with cognate DNA; the noncognate DNA conformation is not substantially distorted (**Figure 6.34**). This lack of distortion has important consequences with regard to catalysis. No phosphate is positioned sufficiently close to the active-site aspartate residues to complete a magnesium ion-binding site (Figure 6.30). Hence, the nonspecific complexes do not bind the magnesium ions and the complete catalytic apparatus is never assembled. The distortion of the substrate and the subsequent binding of the magnesium ion account for the catalytic specificity of more than a million-fold that is observed for EcoRV endonuclease. Thus, enzyme specificity may be determined not by the specificity of substrate binding but rather by the specificity of forming a structure capable of DNA cleavage.

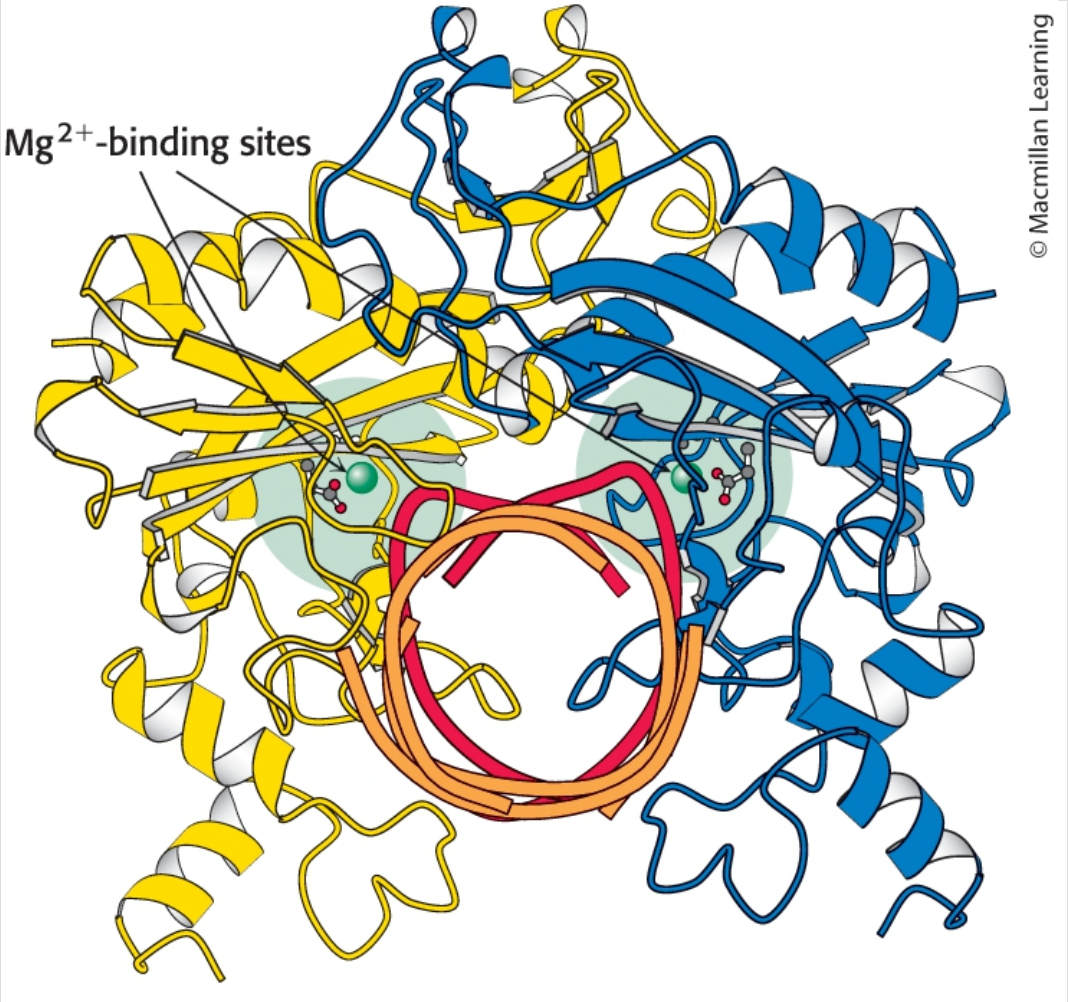


FIGURE 6.34 A comparison of the positions of the nonspecific and the cognate DNA within EcoRV shows the absence and presence of substantial DNA distortion. Note that, in the nonspecific complex (shown in orange compared to the specific complex in red), the DNA backbone is too far from the enzyme to complete the magnesium ion-binding sites required for DNA cleavage.

[Drawn from 1RVB.pdb.]

INTERACT with this model in Achieve

We can now see the role of binding energy in this strategy for attaining catalytic specificity. The distorted DNA makes additional contacts with the enzyme, increasing the binding energy, but the increase in binding energy is canceled by the energetic cost of distorting the DNA from its relaxed conformation into one that is catalytically competent, that is, into a conformation that allows DNA cleavage to proceed (Figure 6.35). Thus, for EcoRV endonuclease, there is little difference in binding affinity for cognate and nonspecific DNA fragments. However, the distortion in the cognate complex dramatically affects DNA hydrolysis by completing the magnesium ion-binding site. This example illustrates how enzymes can use available binding energy to deform substrates and position them for chemical transformation. Interactions that take place within the distorted substrate complex stabilize the transition state leading to DNA hydrolysis.

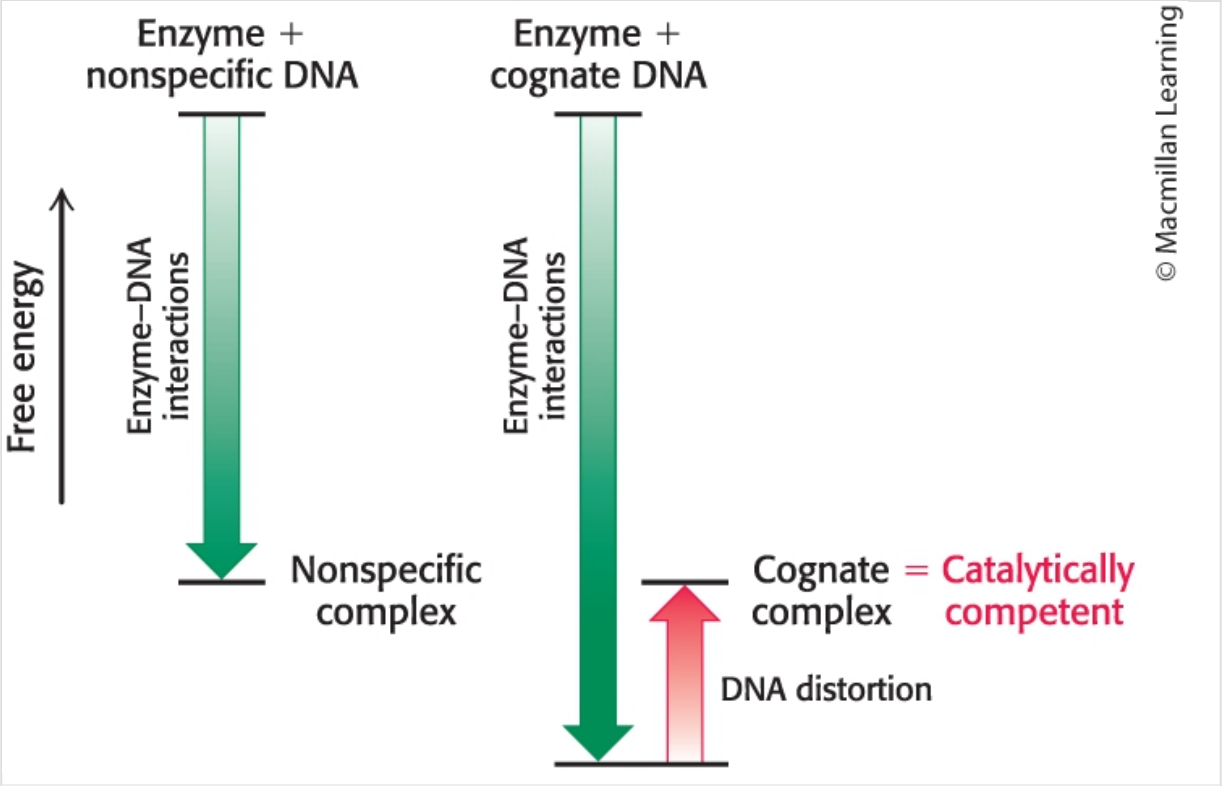

FIGURE 6.35 The binding energy drives DNA distortion. The additional interactions between EcoRV endonuclease and cognate DNA increase the binding energy, driving distortions that form a complex that is catalytically competent for DNA cleavage.

Self-Check Question

The restriction enzyme EcoRI binds DNA fragments containing its recognition site very tightly and specifically; changing even a single base results is a loss of approximately 1000-fold in binding affinity. How does this compare with EcoRV?

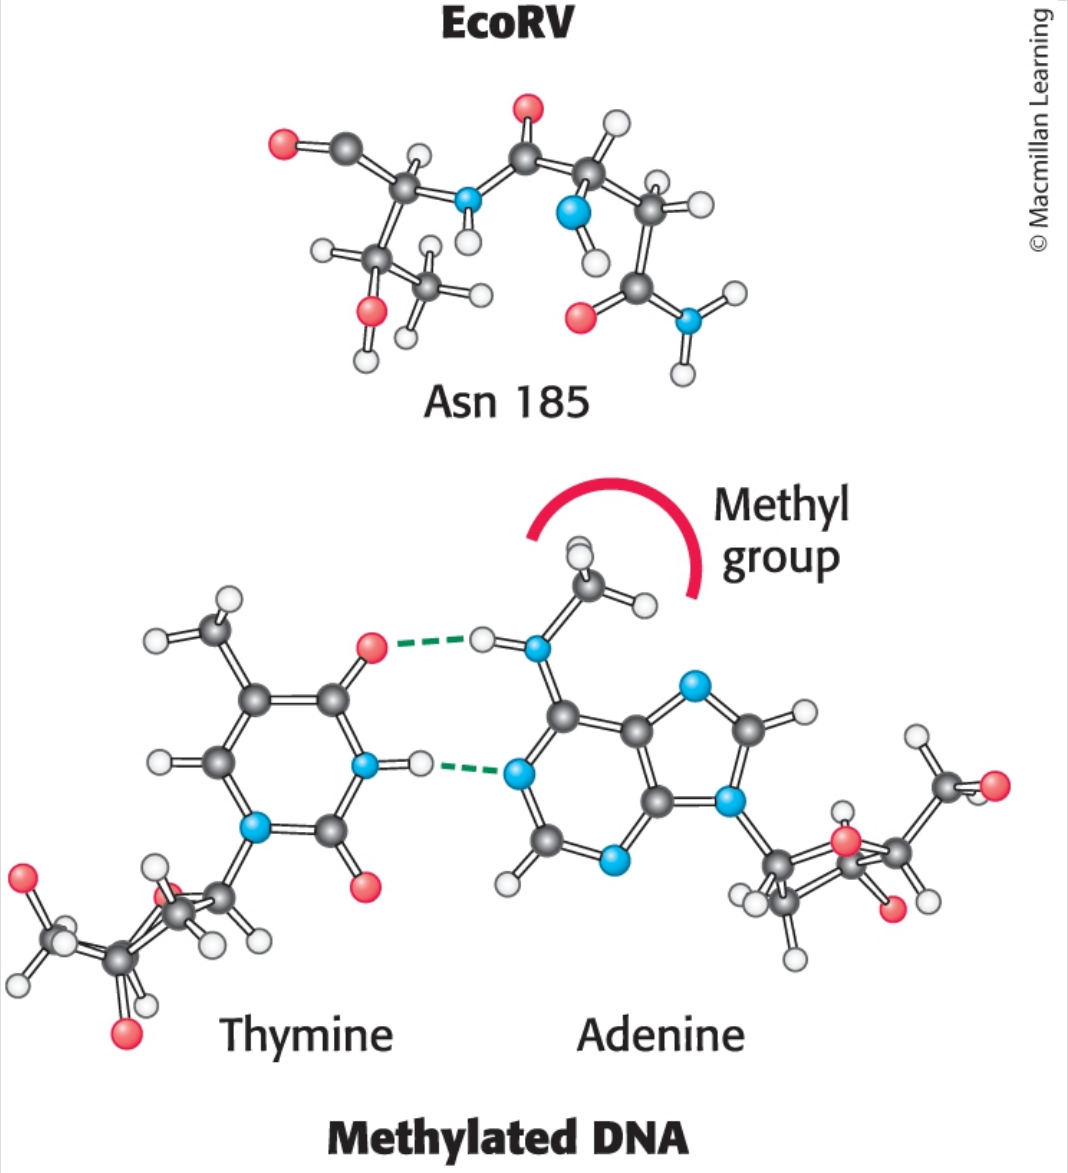
Host-cell DNA is protected by the addition of methyl groups to specific bases

How does a host cell harboring a restriction enzyme protect its own DNA? The host DNA is methylated on specific adenine bases within host recognition sequences by other enzymes called **DNA methylases** (**Figure 6.36**). A restriction enzyme will not cleave DNA if its recognition sequence is methylated. For each restriction enzyme, the host cell produces a corresponding methylase that marks the host DNA at the appropriate methylation site. These pairs of enzymes are referred to as **restriction-modification systems**.

FIGURE 6.36 Methylation of recognition sequences for EcoRV endonuclease protects these DNA sites from cleavage by EcoRV. The specific sites are indicated by asterisks; the structure of a methylated adenine is shown on the right.

The distortion of the DNA explains how methylation blocks catalysis and protects host-cell DNA. The host *E. coli* adds a methyl group to the amino group of the adenine nucleotide at the 5′ end of the recognition sequence for EcoRV endonuclease. The presence of the methyl group blocks the formation of a hydrogen bond between the amino group and the side-chain carbonyl group of asparagine 185 in the endonuclease

(Figure 6.37). This asparagine residue is closely linked to the other amino acids that would form specific contacts with the DNA. The absence of the hydrogen bond disrupts other interactions between the enzyme and the DNA substrate, and the distortion necessary for cleavage will not take place. Thus, these added methyl groups prevent cleavage and protect the host DNA; the methylation reactions are slower than the DNA-cleavage reactions so that injected viral DNA is cleaved before it can be protected.



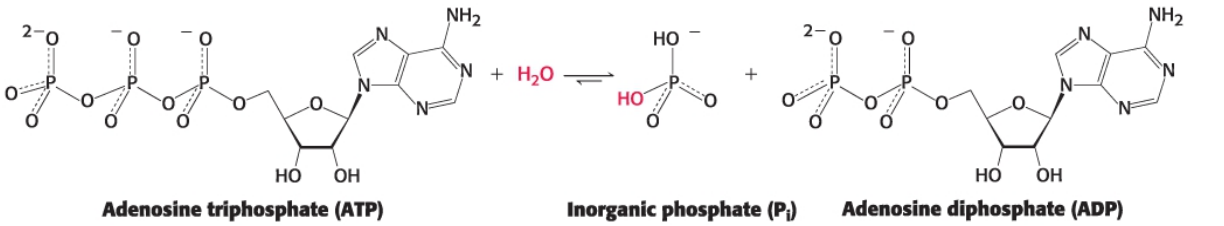


FIGURE 6.37 The methylation of adenine blocks the formation of hydrogen bonds between EcoRV endonuclease and cognate DNA molecules. This blockage prevents

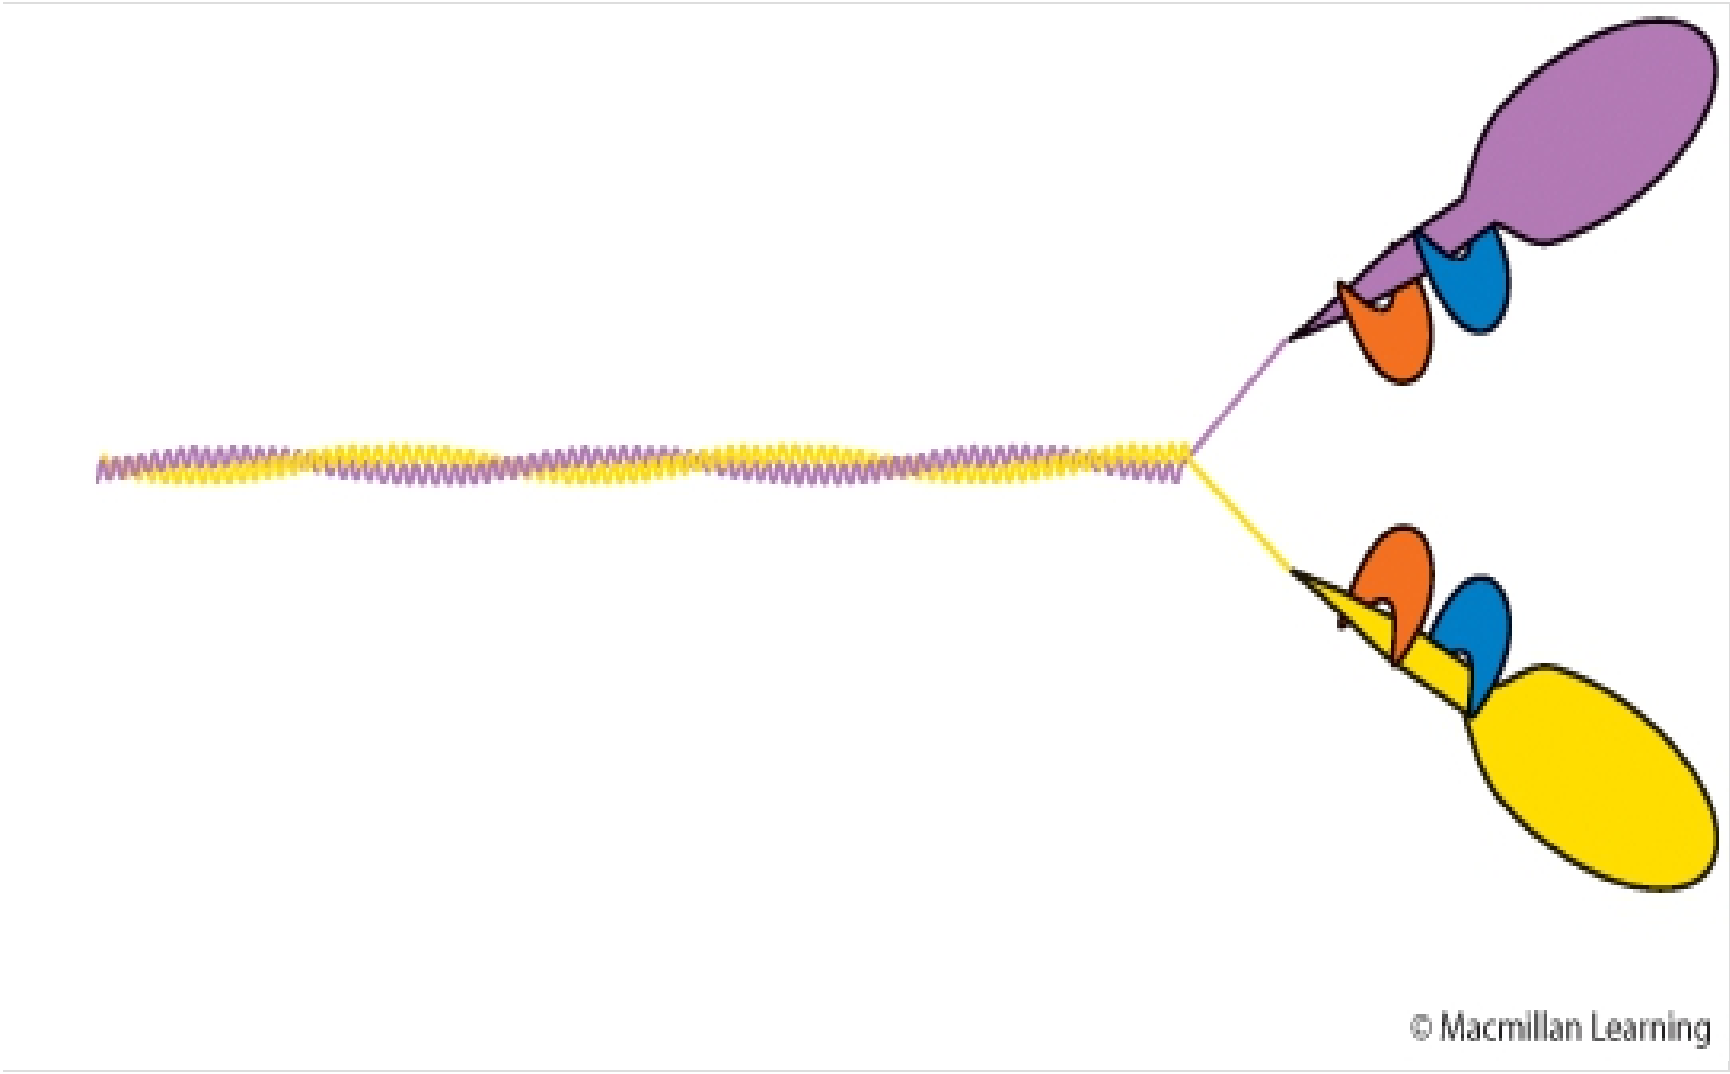
the hydrolysis of methylated DNA.



6.5 Molecular Motor Proteins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

The final enzymes that we will consider are a class of molecular motor proteins called **myosins**. These enzymes catalyze the hydrolysis of adenosine triphosphate (ATP) to form adenosine diphosphate (ADP) and inorganic phosphate (P_i) and use the energy associated with this thermodynamically favorable reaction to drive the motion of molecules within cells.

For example, when we lift a book, the energy required comes from ATP hydrolysis catalyzed by myosin in our muscles. Myosins are found in all eukaryotes, and the human genome encodes more than 40 different myosins, defined by large proteins termed myosin heavy chains. Myosins have elongated structures with globular domains that actually carry out ATP hydrolysis at one end, extended α-helical structures that promote dimer formation, and ancillary associate proteins termed light chains (**Figure 6.38**). We will focus on the globular **ATPase** domains, particularly the strategies that allow myosins to hydrolyze ATP in a

controlled manner and to use the free energy associated with this reaction to promote substantial conformational changes within the myosin molecule. These conformational changes are amplified by other structures in the elongated myosin molecules to transport proteins or other cargo substantial distances within cells.

© Macmillan Learning

FIGURE 6.38 A schematic view of a myosin molecule reveals an elongated dimeric structure. The two heavy chains are shown in purple and yellow, and the light chains are shown in blue and orange.

ATP is used as the major currency of energy inside cells. Many enzymes use ATP hydrolysis to drive other reactions and processes. In almost all cases, an enzyme that hydrolyzed ATP without coupling the reaction to other processes would simply drain the energy reserves of a cell without benefit.

ATP hydrolysis proceeds by the attack of water on the gamma phosphoryl group

In our examination of the mechanism of restriction enzymes, we learned that an activated water molecule performs a nucleophilic attack on phosphorus to cleave the phosphodiester backbone of DNA. The cleavage of ATP by myosins follows an analogous mechanism. To understand the myosin mechanism in more detail, we must first examine the structure of the myosin ATPase domain.

The structures of the ATPase domains of several different myosins have been examined. One such domain, that from the soil-living amoeba *Dictyostelium discoideum*, an organism that has been extremely useful for studying cell movement and molecular-motor proteins, has been studied in great detail. The crystal structure of this protein fragment in the absence of nucleotides reveals a single globular domain comprising approximately 750 amino acids. A water-filled pocket is present toward the center of the structure, suggesting a possible nucleotide-binding active site (**Figure 6.39**). However, when crystals of this protein were soaked in a solution containing ATP, the resulting structure reveals intact ATP bound in the proposed active site, but with very little change

in the overall structure and without evidence of significant hydrolysis. The ATP is also bound to a Mg^{2+} ion.

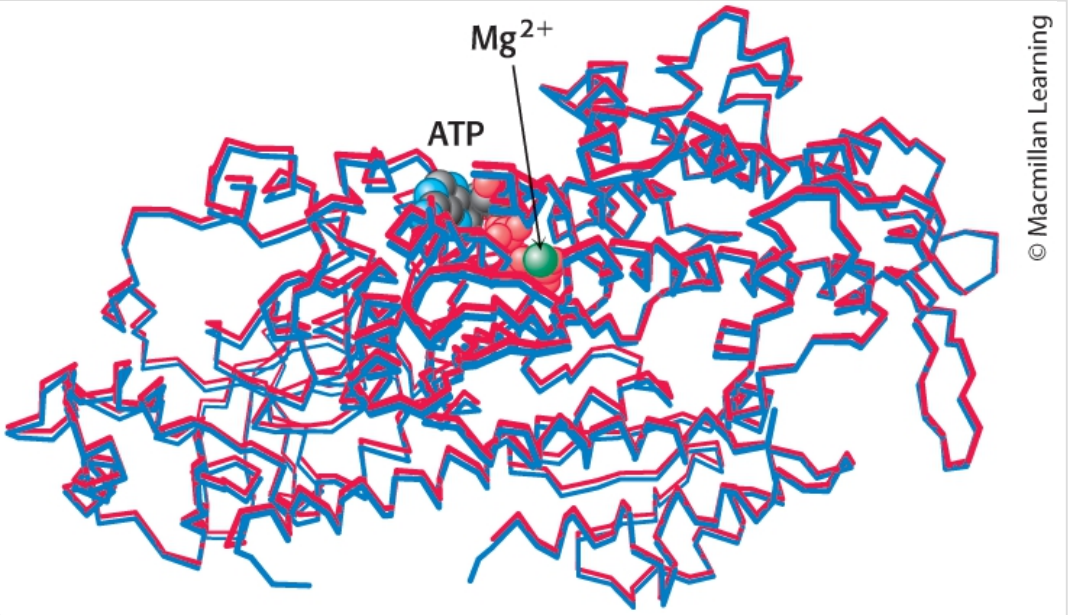


FIGURE 6.39 ATP binding to myosin does not dramatically alter its structure. An overlay of the structures of the ATPase domain from *Dictyostelium discoideum* myosin with nothing bound (blue) and the complex of this protein with ATP and magnesium bound (red) reveals that these two structures are quite similar to one another.

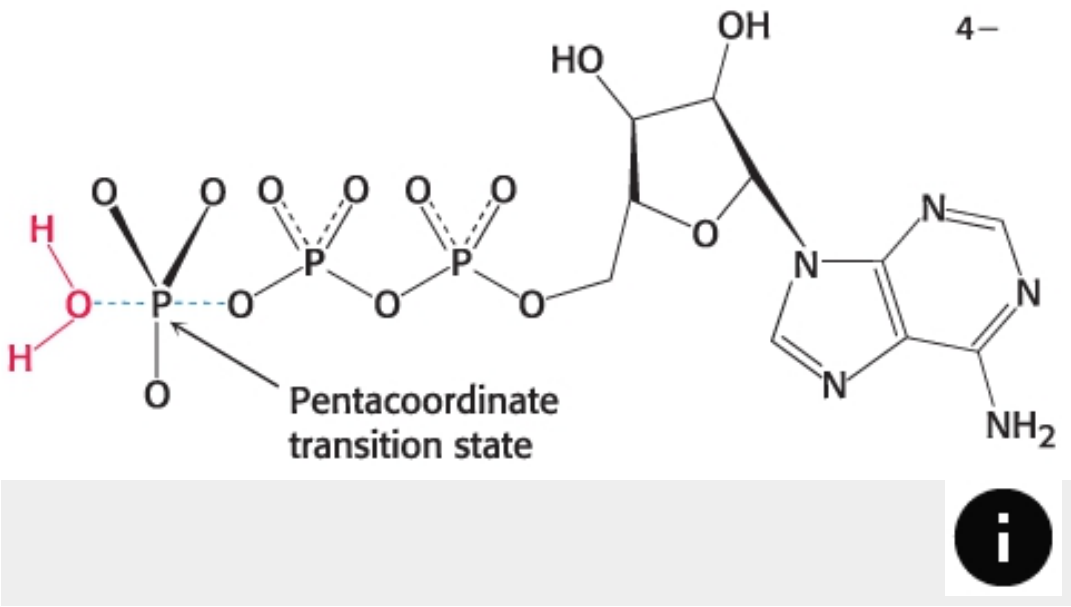
[Drawn from 1FMV.pdb and 1FMW.pdb.]

INTERACT with this model in Achieve



Kinetic studies of myosins, as well as many other enzymes having ATP or other nucleoside triphosphates as a substrate, reveal that these enzymes are essentially inactive in the absence of divalent metal ions such as magnesium (Mg^{2+}) or manganese (Mn^{2+}) but acquire activity on the addition of these ions. In contrast with the enzymes discussed so far, the metal is not a component of the active site. Rather, nucleotides such as ATP bind these ions, and it is the metal ion–nucleotide complex that is the true substrate for the enzymes. The dissociation constant for

the ATP–Mg^{2+} complex is approximately 0.1 mM, and thus, given that intracellular Mg^{2+} concentrations are typically in the millimolar range, essentially all nucleoside triphosphates (NTP) are present as NTP–Mg^{2+} complexes. Magnesium or manganese complexes of nucleoside triphosphates are the true substrates for essentially all NTP-dependent enzymes.

Since the ATP–Mg^{2+} complex was present in the crystallography study discussed above, why was there no evidence for hydrolysis? The nucleophilic attack by a water molecule on the γ-phosphoryl group requires some mechanism to activate the water, such as a basic residue or a bound metal ion. Examination of the myosin–ATP complex structure shows no basic residue in an appropriate position and reveals that the bound Mg^{2+} ion is too far away from the phosphoryl group to play this role. These observations suggest why the ATP complex is relatively stable: The enzyme is not in a conformation that is suitable for promoting the ATP-hydrolysis reaction. This conclusion suggests that the domain must undergo a conformational change in order to carry out catalysis.

Formation of the transition state for ATP hydrolysis is associated with a substantial conformational change

The catalytically competent conformation of the myosin ATPase domain must bind and stabilize the transition state of the reaction. In analogy with restriction enzymes, we expect that ATP hydrolysis includes a pentacoordinate transition state.

Such pentacoordinate structures based on phosphorus are too unstable to be readily observed. However, transition-state analogs in which other atoms replace phosphorus are more stable. The transition metal vanadium, in particular, forms similar structures. After crystallizing the myosin ATPase domain in the presence of ADP and vanadate, VO_4^{3-}, a complex forms that closely matches the expected transition-state structure (Figure 6.40).

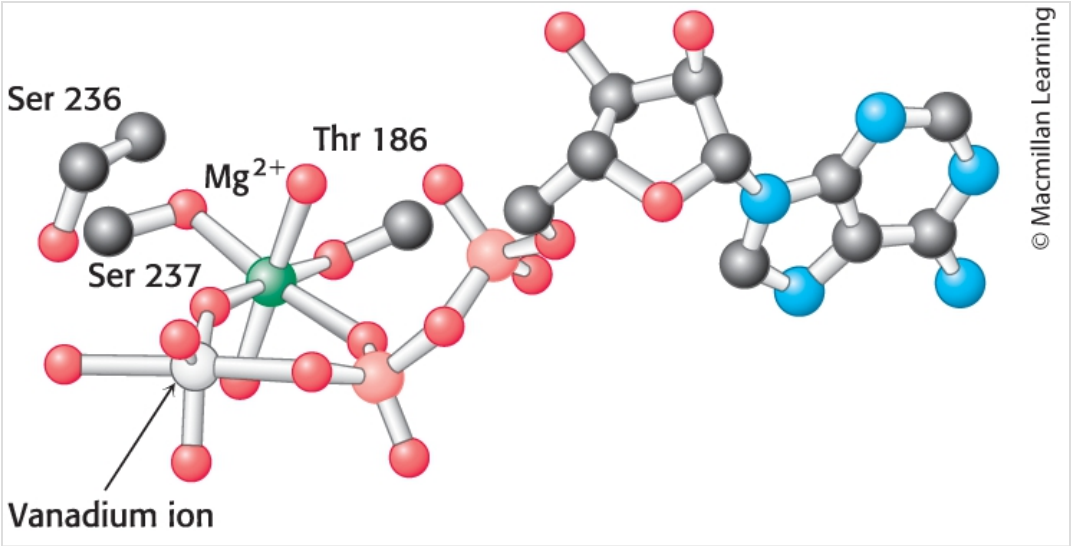


FIGURE 6.40 A stable structural analog of the myosin transition state can be prepared. The transition-state analog formed by treating the myosin ATPase domain

with ADP and vanadate (VO_4^{3-}) in the presence of magnesium shows the vanadium ion (analogous to phosphorus) coordinated to five oxygen atoms including one from ADP. The positions of two residues that bind magnesium as well as Ser 236, a residue that appears to play a direct role in catalysis, are shown.

[Drawn from 1VOM.pdb.]

As expected, the vanadium atom is coordinated to five oxygen atoms, including one oxygen atom from ADP diametrically opposite an oxygen atom that is analogous to the attacking water molecule in the transition state. The Mg^{2+} ion is coordinated to one oxygen atom from the vanadate, one oxygen atom from the ADP, two hydroxyl groups from the enzyme, and two water molecules. In this position, this ion does not appear to play any direct role in activating the attacking water. However, an additional residue from the enzyme, Ser 236, is well positioned to play a role in catalysis (Figure 6.41).

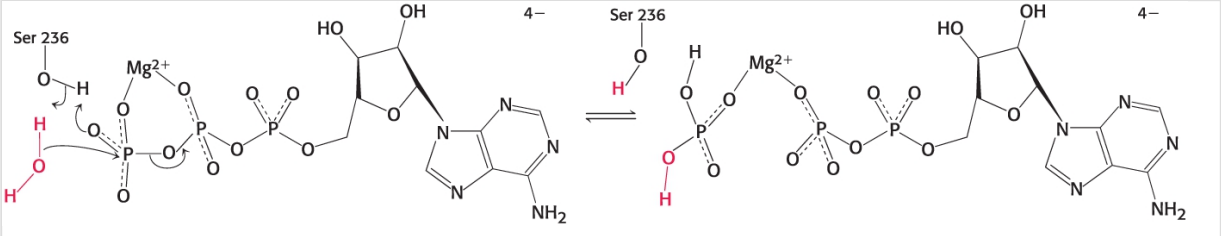

FIGURE 6.41 Water attack is facilitated by Ser 236. The attack of the water molecule on the γ-phosphoryl group of ATP is facilitated by Ser 236, which helps to deprotonate the water molecule. The serine sidechain, in turn, is deprotonated by one of the oxygen atoms of the γ-phosphoryl group forming the $H_2PO_4^-$ product.

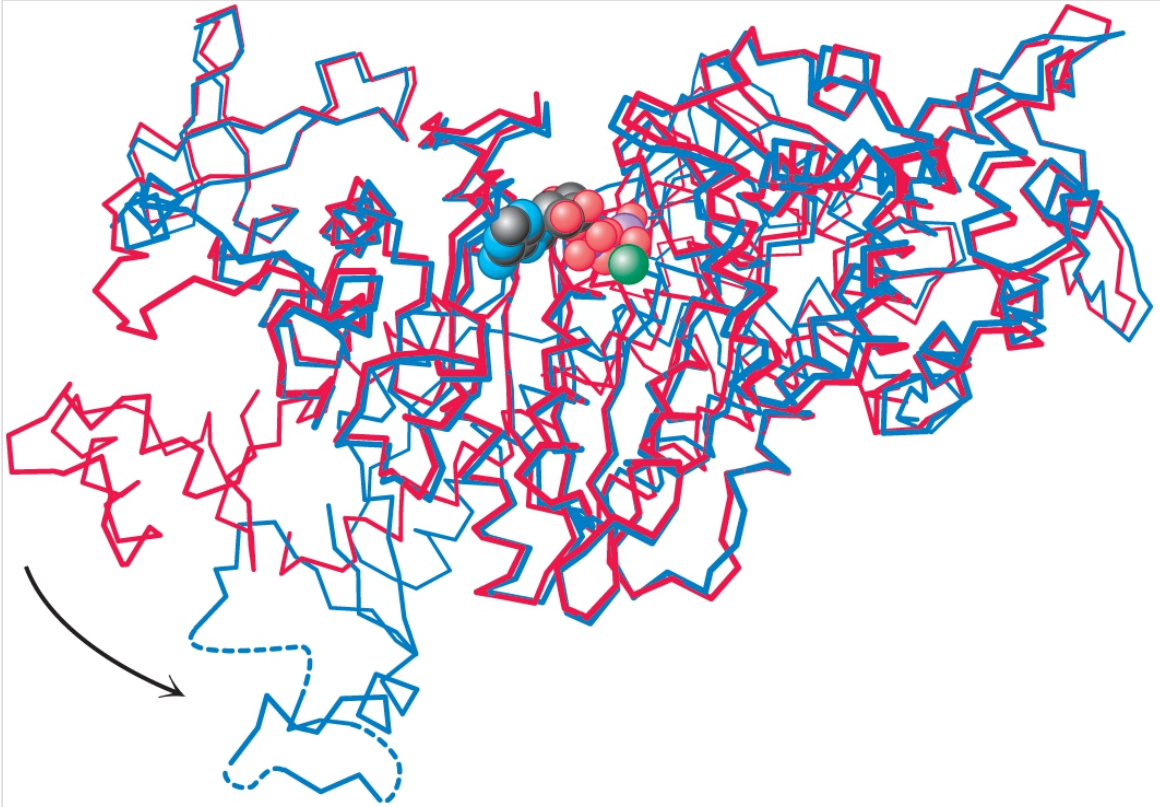
In the proposed mechanism of ATP hydrolysis based on this structure, the water molecule attacks the γ-phosphoryl group, with the hydroxyl

group of Ser 236 facilitating the transfer of a proton from the attacking water to the hydroxyl group of Ser 236, which, in turn, is deprotonated by one of the oxygen atoms of the γ-phosphoryl group. Thus, in effect, the ATP serves as a base to promote its own hydrolysis.

Comparison of the overall structures of the myosin ATPase domain complexed with ATP and with the ADP–vanadate reveals some remarkable differences. Relatively modest structural changes occur in and around the active site. In particular, a stretch of amino acids moves closer to the nucleotide by approximately 2 Å and interacts with the oxygen atom that corresponds to the attacking water molecule. These changes aid the hydrolysis reaction by stabilizing the transition state. However, examination of the overall structure shows even more striking changes.

A region comprising approximately 60 amino acids at the carboxyl-terminus of the domain adopts a different configuration in the ADP–vanadate complex, displaced by as much as 25 Å from its position in the ATP complex (**Figure 6.42**). This displacement tremendously amplifies the relatively subtle changes that take place in the active site, and it even affects locations beyond from the ATPase domain, because the carboxyl-terminus is connected to other atoms within the elongated structures typical of myosin molecules (Figure 6.38). Thus, the conformation that is capable of promoting the ATP hydrolysis reaction is substantially different from other conformations that are present in the course of the catalytic cycle.



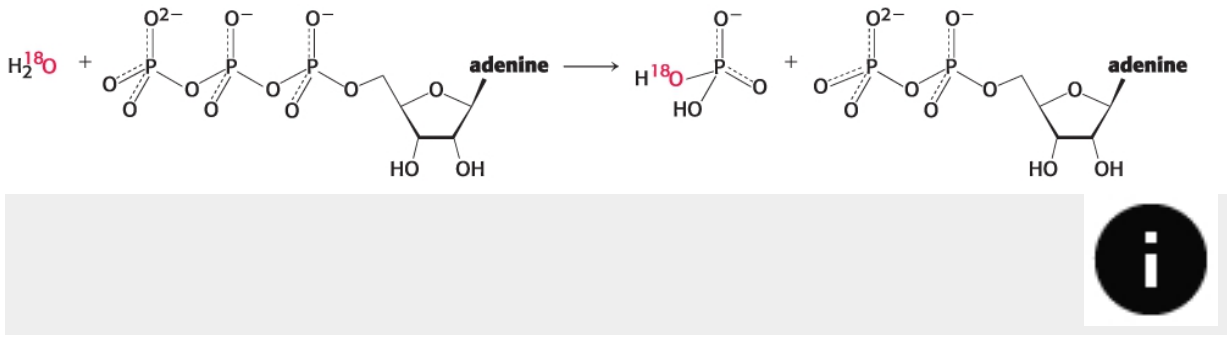


FIGURE 6.42 A substantial conformation change is associated with the formation of the myosin transition state. A comparison of the overall structures of the myosin ATPase domain with ATP bound (shown in red) and that with the transition-state analog ADP–vanadate (shown blue) reveals dramatic conformational changes of a region at the carboxyl-terminus of the domain (see arrow), some parts of which move as much as 25 Å.

[Drawn from 1FMW.pdb and 1VOM.pdb.]

The altered conformation of myosin persists for a substantial period of time

Myosins are slow enzymes, typically turning over approximately once per second. What steps limit the rate of turnover? In a particularly revealing experiment, the hydrolysis of ATP was catalyzed by the

myosin ATPase domain from mammalian muscle. The reaction took place in water labeled with ^{18}O to track the incorporation of solvent oxygen into the reaction products; then the fraction of oxygen in the phosphate product was analyzed. In the simplest case, the phosphate would be expected to contain one oxygen atom derived from water and three initially present in the terminal phosphoryl group of ATP. Instead, between two and three of the oxygen atoms in the phosphate were found, on average, to be derived from water. These observations indicate that the ATP hydrolysis reaction within the enzyme active site is reversible. Each molecule of ATP is cleaved to ADP and P_i and then re-formed from these products several times before the products are released from the enzyme (Figure 6.43).

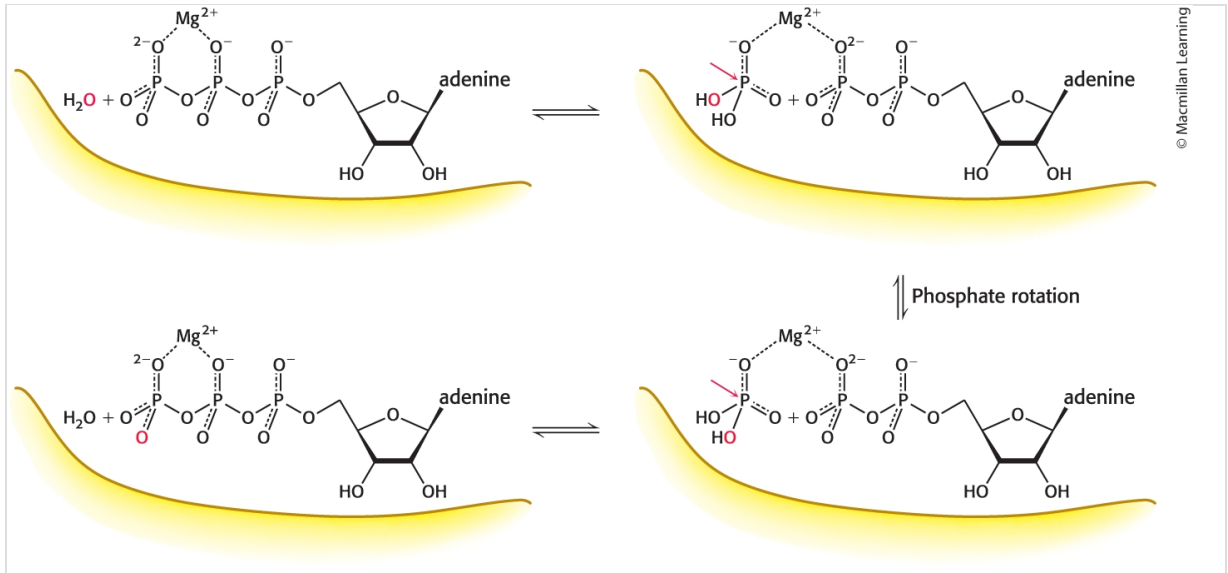

FIGURE 6.43 The hydrolysis of ATP is reversible within the active site of myosin. This is revealed by the fact that more than one atom of oxygen from water is incorporated in inorganic

phosphate. The oxygen atoms are incorporated in cycles of hydrolysis of ATP to ADP and inorganic phosphate, phosphate rotation within the active site, and reformation of ATP now containing oxygen from water.

At first glance, this observation is startling because ATP hydrolysis is a very favorable reaction with an equilibrium constant of approximately 140,000. However, this equilibrium constant applies to the molecules free in solution, not within the active site of an enzyme. Indeed, further analysis suggests that this equilibrium constant on the enzyme is approximately 10.

This result illustrates a general strategy used by enzymes: Enzymes catalyze reactions by stabilizing the transition state. The structure of this transition state is intermediate between the enzyme-bound reactants and the enzyme-bound products. Many of the interactions that stabilize the transition state will help equalize the stabilities of the reactants and the products. Thus, the equilibrium constant between enzyme-bound reactants and products usually 10 or below and is often close to 1, regardless of the equilibrium constant for the reactants and products free in solution.

These observations reveal that the hydrolysis of ATP to ADP and P_i is not the rate-limiting step for the reaction catalyzed by myosin. Instead, the release of the products, particularly P_i, from the enzyme is rate limiting. The fact that a conformation of myosin with ATP hydrolyzed but still bound to the enzyme persists for a significant period of time is critical for coupling conformational changes that take place in the course of the reaction to other processes.

Self-Check Question

Myosin is treated with ATP in the presence of water labelled with $H_2{}^{18}O$. After a period of time, the remaining ATP is isolated and found to contain ^{18}O. Explain.

Actin forms filaments along which myosin can move

Myosin molecules use the free energy of hydrolysis of ATP to drive their own macroscopic movement along a filamentous protein termed *actin*, a 42-kDa protein that very abundant in eukaryotic cells, typically accounting for as much as 10% of the protein. Actin monomers come together to form actin filaments (**Figure 6.44**). Actin filaments have helical structures; each monomer is related to the preceding one by a translation of $27.5\ \text{Å}$ and a rotation of 166 degrees around the helical axis. Because the rotation is nearly 180 degrees, F-actin resembles a two-stranded cable. Note that each actin monomer is oriented in the same direction along the actin filament, and so the structure is polar, with discernibly different ends. One end is called the barbed (plus) end, and the other is called the pointed (minus) end. Each actin monomer contains a bound nucleotide, ATP or ADP.

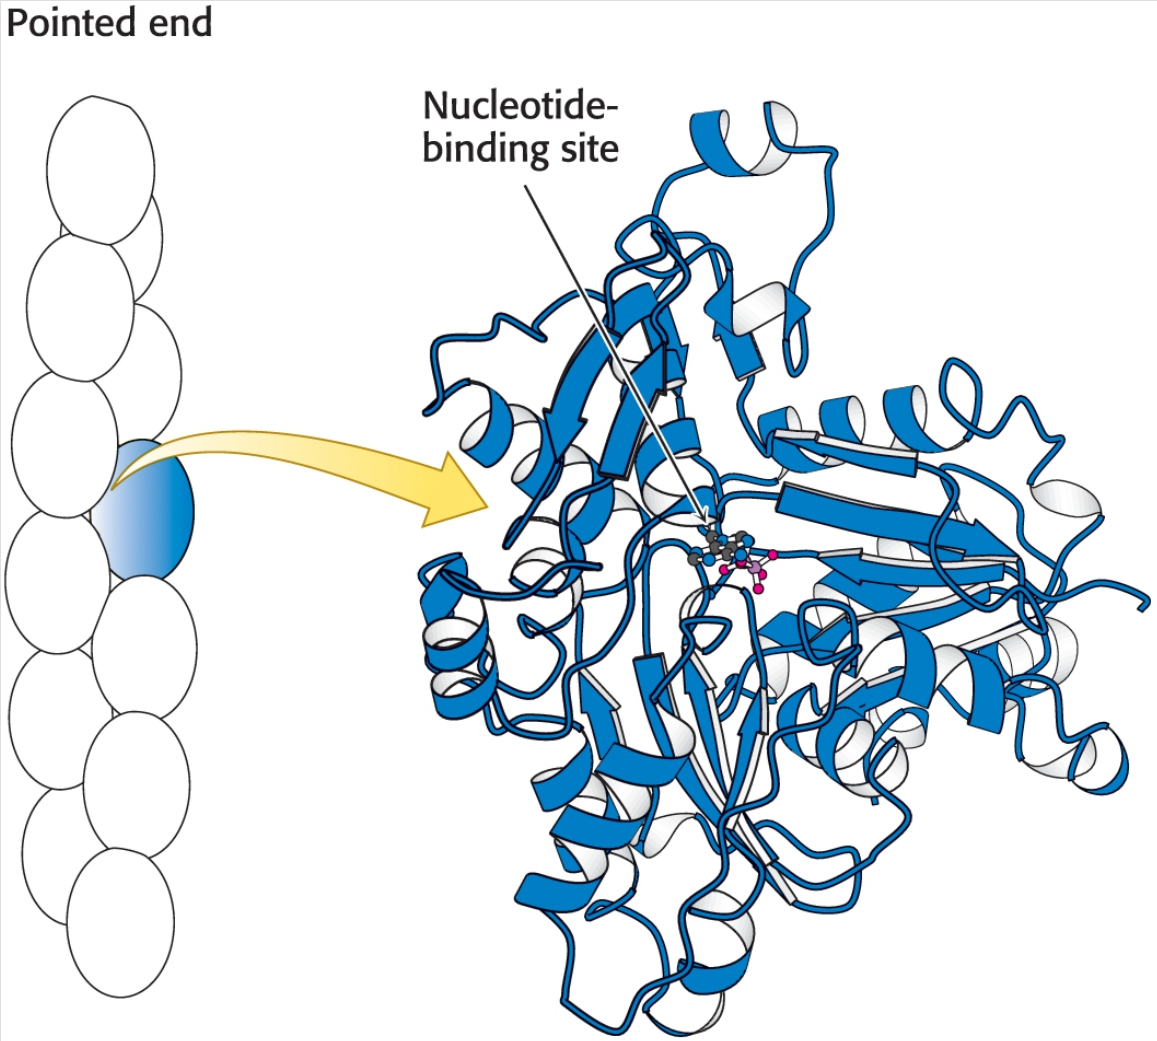

FIGURE 6.44 An actin filament has a polymeric structure. In the schematic view at left, actin monomers are depicted as ovals. The detailed structure of one actin monomer (blue) is shown a right.

[Drawn from 1J6Z.pdb.]

INTERACT with this model in Achieve

Using a variety of physical methods, scientists have been able to watch single myosin molecules moving along actin filaments. For example, a myosin family member termed myosin V can be labeled with

fluorescent tags so that it can be localized when fixed on a surface with a precision of less than 15 Å. When this myosin in the absence of ATP is placed on a surface coated with actin filaments, each molecule remains in a fixed position. However, when ATP is added, each molecule moves along the surface. Tracking individual molecules reveals that each moves in steps of approximately 74 nm (Figure 6.45). The observation of steps of a fixed size as well as the determination of this step size helps reveal details of the mechanism of action of these tiny molecular machines.

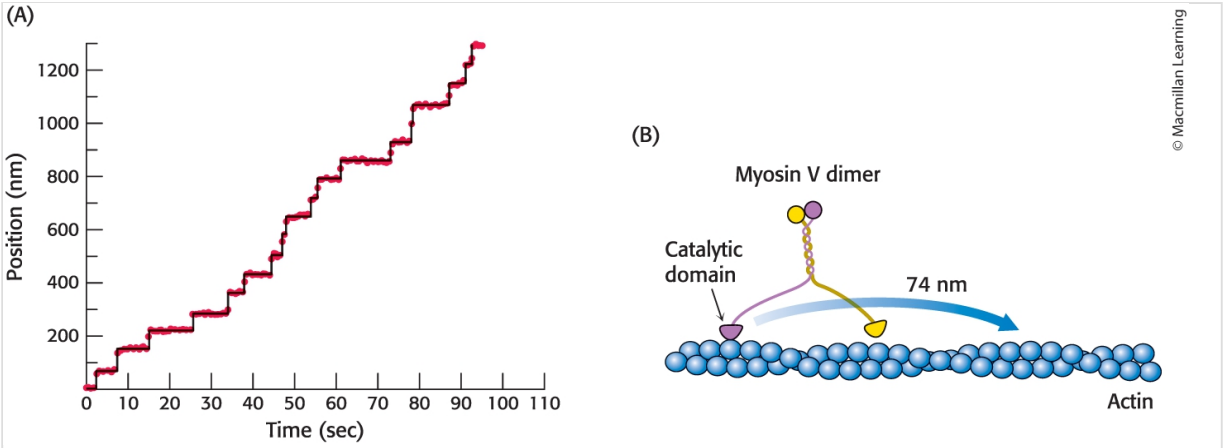

FIGURE 6.45 A molecular motor such as myosin V moves in discrete steps. (A) A trace of the position of a single dimeric myosin V molecule as it moves across a surface coated with actin filaments. (B) A model of how the dimeric molecule moves in discrete steps with an average size of 74 ± 5 nm.

How does ATP hydrolysis drive this motion? A key observation is that the addition of ATP to a complex of myosin and actin results in the dissociation of the complex. Thus, ATP binding and hydrolysis cannot be directly responsible for the power stroke. We can combine this fact with observations from three-dimensional structures of myosin in various forms to construct a mechanism for the motion of myosin along actin (Figure 6.46).

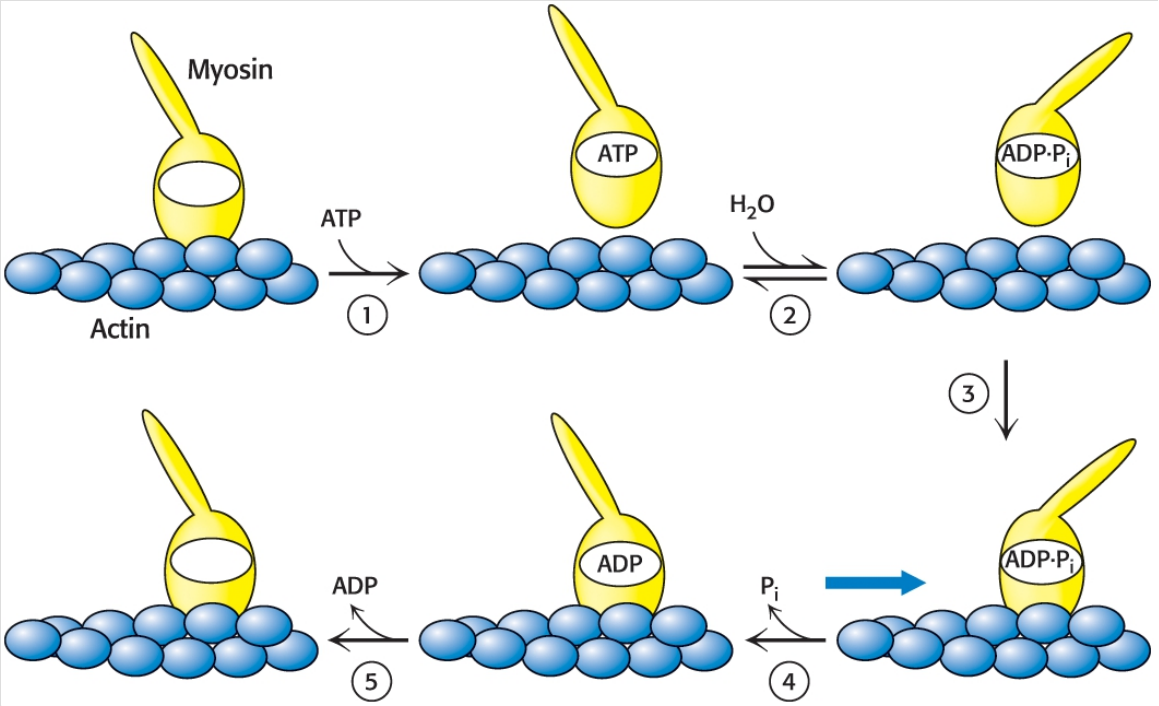

FIGURE 6.46 The mechanism by which myosin moves along an actin filament involves five steps. The binding of ATP (1) results in the release of myosin (yellow) from actin (blue). The reversible hydrolysis of ATP bound to myosin (2) can result in the reorientation of the lever arm. With ATP hydrolyzed but still bound to actin, myosin can bind actin (3). The release of P_i (4) results in the reorientation of the lever arm and the concomitant motion of actin relative to myosin. The release of ADP (5) completes the cycle.

Let us begin with nucleotide-free myosin bound to actin. The binding of ATP to actin results in the dissociation of myosin from actin. With ATP bound and free of actin, the myosin domain can undergo the conformational change associated with the formation of the transition state for ATP hydrolysis. This conformational change results in the reorientation of the lever arm. In this form, the myosin head can dock onto the actin filament; phosphate is released with an accompanying motion of the lever arm. This conformational change represents the power stroke and moves the body of the myosin molecule relative to the actin filament. The release of ADP completes the cycle.

The most well-studied actin-myosin motor system is that from skeletal muscle (Figure 6.47). Muscle contains organized assemblies of actin molecules, referred to as thin filaments, together with multiheaded assemblies of myosin molecules that form thick filaments. Upon activation, the myosin motors move along the actin filaments to cause the combined assembly to contract.

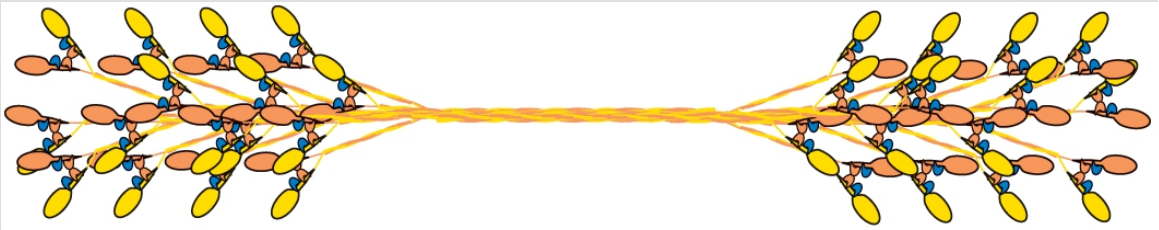

FIGURE 6.47 A myosin assembly from muscle has a two-headed structure. A schematic view shows how multiple myosin molecules come together to form the thick filament.

Other cells contain elaborate meshworks of actin filaments that form an internal cellular skeleton or cytoskeleton, which plays a major role in determining cell shape. Two techniques for observing the cytoskeleton have traditionally been used, but each has shortcomings: Electron microscopy can produce clear images but cannot be performed on living cells, whereas light microscopy that visualizes fluorescent tags attached to actin can be performed on living cells, but the clarity of the images is limited by the relatively long wavelengths of visible light.

Recently, scientists have developed new microscopic methods based on the principle that the position of an isolated fluorescent molecule can be determined much more precisely than the image produced by monitoring the fluorescence. These methods have produced beautiful pictures of the intricate tracks inside living cells along which molecular motors can move (Figure 6.48). With these new tools, scientists can now ask new questions about the elaborate movements that occur within living cells driven by molecular motors.

Chapter 6 Summary

6.1 Enzymes Use a Core Set of Catalytic Strategies

- Enzymes adopt conformations that are structurally and chemically complementary to the transition states of the reactions that they catalyze.
- Enzymes use five basic strategies to form and stabilize the transition state: the use of binding energy to promote both specificity and catalysis, covalent catalysis, general acid–base catalysis, catalysis by approximation, and metal ion catalysis.

6.2 Proteases Facilitate a Fundamentally Difficult Reaction

- The cleavage of peptide bonds by chymotrypsin is initiated by the attack by a serine residue on the peptide carbonyl group with the serine activated by a catalytic triad of Ser-His-Asp.
- The product of this initial reaction is a covalent intermediate formed by the enzyme and an acyl group derived from the bound substrate that is subsequently hydrolyzed.
- Tetrahedral intermediates that occur during these reactions have a negative charge on the peptide carbonyl oxygen atom that is stabilized by interactions with peptide NH groups in a region on the enzyme termed the oxyanion hole.
- Some other proteases employ the same catalytic strategy based on a similar catalytic triad, including homologs of chymotrypsin such as trypsin and elastase and other proteins such as subtilisin that evolved the same catalytic apparatus independently.

6.3 Carbonic Anhydrases Make a Fast Reaction Faster

- Carbonic anhydrases catalyze the reaction of water with carbon dioxide at rates as high as 1 million times per second to generate bicarbonate ion which can be protonated to form carbonic acid.
- A tightly bound zinc ion binds a water molecule, promotes its deprotonation to generate a hydroxide ion at neutral pH, and uses this nucleophile to attack carbon dioxide.
- To overcome limitations imposed by the rate of proton transfer from the zinc-bound water, the most-active carbonic anhydrases have evolved a proton shuttle to transfer protons to buffer components in solution.

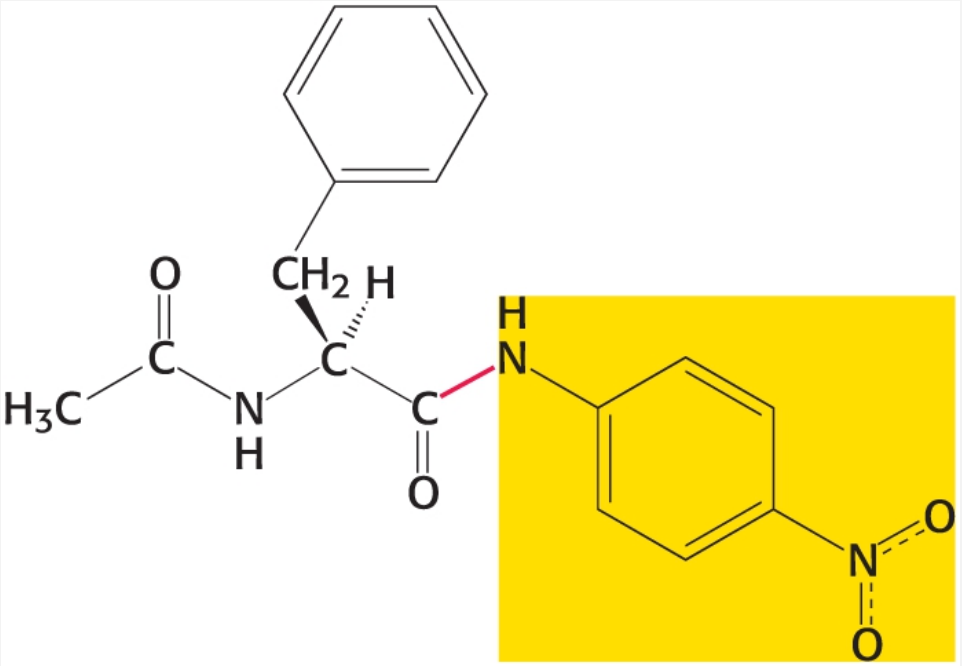
6.4 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions

- Restriction enzymes that cleave DNA at specific recognition sequences discriminate between molecules that contain these recognition sequences and those that do not.
- Restriction enzymes use magnesium ions to bind and activate a water molecule to attacks the phosphodiester backbone and facilitate DNA cleavage.
- EcoRV distorts DNA molecules containing the proper sequence are in a manner that allows magnesium ion binding and, hence, DNA cleavage.
- Restriction enzymes are prevented from acting on the DNA of a host cell by the methylation of key sites within its recognition sequences, blocking specific interactions between the enzymes and the DNA.

6.5 Molecular Motor Proteins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

- Molecular motors called myosins catalyze the hydrolysis of adenosine triphosphate, using the free energy generated to drive large-scale molecular movement.

- Myosin associated with the transition state for ATP hydrolysis has a distinct structure indicating a large-scale conformational change.
- The rate of ATP hydrolysis by myosin is relatively low and is limited by the rate of product release from the enzyme.
- Myosins move along a filamentous protein called actin, binding and releasing actin filaments over the course of its catalytic cycle to facilitate movement.
- Actin filaments occur in muscle and also form a cytoskeleton inside eukaryotic cells along which myosins can move; the cytoskeleton also functions like scaffolding, giving the cell its shape.



Key Terms

Problems

1. Examination of the cleavage of the amide substrate, A, by chymotrypsin with the use of stopped-flow kinetic methods reveals no burst. The reaction is monitored by noting the color produced by the release of the amino part of the substrate (highlighted in orange). Why is no burst observed? 1, 6

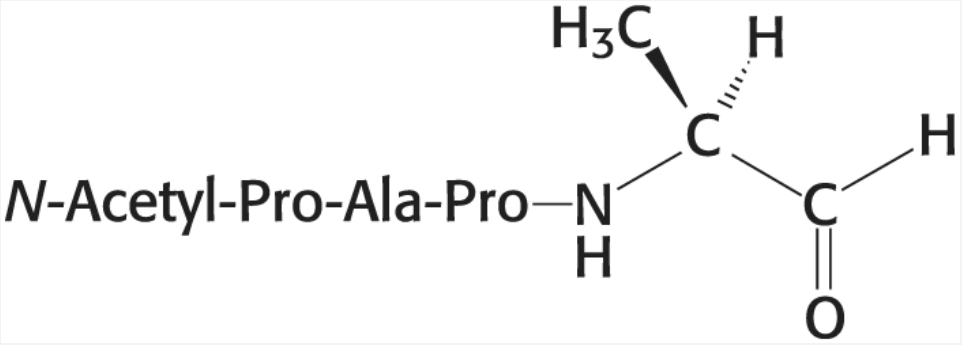
2. Consider the subtilisin substrates A and B.

Phe-Ala-Gln-Phe-X	Phe-Ala-His-Phe-X
A	B

These substrates are cleaved (between Phe and X) by native subtilisin at essentially the same rate. However, the His 64-to-Ala mutant of subtilisin cleaves substrate B more than 1000-fold as rapidly as it cleaves substrate A. Propose an explanation. 2

3. Consider the following argument. In subtilisin, mutation of Ser 221 to Ala results in a 10^6-fold decrease in activity. Mutation of His 64 to Ala results in a similar 10^6-fold decrease. Therefore, simultaneous mutation of Ser 221 to Ala and His 64 to Ala should result in a $10^6 \times 10^6 = 10^{12}$-fold reduction in activity. Is this correct? Why or why not?

4. In chymotrypsin, a mutant was constructed with Ser 189, which is in the bottom of the substrate-specificity pocket, changed to Asp. What effect would you predict for this mutation?

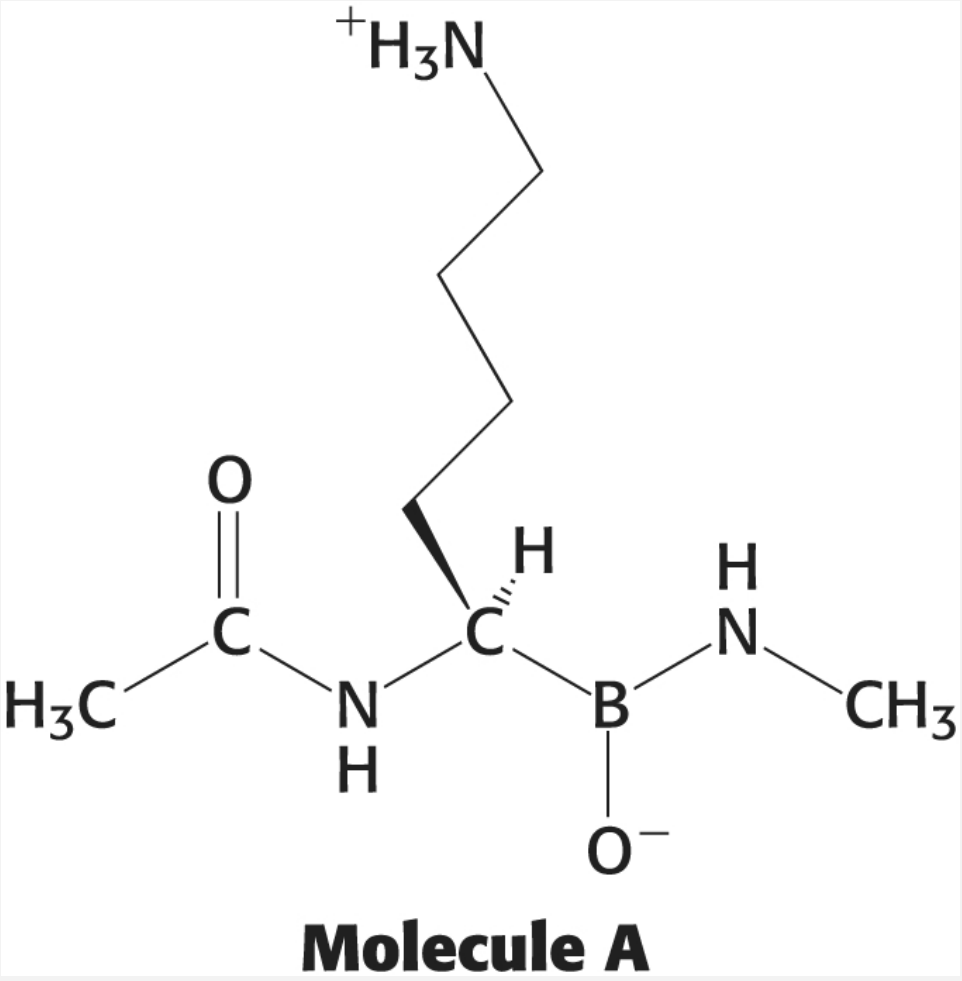


5. In carbonic anhydrase II, mutation of the proton-shuttle residue His 64 to Ala was expected to result in a decrease in the maximal catalytic rate. However, in buffers such as imidazole

with relatively small molecular components, no rate reduction was observed. In buffers with larger molecular components, significant rate reductions were observed. Propose an explanation.

6. Restriction endonucleases are, in general, quite slow enzymes with typical turnover numbers of $1\ s^{-1}$. Suppose that endonucleases were faster, with turnover numbers similar to those for carbonic anhydrase such that they act faster than do methylases. Would this increased rate be beneficial to host cells, assuming that the fast enzymes have similar levels of specificity?

7. Treatment of carbonic anhydrase with high concentrations of the metal chelator EDTA (ethylenediaminetetraacetic acid) results in the loss of enzyme activity. Propose an explanation.
2, 3



8. Elastase is specifically inhibited by an aldehyde derivative of one of its substrates:

a. Which residue in the active site of elastase is most likely to form a covalent bond with this aldehyde?
b. What type of covalent link would be formed?

9. Use the provided structure of molecule A to complete the passage.

Molecule A contains a side chain similar to that of _____. Molecule A effectively inhibits _____ ___ by binding to the _____ residue in the enzyme's S_1 pocket.
2

Molecule A

10. At pH 7.0, carbonic anhydrase exhibits a k_{cat} of $60{,}000\ s^{-1}$. Estimate the value expected for k_{cat} at pH 6.0.

11. To terminate a reaction in which a restriction enzyme cleaves DNA, researchers often add high concentrations of the metal chelator EDTA (ethylenediaminetetraacetic acid). Why does the addition of EDTA terminate the reaction?

12. Many patients become resistant to HIV protease inhibitors with the passage of time, owing to mutations in the HIV gene that encodes the protease. Mutations are not found in the aspartate residue characteristic of aspartyl proteases. Why not? 1, 2

13. Serine 236 in *Dictyostelium discoideum* myosin has been mutated to alanine. The mutated protein showed modestly reduced ATPase activity. Analysis of the crystal structure of the mutated protein revealed that a water molecule occupied the position of the hydroxyl group of the serine residue in the wild-type protein. Propose a mechanism for the ATPase activity of the mutated enzyme. 1, 2, 6

14. The catalytic power of an enzyme can be defined as the ratio of the rate of the enzyme catalyzed reaction to that for the uncatalyzed reaction. Using the information in Figure 6.15 for subtilisin and in Figure 6.19 for carbonic anhydrase, calculate the catalytic powers for these two enzymes.

15. Would a reaction catalyzed by a version of subtilisin with all three residues in the catalytic triad mutated have less or more

activity compared to the uncatalyzed reaction (see Figure 6.15)? Propose an explanation for any remaining catalytic power.

16. On the basis of the information provided in Figure 6.16, complete the mechanisms for peptide-bond cleavage by

a. a cysteine protease,
b. an aspartyl protease, and
c. a metalloprotease. 1, 2

17. Most enzymes are quite specific, catalyzing a particular reaction on a set of substrates that are structurally quite similar to one another. Discuss why this is advantageous from a biological perspective. Suggest why this is likely to be true from a chemical perspective. Why would it be difficult to evolve an enzyme with high catalytic activity but low specificity? 4

18. In the absence of actin, myosin will hydrolyze ATP, but very slowly. Based on the mechanism shown in Figure 6.46, propose an explanation for this slow rate.

Chapter 7
Enzyme Regulatory Strategies

Like motor traffic, metabolic pathways flow more efficiently when regulated by signals. Cytidine triphosphate (CTP), the final product of a multistep pathway, controls flux through the pathway by inhibiting the committed step catalyzed by aspartate transcarbamoylase (ATCase).

Outline

7.1 Allosteric Regulation Enables Control of Metabolic Pathways
7.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages
7.3 Covalent Modification Is a Means of Regulating Enzyme Activity
7.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage

7.5 Enzymatic Cascades Allow Rapid Responses Such as Blood Clotting

---

Learning Goals

By the end of this chapter, you should be able to:

1. Explain how the kinetic properties of allosteric enzymes differ from Michaelis–Menten enzymes.
2. Describe the role of feedback inhibition in the regulation of enzymes.
3. Differentiate between homotropic and heterotropic effects and explain how they modify the equilibrium between the T and R forms of an allosteric enzyme.
4. Explain the role of isozymes in the regulation of metabolism.
5. Describe the activity of protein kinases and protein phosphatases.
6. Explain why phosphorylation is an effective means of regulating the activities of target proteins.
7. Explain why the mechanism of zymogen activation is important physiologically and how it differs from the other control mechanisms discussed in this chapter.

The activity of enzymes must often be regulated so that they function at the proper time and place. This control is essential for coordination of the vast array of biochemical processes taking place at any instant in an organism. While numerous regulatory mechanisms have been elucidated, this chapter explores four commonly utilized methods: (1) allosteric control by regulatory molecules, (2) alternate enzymes that catalyze the same reactions but exhibit different catalytic and regulatory properties, (3) reversible covalent modifications, and (4) irreversible proteolytic cleavage to yield an active enzyme product. Another method, adjusting the amount of enzyme present, usually takes place at the level of gene transcription and will be discussed in Chapter 31.

7.1 Allosteric Regulation Enables Control of Metabolic Pathways

As we shall discuss in Section 8.1, pyrimidines and purines are the aromatic groups that compose the unique bases found in DNA and RNA. Aspartate transcarbamoylase (ATCase) catalyzes the first step in the biosynthesis of pyrimidines: the condensation of aspartate and carbamoyl phosphate to form *N*-carbamoylaspartate and orthophosphate (**Figure 7.1**). This reaction is the **committed step** in the pathway, which consists of 10 reactions that will ultimately yield the pyrimidine nucleotides uridine triphosphate (UTP) and cytidine triphosphate (CTP). The committed step means that the products of the reaction are committed to ultimate synthesis of the end products of the pathway, in this case UTP and CTP. The committed step, in any pathway, is irreversible under cellular conditions and is the reaction catalyzed by allosteric enzymes. How is ATCase regulated to generate precisely the amount of pyrimidines needed by the cell?

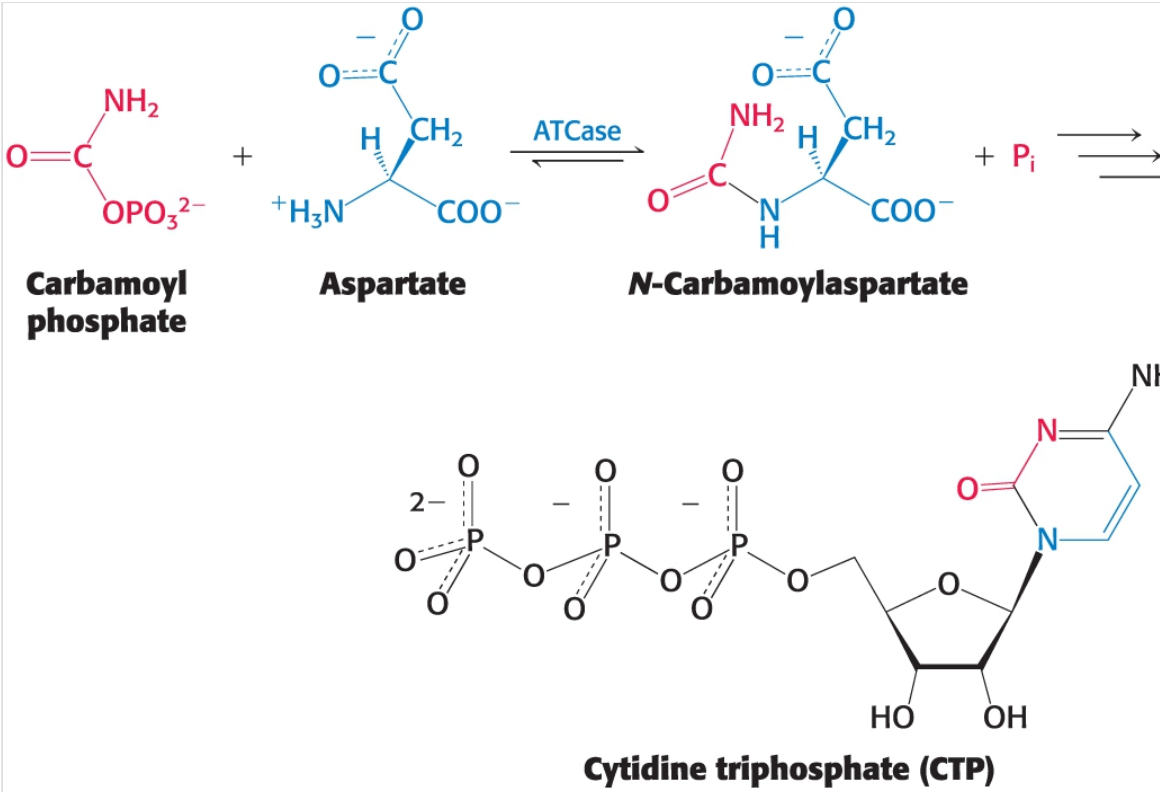

FIGURE 7.1 Aspartate transcarbamoylase (ATCase) catalyzes the committed step in pyrimidir synthesis. The reaction is the condensation of aspartate and carbamoyl phosphate to form *N*-carbamoylaspartate.

ATCase is inhibited by CTP, the final product of the ATCase-initiated pathway. The rate of the reaction catalyzed by ATCase is fast at low concentrations of CTP but slows as CTP concentration increases (Figure 7.2). Thus, the pathway continues to make new pyrimidines until sufficient quantities of CTP have accumulated. The inhibition of ATCase by CTP is an example of **feedback inhibition**, the inhibition of an enzyme by the end product of the pathway. Feedback inhibition by CTP ensures that *N*-carbamoylaspartate and subsequent intermediates in the pathway are not needlessly formed when pyrimidines are abundant.

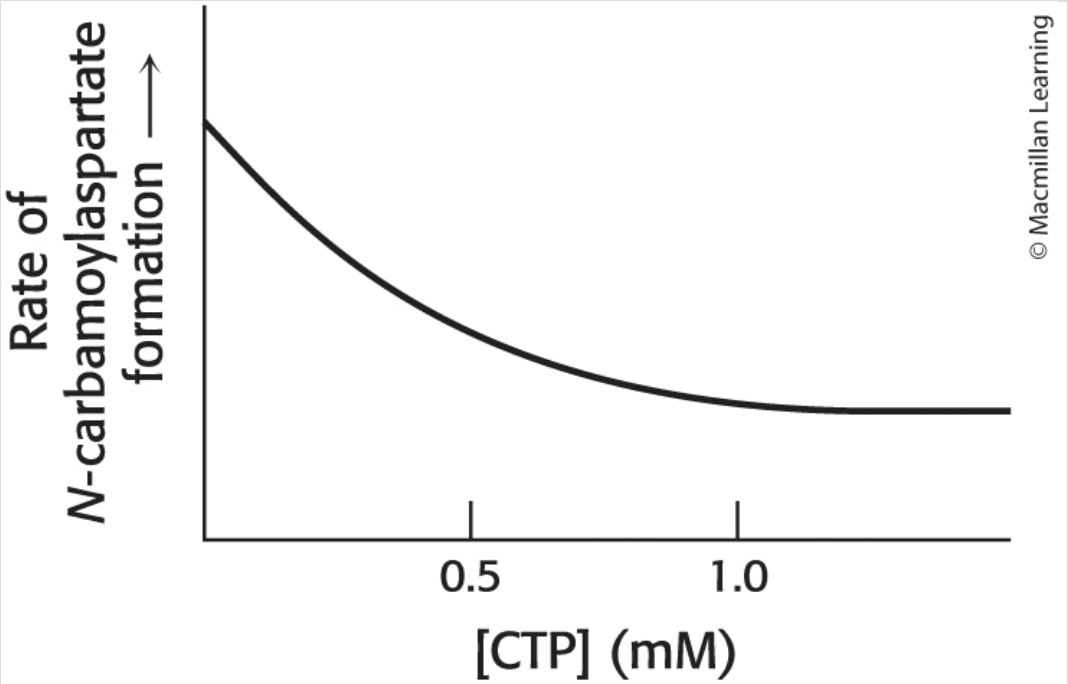

FIGURE 7.2 CTP inhibits ATCase. Cytidine triphosphate, an end product of the pyrimidine-synthesis pathway, inhibits aspartate transcarbamoylase despite having little structural similarity to reactants or products.

The inhibitory ability of CTP is remarkable because CTP is structurally quite different from the substrates of the reaction (Figure 7.1). Thus, CTP must bind to a site distinct from the active site at which substrate binds. Such sites are called **allosteric** (or **regulatory**) **sites**. CTP is an example of an allosteric inhibitor. In ATCase (but not all allosterically regulated enzymes), the catalytic sites and the regulatory sites are on separate polypeptide chains.

Many allosterically regulated enzymes do not follow Michaelis–Menten kinetics

Allosteric enzymes are distinguished by their response to changes in substrate concentration in addition to their susceptibility to regulation

by other molecules. Let us examine the rate of product formation as a function of substrate concentration for ATCase (**Figure 7.3**). The curve differs from that expected for an enzyme that follows Michaelis–Menten kinetics. The observed curve is referred to as sigmoidal because it resembles the letter "S." The vast majority of allosteric enzymes display sigmoidal kinetics. Recall from the discussion of hemoglobin (Chapter 3) that sigmoidal curves result from cooperation between subunits: the binding of substrate to one active site in a molecule increases the likelihood that substrate will bind to other active sites. To understand the basis of sigmoidal enzyme kinetics and inhibition by CTP, we need to examine the structure of ATCase.

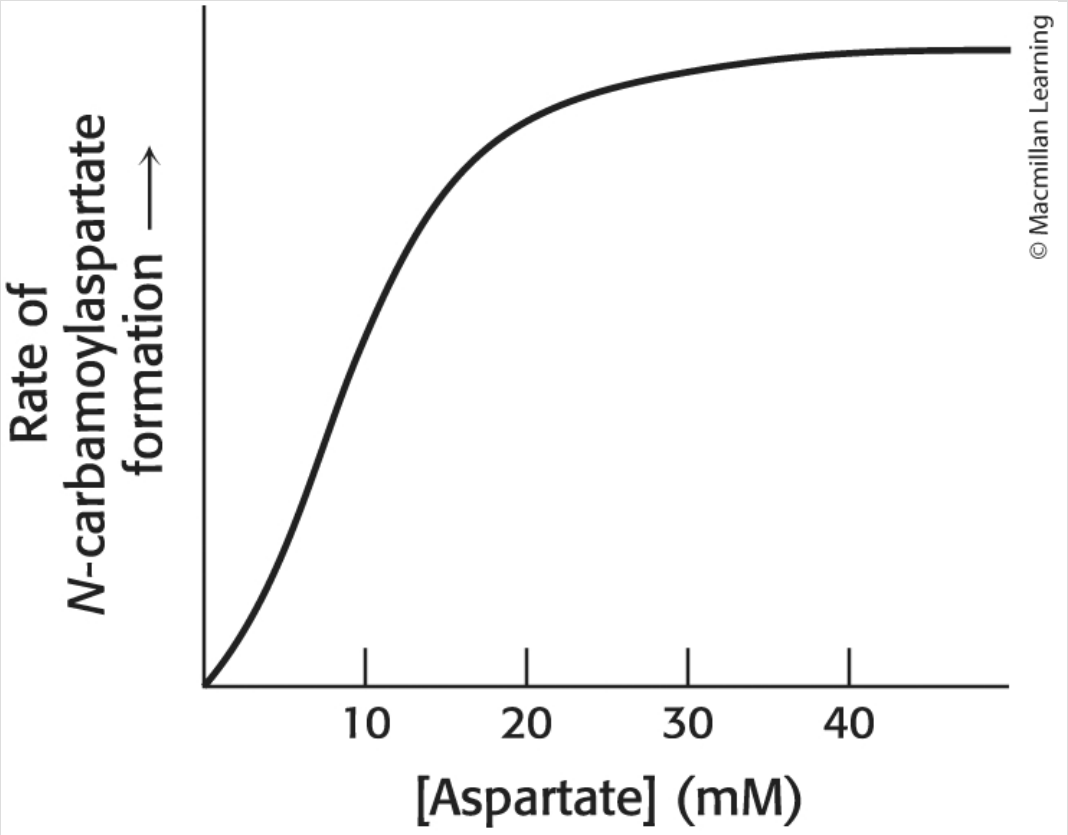

FIGURE 7.3 ATCase displays sigmoidal kinetics. A plot of product formation as a function of substrate concentration produces a sigmoidal curve because the binding of substrate to one active site increases the activity at the other active sites. Thus, the enzyme shows cooperativity.

ATCase consists of separable catalytic and regulatory subunits

What is the evidence that ATCase has distinct regulatory and catalytic sites? ATCase can be separated into regulatory (r) and catalytic (c) subunits by treatment with a mercurial compound such as *p*-hydroxymercuribenzoate, which reacts with sulfhydryl groups and prevents them from re-forming disulfide bonds (**Figure 7.4**). The larger subunit is called the *catalytic subunit.* This subunit has catalytic activity, but when tested by itself, it displays the hyperbolic kinetics of Michaelis–Menten enzymes rather than sigmoidal kinetics. Furthermore, the isolated catalytic subunit is unresponsive to CTP. The isolated smaller subunit can bind CTP but has no catalytic activity. Hence, that subunit is called the *regulatory subunit*. The catalytic subunit (c_3) consists of three c chains (34 kDa each), and the regulatory subunit (r_2) consists of two r chains (17 kDa each).

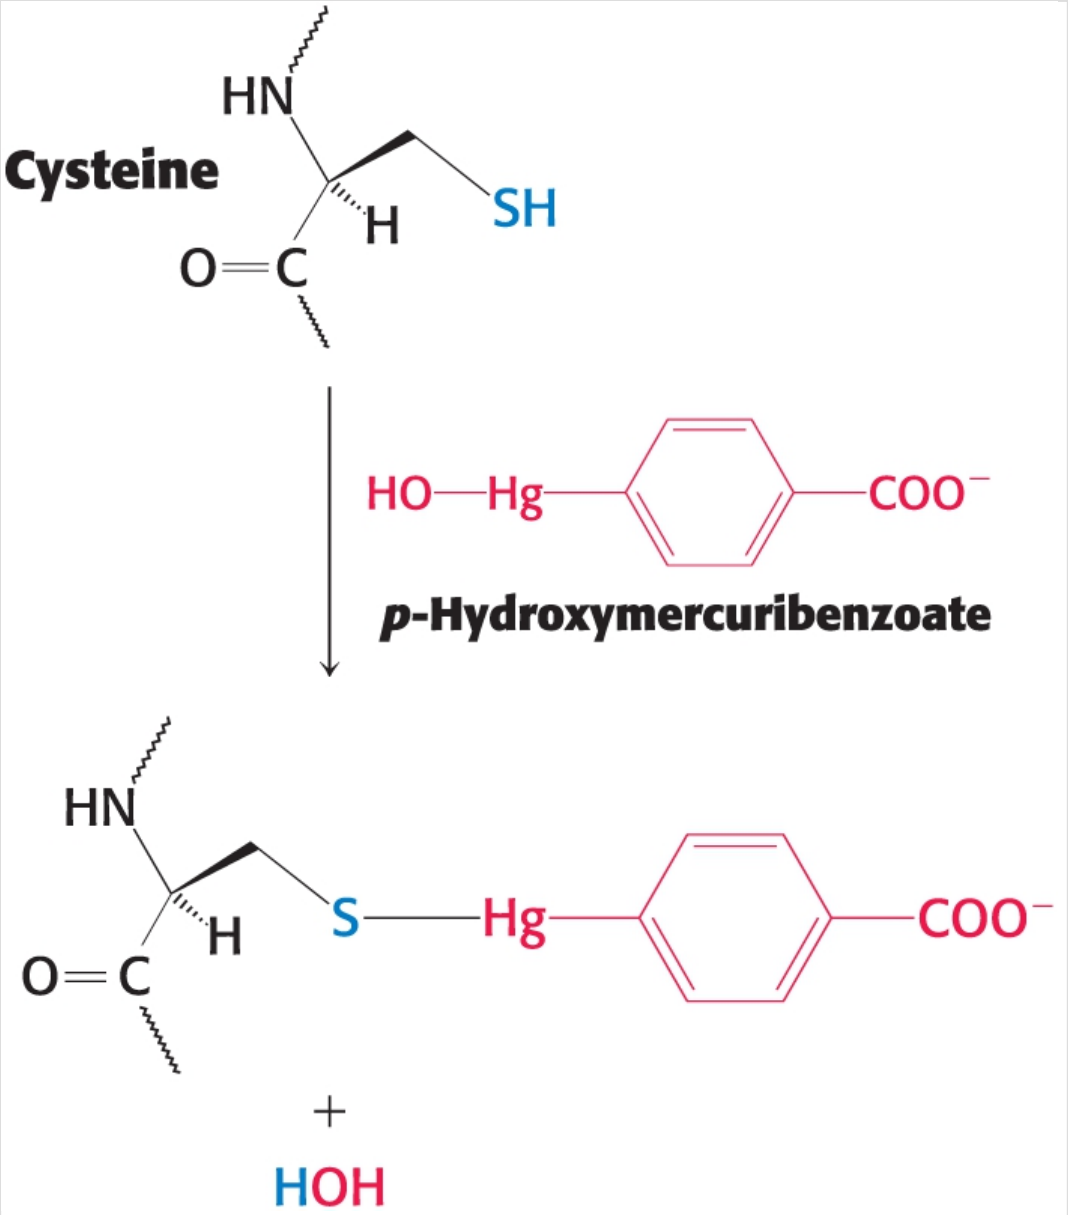

FIGURE 7.4 *p*-Hydroxymercuribenzoate reacts with crucial cysteine residues in aspartate transcarbamoylase. Treatment of ATCase with *p*-hydroxymercuribenzoate separates the enzyme into its regulatory and catalytic subunits.

The catalytic and regulatory subunits combine rapidly when they are mixed. The resulting complex has the same structure, c_6r_6, as the native enzyme: two catalytic trimers and three regulatory dimers.

$$2c_3 + 3r_2 \longrightarrow c_6r_6$$

Most strikingly, the reconstituted enzyme has the same allosteric and kinetic properties as those of the native enzyme. Thus, ATCase is composed of discrete catalytic and regulatory subunits, and the interaction of the subunits in the native enzyme produces its regulatory and catalytic properties. The fact that the enzyme can be separated into isolated catalytic and regulatory subunits, which can be reconstituted back to the functional enzyme, allows for a variety of experiments to characterize the allosteric properties of the enzyme.

Allosteric interactions in ATCase are mediated by large changes in quaternary structure

What are the subunit interactions that account for the properties of ATCase? Significant clues have been provided by the three-dimensional structure of various forms of ATCase (**Figure 7.5**). Two catalytic trimers are stacked one on top of the other, linked by three dimers of the regulatory chains. There are significant contacts between the catalytic and the regulatory subunits: each r chain within a regulatory dimer interacts with a c chain within a catalytic trimer. The c chain makes contact with a structural domain in the r chain that is stabilized by a zinc ion bound to four cysteine residues. The zinc ion is critical for the interaction of the r chain with the c chain. *p*-Hydroxymercuribenzoate is able to dissociate the catalytic and regulatory subunits because mercury binds strongly to the cysteine residues, displacing the zinc and preventing interaction with the c chain.

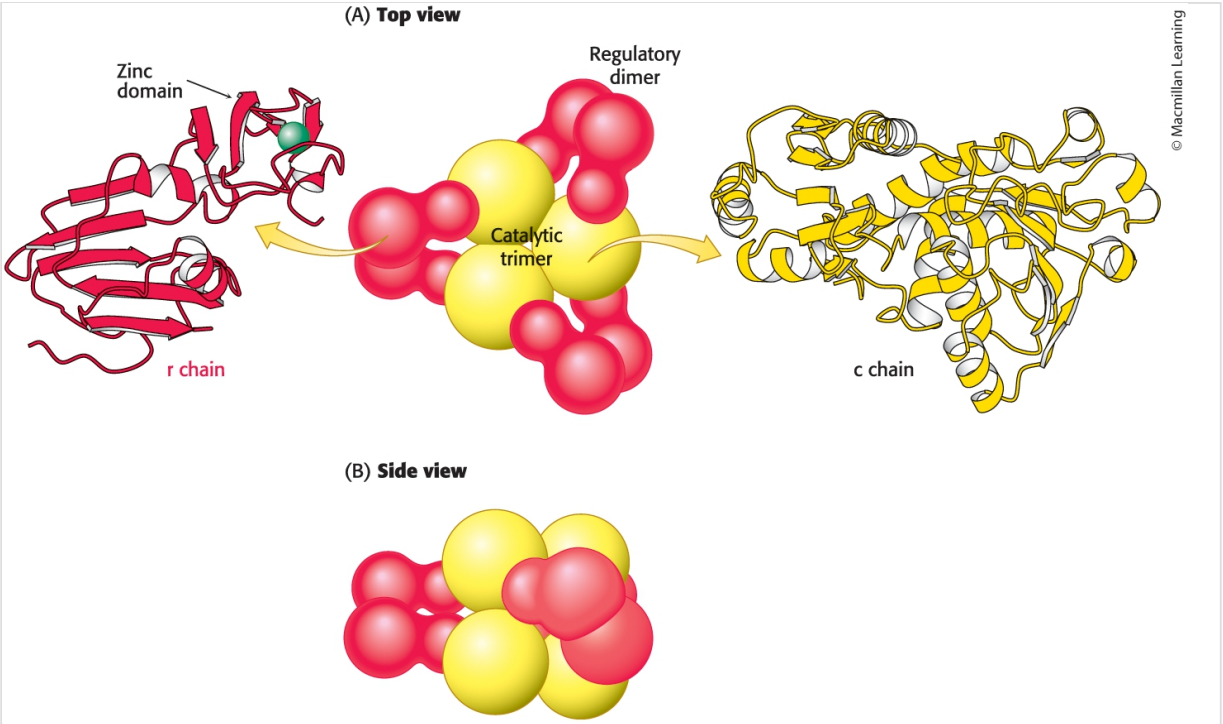

FIGURE 7.5 ATCase consists of a pair of catalytic subunit trimers surrounded by three regulatory subunit dimers. (A) The quaternary structure of aspartate transcarbamoylase as viewed from the top. The drawing in the center is a simplified representation of the relations between subunits. A single catalytic trimer [catalytic (c) chains, shown in yellow] is visible; in this view, the second trimer is hidden below the visible one. Each r chain (red) interacts with a c chain through the zinc domain. (B) A side view of the complex.

[Drawn from 1RAI.pdb.]

INTERACT with this model in Achieve

To locate the active sites, the enzyme has been crystallized in the presence of *N*-(phosphonacetyl)-L-aspartate (PALA), a *bisubstrate analog* (an analog of the two substrates) that resembles an intermediate along the pathway of catalysis (Figure 7.6). PALA is a potent competitive inhibitor of ATCase that binds to and blocks the active sites. The structure of the ATCase–PALA complex reveals that PALA binds at sites lying at the boundaries between pairs of c chains within a catalytic

trimer (Figure 7.7). Each catalytic trimer contributes three active sites to the complete enzyme.

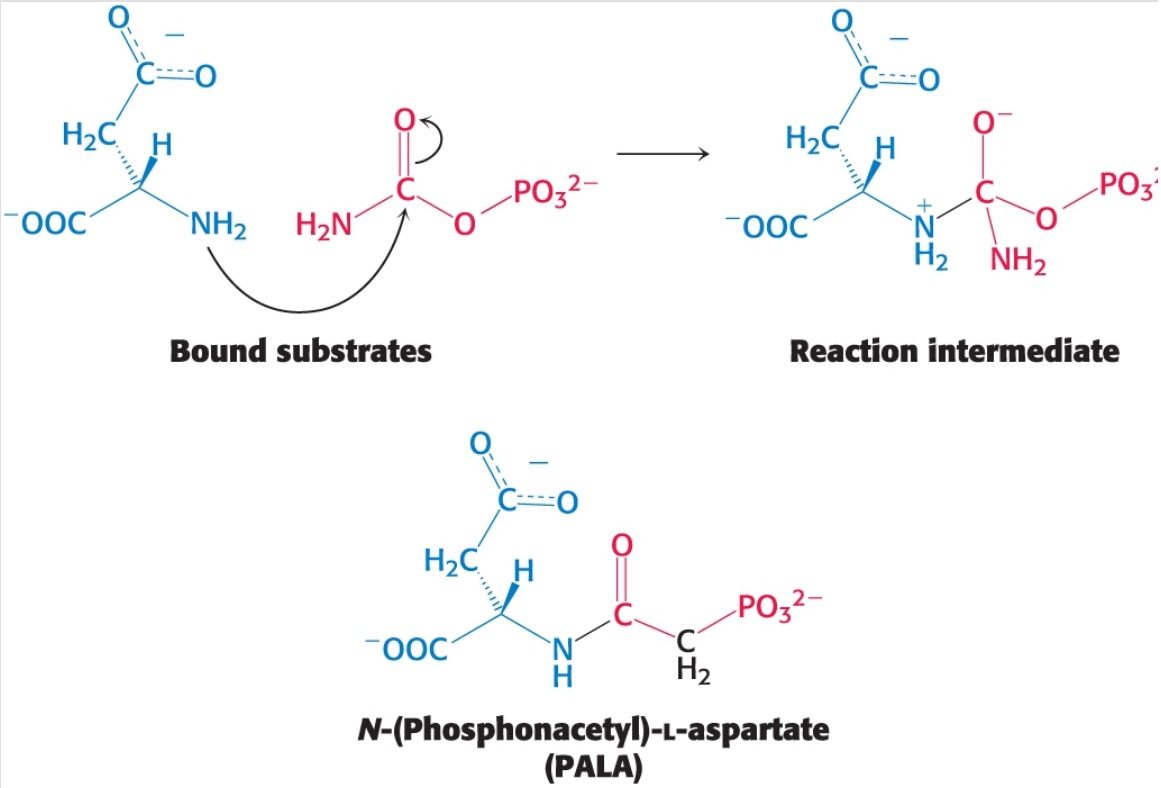

FIGURE 7.6 PALA is a bisubstrate analog representing an intermediate along the ATCase catalytic pathway. (Top) Nucleophilic attack by the amino group of aspartate on the carbonyl carbon atom of carbamoyl phosphate generates an intermediate on the pathway to the formation of *N*-carbamoylaspartate. (Bottom) *N*-(Phosphonacetyl)-L-aspartate (PALA) is an analog of the reaction intermediate and a potent competitive inhibitor of aspartate transcarbamoylase.

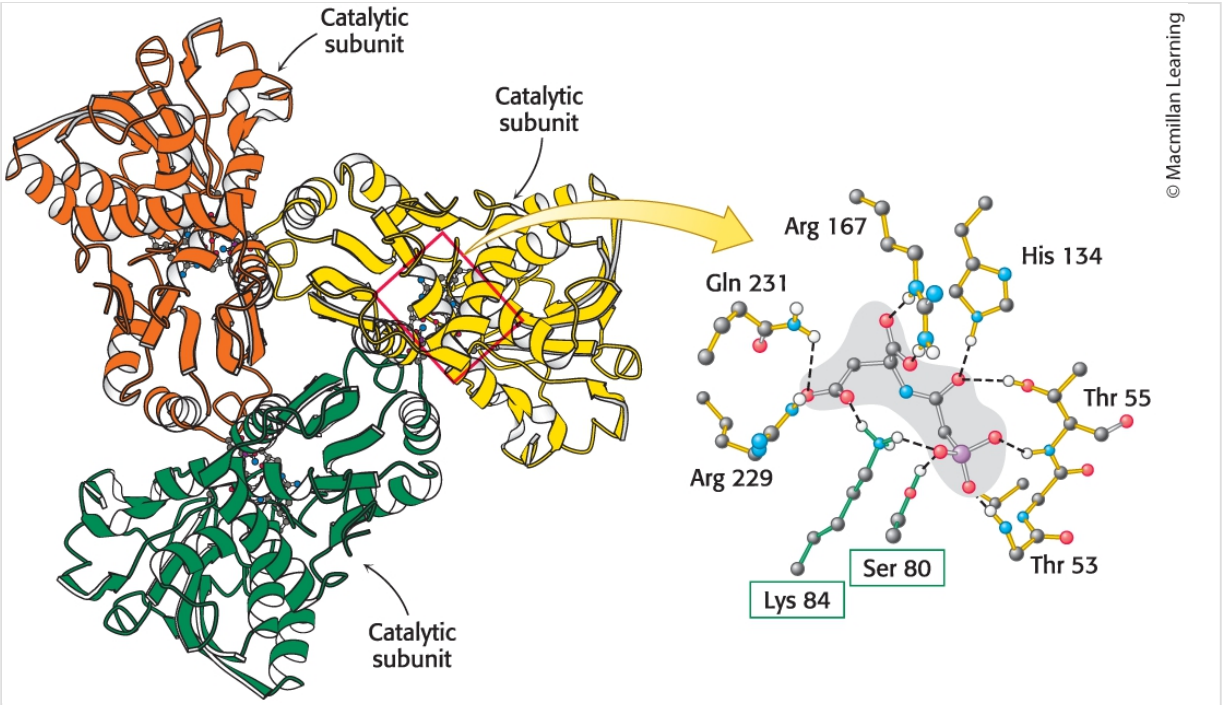

FIGURE 7.7 The structure of PALA bound to ATCase identifies the active site. The catalytic trimer, C_3, of ATCase contains three active sites, each shown bound to a PALA molecule. Some of the crucial active-site residues are shown binding to the inhibitor PALA (shaded gray) via hydrogen bonds (black dotted lines). Notice that an active site is composed mainly of residues from one c chain (yellow bonds), but an adjacent c chain also contributes important residues (green bonds and boxed in green).

[Drawn from 1EKX.pdb.]

INTERACT with this model in Achieve

Further examination of the ATCase–PALA complex reveals a remarkable change in quaternary structure on binding of PALA. The two catalytic trimers move 12 Å farther apart and rotate approximately 10 degrees about their common threefold axis of symmetry. Moreover, the regulatory dimers rotate approximately 15 degrees to accommodate this motion (Figure 7.8). The enzyme literally expands on PALA binding. In essence, ATCase has two distinct quaternary forms: one that predominates in the absence of substrate or substrate analogs, and another that predominates when substrates or analogs are bound. We

call these forms the T (for tense) state and the R (for relaxed) state, respectively, as we did for the two quaternary states of hemoglobin.

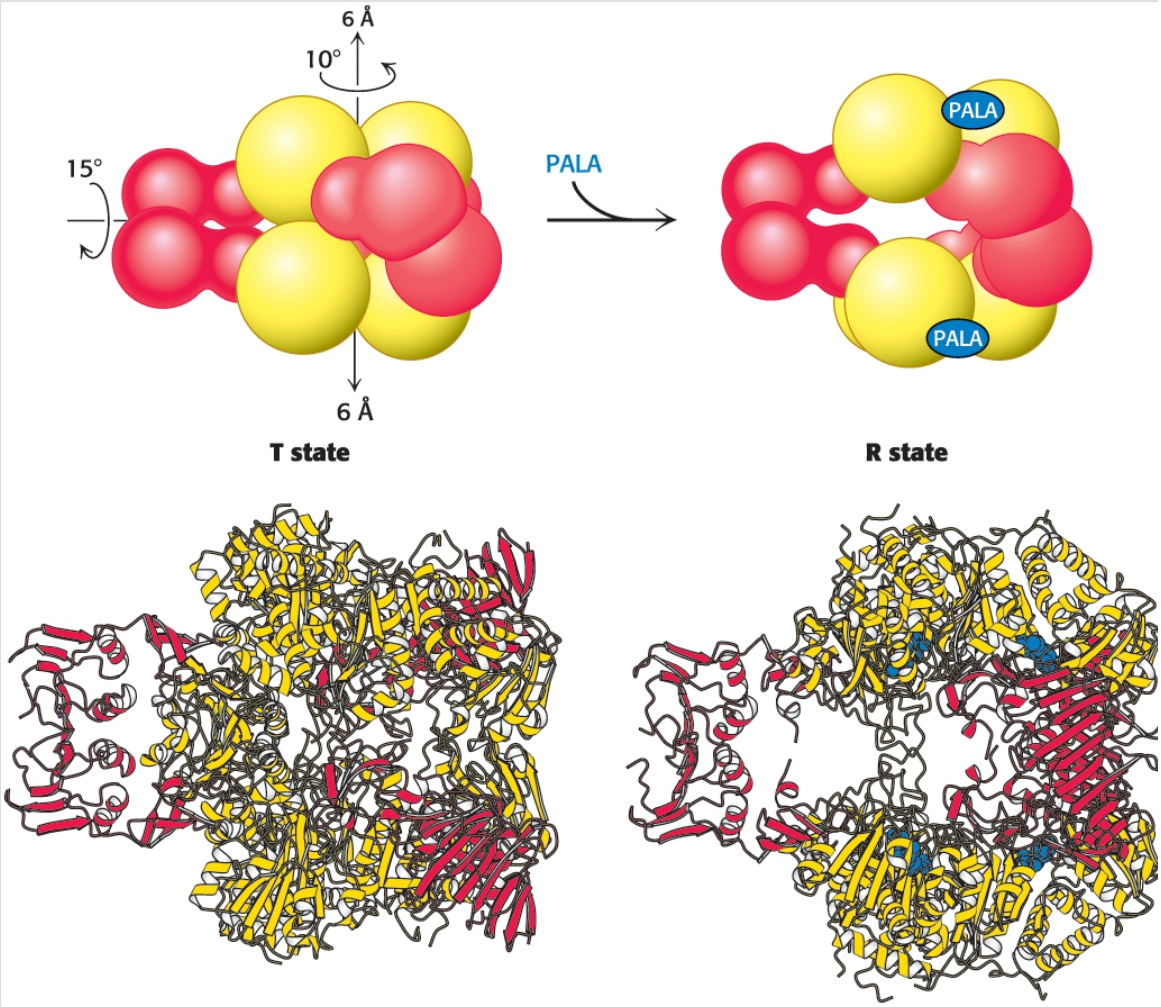

FIGURE 7.8 ATCase exists in two conformations: the tense (T) state and the relaxed (R) state. The structure of ATCase changes dramatically in the transition from the compact, relatively inactive T state to the expanded, active R state. PALA (blue) binding stabilizes the R state.

[Drawn from 6AT1.pdb and 8ATC.pdb.]

How can we explain the enzyme's sigmoidal kinetics in light of the structural observations? Like hemoglobin, the enzyme exists in an equilibrium between the T state and the R state.

In the absence of substrate, almost all the enzyme molecules are in the T state because the T state is energetically more stable than the R state. The ratio of the concentration of enzyme in the T state to that in the R state is called the *allosteric coefficient* (L). For most allosteric enzymes, L is on the order of 10^2 to 10^3.

$$L = \frac{T}{R}$$

The T state has a low affinity for substrate and hence exhibits low catalytic activity. The occasional binding of a substrate molecule to one active site in an enzyme increases the likelihood that the entire enzyme shifts to the R state with its higher binding affinity for substrate.

The addition of more substrate has two effects. First, it increases the probability that each enzyme molecule will bind at least one substrate molecule. Second, it increases the average number of substrate molecules bound to each enzyme. The presence of additional substrate will increase the fraction of enzyme molecules in the more active R state because the position of the equilibrium depends on the number of active sites that are occupied by substrate. We considered this property, called *cooperativity* because the subunits cooperate with one another, when we discussed the sigmoidal oxygen-binding curve of hemoglobin in Chapter 3. The cooperative effects of substrates on allosteric enzymes are also referred to as **homotropic effects** (from the Greek *homós*, "same"), as they reflect the effects of the binding in one site on the

affinity at the comparable site elsewhere in the enzyme. In the case of substrate cooperativity, these homotropic effects act on the enzyme active sites.

Recall that in Chapter 3, we discussed two limiting models for cooperativity: the *concerted* and the *sequential* models (Section 3.3). The mechanism for allosteric regulation of ATCase presented here is best described by the concerted model, as the change in the enzyme is "all or none"; the entire enzyme is converted from T into R, affecting all of the catalytic sites equally. In contrast, the sequential model assumes that the binding of ligand to one site on the complex increases the affinity of neighboring sites without causing a full T-to-R transition of all the sites. Although the concerted model explains the behavior of ATCase well, most other allosteric enzymes exhibit features of both models.

The sigmoidal curve for ATCase can be pictured as a composite of two Michaelis–Menten curves, one corresponding to the less-active T state and the other to the more-active R state. At low concentrations of substrate, the curve closely resembles that of the T state enzyme. As the substrate concentration is increased, the curve progressively shifts to resemble that of the R state enzyme (**Figure 7.9**).

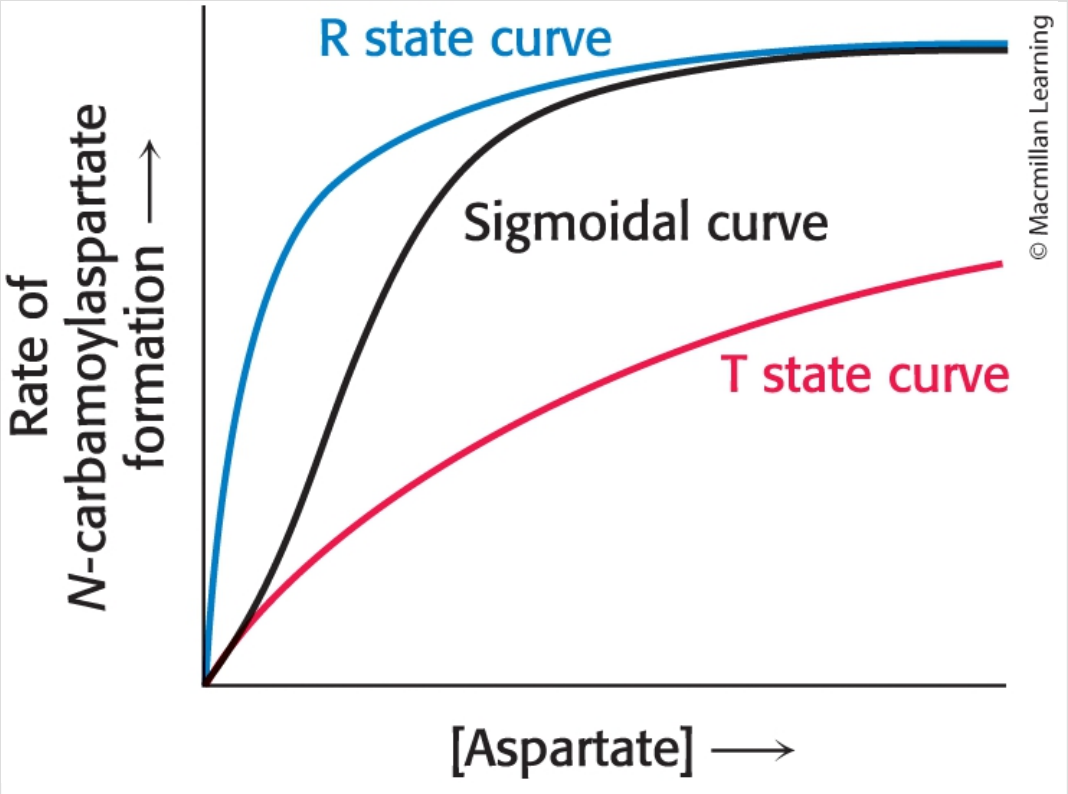

FIGURE 7.9 The sigmoidal curve in cooperative enzymes can be understood as the combination of two Michaelis–Menten enzymes. The first enzyme corresponds to the T state, with a high K_M value, while the second enzyme corresponds to the R state, with a low K_M value. As the concentration of substrate is increased, the equilibrium shifts from the T state to the R state, which results in a steep rise in activity with respect to substrate concentration.

What is the biochemical advantage of sigmoidal kinetics? Allosteric enzymes transition from a less active state to a more active state within a narrow range of substrate concentration. The benefit of this behavior is illustrated in **Figure 7.10**, which compares the kinetics of a Michaelis–Menten enzyme (blue curve) to that of an allosteric enzyme (red curve). In this example, the Michaelis–Menten enzyme requires an approximately 27-fold increase in substrate concentration to increase V_0 from $0.1\ V_{max}$ to $0.8\ V_{max}$. In contrast, the allosteric enzyme requires only about a fourfold increase in substrate concentration to attain the

same increase in velocity. Simply put, the activity of allosteric enzymes is more sensitive to changes in substrate concentration near K_M than are Michaelis–Menten enzymes with the same V_{max}. This sensitivity is called a *threshold effect*: below a certain substrate concentration, there is little enzyme activity. However, after the threshold has been reached, enzyme activity increases rapidly. In other words, much like an "on/off" switch, cooperativity ensures that most of the enzyme is either on (R state) or off (T state). The vast majority of allosteric enzymes display sigmoidal kinetics.

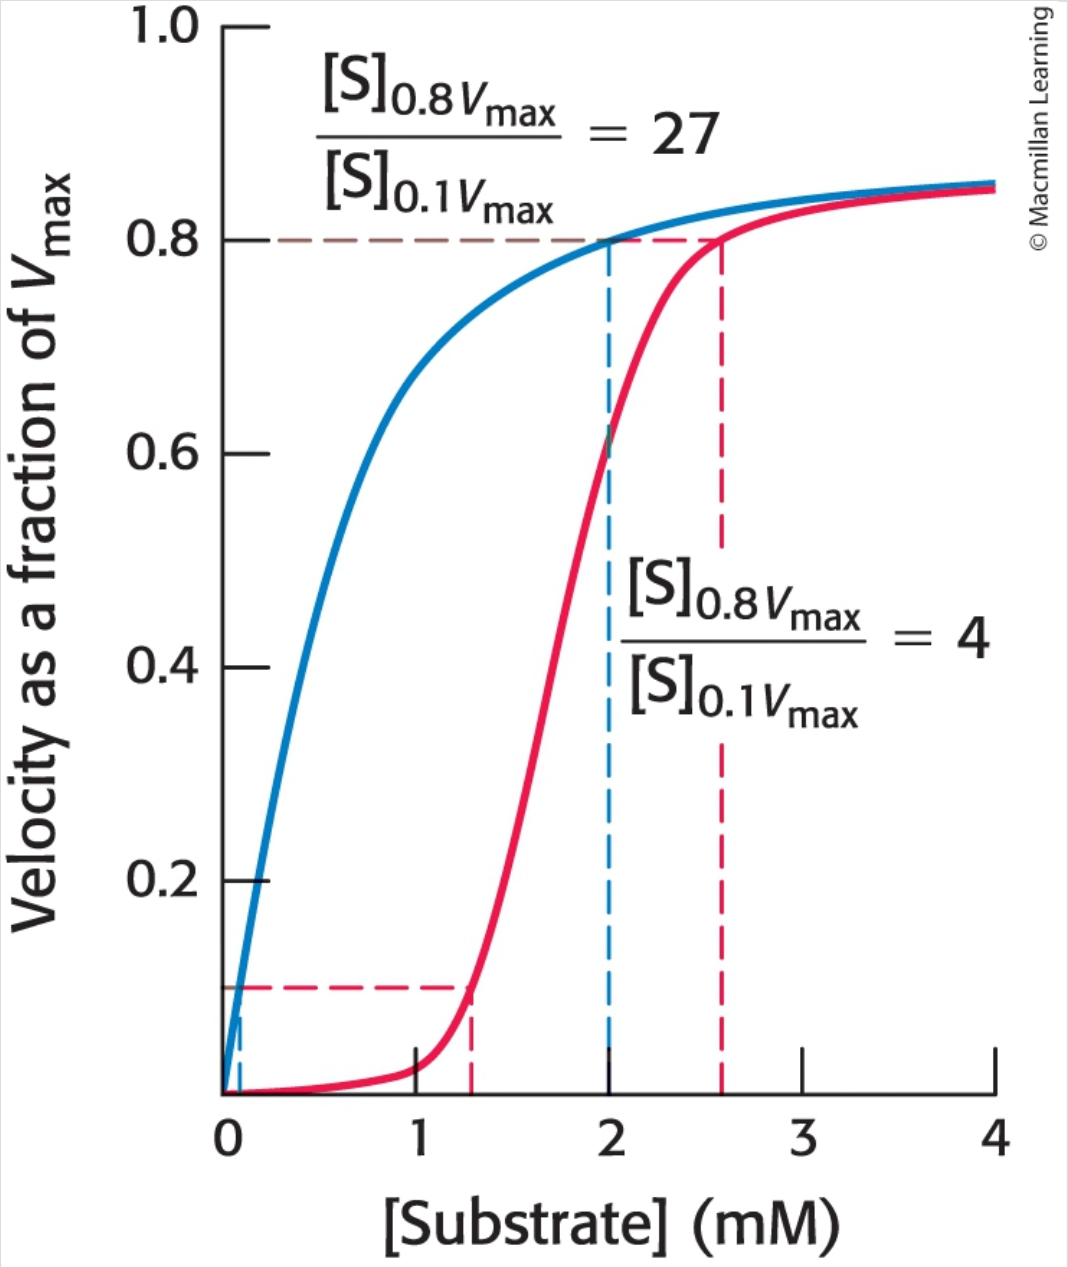

FIGURE 7.10 Allosteric enzymes display threshold effects. As the T-to-R transition occurs, the velocity increases over a narrower range of substrate concentration for an allosteric enzyme (red curve) than for a Michaelis–Menten enzyme (blue curve).

Self-Check Question

What would be the effect of a mutation in an allosteric enzyme that resulted in an allosteric coefficient of 0?

Allosteric regulators modulate the T-to-R equilibrium

We now turn our attention to the effects of pyrimidine nucleotides on ATCase activity. As noted earlier, CTP inhibits the action of ATCase. X-ray studies of ATCase in the presence of CTP reveal (1) that the enzyme is in the T state when bound to CTP and (2) that a binding site for this nucleotide exists in each regulatory chain in a domain that does not interact with the catalytic subunit (**Figure 7.11**). Each active site is more than 50 Å from the nearest CTP-binding site. The question naturally arises: how can CTP inhibit the catalytic activity of the enzyme when it does not interact with the catalytic chain?

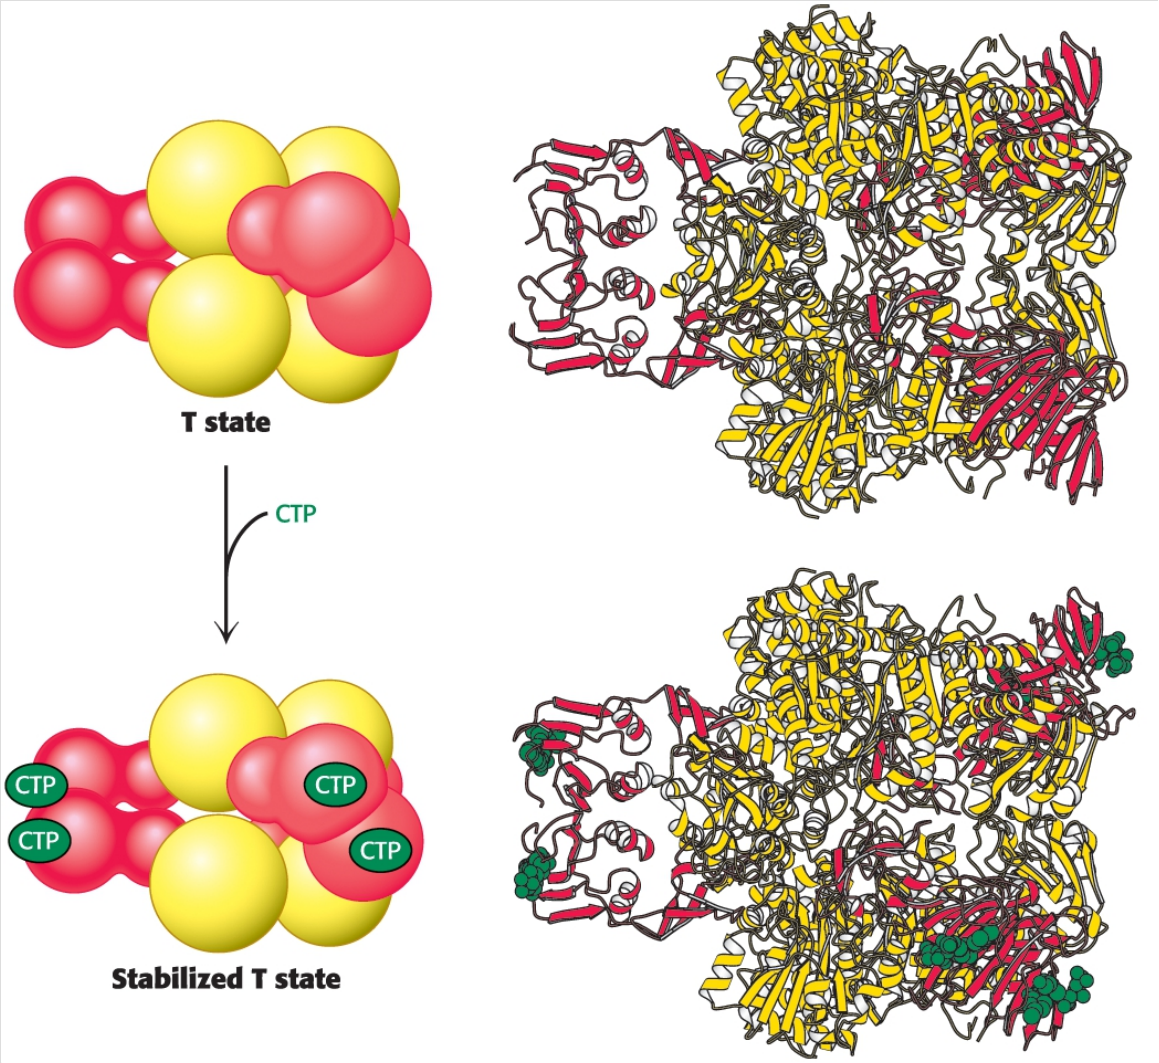

FIGURE 7.11 CTP stabilizes the T state. The binding of CTP (green) to the regulatory subunit of ATCase stabilizes the T state.

[Drawn from 6AT1.pdb and 5AT1.pdb.]

The quaternary structural changes observed on substrate-analog binding suggest a mechanism for inhibition by CTP (Figure 7.12). The binding of the inhibitor CTP to the T state shifts the T-to-R equilibrium in favor of the T state, decreasing net enzyme activity. CTP increases the allosteric coefficient from 200 in its absence to 1250 when all of the regulatory sites are occupied by CTP. Because the binding of CTP makes

it more difficult for substrate binding to convert the enzyme into the R state, CTP increases the initial phase of the sigmoidal curve (Figure 7.13). More substrate is required to attain a given reaction rate. UTP, the immediate precursor to CTP, also regulates ATCase. While unable to inhibit the enzyme alone, UTP synergistically inhibits ATCase in the presence of CTP.

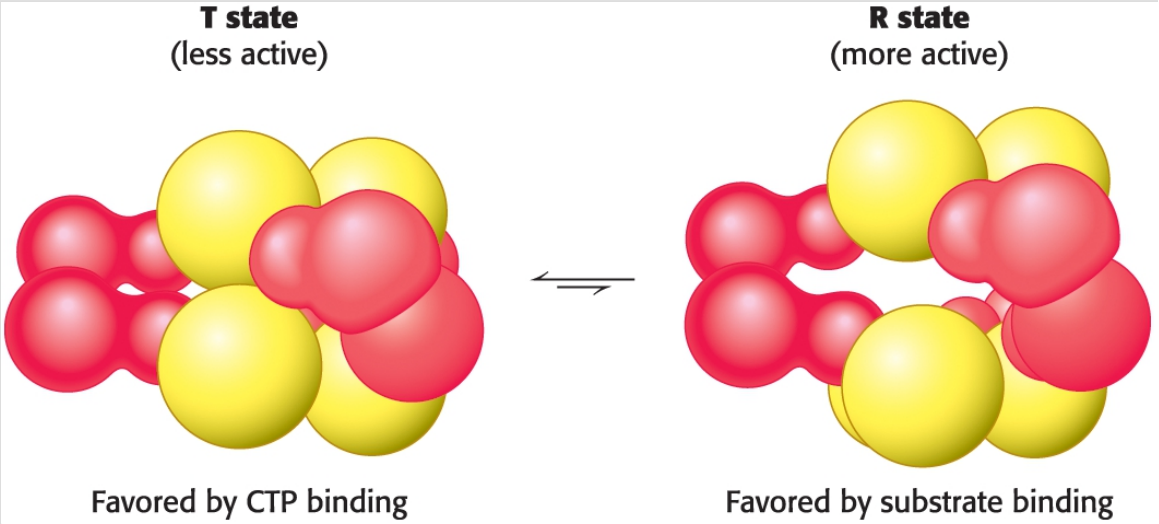

FIGURE 7.12 The R state and the T state are in equilibrium. Even in the absence of any substra or regulators, ATCase exists in equilibrium between the R and the T states. Under these conditions, the T state is favored by a factor of approximately 200.

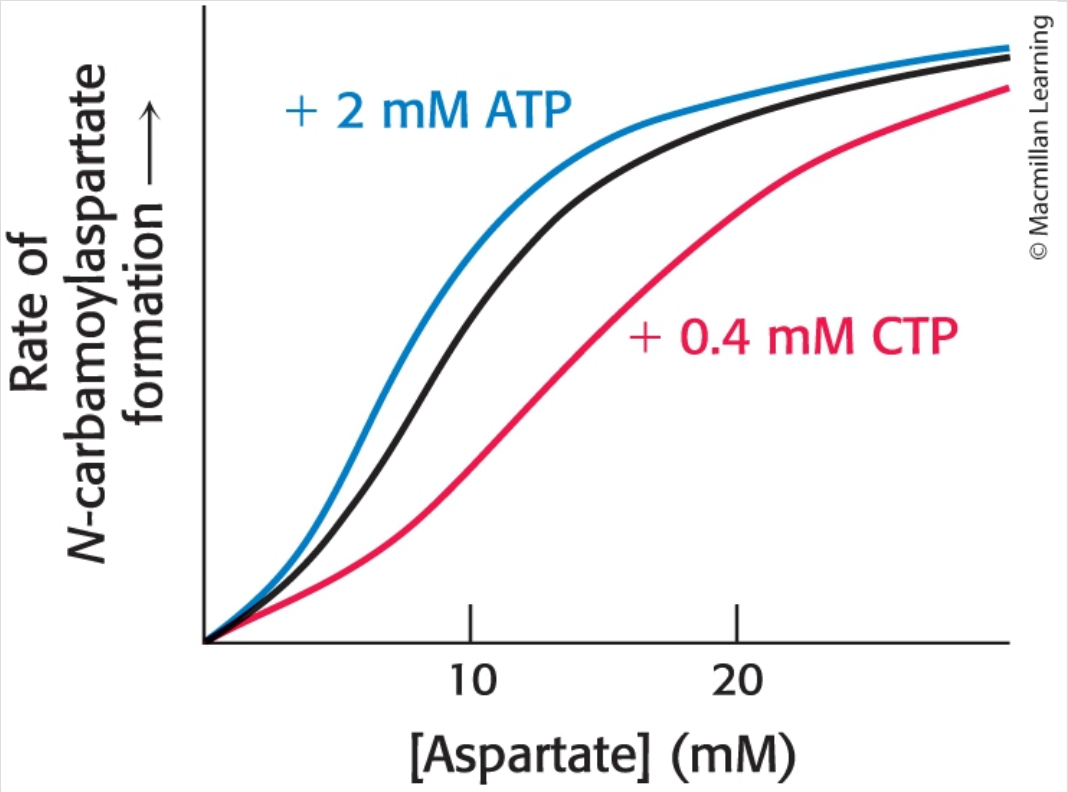

FIGURE 7.13 CTP and ATP impact ATCase kinetics differently. CTP stabilizes the T state of ATCase, making it more difficult for substrate binding to convert the enzyme into the R state. As a result, the curve is shifted to the right, as shown in red. ATP is an allosteric activator of ATCase because it stabilizes the R state, making it easier for substrate to bind. As a result, the curve is shifted to the left, as shown in blue.

Interestingly, ATP, too, is an allosteric effector of ATCase, binding to the same site as CTP. However, ATP binding stabilizes the R state, lowering the allosteric coefficient from 200 to 70 and thus *increasing* the reaction rate at a given aspartate concentration (Figure 7.13). Hence, ATP is an allosteric activator of ATCase, while CTP is an allosteric inhibitor. In the presence of sufficient ATP, the kinetic profile shows a less-pronounced sigmoidal behavior. Because ATP and CTP bind at the same site, high levels of ATP prevent CTP from inhibiting the enzyme. The effects of nonsubstrate molecules on allosteric enzymes (such as those of CTP and ATP on ATCase) are referred to as **heterotropic effects** (from the Greek

héteros, "different"), since they bind at sites distinct from the sites that they affect. In the case of ATCase, CTP and ATP binding at their corresponding site acts on the enzyme active site. In summary, substrates generate the sigmoidal curve (homotropic effects), whereas regulators shift the K_M (heterotropic effects). Note, however, that both types of effects impact ATCase activity by altering the T/R ratio.

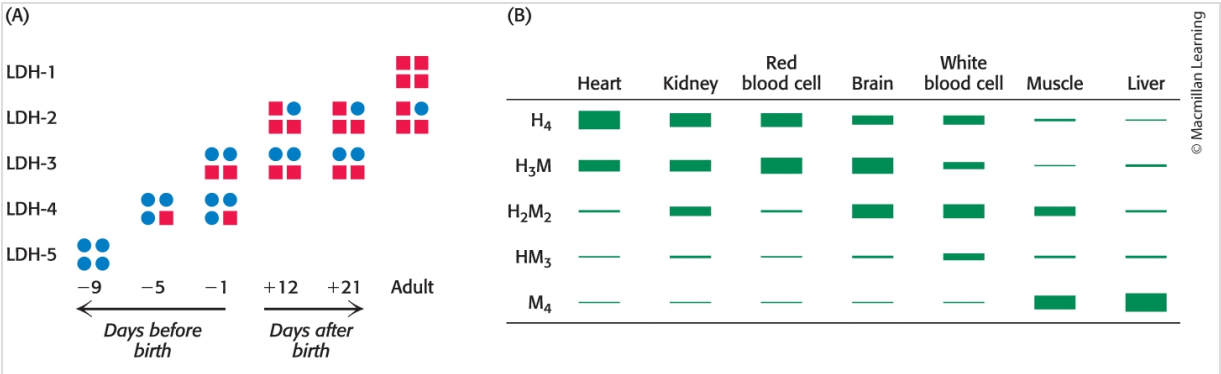
The increase in ATCase activity in response to increased ATP concentration has two potential physiological ramifications. First, high ATP concentration signals a high concentration of purine nucleotides in the cell; the increase in ATCase activity will tend to balance the purine and pyrimidine pools. As we shall see in Chapter 8, this balance is important for the structure and synthesis of DNA. Second, a high concentration of ATP indicates that energy is available for mRNA synthesis and DNA replication and leads to the synthesis of pyrimidines needed for these processes.

7.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages

Enzymes that differ in amino acid sequence yet catalyze the same reaction are called **isozymes**, or **isoenzymes**. Typically, these enzymes display different kinetic parameters, such as K_M, or respond to different regulatory molecules. They are encoded by different genes, which usually arise through gene duplication and divergence. Isozymes can often be distinguished from one another by physical properties such as electrophoretic mobility. *Isoform* is a more generic term used when the protein in question is not an enzyme.

The existence of isozymes permits the fine-tuning of metabolism to meet the needs of a given tissue or developmental stage. Consider the example of lactate dehydrogenase (LDH), an enzyme that catalyzes a step in anaerobic glucose metabolism and glucose synthesis. Human beings have two isozymic polypeptide chains for this enzyme: the H protein is highly expressed in heart muscle, and the M protein is highly expressed in skeletal muscle. The amino acid sequences are 75% identical. Each functional enzyme is tetrameric, and many different combinations of the two isozymic polypeptide chains are possible. The H_4 isozyme, found in the heart, has a higher affinity for substrates than does the M_4 isozyme. In addition, high levels of pyruvate allosterically inhibit the H_4 but not the M_4 isozyme. The other combinations, such as H_3M, have intermediate properties. We will consider these isozymes in their biological context in Chapter 16.

The M_4 isozyme functions optimally in the anaerobic environment of hardworking skeletal muscle, whereas the H_4 isozyme does so in the aerobic environment of heart muscle. Indeed, the proportions of these isozymes change throughout the development of the rat heart as the tissue switches from an anaerobic environment to an aerobic one (Figure 7.14A). The distribution of tissue-specific forms of lactate dehydrogenase in adult rat tissues is shown in Figure 7.14B. Essentially all of the enzymes that we will encounter in later chapters, including allosteric enzymes, exist in isozymic forms.



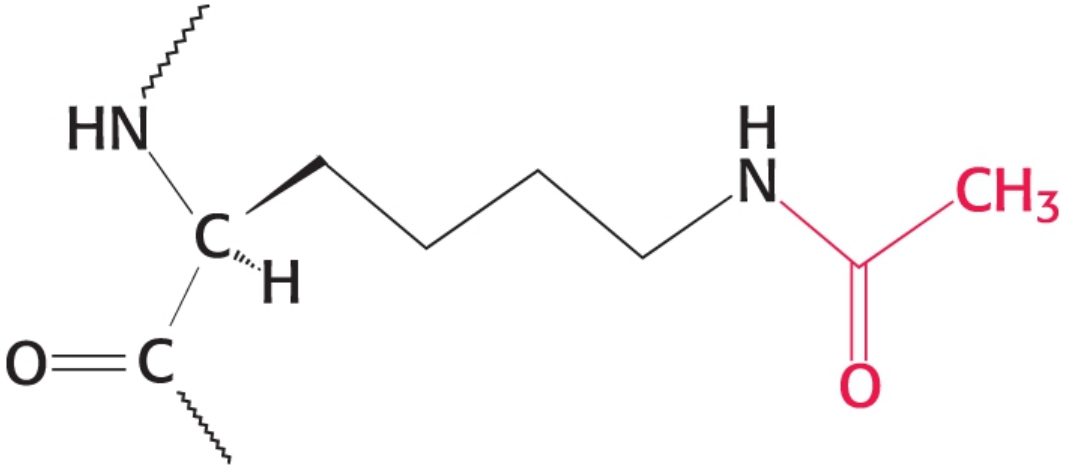


FIGURE 7.14 The five isozymes of lactate dehydrogenase differ in their timing of expression during development and their tissue specificity. (A) The rat heart lactate dehydrogenase (LDH) isozyme profile changes in the course of development. The H isozyme is represented by squares and the M isozyme by circles. (B) LDH isozyme content varies by tissue. The thickness of the green bars represents the relative amounts of the isozymes.

7.3 Covalent Modification Is a Means of Regulating Enzyme Activity

For many enzymes, the covalent attachment of a modifying functional group can markedly alter its catalytic activity. Most covalent modifications are reversible. Phosphorylation and dephosphorylation are common means of reversible covalent modification, which we discuss in detail below.

The attachment of acetyl groups to lysine residues by acetyltransferases and their removal by deacetylases are another example of reversible covalent modifications. Histones — proteins that are packaged with DNA into chromosomes — are extensively acetylated and deacetylated in vivo on lysine residues (Section 31.5). More heavily acetylated histones are associated with genes that are being actively transcribed. Although protein acetylation was originally discovered as a modification of histones, we now know that it is a major means of regulation, with more than 2000 different proteins in mammalian cells regulated by acetylation. Protein acetylation appears to be especially important in the regulation of metabolism. The acetyltransferase and deacetylase enzymes are themselves regulated by phosphorylation, showing that the covalent modification of a protein can be controlled by the covalent modification of the modifying enzymes.

Acetylated lysine

In some cases, the covalent modification is not reversible. The irreversible attachment of a lipid group causes some proteins in signal-transduction pathways, such as Ras (a GTPase), to become affixed to the cytoplasmic face of the plasma membrane. Fixed in this location, the proteins are better able to receive and transmit information that is being passed along their signaling pathways (Section 14.4). Mutations in Ras are seen in a wide array of cancers.

Virtually all metabolic processes are regulated in part by covalent modification. Indeed, the allosteric properties of many enzymes are altered by covalent modification. **Table 7.1** lists some common covalent modifications.

TABLE 7.1 Common covalent modifications of protein activity

Modification	Donor molecule	Example of modified protein	Protein function

Phosphorylation	ATP	Glycogen phosphorylase	Glucose homeostasis; energy transduction
Acetylation	Acetyl CoA	Histones	DNA packing; transcription
Myristoylation	Myristoyl CoA	Src	Signal transduction
ADP ribosylation	NAD^+	RNA polymerase	Transcription
Farnesylation	Farnesyl pyrophosphate	Ras	Signal transduction
γ-Carboxylation	HCO_3^-	Thrombin	Blood clotting
Sulfation	$3'$-Phosphoadenosine-$5'$-phosphosulfate	Fibrinogen	Blood clot formation
Ubiquitination	Ubiquitin	Cyclin	Control of cell cycle

Kinases and phosphatases control the extent of protein phosphorylation

Phosphorylation is a regulatory mechanism in virtually every metabolic process in eukaryotic cells. Indeed, as much as 30% of eukaryotic proteins are phosphorylated. The enzymes catalyzing the phosphorylation of protein substrates are called **protein kinases**. These enzymes constitute one of the largest protein families known: there are

more than 500 homologous protein kinases in human beings. This multiplicity of enzymes allows regulation to be fine-tuned according to a specific tissue, time, or substrate.

ATP is the most common donor of phosphoryl groups. The terminal (γ) phosphoryl group of ATP is transferred to a specific amino acid of the acceptor protein or enzyme. In eukaryotes, the acceptor residue is commonly one of the three containing a hydroxyl group in its side chain. Transfers to serine and threonine residues are handled by one class of protein kinases and transfers to tyrosine residues by another. Tyrosine kinases, which are unique to multicellular organisms, play pivotal roles in growth regulation, and mutations in these enzymes are commonly observed in cancer cells (Section 14.3).

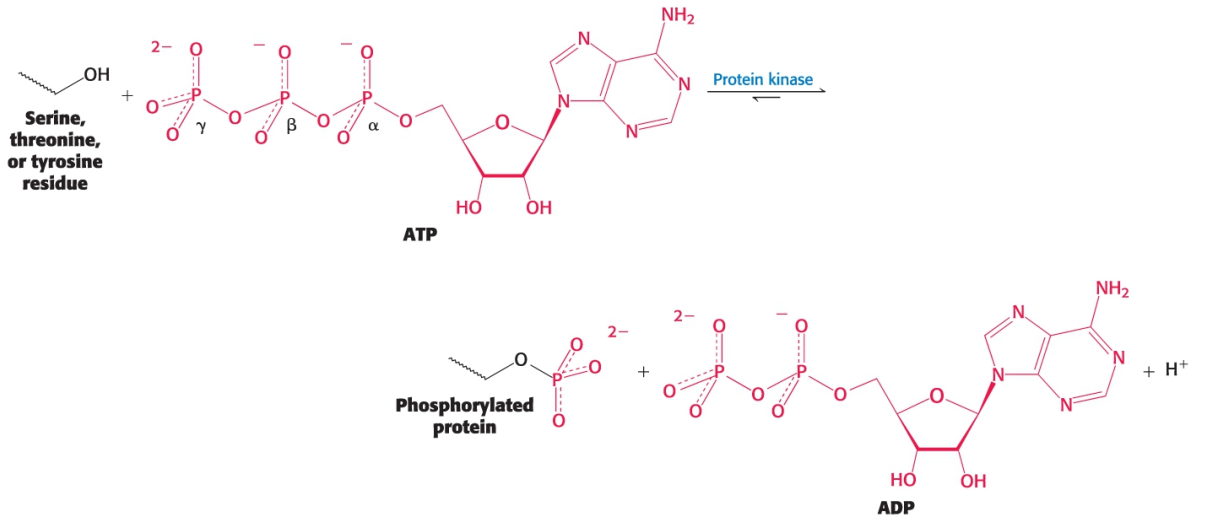

Table 7.2 lists a few of the known serine and threonine protein kinases. Proteins that undergo protein-phosphorylation reactions are located inside cells, where the phosphoryl-group donor ATP is abundant. Proteins that are entirely extracellular are not regulated by reversible phosphorylation.

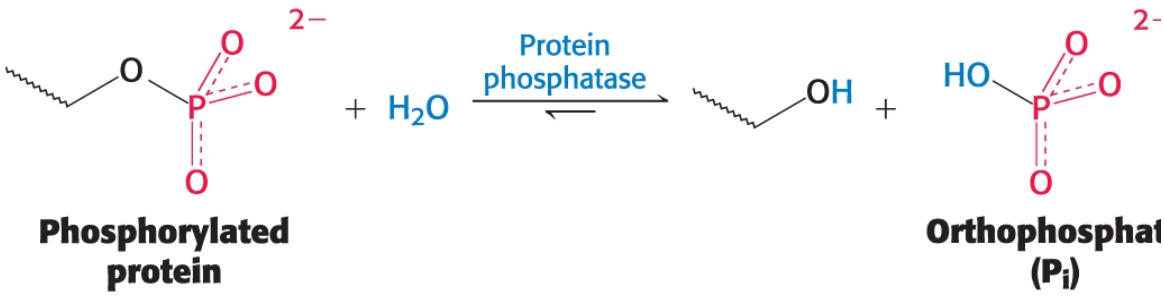

TABLE 7.2 Examples of serine and threonine kinases and their activating signals

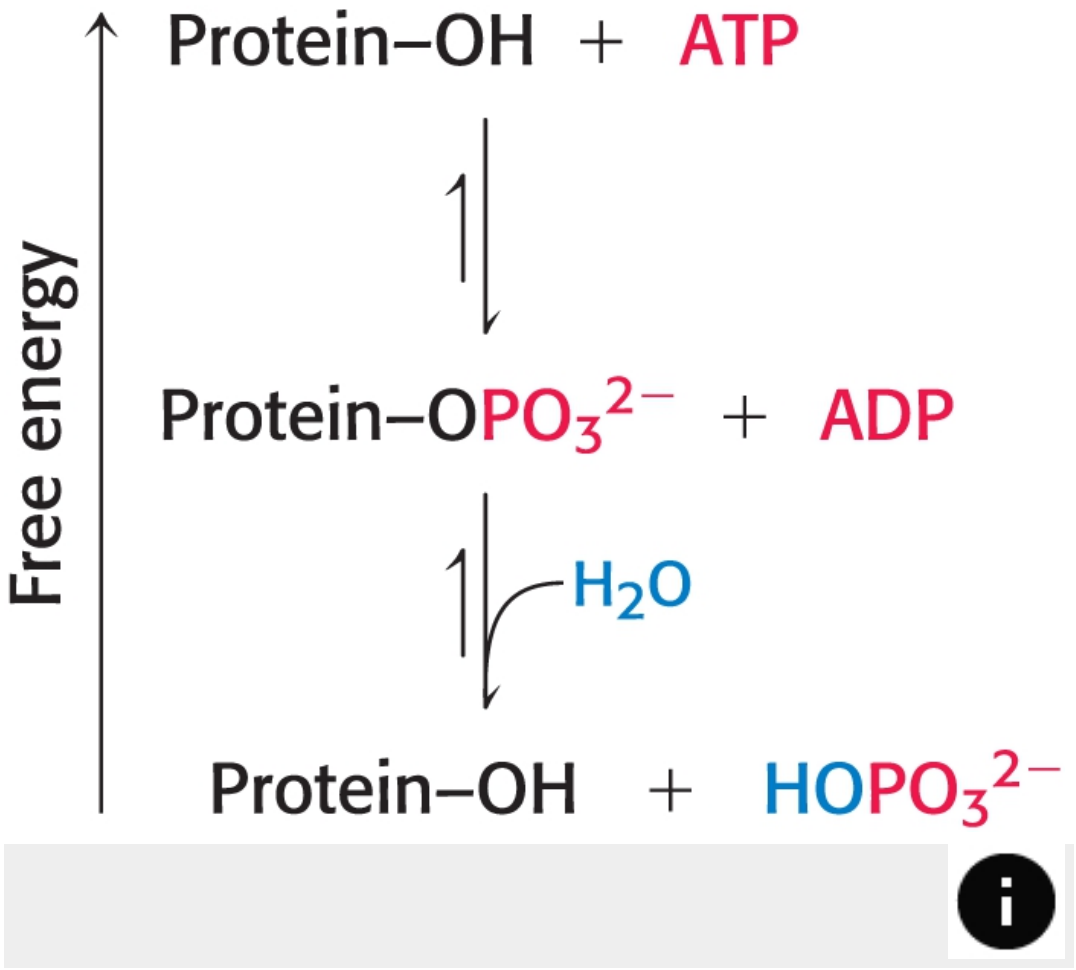
Signal	Enzyme
Cyclic nucleotides	Cyclic AMP-dependent protein kinase Cyclic GMP-dependent protein kinase
Ca^{2+} and calmodulin	Calmodulin-dependent protein kinase Phosphorylase kinase Glycogen synthase kinase
AMP	AMP-activated kinase
Diacylglycerol	Protein kinase C
Metabolic intermediates and other "local" effectors	Many target-specific enzymes, such as pyruvate dehydrogenase kinase and branched-chain ketoacid dehydrogenase kinase

Source: Information from D. Fell, *Understanding the Control of Metabolism* (Portland Press, 1997), Table 7.2.



Comparisons of amino acid sequences of many phosphorylation sites show that an individual kinase may recognize many related sequences. For example, the **consensus sequence** recognized by protein kinase A is Arg-Arg-X-*Ser*-Z or Arg-Arg-X-*Thr*-Z, in which X is a small residue, Z is a large hydrophobic one, and *Ser* or *Thr* is the site of phosphorylation. However, this sequence is not absolutely required. Lysine, for example, can substitute for one of the arginine residues but with some loss of affinity. Thus, the primary determinant of specificity is the amino acid sequence surrounding the serine or threonine phosphorylation site. However, distant residues can contribute to specificity. For instance, a change in protein conformation can open or close access to a possible phosphorylation site.

Protein phosphatases reverse the effects of kinases by catalyzing the removal of phosphoryl groups attached to proteins. The enzyme hydrolyzes the bond attaching the phosphoryl group.

The unmodified hydroxyl-containing side chain is regenerated and orthophosphate (P_i) is produced. These enzymes, of which there are about 200 members in human beings, play a vital role in cells because they turn off the signaling pathways that are activated by kinases. One class of highly conserved phosphatases called PP2A suppresses the cancer-promoting activity of certain kinases.

Importantly, the phosphorylation and dephosphorylation reactions are not the reverse of one another; each is essentially irreversible under physiological conditions. Furthermore, both reactions take place at negligible rates in the absence of enzymes. Thus, phosphorylation of a protein substrate will take place only through the action of a specific protein kinase and at the expense of ATP cleavage, and dephosphorylation will take place only through the action of a phosphatase. The result is that target proteins cycle between unphosphorylated and phosphorylated forms. The rate of cycling between the phosphorylated and the unphosphorylated states depends on the relative activities of the specific kinases and phosphatases.

Phosphorylation is a highly effective means of regulating the activities of target proteins

Phosphorylation is a common covalent modification of proteins in all forms of life, which leads to the question: What makes protein phosphorylation so valuable in regulating protein function that its use is ubiquitous? Phosphorylation is a highly effective means of controlling the activity of proteins for several reasons:

- *The free energy of phosphorylation is large.* Of the $-50\ \text{kJ mol}^{-1}\ (-12\ \text{kcal mol}^{-1})$ provided by ATP, about half is consumed in making phosphorylation irreversible; the other half is

conserved in the phosphorylated protein. A free-energy change of $5.69\ \text{kJ mol}^{-1}$ $(1.36\ \text{kcal mol}^{-1})$ corresponds to a factor of 10 in an equilibrium constant. Hence, phosphorylation can change the conformational equilibrium between different functional states by a large factor, of the order of 10^4. In essence, the energy expenditure allows for a stark shift from one conformation to another.

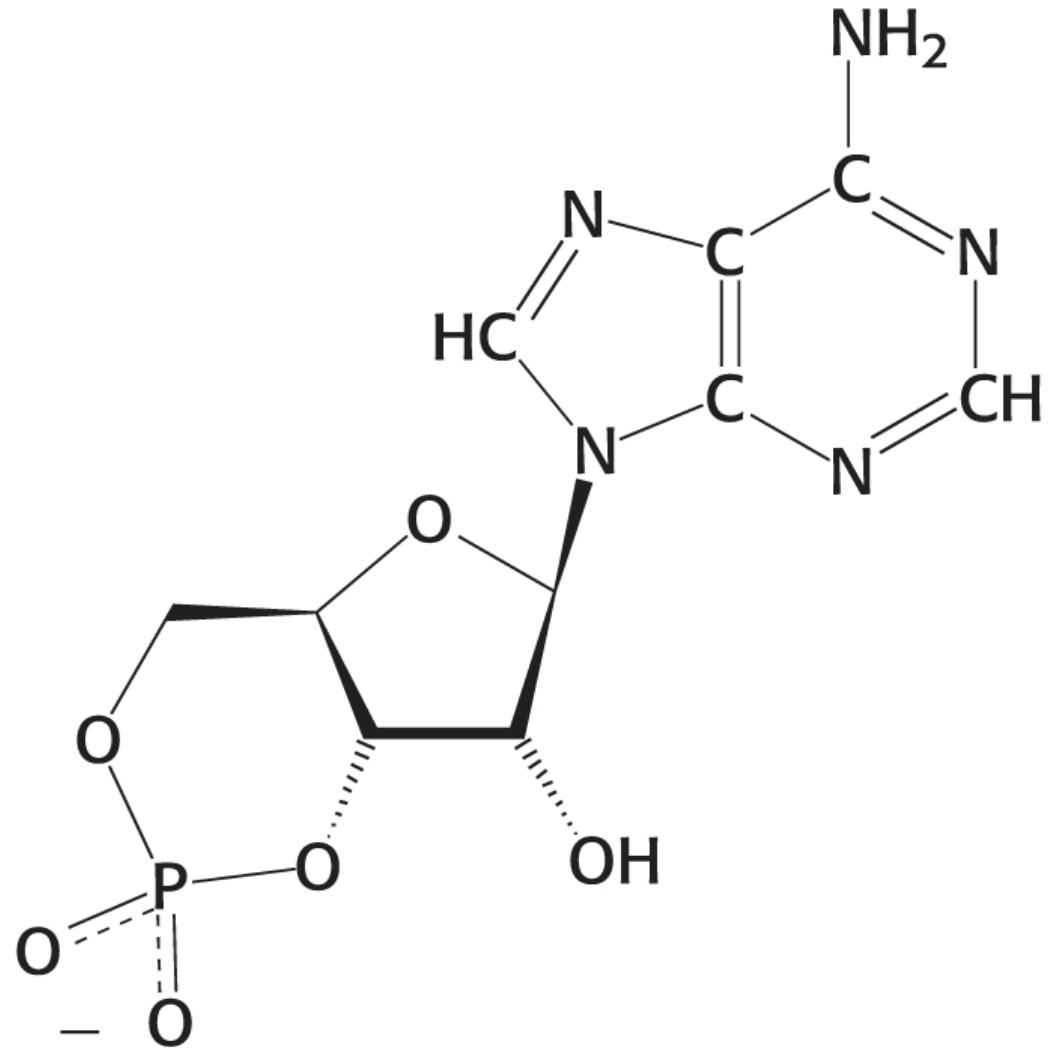
- *A phosphoryl group adds two negative charges to a protein.* These new charges may disrupt electrostatic interactions present in the unmodified protein and allow new electrostatic interactions to be formed. Such structural changes can markedly alter substrate binding and catalytic activity.

- *A phosphoryl group can form three or more hydrogen bonds.* The tetrahedral geometry of a phosphoryl group makes these bonds highly directional, allowing for specific interactions with hydrogen-bond donors.

- *Phosphorylation and dephosphorylation can take place in less than a second or over a span of hours*. The kinetics can be adjusted to meet the timing needs of a particular physiological process.

- *Phosphorylation often evokes highly amplified effects.* A single activated kinase can phosphorylate hundreds of target proteins in a short interval. If the target protein is an enzyme, it can in turn transform a large number of substrate molecules.

- *ATP is the cellular energy currency*. The use of this compound as a phosphoryl-group donor links the energy status of the cell to the regulation of metabolism (Section 15.2).



Self-Check Question

What is the energy cost associated with a single cycle of phosphorylation by a protein kinase and dephosphorylation by a protein phosphatase?

Cyclic AMP activates protein kinase A by altering the quaternary structure

Let us examine a specific protein kinase that helps animals, including humans, cope with stressful situations. As we shall see in Section 14.2, the "fight-or-flight" response — including an increase in heart rate, dilation of the airway muscles, and constriction of the blood vessels in muscle — is common to many animals presented with a dangerous or exciting situation. This response is the result of the activity of the hormone epinephrine (also called adrenaline), which triggers the formation of cyclic AMP (cAMP), an intracellular messenger formed by the cyclization of ATP. Cyclic AMP subsequently activates a key enzyme, protein kinase A (PKA). This kinase alters the activities of target proteins by phosphorylating specific serine or threonine residues. The striking finding is that most effects of cAMP in eukaryotic cells are achieved through the activation of PKA by cAMP.

Cyclic adenosine monophosphate (cAMP)

Similar to ATCase, PKA provides an example of allosteric regulation of enzyme activity. In fact, the quaternary structure of PKA is reminiscent of that of ATCase in that it is comprised of distinct regulatory and catalytic subunits. In the absence of cAMP, the 49-kDa regulatory (R) and 38-kDa catalytic (C) subunits of PKA in muscle form an R_2C_2

complex that is enzymatically inactive (Figure 7.15). The binding of two molecules of cAMP to each of the regulatory subunits leads to the dissociation of R_2C_2 into an R_2 subunit and two C subunits. These free catalytic subunits are enzymatically active. Thus, the binding of cAMP to the regulatory subunit relieves its inhibition of the catalytic subunit. PKA, like most other kinases, exists in isozymic forms for fine-tuning regulation to meet the needs of a specific cell or developmental stage. In mammals, four isoforms of the R subunit and three of the C subunit are encoded in the genome.

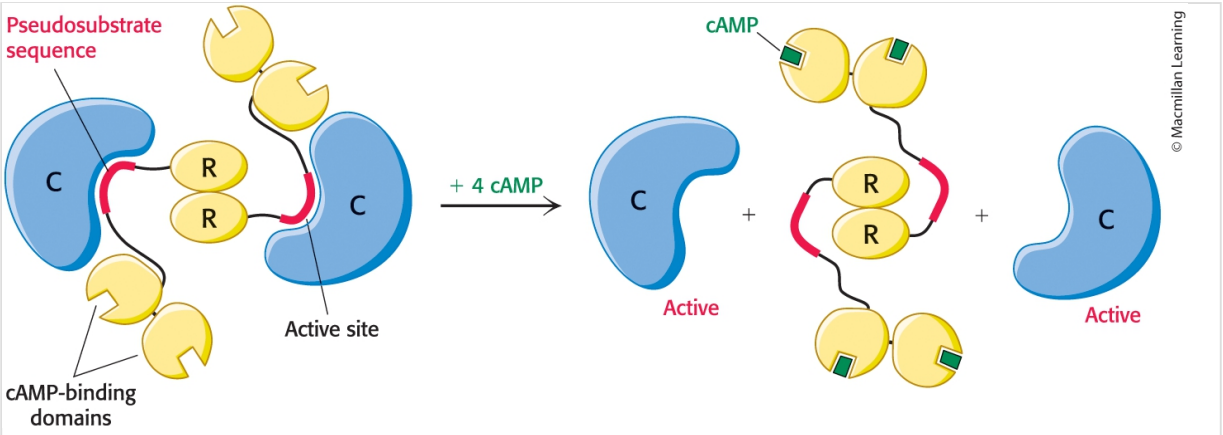


FIGURE 7.15 The binding of cAMP to the regulatory subunits of PKA activates the kinase. The binding of four molecules of cAMP activates protein kinase A by dissociating the inhibited holoenzyme (R_2C_2) into a regulatory subunit (R_2) and two catalytically active subunits (C). Each R chain includes cAMP-binding domains and a pseudosubstrate sequence.

INTERACT with this model in Achieve

How does the binding of cAMP activate the kinase? All four isoforms of the R chain contain an inhibitor site sequence which binds in the active site pocket of the C chains. Two of these R chains contain the sequence Arg-Arg-Gly-*Ala*-Ile, which matches the consensus sequence for phosphorylation except for the presence of alanine in place of serine. In the R_2C_2 complex, this **pseudosubstrate sequence** of R occupies the

catalytic site of C, thereby preventing the entry of protein substrates (Figure 7.15). The remaining two R chains contain the sequence Arg-Arg-Gly-Ser-Ile. In the tetrameric complex, these sequences are packed into the catalytic site of the C chain such that ATP cannot bind, keeping these sequences unphosphorylated. In either case, the binding of cAMP to the R chains allosterically moves the inhibitor site sequences out of the catalytic domains.

Kinetic studies of the activated form of PKA indicate that cAMP enhances the dissociation rate of the C chain from the R chain by almost 700-fold. The released C chains are then free to bind and phosphorylate substrate proteins. However, even after this rate enhancement, the binding affinity between the R and C chains is still significant, and R chains are present in the cell in large molar excess. The net result is that while C chains are free to exert their cellular effects, they are probably re-captured quite rapidly by the R subunits. Hence, the activation mechanism of PKA has evolved to enable control over the active form of kinase.

Mutations in protein kinase A can cause Cushing's syndrome

As we have just seen, the allosteric regulation of kinases such as PKA enables precise timing for the activation and the inhibition of their catalytic activities. The significance of this control is emphasized by disease states in which these mechanisms fail. For example, Cushing's syndrome, a collection of diseases resulting from excess cortisol secretion by the adrenal cortex, is a metabolic disorder characterized by a variety of symptoms such as muscle weakness, thinning skin that is easily bruised, and osteoporosis. Cortisol, a steroid hormone (Section 27.4), has a number of physiological effects including stimulation of

glucose synthesis, suppression of the immune response, and inhibition of bone growth.

The most common cause of Cushing's syndrome, called Cushing's disease, is a tumor of the pituitary gland that overstimulates cortisol secretion by the adrenal cortex. Mutations within the catalytic subunit of PKA have been identified in a number of patients with these tumors. These mutations disrupt the interaction between the R and C subunits. Thus, the enzyme is active even in the absence of cAMP, with the ultimate result being unregulated secretion of cortisol. In Section 14.5, we will discuss other instances where dysregulation of enzymes can lead to disease.

The phosphorylation states of the proteome can be measured

In Section 4.3, we introduced the concept of the proteome, the array of proteins expressed within a cell at a given time under specific conditions. The techniques used to study the proteome have been expanded to include the analysis of protein phosphorylation under specific conditions. The **phosphoproteome** is the name given to all proteins that are modified by phosphorylation. Through study of the phosphoproteome, termed *phosphoproteomics*, one can elucidate the pathways switched on or off under a specific set of conditions.

For example, as we will see more clearly in later chapters, exercise is fundamental to sustaining good health, in part by regulating energy metabolism and maintaining whole-body insulin sensitivity. Given the prominence of phosphorylation in biological regulation, it should come as no surprise that exercise modifies the phosphoproteome. Recent research has shown that exercise results in the phosphorylation of more than 1000 potential phosphorylation sites on almost 600 different proteins. Protein kinase A and AMP-activated kinase (AMPK, Section

22.7) as well as other kinases catalyze these modifications. These modifications alter a number of biological functions, most notably an increase in the ability to process fuels aerobically (Chapters 17 and 18). Determining the functions of the modified proteins will surely keep exercise biochemists engaged for many years.

7.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage

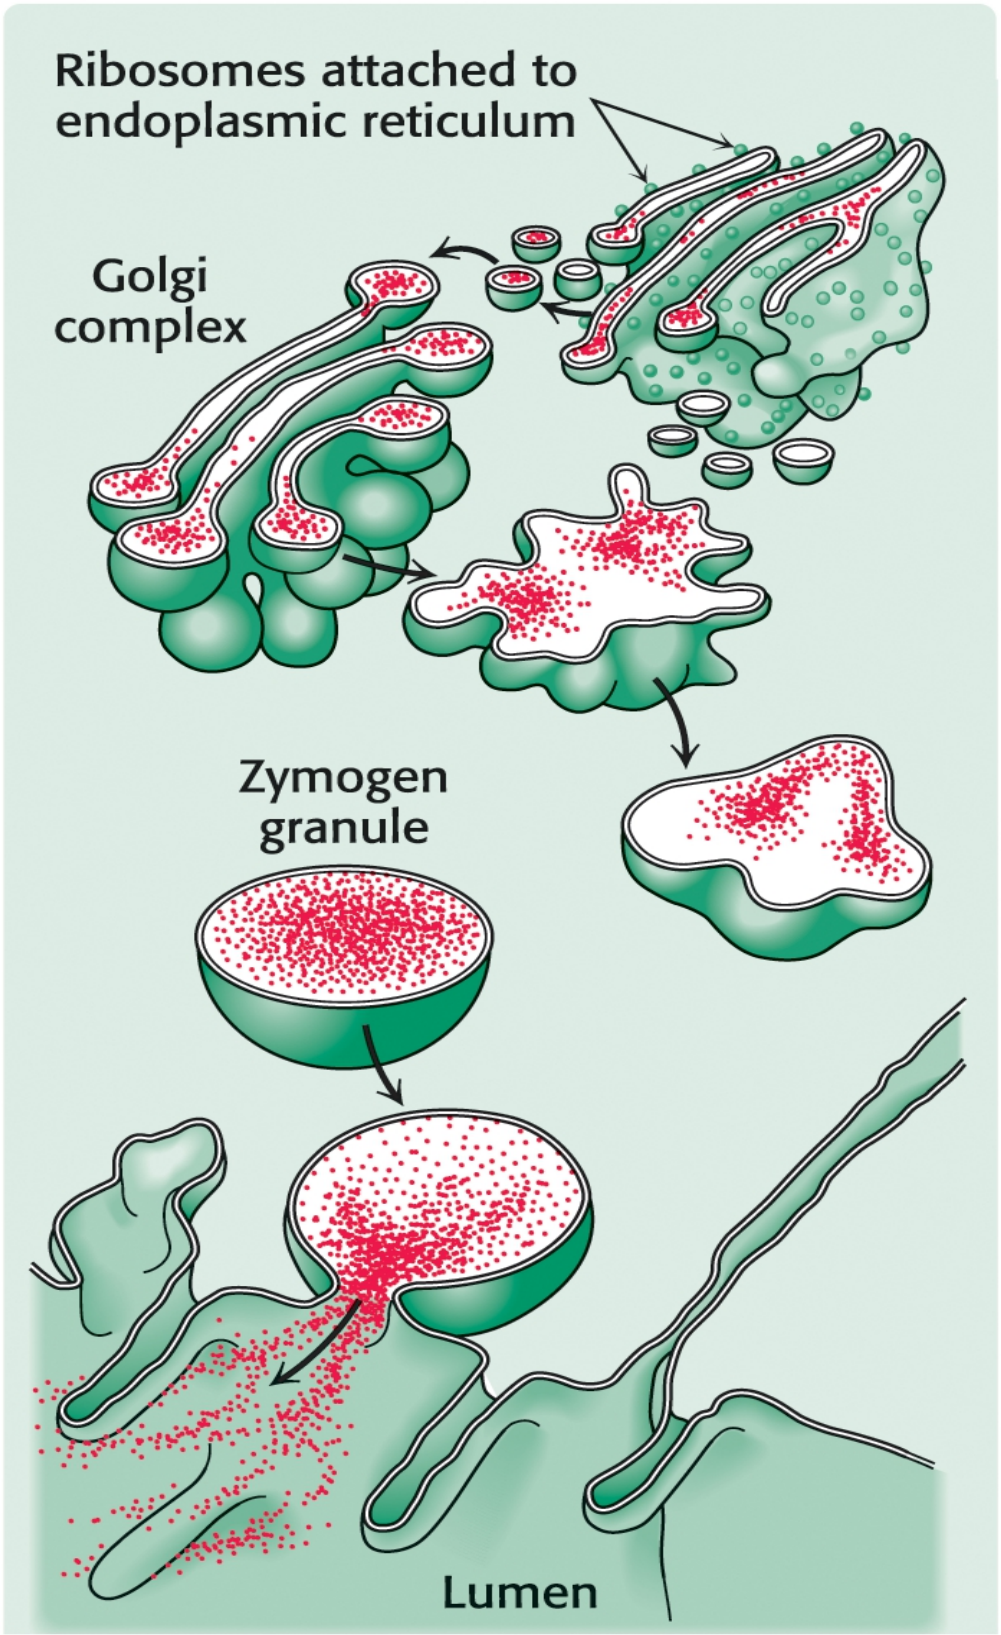
While many enzymes acquire full enzymatic activity as they spontaneously fold into their characteristic three-dimensional forms, the folded forms of other enzymes are inactive until one or a few specific peptide bonds are cleaved. The inactive precursor is called a **zymogen** (or **proenzyme**). Since an energy source such as ATP is not needed for specific proteolytic cleavage, even extracellular proteins can be activated by this means. This contrasts with reversible enzyme regulation by phosphorylation, which requires ATP. Another noteworthy difference is that proteolytic activation, unlike allosteric control and reversible covalent modification, is irreversible, taking place just once in the life of an enzyme molecule.

Specific proteolysis is a common means of activating enzymes and other proteins in biological systems. For example:

- The digestive enzymes that hydrolyze foodstuffs are synthesized as zymogens in the stomach and pancreas (Table 7.3).
- Blood clotting is mediated by a cascade of proteolytic activations that ensures a rapid and amplified response to trauma.
- Some protein hormones are synthesized as inactive precursors. For example, *insulin* is derived from *proinsulin* by proteolytic removal of a peptide.
- The fibrous protein collagen, the major constituent of skin and bone, is derived from procollagen, a soluble precursor.

TABLE 7.3 Zymogens of the stomach and pancreas

Site of synthesis	Zymogen	Active enzyme
Stomach	Pepsinogen	Pepsin
Pancreas	Chymotrypsinogen	Chymotrypsin
Pancreas	Trypsinogen	Trypsin
Pancreas	Procarboxypeptidase	Carboxypeptidase



Many developmental processes are controlled by the activation of zymogens. For example, in the metamorphosis of a tadpole into a frog, large amounts of collagen are resorbed from the tail in the course of a few days. Likewise, much collagen is broken down in a mammalian uterus after delivery. The conversion of procollagenase into collagenase, the active protease responsible for collagen breakdown, is precisely timed in these remodeling processes.

Programmed cell death, also called *apoptosis,* is mediated by proteolytic enzymes called *caspases,* which are synthesized in precursor form as *procaspases*. When activated by various signals, caspases function to cause cell death in most organisms, ranging from *C. elegans* to human beings. Apoptosis provides a means of sculpting the shapes of body parts in the course of development and is a means of eliminating damaged or infected cells.

Chymotrypsinogen is activated by specific cleavage of a single peptide bond

Let us examine the activation and control of zymogens, using enzymes responsible for digestion. Chymotrypsin is a member of a large family of serine proteases whose mechanism of action was described in detail in Section 6.2. Specifically, it is a digestive enzyme that cleaves peptide

bonds on the carboxyl side of amino acid residues with large, hydrophobic R groups (Table 5.7). Its inactive precursor, chymotrypsinogen, is synthesized in the pancreas, as are several other zymogens and digestive enzymes. Indeed, the pancreas is one of the most active organs in synthesizing and secreting proteins. The enzymes and zymogens are synthesized in the acinar cells of the pancreas and stored inside membrane-bounded granules (**Figure 7.16**). The zymogen granules accumulate at the apex of the acinar cell; when the cell is stimulated by a hormonal signal or a nerve impulse, the contents of the granules are released into a duct leading into the duodenum, the first segment of the small intestine into which the stomach empties.

© Macmillan Learning

FIGURE 7.16 The acinar cells of the pancreas secrete zymogens. Zymogens are synthesized on ribosomes attached to the endoplasmic reticulum. They are subsequently processed in the Golgi apparatus and packaged into zymogen or secretory granules. With the proper signal, the granules fuse with the plasma membrane, discharging their contents into the interior (lumen) of the pancreatic ducts. Cell cytoplasm is depicted as pale green. Membranes and lumen are shown as dark green.

Chymotrypsinogen, a single polypeptide chain consisting of 245 amino acid residues, is virtually devoid of enzymatic activity. It is converted into a fully active enzyme when the peptide bond joining arginine 15 and isoleucine 16 is cleaved by trypsin (Figure 7.17). The resulting active enzyme, called π-chymotrypsin, then acts on other π-chymotrypsin molecules by removing two dipeptides to yield α-chymotrypsin, the stable form of the enzyme. The three resulting chains in α-chymotrypsin remain linked to one another by two interchain disulfide bonds. The striking feature of this activation process is that cleavage of a single specific peptide bond transforms the protein from a catalytically inactive form into one that is fully active.

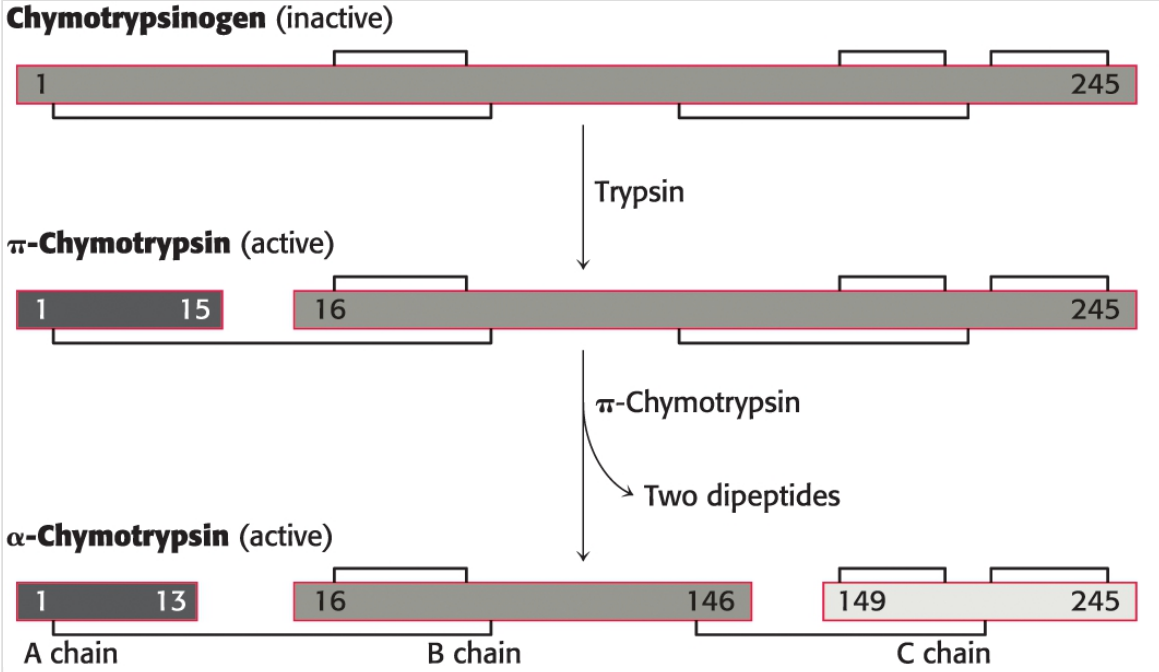


FIGURE 7.17 Proteolysis activates chymotrypsinogen. The three chains of α-chymotrypsin are linked by two interchain disulfide bonds (A to B and B to C). The approximate positions of both inter- and intrachain disulfide bonds are shown.

Proteolytic activation of chymotrypsinogen leads to the formation of a substrate-binding site

How does cleavage of a single peptide bond activate the zymogen? The cleavage of the peptide bond between amino acids 15 and 16 triggers key conformational changes, which were revealed by the elucidation of the three-dimensional structure of chymotrypsinogen.

- The newly formed amino-terminal group of isoleucine 16 turns inward and forms an ionic bond with aspartate 194 in the interior of the chymotrypsin molecule (Figure 7.18).

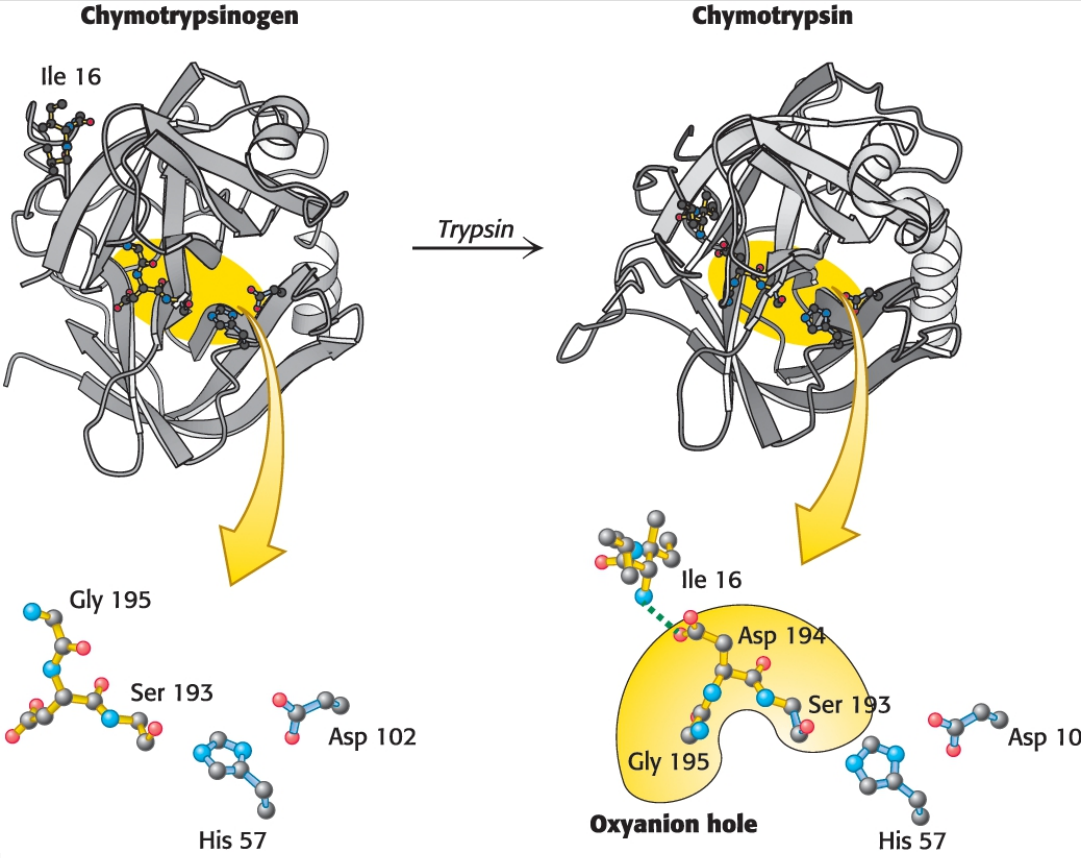

FIGURE 7.18 Cleavage of chymotrypsinogen by trypsin initiates the conformational transition into active chymotrypsin. In chymotrypsinogen, isoleucine 16 is positioned fa away from the active site. Upon cleavage by trypsin, the newly formed α-amino group of isoleucine 16 forms an electrostatic interaction with the carboxylate of aspartate 194 yielding the proper conformation of the oxyanion hole (yellow half-circle) and the formation of the substrate specificity pocket (not shown).

[Drawn from 1CHG.pdb and 5CHA.pdb.]

- This electrostatic interaction triggers a number of conformational changes. Methionine 192 moves from a deeply buried position in the zymogen to the surface of the active enzyme, and residues 187 and 193 move farther apart from each other. These changes result in the formation of the substrate-specificity site for aromatic and bulky nonpolar groups. One side of this site is made up of residues

189 through 192 (Figure 6.10). This cavity for binding part of the substrate is not fully formed in the zymogen.

- The repositioning of aspartate 194 also rearranges the main chain amino group of glycine 195. Recall that the tetrahedral transition state generated by chymotrypsin has an oxyanion (a negatively charged carbonyl oxygen atom) that is stabilized by hydrogen bonds with two NH groups of the main chain of the enzyme (the oxyanion hole, Figure 6.9). The new position of the NH group of glycine 195 enables the proper formation of the oxyanion hole (Figure 7.18).

The conformational changes elsewhere in the molecule are very small. For example, the positions of the residues forming the catalytic triad (Ser 193, His 57, and Asp 102) are essentially the same in both structures (Figure 7.18). Thus, the switching on of enzymatic activity in a protein can be accomplished by discrete, highly localized conformational changes that are triggered by the hydrolysis of a single peptide bond.

The generation of trypsin from trypsinogen leads to the activation of other zymogens

The structural changes accompanying the activation of trypsinogen, the precursor of the proteolytic enzyme trypsin, another serine protease, are different from those in the activation of chymotrypsinogen. Four regions of the polypeptide are very flexible in the zymogen, whereas they have a well-defined conformation in trypsin. The resulting structural changes also complete the formation of the oxyanion hole.

The digestion of proteins and other molecules in the duodenum requires the concurrent action of several enzymes, because each is specific for a limited number of side chains. Thus, the zymogens must be switched on at the same time. Coordinated control is achieved by the action of trypsin as the common activator of all the pancreatic zymogens — trypsinogen, chymotrypsinogen, proelastase,

procarboxypeptidase, and prolipase, the inactive precursor of a lipid-degrading enzyme.

To produce active trypsin, the cells that line the duodenum display a membrane-embedded enzyme, enteropeptidase, which hydrolyzes a unique lysine–isoleucine peptide bond in trypsinogen as the zymogen enters the duodenum from the pancreas. The small amount of trypsin produced in this way activates more trypsinogen and the other zymogens (Figure 7.19). Thus, the formation of trypsin by enteropeptidase is the master activation step.

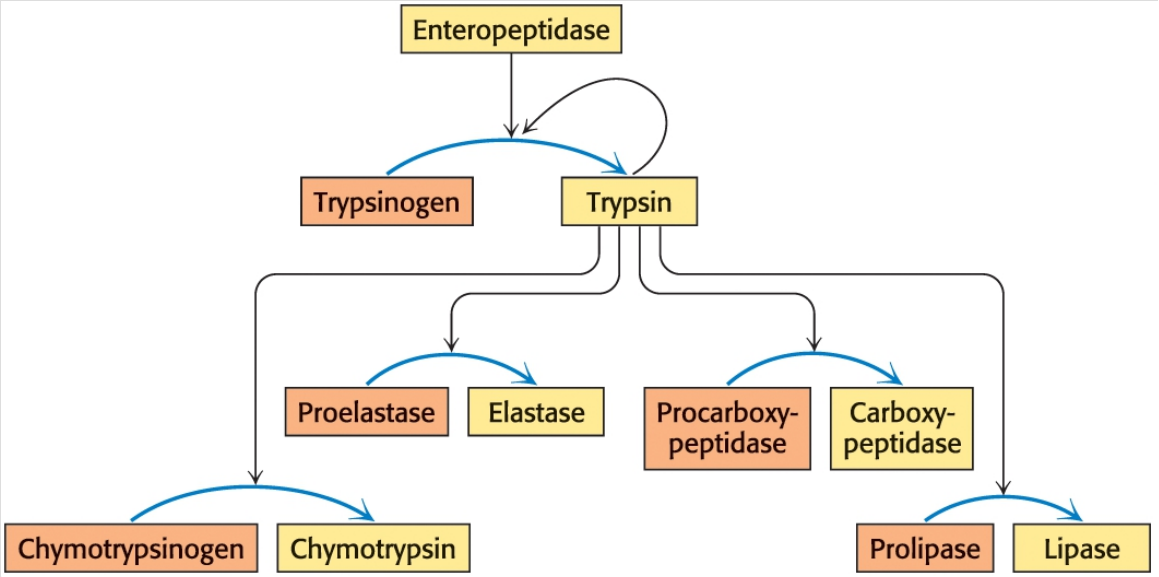

FIGURE 7.19 Enteropeptidase initiates the activation of the pancreatic zymogens by activatir trypsin, which then activates other zymogens. Active enzymes are shown in yellow; zymogens are shown in orange.

Self-Check Question

Predict the physiological effects of a mutation that resulted in a deficiency of enteropeptidase.

Some proteolytic enzymes have specific inhibitors

The conversion of a zymogen into a protease by cleavage of a single peptide bond is a precise means of switching on enzymatic activity. However, this activation step is irreversible, and so a different mechanism is needed to terminate proteolysis. Specific protease inhibitors accomplish this task.

Inhibitors called *serpins*, shorthand for serine protease inhibitors, are an example of one such family of inhibitors. For example, pancreatic trypsin inhibitor, a 6-kDa serpin, inhibits trypsin by binding very tightly to its active site. The dissociation constant of the complex is 0.1 pM, which corresponds to a standard free energy of binding of about $-75\ \text{kJ mol}^{-1}\ (-18\ \text{kcal mol}^{-1})$. In contrast with nearly all known protein assemblies, this complex is not dissociated into its constituent chains by treatment with denaturing agents such as 8 M urea (Section 2.7).

The reason for the exceptional stability of the complex is that pancreatic trypsin inhibitor is a very effective substrate analog. X-ray analyses show that the inhibitor lies in the active site of the enzyme, positioned such that the side chain of lysine 15 of this inhibitor interacts with the aspartate side chain in the specificity pocket of trypsin. In addition, there are many hydrogen bonds between the main chain of trypsin and that of its inhibitor. Furthermore, the carbonyl group of lysine 15 and the surrounding atoms of the inhibitor fit snugly in the active site of the enzyme.

Comparison of the structure of the inhibitor bound to the enzyme with that of the free inhibitor reveals that the structure is essentially unchanged on binding to the enzyme (Figure 7.20). Thus, the inhibitor is preorganized into a structure that is highly complementary to the enzyme's active site. Indeed, the peptide bond between lysine 15 and alanine 16 in pancreatic trypsin inhibitor is cleaved but at a very slow rate: the half-life of the trypsin–inhibitor complex is several months. In essence, the inhibitor is a substrate, but its intrinsic structure is so nicely complementary to the enzyme's active site that it binds very tightly, rarely progressing to the transition state, and is turned over slowly.

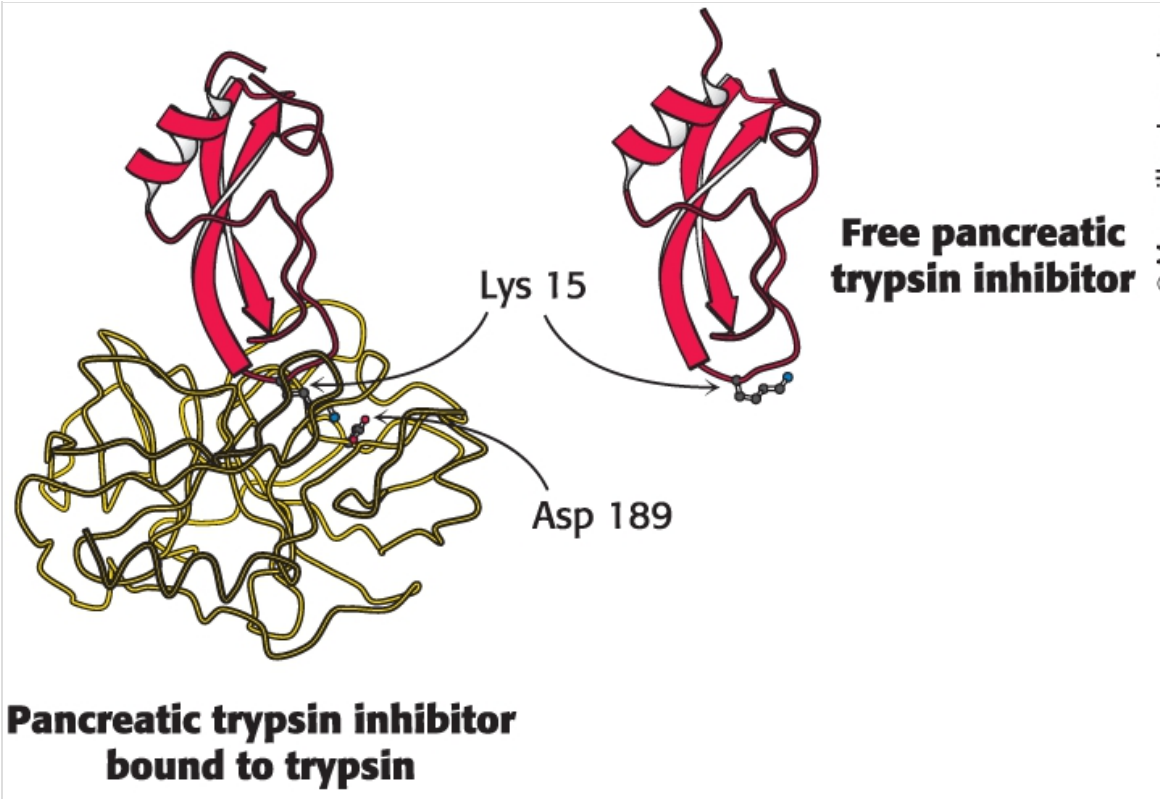

FIGURE 7.20 Trypsin binds very tightly to pancreatic trypsin inhibitor, a serpin. In the structu of a complex of trypsin (yellow) and pancreatic trypsin inhibitor (red), lysine 15 of the inhibitor penetrates into the active site of the enzyme. There it forms an ionic bond with aspartate 189 in the active site. Notice that bound inhibitor and the free inhibitor are almost identical in structu

[Drawn from 2PTC.pdb and 1BPI.pdb.]

INTERACT with this model in Achieve

Why does trypsin inhibitor exist? Recall that trypsin activates other zymogens. Consequently, preventing even small amounts of trypsin from initiating the cascade while the zymogens are still in the pancreas or pancreatic ducts is vital. Trypsin inhibitor binds to any prematurely activated trypsin molecules in the pancreas or pancreatic ducts. This inhibition prevents severe damage to those tissues, which could lead to acute pancreatitis.

Pancreatic trypsin inhibitor is not the only important protease inhibitor. A 53-kDa plasma protein, α_1-antitrypsin (also called α_1-*antiproteinase*), protects tissues from digestion by elastase, a secretory product of neutrophils (white blood cells that engulf bacteria). Antielastase would be a more accurate name for this inhibitor, because it blocks elastase much more effectively than it blocks trypsin. Like pancreatic trypsin inhibitor, α_1-antitrypsin blocks the action of target enzymes by binding nearly irreversibly to their active sites.

 Genetic disorders leading to a deficiency of α_1-antitrypsin illustrate the physiological importance of this inhibitor. For example, the substitution of lysine for glutamate at residue 53 in the type Z mutant slows the secretion of this inhibitor from liver cells. Serum levels of the inhibitor are about 15% of normal in people homozygous for this defect. The consequence is that excess elastase destroys alveolar walls in the lungs by digesting elastic fibers and other connective-tissue proteins.

The resulting clinical condition is called *emphysema*. People with emphysema must breathe much harder than normal people to exchange the same volume of air because their alveoli are much less resilient than

7.5 Enzymatic Cascades Allow Rapid Responses Such as Blood Clotting

Biochemical systems often use a series of zymogen activations, called an **enzymatic cascade**, to achieve a rapid response. In a cascade, a signal initiates a series of steps, each of which is catalyzed by an enzyme. At each step, the signal is amplified. For instance, if a signal molecule activates an enzyme that in turn activates 10 enzymes, and each of the 10 enzymes in turn activates 10 additional enzymes, after four steps the original signal will have been amplified 10,000-fold.

In the previous section, we discussed the cascade of proteolytic enzymes that accompanies digestion of a meal. Another physiological process that requires enzymatic cascades is **hemostasis**, the process of blood clot formation and dissolution. Because the activated form of one clotting factor catalyzes the activation of the next (**Figure 7.22**), a very small amount of the initial factors suffice to trigger the cascade, ensuring a rapid response to trauma.

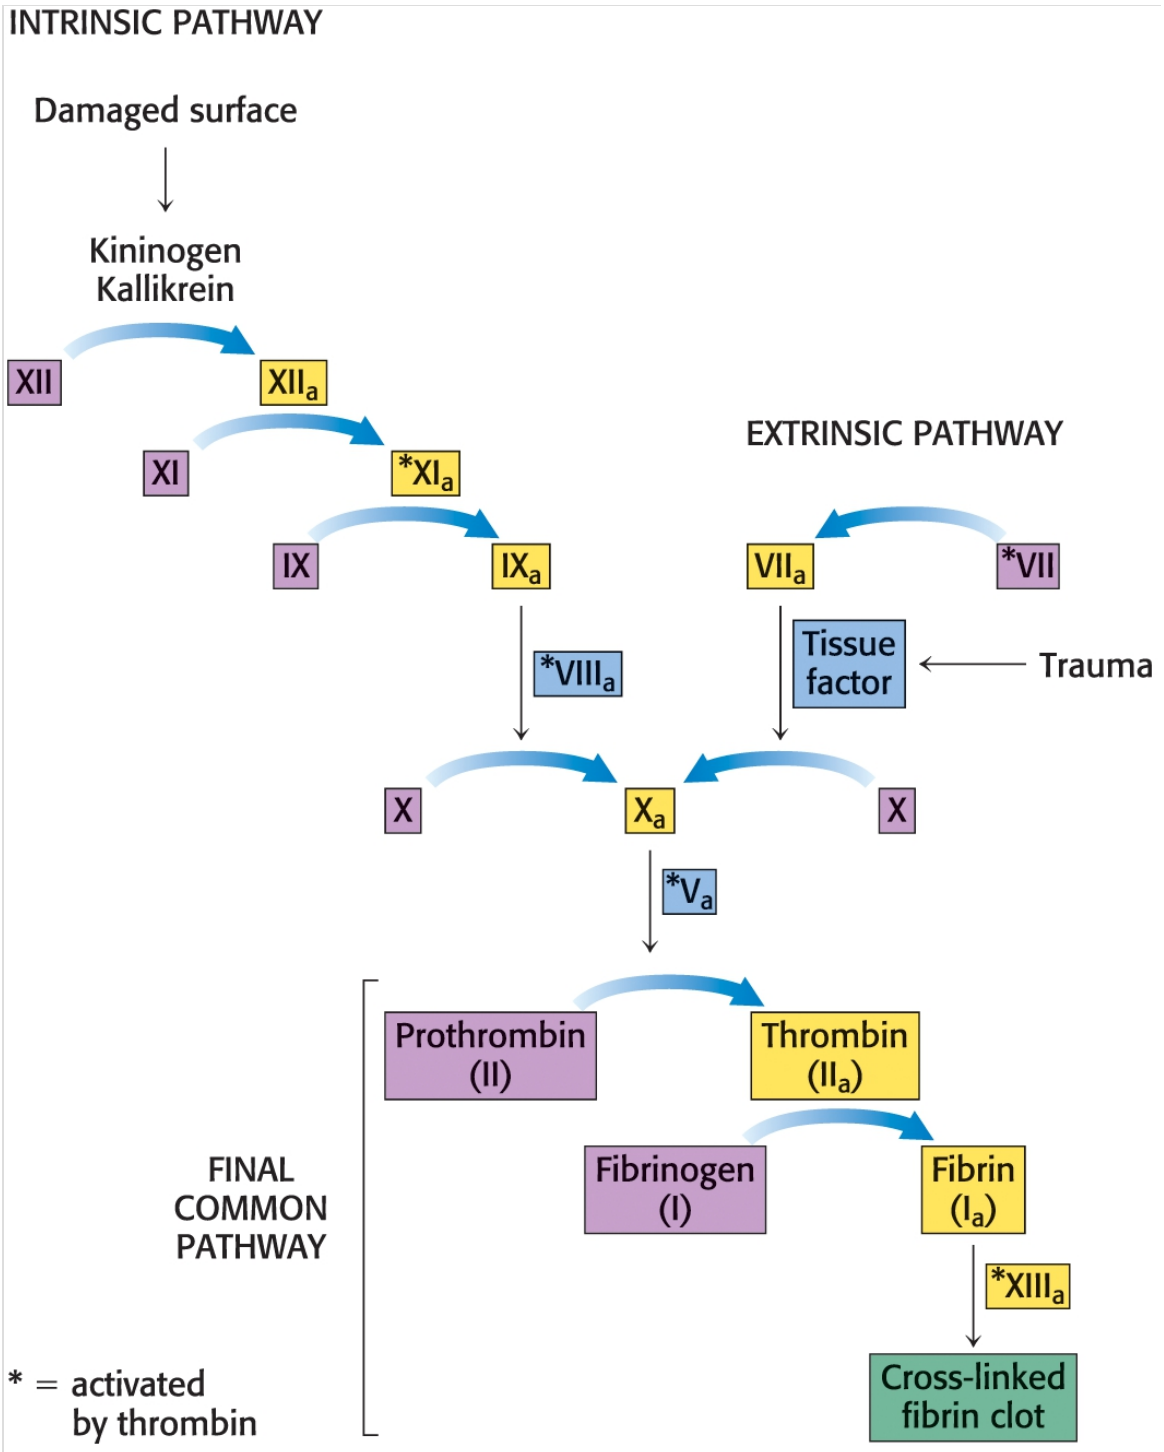

FIGURE 7.22 Blood clotting is the result of an enzymatic cascade. A fibrin clot is formed by the interplay of the intrinsic, extrinsic, and final common pathways. The intrinsic pathway begins with the activation of factor XII (Hageman factor) by contact with abnormal surfaces produced b injury. The extrinsic pathway is triggered by trauma, which releases tissue factor (TF). TF forms complex with VII, which initiates a cascade-activating thrombin. Inactive forms of clotting facto are shown in purple; their activated counterparts (indicated by the subscript "a") are in yellow. Stimulatory proteins that are not themselves enzymes are shown in blue boxes. A striking featu

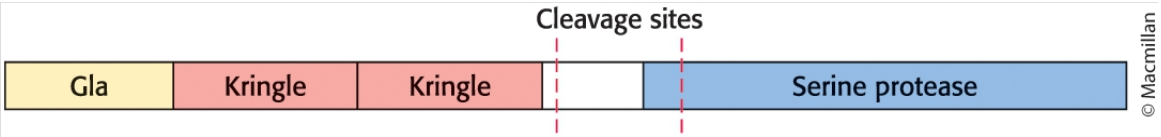
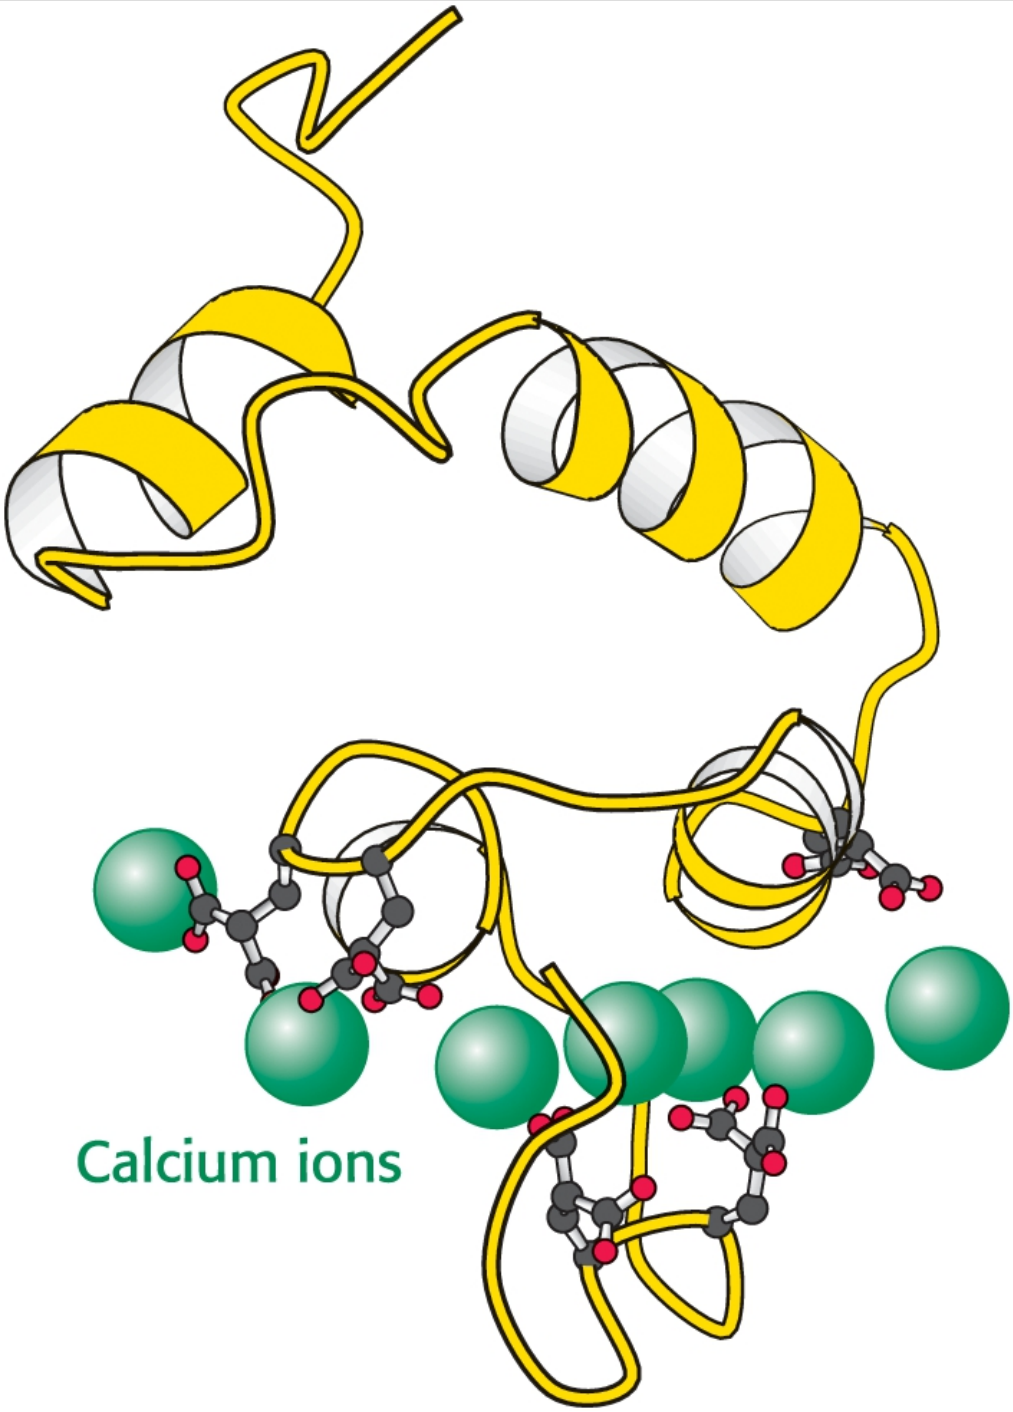
of this process is that the activated form of one clotting factor catalyzes the activation of the ne
factor.



Two means of initiating blood clotting have been elucidated. The *intrinsic pathway* is activated by exposure of anionic surfaces upon rupture of the endothelial lining of the blood vessels. The *extrinsic pathway*, which appears to be most crucial in blood clotting, is initiated when trauma exposes tissue factor (TF), an integral membrane glycoprotein. Upon exposure to the blood, tissue factor binds to factor VII to activate factor X. Both the intrinsic and extrinsic pathways lead to the activation of factor X (a serine protease), which in turn converts prothrombin into thrombin, the key protease in clotting. Thrombin then amplifies the clotting process by activating enzymes and factors that lead to the generation of yet more thrombin, an example of positive feedback. Note that the active forms of the clotting factors are designated with a subscript "a," whereas factors that are enzymes or enzyme cofactors activated by thrombin are designated with an asterisk.

Prothrombin must bind to Ca^{2+} to be converted to thrombin



Thrombin is synthesized as a zymogen called prothrombin. The inactive molecule is comprised of four major domains, with the serine protease domain at its carboxyl terminus (Figure 7.23). The first domain, called the *gla domain*, is rich in γ-carboxyglutamate residues (abbreviation gla), and the second and third domains are called *kringle domains* (named after a Danish pastry that they resemble). These three domains work in concert to keep prothrombin in an inactive form. Moreover, because it is rich in γ-carboxyglutamate, the gla domain is able to bind

Ca^{2+} (Figure 7.24). What is the effect of this binding? The binding of Ca^{2+} by prothrombin anchors the zymogen to phospholipid membranes derived from blood platelets after injury. This binding is crucial because it brings prothrombin into close proximity to two clotting proteins, factor X_a and factor V_a (a stimulatory protein), that catalyze its conversion into thrombin. Factor X_a cleaves the bond between arginine 274 and threonine 275 to release a fragment containing the first three domains. Factor X_a also cleaves the bond between arginine 323 and isoleucine 324 to yield active thrombin.

INTERACT with this model in Achieve

Fibrinogen is converted by thrombin into a fibrin clot

The best-characterized part of the clotting process is the final step in the cascade: the conversion of fibrinogen into fibrin by thrombin. Fibrinogen is a large glycoprotein composed of three nonidentical chains, Aα, Bβ, and γ, and is found in the blood plasma of all vertebrates. The overall composition of this 340-kDa protein is $(A\alpha)_2(B\beta)_2\,\gamma_2$. Three globular units are connected by two rods, and the rod regions are triple-stranded α-helical coiled coils, a recurring motif in proteins (Section 2.5; **Figure 7.25A**). Thrombin cleaves four arginine–glycine peptide bonds in the central globular region of fibrinogen (**Figure 7.25B**). On cleavage, an A peptide of 18 residues is released from each of the two Aα chains, as is a B peptide of 20 residues from each of the two Bβ chains. These A and B peptides are called *fibrinopeptides* (**Figure 7.26**). A fibrinogen molecule devoid of these fibrinopeptides is called a *fibrin monomer* and has the subunit structure $(\alpha\beta\gamma)_2$.

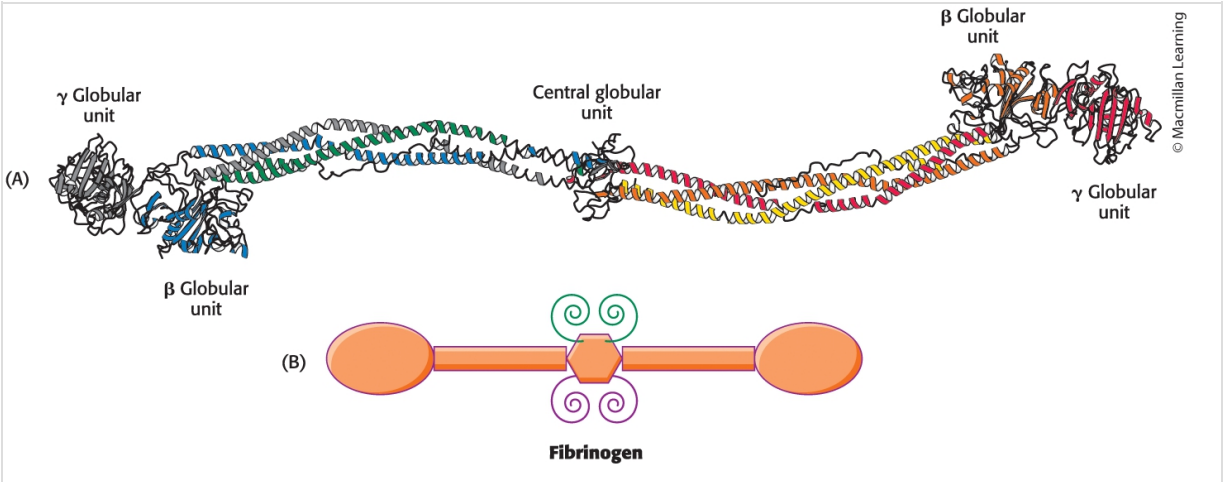

FIGURE 7.25 Fibrinogen contains three globular regions connected by rod-shaped structures. (A) A ribbon diagram. The two rod regions are α-helical coiled coils, connected to the three globular regions. (B) A schematic representation showing the positions of the fibrinopeptides (green and purple) in the central globular region.

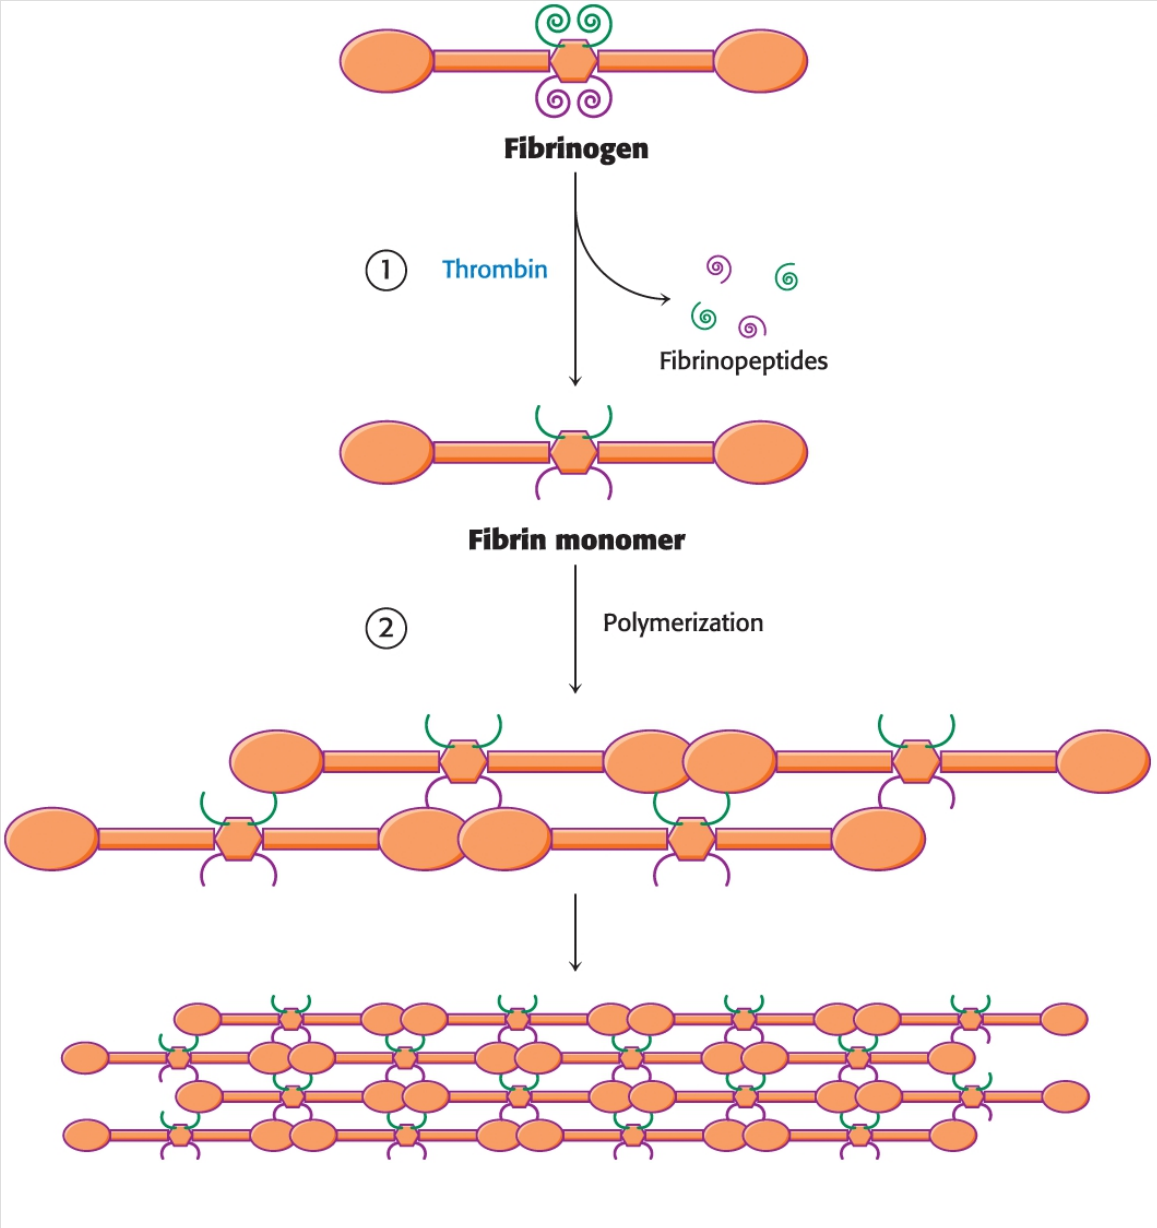
[Part A drawn from 1M1J.pdb.]

INTERACT with this model in Achieve



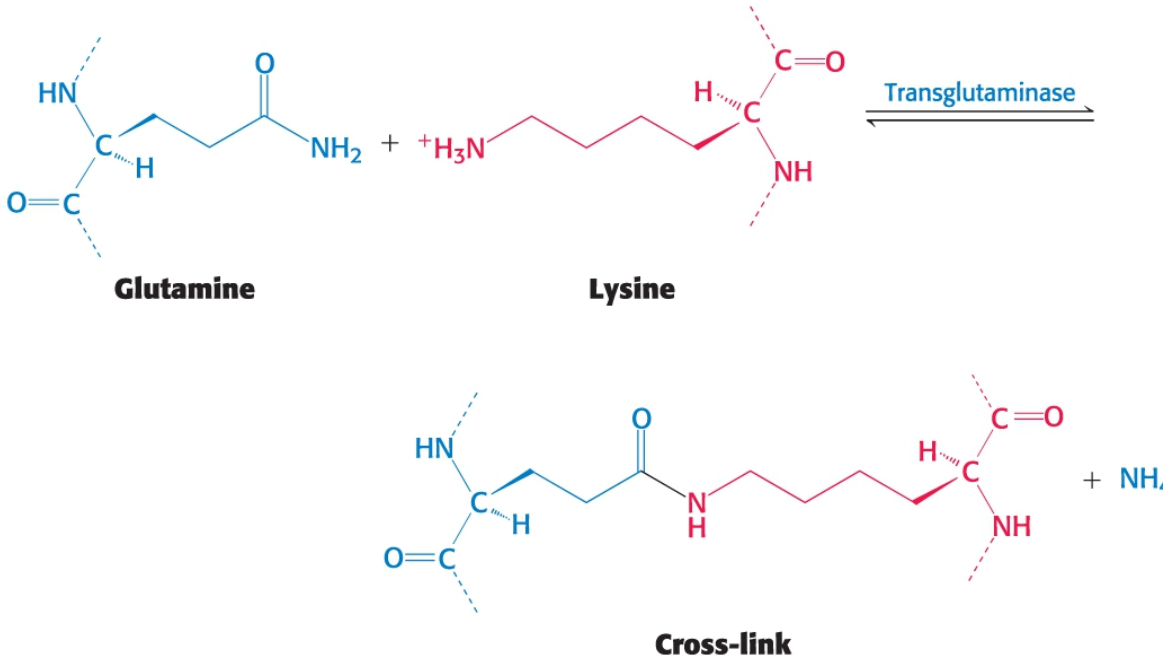


FIGURE 7.26 The cleavage of fibrinogen by thrombin initiates fibrin clot formation. (1) Thrombin cleaves fibrinopeptides from the central globule of fibrinogen. (2) Globular domains a the carboxyl-terminal ends of the β and γ chains interact with the peptides exposed upon thrombin cleavage.

Upon thrombin cleavage, amino acid sequences are exposed in the central globular unit that interact with the γ and β subunits of other monomers. Polymerization occurs as more fibrin monomers interact with one another (Figure 7.26). Thus, analogous to the activation of chymotrypsinogen, peptide-bond cleavage exposes new amino termini that can participate in specific interactions. The newly formed "soft clot" is stabilized by the formation of amide bonds between the side chains of lysine and glutamine residues in different monomers. This cross-linking reaction is catalyzed by transglutaminase (factor $XIII_a$), which itself is activated from its protransglutaminase form by thrombin.

Vitamin K is required for the formation of γ-carboxyglutamate

Vitamin K (Figure 7.27) has been known for many years to be essential for the synthesis of prothrombin and several other clotting factors. Indeed, it is called vitamin K because a deficiency in this vitamin results in defective blood koagulation (Scandinavian spelling). After ingestion, vitamin K is reduced to a dihydro derivative that is required by γ-glutamyl carboxylase to convert the first 10 glutamate residues in the amino-terminal region of prothrombin into γ-carboxyglutamate (Figure 7.28). Recall from above that γ-carboxyglutamate, a strong chelator of Ca^{2+}, is required for the activation of prothrombin.

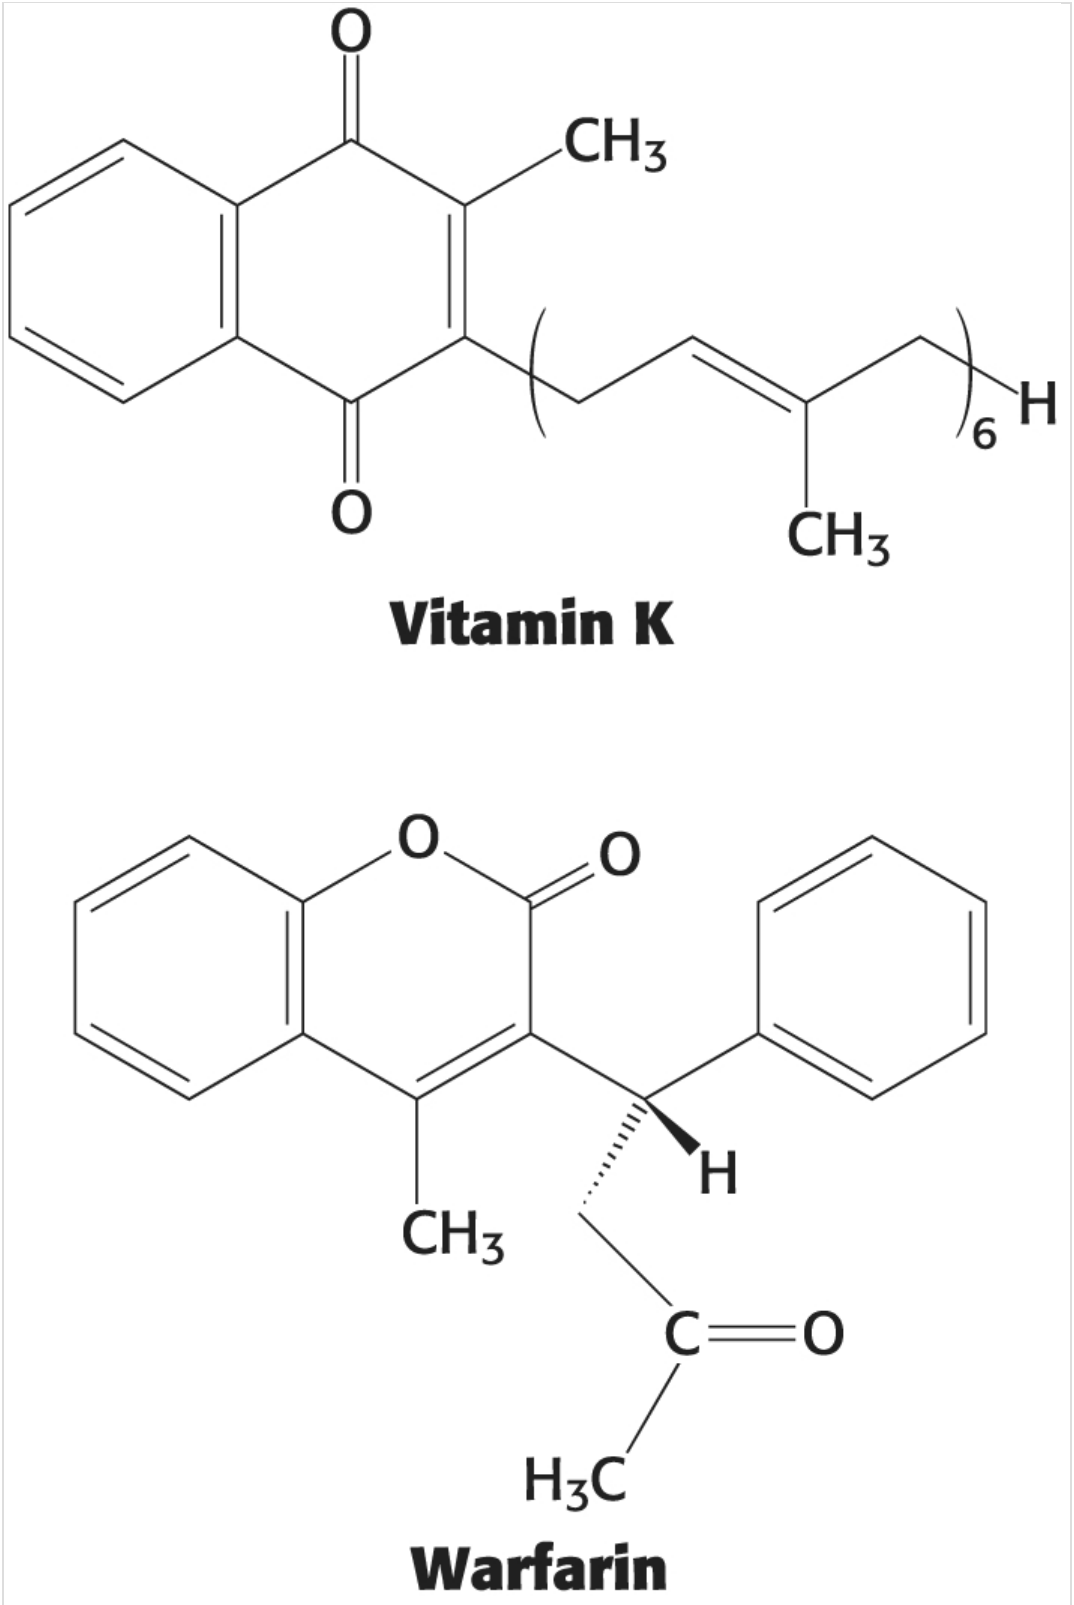

FIGURE 7.27 Vitamin K and the anticoagulant warfarin share structural features.

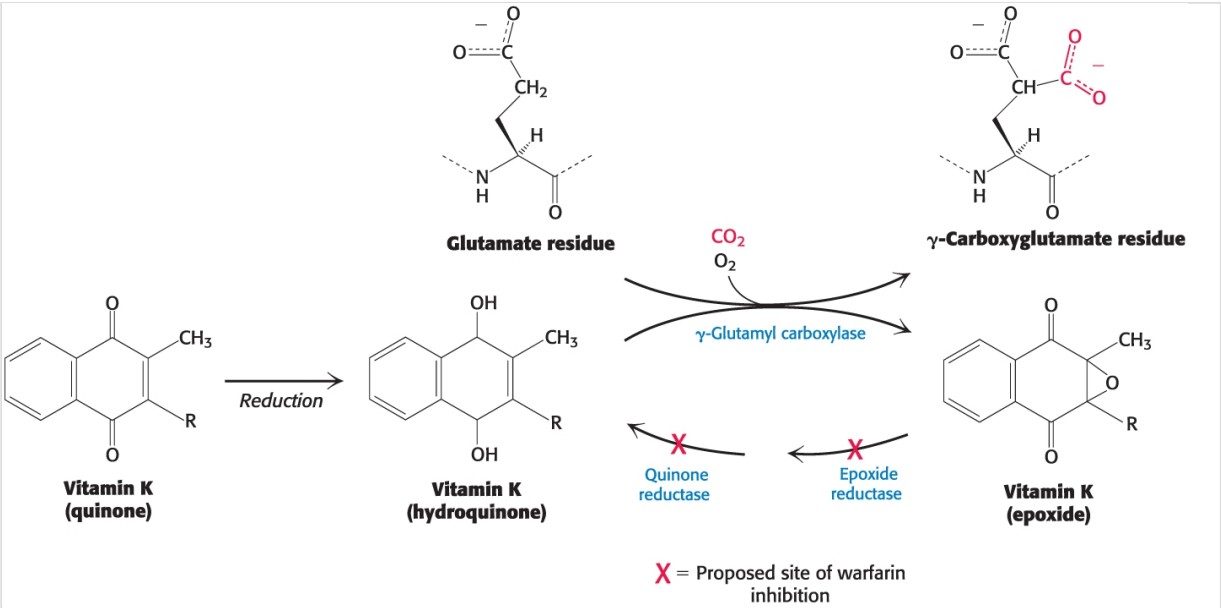

FIGURE 7.28 Vitamin K is required for the synthesis of γ-carboxyglutamate by γ-glutamyl carboxylase. The formation of γ-carboxyglutamate requires the hydroquinone (reduced) derivative of vitamin K, which is then regenerated from the epoxide derivative by the sequential action of epoxide reductase and quinone reductase, both of which are inhibited by warfarin.

Medicines that reduce blood clot formation, known as anticoagulant drugs, play an important role in the prevention of stroke, myocardial infarction (heart attack), and pulmonary embolism in patients with increased clotting risk. One most commonly prescribed anticoagulants is warfarin, a vitamin K antagonist sold under the name of coumadin (Figure 7.27). Warfarin appears to inhibit the epoxide reductase and quinone reductase that are required to regenerate the dihydro derivative of vitamin K (Figure 7.28). Newer anticoagulants have also entered the market, including inhibitors of factor X_a and thrombin.

The clotting process must be precisely regulated

There is a fine line between hemorrhage and thrombosis, the formation of blood clots in blood vessels. Clots must form rapidly yet remain confined to the area of injury. What are the mechanisms that normally limit clot formation to the site of injury? The lability of clotting factors contributes significantly to the control of clotting. Activated factors are short-lived because they are diluted by blood flow, removed by the liver, and degraded by proteases. For example, the stimulatory protein factors V_a and $VIII_a$ are digested by protein C, a protease that is switched on by the action of thrombin. Thus, thrombin has a dual function: it catalyzes the formation of fibrin, and it initiates the deactivation of the clotting cascade.

Specific inhibitors of clotting factors are also critical in the termination of clotting. For instance, tissue factor pathway inhibitor (TFPI) inhibits the complex of $TF-VII_a-X_a$ that activates thrombin. Another key inhibitor is antithrombin III, a member of the serpin family of protease inhibitors that forms an irreversible inhibitory complex with thrombin. Antithrombin III resembles α_1-antitrypsin except that it inhibits thrombin much more strongly than it inhibits elastase (Figure 7.20). Antithrombin III also blocks other serine proteases in the clotting cascade — namely, factors XII_a, XI_a, IX_a, and X_a.

The inhibitory action of antithrombin III is enhanced by the glycosaminoglycan *heparin*, a negatively charged polysaccharide (Section 11.3) found in mast cells near the walls of blood vessels and on the surfaces of endothelial cells. Heparin acts as an anticoagulant by increasing the rate of formation of irreversible complexes between antithrombin III and the serine protease clotting factors.

Self-Check Question

Antithrombin III forms an irreversible complex with thrombin but not with prothrombin. What is the most likely reason for this difference in reactivity?

Chapter 7 Summary

7.1 Allosteric Regulation Enables Control of Metabolic Pathways

- Allosteric proteins constitute an important class of proteins whose biological activity can be altered by binding to distinct regulatory sites.
- Aspartate transcarbamoylase (ATCase), one of the best-understood allosteric enzymes, catalyzes the synthesis of *N*-carbamoylaspartate, the first and committed step in the synthesis of pyrimidines.
- ATCase is feedback inhibited by CTP, the final product of the pathway, and is stimulated by ATP and the bisubstrate analog PALA.
- The inhibitory effect of CTP, the stimulatory action of ATP, and the cooperative binding of substrates to ATCase are mediated by the interconversion between the T (low-affinity for substrate) to the R (high-affinity) states.
- The sigmoidal kinetics exhibited by ATCase can be pictured as a composite of the Michaelis–Menten curves for the T and R states.

7.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages

- Isozymes differ in structural characteristics but catalyze the same reaction.
- Typically, isozymes display different kinetic parameters or respond to different regulatory molecules.
- Isozymic forms of an enzyme can vary by tissue or developmental stage, providing a means of fine-tuning metabolism.

7.3 Covalent Modification Is a Means of Regulating Enzyme Activity

- Reversible and irreversible covalent modifications are powerful means of controlling enzyme activity.
- Phosphorylation is a common type of reversible covalent modification in all forms of life.
- Kinases are the enzymes responsible for protein phosphorylation, while phosphatases catalyze the hydrolysis of attached phosphoryl groups.
- Protein kinase A (PKA) is a kinase whose activity is controlled by allosteric regulation. Cyclic AMP switches on PKA by binding to the regulatory subunit of the enzyme, thereby releasing the active catalytic subunits of PKA.

7.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage

- The activation of an enzyme by the proteolytic cleavage of one or a few peptide bonds is a recurring irreversible control mechanism.
- The inactive precursors of these enzymes are called zymogens.
- Proteolytic cleavage plays an important role in the digestive enzymes, where control over activation prevents tissue damage.
- Trypsinogen is activated by enteropeptidase or trypsin, and trypsin then activates a host of other zymogens, leading to the digestion of foodstuffs.
- Specific inhibitors of proteolytic enzymes, including the serpins, also provide an additional layer of regulatory control.

7.5 Enzymatic Cascades Allow Rapid Responses Such as Blood Clotting

- Blood clotting is an example of a process that utilizes an enzymatic cascade to achieve a rapid response.
- The activated form of one clotting factor, often a serine protease, catalyzes the activation of the next precursor.
- In the final step of clot formation, fibrinogen, a highly soluble molecule in the plasma, is converted by thrombin into fibrin by

the hydrolysis of four arginine–glycine bonds.

Key Terms

committed step
feedback inhibition
allosteric (regulatory) site
homotropic effect
heterotropic effect
isozymes (isoenzymes)
protein kinase
consensus sequence
protein phosphatase
pseudosubstrate sequence
phosphoproteome
zymogen (proenzyme)
enzymatic cascade
hemostasis
anticoagulant drugs

Problems

1. Suppose you have a dimeric allosteric enzyme that follows the concerted model. Which of the following statements are true? 3

a. The equilibrium between the T state and R state favors the T state.
b. The enzyme can exist as a RR dimer.
c. The enzyme can exist as an RT dimer.

d. The RR form of the enzyme is most active.

2. An allosteric enzyme that follows the concerted model has an allosteric coefficient (T/R) of 300 in the absence of substrate. Suppose that a mutation reversed the ratio. Select all of the effects this mutation will have on the relationship between the rate of the reaction (*V*) and substrate concentration, [S]. 3

a. The enzyme would be more active.
b. The enzyme would mostly be in the T form.
c. The enzyme would likely follow Michaelis–Menten kinetics.
d. The plot of *V* versus [S] would be shaped like a hyperbola.
e. The plot of *V* versus [S] would be sigmoidal.

3. Differentiate between homotropic and heterotropic effectors. 3

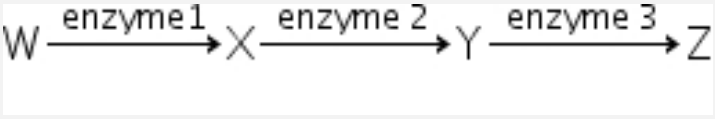
4. As shown in Figure 7.2, CTP inhibits ATCase; however, the inhibition is not complete. Can you suggest another molecule that might enhance the inhibition of ATCase? Hint: See Figure 26.2. 1

5. Classify the following phrases as describing a kinase, a phosphatase, neither, or both. 5

a. May use ATP as a phosphoryl group donor
b. PKA is an example.
c. Removes phosphoryl groups from proteins
d. Catalyzes reactions that are the reverse of dephosphorylation reactions
e. Regulates the activity of other proteins
f. Catalyzes phosphorylation reactions
g. Turns off signaling reactions triggered by kinases
h. In eukaryotes, transfers phosphoryl groups to acidic amino acids

6. Which statements about isozymes are true? 4

a. Isozymes are encoded by the same gene.
b. Isozymes may be expressed in different tissues.
c. Isozymes catalyze different reactions.
d. Isozymes have different amino acid sequences.
e. Isozymes have identical regulatory properties.
f. Lactate dehydrogenase is an example.



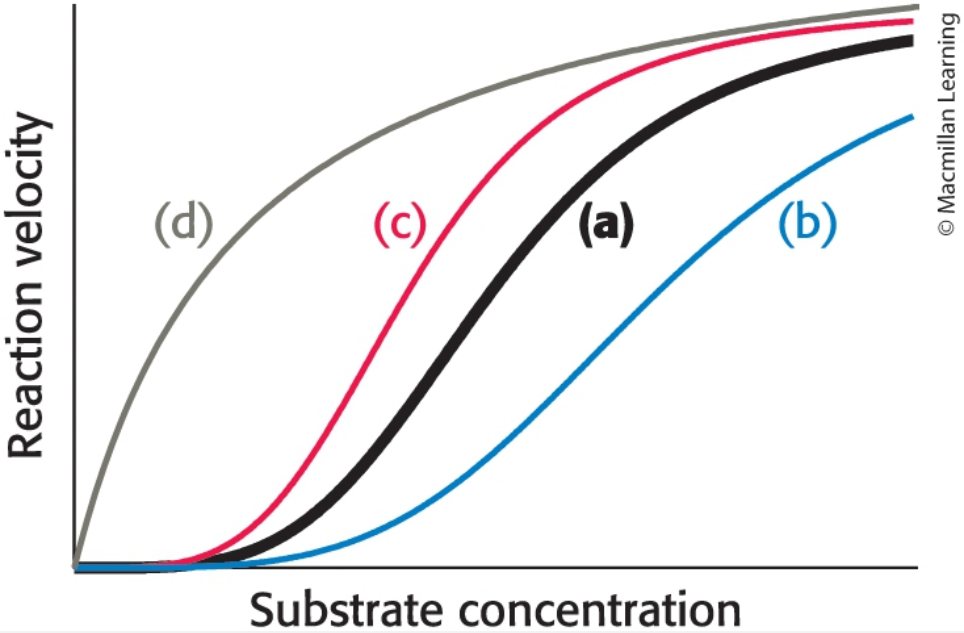
7. Consider the following molecules: ATP, CTP, UTP, cAMP, and PALA. With respect to ATCase, which of these molecules is … 2

a. … a feedback inhibitor?
b. … a bisubstrate analog?
c. … an allosteric activator?

8. Order the steps below for the activation of PKA by cAMP.

a. The free catalytic subunits interact with proteins to phosphorylate Ser and Thr residues.
b. The regulatory subunits move out of the active sites of the catalytic subunits, and the R_2C_2 complex dissociates.
c. Cytosolic cAMP concentration increases.
d. The cAMP molecules bind to each PKA regulatory subunit.

9. Consider the following reaction scheme:



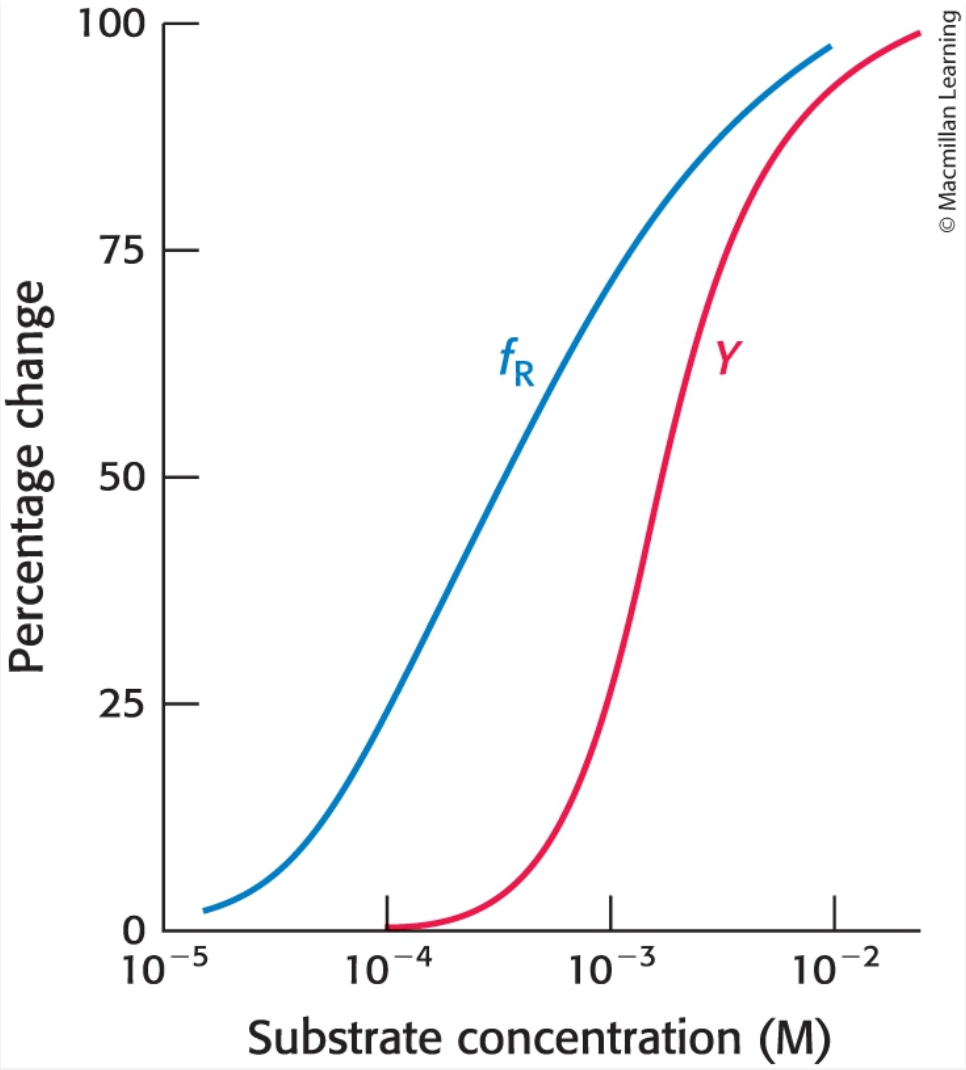
Product Z is a feedback inhibitor of enzyme 1. Assuming Z eventually diffuses out of the cell, in the presence of a high concentration of Z: 2

a. Would the concentration of X increase, decrease, or stay the same?
b. Would the concentration of Y increase, decrease, or stay the same?
c. Would the concentration of Z increase, decrease, or stay the same?
d. What happens to the activity of enzyme 1 if the concentration of Z decreases?

10. A drug company has decided to use recombinant DNA methods to prepare a modified α_1-antitrypsin that will be more resistant to oxidation than is the naturally occurring inhibitor. Which single amino acid substitution would you recommend?

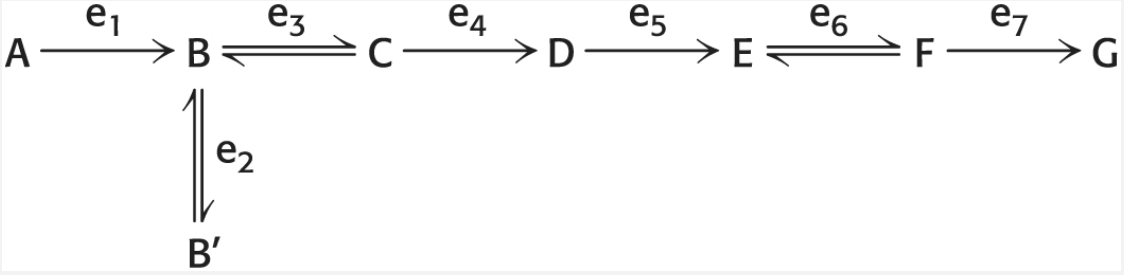
11. Consider the velocity curve of an allosteric enzyme, the thick black curve labeled "(a)" in the graph below.

Which of the four depicted curves correctly illustrates the effect of a negative modifier? 1



12. The proteolytic enzyme trypsin is produced in the pancreas as the zymogen trypsinogen. Trypsinogen is cleaved to yield active trypsin, which, in turn, activates other pancreatic zymogens.

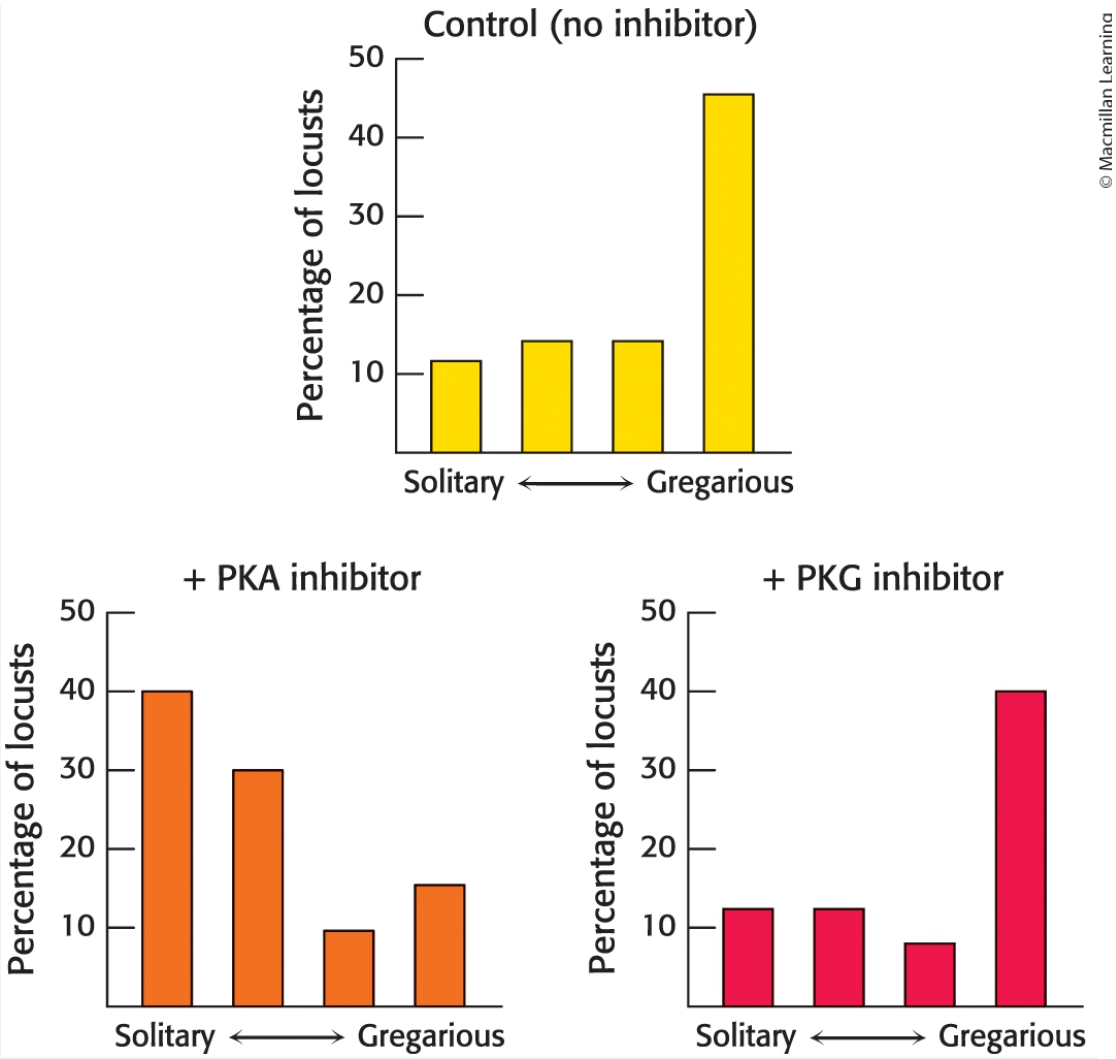
a. Which of the following enzymes is used in the activation of trypsinogen: chymotrypsin, enteropeptidase, fibrin, trypsin?
b. Which of the following zymogens is directly activated by trypsin: chymotrypsinogen, proelastase, procarboxypeptidase, prolipase?



13. Arrange the events of blood clot formation in the correct order:

a. Fibrinogen is converted to fibrin.
b. Trauma releases tissue factor (TF).
c. Transglutaminase cross-links fibrin, yielding a stabilized clot.
d. TF activates factor X to factor X_a.
e. Fibrin threads align, forming a “soft clot.”
f. Prothrombin is converted to thrombin.

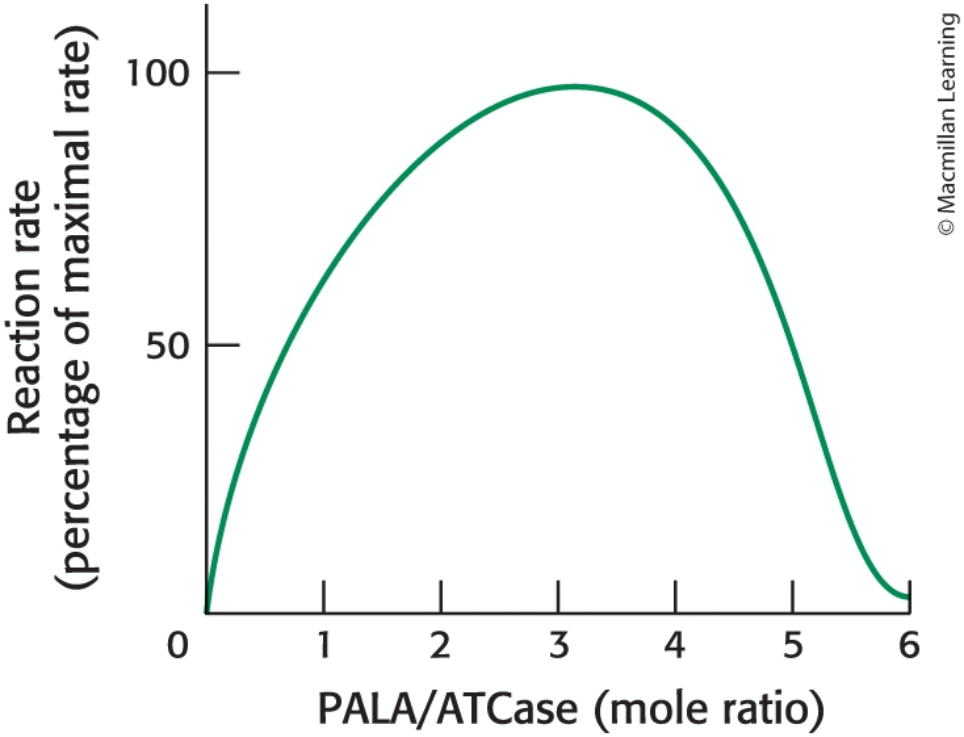
14. The following graph shows the fraction of an allosteric enzyme in the R state (f_R) and the fraction of active sites bound to substrate (Y) as a function of substrate concentration. Which model, the concerted or sequential, best explains these results? 1



15. Examine the following metabolic pathway:

a. Which enzymes catalyze irreversible reactions?
b. Which of the enzymes, identified as “e” with a numeric subscript, is likely to be the allosteric enzyme that controls the synthesis of G?

16. Recent studies have suggested that protein kinase A may be important in establishing behaviors in many organisms, including humans. One study investigated the role of PKA in locust behavior. Certain species of locust live solitary lives until crowded, at which point they become gregarious — they prefer the crowded life.



Locusts were grouped together for one hour, and then allowed to stay with the group or move away. Prior to crowding, some insects were injected with a PKA inhibitor, a cyclic GMP-dependent kinase inhibitor, or no inhibitor, as indicated. The results are shown here: 5

© Macmillan Learning

a. What is the response of the control group to crowding?
b. What is the result if the insects are first treated with PKA inhibitor? PKG inhibitor?
c. What was the purpose of the experiment with the PKG inhibitor?
d. What do these results suggest about the role of PKA in the transition from a solitary to a gregarious lifestyle?

17. Recall that PALA is a potent inhibitor of ATCase because it mimics the two physiological substrates. However, in the presence of substrates, low concentrations of this unreactive bisubstrate analog *increase* the reaction velocity. On the addition of PALA, the reaction rate increases until an average of three molecules of PALA are bound per molecule of enzyme. This maximal velocity is 17-fold greater than it is in the absence of PALA. The reaction rate then decreases to nearly zero on the addition of three more molecules of PALA per molecule of enzyme. Why do low concentrations of PALA activate ATCase?

18. According to the concerted model, the relationship between the concentrations of the T and R states in the presence of substrates can be expressed as:

$$\frac{[T_i]}{[R_i]} = c^i L$$

where c is the ratio of the dissociation constants of the substrate for the R state to the T state, that is:

$$c = \frac{K_d^R}{K_d^T},$$

L is the ratio of [T] to [R] *in the absence of substrate,* and i is the number of substrate molecules bound.

Assume we have an allosteric enzyme for which a substrate binds 100 times as tightly to the R state as to its T state.

a. By what factor does the binding of one substrate molecule per enzyme molecule alter the ratio of the concentrations of enzyme molecules in the R and T states?
b. Suppose that L, the ratio of [T] to [R] in the absence of substrate, is 10^7 and that the enzyme contains four binding sites for substrate. What is the ratio of enzyme molecules in the R state to those in the T state in the presence of saturating amounts of substrate, assuming that the concerted model is obeyed? 3

Chapter 8
DNA, RNA, and the Flow of Genetic Information

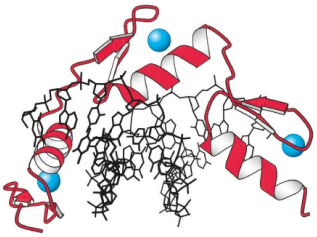


Photo: Lelusy/Shutterstock

Family resemblance, shown here in the likeness of a puppy to its parents, results from having genes in common. Genes must be expressed to exert an effect, and proteins regulate such expression. One such regulatory protein, a zinc-finger protein (zinc ions are blue, protein is red), is shown bound to a control region of DNA (black).

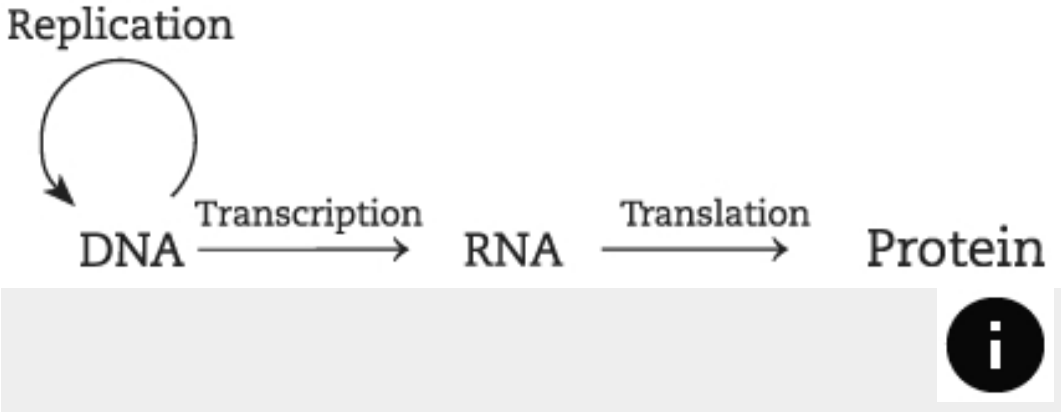
8.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons



Learning Goals

By the end of this chapter, you should be able to:

1. Identify the bases for DNA and RNA and distinguish between nucleosides and nucleotides.
2. Distinguish between DNA and RNA in both structure and function.
3. Explain how DNA is replicated.
4. Explain how information flows from DNA to protein.
5. Identify some key differences between bacterial and eukaryotic genes.

DNA and RNA are long linear polymers, called nucleic acids, that carry information in a form that can be passed from one generation to the next. Due to its remarkable long-term stability and double-helical structure, DNA polymers are well-suited for the storage and replication of the genetic information for all cells and many viruses. However, DNA is not the direct template for protein synthesis. Rather, a DNA strand is copied into a class of RNA molecules called messenger RNA (mRNA). The scheme that underlies information processing at the level of gene expression was first proposed by Francis Crick in 1958.

Crick called this scheme the *central dogma*. The basic tenets of this dogma are true, but, as we will see later, this scheme is not as simple as depicted. This flow of information depends on the genetic code, which defines the relation between the sequence of bases in DNA and the sequence of amino acids in a protein.

8.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar–Phosphate Backbone

The nucleic acids **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)** are well suited to function as the carriers of genetic information by virtue of their covalent structures. These macromolecules are linear polymers built from similar units connected end to end (**Figure 8.1**). Each monomer unit within the polymer is a **nucleotide**. A single nucleotide unit consists of three components: a sugar, a phosphate, and one of four bases. The sequence of bases in the polymer uniquely characterizes a nucleic acid and constitutes a form of linear information — information analogous to the letters that spell a person's name.

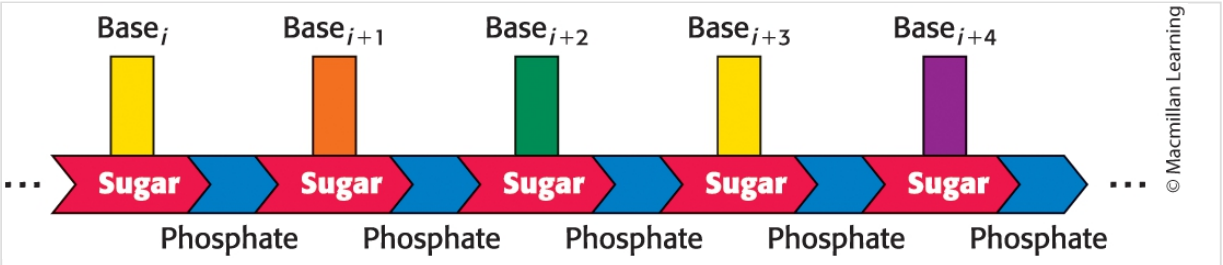


FIGURE 8.1 Nucleic acids are linear polymers of nucleotides. Each nucleotide contains three components: a sugar, a phosphate, and a base.

RNA and DNA differ in the sugar component and one of the bases

The sugar in DNA is **deoxyribose**. The prefix deoxy- indicates that the $2'$-carbon atom of the sugar lacks the oxygen atom that is linked to the $2'$-carbon atom of **ribose**, as shown in **Figure 8.2**. Note that sugar carbons are numbered with primes to differentiate them from atoms in the bases. The sugars in both nucleic acids are linked to one another by phosphodiester bridges. Specifically, the $3'$-hydroxyl ($3'-OH$) group of the sugar moiety of one nucleotide is esterified to a phosphate group, which, in turn, is joined to the $5'$-hydroxyl group of the adjacent sugar.

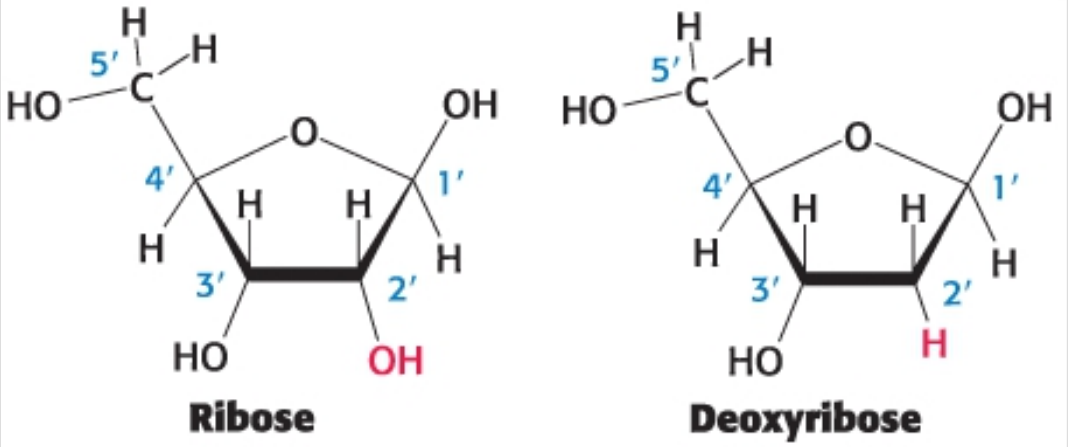

FIGURE 8.2 Ribose and deoxyribose are the sugars found in RNA and DNA, respectively. Atoms in sugar units are numbered with primes to distinguish them from atoms in bases (see Figure 8.4).

The chain of sugars linked by phosphodiester bridges is referred to as the *backbone* of the nucleic acid (**Figure 8.3**). Whereas the backbone is constant in a nucleic acid, the bases vary from one monomer to the

next. Two of the bases of DNA are derivatives of **purine** — adenine (A) and guanine (G) — and two of **pyrimidine** — cytosine (C) and thymine (T), as shown in **Figure 8.4**.

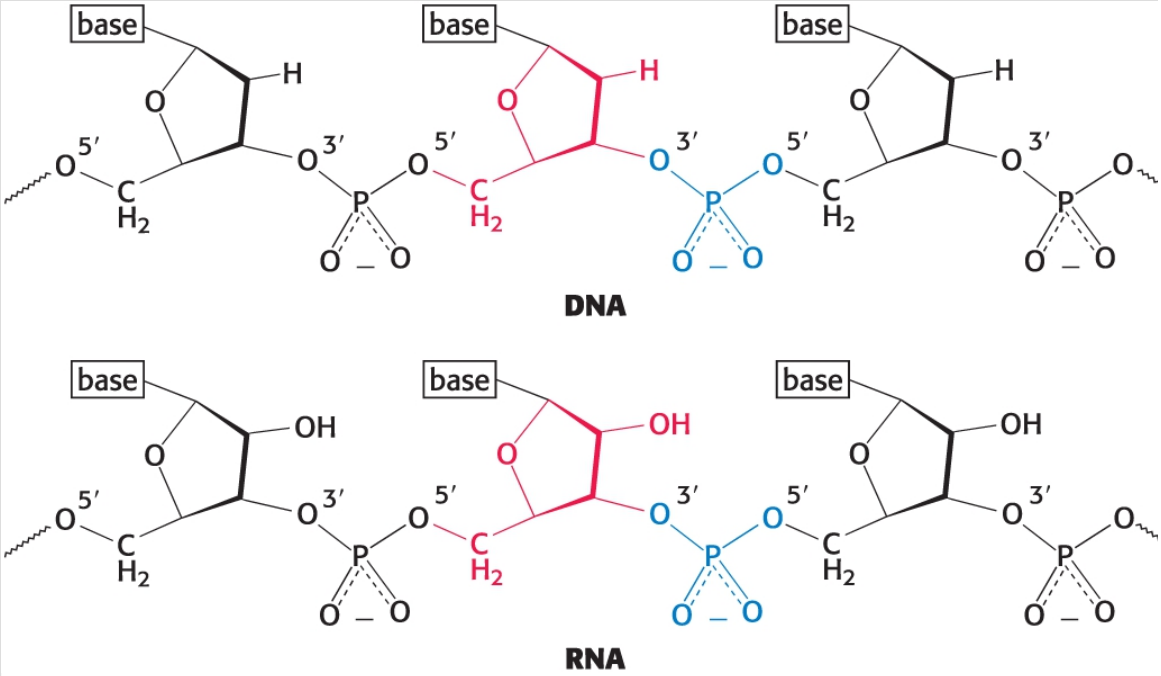

FIGURE 8.3 The sugar–phosphate backbones of nucleic acids are formed by 3′-to-5′ phosphodiester linkages. For each nucleic acid, a sugar unit is highlighted in red and a phosphate group in blue.

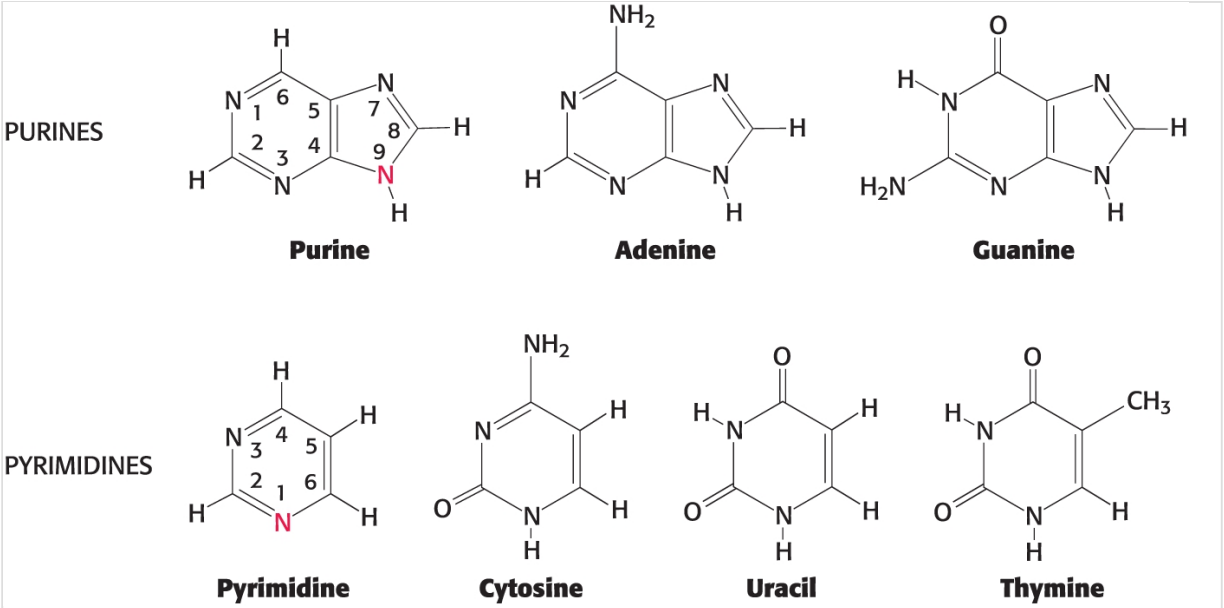

FIGURE 8.4 The bases in nucleic acids are either purines or pyrimidines. Atoms within bases are numbered without primes. Uracil is present in RNA instead of thymine. N-9 in purines and N-1 in pyrimidines form a bond with the sugar (see Figure 8.5).

RNA, like DNA, is a long, unbranched polymer consisting of nucleotides joined by $3'$-to-$5'$ phosphodiester linkages (Figure 8.3). The covalent structure of RNA differs from that of DNA in two respects. First, the sugar units in RNA are riboses rather than deoxyriboses. Ribose contains a $2'$-hydroxyl group not present in deoxyribose (Figure 8.2). Second, one of the four major bases in RNA is uracil (U) instead of thymine (T) (Figure 8.4).

Note that each phosphodiester bridge has a negative charge (Figure 8.3). This negative charge repels nucleophilic species such as hydroxide ions, which are capable of hydrolytic attack on the phosphate backbone. This resistance is crucial for maintaining the integrity of information stored in nucleic acids. The absence of the $2'$-hydroxyl group in DNA further

increases its resistance to hydrolysis. The greater stability of DNA probably accounts for its use rather than RNA as the hereditary material in all modern cells and in many viruses.

Nucleotides are the monomeric units of nucleic acids

The building blocks of nucleic acids and the precursors of these building blocks play many other roles throughout the cell — for instance, as energy currency and as molecular signals. Consequently, it is important to be familiar with the nomenclature of nucleotides and their precursors. A unit consisting of a base bonded to a sugar is referred to as a **nucleoside**. The four nucleoside units in RNA are called *adenosine*, *guanosine*, *cytidine*, and *uridine*, whereas those in DNA are called *deoxyadenosine*, *deoxyguanosine*, *deoxycytidine*, and *thymidine*. (Thymidine contains deoxyribose, and by convention, the prefix deoxy- is not added because thymine-containing nucleosides are only rarely found in RNA.)

In each nucleoside, N-9 of a purine or N-1 of a pyrimidine is attached to $C-1'$ of the sugar by an *N*-β-glycosidic linkage (**Figure 8.5**). The base lies above the plane of the sugar when the structure is written in the standard orientation; that is, the configuration of the *N*-glycosidic linkage is β (Section 11.1).

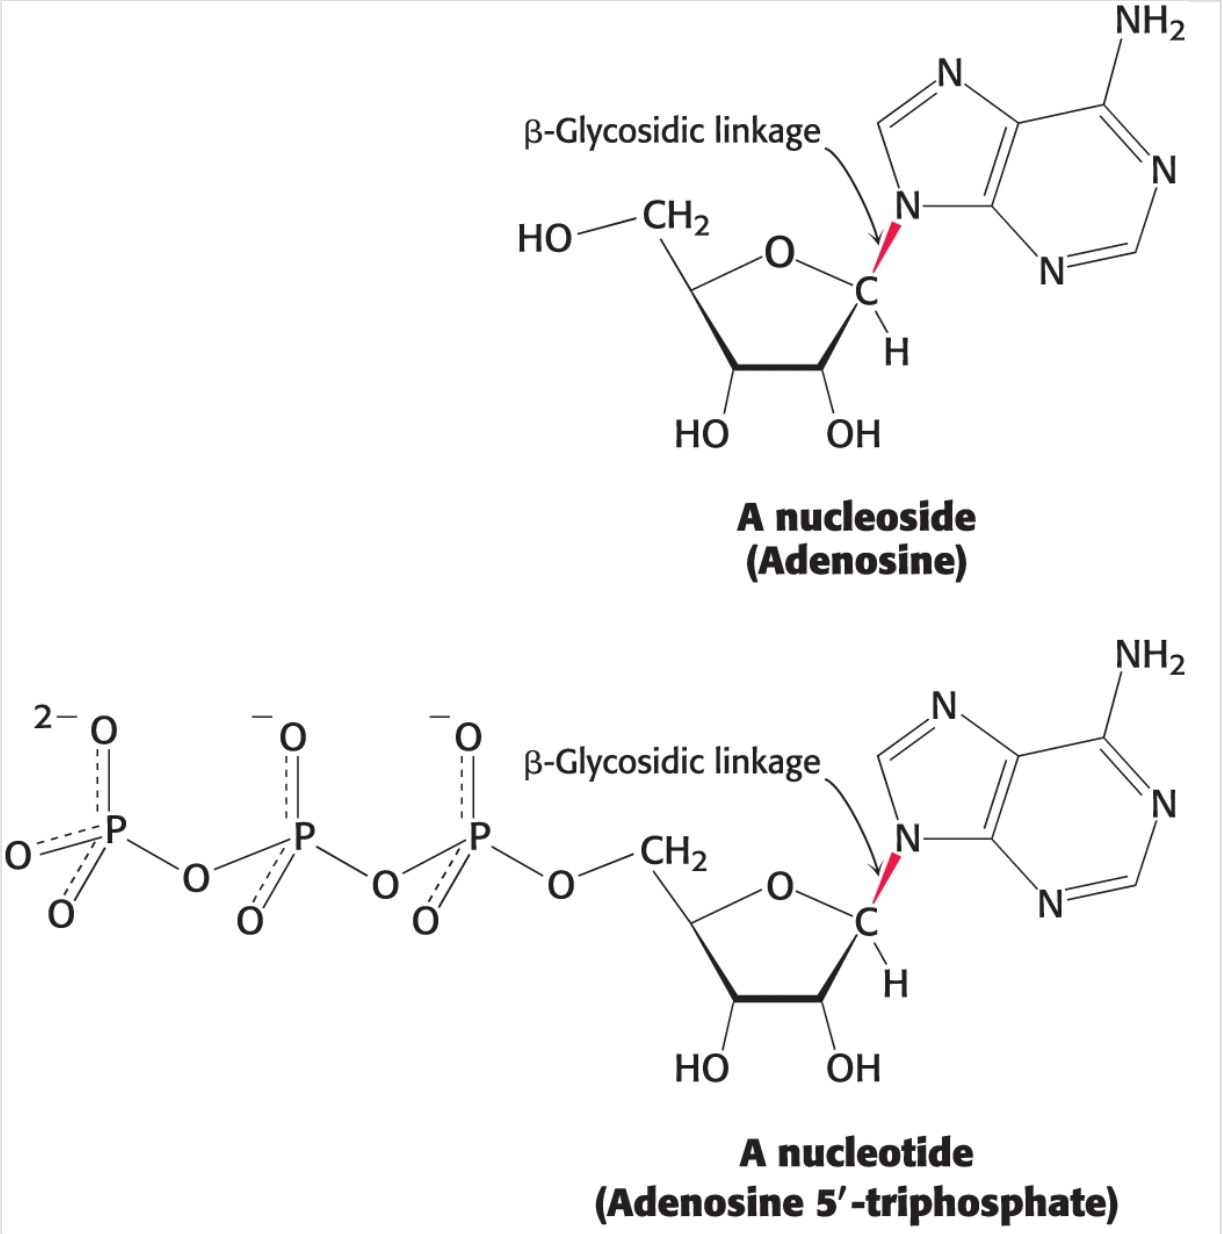

FIGURE 8.5 Nucleosides and nucleotides are distinguished by the presence of phosphoryl groups. A nucleoside contains a sugar and a base joined by an *N*-β-glycosidic linkage. A nucleotide contains a nucleoside linked to one or more phosphoryl groups.

