This release of free energy is substantial. Recall that $\Delta G^{\circ\prime}$ for the synthesis of ATP is $30.5\ kJ\ mol^{-1}$ $(7.3\ kcal\ mol^{-1})$. The released energy is initially used to generate a proton gradient that is then used for the synthesis of ATP and the transport of metabolites across the mitochondrial membrane.

How can the energy associated with a proton gradient be quantified? Recall from Section 13.1 that the free-energy change for a species moving from one side of a membrane where it is at concentration c_1 to the other side where it is at a concentration c_2 is given by

$$\Delta G = RT\ \ln\left(c_2 / c_1\right) + ZF\Delta V \qquad (2)$$

in which Z is the electrical charge of the transported species, and ΔV is the potential in volts across the membrane. Under typical conditions for the inner mitochondrial membrane, the pH outside is 1.4 units lower than inside [corresponding to $\ln\left(c_2/c_1\right)$ of 3.2], and the membrane potential is 0.14 V, the outside being positive. Finally, recall that the gas constant, R, is

$-8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{K}^{-1}$. Because $Z = +1$ for protons, from equation 2 we see that the free-energy change is
$(8.32 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{K}^{-1} \times 310\ \text{K} \times 3.2) + (+1 \times 96.48\ \text{kJ mol}^{-1}\ \text{V}^{-1} \times 0.14\ \text{V}) = 21.8\ \text{kJ mol}^{-1}$
or $5.2\ \text{kcal mol}^{-1}$. Thus, each proton that is transported out of the matrix to the cytoplasmic side corresponds to $21.8\ \text{kJ mol}^{-1}$ of free energy.

Self-Check Question

Identify the oxidant and the reductant in the following reaction: $\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{NAD}^+$

18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle

Electrons are transferred from NADH to O_2 through a chain of three large protein complexes called *NADH-Q oxidoreductase, Q-cytochrome* c *oxidoreductase,* and *cytochrome* c *oxidase* (**Figure 18.4** and **Table 18.2**). Electron flow within these transmembrane complexes is highly exergonic and powers the transport of protons across the inner mitochondrial membrane. A fourth large protein complex, called *succinate-Q reductase,* contains the succinate dehydrogenase that generates $FADH_2$ in the citric acid cycle. Electrons from this $FADH_2$ enter the electron-transport chain at Q-cytochrome *c* oxidoreductase. Succinate-Q reductase, in contrast with the other complexes, does not pump protons. NADH-Q oxidoreductase, succinate-Q reductase, Q-cytochrome *c* oxidoreductase, and cytochrome *c* oxidase are also called *Complex I, II, III,* and *IV,* respectively. Complexes I, III, and IV appear to be associated in a supramolecular complex which facilitates the rapid transfer of substrate and prevents the release of reaction intermediates, as will be discussed further at the end of this section.

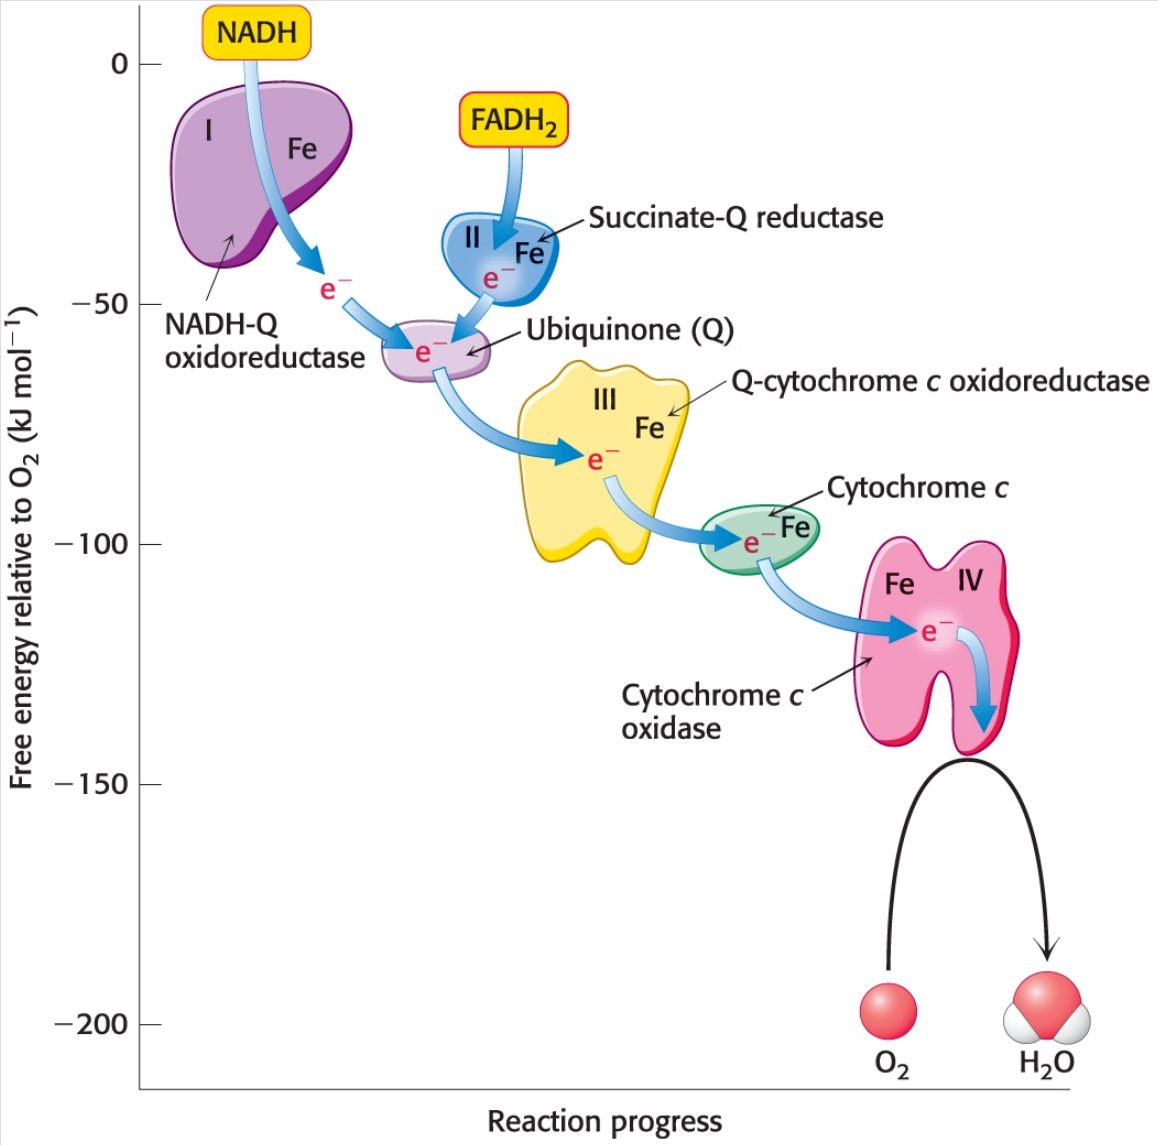

FIGURE 18.4 Components of the electron-transport chain allow the flow of electrons to molecular oxygen. Electrons flow down an energy gradient from NADH or $FADH_2$ to O_2. Th flow is catalyzed by four protein complexes, and the energy released is used to generate a proto gradient.

Two electron carriers ferry the electrons from one complex to the next. The first is **coenzyme Q** (or **Q**, for short), which is also known as *ubiquinone* because it is a ubiquitous quinone in biological systems. Coenzyme Q is a hydrophobic quinone that diffuses rapidly within the inner mitochondrial membrane. Electrons are carried from NADH-Q oxidoreductase to Q-cytochrome *c* oxidoreductase, the third complex of the chain, by the reduced form of Q. Electrons from the $FADH_2$ generated by the citric acid cycle are transferred first to ubiquinone and then to the Q-cytochrome *c* oxidoreductase complex.

Coenzyme Q is a quinone derivative with a long tail consisting of five-carbon isoprene units that account for its hydrophobic nature. The number of isoprene units in the tail depends on the species. The most common mammalian form contains 10 isoprene units (coenzyme Q_{10}). For simplicity, the subscript will be omitted from this abbreviation because all varieties function in an identical manner.

Quinones can exist in several oxidation states. In the fully oxidized state (Q), coenzyme Q has two keto groups (**Figure 18.5**). The addition of one electron and one proton results in the semiquinone form $(QH\cdot)$. The semiquinone can lose a proton to form a semiquinone radical anion $(Q\cdot^-)$. The addition of a second electron and proton to the semiquinone generates ubiquinol (QH_2), the fully reduced form of coenzyme Q, which holds its protons more tightly. Thus, for quinones, electron-transfer reactions are coupled to proton binding and release, a property that is key to transmembrane proton transport. Because ubiquinone is soluble in the membrane, a pool of Q and QH_2 — called the *Q pool* — is thought to exist in the inner mitochondrial membrane, although recent research suggests that the Q pool is confined to the protein complexes of the electron-transport chain.

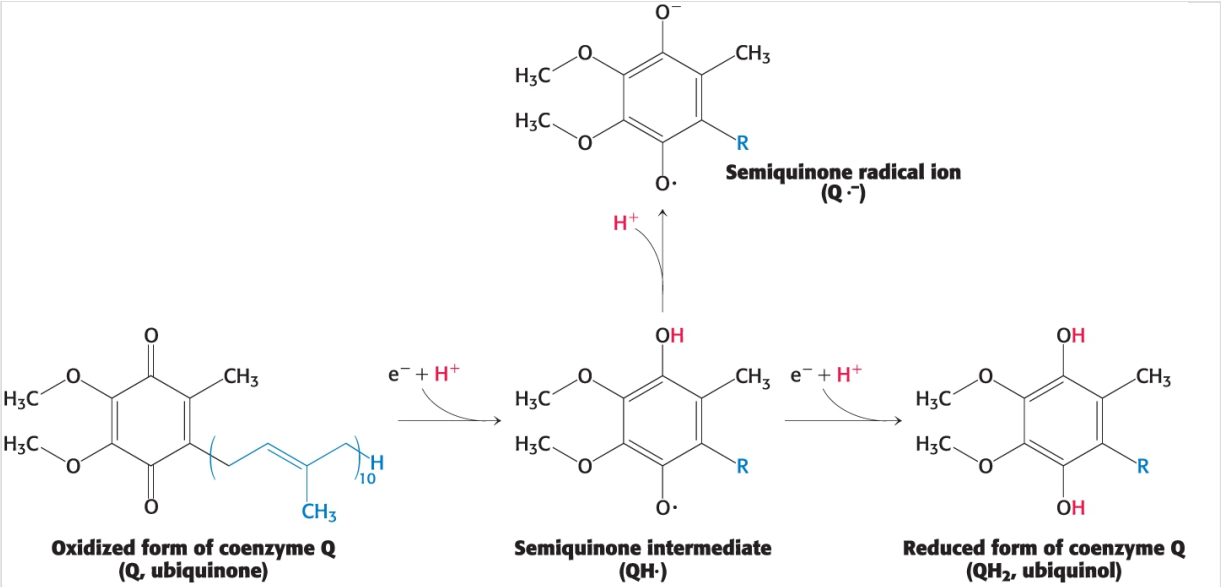

FIGURE 18.5 Quinones can have three different oxidation states, two of which are stable. The reduction of ubiquinone (Q) to ubiquinol (QH_2) proceeds through a semiquinone intermediate $(QH\cdot)$. The R group indicates the same isoprenoid units shown in the image on the left.

In contrast with Q, the second special electron carrier is a protein called a *cytochrome*. ***Cytochromes*** are electron-transferring proteins that contain a heme prosthetic group. **Cytochrome *c***, a small soluble protein that is loosely associated with the inner mitochondrial membrane, shuttles electrons from Q-cytochrome *c* oxidoreductase to cytochrome *c* oxidase, the final component in the chain and the one that catalyzes the reduction of O_2. Cytochrome *c* is present in all organisms having mitochondrial respiratory chains, evolving more than 1.5 billion years ago, before the divergence of plants and animals. Its structure and function have been conserved throughout this period, as evidenced by the fact that the cytochrome c of any eukaryotic species reacts in vitro with the cytochrome c oxidase of any other species. For example, wheat-germ cytochrome *c* reacts with human cytochrome *c* oxidase. Even bacterial cytochromes closely resemble cytochrome *c* from tuna-heart

mitochondria (Figure 18.6). This evidence attests to an efficient evolutionary solution to electron transfer bestowed by the structural and functional characteristics of cytochrome *c*.

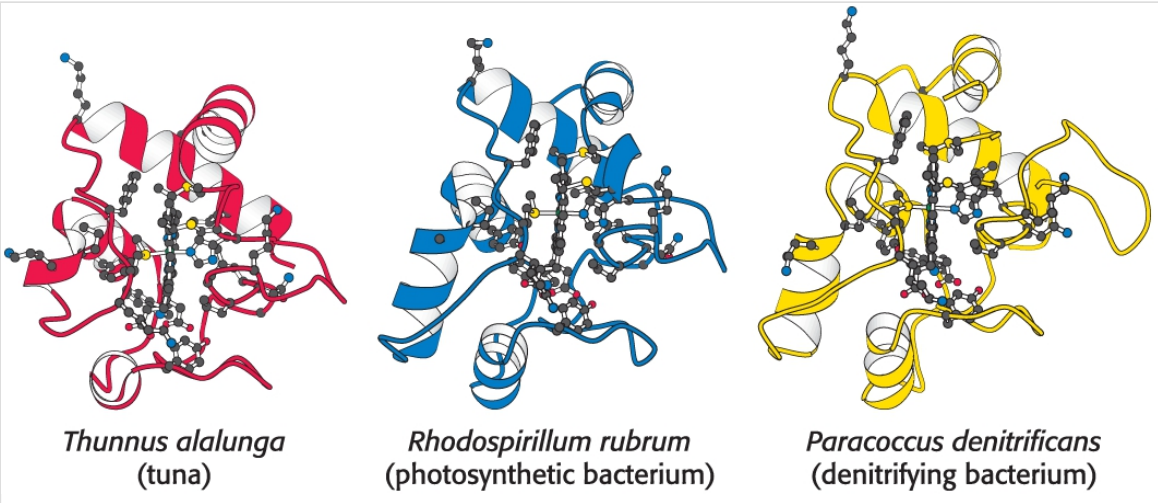

FIGURE 18.6 The three-dimensional structure of cytochrome *c* is remarkably conserved amo distantly related species. The side chains are shown for 21 conserved amino acids as well as th centrally located planar heme.

INTERACT with these models in Achieve

Iron–sulfur clusters are common components of the electron-transport chain

Iron–sulfur clusters in **iron–sulfur proteins** (also called **nonheme iron proteins**) play a critical role in a wide range of reduction reactions in biological systems. Several types of Fe–S clusters are known (**Figure 18.7**). In the simplest kind, a single iron ion is tetrahedrally coordinated to the sulfhydryl groups of four cysteine residues of the protein (Figure 18.7A). A second kind, denoted by 2Fe–2S, contains two iron ions, two inorganic sulfides, and usually four cysteine residues (Figure 18.7B). A

third type, designated 4Fe–4S, contains four iron ions, four inorganic sulfides, and four cysteine residues (Figure 18.7C). NADH-Q oxidoreductase contains both 2Fe–2S and 4Fe–4S clusters. Iron ions in these Fe–S complexes cycle between Fe^{2+} (reduced) and Fe^{3+} (oxidized) states. Unlike quinones and flavins, iron–sulfur clusters generally undergo oxidation–reduction reactions without releasing or binding protons.

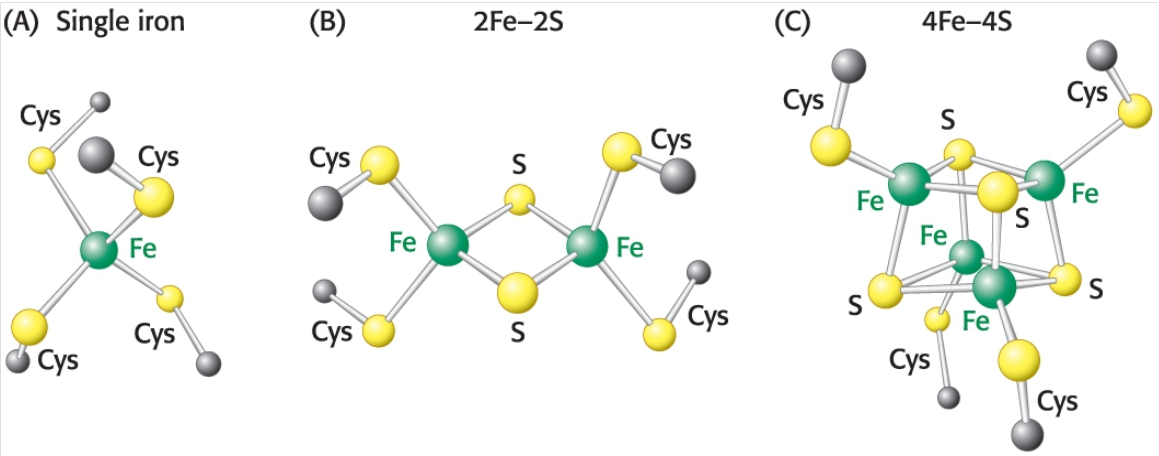

FIGURE 18.7 Three different types of iron–sulfur clusters are commonly found in biological systems. Each of these clusters can undergo oxidation–reduction reactions. (A) A single iron ion bound by four cysteine residues. (B) 2Fe–2S cluster with iron ions bridged by sulfide ions. (C) 4Fe–4S cluster.

The importance of Fe–S clusters is illustrated by the loss of function of the protein frataxin. Frataxin is a small (14.2-kDa) mitochondrial protein that is crucial for the synthesis of Fe–S clusters. Mutations in frataxin causes Friedreich's ataxia, a disease of varying severity that affects the central and peripheral nervous system as well as the heart and skeletal system. Severe cases lead to death in young adult life. The most common mutation is trinucleotide expansion (Section 28.4) in the gene for frataxin.

Self-Check Question

Explain why the structure of coenzyme Q makes it an effective mobile electron carrier in the electron-transport chain.

The high-potential energy electrons of NADH enter the respiratory chain at NADH-Q oxidoreductase

The electrons of NADH enter the chain at **NADH-Q oxidoreductase** (also called **Complex I**), an enormous enzyme $(>900\ \text{kDa})$ consisting of approximately 45 polypeptide chains organized into 14 core subunits that are found in all species with respiratory chains. This proton pump, like that of the other two in the respiratory chain, is encoded by genes residing in both the mitochondria and the nucleus. NADH-Q oxidoreductase is L-shaped, with a horizontal arm lying in the membrane and a vertical arm that projects into the matrix.

The reaction catalyzed by this enzyme appears to be

$$\text{NADH} + \text{Q} + 5\ \text{H}^+_{\text{matrix}} \rightarrow \text{NAD}^+ + \text{QH}_2 + 4\ \text{H}^+_{\text{intermembrane space}}$$

The initial step is the binding of NADH and the transfer of its two high-potential electrons to the flavin mononucleotide (FMN) prosthetic group, yielding the reduced form, FMNH_2 (**Figure 18.8**). The electron acceptor of FMN, the isoalloxazine ring, is identical with that of FAD.

Electrons are then transferred from $FMNH_2$ to a series of iron–sulfur clusters, the second type of prosthetic group in NADH-Q oxidoreductase.

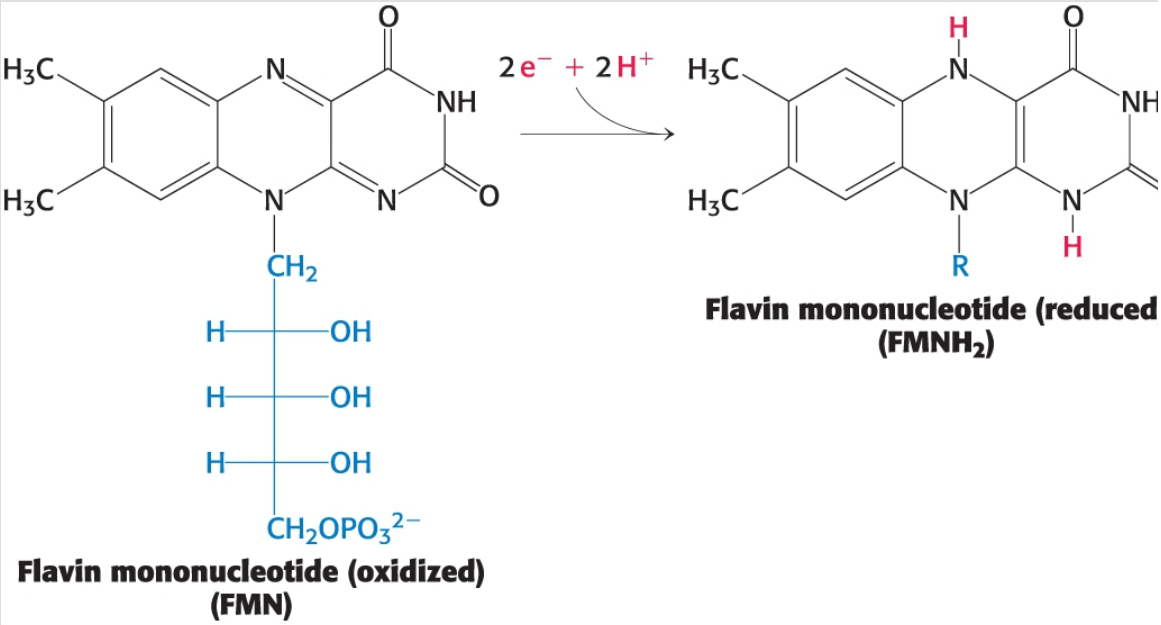

FIGURE 18.8 Flavins have two oxidation states. The states are exchanged by the binding or lo
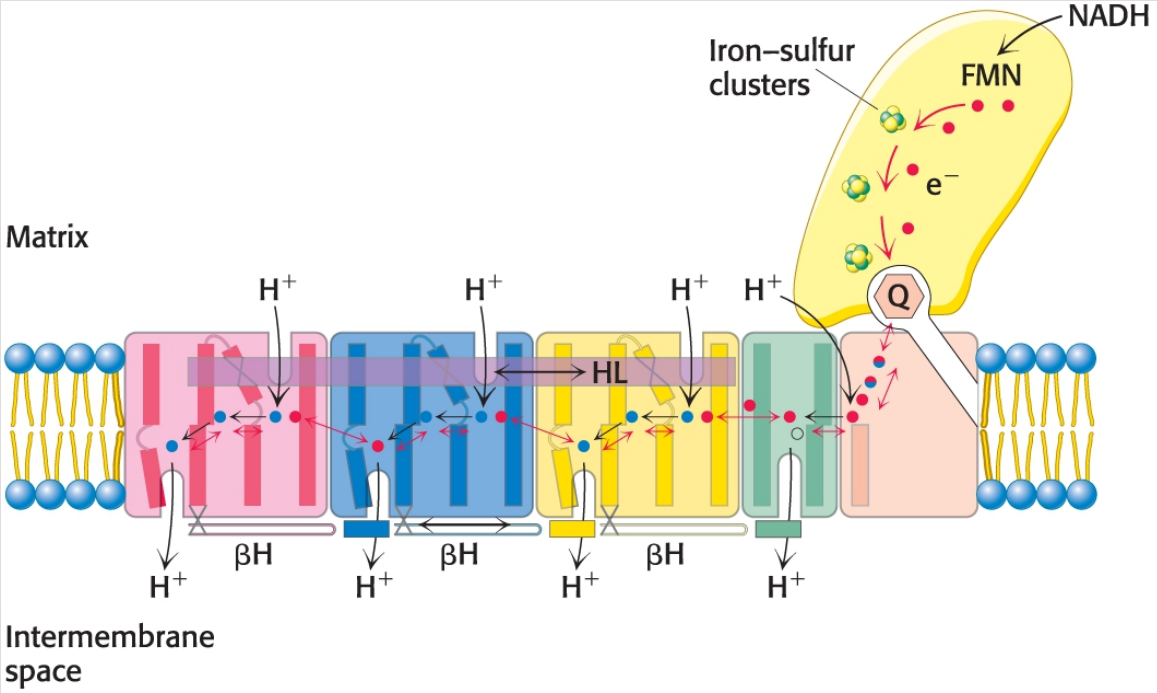
of two electrons and two protons.

Recent structural studies have suggested how Complex I acts as a proton pump. What are the structural elements required for proton-pumping? The membrane-embedded part of the complex has four proton half-channels consisting, in part, of vertical helices. One set of half-channels is exposed to the matrix and the other to the intermembrane space (Figure 18.9). The vertical helices are linked on the matrix side by a long horizontal helix (HL) that connects the matrix half-channels, while the intermembrane space half-channels are joined by a series of β-hairpin-helix connecting elements (βH). An enclosed Q chamber, the site where Q accepts electrons from NADH, exists near the junction of the hydrophilic portion and the membrane-embedded portion. Finally, a

hydrophilic funnel connects the Q chamber to a water-lined channel (into which the half channels open) that extends the entire length of the membrane-embedded portion.



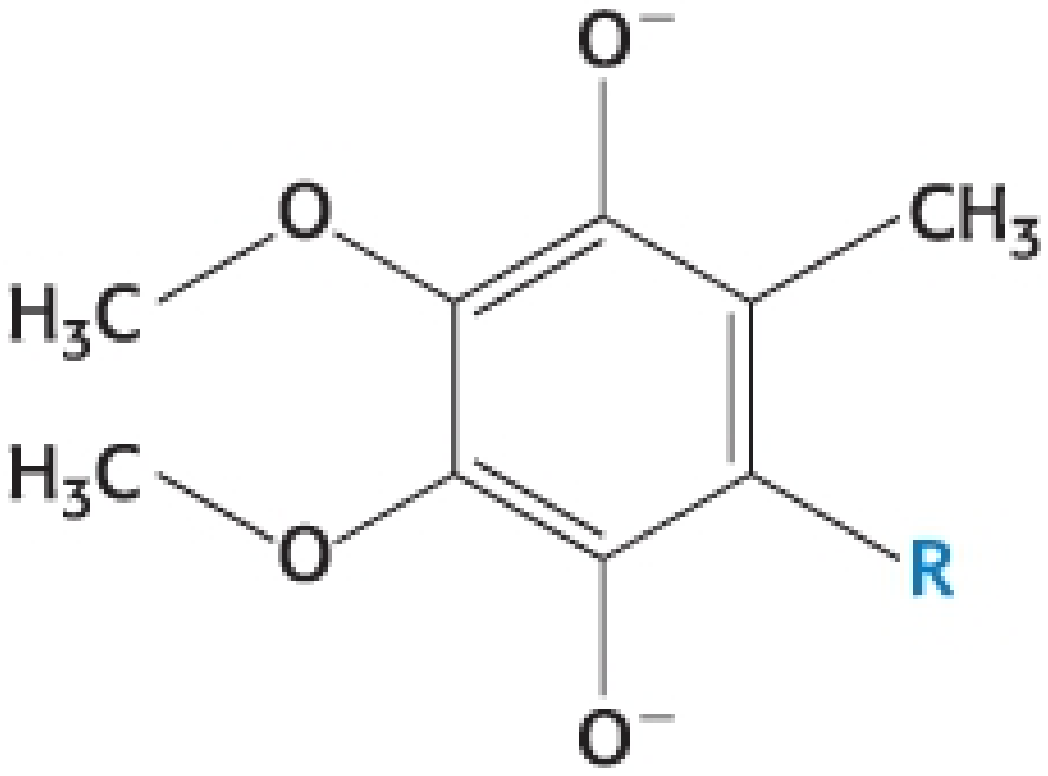


FIGURE 18.9 Electron transfer through NADH-Q oxidoreductase is coupled to proton transfer reactions. Electrons flow in Complex I from NADH through FMN and a series of iron–sulfur clusters to ubiquinone (Q), forming Q^{2-}. The charges on Q^{2-} are electrostatically transmitted to hydrophilic amino acid residues — shown as red (glutamate) and blue (lysine or histidine) balls — that power the movement of HL and βH components. This movement change the conformation of the transmembrane helices and results in the transport of four protons out of the mitochondrial matrix.

[Information from R. Baradaran et al., *Nature* 494:443–448, 2013.]

How do these structural elements cooperate to pump protons out of the matrix? When Q accepts two electrons from NADH, generating Q^{2-}, the negative charges on Q^{2-} interact electrostatically with negatively charged amino acid residues in the membrane-embedded arm, causing

conformational changes in the long horizontal helix and the βH elements. These changes in turn alter the structures of the connected vertical helices that change the pK_a of amino acids, allowing protons from the matrix to first bind to the amino acids, then dissociate into the water-lined channel, and finally enter the intermembrane space. Thus, the flow of two electrons from NADH to coenzyme Q through NADH-Q oxidoreductase leads to the pumping of four hydrogen ions out of the matrix of the mitochondrion. Q^{2-} subsequently takes up two protons from the matrix as it is reduced to QH_2. The removal of these protons from the matrix contributes to the formation of the proton-motive force. The QH_2 subsequently leaves the enzyme for the Q pool, allowing another reaction cycle to occur.

Reduced ubiquinone
(Q^{2-})

It is important to note that the citric acid cycle and the pyruvate dehydrogenase complex are not the only sources of mitochondrial NADH. As we will see in Chapter 22, fatty acid degradation, which also takes place in mitochondria, is another crucial source of NADH for the electron-transport chain. Moreover, electrons from NADH generated in the cytoplasm can be transported into mitochondria for use by the electron-transport chain, as we will see in Section 18.5.

Ubiquinol is the entry point for electrons from $FADH_2$ of flavoproteins

Recall that $FADH_2$ is formed in the citric acid cycle, in the oxidation of succinate to fumarate by succinate dehydrogenase (Section 17.3). Succinate dehydrogenase is part of **succinate-Q reductase (Complex II)**, an integral membrane protein complex of the inner mitochondrial membrane. $FADH_2$ does not actually leave the complex, however. Rather, its electrons are transferred to Fe–S centers and then finally to Q to form QH_2, which then is ready to transfer electrons further down the electron-transport chain. Importantly, succinate-Q reductase, in contrast with NADH-Q oxidoreductase, does not pump protons from one side of the membrane to the other. Consequently, less ATP is formed from the oxidation of $FADH_2$ than from NADH.

Electrons flow from ubiquinol to cytochrome *c* through Q-cytochrome *c* oxidoreductase

What is the fate of ubiquinol generated by Complexes I and II? The electrons from QH_2 are passed on to cytochrome *c* (Cyt *c*) by the second of the three proton pumps in the respiratory chain, **Q-cytochrome *c* oxidoreductase** (also known as **Complex III** and as **cytochrome *c* reductase**). The flow of a pair of electrons through this complex leads to the effective net transport of $2\ H^+$ to the intermembrane space, half the yield obtained with NADH-Q reductase because of a smaller thermodynamic driving force.

$$QH_2 + 2\ \text{Cyt}\ c_{ox} + 2\ H^+_{\text{matrix}} \rightarrow Q + 2\ \text{Cyt}\ c_{red} + 4\ H^+_{\text{intermembrane space}}$$

Q-cytochrome *c* oxidoreductase itself contains two types of cytochromes, named *b* and c_1 (**Figure 18.10**). The heme prosthetic group in cytochromes *b*, c_1, and *c* is iron-protoporphyrin IX, the same heme present in myoglobin and hemoglobin (Section 3.2). The iron ion of a cytochrome, in contrast to hemoglobin and myoglobin, alternates between a reduced ferrous $(+2)$ state and an oxidized ferric $(+3)$ state during electron transport. The two cytochrome subunits of Q-cytochrome *c* oxidoreductase contain a total of three hemes: two hemes within cytochrome *b*, termed heme b_L (L for low affinity) and heme b_H (H for high affinity), and one heme within cytochrome c_1. These identical hemes have different electron affinities because they are in different polypeptide environments. For example, heme b_L, which is located in a cluster of helices near the intermembrane face of the membrane, has lower affinity for an electron than does heme b_H, which is near the matrix side.

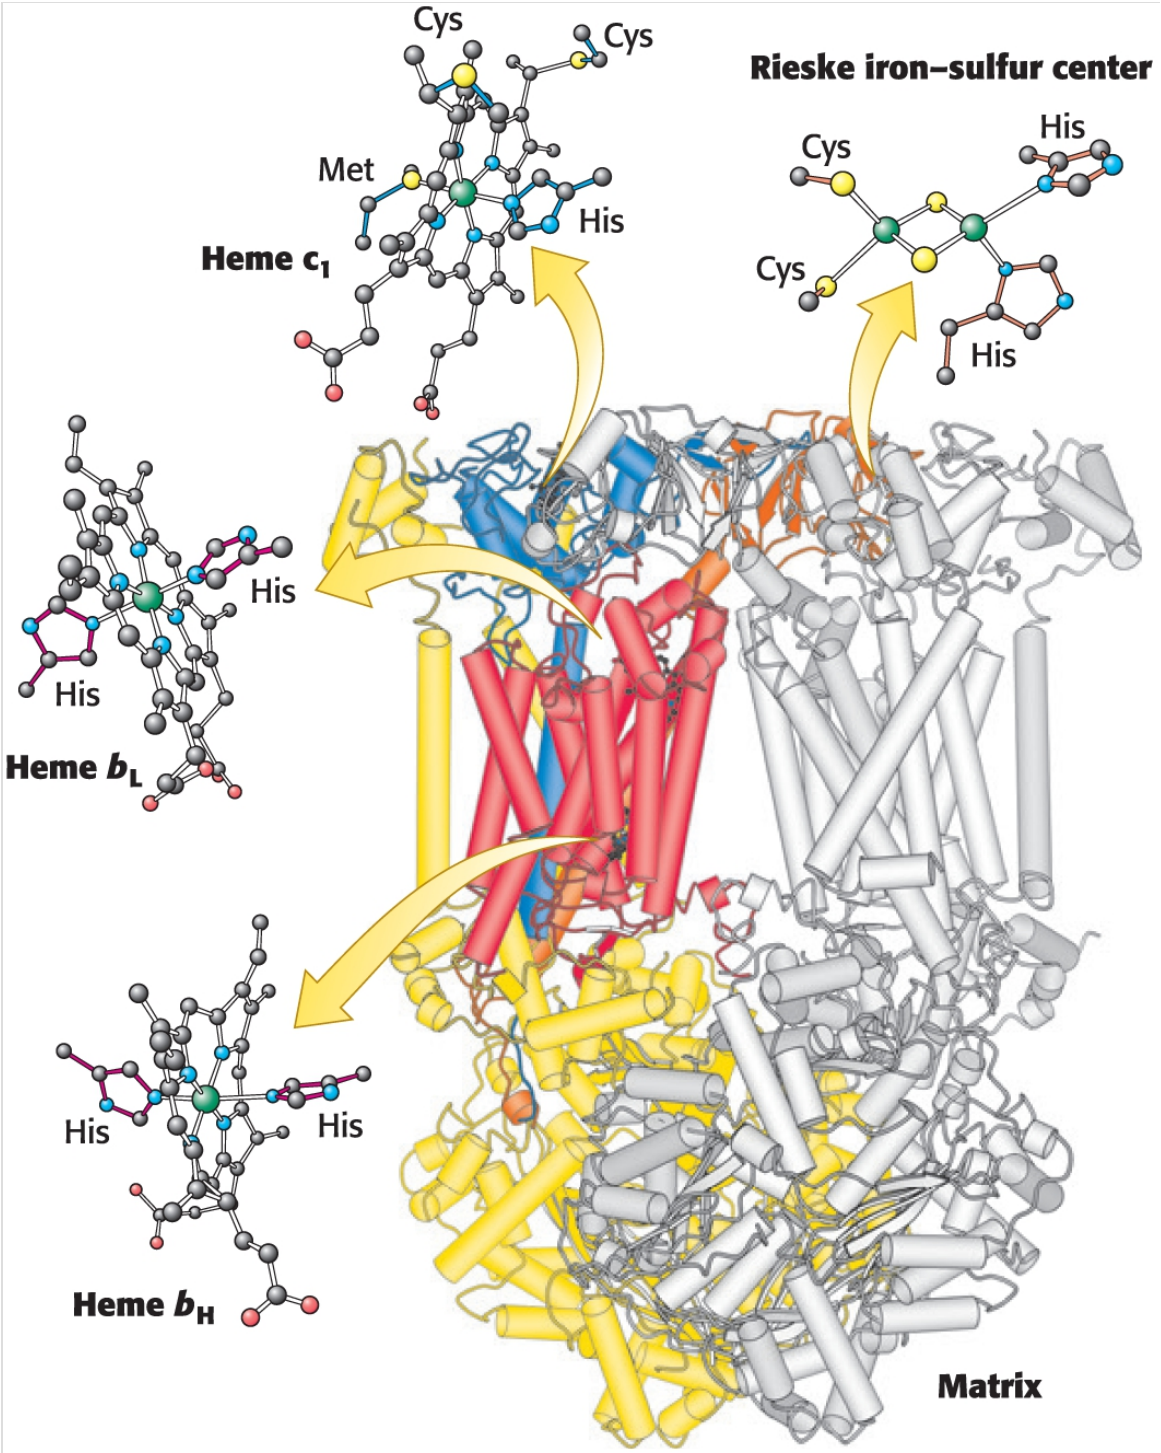

FIGURE 18.10 Q-cytochrome c oxidoreductase is a homodimer, with each monomer consistin of 11 distinct polypeptide chains. Although both monomers are identical, key parts are shown color in only one monomer for ease of viewing. *Notice* that the major prosthetic groups — three hemes and a 2Fe–2S cluster — are located either near the edge of the complex bordering the intermembrane space (top) or in the region embedded in the membrane (α helices represented by tubes). They are well-positioned to mediate the electron-transfer reactions between quinone in the membrane and cytochrome *c* in the intermembrane space.

[Drawn from 1BCC.pdb.]

INTERACT with this model in Achieve

In addition to the hemes, the enzyme contains an iron–sulfur protein with a 2Fe–2S center. This center, termed the *Rieske center*, is unusual in that one of the iron ions is coordinated by two histidine residues rather than two cysteine residues. This coordination stabilizes the center in its reduced form, raising its reduction potential so that it can readily accept electrons from QH_2.

The Q cycle funnels electrons from a two-electron carrier to a one-electron carrier while pumping protons

QH_2 passes two electrons to Q-cytochrome *c* oxidoreductase, but the acceptor of electrons in this complex, cytochrome *c*, can accept only one electron. How does the switch from the two-electron carrier ubiquinol to the one-electron carrier cytochrome *c* take place without the release of dangerous radicals? The mechanism for the coupling of electron transfer from QH_2 to cytochrome *c* to transmembrane proton transport is known as the **Q cycle** (**Figure 18.11**). Two QH_2 molecules bind to the complex consecutively, each giving up two electrons and two H^+. These protons are released to the intermembrane space.

Additionally, one molecule of oxidized Q binds and it is this molecule, along with two molecules of cytochrome c, that accept the four electrons. The Q cycle occurs in two halves:

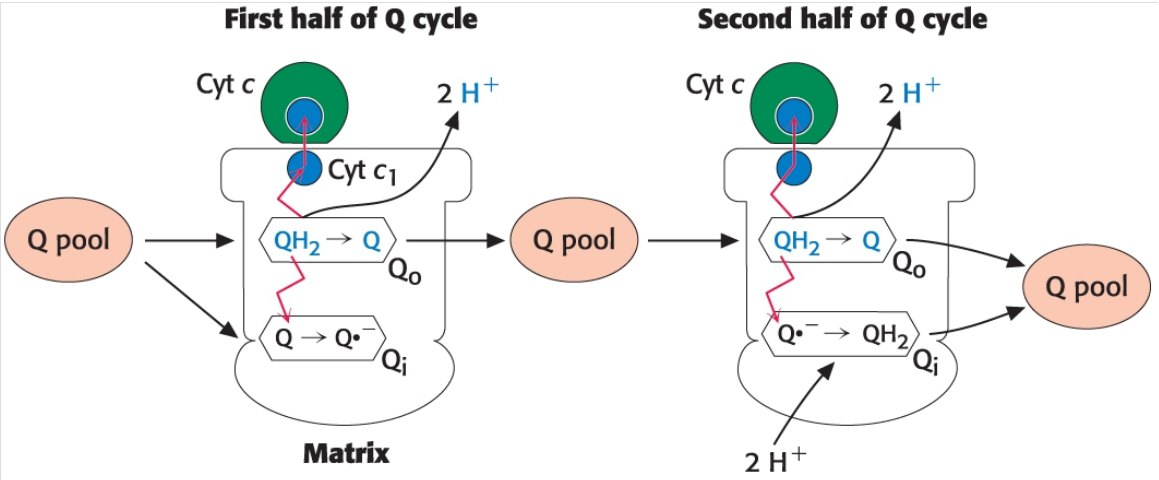

FIGURE 18.11 The Q cycle allows the safe transfer of electrons from QH_2 to cytochrome *c*. The Q cycle takes place in Complex III, which is represented in outline form. In the first half of th cycle, two molecules of Q bind, one oxidized (Q) and the other reduced (QH_2). Two electrons of the bound QH_2 are transferred, one to cytochrome *c* and the other to the bound Q in the second binding site to form the semiquinone radical anion $Q\cdot^-$. The newly formed Q dissociates and enters the Q pool. In the second half of the cycle, a second QH_2 also gives up electrons to Complex III, one to a second molecule of cytochrome *c* and the other to reduce $Q\cdot^-$ to QH_2. This second electron transfer results in the uptake of two protons from the matrix. The path of electron transfer is shown in red.

1. In the first half of the cycle, two molecules of Q from the Q pool — one reduced (QH_2) and one oxidized (Q) — first bind to two distinct sites called Q_o and Q_i, respectively. The QH_2 bound to Q_o passes its two electrons through the complex to different destinations. One electron flows first to the Rieske 2Fe–2S cluster, then to cytochrome c_1, and finally to the first molecule of oxidized cytochrome *c*, converting it into its reduced form. The reduced cytochrome *c* molecule is free to diffuse away from the enzyme to continue down the respiratory chain. The second electron passes through two heme groups of cytochrome *b* to the oxidized Q molecule bound at

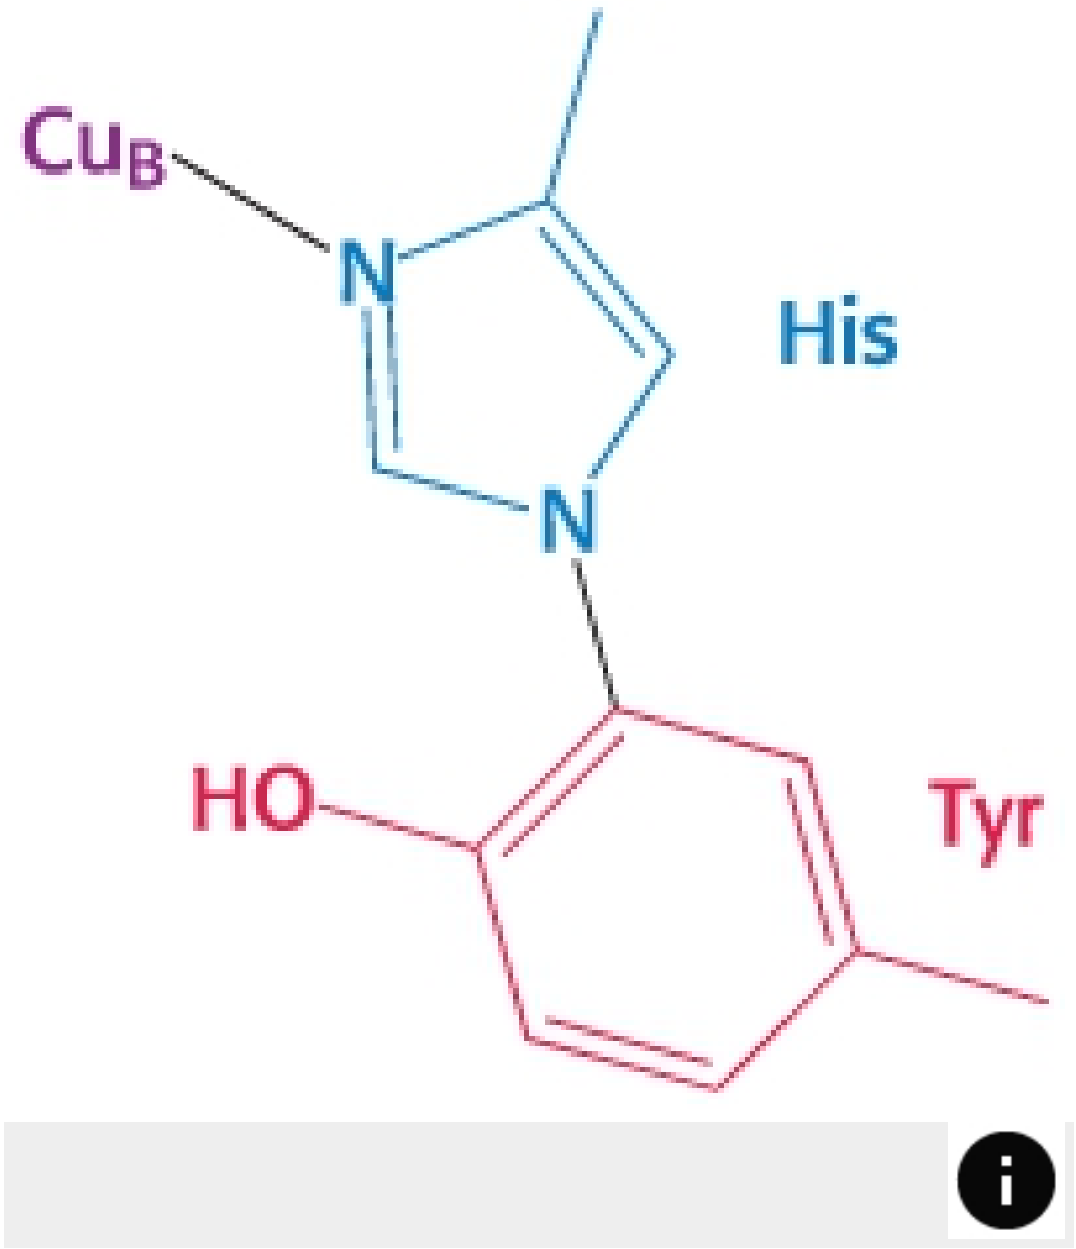
the Q_i site, reducing it to a dangerous semiquinone radical anion $(Q\cdot^-)$ which is held tightly within the complex to prevent its release. The now fully oxidized Q leaves the Q_o site and reenters the Q pool.

2. In the second half of the cycle, a second molecule of QH_2 binds to the Q_o site and reacts in the same way as the first. One of the electrons is transferred to cytochrome *c*, which becomes reduced and leaves, while the second electron is transferred to the semiquinone radical anion still bound in the Q_i binding site from the first half of the cycle. On the addition of the second electron, the radical accepts two protons from the matrix and forms QH_2, which then rejoins the Q pool along with the second oxidized Q molecule from the Q_o site. The removal of these two protons from the matrix contributes to the formation of the proton gradient.

Thus, with each full cycle, two reduced QH_2 and one oxidized Q enter the complex and two oxidized Q and one QH_2 leave. The two electrons that are extracted from the Q pool each cycle pass to two molecules of cytochrome *c*, without releasing a radical to solution. Finally, four protons are released into the intermembrane space, and two protons are removed from the mitochondrial matrix. The overall reaction is:

$$2\ QH_2 + Q + 2\ \text{Cyt}\ c_{ox} + 2\ H^+_{\text{matrix}} \rightarrow 2\ Q + QH_2 + 2\ \text{Cyt}\ \ c_{red} + 4\ H^+_{\text{intermembrane space}}$$

The problem of how to funnel electrons safely and efficiently from a two-electron carrier (QH_2) to a one-electron carrier (cytochrome *c*) is solved by the Q cycle. The cytochrome *b* component of the reductase is in essence a recycling device that enables both electrons of QH_2 to be used effectively.



Cytochrome *c* oxidase catalyzes the reduction of molecular oxygen to water

The last of the three proton-pumping assemblies of the respiratory chain is **cytochrome c oxidase (Complex IV)**. Cytochrome *c* oxidase catalyzes the transfer of electrons from the reduced form of cytochrome *c* to molecular oxygen, the final acceptor.

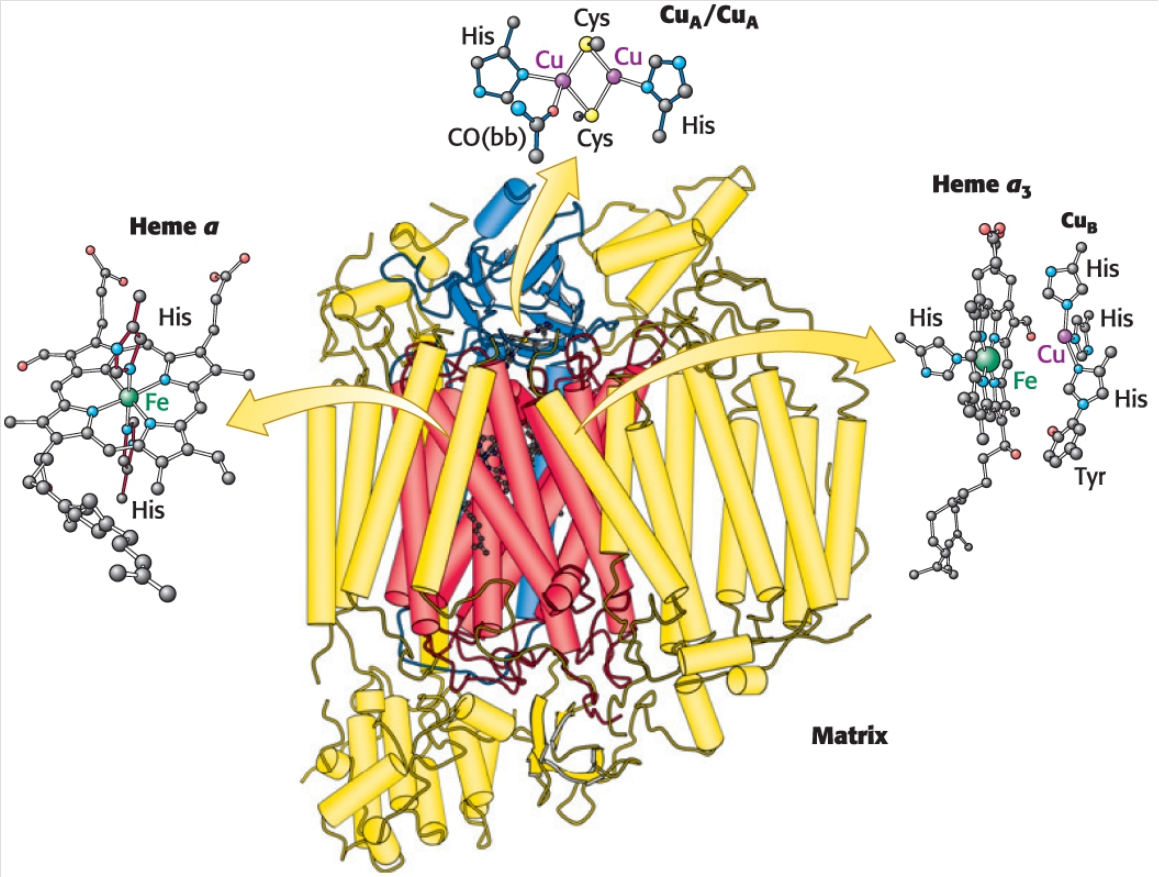
$$4\ \text{Cyt}\ c_{\text{red}} + 8\ \text{H}^+_{\text{matrix}} + \text{O}_2 \rightarrow 4\ \text{Cyt}\ c_{\text{ox}} + 2\ \text{H}_2\text{O} + 4\ \text{H}^+_{\text{intermembrane space}}$$

The requirement of oxygen for this reaction is what makes "aerobic" organisms aerobic. To obtain oxygen for this reaction is the primary reason that human beings must breathe. Four electrons are funneled to O_2 to completely reduce it to H_2O, and, concomitantly, protons are pumped from the matrix into the intermembrane space.

This reaction is quite thermodynamically favorable. From the reduction potentials in Table 18.1, the standard free-energy change for this reaction is calculated to be $\Delta G^{\circ\prime} = -231.8\ \text{kJ mol}^{-1}\ (-55.4\ \text{kcal mol}^{-1})$. As much of this free energy as possible must be captured in the form of a proton gradient for subsequent use in ATP synthesis.

Our understanding of mammalian cytochrome *c* oxidase is reasonably well understood at the structural level because of extensive studies of bovine cytochrome *c* oxidase (Figure 18.12). It consists of 13 subunits, three of which are encoded by the mitochondrion's own genome. Cytochrome *c* oxidase contains two heme A groups and three copper ions, arranged as two copper centers, designated *A* and *B*. One center, Cu_A/Cu_A, contains two copper ions linked by two bridging cysteine

residues. This center initially accepts electrons from reduced cytochrome *c*. The remaining copper ion, Cu_B, is bonded to three histidine residues, one of which is modified by covalent linkage to a tyrosine residue. The copper centers alternate between the reduced Cu^+ (cuprous) form and the oxidized Cu^{2+} (cupric) form as they accept and donate electrons.



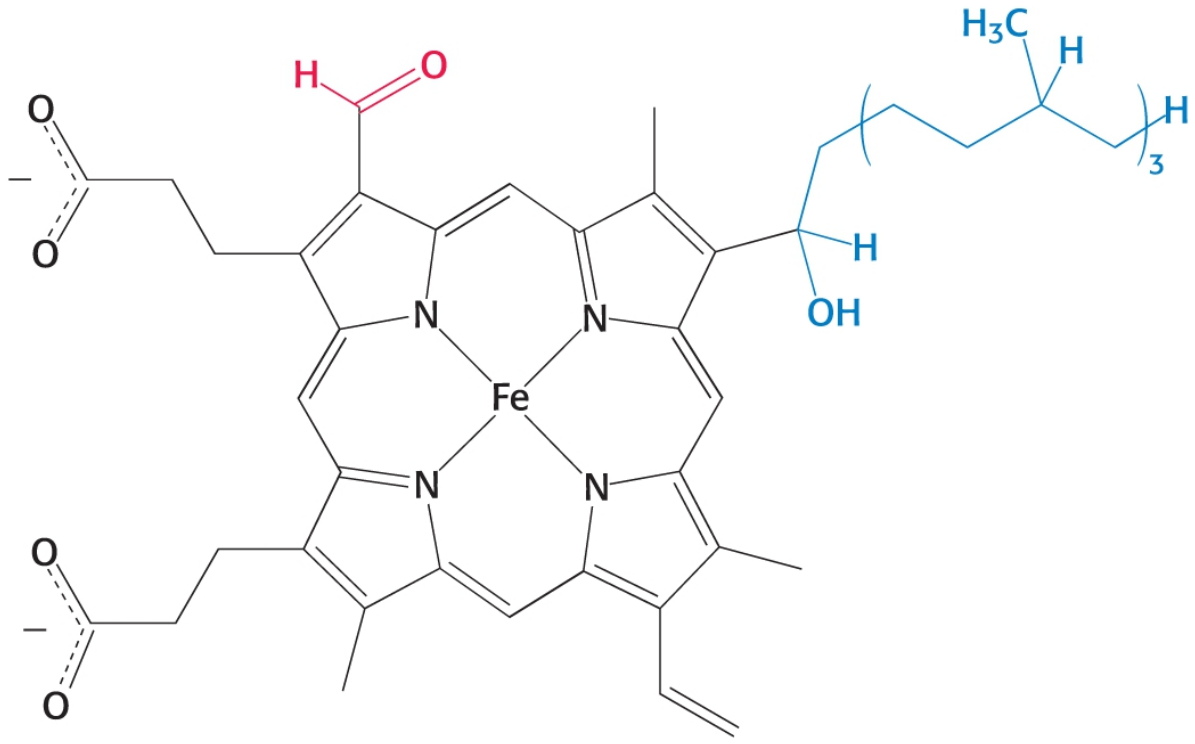


FIGURE 18.12 The structure of bovine cytochrome *c* oxidase reveals 13 polypeptide chains ar numerous electron carriers. Notice that most of the complex, as well as two major prosthetic groups (heme *a* and heme $a_3 - Cu_B$) are embedded in the membrane (α helices are represented by vertical cylinders). Heme $a_3 - Cu_B$ is the site of the reduction of oxygen to water. The Cu_A/Cu_A prosthetic group is positioned near the intermembrane space to bette accept electrons from cytochrome *c*. CO(bb) is a carbonyl group of the peptide backbone. [Drawn from 2OCC.pdb.]

INTERACT with this model in Achieve

In cytochrome *c* oxidase, there are two heme A molecules, called *heme* a and *heme* a_3, which differ from the heme in cytochrome *c* and c_1 in three ways: (1) a formyl group replaces a methyl group, (2) a C_{17} hydrocarbon chain replaces one of the vinyl groups, and (3) the heme is not covalently attached to the protein.

Heme A

Heme *a* and heme a_3 have distinct redox potentials because they are located in different environments within cytochrome *c* oxidase. An electron flows from cytochrome *c* to Cu_A/Cu_A, to heme *a*, to heme a_3,

to Cu_B, and finally to O_2. Heme a_3 and Cu_B are directly adjacent. Together, heme a_3 and Cu_B form the active center at which O_2 is reduced to H_2O.

Four molecules of cytochrome *c* bind consecutively to the enzyme and transfer an electron to reduce one molecule of O_2 to H_2O (**Figure 18.13**):

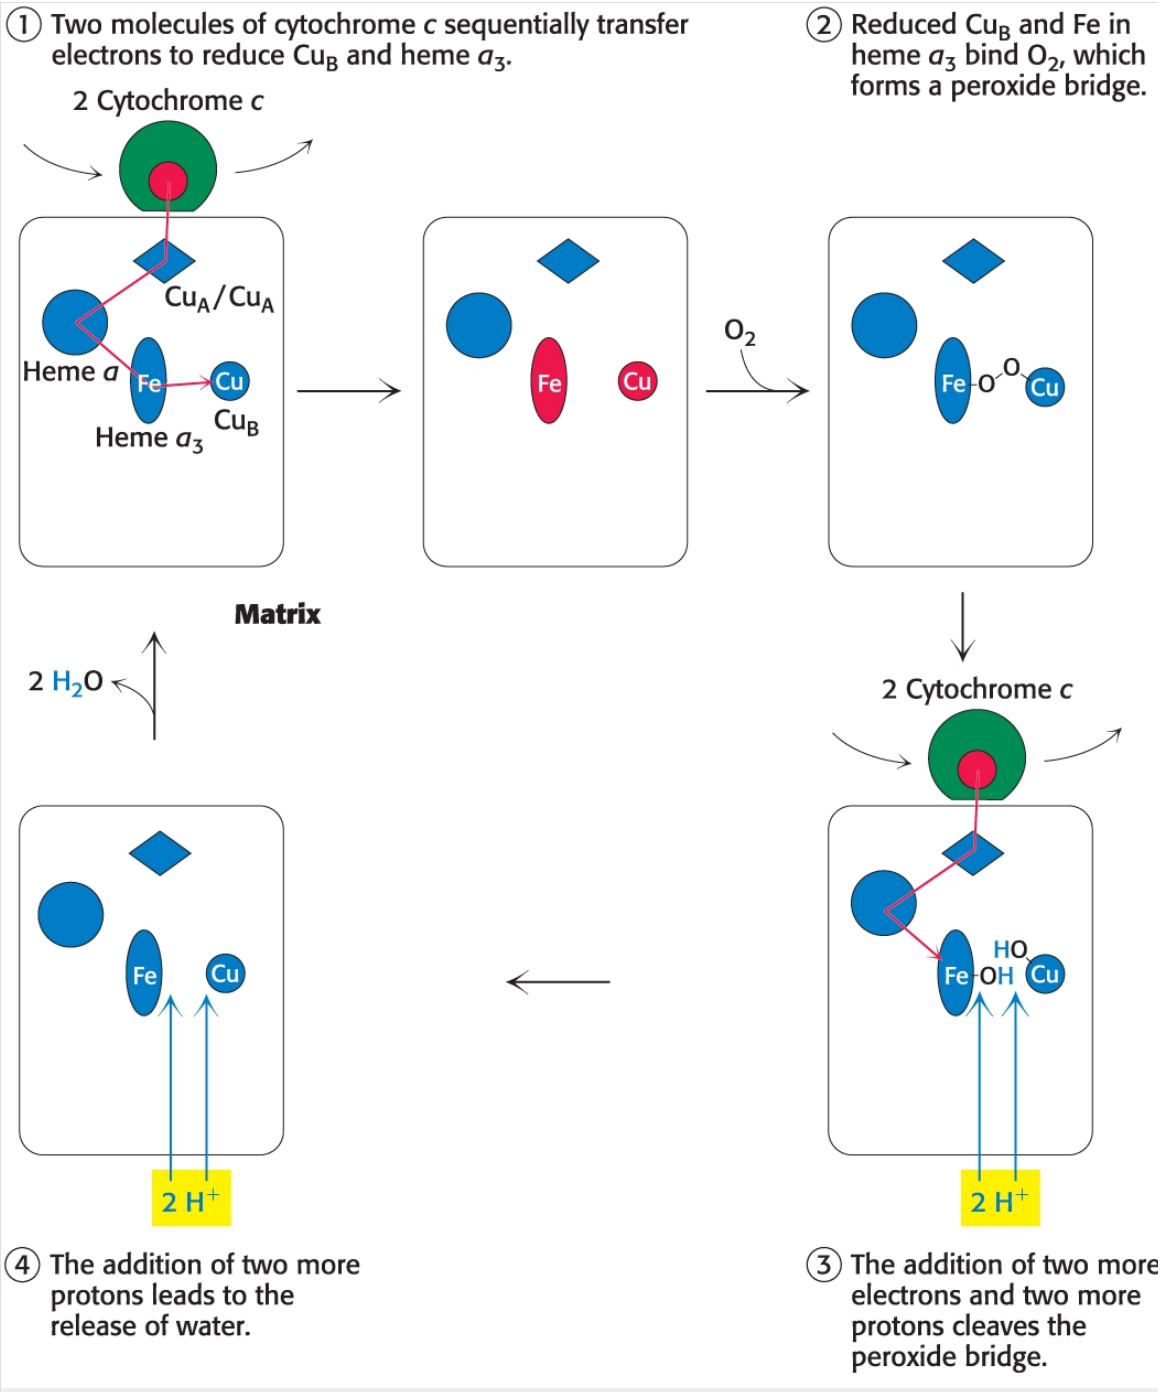

FIGURE 18.13 The mechanism of cytochrome *c* oxidase prevents early oxygen release. The cycle begins and ends with all prosthetic groups in their oxidized forms (shown in blue). Reduce forms are in red. Four cytochrome *c* molecules donate four electrons, allowing the binding and cleavage of an O_2 molecule and the import of four H^+ from the matrix to form two molecules of H_2O, which are released from the enzyme to regenerate the initial state.

1. Electrons from two molecules of reduced cytochrome *c* flow down an electron-transfer pathway within cytochrome *c* oxidase, one stopping at Cu_B and the other at heme a_3. With both centers in the reduced state, they together can now bind an oxygen molecule.
2. As molecular oxygen binds, it abstracts an electron from each of the nearby ions in the active center to form a peroxide (O_2^{2-}) bridge between them (**Figure 18.14**).

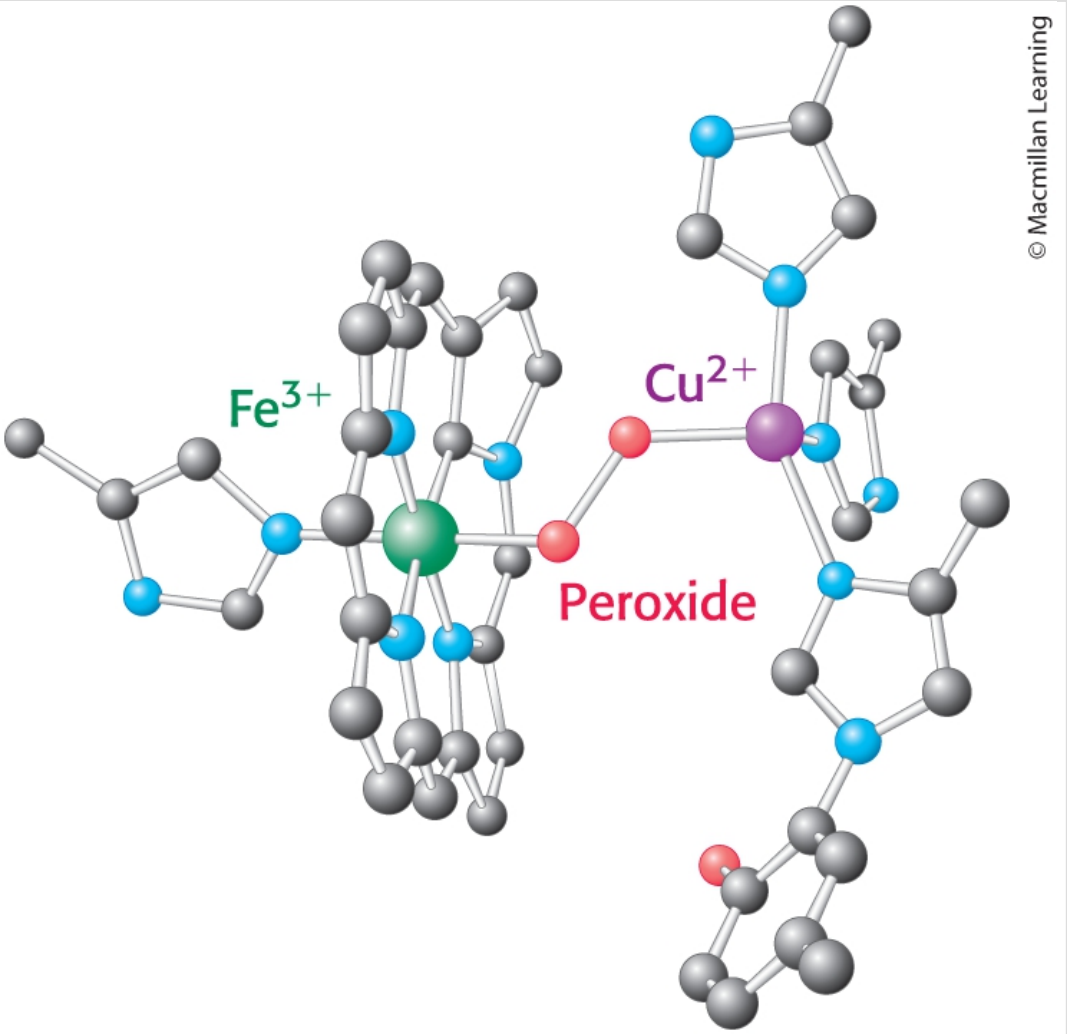

FIGURE 18.14 Two metals form a peroxide bridge in cytochrome *c* oxidase. The oxygen bound to heme a_3 is reduced to peroxide by the presence of Cu_B.

3. Two more molecules of cytochrome *c* bind and release electrons that travel to the active center. The addition of an electron as well as H^+ to each oxygen atom reduces the two ion–oxygen groups to $Cu_B^{2+}—OH$ and $Fe^{3+}—OH$.

4. Reaction with two more H^+ ions allows the release of two molecules of H_2O and resets the enzyme to its initial, fully oxidized form.

$$4\ \text{Cyt}\ c_{red} + 4\ H^+_{matrix} + O_2 \rightarrow 4\ \text{Cyt}\ c_{ox} + 2\ H_2O$$

The four protons in the reaction shown in Step 4 come exclusively from the matrix. Thus, the consumption of these four protons contributes directly to the proton gradient. Recall that each proton contributes $21.8\ \text{kJ mol}^{-1}\ (5.2\ \text{kcal mol}^{-1})$ to the free energy associated with the proton gradient; so these four protons contribute $87.2\ \text{kJ mol}^{-1}\ (20.8\ \text{kcal mol}^{-1})$, an amount substantially less than the free energy available from the reduction of oxygen to water. What is the fate of this missing energy? Remarkably, cytochrome c oxidase uses this energy to pump four additional protons from the matrix into the intermembrane space in the course of each reaction cycle for a total of eight protons removed from the matrix (**Figure 18.15**). The details of how these protons are transported through the protein are still under study. However, two effects contribute to the mechanism. First, charge neutrality tends to be maintained in the interior of proteins. Thus, the addition of an electron to a site inside a protein tends to favor the binding of H^+ to a nearby site. Second, conformational changes take place, particularly around the heme a_3-Cu_B center, in the course of the reaction cycle. Presumably, in one conformation, protons may enter the protein exclusively from the matrix side, whereas, in another, they may exit exclusively to the intermembrane space. Thus, the overall process catalyzed by cytochrome *c* oxidase is

$$4\ \text{Cyt}\ c_{red} + 8\ H^+_{matrix} + O_2 \rightarrow 4\ \text{Cyt}\ c_{ox} + 2\ H_2O + 4\ H^+_{\text{intermembrane space}}$$

FIGURE 18.15 Proton transport by cytochrome *c* oxidase has two components. Four protons are taken up from the matrix side to reduce one molecule of O_2 to two molecules of H_2O. These protons are called *chemical protons* because they participate in a clearly defined reaction with O_2. Four additional *pumped protons* are transported out of the matrix and released into the intermembrane space in the course of the reaction.

[Figure 18.16](#) summarizes the flow of electrons from NADH and $FADH_2$ through the respiratory chain. This series of exergonic reactions is coupled to the pumping of protons from the matrix. As we will see shortly, the energy inherent in the proton gradient will be used to synthesize ATP.

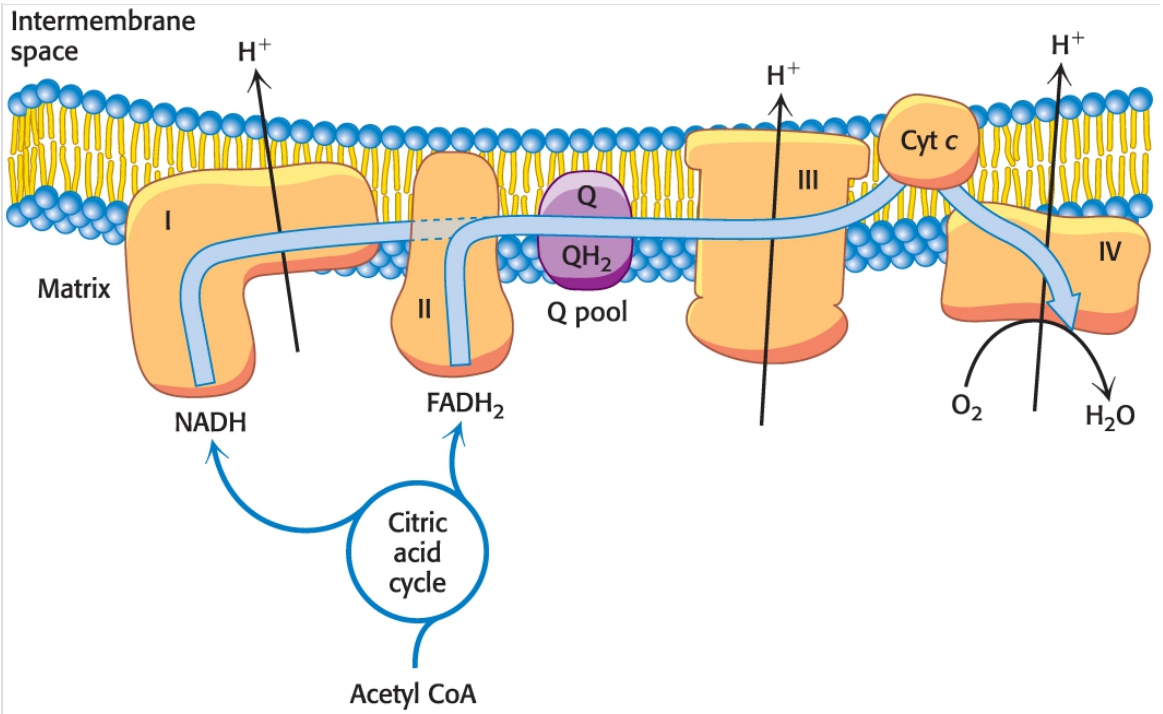

FIGURE 18.16 Electrons flow via two pathways through the electron-transport chain. High-energy electrons in the form of either NADH or $FADH_2$ are generated by the citric acid cycle. These electrons flow through the respiratory chain, which powers proton pumping and results i the reduction of O_2.

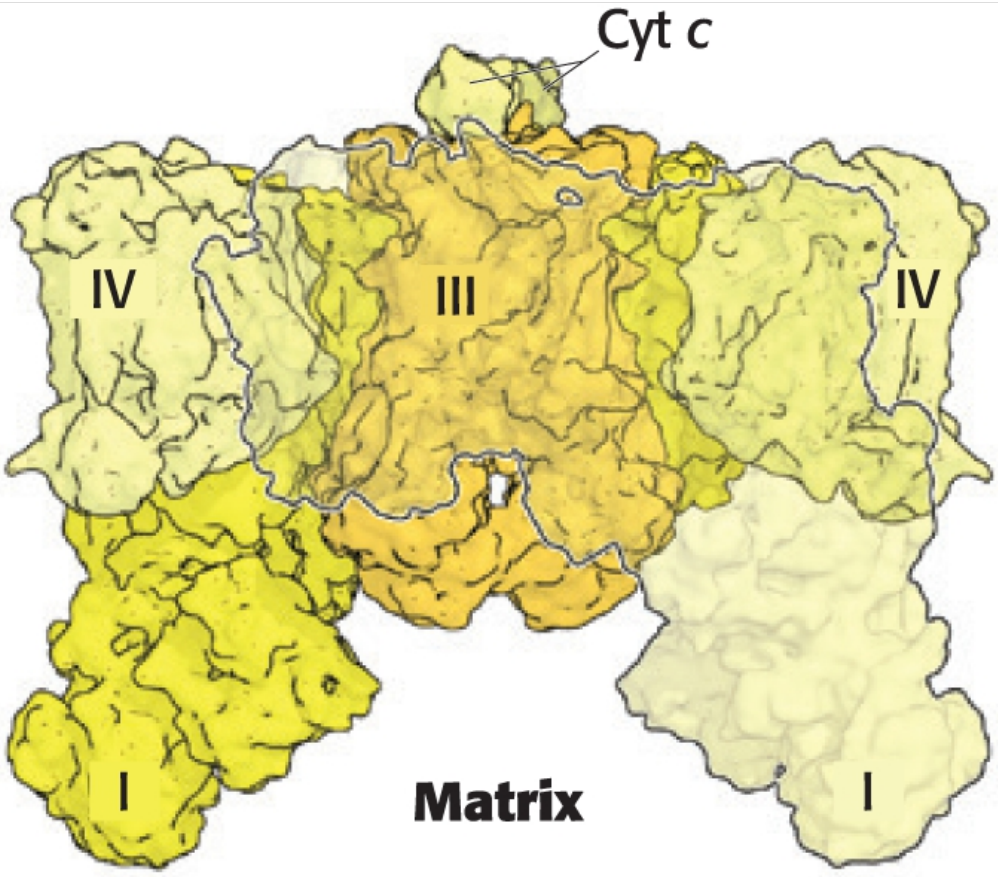
EXPLORE this pathway further in the Metabolic Map in Achieve

Most of the electron-transport chain is organized into a larger complex called the respirasome

The portrayal of the electron-transport chain in Figure 18.16 shows the individual components as isolated units. Although fine for illustrative purposes, this depiction is too simplistic. Recent research has established that three of the components of the electron-transport chain are arranged into a massive complex called the **respirasome**. The human respirasome consists of two copies of Complex I, Complex III, and Complex IV (**Figure 18.17**). The respirasome forms a circular structure with two copies each of Complex I and Complex IV surrounding two copies of Complex III. Although not experimentally established, the structure allows for Complex II to associate in a gap between Complexes I and IV. The structure of the respirasome was solved using the technique of cryo-electron microscopy (cryo-EM) (Section 4.5). The respirasome provides yet another example of multienzyme pathways that are organized into large complexes to enhance efficiency.



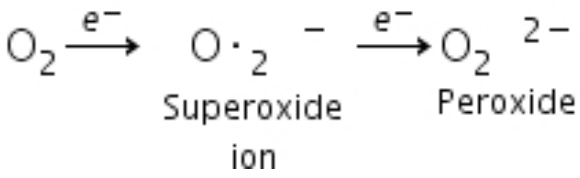


FIGURE 18.17 Three complexes of the ETC associate to form the respirasome. The structure of the electron-transport-chain supercomplex (or respirasome) has been determined by cryo-electron microscopy.

Toxic derivatives of molecular oxygen such as superoxide radicals are scavenged by protective enzymes

As discussed earlier, molecular oxygen is an ideal terminal electron acceptor, because its high affinity for electrons provides a large thermodynamic driving force. However, danger lurks in the reduction of

O_2. The transfer of four electrons leads to safe products (two molecules of H_2O), but partial reduction generates hazardous compounds. In particular, the transfer of a single electron to O_2 forms a superoxide ion, whereas the transfer of two electrons yields peroxide.

Both compounds are potentially destructive. The strategy for the safe reduction of O_2 is clear: the catalyst avoids releasing partly reduced intermediates. Cytochrome *c* oxidase meets this crucial criterion by holding O_2 tightly between Fe and Cu ions.

Although cytochrome *c* oxidase and other proteins that reduce O_2 are remarkably successful in not releasing intermediates, small amounts of superoxide anion and hydrogen peroxide are unavoidably formed. Superoxide, hydrogen peroxide, and species that can be generated from them such as the hydroxyl radical $(OH\cdot)$ are collectively referred to as *reactive oxygen species* or *ROS*. Oxidative damage caused by ROS has been implicated in the aging process as well as in a growing list of diseases (Table 18.3).

Information from M. Lieberman and A. D. Marks, *Basic Medical Biochemistry: A Clinical Approach,* 4th ed. (Lippincott, Williams & Wilkins, 2012), p. 437.

What are the cellular defense strategies against oxidative damage by ROS? Chief among them is the enzyme superoxide dismutase. This enzyme scavenges superoxide radicals by catalyzing the conversion of two of these radicals into hydrogen peroxide and molecular oxygen.

Eukaryotes contain two forms of this enzyme, a manganese-containing version located in mitochondria and a copper-and-zinc-dependent cytoplasmic form. These enzymes perform the dismutation reaction by a similar mechanism (Figure 18.18). The oxidized form of the enzyme is

reduced by superoxide to form oxygen. The reduced form of the enzyme, formed in this reaction, then reacts with a second superoxide ion to form peroxide, which takes up two protons along the reaction path to yield hydrogen peroxide.

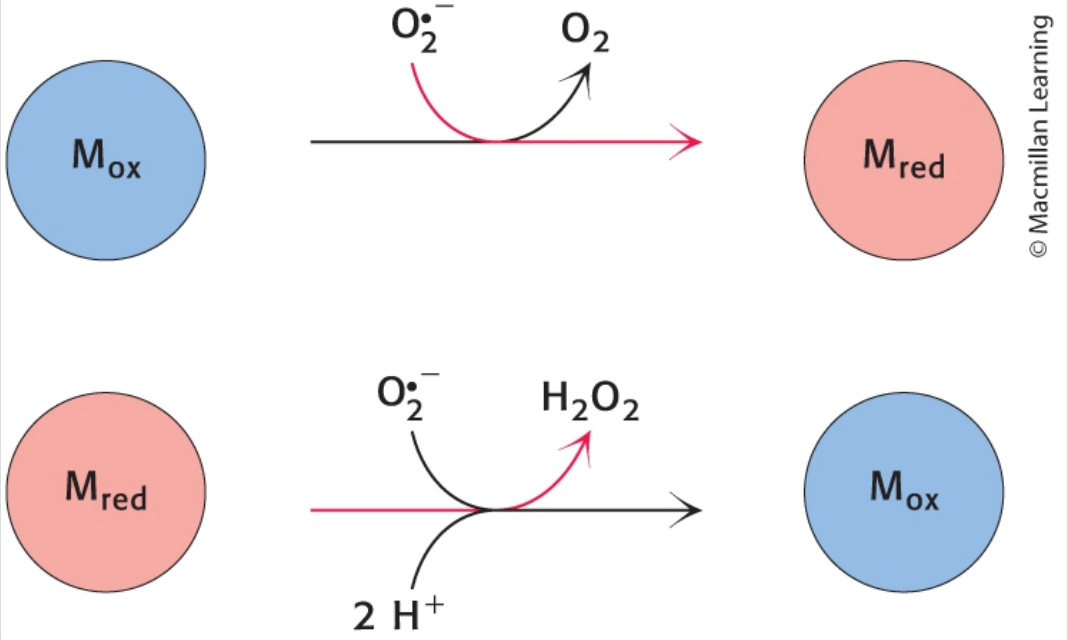

FIGURE 18.18 The superoxide dismutase mechanism has two phases. The oxidized form of superoxide dismutase (M_{ox}) reacts with one superoxide ion to form O_2 and generate the reduced form of the enzyme (M_{red}). The reduced form then reacts with a second superoxide and two protons to form hydrogen peroxide and regenerate the oxidized form of the enzyme.

The hydrogen peroxide formed by superoxide dismutase and by other processes is scavenged by *catalase*, a ubiquitous heme protein that catalyzes the dismutation of hydrogen peroxide into water and molecular oxygen.

$$2H_2O_2 \xrightleftharpoons{\text{Catalase}} O_2 + 2\ H_2O$$

Superoxide dismutase and catalase are remarkably efficient, performing their reactions at or near the diffusion-limited rate (Section 5.4). Glutathione peroxidase also plays a role in scavenging H_2O_2 (Section 20.5). Other cellular defenses against oxidative damage include the antioxidant vitamins, vitamins E and C. Because it is lipophilic, vitamin E is especially useful in protecting membranes from lipid peroxidation.

 A long-term benefit of exercise may be to increase the amount of superoxide dismutase in the cell. The elevated aerobic metabolism during exercise causes more ROS to be generated. In response, the cell synthesizes more protective enzymes. The net effect is one of protection, because the increase in superoxide dismutase more effectively protects the cell during periods of rest.

Despite the fact that reactive oxygen species are known hazards, recent evidence suggests that, under certain circumstances, the controlled generation of these molecules may be an important component of signal-transduction pathways. For instance, growth factors have been shown to increase ROS levels as part of their signaling pathway, which in turn regulate channels and transcription factors. ROS have been implicated in the control of cell differentiation, the immune response, and autophagy, as well as other metabolic activities. The dual role of ROS is an excellent example of the wondrous complexity of biochemistry of living systems: even potentially harmful substances can be harnessed to play useful roles.

Self-Check Question

Which electron-transport chain complex is not a member of the respirasome? Which one contains an enzyme of the citric acid cycle? Finally, which one uses FAD as a coenzyme?

Electrons can be transferred between groups that are not in contact

How are electrons transferred between electron-carrying groups of the respiratory chain? This question is intriguing because these groups are frequently buried in the interior of a protein in fixed positions and are therefore not directly in contact with one another. Electrons can move through space, even through a vacuum. However, the rate of electron transfer through space falls off rapidly as the electron donor and electron acceptor move apart from each other, decreasing by a factor of 10 for each increase in separation of 0.8 Å.

The protein environment provides more-efficient pathways for electron conduction: typically, the rate of electron transfer decreases by a factor of 10 every 1.7 Å (**Figure 18.19**). For groups in contact, electron-transfer reactions can be quite fast, with rates of approximately $10^{13}\ s^{-1}$. Within proteins in the electron-transport chain, electron-carrying groups are typically separated by 15 Å beyond their van der Waals contact distance. For such separations, we expect electron-transfer rates of approximately $10^{4}\ s^{-1}$ (i.e., electron transfer in less than 1 ms), assuming that all other factors are optimal. Without the mediation of the protein, an electron transfer over this distance would take approximately 1 day.

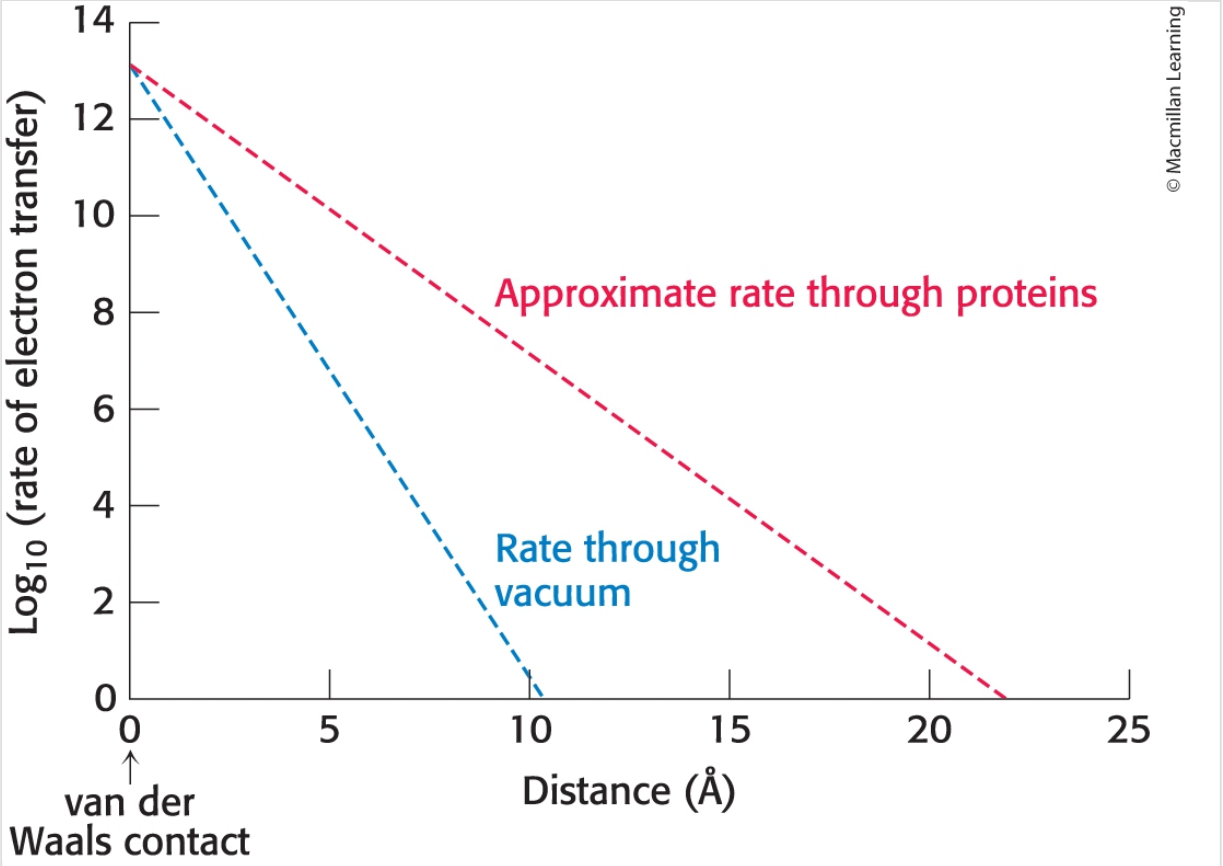

FIGURE 18.19 Proteins dramatically improve the rate of electron transfer between atoms at a distance. The rate of electron transfer decreases as the electron donor and the electron acceptor move apart. In a vacuum, the rate decreases by a factor of 10 for every increase of 0.8 Å. In proteins, the rate decreases more gradually, by a factor of 10 for every increase of 1.7 Å; however, this rate is only approximate because variations in the structure of the intervening protein medium can affect it.

The case is more complicated when electrons must be transferred between two distinct proteins, such as when cytochrome *c* accepts electrons from Complex III or passes them on to Complex IV. A series of hydrophobic interactions bring the heme groups of cytochrome *c* and c_1 to within 4.5 Å of each other, with the iron atoms separated by 17.4 Å. This distance could allow cytochrome *c* reduction at a rate of $8.3 \times 10^6\ s^{-1}$.

18.4 A Proton Gradient Powers the Synthesis of ATP

Thus far, we have considered the flow of electrons from NADH to O_2, an *exergonic* process.

$$NADH + \tfrac{1}{2}O_2 + H^+ \rightleftharpoons H_2O + NAD^+$$
$$\Delta G^{\circ\prime} = -220.1 \text{ kJ mol}^{-1} \ (-52.6 \text{ kcal mol}^{-1})$$

Next, we consider how this process is coupled to the synthesis of ATP, an *endergonic* process.

$$ADP + P_i + H^+ \rightleftharpoons ATP + H_2O$$
$$\Delta G^{\circ\prime} = +30.5 \text{ kJ mol}^{-1} \ (+7.3 \text{ kcal mol}^{-1})$$

A molecular assembly in the inner mitochondrial membrane carries out the synthesis of ATP. This enzyme complex was originally called the *mitochondrial ATPase* or F_1F_0 *ATPase* because it was discovered through its catalysis of the reverse reaction, the hydrolysis of ATP. **ATP synthase**, its preferred name, emphasizes its actual role in the mitochondrion. It is also called **Complex V**.