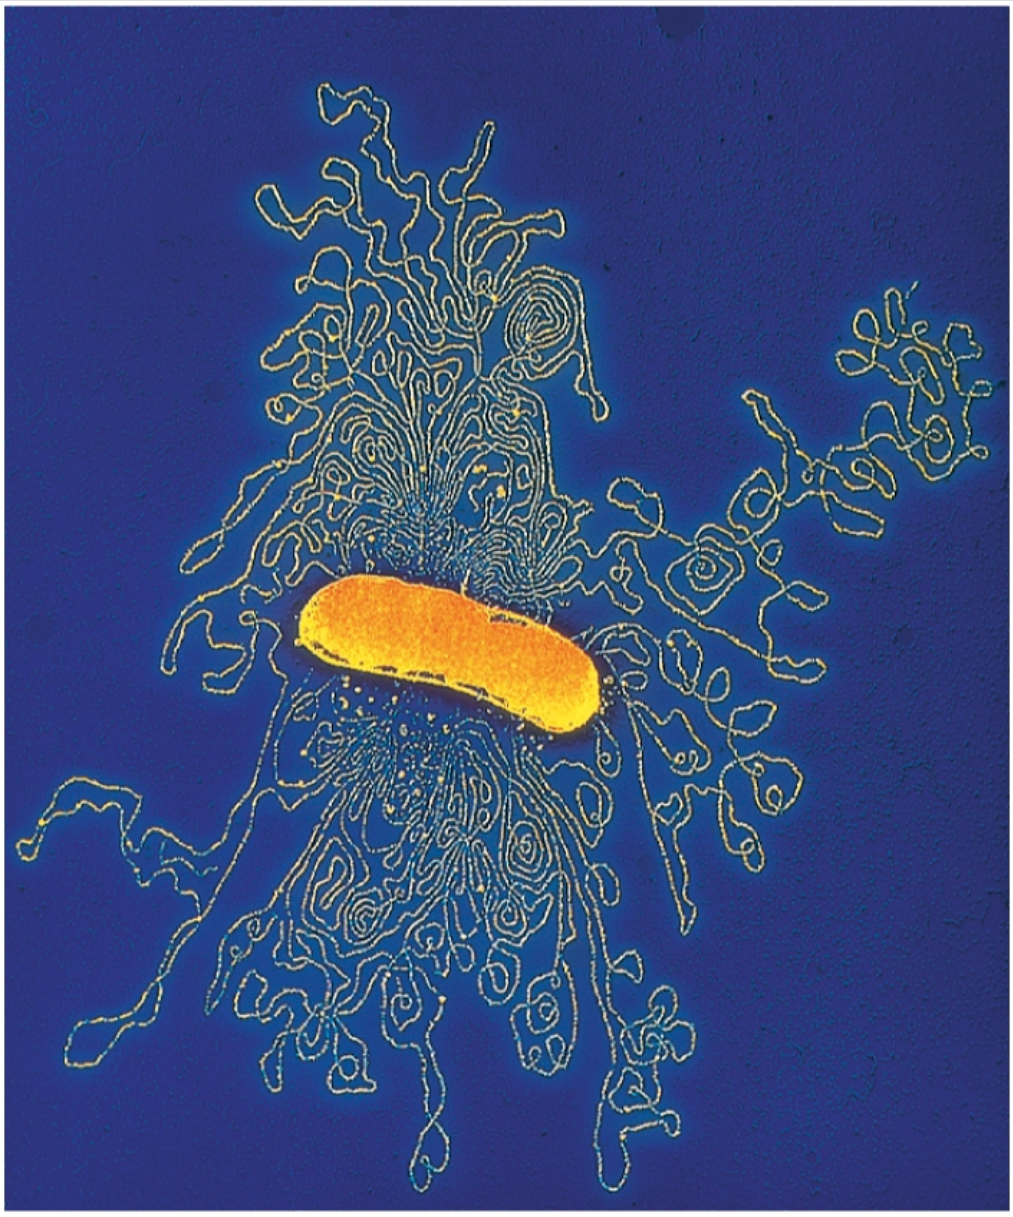


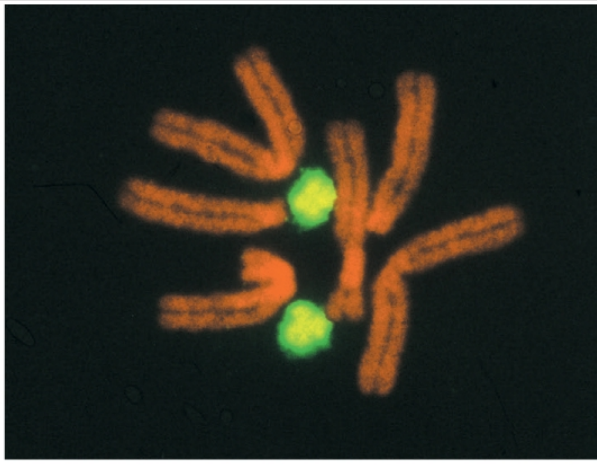
A nucleotide is a nucleoside joined to one or more phosphoryl groups by an ester linkage (Figure 8.5). Nucleoside triphosphates, nucleotides

containing three phosphoryl groups, are the precursors that form RNA and DNA. The four nucleotide units that comprise DNA are nucleoside monophosphates called *deoxyadenylate*, *deoxyguanylate*, *deoxycytidylate*, and *thymidylate*. Note that a pyrophosphate is released when the nucleotides are linked (Section 8.4). Similarly, the most common nucleotides found in RNA are nucleoside monophosphates: *adenylate*, *guanylate*, *cytidylate*, and *uridylate*.

A more precise nomenclature is commonly used to describe the number of phosphoryl groups and the site of attachment to carbon of the ribose. Consider the structure of ATP (Figure 8.5). This compound is formed by the attachment of a phosphoryl group to $C-5'$ of a nucleoside sugar (the most common site of phosphate esterification). In this naming system for nucleotides, the number of phosphoryl groups and the attachment site are designated. Hence, ATP is short for adenosine $5'$-triphosphate. ATP is tremendously important because, in addition to being a building block for RNA, it is the most commonly used energy currency. The energy released from cleavage of the triphosphate group is used to power many cellular processes (Chapter 15).

DNA molecules are very long and have directionality

A striking characteristic of naturally occurring DNA molecules is their length. A DNA molecule must comprise many nucleotides to carry the genetic information necessary for even the simplest organisms. For example, the DNA of a virus such as polyoma, which can cause cancer in certain organisms, consists of two paired strands of DNA, each 5100 nucleotides in length. The *E. coli* genome is a single DNA molecule consisting of two strands of 4.6 million nucleotides each (**Figure 8.6**).



Dr. Gopal Murti/Science Source

FIGURE 8.6 The *E. coli* genome is composed of two paired nucleic acid strands, each with more than 4.5 million nucleotides. As shown by this electron micrograph, the DNA must be tightly compacted in order to fit in such a small volume.

The DNA molecules of higher organisms can be much larger. The human genome comprises approximately 3 billion nucleotides in each strand of DNA, divided among 24 distinct molecules of DNA called

chromosomes (22 autosomal chromosomes plus the X and Y sex chromosomes) of different sizes. One of the largest known DNA molecules is found in the Indian muntjac, an Asiatic deer; its genome is nearly as large as the human genome but is distributed on only 3 chromosomes (**Figure 8.7**). The largest of these chromosomes has two strands of more than 1 billion nucleotides each. If such a DNA molecule could be fully extended, it would stretch more than 1 foot in length. Some plants contain even larger DNA molecules.

Feinberg, Simple purification of human chromosomes to homogeneity using muntjac hybrid cells, vol. 7, pp. 29–33, ©1994, Figure 2b. Permission conveyed through Copyright Clearance Center, Inc.

FIGURE 8.7 The Indian muntjac genome is about as large as a human's but is divided among three chromosome pairs. In cells from a female Indian muntjac (left), the three pairs of very lar chromosomes are stained orange in the right image. The image also shows a pair of human chromosomes (stained green) for comparison.

Note that, like a polypeptide (Section 2.3), a DNA chain has directionality, commonly called polarity. One end of the chain has a free $5'-OH$ group or a $5'-OH$ group attached to a phosphoryl group, and the other end has a free $3'-OH$ group, neither of which is linked to another nucleotide (**Figure 8.8**). When presenting very long sequences

of nucleotides, only the identity of the bases are written, given that these bases represent the genetic information. However, it is important to remember that even if only the bases are presented, the base sequence is written in the $5'$-to-$3'$ direction. Thus, ACG indicates that the unlinked $5'-OH$ group is on deoxyadenylate, whereas the unlinked $3'-OH$ group is on deoxyguanylate. Because of this polarity, ACG and GCA correspond to different compounds.

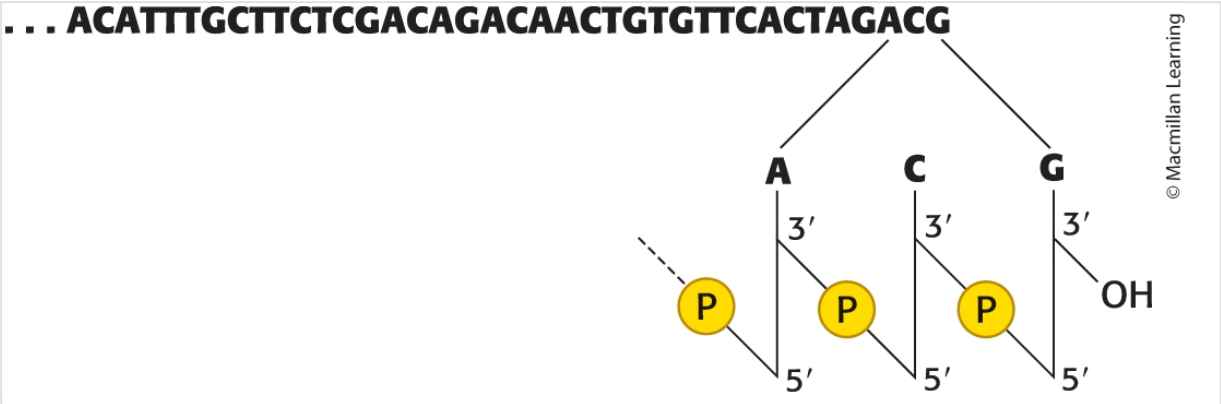


FIGURE 8.8 The structure of a nucleic acid strand can be simplified to the identity of its bases.

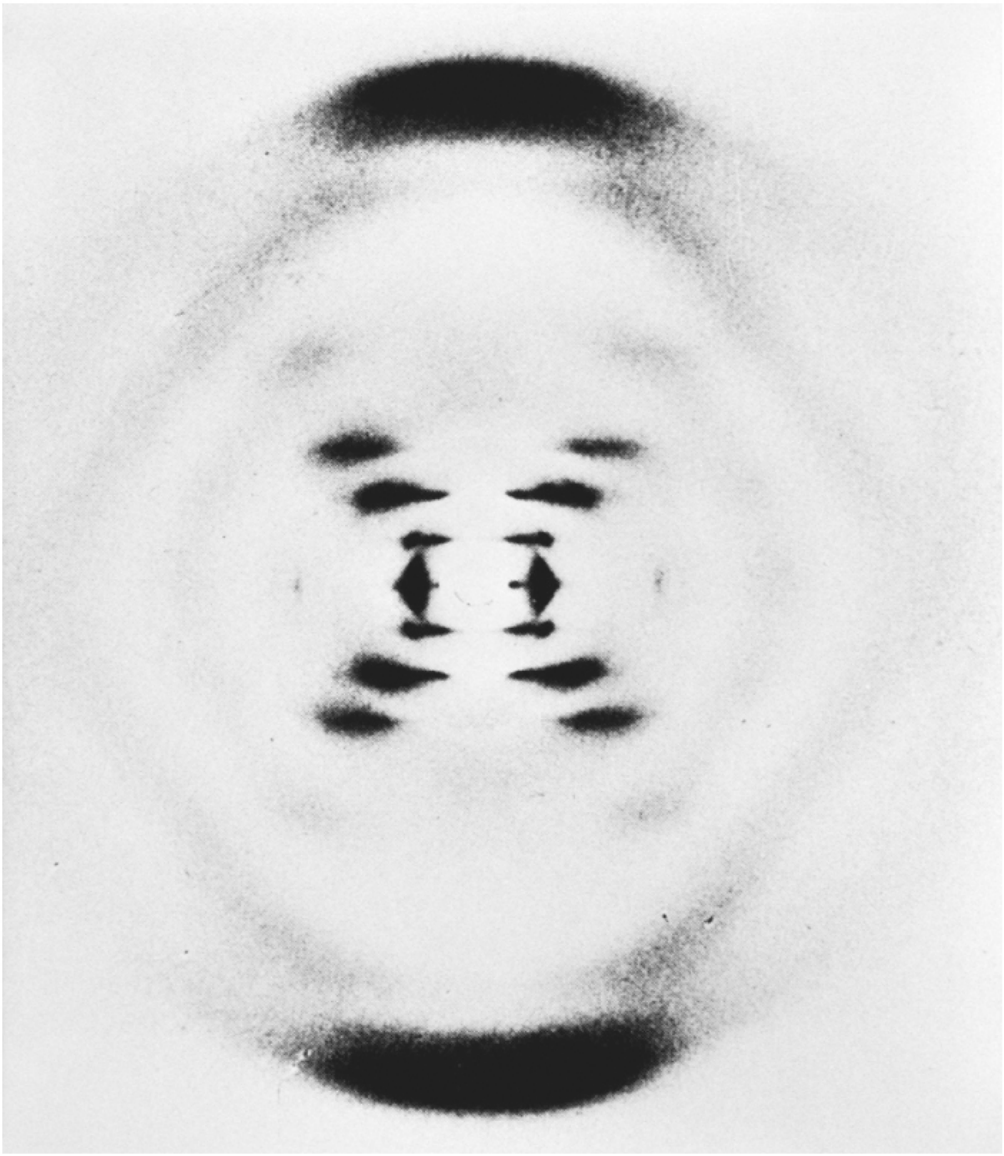
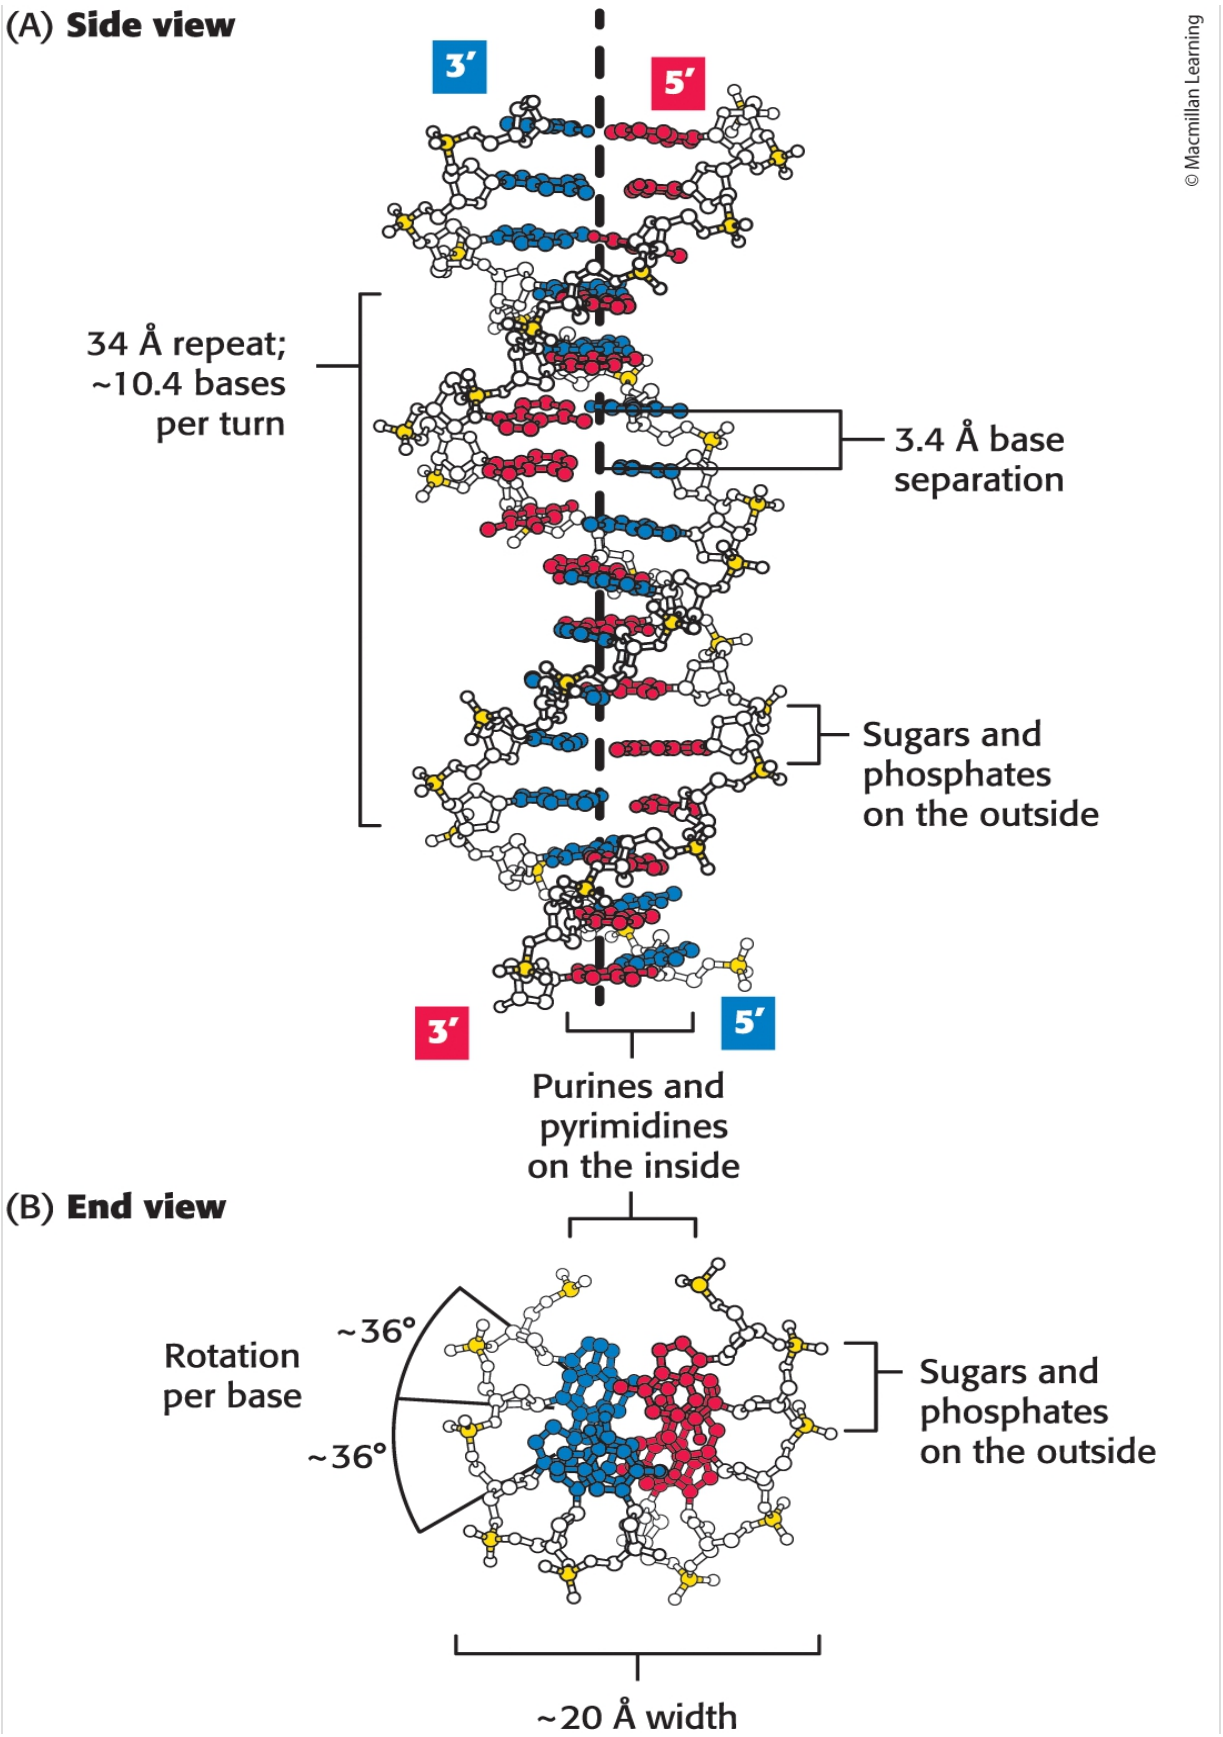


A simplified depiction of a nucleic acid (compare with Figure 8.3). The strand has a $5'$ end, which is usually attached to a phosphoryl group, and a $3'$ end, which is usually a free hydroxyl group.

8.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure

As discussed in Section 1.2, the covalent structure of nucleic acids accounts for their ability to carry information in the form of a sequence of bases along a nucleic acid strand. The bases on the two separate nucleic acid strands form specific base pairs in such a way that a helical structure is formed. The double-helical structure of DNA facilitates the replication of the genetic material — that is, the generation of two copies of a nucleic acid from one.



The double helix is stabilized by hydrogen bonds and van der Waals interactions

The ability of nucleic acids to form specific base pairs was discovered in the course of studies directed at determining the three-dimensional structure of DNA. Maurice Wilkins and Rosalind Franklin obtained x-ray diffraction photographs of fibers of DNA (**Figure 8.9**). The characteristics of these diffraction patterns indicated that DNA is formed of two strands that wind in a regular helical structure. From these data and others, James Watson and Francis Crick deduced a structural model for DNA that accounted for the diffraction pattern and was the source of some remarkable insights into the functional properties of nucleic acids (**Figure 8.10**).

Omikron/Science Source

FIGURE 8.9 The x-ray diffraction photograph of a hydrated DNA fiber provided experimental evidence of DNA's three-dimensional structure. When crystals of a biomolecule are irradiated with x-rays, the x-rays are diffracted, and these diffracted x-rays are seen as a series of spots, called reflections, on a screen behind the crystal. The structure of the molecule can be determined by the pattern of the reflections (Section 4.5). In regard to DNA crystals, the central cross is diagnostic of a helical structure. The strong arcs on the meridian arise from the stack of nucleotide bases, which are 3.4 Å apart.

© Macmillan Learning

FIGURE 8.10 The Watson–Crick model of double-helical DNA reveals critical structural features. In this figure, the bases of the individual strands are colored red and blue, while the phosphates are colored yellow. (A) The side view reveals that adjacent bases are separated by 3.4 Å. The structure repeats along the helical axis (vertical) at intervals of 34 Å, which corresponds to approximately 10 nucleotides on each chain. (B) The end view, looking down the helix axis, reveals a rotation of 36° per base and shows that the bases are stacked on top of one another.

[Drawn from 3BSE.pdb.]

The features of the Watson–Crick model of DNA deduced from the diffraction patterns are:

- Two helical polynucleotide strands are coiled around a common axis with a right-handed screw sense (Section 2.4). The strands are antiparallel, meaning that they have opposite directionality.
- The sugar–phosphate backbones are on the outside and the purine and pyrimidine bases lie on the inside of the helix.
- The bases are nearly perpendicular to the helix axis, and adjacent bases are separated by approximately 3.4 Å. The helical structure repeats on the order of every 34 Å, with about 10.4 bases per turn of helix. There is a rotation of nearly 36 degrees per base (360 degrees per full turn/10.4 bases per turn).
- The diameter of the helix is about 20 Å.

How is such a regular structure able to accommodate an arbitrary sequence of bases, given the different sizes and shapes of the purines and pyrimidines? In attempting to answer this question, Watson and Crick discovered that guanine can be paired with cytosine and adenine with thymine to form base pairs that have essentially the same shape (**Figure 8.11**). These base pairs are held

together by specific hydrogen bonds, which, although weak ($4\text{–}21\ \text{kJ mol}^{-1}$, or $1\text{–}5\ \text{kcal mol}^{-1}$), stabilize the helix because of their large numbers in a DNA molecule. These base-pairing rules account for the observation originally made by biochemist Erwin Chargaff in the 1940s — and subsequently referred to as *Chargaff's rules* — that the ratios of adenine to thymine and of guanine to cytosine are nearly the same in all species studied, whereas the adenine-to-guanine ratio varies considerably (**Table 8.1**).

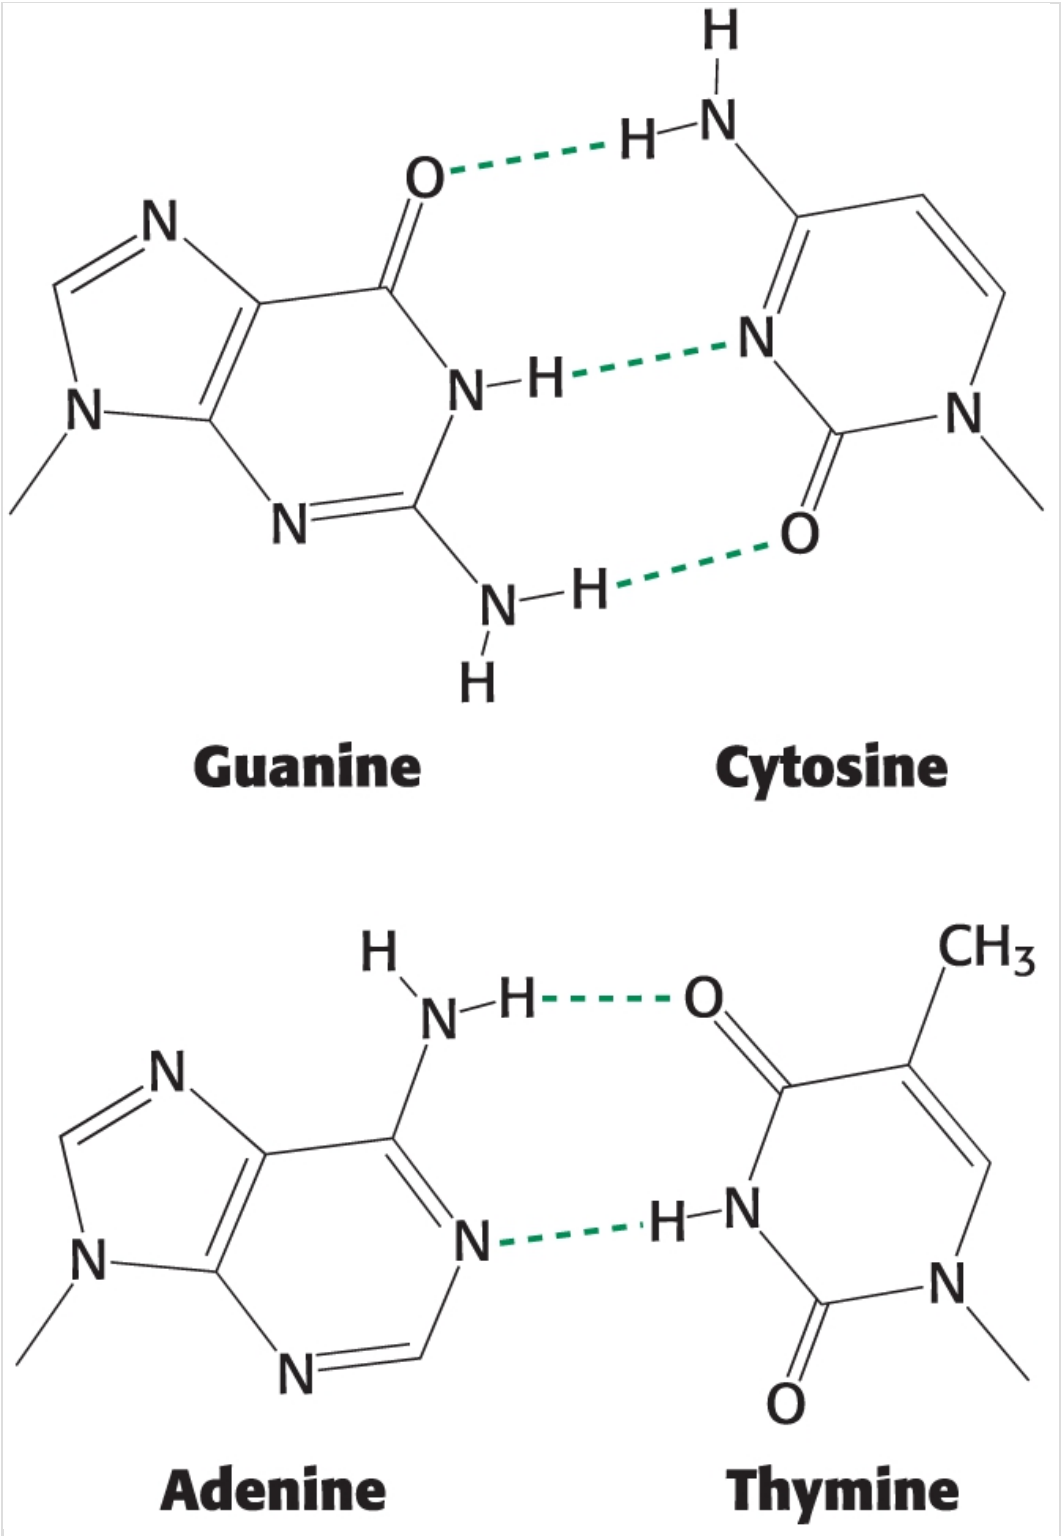


FIGURE 8.11 Watson and Crick proposed two base pairs. In their model, guanine paired with cytosine and adenine paired with thymine.

TABLE 8.1 Base compositions experimentally determined for a variety of organisms

Organism	A : T	G : C	A : G
Human being	1.00	1.00	1.56
Salmon	1.02	1.02	1.43
Wheat	1.00	0.97	1.22
Yeast	1.03	1.02	1.67
Escherichia coli	1.09	0.99	1.05
Serratia marcescens	0.95	0.86	0.70

Inside the helix, the bases are essentially stacked one on top of another (Figure 8.10B). Recall from Section 1.3 that the stacking of base pairs contributes to the stability of the double helix in two ways:

- *The formation of the double helix is facilitated by the hydrophobic effect.* The hydrophobic bases cluster in the interior of the helix away from the surrounding water, whereas the more polar surfaces are exposed to water. This arrangement is reminiscent of protein folding, where hydrophobic amino acids are in the protein's interior and the hydrophilic amino acids are on the exterior (Section 2.5).

- *The stacked base pairs attract one another through van der Waals forces.* These forces, appropriately referred to as *stacking forces*, further contribute to stabilization of the helix (**Figure 8.12**). The energy associated with a single van der Waals interaction is quite small, typically from 2 to $4\ \text{kJ mol}^{-1}$ $(0.5\text{–}1.0\ \text{kcal mol}^{-1})$. In the double helix, however, a large number of atoms are in van der Waals contact, and the net effect, summed over these atom pairs, is substantial. In addition, base stacking in DNA is favored by the conformations of the somewhat rigid five-membered rings of the backbone sugars.

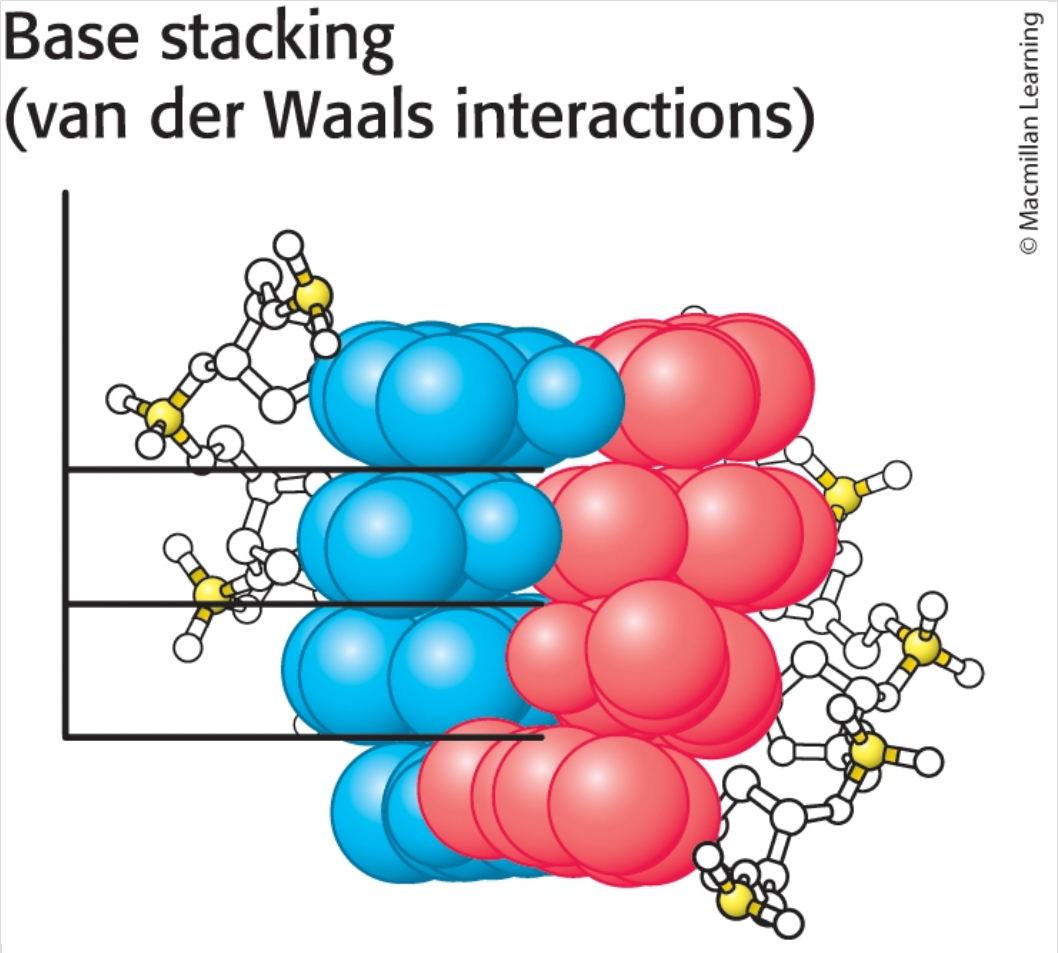

FIGURE 8.12 A side view of DNA reveals the stacking of base pairs within the double helix. The stacked bases interact via van der Waals forces. Such stacking

forces help stabilize the double helix.

Self-Check Question

DNA in the form of a double helix must be associated with cations, usually Mg^{2+}. Why is this requirement the case?

DNA can assume a variety of structural forms

Watson and Crick based their model on x-ray diffraction patterns of highly hydrated DNA fibers, which provided information about properties of the double helix that are averaged over its constituent residues. It is now known that DNA helices can take different forms under different conditions.

Under physiological conditions, most DNA is in the form that Watson and Crick modeled. This form, called *B-DNA*, is a right-handed double helix made up of antiparallel strands held together by Watson–Crick base-pairing. X-ray diffraction studies of less-hydrated DNA fibers have revealed a different form called *A-DNA*. Like B-DNA, A-DNA is a right-handed double helix made up of antiparallel strands held together by Watson–Crick base-pairing.

The A-form helix is wider and shorter than the B-form helix, and its base pairs are tilted rather than perpendicular to the helix axis (Figure 8.13).

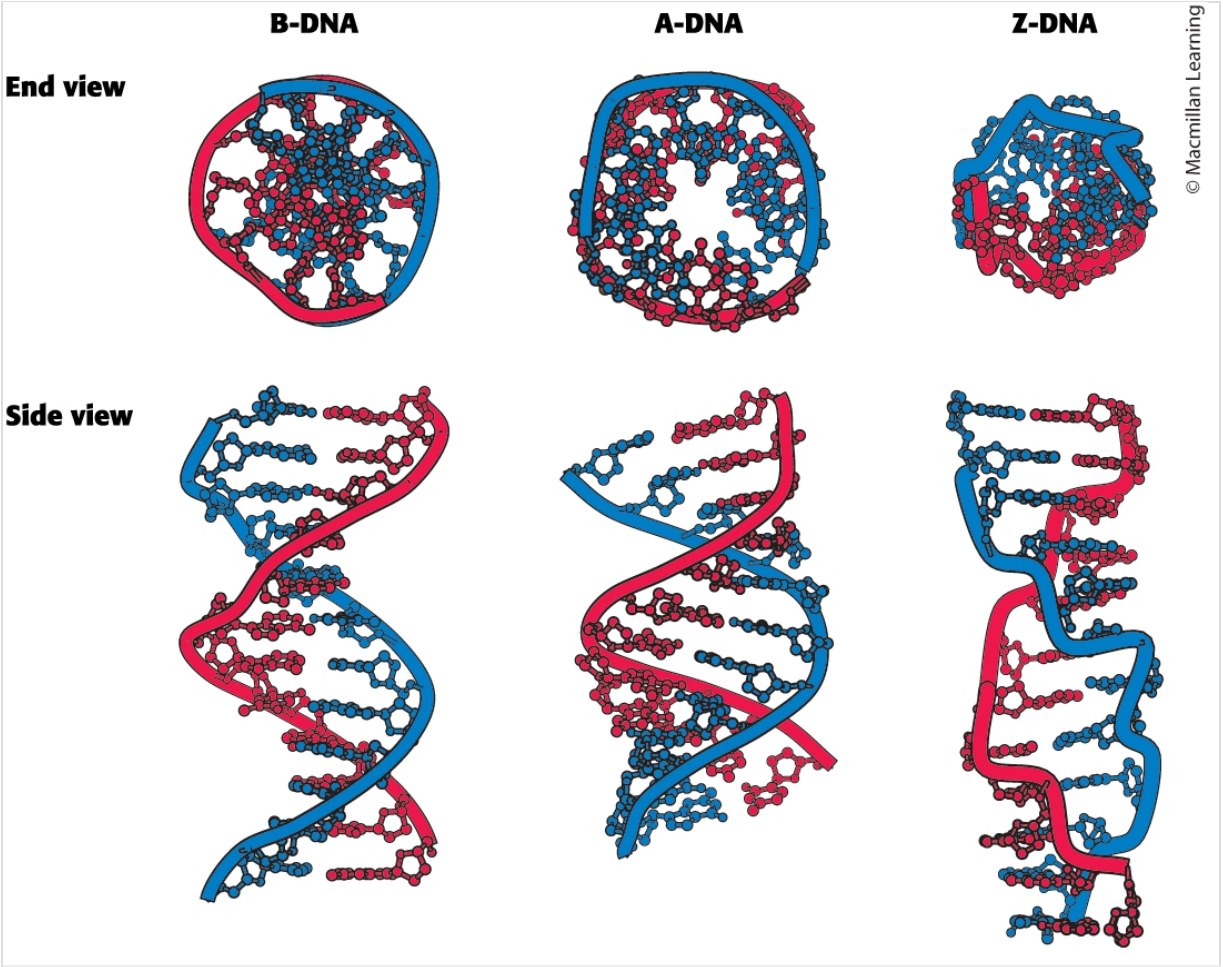

FIGURE 8.13 DNA can adopt different structural forms. Models of B-form and A-form DNA depict their right-handed helical structures. The B-form helix is longer and narrower than the A-form helix. Z-DNA is a left-handed helix in which the phosphoryl groups zigzag along the backbone.

[Drawn from 3BSE.pdb, 3V9D.pdb, and 4OCB.pdb.]

INTERACT with these models Achieve

If the A-form helix were simply a property of dehydrated DNA, it would be of little significance. However, double-stranded regions of RNA and at least some RNA–DNA hybrids adopt a double-helical form very similar to that of A-DNA. What is the biochemical basis for differences between the two forms of DNA? Many of the structural differences between B-DNA and A-DNA arise from different puckerings of their ribose units (Figure 8.14). In A-DNA, C–3′ lies out of the plane (a conformation referred to as C–3′ *endo*) formed by the other four atoms of the ring; in B-DNA, C–2′ lies out of the plane (a conformation called C–2′ *endo*). The C–3′-endo puckering in A-DNA leads to an 11-degree tilting of the base pairs away from being perpendicular to the helix.

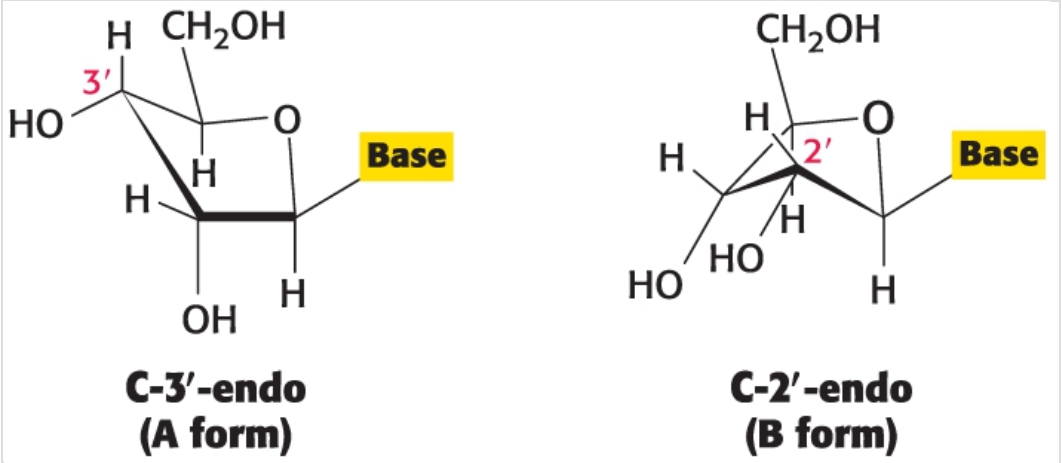

FIGURE 8.14 Sugar pucker explains many of the structural differences between the B-form and A-form of DNA. In A-form DNA, the C–3′ carbon atom lies above the approximate plane defined by the four other sugar nonhydrogen atoms (called C–3′ endo). In B-form DNA, each deoxyribose is in a C–2′-endo conformation, in which C–2′ lies out of the plane.

RNA helices are further induced to take the A-DNA form because of steric hindrance from the $2'$-hydroxyl group: the $2'$-oxygen atom would be too close to three atoms of the adjoining phosphoryl group and to one atom in the next base. In an A-form helix, in contrast, the $2'$-oxygen atom projects outward, away from other atoms. The phosphoryl and other groups in the A-form helix bind fewer H_2O molecules than do those in B-DNA. Hence, dehydration favors the A form.

A third type of double helix is left-handed, in contrast with the right-handed screw sense of the A and B helices. Furthermore, the phosphoryl groups in the backbone are zigzagged; hence, this form of DNA is called *Z-DNA* (Figure 8.13). Although the biological role of Z-DNA is still under investigation, Z-DNA-binding proteins have been isolated, one of which is required for viral pathogenesis of poxviruses, including variola, the agent of smallpox. The existence of Z-DNA shows that DNA is a flexible, dynamic molecule whose parameters are not as fixed as depictions suggest. The properties of B-, A-, and Z-DNA are compared in **Table 8.2**.

TABLE 8.2 Comparison of B-, A-, and Z-DNA

	B	A	Z
Shape	Intermediate	Broadest	Narrowest
Rise per base pair	3.4 Å	2.3 Å	3.8 Å

Helix diameter	~20 Å	~26 Å	~18 Å
Screw sense	Right-handed	Right-handed	Left-handed
Glycosidic bond*	*anti*	*anti*	Alternating *anti* and *syn*
Base pairs per turn of helix	10.4	11	12
Pitch per turn of helix	35.4 Å	25.3 Å	45.6 Å
Tilt of base pairs from perpendicular to helix axis	1 degree	19 degrees	9 degrees

**Syn* and *anti* refer to the orientation of the *N*-glycosidic bond between the base and deoxyribose. In the *anti* orientation, the base extends away from the deoxyribose. In the *syn* orientation, the base is above the deoxyribose. Pyrimidines can be in *anti* orientations only, whereas purines can be *anti* or *syn*.

The major and minor grooves are lined by sequence-specific hydrogen-bonding groups

An examination of the DNA molecule in the B form, as shown in Figure 8.13, reveals the presence of two distinct grooves, called the major groove and the minor groove. These grooves arise because the glycosidic bonds of a base pair are not diametrically opposite each other (**Figure 8.15A**). In B-DNA, the major groove is wider (12 Å versus 6 Å) and deeper (8.5 Å versus 7.5 Å) than the minor groove (**Figure 8.15B**).

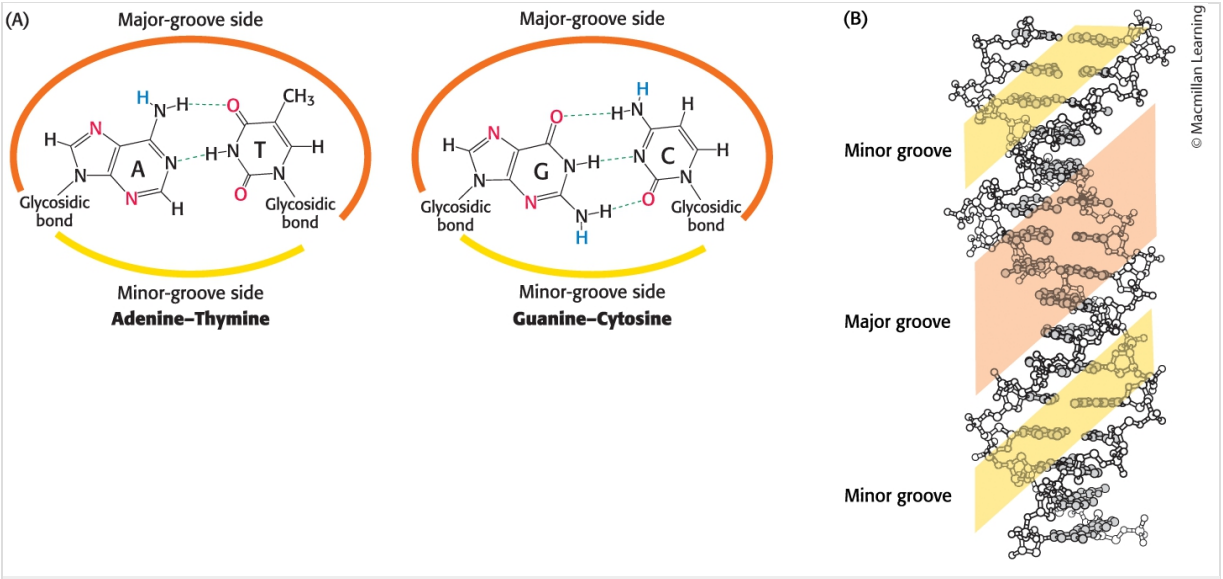

FIGURE 8.15 The DNA double helix features a major and a minor groove. (A) Because the two glycosidic bonds are not directly opposite each other, each base pair has a larger side that defines the major groove and a smaller side that defines the minor groove. The grooves are lined by potential hydrogen-bond donors (blue) and acceptors (red). (B) In a side view of the double helix, the major (orange) and the minor (yellow) grooves alternate with each other.

Each groove is lined by potential hydrogen-bond donor and acceptor atoms that enable interactions with proteins. These interactions are essential for replication and transcription because particular proteins bind to DNA, recognizing specific hydrogen-bond donors and acceptors on the surfaces of the grooves, to catalyze these processes (Chapters 28, 29, and 31).

In the minor groove, N-3 of adenine or guanine and O-2 of thymine or cytosine can serve as hydrogen acceptors, and the amino group attached to C-2 of guanine can be a hydrogen donor. In the major groove, N-7 of guanine or adenine is a potential acceptor, as are O-4 of thymine and O-6 of guanine. The amino groups attached to C-6 of adenine and C-4 of cytosine can serve as hydrogen donors. The

methyl group of thymine also lies in the major groove. Note that the major groove displays more features that distinguish one base pair from another than does the minor groove. The larger size of the major groove in B-DNA makes it more accessible for interactions with proteins that recognize specific DNA sequences.

Some DNA molecules are circular and supercoiled

The DNA molecules in human chromosomes are linear. However, electron microscopic and other studies have shown that intact DNA molecules from bacteria and archaea are circular (**Figure 8.16A**). DNA molecules inside cells necessarily have a very compact shape. Note that the *E. coli* chromosome, fully extended, would be about 1000 times as long as the greatest diameter of the bacterium.

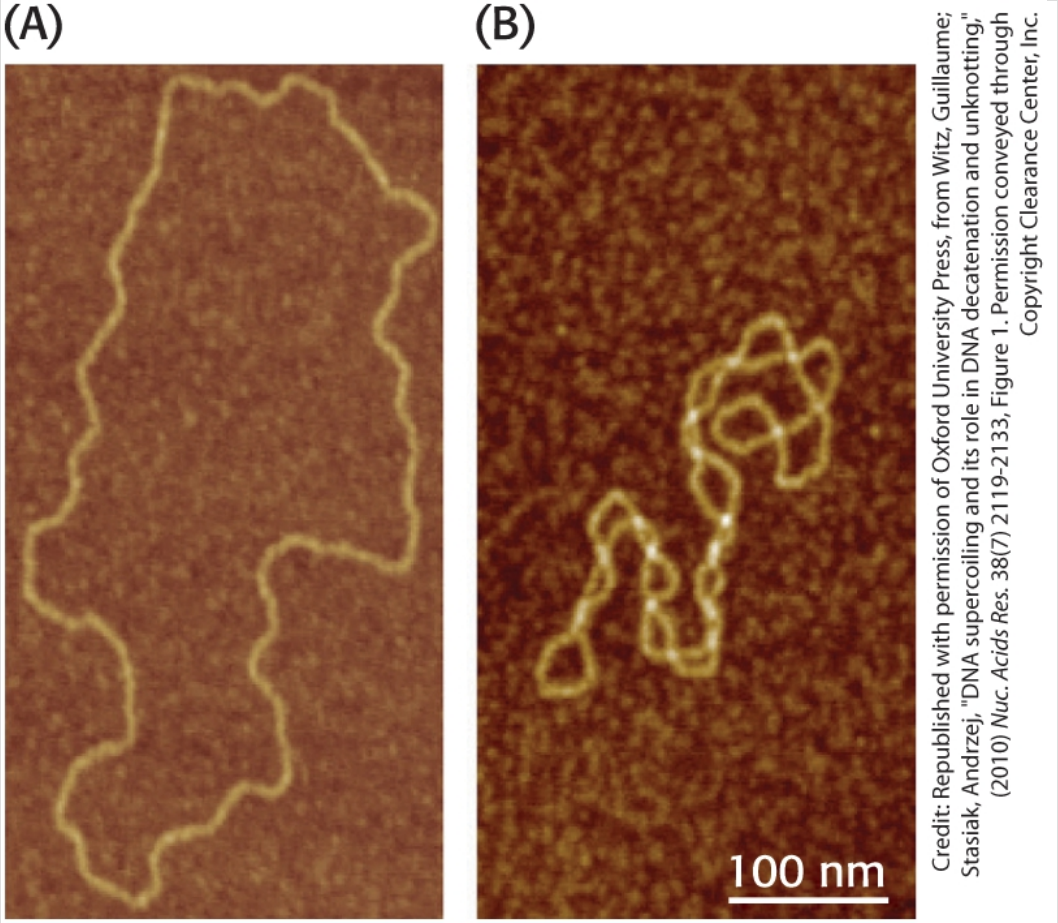

FIGURE 8.16 Atomic force microscopy of circular DNA from bacteria reveals both relaxed and supercoiled forms. (A) Relaxed form. (B) Supercoiled form

A closed DNA molecule has a property unique to circular DNA. The axis of the double helix can itself be twisted into a *superhelix*, where the helix is wound about itself, in a process known as *supercoiling* (**Figure 8.16B**). A circular DNA molecule without any superhelical turns is known as a *relaxed molecule*. Supercoiling is biologically important for two reasons that will be considered further in Chapter 28:

- A supercoiled DNA molecule is more compact than its relaxed counterpart.
- Supercoiling may hinder or favor the capacity of the double helix to unwind and thereby affect the interactions between DNA and other molecules.

Single-stranded nucleic acids can adopt elaborate structures

Single-stranded nucleic acids often fold back on themselves to form well-defined structures. Such structures are especially prominent in RNA and RNA-containing complexes such as the ribosome — a large complex of RNAs and proteins on which proteins are synthesized.

The simplest and most-common structural motif formed is a **stem-loop**, created when two complementary sequences within a single strand come together to form double-helical structures (**Figure 8.17**). In many cases, these double helices are made up entirely of Watson–Crick base pairs. In other cases, however, the structures include mismatched base pairs or unmatched bases that bulge out from the helix. Such mismatches destabilize the local structure but introduce deviations from the standard double-helical structure that can be important for higher-order folding and for function (**Figure 8.18**).

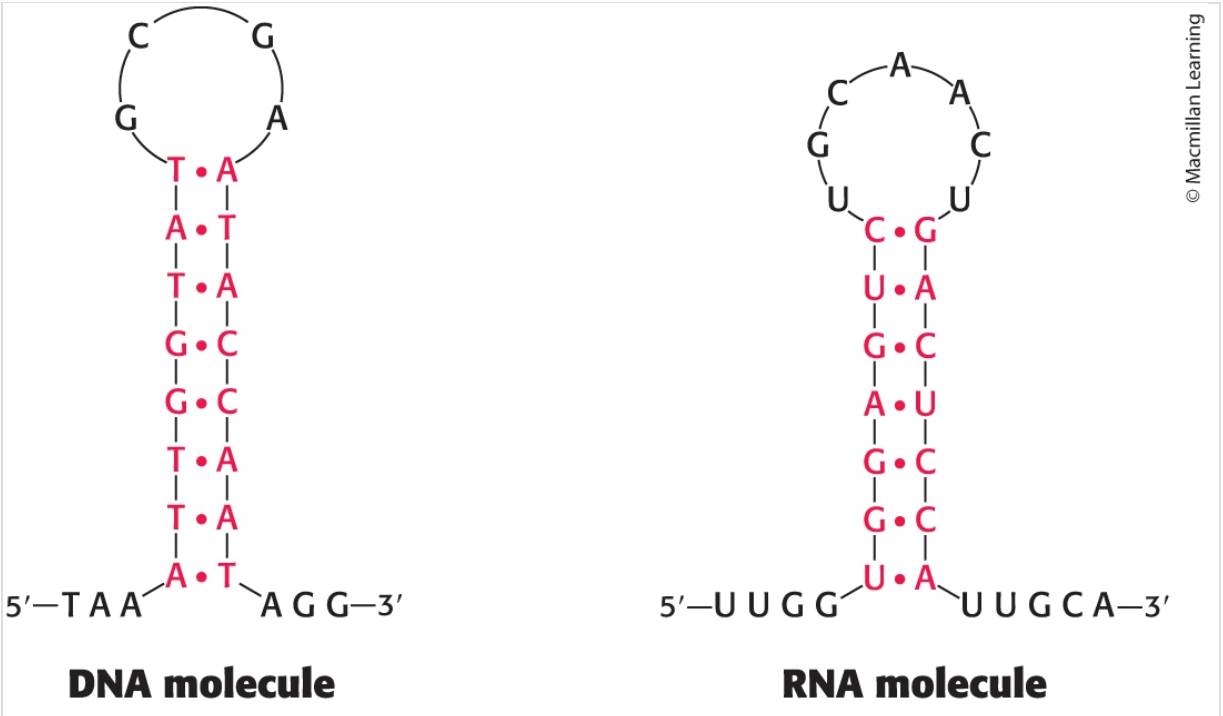

FIGURE 8.17 Stem-loop structures can be formed from single-stranded DNA and RNA molecules.

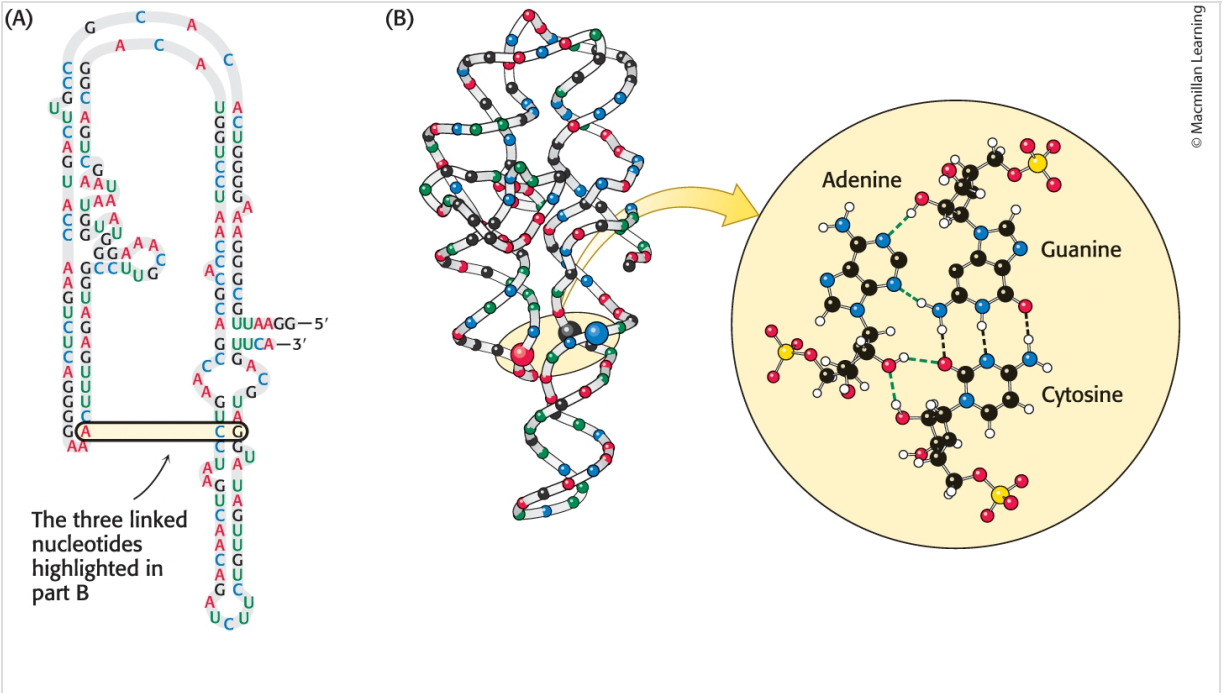

FIGURE 8.18 RNA molecules can adopt complex structures. In this example, a single-stranded RNA molecule folds back on itself. (A) The nucleotide sequence shows Watson–Crick base pairs and other nonstandard base pairings in stem-loop structures. (B) In the three-dimensional structure at the left, cytidine nucleotides are shown in blue, adenosine in red, guanosine in black, and uridine in green. The detailed projection at the right shows an important long-range interaction between three of the bases. Hydrogen bonds within the Watson–Crick base pair are shown as dashed black lines; additional hydrogen bonds are shown as dashed green lines.

Single-stranded nucleic acids can adopt complex structures through the interaction of more widely separated bases. Often, three or more bases interact to stabilize these structures. In such cases, hydrogen-bond donors and acceptors that do not participate in Watson–Crick base pairs participate in hydrogen bonds to form nonstandard pairings (Figure 8.18B). Metal ions such as magnesium ion (Mg^{2+}) often assist in the stabilization of these more elaborate structures. These complex structures allow RNA to perform a host of functions that the double-stranded DNA molecule cannot. Indeed, the complexity of some RNA molecules rivals that of proteins, and these RNA molecules perform a number of functions that had formerly been thought the exclusive domain of proteins.

8.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information

The double-helical model of DNA proposed by Watson and Crick, and in particular the specific base pairing of adenine with thymine and guanine with cytosine, immediately suggested to them how the genetic material might replicate: The sequence of bases of one strand of the double helix precisely determines the sequence of the other strand. A guanine on one strand is always paired with a cytosine on the other strand, and so on. Thus, separation of a double helix into its two component strands would yield two single-stranded templates onto which new double helices could be constructed, each of which would have the same sequence of bases as the parent double helix. The hypothesis was that as DNA is replicated, one of the strands of each daughter DNA molecule is newly synthesized, whereas the other is passed unchanged from the parent DNA molecule. This distribution of parental atoms is called **semiconservative replication**.

Differences in DNA density established the validity of the semiconservative replication hypothesis

Matthew Meselson and Franklin Stahl carried out a critical test of this hypothesis in 1958. They labeled the parent DNA with ^{15}N, a heavy isotope of nitrogen, to make it denser than ordinary DNA. The labeled DNA was generated by growing *E. coli* for many generations in a medium that contained $^{15}NH_4Cl$ as the sole nitrogen source. After the

incorporation of heavy nitrogen was complete, the bacteria were abruptly transferred to a medium that contained only ^{14}N, the ordinary isotope of nitrogen. The question asked was: What is the distribution of ^{14}N and ^{15}N in the DNA molecules after successive rounds of replication?

The distribution of ^{14}N and ^{15}N was revealed by the technique of density-gradient equilibrium sedimentation. A small amount of the *E. coli* DNA was dissolved in a concentrated solution of cesium chloride. This solution was centrifuged until it was nearly at equilibrium. At that point, the opposing processes of sedimentation and diffusion created a stable density gradient in the concentration of cesium chloride across the sample. The DNA molecules in this density gradient were driven by centrifugal force into the region where the solution's density was equal to their own. The DNA yielded a narrow band or bands that were detected by absorption of ultraviolet light by the DNA. A mixture of ^{14}N DNA and ^{15}N DNA molecules gave clearly separate bands because they differ in density by about 1% (**Figure 8.19**).

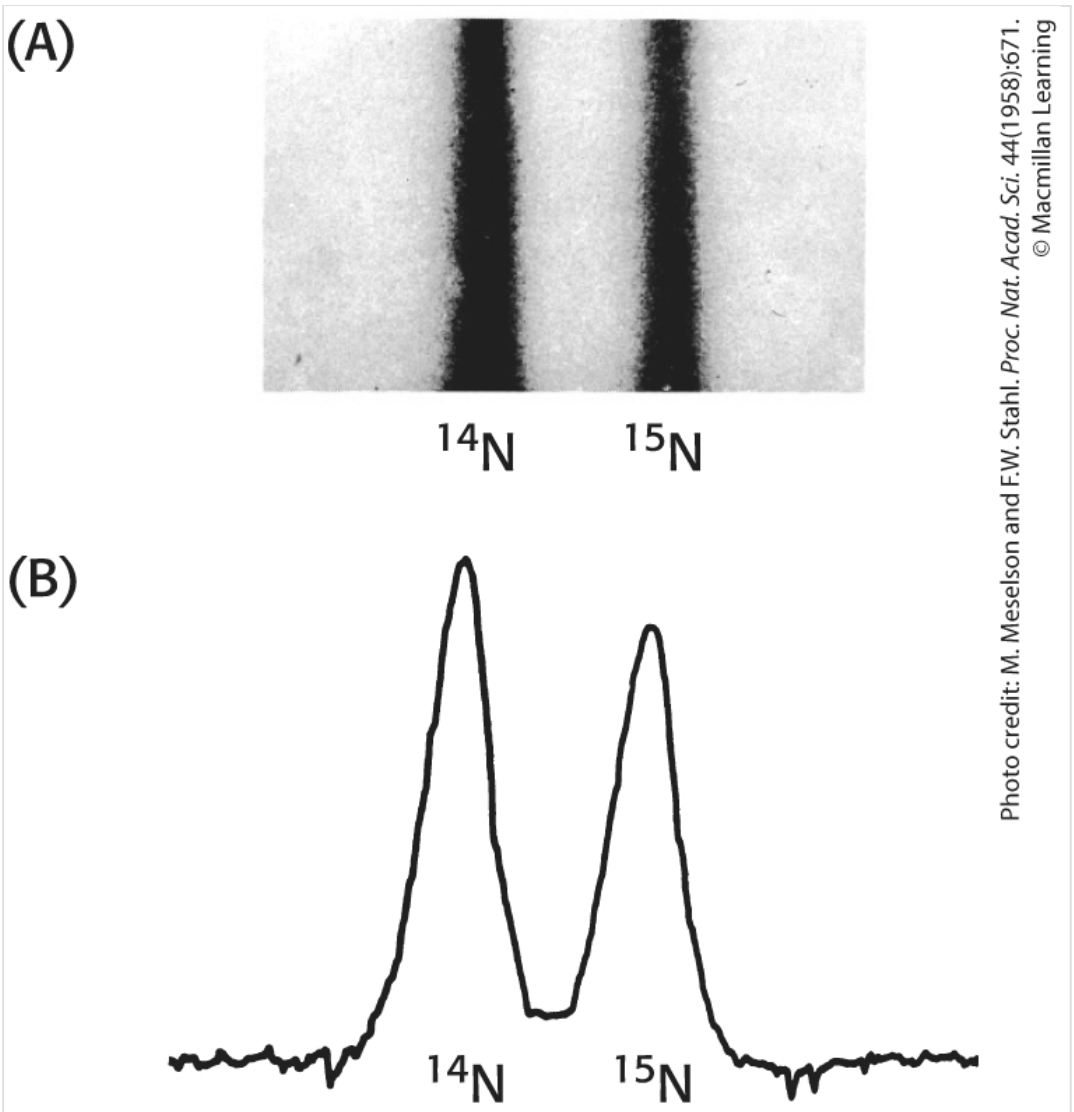

FIGURE 8.19 Meselson and Stahl resolved ^{14}N DNA and ^{15}N DNA by density-gradient centrifugation. (A) An ultraviolet-absorption photograph of a special centrifuged tube shows the two distinct bands of DNA. (B) Densitometric tracing of the absorption photograph.

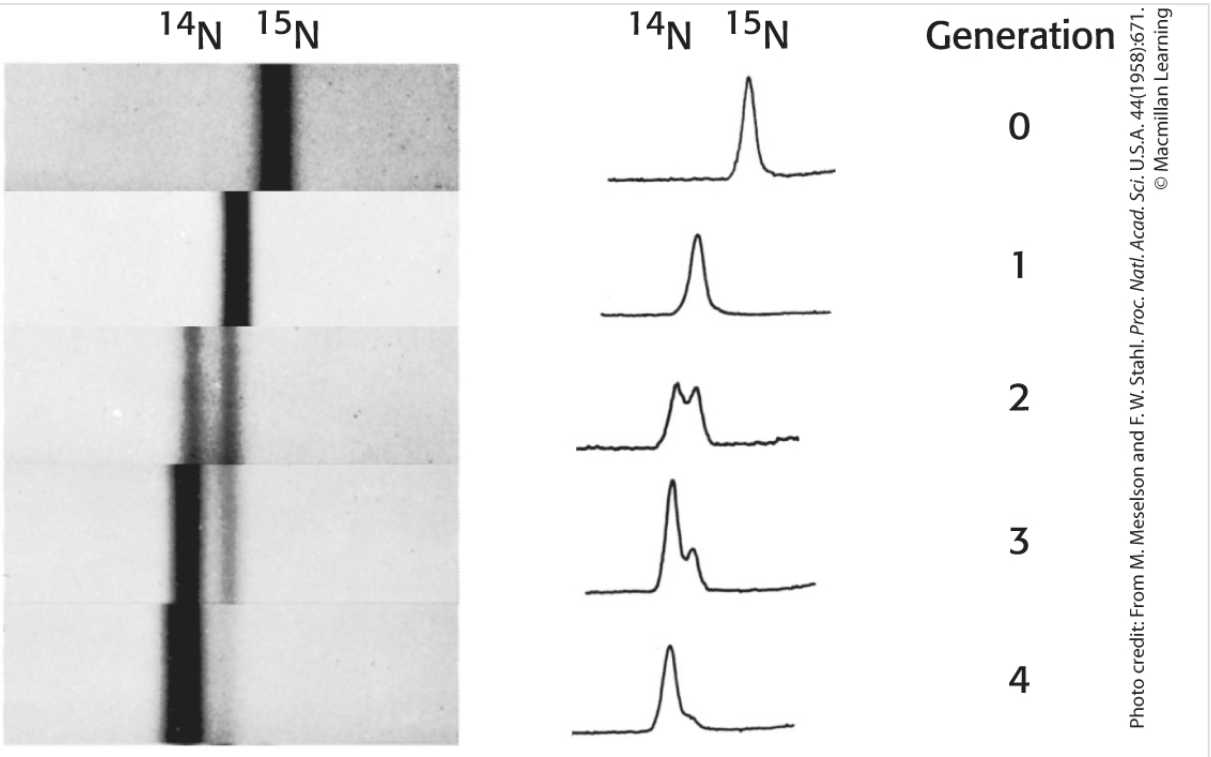
In their experiment, Meselson and Stahl extracted DNA from the bacteria at various times after the bacteria were transferred from ^{15}N-containing to ^{14}N-containing medium and subjected the samples to

density-gradient equilibrium sedimentation. Figure 8.20 shows that all of the DNA is labeled with ^{15}N at the start of the experiment (generation 0). After one generation, all of the DNA is still in a single band, but the band has shifted. The density of this band (called *hybrid DNA*) is precisely halfway between the densities of the ^{14}N DNA and ^{15}N DNA bands. After two generations, there are equal amounts of two bands of DNA. One is hybrid DNA, and the other is ^{14}N DNA. After three rounds of replication, the positions of the two bands remain unchanged, but there is three times the amount of ^{14}N DNA as there is hybrid DNA.



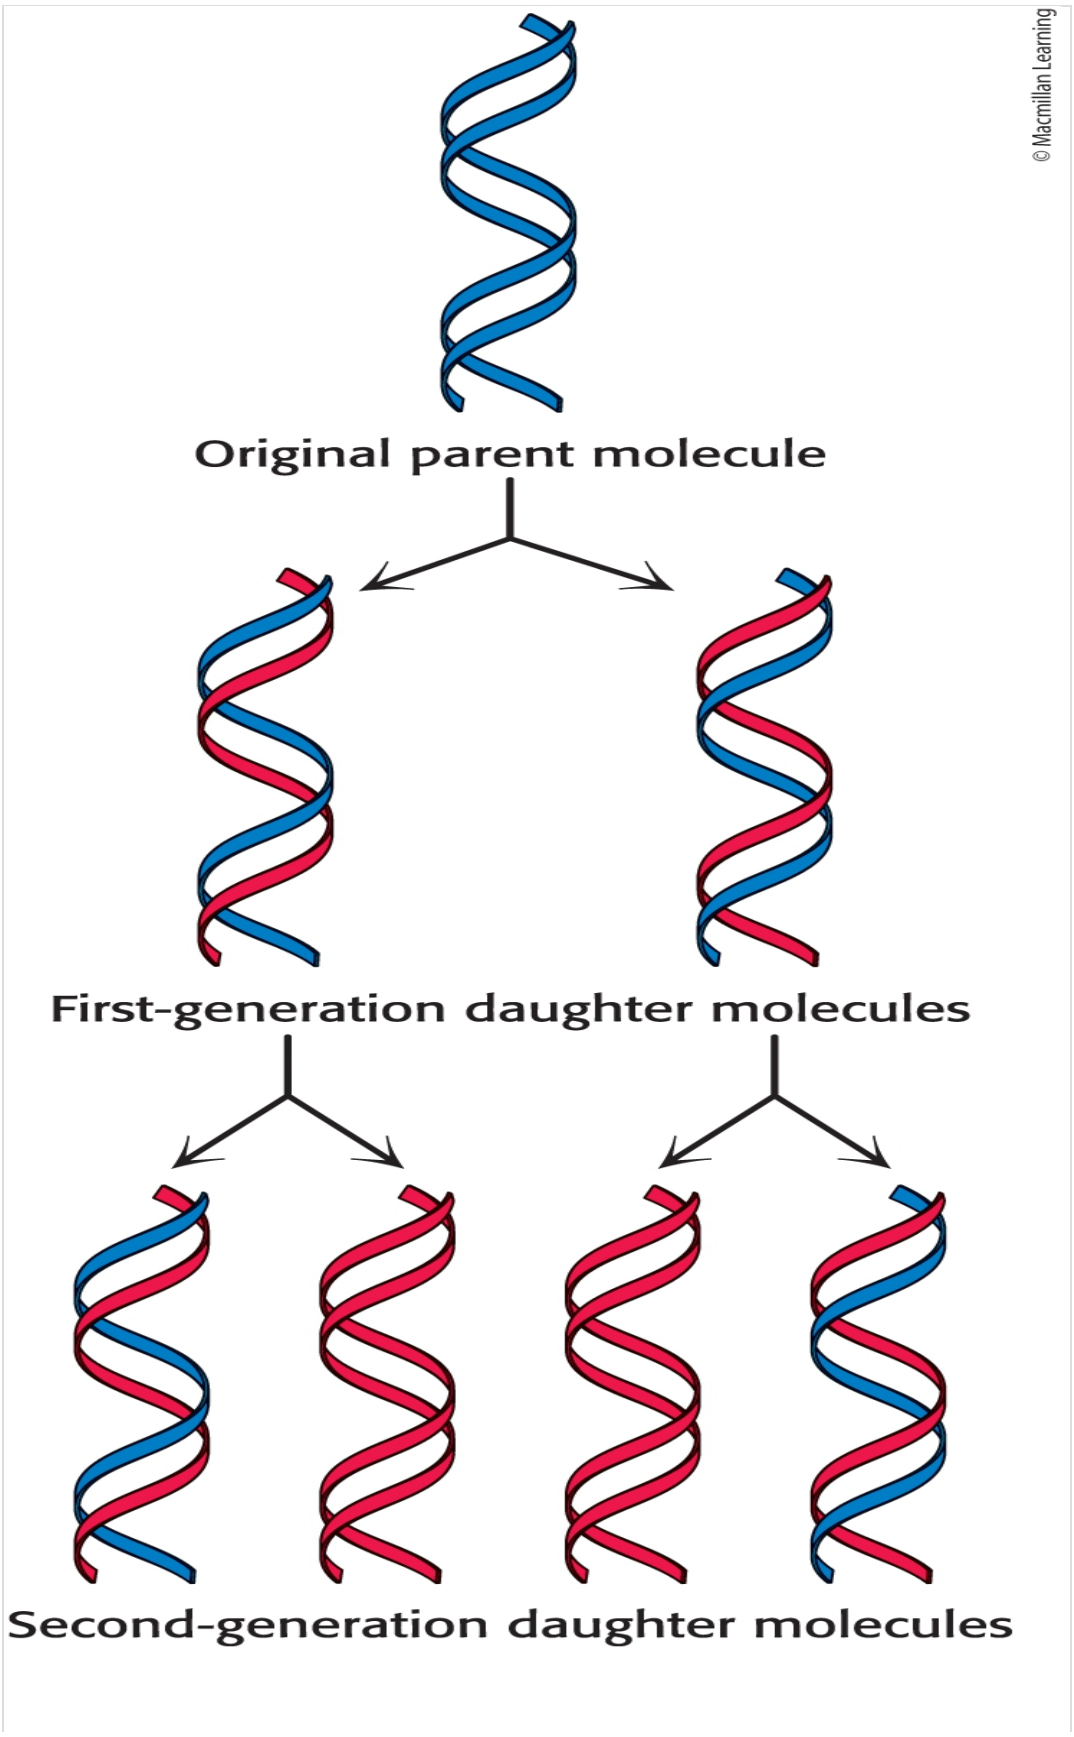


FIGURE 8.20 Semiconservative replication of *E. coli* DNA was detected by density-gradient centrifugation after incubation over several generations. The position of a band of DNA depends on its content of ^{14}N and ^{15}N.

The absence of ^{15}N DNA indicated that parental DNA was not preserved as an intact unit after replication. The absence of ^{14}N DNA in generation 1 indicated that all of the daughter DNA derived some of their atoms from the parent DNA. Additionally, the proportion of atoms derived from the parent had to be half because the density of the hybrid DNA band was halfway between the densities of the ^{14}N DNA and ^{15}N DNA bands.

Meselson and Stahl concluded from these incisive experiments that replication was indeed semiconservative: each new double helix contains a parent strand and a newly synthesized strand. Their results agreed perfectly with the Watson–Crick model for DNA replication (**Figure 8.21**).

The double helix can be reversibly melted

During DNA replication and transcription, the two strands of the double helix must be separated from each other, at least in a local region. The two strands of a DNA helix readily come apart when the hydrogen bonds between base pairs are disrupted. In the laboratory, the double helix can be disrupted by heating a solution of DNA or by adding acid or alkali to ionize its bases.

The dissociation of the double helix is called *melting* because it occurs abruptly at a certain temperature. The **melting temperature** (T_m) of DNA is defined as the temperature at which half the helical structure is lost. Inside cells, however, the double helix is not melted by the addition of heat. Instead, proteins called *helicases* use chemical energy (from ATP) to disrupt the helix (Chapter 29).

Stacked bases in nucleic acids absorb less ultraviolet light at a wavelength of 260 nm than do unstacked bases, an effect called *hypochromism* (**Figure 8.22A**). Thus, as a sample of DNA is heated, the strands separate, increasing the proportion of single-stranded DNA, which is monitored by measuring the increase in absorption of 260 nm light (**Figure 8.22B**).

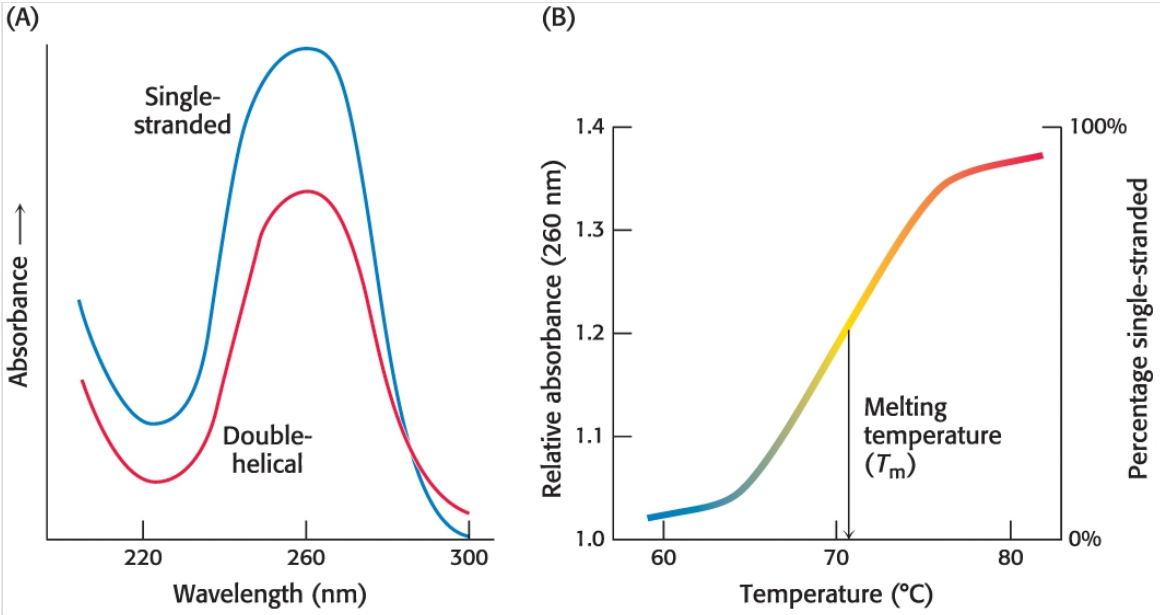

FIGURE 8.22 Single-stranded DNA absorbs light more effectively than does double-helical DNA. (A) The absorbance spectrum of similar quantities of single-stranded and double-helical DNA reveals a lower peak at around 260 nm for the double-helical sample. (B) The absorbance o a DNA solution at a wavelength of 260 nm increases when the double helix is melted into single strands.

Separated complementary strands of nucleic acids spontaneously reassociate to form a double helix when the temperature is lowered below T_m. This renaturation process is called *annealing*. The facility with which double helices can be melted and then reassociated is crucial for the biological functions of nucleic acids. The ability to melt and reanneal DNA reversibly in the laboratory provides a powerful tool for investigating sequence similarity. We will return to this important technique in Chapter 9.

Self-Check Question

In general, the greater the percentage of GC base pairs within a region of DNA, the higher the melting temperature. **(a)** What are the chemical forces that stabilize the double helix? **(b)** Based on your answers to (a), what are some possible explanations for the relationship between GC content and T_m?

8.4 DNA Is Replicated by Polymerases That Take Instructions from Templates

We now turn to the molecular mechanism of DNA replication. The full replication machinery in a cell comprises more than 20 proteins engaged in intricate and coordinated interplay. The primary catalytic components of the replication machinery are enzymes, called *DNA polymerases*, that promote the formation of the bonds joining units of the DNA backbone. *E. coli* has a number of DNA polymerases that participate in DNA replication and repair (Chapter 28).

DNA polymerase catalyzes phosphodiester-bridge formation

DNA polymerases catalyze the step-by-step addition of deoxyribonucleotide units to a DNA strand (**Figure 8.23**). The reaction catalyzed, in its simplest form, is

$$(\mathrm{DNA})_n + \mathrm{dNTP} \rightleftharpoons (\mathrm{DNA})_{n+1} + \mathrm{PP_i}$$

where dNTP stands for any deoxyribonucleotide and $\mathrm{PP_i}$ is a pyrophosphate ion.

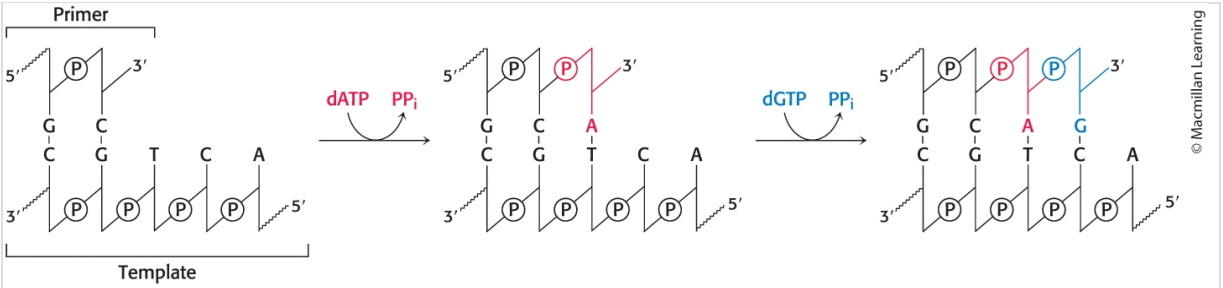

FIGURE 8.23 DNA polymerase catalyzes the polymerization reaction using nucleotide 5′-triphosphates as substrates. The reaction requires a preexisting DNA template and a primer with a free $3'-OH$ group.

DNA synthesis has the following characteristics:

- *The reaction requires all four activated precursors* — that is, the deoxynucleoside $5'$-triphosphates dATP, dGTP, dCTP, and TTP — as well as Mg^{2+} ion.

- *The new DNA strand is assembled directly on a preexisting DNA template*. DNA polymerases catalyze the formation of a phosphodiester linkage efficiently only if the base on the incoming nucleoside triphosphate is complementary to the base on the **template strand**. Thus, DNA polymerase is a template-directed enzyme that synthesizes a product with a base sequence complementary to that of the template.

- *DNA polymerases require a primer to begin synthesis*. A short single-stranded oligonucleotide having a free $3'-OH$ group, called a **primer**, must be already bound to the template strand.

The chain-elongation reaction catalyzed by DNA polymerases is a nucleophilic attack by the $3'-OH$ terminus of the growing strand on the innermost phosphorus atom of the deoxynucleoside triphosphate (Figure 8.24). A phosphodiester bridge is formed and pyrophosphate is released.

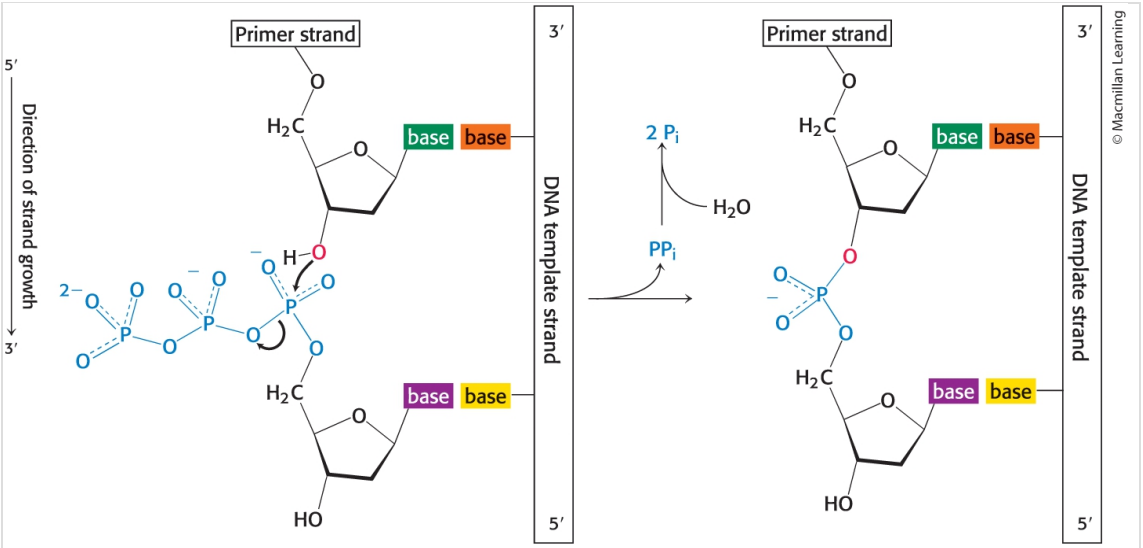

FIGURE 8.24 DNA polymerases catalyze the strand-elongation reaction in the $5'$-to-$3'$ direction. The product of the reaction is the formation of a phosphodiester bridge.

[Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 34.2.]

At this point, the reaction is readily reversible. The subsequent hydrolysis of pyrophosphate to yield two ions of orthophosphate (P_i) by pyrophosphatase, an irreversible reaction under cellular conditions, helps drive the polymerization forward. This is an example of coupled

reactions, where a second reaction provides the energy to drive the first reaction forward, a common occurrence in biochemical pathways (Section 15.1).

- *Elongation of the DNA chain proceeds in the* $5'$ *-to-* $3'$ *direction.*

- *Many DNA polymerases are able to correct mistakes in DNA by removing mismatched nucleotides.* These polymerases have a distinct nuclease activity that allows them to excise incorrect bases by a separate reaction. This nuclease activity contributes to the remarkably high fidelity of DNA replication, which has an error rate of less than 10^{-8} per base pair.

The genes of some viruses are made of RNA

Genes in all cellular organisms are made of DNA. The same is true for some viruses, but for others, the genetic material is RNA. Viruses are genetic elements enclosed in protein coats that can move from one cell to another but are not capable of independent growth. A well-studied example of an RNA virus is the tobacco mosaic virus, which infects the leaves of tobacco plants. This virus consists of a single strand of RNA (6390 nucleotides) surrounded by a protein coat of 2130 identical subunits. An RNA polymerase that takes direction from an RNA template, called an *RNA-directed RNA polymerase*, copies the viral RNA. The infected cells die because of virus-instigated programmed cell death; in essence, the virus instructs the cell to commit suicide. Cell death results in discoloration in the tobacco leaf in a variegated pattern, hence the name mosaic virus.

Another important class of RNA virus comprises the **retroviruses**, so called because the genetic information flows from RNA to DNA rather than from DNA to RNA. This class includes human immunodeficiency virus 1 (HIV-1), the cause of acquired immunodeficiency syndrome (AIDS), as well as a number of RNA viruses that produce tumors in susceptible animals. Retrovirus particles contain two copies of a single-stranded RNA molecule. On entering the cell, the RNA is copied into DNA through the action of a viral enzyme called *reverse transcriptase*, which acts as both a DNA polymerase and an RNase (**Figure 8.25**). The resulting double-helical DNA version of the viral genome can become incorporated into the chromosomal DNA of the host and is replicated along with the normal cellular DNA. At a later time, the integrated viral genome is expressed to form viral RNA and viral proteins, which assemble into new virus particles.

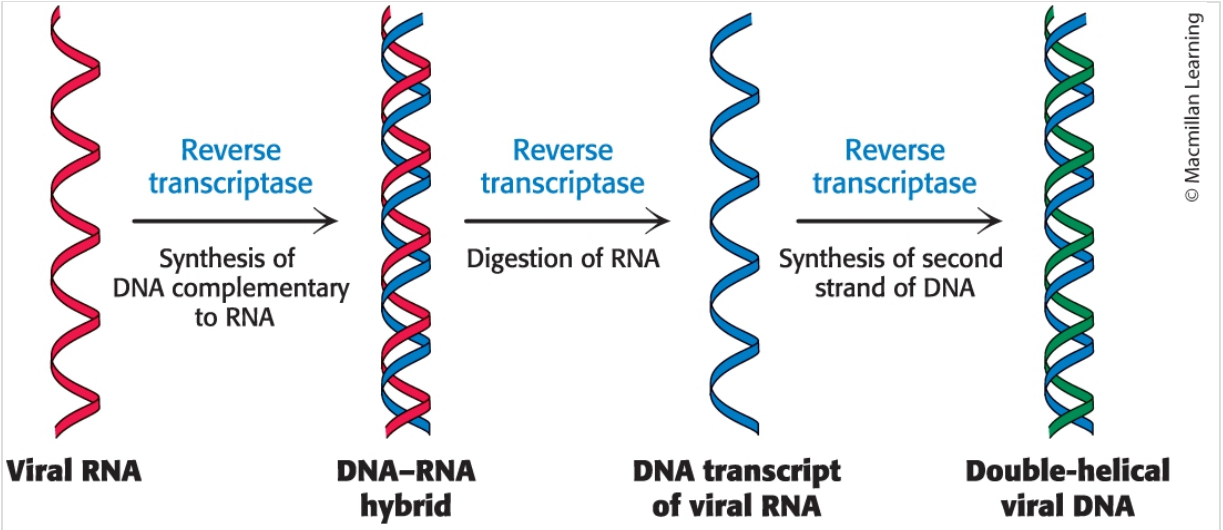

FIGURE 8.25 In retroviruses, information flows from RNA to DNA. The single-stranded RNA genome of a retrovirus is converted into double-stranded DNA by reverse transcriptase, an enzyme brought into the cell by the infecting virus particle. Reverse transcriptase possesses several activities and catalyzes the synthesis of a complementary DNA strand, the digestion of the RNA, and the subsequent synthesis of the second DNA strand.

8.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules

The information stored as DNA becomes useful when it is expressed in the production of RNA and proteins. This rich and complex topic is the subject of several chapters later in this book, but here we introduce the basics of gene expression.

DNA can be thought of as archival information, stored and manipulated in ways that minimize damage (mutations). It is expressed in two steps. First, an RNA copy is made that encodes directions for protein synthesis. This messenger RNA can be thought of as a temporary photocopy of the original information; it can be made in multiple copies, used, and then disposed of. Second, the information in messenger RNA is translated to synthesize functional proteins. Other types of RNA molecules exist to facilitate this translation.

Several kinds of RNA play key roles in gene expression

RNA is more than a passive conveyor of information during gene expression. Scientists have demonstrated that RNA plays a variety of roles, from catalysis to regulation. Cells contain three major kinds of RNA that are involved in gene expression (**Table 8.3**):

1. **Messenger RNA (mRNA)** is the template for protein synthesis. An mRNA molecule may be produced for each gene or group of

genes that is to be expressed in bacteria, whereas a distinct mRNA is produced for each gene in eukaryotes. Consequently, mRNA is a heterogeneous class of molecules. The average length of an mRNA molecule is about 1.2 kilobases (kb) in bacteria and about 2.2 kb in mammals. The mRNA of all organisms has structural features, such as stem-loop structures, that regulate its efficiency of translation and lifetime. Such structural features are more prominent in eukaryotic mRNA (Chapters 29 and 31).

2. **Transfer RNA (tRNA)** carries amino acids in an activated form to the ribosome for peptide-bond formation, in a sequence dictated by the mRNA template. There is at least one kind of tRNA for each of the 20 amino acids. Transfer RNA consists of about 75 nucleotides (having a mass of about 25 kDa).

3. **Ribosomal RNA (rRNA)** is the major component of ribosomes (Chapter 30). In bacteria, there are three kinds of rRNA, called 23S, 16S, and 5S RNA because of their sedimentation behavior (Section 4.1). One molecule of each of these species of rRNA is present in each ribosome. As we shall discuss in Chapter 30, eukaryotic rRNAs, as well as their corresponding ribosomes, are larger. Ribosomal RNA was once thought to play only a structural role in ribosomes. We now know that rRNA is the actual catalyst for protein synthesis.

TABLE 8.3 RNA molecules in *E. coli*

Type	Relative amount (%)	Sedimentation coefficient (*S*)	Mass (kDa)	Number of nucleotides
Ribosomal RNA (rRNA)	80	23	1.2×10^3	3700

		16	0.55×10^3	1700
		5	3.6×10^1	120
Transfer RNA (tRNA)	15	4	2.5×10^1	75
Messenger RNA (mRNA)	5		Heterogeneous	

Ribosomal RNA is the most abundant of these three types of RNA. Transfer RNA comes next, followed by messenger RNA, which constitutes only 5% of the total RNA. Eukaryotic cells contain additional small RNA molecules that play a variety of roles including the regulation of gene expression, the processing of RNA, and the synthesis of proteins. We will examine these small RNAs in later chapters. In this chapter, we will consider rRNA, mRNA, and tRNA.

All cellular RNA is synthesized by RNA polymerases

The synthesis of RNA from a DNA template is called **transcription** and is catalyzed by the enzyme *RNA polymerase* (**Figure 8.26**). RNA polymerase catalyzes the initiation and elongation of RNA chains. The reaction catalyzed by this enzyme is

$$(\text{RNA})_{n\ \text{residues}} + \text{ribonucleoside triphosphate} \rightleftharpoons (\text{RNA})_{n+1\ \text{residues}} + \text{PP}_\text{i}$$

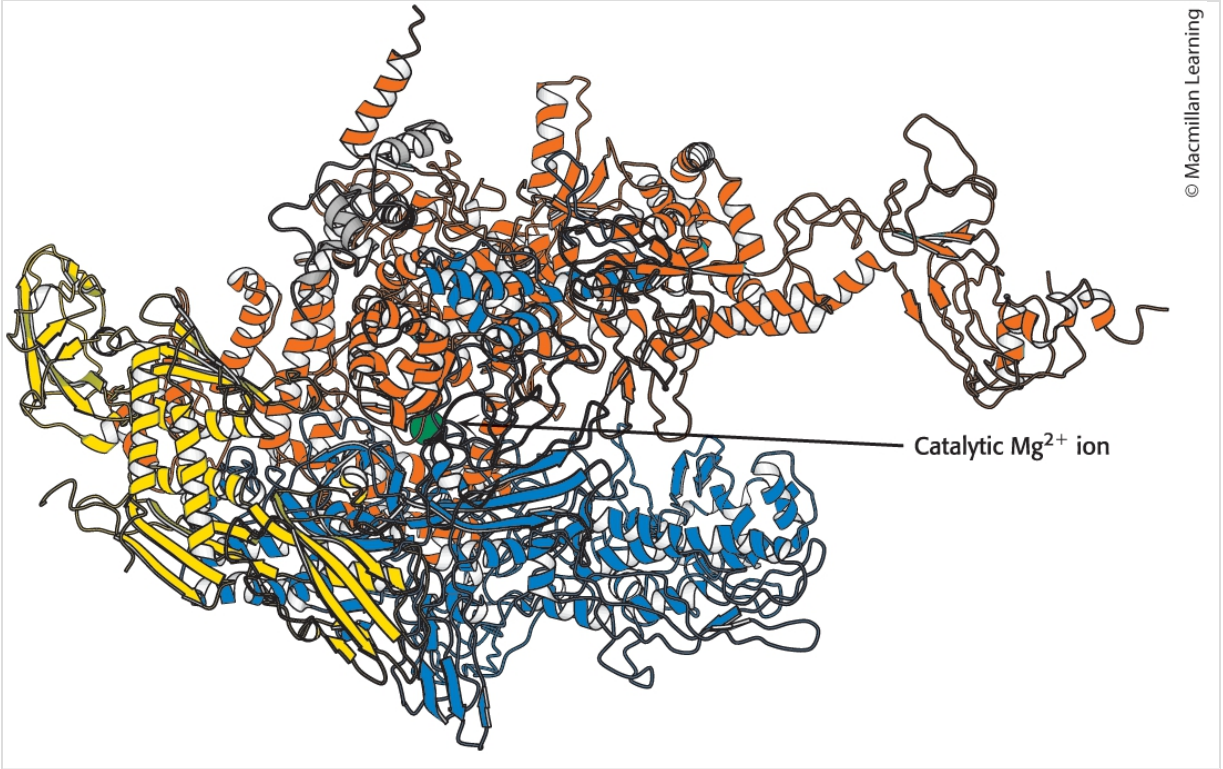

FIGURE 8.26 RNA polymerase is a multisubunit enzyme that catalyzes the synthesis of RNA from a DNA template. This large enzyme comprises many subunits, including β (blue) and β' (orange), which form a "claw" that holds the DNA to be transcribed. The active site includes a Mg^{2+} ion (green) at the center of the structure.

[Drawn from 1IW7.pdb.]

INTERACT with this model in Achieve

RNA polymerase requires the following components:

1. *A template.* The preferred template is double-stranded DNA. Single-stranded DNA also can serve as a template. RNA, whether single or double stranded, is not an effective template, nor are RNA–DNA hybrids.

2. *Activated precursors.* All four ribonucleoside triphosphates — ATP, GTP, UTP, and CTP — are required.

3. *A divalent metal ion.* Either Mg^{2+} or Mn^{2+} is effective.

The synthesis of RNA is like that of DNA in several respects (**Figure 8.27**). First, the direction of synthesis is $5' \rightarrow 3'$. Second, the mechanism of elongation is similar: the $3'-OH$ group at the terminus of the growing chain makes a nucleophilic attack on the innermost phosphoryl group of the incoming nucleoside triphosphate. Third, the synthesis is driven forward by the hydrolysis of pyrophosphate. In contrast with DNA polymerase, however, RNA polymerase does not require a primer. In addition, the ability of RNA polymerase to correct mistakes is not as extensive as that of DNA polymerase.

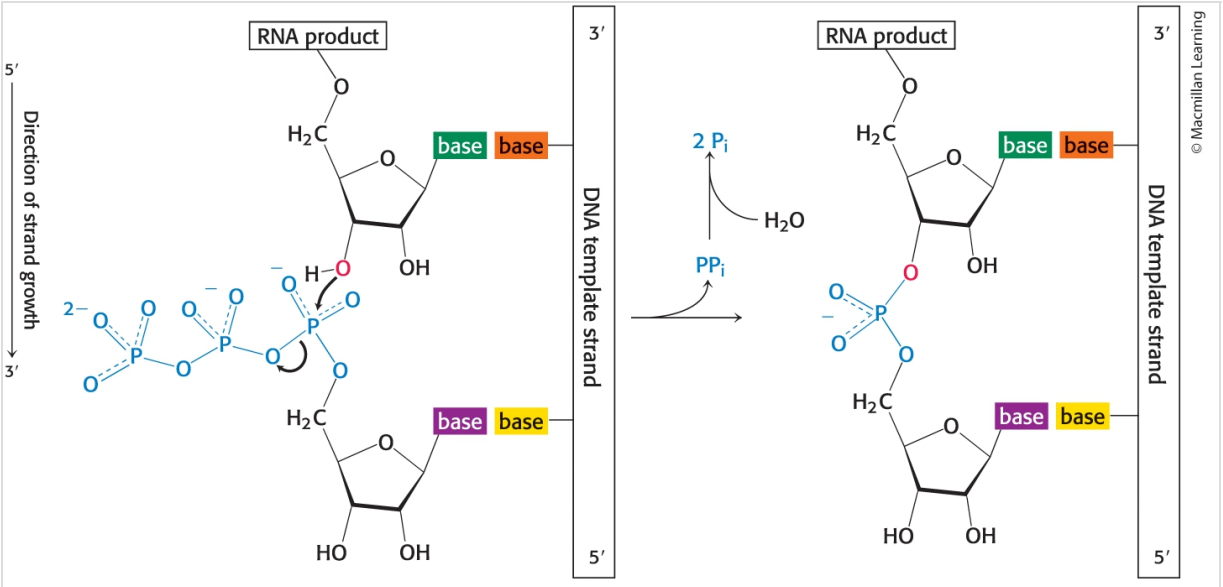

FIGURE 8.27 RNA polymerase catalyzes the strand-elongation reaction in the $5'$-to-$3'$ direction. Note the similarity in mechanism to that of DNA polymerase shown in Figure 8.24.

[Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 36.3.]

All three types of cellular RNA — mRNA, tRNA, and rRNA — are synthesized in *E. coli* by the same RNA polymerase according to instructions given by a DNA template. In mammalian cells, there is a division of labor among several different kinds of RNA polymerases. We shall return to these RNA polymerases in Chapter 29.

RNA polymerases take instructions from DNA templates

RNA polymerase, like the DNA polymerases described earlier, takes instructions from a DNA template. The earliest evidence supporting this conclusion was the finding that the base composition of newly synthesized RNA is the complement of that of the DNA template strand (the plus or coding strand), as exemplified by the RNA synthesized from a template of single-stranded DNA from the ϕX174 virus (**Table 8.4**).

TABLE 8.4 Base composition of RNA synthesized from a viral DNA template

DNA template (plus, or coding, strand of ϕX174)		RNA product	
A	25%	U	25%
T	33%	A	32%

G	24%	C	23%
C	18%	G	20%

The strongest evidence for the fidelity of transcription came from base-sequence studies. For instance, the nucleotide sequence of a segment of the gene encoding the enzymes required for tryptophan synthesis was determined with the use of DNA-sequencing techniques (Section 9.1). Likewise, the sequence of the mRNA for the corresponding gene was determined. The results showed that the RNA sequence is the precise complement of the DNA template (**Figure 8.28**).

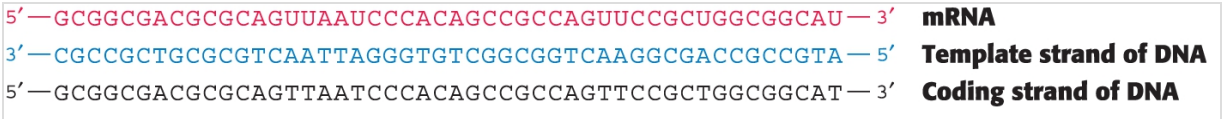

FIGURE 8.28 The sequences of the template DNA strand and its corresponding mRNA are complementary. The base sequence of mRNA (red) is the complement of that of the DNA template strand (blue). The sequence shown here is from the tryptophan operon, a segment of DNA containing the genes for five enzymes that catalyze the synthesis of tryptophan. The other strand of DNA (black) is called the coding strand because it has the same sequence as the RNA transcript except for thymine (T) in place of uracil (U).

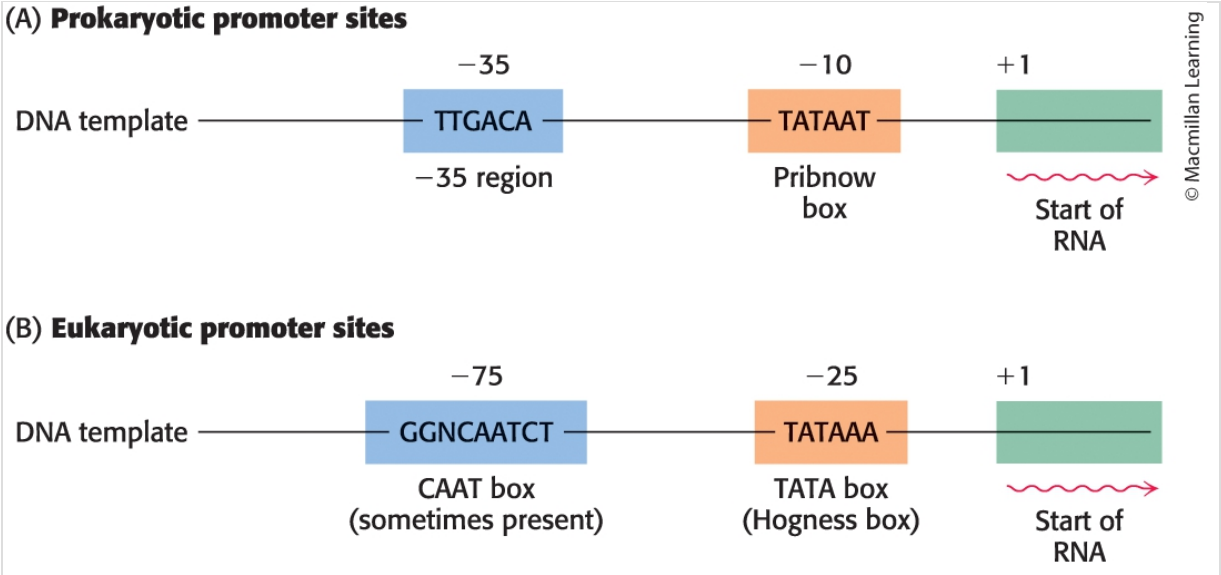
Transcription begins near promoter sites and ends at terminator sites

RNA polymerase must detect and transcribe discrete genes from within large stretches of DNA. What marks the beginning of the unit to be transcribed? DNA templates contain regions called **promoter**

sites that specifically bind RNA polymerase and determine where transcription begins. While not every promoter site of a given type carries the exact same sequence, they typically vary from an idealized single sequence, or *consensus sequence*, by only one or two residues. In prokaryotes, two sequences on the $5'$ (upstream) side of the first nucleotide to be transcribed function as promoter sites (Figure 8.29A). One of them, called the *Pribnow box*, has the consensus sequence TATAAT and is centered at -10 (10 nucleotides on the $5'$ side of the first nucleotide transcribed, which is denoted by $+1$). The other, called the -35 *region*, has the consensus sequence TTGACA. The first nucleotide transcribed is usually a purine.



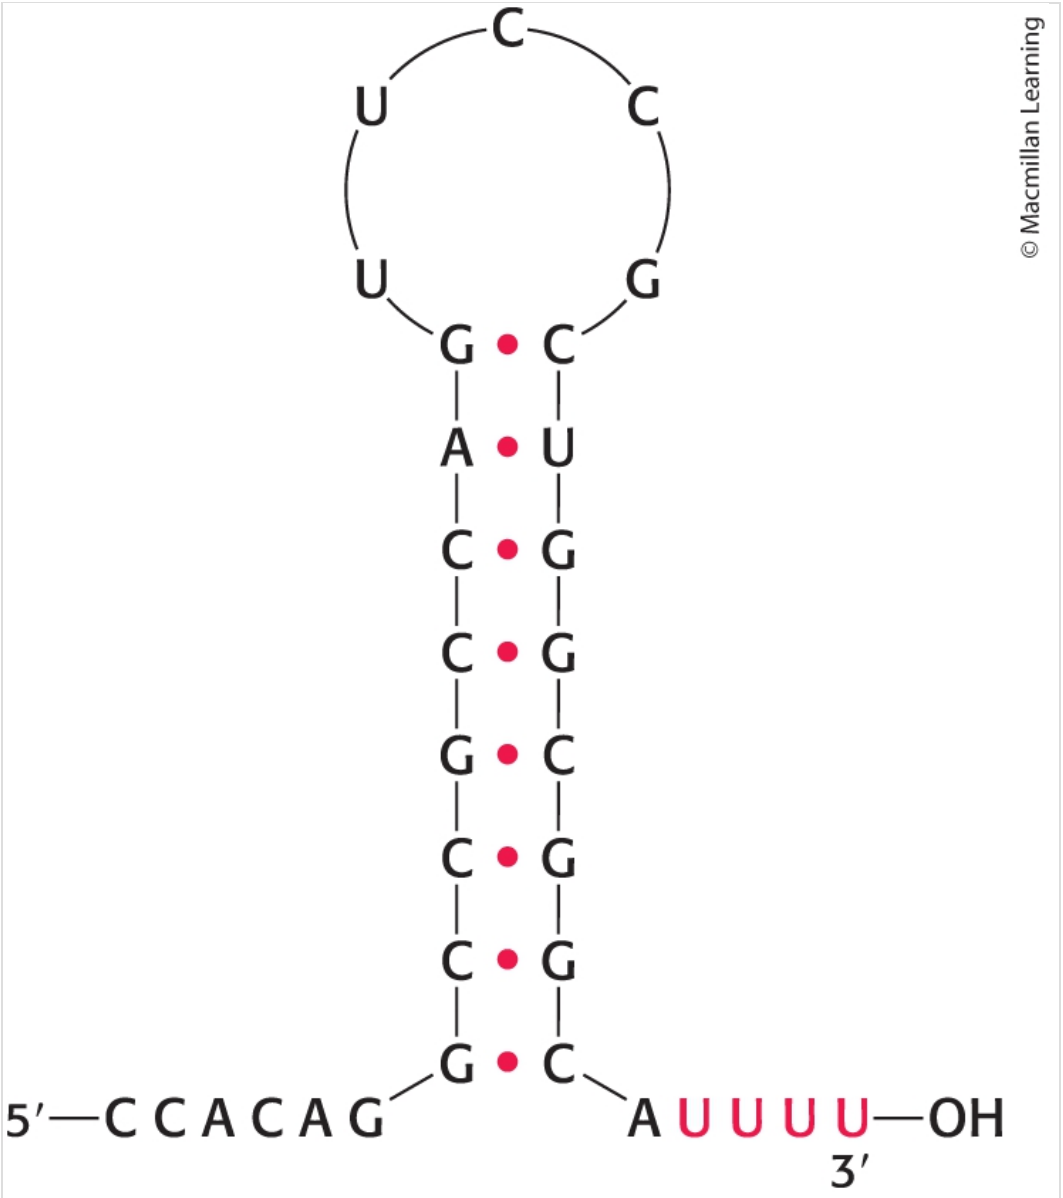


FIGURE 8.29 Promoter sites for transcription initiation differ between prokaryotes and eukaryotes. Consensus sequences are shown for (A) prokaryotic and (B) eukaryotic promoters. The first nucleotide to be transcribed is numbered $+1$. The adjacent nucleotide on the $5'$ side is numbered -1. The sequences shown are those of the coding strand of DNA.

Eukaryotic genes encoding proteins have promoter sites with a TATAAA consensus sequence, called a *TATA box* or a *Hogness box*, centered at about -25 (**Figure 8.29B**). Many eukaryotic promoters also have a *CAAT box* with a GGNCAATCT consensus sequence centered at about -75. The transcription of eukaryotic genes is further stimulated by enhancer sequences, which can be quite distant (as many as several kilobases) from the start site, on either its $5'$ or its $3'$ side.

In *E. coli*, RNA polymerase proceeds along the DNA template, transcribing one of its strands until it synthesizes a terminator sequence. This sequence encodes a termination signal, which is a stem-loop structure on the newly synthesized RNA molecule (**Figure 8.30**). This structure is formed by base-pairing of self-complementary sequences that are rich in G and C. The newly synthesized RNA spontaneously dissociates from RNA polymerase when this stem-loop is followed by a string of U residues. Alternatively, RNA synthesis in *E.coli* can be terminated by the action of the protein rho. Less is known about the termination of transcription in eukaryotes. A more detailed discussion of the initiation and termination of transcription will be given in Chapter 30. The important point now is that discrete start and stop signals for transcription are encoded in the DNA template.

© Macmillan Learning

FIGURE 8.30 The base sequence of the 3′ end of an mRNA transcript in *E. coli* forms a stem-loop structure. This structure is followed by a sequence of uridine (U) residues.

In eukaryotes, the messenger RNA is modified after transcription (Figure 8.31). A “cap” structure — a guanosine nucleotide with an

unusual $5'$-$5'$ triphosphate linkage — is attached to the $5'$ end, and a poly(A) "tail" — a sequence of adenylates — is added to the $3'$ end. These modifications will be presented in detail in Chapter 30.

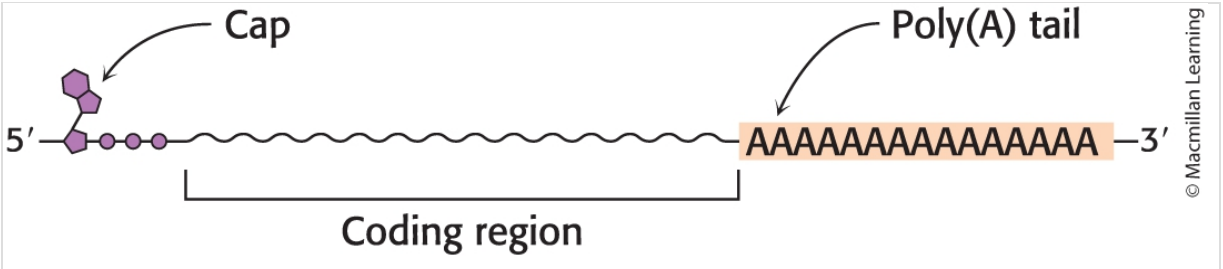

FIGURE 8.31 mRNA in eukaryotes is modified after transcription. A nucleotide "cap" structure is added to the $5'$ end, and a poly(A) tail is added at the $3'$ end.

Transfer RNAs are the adaptor molecules in protein synthesis

We have seen that mRNA is the template for protein synthesis. How then does it direct amino acids to become joined in the correct sequence to form a protein? Specific adaptor RNA molecules called transfer RNAs (tRNAs) bring the amino acids to the mRNA. The structure and reactions of these remarkable molecules will be considered in detail in Chapter 30. For the moment, it suffices to note that tRNAs contain an amino acid-attachment site and a template-recognition site.

Each tRNA molecule is composed of around 75 nucleotides and contains an amino acid-attachment site and a template-recognition site. Within the tRNA structure are several regions of base-paired segments in multiple stem-loops (**Figure 8.32**). The tRNA recognizes the mRNA template via three base pairs at the end of one of the stem-loops. Since the three coding bases on the mRNA template are known as the **codon**, the three complementary bases on the tRNA are referred to as the **anticodon**.

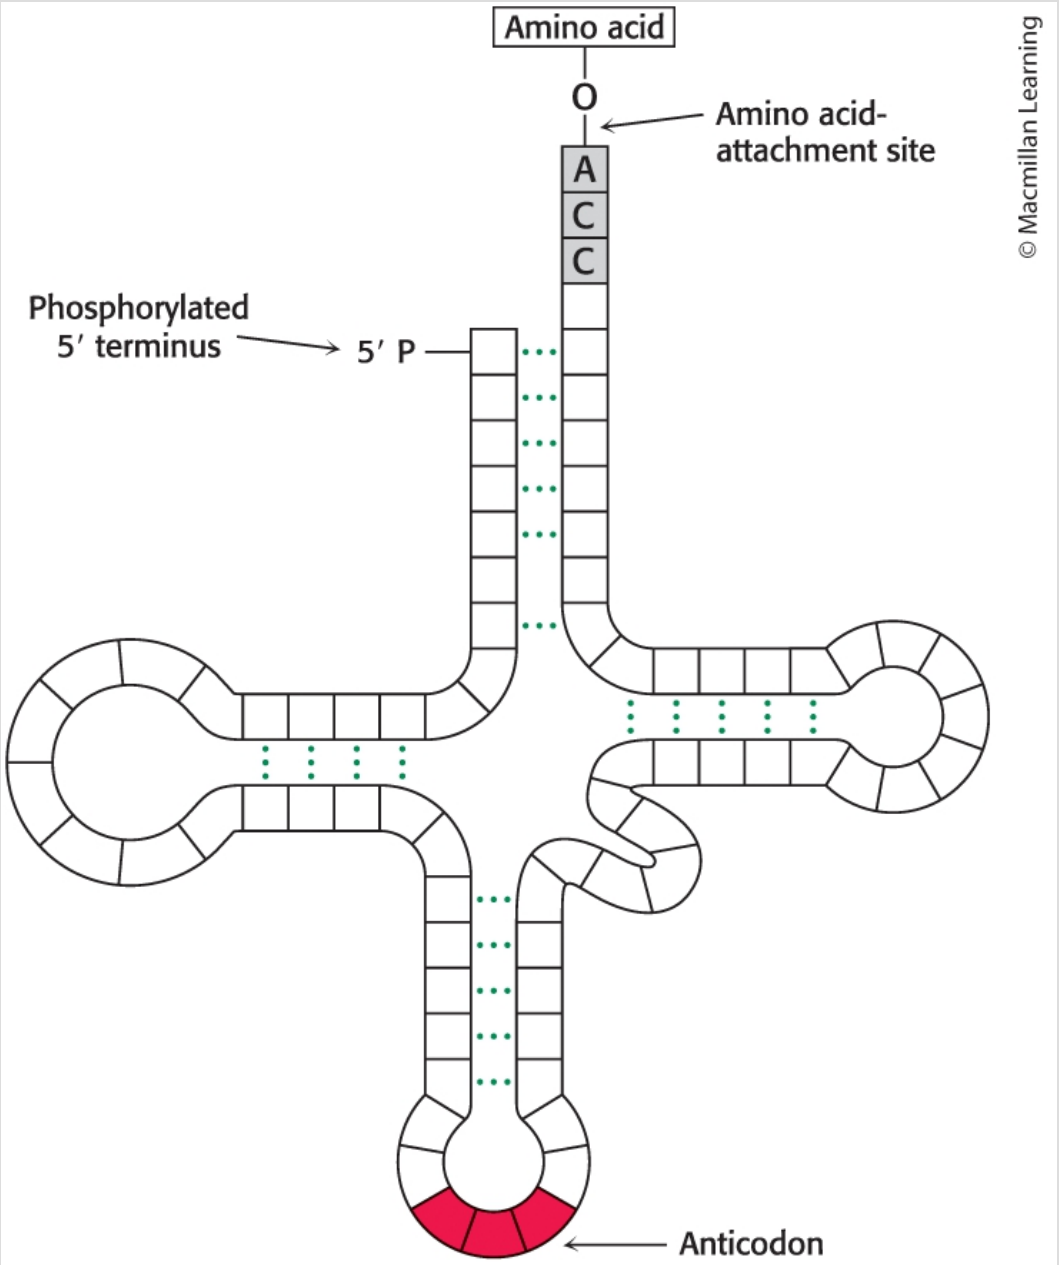

FIGURE 8.32 A tRNA molecule contains multiple stem-loop structures. The amino acid is attached at the 3′ end of the RNA. The anticodon (shown in red) is the template-recognition site. The tRNA has a cloverleaf structure with many hydrogen bonds (green dots) between bases.

Initially, the amino acid is attached to the either the $3'$- or $2'$-hydroxyl group of the ribose at the $3'$ end of the tRNA molecule. However, the amino acid can rapidly equilibrate between the two positions; ultimately, the $3'$-hydroxyl-bound form is the substrate for peptide bond formation. The sequence at the $3'$ end of the tRNA invariably contains two cytidylates followed by an adenylate, yielding what is referred to as the *CCA terminal region* or *CCA terminus* (**Figure 8.33**). The joining of an amino acid to a tRNA molecule to form an **aminoacyl-tRNA** is catalyzed by a specific enzyme called an *aminoacyl-tRNA synthetase*. There is at least one specific synthetase for each of the 20 amino acids.

8.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point

The **genetic code** is the relation between the sequence of bases in DNA (or its RNA transcripts) and the sequence of amino acids in proteins. Numerous experiments established the following features of the genetic code by 1961:

- *Three nucleotides encode an amino acid*. Proteins are built from a basic set of 20 amino acids, but there are only four bases. Simple calculations show that a minimum of three bases is required to encode at least 20 amino acids. Genetic experiments showed that an amino acid is in fact encoded by a group of three bases, or codon.

- *The code is nonoverlapping*. Consider a base sequence ABCDEF. In an overlapping code, ABC specifies the first amino acid, BCD the next, CDE the next, and so on. In a nonoverlapping code, ABC designates the first amino acid, DEF the second, and so forth. Genetic experiments again established the code to be nonoverlapping.

- *The code has no "punctuation."* In principle, one base (denoted as Q) might serve as a "comma" between groups of three bases.

  ...QABCQDEFQGHIQJKLQ ...

  However, this is not the case. Rather, the sequence of bases is read sequentially from a fixed starting point, without

punctuation.

- *The code has directionality*. The code is read from the $5'$ end of the messenger RNA to its $3'$ end.

- *The genetic code is degenerate, in that most amino acids are encoded by more than one codon.* There are 64 possible base triplets and only 20 amino acids; 61 of the 64 possible triplets specify particular amino acids. The remaining three triplets (called **stop codons**) designate the termination of translation.

University of Wisconsin-Madison Archives Collections

HAR GOBIND KHORANA Born in 1922 in a small village in Punjab in British India, Har Gobind Khorana completed his master's degree in India and his PhD at the University of Liverpool. In 1952, he began his independent career at the University of British Columbia (UBC). He synthesized RNA polymers with repeating sequences of two, three, or four nucleotides and used these synthetic RNAs to guide protein synthesis. This work contributed greatly to the elucidation of the genetic code for which he shared the Nobel Prize in 1968. The ability to synthesize oligonucleotides, developed by him and his coworkers,

fueled the development of PCR and many other methods. His work at UBC, the University of Wisconsin, and the Massachusetts Institute of Technology demonstrated his mastery of one of the pillars of chemistry: the powerful ability to synthesize even very complex molecules for a range of applications.

Major features of the genetic code

All 64 codons have been deciphered (Table 8.5). Because the code is highly degenerate, only tryptophan and methionine are encoded by just one triplet each. Each of the other 18 amino acids is encoded by two or more. Indeed, leucine, arginine, and serine are specified by six codons each.

TABLE 8.5 The genetic code

First position	Second position				Third position
(5′ end)	U	C	A	G	(3′ end)
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop	Stop	A
	Leu	Ser	Stop	Trp	G

C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	Glu	Gly	G

Note: This table identifies the amino acid encoded by each triplet. For example, the codon $5'$-AUG-$3'$ on mRNA specifies methionine, whereas CAU specifies histidine. UAA, UAG, and UGA are

termination signals. AUG is part of the initiation signal, in addition to coding for internal methionine residues.

Codons that specify the same amino acid are called *synonyms*. For example, CAU and CAC are synonyms for histidine. Note that synonyms are not distributed haphazardly throughout the genetic code. In Table 8.5, an amino acid specified by two or more synonyms occupies a single box (unless it is specified by more than four synonyms). The amino acids in a box are specified by codons that have the same first two bases but differ in the third base, as exemplified by GUU, GUC, GUA, and GUG. Thus, most synonyms differ only in the last base of the triplet. Inspection of the code shows that XYC and XYU always encode the same amino acid, and XYG and XYA usually encode the same amino acid as well. The structural basis for these equivalences of codons becomes evident when we consider the nature of the anticodons of tRNA molecules (Section 30.1).

What is the biological significance of the extensive degeneracy of the genetic code? If the code were not degenerate, 20 codons would designate amino acids and 44 would lead to chain termination. The probability of mutating to chain termination would therefore be much higher with a nondegenerate code. Chain-termination mutations usually lead to inactive proteins, whereas substitutions of one amino acid for another are usually rather harmless. Moreover, the code is constructed such that a change in any single nucleotide base of a codon results in a synonym or an amino acid with similar chemical properties. Thus, degeneracy minimizes the deleterious effects of mutations.

As we will see many times in our study of biochemistry, often things are not as straightforward as they first appear. Recent research has revealed a nonrandom use of synonymous codons in genes in different organisms, a phenomenon called *codon bias*. In other

words, different organisms prefer different sets of synonymous codons. For example, there are six codons that encode arginine, but the most commonly used codons vary widely, from the bacterium *E. coli* to the yeast *S. cerevisiae* to humans (**Figure 8.34**). The biochemical benefit of codon bias is not yet clearly established, but codon bias may help regulate translation. From an experimental perspective, codon bias can have a significant impact on the efficacy of expressing a human protein within bacteria or yeast using recombinant DNA technology, as we shall discuss in Section 9.2. By adjusting the codon usage within the gene to be expressed to match the host organism, a process called *codon optimization*, one can express the protein at a higher yield without altering the protein sequence.

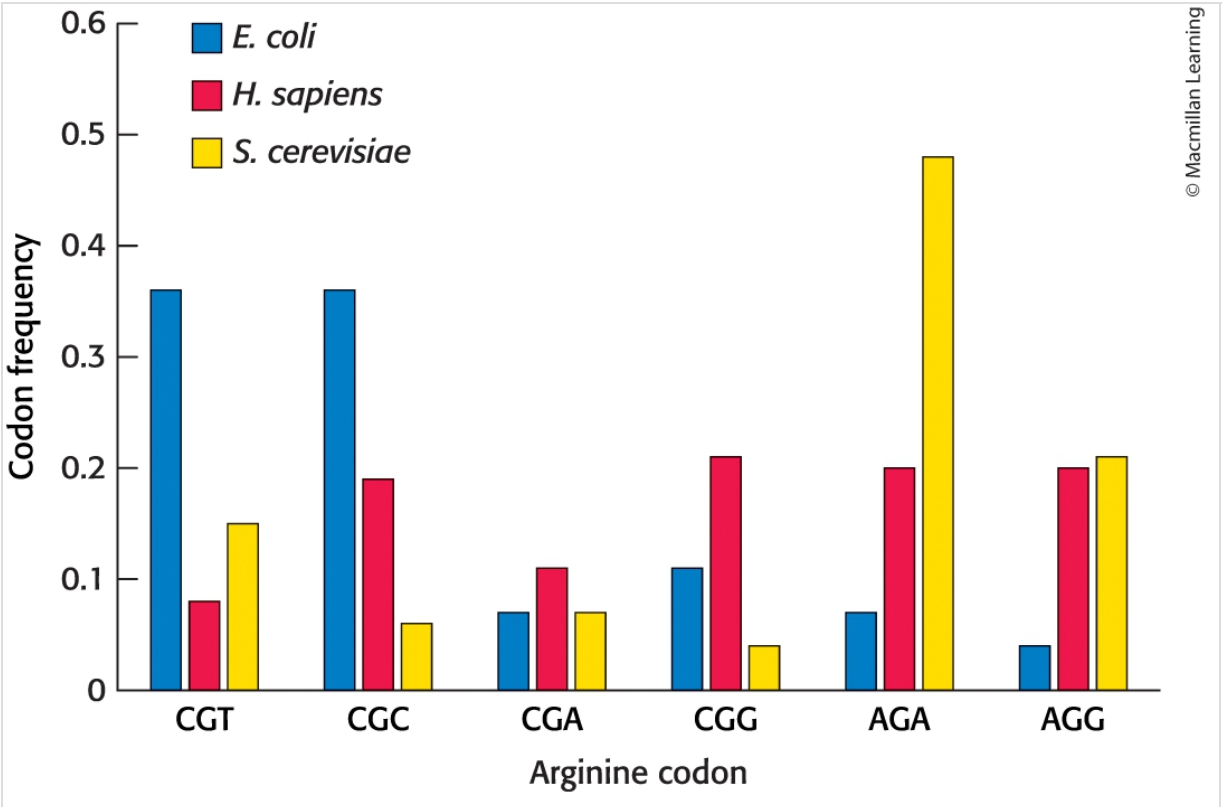

FIGURE 8.34 Different species exhibit different codon usage preferences. The relative preferences for the different arginine-encoding codons across three species — *E. coli* (blue), humans (red), and *S. cerevisiae* (yellow) — are shown. Although all of these codons encode the same amino acid, each organism exhibits a unique set of preferences, or codon bias.

[Source: https://www.genscript.com/tools/codon-frequency-table.]

Self-Check Question

The amino acid sequences of a yeast protein and a human protein having the same function are found to be 60% identical. However, the corresponding DNA sequences are only 45% identical. Account for this differing degree of identity.

Messenger RNA contains start and stop signals for protein synthesis

Messenger RNA is translated into proteins on **ribosomes** — large molecular complexes assembled from proteins and ribosomal RNA. How is mRNA interpreted by the translation apparatus?

The start signal for protein synthesis in bacteria is complex. Polypeptide chains start with a modified amino acid — namely, formylmethionine (fMet). A specific tRNA, called the *initiator tRNA*, carries fMet and recognizes the codon AUG. However, AUG is also the codon for an internal methionine residue. Hence, the signal for the first amino acid in a bacterial polypeptide chain must be more complex than that for all subsequent ones. In fact, the AUG codon is only part of the initiation signal (**Figure 8.35A**). The initiating AUG codon is preceded several nucleotides away by a purine-rich sequence, called the **Shine–Dalgarno sequence** (named after John

Shine and Lynn Dalgarno, who first described the sequence), that base-pairs with a complementary sequence in a ribosomal RNA molecule (Section 30.3).

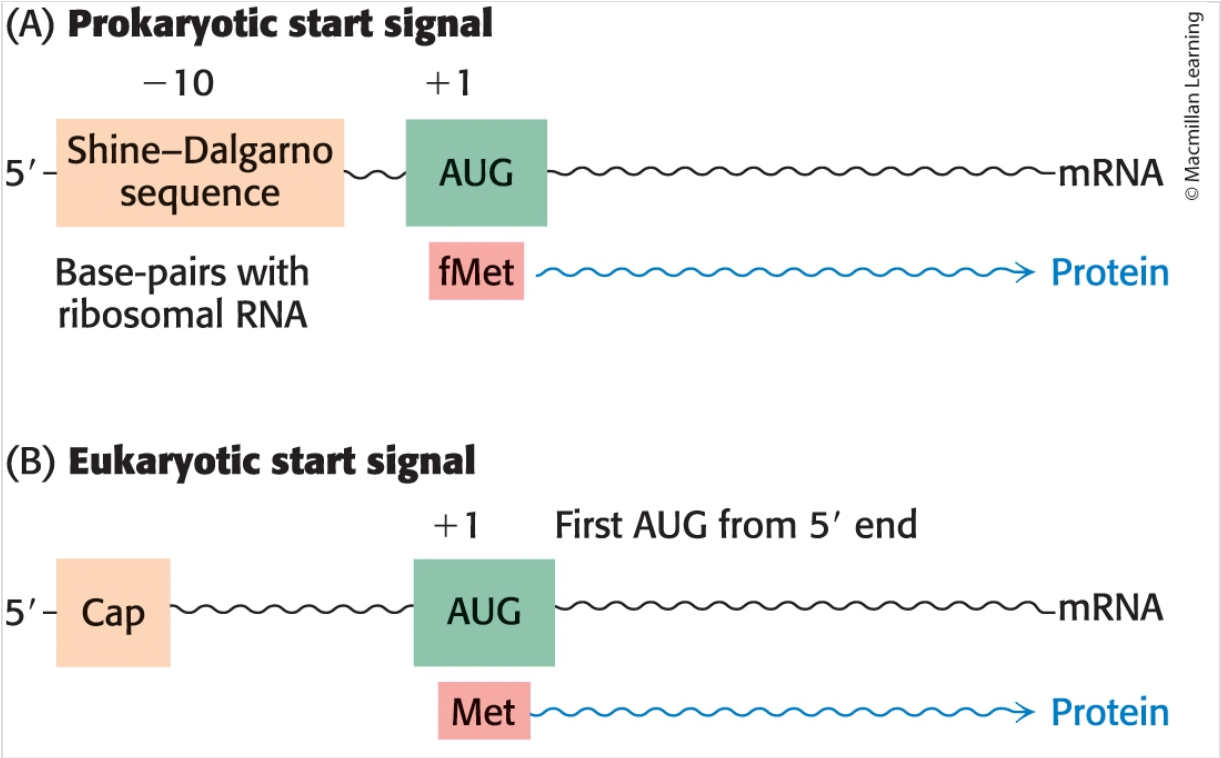

FIGURE 8.35 Initiation of protein synthesis differs between prokaryotes and eukaryotes. In prokaryotes (A), protein synthesis starts at the AUG codon about 10 bases downstream of a Shine–Dalgarno sequence, while in eukaryotes (B), the AUG closest to the 5′ end of the mRNA is usually the start signal.

In eukaryotes, the AUG closest to the 5′ end of an mRNA molecule is usually the start signal for protein synthesis (**Figure 8.35B**). This particular AUG is read by an initiator tRNA conjugated to methionine. After the initiator AUG has been located, the order of

the three nonoverlapping nucleotides, or *reading frame*, is established.

As already mentioned, UAA, UAG, and UGA designate chain termination in most species. These codons are read not by tRNA molecules but rather by specific proteins called *release factors* (Section 30.3). Binding of a release factor to the ribosome releases the newly synthesized protein.

The genetic code is nearly universal

Most organisms use the same genetic code. This universality accounts for the fact that human proteins, such as insulin, can be synthesized in the bacterium *E. coli* and harvested from it for the treatment of diabetes. However, genome-sequencing studies have shown that not all genomes are translated by the same code. Ciliated protozoa, for example, differ from most organisms in that UAA and UAG are read as codons for amino acids rather than as stop signals; UGA is their sole termination signal.

The first variations in the genetic code were found in mitochondria from a number of species, including human beings (**Table 8.6**). As we shall see later (Section 18.1), mitochondria possess their own circular DNA which encodes proteins important for cellular respiration. The genetic code of mitochondria can differ from that of the rest of the cell because mitochondrial DNA also encodes a distinct set of tRNAs that recognize the alternative codons.

TABLE 8.6 Distinctive codons of human mitochondria

Codon	Standard Code	Mitochondrial code

UGA	Stop	Trp
UGG	Trp	Trp
AUA	Ile	Met
AUG	Met	Met
AGA	Arg	Stop
AGG	Arg	Stop

Why has the code remained nearly invariant through billions of years of evolution, from bacteria to human beings? A mutation that altered the reading of mRNA would change the amino acid sequence of most, if not all, proteins synthesized by that particular organism. Many of these changes would undoubtedly be deleterious, and so there would be strong selection against a mutation with such pervasive consequences.

8.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons

In bacteria, polypeptide chains are encoded by a continuous array of triplet codons in DNA. For many years, genes in higher organisms were assumed to be organized in the same manner. This view was unexpectedly shattered in 1977, when investigators discovered that most eukaryotic genes are *discontinuous*. For example, the gene for the β chain of hemoglobin is interrupted within its amino acid-coding sequence by a short stretch of 120 noncoding base pairs and a long one of 550 base pairs. Thus, the β-globin gene is split into three coding sequences (Figure 8.36). Noncoding regions are called **introns** (for intervening sequences), whereas coding regions are called **exons** (for expressed sequences). The average human gene has 8 introns, and some have more than 100. Intron size ranges from 50 to 10,000 nucleotides.

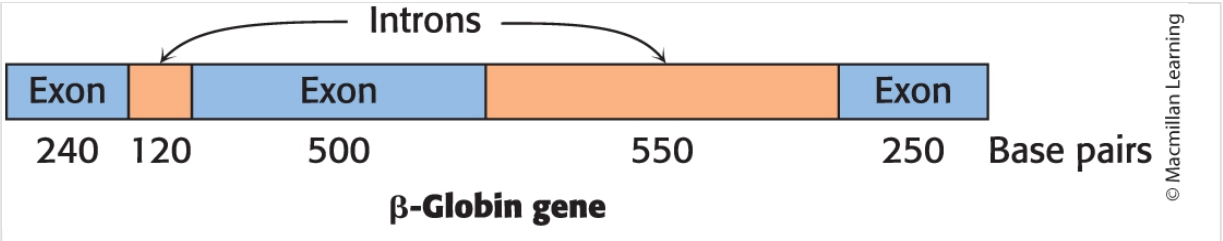

FIGURE 8.36 The β-globin gene is discontinuous. The coding regions, or exons (in blue), are interrupted by noncoding regions, or introns (in orange). This figure does not include regulatory regions (or transcribed but not translated regions) of the gene.

RNA processing generates mature RNA

At what stage in gene expression are introns removed? Newly synthesized RNA molecules (called *pre-mRNAs* or *primary transcripts*) isolated from nuclei are much larger than the mRNA molecules derived from them. In regard to β-globin RNA, the primary transcript consists of approximately 1600 nucleotides, and the processed mRNA (called *mature mRNA*) consists of approximately 900 nucleotides, which includes nontranslated regions of the mRNA. The primary transcript of the β-globin gene contains two regions, corresponding to the introns described above, that are not present in the mRNA. These regions in the primary transcript are excised, and the coding sequences are simultaneously linked by a precise splicing complex to form the mature mRNA (**Figure 8.37**). A common feature in the expression of discontinuous, or split, genes is that their exons are ordered in the same sequence in mRNA as in DNA. Thus, the codons in split genes, like continuous genes, are in the same linear order as the amino acids in the polypeptide products.

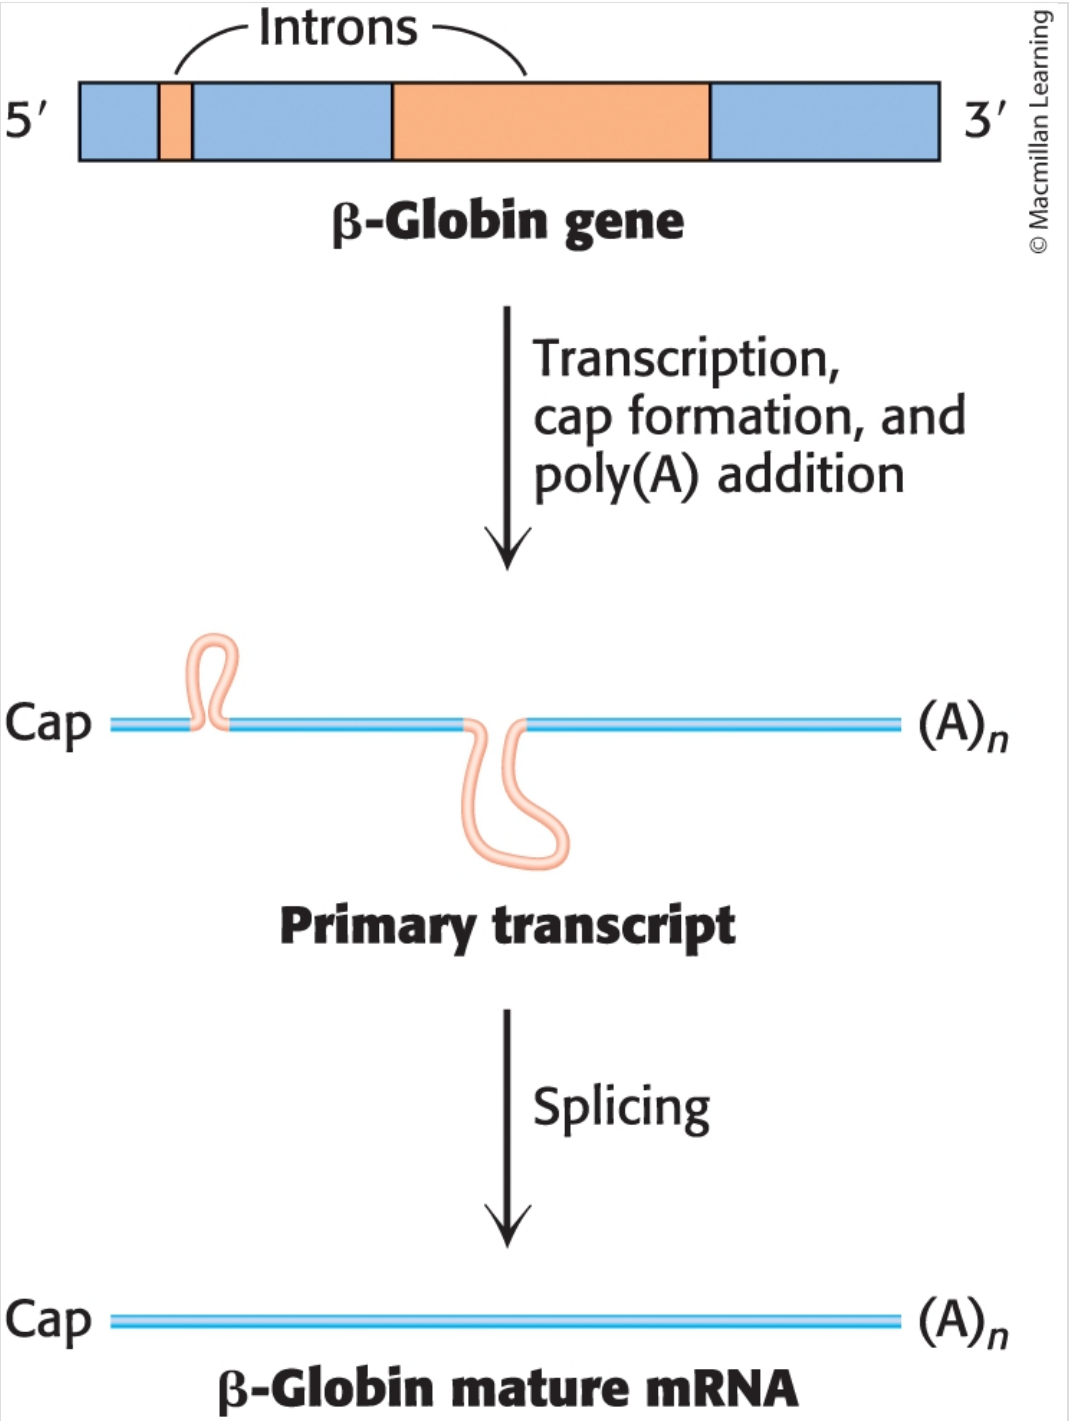

FIGURE 8.37 Transcription and processing of the β-globin gene includes an intermediate step where introns are removed. The gene is transcribed to yield the primary transcript, which is modified by cap and poly(A) addition. The introns in the primary RNA transcript are then removed to form the mature mRNA.

Splicing is a complicated series of reactions carried out by complexes called *spliceosomes*, which are assemblies of proteins and small nuclear RNA molecules (snRNAs). RNA plays the catalytic role (Section 29.4). Spliceosomes recognize signals in the primary transcript that specify the splice sites. Introns nearly always begin with GU and end with an AG that is preceded by a pyrimidine-rich tract (**Figure 8.38**). This consensus sequence is part of the signal for splicing.

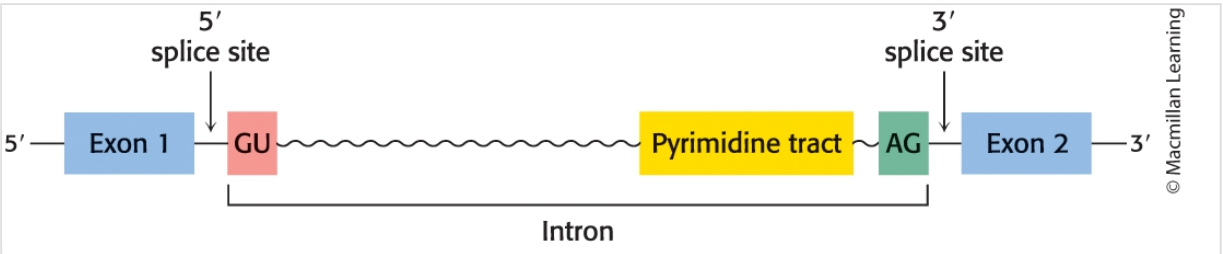

FIGURE 8.38 A consensus sequence ensures that splicing occurs at the correct locations. The introns typically begin with a GU pair and end with an AG pair that is preceded by a pyrimidine-rich tract.

Many exons encode protein domains

Most genes of higher eukaryotes, such as birds and mammals, are split. Lower eukaryotes, such as yeast, have a much higher proportion of continuous genes. In bacteria, split genes are extremely rare. From an evolutionary perspective, this raises the question: have introns been inserted into genes in the evolution of higher organisms or have they been removed from genes to form the streamlined genomes of bacteria and simple eukaryotes? Comparisons of the DNA sequences of genes

encoding evolutionarily conserved proteins suggest that introns were present in ancestral genes and were lost in the evolution of organisms that have become optimized for very rapid growth, such as bacteria. The positions of introns in some genes are at least 1 billion years old. Furthermore, the hypothesis that a common mechanism of splicing developed before the divergence of fungi, plants, and vertebrates is supported by the finding that mammalian cell extracts can splice yeast RNA.

What advantages might split genes confer? An attractive hypothesis is that new proteins arose in evolution by the rearrangement of exons encoding discrete structural elements, binding sites, and catalytic sites, a process called **exon shuffling**. Because it preserves functional units but allows them to interact in new ways, exon shuffling is a rapid and efficient means of generating novel genes. **Figure 8.39** shows the composition of a gene that was formed in part by exon shuffling. DNA can break and recombine in introns with no deleterious effect on encoded proteins. In contrast, the exchange of sequences within different exons usually leads to loss of protein function.

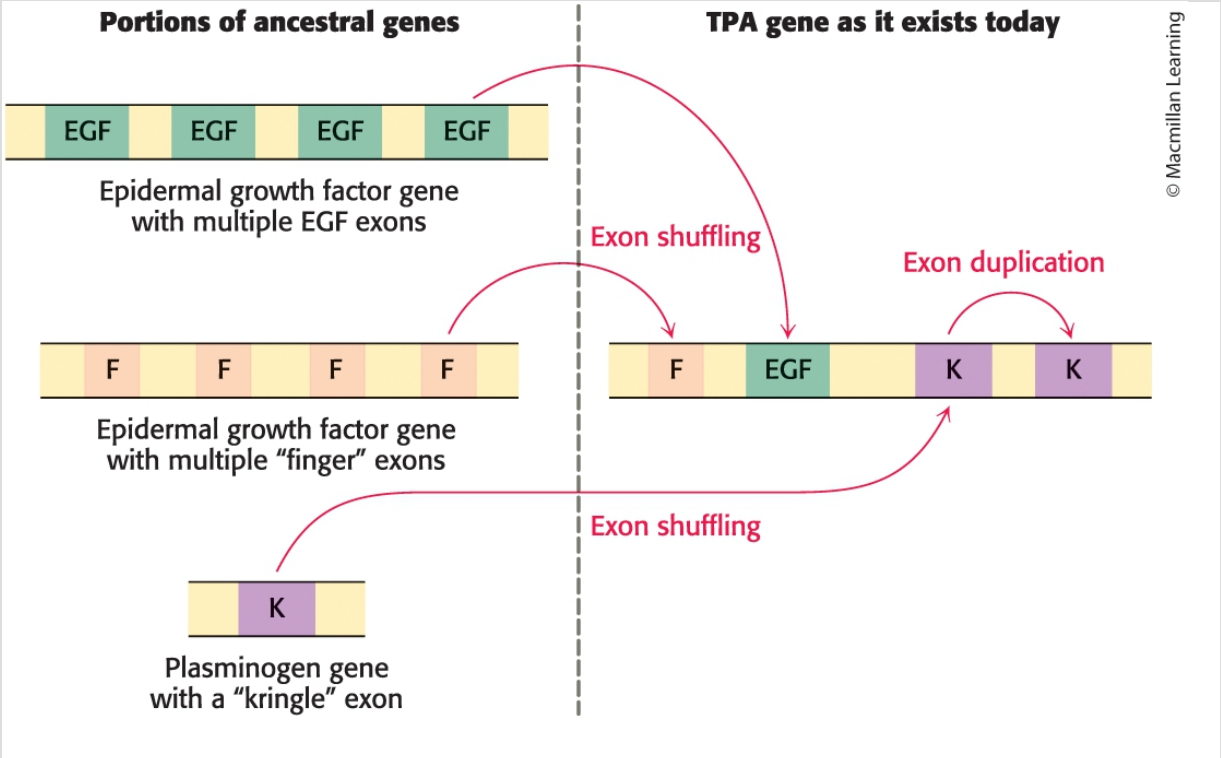

FIGURE 8.39 The tissue plasminogen activator (TPA) gene was generated by exon shuffling. The gene for TPA encodes an enzyme that functions in hemostasis (Section 7.4). This gene consists of 4 exons, one (F) derived from the fibronectin gene which encodes an extracellular matrix protein, one from the epidermal growth factor gene (EGF), and two from the plasminogen gene (K, Section 7.4), the substrate of the TPA protein. The K domain appears to have arrived by exon shuffling and then to have been duplicated to generate the TPA gene that exists today.

[Information from: www.ehu.es/ehusfera/genetica/2012/10/02/demostracion-molecular-de-microevolucion/.]

Another advantage of split genes is the potential for generating a series of related proteins by **alternative splicing** of the primary transcript. For example, a precursor of an antibody-producing cell forms an antibody that is anchored in the cell's plasma membrane (**Figure 8.40**). The attached antibody recognizes a specific foreign antigen, an event that leads to cell differentiation and proliferation. The activated antibody-producing cells then splice their primary transcript in an alternative manner to form soluble antibody molecules that are secreted rather than retained on the cell surface. Alternative splicing is a facile means of forming a set of proteins that are variations of a basic motif without requiring a gene for each protein. Due in large part to alternative splicing, the proteome is more diverse than the genome in eukaryotes.

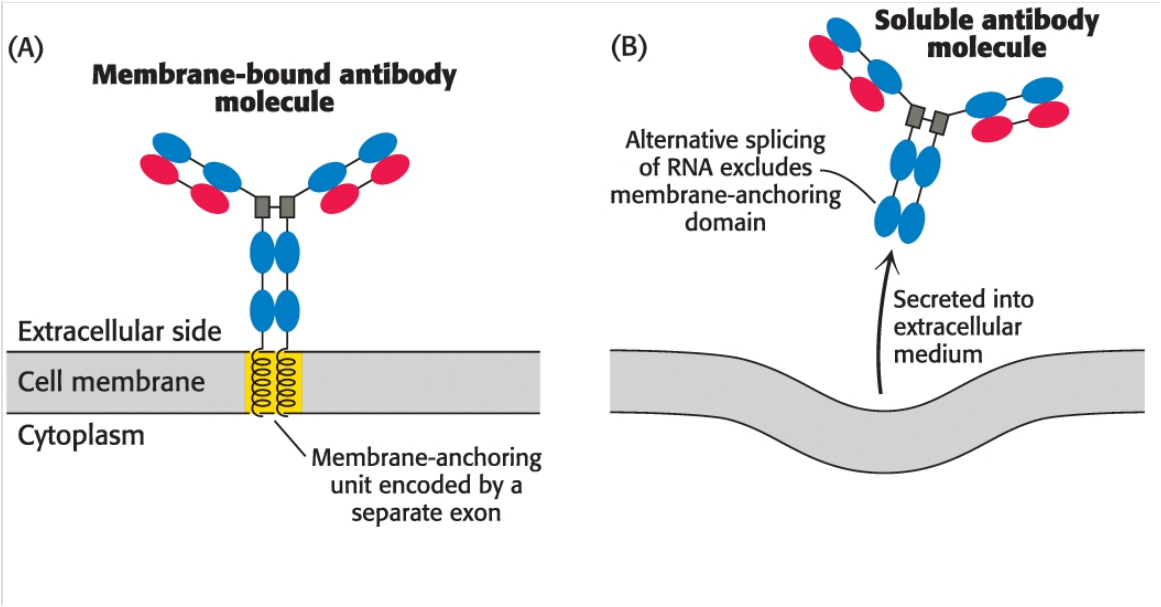

FIGURE 8.40 Alternative splicing generates mRNAs that are templates for different forms of a protein. For example, (A) a membrane-bound antibody on the surface of a lymphocyte and (B) i soluble counterpart, exported from the cell, are products of alternative splicing of the same transcript. The membrane-bound antibody is anchored to the plasma membrane by a helical segment (highlighted in yellow) that is encoded by its own exon.

Chapter 8 Summary

8.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar–Phosphate Backbone

- DNA and RNA are linear polymers of a limited number of nucleotide monomers. Each nucleotide contains a sugar, a phosphate, and a base.
- In DNA, the sugar is deoxyribose, and the bases are adenine (A), thymine (T), guanine (G), and cytosine (C). In RNA, the sugar is ribose, and thymine is replaced with uracil (U).
- Nucleic acids have directionality and are written in the $5'$-to-$3'$ direction.

8.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure

- Cellular DNA consists of two very long, helical polynucleotide strands coiled around a common axis: the double helix.
- The sugar–phosphate backbone of each strand is on the outside of the double helix, whereas the purine and pyrimidine bases are on the inside stabilized by stacking forces.
- The two strands run in opposite directions and are held together by hydrogen bonds between pairs of bases: adenine is always paired with thymine, and guanine is always paired with cytosine. Hence, one strand of a double helix is the complement of the other.
- DNA can exist in a variety of helical forms. including B-DNA (the classic Watson–Crick double helix), A-DNA, and Z-DNA. Most of the DNA in a cell is in the B-form.
- Single-stranded nucleic acids, most notably RNA, can form complicated three-dimensional structures.

8.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information

- In DNA replication, the strands of the helix separate, and a new strand complementary to each of the original strands is synthesized. This mode of replication is called semiconservative because each new helix retains one of the parental strands.
- In order for replication to take place, the strands of the double helix must be separated, or melted.
- In the laboratory, the double helix can be melted by heating the solution above its melting temperature. This process is reversible, and the strands will reassemble spontaneously below the melting temperature.

8.4 DNA Is Replicated by Polymerases That Take Instructions from Templates

- The replication of DNA is a complex process carried out by many proteins, including several DNA polymerases.
- Replication by DNA polymerase requires: all four activated precursors (deoxynucleotide $5'$-triphosphates), a DNA template, and a primer with a free $3'-OH$ group.
- The new strand is synthesized in the $5' \rightarrow 3'$ direction.
- DNA polymerases catalyze the formation of a phosphodiester linkage only if the base on the incoming nucleotide is complementary to the base on the template strand.

8.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules

- The flow of genetic information in normal cells is from DNA to RNA to protein.

- Transcription is the synthesis of RNA from a DNA template, and translation is the synthesis of a protein from an RNA template.
- Cells contain several kinds of RNA, among which are messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA), which vary in size from 75 to more than 5000 nucleotides.
- As with DNA polymerases, RNA polymerases synthesize cellular RNA in the $5'$-to-$3'$ direction according to instructions given by DNA templates. RNA polymerase differs from DNA polymerase in not requiring a primer.

8.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point

- The genetic code is the relationship between the sequence of bases in DNA (or its RNA transcript) and the sequence of amino acids in proteins.
- Amino acids are encoded by codons — groups of three bases — starting from a fixed point known as the start codon.
- Sixty-one of the 64 possible codons specify particular amino acids, whereas the other 3 codons (UAA, UAG, and UGA) are signals for chain termination. Thus, for most amino acids, there is more than one code word.
- Natural mRNAs contain start and stop signals for translation.

8.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons

- Most genes in higher eukaryotes are discontinuous: coding sequences (exons) are separated by noncoding sequences (introns).
- Introns are removed in the conversion of the primary transcript into mature mRNA by a process known as splicing.
- A striking feature of many exons is that they encode functional domains in proteins. New proteins probably arose in the course of evolution by the shuffling of exons.

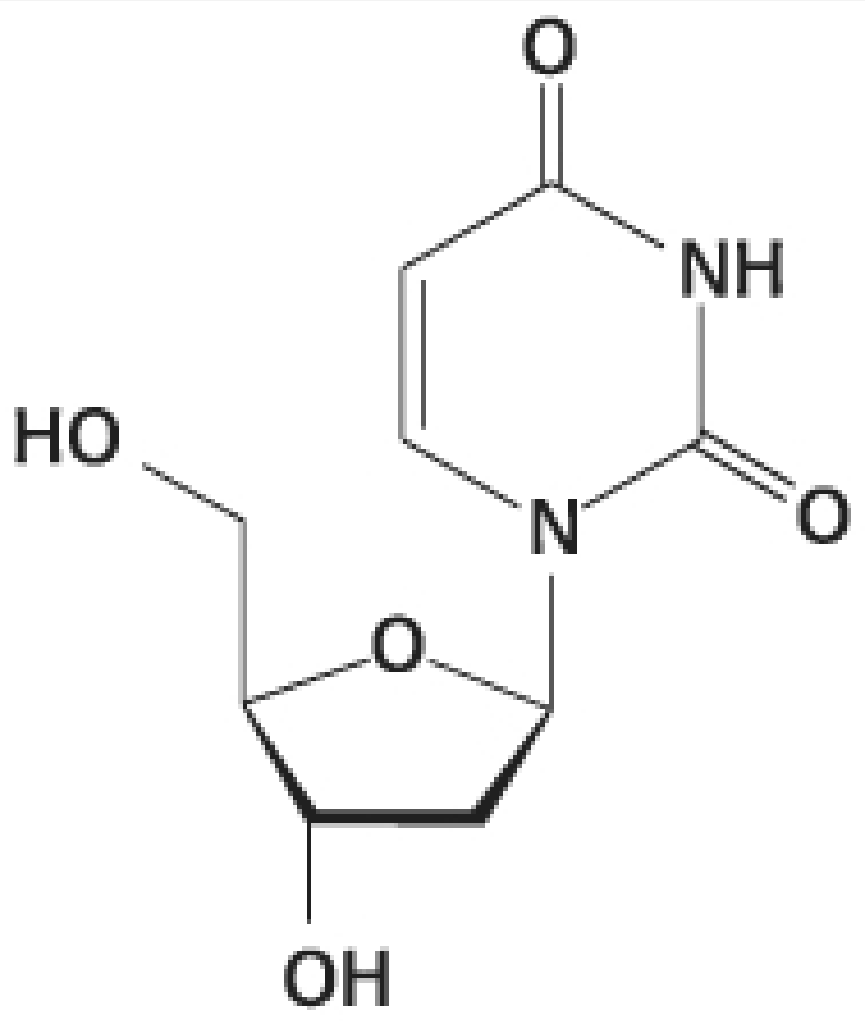
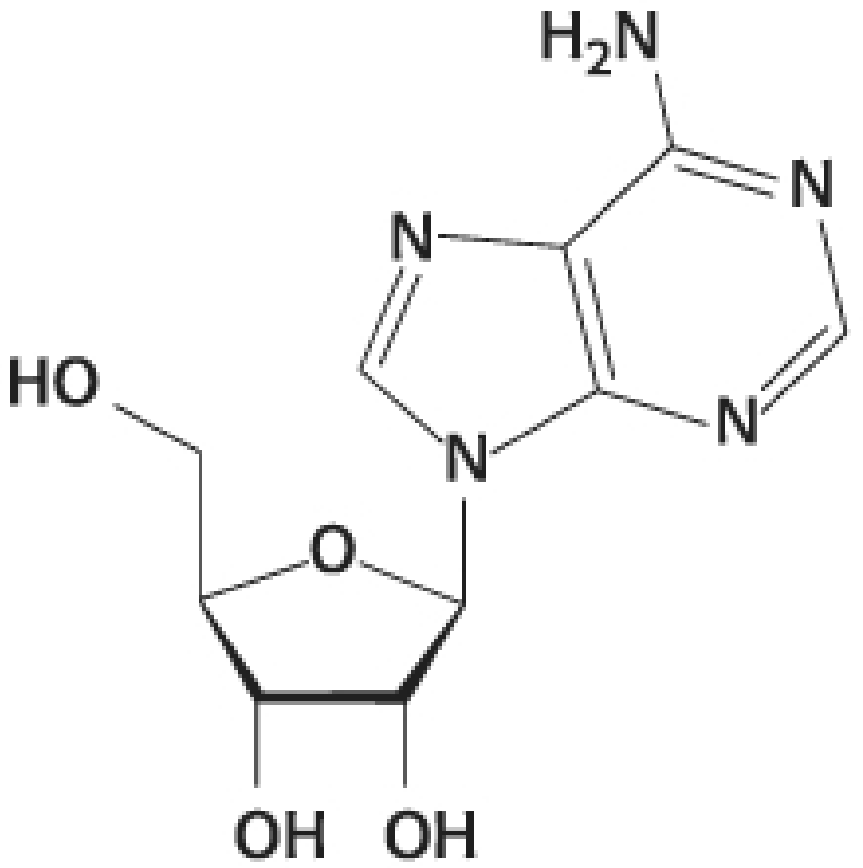
Problems

1. Classify the following descriptions as pertaining to nucleosides, nucleotides, or both nucleosides and nucleotides: 1



a. Contain a base, a sugar, and a phosphate group
b. Are found in RNA and DNA
c. Do not contain a phosphate group
d. May contain either a purine or a pyrimidine
e. One example is adenosine 5′-monophosphate
f. Are the product when a base bonds at C1 of ribose or deoxyribose
g. Are the monomers of nucleic acids
h. Contain a base and a sugar

2. Name the following nucleosides/nucleotides: 1



a.

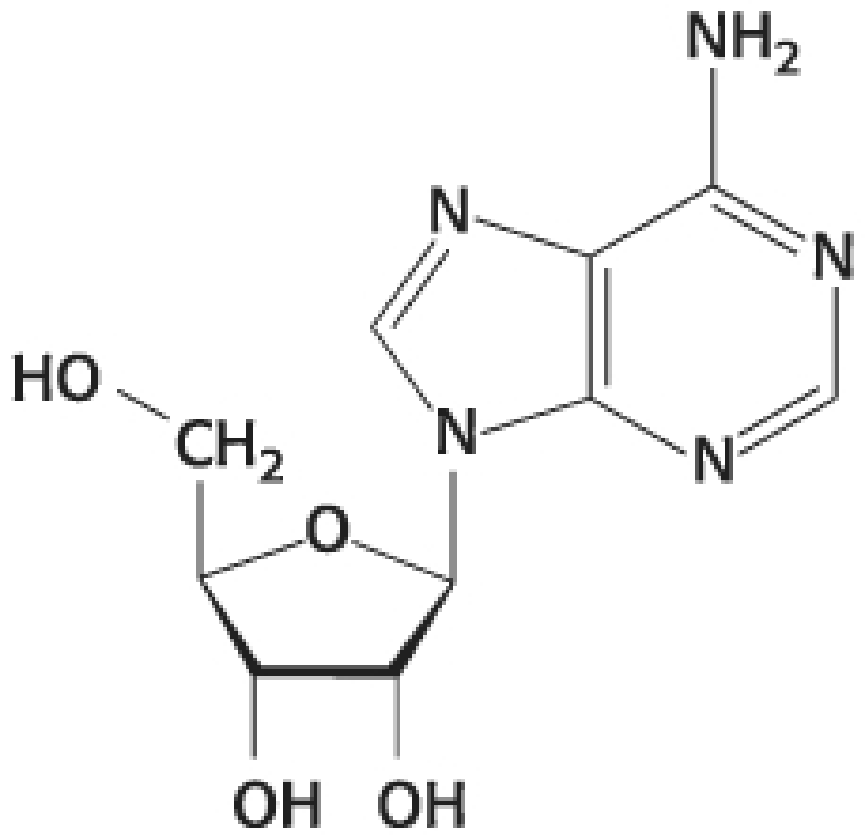
b.

c.

3. Biochemist Erwin Chargaff was the first to note that, in DNA, $[A] = [T]$ and $[G] = [C]$. Using this rule, determine the percentages of all the bases in DNA that is 20% thymine.
1, 2

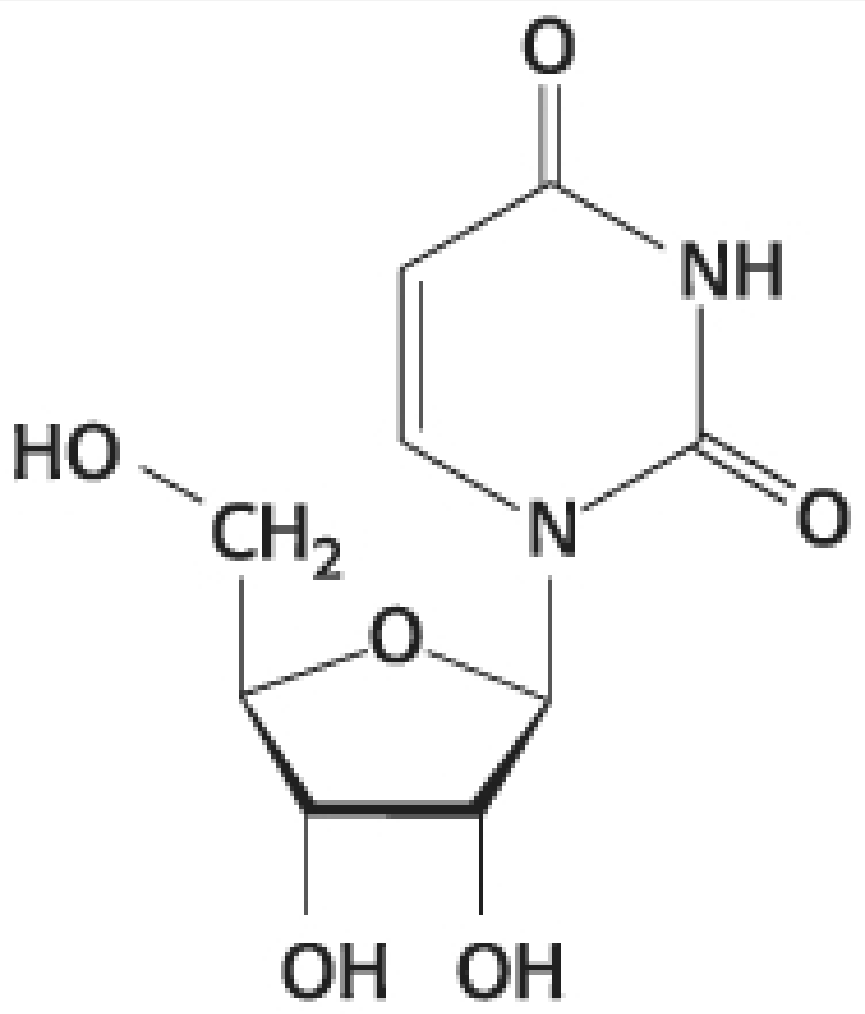
4. Write the complementary sequence (in the standard $5' \rightarrow 3'$ notation) for

a. GATCAA
b. TCGAAC
c. ACGCGT



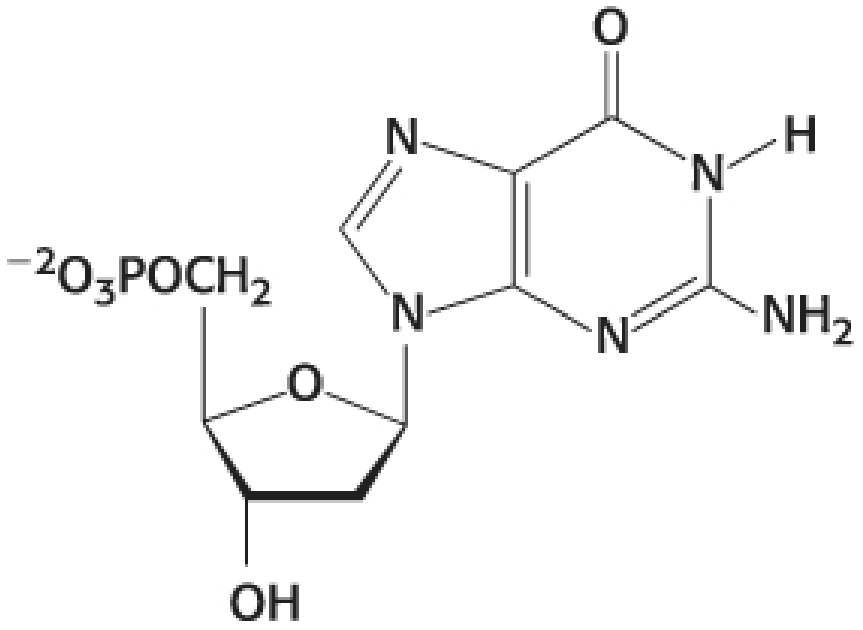
d. TACCAT

5. Classify the following statements as describing DNA or RNA: 2



a. Is usually single-stranded
b. Is the genome for prokaryotic organisms
c. Includes the sugar deoxyribose
d. Includes the base uracil
e. Can form a complex secondary structures
f. Is usually double-stranded
g. Can be translated into a protein

6. Classify each nucleotide or nucleoside by the type of base (purine vs. pyrimidine) and the type of sugar (ribose vs. deoxyribose) 2



a.

b.

c.

7. Classify the following statements as describing B-DNA, A-DNA, Z-DNA, or all three. 2

a. Widest helix diameter
b. Has a helix diameter of ~20 Å
c. C−3′ of deoxyribose is out of the plane of the other sugar ring atoms
d. Left-handed
e. Antiparallel strands
f. Most stable under physiological conditions
g. Narrowest helix diameter
h. G pairs with C; A pairs with T
i. More likely observed in dehydrated DNA fibers

8.

a. Suppose that you want to radioactively label DNA but not RNA in dividing and growing bacterial cells. Which radioactive molecule would you add to the culture medium? 3
b. Suppose that you want to prepare DNA in which the backbone phosphorus atoms are uniformly labeled with ^{32}P. Which precursors should be added to a solution containing DNA polymerase and primed template DNA? Specify the position of radioactive atoms in these precursors.

9. A solution contains DNA polymerase and the Mg^{2+} salts of dATP, dGTP, dCTP, and TTP. The following DNA molecules are added to aliquots of this solution. Which of them would lead to DNA synthesis? Explain your answer. 3

a. A single-stranded closed circle containing 1000 nucleotide units
b. A double-stranded closed circle containing 1000 nucleotide pairs
c. A single-stranded closed circle of 1000 nucleotides base-paired to a linear strand of 500 nucleotides with a free $3'$ -OH terminus
d. A double-stranded linear molecule of 1000 nucleotide pairs with a free $3'-OH$ group at each end

10. In their famous experiment, Matthew Meselson and Franklin Stahl grew *E. coli* cells in a medium containing only the "heavy" isotope of nitrogen, ^{15}N. These cells were then transferred to a medium with the "light" isotope of nitrogen,

^{14}N. The results of the experiment supported the hypothesis of semiconservative replication. 3

a. Heavy DNA (^{15}N DNA), hybrid DNA, and light DNA (^{14}N DNA) can be separated by centrifugation. If cells containing ^{15}N DNA are transferred to a medium with only $^{14}NH_4Cl$ as a nitrogen source, what percentage of daughter molecules are composed of hybrid DNA after 2 generations?
b. Predict what percentage of daughter molecules would be composed of hybrid DNA if DNA exhibited conservative replication (i.e., if a daughter DNA molecule were composed of newly synthesized DNA only).

11. What is the axial ratio (length:diameter) of a DNA molecule $20\ \mu m$ long?

12. The DNA of a deletion mutant of λ bacteriophage has a length of $15\ \mu m$ instead of the $17\ \mu m$ found in the wild type phage. How many base pairs are missing from this mutant? 2

13. Match the components in the right-hand column with the appropriate process in the left-hand column. Terms in the left-hand column may be used more than once. 4

1. Replication _____	1. RNA polymerase
2. Transcription _____	2. DNA polymerase
3. Translation _____	3. Ribosome

4. dNTP

5. tRNA

6. NTP

7. mRNA

8. Primer

9. rRNA

10. Promoter

14.

a. Write the sequence of the mRNA molecule synthesized from a DNA template strand having the following sequence: 4

$$5' - ATCGTACCGTTA - 3'$$

b. What amino acid sequence is encoded by the following base sequence of an mRNA molecule? Assume that the reading frame starts at the $5'$ end.

$$5' - UUGCCUAGUGAUUGGAUG - 3'$$

c. What is the sequence of the polypeptide formed on addition of poly(UUAC) to a cell-free protein-synthesizing system?

15. Compare DNA polymerase and RNA polymerase from *E. coli* in regard to each of the following features: 4

a. Activated precursors
b. Direction of chain elongation
c. Conservation of the template
d. Need for a primer

16. What are the key characteristics of the genetic code? 4

17. Classify the following terms on whether they are associated with tRNA, mRNA, or rRNA. 4

a. Codon
b. Combines with protein to form ribosomes
c. Transports amino acids
d. Product of transcription
e. Anticodon

18. Do the following phrases describe prokaryotic promoters, eukaryotic promoters, or both? 5

a. Includes two conserved sequences at -35 and -10
b. Contains highly conserved DNA sequences that specify the start of transcription
c. Includes a TATA, or Hogness, box upstream of the transcription start site
d. Includes a Pribnow box upstream of the transcription start site
e. May by further stimulated by enhancer sequences

19. What is the significance of the fact that human mRNA can be accurately translated in *E. coli*? 5

The repair of delicate machinery, such as an old pocket watch, requires a steady hand, considerable experience, and the right tools for the job. Likewise, the advent of recombinant DNA technology has unlocked the potential to disrupt and repair DNA sequences with considerable precision. More recent developments have given us the tools such as the Cas9 endonuclease (left) to make directed changes to genomic DNA sequences with a high degree of specificity.

Outline

9.1 The Exploration of Genes Relies on Key Tools
9.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology
9.3 Complete Genomes Have Been Sequenced and Analyzed

[9.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision]

Learning Goals

By the end of this chapter, you should be able to:

1. Explain how restriction enzymes work and their importance to recombinant DNA technology.
2. Describe several methods commonly used for the sequencing of DNA.
3. List the fundamental steps of the polymerase chain reaction.
4. Describe the various types of vectors used in DNA cloning, and explain the difference between a cloning vector and an expression vector.
5. Describe some commonly used methods to introduce mutations into DNA.
6. Explain how genes can be altered in living organisms, and describe some of the applications of these techniques.

Recombinant DNA technology is the fruit of several decades of basic research on DNA, RNA, and viruses. These methods are rapidly evolving in terms of their speed, precision, and complexity. Nevertheless, even the more complex processes can be distilled to their essential biochemical principles, which we explore in this chapter.

The impact of recombinant DNA technology, generally referred to as *biotechnology*, cannot be overstated. In addition to the dramatic expansion of our understanding of human disease, these methods have enabled wide-ranging advancements across a broad spectrum of disciplines, including agriculture, environmental science, forensics, and evolutionary biology.

9.1 The Exploration of Genes Relies on Key Tools

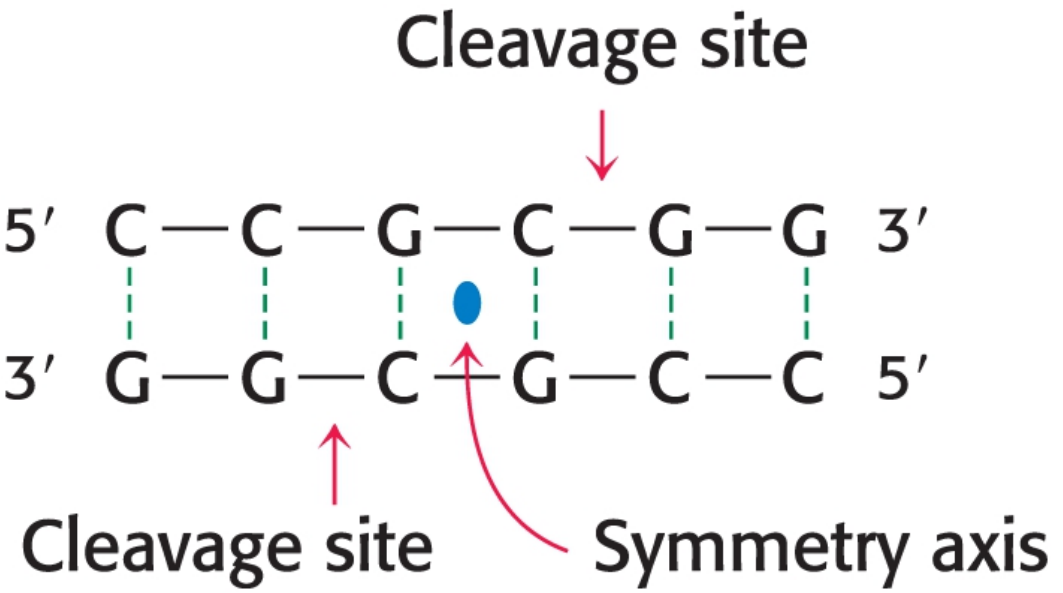
The rapid progress in biotechnology — indeed, its very existence — is a result of a few key techniques.

- *Restriction-enzyme analysis.* Restriction enzymes are precise molecular scalpels that allow an investigator to manipulate DNA segments.

- *Blotting techniques.* Southern and northern blots are used to separate and identify DNA and RNA sequences, respectively. The western blot, which uses antibodies to characterize proteins, was described in Chapter 4.

- *DNA sequencing.* The exact nucleotide sequence of a molecule of DNA can be determined. Sequencing has yielded a wealth of information concerning gene architecture, the control of gene expression, and protein structure.

- *Solid-phase synthesis of nucleic acids.* Specific sequences of nucleic acids can be synthesized de novo and used to identify or amplify other nucleic acids.



- *The polymerase chain reaction* (PCR). The polymerase chain reaction leads to a billionfold amplification of a segment of DNA. One molecule of DNA can be amplified to quantities that permit characterization and manipulation. This powerful technique can be used to detect pathogens and genetic diseases, determine the source of a hair left at the scene of a crime, and resurrect genes from the fossils of extinct organisms.

- *Bioinformatics.* A final set of techniques relies on the computer, without which it would be impossible to catalog, access, and characterize the abundant information generated by the methods outlined above. Such uses of the computer, referred to as *bioinformatics,* will be presented in Chapter 10.

Restriction enzymes split DNA into specific fragments

As discussed in Chapter 6, **restriction enzymes**, also called **restriction endonucleases**, recognize specific base sequences in double-helical DNA and cleave both strands of that duplex at specific places. To biochemists, these exquisitely precise scalpels are marvelous gifts of nature. They are indispensable for analyzing chromosome structure, sequencing very long DNA molecules, isolating genes, and creating new DNA molecules that can be cloned.

Restriction enzymes are found in a wide variety of prokaryotes. Their biological role is to cleave foreign DNA molecules, providing the host organism with a primitive immune system. Many restriction enzymes recognize specific sequences of four to eight base pairs and hydrolyze a phosphodiester bond in each strand in this region. A striking characteristic of these cleavage sites is that they almost always possess twofold rotational symmetry. In other words, the recognized sequence is a palindrome, that is, a sequence that reads the same forwards or backwards. As a consequence of this symmetry, the cleavage sites are also symmetrically positioned. For example, the sequence recognized by a restriction enzyme from *Streptomyces achromogenes* is

In each strand, the enzyme cleaves the C–G phosphodiester bond on the 3′ side of the symmetry axis. As we saw in Chapter 6, this symmetry corresponds to that of the structures of the restriction enzymes themselves.

Several thousand restriction enzymes have been purified and characterized. Their names consist of a three-letter abbreviation for the host organism (e.g., Eco for *Escherichia coli,* Hin for *Haemophilus influenzae,* Hae for *Haemophilus aegyptius*) followed by a strain designation, if needed, and a roman numeral to distinguish multiple enzymes from the same strain. The specificities of several of these enzymes are shown in **Figure 9.1**.

FIGURE 9.1 Restriction endonucleases vary in their sequence specificity and sites of cleavage. The sequences that are recognized by these enzymes contain a twofold axis of symmetry. The two strands in these regions are related by a 180-degree rotation about the axis marked by the green symbol. The cleavage sites are denoted by red arrows. The abbreviated name of each restriction enzyme is given at the right of the sequence that it recognizes. Note that the cuts may be staggered or even.

VIEW an animation of a restriction digest and gel electrophoresis in Achieve

Restriction enzymes are used to cleave DNA molecules into specific fragments that are more readily analyzed and manipulated than the entire parent molecule. For example, the 5.1-kilobase circular duplex DNA of the tumor-producing SV40 virus is cleaved at one site by EcoRI, at four sites by HpaI, and at 11 sites by HindIII. A piece of DNA, called a restriction fragment, produced by the action of one restriction enzyme can be specifically cleaved into smaller fragments by another restriction enzyme. The pattern of such fragments can serve as a fingerprint of a DNA molecule. Indeed, complex chromosomes containing hundreds of millions of base pairs can be mapped by using a series of restriction enzymes.

Self-Check Question

The restriction enzyme AluI cleaves at the sequence $5'-AGCT-3'$, and NotI cleaves at $5'-GCGGCCGC-3'$. What would be the average distance between cleavage

sites for each enzyme on digestion of double-stranded DNA? Assume that the DNA contains equal proportions of A, C, G, and T.

Restriction fragments can be separated by gel electrophoresis and visualized

In Chapter 4, we considered the use of gel electrophoresis to separate protein molecules (Section 4.1). Because the phosphodiester backbone of DNA is highly negatively charged, this technique is also suitable for the separation of nucleic acid fragments. Among the many applications of DNA electrophoresis are the detection of mutations that affect restriction fragment size (such as insertions and deletions) and the isolation, purification, and quantitation of a specific DNA fragment.

For most gels, the shorter the DNA fragment, the farther the migration. Polyacrylamide gels are used to separate, by size, fragments containing as many as 1000 base pairs, whereas more-porous agarose gels are used to resolve mixtures of larger fragments (as large as 20 kilobases, kb). An important feature of these gels is their high resolving power. In certain kinds of gels, fragments differing in length by just one nucleotide out of several hundred can be distinguished. Individual bands or spots of DNA that have been labeled with radioactivity can be visualized by autoradiography after gel electrophoresis. Alternatively, a gel can be stained with a dye such as ethidium bromide, which fluoresces an intense orange under irradiation with ultraviolet light when bound to a double-helical DNA molecule (**Figure 9.2**). A band containing only 10 ng of DNA can be readily seen.

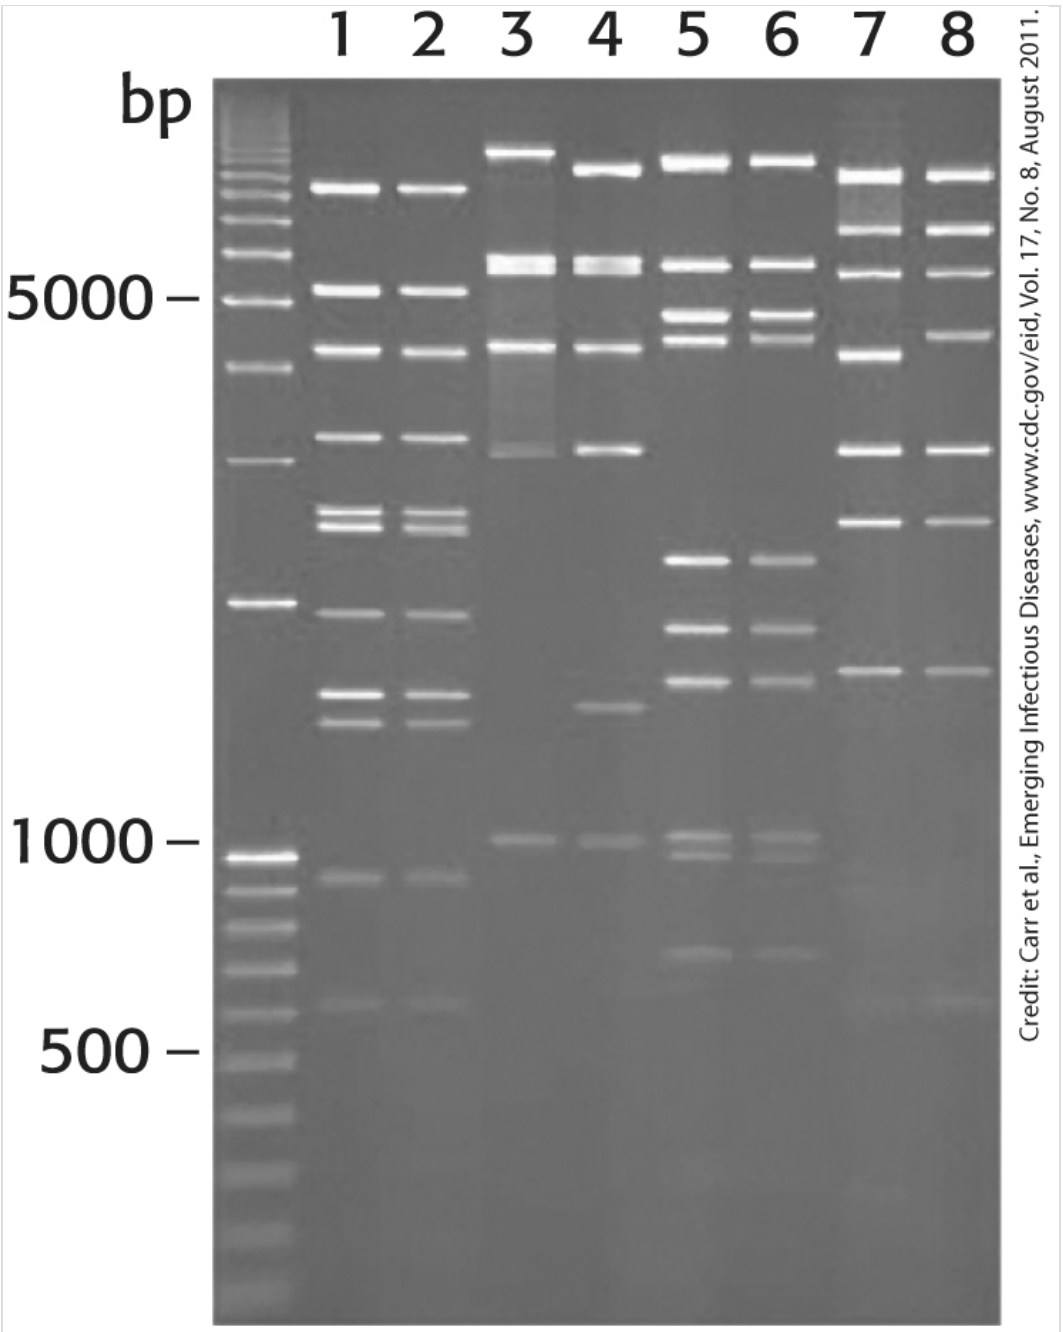

FIGURE 9.2 Gel-electrophoresis separates DNA fragments on the basis of their sizes. This gel shows the fragments produced by cleaving DNA from two viral strains (odd- vs. even-numbered lanes) with each of four restriction enzymes. These fragments were made fluorescent by staining the gel with ethidium bromide.

It is often necessary to determine if a particular base sequence is represented in a given DNA sample. For example, one may wish to confirm the presence of a specific mutation in genomic DNA isolated from patients known to be at risk for a particular disease. This specific sequence can be identified by hybridizing it with a labeled complementary DNA strand using a powerful technique named **Southern blotting**, for its inventor Edwin Southern (**Figure 9.3**).

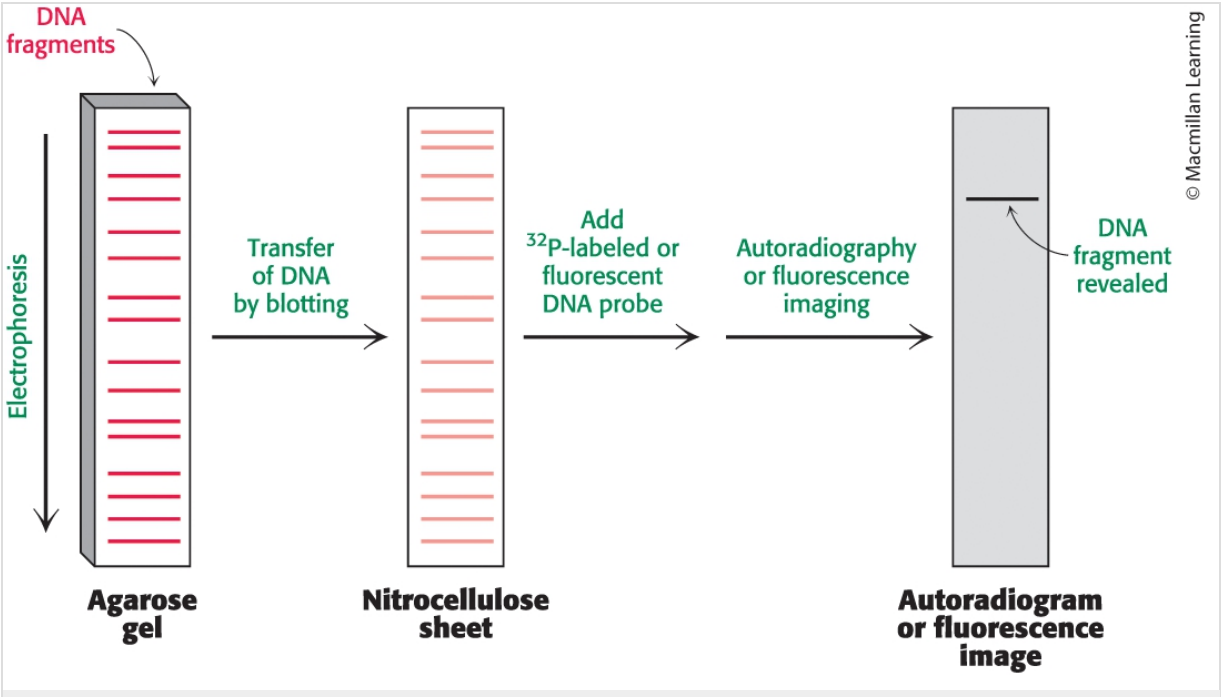

FIGURE 9.3 Southern blotting is used to detect the presence of a particular DNA sequence within a mixture of DNA molecules. A DNA fragment containing a specific sequence can be identified by separating a mixture of fragments by electrophoresis, transferring them to nitrocellulose, and hybridizing with a labeled probe complementary to the sequence. The fragment containing the sequence is then visualized by autoradiography or fluorescence imaging.

1. A mixture of restriction fragments is separated by electrophoresis through an agarose gel, denatured to form

single-stranded DNA, and transferred to a membrane composed of nitrocellulose or nylon. The positions of the DNA fragments in the gel are preserved during the transfer.

2. The membrane is then exposed to a ^{32}P-labeled or fluorescently tagged **DNA probe**, a short stretch of single-stranded DNA which contains a known base sequence.

3. The probe hybridizes with a restriction fragment having a complementary sequence.

4. Autoradiography or fluorescence imaging then reveals the position of the restriction-fragment–probe duplex.

A particular fragment amid a million others can be readily identified in this way.

In a similar manner, RNA molecules of a specific sequence can also be readily identified. After separation by gel electrophoresis and transfer to nitrocellulose, specific sequences can be detected by DNA probes. This analogous technique for the analysis of RNA has been whimsically termed **northern blotting**.

DNA can be sequenced by controlled termination of replication

The analysis of DNA structure and its role in gene expression has been markedly facilitated by the development of powerful techniques for the sequencing of DNA molecules. One of the first and most widely used techniques for DNA sequencing is **controlled termination of replication**, also referred to as the **Sanger dideoxy method** for its pioneer, Frederick Sanger. The key to this approach is

the generation of DNA fragments whose length is determined by the last base in the sequence (**Figure 9.4**).

FIGURE 9.4 Controlled termination of replication uses the separation of fluorescently labeled oligonucleotide fragments to determine an overall sequence. A sequencing reaction is performed with four chain-terminating dideoxy nucleotides, each labeled with a tag that fluoresces at a different wavelength, with the color of each fragment indicating the identity of the last base in the chain. The fragments are separated by size using capillary electrophoresis, and the fluorescence at each of the four wavelengths indicates the sequence of the complement of the original DNA template.

VIEW an animation of the dideoxy sequencing method in Achieve

In the current application of this method, a DNA polymerase is used to make the complement of a particular sequence within a single-stranded DNA molecule. The synthesis is primed by a chemically synthesized fragment that is complementary to a part of the sequence known from other studies. In addition to the four deoxyribonucleoside triphosphates, the reaction mixture contains a small amount of the 2′,3′-dideoxy analog of each nucleotide, each

carrying a different fluorescent label attached to the base (e.g., a green emitter for termination at A and a red one for termination at T).

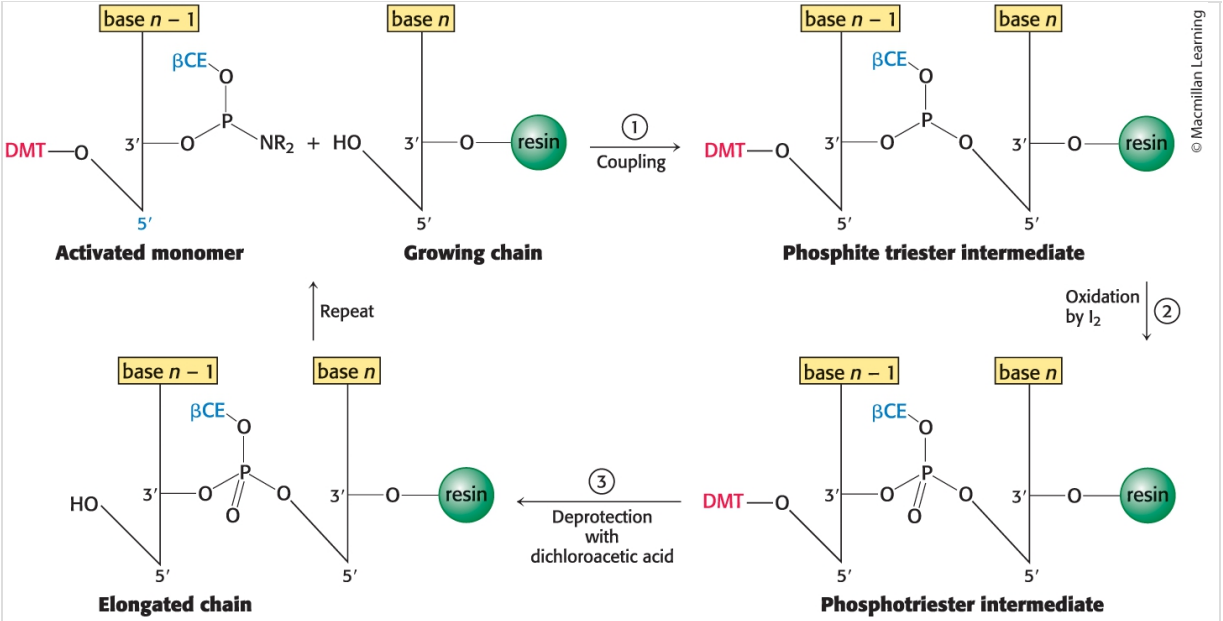
2′, 3′-Dideoxy analog

The incorporation of the dideoxy nucleotide blocks further growth of the new chain because this analog lacks the $3'$-hydroxyl terminus needed to form the next phosphodiester bond. The concentration of the dideoxy analog is low enough that chain termination will take place only occasionally. The polymerase will insert the correct nucleotide sometimes and the dideoxy analog other times, stopping the reaction. For instance, if the dideoxy analog of dATP is present, fragments of various lengths are produced, but all will be terminated by the dideoxy analog. Importantly, this dideoxy analog of dATP will be inserted only where a T was located in the DNA being sequenced. Thus, the fragments of different length will correspond to the positions of T.

The resulting fragments are separated by a technique known as *capillary electrophoresis*, in which the mixture is passed through a very narrow tube containing a gel matrix at high voltage to achieve efficient separation within a short time. As the DNA fragments emerge from the capillary, they are detected by their fluorescence; the sequence of their colors directly gives the base sequence. Sequences of as many as 1000 bases can be determined in this way. Indeed, automated Sanger sequencing machines can read more than 1 million bases per day.

DNA probes and genes can be synthesized by automated solid-phase methods

DNA strands, like polypeptides (Section 4.4), can be synthesized by the sequential addition of activated monomers to a growing chain that is linked to a solid support (resin). The activated monomers are protected deoxyribonucleoside $3'$-phosphoramidites. The synthesis of specific sequences proceeds by the repetition of the following cycle (**Figure 9.5**).



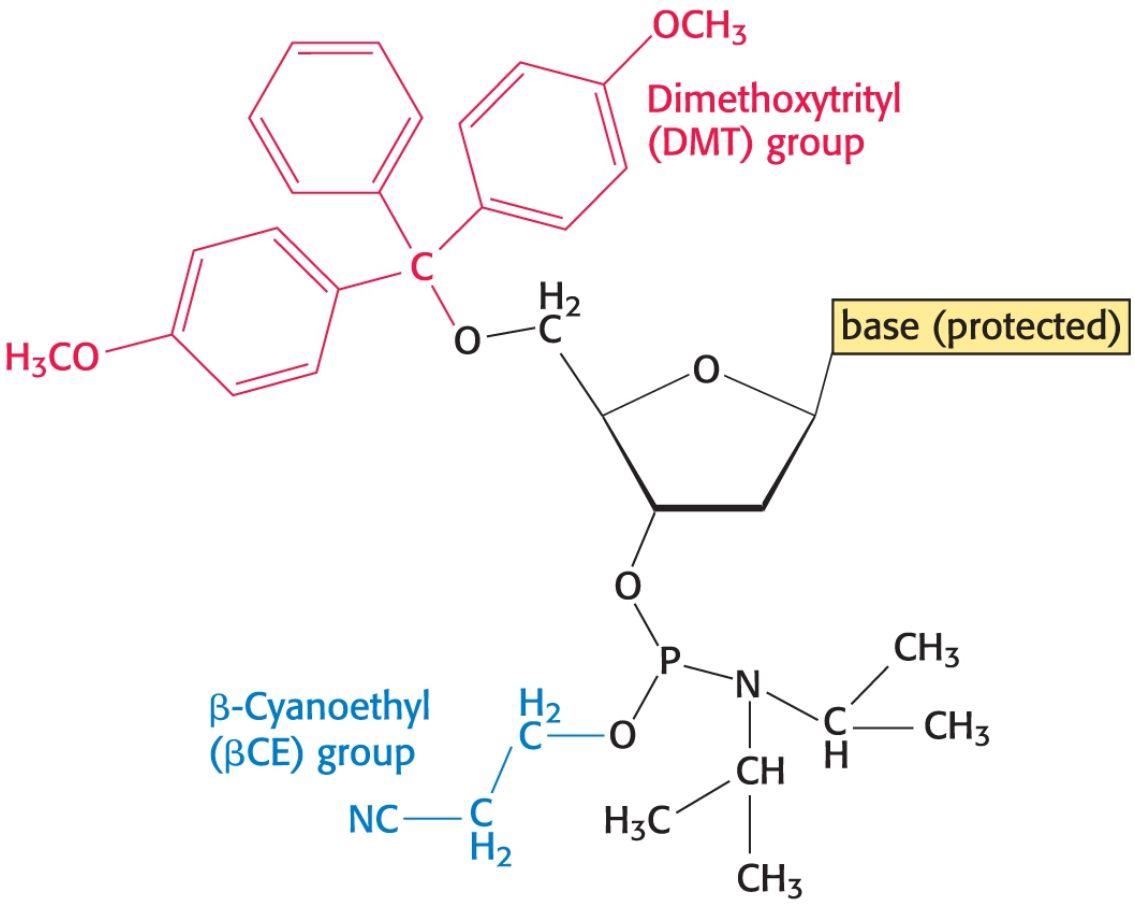


FIGURE 9.5 Oligonucleotides are synthesized in the solid-phase by the phosphite triester method. The activated monomer added to the growing chain is a deoxyribonucleoside $3'$-phosphoramidite containing a dimethoxytrityl (DMT) protecting group on its $5'$-oxygen atom, a β-cyanoethyl (βCE) protecting group on its $3'$-phosphoryl oxygen atom, and a protecting group on the base.

1. The $3'$-phosphorus atom of the incoming unit is joined to the $5'$-oxygen atom of the growing chain to form a phosphite triester. The $5'$-OH group of the activated monomer is unreactive because it is blocked by a dimethoxytrityl (DMT) protecting group, and the $3'$-phosphoryl oxygen atom is rendered unreactive by attachment of the β-cyanoethyl (βCE) group. Likewise, amino groups on the purine and pyrimidine bases are blocked. This step, called *coupling*, is carried out under anhydrous conditions because water reacts with phosphoramidites.

A deoxyribonucleoside 3′-phosphoramidite with DMT and βCE attached

2. The phosphite triester (in which P is trivalent) is oxidized by iodine to form a phosphotriester (in which P is pentavalent).

3. The DMT protecting group on the $5'$-OH group of the growing chain is removed by the addition of dichloroacetic acid, which leaves other protecting groups intact. The DNA chain is now elongated by one unit and ready for another cycle of addition.

Each cycle takes only about 10 minutes and usually elongates more than 99% of the chains that are linked to the solid support resin.

This solid-phase approach is ideal for the synthesis of DNA, as it is for polypeptides, because the desired product stays on the insoluble support until the final release step. All the reactions take place in a single vessel, and excess soluble reagents can be added to drive reactions to completion. At the end of each step, soluble reagents and by-products are washed away from the resin that bears the growing chains.

At the end of the synthesis, NH_3 is added to remove all protecting groups and release the oligonucleotide from the solid support. Because elongation is never 100% complete, the new DNA chains are of diverse lengths — the desired chain is the longest one. The sample can be purified by high-performance liquid chromatography or by electrophoresis on polyacrylamide gels. DNA chains of as many as 100 nucleotides can be readily synthesized by this automated method.

The ability to rapidly synthesize DNA chains of any selected sequence opens many experimental avenues. For example, a synthesized DNA probe labeled at one end with ^{32}P or a fluorescent tag can be used to search for a complementary sequence in a very long DNA molecule or even in a genome consisting of many chromosomes. Such a probe can be used as a primer to initiate the replication of neighboring DNA by DNA polymerase.

Another application of the solid-phase approach is the synthesis of new tailor-made genes. New proteins with novel properties can now be produced in abundance by the expression of synthetic genes. Finally, the synthesis described in the steps above can be slightly modified for the solid-phase synthesis of RNA oligonucleotides,

which can be very powerful reagents for the degradation of specific mRNA molecules in living cells by a technique known as RNA interference (Section 9.4).

Selected DNA sequences can be greatly amplified by the polymerase chain reaction

In 1984, Kary Mullis devised an ingenious method called the **polymerase chain reaction (PCR)** for amplifying specific DNA sequences. Consider a DNA duplex consisting of a target sequence surrounded by nontarget DNA. Millions of copies of the target sequences can be readily obtained by PCR if the sequences flanking the target are known. PCR is carried out by adding the following components to a solution containing the target sequence: (1) a pair of primers that hybridize with the flanking sequences of the target, (2) all four deoxyribonucleoside triphosphates (dNTPs), and (3) a heat-stable DNA polymerase. A PCR cycle consists of three steps (**Figure 9.6**).

Synthesize new DNA

FIGURE 9.6 The first cycle in the polymerase chain reaction (PCR) generates two double-stranded DNA molecules. A cycle consists of three steps: DNA double-strand separation, the hybridization of primers, and the extension of primers by DNA synthesis.

1. *Strand separation.* The two strands of the parent DNA molecule are separated by heating the solution to 95°C for 15 s.

2. *Annealing of primers.* The solution is then abruptly cooled to 54°C to allow each primer to hybridize to a DNA strand, a process called *annealing*. One primer hybridizes to the $3'$ end of the target on one strand, and the other primer hybridizes to the $3'$ end on the complementary target strand. Parent DNA duplexes do not form, because the primers are present in large excess. Primers are typically from 20 to 30 nucleotides long.

3. *DNA synthesis.* The solution is then heated to 72°C, the optimal temperature for heat-stable polymerases. One such enzyme is *Taq* DNA polymerase, which is derived from *Thermus aquaticus*, a thermophilic bacterium that lives in hot springs. The polymerase elongates both primers in the direction of the target sequence because DNA synthesis is in the $5'$-to-$3'$ direction. DNA synthesis takes place on both strands but extends beyond the target sequence in this initial round.

These three steps — strand separation, annealing of primers, and DNA synthesis — constitute one cycle of the PCR amplification and can be carried out repetitively just by changing the temperature of the reaction mixture. The thermostability of the polymerase makes it feasible to carry out PCR in a closed container; no reagents are

added after the first cycle. At the completion of the second cycle, four duplexes containing the target sequence have been generated (**Figure 9.7**). Of the eight DNA strands comprising these duplexes, two short strands constitute only the target sequence — the sequence including and bounded by the primers. Subsequent cycles will amplify the target sequence exponentially. Ideally, after n cycles, the desired sequence is amplified 2^n-fold. The amplification is a millionfold after 20 cycles and a billionfold after 30 cycles, which can be carried out in less than an hour.

Subsequent cycles will amplify the target sequence exponentially and the parent sequence (yellow) arithmetically.

VIEW an animation of this technique in Achieve

Several features of this remarkable method for amplifying DNA are noteworthy. First, the sequence of the target need not be known. All that is required is knowledge of the flanking sequences so that complementary primers can be synthesized. Second, the target can be much larger than the primers. Targets larger than 10 kb have been amplified by PCR. Third, primers do not have to be perfectly matched to flanking sequences to amplify targets. With the use of primers derived from a gene of known sequence, it is possible to search for variations on the theme. In this way, families of genes are being discovered by PCR. Fourth, PCR is highly specific because of the stringency of hybridization at relatively high temperature. *Stringency* is the required closeness of the match between primer and target, which can be controlled by temperature and salt. At high temperatures, only the DNA between hybridized primers is amplified. A gene constituting less than a millionth of the total DNA of a higher organism is accessible by PCR. Fifth, PCR is exquisitely sensitive. A single DNA molecule can be amplified and detected.

Self-Check Question

How would altering the stringency (for example, by changing the temperature of hybridization) affect PCR amplification? Suppose that you have a particular yeast gene

A and that you wish to see if it has a counterpart in humans. How would controlling the stringency of the hybridization help you?

PCR is a powerful technique in medical diagnostics, forensics, and studies of molecular evolution

PCR has been utilized in a wide variety of applications across many different disciplines:

- *Diagnosing certain infections caused by viruses and bacteria.* With the use of specific primers, PCR can reveal the presence of small amounts of DNA from the human immunodeficiency virus (HIV) in persons who have not yet mounted an immune response to this pathogen. In these patients, assays designed to detect antibodies against the virus would yield a false negative test result. Similarly, in patients suspected of having tuberculosis, PCR can be used to rapidly detect as few as 10 tubercle bacilli per million human cells, whereas finding *Mycobacterium tuberculosis* bacilli in tissue specimens would be slow and laborious.

- *Detecting certain cancers early and monitoring chemotherapy.* PCR can identify mutations of certain growth-control genes, such as the *ras* genes (Chapter 14). PCR is also ideal for detecting leukemias caused by chromosomal rearrangements. In addition, tests using PCR can detect when cancerous cells have been eliminated and treatment can be stopped; they can also detect a relapse and the need to immediately resume treatment.

- *Solving forensics cases.* An individual DNA profile is highly distinctive because many genetic loci are highly variable within a population. For example, each chromosome contains regions which vary in length from individual to individual. The pattern of DNA fragment sizes from PCR amplification across these regions provides a unique fingerprint for that individual. Numerous assault and rape cases rely on analyses of blood stains and semen samples by PCR (**Figure 9.8**). The root of a single shed hair found at a crime scene contains enough DNA for typing by PCR.

Martin Shields/Science Source

FIGURE 9.8 PCR can be applied to forensic cases. DNA isolated from sperm obtained during the examination of a rape victim was amplified by PCR, then compared with DNA from the victim and two potential suspects using gel electrophoresis and autoradiography. Sperm DNA matched the pattern of Suspect 1, but not that of Suspect 2.

- *Studying molecular evolution.* DNA is a remarkably stable molecule, particularly when shielded from air, light, and water. Under such circumstances, large fragments of DNA can remain intact for thousands of years or longer. PCR provides an ideal method for amplifying such ancient DNA molecules so that they can be detected and characterized. As will be discussed in Chapter 10, sequences from these PCR products can be sources of considerable insight into evolutionary relationships between organisms.

The tools for recombinant DNA technology have been used to identify disease-causing mutations

Let us consider how the techniques just described have been used to study the molecular underpinning of human disease. Amyotrophic lateral sclerosis (ALS) was first described clinically in 1869 as a fatal neurodegenerative disease of progressive weakening and atrophy of voluntary muscles. ALS is commonly referred to as *Lou Gehrig's disease,* for the baseball legend whose career and life were

prematurely cut short as a result of this devastating disease. For many years, little progress had been made in the study of the mechanisms underlying ALS.

Five percent of all patients suffering from ALS have family members who also have been diagnosed with the disease. A heritable disease pattern is indicative of a strong genetic component of disease causation. To identify these disease-causing genetic alterations, researchers identify **polymorphisms** (instances of genetic variation) within an affected family that correlate with the emergence of disease. These polymorphisms may themselves cause disease or be closely linked to the responsible genetic alteration. **Restriction-fragment-length polymorphisms (RFLPs)** are polymorphisms within restriction sites that change the sizes of DNA fragments produced by the appropriate restriction enzyme. Using restriction digests and Southern blots of the DNA from members of ALS-affected families, researchers identified RFLPs that were found preferentially in those family members diagnosed with the disease. For some of these families, strong evidence was obtained for the disease-causing mutation within a specific region of chromosome 21.

After the probable location of one disease-causing gene had been identified, this same research group compared the locations of the ALS-associated RFLPs with the known sequence of chromosome 21. They noted that this chromosomal locus contains the *SOD1* gene, which encodes the Cu/Zn superoxide dismutase protein SOD1, an enzyme important for the protection of cells against oxidative damage (Section 18.3). PCR amplification of regions of the *SOD1* gene from the DNA of affected family members, followed by Sanger dideoxy sequencing of the targeted fragment, enabled the identification of 11 disease-causing mutations from 13 different families. This work was pivotal for focusing further inquiry into the

roles that superoxide dismutase and its corresponding mutant forms play in the pathology of some forms of ALS.

9.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology

The development of recombinant DNA technology has taken biology from an exclusively analytical science to a synthetic one. New combinations of unrelated genes can be constructed in the laboratory by applying recombinant DNA techniques. These novel combinations can be cloned — amplified many-fold — by introducing them into suitable cells, where they are replicated by the DNA-synthesizing machinery of the host. The inserted genes are often transcribed and translated in their new setting. What is most striking is that the genetic endowment of the host can be permanently altered in a designed way.

Restriction enzymes and DNA ligase are key tools in forming recombinant DNA molecules

Let us begin by exploring how novel DNA molecules can be constructed in the laboratory. An essential tool for the manipulation of recombinant DNA is a **vector**, a DNA molecule that can replicate autonomously in an appropriate host organism. Vectors are designed to enable the rapid, covalent insertion of DNA fragments of interest. **Plasmids**, naturally occurring circles of DNA that act as accessory chromosomes in bacteria, and the virus **bacteriophage lambda (λ phage)** are choice vectors for cloning in *E. coli*. DNA fragments can be inserted into these vectors in several steps.

- *The vector is cut by restriction enzymes, creating sticky ends.* A vector can be prepared for accepting a new DNA fragment by cleaving it at a single specific site with a restriction enzyme. For example, the plasmid pSC101, a 9.9-kb double-helical circular DNA molecule, is split at a unique site by the EcoRI restriction enzyme. The staggered cuts made by this enzyme produce complementary single-stranded ends, which have specific affinity for each other and hence are known as **cohesive** or **sticky ends**. Any DNA fragment can be inserted into this plasmid if it has the same cohesive ends. Such a fragment can be extracted from a larger piece of DNA by using the same restriction enzyme as was used to open the plasmid DNA (**Figure 9.9**).

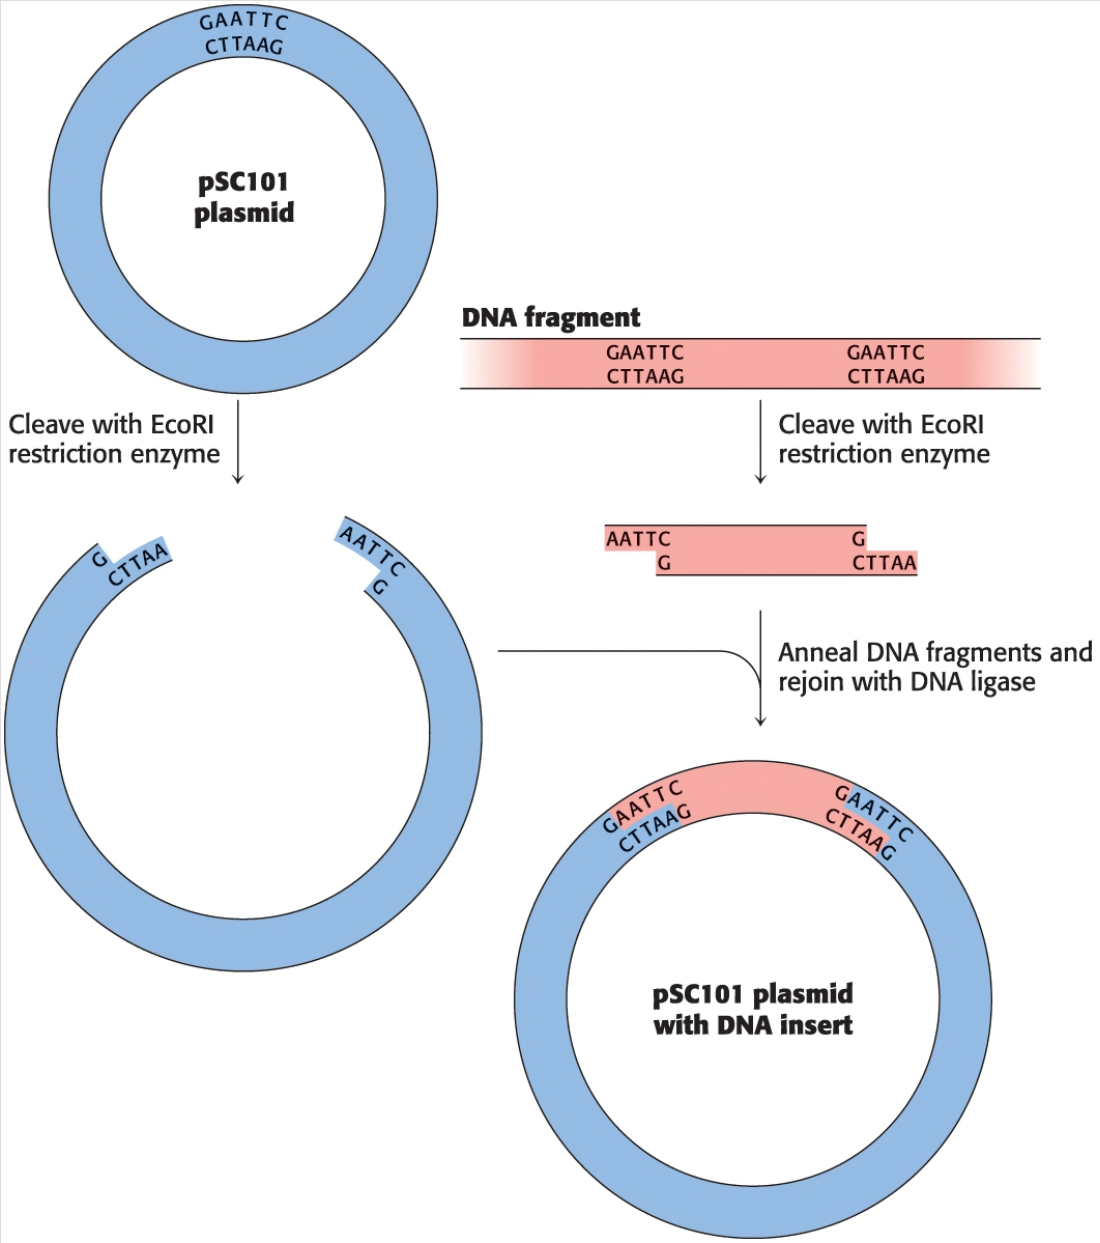

FIGURE 9.9 Different DNA molecules can be joined by the cohesive-end method. The pSC101 plasmid (blue) is cleaved once by EcoRI to yield a pair of cohesive ends. A fragment of DNA (red), also cleaved with EcoRI, can be ligated to the cut plasmid to form a new plasmid with the DNA fragment inserted.

- *DNA ligase inserts the DNA fragment within the cut vector.* The single-stranded ends of the fragment are complementary to those of the cut plasmid. The sticky ends of the DNA fragment and the cut plasmid can base pair with each other, or *anneal,* and then joined by *DNA ligase,* which catalyzes the formation of a phosphodiester bond at a break in a DNA chain. DNA ligase requires a free $3'$-hydroxyl group and a $5'$-phosphoryl group. Furthermore, the chains joined by ligase must be in a double helix. An energy source such as ATP or NAD^+ is required for the joining reaction, as will be discussed in Chapter 28.

- *When necessary, linkers can be added to DNA fragments to yield cohesive ends.* What if the target DNA is not naturally flanked by the appropriate restriction sites? How is the fragment cut and annealed to the vector? The cohesive-end method for joining DNA molecules can still be used in these cases by adding a short, chemically synthesized DNA linker that can be cleaved by restriction enzymes. First, the linker is covalently joined to the ends of a DNA fragment. For example, the $5'$ ends of a decameric linker and a DNA molecule are phosphorylated by polynucleotide kinase and then joined by the ligase from T4 phage (**Figure 9.10**). This particular ligase can form a covalent bond between blunt-ended double-helical DNA molecules. Finally, cohesive ends are produced when these terminal extensions are cut by an appropriate restriction enzyme. Thus, cohesive ends corresponding to the product of a particular restriction enzyme can be added to virtually any DNA molecule. We see here the fruits of combining enzymatic and synthetic chemical approaches in crafting new DNA molecules.

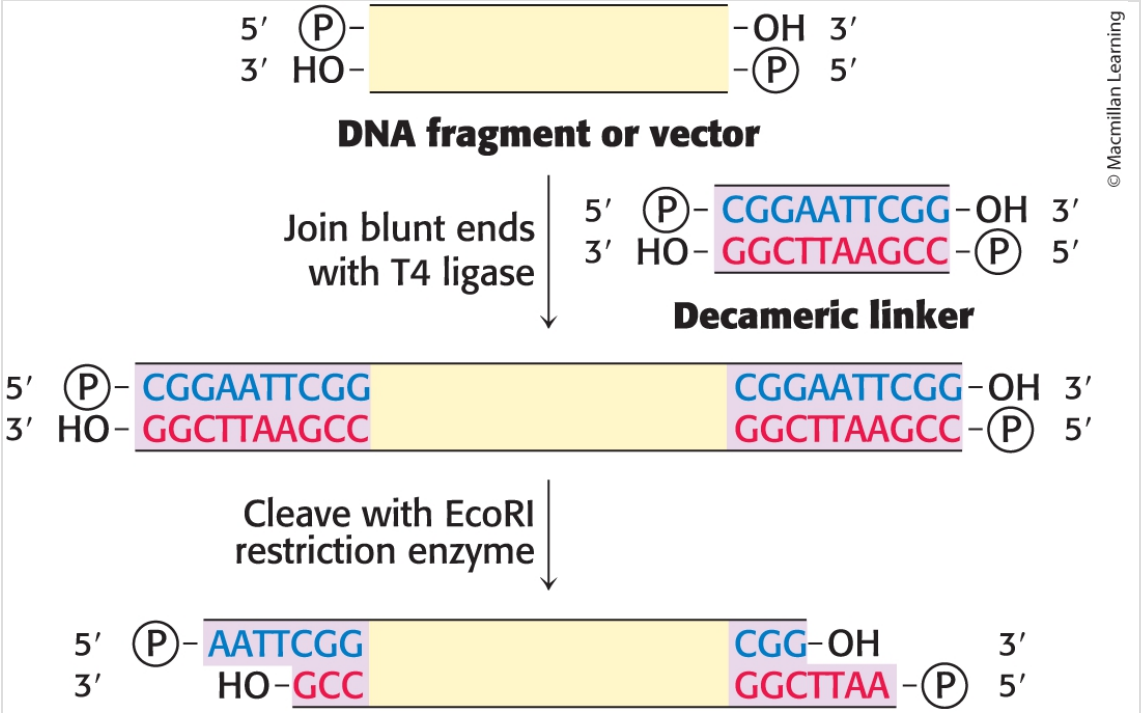

FIGURE 9.10 Cohesive ends can be added to any DNA fragment. A chemically synthesized linker containing a specific restriction site is joined to the ends of the fragment by T4 ligase. Subsequent cleavage by the restriction enzyme yields the new cohesive ends.

Plasmids and λ phage are choice vectors for DNA cloning in bacteria

Many plasmids and bacteriophages have been ingeniously modified by researchers to both enhance the delivery of recombinant DNA molecules into bacteria and to facilitate the genetic selection of bacteria harboring these vectors.

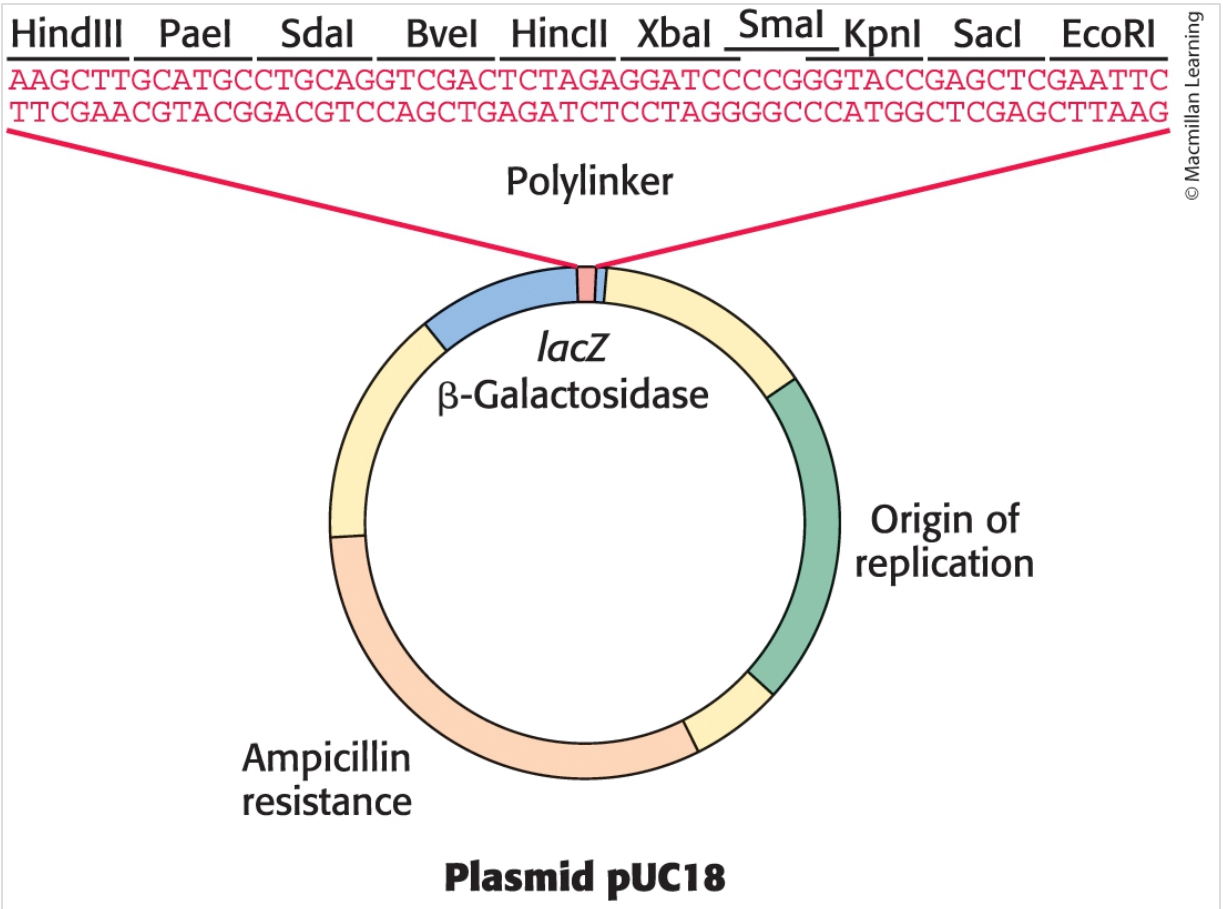
Plasmids

These circular DNA molecules found in bacteria range in size from two to several hundred kilobases and carry genes for the inactivation of antibiotics, the production of toxins, and the breakdown of natural products. As accessory chromosomes, they can replicate independently of the host chromosome and, in contrast with the host genome, are dispensable under certain conditions. A bacterial cell may have no plasmids at all, or it may house as many as 20 copies of a naturally occurring plasmid.

Many plasmids have been optimized for a particular experimental task. Some engineered plasmids, for example, can achieve nearly a thousand copies per bacterial cell. One class of plasmids, known as **cloning vectors**, is particularly suitable for the facile insertion and replication of a collection of DNA fragments. These vectors often feature a **polylinker** region that includes many unique restriction sites within its sequence. This polylinker can be cleaved with a variety of restriction enzymes or combinations of enzymes, providing great versatility in the DNA fragments that can be inserted. In addition, these plasmids contain **reporter genes**, which encode easily detectable markers such as antibiotic-resistance enzymes or fluorescent proteins. Creative placement of these reporter genes within these plasmids enables the rapid identification of those vectors that harbor the desired DNA insert.

For example, let us consider the cloning vector pUC18 (**Figure 9.11**). This plasmid contains three essential components: an origin of replication, so that the plasmid can be replicated when the host bacterium divides; a gene encoding ampicillin resistance, which enables the selection of bacteria that harbor the plasmid; and the *lacZ* gene, which encodes an essential fragment of the enzyme *β-galactosidase*, an enzyme which naturally cleaves the milk sugar lactose (Section 11.2). Insertion of a DNA fragment into the

polylinker region disrupts the *lacZ* gene, an effect called *insertional inactivation*. β-Galactosidase also cleaves the synthetic substrate X-gal, releasing a blue dye. Bacterial cells containing a DNA insert within the polylinker will no longer produce the dye in the presence of X-gal. Hence, bacteria harboring vectors that have received an insert are readily identified by their white color (Figure 9.12).



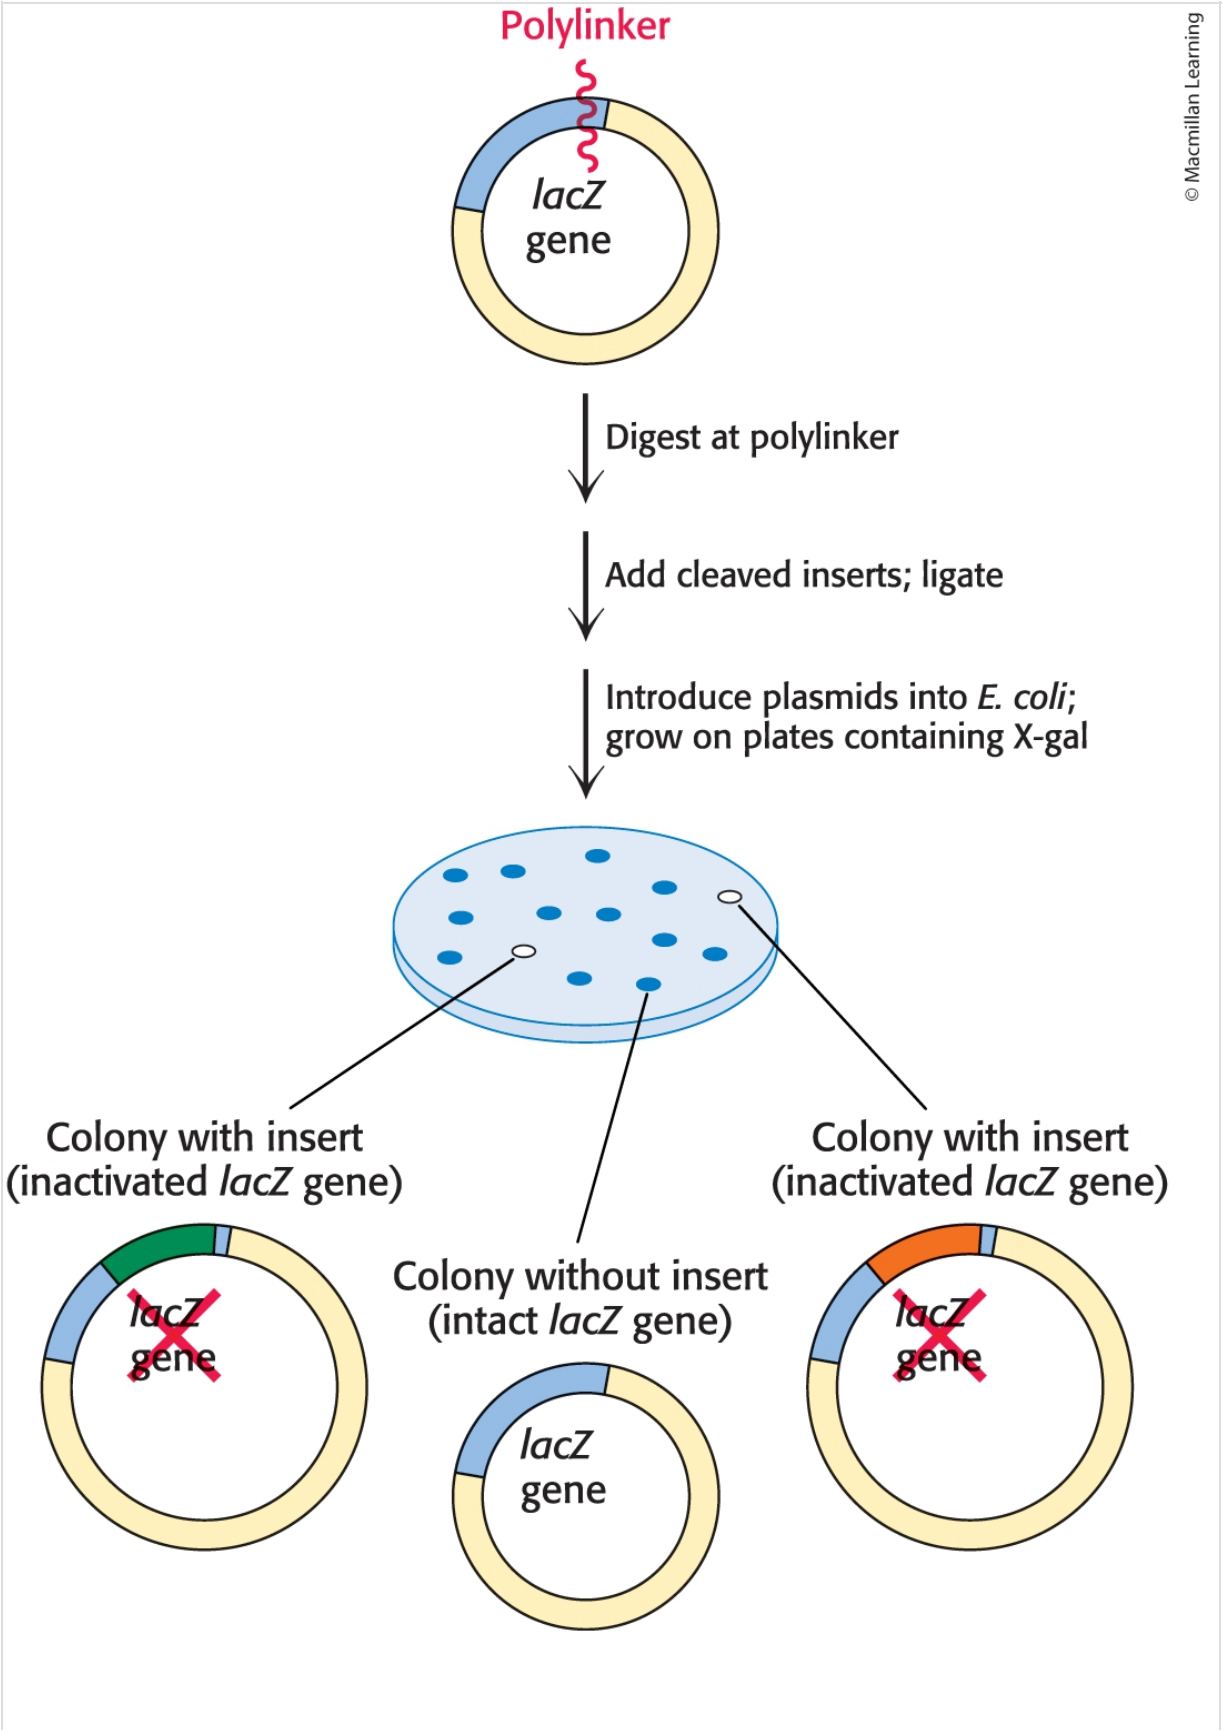


FIGURE 9.11 A polylinker contains multiple unique restriction sites. In addition to an origin of replication and a gene encoding ampicillin resistance, the plasmid pUC18 includes a polylinker within an essential fragment of the β-galactosidase gene (often called the *lacZ* gene).

© Macmillan Learning

FIGURE 9.12 Insertional inactivation allows for the rapid identification of colonies that have new insertions. Successful insertion of DNA fragments into the polylinker region of pUC18 will result in the disruption of the β-galactosidase gene. Bacterial colonies that harbor such plasmids will no longer convert the substrate X-gal into a colored product, and will appear white on the plate.

Another class of plasmids has been optimized for use as **expression vectors** for the production of large amounts of protein. Many different expression vectors are currently in use. **Figure 9.13** depicts the typical elements of a vector designed to express a protein in prokaryotes. In addition to an antibiotic-resistance gene and an origin of replication, an expression vector contains promoter and terminator sequences specifically designed to drive the transcription of large amounts of a protein-coding DNA sequence. As in the cloning vectors, these plasmids also contain a polylinker region, which often contain sequences flanking the cloning site that simplify the addition of fusion tags to the protein of interest (Section 4.1), greatly facilitating purification of the overexpressed protein. Many expression vectors also possess transcriptional repressor and operator sequences (Section 31.2), which enable the precise control of when production of the protein will be turned on.

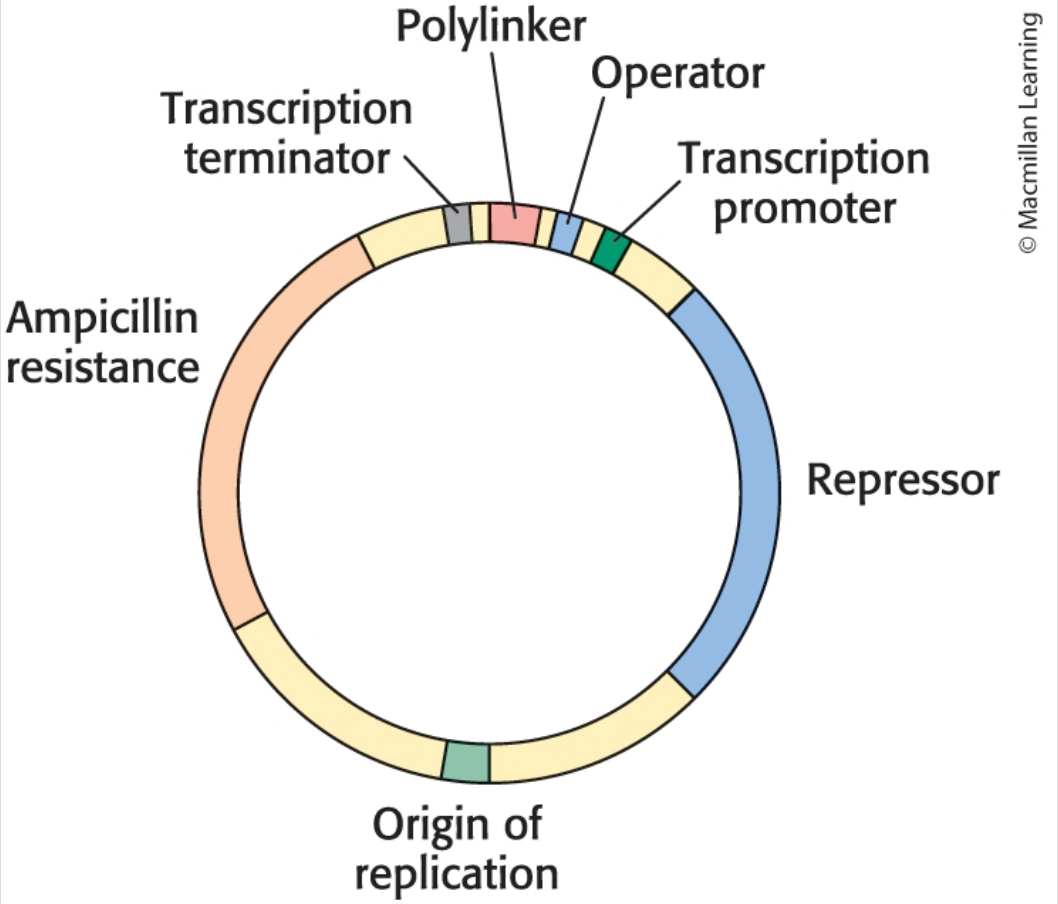

FIGURE 9.13 Expression vectors are designed to generate protein product. As with the cloning vector (Figure 9.11), the prokaryotic expression vector shown here contains an origin of replication and an antibiotic-resistance gene. In addition, these plasmids include transcription initiation (promoter) and termination sequences, required for the expression of a protein-coding gene inserted in the polylinker. Many expression plasmids also contain repressor and operator sequences which allow for the control of the timing of protein production.

λ phage

Another widely used vector is the bacteriophage lambda, or λ phage. Bacteriophages are viruses that infect and replicate within bacteria.

The λ phage enjoys a choice of lifestyles: it can destroy its host or become part of its host (Figure 9.14). In the *lytic pathway*, viral functions are fully expressed: viral DNA and proteins are quickly produced and packaged into virus particles, leading to the lysis (destruction) of the host cell and the sudden appearance of about 100 progeny virus particles, also called *virions*. In contrast, in the *lysogenic pathway*, the phage DNA becomes inserted into the host-cell genome and can be replicated together with host-cell DNA for many generations, remaining inactive. Certain environmental changes can trigger the expression of this dormant viral DNA, which leads to the formation of progeny viruses and lysis of the host. Large segments of the 48-kb DNA genome of λ phage are not essential for productive infection and can be replaced by foreign DNA, thus making λ phage an ideal vector.

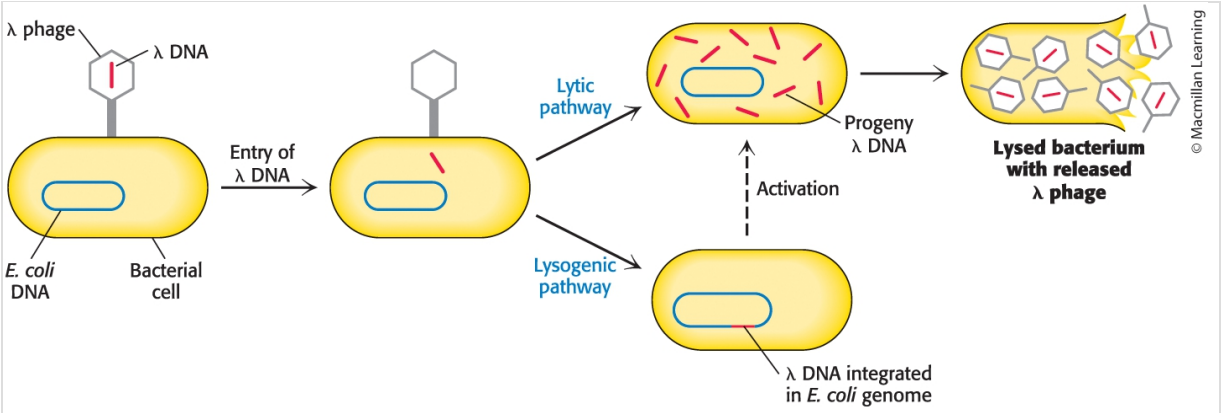

FIGURE 9.14 λ phage alternates between two infection modes. λ phage can multiply within a host and lyse it (lytic pathway), or its DNA can become integrated into the host genome (lysogenic pathway), where it is dormant until activated.

Scientists have constructed mutant λ phages that are well-suited for cloning. An especially useful one called λgt-λβ contains only two EcoRI cleavage sites instead of the five normally present (Figure

9.15). After cleavage, the middle segment of this λ DNA molecule can be removed. The two remaining pieces of DNA (called arms) have a combined length equal to 72% of a normal genome length. This amount of DNA is too little to be packaged into a λ particle, which can take up only DNA measuring from 78% to 105% of a normal genome. However, a suitably long DNA insert (such as 10 kb) between the two ends of λ DNA enables such a recombinant DNA molecule (93% of normal length) to be packaged. Nearly all infectious λ particles formed in this way will contain an inserted piece of foreign DNA. An advantage of using these modified viruses as vectors is that they enter bacteria much more easily than do plasmids.

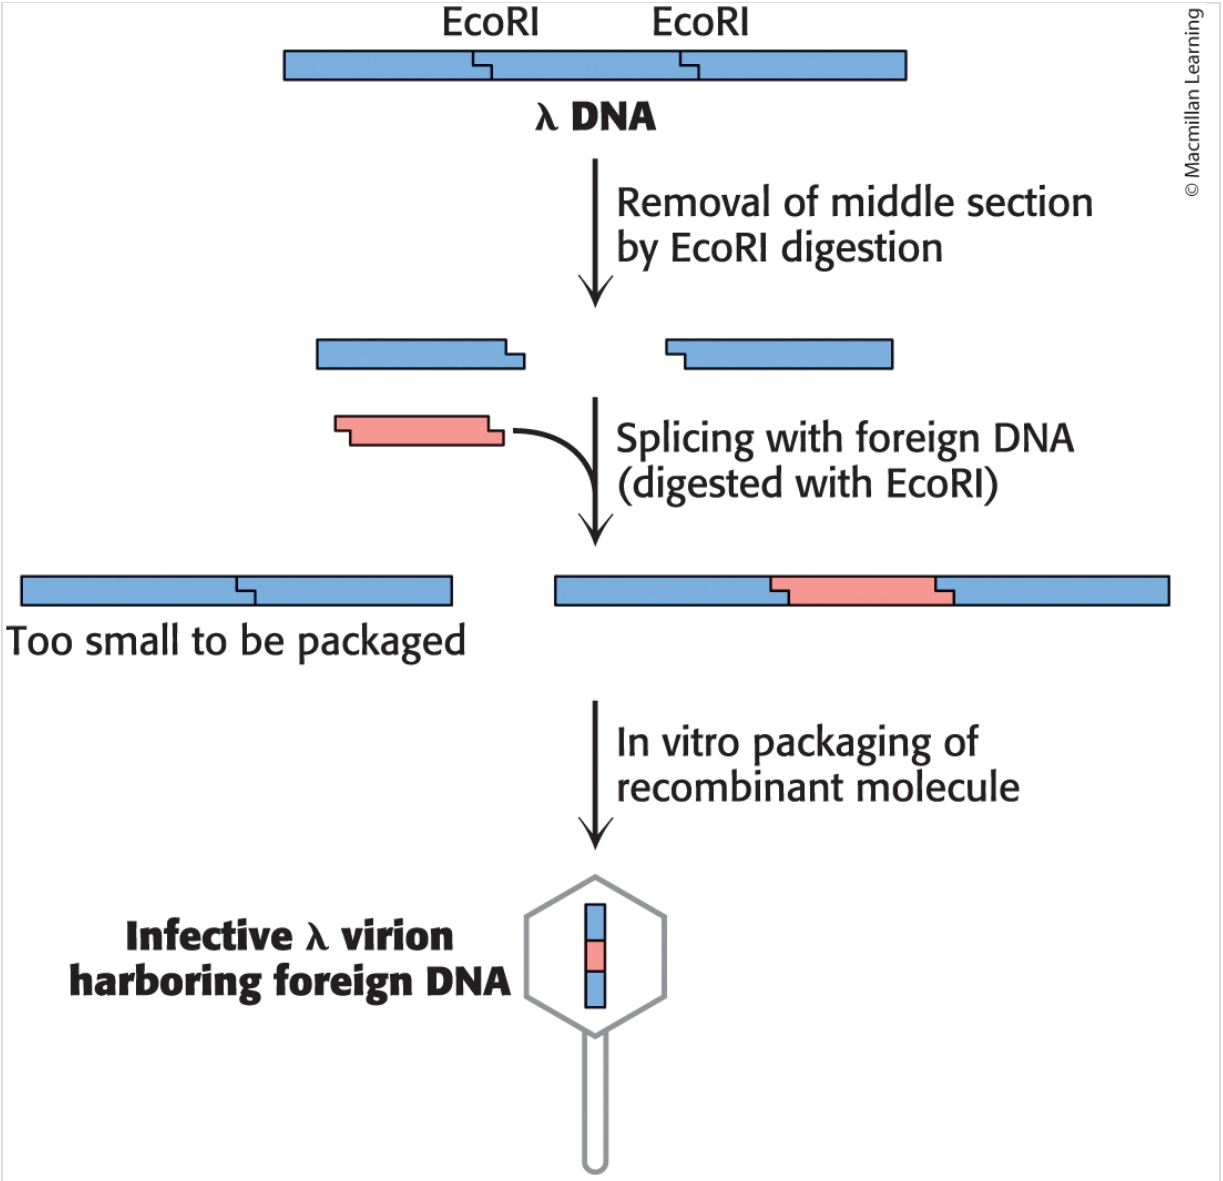

FIGURE 9.15 Mutant λ phage can be used as a cloning vector. The packaging process selects DNA molecules that contain an insert (colored red). DNA molecules that have resealed without an insert are too small to be efficiently packaged.

Specific genes can be cloned from digests of genomic DNA

Ingenious cloning and selection methods have made it possible to isolate small stretches of DNA in a genome containing more than 3×10^6 kb (i.e., 3×10^9 bases). The approach is to prepare a large collection, called a **genomic library**, of DNA fragments and then to identify those members of the collection that have the gene of interest. Hence, to clone a gene that is present just once in an entire genome, two critical components must be available: a specific oligonucleotide probe for the gene of interest, and a DNA library that can be screened rapidly.

How is a specific probe obtained? In one method, a probe for a gene can be prepared if a part of the amino acid sequence of the protein encoded by the gene is known. Peptide sequencing of a purified protein (Chapter 4) or knowledge of the sequence of a homologous protein from a related species (Chapter 10) are two potential sources of such information. However, a problem arises because a single peptide sequence can be encoded by a number of different oligonucleotides (**Figure 9.16**). Thus, for this purpose, peptide sequences containing tryptophan and methionine are preferred, because these amino acids are specified by a single codon, whereas other amino acid residues have between two and six codons (Table 8.5). All the possible DNA sequences (or their complements) that encode the targeted peptide sequence are synthesized by the solid-phase method and made radioactive by phosphorylating their $5'$ ends with ^{32}P.

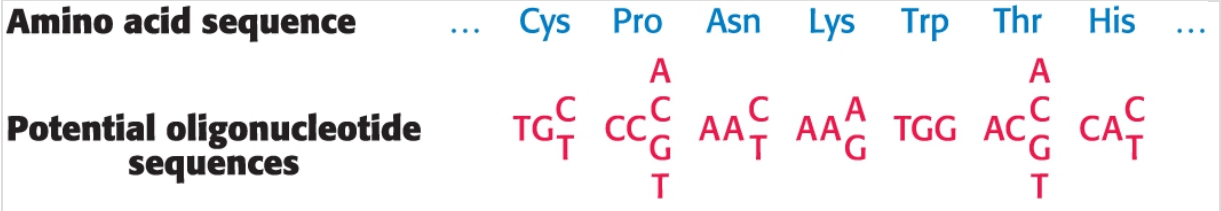

FIGURE 9.16 Oligonucleotide probes can be designed from the target protein sequence. A probe can be generated by synthesizing all possible oligonucleotides encoding a particular sequence of amino acids. Because of the degeneracy of the genetic code, 256 distinct oligonucleotides must be synthesized to ensure that the probe matching the sequence of seven amino acids in this example is present.

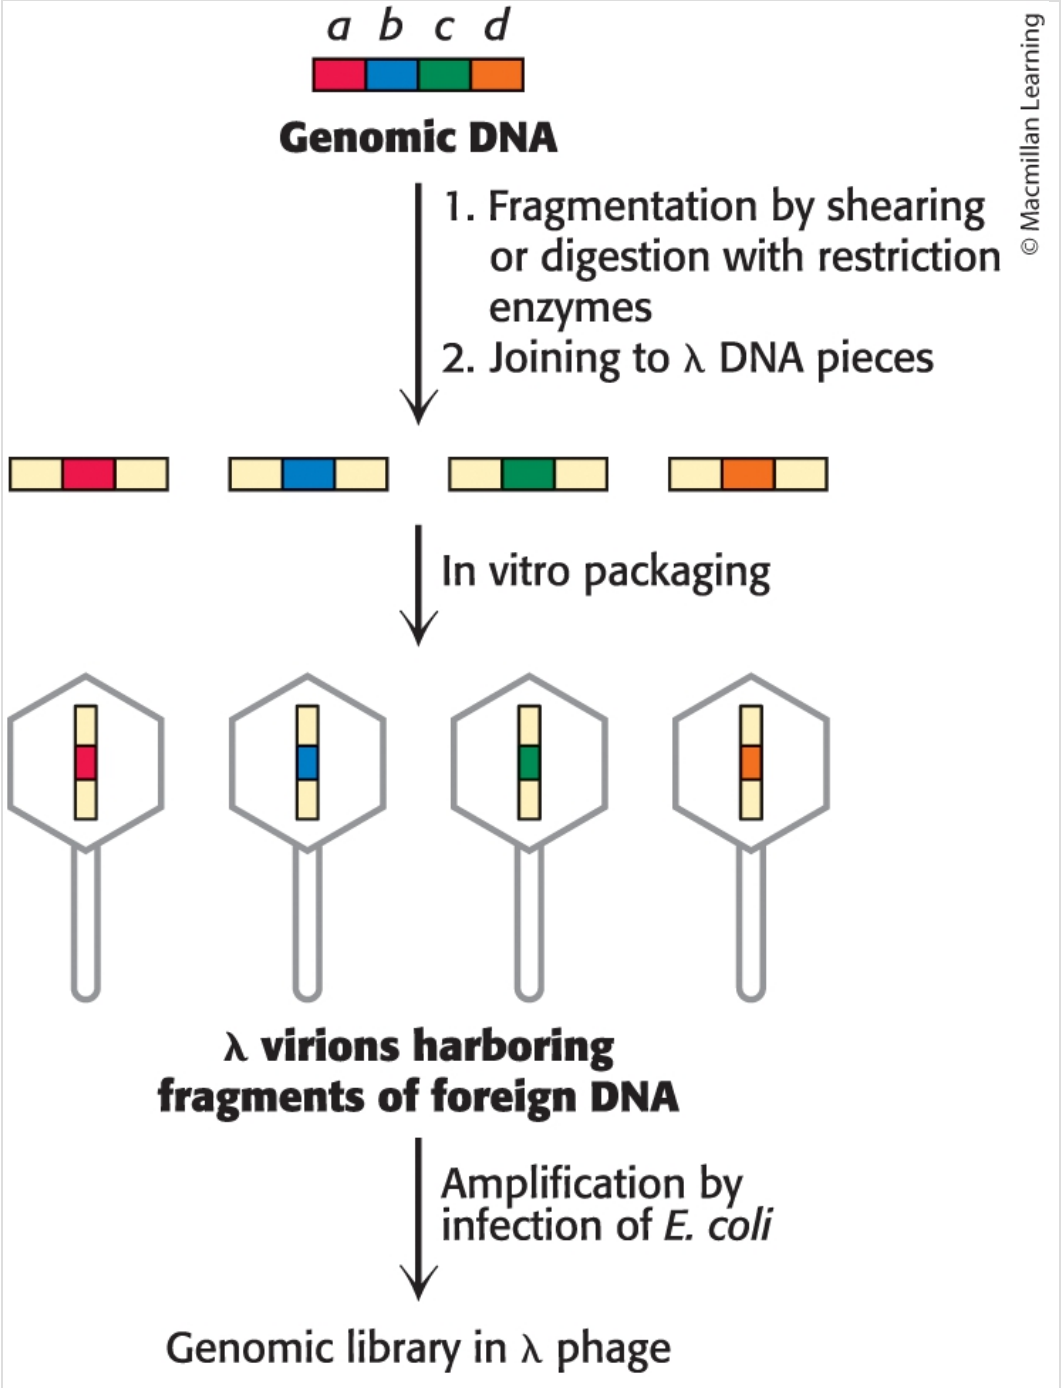
To prepare the DNA library, a sample containing many copies of total genomic DNA is first mechanically sheared or partly digested by restriction enzymes into large fragments (Figure 9.17). This process yields a nearly random population of overlapping DNA fragments. These fragments are then separated by gel electrophoresis to isolate the set of all fragments that are about 15 kb long. Synthetic linkers are attached to the ends of these fragments, cohesive ends are formed, and the fragments are then inserted into a vector, such as λ phage DNA, prepared with the same cohesive ends. *E. coli* bacteria are then infected with these recombinant phages. These phages replicate themselves and then lyse their bacterial hosts. The resulting lysate contains fragments of genomic DNA housed in a sufficiently large number of virus particles to ensure that nearly the entire genome is represented in the library. Phages can be propagated indefinitely such that the library can be used repeatedly over long periods.



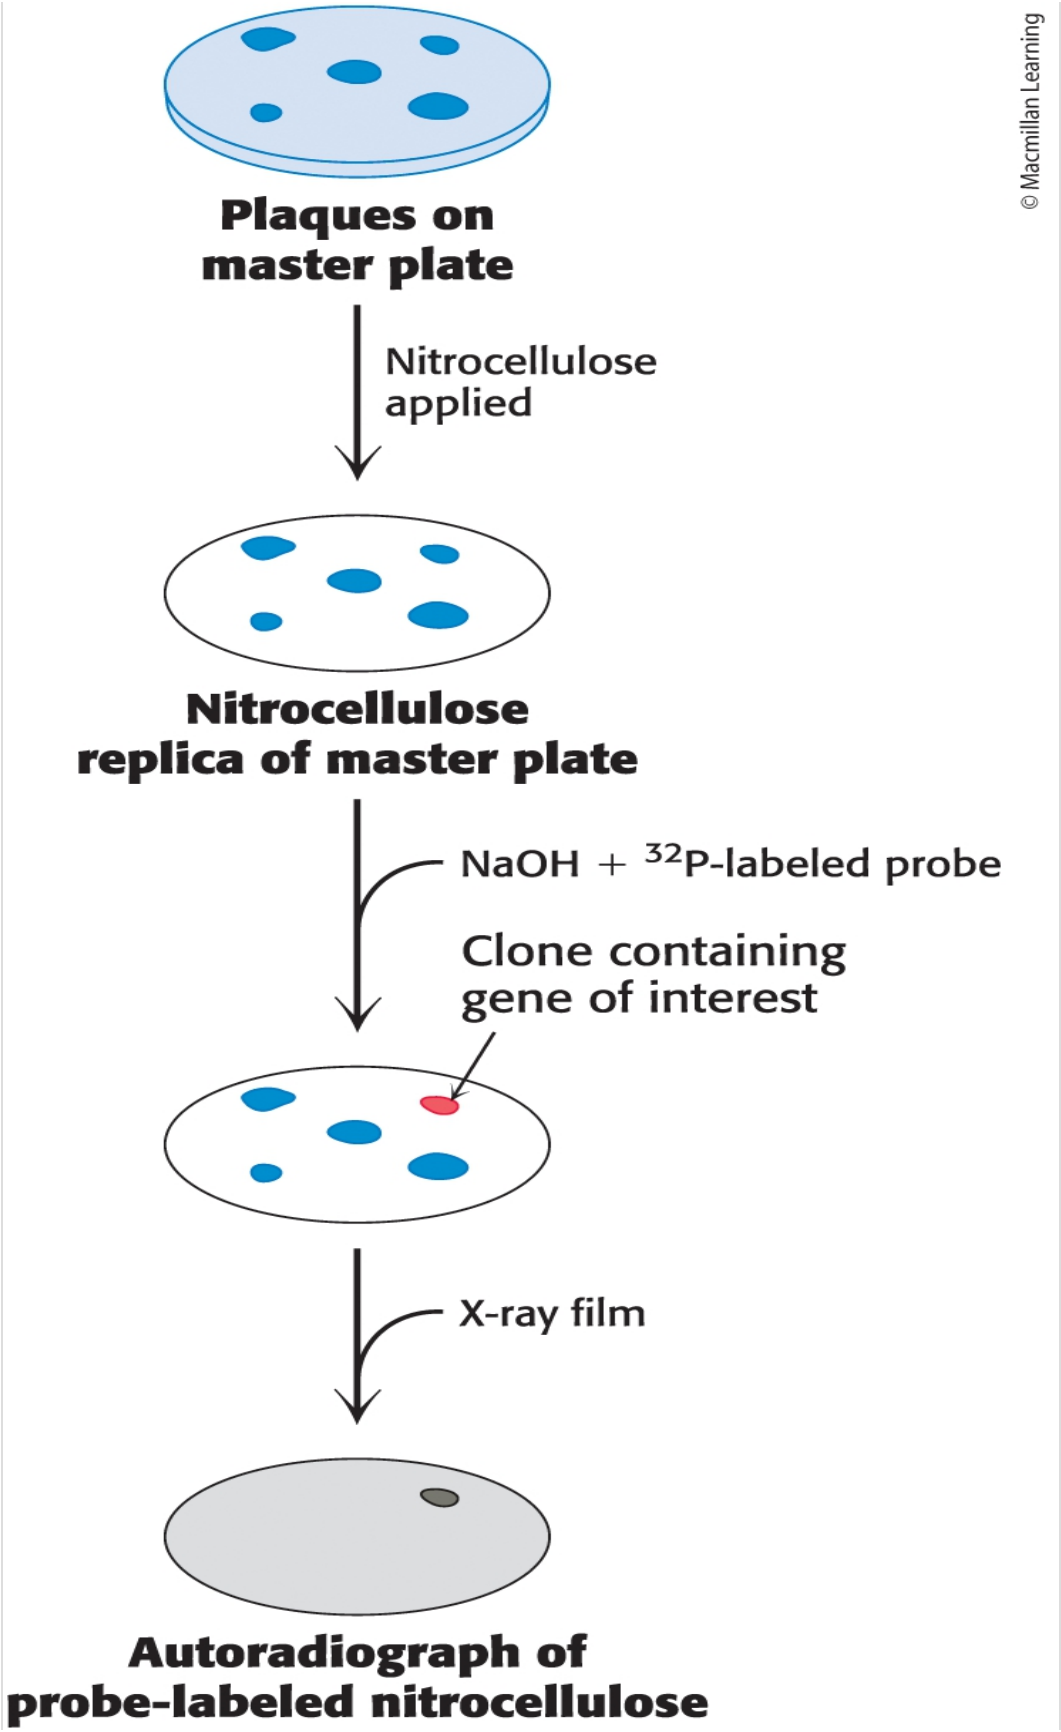


FIGURE 9.17 A genomic library can be created from a digest of a whole genome. After fragmentation of the genomic DNA into overlapping segments, the DNA is inserted into the λ phage vector (shown in yellow). Packaging into virions and amplification by infection in *E. coli* yields a genomic library.

This genomic library is then screened to find the very small number of phages harboring the gene of interest. For the human genome, a calculation shows that a 99% probability of success requires screening about 500,000 clones; hence, a very rapid and efficient screening process is essential. Rapid screening can be accomplished by DNA hybridization.

A dilute suspension of the recombinant phages is first plated on a lawn of bacteria (**Figure 9.18**). Where each phage particle has landed and infected a bacterium, a *plaque* containing identical phages develops on the plate. A replica of this master plate is then made by applying a sheet of nitrocellulose. Infected bacteria and phage DNA released from lysed cells adhere to the sheet in a pattern of spots corresponding to the plaques. Intact bacteria on this sheet are lysed with sodium hydroxide, which also serves to denature the DNA so that it becomes accessible for hybridization with a ^{32}P-labeled probe. The presence of a specific DNA sequence in a single spot on the replica can be detected by using a radioactive complementary DNA or RNA molecule as a probe. Autoradiography then reveals the positions of spots harboring recombinant DNA. The corresponding plaques are picked out of the intact master plate and grown. A single investigator can readily screen a million clones in a day. This method makes it possible to isolate virtually any gene, provided that a probe is available.

Self-Check Question

Suppose that a human genomic library is prepared by exhaustive digestion of human DNA with the EcoRI restriction enzyme. What is the average fragment length generated by this enzyme? Is this procedure suitable for cloning large genes? Why or why not?

Complementary DNA prepared from mRNA can be expressed in host cells

The preparation of eukaryotic genomic libraries presents unique challenges, especially if the researcher is interested primarily in the protein-coding region of a particular gene. Recall that most mammalian genes are mosaics of introns and exons. These interrupted genes cannot be expressed by bacteria, which lack the machinery to splice introns out of the primary transcript. However, this difficulty can be circumvented by causing bacteria to take up recombinant DNA that is complementary to mRNA, where the introns have been removed.

The key to forming **complementary DNA**, or **cDNA**, is the enzyme reverse transcriptase. As discussed in Section 8.4, a retrovirus uses this enzyme to form a DNA–RNA hybrid in replicating its genomic

RNA. Reverse transcriptase synthesizes a DNA strand complementary to an RNA template if the transcriptase is provided with a DNA primer that is base-paired to the RNA and contains a free $3'-OH$ group. We can use a simple sequence of linked thymidine [oligo(T)] residues as the primer. This oligo(T) sequence pairs with the poly(A) sequence at the $3'$ end of most eukaryotic mRNA molecules (Section 4.5), as shown in **Figure 9.19**.

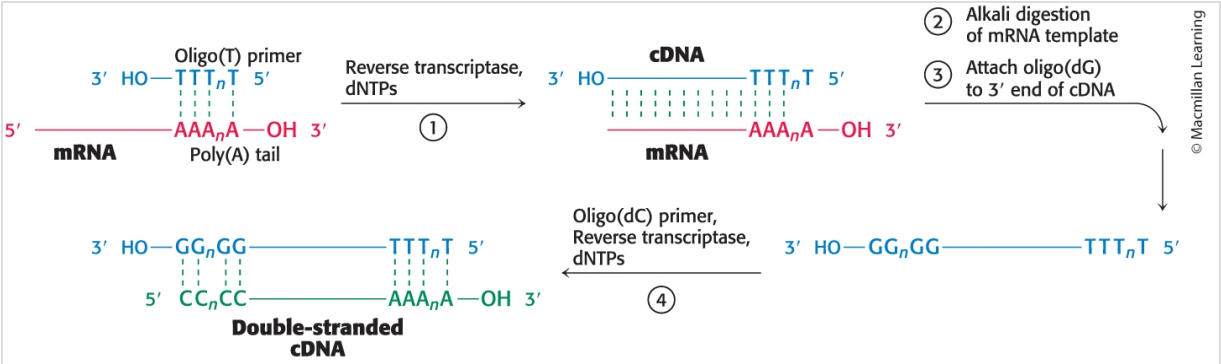

FIGURE 9.19 Double-stranded cDNA is prepared from mRNA using reverse transcriptase. A complementary DNA (cDNA) duplex is created from mRNA by (1) use of reverse transcriptase to synthesize a cDNA strand, (2) digestion of the original RNA strand, (3) addition of several G bases to the DNA by terminal transferase, and (4) synthesis of a complementary DNA strand using the newly synthesized cDNA strand as a template.

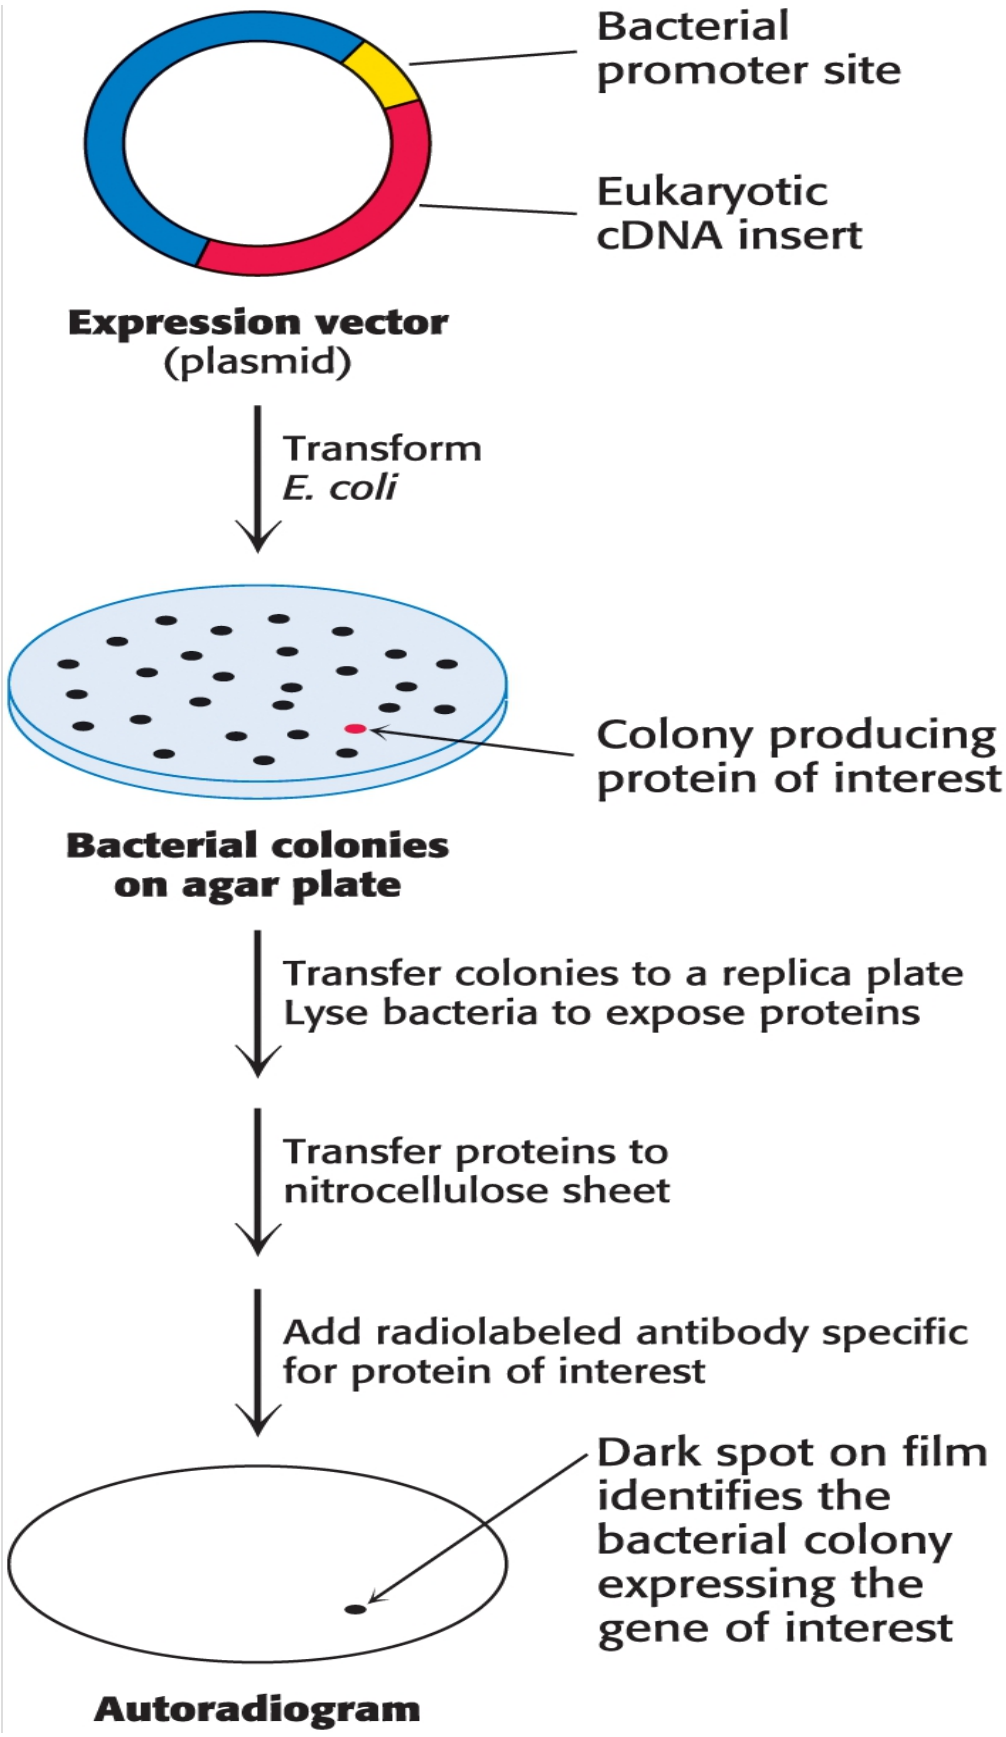
1. The reverse transcriptase synthesizes the rest of the cDNA strand in the presence of the four deoxyribonucleoside triphosphates (dNTPs).



2. The template RNA strand of this RNA–DNA hybrid is hydrolyzed by raising the pH (also called *alkali digestion*). Unlike RNA, DNA is resistant to alkaline hydrolysis.

3. The enzyme terminal transferase adds nucleotides — for instance, several residues of dG — to the $3'$ end of DNA.

4. Oligo(dC) can bind to dG residues and prime the synthesis of the second DNA strand. Synthetic linkers can be added to this double-helical DNA for ligation to a suitable vector.

Complementary DNA for all mRNA that a cell contains can be made, inserted into vectors, and then inserted into bacteria. Such a collection is called a **cDNA library**.

cDNA libraries can be prepared in expression vectors to enable the production of the corresponding protein of interest. Clones are then screened on the basis of their capacity to direct the synthesis of a foreign protein in bacteria, a technique referred to as *expression cloning*. A labeled antibody specific for the protein of interest can be used to identify colonies of bacteria that express the corresponding protein product (**Figure 9.20**). As described earlier, spots of bacteria on a replica plate are lysed to release proteins, which bind to an applied nitrocellulose filter. With the addition of labeled antibody specific for the protein of interest, the location of the desired colonies on the master plate can be readily identified. This immunochemical screening approach can be used whenever a protein is expressed and corresponding antibody is available.

© Macmillan Learning

FIGURE 9.20 Expression cloning identifies colonies in a cDNA library that express the protein of interest. Protein products are identified by staining with antibody specific to the desired protein.

Complementary DNA has many applications beyond the generation of genomic libraries. The overproduction and purification of most eukaryotic proteins in prokaryotic cells necessitates the insertion of cDNA into plasmid vectors. For example, proinsulin, a precursor of insulin, is synthesized by bacteria-harboring plasmids that contain DNA complementary to mRNA for proinsulin (Figure 9.21) to produce much of the insulin used today by millions of diabetics.

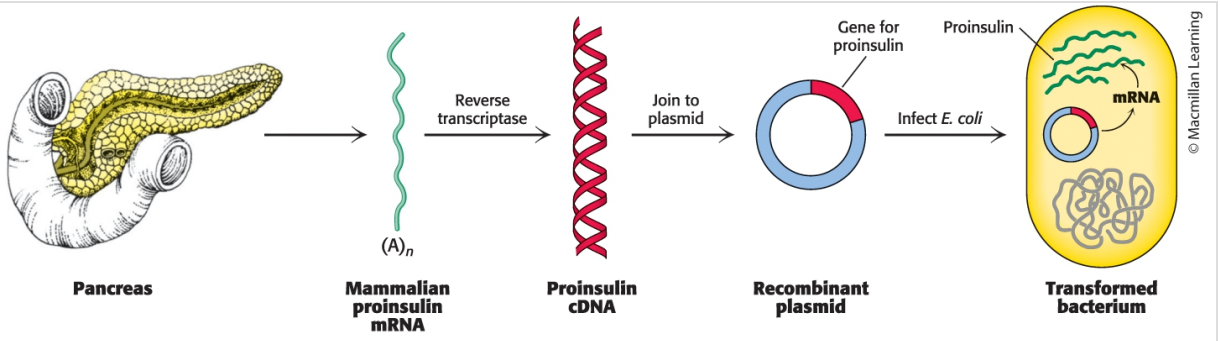


FIGURE 9.21 Bacteria infected with proinsulin cDNA can express the eukaryotic protein. Proinsulin, a precursor of insulin, can be synthesized by transformed (genetically altered) clones of *E. coli.* The clones contain the mammalian proinsulin gene.

Proteins with new functions can be created through directed changes in DNA

Many insights about genes and proteins can be gained by analyzing the effects of genetic mutations on protein structure and function. In the classic genetic approach, mutations are generated randomly throughout the genome of a host organism, and those individuals exhibiting a phenotype of interest are selected. Analysis of these mutants then reveals which genes are altered, and DNA sequencing identifies the precise nature of the changes. Recombinant DNA technology makes the creation of specific mutations feasible in vitro. We can construct new genes with designed properties by making three types of directed changes: deletions, insertions, and substitutions. A variety of methods can be used to introduce these mutations.

Site-directed mutagenesis

Mutant proteins with single amino acid substitutions can be readily produced by **site-directed mutagenesis**. Suppose that we want to replace a particular serine residue with cysteine. This mutation can be made if (1) we have a plasmid containing the gene or cDNA for the protein and (2) we know the base sequence around the site to be altered. If the serine of interest is encoded by TCT, mutation of the central base from C to G yields the TGT codon, which encodes cysteine. This type of mutation is called a *point mutation* because only one base is altered. One method for introducing this mutation into our plasmid is shown in **Figure 9.22**.

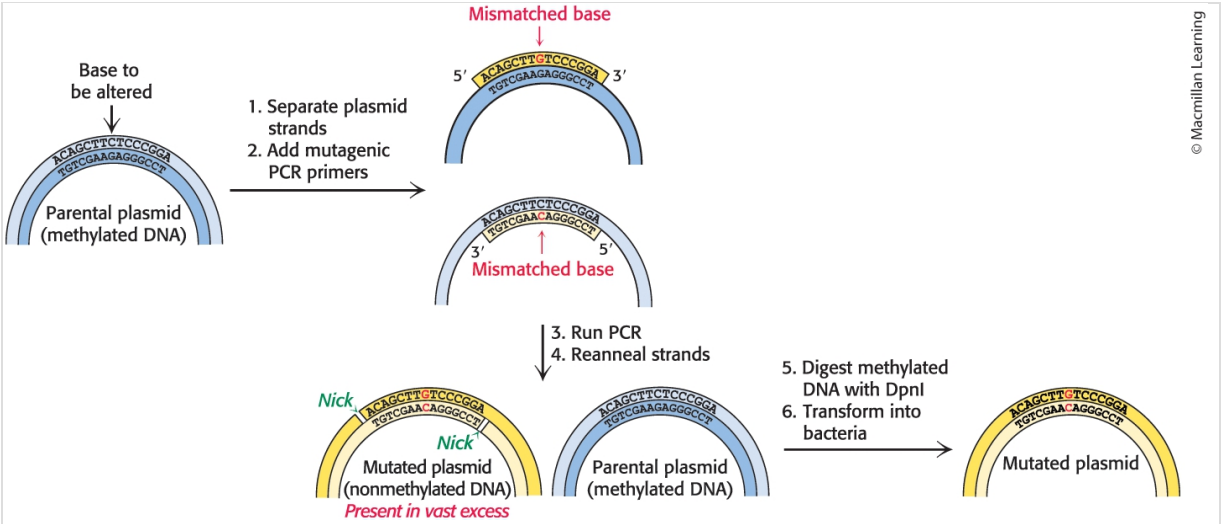

FIGURE 9.22 Site-directed mutagenesis uses mismatched primers in a polymerase chain reaction. The products will be linear strands complementary to the original plasmid strands, except for the desired single base change encoded in the PCR primers. Subsequent cleavage of the methylated parental DNA, using DpnI, and transformation into bacteria will yield the altered plasmid.

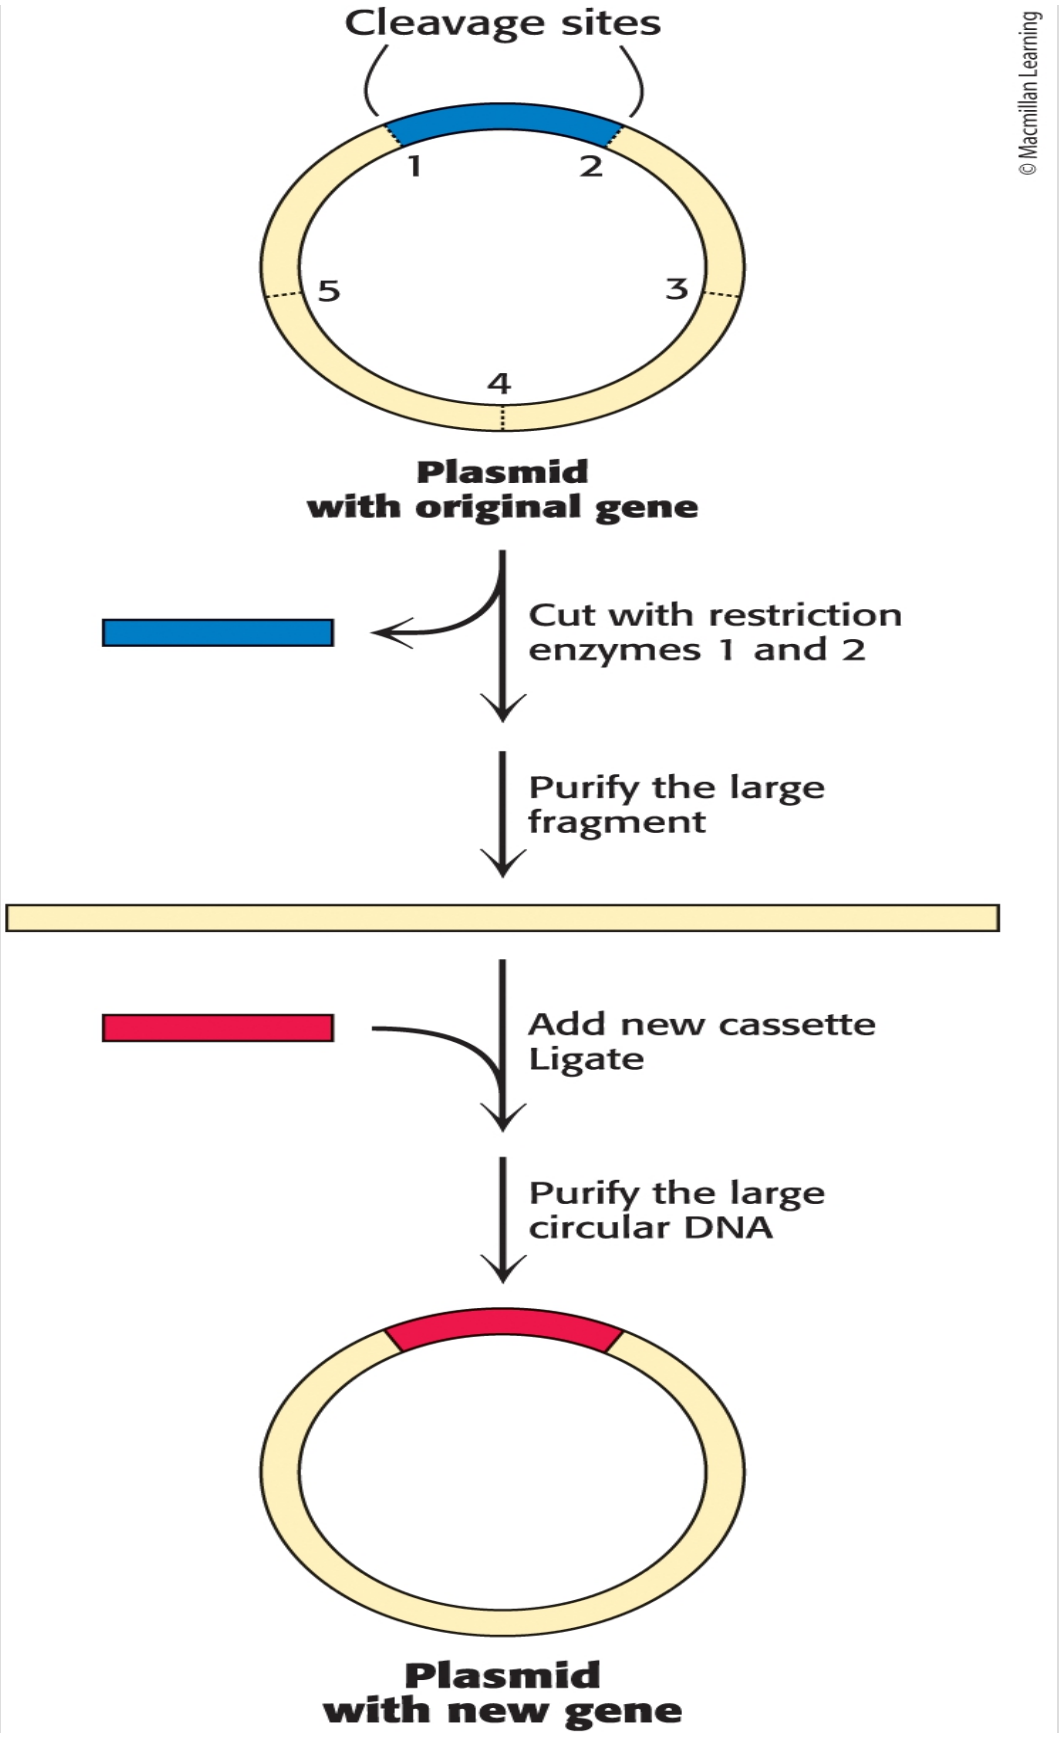
1. The two strands of the plasmid are separated by raising the temperature.

2. Mutagenic PCR primers are added to the mixture. These oligonucleotides contain the desired base change but are otherwise complementary to the neighboring sequence. The single mismatch is tolerable if the annealing is carried out at an appropriate temperature.

3. Using these two primers and the original plasmid as a template, a PCR is run. With each subsequent cycle, new DNA is synthesized that is identical to the parental plasmid, except the single base change is incorporated. Because there is no DNA ligase in the reaction mixture, the product strands are linear.

4. At the completion of the PCR, the strands are reannealed. Since the newly synthesized strands are linear, they contain two single nicks at either side of the PCR primer site. Importantly, the newly mutated DNA product is present in vast excess relative to the parental plasmid.



5. As we have seen in Section 6.3, DNA in bacterial cells is methylated to protect itself from cleavage by its own restriction endonucleases. The *Diplococcus pneumoniae* restriction enzyme DpnI is unique in that it specifically cleaves methylated sequences over a 4 bp recognition site. Since the newly mutated plasmid generated by PCR is not methylated — it has never been inside a living cell — we can use DpnI to cleave any remaining parental plasmid DNA.

6. The mutated plasmid is then transformed into bacteria, where the nicks are sealed.

We will encounter many examples of the use of site-directed mutagenesis to precisely alter regulatory regions of genes and to produce proteins with tailor-made features.

Cassette mutagenesis

In **cassette mutagenesis**, a variety of mutations, including insertions, deletions, and multiple point mutations, can be introduced into the gene of interest. A plasmid harboring the original gene is cut with a pair of restriction enzymes to remove a short segment (**Figure 9.23**). A synthetic double-stranded oligonucleotide — the *cassette* — carrying the genetic alterations of interest is prepared with cohesive ends that are complementary to the ends of the cut plasmid. Ligation of the cassette into the plasmid yields the desired mutated gene product.

© Macmillan Learning

FIGURE 9.23 In cassette mutagenesis, a synthetic DNA fragment is swapped into the plasmid using compatible restriction sites. DNA is cleaved at a pair of unique restriction sites by two different restriction enzymes. A synthetic oligonucleotide with ends that are complementary to these sites (the cassette) is then ligated to the cleaved DNA. The method is highly versatile because the inserted DNA can have any desired sequence.

Mutagenesis by PCR

A number of methods have been developed that use the creative design of PCR primers (Section 9.1) to introduce specific insertions, deletions, and substitutions into a particular sequence. One such method, called *inverse PCR*, introduces deletions into plasmid DNA (**Figure 9.24**). In this approach, primers are designed to flank the sequence to be deleted. However, these primers are oriented in the opposite direction, such that they direct the amplification of the entire plasmid, minus the region to be deleted. If each of the primers contains a $5'$ phosphate group, the amplified product can be recircularized with DNA ligase, yielding the desired deletion mutation.

Plasmid with deletion mutation
© Macmillan Learning

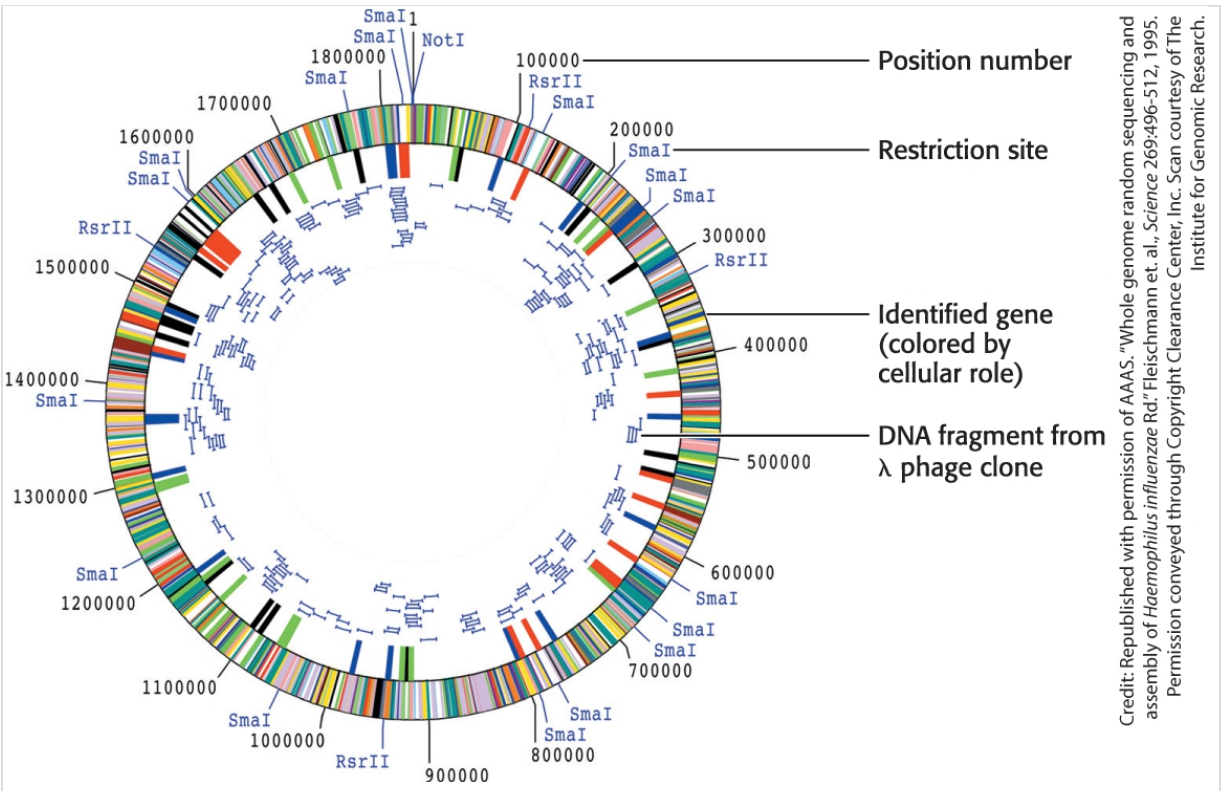
FIGURE 9.24 PCR can be used to generate mutations. In this example of inverse PCR, a deletion can be introduced into a plasmid with primers that flank this region but are oriented away from the segment to be removed. PCR amplification yields a linear product that contains the entire plasmid minus the unwanted sequence. If the primers contained a 5′ phosphate group, this product can be recircularized using DNA ligase, generating a plasmid with the desired mutation.

Designer genes

Novel proteins can also be created by splicing together gene segments that encode domains that are not associated in nature. For example, a gene for an antibody can be joined to a gene encoding a toxic protein, yielding a chimeric protein that kills any cells that are recognized by the antibody. These *immunotoxins* are being evaluated as anticancer agents. Furthermore, noninfectious coat proteins of viruses can be produced in large amounts by recombinant DNA methods. They can serve as *synthetic vaccines* that are safer than conventional vaccines prepared by inactivating pathogenic viruses. For example, a subunit of the hepatitis B virus produced in yeast is proving to be an effective vaccine against this debilitating viral disease. Finally, entirely new genes can be synthesized de novo by the solid-phase method described above. These genes can encode proteins with no known counterparts in nature.

9.3 Complete Genomes Have Been Sequenced and Analyzed

The methods just described are extremely effective for the isolation and characterization of fragments of DNA. However, the genomes of organisms ranging from viruses to human beings contain considerably longer sequences, arranged in very specific ways that are crucial for their integrated functions. Is it possible to sequence complete genomes and analyze them?



For small genomes, complete sequencing was accomplished soon after DNA-sequencing methods were developed. Sanger and his coworkers determined the complete sequence of the 5386 bases in the genome of the φX174 DNA virus in 1977, just a quarter century after Sanger's pioneering elucidation of the amino acid sequence of a protein. This tour de force was followed several years later by the determination of the sequence of human mitochondrial DNA, a double-stranded circular DNA molecule containing 16,569 base pairs that encodes 2 ribosomal RNAs, 22 transfer RNAs, and 13 proteins. Many other viral genomes were sequenced in subsequent years.

However, the genomes of free-living organisms present a much greater challenge because even the simplest comprises more than 1 million base pairs. Thus, sequencing projects require both rapid sequencing techniques and efficient methods for assembling many short stretches of 300 to 500 base pairs into a complete sequence.

The genomes of organisms ranging from bacteria to multicellular eukaryotes have

been sequenced

With the development of automatic DNA sequencers based on fluorescent dideoxynucleotide chain terminators, high-volume, rapid DNA sequencing became a reality. The genome sequence of the bacterium *Haemophilus influenzae* was determined in 1995 using a "shotgun" approach in which the genomic DNA was sheared randomly into fragments that were then sequenced. Computer programs then assembled the complete sequence by matching up overlapping regions between fragments. The *H. influenzae* genome comprises 1,830,137 base pairs and encodes approximately 1740 proteins (**Figure 9.25**). Using similar approaches, as well as more advanced methods described below, investigators have determined the sequences of more than 10,000 bacterial and archaeal species, including key model organisms such as *E. coli*, *Salmonella typhimurium*, and *Archaeoglobus fulgidus*, as well as pathogenic organisms such as *Yersinia pestis* (bubonic plague) and *Bacillus anthracis* (anthrax).

FIGURE 9.25 The genome of *Haemophilus influenzae* was the first of a free-living organism to be completely sequenced. The genome encodes more than 1700 proteins (indicated by the colored bars in the outer circle) and 70 RNA molecules. The likely function of approximately one-half of the proteins was determined by comparisons with sequences of proteins already characterized in other species. Gaps in the final sequence were filled by sequencing genomic DNA inserts from 300 phage clones (indicated by the blue bars in the inner circle), many of these overlap one another.

The first eukaryotic genome to be completely sequenced was that of baker's yeast, *Saccharomyces cerevisiae*, in 1996. This yeast genome comprises approximately 12 million base pairs, distributed on 16 chromosomes, and encodes more than 6000 proteins. This achievement was followed in 1998 by the first complete sequencing of the genome of a multicellular organism, the nematode *Caenorhabditis elegans*, which contains 97 million base pairs and includes more than 19,000 genes. The genomes of many organisms

widely used in biological and biomedical research have now been sequenced, including those of the fruit fly *Drosophila melanogaster*, the model plant *Arabidopsis thaliana*, the mouse, the rat, and the dog. However, note that even after a genome sequence has been considered complete, some sections, such as the repetitive sequences that make up heterochromatin, may be missing because these DNA sequences are very difficult to manipulate with the use of standard techniques.

The sequence of the human genome has been completed

The ultimate goal of much of genomics research has been the sequencing and analysis of the human genome. Given that the human genome comprises approximately 3 billion base pairs of DNA distributed among 24 chromosomes (**Figure 9.26**), the challenge of producing a complete sequence was daunting. However, through an organized international effort of academic laboratories and private companies, the human genome progressed from a draft sequence first reported in 2001 to a finished sequence reported in late 2004.

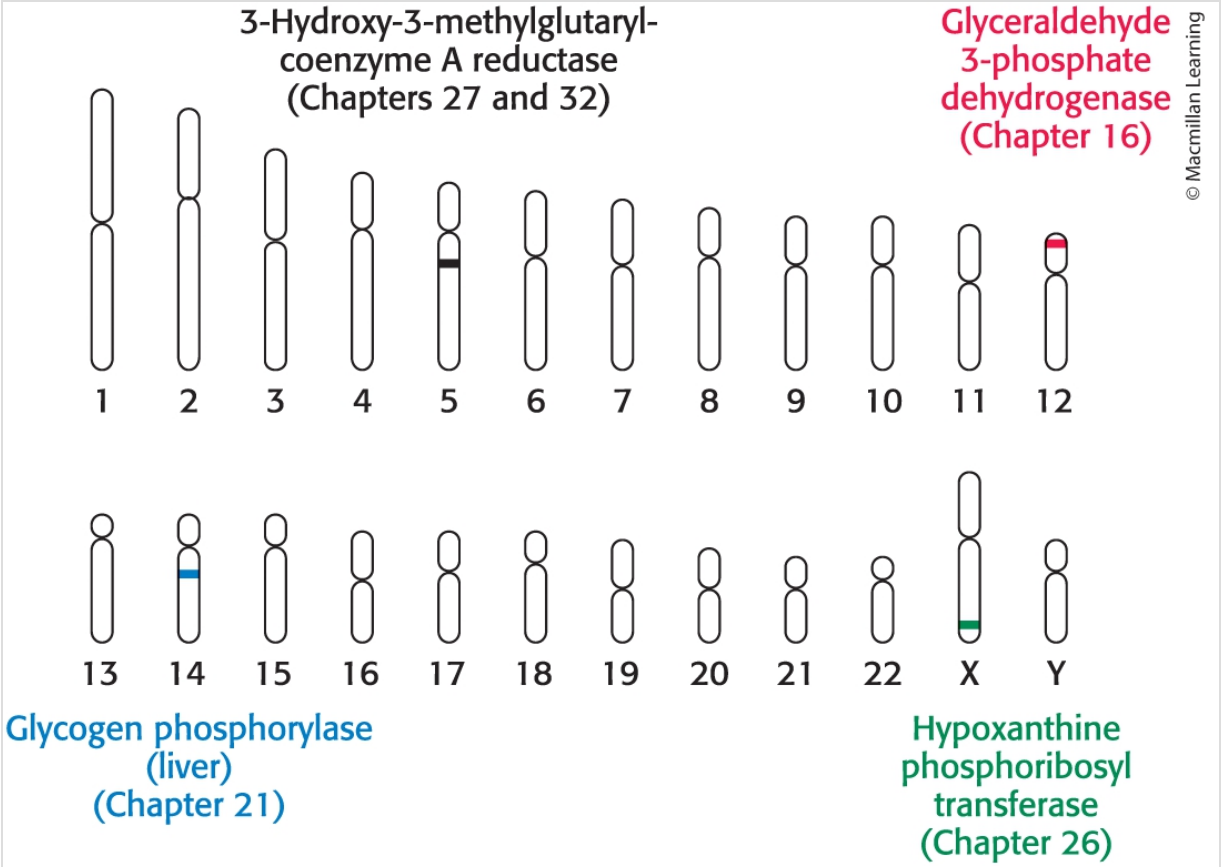

FIGURE 9.26 The human genome has been completely sequenced. The human genome is arrayed on 46 chromosomes — 22 pairs of autosomes and the X and Y sex chromosomes. The locations of several genes associated with important pathways in biochemistry are highlighted.

The human genome is a rich source of information about many aspects of humanity, including our biochemistry and evolution. Analysis of the genome will continue for many years to come. Developing an inventory of protein-encoding genes was one of the first tasks. At the beginning of the genome-sequencing project, the number of such genes was estimated to be approximately 100,000. With the availability of the completed (but not finished) genome, this estimate was reduced to between 30,000 and 35,000. With the

finished sequence, the estimate fell to between 20,000 and 25,000. We will use the estimate of 23,000 throughout this book.

The reduction in this estimate is due, in part, to the realization that there are a large number of **pseudogenes**, formerly functional genes that have accumulated mutations such that they no longer produce proteins. For example, more than half of the genomic regions that correspond to olfactory receptors — key molecules responsible for our sense of smell — are pseudogenes (Section 14.6). In contrast, the corresponding regions in the genomes of other primates and rodents encode functional olfactory receptors.

Nonetheless, the surprisingly small number of genes belies the complexity of the human proteome. Many genes encode more than one protein through mechanisms such as alternative splicing of mRNA and posttranslational modifications of proteins. The different proteins encoded by a single gene often display important variations in functional properties.

The human genome contains a large amount of DNA that does not encode proteins. A great challenge in modern biochemistry and genetics is to elucidate the roles of this noncoding DNA. Much of this DNA is present because *mobile genetic elements*, which are related to retroviruses (Section 8.4), have inserted themselves throughout the genome over time. Most of these elements have accumulated mutations and are no longer functional. For example, more than 1 million *Alu sequences*, each approximately 300 bases in length, are present in the human genome. *Alu* sequences are examples of SINEs, or short interspersed elements. The human genome also includes nearly 1 million LINEs, or long interspersed elements, sequences that can be as long as 10 kilobases (kb). The roles of these elements as neutral genetic parasites or instruments of genome evolution are under current investigation.

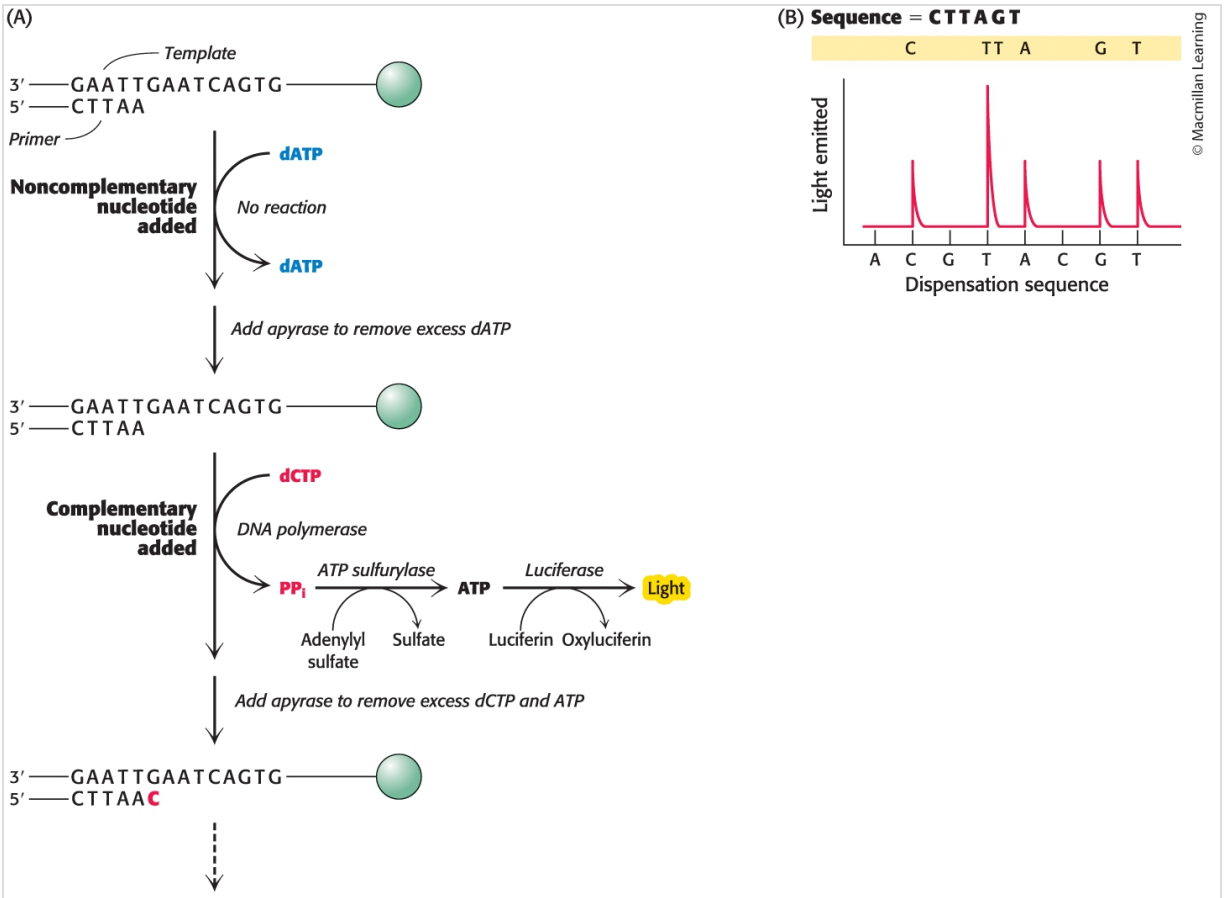
Next-generation sequencing methods enable the rapid determination of a complete genome sequence

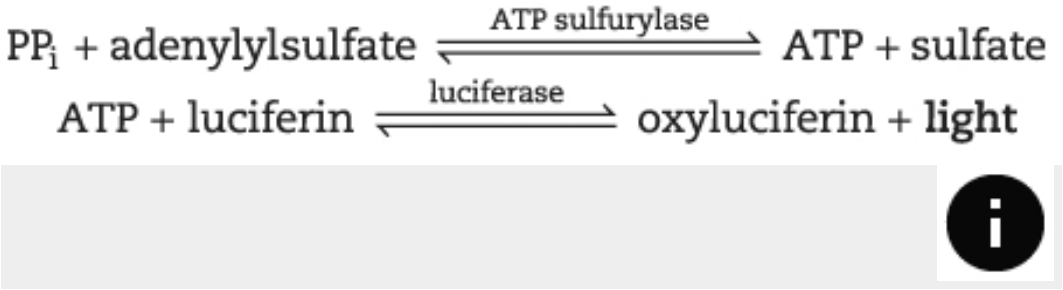
Since the introduction of the Sanger dideoxy method in the mid-1970s, significant advances have been made in DNA-sequencing technologies, enabling the readout of progressively longer sequences with higher fidelity and shorter run times. The development of **next-generation sequencing (NGS)** platforms has extended this capability to formerly unforeseen levels. By combining technological breakthroughs in the handling of very small amounts of liquid, high-resolution optics, and computing power, these methods have already made a significant impact on the ability to obtain whole genome sequences rapidly and cheaply (Section 1.4).

Next-generation sequencing refers to a family of technologies, each of which uses a unique approach for the determination of a DNA sequence. All of these methods are highly parallel: from 1 million to 1 billion DNA fragment sequences are individually acquired in a single experiment. How are NGS methods capable of determining such a high number of sequences in parallel? Individual DNA fragments are amplified by PCR on a solid support — a single bead or a small region of a glass slide — such that clusters of identical DNA fragments are distinguishable by high-resolution imaging. These fragments then serve as templates for DNA polymerase, where the addition of nucleotide triphosphates is converted to a signal that can be detected in a highly sensitive manner.

The technique used to detect individual base incorporation varies among the variety of NGS methods. Let us consider one of these methods, called **pyrosequencing**, in greater detail (**Figure 9.27**). In

this method, a single-stranded fragment of DNA tethered to a solid support serves as the sequencing template. A solution containing one of the four deoxyribonucleoside triphosphates (dATP in Figure 9.27A) is then added to the reaction. If the nucleotide base is not complementary to the next available base on the template strand, no reaction occurs.





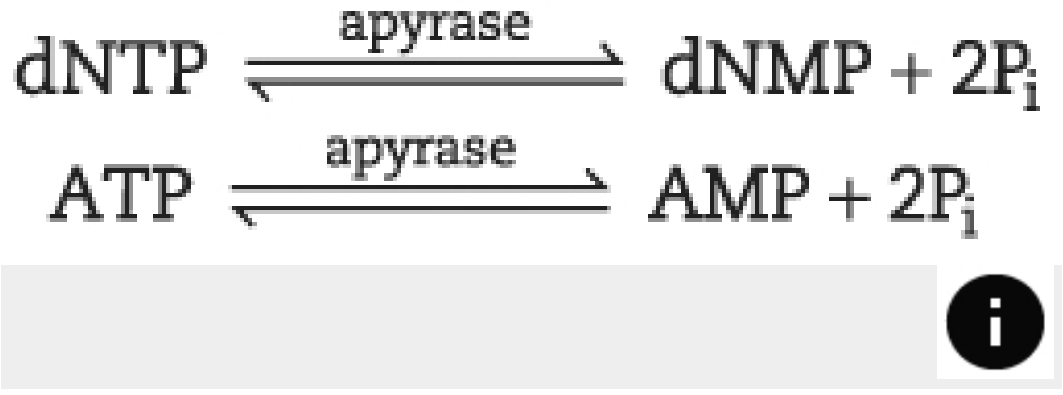


FIGURE 9.27 Pyrosequencing is an example of next-generation sequencing. (A) If a nucleotide is successfully incorporated into the growing duplex, the newly produced pyrophosphate is enzymatically converted into light. (B) Light is measured at each deoxynucleotide addition. A peak indicates the next base in the sequence, and the height of the peak indicates how many of the same deoxynucleotide were incorporated in a row.

However, if the nucleotide base is complementary, and thus incorporated, the released pyrophosphate is coupled to the production of light by the sequential action of the enzymes ATP sulfurylase and luciferase:

The emitted light is measured, indicating that a reaction has occurred, thus revealing the identity of the base at that position (Figure 9.27B). If the template contains a run of one particular base, then multiple consecutive additions will take place in a single reaction; the length of this run can be determined by the intensity of the emitted light.

After each nucleotide addition, the remaining deoxynucleotide and ATP are removed by the enzyme apyrase.

The next nucleotide is added, and the steps are repeated. Nucleotides are added in a defined order, referred to as the

dispensation sequence, and the pattern of peaks that emerge reveals the sequence of the template strand (Figure 9.27B).

Other NGS methods are also commonly used. These methods can be understood simply by considering the overall reaction of chain elongation catalyzed by DNA polymerase (**Figure 9.28**). In the reversible terminator method, the four nucleotides are added to the template DNA, with each base tagged with a unique fluorescent label and a reversibly blocked 3′ end. The blocked end assures that only one phosphodiester linkage will form. Once the nucleotide is incorporated into the growing strand, it is identified by its fluorescent tag, the blocking agent is removed, and the process is repeated. The protocol for ion semiconductor sequencing is similar to pyrosequencing, except that nucleotide incorporation is detected by sensitively measuring the very small changes in pH of the reaction mixture due to the release of a proton upon nucleotide incorporation.

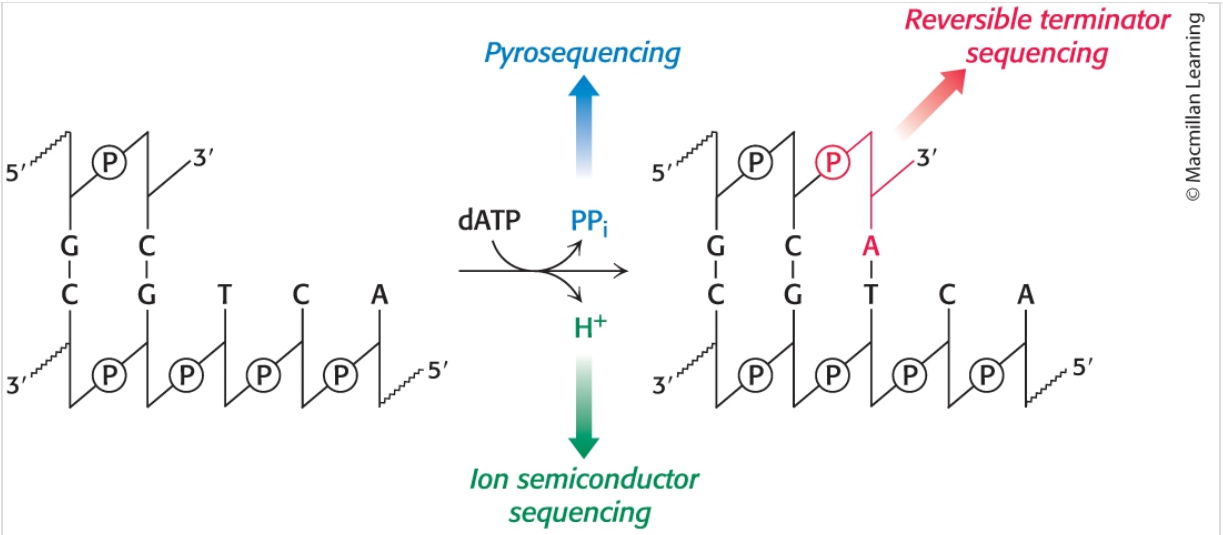

FIGURE 9.28 Next-generation sequencing methods use different approaches to measure nucleotide incorporation. Measurement of base incorporation in next-generation sequencing methods relies on the detection of the various products of the DNA polymerase reaction. Reversible terminator sequencing measures the nucleotide incorporation in a

manner similar to Sanger dideoxy sequencing, while pyrosequencing and ion semiconductor sequencing detect the release of pyrophosphate and protons, respectively.

Regardless of the sequencing method, the technology exists to quantify the signal produced by millions of DNA fragment templates simultaneously. However, for many approaches, as few as 50 bases are read per fragment. Hence, significant computing power is required to both store the massive amounts of sequence data and perform the necessary alignments required to assemble a completed sequence.

NGS methods are being used to answer an ever-growing number of questions in many areas, including genomics, the regulation of gene expression, and evolutionary biology. Additionally, individual genome sequences will provide information about genetic variation within populations and may usher in an era of personalized medicine, when these data can be used to guide treatment decisions.

Comparative genomics is a powerful research tool

Comparisons with genomes from other organisms are sources of insight into the human genome. The sequencing of the genome of the chimpanzee, our closest living relative, as well as that of other mammals that are widely used in biological research, such as the mouse and the rat, has been completed. Comparisons reveal that an astonishing 99% of human genes have counterparts in mouse and rat genomes. However, these genes have been substantially

reassorted among chromosomes in the estimated 75 million years of evolution since humans and these rodents had a common ancestor (Figure 9.29).

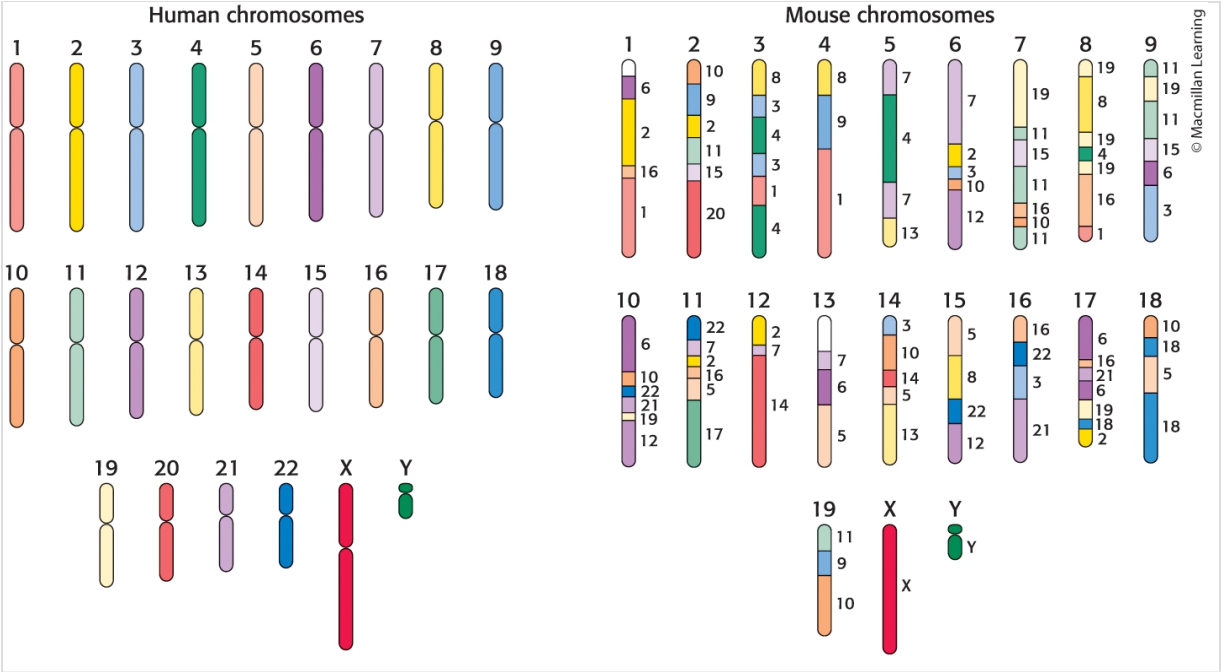

FIGURE 9.29 The human and mouse genomes are closely related, although they have been rearranged relative to each other. A schematic comparison of the human genome and the mouse genome shows reassortment of large chromosomal fragments. The small numbers to the right of the mouse chromosomes indicate the human chromosome to which each region is most closely related.

The genomes of other organisms also have been determined specifically for use in comparative genomics. For example, the genomes of two species of puffer fish, *Takifugu rubripes* and *Tetraodon nigroviridis*, have been determined. These genomes were selected because they are very small and lack much of the noncoding DNA present in such abundance in the human genome. The puffer fish genomes include fewer than 400 megabase pairs (Mbp), one-eighth of the number in the human genome, yet the

puffer fish and human genomes contain essentially the same number of genes.

Comparison of the genomes of these puffer fish species with that of humans revealed more than 1000 formerly unrecognized human genes. Furthermore, comparison of the two species of puffer fish, which had a common ancestor approximately 25 million years ago, is a source of insight into more-recent events in evolution. Comparative genomics is a powerful tool, both for interpreting the human genome and for understanding major events in the origin of genera and species (Section 10.3).

9.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision

After a gene of interest has been identified, cloned, and sequenced, it is often desirable to understand how that gene and its corresponding protein product function in the context of a whole cell or organism. It is now possible to determine how the expression of a particular gene is regulated, how mutations in the gene affect the function of the corresponding protein product, and how the behavior of an entire cell or model organism is altered by the introduction of mutations within specific genes. In addition, levels of transcription of large families of genes within cells and tissues can be readily quantified and compared across a range of environmental conditions.

Gene-expression levels can be comprehensively examined

Most genes are present in the same quantity in every cell — namely, one copy per haploid cell or two copies per diploid cell. However, the level at which a gene is expressed, as indicated by mRNA quantities, can vary widely, ranging from no expression to hundreds of mRNA copies per cell. Gene-expression patterns vary from cell type to cell type, distinguishing, for example, a muscle cell from a nerve cell. Even within the same cell, gene-expression levels may vary as the cell responds to changes in physiological circumstances. Although mRNA levels sometimes correlate with the levels of proteins expressed, this correlation does not always hold. Thus, care

must be exercised when interpreting the results of mRNA levels alone.

Quantitative PCR

The quantity of individual mRNA transcripts can be determined by **quantitative PCR (qPCR)**, or real-time PCR. RNA is first isolated from the cell or tissue of interest. With the use of reverse transcriptase, cDNA is prepared from this RNA sample. In one qPCR approach, the transcript of interest is PCR amplified with the appropriate primers in the presence of the dye SYBR Green I, which fluoresces brightly when bound to double-stranded DNA. In the initial PCR cycles, not enough duplex is present to allow a detectable fluorescence signal. However, after repeated PCR cycles, the fluorescence intensity exceeds the detection threshold and continues to rise as the number of duplexes corresponding to the transcript of interest increases (**Figure 9.30A**).

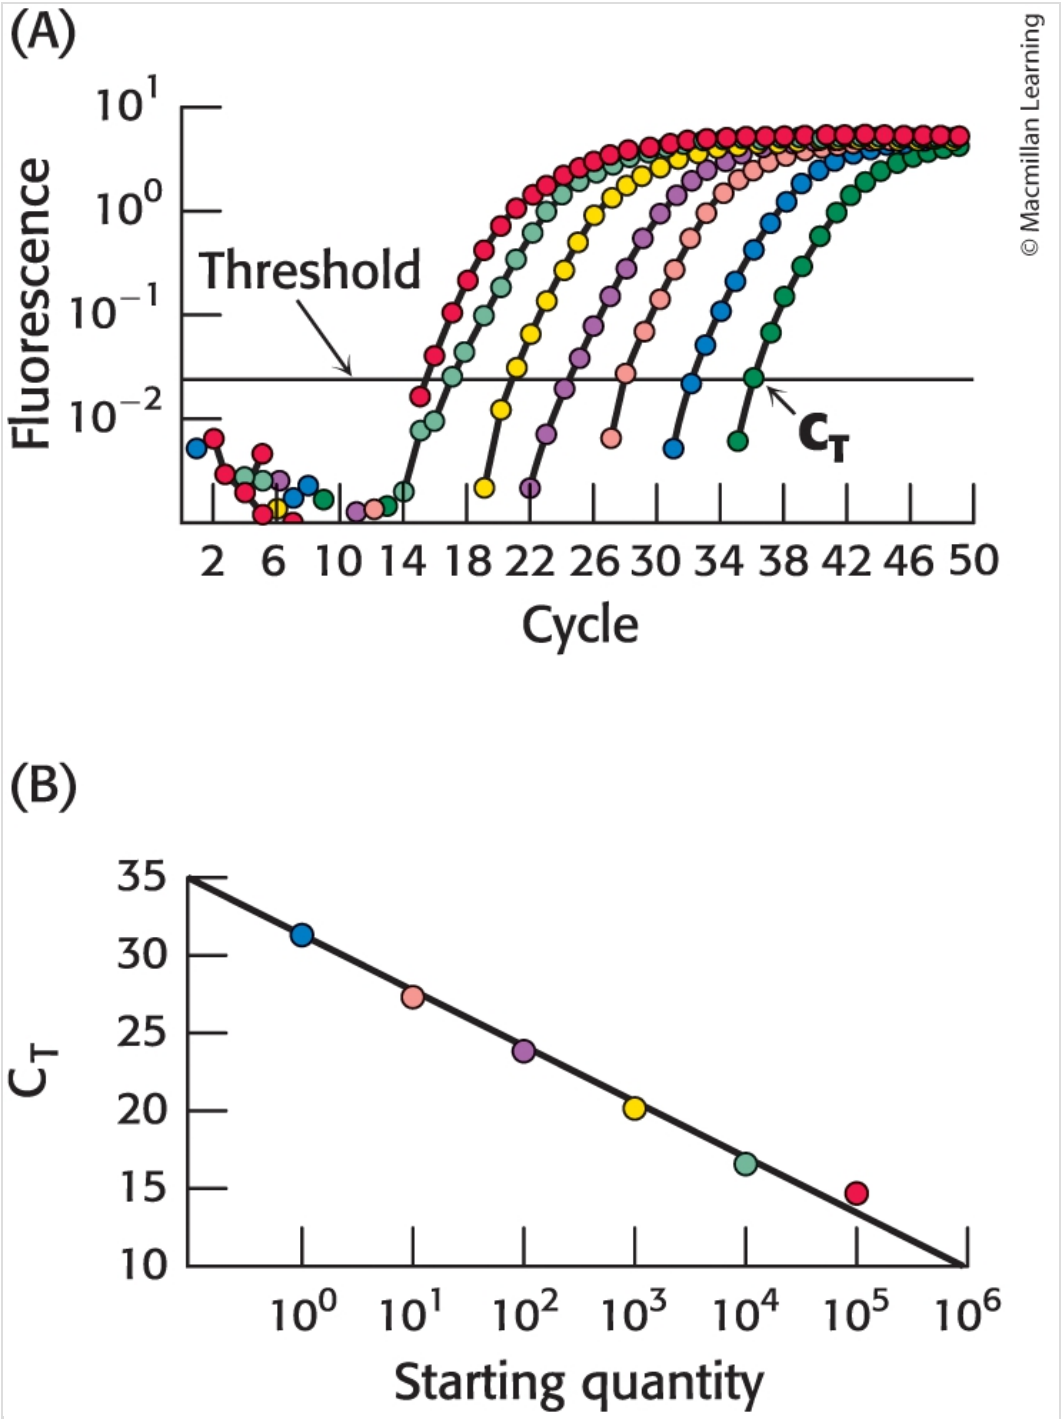

FIGURE 9.30 Quantitative PCR detects the amount of a particular transcript in a sample. (A) In qPCR, fluorescence is monitored in the course of PCR amplification to determine C_T, the cycle at which this signal exceeds a defined threshold. Each color represents a different starting quantity of cDNA. (B) C_T values are inversely proportional to the number of copies of the original cDNA template.

[Data from N. J. Walker, *Science* 296:557–559, 2002.]

Importantly, the cycle number at which the fluorescence becomes detectable over a defined threshold (or C_T) is inversely proportional to the number of copies of the original template (**Figure 9.30B**). After the relation between the original copy number and the C_T has been established with the use of a known standard, subsequent qPCR experiments can be used to determine the number of copies of any desired transcript in the original sample, provided the appropriate primers are available.

DNA microarrays

Although qPCR is a powerful technique for quantitation of a small number of transcripts in any given experiment, we can now use our knowledge of complete genome sequences to investigate an entire **transcriptome**, the pattern and level of expression of all genes in a particular cell or tissue. One of the most powerful methods for this purpose is based on hybridization. Single-stranded oligonucleotides whose sequences correspond to coding regions of the genome are affixed to a solid support such as a microscope slide, creating a **DNA microarray**. Importantly, the position of each sequence within the array is known. **Figure 9.31** outlines the steps in the creation of a DNA microarray.

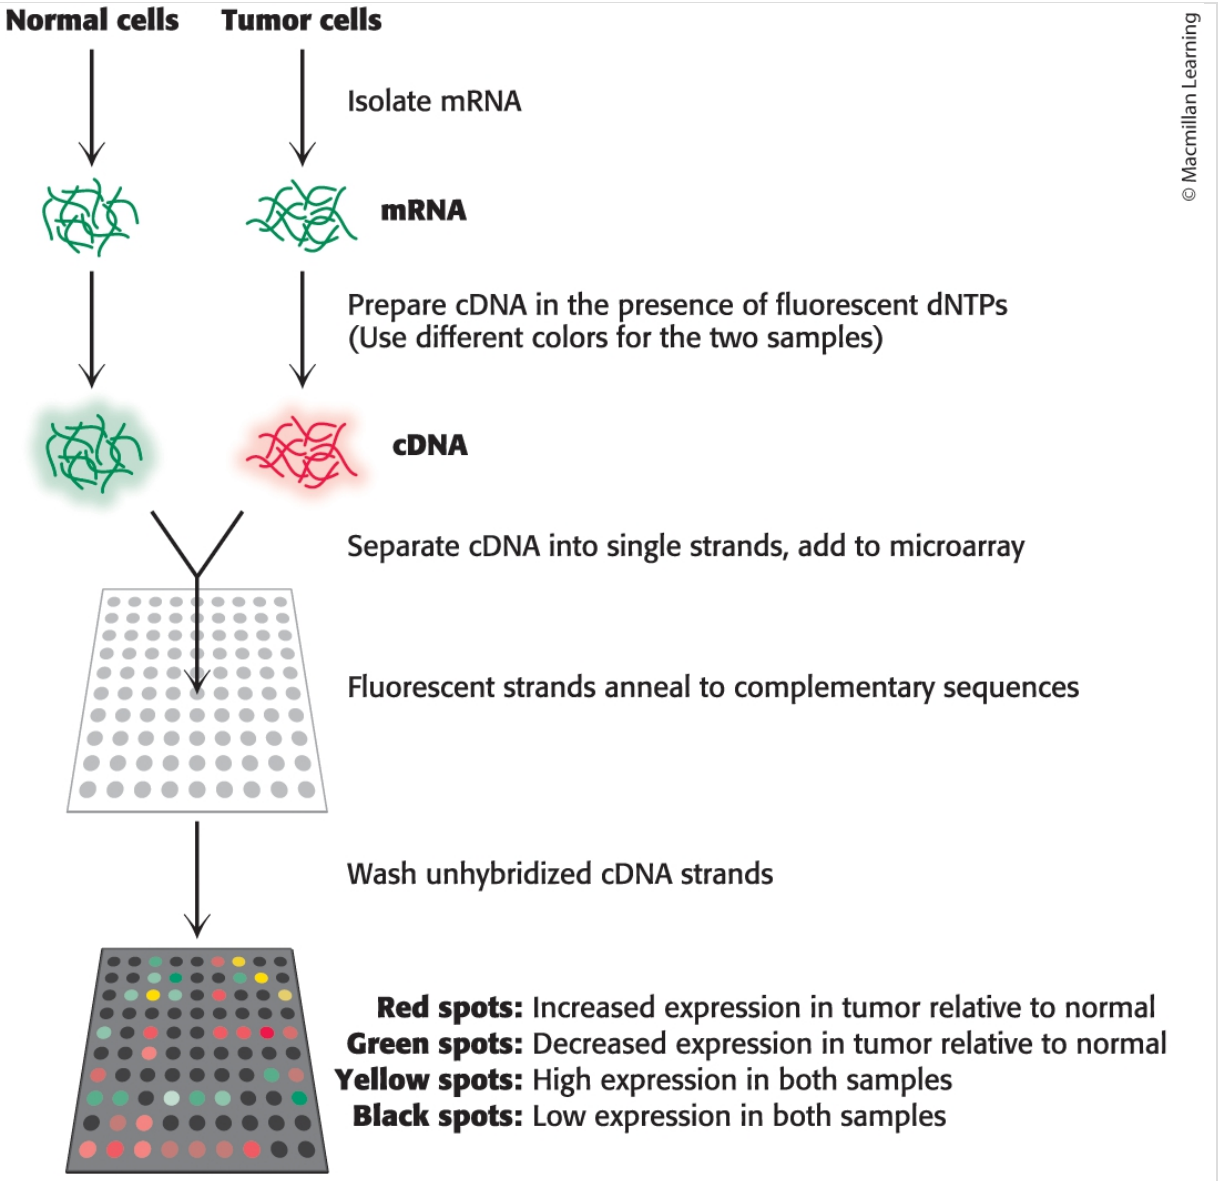

FIGURE 9.31 DNA microarrays can measure gene expression changes in a tumor. mRNA is isolated from two samples, tumor cells and a control sample. From these transcripts, cDNA is prepared in the presence of a fluorescent nucleotide, with a red label for the tumor sample and a green label for the control sample. Spots that are red indicate genes that are expressed more highly in the tumor, while the green spots indicate reduced expression relative to control. Spots that are black or yellow indicate comparable expression at either low or high levels, respectively.

[Information from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 6th ed. (W. H. Freeman and Company, 2013).]

1. mRNA is isolated from the cells of interest (a tumor, for example) as well as a control sample.
2. From this mRNA, cDNA is prepared (Section 9.2) in the presence of fluorescent nucleotides using different labels, usually green and red, for the two samples.
3. The samples are combined, separated into single strands, and added to the microarray.
4. The fluorescent strands anneal their complementary sequences.
5. Any unhybridized cDNA strands are washed off, leaving an array in which relative levels of green and red fluorescence at each spot indicate the differences in expression for each gene.

DNA microarrays have been prepared such that thousands of transcript levels can be assessed in a single experiment. Hence, over several arrays, the differences in expression of many genes across a number of different cell types or conditions can be measured (**Figure 9.32**).

Credit: Kao J, Salari K, Bocanegra M, Choi YL, Girard L, Gandhi J, Kwei KA, Hernandez-Boussard T, Wang P, Gazdar AF, Minna JD, Pollack JR. Molecular profiling of breast cancer cell lines defines relevant tumor models and provides a resource for cancer gene discovery. February 2009. *PLoS One* 4(7):e6146, Figure 1B. DOI:10.1371/journal. pone.0006146.

FIGURE 9.32 Microarrays detect numerous expression changes in a single experiment. The expression levels of thousands of genes can be simultaneously analyzed with DNA microarrays. Here, an analysis of 8750 genes in 50 breast cancer cell lines reveals that these samples can be divided into distinct classes (basal-A, basal-B, and luminal) based on their gene-expression patterns. In this "heat map" representation, each row represents a different gene, and each column represents a different breast cancer cell line (i.e., a separate microarray experiment). Red corresponds to gene induction, and green corresponds to gene repression.

RNA-seq

One disadvantage of the qPCR and microarray methods is that the transcript sequences must be known prior to the experiment, in order to design primers or microarray probes. However, the emergence of next-generation sequencing techniques, such as those described in the previous section, has enabled the detection of the presence and quantitation of virtually all the RNA molecules in a cell under specific conditions. This method, termed **RNA-seq**, consists of several essential steps:

1. *Isolation of RNA from the cells or tissue of interest.* Deoxyribonuclease (DNase), an enzyme which specifically cleaves DNA, can be used at this step to degrade any unwanted genomic DNA.

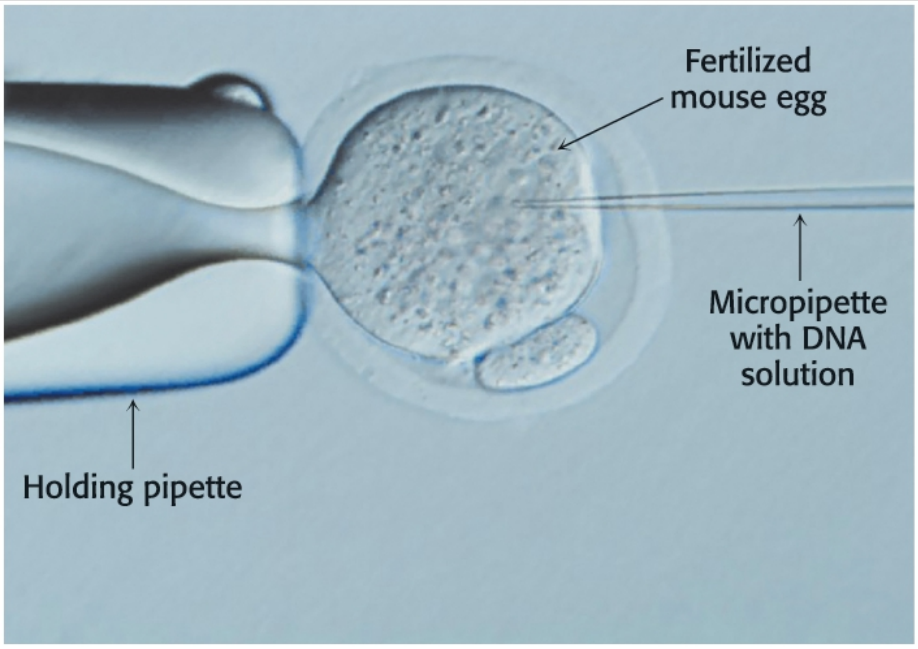
2. *RNA selection.* At this step, mRNA can be selectively enriched by filtering for sequences that contain poly(A) tails. This step allows for the removal of the abundant rRNAs from the sample.

3. *cDNA synthesis.* cDNA is prepared from the RNA sample using reverse transcriptase, as described earlier in the chapter.

4. *Sequencing and assembly.* The cDNA molecules within the sample are then sequenced using an NGS method, such as pyrosequencing. Each sequencing run is typically quite short, yielding only 50–100 bases, but millions of sequences are generated in a single experiment. Computational algorithms are then used to assemble the sequencing data into a comprehensive understanding of the transcripts present within the sample.

RNA-seq is more sensitive than microarray methods, enabling the detection of very low abundance transcripts. This sensitivity has led to the application of RNA-seq to the determination of transcript profiles of individual cells (called *single-cell RNA-seq*, or *scRNA-seq*). These single-cell experiments have broad application across a variety of disciplines, yielding insight on the variability of cancer cells within a single tumor or the changes within individual cell lineages during embryonic development.

New genes inserted into eukaryotic cells can be efficiently expressed



We have seen how bacteria can be turned into factories for the production of a wide range of prokaryotic and eukaryotic proteins. However, bacteria lack the necessary enzymes to carry out posttranslational modifications unique to these proteins, such as the specific cleavage of polypeptides and the attachment of carbohydrate units. Thus, many eukaryotic genes can be expressed correctly only in eukaryotic host cells.

Moreover, the introduction of recombinant DNA molecules into cells of higher organisms can be a source of insight into how their genes

are organized and expressed. How are genes turned on and off in embryological development? How does a fertilized egg give rise to an organism with highly differentiated cells that are organized in space and time? These central questions of biology can now be fruitfully approached by expressing foreign genes in mammalian cells.

Recombinant DNA molecules can be introduced, or *transformed*, into animal cells in several ways:

- Foreign DNA molecules precipitated by calcium phosphate can be taken up by animal cells by a process known as *transfection*. A small fraction of the imported DNA becomes stably integrated into the chromosomal DNA. While the efficiency of incorporation is low, this method is useful because it is easy to apply.
- DNA can be microinjected into cells. A fine-tipped glass micropipette containing a solution of foreign DNA is inserted into the nucleus (**Figure 9.33**). A skilled investigator can inject hundreds of cells per hour.
- Viruses can be used to introduce new genes into animal cells through a process called *transduction*. The most effective vectors are retroviruses, whose genomes are encoded by RNA and replicate through DNA intermediates. The retroviruses used for this purpose typically do not harm their hosts.

Credit: Marh et al, Hyperactive self-inactivating piggyBac for transposase-enhanced pronuclear microinjection transgenesis, PNAS, Vol 109, no. 47, pp. 19184–19189. Copyright 2012 National Academy of Sciences.

FIGURE 9.33 Cloned plasmid DNA is microinjected into a fertilized mouse egg.

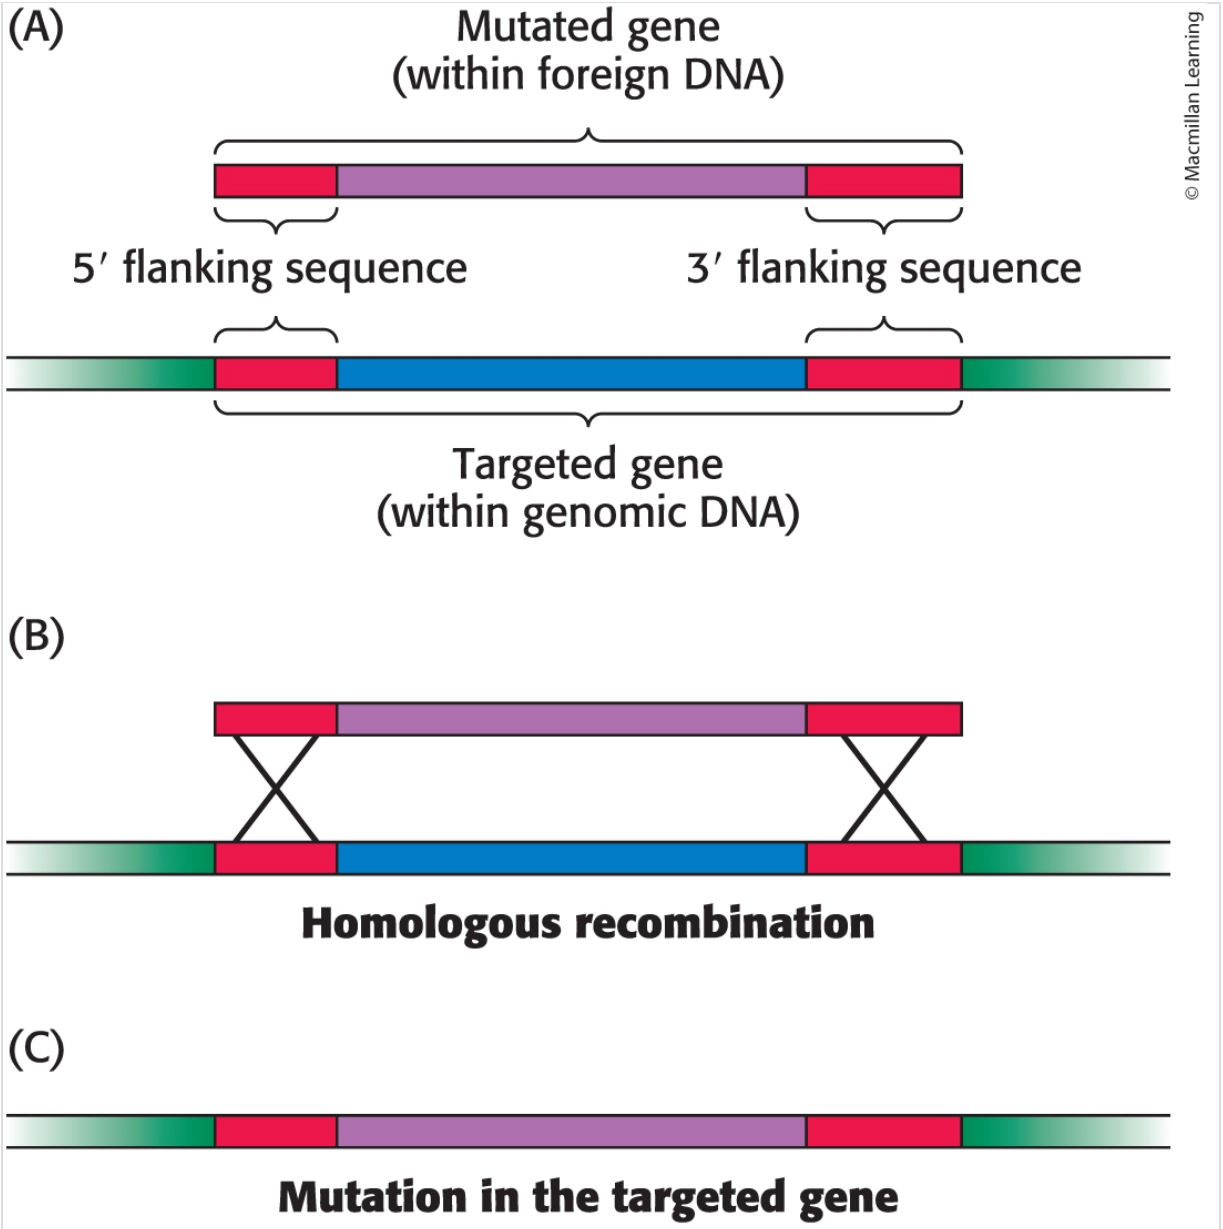
A striking feature of the life cycle of a retrovirus is that the double-helical DNA form of its genome, produced by the action of reverse transcriptase, becomes randomly incorporated into host chromosomal DNA. This DNA version of the viral genome, called *proviral DNA*, can be efficiently expressed by the host cell and replicated along with normal cellular DNA. Foreign genes have been efficiently introduced into mammalian cells by infecting them with vectors derived from the Moloney murine leukemia virus, a retrovirus which can accept inserts as long as 6 kb. Some genes introduced by this vector into the genome of a transformed host cell are efficiently expressed.

Two other vectors based on two large-genome viruses have been engineered to express DNA inserts efficiently. *Vaccinia* virus, a large DNA-containing virus, replicates in the cytoplasm of mammalian

cells, where it shuts down host-cell protein synthesis. *Baculovirus* infects insect cells, which can be conveniently cultured. Insect larvae infected with this virus can serve as efficient protein factories.

Transgenic animals harbor and express genes introduced into their germ lines

As shown in Figure 9.33, plasmids harboring foreign genes can be microinjected into the male pronucleus of fertilized mouse eggs, which are then inserted into the uterus of a foster-mother mouse. A subset of the resulting embryos in this host will then harbor the foreign gene; these embryos may develop into mature animals. Southern blotting or PCR analysis of DNA isolated from the progeny can be used to determine which offspring carry the introduced gene. These **transgenic mice** are a powerful means of exploring the role of a specific gene in the development, growth, and behavior of an entire organism. Transgenic animals often serve as useful models for a particular disease process, enabling researchers to test the efficacy and safety of a newly developed therapy.



Consider the example of ALS, introduced in Section 9.1. Research groups have generated transgenic mouse lines that express forms of human superoxide dismutase that harbor mutations matching those identified in earlier genetic analyses. Many of these strains exhibit a clinical picture similar to that observed in ALS patients: progressive weakness of voluntary muscles and eventual paralysis, motor-neuron loss, and rapid progression to death. Since their first characterization in 1994, these strains continue to serve as valuable sources of information for the exploration of the mechanism and potential treatment of ALS.

Gene disruption and genome editing provide clues to gene function and opportunities for new therapies

The function of a gene can also be probed by inactivating or editing it and looking for resulting abnormalities.

Gene knockouts

Powerful methods have been developed for accomplishing such **gene disruption** (or **gene knockout**) in organisms such as yeast and mice. These methods rely on the process of **homologous recombination** (Section 28.5), in which two DNA molecules with strong sequence similarity exchange segments. If a region of foreign DNA is flanked by sequences that have high homology to a particular region of genomic DNA, two recombination events will yield the transfer of the foreign DNA into the genome (**Figure 9.34**). In this manner, specific genes can be targeted if their flanking nucleotide sequences are known.

© Macmillan Learning

FIGURE 9.34 Foreign DNA can be inserted into the host genome by homologous recombination. (A) A mutated version (purple) of the gene to be disrupted (blue) is constructed, maintaining some regions of homology with the normal gene (red). When the foreign mutated gene is introduced into an embryonic stem cell, (B) recombination takes place at regions of homology and (C) the normal (targeted) gene is replaced, or "knocked out," by the foreign gene. The cell is inserted into embryos, and mice lacking the gene (knockout mice) are produced.

For example, the gene-knockout approach has been applied to the genes encoding gene-regulatory proteins (also called *transcription factors*; Section 29.3) that control the differentiation of muscle cells. When both copies of the gene for the regulatory protein myogenin are disrupted in mice, the animals lack functional skeletal muscle. The impaired formation of respiratory muscles, such as the diaphragm, leads to the inability to breathe and death shortly after birth. Microscopic inspection reveals that the tissues from which muscle normally forms contain precursor cells that have failed to differentiate fully (**Figure 9.35A**). Heterozygous mice containing one normal myogenin gene and one disrupted gene appear normal, suggesting that a reduced level of myogenin gene expression is still sufficient for normal muscle development. The generation and characterization of this knockout mouse provided strong evidence that functional myogenin is essential for proper development of skeletal muscle tissue (**Figure 9.35B**).

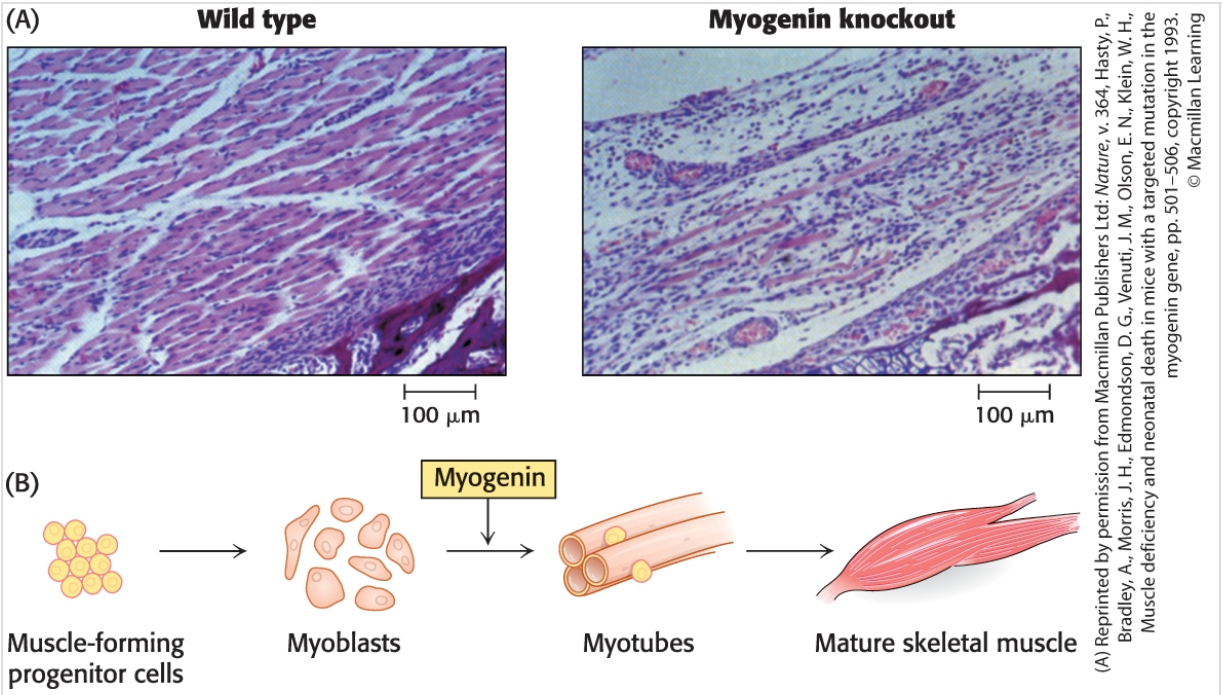


FIGURE 9.35 In knockout mice, gene disruption can have dramatic consequences. (A) Sections of muscle from normal (left) and myogenin-knockout (right) mice, as viewed under the light microscope. Muscles do not develop properly in mice having both myogenin genes

disrupted. (B) Through the gene-disruption studies in (A), myogenin was identified as an essential component of the development of mature skeletal muscle.

[(B) Information from S. Hettmer and A. J. Wagers, *Nat. Med*. 16:171–173, 2010, Fig. 1.]

Analogous studies have probed the function of many other genes in the context of a living organism. Furthermore, mice harboring gene knockouts can be used as animal models for known human genetic diseases, enabling the assessment of new potential therapies for treatment. However, manipulation of genomic DNA using homologous recombination, while a powerful tool, has limitations. Recombination at the desired site can be inefficient and time-consuming. In addition, this method is generally limited to specific model organisms, such as yeast, mice, and fruit flies.

Genome editing

Over the past 10 years, new methods for the highly specific modification of genomic DNA, or **genome editing**, have emerged. These approaches rely on the introduction of double-strand breaks at precisely determined sequences within genomic DNA. The resulting cleavage site is repaired by the DNA repair machinery of the host cell in one of two ways (Section 28.4) If no template is provided, the cell will repair the break using a process known as *non-homologous end joining* (NHEJ; **Figure 9.36**). However, this process is error-prone, and a variety of insertions or deletions will be introduced into the repair site. It is likely that a subset of these modifications will introduce a premature stop codon into the targeted gene, resulting in a gene knockout. Alternatively, if a DNA template containing the desired sequence change is simultaneously introduced with the nucleases, the repair machinery will use this

donor template to introduce these changes directly into the genomic sequence, in a process known as *homology directed repair* (HDR; Figure 9.36).

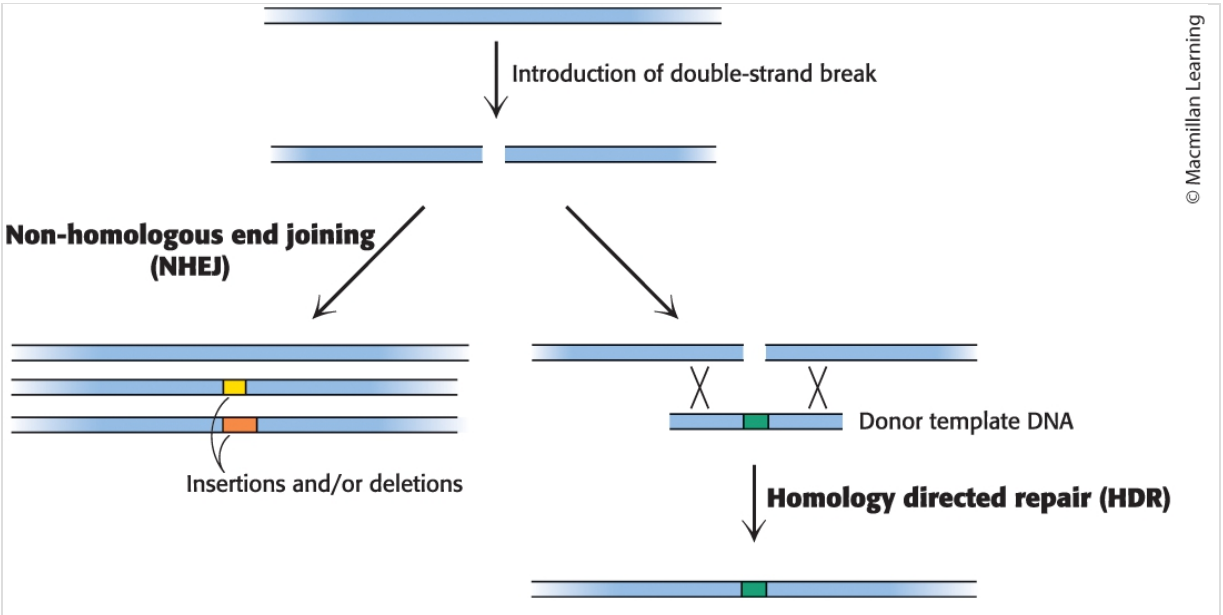

FIGURE 9.36 Genome editing starts with the introduction of precisely generated double-strand breaks in host DNA. These breaks are repaired in the cell by two possible mechanisms. One is non-homologous end joining (NHEJ), a process that is error-prone and may lead to the introduction of insertions or deletions. Such errors may introduce frameshift mutations that ultimately knock out the entire gene. Alternatively, if a donor template DNA fragment is also provided, the break can be repaired by homology directed repair (HDR), which results in the incorporation of the desired modifications (green) into the targeted gene.

How are double-stranded breaks introduced specifically into the gene of interest? In one approach, a sequence-specific nuclease is engineered by fusing the nonspecific nuclease domain of the restriction enzyme FokI to a DNA-binding domain designed to bind to a particular DNA sequence. Two examples of this strategy are in common usage:

- **Zinc-finger nucleases (ZFNs)** are formed by combining the FokI nuclease domain with the DNA-binding domain that contains a series of zinc-finger domains, small zinc-binding motifs that each recognize a sequence of three base pairs. The preferred DNA-binding sequence can be altered by changing the identity of only four contact residues within each finger.

- **Transcription activator-like effector nucleases (TALENs)** are formed from the fusion of the FokI nuclear domain with an array of TALE repeats. Each repeat contains 34 amino acids and two α-helices, yet only two of these residues (at positions 12 and 13) are responsible for the unique recognition of a single nucleotide within the double helix (**Figure 9.37**). Mutation of these residues within an array of repeats enables the recognition of a vast number of possible DNA target sequences with a high degree of specificity.

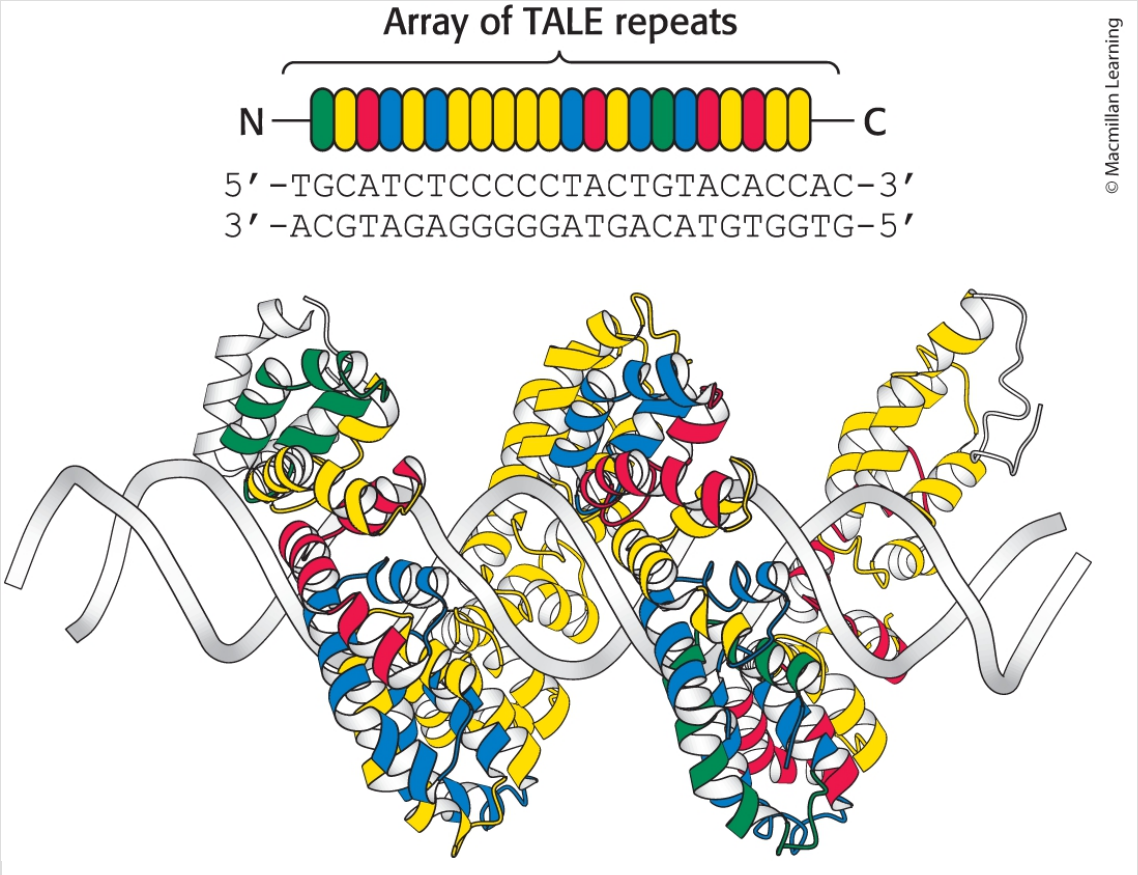

FIGURE 9.37 TALE repeats recognize individual bases in DNA. Each TALE repeat contains 34 amino acids, two of which specify its nucleotide binding partner. In this figure, the identity of these residues is indicated by the color of the repeat. TALE proteins can be designed to uniquely recognize extended oligonucleotide sequences. In this example, a 22 base-pair sequence is bound by a single TALE protein, the bacterial effector PthXo1.

[Drawn from 3UGM.pdb.]

Since the FokI nuclease functions as a dimer, two ZFN/TALEN constructs are necessary to generate a double-stranded break, one for each strand of DNA (Figure 9.38).

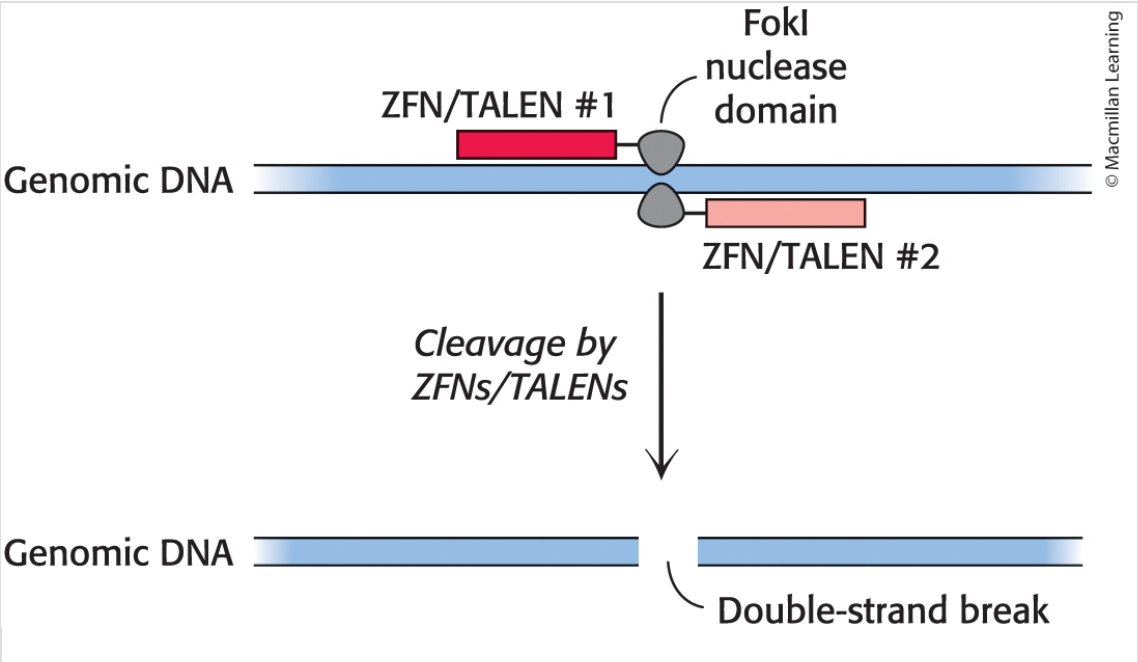

FIGURE 9.38 A pair ZFNs or TALENs introduce double-strand breaks into DNA. The nuclease domain of FokI functions as a dimer. Thus, in order to achieve a sequence-specific double-strand break, two ZFNs or TALENs are required, one for each DNA strand.

- The **CRISPR-Cas system** enables even greater diversity and potential for customization in the generation of precise double-strand DNA breaks. Clustered regularly interspaced palindromic repeats (or CRISPRs) were first discovered in the late 1980s in the genome of the bacterium *E. coli*, then subsequently identified in numerous bacterial and archaeal species. Near these repeats are clusters of genes encoding CRISPR-associated, or *Cas*, proteins, which were predicted to function as enzymes that bind to and cleave DNA. Twenty years later, it was confirmed that these loci constitute a prokaryotic immune system, enabling the cleavage of foreign DNA sequences. Since this discovery, CRISPR-Cas systems have been cleverly adapted to enable customized sequence-specific DNA cleavage.

How do CRISPR-Cas systems achieve sequence-specific double-strand breaks in DNA? Cleavage of target DNA by the CRISPR-Cas system of the bacterium *Streptococcus pyogenes* requires only a single protein, the nuclease Cas9, and an engineered, single-stranded **single guide RNA**, or **sgRNA**. At its $5'$ end, the sgRNA contains approximately 20 nucleotides that can be customized to complement the desired target site, followed by multiple stem-loop structures at its $3'$ end, which are required for binding to the nuclease (**Figure 9.39**). Cas9 is a large, 158 kDa protein which contains two lobes: a REC lobe, which binds to the duplex formed between the sgRNA and the target strand of DNA; and a NUC lobe, which contains the two

nuclease domains that are responsible for cleavage of the two strands of the target DNA (Figure 9.40A).

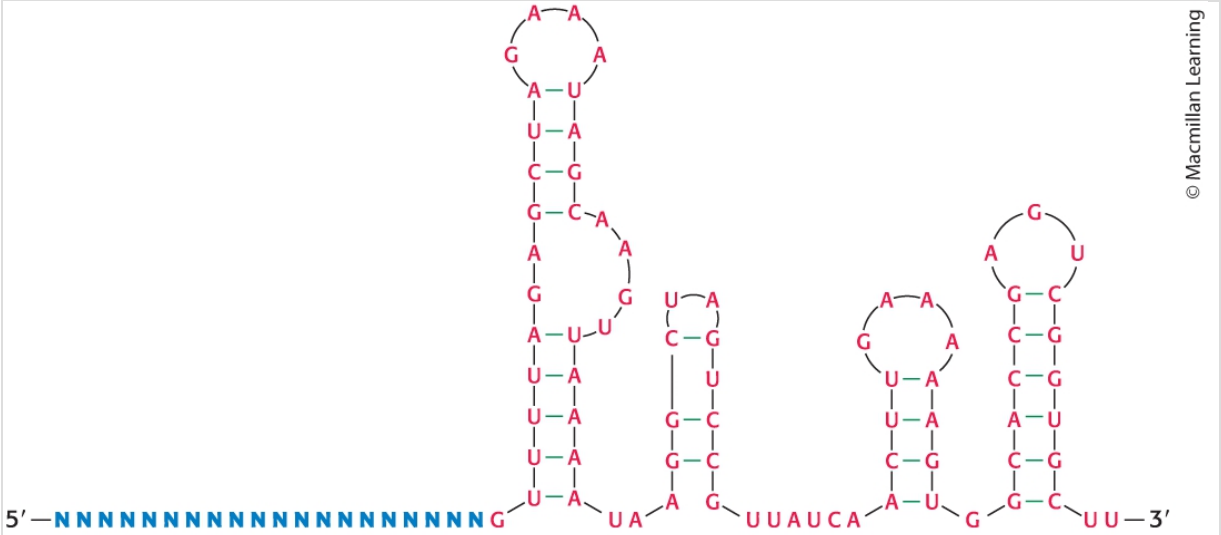

FIGURE 9.39 The single guide RNA contains the sequence that will drive site-specific cleavage. A single guide RNA (sgRNA) contains 20 nucleotides at its 5′ end (blue) which specify the target sequence, followed by multiple stem-loop structures (red) which mediate the interaction with Cas9.

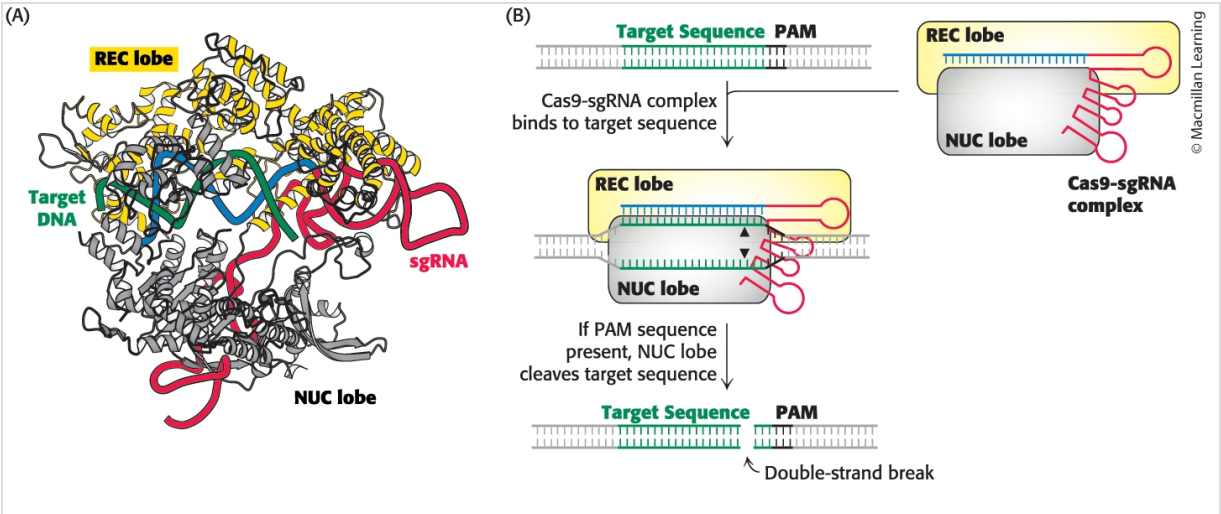

FIGURE 9.40 DNA is cleaved by the CRISPR-Cas system. (A) The structure of a Cas9-sgRNA complex reveals the two lobes of Cas9: the REC lobe (yellow) and the NUC lobe (gray). The REC lobe mediates the interaction with the sgRNA, shown in blue and red as in Figure 9.39. The NUC lobe contains the nuclease domain that will cleave the target DNA (green). (B) If the target DNA sequence contains an adjacent PAM sequence, the sgRNA-Cas9 complex will bind and cleave both strands of the target, at the sites indicated by the black triangles, yielding a double-strand break.

[Part (A) Drawn from 4OO8.pdb.]

VIEW an animation of this technique in Achieve

Cas9 also contains a region that recognizes a short (usually three- or four-nucleotide) sequence of DNA known as the *protospacer-adjacent motif* (PAM). If the target DNA sequence complementary to the sgRNA is adjacent to a PAM, the Cas9 complex cleaves both target strands using the two nuclease domains of the NUC lobe (**Figure 9.40B**). As the specificity of this nuclease is driven by a complementary sequence of RNA, the CRISPR-Cas system can be engineered to cleave virtually any DNA sequence, provided it is adjacent to a PAM, without the need for designing new protein recognition domains such as those required for ZFNs or TALENs.

Site-specific nuclease-based genome editing methods have now been applied to a variety of species, including model organisms used in the laboratory (rat, zebrafish, and fruit fly), various forms of livestock (pig, cow), and a number of plants. In addition, their use as therapeutic tools in humans is currently under investigation. For example, a ZFN that inactivates the human CCR5 gene, a coreceptor for cellular invasion of human immunodeficiency virus (HIV), is currently in clinical trials for the treatment of patients infected with HIV.

dpa picture alliance/Alamy

EMMANUELLE CHARPENTIER AND JENNIFER DOUDNA French microbiologist and biochemist Emmanuelle Charpentier (right) has spent much of her career investigating bacterial pathogens and the factors that contribute to their virulence. In 2011, then working at Umeå University in Sweden, she and her research team published a detailed study on the CRISPR-Cas9 system of *Streptococcus pyogenes*, including characterization of the RNA components that determine the sequence specificity of the Cas9 nuclease enzyme. While presenting her work at a conference later that year, she met Jennifer Doudna (left), a biochemist at the University of California, Berkeley, and a world leader in the structure and function of RNA molecules, who had recently developed an interest in the CRISPR-Cas9 system. Their mutual and complementary interests formed the basis for a collaboration, and the following year they together published a landmark paper demonstrating how an engineered single guide RNA could direct the Cas9-mediated cleavage of almost any DNA sequence. Their work has transformed the field of genome editing and underscores the power of collaboration in the scientific endeavor. In 2020, Charpentier and Doudna shared the Nobel Prize in Chemistry for their discovery.

Self-Check Question

Targeting a DNA sequence for editing by the CRISPR-Cas9 system requires that a PAM sequence be present just downstream of the target sequence. For *S. pyogenes* Cas9, this PAM is $5'-NGG-3'$, where N represents any nucleotide. Mutants of this Cas9 enzyme have been developed which recognize different PAM sequences, such as $5'-NGAN-3'$. Why might these mutants be useful for genome editing studies?

RNA interference enables disruption of gene expression and presents new therapeutic opportunities

An extremely powerful tool for disrupting gene expression was serendipitously discovered in the course of studies that required the introduction of RNA into a cell. The introduction of a specific double-stranded RNA molecule into a cell was found to suppress the transcription of genes that contained sequences present in the double-stranded RNA molecule. Thus, the introduction of a specific RNA molecule can interfere with the expression of a specific gene.

The mechanism of this process, called **RNA interference (RNAi)**, has been largely established (**Figure 9.41**):

1. When a double-stranded RNA molecule is introduced into an appropriate cell, the RNA is cleaved by the enzyme Dicer into

fragments approximately 21 nucleotides in length. Each fragment, termed a small interfering RNA (siRNA), consists of 19 bp of double-stranded RNA and 2 bases of unpaired RNA on each 5′ end.

2. The siRNA is loaded into an assembly of several proteins referred to as the *RNA-induced silencing complex* (RISC).

3. The RISC unwinds the RNA duplex and cleaves one of the strands, the so-called *passenger strand*. The uncleaved single-stranded RNA segment, the *guide strand*, remains incorporated into the enzyme.

4. The fully assembled RISC cleaves mRNA molecules that contain exact complements of the guide-strand sequence. Thus, levels of such mRNA molecules are dramatically reduced.

The technique of RNA interference is called *gene knockdown*, because the expression of the gene is reduced but not eliminated, as is the case with gene knockouts.

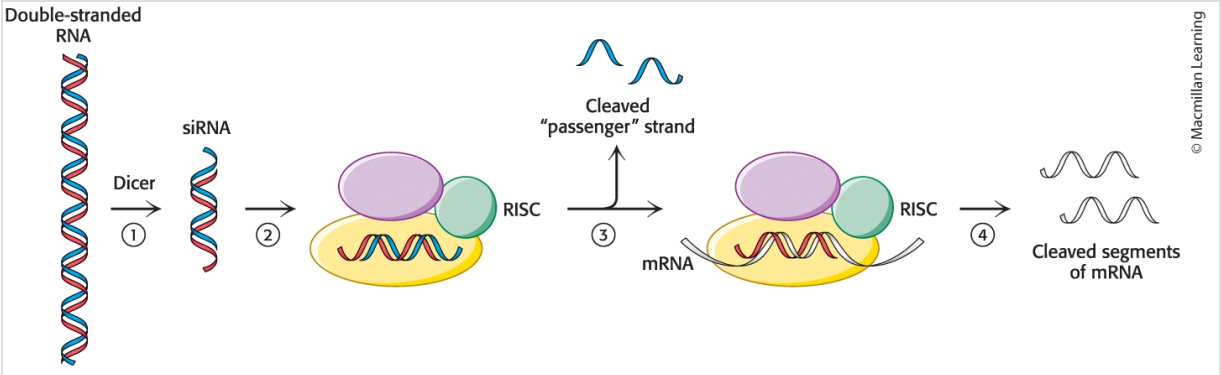

FIGURE 9.41 Specific mRNA transcripts are degraded by RNA interference. A double-stranded RNA molecule is cleaved into 21-bp fragments by the enzyme Dicer to produce siRNAs. These siRNAs are incorporated into the RNA-induced silencing complex (RISC), where the single-stranded RNAs guide the cleavage of mRNAs that contain complementary sequences.

The machinery necessary for RNA interference is found in many cells. In some organisms such as *C. elegans*, RNA interference is quite efficient. Indeed, RNA interference can be induced simply by feeding *C. elegans* strains of *E. coli* that have been engineered to produce appropriate double-stranded RNA molecules. Although not as efficient in mammalian cells, RNA interference has emerged as a powerful research tool for reducing the expression of specific genes. Moreover, in 2017, an siRNA targeting the protein transthyretin achieved positive results in a Phase III clinical trial for the treatment of familial amyloid polyneuropathy.

Foreign DNA can be introduced into plants

Several methods have been developed to introduce foreign DNA into plant cells.

Ti plasmids

The common soil bacterium *Agrobacterium tumefaciens* infects plants and introduces foreign genes into plant cells, causing a lump of tumor tissue called a *crown gall* to grow at the site of infection (**Figure 9.42**). Crown galls synthesize opines, a group of amino acid derivatives that are metabolized by the infecting bacteria. In essence, the bacterium hijacks the metabolism of the plant cells to satisfy its highly distinctive appetite. **Tumor-inducing plasmids (Ti plasmids)** that are carried by *A. tumefaciens* carry instructions for

the switch to the tumor state and the synthesis of opines. A small part of the Ti plasmid becomes integrated into the genome of infected plant cells; this 20-kb segment is called *T-DNA*, for transferred DNA.

Credit: Matthew A. Escobar, Edwin L. Civerolo, Kristin R. Summerfelt, and Abhaya M. Dandekar. RNAi-mediated oncogene silencing confers resistance to crown gall tumorigenesis. *PNAS* 2001 98 (23) 13437–13442. Copyright 2001 National Academy of Sciences, U.S.A.

FIGURE 9.42 Crown gall, a plant tumor, is caused by the bacterium *Agrobacterium tumefaciens*. This bacterial species introduces a tumor-inducing plasmid (Ti plasmid) into the plant host.

Ti-plasmid derivatives can be used as vectors to deliver foreign genes into plant cells. First, a segment of foreign DNA is inserted into the T-DNA region of a small plasmid through the use of restriction enzymes and ligases. This synthetic plasmid is added to

A. tumefaciens colonies harboring naturally occurring Ti plasmids, and, by recombination, Ti plasmids containing the foreign gene are formed. These Ti vectors are valuable tools for exploring the genomes of plant cells and modifying plants to improve their agricultural value and crop yield.

Electroporation

Foreign DNA can also be introduced into plants by applying intense electric fields, a technique called **electroporation** (**Figure 9.43**). First, the cellulose wall surrounding plant cells is removed by adding cellulase; this treatment produces protoplasts, plant cells with exposed plasma membranes. Electric pulses are then applied to a suspension of protoplasts and plasmid DNA. Because high electric fields make membranes transiently permeable to large molecules, plasmid DNA molecules enter the cells. The cell wall is then allowed to re-form, and the plant cells are again viable. Moreover, the transfected cells efficiently express the plasmid DNA. Corn and carrot cells have been stably transfected in this way with the use of plasmid DNA that includes genes for resistance to herbicides. Electroporation is also an effective means of delivering foreign DNA into mammalian and bacterial cells.

FIGURE 9.43 Foreign DNA can be introduced into plant cells by electroporation. In this technique, the application of intense electric fields makes the plant plasma membranes transiently permeable to large molecules, such as plasmid DNA.

Gene guns

The most effective means of transforming plant cells is through the use of so-called *gene guns*, or *bombardment-mediated transformation*. DNA is coated onto $1\text{-}\mu\text{m}\text{-}\text{diameter}$ tungsten pellets, and these microprojectiles are fired at the target cells with a velocity greater than $400\ \text{m}\ \text{s}^{-1}$. Despite its apparent crudeness, this technique is an effective way of transforming plants, especially important crop species such as soybean, corn, wheat, and rice.

The aforementioned techniques afford an opportunity to develop genetically modified organisms (GMOs) with beneficial characteristics, such as the ability to grow in poor soils, resistance to natural climatic variation, resistance to pests, and fortified nutritional content. These crops might be most useful in regions where malnutrition is prevalent. However, the use of GMOs is highly controversial, as some fear that their safety risks have not been adequately addressed.

The first GMO to come to market was a tomato characterized by delayed ripening. This was achieved by disrupting the gene for the enzyme that breaks down pectin, the polysaccharide that gives tomatoes their firmness. During ripening, pectin is destroyed, and the tomatoes soften, making shipment difficult; by disrupting

production of the pectin-destroying enzyme, the tomatoes stayed firm longer. However, the tomato's poor taste hindered its commercial success. An especially successful result of the use of Ti plasmid to modify crops is golden rice. Golden rice is a variety of genetically modified rice that contains the genes for β-carotene synthesis, a required precursor for vitamin A synthesis in humans. Consumption of this rice has the potential to benefit regions of the world where rice is a dietary staple and vitamin A deficiency is common.

Chapter 9 Summary

9.1 The Exploration of Genes Relies on Key Tools

- Restriction enzymes recognize specific base sequences in double-helical DNA and cleave both strands of the duplex, forming specific fragments of DNA.
- A DNA fragment containing a particular sequence can be identified by hybridizing it with a labeled single-stranded DNA probe (Southern blotting).
- DNA can be sequenced by controlled interruption of replication. The fragments produced are separated by capillary electrophoresis and visualized by fluorescent tags at their $5'$ ends.
- DNA probes for hybridization reactions, as well as new genes, can be synthesized by the automated solid-phase method.
- The polymerase chain reaction makes it possible to greatly amplify specific segments of DNA in vitro. The region amplified is determined by the placement of a pair of primers that are added to the target DNA along with a thermostable DNA polymerase and deoxyribonucleoside triphosphates.

9.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology

- Novel DNA molecules are made by joining fragments that have complementary cohesive ends produced by the action of a restriction enzyme. DNA ligase seals breaks in DNA chains.
- Vectors for propagating the DNA include plasmids and λ phage. Two broad categories of plasmids include cloning vectors, used for easy insertion and replication of DNA fragments, and

expression vectors, for generating protein product in large quantities.
- Specific genes can be cloned from a genomic library with the use of a DNA or RNA probe.
- Complementary DNA (cDNA) is produced by reverse transcription of mRNA, yielding DNA corresponding to expressed genes. Because cDNA is generated from mature mRNA, all introns have been removed.
- Mutations can be generated in vitro to engineer novel proteins using site-directed mutagenesis, cassette mutagenesis, and mutagenesis by PCR.

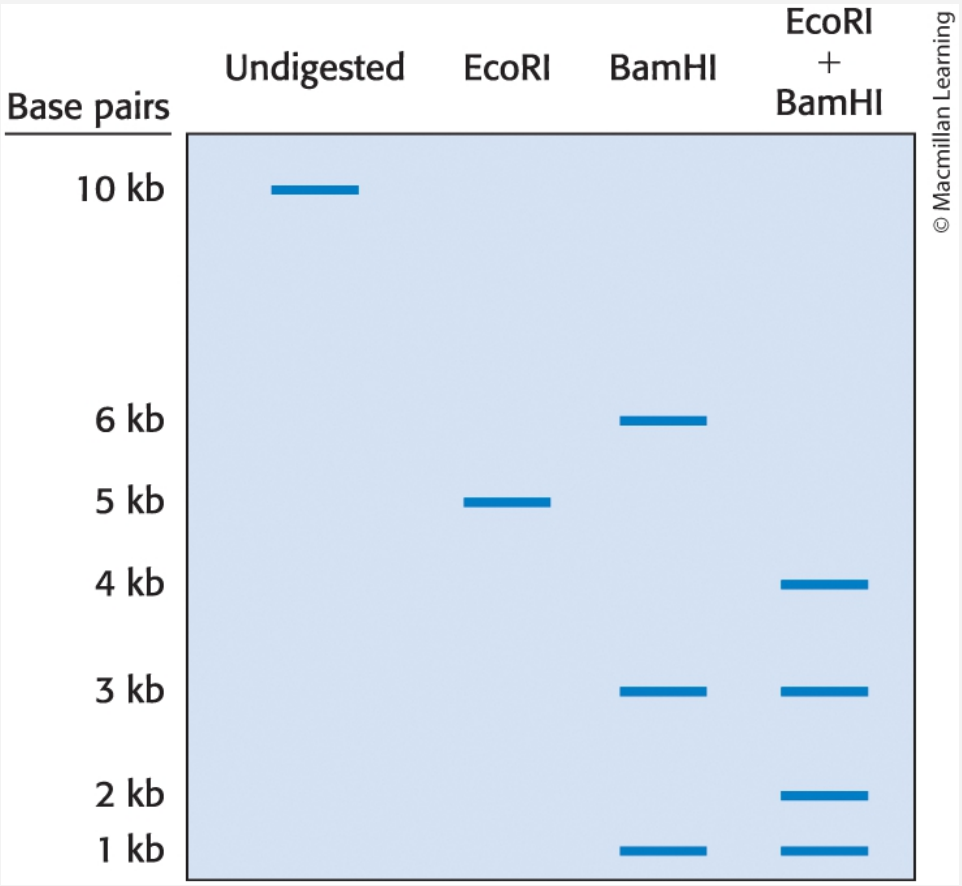
9.3 Complete Genomes Have Been Sequenced and Analyzed

- More than 50,000 bacterial, archaeal, and eukaryotic genomes have been sequenced, including those from key model organisms and important pathogens.
- The sequence of the human genome has now been completed with nearly full coverage and high precision.
- Only from 20,000 to 25,000 protein-encoding genes appear to be present in the human genome, a substantially smaller number than earlier estimates.
- Next-generation sequencing methods have greatly accelerated the pace at which large genomes can be sequenced and analyzed.
- Comparative genomics has become a powerful tool for analyzing individual genomes and for exploring evolution.

9.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision

- Changes in gene expression can be readily determined in cells and tissues by such techniques as quantitative PCR, microarrays, and RNA-seq.

- Transgenic mice, in which a gene has been inserted into the host organism, and knockout mice, in which a gene has been removed, have been a source of considerable insight into disease mechanisms and possible therapies.
- Genome editing techniques, such as those enabled by the CRISPR-Cas system and ZFNs/TALENs, involve the introduction of precise double-strand breaks into the host genome. Repair of these breaks can yield insertions and deletions, often disrupting the target gene, or the template-based replacement of the target gene with a new sequence.
- Another method of disrupting the expression of a particular gene is through RNA interference, which depends on the introduction of specific double-stranded RNA molecules into eukaryotic cells.
- DNA can be transformed into plant cells by the Ti plasmids of the soil bacterium *Agrobacterium tumefaciens*, or by other techniques such as electroporation or gene guns.



Key Terms

restriction enzyme (restriction endonuclease)
Southern blotting
DNA probe
northern blotting
controlled termination of replication (Sanger dideoxy method)

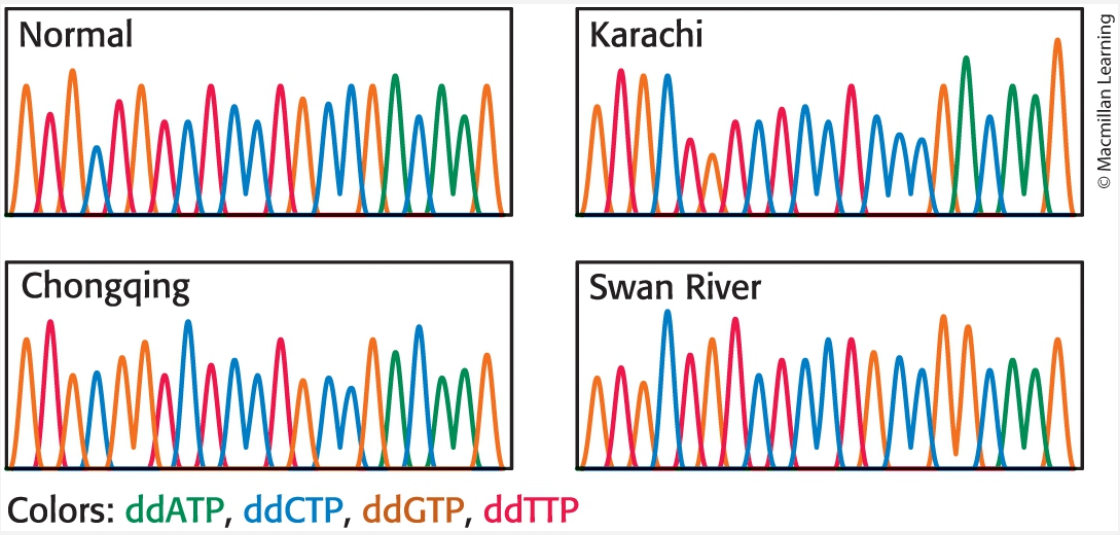
genome editing
zinc-finger nuclease (ZFN)
transcription activator-like effector nuclease (TALEN)
CRISPR-Cas system
single guide RNA (sgRNA)
RNA interference (RNAi)
tumor-inducing plasmid (Ti plasmid)
electroporation

Problems

1. Samples of a linear segment of unknown DNA are digested using the restriction enzymes EcoRI, BamHI, and a combination of EcoRI and BamHI. The digests are then run on an agarose gel in order to separate the resulting fragments by size. Use the results of the gel electrophoresis shown in the image to draw a restriction map, indicating the locations of the restriction sites and the distances between them. 1



2. A series of people are found to have difficulty eliminating certain types of drugs from their bloodstreams. The problem has been linked to a gene X, which encodes an enzyme Y. Six people were tested with the use of various techniques of molecular biology. Person A is a normal control, person B is asymptomatic but some of his children have the metabolic problem, and persons C through F display the trait. Tissue samples from each person were obtained. Southern analysis was performed on the DNA after digestion with the restriction enzyme HindIII. Northern analysis of mRNA also was done. In both types of analysis, the gels were probed with labeled X cDNA. Finally, a western blot with an enzyme-linked monoclonal antibody was used to test for the presence of protein Y. The results are shown below. Why is person B without symptoms? Suggest possible mutations in the other people.  1

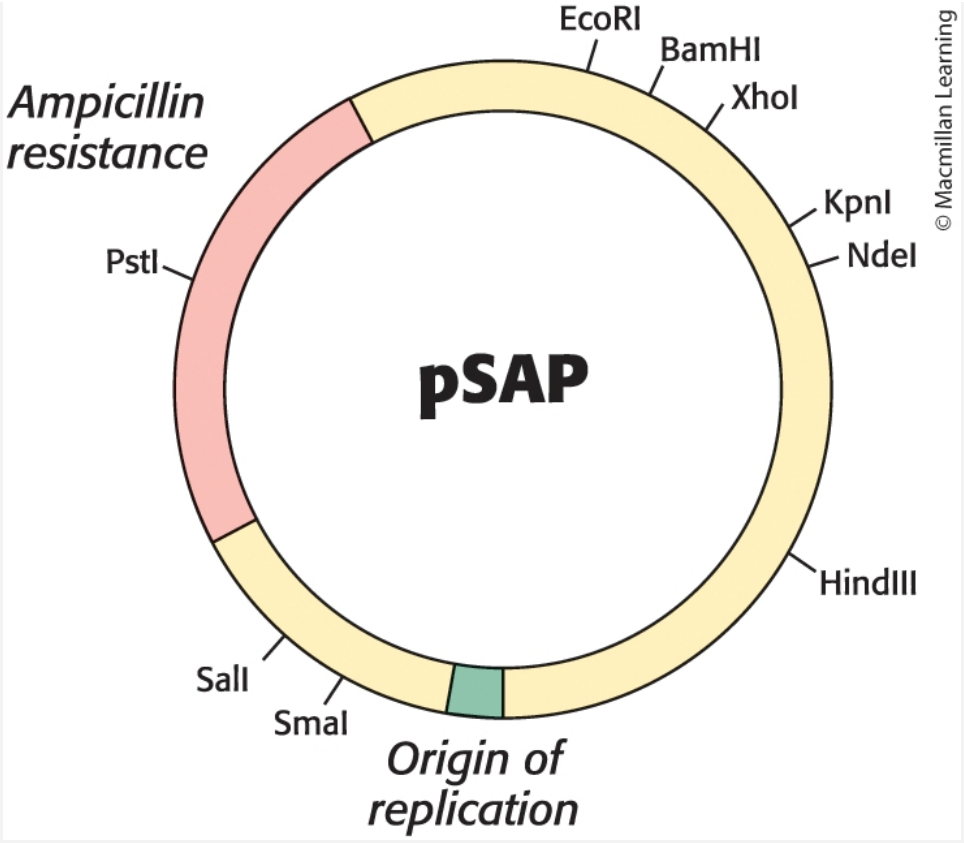
3. Representations of sequencing chromatograms for variants of the α chain of human hemoglobin are shown here. What is the nature of the amino acid change in each of the variants? The first triplet encodes valine. 2

4. You wish to amplify a 250 bp segment of DNA from a plasmid template by PCR with the use of the following primers: $5'-GGATCGATGCTCGCGA-3'$ and $5'-AGGATCGGGTCGCGAG-3'$. Despite repeated attempts, you fail to observe a PCR product of the expected length after electrophoresis on an agarose gel. Instead, you observe a



bright smear on the gel with an approximate length of 25 to 30 base pairs. Explain these results. 3

5. A gel pattern displaying PCR products shows four strong bands. The four pieces of DNA have lengths that are approximately in the ratio of 1:2:3:4. The largest band is cut out of the gel, and PCR is repeated with the same primers. Again, a ladder of four bands is evident in the gel. What does this result reveal about the structure of the encoded protein? 3

6. A young investigator would like to express and purify a newly discovered gene. She decides to clone the gene into an expression plasmid that contains the sequence for a hexahistidine tag. Order the steps for construction of the expression plasmid and generation of the protein. (The gene of interest will be inserted between the NotI and HindIII sites.) 4

a. Ligate the cut plasmid and DNA fragment.
b. Introduce NotI and HindIII restriction sites at the ends of the gene of interest.
c. Transfect the modified plasmid into *E. coli* for expression.
d. Digest the plasmid and the gene insert with NotI and HindIII.

7. The map of a hypothetical plasmid, pSAP, is shown here:

Suppose you have a DNA fragment you would like to insert into pSAP. The fragment has PstI and EcoRI restriction endonuclease sites near the $5'$ end, and HindIII and SmaI restriction endonuclease sites near the $3'$ end. What are the best restriction enzymes to use to digest both the DNA fragment and pSAP? 4

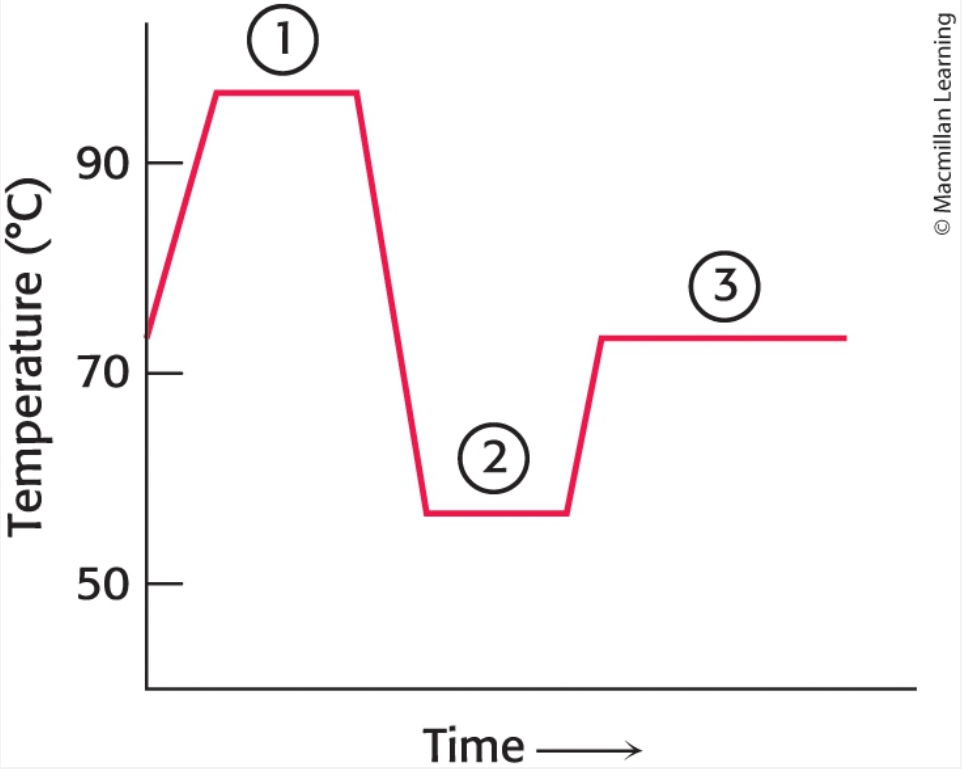
8. You have identified a gene that is located on human chromosome 20 and wish to identify its location within the mouse genome. On which chromosome would you be most likely to find the mouse counterpart of this gene?

9. Which of the following amino acid sequences would yield the most optimal oligonucleotide probe?

Ala-Met-Ser-Leu-Pro-Trp
Gly-Trp-Asp-Met-His-Lys
Cys-Val-Trp-Asn-Lys-Ile
Arg-Ser-Met-Leu-Gln-Asn

How many unique oligonucleotides would be required to detect all sequence possibilities for the optimal probe?

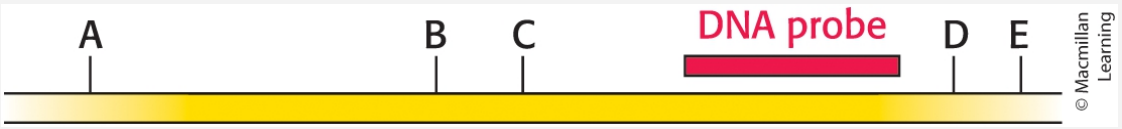
10. Suppose a researcher previously cloned gene *Y* into M13 bacteriophage vector. Gene *Y* encodes a product called peptide Y. A region of gene *Y* contains the DNA sequence ATG–CGC–GAA–CTG–GTG–AAC–TAA. The researcher wishes to change a Val residue to an Ala residue in this region of peptide Y using site-directed mutagenesis. What should be the sequence of the mutant oligonucleotide primer in this region? 5



11. Targeting a DNA sequence for editing by the CRISPR-Cas9 system requires that a PAM sequence be present just downstream of the target sequence. For *S. pyogenes* Cas9, this PAM is $5'-NGG-3'$, where N represents any nucleotide. Assuming a fragment of DNA includes equal amounts of A, C, G, and T bases, how far apart would one expect to find these PAMs? 6

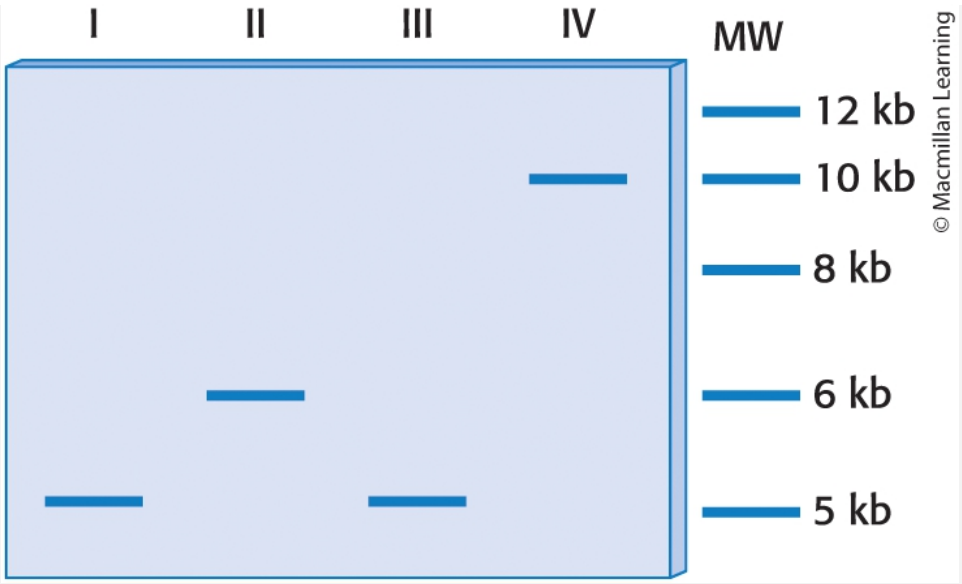
12.

a. Using RNA interference, it is possible to significantly reduce homologous mRNA transcripts and thereby reduce the expression level of a specific gene of interest. What methods could be used to confirm that an RNAi knockdown experiment has been successful?



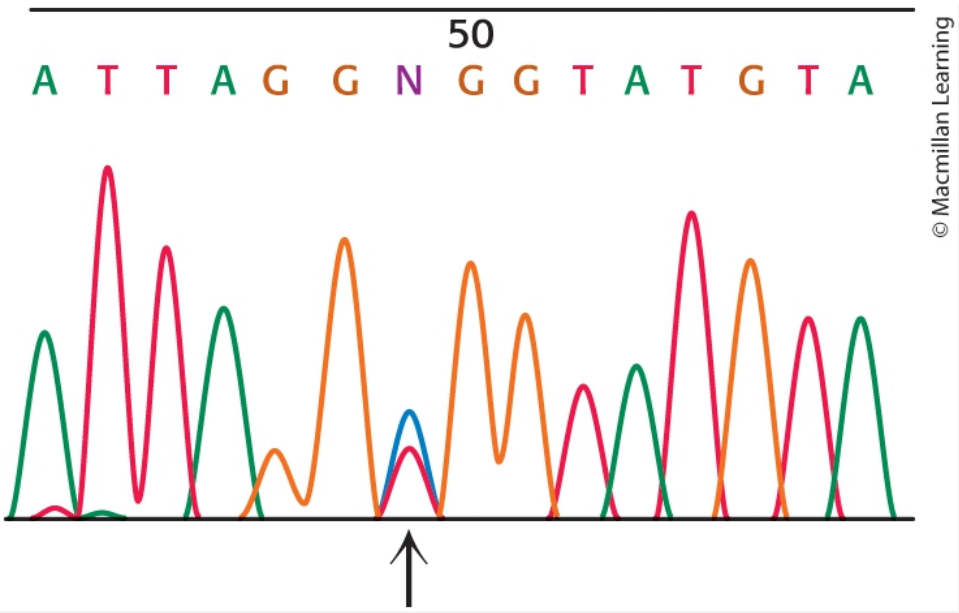
b. The relative ease of RNAi studies means that large-scale screens can be performed to assess a wide array of targets. What source would produce the most functional RNAi library for conducting genome-wide screens: whole-genome DNA, whole-genome proteins, or whole-genome cDNA?

13. The image below shows a time versus temperature plot for one cycle of PCR. Match the events below with the indicated regions (1, 2, and 3) on the plot. 3

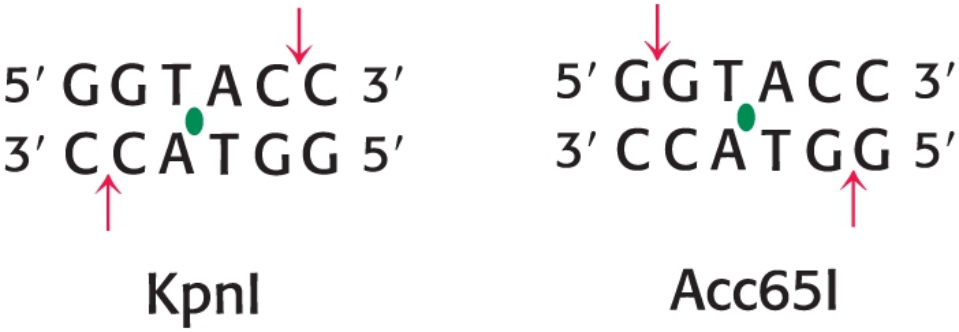


a. DNA polymerase extends primers.
b. DNA separates into single strands.
c. Primers anneal to single-stranded DNA.

14. You are interested in identifying mutations in a region of DNA that, in most individuals, has 5 cleavage sites for EcoRI. In the figure below, these sites are labeled A through E. You also have a probe that is complementary to the region between sites C and D:



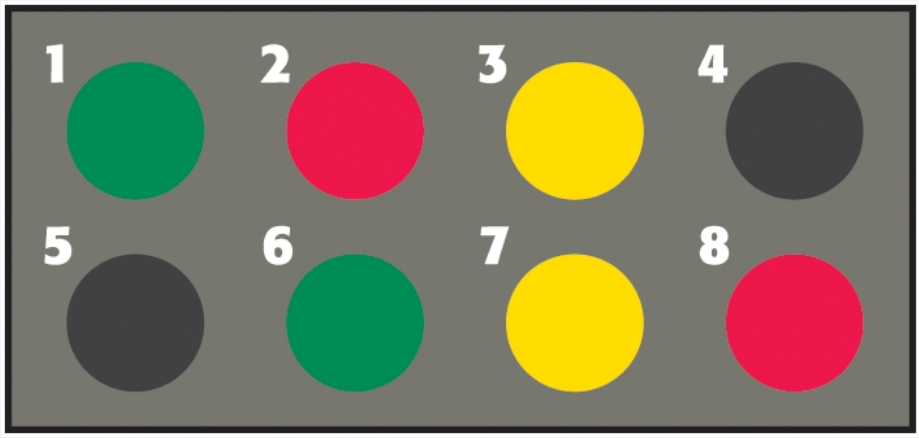
DNA samples from four individuals were cleaved with EcoRI. The DNA fragments were separated by gel electrophoresis, transferred to a membrane, and hybridized with your DNA probe. The image of the Southern blot shows the labeled DNA bands and molecular weight (MW) markers. The lane labels I, II, III, and IV correspond to individuals I, II, III, and IV. Assume that fragments such as C–D and C–E are clearly resolved in this gel system. Fragment sizes are as given: A–B is 4 kb, B–C is 1 kb, C–D is 5 kb, and D–E is 650 bp. Individual I represents the positive control, and has all five EcoRI sites intact.



a. Which individual has at least one point mutation that eliminates restriction site C?
b. Which individual has mutation(s) that eliminate restriction sites B and C?
c. Which individual has at least one point mutation that eliminates restriction site A?

15. In the course of studying a gene and its possible mutation in humans, you obtain genomic DNA samples from a collection of persons and PCR amplify a region of interest within this gene. For one of the samples, you obtain the sequencing chromatogram shown here. Provide an explanation for the appearance of these data at position 49 (indicated by the arrow):

16. The restriction enzymes KpnI and Acc65I recognize and cleave the same 6-bp sequence. However, the sticky end formed from KpnI cleavage cannot be ligated directly to the sticky end formed from Acc65I cleavage. Explain why.



17. Suppose a single linear molecule of double-stranded DNA is amplified by PCR. How many molecules of double-stranded DNA will there be after 1 cycle? After 3 cycles? After 30 PCR cycles (a typical cycle count used in PCR experiments)? 3

18. Which of the following reagents are needed for a typical PCR? 3

a. DNA ligase
b. Four nucleotides (A, U, C, G)
c. *Taq* DNA polymerase
d. Template DNA
e. Two primers
f. *E. coli* DNA polymerase
g. Four nucleotides (A, T, C, G)

19. In preparation for a microarray experiment, cDNA was isolated from tumor tissue and labeled with a red fluorescent probe, while the cDNA from normal tissue was labeled with a green fluorescent probe. A small segment of the resulting microarray data is shown below.

© Macmillan Learning

Classify the individual genes (numbered on the array) based on the following descriptions:

a. Primarily expressed in tumor tissue
b. Primarily expressed in normal tissue
c. Expressed in both tissues
d. Not expressed in either tissue.

20. As RNA-seq becomes cheaper and less computationally intensive, many researchers are replacing microarray analysis with RNA-seq as the preferred method to measure cellular transcript levels. What are some advantages of RNA-seq over microarray analysis?

Chapter 10
Exploring Evolution and Bioinformatics

Evolutionary relationships are clear in protein sequences. The now-extinct woolly mammoth (*Mammuthus primigenius*) coexisted with early humans, as evidenced by Late Stone Age cave paintings such as those at the Rouffignac Cave in France. Using samples obtained from frozen preserved tissue, researchers used recombinant DNA technology to determine the complete sequence of the woolly mammoth genome and the structural and functional adaptations of its proteins. In the case of α-hemoglobin (right), only six residues (shown in green) are nonidentical and dissimilar between the woolly mammoth and human sequences. Amino acid sequence comparisons with living species and functional expression of these extinct proteins have provided new insights into how this species adapted to very cold environments.

Outline

10.1 Homologs Are Descended from a Common Ancestor and Can Be Detected by Sequence Alignments
10.2 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships

10.3 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information
10.4 Modern Techniques Make the Experimental Exploration of Evolution Possible

Learning Goals

By the end of this chapter, you should be able to:

1. Distinguish between homologs, paralogs, and orthologs.
2. Describe how two protein sequences are aligned, and how one can determine whether that alignment is significant.
3. Explain how substitution matrices can be used to facilitate the identification of related protein sequences.
4. Distinguish between divergent and convergent evolution.
5. Describe one way the evolution of biomolecules can be demonstrated in the laboratory.

Like members of a human family, members of molecular families often have features in common. Such family resemblance is most easily detected by comparing three-dimensional structure, the aspect of a molecule most closely linked to function. However, such structures have been determined for only a small proportion of the total number of proteins. In contrast, gene sequences and the corresponding amino acid sequences are available for a great number of proteins, largely owing to the tremendous power of DNA cloning and sequencing techniques, including complete-genome sequencing (Section 9.3). As we will discuss in this chapter, sequence databases can be probed for matches to a newly elucidated sequence to identify related molecules, providing considerable insight into the function, mechanism, and evolutionary history of the molecule encoded by that sequence.

10.1 Homologs Are Descended from a Common Ancestor and Can Be Detected by Sequence Alignments

The exploration of biochemical evolution consists largely of an attempt to determine how proteins, other molecules, and biochemical pathways have been transformed through time. Sequence comparisons can often reveal pathways of evolutionary descent and estimated dates of specific evolutionary landmarks. This information can be used to construct evolutionary trees that trace the evolution of a particular protein or nucleic acid, in many cases from Archaea and Bacteria through Eukarya, including human beings.

Orthologs and paralogs are two different classes of homologous proteins

The most fundamental relationship between two entities is *homology*; two molecules are said to be *homologous* if they are derived from a common ancestor. Homologous molecules, or **homologs**, can be divided into two classes (**Figure 10.1**):

- **Orthologs** are homologs that are present within different species and have very similar or identical functions. In Section 2.6, we discussed the structure of ribonuclease from cows (Figure 10.1; yellow). This protein is highly similar in structure to human ribonuclease (Figure 10.1; red). Both proteins share very similar functions, namely, the hydrolytic cleavage of RNA molecules.

- **Paralogs** are homologs that are present within one species. Paralogs often differ in their detailed biochemical functions. For example, angiogenin (Figure 10.1; blue), a protein that stimulates

the growth of new blood vessels, is also structurally similar to ribonuclease — so similar that both angiogenin and ribonuclease are clearly members of the same protein family. Paralogs such as angiogenin and ribonuclease strongly suggest a common ancestor at some earlier stage of evolution.

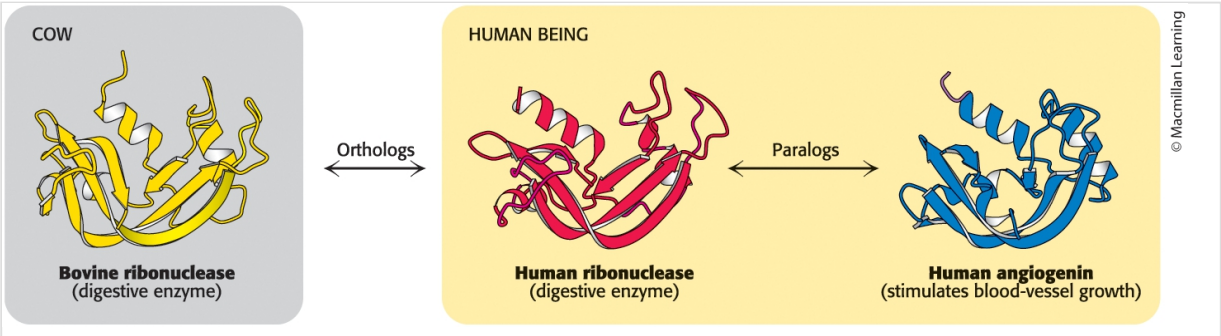

FIGURE 10.1 Homologs can be divided into two classes. Homologs that perform identical or very similar functions in different species are called orthologs, whereas homologs that perform different functions within one species are called paralogs.

[Drawn from 8RAT.pdb, 2RNF.pdb, and 2ANG.pdb.]

Understanding the homology between molecules can reveal the evolutionary history of the molecules as well as information about their function; if a newly sequenced protein is homologous to an already characterized protein, we have a strong indication of the new protein's biochemical function.

Statistical analysis of sequence alignments can detect homology

How can we tell whether two human proteins are paralogs or whether a yeast protein is the ortholog of a human protein? A significant sequence similarity between two molecules implies that they are likely to have the

same evolutionary origin and, therefore, similar three-dimensional structures, functions, and mechanisms. Both nucleic acid and protein sequences can be compared to detect homology. However, the possibility exists that the observed agreement between any two sequences is solely a product of chance. Because nucleic acids are composed of fewer building blocks than proteins (4 bases versus 20 amino acids), the likelihood of random agreement between two DNA or RNA sequences is significantly greater than that for protein sequences. For this reason, detection of homology between protein sequences is typically far more effective.

To illustrate sequence-comparison methods, let us consider the globins, the critical oxygen carrying proteins which we first encountered in Chapter 3. Recall that myoglobin is a monomer, while each human hemoglobin molecule is composed of four heme-containing polypeptide chains, two identical α chains and two identical β chains. Here, we shall consider only the α chain. To examine the similarity between the amino acid sequence of the human α chain of hemoglobin and that of human myoglobin (**Figure 10.2**), we apply a method, referred to as a **sequence alignment**, in which the two sequences are systematically aligned with respect to each other to identify regions of significant overlap.

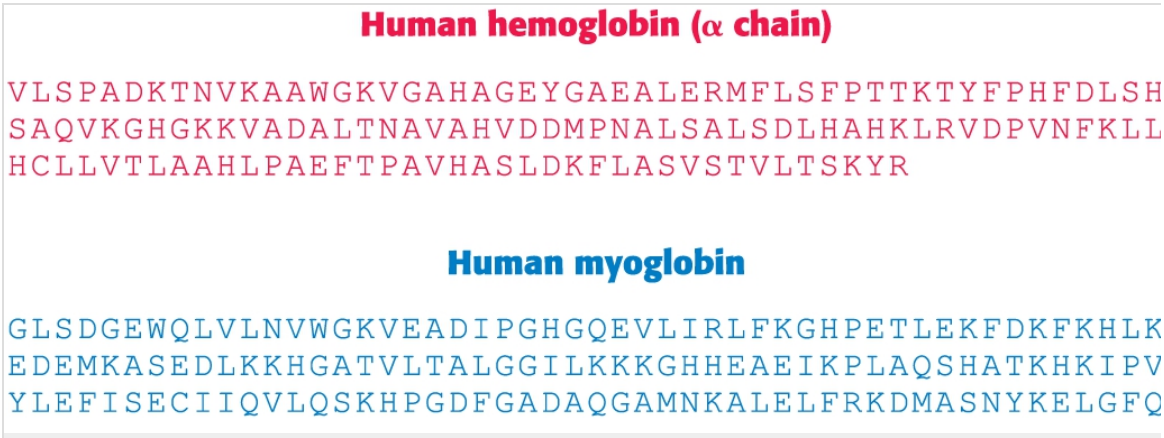

FIGURE 10.2 The amino acid sequences of human hemoglobin (α chain) and human myoglob will be used to demonstrate sequence alignments. α-Hemoglobin is composed of 141 amino acids; myoglobin consists of 153 amino acids. (One-letter abbreviations designating amino acic are used; see Table 2.2.)

How can we tell where to align the two sequences? In the course of evolution, the sequences of two proteins that have an ancestor in common will have diverged in a variety of ways. Insertions and deletions may have occurred at the ends of the proteins or within the functional domains themselves. Individual amino acids may have been mutated to other residues of varying degrees of similarity. To understand how the methods of sequence alignment take these potential sequence variations into account, let us first consider the simplest approach, where we slide one sequence past the other, one amino acid at a time, and count the number of matched residues, or sequence **identities** (**Figure 10.3**). For α-hemoglobin and myoglobin, the best alignment reveals 23 sequence identities spread throughout the central parts of the sequences.

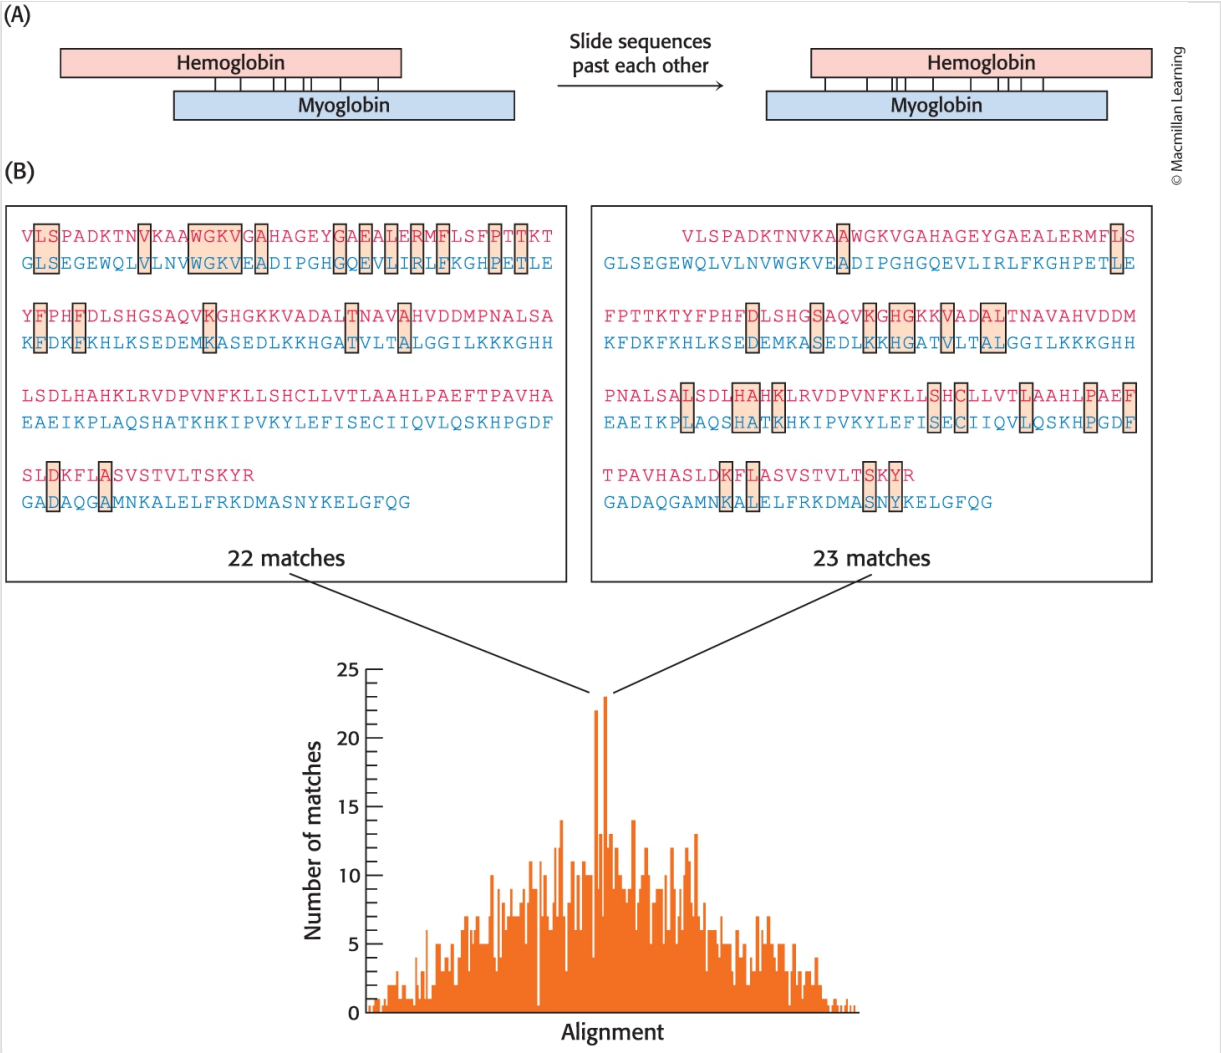

FIGURE 10.3 Amino acid sequences are compared by sliding one sequence past the other, one amino acid at a time. (A) At each step, we count the number of amino acid identities between the two proteins. Shown are representations of just two of the > 100 possible alignments. (B) The two alignments with the largest number of matches are shown above the graph, which plots the matches as a function of alignment.

However, careful examination of all the possible alignments and their scores suggests that important information regarding the relationship between myoglobin and hemoglobin α has been lost with this method. In particular, we see that another alignment, featuring 22 identities, is

nearly as good (Figure 10.3). This alignment is shifted by six residues relative to the preceding alignment and yields identities that are concentrated toward the amino-terminal end of the sequences. By introducing a gap into one of the sequences, the identities found in both alignments will be represented (**Figure 10.4**). The insertion of gaps allows the alignment method to compensate for the insertions or deletions of nucleotides that may have taken place in the gene for one molecule but not the other in the course of evolution.

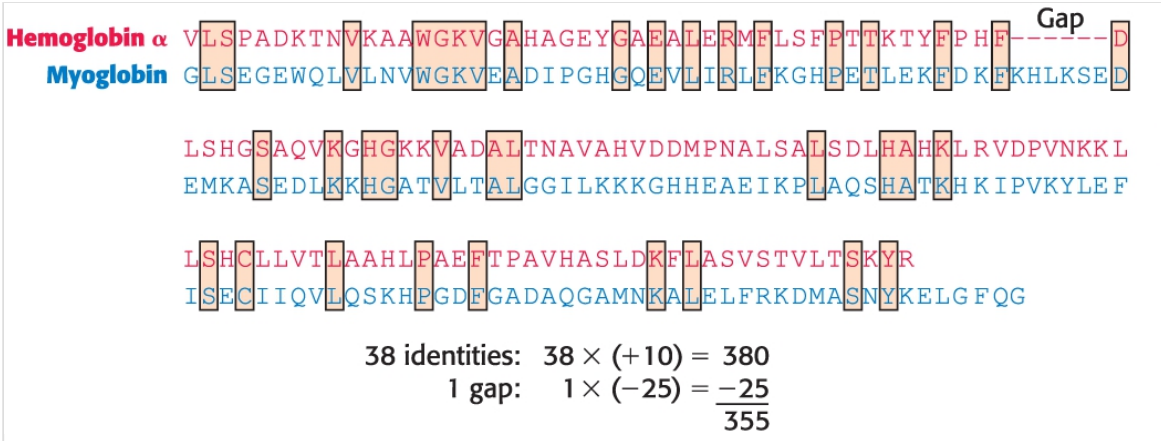

FIGURE 10.4 Addition of a gap improves the alignment between myoglobin and α-hemoglobi
In the scoring method shown in this figure, a penalty is applied for the gap introduced.

The use of gaps substantially increases the complexity of sequence alignment because a vast number of possible gaps, varying in both position and length, must be considered throughout each sequence. Moreover, the introduction of an excessive number of gaps can yield an artificially high number of identities. Nevertheless, methods have been developed for the insertion of gaps in the automatic alignment of sequences. These methods use scoring systems to compare different alignments, including penalties for gaps to prevent the insertion of an unreasonable number of them. For example, in one scoring system, each identity between aligned sequences is counted as $+10$ points,

whereas each gap introduced, regardless of size, counts for -25 points. For the alignment shown in Figure 10.4, there are 38 identities ($38 \times 10 = 380$) and 1 gap ($1 \times -25 = -25$), producing a score of ($380 + -25 = 355$). Overall, there are 38 matched amino acids in an average length of 147 residues; thus, the sequences are 25.9% identical.

Alignments such as the one just described inform us as to the percent identity between two sequences. However, the question remains: how do we interpret this value? For example, we have determined that α-hemoglobin and myoglobin, when allowing for the insertion of gaps, are 25.9% identical. Is this value sufficiently high to suggest a relationship between these two proteins? To answer these questions, we must determine the significance of alignment scores and percent identities.

Self-Check Question

Why is it important to assess penalties for the placement of gaps when scoring an alignment?

The statistical significance of alignments can be estimated by shuffling

The sequence similarities in Figure 10.4 appear striking, yet there remains the possibility that a grouping of sequence identities has occurred by chance alone. Because proteins are composed of the same set of 20 amino acid monomers, the alignment of any two unrelated proteins will yield some identities, particularly if we allow the introduction of gaps. Even if two proteins have identical amino acid composition, they may not be linked by evolution. It is the order of the

residues within their sequences that implies a relationship between them.

We can assess the significance of our alignment by "shuffling," or randomly rearranging, one of the sequences (Figure 10.5), performing the sequence alignment, and determining a new alignment score. This process is repeated many times to yield a histogram showing, for each possible score, the number of shuffled sequences that received that score (Figure 10.6). If the original score is appreciably different from the scores from the shuffled alignments, then it is unlikely that the original alignment is merely a consequence of chance.

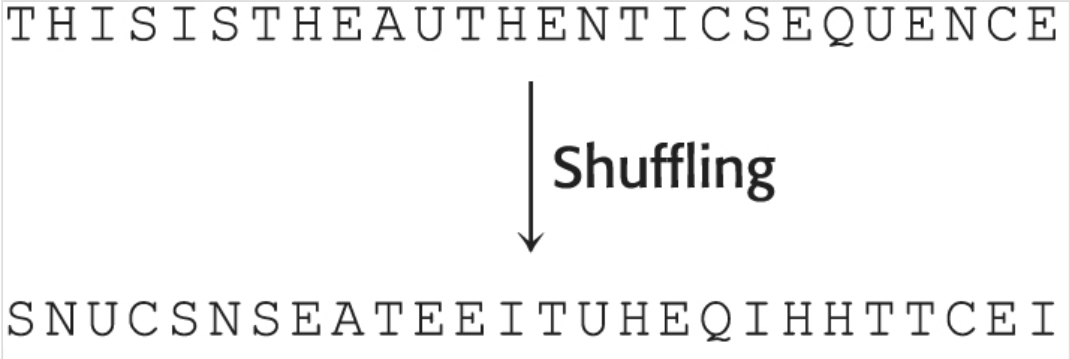

FIGURE 10.5 The individual amino acids are scrambled to generate a shuffled sequence.

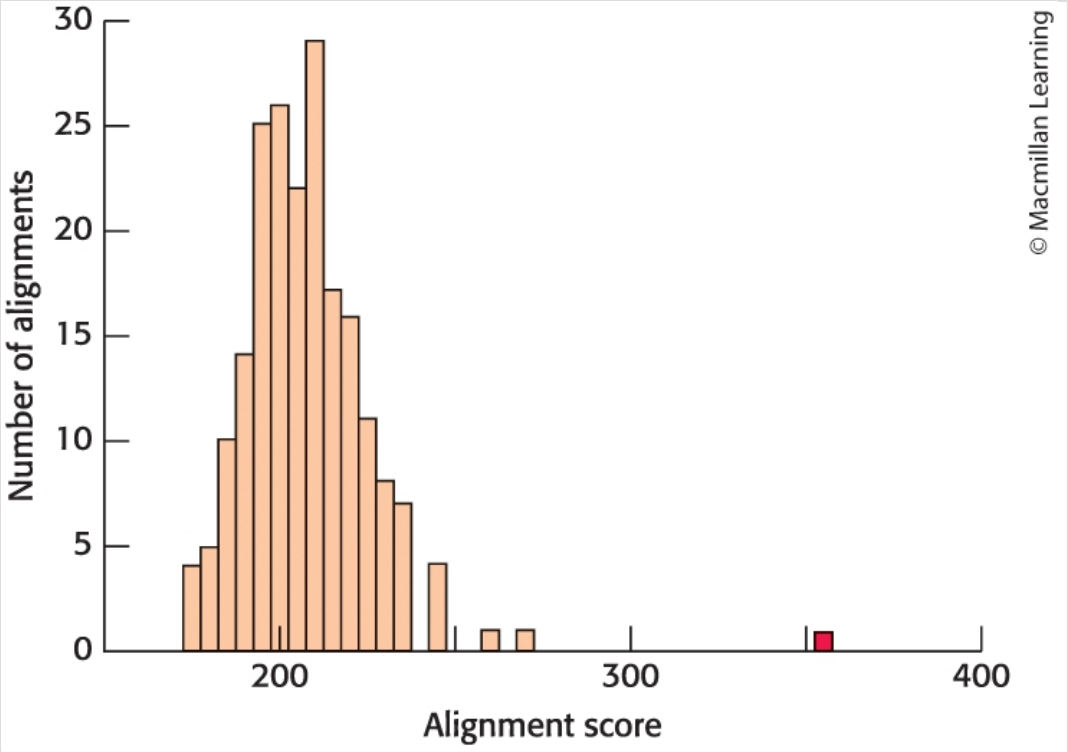

FIGURE 10.6 Comparison of alignment scores reveals the statistical significance of an unshuffled alignment. Alignment scores are calculated for many shuffled sequences, and the number of sequences generating a particular score is plotted against the score. The resulting plot is a distribution of alignment scores occurring by chance. The alignment score for unshuffled α-hemoglobin and myoglobin (shown in red) is substantially greater than any of these scores, strongly suggesting that the sequence similarity is significant.

When this procedure is applied to the sequences of myoglobin and α-hemoglobin, the authentic alignment (indicated by the red bar in Figure 10.6) clearly stands out. Its score is far above the mean for the alignment scores based on shuffled sequences. The probability that such a deviation occurred by chance alone is approximately 1 in 10^{20}.

Thus, we can comfortably conclude that the two sequences are genuinely similar; the simplest explanation for this similarity is that these sequences are homologous — that is, the two molecules have descended from a common ancestor.

Distant evolutionary relationships can be detected through the use of substitution matrices

The scoring scheme described above assigns points only to positions occupied by identical amino acids in the two sequences. No credit is given for any pairing that is not an identity. However, as already discussed, two proteins related by evolution undergo amino acid substitutions as they diverge. A scoring system based solely on amino acid identity cannot account for these changes. To add greater sensitivity to the detection of evolutionary relationships, methods have been developed to compare two amino acids and assess their degree of *similarity*.

Not all substitutions are equivalent. For example, amino acid changes can be classified as structurally conservative or nonconservative. A **conservative substitution** replaces one amino acid with another that is similar in size and chemical properties. Conservative substitutions may have only minor effects on protein structure and often can be tolerated without compromising protein function. In contrast, in a **nonconservative substitution**, an amino acid is replaced by one that is structurally dissimilar. Amino acid changes can also be classified by the fewest number of nucleotide changes necessary to achieve the corresponding amino acid change. Some substitutions arise from the replacement of only a single nucleotide in the gene sequence, whereas others require two or three replacements. Conservative and single-nucleotide substitutions are likely to be more common than are substitutions with more radical effects.

How can we account for the type of substitution when comparing sequences? We can approach this problem by first examining the substitutions that have been observed in proteins known to be evolutionarily related. From an examination of appropriately aligned sequences, substitution matrices have been deduced. A **substitution**

matrix describes a scoring system for the replacement of any amino acid with each of the other 19 amino acids. In these matrices, a large positive score corresponds to a substitution that occurs relatively frequently, whereas a large negative score corresponds to a substitution that occurs only rarely.

One commonly used substitution matrix, the Blosum-62 (for Blocks of amino acid substitution matrix), is illustrated in **Figure 10.7**. In this depiction, each column in this matrix represents 1 of the 20 amino acids, whereas the position of the single-letter codes within each column specifies the score for the corresponding substitution. Notice that scores corresponding to identity (the boxed codes at the top of each column) are not the same for each residue, owing to the fact that less frequently occurring amino acids such as cysteine (C) and tryptophan (W) will align by chance less often than the more common residues. Furthermore, structurally conservative substitutions such as lysine (K) for arginine (R) and isoleucine (I) for valine (V) have relatively high scores, whereas nonconservative substitutions such as lysine for tryptophan result in negative scores (**Figure 10.8**).

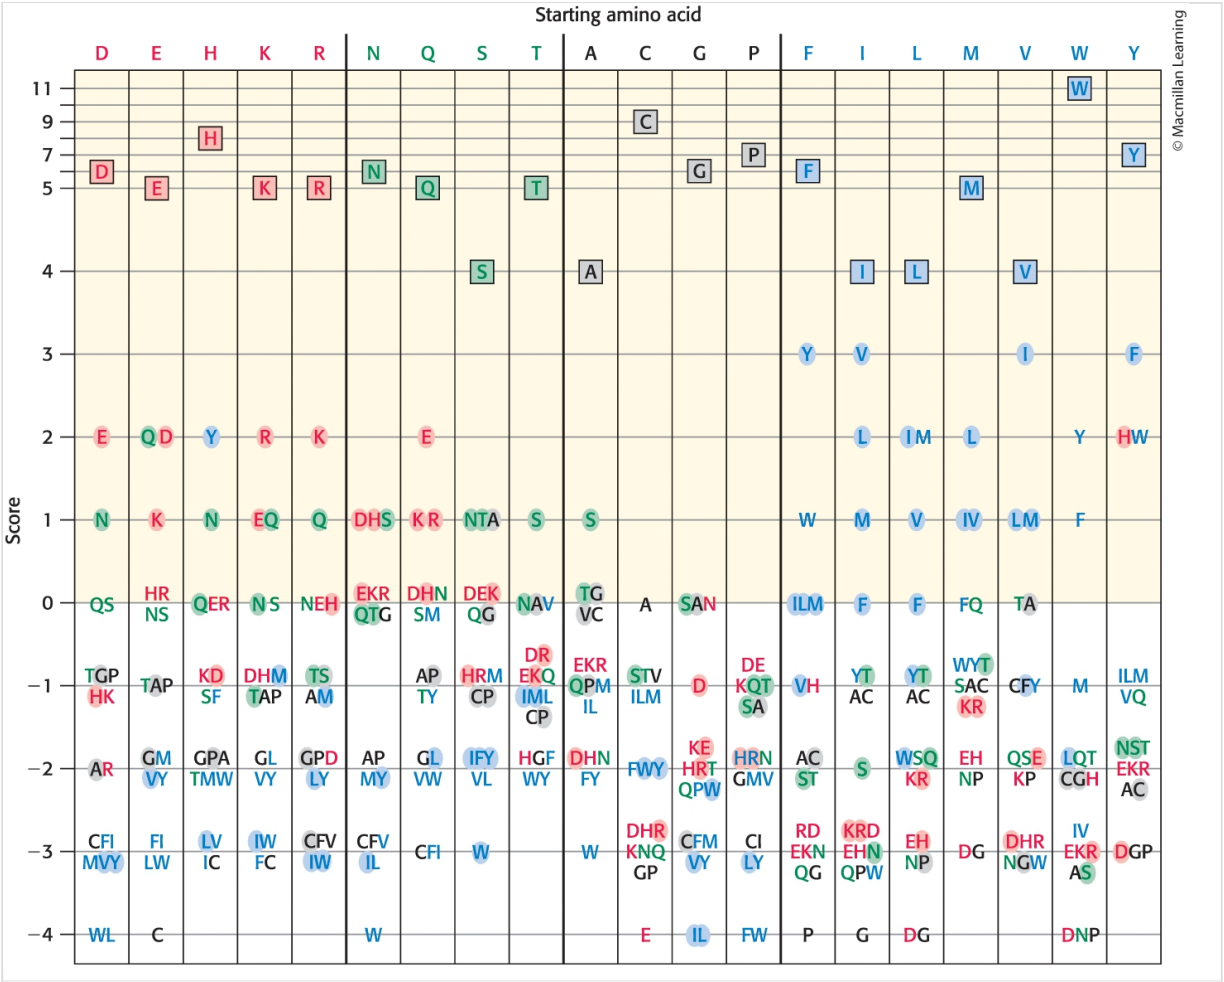

FIGURE 10.7 The Blosum-62 substitution matrix enables scoring based on amino acid similarity. This matrix was derived by examining substitutions within aligned sequence blocks in related proteins. In this graphical view, amino acids are classified into four groups (charged, red; polar, green; large and hydrophobic, blue; other, black). Substitutions that require the change of only a single nucleotide are shaded. Identities are boxed. To find the score for a substitution of, for instance, a Y for an H, you find the Y in the column having H at the top and check the number at the left. In this case, the resulting score is 2.

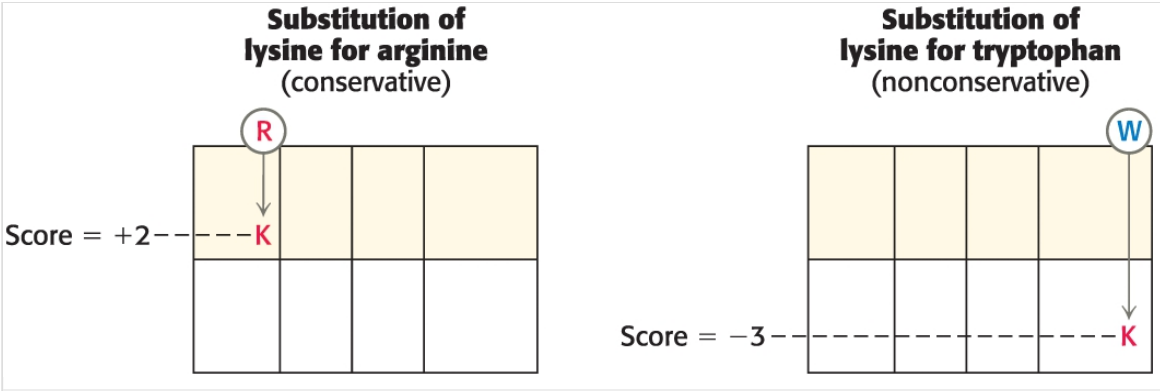

FIGURE 10.8 Conservative and nonconservative substitutions yield very different scores in th Blosum-62 matrix. A conservative substitution (lysine for arginine) receives a positive score, whereas a nonconservative substitution (lysine for tryptophan) is scored negatively. The matrix depicted as an abbreviated form of Figure 10.7.

When two sequences are compared, each pair of aligned residues is assigned a score based on the matrix. In addition, gap penalties are often assessed. For example, the introduction of a single-residue gap lowers the alignment score by 12 points, and the extension of an existing gap costs 2 points per residue. With the use of the Blosum-62 scoring system, the alignment between human α-hemoglobin and human myoglobin shown in Figure 10.4 receives a score of 115. In many regions, most substitutions are conservative (defined as those substitutions with scores greater than 0), and relatively few are strongly disfavored (**Figure 10.9**).

FIGURE 10.9 Counting conservative substitutions reveals strong similarity between α-hemoglobin and myoglobin. Conservative substitutions are indicated by yellow shading and

identities by the orange boxes.

This scoring system detects homology between less obviously related sequences with greater sensitivity than would a comparison of identities only. Consider, for example, the protein leghemoglobin, an oxygen-binding protein found in the roots of leguminous plants. The amino acid sequence of leghemoglobin from the lupine plant can be aligned with that of human myoglobin and scored by using either the simple scoring scheme based on identities only or the Blosum-62 (Figure 10.7). Repeated shuffling and scoring provides a distribution of alignment scores, as shown in **Figure 10.10**.

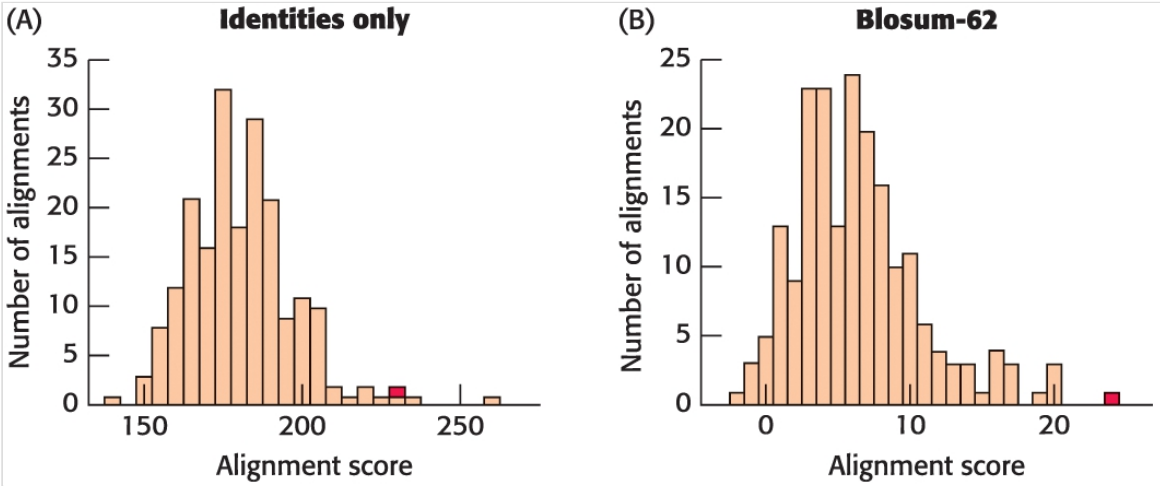

FIGURE 10.10 Alignment using Blosum-62 can uncover more distant evolutionary relationships. Repeated shuffling and scoring reveal the significance of sequence alignment for human myoglobin versus lupine leghemoglobin with the use of either (A) the simple, identity-based scoring system or (B) the Blosum-62. The scores for the alignment of the authentic sequences are shown in red. Accounting for amino acid similarity in addition to identity reveals greater separation between the authentic alignment and the population of shuffled alignments. (Note that these two scoring systems use different scales on their respective *x*-axes, so the raw scores cannot be directly compared.)

Scoring based solely on identities (Figure 10.10A) indicates that the probability of the alignment between myoglobin and leghemoglobin occurring by chance alone is 1 in 20. Thus, although the level of similarity suggests a relationship, there is a 5% chance that the similarity is accidental on the basis of this analysis. In contrast, scoring based on the substitution matrix, which accounts for conservative substitutions, determines that the odds of the alignment occurring by chance are calculated to be approximately 1 in 300 (Figure 10.10B). Thus, an analysis performed with the substitution matrix reaches a much firmer conclusion about the evolutionary relationship between these proteins (**Figure 10.11**).

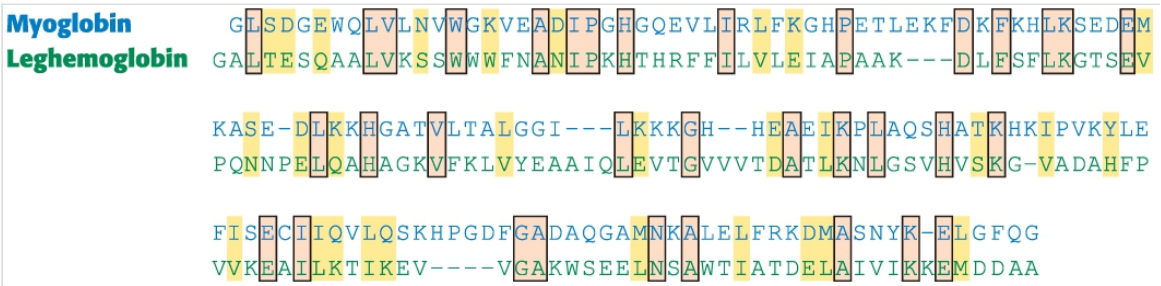

FIGURE 10.11 Alignment of human myoglobin and lupine leghemoglobin reveals many conservative substitutions. The use of Blosum-62 yields the alignment shown between human myoglobin and lupine leghemoglobin, illustrating identities (orange boxes) and conservative substitutions (yellow). These sequences are 23% identical.

Experience with sequence analysis has led to the development of simpler rules of thumb. For sequences longer than 100 amino acids, sequence identities greater than 25% are almost certainly not the result of chance alone; such sequences are probably homologous. In contrast, if two sequences are less than 15% identical, their alignment alone is unlikely to indicate statistically significant similarity. For sequences that are between 15% and 25% identical, further analysis is necessary to determine the statistical significance of the alignment.

It must be emphasized that the lack of a statistically significant degree of sequence similarity does not rule out homology. The sequences of many proteins that have descended from common ancestors have diverged to such an extent that the relationship between the proteins can no longer be detected from their sequences alone. As we will see, such homologous proteins can often be identified by examining their three-dimensional structures.

Databases can be searched to identify homologous sequences

When the sequence of a protein is first determined, comparing it with all previously characterized sequences can provide tremendous insight into its evolutionary relatives and, hence, its structure and function. Indeed, an extensive sequence comparison is almost always the first analysis performed on a newly elucidated sequence. The sequence-alignment methods just described are used to compare an individual sequence with all members of a database of known sequences.

Database searches for homologous sequences are most often accomplished by using resources available on the Internet at the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov). The procedure used is referred to as a **basic local alignment search tool (BLAST) search**. An amino acid sequence is entered into a browser (blast.ncbi.nlm.nih.gov), and a search is performed, most often against a nonredundant database of all known sequences. In 2021, this database included more than 400 million sequences. A BLAST search yields a list of sequence alignments, each accompanied by an estimate giving the likelihood that the alignment occurred by chance (**Figure 10.12**).

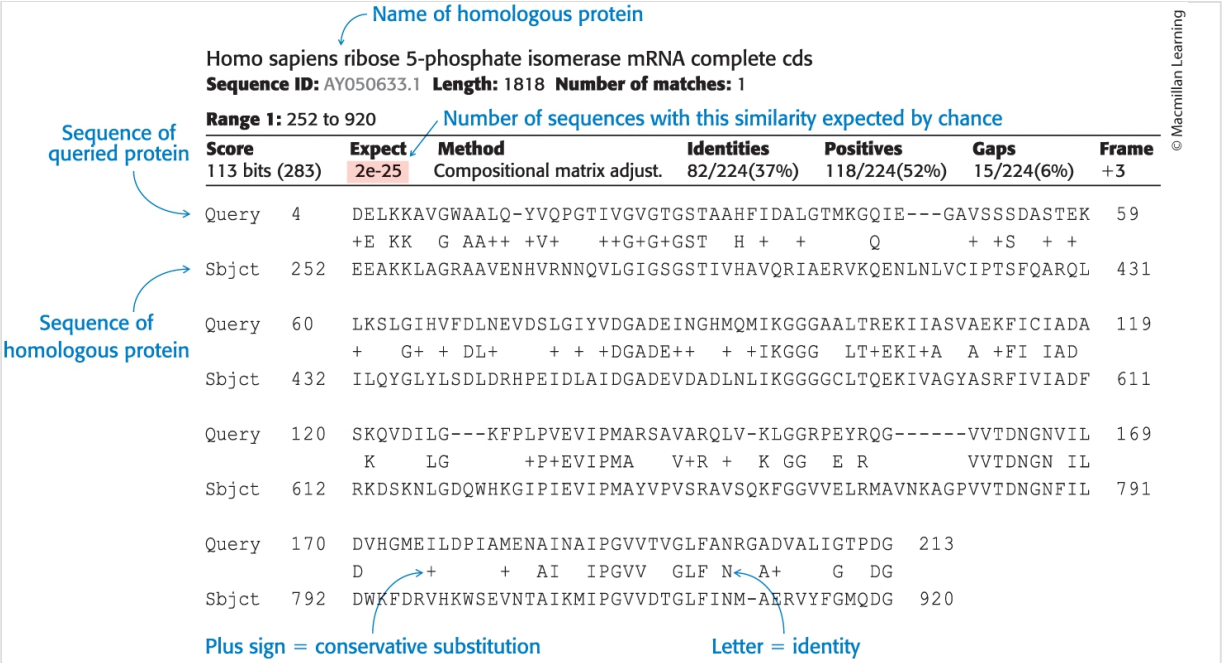

FIGURE 10.12 Related protein sequences can be rapidly identified using online BLAST searches. Part of the results from a BLAST search of the nonredundant (nr) protein sequence database using the sequence of ribose 5-phosphate isomerase (also called phosphopentose isomerase, Chapter 20) from *E. coli* as a query. Among the thousands of sequences found is the orthologous sequence from humans, and the alignment between these sequences is shown. The number of sequences with this level of similarity expected to be in the database by chance is 2×10^{-25} as shown by the E value (highlighted in red). Because this value is much less than 1, we can confidently conclude that the observed sequence alignment is highly significant.

In 1995, investigators reported the first complete sequence of the genome of a free-living organism, the bacterium *Haemophilus influenzae* (Figure 9.25). With the sequences available, they performed a BLAST search with each deduced protein sequence. Of 1743 identified protein-coding regions, also referred to as **open reading frames (ORFs)**, 1007 (58%) could be linked to some protein of known function that had been previously characterized in another organism. An additional 347 ORFs could be linked to sequences in the database for which no function had yet been assigned ("hypothetical proteins"). The remaining 389 sequences did not match any sequence present in the database at that

time. Thus, investigators were able to identify likely functions for more than half the proteins within this organism solely by sequence comparisons.

Self-Check Question

Using the National Center for Biotechnology Information website (www.ncbi.nlm.nih.gov), find the sequences of the enzyme triose phosphate isomerase from *E. coli* strain K-12 and from *Homo sapiens* (use isoform #1). Use the Global Align tool on the NCBI BLAST website to align these two sequences. What is the percent identity between these two proteins?

10.2 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships

Sequence comparison is a powerful tool for extending our knowledge of protein function and kinship. However, biomolecules generally function as intricate three-dimensional structures rather than as linear polymers. Mutations occur at the level of sequence, but the effects of the mutations are at the level of function, and function is directly related to tertiary structure. Consequently, to gain a deeper understanding of evolutionary relationships between proteins, we must examine three-dimensional structures, especially in conjunction with sequence information. The techniques of structural determination were presented in Section 4.5.

Tertiary structure is more conserved than primary structure

Because three-dimensional structure is much more closely associated with function than is sequence, tertiary structure is more evolutionarily conserved than is primary structure. This conservation is apparent in the tertiary structures of the globins (**Figure 10.13**), which are extremely similar even though the similarity between human myoglobin and lupine leghemoglobin is weakly detectable at the sequence level (Figure 10.10) and that between human α-hemoglobin and lupine leghemoglobin is not statistically significant (15% identity). This structural similarity firmly establishes that the framework that binds

the heme group and facilitates the reversible binding of oxygen has been conserved over a long evolutionary period.

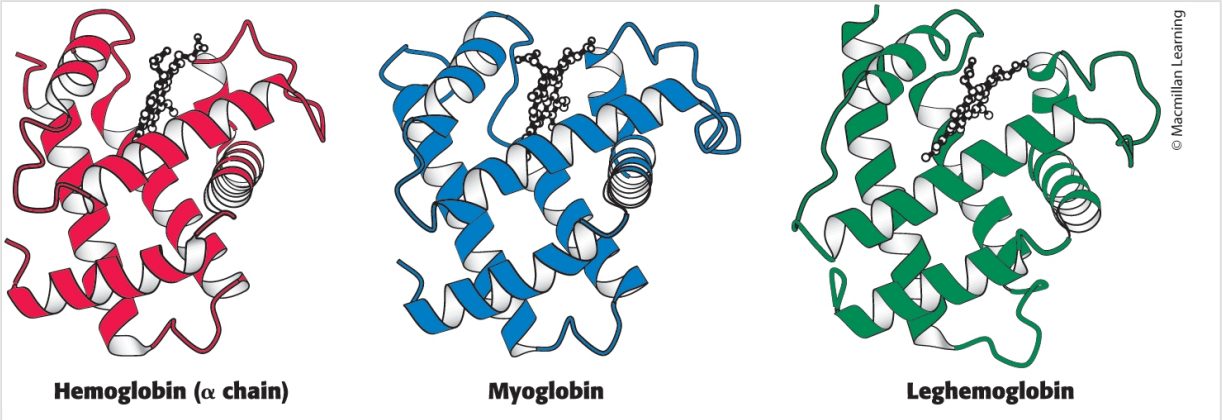

FIGURE 10.13 Three-dimensional structure is more conserved than primary structure. The tertiary structures of human hemoglobin (α chain), human myoglobin, and lupine leghemoglobin are conserved. Each heme group contains an iron atom to which oxygen binds.

[Drawn from 1HBB.pdb, 1MBD.pdb, and 1GDJ.pdb.]

INTERACT with these models in Achieve

Anyone aware of the similar biochemical functions of hemoglobin, myoglobin, and leghemoglobin could expect the structural similarities. In a growing number of other cases, however, a comparison of three-dimensional structures has revealed striking similarities between proteins that were *not* expected to be related, on the basis of their diverse functions. A case in point is the protein actin, a major component of the cytoskeleton (Section 6.5) and heat shock protein 70 (Hsp70), which assists protein folding inside cells. These two proteins were found to be noticeably similar in structure despite only 16% sequence identity (**Figure 10.14**). On the basis of their three-dimensional structures, actin and Hsp70 are paralogs. The level of structural similarity strongly suggests that, despite their different biological roles in modern organisms, these proteins descended from a common ancestor.

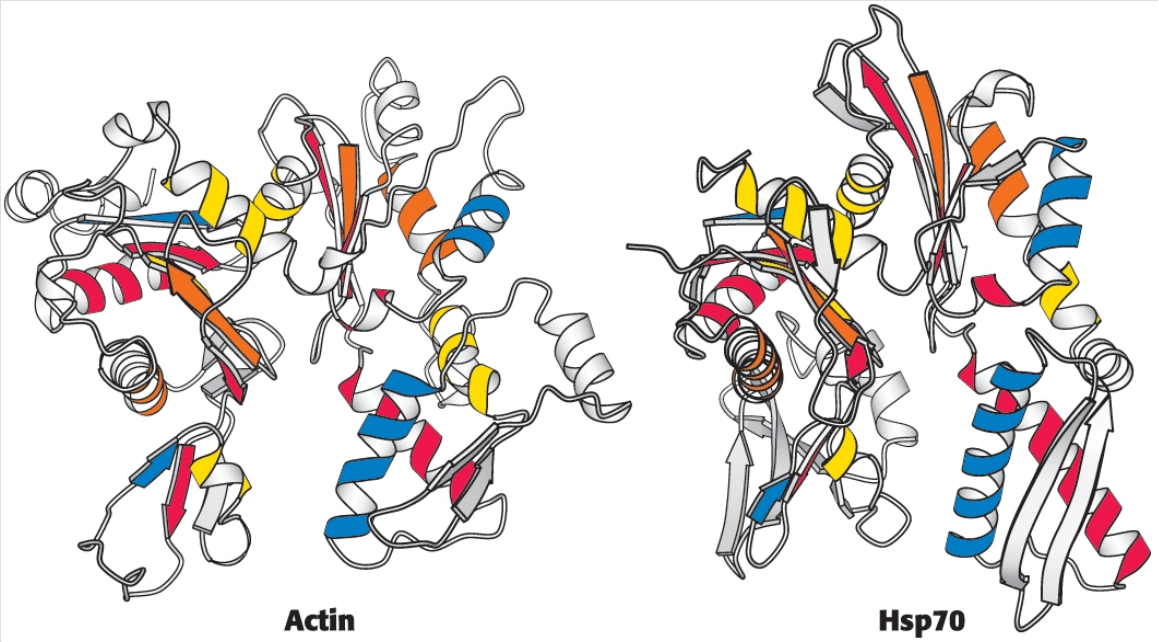

FIGURE 10.14 The structures of actin and a large fragment of heat shock protein 70 (Hsp70) reveal an unexpected relationship. A comparison of the identically colored elements of secondary structure reveals the overall similarity in structure despite the difference in biochemical activities.

[Drawn from 1ATN.pdb and 1ATR.pdb.]

INTERACT with these models in Achieve

As the three-dimensional structures of more proteins are determined, such unexpected kinships are being discovered with increasing frequency. The search for such kinships relies ever more frequently on computer-based searches that are able to compare the three-dimensional structure of any protein with all other known structures.

Knowledge of three-dimensional structures can aid in the evaluation of sequence

alignments

The sequence-comparison methods described thus far treat all positions within a sequence equally. However, we have learned from examining families of homologous proteins for which at least one three-dimensional structure is known that regions and residues critical to protein function are more strongly conserved than are other residues. For example, each type of globin contains a bound heme group with an iron atom at its center. A histidine residue that interacts directly with this iron atom (Section 3.2) is conserved in all globins.

After we have identified key residues or highly conserved sequences within a family of proteins, we can generate a **sequence template** — a map of conserved residues that are structurally and functionally important and are characteristic of particular families of proteins. By preferentially scoring residues known to be important for structure or function, we can sometimes identify other family members even when the overall level of sequence similarity is below statistical significance and might be undetectable by other means.

Still other methods are able to identify conserved residues within a family of homologous proteins, even without a known three-dimensional structure. These methods often use substitution matrices that differ at each position within a family of aligned sequences. Such methods can often detect quite distant evolutionary relationships.

Repeated motifs can be detected by aligning sequences with themselves

As discussed in Section 2.5, domains are compact regions of structure that can be found in a wide variety of proteins. In fact, more than 10% of all proteins contain sets of two or more domains that are similar to

one another. Sequence search methods can often detect these internally repeated sequences that have been characterized in other proteins.

Often, however, internally repeated sequences do not correspond to previously identified domains. In these cases, their presence can be detected by attempting to align a given sequence with itself. The statistical significance of such repeats can be tested by aligning the regions in question as if these regions were sequences from separate proteins. Of course, in a self-alignment, there will be one "hit" that will yield a perfect score. However, additional regions where internal alignment achieves significance may indicate the presence of repeated domains within a given protein.

Consider, for example, the TATA-box-binding protein, a key protein in controlling eukaryotic gene transcription (Section 29.3). Alignment of this protein with itself reveals a significant region of homology between the N-terminal half of the protein with its C-terminal half (**Figure 10.15A**). Comparison of two 65-residue segments from these regions reveals that 40% of the amino acids are identical (**Figure 10.15B**). The estimated probability of such an alignment occurring by chance is less than 1 in 10^{10}. The determination of the three-dimensional structure of the TATA-box-binding protein confirmed the presence of repeated structures; the protein is formed of two nearly identical domains (**Figure 10.15C**). The evidence is convincing that the gene encoding this protein evolved by duplication of a gene encoding a single domain.

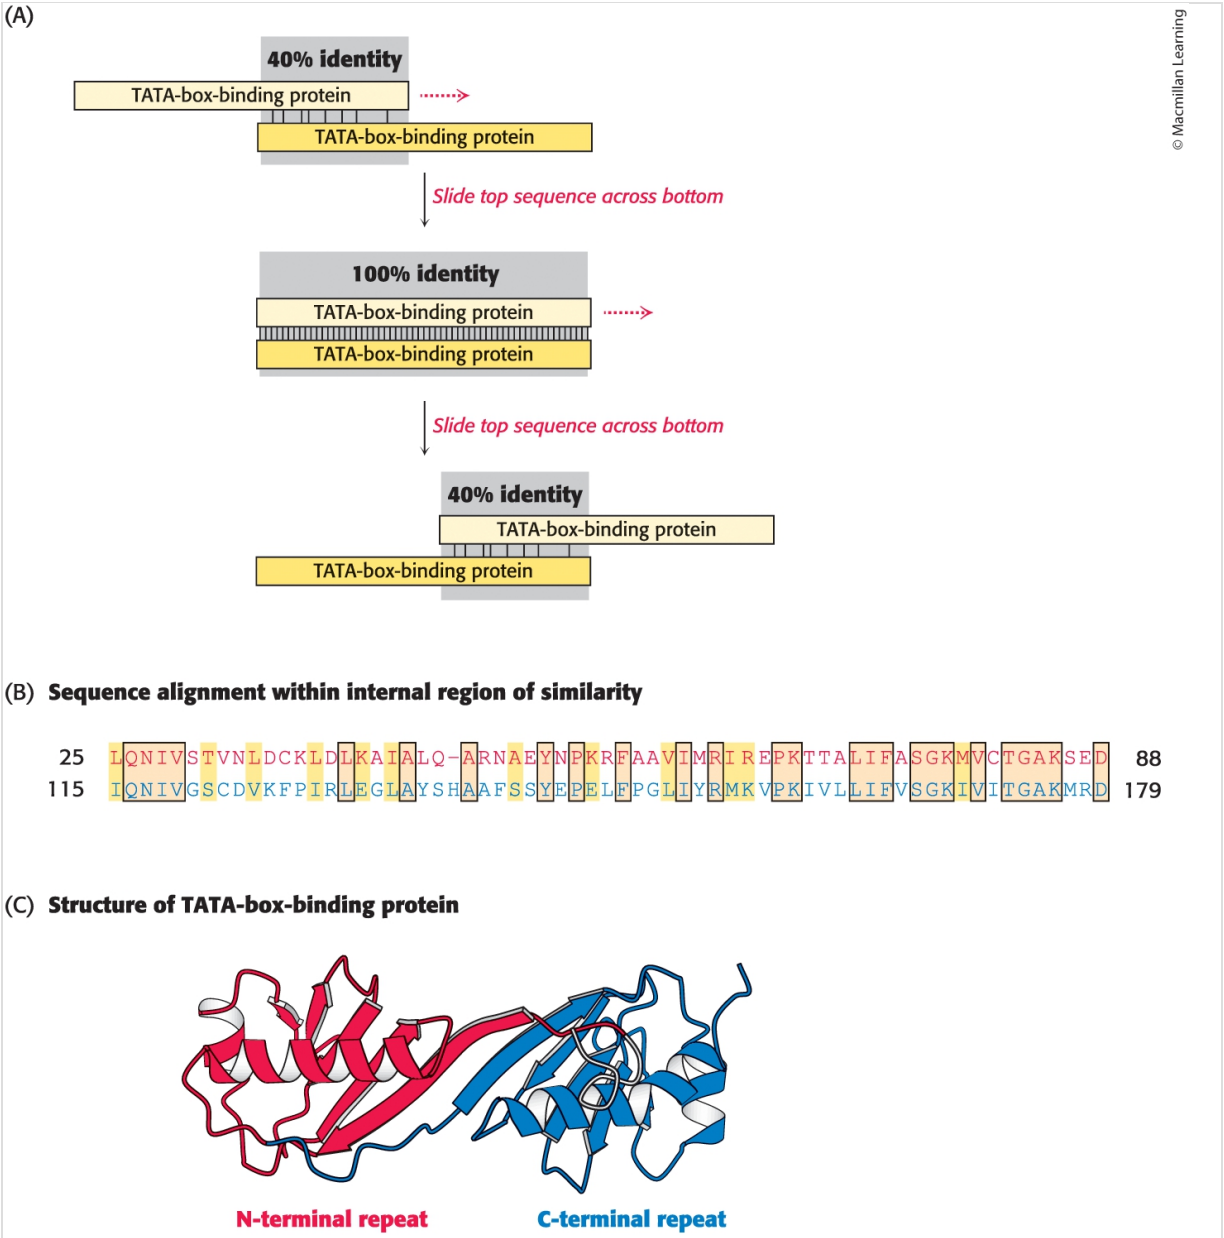

FIGURE 10.15 Internal repeats can be identified using a self-alignment. (A) When the TATA-box-binding protein is aligned against itself, a region of significant identity between the N-terminal and C-terminal halves is revealed. (B) Alignment of these N-terminal and C-terminal sequences shows 40% identity and considerable similarity. The N-terminal region is shown in red and the C-terminal region in blue. (C) Consistent with the sequence alignment data, the three-dimensional structure of the TATA-box-binding protein reveals the presence of two structurally similar repeats. The N-terminal domain is shown in red and the C-terminal domain in blue.

INTERACT with this model in Achieve

Convergent evolution illustrates common solutions to biochemical challenges

Thus far, we have been using sequence analysis methods to identify occurrences of **divergent evolution**, the process by which proteins derived from a common ancestor accumulate differences over time, potentially acquiring new functions. In other examples, proteins have been identified that are structurally similar in important ways but are not descended from a common ancestor. How might two unrelated proteins come to resemble each other structurally? Two proteins evolving independently may have converged on similar structural features to perform a similar biochemical activity. Perhaps that structure was an especially effective solution to a biochemical problem. The process by which very different evolutionary pathways lead to the same solution is called **convergent evolution**.

An example of convergent evolution is found among the serine proteases. Recall that these enzymes cleave peptide bonds by hydrolysis (Section 6.2). The active sites for two such enzymes, mammalian chymotrypsin and bacterial subtilisin, are remarkably similar (**Figure 10.16, top**). In each case, the catalytic triad of a serine residue, a histidine residue, and an aspartate residue is positioned in space in nearly identical arrangements. This conserved spatial arrangement is critical for the activity of these enzymes and affords the same mechanistic solution to the problem of peptide bond hydrolysis.

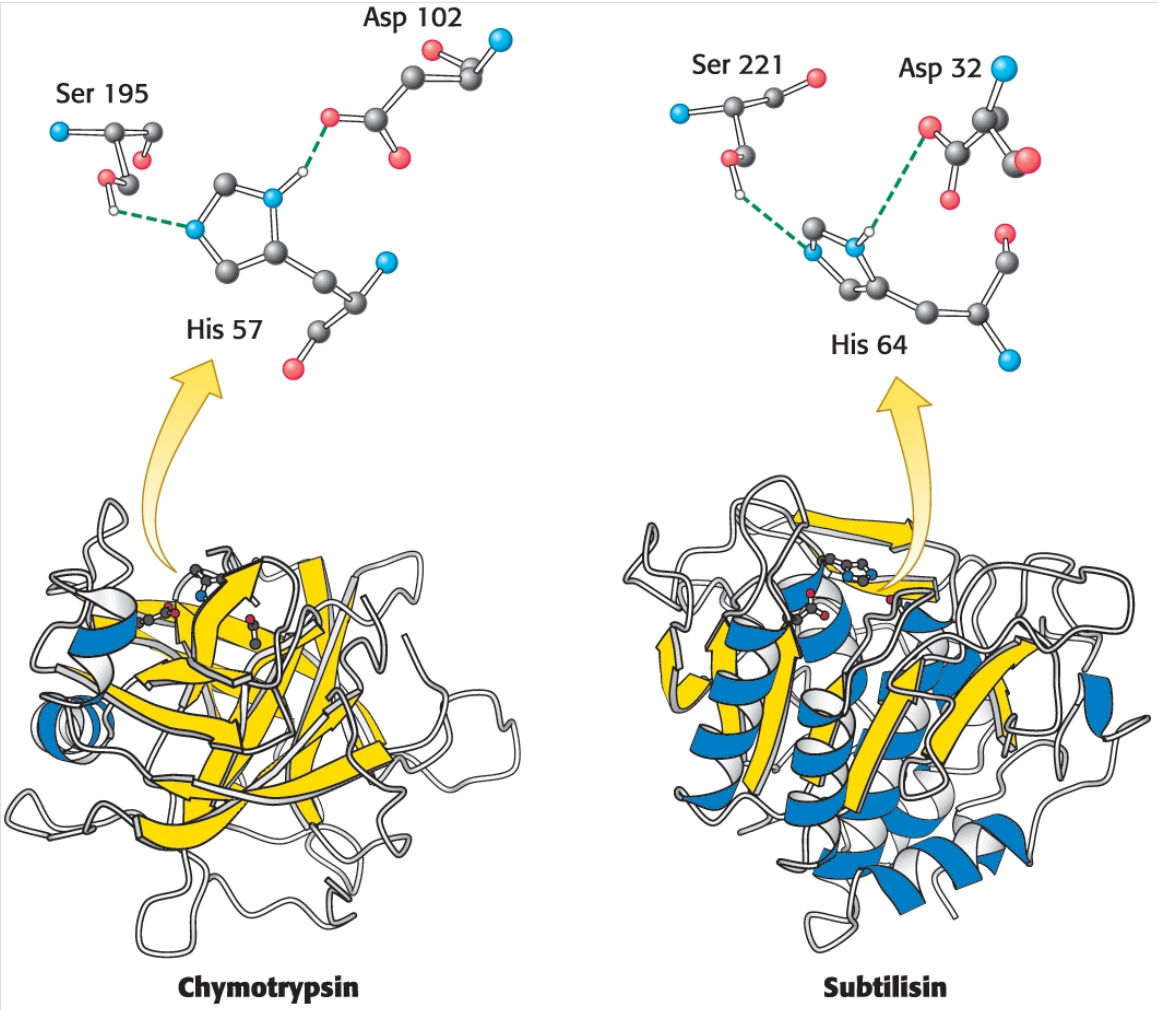

FIGURE 10.16 Mammalian chymotrypsin and bacterial subtilisin are examples of convergent evolution. The relative positions of the three key catalytic residues are nearly identical in the active sites of the serine proteases chymotrypsin and subtilisin. Yet, the overall protein structur are quite dissimilar, suggesting that although these proteins derived from different ancestors, they arrived at a similar solution to the challenge of peptide bond hydrolysis.

[Drawn from 1GCT.pdb and 1SUP.pdb.]

INTERACT with these models in Achieve

At first glance, this similarity between chymotrypsin and subtilisin might suggest that these proteins are homologous. However, striking differences in the overall structures of these proteins make an

evolutionary relationship extremely unlikely (**Figure 10.16, bottom**). Whereas chymotrypsin consists almost entirely of β sheets, subtilisin contains extensive α-helical structure. Moreover, the key serine, histidine, and aspartic acid residues do not even appear in the same order within the two sequences. It is extremely unlikely that two proteins evolving from a common ancestor could have retained similar active-site structures while other aspects of the structure changed so dramatically.

Comparison of RNA sequences can be a source of insight into RNA secondary structures

The methods and interpretation of sequence alignments described above are not limited to proteins. Homologous RNA sequences can also be similarly studied, yielding important insights into evolutionary relationships. Additionally, these analyses provide clues to the three-dimensional structure of the RNA itself. As noted in Chapter 8, single-stranded nucleic acid molecules fold back on themselves to form elaborate structures held together by Watson–Crick base-pairing and other noncovalent interactions. In a family of sequences that form similar base-paired structures, base sequences may vary, but base-pairing ability is conserved.

Consider, for example, a region from a large RNA molecule present in the ribosomes of all organisms (**Figure 10.17**). In the region shown, the *E. coli* sequence has a guanine (G) residue in position 9 and a cytosine (C) residue in position 22, whereas the human sequence has uracil (U) in position 9 and adenine (A) in position 22. Examination of the six sequences shown in Figure 10.17A reveals that the bases in positions 9 and 22, as well as several of the neighboring positions, retain the ability to form Watson–Crick base pairs even though the identities of the bases

in these positions vary. We can deduce that two segments with paired mutations that maintain base-pairing ability are likely to form a double helix (Figure 10.17B), a prediction that was confirmed when the three-dimensional structure of this particular rRNA was determined (Section 30.3). Where sequences are known for several homologous RNA molecules, this type of sequence analysis can often suggest complete secondary structures as well as interactions that do not follow the standard Watson–Crick base-pairing rules (Section 8.2).

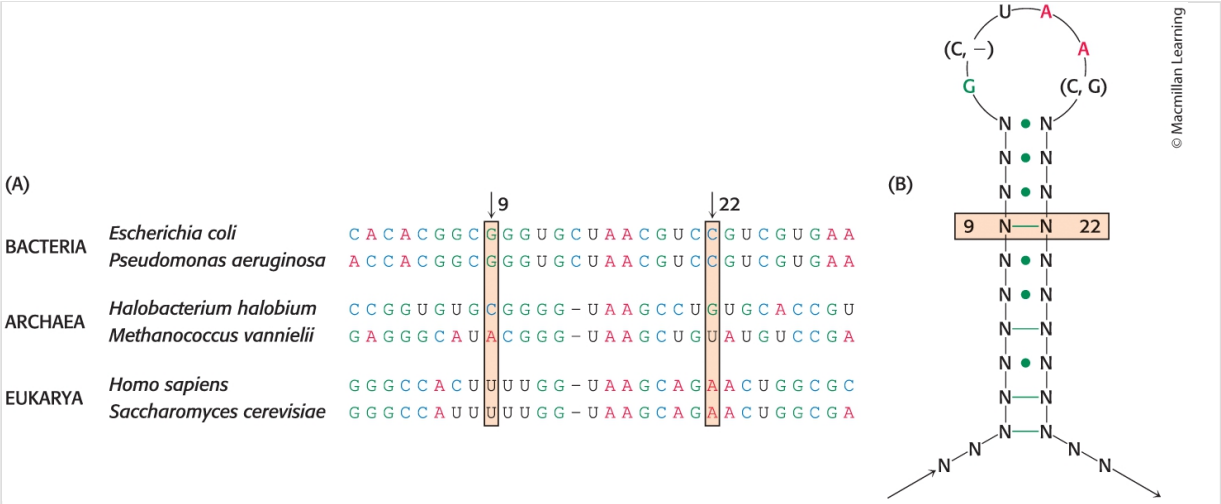

FIGURE 10.17 RNA sequence alignments provide insights into structure based on conservation of base-pairing. (A) A comparison of sequences in a part of ribosomal RNA taken from a variety of species. (B) The implied secondary structure. Green lines indicate positions at which Watson–Crick base-pairing is completely conserved in the sequences shown, whereas dots indicate positions at which Watson–Crick base-pairing is conserved in most cases.

Self-Check Question

When RNA alignments are used to determine secondary structure, it is advantageous to have many sequences representing a wide variety of species. Why?

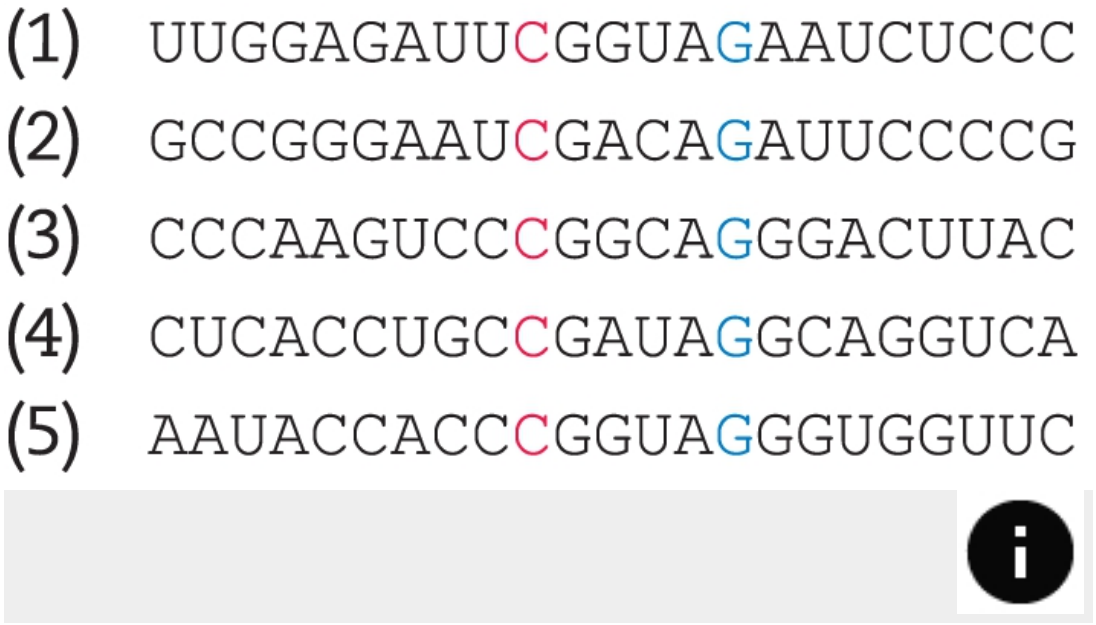
Example

Interpreting an RNA Alignment

Problem:

Sequences of an RNA fragment from five species have been determined and aligned. Propose a likely secondary structure for these fragments:

(1) UUGGAGAUUCGGUAGAAUCUCCC
(2) GCCGGGAAUCGACAGAUUCCCCG
(3) CCCAAGUCCCGGCAGGGACUUAC
(4) CUCACCUGCCGAUAGGCAGGUCA
(5) AAUACCACCCGGUAGGGUGGUUC

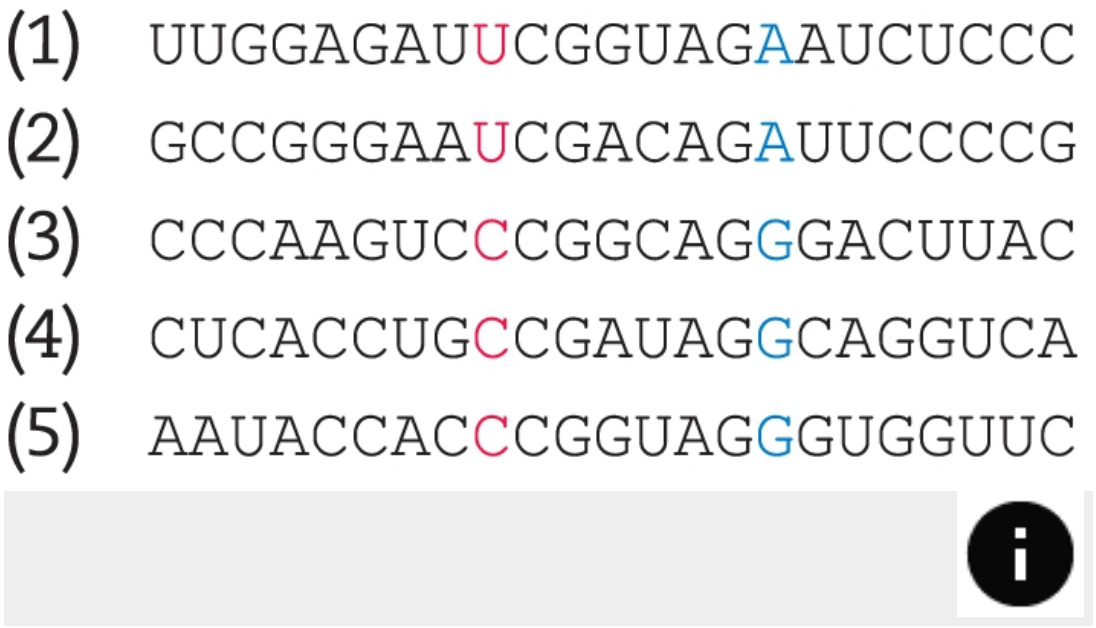


Getting Started:

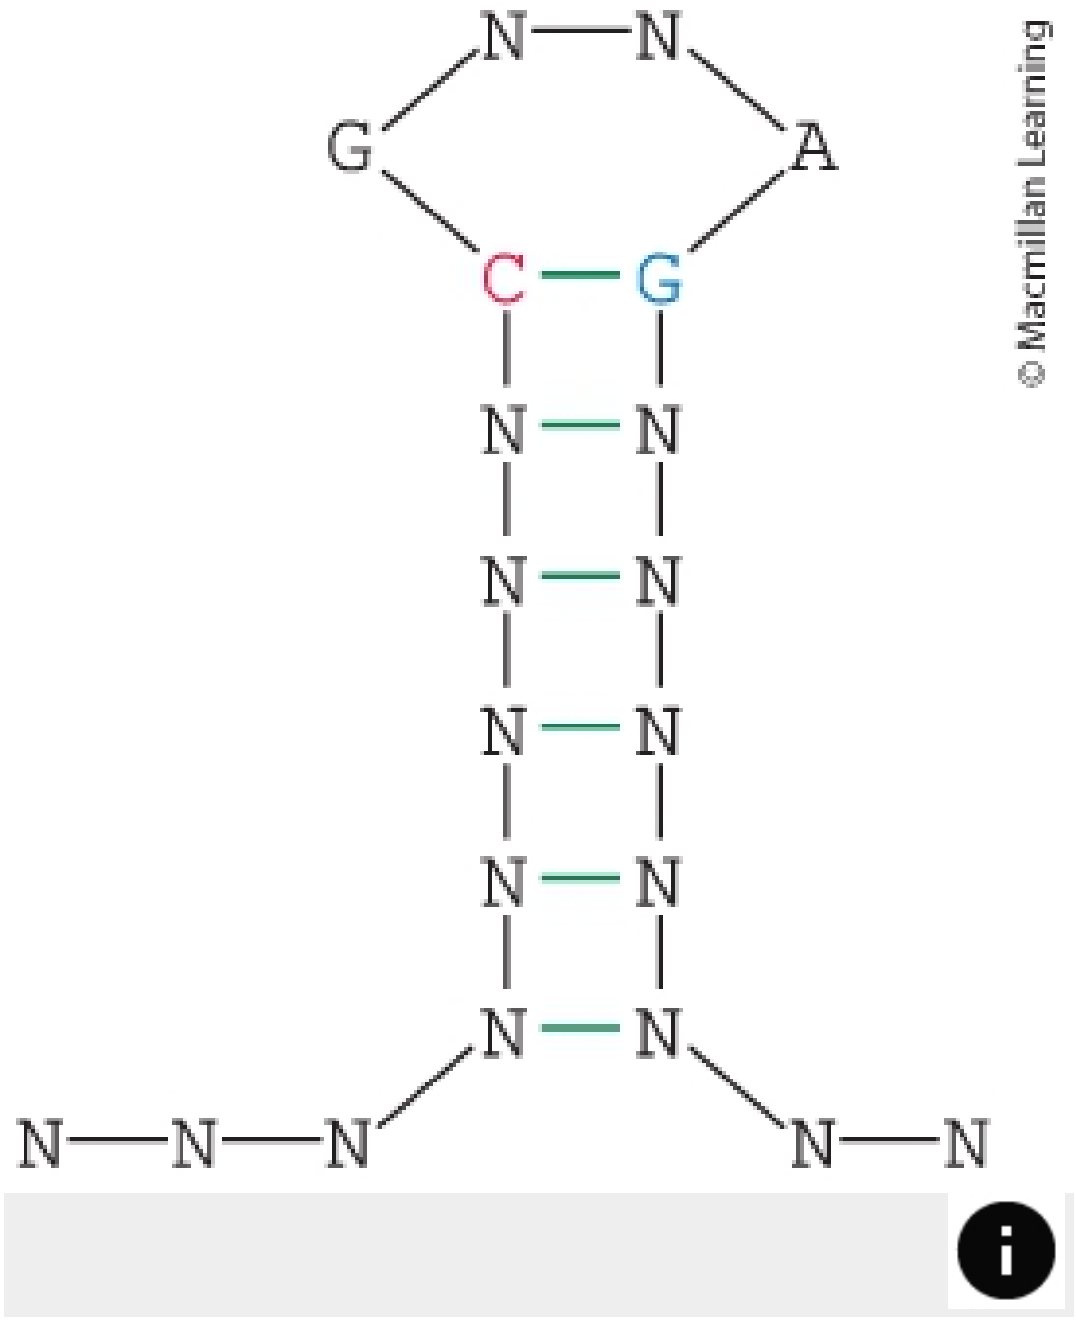
For a simple alignment over a short RNA fragment such as the one featured in this problem, the trick is to look for two positions that could form a base pair in each of the aligned sequences. If the possibility of a

base pair is conserved through all the sequences, then it is likely that this pairing is a component of the predicted secondary structure.

Of particular interest in this alignment is the base highlighted in red:



In all five sequences, this is an absolutely conserved cytosine. In this alignment, there are only two absolutely conserved guanine bases. One is immediately 3′ to this cytosine, and we know from oligonucleotide



structure that a base pair between adjacent positions is highly unlikely. The other is the guanine highlighted in blue, which is separated from the cytosine by four nucleotides. An intriguing possibility!

SOLVE:

Now, we have an “anchor” from which we can continue looking for additional pairings. In order for this red–blue pairing to form, the RNA fragment would need to fold on itself. Hence, we should look outward from this pair to identify additional base pairs:

Again, we have a conserved pairing. In sequences (1) and (2), the red and blue positions feature a U–A pair, while in sequences (3), (4), and (5), these positions form a C–G pair. If we continue to "walk" along the sequence in this manner, a clear stretch of base-pairing emerges. Moreover, since several of these positions are absolutely conserved, we can include them in our proposed structure (shown at right, with the original C–G base pair in red/blue).

Reflect:

Determining secondary structure predictions from oligonucleotide sequences can appear difficult at first. There are only four possible bases, so patterns may not be easily discernible. The key strategy is to look for potential base pairs and work one's way in either direction from

that point. For structure-forming base pairs, while the identities of the bases may not be conserved across the sequence alignments, the possibility of forming a base pair will be absolutely conserved.

10.3 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information

We have discussed previously how measurement of sequence similarity can provide us with information about the evolutionary relationship between two proteins. This concept suggests that by comparing multiple sequences within a protein family, we can deduce their evolutionary history. As we introduced in Section 1.4, this approach is based on the *molecular clock hypothesis*: the notion that sequences that are more similar to one another have had less evolutionary time to diverge than have sequences that are less similar.

This method can be illustrated by using the three globin sequences in Figures 10.9 and 10.11, as well as the sequence for the human hemoglobin β chain. These sequences can be aligned with the additional constraint that gaps, if present, should be at the same positions in all of the proteins. These aligned sequences can be used to construct an **evolutionary tree** in which the length of the branch connecting each pair of proteins is proportional to the number of amino acid differences between the sequences (**Figure 10.18**).

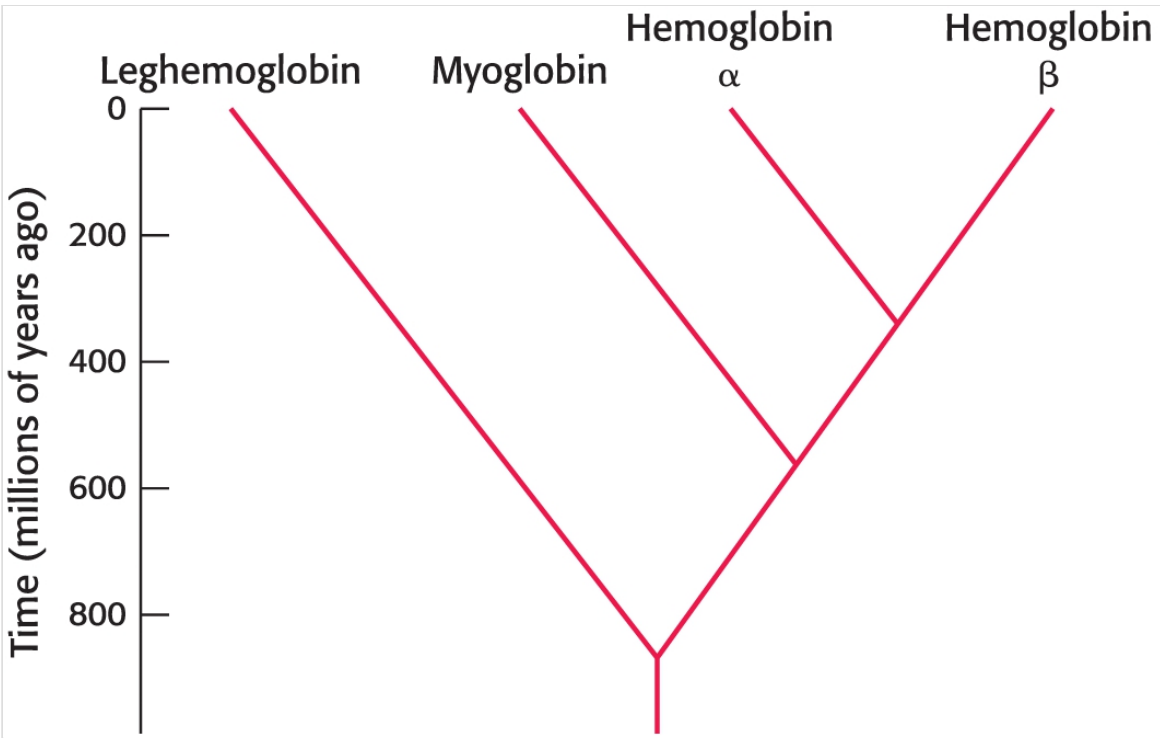


FIGURE 10.18 Sequence alignments enable the construction of an evolutionary tree. In the case of the globins, the branching structure was deduced by sequence comparison, whereas th results of fossil studies provided the overall time scale showing when divergence occurred.

Evolutionary trees can be calibrated using fossil record data

Such comparisons reveal only the relative divergence times — for example, that myoglobin diverged from hemoglobin twice as long ago as the α chain diverged from the β chain. How can we estimate the approximate dates of gene duplications and other evolutionary events? Evolutionary trees can be calibrated by comparing the deduced branch points with divergence times determined from the fossil record. For example, the duplication leading to the two chains of hemoglobin appears to have occurred 350 million years ago. This estimate is supported by the fossil records on the divergence of jawless fish from

bony fish. Jawless fish, such as the lamprey (**Figure 10.19**), contain hemoglobin built from a single subunit. If the fossil record and our globin evolutionary trees are in agreement, jawless fish should have diverged from bony fish at roughly the same time. This is, in fact, the case, as the fossil record suggests this point of divergence was approximately 400 million years ago.

A Hartl/AGE Fotostock

FIGURE 10.19 The lamprey is a jawless fish whose ancestors diverged from bony fishes approximately 400 million years ago. Lamprey hemoglobin molecules contain only a single type of polypeptide chain.

These methods can be applied to both relatively modern and very ancient molecules, such as the ribosomal RNAs that are found in all organisms. Indeed, such an RNA sequence analysis led to the realization that Archaea are a distinct group of organisms that diverged from Bacteria very early in evolutionary history (Figure 1.3).

Russell F. Doolittle, UCSD Chemistry Dept., July 6, 1988, SIO Photographic Laboratory records. SAC 0044. Special Collections & Archives, UC San Diego. https://library.ucsd.edu/dc/object/bb3038569z

RUSSELL DOOLITTLE A pioneer in bioinformatics and the study of molecular evolution, Russell Doolittle compared the sequences of fibrinopeptides (Section 7.5) across animal species and described how this information could illuminate evolutionary relationships during his postdoctoral fellowship in Sweden. Then, as a faculty member at the University of California, San Diego, Doolittle collected blood samples from a variety of mammals at the San Diego Zoo and constructed a detailed evolutionary tree from their fibrinopeptide sequences. Additionally, well before the existence of online sequence databases, Prof. Doolittle established a compendium of known amino acid sequences, single-handedly compiling sequence data from the scientific literature. With his colleagues, he was able to search this information, perform sequence alignments, and construct phylogenetic trees. Prof. Doolittle made numerous additional seminal contributions throughout his career, including the

assessment of sequences for their hydrophobic character (the hydropathy plot, Section 12.4).

Horizontal gene transfer events may explain unexpected branches of the evolutionary tree

Evolutionary trees that encompass orthologs of a particular protein across a range of species can lead to unexpected findings. Consider the unicellular red alga *Galdieria sulphuraria*, a remarkable eukaryote that can thrive in extreme environments, including at temperatures up to 56°C, at pH values between 0 and 4, and in the presence of high concentrations of toxic metals (**Figure 10.20**). *G. sulphuraria* belongs to the order Cyanidiales, clearly within the eukaryotic branch of the evolutionary tree (**Figure 10.21A**). However, the complete genome sequence of this organism revealed that nearly 5% of the *G. sulphuraria* ORFs encode proteins that are more closely related to bacterial or archaeal, not eukaryotic, orthologs. Furthermore, the proteins that exhibited these unexpected evolutionary relationships possess functions that are likely to confer a survival advantage in extreme environments, such as the removal of metal ions from inside the cell (**Figure 10.21B**).

FIGURE 10.20 The unicellular red alga *Galdieria sulphuraria* is a eukaryote that can survive extreme environments. This species has been isolated from hot springs such as the Grand Prismatic Spring in Yellowstone National Park, pictured here.

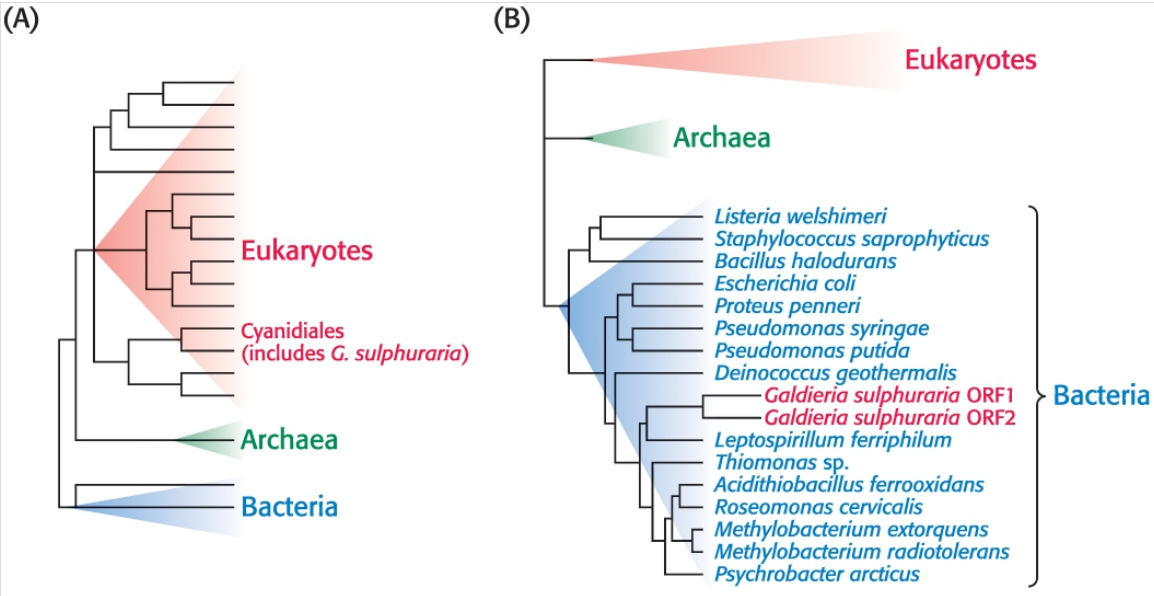

FIGURE 10.21 Proteins encoded within the *G. sulphuraria* genome with high homology to prokaryotic sequences are suggestive of horizontal gene transfer. (A) *Galdieria sulphuraria* belongs to the order Cyanidiales, clearly within the eukaryotic branch of the evolutionary tree. (B) Within the completely sequenced *G. sulphuraria* genome, two ORFs encode proteins involve in transport of arsenate ions across membranes. Alignment of these ORFs against orthologs fro

a variety of species reveals that these pumps are most closely related to their bacterial counterparts, suggesting that a horizontal gene transfer event occurred during the evolution of this species.

[(A) Information from Dr. Gerald Schönknecht; (B) Information from G. Schönknecht et al., *Science* 339:1207–1210, 2013, Fig. 3.]

One likely explanation for these observations is **horizontal gene transfer**, or the exchange of DNA between species that provides a selective advantage to the recipient. Amongst prokaryotes, horizontal gene transfer is a well-characterized and important evolutionary mechanism. For example, exchange of plasmid DNA between bacterial species likely enabled the transfer of genes encoding restriction endonucleases between bacterial species (Section 6.3). For example, EcoRI (from *E. coli*) and RsrI (from *Rhodobacter sphaeroides*) are 50% identical in sequence over 266 amino acids, clearly indicating a close evolutionary relationship. However, these species of bacteria are not as closely related. These species appear to have obtained the gene for these restriction endonucleases from a common source more recently than the time of their evolutionary divergence.

Recent studies such as those on *G. sulphuraria* described above were made possible by the expansive growth of complete genome sequence information. The results of such studies suggest that horizontal gene transfer from prokaryotes to eukaryotes — that is, between different domains of life — may also have led to evolutionarily significant events.

10.4 Modern Techniques Make the Experimental Exploration of Evolution Possible

Two techniques of biochemistry have made it possible to examine the course of evolution directly and not simply by inference. (1) The polymerase chain reaction (Section 9.1) allows the direct amplification and examination of ancient DNA sequences. If DNA samples can be obtained from preserved remains, we can explore genomes from species that are no longer living. (2) Molecular evolution may also be investigated through the process of synthesizing highly diverse populations of molecules and selecting for a biochemical property. The combination of these two techniques provides a glimpse into the types of molecules that may have existed very early in evolution.

Ancient DNA can sometimes be amplified and sequenced

The tremendous chemical stability of DNA makes the molecule well-suited to its role as the storage site of genetic information. So stable is the molecule that samples of DNA have survived for many thousands of years under appropriate conditions. With the development of PCR and advanced DNA-sequencing methods, such ancient DNA can be amplified and sequenced. This approach was first applied to mitochondrial DNA isolated from a Neanderthal humerus bone estimated at 38,000 years of age. Comparison of the complete Neanderthal mitochondrial sequence with those from human beings (*Homo sapiens*) revealed between 201 and 234 nucleotide substitutions, considerably fewer than the approximately 1500 differences between human beings and chimpanzees over the same region of mitochondrial DNA.

Since the initial sequencing of Neanderthal mitochondrial DNA, the complete genome sequences of a Neanderthal and a closely related hominin known as a Denisovan have been obtained using DNA isolated from nearly 50,000-year-old fossils. Comparison of these sequences suggests that the common ancestor of modern human beings and Neanderthals lived approximately 570,000 years ago, while the common ancestor between Neanderthals and Denisovans lived nearly 380,000 years ago. An evolutionary tree constructed from these data revealed that the Neanderthal was not an intermediate between chimpanzees and human beings but, instead, was an evolutionary "dead end" that became extinct (**Figure 10.22**). Further analysis of these sequences has enabled researchers to determine the extent of interbreeding between these groups, map the geographic history of these populations, and make inferences about additional ancestors whose DNA has not yet been sequenced.

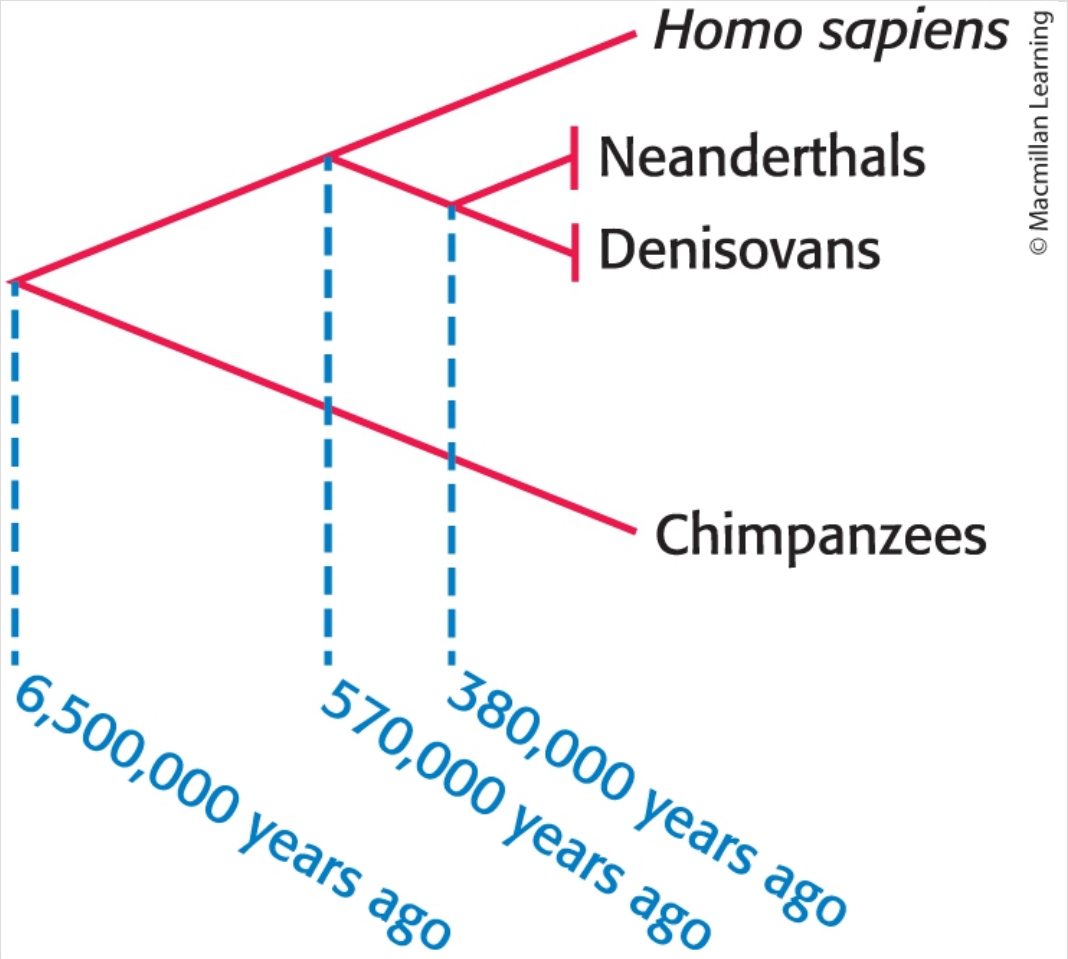

FIGURE 10.22 DNA sequence comparisons enable the placement of Neanderthals and Denisovans on an evolutionary tree. Sequence data suggest that neither Neanderthals nor the Denisovans are on the line of direct descent leading to *Homo sapiens* but, instead, branched off earlier and then became extinct.

A few earlier studies claimed to determine the sequences of far more ancient DNA such as that found in insects trapped in amber, but these studies appear to have been flawed. The source of these sequences turned out to be contaminating modern DNA. Successful sequencing of ancient DNA requires sufficient DNA for reliable amplification and the rigorous exclusion of all sources of contamination.

Molecular evolution can be examined experimentally

For a population to evolve, the following conditions must be met: (1) the generation of a diverse population, (2) the selection of members based on some criterion of fitness, and (3) the reproduction of that population to subsequent generations. This last condition determines, in part, the time under which evolution can occur: organisms with long generation times (such as humans) will evolve much more slowly than those that reproduce rapidly (such as bacteria).

With the advancement of the methods of molecular biology, such as those described in Chapter 9, it is possible to meet these evolutionary conditions using nucleic acid molecules in a controlled experimental setting under convenient time-scales. The results of such studies enable us to glimpse how evolutionary processes might have generated catalytic activities and specific binding abilities — important biochemical functions in all living systems.

Biochemists can synthesize a large, diverse population of nucleic acid molecules in the laboratory using **combinatorial chemistry**, a process by which millions of compounds are synthesized in a single process. A population of molecules of a given size can be generated randomly so that many or all possible sequences are present in the mixture. Once an initial population has been prepared, it is subjected to a selection process that isolates specific molecules with desired binding or reactivity properties. Finally, molecules that have survived the selection process are replicated through the use of PCR; primers are directed toward specific sequences included at the ends of each member of the population. Errors that occur naturally in the course of the replication process introduce additional variation into the population in each generation.

Let us consider an application of this approach. Scientists hypothesize that early in evolution of life, before the emergence of proteins, RNA

molecules may have played all major roles in biological catalysis. To understand the properties of potential RNA catalysts, researchers have used the methods described above to create an RNA molecule capable of binding adenosine triphosphate and related nucleotides.

First, an initial population of RNA molecules 169 nucleotides long was created. In this pool of RNA molecules, 120 of the positions differed randomly, with equimolar mixtures of adenine, cytosine, guanine, and uracil. The initial synthetic pool that was used contained approximately 10^{14} unique RNA molecules — a huge number, but still a very small fraction of the total possible pool of random 120-base sequences. From this pool, affinity chromatography (Section 4.1) was used to select those molecules that bound to ATP (**Figure 10.23**).

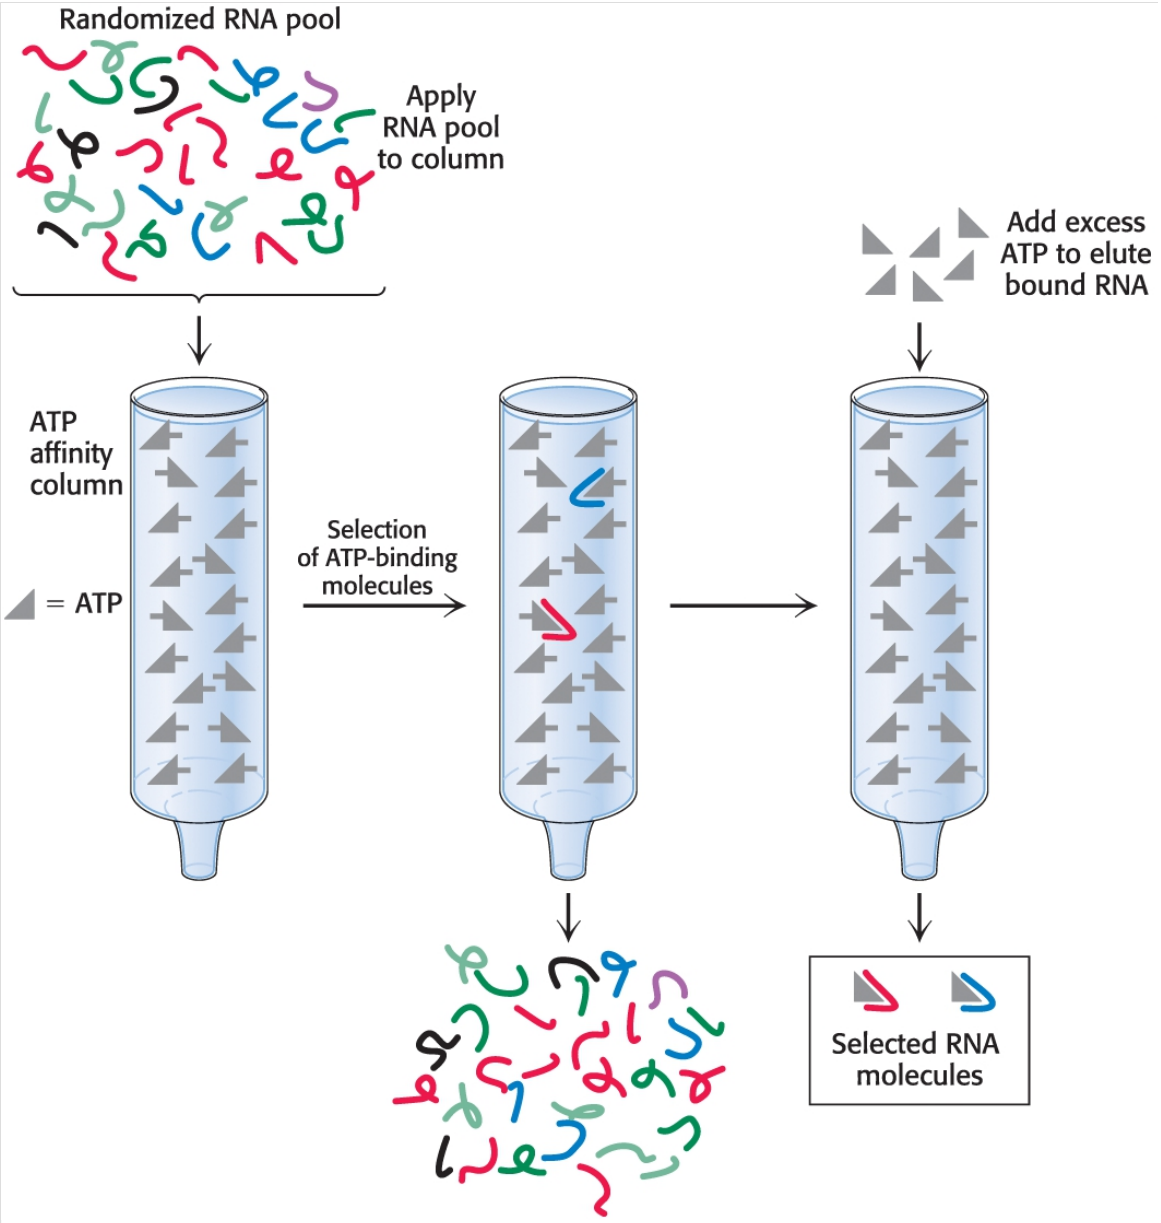

FIGURE 10.23 Evolution can be studied in the laboratory setting. A collection of RNA molecule of random sequences is synthesized by combinatorial chemistry. This collection is selected for the ability to bind ATP by passing the RNA through an ATP affinity column (Section 4.1). The ATP binding RNA molecules are released from the column by washing with excess ATP and then replicated. The process of selection and replication is then repeated several times. The final RN products with significant ATP-binding ability are isolated and characterized.

The molecules that bound well to the ATP affinity column were replicated by reverse transcription into DNA, amplified by PCR, and transcribed back into RNA. Additional diversity was introduced into the pool by the use of a somewhat error-prone reverse transcriptase, which introduces additional mutations into the population during each cycle. The new population was subjected to additional rounds of selection for ATP-binding activity, and after eight generations, members of the selected population were characterized by sequencing. Seventeen different sequences were obtained, 16 of which could form the structure shown in **Figure 10.24**. Each of these molecules bound ATP with dissociation constants less than 50 μM.

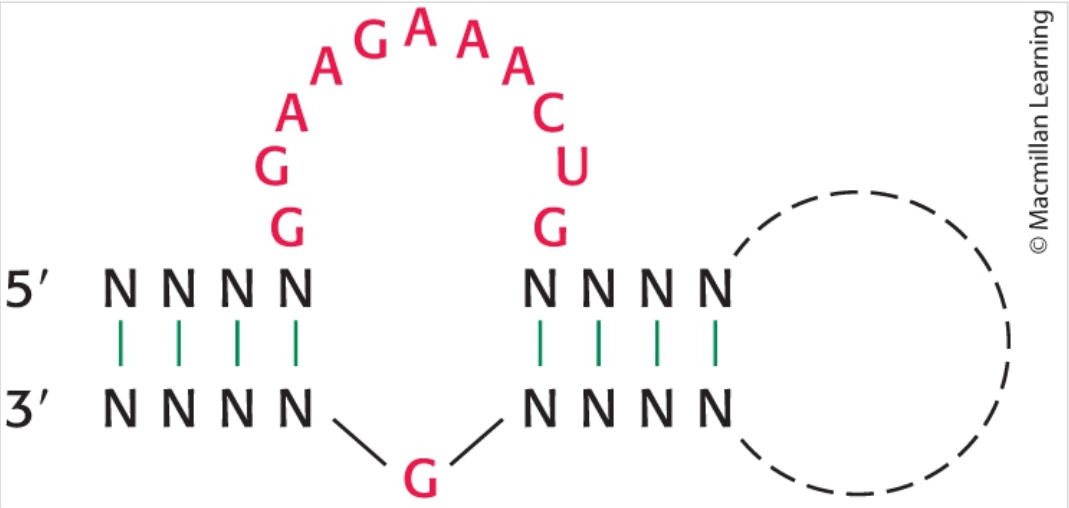

FIGURE 10.24 A conserved secondary structure is common to RNA molecules selected for ATP binding. Bases important for ATP recognition are shown in red. The dashed line indicates a region which varied in length among the various RNA products.

The folded structure of the ATP-binding region from one of these RNAs was determined by nuclear magnetic resonance (NMR) methods (Section 4.5). As expected, this 40-nucleotide molecule is composed of two Watson–Crick base-paired helical regions separated by an 11-nucleotide loop (**Figure 10.25A**). This loop folds back on itself in an

intricate way (Figure 10.25B) to form a deep pocket into which the adenine ring can fit (Figure 10.25C). Thus, a structure had evolved in vitro that was capable of a specific interaction.

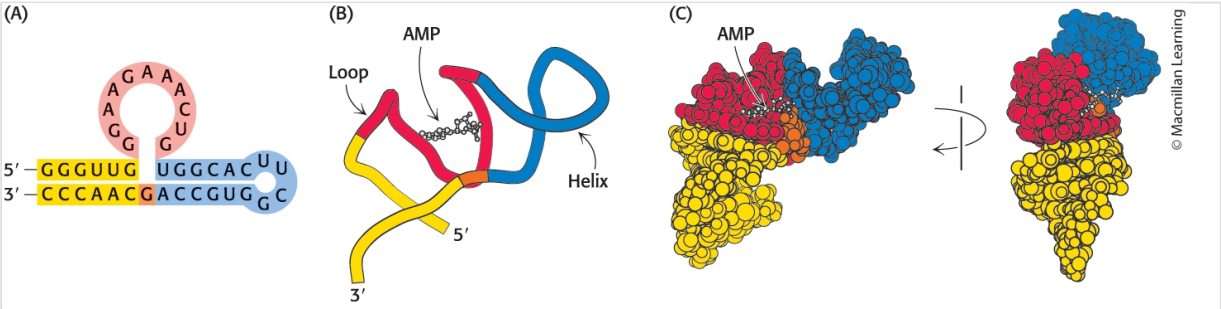

FIGURE 10.25 Experimental molecular evolution yields an ATP-binding RNA molecule. (A) The Watson–Crick base-pairing pattern of an RNA molecule selected to bind adenosine nucleotides is shown. (B) The NMR structure of this RNA molecule reveals how the nucleotide molecule (here, AMP) binds largely to the loop region (red). (C) In this representation, the tight pocket into which the AMP molecule binds is quite clear.

[Drawn from 1RAW.pdb.]

Synthetic oligonucleotides that can specifically bind ligands, such as the ATP-binding RNA molecules described above, are referred to as **aptamers**. In addition to their role in understanding molecular evolution, aptamers have shown promise as versatile tools for biotechnology and medicine. For example, they have been developed for diagnostic applications, serving as sensors for ligands ranging from small organic molecules, such as cocaine, to larger proteins, such as thrombin. Several aptamers are also being tested in clinical trials as therapies for diseases ranging from leukemia to diabetes. Macugen (pegaptanib sodium), an aptamer which binds to and inhibits the protein vascular endothelial growth factor, has been approved for the treatment of age-related macular degeneration.

Chapter 10 Summary

10.1 Homologs Are Descended from a Common Ancestor and Can Be Detected by Sequence Alignments

- Two molecules are homologous if they are derived from a common ancestor.
- Paralogs are homologous molecules that are found in one species and have acquired different functions through evolutionary time.
- Orthologs are homologous molecules that are found in different species and have similar or identical functions.
- Sequences can be aligned to maximize their similarity, and the significance of these alignments can be judged by statistical tests.
- Sequence alignments can be scored based on the number of identities or by the degree of similarity, using a substitution matrix such as Blosum-62.

10.2 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships

- Comparison of three-dimensional structure may reveal evolutionary relationships not detectable by sequence alignments.
- Alignment of a protein sequence against itself may reveal internal repeats, which suggests a gene duplication event occurred in its evolutionary history.
- Proteins may be related by convergent evolution: they evolved from distinct ancestors but use similar structural features to solve biochemical challenges.
- Nucleic acid sequence alignments enable structural predictions through the identification of base-pairing relationships.

10.3 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information

- Evolutionary trees can be constructed with the assumption that the number of sequence differences corresponds to the time since the two sequences diverged.
- Comparison of evolutionary trees based on sequence alignments with those based on fossil records provides a clearer understanding of the timeline of divergences.
- Horizontal gene transfer events can appear as unexpected branches on the evolutionary tree.

10.4 Modern Techniques Make the Experimental Exploration of Evolution Possible

- Recombinant DNA technology now allows for the exploration of evolution as a laboratory science.
- In favorable cases, PCR amplification of well-preserved samples allows the determination of nucleotide sequences from extinct organisms. These sequences can help authenticate parts of an evolutionary tree constructed by other means.
- Molecular evolutionary experiments performed in the laboratory can examine how molecules such as ligand-binding RNA molecules might evolve over time.

Problems

1. Distinguish between paralogs and orthologs. 1

2. A evolutionary tree is shown in the image. Similar genes are represented by boxes. The letters X, Y, and Z represent different species. Similarly colored genes designate genes present in the same species (species X, Y, or Z).

© Macmillan Learning

Indicate whether the following pairs of genes are orthologs or paralogs: 1

a. Zα and $Z\beta_2$
b. X and $Z\beta_2$
c. Yα and Yβ
d. $Z\beta_1$ and $Z\beta_2$
e. Yα and Zα
f. X and Yα

3. Using the identity-based scoring system applied in Figure 10.4, calculate the score for the following alignment. What is the

percent identity between the two sequences? Do you think these two proteins are related? 2

```
(1) WYLGKITRMDAEVLLKKPTVRDGHFLVTQCESSPGEF
(2) WYFGKITRRESERLLLNPENPRGTFLVRESETTKGAY

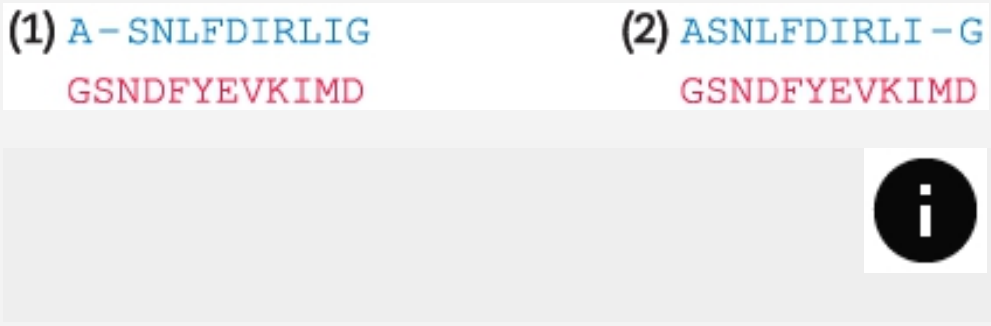
    SISVRFGDSVQ-----HFKVLRDQNGKYYLWAVK-FN
    CLSVSDFDNAKGLNVKHYKIRKLDSGGFYITSRTQFS

    SLNELVAYHRTASVSRTHTILLSDMNV
    SSLQQLVAYYSKHADGLCHRLTNV
```

4. Explain why protein shuffling is a helpful tool for predicting the significance of homology between two protein sequences. 2

5. Using the identity-based scoring system (Section 10.1), calculate the alignment score for the alignment of the following two short sequences:

```
(1) ASNFLDKAGK



(2) ATDYLEKAGK
```

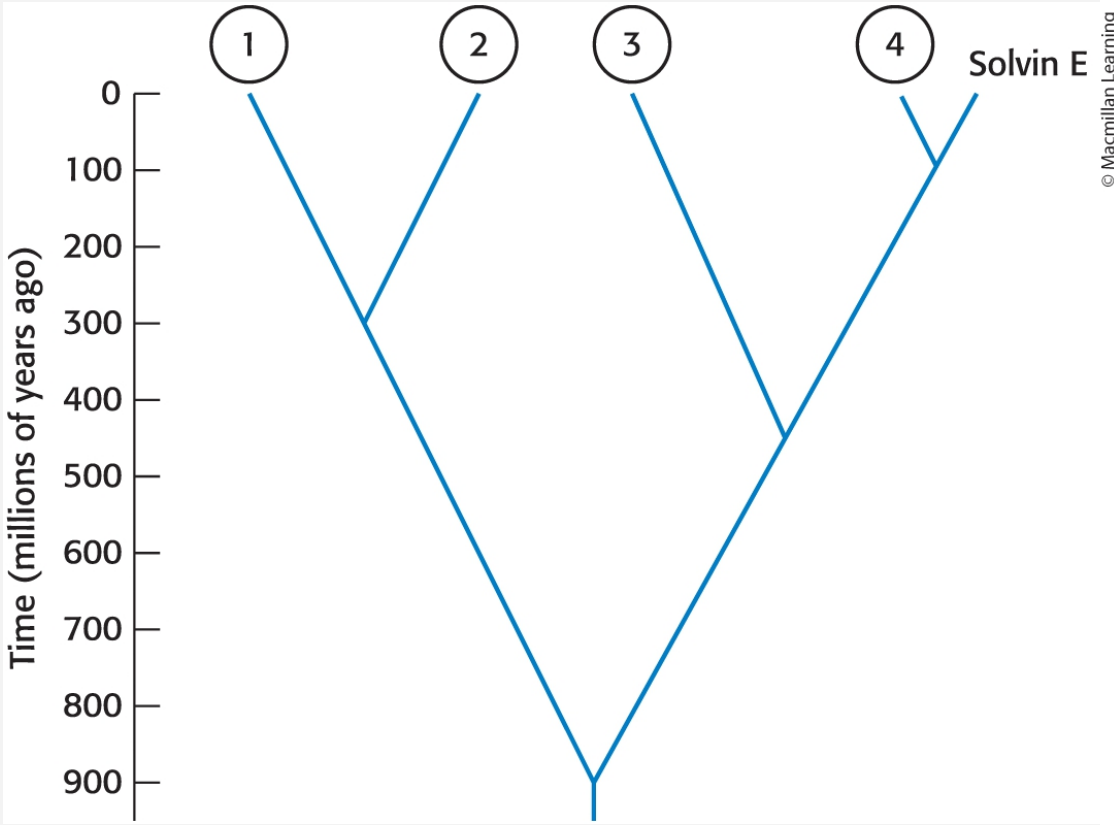
Generate a shuffled version of sequence 2 by randomly reordering these 10 amino acids. Align your shuffled sequence with sequence 1 without allowing gaps, and calculate the alignment score between sequence 1 and your shuffled sequence. 2

6. Consider the Blosum-62 matrix in Figure 10.7. Replacement of which three amino acids never yields a positive score? What features of these residues might contribute to this observation? 3

7. The protein sequence of myoglobin has aspartate (D) in a certain position, whereas the α chain of hemoglobin has glutamate (E) in the same position. How would this substitution be scored in the Blosum-62 matrix? 3

8. Consider the following two sequence alignments:

Which alignment has a higher score if the identity-based scoring system (Figure 10.4) is used? Which alignment has a higher score if the Blosum-62 substitution matrix (Figure 10.7) is used? For the Blosum scoring, you need not apply a gap penalty. 3



9. Suppose that the sequences of two proteins each consisting of 200 amino acids are aligned and that the percentage of identical residues has been calculated. How would you interpret each of

the following results in regard to the possible divergence of the two proteins from a common ancestor? 4

a. 80%
b. 50%
c. 20%
d. 10%

10. Suppose that you wish to synthesize a pool of RNA molecules that contain all four bases at each of 40 positions. How much RNA must you have in grams if the pool is to have at least a single molecule of each sequence? The average molecular weight of a nucleotide is $330\ g\ mol^{-1}$. 5

11. Below is an evolutionary tree for a fictitious protein family, the Solvins. The location of Solvin E is shown.

© Macmillan Learning

Place Solvins A, B, C, and D on the tree in the numbered positions according to the following statements: 1

- The Solvin family results from divergent evolution.
- Solvin A diverged from Solvin E three times as long ago as Solvin D evolved from Solvin A.
- Solvin C diverged from Solvin E 500 million years ago.
- Solvin B is not a direct descendent of Solvin A.

Which two Solvins are most similar? When did Solvin B diverge from Solvin E?

12. Classify the following statements as describing convergent evolution, divergent evolution, or both: 4

a. Proteins with similar functions that are derived from unrelated ancestors
b. May result in proteins with similar functions
c. Change in protein sequence over time
d. Results in homologous proteins
e. Proteins with similar functions that are derived from a common ancestor
f. Chymotrypsin and trypsin are an example.
g. Chymotrypsin and subtilisin are an example.

13. Classify the following evolutionary processes as examples of either convergent of divergent evolution:

a. The gene encoding malate dehydrogenase mutates in a way that confers increased specificity for lactate rather than malate.

b. Coffee and tea plants both have genes to produce caffeine, whereas their most recent common ancestor does not.
c. Some members of the β-helix fold superfamily of proteins are iron-dependent, whereas others are not.

14. The sequences of three proteins (A, B, and C) are compared with one another, yielding the following levels of identity:

	A	B	C
A	100%	65%	15%
B	65%	100%	55%
C	15%	55%	100%

Assume that the sequence matches are distributed uniformly along each aligned sequence pair. Would you expect protein A and protein C to have similar three-dimensional structures? Explain.

15. You have discovered a mutant form of a thermostable DNA polymerase with significantly reduced fidelity in adding the appropriate nucleotide to the growing DNA strand, compared with wild-type DNA polymerase. How might this mutant be useful in the molecular-evolution experiments described in Section 10.4? 5

Chapter 11
Carbohydrates and Glycoproteins

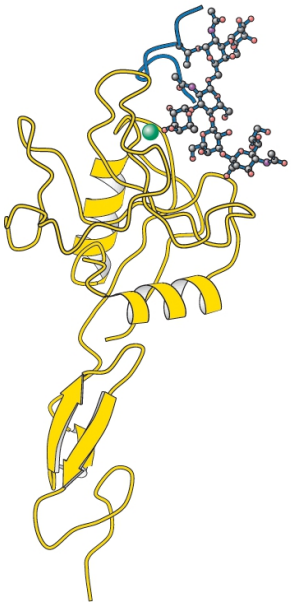


Photo: Shutterstock

Carbohydrates are important fuel molecules, but they play many other biochemical roles. Carbohydrate attachments on proteins fit into the binding sites of other proteins like a key into lock and can act as an ID code that can be read by other proteins, much like a QR code can be read by a phone. The model at left shows the protein P-selectin binding its ligand, a glycoprotei with specific carbohydrates attached.

[Drawn from 1G1S.pdb.]

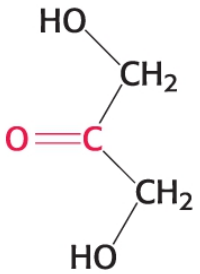
Outline

11.1 Monosaccharides Are the Simplest Carbohydrates
11.2 Monosaccharides Are Linked to Form Complex Carbohydrates
11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins
11.4 Lectins Are Specific Carbohydrate-Binding Proteins

Learning Goals

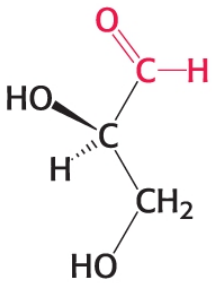
By the end of this chapter, you should be able to:

1. Describe the structure and main roles of carbohydrates in nature.
2. Describe how simple carbohydrates are linked to form complex carbohydrates.
3. Explain how carbohydrates are linked to proteins and what functions the linked carbohydrates play.
4. Describe the three main classes of glycoproteins and explain their biochemical roles.
5. Define what lectins are and outline their biochemical functions.



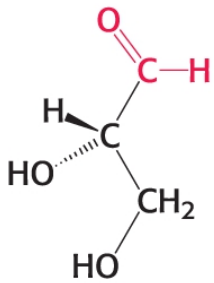
For decades, carbohydrates were recognized as important fuels and structural components but were thought to be peripheral to most key activities of the cell. This view has changed dramatically in recent years, as we now know that cells of all organisms are coated in a dense and complex coat of carbohydrates — frequently attached to lipids and proteins — that are essential to cell survival and cell-to-cell interactions and communication. The attachment of a carbohydrate to a protein is the most common post-translational modification of proteins — typically determining where a protein will be localized — and secreted proteins are often extensively decorated with carbohydrates. The extracellular matrix in higher eukaryotes — the environment in which the cells live — is also rich in secreted carbohydrates. Indeed, rather than being mere energy and infrastructure components, carbohydrates supply details and enhancements to the biochemical architecture of the cell, helping to define the functionality and uniqueness of the cell.

11.1 Monosaccharides Are the Simplest Carbohydrates



Carbohydrates are carbon-based molecules that are rich in hydroxyl groups; the empirical formula for many carbohydrates is $(CH_2O)_n$ — literally, a carbon hydrate. However, many carbohydrates have additional groups or modifications that deviate from this simple empirical formula. Thus, a better definition for carbohydrates is that they are polyhydroxy aldehydes and ketones, and their derivatives.

There are many monosaccharides but they are structurally similar



Simple carbohydrates are **monosaccharides**, also commonly called *sugars*, which are three to seven carbons in length. These simple sugars serve not only as fuel molecules but also as fundamental constituents of living systems. For instance, DNA has a backbone consisting of alternating phosphoryl groups and deoxyribose, the cyclic form of a five-carbon aldehyde sugar. The smallest monosaccharides, composed of three carbon atoms, are dihydroxyacetone and D- and L-glyceraldehyde.

Dihydroxyacetone
(a ketose)

D-Glyceraldehyde
(an aldose)

L-Glyceraldehyd
(an aldose)

Nomenclature

Monosaccharides are typically classified based upon both carbon-chain length and the identity of the most oxidized group. Dihydroxyacetone is called a *ketose* because it contains a keto group (in red, above), whereas glyceraldehyde is called an *aldose* because it contains an aldehyde group (also in red). Both these molecules are referred to as *trioses* (tri- for three, referring to the three carbon atoms that they contain). Similarly, simple monosaccharides with four, five, six, and seven carbon atoms are called *tetroses*, *pentoses*, *hexoses*, and *heptoses*, respectively. Perhaps the monosaccharides of which we are most aware are the hexoses, such as glucose and fructose. Glucose is an essential energy source for virtually all forms of life, and fructose is found commonly in many foods and used as a sweetener; fructose is converted into glucose derivatives inside the cell.

Isomers

Carbohydrates can exist in a dazzling variety of isomeric forms (**Figure 11.1**). Dihydroxyacetone and glyceraldehyde are *constitutional isomers* because they have identical molecular formulas but differ in how the atoms are ordered. These are in contrast to *stereoisomers*, which differ in spatial arrangement but not bonding order. Recall from the discussion of amino acids (Section 2.2) that stereoisomers are designated as having either D or L configuration. Glyceraldehyde has a single asymmetric carbon atom and, thus, there are two stereoisomers of this sugar: D-glyceraldehyde and L-glyceraldehyde. These molecules are a type of stereoisomer called *enantiomers*, which are mirror images of each other. Most monosaccharides from vertebrates have the D configuration.

According to convention, the D and L isomers are determined by the configuration of the asymmetric carbon atom farthest from the aldehyde or keto group. Dihydroxyacetone is the only monosaccharide without at least one asymmetric carbon atom.

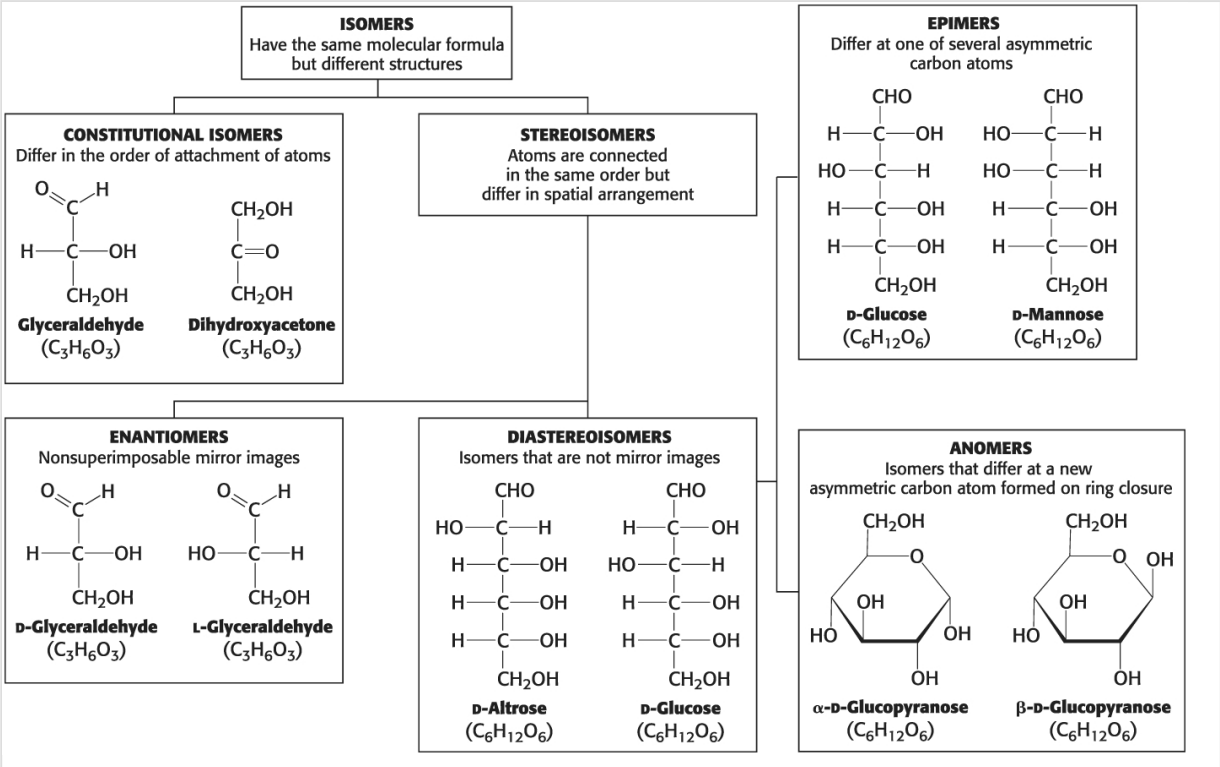


FIGURE 11.1 The complexity of carbohydrate structures results in many different types of isomeric forms.

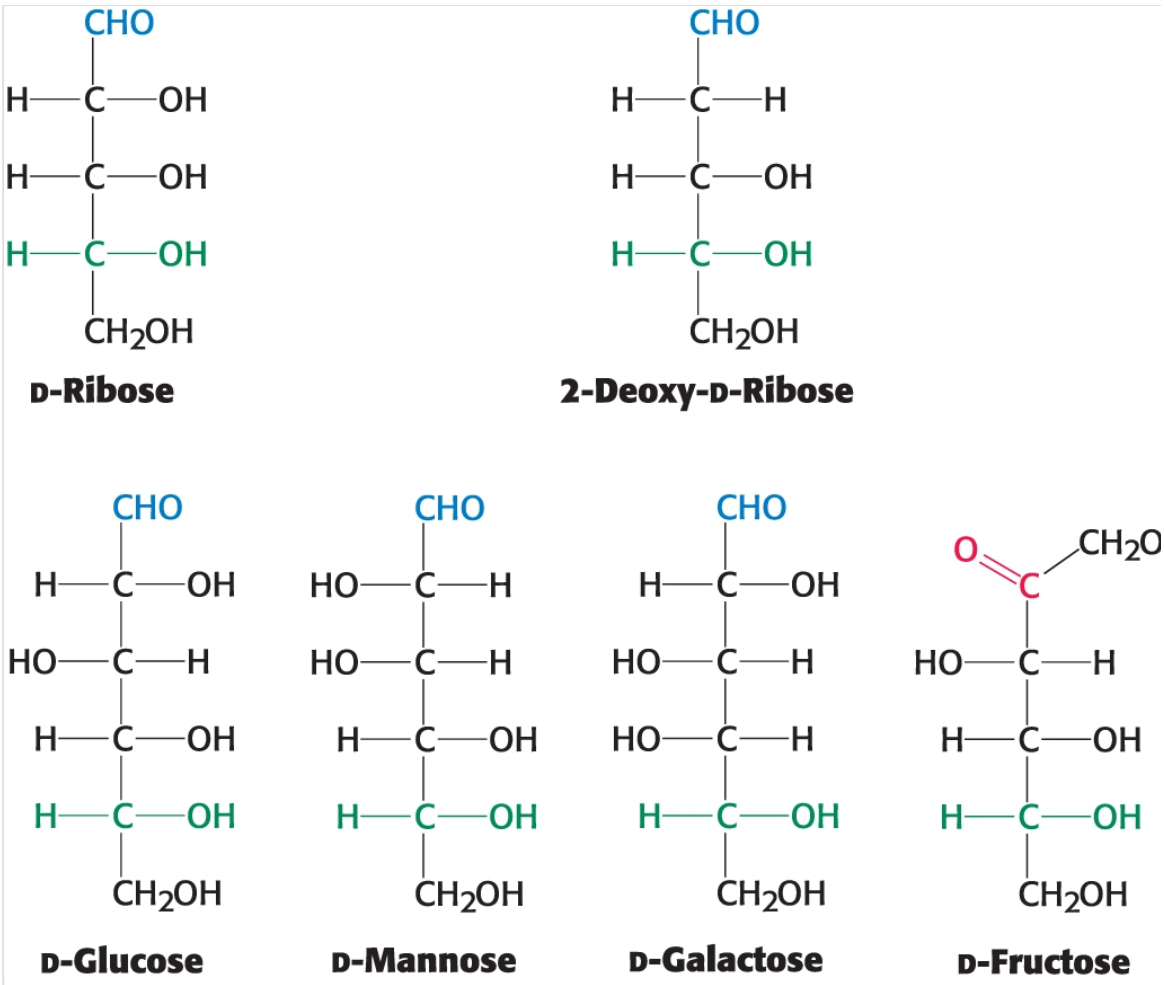
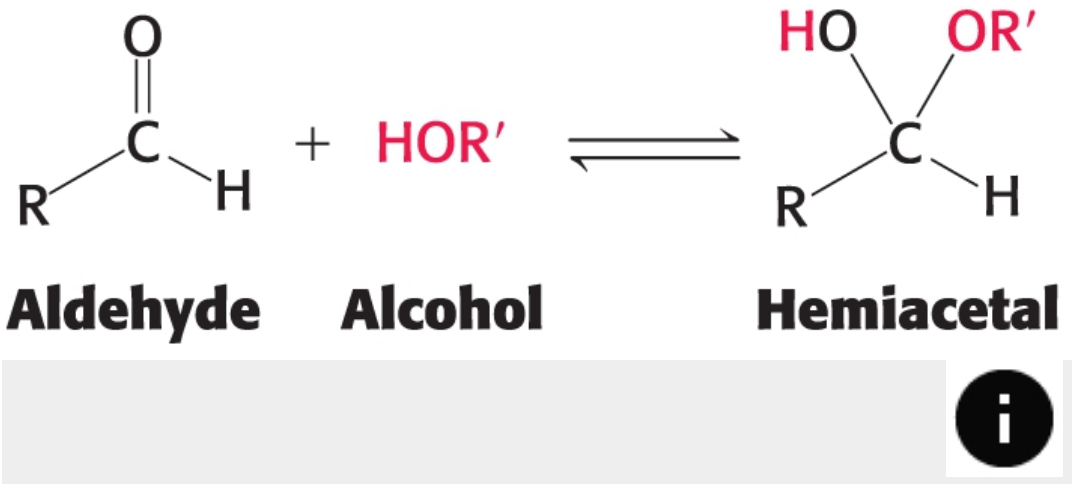
Monosaccharides made up of more than three carbon atoms have multiple asymmetric carbons, and so they can exist not only as enantiomers but also as *diastereoisomers*, stereoisomers that are not mirror images of each other. The number of possible stereoisomers equals 2^n, where n is the number of asymmetric carbon atoms. Thus, a six-carbon aldose with four asymmetric carbon atoms can exist as eight possible diastereoisomers, each of which can exist in two different

enantiomeric forms, for a total of 16 stereoisomers. D-Glucose is one such aldohexose. Note that ketoses have one less asymmetric center than aldoses with the same number of carbon atoms. D-Fructose is the most abundant ketohexose.

Common monosaccharides

The monosaccharides that we will see most frequently in our study of biochemistry are shown in **Figure 11.2**. D-Ribose, the carbohydrate component of RNA, is a five-carbon aldose, as is deoxyribose, the monosaccharide component of deoxynucleotides. D-Glucose, D-mannose, and D-galactose are abundant six-carbon aldoses. Note that D-glucose and D-mannose differ in configuration only at C-2, the carbon atom in the second position. Sugars that are diastereoisomers differing in configuration at only a single asymmetric center are **epimers**. Thus, D-glucose and D-mannose are epimeric at C-2; D-glucose and D-galactose are epimeric at C-4.