How is the oxidation of NADH coupled to the phosphorylation of ADP? Electron transfer was first suggested to lead to the formation of a covalent high-energy intermediate that serves as a compound having a high phosphoryl-transfer potential, analogous to the generation of ATP by the formation of 1,3-bisphosphoglycerate in glycolysis (Section 16.2). An alternative proposal was that electron transfer aids the formation of an activated protein conformation, which then drives ATP synthesis.

However, the search for such intermediates for several decades proved fruitless.

The chemiosmotic hypothesis suggested that ATP formation is powered by a proton gradient

In 1961, Peter Mitchell suggested a radically different mechanism called the *chemiosmotic hypothesis*. He proposed that electron transport and ATP synthesis are coupled by a proton gradient across the inner mitochondrial membrane. In his model, the transfer of electrons through the respiratory chain leads to the pumping of protons from the matrix to the intermembrane space. The H^+ concentration becomes lower in the matrix, and an electric field with the matrix side negative is generated (Figure 18.20). Protons then flow back into the matrix to equalize the distribution. Mitchell's idea was that this flow of protons drives the synthesis of ATP by ATP synthase.

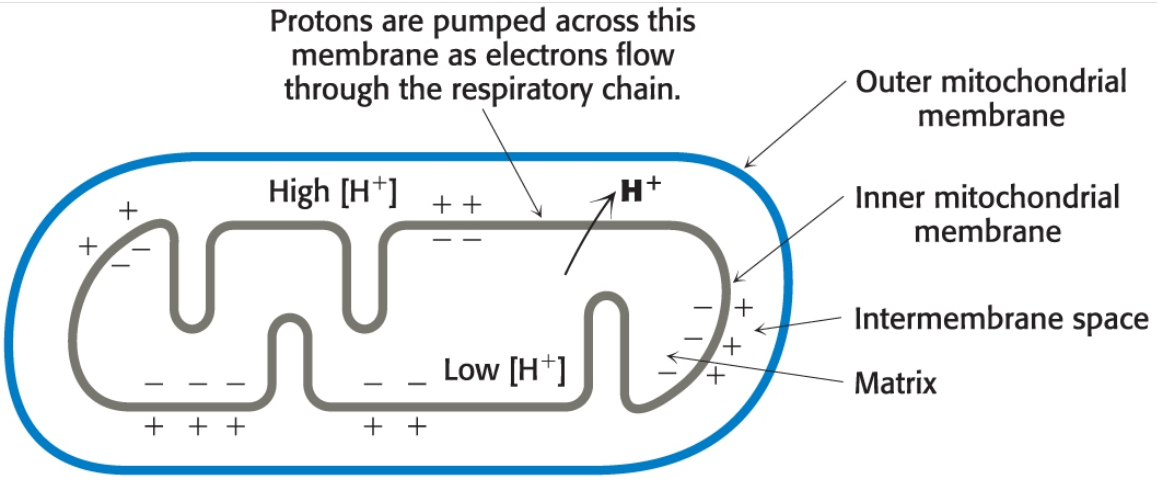

FIGURE 18.20 The chemiosmotic hypothesis states that electron-driven proton transport and ATP synthesis are coupled. Electron transfer through the respiratory chain leads to the pumping of protons from the matrix to the intermembrane space. The pH gradient and membrane potential constitute a proton-motive force that is used to drive ATP synthesis.

As noted earlier, the energy-rich unequal distribution of protons across a membrane is called the *proton-motive force*. The proton-motive force is composed of two components: a chemical gradient and a charge gradient. The chemical gradient for protons can be represented as a pH gradient. The charge gradient is created by the positive charge on the unequally distributed protons forming the chemical gradient. Mitchell proposed that both components power the synthesis of ATP.

$$\text{Proton-motive force } (\Delta p) = \text{chemical gradient } (\Delta p\text{H}) + \text{charge gradient } (\Delta\psi)$$

Mitchell's highly innovative hypothesis is now supported by a wealth of evidence. Indeed, electron transport does generate a proton gradient across the inner mitochondrial membrane. The pH outside is 1.4 units lower than inside, and the membrane potential is 0.14 V, the outside being positive. As we calculated in Section 18.2, this membrane potential corresponds to a free energy of 21.8 kJ (5.2 kcal) per mole of protons.

An artificial system was created to elegantly demonstrate the basic principle of the chemiosmotic hypothesis. The role of the respiratory chain was played by bacteriorhodopsin, a membrane protein from halobacteria that pumps protons when illuminated (Chapter 19). Synthetic vesicles containing bacteriorhodopsin and mitochondrial ATP synthase purified from beef heart were created (**Figure 18.21**). When the vesicles were exposed to light, ATP was formed. This key experiment clearly showed that the respiratory chain and ATP synthase are biochemically separate systems, linked only by a proton-motive force.

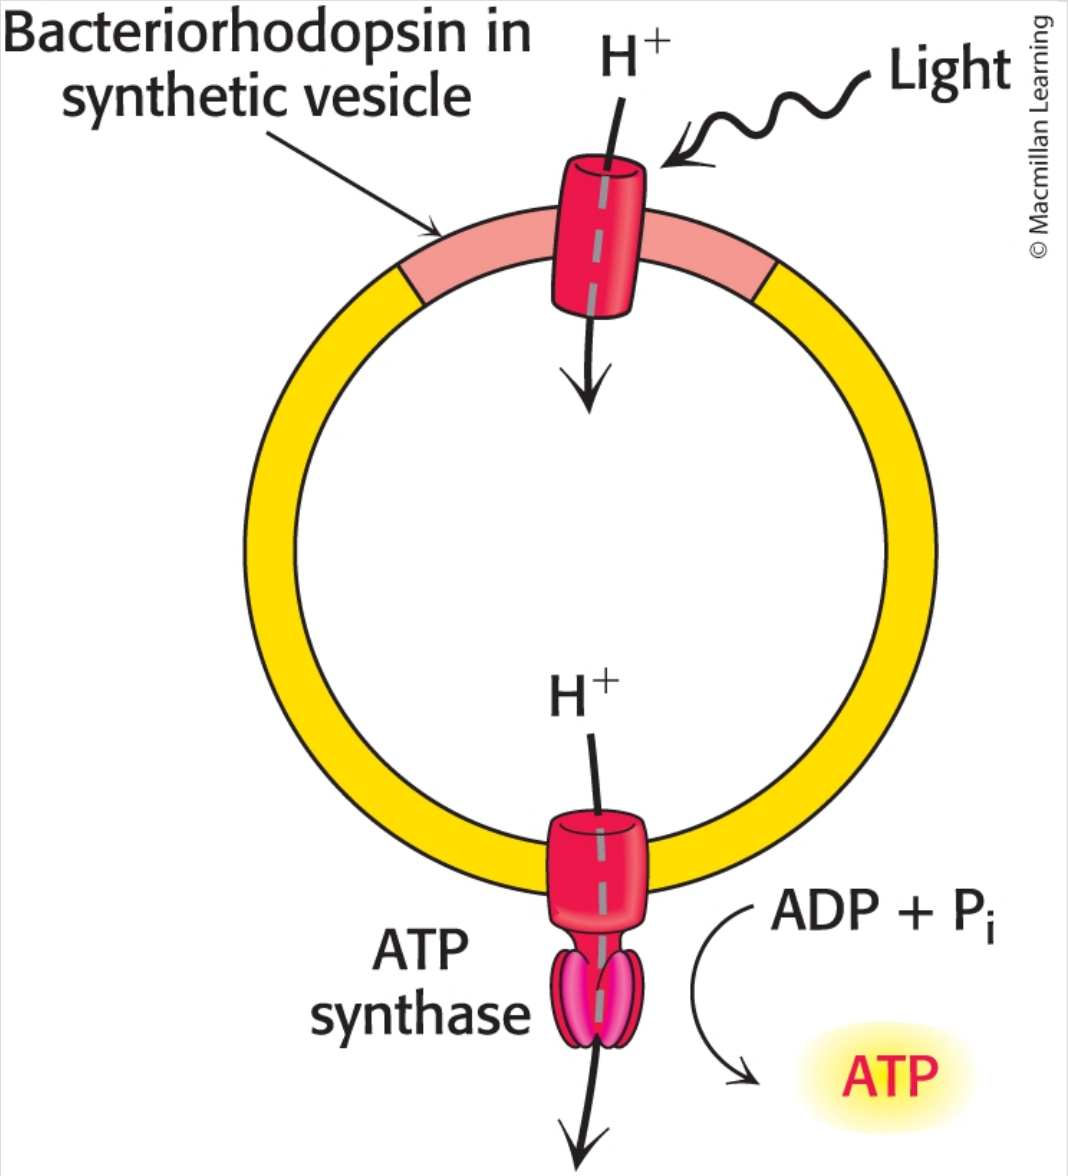

FIGURE 18.21 The chemiosmotic hypothesis is supported by experiments using bacterial proton pumps. ATP is synthesized when reconstituted membrane vesicles containing bacteriorhodopsin (a light-driven proton pump) and ATP synthase are exposed to light.

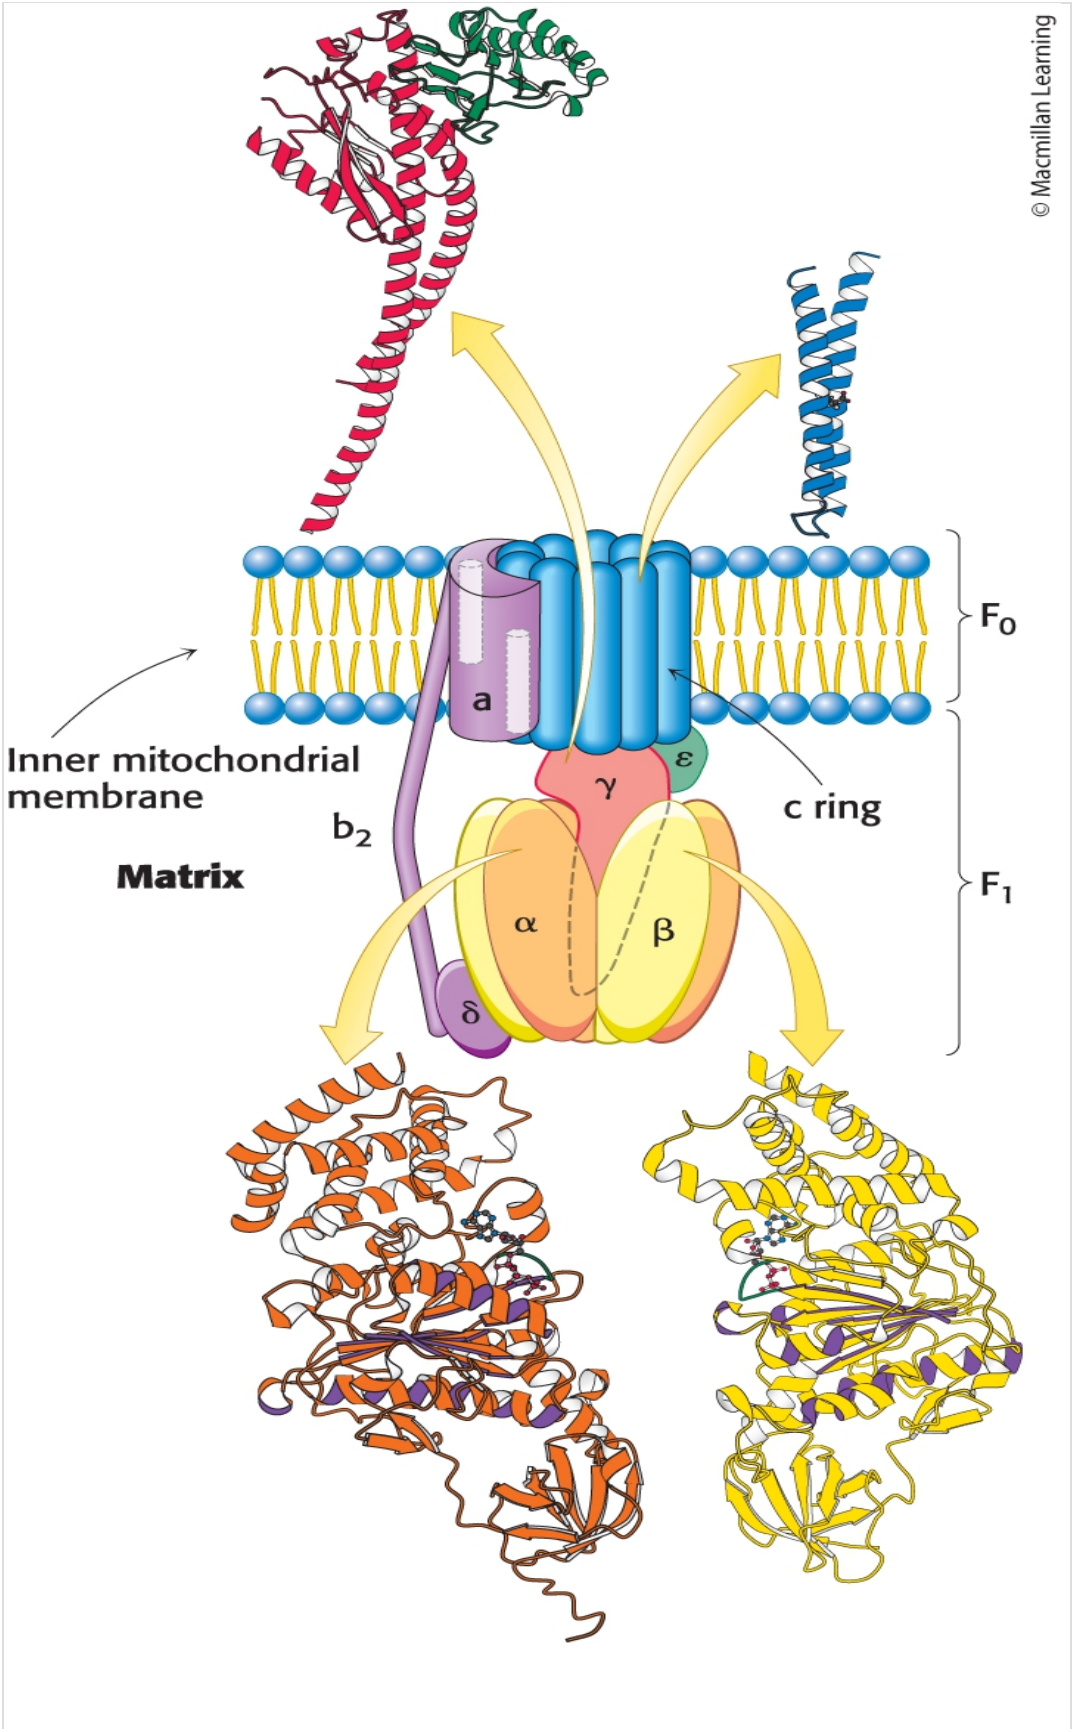

Some have argued that, along with the elucidation of the structure of DNA, the discovery that ATP synthesis is powered by a proton gradient is one of the two major advances in biology in the twentieth century.

Mitchell's initial postulation of the chemiosmotic theory was not warmly received by all: some scientists thought of Mitchell as a "court jester," whose work was of no consequence. In Chapter 19 we will discuss how collaboration with another scientist changed this perception. Eventually, Peter Mitchell was awarded the Nobel Prize in Chemistry for his contributions to understanding oxidative phosphorylation.

ATP synthase is composed of a proton-conducting unit and a catalytic unit

Two parts of the puzzle of how NADH oxidation is coupled to ATP synthesis are now evident: (1) electron transport generates a proton-motive force, and (2) ATP synthesis by ATP synthase can be powered by a proton-motive force. How is the proton-motive force converted into the high phosphoryl-transfer potential of ATP?

Biochemical, electron microscopic, and crystallographic studies of ATP synthase have revealed many details of its structure (**Figure 18.22**). It is a large, complex enzyme resembling a ball on a stick. Much of the "stick" part, called the F_0 subunit, is embedded in the inner mitochondrial membrane. The 85-Å-diameter ball, called the F_1 subunit, protrudes into the mitochondrial matrix. The F_1 subunit contains the catalytic activity of the synthase. In fact, isolated F_1 subunits display ATPase activity.

FIGURE 18.22 The structure of ATP synthase reveals a complex molecular rotational motor. A schematic structure is shown along with representations of the components for which structures have been determined to high resolution. The P-loop NTPase domains of the α and β subunits are indicated by purple shading. Notice that part of the enzyme complex is embedded in the inner mitochondrial membrane, whereas the remainder resides in the matrix.

[Drawn from 1E79.pdb and 1C0V.pdb.]

INTERACT with this model in Achieve

The F_1 subunit consists of five types of polypeptide chains (α_3, β_3, γ, δ, and ε) with the indicated stoichiometry. The α and β subunits, which make up the bulk of the F_1, are arranged alternately in a hexameric ring; they are homologous to one another and are members of the P-loop NTPase family (Section 9.4). Both bind nucleotides but only the β subunits are catalytically active. Just below the α and β subunits is a central stalk consisting of the γ and ε proteins. The γ subunit includes a long helical coiled coil that extends into the center of the $\alpha_3\beta_3$ hexamer. The γ subunit breaks the symmetry of the $\alpha_3\beta_3$ hexamer: each of the β subunits is distinct by virtue of its interaction with a different, asymmetrical, face of γ. Distinguishing the three β subunits is crucial for understanding the mechanism of ATP synthesis.

The F_0 subunit is a hydrophobic segment that spans the inner mitochondrial membrane. F_0 contains the proton channel of the complex. This channel consists of a ring comprising from 8 to 14 **c** subunits that are embedded in the membrane. A single **a** subunit binds to the outside of the ring. The F_0 and F_1 subunits are connected in two ways: by the central γε stalk and by an exterior column. The exterior column consists of one **a** subunit, two **b** subunits, and the δ subunit.

ATP synthases interact with one another to form dimers, which then associate to form large oligomers of dimers (Figure 18.23). This association stabilizes the individual enzymes to the rotational forces required for catalysis, which we will examine shortly, and facilitates the curvature of the inner mitochondrial membrane. The formation of the cristae allows the proton pumps of the electron-transport chain to localize the proton gradient in the vicinity of the synthases, which are located at the tips of the cristae, thereby enhancing the efficiency of ATP synthesis (Figure 18.24).

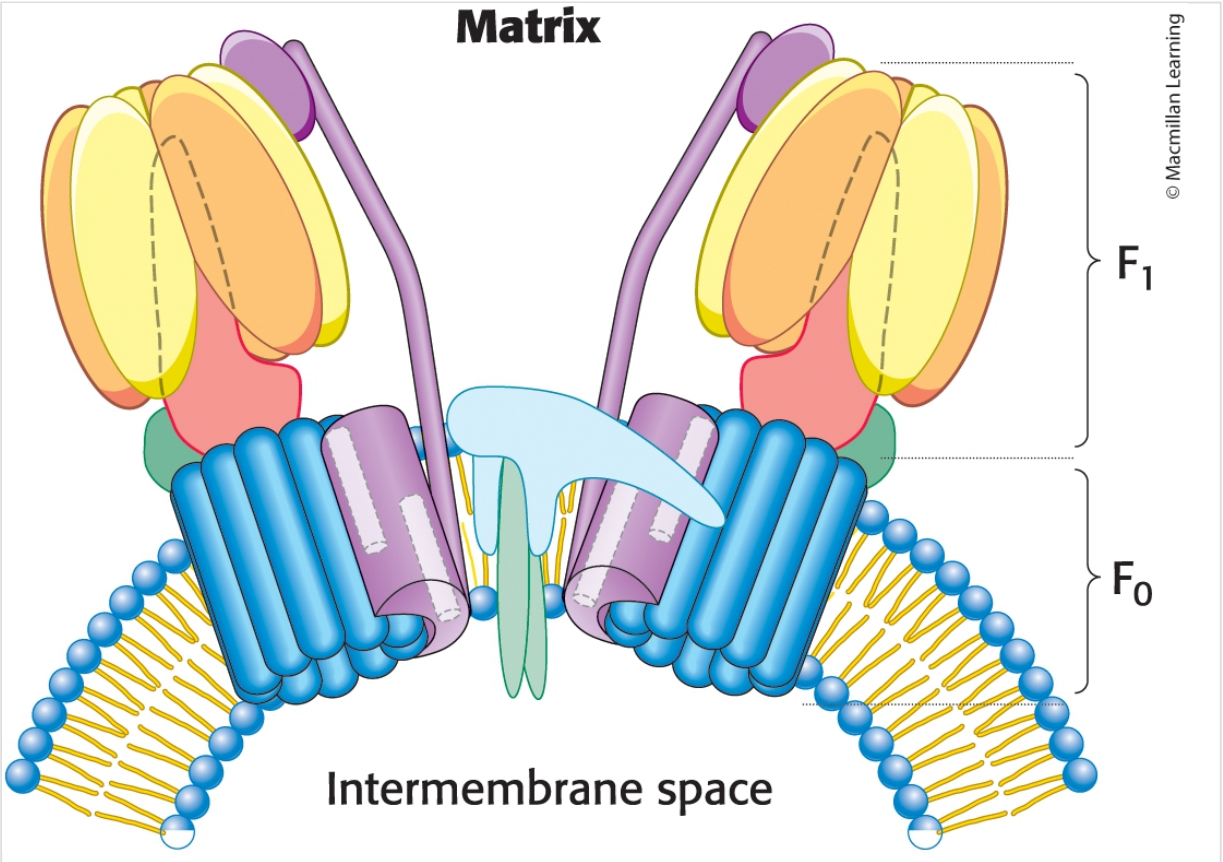

FIGURE 18.23 Mitochondrial ATP synthase forms homodimers. A schematic representation of a dimer of mitochondria ATP synthase is shown embedded in the inner mitochondrial membrane. The dimer, joined by an assortment of proteins, assists in bending the inner mitochondria membrane. The structure of the dimer was determined by cryo-electron microscopy.

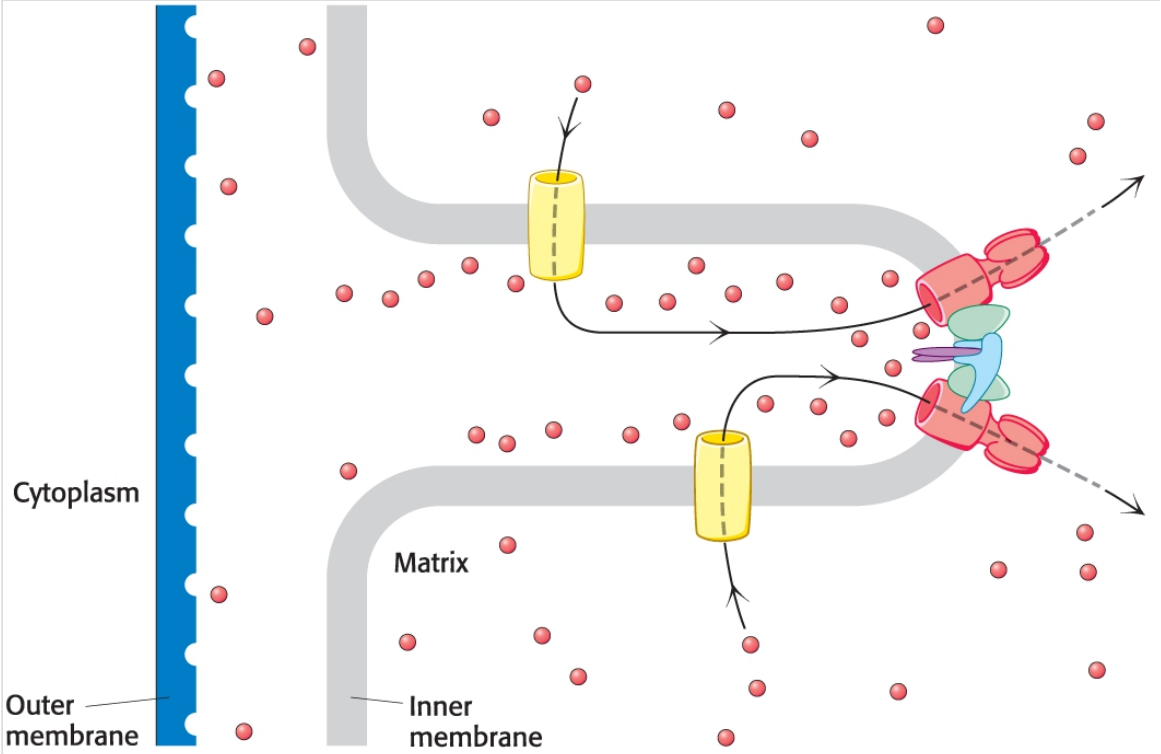

FIGURE 18.24 ATP synthase assists in the formation of cristae. Oligomers of ATP synthase dimers facilitate cristae formation, creating an area where the protons (shown as red balls) are concentrated and have ready access to the F_o portion of the ATP synthase. The electron-transport chain is represented by the yellow cylinders embedded in the inner mitochondrial membrane.

Proton flow through ATP synthase leads to the release of tightly bound ATP via the binding-change mechanism

ATP synthase catalyzes the formation of ATP from ADP and orthophosphate.

$$ADP^{3-} + HPO_4^{2-} + H^+ \rightleftharpoons ATP^{4-} + H_2O$$

The actual substrates are ADP and ATP complexed with Mg^{2+}, as in all known phosphoryl-transfer reactions with these nucleotides. A terminal oxygen atom of ADP attacks the phosphorus atom of P_i to form a pentacovalent intermediate, which then dissociates into ATP and H_2O (Figure 18.25).

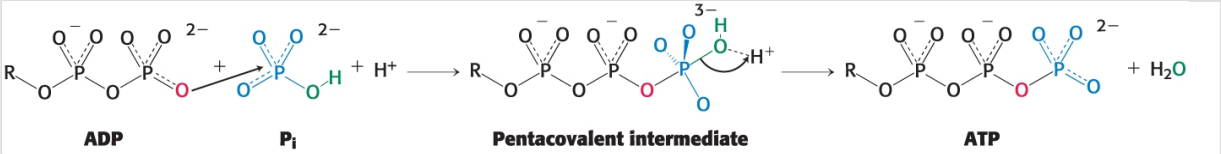

FIGURE 18.25 ATP-synthesis is catalyzed by ATP synthase. One of the oxygen atoms of ADP attacks the phosphorus atom of P_i to form a pentacovalent intermediate, which then forms ATP and releases a molecule of H_2O.

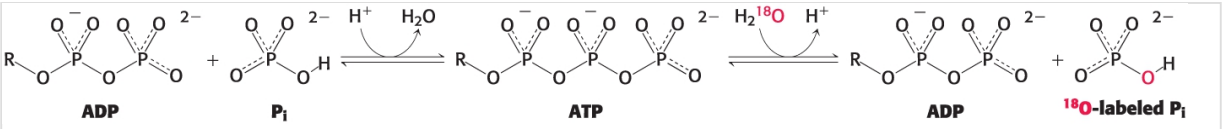
How does the flow of protons drive the synthesis of ATP? Isotopic-exchange experiments unexpectedly revealed that enzyme-bound ATP forms readily in the absence of a proton-motive force. When ADP and P_i were added to ATP synthase in $H_2{}^{18}O$, ^{18}O became incorporated into P_i through the synthesis of ATP and its subsequent hydrolysis (Figure 18.26). The rate of incorporation of ^{18}O into P_i showed that about equal amounts of bound ATP and ADP are in equilibrium at the catalytic site, even in the absence of a proton gradient. However, ATP does not leave the catalytic site unless protons flow through the enzyme. Thus, the role of the proton gradient is not to form ATP but to release it from the synthase.



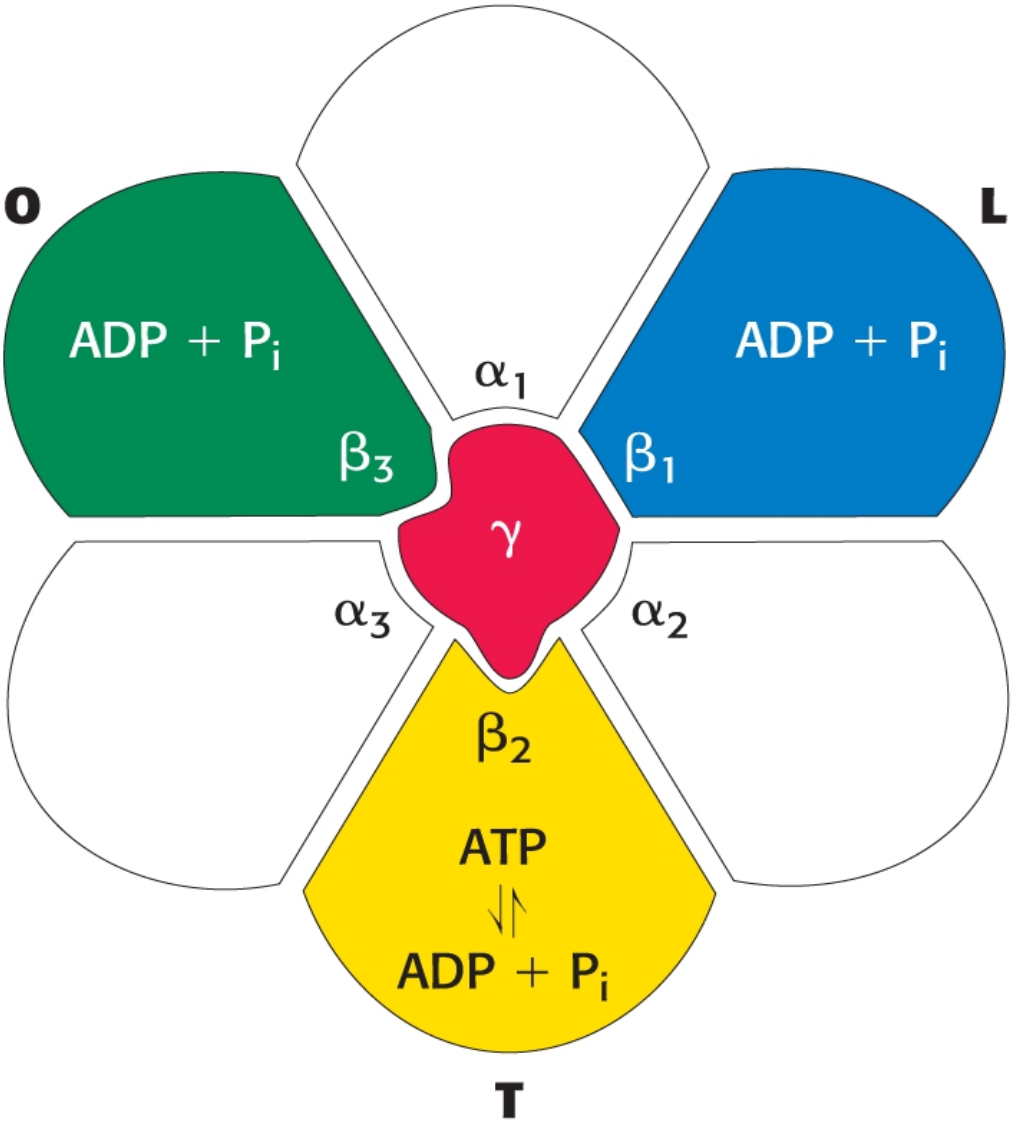


FIGURE 18.26 ATP forms without a proton-motive force but is not released. The results of isotopic-exchange experiments indicate that enzyme-bound ATP is formed from ADP and P_i in the absence of a proton-motive force.

The fact that three β subunits are components of the F_1 moiety of the ATPase means that there are three active sites on the enzyme, each performing one of three different functions at any instant. The proton-motive force causes the three active sites to sequentially change functions as protons flow through the membrane-embedded component of the enzyme. Indeed, we can think of the enzyme as consisting of a moving part and a stationary part: (1) the moving unit, or *rotor,* consists of the **c** ring and the γε stalk; and (2) the stationary unit, or *stator,* is composed of the remainder of the molecule.

How do the three active sites of ATP synthase respond to the flow of protons? A number of experimental observations suggested what is known as the *binding-change mechanism* for proton-driven ATP synthesis. This proposal states that a β subunit can perform each of three sequential steps in the synthesis of ATP by changing conformation. These steps are (1) ADP and P_i binding, (2) ATP synthesis, and (3) ATP release. As already noted, interactions with the γ subunit make the three β subunits structurally distinct (Figure 18.27). At any given moment, one β subunit will be in the L, or loose, conformation. This conformation binds ADP and P_i. A second subunit will be in the T, or tight, conformation. This conformation binds ATP with great affinity, so much so that it will convert bound ADP and P_i into ATP. Both the T and L conformations are sufficiently constrained that they cannot release bound nucleotides. The final subunit will be in the O, or open,

form. This form has a more open conformation and can bind or release adenine nucleotides.

(B)

β subunit 1	L → T → O → L → T → O...
β subunit 2	O → L → T → O → L → T...
β subunit 3	T → O → L → T → O → L...

FIGURE 18.27 ATP synthase nucleotide-binding sites cycle through distinct conformational states. (A) The γ subunit passes through the center of the $\alpha_3\beta_3$ hexamer and makes the nucleotide-binding sites in the β subunits distinct from one another. The β subunits are colored to distinguish them from one another, whereas the conformational states are denoted "O," "L," and "T." (B) The progressive and simultaneous alteration of the conformational states of all three β subunits of ATP synthase shows that each subunit cycles through the three different states in the same order but at different times as the γ subunit rotates.

The rotation of the γ subunit drives the interconversion of these three forms (**Figure 18.28**). Consider a single subunit, like the one shown in yellow in Figure 18.28, which is initially in the T form in which bound ADP and P_i are transiently combining to form ATP. Suppose that the γ subunit is rotated by 120 degrees in a counterclockwise direction (as viewed from the top). This rotation converts the T-form site into an O-form site with the nucleotide bound as ATP. Concomitantly, the L-form site is converted into a T-form site, enabling the transformation of an additional ADP and P_i into ATP. The ATP in the O-form site can now depart from the enzyme to be replaced by ADP and P_i. An additional 120-degree rotation converts this O-form site into an L-form site, trapping these substrates. Each subunit progresses from the T to the O to the L form with no two subunits ever present in the same conformational form. This mechanism suggests that ATP can be synthesized and released by driving the rotation of the γ subunit in the appropriate direction.

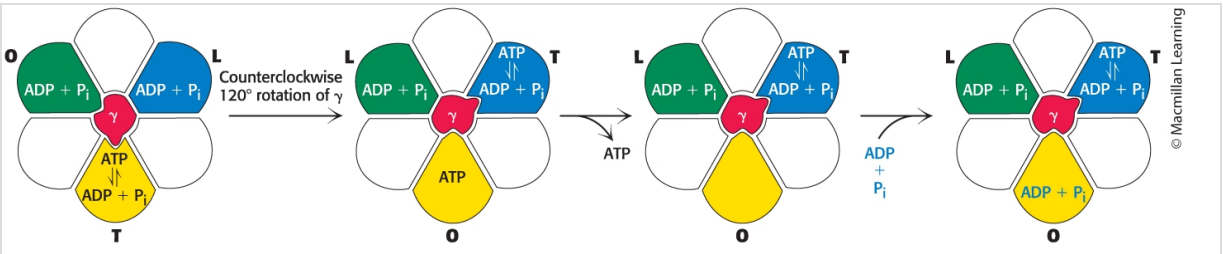

FIGURE 18.28 The binding-change mechanism involves the cycling of all three β subunits through three conformations. The rotation of the γ subunit interconverts the three β subunits.

The subunit in the T (tight) form interconverts ADP and P_i and ATP but does not allow ATP to be released. When the γ subunit is rotated by 120 degrees in a counterclockwise direction, the T-form subunit is converted into the O form, allowing ATP release. ADP and P_i can then bind to the O-form subunit. An additional 120-degree rotation (not shown) traps these substrates in an L-form subunit.

Rotational catalysis is the world's smallest molecular motor

Is it possible to observe the proposed rotation directly? Elegant experiments, using single-molecule techniques (Section 5.5), have demonstrated the rotation through the use of a simple experimental system consisting solely of cloned $\alpha_3\beta_3\gamma$ subunits (**Figure 18.29**). The β subunits were engineered to contain amino-terminal polyhistidine tags, which have a high affinity for nickel ions. This property of the tags allowed the $\alpha_3\beta_3$ assembly to be immobilized on a glass surface that had been coated with nickel ions. The γ subunit was linked to a fluorescently labeled actin filament to provide a long segment that could be observed under a fluorescence microscope. Remarkably, the addition of ATP caused the actin filament to rotate unidirectionally in a counterclockwise direction, confirming visually that the γ subunit was rotating, driven by the hydrolysis of *ATP.* Thus, the catalytic activity of an individual molecule could be observed. The counterclockwise rotation is consistent with the predicted mechanism for hydrolysis because the molecule was viewed from below relative to the view shown in Figure 18.29.

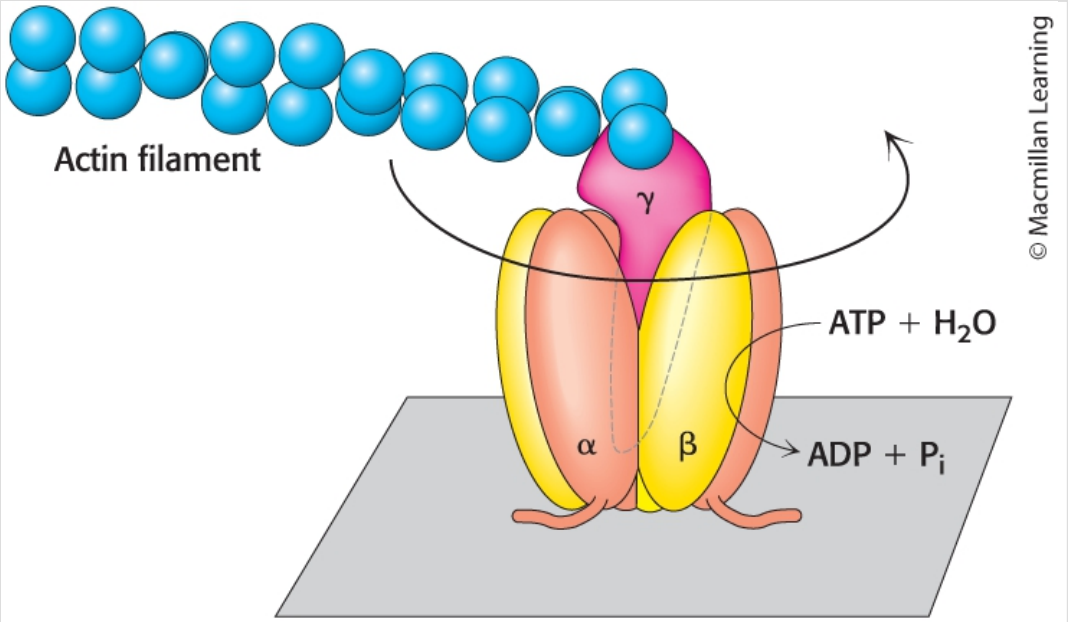

FIGURE 18.29 The ATP-driven rotation in ATP synthase has been directly observed. The $\alpha_3\beta_3$ hexamer of ATP synthase is fixed to a surface, with the γ subunit projecting upward and linked to a fluorescently labeled actin filament. The addition and subsequent hydrolysis of ATP result in the counterclockwise rotation of the γ subunit, which can be directly seen under a fluorescence microscope.

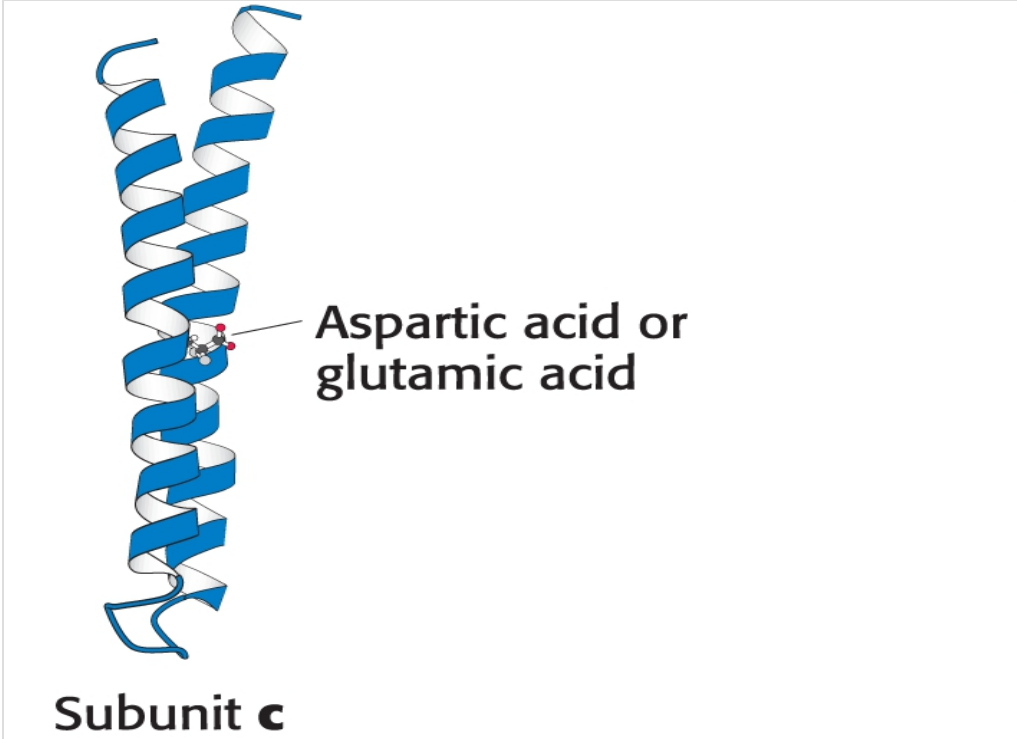

More-detailed analysis in the presence of lower concentrations of ATP revealed that the γ subunit rotates in 120-degree increments. Each increment corresponds to the hydrolysis of a single ATP molecule. In addition, from the results obtained by varying the length of the actin filament and measuring the rate of rotation, the enzyme appears to operate near 100% efficiency; that is, essentially all of the energy released by ATP hydrolysis is converted into rotational motion.

Self-Check Question

Recall our study of enzymes in previous chapters: Why do isolated F_1 subunits of ATP synthase catalyze ATP hydrolysis?

Proton flow around the c ring powers ATP synthesis

The direct observation of rotary motion of the γ subunit is strong evidence for the rotational mechanism for ATP synthesis. The last remaining question is: How does proton flow through F_0 drive the rotation of the γ subunit? The mechanism depends on the structures of the **a** and **c** subunits of F_0 (**Figure 18.30**). The stationary **a** subunit directly abuts the membrane-spanning ring formed by 8 to 14 **c** subunits. The **a** subunit includes two hydrophilic half-channels that do not span the membrane (Figure 18.30). Thus, protons can pass into either of these channels, but they cannot move completely across the membrane. The **a** subunit is positioned such that each half-channel directly interacts with one **c** subunit.

© Macmillan Learning

FIGURE 18.30 Components of the proton-conducting unit of ATP synthase include two half channels and a critical charged residue. The **c** subunit consists of two α helices that span the membrane. In *E. coli*, an aspartic or glutamic acid residue in one of the helices lies on the center of the membrane. The structure of the **a** subunit has not yet been directly observed, but it appears to include two half-channels that allow protons to enter and pass partway but not completely through the membrane.

The structure of the **c** subunit was determined both by NMR methods and by x-ray crystallography. Each polypeptide chain forms a pair of α helices that span the membrane. A glutamic acid (or aspartic acid) residue is found in the middle of one of the helices. If the glutamate is charged (unprotonated), the **c** subunit will not move into the membrane. The key to proton movement across the membrane is that, in a proton-rich environment, such as the intermembrane space, a proton will enter a channel and bind the glutamate residue, while the glutamic acid in a proton-poor environment of the other half-channel will release a proton (Figure 18.31). The **c** subunit with the bound proton then moves into the membrane as the ring rotates by one **c** subunit. This rotation brings the newly deprotonated **c** subunit from the matrix half-channel to the proton-rich intermembrane space half-channel, where it can bind a proton. The movement of protons through the half-channels from the high proton concentration of the intermembrane space to the low proton concentration of the matrix powers the rotation of the **c** ring. The **a** unit remains stationary as the **c** ring rotates. Each proton that enters the intermembrane space half-channel of the **a** unit moves through the membrane by riding around on the rotating **c** ring to exit through the matrix half-channel into the proton-poor environment of the matrix (Figure 18.32).

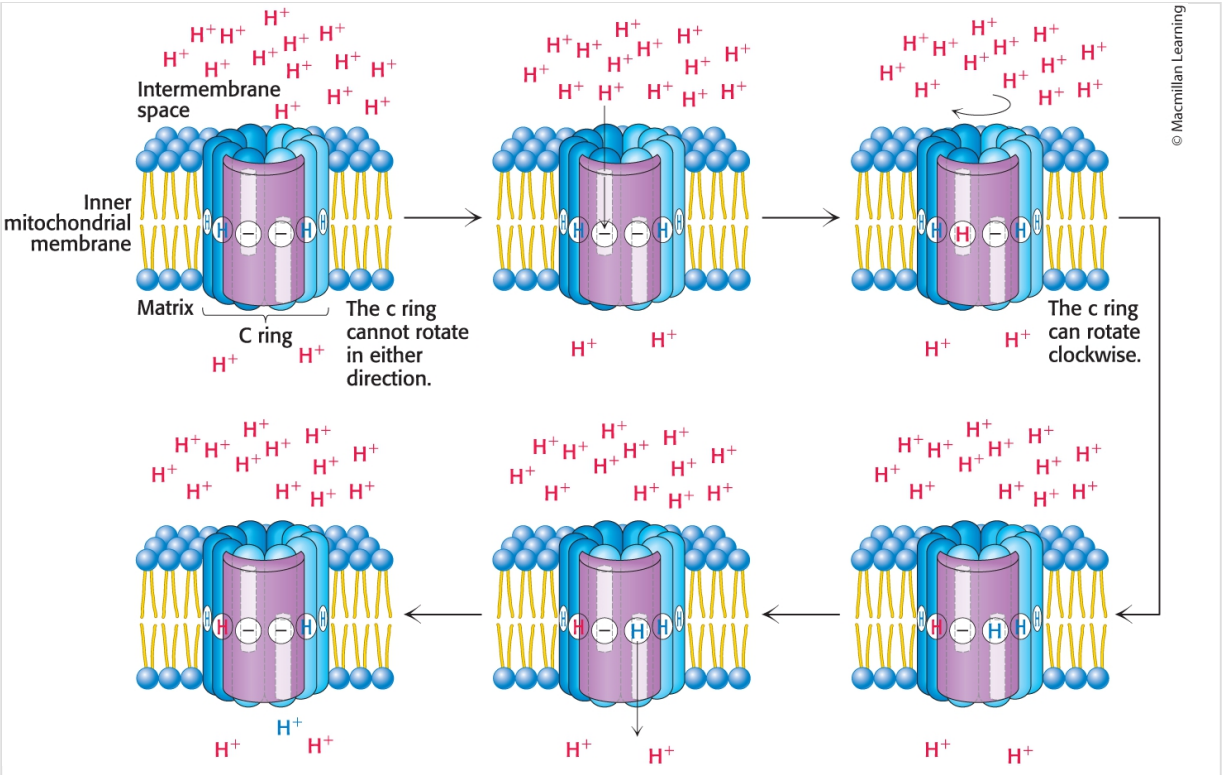

FIGURE 18.31 Proton motion across the membrane drives rotation of the c ring. A proton enters from the intermembrane space into the cytoplasmic half-channel to neutralize the charge on an aspartate or glutamate residue in a **c** subunit. With this charge neutralized, the **c** ring can rotate clockwise by one **c** subunit, moving an aspartic or glutamic acid residue out of the membrane into the matrix half-channel. This proton can move into the matrix, resetting the system to its initial state.

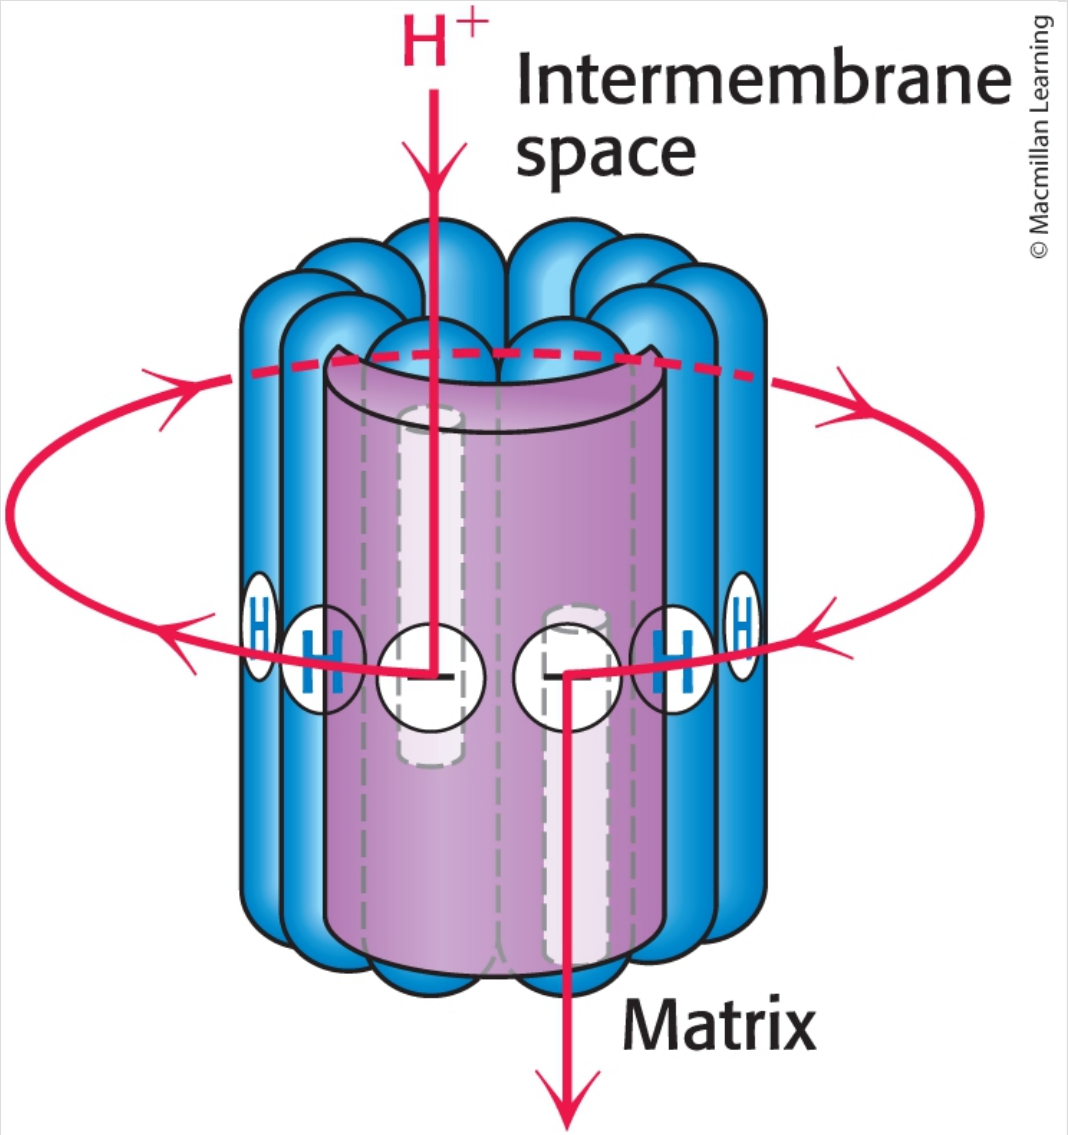

FIGURE 18.32 Protons must travel around the c ring to cross the membrane. Each proton enters the cytoplasmic half-channel, follows a complete rotation of the **c** ring, and exits through the other half-channel into the matrix.

How does the rotation of the **c** ring lead to the synthesis of ATP? The **c** ring is tightly linked to the γ and ε subunits. Thus, as the **c** ring turns, the γ and ε subunits are turned inside the $\alpha_3\beta_3$ hexamer unit of F_1. The rotation of the γ subunit in turn promotes the synthesis of ATP through

the binding-change mechanism. The exterior column formed by the two **b** chains and the δ subunit prevents the $\alpha_3\beta_3$ hexamer from rotating along with the **c** ring. Recall that the dimerization and subsequent oligomerization of the synthase in the cristae also stabilizes the enzyme to rotational forces.

As stated earlier, the number of **c** subunits in the **c** ring appears to range between 8 and 14. This number is significant because it determines the number of protons that must be transported to generate a molecule of ATP. Each 360-degree rotation of the γ subunit leads to the synthesis and release of three molecules of ATP. Thus, if there are 10 **c** subunits in the ring (as was observed in a crystal structure of yeast mitochondrial ATP synthase), each ATP generated requires the transport of $10/3 = 3.33$ protons. Recent evidence shows that the **c** rings of all vertebrates are composed of 8 subunits, making vertebrate ATP synthase the most efficient ATP synthase known, with the transport of only 2.7 protons required for ATP synthesis. For simplicity in calculations, we will assume a rounded average of these two numbers — 3 protons — must flow into the matrix for each ATP formed, but we must keep in mind that the true value may differ. As we will see, the electrons from NADH pump enough protons to generate 2.5 molecules of ATP, whereas those from $FADH_2$ yield 1.5 molecules of ATP.

Let us return for a moment to the example with which we began this chapter. If a resting human being requires 85 kg of ATP per day for bodily functions, then 3.3×10^{25} protons must flow through the ATP synthase per day, or 3.9×10^{20} protons per second. **Figure 18.33** summarizes the process of oxidative phosphorylation.

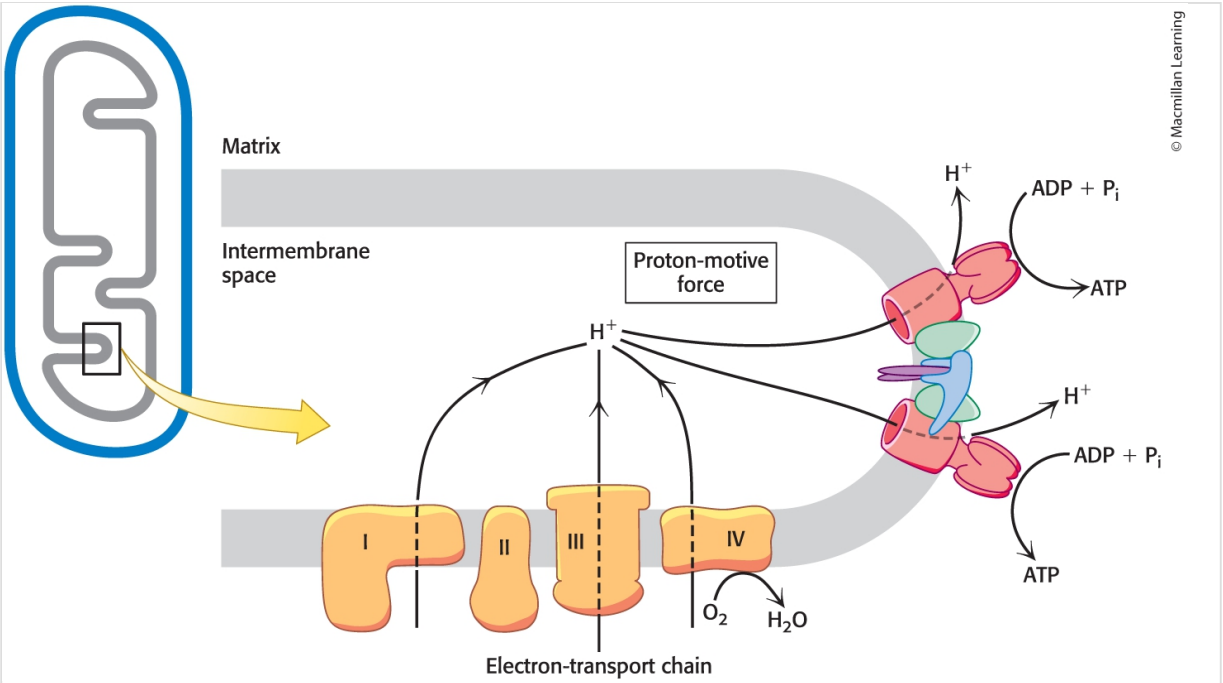

FIGURE 18.33 An overview of oxidative phosphorylation shows the spatial relationship of the components. The electron-transport chain generates a proton gradient by pumping protons into the cristae, which is used to synthesize ATP by ATP synthase concentrated on the ends of the cristae.

ATP synthase and G proteins have several common features

The α and β subunits of ATP synthase are members of the P-loop NTPase family of proteins. In Section 14.2, we learned that the signaling properties of other members of this family, the G proteins, depend on their ability to bind nucleoside triphosphates and diphosphates with great tenacity. They do not exchange nucleotides unless they are stimulated to do so by interaction with other proteins. The binding-change mechanism of ATP synthase is a variation on this theme. The P-loop regions of the β subunits will bind either ADP or ATP (or release

ATP), depending on which of three different faces of the γ subunit they interact with. The conformational changes take place in an orderly way, driven by the rotation of the γ subunit.

Self-Check Question

How many ATP are generated for each 360-degree rotation of the γ subunit of ATP synthase? Recall that the number of **c** subunits in the **c** ring varies across species. How many protons are required to form one ATP if the ring has 14 **c** subunits?

18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes

The inner mitochondrial membrane must be impermeable to most molecules, yet much exchange has to take place between the cytoplasm and the mitochondria. This exchange is mediated by an array of membrane-spanning transporter proteins.

Electrons from cytoplasmic NADH enter mitochondria by shuttles

One function of the respiratory chain is to regenerate NAD^+ for use in glycolysis. NADH generated by the citric acid cycle and fatty acid oxidation is already in the mitochondrial matrix, but how is cytoplasmic NADH reoxidized to NAD^+ under aerobic conditions? NADH cannot simply pass into mitochondria for oxidation by the respiratory chain, because the inner mitochondrial membrane is impermeable to NADH and NAD^+. The solution is that *electrons from NADH,* rather than NADH itself, are carried across the mitochondrial membrane. One of several means of introducing electrons from NADH into the electron-transport chain is the **glycerol 3-phosphate shuttle** (**Figure 18.34**):

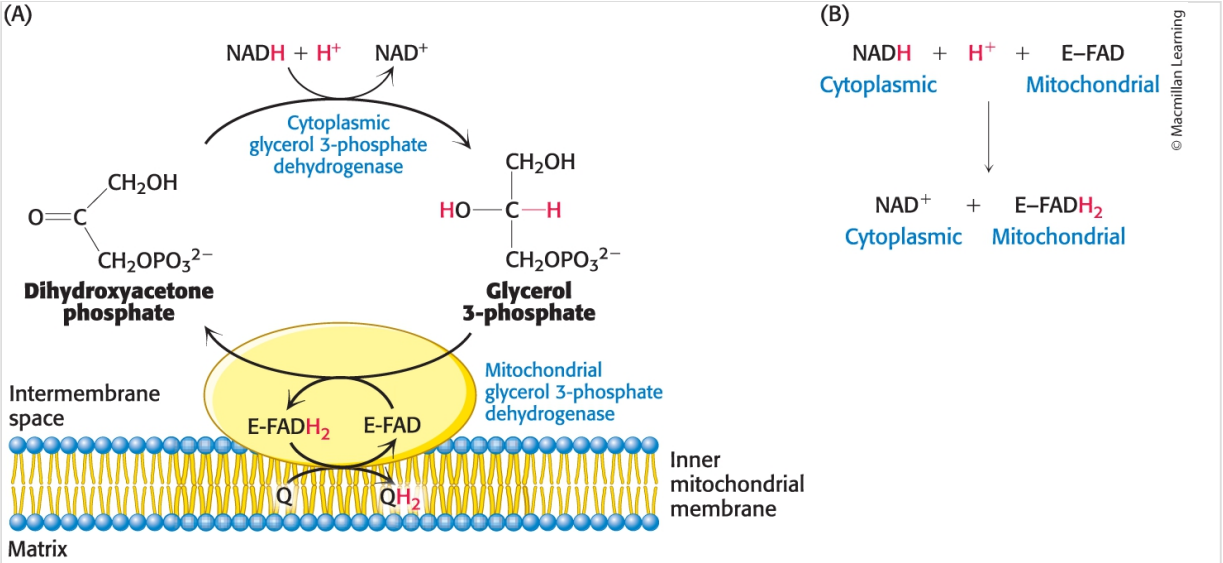

FIGURE 18.34 The glycerol 3-phosphate shuttle allows for rapid rates of oxidative phosphorylation at the cost of energetic efficiency. Electrons from NADH can enter the mitochondrial electron-transport chain by being used to reduce dihydroxyacetone phosphate to glycerol 3-phosphate. Glycerol 3-phosphate is reoxidized by electron transfer to an FAD prosthetic group in a membrane-bound glycerol 3-phosphate dehydrogenase. Subsequent electron transfer to Q to form QH_2 allows these electrons to enter the electron-transport chain.

- First, a pair of electrons is transferred from NADH to dihydroxyacetone phosphate, a glycolytic intermediate, to form glycerol 3-phosphate by cytosolic glycerol 3-phosphate dehydrogenase.
- Next, glycerol 3-phosphate moves into the mitochondrion where it is reoxidized to dihydroxyacetone phosphate on the outer surface of the inner mitochondrial membrane by a membrane-bound isozyme of glycerol 3-phosphate dehydrogenase. The reaction passes the electron pair to an FAD prosthetic group in this enzyme to form $FADH_2$, and regenerates dihydroxyacetone phosphate.
- Finally, the reduced flavin transfers its electrons to a molecule of Q, which then enters the respiratory chain as QH_2, and thus

ultimately delivers the electrons to Complex III.

When cytoplasmic NADH transported by the glycerol 3-phosphate shuttle is oxidized by the respiratory chain, 1.5 rather than 2.5 molecules of ATP are formed. The yield is lower because FAD rather than NAD^+ is the electron acceptor in mitochondrial glycerol 3-phosphate dehydrogenase. The use of FAD enables electrons from cytoplasmic NADH to be transported into mitochondria against an NADH concentration gradient. The price of this transport is one molecule of ATP per two electrons. This glycerol 3-phosphate shuttle is especially prominent in muscle, enabling it to sustain a very high rate of oxidative phosphorylation.

In the heart and liver, electrons from cytoplasmic NADH are brought into mitochondria by the **malate–aspartate shuttle**, which is mediated by two membrane carriers and four enzymes (**Figure 18.35**). Electrons are transferred from NADH in the cytoplasm to oxaloacetate, forming malate, which traverses the inner mitochondrial membrane in exchange for α-ketoglutarate and is then reoxidized by NAD^+ in the matrix to form NADH in a reaction catalyzed by the citric acid cycle enzyme malate dehydrogenase. The resulting oxaloacetate does not readily cross the inner mitochondrial membrane, and so a transamination reaction (Section 23.3) is needed to form aspartate, which can be transported to the cytoplasmic side in exchange for glutamate. Glutamate donates an amino group to oxaloacetate, forming aspartate and α-ketoglutarate. In the cytoplasm, aspartate is then deaminated to form oxaloacetate, and the cycle is restarted.

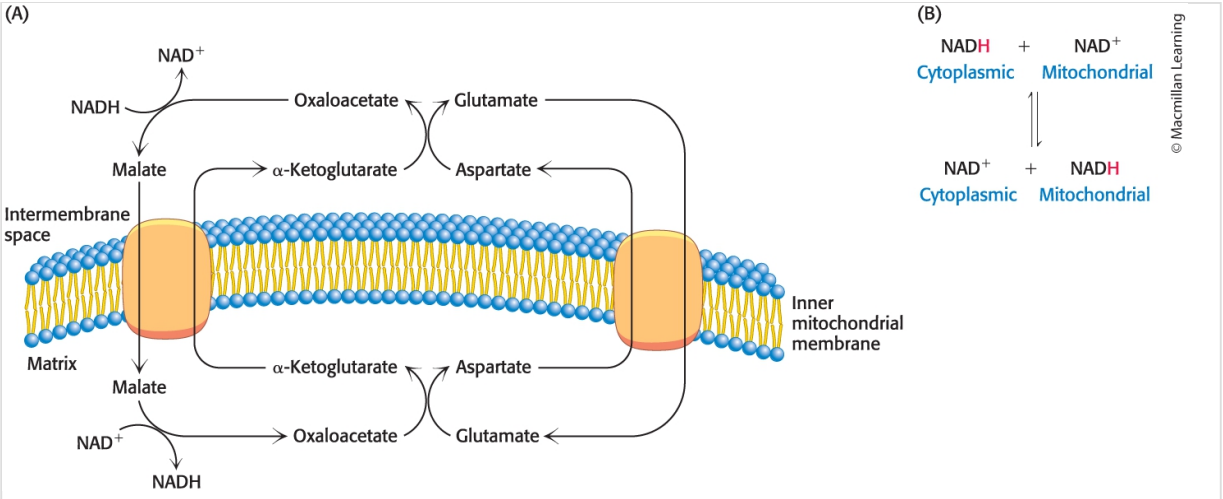

FIGURE 18.35 The malate–aspartate shuttle preserves all the chemical potential energy of cytoplasmically generated NADH. NADH produced in the matrix as a result of the shuttle is free to enter the ETC at Complex I.

The entry of ADP into mitochondria is coupled to the exit of ATP by ATP-ADP translocase

The major function of oxidative phosphorylation is to generate ATP from ADP. ATP and ADP do not diffuse freely across the inner mitochondrial membrane. How are these highly charged molecules moved across the inner membrane into the cytoplasm? A specific transport protein, **ATP-ADP translocase** (also called **adenine nucleotide translocase** or **ANT**), enables these molecules to traverse this permeability barrier. Most important, the flows of ATP and ADP are coupled. ADP enters the mitochondrial matrix only if ATP exits, and vice versa. This process is carried out by the translocase, an antiporter:

$$ADP^{3-}_{cytoplasm} + ATP^{4-}_{matrix} \rightarrow ADP^{3-}_{matrix} + ATP^{4-}_{cytoplasm}$$

ANT is highly abundant, constituting about 15% of the protein in the inner mitochondrial membrane. The abundance is a manifestation of the fact that human beings exchange the equivalent of their weight in ATP each day.

The 30-kDa translocase contains a single nucleotide-binding site that alternately faces the matrix and the cytoplasmic sides of the membrane (Figure 18.36). ATP and ADP bind to ANT without Mg^{2+}, and ATP has one more negative charge than that of ADP. Thus, in an actively respiring mitochondrion with a positive membrane potential, ATP transport out of the mitochondrial matrix is favored, but the additional negative charge moving out dissipates some of the proton-motive force.

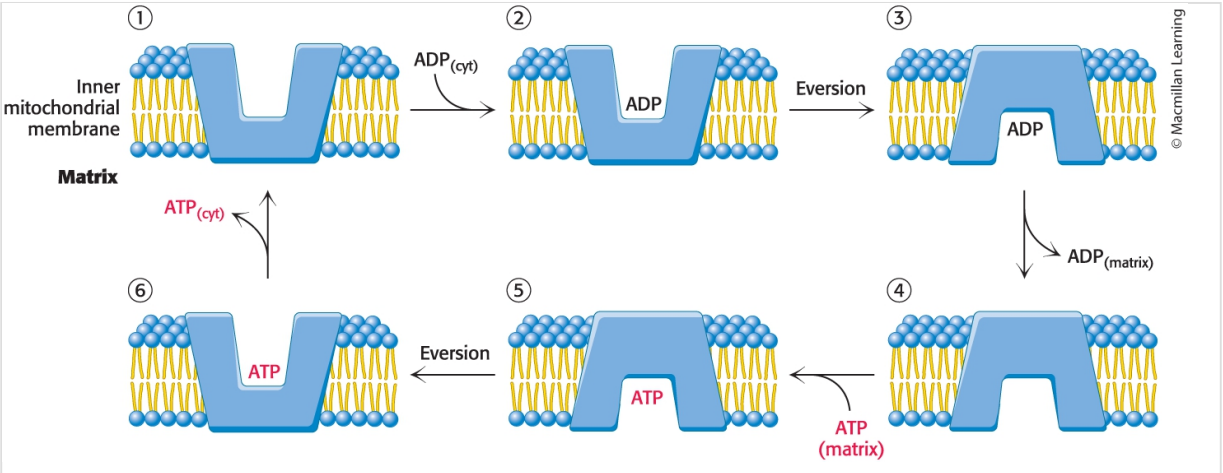

FIGURE 18.36 The ATP-ADP translocase catalyzes the exchange of entry of ADP and ATP. The binding of ADP from the cytoplasm (1) favors eversion of the transporter (2) to release ADP into the matrix (3). Subsequent binding of ATP from the matrix to the everted form (4) favors eversion back to the original conformation (5), releasing ATP into the cytoplasm (6).

A second transporter called the *phosphate carrier* (**Figure 18.37**) works in concert with ANT. By mediating the electroneutral exchange (antiport) of $H_2PO_4^-$ for OH^-, phosphate carrier allows one OH^- to move into the IM space, which is thermodynamically favorable because it is equivalent to a proton moving in the opposite direction. The combined action of these two transporters leads to the exchange of cytoplasmic ADP and P_i for matrix ATP at the expense of about one quarter of the proton-motive force. These two transporters, which provide ATP synthase with its substrates, are associated with the synthase to form a large complex called the *ATP synthasome.* The inhibition of ANT leads to the subsequent inhibition of cellular respiration as well, as we will see in the next section.

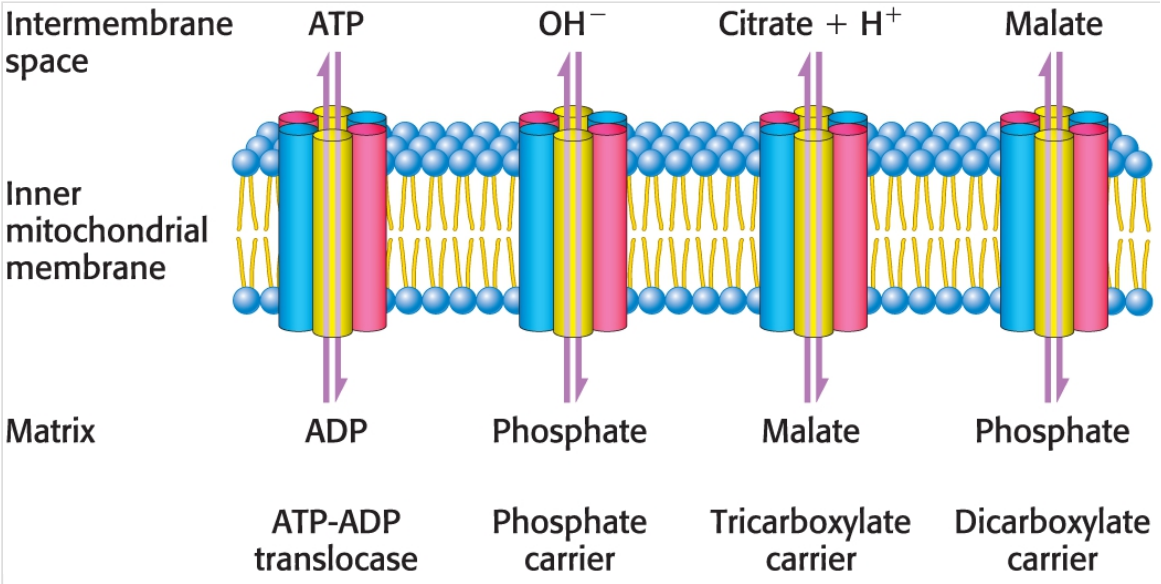

FIGURE 18.37 Multiple structurally homologous mitochondrial transporters carry specific metabolites across the inner mitochondrial membrane.

ANT and phosphate carrier are just two of many structurally homologous mitochondrial transporters for ions and charged metabolites present in the inner mitochondrial membrane (Figure

18.37). The dicarboxylate carrier enables malate, succinate, and fumarate to be exported from the mitochondrial matrix in exchange for P_i. The tricarboxylate carrier exchanges citrate and H^+ for malate. In all, more than 40 such carriers are encoded in the human genome.

Self-Check Question

Recall what thermodynamically drives the action of the ATP-ADP translocase (ANT). Why must this enzyme use Mg^{2+}-free forms of ATP and ADP?

18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

Because ATP is the end product of cellular respiration, the ATP needs of the cell are the ultimate determinant of the rate of respiratory pathways and their components.

The complete oxidation of glucose yields about 30 molecules of ATP

We can now estimate how many molecules of ATP are formed when glucose is completely oxidized to CO_2. The number of ATP molecules formed in glycolysis and the citric acid cycle is unequivocally known because it is determined by the stoichiometries of chemical reactions. In contrast, the ATP yield of oxidative phosphorylation is less certain because the stoichiometries of proton pumping, ATP synthesis, and metabolite-transport processes need not be an integer or even have fixed values.

Recall from Section 18.3 that the best current estimates for the number of protons pumped out of the matrix per electron pair by Complexes I, III, and IV are four, two, and four, respectively. The synthesis of a molecule of ATP is driven by the flow of about three protons through ATP synthase. An additional proton is consumed in transporting ATP from the matrix to the cytoplasm. Hence, about 2.5 molecules of cytoplasmic ATP are generated as a result of the flow of a pair of electrons from NADH to O_2. For electrons that enter at Complex III, such as those from the oxidation of succinate or cytoplasmic NADH

transferred by the glycerol-phosphate shuttle, the yield is about 1.5 molecules of ATP per electron pair.

Hence, as tallied in Table 18.4, about 30 molecules of ATP are formed when glucose is completely oxidized to CO_2. Most of the ATP, 26 of 30 molecules formed, is generated by oxidative phosphorylation, while two of the remaining four are made in the citric acid cycle, which is oxygen-dependent (aerobic). Recall that the anaerobic metabolism of glucose yields only two molecules of ATP. One of the effects of endurance exercise, a practice that calls for much ATP for an extended period of time, is to increase the number of mitochondria and blood vessels in muscle and thus increase the extent of ATP generation by oxidative phosphorylation.

TABLE 18.4 ATP yield from the complete oxidation of glucose

Reaction sequence	ATP yield per glucose molecule
Glycolysis: Conversion of glucose into pyruvate (in the cytoplasm)	
Phosphorylation of glucose	−1
Phosphorylation of fructose 6-phosphate	−1
Dephosphorylation of 2 molecules of 1,3-BPG	+2
Dephosphorylation of 2 molecules of phosphoenolpyruvate	+2
2 molecules of NADH are formed in the oxidation of 2 molecules of glyceraldehyde 3-phosphate	
Conversion of pyruvate into acetyl CoA (inside mitochondria)	

2 molecules of NADH are formed	
Citric acid cycle (inside mitochondria)	
2 molecules of adenosine triphosphate are formed from 2 molecules of succinyl CoA	+2
6 molecules of NADH are formed in the oxidation of 2 molecules each of isocitrate, α-ketoglutarate, and malate	
2 molecules of $FADH_2$ are formed in the oxidation of 2 molecules of succinate	
Oxidative phosphorylation (inside mitochondria)	
2 molecules of NADH formed in glycolysis; each yields 1.5 molecules of ATP (assuming transport of NADH by the glycerol 3-phosphate shuttle)	+3
2 molecules of NADH formed in the oxidative decarboxylation of pyruvate; each yields 2.5 molecules of ATP	+5
2 molecules of $FADH_2$ formed in the citric acid cycle; each yields 1.5 molecules of ATP	+3
6 molecules of NADH formed in the citric acid cycle; each yields 2.5 molecules of ATP	+15
Net Yield per Molecule of Glucose	+30

Information on the ATP yield of oxidative phosphorylation is from values given in P. C. Hinkle, M. A. Kumar, A. Resetar, and D. L. Harris, *Biochemistry* 30:3576, 1991.
Note: The current value of 30 molecules of ATP per molecule of glucose supersedes the earlier value of 36 molecules of ATP. The stoichiometries of proton pumping, ATP synthesis, and metabolite transport should be regarded as estimates. About 2 more molecules of ATP are formed per molecule of glucose oxidized when the malate–aspartate shuttle rather than the glycerol 3-phosphate shuttle is used.

The rate of oxidative phosphorylation is determined by the need for ATP

How is the rate of the electron transport through the chain controlled? Under most physiological conditions, electron transport is tightly coupled to phosphorylation. Electrons do not usually flow through the electron-transport chain to O_2 unless ADP is simultaneously phosphorylated to ATP. When ADP concentration rises, as would be the case in active muscle, the rate of oxidative phosphorylation increases to meet the ATP needs of the muscle. The regulation of the rate of oxidative phosphorylation by the ADP level is called *respiratory control* or *acceptor control*.

The need for ATP likewise affects the rate of the citric acid cycle. At low concentrations of ADP, as in a resting muscle, NADH and $FADH_2$ are not consumed by the electron-transport chain. The citric acid cycle slows because there is less NAD^+ and FAD to feed the cycle. As the ADP level rises and oxidative phosphorylation speeds up, NADH and $FADH_2$ are oxidized, and the citric acid cycle becomes more active. The coordination of the components of cellular respiration, as shown in **Figure 18.38**, makes such regulation possible.

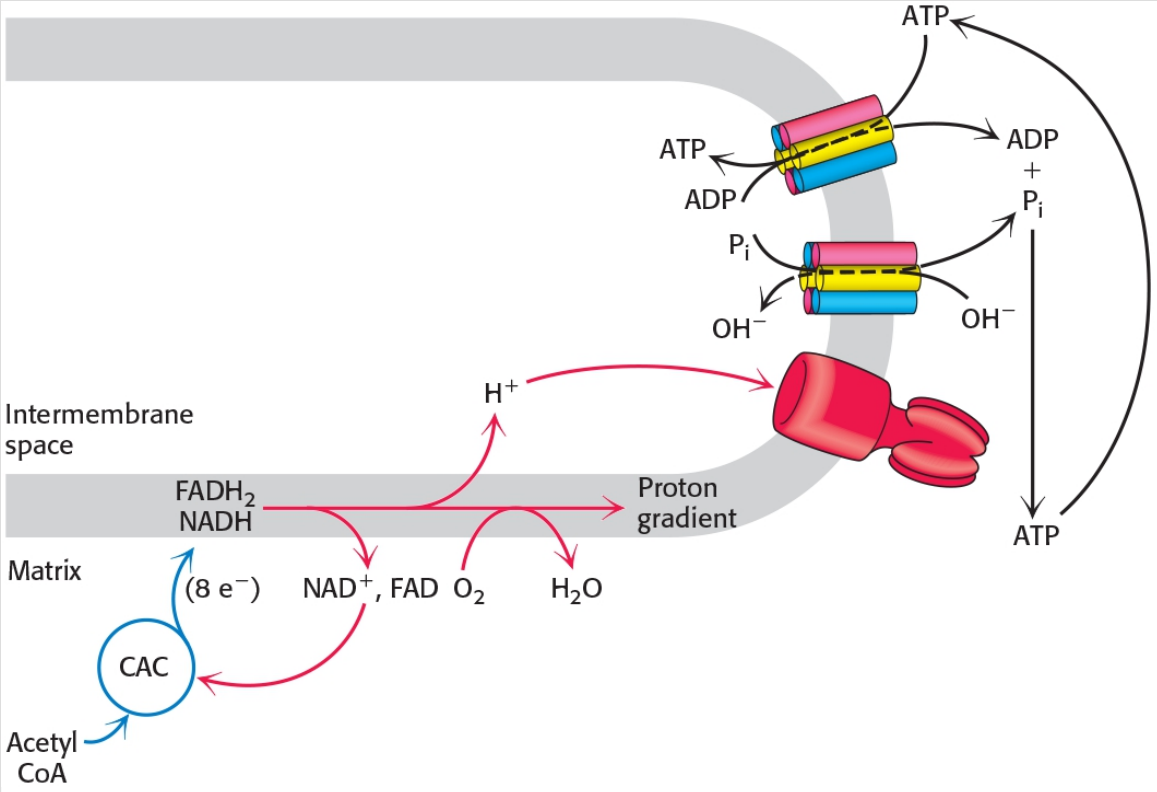

FIGURE 18.38 ATP synthase depends upon the rest of the ATP synthesome, as well as the ETC and CAC. The citric acid cycle (CAC) generates high-energy electrons by oxidizing acetyl CoA. Th electrons are used to reduce oxygen to water and in the process develop a proton gradient. The proton gradient powers the synthesis of ATP, which requires the coordination of ATP synthase, the ATP-ADP translocase, and the phosphate carrier.

ATP synthase can be regulated

Mitochondria contain an evolutionarily conserved protein, *inhibitory factor 1* (IF1), that specifically inhibits the potential hydrolytic activity of the F_0F_1 ATP synthase. What is the function of IF1? Consider a circumstance where tissues may be deprived of oxygen (ischemia), as might happen during a stroke or heart attack. Without oxygen as the electron acceptor, the electron-transport chain will be unable to

generate the proton-motive force. The ATP in the mitochondria would be hydrolyzed by the synthase, working in reverse. The role of IF1 is to prevent the wasteful hydrolysis of ATP by inhibiting the hydrolytic activity of the synthase.

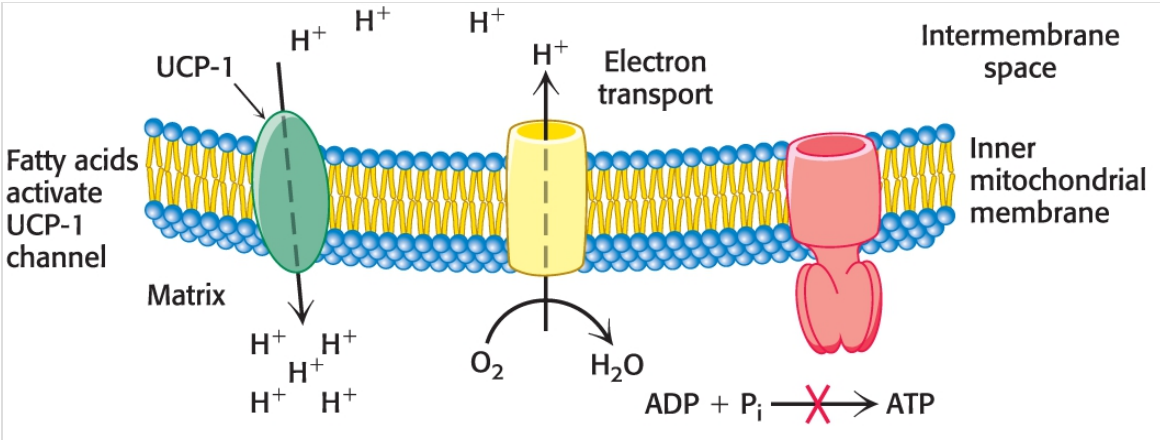
How is this inhibition regulated? IF1 dimerizes when the pH in the matrix decreases due to the dissipation of the proton-motive force. IF1 dimers then bind tightly to ATP synthase dimers, preventing the β subunits from changing conformation and thus halting any action of ATP synthase until the pH of the matrix is returned to normal. IF1 is also overexpressed in many types of cancer. This overexpression plays a role in the induction of the Warburg effect, the switch from oxidative phosphorylation to aerobic glycolysis as the principal means for ATP synthesis (Section 16.3).

Regulated uncoupling leads to the generation of heat

Some organisms possess the ability to uncouple oxidative phosphorylation from ATP synthesis to generate heat. Such uncoupling is a means to maintain body temperature in hibernating animals, in some newborn animals (including human beings), and in many adult mammals, especially those adapted to cold. The skunk cabbage uses an analogous mechanism to heat its floral spikes in early spring, increasing the evaporation of odoriferous molecules that attract insects to fertilize its flowers. In animals, the uncoupling is in brown adipose tissue, which is specialized tissue for the process called *nonshivering thermogenesis,* or the ability to generate heat without using the rapid, unconscious contraction of skeletal muscles (shivering). In contrast, white adipose tissue, which constitutes the bulk of adipose tissue, plays no role in thermogenesis directly but serves as an insulating layer, an energy source, and an endocrine gland (Chapters 24 and 27).

Brown adipose tissue is very rich in mitochondria. The tissue appears brown from the combination of the greenish-colored cytochromes in the numerous mitochondria and the red hemoglobin present in the extensive blood supply, which helps to carry the heat through the body. The inner mitochondrial membrane of these mitochondria contains a large amount of **uncoupling protein (UCP-1)**, also called *thermogenin,* a dimer of 33-kDa subunits that resembles ANT. UCP-1 transports protons from the intermembrane space to the matrix with the assistance of fatty acids.

In essence, UCP-1 generates heat by short-circuiting the mitochondrial proton battery. The energy of the proton gradient, normally captured as ATP, is released as heat as the protons flow through UCP-1 to the mitochondrial matrix. This dissipative proton pathway is activated when the core body temperature begins to fall. In response to a temperature drop, α-adrenergic hormones stimulate the release of free fatty acids from triacylglycerols stored in cytoplasmic lipid granules (**Figure 18.39**). Long-chain fatty acids bind to the cytoplasmic face of UCP-1, and the carboxyl group binds a proton. This causes a structural change in UCP-1 so that the protonated carboxyl now faces the proton-poor environment of the matrix, and the proton is released. Proton release resets UCP-1 to the initial state.



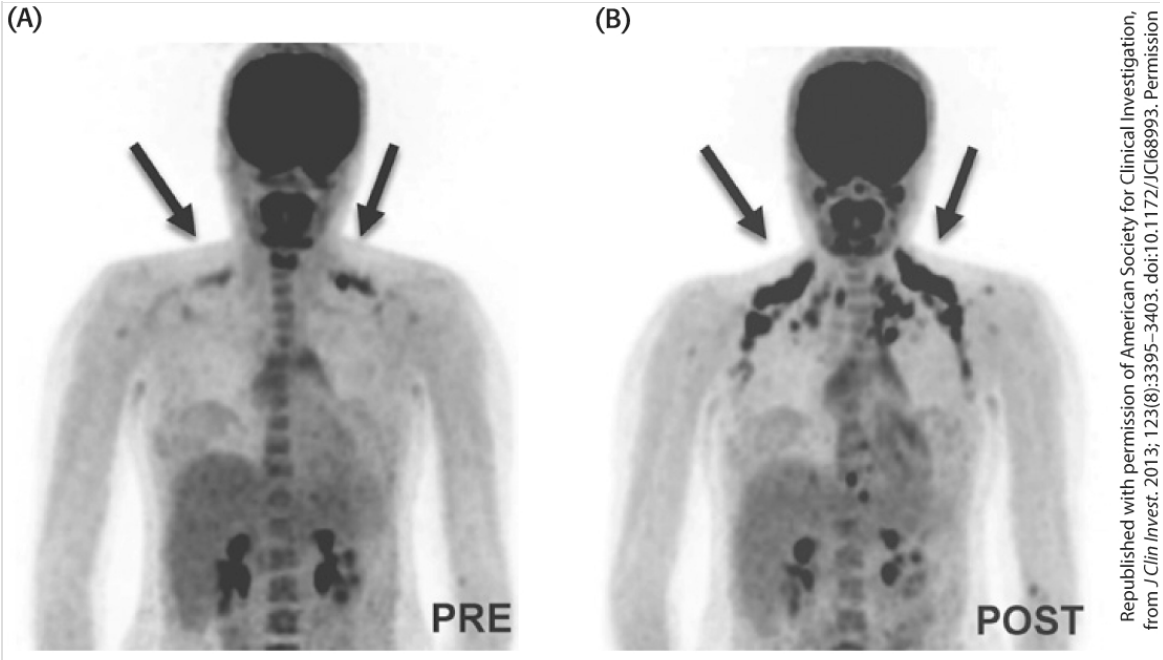


FIGURE 18.39 UCP-1 generates heat by transporting protons without the synthesis of ATP.

In addition to UCP-1, two other uncoupling proteins have been identified: UCP-2, which is found in a wide variety of tissues, and UCP-3, which is localized to skeletal muscle and brown fat. Both proteins share greater than 50% identity with UCP-1. This family of uncoupling proteins may play a role in energy homeostasis, and the genes for UCP-2 and UCP-3 map to regions of the human and mouse chromosomes that have been linked to obesity, supporting the notion that they function as a means of regulating body weight. Until recently, adult humans were believed to lack brown fat tissue. However, new studies have established that adults have brown adipose tissue in the neck and upper chest regions that is activated by cold (Figure 18.40). Obesity, which is predominantly caused by the swelling of intracellular lipid droplets in white adipose tissue, also leads to a decrease in brown adipose tissue.