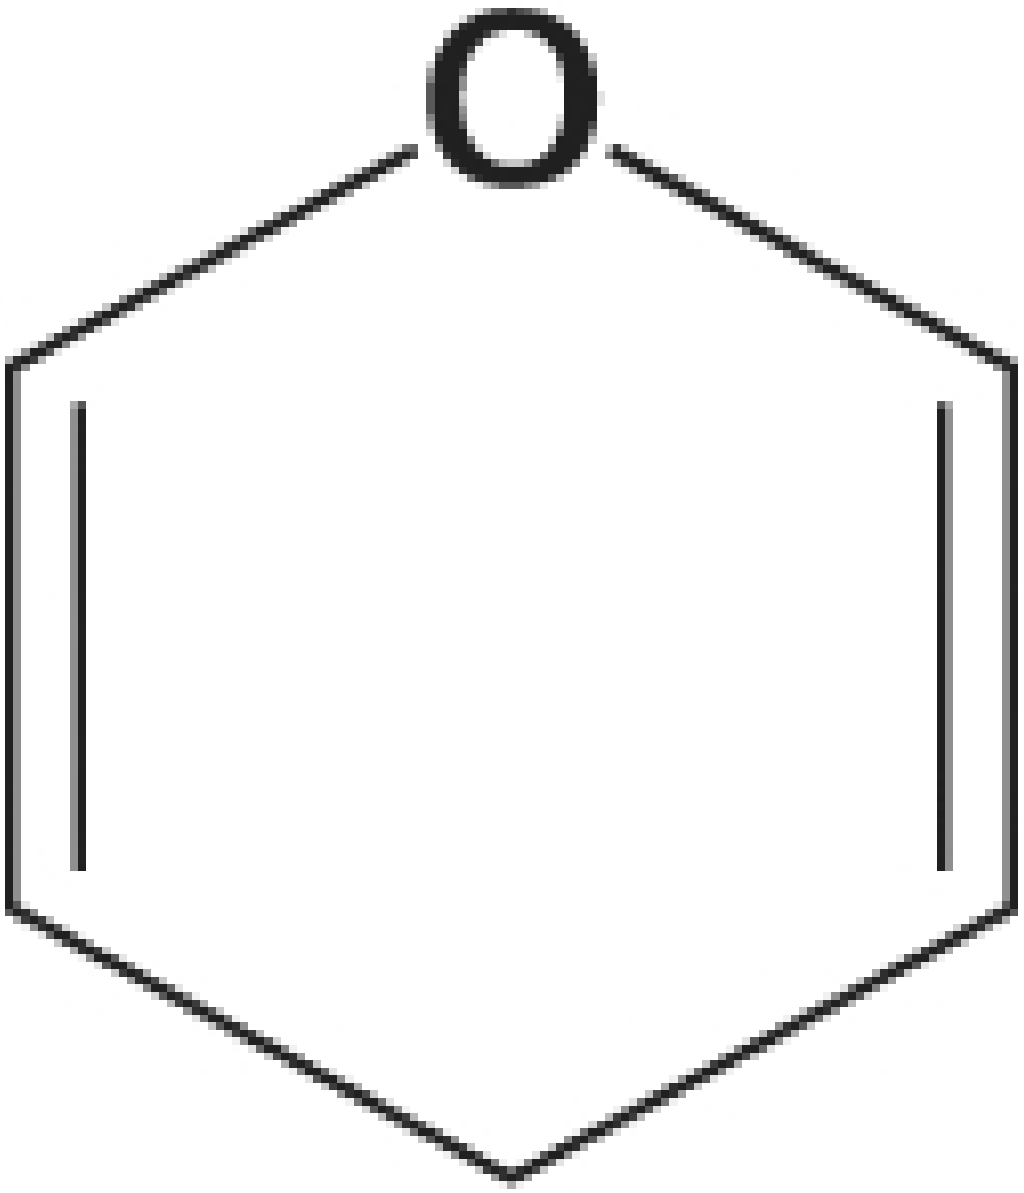


FIGURE 11.2 The most common monosaccharides are pentoses and hexoses. Aldoses contain an aldehyde group (shown in blue), whereas ketoses, such as D-fructose, contain a keto group (shown in red). The asymmetric carbon atom (shown in green) farthest from the aldehyde or ke group designates the structures as being in the D configuration.

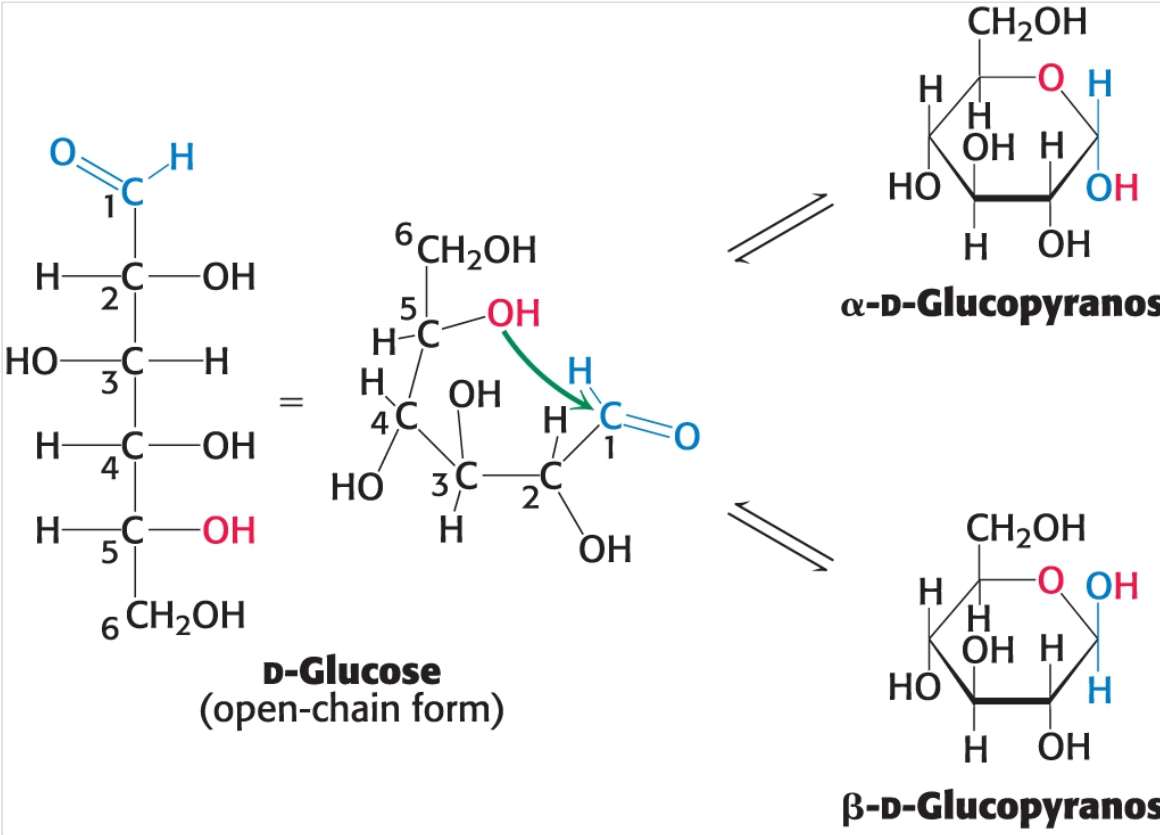
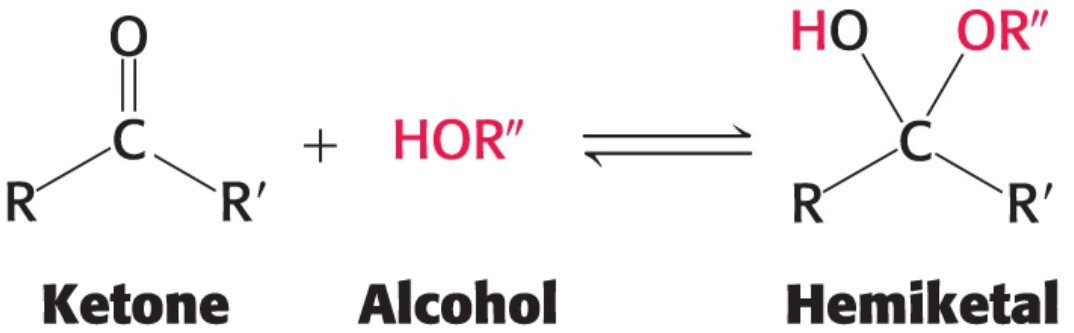
Most monosaccharides exist as interchanging cyclic forms

The predominant forms of ribose, glucose, fructose, and many other sugars in solution, as is the case inside the cell, are not open chains. Rather, the open-chain forms of these sugars cyclize into rings. The chemical basis for ring formation is that an aldehyde can react with an alcohol to form a *hemiacetal*.

For an aldohexose such as glucose, a single molecule provides both the aldehyde and the alcohol: the C-1 aldehyde in the open-chain form of glucose reacts with the C-5 hydroxyl group to form an intramolecular hemiacetal (**Figure 11.3**). The resulting cyclic hemiacetal, a six-membered ring, is called *pyranose* because of its similarity to the cyclic molecule *pyran*.

Pyran





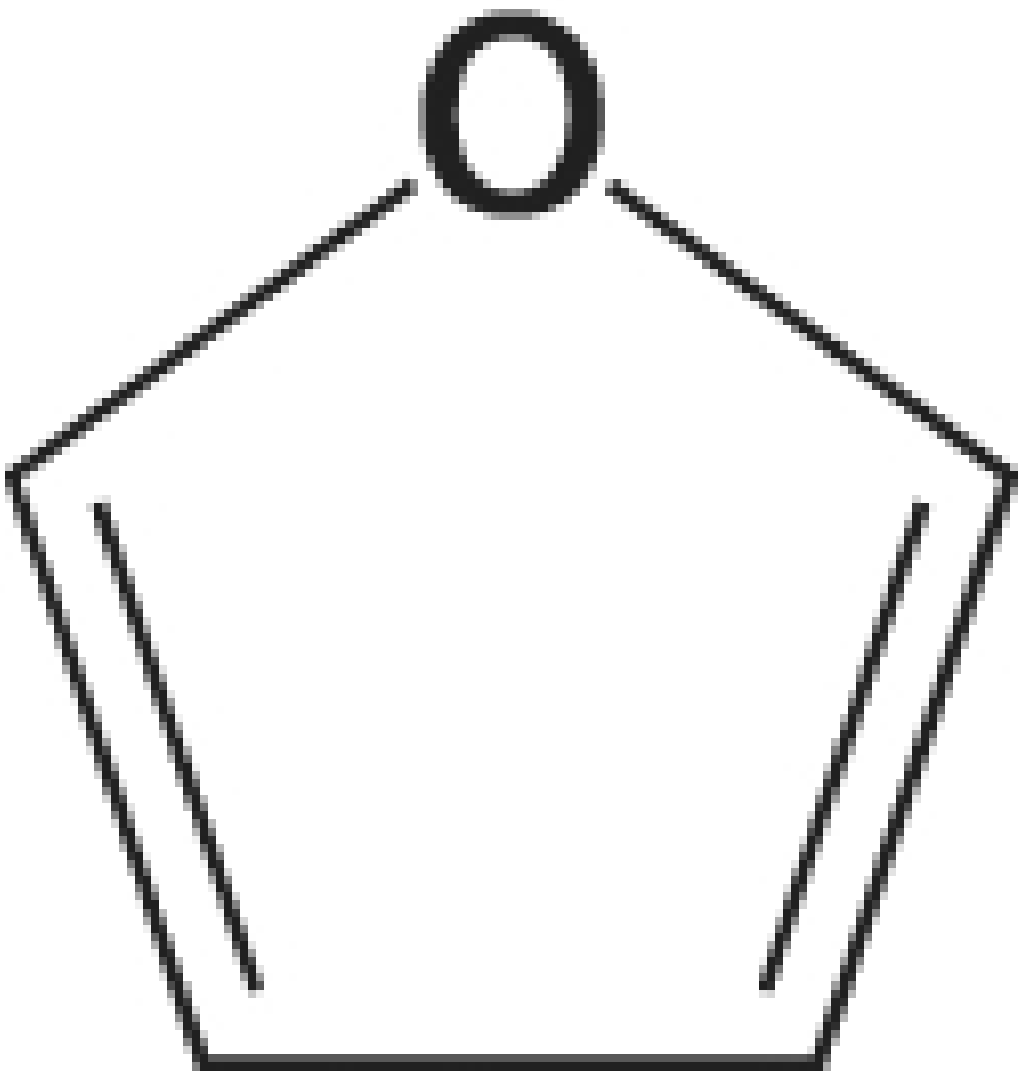


FIGURE 11.3 D-Glucose and other monosaccharides can temporarily form a pyranose ring. Th open-chain form of glucose cyclizes when the C-5 hydroxyl group attacks the oxygen atom of th C-1 aldehyde group to form an intramolecular hemiacetal. Two interchanging anomeric forms c the pyranose ring, designated α and β, can result; both in rapid equilibrium with the open-chair (linear) form.

Similarly, a ketone can react with an alcohol to form a *hemiketal*.

The C-2 keto group in the open-chain form of a ketohexose, such as fructose, can form an intramolecular hemiketal by reacting with either the C-6 hydroxyl group to form a six-membered cyclic hemiketal or the C-5 hydroxyl group to form a five-membered cyclic hemiketal (**Figure 11.4**). The five-membered ring is called a *furanose* because of its similarity to the five-membered heterocycle *furan*.

Furan

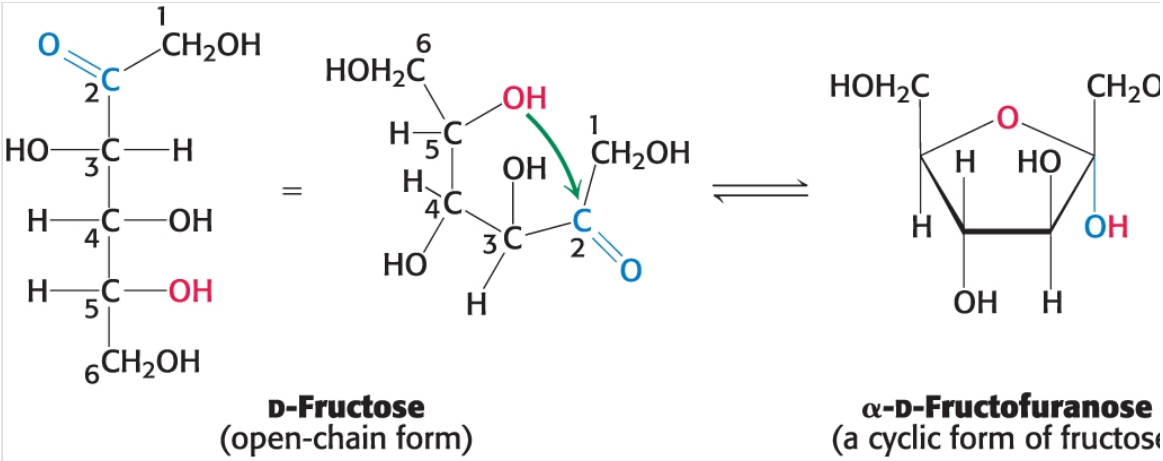

FIGURE 11.4 D-Fructose and other monosaccharides can temporarily form a furanose ring. Th
open-chain form of fructose cyclizes to a five-membered ring when the C-5 hydroxyl group attacks the C-2 ketone to form an intramolecular hemiketal. Two interchanging anomers are formed, but only the α anomer is shown.

The depictions of glucopyranose (glucose) and fructofuranose (fructose) shown in Figures 11.3 and 11.4 are examples of Haworth projections. In such projections, the carbon atoms in the ring are not written out. The approximate plane of the ring is perpendicular to the plane of the paper, with the heavy line on the ring projecting toward the reader.

We have seen that carbohydrates can contain many asymmetric carbon atoms. An additional asymmetric center is created when a cyclic hemiacetal is formed, generating yet another diastereoisomeric form of sugars called an **anomer**. In glucose, C-1 (the carbonyl carbon atom in the open-chain form) becomes an asymmetric center. Thus, two ring structures are formed: α-D-glucopyranose and β-D-glucopyranose (Figure 11.3). For D sugars drawn as Haworth projections in the standard orientation, as shown in Figure 11.3, the designation α means that the hydroxyl group attached to C-1 is on the opposite side of the ring as C-6; β means that the hydroxyl group is on the same side of the ring as C-6. The C-1 carbon atom is called the *anomeric carbon atom.* An equilibrium

mixture of glucose contains approximately one-third α anomer, two-thirds β anomer, and $< 1\%$ of the open-chain form. Note that these structures are constantly interconverting by opening to the linear structure and reclosing again, a process referred to as *mutarotation*. Here again, the biochemical timescale can be illuminating to consider: while the interconversion of epimers is best measured in years, anomers rapidly interconvert in seconds, reaching equilibrium in a matter of minutes. Below we will also consider conformations of sugars, which change in a matter of milliseconds.

The furanose-ring form of fructose also has anomeric forms, in which α and β refer to the hydroxyl groups attached to C-2, the anomeric carbon atom (Figure 11.4). Fructose forms both pyranose and furanose rings. The pyranose form predominates in fructose that is free in solution, due to reduced steric hindrances; the furanose form predominates in many fructose derivatives where additional groups attached to the sugar disfavor or prevent the pyranose ring form (**Figure 11.5**).

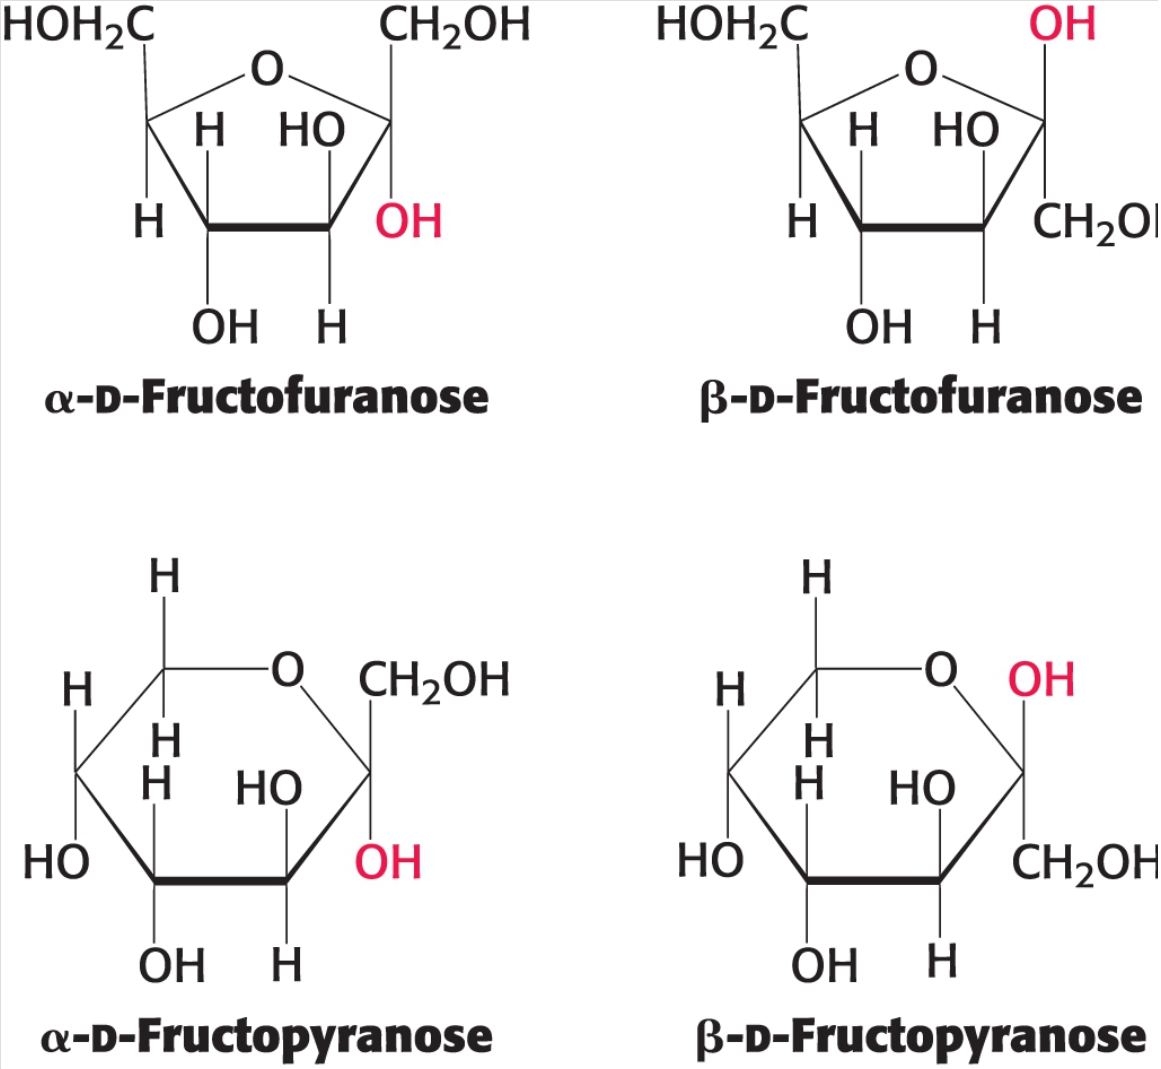

FIGURE 11.5 D-Fructose rapidly interchanges between four distinct ring structures in solutio
D-Fructose can form both five-membered furanose (top) and six-membered pyranose (bottom) rings. In each case, both α and β anomers are possible and all are in rapid equilibrium with the open-chain form.

β-D-Fructopyranose, found in honey and many fruits, is the sweetest common monosaccharide, while the β-D-fructofuranose form is not nearly as sweet. Because heating converts β-fructopyranose into the β-fructofuranose form, corn syrup with a high concentration of fructose

in the β-D-pyranose form is used as a sweetener in cold, but not hot, drinks. Figure 11.6 shows common sugars in their ring forms.

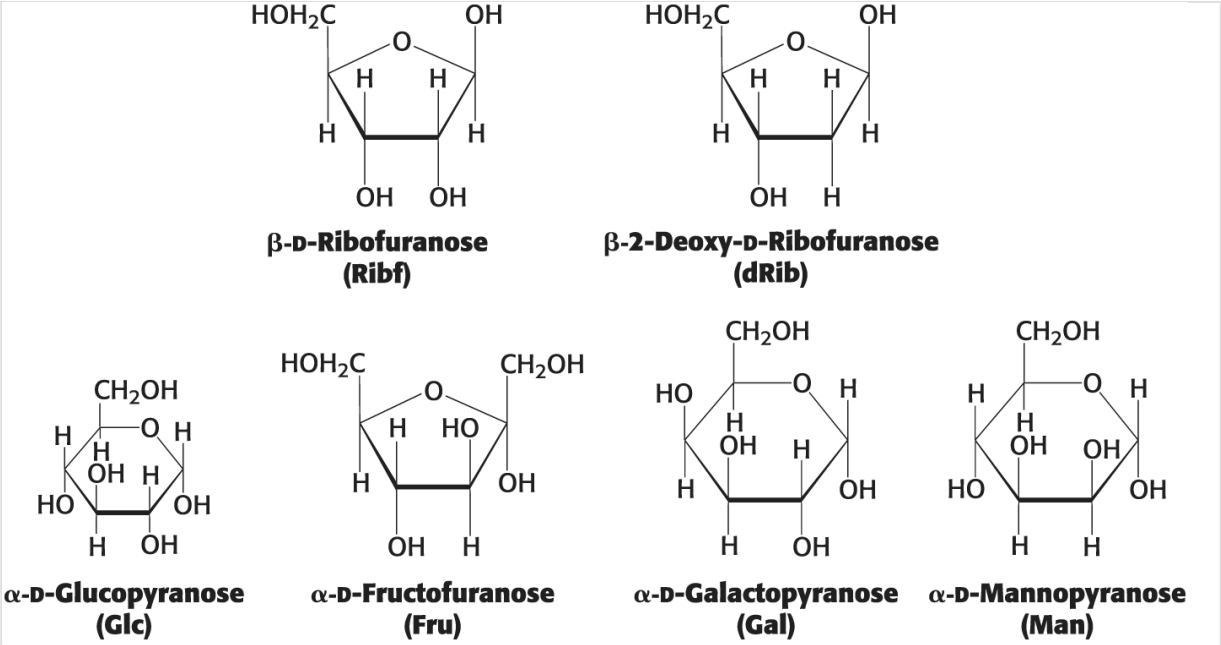

FIGURE 11.6 The most common monosaccharides exist primarily in their ring forms. Only one anomer of each is shown. The shorthand carbohydrate code for each sugar is given in parentheses.

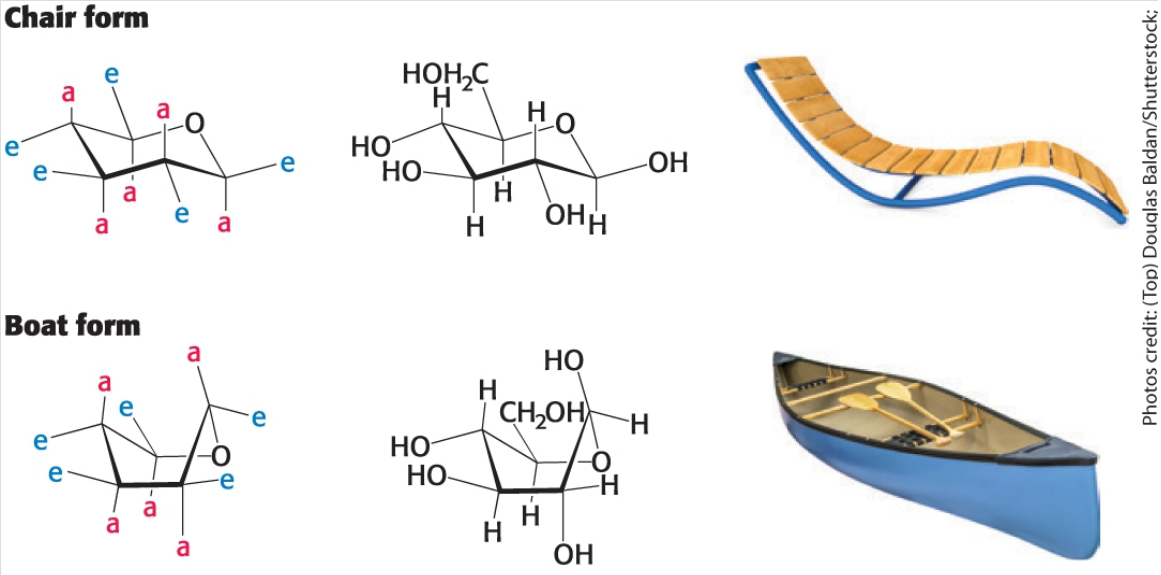
Pyranose and furanose rings can assume different conformations

The six-membered pyranose ring is not planar because of the tetrahedral geometry of its saturated carbon atoms. Instead, pyranose rings adopt two classes of conformations, termed *chair* and *boat* because of the resemblance to these objects (Figure 11.7). In the chair form, the substituents on the ring carbon atoms have two orientations: axial and equatorial. *Axial* bonds are nearly perpendicular to the average plane of

the ring, whereas *equatorial* bonds are nearly parallel to this plane. Axial substituents sterically hinder each other if they emerge on the same side of the ring (e.g., 1,3-diaxial groups). In contrast, equatorial substituents are less crowded.



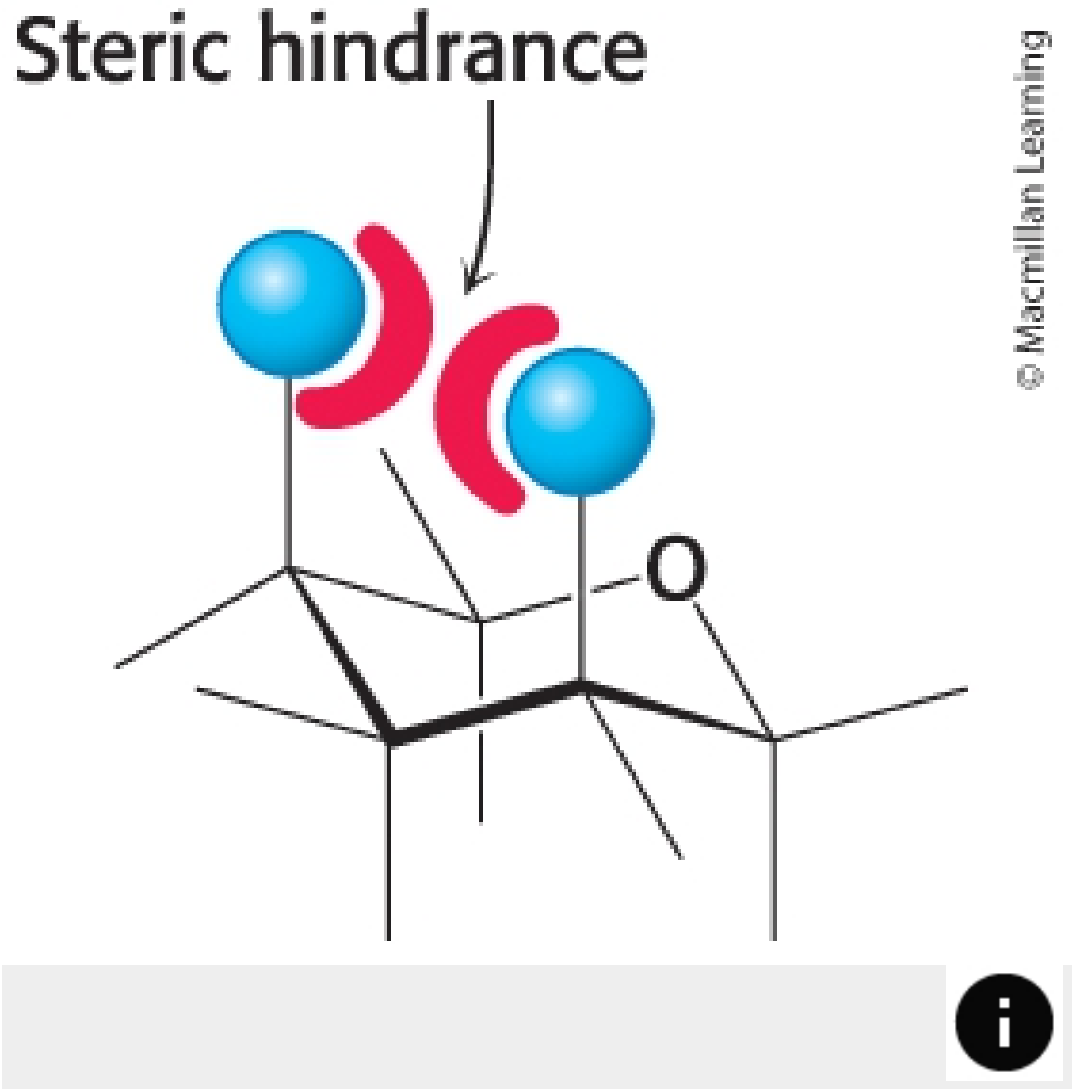


FIGURE 11.7 Pyranose rings like β-D-glucopyranose are not actually planar but adopt chair and boat forms. The chair form is more stable because the less bulky hydrogen atoms occupy a of the axial positions, resulting in less steric hindrance. Abbreviations: a, axial; e, equatorial.

The chair form of β-D-glucopyranose predominates because all axial positions are occupied by hydrogen atoms. The bulkier $-OH$ and $-CH_2OH$ groups emerge at the less-hindered periphery. The boat form of glucose is disfavored because it is quite sterically hindered.

Furanose rings, like pyranose rings, are not planar. They can be puckered so that four atoms are nearly coplanar and the fifth is about 0.5 Å away from this plane (**Figure 11.8**). This conformation is called an *envelope form* because the structure resembles an opened envelope with the back flap raised. In the ribose moiety of most biomolecules, either C-2 or C-3 is out of the plane on the same side as C-5. These conformations are called *C-2-endo* and *C-3-endo*, respectively.

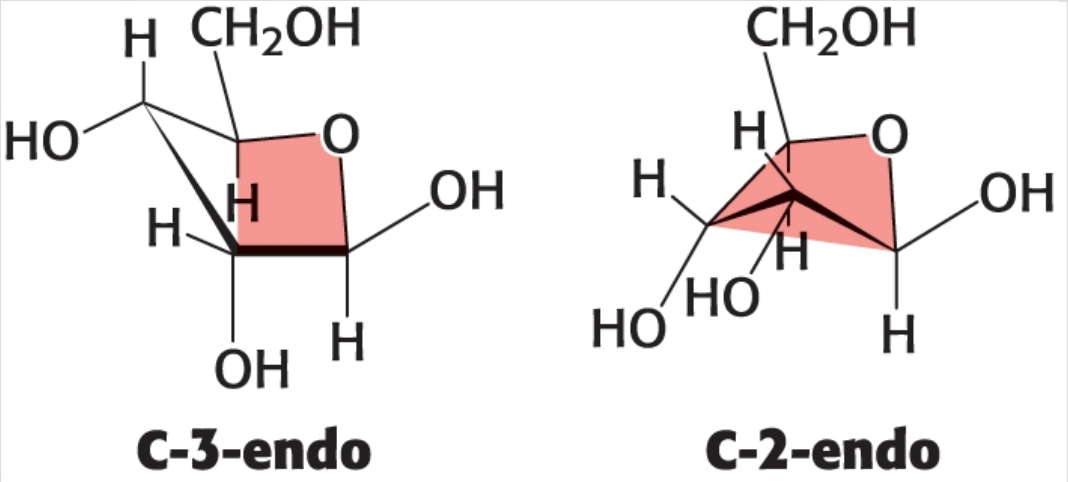

FIGURE 11.8 Furanose rings like β-D-ribofuranose are nonplanar and adopt alternative envelope conformations. The shading indicates the four atoms that lie approximately in a plane.

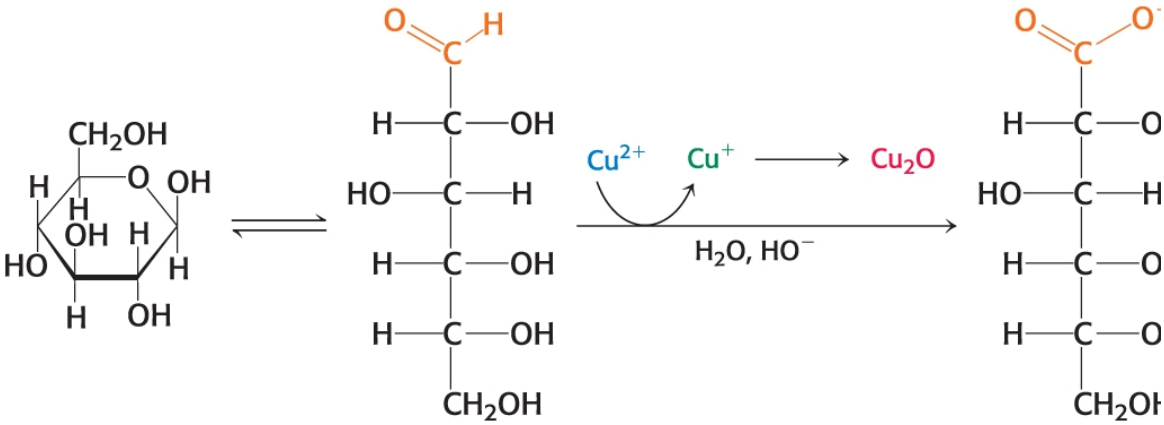
D-Glucose is an important fuel for most organisms

D-Glucose is a common and important fuel molecule in nearly all organisms. In mammals, D-glucose is the predominant form of carbohydrate circulated in the blood — commonly called *blood sugar* — and is the only fuel that the brain uses under non-starvation conditions, and the only fuel used by red blood cells. Why is D-glucose, instead of any of the many other monosaccharides, such a prominent biological fuel molecule? We can speculate on the reasons. First, glucose is one of several monosaccharides formed from formaldehyde under prebiotic conditions, and so it may have been available as a fuel source for primitive biochemical systems. Second, glucose is relatively non-reactive (inert) compared to other monosaccharides and is therefore less likely to react nonenzymatically with proteins, potentially rendering them nonfunctional.

A consideration of glucose's specific chemical structure holds the key to understanding why its selection as life's primary sugar was not arbitrary. From the perspective of chemical stability, six-membered rings are preferable to five-membered rings due to decreased ring strain. Likewise, as noted above, the chair conformation is preferable for a six-membered ring, and the most stable chair conformation will have all bulky groups ($-OH$ and $-CH_2OH$) in the equatorial positions. Of all possible monosaccharides, the most stable six-membered ring structure that can be formed is that of D-glucose in the pyranose form with the anomeric carbon in the β orientation, as this is the only six-membered ring with all five bulky groups in the equatorial positions. This structural observation also explains the roughly 2:1 ratio of β-to-α anomer conformations for D-glucose in an equilibrium solution. Because glucose has such a strong tendency to exist in this stable ring conformation, it consequently has relatively little tendency to modify proteins in a reaction that results from the linear form compared to other sugars, though these reactions do still occur, as described in the next section.



Self-Check Question

Based on ring strain and steric clashes, which is the more stable structure in each pair: D-fructopyranose or D-fructofuranose; boat or chair conformations of D-fructopyranose; bulky groups in axial or equatorial positions about a ring structure; β or α anomer of D-glucopyranose?

Glucose is a reducing sugar and reacts nonenzymatically with hemoglobin

Although 99% of D-glucose molecules in solution are in the pyranose ring forms at any given moment, the α and β anomers of glucose are in an equilibrium that passes through the open-chain form. Thus, glucose has some of the chemical properties of other aldehydes, such as the ability to react with oxidizing agents. For example, glucose in its linear form can react with cupric ion (Cu^{2+}), reducing it to cuprous ion (Cu^{+}), while being oxidized to gluconic acid.

Solutions of cupric ion (known as *Fehling's solution*) provide a simple test for the presence of sugars, such as D-glucose, that at least temporarily adopt an open structure. Sugars that react are called **reducing sugars**. Because ketose sugars can tautomerize to a small degree into temporary structures that have aldehydes, all monosaccharides that can access their open (linear) structures in solution are reducing sugars.

Reducing sugars often nonspecifically react with free amino groups on proteins, usually at a lysine or arginine residue, to form a stable

covalent bond. This nonenzymatic (random) addition of a carbohydrate to another molecule is called *glycation*, as opposed to *glycosylation*, which is enzyme catalyzed. As emphasized above, D-glucose has a low tendency to glycate proteins; however, when the concentrations of both the sugar and the protein are very high for long periods of time — as is the case with both D-glucose and hemoglobin in red blood cells — even unlikely reactions can occur at an appreciable rate. As such, the reducing sugar D-glucose reacts with hemoglobin to form glycated hemoglobin (called *hemoglobin A1c* or often just A1C).

 Monitoring changes in A1C levels — that is, the amount of *glycated hemoglobin* (often incorrectly called *glycosylated hemoglobin*) in the blood — is an especially useful means of assessing the effectiveness of treatments for diabetes mellitus, a serious condition in which insulin, a key hormone in regulating glucose homeostasis, is either absent (type 1 diabetes) or ineffective (type 2 diabetes), resulting in high levels of blood glucose (Section 24.3). Because the glycated hemoglobin remains in circulation, the amount of the modified hemoglobin corresponds to the long-term regulation — over several months — of glucose levels. This kind of measurable sign of an illness that correlates with a disease regardless of whether it is actually mechanistically involved is called a *biomarker*. In nondiabetic individuals, less than 6% of hemoglobin is glycated, whereas in patients with uncontrolled diabetes, almost 10% of hemoglobin is glycated. Thus, glycated hemoglobin (A1C) is a widely used biomarker for the early onset and treatment of diabetes, among other disorders.

Although the glycation of hemoglobin has no effect on oxygen binding and is thus benign, similar reducing reactions with other proteins such as collagen are often detrimental, because the glycations alter the normal biochemical function of the modified proteins. Following the primary modification, cross-linking may occur between the site of the first modification and elsewhere in the protein, further compromising function. These modifications, known as *advanced glycation end products*

(AGEs), have been implicated in aging, arteriosclerosis, and diabetes, as well as other pathological conditions.

Monosaccharides are joined to alcohols and amines through glycosidic linkages by specific enzymes

The biochemical properties of monosaccharides can by modified by reaction with other molecules. These modifications increase the biochemical versatility of carbohydrates, enabling them to serve as signal molecules or facilitating their metabolism. Three common reactants are alcohols, amines, and phosphates.

The covalent linkage formed between the anomeric carbon atom of a carbohydrate and the oxygen atom of an alcohol is called a **glycosidic linkage** — specifically, an O-*glycosidic linkage* (**Figure 11.9A**). *O*-Glycosidic linkages are prominent when carbohydrates are joined together to form long polymers. In addition, the anomeric carbon atom of a sugar can be linked to the nitrogen atom of an amine to form an N-*glycosidic linkage*, such as when nitrogenous bases are attached to ribose units to form nucleotides (**Figure 11.9B**). Both types of linkages are used to attach carbohydrates to proteins. Carbohydrates can also be modified by the attachment of functional groups to carbons other than the anomeric carbon (**Figure 11.10**). For example, *N*-acetylgalactosamine is called an *amino sugar*, so named because an amino group replaces a hydroxyl group.

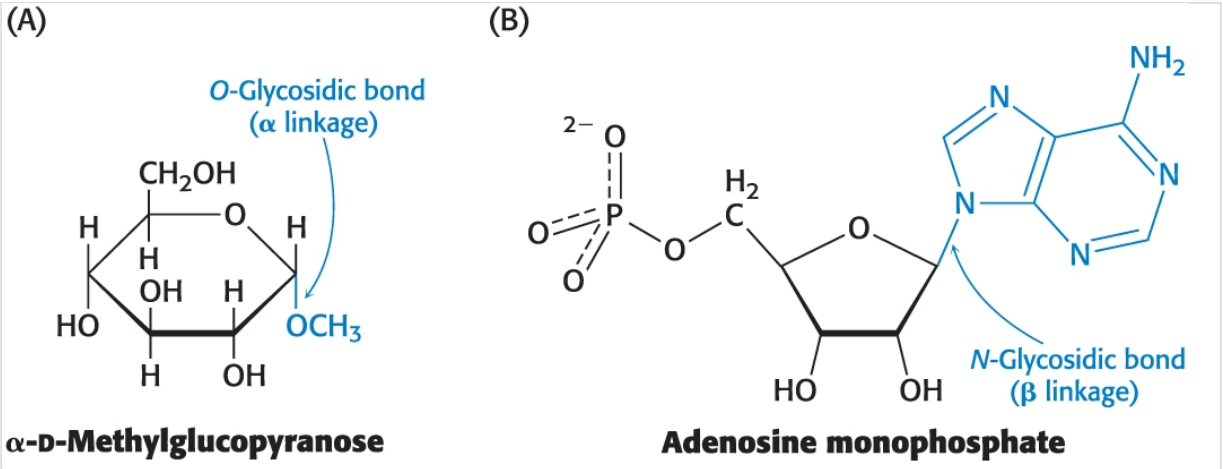


FIGURE 11.9 Carbohydrates are often attached to other molecules through *O*- and *N*-glycosidic linkages. (A) An *O*-glycosidic linkage connects glucose to a methyl group in α-D-methylglucopyranose. (B) An *N*-glycosidic linkage joins ribose to the base adenine in adenosine monophosphate.

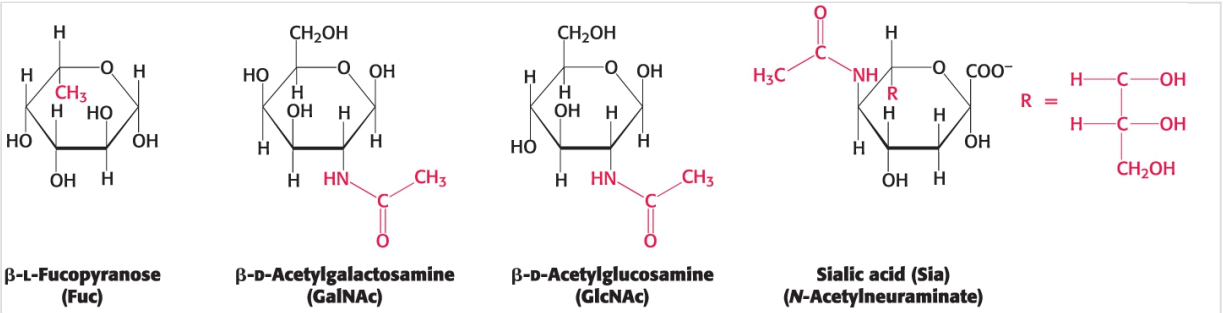

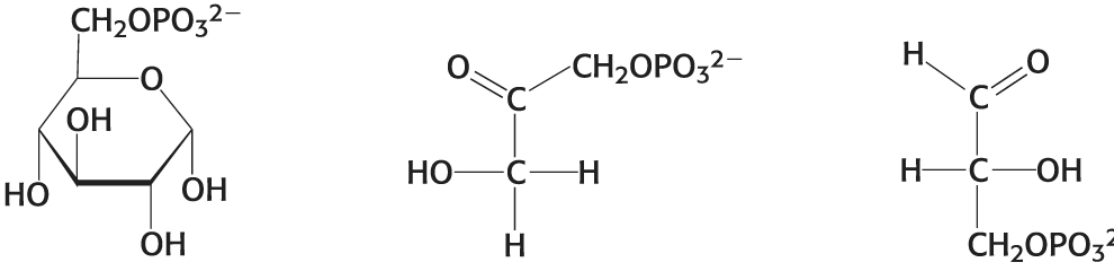

FIGURE 11.10 Monosaccharides can be modified by the addition of substituents other than hydroxyl groups. Additional substituents are shown in red.

Phosphorylated sugars are key intermediates in metabolism

The addition of phosphoryl groups is a common modification of sugars in metabolic reactions. For instance, the first step in the breakdown of glucose to obtain energy is its conversion into glucose 6-phosphate. Several subsequent intermediates in this metabolic pathway, such as dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, are phosphorylated sugars.

Glucose 6-phosphate (G-6P)

Dihydroxyacetone phosphate (DHAP)

Glyceraldehyde 3-phosphate (GAP)

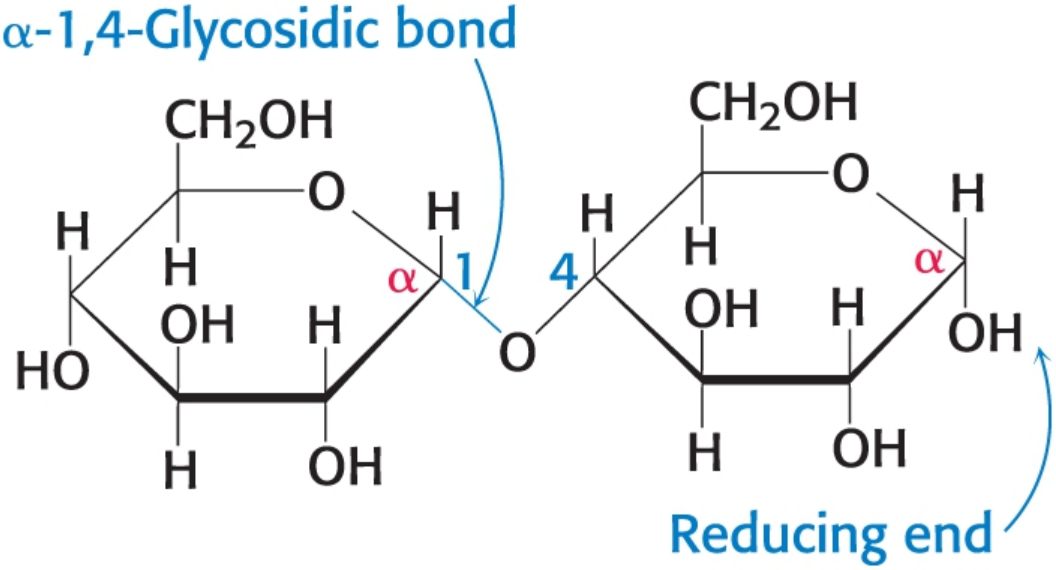
By making sugars anionic (negatively charged), phosphorylation not only prevents these sugars from spontaneously leaving the cell by crossing lipid-bilayer membranes but also prevents them from interacting with transporters of the unmodified sugar. Moreover, phosphorylation blocks the formation of alternative ring conformations; for example, phosphorylation of fructose at C-6 prevents the formation of both pyranose anomers, effectively increasing the concentration of the furanose forms. Finally, phosphorylation creates reactive intermediates that will more readily undergo metabolism. For example, a multiply phosphorylated derivative of ribose plays key roles in the biosyntheses of purine and pyrimidine nucleotides (Chapter 25).

Self-Check Question

Which of the following — D-fructose, D-galactose, β-D-ribofuranose — are reducing sugars like D-glucose?

11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

Because sugars contain hydroxyl groups, glycosidic linkages can join one monosaccharide to another. **Oligosaccharides** are built by the linkage of two or more monosaccharides by *O*-glycosidic bonds (**Figure 11.11**). In the disaccharide maltose, for example, two D-glucose residues are joined by a glycosidic linkage between the α-anomeric form of C-1 on one sugar and the hydroxyl oxygen atom on C-4 of the adjacent sugar. This is called an α-*1,4-glycosidic linkage*.



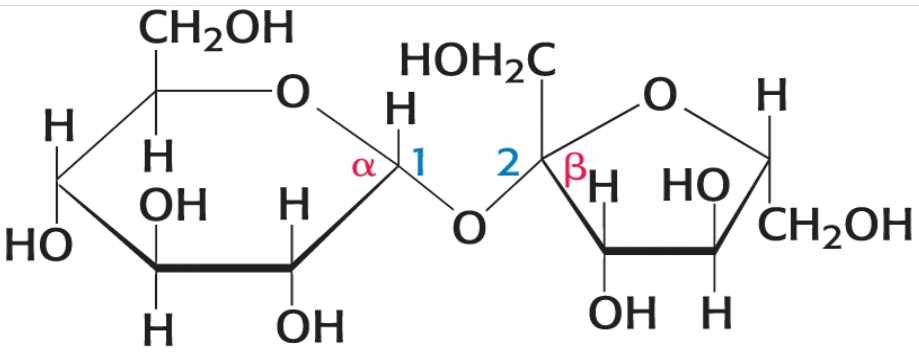


FIGURE 11.11 Maltose is a disaccharide of only D-glucose. Two molecules of glucose are linked by an α-1,4-glycosidic linkage to form the disaccharide maltose. The glucose molecule on the right is capable of assuming the open-chain form, which can act as a reducing agent. The glucose molecule on the left cannot assume the open-chain form, because the C-1 carbon atom is bound to another molecule.

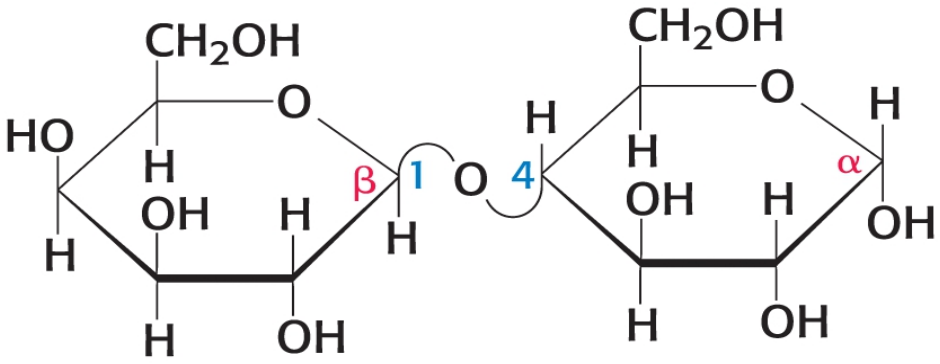
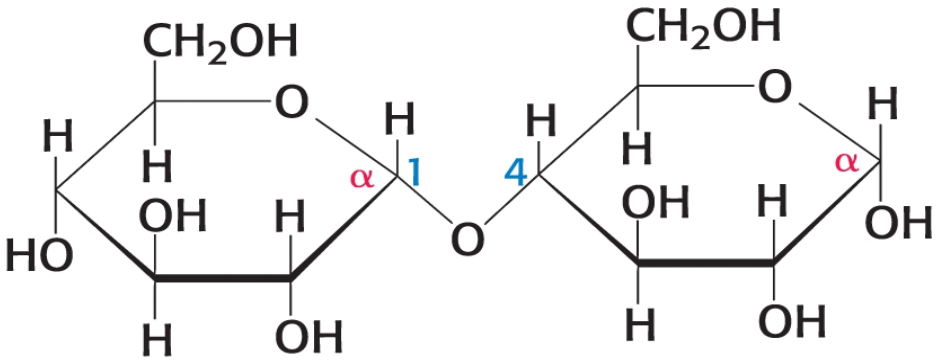
Just as proteins have a directionality defined by the amino and carboxyl ends, oligosaccharides have a directionality defined by their reducing and nonreducing ends. Anomeric carbons in glycosidic linkages are locked in their specific anomeric form and can no longer convert to the open-chain form, or mutarotate. However, the sugar at the reducing end has a free anomeric carbon atom that has reducing activity because it can form the open-chain form. By convention, this end of the oligosaccharide is still called the *reducing end* even when it is bound to another molecule such as a protein and thus no longer has reducing properties.

The fact that monosaccharides have multiple hydroxyl groups means that many different glycosidic linkages are possible. For example, consider three monosaccharides: glucose, mannose, and galactose. In principle, these molecules could be linked together to form more than 12,000 structures differing in the order of the monosaccharides and the hydroxyl groups participating in the glycosidic linkages. In this section, we will look at some of the most common oligosaccharides that actually occur in nature.



Sucrose, lactose, and maltose are common disaccharides

A **disaccharide** consists of two sugars joined by an *O*-glycosidic linkage. Figure 11.12 illustrates three abundant disaccharides.



Sucrose

(α-D-Glucopyranosyl-(1→2)-β-D-Fructofuranose)

α-Lactose

(β-D-Galactopyranosyl-(1→4)-α-D-Glucopyranose)

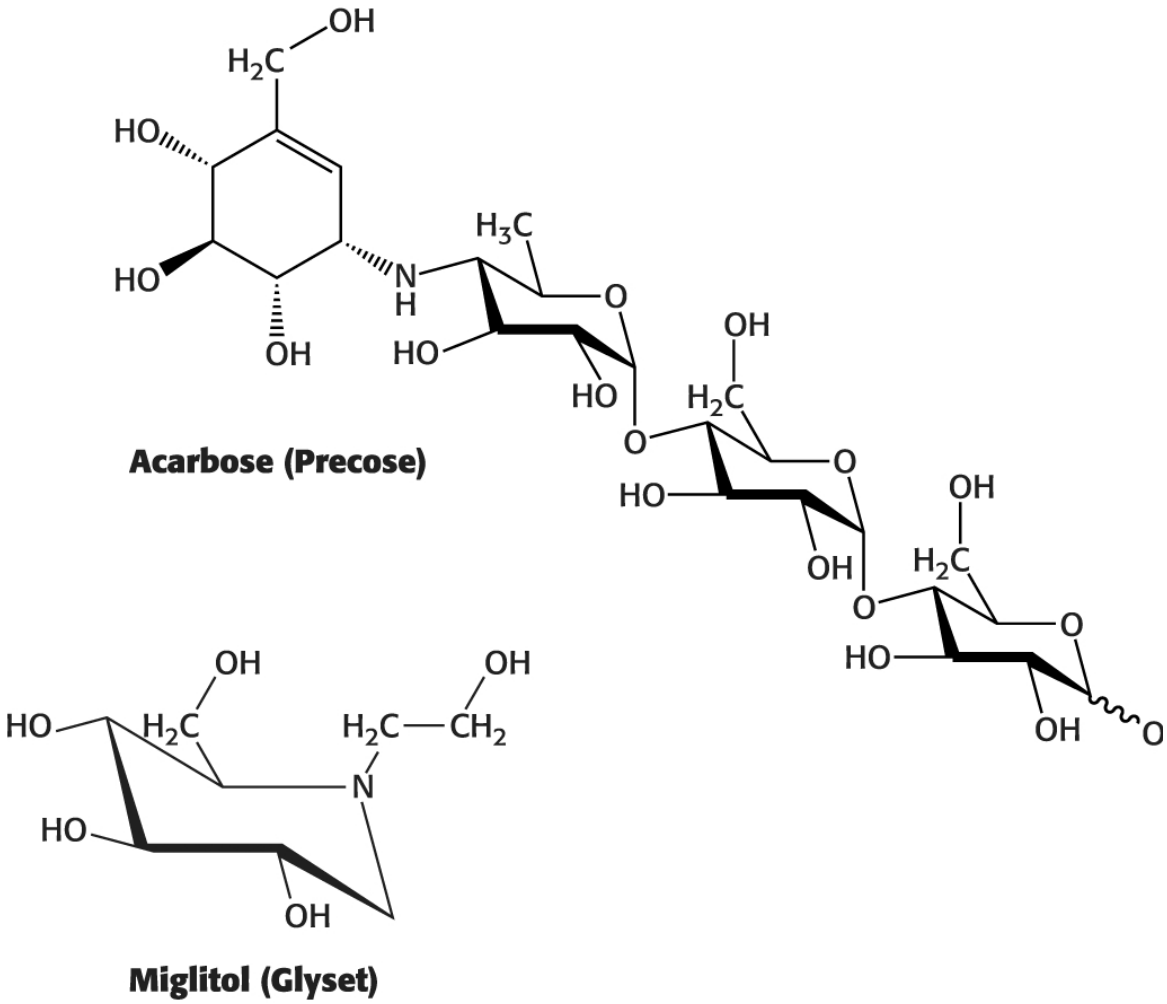
α-Maltose

(α-D-Glucopyranosyl-(1→4)-α-D-Glucopyranose)

FIGURE 11.12 Sucrose, lactose, and maltose are common dietary disaccharides. In sucrose, neither sugar can access the open chain form since both anomeric carbons are in the glycosidic linkage; hence, sucrose is not a reducing sugar, and there are no anomeric forms. For lactose and maltose, only one anomer is shown. In lactose, the curved lines indicate the connectivity of the atoms but are normal covalent bonds. One sugar is upside down with respect to the other in the structure; however, for viewing convenience both sugars here are shown in the normal orientation for a Haworth projection, necessitating curved lines.

- In *sucrose*, obtained commercially from sugar cane or sugar beets and refined into table sugar, both the anomeric carbons of a glucose unit and a fructose unit are joined; the configuration of this glycosidic linkage is α for glucose and β for fructose. Note that because both anomeric carbons are involved in the glycosidic linkage, sucrose is not a reducing sugar. Sucrose can be cleaved into its component monosaccharides by the enzyme *sucrase*, also called *invertase*.

- The disaccharide found in milk, *lactose*, consists of galactose joined to glucose by a β-1,4-glycosidic linkage. Lactose is hydrolyzed to these monosaccharides by *lactase* in human beings and by *β-galactosidase* in bacteria.



- In *maltose*, two glucose units are joined by an α-1,4-glycosidic linkage. Maltose comes from the hydrolysis of large polymeric oligosaccharides such as starch and glycogen and is in turn hydrolyzed to glucose by *maltase* (α-glucosidase). Maltase will also degrade oligosaccharides linked by α-1,4-glycosidic linkages.

The enzymes sucrase, lactase, and maltase are located on the outer surfaces of epithelial cells lining the small intestine. The cleavage products of sucrose, lactose, and maltose can be further processed to provide energy in the form of ATP.

Maltase inhibitors can help to maintain blood glucose homeostasis

Maintaining the proper concentration of glucose in the blood (3.9–5.5 mM) — glucose homeostasis — is vital, since glucose can form advanced glycation products. Moreover, as we noted earlier, elevated blood glucose (hyperglycemia) is characteristic of diabetes. Pharmacological intervention is sometimes required, including the administration of insulin or other drugs that control blood glucose, and maltase is one potential drug target. Following a meal, starch and glycogen are initially degraded by α-amylase secreted by the salivary glands and pancreas. The oligosaccharides generated by α-amylase are further digested by α-glucosidase. Two drugs commonly used to inhibit maltase are acarbose (Precose) and miglitol (Glyset):

Both acarbose and miglitol are competitive inhibitors (Section 5.6) of maltase and are usually ingested at the start of a meal to slow postprandial (after a meal) glucose absorption in the treatment of diabetes.

Human milk oligosaccharides protect newborns from infection

In addition to the disaccharide lactose, more than 150 different oligosaccharides have been identified in human milk; the amount and composition of these sugars vary among lactating women. Interestingly, these carbohydrates are not digested by breastfed infants but play a significant role in protecting them against bacterial infection. In particular, they may protect infants from infections caused by certain types of *Streptococcus* bacteria that are sometimes transmitted during vaginal childbirth. How the protection arises is not firmly established, but the oligosaccharides may serve as a fuel source for beneficial bacteria. Alternatively, or in addition, these carbohydrates may prevent the attachment of microbial pathogens to the intestinal wall of the newborn. Biochemists continue to explore the therapeutic potential of these oligosaccharides.

Glycogen and starch are storage polysaccharides of glucose

As we know, glucose is an important energy source in virtually all life forms. However, free glucose molecules cannot be stored; in high concentrations, glucose will disturb the osmotic balance of the cell, potentially resulting in cell death. The solution is to store glucose as units in a large polymer, which is less osmotically active.

Large polymeric oligosaccharides, formed by the linkage of multiple monosaccharides, are called **polysaccharides**, or *glycans*, and play vital roles in energy storage and in maintaining the structural integrity of an

organism. If all of the monosaccharide units in a polysaccharide are the same, the polymer is called a *homopolymer*.

The most common homopolymer in animal cells is **glycogen**, the storage form of glucose. Glycogen is present in most of our tissues but is most abundant in muscle and liver. As will be considered in detail in Chapter 21, glycogen is a large, branched polymer of glucose residues. Most of the glucose units in glycogen are linked by α-1,4-glycosidic linkages. The branches are formed by α-1,6-glycosidic linkages, present about once in 12 units (**Figure 11.13**). The great degree of branching in glycogen increases the surface area of a glycogen particle, allowing better access for enzymes to rapidly break it down when glucose is needed in animal cells.

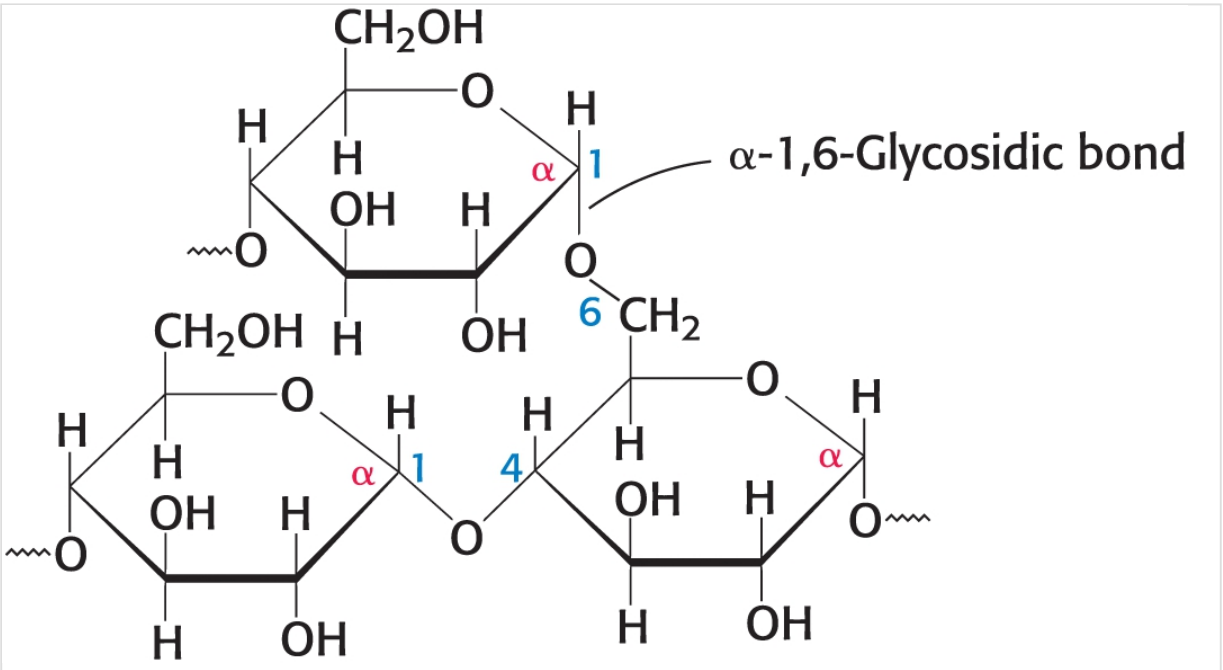


FIGURE 11.13 Glycogen consists of linear polymers with many branch points. Two chains of glucose molecules joined by α-1,4-glycosidic linkages are joined by an α-1,6-glycosidic linkage to create a branch point. Such an α-1,6-glycosidic linkage forms at approximately every 12 glucose units, making glycogen a highly branched molecule.

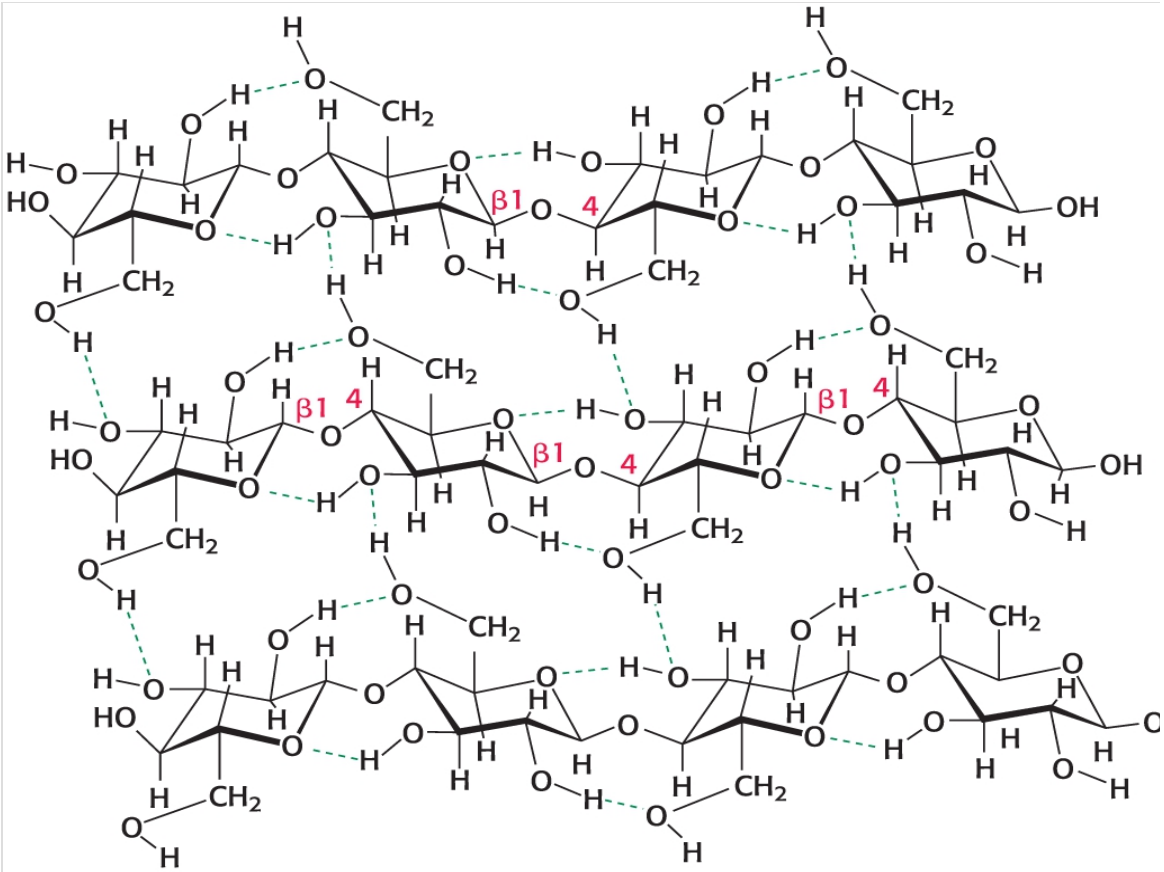
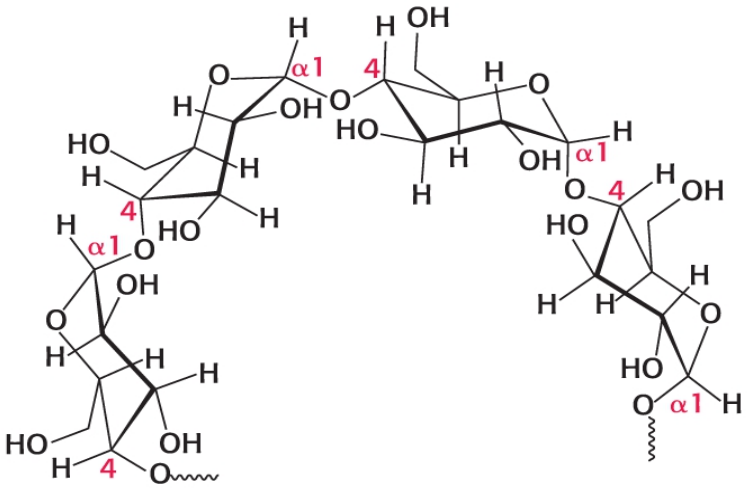


The nutritional reservoir in plants is the homopolymer **starch**, of which there are two forms. *Amylose*, the unbranched type of starch, consists of glucose residues in α-1,4 linkage. *Amylopectin*, the branched form, has about one α-1,6 linkage per 30 α-1,4 linkages. The structure of amylopectin is therefore identical to that of glycogen except for its lower degree of branching, which results in a more compacted structure known as a starch granule. Plants do not need to break down starch as quickly as animals need to degrade glycogen. More than half the carbohydrate ingested by human beings is starch, which is found in wheat, potatoes, rice, and other plant sources. Amylopectin, amylose, and glycogen are all hydrolyzed by α-*amylase*, an enzyme secreted by the salivary glands and the pancreas that can cleave the α-1,4 linkages common to all three glucose-storing homopolymers.

Cellulose is the main structural polysaccharide of plants

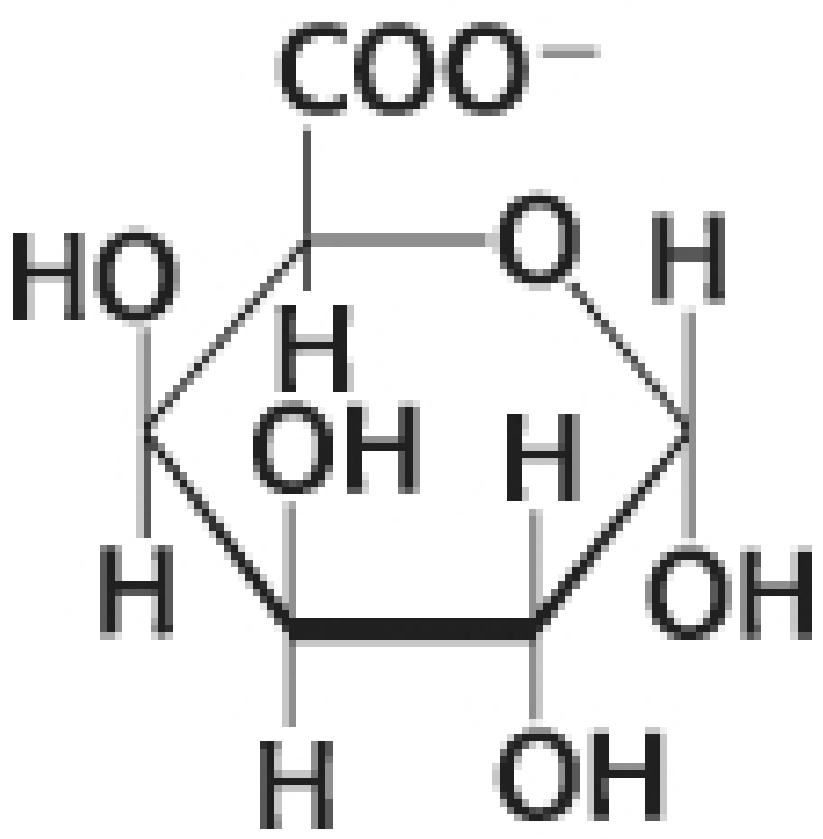


Another major polysaccharide of glucose found in plants, **cellulose**, serves a structural rather than a nutritional role as an important component of the plant cell wall. As one of the most abundant organic compounds in the biosphere, some 10^{15} kg of cellulose is synthesized and degraded on Earth each year, an amount 1000 times as great as the combined weight of the total human population.

Cellulose is an unbranched polymer of glucose residues joined by β-1,4 linkages, in contrast with the α-1,4 linkage seen in starch and glycogen. This simple difference in stereochemistry creates two molecules with very different properties and biological functions. The β configuration allows cellulose to form very long, straight chains. Fibrils of cellulose are formed by parallel chains that interact with one another through hydrogen bonds, generating a rigid, supportive structure (**Figure 11.14, top**). The straight chains formed by β linkages are optimal for the

construction of fibers having a high tensile strength. In contrast, the α-1,4 linkages in glycogen and starch produce a very different molecular architecture: a hollow helix is formed instead of a straight chain (**Figure 11.14, bottom**). The hollow helix formed by α linkages is well suited to the formation of a more compact, accessible store of sugar.

Cellulose
(β-1,4 linkages)



Starch and glycogen
(α-1,4 linkages)

FIGURE 11.14 Glycosidic linkages determine polysaccharide structure. The β-1,4 linkages favo straight chains, which are optimal for structural purposes. The α-1,4 linkages favor bent, helical structures, which are more suitable for storage.

Although animals lack cellulases and therefore cannot digest wood and vegetable fibers, cellulose and other plant fibers are still an important constituent of the mammalian diet as a component of dietary fiber. Soluble fiber such as pectin (polygalacturonic acid) slows the movement of food through the gastrointestinal tract, allowing improved digestion and the absorption of nutrients. Insoluble fibers, such as cellulose, increase the rate at which digestion products pass through the large intestine, softening stools and making them easier to pass.

Galacturonic acid

Chitin is the main structural polysaccharide of fungi and arthropods

Likely the second most abundant polysaccharide on the planet, chitin is found in the cell walls of fungi, in the exoskeletons and shells of arthropods such as insects, arachnids, mollusks, and crustaceans, and in numerous other organisms. The structure of chitin is very similar to cellulose with the exception that each glucose sugar has the C-2

hydroxyl replaced with an amino group which is acetylated such that chitin is a homopolymer of β -1,4 linked *N*-acetylglucosamine, rather than glucose (Figure 11.15). Chitin fibers are also often crosslinked to one another and composited with minerals and proteins to further increase its rigidity and strength. For example, cephalopods such as squid use their razor-sharp beaks, which are made of extensively cross-linked chitin, to disable and consume prey.

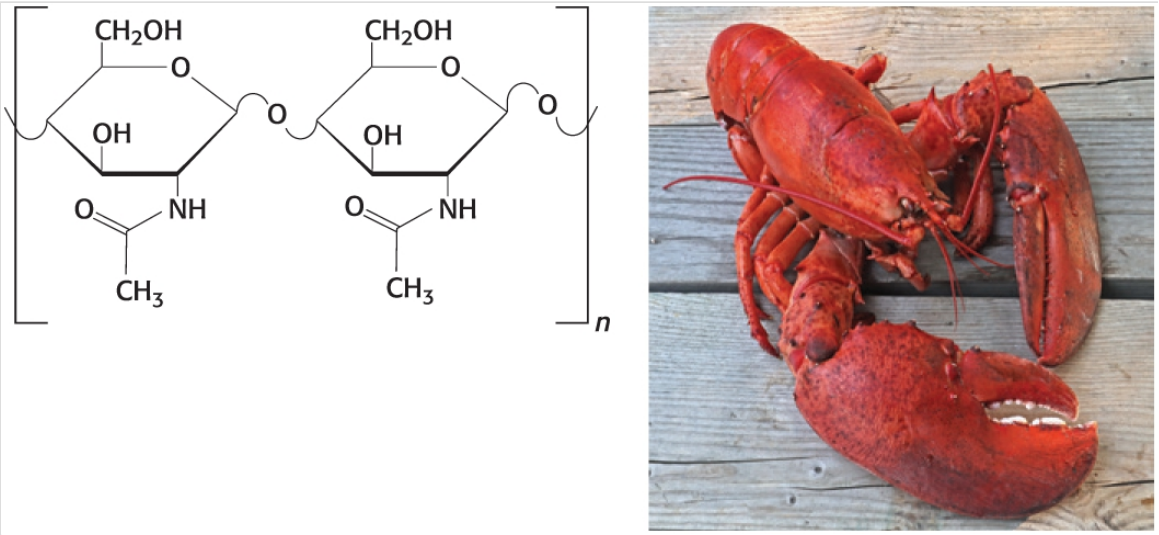


FIGURE 11.15 Chitin, a homopolymer of *N*-Acetylglucosamine, is a structural glycan found in insect wings and the exoskeletons of arthropods, including lobster shells.

Chitin can be processed to a molecule with a variety of uses

We are all aware, in one way or another, of the many uses of the polysaccharide cellulose. It is a major constituent of paper, bioadhesives, and the clothes you are wearing. Less obvious to most of us are uses of chitin. Estimates are that 10,000 tons of chitin could be

recovered from the shellfishing industry by processing the shells into a more versatile molecule called *chitosan.*

Chitosan has a variety of uses. For instance, it is used as a carrier to assist in drug delivery, as surgical stitches, and as a component of cosmetic and food products. Recent research shows that chitosan can be used as a component of an adhesive that strongly adheres to wet tissues, allowing the adhesive to be used as a surgical dressing.

One way to process chitin, which is water-insoluble, to water-soluble chitosan is with a series of microbial/enzymatic processes. First, shells are washed and ground to a fine powder, which is then exposed to lactic acid-generating bacteria. The lactic acid removes minerals from the chitin. Following demineralization, the chitin is treated with protease-secreting bacteria to degrade the protein components. Finally, chitin is treated with chitin deacetylase to remove approximately half of the acetyl groups, generating the more versatile chitosan.

Self-Check Question

Which of these carbohydrates — sucrose, maltose, lactose, cellulose, starch, amylose, glycogen, chitin — are composed entirely of D-glucose monomers? Which are structural (rather than storage) glycans?

11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins

A carbohydrate group can be covalently attached to a protein to form a **glycoprotein**. Such modifications are common; 50% of the human proteome consists of glycoproteins. Many of the proteins secreted from cells are glycosylated, or modified by the attachment of carbohydrates, including most proteins present in the serum component of blood.

Glycosylation greatly increases the complexity of the proteome. A given protein with several potential glycosylation sites can have many different glycosylated forms, called *glycoforms*. Like protein isoforms (Section 7.2), each is typically generated only in a specific cell type or developmental stage.

In this section, we will examine three classes of glycoproteins:

1. In members of the first class, simply referred to as *glycoproteins*, the protein constituent is the largest component by weight. This versatile class plays a variety of biochemical roles. Many glycoproteins are components of cell membranes, where they take part in processes such as cell adhesion, including the binding of sperm to eggs. Other glycoproteins are formed by linking carbohydrates to soluble proteins.

2. In **proteoglycans**, the protein component of the glycoprotein is conjugated to a particular type of polysaccharide called a **glycosaminoglycan**. Carbohydrates make up a much larger percentage by weight of the proteoglycan compared with simple glycoproteins. Proteoglycans function as structural components and lubricants.

3. **Mucins** (or **mucoproteins**) are, like proteoglycans, predominantly carbohydrate, and they are a key component of mucus. In mucins, the protein component is extensively glycosylated at serine or threonine residues, typically by *N*-acetylgalactosamine (Figure 11.10). Mucins serve as lubricants.

Carbohydrates can be linked to proteins through asparagine (*N*-linked) or through serine or threonine (*O*-linked) residues

Sugars in glycoproteins are attached either to the amide nitrogen atom in the side chain of asparagine (termed an N-*linkage*) or to the oxygen atom in the side chain of serine or threonine (termed an O-*linkage*), as shown in **Figure 11.16**. An asparagine residue can accept an oligosaccharide only if the residue is part of an Asn-X-Ser or Asn-X-Thr sequence, in which X can be any residue, except proline.

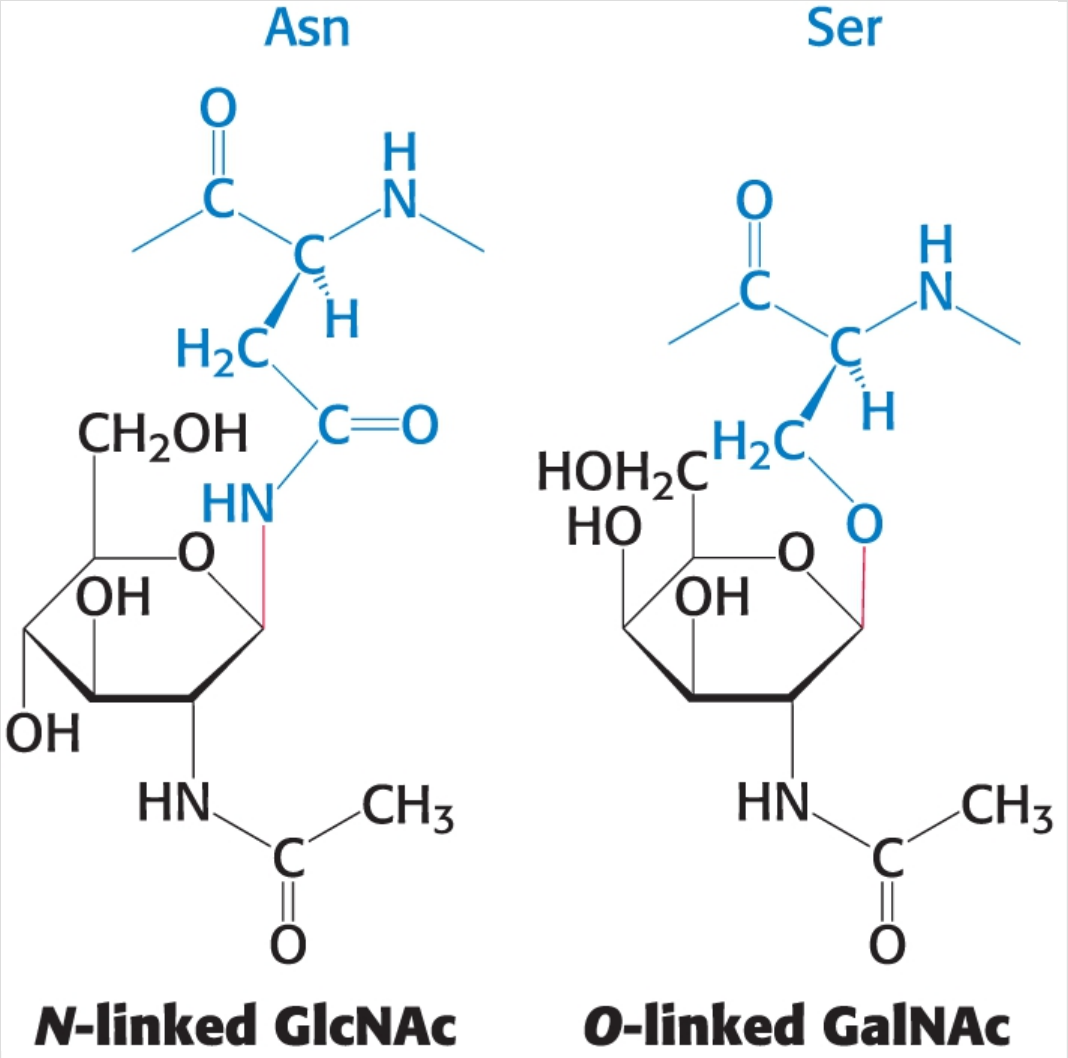

FIGURE 11.16 Glycosidic linkages connect proteins and carbohydrates. A glycosidic linkage connects a carbohydrate to the side chain of asparagine (*N*-linked) or to the side chain of serine or threonine (*O*-linked). The glycosidic linkages are shown in red.

However, not all potential sites are glycosylated. Which sites are glycosylated depends on other aspects of the protein structure and on the cell type in which the protein is expressed. All *N*-linked oligosaccharides have a pentasaccharide core consisting of three mannose and two *N*-acetylglucosamine residues. Additional sugars are

attached to this core to form the great variety of oligosaccharide patterns found in glycoproteins (Figure 11.17).

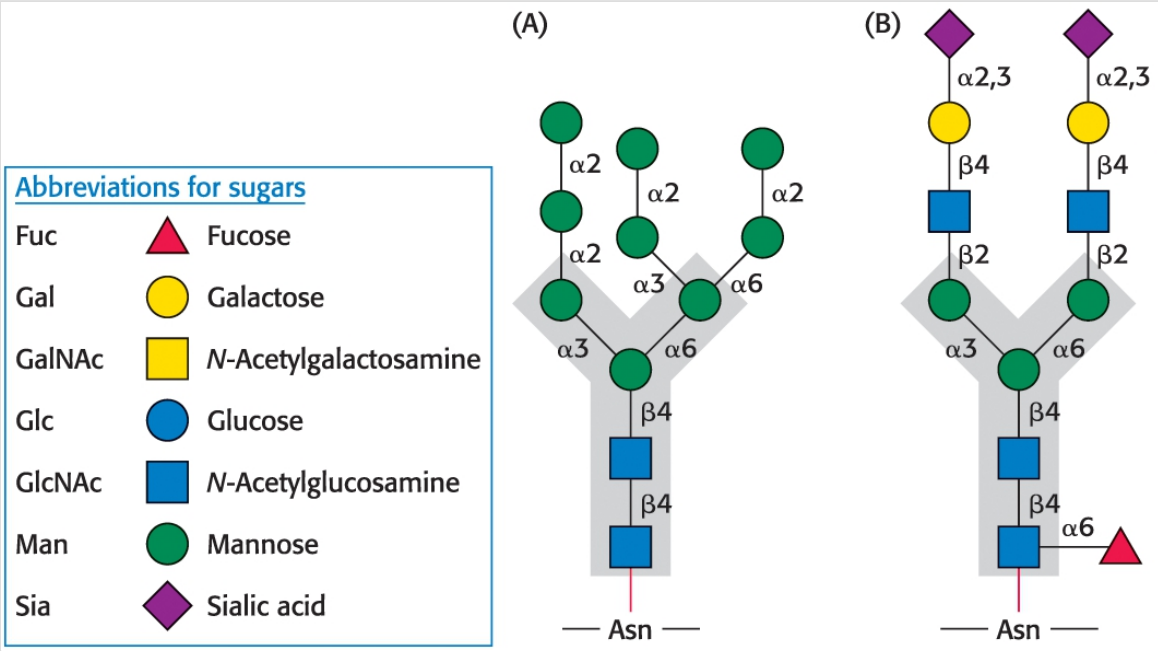

FIGURE 11.17 *N*-linked oligosaccharides have a common core but diverse structures. A pentasaccharide core (shaded gray) is common to all *N*-linked oligosaccharides and serves as th foundation for a wide variety of *N*-linked oligosaccharides, two of which are illustrated: (A) high mannose type; (B) complex type. The carbohydrate structures are depicted symbolically with a scheme widely used by biochemists.

The glycoprotein erythropoietin is a vital hormone

Let us look at a glycoprotein present in the blood serum called *erythropoietin* (EPO), whose cloned recombinant form has dramatically

improved treatment for anemia, particularly that induced by cancer chemotherapy. EPO, which is secreted by the kidneys and stimulates the production of red blood cells, is composed of 165 amino acids and is *N*-glycosylated at three asparagine residues and *O*-glycosylated on a serine residue, resulting in a mature protein that is 40% carbohydrate by weight (**Figure 11.18**). Glycosylation enhances the stability of the protein in the blood; unglycosylated protein has only about 10% of the bioactivity of the glycosylated form because the protein is rapidly removed from the blood by the kidneys.

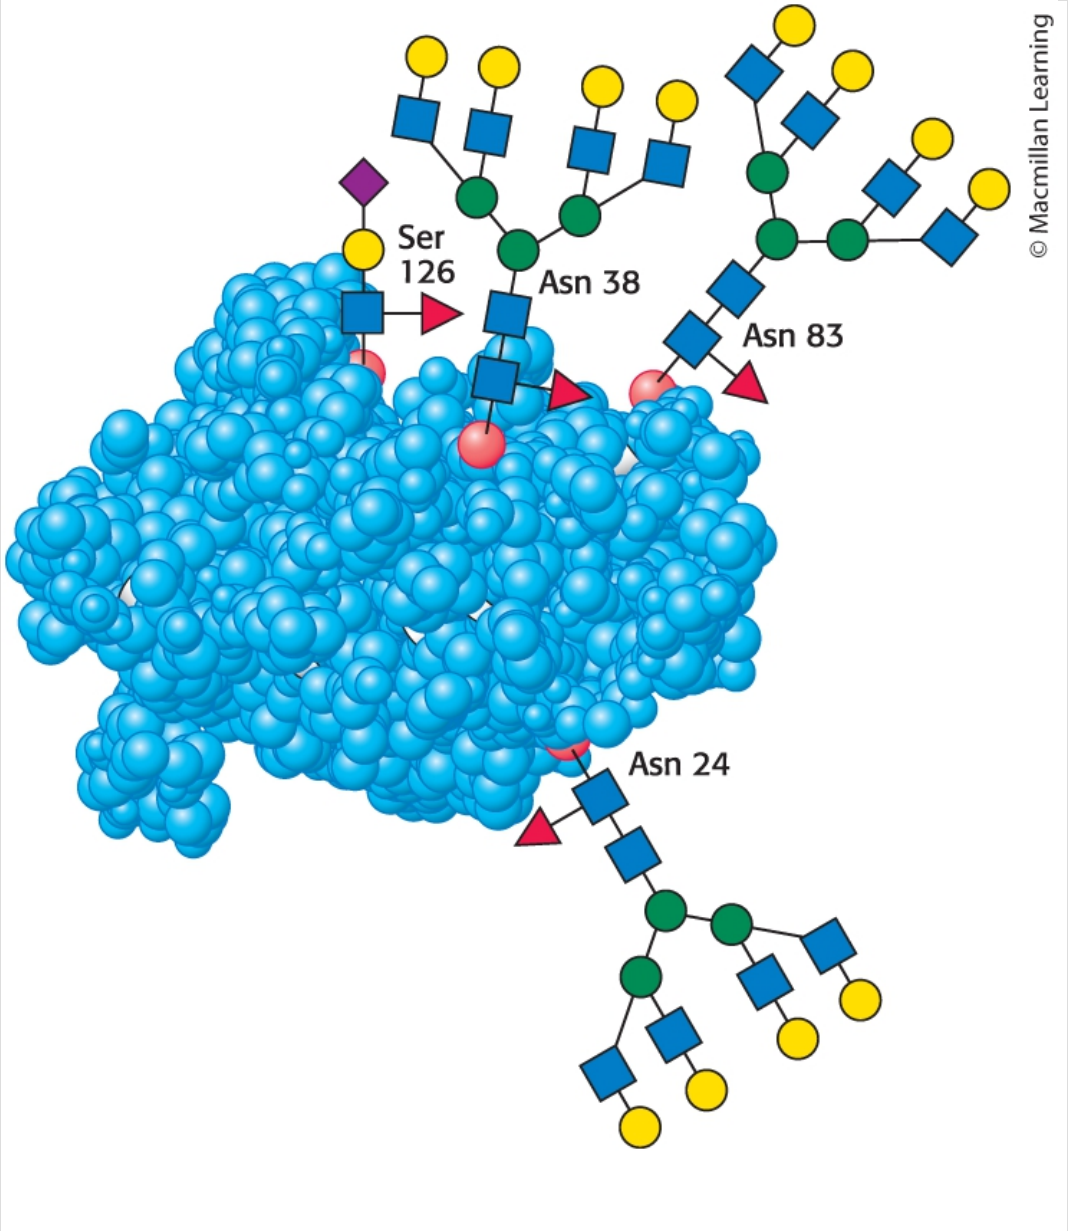

FIGURE 11.18 Erythropoietin has large oligosaccharides linked to three asparagine residues and one serine residue. The structures shown are approximately to scale. See Figure 11.17 for the carbohydrate key.

[Drawn from 1BUY.pdb.]

INTERACT with this model in Achieve

Although the availability of recombinant human EPO has greatly aided the treatment of anemias, some endurance athletes have abused recombinant human EPO to increase the red-blood-cell count and hence their oxygen-carrying capacity. Drug-testing laboratories are able to distinguish some forms of prohibited human recombinant EPO from natural EPO in athletes by detecting differences in their glycosylation patterns.

Glycosylation functions in nutrient sensing

An especially important glycosylation reaction is the covalent attachment of a single *N*-acetylglucosamine (GlcNAc) to serine or threonine residues of cytoplasmic, nuclear, and mitochondrial proteins. The reaction, one of the most common post-translational modifications, is catalyzed by *O*-GlcNAc transferase, a highly conserved enzyme found in all multicellular animals. The concentration of GlcNAc reflects the active metabolism of carbohydrates, amino acids, and fats, indicating that nutrients are abundant (**Figure 11.19**).

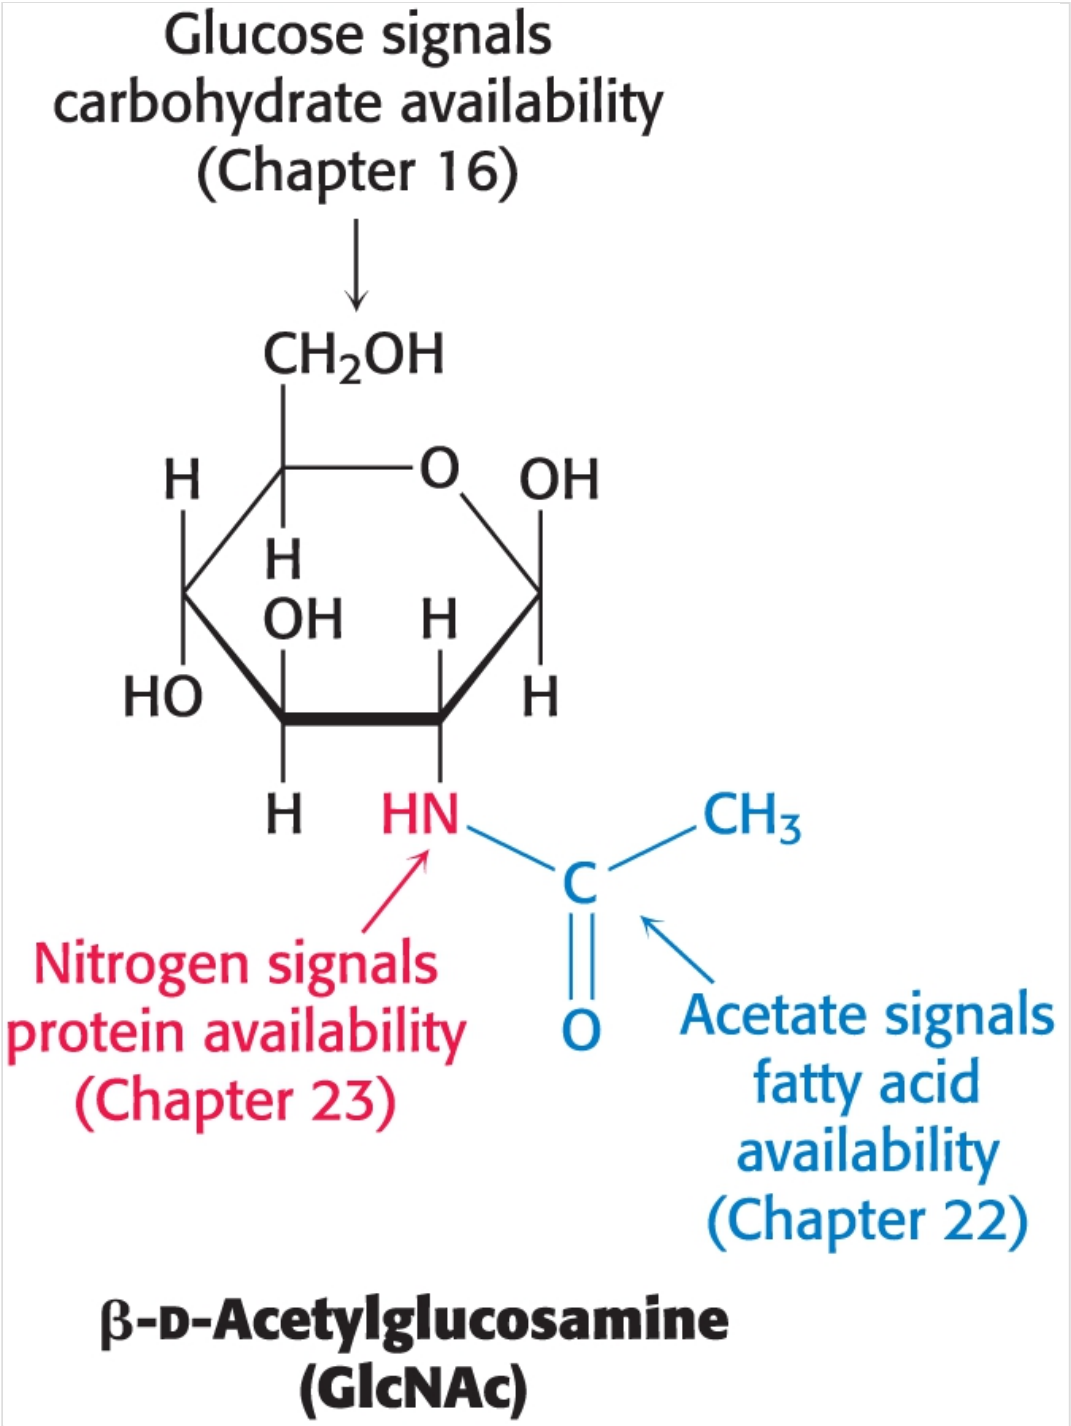

FIGURE 11.19 Glycosylation can serve as a nutrient sensor. *N*-Acetylglucosamine is attached to proteins when nutrients are abundant.

More than 4000 proteins are modified by GlcNAcylation, including transcription factors and components of signaling pathways. Interestingly, because the GlcNAcylation sites are also potential phosphorylation sites, *O*-GlcNAc transferase and protein kinases may be involved in cross talk to modulate one another's signaling activity. Like phosphorylation, GlcNAcylation is reversible, with another enzyme, called *GlcNAcase,* catalyzing the removal of the carbohydrate. Dysregulation of GlcNAc transferase has been linked to insulin resistance, diabetes, cancer, and neurological pathologies.

Proteoglycans have important structural roles

The glycosaminoglycan component of a proteoglycan makes up as much as 95% of the biomolecule by weight, and so a proteoglycan resembles a polysaccharide more than a protein. Proteoglycans not only function as lubricants and structural components in connective tissue but also mediate the adhesion of cells to the extracellular matrix and bind factors that regulate cell proliferation.

The properties of proteoglycans are determined primarily by the glycosaminoglycan component. Many glycosaminoglycans are made of repeating units of disaccharides containing a derivative of an amino sugar, either glucosamine or galactosamine (**Figure 11.20**). At least one of the two sugars in the repeating unit has a negatively charged carboxylate or sulfate group. The major glycosaminoglycans in animals are chondroitin sulfate, keratan sulfate, heparin, dermatan sulfate, and hyaluronate. Recall that heparin acts as an anticoagulant to assist the termination of blood clotting (Section 7.5). The inability to degrade glycosaminoglycans is the cause of a collection of diseases marked by skeletal deformities and reduced life expectancies.

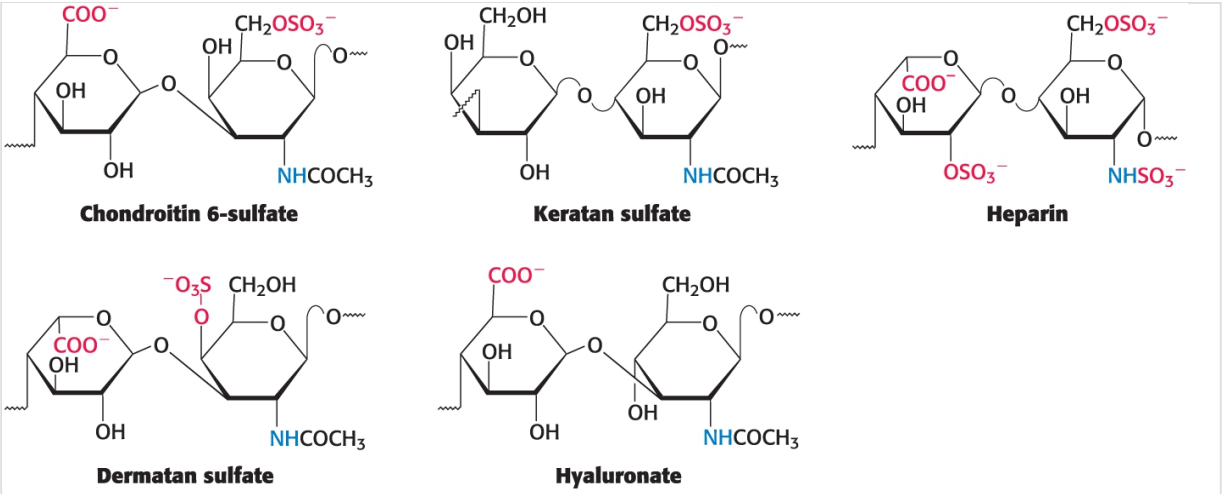

FIGURE 11.20 Glycosaminoglycans are made of repeating units. Structural formulas for five repeating units of important glycosaminoglycans illustrate the variety of possible modifications and linkages. Amino groups are shown in blue and negatively charged groups in red, with hydrogen atoms omitted for clarity. For each molecule shown, the right-hand hexose is a glucosamine derivative.

Proteoglycans are important components of cartilage

Among the best-characterized proteoglycans are those found in the extracellular matrix of cartilage, where they complement the functions of proteins. For example, the triple helix of collagen protein (Section 2.5) provides structure and tensile strength, whereas the proteoglycan aggrecan serves as a shock absorber. The protein component of aggrecan is a large molecule composed of 2397 amino acids with three globular domains (G1, G2, and G3), and the site of glycosaminoglycan attachment is in the extended region between G2 and G3 (**Figure 11.21**). This linear region contains highly repetitive amino acid sequences, which are sites for the attachment of keratan sulfate and chondroitin sulfate. Many molecules of aggrecan are in turn noncovalently bound

through the first globular domain to a very long filament formed by linking together molecules of the sugar component of aggrecan, the glycosaminoglycan hyaluronate (Figure 11.21). In addition, water is bound to the glycosaminoglycans, attracted by the many negative charges.

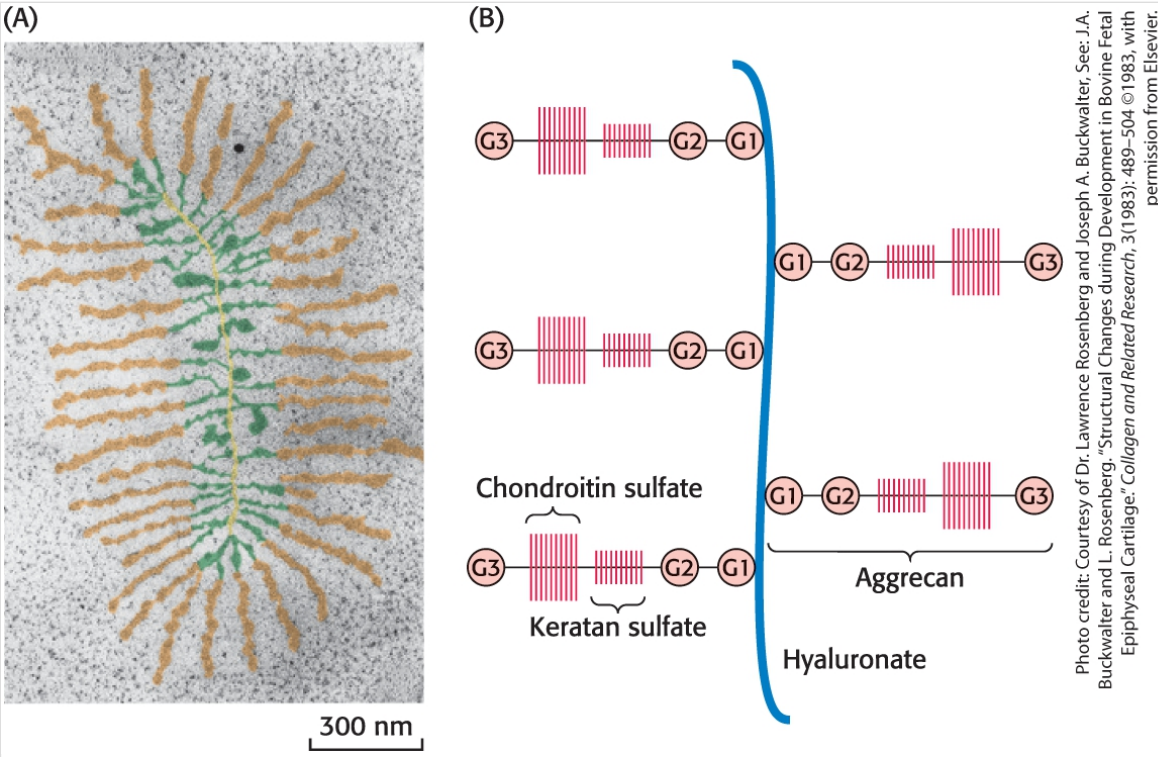

FIGURE 11.21 The proteoglycan from cartilage has an enormous and complex structure. (A) In this electron micrograph of a proteoglycan from cartilage (with false color added), proteoglycan monomers emerge laterally at regular intervals from opposite sides of a central filament of hyaluronate. (B) A schematic representation. The G1 globular domains of multiple aggrecan proteins bind noncovalently to a central polymer of hyaluronate. Multiple polymers of keratan sulfate and chondroitin sulfate glycosaminoglycans are attached to the extended region betwe globular domains G2 and G3 of each aggrecan molecule.

Aggrecan can cushion compressive forces acting on cartilage because the adsorbed water enables it to spring back after having been deformed. When pressure is exerted, as when the foot hits the ground

while walking, water is squeezed from the glycosaminoglycan, cushioning the impact. When the pressure is released, the water rebinds. Osteoarthritis, the most common form of arthritis, results when water is lost from proteoglycan with aging. Other forms of arthritis can result from the proteolytic degradation of aggrecan and collagen in the cartilage.

Mucins are glycoprotein components of mucus

Mucins form large polymeric structures that serve as lubricants in mucous and salivary secretions. These glycoproteins are synthesized by specialized cells in the tracheobronchial, gastrointestinal, and genitourinary tracts.

A model of a mucin is shown in Figure 11.22A. The defining feature of the mucins is a region of the protein backbone termed the *variable number of tandem repeats* (VNTR) region, which is rich in serine and threonine residues that are *O*-glycosylated. Indeed, the carbohydrate moiety can account for as much as 80% of the molecule by weight. A number of core carbohydrate structures are conjugated to the protein component of mucin; Figure 11.22B shows one example.

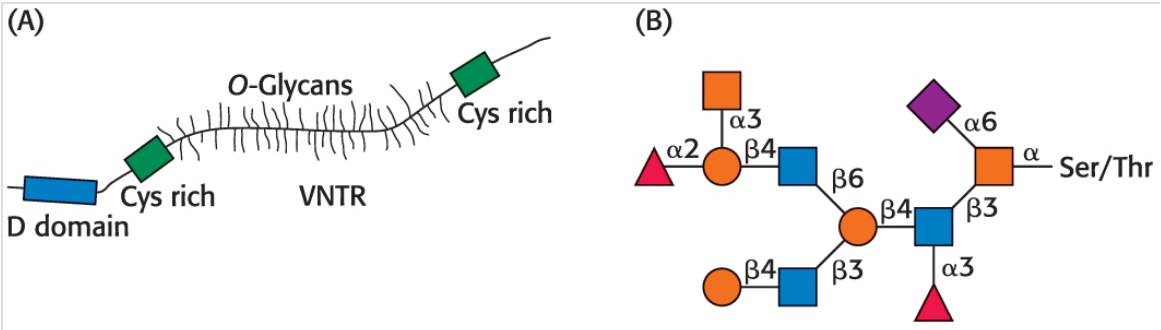

FIGURE 11.22 Mucins have common regions that are heavily *O*-glycosylated. (A) A schematic representation of a mucoprotein. The VNTR region is highly glycosylated, forcing the molecule into an extended conformation. The Cys-rich domains and the D domain facilitate the

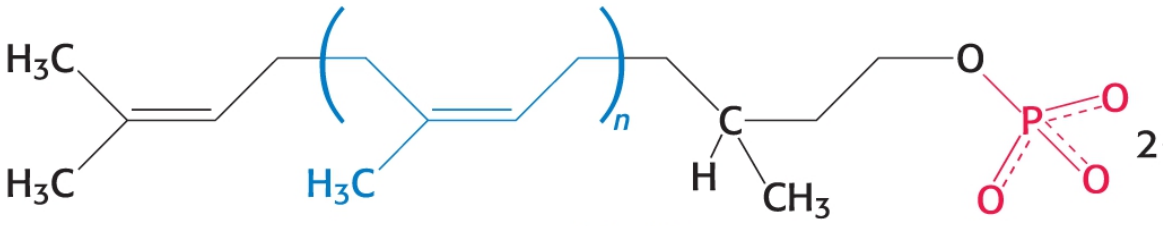
polymerization of many such molecules. (B) An example of an oligosaccharide that is bound to the VNTR region of the protein. See Figure 11.17 for the carbohydrate key.

[Data from A. Varki et al. (Eds.), *Essentials of Glycobiology*, 2nd ed. (Cold Spring Harbor Press, 2009), pp. 117, 118.]

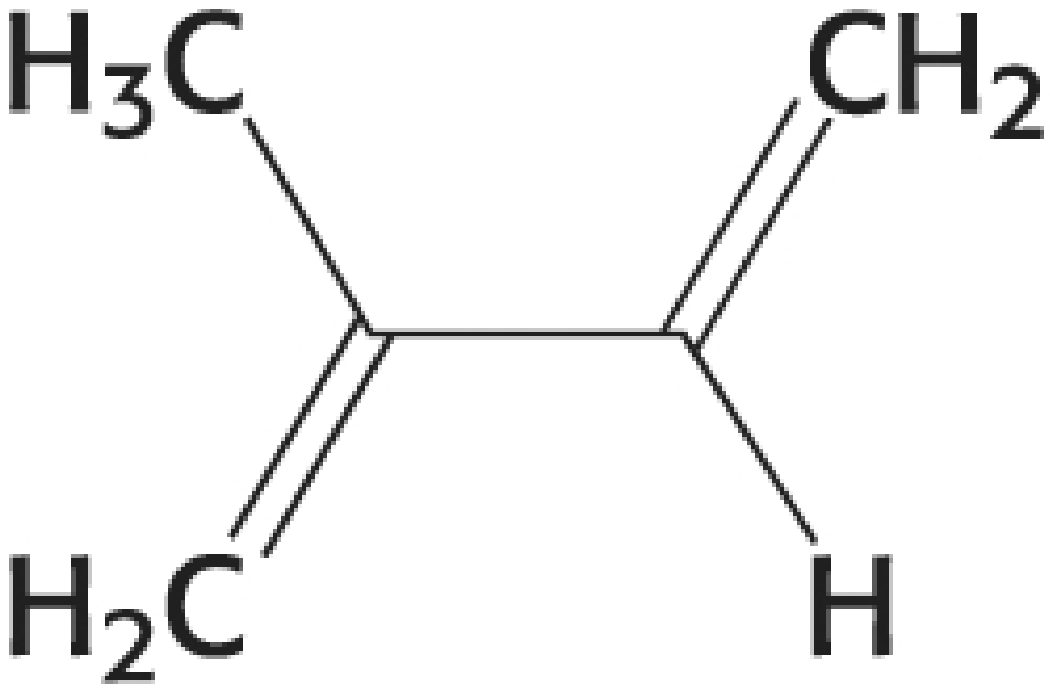
Mucins adhere to epithelial cells and act as a protective barrier; they also hydrate the underlying cells. In addition to protecting cells from environmental insults, such as stomach acid, inhaled chemicals in the lungs, and bacterial infections, mucins have roles in fertilization, the immune response, and cell adhesion. Mucins are overexpressed in bronchitis and cystic fibrosis, and the overexpression of mucins is characteristic of adenocarcinomas — cancers of the glandular cells of epithelial origin.

Protein glycosylation takes place in the lumen of the endoplasmic reticulum and in the Golgi complex



The major pathway for protein glycosylation takes place inside the lumen of the **endoplasmic reticulum (ER)** and in the **Golgi complex**, organelles that play central roles in protein trafficking (**Figure 11.23**). The protein is synthesized by ribosomes attached to the cytoplasmic face of the ER membrane, and the peptide chain is inserted into the lumen of the ER (Section 30.4). The *N*-linked glycosylation begins in the ER and continues in the Golgi complex, whereas the *O*-linked glycosylation takes place exclusively in the Golgi complex.

FIGURE 11.23 The Golgi complex and endoplasmic reticulum are the sites of protein glycosylation. The electron micrograph shows the Golgi complex and adjacent endoplasmic reticulum. The black dots on the cytoplasmic surface of the ER membrane are ribosomes.



A large oligosaccharide destined for attachment to the asparagine residue of a protein is assembled on a specialized lipid molecule called

dolichol phosphate, located in the ER membrane and containing about 20 isoprene (C_5) units.

$n = 15–19$

Dolichol phosphate

Isoprene

The terminal phosphate group of the dolichol phosphate is the site of attachment of the oligosaccharide. This activated (energy-rich) form of the oligosaccharide is subsequently transferred to a specific asparagine residue of the growing polypeptide chain by an enzyme located on the lumenal (interior) side of the ER.

Proteins in the lumen of the ER and in the ER membrane are transported to the Golgi complex, which is a stack of flattened membranous sacs that are the major sorting center of the cell. The *O*-linked sugar units are fashioned there, and the *N*-linked sugars, arriving from the ER as a component of a glycoprotein, are modified in many different ways. Proteins proceed from the Golgi complex to lysosomes, secretory granules, or the plasma membrane, according to signals encoded within their amino acid sequences and three-dimensional structures (**Figure 11.24**).

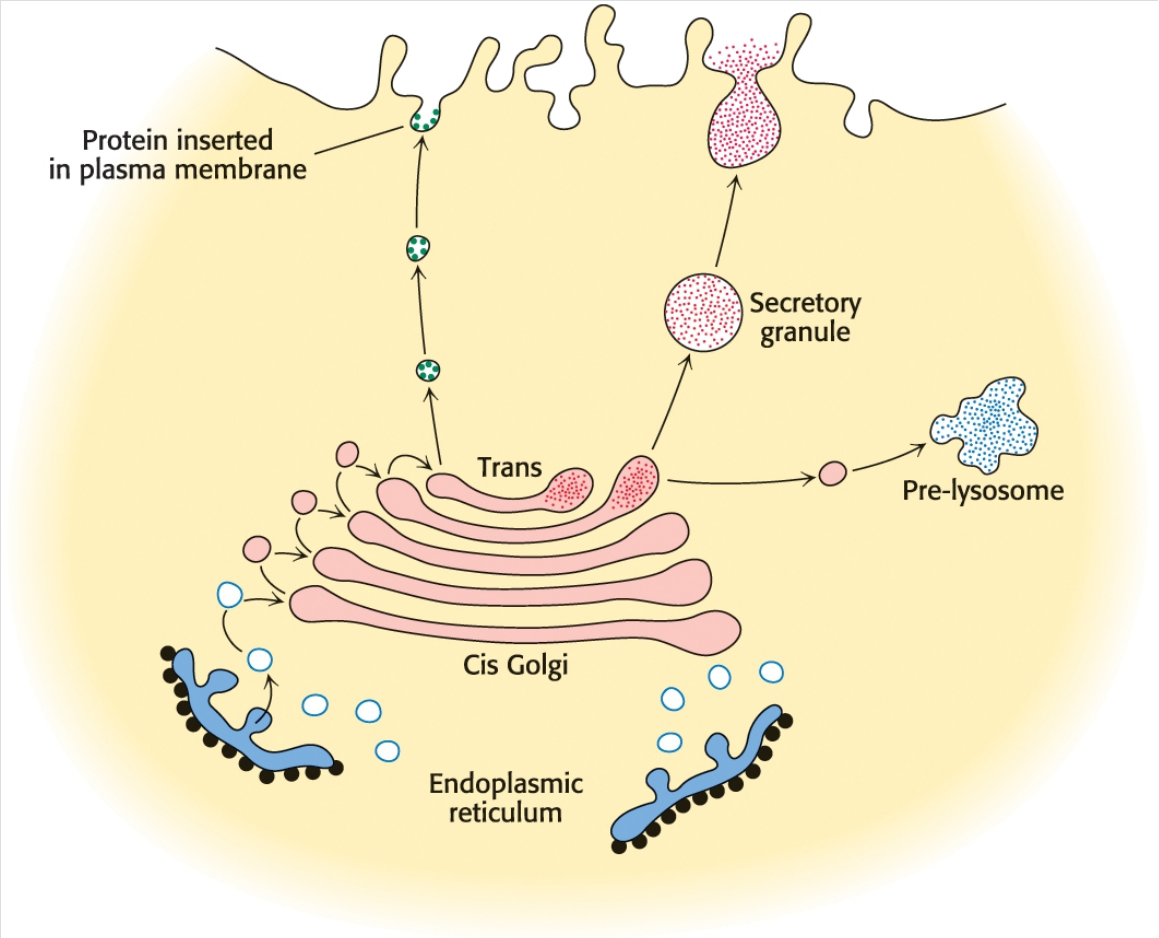


FIGURE 11.24 The Golgi complex is a sorting center. The Golgi complex is the sorting center in the targeting of proteins to lysosomes, secretory vesicles, and the plasma membrane. The cis face of the Golgi complex receives vesicles from the endoplasmic reticulum, and the trans face sends a different set of vesicles to target sites. Vesicles also transfer proteins from one compartment of the Golgi complex to another.

Specific enzymes are responsible for oligosaccharide assembly

Complex carbohydrates are synthesized through the action of specific enzymes called **glycosyltransferases**, which catalyze the formation of glycosidic linkages. Given the diversity of known glycosidic linkages, many different enzymes are required. Indeed, glycosyltransferases account for 1% to 2% of gene products in all organisms examined.

While dolichol phosphate-linked oligosaccharides are substrates for some glycosyltransferases, the most common carbohydrate donors for glycosyltransferases are activated sugar nucleotides, such as UDP-glucose (UDP is the abbreviation for uridine diphosphate; **Figure 11.25**). The attachment of a nucleotide to enhance the energy content of a molecule is a common strategy in biosynthesis that we will see many times in our study of biochemistry. The acceptor substrates for glycosyltransferases are quite varied and include carbohydrates, serine, threonine, and asparagine residues of proteins, lipids, and even nucleic acids.

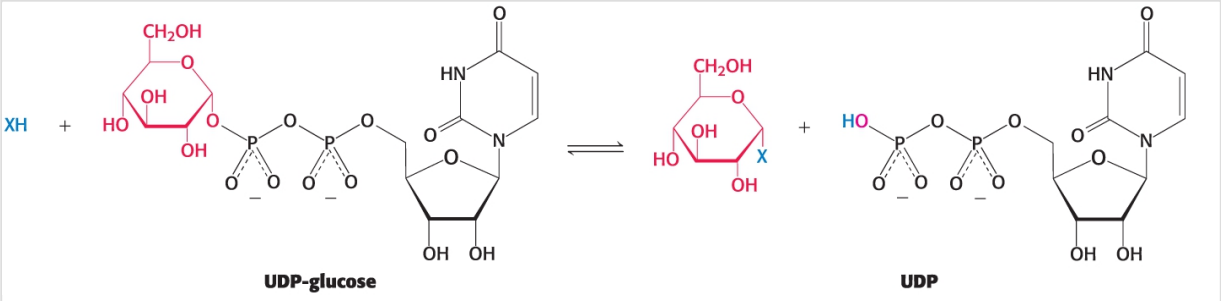

FIGURE 11.25 Glycosyltransferase reactions follow a general form. The sugar to be added comes from a sugar nucleotide — in this case, UDP-glucose. The acceptor, designated X in this illustration, can be one of a variety of biomolecules, including other carbohydrates or proteins.

Blood groups are based on protein glycosylation patterns

The human ABO blood groups illustrate the effects of glycosyltransferases on the formation of glycoproteins. Each blood group is designated by the presence of one of the three different carbohydrates — termed A, B, or O — attached to glycoproteins and glycolipids on the surfaces of red blood cells (Figure 11.26). These structures have in common an oligosaccharide foundation called the O (or sometimes H) antigen. The A and B antigens differ from the O antigen by the addition of one extra monosaccharide, either *N*-acetylgalactosamine (for A) or galactose (for B) through an α-1,3 linkage to a galactose moiety of the O antigen.

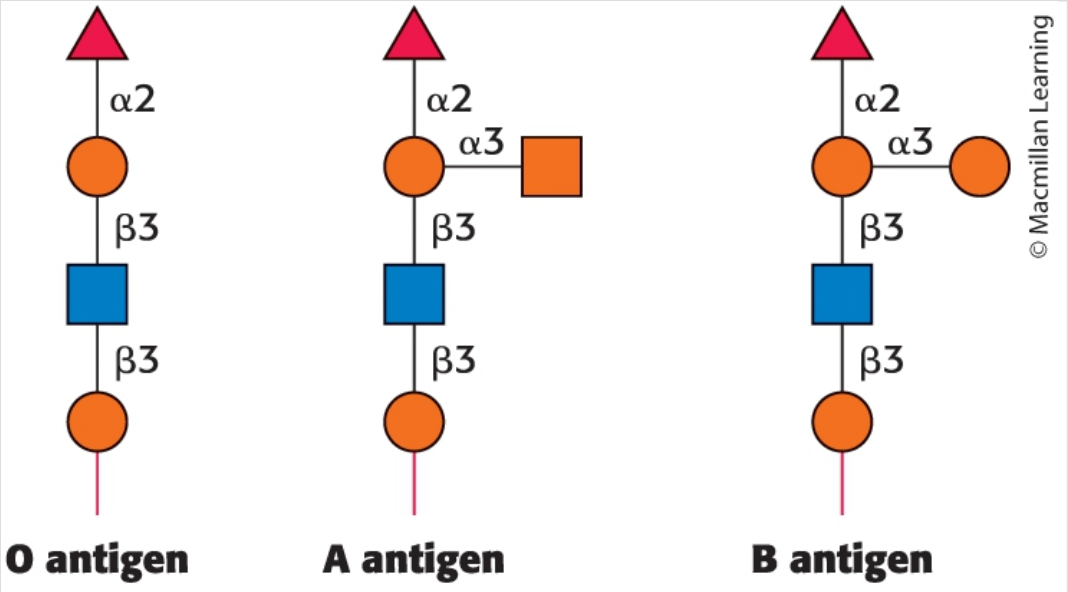

FIGURE 11.26 The A, B, and O oligosaccharide antigens share a common core structure, the O antigen. Different glycosylation patterns account for the different human blood groups.

Specific glycosyltransferases add the extra monosaccharide to the O antigen. Each person inherits the gene for one glycosyltransferase of this type from each parent. The type A transferase specifically adds *N*-acetylgalactosamine, whereas the type B transferase adds galactose. These enzymes are identical in all but 4 of 354 positions. In the AB blood group, both enzymes are present, whereas the O phenotype results if both enzymes are absent.

These structures have important implications for blood transfusions and other transplantation procedures. If an antigen not normally present in a person is introduced, the person's immune system recognizes it as foreign. Red-blood-cell lysis occurs rapidly, leading to a severe drop in blood pressure (hypotension), shock, kidney failure, and death from circulatory collapse.

Why are different blood types present in the human population? Suppose that a pathogenic organism such as a parasite expresses on its cell surface a carbohydrate antigen similar to one of the blood-group antigens. Since this antigen is not detected as foreign in a person whose blood type matches the parasite antigen, the parasite may flourish. However, other people with different blood types will be protected. Hence, there will be selective pressure on human beings to vary blood type to prevent parasitic mimicry and a corresponding selective pressure on parasites to enhance mimicry. The constant "arms race" between pathogenic microorganisms and human beings drives the evolution of diversity of surface antigens within the human population.

 One example of a disease affected by blood type is cholera. Millions of cases of this disease, caused by the organism *Vibrio cholerae*, occur around the world each year, leading to tens of thousands of deaths. Blood type does not appear to influence the likelihood of contracting cholera, but individuals with blood type O are approximately eight times more likely to have severe disease. Biochemical studies show that the O antigen binds more tightly to the

toxin responsible for disease symptoms than do the other blood type antigens (Figure 11.27). The impact of these interactions on human society is revealed by the observation that the frequency of blood type O is notably low in regions where cholera has been endemic for centuries.

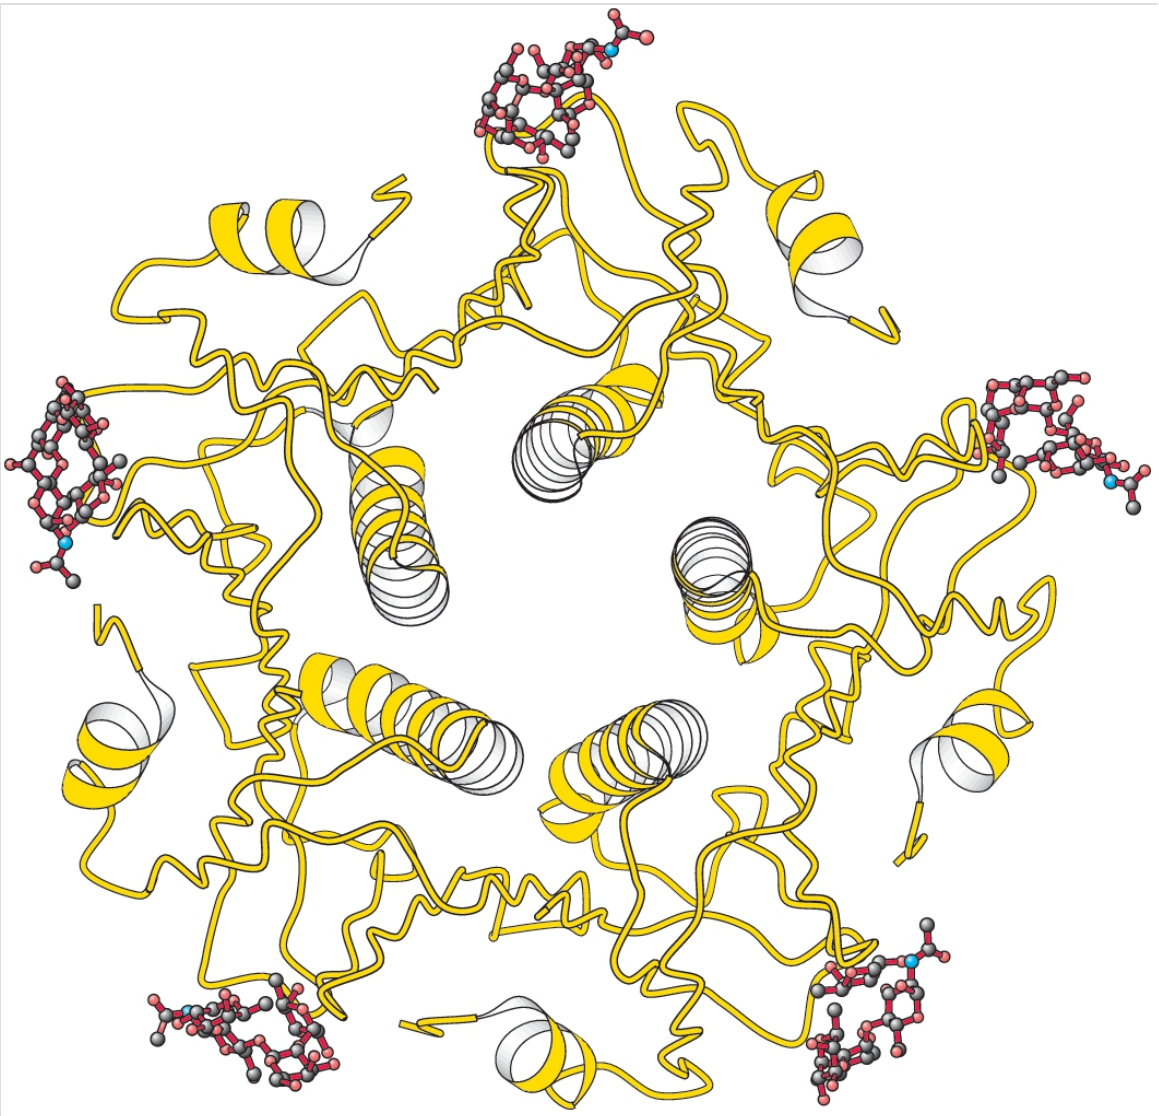

FIGURE 11.27 Cholera toxin makes specific noncovalent interactions with the O antigen, resulting in higher affinity binding. Cholera toxin is shown in yellow and the O antigen as a bal and-stick model.

Errors in glycosylation can result in pathological conditions

Protein function is often compromised when proteins are improperly glycosylated, sometimes resulting in disease. For instance, certain types of muscular dystrophy can be traced to improper glycosylation of dystroglycan, a membrane protein that links the extracellular matrix with the cytoskeleton. Indeed, an entire family of severe inherited human diseases called *congenital disorders of glycosylation* has been identified. These pathological conditions reveal the importance of proper modification of proteins by carbohydrates and their derivatives.

An especially clear example of the role of glycosylation is provided by I-cell disease, a lysosomal storage disease. Normally, a carbohydrate marker directs certain digestive enzymes from the Golgi complex to organelles called *lysosomes*, which degrade and recycle damaged cellular components or material brought into the cell by endocytosis. In patients with I-cell disease, affected lysosomes contain large inclusions of undigested glycosaminoglycans and glycolipids — hence the "I" in the name of the disease — because the enzymes normally responsible for the degradation of glycosaminoglycans are missing. Remarkably, the enzymes are present at very high levels in the blood and urine. Thus, active enzymes are synthesized, but, in the absence of appropriate glycosylation, they are exported instead of being sequestered in lysosomes.

In other words, in I-cell disease, a whole series of enzymes are incorrectly addressed and delivered to the wrong location. Normally, these enzymes contain a mannose 6-phosphate residue as a component of an *N*-oligosaccharide that serves as the marker directing the enzymes from the Golgi complex to lysosomes. In I-cell disease, however, the attached mannose lacks a phosphate. I-cell patients are deficient in the

N-acetylglucosamine phosphotransferase catalyzing the first step in the addition of the phosphoryl group; the consequence is the mistargeting of eight essential enzymes (**Figure 11.28**). I-cell disease causes the patient to suffer severe psychomotor impairment and skeletal deformities. Interestingly, mutations in the phosphotransferase have also been linked to stuttering. Why some mutations cause stuttering while others cause I-cell disease is a mystery.

First, GlcNAc phosphotransferase adds a phospho-*N*-acetylglucosamine unit to the 6-OH group of a mannose; second, an *N*-acetylglucosaminidase removes the added sugar to generate a mannose 6-phosphate residue in the core oligosaccharide.

Biochemists use several techniques to analyze the oligosaccharide components of glycoproteins

How is it possible to determine the structure of a glycoprotein — the oligosaccharide structures and their points of attachment? Most approaches make use of enzymes that cleave oligosaccharides at specific types of linkages.

The first step is to detach the oligosaccharide from the protein. For example, *N*-linked oligosaccharides can be released from proteins by an enzyme such as peptide *N*-glycosidase F, which cleaves the *N*-glycosidic linkages connecting the oligosaccharide to the protein. The oligosaccharides can then be isolated and analyzed.

Matrix-assisted laser desorption/ionization/time-of-flight (MALDI-TOF) or other mass spectrometric techniques (Section 4.3) provide the mass of an oligosaccharide fragment; however, many possible oligosaccharide structures are consistent with a given mass. More complete information can be obtained by cleaving the oligosaccharide with enzymes of varying specificities. For example, β-1,4-galactosidase cleaves β-glycosidic linkages exclusively at galactose residues. The products can again be analyzed by mass spectrometry (**Figure 11.29**). The repetition of this process with the use of an array of enzymes of

different specificity will eventually reveal the structure of the oligosaccharide.

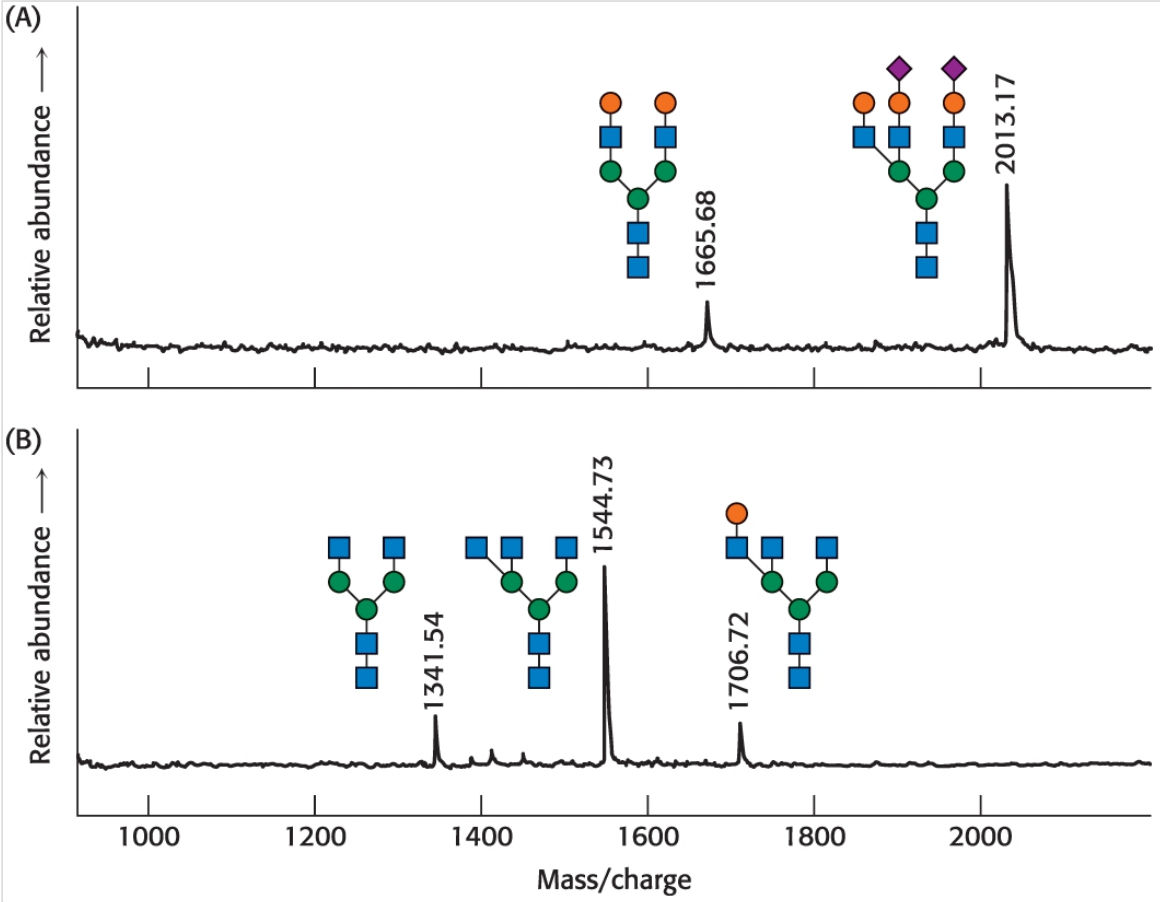

FIGURE 11.29 Oligosaccharides can be characterized by mass spectrometry. Carbohydrate-cleaving enzymes were used to release and specifically cleave the oligosaccharide component c the glycoprotein fetuin. Parts A and B show the masses obtained with MALDI-TOF spectrometry as well as the corresponding structures of the oligosaccharide-digestion products: (A) digestion with peptide *N*-glycosidase F (to release the oligosaccharide from the protein) and neuraminidase (which cleaves at sialic acid residues); (B) digestion with peptide *N*-glycosidase neuraminidase, and β-1,4-galactosidase. Knowledge of the enzyme specificities and the masses of the products permits the characterization of the oligosaccharide. See Figure 11.17 for the carbohydrate key.

[Data from A. Varki, R. D. Cummings, J. D. Esko, H. H. Freeze, G. W. Hart, and J. Marth (Eds.), *Essentials of Glycobiolo* (Cold Spring Harbor Laboratory Press, 1999), p. 596.]

Biochemists can also locate the points of oligosaccharide attachment by applying proteases to glycoproteins. Cleavage by a specific protease yields a characteristic pattern of peptide fragments that can be analyzed chromatographically. Fragments attached to oligosaccharides can be picked out because their chromatographic properties will change on glycosidase treatment. Mass spectrometric analysis or direct peptide sequencing can reveal the identity of the peptide in question and, with additional effort, the exact site of oligosaccharide attachment.

Self-Check Question

Just as all the proteins made by an organism at any given moment are called the *proteome*, all the carbohydrates and carbohydrate-associated molecules can be called the *glycome.* Compare the amount of information inherent in the genome, the proteome, and the glycome.

11.4 Lectins Are Specific Carbohydrate-Binding Proteins

The diversity and complexity of the carbohydrate units and the variety of ways in which they can be joined in oligosaccharides and polysaccharides attest to their biochemical importance. Evolution rarely results in complex patterns when simpler ones are equally effective, so why all this intricacy and diversity? It is now clear that these carbohydrate structures are the recognition sites for a distinct class of proteins. Such proteins, termed *glycan-binding proteins*, bind specific carbohydrate structures on neighboring cell surfaces. Originally discovered in plants, glycan-binding proteins are ubiquitous, and no living organisms have been found that lack these key proteins.

We will focus on a particular class of glycan-binding proteins termed **lectins** (from Latin *legere*, "to select"). The interaction of lectins with their carbohydrate partners is another example of carbohydrates being information-rich molecules that guide many biological processes. The diverse carbohydrate structures displayed on cell surfaces are well-suited to serving as sites of interaction between cells and their environments. Interestingly, the partners for lectin binding are often the carbohydrate moiety of glycoproteins.

Lectins promote interactions between cells and within cells

Cell–cell contact is a vital interaction in a host of biochemical functions, ranging from building a tissue from isolated cells to facilitating the transmission of information. The chief function of lectins is to facilitate cell–cell contact. A lectin usually contains two or more carbohydrate-binding sites, whereby the lectins on the surface of one cell interact

with arrays of carbohydrates displayed on the surface of another cell. Lectins and carbohydrates are linked by a number of weak noncovalent interactions that ensure specificity yet permit unlinking as needed. The weak interactions between one cell surface and another resemble the action of Velcro; each interaction is weak, but the composite is strong.

We have already met a lectin in this chapter, although we didn't name it as such. Recall that, in I-cell disease, lysosomal enzymes lack the appropriate mannose 6-phosphate, a molecule that directs the enzymes to the lysosome. Under normal circumstances, the mannose 6-phosphate receptor, a lectin, binds the enzymes in the Golgi apparatus and directs them to the lysosome. Not surprisingly, I-cell disease can also be caused by a loss of the mannose 6-phosphate receptor.

Lectins are organized into two large classes

Lectins can be divided into two large classes on the basis of their amino acid sequences and biochemical properties.

C-type lectins

C-type (for calcium-requiring) lectins are found in animals. These proteins each have a homologous domain of 120 amino acids that is responsible for carbohydrate binding. The structure of one such domain bound to a carbohydrate target is shown in **Figure 11.30**.

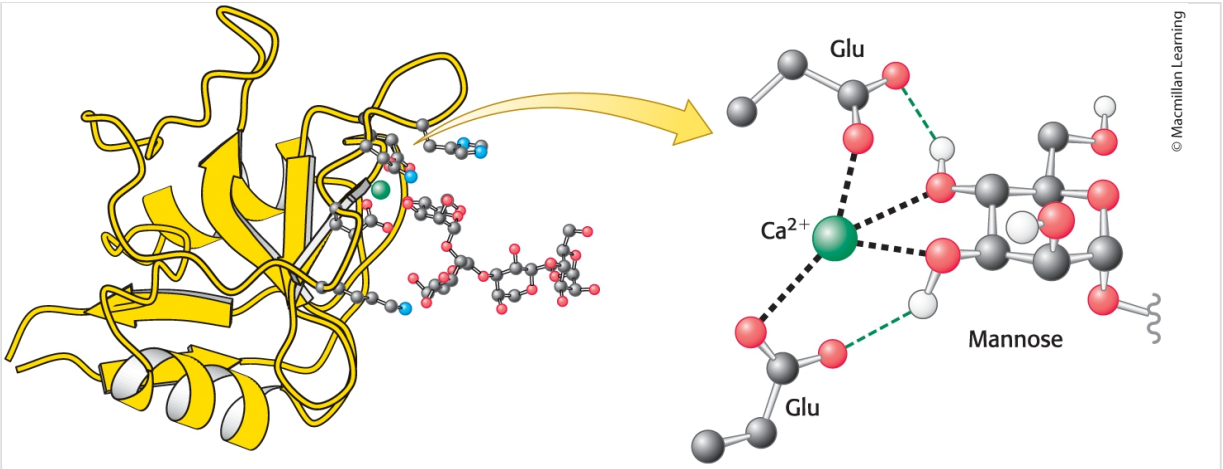

FIGURE 11.30 C-type lectins use calcium ions to bind carbohydrates. Selected interactions of the carbohydrate-binding domain of an animal C-type lectin are shown, with some hydrogen atoms omitted for clarity. A calcium ion tightly bound to two Glu residues of the lectin binds to a mannose residue of the carbohydrate moiety.

[Drawn from 2MSB.pdb.]

INTERACT with this model in Achieve

A calcium ion on the protein acts as a bridge between the protein and the sugar through direct interactions with sugar OH groups. In addition, two glutamate residues in the protein bind to both the calcium ion and the sugar, and other protein side chains form hydrogen bonds with other OH groups on the carbohydrate. The carbohydrate-binding specificity of a particular lectin is determined by the amino acid residues that bind the carbohydrate. C-type lectins function in a variety of cellular activities, including receptor-mediated endocytosis — a process by which soluble molecules are bound to the cell surface and subsequently internalized (Section 27.3) — and cell–cell recognition.

C-type proteins known as **selectins** bind immune-system cells to sites of injury in the inflammatory response. The L, E, and P forms of selectins bind specifically to carbohydrates on lymph-node vessels, endothelium, or activated blood platelets, respectively. Selectins play central roles in

recruiting leukocytes (white blood cells) to sites of inflammation. By participating in a large set of interactions, each of which is relatively weak, selectins can bring cells together where other molecules of the surfaces of the two cells are positioned to interact if they have appropriate affinities for one another.

L-type lectins

The other large class of lectins comprises the L-type lectins. These lectins are especially rich in the seeds of leguminous plants such as beans and peas; many of the initial biochemical characterizations of lectins were performed on these particular lectins because they are so readily available. Although the exact role of lectins in plants is unclear, they can serve as potent toxins to herbivorous insects. Other L-type lectins, such as calnexin and calreticulin, are prominent chaperones in the eukaryotic endoplasmic reticulum. Recall that chaperones are proteins that facilitate the folding of other proteins (Section 2.7).

JAMES TENSUAN/The New York Times/Redux

CAROLYN BERTOZZI Chemist Carolyn Bertozzi is a leader in developing the field of glycobiology and communicating its exciting possibilities. Initially planning to go to medical school, her interest in chemistry developed in college, and she went on to complete a PhD focused on synthesizing carbohydrate-containing molecules and using them as probes for biological systems. After postdoctoral training, she joined the faculty at the University of California, Berkeley, where her training as a synthetic chemist allowed her to think about how to make new molecules with desired properties. She and her coworkers invented new tools for probing the roles of carbohydrates in biology, including those that allow the synthesis of new molecules in living organisms. Her talent was recognized with a MacArthur “genius” grant early in her career. In addition to winning research grants from various governmental agencies, she has been supported by the Howard Hughes Medical Institute, a leading funder of cutting-edge biomedical research since 2000. She now teaches and does research at Stanford University.

Influenza virus binds to sialic acid residues

Many pathogens gain entry into specific host cells by adhering to cell-surface carbohydrates. For example, influenza virus recognizes sialic acid residues (Figure 11.10) linked to galactose residues that are present on cell-surface glycoproteins. The viral protein that binds to these sugars is a lectin called *hemagglutinin* (**Figure 11.31A**).

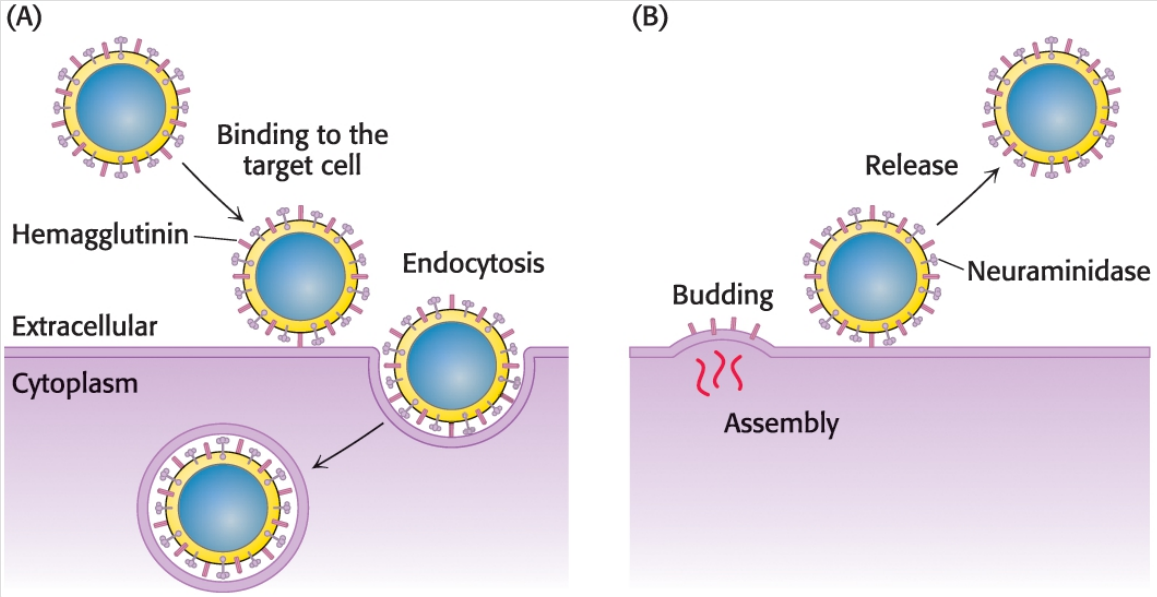

FIGURE 11.31 Influenza virus uses a lectin for specific cell binding. (A) Influenza virus targets cells by binding to sialic acid residues located at the termini of oligosaccharides present on cell-surface glycoproteins and glycolipids. These carbohydrates are bound by the lectin hemagglutinin, one of the major proteins expressed on the surface of the virus. (B) When viral replication is complete, the components (red lines) assemble and the viral particle buds from th cell. The other major viral-surface protein, neuraminidase, cleaves oligosaccharide chains to release the viral particle.

After binding hemagglutinin, the virus is engulfed by the cell and begins to replicate. Viral assembly concludes with the budding of the viral particle from the cell (**Figure 11.31B**). Upon complete assembly, the viral particle is still attached to sialic acid residues of the cell membrane

by hemagglutinin on the surface of the new virions. Another viral protein, neuraminidase (sialidase), cleaves the glycosidic linkages between the sialic acid residues and the rest of the cellular glycoprotein, freeing the virus to infect new cells, and thus spreading the infection throughout the respiratory tract. Inhibitors of this enzyme such as oseltamivir (Tamiflu) and zanamivir (Relenza) are important anti-influenza agents.

Viral hemagglutinin's carbohydrate-binding specificity may play an important role in species specificity of infection and ease of transmission. For instance, avian influenza H5N1 (bird flu) is especially lethal and is readily spread between birds. Although human beings can be infected by this virus, infection is rare and human-to-human transmission rarer still. The biochemical basis of these characteristics is that the avian virus hemagglutinin recognizes a different carbohydrate moiety from that recognized by human influenza hemagglutinin. Although human beings have carbohydrate residues that the avian virus might recognize and bind, they are located deep in the lungs. Infection by the avian virus is thus difficult, and, when it does occur, the avian virus is not readily transmitted by sneezing or coughing.

Chapter 11 Summary

11.1 Monosaccharides Are the Simplest Carbohydrates

- Carbohydrates are aldoses or ketoses that are rich in hydroxyl groups, and their derivatives. The simplest are monosaccharides — sugars that are three to seven carbons in length.
- Pentoses and hexoses can close into five-membered furanose rings or six-membered pyranose rings. Pyranose rings usually adopt the chair conformation, and furanose rings usually adopt the envelope conformation. These ring structures are in rapid equilibrium with the linear forms in aqueous solutions.
- In sugars undergoing cyclization, an additional asymmetric center is formed, resulting in α and β anomer forms that differ by the position of the hydroxyl group on the anomeric carbon. In monosaccharides, these anomers rapidly interchange via the linear form.
- D-Glucose is the most common sugar in living organisms and is the human "blood sugar" most likely because it can form a six-membered ring with all bulky groups in the equatorial positions. As a reducing sugar, it can nonenzymatically react with hemoglobin to form glycated hemoglobin, an important biomarker for diabetes.
- Sugars are joined to alcohols and amines by glycosidic linkages from the anomeric carbon atom. For example, *N*-glycosidic linkages connect sugars to purines and pyrimidines in nucleotides, RNA, and DNA.

11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

- Sugars are linked to one another in disaccharides and polysaccharides by *O*-glycosidic linkages.
- Sucrose, lactose, and maltose are common disaccharides.
- Sucrose (table sugar) consists of α-glucose and β-fructose joined by a glycosidic linkage between their anomeric carbon atoms.
- Lactose (in milk) consists of galactose joined to glucose by a β-1,4 linkage.
- Maltose (from starch) consists of two glucoses joined by an α-1,4 linkage.
- Starch is a storage homopolymer of glucose in plants; glycogen serves a similar role in animals. Glucose units in starch and glycogen are in α-1,4 linkages with α-1,6 linked branches.
- Cellulose, the major structural polymer of plant cell walls, consists of glucose units joined by β-1,4 linkages, which give rise to long straight chains that form fibrils with high tensile strength.
- Chitin is the major structural polymer of fungal cell walls and the exoskeletons and shells of arthropods. Like cellulose, it is a homopolymer composed of β-1,4 linkages, but the monomeric unit is GlcNAc rather than glucose.

11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins

- Carbohydrates are commonly conjugated to proteins; in glycoproteins, the protein component is predominant.
- Most secreted proteins, such as the signal molecule erythropoietin, are glycoproteins that are prominent on the external surface of the plasma membrane.
- Glycosaminoglycans are polymers of repeating disaccharides with a derivative of glucosamine or galactosamine and a high density of carboxylate or sulfate groups.
- Proteoglycans — proteins bearing covalently linked glycosaminoglycans — are found in the extracellular matrices of

animals and are key components of cartilage.
- Mucoproteins, like proteoglycans, serve as lubricants and are predominantly carbohydrate by weight, with the protein component heavily *O*-glycosylated with *N*-acetylgalactosamine joining the oligosaccharide to the protein.
- Glycosyltransferases link the oligosaccharide units on proteins in the lumen of the endoplasmic reticulum. Additional sugars are attached in the Golgi complex to form diverse patterns.

11.4 Lectins Are Specific Carbohydrate-Binding Proteins

- Carbohydrates on cell surfaces are recognized by proteins called lectins. In animals, the interplay of lectins and their sugar targets guides cell–cell contact as well as viral entry.
- Lectins also play a role inside the cell, such as directing proteins to their proper cellular locations and assisting in protein folding.

Key Terms

monosaccharide
epimers
anomers
reducing sugar
glycosidic linkage
oligosaccharide
disaccharide
polysaccharide
glycogen
starch
cellulose
glycoprotein
proteoglycan

glycosaminoglycan
mucin (mucoprotein)
endoplasmic reticulum (ER)
Golgi complex
glycosyltransferase
lectin
selectin

Problems

1. Which of the following are aldoses? 1

a. glyceraldehyde
b. glucose
c. fucose
d. fructose

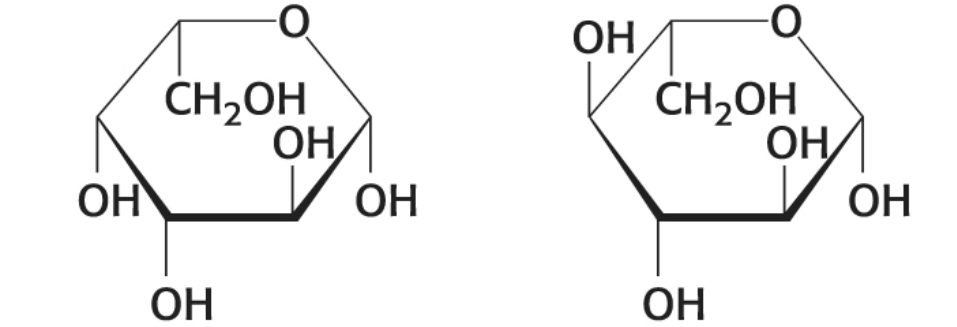
2. Which of the following are reducing sugars? 1

a. sucrose
b. ribose
c. fructose
d. glucose
e. lactose

3. Which of the following is found in glycogen and starch? 2

a. fructose
b. β-D-glucose
c. mannose
d. α-D-glucose

4. How many different oligosaccharides can be made by linking one glucose, one mannose, and one galactose? Assume that each sugar is in its pyranose form. Compare this number with the number of tripeptides that can be made from three different amino acids. 2

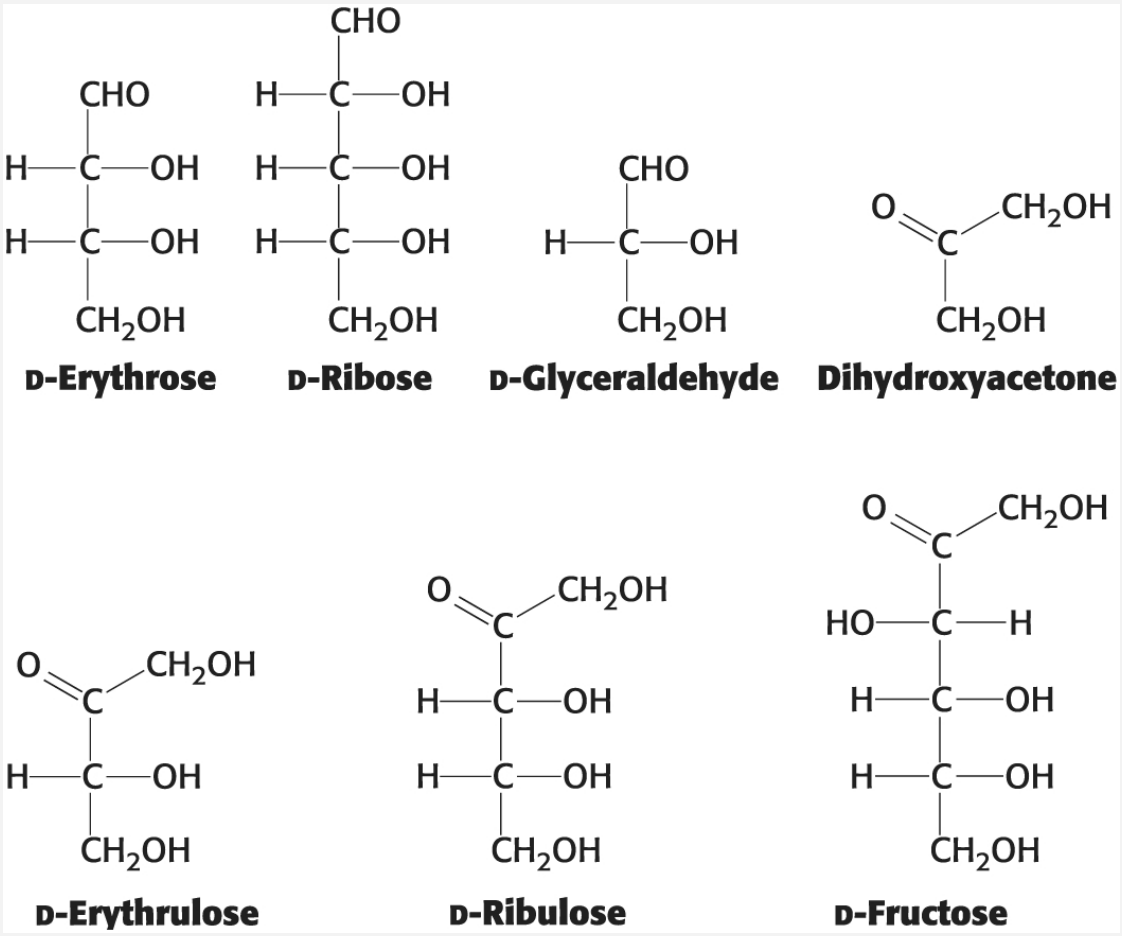


5. Match each term with its description. 1, 2

1. Enantiomers	1. Has the molecular formula $(CH_2O)_n$
2. Cellulose	2. Monosaccharides that differ at a single asymmetric carbon atom
3. Lectins	3. The storage form of glucose in animals
4. Glycosyltransferases	4. The storage form of glucose in plants
5. Epimers	5. Glycoprotein containing glycosaminoglycans
6. Starch	6. The most abundant organic molecule in the biosphere
7. Carbohydrates	7. *N*-Acetylgalactosamine is a key component of this glycoprotein
8. Proteoglycan	8. Carbohydrate-binding proteins
9. Mucoprotein	9. Enzymes that synthesize oligosaccharides
10. Glycogen	10. Stereoisomers that are mirror images of each other

6. Indicate whether each of the following pairs of sugars consists of anomers, epimers, or an aldose–ketose pair: 1

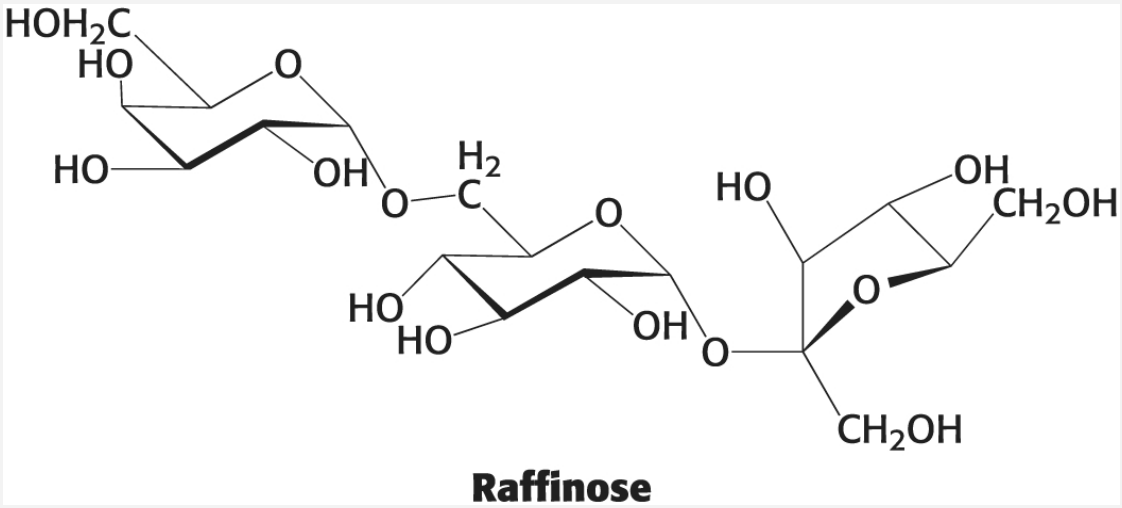
a. D-glyceraldehyde and dihydroxyacetone
b. D-glucose and D-mannose
c. D-glucose and D-fructose
d. α-D-glucose and β-D-glucose
e. D-ribose and D-ribulose
f. D-galactose and D-glucose



7. Analyze the pair of compounds. 1

Which of the terms explains the relationship between the two compounds?

a. Anomers
b. Epimers
c. Diastereomers
d. Enantiomers



8. To which classes of sugars do the monosaccharides shown here belong? 1

9. The specific rotations of the α and β anomers of D-glucose are $+112$ degrees and $+18.7$ degrees, respectively. Specific rotation, $[\alpha]_D$, is defined as the observed rotation of light of wavelength 589 nm (the D line of a sodium lamp) passing through 10 cm of a $1\ g\ ml^{-1}$ solution of a sample. When a crystalline sample of α-D-glucose is dissolved in water, the

specific rotation decreases from 112 degrees to an equilibrium value of 52.7 degrees. On the basis of this result, what are the proportions of the α and β anomers at equilibrium? Assume that the concentration of the open-chain form is negligible. 1

10. Raffinose is a trisaccharide and a minor constituent in sugar beets. 2

Raffinose

a. Is raffinose a reducing sugar? Explain.
b. What are the monosaccharides that compose raffinose?
c. α-Galactosidase is an enzyme that will remove galactose residues from an oligosaccharide. What are the products of α-galactosidase treatment of raffinose?

11.

a. Compare the number of reducing ends to nonreducing ends in a molecule of glycogen.

b. As we will see in Chapter 21, glycogen is an important fuel-storage form that is rapidly mobilized. At which end — the reducing or nonreducing — would you expect most metabolism to take place? 2

12. Glucose and fructose are reducing sugars. Sucrose, or table sugar, is a disaccharide consisting of both fructose and glucose. Is sucrose a reducing sugar? Which statements about reducing sugars are true? 1, 2

a. A reducing sugar will not react with the Cu^{2+} in Fehling's reagent.
b. D-Arabinose (an aldose) is a reducing sugar.
c. The oxidation of a reducing sugar forms a carboxylic acid sugar.
d. Reducing sugars contain ketone groups instead of aldehyde groups.
e. A disaccharide with its anomeric carbons joined by the glycosidic linkage (like sucrose) cannot be a reducing sugar.

13. For each statement below, write which polymers apply from the following list: chitin, glycogen, cellulose, starch. 2

a. Provides structural support for plants
b. Consists of *N*-acetylglucosamine monomers
c. Is a storage form of carbohydrate in animal cells
d. Is a homopolymer
e. Is branched

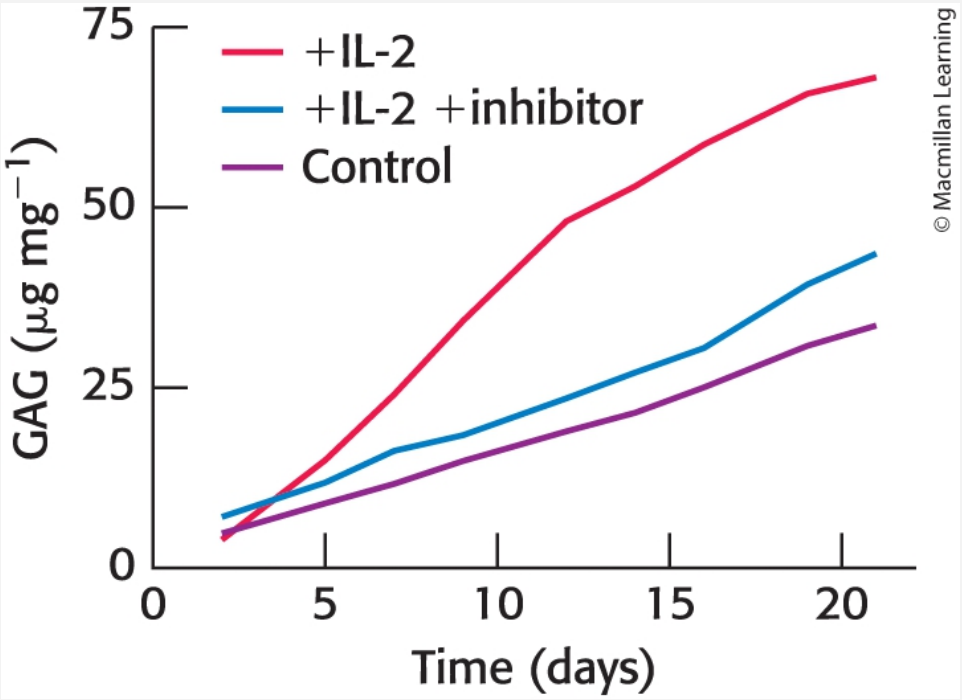
14. List the key classes of glycoproteins, their defining characteristics, and their biological functions. 1, 4

15. Proteoglycans are part of the extracellular matrix; they provide structure, viscosity and lubrication, and adhesiveness.

They are composed of proteins conjugated to carbohydrate components called glycosaminoglycans. The glycosaminoglycan component makes up the majority of the mass of a proteoglycan. Which statements about glycosaminoglycans are true? 3, 4

a. β-D-Fructofuranose and amylose are possible components of glycosaminoglycans.
b. Glycosaminoglycans are heteropolysaccharides composed of repeating disaccharide units.
c. Chondroitin sulfate and heparin are examples of glycosaminoglycans.
d. Glycosaminoglycans are homopolysaccharides composed of repeating glucosamine or galactosamine residues.
e. Because glycosaminoglycans consist of only two residues, they generally have low molecular weights.

16. Which amino acids are used for the attachment of carbohydrates to proteins? 3

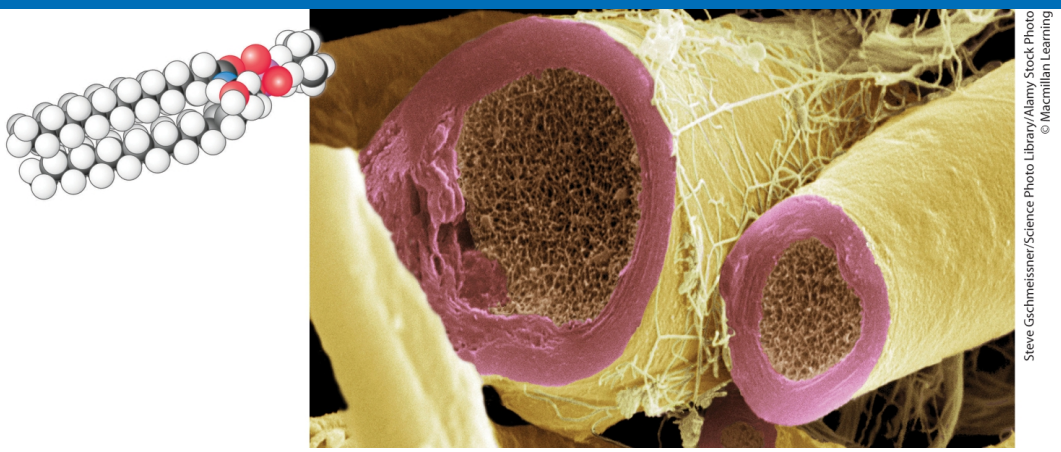


17. Differentiate between a glycoprotein and a lectin. 4, 5

18. Suppose that a protein contains six potential *N*-linked glycosylation sites. How many possible proteins can be generated, depending on which of these sites is actually glycosylated? Do not include the effects of diversity within the carbohydrate added. 3

19. How might the technique of affinity chromatography be used to purify lectins? 5

20. A contributing factor to the development of arthritis is the inappropriate proteolytic destruction of the aggrecan component of cartilage by the proteolytic enzyme aggrecanase.



The immune-system signal molecule interleukin 2 (IL-2) activates aggrecanase; in fact, IL-2 blockers are sometimes used to treat arthritis. Studies were undertaken to determine whether inhibitors of aggrecanase could counteract the effects of IL-2. Pieces of cartilage were incubated in media with various additions, and the amount of aggrecan destruction was measured as a function of time.

a. Aggrecan degradation was measured by the release of glycosaminoglycan. What is the rationale for this assay?
b. Why might glycosaminoglycan release not indicate aggrecan degradation?
c. What is the purpose of the control (cartilage incubated with no additions)?
d. What is the effect of adding IL-2 to the system?

e. What is the response when an aggrecanase inhibitor is added in addition to IL-2?
f. Why is there some aggrecan destruction in the control with the passage of time?

Chapter 12
Lipids and Biological Membranes

Myelin sheaths, such as those seen in this scanning electron micrograph (in pink), enable rapid transmission of electrical impulses in neurons. These membranes, rich in phospholipids such as sphingomyelin (above), wrap around nerve fibers multiple times to create the biological equivalent of an insulated wire. The importance of these structures is emphasized by the existence of demyelination disorders, such as multiple sclerosis, where the myelin sheaths degrade over time.

Outline

12.1 Fatty Acids Are Key Constituents of Lipids
12.2 Biological Membranes Are Composed of Three Common Types of Membrane Lipids
12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media

12.4 Proteins Carry Out Most Membrane Processes
12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane
12.6 Prokaryotes and Eukaryotes Differ in Their Use of Biological Membranes

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the structure of a fatty acid and explain how it is named.
2. Define the three most common types of membrane lipids.
3. Explain how membrane lipids self-assemble into bimolecular sheets.
4. Distinguish between integral and peripheral membrane proteins.
5. Describe how proteins interact with membranes and how membrane-spanning motifs within proteins may be identified.
6. Explain the properties of membrane fluidity and its dependence upon lipid composition.
7. Explain the importance of membranes in eukaryotic cells.

The boundaries of all cells are defined by biological membranes, dynamic structures in which proteins float in a sea of lipids. The lipid component prevents molecules generated inside the cell from leaking out and unwanted molecules from diffusing in, while the protein components act as transport systems that allow the cell to take up specific molecules and remove unwanted ones. In addition to an external cell membrane, eukaryotic cells also contain internal membranes that form the boundaries of organelles such as mitochondria, chloroplasts, peroxisomes, and lysosomes.

Biological membranes serve several additional functions indispensable for life, such as energy storage and information

transduction. The proteins associated with the membrane define these functions for any given cell. In this chapter, we will examine the properties of membrane proteins that enable them to exist in the hydrophobic environment of the membrane while connecting two hydrophilic environments. In the next chapter, we will discuss the functions of these proteins.

12.1 Fatty Acids Are Key Constituents of Lipids

By definition, **lipids** are water-insoluble biomolecules that are highly soluble in organic solvents such as chloroform. The hydrophobic properties of lipids are essential to their ability to form membranes. Most lipids owe their hydrophobic properties to one component, their fatty acids.

Fatty acid names are based on their parent hydrocarbons

Let us first consider how fatty acids are named and distinguished from one another. **Fatty acids** are long hydrocarbon chains of various lengths and numbers of double bonds that terminate with carboxylic acid groups. The systematic name for a fatty acid is derived from the name of its parent hydrocarbon by the substitution of *oic* for the final *e.* For example, the C_{18} saturated fatty acid — that is, containing no double bonds — is called *octadecanoic acid* because the parent hydrocarbon is octadecane. A C_{18} fatty acid with one double bond is called octadec*enoic* acid; with two double bonds, octadeca*dienoic* acid; and with three double bonds, octadeca*trienoic* acid. The notation 18:0 denotes a C_{18} fatty acid with no double bonds, whereas 18:2 signifies that there are two double bonds. The structures of the ionized forms of two common fatty acids — palmitic acid (16:0) and oleic acid (18:1) — are shown in **Figure 12.1**.

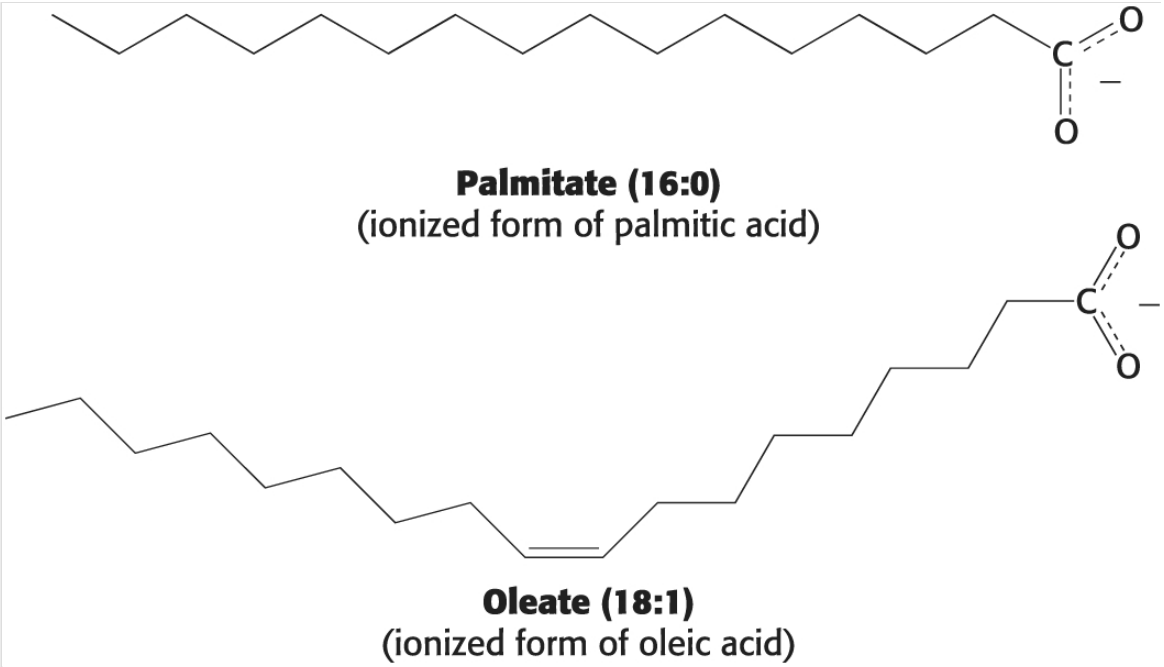

FIGURE 12.1 Fatty acids vary in their chain length and degree of saturation. For example, palmitate is a 16-carbon, saturated fatty acid (16:0), while oleate is an 18-carbon fatty acid with a single cis double bond (18:1).

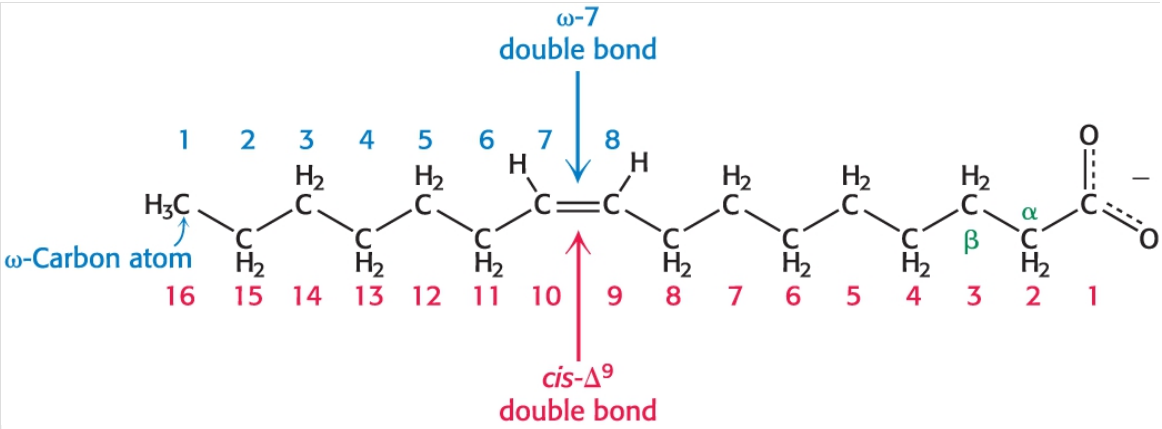
Fatty acid carbon atoms are numbered starting at the carboxyl terminus (Figure 12.2). Carbon atoms 2 and 3 are often referred to as α and β, respectively. The methyl carbon atom at the distal end of the chain is called the *ω-carbon atom.* The position of a double bond is represented by the symbol Δ followed by a superscript number. For example, *cis*-Δ^9 means that there is a cis double bond between carbon atoms 9 and 10; *trans*-Δ^2 means that there is a trans double bond between carbon atoms 2 and 3. Alternatively, the position of a double bond can be denoted by counting from the distal end, with the ω-carbon atom (the methyl carbon) as number 1. Fatty acids are ionized at physiological pH, and so it is appropriate to refer to them according to their carboxylate form; for example, palmitate or hexadecanoate.



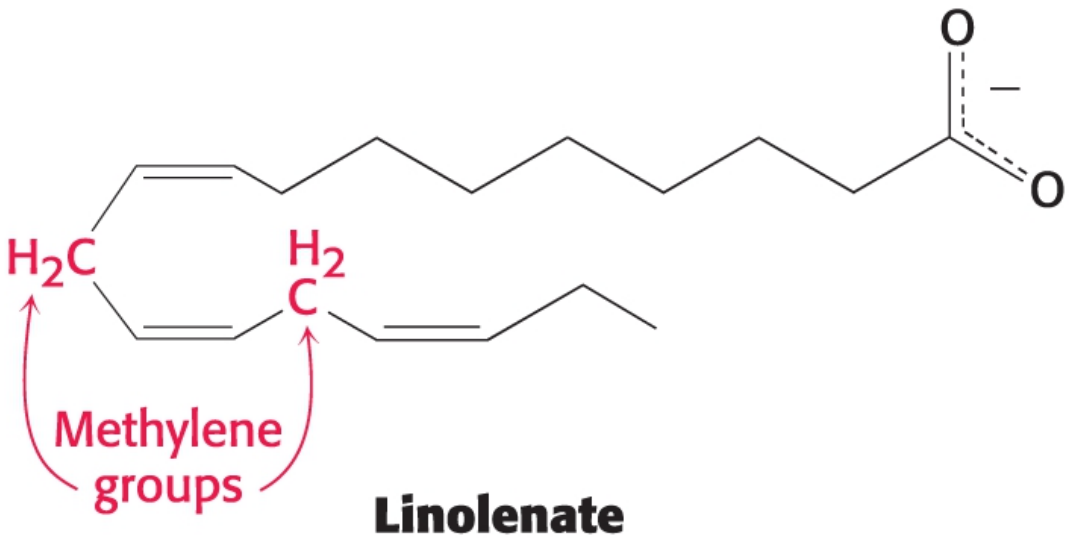


FIGURE 12.2 Fatty acid carbon atoms can be numbered in two ways. In one method (red), the carbon atoms are numbered starting with the carbonyl carbon. Carbon atoms numbered 2 and 3 are often referred to as α and β, respectively (green). The position of a double bond is indicated by the number of the carbon closest to carbon atom 1. Alternatively, carbons can be counted from the distal end, or the ω carbon (blue). For example, a double bond between the ω-7 and ω-8 carbons would be called a ω-7 double bond, as shown.

Chain length and degree of unsaturation affect fatty acid properties

Fatty acids in biological systems usually contain an even number of carbon atoms, typically between 14 and 24 (**Table 12.1**), with the 16- and 18-carbon fatty acids being the most common. The dominance of fatty acid chains containing an even number of carbon atoms reflects the manner in which fatty acids are biosynthesized (Chapter 27). The hydrocarbon chain is almost invariably unbranched in animal fatty acids. The alkyl chain may be saturated, or it may contain one or more double bonds. The configuration of the double bonds in most unsaturated fatty acids is cis. The double bonds in polyunsaturated fatty acids are separated by at least one methylene group.

Linolenate

TABLE 12.1 Some naturally occurring fatty acids in animals

Number of carbons	Number of double bonds	Common name	Systematic name	Formula
12	0	Laurate	*n*-Dodecanoate	$CH_3(CH_2)_{10}COO^-$
14	0	Myristate	*n*-Tetradecanoate	$CH_3(CH_2)_{12}COO^-$
16	0	Palmitate	*n*-Hexadecanoate	$CH_3(CH_2)_{14}COO^-$
18	0	Stearate	*n*-Octadecanoate	$CH_3(CH_2)_{16}COO^-$
20	0	Arachidate	*n*-Eicosanoate	$CH_3(CH_2)_{18}COO^-$

22	0	Behenate	*n*-Docosanoate	$CH_3(CH_2)_{20}COO^-$
24	0	Lignocerate	*n*-Tetracosanoate	$CH_3(CH_2)_{22}COO^-$
16	1	Palmitoleate	*cis*-Δ^9-Hexadecenoate	$CH_3(CH_2)_5CH=CH(CH_2)_7COO^-$
18	1	Oleate	*cis*-Δ^9-Octadecenoate	$CH_3(CH_2)_7CH=CH(CH_2)_7COO^-$
18	2	Linoleate	*cis, cis*-Δ^9, Δ^{12}-Octadecadienoate	$CH_3(CH_2)_4(CH=CHCH_2)_2(CH)_6COO^-$
18	3	Linolenate	all-*cis*-$\Delta^9, \Delta^{12}, \Delta^{15}$-Octadecatrienoate	$CH_3CH_2(CH=CHCH_2)_3(CH_2)_6COO^-$
20	4	Arachidonate	all-*cis* $\Delta^5, \Delta^8, \Delta^{11}, \Delta^{14}$-Eicosatetraenoate	$CH_3(CH_2)_4(CH=CHCH_2)_4(CH_2)_2COO^-$

The properties of fatty acids and of lipids derived from them are markedly dependent on chain length and degree of saturation. Unsaturated fatty acids have lower melting points than do saturated fatty acids of the same length. For example, the melting point of stearic acid is 69.6°C, whereas that of oleic acid (which contains one cis double bond) is 13.4°C. The melting points of polyunsaturated fatty acids of the C_{18} series are even lower. Chain length also affects the melting point, as illustrated

by the fact that the melting temperature of palmitic acid (C_{16}) is 6.5 degrees lower than that of stearic acid (C_{18}). Thus, short chain length and unsaturation enhance the fluidity of fatty acids and of their derivatives.

12.2 Biological Membranes Are Composed of Three Common Types of Membrane Lipids

Lipids have a variety of biological roles: they serve as fuel molecules, highly concentrated energy stores, signal molecules and messengers in signal-transduction pathways, and components of membranes. The first three roles of lipids will be considered in later chapters. Here, we will explore the role of lipids as the essential component of biological membranes.

In order to appreciate the structural and chemical properties of membrane lipids, let us first consider the membranes themselves. While biological membranes are as diverse in structure as they are in function, they do have in common a number of important attributes:

- Membranes are sheetlike structures, only two molecules thick, that form closed boundaries between different compartments. The thickness of most membranes is between 60 Å (6 nm) and 100 Å (10 nm).
- Membranes consist mainly of lipids and proteins. The mass ratio of lipids to proteins ranges from 1:4 to 4:1. Membranes also contain carbohydrates that are linked to lipids and proteins.
- Membrane lipids are small molecules that have both hydrophilic and hydrophobic moieties. These lipids spontaneously form closed bimolecular sheets in aqueous media. These sheets, called *lipid bilayers*, are barriers to the flow of polar molecules.
- Specific proteins mediate distinctive functions of membranes. Proteins serve as pumps, channels, receptors, energy transducers,

and enzymes. Membrane proteins are embedded in lipid bilayers, which create suitable environments for their action.

- Membranes are noncovalent assemblies. The constituent protein and lipid molecules are held together by many noncovalent interactions, which act cooperatively.
- Membranes are asymmetric. The two faces of biological membranes always differ from each other.
- Membranes are fluid structures. Lipid molecules diffuse rapidly in the plane of the membrane, as do proteins, unless they are anchored by specific interactions. In contrast, lipid molecules and proteins do not readily rotate across the membrane. Membranes can be regarded as two-dimensional solutions of oriented proteins and lipids.
- Most cell membranes are electrically polarized, such that the inside is negatively charged. Membrane potential plays a key role in transport, energy conversion, and excitability (Chapter 13).

Here, our focus is on the principal lipids found in the membranes of eukaryotes and bacteria: *phospholipids*, *glycolipids*, and *cholesterol*. While the membrane lipids of archaea are distinct, they have many features related to membrane formation in common with lipids of other organisms.

Phospholipids are the major class of membrane lipids

Phospholipids are abundant in all biological membranes. A **phospholipid** molecule is constructed from four components (**Figure 12.3**):

- One or more fatty acids

- A platform to which the fatty acids are attached
- A phosphate
- An alcohol attached to the phosphate

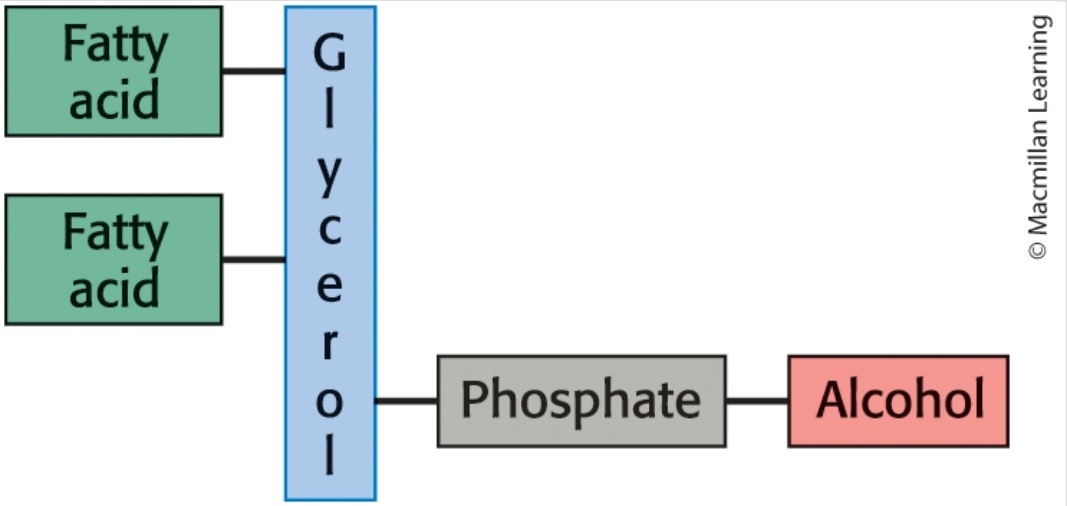

FIGURE 12.3 A phospholipid molecule contains four components. These components are shown here in schematic form: (1) fatty acids (green), (2) a platform for fatty acid attachment (here, glycerol, shown in blue), (3) a phosphate (gray), and (4) an alcohol (red).

The fatty acid components provide a hydrophobic barrier, whereas the remainder of the molecule has hydrophilic properties that enable interaction with the aqueous environment.

The platform on which phospholipids are built may be glycerol, a three-carbon alcohol, or sphingosine, a more complex alcohol. Phospholipids derived from glycerol are called **phosphoglycerides**. A phosphoglyceride consists of a glycerol backbone to which are attached two fatty acid chains and a phosphorylated alcohol.

In phosphoglycerides, the hydroxyl groups at C-1 and C-2 of glycerol are esterified to the carboxyl groups of the two fatty acid chains (**Figure 12.4**). The C-3 hydroxyl group of the glycerol backbone is esterified to phosphoric acid. When no further additions are made, the resulting compound is phosphatidate (diacylglycerol 3-phosphate), the simplest phosphoglyceride. Although only small amounts of phosphatidate are present in membranes, it is a key intermediate in the biosynthesis of the other phosphoglycerides (Section 27.1). The absolute configuration of the glycerol 3-phosphate moiety of membrane lipids is shown in Figure 12.4.

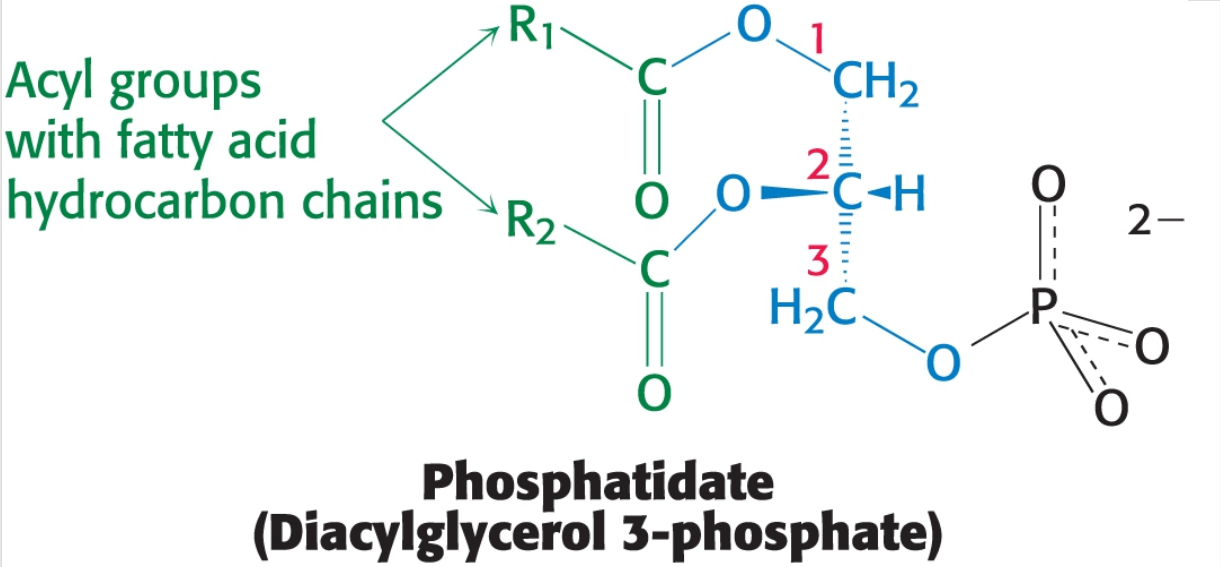

FIGURE 12.4 Phosphatidate, the simplest phosphoglyceride, does not contain an alcohol component. The absolute configuration of the center carbon (C-2) is shown.

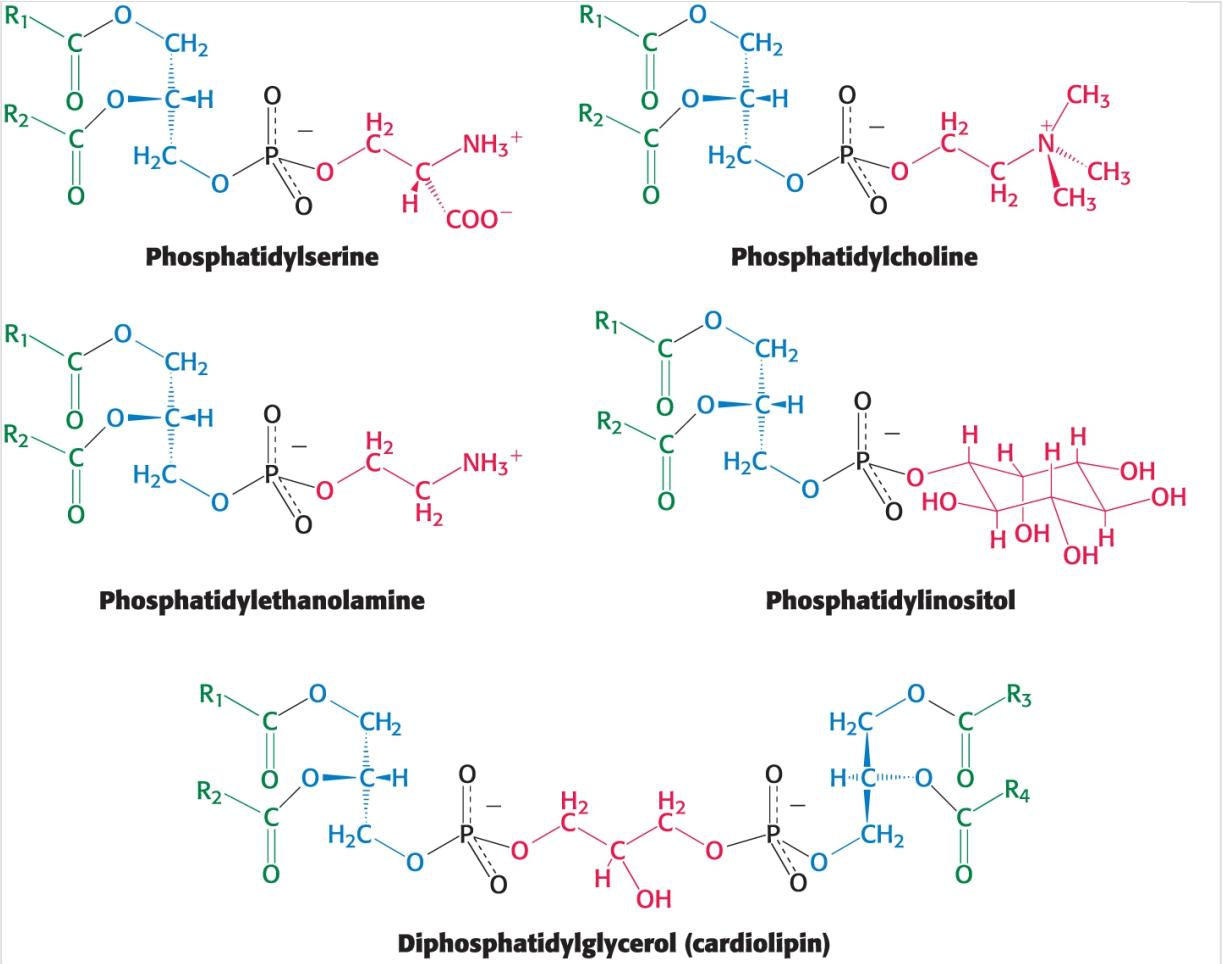
The major phosphoglycerides are derived from phosphatidate by the formation of an ester bond between the phosphate group of phosphatidate and the hydroxyl group of one of several alcohols (**Figure 12.5**).



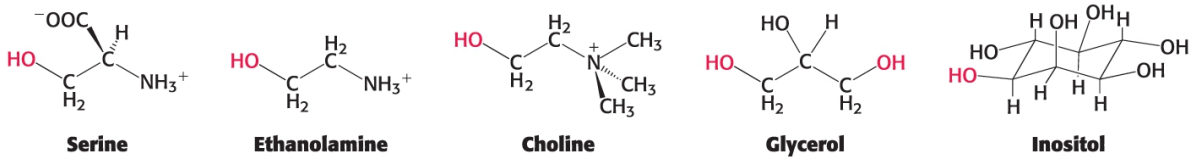


FIGURE 12.5 The common phosphoglycerides found in membranes contain an ester bond between phosphatidate and an alcohol. These structures are colored to match the four phospholipid components depicted in Figure 12.3.

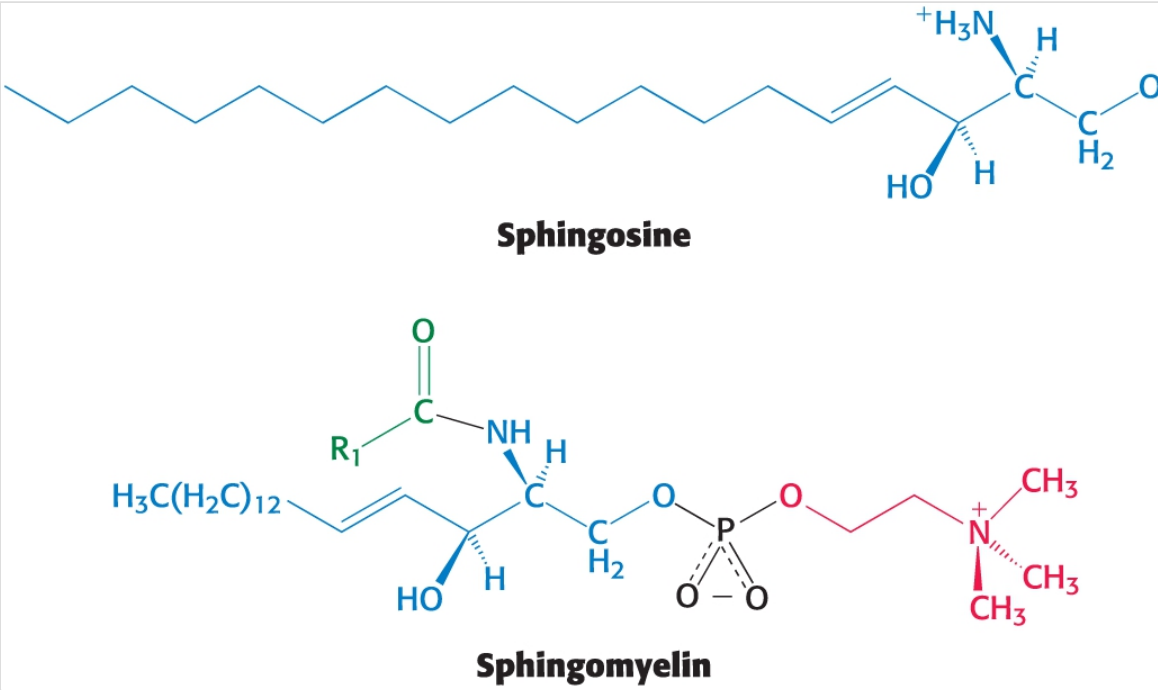
The common alcohol moieties of phosphoglycerides are the amino acid serine, ethanolamine, choline, glycerol, and inositol.

Sphingomyelin is a phospholipid found in membranes that is not derived from glycerol. Instead, the backbone in sphingomyelin is **sphingosine**, an amino alcohol that contains a long, unsaturated hydrocarbon chain (**Figure 12.6**). In sphingomyelin, the amino group of the sphingosine backbone is linked to a fatty acid by an amide bond. In addition, the primary hydroxyl group of sphingosine is esterified to phosphorylcholine.



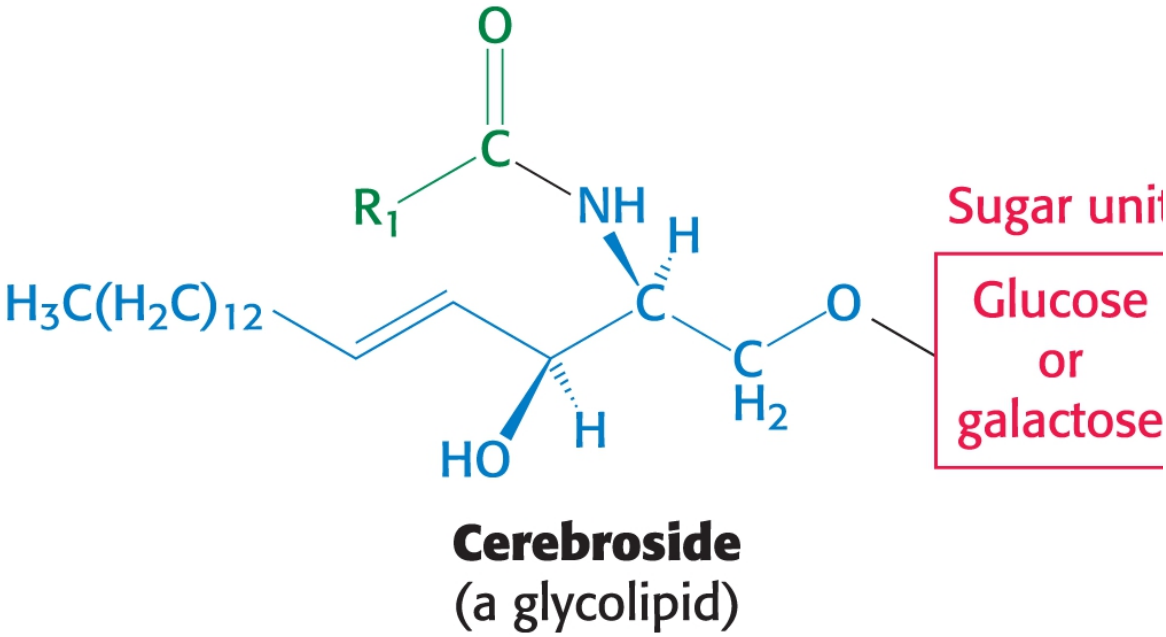


FIGURE 12.6 Sphingosine forms the backbone of the phospholipid sphingomyelin. The sphingosine moiety of sphingomyelin is highlighted in blue.

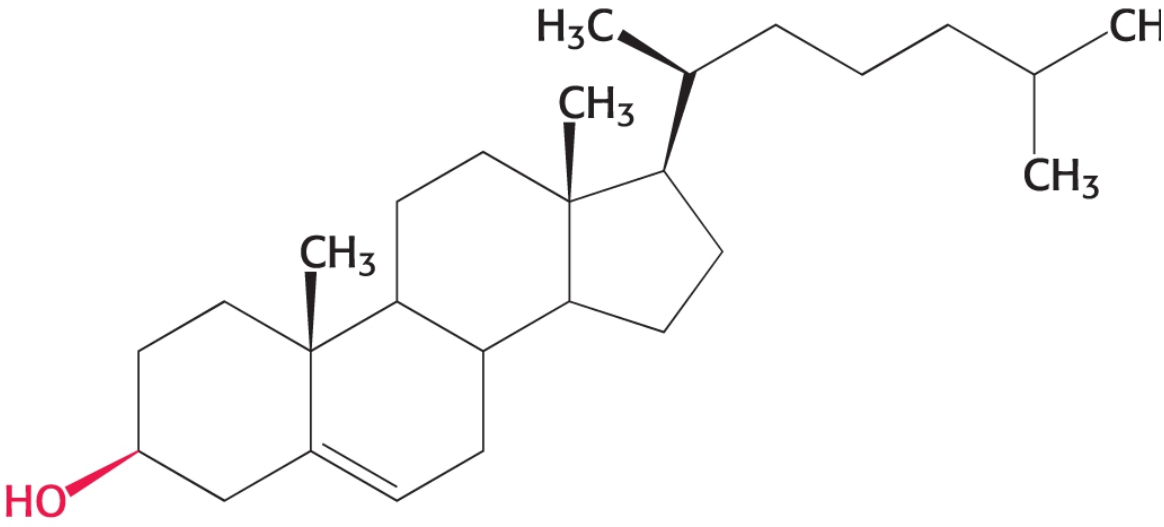
Glycolipids include carbohydrate moieties

The second major class of membrane lipids, **glycolipids**, are sugar-containing lipids. Like sphingomyelin, the glycolipids in animal cells are derived from sphingosine. The amino group of the sphingosine backbone is acylated by a fatty acid, as in sphingomyelin. Glycolipids differ from sphingomyelin in the identity of the unit that is linked to the primary hydroxyl group of the sphingosine backbone. In glycolipids, one or more sugars (rather than phosphorylcholine) are attached to this group. The simplest glycolipid, called a *cerebroside*, contains a single sugar residue, either glucose or galactose.

Cerebroside
(a glycolipid)

More complex glycolipids contain a branched chain of as many as seven sugar residues. Glycolipids are oriented in a completely asymmetric fashion with the sugar residues always on the extracellular side of the membrane.



Archives of the Albert Einstein College of Medicine, Ted Burrows, photographer

MARIE M. DALY In 1947, Marie M. Daly became the first Black woman in the United States to earn a PhD in chemistry. Soon after, she worked with others at Columbia University to examine the role of dietary cholesterol in contributing to hypertension in an animal model system. Later, in an independent faculty position at Albert Einstein College of Medicine, where she remained for more than 25 years, she continued her work on lipids and heart disease and other topics. Dr. Daly demonstrated an interest in promoting the careers of minority women in science. In

1975, she participated in a groundbreaking meeting that led to a report — *The Double Bind: The Price of Being a Minority Woman in Science* — that laid out challenges faced at different career stages. Her energetic pursuit of important scientific questions and her commitment to help others follow in her footsteps illustrate some of the many dimensions of a productive scientific career.

Cholesterol is a lipid based on a steroid nucleus

The third major type of membrane lipid, **cholesterol**, has a structure that is quite different from that of phospholipids. It is a steroid, built from four linked hydrocarbon rings.

Cholesterol

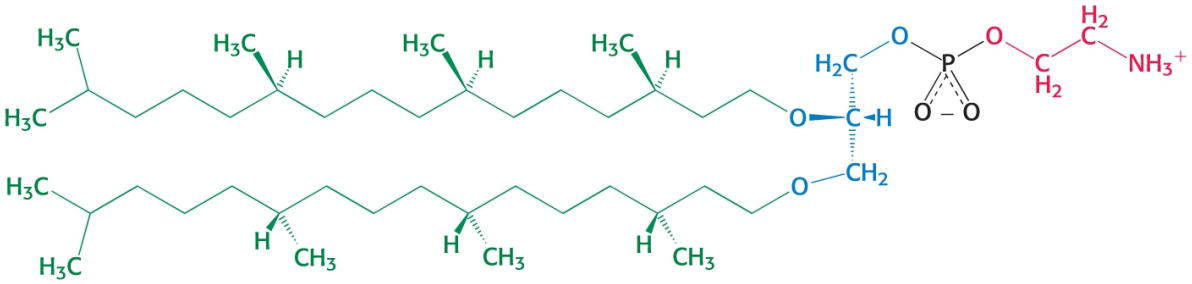
A hydrocarbon tail is linked to the steroid at one end, and a hydroxyl group is attached at the other end. In membranes, the orientation of the molecule is parallel to the fatty acid chains of the phospholipids, and the hydroxyl group interacts with the nearby phospholipid head groups. Cholesterol is absent from prokaryotes but is found to varying degrees

in virtually all animal membranes. It constitutes almost 25% of the membrane lipids in certain nerve cells but is essentially absent from some intracellular membranes.

Archaeal membranes are built from ether lipids with branched chains

The membranes of archaea differ in composition from those of eukaryotes or bacteria in three important ways. The first two of these differences clearly relate to the hostile living conditions of many archaea (**Figure 12.7**):

1. The nonpolar chains are joined to a glycerol backbone by ether rather than ester linkages. The ether linkage is more resistant to hydrolysis.

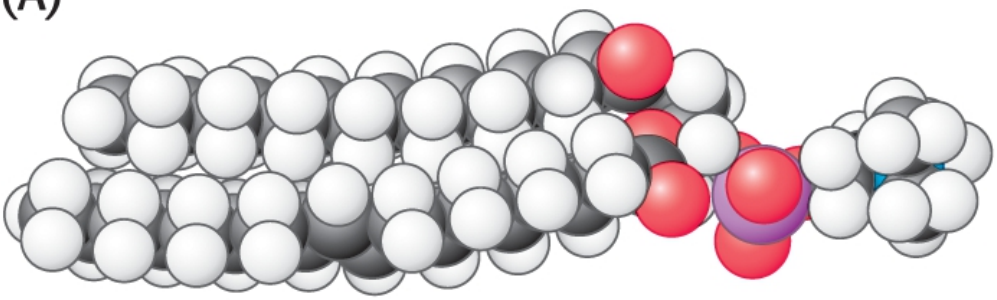


2. The alkyl chains are branched rather than linear. They are built up from repeats of a fully saturated five-carbon fragment. These branched, saturated hydrocarbons are more resistant to oxidation than the unbranched chains of eukaryotic and bacterial membrane lipids. The ability of archaeal lipids to resist hydrolysis and oxidation may help these organisms to withstand the extreme conditions, such as high temperature, low pH, or high salt concentration, under which some of these archaea grow.

3. The stereochemistry of the central glycerol is inverted compared with that shown in Figure 12.4.

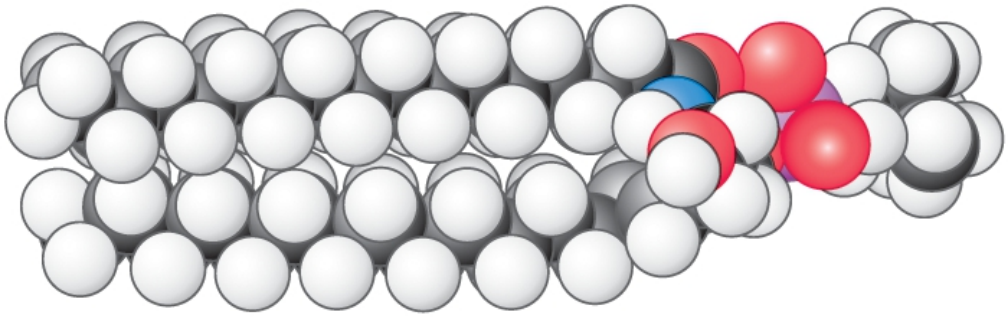
Daniel Viñé Garcia/Getty Images

FIGURE 12.7 Archaea can thrive in harsh habitats. Here, thermophilic archaea are responsible, in part, for the bright colors of the Morning Glory Pool hot spring in Yellowstone National Park.



Membrane lipid from the archaeon *Methanococcus jannaschii*

A membrane lipid is an amphipathic molecule containing a hydrophilic and a hydrophobic moiety



The repertoire of membrane lipids is extensive. However, these lipids possess a critical common structural theme: membrane lipids are **amphipathic molecules (amphiphilic molecules)**, that is, they contain both a hydrophilic and a hydrophobic moiety.

Let us look at a model of a phosphoglyceride, such as phosphatidylcholine. Its overall shape is roughly rectangular (**Figure 12.8A**). The hydrophilic phosphorylcholine moiety lies at one end of the molecule, while the two hydrophobic fatty acid chains project approximately parallel to each other. Sphingomyelin has a similar conformation, as does the archaeal lipid depicted. Therefore, the following shorthand has been adopted to represent these membrane lipids: the hydrophilic unit, also called the *polar head group,* is represented by a circle, and the hydrocarbon tails are depicted by straight or wavy lines (**Figure 12.8B**).

(A) Space-filling models of a phosphoglyceride, sphingomyelin, and an archaeal lipid show their overall rectangular shapes and distribution of hydrophilic and hydrophobic moieties. (B) A shorthand depiction of a membrane lipid.

Self-Check Question

What are the three primary types of membrane lipids? What are some molecules that form the polar head groups of phospholipids?

12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media

What properties enable phospholipids to form membranes? Membrane formation is a consequence of the amphipathic nature of the molecules. Their polar head groups favor contact with water, whereas their hydrocarbon tails interact with one another in preference to water. How can molecules with these preferences arrange themselves in aqueous solutions? One way is to form a globular structure called a **micelle**. The polar head groups form the outside surface of the micelle, which is surrounded by water, and the hydrocarbon tails are sequestered inside, interacting with one another (**Figure 12.9**).

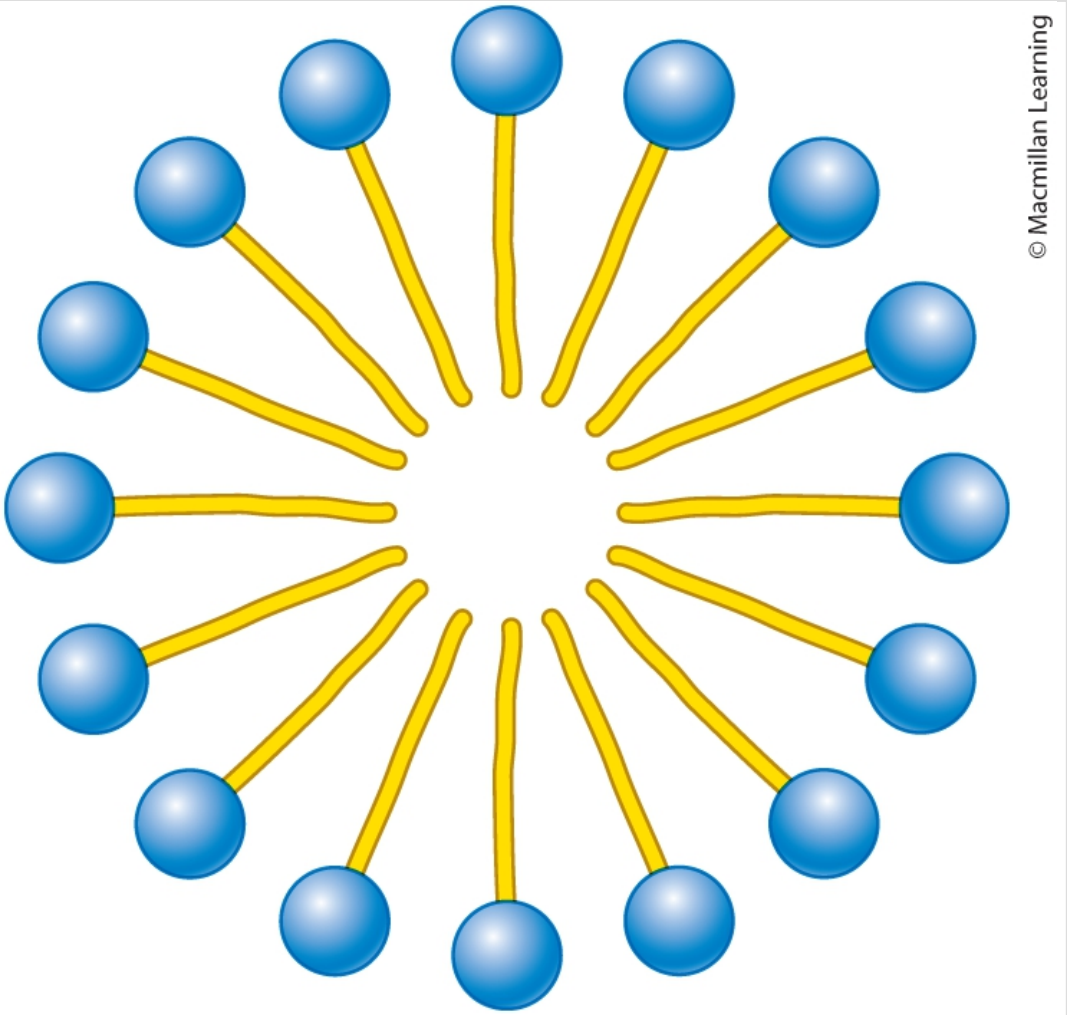

FIGURE 12.9 Micelles are globular structures formed from ionized fatty acids with single tails. Ionized fatty acids readily form such structures, but most phospholipids do not.

Alternatively, the strongly opposed preferences of the hydrophilic and hydrophobic moieties of membrane lipids can be satisfied by forming a **lipid bilayer**, composed of two lipid sheets (**Figure 12.10**). A lipid bilayer is also called a *bimolecular sheet*. The hydrophobic tails of each individual sheet interact with one another, forming a hydrophobic interior that acts as a permeability barrier. The hydrophilic head groups

interact with the aqueous medium on each side of the bilayer. The two opposing sheets are called leaflets.

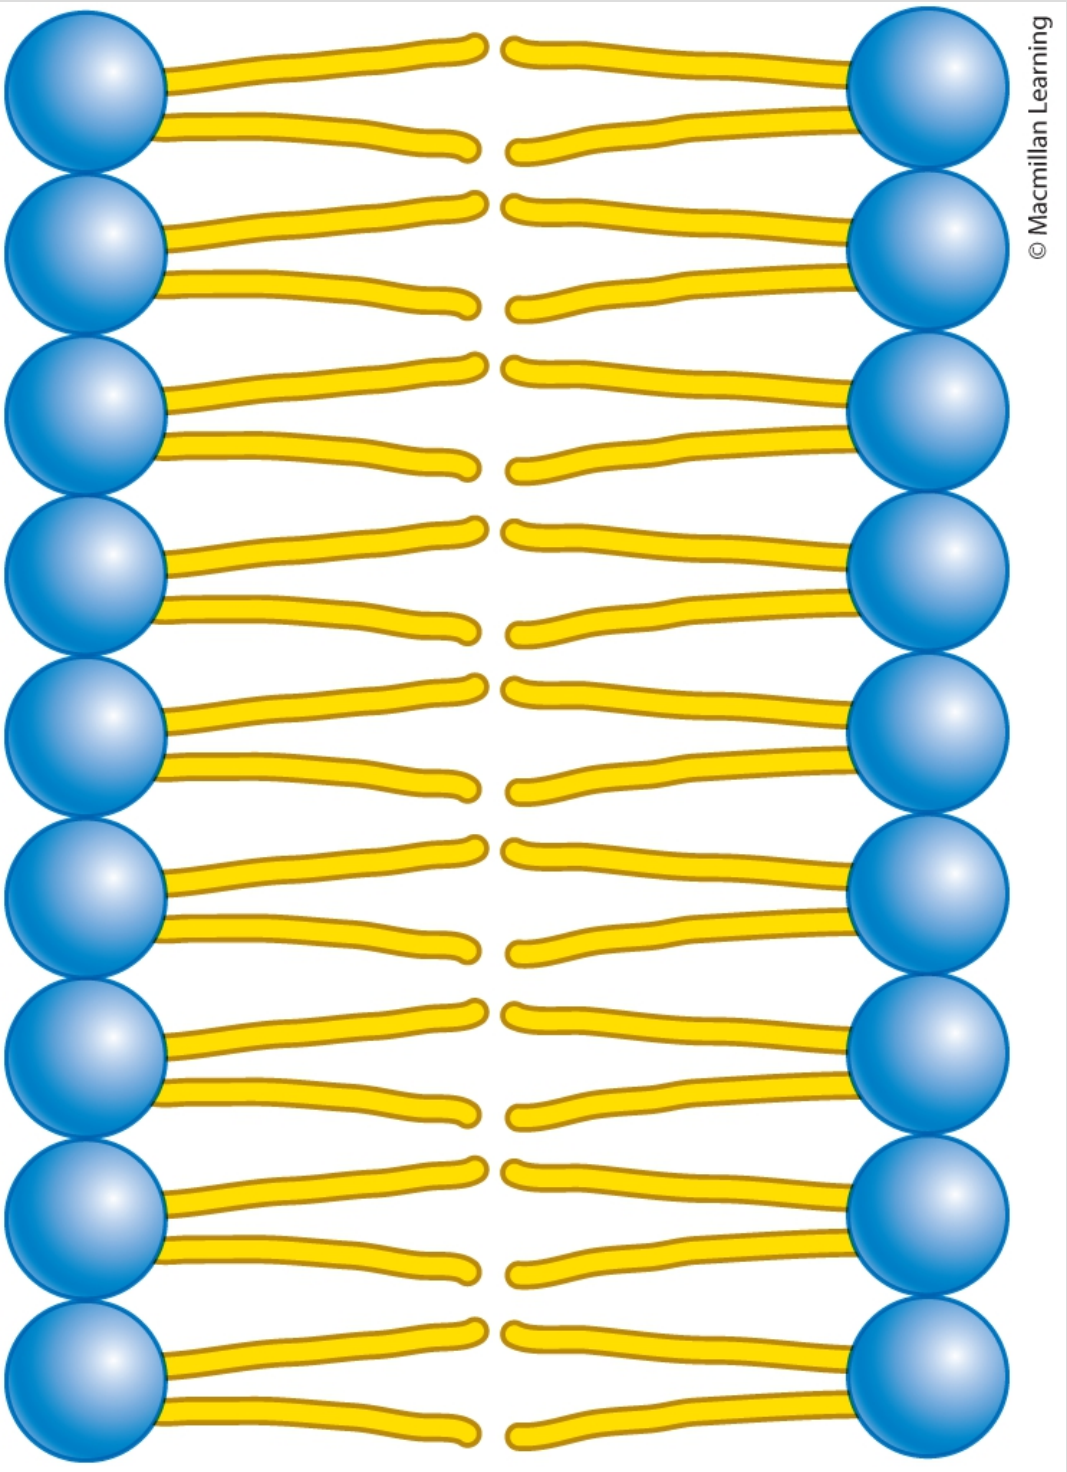

FIGURE 12.10 A lipid bilayer is formed from two opposing lipid sheets.

The favored structure for most phospholipids and glycolipids in aqueous media is a bimolecular sheet rather than a micelle. The reason is that the two fatty acid chains of a phospholipid or a glycolipid are too bulky to fit into the interior of a micelle. In contrast, salts of fatty acids (such as sodium palmitate, a constituent of soap) readily form micelles because they contain only one chain. The formation of bilayers instead of micelles by phospholipids is of critical biological importance. A micelle is a limited structure, usually less than 200 Å (20 nm) in diameter. In contrast, a bimolecular sheet can extend to macroscopic dimensions, as much as a millimeter (10^7 Å, or 10^6 nm) or more. Phospholipids and related molecules are important membrane constituents because they readily form extensive bimolecular sheets.

Lipid bilayers form spontaneously by a self-assembly process. In other words, the structure of a bimolecular sheet is inherent in the structure of the constituent lipid molecules. The growth of lipid bilayers from phospholipids is rapid and spontaneous in water. Bimolecular sheets are stabilized by the full array of forces that mediate molecular interactions in biological systems:

- Hydrophobic interactions are the major driving force for the formation of lipid bilayers. We have already encountered the dominant role that hydrophobic interactions play in the stabilization of double-helical DNA and the folding of proteins (Sections 1.3 and 2.4). Water molecules are released from the hydrocarbon tails of membrane lipids as these tails become sequestered in the nonpolar interior of the bilayer.

- van der Waals attractive forces between the hydrocarbon tails favor close packing of the tails.

- Electrostatic and hydrogen-bonding attractions between the polar head groups and water molecules.

Because lipid bilayers are held together by many reinforcing, noncovalent interactions (predominantly hydrophobic), they are cooperative structures. These hydrophobic interactions have three significant biological consequences: (1) lipid bilayers have an inherent tendency to be extensive; (2) lipid bilayers will tend to close on themselves so that there are no edges with exposed hydrocarbon chains, and so they form compartments; and (3) lipid bilayers are self-sealing because a hole in a bilayer is energetically unfavorable.

Self-Check Question

Phospholipids form lipid bilayers in water. What structure might form if phospholipids were placed in an organic solvent?

Lipid vesicles can be formed from phospholipids

The propensity of phospholipids to form membranes has been used to create important experimental and clinical tools. **Lipid vesicles**, or **liposomes**, are aqueous compartments enclosed by a lipid bilayer (**Figure 12.11**), which can be used to study membrane permeability or to deliver chemicals to cells.

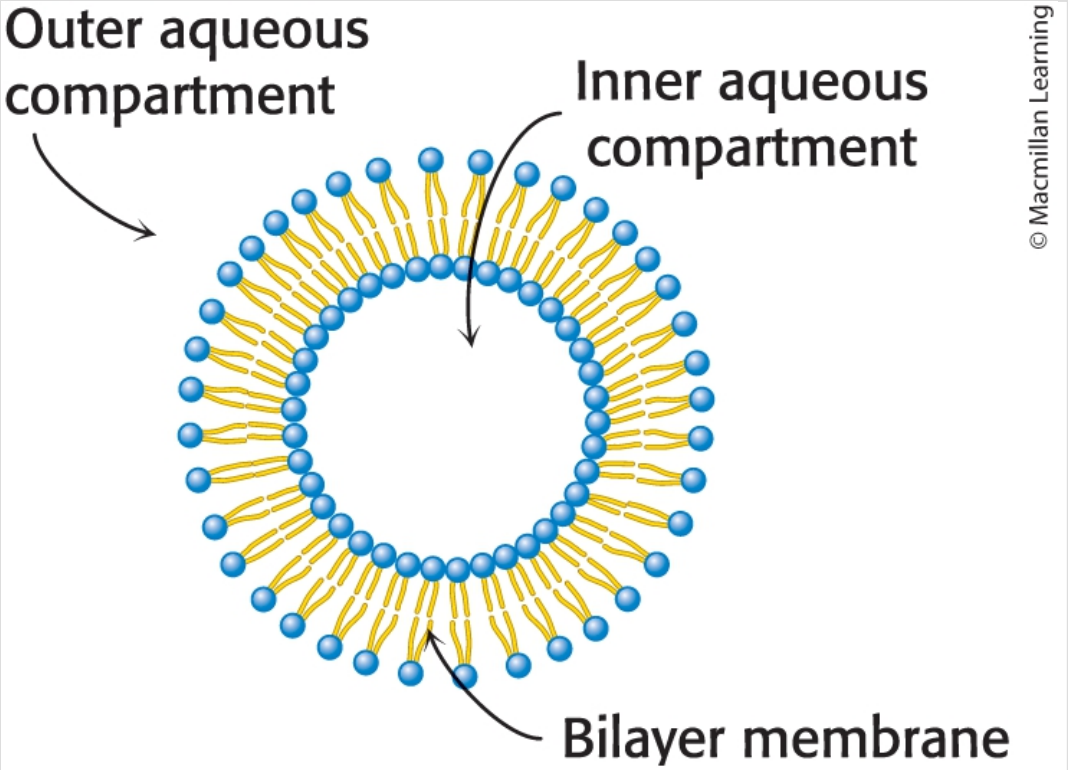

FIGURE 12.11 A liposome is a small aqueous compartment surrounded by a lipid bilayer.

Liposomes are formed by suspending a suitable lipid, such as phosphatidylcholine, in an aqueous medium, and then sonicating (i.e., agitating by high-frequency sound waves) to give a dispersion of closed vesicles that are quite uniform in size (Figure 12.12). Vesicles formed by this method are nearly spherical and have a diameter of about 500 Å (50 nm). Larger vesicles (of the order of $1\ \mu m$ or 10^4 Å in diameter) can be prepared by slowly evaporating the organic solvent from a suspension of phospholipid in a mixed-solvent system.

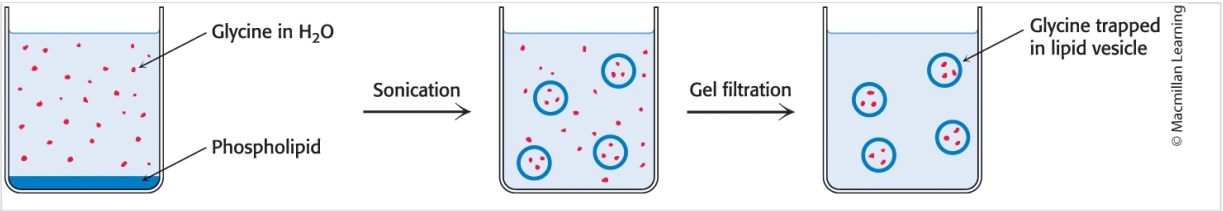

FIGURE 12.12 Liposomes containing trapped ions or molecules can be synthesized. Liposomes containing glycine are formed by the sonication of phospholipids in the presence of glycine. Free glycine is removed by gel filtration.

Ions or molecules can be trapped in the aqueous compartments of lipid vesicles by forming the vesicles in the presence of these substances, as shown in Figure 12.12. For example, 500-Å-diameter vesicles formed in a 0.1 M glycine solution will trap about 2000 molecules of glycine in each inner aqueous compartment. These glycine-containing vesicles can be separated from the surrounding solution of glycine by dialysis or by gel-filtration chromatography (Section 4.1). The permeability of the bilayer membrane to glycine can then be determined by measuring the rate of efflux of glycine from the inner compartment of the vesicle to the ambient solution.

Liposomes can be formed with specific membrane proteins embedded in them by solubilizing the proteins in the presence of detergents and then adding them to the phospholipids from which liposomes will be formed. Protein–liposome complexes provide valuable experimental tools for examining a range of membrane-protein functions.

Therapeutic applications for liposomes are currently under active investigation. For example, liposomes containing drugs or DNA can be injected into patients. These liposomes fuse with the plasma membrane of many kinds of cells, introducing into the cells the molecules they contain. Drug delivery with liposomes often lessens its toxicity. Less of the drug is distributed to normal tissues because long-circulating liposomes concentrate in regions of increased blood circulation, such as solid tumors and sites of inflammation. Moreover, the selective fusion of lipid vesicles with particular kinds of cells is a promising means of controlling the delivery of drugs to target cells.

Another well-defined synthetic membrane adopts the structure of a planar bilayer. This membrane can be formed across a 1-mm hole in a partition between two aqueous compartments by dipping a fine paintbrush into a membrane-forming solution, such as phosphatidylcholine in decane, and stroking the tip of the brush across the hole. The lipid film across the hole thins spontaneously into a lipid bilayer. The electrical conduction properties of this macroscopic bilayer membrane are readily studied by inserting electrodes into each aqueous compartment (**Figure 12.13**). For example, the permeability of the membrane to ions is determined by measuring the current across the membrane as a function of the applied voltage.

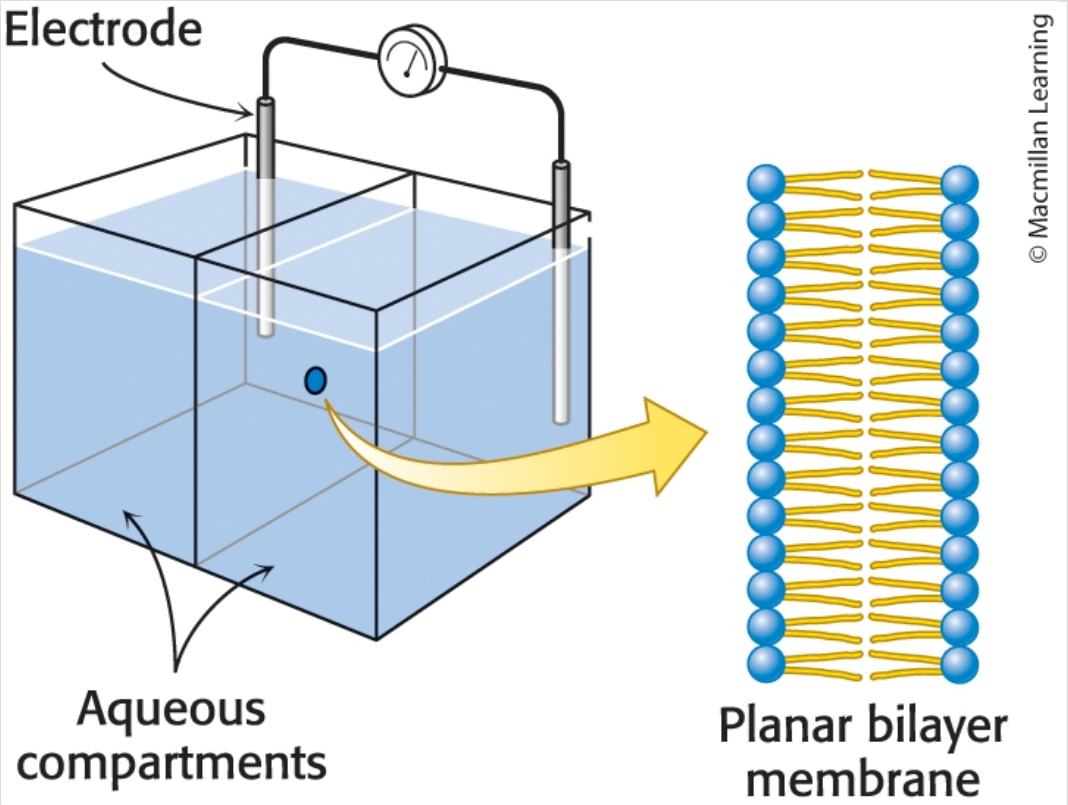

FIGURE 12.13 The properties of planar bilayer membranes can be studied experimentally. A bilayer membrane is formed across a 1-mm hole in a septum that separates two aqueous compartments. This arrangement permits measurements of the permeability and electrical conductance of lipid bilayers.

Lipid bilayers are highly impermeable to ions and most polar molecules

Permeability studies of lipid vesicles and electrical-conductance measurements of planar bilayers have revealed several important properties:

- *Lipid bilayer membranes have a very low permeability for ions and most polar molecules.* Water is a conspicuous exception to this

generalization; it traverses such membranes relatively easily because of its low molecular weight, high concentration, and lack of a complete charge.

- *The range of measured permeability coefficients is very wide* (**Figure 12.14**). For example, Na^+ and K^+ traverse lipid bilayer membranes 10^9 times as slowly as does H_2O. Tryptophan, a zwitterion at pH 7, crosses the membrane 10^3 times as slowly as does indole, a structurally related molecule that lacks ionic groups.

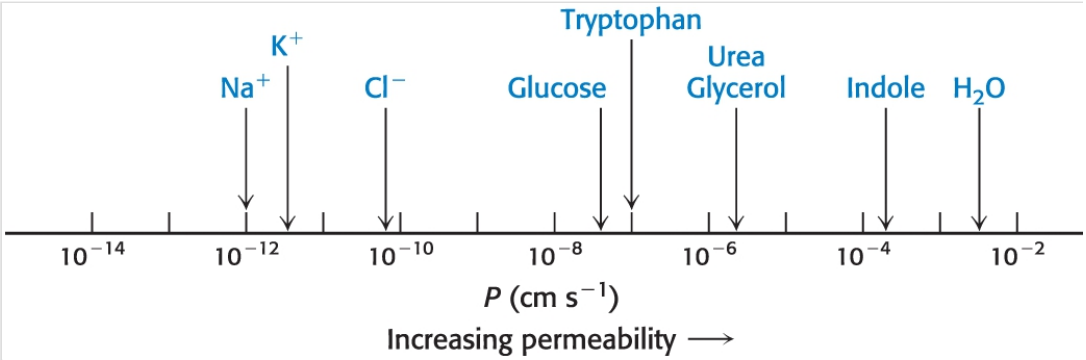

FIGURE 12.14 The permeability coefficients (*P*) of ions and molecules in a lipid bilayer span a wide range of values.

- *The permeability of small molecules is correlated with their solubility in a nonpolar solvent relative to their solubility in water.* This relationship suggests that a small molecule might traverse a lipid bilayer membrane in the following way: first, it sheds any interacting water molecules (Section 1.3); then, it is dissolved in the hydrocarbon core of the membrane; finally, it diffuses through this core to the other side of the membrane, where it becomes resolvated by water. An ion such as Na^+ traverses membranes very slowly because the

replacement of its numerous interactions with polar water molecules by nonpolar interactions with the membrane interior is highly unfavorable energetically.

12.4 Proteins Carry Out Most Membrane Processes

We now turn to membrane proteins, which are responsible for most of the dynamic processes carried out by membranes. Whereas membrane lipids form a permeability barrier and thereby establish compartments, specific proteins mediate nearly all other membrane functions. In particular, proteins transport chemicals and information across a membrane. Membrane lipids create the appropriate environment for the action of such proteins.

Membranes differ in their protein content. For example, relatively pure lipids are well suited for insulation. **Myelin**, a membrane that serves as an electrical insulator around certain nerve fibers, has a low content of protein (18%). As such, myelin plays a critical role in enabling the rapid transmission of nerve impulses, or action potentials (Section 13.4). Its structure is quite unique: the cells that generate myelin wrap their plasma membranes multiple times around the axon, the part of the neuron that conducts the electrical signal (**Figure 12.15**).

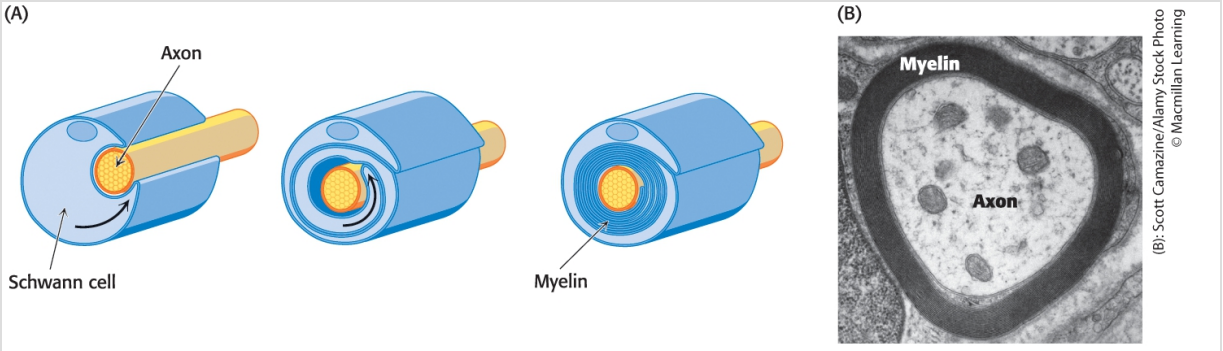

FIGURE 12.15 The lipid-rich membranes of myelin form an electrical insulator around some nerve fibers. (A) Myelin is comprised of the lipid-rich plasma membrane of a Schwann cell in peripheral nerves or the oligodendrocyte in the brain that has wrapped multiple times around the axon, or the portion of the neuron that conducts electrical impulses. [https://biologydictionary.net/myelin-sheath] (B) The myelin sheath around an axon is readily apparent by electron microscopy.

Significant myelination of neurons in the brain occurs during infancy but persists throughout adolescence, a reminder that the brain is an actively developing organ throughout childhood. The importance of myelination is further underscored by the existence of demyelinating diseases, such as multiple sclerosis, where myelin assembly is impaired or existing myelin is damaged.

In contrast to myelin, the plasma membranes, or exterior membranes, of most other cells are much more metabolically active. They contain many pumps, channels, receptors, and enzymes. The protein content of these plasma membranes is typically 50%. Energy-transduction membranes, such as the internal membranes of mitochondria and chloroplasts, have the highest content of protein, around 75%.

The protein components of a membrane can be readily visualized by SDS–polyacrylamide gel electrophoresis. As we discussed in Section 4.1, the electrophoretic mobility of many proteins in SDS-containing gels depends on the mass rather than on the net charge of the protein. The gel-electrophoresis patterns of three membranes are shown in **Figure 12.16**. It is evident that each of these three membranes contains many proteins but has a distinct protein composition. In general, membranes performing different functions contain different repertoires of proteins.

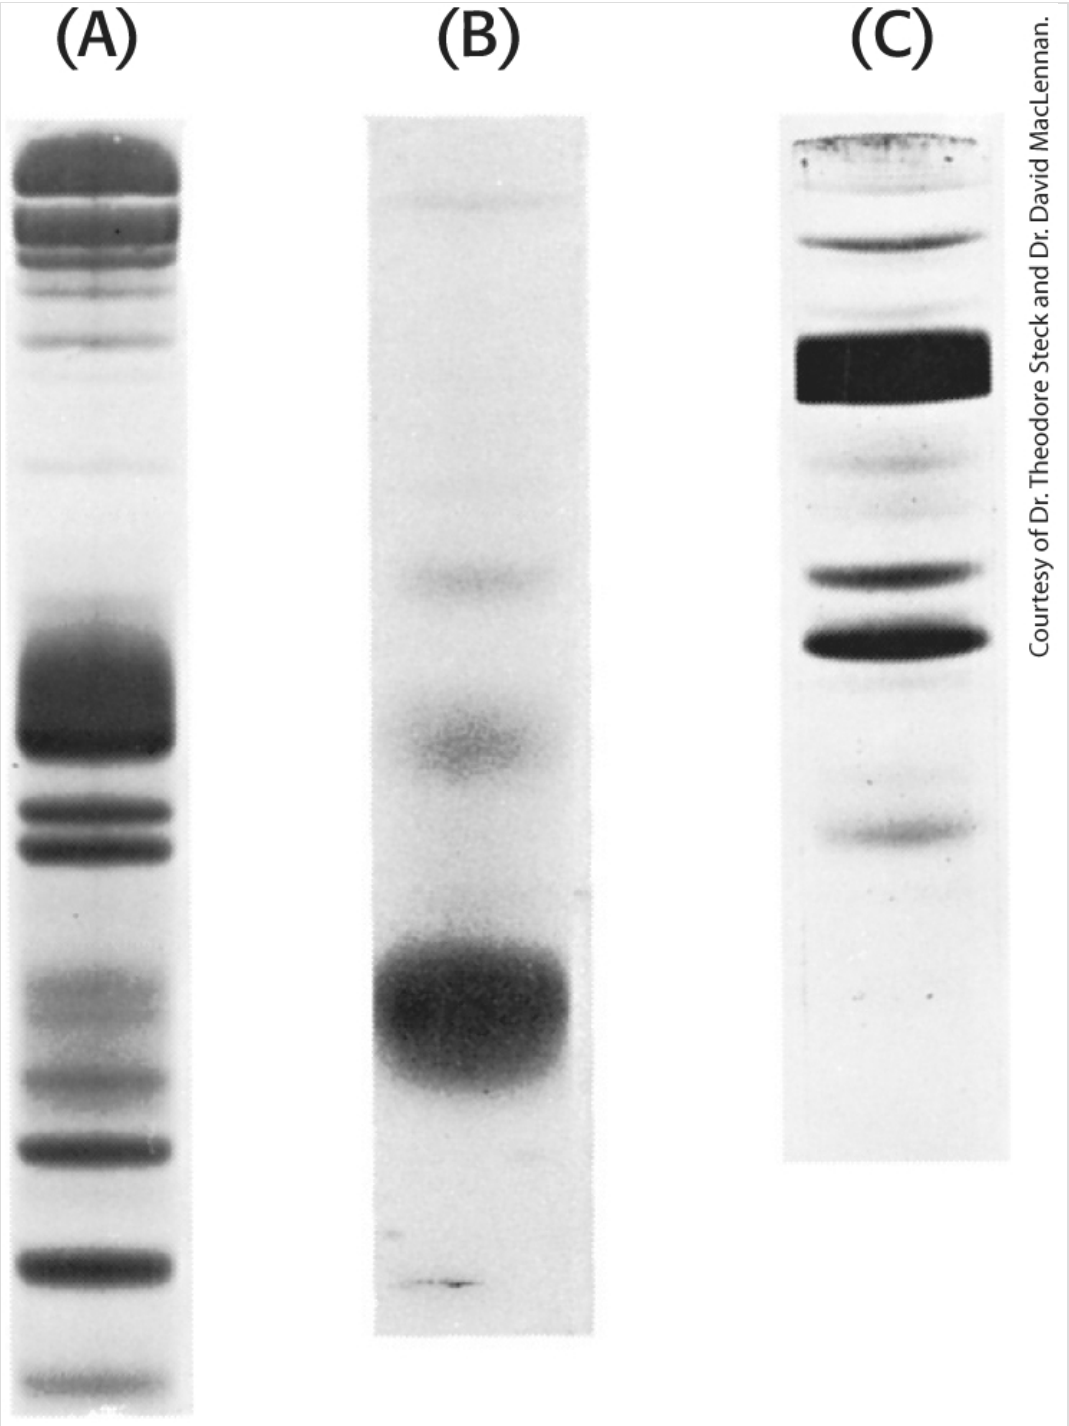

FIGURE 12.16 The protein composition of plasma membranes varies with cell type. Here, the SDS–acrylamide gel patterns of membrane proteins from three different cell types are shown: (A) The plasma membrane of red blood cells. (B) The photoreceptor membranes of retinal rod cells. (C) The sarcoplasmic reticulum membrane of muscle cells.

Proteins associate with the lipid bilayer in a variety of ways

The ease with which a protein can be dissociated from a membrane indicates how intimately it is associated with the membrane. Some membrane proteins can be solubilized by relatively mild means, such as extraction by a solution of high ionic strength (e.g., 1 M NaCl). Other membrane proteins are bound much more tenaciously; they can be solubilized only by using a detergent or an organic solvent. Membrane proteins can be classified as being either peripheral or integral on the basis of their difference in dissociability (**Figure 12.17**):

- **Integral membrane proteins** interact extensively with the hydrocarbon chains of membrane lipids, and they can be released only by agents that compete for these nonpolar interactions. In fact, most integral membrane proteins span the lipid bilayer.

- **Peripheral membrane proteins** are bound to membranes primarily by electrostatic and hydrogen-bond interactions with the head groups of lipids. These polar interactions can be disrupted by adding salts or by changing the pH. Many peripheral membrane proteins are bound to the surfaces of integral proteins, on either the cytoplasmic or the extracellular side of the membrane. Others are anchored to the lipid bilayer by a covalently attached hydrophobic chain, such as a fatty acid.

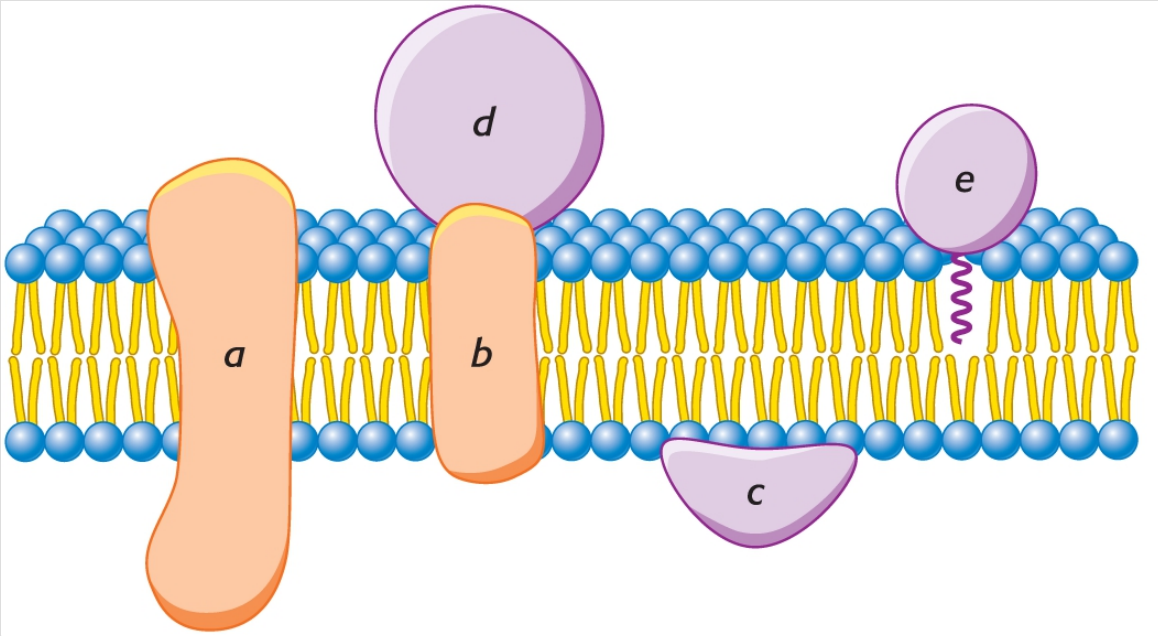

FIGURE 12.17 Membrane proteins interact with lipid bilayers in different ways. Integral membrane proteins (*a* and *b*) interact extensively with the hydrocarbon region of the bilayer. Most known integral membrane proteins traverse the lipid bilayer. Peripheral membrane protei interact with the polar head groups of the lipids (*c*) or bind to the surfaces of integral proteins (*d* Other proteins are tightly anchored to the membrane by a covalently attached lipid molecule (*e*

Proteins interact with membranes in a variety of ways

Membrane proteins are more difficult to purify and crystallize than are water-soluble proteins. Nonetheless, researchers using x-ray crystallography or cryo-electron microscopy have determined the three-dimensional structures of more than 4000 such proteins at sufficiently high resolution to discern the molecular details. As noted in Chapter 2, membrane proteins differ from soluble proteins in the distribution of hydrophobic and hydrophilic groups. We will consider the structures of three membrane proteins in some detail.

- *Membrane-spanning alpha helices are the most common structural motif in membrane proteins.* The first membrane protein that we consider is the archaeal protein bacteriorhodopsin (**Figure 12.18**). We will discuss the function of this important protein in Section 19.1. Bacteriorhodopsin is built almost entirely of α helices; seven closely packed α helices, nearly perpendicular to the plane of the cell membrane, span its 45-Å width. Examination of the primary structure of bacteriorhodopsin reveals that most of the amino acids in these membrane-spanning α helices are nonpolar and only a very few are charged (**Figure 12.19**). This distribution of nonpolar amino acids is sensible because these residues are either in contact with the hydrocarbon core of the membrane or with one another. As will be considered in Section 12.5, membrane-spanning α helices can often be detected by examining amino acid sequence alone.

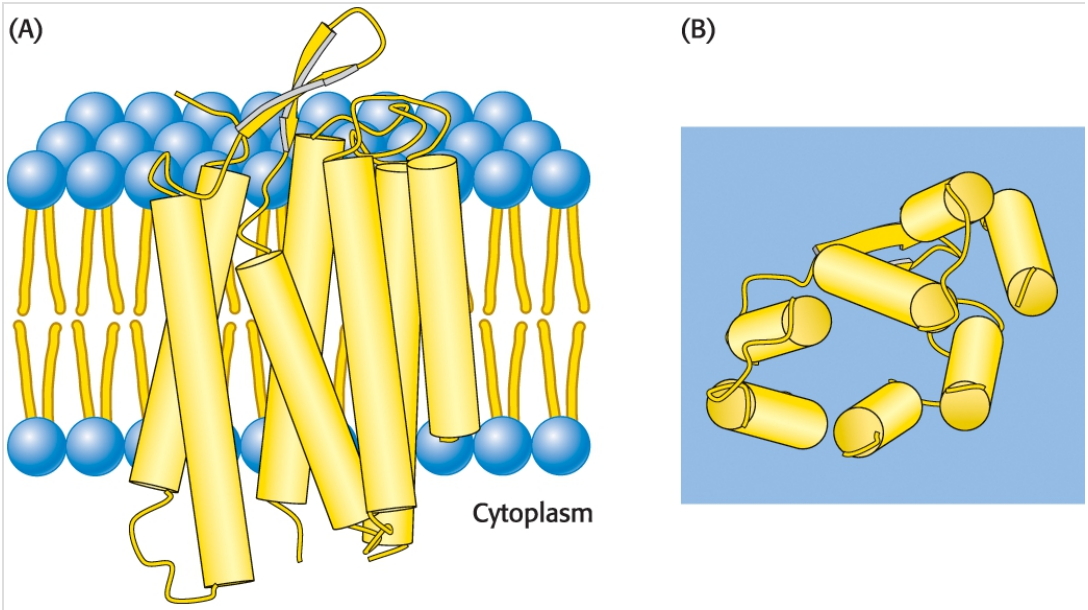

FIGURE 12.18 Bacteriorhodopsin is an integral membrane protein that contains membrane-spanning α helices. These helices are represented by yellow cylinders. (A) Vie through the membrane bilayer. (B) View from the cytoplasmic side of the membrane.

[Drawn from 1BRX.pdb.]

INTERACT with this model in Achieve

FIGURE 12.19 The membrane-spanning helices of bacteriorhodopsin contain predominantly nonpolar amino acids. The seven helical regions are highlighted in yellow and the charged residues in red.

- *A channel protein can be formed from beta strands.* Porin, a protein from the outer membranes of bacteria such as *E. coli* and *Rhodobacter capsulatus*, represents a class of membrane proteins with a completely different type of structure from bacteriorhodopsin. Structures of this type are built from β strands and contain essentially no α helices (Figure 12.20). The arrangement of β strands is quite simple: each strand is hydrogen bonded to its neighbor in an antiparallel arrangement, forming a single β sheet. The β sheet curls up to form a hollow cylinder that, as its name suggests, forms a pore, or channel, in the membrane. The outside surface of porin is appropriately nonpolar, given that it interacts with the hydrocarbon core of the membrane. In contrast, the inside of the channel is quite hydrophilic and is filled with water. This arrangement of nonpolar and polar surfaces is accomplished by the alternation of hydrophobic and hydrophilic amino acids along each β strand (Figure 12.21).

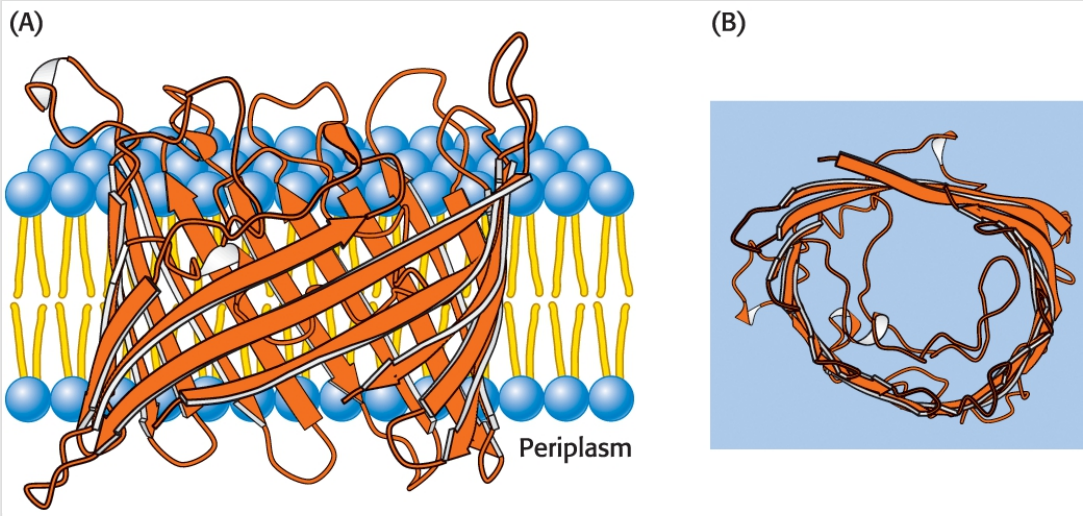

FIGURE 12.20 The bacterial integral membrane protein porin from *Rhodopseudomonas blastica* is built entirely of β strands. (A) Side view. (B) View from the periplasmic space. Only one monomer of the trimeric protein is shown.

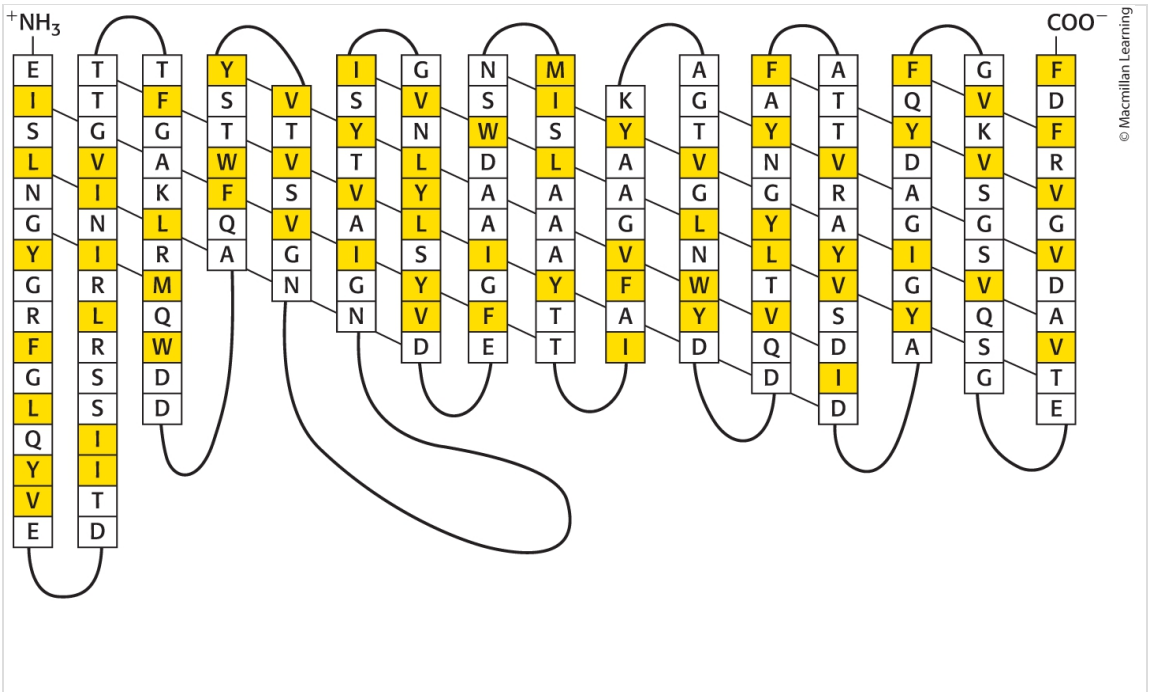

FIGURE 12.21 Porin contains alternating hydrophobic and hydrophilic amino acids along each β strand. The secondary structure of porin from *Rhodopseudomonas blastica* is shown, with the diagonal lines indicating the direction of hydrogen bonding along the β sheet. Hydrophobic residues (F, I, L, M, V, W, and Y) are shown in yellow. These residues tend to lie on the outside of the structure, in contact with the hydrophobic core of the membrane.

- *Embedding part of a protein in a membrane can link the protein to the membrane surface*. The structure of the endoplasmic reticulum membrane-bound enzyme prostaglandin H_2 synthase-1 reveals a rather different role for α helices in protein–membrane associations. This enzyme is a homodimer with a complicated structure consisting primarily of α helices. Unlike bacteriorhodopsin, this protein is not largely embedded in the membrane. Instead, it lies along the outer surface of the membrane, firmly bound by a set of α helices with hydrophobic surfaces that extend from the bottom of the protein into the membrane (Figure 12.22). This linkage is sufficiently strong that only the action of detergents can release the protein from the membrane. Thus, this enzyme is classified as an integral membrane protein, although it does not span the membrane.

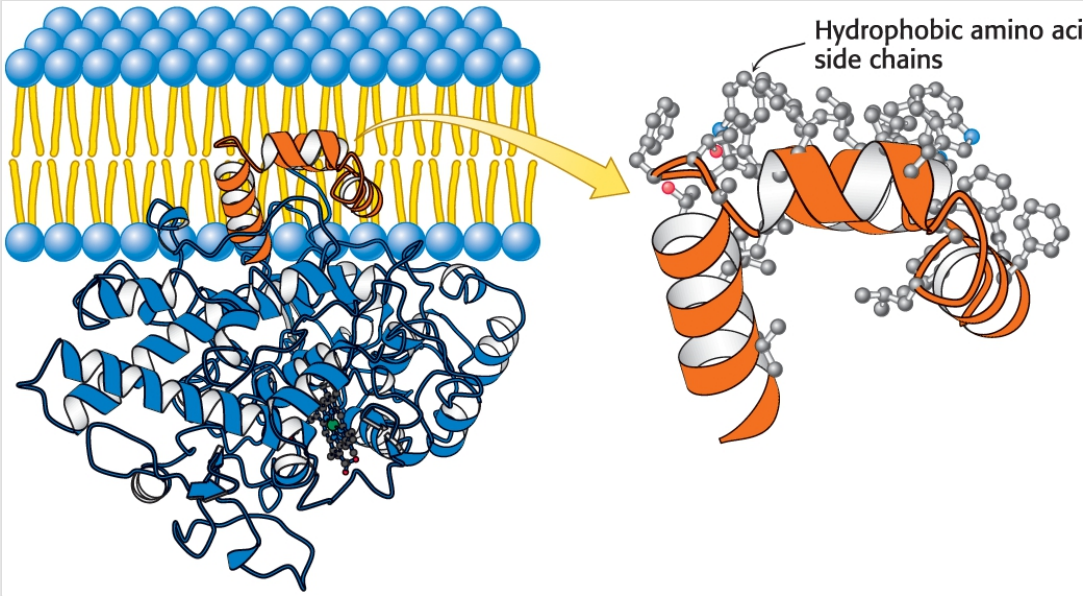

FIGURE 12.22 Prostaglandin H_2 synthase-1 is an integral membrane protein attached the membrane surface. This enzyme is held in the membrane by a set of α helices (orang coated with hydrophobic side chains. One monomer of the dimeric enzyme is shown.

[Drawn from 1PTH.pdb.]

INTERACT with this model in Achieve

The localization of prostaglandin H_2 synthase-1 in the membrane is crucial to its function. This enzyme catalyzes the conversion of arachidonic acid into prostaglandin H_2 in two steps: (1) a cyclooxygenase reaction, and (2) a peroxidase reaction (Figure 12.23). The substrate for this enzyme, arachidonic acid, is a hydrophobic molecule generated by the hydrolysis of membrane lipids. Arachidonic acid reaches the active site of the enzyme from the membrane without entering an aqueous environment by traveling through a hydrophobic channel in the protein (Figure 12.24). The reaction product, prostaglandin H_2, promotes inflammation and modulates gastric acid secretion.

INTERACT with this model in Achieve

Indeed, nearly all of us have experienced the importance of this channel: drugs such as aspirin and ibuprofen block the channel and prevent prostaglandin synthesis by inhibiting the cyclooxygenase activity of the synthase. In particular, aspirin acts through the transfer of its acetyl group to a serine residue (Ser 530) that lies along the path to the active site (Figure 12.25). In response to an injury or infection, prostaglandins promote the inflammatory response, which includes swelling, pain, and fever. Cyclooxygenase inhibitors blunt this response, providing pain relief and fever reduction.

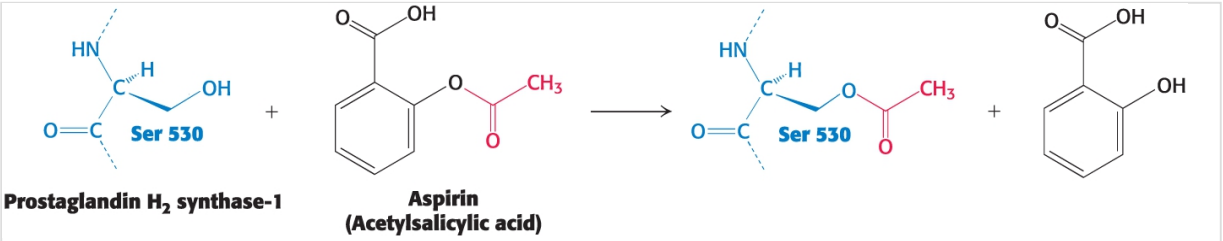

FIGURE 12.25 Aspirin acts by transferring an acetyl group to a serine residue in prostaglandin H_2 synthase-1.

Two important features emerge from our examination of these three examples of membrane-protein structure. First, the parts of the protein that interact with the hydrophobic parts of the membrane are coated with nonpolar amino acid side chains, whereas those parts that interact with the aqueous environment are much more hydrophilic. Second, the structures positioned within the membrane are quite regular and, in particular, all backbone hydrogen-bond donors and acceptors participate in hydrogen bonds. Breaking a hydrogen bond within a

membrane is quite unfavorable, because little or no water is present to compete for the polar groups.

Some proteins associate with membranes through covalently attached hydrophobic groups

The membrane proteins considered thus far associate with the membrane through surfaces generated by hydrophobic amino acid side chains. However, even otherwise soluble proteins can associate with membranes if hydrophobic groups are attached to the proteins. Three such groups are shown in Figure 12.26: (1) a palmitoyl group attached to a specific cysteine residue by a thioester bond, (2) a farnesyl group attached to a cysteine residue at the carboxyl terminus, and (3) a glycolipid structure termed a glycosylphosphatidylinositol (GPI) anchor attached to the carboxyl terminus. These modifications are attached by enzyme systems that recognize specific signal sequences near the attachment site.

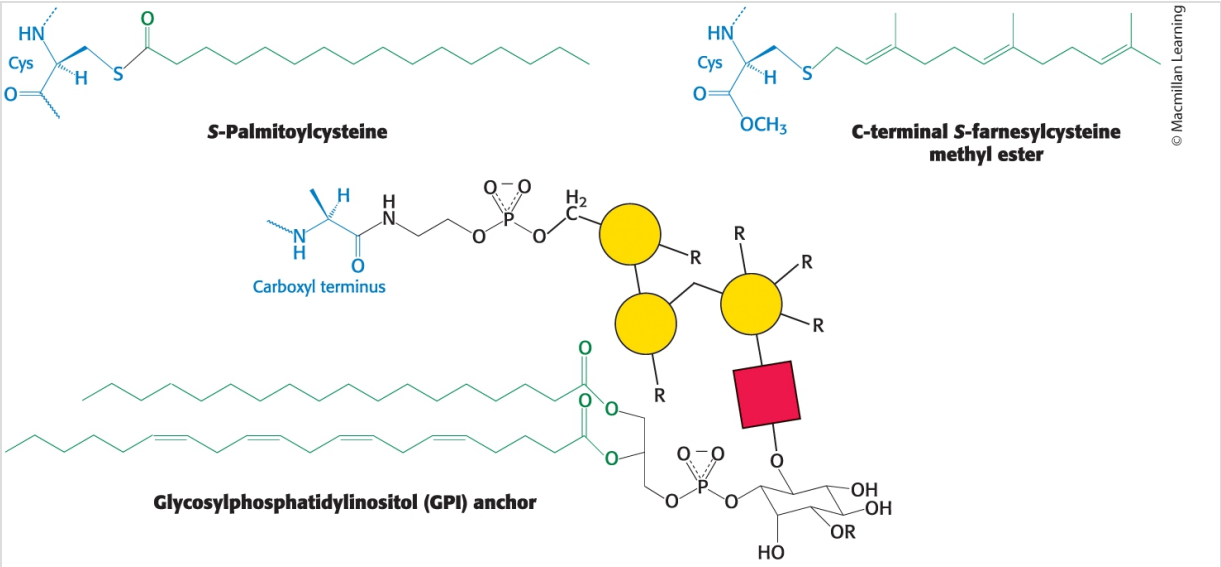

FIGURE 12.26 Membrane anchors are hydrophobic groups that tether proteins to the membrane. The anchors are attached to the proteins (blue) by covalent bonds. The yellow circles

and red square correspond to mannose and β-D-acetylglucosamine (GlcNAc), respectively. R groups represent points of additional modification.

Transmembrane helices can be accurately predicted from amino acid sequences

Many membrane proteins, like bacteriorhodopsin, employ α helices to span the hydrophobic part of a membrane. As noted earlier, most of the residues in these α helices are nonpolar and almost none of them are charged. Can we use this information to identify likely membrane-spanning regions from sequence data alone?

One approach to identifying transmembrane helices is to ask whether a postulated helical segment is likely to be more stable in a hydrocarbon environment or in water. Specifically, we want to estimate the free-energy change when a helical segment is transferred from the interior of a membrane to water. Free-energy changes for the transfer of individual amino acid residues from a hydrophobic to an aqueous environment are given in **Table 12.2**. For example, the transfer of a helix formed entirely of L-arginine residues — a positively charged amino acid — from the interior of a membrane to water would be highly favorable, with a negative transfer free energy of $-51.5\ \text{kJ mol}^{-1}\ (-12.3\ \text{kcal mol}^{-1})$ per arginine residue in the helix. In contrast, the transfer of a helix formed entirely of L-phenylalanine — a hydrophobic amino acid — would be unfavorable, with a positive transfer free energy value of $+15.5\ \text{kJ mol}^{-1}\ (+3.7\ \text{kcal mol}^{-1})$ per phenylalanine residue in the helix.

TABLE 12.2 Polarity scale for identifying transmembrane helices

Amino acid residue	Transfer free energy in $kJ\ mol^{-1}$ $(kcal\ mol^{-1})$
Phe	15.5 (3.7)
Met	14.3 (3.4)
Ile	13.0 (3.1)
Leu	11.8 (2.8)

Source: Data from D. M. Engelman, T. A. Steitz, and A. Goldman. *Annu. Rev. Biophys. Biophys. Chem.* 15(1986):321–353.
Note: The free energies are for the transfer of an amino acid residue in an α helix from the membrane interior (assumed to have a dielectric constant of 2) to water.

The hydrocarbon core of a membrane is typically 30 Å wide, a length that can be traversed by an α helix of about 20 residues. We can take the amino acid sequence of a protein and estimate the free-energy change that takes place when a hypothetical α helix formed of residues 1 through 20 is transferred from the membrane interior to water. The same calculation can be made for residues 2 through 21, 3 through 22, and so forth, until we reach the end of the sequence. The span of 20 residues chosen for this calculation is called a *window*. The free-energy change for each window, termed the *hydropathy index*, is plotted against the first amino acid at the window to create a **hydropathy plot** (**Figure 12.27A**).