FIGURE 18.40 Brown adipose tissue is revealed on en adipose tissue is revealed on exposure t cold. The results of PET–CT scanning show the uptake and distribution of ^{18}F-

fluorodeoxyglucose (^{18}F-FDG) in adipose tissue. The patterns of ^{18}F-FDG uptake in the same subject are dramatically different under thermoneutral conditions (A) and after exposure cold (B).

Reintroduction of UCP-1 into pigs may be economically valuable

We can witness the effects of a lack of nonshivering thermogenesis by examining pig behavior. The ancestors of pigs are believed to have lost the gene for UCP-1 ~20 million years ago when they inhabited tropical and subtropical environments where they could survive without nonshivering thermogenesis. As the range of pigs expanded, however, the lack of UCP-1 (and hence, the absence of functional brown fat) became a liability to which pigs have adapted with distinctive behavioral traits. Among mammals, pigs have unusually large litters, and they are the only ungulates (hoofed mammals) that build nests for birth; piglets generate heat by huddling with their littermates in an insulated nest and shivering.

The deficiency of UCP-1 has important implications for pig farming. Even with the use of heat lamps, which account for 35% of the energy cost of raising pigs, piglet mortality may be as high as 20% because of hypothermia. Furthermore, because of their lack of UCP-1, pigs accumulate fat in white adipose tissue as a thermal insulator, meaning there is less lean meat available.

Recently, researchers have inserted the gene for UCP-1 into pig embryos. The resulting pigs are cheaper to raise due to the decrease in energy costs and provide more high-quality lean meat. The gene for

UCP-1 was inserted into the pig embryos using the CRISPR technique described in Chapter 9. We see here another example of the expanding reach of biochemistry into areas of the economy beyond just the biomedical arena.

Oxidative phosphorylation can be inhibited at many stages

Many potent and lethal poisons exert their effect by inhibiting oxidative phosphorylation at one of a number of different locations (**Figure 18.41**).

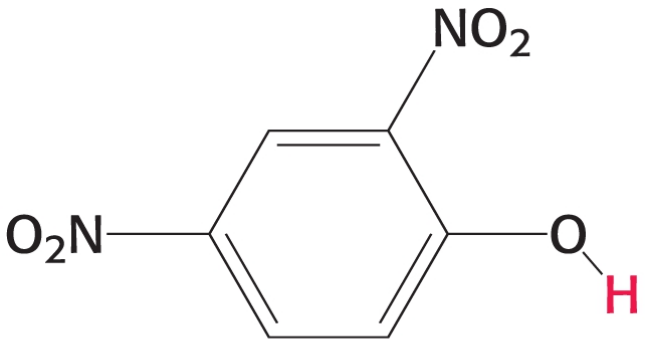
FIGURE 18.41 Inhibitors of electron transport block the process at a variety of sites.

Inhibition of the electron-transport chain

Rotenone, which is used as a fish and insect poison, and amytal, a barbiturate sedative, block electron transfer in NADH-Q oxidoreductase and thereby prevent the use of NADH as a substrate. In the presence of rotenone and amytal, electron flow resulting from the oxidation of succinate is unimpaired, because these electrons enter through QH_2, beyond the block. As an electron-transport-chain inhibitor, rotenone may play a role, along with genetic susceptibility, in the development of Parkinson's disease.

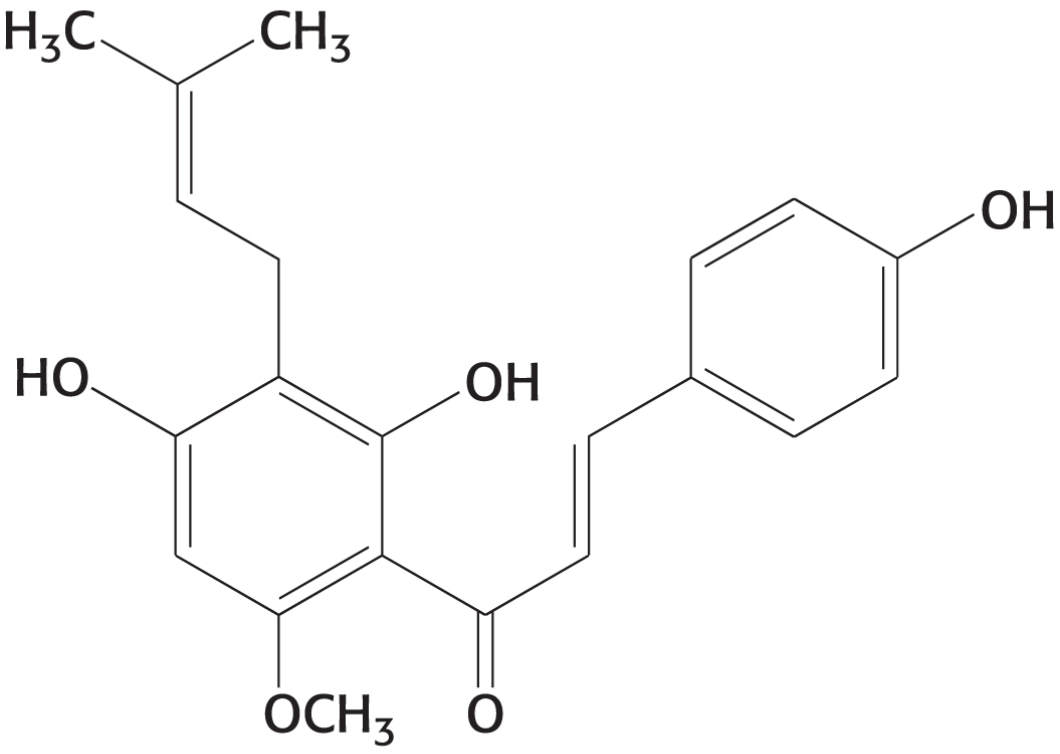
Other drugs block the chain at different points. For example, Antimycin *A* interferes with electron flow from cytochrome b_H in Q-cytochrome *c* oxidoreductase. Furthermore, electron flow in cytochrome *c* oxidase can be blocked by cyanide (CN^-), azide (N_3^-), and carbon monoxide (CO). Cyanide and azide react with the ferric form of heme a_3, whereas carbon monoxide inhibits the ferrous form. Inhibition of the electron-transport chain also inhibits ATP synthesis because the proton-motive force can no longer be generated.

Inhibition of ATP synthase



Oligomycin, an antibiotic used as an antifungal agent, and dicyclohexylcarbodiimide (DCC) prevent the influx of protons through ATP synthase by binding to the carboxylate group of the **c** subunits required for proton binding. Modification of only one **c** subunit by DCC is sufficient to inhibit the rotation of the entire **c** ring and hence ATP

synthesis. If actively respiring mitochondria are exposed to an inhibitor of ATP synthase, the electron-transport chain ceases to operate. This observation clearly illustrates that electron transport and ATP synthesis are normally tightly coupled.



Uncoupling electron transport from ATP synthesis

The tight coupling of electron transport and phosphorylation in mitochondria can be uncoupled *pathologically*, in an unregulated way, by small molecules instead of *beneficially*, in a regulated way, by uncoupling proteins. Certain acidic aromatic compounds, including 2,4-dinitrophenol (DNP), carry protons across the inner mitochondrial membrane, down their concentration gradient. In the presence of these uncouplers, electron transport from NADH to O_2 proceeds in a normal fashion, but ATP is not formed by mitochondrial ATP synthase, because the proton-motive force across the inner mitochondrial membrane is continuously dissipated. This loss of respiratory control leads to increased oxygen consumption and oxidation of NADH. Indeed, in the accidental or intentional ingestion of uncouplers, large amounts of metabolic fuels are consumed, but no energy is captured as ATP. Rather, energy is released as heat.

DNP is the active ingredient in some herbicides and fungicides. There are reports that Soviet soldiers were given DNP to keep them warm during the long Russian winters. Remarkably, some people consume DNP today as a weight-loss drug, despite the fact that the FDA banned its use in 1938, calling it “extremely dangerous and not fit for human consumption.” Its use can lead to death by hyperthermia, with body temperatures reaching in excess of 43°C prior to death.

2,4-Dinitrophenol (DNP)

Xanthohumol

Drugs are being sought that would function as mild uncouplers, uncouplers not as potentially lethal as DNP, for use in treatment of obesity and related pathologies. Xanthohumol, a prenylated chalcone found in hops and beer, shows promise in this regard. Xanthohumol also scavenges free radicals and is used for treatment of certain types of cancers.

Inhibition of ATP export

ANT is specifically inhibited by very low concentrations of atractyloside (a plant glycoside) or bongkrekic acid (an antibiotic from a mold). Atractyloside binds to the translocase when its nucleotide site faces the intermembrane space, whereas bongkrekic acid binds when this site faces the mitochondrial matrix. Oxidative phosphorylation stops soon after either inhibitor is added, demonstrating the essentiality of ANT for maintaining adequate amounts of ADP to accept the energy associated with the proton-motive force.

The effects of various inhibitors can now be reliably measured using Seahorse XF technology (Agilent Technologies), which now allows the measurement of the rate of aerobic respiration and lactic acid fermentation simultaneously in real time in cultured cells. The extent of aerobic respiration is determined by measuring the oxygen consumption rate, while the rate of glycolysis correlates with the extracellular acidification rate. This method is now widely used in both industry and academia in drug discovery, cancer research, and many other areas.

New mitochondrial diseases are constantly being discovered

The number of diseases that can be attributed to mitochondrial mutations is steadily growing in step with our growing understanding of the biochemistry and genetics of mitochondria. Mitochondrial diseases are estimated to affect from 10 to 15 per 100,000 people, roughly equivalent to the prevalence of the muscular dystrophies. Some of these mutations impair the use of NADH, whereas others block electron transfer to Q. Mutations in Complex I are the most frequent cause of mitochondrial diseases; indeed, the first mitochondrial disease to be understood was Leber hereditary optic neuropathy (LHON), a form of blindness that strikes in midlife as a result of mutations in Complex I. The accumulation of mutations in mitochondrial genes in a span of several decades may contribute to aging, degenerative disorders, and cancer.

Mitochondrial disease is primarily inherited maternally, because a human egg harbors several hundred thousand molecules of mitochondrial DNA, whereas a sperm contributes only a few hundred. Thus, the paternal contribution has little effect on the mitochondrial genotype. Because the maternally inherited mitochondria are present in large numbers but not all of the mitochondria may be affected, the pathologies of mitochondrial mutants can be quite complex. Even within a single family carrying an identical mutation, chance variations in the percentage of mitochondria with the mutation lead to large variations in the nature and severity of the symptoms of the pathological condition as well as the time of onset. As the percentage of defective mitochondria increases, energy-generating capacity diminishes until, at some threshold, the cell can no longer function properly. Defects in cellular respiration are doubly dangerous: not only does energy transduction decrease, but also the likelihood that reactive

oxygen species will be generated increases. Organs that are highly dependent on oxidative phosphorylation, such as the nervous system, the retina, and the heart, are most vulnerable to mutations in mitochondrial DNA.

Self-Check Question

4,6-Dinitro-o-cresol (DNOC) was used as a pesticide until it was banned because it causes a dramatic rise in body temperature, profuse sweating, rapid breathing, and a decrease in body fat. When tested, it affected isolated mitochondria. What do you expect is its effect on oxygen consumption by isolated mitochondria, and why?

Mitochondria play a key role in apoptosis

In the course of development or in cases of significant cell damage, individual cells within multicellular organisms undergo a form of programmed cell death called **apoptosis**, with mitochondria acting as control centers regulating this process. Although the details continue to be established, the outer membrane of damaged mitochondria becomes highly permeable, a process referred to as *mitochondrial outer membrane permeabilization* (MOMP). This permeabilization is instigated by a family of proteins (Bcl family) that were initially discovered because of their role in cancer.

One of the most potent activators of apoptosis, cytochrome *c,* exits the mitochondria and interacts with apoptotic peptidase-activating factor 1 (APAF-1), which leads to the formation of a protein complex called the *apoptosome*. The apoptosome recruits and activates a proteolytic enzyme called *caspase 9,* a member of the cysteine protease family (Section 6.2) that in turn activates a cascade of other caspases. Each caspase type

destroys a particular target, such as the proteins that maintain cell structure. Another target is a protein that inhibits an enzyme that destroys DNA (an enzyme called caspase-activated DNAse or CAD), freeing CAD to cleave the genetic material. This cascade of proteolytic enzymes has been called “death by a thousand tiny cuts.”

Self-Check Question

The most common metabolic sign of mitochondrial disorders is lactic acidosis. Why?

18.7 Proton Gradients Generated by Respiratory Chains Drive Many Biochemical Processes

The main concept presented in this chapter is that mitochondrial electron transfer and ATP synthesis are linked by a transmembrane proton gradient. ATP synthesis in bacteria and chloroplasts also is driven by proton gradients. Here we will briefly consider how these gradients can be used in additional ways, sometimes with startling effects. As a case in point, in many bacteria, the proton gradient is responsible for providing the power for a simple but important aspect of these organisms: how they move.

Proton flow through a rotary motor allows bacteria to swim

In one second, a motile bacterium can move 25 μm, or about 10 body lengths. A human being sprinting at a proportional rate would complete the 100-meter dash in slightly more than 5 s. Bacteria such as *Escherichia coli* and *Salmonella typhimurium* swim at such speed by rotating flagella that lie on their surfaces (**Figure 18.42**). When the flagella rotate in a counterclockwise direction (viewed from outside a bacterium), the separate flagella form a bundle that very efficiently propels the bacterium through solution. The motors that power this impressive motion are strikingly different from the eukaryotic motors that we explored in Section 6.5. In the bacterial motor, an element spins around a central axis rather than moving along a polymeric track. Early experiments by Julius Adler demonstrated

that ATP is *not* required for flagellar motion. Rather, the necessary free energy is derived from the proton gradient that exists across the plasma membrane, established by the electron-transport chains of these organisms that pump protons into the periplasm.

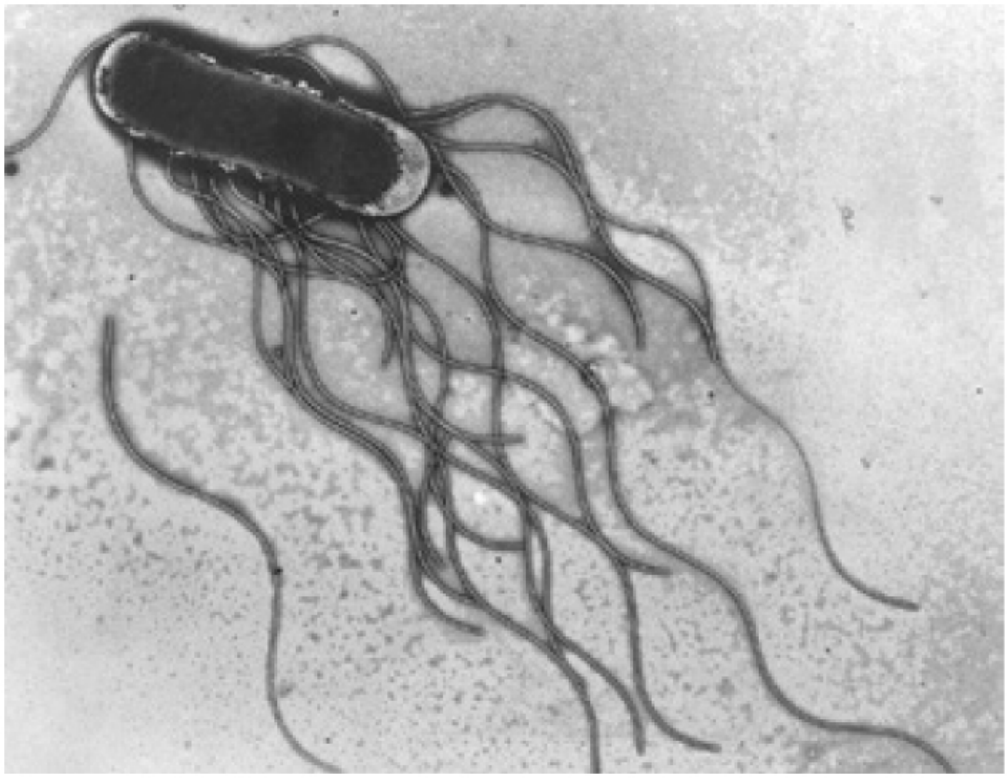


FIGURE 18.42 Bacterial flagella allow bacteria to swim rapidly. An electron micrograph of *Salmonella typhimurium* shows flagella directed backwards, where they can form a bundle under appropriate circumstances. Bacterial flagella are polymers approximately 15 nm in diameter and as much as 15 µm in length, composed of subunits of a protein called flagellin. These subunits associate into a left-handed helical structure with a hollow core. At its base, each flagellum has a rotary motor.

Although the flagellar motor is quite complex, five components particularly crucial to motor function have been identified through genetic studies (Figure 18.43). MotA and MotB are membrane proteins, each with cytoplasmic and periplasmic domains, respectively. Approximately 11 MotA–MotB pairs form a ring around

the base of the flagellum. The proteins FliG, FliM, and FliN are part of a disc-like structure called the MS (membrane and supramembrane) ring, with approximately 30 FliG subunits coming together to form the ring. The MotA–MotB pair and FliG combine to create a proton channel that drives the rotation of the flagellum similar to the proton-driven rotary motion of ATP synthase. In fact, such a mechanism was first proposed by Howard Berg to explain flagellar rotation before the rotary mechanism of ATP synthase was elucidated. Each MotA–MotB pair is conjectured to form a structure that has two half-channels (**Figure 18.44A**); FliG serves as the rotating proton carrier. In this scenario, a proton from the periplasmic space passes into the outer half-channel and is transferred to an FliG subunit. The MS ring rotates, rotating the flagellum with it and allowing the proton to pass into the inner half-channel and into the cell (**Figure 18.44B**). Ongoing structural and mutagenesis studies are testing and refining this hypothesis.

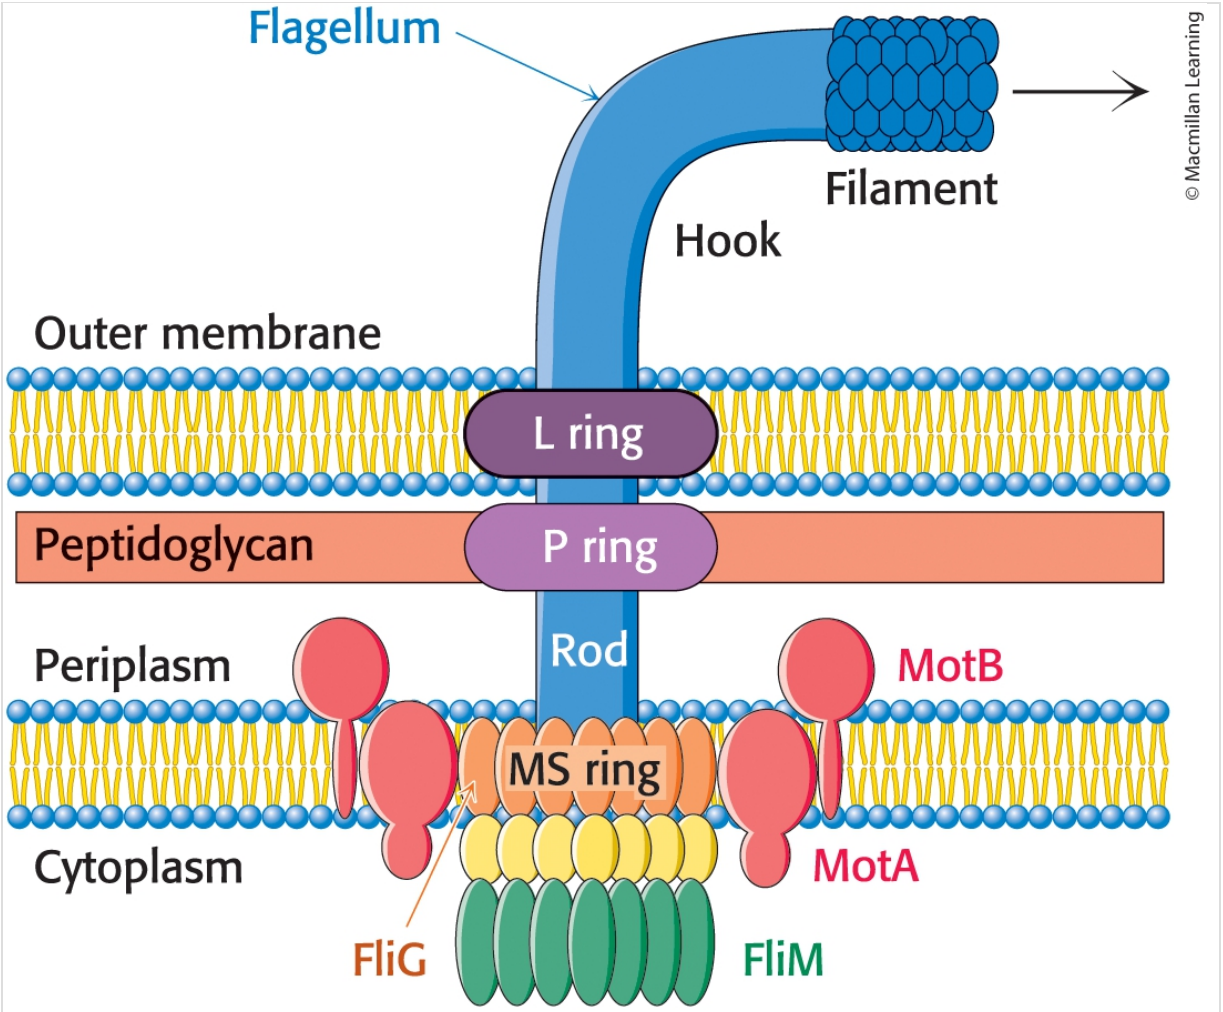

FIGURE 18.43 The flagellar motor is a complex structure containing as many as 40 distinct types of proteins. A schematic view of the flagellar motor is shown with the approximate positions of the proteins MotA and MotB (red), FliG (orange), FliN (yellow), and FliM (green).

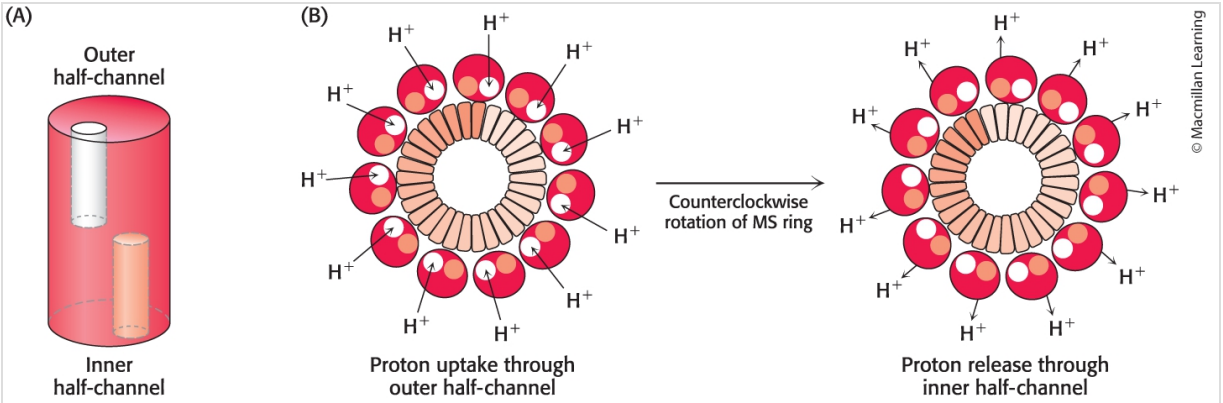

FIGURE 18.44 Rotation of the flagellum involves proton half-channels like ATP synthase. (A) MotA–MotB may form a structure having two half-channels. (B) One model for the mechanism of coupling rotation to a proton gradient requires protons to be taken up into the outer half-channel and transferred to the MS ring. The MS ring rotates in a counterclockwise direction, and the protons are released into the inner half-channel. The flagellum is linked to the MS ring and so the flagellum rotates as well.

Power transmission by proton gradients is a central motif of bioenergetics

Proton gradients power a variety of energy-requiring processes, some of which we have explored already, such as the rotation of bacterial flagella, the generation of heat by nonshivering thermogenesis, the active transport of calcium ions by mitochondria, the entry of some amino acids and sugars into bacteria, and the transfer of electrons from $NADP^+$ to NADPH. It's clear that proton gradients are a central, interconvertible currency of free energy in biological systems (**Figure 18.45**). Peter Mitchell, who established the chemiosmotic hypothesis (Section 18.4), noted that the proton-motive force is a marvelously simple and effective

store of free energy because it requires only a thin, closed lipid membrane between two aqueous phases.

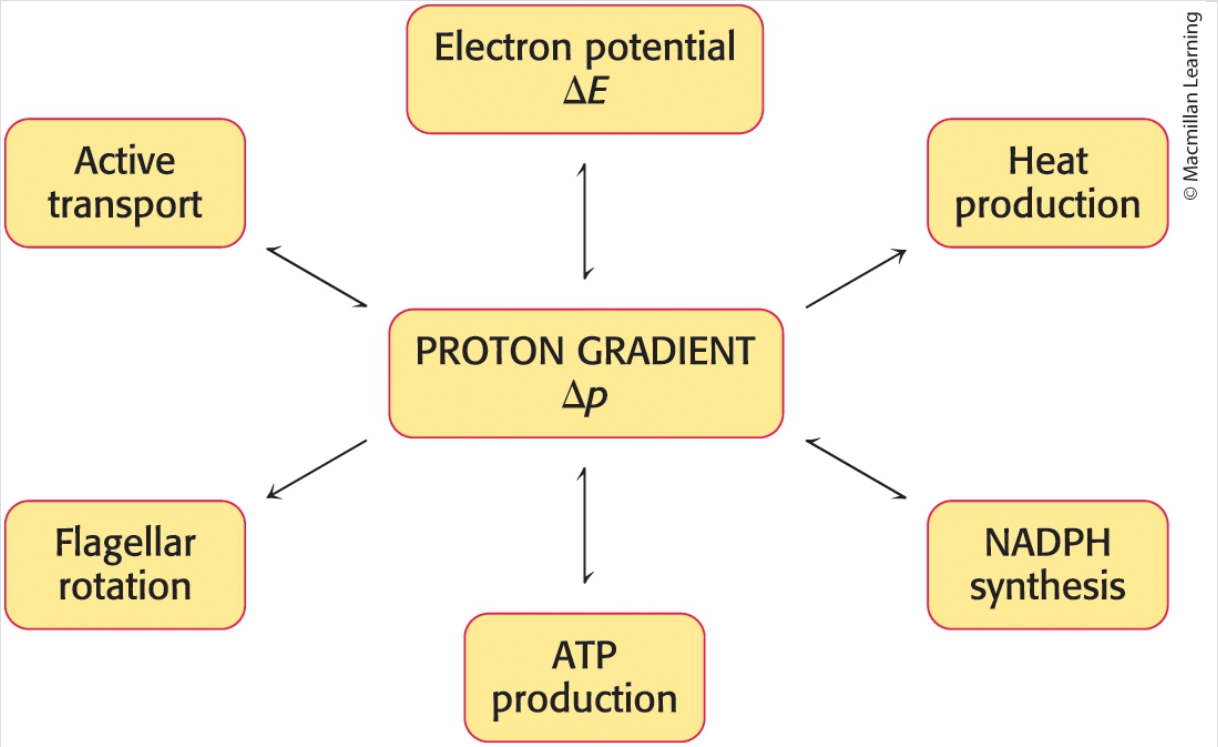

FIGURE 18.45 The proton gradient is an interconvertible form of free energy.

Self-Check Question

When bacteria such as *E. coli* are starved to a sufficient extent, they become nonmotile. However, when such bacteria are placed in an acidic solution, they resume swimming. Explain.

Chapter 18 Summary

18.1 Cellular Respiration Drives ATP Formation by Transferring Electrons to Molecular Oxygen

- Mitochondria generate most of the ATP required by aerobic cells through a combination of the reactions of the citric acid cycle and oxidative phosphorylation.
- Mitochondria are descendants of a free-living bacterium that established a symbiotic relationship with another cell.

18.2 Oxidative Phosphorylation Depends on Electron Transfer

- In oxidative phosphorylation, the synthesis of ATP is coupled to the flow of electrons from NADH or $FADH_2$ to O_2 by a proton gradient across the inner mitochondrial membrane.
- Electron flow through three asymmetrically oriented transmembrane complexes results in the pumping of protons out of the mitochondrial matrix and the generation of a membrane potential. ATP is synthesized when protons flow back to the matrix through ATP synthase.

18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle

- The respiratory assembly of the inner mitochondrial membrane has numerous different electron carriers. Electrons from NADH are transferred to NADH-Q oxidoreductase (Complex I), the first of four complexes with the electrons emerging on QH_2, the reduced form of ubiquinone (Q).
- The citric acid cycle enzyme succinate dehydrogenase is a component of the succinate-Q reductase complex (Complex II), which donates electrons from $FADH_2$ to Q to form QH_2.

Regardless of the source, QH_2 transfers its electrons to Q-cytochrome *c* oxidoreductase (Complex III) which reduces cytochrome *c,* a water-soluble peripheral membrane protein.
- Cytochrome *c* transfers electrons to cytochrome *c* oxidase (Complex IV). A heme iron ion and a copper ion in this oxidase transfer electrons to O_2, the ultimate acceptor, to form H_2O. Complexes I, III, and IV are organized into a large molecular structure called the respirasome.

18.4 A Proton Gradient Powers the Synthesis of ATP

- The flow of electrons through Complexes I, III, and IV leads to the transfer of protons from the matrix to the IM space, generating a proton-motive force consisting of a pH gradient and a membrane potential.
- ATP synthesis is driven by the flow of protons back to the matrix through ATP synthase, an enzyme complex that is a molecular motor made of two operational units: a rotating component and a stationary component.
- The rotation of ATP synthase's γ subunit induces structural changes in the β subunit that result in the synthesis and release of ATP from the enzyme.

18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes

- The electrons of cytoplasmic NADH are transferred into mitochondria by the glycerol phosphate shuttle to form $FADH_2$ from FAD, or by the malate–aspartate shuttle to form mitochondrial NADH.
- The exchange of ADP and ATP between the matrix and IM space is mediated by two transporters, ANT and phosphate carrier, driven by membrane potential.

18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

- Approximately 30 molecules of ATP are generated when a molecule of glucose is completely oxidized to CO_2 and H_2O.
- Electron transport is normally tightly coupled to phosphorylation. NADH and $FADH_2$ are oxidized only if ADP is simultaneously phosphorylated to ATP.
- Proteins and small molecules can inhibit oxidative phosphorylation at many different points, or can uncouple electron transport from ATP synthesis, with dramatic effects on human physiology.

18.7 Proton Gradients Generated by Respiratory Chains Drive Many Biochemical Processes

- A proton gradient across the plasma membrane, rather than ATP hydrolysis, powers the rotational flagellar motor of motile bacteria in a manner analogous to the way ATP synthase functions.
- Proton gradients drive diverse physiological processes because the mechanism is fundamentally simple and can be used in many ways by proteins.

Key Terms

oxidative phosphorylation
electron-transport chain (respiratory chain)
proton-motive force
cellular respiration (respiration)
intermembrane space (IM space)
matrix

reduction potential (redox or oxidation–reduction potential)
coenzyme Q (Q, ubiquinone)
cytochrome *c*
iron–sulfur proteins (nonheme iron proteins)
NADH-Q oxidoreductase (Complex I)
succinate-Q reductase (Complex II)
Q-cytochrome *c* oxidoreductase (Complex III)
Q cycle
cytochrome *c* oxidase (Complex IV)
respirasome
ATP synthase (Complex V)
glycerol 3-phosphate shuttle
malate–aspartate shuttle
ATP-ADP translocase (adenine nucleotide translocase, ANT)
uncoupling protein (UCP-1)
apoptosis

Problems

1. Which of the following electron-transport chain complexes is also a member of the citric acid cycle and not a component of the respirasome? 1

a. Complex I
b. Complex II
c. Complex III
d. Complex IV

2. The final electron acceptor for the electron-transport chain is which of the following? 1

a. O_2
b. Coenzyme Q
c. CO_2
d. NAD^+

3. Electrons are passed on to cytochrome *c* using which of the following? 1

a. The Cori cycle
b. The Q cycle
c. The glucose-alanine cycle
d. The Krebs cycle

4. Which of the following statements about the proton-motive force is not true? 2, 3

a. It requires an intact membrane.
b. It consists of an unequal distribution of protons.
c. It is used to synthesize ATP.
d. It is powered by the hydrolysis of ATP.

5. The standard oxidation–reduction potential (E'_0) for the reduction of O_2 to H_2O is given as 0.82 V in Table 18.1. However, the value given in textbooks of chemistry is 1.23 V. Account for this difference.

6. Why are electrons carried by $FADH_2$ not as energy rich as those carried by NADH? What is the consequence of this difference? Calculate the energy released by the reduction of O_2 with $FADH_2$.

7. Compare the $\Delta G^{\circ\prime}$ values for the oxidation of succinate by NAD^+ and by FAD. Use the data given in Table 18.1 to find the E'_0 of the $NAD^+ - NADH$ and fumarate-succinate couples, and assume that E'_0 for the $FAD - FADH_2$ redox couple is nearly 0.05 V. Why is FAD rather than NAD^+ the electron acceptor in the reaction catalyzed by succinate dehydrogenase?

8. Place the following components of the electron-transport chain in their proper order: 1

a. Cytochrome *c*
b. Q-cytochrome *c* oxidoreductase
c. NADH-Q reductase
d. Cytochrome *c* oxidase
e. Ubiquinone

9. Match each term below with its alternative name. 1

1. Complex I	1. Q-cytochrome *c* oxidoreductase
2. Complex II	2. Coenzyme Q
3. Complex III	3. Succinate-Q reductase
4. Complex IV	4. NADH-Q oxidoreductase
5. Ubiquinone	5. Cytochrome *c* oxidase

---

10. Rotenone inhibits electron flow through NADH-Q oxidoreductase. Antimycin A blocks electron flow between cytochromes *b* and c_1. Cyanide blocks electron flow through cytochrome *c* oxidase to O_2. Predict the relative oxidation–reduction state of each of the following respiratory-chain

components in mitochondria that are treated with each of the inhibitors: 1

a. NAD^+
b. NADH-Q oxidoreductase
c. Coenzyme Q
d. Cytochrome c_1
e. Cytochrome *c*
f. Cytochrome *a*

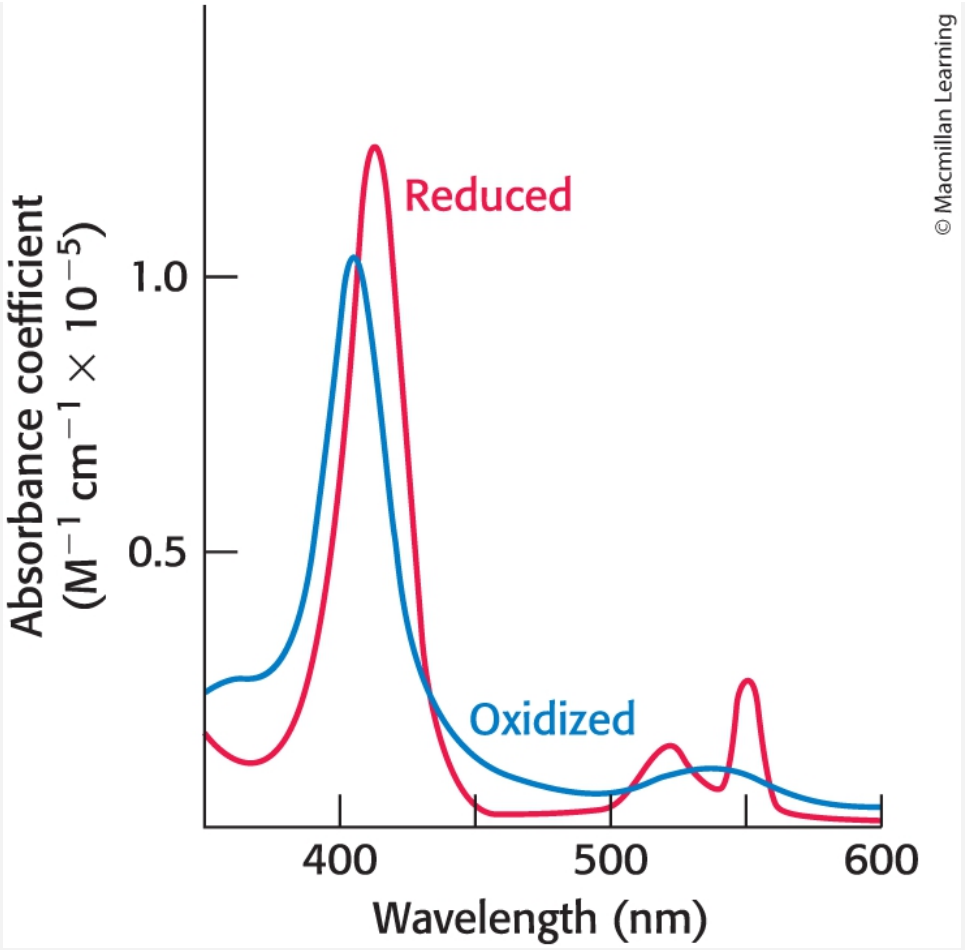
11. What is the yield of ATP when each of the following substrates is completely oxidized to CO_2 by a mammalian cell homogenate? Assume that glycolysis, the citric acid cycle, and oxidative phosphorylation are fully active.

a. Pyruvate
b. Lactate
c. Fructose 1,6-bisphosphate
d. Phosphoenolpyruvate
e. Galactose
f. Dihydroxyacetone phosphate

12. What is the effect of each of the following inhibitors on electron-transport and ATP formation by the respiratory chain? 1, 3

a. Azide
b. Atractyloside
c. Rotenone
d. DNP
e. Carbon monoxide
f. Antimycin A

13. Arsenate (AsO_4^{3-}) closely resembles phosphate in structure and reactivity. However, arsenate esters are unstable and are spontaneously hydrolyzed. If arsenate is added to actively respiring mitochondria, what would be the effect on ATP synthesis? On the rate of the electron-transport chain? Briefly explain.



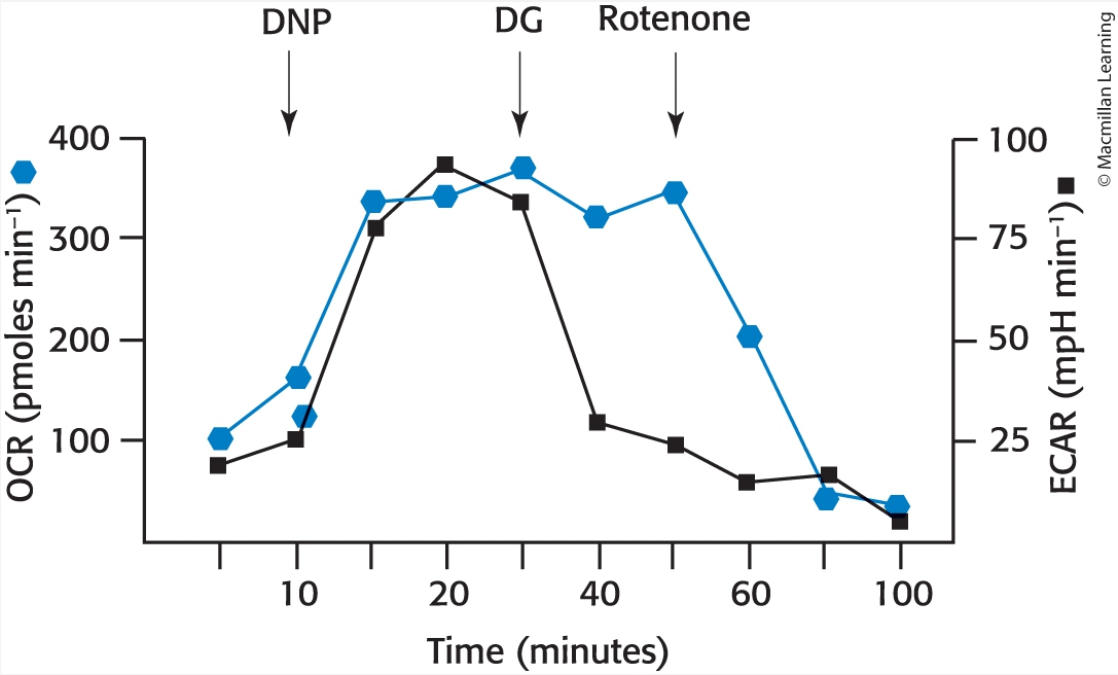
14. Oxidative phosphorylation in mitochondria is often monitored by measuring oxygen consumption. When oxidative phosphorylation is proceeding rapidly, the mitochondria will rapidly consume oxygen. If there is little oxidative phosphorylation, only small amounts of oxygen will be used. You are given a suspension of isolated mitochondria and directed to add the following compounds in the order from *a* to *h*. With the addition of each compound, all of the previously added compounds remain present. Predict the effect of each addition on oxygen consumption by the isolated mitochondria.
1, 2, 3, 4

a. Glucose
b. $ADP + P_i$
c. Citrate
d. Oligomycin
e. Succinate
f. Dinitrophenol
g. Rotenone
h. Cyanide

15. The number of molecules of inorganic phosphate incorporated into organic form per atom of oxygen consumed, termed the *P:O ratio,* was frequently used as an index of oxidative phosphorylation.

a. What are the relationships among the P:O ratio to the ratio of the number of protons translocated per electron pair $(H^+/2e^-)$ and the ratio of the number of protons needed to synthesize ATP and transport it to the cytoplasm (P/H^+)?
b. What are the P:O ratios for electrons donated by matrix NADH and by succinate?

16. The precise site of action of a respiratory-chain inhibitor can be revealed by the *crossover technique*. Britton Chance devised elegant spectroscopic methods for determining the proportions of the oxidized and reduced forms of each carrier. This determination is feasible because the forms have distinctive absorption spectra, as illustrated in the graph for cytochrome *c*.



Suppose you are given a new inhibitor and find that its addition to respiring mitochondria causes the carriers between NADH and QH_2 to become more reduced and those between cytochrome *c* and O_2 to become more oxidized. Where does your inhibitor act? 1, 2

17. Years ago, uncouplers were suggested to make wonderful diet drugs. Explain why this idea was proposed and why it was rejected. Why might the producers of antiperspirants be supportive of the idea? 3, 4

18. Give an example of the use of the proton-motive force in ways other than for the synthesis of ATP.

19. XF technology (Seahorse Bioscience) now allows the measurement of the rate of aerobic respiration and lactic acid fermentation simultaneously in real time in cultured cells. The extent of aerobic respiration is determined by measuring the oxygen consumption rate (OCR, measured in picomoles of oxygen consumed per minute), while the rate of glycolysis correlates with the extracellular acidification rate (ECAR-milli pH per minute, or the changes in pH that occur over time). The next graph shows the results of an experiment using the new technology.

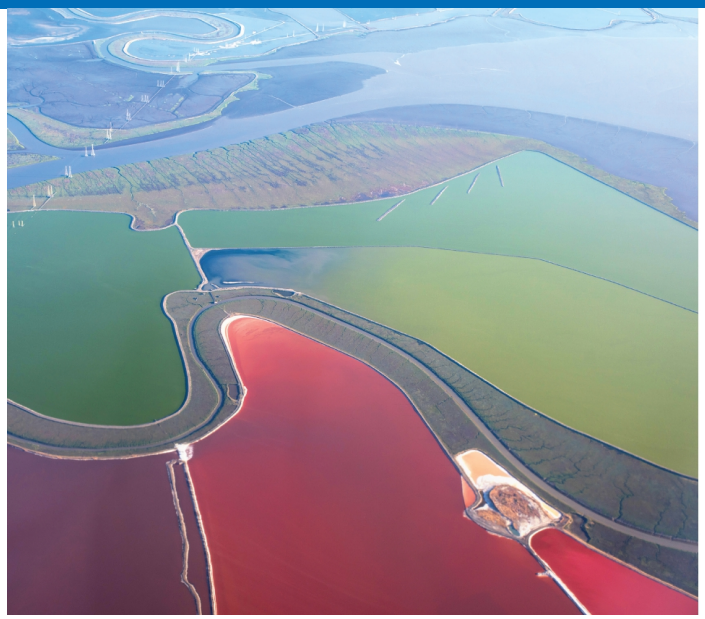
Dinitrophenol (DNP), the glycolysis inhibitor 2-deoxyglucose (DG), and rotenone were added sequentially to cell cultures. **1, 2**

a. What is the effect on OCR and ECAR of adding DNP to the cell culture? Explain these results.
b. Explain the effect of the addition of 2-deoxyglucose.
c. Explain how 2-deoxyglucose acts as an inhibitor of glycolysis?
d. Explain the effect of the addition of rotenone.

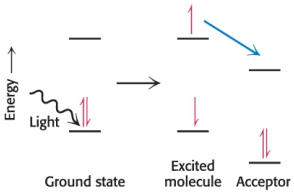
20. A mutation in a mitochondrial gene encoding a component of ATP synthase has been identified. People who have this mutation suffer from muscle weakness, ataxia (a loss of coordination), and retinitis pigmentosa (retinal degeneration). A tissue biopsy was performed on each of three patients having this mutation, and submitochondrial particles were isolated that were capable of succinate-sustained ATP synthesis. First, the activity of the ATP synthase was measured on the addition of succinate and the following results were obtained. 3, 4

ATP synthase activity (nmol of ATP formed $min^{-1} mg^{-1}$)	
Controls	3.0
Patient 1	0.25
Patient 2	0.11
Patient 3	0.17

a. What was the purpose of the addition of succinate?



b. What is the effect of the mutation on succinate-coupled ATP synthesis?



Next, the ATPase activity of the enzyme was measured by incubating the submitochondrial particles with ATP in the absence of succinate.

	ATP hydrolysis (nmol of ATP hydrolyzed $min^{-1} mg^{-1}$)
Controls	33
Patient 1	30
Patient 2	25
Patient 3	31

c. Why was succinate omitted from the reaction?
d. What is the effect of the mutation on ATP hydrolysis?
e. What do these results, in conjunction with those obtained in the first experiment, tell you about the nature of the mutation?

CHAPTER 19
Phototrophy and the Light Reactions of Photosynthesis

flowertiare/Deposit Photos
© Macmillan Learning

Phototrophic halobacteria are visible from the air in salt ponds near the San Francisco Bay. Although nonphotosynthetic, these reddish-purple archaea have the ability to produce additional ATP with energy from sunlight using an evolutionary relative of rhodopsin, a light-activated protein found in your eyes. Photosynthetic green algae are also visible in nearby ponds, which, in contrast, use sunlight exclusively for metabolic energy needs and can produce sugar from carbon dioxide. Both organisms accomplish phototrophy, the key to which is the ability of electrons to absorb visible light and then transfer from one molecule to another using the process of photoinduced charge separation diagrammed above.

19.7 The Ability to Convert Light into Chemical Energy Is Ancient

---

Learning Goals

By the end of this chapter, you should be able to:

1. Describe phototrophy and the light reactions.
2. Identify the key products of the light reactions.
3. Explain how redox balance is maintained during the light reactions.
4. Explain how ATP is synthesized in chloroplasts.
5. Describe the function of the light-harvesting complex.

Every year, Earth is bathed in photons with a total energy content of approximately 10^{24} kJ. By comparison, a major hurricane has one billionth that amount of energy. The source of the energy is, of course, the electromagnetic radiation from the sun. On our planet, there are organisms capable of collecting a fraction, approximately 2%, of this solar energy, and converting it into chemical energy. Green plants are the most obvious of these organisms, although 60%

of this conversion is carried out by algae, bacteria, and archaea. Although only a small amount of the incident energy is captured, it powers almost all life on Earth. This transformation is perhaps the most important of all of the energy transformations that we will see in our study of biochemistry; without it, the vast majority of life as we know it on our planet simply could not exist.

19.1 Phototrophy Converts Light Energy into Chemical Energy

The metabolisms of living organisms can be subdivided into two pairs of fundamental groups based upon how they capture energy and obtain carbon. The process of converting electromagnetic radiation into chemical energy is called *phototrophy*, and, as noted in Chapter 15, organisms which utilize this mechanism to capture energy are called **phototrophs** (literally, "light-feeders").

An example of a phototroph is the archaeon *Halobacterium salinarum* that grows in extremely salty water such as that found in the Dead Sea, the Great Salt Lake, or in evaporation ponds used to isolate salt, as shown at the start of this chapter. When grown under low oxygen conditions, this organism generates additional ATP by using just two membrane proteins (**Figure 19.1**), relatives of which we have already encountered in other contexts. The first is ATP synthase, which utilizes a proton gradient to produce ATP (Section 18.4). The second is **bacteriorhodopsin**, which we discussed briefly in Section 12.4.

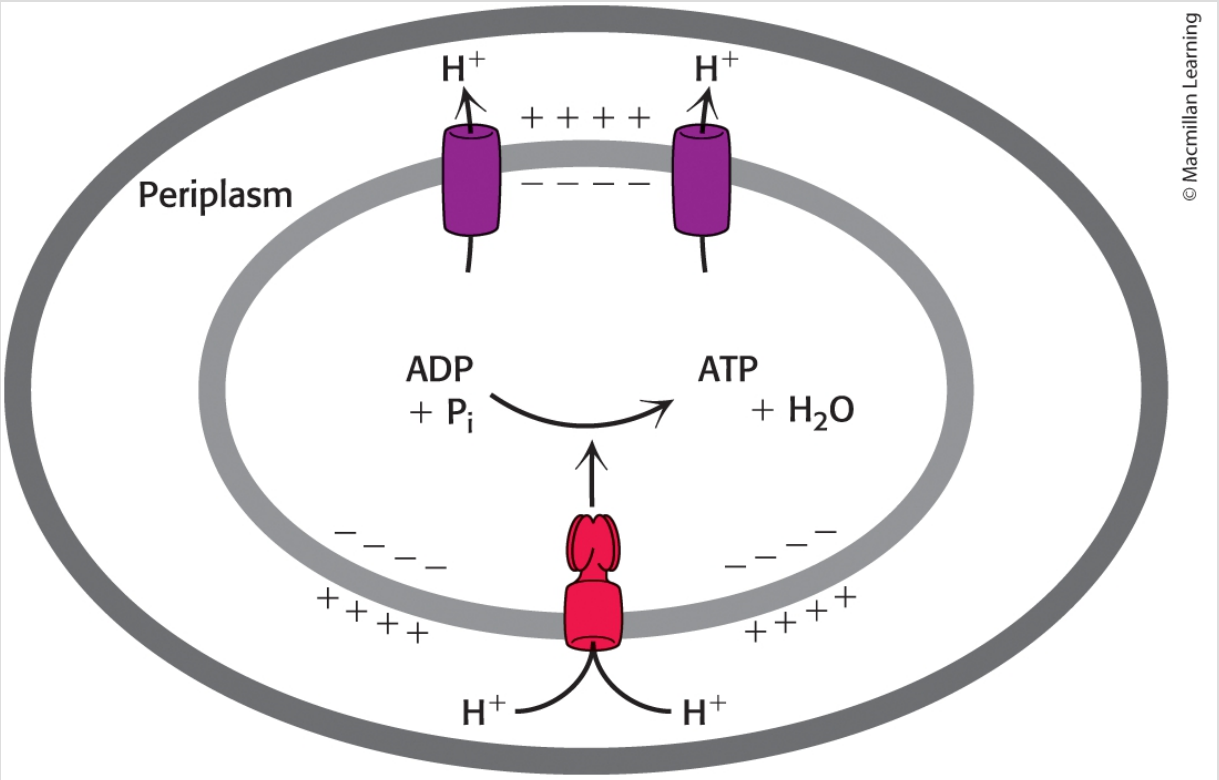

FIGURE 19.1 Phototrophy can be accomplished by the cooperation of just two proteins. The archaeon *Halobacterium salinarum* accomplishes phototrophy by expressing the light-absorbing protein bacteriorhodopsin in its inner cell membrane. Bacteriorhodopsin (purple structures) uses the energy from sunlight to transport protons across the membrane and into the periplasm. These protons return through ATP synthase (red structure) to make ATP.

Bacteriorhodopsin is similar to the 7-transmembrane helix protein rhodopsin involved in vision (Section 14.6). Like rhodopsin, bacteriorhodopsin includes bound 11-*cis* retinal, absorbing sunlight efficiently and producing all-trans retinal. Unlike rhodopsin, bacteriorhodopsin does not signal through other proteins but acts as a proton pump, transporting one proton — for each photon absorbed — from the cytoplasm to the periplasm, the space between the cell membrane and the cell wall.

Many phototrophic organisms use captured light energy, along with electrons harvested from a donor molecule, to convert carbon dioxide into carbohydrate in a complex process known as **photosynthesis**. The most common form of photosynthesis on Earth today, used by all plants, algae, and many bacteria, is called *oxygenic photosynthesis* and is the primary subject of this chapter. Oxygenic photosynthesis is so named because water is the electron donor and oxygen is produced as a waste product.

$$CO_2 + H_2O \xrightarrow{\text{Light}} (CH_2O) + O_2$$

In accordance with how the term is most commonly used, we will simply use the term "photosynthesis" to refer to oxygenic photosynthesis and will explicitly refer to alternative types as *anoxygenic photosynthesis* when they arise. In the above reaction, CH_2O represents carbohydrate, primarily sucrose and starch. Photosynthetic carbohydrate synthesis constantly regenerates organic molecules from carbon dioxide. These can then be used as energy sources for **chemotrophs**, like humans, which derive energy from chemicals as opposed to sunlight.

Photosynthetic organisms are also **autotrophs** ("self-feeders") because they obtain carbon primarily from carbon dioxide, rather than from organic molecules. Autotrophs can synthesize chemical fuels such as glucose from carbon dioxide and water. Photosynthetic organisms capture and store energy from sunlight and then later utilize this energy from the synthesized glucose through the glycolytic pathway and aerobic metabolism. In contrast to autotrophs, organisms that obtain carbon primarily from organic chemicals are called **heterotrophs**, which ultimately depend on autotrophs for these molecules. Thus, the carbohydrates produced

by photosynthetic organisms provide not only energy to run much of the biological world, but also the carbon molecules used by many organisms to make a wide array of biomolecules.

Photosynthesis comprises light reactions and dark reactions

Photosynthesis is composed of two parts: the light reactions and the dark reactions. In the **light reactions**, light energy is captured as chemical energy through the formation of ATP and electrons are extracted to provide reducing power for biosynthetic reactions. The products of the light reactions are then used in the so-called *dark reactions* to drive the reduction of CO_2 and its conversion into glucose and other sugars. The dark reactions are also called the *Calvin–Benson cycle* or *light-independent reactions* and will be discussed in Chapter 20.

The same biochemical principles govern both respiration and photosynthesis

As we will see soon, the light reactions of photosynthesis closely resemble the events of oxidative phosphorylation, whereas the dark reactions accomplish the reversal of cellular respiration. In Chapters 17 and 18, we learned that cellular respiration is the oxidation of glucose to CO_2 with the reduction of O_2 to water, a process that generates ATP.

$$C_6H_{12}O_6 + 6\,O_2 \xrightarrow{\text{Cellular respiration}} 6\,CO_2 + 6\,H_2O + \text{energy}$$

In photosynthesis, this process must be reversed — reducing CO_2 and oxidizing H_2O to synthesize glucose.

$$\text{Energy} + 6\,H_2O + 6\,CO_2 \xrightarrow{\text{Photosynthesis}} C_6H_{12}O_6 + 6\,O_2$$

Although the processes of respiration and photosynthesis are chemically opposite each other, the biochemical principles governing the two processes are nearly identical. The key to both processes is the generation of high-energy electrons.

- *During respiration, the citric acid cycle oxidizes carbon fuels to CO_2 to generate high-energy electrons*. The flow of these high-energy electrons down an electron-transport chain generates a proton-motive force. This proton-motive force is then transduced by ATP synthase to form ATP.

- *During photosynthesis, energy from light boosts electrons from a low-energy state to a high-energy state*. In the high-energy, unstable state, these electrons can be passed to nearby molecules. These electrons are then used to (1) produce reducing power in the form of NADPH and (2) generate a proton-motive force across a membrane, which subsequently drives the synthesis of ATP (**Figure 19.2**).

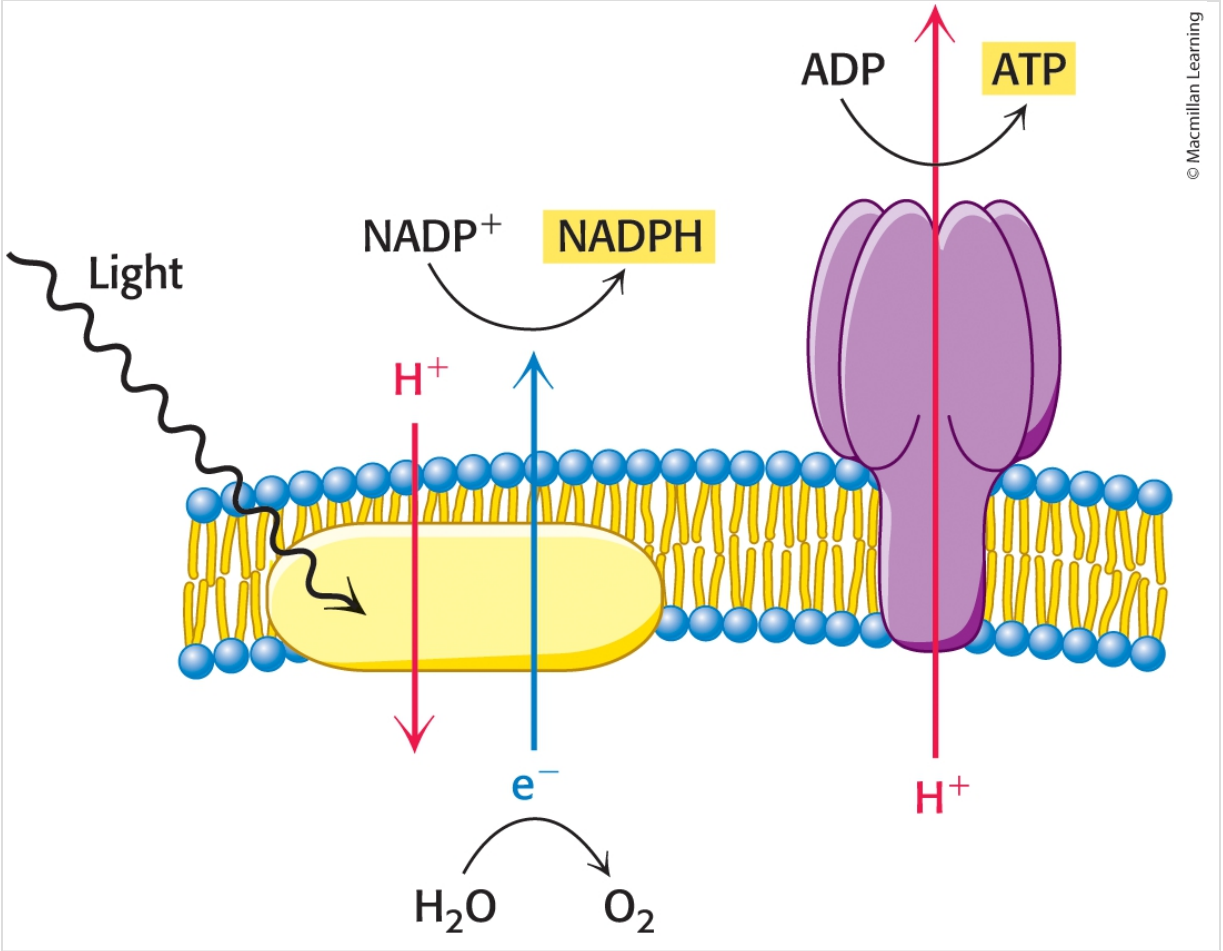

FIGURE 19.2 The light reactions of oxygenic photosynthesis generate both ATP and reducing power. Light is absorbed and the energy is used to drive electrons from water to generate NADPH, which can be used later for reduction reactions, and to drive protons across a membrane. In the same fashion as shown for the halobacterium in Figure 19.1, these protons return through ATP synthase (purple structure) to make ATP.

Self-Check Question

Photosynthesis is a complex metabolic process that is the sum of which two of the following four metabolic schemes for carbon and energy capture: chemotrophy,

Two kinds of light reactions take place in the green plants

Photosynthesis in green plants is mediated by two kinds of light reactions, which take place in two distinct transmembrane protein complexes, called *photosystems*. **Photosystem I** generates reducing power in the form of NADPH but, in the process, becomes electron deficient. **Photosystem II** oxidizes water and transfers the electrons to replenish the electrons lost by photosystem I. A side product of these reactions is O_2. Electron flow from photosystem II to photosystem I generates the transmembrane proton gradient, augmented by the protons released by the oxidation of water, that drives the synthesis of ATP. In keeping with the similarity of their principles of operation, in eukaryotes both respiration and photosynthesis take place in double-membrane organelles: mitochondria for cellular respiration and chloroplasts for photosynthesis.

19.2 In Eukaryotes, Photosynthesis Takes Place in Chloroplasts

In eukaryotes, photosynthesis takes place in specialized organelles called **chloroplasts**, typically $5\ \mu m$ long. Like a mitochondrion, a chloroplast has an outer membrane and an inner membrane, with an intervening intermembrane space (**Figure 19.3**). The inner membrane surrounds a space called the **stroma**, which is the site of the dark reactions of photosynthesis (Chapter 20). In the stroma are membranous structures called **thylakoids**, which are flattened sacs, or discs. The thylakoid sacs are stacked to form a **granum**. Different grana are linked by regions of thylakoid membrane called *stroma lamellae*. The thylakoid membranes separate the thylakoid space from the stroma space. Thus, chloroplasts have three different membranes (*outer, inner*, and *thylakoid membranes*) and three separate spaces (*intermembrane, stroma,* and *thylakoid lumen*). In a developing chloroplast, thylakoids arise from budding of the inner membrane, and so they are analogous to the mitochondrial cristae. Like the mitochondrial cristae, they are the site of coupled oxidation–reduction reactions of the light reactions that generate the proton-motive force.

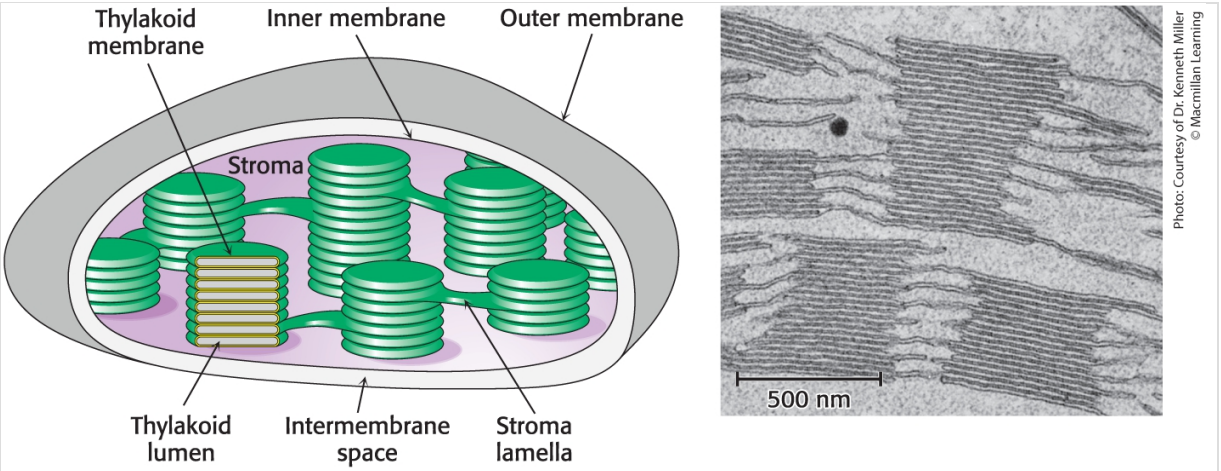

FIGURE 19.3 The anatomy of a chloroplast reveals complex membrane-enclosed structures. Plant-leaf cells contain between 1 and 100 chloroplasts, depending on the species, cell type, and growth conditions. At far right, an electron micrograph of a chloroplast from a spinach leaf shows thylakoid membranes packed together to form grana.

The primary events of photosynthesis take place in thylakoid membranes

The thylakoid membranes contain the energy-transforming machinery: light-harvesting proteins, reaction centers, electron-transport chains, and ATP synthase. These membranes contain nearly equal amounts of lipids and proteins. The lipid composition is highly distinctive: about 75% of the total lipids are galactolipids and 10% are sulfolipids, whereas only 10% are phospholipids. The thylakoid membrane and the inner membrane, like the inner mitochondrial membrane, are impermeable to most molecules and ions. The outer membrane of a chloroplast, like that of a mitochondrion, is highly permeable to small molecules and ions. The stroma contains the soluble enzymes that utilize the NADPH and ATP synthesized by the thylakoids to convert CO_2 into sugar.

Chloroplasts arose from an endosymbiotic event

Chloroplasts contain their own DNA and the machinery for replicating and expressing it. However, chloroplasts are not independent from the rest of the cell; they also contain many proteins encoded by nuclear DNA. How did the intriguing relationship between the cell and its chloroplasts develop? It is now widely accepted that, in a manner analogous to the evolution of mitochondria (Section 18.1), chloroplasts are also the result of endosymbiotic events in which a photosynthetic microorganism was engulfed by a eukaryotic host. Evidence suggests that chloroplasts in both higher plants and green algae are derived from a single endosymbiotic event, when an ancestor of a modern-day cyanobacterium was engulfed (**Figure 19.4**), whereas those in red and brown algae are derived from at least one additional event.

Elif Bayraktar/Shutterstock

FIGURE 19.4 Cyanobacteria are the prokaryotic photosynthesizers that are the most similar to plant chloroplasts. A colony of the photosynthetic filamentous cyanobacterium *Anabaena* is shown at 500× magnification. Ancestors of these bacteria are thought to have evolved into present-day chloroplasts of plants.

The chloroplast genome is smaller than that of a cyanobacterium, but the two genomes have key features in common. Both are circular and have a single start site for DNA replication, and the genes of both are arranged in operons — sequences of functionally related genes under common control. In the course of evolution, many of the genes of the chloroplast ancestor were transferred to the plant cell's nucleus or, in some cases, lost entirely, thus establishing a fully dependent relationship.

Self-Check Question

Explain the relationship between the following terms: thylakoid, stroma, chloroplast, and endosymbiosis.

19.3 Light Absorption by Chlorophyll Molecules Induces Electron Transfer

The trapping of light energy is the key to phototrophy, and therefore also photosynthesis. The first event is the absorption of light by a photoreceptor molecule. The principal photoreceptors in the chloroplasts of most green plants are collectively chlorophylls, and of particular importance among these is the pigment molecule **chlorophyll *a***, a substituted tetrapyrrole (**Figure 19.5**). The four nitrogen atoms of the pyrroles are coordinated to a magnesium ion. Unlike a porphyrin such as heme, chlorophyll *a* has a reduced pyrrole ring and an additional 5-carbon ring fused to one of the pyrrole rings. Another distinctive feature of chlorophyll *a* is the presence of *phytol,* a highly hydrophobic 20-carbon alcohol, esterified to an acid side chain.

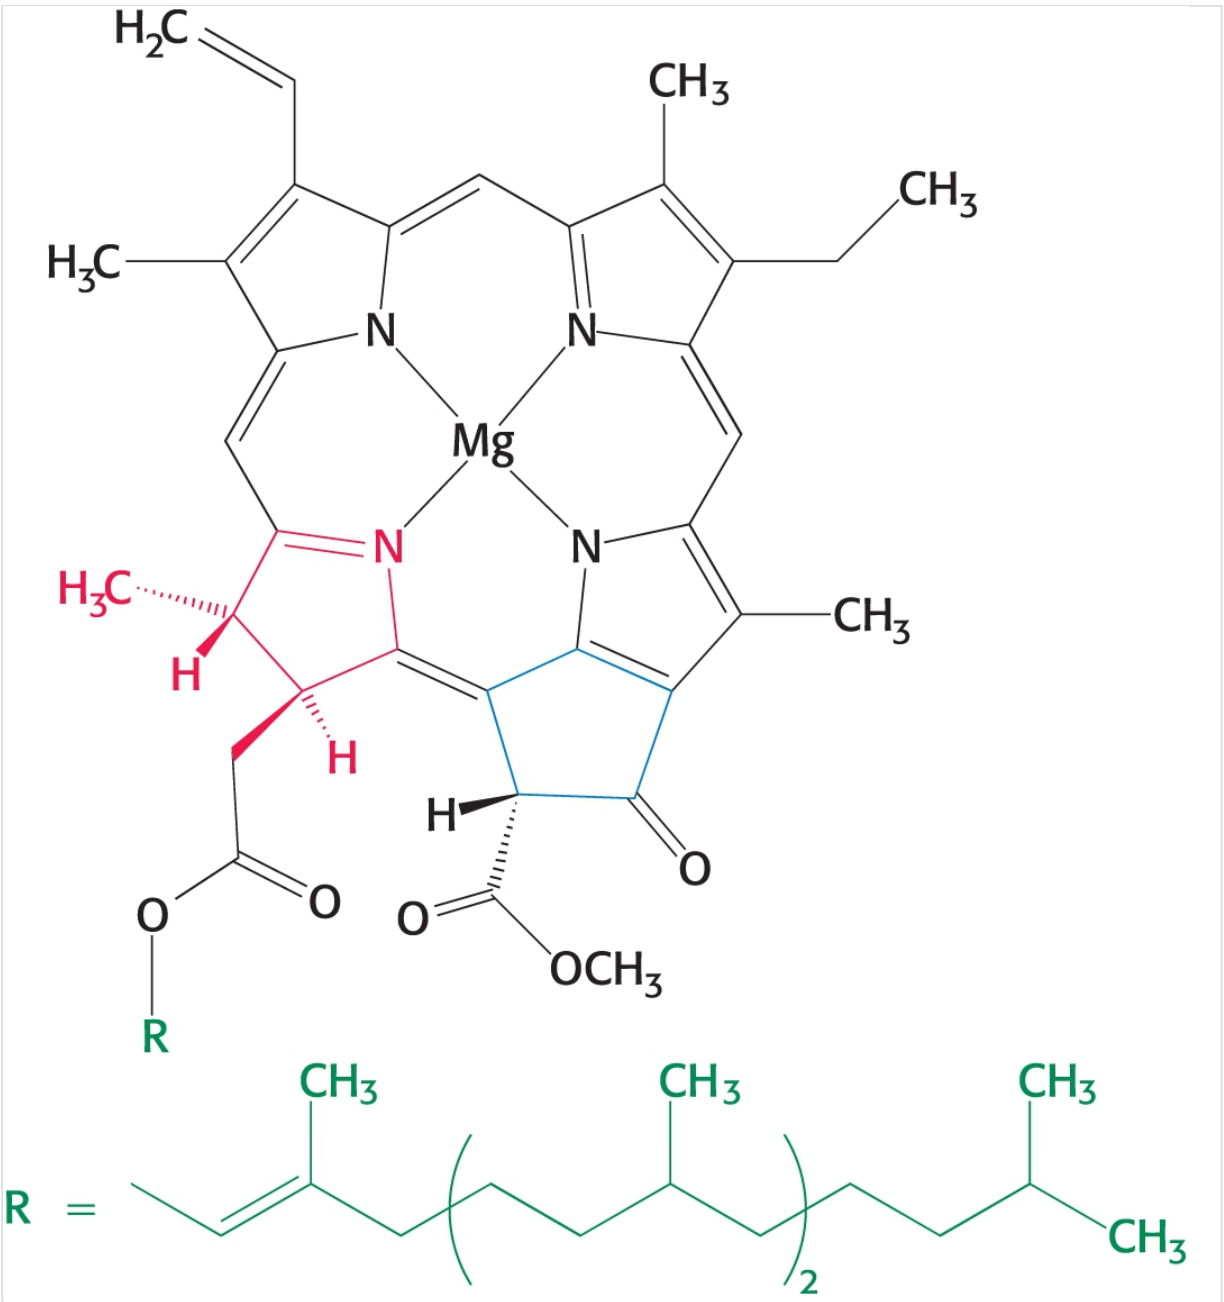

FIGURE 19.5 Chlorophyll *a* is structurally similar to heme. Like heme, chlorophyll *a* is a cyclic tetrapyrrole. One of the pyrrole rings (shown in red) is reduced, and an additional five-carbon ring (shown in blue) is fused to another pyrrole ring. A phytol chain (shown in green) is connected by an ester linkage. Magnesium ion binds at the center of the structure.

Chlorophylls are very effective photoreceptors because they contain networks of conjugated double bonds — alternating single and double bonds. Such compounds are called conjugated polyenes. In polyenes, the electrons are not localized to a particular atomic nucleus. Upon the absorption of light energy, the electron transitions from a low-energy molecular orbital to a higher-energy orbital.

Chlorophylls have very strong absorption bands in the visible region of the spectrum, where the solar output reaching Earth is maximal (**Figure 19.6**). Chlorophyll *a*'s peak molar extinction coefficient (ε), a measure of a compound's ability to absorb light, is greater than $10^5\ M^{-1}\ cm^{-1}$, among the highest observed for organic compounds.

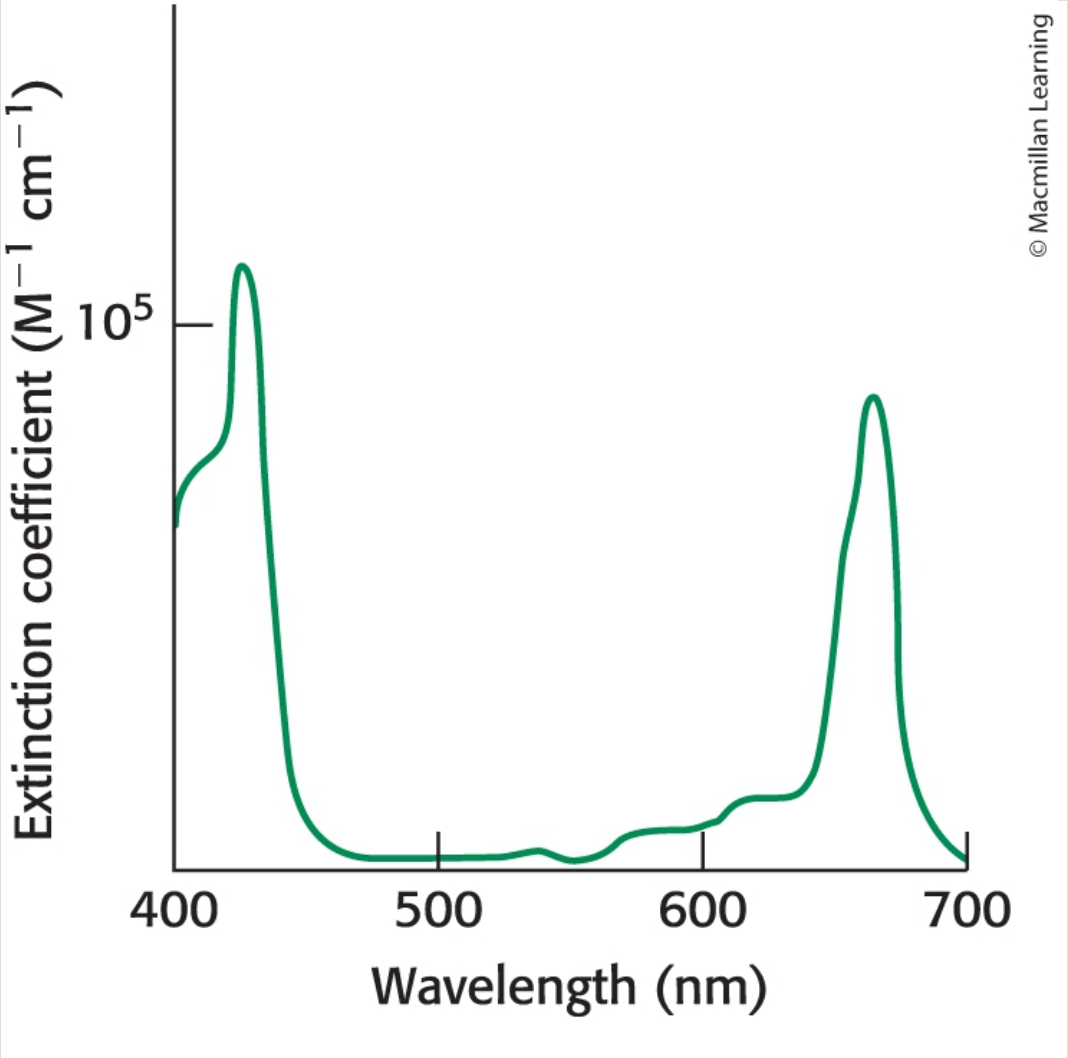

FIGURE 19.6 Chlorophyll *a* has a distinct absorbance spectrum in the visible range. Chlorophyll *a* absorbs visible light efficiently, as judged by the extinction coefficient near $10^5\ M^{-1}\ cm^{-1}$.

Transferring electrons allows energy to be captured instead of lost as heat

What happens when light is absorbed by a pigment molecule? The energy from the light excites an electron from its ground energy level to an excited energy level (Figure 19.7).

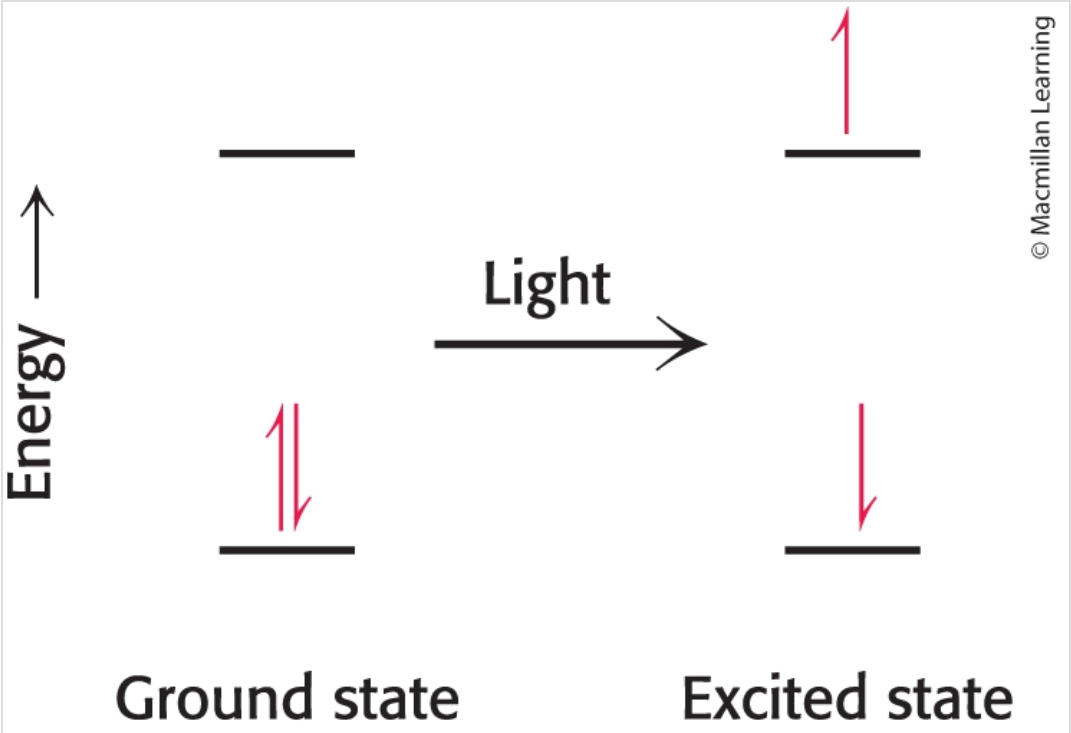

FIGURE 19.7 The absorption of light leads to the excitation of an electron from its ground state to a higher energy level.

This high-energy electron can have one of several fates. For the vast majority of compounds that absorb light, the electron simply returns to the ground state and the absorbed energy is converted into heat; however, the energy can also be emitted as light (fluorescence or phosphorescence) or transferred to another nearby electron (resonance energy transfer). However, one remaining possibility is the key to phototrophy: if a suitable electron acceptor is nearby, as is the case for chlorophylls in photosynthetic systems, the excited electron can move from the initial molecule to the acceptor (Figure 19.8). A positive charge forms on the initial molecule, owing to the loss of an electron, and a negative charge forms on the acceptor, owing to the gain of an electron. Hence, this process is referred to as **photoinduced charge separation**.

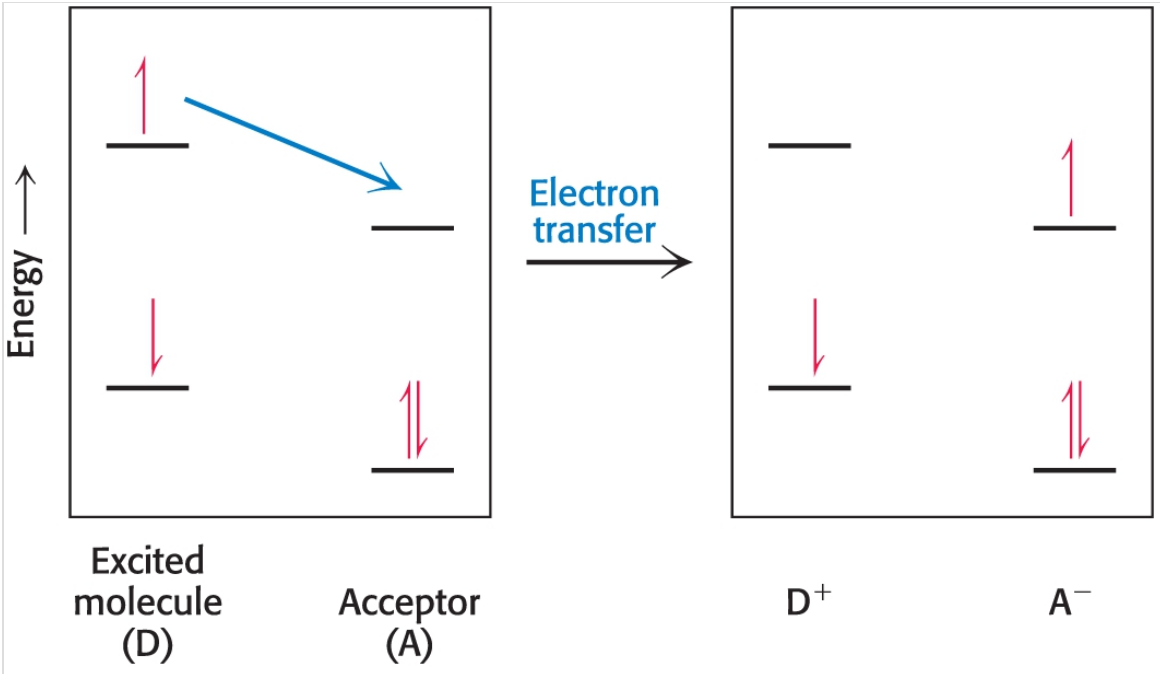

FIGURE 19.8 The key to photosynthesis is photoinduced charge separation. If a suitable electron acceptor is nearby, an electron that has been moved to a high energy level by light absorption can move from the excited molecule to the acceptor.

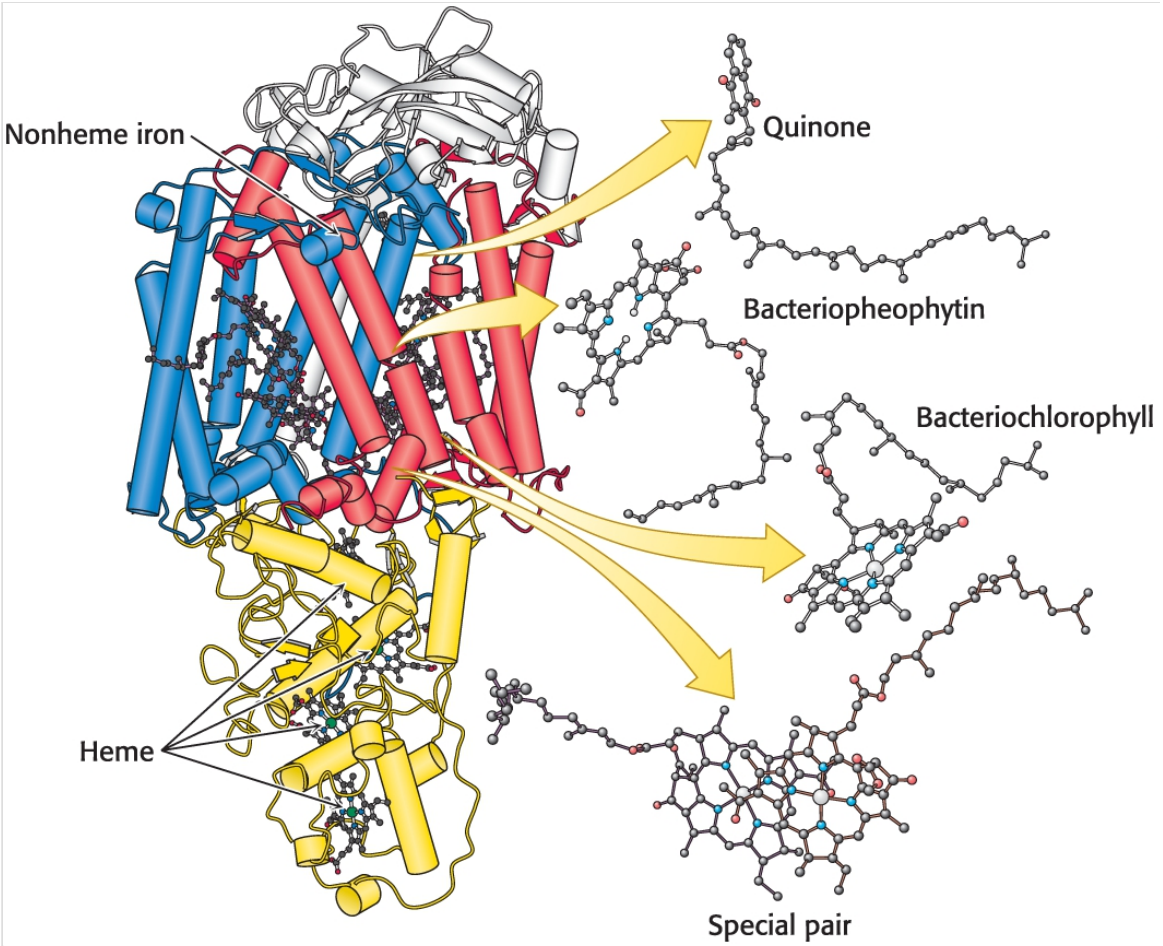
In chloroplasts, the arrangement of the photosynthetic apparatus maximizes photoinduced charge separation and minimizes an unproductive return of the electron to its ground state. The electron, extracted from its initial site by the absorption of light, now has reducing power: it can reduce other molecules to store the energy originally obtained from light in chemical forms.

A "special pair" of chlorophylls initiate charge separation

The specific site at which photoinduced charge separation occurs is called the **reaction center**. The structure of the reaction center from anoxygenic photosynthetic bacteria — such as the nonsulfur purple bacterium *Rhodopseudomonas viridis* — was the first one determined. This reaction center consists of four polypeptides, abbreviated L, M, H, and C (**Figure 19.9**). Sequence comparisons and subsequent structural studies have confirmed that this bacterial reaction center is homologous to the more complex cyanobacterial and plant systems. Thus, many of our observations of the purple bacterial system also apply these other systems.



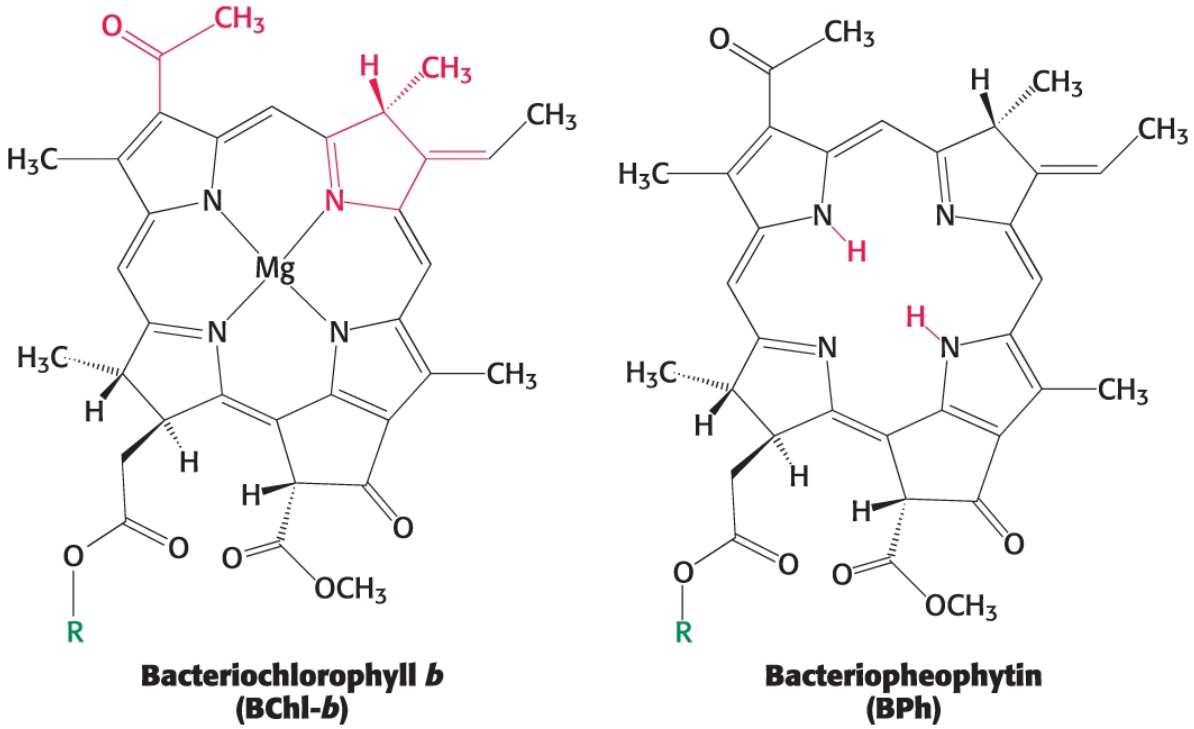


FIGURE 19.9 The photosynthetic reaction center in a nonsulfur purple bacterium is a large complex with many electron-carrying groups and one special pair. The core of the reaction center from *Rhodopseudomonas viridis* consists of two similar chains: L (shown in red) and M (blue). An H chain (white) and a cytochrome subunit (yellow) complete the structure. Notice tha the L and M subunits are composed largely of α helices that span the membrane. Also notice tha a chain of electron-carrying prosthetic groups, beginning with a special pair of bacteriochlorophylls and ending at a bound quinone, runs through the structure from bottom t top in this view.

[Drawn from 1PRC.pdb.]

INTERACT with this model in Achieve

The L and M subunits form the structural and functional core of the purple bacterial photosynthetic reaction center. Each of these

homologous subunits contains five transmembrane helices, in contrast with the H subunit, which has just one. The H subunit lies on the cytoplasmic side of the cell membrane, and the cytochrome subunit lies on the exterior face of the cell membrane, called the *periplasmic side* because it faces the periplasm — the space between the cell membrane and the cell wall. Four bacteriochlorophyll *b* (BChl-*b*) molecules, two bacteriopheophytin *b* (BPh) molecules, two quinones (Q_A and Q_B), and a ferrous ion are associated with the L and M subunits.

Bacteriochlorophylls are photoreceptors similar to chlorophylls, except for the reduction of an additional pyrrole ring and other minor differences that shift their absorption maxima to the near infrared, to wavelengths as long as 1000 nm. *Bacteriopheophytin* is the term for a bacteriochlorophyll that has two protons instead of a magnesium ion at its center.

The reaction begins with light absorption by a pair of BChl-*b* molecules that lie near the periplasmic side of the membrane in the L–M dimer.

The pair of BChl-*b* molecules is called the **special pair** because of its fundamental role in photosynthesis. The special pair absorbs light maximally at 960 nm and, for this reason, is often called P960 (*P* stands for pigment). After absorbing light, the excited special pair ejects an electron, which is transferred through another BChl-*b* to the bacteriopheophytin in the L chain (Figure 19.10, steps 1 and 2). This initial charge separation yields a positive charge on the special pair $(P960^{+})$ and a negative charge on BPh (BPh^{-}). The electron ejection and transfer take place in less than 10 picoseconds $(10^{-12}\ s)$, again illustrating the incredibly short timeframes of molecular interactions at the biochemical timescale.

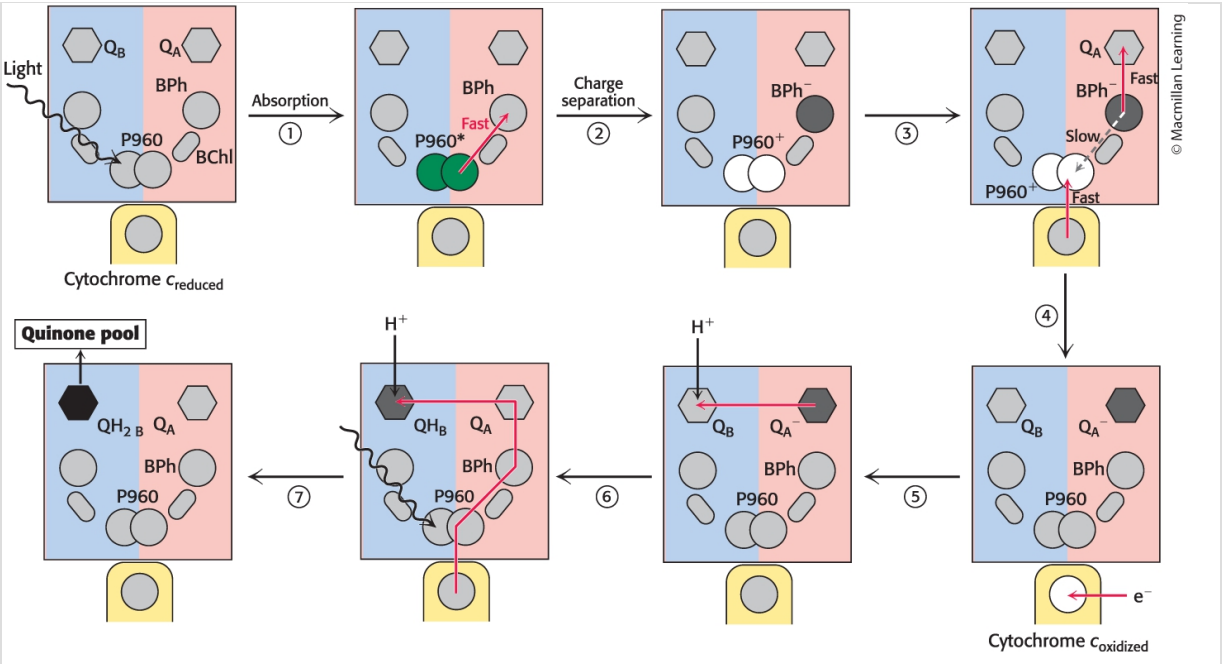

FIGURE 19.10 In the reaction center of nonsulfur purple bacteria, electrons flow from the special pair to a quinone. The absorption of light by the special pair (P960) results in the rapid transfer of an electron from this site to a bacteriopheophytin (BPh), creating a photoinduced charge separation (steps 1 and 2). (The asterisk on P960 stands for excited state.) The possible return of the electron from the pheophytin to the oxidized special pair is suppressed by the "hole" in the special pair being refilled with an electron from the cytochrome subunit and the electron from the pheophytin being transferred to a quinone (Q_A) that is farther away from the special pair (steps 3 and 4). Q_A passes the electron to Q_B. The reduction of a quinone (Q_B) on

the cytoplasmic side of the membrane results in the uptake of two protons from the cytoplasm (steps 5 and 6). The reduced quinone can move into the quinone pool in the membrane (step 7).

A proton gradient across the membrane is established

A nearby electron acceptor, a tightly bound quinone (Q_A), quickly grabs the electron away from BPh^- before the electron has a chance to fall back to the P960 special pair. From Q_A, the electron moves to a more loosely associated quinone, Q_B. The absorption of a second photon and the movement of a second electron from the special pair through the bacteriopheophytin to the quinones completes the two-electron reduction of Q_B from Q to QH_2. Because the Q_B-binding site lies near the cytoplasmic side of the membrane, two protons are taken up from the cytoplasm, contributing to the development of a proton gradient across the cell membrane (Figure 19.10, steps 5, 6, and 7).

In their high-energy states, $P960^+$ and BPh^- could undergo charge recombination; that is, the electron on BPh^- could move back to neutralize the positive charge on the special pair. Its return to the special pair would waste a valuable high-energy electron and simply convert the absorbed light energy into heat. How is charge recombination prevented? Two factors in the structure of the reaction center work together to suppress charge recombination nearly completely (Figure 19.10, steps 3 and 4). First, the next electron acceptor (Q_A) is less than 10 Å away from BPh^-, and so the electron is rapidly transferred farther away from the special pair. Second, one of the hemes of the cytochrome subunit is less than 10 Å away from the

special pair, and so the positive charge on P960 is neutralized by the transfer of an electron from the reduced cytochrome.

Cyclic electron flow reduces the cytochrome of the reaction center

The cytochrome subunit of the reaction center must regain an electron to complete the cycle. It does so by taking back two electrons from reduced quinone (QH_2). QH_2 first enters the Q pool in the membrane where it is reoxidized to Q by complex bc_1, which is homologous to Complex III of the respiratory electron-transport chain. Complex bc_1 transfers the electrons from QH_2 to cytochrome c_2, a water-soluble protein in the periplasm, and in the process pumps protons into the periplasmic space. The electrons now on cytochrome c_2 flow to the cytochrome subunit of the reaction center. The flow of electrons is thus cyclic in these bacteria, and oxygen is not evolved (**Figure 19.11**). The proton gradient generated in the course of this cycle drives the synthesis of ATP through the action of ATP synthase.

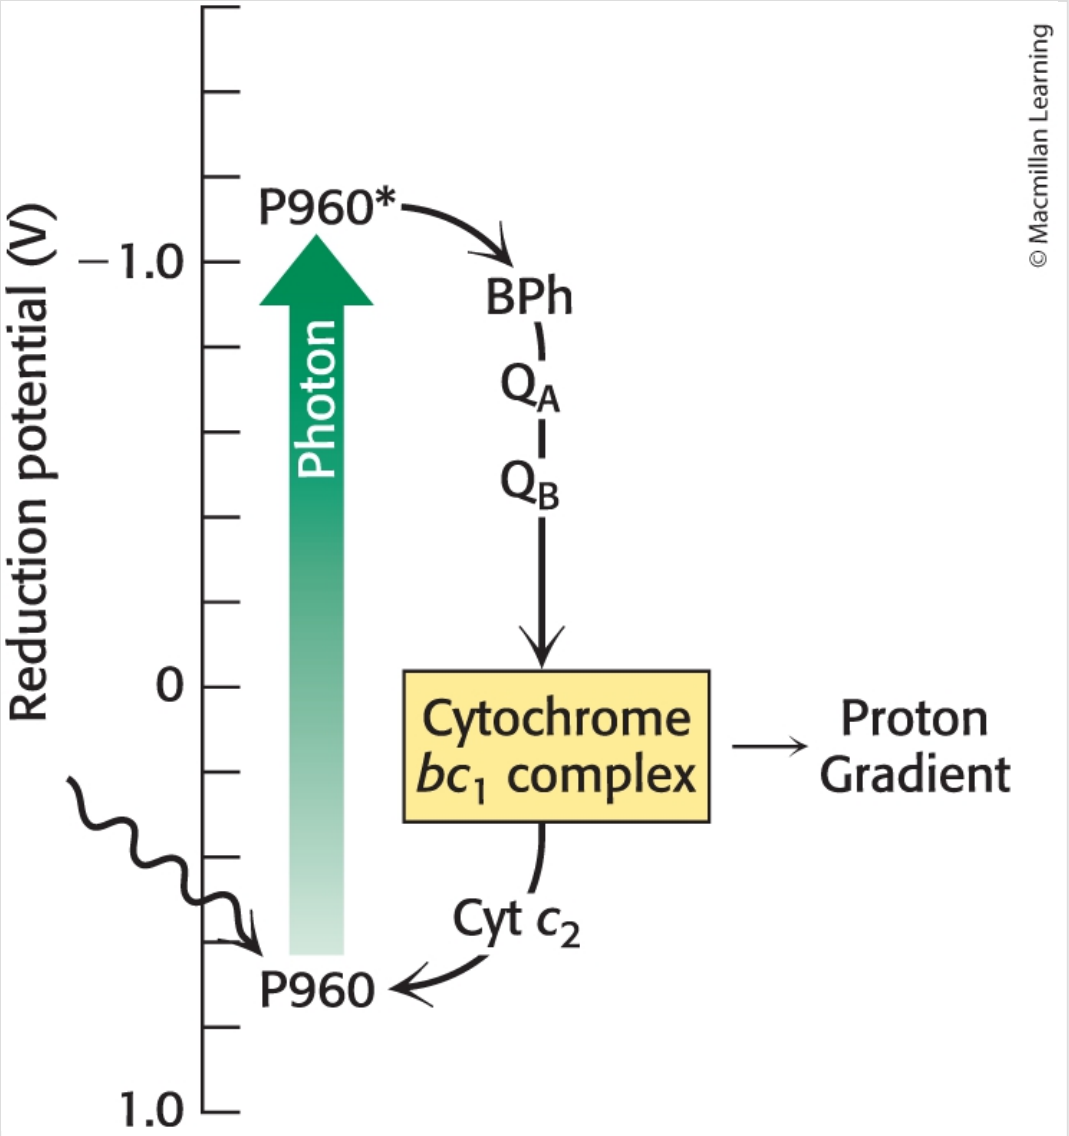

FIGURE 19.11 Cyclic electron flow in the bacterial reaction center allows the generation of ATP but not reducing power. Excited electrons from the P960 reaction center flow through bacteriopheophytin (BPh), a pair of quinone molecules (Q_A and Q_B), cytochrome bc_1 complex, and finally through cytochrome c_2 to the reaction center. The cytochrome bc_1 complex pumps protons as a result of electron flow, which powers the formation of ATP.

Self-Check Question

What is meant by a “special pair” in the context of photosynthesis, and what important role does it play?

19.4 Two Photosystems Generate a Proton Gradient and Reducing Power in Cyanobacteria and Photosynthetic Eukaryotes

Photosynthesis is more complicated in eukaryotes and cyanobacteria than in the purple photosynthetic bacteria discussed in the previous section. In these other organisms including all green plants, photosynthesis depends on the interplay of two kinds of membrane-bound, light-sensitive complexes — photosystem I (PS I) and photosystem II (PS II), as shown in **Figure 19.12**. Note that photosystem I is so named because it was discovered first, but it is actually photosystem II that acts first in the sequence of events that take place during photosynthesis.

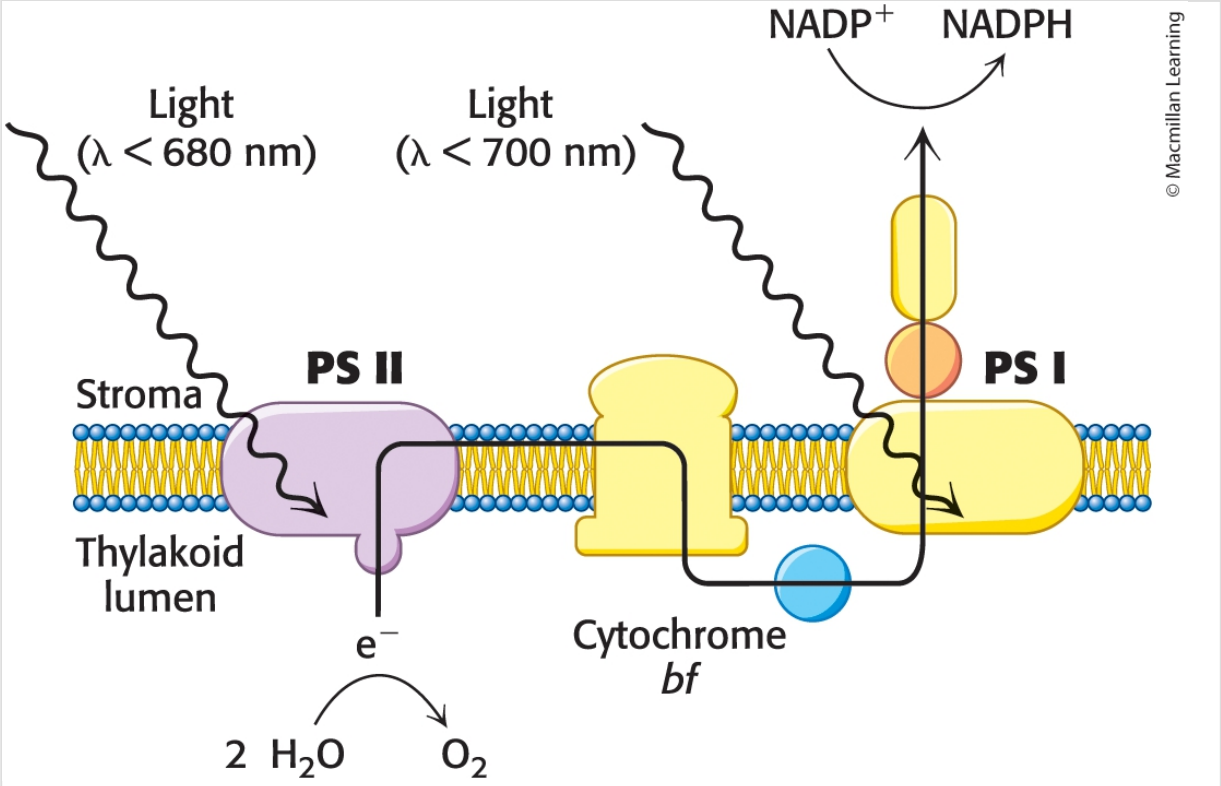

FIGURE 19.12 In green plants, electrons can flow through two photosystems. The absorption of photons by two distinct photosystems (PS II and PS I) is required for complete electron flow from water to $NADP^+$.

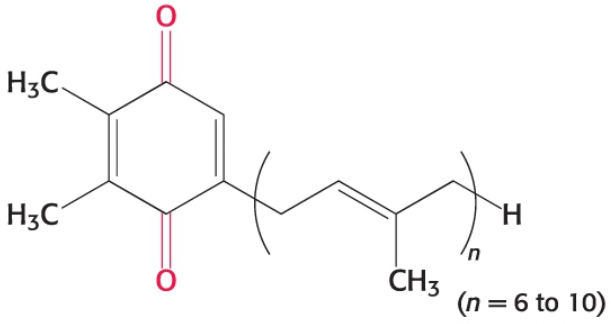
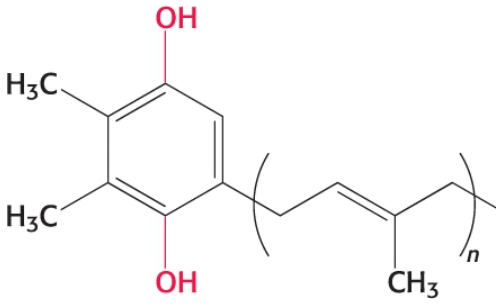
There are similarities in photosynthesis between green plants and purple photosynthetic bacteria. Both require light to energize reaction centers consisting of special pairs, and both transfer electrons by using electron-transport chains. However, in plants, electron flow can be cyclic, but it progresses linearly from photosystem II to photosystem I under most circumstances.



Photosystem II transfers electrons from water to plastoquinone and generates a

proton gradient



Photosystem II, an enormous transmembrane assembly of more than 20 subunits, catalyzes the light-driven transfer of electrons from water to plastoquinone. This electron acceptor closely resembles ubiquinone, a component of the mitochondrial electron-transport chain. Plastoquinone cycles between an oxidized form (Q) and a reduced form (QH_2, plastoquinol). The overall reaction catalyzed by photosystem II is

$$2\,Q + 2\,H_2O \xrightarrow{\text{Light}} O_2 + 2\,QH_2$$

The electrons in QH_2 are at a higher redox potential than those in H_2O. Recall that, in oxidative phosphorylation, electrons flow downhill from ubiquinol to an acceptor, O_2, which is at a *lower* potential. In contrast, photosystem II drives the reaction in a thermodynamically uphill direction by using the energy of light.

Plastoquinone
(oxidized form, Q)

Plastoquinol
(reduced form, QH_2)

Photosystem II is comparable to the purple bacterial reaction center

This light-driven transfer of elections is similar to the transfer reactions catalyzed by the purple bacterial system in that a quinone is converted from its oxidized into its reduced form. The core of photosystem II is reasonably similar to the purple bacterial reaction center (Figure 19.13). The core of the photosystem is formed by D1 and D2, a pair of similar 32-kDa subunits spanning the thylakoid membrane that are homologous to the L and M chains of the bacterial reaction center. Unlike the purple bacterial system, photosystem II contains a large number of additional subunits that bind more than 30 chlorophyll molecules altogether and increase the efficiency with which light energy is absorbed and transferred to the reaction center.

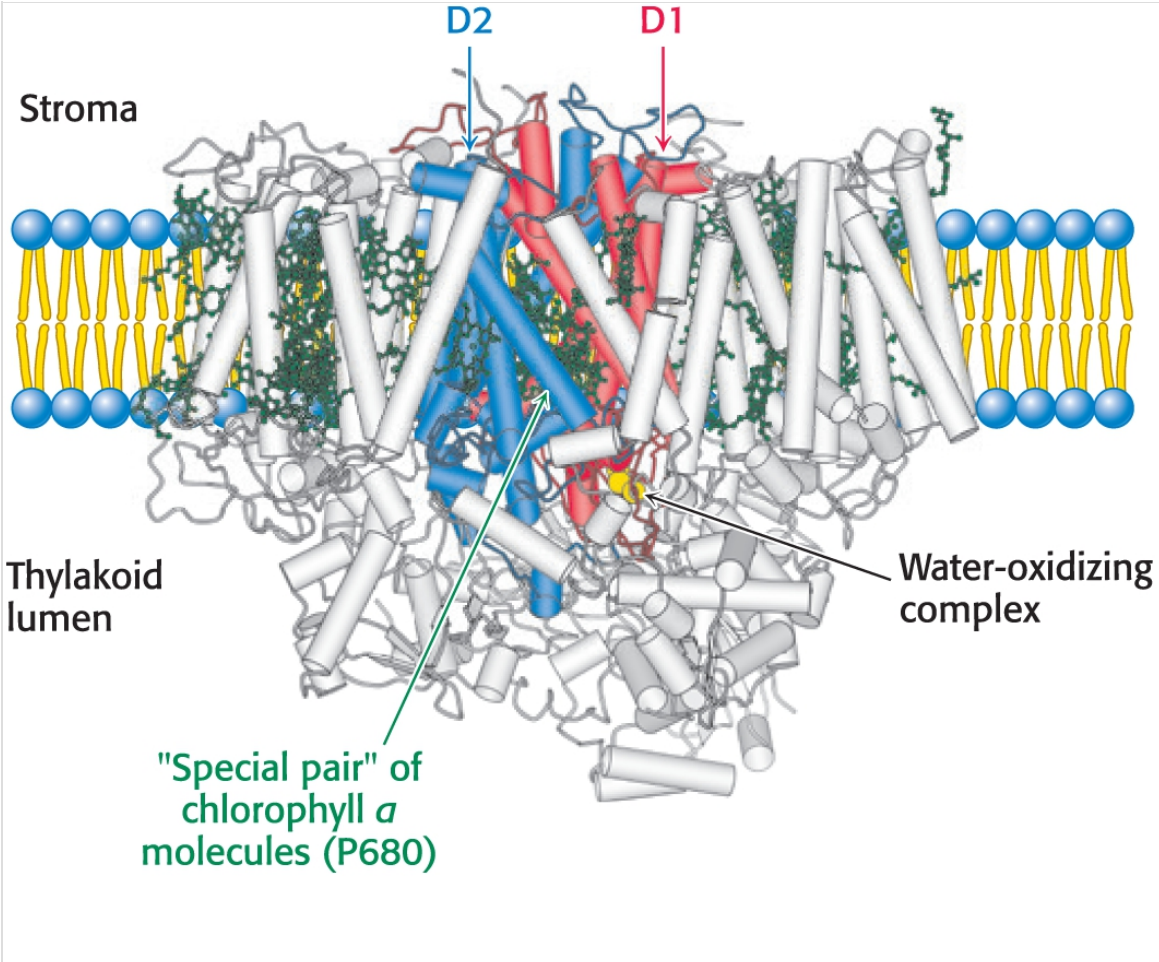


FIGURE 19.13 Photosystem II is a large membrane protein complex with many chlorophyll molecules, one special pair, and the water-oxidizing complex. The D_1 and D_2 subunits and the numerous bound chlorophyll molecules (green) are shown. Notice that the special pair and the water-oxidizing complex lie toward the thylakoid-lumen side of the membrane.

[Drawn from 1S5L.pdb.]

INTERACT with this model in Achieve

The electron flow in the thylakoid membrane is analogous to that in the bacterial membrane. The photochemistry of photosystem II begins with excitation of a special pair of chlorophyll molecules that are bound by the D1 and D2 subunits (Figure 19.14). Because the chlorophyll *a* molecules of the special pair absorb light at 680 nm, the special pair is often called *P680*. On excitation, P680 rapidly transfers an electron to a nearby pheophytin. From there, the electron is transferred first to a tightly bound plastoquinone at site Q_A and then to a mobile plastoquinone at site Q_B. With the arrival of a second electron and the uptake of two protons, the mobile plastoquinone is reduced to QH_2. At this point, the energy of two photons has been safely and efficiently stored in the reducing potential of QH_2.

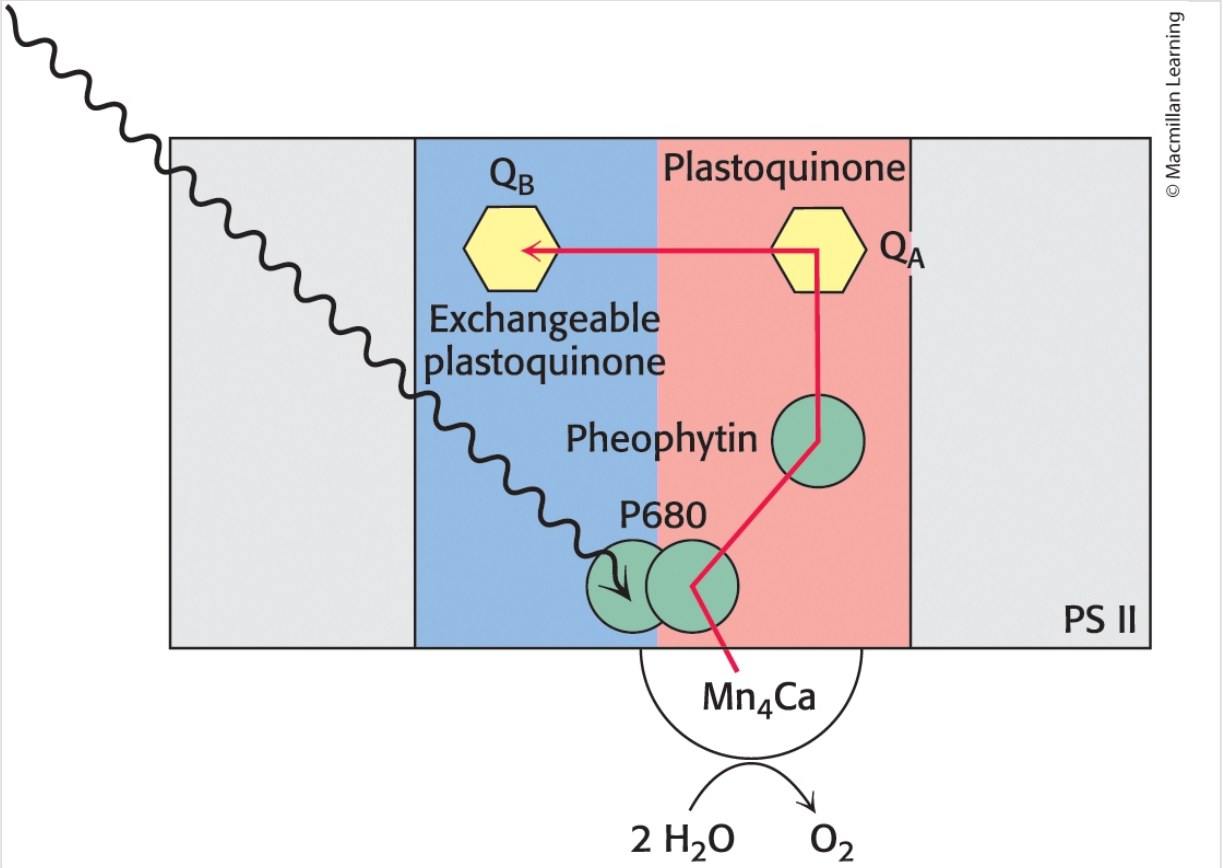

FIGURE 19.14 In photosystem II, electrons flow from manganese atoms to plastoquinone. Light absorption induces electron transfer from P680 down an electron-transfer pathway to an exchangeable plastoquinone. The positive charge on P680 is neutralized by electron flow from water molecules bound at the manganese center. Gray represents the rest of the photosystem beyond the reaction center core.

However, the source of elections is different from that of the bacterial reaction center. The major difference between the bacterial system and photosystem II is the source of the electrons that are used to neutralize the positive charge formed on the special pair. $P680^+$, a very strong oxidant, extracts electrons from water molecules bound at the **water-oxidizing complex (WOC)**, also called the **manganese center**. The core of this complex includes four manganese ions, one calcium ion, five oxide (O^{2-}) ions, and four water molecules (**Figure 19.15**). Manganese

is well suited for a role in this process because of its ability to exist in multiple oxidation states and to form strong bonds with oxygen-containing species.

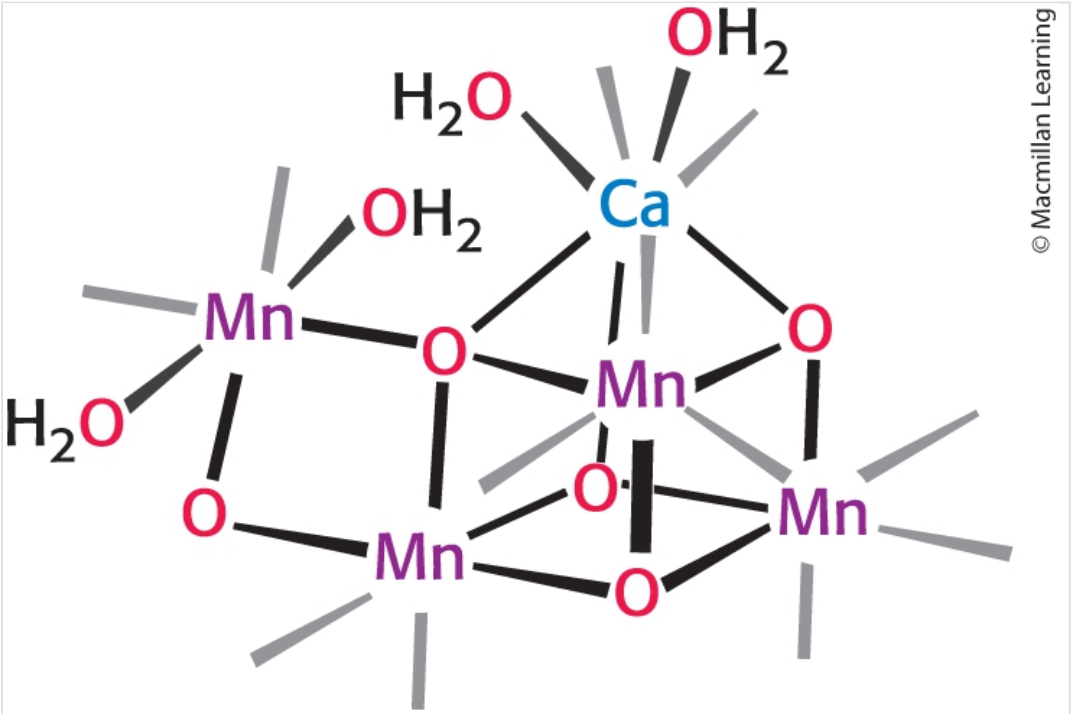

FIGURE 19.15 The core of the water-oxidizing complex includes four manganese ions and one calcium ion. The center is oxidized, one electron at a time, until two H_2O molecules are oxidized to form a molecule of O_2, which is then released from the complex.

Each time the absorption of a photon powers the removal of an electron to form $P680^+$, the positively charged special pair extracts an electron from a tyrosine residue that lies between P680 and the WOC to form a tyrosine radical. The tyrosine radical then removes an electron from the manganese center. Repeats of this process produce a center that is capable of carrying out the remarkable water oxidation reaction that generates oxygen.

The ability to control light pulses in the laboratory provides a powerful probe of the oxygen-generation process (Figure 19.16). Starting with chloroplasts that have remained in the dark for some time, an initial short flash of light produces very little oxygen. Application of a second flash produces the same result. However, with a third flash, a substantial amount of oxygen is produced. Additional flashes reveal that large amounts of oxygen are produced with every fourth flash thereafter.

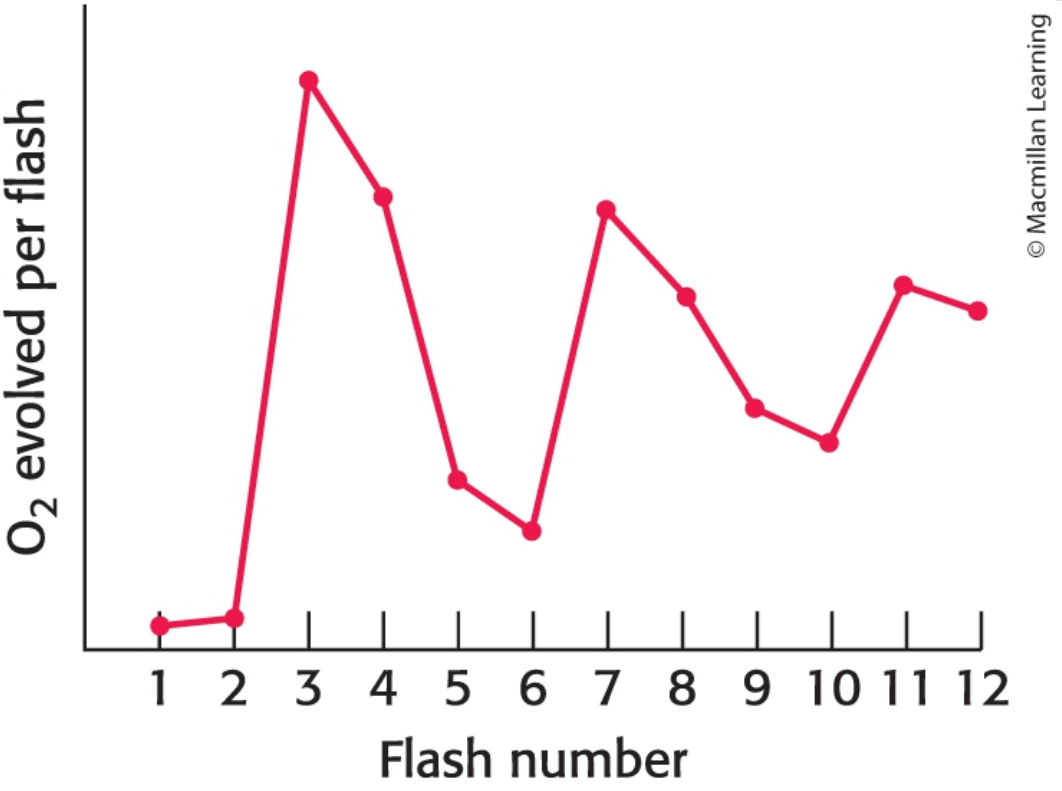

FIGURE 19.16 Four photons are required to generate one oxygen molecule after the first cycle. When dark-adapted chloroplasts are exposed to a brief flash of light, one electron passes through photosystem II. Monitoring the O_2 released after each flash reveals that O_2 is released after the 3rd, 7th, and 11th flashes.

Scientists have combined these observations with the results from other experiments to propose a mechanism for the oxygen-generating process (Figure 19.17). The formation of the oxygen–oxygen bond is proposed to involve an attack of a hydroxide ion bound to the calcium ion on a highly electrophilic oxo group bound to a manganese ion. The formation of the oxygen–oxygen bond requires the release of four electrons. An essential feature of the manganese center is its ability to develop and maintain a sufficiently oxidized state to take up these four electrons. The rates for the steps in this cycle have also been measured, revealing that the process that generates the oxygen powering so much of the life on our planet takes place in less than two milliseconds.

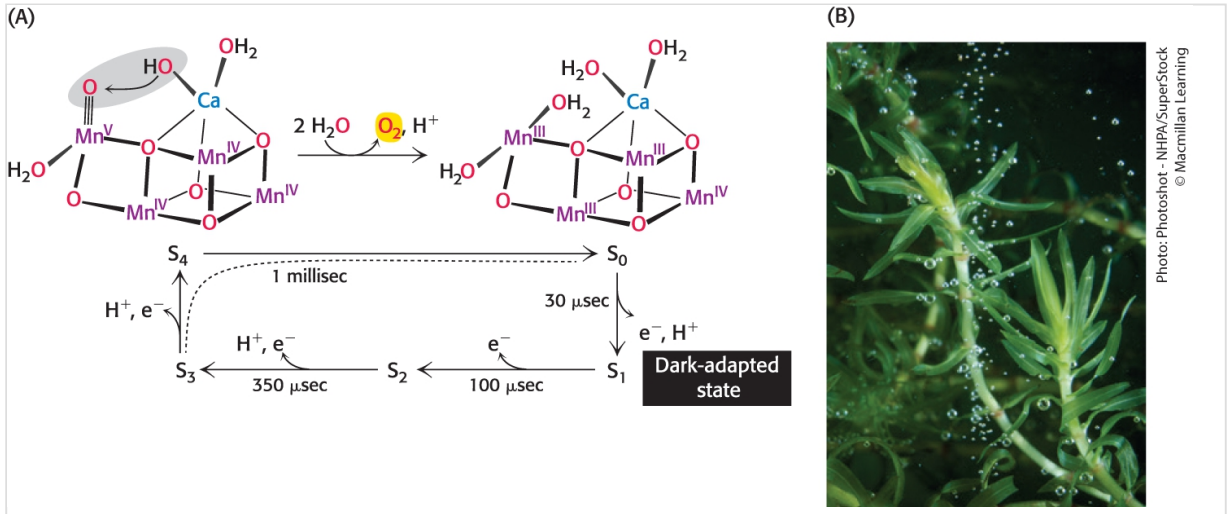

FIGURE 19.17 The model for the water-oxidizing complex explains the light-flash experiments. (A) The absorption of each photon by the reaction center generates a tyrosine radical that extracts one electron at a time from the manganese ions. The structures are designated S_0 to S_4, indicating the number of electrons removed. The model additionally explains why the first O_2 release occurs after three flashes: the dark-adapted chloroplasts start in the S_1 state — that is, the one-electron reduced state. (B) Evolution of oxygen is evident by the generation of bubbles in the aquatic plant *Elodea*.

In summary, all oxygenic phototrophs — the most common type of photosynthetic organism — use the same inorganic core and protein components for capturing the energy of sunlight. A single solution to the biochemical problem of extracting electrons from water evolved billions of years ago, and has been conserved for use under a wide variety of phylogenetic and ecological circumstances.

Similar to those of the purple bacterial reaction center, the reactions of photosystem II establish a proton gradient. Photosystem II spans the thylakoid membrane such that the site of quinone reduction is on the side of the stroma, whereas WOC lies in the thylakoid lumen. Thus, the two protons that are taken up with the reduction of Q to QH_2 come from the stroma, and the four protons that are liberated in the course of water oxidation are released into the lumen. This distribution of protons generates a proton gradient across the thylakoid membrane characterized by an excess of protons in the thylakoid lumen compared with the stroma (**Figure 19.18**).

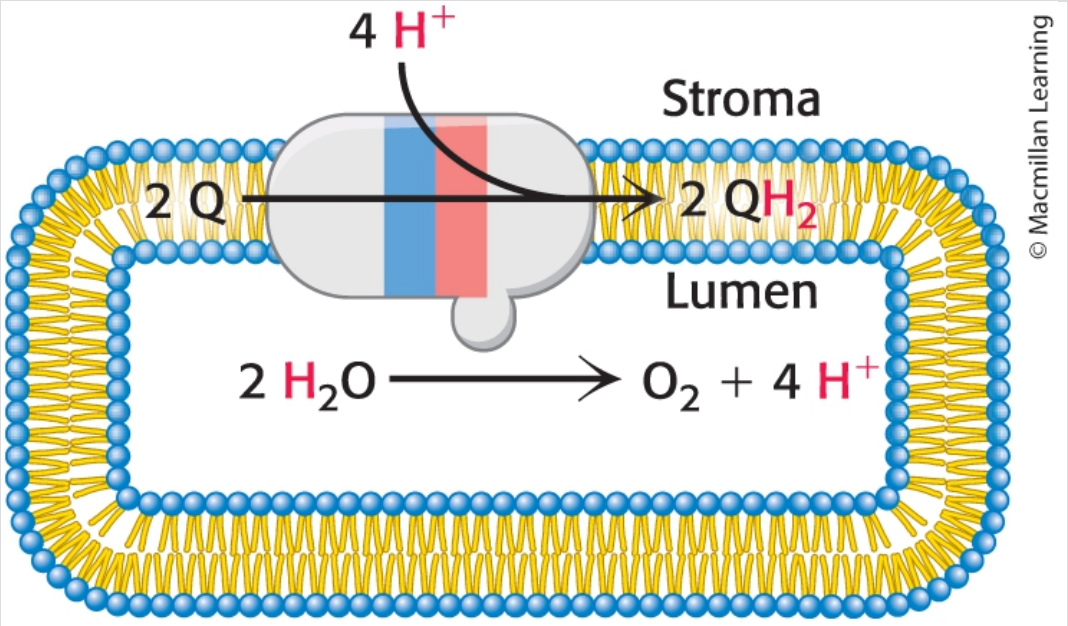

FIGURE 19.18 Photosystem II releases protons into the thylakoid lumen and takes them up from the stroma. The result is a pH gradient across the thylakoid membrane with an excess of protons (low pH) inside.

Cytochrome *bf* links photosystem II to photosystem I

Electrons flow from photosystem II to photosystem I through the **cytochrome *bf*** complex. This complex catalyzes the transfer of electrons from plastoquinol (QH_2) to plastocyanin (Pc), a small, soluble copper protein in the thylakoid lumen.

$$QH_2 + 2\ Pc(Cu^{2+}) \rightarrow Q + 2\ Pc(Cu^{+}) + 2\ H^{+}_{\text{thylakoid lumen}}$$

The two protons from plastoquinol are released into the thylakoid lumen. This reaction is reminiscent of that catalyzed by Complex III in oxidative phosphorylation, and most components of the cytochrome *bf* complex are homologous to those of Complex III.

This complex catalyzes the reaction by proceeding through the Q cycle (Figure 18.11). In the first half of the Q cycle, plastoquinol (QH_2) is oxidized to plastoquinone (Q), one electron at a time. The electrons from plastoquinol flow through the cytochrome *bf* complex to convert oxidized plastocyanin (Pc) into its reduced form (**Figure 19.19**).

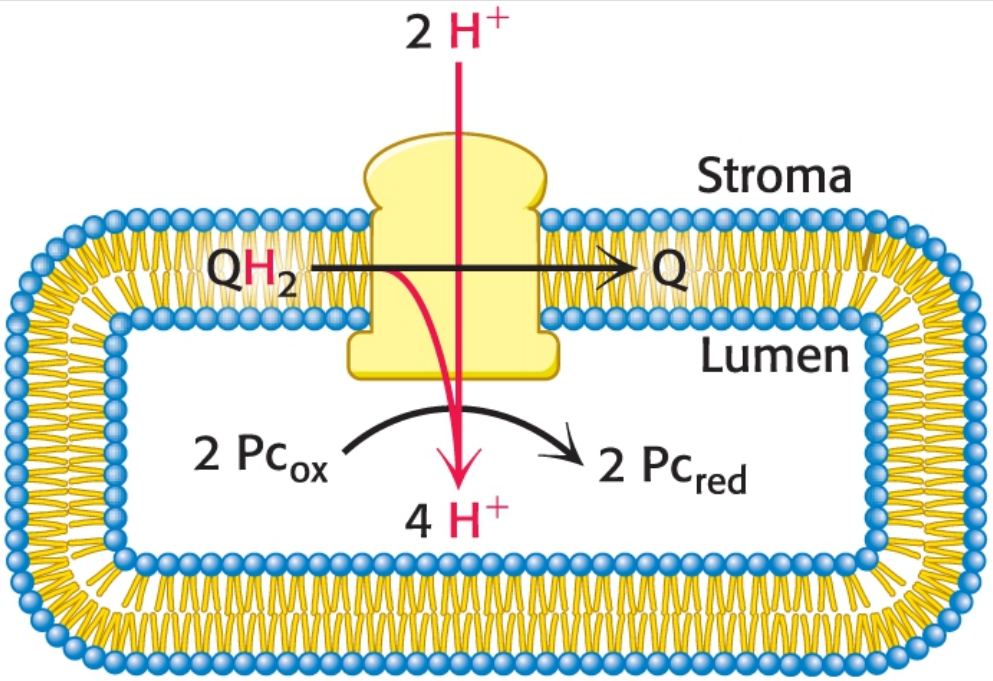

FIGURE 19.19 Electron flow through cytochrome *bf* contributes to the proton gradient. The cytochrome *bf* complex oxidizes QH_2 to Q through the Q cycle. Four protons are released into the thylakoid lumen in each cycle.

In the second half of the Q cycle, cytochrome *bf* reduces a molecule of plastoquinone from the Q pool to plastoquinol, taking up two protons from one side of the membrane, and then reoxidizes plastoquinol to release these protons on the other side. The enzyme is oriented so that protons are released into the thylakoid lumen and taken up from the stroma, contributing further to the proton gradient across the thylakoid membrane (Figure 19.19).

Photosystem I uses light energy to generate reduced ferredoxin, a powerful reductant

The final stage of the light reactions is catalyzed by photosystem I, a transmembrane complex consisting of about 15 polypeptide chains and multiple associated proteins and cofactors (Figure 19.20). The core of this system is a pair of similar subunits — psaA and psaB — which bind 80 chlorophyll molecules as well as other redox factors. These subunits are quite a bit larger than the core subunits of photosystem II and the purple bacterial reaction center. Nonetheless, they appear to be homologous; the terminal 40% of each subunit is similar to a corresponding subunit of photosystem II.

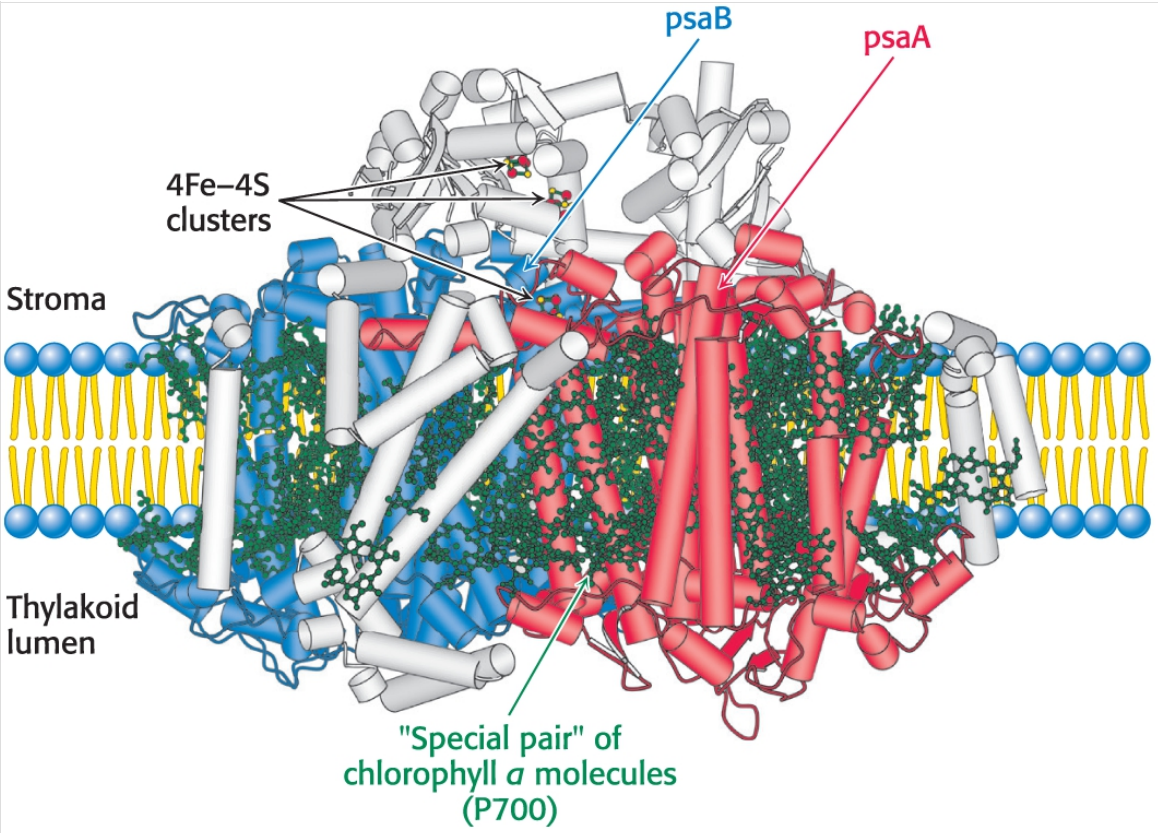

FIGURE 19.20 Photosystem I is a protein complex with numerous chlorophyll molecules and one special pair. Notice the numerous bound chlorophyll molecules, shown in green, including the special pair, as well as the iron–sulfur clusters that facilitate electron transfer from the stroma.

[Drawn from 1JB0.pdb.]

A special pair of chlorophyll *a* molecules lies at the center of photosystem I, where they absorb light maximally at 700 nm. This center, called *P700*, initiates photoinduced charge separation (Figure 19.21). The electron travels from P700 down a pathway through chlorophyll at site A_0 and quinone at site A_1 to a set of 4Fe–4S clusters.

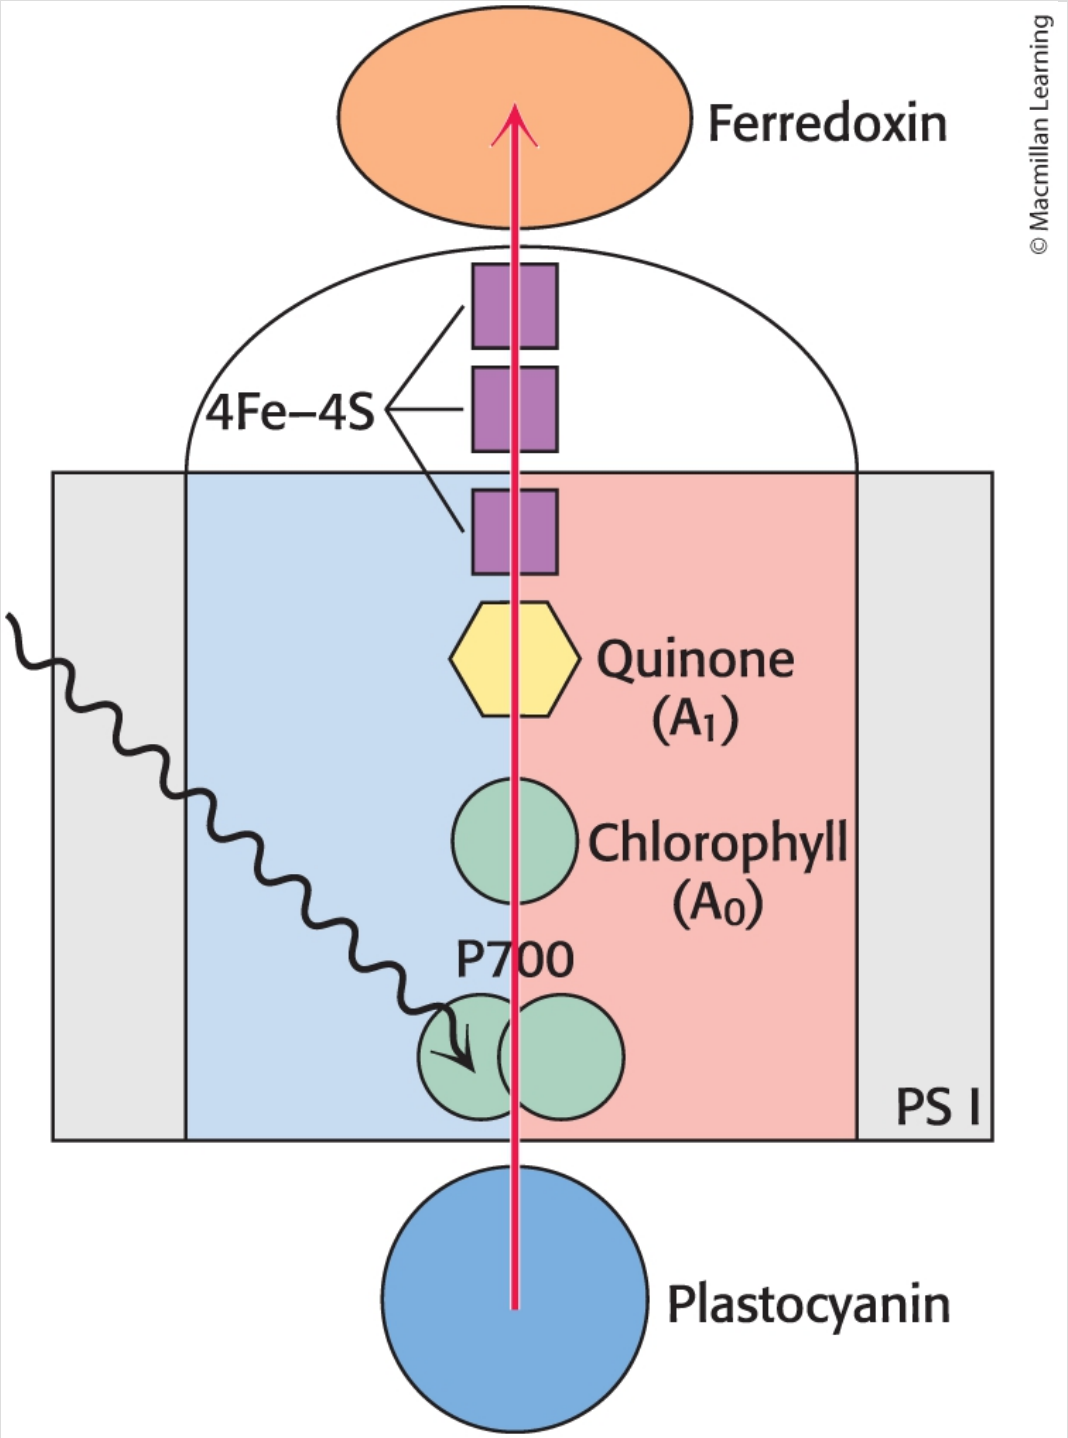

FIGURE 19.21 In photosystem I, electrons flow to ferredoxin. Light absorption induces electron transfer from P700 down an electron-transfer pathway that includes a chlorophyll molecule, a quinone molecule, and three 4Fe–4S clusters to reach ferredoxin. The positive charge left on P700 is neutralized by electron transfer from reduced plastocyanin. Gray represents the rest of the photosystem beyond the reaction center core.

The next step is the transfer of the electron to ferredoxin (Fd), a soluble protein containing a 2Fe–2S cluster coordinated to four cysteine residues (Figure 19.22). Ferredoxin transfers electrons to $NADP^+$. Meanwhile, $P700^+$ captures an electron from reduced plastocyanin provided by photosystem II to return to P700 so that P700 can be excited again. Thus, the overall reaction catalyzed by photosystem I is a simple one-electron oxidation–reduction reaction.

$$Pc(Cu^+) + Fd_{ox} \xrightarrow{\text{Light}} Pc(Cu^{2+}) + Fd_{red}$$

[Drawn from 1FXA.pdb.]

INTERACT with this model in Achieve

Given that the reduction potentials for plastocyanin and ferredoxin are $+0.37\ V$ and $-0.45\ V$, respectively, the standard free energy for this reaction is $+79.1\ kJ\ mol^{-1}\ (+18.9\ kcal\ mol^{-1})$. This uphill reaction is driven by the absorption of a 700-nm photon, which has an energy of $171\ kJ\ mol^{-1}\ (40.9\ kcal\ mol^{-1})$.

Ferredoxin–$NADP^+$ reductase converts $NADP^+$ into NADPH

The reduced ferredoxin generated by photosystem I is a strong reductant that is used as an electron source for a variety of reactions, most notably the fixation of N_2 into NH_3 (Section 25.1). However, ferredoxin is not useful for driving many reactions, in part because ferredoxin carries only one available electron. In contrast, NADPH, a two-electron reductant, is a widely used electron donor in biosynthetic processes, including the reactions of the Calvin–Benson cycle (Chapter 20).

How is reduced ferredoxin used to drive the reduction of $NADP^+$ to NADPH? This reaction is catalyzed by *ferredoxin–$NADP^+$ reductase,* a flavoprotein with an FAD prosthetic group (**Figure 19.23A**). The bound

FAD moiety accepts two electrons and two protons from two molecules of reduced ferredoxin to form $FADH_2$ (Figure 19.23B). The enzyme then transfers a hydride ion (H^-) to $NADP^+$ to form NADPH. This reaction takes place on the stromal side of the membrane. Hence, the uptake of a proton in the reduction of $NADP^+$ further contributes to the generation of the proton gradient across the thylakoid membrane.

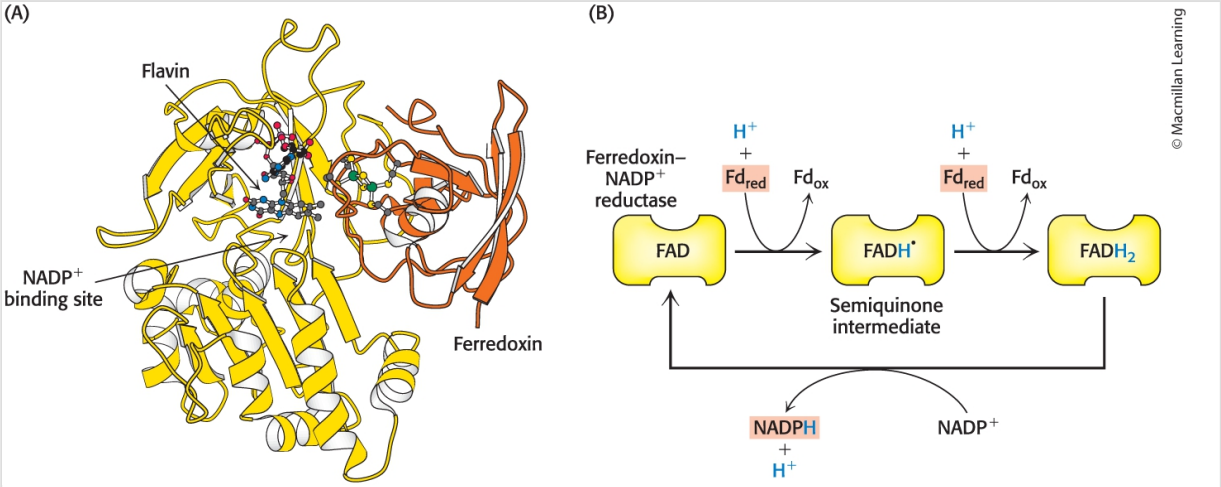

FIGURE 19.23 Ferredoxin–$NADP^+$ reductase transfers electrons from the protein ferredoxin to $NADP^+$. (A) The structure of ferredoxin–$NADP^+$ reductase is shown. This enzyme accepts electrons, one at a time, from ferredoxin (shown in orange). (B) Ferredoxin–$NADP^+$ reductase first accepts two electrons, generated by photosystem I, and two protons from the lumen to form two molecules of reduced ferredoxin (Fd). Reduced ferredoxin is then used to form $FADH_2$, which then transfers two electrons and a proton to $NADP^+$ to form NADPH in the stroma.

[Drawn from 1EWY.pdb.]

INTERACT with this model in Achieve

The cooperation between photosystem I and photosystem II creates a flow of electrons from H_2O to $NADP^+$. The pathway of electron flow is called the **Z scheme of photosynthesis** because the redox diagram from P680 to P700* looks like a letter Z on its side (Figure 19.24).

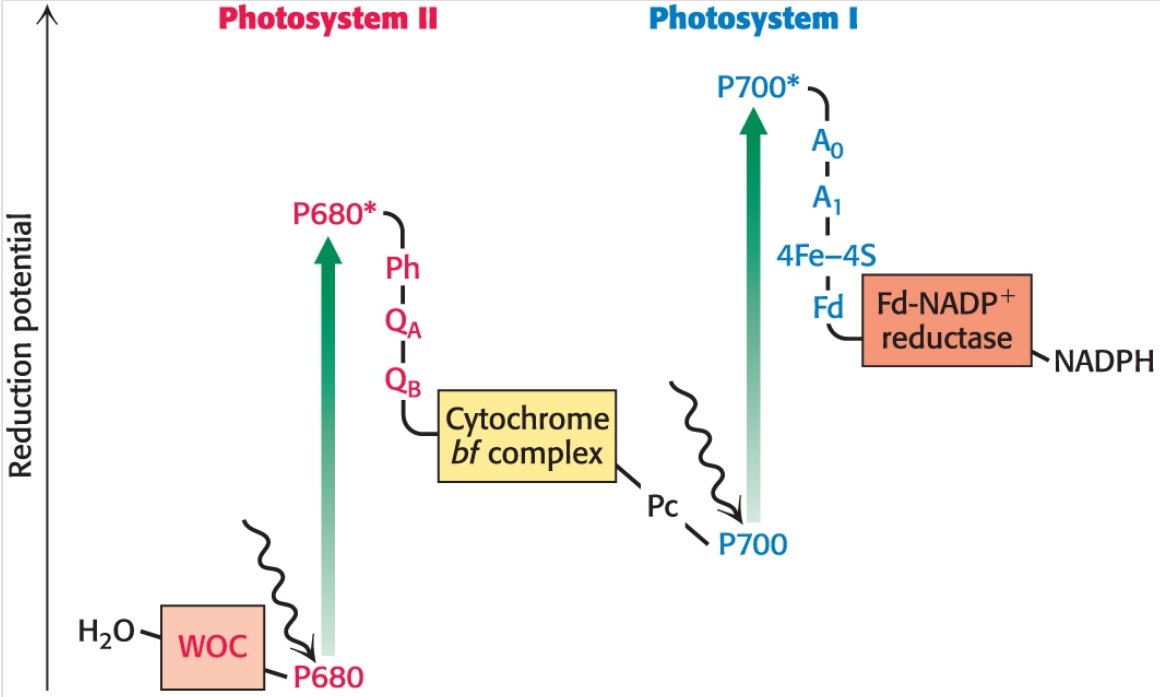

FIGURE 19.24 The "Z" scheme of photosynthesis is the linear path of electrons from H_2O to $NADP^+$. This endergonic reaction is made possible by the absorption of light by photosystem II (P680) and photosystem I (P700). Abbreviations: Ph, pheophytin; Q_A and Q_B, plastoquinone-binding proteins; Pc, plastocyanin; A_0 and A_1, acceptors of electrons from P700*; Fd, ferredoxin; WOC, water-oxidizing complex.

Self-Check Question

PS I creates a powerful reductant, while PS II creates a powerful oxidant. Identify each and describe their roles.

19.5 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis

In 1966, André Jagendorf showed that chloroplasts synthesize ATP in the dark when an artificial pH gradient is imposed across the thylakoid membrane. He soaked chloroplasts in a pH 4.0 buffer and then rapidly mixed them with a pH 8.0 buffer containing ADP and P_i. While the pH of the thylakoid lumen remained at 4.0, the pH of the stroma suddenly increased to 8.0, resulting in a burst of ATP synthesis that accompanied the disappearance of the pH gradient. This incisive experiment was one of the first to unequivocally support the hypothesis put forth by Peter Mitchell that ATP synthesis is driven by proton-motive force (Section 18.4).

Top: AP Images; bottom: Photo courtesy School of Integrative Plant Science, Cornell University

PETER MITCHELL AND ANDRÉ JAGENDORF The chemiosmotic hypothesis proposed by Peter Mitchell (shown at top) was initially poorly received by other scientists. But this changed dramatically when André Jagendorf (shown below Mitchell) demonstrated that chloroplasts can synthesize ATP in the dark if a pH gradient is created. Jagendorf credits a third scientist, Geoffrey Hind, for helping him make the connection. Jagendorf said, "I had heard Peter Mitchell talk about chemiosmosis…. His words went into one of my ears and out the other, leaving me feeling annoyed [that the conference organizers] had allowed such a ridiculous and incomprehensible speaker in. But Geoffrey [Hind] read *Nature*. He read Mitchell's paper and came to me. At this point I began to communicate with Peter [and] later that summer I did the experiment …" Jagendorf's results only made sense through the lens of Mitchell's chemiosmotic hypothesis, which eventually won Mitchell the Nobel Prize in Chemistry. Their mutually beneficial relationship illustrates the importance of open communication and collaboration in science.

The principles of ATP synthesis in chloroplasts are nearly identical to those in mitochondria. ATP formation is driven by a proton-motive force in both photophosphorylation and oxidative phosphorylation. We have seen how light induces electron transfer through photosystems II and I and the cytochrome *bf* complex. At various stages in this process, protons are released into the thylakoid lumen or taken up from the stroma, generating a proton gradient.

As discussed in Section 18.4, energy inherent in the proton gradient, called the *proton-motive force* (Δp), is described as the sum of two components: a charge gradient and a chemical gradient. The gradient is maintained because the thylakoid membrane is essentially impermeable to protons. The thylakoid lumen becomes markedly acidic, with the pH approaching 4.0, whereas the stroma reaches a pH around 8.0. The light-induced transmembrane proton gradient is about 3.5 pH units. In chloroplasts, nearly all of Δp arises from the pH gradient, whereas in mitochondria, the contribution from the membrane potential is larger. The reason for this difference is that the thylakoid membrane is quite permeable to Cl^- and Mg^{2+}. The light-induced transfer of H^+ into the thylakoid space is accompanied by the transfer of either Cl^- in the same direction or Mg^{2+} ($1\ Mg^{2+}$ per $2\ H^+$)

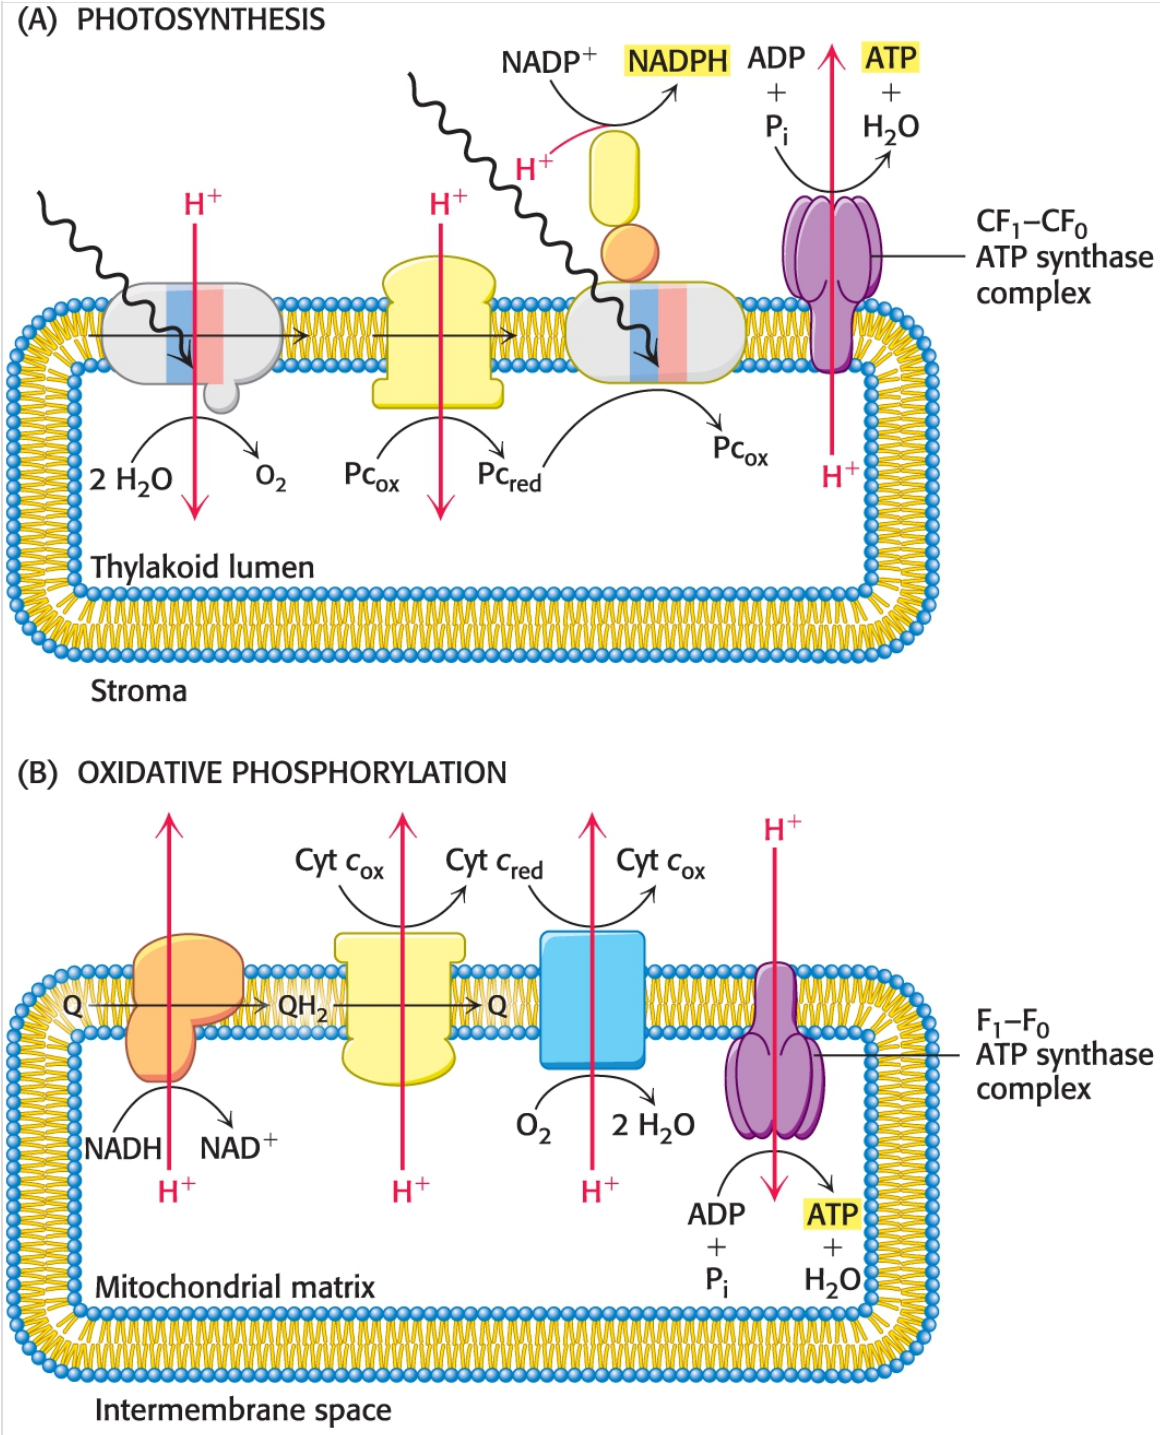
in the opposite direction. Consequently, electrical neutrality is maintained and no membrane potential is generated. The influx of Mg^{2+} into the stroma plays a role in the regulation of the Calvin–Benson cycle (Section 20.2). A pH gradient of 3.5 units across the thylakoid membrane corresponds to a proton-motive force of 0.20 V or a ΔG of $-20.0\ kJ\ mol^{-1}$ $(-4.8\ kcal\ mol^{-1})$.

The ATP synthase of chloroplasts closely resembles those of mitochondria and prokaryotes

The proton-motive force generated by the light reactions is converted into ATP by the **ATP synthase of chloroplasts**, also called the CF_1-CF_0 **complex** (C stands for chloroplast; F for factor). CF_0 conducts protons across the thylakoid membrane, whereas CF_1 catalyzes the formation of ATP from ADP and P_i. The CF_1-CF_0 complex closely resembles the F_1-F_0 ATP synthase of mitochondria (Section 18.4). Remarkably, the β subunits of ATP synthase in corn chloroplasts are more than 60% identical in amino acid sequence with those of human ATP synthase, despite the passage of approximately 1 billion years since the separation of the plant and animal kingdoms.

Note that the membrane orientation of CF_1-CF_0 is reversed compared with that of the mitochondrial ATP synthase (**Figure 19.25**). However, the functional orientation of the two synthases is identical: protons flow from the lumen through the enzyme to either the thylakoid stroma or the mitochondrial matrix, where ATP is synthesized. Because CF_1 is on the stromal surface of the thylakoid membrane, the newly synthesized ATP is released directly into the stromal space. Likewise, NADPH formed by photosystem I is released into the stromal space. Thus, ATP and NADPH, the products of the light reactions of photosynthesis, are

appropriately positioned for the subsequent dark reactions in which CO_2 is converted into carbohydrate (Section 20.1).



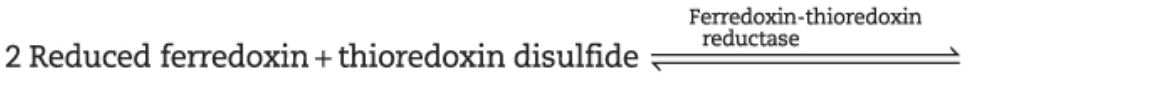


FIGURE 19.25 Photosynthesis and oxidative phosphorylation have a similar layout but differ a number of ways. (A) The light-induced electron transfer in photosynthesis drives protons into the thylakoid lumen. The excess protons flow out of the lumen through ATP synthase to genera

ATP in the stroma. (B) In oxidative phosphorylation, electron flow down the electron-transport chain pumps protons out of the mitochondrial matrix. Excess protons from the intermembrane space flow into the matrix through ATP synthase to generate ATP in the matrix.

The activity of chloroplast ATP synthase is regulated

The activity of the ATP synthase is sensitive to the redox conditions in the chloroplast. For maximal activity, a specific disulfide bond in the γ subunit must be reduced to two cysteines. The reductant is reduced thioredoxin, which is formed from ferredoxin generated in photosystem I, by ferredoxin–thioredoxin reductase, an iron–sulfur containing enzyme.

Conformational changes in the ε subunit also contribute to synthase regulation. The ε subunit appears to exist in two conformations. One conformation inhibits ATP hydrolysis by the synthase, while the other, which is generated by an increase in the proton-motive force, allows ATP synthesis and facilitates the reduction of the disulfide bond in the γ subunit. Thus, synthase activity is maximal when biosynthetic reducing power and a proton gradient are available. We will see in Chapter 20 that redox regulation is also important in photosynthetic carbon metabolism.

Cyclic electron flow through photosystem I leads to the production of ATP instead of NADPH

On occasion, when the ratio of NADPH to $NADP^+$ is very high, as might be the case if there was another source of electrons to form NADPH (Section 20.3), $NADP^+$ may be unavailable to accept electrons from reduced ferredoxin. In these circumstances, specific large protein complexes allow cyclic electron flow that powers ATP synthesis. Excited electrons from P700, the reaction center of photosystem I, generate reduced ferredoxin. The electron in reduced ferredoxin is transferred to the cytochrome *bf* complex rather than to $NADP^+$. This electron then flows back through the cytochrome *bf* complex to reduce plastocyanin, which can then be reoxidized by $P700^+$ to complete a cycle. The net outcome of this cyclic flow of electrons is the pumping of protons by the cytochrome *bf* complex. The resulting proton gradient then drives the synthesis of ATP. In this process, called **cyclic photophosphorylation**, ATP is generated without the concomitant formation of NADPH (**Figure 19.26**), reminiscent of the cyclic phototrophic scheme of the nonsulfur purple bacteria (Section 19.3). Note that because photosystem II does not participate in cyclic photophosphorylation, O_2 is not formed from H_2O.

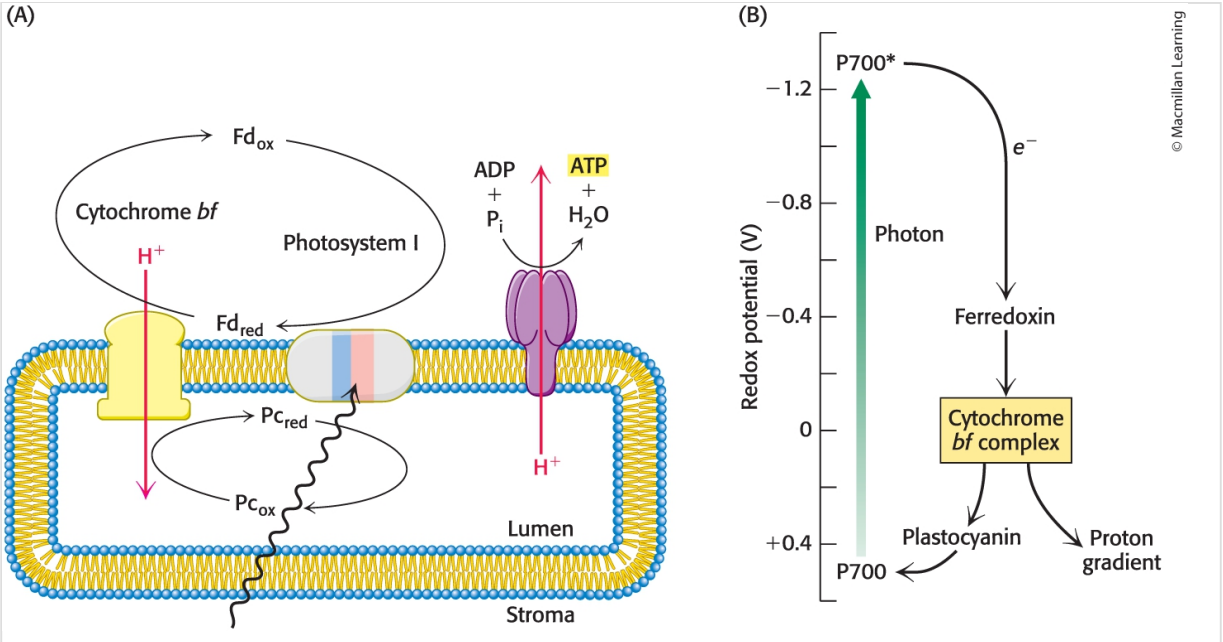

FIGURE 19.26 Cyclic photophosphorylation allows ATP production without a need for an electron source. (A) In this pathway, electrons from reduced ferredoxin are transferred to cytochrome *bf* rather than to ferredoxin–$NADP^+$ reductase, and thus can be reused indefinitely without the need for an external electron source. The flow of electrons through cytochrome *bf* pumps protons into the thylakoid lumen. These protons flow through ATP synthase to generate ATP. Neither NADPH nor O_2 is generated by this pathway. Abbreviations: Fd, ferredoxin; Pc, plastocyanin. (B) A scheme showing the energetic basis for cyclic photophosphorylation.

The absorption of eight photons yields one O_2, two NADPH, and three ATP molecules

We can now estimate the overall stoichiometry for the light reactions. The absorption of four photons by photosystem II generates one molecule of O_2 and releases four protons into the thylakoid lumen. The two molecules of plastoquinol are oxidized by the Q cycle of the cytochrome *bf* complex to release eight protons into the lumen. Finally,

the electrons from four molecules of reduced plastocyanin are driven to ferredoxin by the absorption of four additional photons. The four molecules of reduced ferredoxin generate two molecules of NADPH. Thus, the overall reaction is

$$2\ H_2O + 2\ NADP^+ + 10\ H^+_{stroma} \rightarrow O_2 + 2\ NADPH + 12\ H^+_{lumen}$$

The 12 protons released in the lumen can then flow through ATP synthase. Let's assume that 12 protons must pass through CF_0 to complete one full rotation of CF_1. A single rotation generates three molecules of ATP. Given the ratio of 3 ATP for 12 protons, the overall reaction is

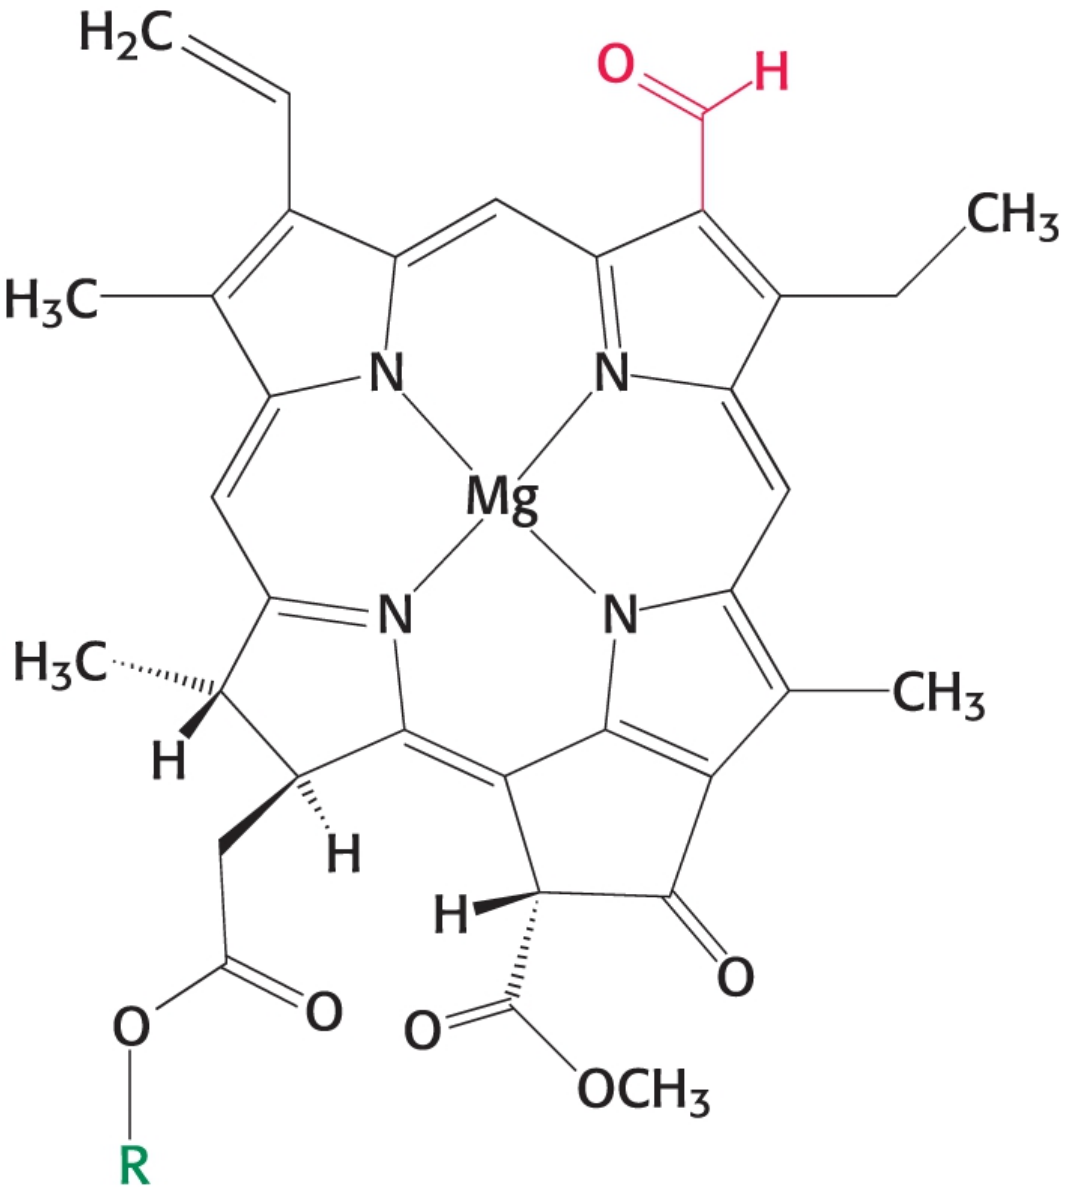
$$2\ H_2O + 2\ NADP^+ + 10\ H^+_{stroma} \longrightarrow O_2 + 2\ NADPH + 12\ H^+_{lumen}$$

$$\frac{3\ ADP^{3-} + 3\ P_i^{2+} + 3\ H^+ + 12\ H^+_{lumen} \longrightarrow 3\ ATP^{4-} + 3\ H_2O + 12H^+_{stroma}}{2\ NADP^+ + 3\ ADP^{3-} + 3\ P_i^{2-} + H^+ \longrightarrow O_2 + 2\ NADPH + 3\ ATP^{4-} + H_2O}$$

Thus, eight photons are required to yield three molecules of ATP (2.7 photons/ATP).

Cyclic photophosphorylation is a somewhat more productive way to synthesize ATP than noncyclic photophosphorylation (the Z scheme shown in Figure 19.24). The absorption of four photons by photosystem I leads to the release of eight protons into the lumen by the cytochrome *bf* system. These protons flow through ATP synthase to yield two molecules of ATP. Thus, each two absorbed photons yield one molecule of ATP. No NADPH is produced.

Self-Check Question



The relative proportions of the components of the proton-motive force that drive ATP synthesis in chloroplasts are different from those in mitochondria. What are these two components, and which dominates in chloroplasts? Given the similarities between the synthases in both organelles, explain the basis of this difference.

19.6 Accessory Pigments Funnel Energy into Reaction Centers

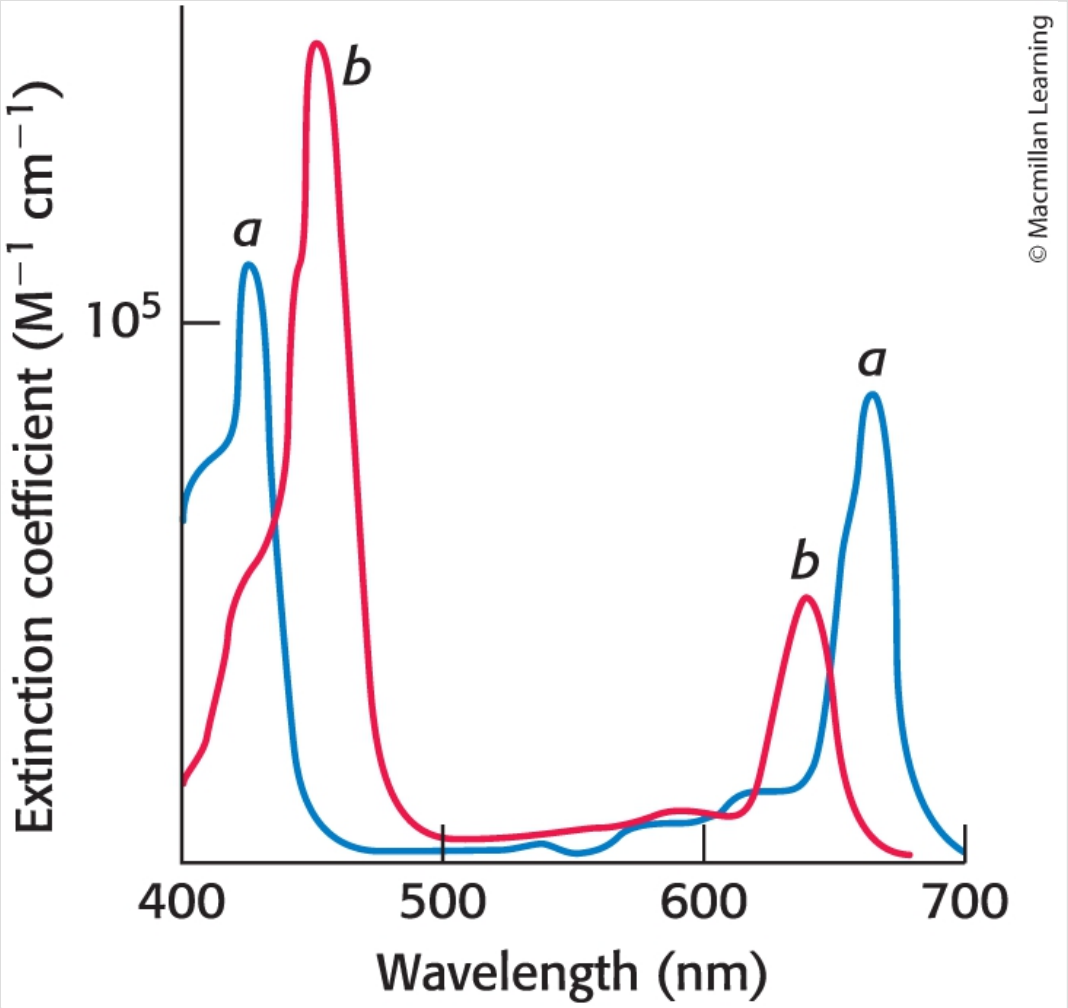
A light-harvesting system that relied only on the chlorophyll *a* molecules of the special pair would be rather inefficient for two reasons. First, chlorophyll *a* molecules absorb light only at specific wavelengths (Figure 19.6). A large gap is present in the middle of the visible region between approximately 450 and 650 nm. This gap falls right at the peak of the solar spectrum, and so failure to collect this light would constitute a considerable lost opportunity. Second, even on a cloudless day, many photons that can be absorbed by chlorophyll *a* pass through the chloroplast without being absorbed, because the density of chlorophyll *a* molecules in a reaction center is not very great.