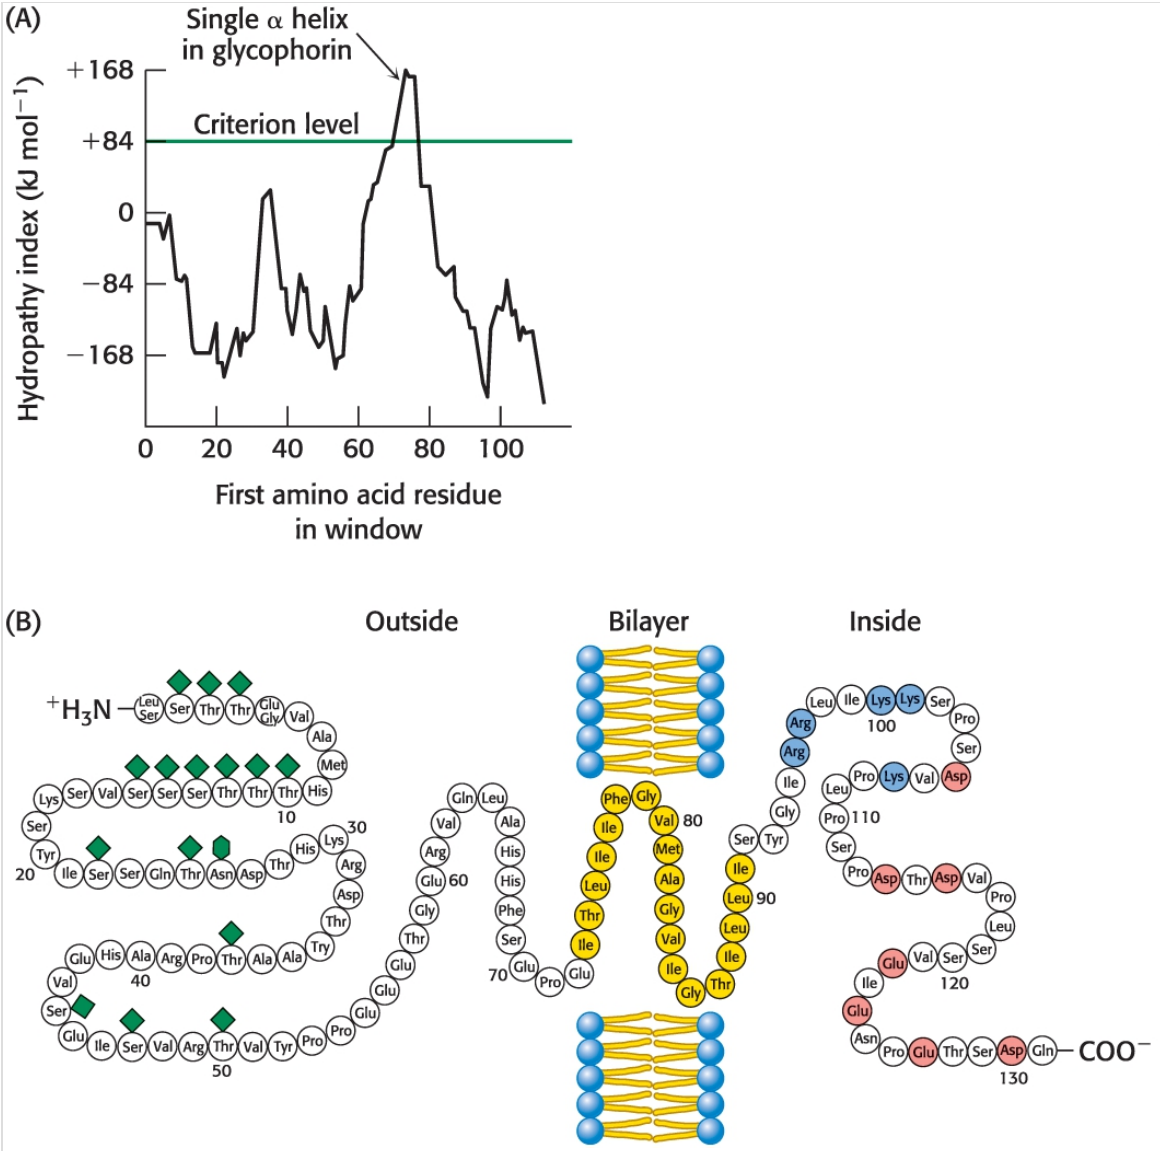

FIGURE 12.27 Hydropathy plots can be used to locate the membrane-spanning helices from protein sequences. (A) The hydropathy plot for glycophorin A is shown. Peaks of greater than $+84\ \text{kJ mol}^{-1}\ (+20\ \text{kcal mol}^{-1})$ in hydropathy plots are indicative of potential transmembrane helices. (B) The amino acid sequence and transmembrane disposition of glycophorin A from the red-blood-cell membrane are shown. Sites of glycosylation are indicated by the green shapes. The hydrophobic residues (yellow) buried in the bilayer form a transmembrane α helix. The negatively charged (red) and positively charged (blue) residues on the interior side of the membrane are indicated.

[(A) Information from Dr. Vincent Marchesi; (B) Data from D. M. Engelman, T. A. Steitz, and A. Goldman, *Annu. Rev. Biophys. Biophys. Chem*. 15:321–353, 1986. Copyright © 1986 by Annual Reviews, Inc. All rights reserved.]

Empirically, a peak of $+84\ \text{kJ mol}^{-1}\ (+20\ \text{kcal mol}^{-1})$ or more in a hydropathy plot based on a window of 20 residues indicates that a polypeptide segment could be a membrane-spanning α helix. For example, glycophorin — a protein found in the membranes of red blood cells — is predicted by this criterion to have one membrane-spanning helix, in agreement with experimental findings (**Figure 12.27B**). Note, however, that a peak in the hydropathy plot does not prove that a segment is a transmembrane helix. Even soluble proteins may have highly nonpolar regions. Conversely, some membrane proteins contain membrane-spanning features (such as a set of cylinder-forming β strands) that escape detection by these plots (**Figure 12.28**).

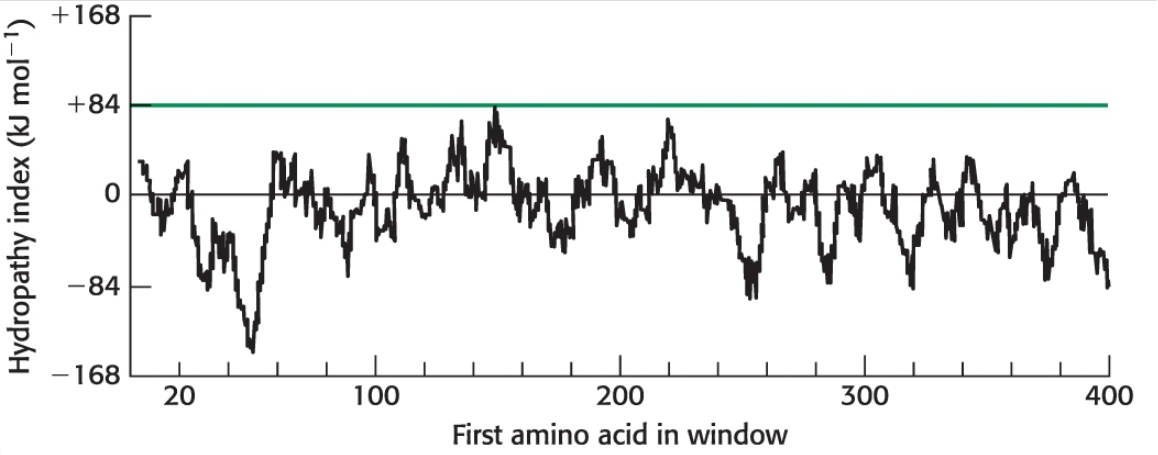

FIGURE 12.28 No strong peaks are observed in the hydropathy plot for porin. Porin is constructed from membrane-spanning β strands rather than α helices (Figure 12.20); hence, it escapes detection using this method.

Self-Check Question

Would a homopolymer of alanine be more likely to form an α helix in water or in a hydrophobic medium? Explain.

12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane

Biological membranes are not rigid, static structures. On the contrary, lipids and many membrane proteins are constantly in lateral motion, a process called **lateral diffusion**. The rapid lateral movement of membrane proteins has been visualized by means of fluorescence microscopy using the technique of fluorescence recovery after photobleaching (FRAP; **Figure 12.29**):

1. A cell-surface component is specifically labeled with a fluorescent chromophore, and a small region of the cell surface $(\sim 3\ \mu m^2)$ is viewed through a fluorescence microscope.

2. The fluorescent molecules in this region are then destroyed (bleached) by a very intense light pulse from a laser, as indicated by the pale spot in Figure 12.29A. The fluorescence of this region is subsequently monitored as a function of time by using a light level sufficiently low to prevent further bleaching.

3. If the labeled component is mobile, bleached molecules leave and unbleached molecules enter the illuminated region, resulting in an increase in the fluorescence intensity, a process called *recovery*. The rate of recovery depends on the lateral mobility of the fluorescence-labeled component, which can be expressed in terms of a diffusion coefficient, *D*. The average distance *S* traversed in time *t* depends on *D* according to the expression

$$S = (4Dt)^{1/2}$$

The diffusion coefficient of lipids in a variety of membranes is about $1\ \mu m^2\ s^{-1}$. Thus, a phospholipid molecule diffuses an average distance of $2\ \mu m$ in 1 s. This rate means that a lipid molecule can travel from one end of a bacterium to the other in a second. The magnitude of the observed diffusion coefficient indicates that the viscosity of the membrane is about 100 times that of water, rather like that of olive oil.

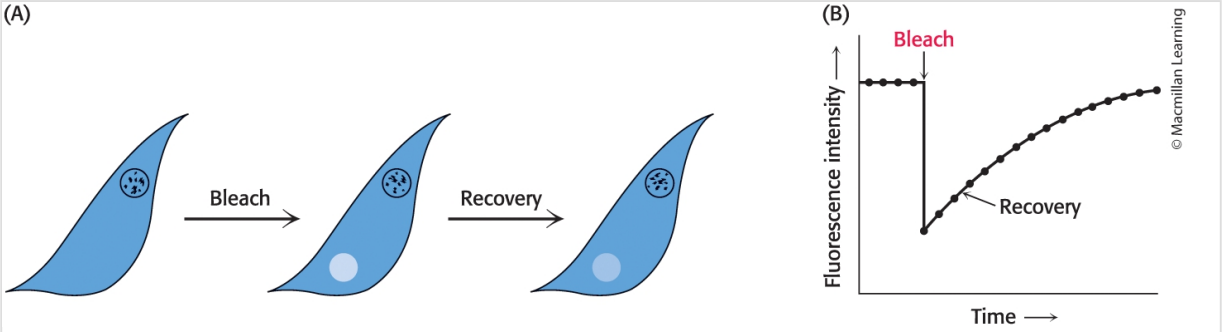

FIGURE 12.29 Lateral diffusion rates within a membrane can be measured using fluorescence recovery after photobleaching (FRAP). (A) The cell surface fluoresces because of a labeled surface component. The fluorescent molecules of a small part of the surface are bleached by an intense light pulse; then the fluorescence intensity recovers as bleached molecules diffuse out of the region and unbleached molecules diffuse into it. (B) The rate of recovery depends on the diffusion coefficient.

In contrast, proteins vary markedly in their lateral mobility. Some proteins are nearly as mobile as lipids, whereas others are virtually immobile. For example, the photoreceptor protein rhodopsin (Section 14.6), a very mobile protein, has a diffusion coefficient of $0.4\ \mu m^2\ s^{-1}$. The rapid movement of rhodopsin is essential for fast signaling. At the other extreme is fibronectin, a peripheral glycoprotein that interacts with the extracellular matrix. For fibronectin, *D* is less than $10^{-4} \mu m^2\ s^{-1}$. Fibronectin has a very low mobility because it is anchored to actin filaments on the inside of the plasma membrane

through integrin, a transmembrane protein that links the extracellular matrix to the cytoskeleton.

The fluid mosaic model allows lateral movement but not rotation through the membrane

On the basis of the mobility of proteins in membranes, in 1972 S. Jonathan Singer and Garth Nicolson proposed a **fluid mosaic model** to describe the overall organization of biological membranes. The essence of their model is that membranes are two-dimensional solutions of oriented lipids and globular proteins. The lipid bilayer has a dual role: it is both a solvent for integral membrane proteins and a permeability barrier. Membrane proteins are free to diffuse laterally in the lipid matrix unless restricted by special interactions.

Although the lateral diffusion of membrane components can be rapid, the spontaneous rotation of lipids from one face of a membrane to the other is a very slow process. The transition of a molecule from one membrane surface to the other is called *transverse diffusion* or *flip-flop* (**Figure 12.30**). The flip-flop of phospholipid molecules in phosphatidylcholine vesicles has been directly measured by electron spin resonance techniques, which show that a phospholipid molecule flip-flops once in several hours. Thus, a phospholipid molecule takes about 10^9 times as long to flip-flop across a membrane as it takes to diffuse a distance of 50 Å in the lateral direction. The free-energy barriers to flip-flopping are even larger for protein molecules than for lipids because proteins have more-extensive polar regions. In fact, the flip-flop of a protein molecule has not been observed. Hence, membrane asymmetry can be preserved for long periods.

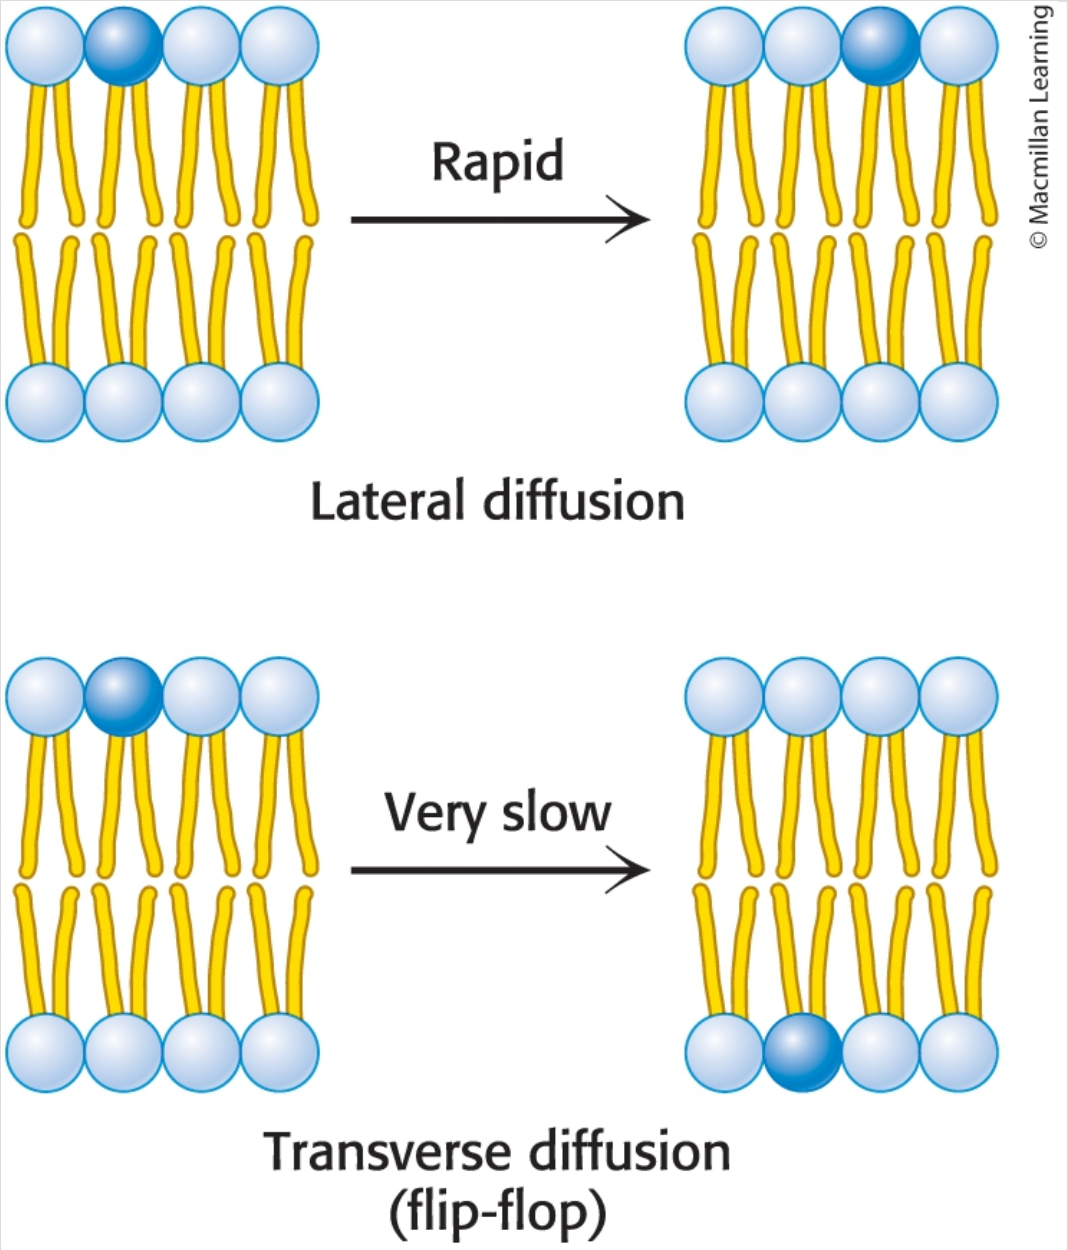

FIGURE 12.30 Lateral diffusion of lipids in membranes is much more rapid than transverse diffusion (flip-flop).

Membrane fluidity is controlled by fatty acid composition and cholesterol content

Many membrane processes, such as transport or signal transduction, depend on the fluidity of the membrane lipids, which in turn depends on the properties of fatty acid chains. Fatty acid chains in membrane bilayers can exist in an ordered, rigid state or in a relatively disordered, fluid state. The transition from the rigid to the fluid state takes place abruptly as the temperature is raised above T_m, the melting temperature (Figure 12.31).

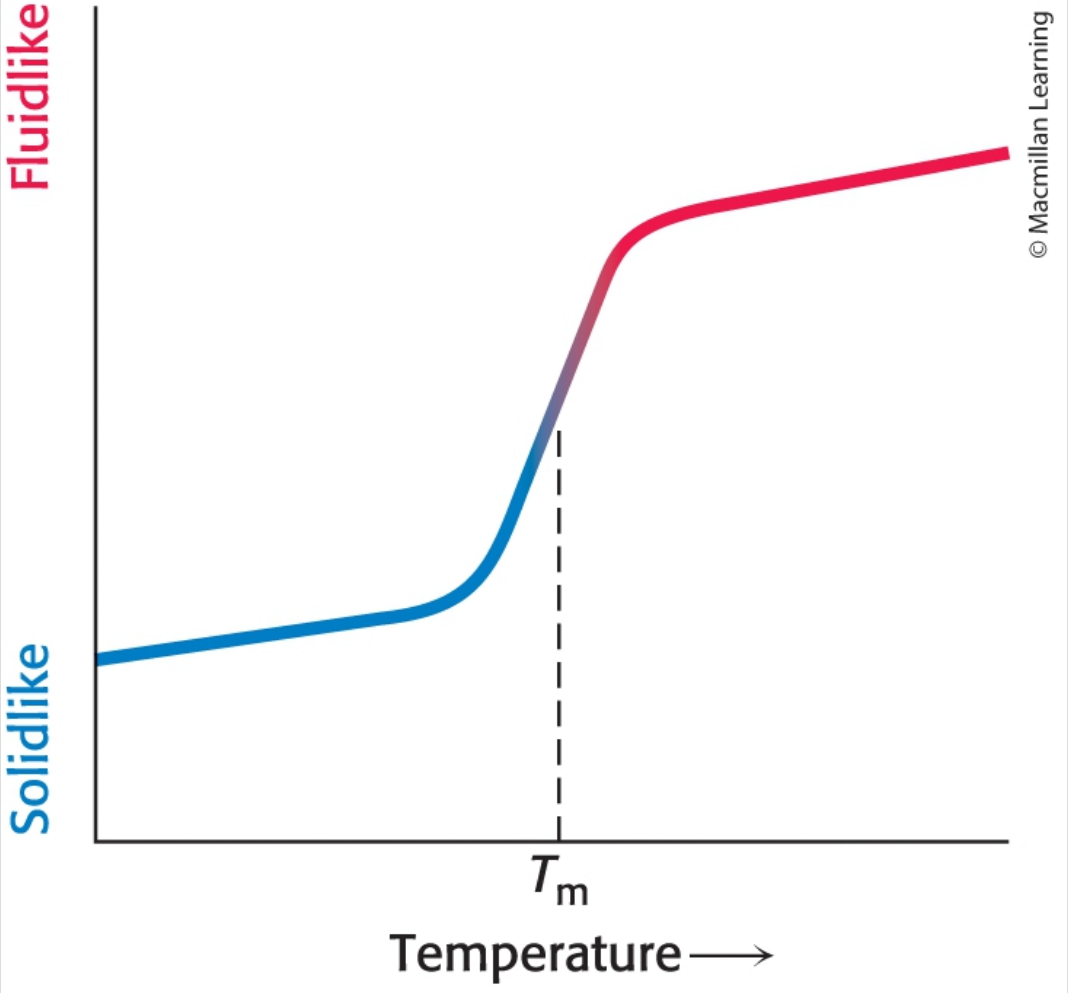

FIGURE 12.31 The melting temperature (T_m) for a phospholipid membrane represents the midpoint along the phase-transition curve. As the temperature is

raised, the phospholipid membrane changes from a packed, ordered state to a more random one.

The melting temperature of a fluid membrane depends on the length of the fatty acid chains and on their degree of unsaturation (Table 12.3). The presence of saturated fatty acid residues favors the rigid state because their straight hydrocarbon chains interact very favorably with one another. On the other hand, a cis double bond produces a bend in the hydrocarbon chain that interferes with a highly ordered packing of fatty acid chains, and so T_m is lowered (Figure 12.32). The length of the fatty acid chain also affects the transition temperature. Long hydrocarbon chains interact more strongly than do short ones. Specifically, each additional $-CH_2-$ group makes a favorable contribution of about $-2\ kJ\ mol^{-1}\ (-0.5\ kcal\ mol^{-1})$ to the free energy of interaction of two adjacent hydrocarbon chains.

TABLE 12.3 The melting temperature of phosphatidylcholine containing different pairs of identical fatty acid chains

		Fatty acid		
Number of carbons	**Number of double bonds**	**Common name**	**Systematic name**	**T_m (°C**
22	0	Behenate	*n*-Docosanoate	75
18	0	Stearate	*n*-Octadecanoate	58
16	0	Palmitate	*n*-Hexadecanoate	41
14	0	Myristate	*n*-Tetradecanoate	24

18	1	Oleate	*cis*-Δ^9-Octadecenoate	−22

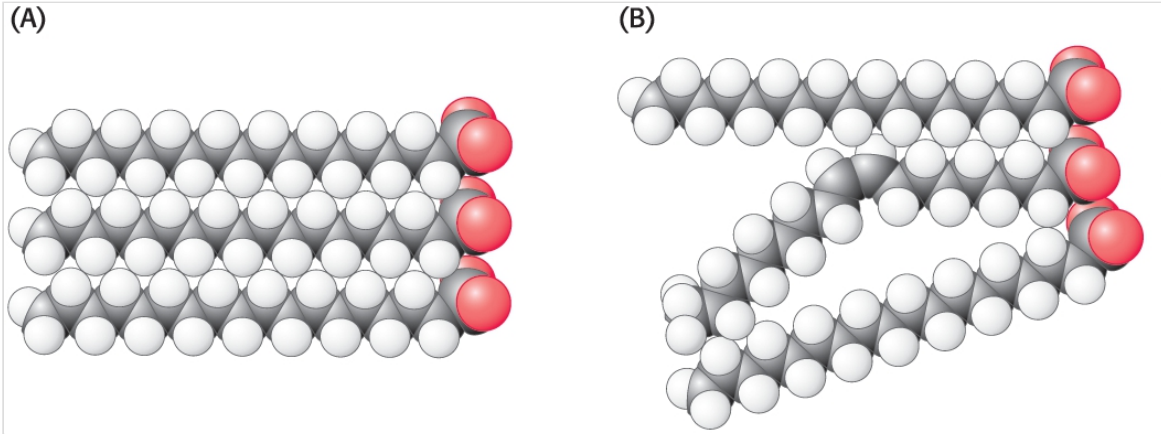

FIGURE 12.32 The highly ordered packing of fatty acid chains in a membrane is disrupted by the presence of cis double bonds. The space-filling models show the packing of (A) three molecules of stearate (C_{18}, saturated) and (B) a molecule of oleate (C_{18}, unsaturated) between two molecules of stearate.

Bacteria regulate the fluidity of their membranes by varying the number of double bonds and the length of their fatty acid chains. For example, the ratio of saturated to unsaturated fatty acid chains in the *E. coli* membrane decreases from 1.6 to 1.0 as the growth temperature is lowered from 42°C to 27°C. This decrease in the proportion of saturated residues prevents the membrane from becoming too rigid at the lower temperature.

In animals, cholesterol is the key regulator of membrane fluidity. Cholesterol contains a bulky steroid nucleus with a hydroxyl group at one end and a flexible hydrocarbon tail at the other end. Cholesterol inserts into bilayers with its long axis perpendicular to the plane of the membrane. The hydroxyl group of cholesterol forms a hydrogen bond

with a carbonyl oxygen atom of a phospholipid head group, whereas the hydrocarbon tail of cholesterol is located in the nonpolar core of the bilayer. The different shape of cholesterol compared with that of phospholipids disrupts the regular interactions between fatty acid chains (Figure 12.33).

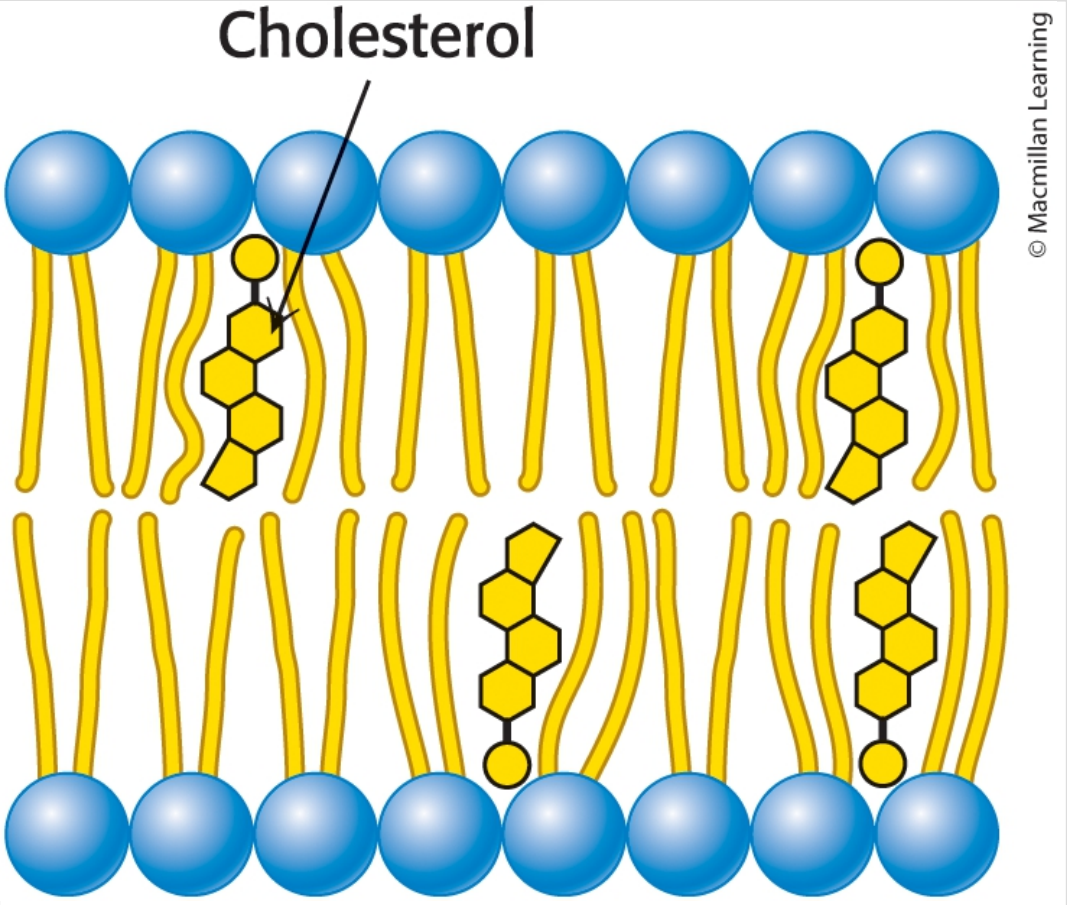

FIGURE 12.33 Cholesterol disrupts the tight packing of the fatty acid chains.

[Information from S. L. Wolfe, *Molecular and Cellular Biology* (Wadsworth, 1993).]

Self-Check Question

Explain why oleic acid (18 carbons, one cis bond) has a lower melting point than stearic acid, which has the same number of carbon atoms but is saturated. How would you expect the melting point of *trans*-oleic acid to compare with that of *cis*-oleic acid? Why might most unsaturated fatty acids in phospholipids be in the cis rather than the trans conformation?

Lipid rafts are highly dynamic complexes formed between cholesterol and specific lipids

In addition to its nonspecific effects on membrane fluidity, cholesterol can form complexes with lipids that contain the sphingosine backbone, including sphingomyelin and certain glycolipids, and with lipid-anchored membrane proteins. These complexes concentrate within small (10–200 nm) and highly dynamic regions within membranes, which have the potential to cluster into larger domains of greater than 300 nm. These structures are referred to as **lipid rafts** (**Figure 12.34A**).

FIGURE 12.34 Lipid rafts are membrane domains exhibiting reduced fluidity. (A) Cholesterol molecules, sphingomyelin (green head groups), and glycolipids (orange head groups) tend to be concentrated within the lipid rafts. These regions (shaded blue) provide the opportunity for changes in protein structure and oligomerization that may have significant functional consequences. (B) Image of a human monocytic cell, stained with a fluorescent dye sensitive to the level of disorder in its environment. Highly ordered regions have been colored red/yellow. Small regions of increased order, consistent with the presence of lipid raft domains, are apparent.

One result of these interactions is the moderation of membrane fluidity, making membranes less fluid but at the same time less subject to phase transitions. The presence of lipid rafts thus represents a modification of the original fluid mosaic model for biological membranes. Although their small size and dynamic nature have made them very difficult to study, recent developments in microscopy have significantly improved the ability to study these domains (**Figure 12.34B**).

What are the functions of lipid rafts? By segregation of certain lipid and protein species into smaller domains, lipid rafts may induce conformational changes in membrane proteins, regulating their functional activities. In addition, lipid rafts provide an environment favorable for specific protein–protein interactions, which can be used to promote signal transduction events (Chapter 14). Furthermore, it appears that pathogens, such as viruses, preferentially bind to lipid rafts to obtain entry into the cell and use lipid rafts to induce membrane budding and subsequent cellular escape. As technology advances, our appreciation of the importance of these membrane domains will likely expand.

All biological membranes are asymmetric

Membranes are structurally and functionally asymmetric: the outer and inner surfaces of all known biological membranes have different components and different enzymatic activities. A clear-cut example is the pump that regulates the concentration of Na^+ and K^+ ions in cells (**Figure 12.35**). This transport protein is located in the plasma membrane of nearly all cells in higher organisms. The $Na^+ - K^+$ pump

is oriented so that it pumps Na^+ out of the cell and K^+ into it. Furthermore, ATP must be on the inside of the cell to drive the pump. Ouabain, a specific inhibitor of the pump, is effective only if it is located outside. We shall consider the mechanism of this important and fascinating family of pumps in Chapter 13.

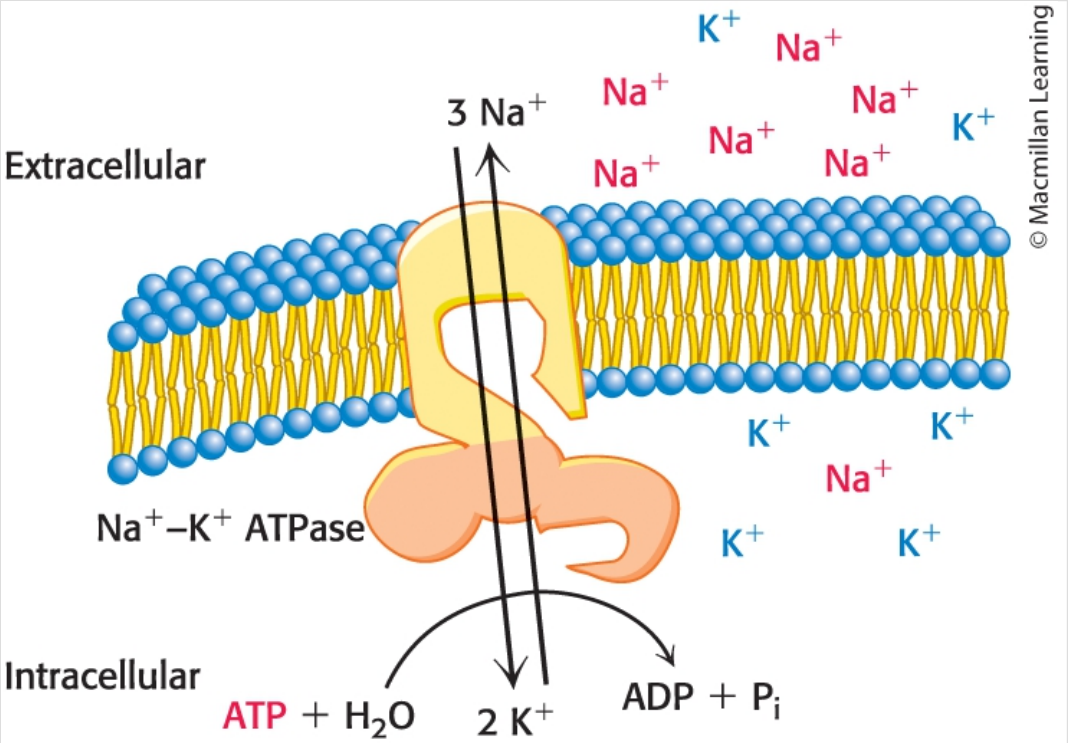

FIGURE 12.35 The orientation of the Na^+-K^+ transport system in the lipid bilayer exemplifies membrane asymmetry. The Na^+-K^+ transport system pumps Na^+ out of the cell and K^+ into the cell by hydrolyzing ATP on the intracellular side of the membrane.

Membrane proteins have a unique orientation because, after synthesis, they are inserted into the membrane in an asymmetric manner. This absolute asymmetry is preserved because membrane proteins do not

rotate from one side of the membrane to the other and because membranes are always synthesized by the growth of preexisting membranes.

Lipids, too, are asymmetrically distributed between the two membrane leaflets. For example, in the red-blood-cell membrane, sphingomyelin and phosphatidylcholine are preferentially located in the outer leaflet of the bilayer, whereas phosphatidylethanolamine and phosphatidylserine are located mainly in the inner leaflet. Large amounts of cholesterol are present in both leaflets.

12.6 Prokaryotes and Eukaryotes Differ in Their Use of Biological Membranes

Thus far, we have considered only the plasma membrane of eukaryotic cells. Some bacteria and archaea have only this single membrane, surrounded by a thick cell wall (Figure 12.36A). Other bacteria, such as *E. coli*, have two membranes separated by a cell wall (made of proteins, peptides, and carbohydrates) lying between them (Figure 12.36B). The inner membrane acts as the permeability barrier, and the outer membrane and the cell wall provide additional protection. The outer membrane is quite permeable to small molecules, owing to the presence of porins. The region between the two membranes containing the cell wall is called the *periplasm*.

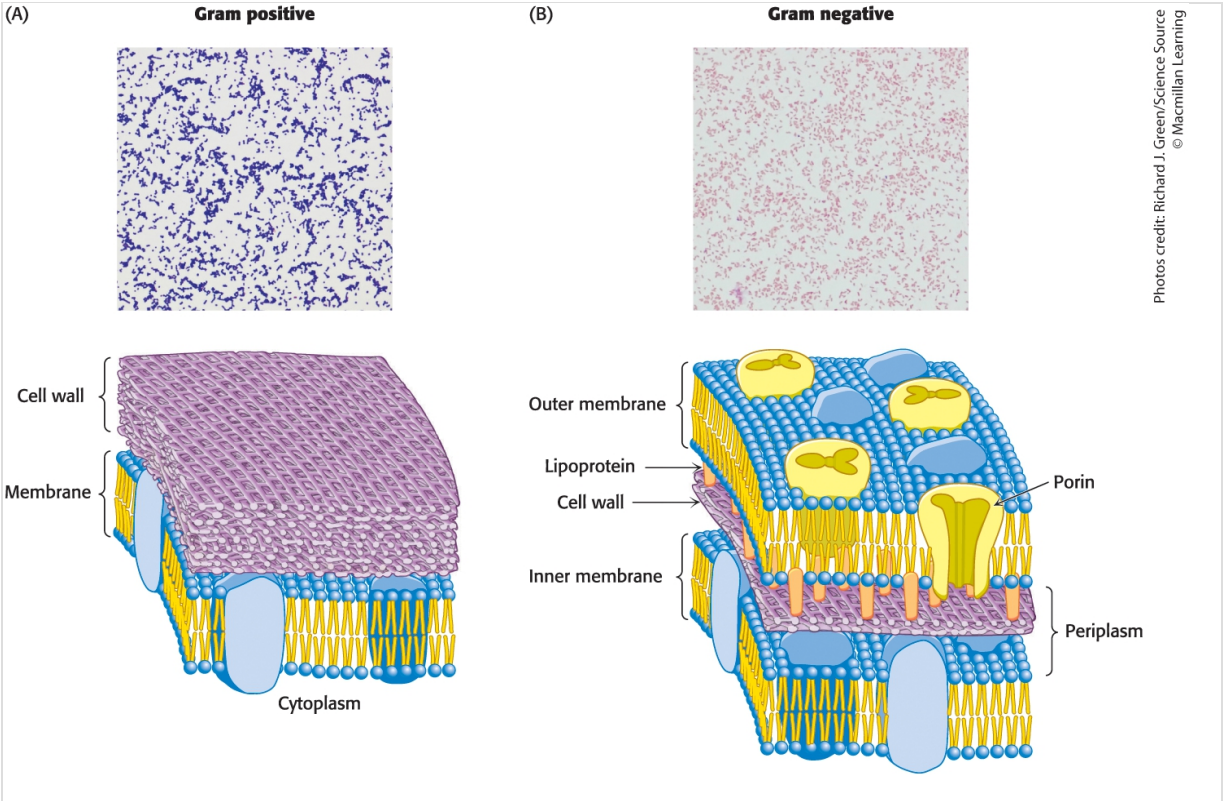

FIGURE 12.36 Bacteria can be classified based on their plasma membranes. (A) Some bacteria are surrounded by a single lipid bilayer encased in a thick cell wall. These bacteria are termed Gram positive since they retain the crystal violet stain in their cell walls. (B) Other bacteria are surrounded by two separate lipid bilayers. These bacteria are termed Gram negative because they do not retain crystal violet stain and appear pink.

The two types of bacterial membranes depicted in Figure 12.36 can be distinguished microscopically using a technique known as **Gram staining**, named for its inventor Hans Christian Gram. The dye called *crystal violet* is added to a fixed sample of bacteria, followed by iodine to trap the dye in the cell. Then, alcohol is used to wash out the dye. In those cells with a thick cell wall, as shown in Figure 12.36A, the trapped dye binds quite tightly and does not wash out. These bacteria stain dark purple, and are referred to as *Gram positive*. In those cells where the cell wall is very thin, the dye washes out quickly; these bacteria appear pink (due to the addition of a second stain at the conclusion of the experiment) and are referred to as *Gram negative* (Figure 12.36B). Gram staining is an important method for the initial classification of a bacterial sample, particularly in fluid samples from an infected patient, where rapid identification of bacterial type is critical for the selection of antibiotic treatment.

Eukaryotic cells contain compartments bounded by internal membranes

Eukaryotic cells, with the exception of plant cells, do not have cell walls, and their plasma membranes consist of a single lipid bilayer. In plant cells, the cell wall is on the outside of the plasma membrane. Eukaryotic cells are distinguished from prokaryotic cells by the presence of membranes inside the cell that form internal compartments. For

example, peroxisomes, organelles that play a major role in the oxidation of fatty acids for energy conversion, are defined by a single membrane. The nucleus is surrounded by a double membrane, the *nuclear envelope*, that consists of a set of closed membranes that come together at structures called *nuclear pores* (Figure 12.37). These pores regulate transport into and out of the nucleus. The nuclear envelope is linked to another membrane-defined structure, the *endoplasmic reticulum*, which plays a host of cellular roles, including drug detoxification and the modification of proteins for secretion.

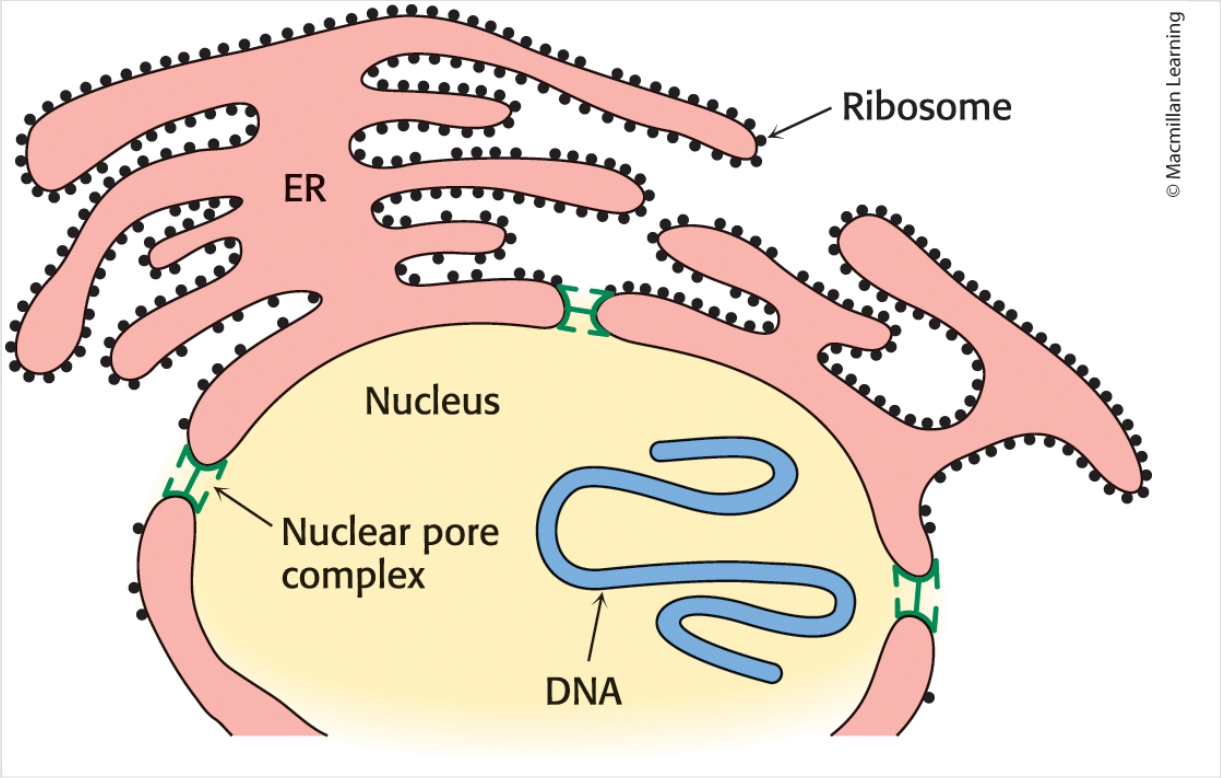

FIGURE 12.37 The nuclear envelope is a double membrane connected to another membrane system of eukaryotes, the endoplasmic reticulum.

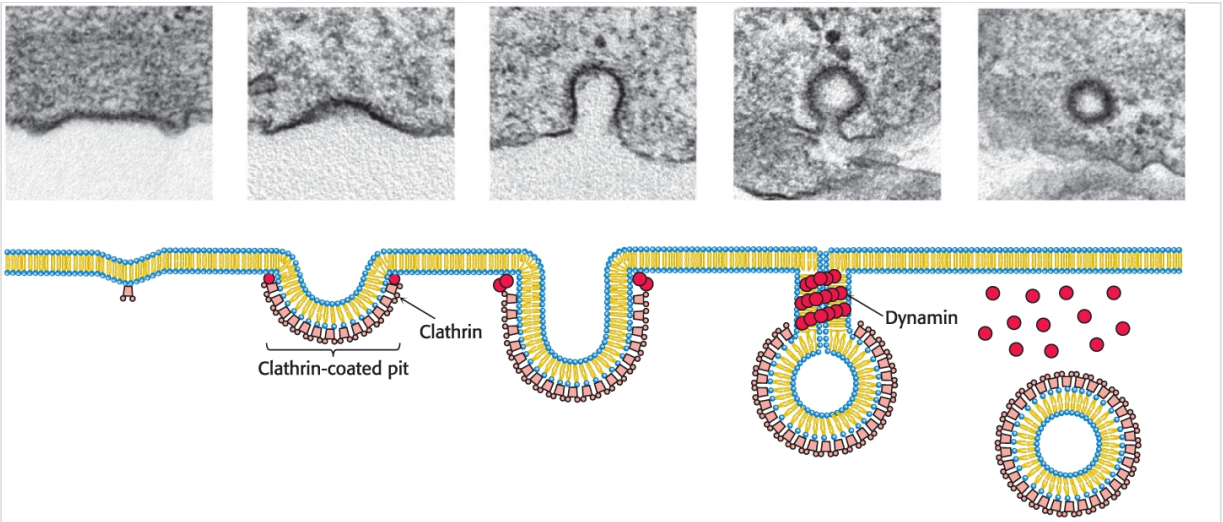
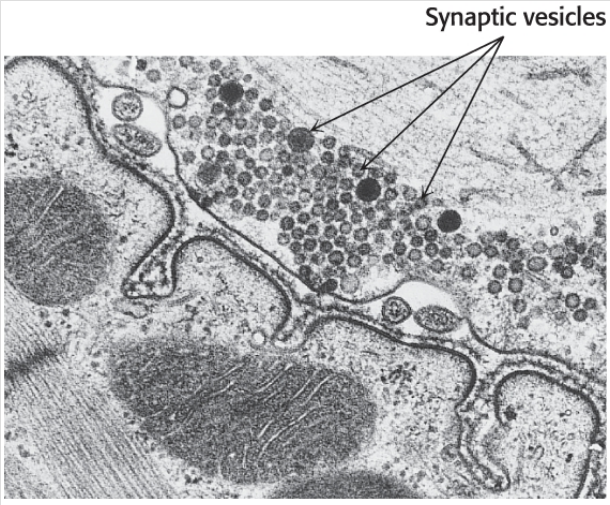


[Information from E. C. Schirmer and L. Gerace, *Genome Biol*. 3(4):1008.1–1008.4, 2002, reviews, Fig.1.]

Mitochondria, the organelles in which ATP is synthesized, are also surrounded by two membranes. As in the case for a bacterium, the

outer membrane is quite permeable to small molecules, whereas the inner membrane is not. Indeed, considerable evidence now indicates that mitochondria evolved from bacteria by endosymbiosis (Section 18.1).



Membrane budding and fusion are highly controlled processes

Membranes must be able to separate (by budding) or join together (by fusion) so that cells and compartments may take up, transport, and release molecules. Let us consider an example of membrane budding using an example at the plasma membrane. Many cells take up molecules through the process of **receptor-mediated endocytosis**. Here, a protein or larger complex initially binds to a receptor on the cell surface. After the receptor is bound, specialized proteins act to cause the membrane in this region to invaginate. One of these specialized proteins is clathrin, which polymerizes into a lattice network around the growing membrane bud, often referred to as a *clathrin-coated pit* (**Figure 12.38**). Through the action of a GTPase enzyme called *dynamin*, the invaginated membrane eventually breaks off and fuses to form a vesicle. Various hormones, transport proteins, and antibodies employ receptor-mediated endocytosis to gain entry into a cell. A less-advantageous consequence is that this pathway is available to viruses and toxins as a means of invading cells. The reverse process — the fusion of a vesicle to a membrane — is a key step in the release of neurotransmitters from a neuron into the synaptic cleft (**Figure 12.39**).

FIGURE 12.39 Vesicle fusion to the plasma membrane is critical for neurotransmitter release. Neurotransmitter-containing synaptic vesicles (indicated by the arrows on the micrograph at le are arrayed near the plasma membrane of a nerve cell. Synaptic vesicles fuse with the plasma membrane, releasing the neurotransmitter into the synaptic cleft.

Let's consider one example of receptor-mediated endocytosis. Iron is a critical element for the function and structure of many proteins, including hemoglobin and myoglobin (Chapter 3). However, free iron ions are highly toxic to cells, owing to their ability to catalyze the formation of free radicals. Hence, the transport of iron atoms from the digestive tract to the cells where they are most needed must be tightly controlled. In the bloodstream, iron is bound very tightly by the protein transferrin, which can bind two Fe^{3+} ions with a dissociation constant of $10^{-23}\ M$ at neutral pH. Cells requiring iron express the transferrin receptor in their plasma membranes (Section 31.6).

Formation of a complex between the transferrin receptor and iron-bound transferrin initiates receptor-mediated endocytosis, internalizing these complexes within vesicles called **endosomes** (**Figure 12.40**). As the endosomes mature, proton pumps within the vesicle membrane lower the lumenal pH to about 5.5. Under these conditions, the affinity of iron ions for transferrin is reduced; these ions are released and are free to pass through channels in the endosomal membranes into the cytoplasm. The iron-free transferrin complex is recycled to the plasma membrane, where transferrin is released back into the bloodstream and the transferrin receptor can participate in another uptake cycle.

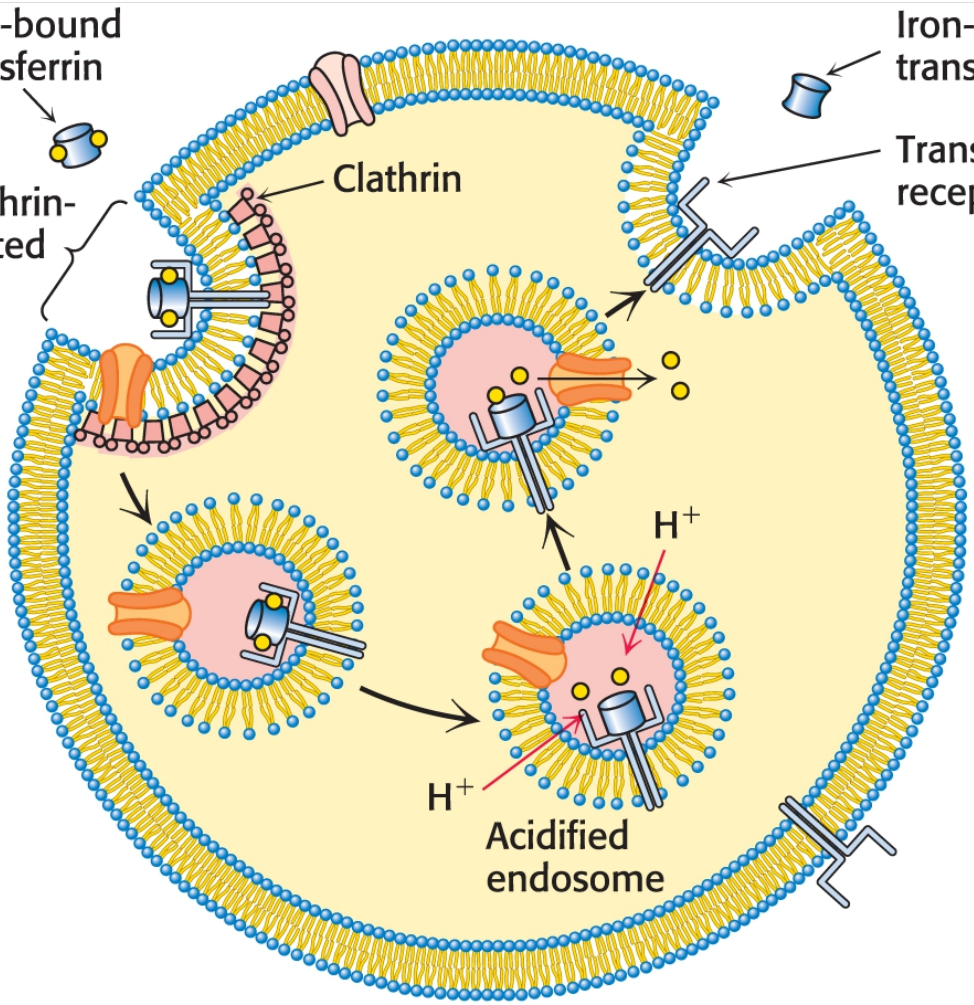

FIGURE 12.40 Receptor-mediated endocytosis of the transferrin receptor mediates cellular uptake of iron. Iron-bound transferrin binds to the transferrin receptor (TfR) on the surface of cells. Receptor-mediated endocytosis occurs, leading to the formation of a vesicle called an endosome. As the lumen of the endosome is acidified by the action of proton pumps, iron is released from transferrin, passes through channels in the membrane, and is used by the cell. Th complex between iron-free transferrin and the transferrin receptor is returned to the plasma membrane for another cycle.

[Information from L. Zecca et al., *Nat. Rev. Neurosci*. 5:863–873, 2004, Fig.1.]

Membrane budding and fusion events throughout the cell must be highly specific in order to prevent incorrect membrane fusion events. The structures of the intermediates in these processes and the detailed

mechanisms remain ongoing areas of investigation. Researchers have identified *SNARE proteins* — short for soluble *N*-ethylmaleimide-sensitive-factor attachment protein receptor — as essential to these processes. SNARE proteins guide membrane fusion by drawing appropriate lipid bilayers together through the formation of tightly coiled four-helical bundles (Figure 12.41). Once these membranes are brought into close proximity with one another, the fusion process can proceed. In addition, SNARE proteins, which are encoded by gene families in all eukaryotic cells, largely determine the compartment with which a vesicle will fuse. The specificity of membrane fusion ensures the orderly trafficking of membrane vesicles and their cargos through eukaryotic cells.

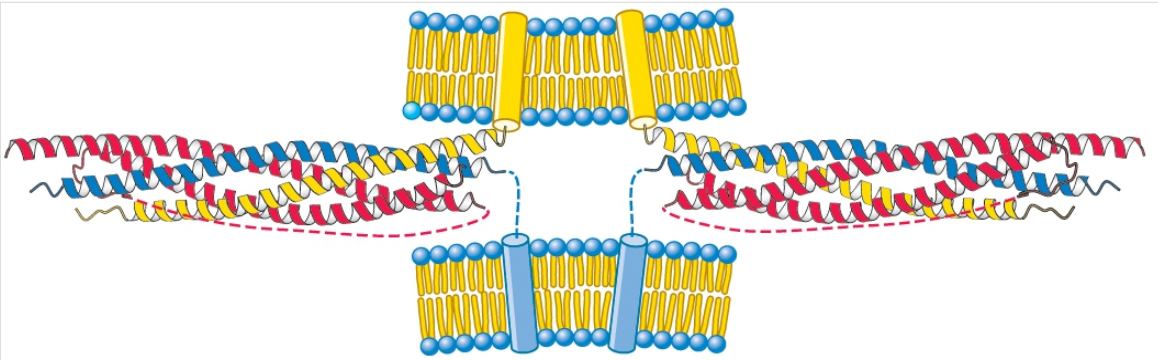

FIGURE 12.41 SNARE complexes initiate membrane fusion. The SNARE protein synaptobrevin (yellow) from one membrane forms a tight four-helical bundle with the corresponding SNARE proteins syntaxin-1 (blue) and SNAP25 (red) from a second membrane. The complex brings the membranes close together, initiating the fusion event.

Chapter 12 Summary

12.1 Fatty Acids Are Key Constituents of Lipids

- Fatty acids are hydrocarbon chains of various lengths and degrees of unsaturation that terminate with a carboxylic acid group.
- The fatty acid chains in membranes usually contain between 14 and 24 carbon atoms; they may be saturated or unsaturated.
- Short chain length and unsaturation enhance the fluidity of fatty acids and their derivatives by lowering the melting temperature.

12.2 Biological Membranes Are Composed of Three Common Types of Membrane Lipids

- The major types of membrane lipids are phospholipids, glycolipids, and cholesterol.
- Phosphoglycerides, a type of phospholipid, consist of a glycerol backbone, two fatty acid chains, and a phosphorylated alcohol.
- Phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine are major phosphoglycerides.
- Sphingomyelin, a different type of phospholipid, contains a sphingosine backbone instead of glycerol.
- Glycolipids are sugar-containing lipids derived from sphingosine.
- Cholesterol, which modulates membrane fluidity, is constructed from a steroid nucleus.

12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media

- Membrane lipids spontaneously form extensive bimolecular sheets in aqueous solutions.
- The driving force for membrane formation is the hydrophobic interactions among the fatty acid tails of membrane lipids. The

hydrophilic head groups interact with the aqueous medium.
- Lipid bilayers are cooperative structures, held together by many weak bonds.
- These lipid bilayers are highly impermeable to ions and most polar molecules, yet they are quite fluid, which enables them to act as a solvent for membrane proteins.

12.4 Proteins Carry Out Most Membrane Processes

- Biological membranes vary in their protein content, which reflects the diverse functions of various cell types.
- Integral membrane proteins interact extensively with the hydrocarbon chains of membrane lipids, and they can be released only by agents that compete for these nonpolar interactions.
- Peripheral membrane proteins are bound to membranes primarily by electrostatic and hydrogen-bond interactions with the head groups of lipids and can be released by adding salt or changing the pH.
- Membrane-spanning proteins have regular structures, including β strands, although the α helix is most common.
- Membrane-spanning α helices can often be predicted from amino acid sequence using a hydropathy plot.

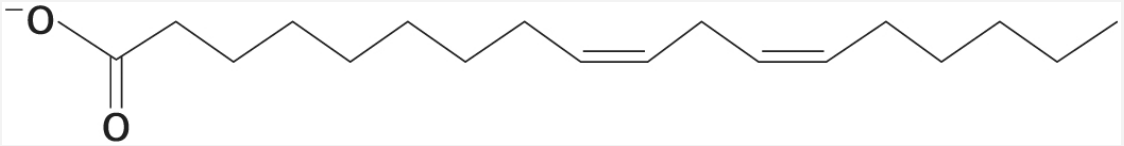
12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane

- Membranes are dynamic structures in which proteins and lipids diffuse rapidly in the plane of the membrane.
- The rotation of lipids from one face of a membrane to the other is usually very slow.
- Proteins do not rotate across bilayers; hence, membrane asymmetry can be preserved.
- The degree of fluidity of a membrane depends on the chain length of its lipids and on the extent to which their constituent

fatty acids are unsaturated.
- In animals, cholesterol content also regulates membrane fluidity.

12.6 Prokaryotes and Eukaryotes Differ in Their Use of Biological Membranes

- Most bacteria exhibit one of two types of membranes: a single membrane surrounded by a cell wall, or a double membrane, where the inner membrane serves as the permeability barrier.
- An extensive array of internal membranes in eukaryotes creates compartments within a cell for distinct biochemical functions.
- The budding and fusion of membranes are highly controlled processes.
- Receptor-mediated endocytosis enables the formation of intracellular vesicles when ligands bind to their corresponding receptor proteins in the plasma membrane.
- The reverse process — the fusion of a vesicle to a membrane — is a key step in the release of signaling molecules outside the cell.

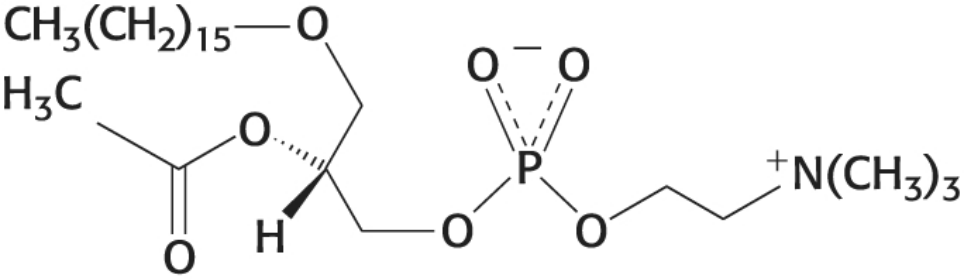


Key Terms

lipids
fatty acid
phospholipid
phosphoglyceride
sphingomyelin
sphingosine
glycolipid
cholesterol
amphipathic (amphiphilic) molecule
micelle
lipid bilayer
liposome (lipid vesicle)

myelin
integral membrane protein
peripheral membrane protein
hydropathy plot
lateral diffusion
fluid mosaic model
lipid rafts
Gram staining
receptor-mediated endocytosis
endosomes

Problems



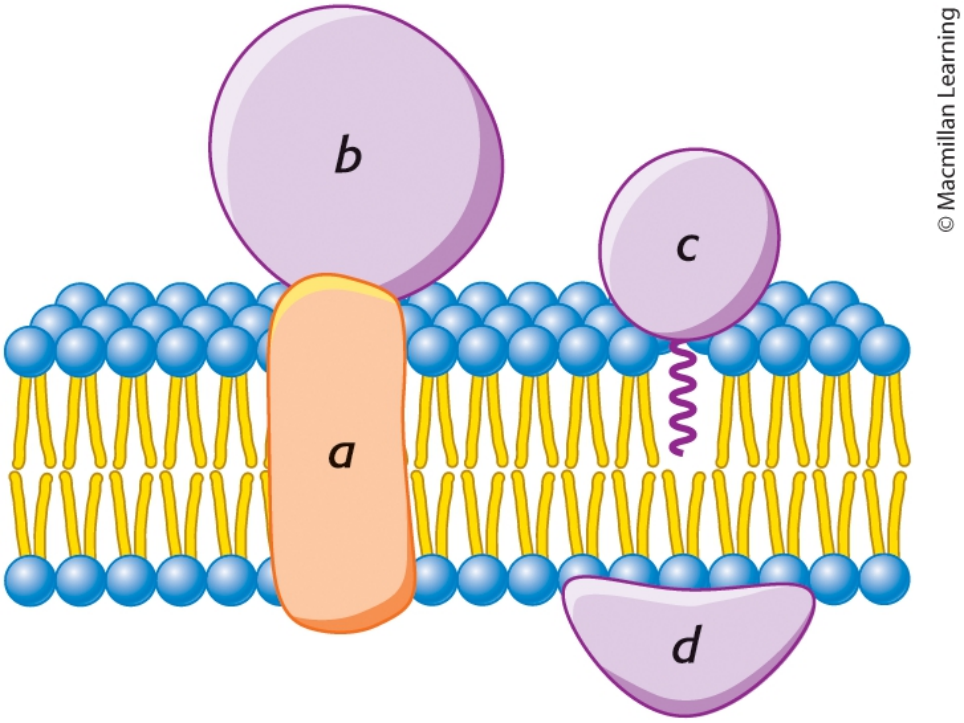
1. Consider the following fatty acid:

What is an accurate designation of this structure that indicates the length, degree of unsaturation, and location of double bonds? What is the common name for this fatty acid (see Table 12.1)? What are the positions of the double bonds expressed in relation to the distal carbon atom? 1

2. Draw the chemical structure of cis-Δ^9-hexadecenoic acid. What is the common name for this fatty acid? 1

3. Platelet-activating factor (PAF) is a phospholipid that plays a role in allergic and inflammatory responses, as well as in toxic shock syndrome. The structure of PAF is shown here. How does it differ from the structures of the phospholipids discussed in this chapter? 2

Platelet-activating factor (PAF)



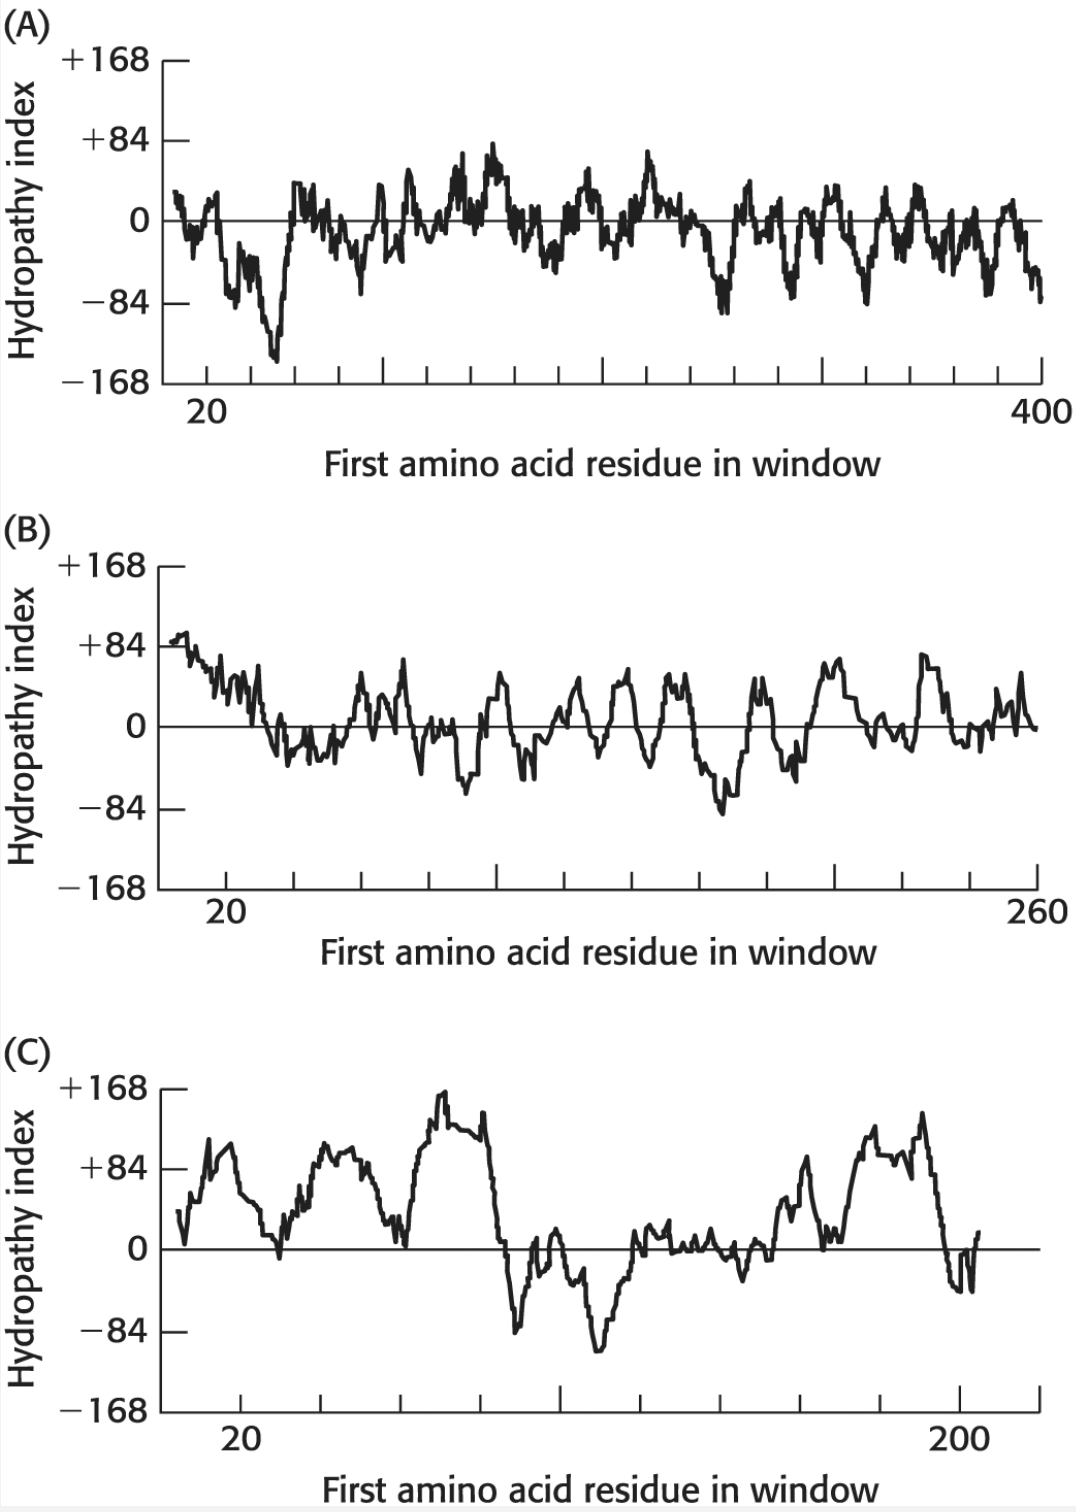
4. Match the following statements with the type of lipid it best describes: phospholipids, sphingolipids, glycolipids, archaeal lipids, or cholesterol. Some statements may describe more than one lipid type: 2

a. Includes two fatty acids joined to glycerol by ester linkages
b. Does not contain glycerol
c. Is a steroid
d. Contains a sphingosine backbone
e. Contains one or more sugars
f. Usually have branched alkyl chains

5. What is the average distance traversed by a membrane lipid in $1\ \mu s$, 1 ms, and 1 s? Assume a diffusion coefficient of $10^{-8}\ cm^2\ s^{-1}$. 6

6. Which of the following molecules could align side-by-side to form a lipid bilayer: phospholipids, fatty acids, triacylglycerol, sphingolipids, cholesterol? 3

7. Label the molecules in the diagram below as either integral membrane proteins, peripheral membrane proteins, or lipid-anchored membrane proteins: 4



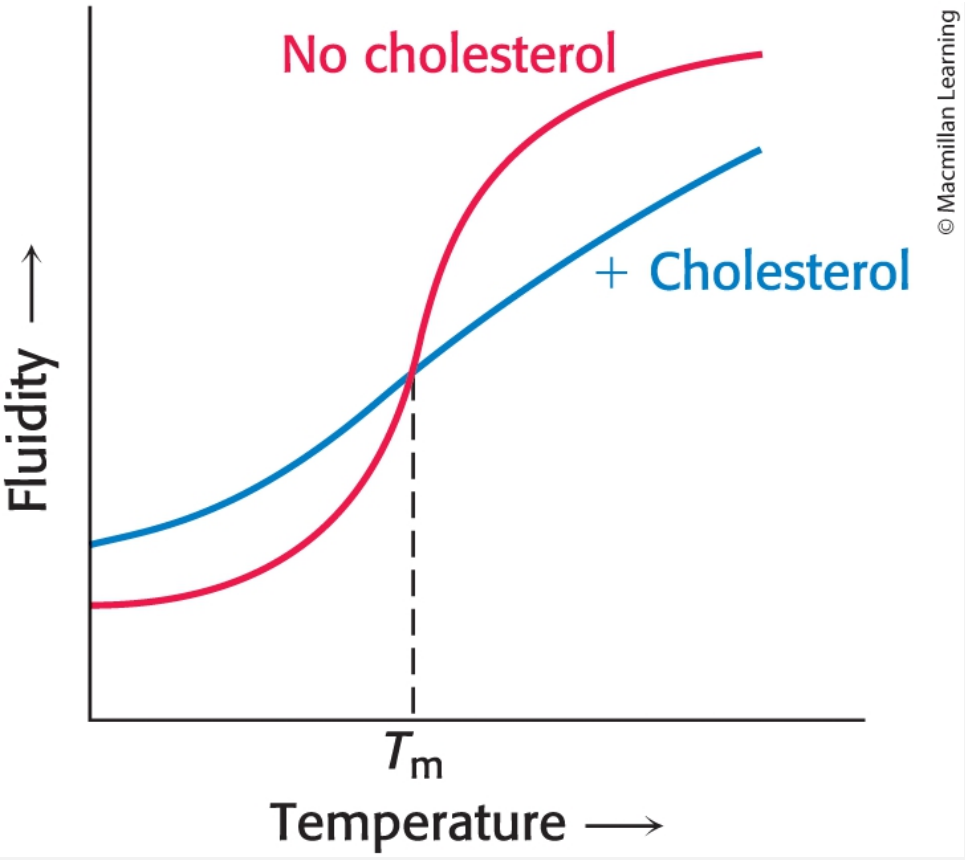
8. Match each statement to the category of membrane-associated protein it describes: membrane-spanning α helix,

membrane spanning β strands, lipid-anchored membrane protein, or peripheral membrane protein: 4

a. Contains residue(s) with covalently attached fatty acyl groups
b. Often tethered to the membrane via a membrane-embedded protein
c. Composed of about 20 hydrophobic residues
d. Can usually be released from the membrane with concentrated salt solutions
e. Features a pattern of alternating nonpolar and polar side chains

9. On the basis of the following hydropathy plots for three proteins (A–C), predict which would be membrane proteins. What are the ambiguities with respect to using such plots to determine if a protein is a membrane protein? 5

© Macmillan Learning



10. Hydropathy plot analysis of your protein of interest reveals a single, prominent hydrophobic peak. However, you later discover that this protein is soluble and not membrane associated. Explain how the hydropathy plot may have been misleading. 5

11. The diffusion coefficient, *D*, of a rigid spherical molecule is given by

$$D = kT/6\pi\eta r$$

in which η is the viscosity of the solvent, *r* is the radius of the sphere, *k* is the Boltzmann constant $(1.38 \times 10^{-16} \text{erg degree}^{-1})$, and *T* is the absolute temperature. What is the diffusion coefficient at 37°C of a 100-kDa protein in a membrane that has an effective viscosity of 1 poise $(1 \text{ poise} = 1 \text{ erg s}^{-1} \text{ cm}^{-3})$? What is the average distance traversed by this protein in $1\ \mu s$, 1 ms, and 1 s? Assume that this protein is an unhydrated, rigid sphere with a density of 1.35 g cm^{-3}. 5

12. The red curve on the following graph shows the fluidity of the fatty acids of a phospholipid bilayer as a function of temperature. The blue curve shows the fluidity in the presence of cholesterol. 6

a. What is the effect of cholesterol?
b. Why might this effect be biologically important?

13. Calculate the distance olive oil (a lipid) could move in a membrane in 13 seconds assuming the diffusion coefficient is $1\ \mu m^2\ s^{-1}$. Use the equation $S = (4Dt)^{1/2}$ where S is the distance traveled, t is time, and D is the diffusion coefficient. 6

14. Arrange the fatty acids in order of increasing melting point:

a. Stearic acid (18:0)

b. Oleic acid (18:1)
c. Palmitoleic acid (16:1)
d. α-Linoleic acid (18:3)
e. Palmitic acid (16:0)

15. Each intracellular fusion of a vesicle with a membrane requires a SNARE protein on the vesicle (called the v-SNARE) and a SNARE protein on the target membrane (called the t-SNARE). Assume that a genome encodes 21 members of the v-SNARE family and 7 members of the t-SNARE family. With the assumption of no specificity, how many potential v-SNARE–t-SNARE interactions could take place? 7

16. Some antibiotics act as carriers that bind an ion on one side of a membrane, diffuse through the membrane, and release the ion on the other side. The conductance of a lipid-bilayer membrane containing a carrier antibiotic decreased abruptly when the temperature was lowered from 40°C to 36°C. In contrast, there was little change in conductance of the same bilayer membrane when it contained a channel-forming antibiotic. Why?

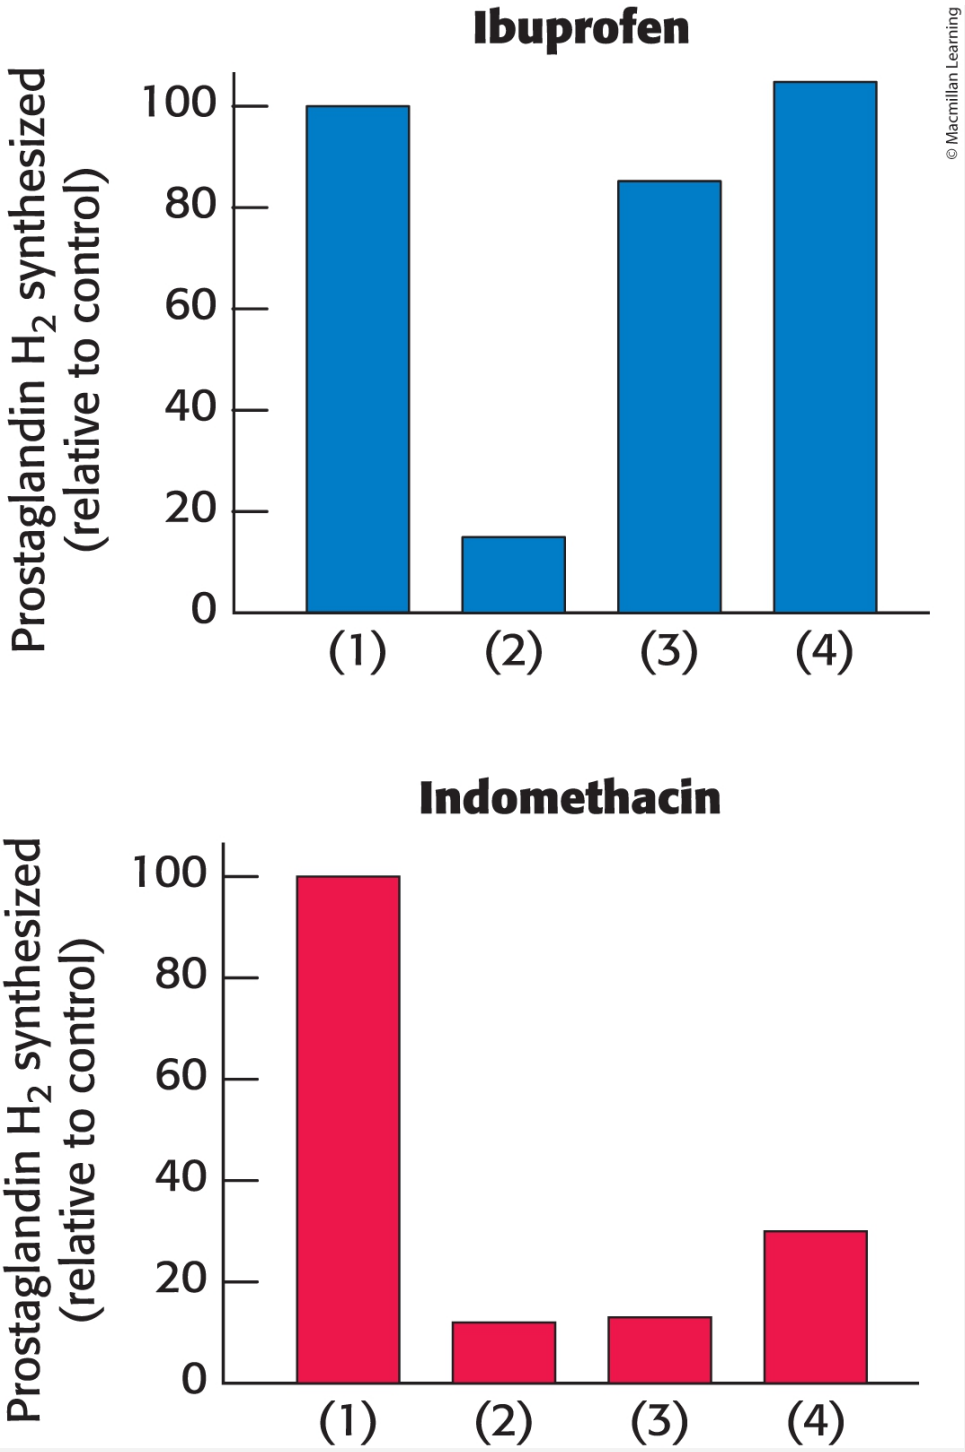
17. Of the following pairs of ions and/or molecules, identify which one is more permeable across a lipid bilayer:

a. K^+ vs. H_2O
b. Tryptophan vs. indole
c. H_2O vs. Cl^-

In general the permeability coefficient is most directly correlated with which property: size, flexibility, solubility in nonpolar solvents, or interaction with polar head groups?

18. Small mammalian hibernators can withstand body temperatures of 0 – 5°C without injury. However, the body fats of

most mammals have melting temperatures of approximately 25°C. Predict how the composition of the body fat of hibernators might differ from that of their nonhibernating cousins. 6

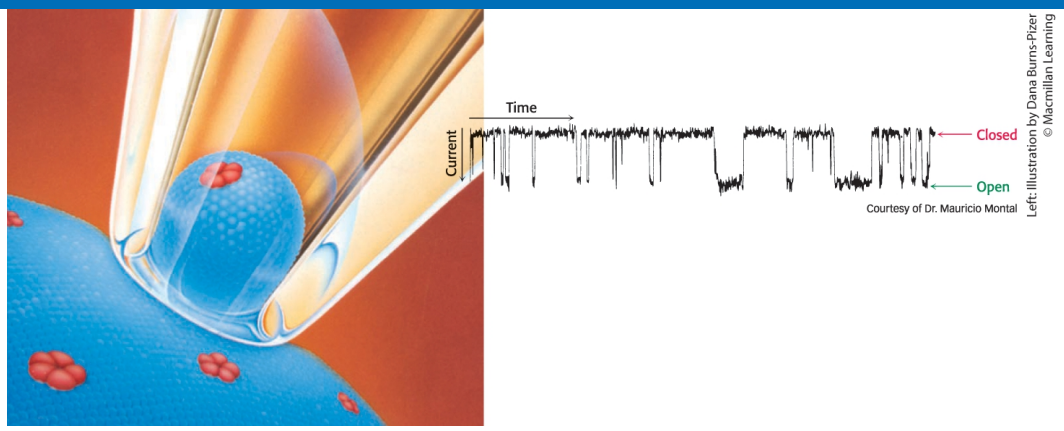


19. Classify each of these statements as to whether they describe saturated phospholipids, unsaturated phospholipids, or both:

a. Contain one or more double bonds within their fatty acid tails
b. Are built upon a glycerol backbone
c. Produce a fairly inflexible membrane at low temperatures
d. Have bent fatty acid tails

20. Ibuprofen and indomethacin are clinically important inhibitors of prostaglandin H_2 synthase-1. Cells expressing this enzyme were incubated under the following conditions, after which the activity of the enzyme was measured by adding radiolabeled arachidonic acid and detecting newly produced prostaglandin H_2:

1. 40 min *without* inhibitor (control)
2. 40 min with inhibitor
3. 40 min with inhibitor, after which the cells were resuspended in medium *without* inhibitor
4. 40 min with inhibitor, after which the cells were resuspended in medium *without* inhibitor and incubated for an additional 30 minutes



The results are shown below:

© Macmillan Learning

a. Provide a hypothesis explaining the different results for these two inhibitors.
b. How would these results look if aspirin were tested in a similar fashion?

Chapter 13
Membrane Channels and Pumps

The flow of ions through a single membrane channel (channels are shown in red in the illustration at the left) can be detected by the patch-clamp technique, which records current changes as the channel alternates between open and closed states.

Outline

13.1 The Transport of Molecules Across a Membrane May Be Active or Passive
13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Pump Ions and Molecules Across Membranes
13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another
13.4 Specific Channels Can Rapidly Transport Ions Across Membranes
13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells

[13.6 Specific Channels Increase the Permeability of Some Membranes to Water]

Learning Goals

By the end of this chapter, you should be able to:

1. Distinguish between passive and active transport.
2. Calculate the free energy stored in a concentration or electrochemical gradient.
3. Compare the mechanisms of the P-type ATPase pump and the ABC transporter pump.
4. Contrast primary and secondary active transport.
5. Explain how channels are able to rapidly and selectively move ions across membranes.
6. Describe two mechanisms by which ion channels are gated.
7. Explain the steps that lead to the formation of an action potential.

The lipid bilayer of biological membranes is intrinsically impermeable to ions and polar molecules, yet these species must be able to cross these membranes for normal cell function. As we will discuss in this chapter, permeability is conferred by three classes of membrane transporter proteins: pumps, carriers, and channels. These proteins are critical for many basic cellular functions, including access to ions and solutes for metabolism, conduction of nerve impulses, contraction of muscles, and communication of signals within cells.

Consider, for example, the rhythmic beating of the heart: the coordinated movement of ions across cardiac cellular membranes can sustain the contraction of heart muscle for, on average, 60 times each minute for over 70 years — a total of over 2.2 billion

contractions! The remarkable consistency of cardiac contraction is just one example of the importance of these protein classes.

13.1 The Transport of Molecules Across a Membrane May Be Active or Passive

We will first consider some general principles of membrane transport. Two factors determine whether a molecule will cross a membrane: (1) the permeability of the molecule in a lipid bilayer and (2) the availability of an energy source.

Many molecules require protein transporters to cross membranes

As stated in Chapter 12, some molecules can pass through cell membranes because they dissolve in the lipid bilayer. Such molecules are called *lipophilic molecules*. The steroid hormones provide a physiological example. These cholesterol relatives can pass through a membrane, but what determines the direction in which they will move? Such molecules will pass through a membrane down their concentration gradient in a process called **simple diffusion**. In accord with the Second Law of Thermodynamics, molecules spontaneously move from a region of higher concentration to one of lower concentration.

Matters become more complicated when the molecule is highly polar. For example, sodium ions are present at 143 mM outside a typical cell and at 14 mM inside the cell. However, sodium does not freely enter the cell, because the charged ion cannot pass through the hydrophobic membrane interior. In some circumstances, as

during a nerve impulse, sodium ions must enter the cell. How are they able to do so? Sodium ions pass through specific channels in the hydrophobic barrier formed by membrane proteins. This means of crossing the membrane is called **facilitated diffusion** because the diffusion across the membrane is facilitated by the channel. It is also called **passive transport** because the energy driving the ion movement originates from the ion gradient itself, without any contribution by the transport system. Channels, like enzymes, display substrate specificity in that they facilitate the transport of some ions, but not other, even closely related, ions.

How is the sodium gradient established in the first place? In this case, sodium must move, or be pumped, *against* a concentration gradient. Because moving the ion from a low concentration to a higher concentration results in a decrease in entropy, it requires an input of free energy. Protein transporters embedded in the membrane are capable of using an energy source to move the molecule up a concentration gradient. Because an input of energy from another source is required, this means of crossing the membrane is called **active transport**.

Free energy stored in concentration gradients can be quantified

An unequal distribution of molecules is an energy-rich condition because free energy is minimized when all concentrations are equal. Consequently, to attain such an unequal distribution of molecules requires an input of free energy. How can we quantify the amount of energy required to generate a concentration gradient (**Figure 13.1**)?

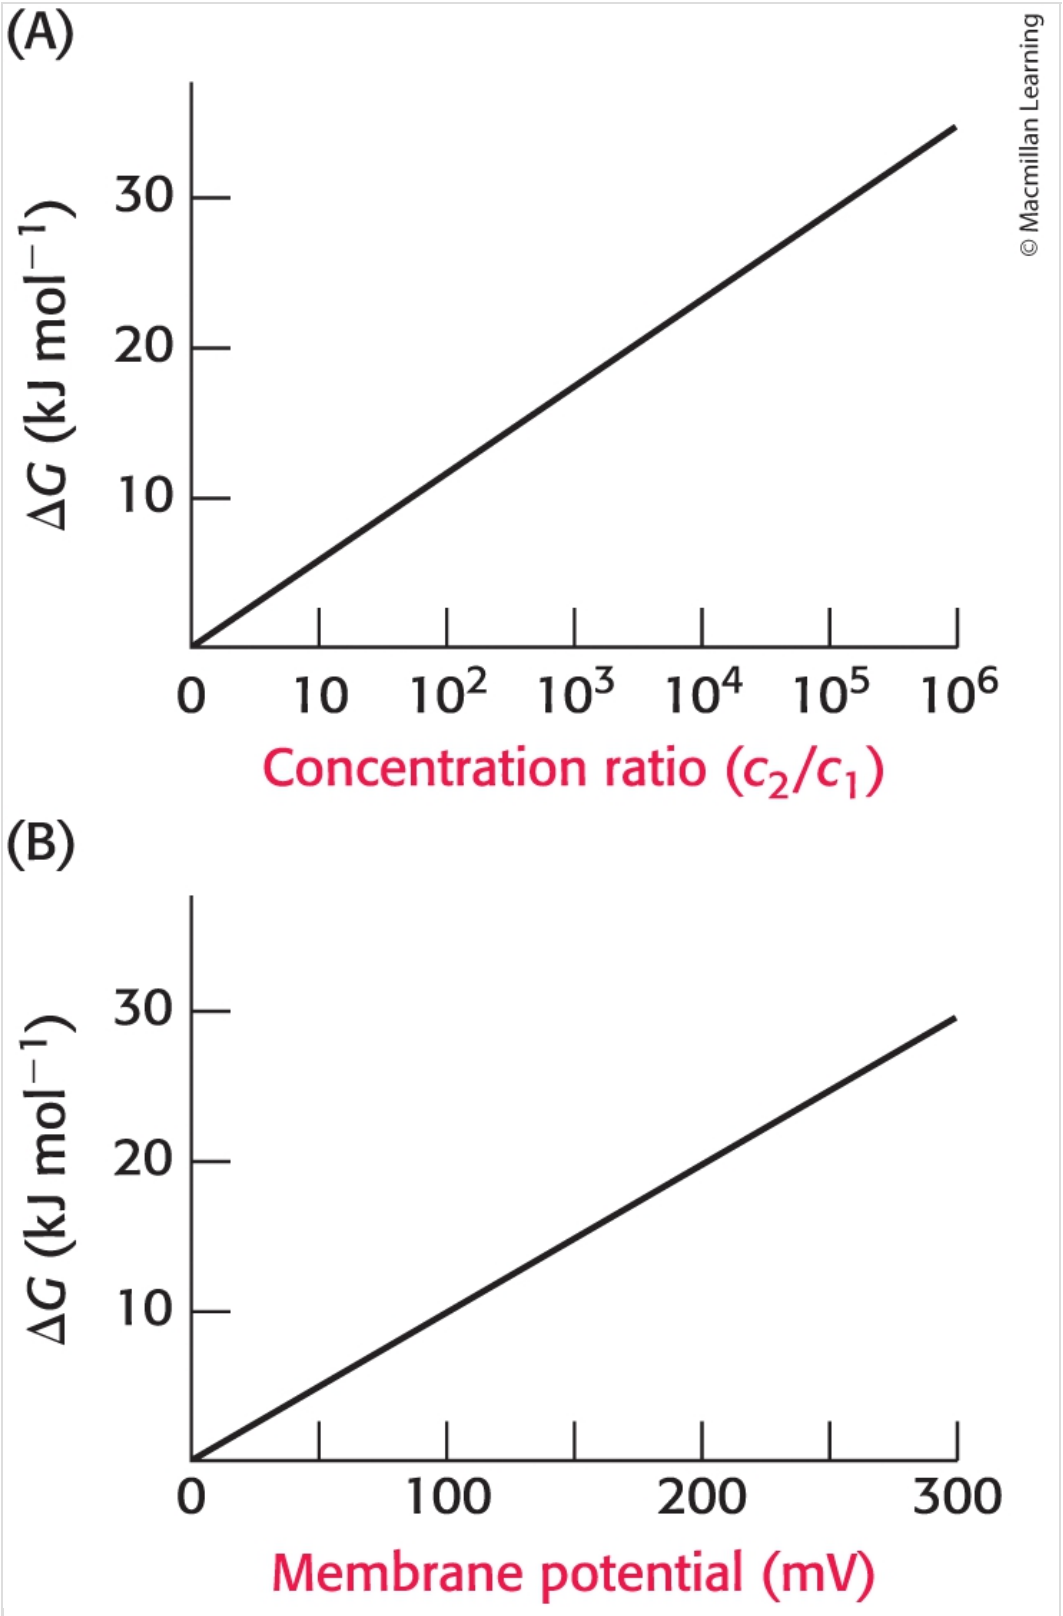


FIGURE 13.1 Transport of solutes and ions across a membrane imposes an energetic cost. The free-energy change in transporting (A) an uncharged solute

from a compartment at concentration c_1 to one at c_2 and (B) a singly charged species across a membrane to the side having the same charge as that of the transported ion are shown. The free-energy change imposed by a membrane potential of 59 mV is equivalent to that imposed by a concentration ratio of 10 for a singly charged ion at 25°C.

Consider an *uncharged* solute molecule. The free-energy change in transporting this species from side 1, where it is present at a concentration of c_1, to side 2, where it is present at concentration c_2, is

$$\Delta G = RT \ln (c_2 / c_1)$$

where R is the gas constant (8.315×10^{-3} kJ mol^{-1} deg^{-1}, or 1.987×10^{-3} kcal mol^{-1} deg^{-1}) and T is the temperature in kelvins. A transport process must be active when ΔG is positive, whereas it can be passive when ΔG is negative. For example, consider the transport of an uncharged molecule from $c_1 = 10^{-3}$ M to $c_2 = 10^{-1}$ M at 25°C (298 K).

$$\begin{aligned}\Delta G &= RT \ln (10^{-1} / 10^{-3}) \\ &= (8.315 \times 10^{-3}) \times 298 \times \ln (10^2) \\ &= +11.4 \text{ kJ mol}^{-1} (+2.7 \text{ kcal mol}^{-1})\end{aligned}$$

The ΔG is $+11.4\ \text{kJ mol}^{-1}\ (+2.7\ \text{kcal mol}^{-1})$, indicating that this transport process requires an input of free energy.

For a *charged* species, the unequal distribution across the membrane generates an electrical potential that also must be considered because the ions will be repelled by like charges. The sum of the concentration and electrical terms is called the **electrochemical potential** or **membrane potential**. The free-energy change is then given by

$$\Delta G = RT \ln (c_2 / c_1) + ZF\Delta V$$

in which Z is the electrical charge of the transported species, ΔV is the potential in volts across the membrane (expressed as $V_{\text{side 2}} - V_{\text{side 1}}$), and F is the Faraday constant ($96.5\ \text{kJ V}^{-1}\ \text{mol}^{-1}$, or $23.1\ \text{kcal V}^{-1}\ \text{mol}^{-1}$).

Example

Calculating the Energetic Cost of Ion Transport

Problem:

Suppose that the concentrations of Na^+ outside and inside the cell are 143 and 14 mM, respectively, and the corresponding values for K^+ are 4 and 157 mM. At a membrane potential of $-50\ \text{mV}$ and a

temperature of 37°C what are the energetic costs of transporting a K^+ ion into the cell and a Na^+ ion out of the cell?

Getting Started:

Since potassium and sodium ions are both charged species, we must use the electrochemical potential equation described in this section to determine the free energy change. As both ions carry a single positive charge, *Z* will be $+1$ for each calculation. Applying the equation is rather straightforward, as long as we make sure we're keeping each side of the membrane and the direction of transport consistent. It is important to remember that, by convention, the membrane potential ΔV is expressed as the voltage of the inside of the cell minus the voltage of the outside of the cell ($V_{inside} - V_{outside}$).

Calculate:

For K^+ transport, the problem asks us to move the ion into the cell.

Hence, the inside of the cell will be side 2 and the outside of the cell will be side 1.

$$\Delta G = RT \ln (c_2/c_1) + ZF\Delta V = RT \ln(c_2/c_1) + ZF(V_2 - V_1)$$

$$\Delta G = (8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{deg}^{-1}) \times (310\ \text{deg}) \times \ln(157/4) + (1) \times (96.5\ \text{kJ mol}^{-1}\ \text{V}^{-1}) \times (-0.05\ \text{V})$$

$$\Delta G = 4.64\ \text{kJ mol}^{-1}$$

For Na^+ transport, we are calculating the cost of moving the ion out of the cell, so the *outside* of the cell is side 2 and the *inside* is side 1. Thus, the sign of the ΔV term is opposite that of the first part of the question.

$$\Delta G = RT\ \ln(c_2/c_1) + ZF\Delta V = RT\ln(c_2/c_1) + ZF(V_2 - V_1)$$

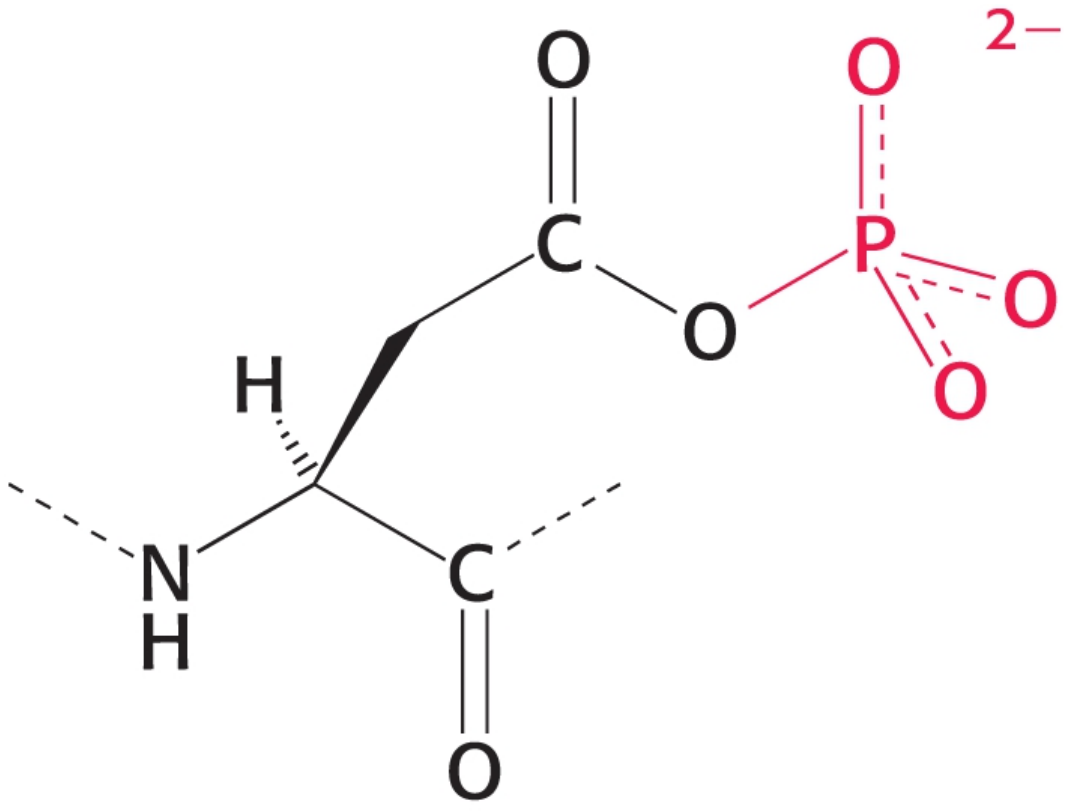
$$\Delta G = (8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{deg}^{-1}) \times (310\ \text{deg}) \times \ln(143/14) + (1) \times (96.5\ \text{kJ mol}^{-1}\ \text{V}^{-1}) \times (0.05\ \text{V})$$

$$\Delta G = 10.82\ \text{kJ mol}^{-1}$$

Reflect:

For both ions, moving the charge against its concentration gradient is energetically unfavorable. However, the cost is significantly greater for Na^+ than K^+. Why is this the case? Note that while that the chemical term is positive (unfavorable) for both ions, the electrical term is favorable for K^+ (ΔV is negative) and unfavorable for Na^+ (ΔV is positive) as the membrane has net negative charge on its inner surface. Essentially, transporting Na^+ out of the cell requires movement against its chemical gradient and in an electrically unfavorable direction.

13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Actively Transport Ions and Molecules Across Membranes



The extracellular fluid of animal cells has a salt concentration similar to that of seawater. However, cells must control their intracellular salt concentrations to facilitate specific processes, such as signal transduction and action potential propagation, and prevent unfavorable interactions with high concentrations of ions such as Ca^{2+}. For instance, most animal cells contain a high concentration of K^+ and a low concentration of Na^+ relative to the external medium. To generate these gradients, energy expenditure is required. **Pumps** are membrane proteins that catalyze the active transport of ions against their electrochemical gradients. The sodium and potassium gradients across the plasma membrane are generated by a specific transport system, an enzyme that is called the Na^+-K^+ *pump*, or the Na^+-K^+ *ATPase*. The hydrolysis of ATP by the pump provides the energy needed for the active transport of Na^+ out of the cell and K^+ into the cell, generating the gradients. The pump is called the Na^+-K^+ ATPase because the hydrolysis of ATP takes place only when Na^+ and K^+ are present. This ATPase, like all such enzymes, requires Mg^{2+}.

The Na^+-K^+ ATPase transports ions with a stoichiometry of $3\ Na^+$ ions and $2\ K^+$ ions per catalytic cycle. In the example at the end of the last

section, we calculated change in free energy accompanying the transport of Na^+ and K^+. Taking into account the transport of $3\ Na^+$ ions and $2\ K^+$ ions for every transport cycle, the free energy required to operate the pump is:

$$\Delta G = 3 \times (10.82\ \text{kJ mol}^{-1}) + 2 \times (4.64\ \text{kJ mol}^{-1})$$
$$\Delta G = 41.7\ \text{kJ mol}^{-1}$$

Under typical cellular conditions, the hydrolysis of a single ATP molecule per transport cycle provides sufficient free energy, about $-50\ \text{kJ mol}^{-1}\ (-12\ \text{kcal mol}^{-1})$ to drive the uphill transport of these ions. The active transport of Na^+ and K^+ is of great physiological significance. Indeed, more than a third of the ATP consumed by a resting animal is used to pump these ions. The Na^+-K^+ gradient in animal cells controls cell volume, renders neurons and muscle cells electrically excitable, and drives the active transport of sugars and amino acids. The purification of other ion pumps has revealed a large family of evolutionarily related ion pumps including proteins from bacteria, archaea, and all eukaryotes. Each of these pumps is specific for a particular ion or set of ions. Two are of particular interest: the *sarcoplasmic reticulum* Ca^{2+} *ATPase* (or SERCA) transports Ca^{2+} out of the cytoplasm and into the sarcoplasmic reticulum of muscle cells, and the *gastric* H^+-K^+ *ATPase* is the enzyme responsible for pumping sufficient protons into the stomach to lower the pH to 1.0. These enzymes and the hundreds of known homologs, including the Na^+-K^+ ATPase, are referred to as **P-type ATPases** because they form a key phosphorylated intermediate. In the formation of this intermediate, a phosphoryl group from ATP is linked to the side chain of a specific conserved aspartate residue in the ATPase to form phosphorylaspartate.

Phosphorylaspartate

P-type ATPases couple phosphorylation and conformational changes to pump calcium ions across membranes

Membrane pumps function by mechanisms that are simple in principle but often complex in detail. Fundamentally, each pump protein can exist in two principal conformational states, one with ion-binding sites open to one side of the membrane and the other with ion-binding sites open to the other side (Figure 13.2). To pump ions in a single direction

across a membrane, the free energy of ATP hydrolysis must be coupled to the interconversion between these conformational states.

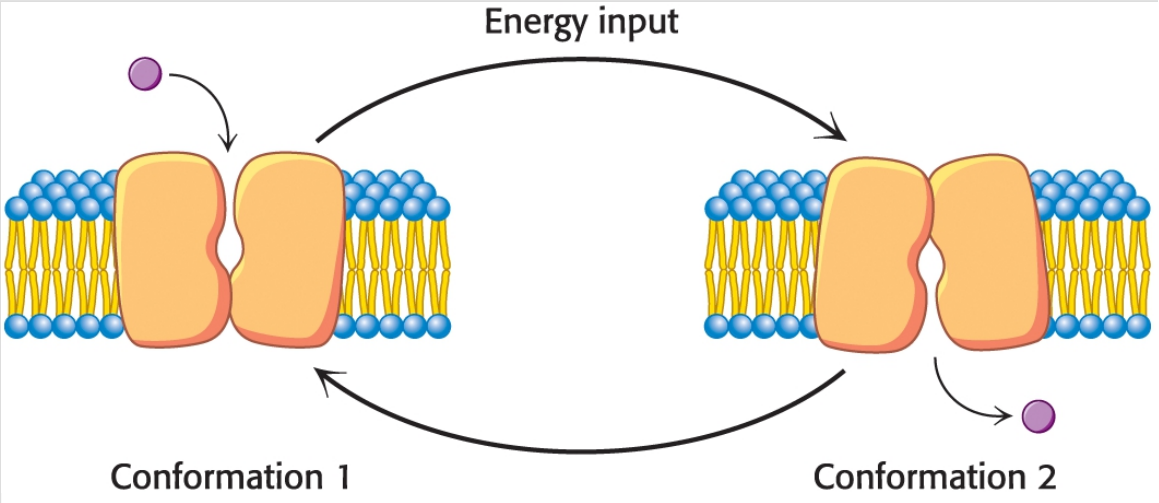


FIGURE 13.2 Pumps use the input of energy to transport ions across a membrane. This simple scheme illustrates the pumping of a molecule across a membrane. The pump interconverts between two conformational states, each with a binding site accessible to a different side of the membrane.

We will consider the structural and mechanistic features of P-type ATPases by examining SERCA. The properties of this P-type ATPase have been established in great detail by relying on crystal structures of the pump in five different states. This enzyme, which constitutes 80% of the total protein in the sarcoplasmic reticulum membrane, plays an important role in relaxation of contracted muscle. Muscle contraction is triggered by an abrupt rise in the cytoplasmic calcium ion level. Subsequent muscle relaxation depends on the rapid removal of Ca^{2+} from the cytoplasm into the sarcoplasmic reticulum, a specialized compartment for Ca^{2+} storage, by SERCA. This pump maintains a Ca^{2+} concentration of approximately $0.1\ \mu M$ in the cytoplasm, compared to nearly 1.5 mM in the sarcoplasmic reticulum.

The first structure of SERCA to be determined had Ca^{2+} bound, but no nucleotides present (Figure 13.3). SERCA is a single 110-kDa polypeptide with a transmembrane domain consisting of 10 α helices. The transmembrane domain includes sites for binding two calcium ions. Each calcium ion is coordinated to seven oxygen atoms coming from a combination of side-chain glutamate, aspartate, threonine, and asparagine residues, backbone carbonyl groups, and water molecules. A large cytoplasmic headpiece constitutes nearly half the molecular weight of the protein and consists of three distinct domains, each with a distinct function. One domain (N) binds the ATP nucleotide, another (P) accepts the phosphoryl group on a conserved aspartate residue, and the third (A) serves as an actuator, linking changes in the N and P domains to the transmembrane part of the enzyme.

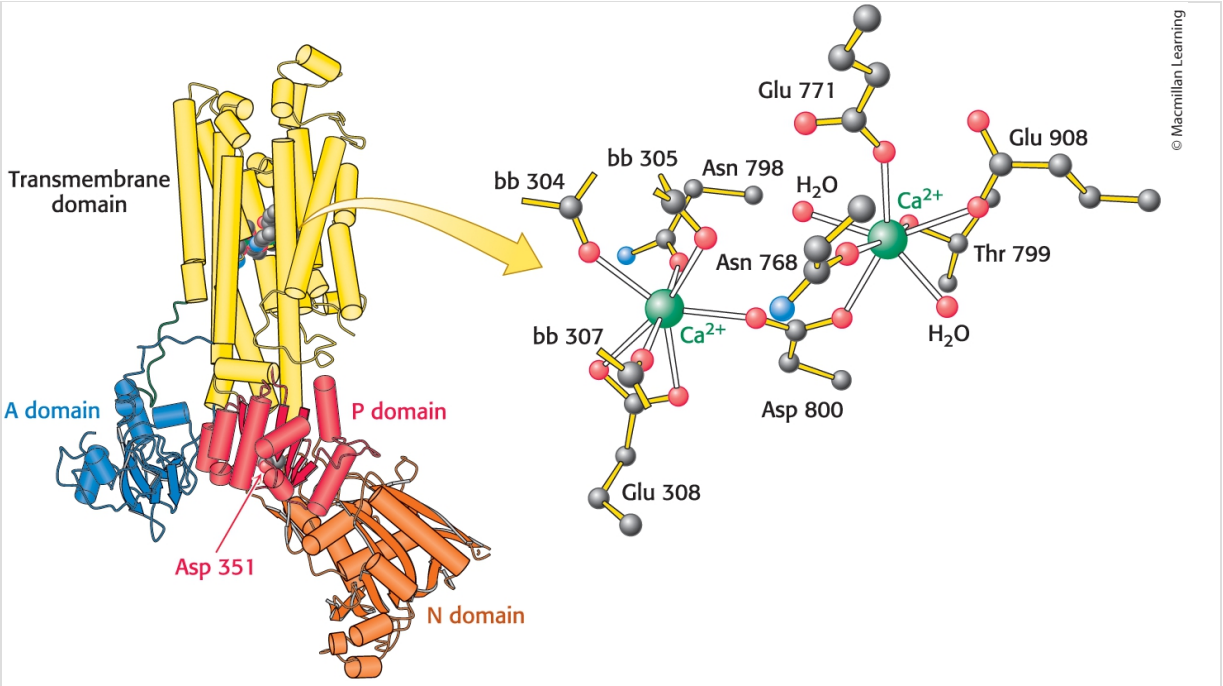

FIGURE 13.3 SERCA is a well-characterized example of a P-type ATPase pump. The overall structure of the SERCA P-type ATPase with calcium, but no nucleotide, bound is shown. Notice the two calcium ions (green) that lie in the center of the transmembrane domain. A conserved aspartate residue (Asp 351) that binds a phosphoryl group lies in the P domain. The designation bb refers to backbone carbonyl groups.

[Drawn from 1SU4.pdb.]

INTERACT with this model in Achieve

SERCA is a remarkably dynamic protein. For example, the structure of SERCA without bound Ca^{2+}, but with a phosphorylaspartate analog present in the P domain, is shown in **Figure 13.4**. The N and P domains are now closed around the phosphorylaspartate analog, and the A domain has rotated substantially relative to its position in SERCA with Ca^{2+} bound and without the phosphoryl analog. Furthermore, the transmembrane part of the enzyme has rearranged significantly and the well-organized Ca^{2+}-binding sites are disrupted. These sites are now accessible from the side of the membrane opposite the N, P, and A domains.

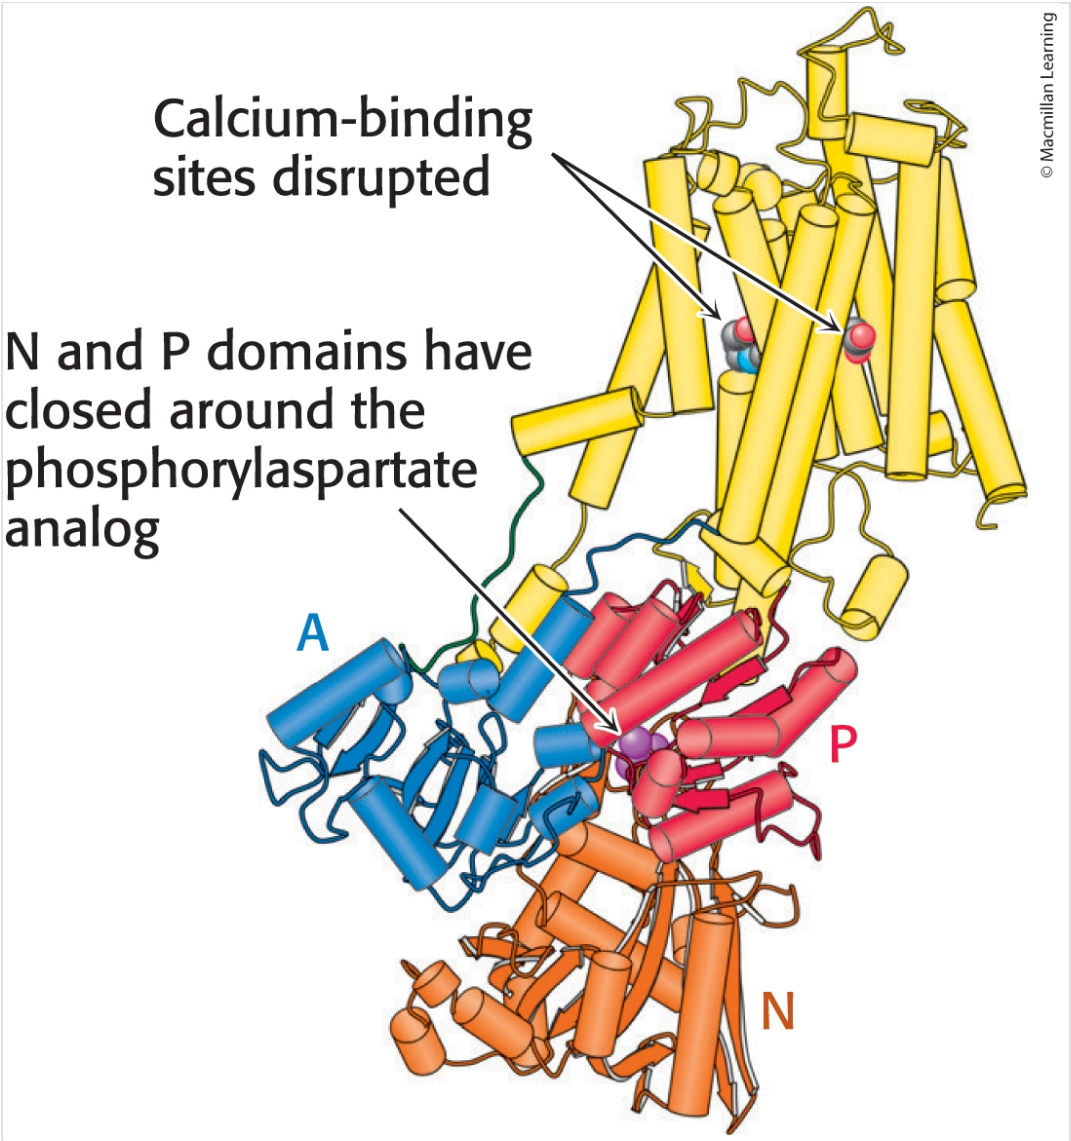

FIGURE 13.4 SERCA undergoes dynamic conformational changes. This structure was determined in the absence of bound calcium but with a phosphorylaspartate analog present in the P domain. Notice how different this structure is from the calcium-bound form shown in Figure 13.3: both the transmembrane part (yellow) and the A, P, and N domains have substantially rearranged.

[Drawn from 1WPG.pdb.]

INTERACT with this model in Achieve

The structural results can be combined with other studies to construct a detailed mechanism for Ca^{2+} pumping by SERCA (Figure 13.5):

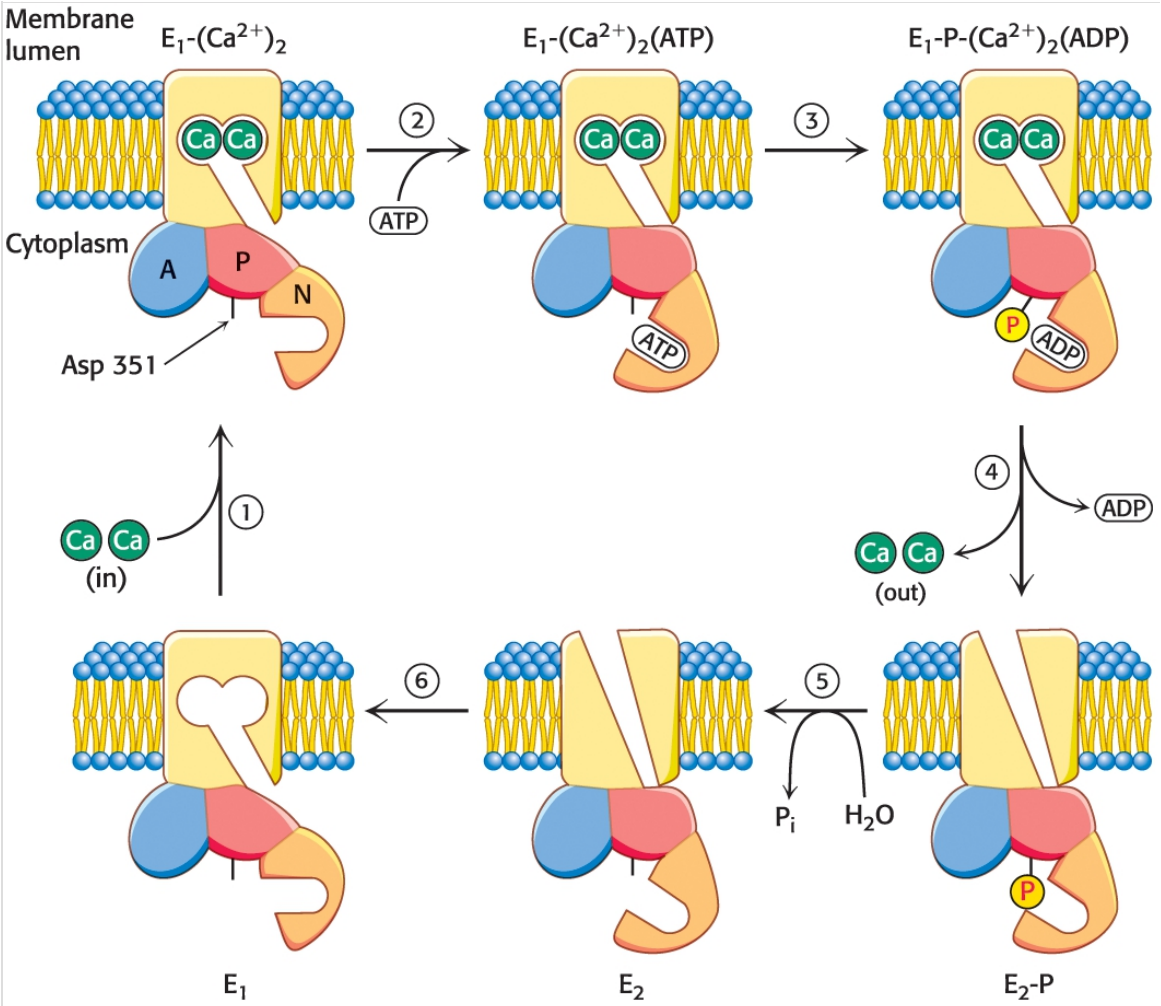

FIGURE 13.5 SERCA interconverts between E_1 and E_2 conformations during a catalytic cycl

Ca^{2+} ATPase transports Ca^{2+} through the membrane by a mechanism that includes (1) Ca^{2+} binding from the cytoplasm, (2) ATP binding, (3) ATP cleavage with the transfer of a phosphoryl group to Asp 351 on the enzyme, (4) ADP release and eversion of the enzyme to release Ca^{2+} on the opposite side of the membrane, (5) hydrolysis of the phosphorylaspartat residue, and (6) eversion to prepare for the binding of Ca^{2+} from the cytoplasm.

1. The catalytic cycle begins with the enzyme in its unphosphorylated state with two calcium ions bound. We will refer to the overall enzyme conformation in this state as E_1; with Ca^{2+} bound, it is E_1-$(Ca^{2+})_2$. In this conformation, SERCA can bind calcium ions only on the cytoplasmic side of the membrane. This conformation is shown in Figure 13.3.

2. In the E_1 conformation, the enzyme can bind ATP. The N, P, and A domains undergo substantial rearrangement as they close around the bound ATP, but there is no substantial conformational change in the transmembrane domain. The calcium ions are now trapped inside the enzyme.

3. The phosphoryl group is then transferred from ATP to Asp 351.

4. Upon ADP release, the enzyme again changes its overall conformation, including the membrane domain this time. This new conformation is referred to as E_2 or E_2-P in its phosphorylated form. The process of interconverting the E_1 and E_2 conformations is sometimes referred to as **eversion**. In the E_2-P conformation, the Ca^{2+}-binding sites become disrupted and the calcium ions are released to the side of the membrane opposite that at which they entered; ion transport has been achieved. This conformation is shown in Figure 13.4.

5. The phosphorylaspartate residue is hydrolyzed to release inorganic phosphate.

6. With the release of phosphate, the interactions stabilizing the E_2 conformation are lost, and the enzyme everts to the E_1

conformation. The binding of two calcium ions from the cytoplasmic side of the membrane completes the cycle.

This mechanism likely applies to other P-type ATPases. For example, Na^+-K^+ ATPase is an $\alpha_2\beta_2$ tetramer. Its α subunit is homologous to SERCA and includes a key aspartate residue analogous to Asp 351. The β subunit does not directly take part in ion transport. A mechanism analogous to that shown in Figure 13.5 applies, with three Na^+ ions binding from the inside of the cell to the E_1 conformation and two K^+ ions binding from outside the cell to the E_2 conformation.

Digoxin specifically inhibits the Na^+-K^+ pump by blocking its dephosphorylation

Certain steroids derived from plants are potent inhibitors $(K_i \approx 10\ nM)$ of the Na^+-K^+ pump. Digoxin and ouabain are members of this class of inhibitors, which are known as *cardiotonic steroids* because of their strong effects on the heart (**Figure 13.6**). These compounds inhibit the dephosphorylation of the E_2-P form of the ATPase when applied on the extracellular face of the membrane.

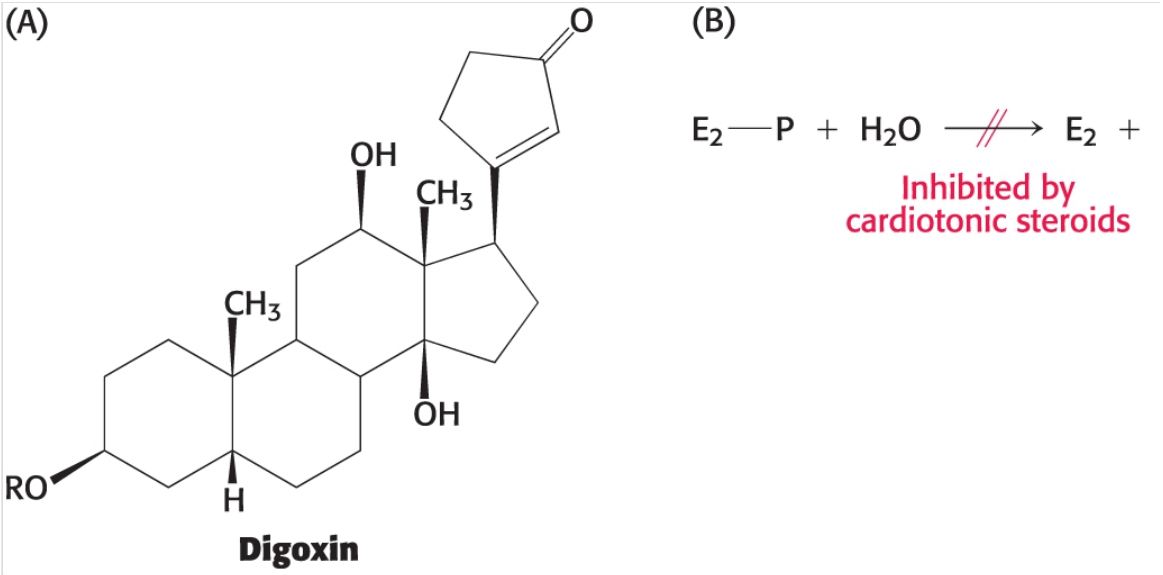

FIGURE 13.6 Digoxin is an example of a cardiotonic steroid. (A) The chemical structure of the cardiotonic steroid digoxin is shown. (B) Cardiotonic steroids inhibit the Na^+–K^+ pump by blocking the dephosphorylation of E_2-P.

Digoxin is one of the cardiotonic steroids derived from the dried leaf of the foxglove plant, *Digitalis purpurea* (**Figure 13.7**). The compound increases the force of contraction of heart muscle and is consequently administered for the treatment of congestive heart failure. Inhibition of the Na^+–K^+ pump by digoxin leads to a higher level of Na^+ inside the cell. As we shall see (Section 13.3), the diminished Na^+ gradient results in slower removal of Ca^{2+} from the cytoplasm. The subsequent increase in the intracellular level of Ca^{2+} enhances the ability of cardiac muscle to contract.

Roger Hall/Shutterstock

FIGURE 13.7 Foxglove (*Digitalis purpurea*) is a naturally occurring source of digoxin.

It is interesting to note that cardiotonic steroids were used effectively long before the discovery of the Na^+-K^+ ATPase. In 1785, William

Withering, a British physician, heard tales of an elderly woman, known as "the old woman of Shropshire," who cured people of "dropsy" (which today would be recognized as congestive heart failure) with an extract of foxglove. Withering conducted the first scientific study of the effects of foxglove on congestive heart failure and documented its effectiveness.

P-type ATPases are evolutionarily conserved and play a wide range of roles

Analysis of the complete yeast genome revealed the presence of 16 proteins that clearly belong to the P-type ATPase family. More-detailed sequence analysis suggests that two of these proteins transport H^+ ions, two transport Ca^{2+}, three transport Na^+, and two transport metals such as Cu^{2+}. In addition, five members of this family appear to participate in the transport of phospholipids with amino acid head groups. These five proteins help maintain membrane asymmetry by transporting lipids such as phosphatidylserine from the outer to the inner leaflet of the bilayer membrane. Such enzymes have been termed *flippases*. Remarkably, the human genome encodes 70 P-type ATPases. All members of this protein family employ the same fundamental mechanism: the free energy of ATP hydrolysis drives membrane transport by means of conformational changes, which are induced by the addition and removal of a phosphoryl group at an analogous aspartate site in each protein.

Multidrug resistance highlights a family of membrane pumps with ATP-binding cassette

domains

Studies of human disease have revealed another large and important family of active-transport proteins, with structures and mechanisms quite different from those of the P-type ATPase family. These pumps were identified from studies on tumor cells in culture that developed resistance to drugs that had been initially quite toxic to the cells. Remarkably, the development of resistance to one drug had made the cells less sensitive to a range of other compounds, a phenomenon known as **multidrug resistance**.

In a significant discovery, the onset of multidrug resistance was found to correlate with the expression and activity of a membrane protein with an apparent molecular mass of 170 kDa. This protein acts as an ATP-dependent pump that extrudes a wide range of small molecules from cells that express it. The protein is called the *multidrug-resistance (MDR) protein* or *P-glycoprotein* ("glyco" because it includes a carbohydrate moiety). Thus, when cells are exposed to a drug, the MDR pumps the drug out of the cell before the drug can exert its effects.

Analysis of the amino acid sequences of MDR and homologous proteins revealed a common architecture (**Figure 13.8A**). Each protein comprises four domains: two membrane-spanning domains and two ATP-binding domains. The ATP-binding domains of these proteins are called **ATP-binding cassettes (ABCs)** and are homologous to domains in a large family of transport proteins in bacteria and archaea. Transporters that include these domains are called **ABC transporters**. With 79 members, the ABC transporters are the largest single family identified in the *E. coli* genome. The human genome includes more than 150 ABC transporter genes.

FIGURE 13.8 ABC transporter are a large family of membrane pumps that share a common architecture. These proteins are composed of two transmembrane domains and two ATP-binding domains called ATP-binding cassettes (ABCs). (A) The multidrug-resistance protein is a single polypeptide chain containing all four domains, whereas (B) the bacterial lipid transporter MsbA consists of a dimer of two identical chains, containing one of each domain.

The three-dimensional structures of several members of the ABC transporter family have now been determined, including that of the bacterial lipid transporter MsbA. In contrast with the eukaryotic MDR protein, this protein is a dimer of 62-kDa chains: the amino-terminal half of each protein contains the membrane-spanning domain, and the carboxyl-terminal half contains the ATP-binding cassette (Figure 13.8B). Prokaryotic ABC proteins are often made up of multiple subunits, such as a dimer of identical chains, or as a heterotetramer of two membrane-spanning domain subunits and two ATP-binding-cassette subunits. The two ATP-binding cassettes are in contact, but they do not interact strongly in the absence of bound ATP (Figure 13.9A). The consolidation of the enzymatic activities of several polypeptide chains in prokaryotes to a single chain in eukaryotes is a theme that we will see again.

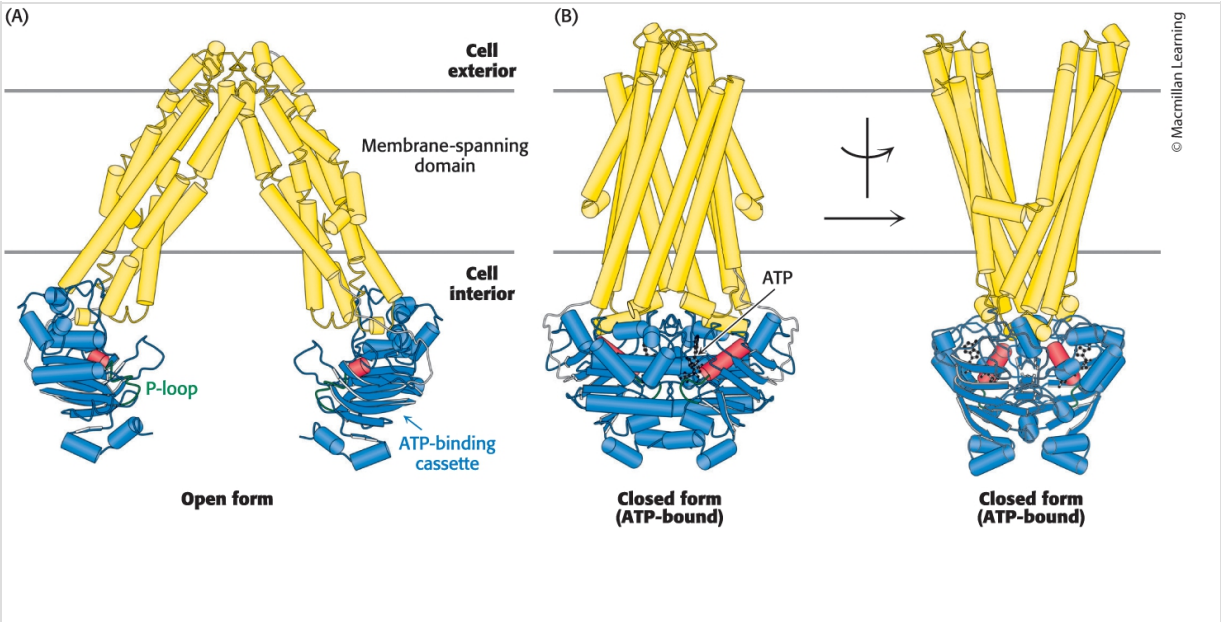

FIGURE 13.9 ABC transporters undergo significant conformational change upon ATP binding. Two structures of the bacterial lipid transporter MsbA, a representative ABC transporter: (A) The nucleotide-free, inward-facing form and (B) the ATP-bound, outward-facing form is shown in two views (rotated by 90 degrees). Upon nucleotide binding, the two ATP-binding cassettes (blue) interact strongly with one another, resulting in reorientation of the substrate binding site. The gray lines indicate the extent of the plasma membrane.

[Drawn from 3B5W.pdb and 3B60.pdb.]

INTERACT with this model in Achieve

On the basis of several solved structures of ABC transporters, combined with data from other experiments, a mechanism for active transport by these proteins has been proposed (Figure 13.10):

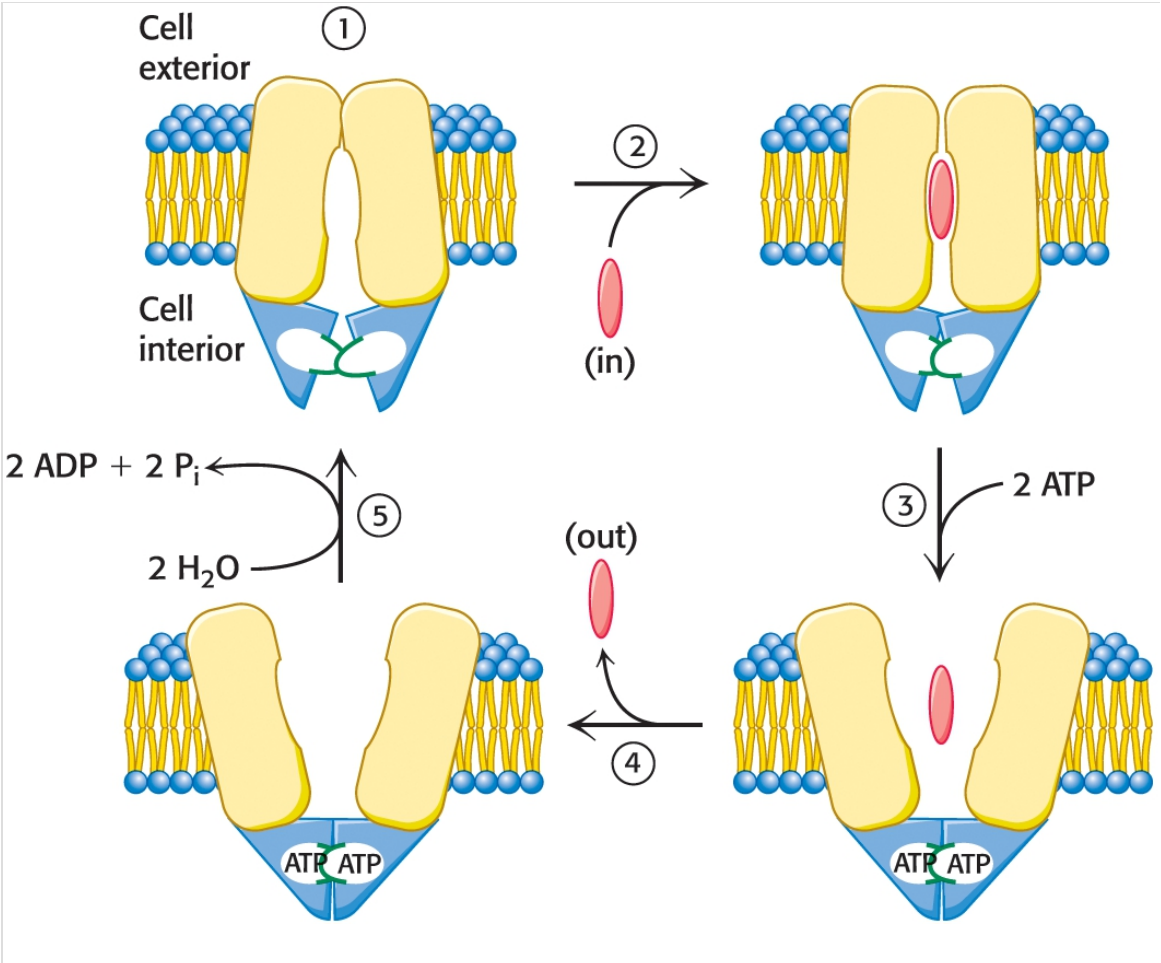

FIGURE 13.10 The open surface of ABC transporters alternates between conformations based on the presence of bound nucleotide. The mechanism includes the following steps: (1) opening of the channel toward the inside of the cell, (2) substrate binding and conformational changes in the ATP-binding cassettes, (3) ATP binding and opening of the channel to the opposite face of the membrane, (4) release of the substrate to the outside of the cell, and (5) ATP hydrolysis to reset the transporter to its initial state.

1. The catalytic cycle begins with the transporter free of both ATP and substrate. While the distance between the ATP-binding cassettes in this form may vary with the individual transporter, the substrate binding region of the transporter faces inward.

2. Substrate enters the central cavity of the transporter from inside the cell. Substrate binding induces conformational changes in the ATP-binding cassettes that increase their affinity for ATP.

3. ATP binds to the ATP-binding cassettes, changing their conformations so that the two domains interact strongly with one another. The close interaction of the ABCs reorients the transmembrane helices such that the substrate binding site is now facing outside the cell (**Figure 13.9B**).

4. The outward facing conformation of the transporter has reduced affinity for the substrate, enabling the release of the substrate on the opposite face of the membrane.

5. The hydrolysis of ATP and the release of ADP and inorganic phosphate reset the transporter for another cycle.

Whereas eukaryotic ABC transporters generally act to export molecules from inside the cell, prokaryotic ABC transporters often act to import specific molecules from *outside* the cell. A specific binding protein acts in concert with the bacterial ABC transporter, delivering the substrate to the transporter and stimulating ATP hydrolysis inside the cell. These binding proteins are present in the periplasm, the compartment

between the two membranes that surround some bacterial cells (Figure 12.36B).

Thus, ABC transporters use a substantially different mechanism from the P-type ATPases to couple the ATP hydrolysis reaction to conformational changes. Nonetheless, the net result is the same: The transporters are converted from one conformation capable of binding substrate from one side of the membrane to another that releases the substrate on the other side.

Self-Check Question

When SERCA is incubated with $[\gamma-{}^{32}P]$ ATP (in which the terminal phosphate is radiolabeled) and calcium, and then analyzed by gel electrophoresis, a radioactive band is observed at the molecular weight corresponding to full-length SERCA. Explain the result. Would you expect a similar band if you were performing a similar assay, with a suitable substrate, for the MDR protein?

13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another

Carriers are proteins that transport ions or molecules across the membrane without hydrolysis of ATP. The mechanism of carriers involves both large conformational changes and the interaction of the protein with only a few molecules per transport cycle, limiting the maximum rate at which transport can occur. Although carriers cannot mediate primary active transport — owing to their inability to hydrolyze ATP — they can couple the thermodynamically unfavorable flow of one species of ion or molecule *up* a concentration gradient to the favorable flow of a different species *down* a concentration gradient, a process referred to as **secondary active transport**. Carriers that move ions or molecules "uphill" by this means are termed **secondary transporters** or **cotransporters**.

Secondary transporters can be classified as either antiporters or symporters. **Antiporters** couple the downhill flow of one species to the uphill flow of another in the *opposite direction* across the membrane; **symporters** use the flow of one species to drive the flow of a different species in the *same direction* across the membrane. **Uniporters**, another class of carriers, are able to transport a specific species in either direction governed only by concentrations of that species on either side of the membrane (**Figure 13.11**).

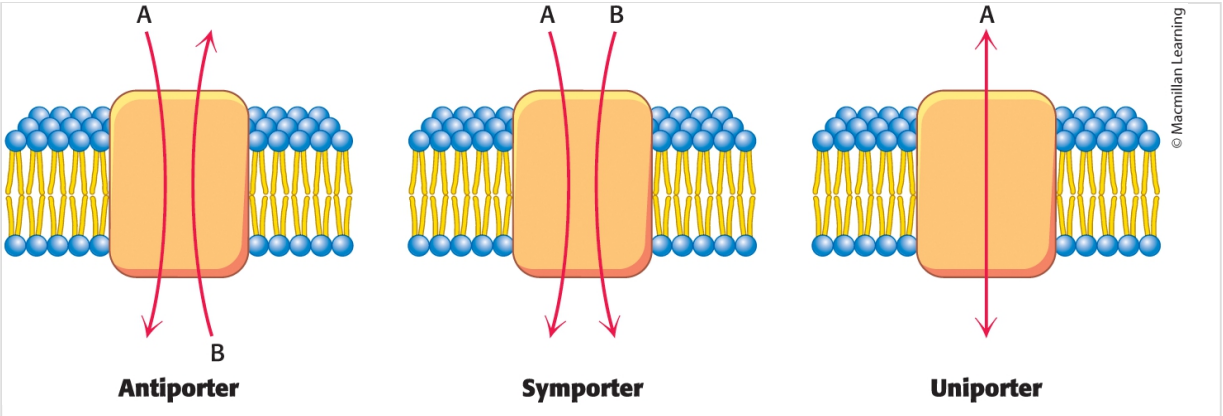

FIGURE 13.11 The three classes of secondary transporters are antiporters, symporters, and uniporters. Secondary transporters can transport two substrates in opposite directions (antiporters), two substrates in the same direction (symporters), or one substrate in either direction (uniporter).

Secondary transporters are ancient molecular machines, common today in bacteria and archaea as well as in eukaryotes. For example, approximately 160 (of around 4000) proteins encoded by the *E. coli* genome are secondary transporters. Sequence comparison and hydropathy analysis suggest that members of the largest family have 12 transmembrane helices that appear to have arisen by duplication and fusion of a membrane protein containing 6 transmembrane helices.

Lactose permease, an *E. coli* symporter, uses the H^+ gradient across the *E. coli* membrane (outside has higher H^+ concentration) generated by the oxidation of fuel molecules to drive the uptake of lactose and other sugars against a concentration gradient. This transporter has been extensively studied for many decades and is a useful archetype for this family. As expected from the sequence analysis, the lactose permease consists of two domains, each of which comprises six membrane-spanning α helices (Figure 13.12). The two domains are well separated and are joined by a single polypeptide. In this structure, a sugar

molecule lies in a pocket in the center of the protein and is accessible from a path that leads from the interior of the cell.

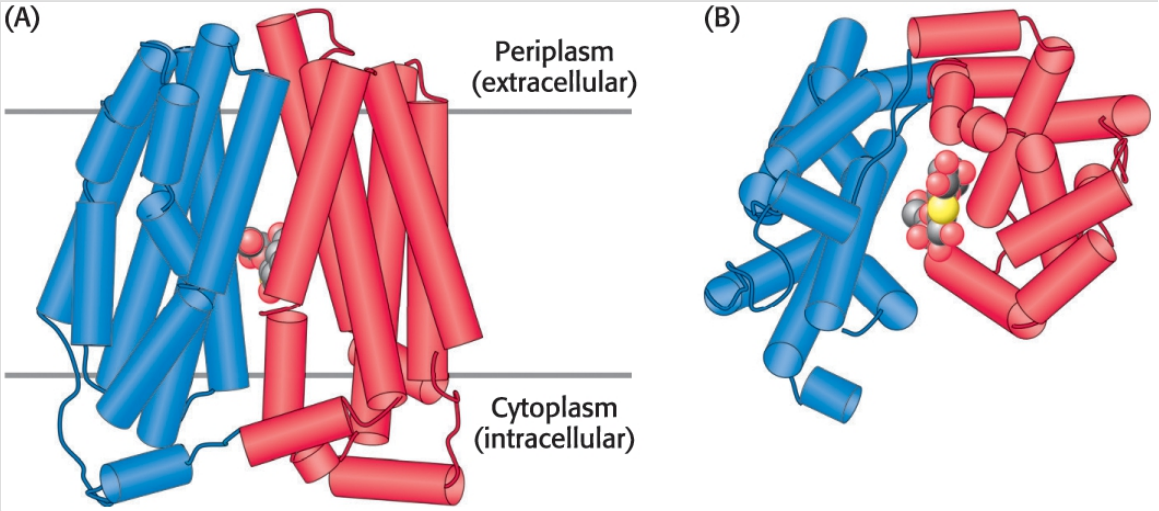

FIGURE 13.12 Lactose permease from *E. coli* is a well-studied example of a secondary transporter. The amino-terminal half of the protein is shown in blue and the carboxyl-terminal half in red. (A) Side view. The gray lines indicate the extent of the plasma membrane. (B) Botton view (from inside the cell). The protein consists of two halves that surround the sugar and are linked to one another by only a single stretch of polypeptide.

[Drawn from 1PV7.pdb.]

INTERACT with this model in Achieve

On the basis of this structure and a wide range of other experiments, a mechanism for symporter action has been developed. This mechanism (Figure 13.13) has many features similar to those for P-type ATPases and ABC transporters:

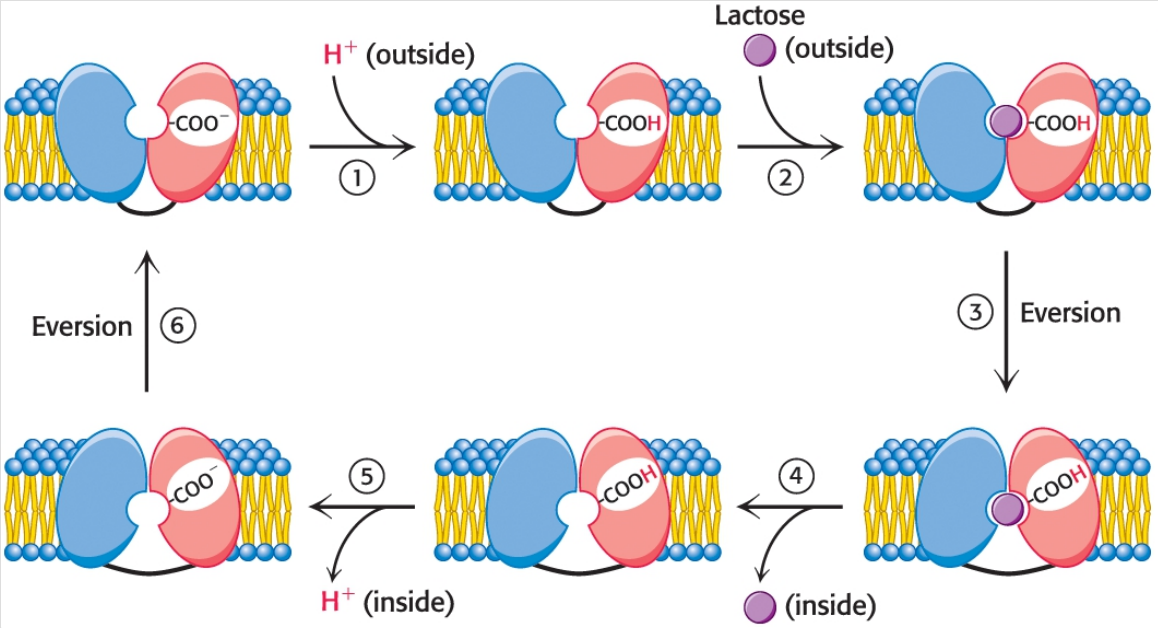

FIGURE 13.13 Lactose permease catalyzes the symport of a proton and lactose across the membrane. The mechanism begins with the permease open to the outside of the cell (upper left). The permease binds a proton from the outside of the cell (1) and then binds its substrate (2 The permease everts (3) and then releases its substrate (4) and a proton (5) to the inside of the cell. It then everts (6) to complete the cycle.

1. The cycle begins with the two domains oriented so that the opening to the binding pocket faces outside the cell, in a conformation different from that observed in the structures solved to date. A proton from outside the cell binds to a residue in the permease, quite possibly Glu 325. Although not shown in the figure, the site of protonation likely changes in the course of this cycle.

2. In the protonated form, the permease binds lactose from outside the cell.

3. The structure everts to the form observed in the crystal structure (Figure 13.12).

4. The permease releases lactose to the inside of the cell.

5. The permease releases a proton to the inside of the cell.
6. The permease everts to complete the cycle.

It is thought that this eversion mechanism applies to all classes of secondary transporters, which resemble the lactose permease in overall architecture.

Self-Check Question

Carbonyl cyanide 4-(trifluoromethoxy) phenylhydrazone (FCCP) is a proton ionophore: it enables protons to pass freely through membranes. Treatment of *E. coli* with FCCP prevents the accumulation of lactose in these cells. Explain.

13.4 Specific Channels Can Rapidly Transport Ions Across Membranes

Pumps and carriers can move ions and substrates across the membrane at rates approaching several thousand molecules per second. Other membrane proteins, the passive-transport systems called **ion channels**, are capable of ion-transport rates that are more than 1000 times as fast. These rates of transport through ion channels are close to rates expected for ions diffusing freely through aqueous solution. Yet ion channels are not simply tubes that span membranes through which ions can rapidly flow. Instead, they are highly sophisticated molecular machines that respond to chemical and physical changes in their environments and undergo precisely timed conformational changes.

Action potentials are mediated by transient changes in Na^+ and K^+ permeability

One of the most important manifestations of ion-channel action is the nerve impulse, which is the fundamental means of communication in the nervous system. A **nerve impulse**, or **action potential**, is an electrical signal produced by the flow of ions across the plasma membrane of a neuron. The interior of a neuron, like that of most other cells, contains a high concentration of K^+ and a low concentration of Na^+. These ionic gradients are generated by the Na^+-K^+ ATPase. The cell membrane has an electrical potential determined by the ratio of the internal to the external concentration of ions. In the resting state, the membrane potential is typically $-60\ mV$. An action potential is generated when the membrane potential is depolarized beyond a critical threshold value (e.g., from -60 to $-40\ mV$). The membrane potential becomes positive within about a millisecond and attains a

value of about $+30\ mV$ before turning negative again (repolarization). This amplified depolarization is propagated along the nerve terminal (Figure 13.14).

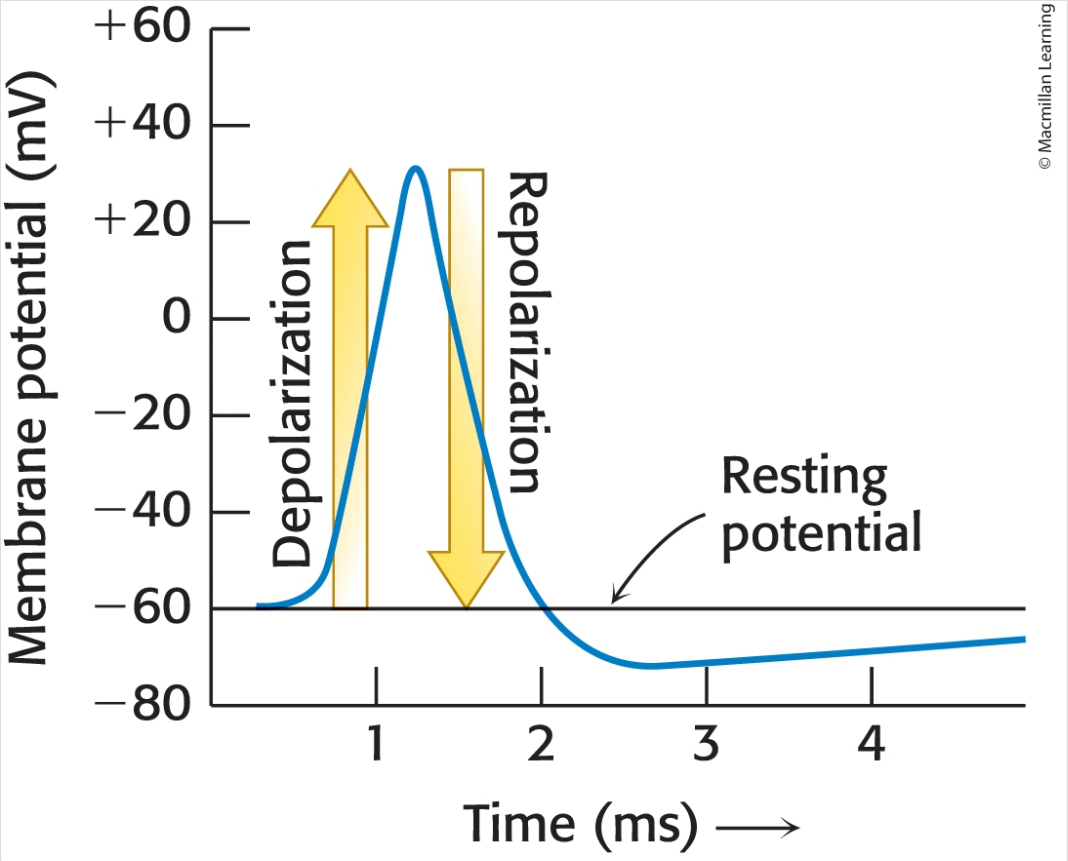

FIGURE 13.14 The action potential is a rapid electrical signal across a plasma membrane. Signals are sent along neurons by the transient depolarization and repolarization of the membrane.

Ingenious experiments carried out by Alan Hodgkin and Andrew Huxley revealed that action potentials arise from large, transient changes in the permeability of the axon membrane to Na^+ and K^+ ions. Depolarization of the membrane beyond the threshold level leads to an increase in permeability to Na^+. Sodium ions begin to flow into the cell because of

the large electrochemical gradient across the plasma membrane. The entry of Na^+ further depolarizes the membrane, leading to an added increase in Na^+ permeability. This positive feedback yields the very rapid and large change in membrane potential described above and shown in Figure 13.14.

The membrane spontaneously becomes less permeable to Na^+ and more permeable to K^+. Consequently, K^+ flows outward, and so the membrane potential returns to a negative value. The resting level of $-60\ mV$ is restored in a few milliseconds as the K^+ conductance decreases to the value characteristic of the unstimulated state. The wave of depolarization followed by repolarization moves rapidly along a nerve cell. The propagation of these waves allows a touch at the tip of your toe to be detected in your brain in a few milliseconds.

The proposal that action potentials arise from changes in Na^+ and K^+ membrane permeability postulated the existence of channels specific for these ions. These channels must open in response to changes in membrane potential and then close after having remained open for a brief period of time. The bold hypotheses of Hodgkin and Huxley predicted the existence of molecules with a well-defined set of properties long before tools existed for their direct detection and characterization.

Patch-clamp conductance measurements reveal the activities of single channels

Direct evidence for the existence of these channels was elucidated using the **patch-clamp technique**. This powerful method enables the measurement of the ion conductance through a small patch of cell

membrane (Figure 13.15). A clean glass pipette with a tip diameter of about $1\ \mu m$ is pressed against an intact cell to form a seal. Slight suction leads to the formation of a very tight seal so that the resistance between the inside of the pipette and the bathing solution is many gigaohms (1 gigaohm is equal to 10^9 ohms). Thus, a gigaohm seal (called a *gigaseal*) ensures that an electric current flowing through the pipette is identical with the current flowing through the membrane covered by the pipette. The gigaseal makes possible high-resolution current measurements while a known voltage is applied across the membrane.

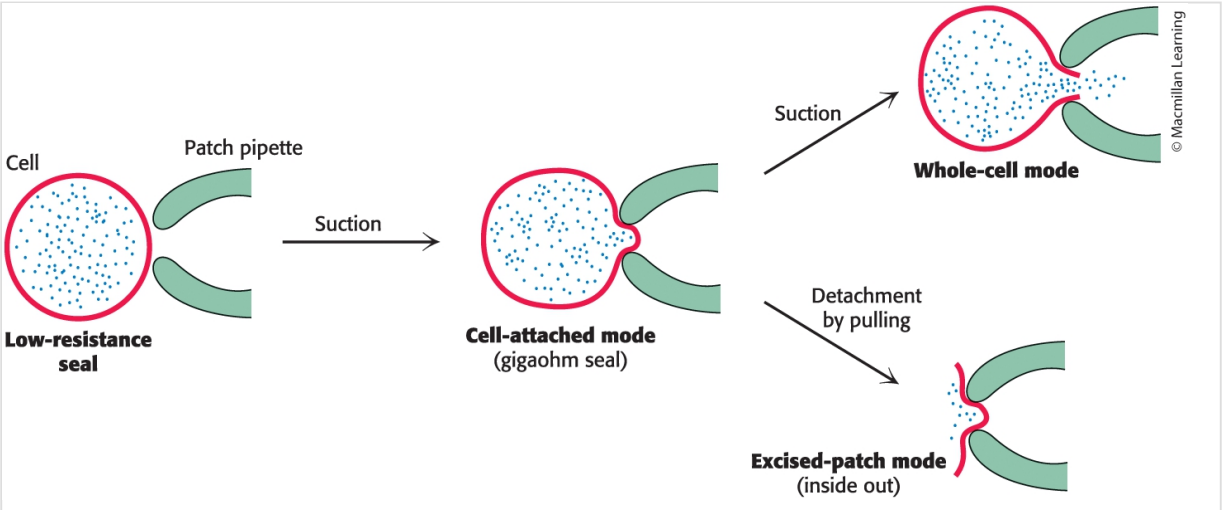

FIGURE 13.15 The patch-clamp technique for monitoring channel activity is highly versatile. A high-resistance seal (gigaseal) is formed between the pipette and a small patch of plasma membrane. This configuration is called the *cell-attached mode*. The breaking of the membrane patch by increased suction produces a low-resistance pathway between the pipette and the interior of the cell. The activity of the channels in the entire plasma membrane can be monitored in this *whole-cell mode*. To prepare a membrane in the *excised-patch mode*, the pipette is pulled away from the cell. A piece of plasma membrane with its cytoplasmic side now facing the medium is monitored by the patch pipette.

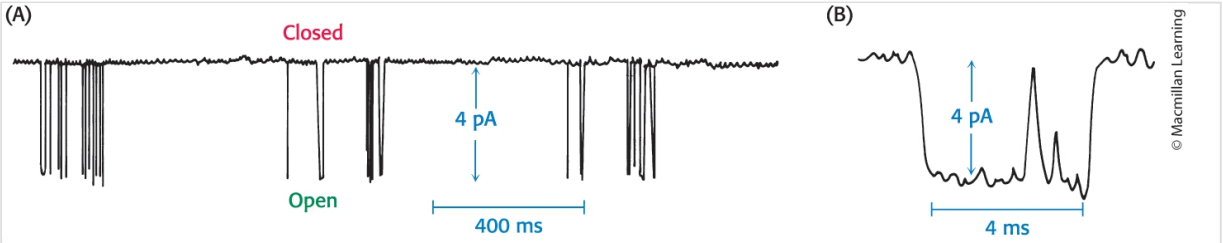
Remarkably, the flow of ions through a single channel and transitions between the open and closed states of a channel can be monitored with a time resolution of microseconds (Figure 13.16). Furthermore, the

activity of a channel in its native membrane environment, even in an intact cell, can be directly observed. Patch-clamp methods provided one of the first views of single biomolecules in action. Subsequently, other methods for observing single molecules were invented, opening new vistas on biochemistry at its most fundamental level.



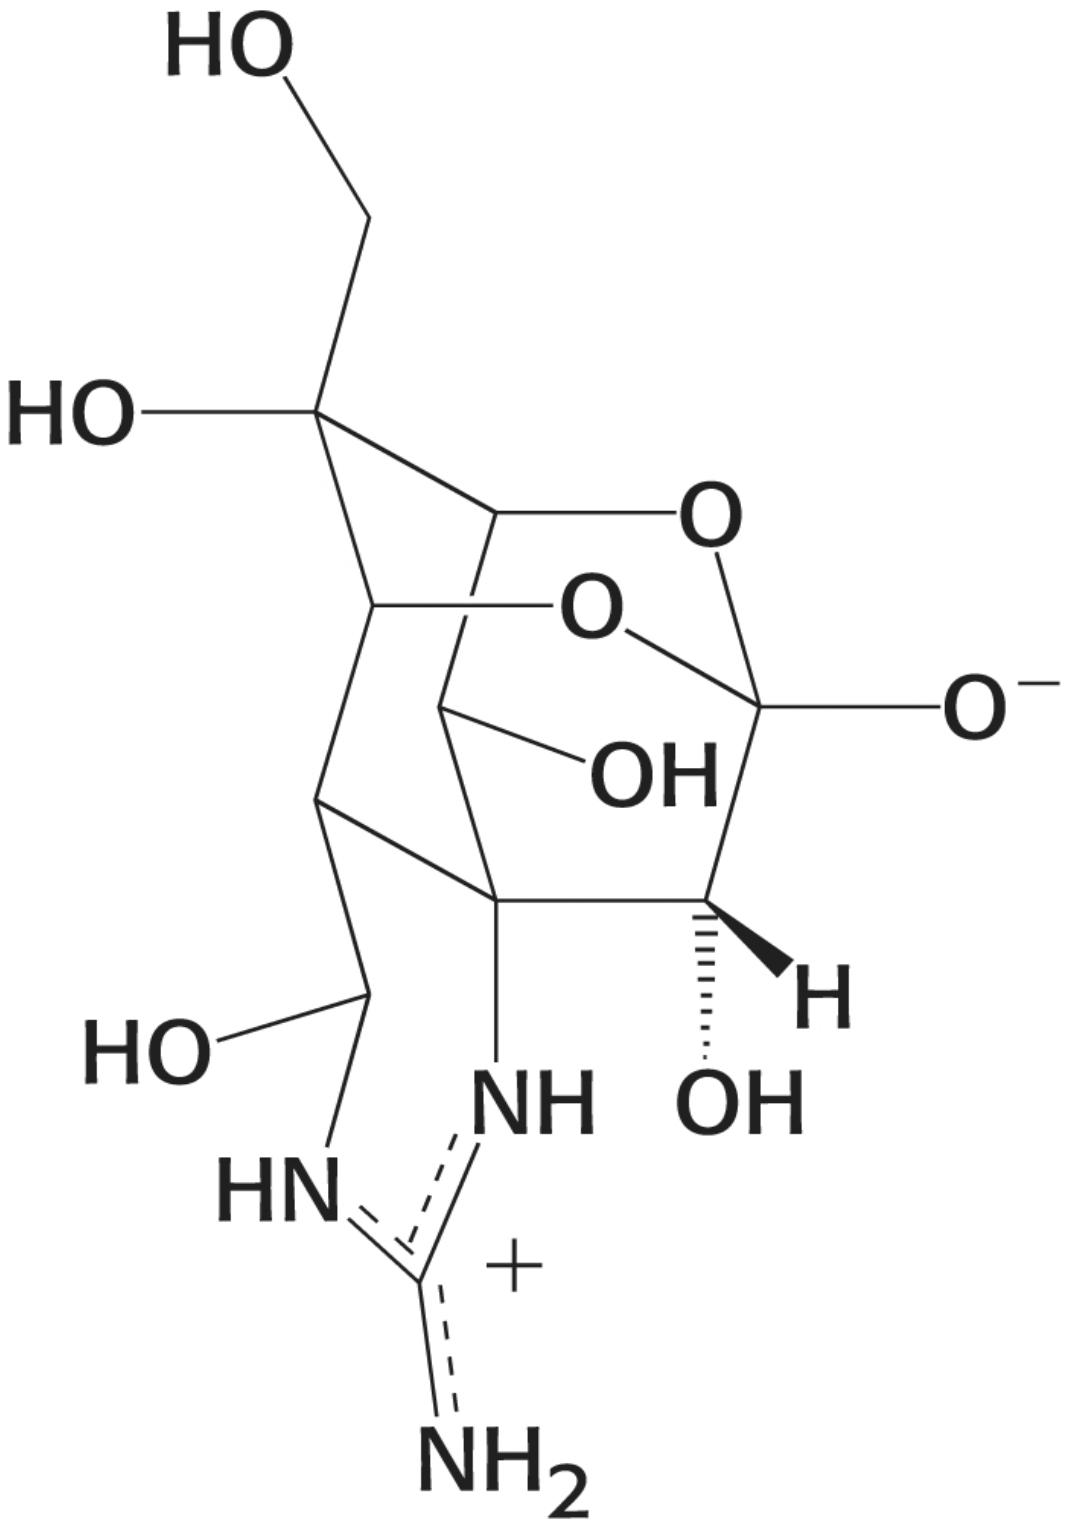


FIGURE 13.16 Patch-clamp methods enable the observation of ion movement across single channels. (A) The results of a patch-clamp experiment reveal the small amount of current, measured in picoamperes (pA, 10^{-12} amperes), passing through a single ion channel. The downward spikes indicate transitions between closed and open states. (B) Closer inspection of one of the spikes in (A) reveals the length of time the channel is in the open state.

The structure of a potassium ion channel is an archetype for many ion-channel structures

With the existence of ion channels firmly established by patch-clamp methods, scientists sought to identify the molecules that form ion channels. The Na^+ channel was first purified from the electric organ of the electric eel, which is a rich source of the protein forming this channel. The channel was purified on the basis of its ability to bind tetrodotoxin, a neurotoxin from the puffer fish that binds to Na^+

channels very tightly ($K_i \approx 1$ nM). The lethal dose of this poison for an adult human being is about 10 ng.

Tetrodotoxin

The isolated Na^+ channel is a single 260-kDa chain. Cloning and sequencing of cDNAs encoding Na^+ channels revealed that the channel contains four internal repeats, each having a similar amino acid sequence, suggesting that gene duplication and divergence have produced the gene for this channel (Figure 13.17A). Hydrophobicity profiles indicate that each repeat contains five hydrophobic segments (S1, S2, S3, S5, and S6). Each repeat also contains a highly positively charged S4 segment; positively charged arginine or lysine residues are present at nearly every third residue. It was proposed that segments S1 through S6 are membrane-spanning α helices, while the positively charged residues in S4 act as the voltage sensors of the channel. Ca^{2+} channels also share the same sequence pattern as Na^+ channels.

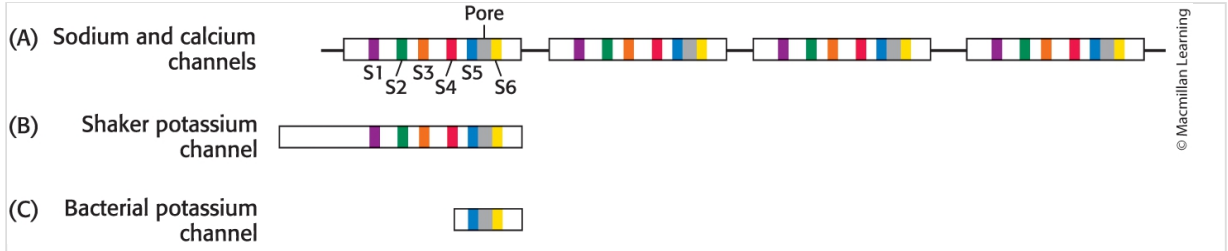

FIGURE 13.17 Ion channels share structural features. Like colors indicate structurally similar regions of the (A) sodium and calcium channels, (B) the Shaker potassium channel, and (C) the bacterial potassium channel. Each of these channels exhibits approximate fourfold symmetry, either within one chain (sodium, calcium channels) or by forming tetramers (potassium channels).

The purification of K^+ channels proved to be much more difficult because of their low abundance and the lack of known high-affinity

ligands comparable to tetrodotoxin. The breakthrough came in studies of mutant fruit flies that shake violently when anesthetized with ether. The mapping and cloning of the gene, termed *Shaker*, responsible for this phenotype revealed the amino acid sequence encoded by a K^+-channel gene. The *Shaker* gene encodes a 70-kDa protein that contains sequences corresponding to segments S1 through S6 in one of the repeated units of the Na^+ channel (**Figure 13.17B**). Thus, a K^+-channel subunit is homologous to one of the repeated units of Na^+ channels. Consistent with this homology, four Shaker polypeptides come together to form a functional channel. Bacterial K^+ channels have also been discovered that contain only the two membrane-spanning regions corresponding to segments S5 and S6 (**Figure 13.17C**). This and other information suggested that S5 and S6 — including the region between them — form the actual pore in the K^+ channel and that segments S1 through S4 contain the apparatus that opens the pore.

In 1998, Roderick MacKinnon and coworkers determined the structure of a K^+ channel from the bacterium *Streptomyces lividans* by x-ray crystallography. This channel contains only the pore-forming segments S5 and S6. As expected, the K^+ channel is a tetramer of identical subunits, each of which includes two membrane-spanning α helices (**Figure 13.18**). The four subunits come together to form a pore in the shape of a cone that runs through the center of the structure.

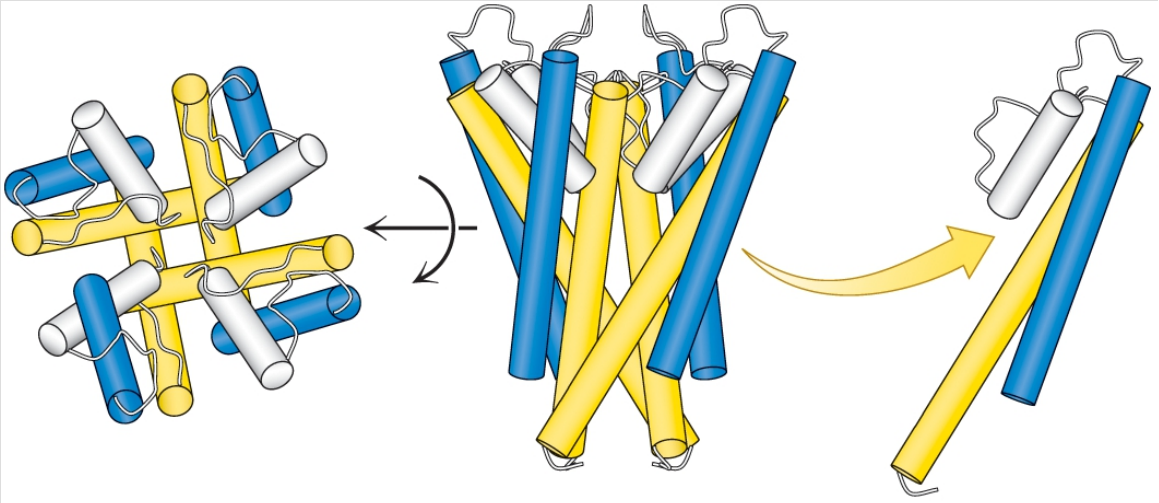

FIGURE 13.18 The bacterial potassium ion channel forms a pore at the center of a tetrameric complex. The K^+ channel, composed of four identical subunits, is cone shaped, with the large opening facing the inside of the cell (center). A view down the pore, looking toward the outside the cell, shows the relations of the individual subunits (left). One of the four identical subunits c the pore is illustrated at the right, with the pore-forming region shown in gray.

University of Utah

BALDOMERO OLIVERA After completing his PhD and postdoctoral training in the United States, Dr. Baldomero "Toto" Olivera returned to his native Philippines to start a faculty position. There, he began studying toxins from readily available cone snails, with which he was familiar from shell-collecting as a child. Cone snails deploy these potent toxins to paralyze their prey. Using chromatography, Dr. Olivera and his coworkers separated the toxins into hundreds of components that they then injected directly into the nervous system of mice. They discovered that each component could induce specific behavioral responses, and subsequent studies revealed that many components can bind and inhibit a single ion channel or pump in a highly specific manner. The different peptide toxins, now called *conotoxins*, are powerful tools, and

one has been developed into a drug to treat intractable pain. In the mid-1970s, Dr. Olivera moved to the University of Utah, where he is now Distinguished Professor of Biology.

The structure of the potassium ion channel reveals the basis of ion specificity

The structure of the bacterial potassium channel revealed much about how these proteins efficiently and selectively transport ions across a membrane. Beginning from the inside of the cell, the pore starts with a diameter of approximately 10 Å and then constricts to a smaller cavity with a diameter of 8 Å (**Figure 13.19**). Both the opening to the outside and the central cavity of the pore are filled with water, and a K^+ ion can fit in the pore without losing its shell of bound water molecules. Approximately two-thirds of the way through the membrane, the pore becomes more constricted (3-Å diameter, shaded yellow in **Figure 13.19**), and at that point, any K^+ ions must give up their water molecules and interact directly with groups from the protein. The channel structure effectively reduces the thickness of the membrane from 34 Å to 12 Å by allowing the solvated ions to penetrate into the membrane before the ions must directly interact with the channel.

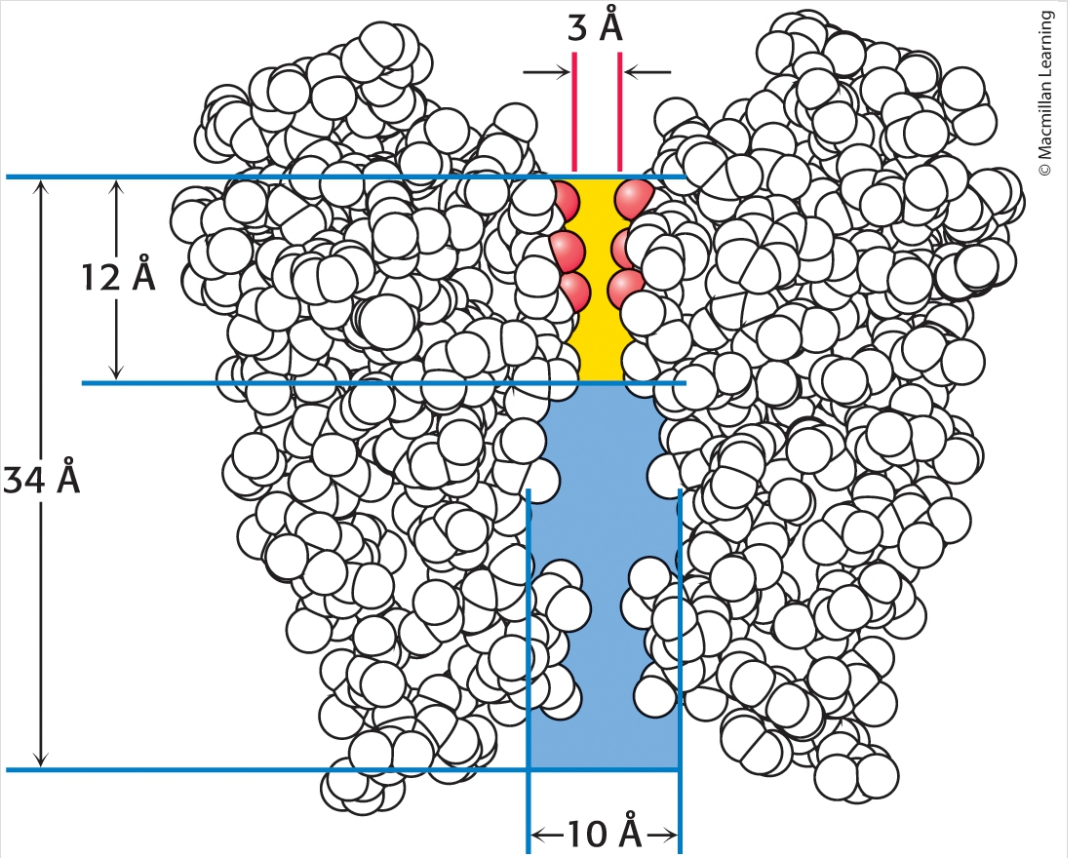

FIGURE 13.19 The path through the potassium channel features only a short region where the ion must be desolvated. A potassium ion entering the K^+ channel can pass a distance of 22 Å into the membrane while remaining solvated with water (blue). At this point, the pore diameter narrows to 3 Å (yellow), and potassium ions must shed their water and interact with carbonyl groups (red) of the pore amino acids.

The restricted part of the pore is built from residues contributed by the two transmembrane α helices. In particular, a five-amino-acid stretch within this region functions as the **selectivity filter** that determines the preference for K^+ over other ions (Figure 13.20). The stretch has the sequence Thr-Val-Gly-Tyr-Gly (TVGYG), and is nearly completely conserved in all K^+ channels. The region of the strand containing the conserved sequence lies in an extended conformation and is oriented

such that the peptide carbonyl groups are directed into the channel, in good position to interact with the desolvated potassium ions.

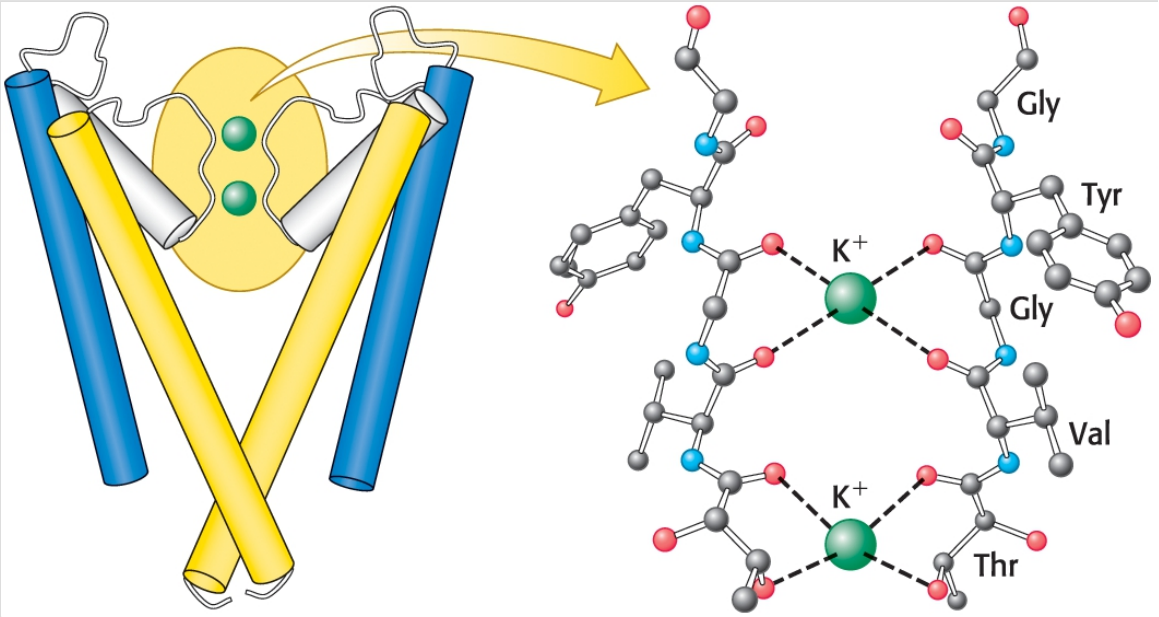

FIGURE 13.20 The selectivity filter determines the preference of the channel for K^+ over oth

ions. Potassium ions interact with the carbonyl groups of the TVGYG sequence of the selectivity filter, located at the 3-Å-diameter pore of the K^+ channel. Only two of the four channel subuni are shown.

Potassium ion channels are 100-fold more permeable to K^+ than to Na^+. How is this high degree of selectivity achieved? Ions having a radius larger than 1.5 Å cannot pass into the narrow diameter (3 Å) of the selectivity filter of the K^+ channel. However, a desolvated Na^+ is small enough (Table 13.1) to pass through the pore. Indeed, the ionic radius of Na^+ is substantially smaller than that of K^+. How then is Na^+ rejected?

TABLE 13.1 Properties of alkali cations

Ion	Ionic radius (Å)	Hydration free energy in $kJ\ mol^{-1}(kcal\ mol^{-1})$
Li^+	0.60	−410(−98)
Na^+	0.95	−301(−72)
K^+	1.33	−230(−55)
Rb^+	1.48	−213(−51)
Cs^+	1.69	−197(−47)

The key point is that the free-energy costs of dehydrating ions are considerable. For example, Table 13.1 reveals that the cost of dehydrating Na^+ is $301\ kJ\ mol^{-1}$($72\ kcal\ mol^{-1}$), while that of K^+ is $230\ kJ\ mol^{-1}$ ($55\ kcal\ mol^{-1}$). The channel pays the cost of desolvating K^+ by providing optimal compensating interactions with the carbonyl oxygen atoms lining the selectivity filter. Careful studies of the potassium channel, enabled by the determination of its three-dimensional structure, have revealed that the interior of the pore is a highly dynamic, fluid environment. The favorable resolvation interactions between the carbonyl oxygen atoms, which carry a partial negative charge, with the cation are balanced by the repulsion of these oxygen atoms from one another. For this channel, the ideal balance is achieved with K^+, but not with Na^+ (**Figure 13.21**). Hence, sodium ions are rejected because the higher energetic cost of dehydrating them would not be recovered.

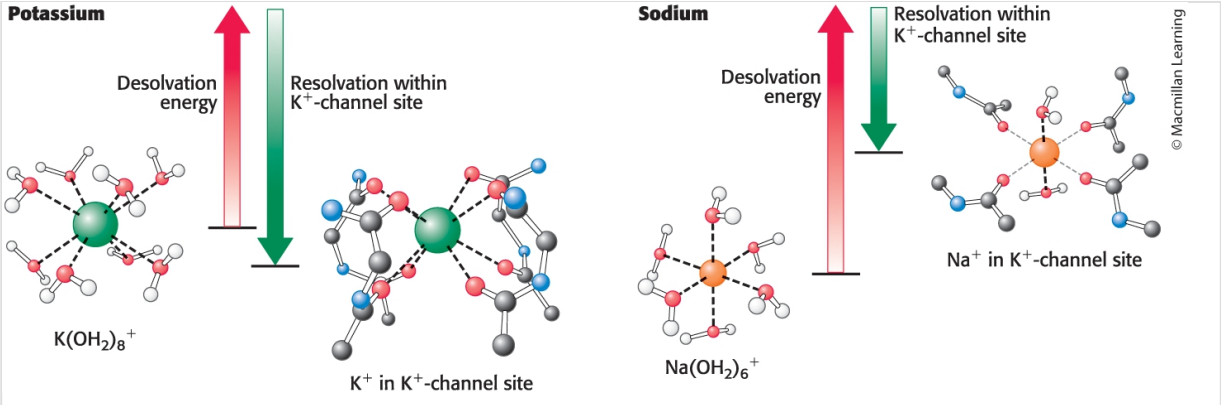

FIGURE 13.21 Ion selectivity is driven by the energetic balance between ion desolvation and coordination within the selectivity filter. The energy cost of dehydrating a potassium ion is compensated by favorable interactions with the selectivity filter. Because a sodium ion is too small to interact favorably with the selectivity filter, the free energy of desolvation cannot be compensated and the sodium ion does not pass through the channel.

The K^+ channel structure enables a clearer understanding of the structure and function of Na^+ and Ca^{2+} channels because of their homology to K^+ channels (Figure 13.17). Sequence comparisons and the results of mutagenesis experiments have implicated the region between segments S5 and S6 in ion selectivity in the Ca^{2+} channel. In Ca^{2+} channels, one glutamate residue of this region in each of the four repeated units plays a major role in determining ion selectivity (**Figure 13.22**). Residues in the positions corresponding to the glutamate residues in Ca^{2+} channels are major components of the selectivity filter of the Na^+ channel. These residues — aspartate, glutamate, lysine, and alanine — are located in each of the internal repeats of the Na^+ channel, forming a region termed the DEKA locus. Thus, the potential fourfold symmetry of the channel is clearly broken in this region, which explains why Na^+ channels consist of a single large polypeptide chain

rather than a noncovalent assembly of four identical subunits. The preference of the Na^+ channel for Na^+ over K^+ depends on ionic radius; the diameter of the pore determined by these residues and others is sufficiently restricted that small ions such as Na^+ and Li^+ can pass through the channel, but larger ions such as K^+ are significantly hindered.

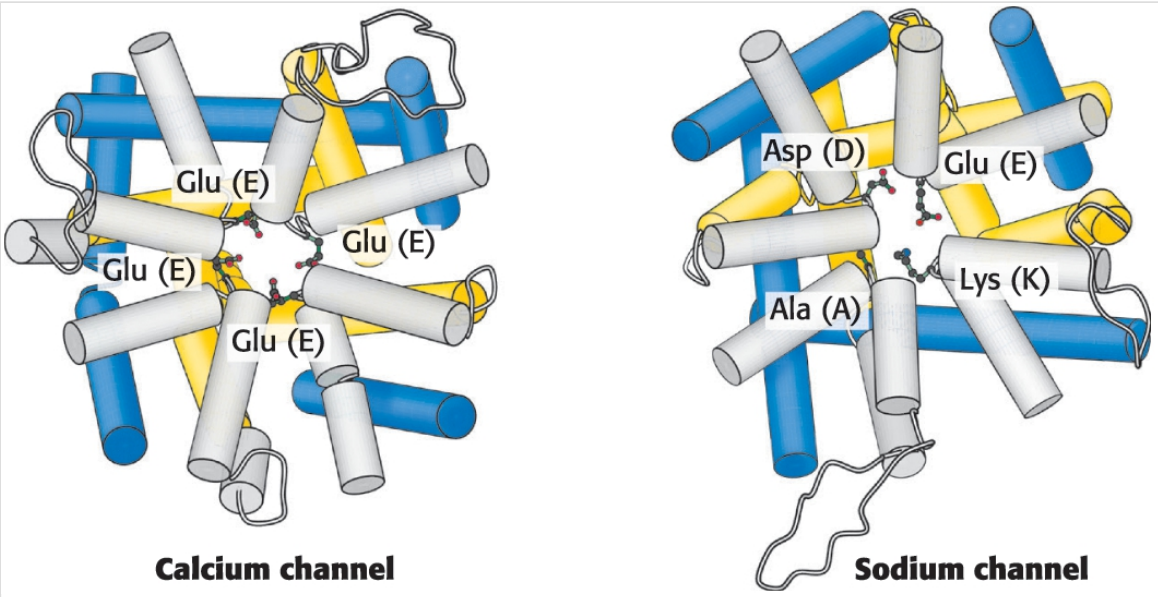

FIGURE 13.22 The amino acids defining the selectivity filter differ between calcium and sodium channels. The pores of eukaryotic calcium and sodium channels are comprised of sing polypeptide chains. In these views, we are looking down the pore; for simplicity, only the S5 (blue), S6 (yellow), and pore-forming (white) regions are drawn. The selectivity filter for the calcium channel contains four glutamate (E) residues, while the filter for the sodium channel contains four different residues (the DEKA locus): aspartate (D), glutamate (E), lysine (K), and alanine (A).

[Drawn from 5GJV.pdb and 5X0M.pdb.]

The structure of the potassium ion channel explains its rapid rate of transport

The tight binding sites required for ion selectivity should slow the progress of ions through a channel, yet ion channels achieve rapid rates of ion transport. How is this paradox resolved? A structural analysis of the channel at high resolution provides an appealing explanation. Consider the process of ion conductance starting from inside the cell (Figure 13.23). Four K^+-binding sites crucial for rapid ion flow are present in the constricted region of the K^+ channel. A hydrated potassium ion proceeds into the channel and through the relatively unrestricted part of the channel. The ion then gives up its coordinated water molecules and binds to a site within the selectivity-filter region. The ion can move between the four sites within the selectivity filter because they have similar ion affinities. As each subsequent potassium ion moves into the selectivity filter, its positive charge will repel the potassium ion at the nearest site, causing it to shift to a site farther up the channel and in turn push upward any potassium ion already bound to a site farther up. Thus, each ion that binds anew favors the release of an ion from the other side of the channel. This multiple-binding-site mechanism solves the paradox of high ion selectivity and rapid flow.

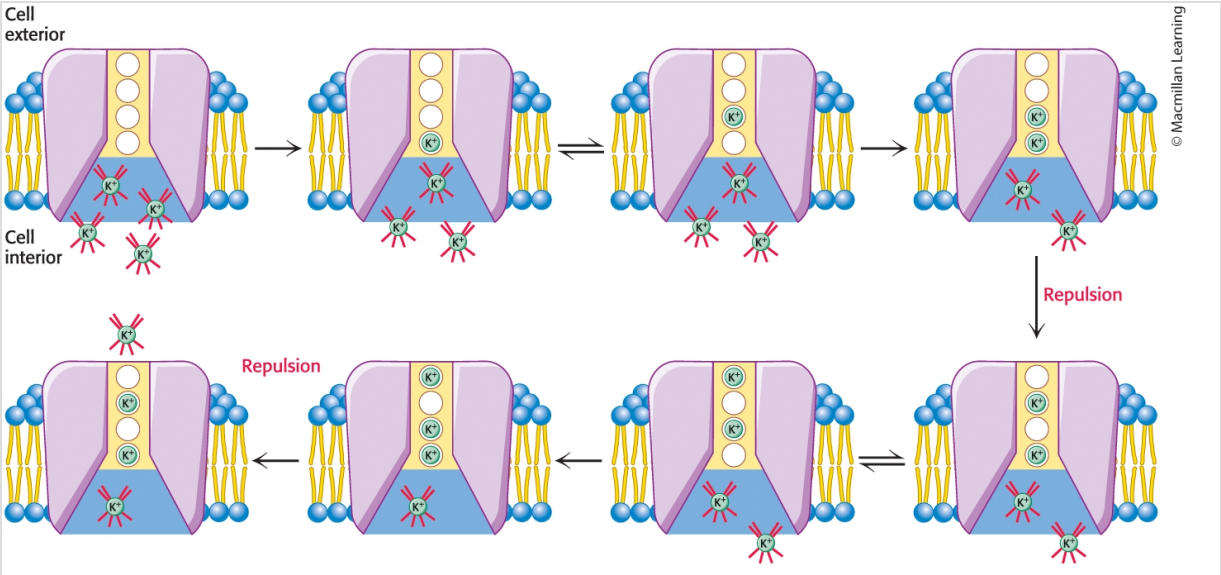

FIGURE 13.23 The model for K^+-channel ion transport relies on multiple ion binding sites within the pore. The selectivity filter has four binding sites. Hydrated potassium ions can enter these sites, one at a time, losing their hydration shells. When two ions occupy adjacent sites, electrostatic repulsion forces them apart. Thus, as ions enter the channel from one side, other ions are pushed out the other side.

Self-Check Question

The K^+ channel and the Na^+ channel have similar structures and are arranged in the same orientation in the cell membrane. Yet the Na^+ channel allows sodium ions to flow into the cell and the K^+ channel allows potassium ions to flow out of the cell. Explain.

Voltage gating requires substantial conformational changes in specific ion-channel domains

Na^+ and K^+ channels are gated by membrane potential; that is, they change conformation to a highly conducting form in response to changes in voltage across the membrane. As already noted, these voltage-gated channels include segments S1 through S4 in addition to the pore itself formed by S5 and S6. The structure of a voltage-gated K^+ channel from *Aeropyrum pernix* reveals that the segments S1 through S4

form domains, termed *paddles*, that extend from the core of the channel (Figure 13.24). These paddles include the segment S4, the voltage sensor itself. Segment S4 forms an α helix lined with positively charged residues. In contrast with expectations, segments S1 through S4 are not enclosed within the protein but, instead, are positioned to lie in the membrane itself.

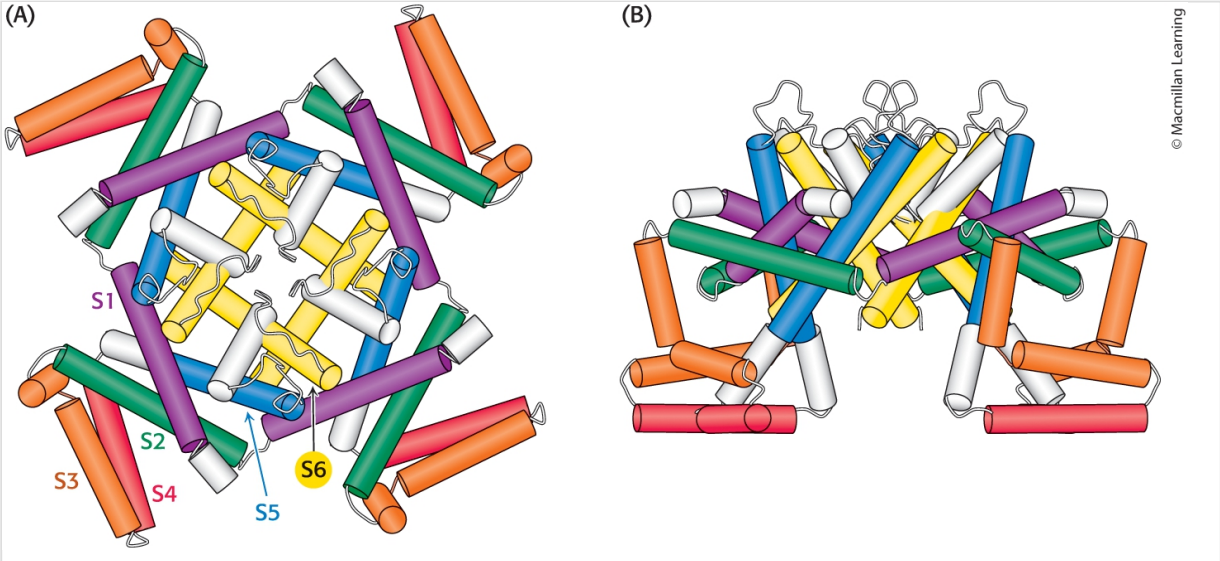

FIGURE 13.24 The S4 region lies on the outer surface of the voltage-gated potassium channel. (A) A view looking down through the pore and (B) a side view of the structure are shown. The positively charged S4 region (red) lies on the outside of the structure at the bottom of the pore.

[Drawn from 1ORQ.pdb.]

A model for voltage gating has been proposed by Roderick MacKinnon and coworkers on the basis of this structure and a range of other experiments (Figure 13.25). In the closed state, the paddles lie in a "down" position. On membrane depolarization, the cytoplasmic side of the membrane becomes more positively charged, repelling the paddles through the membrane into an "up" position. In this position, they pull the four sides of the base on the pore apart, increasing access to the selectivity filter and opening the channel.

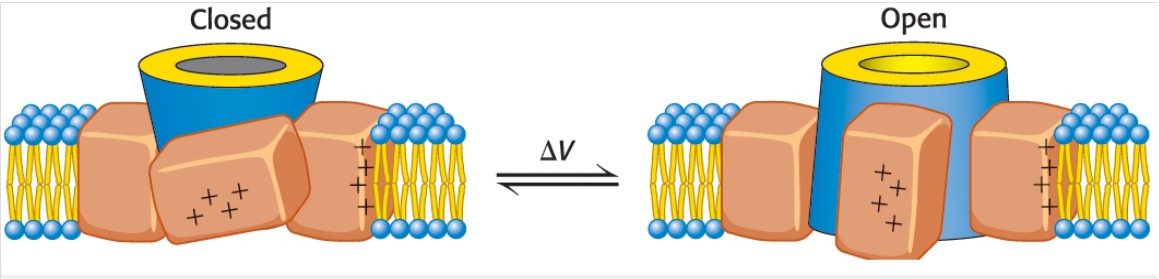

FIGURE 13.25 Movement of the S4 region controls the opening of the voltage-gated potassiu channel. The voltage-sensing paddles lie in the "down" position below the closed channel (left) Membrane depolarization pulls these paddles through the membrane. The motion pulls the ba of the channel apart, opening the channel (right).

A channel can be inactivated by occlusion of the pore: the ball-and-chain model

The K^+ channel and the Na^+ channel undergo inactivation within milliseconds of opening (Figure 13.26A). A first clue to one mechanism of inactivation came from exposing the cytoplasmic side of either channel to the protease trypsin. Cleavage by trypsin produced trimmed channels that stayed persistently open after depolarization, suggesting that a flexible (i.e., accessible to protease) region of the protein was responsible for inactivation. Furthermore, a mutant Shaker channel lacking 42 amino acids near the amino terminus opened in response to depolarization but did not inactivate (Figure 13.26B). Remarkably, inactivation was restored by adding a synthetic peptide corresponding to the first 20 residues of the native channel (Figure 13.26C).

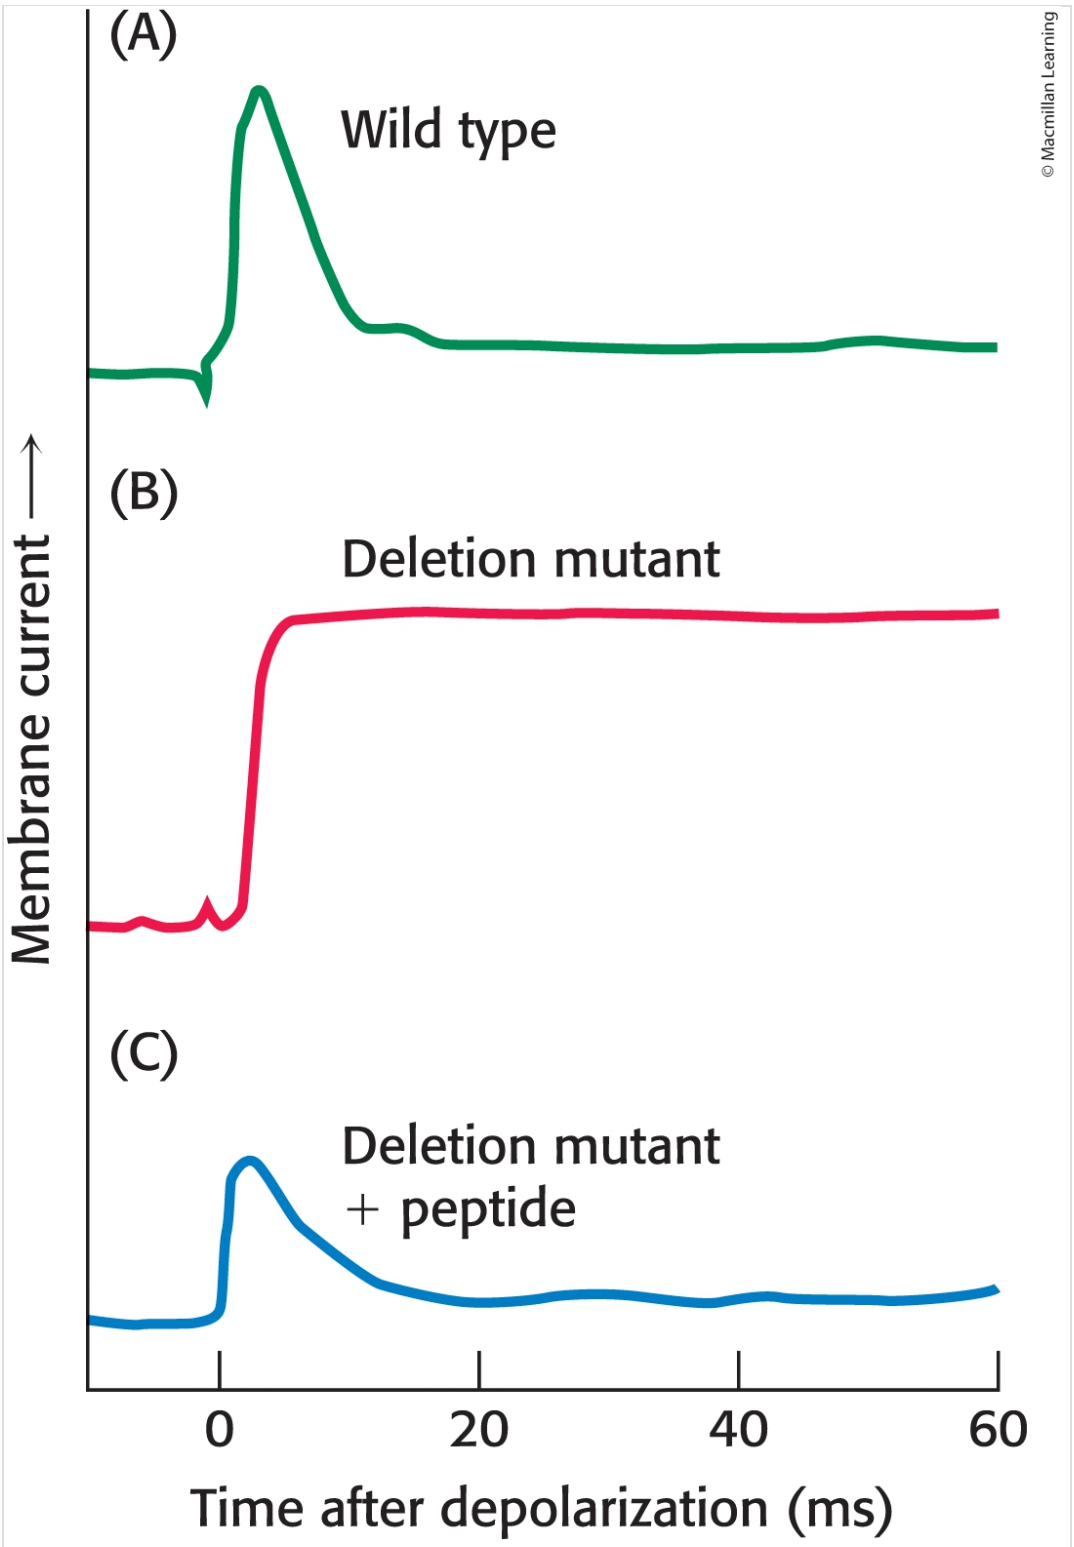

FIGURE 13.26 The amino-terminal region of the K^+ channel is critical for inactivation. (A) The wild-type Shaker K^+ channel displays rapid inactivation after

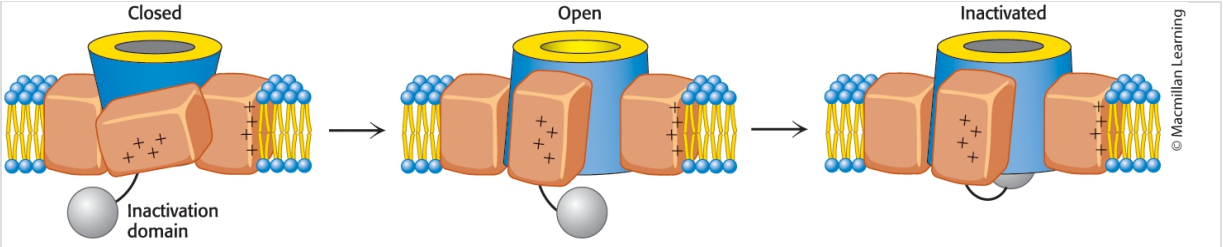
opening. (B) A mutant channel lacking residues 6 through 46 does not inactivate. (C) Inactivation can be restored by adding a peptide consisting of residues 1 through 20 at a concentration of $100\ \mu M$.

[Data from W. N. Zagotta, T. Hoshi, and R. W. Aldrich, *Science* 250:568–571, 1990.]

These experiments strongly support the **ball-and-chain model** for channel inactivation that had been proposed years earlier (**Figure 13.27**). According to this model, the first 20 residues of the K^+ channel form a cytoplasmic unit (the *ball*) that is attached to a flexible segment of the polypeptide (the *chain*). When the channel is closed, the ball rotates freely in the aqueous solution. When the channel opens, the ball quickly finds a complementary site in the open pore and occludes it. Hence, the channel opens for only a brief interval before it undergoes inactivation by occlusion. Shortening the chain speeds inactivation because the ball finds its target more quickly. Conversely, lengthening the chain slows inactivation. Thus, the duration of the open state can be controlled by the length and flexibility of the tether. In some senses, the "ball" domains, which include substantial regions of positive charge, can be thought of as large, tethered cations that are pulled into the open channel but get stuck and block further ion conductance.



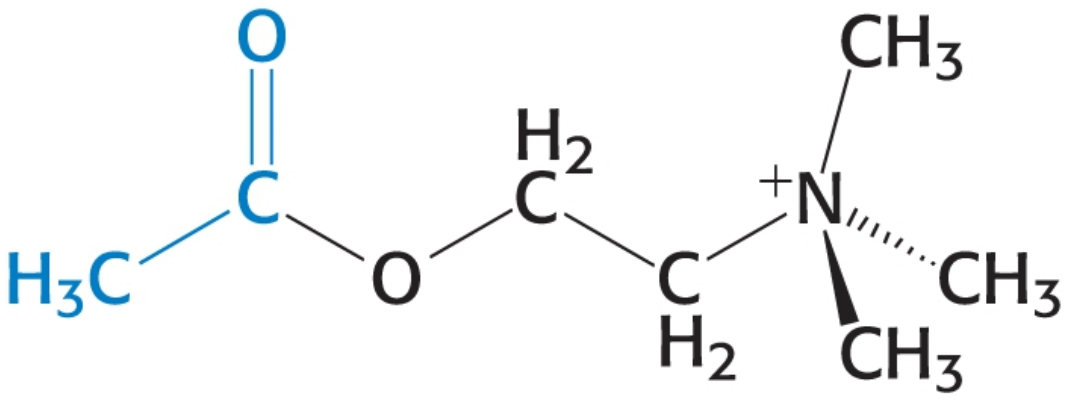


FIGURE 13.27 The ball-and-chain model provides a mechanism for channel inactivation. The inactivation domain, or "ball" (gray), is tethered to the channel by a flexible "chain." In the closed state, the ball is located in the cytoplasm. Depolarization opens the channel and creates a binding site for the positively charged ball in the mouth of the pore. Movement of the ball into this site inactivates the channel by occluding it.

It is apparent from the example in Figure 13.27 that the closed and inactivated states of the ion channel are not identical. The process of returning the inactivated channel to its initial closed state, termed **recovery**, requires disengagement of the ball domain from the pore opening as well as realignment of the voltage-sensing paddles. Depending upon the mechanism of inactivation, recovery can take milliseconds to seconds. Importantly, while inactivated, the channel cannot be opened by further membrane depolarization. As we shall see, the time needed for channel recovery has implications for repeated action potential generation.

The acetylcholine receptor is an archetype for ligand-gated ion channels

Nerve impulses are communicated across synapses by small, diffusible molecules called **neurotransmitters**. For example, one function of the neurotransmitter acetylcholine is to stimulate skeletal muscle contraction when released by contacting neurons. The presynaptic membrane of a synapse is separated from the postsynaptic membrane by a gap of about 50 nm called the **synaptic cleft**. The arrival of a nerve impulse at the end of an axon leads to the synchronous export of the contents of some 300 membrane-bound compartments, or vesicles, of acetylcholine into the cleft (**Figure 13.28**). The binding of acetylcholine to the postsynaptic membrane markedly changes its ionic permeability, triggering an action potential. Acetylcholine opens a single kind of cation channel, called the *acetylcholine receptor*, which is almost equally permeable to Na^+ and K^+.

Acetylcholine

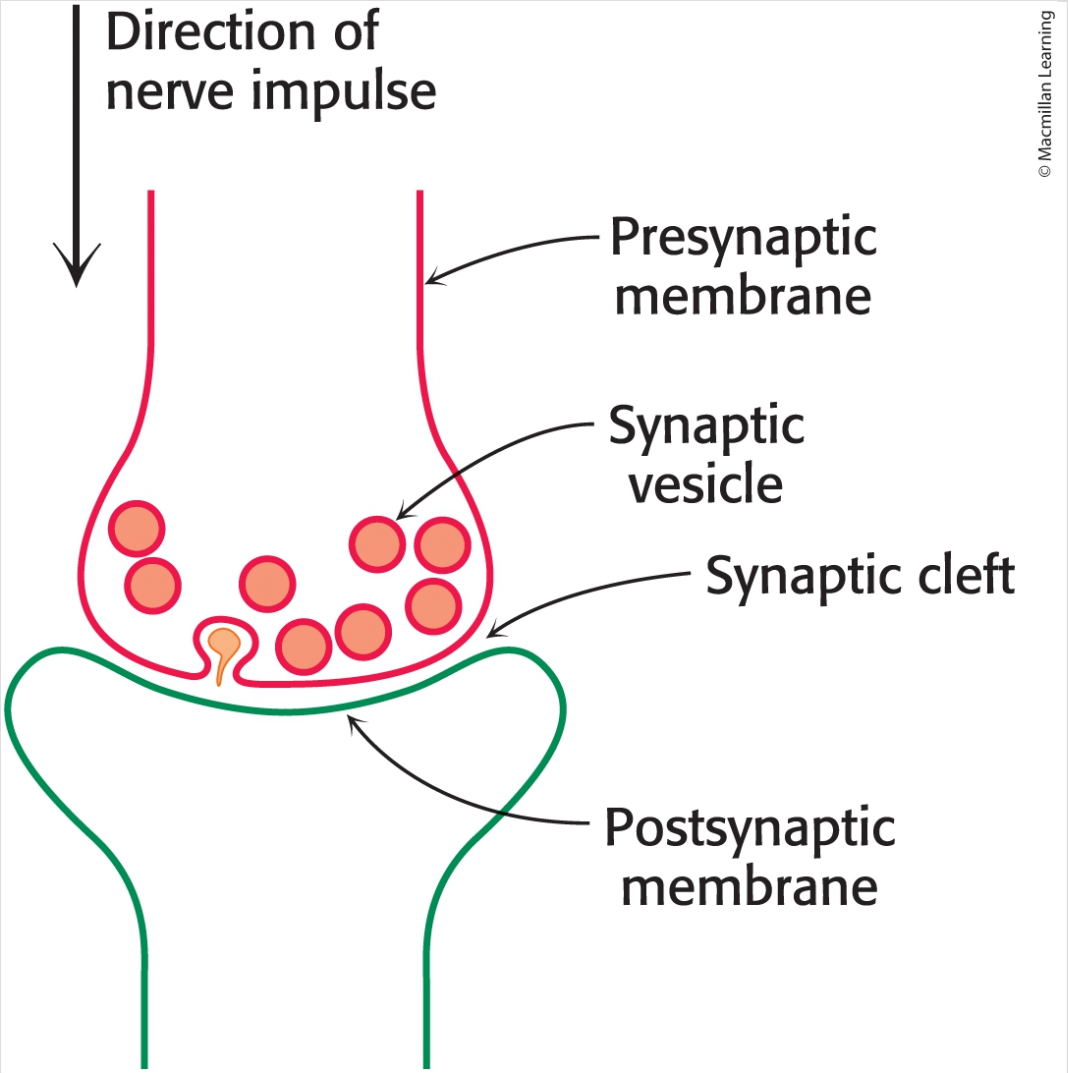

FIGURE 13.28 The synapse is the gap between cells where nerve impulses are transmitted.

The acetylcholine receptor is the best-understood **ligand-gated channel**, a channel that is gated not by voltage but by the presence of specific ligands. The binding of acetylcholine to the channel is followed by its transient opening. The electric organ of *Torpedo marmorata*, an electric ray (**Figure 13.29**), is a choice source of acetylcholine receptors for study because its electroplaxes (voltage-generating cells) are very rich in postsynaptic membranes densely packed with acetylcholine

receptors $(\sim 20{,}000\ \mu m^{-2})$ and therefore highly responsive to this neurotransmitter.

A. Martin UW Photography/Moment/Getty Images

FIGURE 13.29 The marbled electric ray (*Torpedo marmorata*) has an electric organ rich in acetylcholine receptors. These organs, called electroplaxes, can deliver a shock of as much as 200 V for approximately 1 second.

In order to study the acetylcholine receptor in molecular detail, biochemists solubilized the protein by adding a nonionic detergent to a postsynaptic membrane preparation from the electric organ and purified it by affinity chromatography on a column bearing covalently attached cobratoxin, a small protein toxin from snakes that has a high affinity for acetylcholine receptors. With the use of techniques presented in Chapter 4, the 268-kDa receptor was identified as a pentamer of four kinds of membrane-spanning subunits — α_2, β, γ, and δ. The cloning and sequencing of the cDNAs for the four kinds of subunits (50–58 kDa) showed that they have clearly similar sequences; the genes for the α, β, γ, and δ subunits arose by duplication and

divergence of a common ancestral gene. Each subunit has a large extracellular domain, followed at the carboxyl end by four predominantly hydrophobic segments that span the bilayer membrane.

Using cryo-EM and x-ray crystallographic methods (Section 4.5), the structure of purified acetylcholine receptors has been determined to have approximate fivefold symmetry, in harmony with the similarity of its five constituent subunits (**Figure 13.30A**). The subunits are arranged in the form of a ring that creates a pore through the membrane. Acetylcholine binds at the $\alpha-\gamma$ and $\alpha-\delta$ interfaces (**Figure 13.30B**).

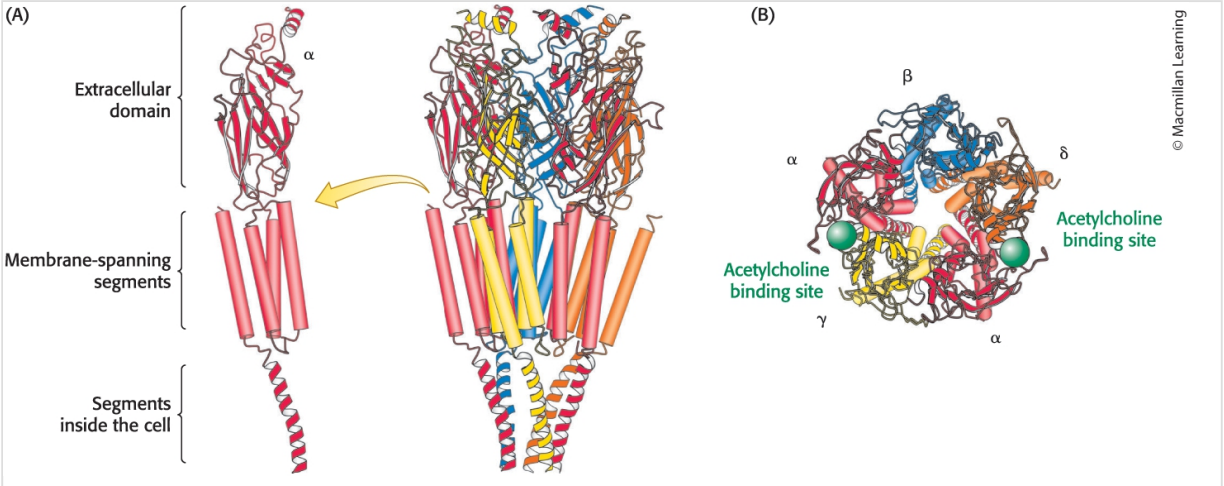

FIGURE 13.30 The acetylcholine receptor is a pentamer formed from four different subunit proteins. A model for the structure of the acetylcholine receptor deduced from high-resolution electron microscopic studies reveals that each subunit consists of a large extracellular domain consisting primarily of β strands, four membrane-spanning α helices, and a final α helix inside the cell. (A) A side view shows the pentameric receptor with each subunit type in a different color. One copy of the α subunit is shown in isolation. (B) A view down the channel from outside the cell shows the pore opening as well as the binding sites for the acetylcholine ligand, indicated in green.

[Drawn from 2BG9.pdb.]

INTERACT with this model in Achieve

What is the basis of channel opening in the acetylcholine receptor? A high-resolution answer to this question has remained elusive, but the details of this mechanism are becoming apparent. Cryo-EM images of the receptor in the open and closed states have been determined, albeit at low resolution. These structures indicate that the binding of acetylcholine to the extracellular domain ultimately leads to the straightening of the α-helices from the α and δ subunits that line the pore (Figure 13.31). In the closed state, the region of narrowest diameter in the pore (the "gate") is located about midway through the membrane. This region is lined with nonpolar residues, which cannot form favorable interactions with K^+ and Na^+ ions. However, once the helices are straightened, the region of narrowest diameter shifts closer to the inner membrane leaflet. This region is lined with polar residues and can conduct K^+ and Na^+ ions freely.

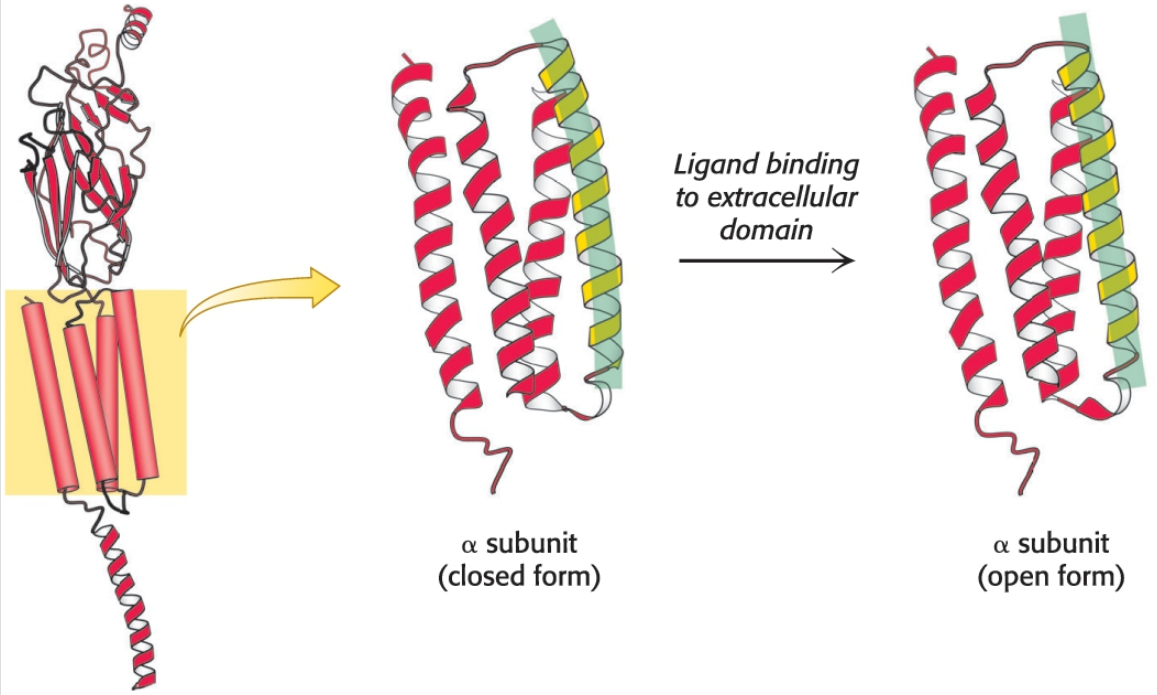

FIGURE 13.31 Ligand binding induces the opening of the acetylcholine receptor. Binding of acetylcholine to the extracellular region of the receptor leads to a series of conformational changes that are transmitted to the pore-lining helices. Notice that upon ligand binding, the pore-lining helix of the α subunit straightens (green bar). This subtle structural adjustment changes the gating properties of the pore, enabling cations to pass through.

Action potentials integrate the activities of several ion channels working in concert

To see how ligand-gated and voltage-gated channels work together to generate a sophisticated physiological response, we now revisit the action potential introduced at the beginning of this section. First, we need to introduce the concept of **equilibrium potential**. Suppose that a membrane separates two solutions that contain different concentrations of some cation X^+, as well as an equivalent amount of anions to balance the charge in each solution (**Figure 13.32**).

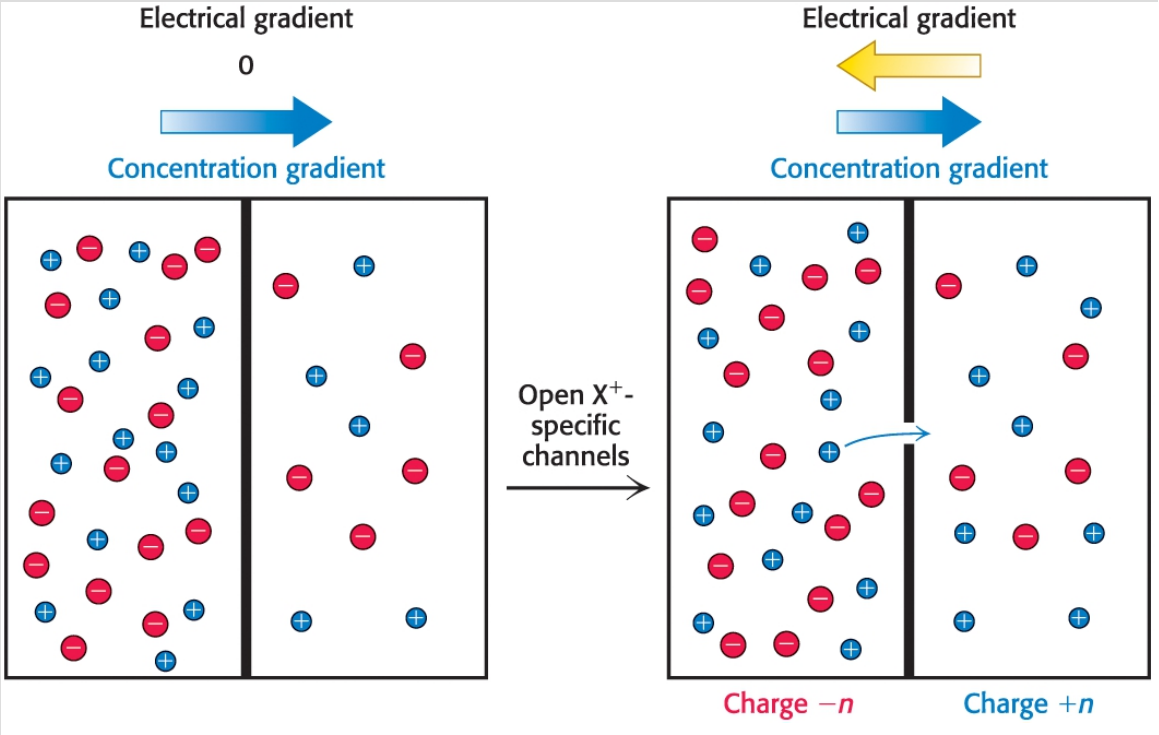

FIGURE 13.32 The equilibrium potential represents the balance between chemical and electrical gradients. The membrane potential reaches equilibrium when the driving force due t

the concentration gradient is exactly balanced by the opposing force due to the repulsion of like charges.

Let $[X^+]_{in}$ be the concentration of X^+ on one side of the membrane (corresponding to the inside of a cell) and $[X^+]_{out}$ be the concentration of X^+ on the other side (corresponding to the outside of a cell). Now let us assume that an ion channel opens that allows X^+ to move across the membrane. What will happen? It seems clear that X^+ will move through the channel from the side with the higher concentration to the side with the lower concentration. However, positive charges will start to accumulate on the side with the lower concentration, making it more difficult to move each additional positively charged ion. An equilibrium will be achieved when the driving force due to the concentration gradient is balanced by the electrostatic force resisting the motion of an additional charge. In these circumstances, the membrane potential is given by the Nernst equation:

$$V_{eq} = -(RT/zF)\ln([X]_{in}/[X]_{out})$$

where R is the gas constant and F is the Faraday constant ($96.5\ \text{kJ V}^{-1}\text{mol}^{-1}$, or $23.1\ \text{kcal V}^{-1}\text{mol}^{-1}$) and z is the charge on the ion X (e.g., $+1$ for X^+).

The membrane potential at equilibrium is called the equilibrium potential for a given ion at a given concentration ratio across a membrane. For sodium with $[Na^+]_{in} = 14\ \text{mM}$ and $[Na^+]_{out} = 143\ \text{mM}$,

the equilibrium potential is $+62\ \text{mV}$ at $37°\text{C}$. Similarly, for potassium with $[K^+]_{in} = 157\ \text{mM}$ and $[K^+]_{out} = 4\ \text{mM}$, the equilibrium potential is $-98\ \text{mV}$. In the absence of stimulation, the resting potential for a typical neuron is $-60\ \text{mV}$. This value is close to the equilibrium potential for K^+ owing to the fact that a small number of K^+ channels are open.

Example

Calculating Equilibrium Potentials

Problem:

For a typical mammalian cell, the intracellular and extracellular concentrations are of the calcium ion (Ca^{2+}) are $0.2\ \mu\text{M}$ and 1.8 mM, respectively. Calculate the equilibrium potential at 37° for Ca^{2+}.

Getting Started:

This problem represents a fairly straightforward application of the Nernst equation:

$$V_{eq} = -(RT/zF)\ln([X]_{in}/[X]_{out})$$

The most common pitfalls made in the application of this equation are mixing up the inside and outside concentrations and applying the incorrect ion charge (z). The calcium ion is a divalent cation, so $z = +2$.

Calculate:

Using the concentrations given (note that the two concentrations are given in different units!), substitute into the Nernst equation:

$$V_{eq} = -(RT/zF)\ln([X]_{in}/[X]_{out})$$

$$V_{eq} = -\left(\frac{(8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{deg}^{-1}) \times (310\ \text{deg})}{(+2) \times (96.5\ \text{kJ V}^{-1}\ \text{mol}^{-1})}\right)\ln\left(\frac{0.0002\ \text{mM}}{1.8\ \text{mM}}\right)$$

$$V_{eq} = +122\ \text{mV}$$

Reflect:

Calcium ions are maintained at a very low intracellular concentration, owing to the activity of Ca^{2+} pumps such as SERCA. Hence, the equilibrium potential is quite high, over 120 millivolts. Cells are highly sensitive to changes in intracellular Ca^{2+}, which can be exploited by signal transduction pathways (Section 14.2).

We are now prepared to consider what happens in the generation of an action potential (**Figure 13.33**):

FIGURE 13.33 The action potential is generated by the coordinated opening, closing, and inactivation of Na^+ and K^+ channels. (A) On the initiation of an action potential, the membrane potential moves from the resting potential upward toward the Na^+ equilibrium potential and then downward toward the K^+ equilibrium potential. (B) The currents through the Na^+ and K^+ channels underlying the action potential. (C) The states of the Na^+ and K^+ channels during the action potential.

- Initially, a neurotransmitter such as acetylcholine is released into the synaptic cleft from a presynaptic membrane (Figure 13.28). The released acetylcholine binds to the acetylcholine receptor on the postsynaptic membrane, causing it to open within less than a millisecond. The acetylcholine receptor is a nonspecific cation channel. Sodium ions flow into the cell and potassium ions flow out of the cell. Without any further events, the membrane potential would move to a value corresponding to the average of the equilibrium potentials for Na^+ and K^+, approximately $-2\ mV$.

- As the membrane potential approaches $-40\ mV$, the voltage-sensing paddles of Na^+ channels are pulled into the membrane, opening the Na^+ channels. With these channels open, sodium ions flow rapidly into the cell and the membrane potential rises rapidly toward the Na^+ equilibrium potential (Figure 13.33B, red curve).

- The voltage-sensing paddles of K^+ channels also are pulled into the membrane by the changed membrane potential, but more slowly than Na^+ channel paddles. Nonetheless, after approximately 1 ms, many K^+ channels start to open.

- As the K^+ channels open, inactivation "ball" domains plug the open Na^+ channels, decreasing the Na^+ current. The acetylcholine receptors that initiated these events are also inactivated on this time scale.
- With the Na^+ channels inactivated and only the K^+ channels open, the membrane potential drops rapidly toward the K^+ equilibrium potential (Figure 13.33B, blue curve). The open K^+ channels are susceptible to inactivation by their "ball" domains, and these K^+ currents, too, are blocked.
- With the membrane potential returned to close to its initial value, the inactivation domains are released and the channels undergo recovery to return to their original closed states. During the time preceding this recovery, the Na^+ channels cannot be reopened by membrane depolarization. Hence, a new action potential cannot be induced for a short interval, termed the **refractory period**, which usually lasts around one millisecond in neurons.

These events propagate along the neuron as the depolarization of the membrane opens channels in nearby patches of membrane. Note that the refractory period ensures that an action potential does not recur in parts of the membrane that were just depolarized. The net result is that the action potential travels along the membrane in one direction.

How much current actually flows across the membrane over the course of an action potential? Consider that a typical nerve cell contains $100\ Na^+$ channels per square micrometer. At a membrane potential of $+20\ mV$, each channel conducts 10^7 ions per second. Thus, in a period of 1 millisecond, approximately 10^5 ions flow through each square micrometer of membrane surface. Assuming a cell volume of $10^4\ \mu m^3$

and a surface area of $10^4\ \mu m^2$, this rate of ion flow corresponds to an increase in the Na^+ concentration of less than 1%. How can this be? A robust action potential is generated because the membrane potential is very sensitive to even a slight change in the distribution of charge. This sensitivity makes the action potential a very efficient means of signaling over long distances and with rapid repetition rates.

Disruption of ion channels by mutations or chemicals can be potentially life-threatening

The generation of an action potential requires the precise coordination of gating events of a collection of ion channels. Perturbation of this timing can have devastating effects. For example, the rhythmic generation of action potentials by the heart is absolutely essential to maintain delivery of oxygenated blood to the peripheral tissues. **Long QT syndrome (LQTS)** is a genetic disorder in which the recovery of the action potential from its peak potential to the resting equilibrium potential is delayed. The term *QT* refers to a specific feature of the cardiac electrical activity pattern as measured by electrocardiography. LQTS can lead to brief losses of consciousness (syncope), disruption of normal cardiac rhythm (arrhythmia), and sudden death. The most common mutations identified in LQTS patients inactivate K^+ channels or prevent the proper trafficking of these channels to the plasma membrane. The resulting loss in potassium permeability slows the repolarization of the membrane and delays the induction of the subsequent cardiac contraction, rendering the cardiac tissue susceptible to arrhythmias.

 Prolongation of the cardiac action potential in this manner can also be a potentially dangerous side effect of certain therapeutic drugs.

In particular, the K^+ channel hERG (for human *ether-a-go-go*-related gene, named for its ortholog in *Drosophila melanogaster*) is highly susceptible to interactions with certain drugs. The hydrophobic regions of these drugs can block hERG by binding to two nonconserved aromatic residues on the internal surface of the channel cavity. In addition, this cavity is predicted to be wider than other K^+ channels because of the absence of a conserved Pro-X-Pro motif within the S6 hydrophobic segment. Inhibition of hERG by these drugs can lead to an increased risk of cardiac arrhythmias and sudden death. Accordingly, a number of these agents, such as the antihistamine terfenadine, have been withdrawn from the market. Screening for the inhibition of hERG is now a critical safety hurdle for the pharmaceutical advancement of a molecule to an approved drug.

Hyperpolarization-activated ion channels enable pacemaker activity in the heart

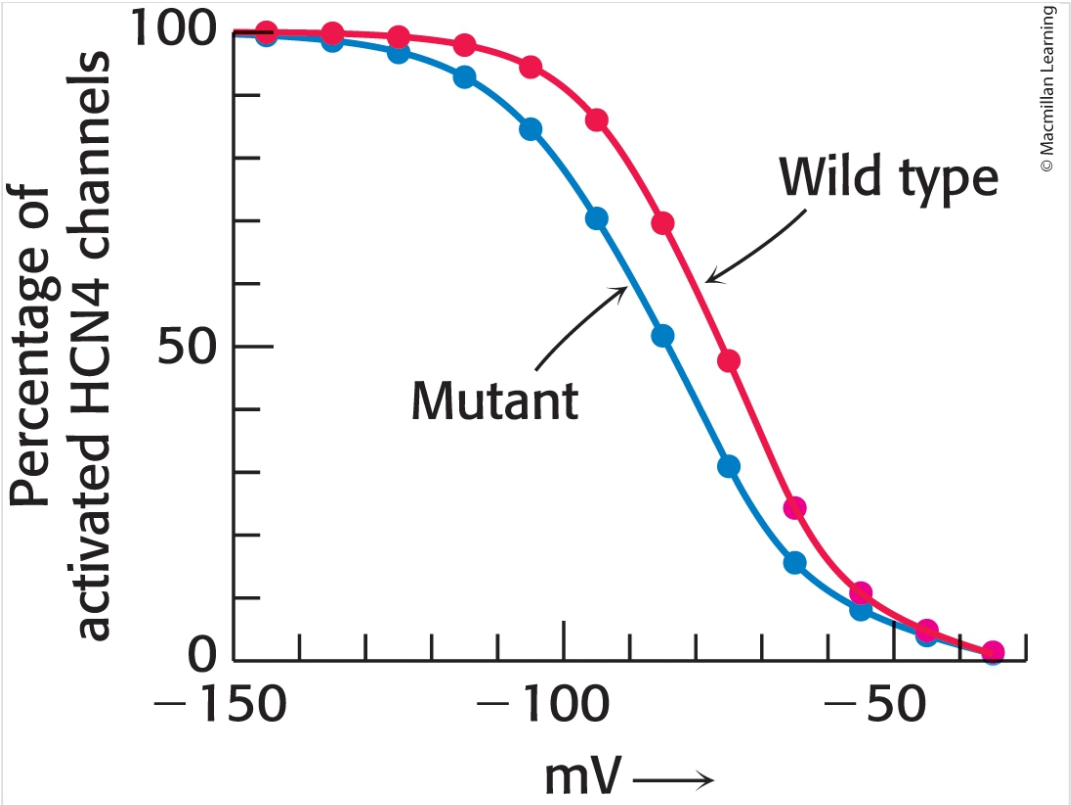
The heart utilizes coordinated changes in the membrane potential to facilitate the efficient muscular contractions necessary to pump blood throughout the body effectively. However, the heart can beat spontaneously, without the use of a neurotransmitter such as acetylcholine. How does the heart initiate an action potential without such an input?

The answer lies within a collection of cardiac cells known as the pacemaker. While there are several pacemakers in the human heart, the most important of these is the sinoatrial (SA) node, located on the posterior wall of the right atrium. The cells of the SA node spontaneously generate action potentials at rates from 60 to 100 per second. Researchers have known for many years that these cells possess an unusual capacity for mixed Na^+/K^+ conductance when their membranes are hyperpolarized. This membrane permeability has been

referred to as the *funny current* (I_f). At rest, this current is active, leading to a gradual depolarization of the membrane to a level that triggers the initiation of an action potential. During the action potential, this current shuts off. However, once the action potential is complete and the membrane returns to its resting potential, the funny current turns back on, repeating the cycle. The action potential propagates from the SA node to the rest of the cardiac tissue in a highly organized manner, stimulating muscle contraction and the movement of blood.

The channels responsible for the funny current have been identified. The hyperpolarization-activated cyclic nucleotide-gated (HCN) channels comprise four isoforms. Functional channels are composed of tetramers of these isoforms, either all of the same type (homotetramers) or of a combination of types (heterotetramers). HCN4 is the most prominently expressed in the SA node. These channels are unusual in that they are opened by hyperpolarization, and close when the membrane is depolarized. Moreover, these channels are responsive to changing levels of intracellular cyclic AMP (cAMP), as expected: while the heart can beat spontaneously, neuronal and hormonal input can affect this rate to accommodate the body's changing energetic needs.

Mutations in the *HCN4* gene have been identified in patients with sick sinus syndrome, a condition where patients exhibit an abnormally low heart rate (bradycardia) that may manifest with symptoms of dizziness, fainting, headaches, and fatigue. In one family, the identified mutation resulted in a greater hyperpolarization required to achieve HCN4 opening (**Figure 13.34**) when these channels were expressed in cultured cells. In a patient carrying this mutation, fewer HCN4 channels are open at a given resting potential, leading to a slower depolarization and a reduced heart rate.



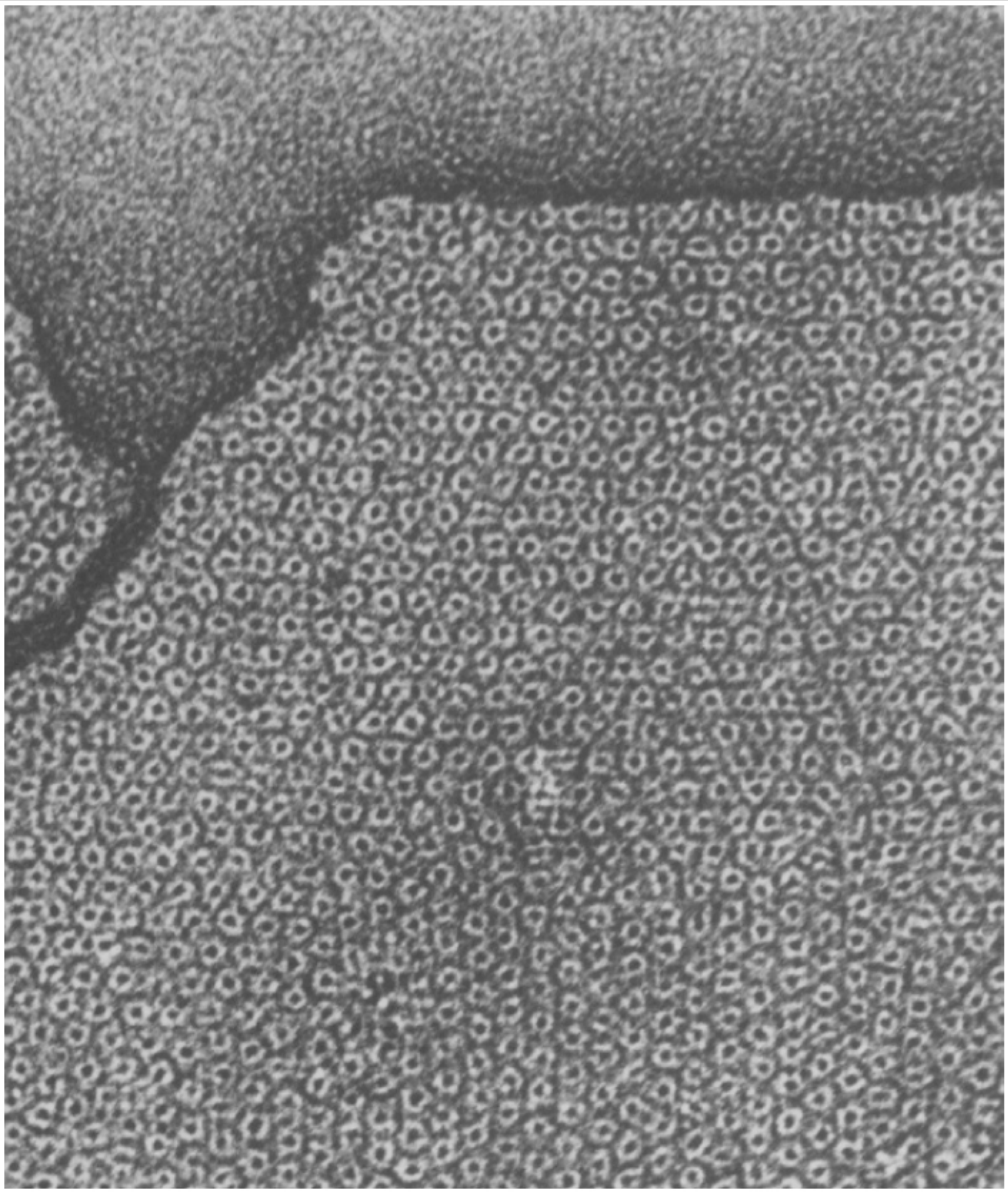


FIGURE 13.34 A disease-causing HCN4 mutant requires greater membrane hyperpolarization to open the channel. This graph shows the percentage of open channels at a given membrane potential. HCN4 channels are open at hyperpolarized membrane potentials, and close as the membrane depolarizes. For the mutant HCN4 channels (blue circles), the channel requires a more hyperpolarized state to be open to the same extent as the wild-type channels (red circles). [R. Milanese, M. Baruscotti, T. Gnecchi-Ruscone, and D. DiFrancesco, *New Eng. J. Med.* 354:151–157, 2006, Fig. 3A.]

13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells

The ion channels we have considered thus far have narrow pores and are moderately to highly selective in the ions they allow to pass through them. They are closed in the resting state and have short lifetimes in the open state, typically a millisecond, that enable them to transmit frequent neural signals. Let us turn now to a channel with a very different role. **Gap junctions**, also known as **cell-to-cell channels**, serve as passageways between the interiors of contiguous cells. Gap junctions are clustered in discrete regions of the plasma membranes of apposed cells. Electron micrographs of sheets of gap junctions show them tightly packed in a regular hexagonal array (**Figure 13.35**). An approximately 20-Å central hole, the lumen of the channel, is prominent in each gap junction. These channels span the intervening space, or gap, between apposed cells (hence, the name *gap junction*).

Don W. Fawcett/Science Source

FIGURE 13.35 Gap junctions form tightly packed arrays. This electron micrograph shows a sheet of isolated gap junctions. The cylindrical connexons form a hexagonal lattice having a unit-cell length of 85 Å. The densely stained central hole has a diameter of about 20 Å.

Small hydrophilic molecules as well as ions can pass through gap junctions. The pore size of the junctions was determined by microinjecting a series of fluorescent molecules into cells and observing their passage into adjoining cells. All polar molecules with a mass of less than about 1 kDa can readily pass through these

cell-to-cell channels. Thus, inorganic ions and most metabolites (e.g., sugars, amino acids, and nucleotides) can flow between the interiors of cells joined by gap junctions. In contrast, proteins, nucleic acids, and polysaccharides are too large to traverse these channels.

Gap junctions are important for intercellular communication. Cells in some excitable tissues, such as heart muscle, are coupled by the rapid flow of ions through these junctions, which ensures a speedy and synchronous response to stimuli. Gap junctions are also essential for the nourishment of cells that are distant from blood vessels, as in bone and the lens of the eye. Moreover, communicating channels are important in development and differentiation. For example, the quiescent (calm) uterus transforms to a forcefully contracting organ at the onset of labor; the formation of functional gap junctions at that time creates a syncytium of muscle cells that contract in synchrony.

A gap junction is made of 12 molecules of connexin, one of a family of transmembrane proteins with molecular masses ranging from 30 to 42 kDa. Each connexin molecule contains four membrane-spanning helices (**Figure 13.36A**). Six connexin molecules are hexagonally arrayed to form a half-channel, called a **connexon** or **hemichannel**. Two connexons join end to end in the intercellular space to form a functional channel between the communicating cells (**Figure 13.36B**). Each connexon adopts a funnel shape: At the cytoplasmic face, the inner diameter of the channel is 35 Å, while at its innermost point, the pore narrows to a diameter of 14 Å (**Figure 13.36C**). Cell-to-cell channels differ from other membrane channels in three respects:

1. They traverse *two* membranes rather than one.

2. They connect cytoplasm to cytoplasm, rather than to the extracellular space or the lumen of an organelle.

3. The connexons forming a channel are synthesized by different cells.

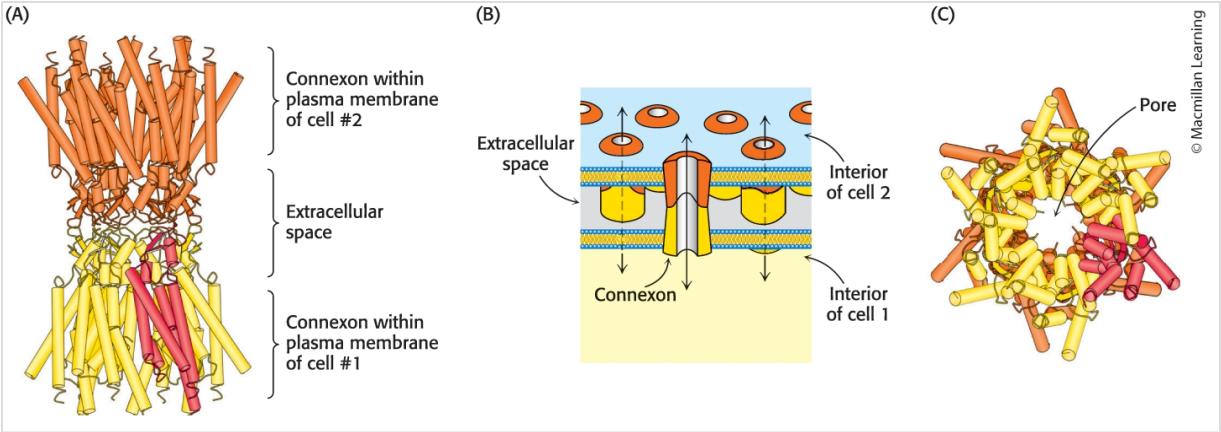

FIGURE 13.36 Gap junctions are formed from connexons of neighboring cells. (A) Six connexins join to form a connexon, or hemichannel, within the plasma membrane (yellow). A single connexin monomer is highlighted in red. The extracellular region of one connexon binds to the same region of a connexon from another cell (orange), forming a complete gap junction. (B) A schematic view of the gap junction, oriented in the same direction as in (A). (C) A bottom-up view looking through the pore of a gap junction. This perspective is visualized in Figure 13.35.

[(A) and (C) Drawn from 2ZW3.pdb; (B) Information from Dr. Werner Loewenstein.]

Gap junctions form readily when cells are brought together. A cell-to-cell channel, once formed, tends to stay open for seconds to minutes. They are closed by high concentrations of calcium ion and by low pH. The closing of gap junctions by Ca^{2+} and H^{+} serves to seal normal cells from injured or dying neighbors. Gap junctions are also controlled by membrane potential and by hormone-induced phosphorylation.

Self-Check Question

The human genome contains more than 20 connexin-encoding genes. Several of these genes are expressed in high levels in the heart. Why are connexins so highly expressed in cardiac tissue?

13.6 Specific Channels Increase the Permeability of Some Membranes to Water

One more important class of channels does not take part in ion transport at all. Instead, these channels increase the rate at which water flows through membranes. As noted in Section 12.3, membranes are reasonably permeable to water. Why, then, are water-specific channels required? In certain tissues, in some circumstances, rapid water transport through membranes is necessary. In the kidney, for example, water must be rapidly reabsorbed into the bloodstream after filtration. Similarly, in the secretion of saliva and tears, water must flow quickly through membranes. These observations suggested the existence of specific water channels, but initially the channels could not be identified.

The channels, now called **aquaporins**, were discovered serendipitously. Peter Agre (pictured at the beginning of Chapter 1) noticed a protein present at high levels in red-blood-cell membranes that had not been previously identified because the protein does not stain well with Coomassie blue, the stain commonly used in protein SDS-PAGE (Section 4.1). In addition to red blood cells, this protein was found in large quantities in tissues such as the kidney and the cornea, precisely the tissues hypothesized to contain water channels. On the basis of this observation, further studies were designed, revealing that this 24-kDa membrane protein is, indeed, a water channel.

The structure of aquaporin consists of six membrane-spanning α helices (**Figure 13.37**). Two loops containing hydrophilic residues line the actual channel. Water molecules pass through in single file at a rate of 10^6 molecules per second. Importantly, specific positively charged

residues toward the center of the channel prevent the transport of protons through aquaporin. Thus, aquaporin channels will not disrupt proton gradients, which play fundamental roles in energy transduction, as we will see in Chapter 18. Remarkably, the aquaporins are channels that have evolved specifically to conduct uncharged substrates.

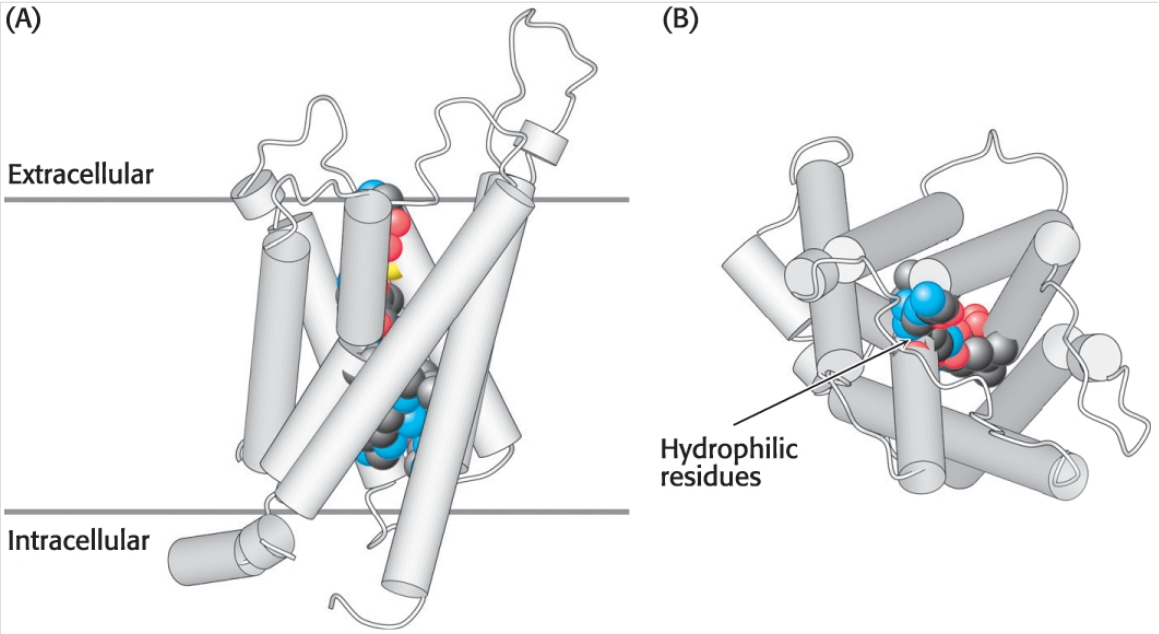

FIGURE 13.37 Aquaporins are channels specifically permeable to water. The structure of aquaporin viewed (A) from the side and (B) from the top. Notice the hydrophilic residues (shown as space-filling models) that line the water channel. The gray lines in (A) indicate the extent of the plasma membrane.

Chapter 13 Summary

13.1 The Transport of Molecules Across a Membrane May Be Active or Passive

- Lipophilic molecules can pass through a membrane's hydrophobic interior by simple diffusion.
- Passive transport or facilitated diffusion takes place when an ion or polar molecule moves down its concentration gradient with the assistance of a channel.
- Active transport uses an input of energy to move molecules against a concentration gradient.
- The electrochemical potential measures the combined ability of a concentration gradient and an uneven distribution of charge to drive species across a membrane.

13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Actively Transport Ions and Molecules Across Membranes

- Pumps are membrane proteins that catalyze the active transport of ions against their electrochemical gradients.
- P-type ATPases are pumps that are transiently phosphorylated on an aspartic acid residue during the transport cycle.
- ABC transporters are pumps that use ATP-binding cassettes to control protein conformation.

13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another

- Carriers are proteins that transport ions or molecules across the membrane without hydrolysis of ATP.
- Uniporters transport a substrate in either direction, determined by the concentration gradient.

- Antiporters couple the downhill flow of one substrate in one direction to the uphill flow of another in the opposite direction.
- Symporters couple the downhill flow of one substrate in one direction to the uphill flow of another in the same direction.

13.4 Specific Channels Can Rapidly Transport Ions Across Membranes

- Ion channels allow the rapid movement of ions across the hydrophobic barrier of the membrane.
- Ions must transiently lose their coordinated water molecules as they move to the narrowest part of an ion channel — the selectivity filter — which determines the specificity of the ion channel.
- Voltage-gated ion channels are opened by changes in membrane potential.
- Many channels spontaneously inactivate after having been open for a short period of time.
- Ligand-gated channels are opened or closed by the binding of ligands.
- Nerve impulses, or action potentials, are electrical signals produced by the coordinated flow of K^+ and Na^+ ions through their respective ion channels.

13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells

- Gap junctions, or cell-to-cell channels, serve to connect the interiors of contiguous groups of cells.
- Gap junctions are important for intercellular communication, enabling the coordinated contraction of the heart during a beat or the uterus during labor.

13.6 Specific Channels Increase the Permeability of Some Membranes to Water

- Aquaporin, a water-channel-forming protein, consists of six membrane-spanning α helices and a central channel lined with hydrophilic residues that allow water molecules to pass in single file.
- Aquaporins do not transport protons, and thus do not disrupt protein gradients across membranes.

Key Terms

[refractory period]
[long QT syndrome (LQTS)]
[gap junction (cell-to-cell channels)]
[connexon (hemichannel)]
[aquaporin]

Problems

1. Differentiate between simple diffusion and facilitated diffusion. 1

2. Distinguish the mechanisms by which uniporters and channels transport ions or molecules across the membrane. 1, 4

3. Which of the following statements applies to passive transport or active transport? 1

a. Moves substances from an area of low concentration to an area of higher concentration
b. Does not require energy
c. Requires energy
d. Moves substances from an area of high concentration to an area of lower concentration

4. For a typical mammalian cell, the intracellular and extracellular concentrations of the chloride ion (Cl^-) are $4\ \mu M$ and 150 mM, respectively. Calculate the equilibrium potential at 37°C for the chloride ion. 2

5. Intestinal epithelial cells pump glucose into the cell against its concentration gradient using the Na^+–glucose symporter. The symporter couples the "downhill" transport of two Na^+ ions into the cell to the "uphill" transport of glucose into the cell.

a. If the Na^+ concentration outside the cell is 155 mM and that inside the cell is 17 mM, and the membrane potential is $-55\ mV$, what is the maximum energy available for pumping a mole of glucose into the cell?
b. What is the maximum ratio of $[glucose]_{in} / [glucose]_{out}$ that could theoretically be produced if the energy coupling were 100% efficient? 2

6. If the pH of the interior of the stomach is pH 2, what is the amount of energy required for the transport of protons from the interior of the cell (pH 7.4) into the stomach lumen? Assume the membrane potential across this membrane is $-70\ mV$ and the temperature is 37°C. 2

7. Classify each phrase as a descriptor of ABC transporters, P-type ATPases, or both: 3

a. Substrate binds before ATP
b. The multidrug resistance protein is an example.
c. An aspartate residue in the membrane pump is phosphorylated.
d. The gastric H^+-K^+ ATPase is an example.
e. ATP-dependent
f. Two ATP-binding domains

8. Which of the following binding states are present in the SERCA catalytic cycle? For each state, assume that only the species mentioned are bound. 3

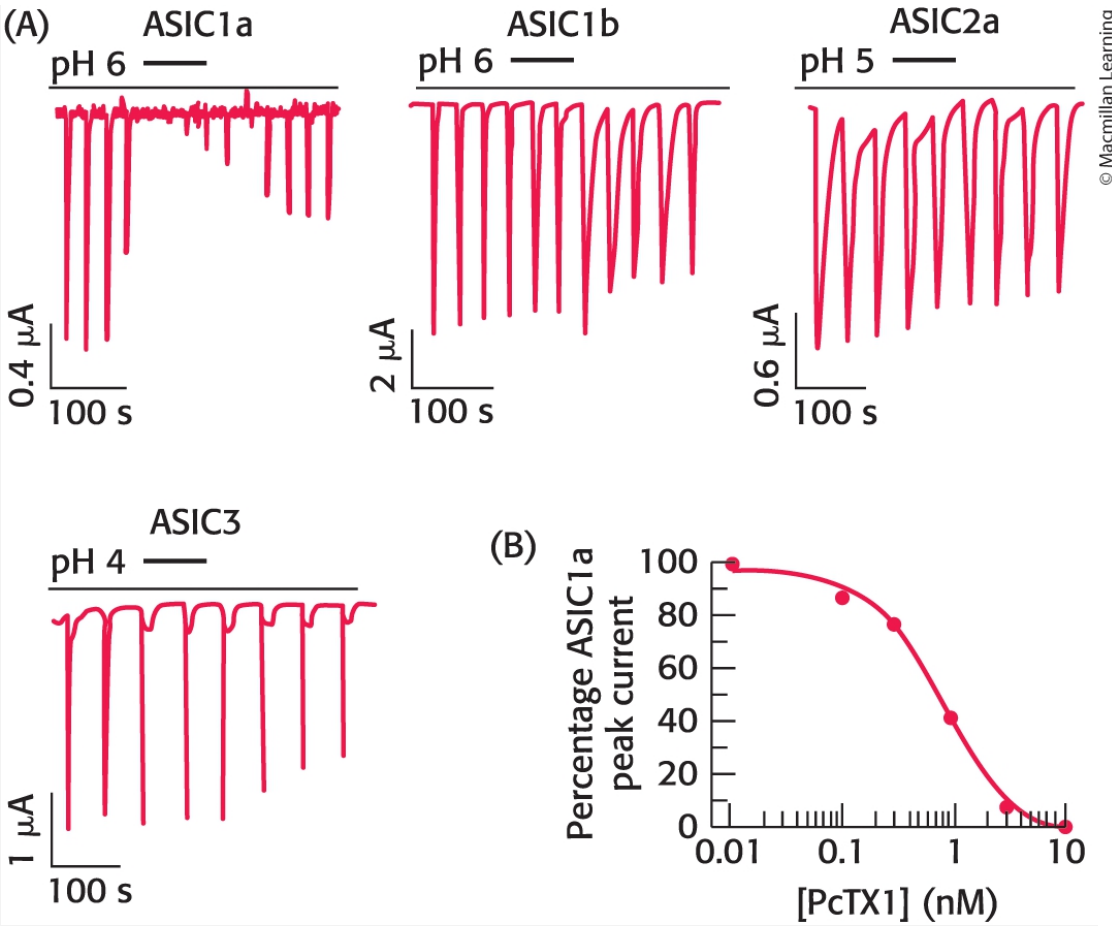
a. AMP bound
b. 2 Ca^{2+}, ADP, and P_i bound
c. 2 Ca^{2+} bound
d. 2 Ca^{2+} and ADP bound
e. ADP bound
f. 2 Ca^{2+} and ATP bound
g. P_i bound

9. To study the mechanism of SERCA, you prepare membrane vesicles containing this protein oriented such that its ATP binding site is on the outer surface of the vesicle. To measure pump activity, you use an assay that detects the formation of inorganic phosphate in the medium. When you add calcium and ATP to the medium, you observe phosphate production for only a short period of time. Only after the addition of calcimycin, a molecule that makes membranes selectively permeable to calcium, do you observe sustained phosphate production. Explain. 3

10. Name the three types of carrier proteins. Which of these can mediate secondary active transport? 4

11. Classify each description as characterizing facilitated diffusion, primary active transport, secondary active transport, or both primary and secondary active transport:

a. Requires ATP
b. Includes the Na^+-K^+ ATPase pump
c. Uses energy stored in electrochemical gradients generated by pumps
d. Always moves more than one substance at a time
e. Does not require energy input



f. Moves substances against a chemical gradient
g. Directly uses ATP hydrolysis to pump substances across the membrane
h. Includes lactose permease
i. Includes uniporters

12. In energetic terms, why do K^+ channels not enable Na^+ ions to cross the membrane? 5

13. How might a mutation in a cardiac voltage-dependent sodium channel cause long QT syndrome? 7

14. Batrachotoxin (BTX) is a steroidal alkaloid from the skin of *Phyllobates terribilis*, a poisonous Colombian frog (the source of the poison used on blowgun darts). In the presence of BTX, Na^+ channels in an excised patch stay persistently open when the membrane is depolarized. They close when the membrane is repolarized. Which transition is blocked by BTX?

15. Acid sensing is associated with pain, tasting, and other biological activities. Acid sensing is carried out by a ligand-gated channel that permits Na^+ influx in response to H^+. This family of acid-sensitive ion channels (ASICs) includes a number of members. Psalmotoxin 1 (PcTX1), a venom from the tarantula, inhibits some members of this family. The following electrophysiological recordings of cells containing several members of the ASIC family were made in the presence of the toxin at a concentration of 10 nM. The channels were opened by changing the pH from 7.4 to the indicated values. The PcTX1 was present for a short time (indicated by the black bar above the recordings below), after which time it was rapidly washed from the system.

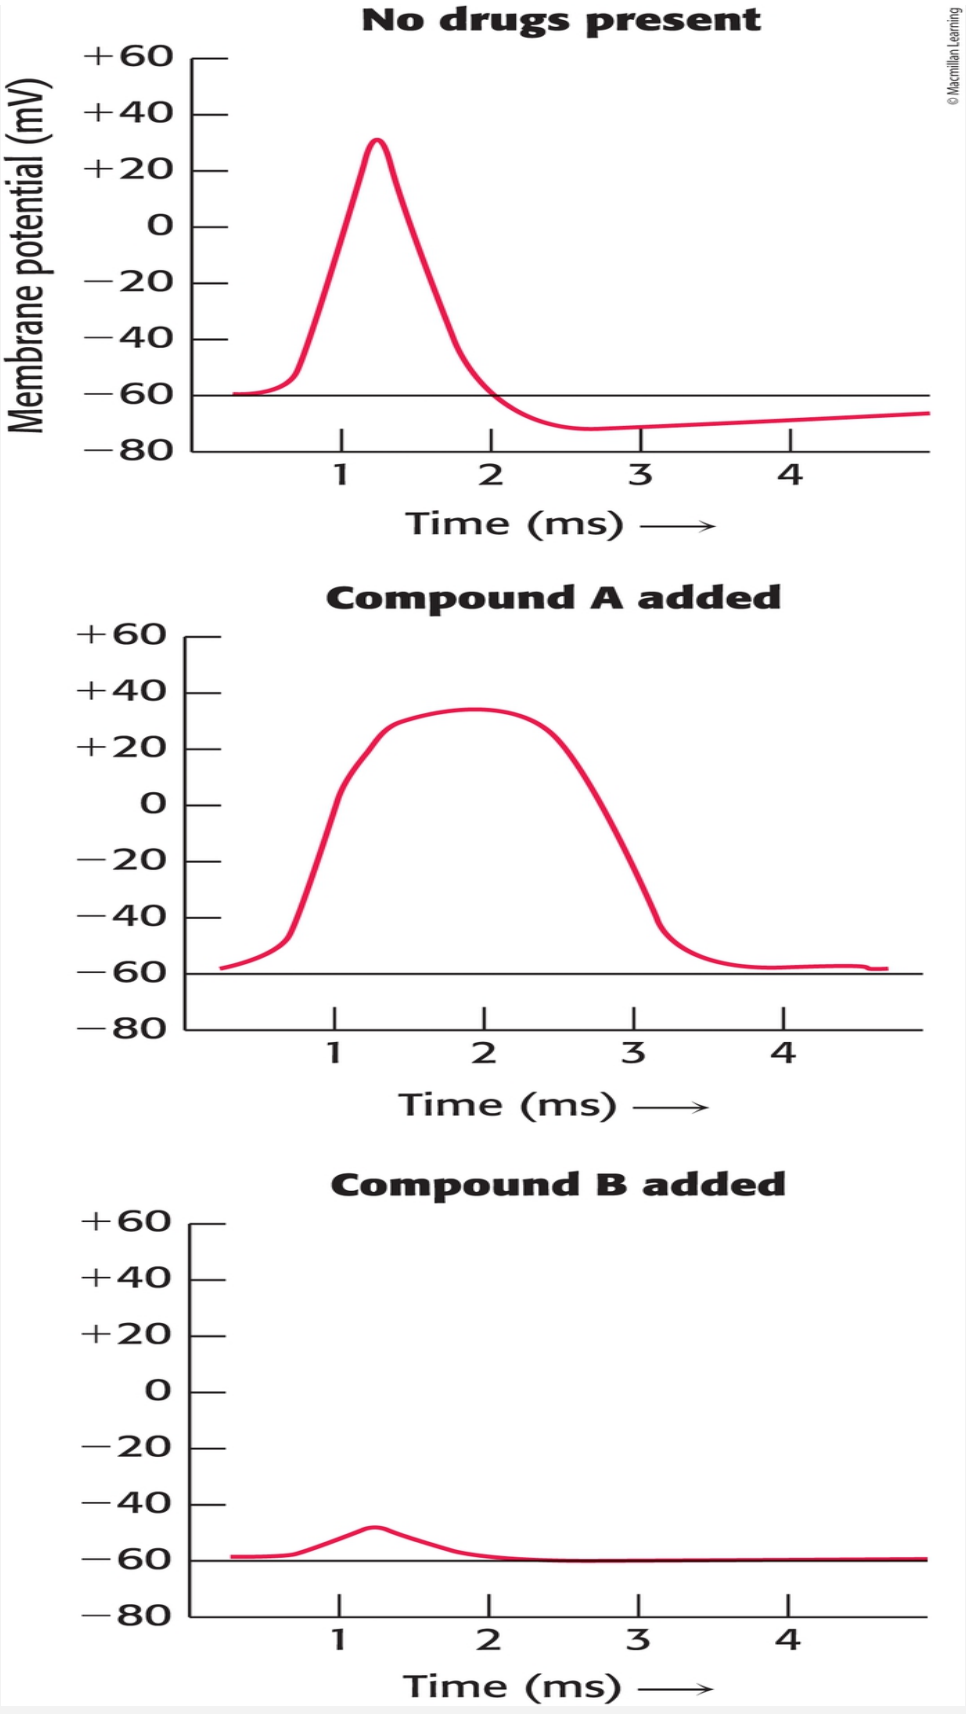
© Macmillan Learning

a. Which member of the ASIC family — ASIC1a, ASIC1b, ASIC2a, or ASIC3 — is most sensitive to the toxin?
b. Is the effect of the toxin reversible? Explain.
c. What concentration of PcTX1 yields 50% inhibition of the sensitive channel?

16. Cone snails are carnivores that inject a powerful set of toxins into their prey, leading to rapid paralysis. Many of these toxins are found to bind to specific ion-channel proteins. Why are such

molecules so toxic? How might such toxins be useful for biochemical studies? 7

17. Determine whether each phrase describes ligand-gated ion channels, voltage-gated ion channels, or both: 6

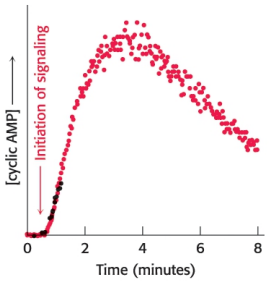


a. Change conformation in response to changing membrane potential
b. May participate in an action potential
c. An example is the acetylcholine receptor
d. Is a form of passive transport
e. Change conformation in response to a signal-molecule binding

18. Immediately after the repolarization phase of an action potential, the neuronal membrane is temporarily unable to respond to the stimulation of a second action potential, a phenomenon referred to as the *refractory period*. What is the mechanistic basis for the refractory period? 7

19. Place the events of an action potential in order, starting and ending with a cell at its resting membrane potential. 7

a. K^+ rushes out of the cell, causing repolarization.
b. Ligand activation of the acetylcholine receptor depolarizes the membrane.
c. K^+ channels fully open, and Na^+ channels are inactivated.
d. Fast Na^+ and slow K^+ channels are activated.
e. Na^+ rushes into the cell, causing membrane depolarization.
f. K^+ channels close slowly, resulting in hyperpolarization. Na^+ channel gates reset.



20. Drugs like tetrodotoxin (TTX) and tetraethylammonium (TEA) alter action potentials in neurons. TTX is able to block voltage-gated sodium (Na^+) channels, whereas TEA is able to block voltage-gated potassium (K^+) channels. The first graph shows an action potential in the absence of any of these drugs. The next two graphs show the effect of either TTX or TEA on the action potential. Match these graphs with the likely drug that was used. 7

Chapter 14
Signal-Transduction Pathways

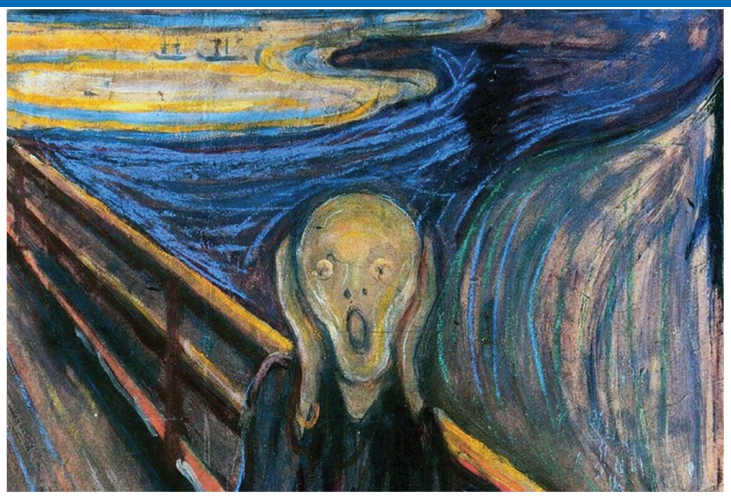

Photo12/Universal Images Group/Getty Images
© Macmillan Learning

Many biological processes involve biochemical signaling. The "fight-or-flight" response triggered by fear or shock is mediated by the release of the hormone adrenaline (epinephrine). Information about the arrival of this molecule at specific receptors on cell surfaces is converted rapidly into increases in the concentration of cyclic adenosine monophosphate (cAMP) inside cells. This, in turn, drives other biochemical responses.

Outline

14.1 Many Signal-Transduction Pathways Share Common Themes
14.2 Epinephrine Signaling: Heterotrimeric G Proteins Transmit Signals and Reset Themselves
14.3 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes

14.4 Epidermal Growth Factor: Receptor Dimerization Can Drive Signaling
14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases
14.6 Sensory Systems Are Based on Specialized Signal-Transduction Pathways

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the essential features of a signal-transduction circuit.
2. Define what is meant by a second messenger and give several examples.
3. Compare and contrast how the adrenergic receptors, the insulin receptor, and the epidermal growth factor receptors transmit a ligand-binding event across the plasma membrane to initiate an intracellular signaling cascade.
4. Give examples of how mutations in signaling proteins can result in cancer.
5. Discuss the signal-transduction pathways that are central to the senses of smell, vision, and hearing.

Imagine you and a group of friends are sitting around a firepit, waiting to finish cooking your dinner. Unexpectedly, you hear a rustling sound and fear that you may have an uninvited animal visitor. Your heart pounds, your eyes grow wide, and you turn pale, as you and your friends quickly run away from the sound. After 15 minutes, when you have calmed down and return to the fire; everything seems untouched. The same cannot be said for your leg, however, which sustained a deep scratch as you made your escape. After your friends help you clean and dress your wound, your thoughts return to dinner. The food smells, looks, and tastes delicious. After enjoying a nice meal, you feel satisfied.

Many of the steps in this encounter involve biochemical signaling processes within your cells. These chains of events, termed *signal-transduction pathways*, convert molecular messages into a range of physiological responses. In this chapter, we will focus on sets of signal-transduction pathways that affect circulation, metabolism, cell growth and division, and sensory perception.