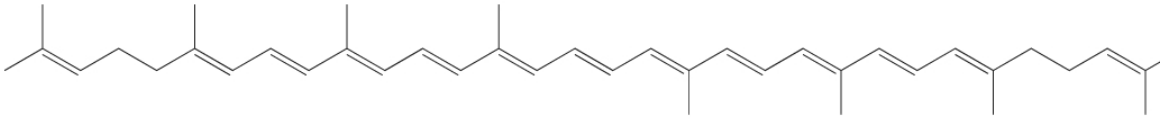
Helping to solve these problems are accessory pigments, both additional chlorophylls, such as chlorophyll *b*, and other classes of molecules, such as carotenoids. Accessory pigments are closely associated with reaction centers, where they absorb light and funnel the energy to the reaction center for conversion into chemical forms. Thus, accessory pigments prevent the reaction center from sitting idle.

Chlorophyll *b*

Chlorophyll *b* and carotenoids are important accessory pigments that funnel energy to the reaction center. Chlorophyll *b* differs from chlorophyll *a* in having a formyl group in place of a methyl group. This small difference shifts its two major absorption peaks toward the center

of the visible region. In particular, chlorophyll *b* efficiently absorbs light with wavelengths between 450 and 500 nm (Figure 19.27).





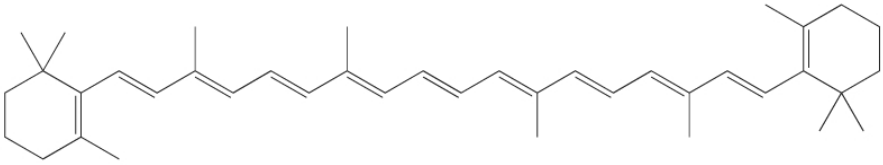


FIGURE 19.27 Chlorophylls *a* and *b* absorb light maximally at different wavelengths. Shown are the absorption spectra of chlorophylls *a* and *b*.

Carotenoids are extended polyenes that absorb light between 400 and 500 nm. The carotenoids are responsible for most of the yellow and red colors of fruits and flowers, and they provide the brilliance of fall, when the chlorophyll molecules degrade first, revealing the carotenoids. Tomatoes are especially rich in the carotenoid lycopene, which accounts

for their red color, whereas carrots and pumpkins have abundant amounts of the carotenoid β-carotene, accounting for their orange color.

Lycopene

β-Carotene

Resonance energy transfer allows energy to move from the site of initial absorbance to the reaction center

How is energy funneled from accessory pigments to a reaction center? As discussed at the beginning of the chapter, the absorption of a photon does not always lead to electron excitation and transfer. More commonly, excitation energy is transferred from one molecule to a nearby molecule through electromagnetic interactions through space (**Figure 19.28**). The rate of this process, called *resonance energy transfer,* depends strongly on the distance between the energy-donor and the energy-acceptor molecules; an increase in the distance between the donor and the acceptor by a factor of 2 typically results in a decrease in the energy-transfer rate by a factor of $2^6 = 64$. For reasons of energy conservation, energy transfer must be from a donor in the excited state to an acceptor of equal or lower energy. The excited state of the special

pair of chlorophyll molecules is lower in energy than that of single chlorophyll molecules, allowing reaction centers to trap the energy transferred from other molecules.

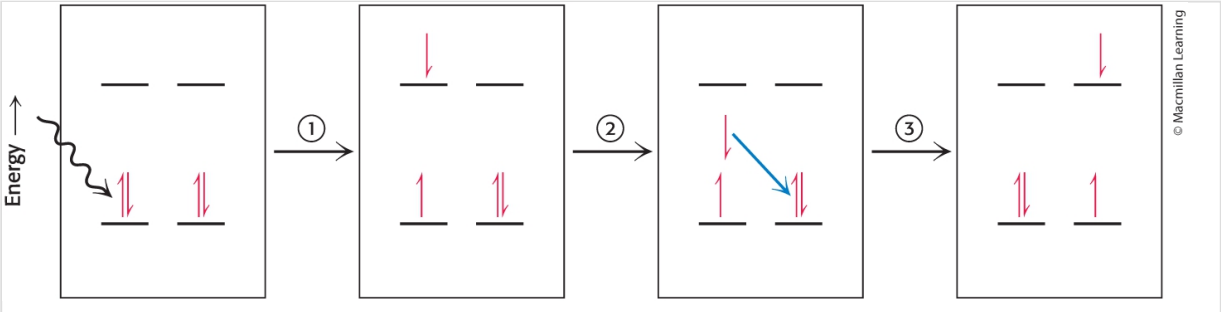

FIGURE 19.28 Resonance energy transfer allows electrons to transfer energy over a distance. (1) An electron can accept energy from electromagnetic radiation of appropriate wavelength and jump to a higher energy state. (2) When the excited electron falls back to its lower energy state, the absorbed energy is released. (3) The released energy can be absorbed by an electron in a nearby molecule, and this electron jumps to a high energy state.

What is the structural relationship between the accessory pigment and the reaction center? The accessory pigments are arranged in numerous **light-harvesting complexes** that completely surround the reaction center (**Figure 19.29**). The 26-kDa subunit of light-harvesting complex II (LHC-II) is the most abundant membrane protein in chloroplasts. This subunit binds seven chlorophyll *a* molecules, six chlorophyll *b* molecules, and two carotenoid molecules. Similar light-harvesting assemblies exist in many photosynthetic bacteria.

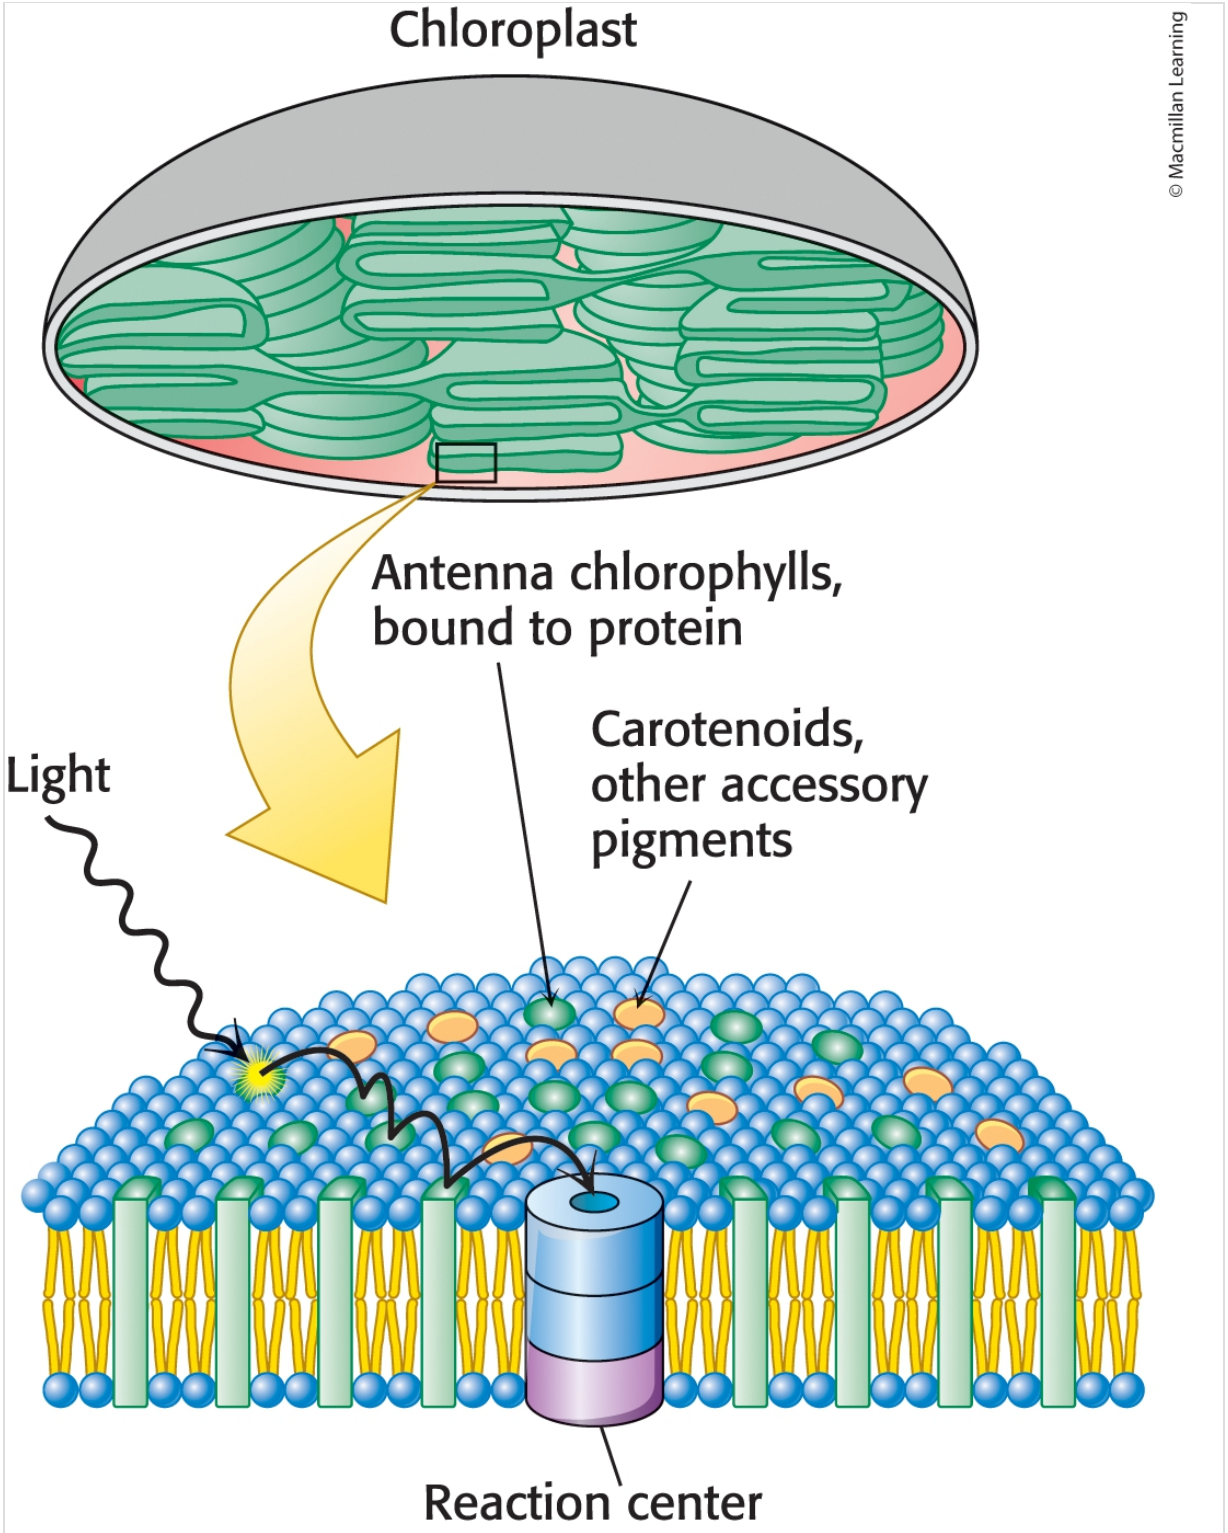

FIGURE 19.29 Energy is transferred from accessory pigments to reaction centers. Light energy absorbed by accessory chlorophyll molecules or other pigments can be transferred to reaction centers by resonance energy transfer (black arrows), where it drives photoinduced charge separation.

[Source: D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2008), Fig. 19.52.]

Accessory pigments also protect plants from reactive oxygen

In addition to their role in transferring energy to reaction centers, the carotenoids and other accessory pigments serve a safeguarding function. Carotenoids suppress harmful photochemical reactions, particularly those including oxygen, that can be induced by bright sunlight. The reactive oxygen species would otherwise damage the cell and eventually the entire plant. To protect against bright sunlight, plants use a mechanism called **nonphotochemical quenching (NPQ)**. When NPQ is operating, photons are directed away from the light-harvesting complex, and the energy of the photons is released as heat. This protection may be especially important in the fall when the primary pigment chlorophyll is being degraded and thus not able to absorb light energy. Plants lacking carotenoids are quickly killed on exposure to light and oxygen.

Increasing the efficiency of photosynthesis will increase crop yields

NPQ is a means by which plants protect themselves from damaging reactive oxygen species that are generated by intense sunlight — essentially a botanical sunscreen. Understanding NPQ, a complex process consisting of several components, is an active area of research. It is established that NPQ requires a proton gradient across the

thylakoid membrane and, in higher photosynthetic organisms such as plants, a particular protein, photosystem II subunit S (PsbS). PsbS, in the presence of a pH gradient, acts in seconds to help to initiate NPQ by interacting with protein components of the light-harvesting complex. This interaction redirects the energy absorbed by the light-harvesting complex from the reaction centers so that the energy is lost as heat. Although quick to be activated, NPQ is slow to turn off, depressing photosynthetic yields to be as much as 30% in some crops. This slow turn off is a target for biochemists hoping to increase the efficiency of photosynthesis and, consequently, crop yield.

Why is it necessary to boost photosynthesis? Traditional plant breeding has greatly increased crop yield over the past century. Additionally, modern farming practices and tools such as fertilizers, pesticides, and irrigation have contributed to increased yield. However, studies suggest that the ability to increase crop yields by traditional means may have reached its limits. And yet, the Food and Agricultural Organization of the United Nations estimates that in 30 years, the world's population will be about 10 billion, an increase of more than 2 billion from the current 7.8 billion. To feed all of these people, agricultural production will need to increase by 50% in the developed world and 400% in the developing world.

To tackle the problem of not enough food, biochemists are trying to increase the efficiency of photosynthesis by reducing the time required to turn off NPQ. Using techniques described in Chapter 9, genes were introduced into the model organism — the tobacco plant — that increased the speed of NPQ shutdown. The result was a 15% increase in plant size. Similar results have now been observed in rice, and the next steps are to modify other crops such as wheat and cowpea — important sources of protein in sub-Saharan Africa.

The components of photosynthesis are highly organized

The intricacy of photosynthesis, seen already in the elaborate interplay of complex components, extends even to the placement of the components in the thylakoid membranes. Thylakoid membranes of most plants are differentiated into stacked and unstacked regions (**Figure 19.30**). Stacking increases the amount of thylakoid membrane in a given chloroplast volume. Both regions surround a common internal thylakoid space, but only unstacked regions make direct contact with the chloroplast stroma.

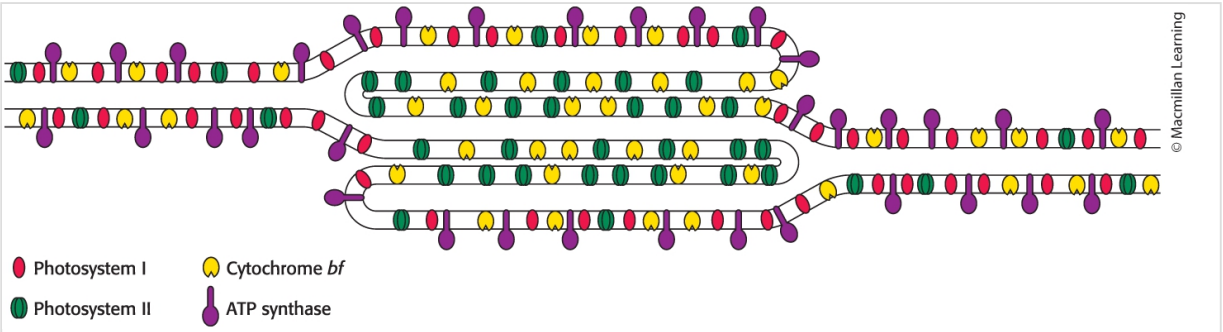

FIGURE 19.30 Photosynthetic assemblies are differentially distributed in the stacked and unstacked regions of thylakoid membranes.

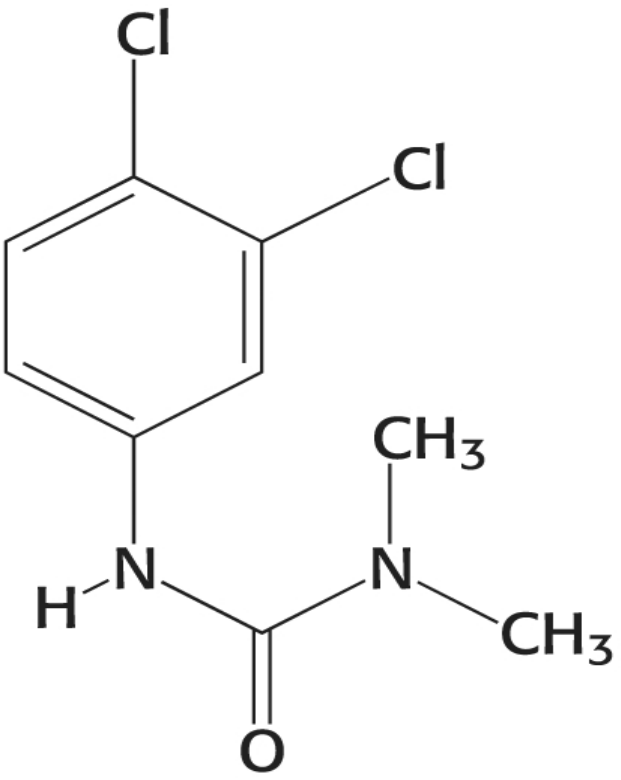
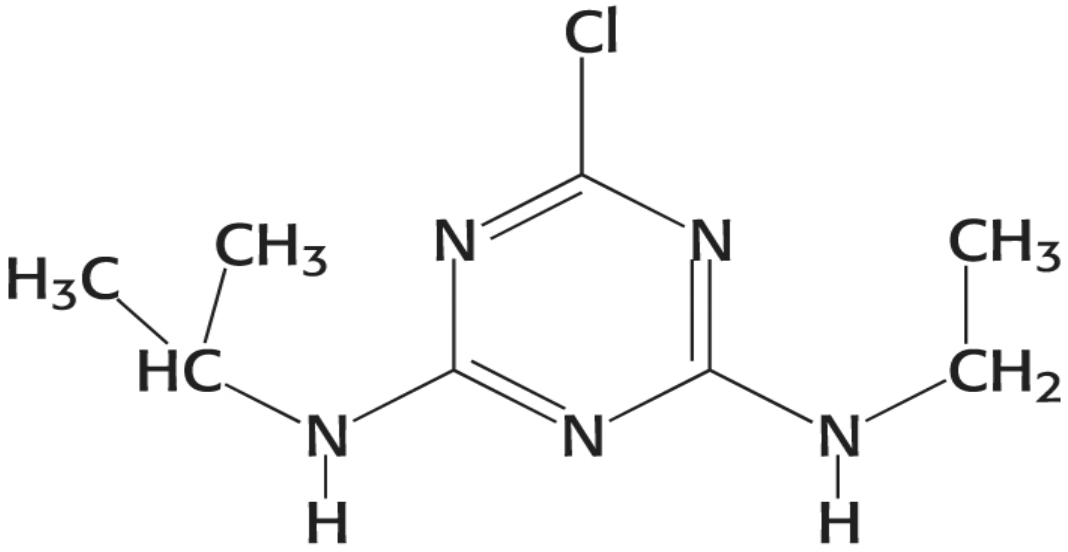
[Information from Dr. Jan M. Anderson and Dr. Bertil Andersson.]



Stacked and unstacked regions differ in the nature of their photosynthetic assemblies (Figure 19.30). Photosystem I and ATP synthase are located almost exclusively in unstacked regions, whereas photosystem II is present mostly in stacked regions. The cytochrome *bf* complex is found in both regions. A common internal thylakoid space enables protons liberated by photosystem II in stacked membranes to be used by ATP synthase molecules that are located far away in unstacked membranes. Plastoquinone and plastocyanin are the mobile

carriers of electrons between assemblies located in different regions of the thylakoid membrane.



What is the functional significance of the structural variety in the thylakoid membrane system? The positioning of photosystem I in the unstacked membranes gives it direct access to the stroma for the reduction of $NADP^+$. ATP synthase is also located in the unstacked region, which provides the space needed for its large CF_1 globule and gives it access to ADP. In contrast, the tight quarters of the stacked region pose no problem for photosystem II, which interacts with a small polar electron donor (H_2O) and a highly lipid-soluble electron carrier (plastoquinone).

Many herbicides inhibit the light reactions of photosynthesis

Many commercial herbicides kill weeds by interfering with the action of photosystem II or photosystem I. Inhibitors of PS II block electron flow, whereas inhibitors of PS I divert electrons from its terminal part. PS II inhibitors include urea derivatives such as *diuron* and triazine derivatives such as *atrazine*. These chemicals bind to the Q_B site of the D1 subunit of photosystem II and block the formation of plastoquinol (QH_2). PS I inhibitors include Paraquat $(1,1'-dimethyl-4-4'-bipyridinium)$, a dication, which can accept electrons from photosystem I to become a radical. This radical reacts with O_2 to produce reactive oxygen species such as superoxide (O_2^-) and hydroxyl radical (OH•). Such reactive oxygen species react with many biomolecules, including double bonds in membrane lipids, damaging the membrane.

Atrazine

19.7 The Ability to Convert Light into Chemical Energy Is Ancient

The ability to convert light energy into chemical energy is a tremendous evolutionary advantage. Geological evidence suggests that oxygenic photosynthesis became important approximately 2 billion years ago. Anoxygenic photosynthetic systems arose much earlier in the 3.5-billion-year history of life on Earth (Table 19.1).

TABLE 19.1 Major groups of photosynthetic prokaryotes

Bacteria	Photosynthetic electron donor	O_2 use
Green sulfur	H_2, H_2S, S	Anoxygenic
Green nonsulfur	Variety of amino acids and organic acids	Anoxygenic
Purple sulfur	H_2, H_2S, S	Anoxygenic
Purple nonsulfur	Usually organic molecules	Anoxygenic
Cyanobacteria	H_2O	Oxygenic

As we discussed at various points in this chapter, the photosynthetic reaction center of the nonsulfur purple bacterium *Rhodopseudomonas viridis* has many features common to oxygenic photosynthetic systems and clearly predates them. Green sulfur bacteria such as *Chlorobium thiosulfatophilum* carry out a reaction that also seems to have appeared before oxygenic photosynthesis and is even more similar to oxygenic photosynthesis than the photosystem of *R. viridis*. Reduced sulfur

species such as H_2S are electron donors in the overall photosynthetic reaction

$$CO_2 + 2\ H_2S \xrightarrow{\text{Light}} (CH_2O) + 2\ S + H_2O$$

Nonetheless, photosynthesis did not evolve immediately at the origin of life. No photosynthetic organisms have been discovered in the domain Archaea, implying that photosynthesis evolved in the domain Bacteria after archaea and bacteria diverged from a common ancestor. All domains of life do have electron-transport chains in common, however. As we have seen, components such as the ubiquinone–cytochrome *c* oxidoreductase (Section 18.3) and cytochrome *bf* family (Section 19.4) are present in both respiratory and photosynthetic electron-transport chains. These components were the foundations on which light-energy-capturing systems evolved.

Artificial photosynthetic systems may provide clean, renewable energy

As we have learned, oxygenic photosynthetic organisms use sunlight to oxidize H_2O, producing O_2 and protons used to power ATP synthesis and generate NADPH. Research is currently underway to try to mimic this process in order to provide clean energy. The idea is that photovoltaic cells could use light energy to oxidize water, producing O_2 as well as H_2. Hydrogen gas is a fuel that, upon reaction with oxygen, releases energy and only water as a waste product. Recent work suggests that semiconductors composed of organic–inorganic material show great promise in this application.

Photovoltaic cells are now being paired with microorganisms to generate a variety of biomolecules, including fuels, in a clean,

renewable fashion. One example of such a hybrid-biological-inorganic (HBI) system is shown in **Figure 19.31**). Sunlight is converted into an electrical current by the photovoltaic cell. The current flows to the anode, where water is oxidized and the resulting electrons are taken up by the cathode. Bacteria, such as *Cupriavidus necator* (also used in bioremediation because of its ability to degrade chlorinated hydrocarbons) live in direct contact with the cathode. The bacteria use the electrons generated by the oxidation of water to reduce CO_2 to industrially important biomolecules. The efficiency of such HBI systems for converting sunlight into chemical energy is nearly 10%, with the potential for improvement, surpassing the efficiency of natural photosynthesis, which has an efficiency of 2%.

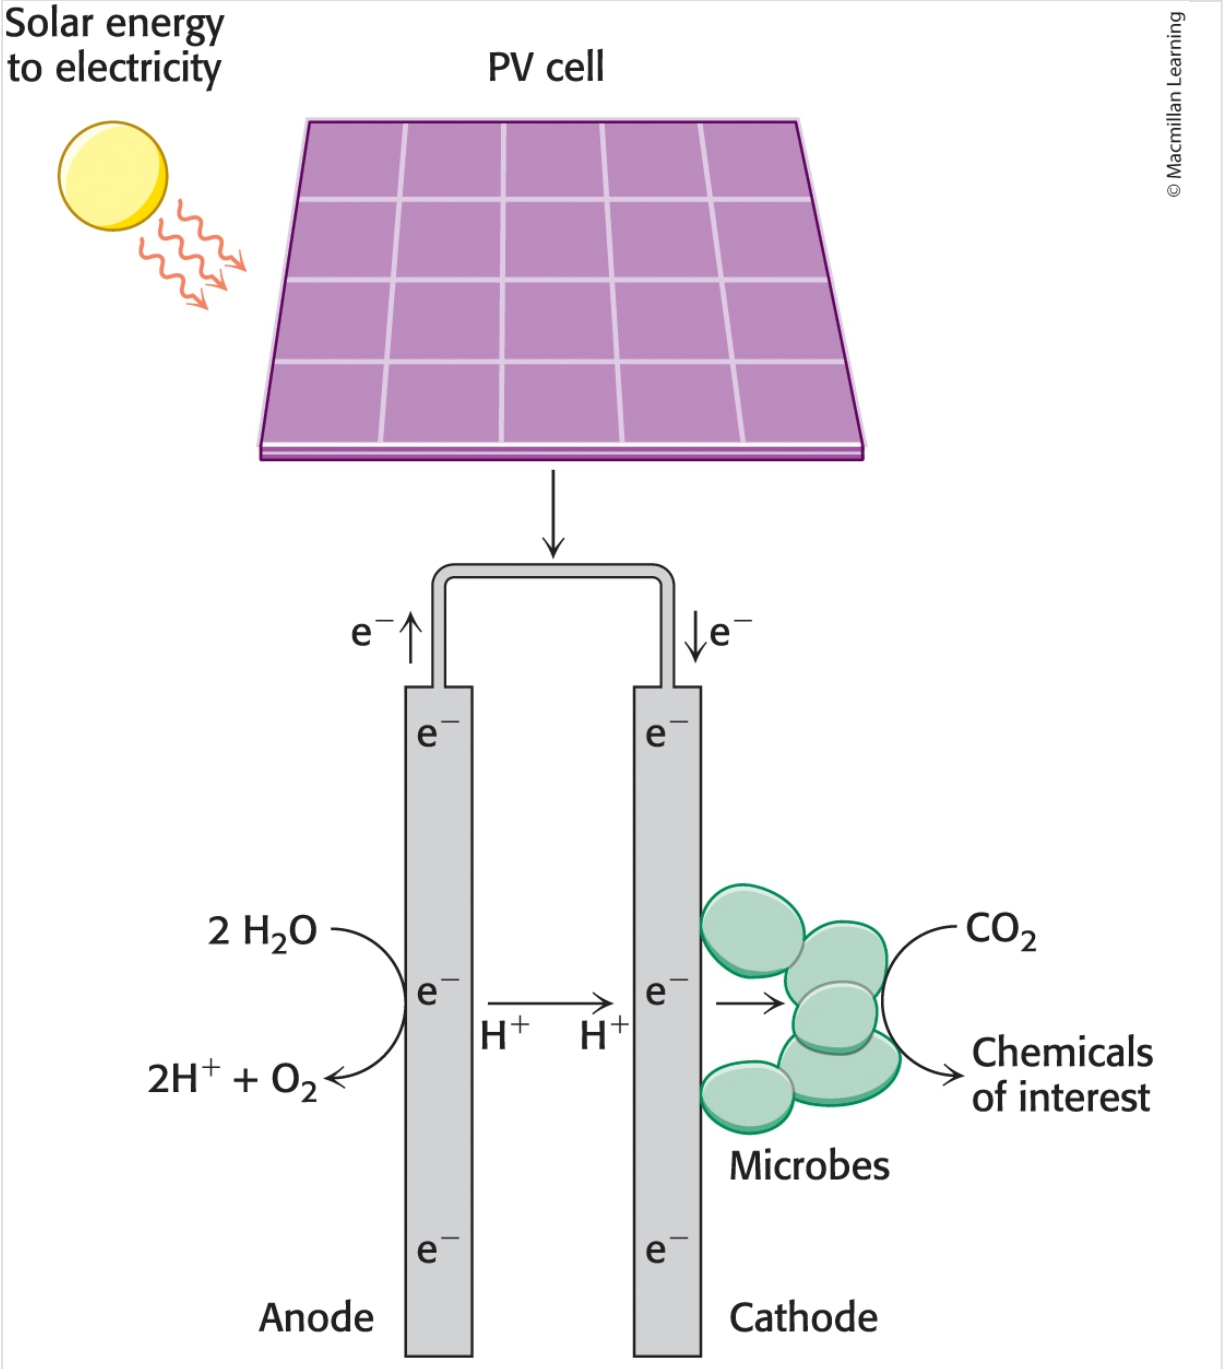

FIGURE 19.31 Photovoltaic cells can drive artificial photosynthesis. After a PV cell absorbs light, the resulting current flows to the anode to oxidize water, with the electrons then taken up by the cathode. Bacteria in contact with the cathode use the electrons to reduce CO_2 to biomolecules.

Photosensitive proteins are transforming other fields

Phototrophic organisms use a range of light-sensitive proteins in addition to those discussed thus far. Scientists have taken advantage of these proteins to develop new research tools and even therapies. A key example is channelrhodopsin first characterized from green algae, where it plays a role in light sensing. Channelrhodopsin is homologous to bacteriorhodopsin but functions as an ion channel rather than a proton pump. Thus, exposure of cells with channelrhodopsin present in their cell membranes to light results in ion channel opening and the flow of ions down any gradients.

Scientists have expressed channelrhodopsin in neurons, making these neurons sensitive to light. The firing of these neurons can then be controlled by applying short flashes of light to initiate action potentials (Figure 19.32) for cells in culture but also in engineered experimental animals. These methods, termed *optogenetics*, facilitate exploration of the mechanisms of nervous system function with unprecedented precision, again demonstrating the power of biochemical discoveries to transform other fields.

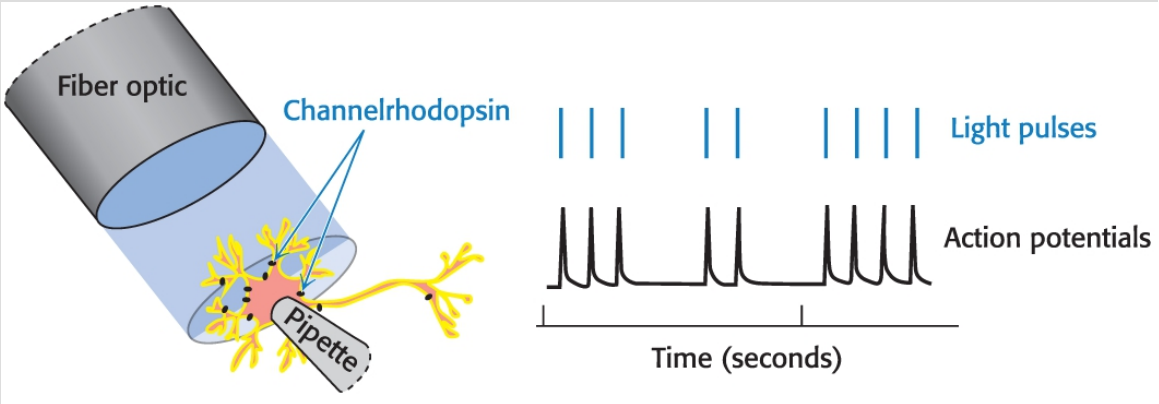

FIGURE 19.32 Optogenetics allows neurons to be controlled using light. Neurons engineered t
express the light-sensitive ion channel channelrhodopsin in their cell membrane respond to

pulses of light. Light causes channelrhodopsin to open and allow the flow of ions across the membrane. This flow of ions triggers neuron action potentials, which can be detected with a small pipette in a setup known as a patch clamp.

Chapter 19 Summary

19.1 Phototrophy Converts Light Energy into Chemical Energy

- The process of living organisms capturing light energy as chemical energy is called phototrophy.
- Photosynthesis is the combination of phototrophy with the reduction of carbon dioxide to form carbohydrate.

19.2 In Eukaryotes, Photosynthesis Takes Place in Chloroplasts

- The proteins that participate in the light reactions of photosynthesis are located in the thylakoid membranes of chloroplasts.
- The light reactions result in (1) the creation of reducing power for the production of NADPH, (2) the generation of a transmembrane proton gradient for the formation of ATP, and (3) the production of O_2.

19.3 Light Absorption by Chlorophyll Molecules Induces Electron Transfer

- An electron excited to a high-energy state by the absorption of a photon can move to nearby electron acceptors. In photosynthesis, an excited electron leaves a pair of associated chlorophyll molecules — the special pair — that are located in reaction centers.
- In the reaction center of a purple bacterium, the electron moves from the special pair containing bacteriochlorophyll to a bacteriopheophytin to quinones.
- The reduction of quinones leads to the generation of a proton gradient, which drives ATP synthesis in a manner analogous to that of oxidative phosphorylation.

19.4 Two Photosystems Generate a Proton Gradient and Reducing Power in Cyanobacteria and Photosynthetic Eukaryotes

- Photosynthesis in green plants, algae, and cyanobacteria is mediated by two linked photosystems. In photosystem II (PS II), the excitation of a special pair of chlorophyll molecules called P680 leads to electron transfer to plastoquinone. The electrons are replenished by the extraction of electrons from a water molecule at the manganese-containing water-oxidizing complex, generating O_2.
- The plastoquinol produced by PS II is reoxidized by the cytochrome *bf* complex. The electrons are transferred to plastocyanin, and then photosystem I (PS I).
- In PS I, the excitation of special pair P700 releases electrons that flow to ferredoxin, a powerful reductant. Ferredoxin–$NADP^+$ reductase, a flavoprotein, then catalyzes the formation of NADPH.
- A proton gradient is generated as electrons pass through PS II, through the cytochrome *bf* complex, and through ferredoxin–$NADP^+$ reductase.

19.5 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis

- The proton gradient across the thylakoid membrane creates a proton-motive force that is used by the $CF_0 - CF_1$ ATP synthase of chloroplasts synthase to form ATP.
- If the NADPH:$NADP^+$ ratio is high, electrons transferred to ferredoxin by PS I can reenter the cytochrome *bf* complex during cyclic photophosphorylation, which leads to the generation of a proton gradient by the cytochrome *bf* complex without the formation of NADPH or O_2.

19.6 Accessory Pigments Funnel Energy into Reaction Centers

- Light-harvesting complexes that surround the reaction centers contain additional chlorophyll and carotenoid molecules that absorb light in the center of the visible spectrum.
- These accessory pigments increase the efficiency of light capture by absorbing light and transferring the energy to reaction centers through resonance energy transfer.

19.7 The Ability to Convert Light into Chemical Energy Is Ancient

- The photosystems have structural features in common that suggest a mutual evolutionary origin.
- Similarities in organization and molecular structure to those of oxidative phosphorylation suggest that the photosynthetic apparatus evolved from an early energy-transduction system.

Key Terms

chlorophyll *a*

photoinduced charge separation
reaction center
special pair
water-oxidizing complex (WOC) (manganese center)
cytochrome *bf*
Z scheme of photosynthesis
ATP synthase of chloroplasts ($CF_1 - CF_0$ complex)
cyclic photophosphorylation
carotenoid
light-harvesting complex
nonphotochemical quenching (NPQ)

Problems

1. Under normal circumstances, photosystem I donates electrons to:

a. Photosystem II
b. ATP synthase
c. P700
d. $NADP^+$

2. The water-oxidizing complex provides electrons to:

a. P680
b. P450
c. P700
d. Cytochrome *c*

3. Cyclic photophosphorylation allows the generation of _____ without the synthesis of _____.

a. ATP, NADPH
b. NADPH, ATP
c. ATP, NADH
d. ATP, O_2

4. Which description of resonance energy transfer is true?

a. Results in separation of charge
b. Directly powers ATP synthesis
c. Allows energy flux in the light-harvesting complex
d. Does not exist

5. Human beings do not capture energy by photosynthesis, yet this process is critical to our survival. Explain.

6. What is the overall reaction for the light reactions of photosynthesis? 1

7. Indicate whether each of the following applies to photosystem I or photosystem II: 1

a. Generates NADPH
b. Establishes a proton gradient
c. Oxidizes water
d. Produces O_2
e. Uses reduced ferredoxin to generate a biosynthetic reductant

8. Photosynthesis can be measured by measuring the rate of oxygen production. When plants are exposed to light of wavelength 680 nm, more oxygen is evolved than if the plants are exposed to light of 700 nm. If plants are illuminated by a combination of light of 680 nm and 700 nm, the oxygen production exceeds that of either wavelength alone. Explain both results. 1

9. What is the advantage of having an extensive set of thylakoid membranes in the chloroplasts? 1, 2

10. Explain how light-harvesting complexes enhance the efficiency of photosynthesis. 5

11. What is the ultimate electron acceptor in oxygenic photosynthesis? The ultimate electron donor? What powers the electron flow between the donor and the acceptor? 3

12. What are the various sources of protons that contribute to the generation of a proton gradient in chloroplasts? 4

13. Calculate the $\Delta E'_0$ and $\Delta G^{\circ\prime}$ for the reduction of $NADP^+$ by ferredoxin. Use data given in Table 18.1.

14. It can be argued that, if life were to exist elsewhere in the universe, it would require some process like photosynthesis. If a starship were to land on a distant planet and find no measurable oxygen in the atmosphere, could the crew conclude that photosynthesis is not taking place? 1

15. Dichlorophenyldimethylurea (DCMU), a herbicide, interferes with photophosphorylation and O_2 evolution. However, it does not block O_2 evolution in the presence of an artificial electron acceptor such as ferricyanide. Propose a site for the inhibitory action of DCMU.

16. Predict the effect of the herbicide dichlorophenyldimethylurea (DCMU) on a plant's ability to perform cyclic photophosphorylation.

17. Consider the relation between the energy of a photon and its wavelength.

a. Some bacteria are able to harvest 1000-nm light. What is the energy (in kilojoules or kilocalories) of a mole (also called an *einstein*) of 1000-nm photons?
b. What is the maximum increase in redox potential that can be induced by a 1000-nm photon?
c. What is the minimum number of 1000-nm photons needed to form ATP from ADP and P_i? Assume a ΔG of $50\ kJ\ mol^{-1}\ (12\ kcal\ mol^{-1})$ for the phosphorylation reaction.

18. What structural features of mitochondria corresponds to the thylakoid membranes and the stroma? 1, 2, 3, 4

19. Compare and contrast oxidative phosphorylation and photosynthesis. 1, 2, 3, 4

CHAPTER 20

The Calvin–Benson Cycle and the Pentose Phosphate Pathway

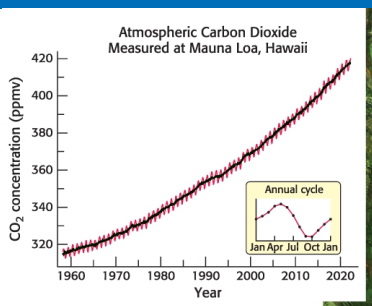

Photo: Travelpix Ltd/Photographer's Choice RF/Getty Images
© Macmillan Learning

Atmospheric carbon dioxide measurements at Mauna Loa, Hawaii, show the increase in atmospheric carbon dioxide concentration since 1960 in units of parts per million by volume (ppmv). The sawtooth appearance of the curve is the result of annual cycles resulting from seasonal variation in CO_2 fixation by the Calvin–Benson cycle in terrestrial plants (graph inset). Much of this fixation takes place in rain forests, which account for approximately 50% of terrestrial fixation.

[Data from http://www.esrl.noaa.gov/gmd/ccgg/trends]

OUTLINE

20.1 The Calvin–Benson Cycle Synthesizes Hexoses from Carbon Dioxide and Water
20.2 The Activity of the Calvin–Benson Cycle Depends on Environmental Conditions
20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Pentoses
20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis
20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

Learning Goals

By the end of this chapter, you should be able to:

1. Explain the function of the Calvin–Benson cycle.
2. Describe how the light reactions and the Calvin–Benson cycle are coordinated.
3. Identify the two stages of the pentose phosphate pathway and explain how the pathway is coordinated with glycolysis and gluconeogenesis.
4. Identify the regulation of the oxidative phase of the pentose phosphate pathway, including the key enzyme and its importance in health and disease.

Photosynthesis proceeds in two parts. The light reactions, discussed in Chapter 19, transform light energy into ATP and biosynthetic reducing power, NADPH. The dark reactions use the ATP and NADPH produced by the light reactions to reduce carbon atoms from their fully oxidized state as carbon dioxide to a more reduced state as a hexose. The dark reactions are called the **Calvin–Benson cycle**, after Melvin Calvin and Andrew Benson, two of the biochemists who helped elucidated the pathway, or sometimes simply the Calvin cycle.

This chapter also examines the pentose phosphate pathway that allows glucose to be oxidized to generate NADPH. The pentose phosphate pathway and Calvin–Benson cycle have several enzymes and intermediates in common. The Calvin–Benson cycle uses NADPH to reduce carbon dioxide to generate hexoses, whereas the pentose phosphate pathway oxidizes glucose to carbon dioxide to generate NADPH.

20.1 The Calvin–Benson Cycle Synthesizes Hexoses from Carbon Dioxide and Water

As we learned in Chapter 16, glucose can be formed from noncarbohydrate precursors, such as lactate and amino acids, by gluconeogenesis. The energy powering gluconeogenesis ultimately comes from previous catabolism of carbon fuels. In contrast, photosynthetic organisms can use the Calvin–Benson cycle to synthesize glucose from carbon dioxide gas and water, by using sunlight as an energy source. The Calvin–Benson cycle introduces into life all the carbon atoms that will be used as fuel and as the carbon backbones of biomolecules. Photosynthetic organisms are autotrophs as they can convert sunlight into chemical energy, which they subsequently use to power their biosynthetic processes.

The Calvin–Benson cycle was elucidated through studies that depended on the availability of radioactive ^{14}C through cyclotrons at the University of California, Berkeley, starting just after World War II. Unicellular algae were exposed to $^{14}CO_2$ for short periods of time, and the radioactive compounds were separated, identified, and quantified.

Arthur Nonomura, Ph. D.

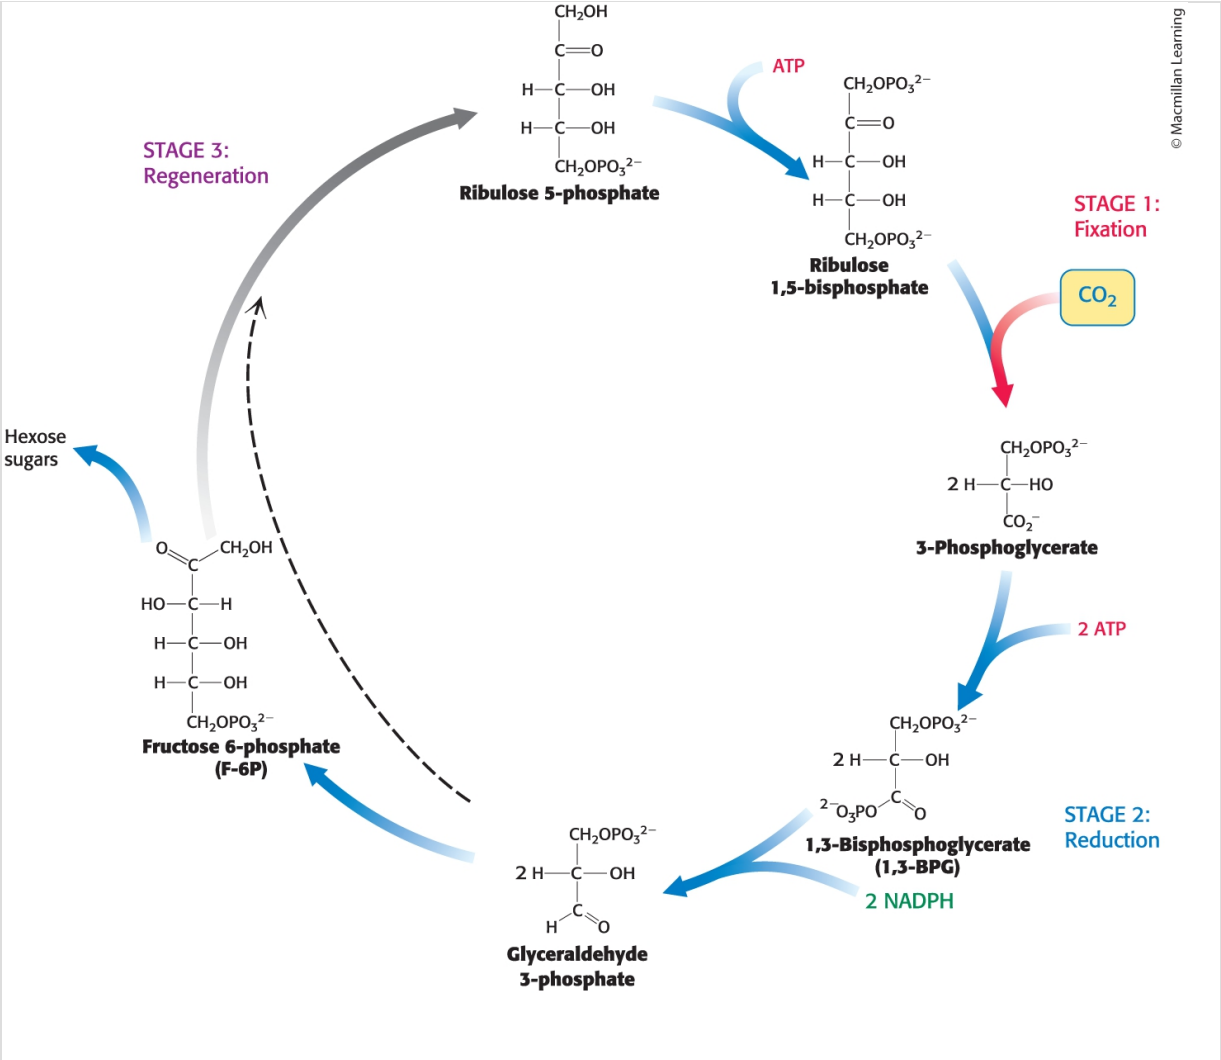
ANDREW BENSON After completing his PhD in carbohydrate chemistry from Caltech, Andrew Benson moved to the University of California, Berkeley, where he was exposed to research in photosynthesis. Using radioisotopes of carbon including ^{14}C, he worked as part of a team with Melvin Calvin on the pathway of CO_2 fixation. He was the first to identify ribulose 1,5-bisphosphate as the key component that captures CO_2, among other discoveries.

The elucidation of this pathway represents a good example of how a team of scientists from different backgrounds can solve important problems. Unfortunately, it also revealed the challenges of such collaborations. Calvin dismissed Benson in 1954, shortly after the pathway was elucidated. Calvin was awarded the Nobel Prize by himself in 1961 and barely mentioned Benson in his Nobel lecture. After leaving Berkeley, Dr. Benson went on to have an impressive career working on plant lipids

and a range of topics in marine biology, primarily at the Scripps Institution for Oceanography, where he also served as an important scientific leader.

These studies revealed that the Calvin–Benson cycle comprises three stages (**Figure 20.1**):

1. The fixation of CO_2 to ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate;
2. The reduction of 3-phosphoglycerate to form hexose sugars; and
3. The regeneration of ribulose 1,5-bisphosphate so that more CO_2 can be fixed.



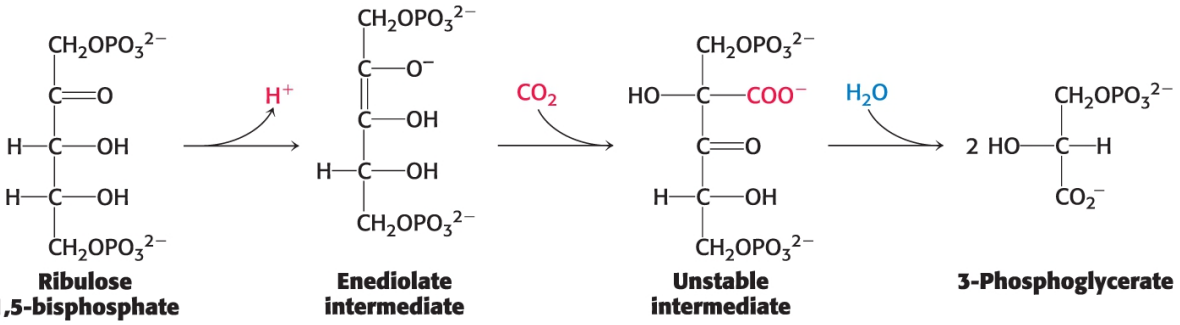


FIGURE 20.1 The Calvin–Benson cycle consists of three stages. Stage 1 is the fixation of carbon by the carboxylation of ribulose 1,5-bisphosphate. Stage 2 is the reduction of the fixed carbon to begin the synthesis of hexose. Stage 3 is the regeneration of the starting compound ribulose 1,5-bisphosphate.

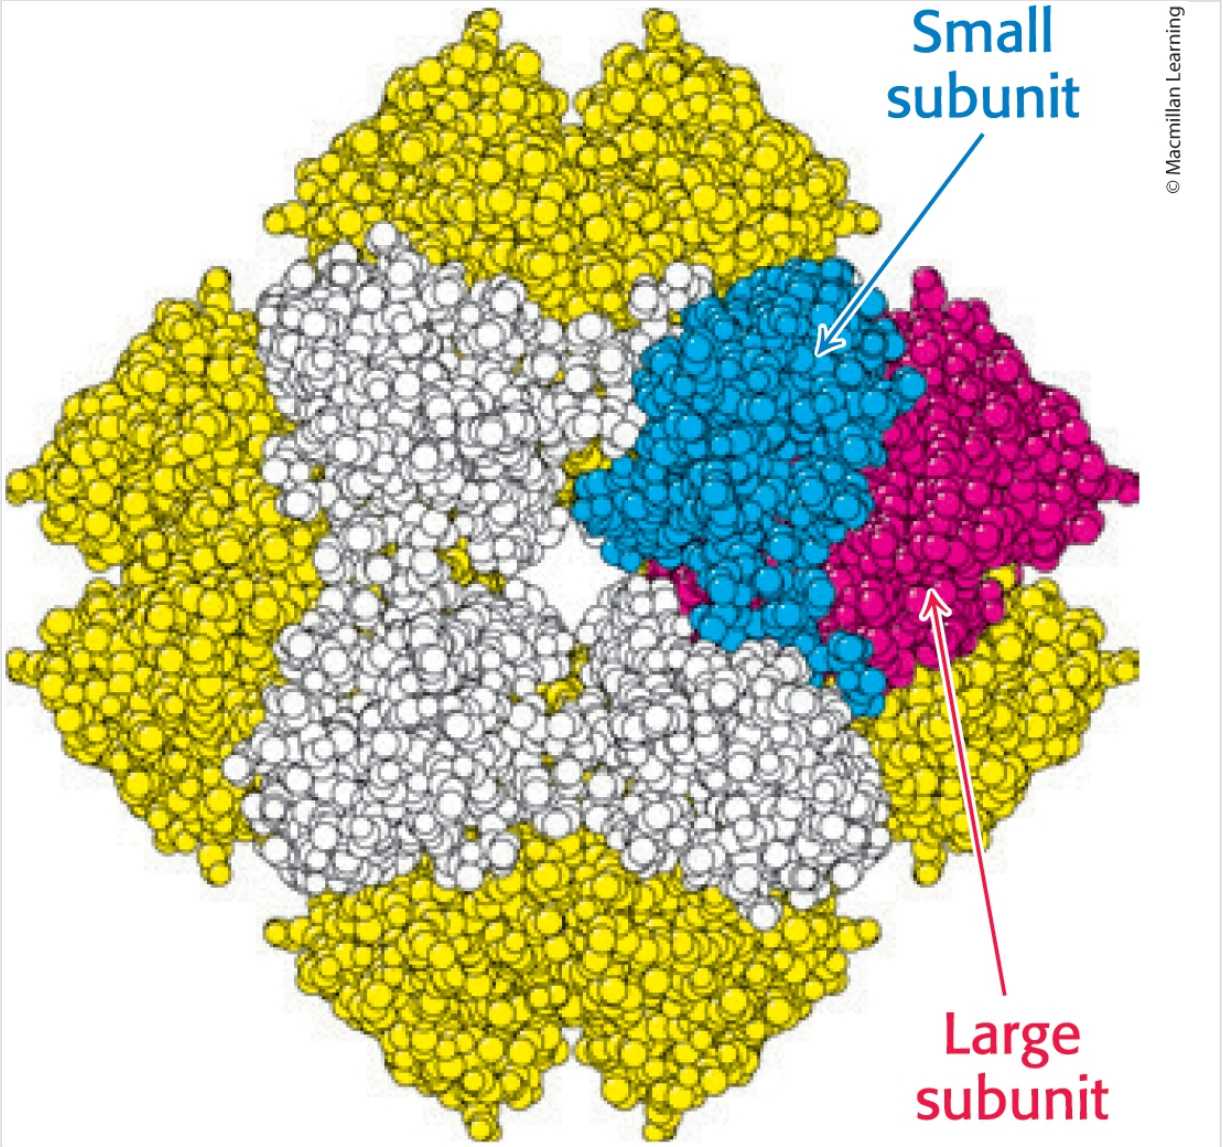
This set of reactions takes place in the stroma of chloroplasts — the photosynthetic organelles (Figure 19.3).

Stage 1: Carbon dioxide reacts with ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate

The first step in the Calvin–Benson cycle is the fixation of CO_2. This begins with the conversion of ribulose 1,5-bisphosphate into a highly reactive enediolate intermediate. The CO_2 molecule condenses with the enediolate intermediate to form an unstable six-carbon compound, which is rapidly hydrolyzed to two molecules of 3-phosphoglycerate.

This highly exergonic reaction $[\Delta G^{\circ\prime} = -51.9\ \text{kJ mol}^{-1}\ (-12.4\ \text{kcal mol}^{-1})]$ is catalyzed by **ribulose 1,5-bisphosphate carboxylase/oxygenase** (often called *Rubisco* or *RuBisCo*), an enzyme located on the stromal surface of the thylakoid membranes of chloroplasts. This important reaction is the rate-limiting step in hexose synthesis.

In plants and green algae, Rubisco consists of eight large (L, 55-kDa) subunits and eight small (S, 15-kDa) ones (**Figure 20.2**). Each L chain contains a catalytic site and a regulatory site. The S chains enhance the catalytic activity of the L chains. This enzyme is abundant in chloroplasts, accounting for approximately 30% of the total leaf protein in some plants. In fact, Rubisco is the most abundant enzyme and perhaps the most abundant protein in the entire biosphere. Large amounts are present because Rubisco is a relatively slow enzyme; its maximal catalytic rate is only $3\ \text{s}^{-1}$.



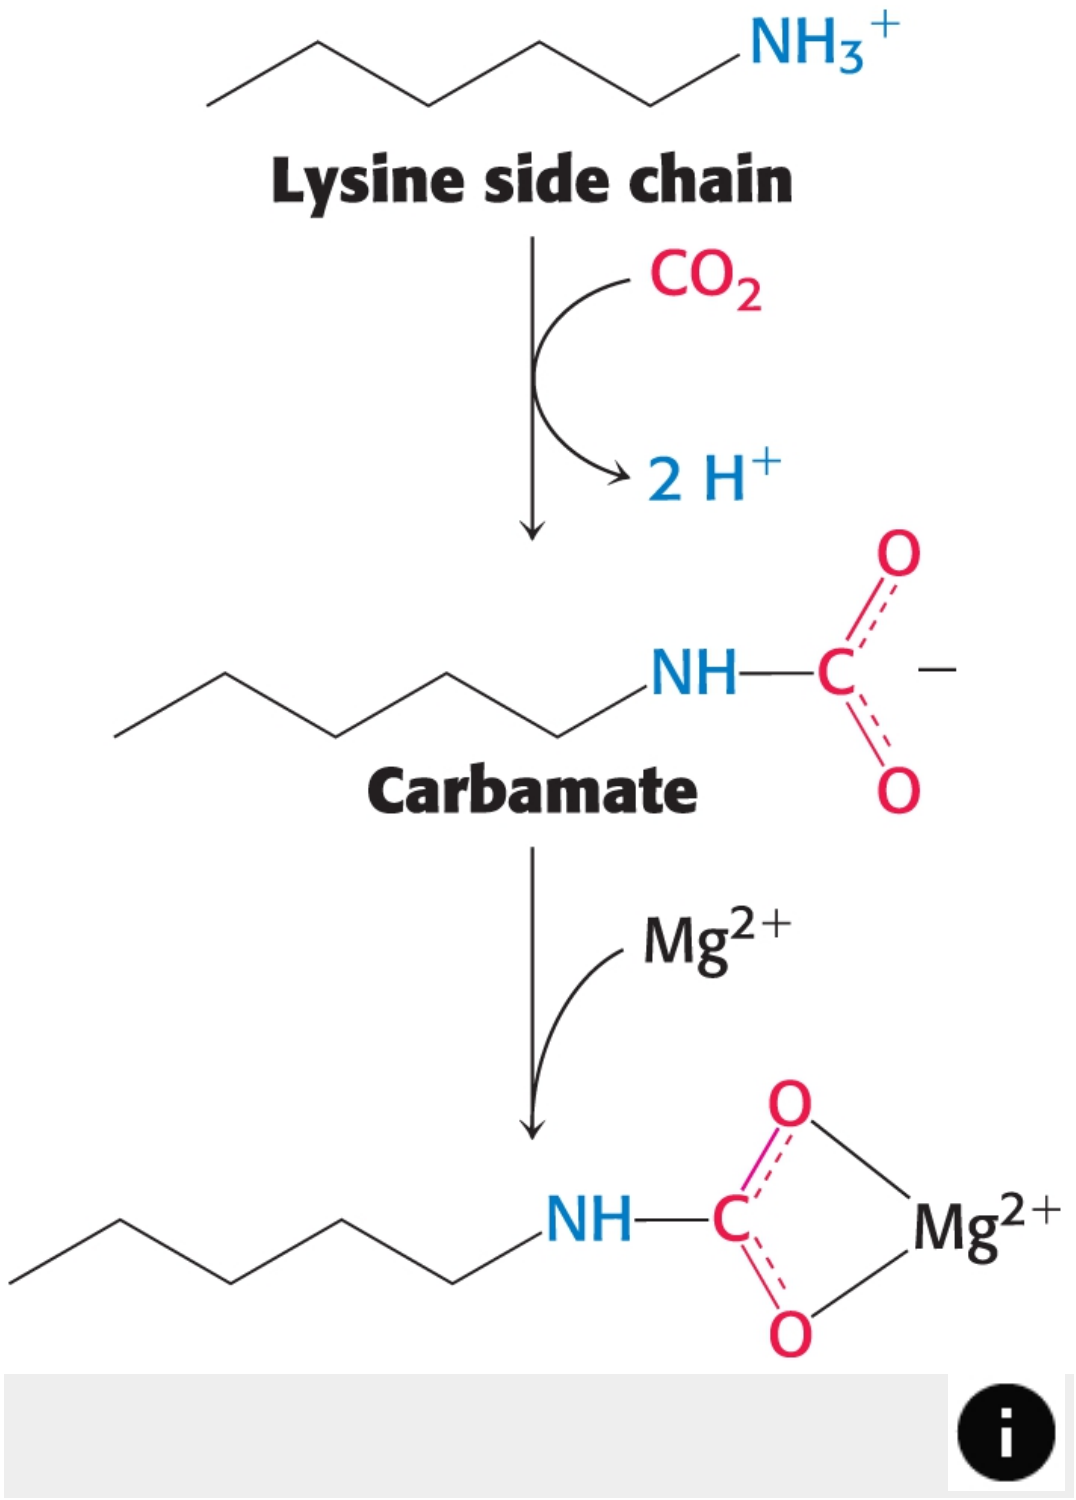


FIGURE 20.2 The enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) comprises 16 subunits. There are eight small subunits, one shown in blue and the others in white, and eight large subunits (partially obscured by the small units), one shown in red and the others in yellow. The active sites lie in the large subunits.

[Drawn from 1RXO.pdb.]

INTERACT with this model in Achieve

Rubisco activity depends on magnesium and carbamate

Rubisco requires a bound divalent metal ion for activity, usually magnesium ion. Like the zinc ion in the active site of carbonic anhydrase (Section 6.3), this metal ion serves to activate a bound substrate molecule by stabilizing a negative charge. Interestingly, a CO_2 molecule other than the substrate is required to complete the assembly of the Mg^{2+}-binding site in Rubisco. This CO_2 molecule adds to the uncharged ε-amino group of lysine 201 to form a carbamate. This negatively charged carbamate then binds the Mg^{2+} ion.

The metal center plays a key role in binding ribulose 1,5-bisphosphate and activating it so that it reacts with CO_2 (Figure 20.3). Ribulose 1,5-

bisphosphate binds to Mg^{2+} through its keto group and an adjacent hydroxyl group. This complex is readily deprotonated to form an enediolate intermediate. This reactive species, analogous to the zinc-hydroxide species in carbonic anhydrase, reacts with CO_2, forming the new carbon–carbon bond. The resulting 2-carboxy-3-keto-D-arabinitol 1,5-bisphosphate is coordinated to the Mg^{2+} ion through three groups, including the newly formed carboxylate. A molecule of H_2O is then added to this β-ketoacid to form an intermediate that cleaves to form two molecules of 3-phosphoglycerate (Figure 20.4).

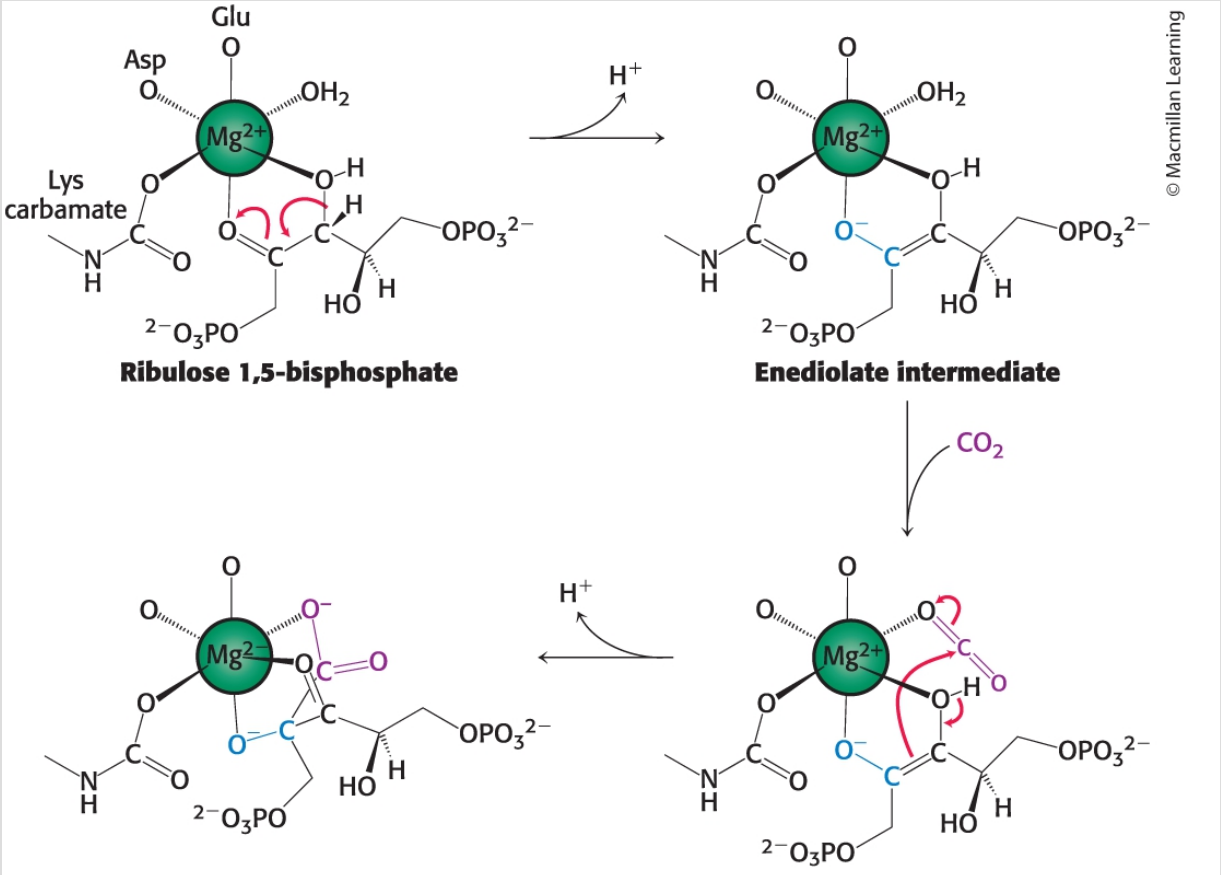

FIGURE 20.3 Magnesium-coordinated ribulose 1,5-bisphosphate facilitates CO_2 fixation.

Ribulose 1,5-bisphosphate binds to a magnesium ion that is linked to Rubisco through a glutamate residue, an aspartate residue, and the lysine carbamate. The coordinated ribulose 1,5-bisphosphate gives up a proton to form a reactive enediolate species that reacts with CO_2 to form a new carbon–carbon bond.

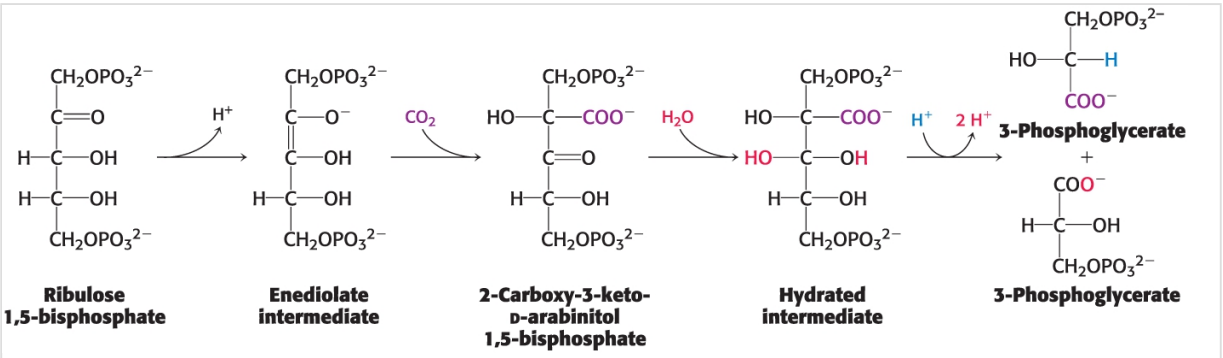

FIGURE 20.4 In stage 1 of the Calvin–Benson cycle, 3-phosphoglycerate is formed. The pathway for the conversion of ribulose 1,5-bisphosphate and CO_2 into two molecules of 3-phosphoglycerate is shown. Although the free species are shown, these steps take place on the magnesium ion.

Rubisco also catalyzes a wasteful oxygenase reaction

The reactive enediolate intermediate generated on the Mg^{2+} ion sometimes reacts with O_2 instead of CO_2; thus, Rubisco also catalyzes a deleterious oxygenase reaction, yielding the products phosphoglycolate and 3-phosphoglycerate (Figure 20.5). The rate of the carboxylase reaction is four times that of the oxygenase reaction under normal atmospheric conditions at 25°C; the stromal concentration of CO_2 is then 10 μM and that of O_2 is 250 μM. The oxygenase reaction, like the carboxylase reaction, requires that lysine 201 be in the carbamate form.

Because this carbamate forms only in the presence of CO_2, Rubisco is prevented from catalyzing the oxygenase reaction exclusively when CO_2 is absent.

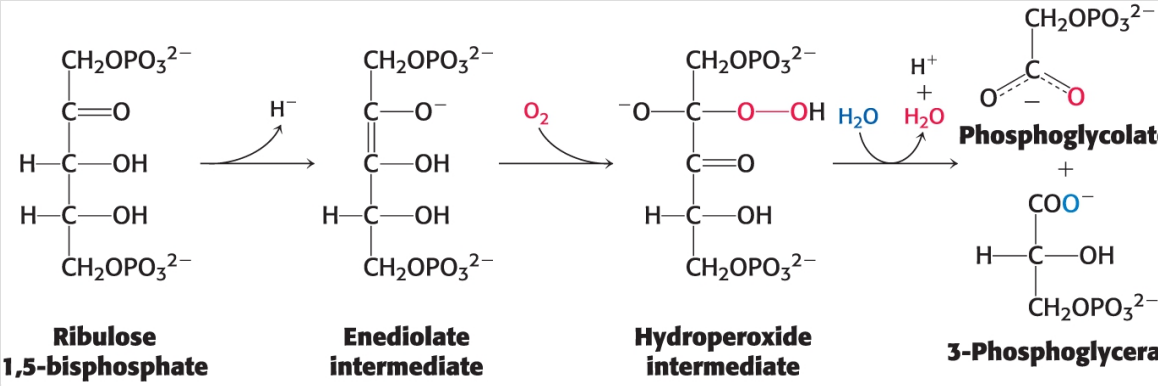

FIGURE 20.5 The enediolate on Rubisco can react with oxygen in a wasteful side reaction. The reactive enediolate intermediate on Rubisco also reacts with molecular oxygen to form a hydroperoxide intermediate, which then proceeds to form one molecule of 3-phosphoglycerate and one molecule of phosphoglycolate.

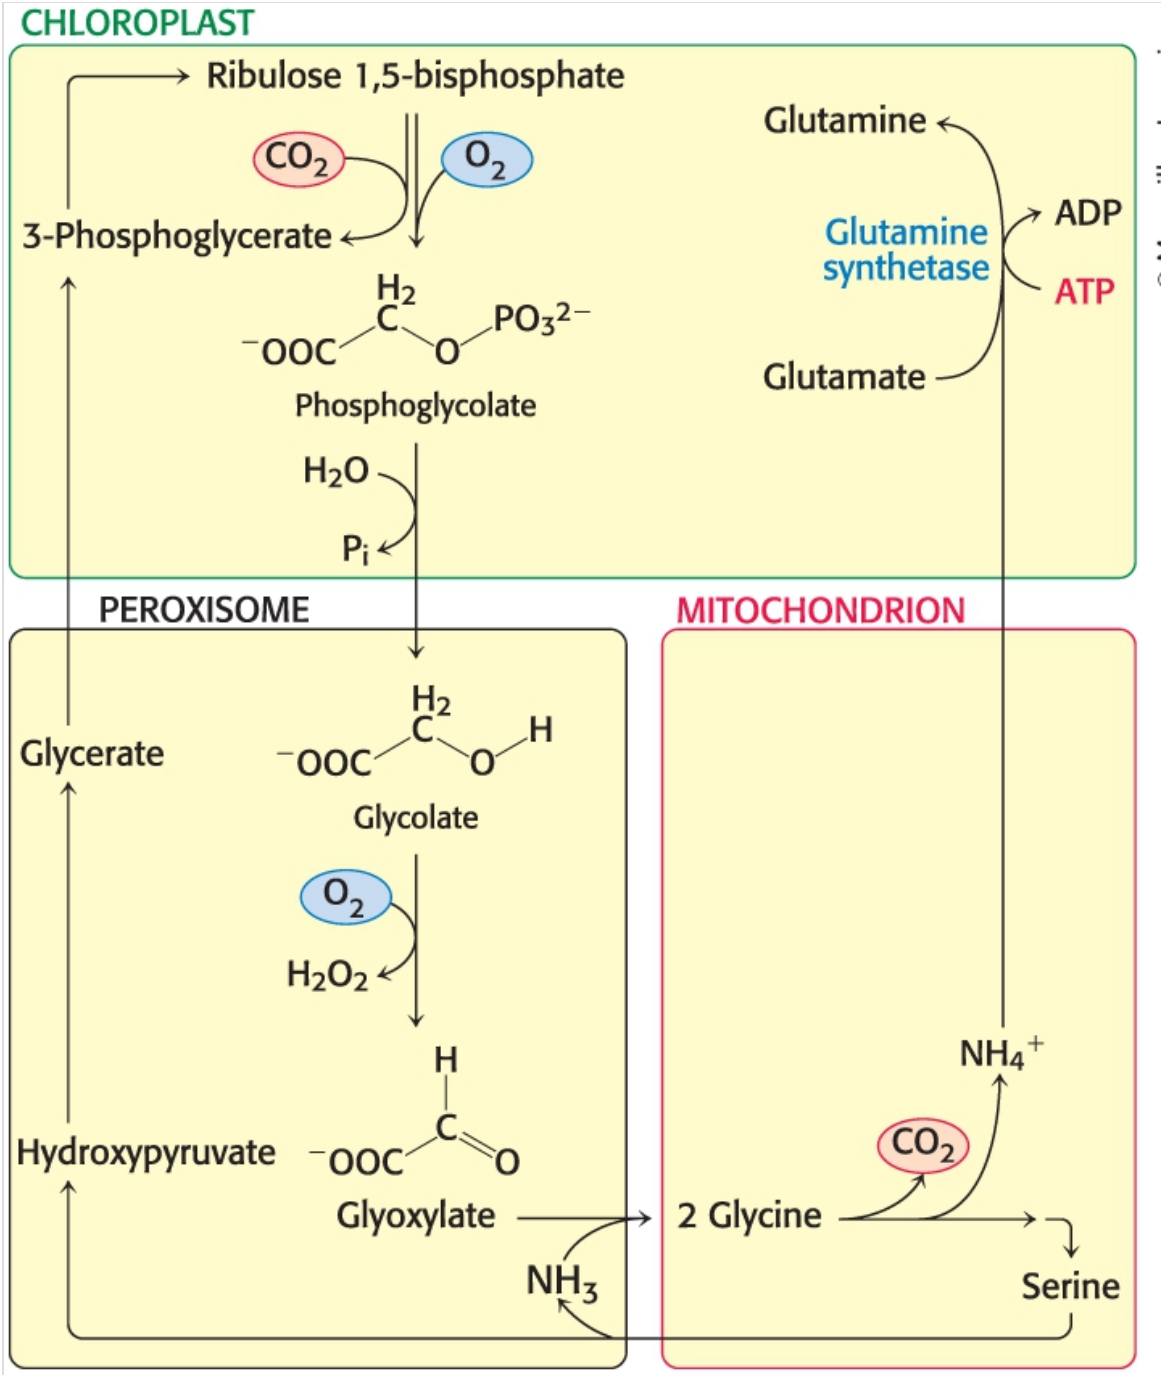
Phosphoglycolate is not a versatile metabolite. A salvage pathway recovers part of its carbon skeleton (Figure 20.6). A specific phosphatase converts phosphoglycolate into glycolate, which enters peroxisomes (Figure 20.7). Glycolate is then oxidized to glyoxylate by glycolate oxidase, an enzyme with a flavin mononucleotide prosthetic group. The H_2O_2 produced in this reaction is cleaved by catalase to H_2O and O_2. Transamination of glyoxylate then yields glycine, which then enters the mitochondria.



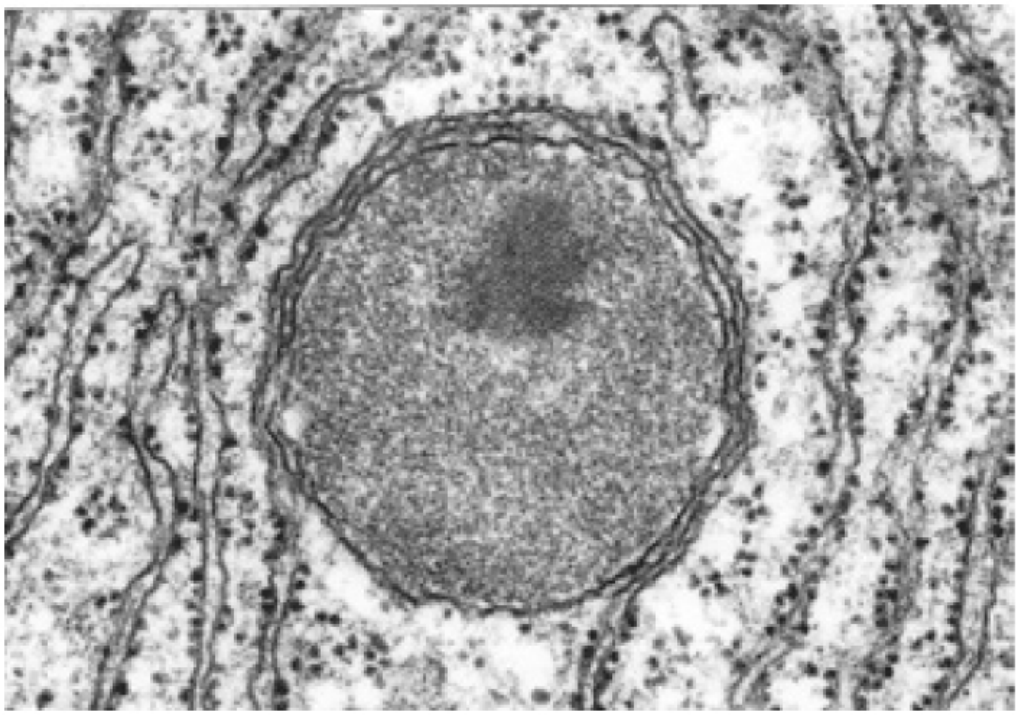


FIGURE 20.6 Photorespiration consumes O_2 and produces CO_2. Phosphoglycolate is forme as a product of the oxygenase reaction in chloroplasts. After dephosphorylation, glycolate is transported into peroxisomes, where it is converted into glyoxylate and then glycine. In mitochondria, two glycines are converted into serine, after losing a carbon as CO_2 and ammonium ion. The serine is converted back into 3-phosphoglycerate, and the ammonium ion salvaged in chloroplasts.

Don W. Fawcett/Science Source

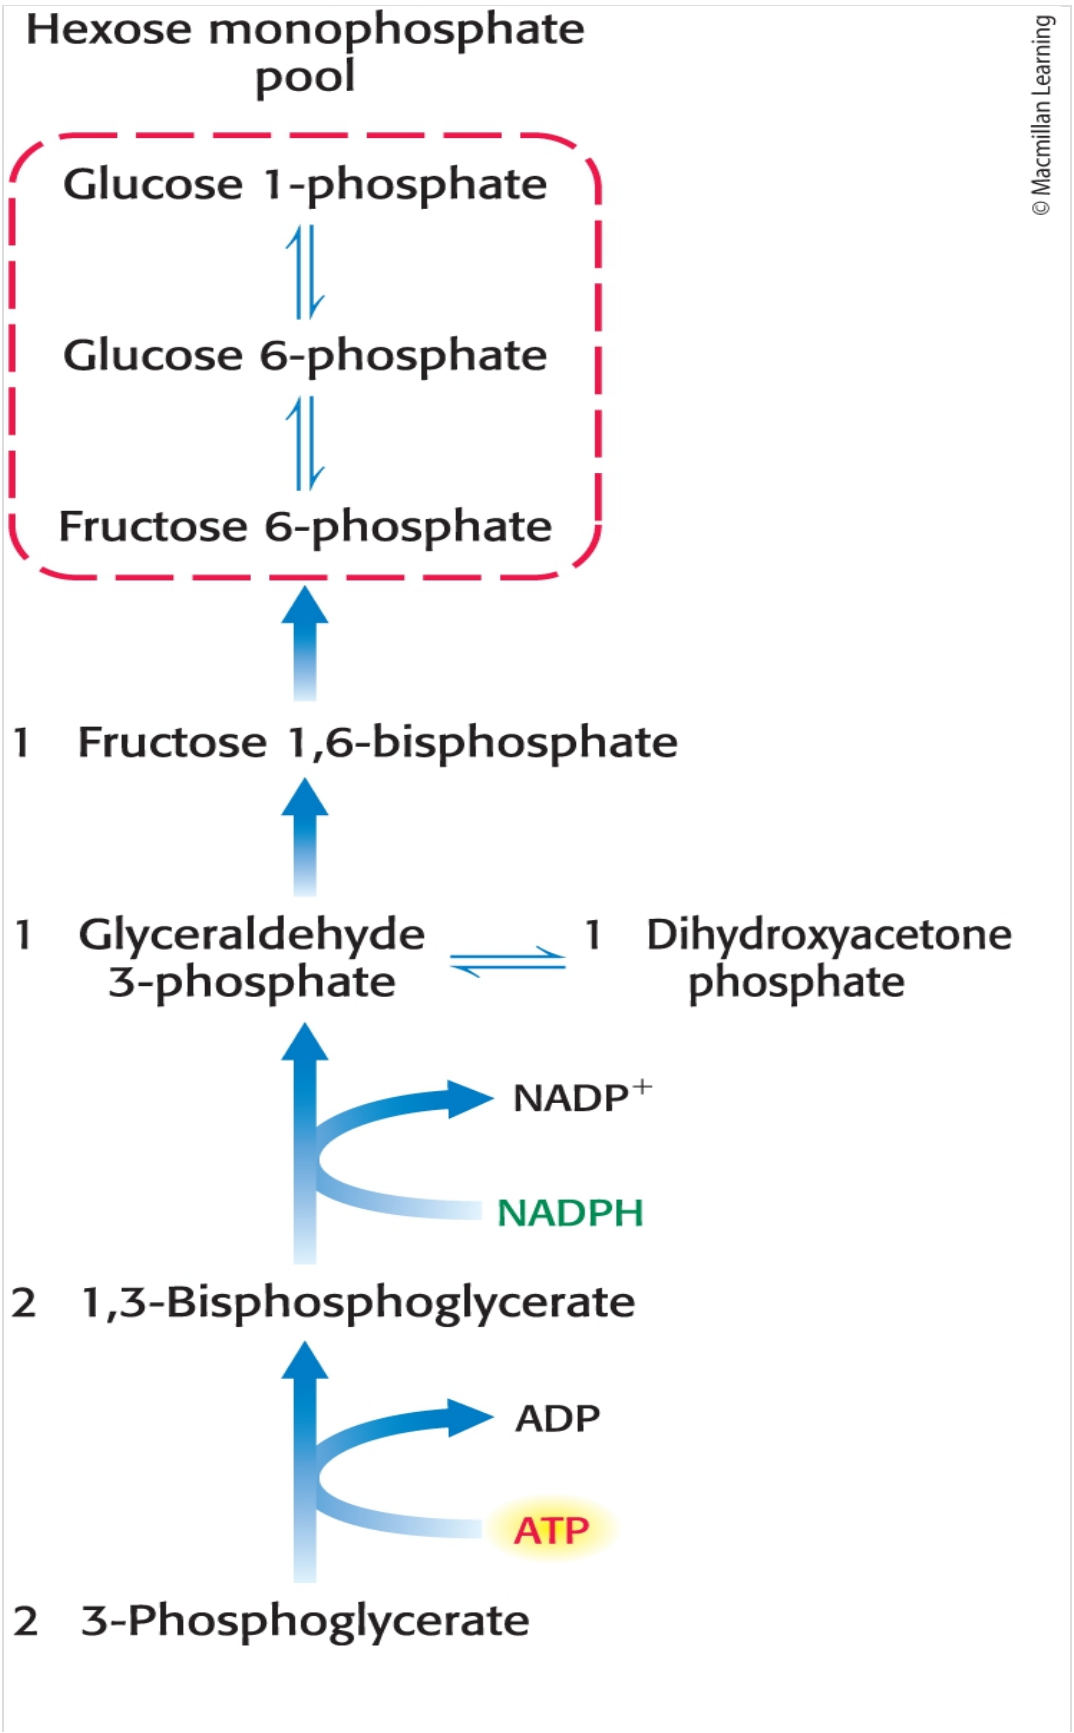
FIGURE 20.7 Peroxisomes are organelles defined by a single membrane. An electron micrograph of a peroxisome is shown. The peroxisomes are surrounded by rough endoplasmic reticulum.

Two glycine molecules can unite to form serine with the release of CO_2 and ammonium ion (NH_4^+). The ammonium ion, used in the synthesis of nitrogen-containing compounds, is salvaged by a glutamine synthetase reaction. Serine reenters the peroxisome, where it donates its ammonia to glyoxylate and is subsequently converted back into 3-phosphoglycerate.

This salvage pathway serves to recycle three of the four carbon atoms of two molecules of glycolate. However, one carbon atom is lost as CO_2. This process is called **photorespiration** because O_2 is consumed and

CO_2 is released. Photorespiration is wasteful because organic carbon is converted into CO_2 without the production of ATP, NADPH, or another energy-rich metabolite. Although evolutionary processes have presumably enhanced the preference of Rubisco for carboxylation — for instance, the Rubisco of higher plants is eight times more specific for carboxylation than that of photosynthetic bacteria — photorespiration still accounts for the loss of up to 25% of the carbon fixed.

Self-Check Question

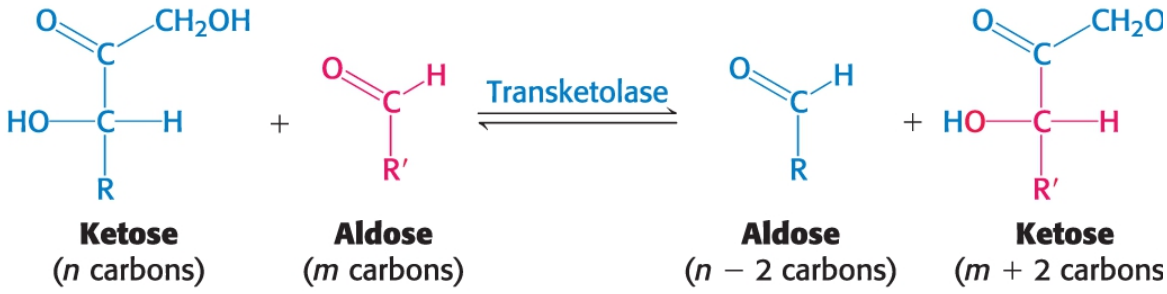


Suppose ribulose 1,5-bisphosphate reacts with pure $^{14}CO_2$ in the absence of oxygen. One half of the 3-phosphoglycerate is labeled with ^{14}C. Why?

Stage 2: Hexose phosphates are made from phosphoglycerate

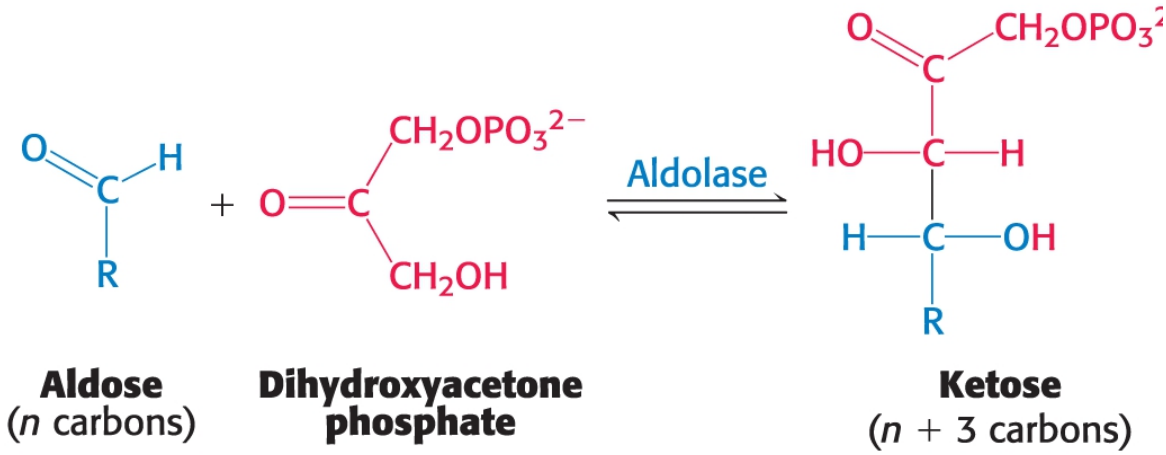
The 3-phosphoglycerate product of Rubisco is used to synthesize 6-carbon sugars. First, 3-phosphoglycerate is converted into fructose 6-phosphate, which is readily converted to glucose 6-phosphate and then to glucose 1-phosphate. The mixture of the three phosphorylated hexoses is called the hexose monophosphate pool. The steps in this conversion (Figure 20.8) are like those of the gluconeogenic pathway, except that glyceraldehyde 3-phosphate dehydrogenase in chloroplasts — which generates glyceraldehyde 3-phosphate (GAP) — is specific for NADPH rather than NADH. These reactions and that catalyzed by Rubisco bring CO_2 to the level of a hexose, converting CO_2 into a

chemical fuel at the expense of NADPH and ATP generated from the light reactions.



© Macmillan Learning

FIGURE 20.8 In stage 2 of the Calvin–Benson cycle, hexose phosphate is formed. 3-Phosphoglycerate is converted into fructose 6-phosphate in a pathway parallel to that of gluconeogenesis.



Stage 3: Ribulose 1,5-bisphosphate is regenerated

The third phase of the Calvin–Benson cycle is the regeneration of ribulose 1,5-bisphosphate, the acceptor of CO_2 in the first step. The problem is to construct a five-carbon sugar from six-carbon and three-carbon sugars. A transketolase and an aldolase play the major role in the rearrangement of the carbon atoms. The transketolase, which we will see again in the pentose phosphate pathway, requires the coenzyme thiamine pyrophosphate (TPP) to transfer a two-carbon unit $(CO—CH_2OH)$ from a ketose to an aldose.

The **transketolase** converts fructose 6-phosphate and glyceraldehyde 3-phosphate into erythrose 4-phosphate and xylulose 5-phosphate.

Aldolase, which we have already encountered in glycolysis, catalyzes an aldol condensation between dihydroxyacetone phosphate (DHAP) and an aldehyde. This enzyme is highly specific for dihydroxyacetone phosphate, but it accepts a wide variety of aldehydes.

Aldolase generates sedoheptulose 1,7-bisphosphate from erythrose 4-phosphate and dihydroxyacetone phosphate. A phosphatase removes a phosphate from sedoheptulose 1,7-bisphosphophosphate to form sedoheptulose 7-phosphate. Transketolase again enters the action to combine sedoheptulose 7-phosphate with another molecule of glyceraldehyde 3-phosphate to form the five-carbon sugar ribose 5-phosphate as well as a second molecule of xylulose 5-phosphate (Figure 20.9).

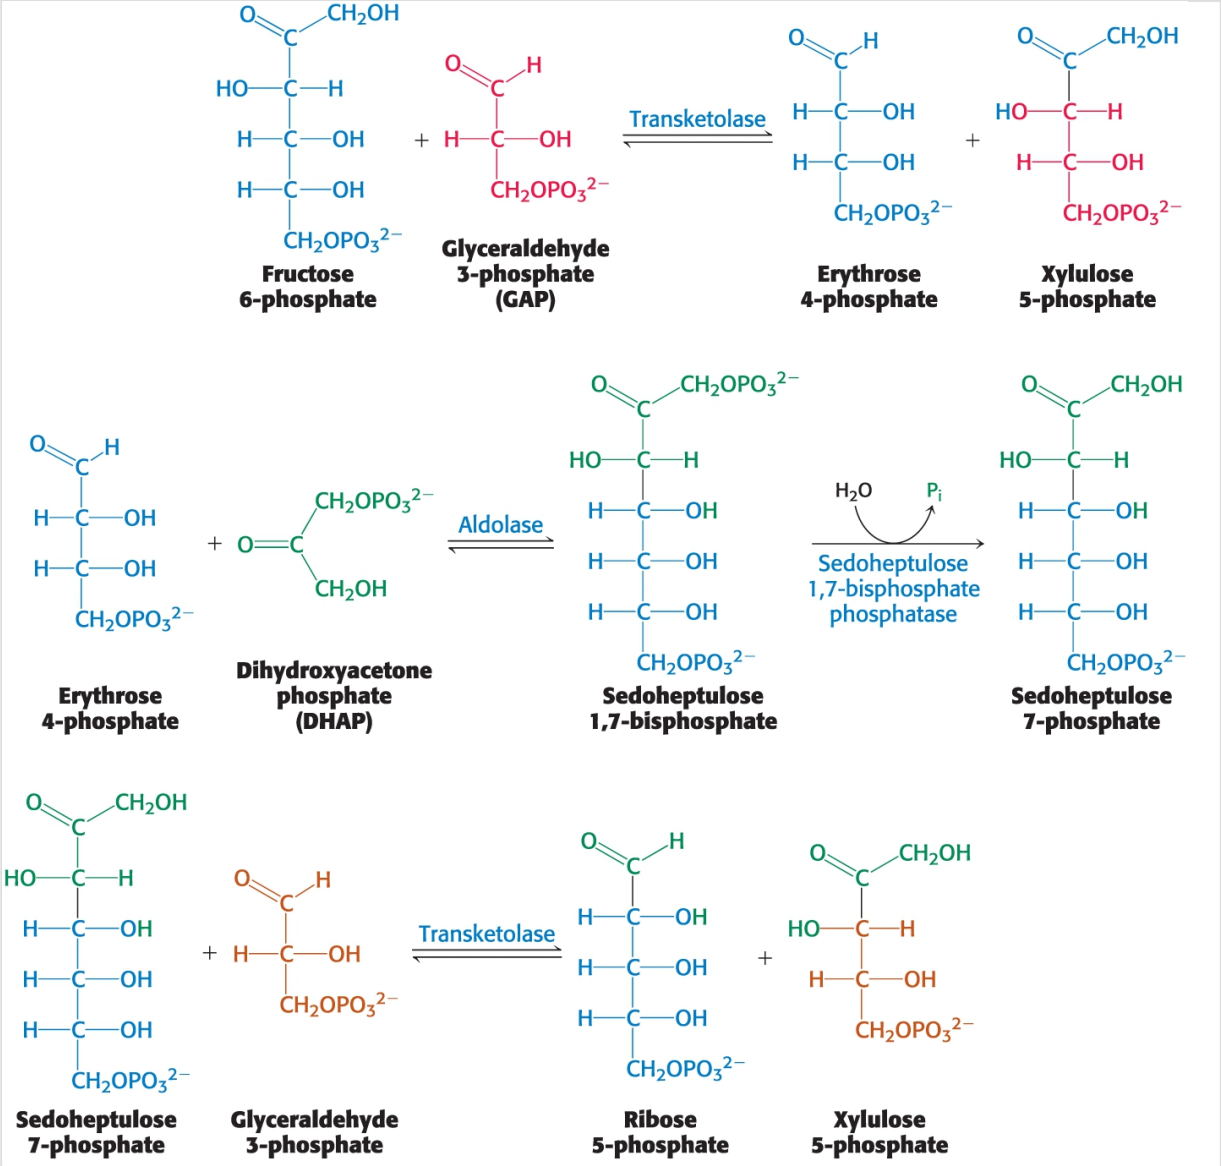


FIGURE 20.9 Five-carbon sugars are formed from six-carbon and three-carbon sugars. First, transketolase converts a six-carbon sugar and a three-carbon sugar into a four-carbon sugar and a five-carbon sugar. Then, aldolase combines the four-carbon product and a three-carbon sugar to form a seven-carbon sugar. Finally, this seven-carbon sugar reacts with another three-carbon sugar to form two additional five-carbon sugars.

Finally, ribose 5-phosphate is converted into ribulose 5-phosphate by phosphopentose isomerase, whereas the two molecules of xylulose 5-

phosphate are converted into ribulose 5-phosphate by phosphopentose epimerase. Ribulose 5-phosphate is converted into ribulose 1,5-bisphosphate through the action of phosphoribulokinase (Figure 20.10).

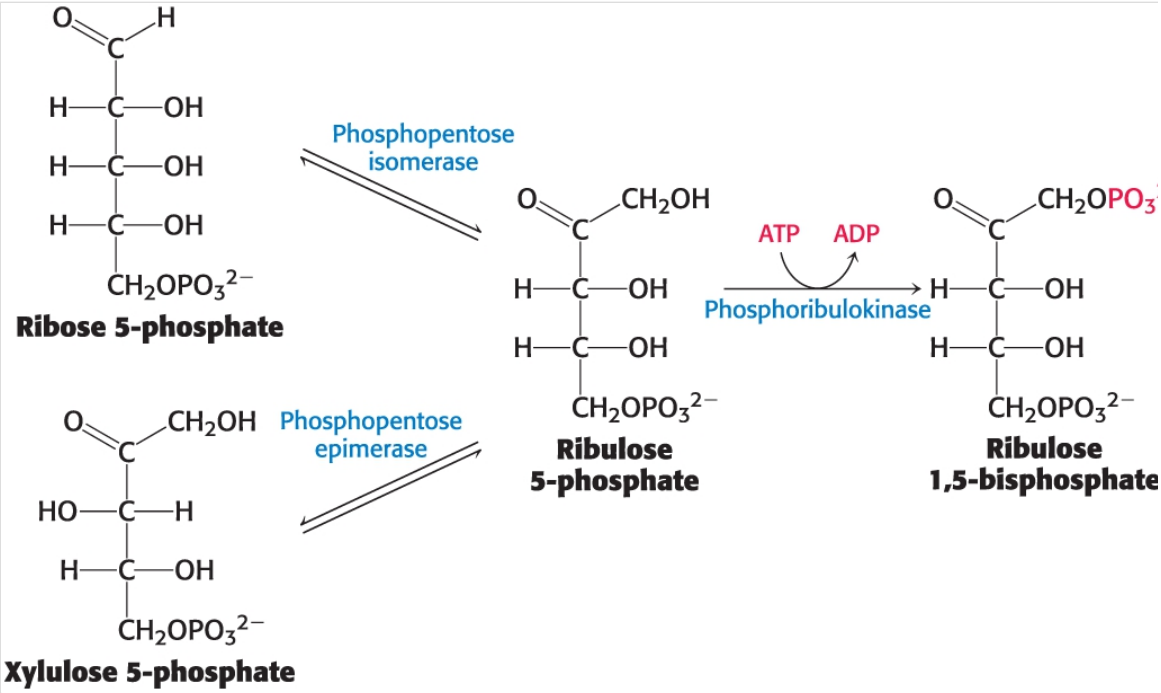

FIGURE 20.10 In stage 3 of the Calvin–Benson cycle, ribulose 1,5-bisphosphate is regenerated
Both ribose 5-phosphate and xylulose 5-phosphate are converted into ribulose 5-phosphate, which is then phosphorylated to complete the regeneration of ribulose 1,5-bisphosphate.

The sum of these reactions shown in Figures 20.9 and 20.10 is:

Fructose 6–phosphate + 2 glyceraldehyde 3–phosphate + dihydroxyacetone phosphate + 3 ATP → 3 ribulose 1,5–bisphosphate + 3 ADP

Figure 20.11 presents the required reactions with the proper stoichiometry to convert three molecules of CO_2 into one molecule of DHAP. However, two molecules of DHAP are required for the synthesis of a member of the hexose monophosphate pool. Consequently, the cycle as presented must take place twice to yield a hexose monophosphate. The outcome of the Calvin–Benson cycle is the generation of a hexose and the regeneration of the starting compound, ribulose 1,5-bisphosphate. In essence, ribulose 1,5-bisphosphate acts catalytically, similarly to oxaloacetate in the citric acid cycle.

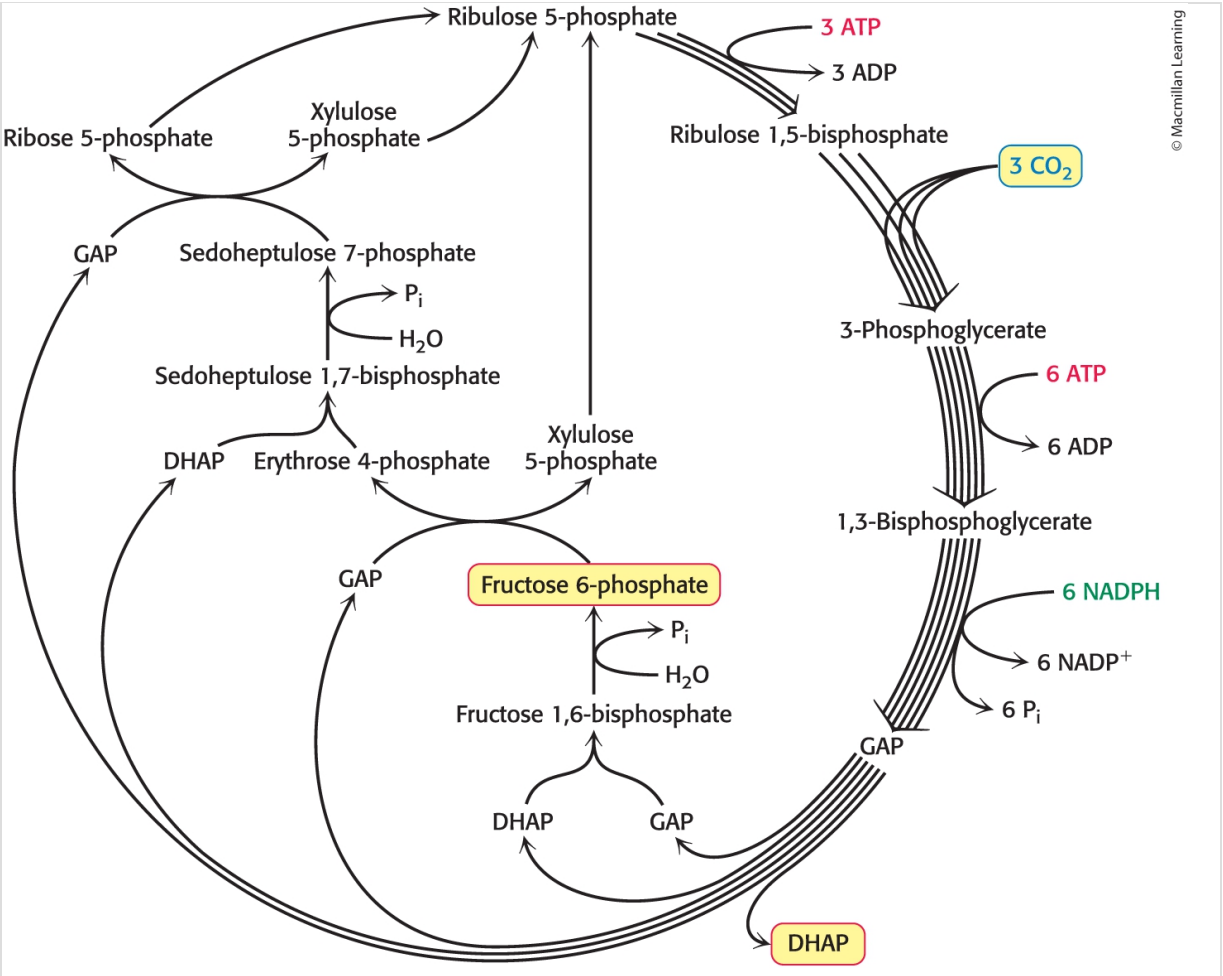

FIGURE 20.11 The full Calvin–Benson cycle process for converting three molecules of CO_2 to dihydroxyacetone phosphate is complex. The cycle is not as simple as presented in Figure 20.1; rather, it entails many reactions that lead ultimately to the synthesis of glucose and the regeneration of ribulose 1,5-bisphosphate.

[Information from J. R. Bowyer and R. C. Leegood. "Photosynthesis," in *Plant Biochemistry*, P. M. Dey and J. B. Harborne, Eds. (Academic Press, 1997), p. 85.]

18 ATP and 12 NADPH molecules are used to bring six carbon dioxides to the level of a hexose

What is the energy expenditure for synthesizing a hexose?

- Six rounds of the Calvin–Benson cycle are required, because one carbon atom is reduced in each round.
- 12 molecules of ATP are expended in phosphorylating 12 molecules of 3-phosphoglycerate to 1,3-bisphosphoglycerate.
- 12 molecules of NADPH are consumed in reducing 12 molecules of 1,3-bisphosphoglycerate to glyceraldehyde 3-phosphate.
- An additional six molecules of ATP are spent in regenerating ribulose 1,5-bisphosphate.

We can now write a balanced equation for the net reaction of the Calvin–Benson cycle:

$$6\,CO_2 + 18\,ATP + 12\,NADPH + 12\,H_2O \rightarrow$$
$$C_6H_{12}O_6 + 18\,ADP + 18\,P_i + 12\,NADP^+ + 6\,H^+$$

Thus, three molecules of ATP and two molecules of NADPH are consumed in incorporating a single CO_2 molecule into a hexose such as glucose or fructose.

Starch and sucrose are the major carbohydrate stores in plants

What are the fates of the members of the hexose monophosphate pool? These molecules are used in a variety of ways, but there are two primary roles. Plants contain two major storage forms of sugar: starch and sucrose. **Starch**, like its animal counterpart glycogen, is a polymer of glucose residues, but it is less branched than glycogen because it contains a smaller proportion of α-1,6-glycosidic linkages. Another difference is that ADP-glucose, not UDP-glucose, is the activated precursor. Starch is synthesized and stored in chloroplasts.

In contrast, **sucrose** (common table sugar), a disaccharide, is synthesized in the cytoplasm. Plants lack the ability to transport hexose phosphates across the chloroplast membrane, but they are able to transport triose phosphates from chloroplasts to the cytoplasm. Triose phosphate intermediates such as glyceraldehyde 3-phosphate cross into the cytoplasm in exchange for phosphate through the action of an abundant triose phosphate-phosphate antiporter. Fructose 6-phosphate formed from triose phosphates joins the glucose unit of UDP-glucose to form sucrose 6(F)-phosphate (**Figure 20.12**). The hydrolysis of the phosphate ester by sucrose phosphatase yields sucrose, a readily transportable and mobilizable sugar that is stored in many plant cells, such as those in sugar beets and sugarcane.

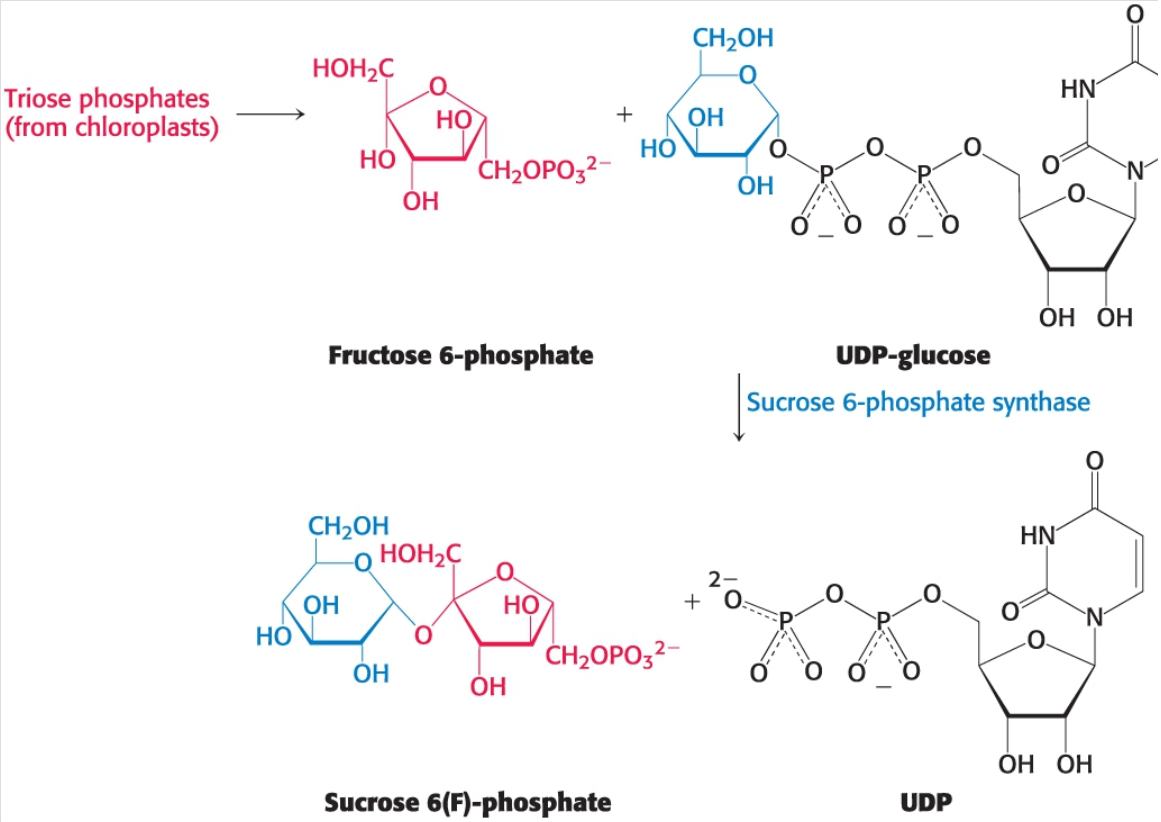

FIGURE 20.12 Carbohydrates are stored as sucrose. Sucrose 6-phosphate is formed by the reaction between fructose 6-phosphate and the activated intermediate uridine diphosphate glucose (UDP-glucose). Sucrose phosphatase subsequently generates free sucrose (not shown).

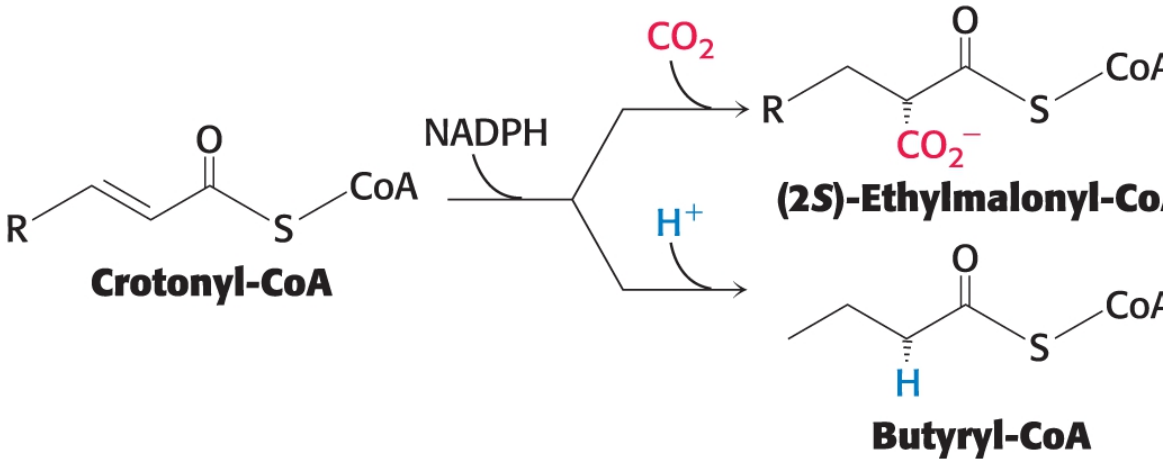
Self-Check Question



What role does magnesium play in the dark reactions of photosynthesis? Explain the role that this same element plays in the light reactions.

Inspired by the Calvin–Benson cycle, scientists are developing new methods for fixing carbon dioxide

Carbon dioxide is a potential plentiful carbon source for the production of organic compounds. Applying the knowledge of biochemical pathways from a wide range of organisms, scientists have conceptually developed and, in some cases, implemented cycles that fix carbon dioxide into organic compounds. One such cycle referred to as the CETCH cycle — for crotonyl–coenzyme A (CoA)/ethylmalonyl-CoA/hydroxybutyryl-CoA — catalyzes the conversion of 2 molecules of CO_2 to 1 molecule of glyoxylate, $^{-}O_2C-CHO$, C-CHO. This cycle involves 12 steps and 15 enzymes. The balanced chemical reaction is

$$2\,CO_2 + 4\,NADPH + 2\,FADH2 + 4\,ATP + 2\,O_2 + 3\,H^+ \rightarrow$$
$$^{-}O_2C-CHO + 4\,NADP^+ + 2\,FAD + 4\,ADP + 2\,P_i + 5\,H_2O$$

Carbon fixation occurs via the reaction catalyzed by enoyl-CoA carboxylases/reductases.

These enzymes are several times more efficient at fixing CO_2 than is Rubisco and do not react with oxygen.

This reaction scheme has been harnessed in an artificial photosynthesis system in microdroplets containing thylakoids to generate ATP and NADPH in response to light (Figure 20.13). With the addition of one additional step to the CETCH cycle, this process allows CO_2 to be converted to glycolate, a versatile organic building block, in a light-driven process. This is an example of synthetic biology, where engineering principles are used to develop potentially useful devices.

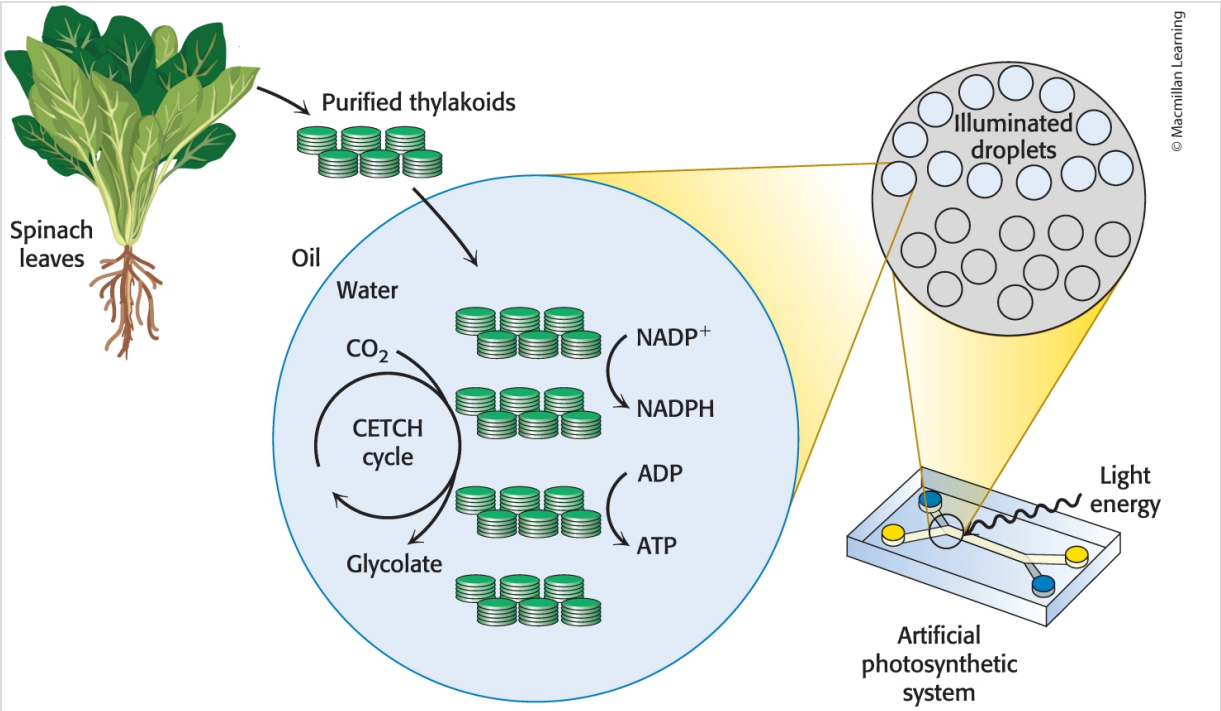


FIGURE 20.13 Scientists have engineered artificial photosynthesis using alternative CO_2 fixation pathways. A synthetic photosynthetic system is shown using purified thylakoids to drive the light reactions and a designed CO_2 fixation system for the dark reactions.

[From N. J. Gaut and K. P. Adamala, "Toward Artificial Photosynthesis," *Science* 368:587–588, 2020.]

20.2 The Activity of the Calvin–Benson Cycle Depends on Environmental Conditions

Light levels, temperature, and availability of CO_2 in different environments are crucial factors for effective carbon fixation and avoidance of processes damaging to plants. How are the light reactions linked to the dark reactions to regulate fixing CO_2 into biomolecules? The principal means of regulation is alteration of the stromal environment by the light reactions. The light reactions lead to an increase in stromal pH (a decrease in the H^+ concentration), as well as an increase in the stromal concentrations of Mg^{2+}, NADPH, and reduced ferredoxin — changes that contribute to the activation of certain Calvin–Benson cycle enzymes, located in the stroma (Figure 20.14).

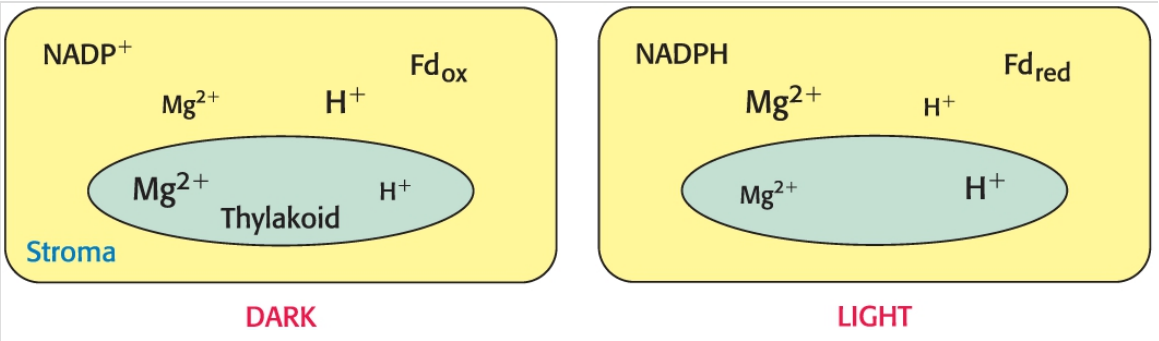

FIGURE 20.14 Light regulates the Calvin–Benson cycle. The light reactions of photosynthesis transfer electrons out of the thylakoid lumen into the stroma and transfer protons from the stroma into the thylakoid lumen. As a consequence of these processes, the concentrations of NADPH, reduced ferredoxin (Fd), and Mg^{2+} in the stroma are higher in the light than in the dark. The stromal pH is also increased (the concentration of H^+ is lowered) in the light as a result of proton pumping from the stroma to the thylakoid lumen. Each of these concentration changes helps couple the Calvin–Benson cycle reactions to the light reactions.

Rubisco is activated by light-driven changes in proton and magnesium ion concentrations

As stated earlier, the rate-limiting step in the Calvin–Benson cycle is the carboxylation of ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate. The activity of Rubisco increases markedly on illumination because light facilitates the carbamate formation necessary for enzyme activity (Figure 20.3). In the stroma, the pH increases from 7 to 8, and the level of Mg^{2+} rises. Both effects are consequences of the light-driven pumping of protons into the thylakoid space. Mg^{2+} ions from the thylakoid space are released into the stroma to compensate for the influx of protons. Carbamate formation is favored at alkaline pH. CO_2 adds to a deprotonated form of lysine 201 of Rubisco, and Mg^{2+} ion binds to the carbamate to generate the active form of the enzyme. Thus, light leads not only to the generation of ATP and NADPH, but also to regulatory signals that stimulate CO_2 fixation.

Thioredoxin plays a key role in regulating the Calvin–Benson cycle

As we saw in Chapter 19, light-driven reactions lead to electron transfer from water to ferredoxin and, eventually, to NADPH in photosystem I. The presence of reduced ferredoxin and NADPH are good signals that conditions are right for biosynthesis. One way in which this information is conveyed to biosynthetic enzymes is by thioredoxin, a 12-kDa protein

containing neighboring cysteine residues that cycle between a reduced sulfhydryl and an oxidized disulfide form (Figure 20.15).

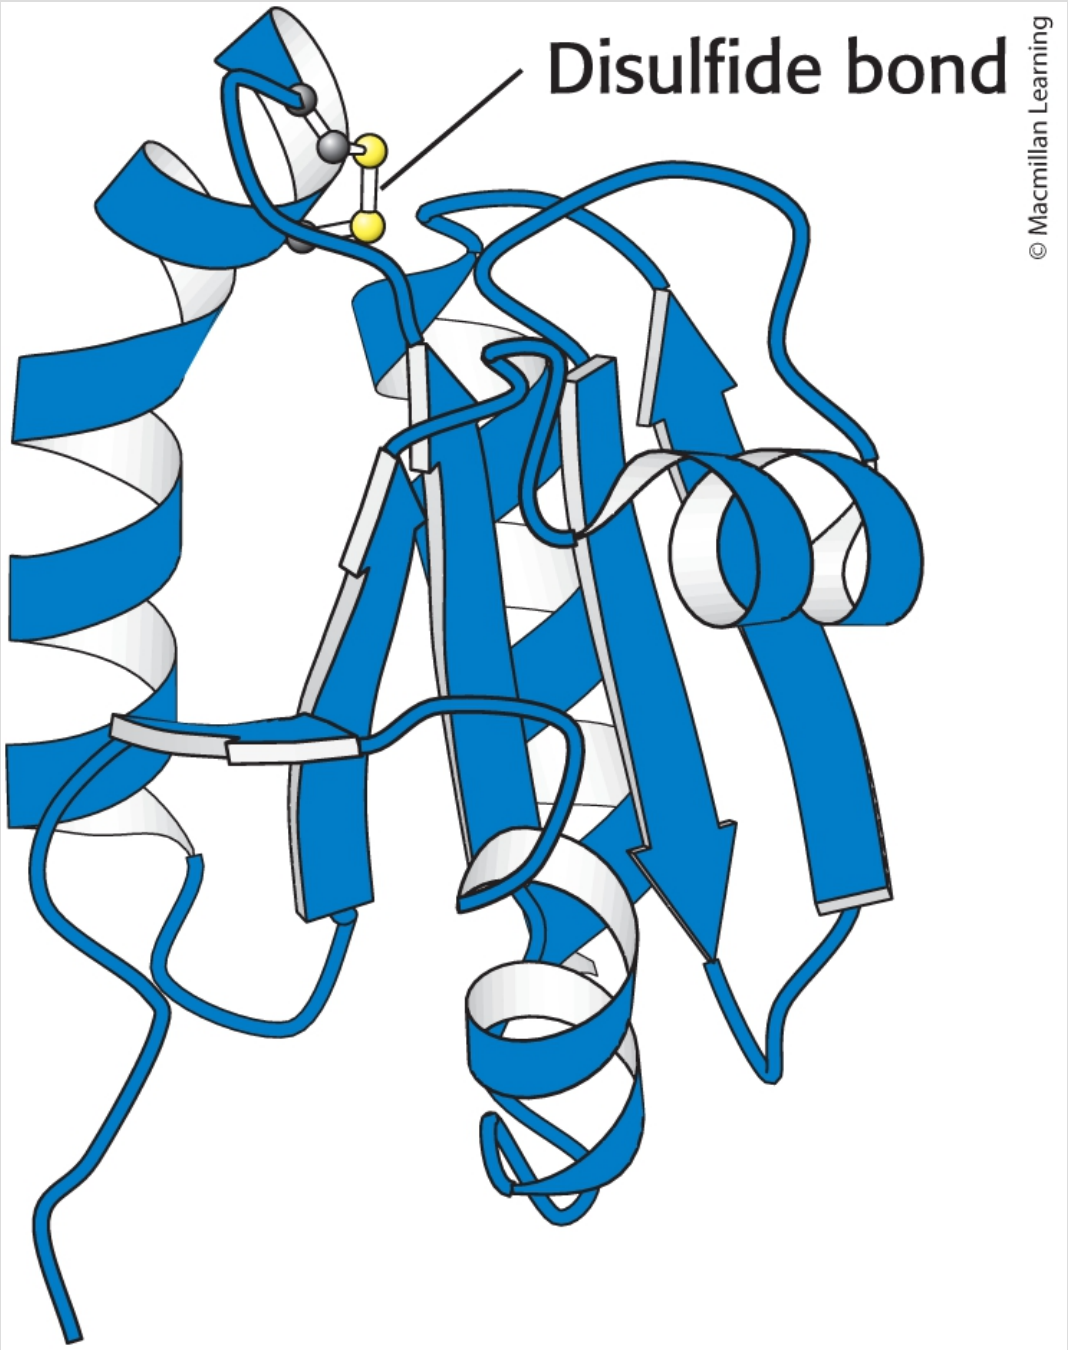

FIGURE 20.15 Thioredoxin has a redox-active disulfide bond. The oxidized form of thioredoxin contains a disulfide bond. When thioredoxin is reduced by reduced ferredoxin, the disulfide bond is converted into two free sulfhydryl groups. Reduced thioredoxin can cleave disulfide bonds in enzymes, activating certain Calvin–Benson cycle enzymes and inactivating some degradative enzymes.

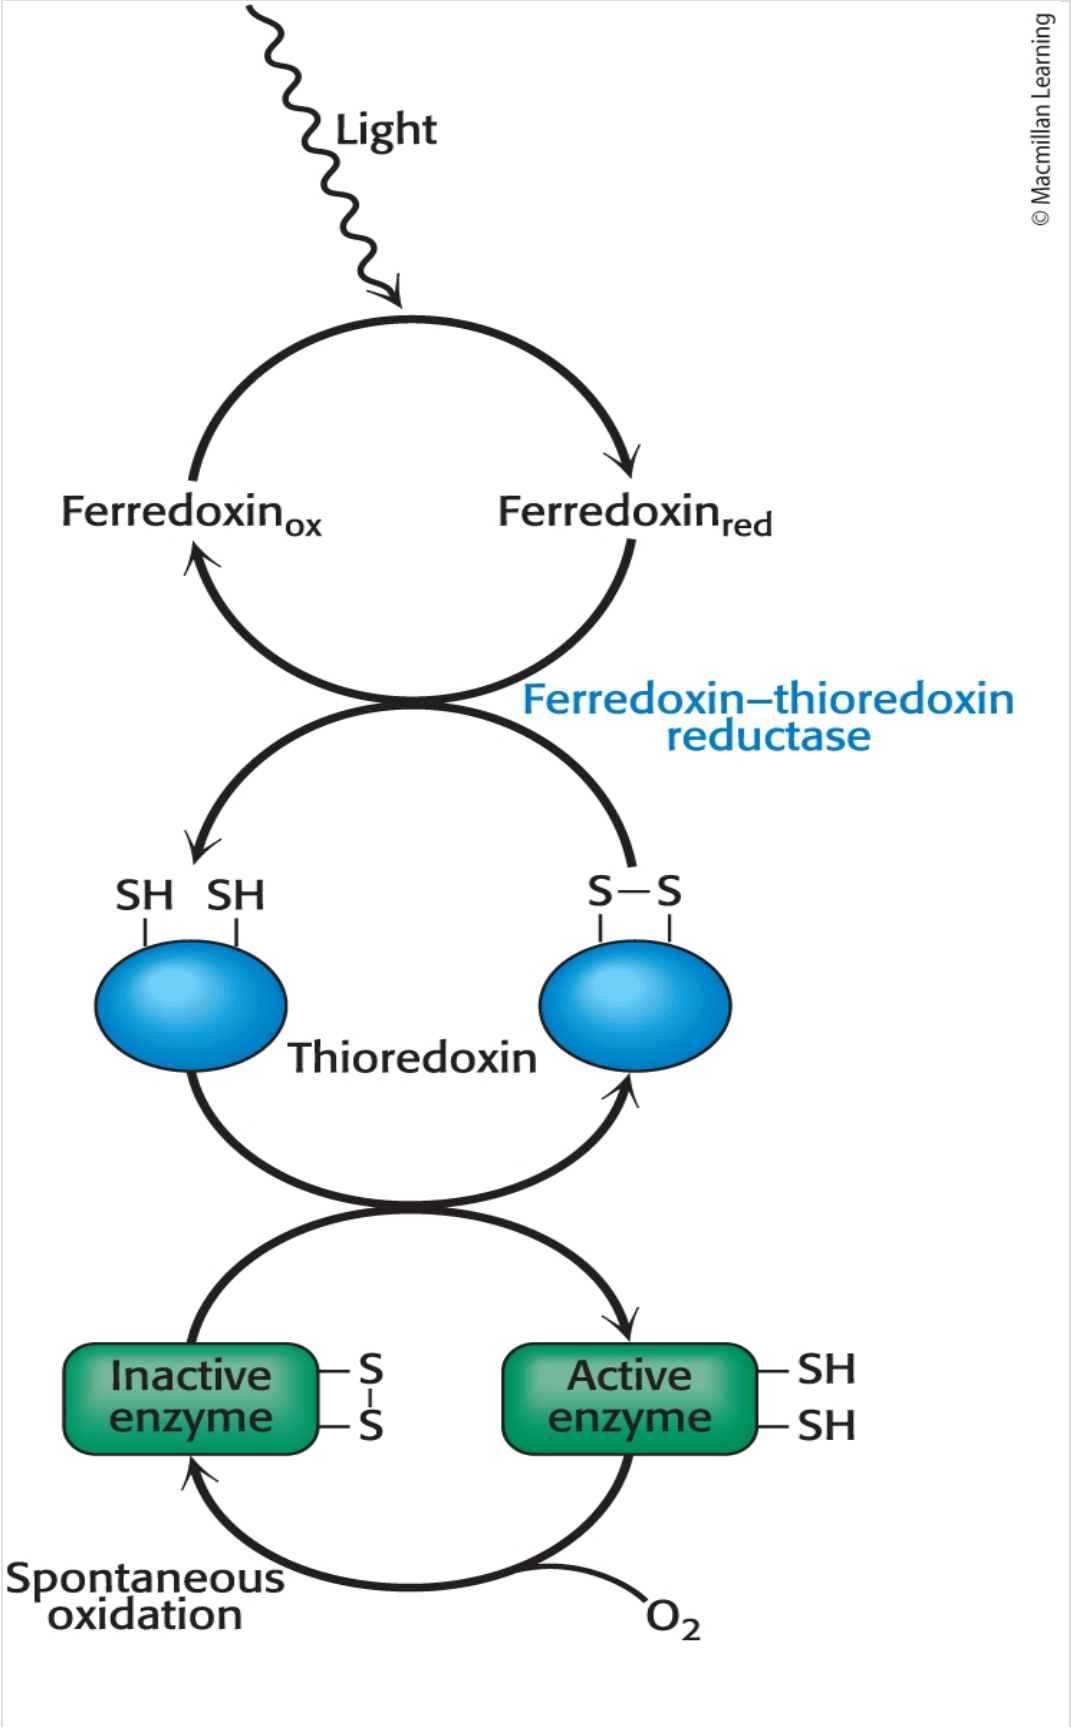
[Drawn from 1F9M.pdb.]



INTERACT with this model in Achieve

The reduced form of thioredoxin activates many biosynthetic enzymes, including the chloroplast ATP synthase, by reducing disulfide bridges that control their activity. Reduced thioredoxin also inhibits several degradative enzymes by the same means (Table 20.1).

TABLE 20.1 Enzymes regulated by thioredoxin

Enzyme	Pathway
Rubisco	Carbon fixation in the Calvin–Benson cycle
Fructose 1,6-bisphosphatase	Gluconeogenesis
Glyceraldehyde 3-phosphate dehydrogenase	Calvin–Benson cycle, gluconeogenesis, glycolysis
Sedoheptulose 1,7-bisphosphatase	Calvin–Benson cycle
Glucose 6-phosphate dehydrogenase	Pentose phosphate pathway
Phenylalanine ammonia lyase	Lignin synthesis
Phosphoribulokinase	Calvin–Benson cycle
$NADP^+$-malate dehydrogenase	C_4 pathway
CF_1–CF_0 ATP synthase	The light reactions

In chloroplasts, oxidized thioredoxin is reduced by ferredoxin in a reaction catalyzed by ferredoxin–thioredoxin reductase. Thus, the activities of the light and dark reactions of photosynthesis are coordinated through electron transfer from reduced ferredoxin to thioredoxin and then to component enzymes containing regulatory disulfide bonds (**Figure 20.16**).

© Macmillan Learning

FIGURE 20.16 Thioredoxin can activate enzymes by reducing them. Reduced thioredoxin activates certain Calvin–Benson cycle enzymes by cleaving regulatory disulfide bonds.

NADPH is a signal molecule that activates two biosynthetic enzymes, phosphoribulokinase and glyceraldehyde 3-phosphate dehydrogenase. In the dark, these enzymes are inhibited by association with an 8.5-kDa protein called CP12, an intrinsically disordered protein. NADPH disrupts this association by promoting the formation of two disulfide bonds in CP12, leading to the release of the active enzymes.

The C_4 pathway of tropical plants and grasses accelerates photosynthesis by concentrating carbon dioxide

The oxygenase activity of Rubisco presents a biochemical challenge to tropical plants because the oxygenase activity increases more rapidly with temperature than does the carboxylase activity. How, then, do plants that grow in hot climates, such as sugarcane, prevent very high rates of wasteful photorespiration? Their solution to this problem is to achieve a high local concentration of CO_2 at the site of the Calvin–Benson cycle in their photosynthetic cells. The essence of this process is that four-carbon (C_4) compounds such as oxaloacetate and malate carry CO_2 from mesophyll cells, which are in contact with air, to bundle-sheath cells, which are the major sites of photosynthesis (Figure 20.17). The decarboxylation of the four-carbon compound in a bundle-sheath cell maintains a high concentration of CO_2 at the site of the Calvin–Benson cycle. The three-carbon product returns to the mesophyll cell

for another round of carboxylation. This metabolic pathway is called the C_4 pathway or the Hatch–Slack pathway.

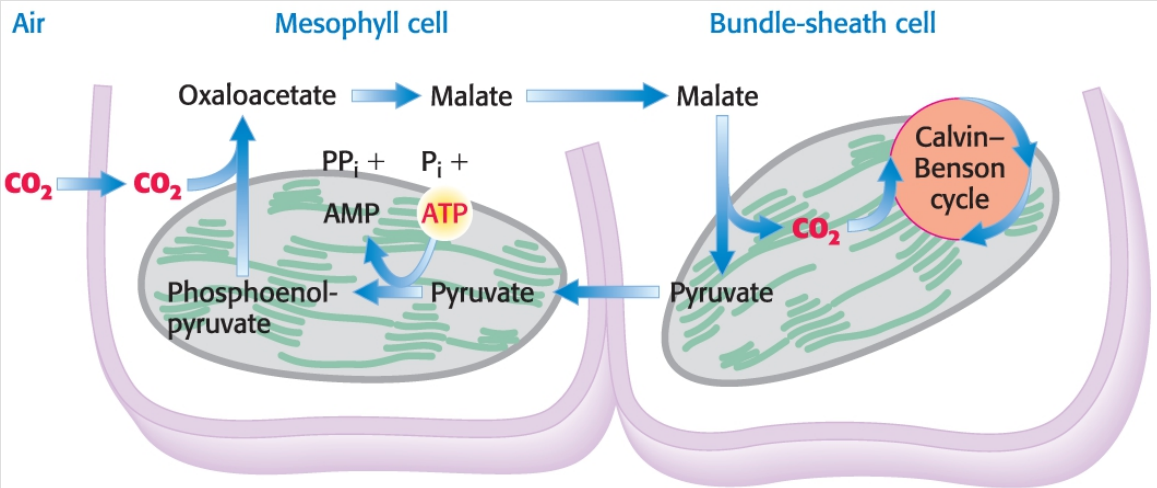


FIGURE 20.17 The C_4 pathway can concentrate CO_2. Carbon dioxide is concentrated in bundle-sheath cells by the expenditure of ATP in mesophyll cells.

In addition to tropical plants, grasses and sedges in temperate climates employ the C_4 pathway. In fact, they are the most common users of the pathway. Corn or maize, domesticated by selective breeding from the Mexican grass teosinte about 9,000 years ago, is a C_4 plant of tremendous economic and agricultural importance, accounting for approximately 20% of human nutrition worldwide.

The C_4 pathway for the transport of CO_2 starts in a mesophyll cell, with the condensation of CO_2 in the form of bicarbonate and phosphoenolpyruvate to form *oxaloacetate* in a reaction catalyzed by phosphoenolpyruvate carboxylase. Oxaloacetate is converted into malate by an $NADP^+$-linked malate dehydrogenase. Malate enters the bundle-sheath cell and is oxidatively decarboxylated within the

chloroplasts by an $NADP^+$-linked malate dehydrogenase. The released CO_2 enters the Calvin–Benson cycle in the usual way by condensing with ribulose 1,5-bisphosphate. Pyruvate formed in this decarboxylation reaction returns to the mesophyll cell. Finally, phosphoenolpyruvate is formed from pyruvate by pyruvate-P_i dikinase.

The net reaction of this C_4 pathway is

$$CO_2 \text{ (in mesophyll cell)} + ATP + 2\ H_2O \rightarrow$$
$$CO_2 \text{ (in bundle-sheath cell)} + AMP + 2\ P_i + 2\ H^+$$

Since the products are AMP and two equivalents of inorganic phosphate, the energetic equivalent of two ATP molecules is consumed in transporting CO_2 to the chloroplasts of the bundle-sheath cells. Note that six molecules of CO_2 are required to synthesize glucose so the C_4 pathway requires an extra 12 ATP when compared to the C_3 pathway. In essence, this process is active transport: the pumping of CO_2 into the bundle-sheath cell is driven by the hydrolysis of one molecule of ATP to one molecule of AMP and two molecules of orthophosphate. The CO_2 concentration can be 20 times as great in the bundle-sheath cells as in the mesophyll cells. Interestingly, phosphoenolpyruvate carboxylase has a higher affinity for CO_2 (as bicarbonate) than does Rubisco. C_4 plants use this affinity difference to their advantage. The high CO_2 affinity of phosphoenolpyruvate carboxylase means Rubisco can be adequately supplied with CO_2, while the stomata — the openings in the leaves that allow gas exchange (**Figure 20.18**) — do not have to open as completely in the heat of the tropical day, thereby preventing water loss.

Power and Syred/Science Source

FIGURE 20.18 Stomata can open to facilitate gas exchange. A scanning electron micrograph shows a closed stoma and an open stoma.

When the C_4 pathway and the Calvin–Benson cycle operate together, the net reaction is

$$6\,CO_2 + 30\,ATP + 12\,NADPH + 24\,H_2O \rightarrow$$
$$C_6H_{12}O_6 + 30\,ADP + 30\,P_i + 12\,NADP^+ + 18\,H^+$$

Note that 30 molecules of ATP are consumed per hexose molecule formed when the C_4 pathway delivers CO_2 to the Calvin–Benson cycle, in contrast with 18 molecules of ATP per hexose molecule in the absence of the C_4 pathway. The high concentration of CO_2 in the bundle-sheath cells of C_4 plants — which is the result of the expenditure of the additional 12 molecules of ATP — is critical for their rapid

photosynthetic rate, because CO_2 is limiting when light is abundant. A high CO_2 concentration also minimizes the energy loss caused by photorespiration.

Tropical plants with a C_4 pathway do little photorespiration because the high concentration of CO_2 in their bundle-sheath cells accelerates the carboxylase reaction relative to the oxygenase reaction. This effect is especially important at higher temperatures. The geographic distribution of plants having this pathway (C_4 plants) and those lacking it (C_3 plants) can now be understood in molecular terms. C_4 plants have the advantage in a hot environment and under high illumination, which accounts for their prevalence in the tropics. C_3 plants, which consume only 18 molecules of ATP per hexose molecule formed in the absence of photorespiration (compared with 30 molecules of ATP for C_4 plants), are more efficient at temperatures lower than about 28°C, and so they predominate in temperate environments (Figure 20.19). Although C_4 plants comprise only 3% of all flowering plants, they account for 25% of all terrestrial carbon fixation because of their minimization of photorespiration.

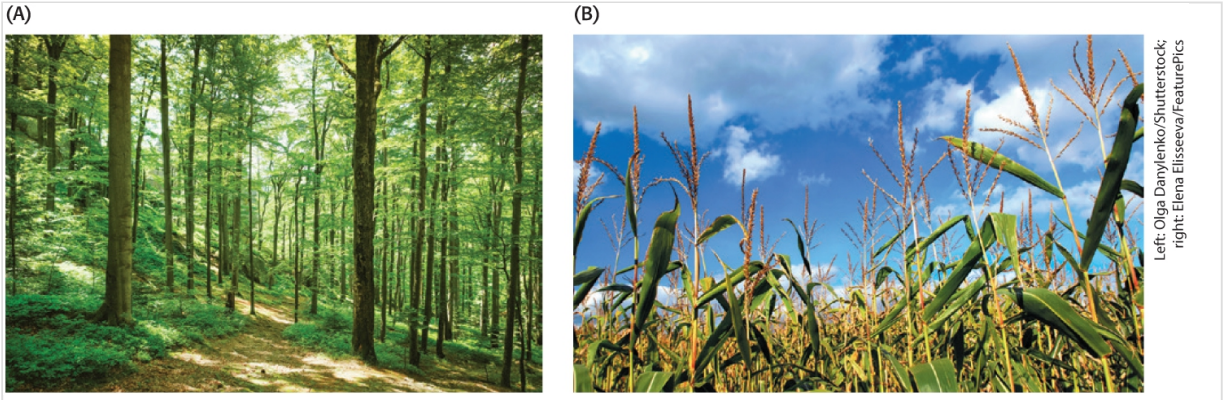

FIGURE 20.19 Both C_3 and C_4 plants are important. (A) C_3 plants, such as trees, account for approximately 95% of plant species. (B) Corn is a C_4 plant of tremendous agricultural importance.

Crassulacean acid metabolism permits growth in arid ecosystems

Many plants, including some that grow in hot, dry climates, keep the stomata of their leaves closed in the heat of the day to prevent water loss (see Figure 20.18). As a consequence, CO_2 cannot be absorbed during the daylight hours, when it is needed for glucose synthesis. Rather, CO_2 enters the leaf when the stomata open at the cooler temperatures of night.

To store the CO_2 until it can be used during the day, such plants make use of an adaptation called **crassulacean acid metabolism (CAM)**, named after the genus *Crassulacea* (the succulents). Carbon dioxide is fixed by the C_4 pathway into malate, which is stored in vacuoles. During the day, malate is decarboxylated and the CO_2 becomes available to the Calvin–Benson cycle. In contrast with C_4 plants, CAM plants separate CO_2 accumulation from CO_2 utilization temporally rather than spatially.

Although CAM plants do prevent water loss, the use of malate as the sole source of CO_2 comes at a metabolic cost. Because malate storage is limited, CAM plants cannot generate CO_2 as rapidly as it can be imported by C_3 and C_4 plants. Consequently, the growth rate of CAM plants is slower than that of C_3 and C_4 plants. The saguaro cactus, a CAM plant that can live up to 200 years and reach a height of 60 feet, can take 15 years to grow to only 1 foot in height (**Figure 20.20**).

yenwen/Getty Images

FIGURE 20.20 Crassulacean acid metabolism facilitates growth in arid climates. Because of crassulacean acid metabolism, plants such as cacti are well suited to life in the desert.

20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Pentoses

While photosynthetic organisms can use the light reactions for generation of some NADPH, the **pentose phosphate pathway** meets the NADPH needs of nonphotosynthetic organisms and of the non-photosynthetic tissues in plants. The pentose phosphate pathway occurs in the cytoplasm of all organisms and is a crucial source of NADPH for use in reductive biosynthesis (Table 20.2) as well as for protection against oxidative stress. It consists of two phases (Figure 20.21):

1. *The oxidative generation of NADPH*. In the oxidative phase, NADPH is generated when glucose 6-phosphate is oxidized to ribulose 5-phosphate.

$$\text{Glucose 6-phosphate} + 2\ \text{NADP}^+ + \text{H}_2\text{O} \rightarrow$$
$$\text{ribulose 5-phosphate} + 2\ \text{NADPH} + 2\ \text{H}^+ + \text{CO}_2$$

2. *The nonoxidative interconversion of sugars.* In the nonoxidative phase, the pathway catalyzes the interconversion of three-, four-, five-, six-, and seven-carbon sugars in a series of nonoxidative reactions. Excess five-carbon sugars may be converted into intermediates of the glycolytic pathway. These interconversions rely on the same reactions that lead to the regeneration of ribulose 1,5-bisphosphate in the Calvin–Benson cycle.

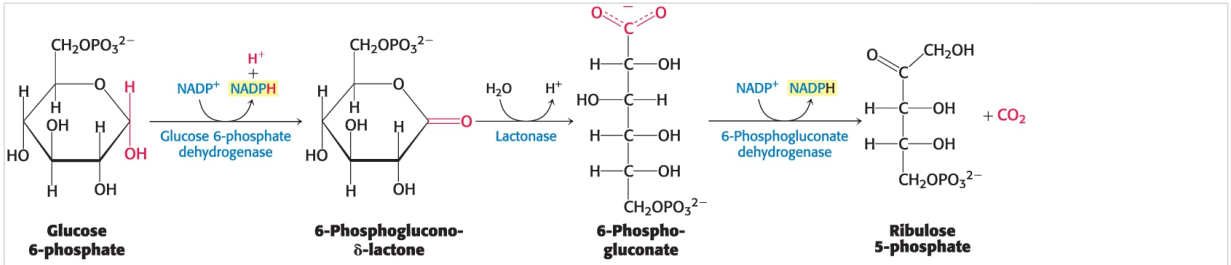
EXPLORE this pathway further in the Metabolic Map in Achieve

Two molecules of NADPH are generated in the conversion of glucose 6-phosphate into ribulose 5-phosphate

The oxidative phase of the pentose phosphate pathway starts with the dehydrogenation of glucose 6-phosphate at carbon 1, a reaction catalyzed by glucose 6-phosphate dehydrogenase (Figure 20.22). This enzyme is highly specific for $NADP^+$; the K_M for NAD^+ is about a thousand times as great as that for $NADP^+$.

The product is 6-phosphoglucono-δ-lactone, which is an intramolecular ester between the C-1 carboxyl group and the C-5 hydroxyl group. The next step is the hydrolysis of 6-phosphoglucono-δ-lactone by a specific lactonase to give 6-phosphogluconate. This six-carbon sugar acid is then oxidatively decarboxylated by 6-phosphogluconate dehydrogenase to yield ribulose 5-phosphate. $NADP^+$ is again the electron acceptor.



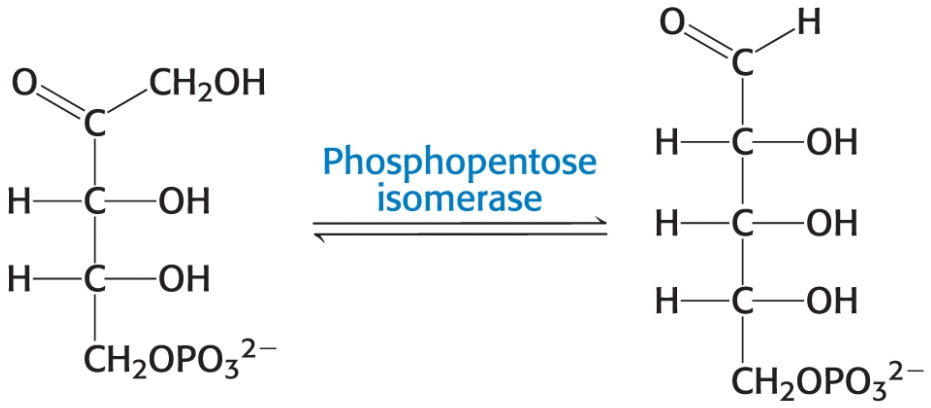


FIGURE 20.22 The oxidative phase of the pentose phosphate pathway yields two molecules of NADPH. Glucose 6-phosphate is oxidized to 6-phosphoglucono-δ-lactone to generate one molecule of NADPH. The lactone product is hydrolyzed to 6-phosphogluconate, which is oxidatively decarboxylated to ribulose 5-phosphate with the generation of a second molecule of NADPH.

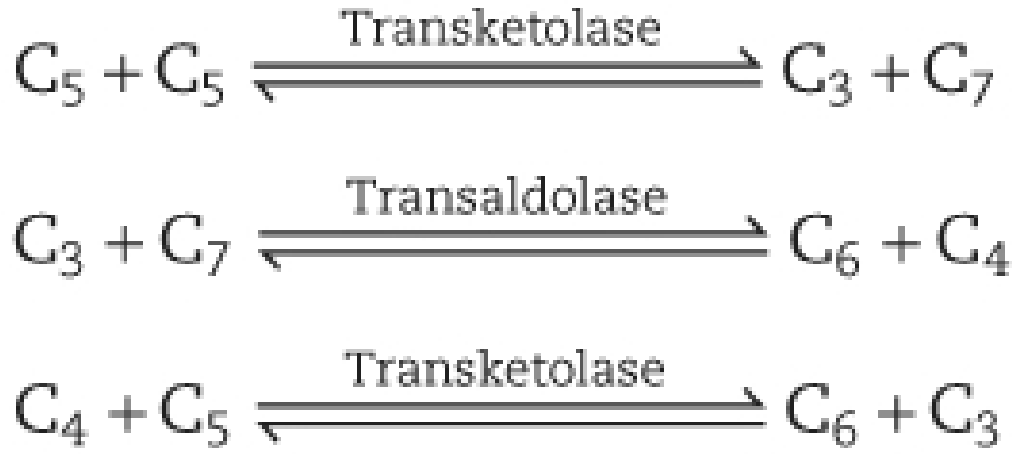
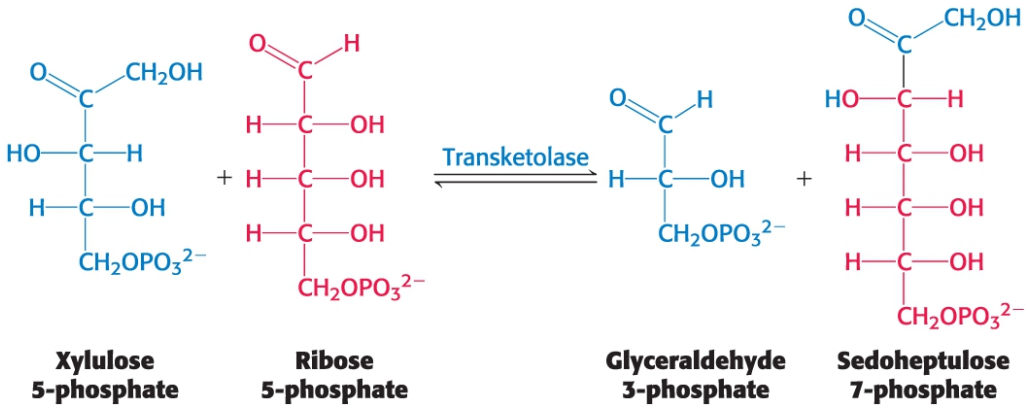
EXPLORE this pathway further in the Metabolic Map in Achieve



The pentose phosphate pathway and glycolysis are linked by transketolase and transaldolase

The preceding reactions yield two molecules of NADPH and one molecule of ribulose 5-phosphate for each molecule of glucose 6-phosphate oxidized. The ribulose 5-phosphate is subsequently isomerized to ribose 5-phosphate by phosphopentose isomerase.

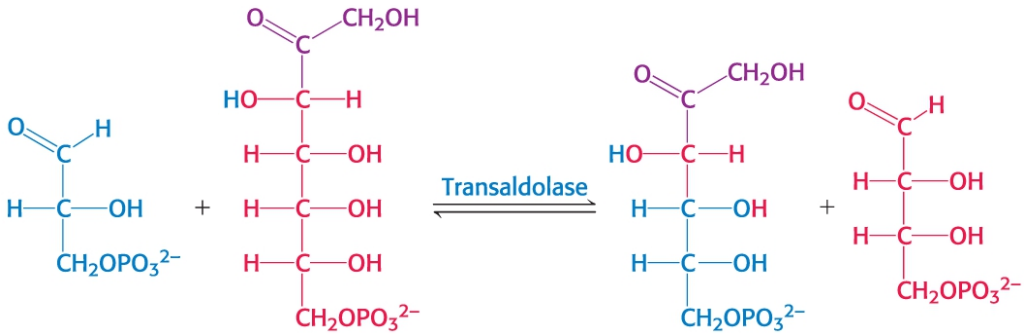
Ribulose 5-phosphate **Ribose 5-phosphate**



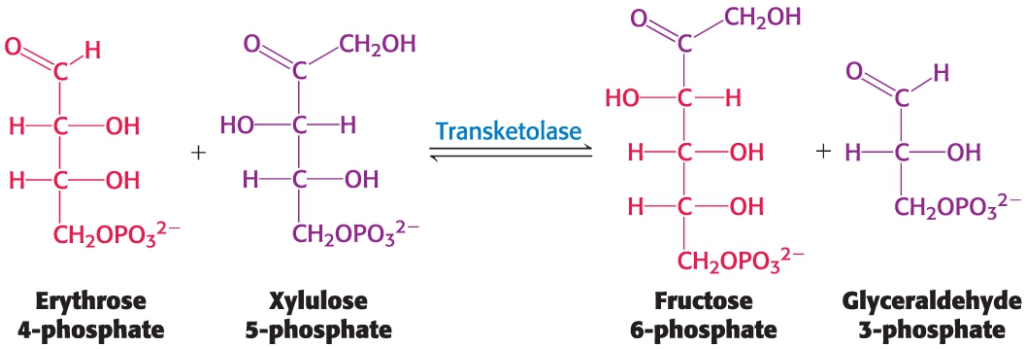
Ribose 5-phosphate and its derivatives are components of RNA and DNA, as well as of ATP, NADH, FAD, and coenzyme A. Although ribose 5-phosphate is a precursor to many biomolecules, many cells need NADPH for reductive biosyntheses much more than they need ribose 5-phosphate for incorporation into nucleotides. For instance, adipose tissue, the liver, and mammary glands require large amounts of NADPH for fatty acid synthesis. In these cases, ribose 5-phosphate is converted into the glycolytic intermediates glyceraldehyde 3-phosphate and fructose 6-phosphate by transketolase and transaldolase. These enzymes create a reversible link between the pentose phosphate pathway and glycolysis by catalyzing three successive reactions:

The net result of these reactions is the formation of two hexoses and one triose from three pentoses:

The first of the three reactions linking the pentose phosphate pathway and glycolysis is the formation of glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate from two pentoses.



The donor of the two-carbon unit in this reaction is xylulose 5-phosphate, an epimer of ribulose 5-phosphate. A ketose is a substrate of transketolase only if its hydroxyl group at C-3 has the configuration of xylulose rather than ribulose. Ribulose 5-phosphate is converted into the appropriate epimer for the transketolase reaction by phosphopentose epimerase in the reverse reaction of that which takes place in the Calvin–Benson cycle.



Ribulose 5-phosphate **Xylulose 5-phosphate**

Glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate generated by the transketolase then react to form fructose 6-phosphate and erythrose 4-phosphate. This synthesis of a four-carbon sugar and a six-carbon sugar is catalyzed by transaldolase.

Glyceraldehyde 3-phosphate **Sedoheptulose 7-phosphate** **Fructose 6-phosphate** **Erythrose 4-phosphate**

In the third reaction, transketolase catalyzes the synthesis of fructose 6-phosphate and glyceraldehyde 3-phosphate from erythrose 4-phosphate and xylulose 5-phosphate.

The sum of these reactions is

$$2\ \text{Xylulose 5-phosphate} + \text{ribose 5-phosphate} \rightleftharpoons 2\ \text{fructose 6-phosphate} + \text{glyceraldehyde 3-phosphate}$$

Xylulose 5-phosphate can be formed from ribose 5-phosphate by the sequential action of phosphopentose isomerase and phosphopentose epimerase, and so the net reaction starting from ribose 5-phosphate is

$$3\ \text{Ribose 5-phosphate} \rightleftharpoons 2\ \text{fructose 6-phosphate} + \text{glyceraldehyde 3-phosphate}$$

Thus, excess ribose 5-phosphate formed by the pentose phosphate pathway can be completely converted into glycolytic intermediates. Moreover, any ribose ingested in the diet can be processed into glycolytic intermediates by this pathway. The carbon skeletons of sugars can be extensively rearranged to meet physiological needs (Table 20.3).

	Transaldolase
	Transketolase

Transketolase and transaldolase stabilize carbanionic intermediates by different mechanisms

The reactions catalyzed by transketolase and transaldolase are distinct, yet similar in many ways. One difference is that transketolase transfers a two-carbon unit, whereas transaldolase transfers a three-carbon unit. Each of these units is transiently attached to the enzyme in the course of the reaction, and thus, these enzymes are examples of double displacement reactions.

Transketolase reaction

Transketolase contains a tightly bound thiamine pyrophosphate as its prosthetic group. The enzyme transfers a two-carbon glycoaldehyde from a ketose donor to an aldose acceptor. The site of the addition of the two-carbon unit is the thiazole ring of thiamine pyrophosphate (TPP).

Transketolase is homologous to the E_1 subunit of the pyruvate dehydrogenase complex, and the reaction mechanism is similar (**Figure 20.23**), proceeding as follows:

1. The C-2 carbon atom of bound TPP readily ionizes to give a carbanion.
2. The negatively charged carbon atom of this reactive intermediate attacks the carbonyl group of the ketose substrate.
3. The resulting addition compound releases the aldose product to yield an activated glycoaldehyde unit.
4. The positively charged nitrogen atom in the thiazole ring acts as an electron sink in the development of this activated intermediate. The carbonyl group of a suitable aldose acceptor then condenses with the activated glycoaldehyde unit to form a new ketose.
5. The ketose is then released from the enzyme.

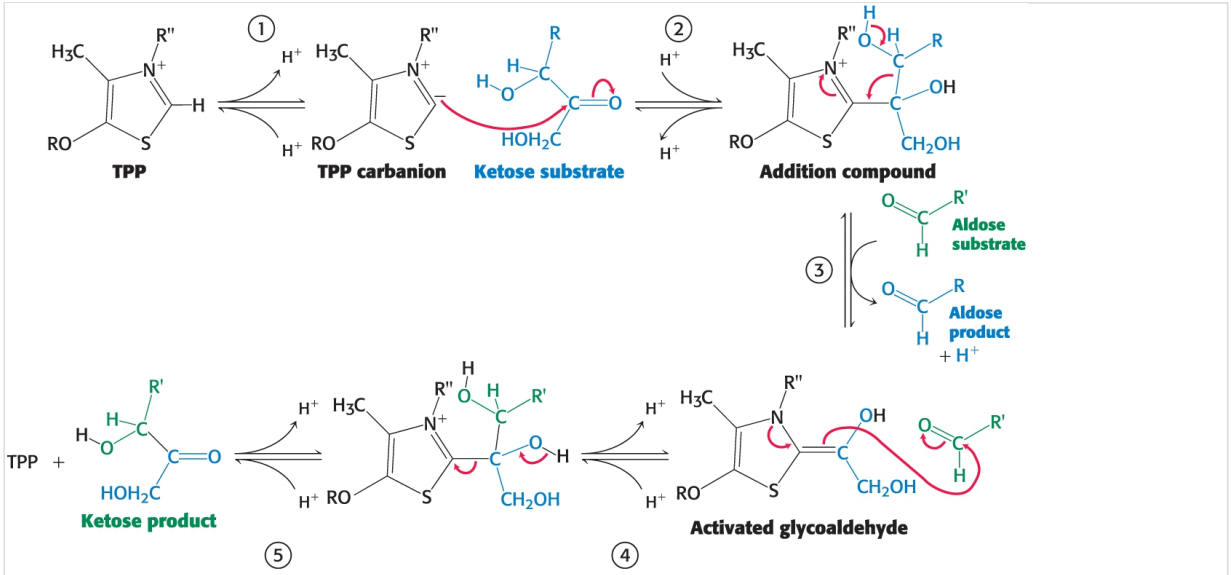

FIGURE 20.23 The transketolase reaction takes place on thiamine pyrophosphate. (1) Thiamine pyrophosphate (TPP) ionizes to form a carbanion. (2) The carbanion of TPP attacks the ketose substrate. (3) Cleavage of a carbon–carbon bond frees the aldose product and leaves a two-carbon fragment joined to TPP. (4) This activated glycoaldehyde intermediate attacks the aldose substrate to form a new carbon–carbon bond. (5) The ketose product is released, freeing the TPP for the next reaction cycle.

Transaldolase reaction

Transaldolase transfers a three-carbon dihydroxyacetone unit from a ketose donor to an aldose acceptor. Transaldolase, in contrast to transketolase, does not contain a prosthetic group. Rather, a Schiff base is formed between the carbonyl group of the ketose substrate and the ε-amino group of a lysine residue at the active site of the enzyme (Figure 20.24). This kind of covalent enzyme–substrate intermediate is like that formed in fructose 1,6-bisphosphate aldolase in the glycolytic pathway and, indeed, the enzymes are homologous. The reaction proceeds as follows:

1. The first step is the formation of the Schiff base.
2. The Schiff base becomes protonated and the bond between C-3 and C-4 is split.
3. Upon reprotonation, the aldose product is released, leaving a three-carbon fragment bound to the enzyme. The negative charge on the Schiff-base carbanion moiety is stabilized by resonance (Figure 20.24). The positively charged nitrogen atom of the protonated Schiff base acts as an electron sink.

4. The Schiff-base adduct is stable until a suitable aldose becomes bound.

5. The dihydroxyacetone moiety then reacts with the carbonyl group of the aldose. Protonation allows the formation of a new carbon–carbon bond.

6. Subsequent deprotonation occurs.

7. Following deprotonation, hydrolysis of the Schiff base releases the ketose product.

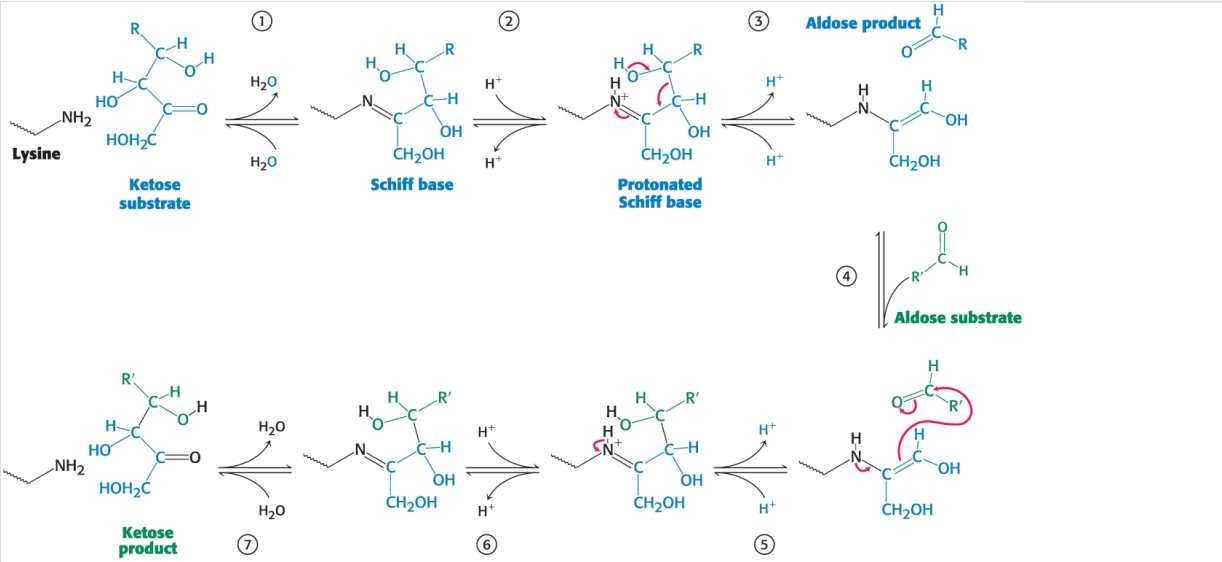

FIGURE 20.24 The transaldolase reaction involves a Schiff base intermediate. (1) The reaction begins with the formation of a Schiff base between a lysine residue in transaldolase and the ketose substrate. (2) Protonation of the Schiff base occurs. (3) Deprotonation leads to the release of the aldose product, leaving a three-carbon fragment attached to the lysine residue. (4) This intermediate adds to the aldose substrate. (5) Protonation occurs, forming a new carbon–carbon bond. (6) Subsequent deprotonation and (7) hydrolysis of the Schiff base releases the ketose product from the lysine side chain, completing the reaction cycle.

The nitrogen atom of the protonated Schiff base plays the same role in transaldolase as the thiazole-ring nitrogen atom does in transketolase. In each enzyme, a group within an intermediate reacts like a carbanion in attacking a carbonyl group to form a new carbon–carbon bond. In each case, the charge on the carbanion is stabilized by resonance (Figure 20.25).

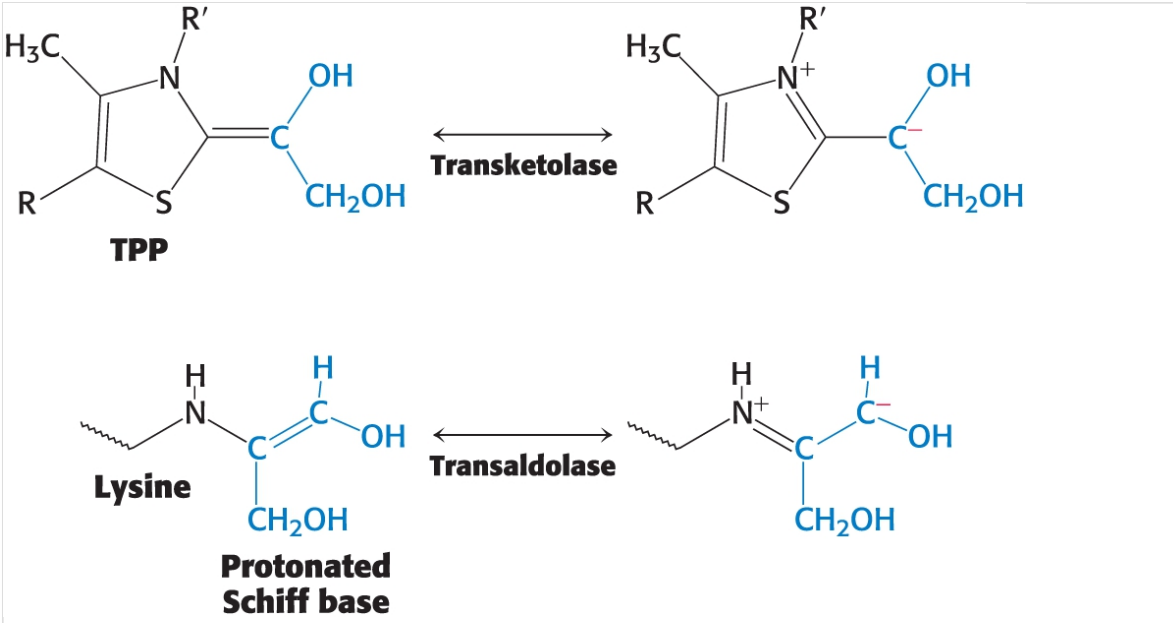

FIGURE 20.25 For transketolase and transaldolase, a carbanion intermediate is stabilized by resonance. In transketolase, TPP stabilizes this intermediate; in transaldolase, a protonated Schiff base plays this role.

20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis

Glucose 6-phosphate is metabolized by both the glycolytic pathway and the pentose phosphate pathway. How is the processing of this important metabolite partitioned between these two metabolic routes? The cytoplasmic concentration of $NADP^+$ plays a key role in determining the fate of glucose 6-phosphate.

The rate of the oxidative phase of the pentose phosphate pathway is controlled by the level of $NADP^+$

The first reaction in the oxidative branch of the pentose phosphate pathway — the dehydrogenation of glucose 6-phosphate — is essentially irreversible. In fact, this reaction is rate limiting under physiological conditions and serves as the control site for the oxidative branch of the pathway. The most important regulatory factor is the level of $NADP^+$. Low levels of $NADP^+$ limit the dehydrogenation of glucose 6-phosphate because it is needed as the electron acceptor. The effect of low levels of $NADP^+$ is intensified by the fact that NADPH competes with $NADP^+$ in binding to the

enzyme. The ratio of $NADP^+$ to NADPH in the cytoplasm of a liver cell from a well-fed rat is about 0.014.

The marked effect of the $NADP^+$ level on the rate of the oxidative phase ensures that NADPH is not generated unless the supply needed for reductive biosyntheses or protection against oxidative stress is low. The nonoxidative phase of the pentose phosphate pathway is controlled primarily by the availability of substrates.

The flow of glucose 6-phosphate depends on the need for NADPH, ribose 5-phosphate, and ATP

We can grasp the intricate interplay between glycolysis and the pentose phosphate pathway by examining the metabolism of glucose 6-phosphate in four different metabolic situations (**Figure 20.26**).

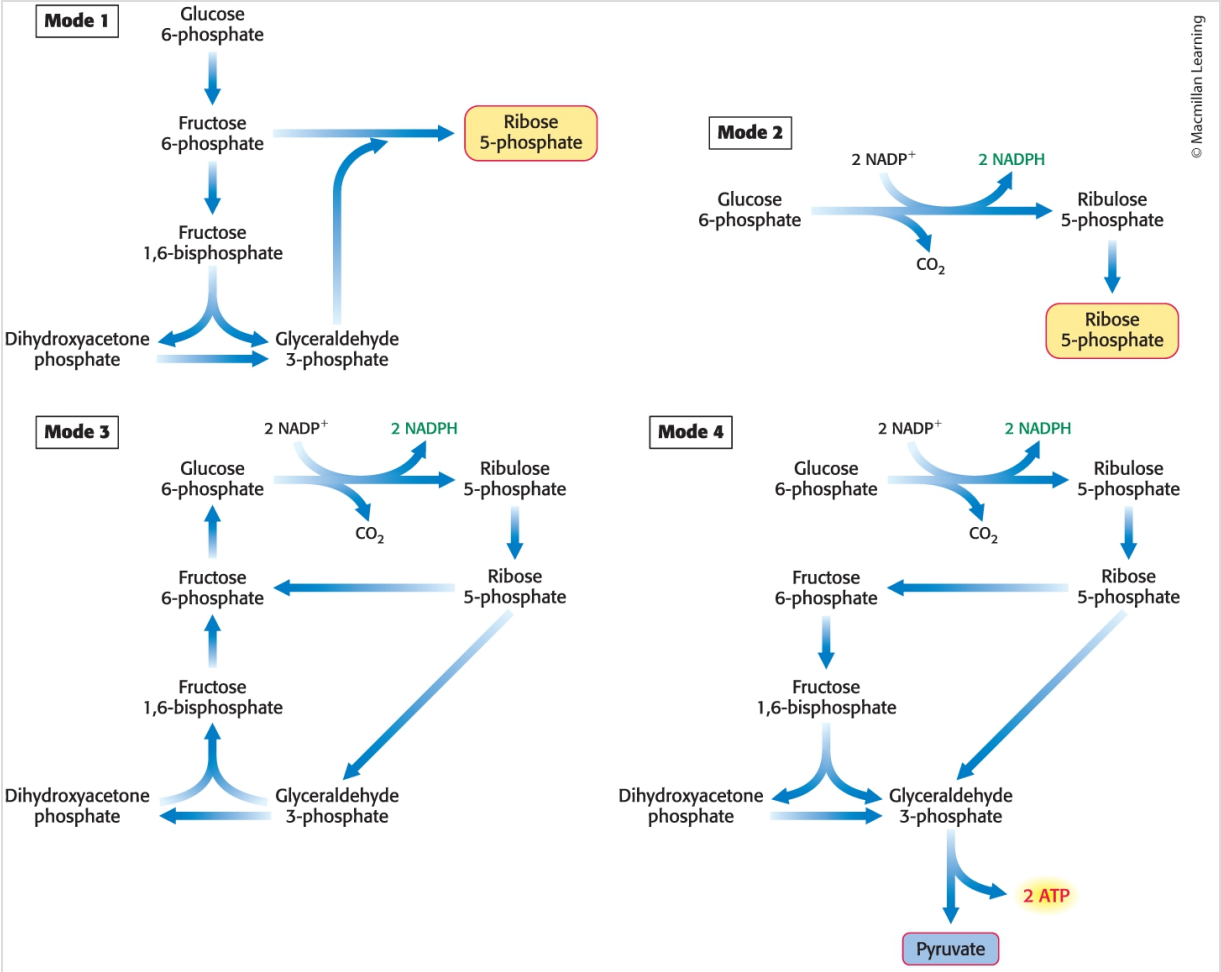

FIGURE 20.26 The pentose phosphate pathway can operate in four modes. Major products are shown in color.

EXPLORE this pathway further in the Metabolic Map in Achieve

Mode 1

Much more ribose 5-phosphate than NADPH is required. For example, rapidly dividing cells need ribose 5-phosphate for the synthesis of nucleotide precursors of DNA. Most of the glucose 6-phosphate is converted into fructose 6-phosphate and glyceraldehyde 3-

phosphate by the glycolytic pathway. Transaldolase and transketolase then convert two molecules of fructose 6-phosphate and one molecule of glyceraldehyde 3-phosphate into three molecules of ribose 5-phosphate by a reversal of the reactions described earlier. The stoichiometry of mode 1 is

$$5\ \text{Glucose 6–phosphate} + \text{ATP} \rightarrow 6\ \text{ribose 5–phosphate} + \text{ADP} + H^+$$

Mode 2

The needs for NADPH and for ribose 5-phosphate are balanced. Under these conditions, glucose 6-phosphate is processed to one molecule of ribulose 5-phosphate while generating two molecules of NADPH. Ribulose 5-phosphate is then converted into ribose 5-phosphate. The stoichiometry of mode 2 is

$$\text{Glucose 6–phosphate} + 2\ NADP^+ + H_2O \rightarrow$$
$$\text{ribose 5–phosphate} + 2\ NADPH + 2\ H^+ + CO_2$$

Mode 3

Much more NADPH than ribose 5-phosphate is required. For example, adipose tissue requires a high level of NADPH for the synthesis of fatty acids (**Table 20.4**). In this case, glucose 6-phosphate is completely oxidized to CO_2.

TABLE 20.4 Tissues with active pentose phosphate pathways

Tissue	Function
Adrenal gland	Steroid synthesis
Liver	Fatty acid and cholesterol synthesis
Testes	Steroid synthesis
Adipose tissue	Fatty acid synthesis
Ovary	Steroid synthesis
Mammary gland	Fatty acid synthesis
Red blood cells	Maintenance of reduced glutathione

Three groups of reactions are active in this situation. First, the oxidative phase of the pentose phosphate pathway forms two molecules of NADPH and one molecule of ribulose 5-phosphate. Then, ribulose 5-phosphate is converted into fructose 6-phosphate and glyceraldehyde 3-phosphate by transketolase and transaldolase. Finally, glucose 6-phosphate is resynthesized from fructose 6-phosphate and glyceraldehyde 3-phosphate by the gluconeogenic pathway. The stoichiometries of these three sets of reactions are

$$6\ \text{Glucose 6–phosphate} + 12\ NADP^+ + 6\ H_2O \rightarrow$$
$$6\ \text{Ribose 5–phosphate} + 12\ NADPH + 12\ H^+ + 6\ CO_2$$
$$6\ \text{Ribose 5–phosphate} \rightarrow$$
$$4\ \text{Fructose 6–phosphate} + 2\ \text{glyceraldehyde 3–phosphate}$$
$$4\ \text{Fructose 6–phosphate} + 2\ \text{glyceraldehyde 3–phosphate} + H_2O \rightarrow$$
$$5\text{–Glucose 6–phosphate} + P_i$$

The sum of the mode 3 reactions is

$$\text{Glucose 6–phosphate} + 12\ NADP^+ + 7\ H_2O \rightarrow 6\ CO_2 + 12\ NADPH + 12\ H^+ + P_i$$

Thus, the equivalent of glucose 6-phosphate can be completely oxidized to CO_2 with the concomitant generation of NADPH. In essence, ribose 5-phosphate produced by the pentose phosphate pathway is recycled into glucose 6-phosphate by transketolase, transaldolase, and some of the enzymes of the gluconeogenic pathway.

Mode 4

Both NADPH and ATP are required. Alternatively, ribulose 5-phosphate formed from glucose 6-phosphate can be converted into pyruvate. Fructose 6-phosphate and glyceraldehyde 3-phosphate derived from ribose 5-phosphate enter the glycolytic pathway rather than reverting to glucose 6-phosphate. In this mode, ATP and NADPH are concomitantly generated, and five of the six carbons of glucose 6-phosphate emerge in pyruvate.

$$3\ \text{Glucose 6–phosphate} + 6\ NADP^+ + 5\ NAD^+ + 5\ P_i + 8\ ADP \rightarrow$$
$$5\ \text{pyruvate} + 3\ CO_2 + 6\ NADPH + 5\ NADH + 8\ ATP + 2\ H_2O + 8\ H^+$$

Pyruvate formed by these reactions can be oxidized to generate more ATP, or it can be used as a building block in a variety of biosyntheses.