14.1 Many Signal-Transduction Pathways Share Common Themes

The conversion of information of the presence or concentration of a signal molecule into other forms is called **transduction**. Signal-transduction pathways often include many components and branches. Moreover, they show variations that are used in different tissues and cell types. They can be immensely complicated and confusing. Nonetheless, the logic of signal transduction can be simplified by examining the common strategies and classes of molecules that recur in these pathways. These principles of signal-transduction pathways introduced here are at play in essentially all the metabolic pathways we will be exploring throughout the rest of the book.

Signal transduction depends on molecular circuits

Signal-transduction pathways follow a broadly similar course that can be viewed as a molecular circuit (**Figure 14.1**).

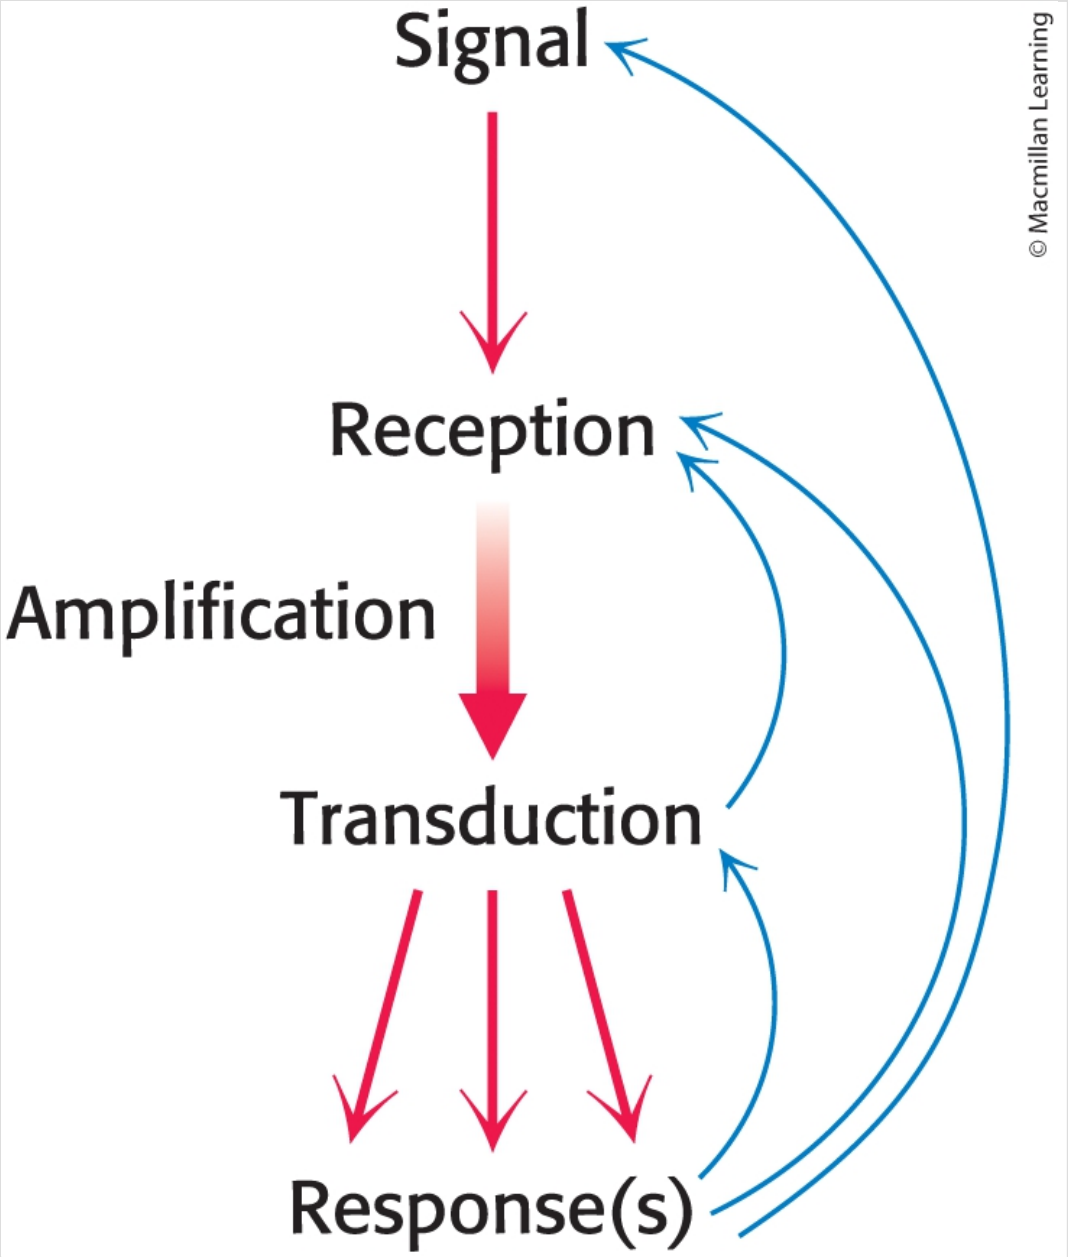

FIGURE 14.1 Signals such as changes in hormone levels lead to responses through signal-transduction pathways. An environmental signal is first received by interaction with a cellular component, most often a cell-surface receptor. Typically, the transduction process comprises many steps. The signal is often amplified before evoking one or more responses. Feedback pathways regulate the entire signaling process.

All such circuits contain certain key steps:

1. *Release of the primary messenger ("signal")*. A stimulus such as stress, a wound, or a digested meal triggers the release of the signal molecule, also called the **primary messenger**.

2. *Reception of the primary messenger*. Most signal molecules do not enter cells. Instead, proteins in the cell membrane act as **receptors** that convert signal molecule binding on the cell surface to a structural change within the cell's interior. Receptors span the cell membrane and thus have both extracellular and intracellular components. A binding site on the extracellular side specifically recognizes the signal molecule. Such binding sites are analogous to enzyme active sites except that no catalysis takes place within them. The interaction of the ligand and the receptor alters the tertiary or quaternary structure of the receptor to induce a structural change on the intracellular side.

3. *Delivery of the message inside the cell by the second messenger*. Other small molecules, called **second messengers**, are used to relay information from receptor–ligand complexes. Second messengers are intracellular molecules that change in concentration in response to environmental signals and mediate the next step in the molecular information circuit. Some particularly important second messengers are cyclic AMP (cAMP) and cyclic GMP (cGMP), calcium ion, inositol 1,4,5-trisphosphate (IP_3), and diacylglycerol (DAG), shown in **Figure 14.2**.

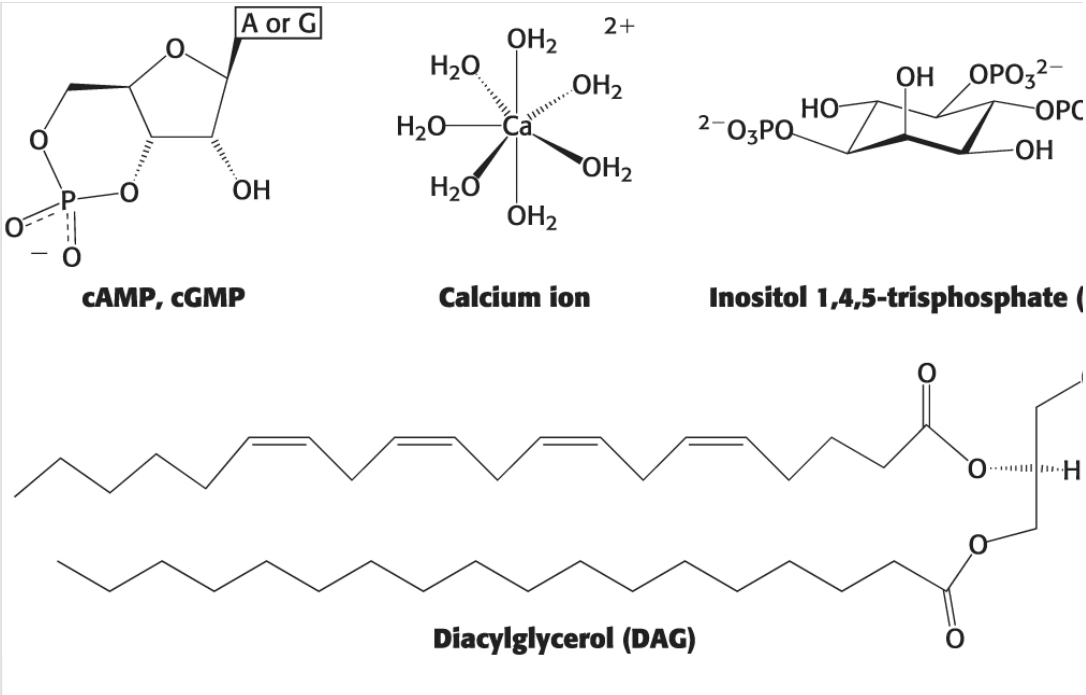

FIGURE 14.2 Several molecules function as second messengers common to many signa transduction pathways. As intracellular molecules that change in concentration in response to environmental signals, second messengers convey information inside the cel

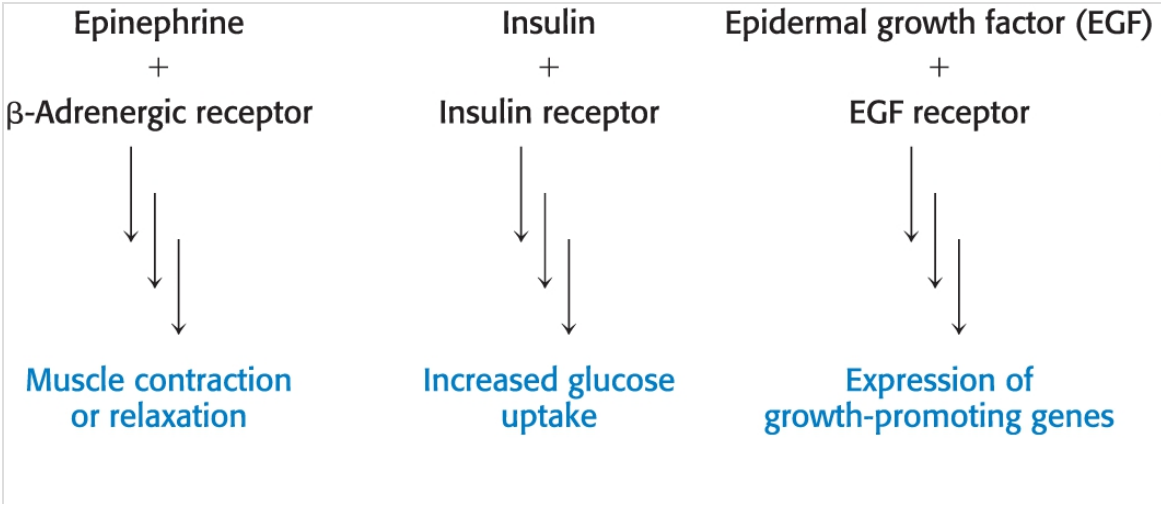
The use of second messengers has several consequences. First, the signal may be amplified significantly: Only a small number of receptor molecules may be activated by the direct binding of signal molecules, but each activated receptor molecule can lead to the generation of many second messengers. Thus, a low concentration of signal in the environment, even as little as a single molecule, can yield a large intracellular signal and response. Second, these messengers are often free to diffuse so that they can influence processes throughout the cell. Third, the use of common second messengers in multiple signaling pathways creates both opportunities and potential challenges. Input from several signaling pathways, often called cross talk, may alter the concentration of a common second messenger. Cross talk permits

more finely tuned regulation of cell activity than would the action of individual independent pathways. However, inappropriate cross talk has the potential for misinterpretation of changes in second-messenger concentration.

4. *Activation of other molecules that directly alter the physiological response*. The ultimate effect of the signal pathway is to activate (or inhibit) the enzymes, ion channels, pumps, and transcription factors that directly control metabolic pathways, the permeability of membranes to specific ions, and gene expression.

5. *Termination of the signal.* After a cell has completed its response to a signal, the signaling process must be terminated or the cell would lose its responsiveness to incoming signals. Moreover, signaling processes that fail to terminate properly can have highly undesirable consequences. Many cancers are associated with signal-transduction processes that are overly active, especially processes that control cell growth.

We will examine components of the three signal-transduction pathways shown in **Figure 14.3**. In doing so, we will encounter many classes of proteins and other molecules that are present in many other signal-transduction pathways as well as some common strategies. It is important to keep in mind that each specific example reveals components present in many other pathways.



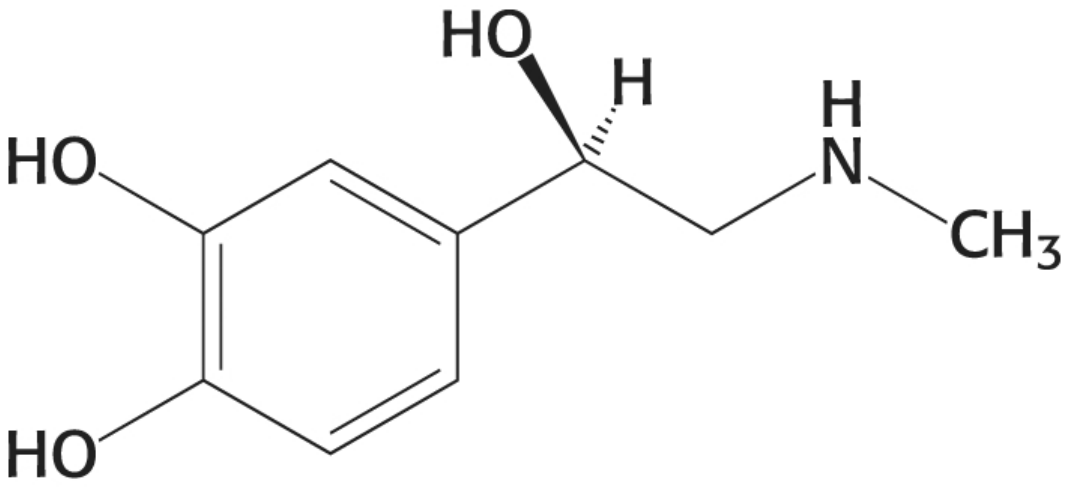


FIGURE 14.3 Three pathways illustrate many of the principles of signal transduction. The binding of signaling molecules to their receptors initiates pathways that lead to important physiological responses.

14.2 Epinephrine Signaling: Heterotrimeric G Proteins Transmit Signals and Reset Themselves

Your fear at hearing a potentially menacing sound triggers the release of a chemical signal that begins a coordinated response. The hormone **epinephrine** is one such signal, secreted by the adrenal glands of mammals in response to internal and external stressors. The molecule is often called **adrenaline**.

Epinephrine (Adrenaline)

Epinephrine exerts a wide range of effects — collectively referred to as the fight-or-flight response — that help organisms anticipate the need for rapid muscular activity, including acceleration of heart rate, dilation of the smooth muscle of the airways and constriction of blood vessels in

the skin and skeletal muscles, and initiation of the breakdown of glycogen (Chapter 21) and fatty acids (Chapter 22).

Epinephrine signaling begins with ligand binding to cell-surface proteins called **adrenergic receptors**. Nine adrenergic receptors are encoded within the human genome, and they fall into two classes: α-adrenergic receptors and β-adrenergic receptors. These initiate analogous and, in many ways, complementary signaling pathways, as we shall see shortly. These receptors are members of the largest class of cell-surface receptors, called the **seven-transmembrane-helix (7TM) receptors**. Members of this family are responsible for transmitting information initiated by signals as diverse as hormones, neurotransmitters, odorants, and even light. Tens of thousands of such receptors are now known, including nearly 1000 encoded in the human genome. Furthermore, about one-third of the marketed therapeutic drugs target receptors of this class. As the name indicates, these receptors contain seven helices that span the membrane bilayer, as originally deduced from the patterns of hydrophobic residues in the amino acid sequences of these receptors (**Figure 14.4**).

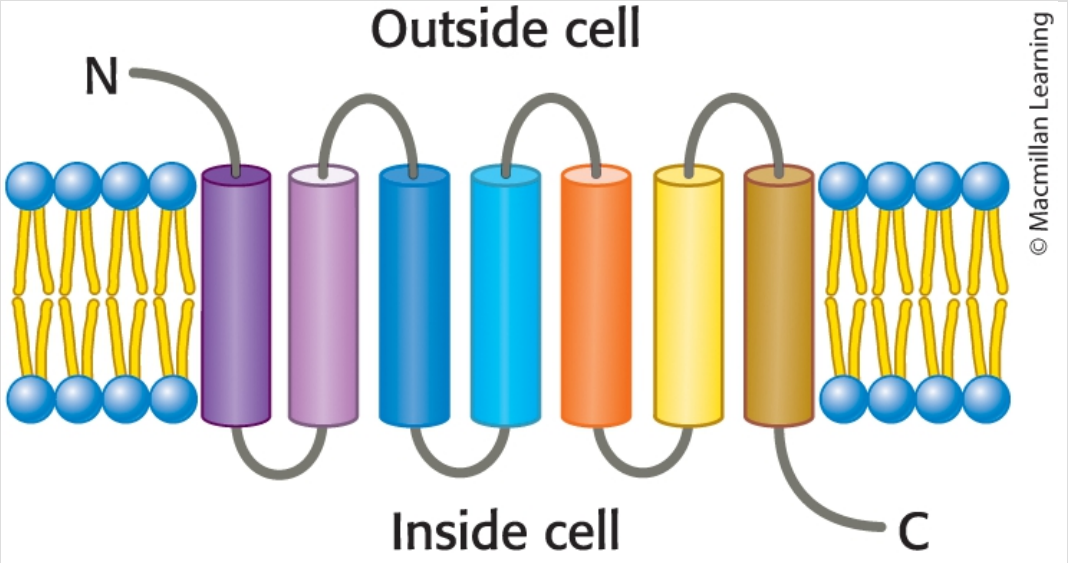

FIGURE 14.4 A large and important family of receptors share a common structure with seven transmembrane (7TM) helices. This schematic representation of a 7TM helix receptor shows its passage through the membrane seven times.

We begin our more-detailed discussion of 7TM receptors with the β-adrenergic receptors that are typically present in tissues such as the heart and the airways. The three-dimensional structure of human β-adrenergic receptors (β-AR) have been determined in a variety of forms by x-ray crystallography. As anticipated, the receptor structure consists of a bundle of seven membrane-spanning alpha helices, with helices adjacent in the sequence next to one another, circling in a counterclockwise direction when viewed from the extracellular side (Figure 14.5).

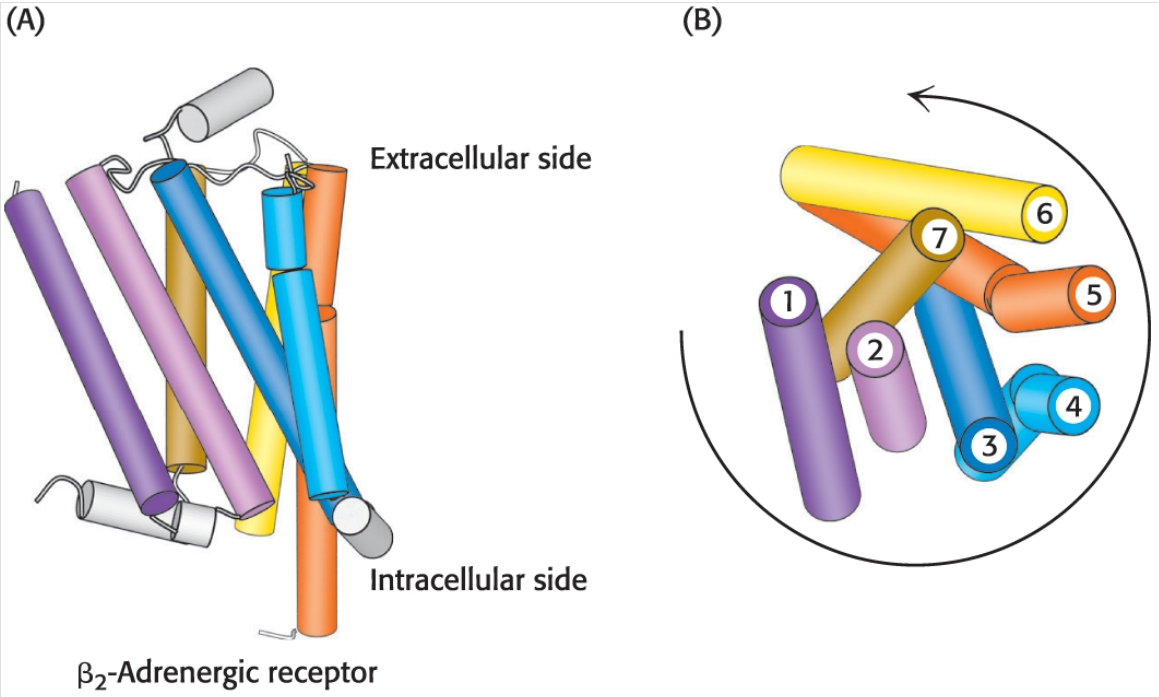

FIGURE 14.5 The three-dimensional structure of the β-adrenergic receptor reveals the arrangement of helices in 7TM receptors. (A) A side view shows the 7TM helices spanning the membrane. (B) A top view from the extracellular side shows the 7TM helices arranged in a counterclockwise manner.

The binding site for ligands such as epinephrine that activate the receptor as well as other compounds that block this site and prevent activation is present toward the center of the bundle of helices, about 20% of the way into the receptor from the extracellular side. Ligands that activate receptors are referred to as **agonists**. The presence of a bound agonist stabilizes a modified conformation of the receptor (**Figure 14.6**). Most notably, helix 5 extends deeper into the cell, and helix 6 moves outward from the center of the receptor. This change in conformational preference is crucial since it represents the transmission of information from a ligand increasing in concentration outside the cell to structural changes inside the cell.

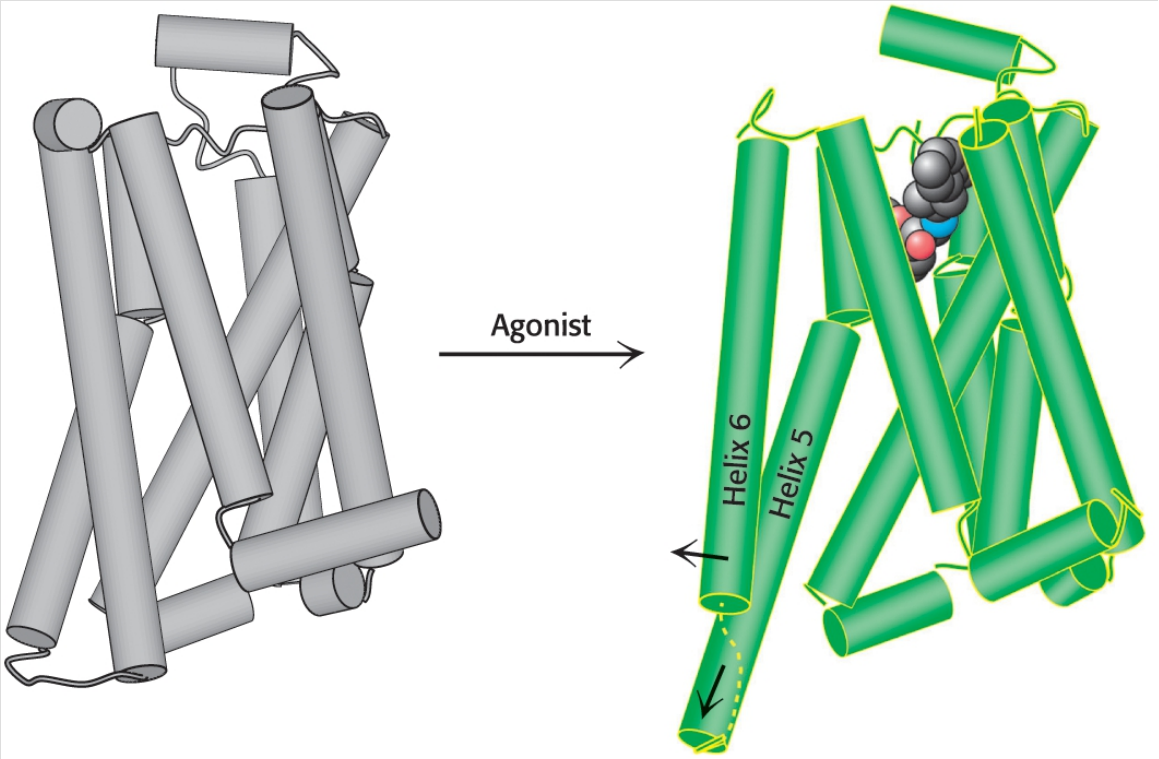

FIGURE 14.6 The binding of an agonist to the β-adrenergic receptor results in stabilization of an activated conformation of the receptor. The largest changes involve the movement of helix away from the center of the receptor and the extension of helix 5 deeper into the cell.

Ligand binding to 7TM receptors leads to the activation of heterotrimeric G proteins

What are the next steps in signaling after the binding of epinephrine? Biochemical studies had revealed that this signaling process required a specific nucleotide, GTP. The conformational change on the cytoplasmic side of the receptor activates a protein called a **G protein**, named for its requirement for guanyl nucleotides. We will examine this process in three types of muscle cells: cardiac muscle cells, cells of the constrictor muscle that controls dilation of the pupil of the eye, and smooth muscle cells in the small blood vessels.

Let us begin with cardiac muscles, which express β-adrenergic receptors. Here, the associated G protein, when activated, stimulates the activity of adenylate cyclase, an enzyme that catalyzes the conversion of ATP into cAMP. The G protein and adenylate cyclase remain attached to the membrane, whereas cAMP, a second messenger, can travel throughout the cell carrying the signal originally brought by the binding of epinephrine. **Figure 14.7** provides a broad overview of these steps.

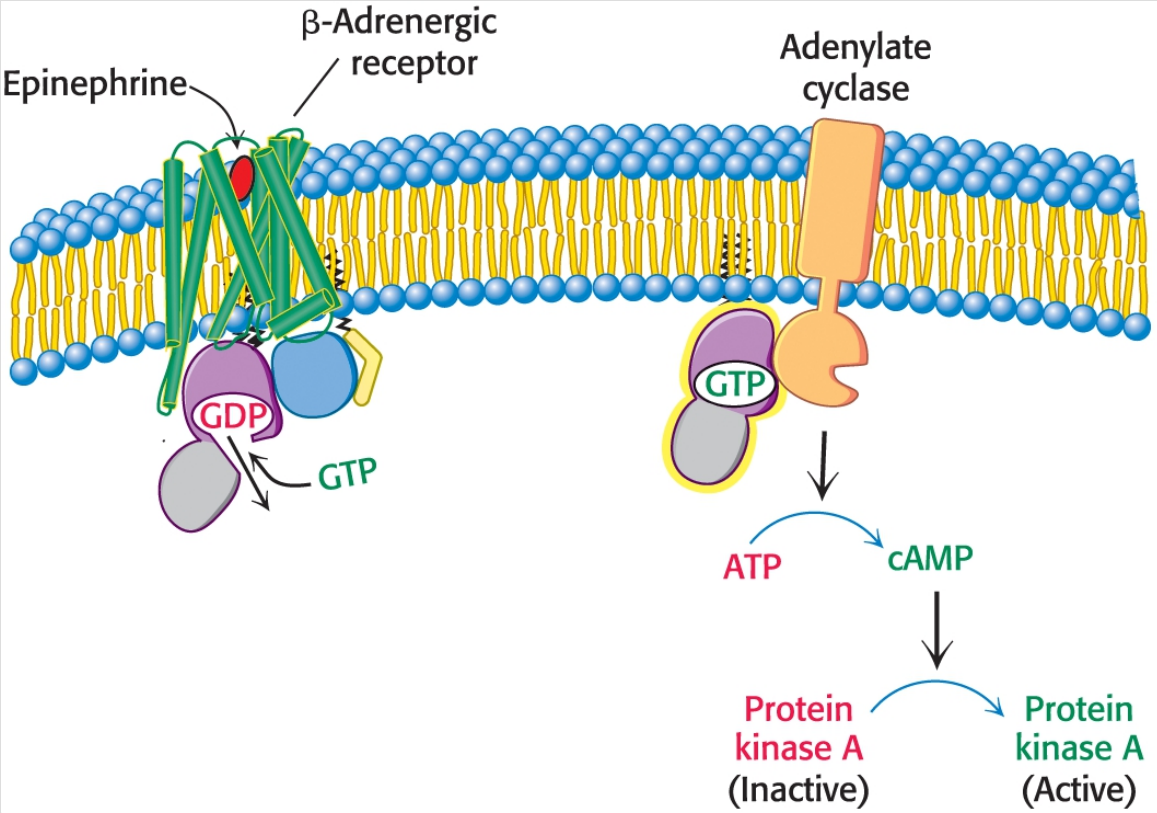

FIGURE 14.7 The signal-transduction pathway initiated by epinephrine in cardiac muscle cell results in an increase in cAMP concentration, increasing contraction. Epinephrine binding to the 7TM receptor initiates a signal-transduction pathway that acts through a G protein and cAM to activate protein kinase A. Phosphorylation of certain muscle proteins promotes muscle contraction.

- *The role of the hormone-bound receptor is to catalyze the exchange of GTP for bound GDP.* Let us consider the role of the G protein in this signaling pathway in more detail. In its inactive state, the G protein is bound to GDP. In this form, the G protein exists as a heterotrimer consisting of α, β, and γ subunits; the α subunit (referred to as G_α) binds the nucleotide at the interface between two domains (Figure 14.8). The α and γ subunits are usually anchored to the membrane by covalently attached fatty acids.

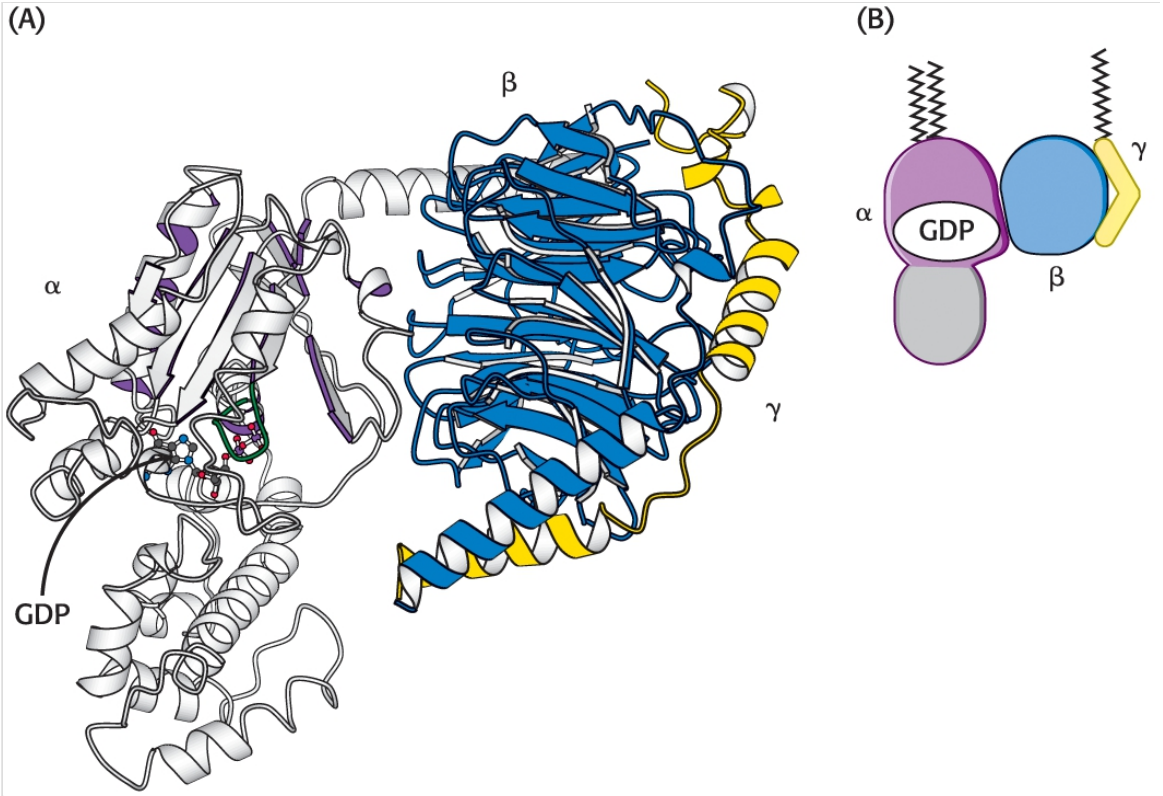

FIGURE 14.8 An inactive G protein exists as a heterotrimer consisting of α, β, and γ subunits. (A) A ribbon diagram shows the relation between the three subunits. In this complex, GDP is bound to the α subunit (gray and purple) in a pocket close to the surface through which the α subunit interacts with the βγ dimer. (B) A schematic representation of the heterotrimeric G protein is shown.

[Drawn from 1GOT.pdb.]

INTERACT with this model in Achieve

- *Analysis of the hormone-G-protein complex structure reveals its mechanism.* The structure of the complex between the hormone–β_2_AR complex and the heterotrimeric G protein shows that the G_α subunit interacts with the surface of the receptor, primarily with the two helices (helix 5 and helix 6) that changes most dramatically upon agonist binding (Figure 14.9). When bound to the receptor, the two domains of the G protein are relatively free to move with

respect to one another, allowing G_α to open substantially, enabling the replacement of GDP with GTP from solution.

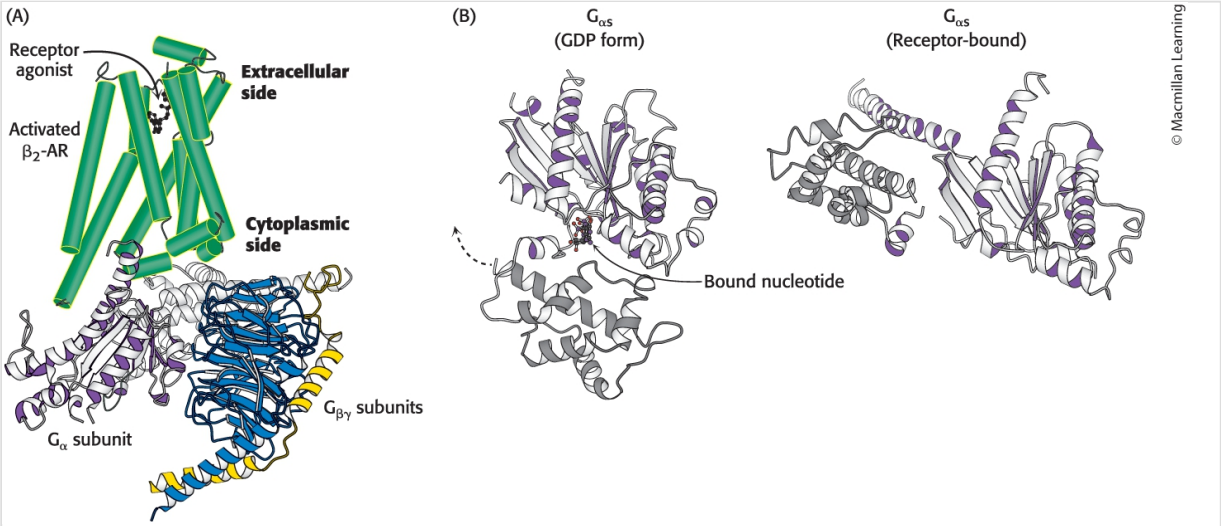

FIGURE 14.9 The activated β_2-AR activates a heterotrimeric G protein by allowing the α subunit to open and release GDP and bind GTP. (A) When the β_2-AR (green) binds a receptor agonist, the cytoplasmic face of the receptor forms an interaction surface with the G_α subunit of a heterotrimeric G protein. (B) The interaction with the activated receptor leads to a substantial conformational change in the G_α protein, in which the guanine nucleotide binding site is opened, enabling nucleotide exchange.

[Drawn from 3SN6.pdb and 1AZT.pdb.]

- *A single hormone–receptor complex can stimulate nucleotide exchange in many G-protein heterotrimers.* On GTP binding, the α subunit dissociates from the βγ dimer $(G_{\beta\gamma})$ and from the receptor. The freed receptor is available to bind other G-protein heterotrimers and to catalyze the exchange of GTP for GDP. Thus, hundreds of G_α molecules can be converted from their GDP form into their GTP form for each bound molecule of hormone, amplifying the

response. Because they signal through G proteins, 7TM receptors are often called G-protein-coupled receptors (GPCRs).

Activated G proteins transmit signals by binding to other proteins

In the GTP form, the surface of G_{α} that had been bound to $G_{\beta\gamma}$ has changed its conformation from the GDP form so that it no longer has a high affinity for $G_{\beta\gamma}$. This surface is now exposed for binding to other proteins. In the β-AR pathway, the new binding partner is adenylate cyclase, the enzyme that converts ATP into cAMP. This enzyme includes 12 membrane-spanning helices with two cytoplasmic domains that come together to form the catalytic part of the enzyme (Figure 14.10).

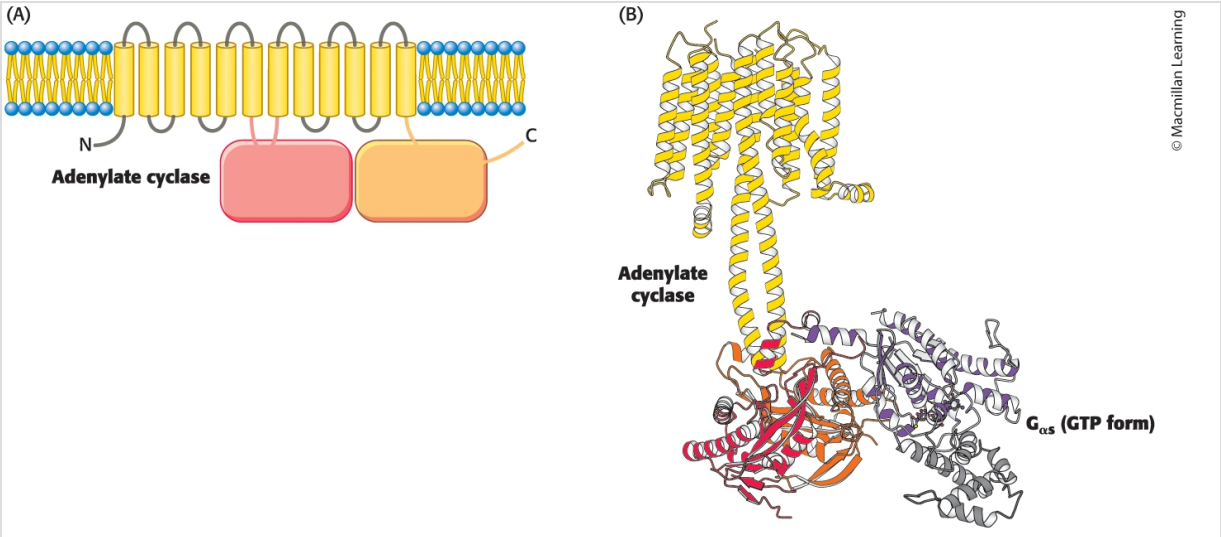

FIGURE 14.10 Adenylate cyclase is activated by binding of $G_{\alpha s}$ (GTP). (A) Adenylate cyclase is a membrane protein with two intracellular domains that come together to form the catalytic apparatus. (B) The structure of a complex between G_{α} in its GTP form bound to a adenylate cyclase is shown. The surface of $G_{\alpha s}$ that had been bound to the βγ dimer now binds adenylate cyclase.

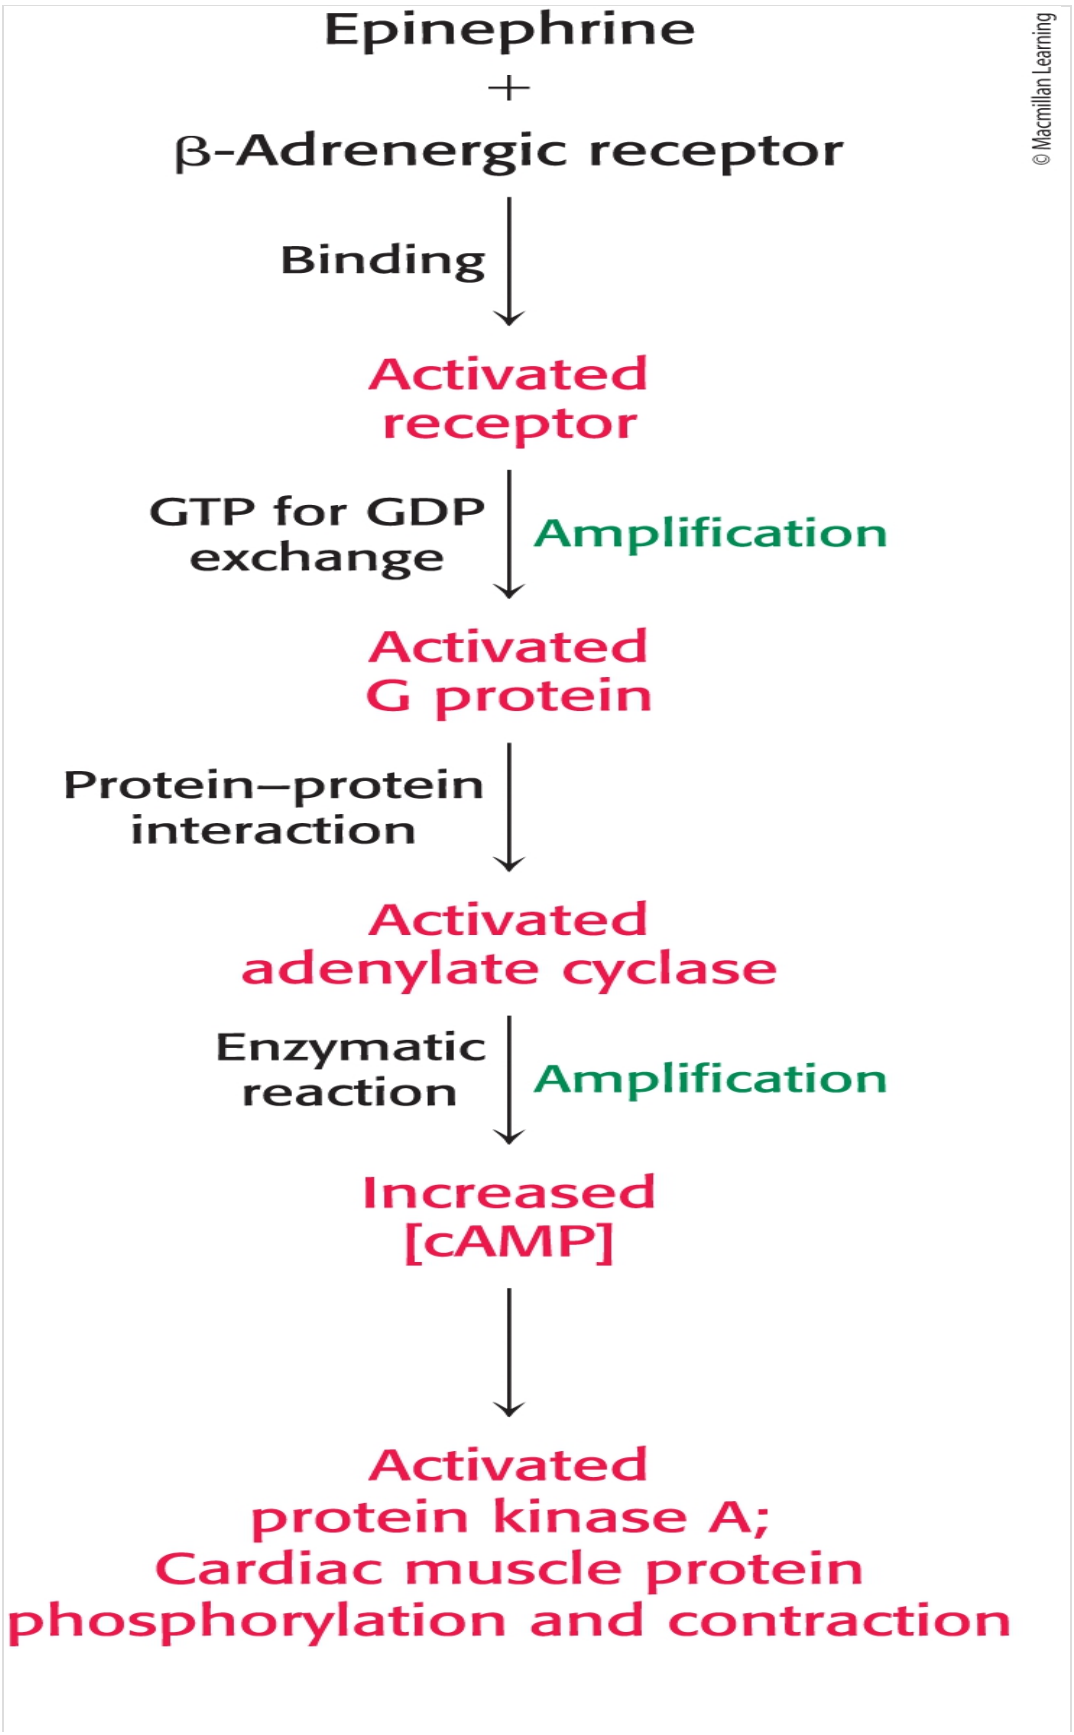
[Drawn from 1AZS.pdb.]

INTERACT with this model in Achieve



The interaction of G_α with adenylate cyclase favors a more catalytically active conformation of the enzyme, thus stimulating cAMP production. Indeed, the G_α subunit that participates in the β-AR pathway is called $G_{\alpha s}$, where "s" stands for *stimulatory*. The generation of cAMP by adenylate cyclase provides a second level of amplification because each activated adenylate cyclase molecule can convert ATP into cAMP at a rate of approximately $100\ s^{-1}$. The net result is that the binding of epinephrine to the receptor on the cardiac muscle cell surface increases the level of cAMP inside the cell rapidly.

Cyclic AMP stimulates the phosphorylation of many target proteins by activating protein kinase A

In all eukaryotic cells, most effects of cAMP are mediated by the activation of a single protein kinase, protein kinase A (PKA). As described in Chapter 7, PKA consists of two regulatory (R) chains and two catalytic (C) chains (R_2C_2). In the absence of cAMP, the R_2C_2 complex is catalytically inactive. The binding of cAMP to the regulatory chains decreases their affinity for the catalytic chains, which are catalytically active when freed. Activated PKA then phosphorylates specific serine and threonine residues in many targets to alter their activity.

In cardiac muscle cells, increases in cAMP levels leads to increased contraction. In these cells, one of these PKA substrates is troponin I.

This protein is part of the troponin complex found in cardiac and skeletal muscle but not smooth muscle. The troponin complex blocks the ability of myosin to bind to actin, preventing muscle contraction (see Chapter 6). Upon phosphorylation of troponin I, the binding of troponin to actin is weakened and myosin is more likely to bind to actin, driving muscle contraction. PKA also phosphorylates certain calcium-specific ion channels and activates them. The increased level of calcium ions binds to another troponin subunit and stimulates muscle contraction. The signal-transduction pathway initiation by epinephrine with the β-adrenergic receptor is summarized in **Figure 14.11**.

FIGURE 14.11 Epinephrine binding promotes cardiac muscle contraction. The binding of epinephrine to the β-adrenergic receptor initiates the signal-transduction pathway. The process in each step is indicated in black at the left of each arrow. Steps that have the potential for signal amplification are indicated at the right in green. The final step is phosphorylation of key cardiac muscle proteins, promoting muscle contraction.

G proteins spontaneously reset themselves through GTP hydrolysis

How is the signal initiated by epinephrine switched off? G_α subunits have intrinsic GTPase activity, that is, by themselves they can promote the hydrolysis of bound GTP to GDP and P_i. This hydrolysis reaction is slow, however, requiring from seconds to minutes. Thus, the GTP form of G_α is able to activate downstream components of the signal-transduction pathway before it is deactivated by GTP hydrolysis. In essence, the bound GTP acts as a built-in clock that spontaneously resets the G_α subunit after a short time. After GTP hydrolysis and the release of P_i, the GDP-bound form of G_α then reassociates with $G_{\beta\gamma}$ to re-form the inactive heterotrimeric protein (Figure 14.12). The GTP hydrolysis step also provides an additional opportunity for regulation; Some G-protein signaling pathways include additional components called GTPase-activating proteins that increase the rate of GTP hydrolysis by G-protein α subunits.

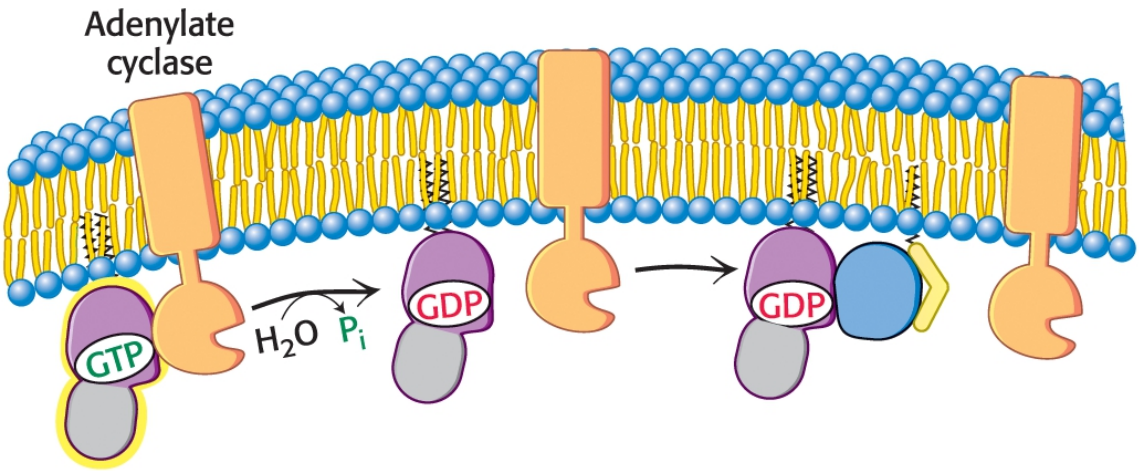

FIGURE 14.12 G proteins reset themselves by GTP hydrolysis. On hydrolysis of the bound GTP promoted by the GTPase activity of G_α, G_α dissociates from adenylate cyclase, reversing its stimulation. G_α in its GDP form then reassociates with the βγ dimer to reform the heterotrimer G protein.

The hormone-bound activated receptor must be reset as well to prevent the continuous activation of G proteins. This resetting is accomplished by two processes (Figure 14.13). First, the hormone can dissociate, returning the receptor to its initial inactive state. The likelihood that the receptor remains in its unbound state depends on the extracellular concentration of hormone. Second, members of a specialized family of enzymes, the G-protein receptor kinases, are bound by activated receptors and phosphorylates serine and threonine residues in their carboxyl-terminal tails. Finally, proteins called β-arrestins bind to the phosphorylated receptors and block their ability to activate G proteins.

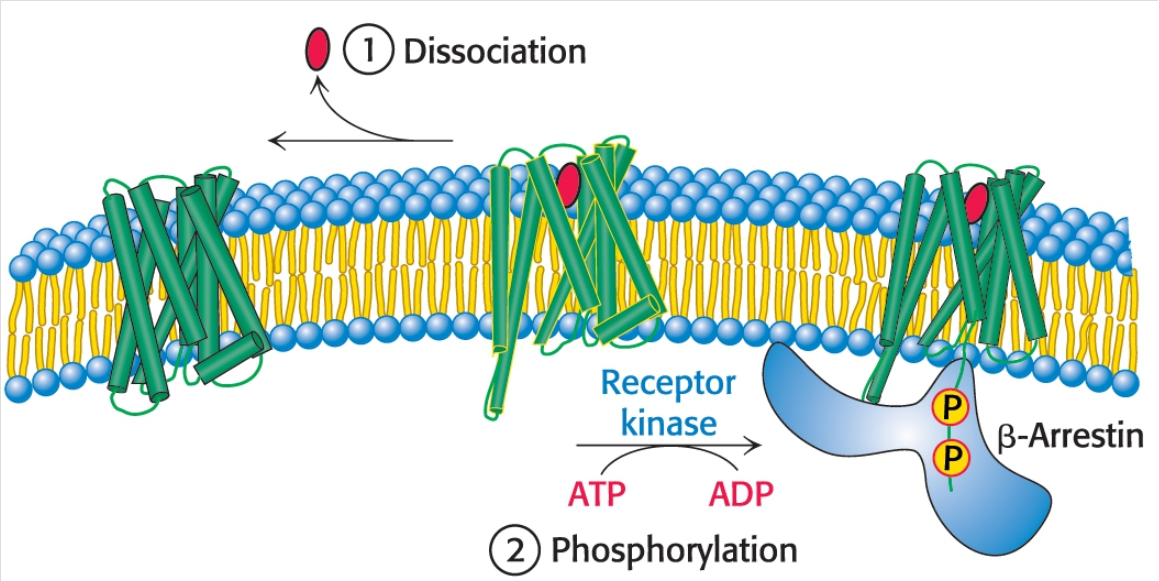

FIGURE 14.13 β-Adrenergic receptor signaling is terminated by two processes. Signal transduction by the 7TM receptor is halted (1) by dissociation of the signal molecule from the receptor and (2) by phosphorylation of the cytoplasmic C-terminal tail of the receptor and the subsequent binding of β-arrestin.

Some 7TM receptors activate the phosphoinositide cascade

We now turn to the muscle cells that control dilation of the pupils of our eyes and those that line small blood vessels in our skin. These cells express α1-adrenergic receptors rather than β-adrenergic receptors. α-Adrenergic receptors are homologous to β-adrenergic receptors, also bind epinephrine, and have very similar three-dimensional structures. They differ, however, in the G proteins to which they are coupled in their signal-transduction pathway by virtue of differences in parts of the intracellular face of the receptors. α1-Adrenergic receptors activate a G protein called $G_{\alpha q}$. In its GTP form, $G_{\alpha q}$ binds to and activates a form of the enzyme phospholipase C.

Phospholipase C catalyzes the cleavage of a phospholipid present in cell membranes, phosphatidylinositol 4,5-bisphosphate (PIP_2), into the two second messengers — inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG; **Figure 14.14**). IP_3 is soluble and diffuses away from the membrane. This second messenger causes the rapid release of Ca^{2+} from the intracellular stores in the endoplasmic reticulum (ER), which accumulates a reservoir of Ca^{2+} through the action of transporters such as the Ca^{2+} ATPase (Section 13.2). On binding IP_3, specific IP_3-gated Ca^{2+}–channel proteins in the ER membrane open to allow calcium ions to flow from the ER into the cytoplasm. Calcium ion is itself a signaling molecule: it can bind proteins, including a ubiquitous signaling protein called **calmodulin (CaM)**, and enzymes such as protein kinase C.

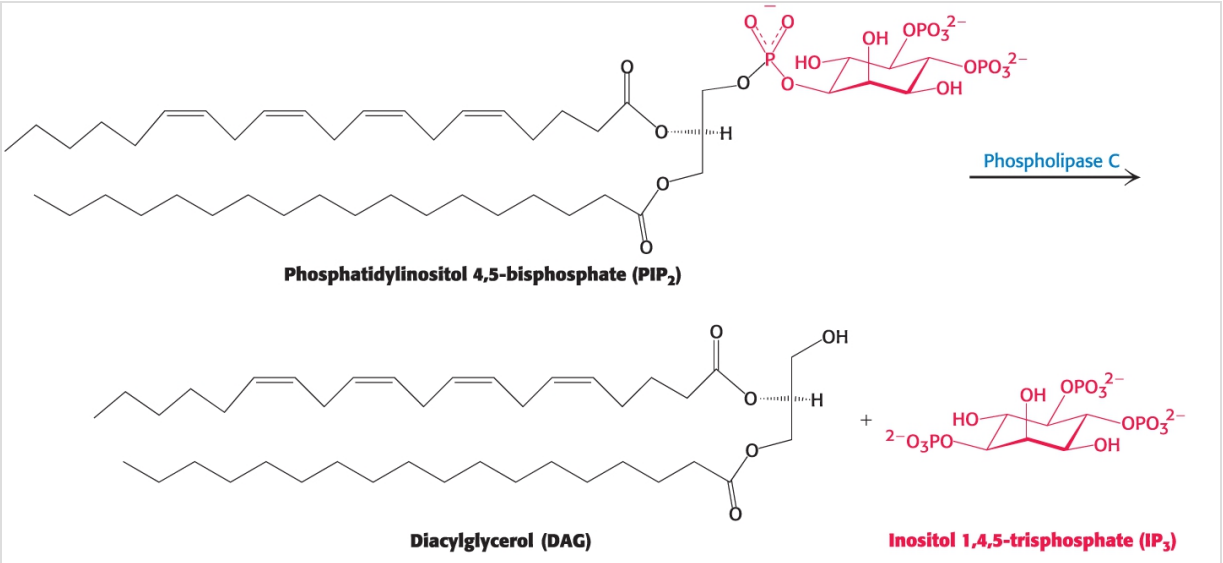

FIGURE 14.14 Phospholipase C cleaves the membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP_2) into two second messengers. The two messengers are diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). DAG remains in the membrane while IP_3 is free to diffuse away.

DAG remains in the plasma membrane where it binds and activates protein kinase C (PKC), a protein kinase that phosphorylates serine and threonine residues in many target proteins. Specialized domains of this kinase bind DAG and require bound calcium to do so. Thus, DAG and IP_3 work in tandem: IP_3 increases the Ca^{2+} concentration, and Ca^{2+} facilitates the DAG-mediated activation of protein kinase C. Like PKA (Chapter 7), activation involves removal of a pseudo-substrate in a regulatory domain from the active site. The overall signal-transduction pathway, referred to as the phosphoinositide cascade, is summarized in **Figure 14.15**. Both IP_3 and DAG act transiently because they are converted into other species by phosphorylation or other processes.

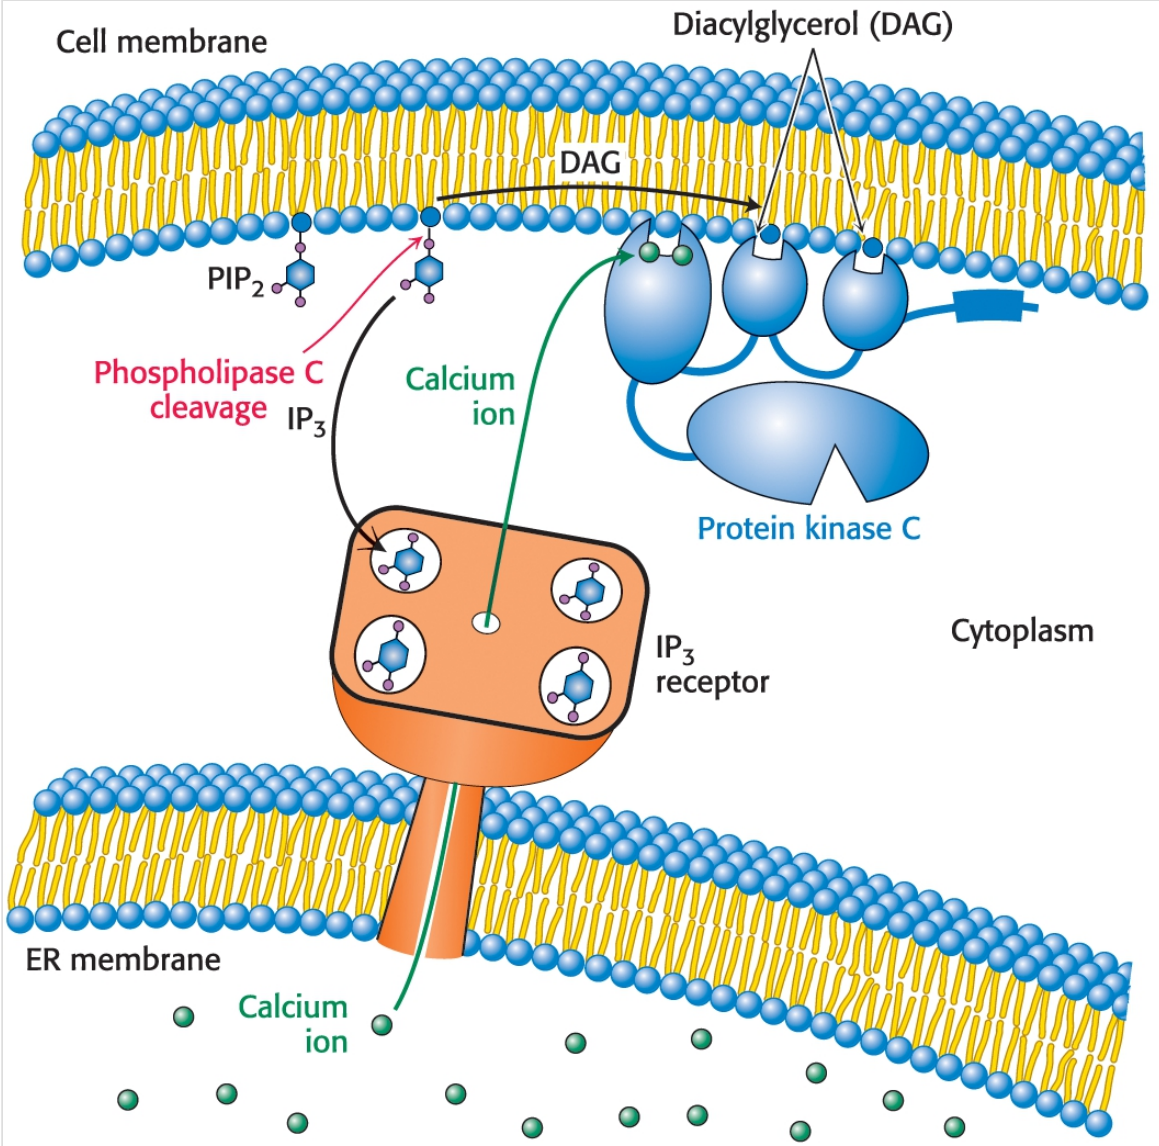

FIGURE 14.15 The phosphoinositide cascade results in protein kinase C activation.
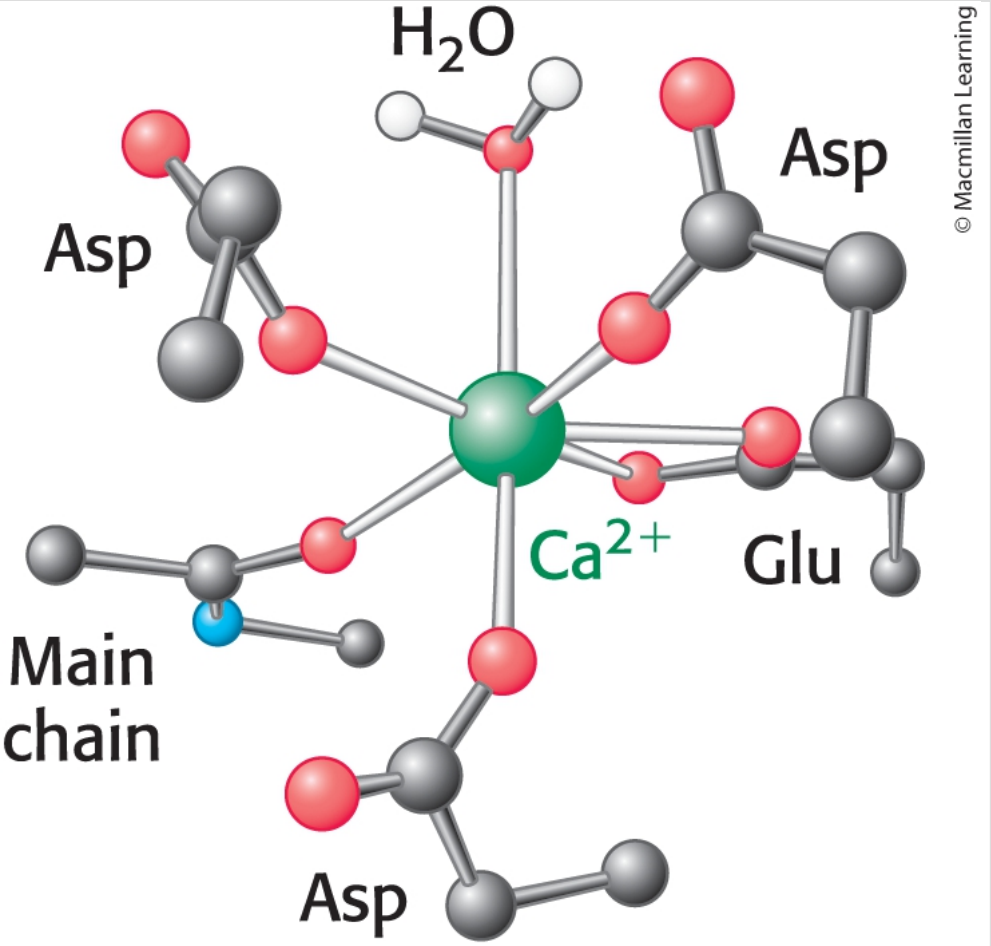
Phospholipase C cleaves PIP_2 into IP_3 and DAG. IP_3 release results in the influx of calcium ions (owing to the opening of the IP_3 receptor ion channels), and DAG accumulation results in the activation of protein kinase C when protein kinase C binds to DAG in the membrane. Calciur ions bind to domains in protein kinase C and help facilitate its binding to DAG.

Calcium ion is a widely used second messenger

Calcium ion participates in many signaling processes in addition to the phosphoinositide cascade. Two properties of this ion account for its widespread use as an intracellular messenger:

- *Fleeting changes in Ca^{2+} concentration are readily detected.* At steady state, intracellular levels of Ca^{2+} must be kept low to prevent the precipitation of carboxylated and phosphorylated compounds, which form poorly soluble salts with Ca^{2+}. Transport systems extrude Ca^{2+} from the cytoplasm, maintaining the cytoplasmic concentration of Ca^{2+} at approximately 100 nM — several orders of magnitude lower than that of the extracellular medium. Given this low steady-state level, transient increases in Ca^{2+} concentration produced by signaling events can be readily sensed.
- *Ca^{2+} can bind tightly to proteins and induce substantial structural rearrangements.* A second property of Ca^{2+} that makes it a highly suitable intracellular messenger is its ability to interact with protein through many points of contact. Calcium ions bind well to negatively charged oxygen atoms (from the side chains of glutamate and aspartate) and uncharged oxygen atoms (main-chain carbonyl groups and side-chain oxygen atoms from glutamine and asparagine; **Figure 14.16**). The capacity of Ca^{2+} to be coordinated to multiple ligands — from six to eight oxygen atoms — enables it to cross-link different segments of a protein and induce significant conformational changes.



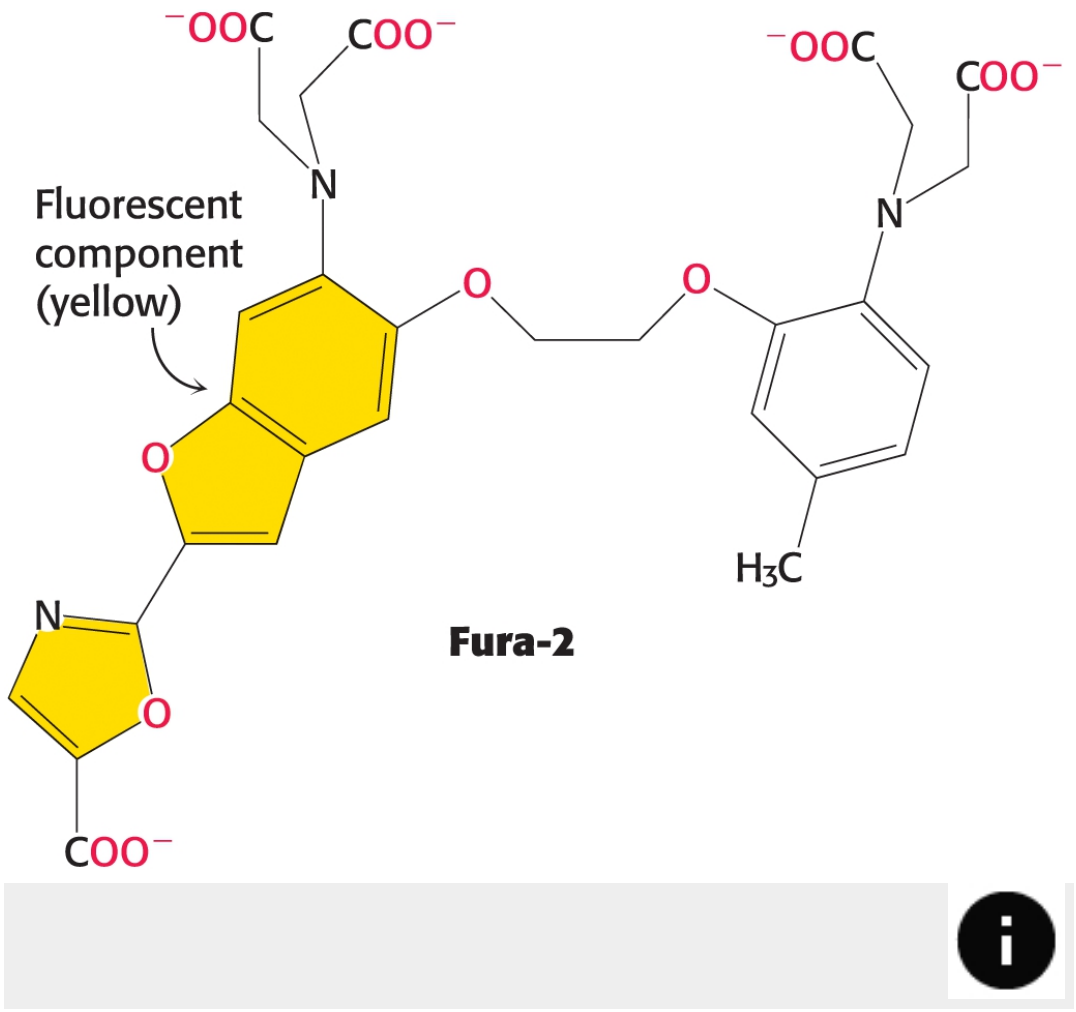


FIGURE 14.16 Calcium-binding sites typically include seven oxygen atoms. In one common mode of binding, calcium is coordinated to six oxygen atoms from a protein and one from water. The multiple protein-based ligands allow calcium ions to stabilize particular protein structures.

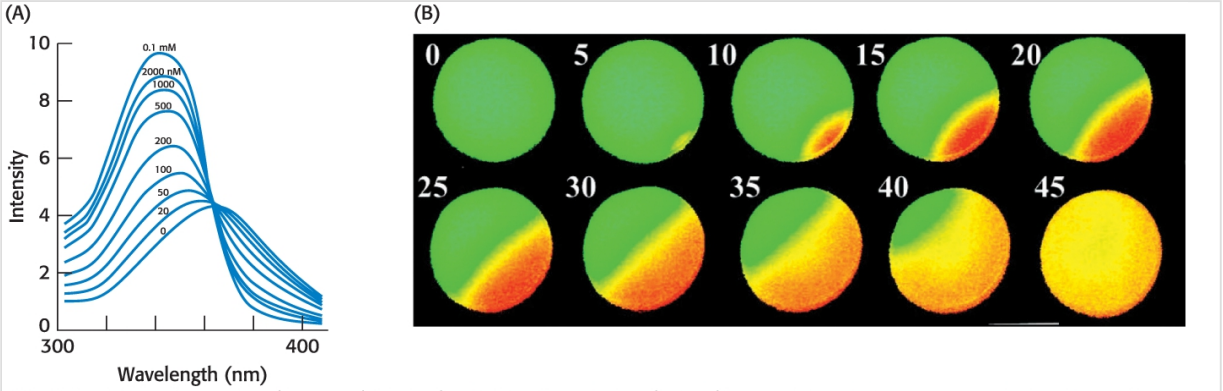
Our understanding of the role of Ca^{2+} in cellular processes has been greatly enhanced by our ability to detect changes in Ca^{2+} concentrations inside cells and even monitor these changes in real time. In Section 4.2, we discussed how intact proteins can be detected in live cells using fluorescence microscopy. A similar approach can be used for



the visualization of changes in Ca^{2+} concentrations. This ability depends on the use of specially designed dyes such as Fura-2 that bind Ca^{2+} and change their fluorescent properties on Ca^{2+} binding. Fura-2 binds Ca^{2+} through appropriately positioned oxygen atoms (shown in red) within its structure:

Fura-2

When such a dye is introduced into cells, changes in available Ca^{2+} concentration can be monitored with microscopes capable of detecting changes in fluorescence (Figure 14.17). Following pioneering work on calcium sensors, probes for sensing other second messengers such as

cAMP also have been developed. These molecular-imaging agents are greatly enhancing our understanding of signal-transduction processes.

FIGURE 14.17 Free calcium ion concentrations inside cells can be imaged using fluorescence microscopy with appropriate dyes. (A) The fluorescence spectra of the calcium-binding dye Fura-2 can be used to measure available calcium ion concentrations in solution and in cells. (B) A series of images show Ca^{2+} spreading across an egg cell following fertilization by sperm, with the numbers indicating time elapsed in seconds. These images were obtained through the use of Fura-2. The images are false colored: orange represents high Ca^{2+} concentrations, and green represents low Ca^{2+} concentrations.

[(A) Information from S. J. Lippard and J. M. Berg, *Principles of Bioinorganic Chemistry* (University Science Books, 1994), p. 193.]

Calcium ion often activates the regulatory protein calmodulin

Calmodulin (CaM), a 17-kDa protein with four Ca^{2+}-binding sites, serves as a calcium sensor in nearly all eukaryotic cells. At cytoplasmic

concentrations above about 500 nM, Ca^{2+} binds to and activates calmodulin. Calmodulin is a member of the EF-hand protein family. The **EF hand** is a Ca^{2+}-binding motif that consists of a helix, a loop, and a second helix. This motif was named the *EF hand* because the two key helices designated *E* and *F* in parvalbumin, the first protein where the motif was observed, are positioned like the forefinger and thumb of the right hand (**Figure 14.18**). The two helices and the intervening loop of the EF hand form the Ca^{2+}-binding motif. Seven oxygen atoms are coordinated to each Ca^{2+}, six from the protein and one from a bound water molecule. Calmodulin is made up of four EF-hand motifs, each of which can bind a single Ca^{2+} ion.

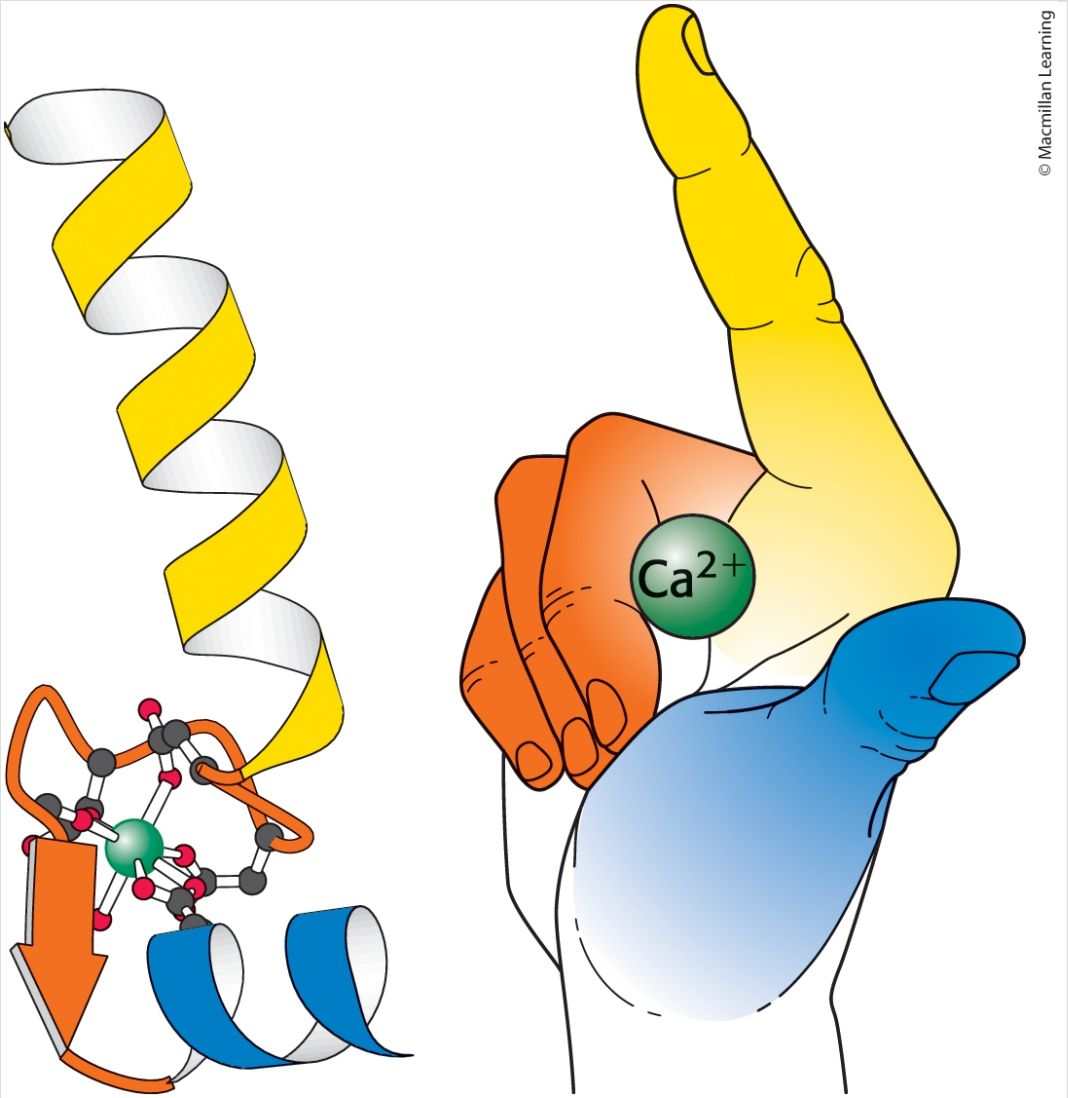

FIGURE 14.18 An EF hand is a binding site for Ca^{2+} in many calcium-sensing proteins. The structure, resembling a hand, is formed by a helix-loop-helix unit with the E helix is yellow, the loop in red, the F helix is blue, and calcium is represented by the green sphere.

[Drawn from 1CLL.pdb.]

The binding of Ca^{2+} to calmodulin induces substantial conformational changes in its EF hands, exposing hydrophobic surfaces that can be

used to bind other proteins. Using its two sets of two EF hands, calmodulin clamps down around specific regions of target proteins — usually exposed α helices with appropriately positioned hydrophobic and charged groups (Figure 14.19). Some protein kinases, for example, are activated when calmodulin binds to a target α helix and removes it from a position when it inhibits kinase function.

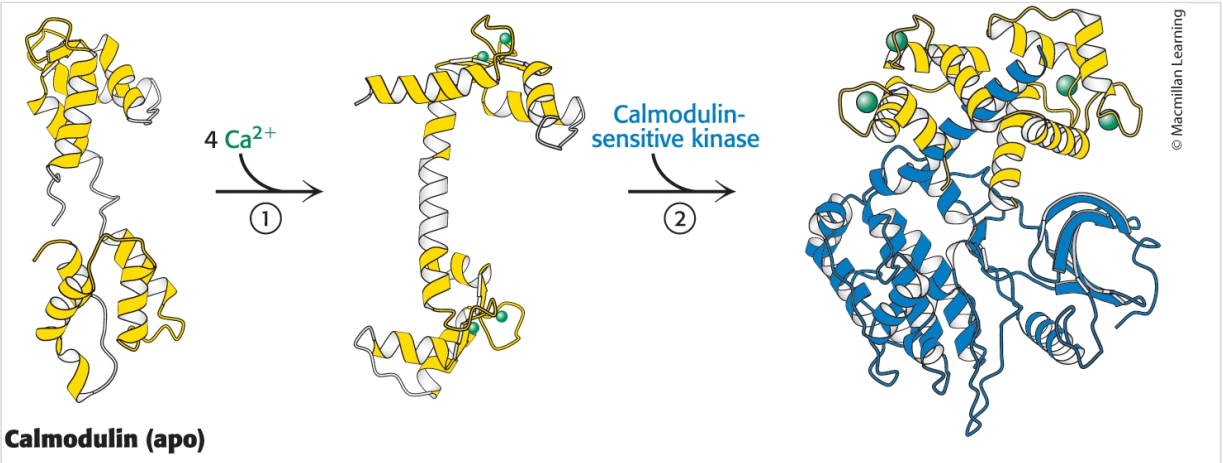

FIGURE 14.19 Calmodulin binds calcium and activates some protein kinases. On Ca^{2+} binding to the apo, or calcium-free, form of calmodulin, the two halves of calmodulin change conformation. Calmodulin can then clamp down around an α helix through surfaces that are exposed. Some kinases have an α helix that inhibits enzyme activity and calmodulin binding can relieve this inhibition.

INTERACT with the models shown in Figure 14.18 and 14.19 in Achieve

How, then, does initiation of the phosphoinositide cascade lead to smooth muscle contraction? Smooth muscle does not contain the troponin complex. However, myosin binding to actin and subsequent contraction is stimulated by phosphorylation of a component of myosin, the regulatory light chain. The increased level of calcium activates calmodulin, which, in turn, binds to and activates myosin light chain kinase. The activated kinase phosphorylates the myosin light chain and

facilitates contraction. This signal-transduction-pathway-induced contraction leads to pupil dilation and pale skin as blood flow is restricted.

Some receptors signal through G proteins that inhibit rather than stimulate adenylate cyclase

Some blood vessel smooth muscle cells express a different class of 7TM receptors termed α_2-adrenergic receptors. These receptors are quite similar to the α_1- and β-adrenergic receptors, but signal through a third class of G protein, $G_{\alpha i}$. Like $G_{\alpha s}$, this G-protein α subunit binds adenylate cyclase, but $G_{\alpha i}$-binding inhibits cyclase activity rather than simulating it. Thus, activation of this signaling pathway results in a decrease in cAMP levels. Such lower cAMP levels influence a protein kinase cascade (**Figure 14.20**). The net result is increased smooth muscle contraction.

FIGURE 14.20 α2-Adrenergic receptors signal through the G protein $G_{\alpha i}$, which inhibits adenylate cyclase. The signal-transduction pathway from epinephrine binding to α2-adrenergic receptors results in smooth muscle contraction. This is achieved through a decrease in cAMP concentration and the associated reduction in protein kinase A activity.

Self-Check Question

Why is increased cardiac muscle contraction favored by increased cAMP levels but increased smooth muscle contraction favored by reduced cAMP levels?

G-protein βγ-dimers can also directly participate in signaling

When a heterotrimeric G protein is activated, it dissociates into a G_{α} subunit and a $G_{\beta\gamma}$ dimer. It was widely believed that the only role of the $G_{\beta\gamma}$ dimer was to sequester G_{α} subunits. However, through studies using purified G-protein subunits led to the discovery that the $G_{\beta\gamma}$ dimer was the active component in activating a key ion channel in the heart (Figure 14.21). Subsequent studies have revealed that these subunits play active roles in a wide range of signaling pathways, revealing an additional level of complexity and control.

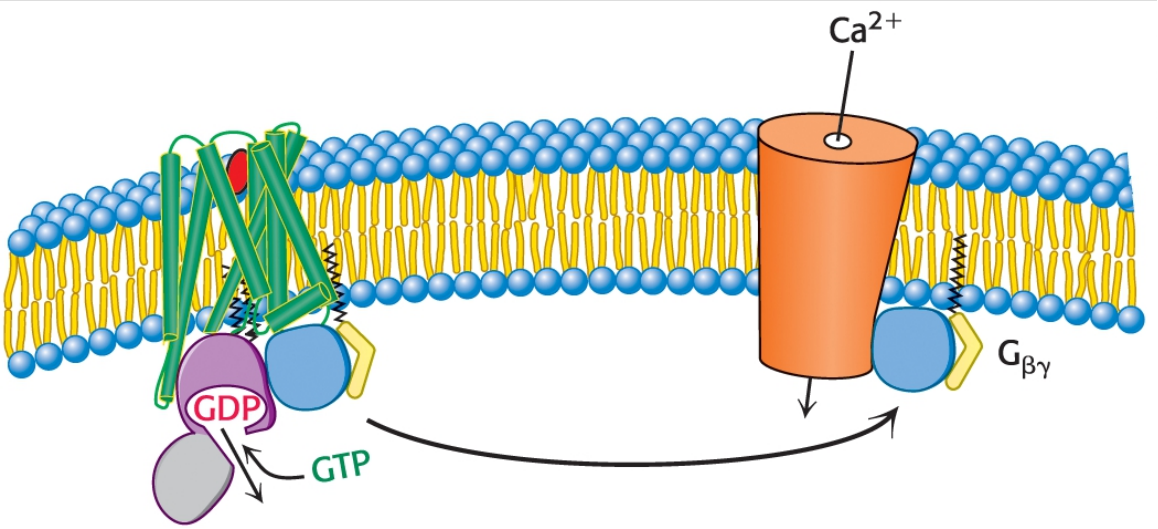

FIGURE 14.21 The G protein βγ dimer actively participates in some signal-transduction pathways. When released from the G protein α subunit, the βγ dimer can bind to other proteins and, for example, open certain ion channels.

Barbara Steiner

EVA NEER Born in Poland in 1938, Eva Neer escaped from the Nazis at the age of one, hiding under her mother's skirt. Her family emigrated first to Brazil, then to the United States. After completing her MD degree, she began research purifying the membrane protein adenylate cyclase; this was an enzyme of much interest, given research by Earl Sutherland, Martin Rodbell, and Alfred Gilman implicating cAMP as a key intracellular messenger. Dr. Neer continued her career as a faculty member, working on many aspects of G-protein signaling and sharing some of her partially

purified G_{as} with David Clapham, a colleague interested in ion-channel activation. Her preparation potently activated the ion channels, but subsequent studies revealed that this was due not to $G_{\alpha s}$ but to contaminating $G_{\beta\gamma}$ that was present. This serendipitous discovery revealed the active role $G_{\beta\gamma}$ plays in some signaling systems and laid the foundation for many future studies. Dr. Neer was known for her great integrity; she trained many graduate students and postdoctoral fellows before she died prematurely of breast cancer at the age of 62.

7TM receptors trigger signaling through G proteins in many other cell types

We noted earlier that the human genome encodes nearly 1000 7TM receptors. Approximately 1/3 of these participate in our sense of smell, and a few others are central to vision. We will explore these specialized receptors at the end of this chapter. The others participate in one or more processes in almost all aspects of physiology.

This array of signaling molecules, receptors, and pathways can be dizzyingly complex. However, once we know that a pathway involves a 7TM receptor and we identify the participating G protein, we can deduce the participating second messengers and key steps in the pathway (**Figure 14.22**).

Responses

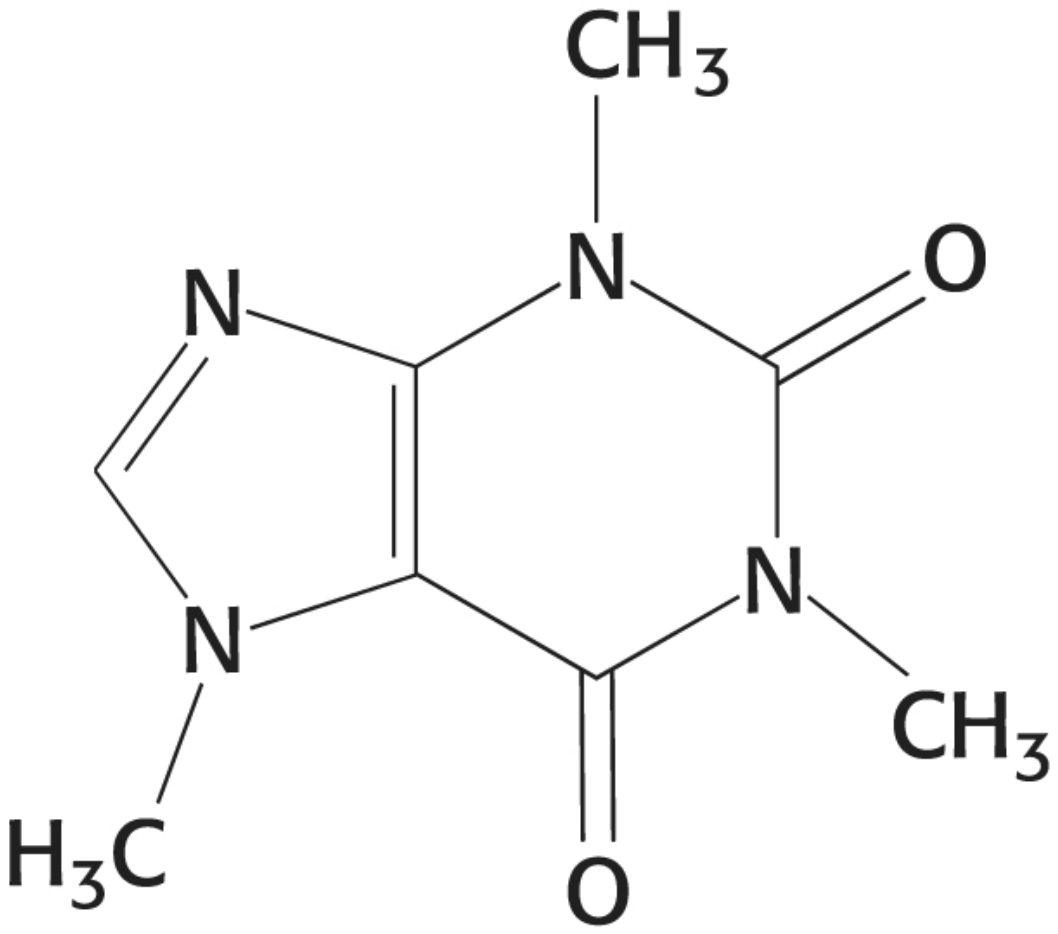

FIGURE 14.22 Common pathways recur in many different signaling processes involving G proteins. A very large number of 7TM receptors and their associated ligands signal through the three classes of G protein α subunits: $G_{\alpha s}$, $G_{\alpha q}$, and $G_{\alpha i}$. The occurrence of these α subunits in the pathways dictate several steps in the pathways. After these steps, a wide variety of responses can occur.

For example, the peptide hormone glucagon, which plays a central role in control of metabolism during fasting, has a receptor that signals through $G_{\alpha s}$. We can deduce that cAMP levels will rise in cells that express the receptor, and this will activate PKA. PKA phosphorylates two enzymes that lead to the breakdown of glycogen, the polymeric store of glucose, and the inhibition of further glycogen synthesis (Section 21.4). Our genome encodes four receptors for the nucleoside adenosine that are expressed throughout the body, including the heart and the brain. One of these, the adenosine A_1 receptor, signals through $G_{\alpha i}$. The A_1 pathway slows the heartbeat as we would anticipate due to a decreased level of cAMP. In the brain, it decreases the release of certain neurotransmitters. Compounds that block receptors without activating them are referred to as **antagonists**. You are likely familiar with the actions of a widely occurring adenosine receptor antagonist, caffeine.

Adenosine

Caffeine

14.3 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes

We now turn to a signaling pathway that comes into play after you return to complete your meal after your quick retreat. The maintenance of blood glucose levels with a relatively narrow range in the face of substantial changes in food intake and activity is a major challenge that we will explore extensively later in the book. For now, we will explore the signal-transduction pathway initiated by **insulin**, the hormone released in response to increased blood-glucose levels after a meal (**Figure 14.23**). In all of its detail, this multifaceted pathway is quite complex. Hence, we will focus solely on the major branch, which leads to the movement of glucose transporters to the surfaces of fat and muscle cells. These transporters allow these cells to take up the glucose that is plentiful in the bloodstream after a meal. We will discuss the mechanisms by which pancreatic β-cells sense glucose levels and release insulin in Chapter 15.

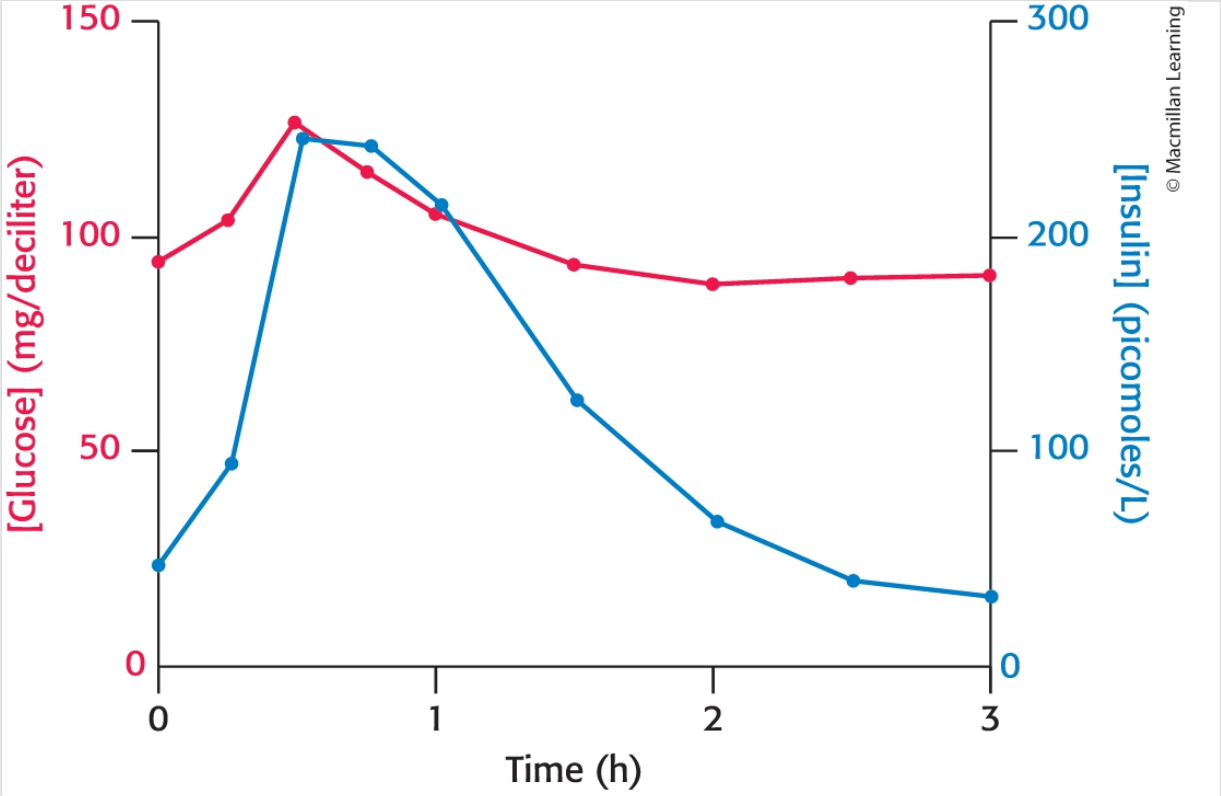

FIGURE 14.23 Glucose and insulin levels increase and then decrease following a meal. Shortly after eating, glucose levels in the bloodstream increase. These increased levels are sensed and insulin is released into the bloodstream from the pancreas. Insulin then stimulates absorption of glucose by muscle and fat cells, decreasing the glucose levels.

The signaling pathways we have examined so far have activated protein kinases as downstream components. The receptor for insulin is a member of a large family of receptors that include protein kinases as a key part of their covalent structures that are inactive under resting conditions. The activation of these protein kinases sets in motion other processes that ultimately modify the effectors of these pathways.

The insulin receptor is a protein kinase that is autoinhibited prior to insulin binding

Insulin is a peptide hormone, consisting of two chains that are linked by three disulfide bonds (Figure 14.24).

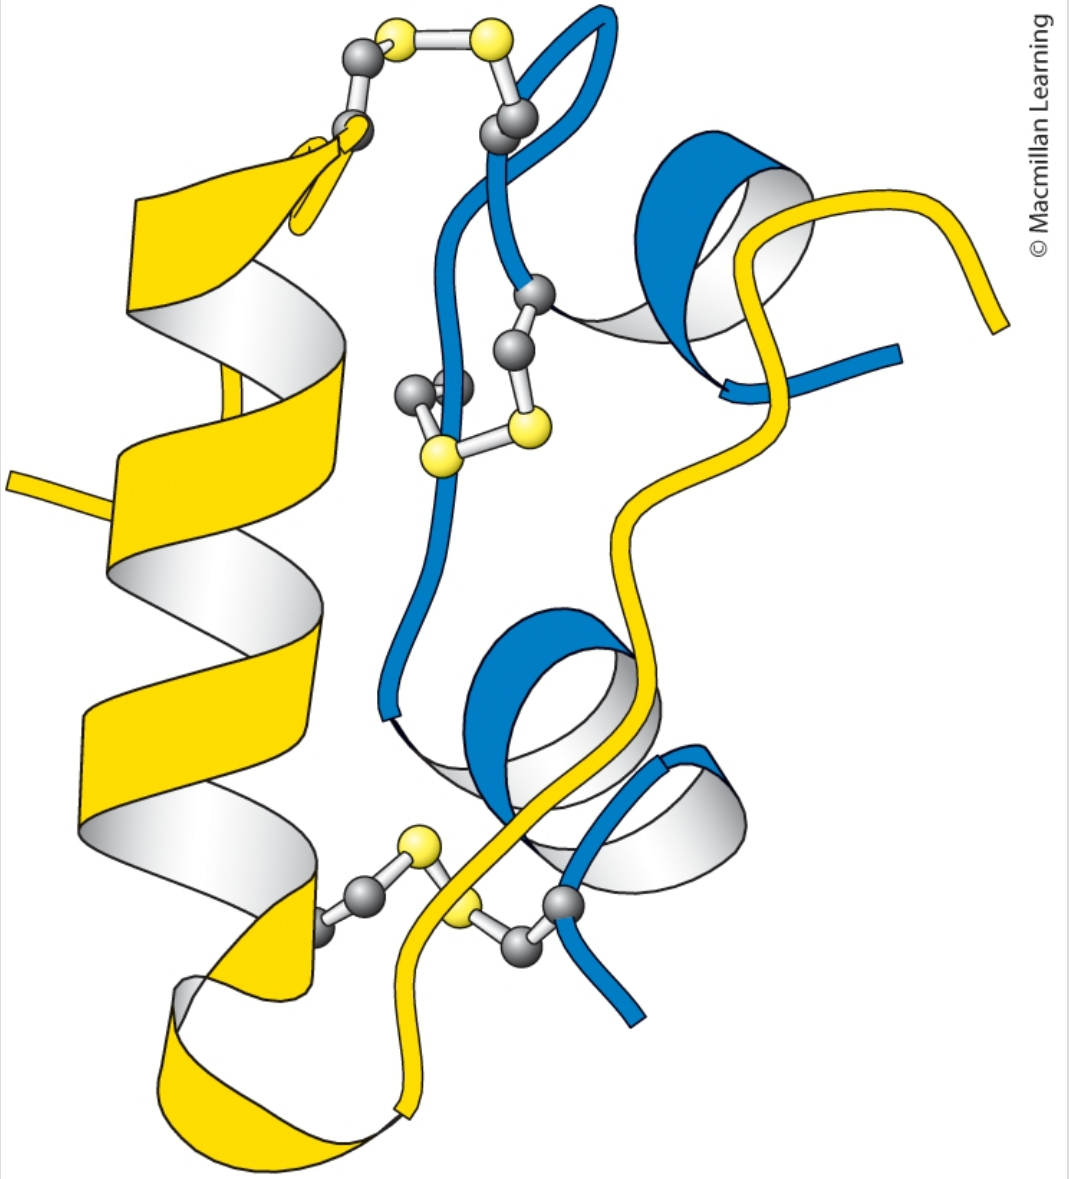

FIGURE 14.24 Insulin comprises two chains linked by two interchain disulfide bonds. The α chain (blue) also has an intrachain disulfide bond. The β chain is shown in yellow.

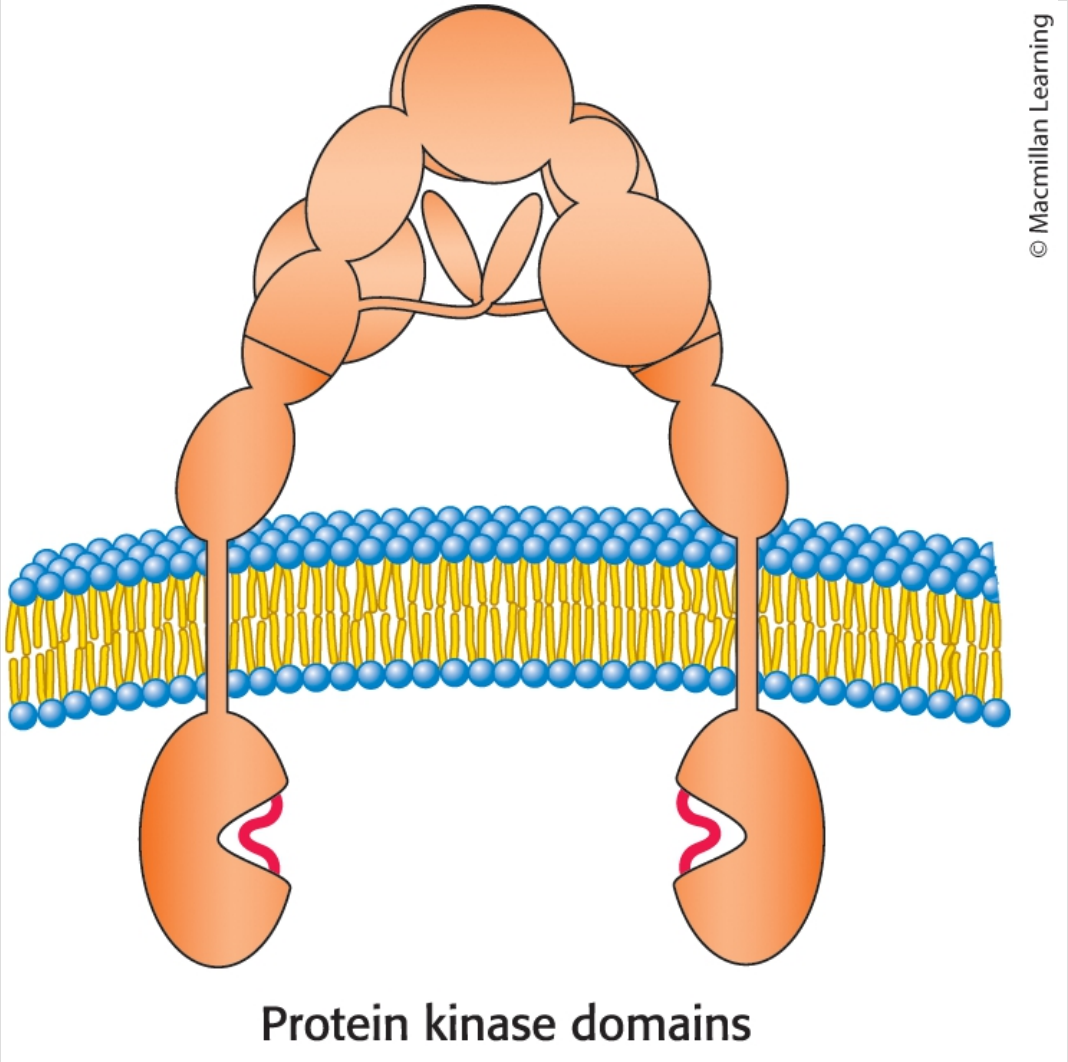
[Drawn from 1B2F.pdb.]

Its receptor has a quite different structure from that of the β-AR. The insulin receptor is a homodimer of heterodimers. Each component of the homodimer consists of one α chain and one β chain (Figure 14.25). The α chain has an elaborate structure with six domains while the β chain has two domains in addition to a protein kinase domain. Each α chain lies completely outside the cell, whereas each β chain lies primarily inside the cell, spanning the membrane with a single transmembrane segment.



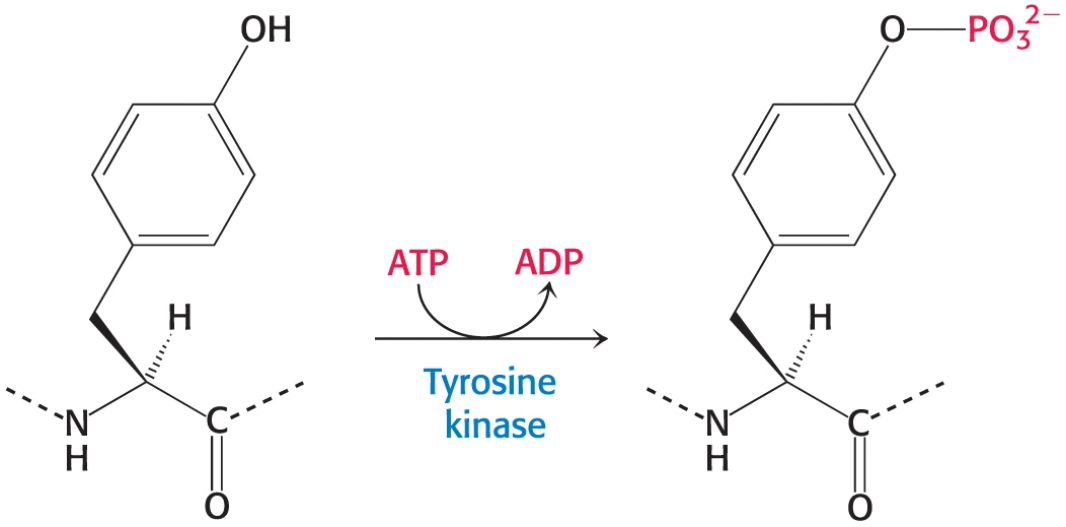


FIGURE 14.25 The insulin receptor consists of two subunits, each of which consists of an α chain and a β chain with protein kinase domains inside the cell. The two α chains are depicted in a lighter shade of orange than are the β chains. Each α chain is entirely outside the cell, while each β chain lies primarily inside the cell and includes a protein kinase domain.

The kinase domain in the β chain is homologous to that from protein kinase A but differs in two important ways. First, the insulin-receptor kinase is a tyrosine kinase; that is, it catalyzes the transfer of a phosphoryl group from ATP to the hydroxyl group of tyrosine, rather than serine or threonine.

Because this tyrosine kinase is a component of the receptor itself, the insulin receptor is referred to as a receptor tyrosine kinase. Second, the insulin receptor kinase is in an inactive conformation when the domain is not covalently modified.

The structure of this inactive form reveals an intricate mechanism for maintaining this inactivity. The key element is a relatively unstructured region termed the **activation loop**. Tyrosine kinases have two substrates, a peptide containing a tyrosine residue and ATP. The binding sites for these two substrates, determined from the active form of the enzyme, are shown in **Figure 14.26**. In the inactive form, one of the tyrosine residues that is to be phosphorylated as part of the activation process and is part of the activation loop is bound in the active site. However, ATP cannot bind because the ATP binding site is occupied by another part of the activation loop with the sequence Asp-Phe-Gly (DFG). The phenylalanine sidechain mimics the adenine ring of ATP while the aspartate provides a negative charge. Thus, even though a potential substrate is the active site, no reaction can take place as the DFG sequence is tethered closely enough to the protein structure that it cannot move out of the way. This is analogous to the impossibility of scratching your right elbow with your right hand.

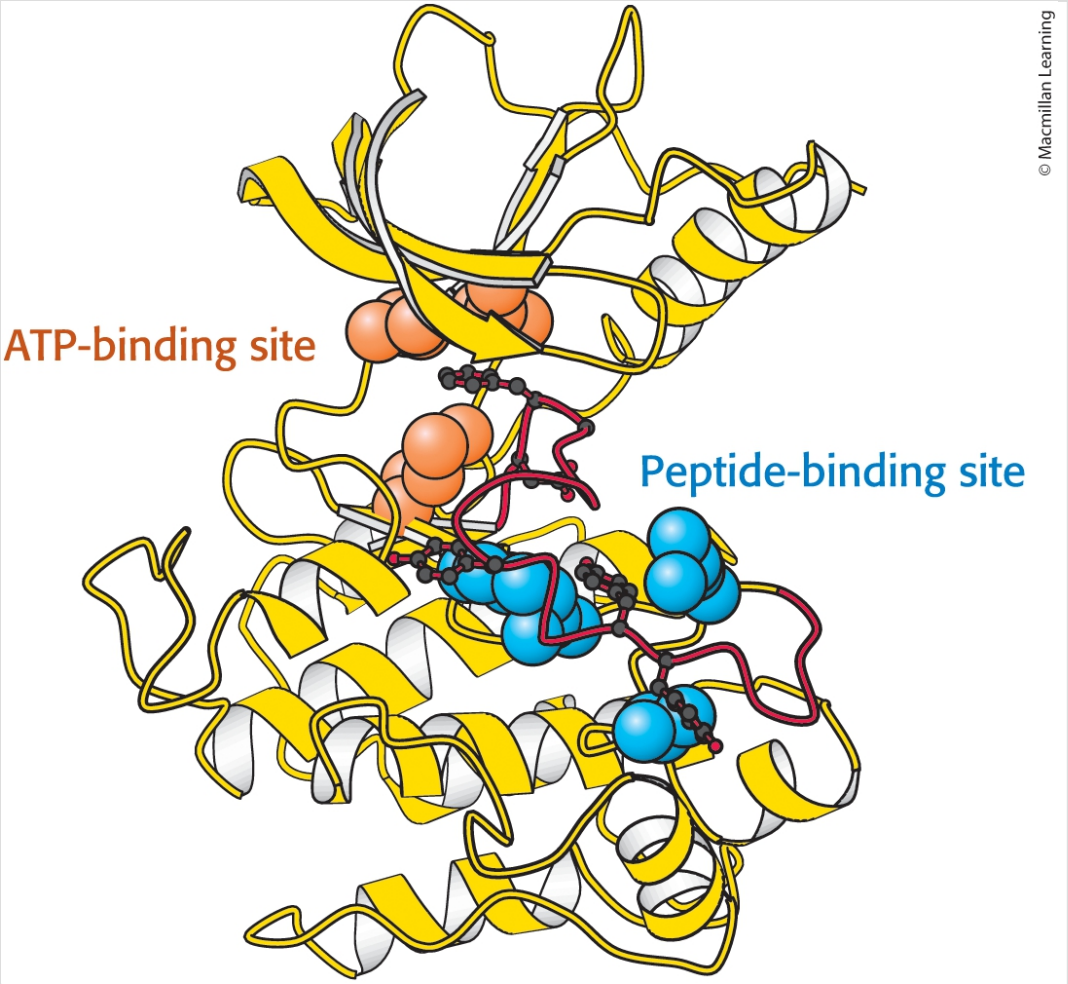

FIGURE 14.26 The insulin receptor kinase is inactive due to part of the activation loop blocking the ATP-binding site. The structure of the unactivated form of the insulin receptor kinase is shown with residues from the ATP-binding site in orange and residues from the peptide substrate binding site in blue. The activation loop, shown in red, has a tyrosine residue in the active site, but it cannot be phosphorylated because the ATP-binding site is blocked.

[Drawn from 1IRK.pdb.]

Insulin binding results in the cross-phosphorylation and activation of the

insulin receptor

In the absence of bound insulin, the insulin receptor dimer has an inverted “V”-like structure. Most importantly, this structure holds the kinase domains apart so that they cannot interact with one another. Insulin binds first to a site that includes elements from both subunits with a substantial conformation change induced upon binding. Overall, each receptor can bind up to four insulin molecules, and the final dimer has a “T”-like structure (Figure 14.27).

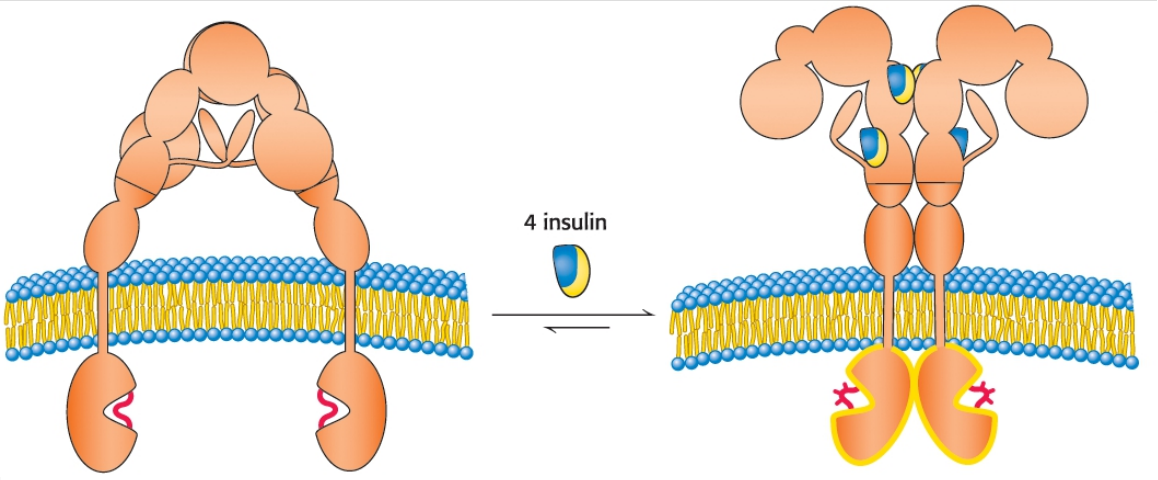

FIGURE 14.27 The insulin receptor dramatically changes conformation when it binds insulin. Upon binding insulin, the extracellular domains of the insulin receptor change conformation, causing the overall receptor to convert from an inverted “V” shape to a “T” shape. This allows th protein kinase domains to come together. The receptor dimer can bind up to four insulin molecules.

In this structure, the two protein kinase domains inside of the cell are pushed together. The flexible activation loop of one kinase subunit can fit into the active site of the other kinase subunit within the dimer in place of the domain’s own activation loop, opening up an ATP-binding site, and allowing the phosphorylation reaction to occur. When these tyrosine residues are phosphorylated, they can no longer fit into the

active site and the activation loops swings out into a different conformation with both the ATP- and peptide-binding sites available to phosphorylated additional substrates. Three tyrosine residues in each activation loop are phosphorylated (Figure 14.28). The net result of this overall process is that insulin binding on the outside of the cell results in the activation of a membrane-associated kinase within the cell.

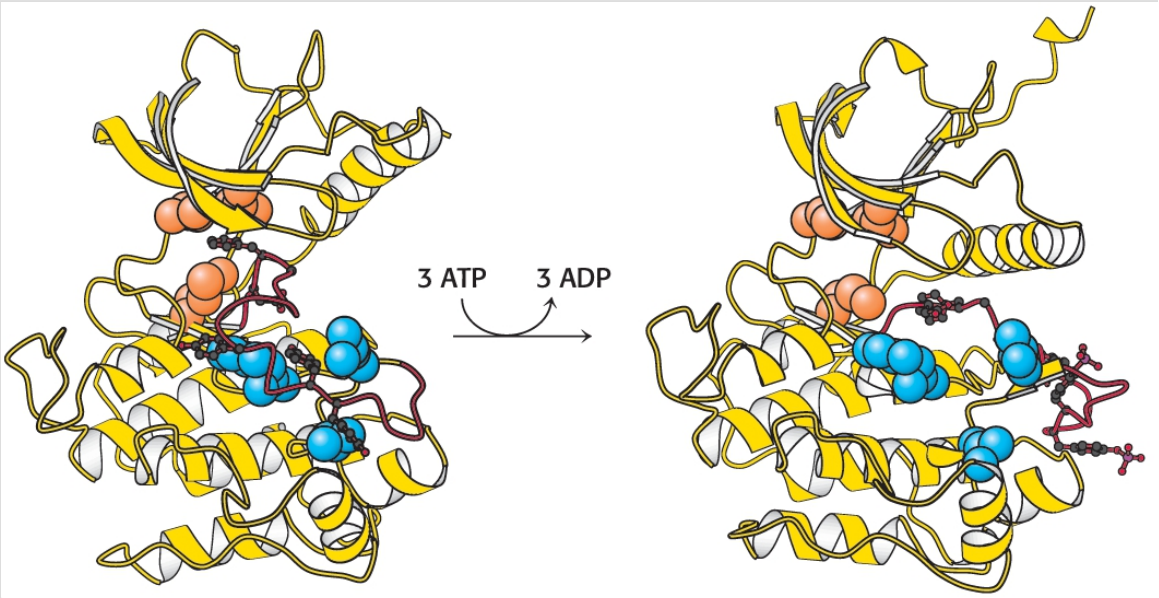

FIGURE 14.28 Activation of the insulin receptor involves phosphorylation of tyrosine residues in the kinase domain. One kinase domain phosphorylates tyrosine residues in the other. When tyrosine residues in the activation loop are phosphorylated, they can no longer fit into the activ site; the activation loop is released, opening up the ATP-binding site and activating the kinase.

[Drawn from 1IRK.pdb and 1IR3.pdb.]

The activated insulin-receptor kinase initiates a kinase cascade

With the kinase activated, additional sites within the receptor are also as the two subunits of the receptor are in close proximity to one

another. These phosphorylated sites act as docking sites for other substrates, including a class of molecules referred to as insulin-receptor substrates (IRS). IRS-1 and IRS-2 are two homologous proteins with a common modular structure (Figure 14.29). The amino-terminal part includes a **pleckstrin homology domain**, which binds phosphoinositide, and a phosphotyrosine-binding domain. These domains act together to anchor the IRS protein to the insulin receptor and the associated membrane.

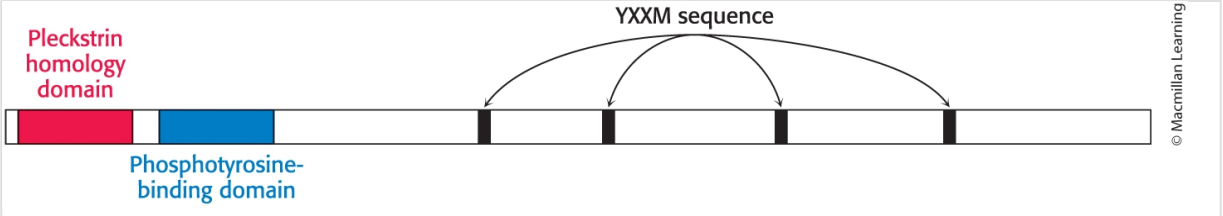

FIGURE 14.29 Insulin-receptor substrates IRS-1 and IRS-2 have modular structures. This schematic view represents the amino acid sequence common to IRS-1 and IRS-2. Each protein contains a pleckstrin homology domain (which binds phosphoinositide lipids), a phosphotyrosine-binding domain, and four sequences that approximate Tyr-X-X-Met (YXXM). The four sequences are phosphorylated by the insulin-receptor tyrosine kinase.

Each IRS protein contains four sequences of the form Tyr-X-X-Met. These sequences are also substrates for the activated insulin-receptor kinase. When the tyrosine residues within these sequences are phosphorylated, IRS molecules can act as adaptors, bringing additional components of this signaling pathway together at the membrane. The most important proteins that bind to the phosphorylated IRS molecules are specific lipid kinases, called phosphoinositide 3-kinases (PI3Ks), that add a phosphoryl group to the 3-position of inositol in phosphatidylinositol 4,5-bisphosphate (PIP_2) to form phosphatidylinositol 3,4,5-trisphosphate (PIP_3) (Figure 14.30). These enzymes are dimers of 110-kDa catalytic subunits and 85-kDa regulatory subunits. These enzymes bind to the phosphorylated IRS proteins and are drawn to the membrane where they can phosphorylate PIP_2 to form

PIP_3. The PIP_3 molecules serve as gathering points for other proteins, continuing a kinase cascade (Figure 14.31).

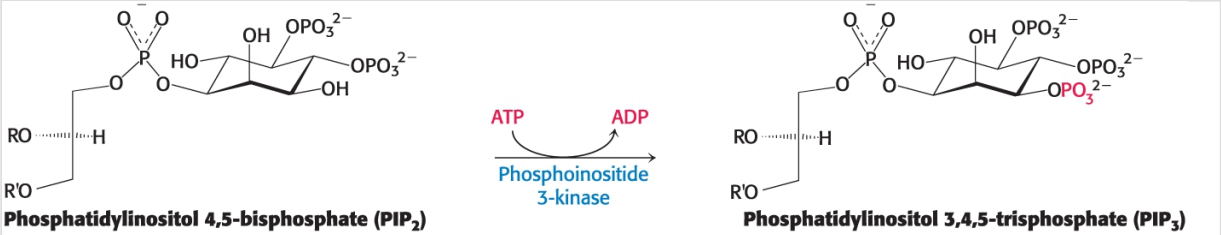

FIGURE 14.30 Phosphoinositide 3-kinase adds a phosphoryl group to PIP_2, forming PIP_3.

This generates a modified lipid headgroup that can be recognized by other enzymes.

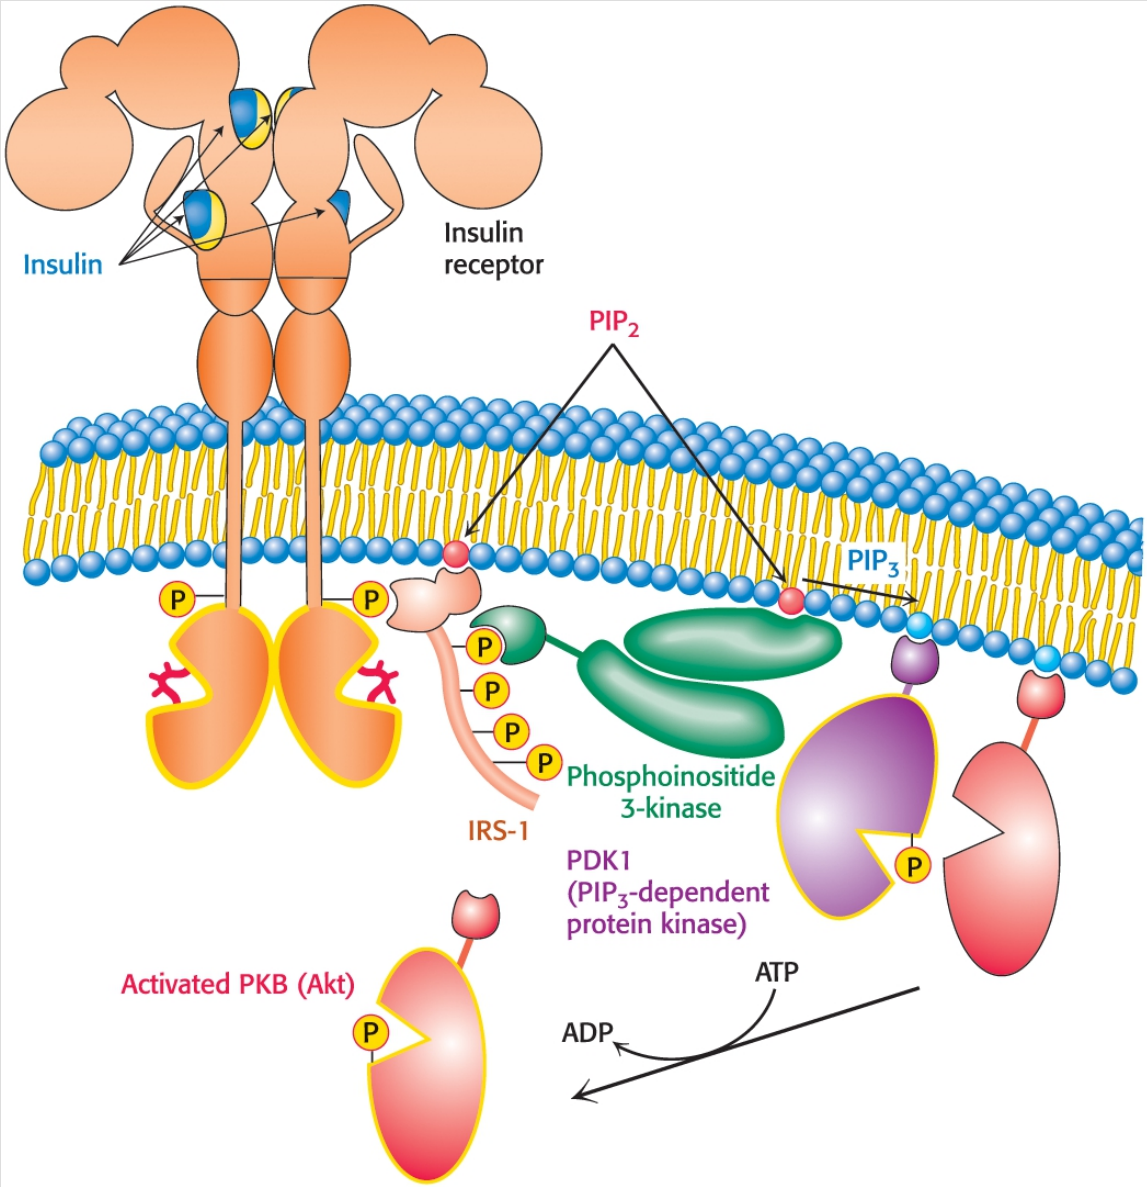

FIGURE 14.31 The insulin signaling pathway results in protein kinase activation. The binding insulin results in the cross-phosphorylation and activation of the insulin receptor. Phosphorylated sites on the receptor act as binding sites for insulin-receptor substrates such as IRS-1. The lipid kinase phosphoinositide 3-kinase binds to phosphorylated sites on IRS-1 through its regulatory domain and converts PIP_2 into PIP_3. PIP_3 then serves as a binding site for PIP_3-dependent protein kinase (PDK1), which phosphorylates and activates kinases such as PKB. Activated PKB can then diffuse throughout the cell to continue the signal-transduction pathway.

The first protein recruited to the PIP_3 molecules is phosphoinositide-dependent kinase-1 (PDK1). PDK1 is a member of a large class of serine/threonine-specific kinases that require phosphorylation on their activation loops in a manner similar to the insulin-receptor kinase. However, the activation mechanism is different. For the serine-threonine kinases, the enzymes adapt an inactivate conformation even through the ATP- and peptide-binding sites are accessible. Phosphorylation results in a change to an active conformation (**Figure 14.32**).

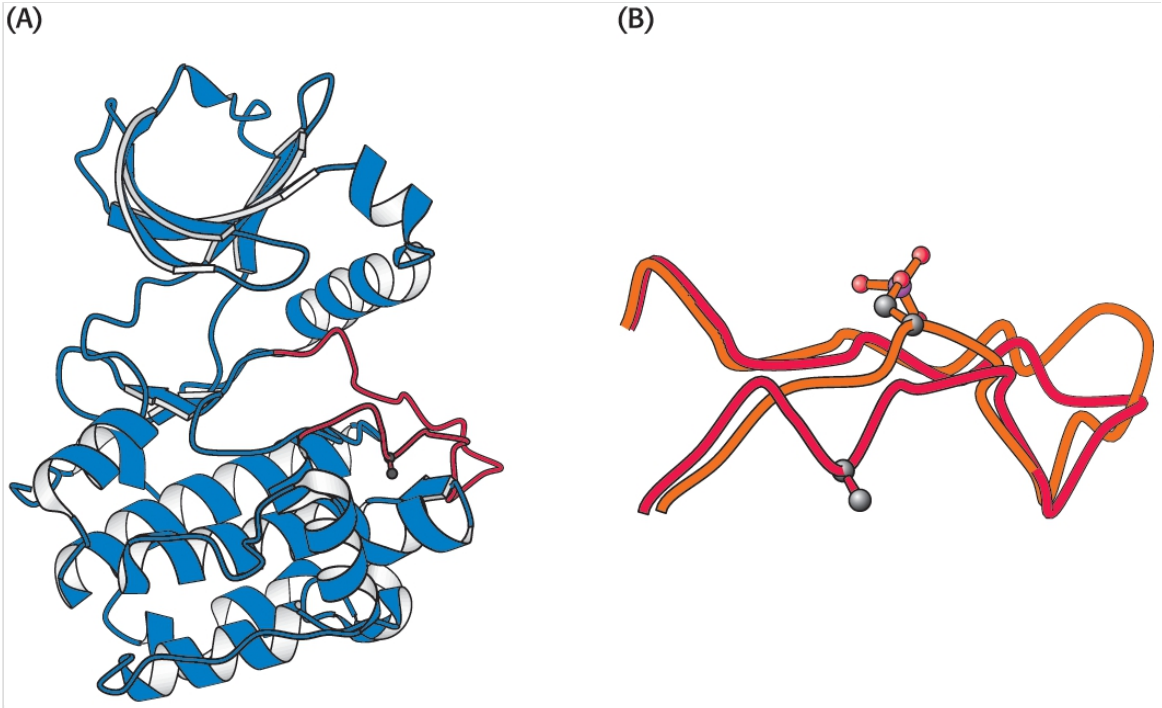

FIGURE 14.32 Phosphorylation activates phosphoinositide-dependent protein kinase. (A) The structure of phosphoinositide-dependent protein kinase (PDK1) is shown in an inactive conformation (with an alanine replacing a key serine to prevent self-activation). (B) A comparis of the structures of the activation loops of PDK1, in inactive and active forms, shows the conformation change associated with activation.

[Drawn from 2BIY.pdb and 3HRF.pdb.]

The most important characteristics of a protein kinase are its substrate sequence preferences and the sequence around its activation site. For PDK1, its substrates approximate the sequence -XXTX(**S,T**)FCGT-, where X represents relatively variable positions. Its activation site has the sequence -QARAN**S**FGVTA-, where the underlined residues match the preferred substrate sequence. The match between this sequence and the substrate preference indicates that PDK1 can activate itself by cross-phosphorylation. PDK1 also includes a pleckstrin homology domain that is specific for PIP_3 and, thus, PDK1 is concentrated at PIP_3-rich sites generated by PI3K (Figure 14.31).

Other kinases that include pleckstrin homology domains are also concentrated at these sites including Protein Kinase B (PKB, also known as Akt). The activation loop of this kinase has the sequence -GATMK**T**FCGTPE-, which matches the substrate preference for PDK1. The substrate preference for PKB is quite different with the form -RRRXX(**S,T**)XSXSX-. Thus, PKB can be activated by PDK1 but is not capable of self-activation. Once activated, PKB can leave the membrane and move throughout the cell to phosphorylate other targets. These include components that control the trafficking of the glucose receptor GLUT4 to the cell surface. This completes the part of the insulin-signaling pathway we have been considering after our meal, namely, the process from an increase in insulin concentration in the bloodstream to enhanced glucose uptake.

The cascade initiated by the binding of insulin to the insulin receptor is summarized in **Figure 14.33**. The signal is amplified at several stages along this pathway. Because the activated insulin receptor itself is a protein kinase, each activated receptor can phosphorylate multiple IRS molecules. Activated enzymes further amplify the signal in at least two of the subsequent steps. Thus, a small increase in the concentration of circulating insulin can produce a robust intracellular response.

FIGURE 14.33 Insulin binding initiates a signaling pathway leading to a protein kinase cascade. Key steps in the signal-transduction pathway are shown. The result is activation of protein kinases that phosphorylate targets, leading to an increase in glucose transporters on cell surfaces, among other effects.

Self-Check Question

Can a kinase with substrate preference XXXPX(**S,T**)PXXXX and an activation loop sequence of -HTGFL**T**EYVAT- activate itself?

Insulin signaling is terminated by the action of phosphatases

We have seen that the activated G protein promotes its own inactivation by the catalytic release of a phosphoryl group from GTP. In contrast, proteins phosphorylated on serine, threonine, or tyrosine residues are extremely stable kinetically. Specific enzymes, called protein phosphatases, are required to hydrolyze these phosphorylated proteins and return them to their initial states. Similarly, enzymes called lipid phosphatases are required to remove phosphoryl groups from inositol lipids that had been activated by lipid kinases.

In insulin signaling, three classes of enzymes are of particular importance in shutting off the signaling pathway:

1. Protein tyrosine phosphatases that remove phosphoryl groups from tyrosine residues on the insulin receptor and the IRS adaptor

proteins

2. Lipid phosphatases that hydrolyze PIP_3 to PIP_2

3. Protein serine phosphatases that remove phosphoryl groups from activated protein kinases such as PKB

Many of these phosphatases are activated or recruited as part of the response to insulin. Thus, the binding of the initial signal sets the stage for the eventual termination of the response.

14.4 Epidermal Growth Factor: Receptor Dimerization Can Drive Signaling

Next, we will look at the signaling that takes place shortly after you are wounded. Within a few hours, signaling molecules such as epidermal growth factor (EGF) are released into the affected region. EGF is a 6-kDa polypeptide that stimulates the growth of epidermal and epithelial cells (**Figure 14.34**).

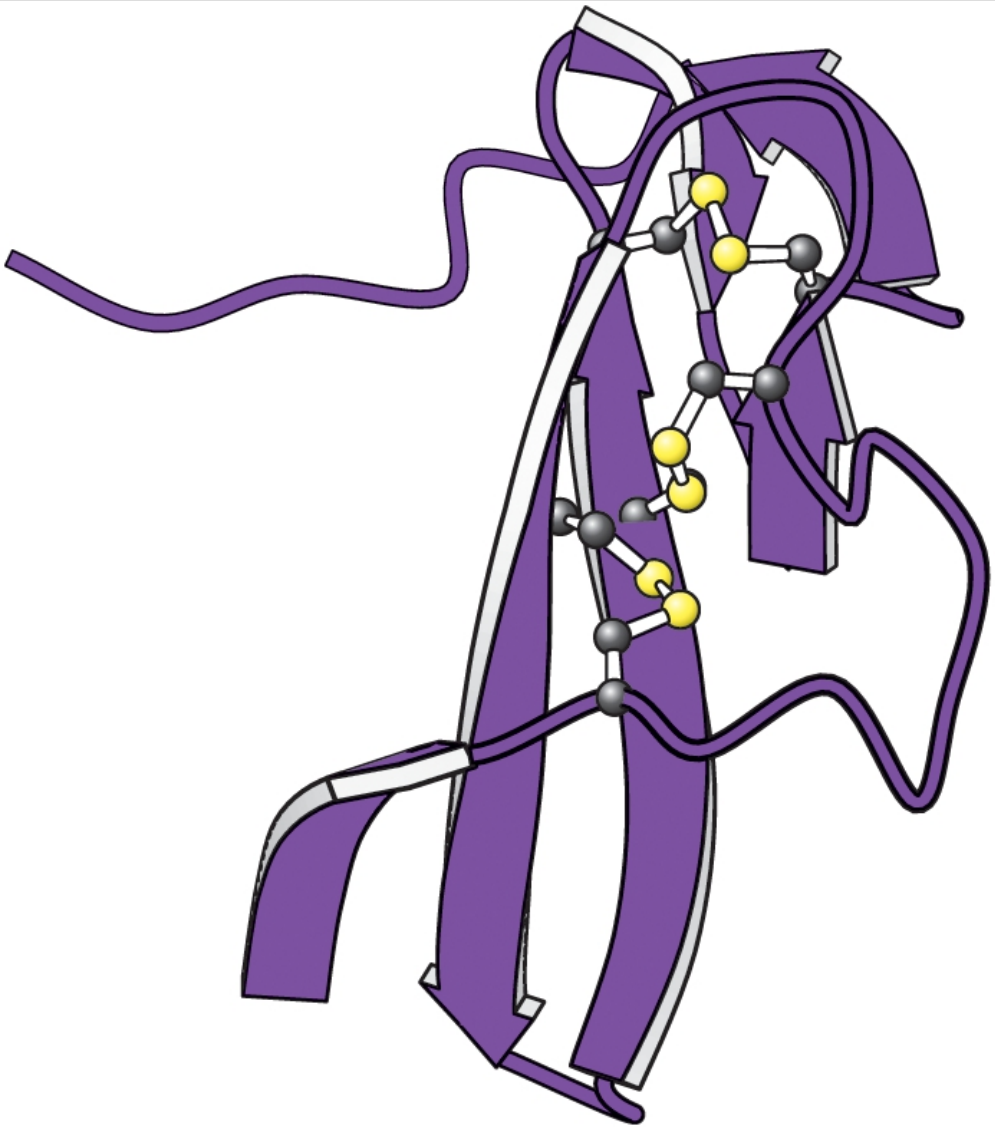

FIGURE 14.34 Epidermal growth factor consists of a single polypeptide chain stabilized by three disulfide bonds.

[Drawn from 1EGF.pdb.]

INTERACT with this model in Achieve

EGF is bound by a family of receptor tyrosine kinases, similar in some ways to the insulin receptor, but quite different in others. Unlike those of the insulin receptor, however, these receptors exist as monomers. Each EGF receptor monomer binds a single molecule of EGF in its extracellular domain. EGF binding results in a substantial rearrangement of the extracellular domain (Figure 14.35). After this rearrangement, the receptors dimerize, stabilized by a structure termed the *dimerization arm* from each monomer. This arm is buried within the monomer structure prior to EGF binding but inserts into a binding pocket on the other monomer after EGF binding.

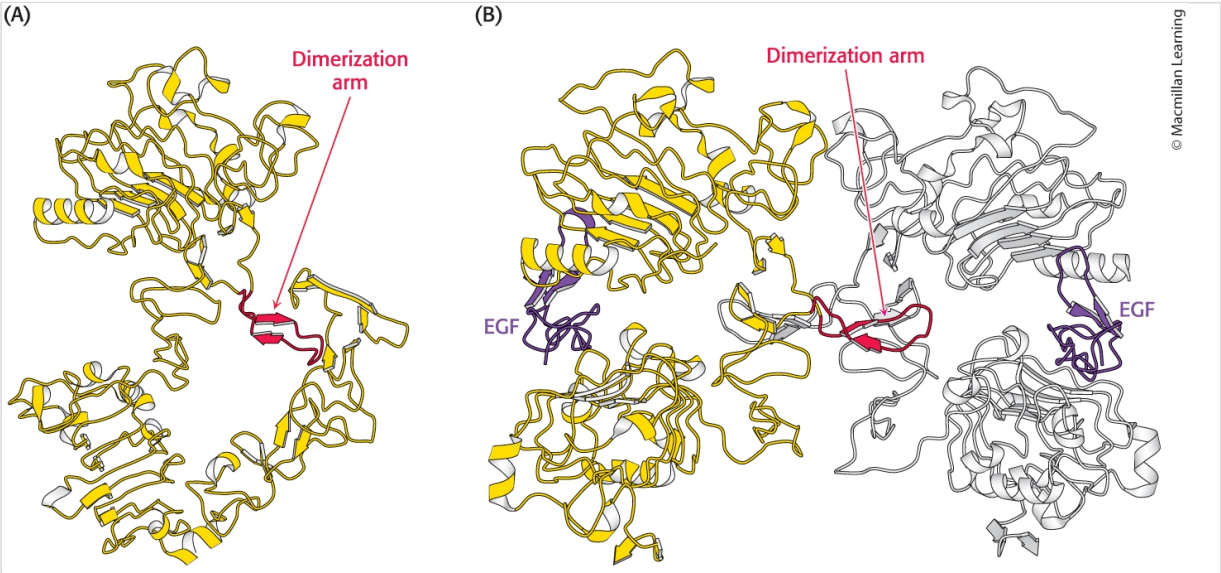

FIGURE 14.35 EGF binding to the EGF receptor results in a substantial rearrangement and facilitates receptor dimerization. (A) The structure of the extracellular domain of the EGF receptor is folded so that a region termed the dimerization loop is facing toward the interior of the structure. (B) Upon EGF binding, the structure rearranges so that the dimerization arm points outward and participates with dimerization with another receptor molecule.

INTERACT with this model in Achieve

The EGF receptor undergoes phosphorylation of its carboxyl-terminal tail

Like the insulin receptor, the kinase domains of the EGF receptor are inactive prior to dimerization. When an EGF receptor dimerizes, the kinase domains come together to form an asymmetric dimer with one kinase domain functioning as an allosteric activator of the other, stabilizing an active conformation. This active kinase phosphorylates tyrosine residues on the other subunit, but in a region that lies on the C-terminal side of the kinase domain, rather in an activation loop. As many as five tyrosine residues in this region are phosphorylated.

EGF signaling leads to the activation of Ras, a small G protein

The phosphotyrosines on the EGF receptors act as docking sites for phosphotyrosine-binding domains on other proteins. The intracellular signaling cascade begins with the binding of Grb2, a key adaptor protein that contains one phosphotyrosine-binding domain and two domains that recognize extended, proline-rich sequences. On phosphorylation of the receptor, Grb2 binds to the phosphotyrosine residues of the EGF receptor. Through its other domains, Grb2 then binds polyproline-rich polypeptides within a protein called Sos. Sos, in turn, binds to a protein called Ras and activates it.

A very prominent signal-transduction component, Ras is a member of a class of proteins called the small G proteins. These proteins have many key mechanistic and structural motifs in common with the G_{α} subunit of the heterotrimeric G proteins and are related by divergent evolution. In keeping with this relationship, Ras contains bound GDP in its unactivated form. Sos opens up the nucleotide-binding pocket of Ras, allowing GDP to escape and GTP to enter in its place. Because of its

effect on Ras, Sos is referred to as a guanine-nucleotide-exchange factor (GEF). Thus, the binding of EGF to its receptor leads to the conversion of Ras into its GTP form through the intermediacy of Grb2 and Sos (Figure 14.36). This occurs on the membrane surface as Ras is anchored via covalently attached lipids.

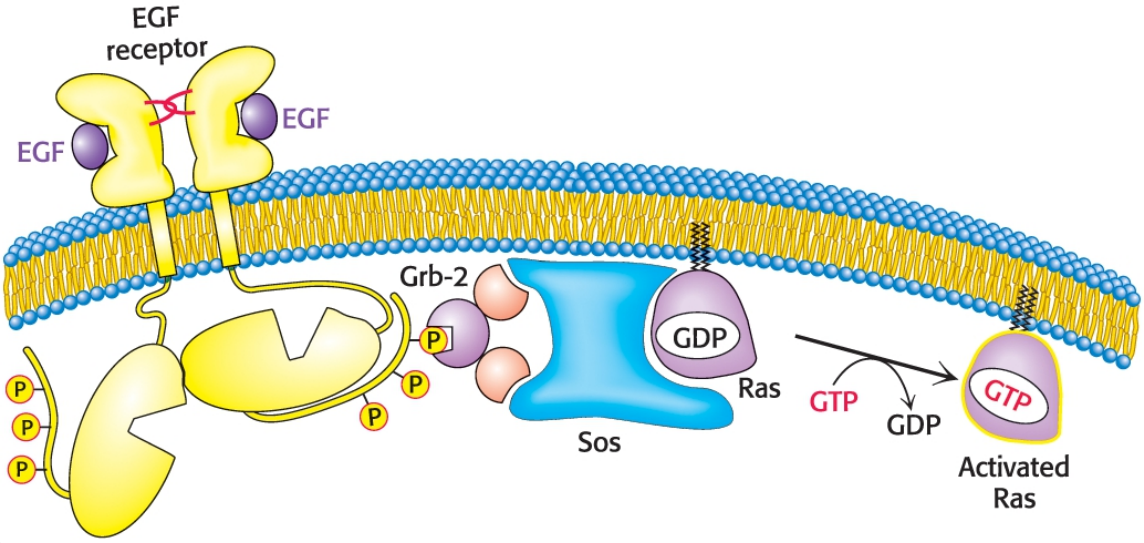

FIGURE 14.36 The binding of EGF to the EGF receptor results in the activation of Ras. The dimerization of the EGF receptor due to EGF binding leads to the phosphorylation of the C-terminal tails of the receptor. This, in turn, results in the recruitment of Grb2 and Sos, and the exchange of GTP for GDP in Ras. This signal-transduction pathway results in the conversion of Ras into its activated GTP-bound form.

Activated Ras initiates a protein kinase cascade

Ras changes conformation when it is transformed from its GDP into its GTP form. In the GTP form, Ras binds other proteins, including a membrane-anchored protein kinase termed Raf. When bound to Ras, Raf undergoes a conformational change that activates the Raf protein

kinase. Activated Raf then phosphorylates other proteins, including protein kinases termed MEKs. In turn, MEKs activate kinases called extracellular signal-regulated kinases (ERKs). ERKs then phosphorylate numerous substrates, including transcription factors in the nucleus as well as other protein kinases. The flow of information from the arrival of EGF at the cell surface to changes in gene expression is summarized in **Figure 14.37**.

FIGURE 14.37 The EGF signaling pathway results in a protein kinase cascade. The key steps in the pathway are shown. A kinase cascade leads to the phosphorylation of transcription factors and concomitant changes in gene expression.

EGF signaling is terminated by protein phosphatases and the intrinsic GTPase activity of Ras

Because so many components of the EGF signal-transduction pathway are activated by phosphorylation, we can expect protein phosphatases to play key roles in the termination of EGF signaling. Indeed, crucial phosphatases remove phosphoryl groups from tyrosine residues on the EGF receptor and from serine, threonine, and tyrosine residues in the protein kinases that participate in the signaling cascade. The signaling process itself sets in motion the events that activate many of these phosphatases. Consequently, signal activation also initiates signal termination.

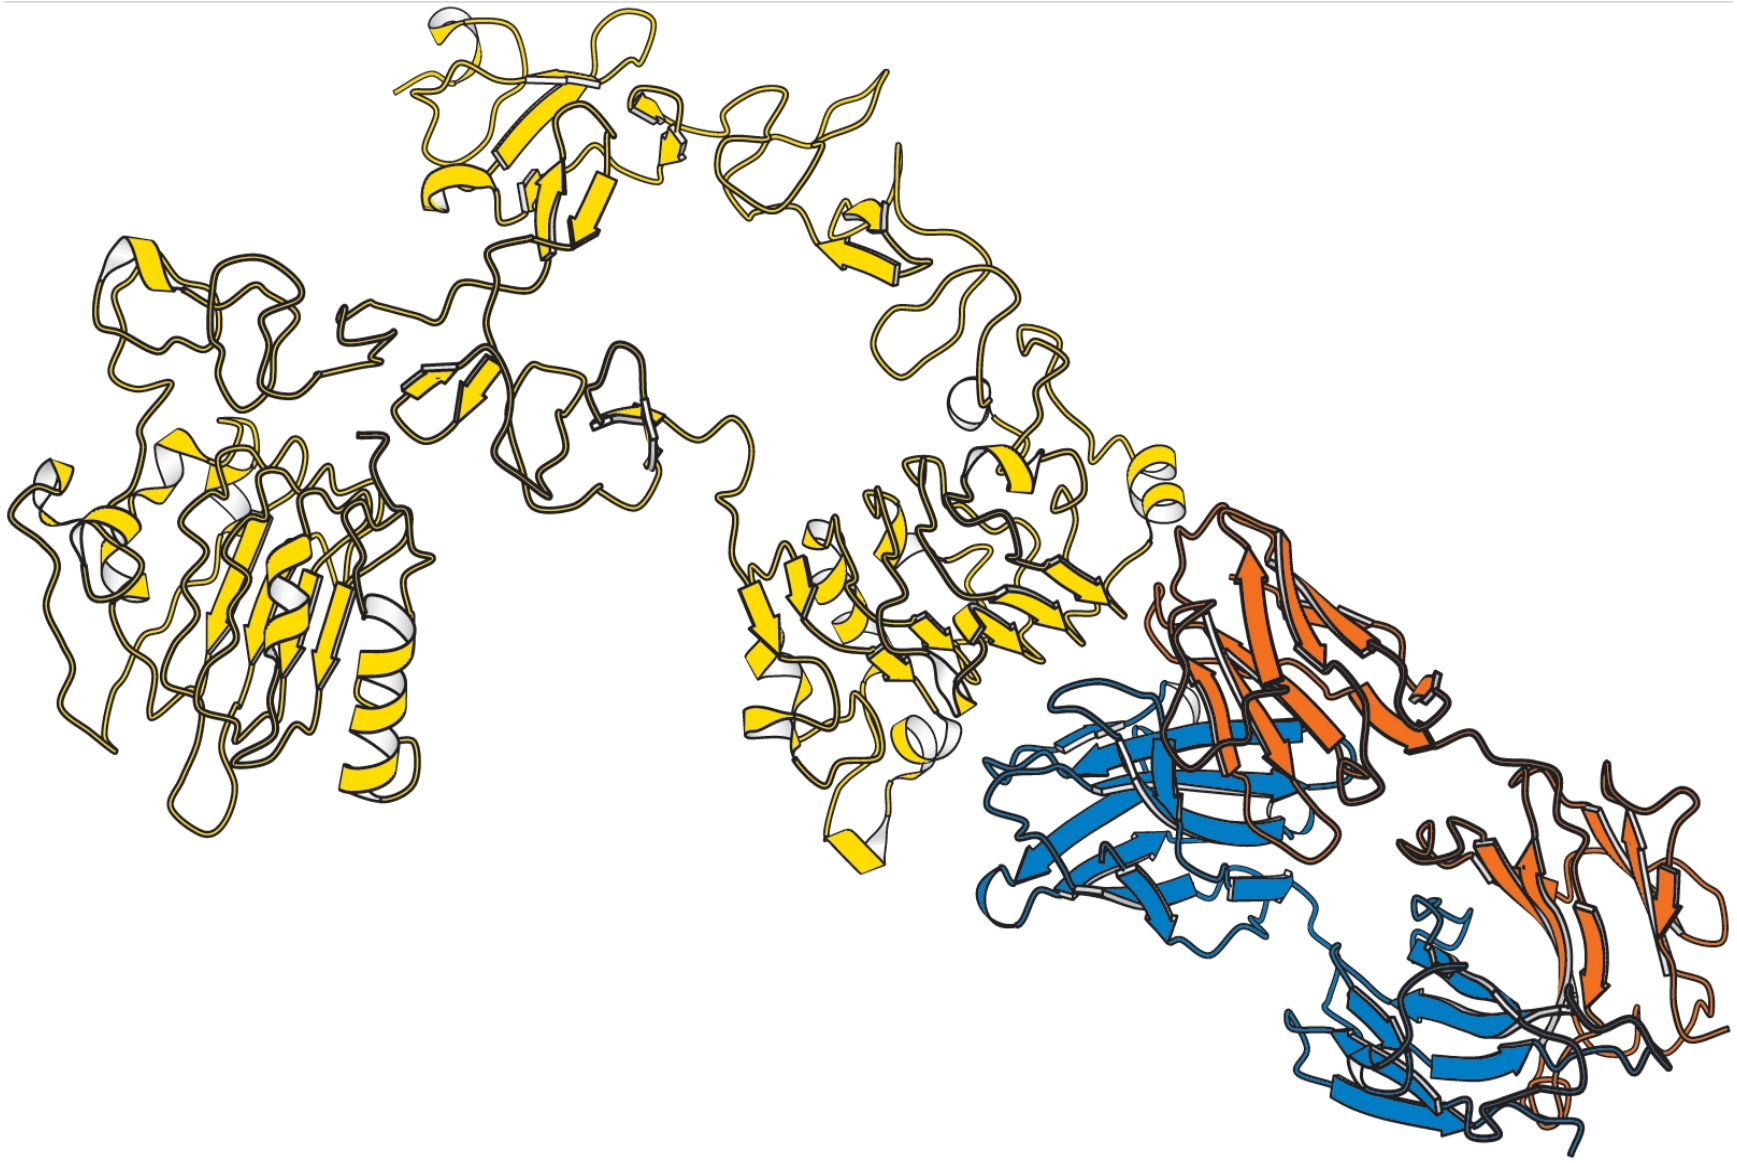
Like the G proteins activated by 7TM receptors, Ras possesses intrinsic GTPase activity. Thus, the activated GTP form of Ras spontaneously converts into the inactive GDP form. The rate of conversion can be accelerated in the presence of GTPase-activating proteins (GAPs), which interact with small G proteins in the GTP form and facilitate GTP hydrolysis. Thus, the lifetime of activated Ras is regulated by accessory proteins in the cell.

Self-Check Question

List one important similarity and one important difference between Ras and a heterotrimeric G protein.

14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases

In light of their complexity, it comes as no surprise that signal-transduction pathways occasionally fail, leading to disease states. Cancer, a set of diseases characterized by uncontrolled or inappropriate cell growth, is strongly associated with defects in signal-transduction proteins, particularly those that play key roles in growth-control pathways. Indeed, the study of cancer — particularly cancers caused by certain viruses — has contributed greatly to our understanding of signal-transduction proteins and pathways.



Mammalian cells may contain three distinct Ras proteins (H-, K-, and N-Ras), each of which cycles between inactive GDP and active GTP forms. The genes encoding members of the Ras family are among the most commonly mutated in human tumors. The most common mutations in tumors lead to a loss of the ability to hydrolyze GTP. Thus, the Ras protein is trapped in the "on" position and continues to stimulate cell growth, even in the absence of a continuing signal. Genes such as these mutated Ras genes are referred to **oncogenes** because they can induce cancer under appropriate circumstances. Unmutated Ras genes are referred to as **proto-oncogenes** since they can be converted into oncogenes through mutation.

Other genes can contribute to cancer development only when both copies of the gene normally present in a cell are deleted or otherwise damaged. Such genes are called **tumor-suppressor genes**. For example, genes for some of the phosphatases that participate in the termination of EGF signaling are tumor suppressors. Without any functional phosphatase present, EGF signaling persists once initiated, stimulating inappropriate cell growth.

Monoclonal antibodies can be used to inhibit signal-transduction pathways activated in tumors

Mutated or overexpressed receptor tyrosine kinases are frequently observed in tumors. For instance, the epidermal-growth-factor receptor (EGFR) is overexpressed in some human epithelial cancers, including breast, ovarian, and colorectal cancer. Because some small amount of the receptor can dimerize and activate the signaling pathway even without binding to EGF, overexpression of the receptor increases the likelihood that a "grow and divide" signal will be inappropriately sent to the cell.

This understanding of cancer-related signal-transduction pathways has led to a therapeutic approach that targets the EGFR. The strategy is to produce monoclonal antibodies to the extracellular domains of the offending receptors. One such antibody, cetuximab (Erbitux), has effectively targeted the EGFR in colorectal cancers. Cetuximab inhibits the EGFR by competing with EGF for the binding site on the receptor (**Figure 14.38**). Because the antibody sterically blocks the change in conformation that exposes the dimerization arm, the antibody itself cannot induce dimerization. The result is that the EGFR-controlled pathway is not initiated.

© Macmillan Learning

FIGURE 14.38 The monoclonal antibody drug cetuximab binds to the EGF receptor and prevents receptor signaling. The structure of the complex between the extracellular domain of the EGF receptor and an F_{ab} fragment from cetuximab reveals that the antibody binds in a manner that blocks the conformational changes necessary for productive dimerization and signaling.

[Drawn from 1YY9.pdb.]

Cetuximab is not the only monoclonal antibody that has been developed to target a receptor tyrosine kinase. Trastuzumab (Herceptin) inhibits another EGFR family member, HER2, that is overexpressed in approximately 30% of breast cancers (**Figure 14.39**). HER2 normally forms heterodimers with other members of the EGFR family, but it can signal even in the absence of ligand when it homodimerizes. Thus, overexpression of HER2 can stimulate cell proliferation. Breast tumors are now routinely screened for HER2 overexpression, and patients showing such overexpression may be treated with Herceptin if appropriate. Thus, this cancer treatment is tailored to the genetic characteristics of the tumor.

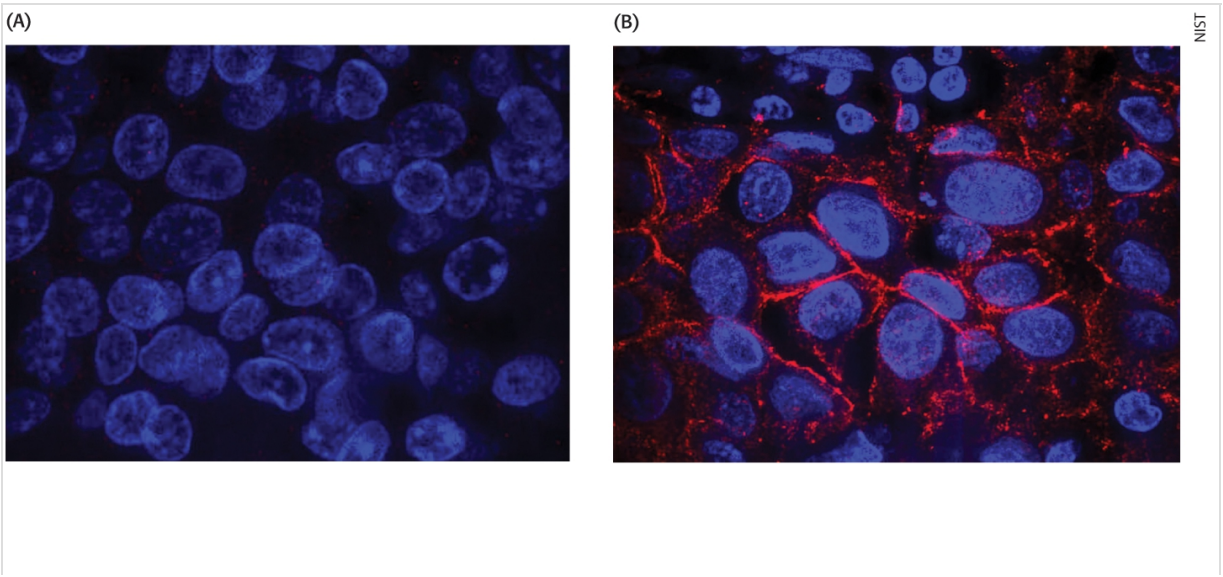


FIGURE 14.39 The EGF receptor family member HER2 is overexpressed in some breast cancer cells. (A) A panel of breast cancer cells expressing HER2 at normal levels. Cell nuclei are blue, and HER2 would be red if detectable. (B) A panel of breast cancer cells overexpressing HER2. The overexpression is due to amplification of the *HER2* gene such that many more than the normal two copies are present.

Protein kinase inhibitors can be effective anticancer drugs

The widespread occurrence of overactive protein kinases in cancer cells suggests that molecules that inhibit these enzymes might act as antitumor agents. For example, more than 90% of patients with chronic myelogenous leukemia (CML) show a specific chromosomal defect in cancer cells (**Figure 14.40**). The translocation of genetic material between chromosomes 9 and 22 causes the c-*abl* gene, which encodes a tyrosine kinase of the Src family, to be inserted into the *bcr* gene on chromosome 22. The result is the production of a fusion protein called Bcr-Abl that consists primarily of sequences for the c-Abl kinase. However, the *bcr-abl* gene is not regulated appropriately; it is expressed at higher levels than that of the gene encoding the normal c-Abl kinase, stimulating a growth-promoting pathway.

FIGURE 14.40 Translocation of DNA from one chromosome to another results in the formation of the *bcr-abl* gene. In chronic myelogenous leukemia, parts of chromosomes 9 and 22 are reciprocally exchanged, causing the *bcr* and *abl* genes to fuse. The protein kinase encoded by the *bcr-abl* gene is expressed at higher levels in tumor cells than is the c-*abl* gene in normal cells, leading to inappropriate cell proliferation.

Because of this overexpression, leukemia cells express a unique target for chemotherapy. A specific inhibitor of the Bcr-Abl kinase, Gleevec (STI-571, imatinib mesylate), has proved to be a highly effective treatment for patients with CML (**Figure 14.41**). This approach to cancer chemotherapy is fundamentally distinct from most approaches, which target all rapidly growing cells, including normal ones. Because Gleevec targets tumor cells specifically, side effects caused by the impairment of normal dividing cells can be minimized. Subsequently, drugs that target other protein kinases have been developed for treatment of other cancer types. Thus, our understanding of signal-transduction pathways has enabled conceptually new disease treatment strategies.

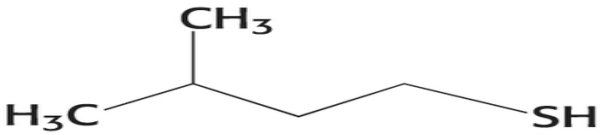
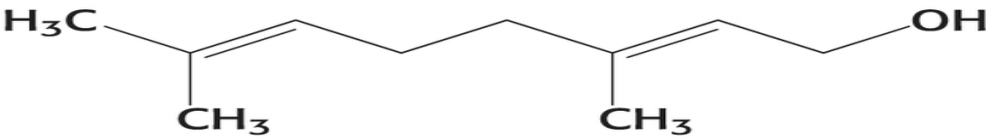
14.6 Sensory Systems Are Based on Specialized Signal-Transduction Pathways

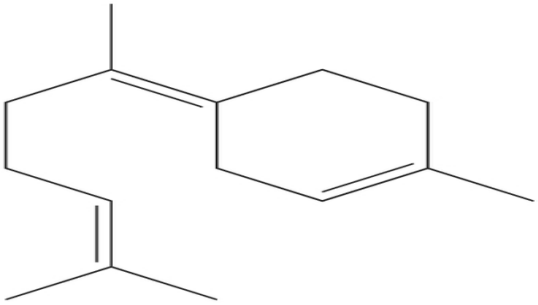


Recall once again the scene you imagined at the start of this chapter. One enticement to eating dinner after your return to the campfire was the delicious smell of the cooked food. Many organic compounds can evaporate from the surface of food, and both the number and amount of these increases as food is heated. How are these compounds sensed and distinguished from one another? In this section, we will explore the signal-transduction pathways behind smell and other senses as well, including vision and hearing.

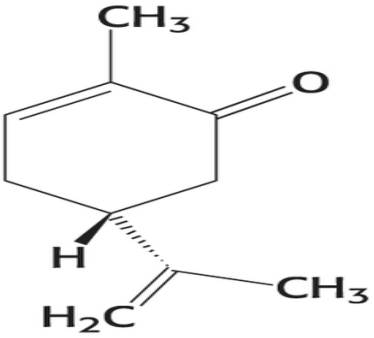
A huge family of 7TM receptors detect a wide variety of organic compounds



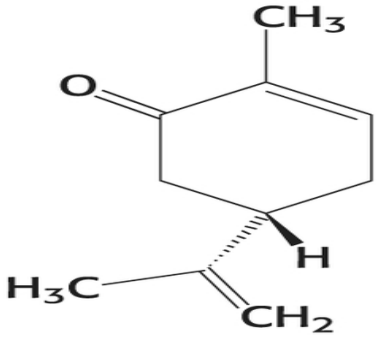
Human beings can detect and distinguish thousands of different compounds by smell, often with considerable sensitivity and specificity. Most odorants are small organic compounds with sufficient volatility that they can be carried as vapors into the nose. For example, a major component responsible for the odor of almonds is the simple aromatic compound benzaldehyde, whereas the sulfhydryl compound 3-methylbutane-1-thiol is a major component of the odor of skunks.



Benzaldehyde
(Almond)



3-Methylbutane-1-thiol
(Skunk)



Geraniol
(Rose)

Zingiberene
(Ginger)

***R*-Carvone**
(Spearmint)

***S*-Carvone**
(Caraway)

What properties of these molecules are responsible for their odors? First, the shape of the molecule rather than its other physical properties is crucial. We can most clearly see the importance of shape by comparing molecules such as those responsible for the odors of spearmint and caraway. These compounds are identical in essentially all physical properties such as hydrophobicity because they are exact mirror images of one another. Thus, the odor produced by an odorant depends not on a physical property but on the compound's interaction with specific receptors.

Investigations revealed that olfaction depends on cAMP and GTP, and a G-protein α subunit, termed $G_{(olf)}$, was discovered that is uniquely expressed in the olfactory system. From our knowledge, these factors should strongly suggest the involvement of 7TM receptors. Complementary DNAs were sought that (1) were expressed primarily in the sensory neurons lining the nasal epithelium, (2) encoded members of the 7TM-receptor family, and (3) were present as a large and diverse family to account for the range of odorants. Based on these criteria, cDNAs for odorant receptors from rats were identified in 1991 by Richard Axel and Linda Buck.

The odorant receptor (OR) family is even larger than expected: more than 1000 OR genes are present in the mouse and the rat, whereas the human genome encodes approximately 400 ORs. The OR proteins are typically 20% identical in sequence with the β-adrenergic receptor and from 30% to 60% identical with one another.

Interestingly, each olfactory neuron expresses only a single OR gene, among the hundreds available. The binding of an odorant to an OR on the neuronal surface initiates a signal-transduction cascade, quite similar to that from the β-adrenergic receptor, that results in an action

potential (Figure 14.42). The ligand-bound OR activates $G_{(olf)}$, which releases GDP, binds GTP, and dissociates its βγ subunits. The α subunit then binds to and stimulates a specific adenylate cyclase, increasing the intracellular concentration of cAMP. The rise in the intracellular concentration of cAMP activates a nonspecific cation channel that allows calcium and other cations into the cell. The flow of cations through the channel depolarizes the neuronal membrane and initiates an action potential. This action potential, combined with those from other olfactory neurons, leads to the perception of a specific odor.

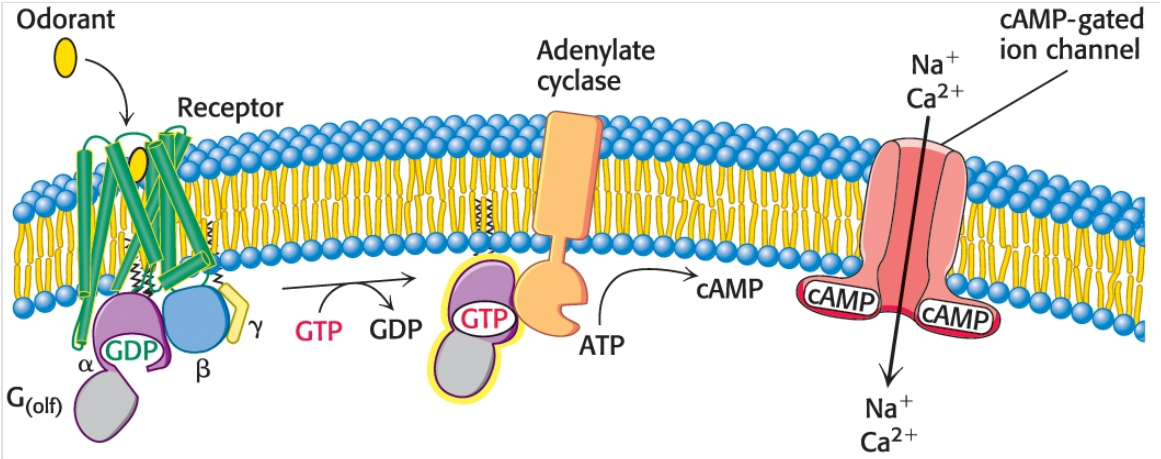


FIGURE 14.42 The olfactory signal-transduction cascade is similar to that for the β-adrenergi receptor. The binding of odorant to an olfactory receptor results in stimulating the activity of adenylate cyclase. The final result is the opening of cAMP-gated ion channels and the initiation an action potential.

An obvious challenge presented to an investigator by the large size of the OR family is to match each OR with the one or more odorant molecules to which it binds. Dramatic progress was made by taking advantage of our knowledge of the OR signal-transduction pathway. A section of nasal epithelium from a mouse was loaded with the calcium-sensitive dye Fura-2. The tissue was then treated with different odorants, one at a time, at a specific concentration (Figure 14.43). If the odorant had bound to an OR and activated it, that neuron could be

detected under a microscope by the change in fluorescence caused by the influx of calcium that takes place as part of the signal-transduction process.

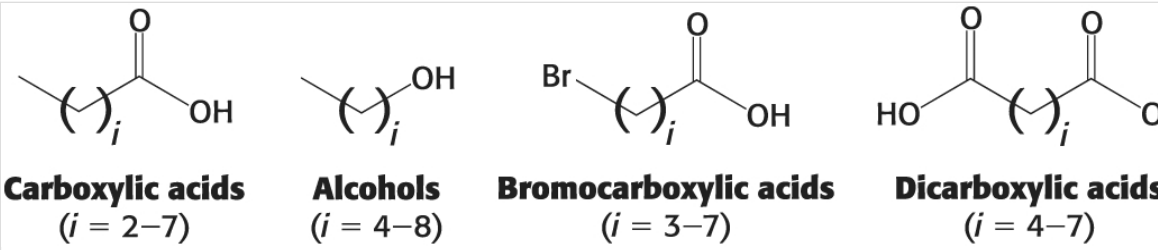

FIGURE 14.43 Olfactory-receptor activation has been tested with sets of closely related compounds. The structures of four series of compounds are shown.

To determine which OR was responsible for the response, cDNA was generated from mRNA that had been isolated from single identified neurons, and cDNAs were produced that encoded ORs. These studies revealed there is not a simple 1:1 correspondence between odorants and receptors. Almost every odorant activates a number of receptors (usually to different extents) and almost every receptor is activated by more than one odorant (Figure 14.44). Note, however, that each odorant activates a unique combination of receptors. This combinatorial mechanism allows even a small array of receptors to distinguish a vast number of odorants.

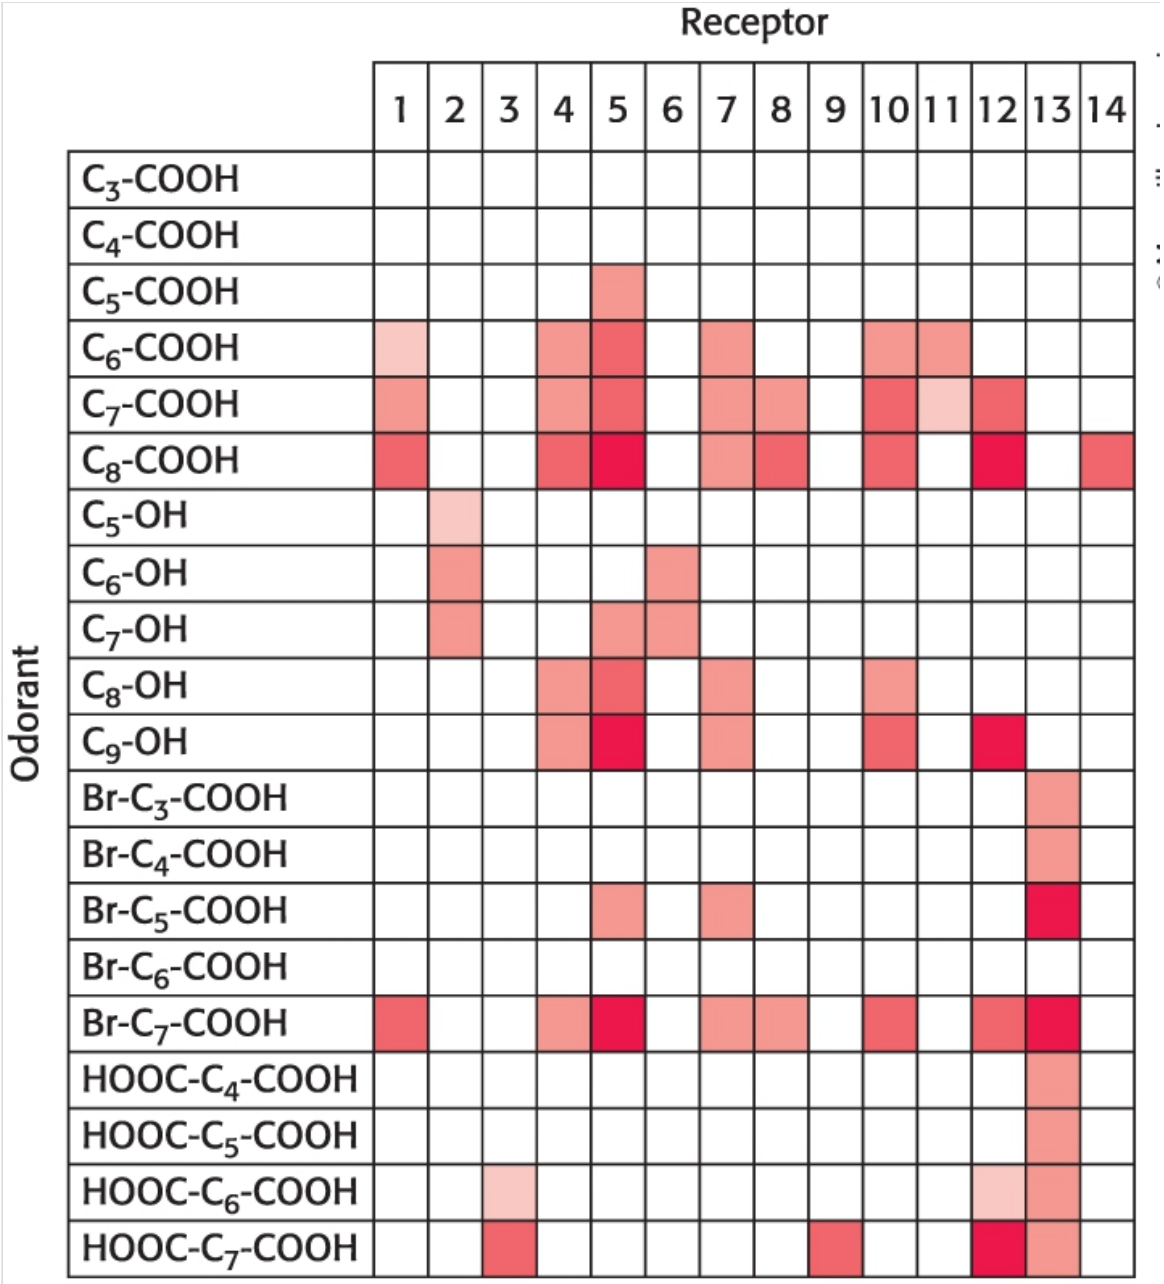

FIGURE 14.44 Different compounds result in distinct patterns of olfactory-receptor activation
Fourteen different receptors were tested for responsiveness to the compounds shown in Figure 14.43. A colored box indicates that the receptor at the top responded to the compound at the le Darker colors indicate that the receptor was activated at a lower concentration of odorant.

One of the manifestations of COVID-19 in many people is a loss of the sense of smell. While the cause of this is still under investigation, a clue has come from genomic studies of populations of individuals who either have or have not lost their sense of smell. These studies have suggested that enzymes that add sugars to some odorants to help terminate olfactory signaling may differ in these two groups of people. This example highlights another mechanism for signal termination, but also another role of carbohydrates that we will see again when we discuss drug metabolism.

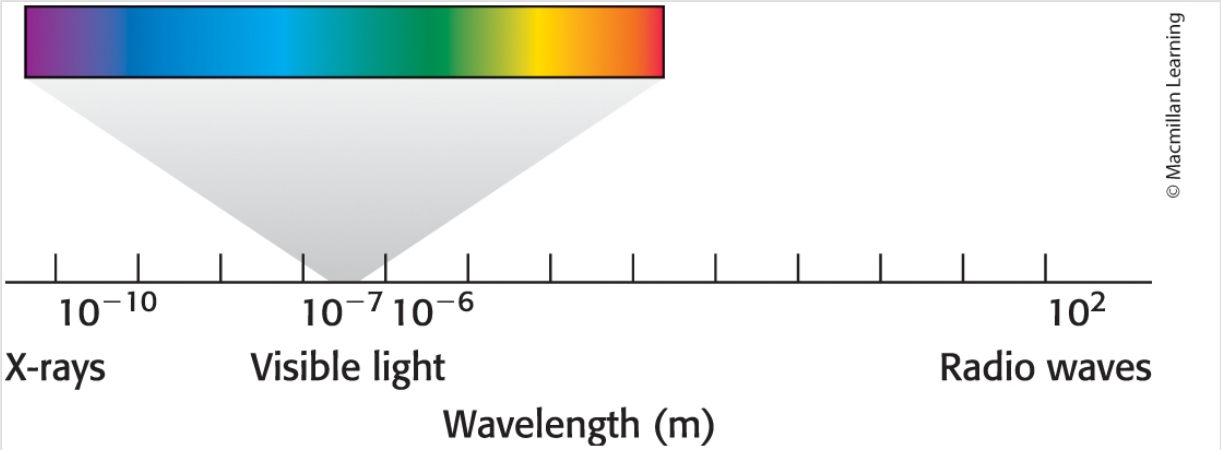
Self-Check Question

What symptoms would you expect if an individual had a mutation that disrupted an olfactory receptor gene?

Vision relies on a specialized 7TM receptor to signal in response to absorbed light

We now turn from olfaction to vision. Vision is based on the absorption of light by photoreceptor cells in the eye. These cells are sensitive to light in a narrow region of the electromagnetic spectrum — the region with wavelengths between 390 and 750 nm (Figure 14.45). Vertebrates have two kinds of photoreceptor cells, called rods and cones because of their distinctive shapes. Cones function in bright light and are responsible for color vision, whereas rods function in dim light but do not perceive color. A human retina contains about 3 million cones and 100 million rods. Remarkably, a rod cell can respond to a single photon,

and the brain requires fewer than 10 such responses to register the sensation of a flash of light.



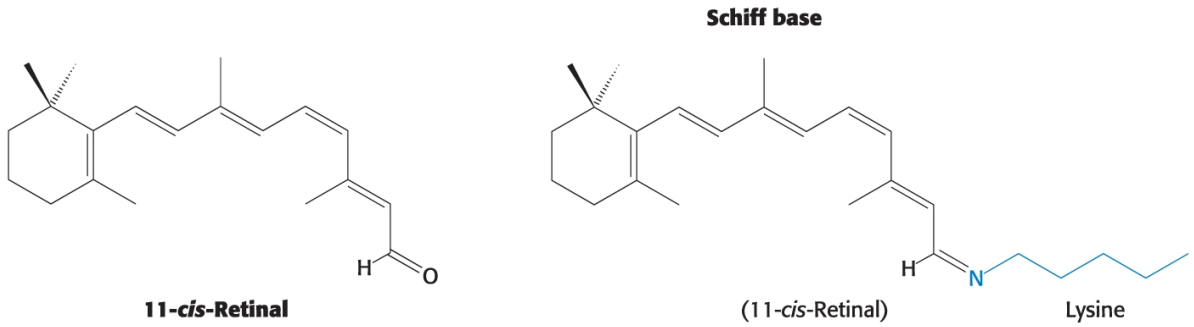


FIGURE 14.45 Visible light represents a small region of the electromagnetic spectrum. Visible light has wavelengths between 390 and 750 nm.

Rods are slender, elongated structures; the outer segment is specialized for photoreception (Figure 14.46). It contains a stack of about 1000 discs, which are membrane-enclosed sacs densely packed with photoreceptor molecules. The photosensitive molecule is often called a visual pigment because it is highly colored owing to its ability to absorb light. The photoreceptor molecule in rods is rhodopsin, which consists of the protein opsin linked to 11-*cis*-retinal, a prosthetic group, via a lysine residue.

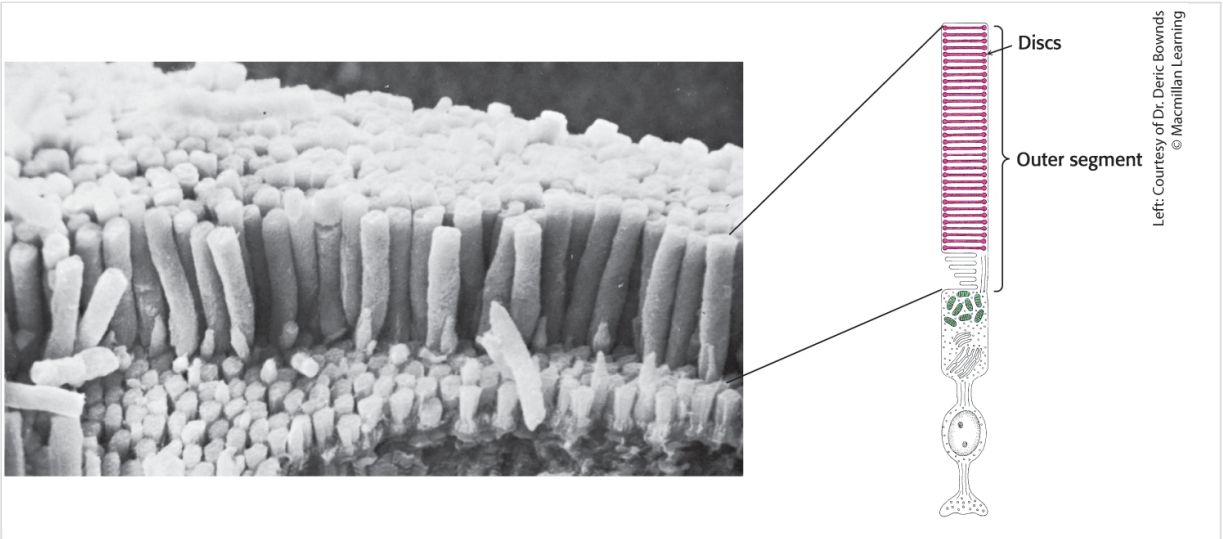

FIGURE 14.46 Rod cells have elongated structures including stacked discs where light absorption occurs. (Left) A scanning electron micrograph of retinal rod cells. (Right) A schematic representation of a rod cell.

Rhodopsin absorbs light very efficiently in the middle of the visible spectrum, its absorption being centered on 500 nm, which nicely matches the solar output (Figure 14.47). A rhodopsin molecule will absorb a high percentage of the photons of the correct wavelength that strike it. Opsin is a member of the 7TM-receptor family. Indeed, rhodopsin was the first member of this family to be purified, its gene was the first to be cloned and sequenced, and its three-dimensional structure was the first to be determined. The color of rhodopsin and its responsiveness to light depend on the presence of the light-absorbing group 11-*cis*-retinal.

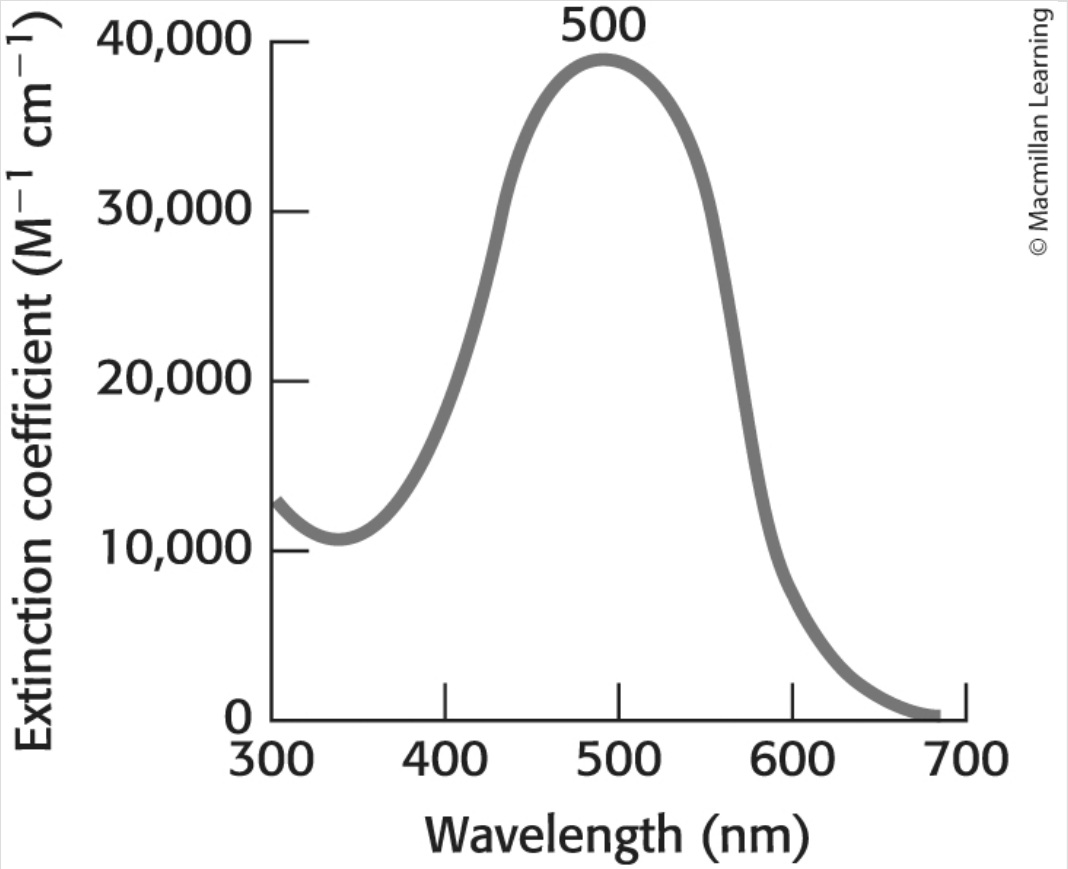

FIGURE 14.47 Rhodopsin absorbs light quite effectively toward the blue end of the visible spectrum. The absorption spectrum of rhodopsin is shown. The large ($> 10{,}000\ M^{-1}\ cm^{-1}$) extinction coefficients reveal that most of the light striking a rhodopsin molecule is absorbed.

Light absorption induces a specific isomerization of bound 11-*cis*-retinal

How does the absorption of light by retinal generate a signal? George Wald and his coworkers discovered that light absorption results in the isomerization of the 11-*cis*-retinal group of rhodopsin to its all-trans

form (Figure 14.48). This isomerization causes the nitrogen atom from the linked lysine residue to move approximately 5Å, assuming that the cyclohexane ring of the retinal group remains fixed. In essence, the light energy of a photon is converted into atomic motion. The change in atomic positions, like the binding of a ligand to other 7TM receptors, sets in motion a series of events that lead to the closing of ion channels and the generation of a nerve impulse.

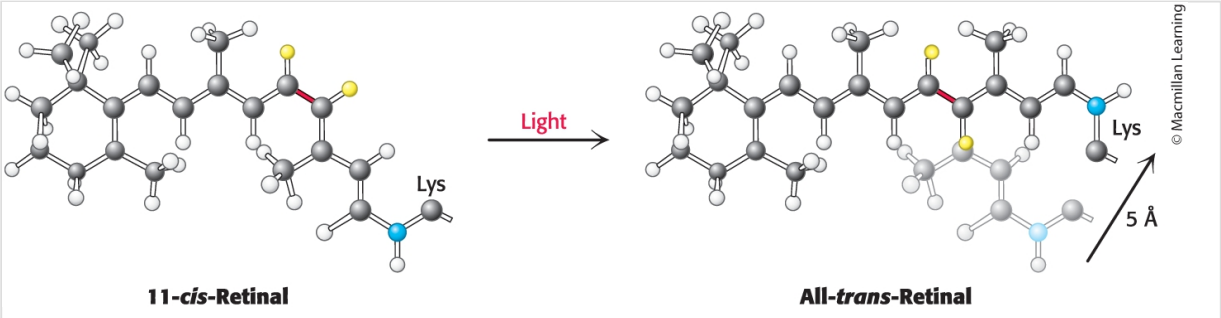

FIGURE 14.48 Isomerization of retinal results in a substantial motion. The nitrogen atom of the lysine residue linked to retinal moves 5Å as a consequence of the light-induced isomerization of 11-*cis*-retinal to all-*trans*-retinal by rotation about the bond shown in red.

Like these receptors, this form of rhodopsin activates a heterotrimeric G protein that propagates the signal. The G protein associated with rhodopsin is called transducin. Light absorption and retinal isomerization triggers the exchange of GDP for GTP by the α subunit of transducin (Figure 14.49). On the binding of GTP, the βγ subunits of transducin are released and the GTP form of the α subunit is free to bind to its target. The target for transducing is not adenylate cyclase, but rather a specific cGMP phosphodiesterase. Transducin binds to an inhibitory subunit of this enzyme and removes it. The activated phosphodiesterase is a potent enzyme that rapidly hydrolyzes cGMP to GMP. The reduction in cGMP concentration causes cGMP-gated ion channels to close, leading to the hyperpolarization of the membrane and neuronal signaling. At each step in this process, the initial signal —

the absorption of a single photon — is amplified so that it leads to sufficient membrane hyperpolarization to result in signaling. For a multistep, enzyme-based process, the visual signal-transduction system is strikingly fast, responding in approximately 1 ms.

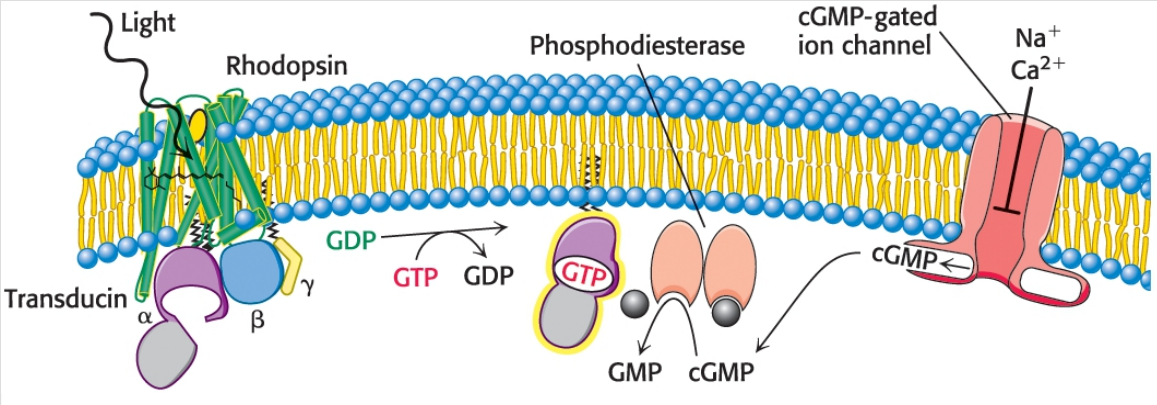

FIGURE 14.49 Visual signal transduction involves G-protein activation of cGMP phosphodiesterase. The light-induced activation of rhodopsin activates a novel G protein, transducin, which leads to the hydrolysis of cGMP. This, in turn, leads to ion-channel closing and the initiation of an action potential.

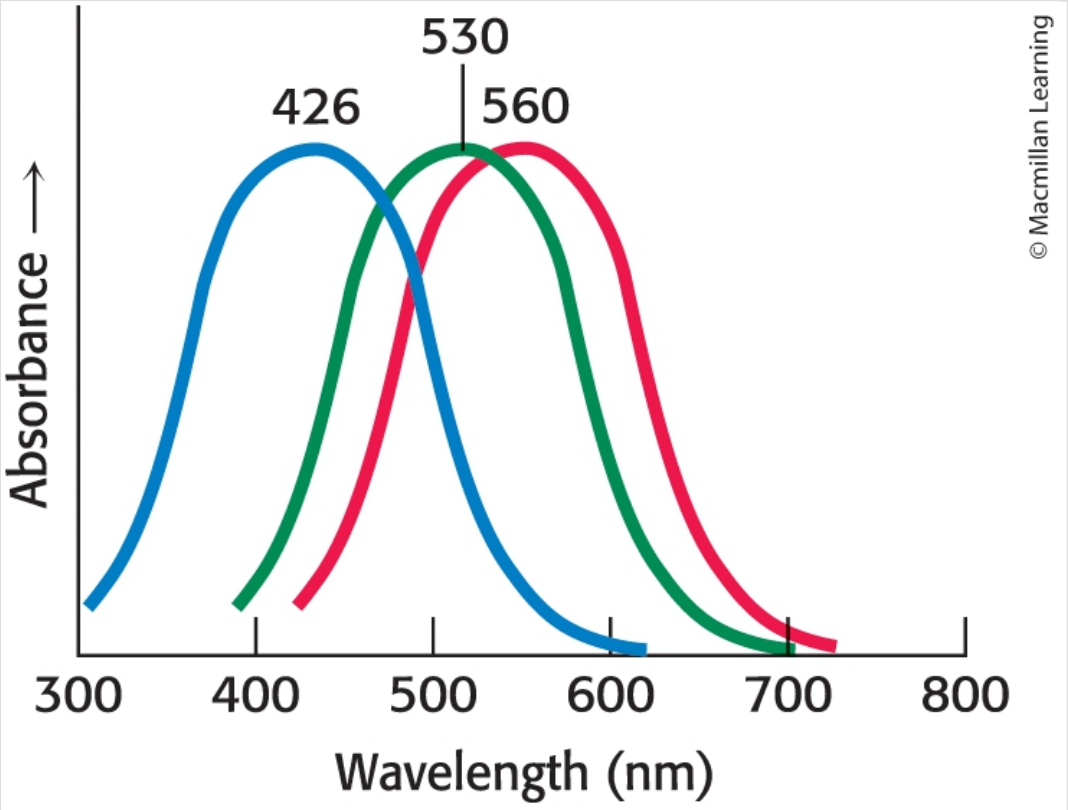
Color vision is mediated by three cone receptors that are homologs of rhodopsin

Cone cells, like rod cells, contain visual pigments. Like rhodopsin, these photoreceptor proteins are members of the 7TM-receptor family and use 11-*cis*-retinal as their chromophore. In human cone cells, there are three distinct photoreceptor proteins with absorption maxima at 426, 530, and ~560 nm (Figure 14.50). These absorbances correspond to the blue, green, and yellow-green regions of the spectrum. Recall that the absorption maximum for rhodopsin is 500 nm. The photoreceptor protein with its absorption maximum near 560 nm absorbs red light

(with wavelength > 620 nm), whereas the other two photoreceptors do not. These three proteins are often referred to as the blue, green, and red photoreceptors. The cone photoreceptors signal through pathways that are identical to that used by rhodopsin.



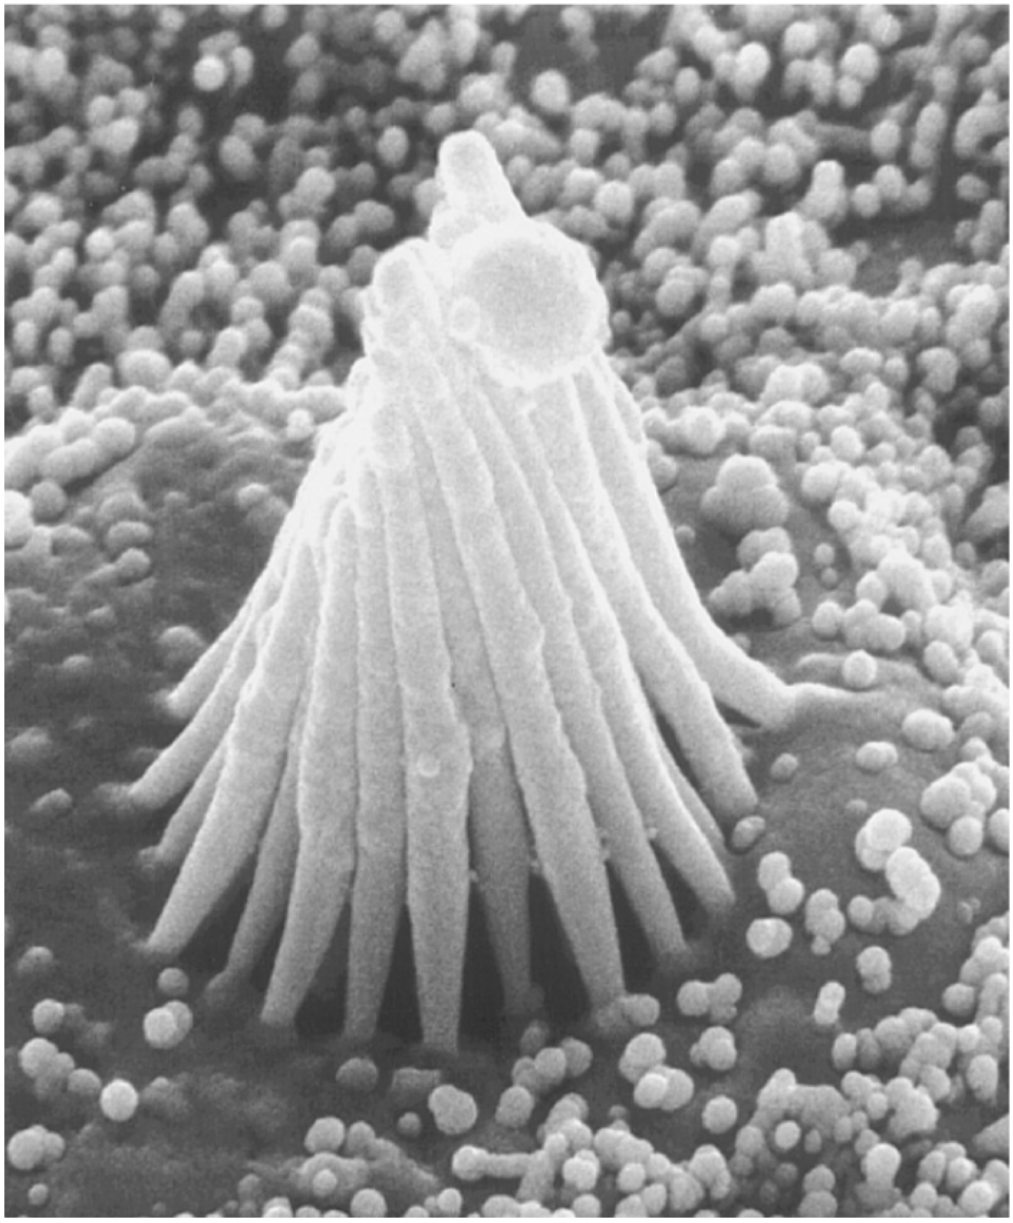


FIGURE 14.50 Color vision is mediated by visual pigments that absorb light of different colors. The absorption spectra of the three types of light receptors from human cone cells are shown.

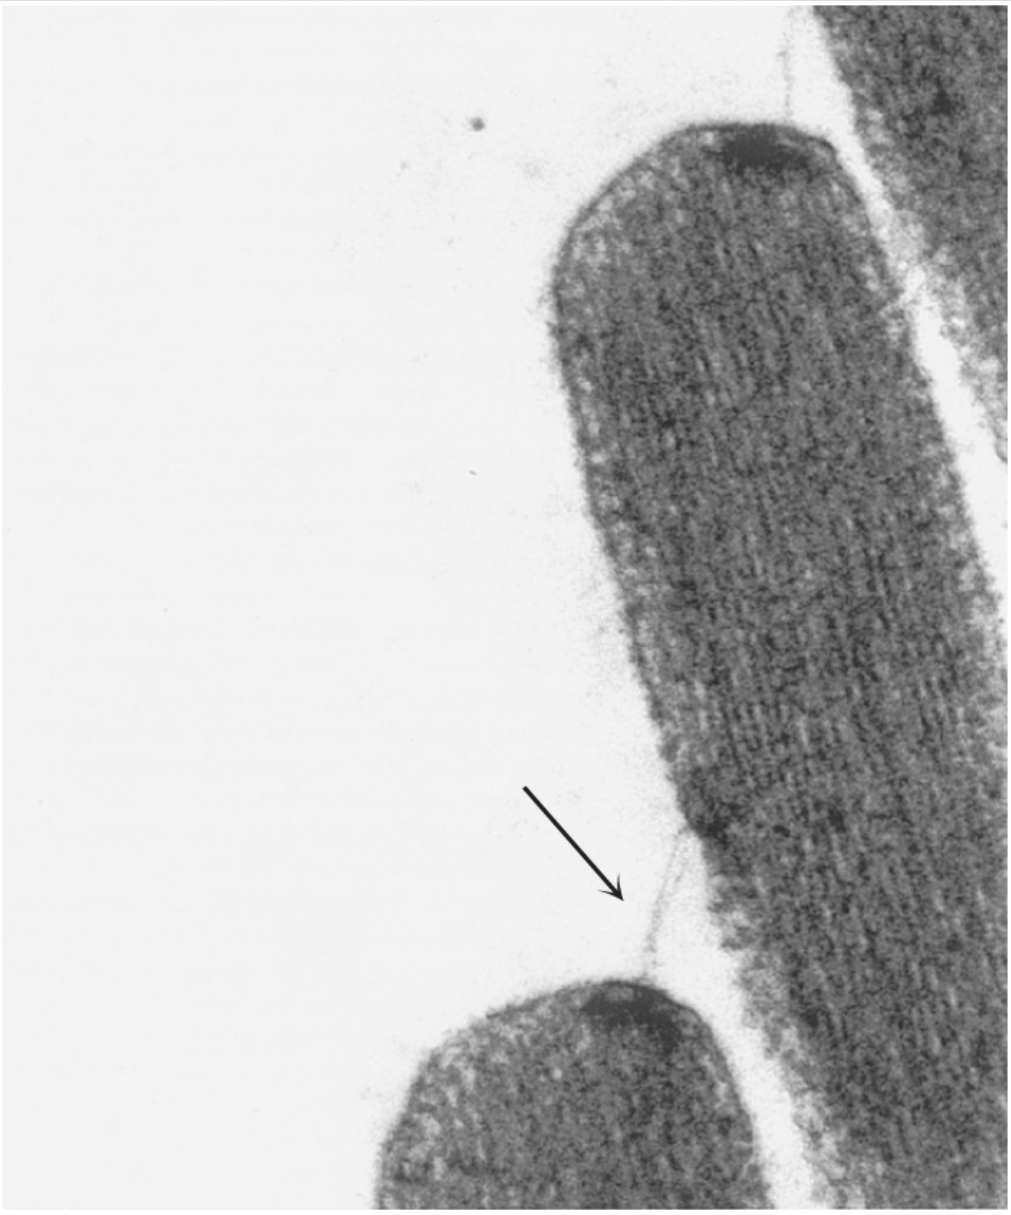
The decoding of color vision is analogous to olfaction. Each cone expresses only one of the photoreceptors, but most wavelengths of light activate more than one type of photoreceptor. Our brains compare the signals from the three classes of cones to assign a color to an object in our field of view based on the light that it reflects.

Hearing depends on hair cells that use mechanosensitive ion channels to detect tiny motions

The first indications that we had about our animal intruder were the sounds we heard coming from behind us. Our sense of hearing operates at a remarkable speed. We hear frequencies ranging from 200 to 20,000 Hz (cycles per second), corresponding to times of 5 to 0.05 ms. Furthermore, our ability to locate sound sources — one of the most important functions of hearing — depends on the ability to detect the time delay between the arrival of a sound at one ear and its arrival at the other. Given the separation of our ears and the speed of sound, we must be able to accurately sense time differences of 0.7 ms. In fact, human beings can locate sound sources associated with temporal delays as short as 0.02 ms. This high time resolution implies that hearing depends on direct transduction mechanisms that do not use enzymes or second messengers.

Sound waves are detected inside the cochlea of the inner ear. The cochlea is a fluid-filled, membranous sac that is coiled like a snail shell. The primary detection is accomplished by specialized neurons inside the cochlea called hair cells. Each cochlea contains approximately 16,000 hair cells, and each hair cell contains a hexagonally shaped bundle of 20 to 300 hairlike projections called stereocilia (**Figure 14.51**). These stereocilia are graded in length across the bundle. Mechanical deflection of the hair bundle, as takes place when a sound wave arrives at the ear, creates a change in the membrane potential of the hair cell.



Courtesy of R. Jacobs and A.J. Hudspeth

FIGURE 14.51 Hearing is mediated by bundles of stereocilia on hair cells. An electron micrograph of a stereocilia bundle is shown.

Micromanipulation experiments have directly probed the connection between mechanical stimulation and membrane potential. Displacement toward the direction of the tallest part of the hair bundle results in the depolarization of the hair cell, whereas displacement in

the opposite direction results in its hyperpolarization. Remarkably, displacement of the hair bundle by as little as 3Å (0.3 nm) results in a measurable (and functionally important) change in membrane potential. This motion of 0.001 degree corresponds to a 0.3-inch movement of the top of a 100-story building.

The rapid response, within microseconds, suggests that the movement of the hair bundle acts on ion channels directly. An important observation is that adjacent stereocilia are linked by individual filaments called tip links (**Figure 14.52**). The presence of these tip links suggests a simple mechanical model for transduction by hair cells (**Figure 14.53**). The tip links are coupled to ion channels in the membranes of the stereocilia that are gated by mechanical stress. In the absence of a stimulus, approximately 15% of these channels are open. When the hair bundle is displaced toward its tallest part, the stereocilia slide across one another and the tension on the tip links increases, causing additional channels to open. The flow of ions through the newly opened channels depolarizes the membrane. Conversely, if the displacement is in the opposite direction, the tension on the tip links decreases, the open channels close, and the membrane hyperpolarizes. Thus, the mechanical motion of the hair bundle is directly converted into current flow across the hair-cell membrane. Many of the molecular components of this elegant micromechanical system have now been identified, including those from the mechanosensitive ion channel and the tip link filaments, as well as specialized myosin motors that maintain appropriation tension in the system.

Courtesy of R. Jacobs and A.J. Hudspeth

FIGURE 14.52 Tip links that connect adjacent stereocilia are crucial for signal detection in hearing. An electron micrograph of tip links is shown. The tip link between two stereocilia is marked by an arrow.

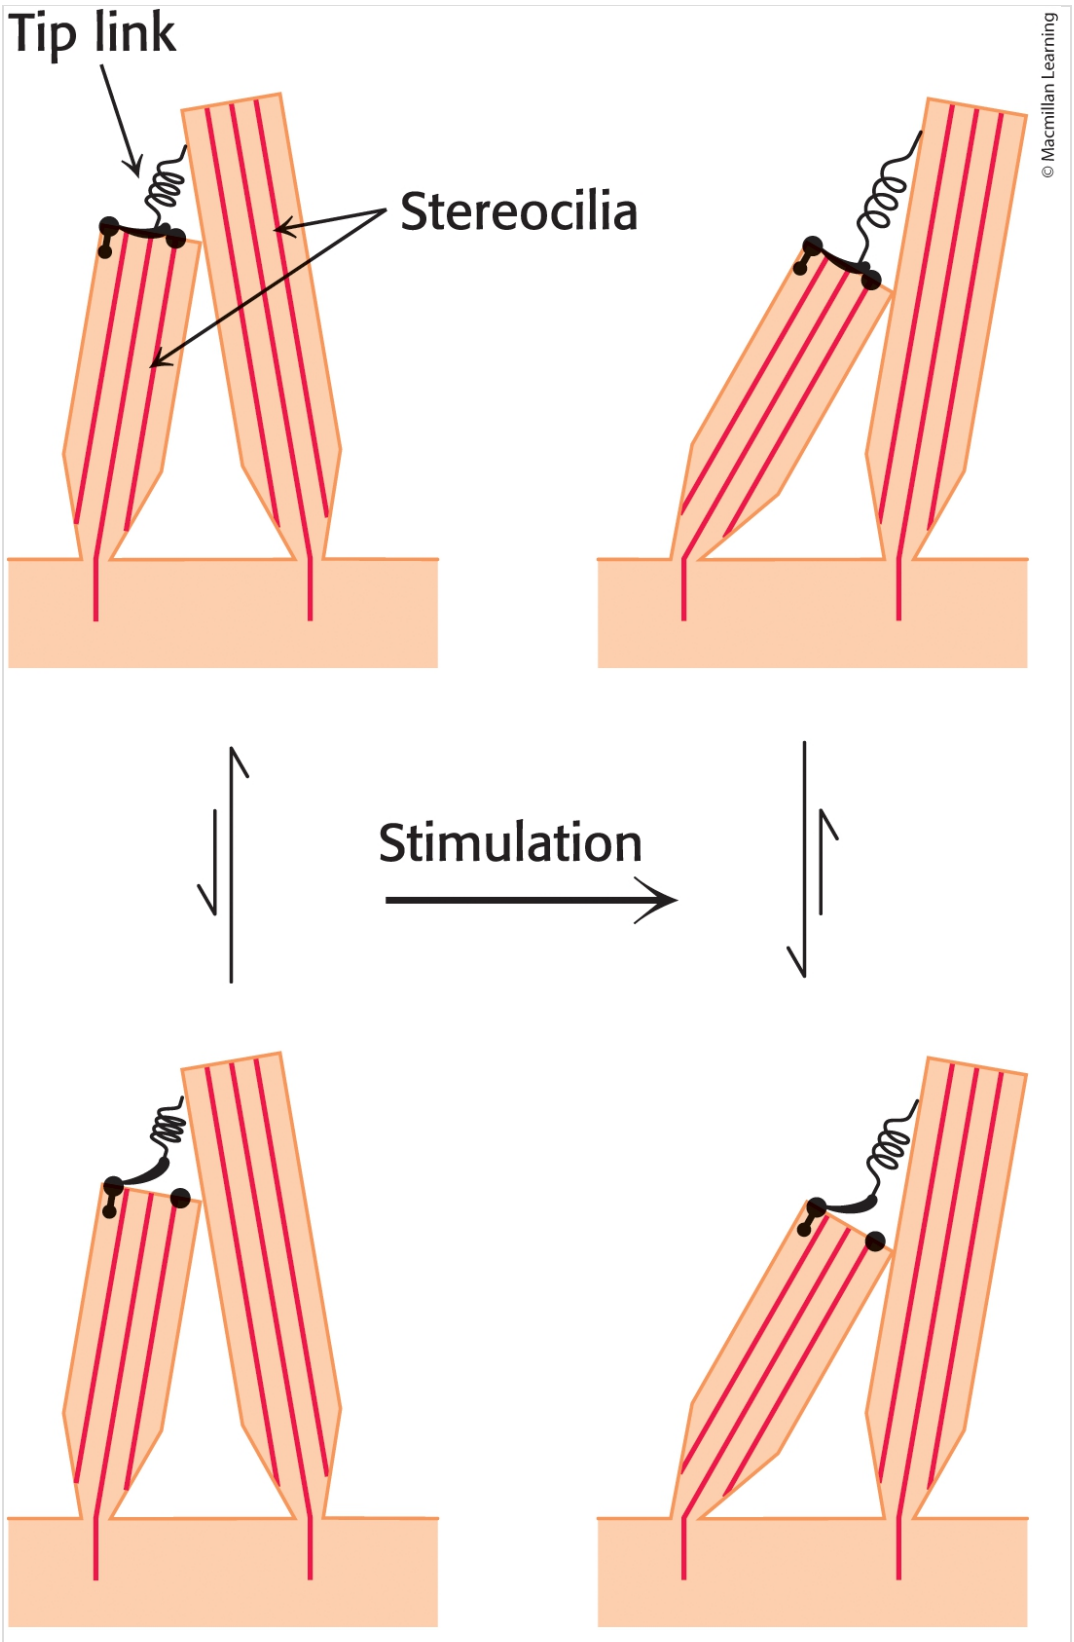


FIGURE 14.53 Hair cell signal detection involves ion-channel opening in response to small displacements of stereocilia bundles. When the hair bundle is tipped

toward the tallest part, the tip link pulls on an ion channel and opens it. Movement in the opposite direction relaxes the tension in the tip link, increasing the probability that any open channels will close.

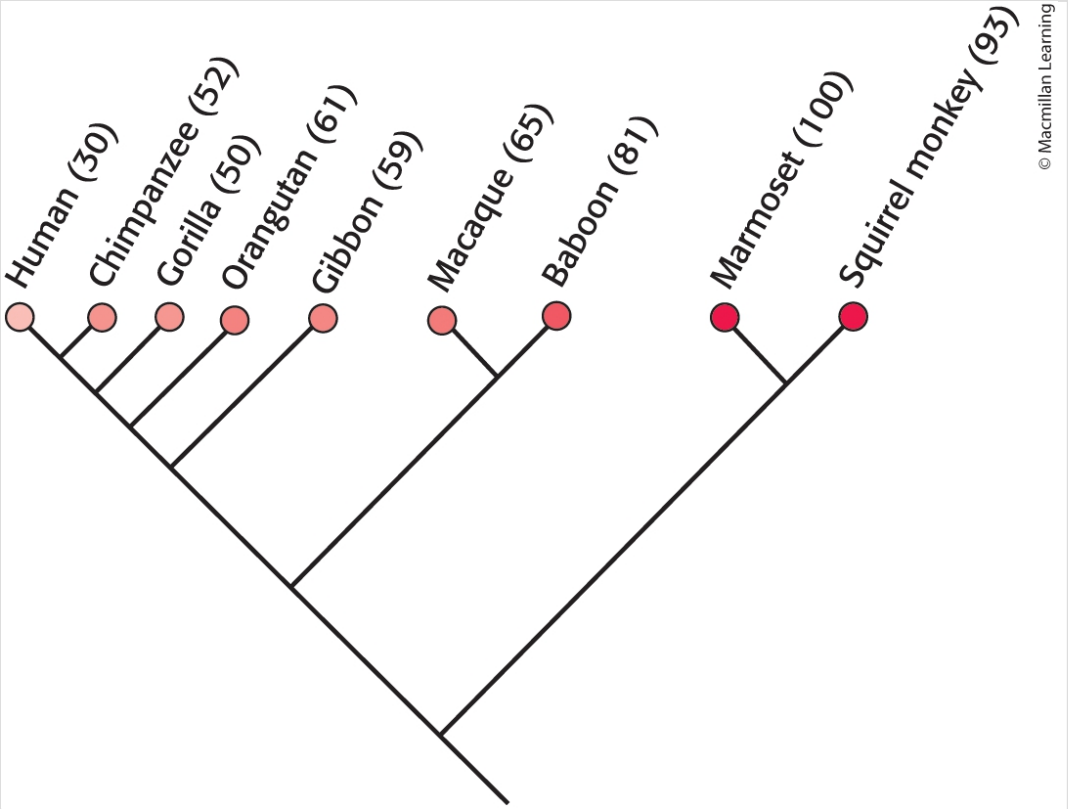
[Information from A. J. Hudspeth, *Nature* 341:397–404, 1989 and M. Beurg, R. Fettiplace, J. H. Nam, and A. J. Ricci, *Nature Neuroscience* 12:553–558, 2009.]

Self-Check Question

What are the primary signals in olfaction, vision, and hearing? Compare the mechanisms by which these primary signals are first detected in the three sensory systems.

Comparison of different organisms yields insights into sensory system evolution

In addition to representing instructive examples of applying the knowledge we have gained about signal-transduction pathways, sensory systems also provide compelling glimpses into evolution at the molecular level. As we noted, rodents have more than 1000 ORs, whereas our genomes only include only approximately 400 functional genes. Further examination reveals that our genomes contain hundreds of OR pseudogenes, DNA segments that encode ORs but have one or more defects so that they will not produce functional receptors. Examination of other organisms reveals a steady conversion from functional OR genes into pseudogenes over the course of the primate evolution (Figure 14.54).



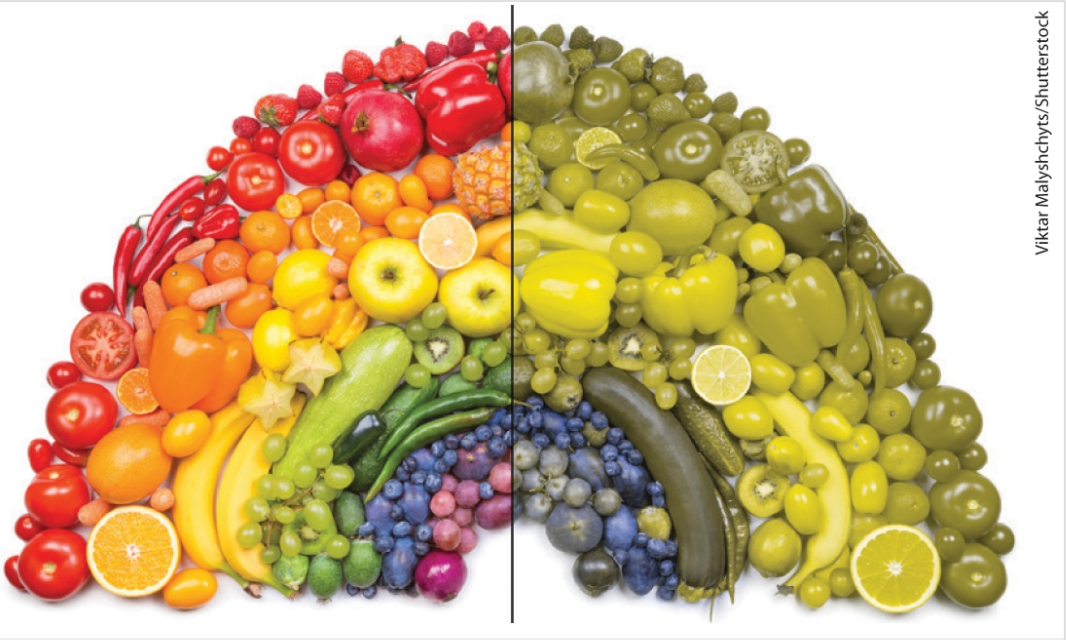


FIGURE 14.54 Functional odorant receptor genes have been lost over the course of primate evolution. Odorant receptors appear to have lost function through conversion into pseudogenes during primate evolution. The percentage of OR genes that appear to be functional for each species is given in parentheses.

The opposite has occurred with regard to color vision. Human beings and many other primates have three cone receptors. Most other placental mammals have only two. Thus, rodents as well as organisms such as dogs do sense color but are not capable of distinguishing color such as red and green as well as we are. Indeed, some human beings have variations in their visual pigments (so-called “color blindness”) so that they see colors differently (Figure 14.55). Earlier ancestors of all animals had four cone pigments as do some modern organisms such as many birds. In addition to better color discrimination, the absorption spectra extend further into the ultraviolet region so that they can sense colors that we cannot. These differences provide vivid examples of how

signal-transduction pathways have a profound influence on how we experience the world.

Viktar Malyshchyts/Shutterstock

FIGURE 14.55 More colors can be distinguished with three versus two cone pigments. The left side of the image shows its appearance with three cone pigments, while the right side show its appearance with two. Most human beings have three functional pigments, whereas mammals such as rodents and dogs have two.

Chapter 14 Summary

14.1 Many Signal-Transduction Pathways Share Common Themes

- Most signal-transduction pathways involve a common set of steps: Binding of a primary messenger to a receptor on the cell surface; transduction of the information across the cell membrane to the interior of the cell; a change in the concentration of one or more second messenger molecules inside the cell; initiation of other processes by the second messenger; and termination of the signaling.
- Signal-transduction processes can be very intricate as they occur with variation in different biological contexts and cell types, but common themes and classes of molecules do occur.

14.2 Epinephrine Signaling: Heterotrimeric G Proteins Transmit Signals and Reset Themselves

- Hormones such as epinephrine bind to members of a large family of cell-surface receptors that have a common structure of seven transmembrane (7TM) helices.
- When activated by ligand binding, these 7TM helix receptors bind to specific heterotrimeric G proteins and stimulate the release of bound GDP and the binding of GTP in the α subunit of the G protein.
- When activated by GTP binding, the α subunit of the G protein releases the heterodimer consisting of the β and γ subunits and then binds to other targets such as the enzyme adenylate cyclase.
- Stimulation of adenylate cyclase increases the concentration of the second messenger cyclic AMP, which, in turn, activates protein kinase A.
- Some 7TM receptors signal through different heterotrimeric G proteins that inhibit the activity of adenylate cyclase or activate

the phosphoinositide pathway, starting with the activation of phospholipase C, which cleaves a membrane lipid to produce two secondary messengers, diacylglycerol and inositol 1,4,5-trisphosphate.
- G-protein signaling is terminated by the hydrolysis of the bound GTP to GDP.

14.3 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes

- Protein kinases are key components in many signal-transduction pathways, including some for which the protein kinase is an integral component of the initial receptor.
- Insulin binds to a dimeric receptor that includes an intracellular tyrosine kinase as part of its structure that is activated by the kinase domain of one subunit of the dimer phosphorylating certain tyrosine residues on the other subunit.
- The activated receptor kinase initiates a signaling cascade that includes both lipid kinases and protein kinases that eventually leads to the mobilization of glucose transporters to the cell surface, increasing glucose uptake.
- Insulin signaling is terminated through the action of phosphatases.

14.4 Epidermal Growth Factor: Receptor Dimerization Can Drive Signaling

- Epidermal growth factor also signals through a receptor tyrosine kinase, but this receptor is a monomer prior to EGF binding.
- EGF binding induces a conformational change that allows receptor dimerization and cross-phosphorylation.
- The phosphorylated receptor binds adaptor proteins that mediate the activation of Ras, a small G protein that initiates a protein kinase cascade that eventually leads to the

phosphorylation of transcription factors and changes in gene expression.
- EGF signaling is terminated by the action of phosphatases and the hydrolysis of GTP by Ras.

14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases

- Genes encoding components of signal-transduction pathways that control cell growth are often mutated in cancer.
- Some genes can be mutated to forms called oncogenes that are active regardless of appropriate signals.
- Monoclonal antibodies directed against cell-surface receptors that participate in signaling have been developed for use in cancer treatment.
- Our understanding of the molecular basis of cancer has enabled the development of anticancer drugs directed against specific targets, such as specific protein kinase inhibitors.

14.6 Sensory Systems Are Based on Specialized Signal-Transduction Pathways

- Olfaction involves a large family of 7TM receptors that signal through a pathway involving adenylate cyclase, leading to ion-channel opening.
- Vision uses a specialized 7TM receptor called rhodopsin that includes a covalently bound ligand, 11-*cis*-retinal, that isomerizes upon absorbing light, activating the receptor.
- Color vision is mediated by a set of three receptors similar to rhodopsin that tune the absorption of light to different wavelengths.
- Hearing involves specialized cells called hair cells that have bundles of stereocilia that move subtly in response to sound waves in the air.

- Signal transduction is very fast, depending on the direct coupling of stereocilia motion to ion-channel opening, without any chemical steps.

Key Terms

transduction
primary messenger
receptor
second messenger
epinephrine (adrenaline)
adrenergic receptor
seven-transmembrane-helix (7TM) receptor
agonist
G protein
G-protein-coupled receptor (GPCR)
adenylate cyclase
calmodulin (CaM)
EF hand
antagonist
insulin
activation loop
pleckstrin homology domain
oncogene
proto-oncogene
tumor-suppressor gene

Problems

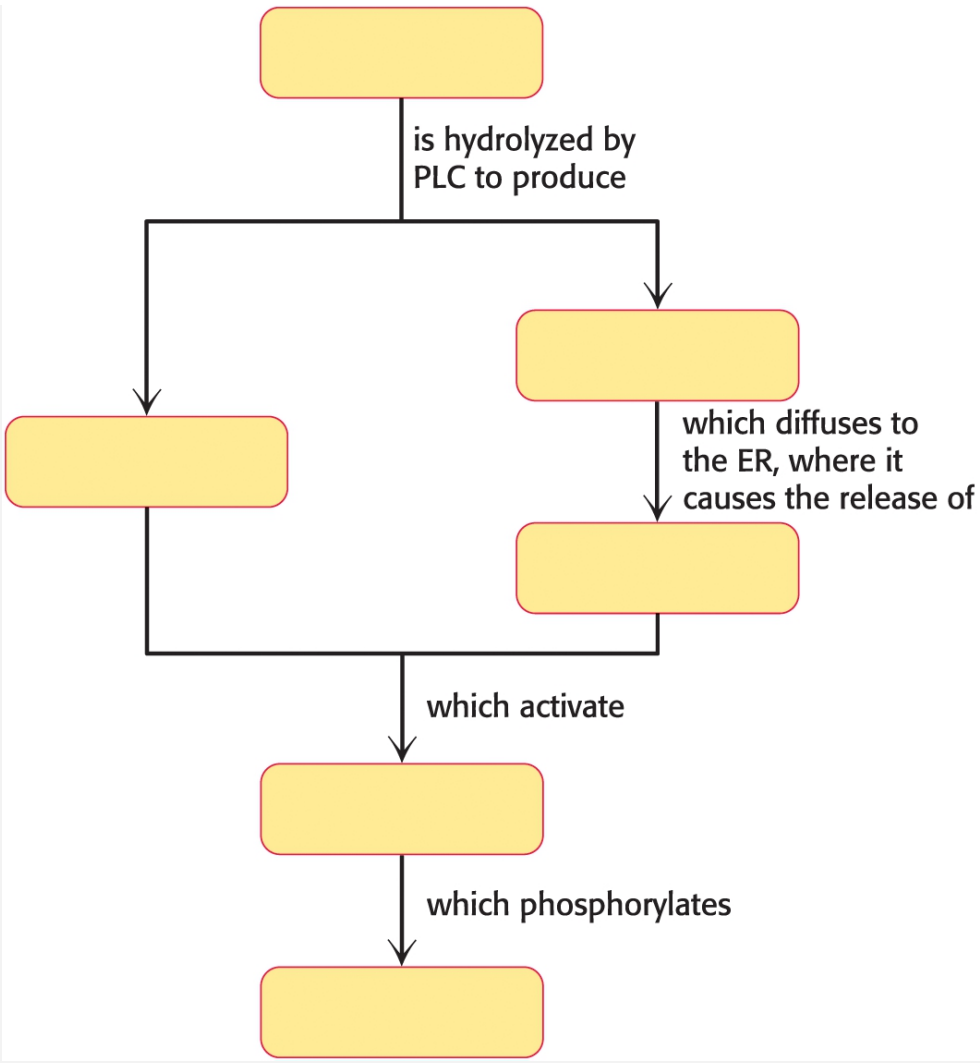
1. Place the steps of the insulin-signaling pathway in the correct order: 1

a. Phosphorylation of IRS proteins
b. Alteration of glucose metabolism in response to insulin
c. Binding of insulin to the α subunit of the insulin receptor
d. Activation of insulin receptor tyrosine kinase
e. Activation of PKB by PDK1
f. Recruitment of PI3K to the cell membrane
g. Conversion of PIP_2 to PIP_3

2. Glucagon is a hormone that is released when the level of circulating glucose in the blood is low. Glucagon signals the cell via a $G_{\alpha s}$ signaling pathway. Put the steps of the glucagon signal-transduction pathway in order. 1

a. Adenylate cyclase converts ATP to cAMP.
b. $G_{\alpha s}$ releases GDP and binds GTP.
c. Glucagon binds extracellularly to the G-protein-coupled receptor.
d. Activated $G_{\alpha s}$ activates adenylate cyclase.
e. cAMP activates protein kinase A (PKA).
f. PKA activates enzymes needed for glucose release.

3. Suppose that each β-adrenergic receptor bound to epinephrine converts 100 molecules of $G_{\alpha s}$ into their GTP forms and that each molecule of activated adenylate cyclase produces 1000 molecules of cAMP per second. With the assumption of a full response, how many molecules of cAMP will be produced in 10 s after the formation of a single complex between



epinephrine and the β-adrenergic receptor? Assume the pathway is fully responsive. 1

4. A mutated form of the α subunit of the heterotrimeric G protein has been identified; this form readily exchanges nucleotides even in the absence of an activated receptor. What would be the effect on a signaling pathway containing the mutated α subunit? 5

5. Glucose is mobilized for ATP generation in muscle in response to epinephrine, which activates $G_{\alpha s}$. Cyclic AMP phosphodiesterase is an enzyme that converts cAMP into AMP. How would inhibitors of cAMP phosphodiesterase affect glucose mobilization in muscle? 2

6. Some G-protein-coupled receptors are sensitive to hormones such as angiotensin II and oxytocin and act through molecules such as phospholipase C (PLC) and IP_3. 1

a. Complete the flowchart showing the cleavage of a membrane lipid to form compounds that ultimately cause the phosphorylation of specific proteins. Use the following terms to complete the steps: IP_3, Ser/Thr residues, DAG, PIP_3, PKC, Ca^{2+}.

© Macmillan Learning

b. Of the terms you used to complete the chart, which can be considered second messengers?

7. Consider the structure of calmodulin (Figure 14.19). Which of the following statements are correct?

a. Calmodulin contains two Ca^{2+} binding sites.

b. Binding of Ca^{2+} activates calmodulin.

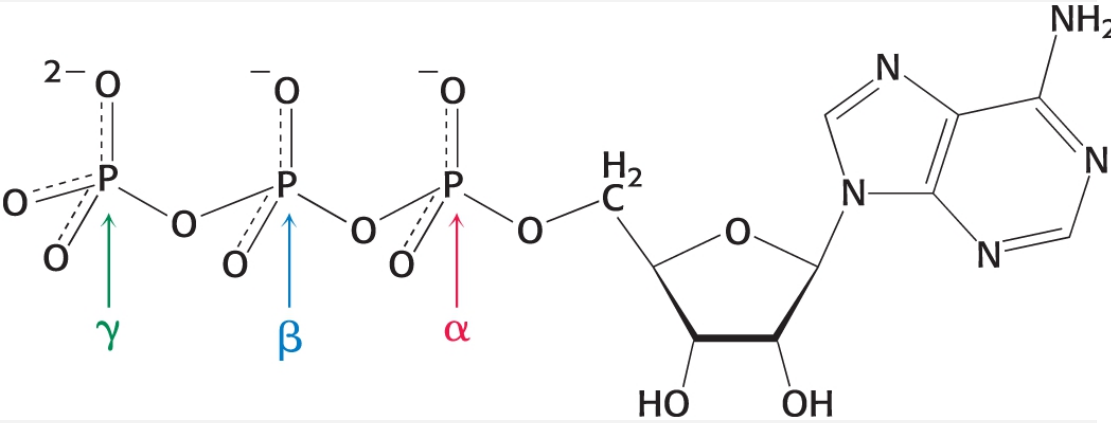
c. Each calcium-binding domain in calmodulin is formed from a helix-loop-helix motif.
d. Calmodulin is a structural subunit of proteins such as CaM kinase.
e. Calmodulin contains a central, flexible β sheet that enables it to wrap around another protein, inhibiting the protein's activity.
f. A calcium ion is bound in the loop of an EF hand.

8. Classify each statement as describing G-protein-coupled receptors, receptor tyrosine kinases, both, or neither: 3

a. An example is the insulin receptor.
b. They transport some ligands through the membrane.
c. Their structure contains seven transmembrane helices.
d. An example is the adrenergic receptor.
e. Receptor activation causes phosphorylation of their cytosolic subunits.
f. Ligand binding induces conformational change in these receptors.
g. They activate heterotrimeric G proteins directly.
h. Autophosphorylation of these receptors can initiate signal.
i. Phosphorylation of these receptors can terminate signal.

9. Drugs like imatinib (Gleevec) and cetuximab (Erbitux) are approved for the treatment of various types of cancer. Contrast these two drugs based on their mechanism of action. 4

10. Which of the following events contribute to the termination of a response in a GPCR signaling pathway? 1

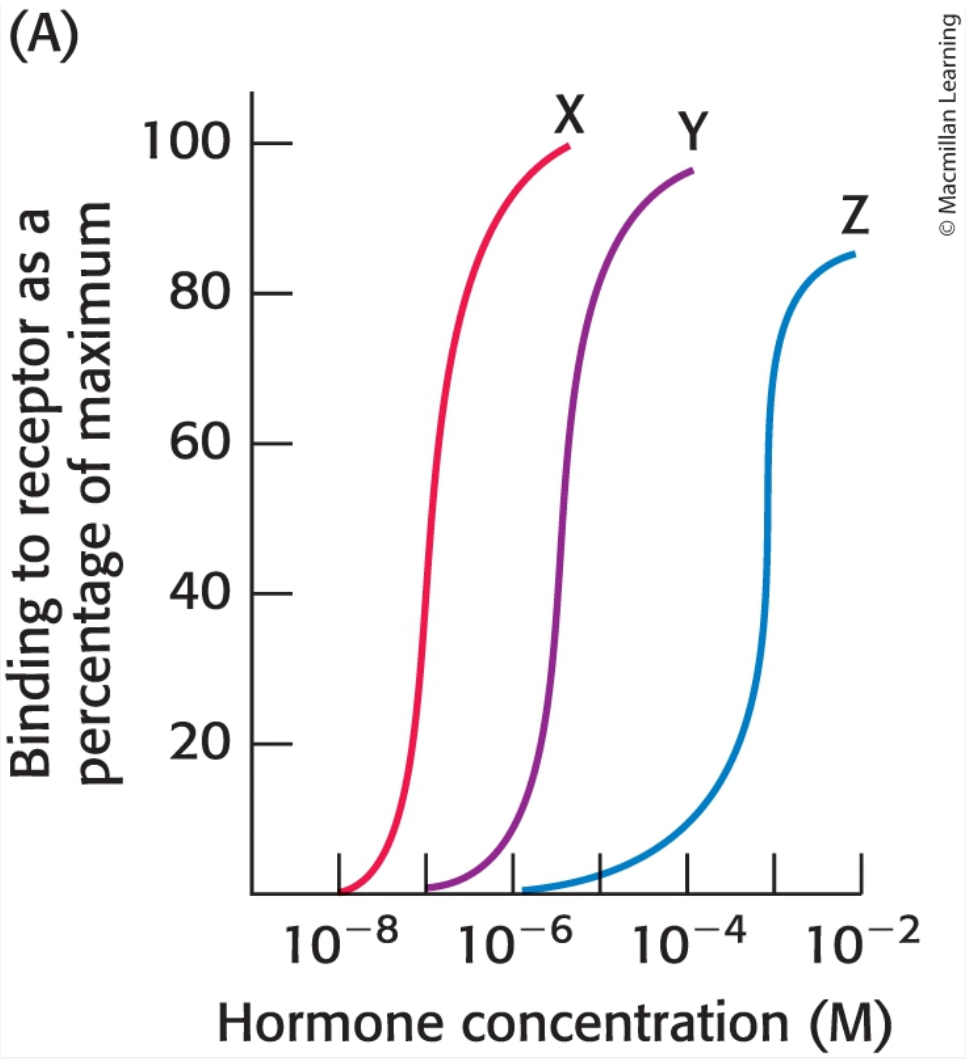


a. The ligand dissociates from the receptor, which resumes its inactive conformation.

b. G_α dissociates from the $G_{\beta\gamma}$ subunits.
c. G_α releases GDP and binds GTP.
d. G_α hydrolyzes GTP to GDP and P_i.
e. The receptor is inactivated by phosphorylation of Ser and other residues on its intracellular domain.

11. The structure of adenylate cyclase is similar to the structures of some types of DNA polymerases, suggesting that these enzymes derived from a common ancestor. Compare the reactions catalyzed by these two enzymes. In what ways are they similar?

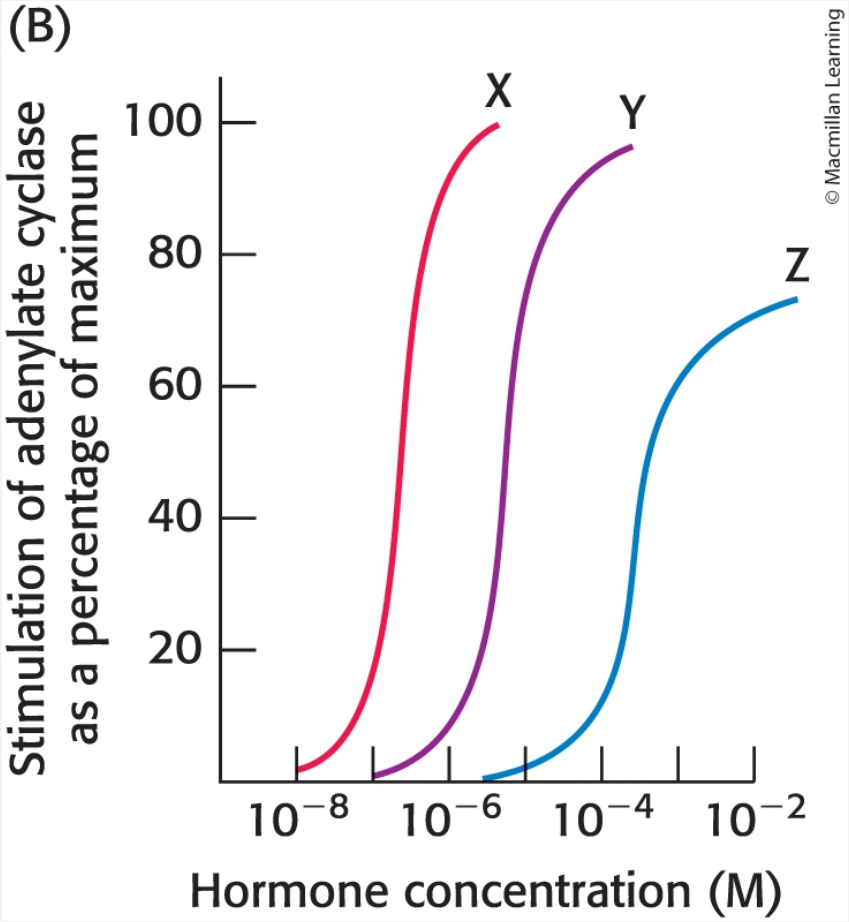
12. Suppose you were investigating a newly discovered growth-factor signal-transduction pathway, involving a G-protein-coupled receptor system. When you add $GTP_{\gamma S}$, a nonhydrolyzable analog of GTP, the duration of the hormonal response increased. Why does the response last longer in the presence of $GTP_{\gamma S}$? 2



13. Consider the structure of ATP, and the identification of the individual phosphate groups.

a. If you wanted to identify the substrates of a particular kinase in a signaling pathway, you should use a version of ATP with ^{33}P-labeling at which phosphate?

b. If you wanted to generate a labeled form of cAMP by the enzymatic action of adenylate cyclase, you should use a version of ATP with ^{33}P labeling at which phosphate?

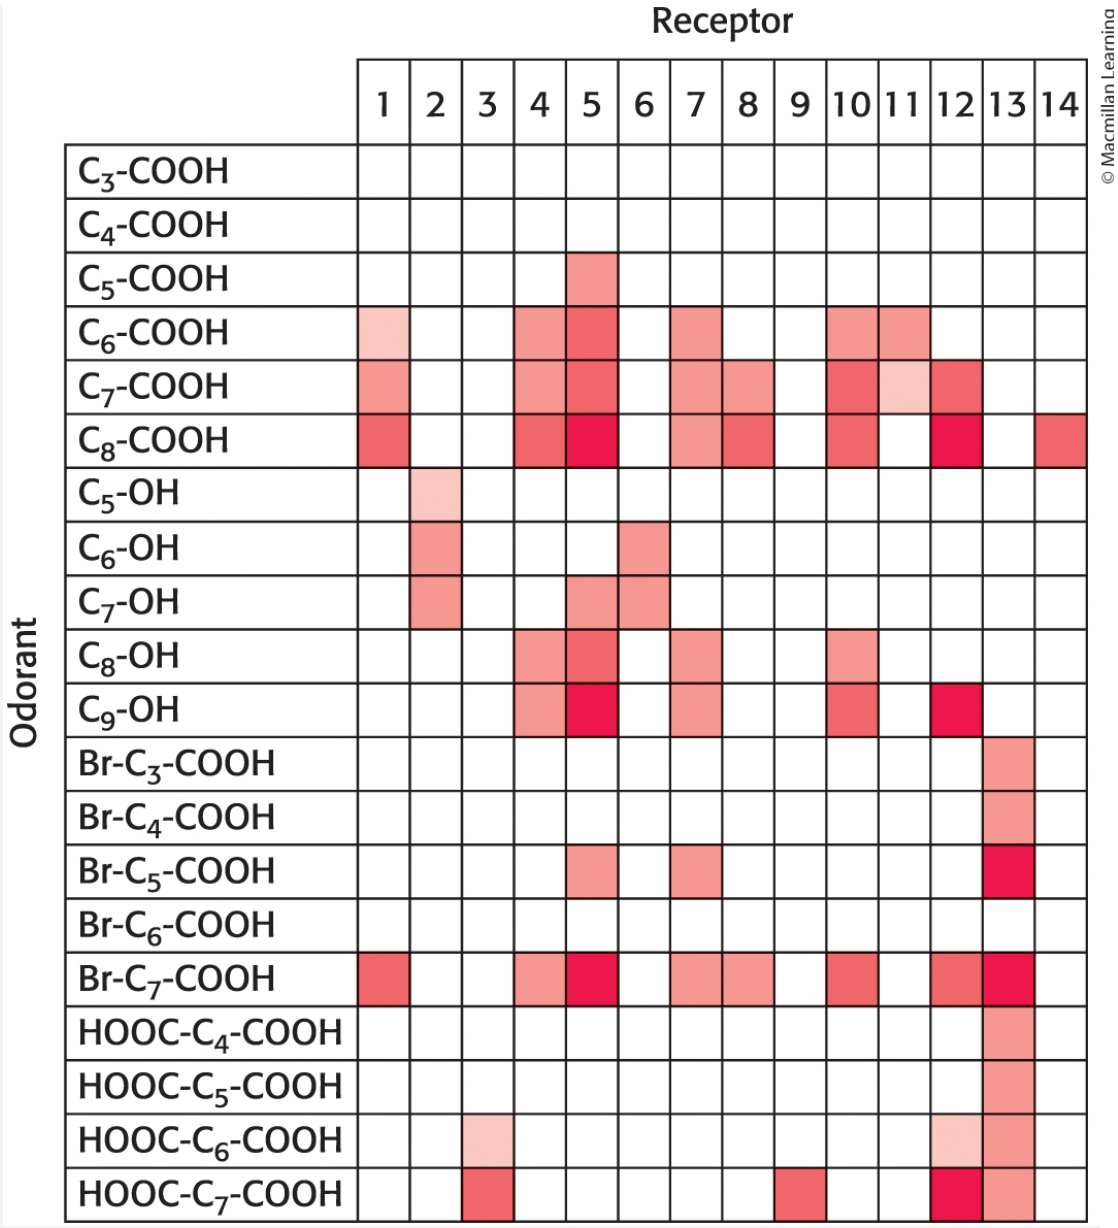


14. You wish to determine the hormone-binding specificity of a newly identified membrane receptor. Three different hormones, X, Y, and Z, were mixed with the receptor in separate experiments, and the percentage of binding capacity of the receptor was determined as a function of hormone concentration, as shown in graph A.

a. What concentrations of each hormone yield 50% maximal binding?
b. Which hormone shows the highest binding affinity for the receptor?

You next wish to determine whether the hormone–receptor complex stimulates the adenylate cyclase cascade. To do so, you measure adenylate cyclase activity

as a function of hormone concentration, as shown in graph B.



c. What is the relationship between the binding affinity of the hormone–receptor complex and the ability of the hormone to enhance adenylate cyclase activity? What can you conclude about the mechanism of action of the hormone–receptor complex?

d. Suggest experiments that would determine whether a $G_{\alpha s}$ protein is a component of the signal-transduction

pathway.

15. Unlike the olfactory neurons in the mammalian systems discussed herein, olfactory neurons in the nematode *C. elegans* express multiple olfactory receptors. In particular, one neuron (called AWA) expresses receptors for compounds to which the nematode is attracted, whereas a different neuron (called AWB) expresses receptors for compounds that the nematode avoids. Suppose that a transgenic nematode is generated such that one of the receptors for an attractant is expressed in AWB rather than AWA. What behavior would you expect in the presence of the corresponding attractant? 5

16. A mixture of two compounds is applied to a section of olfactory epithelium. Only receptors 3, 5, 9, 12, and 13 are activated. Using the figure, identify the likely compounds in the mixture. 5

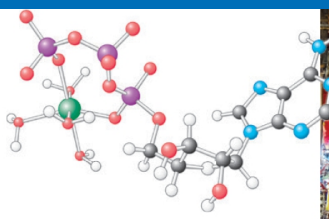
17. Our ability to determine the direction from which a sound is coming is partly based on the difference in time at which our two ears detect the sound. Given the speed of sound $(350\ ms^{-1})$



and the separation between our ears (0.15 m), what difference is expected in the times at which a sound arrives at our two ears? How does this difference compare with the time resolution of the human hearing system? Would a sensory system that utilized 7TM receptors and G proteins be capable of adequate time resolution? 5

18. Suppose humans have 380 different odorant receptors.

a. How many different odorants could a person distinguish if each odorant is bound by a single type of receptor and each receptor binds only a single odorant? 5
b. How many if each odorant binds to two different odorant receptors?
c. How many if each odorant binds to three different odorant receptors?

19. Describe the effect of light absorption on 11-*cis*-retinal bound within rhodopsin. 5

Chapter 15
Metabolism: Basic Concepts and Themes

Dani Salvà/VWPics/Alamy
© Macmillan Learning

Currencies are used as a "go-between" in the exchange of labor and resources: people first earn money and later exchange it for goods and services. In an analogous way, organisms extract and store energy and later use it to power almost all biological processes requiring the input of energy, including homeostasis, biosynthesis, and motion. Within all organisms, this exchange is accomplished during cellular metabolism using a single energy currency: ATP.

Outline

15.1 Metabolism Is Composed of Many Interconnected Reactions
15.2 ATP Is the Universal Currency of Free Energy in Biological Systems
15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy
15.4 Metabolic Pathways Contain Many Recurring Motifs

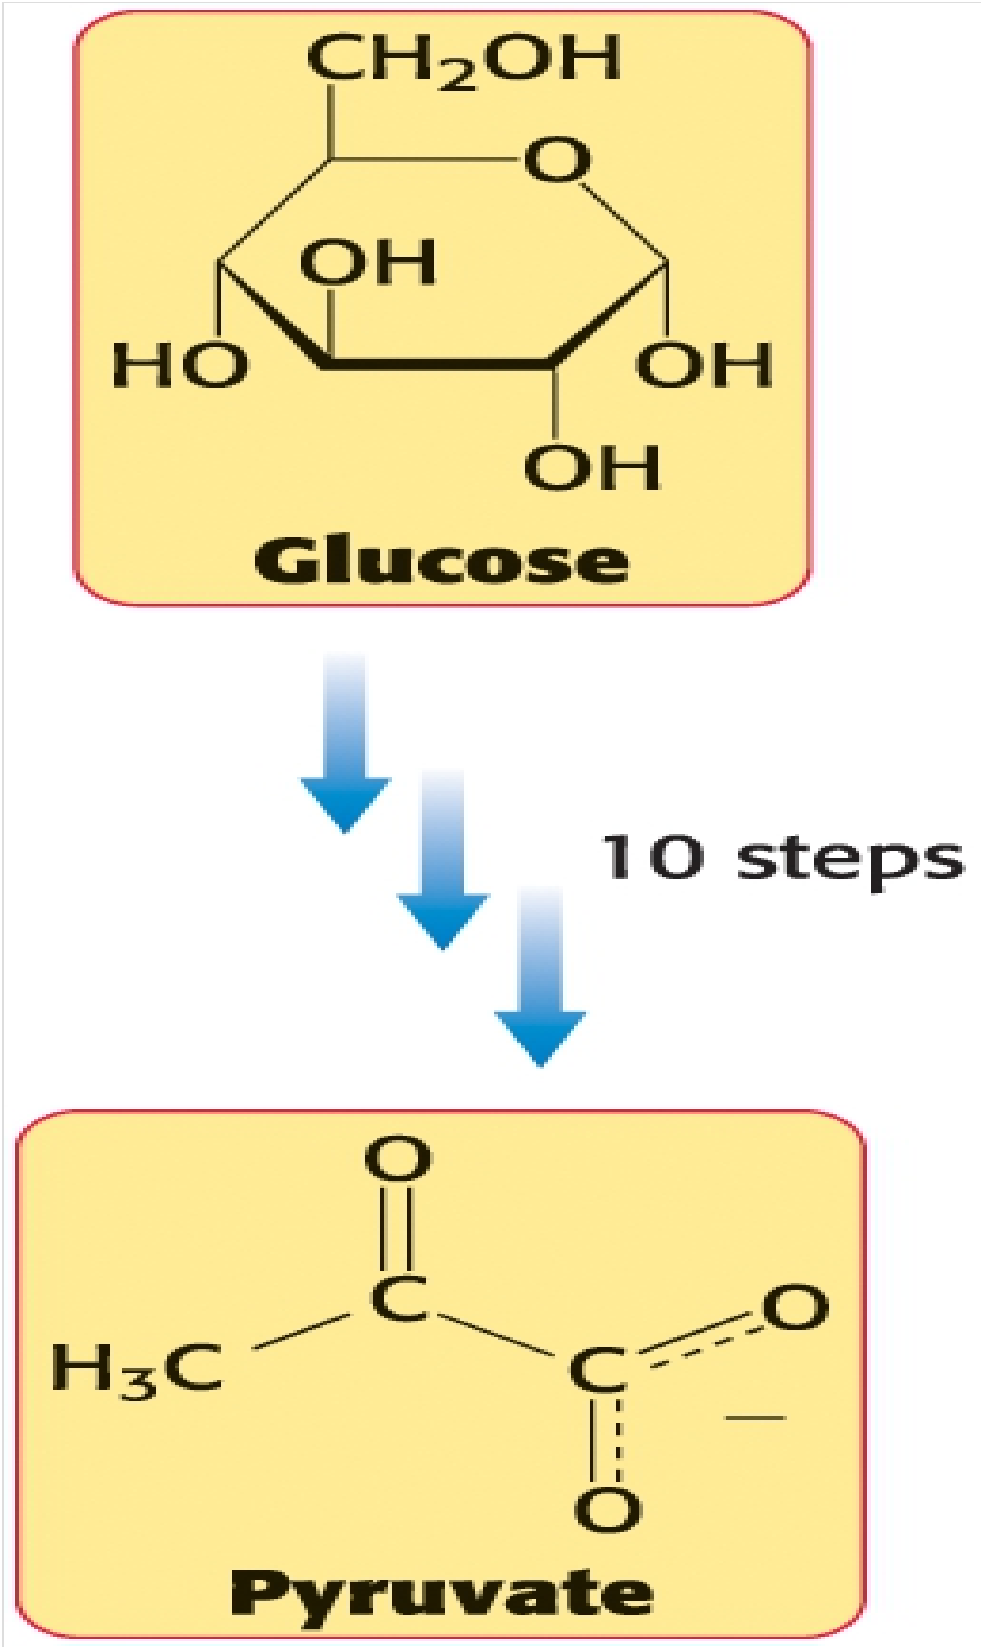
Learning Goals

By the end of this chapter, you should be able to:

1. Explain what is meant by metabolism in terms of both catabolic and anabolic processes.
2. Identify the factors that make ATP a useful molecule for capturing and transferring chemical energy.
3. Explain how ATP can power reactions that would otherwise not take place.
4. Describe the relationship between the oxidation state of a carbon molecule and its usefulness as a fuel.
5. Summarize the recurring motifs in metabolic pathways.

The concepts of conformation and dynamics developed in this book so far — especially those dealing with enzymatic activity and the transport of molecules and ions across membranes — are fundamental tools for understanding biochemistry. In this chapter, you will be introduced to the recurring themes of metabolism that together form the foundation for many of the concepts in the rest of this book. The distinct combinations of a limited selection of enzymes and cofactors can perform a vast array of biochemical feats using the universal energy currency of life, ATP. Combining knowledge of this currency and the themes of metabolism with the concepts of the previous chapters will allow us to tackle two of the fundamental questions of biochemistry:

1. How does a cell extract energy and reducing power from its environment?



2. How does a cell synthesize the building blocks of its macromolecules and then the macromolecules themselves?

While this chapter gives many specific examples of reaction classes and patterns, it's important to first focus on familiarizing yourself with the broad patterns; the examples will be covered in greater depth in subsequent chapters.

15.1 Metabolism Is Composed of Many Interconnected Reactions

Living organisms require a continual input of free energy for three major purposes: (1) mechanical work in muscle contraction and cellular movements, (2) the active transport of molecules and ions, and (3) the synthesis of macromolecules and other biomolecules from simple precursors. The free energy used in these processes, which maintain an organism in a steady state that is far from equilibrium, is derived from the environment. **Phototrophs**, which include all photosynthetic organisms, capture energy from sunlight, whereas **chemotrophs**, which include all animals, capture energy through the oxidation of chemicals, often generated by phototrophs. Despite this difference, all living organisms share a tremendous number of metabolic reactions to utilize and produce lipids, proteins, nucleic acids, and common carbohydrates like glucose.

The fundamental cellular processes of extracting energy and synthesizing new material are carried out by a highly integrated network of chemical reactions collectively known as **metabolism** (or **intermediary metabolism**). Metabolism is essentially a sequence of chemical reactions that begins with a particular molecule and results in the formation of some other molecule or molecules in a carefully defined fashion (**Figure 15.1**). There are many such defined pathways in the cell (**Figure 15.2**), and we will examine a few of them in some detail later. Advances in analytical techniques such as mass spectrometry (Section 4.3) have greatly facilitated the study of metabolism and generated yet another "omics" — metabolomics.

FIGURE 15.1 Glucose metabolism in human beings starts with glycolysis. Glycolysis is a metabolic pathway consisting of 10 linked reactions (steps) transforming the molecules into pyruvate.

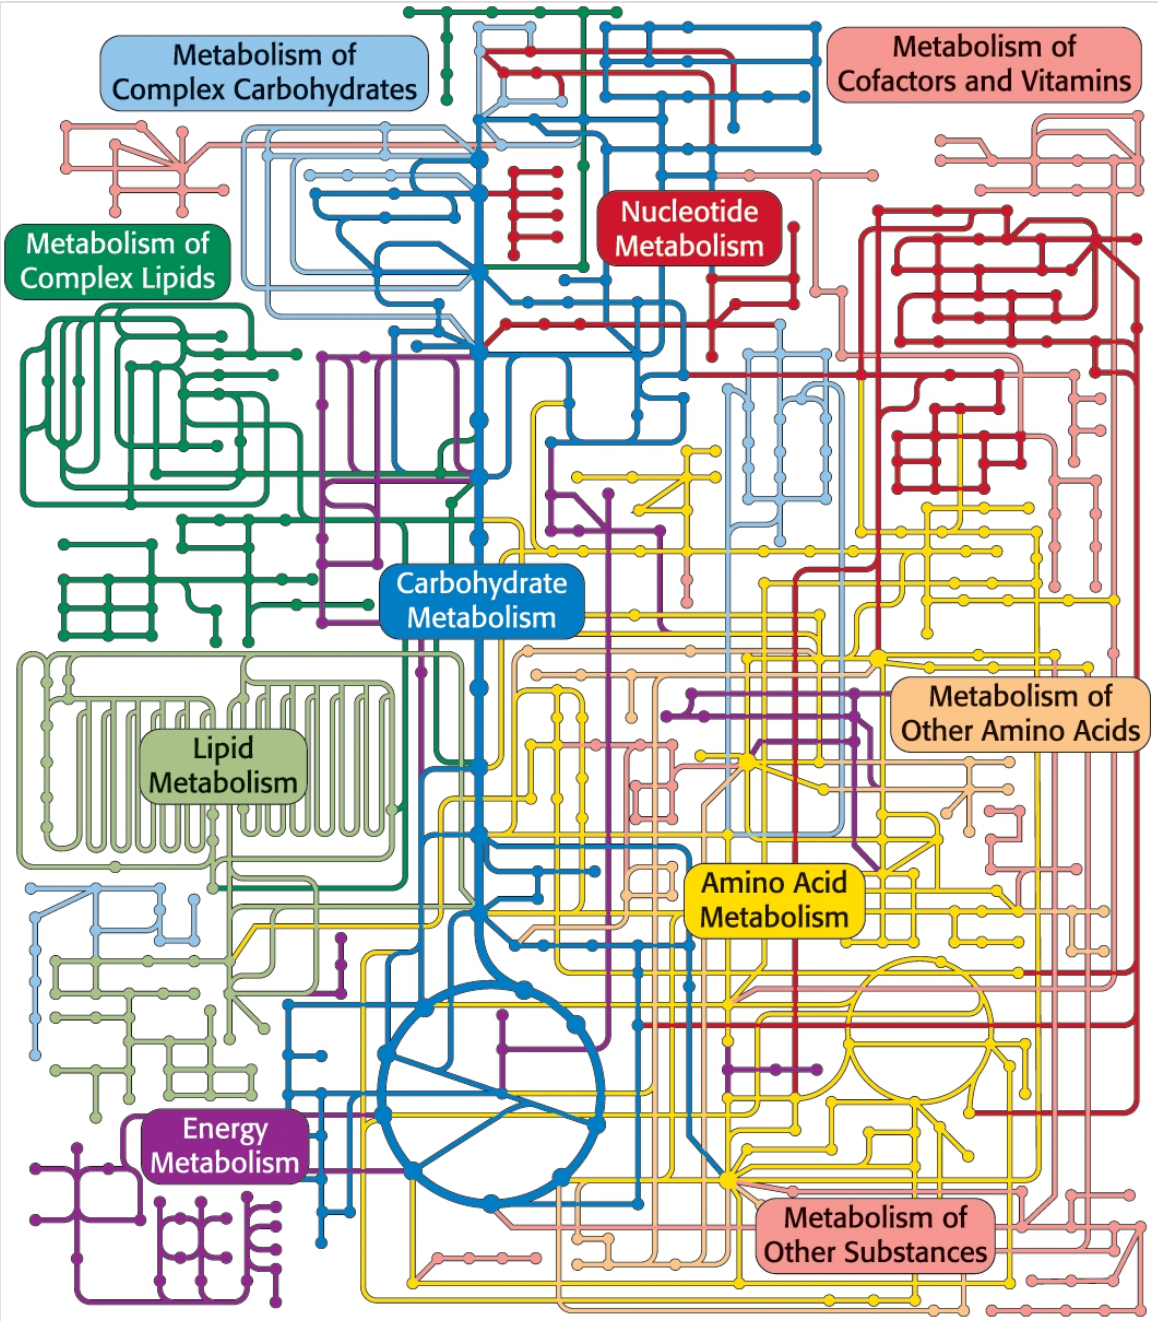

FIGURE 15.2 Metabolic pathways are interconnected series of enzyme-catalyzed reactions. Each node in the diagram represents a specific metabolite, whereas lines connecting nodes represent enzyme-catalyzed reactions. These reactions and the pathways they make up form a deeply integrated network in which reactions communicate with one another through multiple modes of regulation. The details of this figure will be explored over the next 12 chapters.

[From the Kyoto Encyclopedia of Genes and Genomes (www.genome.ad.jp/kegg).]

EXPLORE this pathway further in the Metabolic Map in Achieve

This chapter highlights unifying themes common to all metabolic reactions:

- *Metabolism is a coherent network containing many common motifs.* More than a thousand chemical reactions take place in even as simple an organism as *Escherichia coli*. The array of reactions may seem overwhelming at first glance, but closer scrutiny reveals common motifs. One motif across all life forms is the use of a common energy currency, **adenosine triphosphate (ATP)**, which links energy-releasing (exergonic) pathways with energy-requiring (endergonic) pathways. In all organisms, either sunlight or the oxidation of chemical fuels powers the formation of ATP. Another motif is the repeated appearance of a limited number of activated intermediates; about 100 molecules play central roles in all forms of life.

- *While metabolism involves many different reactions, it uses only a few kinds of mechanisms.* Furthermore, these mechanisms are usually quite simple.

- *Metabolic reactions are highly regulated.* Fuels are degraded and large molecules are constructed step by step in a series of linked reactions called *metabolic pathways*. The total number of intricately connected metabolic pathways taking place in your cells is mind-boggling (Figure 15.2); for obvious reasons, a high degree of

coordination is required to keep all the reactions running smoothly. Metabolic pathways are interdependent, and their activity is carefully coordinated by exquisitely sensitive means of communication in which allosteric enzymes are regulated by small molecules (Chapter 7) as well as being subject to external hormonal control (Chapter 14).

- *Many of the enzymes involved in metabolism are organized into large complexes.* This arrangement increases speed and efficiency by facilitating substrate and product movement between the individual enzymes of the complex. Furthermore, the arrangement allows efficient processing of unstable or even toxic intermediates that are often produced or consumed in metabolic pathways.

Metabolism consists of destructive and constructive reactions that typically yield or require energy

We can divide metabolic pathways into two broad classes: (1) those that convert energy from fuels into biologically useful forms, and (2) those that require inputs of energy to proceed. Although this division is often imprecise, it is nonetheless a useful distinction in an examination of metabolism. Reactions that break down complex molecules, like fuels, into simpler ones are called *catabolic reactions* or, more generally, **catabolism**. Catabolism allows energy to be captured in useful forms, such as the oxidation of carbohydrates and fats which generates ATP along with the waste products carbon dioxide and water.

$$\text{Fuel (carbohydrates, fats)} \xrightarrow{\text{Catabolism}} CO_2 + H_2O + \text{useful energy}$$

Reactions that construct a more complex molecule from simpler components are called *anabolic reactions* or **anabolism**. These reactions — such as the synthesis of glucose, fats, or DNA — usually require energy. Useful forms of energy that are produced in catabolism are employed in anabolism to generate complex structures from simple ones, or energy-rich states from energy-poor ones.

$$\text{Useful energy} + \text{simple precursors} \xrightarrow{\text{Anabolism}} \text{complex molecules}$$

cnding on the energy conditions in the cell. These pathways are referred to as **amphibolic pathways**.

An important general principle of metabolism is that biosynthetic and degradative pathways are almost always distinct. This separation is necessary for energetic reasons, as will be evident in subsequent chapters. It also facilitates the control of metabolism.

A thermodynamically unfavorable reaction can be driven by a favorable reaction

How are specific pathways constructed from individual reactions? A pathway must satisfy minimally two criteria: (1) the individual reactions must be specific, and (2) each of the reactions that constitutes the pathway must be thermodynamically favored under real, rather than standard, conditions. A reaction that is specific will yield only one particular product or set of products from its reactants. As discussed in Section 5.1, enzymes provide this specificity.

The thermodynamics of metabolism are most readily approached in relation to free energy, which was discussed in Sections 1.3 and 5.2. A reaction can occur spontaneously only if ΔG, the change in free energy,

is negative. Recall that ΔG for the formation of products C and D from substrates A and B is given by

$$\Delta G = \Delta G^{\circ\prime} + RT \ln \frac{[C][D]}{[A][B]}$$

Thus, the ΔG of a reaction depends on the nature of the reactants and products (expressed by the $\Delta G^{\circ\prime}$ term, the standard free-energy change) and on their concentrations (expressed by the second term). In a metabolic pathway, reactions with a positive $\Delta G^{\circ\prime}$ can proceed under physiological conditions because the concentrations of reactants and products are far from standard conditions, such that the ΔG of the reaction is negative. Another important thermodynamic fact is that the overall free-energy change for a chemically coupled series of reactions is equal to the sum of the free-energy changes of the individual steps. Consider the following reactions:

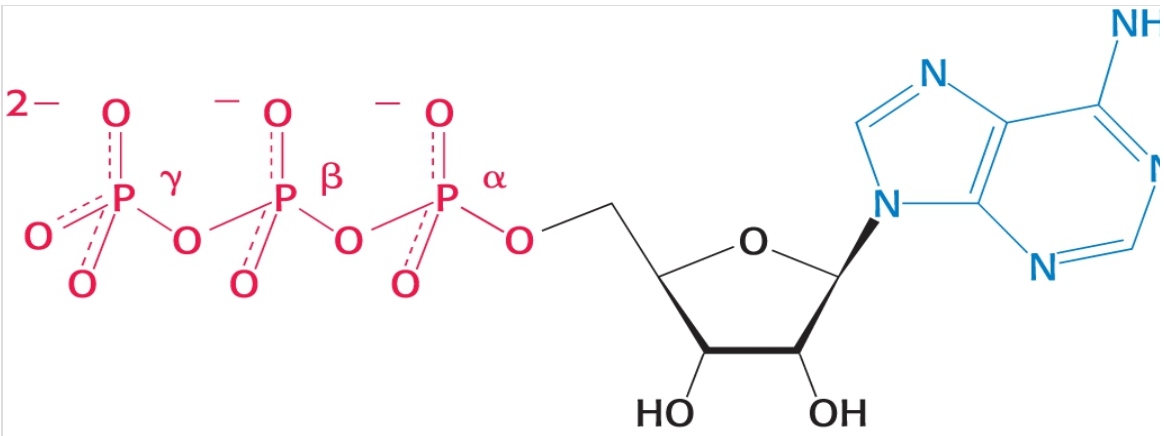
$A \rightleftharpoons B + C$	$\Delta G^{\circ\prime} = +21$ kJ mol^{-1} (+5 kcal mol^{-1})
$B \rightleftharpoons D$	$\Delta G^{\circ\prime} = -34$ kJ mol^{-1} (–8 kcal mol^{-1})
$A \rightleftharpoons C + D$	$\Delta G^{\circ\prime} = -13$ kJ mol^{-1} (–3 kcal mol^{-1})

Under standard conditions, A cannot be spontaneously converted into B and C, because $\Delta G^{\circ\prime}$ is positive. However, the conversion of B into D under standard conditions is thermodynamically feasible; if the two reactions are coupled such that one cannot occur without the other, then the free-energy changes are additive. Thus, the conversion of A

into C and D has a $\Delta G^{\circ\prime}$ of $-13\ \text{kJ mol}^{-1}\ (-3\ \text{kcal mol}^{-1})$, which means that it can occur spontaneously under standard conditions.

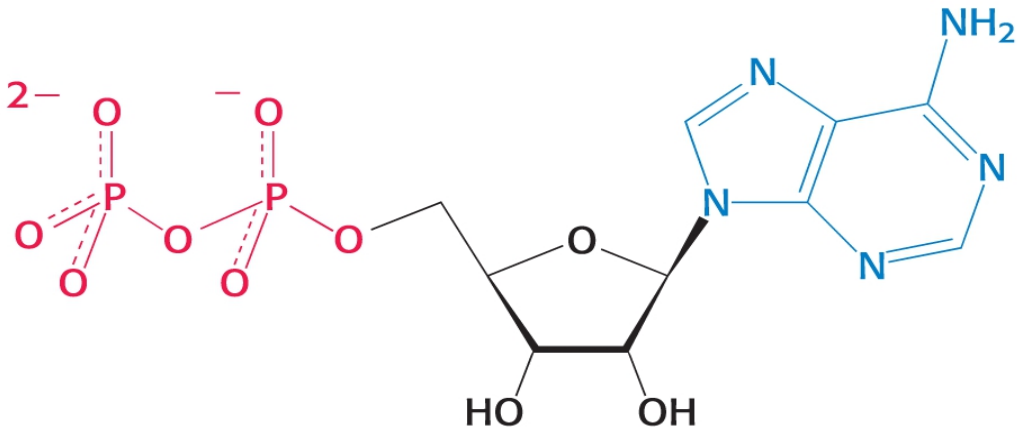
Thus, a thermodynamically unfavorable reaction can be driven by a thermodynamically favorable reaction to which it is coupled. This kind of coupling occurs in the active sites of enzymes; in this example, the reactions are coupled by the shared chemical intermediate B, which is both formed and destroyed in the course of the reaction. Metabolic pathways often employ the coupling of thermodynamically favorable reactions to unfavorable reactions to create new enzymatically catalyzed reactions that have an overall negative change in free energy.