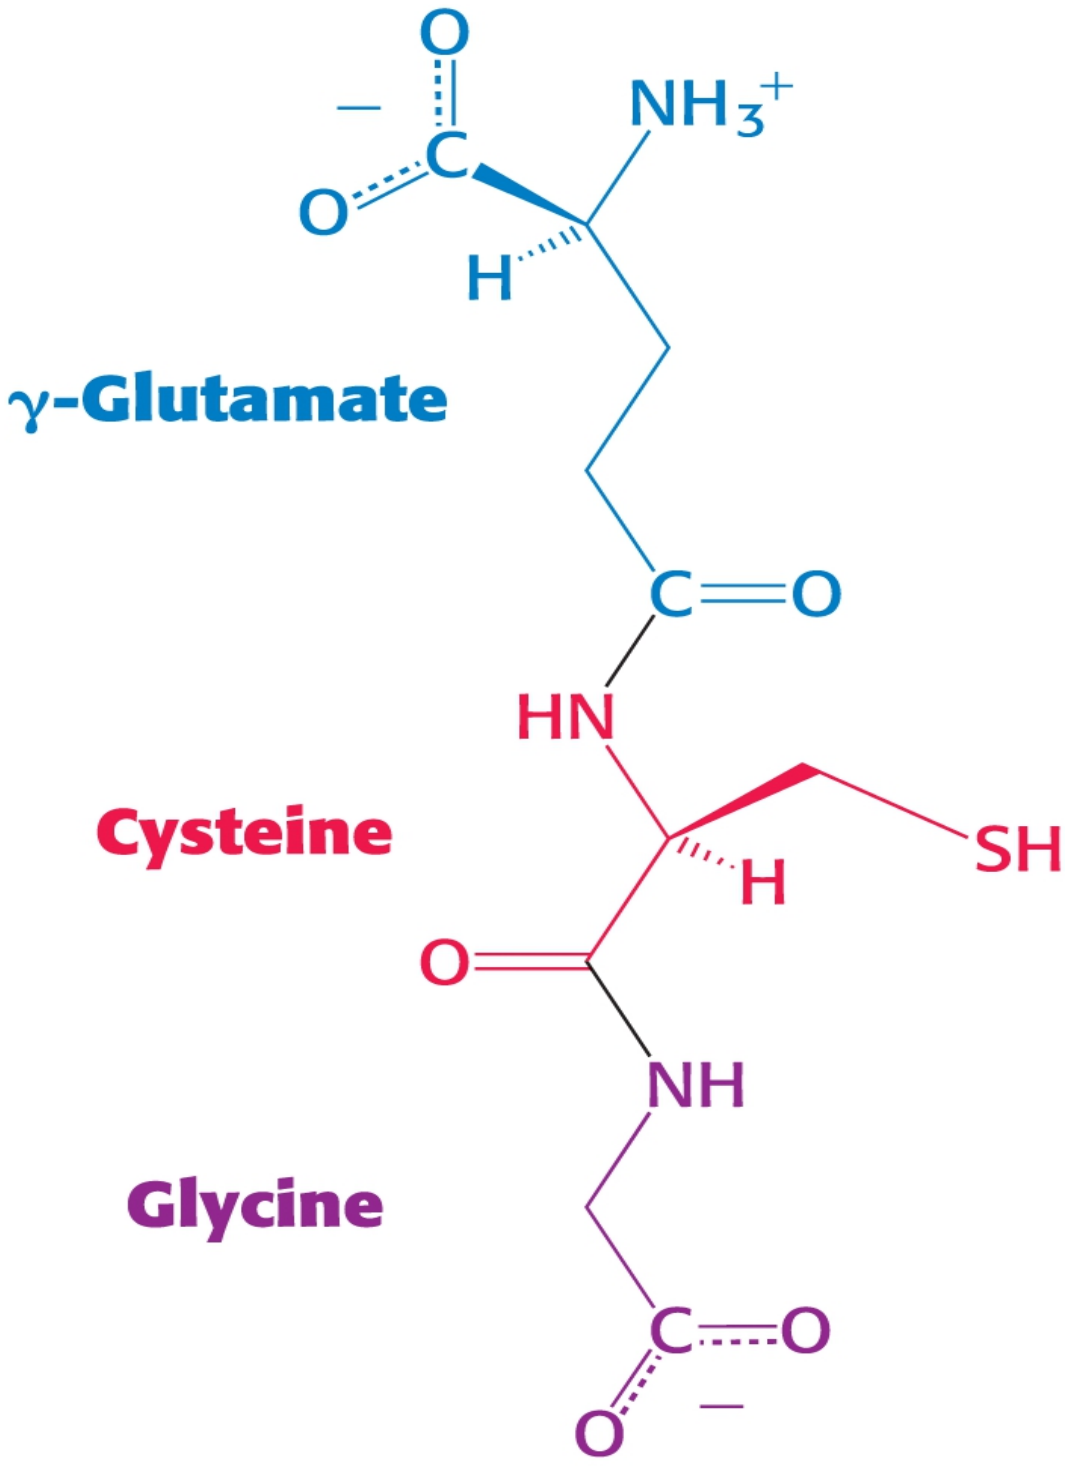
The pentose phosphate pathway is required for rapid cell growth

Rapidly dividing cells, such as cancer cells, require ribose 5-phosphate for nucleic acid synthesis and NADPH for fatty acid synthesis, which in turn is required to form membrane lipids. Recall that rapidly dividing cells switch to aerobic glycolysis to meet their ATP needs. Glucose 6-phosphate and glycolytic intermediates are then used to generate NADPH and ribose 5-phosphate using the nonoxidative phase of the pentose phosphate pathway.

The diversion of glycolytic intermediates into the nonoxidative phase is facilitated by the expression of the gene for a pyruvate kinase isozyme, PKM. PKM has a low catalytic activity, creating a bottleneck in the glycolytic pathway. Glycolytic intermediates accumulate and are then used by the pentose phosphate pathway to synthesize NADPH and ribose 5-phosphate. The shunting of phosphorylated intermediates into the nonoxidative phase of the pentose phosphate pathway is further enabled by the inhibition of triose phosphate isomerase by phosphoenolpyruvate, the substrate of PKM.

The Calvin–Benson cycle and the pentose phosphate pathway are essentially mirror images of one another

The complexities of the Calvin–Benson cycle and the pentose phosphate pathway are easier to comprehend if we consider them as functional mirror images of each other. The Calvin–Benson cycle begins with the fixation of CO_2 and proceeds to use NADPH in the synthesis of glucose. The pentose phosphate pathway begins with the oxidation of a glucose-derived carbon atom to CO_2 and concomitantly generates NADPH. The regeneration phase of the Calvin–Benson cycle converts C_6 and C_3 molecules back into the starting material — the C_5 molecule ribulose 1,5-bisphosphate. The pentose phosphate pathway converts a C_5 molecule, ribulose 5-phosphate, into C_6 and C_3 intermediates of the glycolytic pathway. Not surprisingly, in photosynthetic organisms, many enzymes are common to the two pathways. We see here the economy of evolution: the use of identical enzymes for similar reactions with different ends.

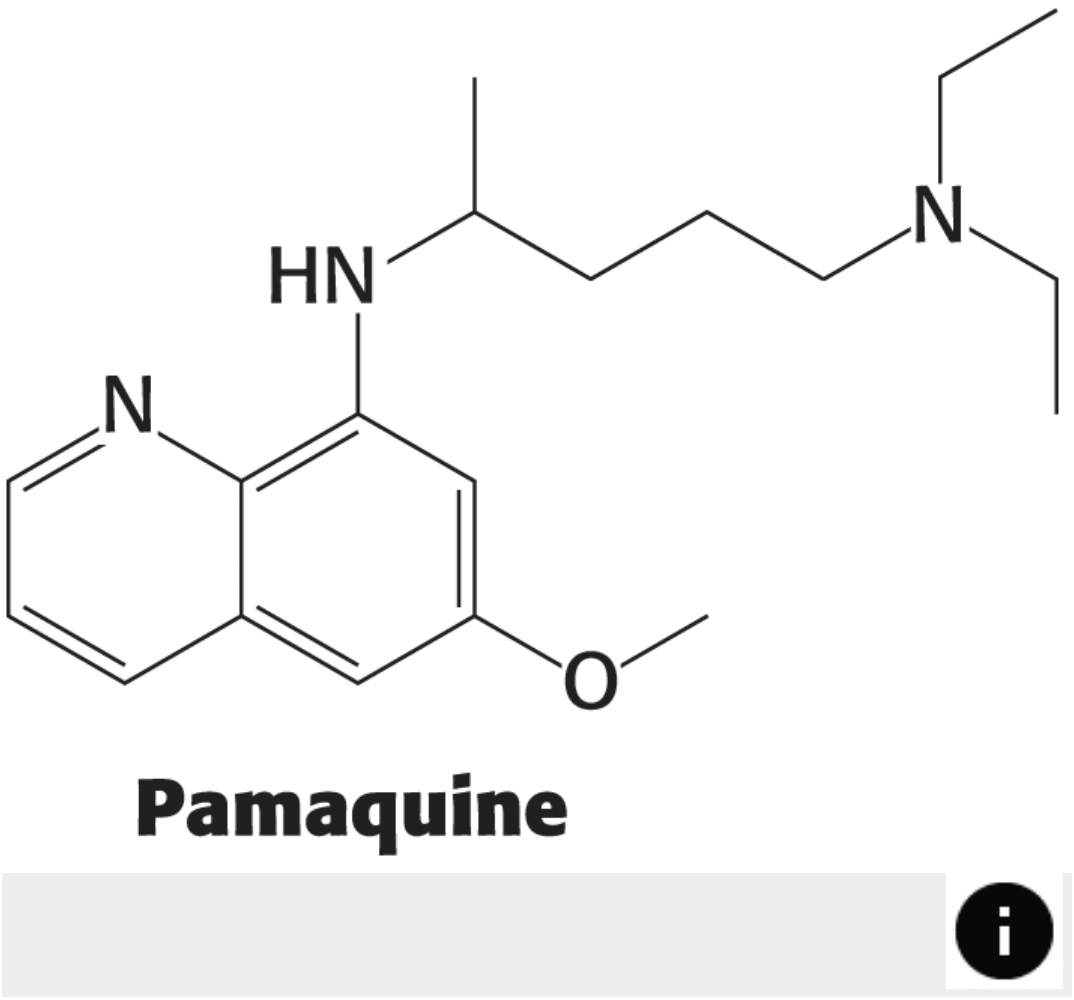


Self-Check Question

Name a reaction in the pentose phosphate pathway that involves erythrose 4-phosphate, and name the associated enzyme. Which reaction in the Calvin–Benson cycle involves erythrose 4-phosphate and the same enzyme?

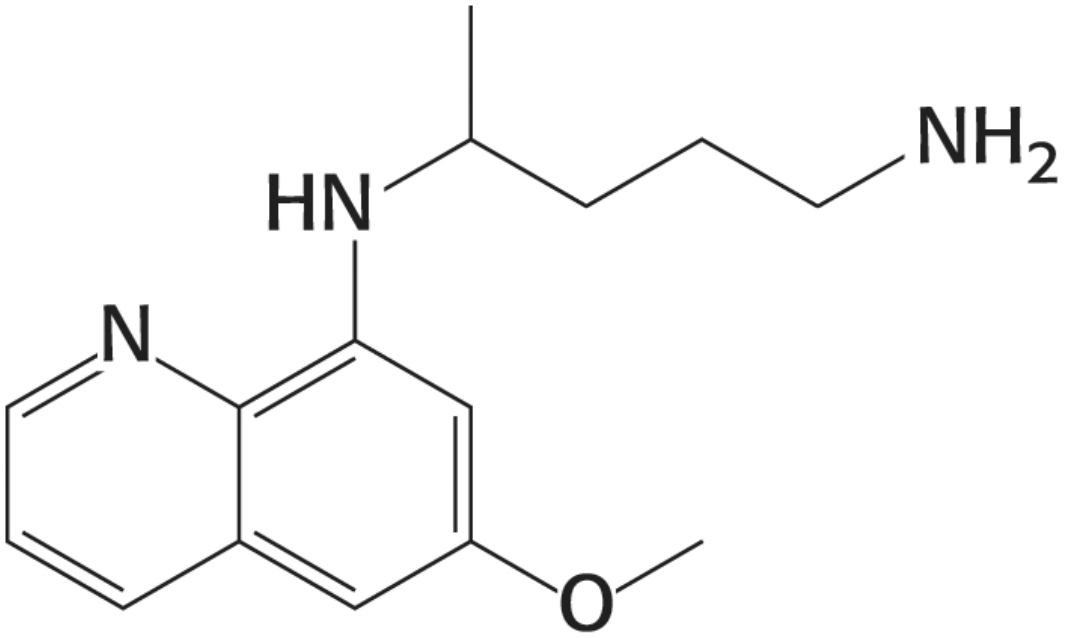
20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

The NADPH generated by the pentose phosphate pathway plays a vital role in protecting the cells from reactive oxygen species (ROS). Reactive oxygen species generated in oxidative metabolism inflict damage on all classes of macromolecules and can ultimately lead to cell death. Indeed, ROS are implicated in a number of human diseases, such as diabetes. Reduced **glutathione** (GSH), a tripeptide with a free sulfhydryl group, combats oxidative stress by reducing ROS to harmless forms. Its task accomplished, the glutathione is now in the oxidized form (GSSG) and must be reduced to regenerate GSH. The reducing power is supplied by the NADPH generated by glucose 6-phosphate dehydrogenase in the pentose phosphate pathway. Indeed, cells with reduced levels of glucose 6-phosphate dehydrogenase are especially sensitive to oxidative stress.



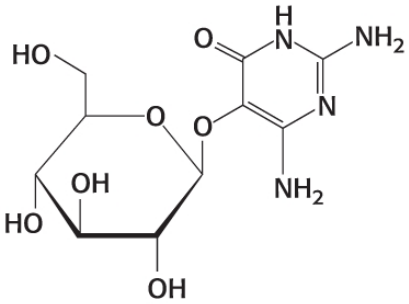
Glutathione (reduced)
(γ-Glutamylcysteinylglycine)

Glucose 6-phosphate dehydrogenase deficiency causes a drug-induced hemolytic anemia



The importance of the pentose phosphate pathway is highlighted by some people's atypical responses to certain drugs. For instance, pamaquine, the first synthetic antimalarial drug introduced in 1926, was associated with the appearance of severe and mysterious ailments. Most patients tolerated the drug well, but a few developed severe symptoms within a few days after therapy was started. Their urine turned black, jaundice developed, and the hemoglobin content of the blood dropped sharply. In some cases, massive destruction of red blood cells caused death.

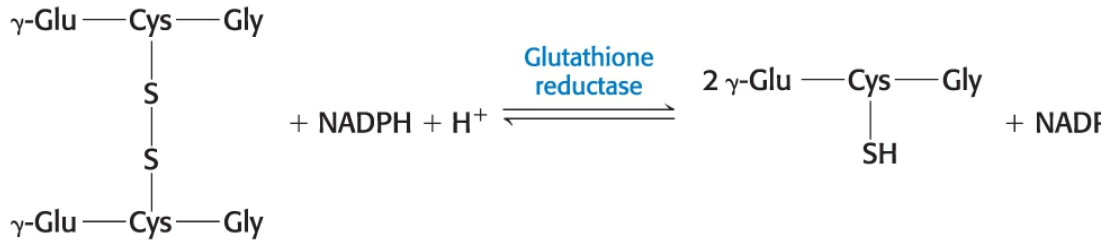
This drug-induced hemolytic anemia was shown 30 years later to be caused by a deficiency of glucose 6-phosphate dehydrogenase, the enzyme catalyzing the first step in the oxidative branch of the pentose phosphate pathway. The result is a dearth of NADPH in all cells, but this deficiency is most acute in red blood cells because they lack mitochondria and have no alternative means of generating reducing power. This defect, which is inherited on the X chromosome, is the most common condition that results from an enzyme malfunction, affecting hundreds of millions of people.



Pamaquine sensitivity is not simply a historical oddity about malaria treatment many decades ago. Primaquine, an antimalarial closely related to pamaquine, is widely used in malaria-prone regions of the world. Vicine, a pyrimidine glycoside of fava beans (**Figure 20.27**), can

also induce hemolysis. People deficient in glucose 6-phosphate dehydrogenase suffer hemolysis from eating fava beans or inhaling the pollen of the fava flowers, a response called favism.

Primaquine



Vicine

FIGURE 20.27 Fava beans produce a pyrimidine glycoside. The Mediterranean plant *Vicia fabia* the source of fava beans that contain the pyrimidine glycoside vicine.

How can we explain hemolysis caused by pamaquine, primaquine, and vicine biochemically? These chemicals are oxidative agents that generate peroxides, reactive oxygen species that can damage membranes as well as other biomolecules. Peroxides are usually eliminated by the enzyme glutathione peroxidase, which uses reduced glutathione as a reducing agent.

$$2\ GSH + ROOH \xrightarrow{\text{Glutathione peroxidase}} GSSG + H_2O + ROH$$

The major role of NADPH in red blood cells is to reduce the disulfide form of glutathione to the sulfhydryl form. The enzyme that catalyzes the regeneration of reduced glutathione is glutathione reductase.

Oxidized glutathione (GSSG) **Reduced glutathione (GSH)**

Red blood cells with a lowered level of reduced glutathione are more susceptible to hemolysis. In the absence of glucose 6-phosphate dehydrogenase, peroxides continue to damage membranes because no

NADPH is being produced to restore reduced glutathione. Thus, the answer to our question is that glucose 6-phosphate dehydrogenase is required to maintain reduced glutathione levels to protect against oxidative stress. In the absence of oxidative stress, however, the deficiency is quite benign. The sensitivity to oxidative agents of people having this dehydrogenase deficiency also clearly demonstrates that atypical reactions to drugs may have a genetic basis.

Reduced glutathione is also essential for maintaining the normal structure of red blood cells by maintaining the structure of hemoglobin. The reduced form of glutathione serves as a sulfhydryl buffer that keeps the residues of hemoglobin in the reduced sulfhydryl form. Without adequate levels of reduced glutathione, the hemoglobin sulfhydryl groups can no longer be maintained in the reduced form. Hemoglobin molecules then cross-link with one another to form aggregates called *Heinz bodies* on cell membranes (**Figure 20.28**). Membranes damaged by Heinz bodies and reactive oxygen species become deformed, and the cell is likely to undergo lysis.

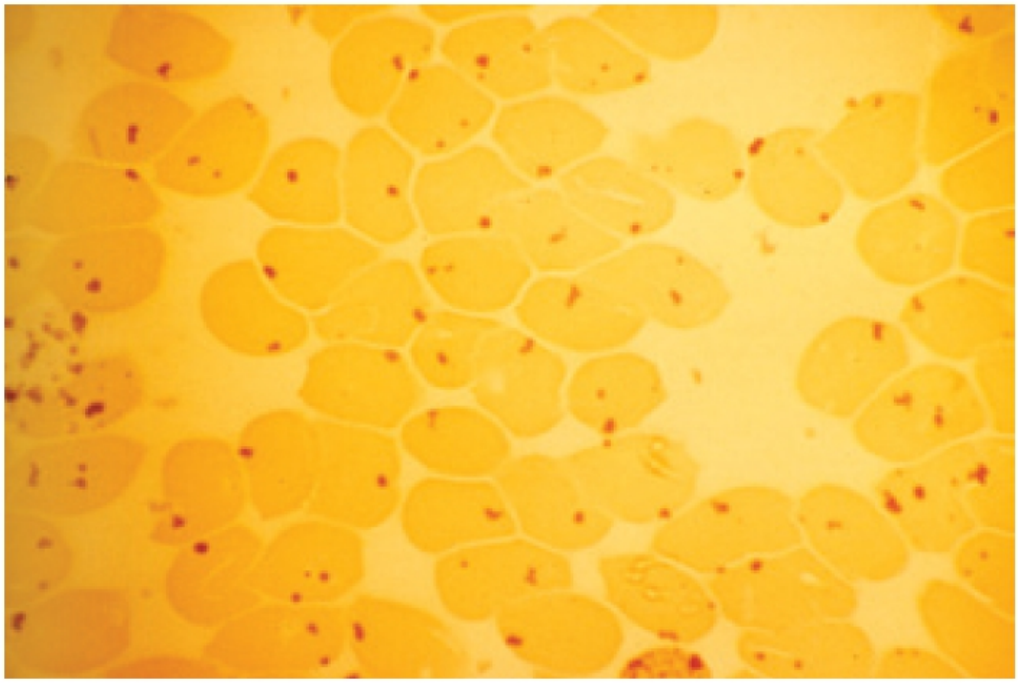


FIGURE 20.28 Heinz bodies are made of denatured hemoglobin. The light micrograph shows red blood cells obtained from a person deficient in glucose 6-

phosphate dehydrogenase. The dark particles, called Heinz bodies, inside the cells are clumps of denatured hemoglobin that adhere to the plasma membrane and stain with basic dyes. Red blood cells in such people are highly susceptible to oxidative damage.

A deficiency of glucose 6-phosphate dehydrogenase can be protective against malaria

The incidence of the most common form of glucose 6-phosphate dehydrogenase deficiency, characterized by a 10-fold reduction in enzymatic activity in red blood cells, is 11% among Americans of African heritage compared to less than 1% in Americans of European descent. This high frequency suggests that the deficiency may be advantageous under certain environmental conditions found in Africa but not Europe. Indeed, glucose 6-phosphate dehydrogenase deficiency protects against the deadliest form of malaria, which is prevalent in Africa's subtropical regions. The parasites causing this disease require NADPH for growth. Moreover, infection by the parasites induces oxidative stress in infected human cells. Because the pentose phosphate pathway is compromised, the cells and parasite die from oxidative damage. Thus, glucose 6-phosphate dehydrogenase deficiency is a mechanism of protection against malaria, which accounts for its high frequency in malaria-prone regions of the world. We see here once again the interplay of heredity and environment in the effect of drugs and diet on physiology.

The ability of glucose 6-phosphate dehydrogenase deficiency to protect against malaria does, however, create a public health conundrum. Primaquine is a commonly used and effective antimalarial drug. However, indiscriminate use of primaquine causes hemolysis in individuals deficient in glucose 6-phosphate dehydrogenase. Scientists

are actively pursuing alternative ways of addressing malaria, and the first antimalarial vaccine was approved in late 2021.

Chapter 20 Summary

20.1 The Calvin–Benson Cycle Synthesizes Hexoses from Carbon Dioxide and Water

- The dark phase of photosynthesis, called the Calvin–Benson cycle, starts with the reaction of CO_2 and ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate, in a reaction catalyzed by Rubisco.
- The steps in the conversion of 3-phosphoglycerate into fructose 6-phosphate and glucose 6-phosphate are like those of gluconeogenesis, except that glyceraldehyde 3-phosphate dehydrogenase in chloroplasts is specific for NADPH rather than NADH.
- Ribulose 1,5-bisphosphate is regenerated from fructose 6-phosphate, glyceraldehyde 3-phosphate (GAP), and dihydroxyacetone phosphate by a complex series of reactions.
- Three molecules of ATP and two molecules of NADPH are consumed for each molecule of CO_2 converted into a hexose.
- Rubisco also catalyzes a competing oxygenase reaction, which produces phosphoglycolate and 3-phosphoglycerate. The process of photorespiration recycles phosphoglycolate, which leads to the release of CO_2 and further consumption of O_2.

20.2 The Activity of the Calvin–Benson Cycle Depends on Environmental Conditions

- Reduced thioredoxin formed by the light-driven transfer of electrons from ferredoxin activates enzymes of the Calvin–Benson cycle by reducing disulfide bridges.
- The light-induced increase in pH and Mg^{2+} levels of the stroma are important in stimulating the carboxylation of ribulose 1,5-

bisphosphate by Rubisco.
- Photorespiration is minimized in tropical plants and grasses, which have an accessory pathway — the C_4 pathway — for concentrating CO_2 at the site of the Calvin–Benson cycle.
- Some plants use crassulacean acid metabolism (CAM) to prevent dehydration. In CAM plants, the C_4 pathway is active during the night; during the day, gas exchange is eliminated and CO_2 is generated from malate stored in vacuoles.

20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Pentoses

- The pentose phosphate pathway consists of two phases: an oxidative phase that generates NADPH and ribulose 5-phosphate in the cytoplasm, and a nonoxidative phase.
- In the nonoxidative phase, ribose 5-phosphate is converted into GAP and fructose 6-phosphate by transketolase and transaldolase. These two enzymes create a reversible link between the pentose phosphate pathway and glycolysis.
- When NADPH needs are paramount, fructose 6-phosphate and GAP from the nonoxidative phase are used to synthesize glucose 6-phosphate for metabolism in the oxidative phase, generating 12 molecules of NADPH for each molecule of glucose 6-phosphate that is completely oxidized to CO_2.

20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis

- Only the nonoxidative branch of the pathway is significantly active when much more ribose 5-phosphate than NADPH must be synthesized.
- Under these conditions, fructose 6-phosphate and GAP are converted into ribose 5-phosphate without the formation of NADPH. Alternatively, ribose 5-phosphate formed by the

oxidative branch can be converted into pyruvate through fructose 6-phosphate and GAP. In this mode, ATP and NADPH are generated.
- The interplay of the glycolytic and pentose phosphate pathways enables the levels of NADPH, ATP, and building blocks such as ribose 5-phosphate and pyruvate to be continuously adjusted to meet cellular needs.

20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

- NADPH generated by glucose 6-phosphate dehydrogenase maintains the appropriate levels of reduced glutathione required to combat oxidative stress, and it ensures the proper reducing environment in the cell.
- Cells with diminished glucose 6-phosphate dehydrogenase activity are especially sensitive to oxidative stress.

Problems

1. In chloroplasts, glyceraldehyde 3-phosphate dehydrogenase uses NADPH as a cofactor in the synthesis of glucose. In cytoplasmic gluconeogenesis, however, the isozyme of this dehydrogenase uses NADH. Why is it advantageous for the enzyme in the chloroplast to use NADPH? 1

a. NADPH is harmful to chloroplasts when levels become too high.
b. NADPH is abundant in chloroplasts, because it is generated by the light reactions.
c. The presence of NADH increases the rate of wasteful photorespiration.

2. Arrange the steps to outline the Calvin–Benson cycle (first stage to last stage) 1

a. Conversion of 3-phosphoglycerate into hexose
b. Regeneration of ribulose 1,5-bisphosphate
c. Fixation of CO_2 with ribulose 1,5-bisphosphate
d. Formation of 3-phosphoglycerate

3. Match each characteristic to either the Calvin–Benson cycle or the Krebs cycle. 1

a. Matrix
b. Requires high-energy electrons from NADPH
c. Regenerates ribose 1,5-bisphosphate

d. Regenerates oxaloacetate
e. Releases CO_2
f. Stroma
g. Carbon chemistry for photosynthesis
h. Fixes CO_2
i. Harvests high-energy electrons to form NADH
j. Carbon chemistry for cellular respiration

4. What statement best describes photorespiration? 1

a. Plants transform light energy into ATP.
b. Plants consume NADPH to reduce carbon atoms.
c. Plants consume O_2 and release CO_2.
d. Plants oxidize glucose to generate NADPH.

5. Rubisco catalyzes both a carboxylase reaction and a wasteful oxygenase reaction. Use the kinetic parameters for the two reactions in the table to determine the specificity constant, k_{cat}/K_M, for each substrate in units of $M^{-1}s^{-1}$. 1

Substrate	$k_{cat}(s^{-1})$	$K_M(mM)$
CO_2	3	10
O_2	2	500

6. Which of the following stromal changes occur in response to light that regulate the Calvin–Benson cycle? 2

a. Increased pH
b. Increased levels of Mg^{2+}

c. Decreased levels of carbamate
d. Decreased concentration of NADPH
e. Increased amounts of the reduced form of ferredoxin

7. Rubisco requires a molecule of CO_2 covalently bound to lysine 201 for catalytic activity. The carboxylation of Rubisco is favored by high pH and high Mg^{2+} concentration in the stroma. Why does it make physiological sense for these conditions to favor Rubisco carboxylation? 2

a. They are present when the light reactions occur.
b. They are the normal environment in the stroma.
c. They are present in the dark, when Calvin–Benson cycle reactions occur.
d. They concentrate CO_2 and prevent photorespiration.

8. The enzyme ribose 5-phosphate isomerase catalyzes the conversion between ribose 5-phosphate (R5P) and ribulose 5-phosphate (Ru5P) through an enediolate intermediate. In the Calvin–Benson cycle, Ru5P is used to replenish ribulose 1,5-bisphosphate, a substrate for Rubisco.

For the conversion of R5P to Ru5P, if $G^{\circ\prime} = 0.460\ \text{kJ/mol}$ and $\Delta G = 3.80\ \text{kJ/mol}$, what is the ratio of Ru5P to R5P at 298 K? Which of the statements is true?

a. This reaction is favorable, and it is likely regulated.
b. This reaction is not favorable, and it is likely regulated.
c. This reaction is favorable, and it is not likely regulated.
d. This reaction is not favorable, and it is not likely regulated.

9. Which phrases describe the light reactions of photosynthesis, which describe the Calvin–Benson cycle, and which describe both? 2

a. Capture light energy using chlorophyll
b. Use CO_2
c. Require water
d. Take place in the chloroplasts of plants
e. Generate oxygen gas
f. Synthesize ATP and NADPH
g. Produce sugars
h. Need ribulose 1,5-bisphosphate

10. The Calvin–Benson cycle must repeat six times in order for a cell to have enough material to construct a complete glucose molecule. A variety of molecules are used and produced during this process. Sort the molecules into three categories: molecules brought in and used in six turns of the Calvin–Benson cycle, molecules produced during six turns of the Calvin–Benson cycle that leave the cycle, and molecules used and regenerated within the Calvin–Benson cycle during six turns. 1

a. 18 ATP
b. 18 ADP
c. 6 Ribulose 1,5-bisphosphate
d. 12 NADPH
e. $12\ NADP^+ + 12\ H^+$
f. $6\ CO_2$
g. 2 glyceraldehyde 3-phosphate
h. 10 glyceraldehyde 3-phosphate

11. Fill in the blanks: Insulin _____ glucose uptake and oxidation. Entry of glucose into cells is accompanied by its

phosphorylation to form glucose 6-phosphate (G6P). Not only is G6P able to be processed glycolytically to generate ATP, but it can also be shunted into the pentose phosphate pathway (PPP) to generate _____ and _____. An abundance of G6P, as would be present upon insulin signaling, would likely _____ the flux of G6P into the PPP. 3

12. The net equation for the oxidative reactions of the pentose phosphate pathway is

$$\text{Glucose 6-phosphate} + 2\ NADP^+ + H_2O \rightarrow$$
$$\text{ribulose 5-phosphate} + 2\ NADPH + CO_2 + 2\ H^+$$

Select true statements about the pentose phosphate pathway. 3

a. Glucose is a precursor of the pentose phosphate pathway.
b. The pentose phosphate pathway contributes to nucleotide synthesis.
c. Carbon atoms from the pentose sugar products may enter the glycolytic pathway.
d. Glucose 6-phosphate is reduced to ribulose 5-phosphate in this series of reactions.

13. Consider a cell that requires much more ribose 5-phosphate than NADPH. The cell needs ribose 5-phosphate but has a relatively high concentration of NADPH and a low concentration of $NADP^+$. These conditions may occur in rapidly dividing cells. Choose the statements that describe the fate of glucose 6-phosphate, glycolytic intermediates, and pentose phosphate pathway intermediates in this cell. 3

a. Conversion of glycolytic intermediates to ribose 5-phosphate requires transketolase and transaldolase.
b. Most of the glucose 6-phosphate enters the glycolytic pathway and is converted to fructose 6-phosphate and glyceraldehyde 3-phosphate.
c. The oxidative pentose phosphate pathway reaction catalyzed by glucose 6-phosphate dehydrogenase is slowed down.
d. Three molecules of glyceraldehyde 3-phosphate and two molecules of fructose 6-phosphate are used to generate five molecules of ribose 5-phosphate.
e. Under the given conditions, all triose phosphates are converted to pyruvate by the glycolytic pathway.
f. Most of the glucose 6-phosphate enters the pentose phosphate pathway.

14. Radioactive-labeling experiments can yield estimates of the amount of glucose 6-phosphate metabolized by the pentose phosphate pathway (PPP) and the amount metabolized aerobically by the combined action of glycolysis, the pyruvate dehydrogenase complex, and the citric acid cycle. A researcher has a tissue sample and two radioactively labeled glucose samples, one labeled with ^{14}C at C-1 and the other labeled with ^{14}C at C-6. To determine the relative activity of aerobic glucose metabolism compared with glucose metabolism by the PPP, the research should compare the radioactivity of which product? What is the rationale for the experiment? 3

a. Aerobic glucose metabolism decarboxylates C-1 and C-6, whereas the PPP only decarboxylates C-1.
b. Glucose 6-phosphate is only metabolized by the PPP.
c. Aerobic glucose metabolism in oxidative, whereas the PPP is completely nonoxidative.

d. Aerobic glucose metabolism reduces NAD^+, whereas the PPP reduces $NADP^+$.
e. In the PPP, C-1 of glucose 6-phosphate becomes C-1 of ribose 5-phosphate.

15. Which molecule controls the rate of the pentose phosphate pathway? 3

a. $NADP^+/NADPH$
b. Ribose 5-phosphate
c. ADP/ATP
d. Glucose
e. $NAD^+/NADH$

16. Think about which reaction is influenced by the molecule in Question 15. Choose the enzyme that catalyzes the reaction.

a. Glucose 6-phosphate dehydrogenase
b. Transketolase
c. Transaldolase
d. Lactonase
e. Phosphopentose isomerase
f. Phosphopentose epimerase

17. Provide an example of pathogen resistance provided by the loss of the activity of an enzyme (name the pathogen and the enzyme). Provide an example of another genetic modification associated with resistance to this pathogen. 4

18. Why might a diet that includes fava beans pose a risk for some individuals? 4

19. What is the stoichiometry of the synthesis of

a. ribose 5-phosphate from glucose 6-phosphate without the concomitant generation of NADPH, and
b. NADPH from glucose 6-phosphate without concomitant formation of pentose sugars? 3

20. Why is the C_4 pathway valuable for tropical plants? 1

21. Which of the following is not a component of the pentose phosphate pathway? 3

a. NADPH
b. CO_2
c. Ribose 5-phosphate
d. Phosphoenolpyruvate
e. Erythrose 4-phosphate

Chapter 21
Glycogen Metabolism

Left: DE AGOSTINI PICTURE LIBRARY/De Agostini/Getty Images; right: WESTOCK PRODUCTIONS/Shutterstock

The brain requires glucose at all times, while muscles require extra glucose during bouts of exercise. Glycogen, a molecule used to store glucose, is used by the liver to keep the brain fed between meals, including while you sleep. The same molecule is used by muscles to power intense exercise.

Outline

21.1 Glycogen Metabolism Is the Regulated Release and Storage of Glucose in Multiple Tissues
21.2 Glycogen Breakdown Requires the Interplay of Several Enzymes
21.3 Phosphorylase Is Regulated by Allosteric Interactions and Controlled by Reversible Phosphorylation
21.4 Glucagon and Epinephrine Signal the Need for Glycogen Breakdown
21.5 Glycogen Synthesis Requires Several Enzymes and Uridine Diphosphate Glucose

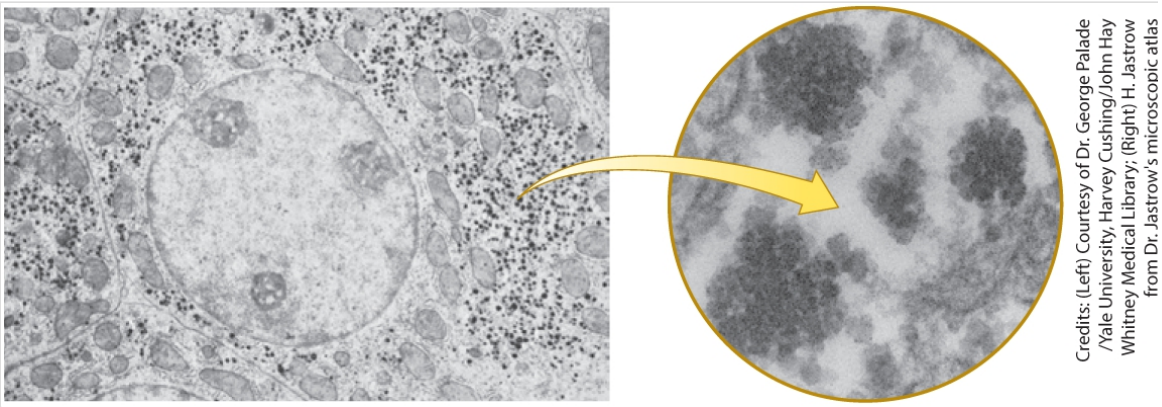
21.6 Glycogen Breakdown and Synthesis Are Reciprocally Controlled by Hormones

---

Learning Goals

By the end of this chapter, you should be able to:

1. List and describe the steps of glycogen breakdown and identify the enzymes required.
2. Explain the regulation of glycogen breakdown.
3. Describe the steps of glycogen synthesis and identify the enzymes required.
4. Describe how glycogen degradation and synthesis are coordinated and regulated.
5. Compare the different roles of glycogen metabolism in liver and muscle.



Glucose is an important fuel and a key precursor for the biosynthesis of many molecules. However, glucose itself cannot be stored, because high concentrations of glucose disrupt the osmotic balance of the cell, which would cause cell damage or death. Instead, glucose is stored as glycogen, a significantly less osmotically active and highly branched polymer that can be rapidly broken down to yield glucose molecules when energy is needed. Glycogen is present in bacteria, archaea, protists, and animals, while plants store glucose primarily as starch, a similar, but less-branched polymer.

Glycogen is not as reduced as fatty acids are and consequently is not as energy-rich, so why isn't all excess fuel stored as fatty acids rather than as glycogen? In animals, the controlled release of glucose from glycogen maintains blood-glucose concentration between meals, including during sleep. The circulating blood keeps the brain

supplied with glucose, which is virtually the only fuel it uses, except during prolonged starvation (Chapter 24). Moreover, the readily mobilized glucose from glycogen is a good source of energy for sudden, strenuous activity as, unlike fatty acids, it can be metabolized in the absence of oxygen and can thus supply energy for anaerobic activity (Section 16.2).

21.1 Glycogen Metabolism Is the Regulated Release and Storage of Glucose in Multiple Tissues

In humans, most tissues have some glycogen, although the two major sites of glycogen storage are the liver and skeletal muscle. The concentration of glycogen is higher in the liver than in muscle (10% versus 2% by weight), but more glycogen is stored in skeletal muscle overall because of muscle's much greater mass. Glycogen is present in the cytoplasm, with the molecule appearing as granules consisting of multiple glycogen molecules (Figure 21.1). An individual glycogen molecule has approximately 12 layers of glucose molecules and can be as large as 40 nm, containing approximately 55,000 glucose residues and a single protein, called *glycogenin*, at the core (Figure 21.2).

FIGURE 21.1 Liver and muscle tissue are the primary storage sites for glycogen. An electron micrograph of a liver cell reveals a high density of glycogen granules (the dark spots) in the cytoplasm.

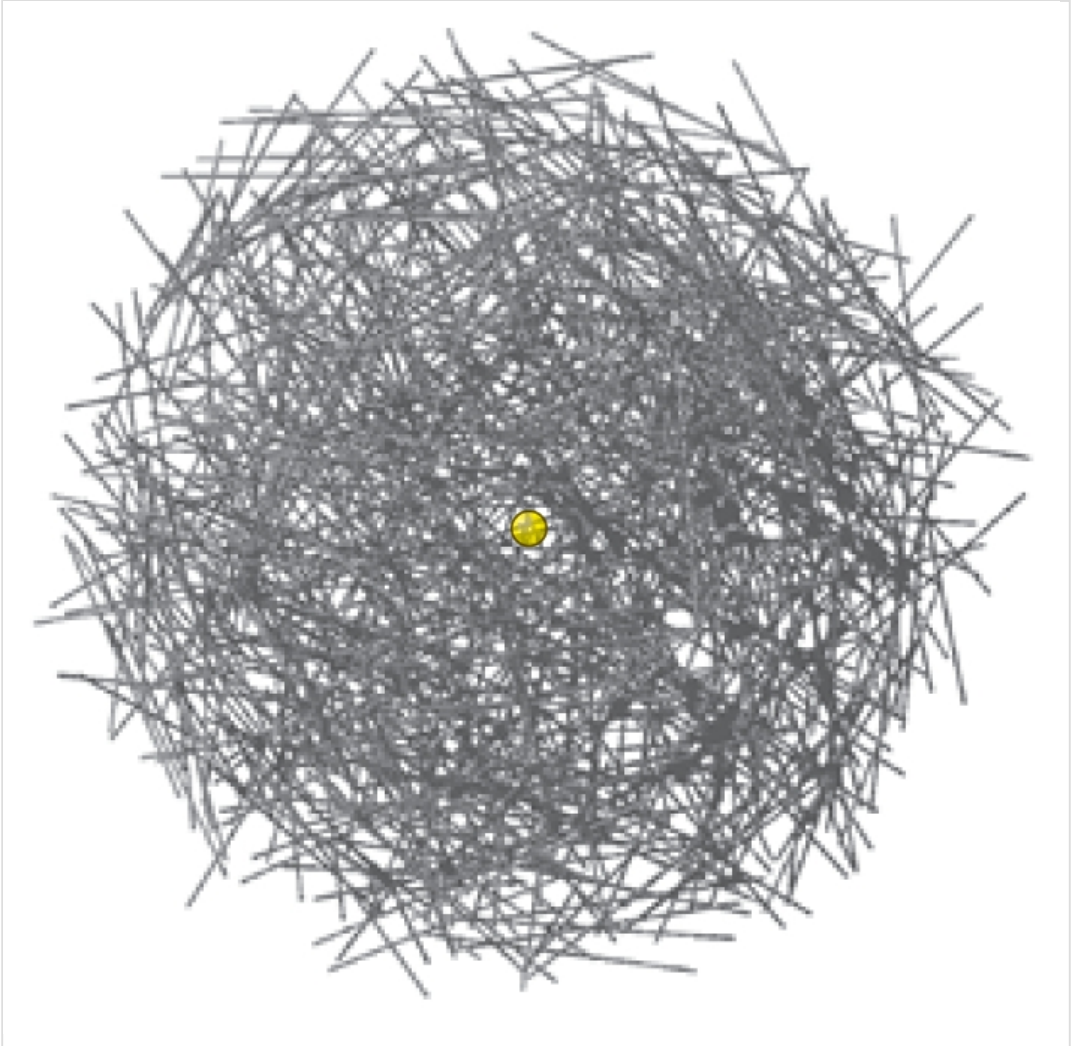

FIGURE 21.2 Glycogen is a complex homopolymer of glucose with a protein core. At the core of the glycogen molecule is the protein glycogenin (yellow). Each line represents glucose molecules joined by α-1,4-glycosidic linkages. The nonreducing ends of the glycogen molecule form the surface of the glycogen granule, where degradation takes place.

[Information from R. Melendez et al., *Biophys. J.* 77:1327–1332, 1999.]

Recall that most of the glucose residues in glycogen are linked by α-1,4-glycosidic bonds (**Figure 21.3**); but branches at about every 12 residues are created by α-1,6-glycosidic bonds. α-Glycosidic linkages form open helical polymers, whereas β linkages produce nearly straight strands that form structural fibrils, as in cellulose (Figure 11.14).

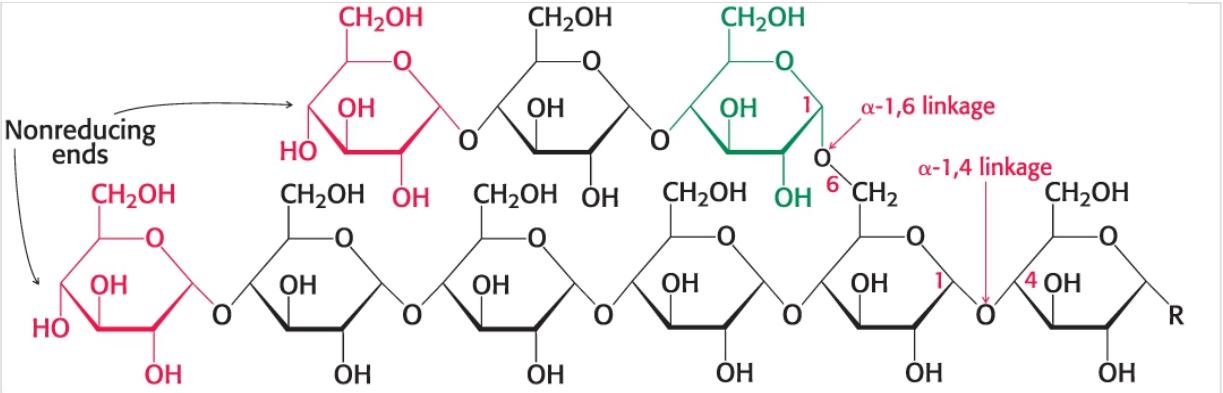

FIGURE 21.3 The fundamental structure of glycogen is a linear polymer with occasional branches. In this structure of two outer branches of a glycogen molecule, the residues at the nonreducing ends are shown in red and the residue that starts a branch is shown in green. The rest of the glycogen molecule is represented by R.

Glycogen degradation and synthesis are relatively simple biochemical processes. Glycogen degradation consists of three steps, ultimately producing glucose 6-phosphate for further metabolism. Glucose 6-phosphate has three possible fates (Figure 21.4): (1) it can be metabolized by glycolysis, (2) in the liver it can be converted into free glucose for release into the bloodstream, or (3) it can be processed by the pentose phosphate pathway to yield NADPH and ribose derivatives. Glycogen synthesis also requires several steps; it takes place when glucose is abundant and glycogen is depleted.

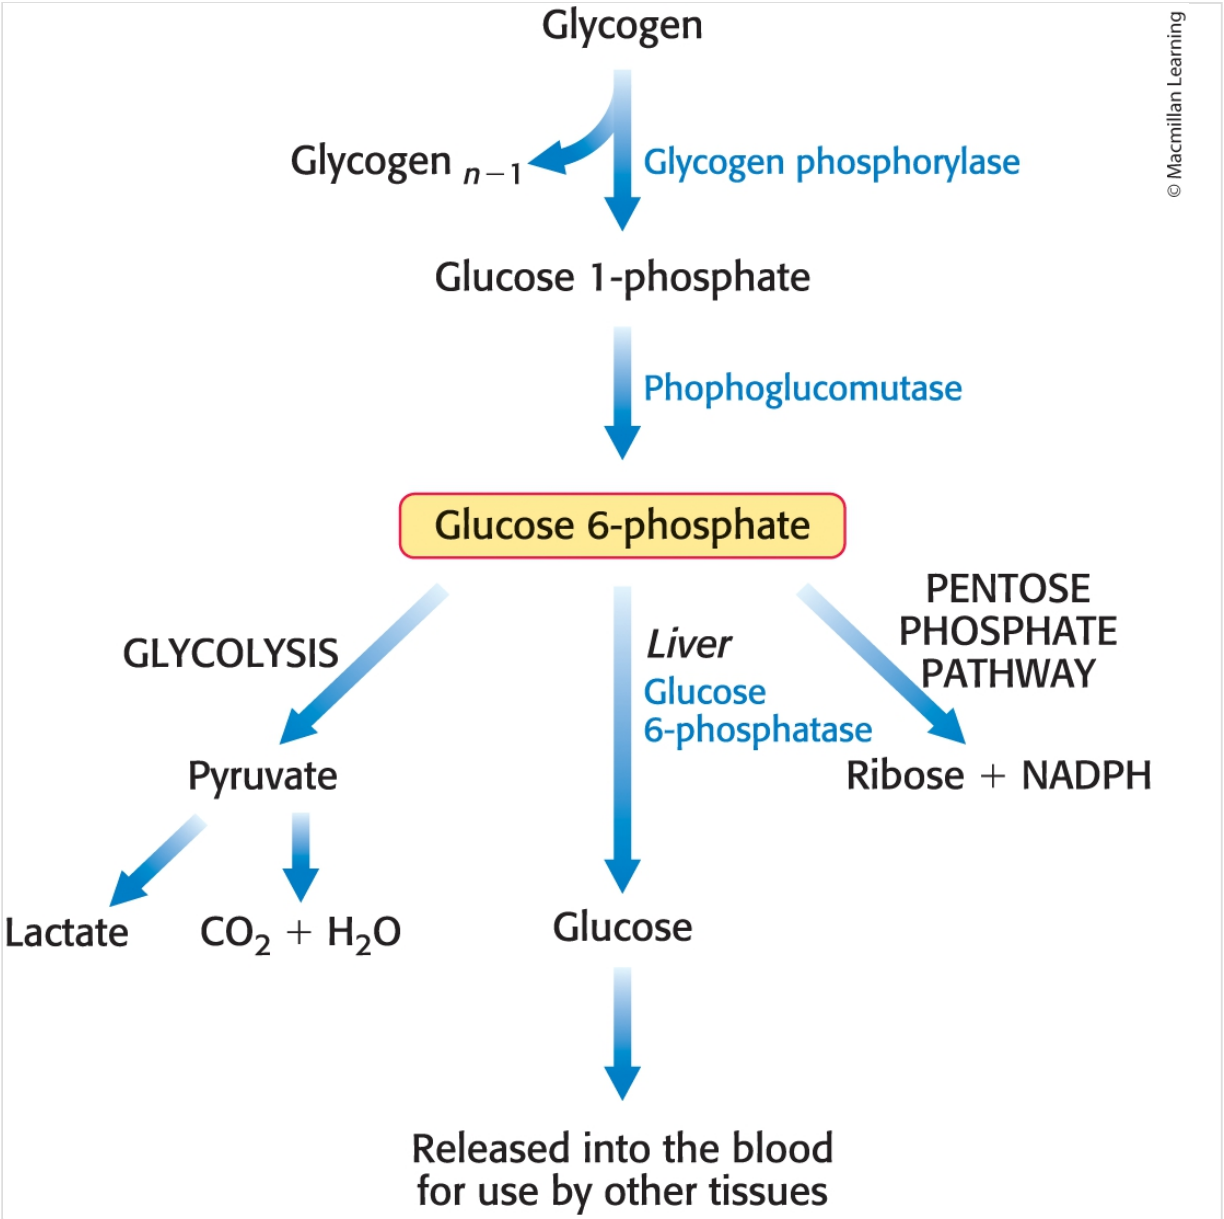

FIGURE 21.4 Glucose 6-phosphate can have many metabolic fates. Glucose 6-phosphate derived from glycogen can be (1) used as a fuel for anaerobic or aerobic metabolism as in, for instance, muscle; (2) converted into free glucose in the liver and subsequently released into the blood; or (3) processed by the pentose phosphate pathway to generate NADPH and ribose in a variety of tissues.

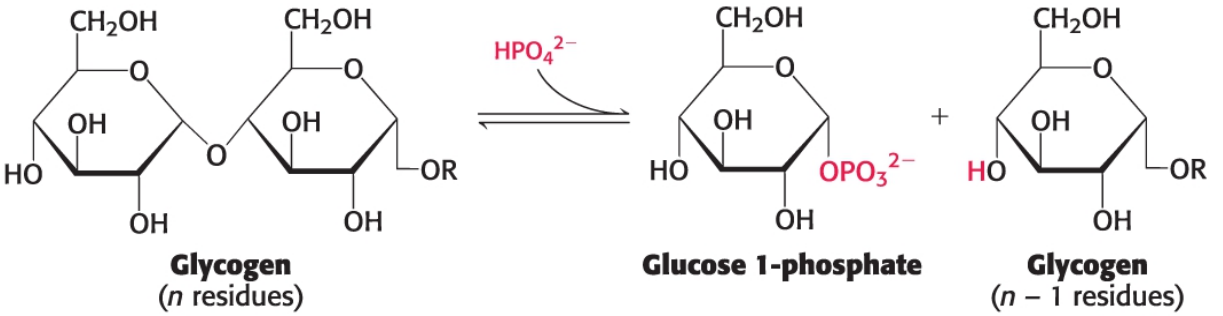
The regulation of glycogen degradation and synthesis is complex, in part because all of the enzymes involved in glycogen metabolism and its regulation are associated with the glycogen particle. Several enzymes taking part in glycogen metabolism allosterically respond to metabolites that signal the energy needs of the cell. Through these allosteric responses, enzyme activity is adjusted to meet the needs of the individual cell. In contrast, hormones may initiate signal cascades that lead to the reversible phosphorylation of enzymes, which alters their catalytic rates in tissue-specific manners to meet the needs of the whole organism.

21.2 Glycogen Breakdown Requires the Interplay of Several Enzymes

The efficient breakdown of glycogen to provide glucose 6-phosphate for further metabolism requires four enzyme activities: one to degrade glycogen, two to remodel glycogen so that it can remain a substrate for degradation, and one to convert the product of glycogen breakdown into a form suitable for further metabolism. We will examine each of these activities in turn.



Phosphorylase catalyzes the phosphorolytic cleavage of glycogen to release glucose 1-phosphate

The key enzyme in glycogen breakdown, **glycogen phosphorylase** (often just called **phosphorylase**), cleaves its substrate by the addition of orthophosphate (P_i) to yield glucose 1-phosphate. The cleavage of a bond by the addition of orthophosphate is referred to as **phosphorolysis**.

$$\underset{(n \text{ residues})}{\text{Glycogen} + P_i} \rightleftharpoons \text{glucose 1-phosphate} + \underset{(n-1 \text{ residues})}{\text{glycogen}}$$

Phosphorylase catalyzes the sequential removal of glucosyl residues from the nonreducing ends of the glycogen molecule (the ends with a free OH group on carbon 4). Orthophosphate splits the glycosidic linkage between C-1 of the terminal residue and C-4 of the adjacent one. Specifically, it cleaves the bond between the C-1 carbon atom

and the glycosidic oxygen atom, and the α configuration at C-1 is retained.

Glucose 1-phosphate released from glycogen can be readily converted into glucose 6-phosphate, an important metabolic intermediate, by the enzyme phosphoglucomutase.

The reaction catalyzed by phosphorylase is readily reversible in vitro. At pH 6.8, the equilibrium ratio of orthophosphate to glucose 1-phosphate is 3.6. The value of $\Delta G^{\circ\prime}$ for this reaction is small because a glycosidic bond is replaced by a phosphoryl ester bond that has a nearly equal transfer potential. However, phosphorolysis proceeds far in the direction of glycogen breakdown in vivo because the $[P_i]/[\text{glucose 1-phosphate}]$ ratio is usually greater than 100, substantially favoring phosphorolysis. We see here an example of how the cell can alter the free-energy change to favor a reaction's occurrence by altering the ratio of substrate and product.

The phosphorolytic cleavage of glycogen is energetically advantageous because the released sugar is already phosphorylated. In contrast, a hydrolytic cleavage would yield glucose, which would then have to be phosphorylated at the expense of a molecule of ATP

to enter the glycolytic pathway. An additional advantage of phosphorolytic cleavage for muscle cells is that no transporters exist for glucose 1-phosphate, which is negatively charged under physiological conditions, and so it cannot be transported or diffuse out of the cell.

Mechanism: Pyridoxal phosphate participates in the phosphorolytic cleavage of glycogen

The special challenge faced by phosphorylase is to cleave glycogen phosphorolytically rather than hydrolytically to save the ATP required to phosphorylate free glucose. Thus, water must be excluded from the active site. Phosphorylase is a dimer of two identical 97-kDa subunits, each compactly folded into an amino-terminal domain containing a glycogen-binding site and a carboxyl-terminal domain (**Figure 21.5**). The catalytic site in each subunit is located in a deep crevice formed by residues from both domains. Substrates bind synergistically, causing the crevice to narrow, thereby excluding water.

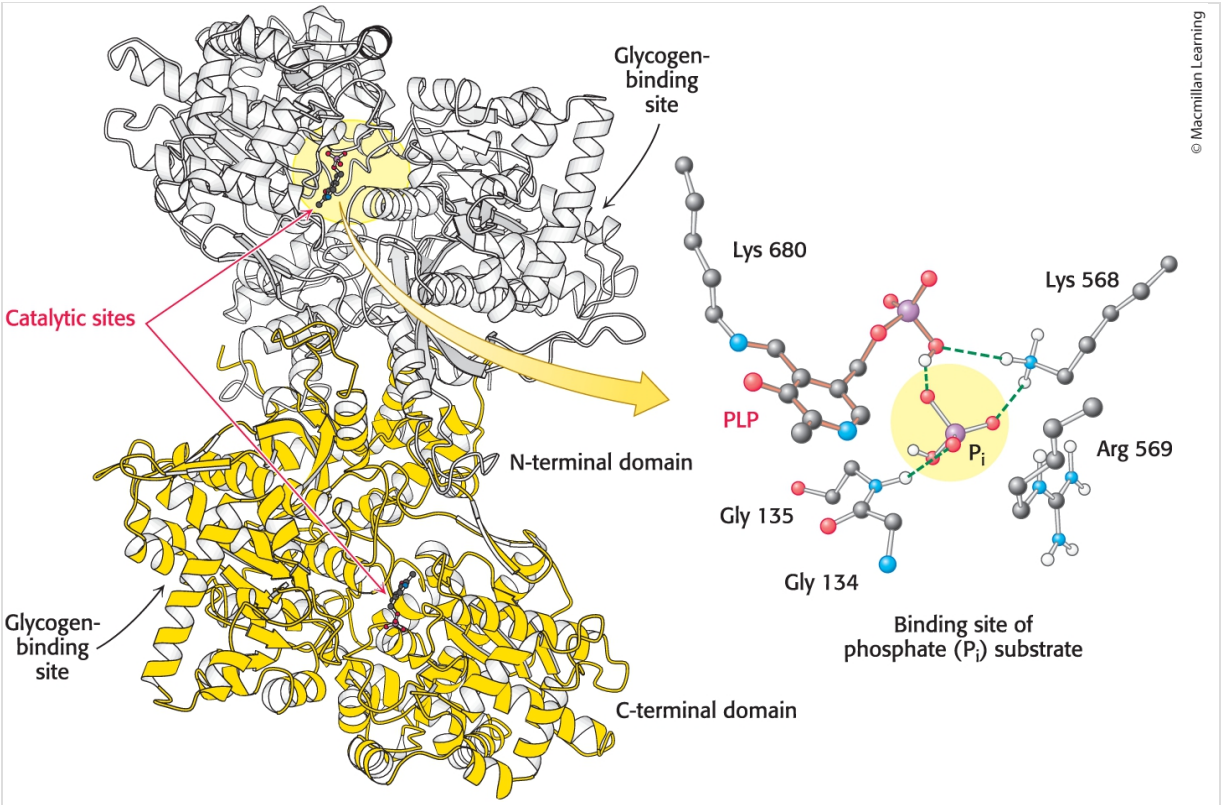


FIGURE 21.5 Glycogen phosphorylase forms a homodimer with a pyridoxal phosphate (PLP) group in each active site. One subunit is shown in white and the other in yellow. Each catalytic site includes a PLP group linked to lysine 680 of the enzyme. The binding site for the phosphate (P_i) substrate is shown. Notice that the catalytic site lies between the C-terminal domain and the glycogen-binding site. A narrow crevice, which binds four or five glucose units of glycogen, connects the two sites. The separation of the sites allows the catalytic site to phosphorolyze several glucose units before the enzyme must rebind the glycogen substrate.

[Drawn from 1NOI.pdb.]

INTERACT with this model in Achieve

What is the mechanistic basis of the phosphorolytic cleavage of glycogen? Several clues suggest a mechanism. First, both the glycogen substrate and the glucose 1-phosphate product have an α configuration at C-1. A direct attack by phosphate on C-1 of a sugar

would invert the configuration at this carbon atom because the reaction would proceed through a pentacovalent transition state. The observation that the glucose 1-phosphate formed has an α rather than a β configuration suggests that an even number of steps (most simply, two) is required. A likely explanation for these results is that a carbocation intermediate is formed from the glucose residue.

A second clue to the catalytic mechanism of phosphorylase is its requirement for the coenzyme **pyridoxal phosphate (PLP)**, a derivative of pyridoxine (vitamin B_6, Section 15.4). The aldehyde group of this coenzyme forms a Schiff-base linkage with a specific lysine side chain of the enzyme (**Figure 21.6**). Structural studies indicate that the reacting orthophosphate group takes a position between the $5'$-phosphate group of PLP and the glycogen substrate (**Figure 21.7**). The $5'$-phosphate group of PLP acts in tandem with orthophosphate by serving as a proton donor and then as a proton acceptor (i.e., as a general acid–base catalyst). Orthophosphate (in the HPO_4^{2-} form) donates a proton to the oxygen atom attached to carbon 4 of the departing glycogen chain and simultaneously acquires a proton from PLP. The carbocation intermediate formed in this step is then attacked by orthophosphate to form α-glucose 1-phosphate, with the concomitant return of a proton to pyridoxal phosphate.

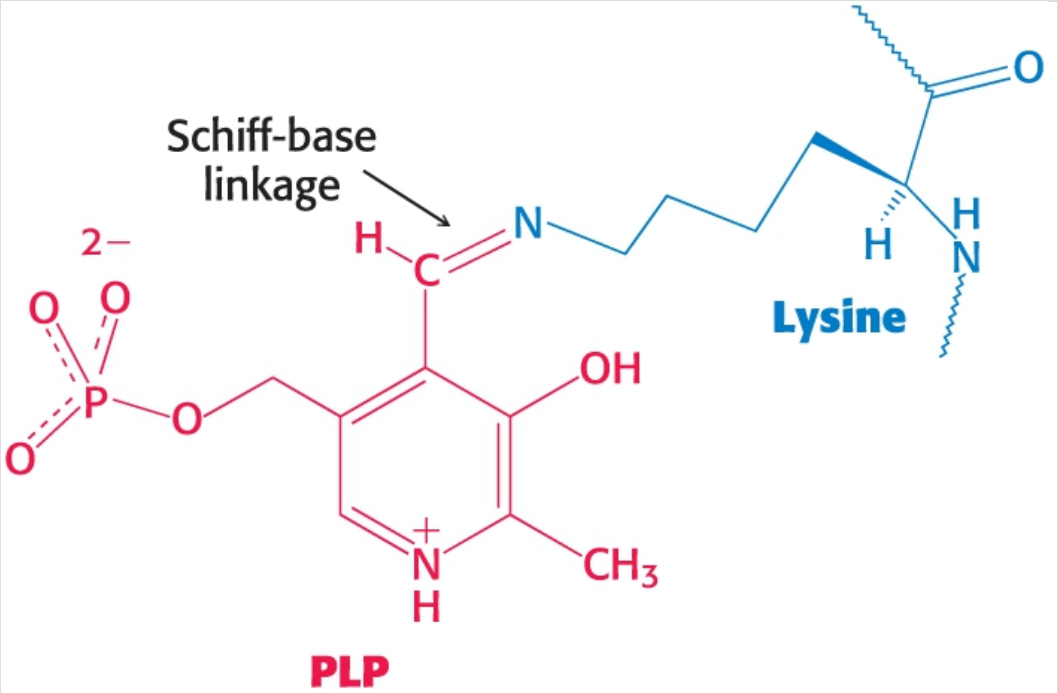

FIGURE 21.6 PLP forms a Schiff-base linkage with lysine. A pyridoxal phosphate (PLP) group (red) forms a Schiff base with a lysine residue (blue) at the active site of phosphorylase, where it functions as a general acid–base catalyst.

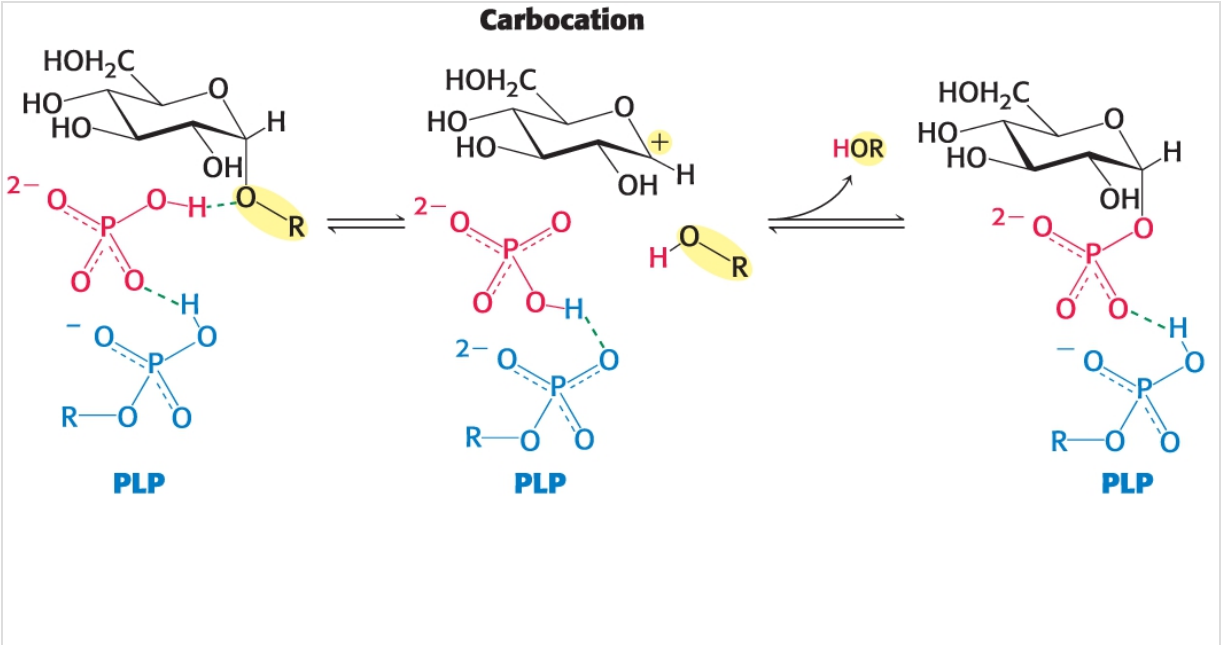

FIGURE 21.7 The mechanism of phosphorylase involves PLP and the formation of a carbocation. A bound HPO_4^{2-} group (red) favors the cleavage of the glycosidic bond by donating a proton to the C-4 oxygen of the departing glycosyl group (black).

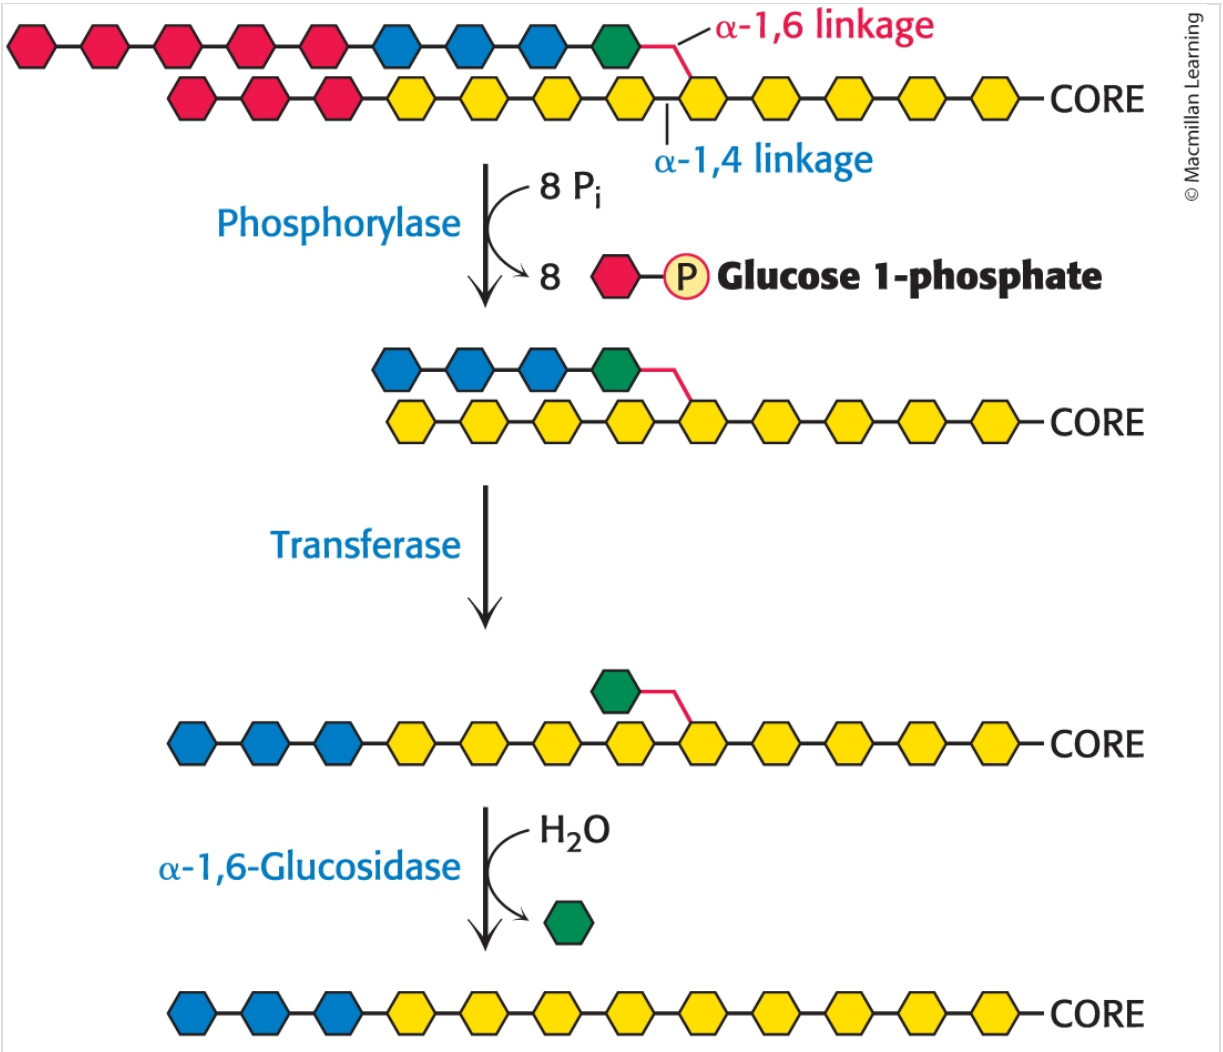
The glycogen-binding site is 30 Å away from the catalytic site (Figure 21.5), but it is connected to the catalytic site by a narrow crevice able to accommodate four or five glucose units. The large separation between the binding site and the catalytic site enables the enzyme to phosphorolyze many residues without having to dissociate and reassociate after each catalytic cycle. An enzyme that can catalyze many reactions without having to dissociate and reassociate after each catalytic step is said to be *processive* — a property of enzymes that synthesize and degrade large polymers. We will see such enzymes again when we consider DNA and RNA synthesis.

Debranching enzyme also is needed for the breakdown of glycogen

Glycogen phosphorylase acting alone degrades glycogen to a limited extent. The enzyme can break α-1,4-glycosidic bonds on glycogen branches but soon encounters an obstacle. The α-1,6-glycosidic bonds at the branch points are not susceptible to cleavage by phosphorylase. Indeed, phosphorylase stops cleaving α-1,4 linkages when it reaches a terminal residue four residues away from a branch point. Because about 1 in 12 residues is branched, cleavage by the phosphorylase alone would come to a halt after the release of eight glucose molecules per branch.

How can the remainder of the glycogen molecule be mobilized for use as a fuel? Two additional enzyme activities are necessary to remodel glycogen for continued degradation by the phosphorylase (Figure 21.8).



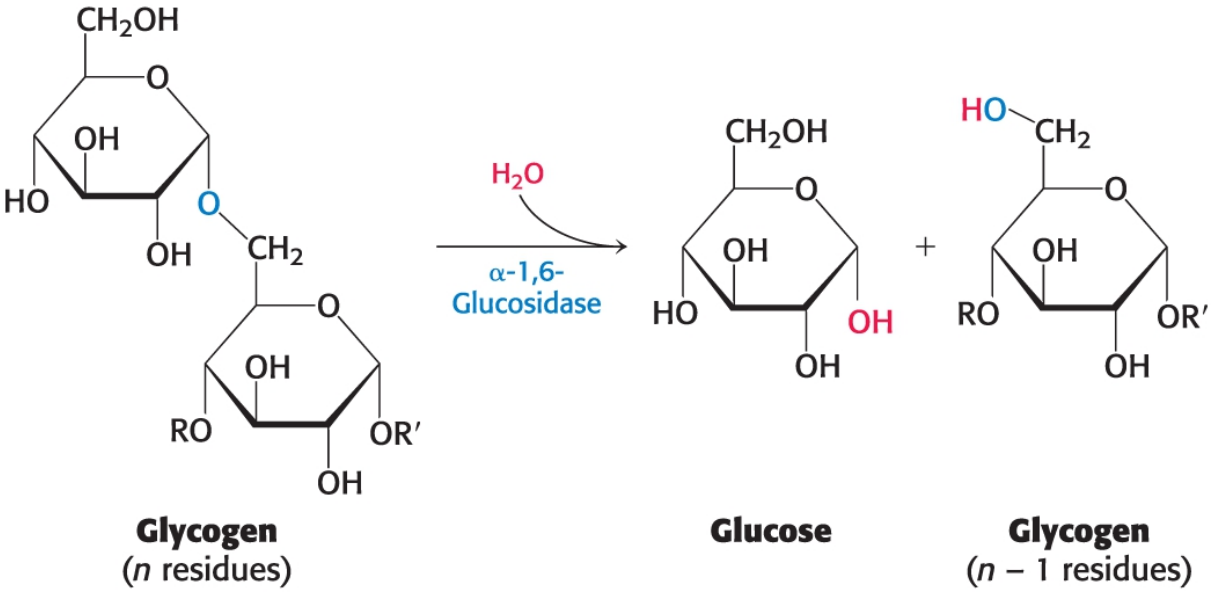


FIGURE 21.8 Glycogen remodeling requires three distinct catalytic activities. First, α-1,4-glycosidic bonds on each branch are cleaved by phosphorylase, leaving four residues along each branch. The transferase shifts a block of three glucosyl residues from one outer branch to the other. In this reaction, the α-1,4-glycosidic link between the blue and the green residues is broken and a new α-1,4 link between the blue and the yellow residues is formed. The green residue is then removed by α-1,6-glucosidase, leaving a linear chain with all α-1,4 linkages, suitable for further cleavage by phosphorylase.

A transferase shifts a block of three glucosyl residues from one outer branch to another, thus exposing a single glucose residue joined by an α-1,6-glycosidic linkage. The α-1,6-glucosidase activity then hydrolyzes the α-1,6-glycosidic bond.

In eukaryotes, the transferase and the α-1,6-glucosidase activities are present in a single 160-kDa protein, called *debranching enzyme*, providing yet another example of a bifunctional enzyme. A free glucose molecule is released and then phosphorylated by the glycolytic enzyme hexokinase, if the glucose is to be processed by glycolysis or the pentose phosphate pathway. Thus, the transferase and α-1,6-glucosidase activities of debranching enzyme convert the

branched structure into a linear one, which paves the way for further cleavage by phosphorylase.

Phosphoglucomutase converts glucose 1-phosphate into glucose 6-phosphate

Glucose 1-phosphate formed in the phosphorolytic cleavage of glycogen must be converted into glucose 6-phosphate to enter the metabolic mainstream. This shift of a phosphoryl group is catalyzed by phosphoglucomutase. Recall that this enzyme is also used in galactose metabolism (Section 16.2). To cause this shift, the enzyme exchanges a phosphoryl group with the substrate (**Figure 21.9**). The key to this mechanism is that the catalytic site of an active mutase molecule already contains a phosphorylated serine residue. This phosphoryl group is transferred from the serine residue to the C-6 hydroxyl group of glucose 1-phosphate to form glucose 1,6-bisphosphate. To regenerate the phosphoserine and complete the mechanism, the C-1 phosphoryl group of the bisphosphate intermediate is then shuttled to the same serine residue, resulting in the formation of glucose 6-phosphate and the regeneration of the phosphoenzyme.

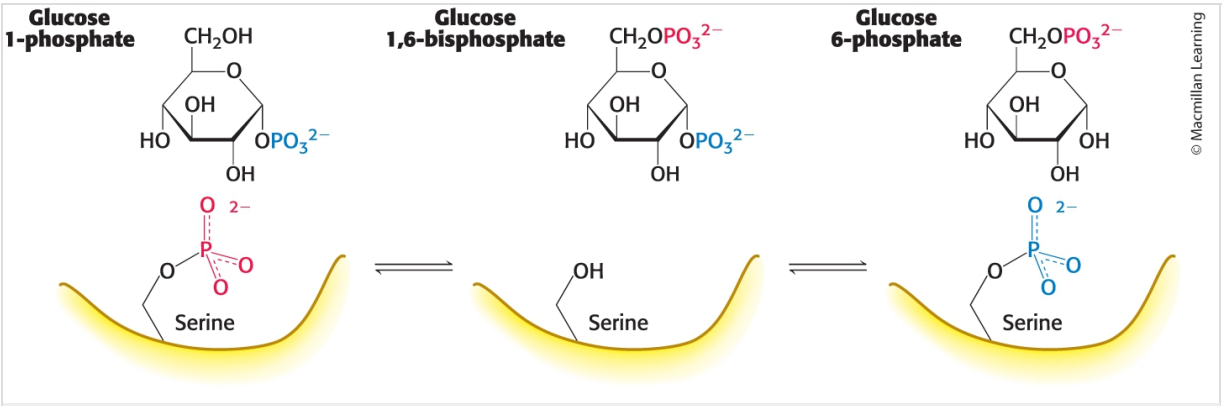

FIGURE 21.9 Phosphoglucomutase transfers a phosphoryl group to the substrate. A different phosphoryl group is transferred back to restore the enzyme to its initial state.

Self-Check Question

The complete oxidation of glucose 6-phosphate derived from free glucose yields 30 molecules ATP, whereas glucose 6-phosphate derived from glycogen yields 31 molecules of ATP. How can you account for this difference?

The liver contains glucose 6-phosphatase, a hydrolytic enzyme absent from muscle

A major function of the liver is to maintain a nearly constant concentration of glucose in the blood to keep the brain, red blood cells, and other tissues adequately supplied. The liver achieves this by releasing glucose into the blood between meals and during muscular activity through the action of glucose 6-phosphatase, the last enzyme in gluconeogenesis (Section 16.4). This enzyme hydrolytically cleaves the phosphoester linkage to form orthophosphate and free glucose, which can then exit the liver by the action of GLUT transporters (Section 16.1). Recall that glucose 6-phosphatase is located on the lumenal side of the smooth endoplasmic reticulum membrane, and so glucose 6-phosphate is transported into the endoplasmic reticulum while glucose and orthophosphate are then shuttled back into the cytoplasm (Section 16.4).

$$\text{Glucose 6-phosphate} + H_2O \rightarrow \text{glucose} + P_i$$

Glucose 6-phosphatase is absent from most other tissues. Muscle tissues retain glucose 6-phosphate for the generation of ATP. In contrast, glucose is not a major fuel for the liver.

Self-Check Question

What four enzymes are required for the liver to release glucose into the blood when an animal is asleep and fasting?

21.3 Phosphorylase Is Regulated by Allosteric Interactions and Controlled by Reversible Phosphorylation

Glycogen degradation is precisely controlled by multiple interlocking mechanisms, with the enzyme glycogen phosphorylase playing a central role. Phosphorylase is regulated by several allosteric effectors that signal the energy state of the cell, as well as controlled by reversible phosphorylation, which is responsive to hormones such as insulin, epinephrine, and glucagon. We will examine the differences in the control of two isozymic forms of glycogen phosphorylase: one specific to liver and one specific to skeletal muscle. These differences are because the liver maintains glucose homeostasis of the organism as a whole, whereas the muscle uses glucose to produce energy for itself.

Liver phosphorylase produces glucose for use by other tissues

The dimeric phosphorylase exists in two interconvertible forms: a usually *active* phosphorylated *a* form and a usually *inactive* unphosphorylated *b* form (**Figure 21.10**). Each of these two forms exists in equilibrium between an active relaxed (R) state and a much less active tense (T) state, but the equilibrium for phosphorylase *a* favors the active R state, whereas the equilibrium for phosphorylase *b* favors the less-active T state (**Figure 21.11**).

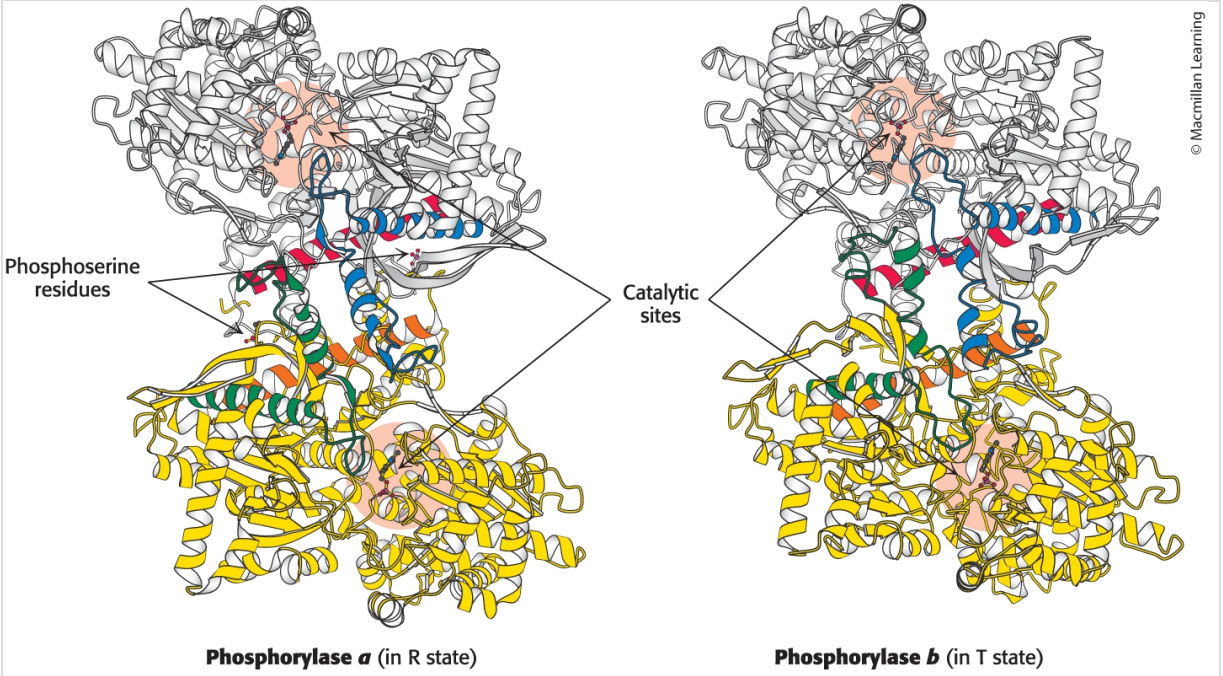

FIGURE 21.10 Phosphorylase exists in two distinct quaternary states. Phosphorylase *a* is phosphorylated on serine 14 of each subunit. This modification favors the structure of the more-active R state. One subunit is shown in white, with helices and loops important for regulation shown in blue and red. The other subunit is shown in yellow, with the regulatory structures shown in orange and green. Phosphorylase *b* is not phosphorylated and exists predominantly in the T state. Notice that the catalytic sites are partly occluded in the T state.

[Drawn from 1GPA.pdb and 1NOJ.pdb.]

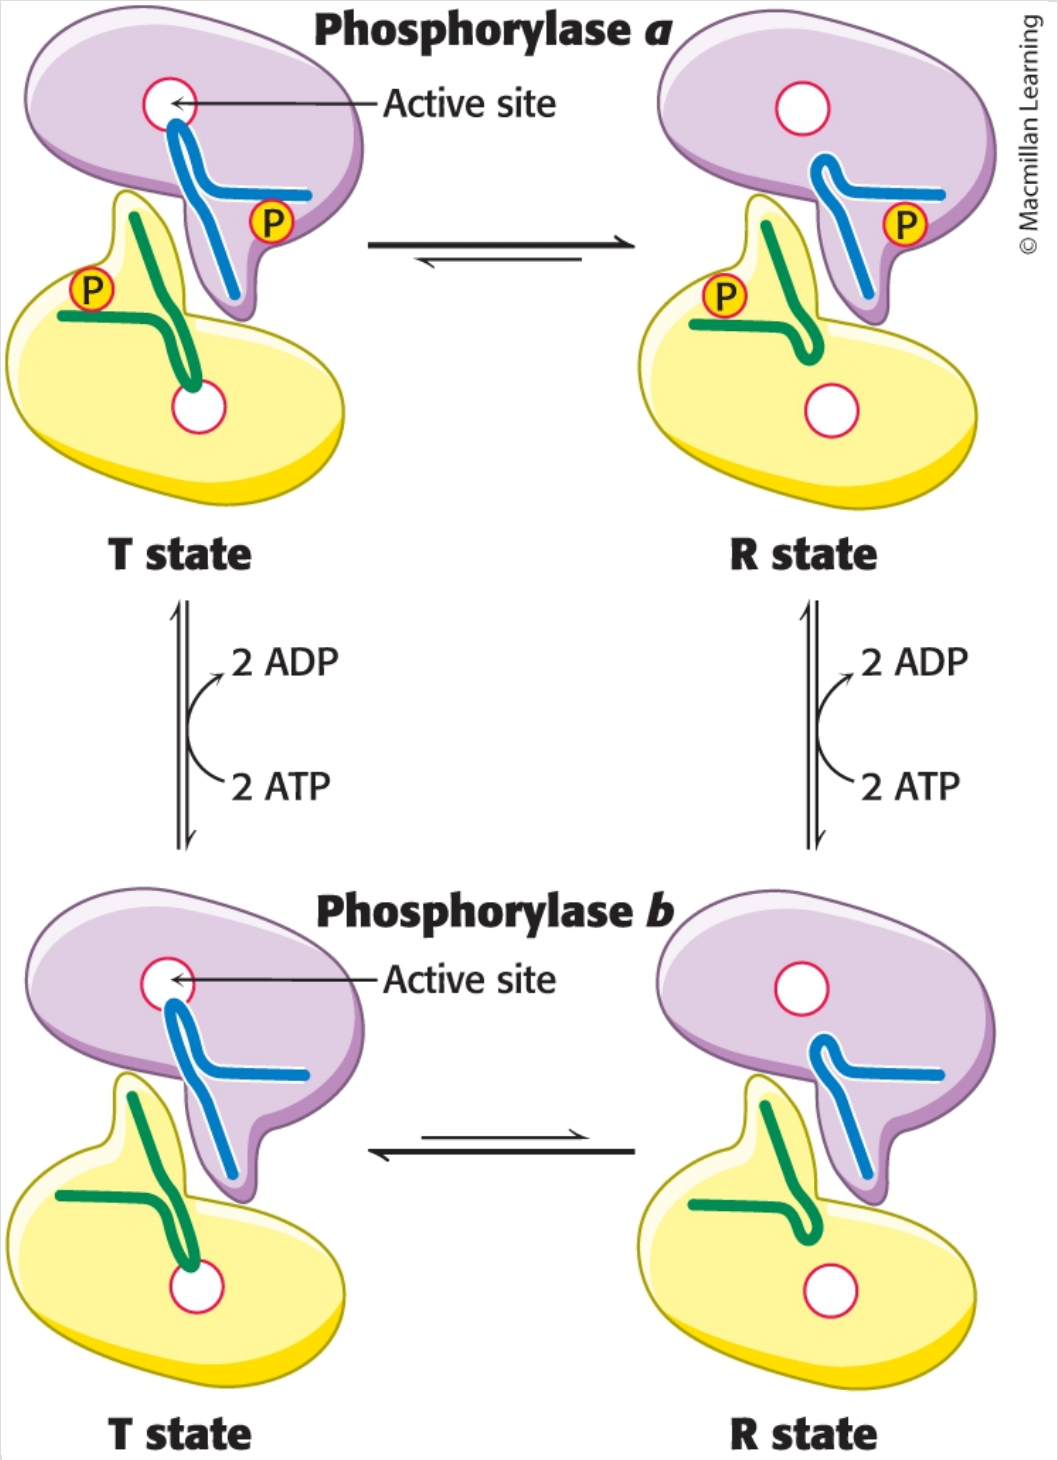

FIGURE 21.11 Phosphorylase is regulated by phosphorylation. Both phosphorylase *b* and phosphorylase *a* exist as equilibria between an active R state and a less-active T state. Phosphorylase *b* is usually inactive because the equilibrium favors the T state. Phosphorylase *a* is usually active because the equilibrium favors the R state. Regulatory structures are shown in blue and green.