Self-Check Question



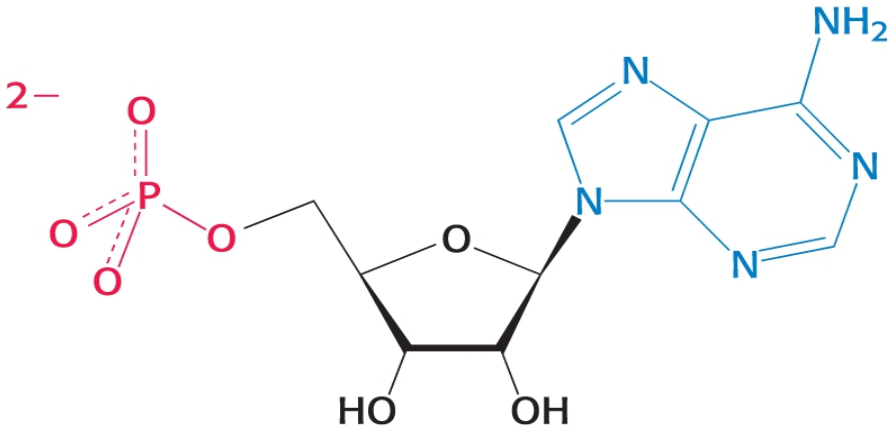
Imagine that a cell needs to produce a compound B, but the reaction converting A into B has a positive $\Delta G^{\circ\prime}$ value. There are two ways that A can still be converted to B; one involves changing the reaction itself, and the other does not. What are they?

15.2 ATP Is the Universal Currency of Free Energy in Biological Systems



Just as commerce is facilitated by the use of a common currency, the commerce of the cell — metabolism — is facilitated by the use of a common energy currency, adenosine triphosphate (ATP). Part of the free energy derived from light or the oxidation of food is transformed into this highly accessible molecule, which acts as the free-energy donor in most energy-requiring processes such as motion, active transport, and biosynthesis. Indeed, most of catabolism consists of reactions that extract energy from fuels such as carbohydrates and fats and capture it through the production of ATP.

ATP hydrolysis is exergonic



ATP is a nucleotide consisting of adenine, a ribose, and a triphosphate unit (**Figure 15.3**). The active form of ATP is usually a complex of ATP with Mg^{2+} or Mn^{2+}. In considering the role of ATP as an energy carrier, we can focus on its triphosphate moiety.

Adenosine triphosphate (ATP)

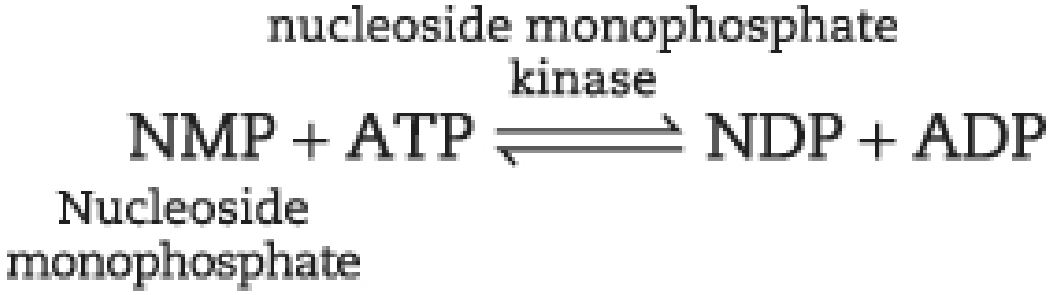
Adenosine diphosphate (ADP)

Adenosine monophosphate (AMP)

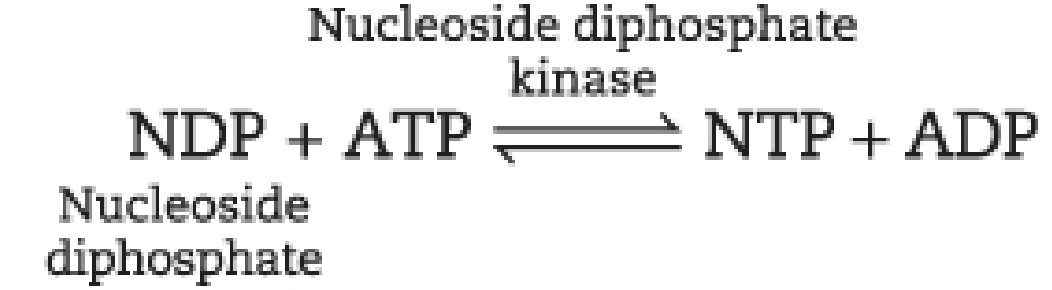
FIGURE 15.3 Structures of ATP, ADP, and AMP differ only by the number of phosphates. These adenylates consist of adenine (blue), a ribose (black), and a tri-, di-, or monophosphate unit (red). The innermost phosphorus atom of ATP is designated P_α, the middle one P_β, and the outermost one P_γ.

- *ATP is an energy-rich molecule because its triphosphate unit contains two phosphoanhydride linkages*. A large amount of free energy is released when ATP is hydrolyzed to adenosine diphosphate (ADP) and orthophosphate (P_i), or when ATP is hydrolyzed to adenosine monophosphate (AMP) and pyrophosphate (PP_i).

$$ATP + H_2O \rightleftharpoons ADP + P_i$$
$$\Delta G^{\circ\prime} = -30.5 \text{ kJ mol}^{-1} (-7.3 \text{ kcal mol}^{-1})$$



$$ATP + H_2O \rightleftharpoons AMP + PP_i$$
$$\Delta G^{\circ\prime} = -45.6 \text{ kJ mol}^{-1} (-10.9 \text{ kcal mol}^{-1})$$



However, this hydrolysis reaction is frequently misunderstood. It is imperative to note that this release of free energy does *not* derive from the cleavage of the any of the covalent bonds in ATP, as it requires energy to break a covalent bond. Instead, the energy is released by the formation of new covalent bonds and noncovalent interactions with water, and from the increase in entropy of the products relative to the reactants. Furthermore, the precise ΔG for these reactions depends on the ionic strength of the medium and on the concentrations of Mg^{2+} and other metal ions. Under typical

cellular concentrations, the ΔG for these hydrolyses is approximately $-50\ \text{kJ mol}^{-1}(-12\ \text{kcal mol}^{-1})$.

- *The ATP–ADP cycle is the fundamental mode of energy exchange in biological systems.* The free energy released in the hydrolysis of ATP is harnessed to drive reactions that require an input of free energy, such as muscle contraction. In turn, ATP is formed from ADP and P_i when fuel molecules are oxidized in chemotrophs or when light is trapped by phototrophs.

- *Enzymes catalyze the exchange of phosphoryl groups from one nucleotide to another.* Some biosynthetic reactions are driven not by ATP, but by guanosine triphosphate (GTP), uridine triphosphate (UTP), and cytidine triphosphate (CTP). The diphosphate forms of these nucleotides are denoted by GDP, UDP, and CDP, and the monophosphate forms by GMP, UMP, and CMP. The phosphorylation of nucleoside monophosphates is catalyzed by a family of nucleoside monophosphate kinases. The phosphorylation of nucleoside diphosphates is catalyzed by nucleoside diphosphate kinase, an enzyme with broad specificity.

- *Although all of the nucleoside triphosphates are energetically equivalent, ATP is nonetheless the primary cellular energy carrier and therefore the energy currency.* In addition, two important electron carriers — NAD^+ and FAD — as well the acyl group carrier, coenzyme A, are derivatives of ATP. It is intriguing to consider why evolution selected adenosine derivatives, but it may be due to differences in the stability of adenine compared to the other bases in prebiotic conditions. Regardless of the reason, the role of adenosine phosphates — particularly ATP — in energy metabolism is paramount.

ATP hydrolysis drives metabolism by shifting the equilibrium of coupled reactions

An otherwise unfavorable reaction can be made possible by coupling to ATP hydrolysis. Consider a reaction that is thermodynamically unfavorable without an input of free energy, a situation common to most biosynthetic reactions. Suppose that the standard free energy of the B is $+16.7\ \text{kJ mol}^{-1}$ or $+4.0\ \text{kcal mol}^{-1}$

$$\text{A} \rightleftharpoons \text{B} \quad \Delta G^{\circ\prime} = +16.7\ \text{kJ mol}^{-1}\ (+4.0\ \text{kcal mol}^{-1})$$

The equilibrium constant K'_{eq} of this reaction at 25°C is related to $\Delta G^{\circ\prime}$ (in units of kilojoules per mole) by

$$K'_{eq} = [\text{B}]_{eq}/[\text{A}]_{eq} = e^{-\Delta G^{\circ\prime}/2.47} = 1.15 \times 10^{-3}$$

Thus, net conversion of A into B cannot take place when the molar ratio of B to A is equal to or greater than 1.15×10^{-3}.

However, A can be converted into B under these conditions if the reaction is coupled to the hydrolysis of ATP. Under standard conditions, the $\Delta G^{\circ\prime}$ of hydrolysis is approximately $-30.5\ \text{kJ mol}^{-1}$ or $-7.3\ \text{kcal mol}^{-1}$. The new overall reaction is

$$\text{A} + \text{ATP} + \text{H}_2\text{O} \rightleftharpoons \text{B} + \text{ADP} + \text{P}_i$$
$$\Delta G^{\circ\prime} = -13.8\ \text{kJ mol}^{-1}\ (-3.3\ \text{kcal mol}^{-1})$$

Its free-energy change of $-13.8\ \text{kJ mol}^{-1}$ or $-3.3\ \text{kcal mol}^{-1}$ is the sum of the value of $\Delta G^{\circ\prime}$ for the conversion of A into B ($+16.7\ \text{kJ mol}^{-1}$ or $+4.0\ \text{kcal mol}^{-1}$) and the value of $\Delta G^{\circ\prime}$ for the hydrolysis of ATP ($-30.5\ \text{kJ mol}^{-1}$ or $-7.3\ \text{kcal mol}^{-1}$). At pH 7, the equilibrium constant of this coupled reaction is

$$K'_{eq} = \frac{[B]_{eq}}{[A]_{eq}} \times \frac{[ADP]_{eq}[P_i]_{eq}}{[ATP]_{eq}} = e^{13.8/2.47} = 2.67 \times 10^2$$

At equilibrium, the ratio of [B] to [A] is given by

$$\frac{[B]_{eq}}{[A]_{eq}} = K'_{eq} \frac{[ATP]_{eq}}{[ADP]_{eq}[P_i]_{eq}}$$

which means that the hydrolysis of ATP enables A to be converted into B until the [B]/[A] ratio reaches a value of 2.67×10^2.

This equilibrium ratio is strikingly different from the value of 1.15×10^{-3} for the reaction $A \rightarrow B$ in the absence of ATP hydrolysis. In other words, coupling the hydrolysis of ATP with the conversion of A into B under standard conditions has changed the equilibrium ratio of B to A by a factor of about 10^5. If we were to use the ΔG of hydrolysis of

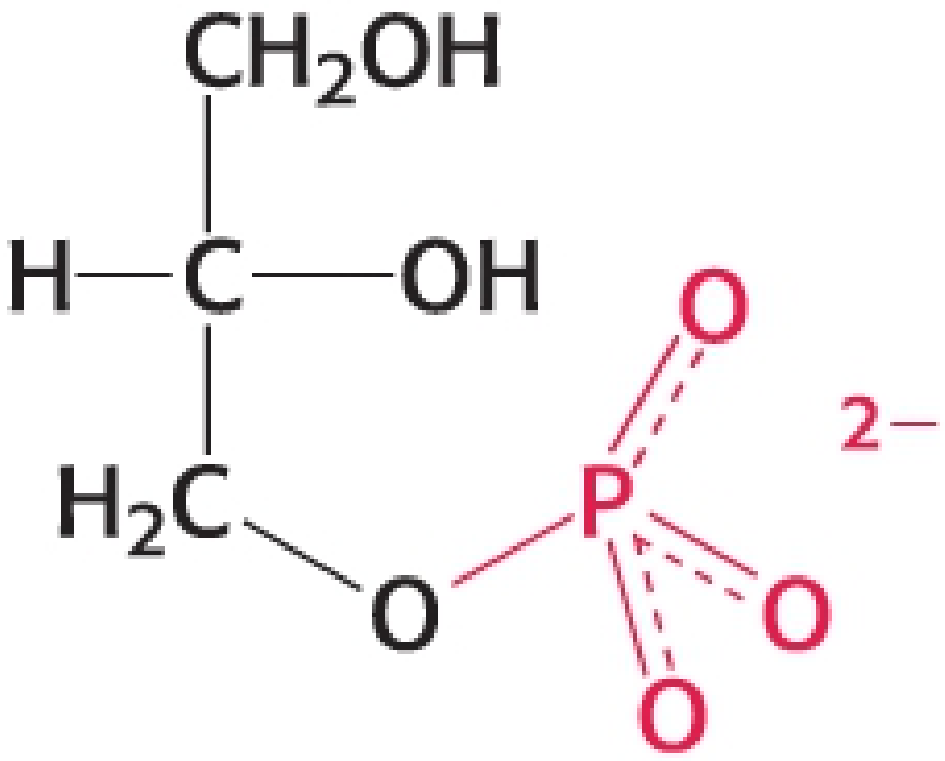
ATP under cellular conditions ($-50.2\ \text{kJ mol}^{-1}$ or $-12\ \text{kcal mol}^{-1}$) in our calculations instead of $\Delta G^{\circ\prime}$, the change in the equilibrium ratio would be even more dramatic, on the order of 10^8.

We see here the thermodynamic essence of ATP's action as an energy-coupling agent. Cells maintain ATP levels by using oxidizable substrates or light as sources of free energy for synthesizing the molecule. In the cell, the hydrolysis of an ATP molecule in a coupled reaction then changes the equilibrium ratio of products to reactants by a very large factor, of the order of 10^8. More generally, the hydrolysis of *n* ATP molecules changes the equilibrium ratio of a coupled reaction (or sequence of reactions) by a factor of 10^{8n}. For example, the theoretical hydrolysis of three ATP molecules in a coupled reaction changes the equilibrium ratio by a factor of 10^{24}. Thus, a thermodynamically unfavorable process can be converted into a favorable one by coupling it to the hydrolysis of a sufficient number of ATP molecules in a new reaction.

It should also be emphasized that A and B in the preceding coupled reaction may be interpreted very generally, not only as different chemical species. For example, A and B may represent activated and unactivated conformations of a protein that is activated by phosphorylation with ATP. Through such changes in protein conformation, molecular motors such as myosin, kinesin, and dynein convert the chemical energy of ATP into mechanical energy (Section 6.5). Indeed, this conversion is the basis of muscle contraction.

Alternatively, A and B may refer to the concentrations of an ion or molecule on the outside and inside of a cell, as in the active transport of a nutrient. The active transport of Na^+ and K^+ across membranes is

driven by the phosphorylation of the sodium–potassium pump by ATP and its subsequent dephosphorylation (Section 13.2).



The high phosphoryl potential of ATP results from structural differences between ATP and its hydrolysis products

What makes ATP an efficient phosphoryl-group donor? Let us compare the standard free energy of hydrolysis of ATP with that of a phosphate ester, such as glycerol 3-phosphate:

$$\text{ATP} + \text{H}_2\text{O} \rightleftharpoons \text{ADP} + \text{P}_\text{i}$$
$$\Delta G^{\circ\prime} = -30.5 \text{ kJ mol}^{-1} (-7.3 \text{ kcal mol}^{-1})$$

$$\text{Glycerol 3-phosphate} + \text{H}_2\text{O} \rightleftharpoons \text{glycerol} + \text{P}_\text{i}$$
$$\Delta G^{\circ\prime} = -9.2 \text{ kJ mol}^{-1} (-2.2 \text{ kcal mol}^{-1})$$

Glycerol 3-phosphate

The magnitude of $\Delta G^{\circ\prime}$ for the hydrolysis of glycerol 3-phosphate is much smaller than that of ATP, which means that ATP has a stronger tendency to transfer its terminal phosphoryl group to water than does glycerol 3-phosphate. In other words, ATP has a higher **phosphoryl-transfer potential** than glycerol 3-phosphate.

The high phosphoryl-transfer potential of ATP can be explained by features of the ATP structure. Because $\Delta G^{\circ\prime}$ depends on the difference in free energies of the products and reactants, we need to examine the

structures of both ATP and its hydrolysis products, ADP and P_i, to answer this question. Four factors are important:

1. *Resonance stabilization*. Orthophosphate (P_i), one of the products of ATP hydrolysis, has greater resonance stabilization than do any of the ATP phosphoryl groups. Orthophosphate has several resonance forms of similar energy (**Figure 15.4**), whereas the γ phosphoryl group of ATP has a smaller number.

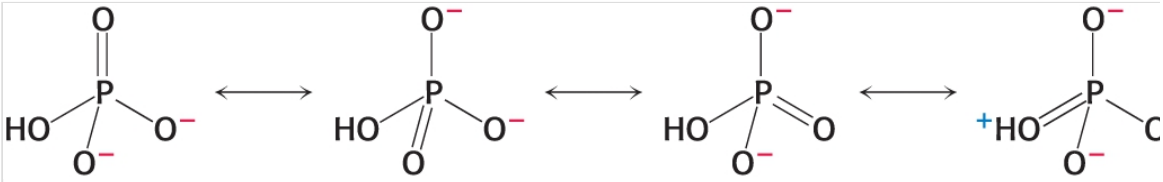


FIGURE 15.4 Orthophosphate has four favorable resonance structures.

2. *Electrostatic repulsion.* At pH 7, the triphosphate unit of ATP carries about four negative charges. These charges repel one another because they are in close proximity. The repulsion between them is reduced when ATP is hydrolyzed.

3. *Increase in entropy*. The entropy of the products of ATP hydrolysis is greater, in that there are now two molecules instead of a single ATP molecule. We disregard the molecule of water used to hydrolyze the ATP; given the high concentration (55.5 M), there is effectively no change in the concentration of water during the reaction.

4. *Stabilization due to hydration.* Water binds to ADP and P_i, stabilizing these molecules, and rendering the reverse reaction — the synthesis of ATP — more unfavorable.

ATP is often called a high-energy phosphate compound, and its phosphoanhydride linkages are sometimes referred to as high-energy

bonds. Indeed, a “squiggle” $(\sim P)$ is often used to indicate the bonds that can be broken in ATP hydrolysis. This is a misnomer, however, as there is nothing special about the bonds themselves. The phosphoanhydride linkages are high-energy in the sense that much free energy is released when they are hydrolyzed — a reaction with water — for the reasons listed above, but the energy release comes from entropy and new bond formation, rather than bond cleavage.

Phosphoryl-transfer potential is an important form of cellular energy transformation

The standard free energies of hydrolysis provide a convenient means of comparing the phosphoryl-transfer potential of phosphorylated compounds. Such comparisons reveal that ATP is not the only compound with a high phosphoryl-transfer potential. In fact, some compounds in biological systems have a higher phosphoryl-transfer potential than that of ATP. These compounds include phosphoenolpyruvate (PEP), 1,3-bisphosphoglycerate (1,3-BPG), and creatine phosphate (**Figure 15.5**).

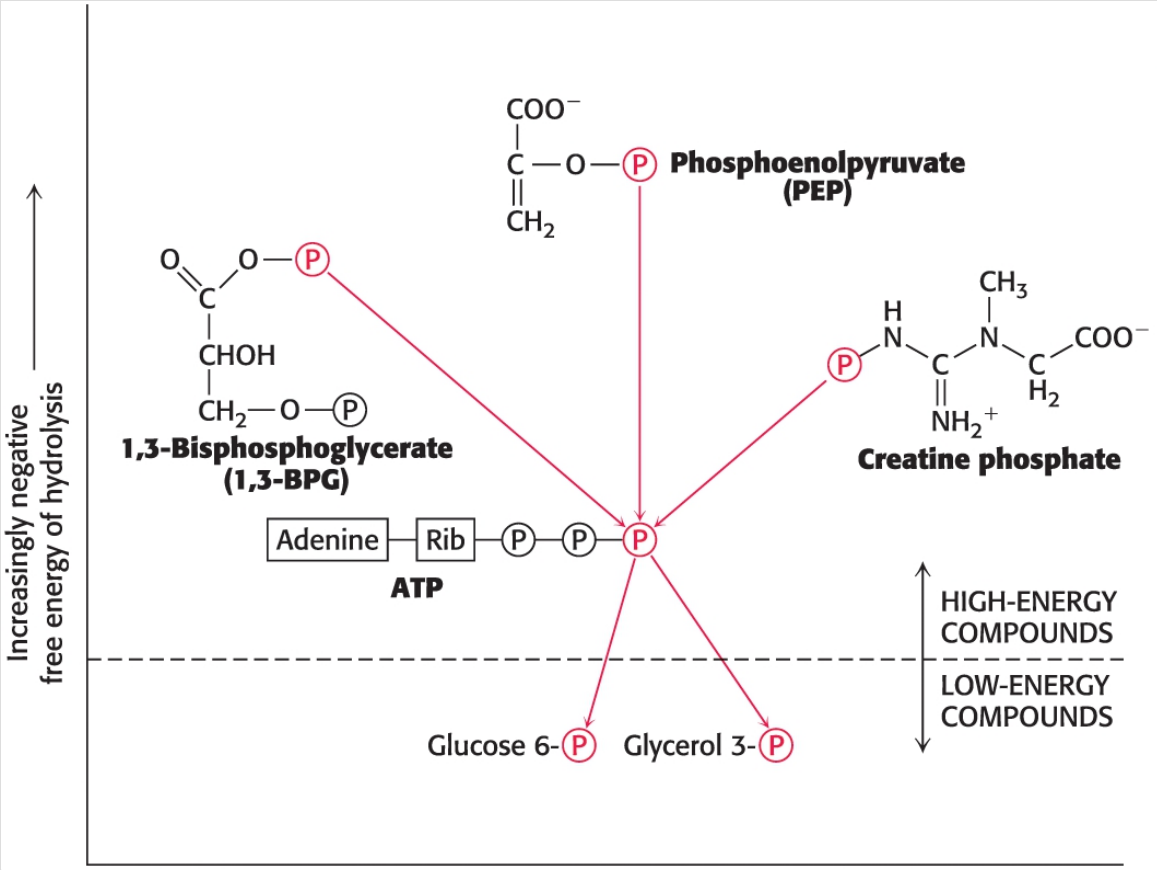

FIGURE 15.5 Compounds with high phosphoryl-transfer potential can be used to make ATP from ADP. The role of ATP as the cellular energy currency is illustrated by its relation to other phosphorylated compounds. ATP has a phosphoryl-transfer potential that is intermediate among the biologically important phosphorylated molecules. High-phosphoryl-transfer-potential compounds (1,3-BPG, PEP, and creatine phosphate) derived from the metabolism of fuel molecules are used to power ATP synthesis. In turn, ATP donates a phosphoryl group to other biomolecules to facilitate their metabolism.

[Data from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2009), Fig. 13-19.]

PEP can transfer its phosphoryl group to ADP to form ATP. Indeed, this transfer is one of the ways in which ATP is generated in the breakdown of sugars (Section 16.1). It is significant that ATP has a phosphoryl-transfer potential that is intermediate among the biologically important phosphorylated molecules (**Table 15.1**). This intermediate position enables ATP to function efficiently as a carrier of phosphoryl groups.

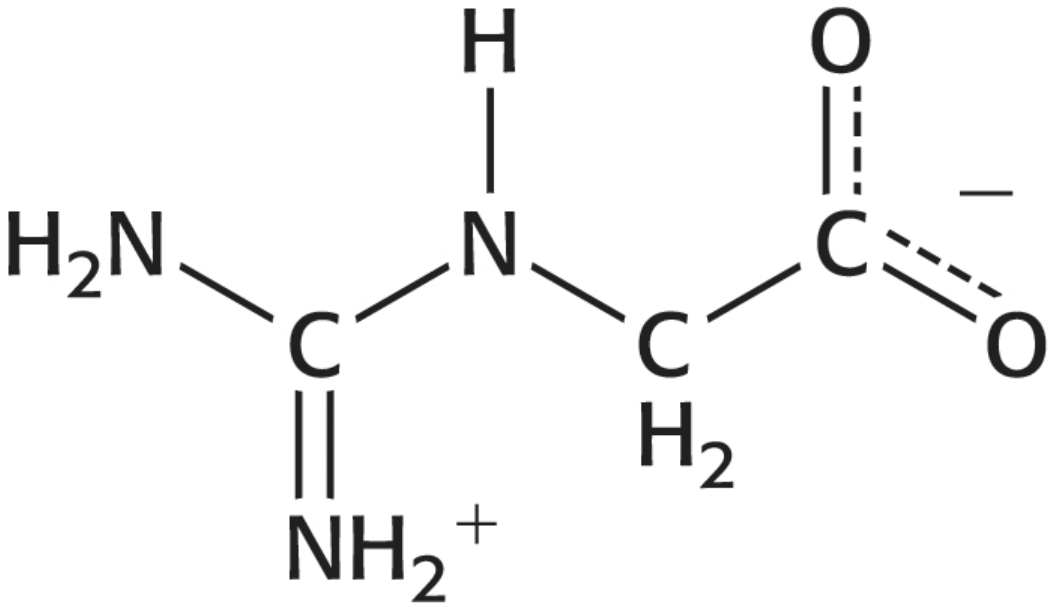

TABLE 15.1 Standard free energies of hydrolysis of some phosphorylated compounds

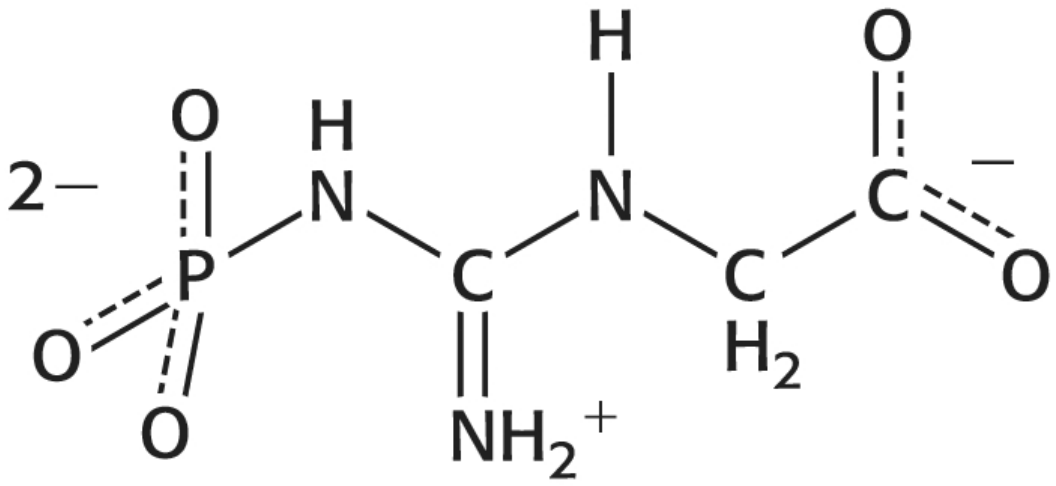
Compound	$kJ\ mol^{-1}$	$kJ\ mol^{-1}$
Phosphoenolpyruvate	−61.9	−14.8
1,3-Bisphosphoglycerate	−49.4	−11.8
Creatine phosphate	−43.1	−10.3
ATP (to ADP)	−30.5	−7.3
Glucose 1-phosphate	−20.9	−5.0
Pyrophosphate	−19.3	−4.6
Glucose 6-phosphate	−13.8	−3.3
Glycerol 3-phosphate	−9.2	−2.2



The amount of ATP in muscle suffices to sustain contractile activity for less than a second. Creatine phosphate in vertebrate muscle serves as a reservoir of high-potential phosphoryl groups that can be readily transferred to ADP. Indeed, we use creatine phosphate to regenerate ATP from ADP every time we exercise strenuously. This reaction is catalyzed by creatine kinase.

$$\text{Creatine phosphate} + \text{ADP} \xrightleftharpoons{\text{creatine kinase}} \text{ATP} + \text{creatine}$$

At pH 7, the standard free energy of hydrolysis of creatine phosphate is $-43.1\ \text{kJ mol}^{-1}\ (-10.3\ \text{kcal mol}^{-1})$ compared with $-30.5\ \text{kJ mol}^{-1}\ (-7.3\ \text{kcal mol}^{-1})$ for ATP.

Creatine

Creatine phosphate

As illustrated in the next boxed example, there is a large amount of creatine phosphate present in resting muscle. Because of its abundance and high phosphoryl-transfer potential relative to that of ATP, creatine phosphate is a highly effective phosphoryl buffer. Indeed, creatine phosphate is the major source of phosphoryl groups for ATP regeneration for a runner during the first 4 seconds of a 100-meter sprint. The fact that creatine phosphate can replenish ATP pools is the basis of the use of creatine as a dietary supplement by athletes in sports requiring short bursts of intense activity. After the creatine phosphate pool is depleted, ATP must be generated through anaerobic or aerobic metabolism (Figure 15.6).

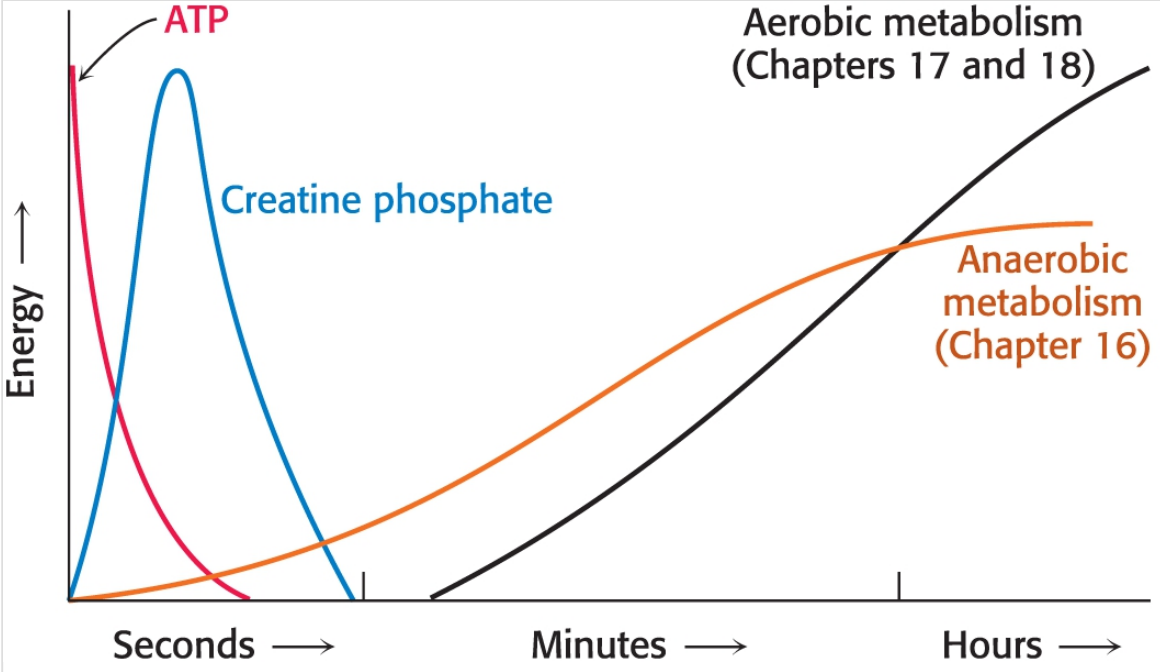


FIGURE 15.6 The sources of ATP change as exercise duration increases, even within the first few seconds. In the initial seconds of exertion, power is generated by existing high-phosphoryl-transfer compounds (ATP and creatine phosphate). Subsequently, the ATP must be regenerated by metabolic pathways.

EXAMPLE

Calculating ΔG for a Coupled Reaction Under Real Conditions

PROBLEM:

Creatine phosphate is used as a phosphoryl donor for ATP synthesis in muscle in the following reaction:

$$\text{Creatine phosphate} + \text{ADP} \overset{\text{creatine kinase}}{\rightleftharpoons} \text{ATP} + \text{creatine}$$

When muscles are at rest, the reaction proceeds in the reverse direction, synthesizing creatine phosphate. As noted above, for a skeletal muscle at rest, the following metabolites are present at the indicated concentrations.

$$[\text{ATP}] = 4\ \text{mM}; \text{ADP} = 0.013\ \text{mM}$$
$$[\text{creatine phosphate}] = 25\ \text{mM}; [\text{creatine}] = 13\ \text{mM}$$

Calculate the ΔG for the creatine kinase reaction as written above for a muscle at rest assuming body temperature is 37°C.

Getting Started:

What formula do we need to calculate ΔG, and what information are we missing to complete this calculation?

$$\Delta G = \Delta G^{\circ\prime} + RT \ln \frac{[C][D]}{[A][B]}$$

Analyze:

The values necessary for the right-hand term are provided, but we need to know $\Delta G^{\circ\prime}$ for the kinase reaction. How do we determine $\Delta G^{\circ\prime}$? Recall from this chapter that two component parts of a reaction have

additive $\Delta G^{\circ\prime}$ values. We need to dissect the creatine kinase reaction into its two component reactions and look up the $\Delta G^{\circ\prime}$ values for each of the component reactions. These are:

$$ADP + P_i \rightarrow ATP + H_2O$$
$$\text{Creatine phosphate} + H_2O \rightarrow \text{creatine} + P_i$$

Using Table 15.1, we can determine the $\Delta G^{\circ\prime}$ values for both reactions.

For ATP synthesis, $\Delta G^{\circ\prime} = +30.5\ \text{kJ mol}^{-1}$. For creatine phosphate hydrolysis, $\Delta G^{\circ\prime} = -43.1\ \text{kJ mol}^{-1}$.

Calculate:

What is the $\Delta G^{\circ\prime}$ of the overall creatine kinase reaction in the direction written?

$\Delta G^{\circ\prime}$ values are additive, so the $\Delta G^{\circ\prime}$ for the kinase reaction is $-43.1\ \text{kJ mol}^{-1} + 30.5\ \text{kJ mol}^{-1} = -12.6\ \text{kJ mol}^{-1}$.

Now, having determined $\Delta G^{\circ\prime}$, we can use the equation above and the values provided to determine ΔG.

$$\Delta G = -12.6\ \text{kJ mol}^{-1} + RT \ln\left(\frac{[\text{ATP}][\text{creatine}]}{[\text{ADP}][\text{creatine phosphate}]}\right)$$

$$= -12.6\ \text{kJ mol}^{-1} + (0.0083\ \text{kJ K}^{-1}\ \text{mol}^{-1})(310\ \text{K}) \ln\left(\frac{[4\ \text{mM}][13\ \text{mM}]}{[0.013\ \text{mM}][25\ \text{mM}]}\right)$$

$$= -12.6\ \text{kJ mol}^{-1} + (2.573\ \text{kJ mol}^{-1}) \ln(160)$$

$$= 0.5\ \text{kJ mol}^{-1}$$

Reflect:

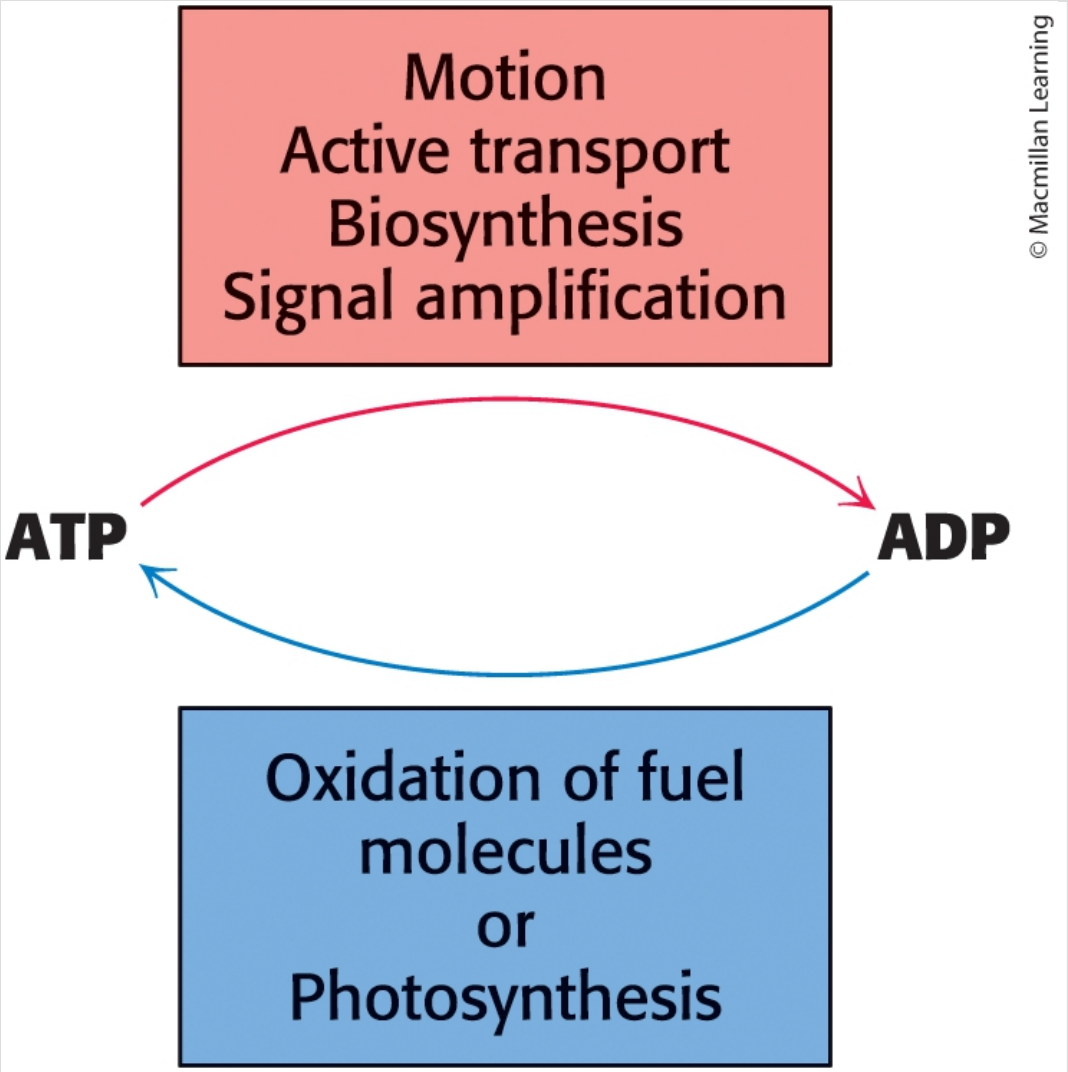
Note that this value is close to zero, indicating that the reaction is very near equilibrium. Does this make sense to you, for resting muscle? Consider that upon sudden muscle contraction during exercise, the depletion of ATP shifts the reaction toward creatine and ATP. Conversely, during the recovery from exercise, the replenishment of ATP from oxidative phosphorylation shifts the reaction back toward the formation of creatine phosphate. Once replenished, and when the muscle is at rest, we should expect that the reaction will eventually settle at equilibrium concentrations and, therefore, ΔG should be near zero.

15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy

ATP serves as the principal immediate donor of free energy in biological systems rather than as a long-term storage form of free energy. In a typical cell, an ATP molecule is consumed within a minute of its formation.

- *Having mechanisms for regenerating ATP is vital.* Although the total quantity of ATP in the body is limited to approximately 100 g, the turnover of this small quantity of ATP is very high. For example, a resting human being consumes about 40 kg (88 pounds) of ATP in 24 hours. During strenuous exertion, the rate of utilization of ATP may be as high as 0.5 kg/minute. For a 2-hour run, 60 kg (132 pounds) of ATP is utilized. Of course, this is essentially the same 100 g of ATP being used and regenerated again and again.

- *The regeneration of ATP is one of the primary roles of catabolism.* Motion, active transport, signal amplification, and biosynthesis can take place only if ATP is continually regenerated from ADP (**Figure 15.7**). In most aerobic organisms, the carbon in fuel molecules — such as glucose and fats — is oxidized to CO_2. The resulting electrons are captured and their energy is used to regenerate ATP from ADP and P_i.



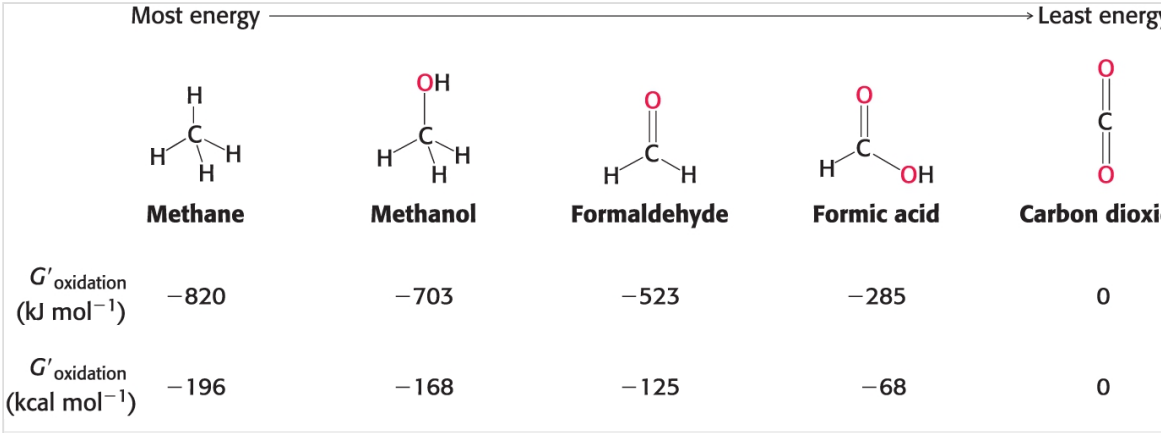


FIGURE 15.7 The ATP–ADP cycle is the fundamental mode of energy exchange in biological systems.

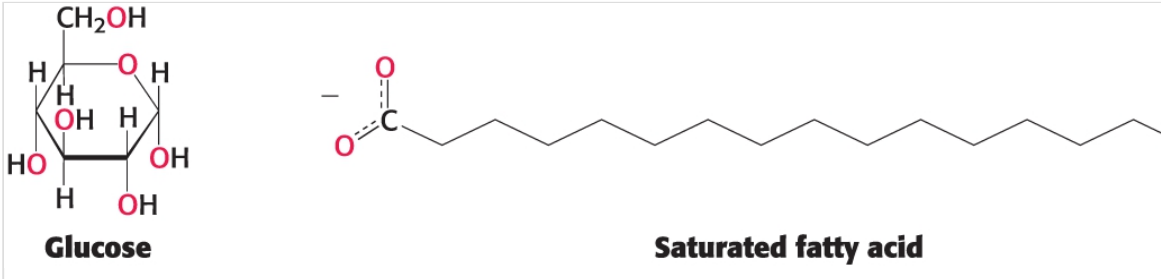
- *Oxidation of fuels takes place one carbon at a time.* The ultimate electron acceptor for the aerobic oxidation of carbon is O_2, which is reduced to water, and the oxidation product is CO_2. Consequently, the more reduced a carbon is to begin with, the more free energy is released by its oxidation. Figure 15.8 shows the $\Delta G^{\circ\prime}$ of oxidation for one-carbon compounds. While fuel molecules are more

complex (Figure 15.9) than these single-carbon compounds, their oxidation nevertheless takes place one carbon at a time. The carbon-oxidation energy is used in some cases to create a compound with high phosphoryl-transfer potential and in other cases to create an ion gradient. In either case, the end point is the formation of ATP.

	Methane	Methanol	Formaldehyde	Formic acid	Carbon dioxi
$G'_{oxidation}$ (kJ mol^{-1})	−820	−703	−523	−285	0
$G'_{oxidation}$ (kcal mol^{-1})	−196	−168	−125	−68	0

FIGURE 15.8 The free energy of oxidation of single-carbon compounds increases with the degree of hydrogen saturation.



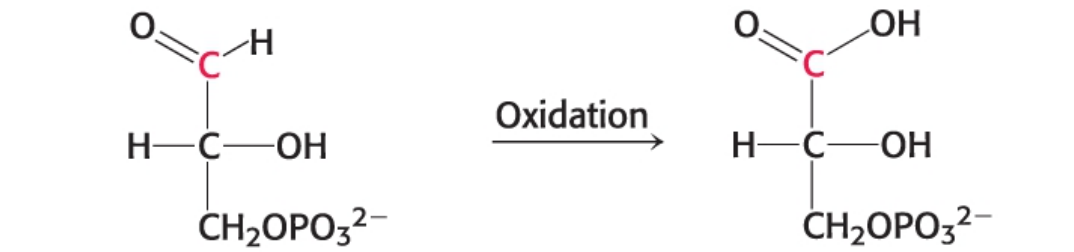


FIGURE 15.9 Fats are a more efficient fuel source than carbohydrates such as glucose becaus the carbon in fats is more reduced.

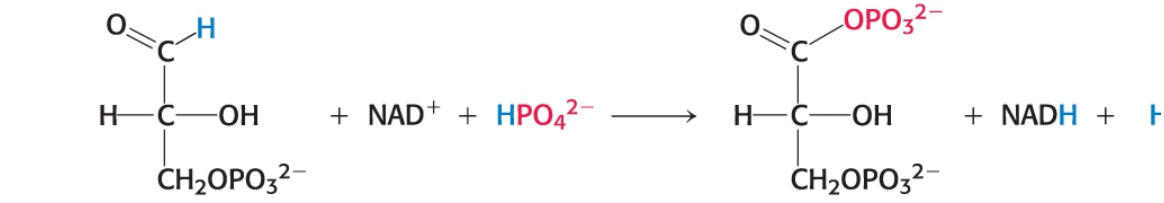

Compounds with high phosphoryl-transfer potential can couple carbon oxidation to ATP synthesis

How is the energy released from the oxidation of a carbon compound captured in ATP? As an example, consider glyceraldehyde 3-phosphate (shown below), which is a metabolite of glucose formed during the oxidation of that sugar. The C-1 carbon (shown in red) is at the aldehyde-oxidation level and is not in its most oxidized state. Oxidation of the aldehyde to an acid will release energy.

Glyceraldehyde 3-phosphate **3-Phosphoglyceric acid**

However, the oxidation does not take place directly. Instead, the carbon oxidation generates an acyl phosphate, 1,3-bisphosphoglycerate (1,3-BPG). The electrons released are captured by NAD^+,forming NADH, in a process that we will consider shortly.

Glyceraldehyde 3-phosphate (GAP) **1,3-Bisphosphoglycerate (1,3-BPG)**

For reasons similar to those discussed for ATP, 1,3-BPG has a high phosphoryl-transfer potential that is, in fact, greater than that of ATP. Thus, the hydrolysis of 1,3-BPG can be coupled to the synthesis of ATP.

1,3-Bisphosphoglycerate **3-Phosphoglyceric acid**

The energy of oxidation is initially trapped as a high-phosphoryl-transfer-potential compound and then used to form ATP. The oxidation energy of a carbon atom is transformed into phosphoryl-transfer potential, first as 1,3-BPG and ultimately as ATP. We will consider these reactions in mechanistic detail in Chapter 16.

Ion gradients across membranes provide an important form of cellular energy that can be coupled to ATP synthesis

As described in Section 13.1, electrochemical potential is an effective means of storing free energy. In fact, the electrochemical potential of ion gradients across membranes — produced by the oxidation of fuel molecules or by phototrophy — ultimately powers the synthesis of most

of the ATP in cells. In general, ion gradients are versatile means of coupling thermodynamically unfavorable reactions to favorable ones.

In animals, proton gradients generated by the oxidation of carbon fuels account for more than 90% of ATP generation (**Figure 15.10**). This process, called *oxidative phosphorylation,* will be explored in depth in Chapter 18. ATP hydrolysis can then be used to form ion gradients of different types and functions. The electrochemical potential of a Na^+ gradient, for example, can be tapped to pump Ca^{2+} out of cells or to transport nutrients such as sugars and amino acids into cells.

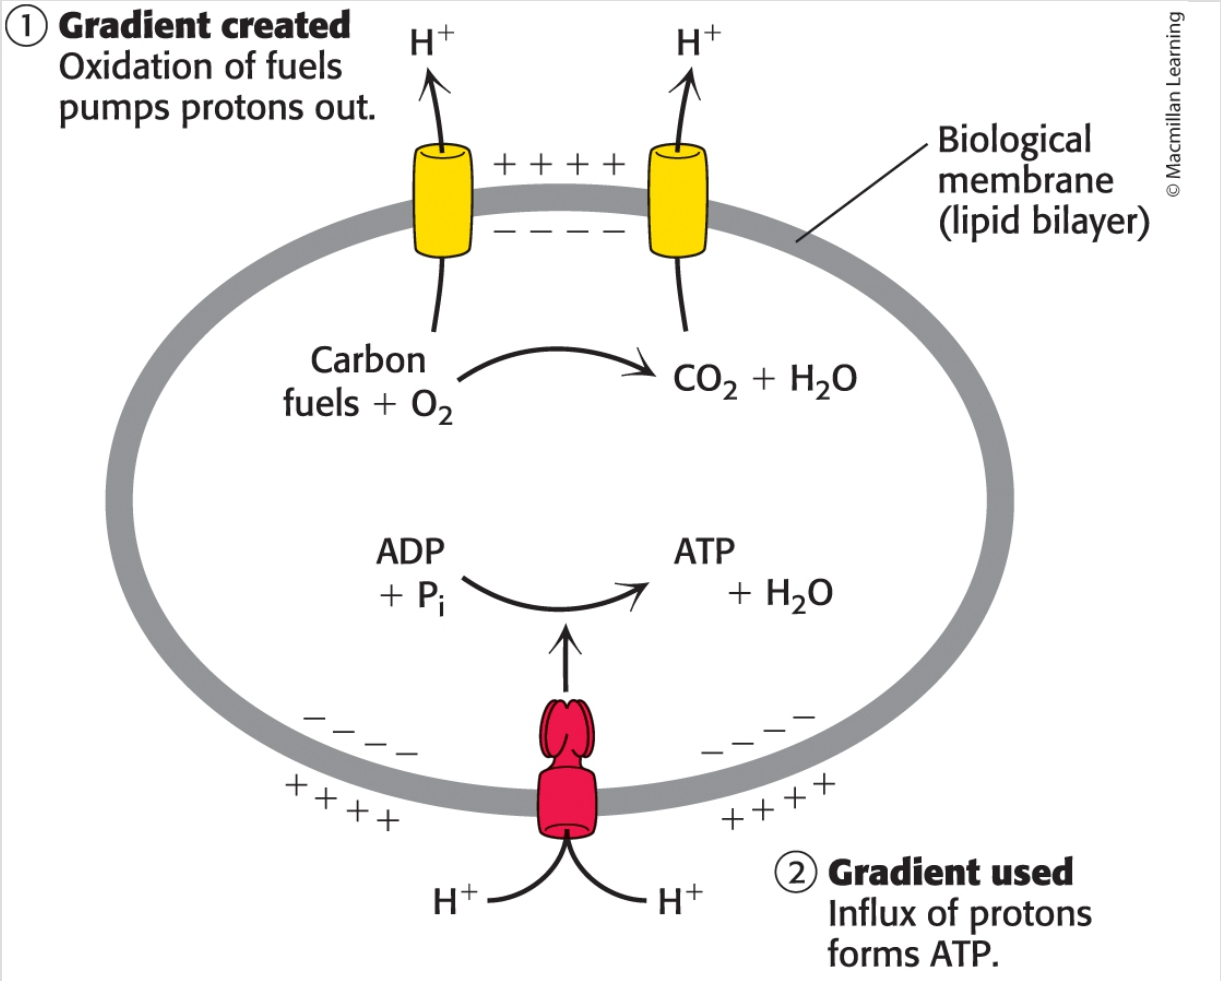

FIGURE 15.10 Proton gradients formed using the energy from either sunlight or chemical oxidation can power ATP synthesis. Either the oxidation of fuels or the capture of the energy from sunlight can power the formation of proton gradients by the action of specific proton

pumps (yellow cylinders). These proton gradients can in turn drive the synthesis of ATP when the protons flow through an ATP-synthesizing enzyme (red complex).

Phosphates play a prominent role in biochemical processes

We have seen in Chapter 14 and in this chapter the prominence of phosphoryl group transfer from ATP to acceptor molecules. How is it that phosphate came to play such a prominent role in biology? Phosphate and its esters have several characteristics that render them useful for biochemical systems:

- *The energy release from phosphate esters can be manipulated by enzymes, making them ideal regulatory molecules.* Phosphate esters have an important chemical characteristic by being thermodynamically unstable yet kinetically stable in water. Phosphate esters are thus molecules whose energy release can be manipulated by enzymes. The kinetic stability of phosphate esters is due to the negative charges that make them resistant to hydrolysis in the absence of enzymes. This accounts for the presence of phosphate in the backbone of DNA and explains why they are ideal regulatory molecules; protein structure and function can be reliably controlled through the stable addition and removal of phosphates. Because both phosphate ester formation and hydrolysis are both very slow in free solution, these changes are not readily reversed without the action of an enzyme: protein kinases normally add phosphates to proteins while protein phosphatases typically remove them, as we explored in Section 7.3.

- *The addition of a phosphate group changes molecule conformation and behavior.* Phosphates are also frequently added to metabolites that might otherwise diffuse through the cell membrane. Even when transporters exist for unphosphorylated forms of a metabolite, the addition of a phosphate changes the geometry and polarity of the molecules so that they no longer fit in the binding sites of the transporters.

- *All other ions fall short.* No other ions have the chemical characteristics of phosphate. Citrate is not sufficiently charged to prevent hydrolysis. Arsenate forms esters that are unstable and susceptible to spontaneous hydrolysis. Indeed, arsenate is poisonous to cells because it can replace phosphate in reactions required for ATP synthesis, generating unstable compounds and preventing ATP synthesis. Silicate is more abundant than phosphate, but silicate salts are virtually insoluble and are used for biomineralization, as in diatoms and certain sponges. Only phosphate has the chemical properties to meet the needs of living systems.

Energy from food is extracted in three stages

Let us take an overall view of the processes of energy conversion in animals before considering them in detail in subsequent chapters. Hans Krebs described three stages in the generation of energy from the oxidation of food (**Figure 15.11**).

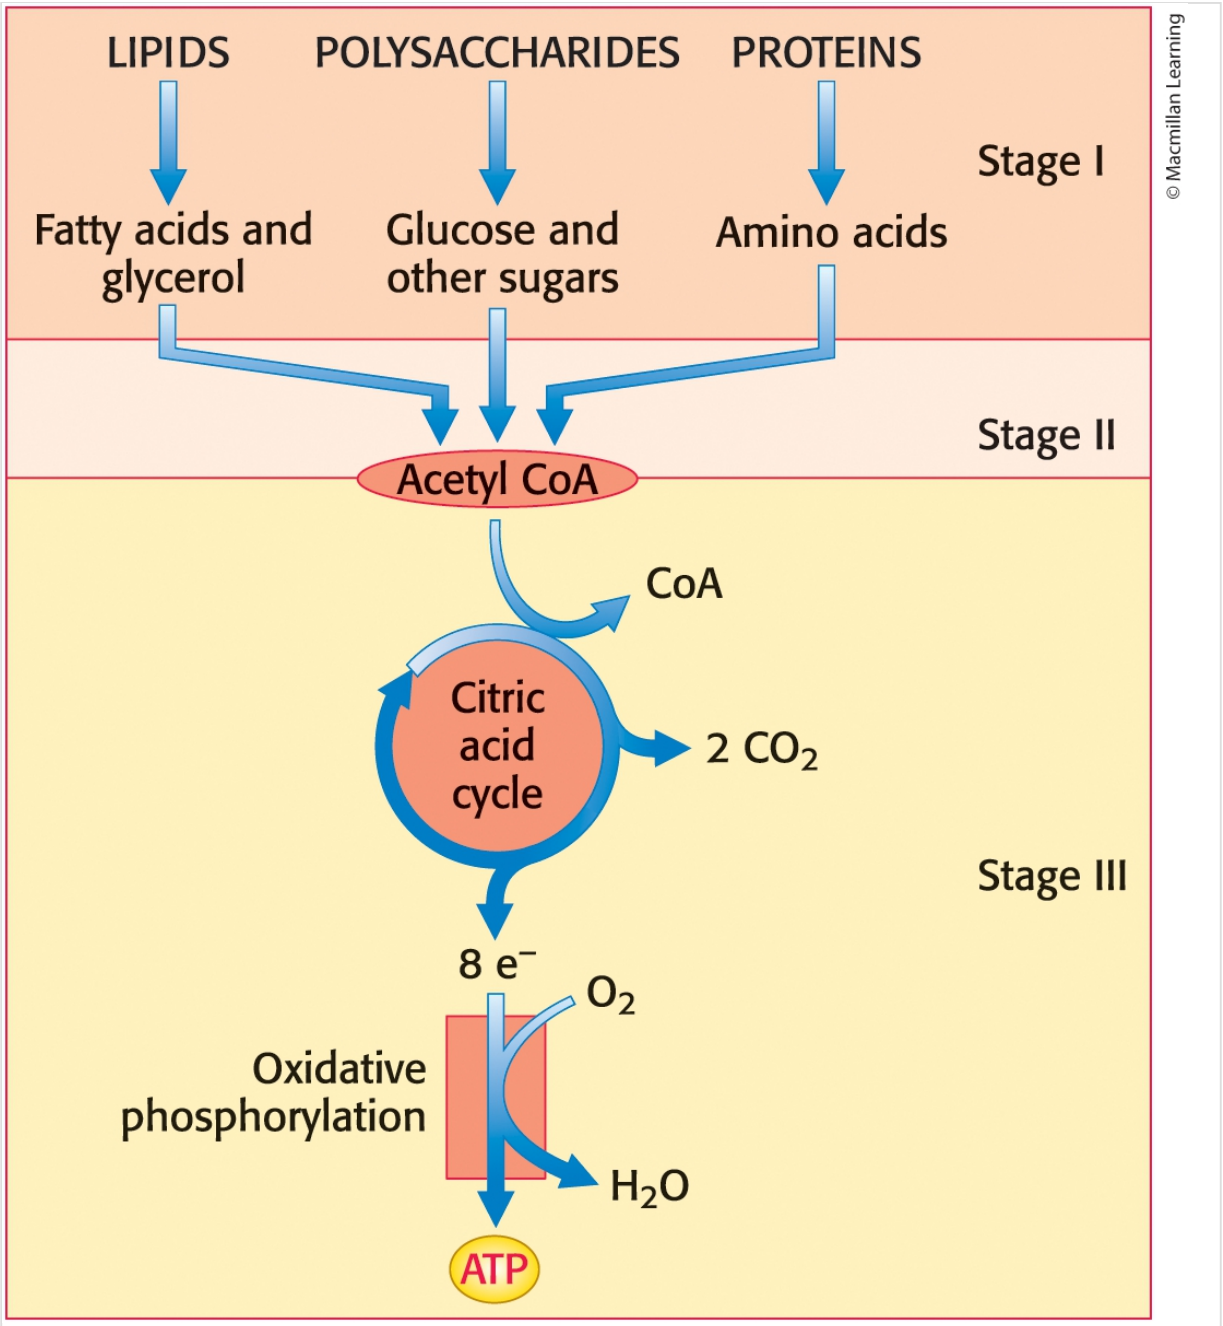

FIGURE 15.11 The extraction of energy from food molecules by aerobic organisms can be described as taking place in three stages.

1. *Large molecules in food are broken down into smaller units in the process of digestion*. Proteins are hydrolyzed to their 20 different amino acids, polysaccharides are hydrolyzed to simple sugars such as glucose, and lipids are hydrolyzed to glycerol and fatty acids. The degradation products are then absorbed by the cells of the intestine and distributed throughout the body. This stage is strictly a preparation stage; no useful energy is captured in this phase.

2. *Numerous small molecules resulting from digestion are degraded to a few simple units that play a central role in metabolism*. In fact, most of them — sugars, fatty acids, glycerol, and several amino acids — are converted into the acetyl unit of acetyl CoA. Some ATP is generated in this stage, but the amount is small compared with that obtained in the third stage.

3. *ATP is produced from the complete oxidation of the acetyl unit of acetyl CoA*. The third stage consists of the citric acid cycle and oxidative phosphorylation, which are the final common pathways in the oxidation of fuel molecules. Acetyl CoA brings acetyl units into the citric acid cycle — also called the CAC, the tricarboxylic acid (TCA) cycle, or the Krebs cycle — where they are completely oxidized to CO_2. Four pairs of electrons are transferred (three to NAD^+ and one to FAD) for each acetyl group that is oxidized (Chapter 17). Then, a proton gradient is generated as electrons flow from the reduced forms of these carriers to O_2. This gradient is used to synthesize ATP (Chapter 18).

Self-Check Question

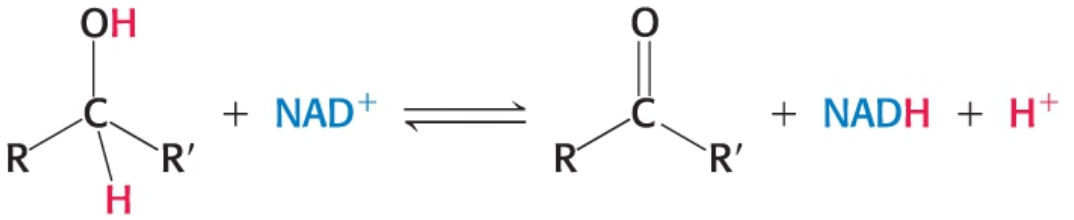
Which of the following statements is/are true? (1) Energy is released when the covalent bond linking two phosphates in ATP is broken. (2) ATP is the cellular energy currency because it has the highest phosphoryl transfer potential of any biological molecule. (3) ATP has two

phosphoanhydride linkages, each of which can be hydrolyzed to provide useable energy for an organism.

15.4 Metabolic Pathways Contain Many Recurring Motifs

The sheer number of reactants and reactions of metabolism makes it seem very complex. Fortunately, we can look to several unifying themes to help make sense of it all. These themes include common metabolites, reactions, and regulatory schemes that stem from a common evolutionary heritage.

Activated carriers exemplify the modular structure and economy of metabolism



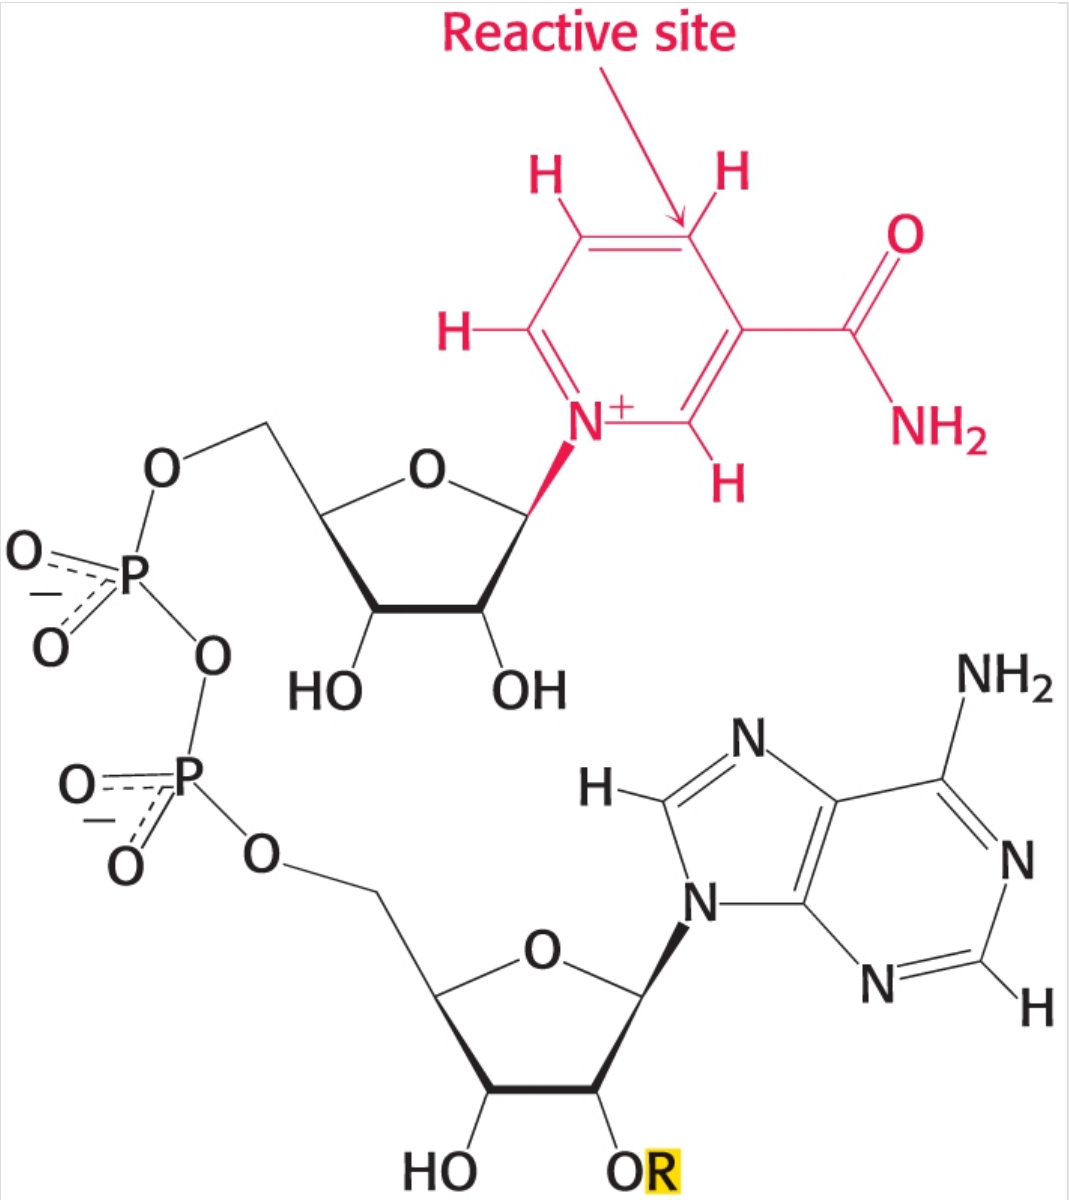
We have seen that phosphoryl transfer can be used to drive otherwise endergonic reactions, alter the conformation energy of a protein, or serve as a signal to alter the activity of a protein. The phosphoryl-group donor in all these reactions is ATP. In summary, ATP is an **activated carrier** of phosphoryl groups because phosphoryl transfer from ATP is an exergonic process. Activated carriers are small molecules to which a chemical group or electrons have been added, which can then be donated to another molecule; they frequently act as coenzymes or cosubstrates in enzyme-catalyzed reactions.

The use of ATP and other activated carriers is a recurring motif in biochemistry. Here we introduce the activated carriers that will appear repeatedly in the next several chapters, often functioning as coenzymes. Next, we provide an overview of their key roles.

NADH and $FADH_2$: Activated carriers of electrons for fuel oxidation

In aerobic organisms, the ultimate electron acceptor in the oxidation of fuel molecules is O_2. However, electrons are not transferred directly from the fuel molecule to O_2. Instead, fuel molecules transfer electrons to carriers, which then transfer their high-potential electrons to O_2.

One of the major electron carriers in the oxidation of fuel molecules is nicotinamide adenine dinucleotide (NAD^+; Figure 15.12). The reactive part of NAD^+ is its nicotinamide ring, derived from vitamin B_3 (niacin). In the oxidation of a substrate, the nicotinamide ring of NAD^+ accepts a proton and two electrons, which are equivalent to a hydride ion $(H:^-)$. The reduced form of this carrier is NADH. In the oxidized form, the nitrogen atom carries a positive charge, as indicated by NAD^+. NAD^+ is the electron acceptor in many reactions of the type



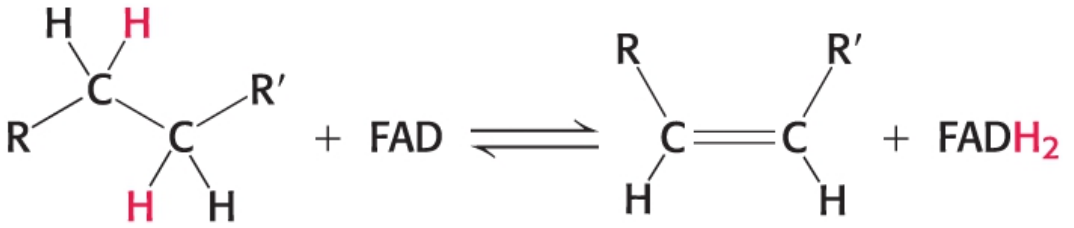


FIGURE 15.12 Nicotinamide adenine dinucleotide (NAD^+) and nicotinamide adenine dinucleotide phosphate $(NADP^+)$ are prominent carriers of high-energy electrons. The oxidized forms are shown; in NAD^+, $R = H$; in $NADP^+$, $R = PO_3^{2-}$. A hydride ion (H^-) can be accepted by the nicotinamide ring (shown in red).

In this dehydrogenation, one hydrogen atom of the substrate is directly transferred to NAD^+, whereas the other appears in the solvent as a proton. Both electrons lost by the substrate are transferred to the nicotinamide ring.

The other major electron carrier in the oxidation of fuel molecules is the coenzyme flavin adenine dinucleotide (FAD; **Figure 15.13**). The abbreviations for the oxidized and reduced forms of this carrier are FAD and $FADH_2$, respectively. FAD is the electron acceptor in reactions of this type:

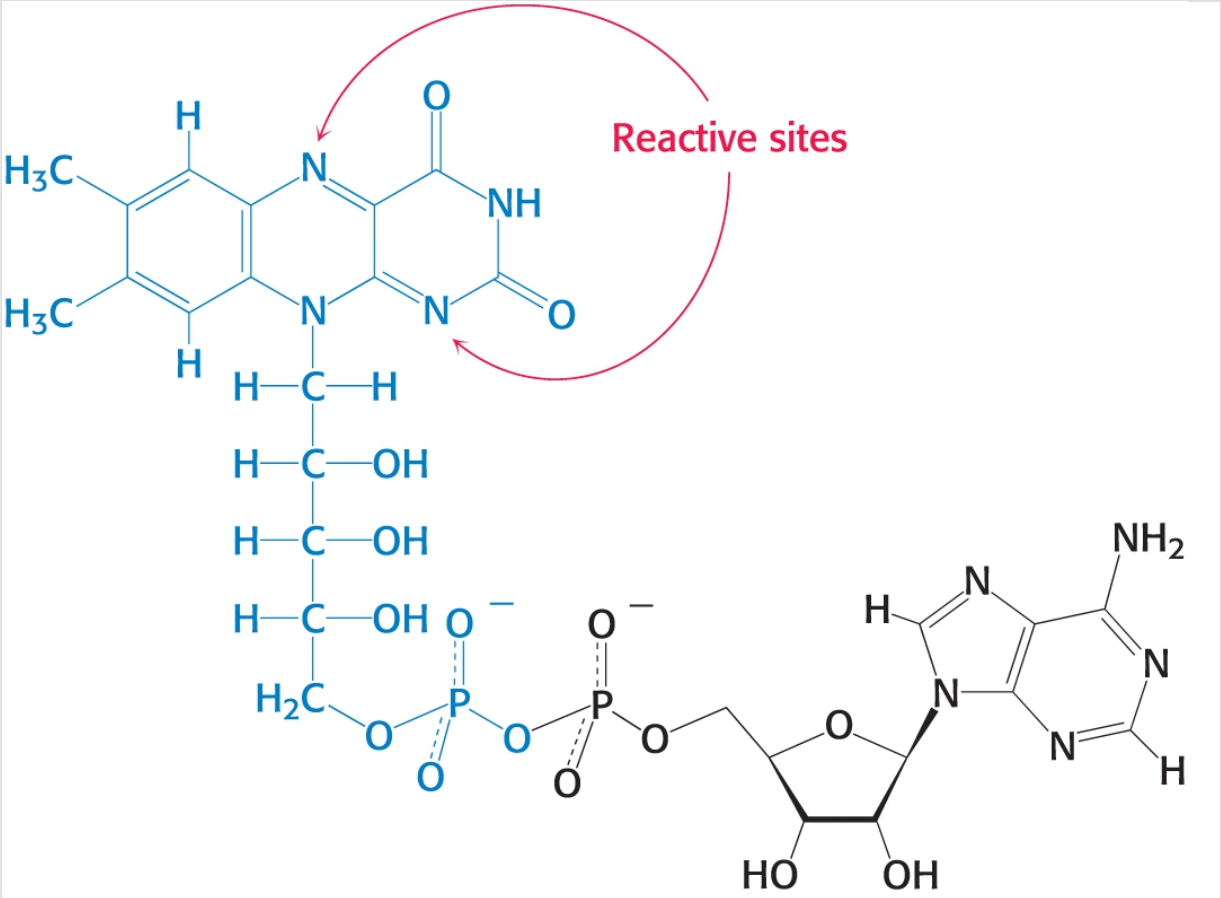

FIGURE 15.13 The oxidized form of flavin adenine dinucleotide (FAD) consists of two units. FAD has a flavin mononucleotide (FMN) unit (shown in blue) and an AMP unit (shown in black).

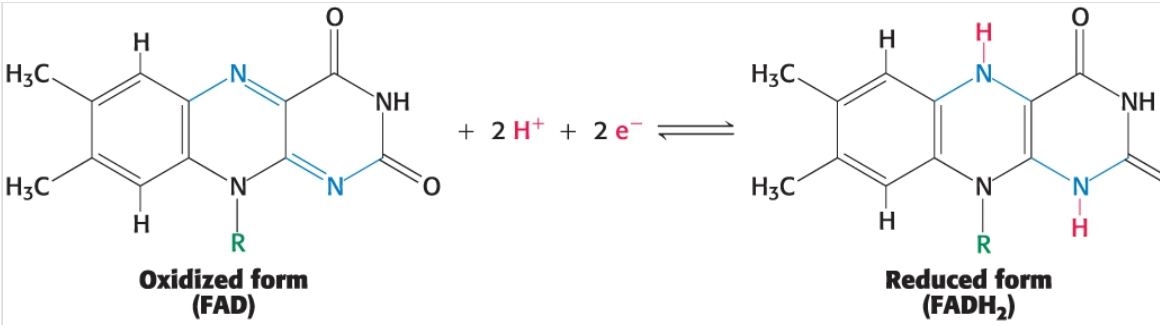
The reactive part of FAD is its isoalloxazine ring, a derivative of the vitamin riboflavin (**Figure 15.14**). FAD, like NAD^+, can accept two electrons. In doing so, FAD, unlike NAD^+, takes up two protons; its reduced form is $FADH_2$. These carriers of high-potential electrons as well as flavin mononucleotide (FMN) — an electron carrier similar to FAD but lacking the adenine nucleotide — will be considered further in Chapter 18.



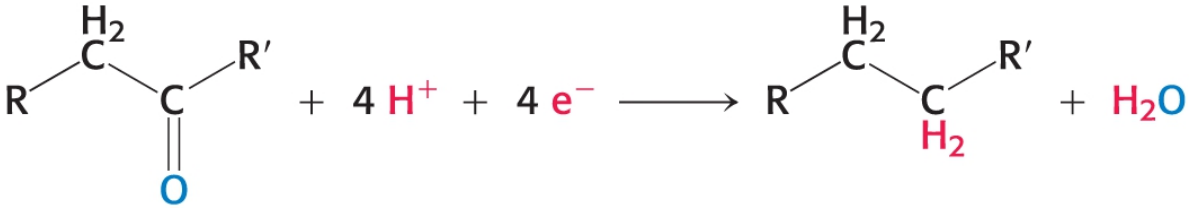


FIGURE 15.14 Structures of the reactive components of FAD and $FADH_2$ reveal that electrons and protons are carried by the reactive isoalloxazine ring component.

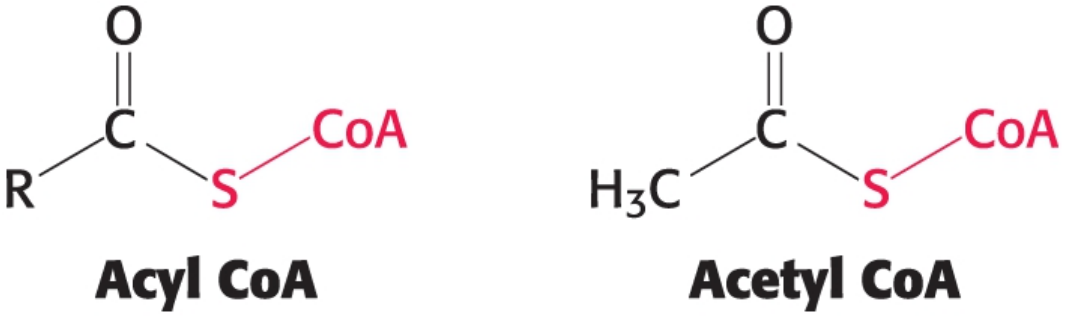
NADPH: Activated carrier of electrons for reductive biosynthesis

High-potential electrons are required in most biosyntheses because the precursors are more oxidized than the products. Hence, reducing power is needed in addition to ATP. For example, in the biosynthesis of fatty acids, a keto group is reduced to a methylene group in several steps. This sequence of reactions requires an input of four electrons.

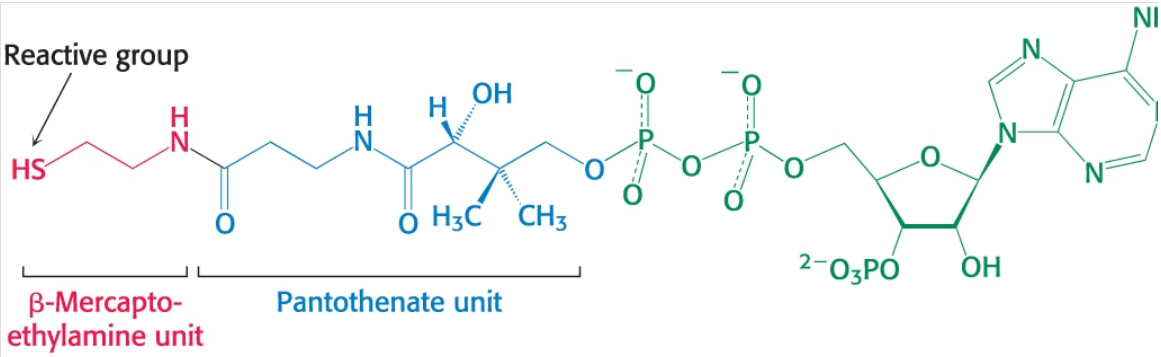


The electron donor in most reductive biosyntheses is NADPH, the reduced form of nicotinamide adenine dinucleotide phosphate (Figure

15.12). Its oxidized form is $NADP^+$. NADPH differs from NADH in that the $2'$–hydroxyl group of its adenosine moiety is esterified with phosphate. NADPH carries electrons in the same way as NADH. However, NADPH is used almost exclusively for reductive biosyntheses, whereas NADH is used primarily for the generation of ATP. The extra phosphoryl group on NADPH is a tag that enables enzymes to distinguish between high-potential electrons to be used in anabolism and those to be used in catabolism.

Coenzyme A: Activated carrier of two-carbon fragments

Coenzyme A (CoA), another central molecule in metabolism, is a carrier of acyl groups that is derived from vitamin B_5 (pantothenate) (**Figure 15.15**). The terminal sulfhydryl group in CoA is the reactive site. Acyl groups are linked to CoA by thioester bonds. The resulting derivative is called an *acyl CoA*. An acyl group often linked to CoA is the acetyl unit; this derivative is called *acetyl CoA*.



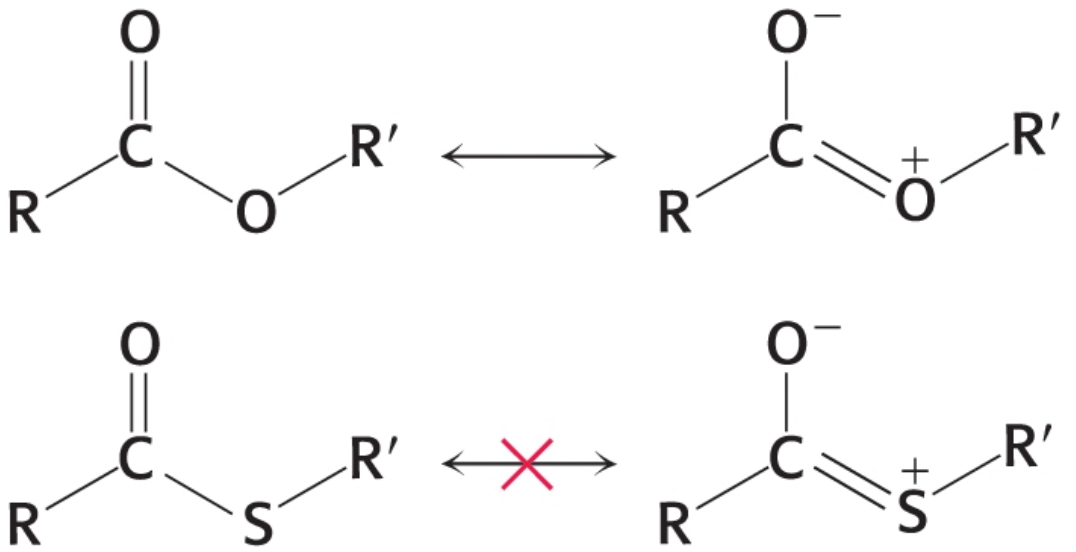


FIGURE 15.15 Structure of coenzyme A (CoA) reveals its derivation from both ADP and the vitamin pantothenate.

Acyl groups are important constituents both in catabolism, as in the oxidation of fatty acids, and in anabolism, as in the synthesis of membrane lipids.

The $\Delta G^{\circ\prime}$ for the hydrolysis of acetyl CoA has a large negative value:

$$\text{Acetyl CoA} + H_2O \rightleftharpoons \text{acetate} + \text{CoA} + H^+$$
$$\Delta G^{\circ\prime} = -31.4 \text{ kJ mol}^{-1} \ (-7.5 \text{ kcal mol}^{-1})$$

A thioester is thermodynamically more unstable than an oxygen ester because the electrons of the $C{=}O$ bond cannot form resonance structures with the $C{-}S$ bond that are as stable as those that they can form with the $C{-}O$ bond.

Consequently, acetyl CoA has a high acetyl-group-transfer potential because transfer of the acetyl group is exergonic. Acetyl CoA carries an activated acetyl group, just as ATP carries an activated phosphoryl group.

The use of activated carriers illustrates two key aspects of metabolism:

1. *Kinetic stability allows enzymatic control over the flow of energy.* First, NADH, NADPH, and $FADH_2$ react slowly with O_2 in the absence of a catalyst. Likewise, ATP and acetyl CoA are hydrolyzed slowly (over many hours or even days) in the absence of a catalyst. These molecules are kinetically quite stable in the face of a large thermodynamic driving force for reaction with O_2 (in regard to the electron carriers) and H_2O (for ATP and acetyl CoA). The kinetic stability of these molecules in the absence of specific catalysts is

essential for their biological function because it enables enzymes to control the flow of free energy and reducing power.

2. *A small set of carriers accomplishes the majority of the exchanges of activated groups in metabolic pathways* (Table 15.2). The existence of a recurring "cast of characters" — a small set of activated carriers in all organisms — illustrates the modular design of metabolism. A small set of molecules carries out a very wide range of tasks.

TABLE 15.2 Some activated carriers in metabolism

Carrier molecule in activated form	Group carried	Vitamin precursor
ATP	Phosphoryl	
NADH and NADPH	Electrons	Nicotinate (niacin) (vitamin B_3)
$FADH_2$ and $FMNH_2$	Electrons	Riboflavin (vitamin B_2)
Coenzyme A	Acyl	Pantothenate (vitamin B_5)
Lipoamide	Acyl	
Thiamine pyrophosphate	Aldehyde	Thiamine (vitamin B_1)
Biotin	CO_2	Biotin (vitamin B_7)
Tetrahydrofolate	One-carbon units	Folate (vitamin B_9)
S-Adenosylmethionine	Methyl	

Uridine diphosphate glucose	Glucose
Cytidine diphosphate diacylglycerol	Phosphatidate
Nucleoside triphosphates	Nucleotides

Note: Many of the activated carriers are coenzymes that are derived from water-soluble vitamins.

Many activated carriers are derived from vitamins

As noted in Table 15.2, most activated carriers that act as coenzymes are derived from **vitamins**, organic molecules that are needed in small amounts in the diets of some higher animals. In all cases, a vitamin must be modified before it can serve its function. **Table 15.3** lists the vitamins that act as coenzymes, and **Figure 15.16** shows the structures of some of B group vitamins.

TABLE 15.3 The B vitamins

Vitamin	Coenzyme	Typical reaction Type	Consequences of Deficiency
Thiamine (B_1)	Thiamine pyrophosphate (TPP)	Aldehyde transfer	Beriberi (weight loss, heart problems, neurological dysfunction)
Riboflavin (B_2)	Flavin adenine dinucleotide (FAD)	Oxidation–reduction	Lesions of the mouth, dermatitis

Pyridoxine (B_6)	Pyridoxal phosphate (PLP)	Group transfer to or from amino acids	Depression, confusion, convulsions
Nicotinic acid (niacin) (B_3)	Nicotinamide adenine dinucleotide (NAD^+)	Oxidation–reduction	Pellagra (dermatitis, depression, diarrhea)
Pantothenic acid (B_5)	Coenzyme A (CoA)	Acyl-group transfer	Hypertension
Biotin (B_7)	Biotin–lysine adducts (biocytin)	ATP-dependent carboxylation and carboxyl-group transfer	Rash about the eyebrows, muscle pain, fatigue (rare)
Folic acid (B_9)	Tetrahydrofolate (THF)	Transfer of one-carbon components; thymine synthesis	Anemia, neural-tube defects in development
Cobalamin (B_{12})	5′-Deoxyadenosyl-cobalamin	Transfer of methyl groups; intramolecular rearrangements	Anemia, pernicious anemia, methylmalonic acidosis

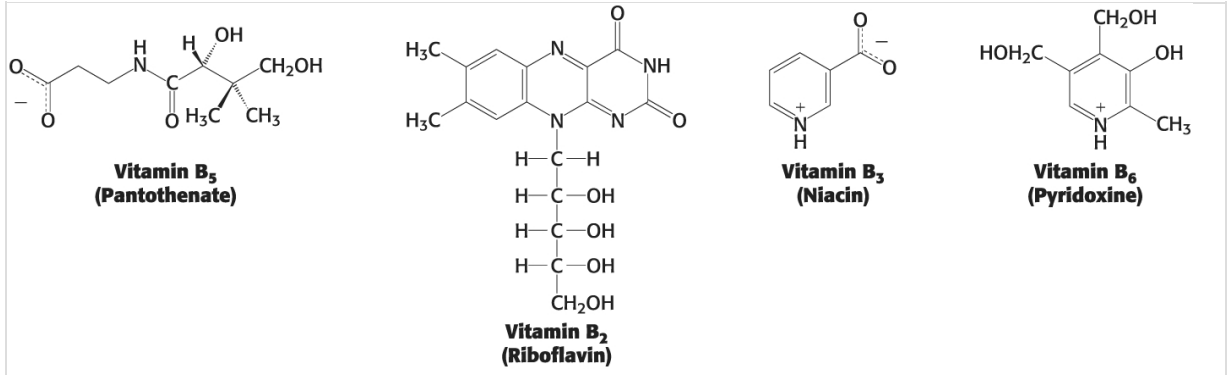

FIGURE 15.16 The B vitamins are a diverse group of small, water-soluble molecules. These vitamins, along with vitamin C, are often referred to as water-soluble vitamins because of the

ease with which they dissolve in water.

Not all vitamins function as coenzymes; vitamins designated by the letters A, C, D, E, and K (Table 15.4) have a diverse array of functions that we will encounter, along with the B vitamins, in our study of biochemistry.

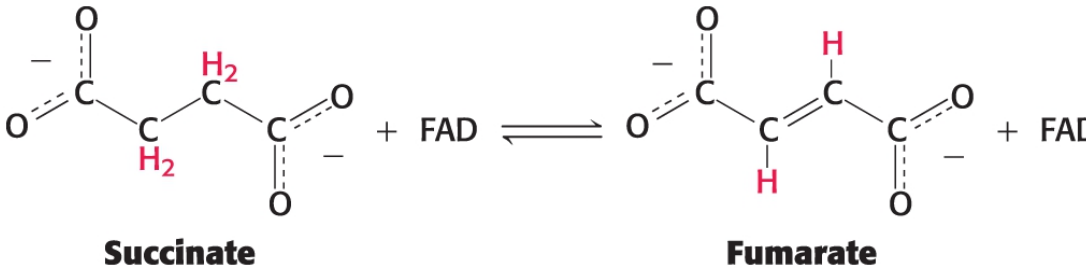
TABLE 15.4 Noncoenzyme vitamins

Vitamin	Function	Deficiency
A	Roles in vision, growth, reproduction	Night blindness, cornea damage, damage to respiratory tract and gastrointestinal tract
C	Antioxidant, essential for collagen production	Scurvy (swollen and bleeding gums, subdermal hemorrhaging)
D	Regulation of calcium and phosphate metabolism	Rickets (children): skeletal deformities, impaired growth Osteomalacia (adults): soft, bending bones
E	Antioxidant	Lesions in muscles and nerves (rare)
K	Blood coagulation	Subdermal and cerebral hemorrhaging

Vitamins serve the same roles in nearly all forms of life, but higher animals lost the capacity to synthesize them in the course of evolution. For instance, whereas *E. coli* can thrive on glucose and organic salts, human beings require at least 12 vitamins in their diet. The biosynthetic pathways for vitamins can be complex; thus, it is

biologically more efficient to ingest vitamins than to synthesize the enzymes required to construct them from simple molecules. This efficiency comes at the cost of dependence on other organisms for chemicals essential for life. Indeed, vitamin deficiency can generate diseases in all organisms requiring these molecules (Tables 15.3 and 15.4).

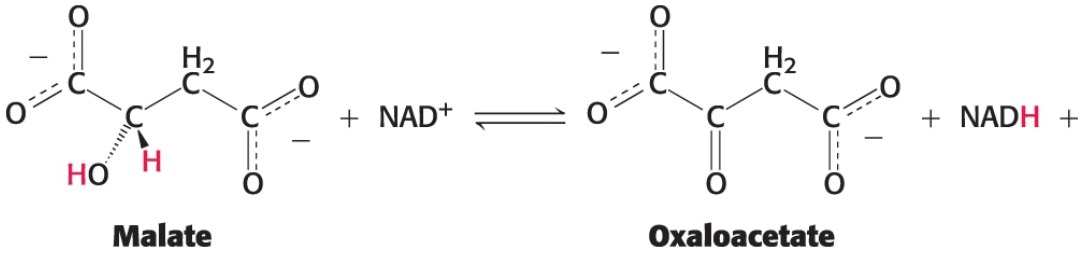
Key reactions are reiterated throughout metabolism



Just as there is an economical use of the same small set of activated carriers, there is also an economical use of a small set of biochemical reactions. In fact, the thousands of metabolic reactions can be subdivided into just six types (**Table 15.5**). These six types of reactions correspond to the six major classes of enzymes discussed in Section 5.1. Specific reactions of each type appear repeatedly.

TABLE 15.5 Types of chemical reactions in metabolism

Type of reaction	Description
Oxidation–reduction	Electron transfer
Group transfer	Transfer of a functional group from one molecule to another
Hydrolytic	Cleavage of bonds by the addition of water
Carbon bond cleavage by means other than hydrolysis or oxidation	Two substrates yielding one product or vice versa. When H_2O or CO_2 are a product, a double bond is formed.

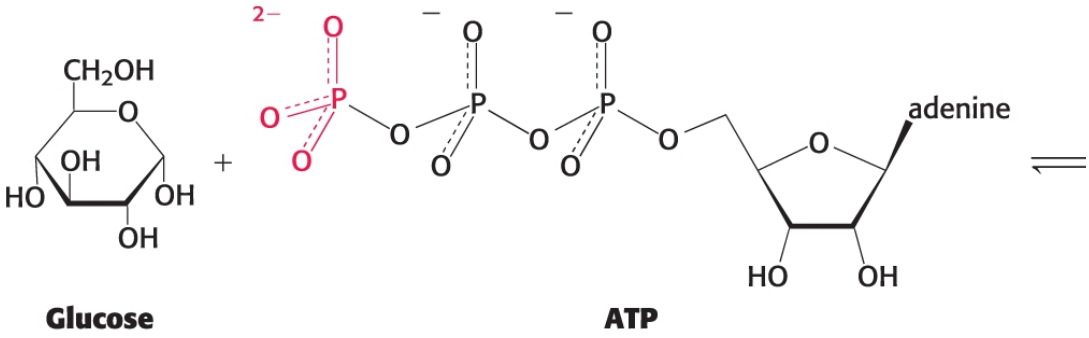


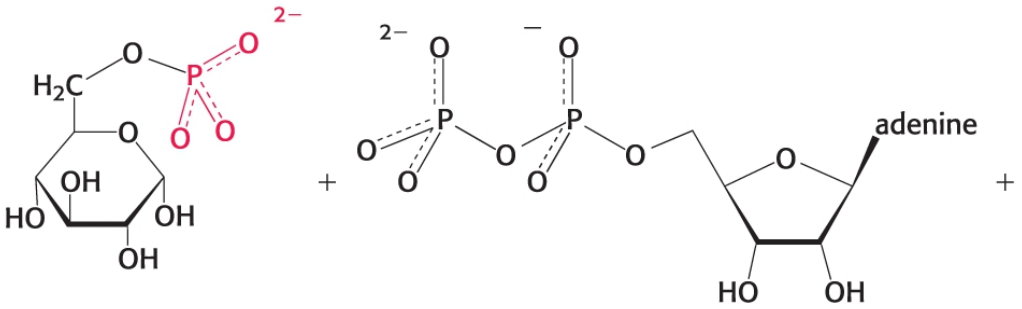
Isomerization	Rearrangement of atoms to form isomers
Ligation requiring ATP cleavage	Formation of covalent bonds (i.e., carbon–carbon bonds)

1. *Oxidation–reduction reactions are essential components of many pathways.* Useful energy is often derived from the oxidation of carbon compounds. Consider the following two reactions:

Succinate **Fumarate**

(1)



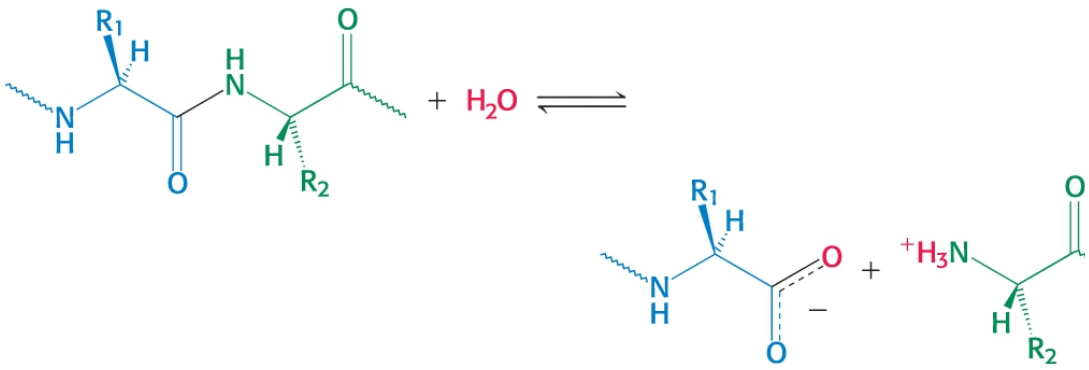


Malate **Oxaloacetate**

(2)

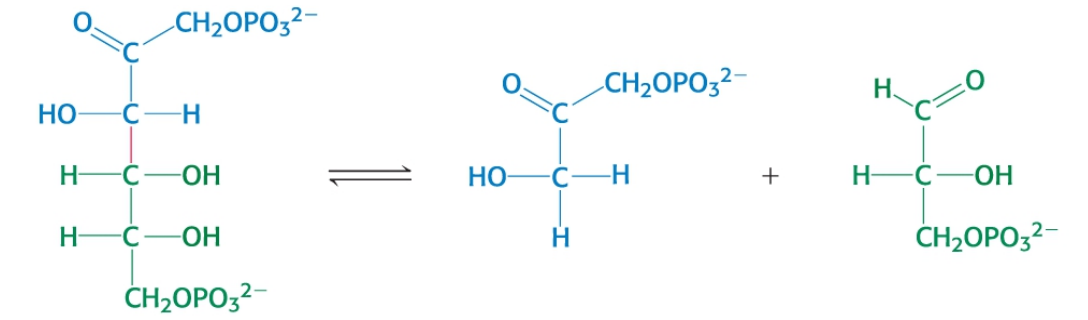
These two oxidation–reduction reactions are components of the citric acid cycle (Chapter 17), which completely oxidizes the activated two-carbon fragment of acetyl CoA to two molecules of CO_2. In reaction 1, $FADH_2$ carries the electrons, whereas in reaction 2, electrons are carried by NADH.

2. *Group-transfer reactions play a variety of roles.* Phosphoryl group transfer is representative of such a reaction:



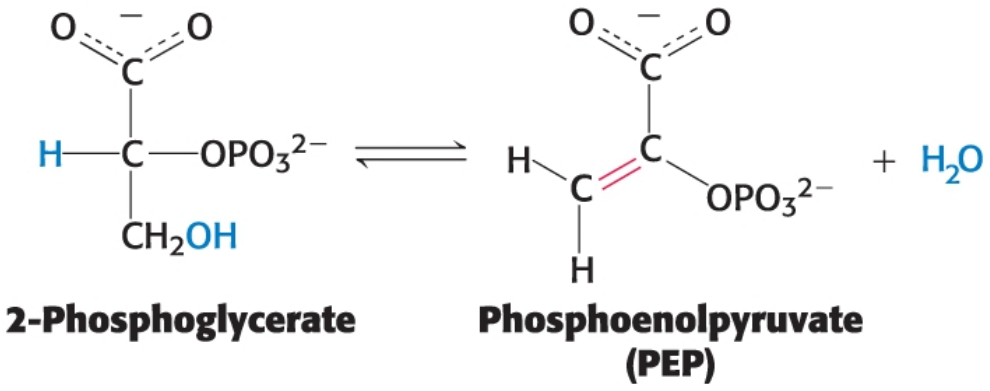
(3)

A phosphoryl group is transferred from the activated phosphoryl-group carrier, ATP, to glucose in the initial step in glycolysis, a key pathway for extracting energy from glucose (Chapter 16). This



reaction traps glucose in the cell so that further catabolism can take place. As stated earlier, group-transfer reactions are used to synthesize ATP. We also saw examples of their use in signaling pathways (Chapter 14).

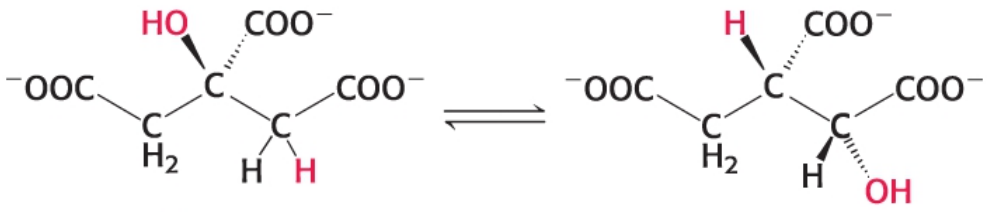
3. *Hydrolytic reactions cleave bonds by the addition of water.* Hydrolysis is a common means of degrading large molecules, either to facilitate further metabolism or to reuse some of the components for biosynthetic purposes. For example, recall from Section 6.1 that proteins are digested by hydrolytic cleavage:



(4)

4. *Carbon bonds can be cleaved by means other than hydrolysis or oxidation.* When CO_2 or H_2O is released, a double bond is formed. The enzymes that catalyze these types of reactions are classified as *lyases*. An important example is the conversion of the six-carbon molecule fructose 1,6-bisphosphate into two three-carbon fragments:

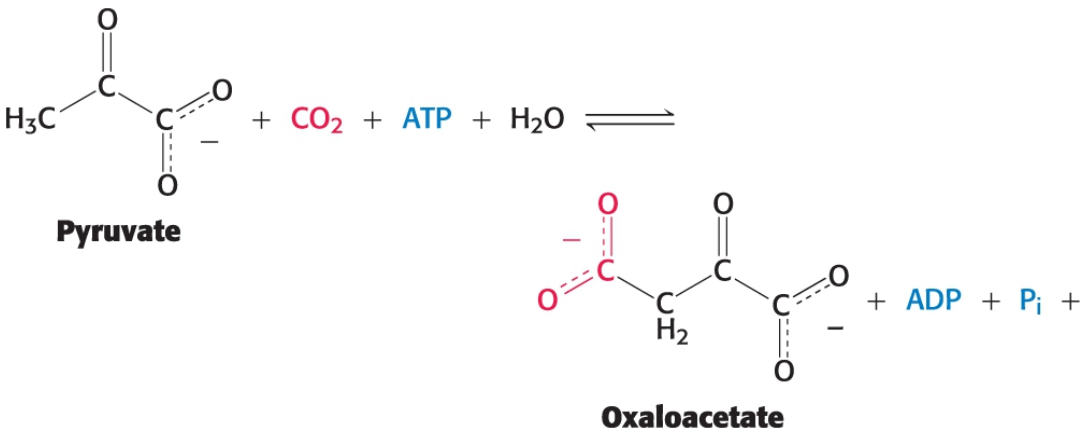
(5)



This reaction is a critical step in glycolysis (Chapter 16). In addition, the formation of double bonds through dehydration — such as generating phosphoenolpyruvate (Figure 15.5) from 2-phosphoglycerate — is an important subclass of this reaction type:

(6)

This dehydration sets up the next step in the pathway, a group-transfer reaction that uses the high phosphoryl-transfer potential of the product PEP to form ATP from ADP.



5. *Isomerization reactions rearrange particular atoms within a molecule.* The role of these reactions is often to prepare the molecule for subsequent reactions such as the oxidation–reduction reactions described above.

(7)

The reaction above is an essential component of the citric acid cycle, analyzed in detail in Chapter 17.

6. *Ligation reactions form bonds by using free energy from ATP hydrolysis.* In many cases, the free energy from ATP hydrolysis is necessary to combine smaller molecules to form larger ones. For example, oxaloacetate is formed from pyruvate and CO_2, using energy from ATP to form the carbon–carbon bond.

(8)

The oxaloacetate can be used in the citric acid cycle, or converted into glucose or amino acids such as aspartic acid.

These six fundamental reaction types are the basis of metabolism; you will encounter them repeatedly in the next few chapters. Remember, all six types can proceed in either direction, depending on the standard free energy for the specific reaction and the concentrations of the reactants and products inside the cell.

Metabolic processes are regulated in three principal ways

Because the network of metabolic reactions is so complex, it must be rigorously regulated. Cells have feedback mechanisms that monitor and adjust levels of available nutrients and the activity of metabolic pathways to create *homeostasis*, a stable biochemical environment. At the same time, metabolic control must be flexible, able to adjust to the

constantly changing external environments of cells. Metabolism is regulated through three principal mechanisms:

1. *The amounts of enzymes can be altered.* The amount of a particular enzyme depends on both its rate of synthesis and its rate of degradation. For many enzymes, their abundance is principally adjusted by a change in the rate of transcription of the genes encoding them (Section 29.3). In *E. coli,* for example, within minutes the presence of lactose induces a more-than-50-fold increase in the rate of synthesis of β-galactosidase, the enzyme required for the breakdown of this disaccharide.

2. *The accessibility of substrates by enzymes can be restricted.* Limiting the availability of substrates is another means of regulating metabolism in all organisms. For instance, glucose breakdown can take place in many cells only if insulin is present to promote the entry of glucose into the cell. In eukaryotes, access to substrates is regulated in part by compartmentalization. For example, fatty acid oxidation takes place in mitochondria, whereas fatty acid synthesis takes place in the cytoplasm. Compartmentalization often segregates opposed reactions.

3. *The catalytic activity of enzymes can be internally regulated or externally controlled.* The catalytic activity of enzymes is continuously adjusted in several ways. Allosteric regulation is especially important; for example, the first reaction in many biosynthetic pathways is allosterically inhibited by the ultimate product of the pathway, called *feedback inhibition,* which can be almost instantaneous. A well-understood example is the inhibition of aspartate transcarbamoylase (ATCase) by cytidine triphosphate (Section 7.1). Another recurring mechanism is reversible covalent modification (Section 7.3). Hormones like adrenaline externally control the catalytic rates of enzymes often by inducing reversible covalent modification of key enzymes or by changing the concentrations of allosteric activators and inhibitors, as we explored in Chapter 14. Finally, many reactions are regulated by the

energy status of the cell. One useful concept that can serve as an index of the energy status is the **energy charge**, which is proportional to the mole fraction of ATP plus half the mole fraction of ADP, given that ATP contains two anhydride bonds, whereas ADP contains one. Hence, the energy charge is defined as

$$\text{Energy charge} = \frac{[\text{ATP}] + \frac{1}{2}[\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]}$$

The energy charge can have a value ranging from 0 (all AMP) to 1 (all ATP). ATP-generating pathways are inhibited under conditions of high-energy charge, whereas ATP-utilizing pathways are often stimulated under those same conditions. In plots of the reaction rates of such pathways versus the energy charge, the curves are steep near an energy charge of 0.9, where they usually intersect (**Figure 15.17**). Regulation of these pathways has evolved to maintain the energy charge within rather narrow limits. In other words, the energy charge, like the pH of a cell, is buffered. The energy charge of most cells ranges from 0.90 to 0.95, but can fall to less than 0.7 in muscle during high-intensity exercise. However, energy charge itself does not directly regulate pathways; rather, enzymes regulating these pathways are allosterically inhibited or activated by binding to ATP or AMP, specifically.

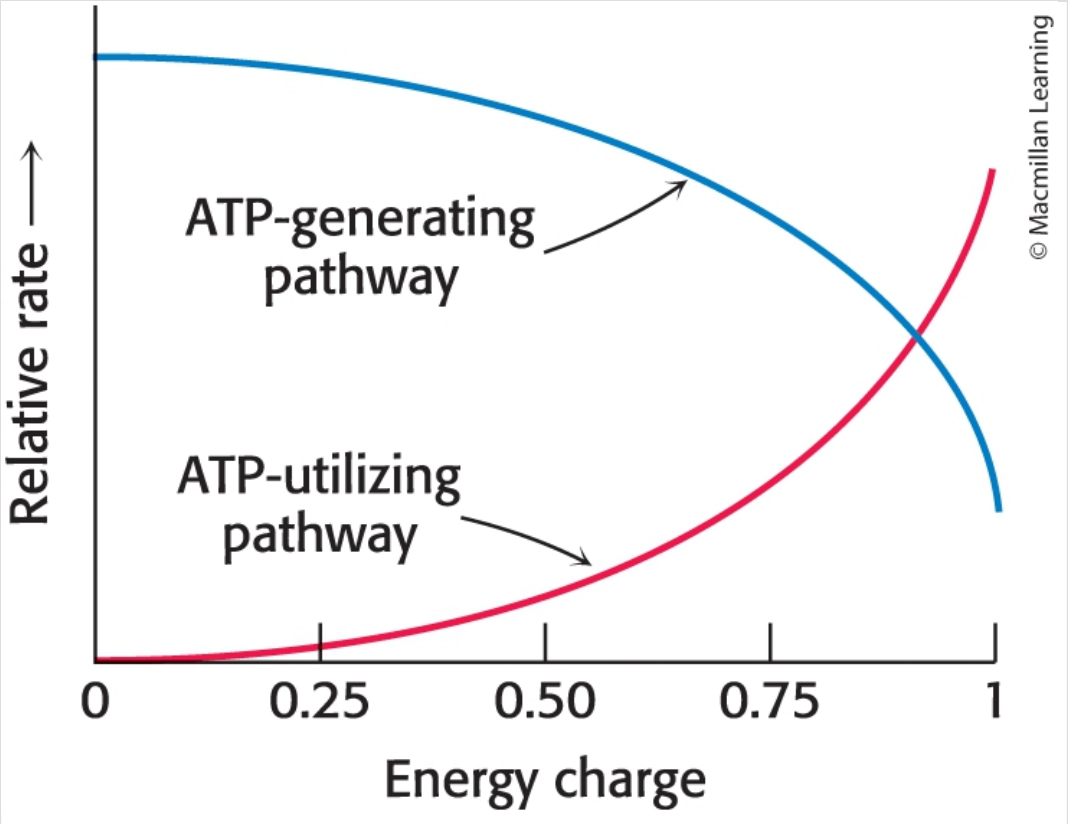


FIGURE 15.17 Energy charge is a useful concept for understanding how metabolism is regulated. When the energy charge is high, ATP commonly inhibits the relative rates of a typical ATP-generating pathway and stimulates the typical ATP-utilizing pathway, while AMP has the opposite effects.

EXPLORE this pathway further in the Metabolic Map in Achieve

Looking at the commonalities in diverse metabolic pathways exposes a chemical logic that renders the complexity of the chemistry of living systems more manageable and reveals its elegance. As you delve into any of the next 12 chapters, you might find it useful to return to this chapter to review the common themes.

Self-Check Question

Name the common cellular carrier of activated two-carbon fragments, and name the common carrier of electrons for biosynthesis. Both these molecules have parts derived from which group of small organic molecules that are precursors to coenzymes?

Chapter 15 Summary

15.1 Metabolism Is Composed of Many Interconnected Reactions

- All cells transform energy. They extract energy from their environment and use this energy to convert simple molecules into cellular components.
- The process of energy transduction takes place through metabolism, a highly integrated network of chemical reactions.
- Metabolism can be subdivided into catabolism (processes that break complex things into simpler ones and typically extract energy from fuels) and anabolism (biosynthetic processes that typically require energy).
- The most valuable thermodynamic concept for understanding bioenergetics is free energy. A reaction can occur spontaneously only if the change in free energy (ΔG) is negative.
- A thermodynamically unfavorable reaction can be driven by a thermodynamically favorable one, which is the hydrolysis of ATP in many cases.

15.2 ATP Is the Universal Currency of Free Energy in Biological Systems

- The energy derived from catabolism is captured in the form of adenosine triphosphate (ATP).
- ATP hydrolysis is exergonic and the energy released can be used to power cellular processes, including motion, active transport, and biosynthesis.
- ATP, the universal currency of energy in biological systems, is an energy-rich molecule because it contains two kinetically

stable, but thermodynamically unstable, phosphoanhydride linkages.

15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy

- ATP formation is coupled to the oxidation of chemicals, either directly or through the formation of ion gradients in chemotrophs. Phototrophic organisms, including all photosynthetic organisms, can use light to generate such gradients.
- The extraction of energy from food by aerobic organisms comprises three stages: (1) large molecules are catabolized into smaller ones, such as amino acids, sugars, and fatty acids; (2) these small molecules are degraded to a few simple units, such as acetyl CoA; (3) the citric acid cycle and oxidative phosphorylation generate ATP as electrons flow to O_2, the ultimate electron acceptor, and fuels are completely oxidized to CO_2.

15.4 Metabolic Pathways Contain Many Recurring Motifs

- Metabolism is characterized by common motifs. A small number of recurring activated carriers, such as ATP, NADH, and acetyl CoA, transfer activated groups in many metabolic pathways. Many activated carriers are derived from vitamins — small organic molecules required in the diets of many higher organisms.
- NADPH, which carries two electrons at a high potential, provides reducing power for reductive biosynthesis of cell components.
- Key reaction types are used repeatedly in metabolic pathways. Metabolism is regulated in a variety of ways: the amounts of enzymes are altered, the catalytic activities of many enzymes

are regulated by allosteric interactions and controlled by covalent modification, and the availability of many substrates is also limited.
- The energy charge, which is a measure of the relative amounts of ATP, ADP, and AMP, is a useful concept for approximating the energy status of a cell. ATP generally inhibits ATP-generating pathways and stimulates ATP-utilizing pathways, while AMP often has the opposite effects.

Key Terms

phototroph
chemotroph
metabolism (intermediary metabolism)
adenosine triphosphate (ATP)
catabolism
anabolism
amphibolic pathway
phosphoryl-transfer potential
activated carrier
vitamin
energy charge

Problems

1. Differentiate between anabolism and catabolism. 1

2. Distinguish between a phototroph and a chemotroph. 1

3. What are the three major stages in the energy extraction from food? Assess the contribution of each stage to ATP synthesis. 1

4. What are the three primary uses for cellular energy?

5. What factors account for the high phosphoryl-transfer potential of nucleoside triphosphates? 2

6. The standard free energy of hydrolysis for ATP is $-30.5\ \text{kJ mol}^{-1}\ (-7.3\ \text{kcal mol}^{-1})$.

$$\text{ATP} + \text{H}_2\text{O} \rightleftharpoons \text{ADP} + \text{P}_i$$

How might physiological conditions, such as rest, intense exercise, or an alteration of intracellular ionic environment, alter the free energy of hydrolysis? 3

7. What is the direction of each of the following reactions when the reactants are initially present in equimolar amounts? Use the data given in Table 15.1. 3

a. $\text{ATP} + \text{creatine} \rightleftharpoons \text{creatine phosphate} + \text{ADP}$

b. $\text{ATP} + \text{glycerol} \rightleftharpoons \text{glycerol 3-phosphate} + \text{ADP}$

c. $\text{ATP} + \text{pyruvate} \rightleftharpoons \text{phosphoenolpyruvate} + \text{ADP}$

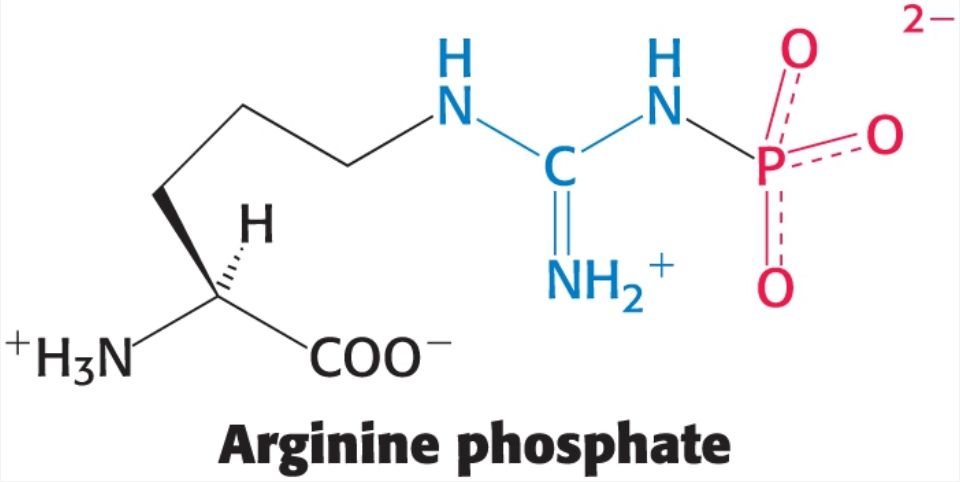
d. $\text{ATP} + \text{glucose} \rightleftharpoons \text{glucose 6-phosphate} + \text{ADP}$

8. Consider the following reaction:

$$\text{ATP} + \text{pyruvate} \rightleftharpoons \text{phosphoenolpyruvate} + \text{ADP}$$

a. Calculate $\Delta G^{\circ\prime}$ and K'_{eq} at 25°C for this reaction by using the data given in Table 15.1.
b. What is the equilibrium ratio of pyruvate to phosphoenolpyruvate if the ratio of ATP to ADP is 10? 3

9. Using the information in Table 15.1, calculate $\Delta G^{\circ\prime}$ for the isomerization of glucose 6-phosphate to glucose 1-phosphate. What is the equilibrium ratio of glucose 6-phosphate to glucose 1-phosphate at 25°C?



10. The formation of acetyl CoA from acetate is an ATP-driven reaction:

$$\text{Acetate} + \text{ATP} + \text{CoA} \rightleftharpoons \text{acetyl CoA} + \text{AMP} + \text{PP}_i$$

3

a. Calculate $\Delta G^{\circ\prime}$ for this reaction by using data given in this chapter.
b. The PP_i formed in the preceding reaction is rapidly hydrolyzed in vivo because of the ubiquity of inorganic pyrophosphatase. The $\Delta G^{\circ\prime}$ for the hydrolysis of PP_i is $-19.2\ \text{kJ mol}^{-1}(-4.6\ \text{kcal mol}^{-1})$. Calculate the $\Delta G^{\circ\prime}$ for the overall reaction, including pyrophosphate hydrolysis. What effect does the hydrolysis of PP_i have on the formation of acetyl CoA? 3, 5

11. The muscles of some invertebrates are rich in arginine phosphate (phosphoarginine). Propose a function for this amino acid derivative. 2

Arginine phosphate

12. What is the structural feature common to ATP, FAD, NAD^+, and CoA? 5

13. Creatine is a popular dietary supplement.

a. What is the biochemical rationale for the use of creatine?
b. What type of exercise would benefit most from creatine supplementation? 3

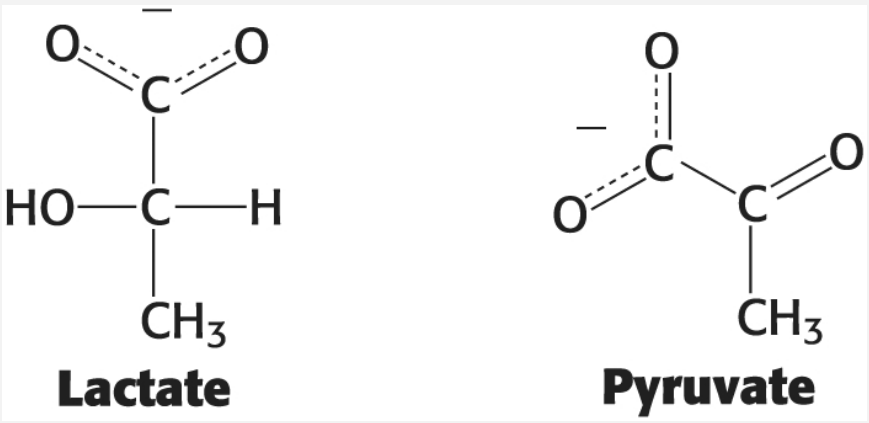
14. The enzyme aldolase catalyzes the following reaction in the glycolytic pathway:

$$\text{Fructose 1, 6-bisphosphate} \xrightleftharpoons{\text{Aldolase}} \text{dihydroxyacetone phosphate} + \text{glyceraldehyde 3-phosphate}$$

The $\Delta G^{\circ\prime}$ for the reaction is $+23.8\ \text{kJ mol}^{-1}\ (+5.7\ \text{kcal mol}^{-1})$, whereas the ΔG in the cell is $-1.3\ \text{kJ mol}^{-1}\ (-0.3\ \text{kcal mol}^{-1})$. Calculate the ratio of reactants to products under equilibrium and intracellular conditions. Using your results, explain how the reaction can be endergonic under standard conditions and exergonic under intracellular conditions.

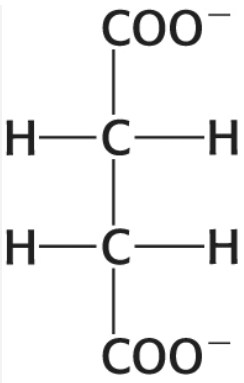
15. The concentrations of ATP, ADP, and P_i differ with cell type. Consequently, the release of free energy with the hydrolysis of ATP will vary with cell type. Using the following table, calculate the ΔG for the hydrolysis of ATP in liver, muscle, and brain cells. In which cell type is the free energy of ATP hydrolysis most negative? 2

	ATP (mM)	ADP (mM)	P_i (mM)
Liver	3.5	1.8	5.0
Muscle	8.0	0.9	8.0

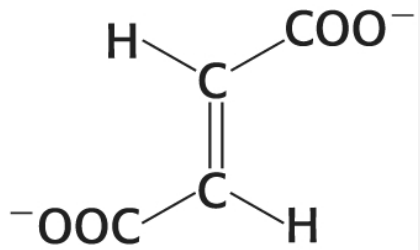


Brain	2.6	0.7	2.7

16. Examine the pairs of molecules and identify the more-reduced molecule in each pair. 4

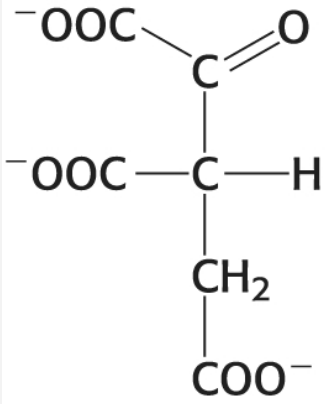


a.

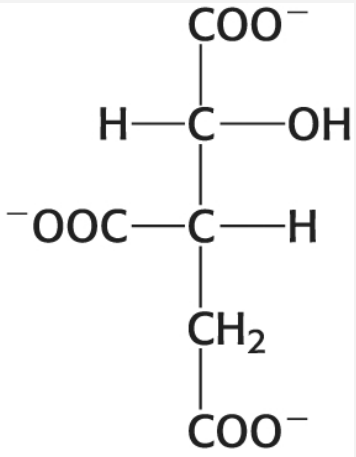


b.

c.

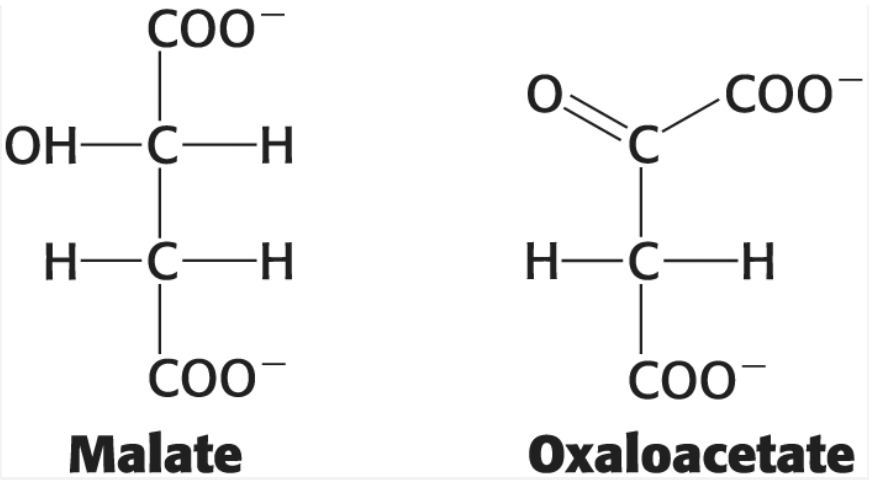


Succinate



Fumarate

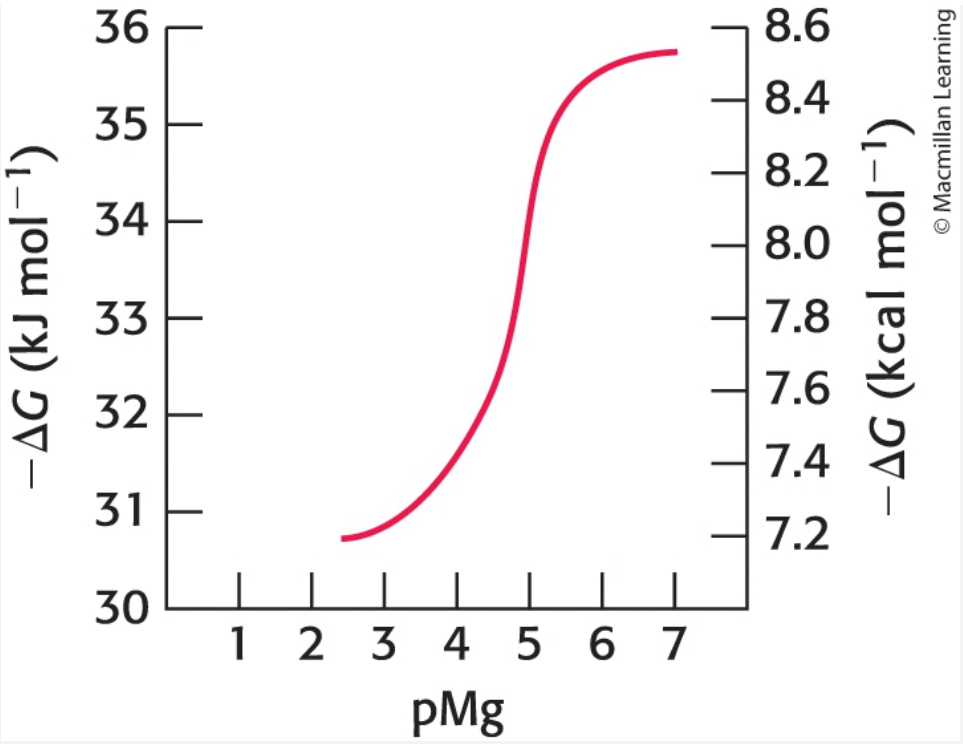
d.



Oxalosuccinate

Isocitrate

e.



17. What are the activated electron carriers for catabolism? For anabolism? 5

18. What are the six common types of reactions seen in biochemistry? 5

19. What are the three principal means of controlling metabolic reactions described in this chapter? 5

20. The following graph shows how the ΔG for the hydrolysis of ATP varies as a function of the Mg^{2+} concentration, $pMg = -\log[Mg^{2+}]$. 2

a. How does decreasing $[Mg^{2+}]$ affect the ΔG of hydrolysis for ATP?
b. Explain this effect.

Chapter 16
Glycolysis and Gluconeogenesis

Glucose metabolism can generate the ATP to power muscle contraction. During a sprint, when the ATP needs outpace oxygen delivery, glucose is metabolized to lactate (pathway A). When oxygen delivery is adequate, glucose is metabolized more efficiently to carbon dioxide and water (pathway B).

Outline

16.1 Glycolysis Is an Energy-Conversion Pathway in Most Organisms
16.2 Glycolysis Can Be Divided into Two Parts
16.3 The Glycolytic Pathway Is Tightly Controlled
16.4 Glucose Can Be Synthesized from Noncarbohydrate Precursors
16.5 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

Learning Goals

By the end of this chapter, you should be able to:

1. Describe how ATP is generated in glycolysis.
2. Explain why the regeneration of NAD^+ is crucial to fermentations.

3. Describe how gluconeogenesis is powered in the cell.
4. Describe the coordinated regulation of glycolysis and gluconeogenesis.

Our understanding of carbohydrate metabolism has a rich history. Indeed, the development of biochemistry and the delineation of the metabolic pathways that begin with glucose went hand in hand. A key discovery was made in 1897 by a pair of biochemist brothers, Hans and Eduard Buchner, quite by accident. The Buchners were interested in manufacturing cell-free extracts of baker's yeast for possible therapeutic use. These extracts had to be preserved without the use of antiseptics such as phenol, and so they decided to try sucrose, a commonly used preservative in kitchen chemistry. They obtained a startling result: sucrose was rapidly fermented into ethanol by the yeast juice. The Buchners demonstrated for the first time that fermentation could take place outside living cells.

The significance of this finding was immense. The accepted view of their day, asserted by Louis Pasteur in 1860, was that fermentation is inextricably tied to living cells. The chance discovery by the Buchners refuted this dogma. The Buchners' discovery inspired the search for the biochemicals that catalyze the conversion of sucrose into alcohol and opened the door to modern biochemistry.

16.1 Glycolysis Is an Energy-Conversion Pathway in Most Organisms

The first metabolic pathway that we encounter is glycolysis, an ancient energy-conversion pathway employed by a host of organisms. **Glycolysis** is the sequence of reactions that metabolizes one molecule of glucose to two molecules of pyruvate with the concomitant net production of two molecules of ATP. This process is anaerobic, meaning that it does not require O_2, because it evolved before substantial amounts of oxygen accumulated in the atmosphere. Glycolysis is common to virtually all cells, both prokaryotic and eukaryotic. The complete glycolytic pathway is also known as the *Embden-Meyerhof-Parnas pathway*, named after three pioneers of research on glycolysis. As observed accidentally by the Buchners, pyruvate can be further processed anaerobically by fermentation to lactic acid, ethanol, or a variety of other final products depending on the organism. Under aerobic conditions, pyruvate can be completely oxidized to CO_2, generating much more ATP, as will be described in Chapters 17 and 18. **Figure 16.1** shows a few possible fates of pyruvate produced by glycolysis.

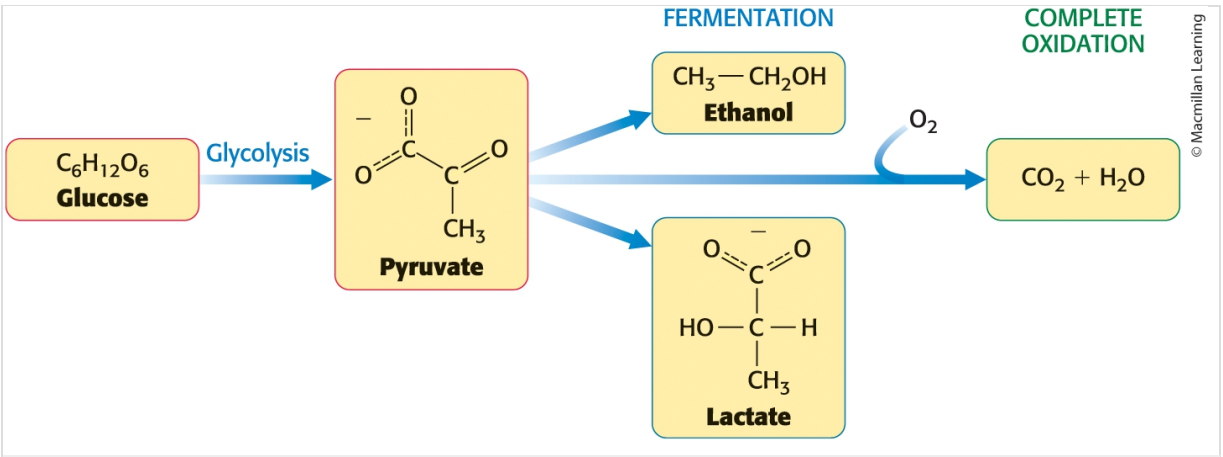


FIGURE 16.1 Glucose can be metabolized to different products depending on the organism and the presence or absence of oxygen.

Recall from Chapter 11 that glucose is a common but yet precious fuel for almost all organisms. In mammals, it is the only fuel that the brain uses under nonstarvation conditions and the only fuel that red blood cells can use at all. Because glucose is such a precious fuel, metabolic products, such as pyruvate and lactate, are salvaged to synthesize glucose in the process of **gluconeogenesis**, but the majority of glucose circulating in our blood each day originates directly from our diet.

Glucose is generated from dietary carbohydrates

In our diets, we typically consume a generous amount of glucose in the form of starch and a smaller amount as glycogen. These complex carbohydrates must be converted into simpler carbohydrates for absorption by the intestine and transport in the blood. Starch and glycogen are digested primarily by the pancreatic

and salivary enzyme α-*amylase*. Amylase cleaves the α-1,4 bonds of starch and glycogen, but not the α-1,6 bonds. The products are the di- and trisaccharides maltose and maltotriose. The material not digestible because of the α-1,6 bonds is called the *limit dextrin*.

α-Glucosidase (maltase) cleaves maltose and maltotriose, as well as any other α-1,4-linked oligosaccharides that may have escaped digestion by the amylase, into glucose molecules. α-Dextrinase further digests the limit dextrin. α-Glucosidase is located on the surface of the intestinal cells, as are sucrase and lactase. Sucrase degrades ingested sucrose to fructose and glucose, while lactase is responsible for degrading the milk sugar lactose into glucose and galactose. The monosaccharides are transported into the endothelial cells lining the intestine by the action of active transporters. Glucose then moves passively down its concentration gradient out of endothelial cells and into the bloodstream, and again passively into cells that will finally utilize it. How is this directional movement from one tissue to another accomplished?

A family of transporters enables glucose to enter and leave animal cells

Several glucose transporters (named GLUT1 to GLUT5) mediate the thermodynamically downhill movement of glucose across the plasma membranes of animal cells. Although all have a 12-transmembrane-helix structure similar to that of lactose permease (Section 13.3), the members of this family have distinctive roles, summarized in **Table 16.1**. GLUT1 and GLUT3, present in nearly all mammalian cells, are responsible for basal glucose uptake. Their K_M value for glucose is about 1 mM, significantly less than the normal blood serum-glucose range of 4–8 mM. Hence, GLUT1 and GLUT3

continually transport glucose into cells at an essentially constant rate.

TABLE 16.1 Family of glucose transporters

Name	Tissue location	K_M	Comments
GLUT 1	All mammalian tissues	1 mM	Basal glucose uptake
GLUT 2	Liver and pancreatic β cells	15–20 mM	In the pancreas, plays a role in the regulation of insulin In the liver, removes excess glucose from the blood
GLUT 3	All mammalian tissues	1 mM	Basal glucose uptake
GLUT 4	Muscle and fat cells	5 mM	Amount in muscle plasma membrane increases with endurance training and in response to insulin
GLUT 5	Small intestine	—	Primarily a fructose transporter

As described in Section 14.3, the number of GLUT4 transporters in the plasma membrane of muscle and fat cells increases rapidly in the presence of insulin, which signals the fed state. Thus, insulin promotes the uptake of glucose by muscle and fat. Endurance exercise training also increases the amount of this transporter

present in muscle membranes. GLUT2 is present in liver and pancreatic β cells but is distinctive in having a very high K_M value for glucose (15–20 mM). Because of this, glucose enters these tissues at a biologically significant rate only when there is much glucose in the blood. The pancreas can sense the glucose level and accordingly adjust the rate of insulin secretion. Lastly, while GLUT5 can also transport glucose, it functions primarily as a fructose transporter in the small intestine. Once finally in the cytoplasm of a glycolytically active cell, glucose and other monosaccharides are ready to enter the glycolytic pathway.

16.2 Glycolysis Can Be Divided into Two Parts

The 10 enzyme-catalyzed reactions that make up the glycolytic pathway can be thought of as comprising two stages (Figure 16.2). Stage 1 is the trapping and preparation phase. No ATP is generated in this stage. In stage 1, glucose is converted into fructose 1,6-bisphosphate in three steps: a phosphorylation, an isomerization, and a second phosphorylation reaction. The strategy of these initial steps in glycolysis is to trap the glucose in the cell and form a compound that can be readily cleaved into phosphorylated three-carbon units (Figure 16.3). Stage 1 is completed with the cleavage of the fructose 1,6-bisphosphate into two three-carbon fragments. These resulting three-carbon units are readily interconvertible. In stage 2, ATP is harvested when the three-carbon fragments are oxidized to pyruvate.

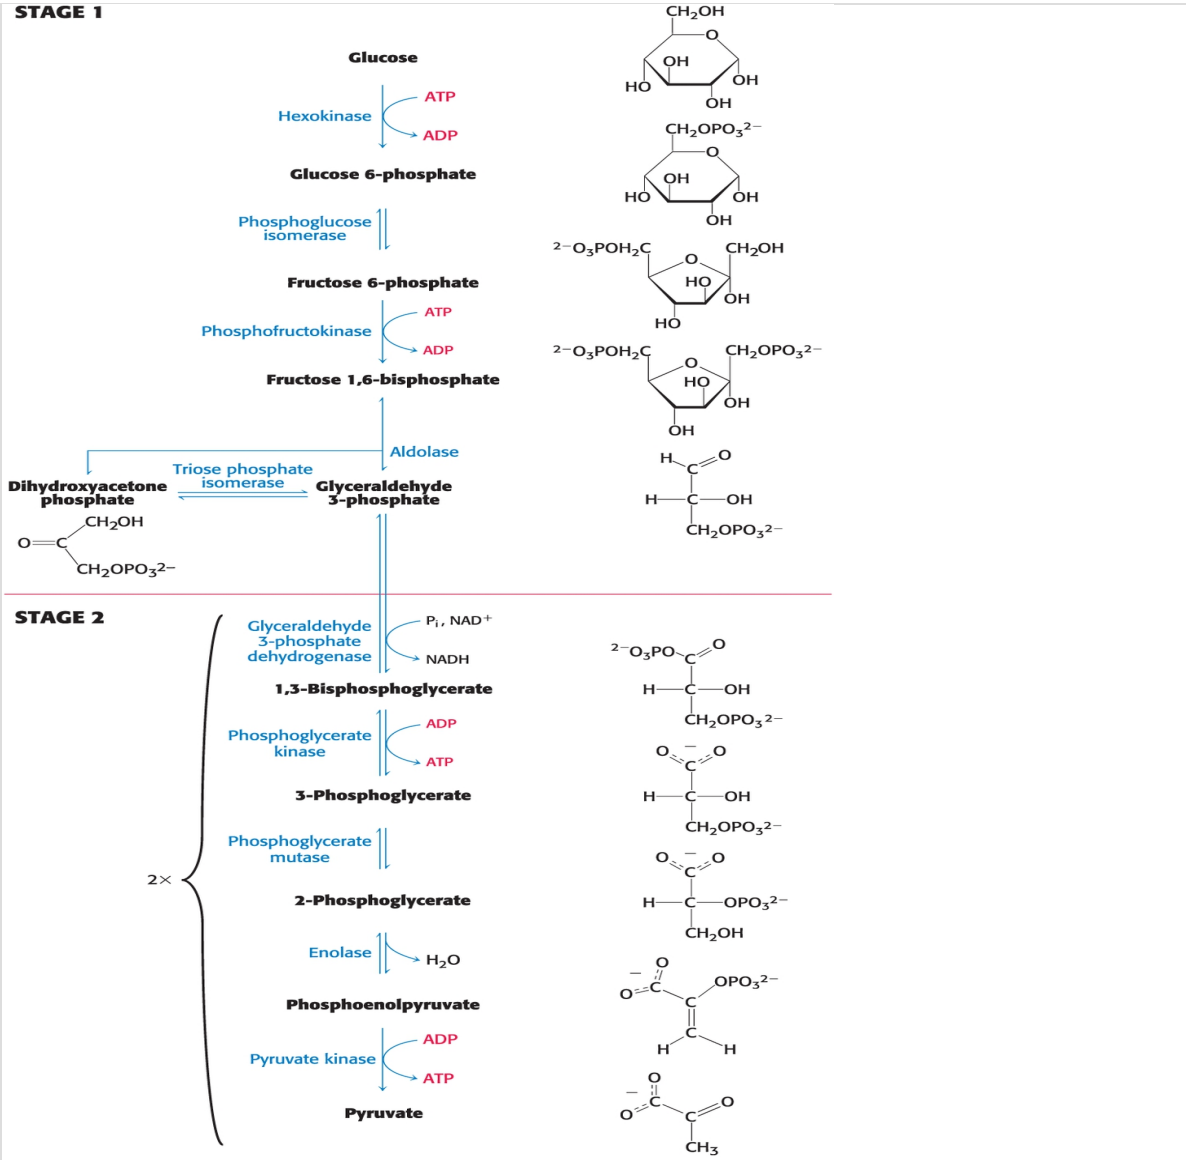

FIGURE 16.2 The glycolytic pathway can be divided into two stages. In Stage 1, glucose is trapped, destabilized, and cleaved into two interconvertible three-carbon molecules generated by cleavage of six-carbon fructose; and in Stage 2, ATP is generated.

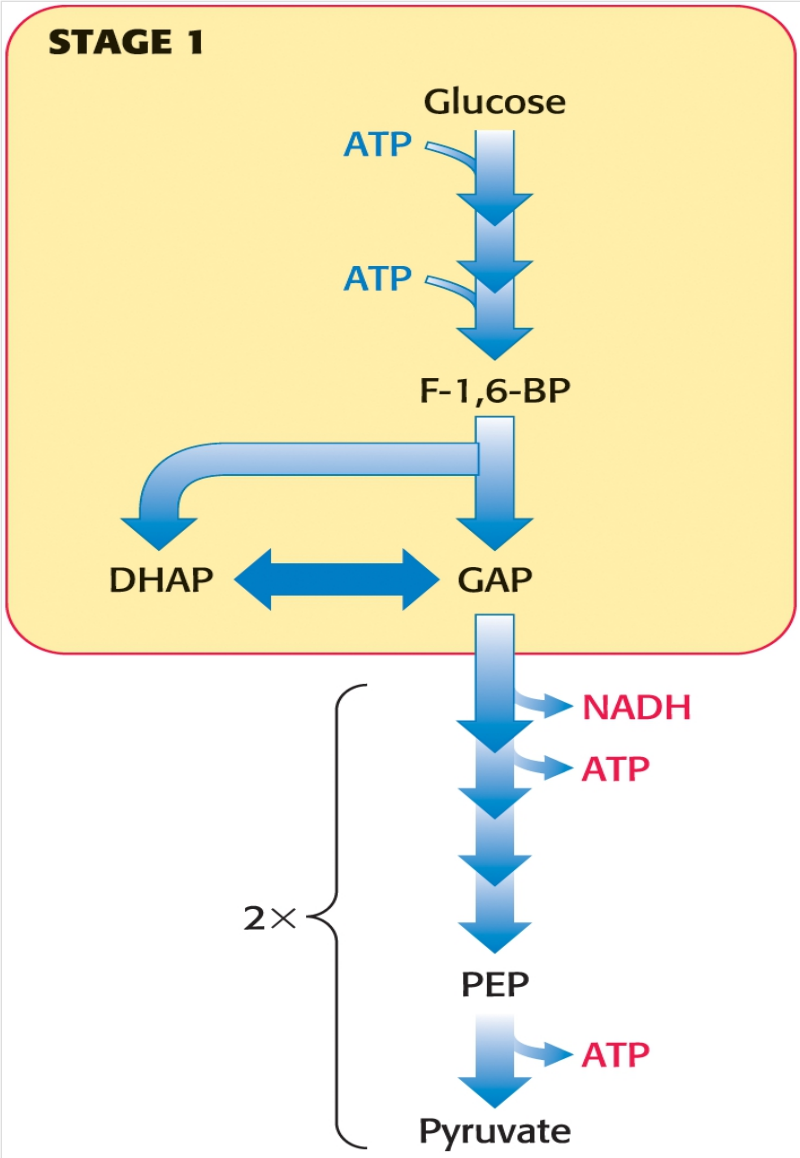

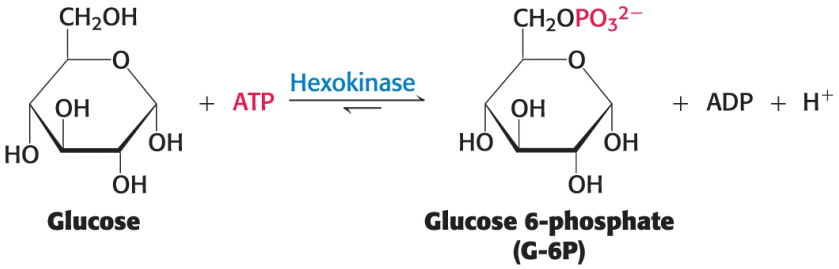

FIGURE 16.3 The first or "investment" stage of glycolysis uses the energy from two molecules of ATP. The products of this stage are two molecules of GAP for every molecule of glucose entering the pathway.

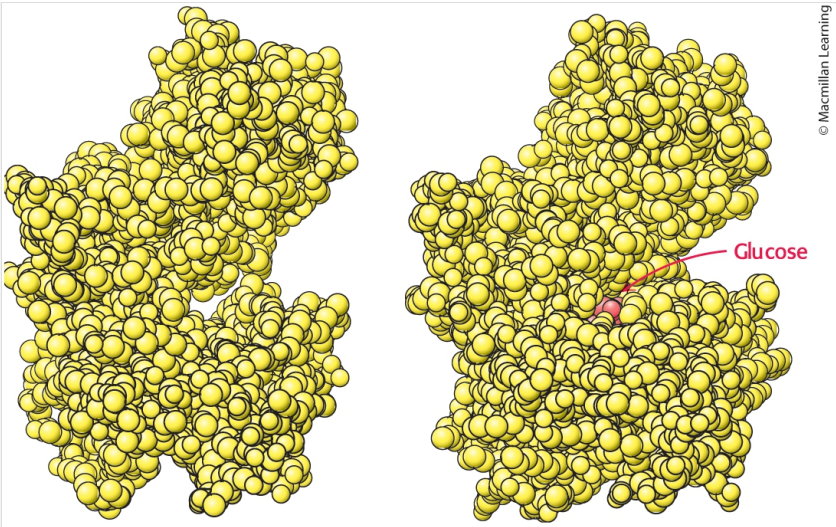
Stage 1 begins: Hexokinase traps glucose in the cell and begins glycolysis

Glucose entering a glycolytically active cell has one principal fate: it is phosphorylated by ATP to form glucose 6-phosphate. This step is notable for several reasons. Glucose 6-phosphate cannot pass through the membrane because of the negative charges on the phosphoryl groups, and it is not a substrate for glucose transporters. Also, the addition of the phosphoryl group facilitates the eventual metabolism of glucose into three-carbon molecules with high phosphoryl-transfer potential. The transfer of the phosphoryl group from ATP to the hydroxyl group on carbon 6 of glucose is catalyzed by hexokinase.

Phosphoryl transfer is a fundamental reaction in biochemistry. **Kinases** are enzymes that catalyze the transfer of a phosphoryl group from ATP to an acceptor, or to ADP from a phosphoryl donor. Hexokinase, then, catalyzes the transfer of a phosphoryl group from ATP to a variety of six-carbon sugars (hexoses), such as glucose and mannose. Hexokinase, like adenylate kinase (Section 6.1) and all other kinases, requires Mg^{2+} (or another divalent metal ion such as Mn^{2+}) for activity. The divalent metal ion forms a complex with ATP.

X-ray crystallographic studies of yeast hexo-kinase revealed that the binding of glucose induces a large conformational change in the enzyme. Hexokinase consists of two lobes, which move toward each other when glucose is bound (**Figure 16.4**). On glucose binding, one lobe rotates 12 degrees with respect to the other, resulting in movements of the polypeptide backbone of as much as 8 Å. The cleft between the lobes closes, and the bound glucose becomes surrounded by protein, except for the hydroxyl group of carbon 6, which will accept the phosphoryl group from ATP. The closing of the cleft in hexokinase is a striking example of the role of induced fit in enzyme action (Section 5.3).



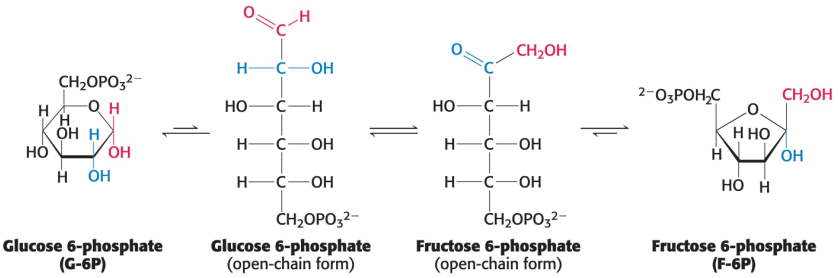


FIGURE 16.4 The induced fit of hexokinase is due to large structural changes upon binding the first of its two substrates. The two lobes of hexokinase are separated in the absence of glucose (left). The conformation of hexokinase changes markedly on binding glucose as the two lobes of the enzyme come together, creating the necessary environment for catalysis (right).

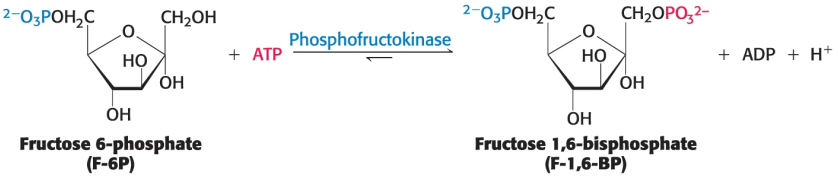
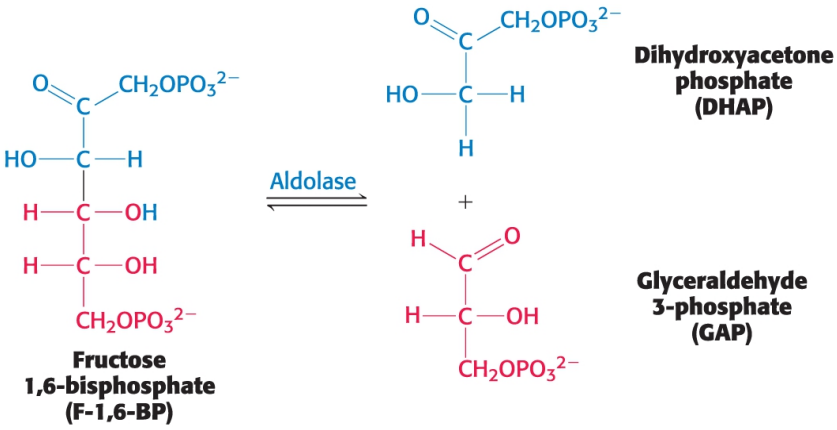
[Drawn from 2YHX.pdb and 1HKG.pdb.]



The glucose-induced structural changes are significant in two respects. First, the environment around the glucose becomes more nonpolar, which favors reaction between the hydrophilic hydroxyl group of glucose and the terminal phosphoryl group of ATP. Second, the conformational changes enable the kinase to discriminate against H_2O as a substrate. The closing of the cleft keeps water molecules away from the active site. If hexokinase were rigid, a molecule of H_2O occupying the binding site for the $-CH_2OH$ of glucose could attack the γ phosphoryl group of ATP, forming ADP and P_i. In other words, a rigid kinase would likely also be an ATPase.

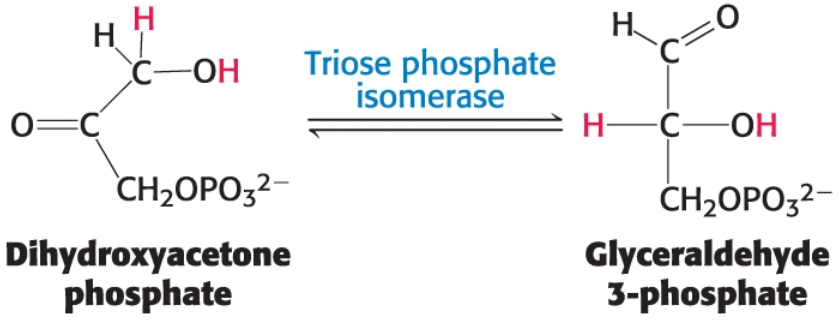
Fructose 1,6-bisphosphate is generated from glucose 6-phosphate

A crucial step toward completion of the first phase of glycolysis — the formation of fructose 1,6-bisphosphate — is the isomerization of glucose 6-phosphate to fructose 6-phosphate. Recall that the open-chain form of glucose has an aldehyde group at carbon 1, whereas the open-chain form of fructose has a keto group at carbon 2. Thus, the isomerization of glucose 6-phosphate to fructose 6-phosphate is a conversion of an aldose into a ketose. The reaction catalyzed by phosphoglucose isomerase takes several steps because both glucose 6-phosphate and fructose 6-phosphate are present primarily in the cyclic forms. The enzyme must first open the six-membered ring of glucose 6-phosphate, catalyze the isomerization, and then promote the formation of the five-membered ring of fructose 6-phosphate.



A second phosphorylation reaction follows the isomerization step. Fructose 6-phosphate is phosphorylated at the expense of ATP to fructose 1,6-bisphosphate (F-l,6-BP). The prefix *bis-* in bisphosphate means that two separate monophosphoryl groups are present, whereas the prefix *di-* in diphosphate (as in adenosine diphosphate) means that two phosphoryl groups are present and are connected by an anhydride linkage.

This reaction is catalyzed by phosphofructokinase (PFK), an allosteric enzyme that sets the pace of glycolysis. As we will learn, this enzyme plays a central role in the metabolism of many molecules in all parts of the body.



The six-carbon sugar is cleaved into two three-carbon fragments

The newly formed fructose 1,6-bisphosphate is cleaved into glyceraldehyde 3-phosphate (GAP) and dihydroxyacetone phosphate (DHAP), completing stage 1 of glycolysis. The products of the remaining steps in glycolysis consist of three-carbon units rather than six-carbon units. This reaction, which is readily reversible, is catalyzed by aldolase. This enzyme derives its name from the nature of the reverse reaction, an aldol addition.

What is the biochemical rationale for the isomerization of glucose 6-phosphate to fructose 6-phosphate and its subsequent phosphorylation to form fructose 1,6-bisphosphate? First, phosphorylation of the fructose 6-phosphate to fructose 1,6-bisphosphate prevents the reformation of glucose 6-phosphate. Second, and perhaps more important, had the aldol cleavage taken place in the aldose glucose, a two-carbon and a four-carbon fragment would have resulted. Two different metabolic pathways — one to process the two-carbon fragment and one for the four-carbon fragment — would have been required to extract energy. Instead, the cleavage of fructose 1,6-bisphosphate yields two phosphorylated interconvertible three-carbon fragments that will be oxidized in the later steps of glycolysis to capture energy in the form of ATP.

Glyceraldehyde 3-phosphate is on the direct pathway of glycolysis, whereas dihydroxyacetone phosphate is not. Unless a means exists to convert dihydroxyacetone phosphate into glyceraldehyde 3-phosphate, a three-carbon fragment useful for generating ATP will be lost. These compounds are isomers that can be readily interconverted: dihydroxyacetone phosphate is a ketose, whereas glyceraldehyde 3-phosphate is an aldose. The isomerization of these three-carbon phosphorylated sugars is catalyzed by triose phosphate isomerase (TPI, sometimes abbreviated TIM).

This reaction is rapid and reversible. At equilibrium, 96% of the triose phosphate is dihydroxyacetone phosphate. However, the reaction proceeds readily from dihydroxyacetone phosphate to glyceraldehyde 3-phosphate because the subsequent reactions of glycolysis remove this product.

Mechanism: Triose phosphate isomerase salvages a three-carbon fragment

Much is known about the catalytic mechanism of triose phosphate isomerase (Figure 16.5). TPI catalyzes the transfer of a hydrogen atom from carbon 1 to carbon 2, an intramolecular oxidation–reduction. This isomerization of a ketose into an aldose proceeds through an enediol intermediate (Figure 16.6).

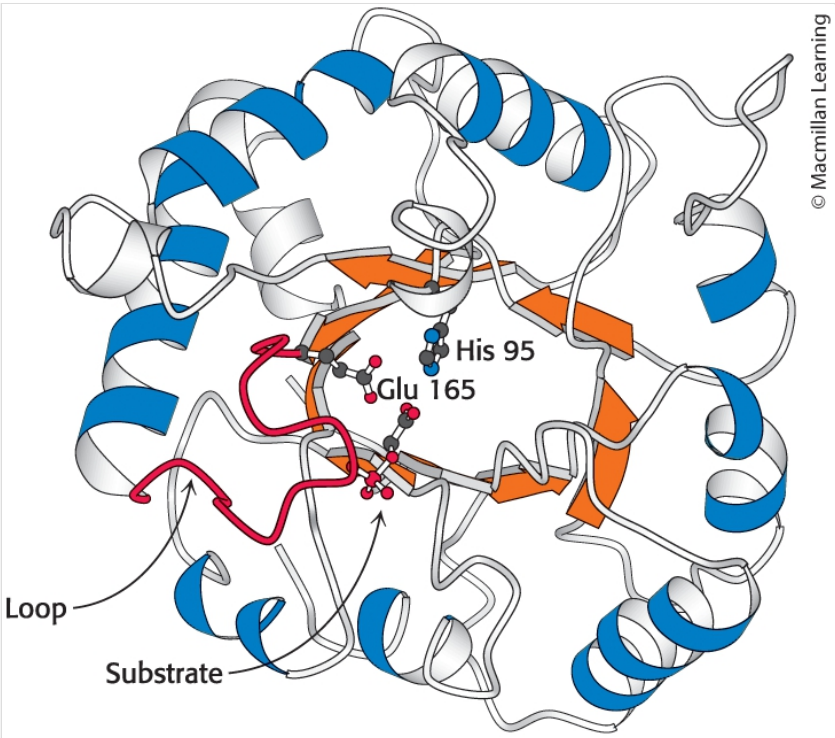


FIGURE 16.5 Triose phosphate isomerase is an example of a common "barrel" motif, with the active site buried in the center. This enzyme consists of a central core of eight parallel β strands (orange) surrounded by eight α helices (blue). This structural motif, called an αβ barrel or a TIM barrel because of this enzyme, is also found in the glycolytic enzymes aldolase, enolase, and pyruvate kinase. Notice that histidine 95 and glutamate 165, essential components of the active site of triose phosphate isomerase, are located in the barrel. A loop (red) closes off the active site on substrate binding.

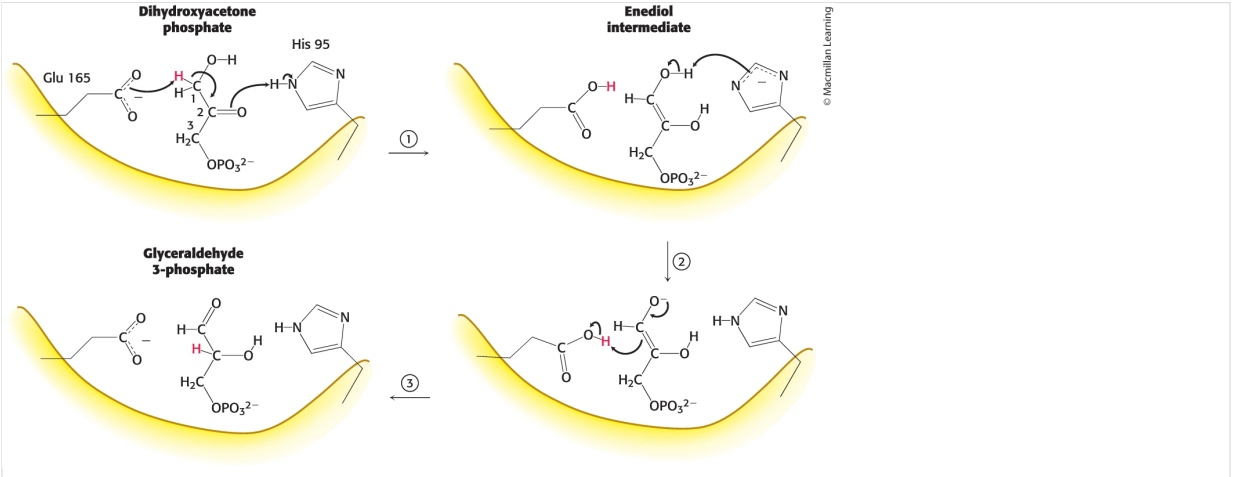
[Drawn from 2YPI.pdb.]

INTERACT with this model in Achieve



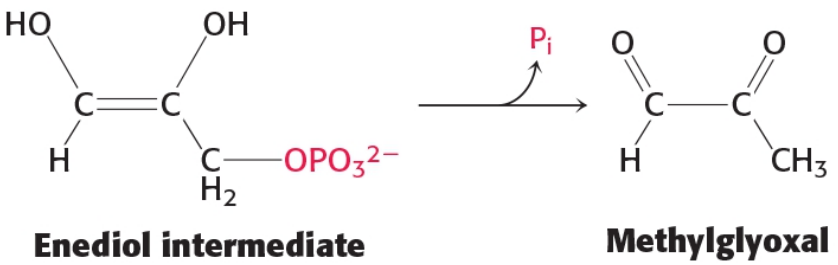


FIGURE 16.6 The catalytic mechanism of triose phosphate isomerase is an acid/base mechanism proceeding through an enediol intermediate. (1) Glutamate 165 acts as a general base by abstracting a proton (H^+) from carbon 1. Histidine 95, acting as a general acid, donates a proton to the oxygen atom bonded to carbon 2, forming the enediol intermediate. (2) Glutamic acid, now acting as a general acid, donates a proton to C-2, while histidine removes a proton from the OH group of C-1. (3) The product is formed, and glutamate and histidine are returned to their ionized and neutral forms, respectively.

X-ray crystallographic and other studies showed that glutamate 165 plays the role of a general acid–base catalyst: it abstracts a proton (H^+) from carbon 1 and then donates it to carbon 2. However, the carboxylate group of glutamate 165 by itself is not basic enough to pull a proton away from a carbon atom adjacent to a carbonyl group. Histidine 95 assists catalysis by donating a proton to stabilize the negative charge that develops on the C-2 carbonyl group.

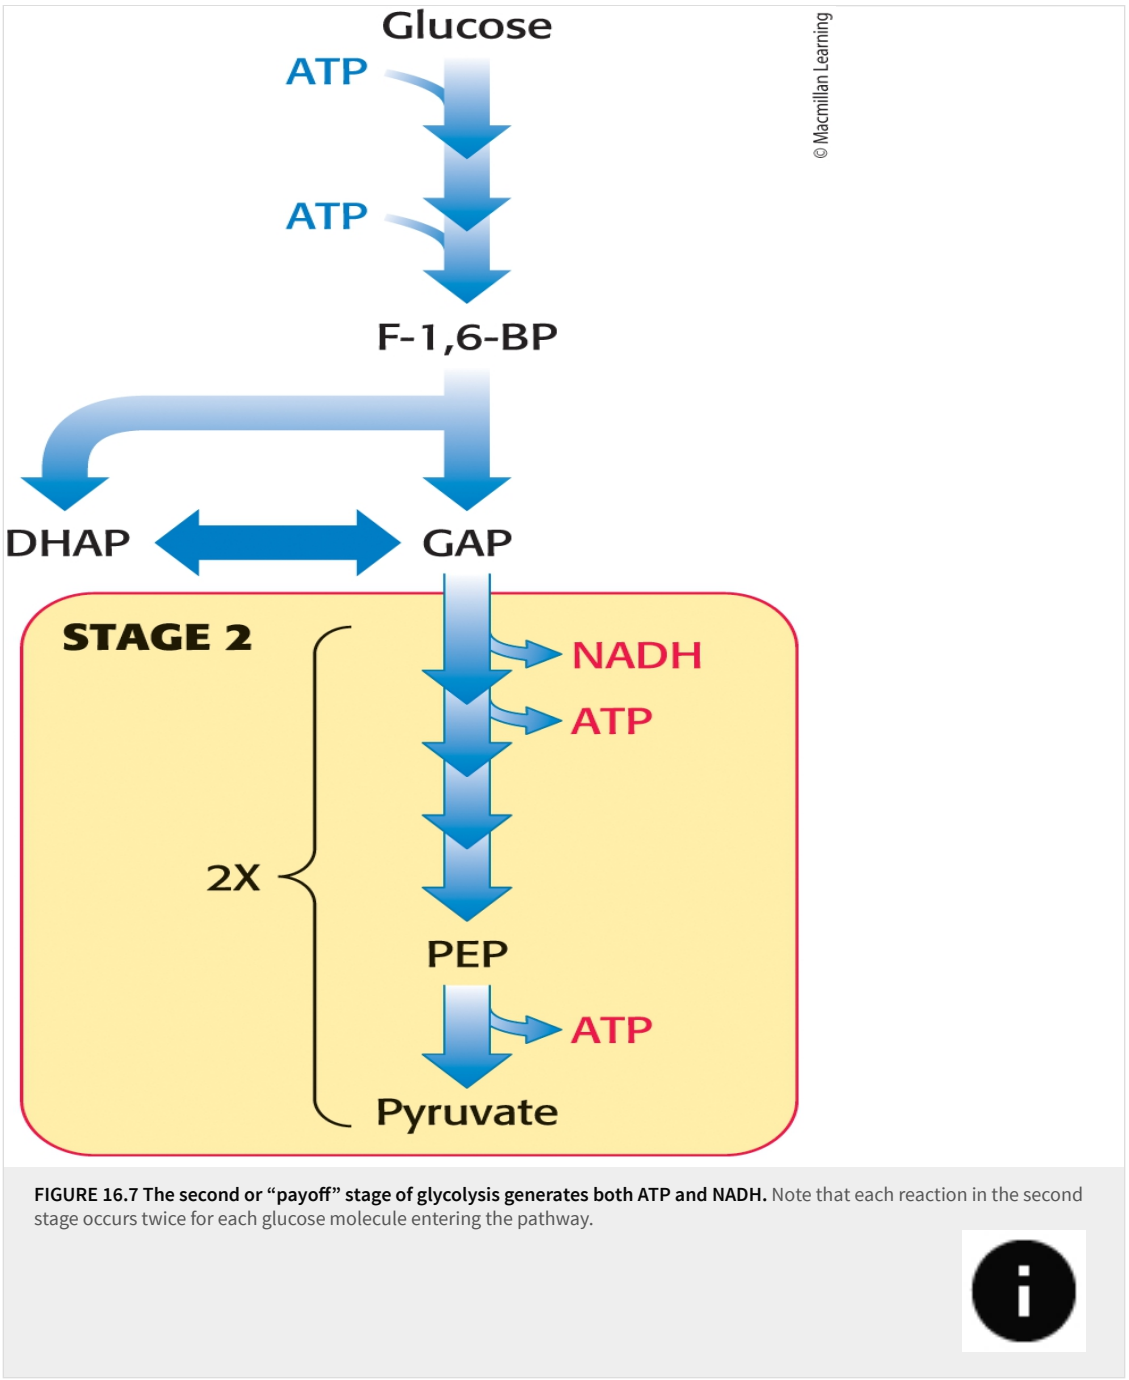
Two features of this enzyme are noteworthy. First, TPI displays great catalytic prowess. It accelerates isomerization by a factor of 10^{10} compared with the rate obtained with a simple base catalyst such as acetate ion. Indeed, the k_{cat}/K_M ratio for the isomerization of glyceraldehyde 3-phosphate is $2 \times 10^8\ M^{-1}\,s^{-1}$, which is close to the diffusion-controlled limit. In other words, catalysis takes place every time that enzyme and substrate meet. The diffusion-controlled encounter of substrate and enzyme is thus the rate-limiting step in catalysis. TPI is an example of a kinetically perfect enzyme (Section 5.4). Second, TPI suppresses an undesired side reaction, the decomposition of the enediol intermediate into methylglyoxal and orthophosphate.

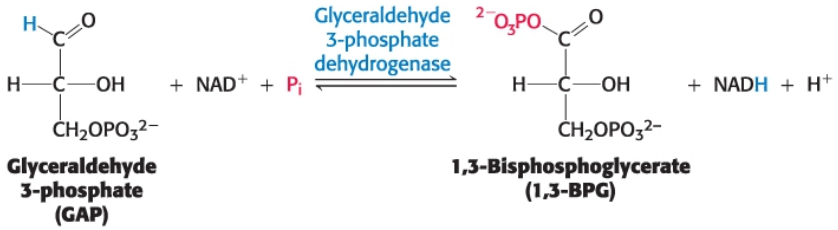
In solution, this physiologically useless reaction is 100 times as fast as isomerization. Moreover, methylglyoxal is a highly reactive compound that can modify the structure and function of a variety of biomolecules, including proteins and DNA. The reaction of methylglyoxal with a biomolecule is an example of deleterious reactions called advanced glycation end products, discussed earlier (AGEs, Section 11.1). Hence, TPI must prevent the enediol from leaving the enzyme. This labile intermediate is trapped in the active site by the movement of a loop of 10 residues (Figure 16.5). This loop serves as a lid on the active site, shutting it when the enediol is present and reopening it when isomerization is completed. We see here a striking example of one means of preventing an undesirable alternative reaction: the active site is kept closed until the desirable reaction takes place.

Thus, two molecules of glyceraldehyde 3-phosphate are formed from one molecule of fructose 1,6-bisphosphate by the sequential action of aldolase and triose phosphate isomerase. The economy of metabolism is evident in this reaction sequence. The isomerase funnels dihydroxyacetone phosphate into the main glycolytic pathway; a separate set of reactions is not needed.

Stage 2 begins: The oxidation of an aldehyde powers the formation of a compound with high phosphoryl-transfer potential

The preceding steps in glycolysis have transformed one molecule of glucose into two molecules of glyceraldehyde 3-phosphate, but no energy has yet been extracted. On the contrary, thus far, two molecules of ATP have been invested. We come now to the second stage of glycolysis — a series of steps that harvest some of the energy contained in glyceraldehyde 3-phosphate as ATP (**Figure 16.7**).





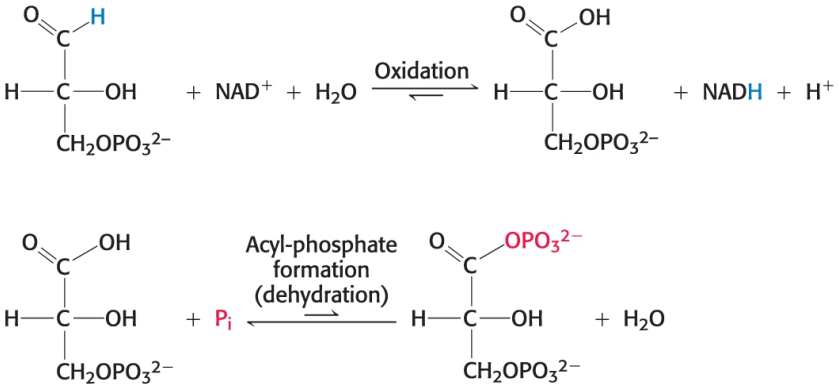


FIGURE 16.7 The second or "payoff" stage of glycolysis generates both ATP and NADH. Note that each reaction in the second stage occurs twice for each glucose molecule entering the pathway.

The initial reaction in this sequence is the conversion of glyceraldehyde 3-phosphate into 1,3-bisphosphoglycerate (1,3-BPG), a reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (GAPDH).

1,3-Bisphosphoglycerate is an acyl phosphate, which is a mixed anhydride of phosphoric acid and a carboxylic acid. Such compounds have a high phosphoryl-transfer potential (Section 15.2); one of its phosphoryl groups is transferred to ADP in the next step in glycolysis.

The reaction catalyzed by GAPDH can be viewed as the sum of two processes: the oxidation of the aldehyde to a carboxylic acid by NAD^+, and the joining of the carboxylic acid and orthophosphate to form the acyl-phosphate product.

The first reaction is thermodynamically quite favorable, with a standard free-energy change, $\Delta G^{\circ\prime}$, of approximately $-50\ \text{kJ mol}^{-1}\ (-12\ \text{kcal mol}^{-1})$, whereas the second reaction is quite unfavorable, with a standard free-energy change of the same magnitude but the opposite sign. If these two reactions simply took place in succession, the second reaction would have a very large activation energy and thus not take place at a biologically significant rate. These two processes must be coupled so the favorable aldehyde oxidation can be used to drive the formation of the acyl phosphate.

How are these reactions coupled? The key is an intermediate, formed as a result of the aldehyde oxidation, that is connected to the enzyme by a thioester linkage (Section 15.4). The thioester intermediate, which is higher in free energy than the free carboxylic acid is, couples the favorable oxidation and the unfavorable phosphorylation reactions. This coupling preserves much of the free

energy released in the oxidation reaction. The thioester intermediate reacts with orthophosphate to form the high-energy compound 1,3-bisphosphoglycerate.

We see here the use of a covalent enzyme-bound intermediate as a mechanism of energy coupling. A free-energy profile of the GAPDH reaction, compared with a hypothetical process in which the reaction proceeds without this intermediate, reveals how this intermediate allows a favorable process to drive an unfavorable one (Figure 16.8).

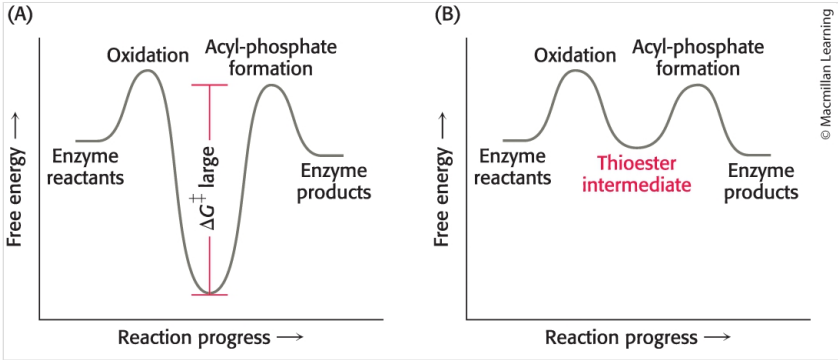

FIGURE 16.8 Free-energy profiles for glyceraldehyde oxidation followed by acyl-phosphate formation demonstrate the importance of the reaction coupling. (A) A hypothetical case with no coupling between the two processes. The second step would have a very large activation barrier, making the reaction very slow. (B) The actual case with the two reactions coupled through a thioester intermediate vastl accelerates the reaction and allows a favorable reaction to drive an unfavorable one.

Mechanism: Phosphorylation is coupled to the oxidation of glyceraldehyde 3-phosphate by a thioester intermediate

The active site of GAPDH includes a reactive cysteine residue, as well as NAD^+ and a crucial histidine (Figure 16.9).

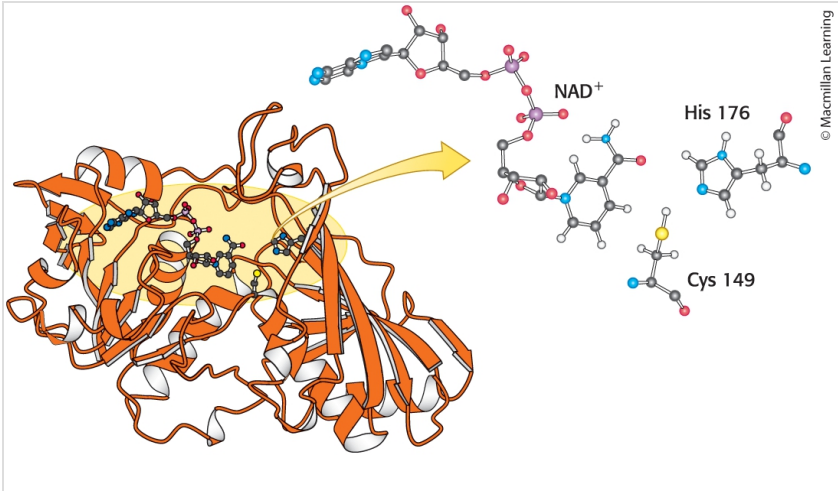

FIGURE 16.9 The active site of GAPDH includes cysteine and histidine residues adjacent to a bound NAD^+ molecule. The sulfur atom of cysteine will react with the substrate to form a transitory thioester intermediate.

[Drawn from 1GAD.pdb.]

INTERACT with this model in Achieve

Let's consider in detail how these components cooperate in the reaction mechanism (Figure 16.10) in the following four steps:

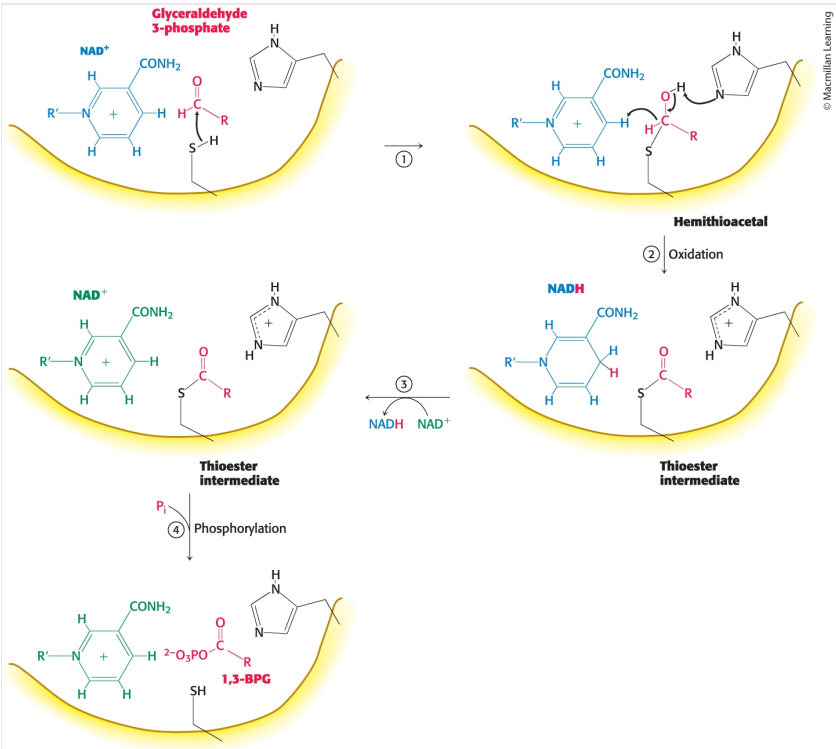

FIGURE 16.10 The catalytic mechanism of GAPDH is an example of covalent catalysis to form a key intermediate. The reaction proceeds through a thioester intermediate, which allows the oxidation of glyceraldehyde to be coupled to the phosphorylation of 3-phosphoglycerate. (1) Cysteine reacts with the aldehyde group of the substrate, forming a hemithioacetal. (2) An oxidation takes place with the transfer of a hydride ion to NAD^+, forming a thioester. This reaction is facilitated by the transfer of a proton to histidine. (3) The reduced NADH is exchanged for an NAD^+ molecule. (4) Orthophosphate attacks the thioester, forming the product 1,3-BPG.

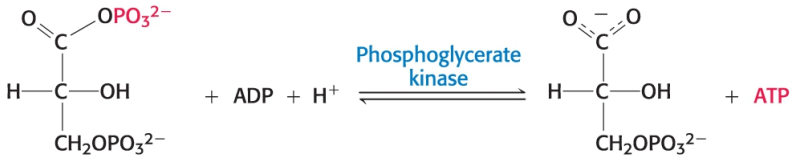
1. The aldehyde substrate reacts with the sulfhydryl group of cysteine 149 on the enzyme to form a hemithioacetal.

2. The hydride ion is transferred to a molecule of NAD^+ that is bound to the enzyme and is adjacent to the cysteine residue. This reaction is favored by the deprotonation of the hemithioacetal by histidine 176. The products are the reduced coenzyme NADH and a thioester intermediate. This thioester intermediate has a free energy close to that of the reactants (Figure 16.8).



3. The NADH formed from the aldehyde oxidation leaves the enzyme and is replaced by a second molecule of NAD^+. This step is important because the positive charge on NAD^+ polarizes the thioester intermediate to facilitate the attack by orthophosphate.

4. The orthophosphate attacks the thioester to form 1,3-BPG and free the cysteine residue.

This example illustrates the essence of energy transformations and of metabolism itself: energy released by carbon oxidation is converted into high phosphoryl-transfer potential.

ATP is formed by phosphoryl transfer from 1,3-bisphosphoglycerate

1,3-Bisphosphoglycerate is an energy-rich molecule with a greater phosphoryl-transfer potential than that of ATP (Section 15.2). Thus, 1,3-BPG can be used to power the synthesis of ATP from ADP. Phosphoglycerate kinase catalyzes the transfer of the phosphoryl group from the acyl phosphate of 1,3-bisphosphoglycerate to ADP; ATP and 3-phosphoglycerate are the products.

1,3-Bisphosphoglycerate **3-Phosphoglycerate**

The formation of ATP in this manner is referred to as **substrate-level phosphorylation** because the phosphate donor, 1,3-BPG, is a substrate with high phosphoryl-transfer potential. We will contrast this manner of ATP formation with the formation of ATP from ionic gradients in Chapters 18 and 19.

Thus, the outcomes of the reactions catalyzed by glyceraldehyde 3-phosphate dehydrogenase and phosphoglycerate kinase are:

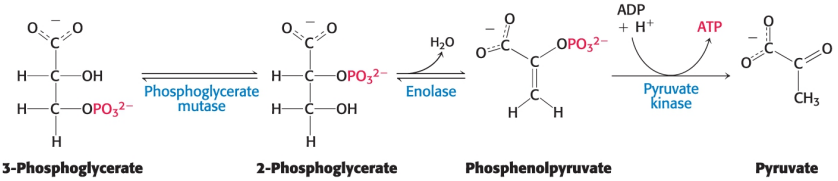
1. Glyceraldehyde 3-phosphate, an aldehyde, is oxidized to 3-phosphoglycerate, a carboxylic acid.

2. NAD^+ is concomitantly reduced to NADH.

3. ATP is formed from P_i and ADP at the expense of carbon-oxidation energy.

In essence, the energy released during the oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate is temporarily trapped as 1,3-bisphosphoglycerate. This energy powers the transfer of

a phosphoryl group from 1,3-bisphosphoglycerate to ADP to yield ATP. Keep in mind that, because of the actions of aldolase and triose phosphate isomerase, two molecules of glyceraldehyde 3-phosphate were formed, and hence two molecules of ATP were generated. These ATP molecules make up for the two molecules of ATP consumed in the first stage of glycolysis.



Self-Check Question

Arsenate (AsO_4^{3-}) resembles P_i in structure and reactivity closely enough that GAPDH can incorporate arsenate instead of phosphate. The product, 1-arseno-3-phosphoglycerate, is highly unstable and rapidly hydrolyzed by the surrounding water molecules producing 3-phosphoglycerate and arsenate. Based on this information, what would be the effect of arsenate on ATP generation in a cell?

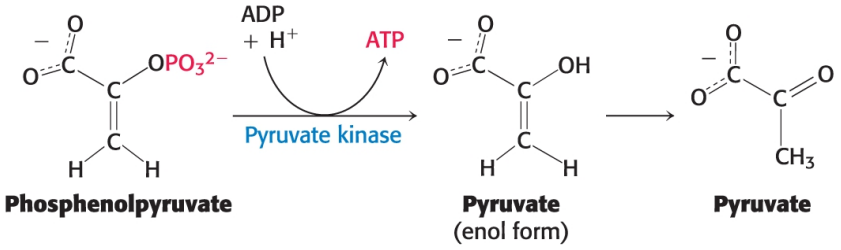
Additional ATP is generated with the formation of pyruvate

In the remaining steps of glycolysis, 3-phosphoglycerate is converted into pyruvate, and a second molecule of ATP is formed from ADP.

The first reaction is a rearrangement. The position of the phosphoryl group shifts in the conversion of 3-phosphoglycerate into 2-phosphoglycerate, a reaction catalyzed by phosphoglycerate mutase. In general, a mutase is an enzyme that catalyzes the intramolecular shift of a chemical group, such as a phosphoryl group. The phosphoglycerate mutase reaction has an interesting mechanism: the phosphoryl group is not simply moved from one carbon atom to another. This enzyme requires catalytic amounts of 2,3-bisphosphoglycerate (2,3-BPG) to maintain an active-site histidine residue in a phosphorylated form. This phosphoryl group is transferred to 3-phosphoglycerate to reform 2,3-bisphosphoglycerate.

Enz-His-phosphate + 3-phosphoglycerate $\rightleftharpoons$ Enz-His + 2,3-bisphosphoglycerate

The mutase then functions as a phosphatase: it converts 2,3-bisphosphoglycerate into 2-phosphoglycerate. The mutase retains the phosphoryl group to regenerate the modified histidine.



Enz-His + 2,3-bisphosphoglycerate $\rightleftharpoons$ Enz-His-phosphate + 2-phosphoglycerate

The sum of these reactions yields the mutase reaction:

3-Phosphoglycerate $\rightleftharpoons$ 2-phosphoglycerate

In the next reaction, the dehydration of 2-phosphoglycerate introduces a double bond, creating an enol. Enolase catalyzes this formation of the enol phosphate phosphoenolpyruvate (PEP). This dehydration markedly elevates the transfer potential of the phosphoryl group. An enol phosphate has a high phosphoryl-transfer potential, whereas the phosphate ester of an ordinary alcohol, such as 2-phosphoglycerate, has a low one. The $\Delta G^{\circ\prime}$ of the hydrolysis of a phosphate ester of an ordinary alcohol is $-13\ \text{kJ mol}^{-1}\ (-3\ \text{kcal mol}^{-1})$, while that of phosphoenolpyruvate is $-62\ \text{kJ mol}^{-1}\ (-15\ \text{kcal mol}^{-1})$.

Why does phosphoenolpyruvate have such a high phosphoryl-transfer potential? The phosphoryl group traps the molecule in its unstable enol form. When the phosphoryl group has been donated to ATP, the enol undergoes a conversion into the more stable ketone — namely, pyruvate.

Thus, the high phosphoryl-transfer potential of phosphoenolpyruvate arises primarily from the large driving force of the subsequent enol–ketone conversion. Hence, pyruvate is formed, and ATP is generated concomitantly. The virtually irreversible transfer of a phosphoryl group from phosphoenolpyruvate to ADP is catalyzed by pyruvate kinase.

What is the energy source for the formation of phosphoenolpyruvate? The answer to this question becomes clear when we compare the structures of 2-phosphoglycerate and pyruvate. The formation of pyruvate from 2-phosphoglycerate is, in essence, an internal oxidation–reduction reaction; carbon 3 takes electrons from carbon 2 in the conversion of 2-phosphoglycerate into pyruvate. Compared with 2-

phosphoglycerate, C-3 is more reduced in pyruvate, whereas C-2 is more oxidized. Once again, carbon oxidation powers the synthesis of a compound with high phosphoryl-transfer potential, phosphoenolpyruvate here and 1,3-bisphosphoglycerate earlier, which allows the synthesis of ATP.

Because the molecules of ATP used in forming fructose 1,6-bisphosphate have already been regenerated, the two molecules of ATP generated from phosphoenolpyruvate are "profit."

Two ATP molecules are formed in the conversion of glucose into pyruvate

The net reaction in the transformation of glucose into pyruvate is

$$\text{Glucose} + 2\ P_i + 2\ \text{ADP} + 2\ \text{NAD}^+ \rightarrow 2\ \text{pyruvate} + 2\ \text{ATP} + 2\ \text{NADH} + 2\ \text{H}^+ + 2\ \text{H}_2\text{O}$$

Thus, two molecules of ATP are generated in the conversion of glucose into two molecules of pyruvate. The reactions of glycolysis are summarized in Table 16.2.

TABLE 16.2 Reactions of glycolysis

Step	Reaction	Enzyme	Reaction type	$\Delta G^{\circ\prime}$ in kJ mol^{-1} (kcal mol
1	Glucose + ATP → glucose 6–phosphate + ADP + H^+	Hexokinase	Phosphoryl transfer	−16.7 (−4.0)
2	Glucose 6-phosphate ⇌ fructose 6-phosphate	Phosphoglucose isomerase	Isomerization	+1.7 (+0.4)
3	Fructose 6–phosphate + ATP → fructose 1,6–bisphosphate + ADP + H^+	Phosphofructokinase	Phosphoryl transfer	−14.2 (−3.4)
4	Fructose 1,6-bisphosphate ⇌ dihydroxyacetone phosphate + glyceraldehyde 3-phosphate	Aldolase	Aldol cleavage	+23.8 (+5.7)
5	Dihydroxyacetone phosphate ⇌ glyceraldehyde 3-phosphate	Triose phosphate isomerase	Isomerization	+7.5 (+1.8)

TABLE 16.2 Reactions of glycolysis

Step	Reaction	Enzyme	Reaction type	$\Delta G^{\circ\prime}$ in kJ mol^{-1} (kcal mol^{-1})
6	Glyceraldehyde 3-phosphate + P_i + NAD^+ ⇌ 1,3-bisphosphoglycerate + NADH + H^+	Glyceraldehyde 3-phosphate dehydrogenase	Phosphorylation coupled to oxidation	+6.3 (+1.5)
7	1,3-Bisphosphoglycerate + ADP ⇌ 3-phosphoglycerate + ATP	Phosphoglycerate kinase	Phosphoryl transfer	−18.8 (−4.5)
8	3-Phosphoglycerate ⇌ 2-phosphoglycerate	Phosphoglycerate mutase	Phosphoryl shift	+4.6 (+1.1)
9	2-Phosphoglycerate ⇌ phosphoenolpyruvate + H_2O	Enolase	Dehydration	+1.7 (+0.4)
10	Phosphoenolpyruvate + ADP + H^+ → pyruvate + ATP	Pyruvate kinase	Phosphoryl transfer	−31.4 (−7.5)

Note: ΔG, the actual free-energy change, has been calculated from $\Delta G^{\circ\prime}$ and known concentrations of reactants under typical physiological conditions. Glycolysis can proceed only if the ΔG values of all reactions are negative. The small positive ΔG values of three of the above reactions indicate that the concentrations of metabolites in vivo in cells undergoing glycolysis are not precisely known.

The energy released in the anaerobic conversion of glucose into two molecules of pyruvate is about $-90\ \text{kJ mol}^{-1}$ ($-22\ \text{kcal mol}^{-1}$). We shall see in Chapters 17 and 18 that much more energy can be released from glucose in the presence of oxygen.

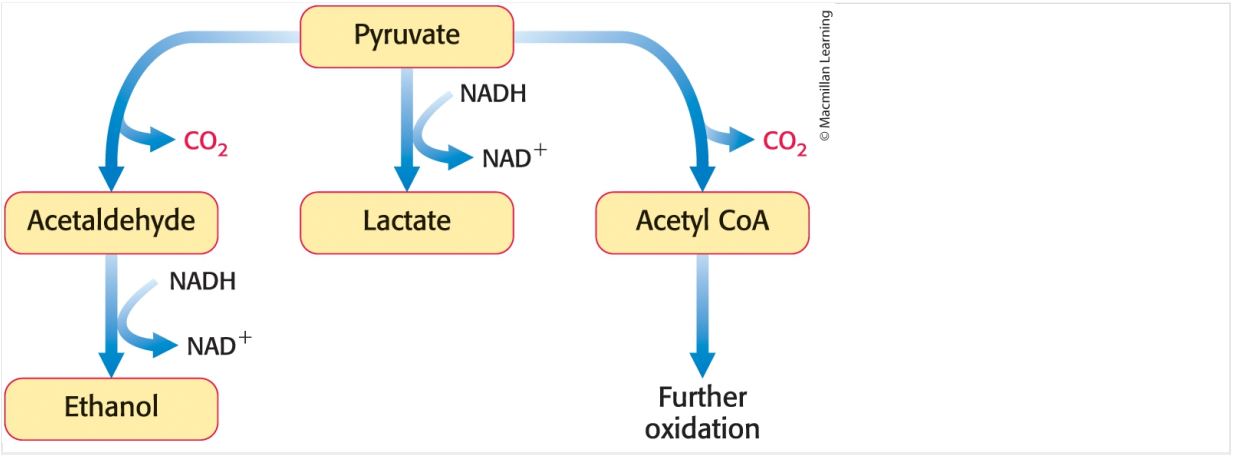
Self-Check Question

The conversion of one molecule of fructose 1,6-bisphosphate into two molecules of pyruvate results in the net synthesis of how many molecules each of NADH and ATP?

NAD^+ is regenerated from the metabolism of pyruvate

The conversion of glucose into two molecules of pyruvate has resulted in the net synthesis of ATP. However, an energy-converting pathway that stops at pyruvate will not proceed for long, because redox balance has not been maintained. As we have seen, the activity of glyceraldehyde 3-phosphate dehydrogenase, in addition to generating a compound with high phosphoryl-transfer potential, reduces NAD^+ to NADH. In the cell, there are limited amounts of NAD^+, which is derived from the vitamin niacin (B_3), a dietary requirement for human beings. Consequently, NAD^+ must be regenerated for glycolysis to proceed. Thus, the final process in the pathway is the regeneration of NAD^+ through the metabolism of pyruvate.

The sequence of reactions from glucose to pyruvate is similar in most organisms and most types of cells. In contrast, the fate of pyruvate is variable. Three reactions of pyruvate are of primary importance: conversion into ethanol, lactate, or carbon dioxide (Figure 16.11). The first two reactions are fermentations that take place in the absence of oxygen. A **fermentation** is an ATP-generating process in which organic compounds act both as the donor and as the acceptor of electrons; thus, they are redox neutral pathways for the production of ATP from an organic fuel molecule. In contrast, in the presence of oxygen — the most common situation in multicellular organisms and in many unicellular ones — pyruvate is oxidized to carbon dioxide and water through the citric acid cycle and the electron-transport chain, with oxygen serving as the final electron acceptor. We now take a closer look at these three examples of possible fates of pyruvate.



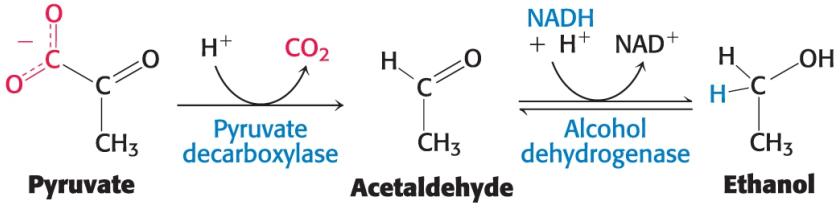


FIGURE 16.11 Pyruvate has many possible fates. Shown are just three possible fates, but many others exist. Ethanol and lactate can be formed by reactions that include NADH. Alternatively, a two-carbon unit from pyruvate can be coupled to coenzyme A (Chapter 17) to form acetyl CoA.

Ethanol fermentation

Ethanol is formed from pyruvate in yeast and several other microorganisms. The conversion of glucose into ethanol in anerobic conditions is called **ethanol fermentation**. The first step is the decarboxylation of pyruvate. This reaction is catalyzed by pyruvate decarboxylase, which requires the coenzyme

thiamine pyrophosphate that is derived from the vitamin thiamine (B_1). The second step is the reduction of acetaldehyde to ethanol by NADH, in a reaction catalyzed by alcohol dehydrogenase. This reaction regenerates NAD^+.

The active site of alcohol dehydrogenase contains a zinc ion that is coordinated to the sulfur atoms of two cysteine residues and a nitrogen atom of histidine (Figure 16.12). This zinc ion polarizes the carbonyl group of the substrate to favor the transfer of a hydride from NADH.

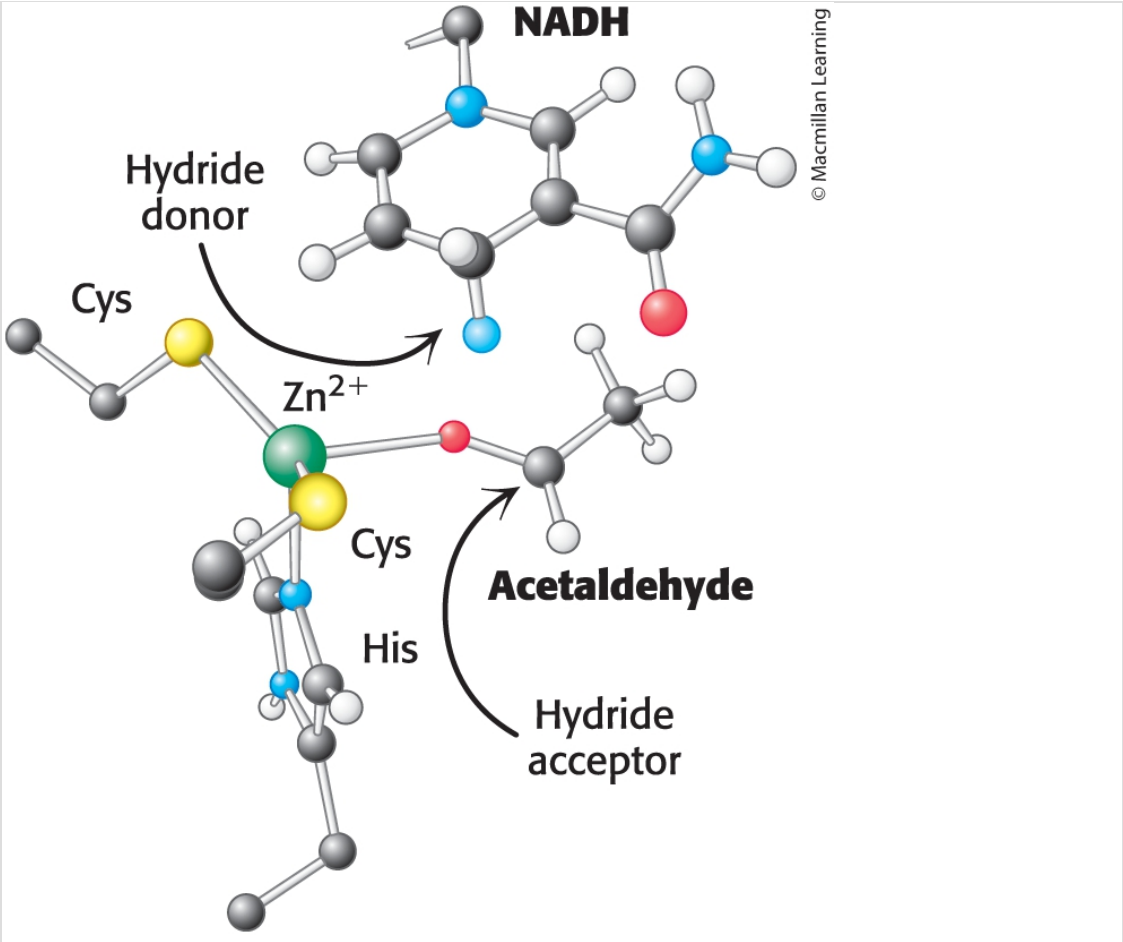

FIGURE 16.12 The active site of alcohol dehydrogenase contains a critical zinc ion bound to two cysteine residues and one histidine residue. The zinc ion binds the acetaldehyde substrate through its oxygen atom, polarizing the substrate so that it more easily accepts a hydride from NADH. Only the nicotinamide ring of NADH is shown.

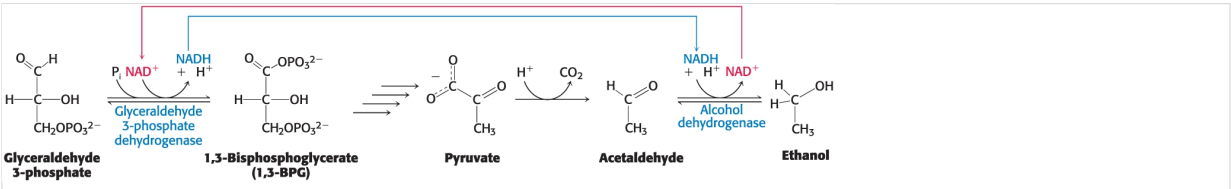
The net result of this anaerobic process is

$$\text{Glucose} + 2\ P_i + 2\ \text{ADP} + 2\ H^+ \rightarrow 2\ \text{ethanol} + 2\ CO_2 + 2\ \text{ATP} + 2\ H_2O$$

Note that NAD^+ and NADH do not appear in this equation, even though they are crucial for the overall process. NADH generated by the oxidation of glyceraldehyde 3-phosphate is consumed in the reduction of acetaldehyde to ethanol. Thus, there is no net oxidation–reduction in the conversion of glucose into ethanol (**Figure 16.13**). The ethanol formed during fermentation provides a key ingredient for brewing and winemaking.



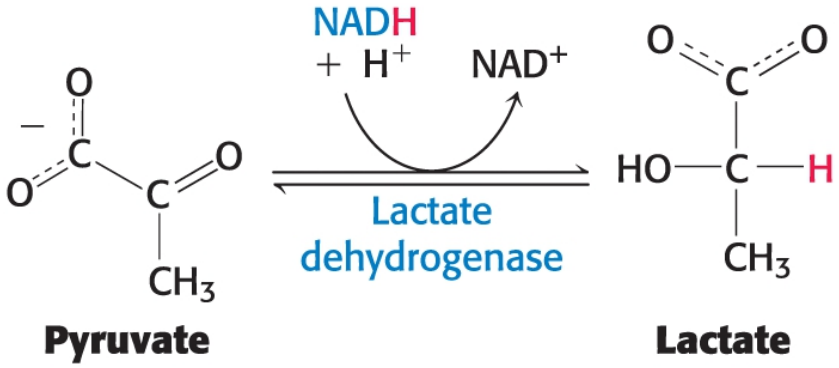


FIGURE 16.13 The NADH produced in glycolysis must be reoxidized to NAD^+ for the glycolytic pathway to continue. NADH is constantly generated by the glyceraldehyde 3-phosphate dehydrogenase reaction. In ethanol fermentation, alcohol dehydrogenase oxidizes NADH and generates ethanol.

Lactic acid fermentation

Lactate is formed from pyruvate under anaerobic conditions in a variety of microorganisms and in a variety of animal tissues. The conversion of glucose to lactate in anaerobic conditions is called **lactic acid fermentation**. After the Buchners' original discovery of ethanol fermentation by yeast, studies of muscle extracts later showed that many of the reactions of lactic acid fermentation were the same as those of ethanol fermentation. This second exciting discovery revealed an underlying unity in biochemistry. Lactic acid fermentation occurs regularly in the retina of the eye and in erythrocytes (red blood cells), even in the presence of oxygen, as well as in tissues like the outer layers of the skin that are perpetually limited in oxygen availability. Additionally, certain types of skeletal muscles in most animals can also function anaerobically for short periods. For example, lactic acid fermentation occurs when a specific type of muscle fiber, called fast-twitch or type IIb fibers, performs short bursts of intense exercise because the ATP needs rise faster than the ability of the body to provide oxygen to the muscle. The muscle functions anaerobically until fatigue sets in, which is caused, in part, by lactate buildup. Indeed, the pH of resting type IIb muscle fibers, which is about 7.0, may fall to as low as 6.3 during the bout of exercise. The drop in pH inhibits phosphofructokinase, as we will discuss shortly. A

$lactate/H^+$ symporter allows the exit of lactate from the muscle cell. The reduction of pyruvate by NADH to form lactate is catalyzed by lactate dehydrogenase.

The overall reaction in the conversion of glucose into lactate is

$$\text{Glucose} + 2\ P_i + 2\ \text{ADP} \rightarrow 2\ \text{lactate} + 2\ \text{ATP} + 2\ H_2O$$

As in ethanol fermentation, there is no net oxidation–reduction. The NADH formed in the oxidation of glyceraldehyde 3-phosphate is consumed in the reduction of pyruvate. The regeneration of NAD^+ in the reduction of pyruvate to lactate or ethanol sustains the continued process of glycolysis under anaerobic conditions (**Figure 16.14**).

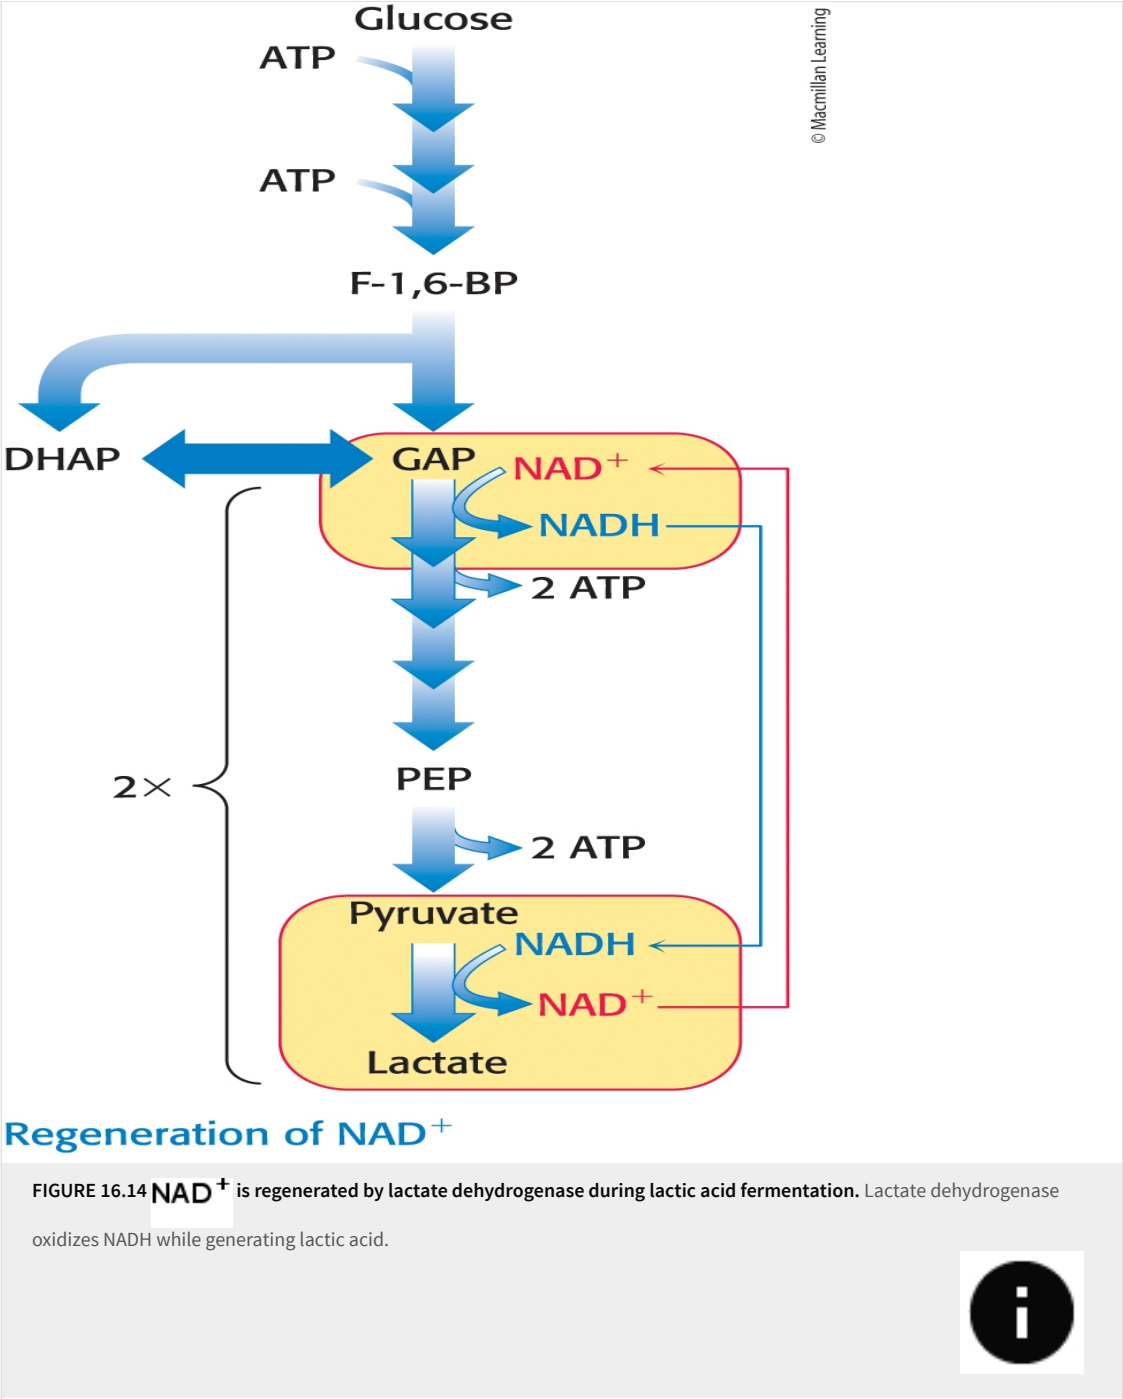

FIGURE 16.14 NAD^+ is regenerated by lactate dehydrogenase during lactic acid fermentation. Lactate dehydrogenase oxidizes NADH while generating lactic acid.

Oxidation by the citric acid cycle and the electron transport chain

Carbon dioxide and water are formed, and a great deal of energy extracted, when pyruvate is metabolized under aerobic conditions by means of the citric acid cycle and the electron-transport chain. In contrast, only a fraction of the energy of glucose is released in its anaerobic conversion into ethanol or lactate. The entry point to this oxidative pathway is acetyl coenzyme A (acetyl CoA), which is formed inside mitochondria by the oxidative decarboxylation of pyruvate.

$$\text{Pyruvate} + \text{NAD}^+ + \text{CoA} \rightarrow \text{acetyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+$$

This reaction, which is catalyzed by the pyruvate dehydrogenase complex, will be considered in detail in Chapter 17. The NAD^+ required for this reaction and for the oxidation of glyceraldehyde 3-phosphate is regenerated when NADH ultimately transfers its electrons to O_2 through the electron-transport chain in mitochondria.

Fermentations provide usable energy in the absence of oxygen

Fermentations yield only a fraction of the energy available from the complete combustion of glucose. Why is a relatively inefficient metabolic pathway so extensively used? The fundamental reason is that oxygen is not required. The ability to survive without oxygen affords a host of living accommodations such as soils, deep water, and skin pores. Some organisms, called **obligate anaerobes**, cannot survive in the presence of O_2, a highly reactive compound. The bacterium *Clostridium perfringens*, the cause of gangrene, is an example of an obligate anaerobe. Other pathogenic obligate anaerobes are listed in **Table 16.3**. Some organisms, such as yeast, are **facultative anaerobes** that metabolize glucose aerobically when oxygen is present and perform fermentation when oxygen is absent.

TABLE 16.3 Examples of pathogenic obligate anaerobes

Bacterium	Result of infection
Clostridium tetani	Tetanus (lockjaw)
Clostridium botulinum	Botulism (an especially severe type of food poisoning)
Clostridium perfringens	Gas gangrene (gas is produced as an end point of the fermentation, distorting and destroying the tissue)
Bartonella hensela	Cat-scratch fever (flu-like symptoms)
Bacteroides fragilis	Abdominal, pelvic, pulmonary, and blood infections

Many food products, including sour cream, yogurt, various cheeses, beer, wine, and sauerkraut, result from fermentation. Yogurt is produced by the fermentation of lactose in milk to lactate by a mixed culture of *Lactobacillus acidophilus* and *Streptococcus thermophilus*. Sour cream begins with pasteurized light cream, which is fermented to lactate by *Streptococcus lactis*. The lactate is further fermented to ketones and aldehydes by *Leuconostoc citrovorum*. The second fermentation adds to the taste and aroma of sour cream. Yeast, *Saccharomyces cerevisiae*, ferments carbohydrates to ethanol and carbon dioxide, providing some of the ingredients for an array of alcohol beverages. Although we have considered only lactic acid and ethanol fermentation, microorganisms are capable of generating a wide array of molecules as end points of fermentation (**Table 16.4**).

TABLE 16.4 Starting and ending points of various fermentations

Glucose	→	Lactate
Lactate	→	Acetate
Glucose	→	Ethanol
Ethanol	→	Acetate
Purines	→	Formate
Ethylene glycol	→	Acetate
Threonine	→	Propionate
Leucine	→	2-Alkylacetate
Phenylalanine	→	Propionate

Note: The products of some fermentations are the substrates for others.

Self-Check Question

The conversion of one molecule of glucose into two molecules of lactate results in the net synthesis of how many ATP and how many NADH molecules?

Fructose is converted into glycolytic intermediates by fructokinase

Although glucose is the most widely used monosaccharide, others also are important fuels. Let us consider how fructose is funneled into the glycolytic pathway (Figure 16.15). There is no separate catabolic pathway for metabolizing fructose, and so the strategy is to convert this sugar into a metabolite of glucose.

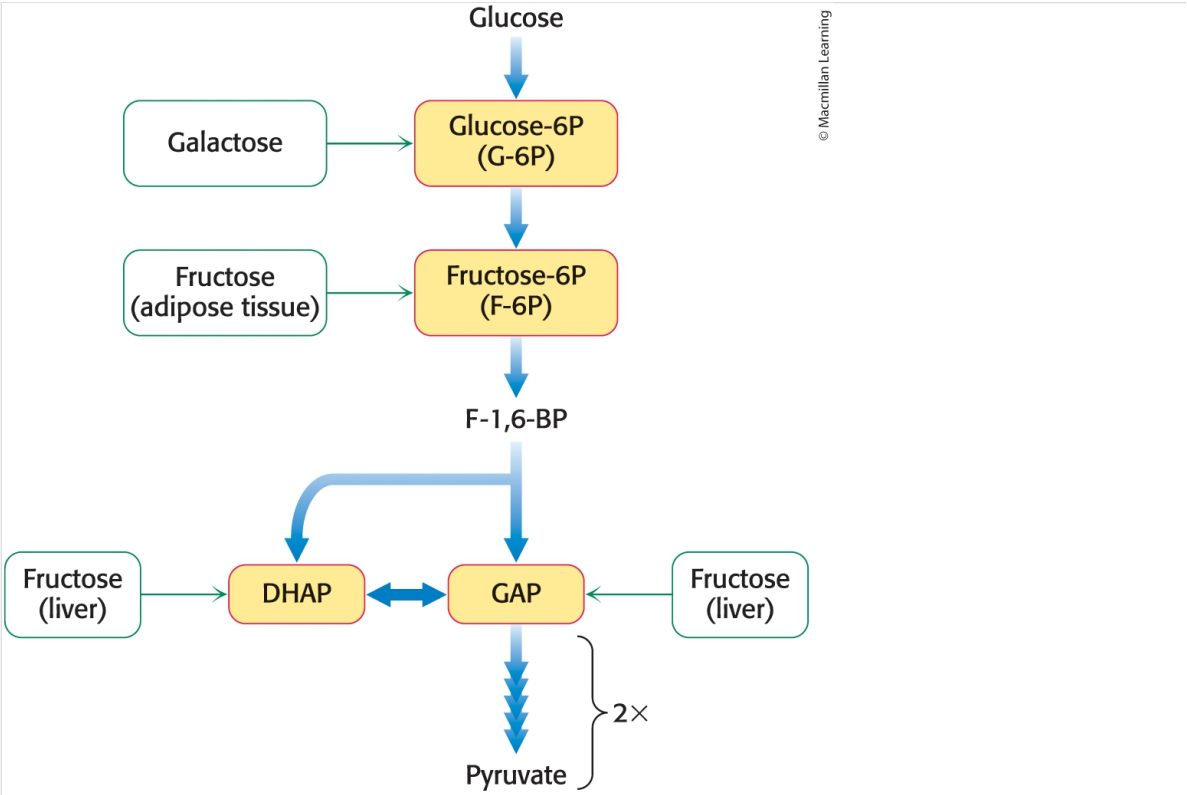

FIGURE 16.15 Additional sugars such as fructose and galactose can enter glycolysis at a variety of points.

The main site of fructose metabolism is the liver, using the fructose 1-phosphate pathway (Figure 16.16). The first step is the phosphorylation of fructose to fructose 1-phosphate by fructokinase. Fructose 1-phosphate is then split into glyceraldehyde and dihydroxyacetone phosphate, an intermediate in glycolysis. This aldol cleavage is catalyzed by a specific fructose 1-phosphate aldolase. Glyceraldehyde is then phosphorylated to glyceraldehyde 3-phosphate, a glycolytic intermediate, by triose kinase. In other tissues, such as adipose tissue, fructose can be phosphorylated to fructose 6-phosphate by hexokinase.

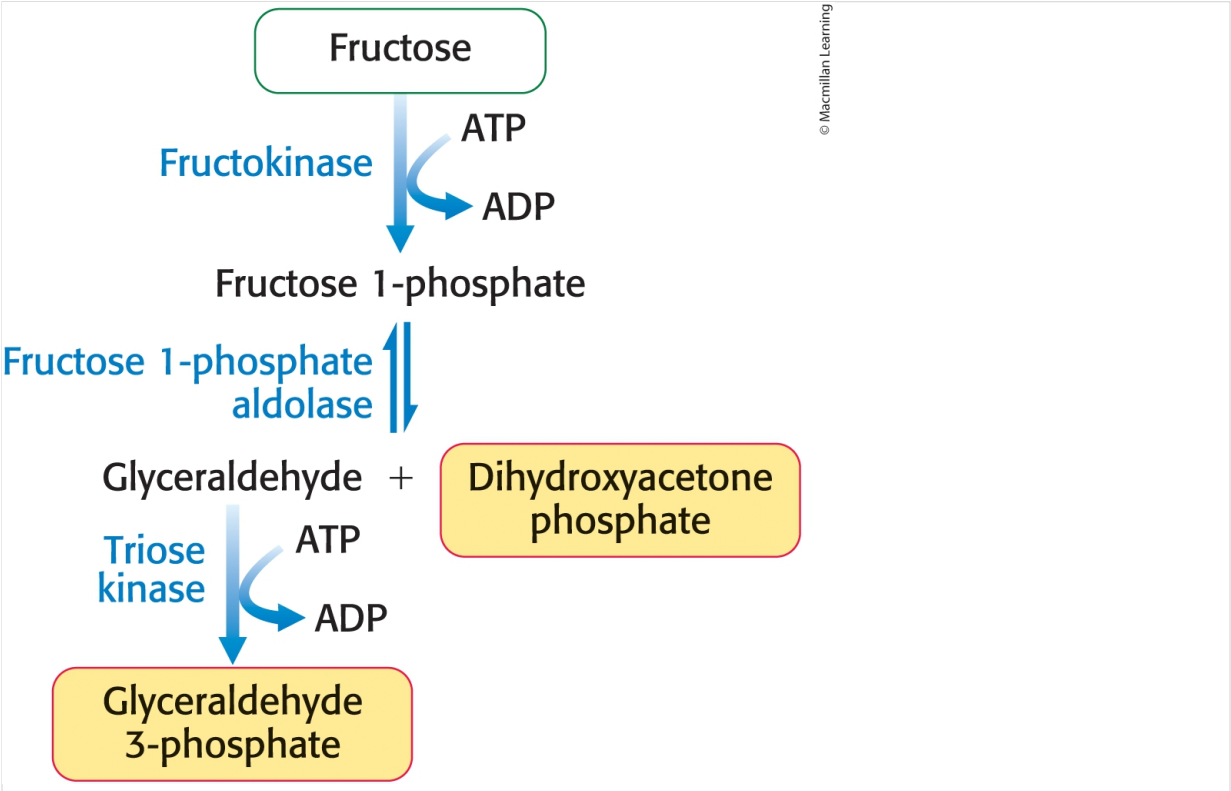

FIGURE 16.16 In the liver, fructose enters the glycolytic pathway through the fructose 1-phosphate pathway.

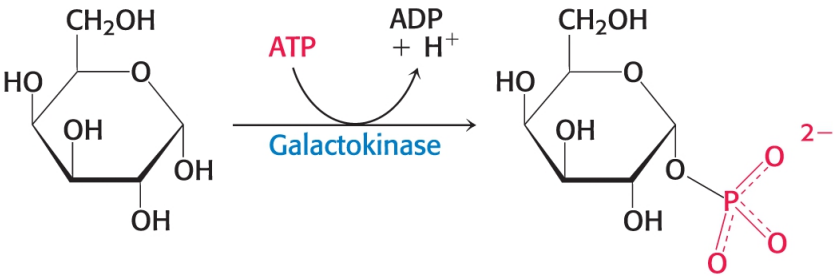
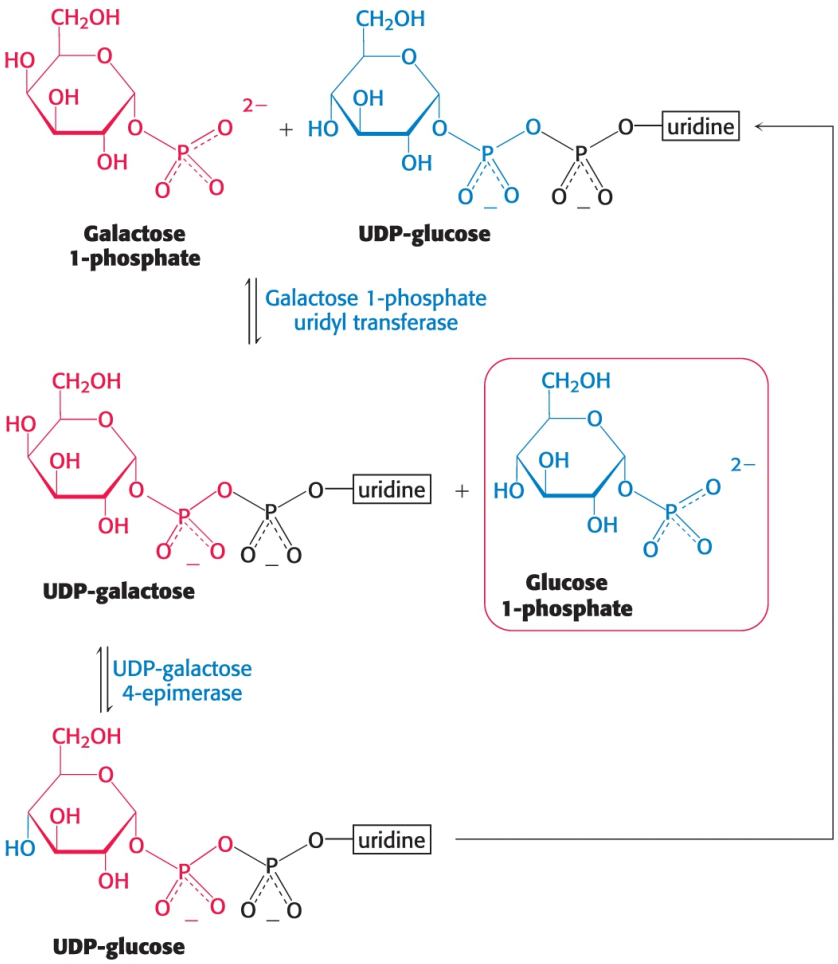


Fructose consumption, previously associated with pathological conditions, is likely inconsequential relative to caloric intake. Fructose, a commonly used sweetener, is a component of sucrose and high fructose corn syrup (which contains approximately 55% fructose and 45% glucose). Epidemiological as well as clinical studies previously linked excessive fructose consumption to fatty liver, insulin insensitivity, and obesity, while other studies found negligible or even beneficial effects of fructose consumption, relative to calorically equivalent quantities of other sugars like glucose and sucrose. Recent meta-analyses, large studies which methodically evaluate the results of many other experiments collectively, now indicate that the widely held belief in the negative effects of fructose is no longer supported by the current literature. Interestingly, the hypothesis that overconsumption of fructose, specifically, contributed to poor health outcomes has a biochemical underpinning.

Note that, as shown in Figure 16.16, the actions of fructokinase and triose kinase bypass the most important regulatory step in glycolysis, the phosphofructokinase-catalyzed reaction. Thus, the fructose-derived glyceraldehyde 3-phosphate and dihydroxyacetone phosphate are produced in an unregulated fashion. However, it is likely that additional regulatory enzymes prevent any further unregulated metabolism of the downstream product pyruvate. Although the type of sugar may be unimportant, the overconsumption of sugars and fats is still strongly associated with fatty liver, insulin insensitivity, and obesity, conditions that may eventually result in type 2 diabetes (Chapter 24). Excess pyruvate produced in glycolysis, from any source, is metabolized to acetyl CoA. As we will see in Chapter 22, this excess

acetyl CoA is converted to fatty acids, which can be transported to adipose tissue and result in obesity. The liver also begins to accumulate fatty acids, resulting in fatty liver. We will return to the topic of obesity and caloric homeostasis in Chapter 24.



Galactose is converted into glucose 6-phosphate

Like fructose, galactose is an abundant sugar common in dairy products that must be converted into metabolites of glucose (Figure 16.15). Galactose is converted into glucose 6-phosphate in four steps. The first reaction in the galactose–glucose interconversion pathway is the phosphorylation of galactose to galactose 1-phosphate by galactokinase.

Galactose **Galactose 1-phosphate**

Galactose 1-phosphate then acquires a uridyl group from uridine diphosphate glucose (UDP-glucose), an activated intermediate in the synthesis of carbohydrates (Section 21.4).

The products of this reaction, which is catalyzed by galactose 1-phosphate uridyl transferase, are UDP-galactose and glucose 1-phosphate. The galactose moiety of UDP-galactose is then epimerized to glucose. The configuration of the hydroxyl group at carbon 4 is inverted by UDP-galactose 4-epimerase.

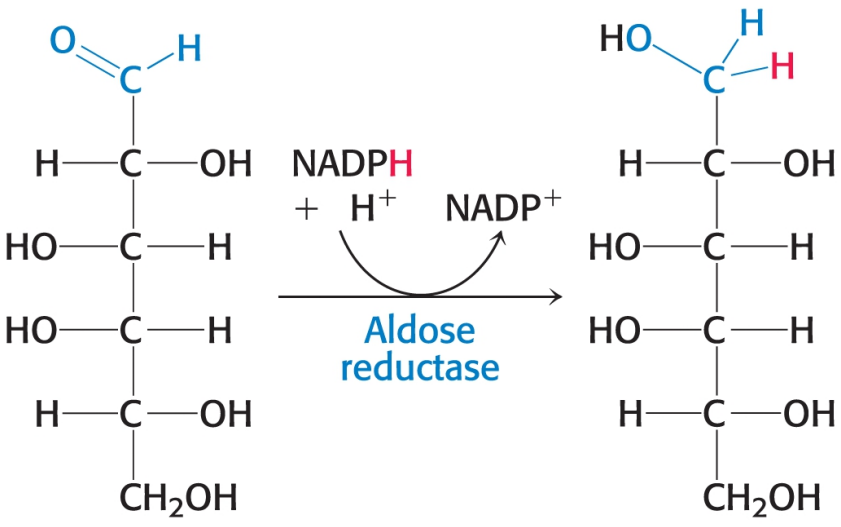
The sum of the reactions catalyzed by galactokinase, the transferase, and the epimerase is

$$\text{Galactose} + \text{ATP} \rightarrow \text{glucose 1-phosphate} + \text{ADP} + \text{H}^+$$

Note that UDP-glucose is not consumed in the conversion of galactose into glucose, because it is regenerated from UDP-galactose by the epimerase. This reaction is reversible, and the product of the reverse direction also is important. The conversion of UDP-glucose into UDP-galactose is essential for the synthesis of galactosyl residues in complex polysaccharides and glycoproteins if the amount of galactose in the diet is inadequate to meet these needs.

Finally, glucose 1-phosphate, formed from galactose, is isomerized to glucose 6-phosphate by phosphoglucomutase.

We shall return to this reaction when we consider the synthesis and degradation of glycogen, which proceeds through glucose 1-phosphate, in Chapter 21.



Galactose can be highly toxic with a defective metabolic pathway

Rare disorders that interfere with the metabolism of galactose are collectively referred to as *galactosemias.* The most common form, called classic galactosemia, is an inherited deficiency in galactose 1-phosphate uridyl transferase activity. Afflicted infants fail to thrive; they vomit or have diarrhea after consuming milk, and enlargement of the liver and jaundice are common, sometimes progressing to cirrhosis. Cataracts will form, and lethargy and delayed neurological development also are common. The blood-galactose level is markedly elevated, and galactose is found in the urine.

The most common treatment is to remove galactose (and lactose) from the diet. An enigma of galactosemia is that, although elimination of galactose from the diet prevents liver disease and cataract development, the majority of patients still suffer from central nervous system malfunction, most commonly a delayed acquisition of language skills. Female patients also display ovarian failure.

Cataract formation is better understood. A cataract is the clouding of the normally clear lens of the eye due to pathological protein aggregation (**Figure 16.17**). If the transferase is not active in the lens of the eye, the presence of aldose reductase causes the accumulating galactose to be reduced to galactitol.

Galactose **Galactitol**

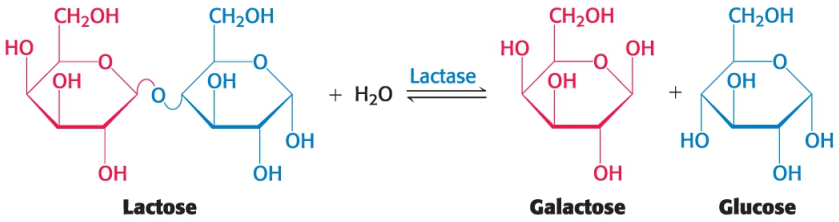


FIGURE 16.17 Cataracts are evident as the clouding of the lens. (A) A healthy eye. (B) An eye with a cataract.

Galactitol is poorly metabolized and accumulates in the lens. Water will diffuse into the lens to maintain osmotic balance, triggering the formation of cataracts. In fact, there is a high incidence of cataract formation with age in populations that consume substantial amounts of milk into adulthood.

Many adults worldwide are intolerant of milk because they are deficient in lactase

Many adults are unable to metabolize the milk sugar lactose and experience gastrointestinal disturbances if they drink milk. Lactose intolerance is most commonly caused by a deficiency of the enzyme lactase, which cleaves lactose into glucose and galactose.

"Deficiency" is not quite the appropriate term, because a decrease in lactase is normal in the course of development in all mammals. As children are weaned and milk becomes less prominent in their diets, lactase activity normally declines to about 5% to 10% of the level at birth. This decrease is not as pronounced with some groups of people, and people from these groups can continue to ingest milk without gastrointestinal difficulties.

How did this tolerance evolve? With the development of dairy farming, an adult with active lactase would have a selective advantage in being able to consume calories from the readily available milk. Indeed, estimates suggest that people with the mutation would have produced almost 20% more fertile offspring. Some form of lactose tolerance evolved independently at least four different times in different human populations in the last 10,000 years, indicating that the evolutionary selective pressure on lactase persistence must have been substantial, attesting to the biochemical value of being able to use milk as an energy source into adulthood.

What happens to the lactose in the intestine of a lactase-deficient person? The lactose is a good energy source for microorganisms in the colon (Figure 16.18), which ferment it to lactic acid while generating methane (CH_4) and hydrogen gas (H_2). The gas produced creates the uncomfortable feeling of gut distension and the annoying problem of flatulence. The lactate produced by these microorganisms is osmotically active and draws water into the intestine, as does any undigested lactose, resulting in diarrhea. If severe enough, the gas and diarrhea hinder the absorption of other nutrients such as fats and proteins. The simplest treatment is to avoid the consumption of products containing much lactose. Alternatively, the enzyme lactase can be ingested with milk products.

SPL/Science Source

FIGURE 16.18 *Lactobacillus* is one example of an industrially useful anaerobic bacterium. A scanning electron micrograph of an anaerobic bacterial species from the genus *Lactobacillus* is shown. As suggested by its name, this genus ferments glucose into lactic acid. *Lactobacillus* is widely used in the food industry and is an important component of the normal human bacterial flora of the urogenital tract, where it prevents the growth of harmful organisms by creating an acid environment.

Self-Check Question

Which condition is more detrimental to human health: lactose intolerance or classic galactosemia? Also, if a person were galactosemic, would it be better to be lactose tolerant or intolerant?

16.3 The Glycolytic Pathway Is Tightly Controlled

The glycolytic pathway has a dual role: it degrades glucose to generate ATP, and it provides building blocks for biosynthetic reactions. The rate of conversion of glucose into pyruvate is regulated to meet these two major cellular needs. In metabolic pathways, enzymes catalyzing essentially irreversible reactions are potential sites of control. In glycolysis, the reactions catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase are virtually irreversible, and each of them serves as a control site. These enzymes become more active or less so in response to the reversible binding of allosteric effectors or to covalent modification. In addition, the amounts of these important enzymes are varied by the regulation of transcription to meet changing metabolic needs. The time required for allosteric regulation, control by phosphorylation, and transcriptional change is measured typically in milliseconds, seconds, and hours, respectively. We will consider the control of glycolysis in two different tissues — skeletal muscle and liver.

Glycolysis in muscle is regulated to meet the need for ATP

Glycolysis in skeletal muscle provides ATP primarily to power contraction. Consequently, the primary regulation of muscle glycolysis is the ratio of ATP to AMP. Let's examine how each of the key regulatory enzymes responds to changes in the amounts of ATP and AMP present in the cell.

Phosphofructokinase

Phosphofructokinase is the most important control site in the mammalian glycolytic pathway (Figure 16.19). High levels of ATP allosterically inhibit the enzyme (a 340-kDa tetramer). ATP binds to a specific regulatory site that is distinct from the catalytic site.

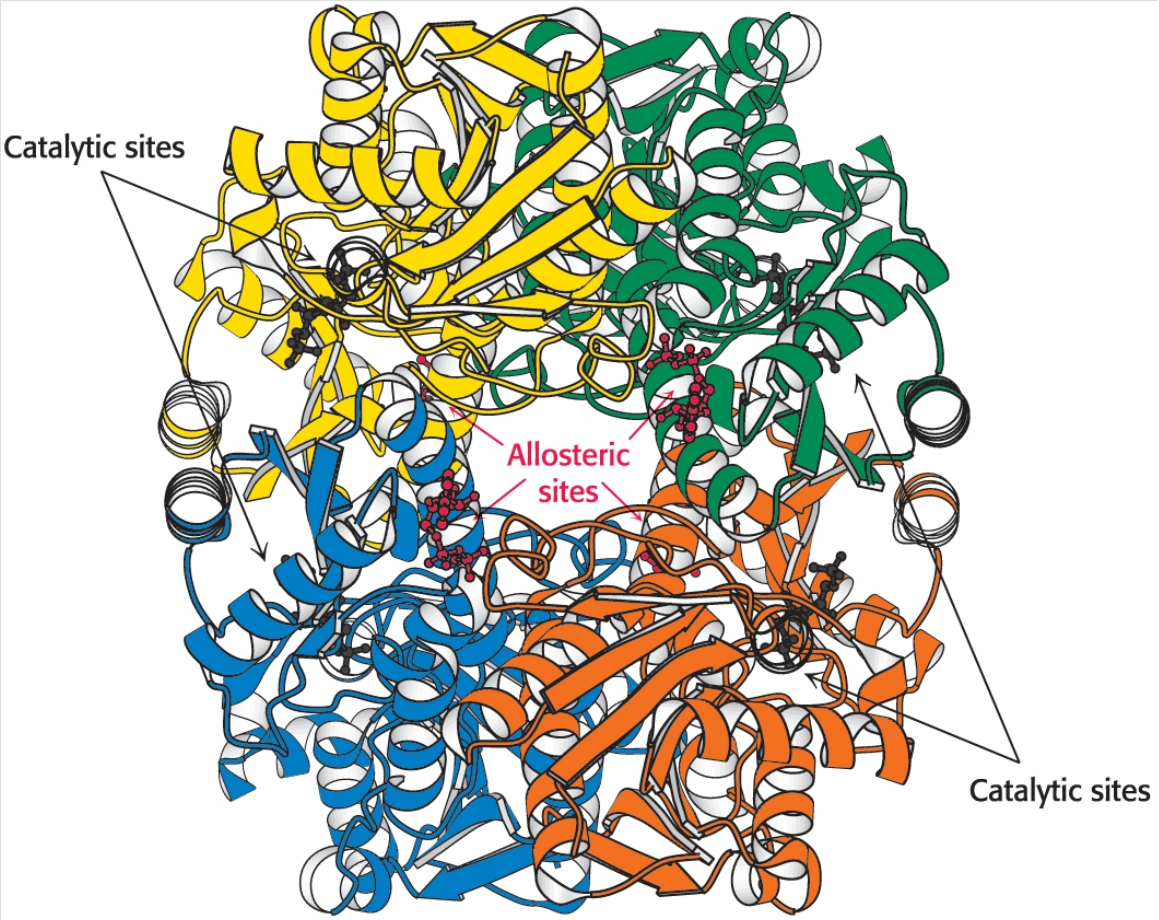

FIGURE 16.19 Phosphofructokinase from *E. coli* is comprised of four identical subunits with separate catalytic and allosteric sites. Each subunit of the human liver enzyme consists of two domains that are similar to the *E. coli* enzyme.

[Drawn from 1PFK.pdb.]

The binding of ATP lowers the enzyme's affinity for fructose 6-phosphate. Thus, a high concentration of ATP converts the hyperbolic binding curve of fructose 6-phosphate into a sigmoidal one (**Figure 16.20**). AMP reverses the inhibitory action of ATP, and so the activity of the enzyme increases when the ATP/AMP ratio is lowered. A decrease in pH also inhibits phosphofructokinase activity by augmenting the inhibitory effect of ATP. The pH might fall when fast-twitch muscle is functioning anaerobically, producing excessive quantities of lactic acid. The inhibitory effect protects the muscle from damage that would result from the accumulation of too much acid.

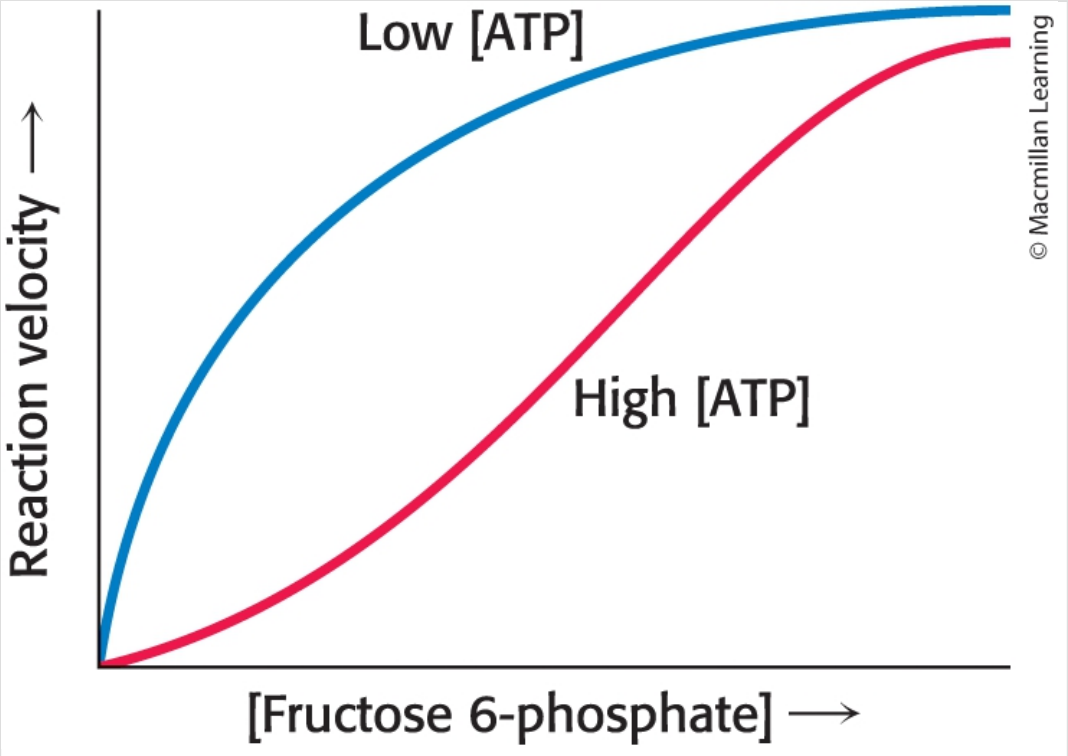

FIGURE 16.20 A high level of ATP allosterically inhibits phosphofructokinase by decreasing its affinity for fructose 6-phosphate.

Why is AMP and not ADP the positive regulator of phosphofructokinase? When ATP is being utilized rapidly, the enzyme adenylate kinase can

form ATP from ADP by the following reaction:

$$\mathrm{ADP} + \mathrm{ADP} \rightleftharpoons \mathrm{ATP} + \mathrm{AMP}$$

Thus, some ATP is salvaged from ADP, and AMP becomes the signal for the low-energy state.

Moreover, the use of AMP as an allosteric effector provides an especially sensitive regulation. We can understand why by considering the following. First, the total adenylate pool ([ATP], [ADP], [AMP]) in a cell is constant over the short term. Second, the concentration of ATP is greater than that of ADP, and the concentration of ADP is, in turn, greater than that of AMP. Consequently, small percentage changes in [ATP] result in larger percentage changes in the concentrations of the other adenylate nucleotides. This magnification of small changes in [ATP] to larger changes in [AMP] leads to tighter regulation by increasing the range of sensitivity of phosphofructokinase.

Hexokinase

Phosphofructokinase is the most prominent regulatory enzyme in glycolysis, but it is not the only one. Hexokinase, the enzyme catalyzing the first step of glycolysis, is inhibited by its product, glucose 6-phosphate. High concentrations of this molecule signal that the cell no longer requires glucose for energy or for the synthesis of glycogen, a storage form of glucose (Chapter 21), and the glucose will be left in the blood. A rise in glucose 6-phosphate concentration is a means by which phosphofructokinase communicates with hexokinase. When phosphofructokinase is inactive, the concentration of fructose 6-phosphate rises. In turn, the level of glucose 6-phosphate rises because it is in equilibrium with fructose 6-phosphate. Hence, the inhibition of phosphofructokinase leads to the inhibition of hexokinase.

Why is phosphofructokinase rather than hexokinase the pacemaker of glycolysis? The reason becomes evident on noting that glucose 6-phosphate is not solely a glycolytic intermediate. In muscle, glucose 6-phosphate can also be converted into glycogen. The first irreversible reaction unique to the glycolytic pathway, the **committed step**, is the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate. Thus, it is highly appropriate for phosphofructokinase to be the primary control site in glycolysis. In general, the enzyme catalyzing the committed step in a metabolic sequence is the most important control element in the pathway.

Pyruvate kinase

Pyruvate kinase, the enzyme catalyzing the third irreversible step in glycolysis, controls the outflow from this pathway. This final step yields ATP and pyruvate, a central metabolic intermediate that can be oxidized further or used as a building block. ATP allosterically inhibits pyruvate kinase to slow glycolysis when the energy charge is high. When the pace of glycolysis increases, fructose 1,6-bisphosphate — the product of the preceding irreversible step in glycolysis — activates the kinase to enable it to keep pace with the oncoming high flux of intermediates. Such a process is called **feedforward stimulation** or **feedforward activation**. A summary of the regulation of glycolysis in resting and active muscle is shown in **Figure 16.21**.

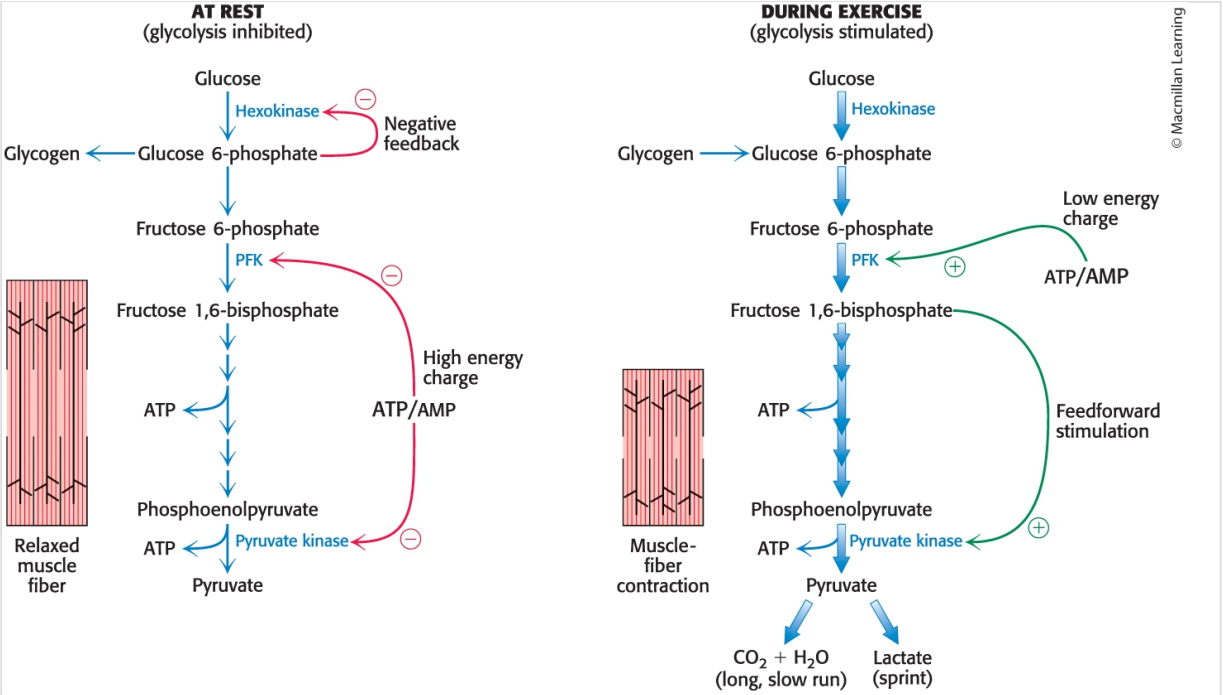

FIGURE 16.21 Regulation of glycolysis in muscle. At rest (left), glycolysis is not very active (thin arrows). The high concentration of ATP inhibits phosphofructokinase (PFK), pyruvate kinase, and hexokinase. Glucose 6-phosphate is converted into glycogen (Chapter 21). During exercise (right), the decrease in the ATP/AMP ratio resulting from muscle contraction activates phosphofructokinase and hence glycolysis. The flux down the pathway is increased, as represented by the thick arrows.

The regulation of glycolysis in the liver illustrates the biochemical versatility of the liver

The liver has more diverse biochemical functions than does muscle. Significantly, the liver maintains blood-glucose concentration: it stores glucose as glycogen when glucose is plentiful, and it releases glucose when supplies are low. It also uses glucose to generate reducing power

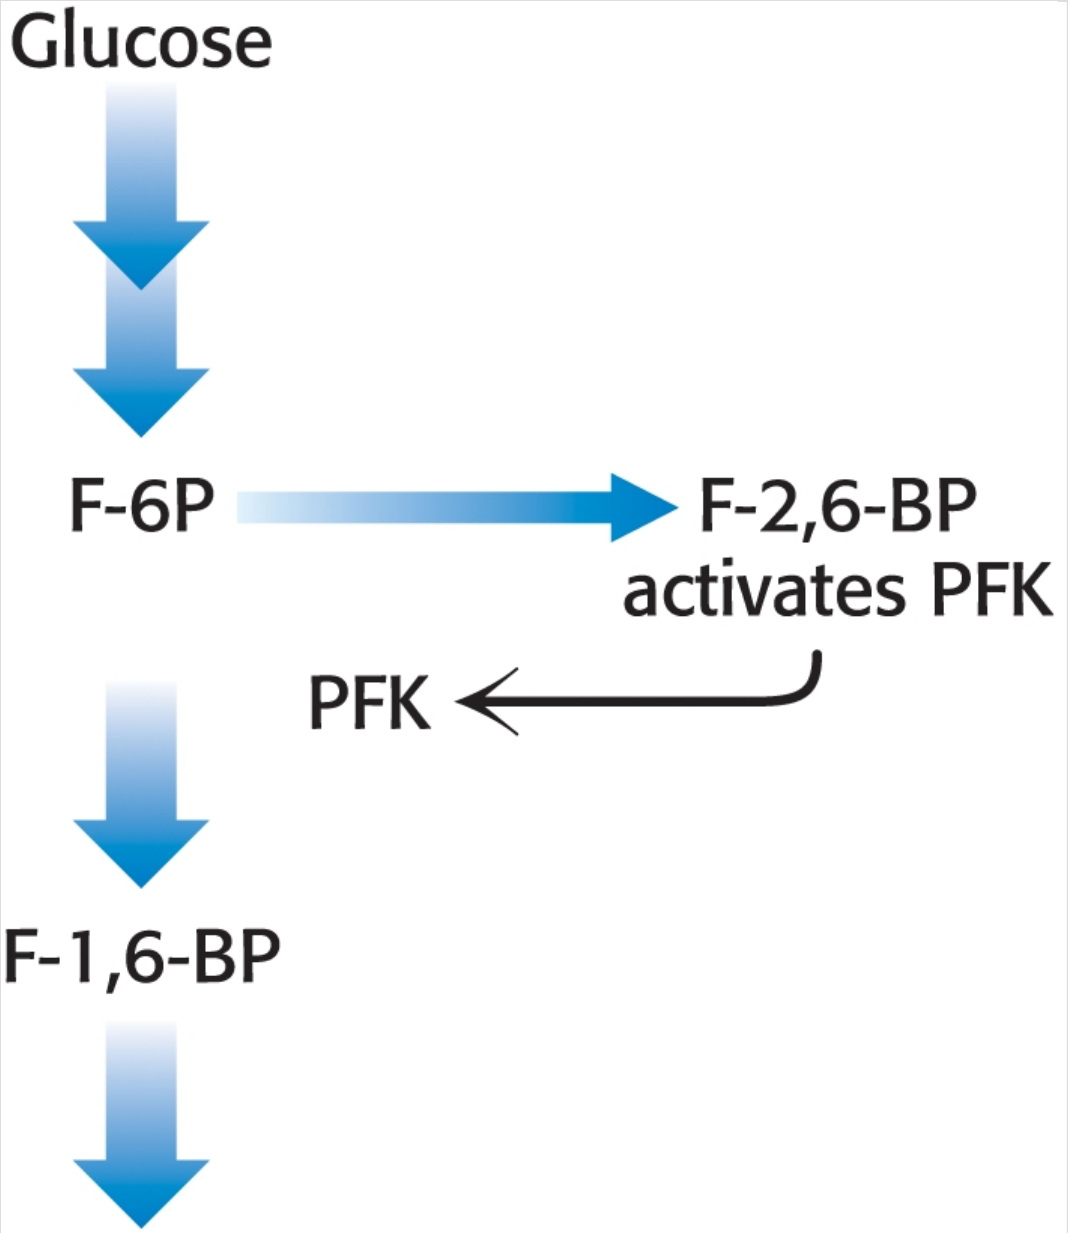
for biosynthesis (Section 20.3) as well as to synthesize a host of biochemicals. So, although the liver has many of the regulatory features of muscle glycolysis, the regulation of glycolysis in the liver is more complex.

Phosphofructokinase

Liver phosphofructokinase can be regulated by ATP as in muscle, but such regulation is not as important since the liver does not experience the sudden ATP needs that a contracting muscle does. Likewise, low pH is not an important metabolic signal for the liver enzyme, because lactate is not normally produced in the liver. Indeed, as we will see, lactate is converted into glucose in the liver.

Glycolysis in the liver furnishes carbon skeletons for biosyntheses, and so a signal indicating whether building blocks are abundant or scarce should also regulate phosphofructokinase. In the liver, phosphofructokinase is inhibited by citrate, an early intermediate in the citric acid cycle (Chapter 17). A high level of citrate in the cytoplasm means that biosynthetic precursors are abundant, and so there is no need to degrade additional glucose for this purpose. Citrate inhibits phosphofructokinase by enhancing the inhibitory effect of ATP.

The key means by which glycolysis in the liver responds to changes in blood glucose is through the signal molecule fructose 2,6-bisphosphate (F-2,6-BP), a potent activator of phosphofructokinase. In the liver, the concentration of fructose 6-phosphate rises when blood-glucose concentration is high, and the abundance of fructose 6-phosphate accelerates the synthesis of F-2,6-BP (**Figure 16.22**). Hence, an abundance of fructose 6-phosphate leads to a higher concentration of F-2,6-BP.



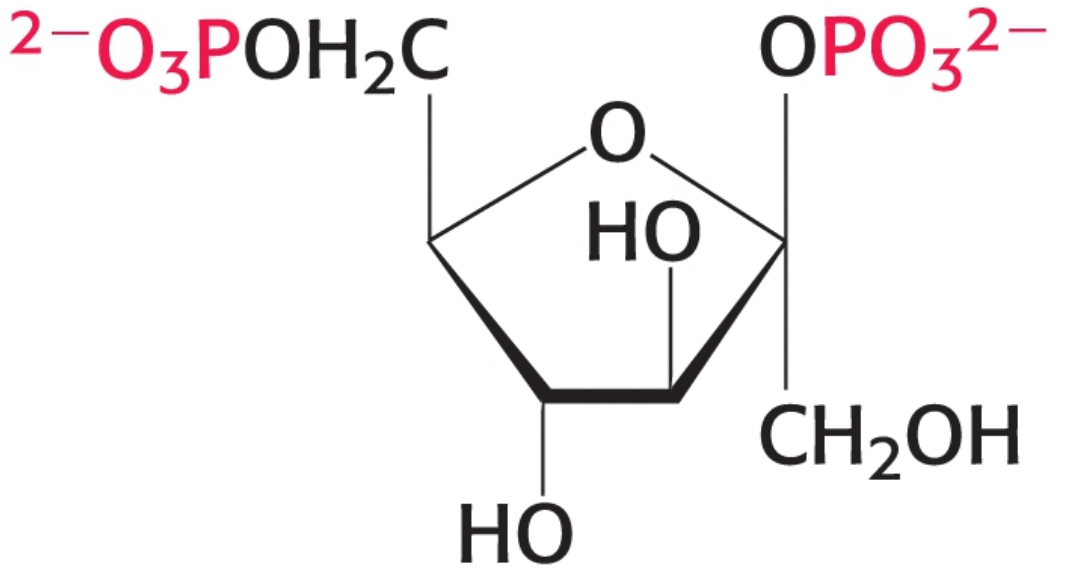


FIGURE 16.22 Fructose 2,6-bisphosphate allosterically activates phosphofructokinase. In high concentrations, fructose 6-phosphate (F-6P) activates the enzyme phosphofructokinase (PFK) through an intermediary, fructose 2,6-bisphosphate (F-2,6-BP).

The binding of fructose 2,6-bisphosphate increases the affinity of phosphofructokinase for fructose 6-phosphate and diminishes the

inhibitory effect of ATP (Figure 16.23). Glycolysis is thus accelerated when glucose is abundant. We will further explore the additional hormonal control over the synthesis and degradation of this important regulatory molecule after we have considered gluconeogenesis.

Fructose 2,6-bisphosphate (F-2,6-BP)

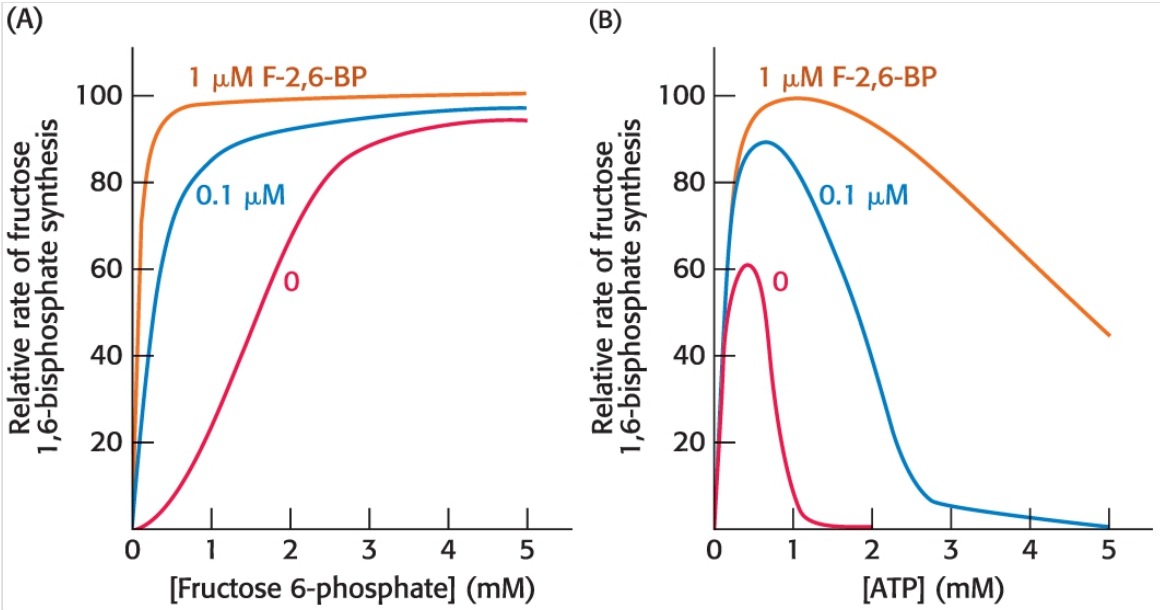

FIGURE 16.23 Activation of phosphofructokinase by fructose 2,6-bisphosphate changes the properties of the enzyme and counteracts inhibition by ATP. (A) The sigmoidal dependence of velocity on substrate concentration becomes hyperbolic in the presence of 1 μM fructose 2,6-bisphosphate. (B) ATP, acting as a substrate, initially stimulates the reaction. As the concentration of ATP increases, it acts as an allosteric inhibitor. The inhibitory effect of ATP is reversed by fructose 2,6-bisphosphate.

[Data from E. Van Schaftingen, M. F. Jett, L. Hue, and H. G. Hers, *Proc. Natl. Acad. Sci. U.S.A.* 78:3483–3486, 1981.]

Hexokinase and glucokinase

The hexokinase reaction in the liver is regulated as in the muscle. However, the liver, in keeping with its role as monitor of blood-glucose levels, possesses another specialized isozyme of hexokinase, called *glucokinase*, which is not inhibited by glucose 6-phosphate. The role of glucokinase is to provide glucose 6-phosphate for the synthesis of glycogen and for the formation of fatty acids (Chapter 22).

Remarkably, glucokinase displays the sigmoidal kinetics characteristic of an allosteric enzyme even though it functions as a monomer.

Glucokinase phosphorylates glucose only when glucose is abundant because the affinity of glucokinase for glucose is about 50-fold lower than that of hexokinase. Moreover, when glucose concentration is low, glucokinase is inhibited by the liver-specific glucokinase regulatory protein (GKRP), which sequesters the kinase in the nucleus until the glucose concentration increases. The low affinity of glucokinase for glucose gives the brain and muscles first call on glucose when its supply is limited, and it ensures that glucose will not be wasted when it is abundant.

 Glucokinase is also present in the β cells of the pancreas, which secrete the hormone insulin in response to the increased formation of glucose 6-phosphate by glucokinase when blood-glucose levels are elevated. Insulin signals the need to remove glucose from the blood for storage as glycogen or conversion into fat. Drugs that activate liver glucokinase or disrupt its interaction with GKRP are being evaluated as a treatment for type 2 diabetes, in which the sensitivity to natural levels of insulin has decreased.

Pyruvate kinase

Several isozymic forms of pyruvate kinase (a tetramer of 57-kDa subunits) encoded by different genes are present in mammals: The L type predominates in the liver, and the M type in muscle and the brain. The L and M forms of pyruvate kinase have many properties in common. Indeed, the liver enzyme behaves much like the muscle enzyme with regard to allosteric regulation, except that the liver enzyme is also inhibited by alanine (synthesized in one step from pyruvate), a signal that building blocks are available. Moreover, the isozymic forms differ in their susceptibility to covalent modification. The catalytic properties of the L form — but not of the M form — are also controlled by reversible phosphorylation (**Figure 16.24**). When the blood-glucose level is low, the glucagon-triggered cyclic AMP cascade

(Section 14.2) leads to the phosphorylation of pyruvate kinase, which diminishes its activity. This hormone-triggered phosphorylation prevents the liver from consuming glucose when it is more urgently needed by the brain and muscle. We see here a clear-cut example of how isoenzymes contribute to the metabolic diversity of different organs.

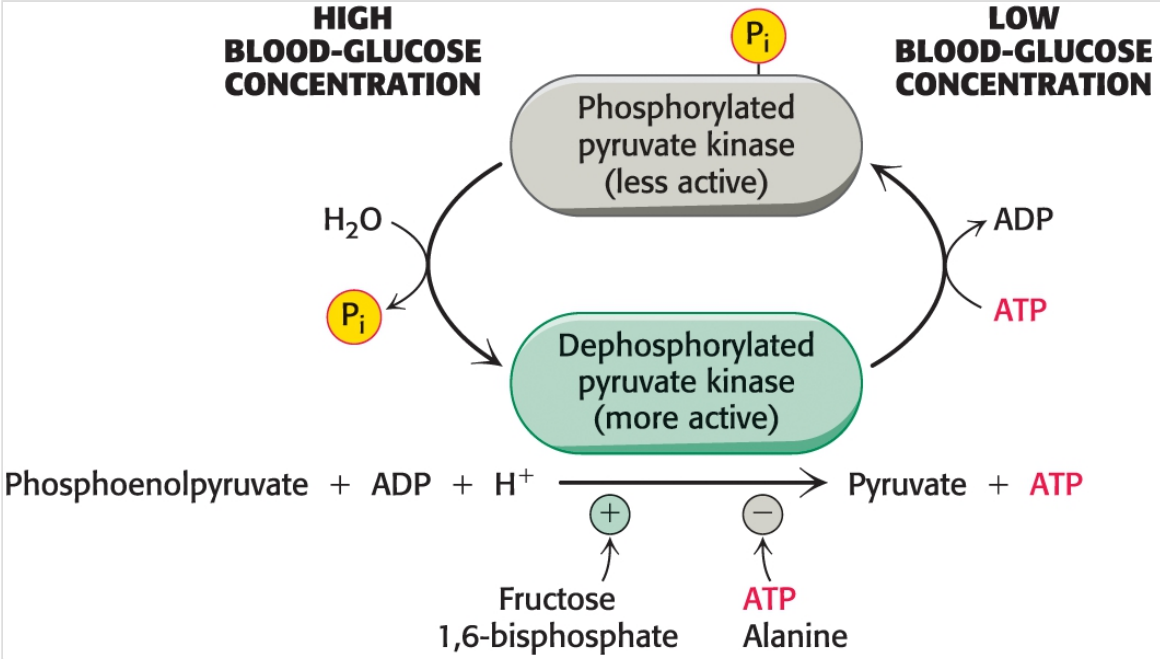

FIGURE 16.24 Pyruvate kinase activity is controlled by phosphorylation and dephosphorylation. Pyruvate kinase is automatically regulated by allosteric effectors but controlled by extracellular signals through reversible covalent modification. Fructose 1,6-bisphosphate allosterically stimulates the enzyme, while ATP and alanine are allosteric inhibitors. Glucagon, secreted in response to low blood glucose, promotes phosphorylation and inhibition of the enzyme. When blood glucose concentration is adequate, the enzyme is dephosphorylated and activated.

The enzymes of glycolysis are physically associated with one another

Evidence has accumulated that the enzymes of glycolysis in eukaryotes are organized into complexes. For example, in yeast, the glycolytic enzymes are associated with the mitochondria, while in mammalian erythrocytes, the enzymes are found bound to the inner surface of the cell membrane. Indeed, some level of organization appears to occur in all cell types. This arrangement increases enzyme efficiency by facilitating movement of substrates and products between enzymes — a process called **substrate channeling** — and prevents the release of any toxic intermediates. We will see that the organization of metabolic pathways into large complexes is a common occurrence inside the cell.

Aerobic glycolysis is a property of tumor cells and other rapidly growing cells

Tumors have been known for decades to display enhanced rates of glucose uptake and glycolysis. Indeed, rapidly growing tumor cells will metabolize glucose to lactate even in the presence of oxygen, a process called **aerobic glycolysis** or the *Warburg effect*, after Otto Warburg, the biochemist who first noted this characteristic of cancer cells in the 1920s. In fact, tumors with a high glucose uptake are particularly aggressive, and the cancer is likely to have a poor prognosis. A nonmetabolizable glucose analog, 2-^{18}F-2-D-deoxyglucose, detectable by a combination of positron emission tomography (PET) and computer-aided tomography (CAT), easily visualizes tumors and allows monitoring of treatment effectiveness (**Figure 16.25**).

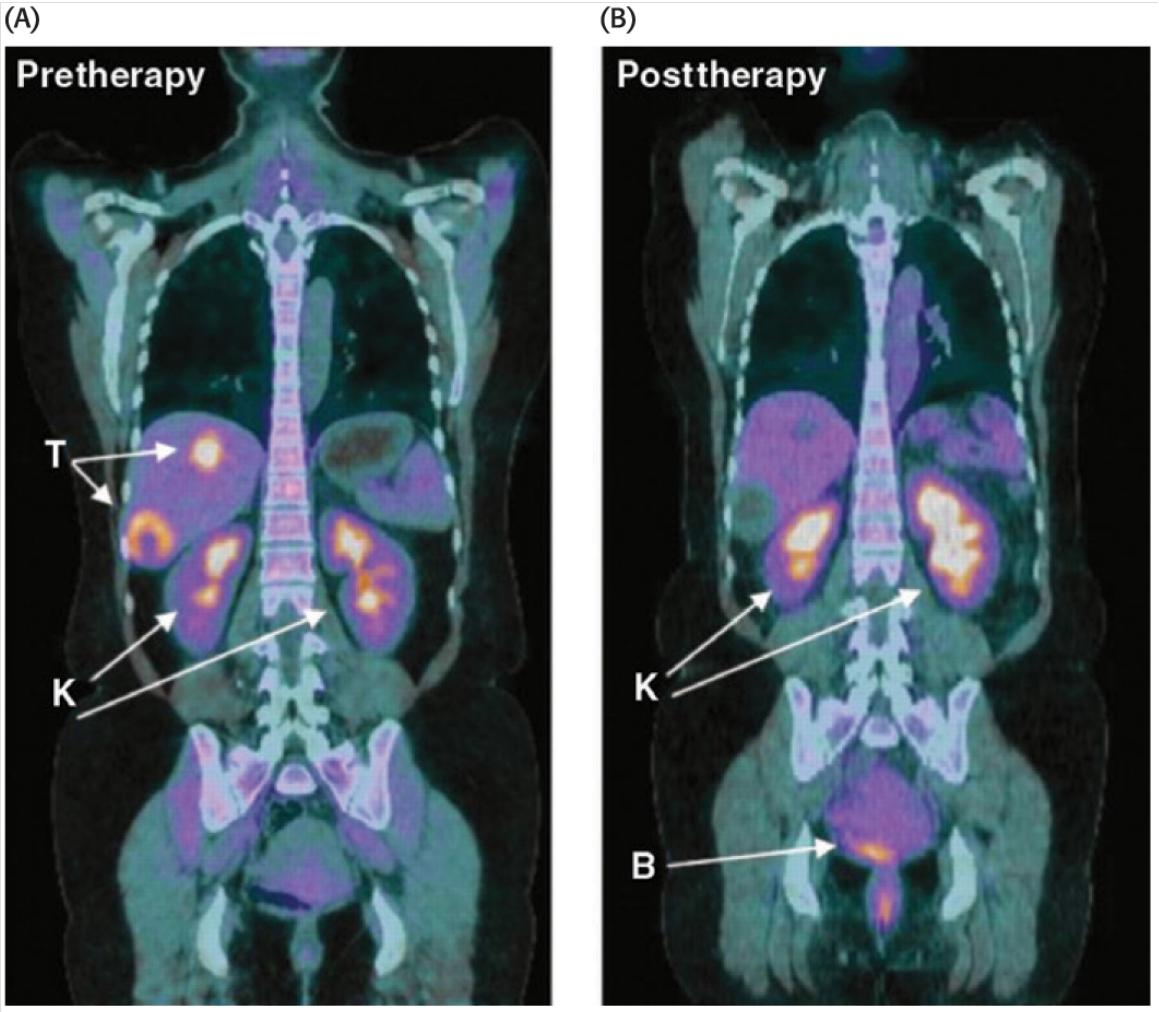

FIGURE 16.25 Tumors can be visualized with 2-^{18}F-2-D-deoxyglucose (FDG) and positron emission tomography. (A) A nonmetabolizable glucose analog infused into a patient and detected by a combination of positron emission and computer-aided tomography reveals the presence of a malignant tumor (T). (B) After 4 weeks of treatment with a tyrosine kinase inhibitc (Section 14.5), the tumor shows no uptake of FDG, indicating decreased metabolism. Excess FD which is excreted in the urine, also visualizes the kidneys (K) and bladder (B).

What selective advantage does aerobic glycolysis offer the tumor over the energetically more efficient oxidative phosphorylation? Researchers are actively pursuing the answer to this question, but we can speculate on the benefits. First, aerobic glycolysis generates lactic acid that is then

secreted. Acidification of the tumor environment has been shown to facilitate tumor invasion. Moreover, lactate impairs the activation of $CD8^+$ T and NK immune system cells that normally attack the tumor. However, even leukemias perform aerobic glycolysis, and leukemia is not an invasive cancer. Second, and perhaps more importantly, the increased uptake of glucose and formation of glucose 6-phosphate provides substrates for another metabolic pathway — the pentose phosphate pathway (Section 20.3) — that generates biosynthetic reducing power, NADPH. Finally, cancer cells grow more rapidly than the blood vessels that nourish them; thus, as solid tumors grow, the oxygen concentration in their environment falls. In other words, they begin to experience a deficiency of oxygen, called *hypoxia*. The use of aerobic glycolysis reduces the dependence of cell growth on oxygen.

What biochemical alterations facilitate the switch to aerobic glycolysis? Again, the answers are not complete, but changes in gene expression of isozymic forms of two glycolytic enzymes may be crucial. Tumor cells express an isozyme of hexokinase that binds to mitochondria. There, the enzyme has ready access to any ATP generated by oxidative phosphorylation and is not susceptible to feedback inhibition by its product, glucose 6-phosphate. More importantly, an embryonic isozyme of pyruvate kinase, pyruvate kinase M, is also expressed. Remarkably, this isozyme has a lower catalytic rate than normal pyruvate kinase and creates a bottleneck, allowing the use of glycolytic intermediates for biosynthetic processes required for cell proliferation. The need for biosynthetic precursors is greater than the need for ATP, suggesting that even glycolysis at a reduced rate produces sufficient ATP to allow cell proliferation. Although originally observed in cancer cells, the Warburg effect is also seen in noncancerous, rapidly dividing cells.

Cancer and endurance training affect glycolysis in a similar fashion

The hypoxia that some tumors experience with rapid growth activates a transcription factor, hypoxia-inducible transcription factor (HIF-1). HIF-1 increases the expression of most glycolytic enzymes and the glucose transporters GLUT1 and GLUT3 (Table 16.5). These adaptations by the cancer cells enable a tumor to survive until blood vessels can grow. HIF-1 also increases the expression of signal molecules, such as vascular endothelial growth factor (VEGF), that facilitate the growth of blood vessels that will provide nutrients to the cells (Figure 16.26). Without new blood vessels, a tumor would cease to grow and either die or remain harmlessly small.

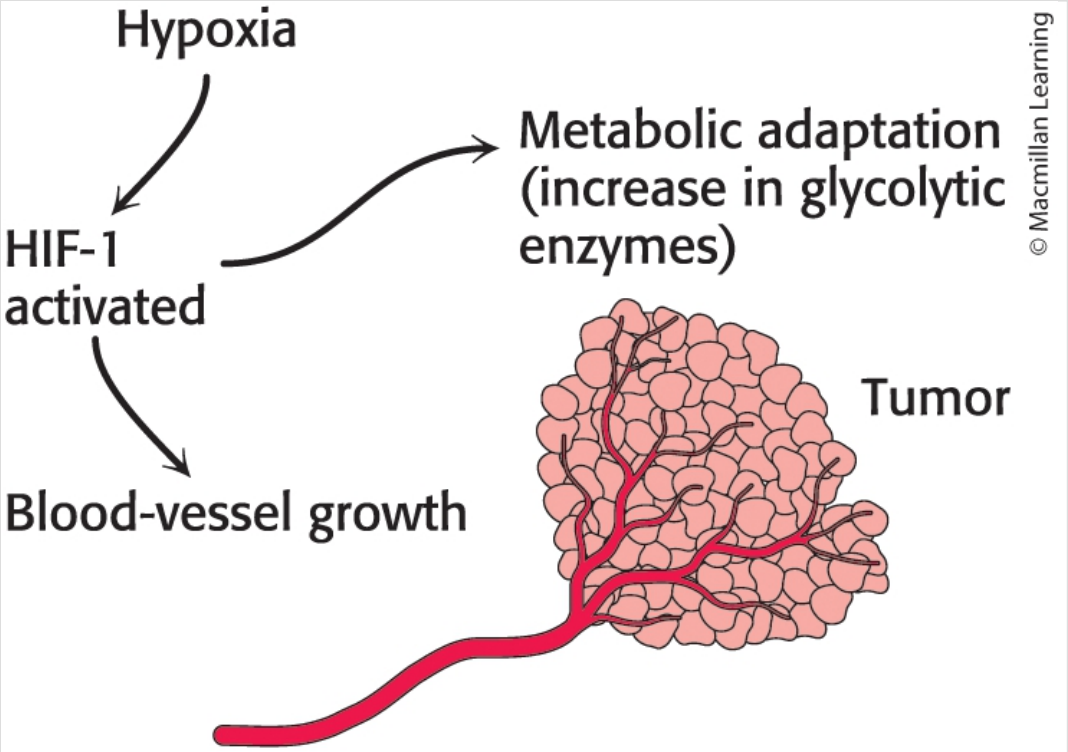

FIGURE 16.26 Hypoxia alters gene expression in tumors. The hypoxic conditions inside a tumor mass lead to the activation of the hypoxia-inducible transcription factor (HIF-1), which induces metabolic adaptation (an increase in glycolytic enzymes) and activates angiogenic factors that stimulate the growth of new blood vessels.

[Information from C. V. Dang and G. L. Semenza, *Trends Biochem. Sci.* 24:68–72, 1999.]

Efforts are underway to develop drugs that inhibit the growth of blood vessels in tumors. Indeed, bevacizumab, a monoclonal antibody that binds to VEGF and prevents activation of angiogenesis, has been approved for treatment of glioblastomas, which are fast-growing cancers of the central nervous system derived from glial cells.

Interestingly, anaerobic exercise training — forcing muscles to rely on lactic acid fermentation for ATP production — also activates HIF-1, producing the same effects as those seen in the tumor — enhanced ability to generate ATP anaerobically and a stimulation of blood-vessel growth. These biochemical effects account for the improved athletic performance that results from training and demonstrate how behavior can affect biochemistry. Other signals from sustained muscle contraction trigger muscle mitochondrial biogenesis, allowing for more efficient aerobic energy generation and forestalling the need to resort to lactic acid fermentation for ATP synthesis.

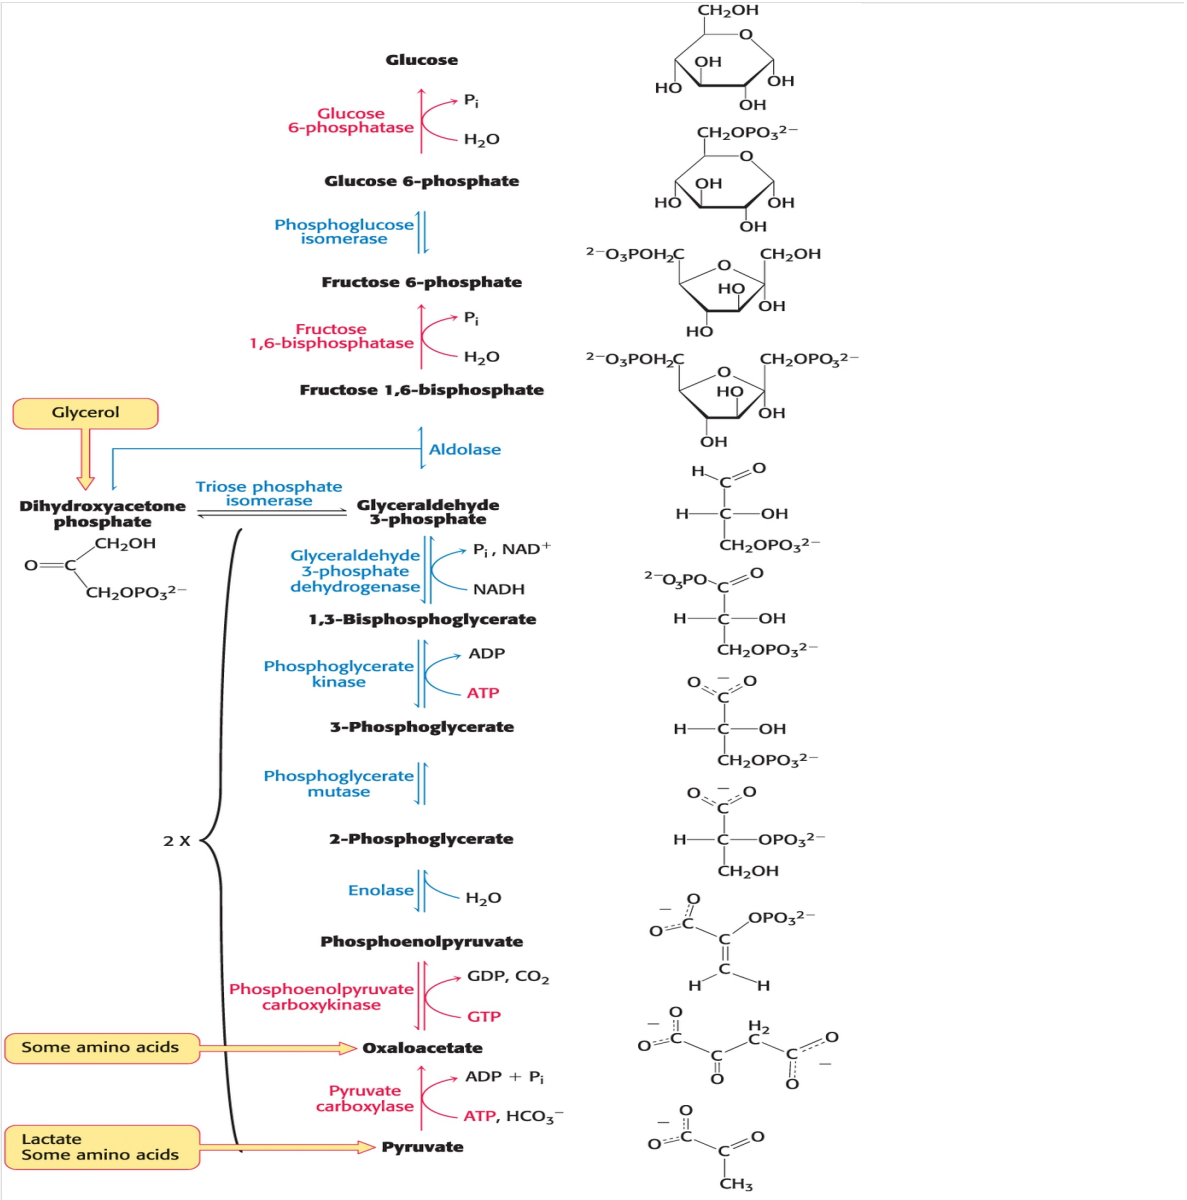
Self-Check Question

Muscle phosphofructokinase activity increases as a function of ATP concentration, but only up to a point, and then it falls rapidly. Explain these results and how they relate to the role of phosphofructokinase in glycolysis.

16.4 Glucose Can Be Synthesized from Noncarbohydrate Precursors

We now turn to the synthesis of glucose from noncarbohydrate precursors, a process called *gluconeogenesis.* Maintaining levels of glucose is important because the brain depends on glucose as its primary fuel and red blood cells use glucose as their only fuel. The daily glucose requirement of the brain in a typical adult human being is about 120 g, which accounts for most of the 160 g of glucose needed daily by the whole body. The amount of glucose present in body fluids is about 20 g, and that readily available from glycogen is approximately 190 g. Thus, the direct glucose reserves are sufficient to meet glucose needs for about a day. Gluconeogenesis is especially important during a longer period of fasting or starvation (Section 24.2) and to constantly remove and recycle lactate, which is always being produced by some tissues.

The gluconeogenic pathway converts pyruvate into glucose. The major noncarbohydrate precursors of glucose — lactate, amino acids, and glycerol — are first converted into pyruvate or enter the pathway at later intermediates such as oxaloacetate and dihydroxyacetone phosphate (**Figure 16.27**). Lactate is readily converted into pyruvate by the action of lactate dehydrogenase (Section 16.2). Amino acids are derived from proteins in the diet and, during starvation, from the breakdown of proteins in skeletal muscle (Section 23.1).



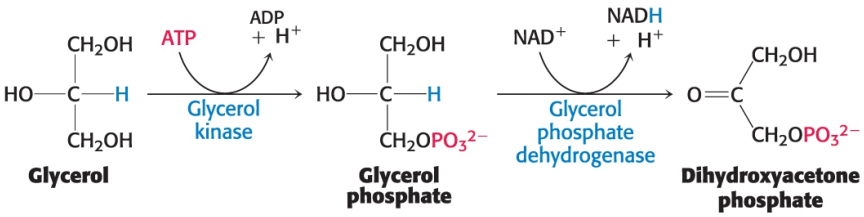


FIGURE 16.27 Gluconeogenesis shares many enzymatic steps with glycolysis. The reactions and enzymes unique to gluconeogenesis are shown in red. The other shared reactions are in black. The enzymes for gluconeogenesis are located in the cytoplasm, except for pyruvate carboxylase (in the mitochondria) and glucose 6-phosphatase (membrane bound in the lumen of the endoplasmic reticulum). The entry points for lactate, glycerol, and amino acids are shown.

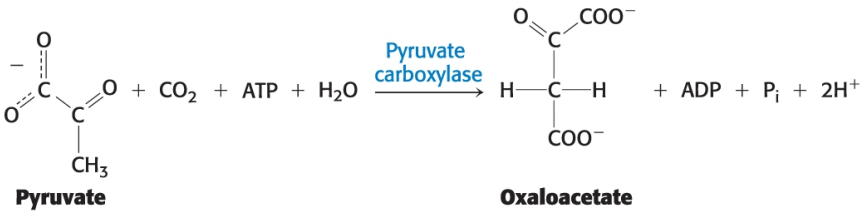
The hydrolysis of triacylglycerols (Section 22.2) in fat cells yields glycerol and fatty acids. Glycerol is a precursor of glucose, but animals cannot convert fatty acids into glucose, for reasons that will be discussed in Chapter 17. Glycerol may enter either the gluconeogenic or the glycolytic pathway as dihydroxyacetone phosphate.

The major site of gluconeogenesis is the liver, with a small amount also taking place in the kidney and other tissues. Gluconeogenesis in the liver and kidney helps to maintain the glucose concentration in the blood so that the brain and muscle can extract sufficient glucose from it to meet their metabolic demands.

Gluconeogenesis is not a reversal of glycolysis

In glycolysis, glucose is converted into pyruvate; in gluconeogenesis, pyruvate is converted into glucose. However, gluconeogenesis is not a reversal of glycolysis. Several reactions must differ because the equilibrium of glycolysis lies far on the side of pyruvate formation. The actual free-energy change for the formation of pyruvate from glucose is about $-90\ \text{kJ mol}^{-1}\ (-22\ \text{kcal mol}^{-1})$ under typical cellular conditions. Most of the decrease in free energy in glycolysis takes place in the three essentially irreversible steps catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase.

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{Hexokinase}} \text{glucose 6-phosphate} + \text{ADP} \qquad \Delta G = -33\ \text{kJ mol}^{-1}\ (-8.0\ \text{kcal mol}^{-1})$$



$$\text{Fructose 6-phosphate} + \text{ATP} \xrightarrow{\text{Phosphofructokinase}} \text{fructose 1,6-bisphosphate} + \text{ADP} \qquad \Delta G = -22\ \text{kJ mol}^{-1}\ (-5.3\ \text{kcal mol}^{-1})$$

$$\text{Phosphoenolpyruvate} + \text{ADP} \xrightarrow{\text{Pyruvate kinase}} \text{pyruvate} + \text{ATP} \qquad \Delta G = -17\ \text{kJ mol}^{-1}\ (-4.0\ \text{kcal mol}^{-1})$$

In gluconeogenesis, these virtually irreversible reactions of glycolysis must be bypassed.

The conversion of pyruvate into phosphoenolpyruvate begins with the formation of oxaloacetate

The first step in gluconeogenesis is the carboxylation of pyruvate to form oxaloacetate at the expense of a molecule of ATP, a reaction catalyzed by pyruvate carboxylase. This reaction occurs in the mitochondria.

Pyruvate carboxylase requires biotin, a covalently attached prosthetic group, which serves as the carrier of activated CO_2. The carboxylate group of biotin is linked to the ε-amino group of a specific lysine residue by an amide bond (**Figure 16.28**). Recall that, in aqueous solutions, CO_2 exists primarily as HCO_3^- with the aid of carbonic anhydrase (Section 6.2).

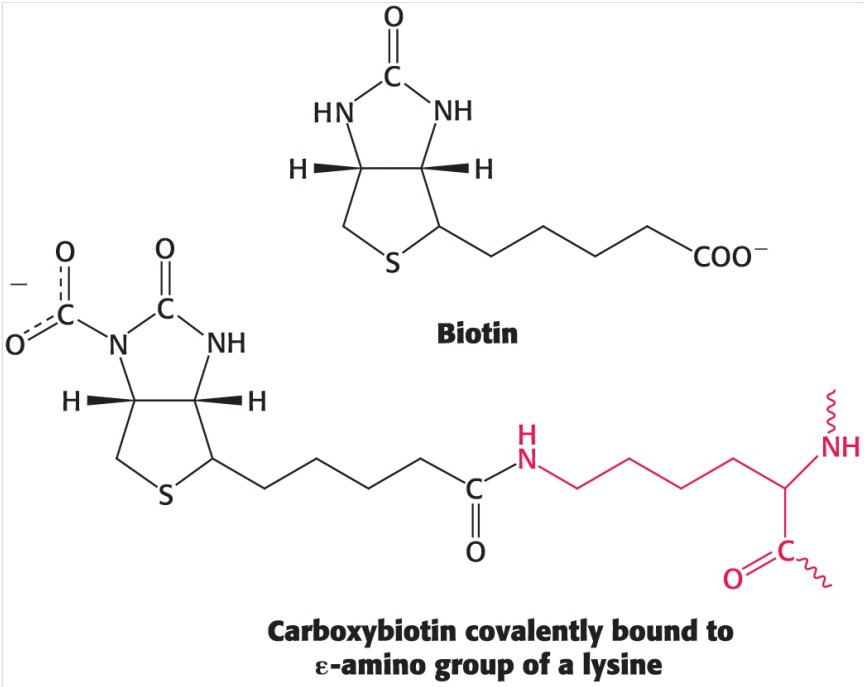


FIGURE 16.28 Carboxybiotin linked to lysine can act as a movable "arm" carrying activated CO_2 groups. Notice the great distance between the bound CO_2 group and where the lysine connects to the rest of the protein. This allows the lysyl-carboxybiotin moiety to act like a long lever arm to move CO_2 from one location in a protein to another. This movement is usually from one distinct active site to a second active site within the same or, in the case of pyruvate carboxylase, in a different subunit.

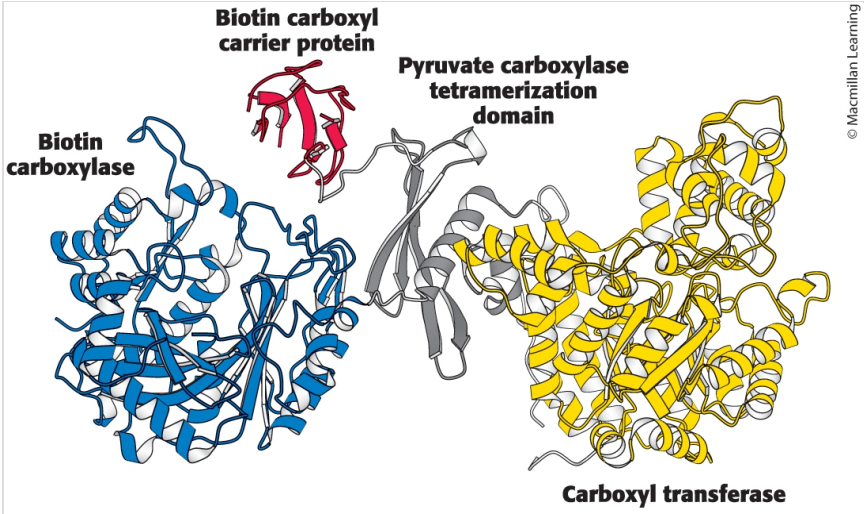
The carboxylation of pyruvate takes place in three stages:

$$HCO_3^- + ATP \rightleftharpoons HOCO_2 - PO_3^{2-} + ADP$$

$$\text{Biotin–enzyme} + HOCO_2 - PO_3^{2-} \rightarrow CO_2 - \text{biotin–enzyme} + P_i$$

$$CO_2 - \text{biotin-enzyme} + \text{pyruvate} \rightleftharpoons \text{biotin-enzyme} + \text{oxaloacetate}$$

Pyruvate carboxylase functions as a tetramer composed of four identical subunits, and each subunit consists of four domains (Figure 16.29). The biotin carboxylase domain (BC) catalyzes the formation of carboxyphosphate and the subsequent attachment of CO_2 to the second domain, the biotin carboxyl carrier protein (BCCP) — the site of the covalently attached biotin. Once bound to CO_2, BCCP leaves the biotin carboxylase active site and swings almost the entire length of the subunit (≈ 75 Å) to the active site of the carboxyl transferase domain (CT), which transfers the CO_2 to pyruvate to form oxaloacetate. BCCP in one subunit interacts with the active sites on an adjacent subunit. The fourth domain (PT) facilitates the formation of the tetramer and is the binding site for acetyl CoA, a required allosteric activator.



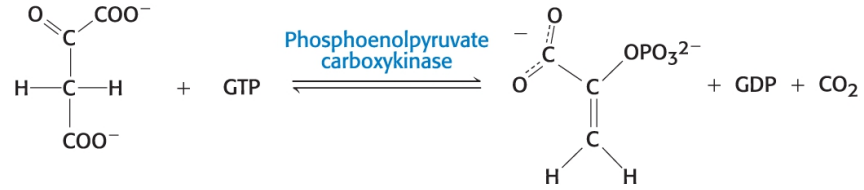


FIGURE 16.29 A subunit of pyruvate carboxylase shows the complexity of the enzyme. The functional enzyme is a tetramer compose of these complex subunits which each have four distinct domains as shown. Biotin, covalently attached to the biotin carboxyl carrier protein, transports CO_2 from the biotin carboxylase active site to the carboxyl transferase active site.

[Information from G. Lasso, L. P. C. Yu, D. Gil, S. Xiang, L. Tong, and M. Valle, *Structure* 18:1300–1310, 2010.]

How acetyl CoA facilitates the carboxylase reaction is under investigation. Recent research suggests that by binding to the enzyme, acetyl CoA enhances conformational communication between the BC and CT domains that enables the movement of the BCCP domain between two catalytic sites. The allosteric activation of pyruvate carboxylase by acetyl CoA is also an important physiological control mechanism that will be discussed in Section 17.5.

Oxaloacetate is shuttled into the cytoplasm and converted into phosphoenolpyruvate

Oxaloacetate must thus be transported to the cytoplasm to complete the synthesis of phosphoenolpyruvate. Oxaloacetate is first reduced to malate by malate dehydrogenase. Malate is transported across the mitochondrial membrane and reoxidized to oxaloacetate by a cytoplasmic NAD^+-linked malate dehydrogenase (**Figure 16.30**). The formation of oxaloacetate from malate also provides NADH for use in subsequent steps in gluconeogenesis. Finally, oxaloacetate is simultaneously decarboxylated and phosphorylated by phosphoenolpyruvate carboxykinase (PEPCK) to generate phosphoenolpyruvate. The phosphoryl donor is GTP. The CO_2 that was added to pyruvate by pyruvate carboxylase comes off in this step.

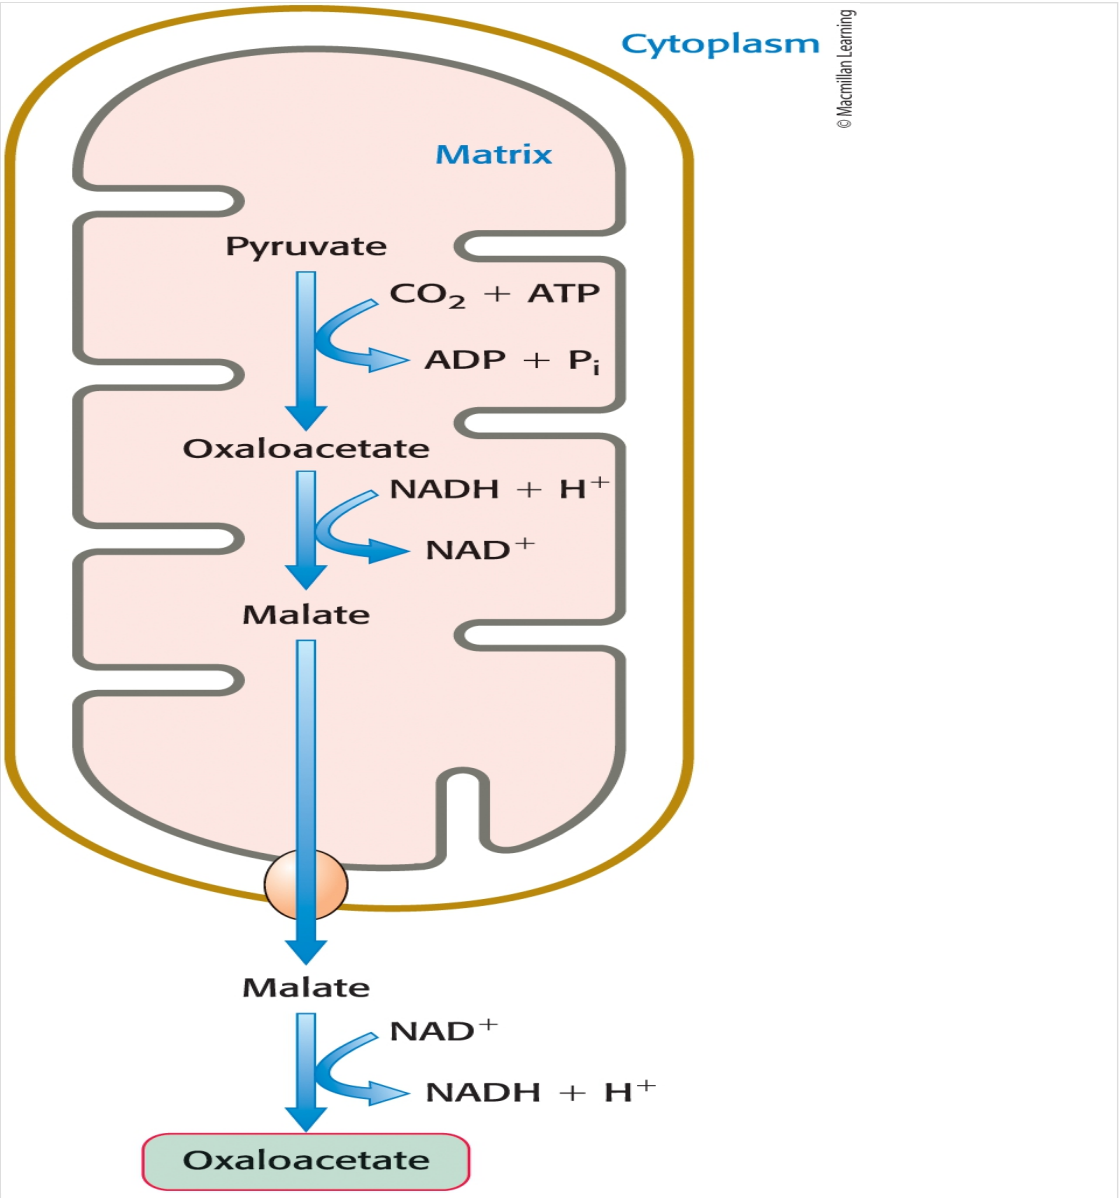

FIGURE 16.30 Oxaloacetate used in the cytoplasm for gluconeogenesis is formed in the mitochondrial matrix. Pyruvate is carboxylated to form oxaloacetate that then leaves the mitochondrion by a specific transport system (oval structure in the mitochondrial membranes) in the form of malate. Malate is reoxidized to oxaloacetate in the cytoplasm.

The sum of the reactions catalyzed by pyruvate carboxylase and phosphoenolpyruvate carboxykinase is

$$\text{Pyruvate} + \text{ATP} + \text{GTP} + H_2O \rightarrow \text{phosphoenolpyruvate} + \text{ADP} + \text{GDP} + P_i + 2H^+$$

This pair of reactions bypasses the irreversible reaction catalyzed by pyruvate kinase in glycolysis.

Why is a carboxylation and a decarboxylation required to form phosphoenolpyruvate from pyruvate? Recall that, in glycolysis, the presence of a phosphoryl group traps the unstable enol isomer of pyruvate as phosphoenolpyruvate (Section 16.2). However, the addition of a phosphoryl group to pyruvate is a highly unfavorable reaction: the $\Delta G^{\circ\prime}$ of the reverse of the glycolytic reaction catalyzed by pyruvate kinase is $+31\ \text{kJ mol}^{-1}\ (+7.5\ \text{kcal mol}^{-1})$. In gluconeogenesis, the use of the carboxylation and decarboxylation steps results in a much more favorable $\Delta G^{\circ\prime}$. The formation of phosphoenolpyruvate from pyruvate in the gluconeogenic pathway has a $\Delta G^{\circ\prime}$ of $+\ 0.8\ \text{kJ mol}^{-1}\ (+0.2\ \text{kcal mol}^{-1})$. A molecule of ATP is used to power the addition of a molecule of CO_2 to pyruvate in the carboxylation step. That CO_2 is then removed to power the formation of phosphoenolpyruvate in the decarboxylation step.

Decarboxylations often drive reactions that are otherwise highly endergonic. This metabolic motif is used in the citric acid cycle (Chapter 17), the pentose phosphate pathway (Chapter 20), and fatty acid synthesis (Section 22.4).

The conversion of fructose 1,6-bisphosphate into fructose 6-phosphate and orthophosphate is an irreversible step

On formation, phosphoenolpyruvate is metabolized by the enzymes of glycolysis but in the reverse direction. These reactions are near equilibrium under intracellular conditions; so, when conditions favor gluconeogenesis, the reverse reactions will take place until the next irreversible step is reached. This step is the hydrolysis of fructose 1,6-bisphosphate to fructose 6-phosphate and P_i.

$$\text{Fructose 1,6–bisphosphate} + H_2O \xrightarrow{\text{Fructose 1,6–bisphosphatase}} \text{fructose 6–phosphate} + P_i$$

The enzyme responsible for this step is fructose 1,6-bisphosphatase (FBPase). Like its glycolytic counterpart, it is an allosteric enzyme that participates in the regulation of gluconeogenesis. It is also an example of a **phosphatase**, an enzyme that catalyzes the hydrolysis of a phosphate to form inorganic phosphate and the reverse reaction. Note that the difference between kinases and phosphatases is not the physiologically relevant direction of the reaction but whether the phosphate is transferred to water or ADP.

The generation of free glucose occurs only in some tissues and is an important control point

The fructose 6-phosphate generated by fructose 1,6-bisphosphatase is readily converted into glucose 6-phosphate. The final step in the generation of free glucose takes place primarily in the liver, a

tissue whose metabolic duty is to maintain adequate glucose concentration in the blood for use by other tissues. Free glucose is not formed in the cytoplasm. Rather, glucose 6-phosphate is transported into the lumen of the endoplasmic reticulum, where it is hydrolyzed to glucose by glucose 6-phosphatase, which is bound to the ER membrane (**Figure 16.31**). Glucose and P_i are then shuttled back to the cytoplasm by a pair of transporters.

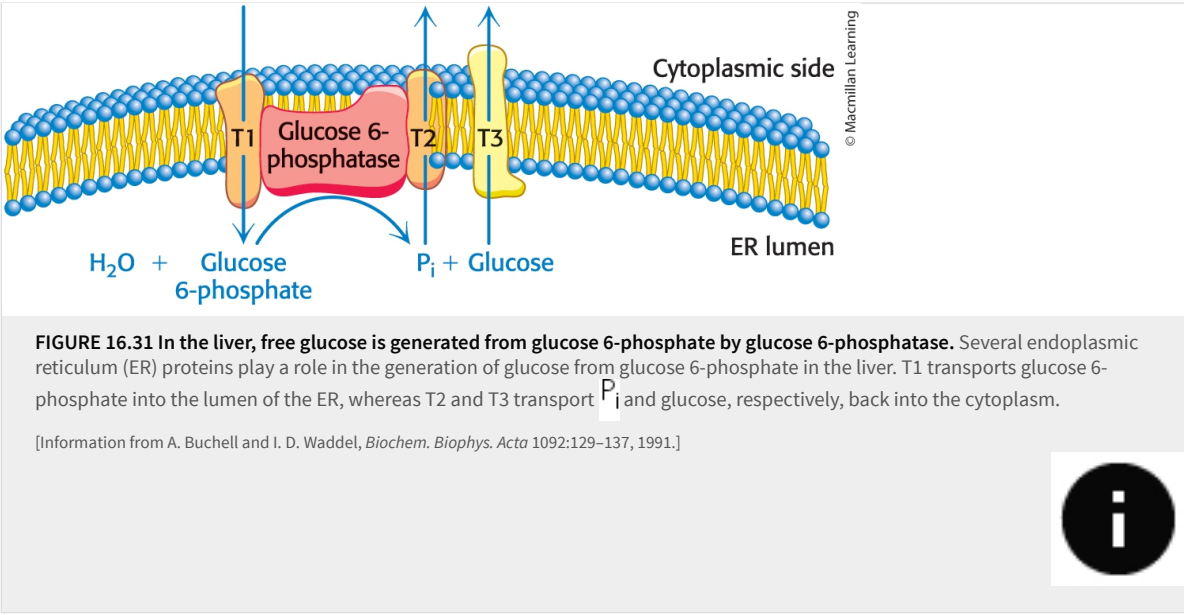

FIGURE 16.31 In the liver, free glucose is generated from glucose 6-phosphate by glucose 6-phosphatase. Several endoplasmic reticulum (ER) proteins play a role in the generation of glucose from glucose 6-phosphate in the liver. T1 transports glucose 6-phosphate into the lumen of the ER, whereas T2 and T3 transport P_i and glucose, respectively, back into the cytoplasm.

[Information from A. Buchell and I. D. Waddel, *Biochem. Biophys. Acta* 1092:129–137, 1991.]

In most tissues, gluconeogenesis ends with the formation of glucose 6-phosphate. Free glucose is not generated because most tissues lack glucose 6-phosphatase. Rather, the glucose 6-phosphate is commonly converted into glycogen, the storage form of glucose (Chapter 21).

Six high-transfer-potential phosphoryl groups are spent in synthesizing glucose from pyruvate

The formation of glucose from pyruvate is energetically unfavorable unless it is coupled to reactions that are favorable. Compare the stoichiometry of gluconeogenesis with that of the reverse of glycolysis.

The stoichiometry of gluconeogenesis is

$$2\ \text{Pyruvate} + 4\ \text{ATP} + 2\ \text{GTP} + 2\ \text{NADH} + 6\ H_2O \rightarrow \text{glucose} + 4\ \text{ADP} + 2\ \text{GDP} + 6\ P_i + 2\ NAD^+ + 2\ H^+$$

$$\Delta G^{\circ\prime} = -48\ \text{kJ mol}^{-1}\ (-11\ \text{kcal mol}^{-1})$$

In contrast, the stoichiometry for the reversal of glycolysis is

$$2\ \text{Pyruvate} + 2\ \text{ATP} + \text{NADH} + 2\ H_2O \rightarrow \text{glucose} + 2\ \text{ADP} + 2\ P_i + 2\ NAD^+ + 2\ H^+$$
$$\Delta G^{\circ\prime} = +90\ \text{kJ mol}^{-1}\ (+22\ \text{kcal mol}^{-1})$$

Note that *six* nucleoside triphosphate molecules are hydrolyzed to synthesize glucose from pyruvate in gluconeogenesis, whereas only *two* molecules of ATP are generated in glycolysis in the conversion of glucose into pyruvate. Thus, the extra cost of gluconeogenesis is four high-phosphoryl-transfer-potential molecules for each molecule of glucose synthesized from pyruvate. The four additional molecules having high phosphoryl-transfer potential are needed to turn an energetically unfavorable process (the reversal of glycolysis) into a favorable one (gluconeogenesis). Here we have a clear example of the coupling of reactions: NTP hydrolysis is used to power an energetically unfavorable reaction. The reactions of gluconeogenesis are summarized in Table 16.6.

TABLE 16.6 Reactions of gluconeogenesis

Step	Reaction	Enzyme	Reaction type	$\Delta G^{\circ\prime}$ in kJ mol^{-1}
1	$\text{Pyruvate} + CO_2 + \text{ATP} + H_2O \rightarrow \text{oxaloacetate} + \text{ADP} + P_i + 2H^+$	Pyruvate carboxylase	Phosphoryl transfer	−2.1
2	$\text{Oxaloacetate} + \text{GTP} \rightleftharpoons \text{phosphoenolpyruvate} + \text{GDP} + CO_2$	Phosphoenolpyruvate carboxykinase	Phosphoryl-coupled oxidation	+2.9
3	$\text{Phosphoenolpyruvate} + H_2O \rightleftharpoons \text{2-phosphoglycerate}$	Enolase	Hydration	−1.7
4	$\text{2-Phosphoglycerate} \rightleftharpoons \text{3-phosphoglycerate}$	Phosphoglycerate mutase	Phosphoryl shift	−4.6
5	$\text{3-Phosphoglycerate} + \text{ATP} \rightleftharpoons \text{1,3-bisphosphoglycerate} + \text{ADP}$	Phosphoglycerate kinase	Phosphoryl transfer	+18.8
6	$\text{1,3-Bisphosphoglycerate} + \text{NADH} + H^+ \rightleftharpoons \text{glyceraldehyde 3-phosphate} + NAD^+ + P_i$	Glyceraldehyde 3-phosphate dehydrogenase	Phosphoryl-coupled reduction	−6.3

7	Glyceraldehyde 3-phosphate $\rightleftharpoons$ dihydroxyacetonephosphate	Triose phosphate isomerase	Isomerization	−7.5
8	Glyceraldehyde 3-phosphate + dihydroxyacetone phosphate $\rightleftharpoons$ fructose 1,6-bisphosphate	Aldolase	Aldol addition	−23.8
9	$\text{Fructose 1,6–bisphosphate} + H_2O \rightarrow \text{fructose 6–phosphate} + P_i$	Fructose 1,6-bisphosphatase	Phosphoryl transfer	−16.3
10	Fructose 6-phosphate $\rightleftharpoons$ glucose 6-phosphate	Phosphoglucose isomerase	Isomerization	−1.7
11	$\text{Glucose 6–phosphatase} + H_2O \rightarrow \text{glucose} + P_i$	Glucose 6-phosphatase	Phosphoryl transfer	−12.1

16.5 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

Gluconeogenesis and glycolysis are coordinated so that, within a cell, one pathway is relatively inactive while the other is highly active. If both sets of reactions were highly active at the same time, the net result would be the hydrolysis of four nucleoside triphosphates (two ATP molecules plus two GTP molecules) per reaction cycle. Both glycolysis and gluconeogenesis are highly exergonic under cellular conditions, and so there is no thermodynamic barrier to such simultaneous activity. However, the amounts and activities of the distinctive enzymes of each pathway are controlled so that both pathways are not highly active at the same time. The rate of glycolysis is also determined by the concentration of glucose, and the rate of gluconeogenesis by the concentrations of lactate and other precursors of glucose. The basic premise of the reciprocal regulation is that, when energy is needed or glycolytic intermediates are needed for biosynthesis, glycolysis will predominate. When there is a surplus of energy and glucose precursors, gluconeogenesis will take over.

Glycolysis and gluconeogenesis are regulated by adenosine nucleotides and other metabolic intermediates

The first important regulation site is the interconversion of fructose 6-phosphate and fructose 1,6-bisphosphate (**Figure 16.32**). Consider first a situation in which energy is needed, as in active muscle. In this case, the concentration of AMP is high. Under this condition, AMP stimulates phosphofructokinase but inhibits fructose 1,6-bisphosphatase. Thus, glycolysis is turned on and gluconeogenesis is inhibited. Conversely, high levels of ATP and citrate, and therefore low levels of AMP, indicate

that the energy charge is high and that biosynthetic intermediates are abundant. ATP and citrate both inhibit phosphofructokinase, whereas the decrease in AMP relieves inhibition of fructose 1,6-bisphosphatase. Under these conditions, glycolysis is nearly switched off and gluconeogenesis is promoted. Why does citrate take part in this regulatory scheme? As we will see in Chapter 17, citrate reports on the status of the citric acid cycle, the primary pathway for oxidizing fuels in the presence of oxygen. High levels of citrate indicate an energy-rich situation and the presence of precursors for biosynthesis.

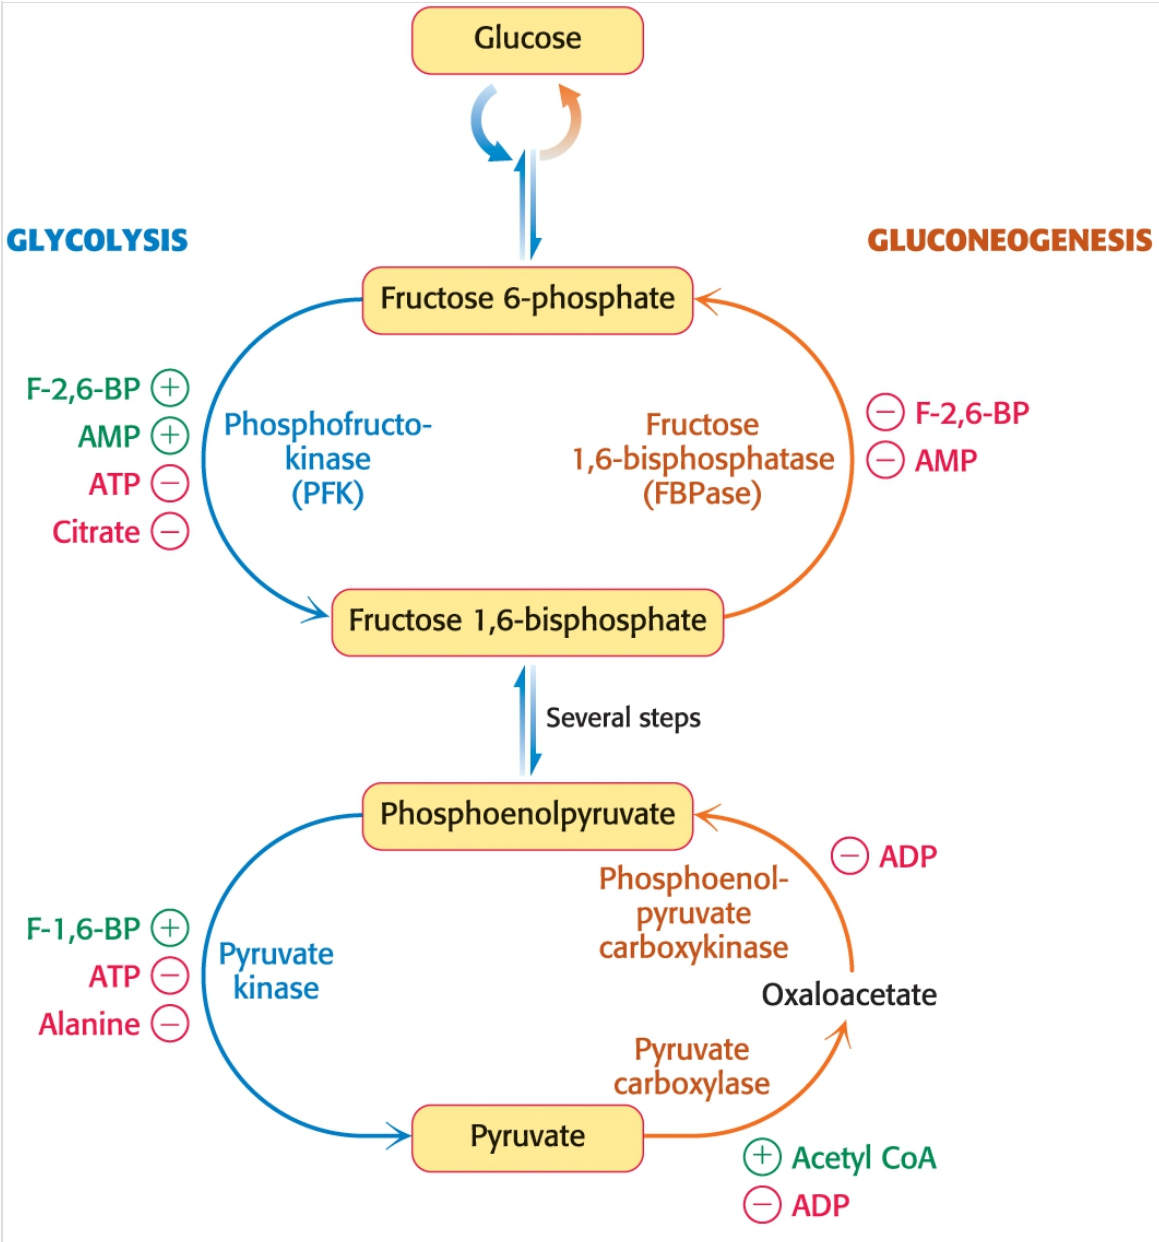

FIGURE 16.32 Gluconeogenesis and glycolysis in the liver are under reciprocal regulation. The concentration of fructose 2,6-bisphosphate is high in the fed state and low in starvation. Another important control is the inhibition of pyruvate kinase by phosphorylation during starvation.

Glycolysis and gluconeogenesis are also reciprocally regulated at the interconversion of phosphoenolpyruvate and pyruvate in the liver. The glycolytic enzyme pyruvate kinase is inhibited by allosteric effectors ATP and alanine, which signal that the energy charge is high and that building blocks are abundant. Conversely, pyruvate carboxylase and phosphoenolpyruvate carboxykinase, which catalyze the first two steps of gluconeogenesis from pyruvate, are inhibited by ADP. Pyruvate carboxylase is also activated by acetyl CoA, which, like citrate, indicates that the citric acid cycle is producing energy and biosynthetic intermediates (Chapter 17). Hence, gluconeogenesis is favored when the cell is rich in biosynthetic precursors and ATP.

In mammals, glycolysis and gluconeogenesis in the liver are controlled by hormones sensitive to blood-glucose concentration

In the liver, rates of glycolysis and gluconeogenesis are adjusted to maintain the blood-glucose concentration. The signal molecule fructose 2,6-bisphosphate strongly stimulates phosphofructokinase (PFK) and inhibits fructose 1,6-bisphosphatase (FBPase). When blood glucose is low, fructose 2,6-bisphosphate (F-2,6-BP) loses a phosphoryl group to form fructose 6-phosphate, which is not an allosteric effector of either PFK or FBPase.

How is the concentration of fructose 2,6-bisphosphate controlled to rise and fall with blood-glucose levels?

- *A bifunctional enzyme determines fructose 2,6-bisphosphate levels.* Two enzyme activities regulate the concentration of F-2,6-BP: one phosphorylates fructose 6-phosphate to form F-2,6-BP, and the other dephosphorylates F-2,6-BP, converting it back to fructose 6-phosphate. The formation reaction is catalyzed by phosphofructokinase 2 (PFK2), a different enzyme from phosphofructokinase. F-2,6-BP is degraded by a specific phosphatase, fructose bisphosphatase 2 (FBPase2).

  The striking finding is that both PFK2 and FBPase2 are present in a single 55-kDa polypeptide chain (**Figure 16.33**). This **bifunctional enzyme**, PFK2/FBPase2, contains an N-terminal regulatory domain, followed by a kinase domain and a phosphatase domain. PFK2 resembles adenylate kinase, whereas FBPase2 resembles phosphoglycerate mutase (Section 16.2). Recall that the mutase is essentially a phosphatase. In the bifunctional enzyme, the phosphatase activity evolved to become specific for F-2,6-BP. The bifunctional enzyme itself probably arose by the fusion of genes encoding the kinase and phosphatase domains.

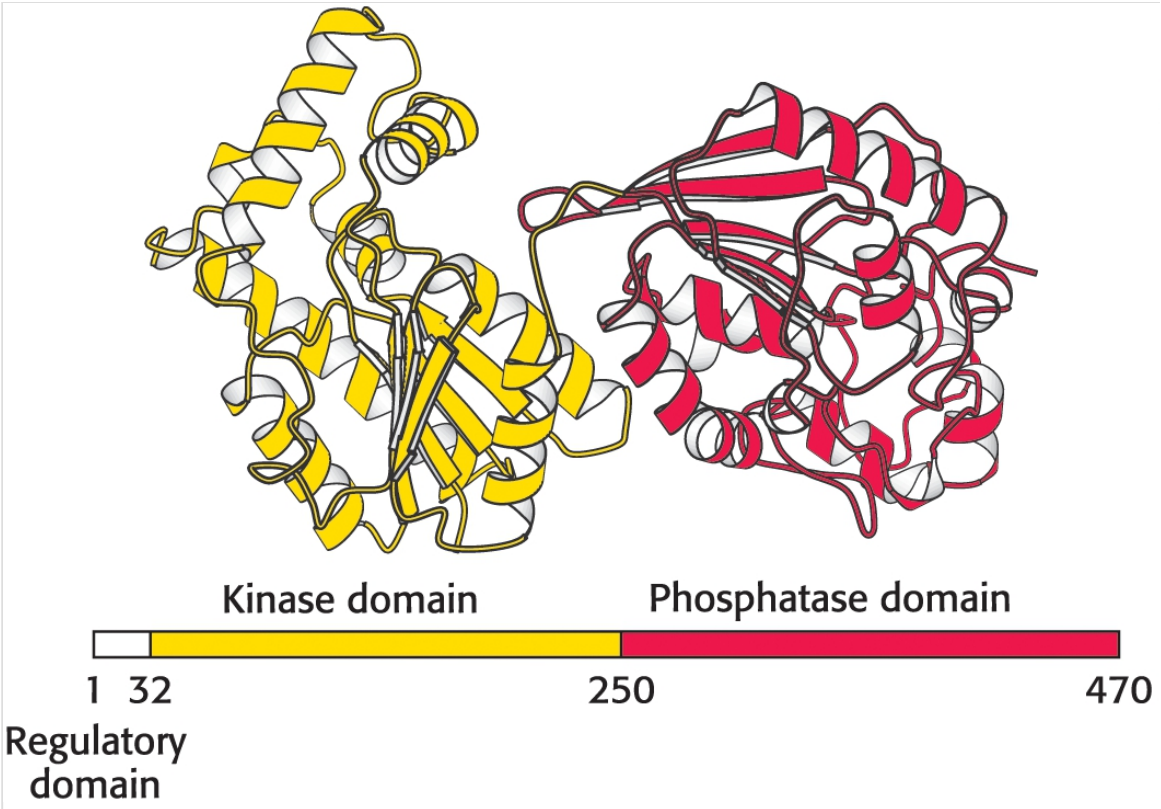

FIGURE 16.33 The bifunctional enzyme PFK2/FBPase2 has two distinct domains. The kinase domain (yellow) is fused to the phosphatase domain (red). The bar represents the amino acid sequence of the enzyme.

[Drawn from 1BIF.pdb.]

INTERACT with this model in Achieve

- *The bifunctional enzyme is controlled by reversible phosphorylation.* What controls whether PFK2 or FBPase2 dominates the bifunctional enzyme's activities in the liver? The activities of PFK2 and FBPase2 are reciprocally controlled by phosphorylation of a single serine residue. When glucose is scarce, such as during a night's fast, a rise in the blood concentration of the hormone glucagon triggers a cyclic AMP signal cascade (Section 14.2), leading to the phosphorylation of this bifunctional enzyme by protein kinase A (**Figure 16.34**). This covalent modification

activates FBPase2 and inhibits PFK2, lowering the level of F-2,6-BP. Gluconeogenesis predominates. Glucose formed by the liver under these conditions is essential for the viability of the brain. Glucagon stimulation of protein kinase A also inactivates pyruvate kinase in the liver.

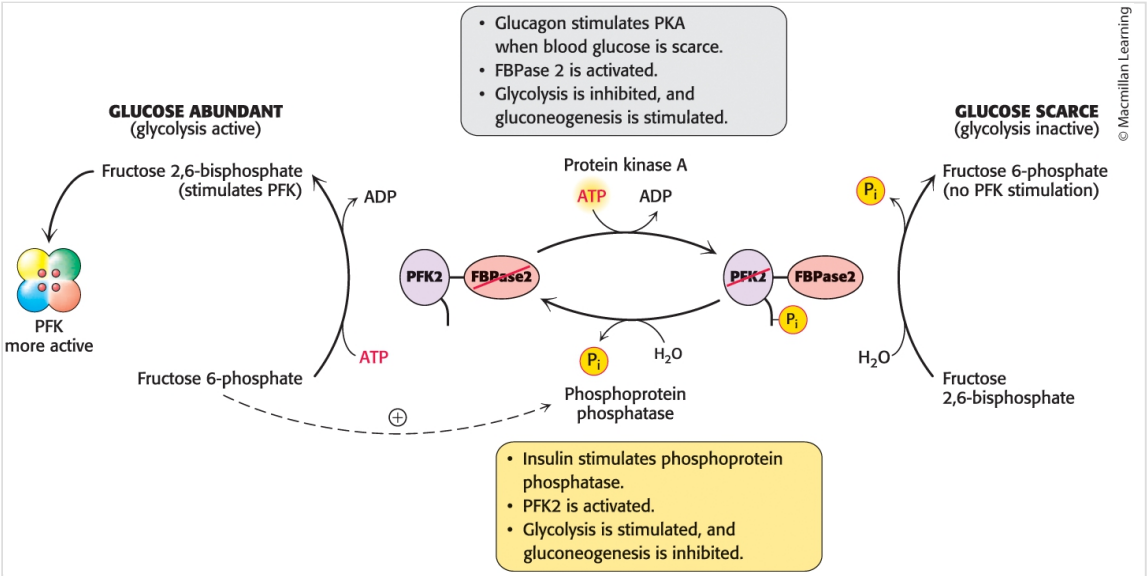

FIGURE 16.34 The synthesis and degradation of fructose 2,6-bisphosphate is hormonally controlled. A low blood-glucose concentration as signaled by glucagon leads to the phosphorylation of the bifunctional enzyme and hence to a lower concentration of fructose 2,6-bisphosphate, slowing glycolysis. Insulin accelerates the formation of fructose 2,6-bisphosphate by facilitating the dephosphorylation of the bifunctional enzyme.

Conversely, when the blood-glucose concentration is high, such as after a meal, gluconeogenesis is not needed. Insulin is secreted and initiates a signal pathway that activates a protein phosphatase, which removes the phosphoryl group from the bifunctional enzyme. This covalent modification activates PFK2 and inhibits FBPase2. The resulting rise in the level of F-2,6-BP accelerates glycolysis. In liver, a key role of glycolysis is to generate metabolites for biosynthesis. The coordinated control of glycolysis and

gluconeogenesis is facilitated by the location of the kinase and phosphatase domains on the same polypeptide chain as the regulatory domain.

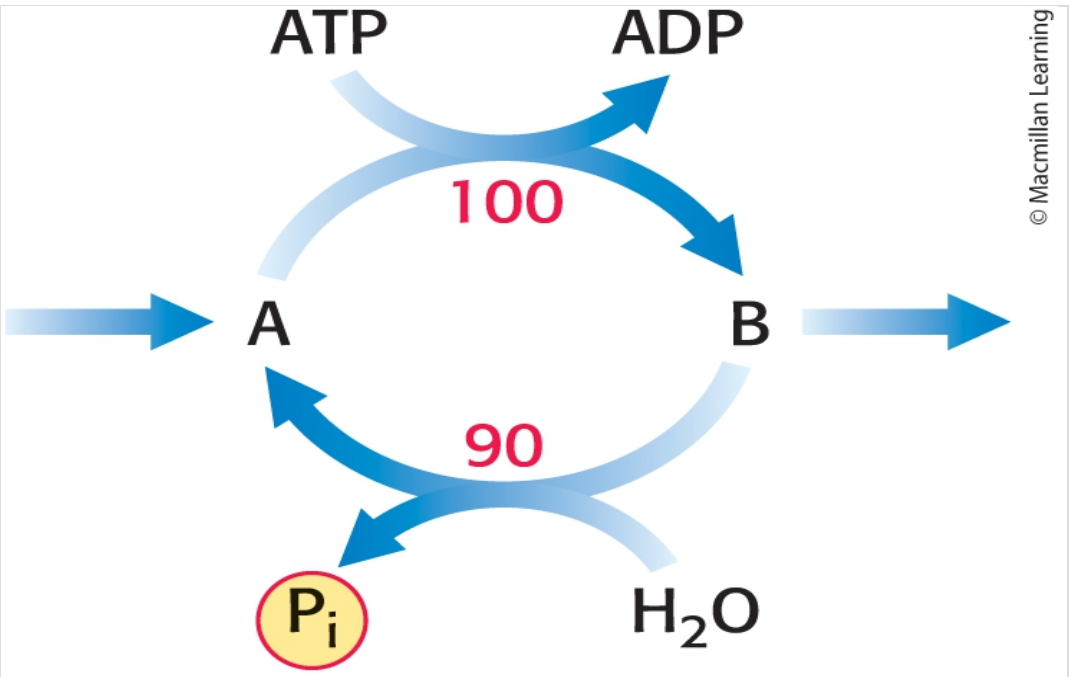
- *The bifunctional enzyme is also under transcriptional control by glucagon and insulin.* The hormones glucagon and insulin also regulate the amounts of essential enzymes by altering gene expression, primarily by changing the rate of transcription. Transcriptional control in eukaryotes is much slower than allosteric control, taking hours or days instead of seconds to minutes.

  Glucagon rises during fasting, when gluconeogenesis is needed to replace scarce glucose. To encourage gluconeogenesis, glucagon inhibits the expression of the three regulated glycolytic enzymes and stimulates instead the production of two key gluconeogenic enzymes, phosphoenolpyruvate carboxykinase and fructose 1,6-bisphosphatase.

  In contrast, insulin levels rise subsequent to eating, when there is plenty of glucose for glycolysis. To encourage glycolysis, insulin stimulates the expression of phosphofructokinase, pyruvate kinase, and the bifunctional enzyme that makes and degrades F-2,6-BP.

Self-Check Question

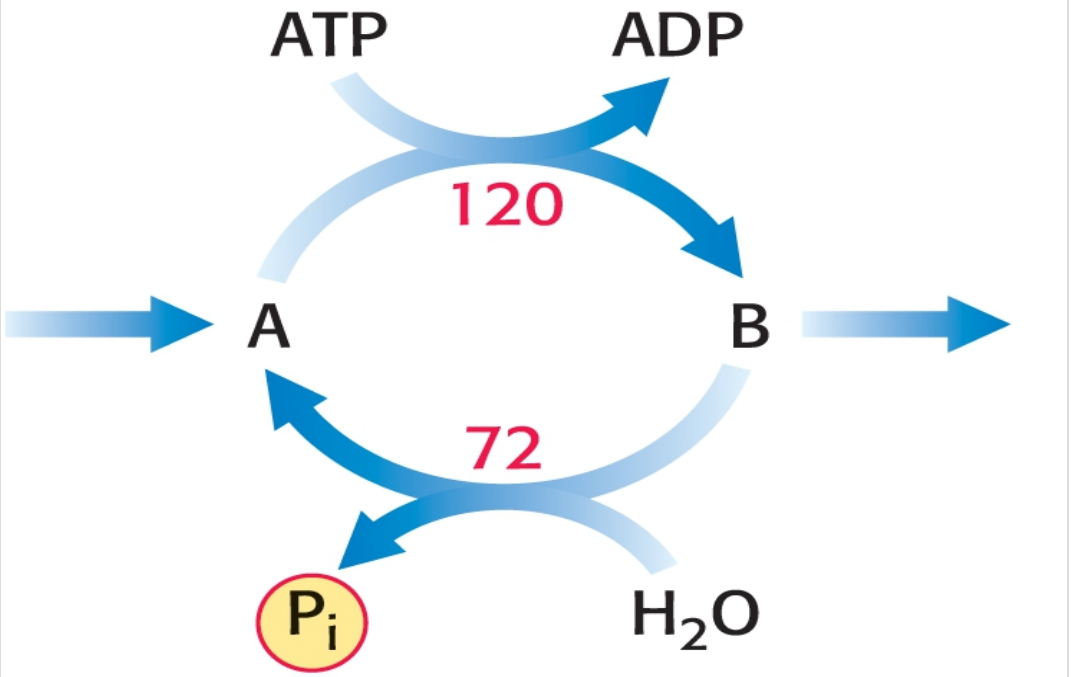
Why is the regulation of phosphofructokinase by ATP and AMP not as important in the liver as it is in muscle?



Substrate cycles amplify metabolic signals and produce heat

A pair of reactions such as the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate and its hydrolysis back to fructose 6-phosphate is called a **substrate cycle**. As already mentioned, both reactions are not fully active at the same time because of reciprocal regulation. However, isotope-labeling studies have shown that some fructose 6-phosphate is phosphorylated to fructose 1,6-bisphosphate even during gluconeogenesis. There also is a limited degree of cycling in other pairs of opposed irreversible reactions. This cycling was regarded as an imperfection in metabolic control, and so substrate cycles have sometimes been called *futile cycles*.

 Pathological conditions may result from futile cycles. A clear example is malignant hyperthermia, which occurs predominantly in muscle tissue. Susceptible individuals are sensitive to certain anesthetics which cause uncontrolled calcium release from the sarcoplasmic reticulum through the calcium channel. The rapid rise in cytoplasmic calcium activates the sarcoplasmic reticulum calcium pump, the Ca^{2+} ATPase, a P-type ATPase, in an attempt to remove the calcium from the cytoplasm. The constant release and reuptake of calcium, and the consequent rapid hydrolysis of ATP, raises the body temperature to 44°C (111°F) and depletes muscle ATP. Muscle damage and death may occur if untreated with an inhibitor of the calcium channel.



Despite such extraordinary circumstances, substrate cycles now seem likely to be biologically important. One possibility is that substrate cycles amplify metabolic signals. Suppose that the rate of conversion of A into B is 100 and of B into A is 90, giving an initial net flux of 10. Assume that an allosteric effector increases the $A \rightarrow B$ rate by 20% to

120 and reciprocally decreases the $B \rightarrow A$ rate by 20% to 72. The new net flux is 48, and so a 20% change in the rates of the opposing reactions has led to a 380% increase in the net flux. In the example shown in **Figure 16.35**, this amplification is made possible by the rapid hydrolysis of ATP. The flux down the glycolytic pathway has been suggested to increase as much as 1000-fold at the initiation of intense exercise. Because the allosteric activation of enzymes alone seems unlikely to explain this increased flux, the existence of substrate cycles may partly account for the rapid rise in the rate of glycolysis.

© Macmillan Learning

Net flux of B = 10

Net flux of B = 48

FIGURE 16.35 Substrate cycles can have advantages. This ATP-driven cycle operates at two different rates. A small change in the rates of the two opposing reactions results in a large change in the *net* flux of product B.

Lactate and alanine formed by contracting muscle and peripheral tissues are used by other organs

Lactate produced by active skeletal muscle, erythrocytes, skin, and other tissues is a source of energy for other organs. Erythrocytes lack mitochondria and can never oxidize glucose completely, whereas other tissues like the skin remain largely anaerobic at all times due to the distance from the arterial blood supply. In contracting fast-twitch skeletal muscle fibers during vigorous exercise, the rate at which glycolysis produces pyruvate exceeds the rate at which the citric acid cycle oxidizes it. In these cells, lactate dehydrogenase reduces excess pyruvate to lactate to restore redox balance (Section 16.2). However, lactate is a dead-end in metabolism. It must be converted back into pyruvate before it can be metabolized. Both pyruvate and lactate diffuse out of these cells through carriers into the blood. In contracting skeletal muscle, the formation and release of lactate lets the muscle generate ATP in the absence of oxygen and shifts the burden of metabolizing lactate from muscle to other organs.

The pyruvate and lactate in the bloodstream have two fates. In one fate, the plasma membranes of some cells — particularly cells in cardiac muscle and slow-twitch (type 1) skeletal muscle — contain carriers that make the cells highly permeable to lactate and pyruvate. These molecules diffuse from the blood into such permeable cells. Once inside these well-oxygenated cells, lactate can be reverted back to pyruvate

and metabolized through the citric acid cycle and oxidative phosphorylation to generate ATP. The use of lactate in place of glucose by these cells makes more circulating glucose available to the active muscle cells. In the other fate, excess lactate enters the liver and is converted first into pyruvate and then into glucose by the gluconeogenic pathway. Contracting skeletal muscle supplies lactate to the liver, which uses it to synthesize and release glucose. Thus, the liver restores the level of glucose necessary for active muscle cells, which derive ATP from the glycolytic conversion of glucose into lactate. Because this multi-tissue cooperation was elucidated by Gerty and Carl Cori, it is known as the **Cori cycle** (**Figure 16.36**).

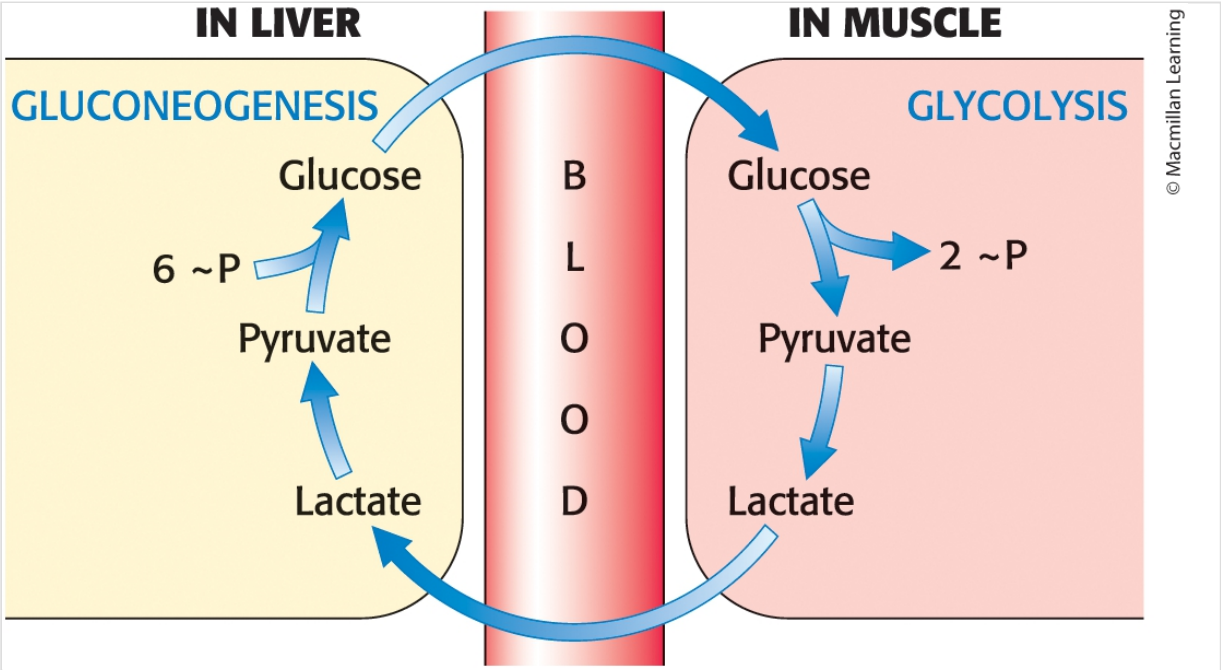


FIGURE 16.36 The Cori cycle allows the liver to better support other tissues, such as skeletal muscle. Lactate formed by active muscle is converted into glucose by the liver. This cycle shifts part of the metabolic burden of active muscle to the liver. The symbol, ~P represents nucleoside triphosphates.

GERTY CORI After growing up in a Jewish family in Austria-Hungary, Gerty Cori (*née* Radnitz) attended medical school at the German University of Prague. During medical school she met Carl Cori, and the two were married and became lifelong research partners, working together as equals. Despite this, Carl often received more recognition than Gerty due to gender discrimination, something he ardently opposed his entire career. They relocated to the United States in 1922 due to rising anti-Semitism in Europe. Dr. Cori published numerous papers with Carl, and independently, on tumor and carbohydrate metabolism. She became the first woman to win the Nobel Prize in Physiology or Medicine, which she shared with Carl for their work on glycogen metabolism and the elaboration of the Cori Cycle. Notably, six other scientists who were mentored by the Coris also went on to win Nobel Prizes.

Studies have shown that alanine, like lactate, is a major precursor of glucose in the liver. The alanine is generated in muscle when the carbon skeletons of some amino acids are used as fuels. The nitrogens from these amino acids are transferred to pyruvate to form alanine; the reverse reaction takes place in the liver. This process also helps maintain nitrogen balance. The interplay between glycolysis and gluconeogenesis is summarized in Figure 16.37, which shows how these pathways help meet the energy needs of different cell types.

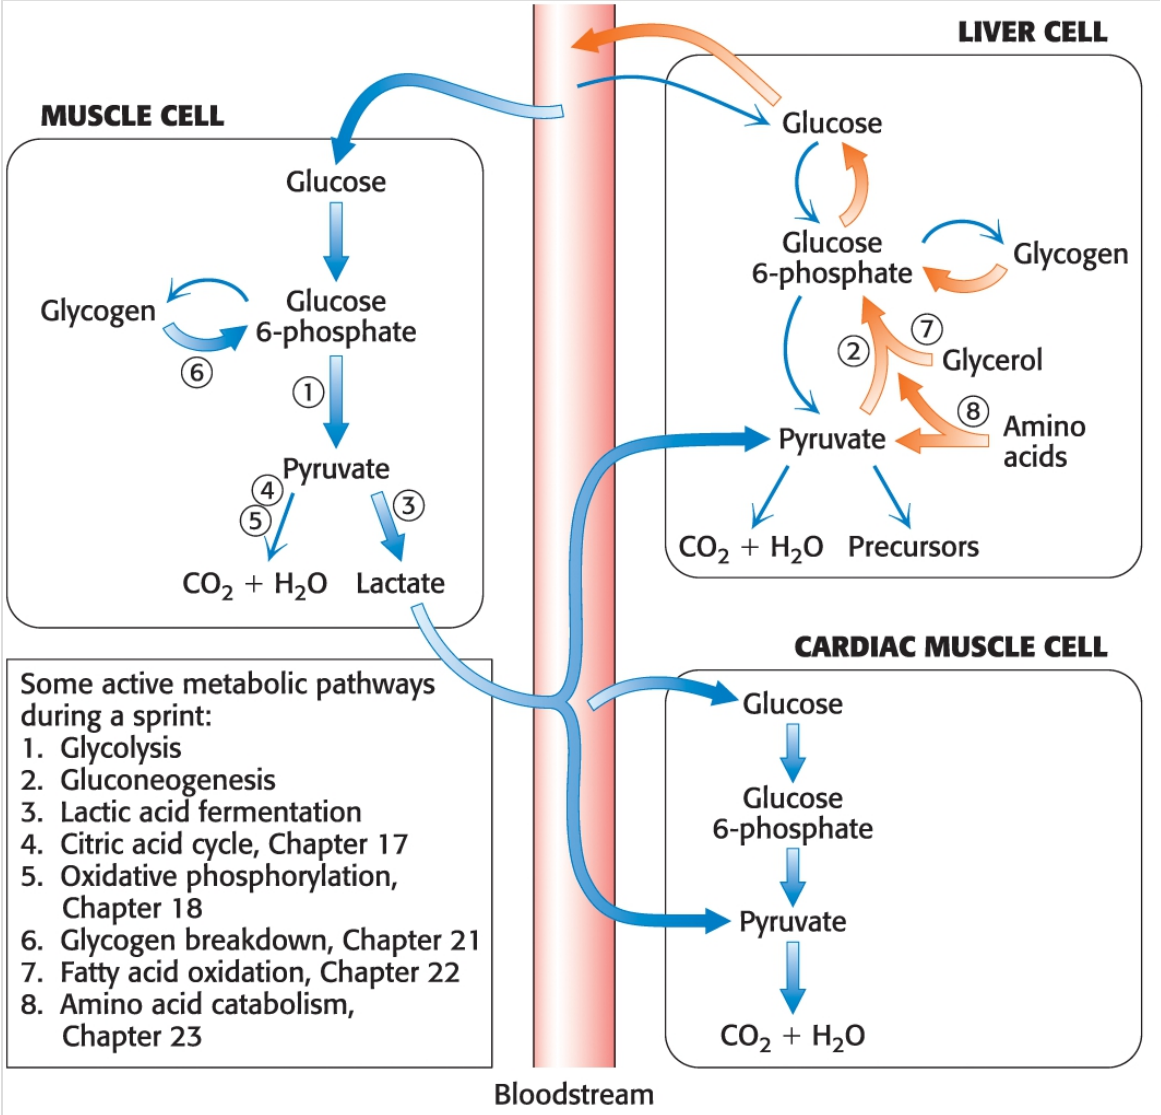

FIGURE 16.37 During a sprint, cooperation between glycolysis and gluconeogenesis occurs within multiple tissues. Glycolysis and gluconeogenesis are coordinated, in a tissue-specific fashion, to ensure the energy needs of all cells are met. Consider a sprinter. In skeletal leg musc

glucose will be metabolized aerobically to CO_2 and H_2O or, more likely (thick arrows) during a sprint, anaerobically to lactate. In cardiac muscle, the lactate can be converted into pyruvate and used as a fuel, along with glucose, to power the heartbeats to keep the sprinter's blood flowing. Gluconeogenesis, a primary function of the liver, will be taking place rapidly (thick arrows) to ensure that enough glucose is present in the blood for skeletal and cardiac muscle, as well as for other tissues. Glycogen, glycerol, and amino acids are other sources of energy that will learn about in later chapters.

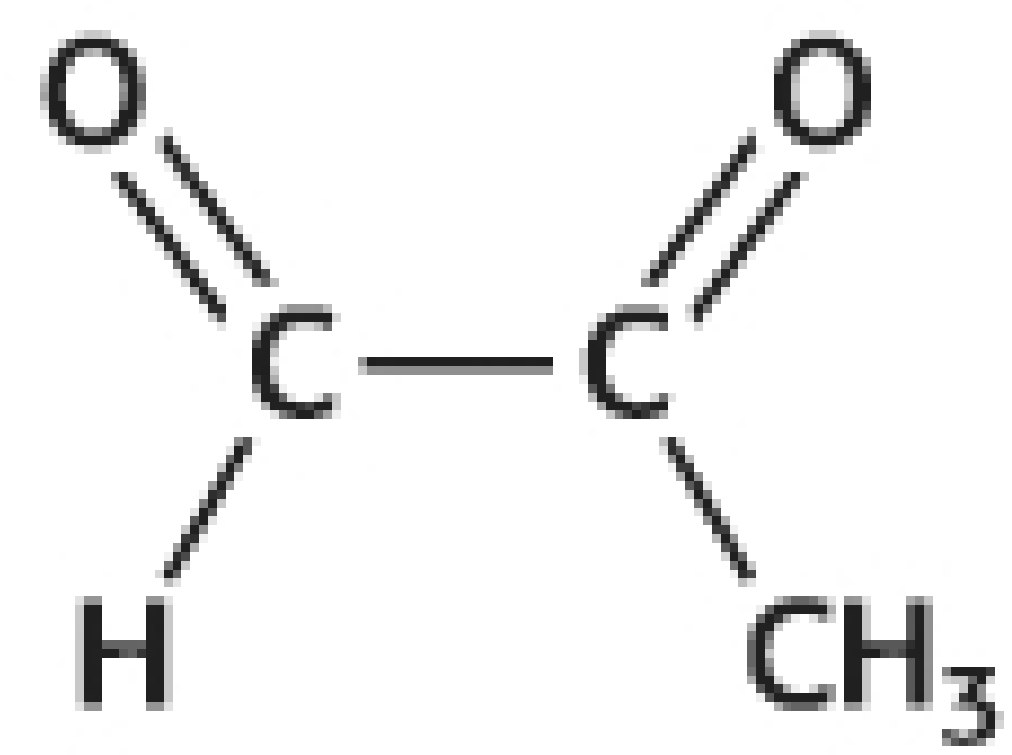
Self-Check Question

If lactate is a dead-end product in that its sole fate is to be converted back into glucose, then why do cells bother to form lactate at all?

Deficiencies in glycolytic or gluconeogenic enzymes are rare genetic disorders



Genetically inherited deficiencies in the activity or regulation of specific enzymes are sometimes called *inborn errors of metabolism*. Because the enzymes of glycolysis and gluconeogenesis are so central to human metabolism, nonlethal deficiencies in these enzymes are rare but do still occur. Here we will briefly discuss two:

Triose phosphate isomerase deficiency

TPID is a multisystem disorder presenting in early childhood. Symptoms include congenital hemolytic anemia (deficiency of red cells due to premature destruction of the cell that is present at birth) and progressive neuromuscular disorder, including cardiomyopathy (inflammation and damage to the heart muscle). In severe cases, TPID can lead to death in early childhood. Dihydroxyacetone phosphate accumulates in cells, especially red blood cells. TPID is rare, so the causal relationship between the biochemical defect and the clinical features remains to be established. Let's consider a hypothesis regarding the pathologies of TPID.

First of all, recall that central nervous system and red blood cells rely on glucose metabolism exclusively for energy. Thus, any disruption in glycolysis would impact these tissues. Also, though resting skeletal muscles utilize fats as fuels, rapidly contracting muscle quickly becomes reliant on glucose for lactic acid fermentation.

Consider the consequences of TPID by reviewing its role in glycolysis in Figure 16.2. If the isomerase activity is missing, then half of the carbons of glucose cannot be metabolized to yield ATP. These observations account for the nature of the symptoms: without adequate ATP, neuromuscular function would be compromised. However, research suggests that disruption of energy metabolism is not the cause of the more serious consequences of TPID. Even if the cells try to compensate for lack of isomerase activity by processing more glucose, there will be an unavoidable buildup of dihydroxyacetone phosphate. Strong evidence now exists that this buildup of dihydroxyacetone phosphate is to blame, as it can be converted into methylglyoxal.

Methylglyoxal

Methylglyoxal, a highly reactive molecule, covalently binds to available amino groups on proteins, yielding advanced glycation end products (AGEs) (Section 11.1). These modifications inhibit protein function. Extensive loss of protein function would then contribute to the pathologies observed in TPID, including early death. AGEs have also been implicated in aging, arteriosclerosis (thickening and hardening of artery walls), and diabetes. Clearly establishing the causes of all TPID pathologies awaits further research.

Pyruvate carboxylase deficiency

PCD is another rare disorder of carbohydrate metabolism. Several types vary in the seriousness of clinical outcomes, but all are characterized to some extent by hypoglycemia (low concentration of blood glucose) and lactic acidosis (excessive lactic acid in the blood). Symptoms include lethargy, seizures, and, in severe cases, death in the first few months of life. In this case the two primary biochemical characteristics, hypoglycemia and lactic acidosis, are reasonably easy to explain. Again, as with TPID, lack of glucose would impair neuromuscular functions.

Because pyruvate carboxylase is a key regulatory enzyme in gluconeogenesis, which occurs primarily in the liver, we can surmise that the lack of the pyruvate carboxylase would account for the hypoglycemia. Lacking this enzyme, the liver cannot serve its role in maintaining adequate blood glucose concentration for tissues that depend on glucose. Likewise, an important role of liver is to remove lactic acid from the blood and use it as a gluconeogenic precursor. However, lactic acid can't be used to form glucose due to the lack of pyruvate carboxylase, causing it to remain in the blood, leading to a fall in blood pH (acidosis). In later chapters we will see that the oxaloacetate formed by pyruvate carboxylase is an important and versatile molecule, so the lack of carboxylase activity has greater effects than discussed here.

Glycolysis and gluconeogenesis are evolutionarily intertwined

The metabolism of glucose has ancient origins. Organisms living in the early biosphere depended on the anaerobic generation of energy until significant amounts of oxygen began to accumulate 2 billion years ago. Glycolytic enzymes were most likely derived independently rather than

by gene duplication, because glycolytic enzymes with similar properties do not have similar amino acid sequences. Although there are four kinases and two isomerases in the pathway, sequence and structural comparisons suggest that these sets of enzymes are not related to one another by divergent evolution.

We can speculate on the relationship between glycolysis and gluconeogenesis if we think of glycolysis as consisting of two segments: the metabolism of hexoses (the upper segment of Figure 16.2) and the metabolism of trioses (the lower segment of Figure 16.2). The enzymes of the upper segment are different in some species and are missing entirely in some archaea, whereas enzymes of the lower segment are quite conserved. In fact, four enzymes of the lower segment are present in all species. The lower part of the glycolytic pathway is used by gluconeogenesis, too. This common part of the two pathways may be the oldest part, constituting the core to which the other steps were added. The upper part would have varied according to the sugars that were available to evolving organisms in particular niches. Interestingly, this core part of carbohydrate metabolism can generate triose precursors for ribose sugars, a component of RNA and a critical requirement for the RNA world. Thus, we are left with the unanswered question: Was the original core pathway used for energy conversion or biosynthesis?

Self-Check Question

What are the likely consequences of a genetic disorder rendering fructose 1,6-bisphosphatase in the liver less sensitive to regulation by fructose 2,6-bisphosphate?

Chapter 16 Summary

16.1 Glycolysis Is an Energy-Conversion Pathway in Most Organisms

- Glycolysis is a highly common pathway among most organisms; it consists of a set of 10 cytoplasmic reactions that convert glucose into pyruvate.
- Glucose and other monosaccharides are generated from the breakdown of dietary starch, glycogen, sucrose, and other nutrients.
- A family of glucose transporters facilitates the movement of glucose throughout the body.

16.2 Glycolysis Can Be Divided into Two Parts

- The first stage consumes two molecules of ATP as glucose is converted into dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, which are readily interconvertible.
- In the second stage, glyceraldehyde 3-phosphate is oxidized and ultimately converted into pyruvate, generating two molecules of ATP.
- There is a net gain of two molecules of ATP in the formation of two molecules of pyruvate from one molecule of glucose because each of the ATP-generating second stage steps occur twice for each molecule of glucose metabolized.
- The electron acceptor in the oxidation of glyceraldehyde 3-phosphate is NAD^+, which must be regenerated for glycolysis to continue.
- In aerobic organisms, the NADH formed in glycolysis transfers its electrons to O_2 through the electron-transport chain, which thereby regenerates NAD^+.

- Under anaerobic conditions and in some microorganisms, NAD^+ is regenerated by the reduction of pyruvate to lactate. In other microorganisms, NAD^+ is regenerated by the reduction of pyruvate to ethanol. These two processes are examples of fermentations.

16.3 The Glycolytic Pathway Is Tightly Controlled

- The rate of conversion of glucose into pyruvate is tightly regulated at specific steps.
- Phosphofructokinase — the most important control element in glycolysis — is inhibited by high levels of ATP and citrate and activated by AMP and fructose 2,6-bisphosphate.
- Hexokinase is inhibited by glucose 6-phosphate, which accumulates when phosphofructokinase is inactive.
- ATP and alanine allosterically inhibit pyruvate kinase, whereas fructose 1,6-bisphosphate activates it.

16.4 Glucose Can Be Synthesized from Noncarbohydrate Precursors

- Gluconeogenesis, which occurs primarily in the liver, is the synthesis of glucose from noncarbohydrate sources, such as lactate, amino acids, glycerol, and alanine produced from pyruvate by active skeletal muscle.
- Gluconeogenesis requires four new reactions to bypass the essential irreversibility of three reactions in glycolysis.
- In two of the new reactions, pyruvate is carboxylated in mitochondria to oxaloacetate, which in turn is decarboxylated and phosphorylated in the cytoplasm to phosphoenolpyruvate, at the expense of one ATP and one GTP.
- The other distinctive reactions of gluconeogenesis are the hydrolyses of fructose 1,6-bisphosphate and glucose 6-phosphate, which are catalyzed by specific phosphatases.

16.5 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

- Gluconeogenesis and glycolysis are reciprocally regulated so that one pathway is relatively inactive while the other is highly active.
- Phosphofructokinase and fructose 1,6-bisphosphatase are key control elements of gluconeogenesis and glycolysis.
- Fructose 2,6-bisphosphate, an intracellular signal molecule present at higher levels when glucose is abundant, activates glycolysis and inhibits gluconeogenesis by regulating these enzymes.
- Pyruvate kinase and pyruvate carboxylase are regulated by other effectors so that both are not maximally active at the same time.
- Allosteric regulation and reversible phosphorylation, which are rapid, are complemented by transcriptional control, which takes place in hours or days.

Key Terms

glycolysis
gluconeogenesis
kinase
substrate-level phosphorylation
fermentation
ethanol fermentation
lactic acid fermentation
obligate anaerobe
facultative anaerobe
committed step
feedforward stimulation (feedforward activation)
substrate channeling
aerobic glycolysis
phosphatase
bifunctional enzyme
substrate cycle

[Cori cycle]

Problems

1. Select all the steps of glycolysis in which ATP is produced.

a. 1,3-bisphosphoglycerate → 3-phosphoglycerate
b. Glyceraldehyde 3-phosphate → 1,3-bisphosphoglycerate
c. Fructose 6-phosphate → fructose 1,6-bisphosphate
d. Glucose → glucose 6-phosphate
e. Phosphoenolpyruvate → pyruvate

2. Which of the following statements is (are) true for a muscle performing lactic acid fermentation?

a. The process is inhibited by AMP.
b. The process is inhibited by ATP.
c. There is a net synthesis of NADH.
d. The process is exergonic.

3. Match each term with its description.  1

1. Hexokinase
2. Phosphoglucose isomerase
3. Phosphofructokinase
4. Aldolase
5. Triose phosphate isomerase
6. Glyceraldehyde 3-phosphate dehydrogenase

1. Forms fructose 1,6-bisphosphate
2. Generates the first high-phosphoryl-transfer-potential compound that is not ATP
3. Converts glucose 6-phosphate into fructose 6-phosphate
4. Phosphorylates glucose
5. Generates the second molecule of ATP
6. Cleaves fructose 1, 6-bisphosphate
7. Generates the second high-phosphoryl-transfer-potential

7. Phosphoglycerate kinase
8. Phosphoglycerate mutase
9. Enolase
10. Pyruvate kinase

compound that is not ATP
8. Catalyzes the interconversion of three-carbon isomers
9. Converts 3-phosphoglycerate into 2-phosphoglycerate
10. Generates the first molecule of ATP

---

4. Lactic acid fermentation and ethanol fermentation are oxidation–reduction reactions. Identify the ultimate electron donor and electron acceptor. 2

5. Why is it advantageous for the liver to have both hexo-kinase and glucokinase to phosphorylate glucose?

6. The interconversion of DHAP and GAP greatly favors the formation of DHAP at equilibrium. Yet the conversion of DHAP by triose phosphate isomerase proceeds readily. Why?

7. Although both hexokinase and phosphofructokinase catalyze irreversible steps in glycolysis and the hexokinase-catalyzed step is first, phosphofructokinase is nonetheless the pacemaker of glycolysis. What does this information tell you about the fate of the glucose 6-phosphate formed by hexokinase?

8. What reactions of glycolysis are not readily reversible under intracellular conditions? 4

9. Why is it physiologically advantageous for the pancreas to use GLUT2, with a high K_M, as the transporter that allows glucose entry into β cells?

10. Suppose that a microorganism that was an obligate anaerobe suffered a mutation that resulted in the loss of triose phosphate isomerase activity. How would this loss affect the ATP yield of fermentation? Could such an organism survive? 1

11. What are the equilibrium concentrations of fructose 1,6-bisphosphate, dihydroxyacetone phosphate, and glyceraldehyde 3-phosphate when 1 mM fructose 1,6-bisphosphate is incubated with aldolase under standard conditions?

12. Indicate which of the conditions listed in the right-hand column increase the activity of the glycolytic and gluconeogenic pathway in the liver. 4

1. Glycolysis 2. Gluconeogenesis	1. Increase in ATP 2. Increase in AMP 3. Increase in fructose 2,6-bisphosphate 4. Increase in citrate 5. Increase in acetyl CoA 6. Increase in insulin 7. Increase in glucagon 8. Fasting 9. Fed

---

13. Why does the lack of glucose 6-phosphatase activity in the brain and muscle make good physiological sense?

14. How many NTP molecules are required for the synthesis of one molecule of glucose from two molecules of pyruvate? How many NADH molecules? 3

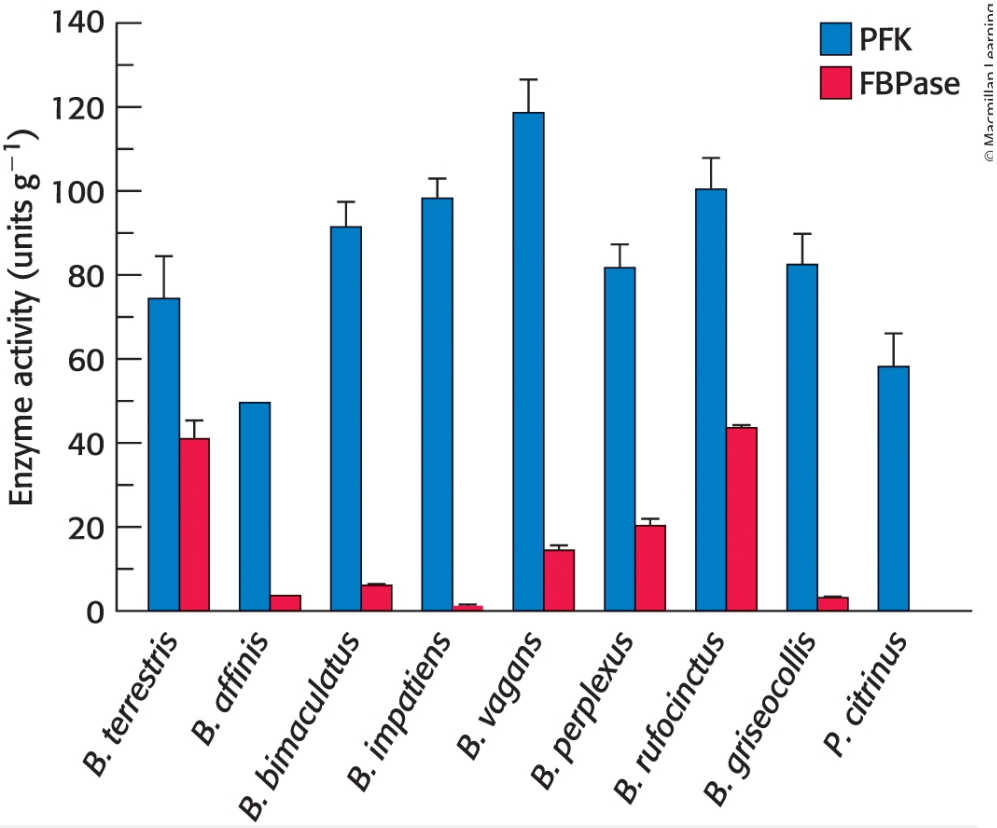
15. Suppose 25 glucose molecules are formed during gluconeogenesis. Calculate the amount of pyruvate, ATP, and NADH molecules required.

16. Predict the effect of each of the following mutations on the pace of glycolysis in liver cells: 4

a. Loss of the allosteric site for ATP in phosphofructokinase

b. Loss of the binding site for citrate in phosphofructokinase
c. Loss of the phosphatase domain of the bifunctional enzyme that controls the level of fructose 2,6-bisphosphate
d. Loss of the binding site for fructose 1,6-bisphosphate in pyruvate kinase

17. Avidin, a 70-kDa protein in egg white, has very high affinity for biotin. In fact, it is a highly specific inhibitor of biotin enzymes. Which of the following conversions would be blocked by the addition of avidin to a cell homogenate?

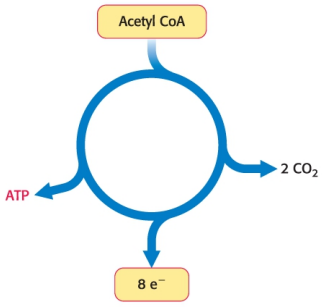


a. Glucos → pyruvate
b. Pyruvate → glucose
c. Oxaloacetate → glucose
d. Malate → oxaloacetate
e. Pyruvate → oxaloacetate
f. Glyceraldehyde 3 → fructose 1,6-bisphosphate

18. In the conversion of glucose into two molecules of lactate, the NADH generated earlier in the pathway is oxidized to NAD^+. Why is it not to the cell's advantage to simply make more NAD^+ so that the regeneration would not be necessary? After all, the cell would save much energy because it would no longer need to synthesize lactic acid dehydrogenase. 2

19. Hexokinase in red blood cells has a K_M of approximately $50\ \mu M$. Because life is hard enough as it is, let's assume that the hexokinase displays Michaelis–Menten kinetics. What concentration of blood glucose would yield V_0 equal to 90% V_{max}? What does this result tell you if normal blood glucose levels range between approximately 3.6 and 6.1 mM?

20. In principle, a futile cycle that includes phosphofructokinase and fructose 1,6-bisphosphatase could be used to generate heat. The heat could be used to warm tissues. For instance, certain bumblebees have been reported to use such a futile cycle to warm their flight muscles on cool mornings. Scientists undertook a series of experiments to determine if a number of species of bumblebee use this futile cycle. Their approach was to measure the activity of PFK and F-1,6-BPase in flight muscle.



a. What was the rationale for comparing the activities of these two enzymes?
b. The data below show the activities of both enzymes for a variety of bumblebee species (genera *Bombus* and *Psithyrus*). Do these results support the notion that bumblebees use futile cycles to generate heat? Explain.
c. In which species might futile cycling take place? Explain your reasoning.
d. Do these results prove that futile cycling does not participate in heat generation?

Chapter 17
Pyruvate Dehydrogenase and the Citric Acid Cycle

Chalermkiat Seedokmai/Getty Images
© Macmillan Learning

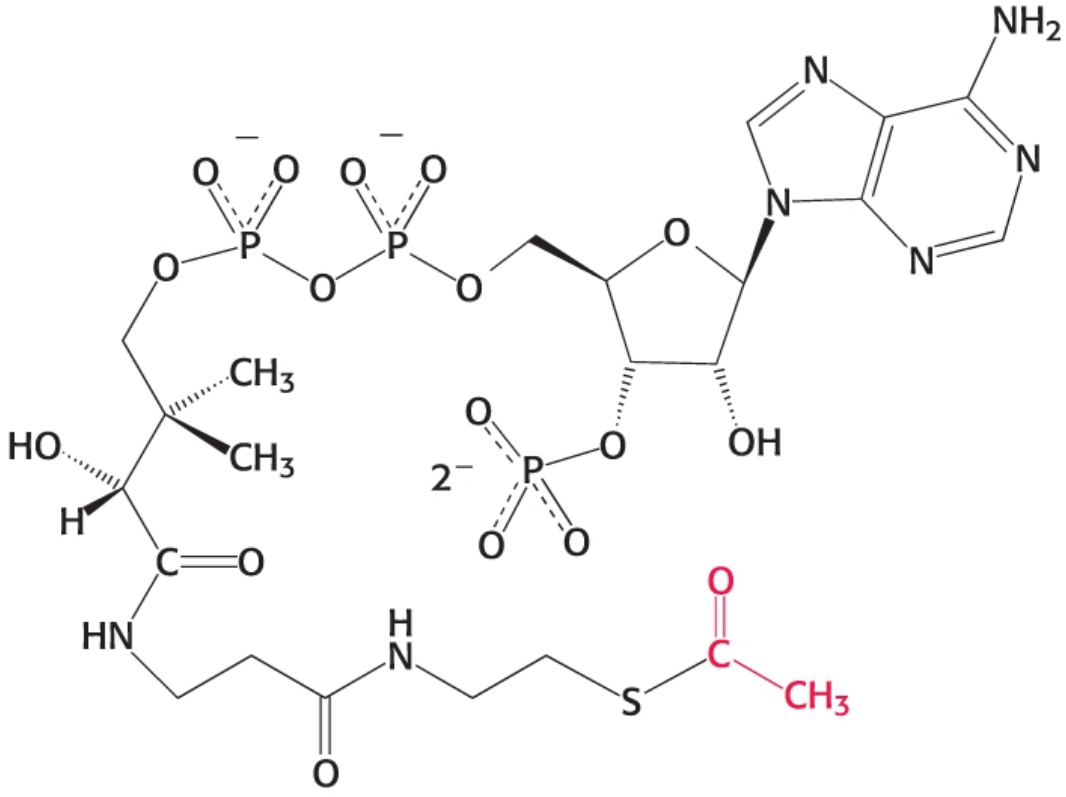
Roundabouts, or traffic circles, function as hubs to facilitate traffic flow. Likewise, the citric acid cycle is the biochemical hub of the cell, oxidizing carbon fuels, usually in the form of acetyl CoA, as well as serving as a source of precursors for biosynthesis.

Outline

17.1 The Citric Acid Cycle Harvests High-Energy Electrons
17.2 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle
17.3 The Citric Acid Cycle Oxidizes Two-Carbon Units
17.4 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled

17.5 The Citric Acid Cycle Is a Source of Biosynthetic Precursors
17.6 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate

Learning Goals



By the end of this chapter, you should be able to:

1. Explain why the reaction catalyzed by the pyruvate dehydrogenase complex is a crucial juncture in metabolism.
2. Identify the means by which the pyruvate dehydrogenase complex is regulated.
3. Identify the primary catabolic purpose of the citric acid cycle.
4. Explain the efficiency of using the citric acid cycle to oxidize acetyl CoA.
5. Describe how the citric acid cycle is regulated.
6. Describe the role of the citric acid cycle in biosynthesis.
7. Identify the biochemical advantages that the glyoxylate cycle provides.

The metabolism of glucose to pyruvate in glycolysis, an anaerobic process, harvests but a fraction of the ATP available from glucose. Most of the ATP generated in metabolism is provided by the *aerobic* processing of glucose. This process starts with the complete oxidation of glucose derivatives to carbon dioxide. This oxidation begins with pyruvate and takes place in a series of reactions catalyzed by an enormous enzyme cluster called the *pyruvate dehydrogenase complex*. The oxidation ends with the citric acid cycle, a set of eight reactions that forms essentially the center of the complex web of catabolic and biosynthetic transformations known as *metabolism*. The electrons removed in the conversion of pyruvate to carbon dioxide ultimately provide the energy for the synthesis of most of the ATP within a cell.

17.1 The Citric Acid Cycle Harvests High-Energy Electrons

The **citric acid cycle (CAC)**, also known as the **tricarboxylic acid (TCA) cycle** or the **Krebs cycle**, is the final pathway for the oxidation of fuel molecules — carbohydrates, fatty acids, and amino acids. Most fuel molecules enter the cycle as **acetyl CoA** (acetyl coenzyme A).

Acetyl coenzyme A (Acetyl CoA)

Under aerobic conditions, the pyruvate generated from glucose is first oxidatively decarboxylated to form acetyl CoA by a large enzyme

complex called the **pyruvate dehydrogenase complex**. The acetyl CoA then enters the citric acid cycle, where all remaining carbons originally derived from glucose are completely oxidized to CO_2. In eukaryotes, the reactions of the pyruvate dehydrogenase complex and the citric acid cycle take place in the matrix of the mitochondria (**Figure 17.1**), in contrast with those of glycolysis, which take place in the cytoplasm.

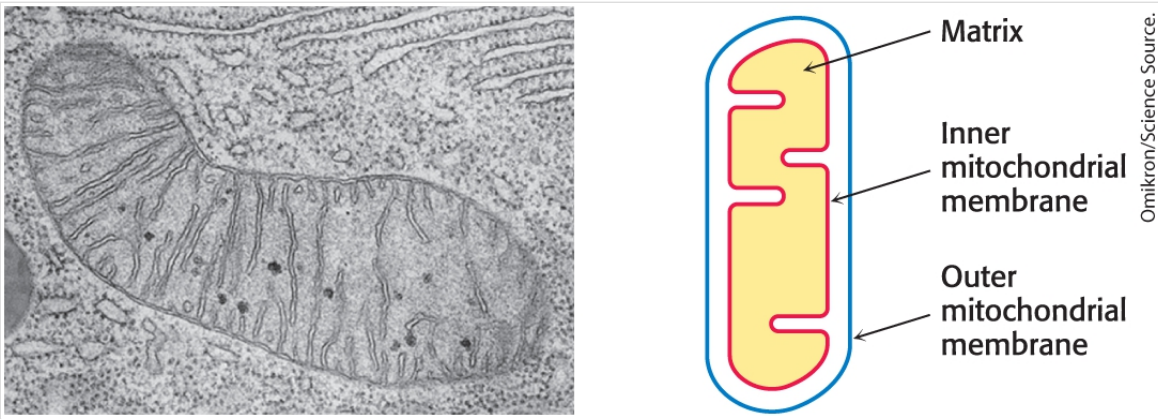


FIGURE 17.1 Mitochondria have distinct compartments defined by two membranes. The double membrane of a single mitochondrion is evident in this electron micrograph. The numerous invaginations of the inner mitochondrial membrane are called *cristae*. The oxidative decarboxylation of pyruvate and the sequence of reactions in the citric acid cycle take place within the matrix.

What is the function of the citric acid cycle in transforming fuel molecules into ATP? Recall that fuel molecules are carbon compounds that are capable of being oxidized — that is, of losing electrons (Section 15.3). The citric acid cycle includes a series of oxidation–reduction reactions that result in the oxidation of an acetyl group to two molecules of carbon dioxide. This oxidation generates high-energy electrons that will be used to power the synthesis of ATP. The catabolic function of the citric acid cycle is the harvesting of high-energy electrons from carbon fuels.

The citric acid cycle is also the central metabolic hub of the cell, providing a link that connects both catabolic and anabolic pathways. It is the gateway to the aerobic metabolism of any molecule that can be transformed into an acetyl group or a component of the citric acid cycle. The cycle is also an important source of precursors for the building blocks of many other molecules such as amino acids, nucleotide bases, and porphyrin (the organic component of heme). The citric acid cycle component, oxaloacetate, is also an important precursor to glucose (Section 16.4).

The overall pattern of the citric acid cycle is shown in **Figure 17.2**. A four-carbon compound (oxaloacetate) condenses with a two-carbon acetyl unit to yield a six-carbon tricarboxylic acid. The six-carbon compound releases CO_2 twice in two successive oxidative decarboxylations that yield high-energy electrons. What remains is a four-carbon compound that is further processed to regenerate oxaloacetate, which can initiate another round of the cycle. Two carbon atoms enter the cycle as an acetyl unit, and two carbon atoms leave the cycle in the form of two molecules of CO_2.

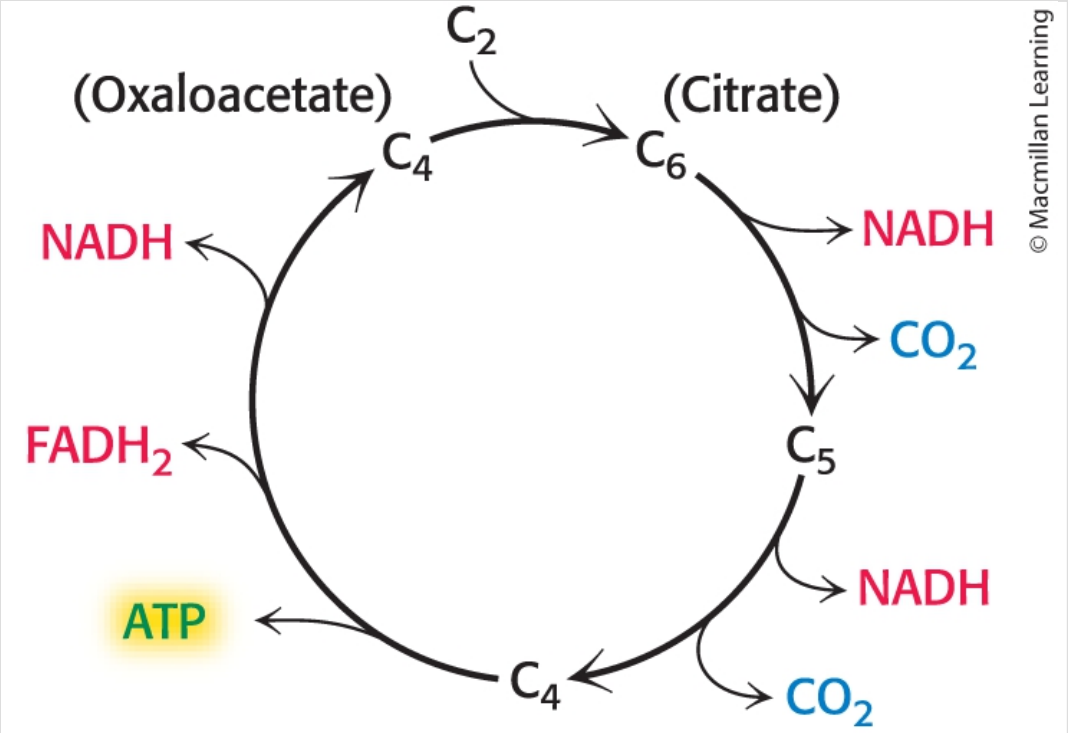

FIGURE 17.2 An overview of the citric acid cycle reveals the flow of carbon atoms and the major products of the cycle. A two-carbon group (C_2) combines with a four-carbon molecule (C_4, oxaloacetate) to form a six-carbon molecule (C_6, citrate). Two carbons are lost as CO_2 in the cycle, ending with the regeneration of oxaloacetate for another round. As the result, each round of the citric acid cycle oxidizes two-carbon units, producing two molecules of CO_2, one molecule of ATP, and high-energy electrons in the form of NADH and $FADH_2$.

Note that the citric acid cycle itself neither generates much ATP nor includes oxygen as a reactant (Figure 17.3). Instead, the citric acid cycle removes electrons from acetyl CoA and uses these electrons to reduce NAD^+ and FAD to form NADH and $FADH_2$. Three hydride ions (hence, six electrons) are transferred to three molecules of nicotinamide adenine dinucleotide (NAD^+), and one pair of hydrogen atoms (hence,

two electrons) is transferred to one molecule of flavin adenine dinucleotide (FAD) each time an acetyl CoA is processed by the cycle. Electrons released in the reoxidation of NADH and $FADH_2$ flow through a series of membrane proteins (referred to as the *electron-transport chain*) to generate a proton gradient across the inner mitochondrial membrane. These protons then flow through ATP synthase to generate ATP from ADP and inorganic phosphate. These electron carriers yield nine molecules of ATP when they are oxidized by O_2 through the process of oxidative phosphorylation (Chapter 18).

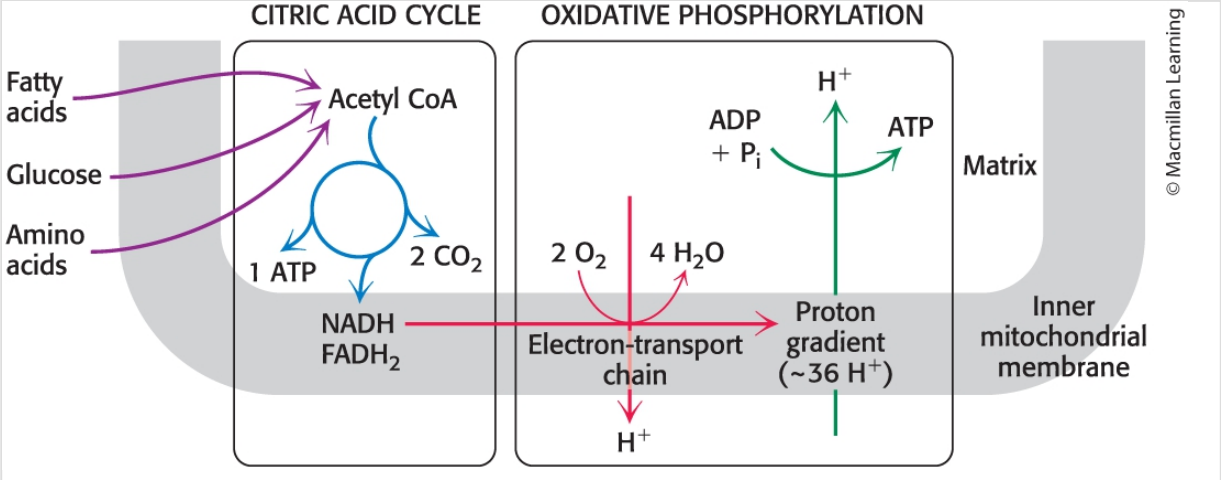

FIGURE 17.3 Cellular respiration removes high-energy electrons from carbon fuel molecules to generate ATP. The citric acid cycle constitutes the first stage in cellular respiration, the removal of high-energy electrons from carbon fuels in the form of NADH and $FADH_2$ (blue pathway). These electrons reduce O_2 to generate a proton gradient (red pathway), which is used to synthesize ATP (green pathway). The reduction of O_2 and the synthesis of ATP constitute oxidative phosphorylation.

The citric acid cycle, in conjunction with oxidative phosphorylation, provides the bulk of energy used by aerobic cells — in human beings, greater than 90%. It is highly efficient because the oxidation of a limited number of citric acid cycle molecules can generate large amounts of

NADH and $FADH_2$. Note in Figure 17.2 that the four-carbon molecule, oxaloacetate, that initiates the first step in the citric acid cycle is regenerated at the end of one passage through the cycle. Thus, one molecule of oxaloacetate is capable of participating in the oxidation of many acetyl groups.

17.2 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle

Carbohydrates, most notably glucose, are processed by glycolysis into pyruvate (Chapter 16). Under anaerobic conditions, the pyruvate is converted into lactate or ethanol, depending on the organism. Under aerobic conditions, the pyruvate is transported into mitochondria by a specific carrier protein embedded in the mitochondrial membrane. In the mitochondrial matrix, pyruvate is oxidatively decarboxylated by the pyruvate dehydrogenase complex — a highly integrated unit of three distinct enzymes — to form acetyl CoA.

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \rightarrow \text{acetyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+$$

This irreversible reaction is the link between glycolysis and the citric acid cycle (**Figure 17.4**). Note that the pyruvate dehydrogenase complex produces CO_2 and captures high-transfer-potential electrons in the form of NADH. Thus, the pyruvate dehydrogenase reaction has many of the key features of the reactions of the citric acid cycle itself.

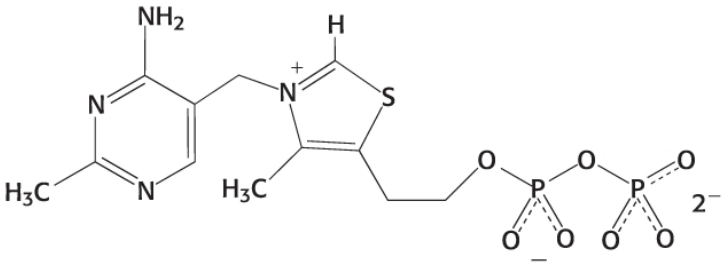
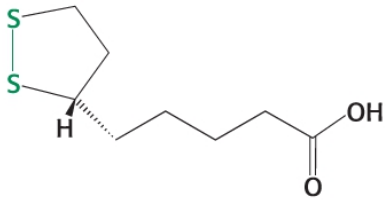
FIGURE 17.4 The pyruvate dehydro-genase complex connects glycolysis and the citric acid cycle. Pyruvate produced by glycolysis is converted into acetyl CoA, the fuel of the citric acid cycle.



The pyruvate dehydrogenase complex, the components of which are detailed in **Table 17.1**, is another example of the organization of enzymes into supramolecular structures (Section 16.3). Pyruvate dehydrogenase complex is a member of a family of homologous complexes that include the citric acid cycle enzyme α-ketoglutarate dehydrogenase complex (Section 17.3). These complexes are giant, larger than ribosomes, with molecular masses ranging from 4 million to 10 million Da. As we will see, their elaborate structures allow groups to travel from one active site to another, connected by tethers to the core of the structure.

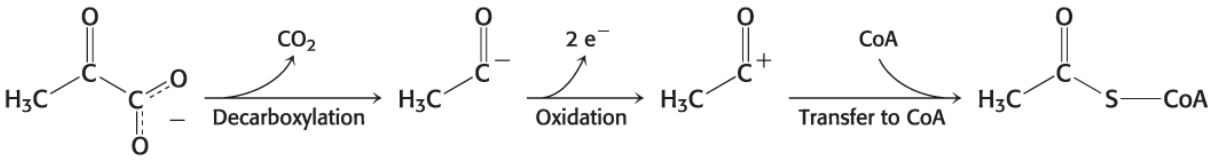
TABLE 17.1 Pyruvate dehydrogenase complex of *E. coli*



Enzyme	Abbreviation	Prosthetic group	Reaction catalyzed
Pyruvate dehydrogenase component	E_1	TPP	Oxidative decarboxylation of pyruvate
Dihydrolipoyl transacetylase	E_2	Lipoamide	Transfer of acetyl group to CoA
Dihydrolipoyl dehydrogenase	E_3	FAD	Regeneration of the oxidized form of lipoamide

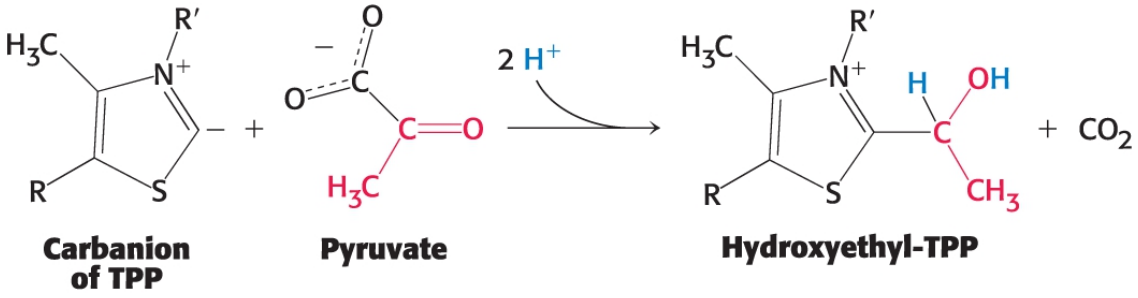
Mechanism: The synthesis of acetyl coenzyme A from pyruvate requires three enzymes and five coenzymes

The mechanism of the pyruvate dehydrogenase reaction is wonderfully complex, more so than is suggested by its simple stoichiometry. The reaction requires the participation of the three enzymes of the pyruvate dehydrogenase complex and five coenzymes. The coenzymes thiamine pyrophosphate (TPP), lipoic acid, and FAD serve as catalytic cofactors, and CoA and NAD^+ are stoichiometric cofactors, cofactors that function as substrates.



Thiamine pyrophosphate (TPP)

Lipoic acid



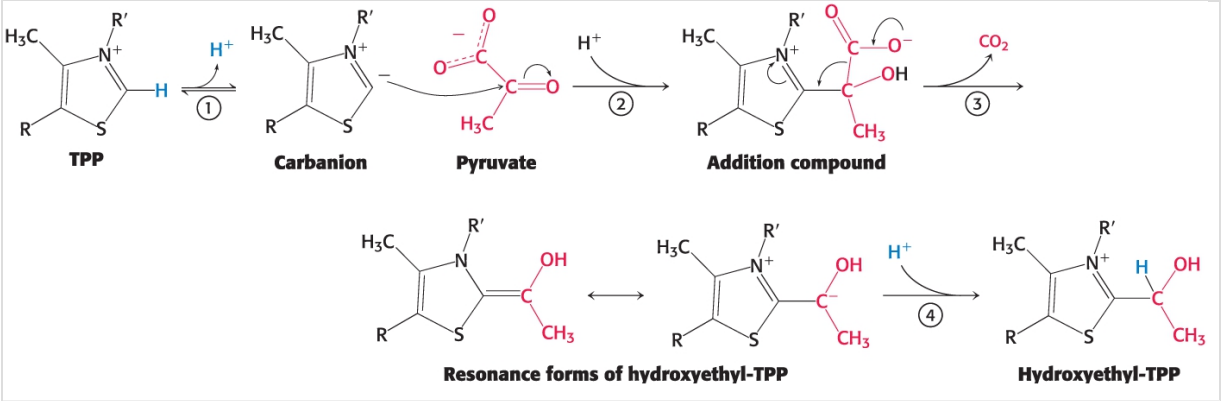
The conversion of pyruvate into acetyl CoA consists of decarboxylation, oxidation, and transfer of the resultant acetyl group to CoA. A fourth step is required to regenerate the active enzyme.

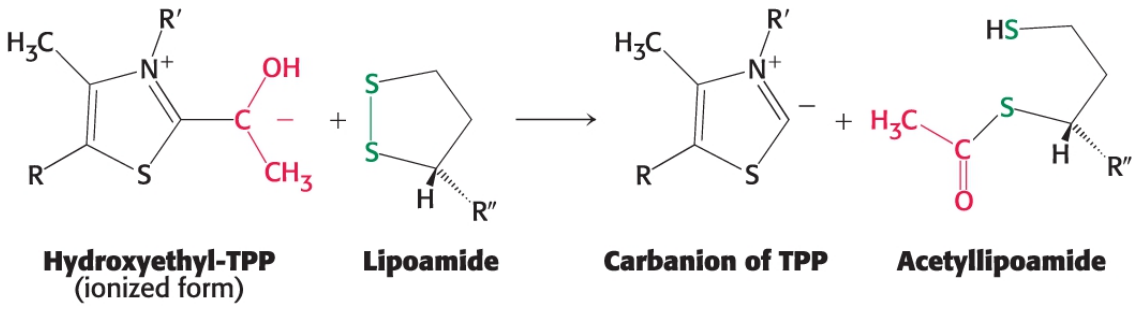
Pyruvate **Acetyl CoA**

These steps must be coupled to preserve the free energy derived from the decarboxylation step to drive the formation of NADH and acetyl CoA. Let us look into each step in more detail:

1. *Decarboxylation*. Pyruvate combines with TPP and is then decarboxylated to yield hydroxyethyl-TPP.

This reaction, the rate-limiting step in acetyl CoA synthesis, is catalyzed by the pyruvate dehydrogenase component (E_1) of the multienzyme complex. TPP is the prosthetic group of the pyruvate dehydrogenase component (**Figure 17.5**).





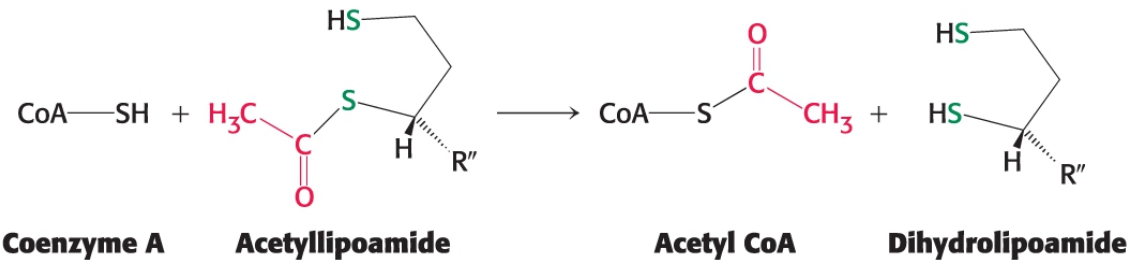


FIGURE 17.5 The mechanism of the E_1 decarboxylation reaction uses a critical thiamine-derived prosthetic group. E_1 is the pyruvate dehydrogenase component of the pyruvate dehydrogenase complex. A key feature of the prosthetic group, TPP, is that the carbon atom between the nitrogen and sulfur atoms in the thiazole ring is much more acidic than most $=C-$ groups, with a pK_a value near 10. (1) This carbon center ionizes to form a *carbanion.* (2) The carbanion readily adds to the carbonyl group of pyruvate. (3) This addition is followed by the decarboxylation of pyruvate. The positively charged ring of TPP acts as an electron sink that stabilizes the negative charge that is transferred to the ring as part of the decarboxylation. (4) Protonation yields hydroxyethyl-TPP.

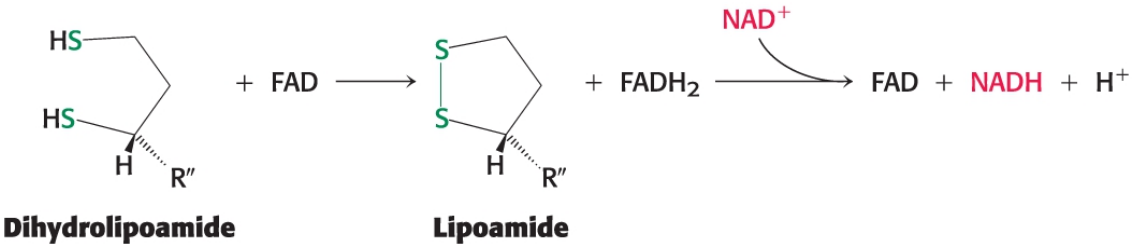
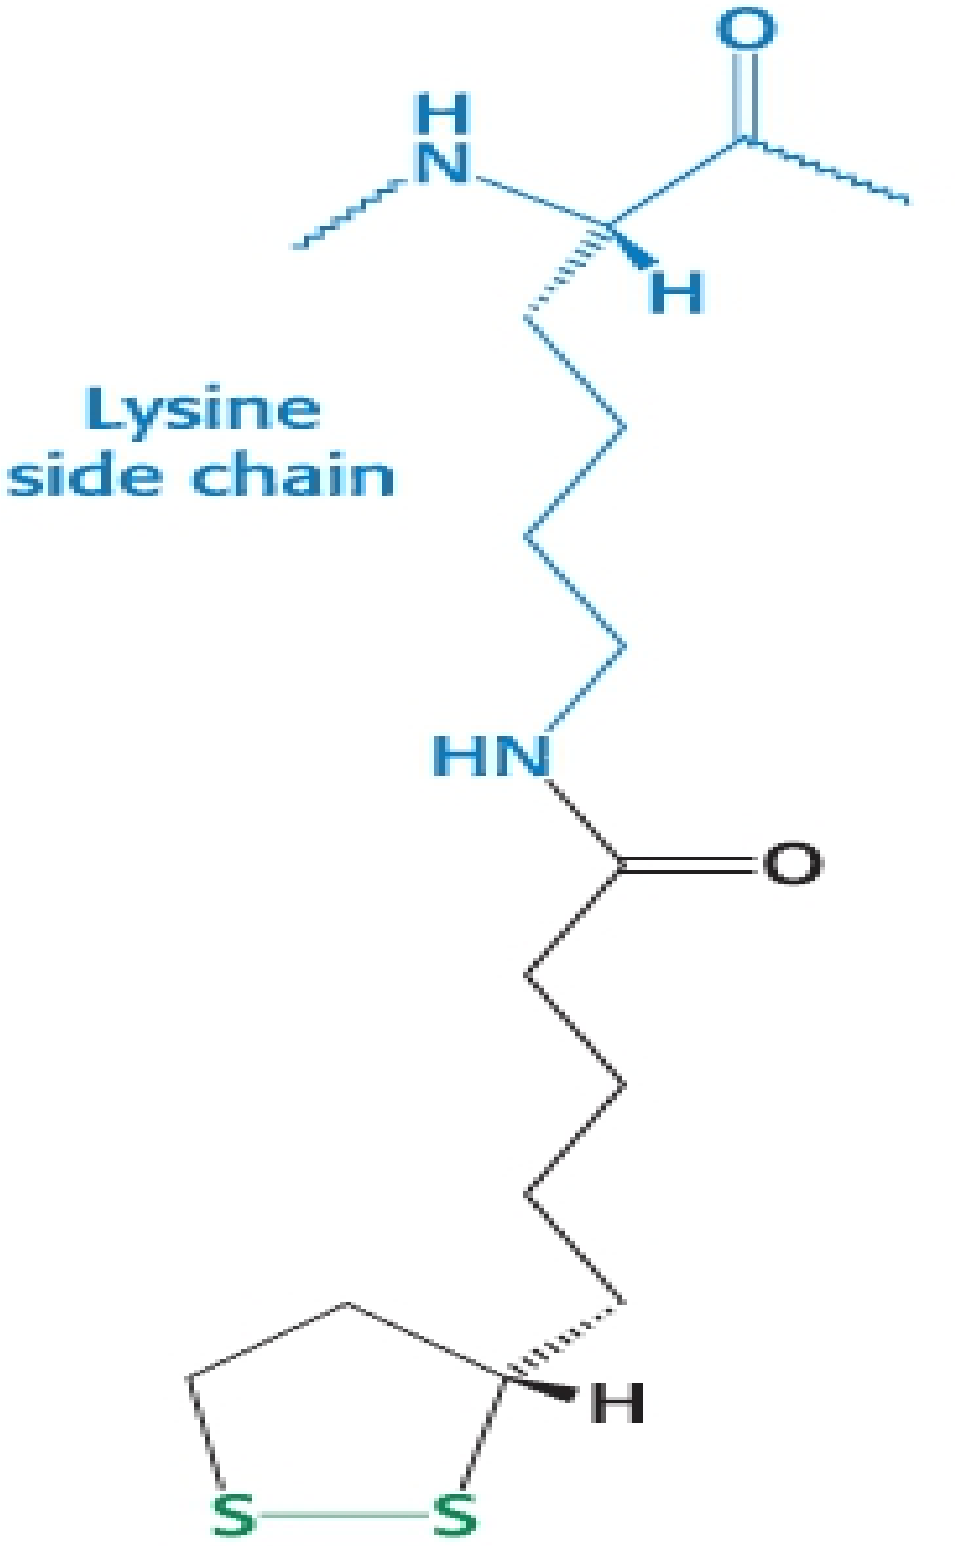
2. *Oxidation*. The hydroxyethyl group attached to TPP is oxidized to form an acetyl group while being simultaneously transferred to lipoamide, a derivative of lipoic acid that is linked to the side chain of a lysine residue by an amide linkage. Note that this transfer results in the formation of an energy-rich thioester bond.

The oxidant in this reaction is the disulfide group of lipoamide, which is reduced to its disulfhydryl form. This reaction, also catalyzed by the pyruvate dehydrogenase component E_1, yields acetyllipoamide.



3. *Formation of acetyl CoA*. The acetyl group is transferred from acetyllipoamide to CoA to form acetyl CoA.



Dihydrolipoyl transacetylase (E_2) catalyzes this reaction. The energy-rich thioester bond is preserved as the acetyl group is transferred to CoA. Recall that CoA serves as a carrier of many activated acyl groups, of which acetyl is the simplest (Section 15.4). Acetyl CoA, the fuel for the citric acid cycle, has now been generated from pyruvate.

4. *Regeneration of oxidized lipoamide*. The pyruvate dehydrogenase complex cannot complete another catalytic cycle until the dihydrolipoamide is oxidized to lipoamide. In the fourth step,

the oxidized form of lipoamide is regenerated by dihydrolipoyl dehydrogenase (E_3). Two electrons are transferred to an FAD prosthetic group of the enzyme and then to NAD^+.

This electron transfer from FAD to NAD^+ is unusual because the common role for FAD is to receive electrons from NADH. The electron-transfer potential of FAD is increased by its chemical environment within the enzyme, enabling it to transfer electrons to NAD^+. Proteins tightly associated with FAD or flavin mononucleotide (FMN) are called **flavoproteins**.

Reactive disulfide bond

Lipoamide

Flexible linkages allow lipoamide to move between different active sites

The structures and precise composition of the component enzymes of the pyruvate dehydrogenase complex vary among species. However, there are common features.

The core of the complex is formed by 60 molecules of the transacetylase component E_2 (**Figure 17.6**). Transacetylase consists of 20 catalytic trimers assembled to form a hollow cube. Each of the three subunits forming a trimer has three major domains (**Figure 17.7**). At the amino terminus is a small domain that contains a bound flexible lipoamide cofactor attached to a lysine residue. This domain is homologous to biotin-binding domains such as that of pyruvate carboxylase (Figure 16.29). The lipoamide domain is followed by a small domain that interacts with E_3 within the complex. A larger transacetylase domain completes an E_2 subunit.

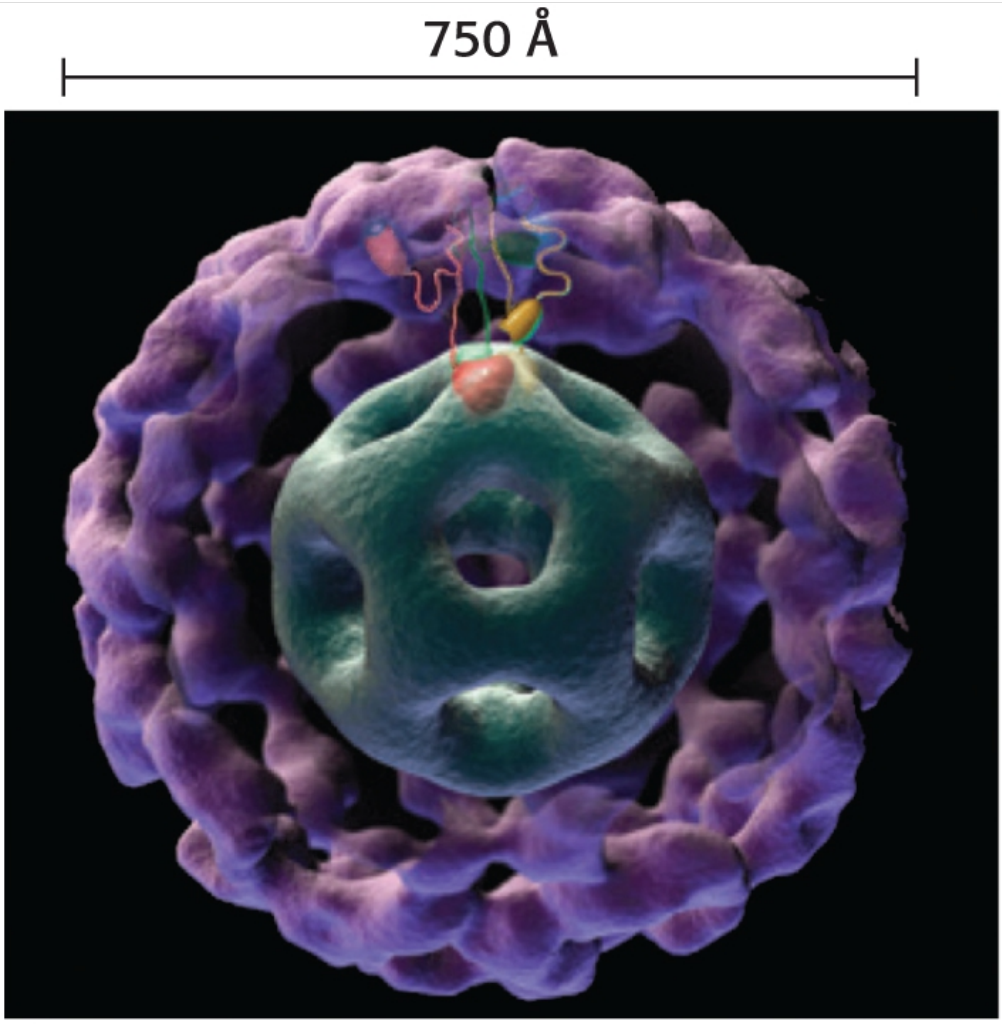


FIGURE 17.6 The structure of the pyruvate dehydrogenase complex from bacteria reveals a massive protein complex. The image of the complex from *B. stearothermophilus*, which was derived from cryo-electron microscopic data (Section 4.5), shows an inner core consisting of the E_2 enzyme. The shell surrounding the core consists of E_1 and E_3 enzymes, although only the E_1 enzymes are shown in this structure. Two of the 60 lipoamide arms are shown (red and yellow).

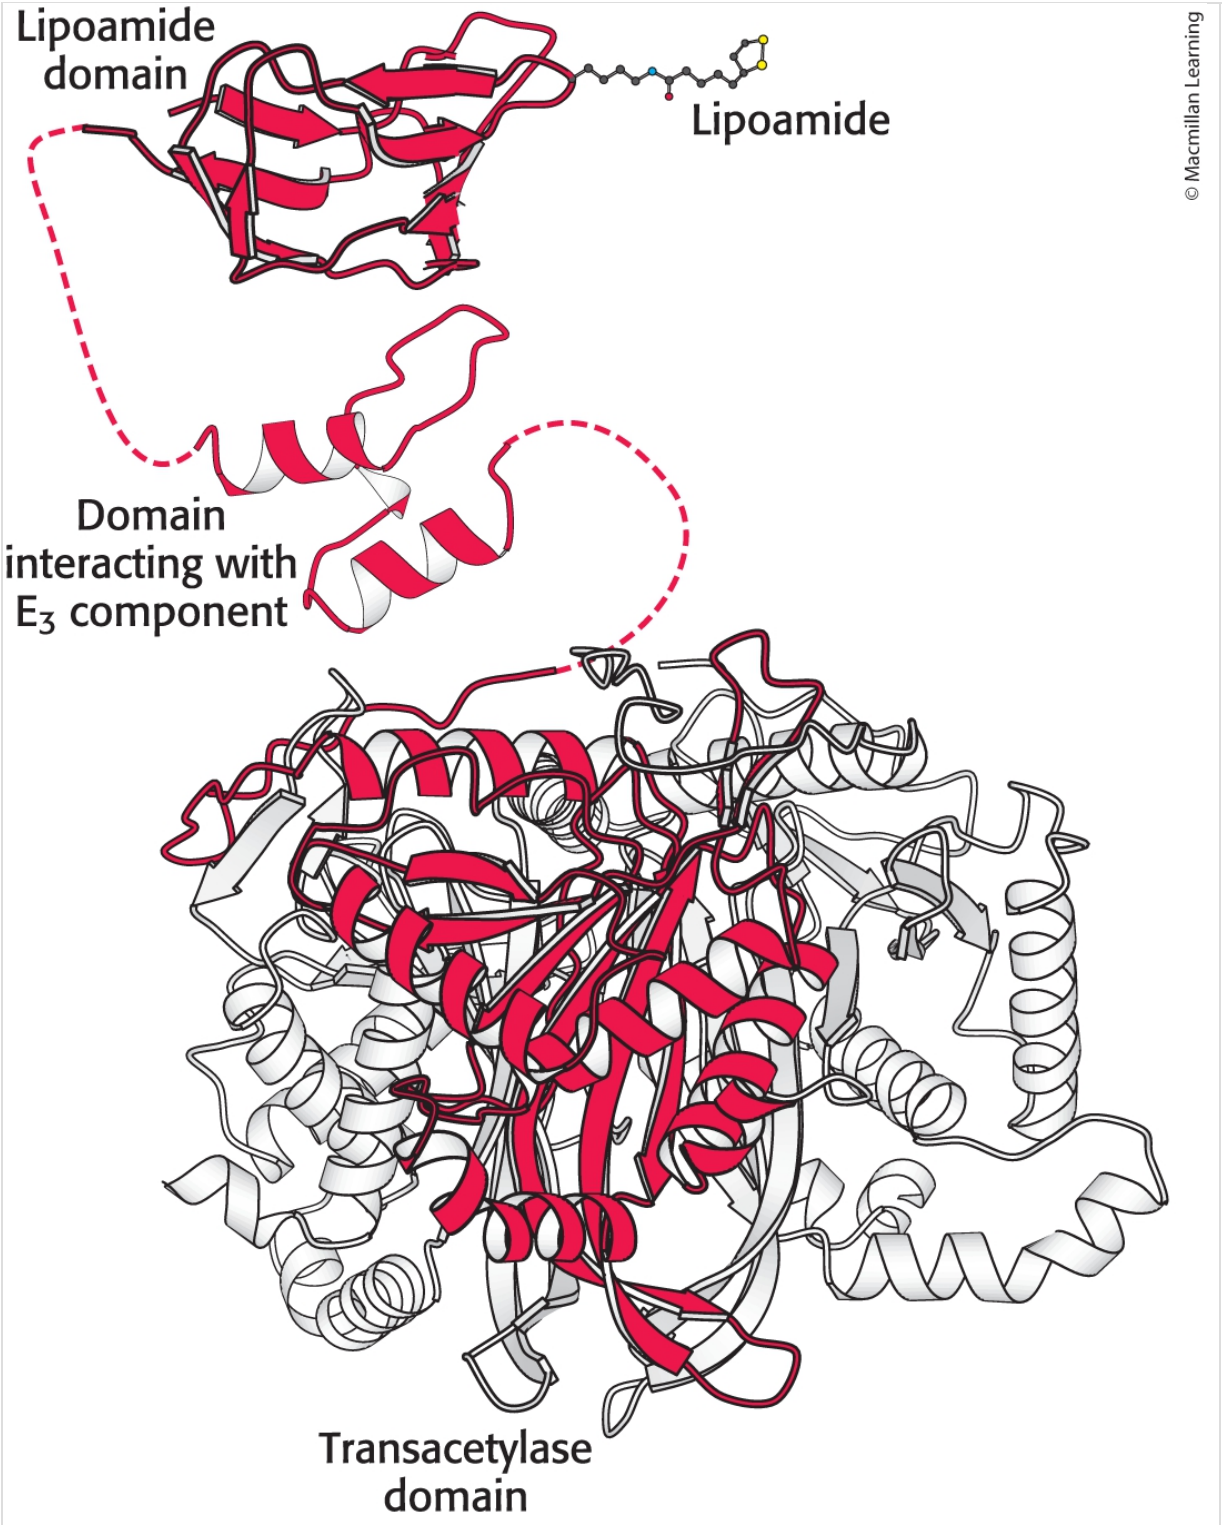

FIGURE 17.7 The transacetylase (E_2) core is made up of three distinct domains. The figure shows one subunit of the transacetylase trimer. *Notice* that each subunit consists of three domains: a lipoamide-binding domain, a small domain that interacts with E_3, and a

large transacetylase catalytic domain. The catalytic domains interact with one another to form the catalytic trimer. Transacetylase domains of three identical subunits are shown, with one depicted in red and the others in white in the ribbon representation.

Surrounding the core transacetylase is a shell composed of ~ 45 copies of the E_1 and ~ 10 copies of E_3 enzymes. In mammals, E_1 is an $\alpha_2\beta_2$ tetramer, and E_3 is an $\alpha\beta$ dimer, and this core contains another protein, E_3-binding protein (E_3-BP), which facilitates the interaction between E_2 and E_3. If E_3-BP is missing, the complex has greatly reduced activity. The gap between the outer shell and the transacetylase core allows the lipoamide arms to visit the various active sites (Figure 17.6).

How do the three distinct active sites work in concert? The key is the long, flexible lipoamide arm of the E_2 subunit, which carries substrate from active site to active site (**Figure 17.8**):

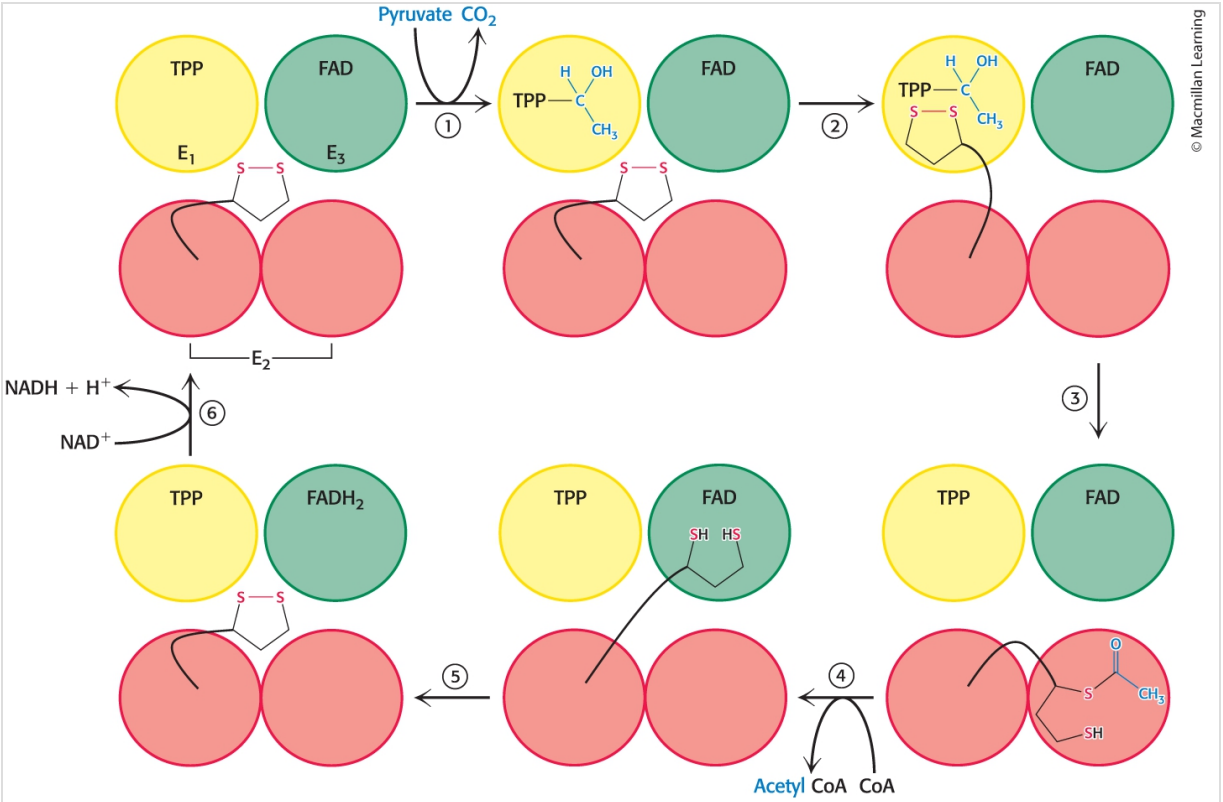

FIGURE 17.8 Three enzymes cooperate in the full reactions of the pyruvate dehydrogenase complex. At the top left, the enzyme (represented by a yellow, a green, and two red spheres) is unmodified and ready for a catalytic cycle. (1) Pyruvate is decarboxylated to form hydroxyethyl-TPP. (2) The lipoamide arm of E_2 moves into the active site of E_1. (3) E_1 catalyzes the transfer of the two-carbon group to the lipoamide group to form the acetyl–lipoamide complex. (4) E_2 catalyzes the transfer of the acetyl moiety to CoA to form the product acetyl CoA. The dihydrolipoamide arm then swings to the active site of E_3. E_3 catalyzes (5) the oxidation of the dihydrolipoamide and (6) the transfer of the protons and electrons to NAD^+ to complete the reaction cycle.

1. Pyruvate is decarboxylated at the active site of E_1, forming the hydroxyethyl-TPP intermediate, and CO_2 leaves as the first product. This active site lies deep within the E_1 complex,

connected to the enzyme surface by a 20-Å-long hydrophobic channel.

2. E_2 inserts the lipoamide arm of the lipoamide domain into the deep channel in E_1 leading to the active site.

3. E_1 catalyzes the transfer of the acetyl group to the lipoamide. The acetylated arm then leaves E_1 and enters the E_2 cube to visit the active site of E_2, located deep in the cube at the subunit interface.

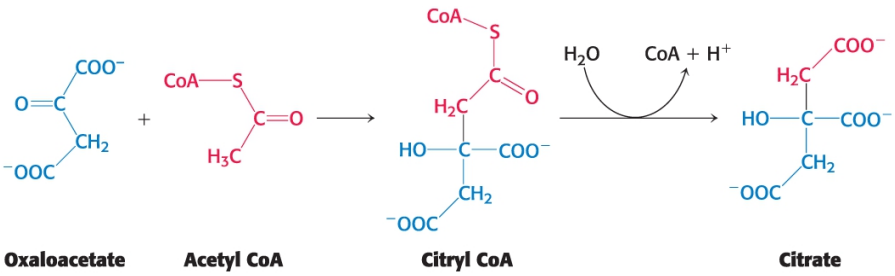
4. The acetyl moiety is then transferred to CoA, and the second product, acetyl CoA, leaves the cube. The reduced lipoamide arm then swings to the active site of the E_3 flavoprotein.

5. At the E_3 active site, the lipoamide is oxidized by coenzyme FAD. The reactivated lipoamide is ready to begin another reaction cycle.

6. The final product, NADH, is produced with the reoxidation of $FADH_2$ to FAD.

The structural integration of three kinds of enzymes and the long, flexible lipoamide arm make the coordinated catalysis of a complex reaction possible. The proximity of one enzyme to another increases the overall reaction rate and minimizes side reactions. All the intermediates in the oxidative decarboxylation of pyruvate remain bound to the complex throughout the reaction sequence and are readily transferred as the flexible arm of E_2 calls on each active site in turn.

Self-Check Question



A key product of pyruvate dehydrogenase complex reaction, acetyl CoA, is released after the fourth step. What is the purpose of the remaining steps?

17.3 The Citric Acid Cycle Oxidizes Two-Carbon Units

The conversion of pyruvate into acetyl CoA by the pyruvate dehydrogenase complex is the link between glycolysis and cellular respiration because acetyl CoA is the fuel for the citric acid cycle. Indeed, under aerobic conditions, all fuels are ultimately metabolized to acetyl CoA or components of the citric acid cycle.

Citrate synthase forms citrate from oxaloacetate and the acetyl group from acetyl coenzyme A

The citric acid cycle begins with the addition of a four-carbon unit, oxaloacetate, and a two-carbon unit, the acetyl group of acetyl CoA. Oxaloacetate reacts with acetyl CoA and H_2O to yield citrate and CoA.

This reaction, which is an aldol addition followed by a hydrolysis, is catalyzed by citrate synthase. Oxaloacetate first combines with acetyl CoA to form citryl CoA, a molecule that is energy rich because it contains the thioester bond that originated in acetyl CoA. The hydrolysis of citryl CoA thioester to citrate and CoA drives the overall reaction far in the direction of the synthesis of citrate. In essence, the hydrolysis of the thioester powers the synthesis of a new molecule from two precursors.

Mechanism: The mechanism of citrate synthase prevents undesirable reactions

Because the condensation of acetyl CoA and oxaloacetate initiates the citric acid cycle, it is very important that side reactions, notably the hydrolysis of acetyl CoA to acetate and CoA, be

minimized. Let us briefly consider how citrate synthase prevents the wasteful hydrolysis of acetyl CoA.

Mammalian citrate synthase is a dimer of identical 49-kDa subunits. Each active site is located in a cleft between the large and the small domains of a subunit, adjacent to the subunit interface. X-ray crystallographic studies of citrate synthase and its complexes with several substrates and inhibitors have revealed that the enzyme undergoes large conformational changes in the course of catalysis. Citrate synthase exhibits sequential, ordered kinetics: oxaloacetate binds first, followed by acetyl CoA.

The reason for the ordered binding is that oxaloacetate induces a major structural rearrangement leading to the creation of a binding site for acetyl CoA. The binding of oxaloacetate converts the open form of the enzyme into a more closed form (Figure 17.9). In each subunit, the small domain rotates 19 degrees relative to the large domain. Movements as large as 15 Å are produced by the rotation of α helices elicited by quite small shifts of side chains around bound oxaloacetate. These structural changes create a binding site for acetyl CoA.

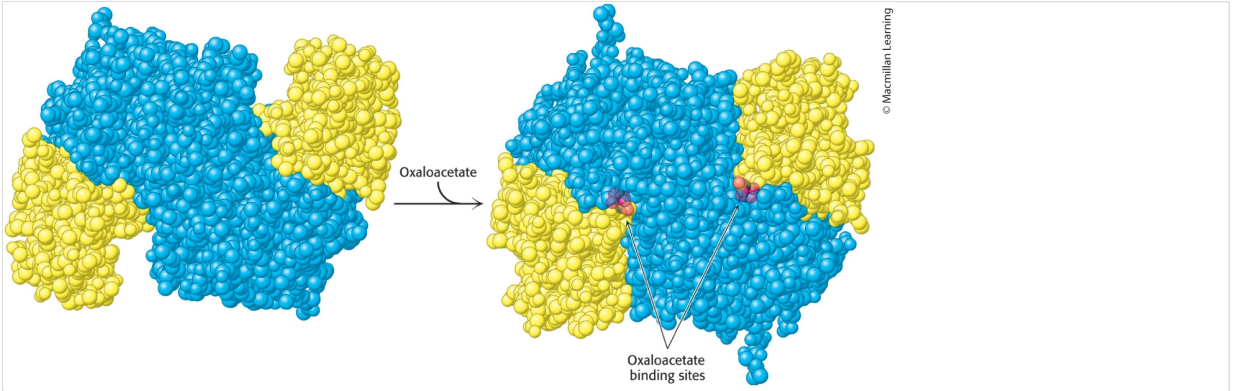


FIGURE 17.9 The ordered binding of substrates by citrate synthase is explained by conformational changes upon binding oxaloacetate. The small domain of each subunit of the homodimer is shown in yellow; the large domains are shown in blue. (Left) The open form of enzyme alone is shown. (Right) The closed form of the oxaloacetate-enzyme complex reveals significant structural changes upon oxaloacetate binding that create a binding site with high affinity for acetyl CoA, the second substrate to bind.

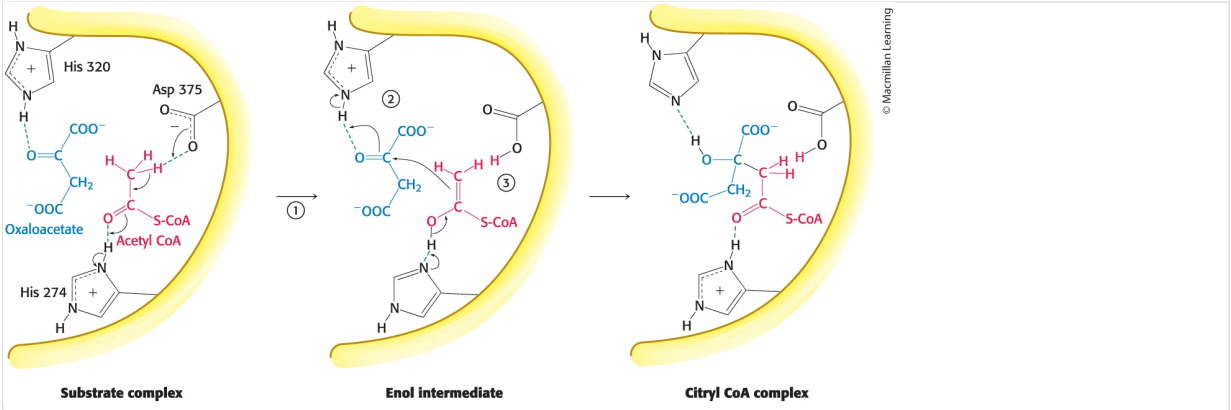
[Drawn from 5CSC.pdb and 4CTS.pdb.]

INTERACT with this model in Achieve

Citrate synthase catalyzes the condensation reaction by bringing the substrates into close proximity, orienting them, and polarizing certain bonds (Figure 17.10). The donation and removal of protons transforms acetyl CoA into an enol intermediate. The enol attacks oxaloacetate to form a carbon–carbon double bond linking acetyl CoA and oxaloacetate. The newly formed citryl CoA induces additional structural changes in the enzyme, causing the active site to become completely enclosed. The enzyme cleaves the citryl CoA thioester by hydrolysis.

CoA leaves the enzyme, followed by citrate, and the enzyme returns to the initial open conformation.



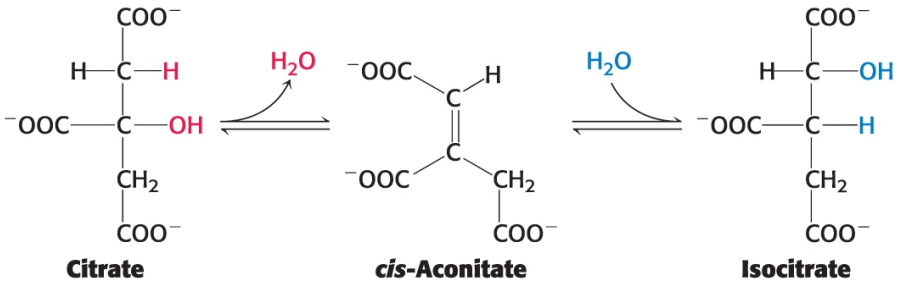


FIGURE 17.10 The first part of the citrate synthase mechanism forms citryl CoA. (1) In the substrate complex (left), His 274 donates a proton to the carbonyl oxygen of acetyl CoA to promote the removal of a methyl proton by Asp 375 to form the enol intermediate (center). (2) Oxaloacetate is activated by the transfer of a proton from His 320 to its carbonyl carbon atom. (3) Simultaneously, the enol of acetyl CoA attacks the carbonyl carbon of oxaloacetate to form a carbon–carbon bond linking acetyl CoA and oxaloacetate. His 274 is reprotonated, and citryl CoA is formed. His 274 participates again as a proton donor to hydrolyze the thioester (not shown), yielding citrate and CoA.

We can now understand how the wasteful hydrolysis of acetyl CoA is prevented. Citrate synthase is well suited to hydrolyze *citryl* CoA but not *acetyl* CoA. How is this discrimination accomplished? First, acetyl CoA does not bind to the enzyme until oxaloacetate is bound and ready for condensation. Second, the catalytic residues crucial for the hydrolysis of the thioester linkage are not appropriately positioned until citryl CoA is formed. As with hexokinase and triose phosphate isomerase (Section 16.2), induced fit prevents an undesirable side reaction.

Citrate is isomerized into isocitrate

The hydroxyl group is not properly located in the citrate molecule for the oxidative decarboxylations that follow. Thus, citrate is isomerized into isocitrate to enable the six-carbon unit to undergo oxidative decarboxylation. The isomerization of citrate is accomplished by a dehydration step followed by a hydration step. The result is an interchange of an H and an OH. The enzyme catalyzing both steps is called *aconitase* because *cis*-aconitate is an intermediate.

Aconitase is an iron–sulfur protein, or nonheme iron protein, in that it contains iron that is not bonded to heme. Rather, its four iron atoms are complexed to four inorganic sulfides and three cysteine sulfur atoms, leaving one iron atom available to bind citrate through one of its COO^- groups and an OH group (Figure 17.11). This Fe–S cluster participates in dehydrating and rehydrating the bound substrate.

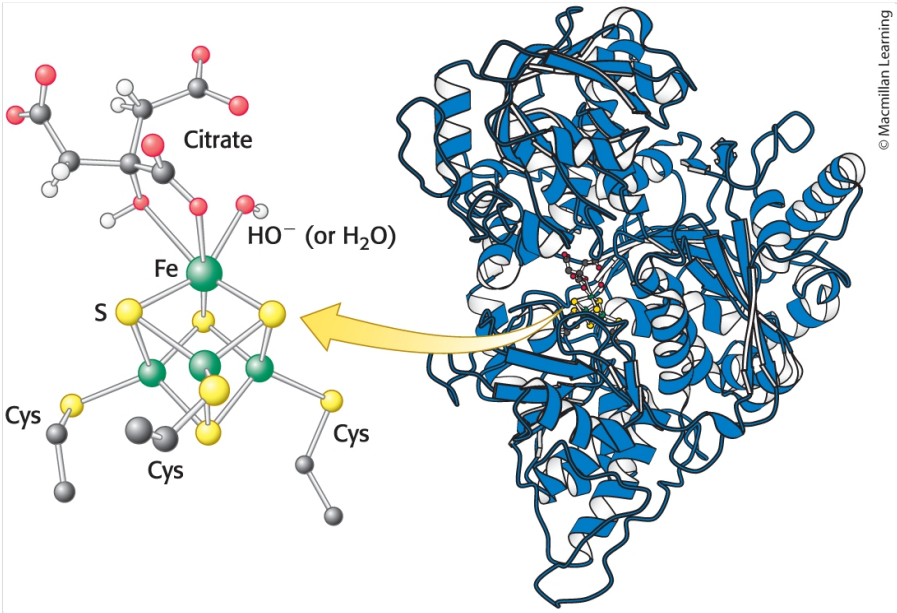

FIGURE 17.11 Citrate binds directly to the iron–sulfur complex of aconitase. A 4Fe–4S iron–sulfur cluster is a component of the active site of aconitase. Notice that one of the iron atoms of the cluster binds to a COO^- group and an OH group of citrate.

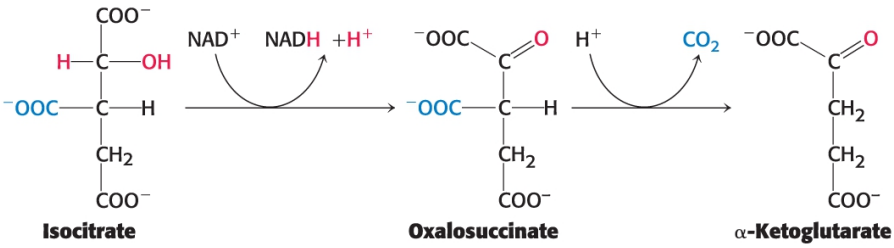
[Drawn from 1C96.pdb.]

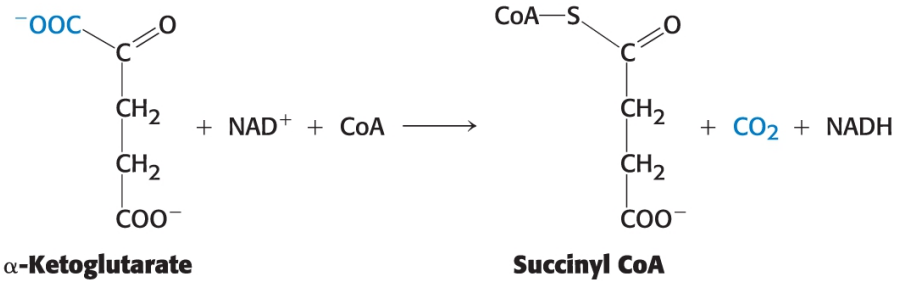


INTERACT with this model in Achieve

Isocitrate is oxidized and decarboxylated to alpha-ketoglutarate

We come now to the first of four oxidation–reduction reactions in the citric acid cycle. The oxidative decarboxylation of isocitrate is catalyzed by isocitrate dehydrogenase.

$$\text{Isocitrate} + \text{NAD}^+ \rightarrow \alpha\text{–ketoglutarate} + \text{CO}_2 + \text{NADH}$$



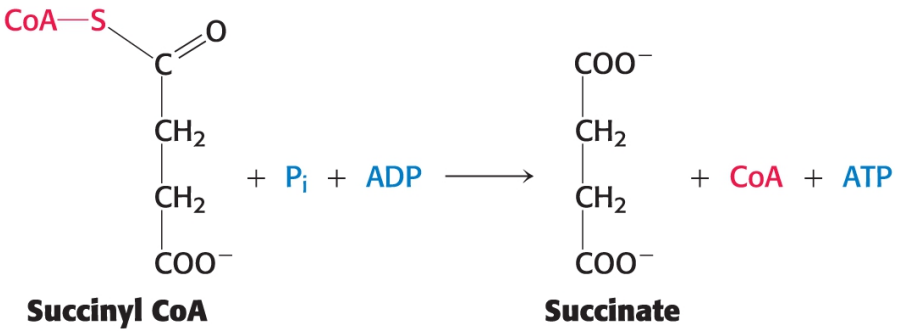
The intermediate in this reaction is oxalosuccinate, an unstable β-ketoacid. While bound to the enzyme, it loses CO_2 to form α-ketoglutarate.

This oxidation generates the first high-transfer-potential electron carrier, NADH, in the cycle.

Succinyl coenzyme A is formed by the oxidative decarboxylation of alpha-ketoglutarate

The conversion of isocitrate into α-ketoglutarate is followed by a second oxidative decarboxylation reaction, the formation of succinyl CoA from α-ketoglutarate.

This reaction is catalyzed by the **α-ketoglutarate dehydrogenase complex**, an organized assembly of three kinds of enzymes that is homologous to the pyruvate dehydrogenase complex. In fact, the E_3 component is identical in both enzymes. The oxidative decarboxylation of α-ketoglutarate closely resembles that of pyruvate (Section 17.2), also an α-ketoacid.



$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \xrightarrow{\text{Pyruvate dehydrogenase complex}} \text{acetyl CoA} + \text{CO}_2 + \text{NADH} + \text{H}^+$$

$$\alpha\text{–Ketoglutarate} + \text{CoA} + \text{NAD}^+ \xrightarrow{\alpha\text{–Ketoglutarate dehydrogenase complex}} \text{succinyl CoA} + \text{CO}_2 + \text{NADH}$$

Both reactions include the decarboxylation of an α-ketoacid and the subsequent formation of a thioester linkage with CoA that has a high transfer potential. The reaction mechanisms are entirely analogous.

A compound with high phosphoryl-transfer potential is generated from succinyl coenzyme A

Succinyl CoA is an energy-rich thioester compound. The $\Delta G^{\circ\prime}$ for the hydrolysis of succinyl CoA is about $-33.5\ \text{kJ mol}^{-1}(-8.0\ \text{kcal mol}^{-1})$, which is comparable to that of ATP $(-30.5\ \text{kJ mol}^{-1}$, or $-7.3\ \text{kcal mol}^{-1})$. In the citrate synthase reaction, the cleavage of the thioester bond powers the synthesis of the six-carbon citrate from the four-carbon oxaloacetate and the two-carbon fragment. The cleavage of the thioester bond of succinyl CoA is coupled to the phosphorylation of a purine nucleoside diphosphate, usually ADP. This reaction, which is readily reversible, is catalyzed by succinyl CoA synthetase.

This reaction is the only step in the citric acid cycle that directly yields a compound with high phosphoryl-transfer potential. In mammals, there are two isozymic forms of the enzyme, one specific for ADP and one for GDP. In tissues that perform large amounts of cellular respiration, such as skeletal and heart muscle, the ADP-requiring isozyme predominates. In tissues that perform many anabolic reactions, such as the liver, the GDP-requiring enzyme is common. The GDP-requiring enzyme is believed to work in reverse of the direction observed in the TCA cycle; that is, GTP is used to power the synthesis of succinyl CoA, which is a precursor for heme synthesis (Section 25.4). The specificity and nucleoside used varies also by species. For example, the enzyme in *E. coli* can use either GDP or ADP as the phosphoryl-group acceptor.

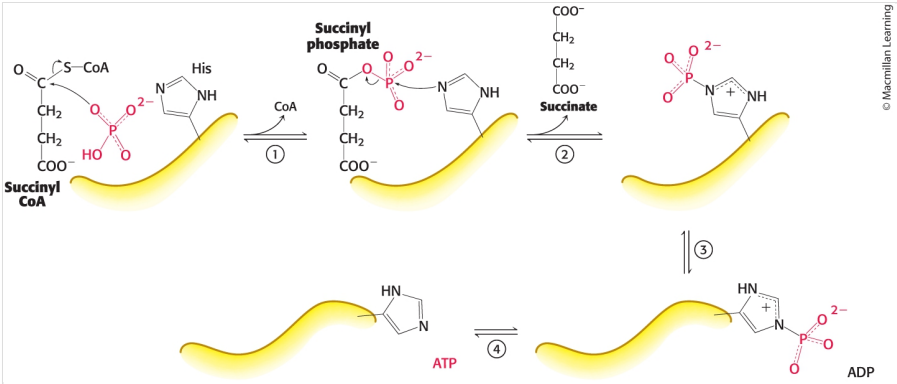
Note that the enzyme **nucleoside diphosphokinase**, which catalyzes the following reaction,

$$\mathrm{XTP} + \mathrm{YDP} \rightleftharpoons \mathrm{XDP} + \mathrm{YTP}$$

allows the γ phosphoryl group to be readily transferred from any nucleotide triphosphate (XTP) to any other nucleotide diphosphate (YDP); for example, from GTP to form ATP from ADP. This reaction thereby allows the adjustment of the concentration of GTP or ATP to meet the cell's need and keeps the concentrations of all the various nucleoside triphosphates in the cell near equilibrium with one another.

Mechanism: Succinyl coenzyme A synthetase transforms types of biochemical energy

The mechanism of this reaction is a clear example of an energy transformation: energy inherent in the thioester molecule is transformed into phosphoryl-group-transfer potential (**Figure 17.12**). First, coenzyme A is displaced by orthophosphate (step 1), which generates another energy-rich compound, succinyl phosphate. A histidine residue plays a key role as a moving arm that detaches the phosphoryl group (step 2), then swings over to a bound ADP (step 3) and transfers the group to form ATP (step 4). The participation of high-energy compounds in all the steps is attested to by the fact that the reaction is readily reversible:
$\Delta G^{\circ\prime} = -3.4\ \mathrm{kJ\ mol^{-1}} (-0.8\ \mathrm{kcal\ mol^{-1}})$. The formation of ATP at the expense of succinyl CoA is an example of substrate-level phosphorylation (Section 16.2).



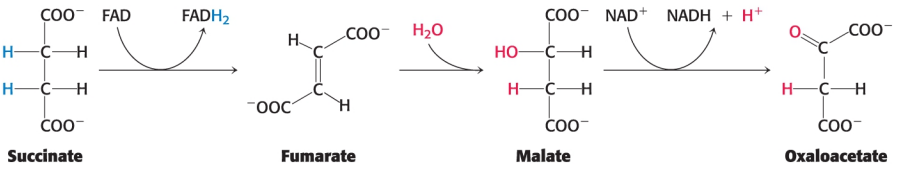


FIGURE 17.12 The mechanism of succinyl CoA synthetase allows the formation of a phosphoanhydride through a phosphorylated enzyme intermediate. (1) Orthophosphate displaces coenzyme A, which generates another energy-rich compound, succinyl phosphate. (2) A histidine residue removes the phosphoryl group with the concomitant generation of succinate and phosphohistidine. (3) The phosphohistidine residue then swings over to a bound ADP, and (4) the phosphoryl group is transferred to form ATP.

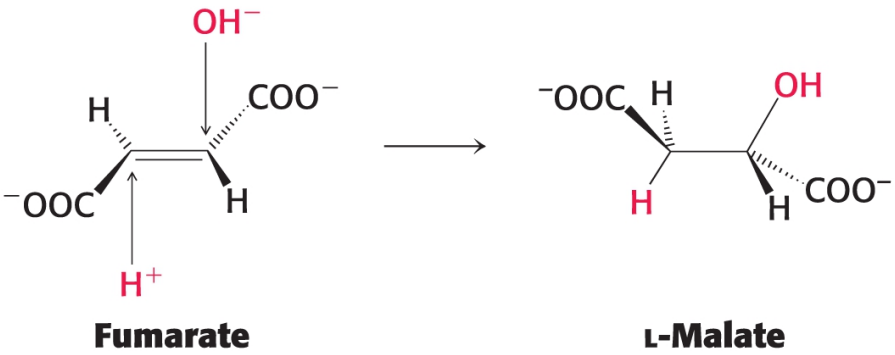
Oxaloacetate is regenerated by the oxidation of succinate

Reactions of four-carbon compounds constitute the final stage of the citric acid cycle: the regeneration of oxaloacetate.

The reactions constitute a metabolic motif that we will see again in fatty acid synthesis and degradation as well as in the degradation of some amino acids. A methylene group (CH_2) is converted into a carbonyl group $C{=}O$ in three steps: an oxidation, a hydration, and a second oxidation reaction. Oxaloacetate is thereby regenerated for another round of the cycle, and more energy is extracted in the form of $FADH_2$ and NADH.

Succinate is oxidized to fumarate by succinate dehydrogenase. The hydrogen acceptor is FAD rather than NAD^+, which is used in the other three oxidation reactions in the cycle. FAD is the electron acceptor in this reaction because the free-energy change is insufficient to reduce



NAD^+. FAD is nearly always the electron acceptor in oxidations that remove two hydrogen atoms from a substrate. In succinate dehydrogenase, the isoalloxazine ring of FAD is covalently attached to a histidine side chain of the enzyme (denoted E-FAD).

$$\text{E-FAD} + \text{succinate} \rightleftharpoons \text{E-FADH}_2 + \text{fumarate}$$

Succinate dehydrogenase, like aconitase, is an iron–sulfur protein. Indeed, succinate dehydrogenase contains three different kinds of iron–sulfur clusters: 2Fe–2S (two iron atoms bonded to two inorganic sulfides), 3Fe–4S, and 4Fe–4S. Succinate dehydrogenase differs from other enzymes in the citric acid cycle because it is embedded in the inner mitochondrial membrane. In fact, succinate dehydrogenase is directly associated with the electron-transport chain, the link between the citric acid cycle and ATP formation.

$FADH_2$ produced by the oxidation of succinate does not dissociate from the enzyme, in contrast with NADH produced in other oxidation–reduction reactions. Rather, two electrons are transferred from $FADH_2$ directly to iron–sulfur clusters of the enzyme, which in turn passes the electrons to coenzyme Q. Coenzyme Q, an important member of the electron-transport chain, passes electrons ultimately to the final acceptor, molecular oxygen, as we shall see in Chapter 18.

The next step is the hydration of fumarate to form L-malate. Fumarase catalyzes a stereospecific trans addition of H^+ and OH^-. The OH^- group adds to only one side of the double bond of fumarate; hence, only the L isomer of malate is formed.

Fumarate **L-Malate**

Finally, malate is oxidized to form oxaloacetate. This reaction is catalyzed by malate dehydrogenase, and NAD^+ is again the hydrogen acceptor.

$$\text{Malate} + \text{NAD}^+ \rightleftharpoons \text{oxaloacetate} + \text{NADH} + \text{H}^+$$

The standard free energy for this reaction, unlike that for the other steps in the citric acid cycle, is significantly positive ($\Delta G^{\circ\prime} = +29.7\ \text{kJ mol}^{-1}$, or $+7.1\ \text{kcal mol}^{-1}$). The oxidation of malate is driven by the use of the products — oxaloacetate by citrate synthase and NADH by the electron-transport chain.

Self-Check Question

Fluoroacetate is a toxic molecule that enters the citric acid cycle (CAC) due to its similarity to an acetyl group, but ultimately it inhibits the CAC. When fluoroacetate is added to mitochondria, fluorocitrate builds up. What step of the CAC is inhibited by fluoroacetate?

The citric acid cycle produces high-transfer-potential electrons, ATP, and CO_2

The net reaction of the citric acid cycle is

$$\text{Acetyl CoA} + 3\ \text{NAD}^+ + \text{FAD} + \text{ADP} + \text{P}_\text{i} + 2\ \text{H}_2\text{O} \rightarrow 2\ \text{CO}_2 + 3\ \text{NADH} + \text{FADH}_2 + \text{ATP} + 2\text{H}^+ + \text{CoA}$$

Let us recapitulate the reactions that give this stoichiometry (Figure 17.13 and Table 17.2) and summarize.

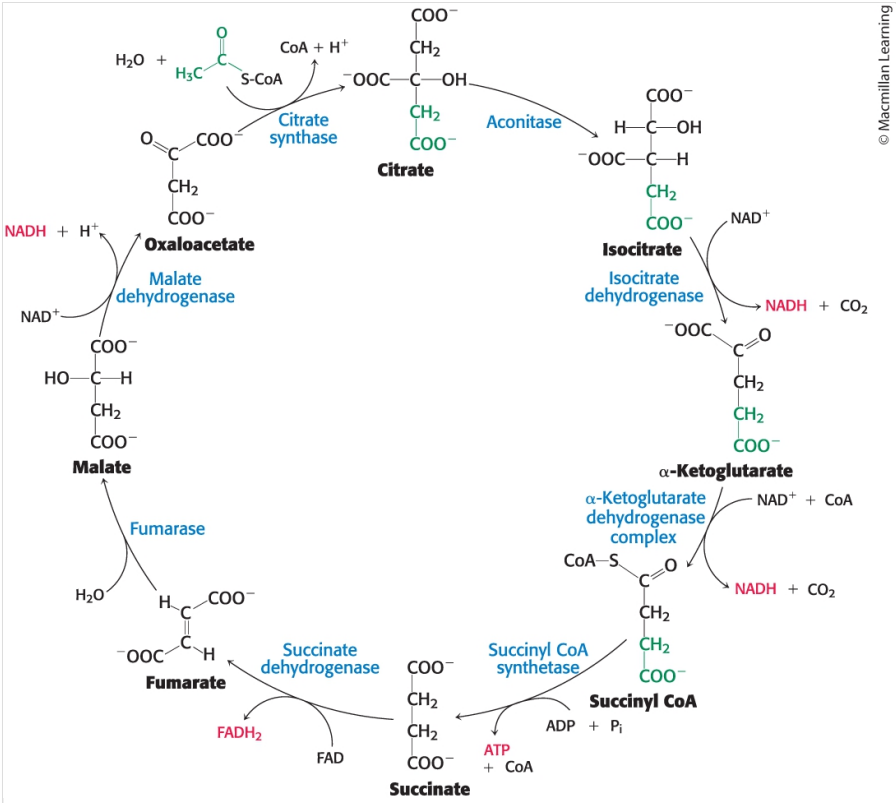


FIGURE 17.13 Eight enzyme-catalyzed reactions make up the full citric acid cycle. Notice that since succinate is a symmetric molecule, the identity of the carbons from the acetyl unit is lost.

*Reaction type: (a) condensation; (b) dehydration; (c) hydration; (d) decarboxylation; (e) oxidation; (f) substrate-level phosphorylation.

- Two carbon atoms enter the cycle in the condensation of an acetyl unit (from acetyl CoA) with oxaloacetate. Two carbon atoms leave the cycle in the form of CO_2 in the successive decarboxylations catalyzed by isocitrate dehydrogenase and α-ketoglutarate dehydrogenase.

- Four pairs of hydrogen atoms leave the cycle in four oxidation reactions. Two NAD^+ molecules are reduced in the oxidative decarboxylations of isocitrate and α-ketoglutarate, one FAD molecule is reduced in the oxidation of succinate, and one NAD^+ molecule is reduced in the oxidation of malate. Recall also that one NAD^+ molecule is reduced in the oxidative decarboxylation of pyruvate to form acetyl CoA.
- One compound with high phosphoryl-transfer potential, usually ATP, is generated from the cleavage of the thioester linkage in succinyl CoA.
- Two water molecules are consumed: one in the synthesis of citrate by the hydrolysis of citryl CoA and the other in the hydration of fumarate.

Isotope-labeling studies have revealed that the two carbon atoms that enter each cycle are not the ones that leave. The two carbon atoms that enter the cycle as the acetyl group are retained during the initial two decarboxylation reactions (Figure 17.13) and then remain incorporated in the four-carbon acids of the cycle. Note that succinate is a symmetric molecule. Consequently, the two carbon atoms that enter the cycle can occupy any of the carbon positions in the subsequent metabolism of the four-carbon acids. The two carbons that enter the cycle as the acetyl group will be released as CO_2 in later rounds of the cycle.

Various techniques, such as fluorescence recovery after photobleaching (FRAP, Section 12.5) and tandem mass spectroscopy analysis (Section 4.3), have established that there is a physical association of all of the enzymes of the citric acid cycle into a supramolecular complex. Recall that this close arrangement of enzymes allows for substrate channeling (Chapter 16), which enhances the efficiency of the citric acid cycle because a reaction product can pass directly from one active site to the next through connecting channels.

As will be considered in Chapter 18, the electron-transport chain oxidizes the NADH and $FADH_2$ formed in the citric acid cycle. The transfer of electrons from these carriers to O_2, the final electron acceptor, leads to the generation of a proton gradient across the inner mitochondrial membrane. This proton-motive force then powers the generation of ATP; the net stoichiometry is about 2.5 ATP per NADH, and 1.5 ATP per $FADH_2$. Consequently, nine high-transfer-potential phosphoryl groups are generated when the electron-transport chain oxidizes 3 NADH molecules and $1\ FADH_2$ molecule, and one ATP is directly formed in one round of the citric acid cycle. Thus, one acetyl unit generates approximately 10 molecules of ATP. In dramatic contrast, the anaerobic glycolysis of an entire glucose molecule generates only 2 molecules of ATP (and 2 molecules of lactate).

Recall that molecular oxygen does not participate directly in the citric acid cycle. However, the cycle operates only under aerobic conditions because NAD^+ and FAD can be regenerated in the mitochondrion only by the transfer of electrons to molecular oxygen. In contrast, glycolysis can proceed under anaerobic conditions because NAD^+ is regenerated in the conversion of pyruvate into lactate. Glycolysis has both an aerobic and an anaerobic mode, whereas the citric acid cycle is strictly aerobic.

Self-Check Question

The nucleoside trisphosphate produced directly in the citric acid cycle is sometimes GTP. Explain why a GTP molecule, or another nucleoside triphosphate, is energetically equivalent to an ATP molecule in metabolism.

17.4 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled

The citric acid cycle is the final common pathway for the aerobic oxidation of fuel molecules. Moreover, as we will see shortly (Section 17.5) and repeatedly elsewhere in our study of biochemistry, the cycle is an important source of building blocks for a host of important biomolecules. As befits its role as the metabolic hub of the cell, entry into the cycle and the rate of the cycle itself are controlled at several stages.

The pyruvate dehydrogenase complex is regulated allosterically and by reversible phosphorylation

As stated earlier, glucose can be formed from pyruvate. However, the formation of acetyl CoA from pyruvate is an irreversible step in animals and thus they are unable to convert acetyl CoA back into glucose. The oxidative decarboxylation of pyruvate to acetyl CoA commits the carbon atoms of glucose to one of two principal fates: oxidation to CO_2 by the citric acid cycle, with the concomitant generation of energy, or incorporation into lipids (**Figure 17.14**).

FIGURE 17.14 The synthesis of acetyl CoA by the pyruvate dehydrogenase complex is a key irreversible step in glucose metabolism.

EXPLORE this pathway further in the Metabolic Map in Achieve

As expected of an enzyme at a critical branch point in metabolism, the activity of the pyruvate dehydrogenase complex is tightly regulated. High concentrations of reaction products inhibit the reaction: acetyl CoA inhibits the transacetylase component (E_2) by binding directly, whereas NADH inhibits the dihydrolipoyl dehydrogenase (E_3). High concentrations of NADH and acetyl CoA inform the enzyme that the energy needs of the cell have been met or that fatty acids are being degraded to produce acetyl CoA and NADH. In either case, there is no need to metabolize pyruvate to acetyl CoA. This inhibition has the effect of conserving glucose, because most pyruvate is derived from glucose by glycolysis (Section 16.2).

The key means of regulation of the complex in eukaryotes is reversible covalent modification (**Figure 17.15**). Phosphorylation of the pyruvate dehydrogenase component (E_1) by one of four tissue-specific isozymes of pyruvate dehydrogenase kinase (PDK) switches off the activity of the complex. Deactivation is then reversed by one of two isozymes of pyruvate dehydrogenase phosphatase (PDP). In mammals, both the kinase and phosphatase are associated with the E_2-E_3-BP core complex, and the activities of both are regulated and subject to tissue-specific hormonal control.

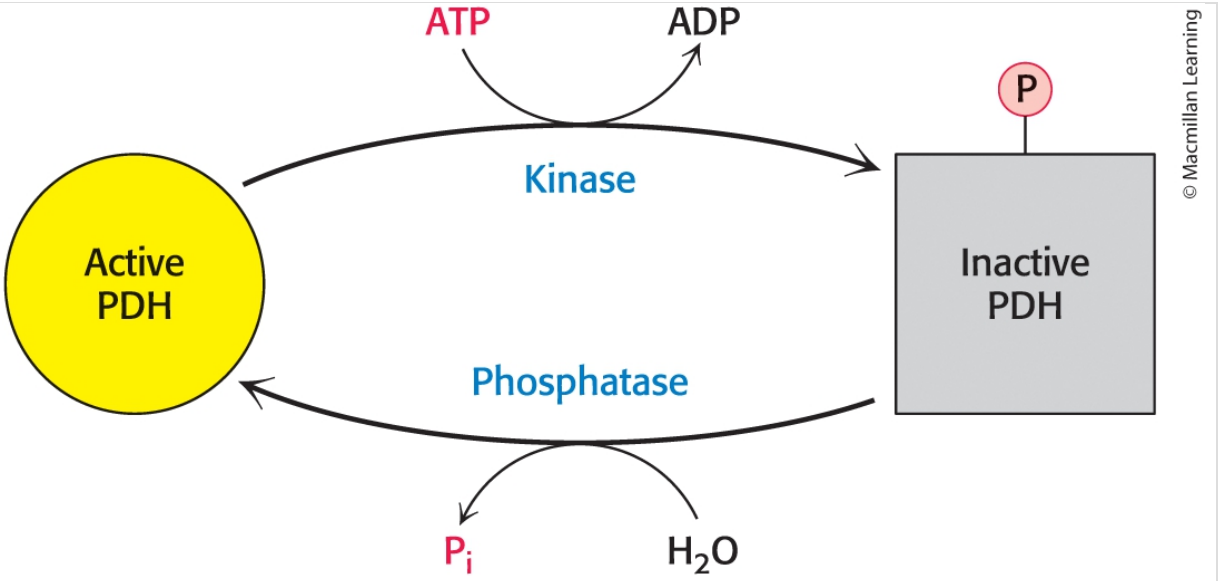

FIGURE 17.15 The activity of the pyruvate dehydrogenase complex is regulated by reversible phosphorylation. A specific kinase phosphorylates and inactivates pyruvate dehydrogenase (PDH), and a phosphatase activates the dehydrogenase by removing the phosphoryl group. The kinase and the phosphatase also are highly regulated enzymes.

To see how this regulation works in biological conditions, consider muscle that is becoming active after a period of rest (Figure 17.16). At rest, the muscle will not have significant energy demands. Consequently, the $NADH/NAD^+$, acetyl CoA/CoA, and ATP/ADP ratios will be high. These high ratios promote phosphorylation and inactivation of the complex by activating PDK. In other words, high concentrations of immediate products of the reaction (acetyl CoA and NADH) and a final product of the pathway (ATP) inhibit the activity. Thus, pyruvate dehydrogenase is switched off when the energy charge is high.

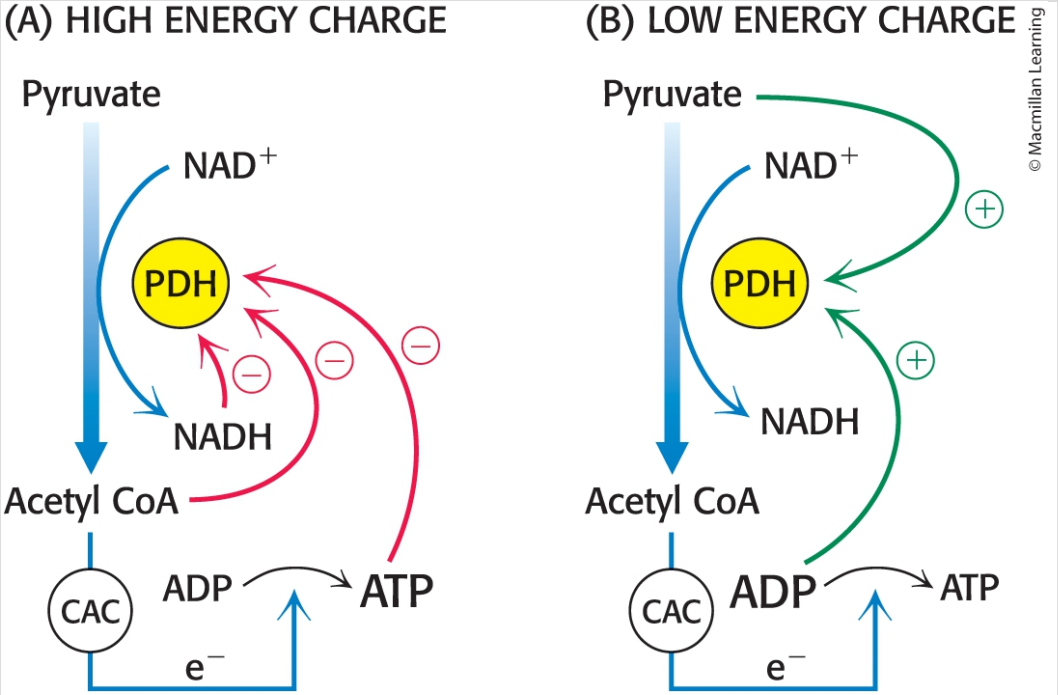

FIGURE 17.16 The pyruvate dehydrogenase complex responds to changes in the energy charge of the cell. (A) The complex (PDH) is inhibited by its immediate products, NADH and acetyl CoA, as well as by the ultimate product of the citric acid cycle (CAC) and oxidative phosphorylation, ATP. (B) PDH is activated by pyruvate and ADP, which inhibit the kinase that phosphorylates PDH.

As exercise begins, the concentrations of ADP and pyruvate will increase as muscle contraction consumes ATP and glucose is converted into pyruvate to meet the energy demands. Both ADP and pyruvate activate the dehydrogenase by inhibiting the kinase. Moreover, the phosphatase is stimulated by Ca^{2+}, the same signal that initiates muscle contraction. A rise in the cytoplasmic Ca^{2+} concentration increases the mitochondrial Ca^{2+} concentration. The rise in mitochondrial Ca^{2+} activates the phosphatase, enhancing pyruvate dehydrogenase activity.

In some tissues, the phosphatase is also controlled by hormones. For example, in liver tissue, epinephrine binds to the α-adrenergic receptor to initiate the phosphatidylinositol pathway (Section 14.2), causing an increase in Ca^{2+} concentration that activates the phosphatase. In tissues capable of fatty acid synthesis, such as liver and adipose tissue, insulin — the hormone that signifies the fed state — stimulates the phosphatase, increasing the conversion of pyruvate into acetyl CoA. Acetyl CoA is the precursor for fatty acid synthesis (Section 22.5). In these tissues, the pyruvate dehydrogenase complex is activated to funnel glucose to pyruvate and then to acetyl CoA and ultimately to fatty acids. In people with a pyruvate dehydrogenase phosphatase deficiency, pyruvate dehydrogenase is always phosphorylated and thus inactive. Consequently, glucose is processed to lactate rather than acetyl CoA, resulting in lactic acidosis. Lactic acidosis causes many tissues to malfunction, including the central nervous system.

Diabetic neuropathy may be due to inhibition of the pyruvate dehydrogenase complex

Diabetic neuropathy — a numbness, tingling, or pain in the hands, arm, fingers, toes, feet, and legs — is a common complication of both type 1 and type 2 diabetes, affecting approximately 50% of patients. There is no cure for the condition, and treatment relies on painkillers. Recent research in mice and tissue culture suggests that overproduction of lactic acid by cells in the dorsal root ganglion, a

part of the nervous system responsible for pain perception, may be a significant contributor.

Lactate, which is produced by some cells of the nervous system, is a common fuel for neurons, which import and convert it to pyruvate for use in cellular respiration. However, it appears that hyperglycemia (high glucose concentration), the defining feature of diabetes, increases pyruvate dehydrogenase kinase activity in the cells of the dorsal root ganglion, leading to inhibition of the pyruvate dehydrogenase complex. Glycolytically produced pyruvate is then processed to lactate. The overabundance of lactate leads to an increase in acid-sensing nociceptors (pain receptors), a type of G-protein-coupled receptor (Section 14.2), resulting in diabetic neuropathy. In experimental systems, three approaches — pharmacological inhibition of either pyruvate dehydrogenase kinase or lactic acid dehydrogenase, or genetic elimination of the kinase gene — greatly reduce, but do not eliminate, diabetic neuropathy. Thus, the search for good therapeutics shows promise but must continue.

The citric acid cycle is regulated at several points

The rate of the citric acid cycle is precisely adjusted to meet an animal cell's needs for ATP (**Figure 17.17**). Two allosteric enzymes primarily regulate the rate of cycling: isocitrate dehydrogenase and α-ketoglutarate dehydrogenase, the first two enzymes in the cycle to generate high-energy electrons.

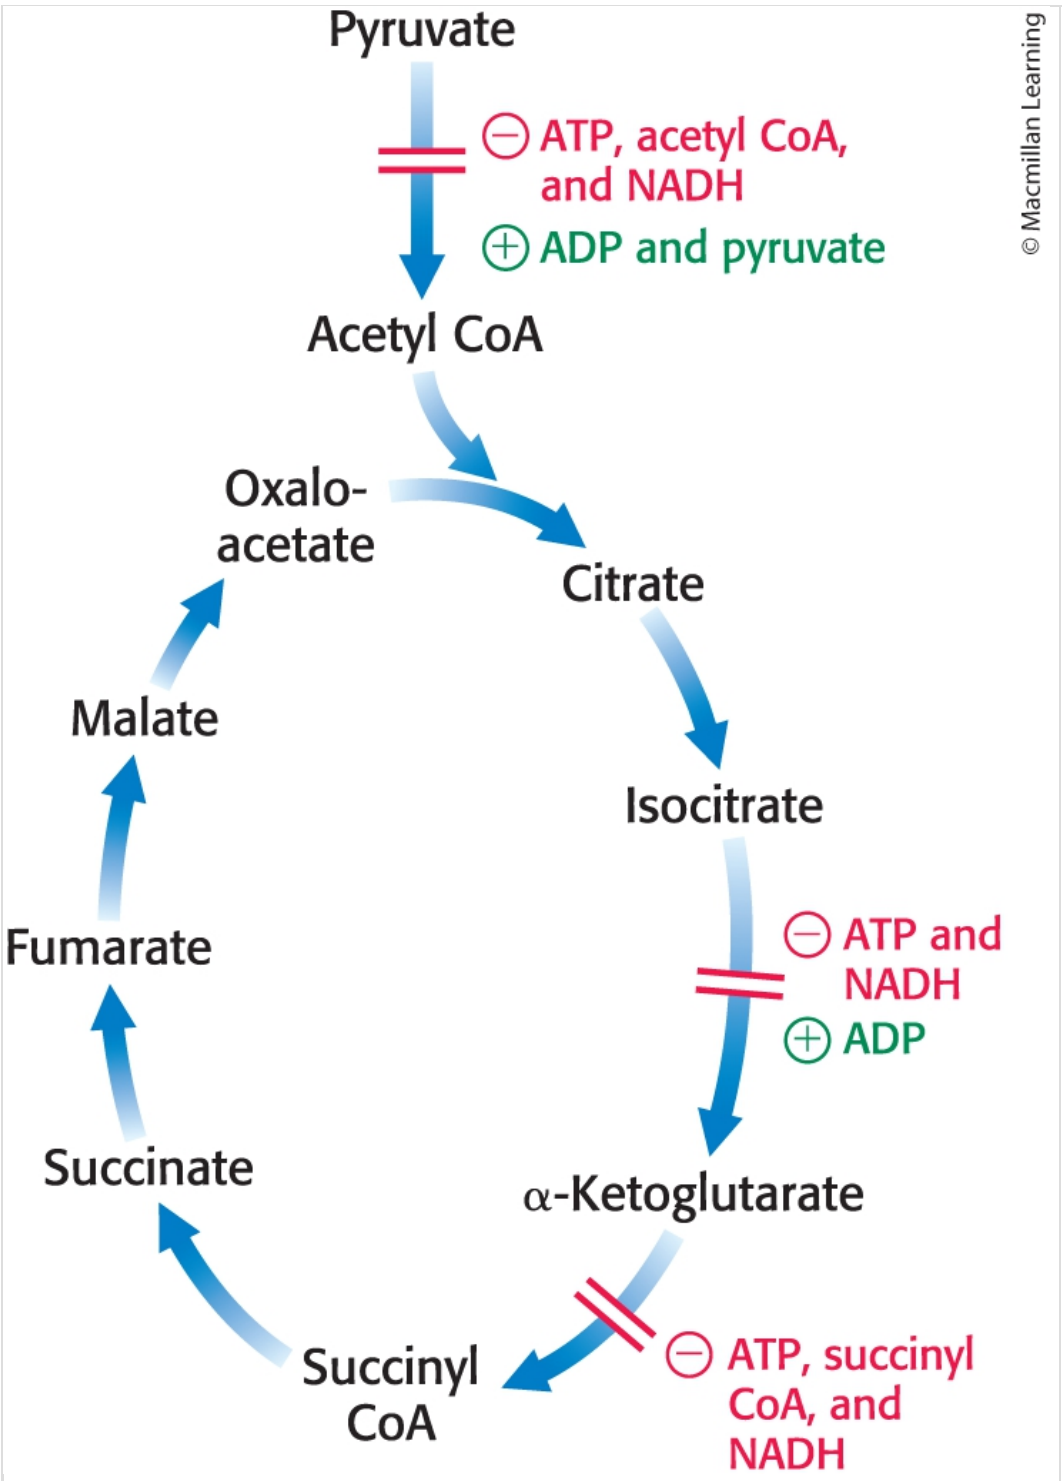

FIGURE 17.17 The citric acid cycle is regulated primarily by the concentrations of ATP and NADH. The key control points are the enzymes isocitrate dehydrogenase and α-ketoglutarate dehydrogenase.

1. *Isocitrate dehydrogenase is allosterically stimulated by ADP, which enhances the enzyme's affinity for substrates.* The binding of isocitrate, NAD^+, Mg^{2+}, and ADP are all mutually synergistic, whereas ATP is inhibitory. The reaction product NADH also inhibits isocitrate dehydrogenase by directly displacing NAD^+. It is important to note that several steps in the cycle require NAD^+ or FAD, which are abundant only when the energy charge is low.

2. The α-*ketoglutarate dehydrogenase complex catalyzes the rate-limiting step.* Some aspects of this enzyme complex's regulation are like those of the pyruvate dehydrogenase complex, as might be expected from the homology of the two enzymes. α-Ketoglutarate dehydrogenase is inhibited by succinyl CoA and NADH, the products of the reaction that it catalyzes. In addition, α-ketoglutarate dehydrogenase is inhibited by ATP, so that the rate of the citric acid cycle is reduced when cellular ATP is abundant. *α*-Ketoglutarate dehydrogenase deficiency is observed in a number of neurological disorders, including Alzheimer's disease.

In many bacteria, the synthesis of citrate from oxaloacetate and acetyl CoA carbon units is another important control point. In these organisms, ATP is an allosteric inhibitor of citrate synthase, causing an increase in the apparent value of K_M for acetyl CoA. The result is that as the level of ATP increases, less citrate synthase is bound to acetyl CoA and so less citrate is formed.

The use of isocitrate dehydrogenase and α-ketoglutarate dehydrogenase as points of regulation in human metabolism integrates the citric acid cycle with other pathways and highlights the central role of the citric acid cycle in metabolism. For instance, the inhibition of isocitrate dehydrogenase leads to a buildup of citrate, because the interconversion of isocitrate and citrate is readily reversible under intracellular conditions. Citrate can be transported to the cytoplasm, where it signals phosphofructokinase to halt glycolysis (Section 16.3) and where it can serve as a source of acetyl CoA for fatty acid synthesis (Section 22.5). The α-ketoglutarate that accumulates when α-ketoglutarate dehydrogenase is inhibited can be used as a precursor for several amino acids and the purine bases (Chapters 25 and 26). Finally, as we will explore in Chapter 24, defects in the citric acid cycle and related enzymes can lead to the formation of cancer.

Self-Check Question

The citric acid cycle is part of aerobic respiration, but no O_2 is required for the cycle. Explain this apparent paradox.

17.5 The Citric Acid Cycle Is a Source of Biosynthetic Precursors

Thus far, discussion has focused on the citric acid cycle as the major degradative pathway for the generation of ATP. As a major metabolic hub of the cell, the citric acid cycle also integrates many of the cell's other metabolic pathways, including those of carbohydrates, fats, amino acids, and porphyrins. This integration is aided by the fact that the cytoplasmic and mitochondrial pools of citric acid cycle components are shared, allowing the use of citric acid intermediates for biosyntheses taking place throughout the cell (**Figure 17.18**). For example, most of the carbon atoms in porphyrins come from succinyl CoA in a pathway that occurs both in the cytoplasm and mitochondria; fats are synthesized in the cytoplasm from mitochondrial citrate; and many of the amino acids, used throughout the cell, are derived from α-ketoglutarate and oxaloacetate. The details of these biosynthetic processes will be considered in subsequent chapters.

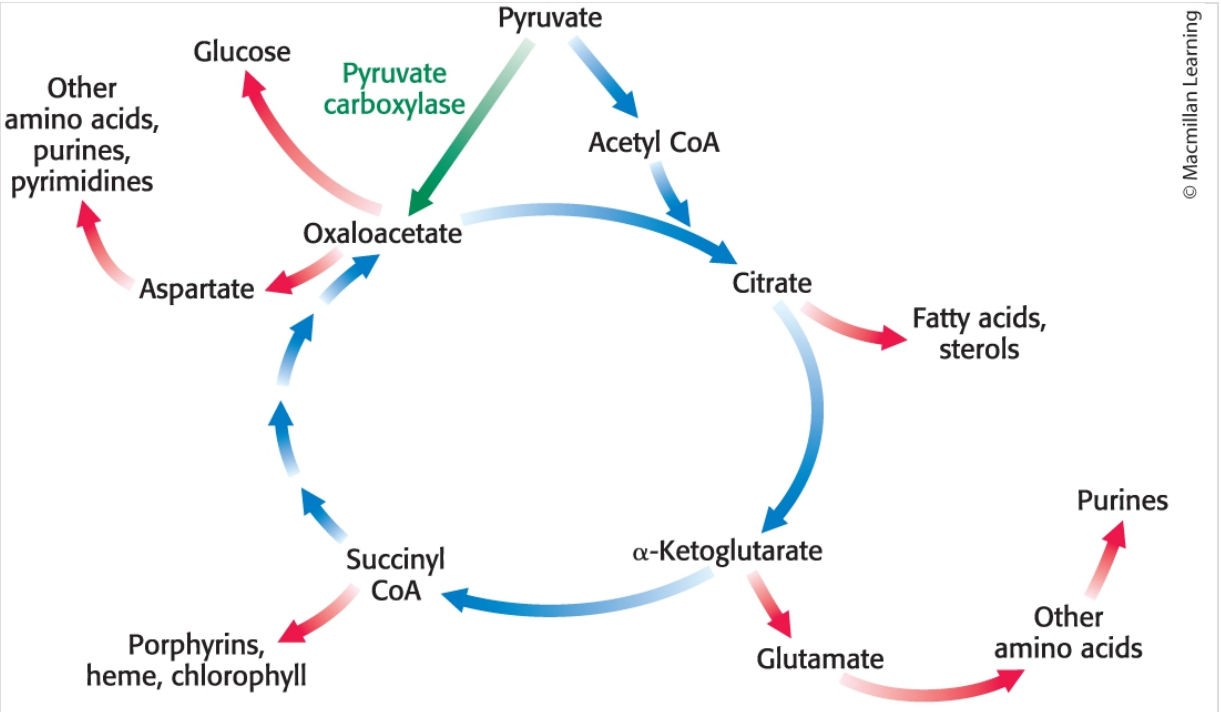

FIGURE 17.18 The citric acid cycle plays an important role in biosynthesis. Intermediates are drawn off for biosyntheses (shown by red arrows) when the energy needs of the cell are met. Intermediates are replenished by a variety of anaplerotic reactions, the most important of which is the formation of oxaloacetate from pyruvate by pyruvate carboxylase.

EXPLORE this pathway further in the Metabolic Map in Achieve

The citric acid cycle must be capable of being rapidly replenished

An important consideration is that citric acid cycle intermediates must be replenished if any are drawn off for biosyntheses. Suppose that much oxaloacetate is converted into amino acids for protein synthesis and, subsequently, the energy needs of the cell rise. The citric acid cycle will operate to a reduced extent unless new oxaloacetate is formed, because acetyl CoA cannot enter the cycle

unless it condenses with oxaloacetate. Even though oxaloacetate is recycled, a minimal level must be maintained to allow the cycle to function.

How is oxaloacetate replenished? Mammals lack the enzymes for the net conversion of acetyl CoA into oxaloacetate or any other citric acid cycle intermediate, so no matter how much acetyl CoA enters the cycle, there is never any *net* increase in the number of oxaloacetate molecules. Rather, oxaloacetate is formed by the carboxylation of pyruvate, in a reaction catalyzed by the biotin-dependent enzyme pyruvate carboxylase (Figure 17.18).

$$\text{Pyruvate} + CO_2 + \text{ATP} + H_2O \rightarrow \text{oxaloacetate} + \text{ADP} + P_i + 2H^+$$

Recall that this enzyme plays a crucial role in gluconeogenesis (Section 16.4). It is active only in the presence of acetyl CoA, which signifies the need for more oxaloacetate. If the energy charge is high, oxaloacetate is converted into glucose. If the energy charge is low, oxaloacetate replenishes the citric acid cycle. The synthesis of oxaloacetate by the carboxylation of pyruvate is an example of an **anaplerotic reaction** (*anaplerotic* is of Greek origin, meaning to "fill up"), a reaction that leads to the net synthesis, or replenishment, of pathway components. Note that because the citric acid cycle is a cycle, it can be replenished by the generation of any of the intermediates. For example, aspartate can be deaminated to also generate oxaloacetate. Glutamine is an especially important source of citric acid cycle intermediates in rapidly growing cells, including cancer cells. Glutamine is converted into glutamate and then into α-ketoglutarate (Section 23.5).

The disruption of pyruvate metabolism is the cause of beriberi and poisoning by mercury and arsenic

A neurologic and cardiovascular disorder known as **beriberi** is caused by a dietary deficiency of thiamine (also called *vitamin* B_1). The disease is prevalent in areas of the world where rice is the major food staple, because white rice has a rather low content of thiamine. This deficiency is partly overcome if the whole rice grain is soaked in water before milling, because some of the thiamine in the husk then leaches into the rice kernel. The problem is worsened if the rice is polished to remove the outer layer (that is, converted from brown to white rice), because only the outer layer contains significant amounts of thiamine. A common form of beriberi called *wet beriberi* is characterized by swelling in the abdomen and legs due to cardiac abnormalities.

Another form of beriberi, called *Wernicke's encephalopathy*, is also occasionally seen in alcoholics who are severely malnourished and thus thiamine deficient. The disease is characterized by neurologic and cardiac symptoms. Damage to the peripheral nervous system is expressed as pain in the limbs, weakness of the musculature, and distorted skin sensation. The heart may be enlarged and the cardiac output inadequate.

Which biochemical processes might be affected by a deficiency of thiamine? Thiamine is the precursor of the cofactor thiamine pyrophosphate (TPP). This cofactor is the prosthetic group of three important enzymes: pyruvate dehydrogenase, α-ketoglutarate

dehydrogenase, and transketolase. (Transketolase functions in the pentose phosphate pathway, which will be considered in Chapter 20.) The common feature of enzymatic reactions using TPP is the transfer of an activated aldehyde unit.

In patients with beriberi, the levels of pyruvate and α-ketoglutarate in the blood are higher than normal, and the increase in the level of pyruvate in the blood is especially pronounced after the ingestion of glucose. A related finding is that the activities of the pyruvate and α-ketoglutarate dehydrogenase complexes are abnormally low. The low transketolase activity of red blood cells in beriberi is an easily measured and reliable diagnostic indicator of the disease.

Why does TPP deficiency lead primarily to cardiac and neurological disorders? Heart tissue is highly sensitive to metabolic disruptions, as its need for ATP is never-ending and it has no appreciable stores of energy. The nervous system relies essentially on glucose as its only fuel. The product of glycolysis, pyruvate, can enter the citric acid cycle only through the pyruvate dehydrogenase complex. With that enzyme deactivated, the nervous system has no source of fuel. In contrast, most other tissues can use fats as a source of fuel for the citric acid cycle.

Symptoms similar to those of beriberi appear in organisms exposed to mercury or arsenite (AsO_3^{3-}). Both materials have a high affinity for neighboring (vicinal) sulfhydryls, such as those in the reduced dihydrolipoyl groups of the E_3 component of the pyruvate dehydrogenase complex (**Figure 17.19**). The binding of mercury or arsenite to the dihydrolipoyl groups inhibits the complex and leads to central nervous system pathologies. The proverbial phrase “mad as a hatter” refers to the strange behavior of poisoned hatmakers who used mercury nitrate, which is absorbed through the skin, to soften and shape animal furs. Similar symptoms afflicted the early

photographers, who used vaporized mercury to create daguerreotypes.

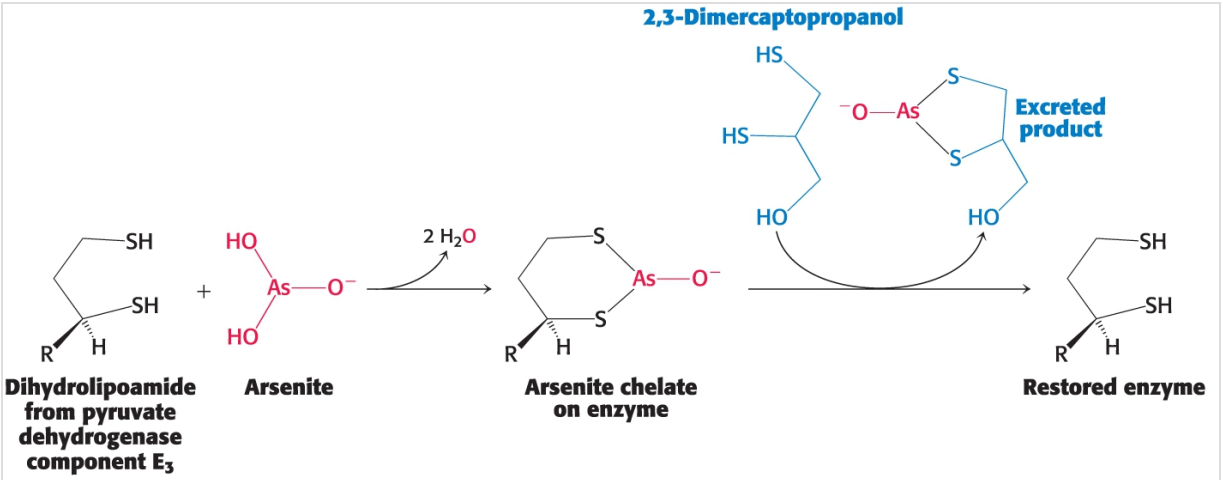

FIGURE 17.19 Arsenite inhibits the pyruvate dehydrogenase complex by inactivating the dihydrolipoamide component of the transacetylase. Some sulfhydryl reagents, such as 2,3-dimercaptoethanol, relieve the inhibition by forming a complex with the arsenite that can be excreted.

Treatment for these poisons is the administration of sulfhydryl reagents with adjacent sulfhydryl groups to compete with the dihydrolipoyl residues for binding with the metal ion. The reagent–metal complex is then excreted in the urine. Indeed, 2,3-dimercaptopropanol (Figure 17.19) was developed after World War I as an antidote to an arsenic-based chemical weapon.

The citric acid cycle likely evolved from preexisting pathways

How did the citric acid cycle come into being? Although definitive answers are elusive, informed speculation is possible. We can hypothesize how evolution might work at the level of biochemical pathways.

The citric acid cycle was most likely assembled from preexisting reaction pathways. As noted earlier, many of the intermediates formed in the citric acid cycle are used in metabolic pathways for amino acids and porphyrins. Thus, compounds such as pyruvate, α-ketoglutarate, and oxaloacetate were likely present early in evolution for biosynthetic purposes. The oxidative decarboxylation of these α-ketoacids is quite favorable thermodynamically and can be used to drive the synthesis of both acyl CoA derivatives and NADH. These reactions almost certainly formed the core of processes that preceded the citric acid cycle evolutionarily. Interestingly, α-ketoglutarate and oxaloacetate can be interconverted by transamination of the respective amino acids by aspartate aminotransferase, another key biosynthetic enzyme. Thus, cycles comprising smaller numbers of intermediates used for a variety of biochemical purposes could have existed before the present form evolved.

17.6 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate

Acetyl CoA that enters the citric acid cycle has but one fate: oxidation to CO_2 and H_2O. The citric acid cycle cannot convert acetyl CoA into glucose. Although oxaloacetate, a key precursor to glucose, is formed in the citric acid cycle, the two decarboxylations that take place before the regeneration of oxaloacetate preclude the *net* conversion of acetyl CoA into glucose.

However, in plants and in some microorganisms, there is a metabolic pathway that allows the conversion of acetyl CoA generated from fat stores into glucose. This reaction sequence, called the **glyoxylate cycle**, is similar to the citric acid cycle in some ways but different in that it bypasses the two decarboxylation steps of the cycle. Another important difference is that two molecules of acetyl CoA enter per turn of the glyoxylate cycle, compared with one in the citric acid cycle.

The glyoxylate cycle (**Figure 17.20**), like the citric acid cycle, begins with the condensation of acetyl CoA and oxaloacetate to form citrate, which is then isomerized to isocitrate. Instead of being decarboxylated, as in the citric acid cycle, isocitrate is cleaved by isocitrate lyase into succinate and glyoxylate. The ensuing steps regenerate oxaloacetate from glyoxylate. First, acetyl CoA condenses with glyoxylate to form malate in a reaction catalyzed by malate synthase, and then malate is oxidized to oxaloacetate, as in the citric acid cycle. The sum of these reactions is

$$2\ \text{Acetyl CoA} + \text{NAD}^+ + 2\ \text{H}_2\text{O} \rightarrow \text{succinate} + 2\ \text{CoA} + \text{NADH} + 2\ \text{H}^+$$

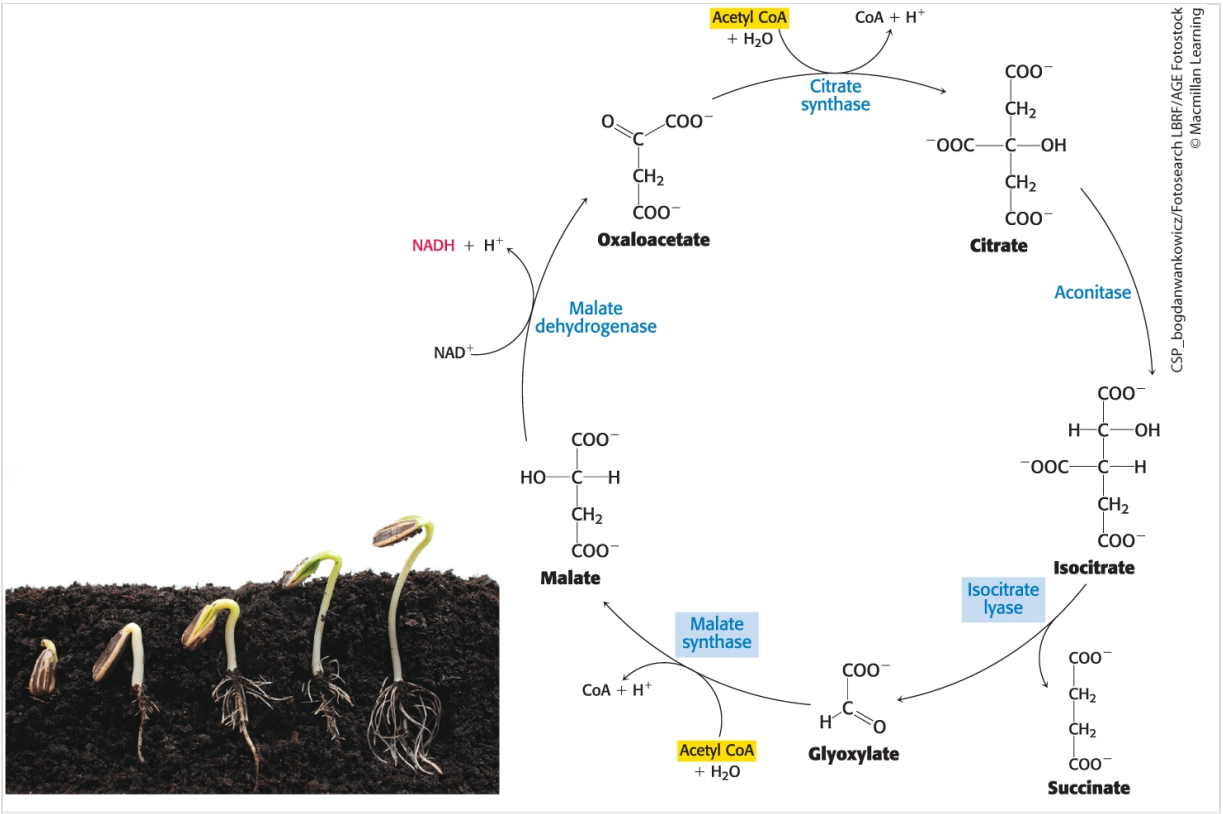

FIGURE 17.20 The glyoxylate cycle allows plants to use acetyl groups for biosynthesis. Plant seeds germinate using acetyl groups derived from stored triacylglycerides. The cycle bypasses the decarboxylation steps of the citric acid cycle and incorporates two acetyl groups per cycle. The reactions of this cycle are the same as those of the citric acid cycle except for the ones catalyzed by isocitrate lyase and malate synthase, which are boxed in blue.

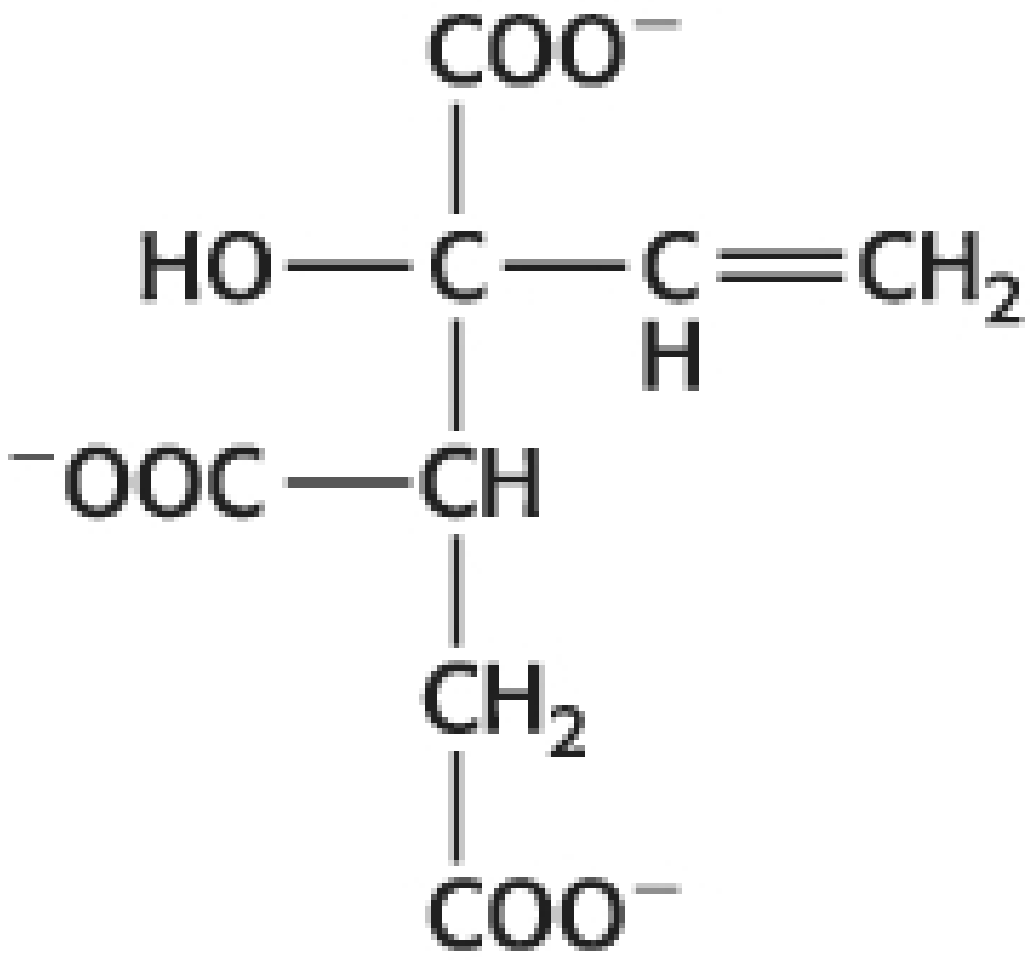
The glyoxylate cycle is especially prominent in oil-rich seeds, such as those from sunflowers, cucumbers, and castor beans, where it takes place in organelles called **glyoxysomes**. Succinate, released midcycle, can be converted into carbohydrates by a combination of the citric acid cycle and gluconeogenesis. The carbohydrates power

seedling growth until the cell can begin photosynthesis. Thus, organisms with the glyoxylate cycle gain metabolic versatility because they can use acetyl CoA as a precursor of glucose and other biomolecules.

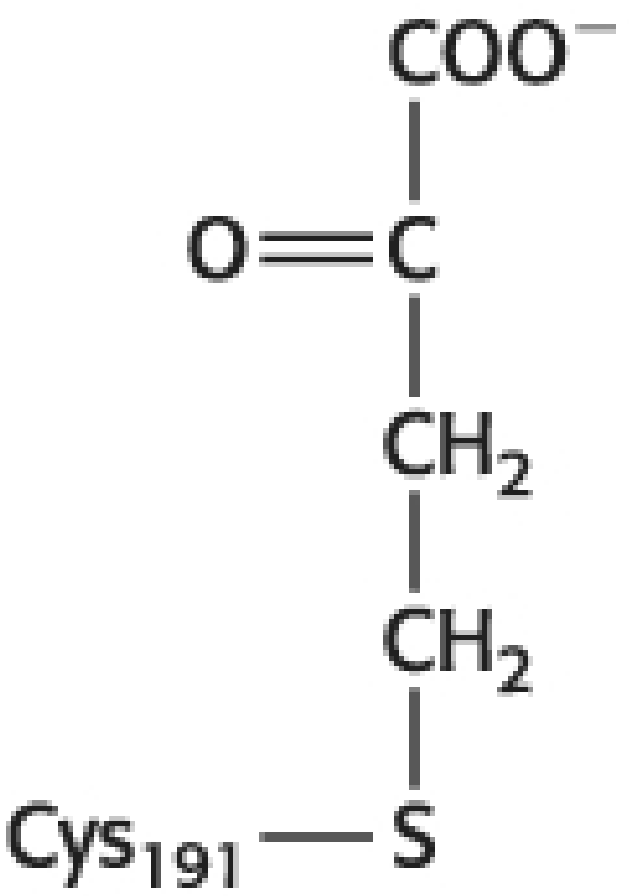
ZUMAPRESS.com/Keystone Pictures USA/AGE Fotostock

HANS KREBS The groundbreaking work of Hans Krebs, a German-born scientist of Jewish ancestry, resulted in his co-discoveries of the urea cycle (Chapter 23), the citric acid cycle (later named for him), and the glyoxylate cycle. Despite his tremendous successes, Krebs also experienced significant setbacks in his career. Foremost, following his work identifying the urea cycle as the first cyclic pathway in human metabolism, his life was upended when he was dismissed



from his position by the Nazi Party in 1933. Then, after moving to the University of Cambridge, UK, his paper announcing the elucidation of the citric acid cycle was famously rejected from the journal *Nature*, in 1937. For the rest of his life he proudly showed the rejection letter to younger scientists to encourage them to persevere in the face of adversity. Finally, experiments in 1941 appeared to discredit his work on the citric acid cycle (see problem 18 at the end of the chapter). This issue plagued him until it was finally resolved by another investigator in 1948. In 1953 Krebs received the Nobel Prize in Physiology or Medicine for his work in determining the pathways of central metabolism.

Blocking the glyoxylate cycle may lead to new treatments for tuberculosis



Tuberculosis (TB) is one of the leading causes of death throughout the world. In 2020, according to the World Health Organization, 10 million people contracted TB, including 1.1 million children, and 1.5 million people died from the disease. The bacterium responsible, *Mycobacterium tuberculosis*, is transmitted by people with active lung infections by coughing and sneezing. A common treatment for tuberculosis is the antibiotic rifampicin, an inhibitor of bacterial RNA synthesis (Chapter 31). However, strains of *M. tuberculosis* are developing resistance to rifampicin, so new treatments are urgently needed.

Some exciting new research suggests a possible treatment that relies on the bacterium's dependence on the glyoxylate cycle to convert fats to glucose, especially when in a latent (not actively dividing) state in the lungs. A suicide inhibitor or mechanism-based inhibitor (Section 5.6) for isocitrate lyase, 2-vinyl-isocitrate, has been synthesized that may halt the bacterium's metabolism.

2-Vinyl-isocitrate

During catalysis, a reactive thiolate is formed on $^{Cys}_{191}$ in the active site. When the lyase reacts with the inhibitor, succinate is released as in the normal reaction, but a thioether-linked homopyruvoyl moiety is covalently linked to $^{Cys}_{191}$, inhibiting the enzyme.

Homopyruvoyl-modified isocitrate lyase

This development may be an important opening into TB therapy because the active site $^{Cys}{}_{191}$ is conserved in all strains of *M. tuberculosis*, which reduces the likelihood of the development of resistance to the treatment. Although this research is quite new, it will be interesting to see if this ultimately leads to an effective medication for TB.

Chapter 17 Summary

17.1 The Citric Acid Cycle Harvests High-Energy Electrons

- The citric acid cycle is the final common pathway for the oxidation of fuel molecules and also serves as a source of building blocks for biosyntheses.
- Most fuel molecules enter the cycle as acetyl CoA.

17.2 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle

- The link between glycolysis and the citric acid cycle is the oxidative decarboxylation of pyruvate to form acetyl CoA by a massive three-enzyme complex.
- In eukaryotes, this reaction and those of the cycle take place inside mitochondria, in contrast with glycolysis, which takes place in the cytoplasm.

17.3 The Citric Acid Cycle Oxidizes Two-Carbon Units

- The cycle starts with the condensation of oxaloacetate and the acetyl unit of acetyl CoA to produce citrate (the citrate synthase reaction).
- Two carbon atoms from acetyl CoA leave the cycle as CO_2 in two successive decarboxylations catalyzed by isocitrate dehydrogenase and α-ketoglutarate dehydrogenase, resulting in the formation of succinyl CoA.
- The thioester bond of succinyl CoA is cleaved by orthophosphate to yield succinate, and a nucleoside trisphosphate is concomitantly generated.
- Succinate is oxidized to fumarate, which is then hydrated to form malate. Finally, malate is oxidized to regenerate a

molecule of oxaloacetate for the next round of the cycle.
- In the four oxidation–reduction reactions in the cycle, three pairs of electrons are transferred to NAD^+ and one pair to FAD.

  These reduced electron carriers are subsequently oxidized by the electron-transport chain to generate approximately nine additional molecules of ATP.
- A total of 10 molecules of ATP are generated for each two-carbon fragment that is completely oxidized to H_2O and CO_2.

17.4 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled

- The citric acid cycle operates only under aerobic conditions because it requires a supply of NAD^+ and FAD, which are

  regenerated in oxidative phosphorylation. Consequently, the rate of the citric acid cycle depends on the need for ATP.
- The irreversible formation of acetyl CoA from pyruvate is an important regulatory point: the activity of the pyruvate dehydrogenase complex is stringently regulated by reversible phosphorylation.
- In eukaryotes, two enzymes in the citric acid cycle are also important for regulation: isocitrate dehydrogenase and α-ketoglutarate dehydrogenase. Energy-rich molecules decrease the activities of these regulatory enzymes.
- These mechanisms complement each other in reducing the rate of formation of acetyl CoA when the energy charge of the cell is high and when biosynthetic intermediates are abundant.

17.5 The Citric Acid Cycle Is a Source of Biosynthetic Precursors

- When the cell has adequate energy available, the citric acid cycle can provide a source of building blocks for a host of important biomolecules, such as nucleotide bases, proteins, and heme groups. This use depletes the cycle of intermediates.

- When the cycle again needs to metabolize fuel, anaplerotic reactions replenish the cycle intermediates.

17.6 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate

- The glyoxylate cycle enables plants and bacteria to subsist on acetate because it bypasses the two decarboxylation steps of the citric acid cycle.
- The glyoxylate cycle is especially prominent in oil-rich seeds where it takes place in glyoxysomes. The succinate produced can be converted into carbohydrates by a combination of the citric acid cycle and gluconeogenesis.

Key Terms

citric acid (tricarboxylic acid, TCA; Krebs) cycle (CAC)
acetyl CoA
pyruvate dehydrogenase complex
flavoprotein
iron–sulfur protein (nonheme iron protein)
α-ketoglutarate dehydrogenase complex
nucleoside diphosphokinase
anaplerotic reaction
beriberi
glyoxylate cycle
glyoxysome

Problems

1. Write the reaction that links glycolysis and the citric acid cycle. What is the enzyme that catalyzes the reaction? 1

2. Which of the following catalytic cofactors are required by the pyruvate dehydrogenase complex?

a. NAD^+, lipoic acid, thiamine pyrophosphate

b. NAD^+, biotin, thiamine pyrophosphate

c. NAD^+, FAD, lipoic acid

d. FAD, lipoic acid, thiamine pyrophosphate

3. The pyruvate dehydrogenase complex is mechanistically and structurally similar to which of the following?

a. Isocitrate dehydrogenase
b. α-Ketoglutarate dehydrogenase
c. Glyceraldehyde 3-phosphate dehydrogenase
d. Fumarase

4. What coenzymes are required by the pyruvate dehydrogenase complex? What are their roles? 1

5. Distinguish between catalytic coenzymes and stoichiometric coenzymes in the pyruvate dehydrogenase complex.

6. What is the $\Delta G^{\circ\prime}$ for the complete oxidation of the acetyl unit of acetyl CoA by the citric acid cycle?

7. Patients with pyruvate dehydrogenase deficiency show high levels of lactic acid in the blood. However, in some cases,

treatment with dichloroacetate (DCA), which inhibits the kinase associated with the pyruvate dehydrogenase complex, lowers lactic acid levels. 2

a. How does DCA act to stimulate pyruvate dehydrogenase activity?
b. What does this suggest about pyruvate dehydrogenase activity in patients who respond to DCA?

8.

a. Predict the effect of a mutation that enhances the activity of the kinase associated with the pyruvate dehydrogenase complex. 2
b. Predict the effect of a mutation that reduces the activity of the phosphatase associated with the pyruvate dehydrogenase complex.

9. Match each term with its description.

1. Acetyl CoA
2. Citric acid cycle
3. Pyruvate dehydrogenase complex
4. Thiamine pyrophosphate
5. Lipoic acid

1. Catalyzes the link between glycolysis and the citric acid cycle
2. Coenzyme required by transacetylase
3. Final product of pyruvate dehydrogenase
4. Catalyzes the formation of acetyl CoA
5. Regenerates active transacetylase
6. Fuel for the citric acid cycle

6. Pyruvate dehydrogenase
7. Acetyllipoamide
8. Dihydrolipoyl transacetylase
9. Dihydrolipoyl dehydrogenase
10. Beriberi

7. Coenzyme required by pyruvate dehydrogenase
8. Catalyzes the oxidative decarboxylation of pyruvate
9. Due to a deficiency of thiamine
10. Central metabolic hub

---

10. Match each enzyme with its description.

1. Pyruvate dehydrogenase complex
2. Citrate synthase
3. Aconitase
4. Isocitrate dehydrogenase
5. α-Ketoglutarate dehydrogenase
6. Succinyl CoA synthetase
7. Succinate dehydrogenase
8. Fumarase

1. Catalyzes the formation of isocitrate
2. Synthesizes succinyl CoA
3. Generates malate
4. Generates ATP
5. Converts pyruvate into acetyl CoA
6. Converts pyruvate into oxaloacetate
7. Condenses oxaloacetate and acetyl CoA

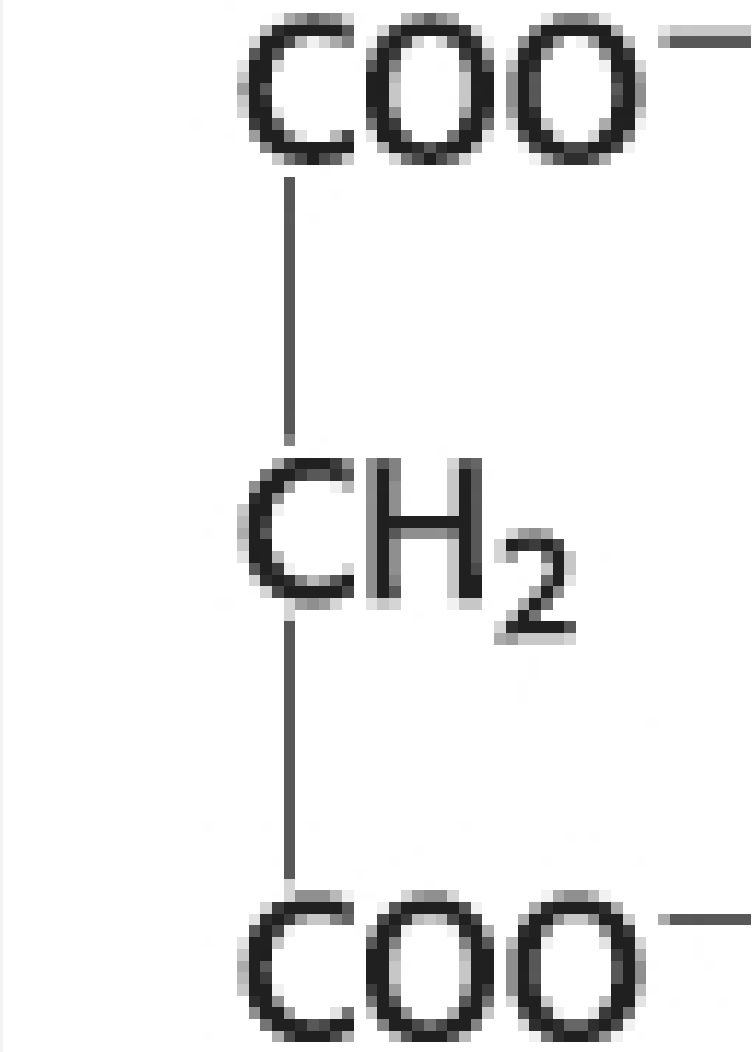
9. Malate dehydrogenase	9. Synthesizes fumarate
10. Pyruvate carboxylase	10. Catalyzes the formation of α-ketoglutarate

---



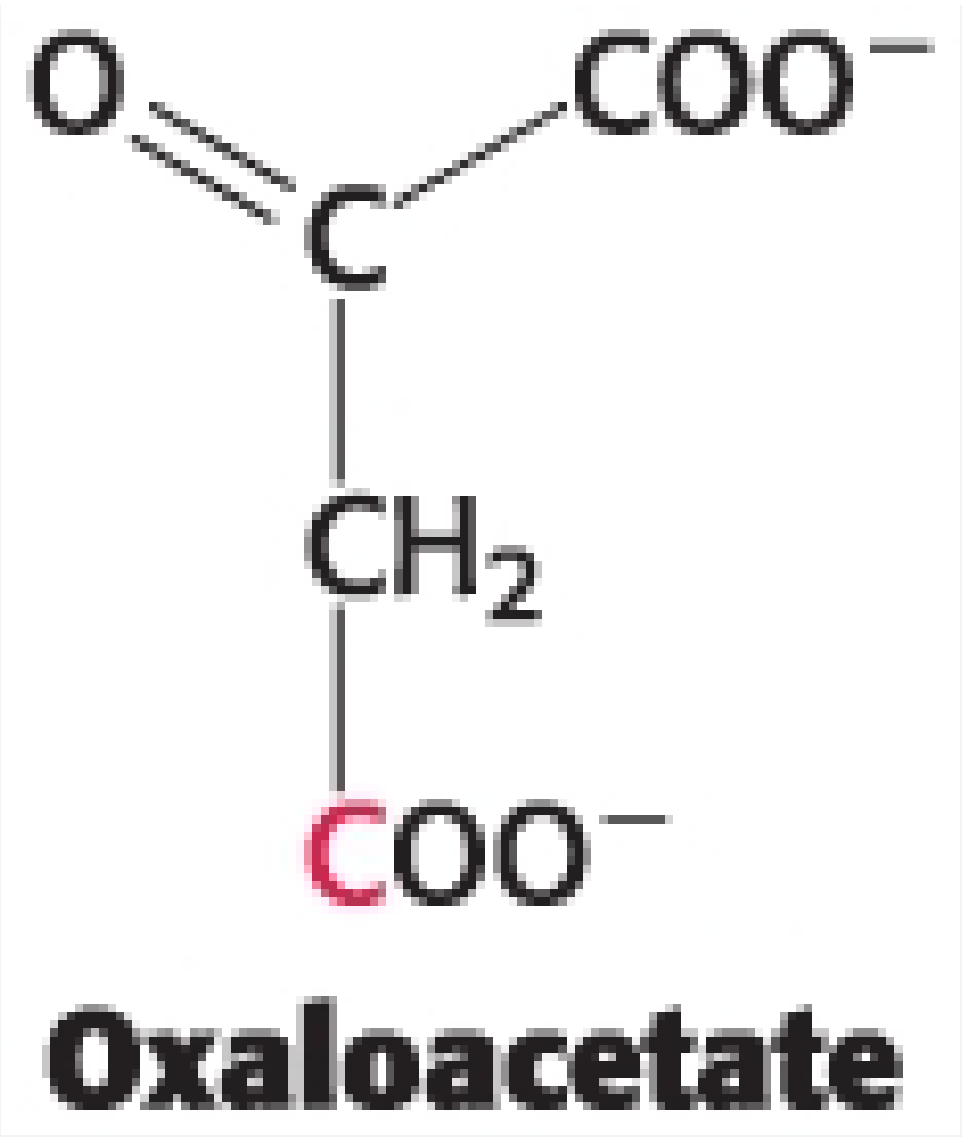
11. How is succinate dehydrogenase unique compared with the other enzymes in the citric acid cycle?

12. The oxidation of malate by NAD^+ to form oxaloacetate is a highly endergonic reaction under standard conditions [$\Delta G^{\circ\prime} = 29\ kJ\ mol^{-1}\ (7\ kcal\ mol^{-1})$]. The reaction proceeds readily under physiological conditions. 4

a. Explain why the reaction proceeds as written under physiological conditions.
b. Assuming an $[NAD^+]/[NADH]$ ratio of 8 and a pH of 7, what is the lowest [malate]/[oxaloacetate] ratio at which oxaloacetate can be formed from malate?

13. It is possible, with the use of the reactions and enzymes considered in this chapter, to convert pyruvate into α-ketoglutarate without depleting any of the citric acid cycle components. Write a balanced reaction scheme for this conversion, showing cofactors and identifying the required enzymes. 6

14. Malonate is a competitive inhibitor of succinate dehydrogenase. How will the concentrations of citric acid cycle intermediates change immediately after the addition of malonate? Why is malonate not a substrate for succinate dehydrogenase?



Malonate

15. What is the chief benefit of being able to perform the glyoxylate cycle? 7

16. Fats are usually metabolized into acetyl CoA and then further processed through the citric acid cycle. In Chapter 16, we saw that glucose can be synthesized from oxaloacetate, a citric acid cycle intermediate. Why, then, after a long bout of exercise depletes our carbohydrate stores, do we need to replenish those stores by eating carbohydrates? Why do we not simply replace them by converting fats into carbohydrates?

17. As we will see (Chapter 22), fatty acid breakdown generates a large amount of acetyl CoA. What will be the effect of fatty acid breakdown on pyruvate dehydrogenase complex activity? On glycolysis? 2

18. In experiments carried out in 1941 to investigate the citric acid cycle, oxaloacetate labeled with ^{14}C in the carboxyl carbon atom farthest from the keto group was introduced to an active preparation of mitochondria.

Analysis of the α-ketoglutarate formed showed that none of the radioactive label had been lost. Decarboxylation of α-ketoglutarate then yielded succinate devoid of radioactivity. All the label was in the released CO_2.

a. Why were the early investigators of the citric acid cycle surprised that *all* the label emerged in the CO_2? (*Note: you should answer this question first before reading any further.*)
b. The interpretation of these experiments was that citrate (or any other symmetric compound) cannot be an intermediate in the formation of α-ketoglutarate, because of the asymmetric fate of the label, thus appearing to disprove Hans Krebs's assertions about the cycle. This view seemed compelling until Alexander Ogston incisively pointed out in 1948 that "it is possible that an asymmetric enzyme which attacks a symmetrical compound can distinguish between its identical groups." For simplicity, consider a molecule in which two hydrogen atoms, a group X and a different group Y, are bonded to a tetrahedral carbon atom as a model for citrate. Explain how a symmetric molecule can react with an enzyme in an asymmetric way.

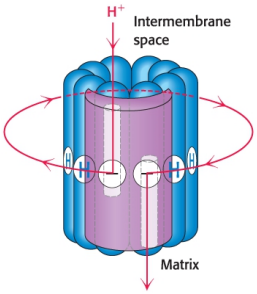
19. As will become clearer in Chapter 18, the activity of the citric acid cycle can be monitored by measuring the amount of O_2 consumed. The greater the rate of O_2 consumption, the faster the rate of the cycle. Hans Krebs used this assay to investigate the cycle in 1937. He used as his experimental system minced pigeon-breast muscle, which is rich in mitochondria. In one set of experiments, Krebs measured the O_2 consumption in the presence of carbohydrate only and in the presence of carbohydrate and citrate. The results are shown in the following table. 5

Effect of citrate on oxygen consumption by minced pigeon-breast muscle

	Micromoles of oxygen consumed	
Time (min)	**Carbohydrate only**	**Carbohydrate plus 3 µmol of citrate**
10	26	28
60	43	62
90	46	77
150	49	85

a. How much O_2 would be absorbed if the added citrate were completely oxidized to H_2O and CO_2?
b. On the basis of your answer to part (a), what do the results given in the table suggest?

20. The bacterium *Mycobacterium tuberculosis*, the cause of tuberculosis, can invade the lungs and persist in a latent state for years. During this time, the bacteria reside in granulomas — nodular scars containing bacteria and host-cell debris in the center and surrounded by immune cells. The granulomas are lipid-rich, oxygen-poor environments. How these bacteria manage to persist is something of a mystery. The results of research suggest that the glyoxylate cycle is required for the persistence. The following data show the amount of bacteria, presented as colony-forming units (cfu), in mice lungs in the weeks after an infection. 7



In graph A, the black circles represent the results for wild-type bacteria and the red circles represent the results for bacteria from which the gene for isocitrate lyase was deleted.

a. What is the effect of the absence of isocitrate lyase?

The techniques described in Chapter 9 were used to reinsert the gene encoding isocitrate lyase into bacteria from which it had previously been deleted. In graph B, black circles represent bacteria into which the gene was reinserted and red circles represent bacteria in which the gene was still missing.

b. Do these results support those obtained in part (a)?
c. What is the purpose of the experiment in part (b)?
d. Why do these bacteria perish in the absence of the glyoxylate cycle?

Chapter 18
Oxidative Phosphorylation

Waterwheels capture and convert the kinetic energy of water by rotating a wheel which spins a central axis, or rotor. While humans have used waterwheels for millennia to mill grains and accomplish many other tasks, nature beat humans in the race to develop a rotational motor by at least 1.5 billion years, prior to the divergence of eukaryotes and prokaryotes. Remarkably, ATP synthase, the final complex of the mitochondrial respiratory machinery, uses the flow of protons across a membrane to spin a protein wheel and rotor to generate ATP. This enzyme is the world's smallest rotary motor.

---

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the key components of the electron-transport chain and how they are arranged.
2. Explain the benefits of having the electron-transport chain located in a membrane.
3. Describe how the proton-motive force is converted into ATP.
4. Identify the ultimate determinant of the rate of cellular respiration.

The amount of ATP that human beings require to go about their lives is staggering: a sedentary person of 70 kg (154 lbs) requires about 8400 kJ (2000 kcal) for a day's worth of activity. To provide this much energy requires 83 kg of ATP. However, human beings possess only about 250 g of ATP at any given moment.

The disparity between the amount of ATP that we have and the amount that we require is compensated by recycling ADP back to ATP. Each ATP molecule is recycled approximately 300 times per day. This recycling takes place primarily through oxidative

phosphorylation. The process of oxidative phosphorylation finally completes the capture of chemical energy from glucose and its derivatives that originated with glycolysis.

18.1 Cellular Respiration Drives ATP Formation by Transferring Electrons to Molecular Oxygen

We begin our study of **oxidative phosphorylation** by examining the oxidation–reduction reactions that allow the flow of electrons from NADH and $FADH_2$ to oxygen. The electron flow takes place in four large protein complexes that are embedded in the inner mitochondrial membrane, together called the **respiratory chain** or the **electron-transport chain**.

$$NADH + {}^1/_2O_2 + H^+ \rightarrow H_2O + NAD^+$$
$$\Delta G^{\circ\prime} = -220.1\ \text{kJ mol}^{-1} (-52.6\ \text{kcal mol}^{-1})$$

The overall reaction is exergonic. Importantly, three of the complexes of the electron-transport chain use the energy released by the electron flow to pump protons out of the mitochondrial matrix. In essence, energy is transformed. The resulting unequal distribution of protons generates a pH gradient and a transmembrane electrical potential that creates a **proton-motive force**. ATP is synthesized when protons flow back to the mitochondrial matrix through an enzyme complex.

$$ADP + P_i + H^+ \rightarrow ATP + H_2O$$
$$\Delta G^{\circ\prime} = +30.5\ \text{kJ mol}^{-1} (+7.3\ \text{kcal mol}^{-1})$$

Thus, the oxidation of fuels and the phosphorylation of ADP are coupled by a proton gradient across the inner mitochondrial membrane (**Figure**

18.1). Collectively, the generation of high-transfer-potential electrons by the citric acid cycle, their flow through the respiratory chain, and the accompanying synthesis of ATP is called **respiration** or **cellular respiration**.

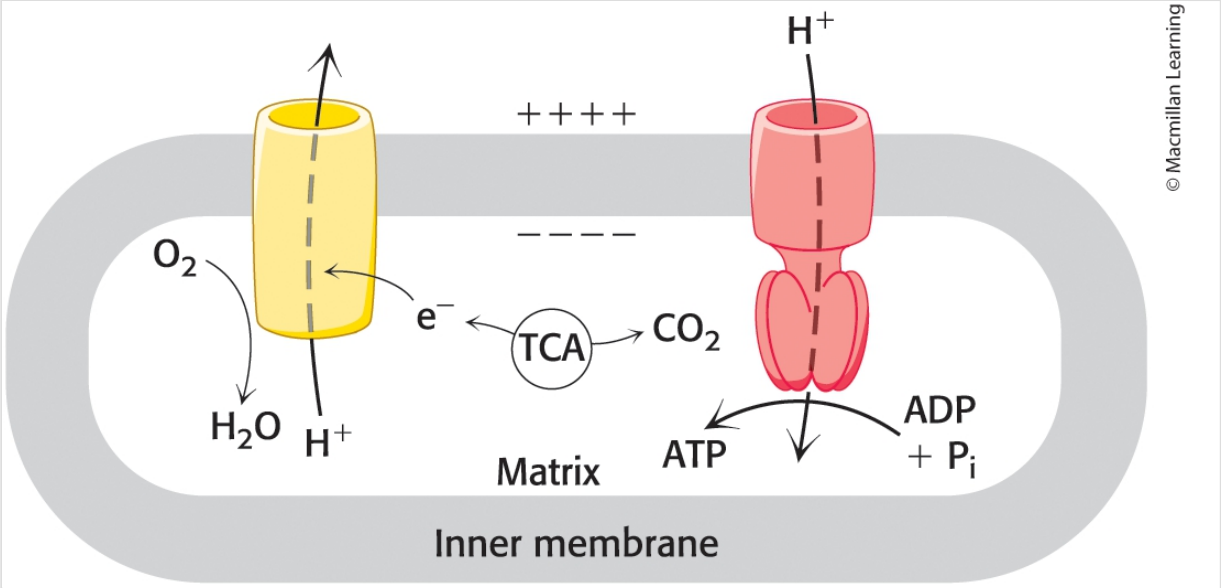

FIGURE 18.1 Oxidative phosphorylation is fundamentally the combination of two processes. Oxidation and ATP synthesis are coupled by transmembrane proton fluxes. Electrons from NADH and $FADH_2$, formed in the TCA cycle, flow through the electron-transport chain to reduce oxygen to water (yellow cylinder). Some components of the chain pump protons from the mitochondrial matrix to the intermembrane space. The protons return to the matrix by flowing through another protein complex, ATP synthase (red structure), powering the synthesis of ATP.

Eukaryotic oxidative phosphorylation takes place in mitochondria

Recall that a biochemical role of the citric acid cycle, which takes place in the mitochondrial matrix, is the generation of high-energy electrons. It is fitting, therefore, that oxidative phosphorylation, which will utilize

the energy of these electrons to create ATP, also takes place in mitochondria.

Electron microscopic studies revealed that mitochondria have two membranes: an *outer membrane* and an extensive, highly folded *inner membrane.* Hence, there are two compartments in mitochondria: (1) the **intermembrane space (IM space)** between the outer and the inner membranes and (2) the **matrix**, which is bounded by the inner membrane (**Figure 18.2**). The mitochondrial matrix is the site of most of the reactions of the citric acid cycle and fatty acid oxidation, whereas oxidative phosphorylation takes place in the inner mitochondrial membrane.

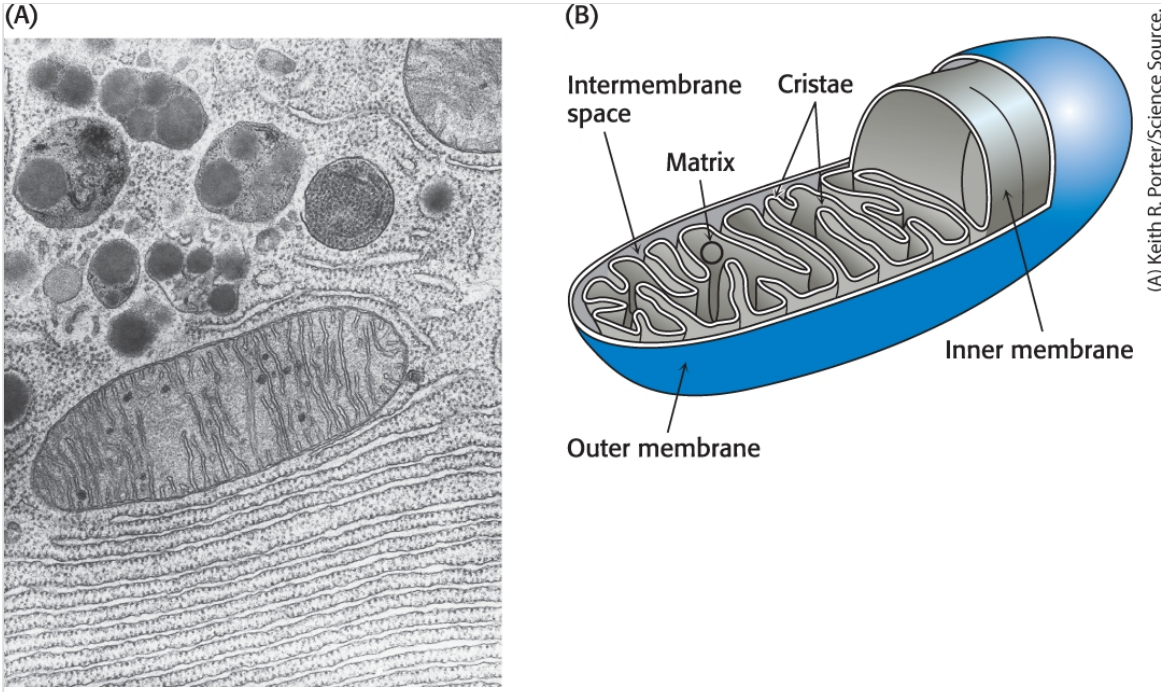

FIGURE 18.2 Mitochondria are bound by a double membrane, which creates two distinct internal compartments. (A) An electron micrograph and (B) a diagram of a mitochondrion. Mitochondria are oval-shaped organelles, typically ~2 μm in length and 0.5 μm in diameter, or approximately the size of a bacterium.

The inner membrane is folded into a series of internal ridges and tube-like structures collectively called *cristae*. The increase in surface area of the inner mitochondrial membrane provided by the cristae creates more sites for oxidative phosphorylation than would be the case with a simple, unfolded membrane. Humans contain an estimated $14{,}000\ m^2$ of inner mitochondrial membrane, which is the approximate equivalent of three football fields in the United States.

The outer membrane is quite permeable to most small molecules and ions because it contains mitochondrial porin, a 30- to 35-kDa pore-forming protein also known as VDAC, for voltage-dependent anion channel. VDAC, the most prevalent protein in the outer mitochondrial membrane, plays a role in the regulated flux of metabolites — usually anionic species such as phosphate, chloride, organic anions, and the adenine nucleotides — across the outer membrane. In contrast, the inner membrane is impermeable to nearly all ions and polar molecules. A large family of transporters shuttles metabolites such as ATP, pyruvate, and citrate across the inner mitochondrial membrane. The two faces of this membrane will be referred to as the *matrix side* and the *cytoplasmic side* (the latter because it is freely accessible to most small molecules in the cytoplasm). They are also called the *N* and *P* sides, respectively, because the membrane potential is negative on the matrix side and positive on the cytoplasmic side (Figure 18.1).

In bacteria, the electron-driven proton pumps and ATP-synthesizing complexes are located in the cytoplasmic membrane, the inner of two membranes. In many bacteria, the outer membrane, like that of mitochondria, is permeable to most small metabolites because of the presence of porins.

Mitochondria are the result of an endosymbiotic event

Mitochondria are semiautonomous organelles that live in an endosymbiotic relationship with the host cell. These organelles contain their own DNA, which encodes a variety of different proteins and RNAs. The genomes of mitochondria range broadly in size across species. Human mitochondrial DNA comprises 16,569 bp and encodes 13 respiratory-chain proteins as well as the small and large ribosomal RNAs and enough tRNAs to translate all codons. However, mitochondria also contain many proteins encoded by nuclear DNA. Cells that contain mitochondria depend on these organelles for oxidative phosphorylation, and the mitochondria in turn depend on the cell for their very existence. How did this intimate symbiotic relationship come to exist?

It is now well established that an endosymbiotic event occurred in the evolution of eukaryotic organisms in which a free-living organism capable of oxidative phosphorylation was engulfed by another cell. Formerly a hypothesis famously championed by biologist Lynn Margulis, this explanation of the origins of both mitochondria and chloroplasts is now widely accepted as the *endosymbiotic theory*. The shape, size, double-membrane, and circular DNA (with exceptions) all resemble characteristics of some gram-negative bacteria; however, it is the evidence from DNA sequences that is conclusive. Thanks to the rapid accumulation of sequence data for mitochondrial and bacterial genomes, speculation on the origin of the first mitochondrion with some authority is now possible. The most mitochondrial-like bacterial genome is that of *Rickettsia prowazekii,* the cause of louse-borne typhus. The genome for this organism is more than 1 million base pairs in size and contains 834 protein-encoding genes. Sequence data suggest that all extant mitochondria are derived from an ancestor of *R. prowazekii* as the result of a single endosymbiotic event.

Nancy R. Schiff/Getty Images

LYNN MARGULIS The concept of an endosymbiotic origin for mitochondria and chloroplasts, first proposed over a century ago, was quite controversial for decades. In 1967, Professor Lynn Margulis (then Lynn Sagan) published a 50-page paper, “On the Origin of Mitosing Cells,” with an extensive analysis of the characteristics of different groups of unicellular organisms and possible endosymbiotic events. She and others continued to collect evidence to support the claims in the paper, but the scientific community remained skeptical of the endosymbiosis hypothesis for many

years. Eventually, many lines of evidence came together to support the conclusion that chloroplasts and mitochondria each arose from independent endosymbiotic events more than 1 billion years ago. Margulis received the National Medal of Science in 1999 and has been described as a “vindicated heretic.”

The evidence that modern mitochondria result from a single event comes from examination of the most bacteria-like mitochondrial genome, that of the protozoan *Reclinomonas americana.* Its genome contains 97 genes, of which 62 specify proteins. The genes encoding these proteins include all of the protein-coding genes found in all of the sequenced mitochondrial genomes. Yet, this genome encodes less than 2% of the protein-coding genes in the bacterium *E. coli.* In other words, a small fraction of bacterial genes — 2% — is found in all examined mitochondria.

How is it possible that all mitochondria have the same 2% of the bacterial genome? It seems unlikely that mitochondrial genomes resulting from several endosymbiotic events could have been independently reduced to the same set of genes found in *R. americana.* What was the fate of the mitochondrial genes no longer harbored by the mitochondria? The reduced genomes of the mitochondria are the result of endosymbiotic gene transfer, in which the mitochondrial genes became part of the nuclear genome. Thus, the original bacterial cell lost DNA, making it incapable of independent living, and the host cell became dependent on the ATP generated by its tenant.

Self-Check Question

Name the cellular compartments and membranes, in order, that a molecule passes through when traveling from the cytosol into the center of a mitochondrion. Additionally, what are the ridges and tube-like structures in a mitochondrion called, and what membrane are they made from?

18.2 Oxidative Phosphorylation Depends on Electron Transfer

In Chapter 17, the generation of NADH and $FADH_2$ by the oxidation of acetyl CoA was identified as an important function of the citric acid cycle. In oxidative phosphorylation, electrons from NADH and $FADH_2$ are used to reduce molecular oxygen to water. The highly exergonic reduction is accomplished by a number of electron-transfer reactions, which take place in a set of membrane proteins known as the electron-transport chain.

The electron-transfer potential of an electron is measured as redox potential

In oxidative phosphorylation, the *electron*-transfer potential of NADH or $FADH_2$ is converted into the *phosphoryl*-transfer potential of ATP. To better understand this conversion, we need quantitative expressions for these forms of free energy. The measure of phosphoryl-transfer potential is already familiar to us: it is given by $\Delta G^{\circ\prime}$ for the hydrolysis of the activated phosphoryl compound. The corresponding expression for the electron-transfer potential is E'_0, the **reduction potential** (also called the **redox potential** or **oxidation–reduction potential**).

Consider a substance that can exist in an oxidized form X and a reduced form X^-. Such a pair is called a *redox couple* and is designated $X : X^-$. The reduction potential of this couple can be determined by measuring the electromotive force generated by an apparatus called a *sample half-cell* connected to a *standard reference half-cell* (**Figure 18.3**). The sample half-cell consists of an electrode immersed in a solution of 1 M oxidant (X) and 1 M reductant (X^-). The standard reference half-cell consists of an electrode immersed in a $1\ M\ H^+$ solution that is in equilibrium with H_2 gas at 1 atm of pressure. The electrodes are connected to a voltmeter, and an agar bridge allows ions to move from one half-cell to the other, establishing electrical continuity between the half-cells. Electrons then flow from one half-cell to the other through the wire connecting the two half-cells to the voltmeter. If the reaction proceeds in the direction

$$X^- + H^+ \rightarrow X + {}^1/_2\ H_2$$

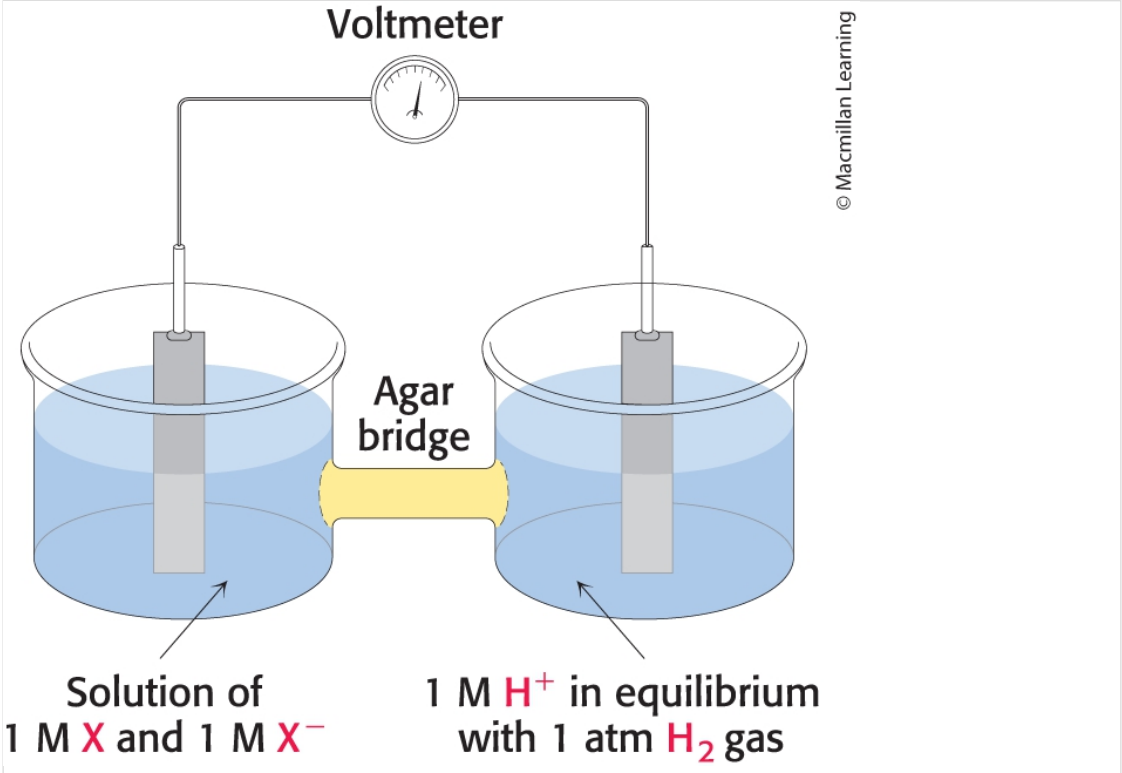

FIGURE 18.3 Redox potential can be precisely measured. In the apparatus for the measurement of the standard oxidation–reduction potential of a redox couple, electrons flow through the wire connecting the cells, whereas ions flow through the agar bridge.

the reactions in the half-cells (referred to as *half-reactions* or *couples*) must be

$$X^- \rightarrow X + e^- \qquad H^+ + e^- \rightarrow \tfrac{1}{2} H_2$$

Thus, electrons flow from the sample half-cell to the standard reference half-cell, and the sample-cell electrode is taken to be negative with respect to the standard-cell electrode. The reduction potential of the $X : X^-$ couple is the observed voltage at the start of the experiment (when X, X^-, and H^+ are 1 M with 1 atm of H_2). The reduction potential of the $H^+ : H_2$ couple is defined to be 0 volts. In oxidation–reduction reactions, the donor of electrons, in this case X^-, is called the *reductant* or *reducing agent*, whereas the acceptor of electrons, H^+ here, is called the *oxidant* or *oxidizing agent*.

The meaning of the reduction potential is now evident. A negative reduction potential means that the oxidized form of a substance has lower affinity for electrons than does H_2, as in the preceding example. A positive reduction potential means that the oxidized form of a substance has higher

affinity for electrons than does H_2. These comparisons refer to standard conditions — namely, 1 M oxidant, 1 M reductant, $1\ M\ H^+$, and 1 atm H_2. Thus, a strong reducing agent (such as NADH) is poised to donate electrons and has a negative reduction potential, whereas a strong oxidizing agent (such as O_2) is ready to accept electrons and has a positive reduction potential.

The reduction potentials of many biologically important redox couples are known (**Table 18.1**). Table 18.1 is like those presented in chemistry textbooks, except that a hydrogen ion concentration of $10^{-7}\ M$ (pH 7) instead of 1 M (pH 0) is the standard state adopted by biochemists. This difference is denoted by the prime in E'_0. Recall that the prime in $\Delta G^{\circ\prime}$ denotes a standard free-energy change at pH 7.

TABLE 18.1 Standard reduction potentials of some reactions

Oxidant	Reductant	*n*	E'_0 (V)
Succinate + CO_2	α-Ketoglutarate	2	−0.67
Acetate	Acetaldehyde	2	−0.60
Ferredoxin (oxidized)	Ferredoxin (reduced)	1	−0.43
$2\ H^+$	H_2	2	−0.42
NAD^+	$NADH + H^+$	2	−0.32
$NADP^+$	$NADPH + H^+$	2	−0.32
Lipoate (oxidized)	Lipoate (reduced)	2	−0.29
Glutathione (oxidized)	Glutathione (reduced)	2	−0.23
FAD	$FADH_2$	2	−0.22
Acetaldehyde	Ethanol	2	−0.20
Pyruvate	Lactate	2	−0.19

TABLE 18.1 Standard reduction potentials of some reactions

$2\ H^+$	H_2	2	0.00[1]
Fumarate	Succinate	2	−0.03
Cytochrome *b* $(+3)$	Cytochrome *b* $(+2)$	1	+0.07
Dehydroascorbate	Ascorbate	2	+0.08
Ubiquinone (oxidized)	Ubiquinone (reduced)	2	+0.10
Cytochrome *c* $(+3)$	Cytochrome *c* $(+2)$	1	+0.22
Fe $(+3)$	Fe $(+2)$	1	+0.77
$\frac{1}{2}\ O_2 + 2\ H^+$	H_2O	2	+0.82

Note: E'_0 is the standard oxidation–reduction potential (pH 7, 25°C), and *n* is the number of electrons transferred. E'_0 refers to the partial reaction written as $\text{Oxidant} + e^- \rightarrow \text{reductant}$.

[1] Standard oxidation − reduction potential at $pH = 0$. Compare with $E'_0 = -0.42$ at $pH = 7$.

The standard free-energy change $\Delta G^{\circ\prime}$ is related to the change in reduction potential $\Delta E'_0$ by

$$\Delta G^{\circ\prime} = -nF\Delta E'_0 \tag{1}$$

in which *n* is the number of electrons transferred, *F* is a proportionality constant called the *Faraday constant* ($96.48\ \text{kJ mol}^{-1}\text{V}^{-1}$ or $23.06\ \text{kcal mol}^{-1}\text{V}^{-1}$), $\Delta E'_0$ is in volts, and $\Delta G^{\circ\prime}$ is in kilojoules or kilocalories per mole.

The free-energy change of an oxidation–reduction reaction can be readily calculated from the reduction potentials of the reactants.

Example

Calculating the Standard Free Energy of a Reaction from Reduction Potentials

Problem:

Calculate $\Delta G^{\circ\prime}$ for the reduction of pyruvate by NADH, catalyzed by lactate dehydrogenase. Recall that this reaction maintains redox balance in lactic acid fermentation (see Figure 16.11).

$$\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{NAD}^+ \tag{A}$$

Getting Started:

From Table 18.1 we see that the reduction potential of the NAD^+ : NADH couple, or half-reaction, is $-0.32\ \text{V}$, whereas that of the pyruvate:lactate couple is $-0.19\ \text{V}$. By convention, reduction potentials (as in Table 18.1) refer to partial reactions written as reductions: $\text{oxidant} + \text{e}^- \rightarrow \text{reductant}$. Hence,

$$\text{Pyruvate} + 2\ \text{H}^+ + 2\ \text{e}^- \rightarrow \text{lactate} \quad E'_0 = -0.19\ \text{V} \tag{B}$$

$$\text{NAD}^+ + \text{H}^+ + 2\ \text{e}^- \rightarrow \text{NADH} \quad E'_0 = -0.32\ \text{V} \tag{C}$$

To obtain reaction A from reactions B and C, we need to reverse the direction of reaction C so that NADH appears on the left side of the arrow. In doing so, the sign of E'_0 must be changed.

$$\text{Pyruvate} + 2\ \text{H}^+ + 2\ \text{e}^- \rightarrow \text{lactate} \quad E'_0 = -0.19\ \text{V} \tag{B}$$

$$\text{NADH} \rightarrow \text{NAD}^+ + \text{H}^+ + 2\text{e}^- \quad E'_0 = +0.32\ \text{V} \tag{D}$$

Finally, recall that the Faraday constant is $96.48\ \text{kJ mol}^{-1}\ \text{K}^{-1}$.

Calculate:

Let's begin by calculating $\Delta G^{\circ\prime}$ for reaction B using equation 1 and substituting in the value of the Faraday constant and $n = 2$ since two electrons are exchanged.

$$\begin{aligned}\Delta G^{\circ\prime} &= -2 \times 96.48\ \text{kJ mol}^{-1}\,\text{V}^{-1} \times -0.19\ \text{V} \\ &= +36.7\ \text{kJ mol}^{-1}\end{aligned}$$

Likewise, for reaction D,

$$\begin{aligned}\Delta G^{\circ\prime} &= -2 \times 96.48\ \text{kJ mol}^{-1}\,\text{V}^{-1} \times +0.32\ \text{V} \\ &= -61.7\ \text{kJ mol}^{-1}\end{aligned}$$

Thus, the free energy for reaction A is given by

$$\begin{aligned}\Delta G^{\circ\prime} &= \Delta G^{\circ\prime}\,(\text{for reaction B}) + \Delta G^{\circ\prime}\,(\text{for reaction D}) \\ &= +36.7\ \text{kJ mol}^{-1} - 61.7\ \text{kJ mol}^{-1} \\ &= -25.0\ \text{kJ mol}^{-1}\ \text{or}\ -6.0\ \text{kcal mol}^{-1}\end{aligned}$$

Reflect:

What does $\Delta G^{\circ\prime}$ tell us? We can see from this result that under standard conditions the reaction is exergonic, releasing 25.0 kJ per mole. Thus, the reduction of pyruvate to lactate by NADH is spontaneous because electrons are more attracted to pyruvate than NAD^+. Note that all of this information was deduced entirely from the known reduction potentials.

Electron flow from NADH to molecular oxygen powers the formation of a proton gradient

Let's now consider the driving force of oxidative phosphorylation, which is the electron-transfer potential of NADH or $FADH_2$ relative to that of O_2. How much energy is released by the reduction of

O_2 with NADH? Let us calculate $\Delta G^{\circ\prime}$ for this reaction. The pertinent half-reactions are

$$\tfrac{1}{2}\,O_2 + 2\,H^+ + 2e^- \rightarrow H_2O \quad E'_0 = +0.82\ V$$
$$NAD^+ + H^+ + 2e^- \rightarrow NADH \quad E'_0 = -0.32\ V$$

The combination of the two half-reactions, as it proceeds in the electron-transport chain, yields

$$\tfrac{1}{2}O_2 + NADH + H^+ \rightarrow H_2O + NAD^+$$

The standard free energy for this reaction is then given by

$$\begin{aligned}\Delta G^{\circ\prime} &= (-2 \times 96.48\ kJ\ mol^{-1}V^{-1} \times +0.82\ V) \\ &\quad + (-2 \times 96.48\ kJ\ mol^{-1}V^{-1} \times +0.32\ V) \\ &= -158.2\ kJ\ mol^{-1} + (-61.9)\ kJ\ mol^{-1} \\ &= -220.1\ kJ\ mol^{-1}\ or\ -52.6\ kcal\ mol^{-1}\end{aligned}$$