The role of glycogen degradation in the liver is to form glucose for export to other tissues when the blood-glucose concentration is low. Consequently, we can think of the default state of liver phosphorylase as being the *a* form: glucose is to be generated unless the enzyme is signaled otherwise. The liver phosphorylase *a* form thus exhibits the most responsive R ↔ T transition (Figure 21.12). The binding of glucose to the active site shifts the *a* form from the active R state to the less-active T state. In essence, the enzyme reverts to the low-activity T state only when it detects the presence of sufficient glucose. If glucose is present in the diet, there is no need to degrade glycogen.

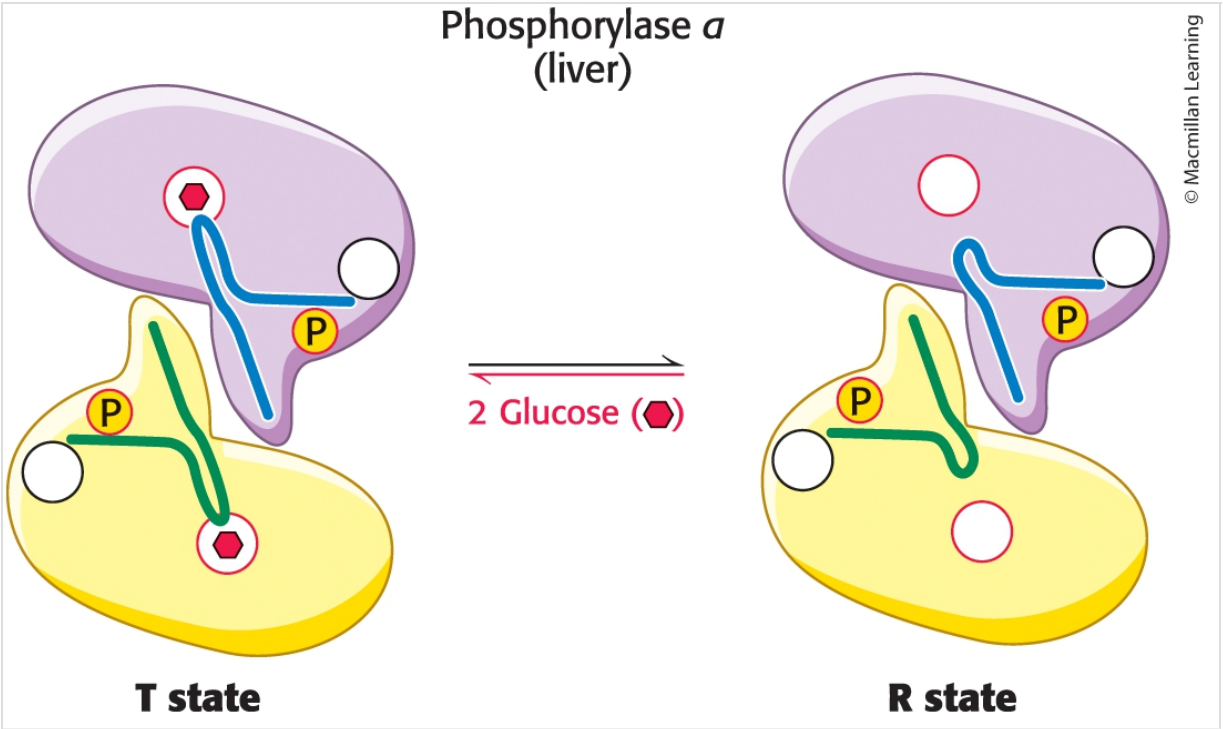

FIGURE 21.12 Liver phosphorylase is allosterically inhibited by glucose. The binding of glucose to phosphorylase *a* shifts the equilibrium to the T state and inactivates the enzyme. Thus, glycogen is not mobilized when glucose is already abundant.

Muscle phosphorylase is regulated by changes in AMP and ATP concentrations

In contrast to the liver isozyme, the default state of muscle phosphorylase is the *b* form, owing to the fact that, for muscle, phosphorylase must be primarily active only during muscle contraction. Muscle phosphorylase *b* is activated by the presence of high concentrations of AMP, which binds to a nucleotide-binding site and stabilizes the conformation of phosphorylase *b* in the active R state (**Figure 21.13**). Thus, when a muscle contracts and ATP is converted into AMP by the sequential action of myosin (Section 6.4) and adenylate kinase (Section 16.3), the phosphorylase is signaled to degrade glycogen. ATP acts as a negative allosteric effector by competing with AMP. Thus, the transition of phosphorylase *b* between the active R state and the less-active T state is controlled by the concentrations of these metabolites in muscle cells. If ATP is unavailable, glucose 6-phosphate may bind at the ATP-binding site and stabilize the less-active state of phosphorylase *b*, an example of feedback inhibition. In resting muscle, phosphorylase *b* is inactive because of the inhibitory effects of ATP and glucose 6-phosphate. In contrast, phosphorylase *a* is fully active, regardless of the concentration of AMP, ATP, and glucose 6-phosphate.

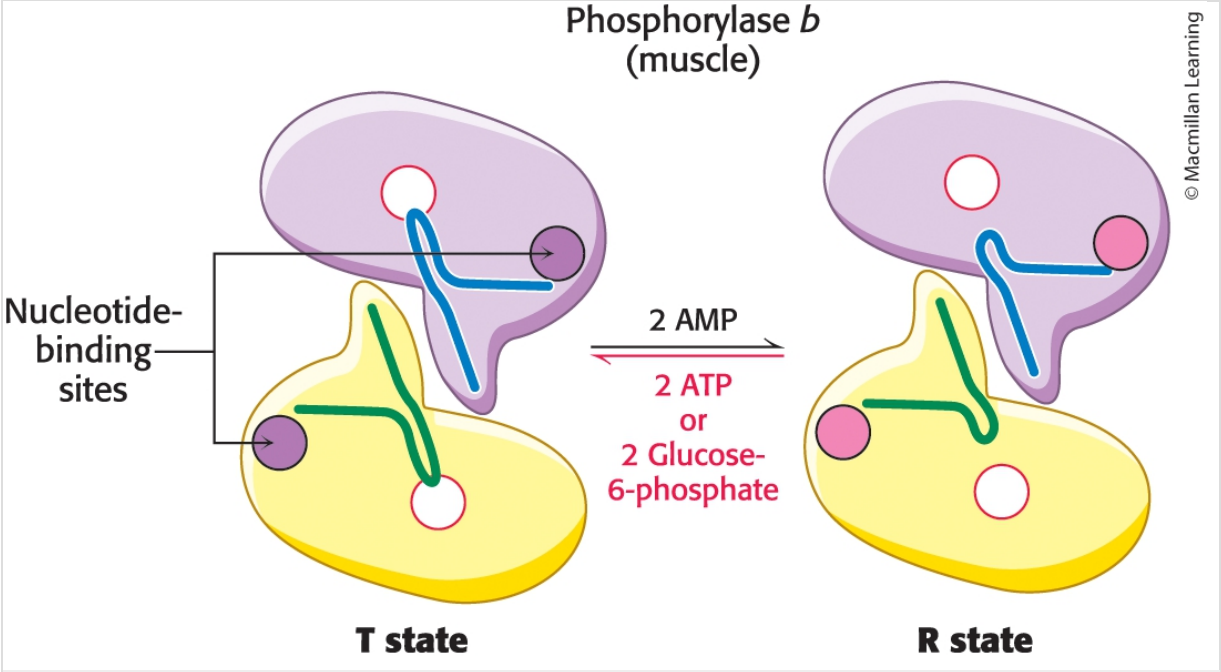

FIGURE 21.13 Muscle phosphorylase is allosterically regulated by ATP, AMP, and glucose 6-phosphate. A low energy charge, represented by high concentrations of AMP, favors the transition to the R state. ATP and glucose 6-phosphate stabilize the T state.

Unlike the enzyme in muscle, the liver phosphorylase is insensitive to regulation by AMP because the liver does not undergo the dramatic changes in the concentrations of AMP and ATP seen in a contracting muscle. We see here a clear example of the use of isozymes to establish the tissue-specific biochemical properties of the liver and muscle. In human beings, liver phosphorylase and muscle phosphorylase are approximately 90% identical in amino acid sequence, yet the 10% difference results in subtle but important shifts in the regulation of the two enzymes.

Self-Check Question

Crystals of phosphorylase *a* grown in the presence of glucose shatter when a substrate such as glucose 1-phosphate is added. Why?

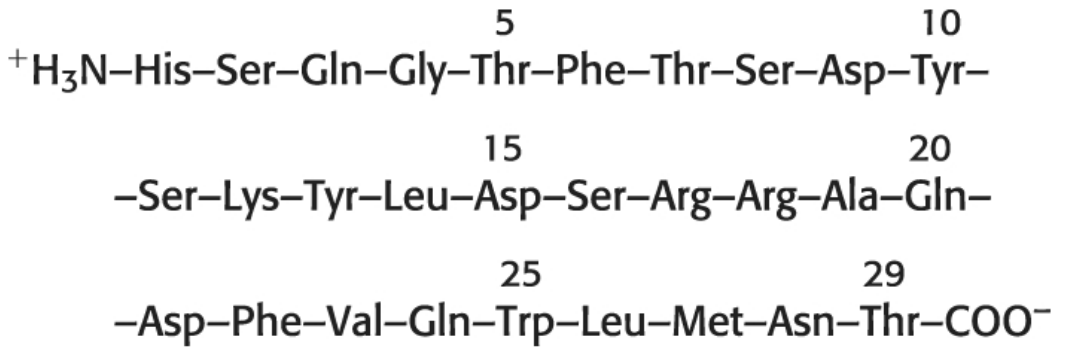
Biochemical characteristics of muscle fiber types differ

Not only do the biochemical needs of liver and muscle differ with respect to glycogen metabolism, but the biochemical needs of different muscle fiber types also vary. Skeletal muscle consists of three different fiber types: type I, or slow-twitch muscle; type IIb (also called type IIx), or fast-twitch fibers; and type IIa fibers that have properties intermediate between the other two fiber types.

- *Type I (slow-twitch) fibers rely predominantly on cellular respiration to derive energy.* These fibers are powered by fatty acid degradation and are rich in mitochondria, the site of fatty acid degradation and the citric acid cycle. As we will see in Chapter 22, fatty acids are an excellent energy storage form, but generating ATP from fatty acids is slower than from glycogen. Glycogen is not an important fuel for type I fibers, and consequently the amount of glycogen phosphorylase is low. Type I fibers power endurance activities.

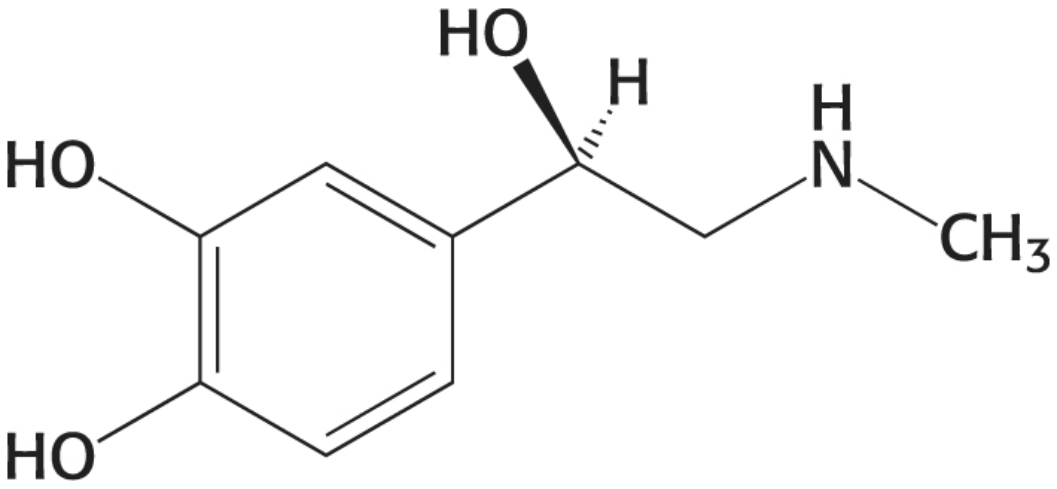
- *Type IIb (fast-twitch) fibers use glycogen as their main fuel.* Consequently, the glycogen and glycogen phosphorylase are abundant. These fibers are also rich in glycolytic enzymes

needed to process glucose quickly in the absence of oxygen and poor in mitochondria. Type IIb fibers power burst activities such as sprinting and weight lifting.



No amount of training can interconvert type I fibers and type IIb fibers. However, there is some evidence that type IIa fibers are "trainable"; that is, endurance training enhances the oxidative capacity of type IIa fibers, while burst activity training enhances the glycolytic capacity. Table 21.1 shows the biochemical profile of the fiber types.

TABLE 21.1 Biochemical characteristics of muscle fiber types



Characteristic	Type I	Type IIa	Type IIb
Fatigue resistance	High	Intermediate	Low
Mitochondrial density	High	Intermediate	Low
Metabolic type	Oxidative	Oxidative/glycolytic	Glycolytic
Myoglobin content	High	Intermediate	Low
Glycogen content	Low	Intermediate	High
Triacylglycerol content	High	Intermediate	Low
Glycogen phosphorylase activity	Low	Intermediate	High
Phosphofructokinase activity	Low	Intermediate	High
Citrate synthase activity	High	Intermediate	Low

Phosphorylation promotes the conversion of phosphorylase *b* to phosphorylase *a*

In both liver and muscle, hormones initiate the conversion of phosphorylase *b* into phosphorylase *a* by the phosphorylation of a single serine residue (serine 14) in each subunit. Low blood concentration of glucose leads to the secretion of the peptide hormone **glucagon** from the α cells of the pancreas, which results in phosphorylation of the enzyme, converting it to the phosphorylase *a* form in liver. The hormone **epinephrine (adrenaline)**, a catecholamine derived from tyrosine, also induces this conversion when it binds to receptors in muscle and liver.

Glucagon

Epinephrine

Emotions like the excitement of exercise or fear will cause release of epinephrine from the adrenal medulla into the blood. Epinephrine binds to receptors in muscle (and in liver), again inducing the phosphorylation of phosphorylase *b* to phosphorylase *a*. The regulatory enzyme **phosphorylase kinase** catalyzes this covalent modification in response to either hormone.

Comparison of the structures of phosphorylase *a* in the R state and phosphorylase *b* in the T state reveals that subtle structural changes at the subunit interfaces are transmitted to the active sites (Figure 21.10). The transition from the T state (the prevalent state of phosphorylase *b*) to the R state (the prevalent state of phosphorylase *a*) entails a 10-degree rotation around the twofold axis of the dimer. Most important, this transition is associated with structural changes in α helices that move a loop out of the active site of each subunit. Thus, the T state is less active because the catalytic site is partly blocked. In contrast, in the R state, the catalytic site is more accessible, and a binding site for orthophosphate is well organized.

Phosphorylase kinase is activated by phosphorylation and calcium ions

Phosphorylase kinase converts phosphorylase *b* into the *a* form by attaching a phosphoryl group. The subunit composition of phosphorylase kinase in skeletal muscle is $(\alpha\beta\gamma\delta)_4$, and the mass of this very large protein is 1300 kDa. The enzyme consists of two $(\alpha\beta\gamma\delta)_2$ lobes that are joined by a β_4 bridge that is the core of the enzyme and serves as a scaffold for the other subunits (**Figure 21.14**). The γ subunit contains the active site, while all of the remaining subunits ($\approx 90\%$ by mass) play regulatory roles. The δ subunit is the Ca^{2+} binding protein calmodulin, a calcium sensor that stimulates many enzymes in eukaryotes (Section 14.2).

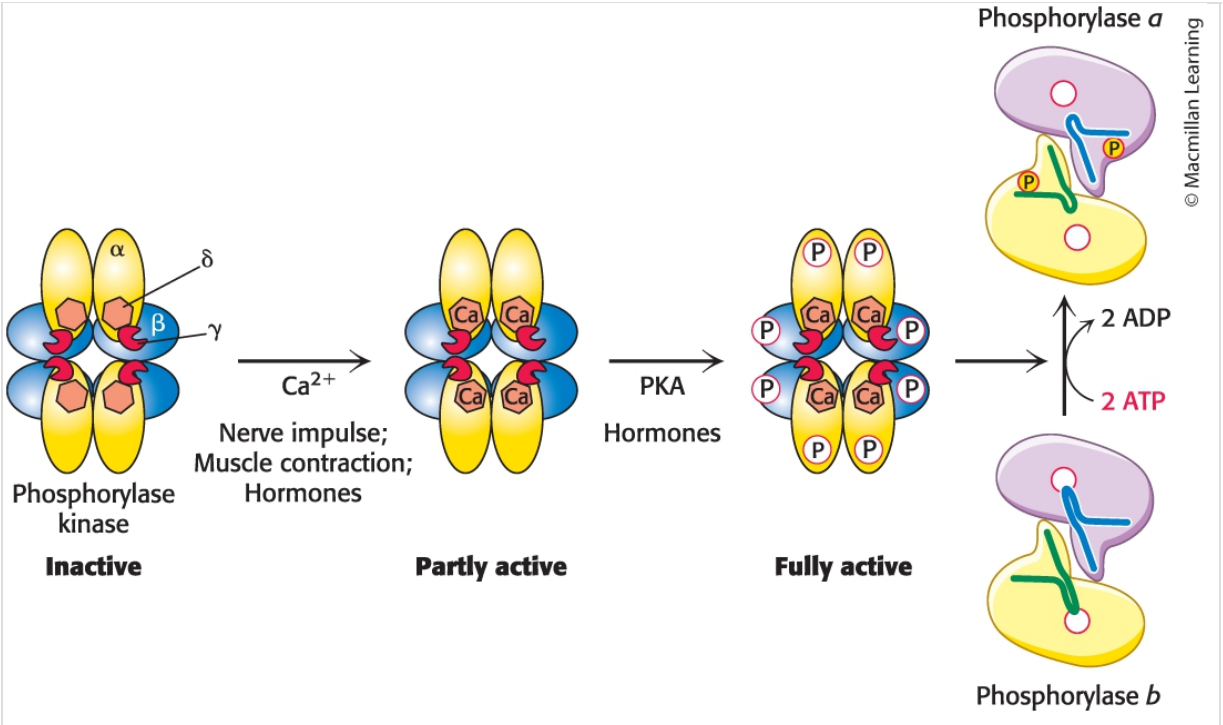


FIGURE 21.14 Phosphorylase kinase is activated by calcium ions and hormonally controlled phosphorylation. Phosphorylase kinase, an $(\alpha\beta\gamma\delta)_4$ assembly, is partly

activated by Ca^{2+} binding to the δ subunits. Activation is maximal when the β and α subunits are phosphorylated in response to hormonal signals. When active, the enzyme converts phosphorylase *b* into phosphorylase *a*.

Activation of phosphorylase kinase is initiated when Ca^{2+} binds to the δ subunit. This mode of activation of the kinase is especially noteworthy in muscle, where muscle contraction is triggered by the release of Ca^{2+} from the sarcoplasmic reticulum (Figure 21.14). Maximal activation is achieved with the phosphorylation of the β and α subunits of the Ca^{2+}-bound kinase. The α and β subunits of the calcium-bound enzyme are targets of protein kinase A. The β subunit is phosphorylated first, followed by the phosphorylation of the α subunit. The stimulation of phosphorylase kinase is one step in a signal-transduction cascade initiated by signal molecules such as glucagon and epinephrine.

21.4 Glucagon and Epinephrine Signal the Need for Glycogen Breakdown

Protein kinase A (PKA) activates phosphorylase kinase, which in turn activates glycogen phosphorylase. But what activates PKA? What is the signal that ultimately triggers an increase in glycogen breakdown?

G proteins transmit the signal for the initiation of glycogen breakdown

Let's now explore in greater depth the signaling mechanisms of the two hormones that trigger glycogen breakdown: glucagon and epinephrine. Their activities are tissue-dependent. The liver is highly responsive to glucagon, which is released in response to low glucose concentrations in the blood. Physiologically, glucagon signifies the fasted state (**Figure 21.15**) and stimulates the liver to release glucose into the blood. In contrast, because muscle plays no regulatory role in maintaining glucose concentrations and cannot release glucose into the blood, muscle is insensitive to glucagon. Instead, muscular activity or its anticipation leads to the release of epinephrine, which markedly stimulates glycogen breakdown in muscle and, to a lesser extent, in the liver. The breakdown of liver glycogen in response to epinephrine is meant to provide adequate glucose to the muscles for the expected increase in muscle contraction following the initiation of the "fight-or-flight" response.

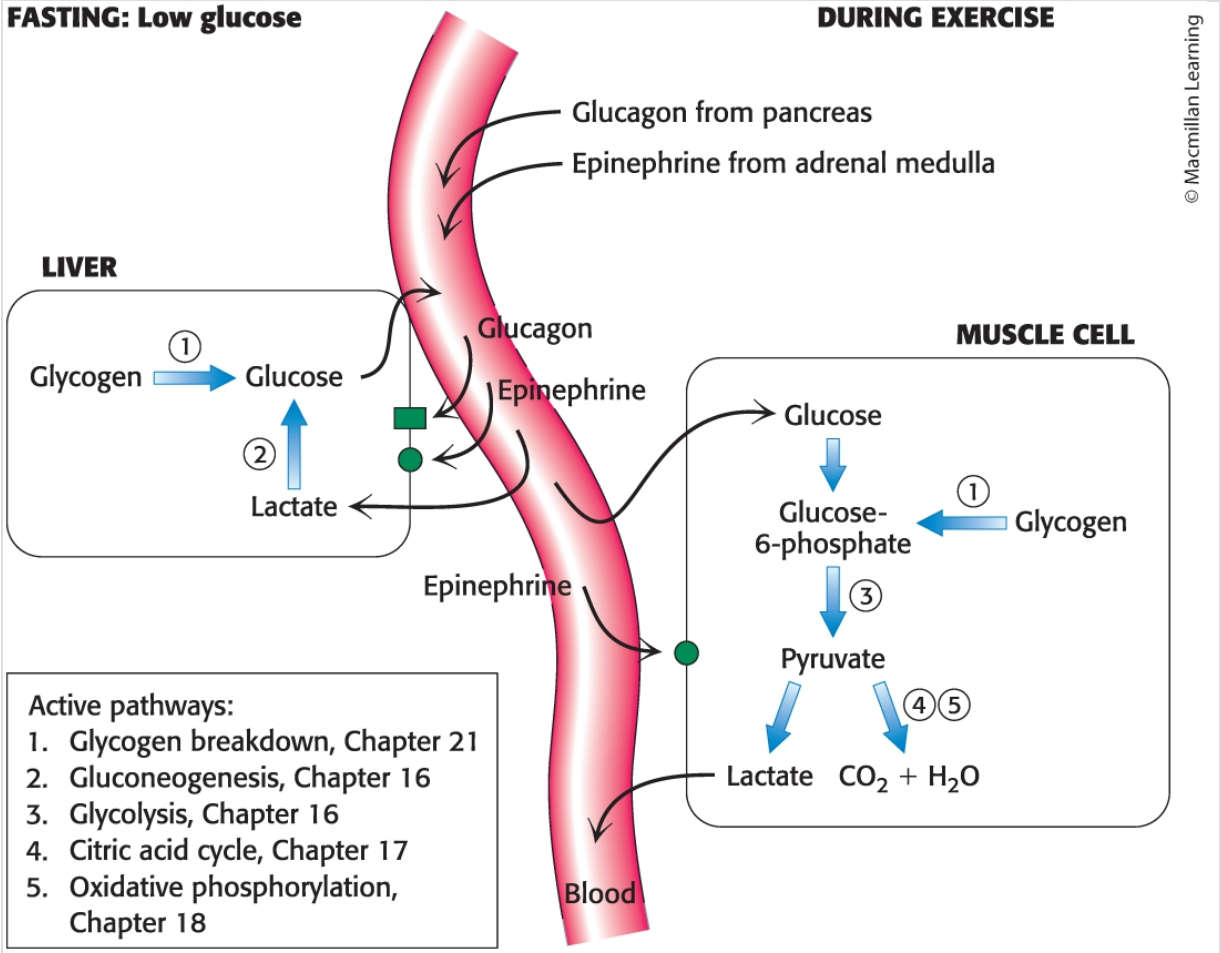

FIGURE 21.15 Glycogen breakdown is controlled by the combined effects of multiple hormones in a tissue-specific manner. Glucagon stimulates liver-glycogen breakdown when blood glucose is low. Epinephrine enhances glycogen breakdown in muscle and the liver to provide fuel for muscle contraction.

EXPLORE this pathway further in the Metabolic Map in Achieve

How do glucagon and epinephrine trigger the breakdown of glycogen? They initiate a cyclic AMP signal-transduction cascade (**Figure 21.16**):

1. The signal molecules glucagon and epinephrine bind to specific seven-transmembrane (7TM) receptors in the plasma

membranes of target cells (Section 14.2). Epinephrine binds to the β-adrenergic receptor in muscle, whereas glucagon binds to the glucagon receptor in the liver. These binding events activate the G_s protein: a specific external signal has been transmitted into the cell through structural changes, first in the receptor and then in the G protein.

2. The GTP-bound subunit of G_s activates the transmembrane protein adenylate cyclase. This enzyme catalyzes the formation of the second messenger cyclic AMP (cAMP) from ATP.

3. The elevated cytoplasmic concentration of cAMP activates PKA (Section 7.3). The binding of cAMP to inhibitory regulatory subunits of PKA triggers their dissociation from the catalytic subunits. The free catalytic subunits are now active.

4. PKA phosphorylates phosphorylase kinase, first on the β subunit and then on the α subunit, which activates glycogen phosphorylase.

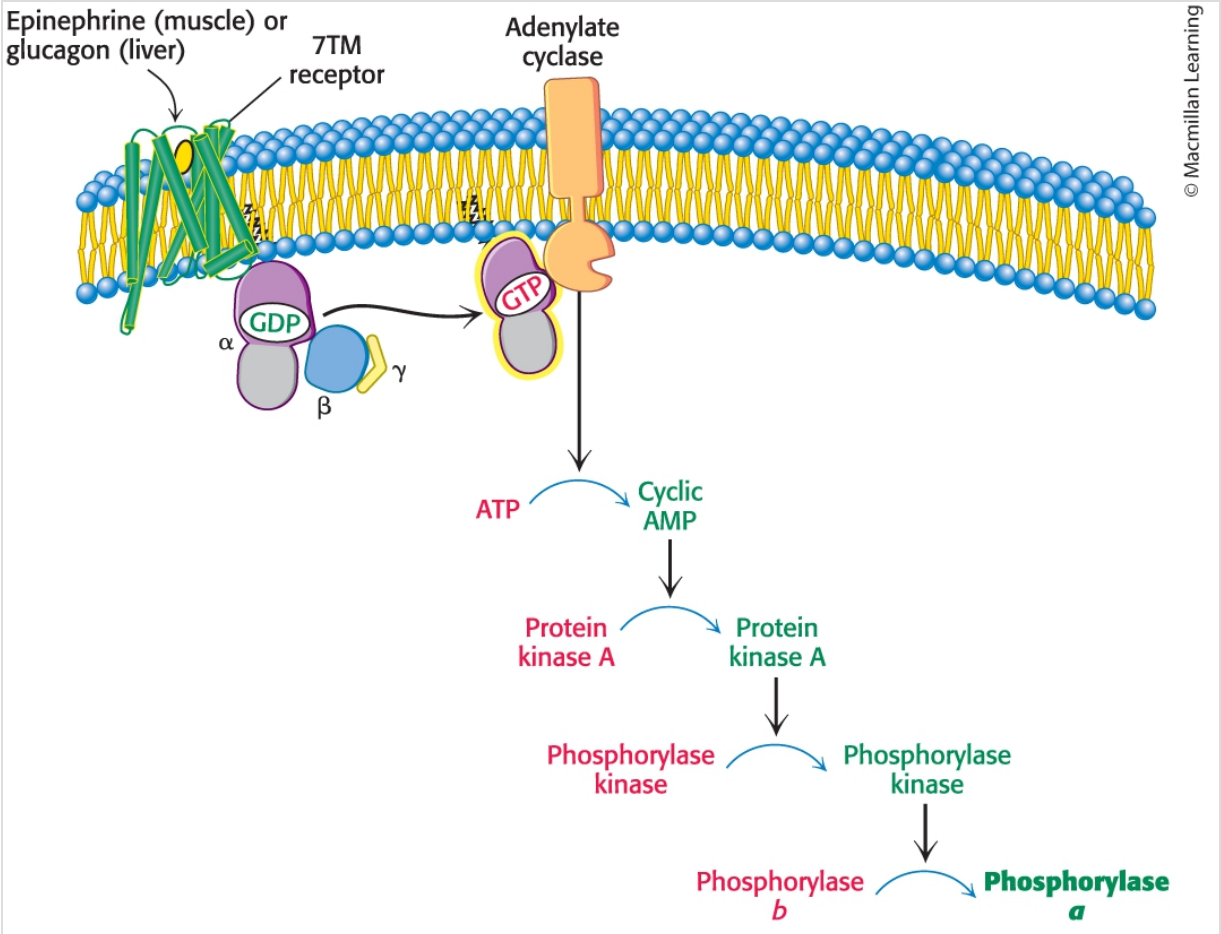

FIGURE 21.16 Glycogen degradation is stimulated by hormone binding to 7TM receptors. Hormone binding to 7TM receptors in the appropriate cells (liver or muscle) initiates a G-protein-dependent signal-transduction pathway that results in the phosphorylation and activation of glycogen phosphorylase. The inactive forms of the enzymes are shown in red and the active forms in green.

The signal-transduction processes in the liver are more complex than those in muscle. Epinephrine can also elicit glycogen degradation in the liver. However, in addition to binding to the β-adrenergic receptor, it binds to the 7TMα-adrenergic receptor, which then initiates the *phosphoinositide cascade* (Section 14.2) that induces the release of Ca^{2+} from endoplasmic reticulum stores. Recall that

the δ subunit of phosphorylase kinase is the Ca^{2+} sensor calmodulin. The binding of Ca^{2+} to calmodulin leads to a partial activation of phosphorylase kinase. Stimulation by both glucagon and epinephrine leads to maximal mobilization of liver glycogen.

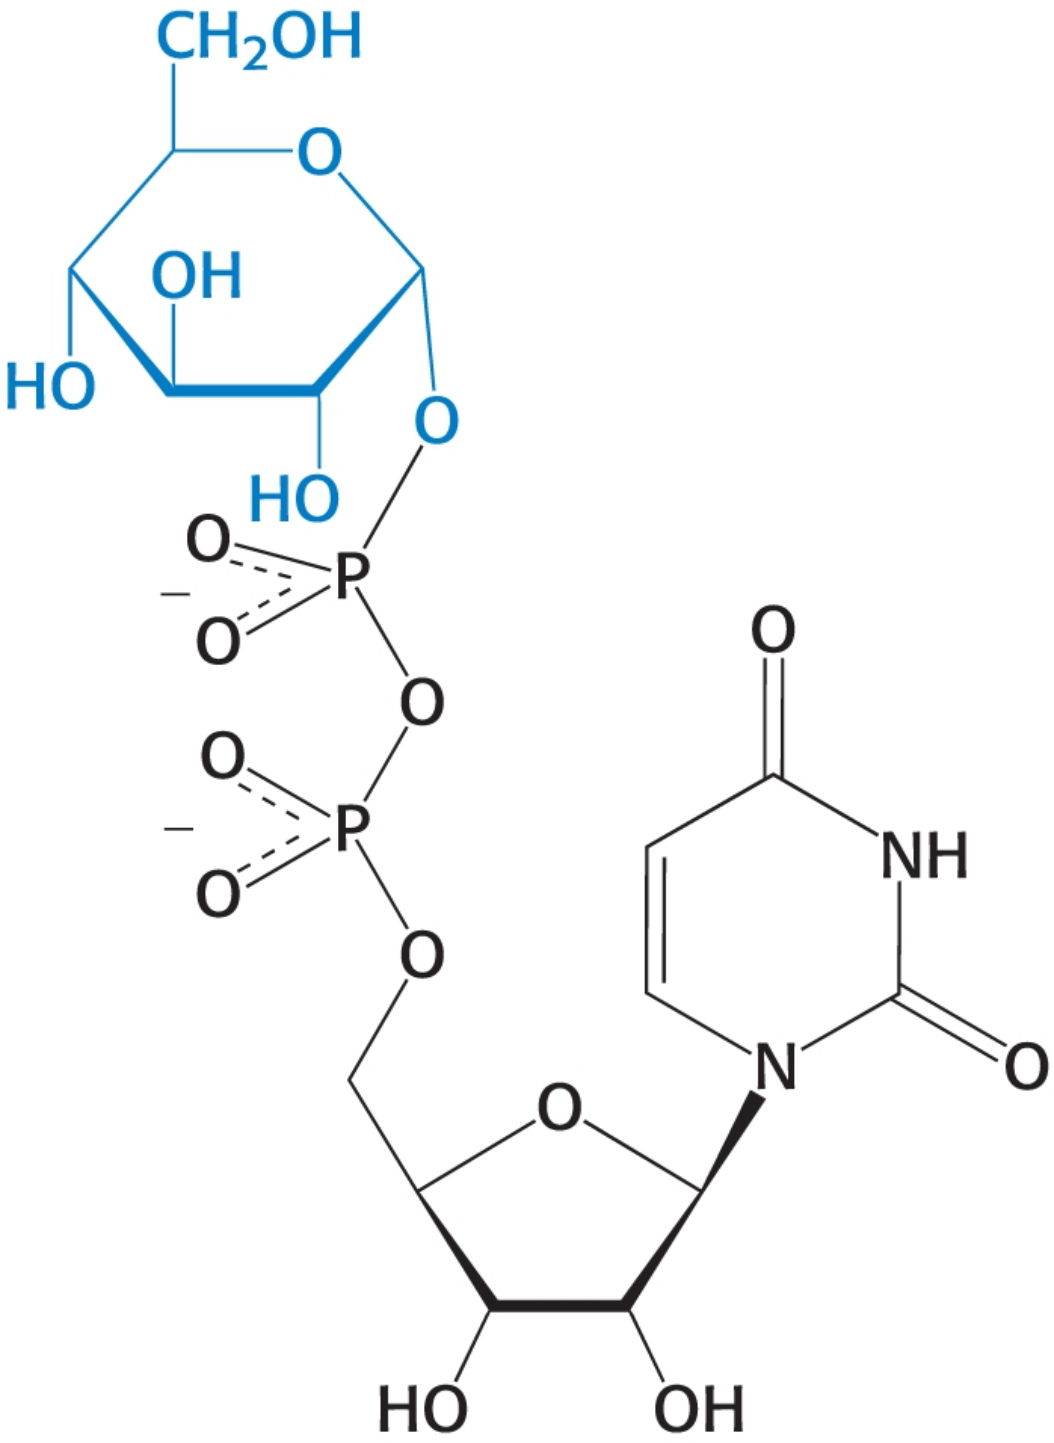
The cyclic AMP cascade highly amplifies the effects of hormones, resulting in a high-gain system. Gain is the ratio of the output signal to the input signal. In the case of glycogen metabolism, the binding of a small number of hormone molecules to cell-surface receptors leads to the release of a very large number of glucose units. Indeed, much of the stored glycogen would be mobilized within seconds were it not for a counterregulatory system.

Glycogen breakdown must be rapidly turned off when necessary

It is crucial that the high-gain system of glycogen breakdown be terminated quickly to prevent the wasteful depletion of glycogen after energy needs have been met and to prevent dangerously high blood-glucose concentrations. When glucose needs have been satisfied, phosphorylase kinase and glycogen phosphorylase are dephosphorylated and inactivated. Simultaneously, glycogen synthesis is activated.

The signal-transduction pathway leading to the activation of glycogen phosphorylase is shut down automatically when secretion of the initiating hormone ceases. The inherent GTPase activity of the G protein converts the bound GTP into inactive GDP, and phosphodiesterases that are always present in the cell convert cyclic AMP into AMP. **Protein phosphatase 1 (PP1)** removes the

phosphoryl groups from phosphorylase kinase, thereby inactivating the enzyme. Finally, PP1 also removes the phosphoryl group from glycogen phosphorylase, converting the enzyme into the usually inactive *b* form.



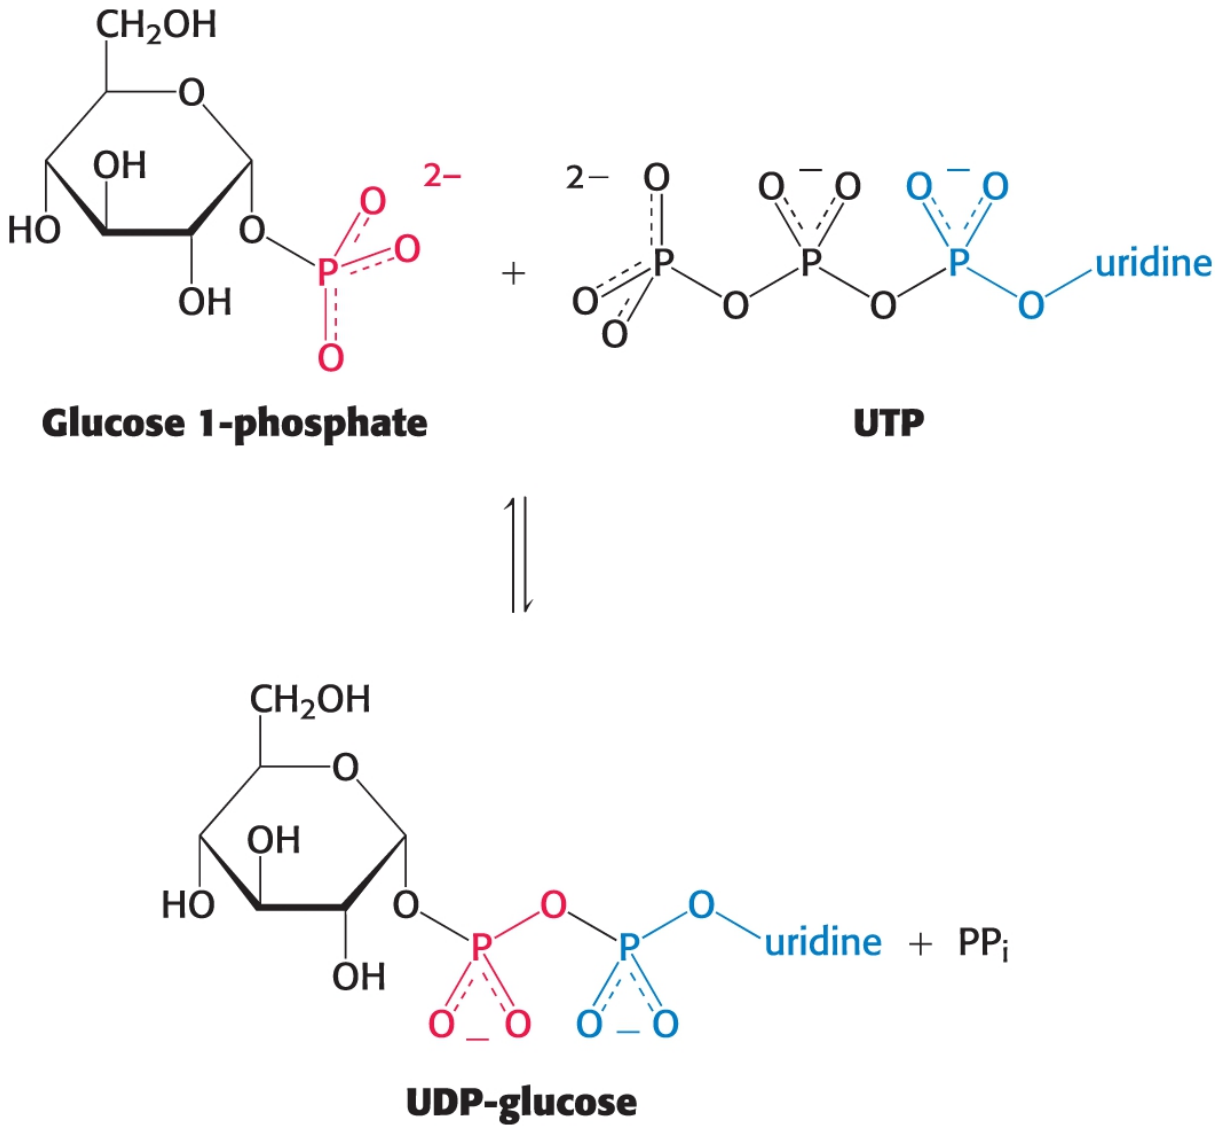
21.5 Glycogen Synthesis Requires Several Enzymes and Uridine Diphosphate Glucose

As we saw with glycolysis and gluconeogenesis (Chapter 16), related degradative and biosynthetic pathways rarely operate by precisely the same reactions in the forward and reverse directions. Glycogen metabolism provided the first known example of this important principle: separate pathways afford much greater flexibility, both in energetics and in control.

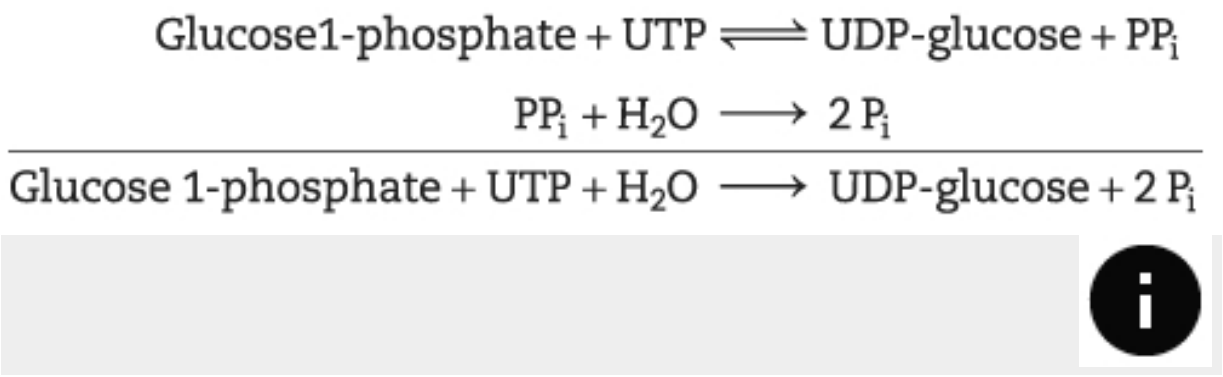
Glycogen is synthesized by a pathway that utilizes **uridine diphosphate glucose (UDP-glucose)** as the activated glucose donor.

$$\text{Synthesis: Glycogen}_n + \text{UDP–glucose} \rightarrow \text{glycogen}_{n+1} + \text{UDP}$$

$$\text{Degradation: Glycogen}_{n+1} + P_i \rightarrow \text{glycogen}_n + \text{glucose 1–phosphate}$$



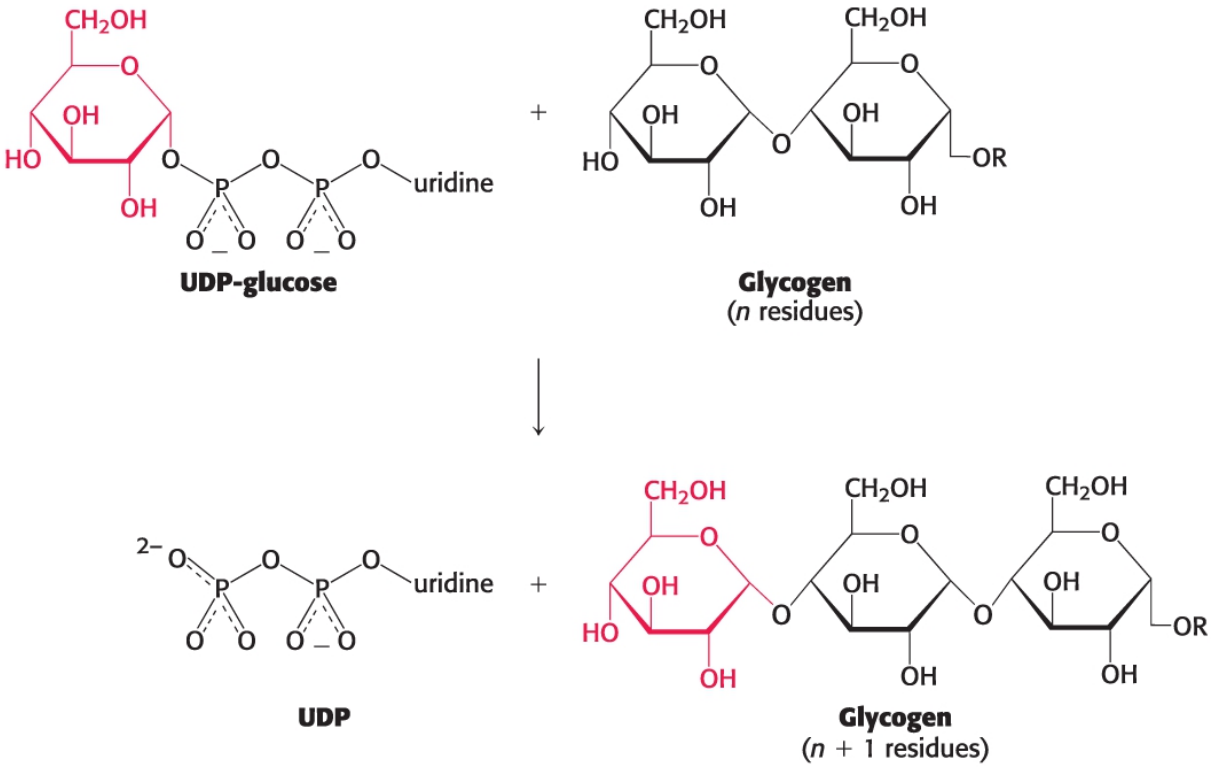
Uridine diphosphate glucose (UDP-glucose)



UDP-glucose is an activated form of glucose

UDP-glucose, the glucose donor in the biosynthesis of glycogen, is called an *activated* form of glucose, just as ATP and acetyl CoA are activated forms of orthophosphate and acetate, respectively. The C-1 carbon atom of the glucosyl unit of UDP-glucose is activated because its hydroxyl group is esterified to the diphosphate moiety of UDP.

UDP-glucose is synthesized from glucose 1-phosphate and uridine triphosphate (UTP) in a reaction catalyzed by UDP-glucose pyrophosphorylase. This reaction liberates the outer two phosphoryl residues of UTP as pyrophosphate.



This reaction is readily reversible. However, pyrophosphate is rapidly hydrolyzed in vivo to orthophosphate by an inorganic pyrophosphatase, keeping the concentration of pyrophosphate consistently low. Thus, the essentially irreversible hydrolysis of pyrophosphate drives the synthesis of UDP-glucose because the concentration of one of the products is kept near zero, making ΔG large and negative.

The synthesis of UDP-glucose exemplifies another recurring theme in biochemistry: many biosynthetic reactions are driven by the hydrolysis of pyrophosphate.

Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to growing chains

The key regulatory enzyme in glycogen synthesis is **glycogen synthase**, which adds new glucosyl units to the nonreducing terminal residues of glycogen. Humans have two isozymes of glycogen synthase: one is specific to the liver, while the other is expressed in muscle and other tissues. The activated glucosyl unit of UDP-glucose is transferred to the hydroxyl group at C-4 of a terminal residue to form an α-1,4-glycosidic linkage. UDP is displaced by the terminal hydroxyl group of the growing glycogen molecule.

Glycogen synthase can add glucosyl residues only to a polysaccharide chain already containing at least four residues. Thus, glycogen synthesis requires a primer. This priming function is carried out by **glycogenin**, a Mn^{2+}-requiring glycosyltransferase composed of two identical 37-kDa subunits. Each subunit of glycogenin catalyzes the formation of α-1,4-glucose polymers on the other subunit (*inter*molecular autoglycosylation), or within the same subunit (*intra*molecular autoglycosylation). UDP-glucose is used to processively add glucosyl units to the phenolic hydroxyl group of a specific tyrosine residue in each glycogenin subunit. This proceeds until the chains reach 10 to 20 glucosyl units in length, at which point glycogen synthase takes over to extend the glycogen molecules attached to each subunit. Thus, every glycogen molecule has a glycogenin monomer covalently attached at its core (Figure 21.2).

A branching enzyme forms α-1,6 linkages

Glycogen synthase catalyzes only the synthesis of α-1,4 linkages; another enzyme is required to form the α-1,6 linkages that make glycogen a branched polymer. Branching takes place after a number of glucosyl residues are joined in α-1,4 linkages by glycogen synthase (Figure 21.17).

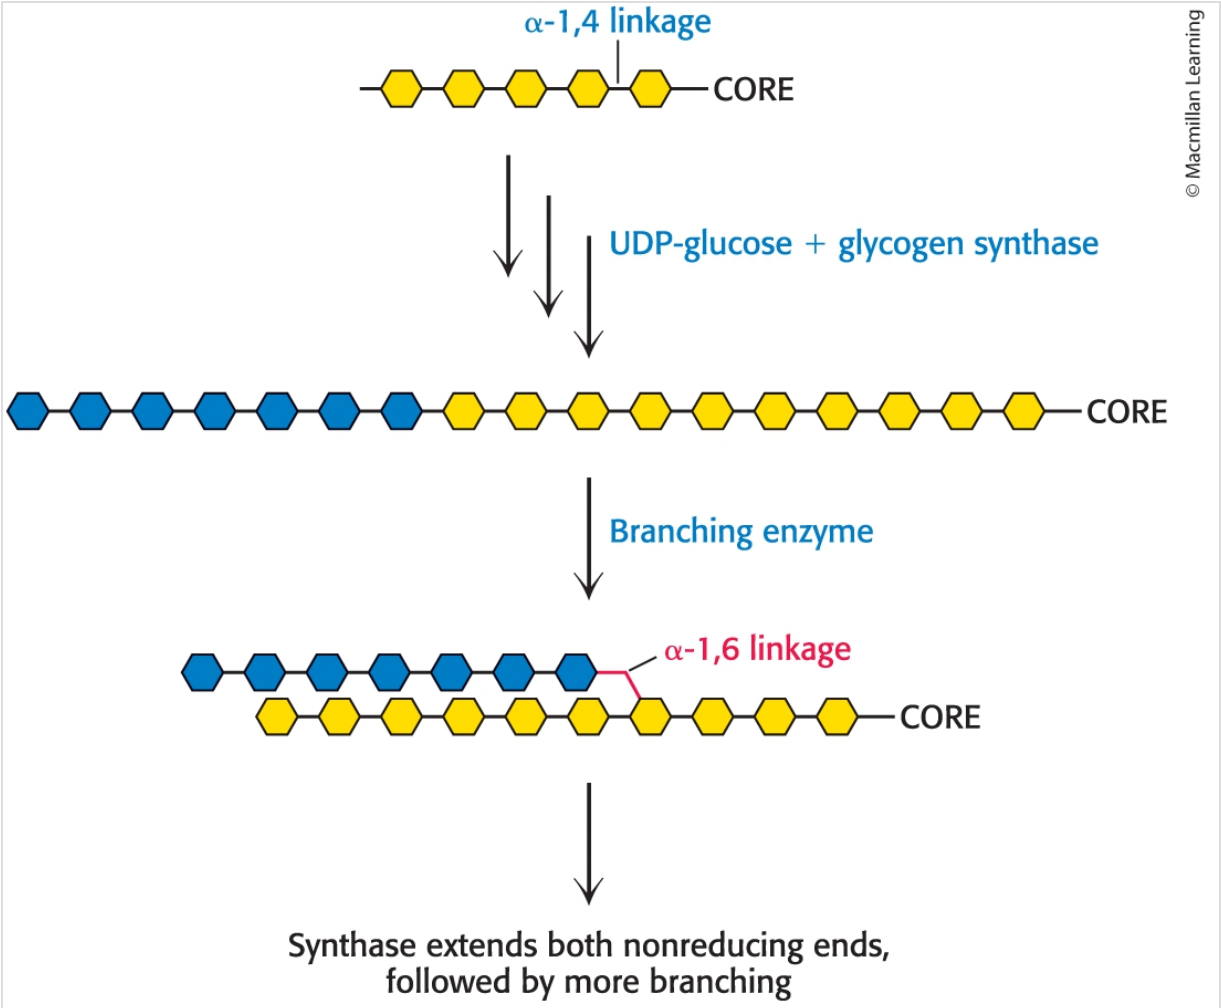


FIGURE 21.17 Branching enzyme removes approximately seven residues from the nonreducing end and reattaches them with an α-1,6 linkage.

A branch is created by the breaking of an α-1,4 link and the formation of an α-1,6 link, transferring a block of residues, typically seven, to a more interior site. The branching enzyme catalyzing this reaction requires that the block of residues must include the nonreducing terminus, and must come from a chain at least 11 residues long. In addition, the new branch point must be at least four residues away from a preexisting one.

Branching is important because it increases the solubility of glycogen. Furthermore, branching creates a large number of terminal residues, the sites of action of glycogen phosphorylase and synthase (**Figure 21.18**). Thus, branching increases the rate of glycogen synthesis and degradation.

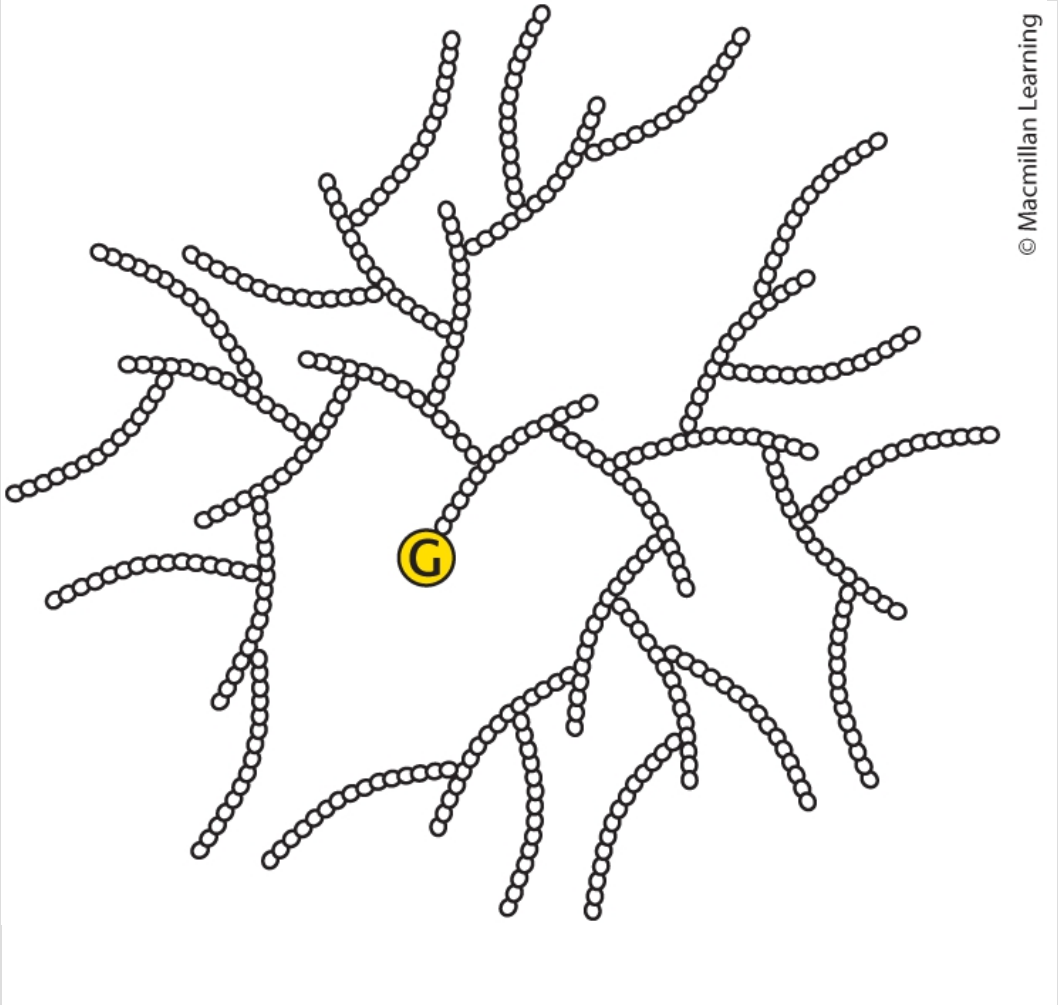

FIGURE 21.18 A cross section of a glycogen molecule reveals the basic branching structure. The component labeled G is glycogenin. Note that this is a cross section of the three-dimensional structure illustrated in Figure 21.2.

Glycogen synthase is the key regulatory enzyme in glycogen synthesis

Glycogen synthase, like phosphorylase, exists in two forms: an active nonphosphorylated *a* form and a usually inactive phosphorylated *b* form. Again, like the phosphorylase, the interconversion of the two forms is controlled extracellularly by the action of hormones; however, note that phosphorylation has opposite effects on the enzymatic activities of glycogen synthase and glycogen phosphorylase.

Glycogen synthase is phosphorylated at multiple sites by several protein kinases — notably, **glycogen synthase kinase**, which is under the control of insulin, and PKA. The function of the multiple phosphorylation sites is still under investigation. In contrast, the key means of automatically regulating glycogen synthase activity is by allosteric regulation of the phosphorylated form of the enzyme, glycogen synthase *b*. Glucose 6-phosphate is a powerful activator of the enzyme, stabilizing the R state of the enzyme relative to the T state and providing automatic activation of the enzyme when the concentrations of glucose-phosphates are high within a given cell.

Glycogen is an efficient storage form of glucose

What is the cost of converting glucose 6-phosphate into glycogen and back into glucose 6-phosphate? The pertinent reactions have already been described except for reaction 5 below, which is the regeneration of UTP. ATP phosphorylates UDP in a reaction catalyzed by nucleoside diphosphokinase.

$$\text{Glucose 6-phosphate} \rightarrow \text{glucose 1-phosphate} \quad \textbf{(1)}$$

$$\text{Glucose 1-phosphate} + \text{UTP} \rightarrow \text{UDP-glucose} + PP_i \quad \textbf{(2)}$$

$$PP_i + H_2O \rightarrow 2\ P_i \quad \textbf{(3)}$$

$$\text{UDP-glucose} + \text{glycogen}_n \rightarrow \text{glycogen}_{n+1} + \text{UDP} \quad \textbf{(4)}$$

$$\text{UDP} + \text{ATP} \rightarrow \text{UTP} + \text{ADP} \quad \textbf{(5)}$$

Sum: $\text{Glucose 6-phosphate} + \text{ATP} + \text{glycogen}_n + H_2O \rightarrow \text{glycogen}_{n+1} + \text{ADP} + 2\ P_i$

Thus, one molecule of ATP is hydrolyzed to incorporate glucose 6-phosphate into glycogen. The energy yield from the breakdown of glycogen is highly efficient. About 90% of the residues are phosphorolytically cleaved to glucose 1-phosphate, which is converted at no cost into glucose 6-phosphate. The other residues are branch residues, which are hydrolytically cleaved. One molecule of ATP is then used to phosphorylate each of these glucose molecules to glucose 6-phosphate. The complete oxidation of glucose 6-phosphate yields about 31 molecules of ATP, and storage consumes slightly more than one molecule of ATP per molecule of glucose 6-phosphate; so the overall efficiency of storage is nearly 97%.

21.6 Glycogen Breakdown and Synthesis Are Reciprocally Controlled by Hormones

An important control mechanism prevents glycogen from being synthesized at the same time as it is being broken down. The same glucagon- and epinephrine-triggered cAMP cascades that initiate glycogen breakdown in the liver and muscle, respectively, also shut off glycogen synthesis. Glucagon and epinephrine control both glycogen breakdown and glycogen synthesis through PKA (**Figure 21.19**). Recall that PKA adds a phosphoryl group to phosphorylase kinase, activating that enzyme and initiating glycogen breakdown. Both glycogen synthase kinase and PKA add phosphoryl groups to glycogen synthase, but this phosphorylation leads to a *decrease* in enzymatic activity. In this way, glycogen breakdown and synthesis are reciprocally regulated. How is the enzymatic activity reversed so that glycogen breakdown halts and glycogen synthesis begins?

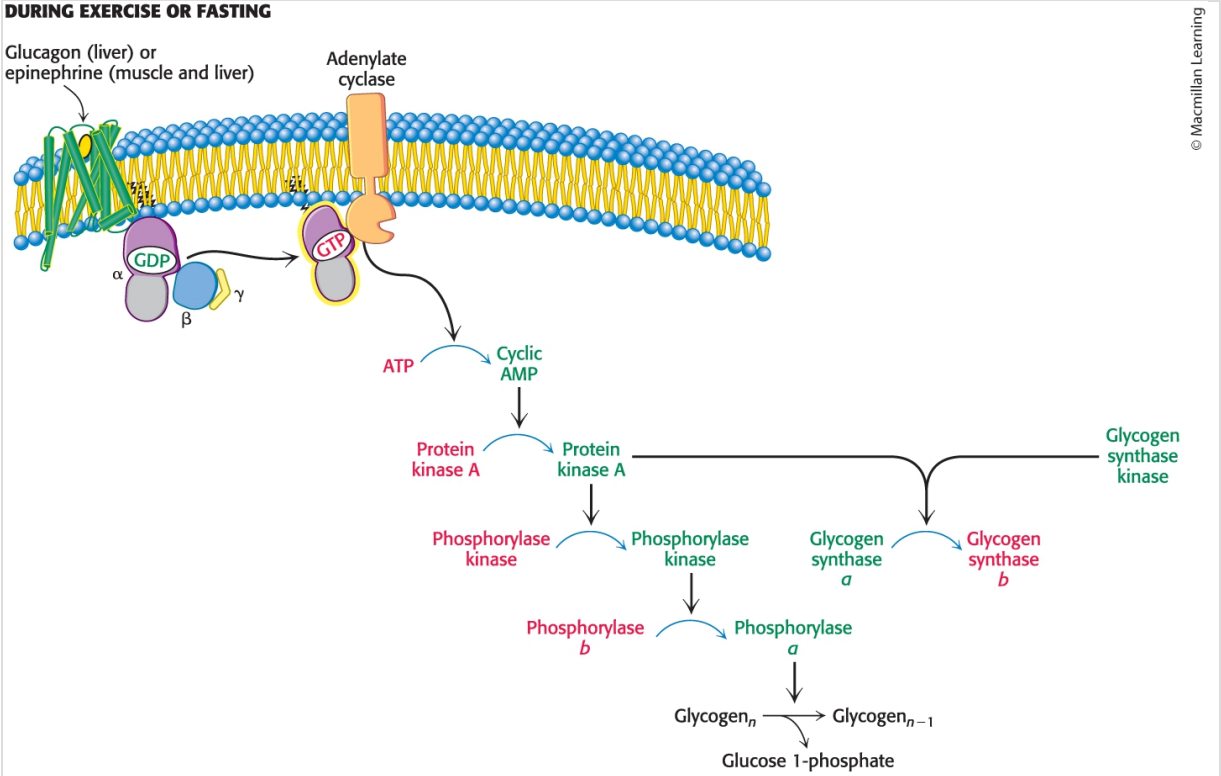

FIGURE 21.19 Glycogen metabolism is regulated in part by hormone-triggered cyclic AMP cascades. The sequence of reactions leading to the activation of protein kinase A ultimately activates glycogen degradation. At the same time, protein kinase A along with glycogen synthase kinase inactivates glycogen synthase, shutting down glycogen synthesis. The inactive forms of the enzymes are shown in red and the active forms in green.

EXPLORE this pathway further in the Metabolic Map in Achieve

Protein phosphatase 1 reverses the effects of kinases on glycogen metabolism

After a bout of exercise, muscle must shift from a glycogen-degrading mode to one of glycogen replenishment. A first step in this metabolic task is to shut down the phosphorylated proteins that stimulate glycogen breakdown. This task is accomplished by protein

phosphatases that catalyze the hydrolysis of phosphorylated serine and threonine residues in proteins.

Protein phosphatase 1 (PP1) plays key roles in regulating glycogen metabolism (Figure 21.20). PP1 decreases the rate of glycogen breakdown by reversing the effects of the phosphorylation cascade: it inactivates phosphorylase *a* and phosphorylase kinase by dephosphorylating them. PP1 also removes phosphoryl groups from glycogen synthase *b* to convert it into the more active glycogen synthase *a* form. Thus, PP1 accelerates glycogen synthesis; it is yet another molecular device for coordinating carbohydrate storage.

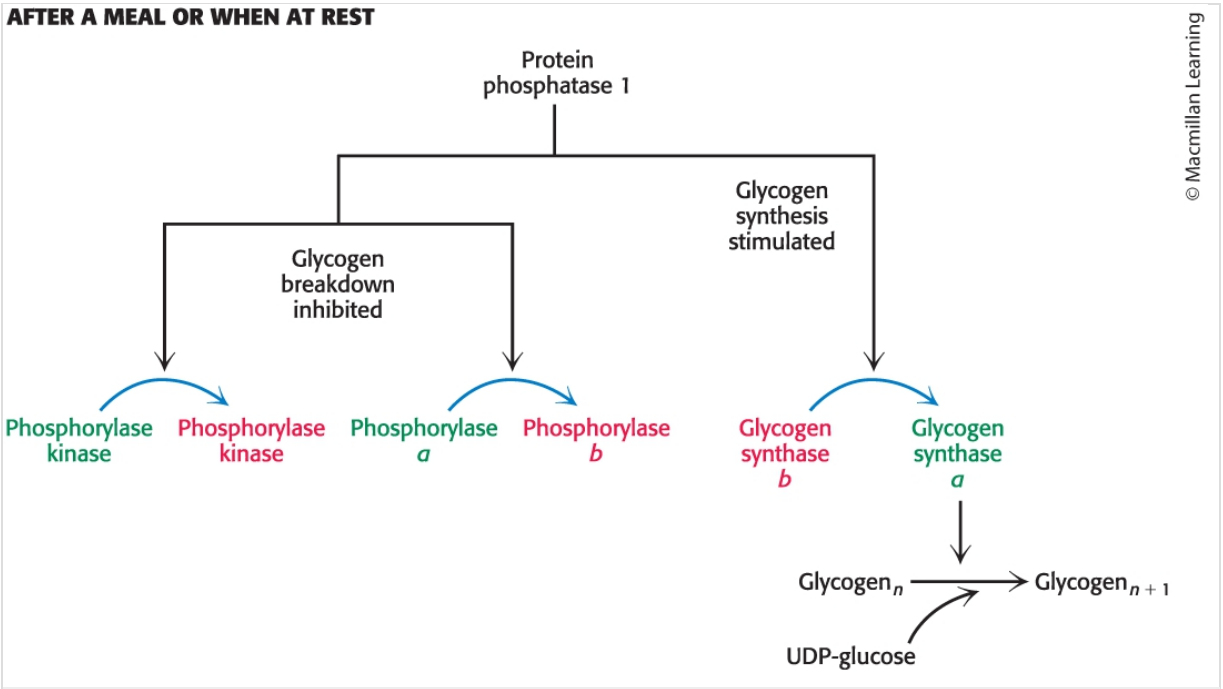

FIGURE 21.20 Glycogen synthesis is regulated by protein phosphatase 1 (PP1). PP1 stimulates glycogen synthesis while inhibiting glycogen breakdown. The inactive forms of the enzymes are shown in red and the active forms in green.

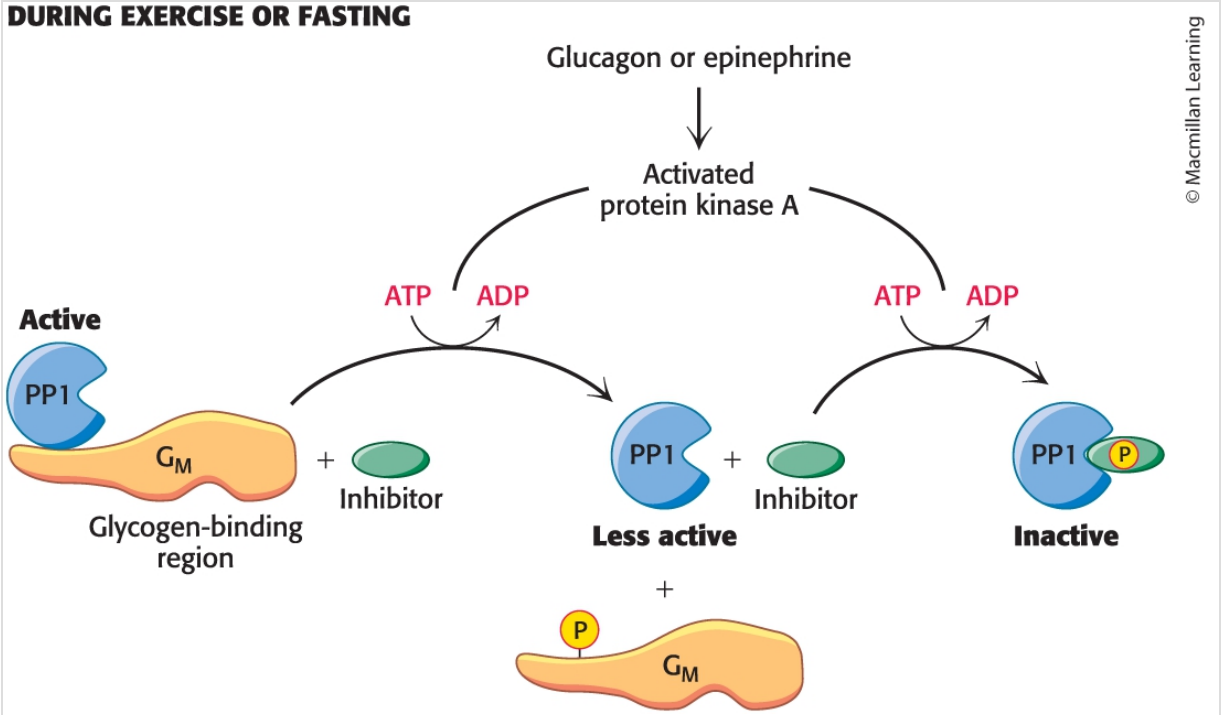
The catalytic subunit of PP1 is a 37-kDa single-domain protein that is usually bound to one of a family of regulatory subunits with masses of approximately 120 kDa. In skeletal muscle and heart, the most prevalent regulatory subunit is G_M, whereas in the liver, the most prevalent subunit is G_L. These regulatory subunits have modular structures with domains that participate in interactions with glycogen, with the catalytic subunit, and with target enzymes. Thus, these regulatory subunits act as scaffolds, bringing together the phosphatase and its substrates on the glycogen particle.

What prevents the phosphatase activity of PP1 from always inhibiting glycogen degradation? When glycogen degradation is called for, glucagon or epinephrine initiates the cAMP cascade that activates PKA (**Figure 21.21**), which reduces the activity of PP1 by two mechanisms. First, in muscle, G_M is phosphorylated in the domain responsible for binding the catalytic subunit. The catalytic subunit is released from glycogen and from its substrates, and its phosphatase activity is greatly reduced. Second, almost all tissues contain small proteins (Inhibitor in Figure 21.21) that, when phosphorylated, bind to the catalytic subunit of PP1 and inhibit it. Thus, when glycogen degradation is switched on by cAMP, the accompanying phosphorylation of these inhibitors keeps phosphorylase in its active *a* form and glycogen synthase in its inactive *b* form.



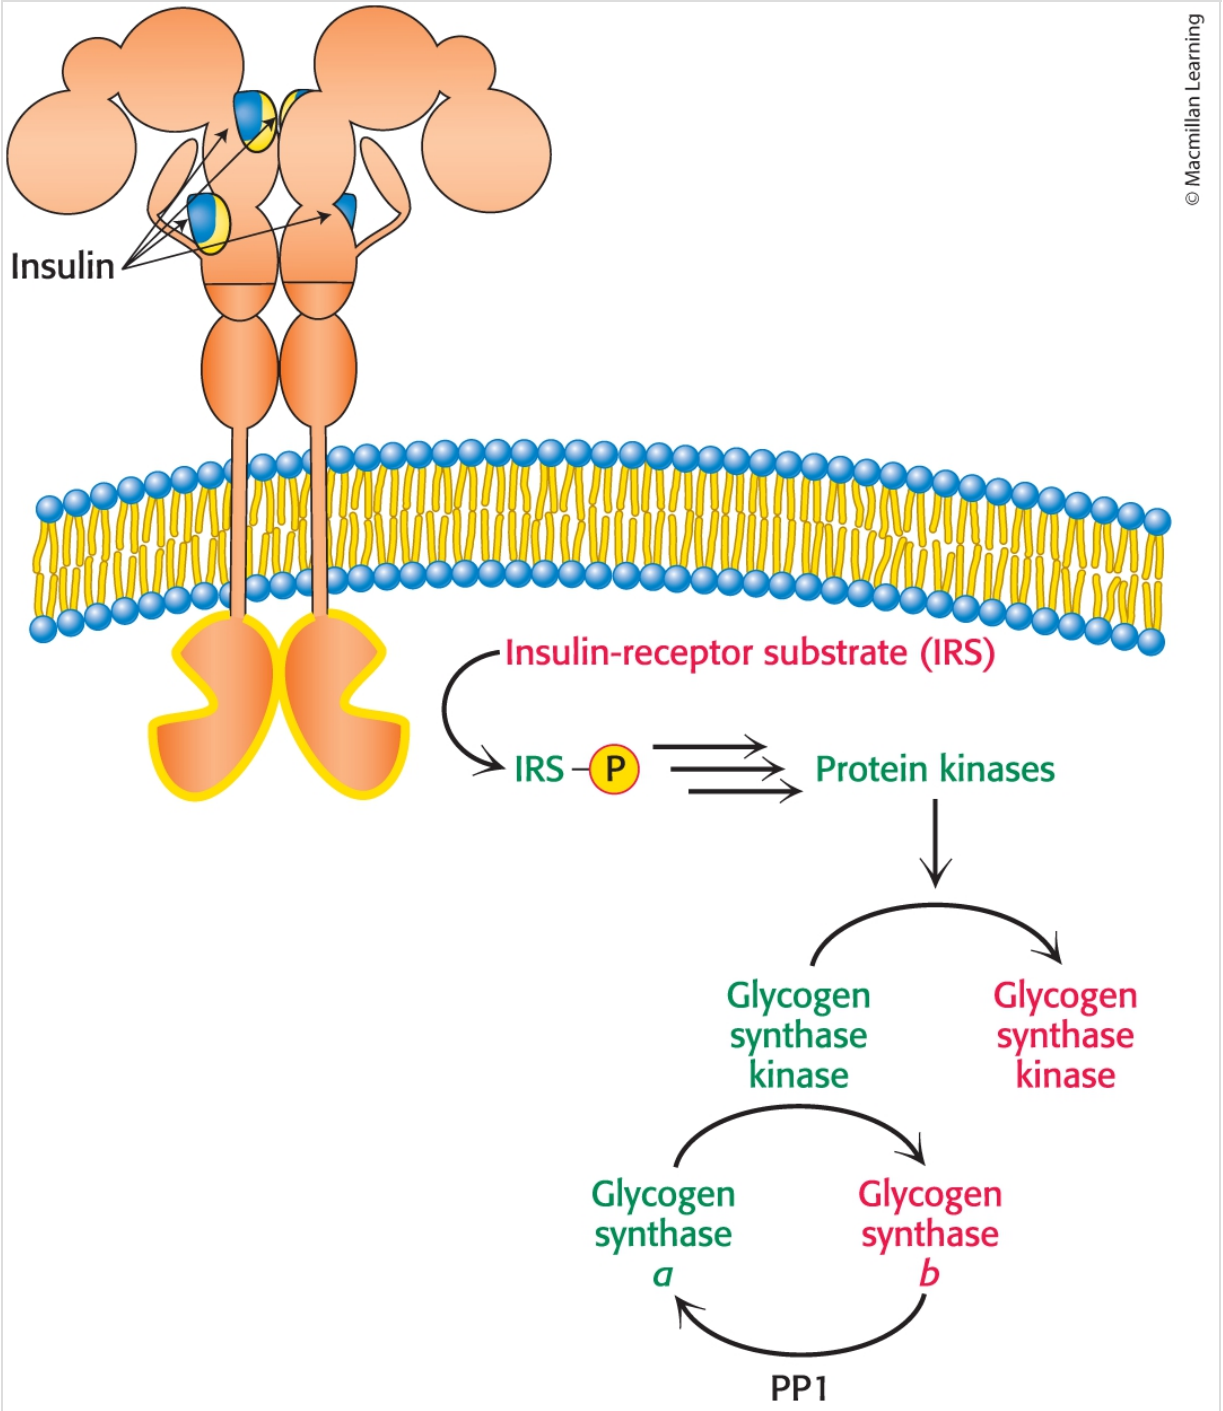


FIGURE 21.21 PP1 is regulated by hormonally controlled cascades. Protein phosphatase 1 (PP1) regulation in muscle takes place in two steps. First, phosphorylation of G_M by protein kinase A dissociates the catalytic subunit from its substrates in the glycogen particle and reduces its activity. Then, phosphorylation of the inhibitor subunit by protein kinase A and its subsequent binding by the phosphatase completely inactivates the catalytic subunit of PP1.

Interestingly, recent research suggests that glycogen phosphorylase is also regulated by acetylation (Section 7.3). Acetylation not only inhibits the enzyme, but also enhances dephosphorylation by promoting the interaction with PP1. Acetylation is stimulated by glucose and insulin, but inhibited by glucagon. It is fascinating that glycogen phosphorylase, one of the first allosteric enzymes identified and one of the most studied enzymes, is still revealing secrets.

Insulin stimulates glycogen synthesis by inactivating glycogen synthase kinase

After exercise, people often consume carbohydrate-rich foods to restock their glycogen stores. How is glycogen synthesis stimulated? When blood-glucose concentration is high, insulin stimulates the synthesis of glycogen by inactivating glycogen synthase kinase, one of the enzymes that maintains glycogen synthase in its phosphorylated, inactive state (**Figure 21.22**). The first step in the action of insulin is its binding to its receptor, a tyrosine kinase receptor in the plasma membrane which, once activated, phosphorylates insulin-receptor substrates (Section 14.3). These phosphorylated proteins then trigger signal-transduction pathways that eventually lead to the activation of protein kinases that phosphorylate and inactivate glycogen synthase kinase. The inactive kinase can no longer maintain glycogen synthase in its phosphorylated, inactive state. Additionally, PP1 dephosphorylates glycogen synthase, activating it, and restoring glycogen reserves. Finally, recall that insulin also increases the amount of glucose in the cell by increasing the number of glucose transporters in the membrane (Section 16.1). The net effect of insulin is thus the replenishment of glycogen stores.

© Macmillan Learning

FIGURE 21.22 Insulin inactivates glycogen synthase kinase. Insulin triggers a cascade that leads to the phosphorylation and inactivation of glycogen synthase kinase and prevents the phosphorylation of glycogen synthase. Protein phosphatase 1 (PP1) removes the phosphates from glycogen synthase, thereby activating the enzyme and allowing glycogen synthesis. The inactive forms of the enzymes are shown in red and the active forms in green.

Glycogen metabolism in the liver regulates the blood-glucose concentration

After a meal rich in carbohydrates, blood-glucose concentration rises, and glycogen synthesis is stepped up in the liver. Although insulin is the primary signal for glycogen synthesis, another is the concentration of glucose in the blood, which normally ranges from about 4.4–6.7 mM. The liver senses the concentration of glucose in the blood and takes up or releases glucose accordingly. Experiments performed in rodents established that the amount of liver phosphorylase *a* decreases rapidly when glucose is infused (**Figure 21.23**). After a lag period, the amount of glycogen synthase *a* increases, which results in glycogen synthesis. How does phosphorylase perform its function as the glucose sensor in liver cells, facilitating the switch from degradation to synthesis?

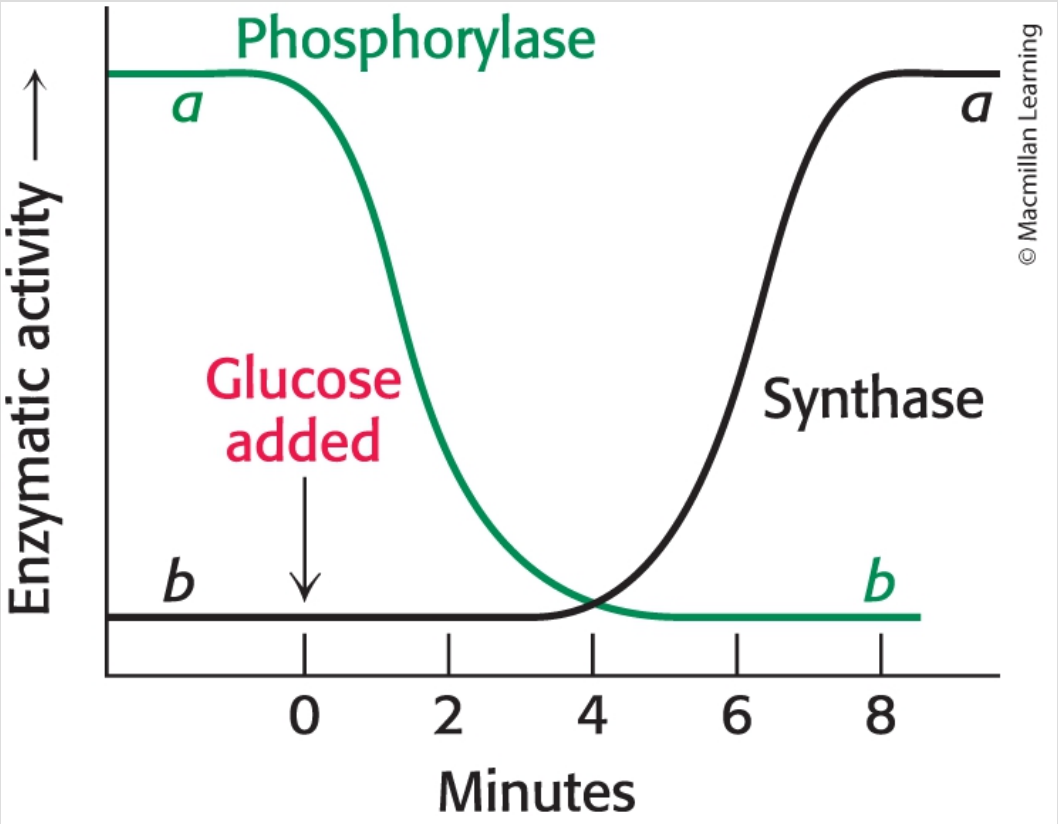

FIGURE 21.23 Blood glucose regulates liver-glycogen metabolism. The infusion of glucose into the bloodstream leads to the inactivation of phosphorylase, followed by the activation of glycogen synthase, in the liver.

[Data from W. Stalmans, H. De Wulf, L. Hue, and H.-G. Hers, *Eur. J. Biochem.* 41:117–134, 1974.]

Phosphorylase *a* and PP1 are localized to the glycogen particle by interactions with the G_L subunit of PP1. The binding of glucose to phosphorylase *a* shifts its allosteric equilibrium from the active R form to the inactive T form (Figure 21.12). This conformational change renders the phosphoryl group on serine 14 a substrate for PP1. PP1 binds tightly to phosphorylase *a* only when the phosphorylase is in the R state, but PP1 is inactive when bound. When glucose induces the transition to the T form, PP1 and the phosphorylase dissociate from each other and the glycogen particle,

and PP1 becomes active, converting phosphorylase *a* to the *b* form (Figure 21.11). Recall that the R ↔ T transition of muscle phosphorylase *a* is unaffected by glucose and is thus unaffected by the rise in blood-glucose concentration (Section 21.3).

How does glucose binding to glycogen phosphorylase stimulate glycogen synthesis? As mentioned above, the conversion of *a* into *b* is accompanied by the release of PP1, which is then free to activate glycogen synthase (**Figure 21.24**). The removal of the phosphoryl group of inactive glycogen synthase *b* converts it into the active *a* form. What accounts for the lag between termination of glycogen degradation and the beginnings of glycogen synthesis (Figure 21.23)? There are about 10 phosphorylase *a* molecules per molecule of PP1. Consequently, the activity of glycogen synthase begins to increase only after most of phosphorylase *a* is converted into *b*. The lag between the decrease in glycogen degradation and the increase in glycogen synthesis prevents the two pathways from operating simultaneously. This remarkable glucose-sensing system depends on three key elements: (1) communication within phosphorylase between the allosteric site for glucose and the serine phosphate, (2) the use of PP1 to inactivate phosphorylase and activate glycogen synthase, and (3) the binding of PP1 to phosphorylase *a* to prevent the premature activation of glycogen synthase.

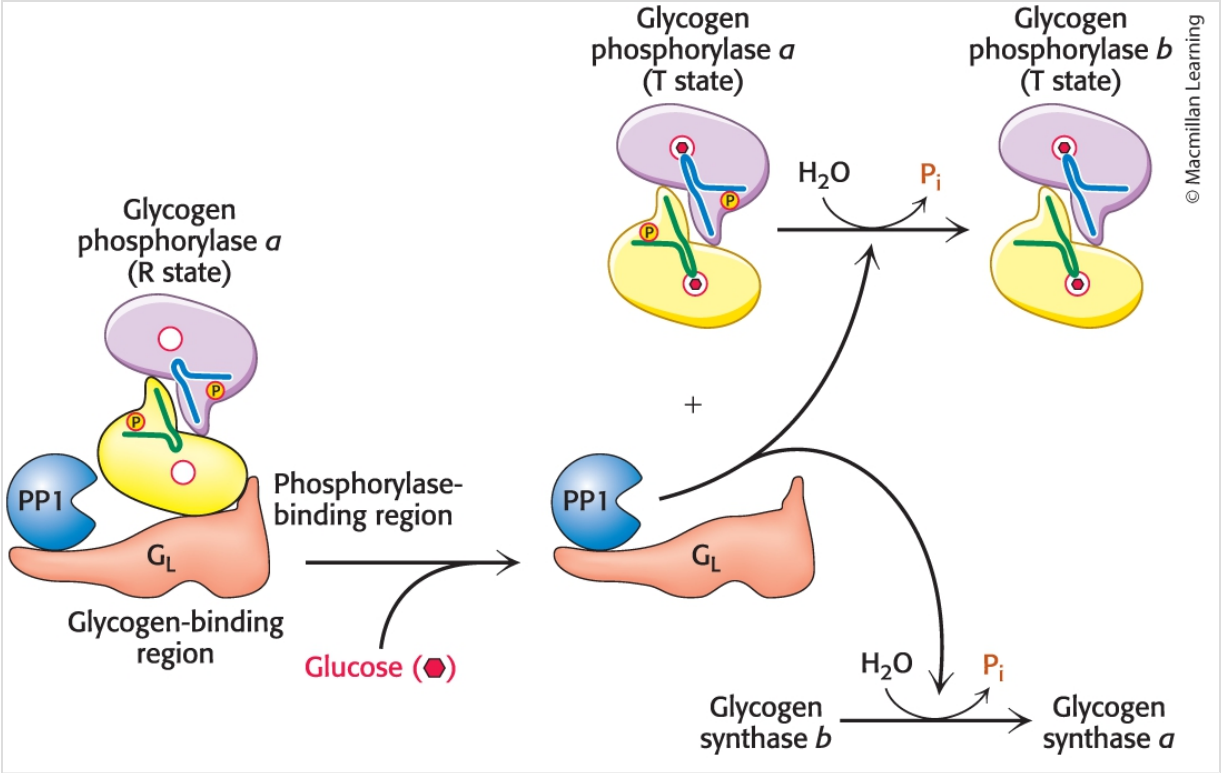

FIGURE 21.24 Glucose regulates liver-glycogen metabolism. After a carbohydrate-rich meal, glucose binds to and inhibits glycogen phosphorylase *a* in the liver, facilitating the formation of the T state of phosphorylase *a*. The T state of phosphorylase *a* does not bind protein phosphate 1 (PP1), leading to the dissociation of PP1 from glycogen phosphorylase *a*. The free PP1 is no longer inhibited and dephosphorylates glycogen phosphorylase *a* and glycogen synthase *b*, leading to the inactivation of glycogen breakdown and the activation of glycogen synthesis.

Efforts are underway to develop drugs that disrupt the interaction of liver phosphorylase with the G_L subunit as a treatment for type 2 diabetes, a disease characterized by excess blood glucose (Section 24.3). One experimental drug binds at a unique site on the enzyme that, synergistically with glucose, stabilizes the T state of phosphorylase and thereby enhances the transition to glycogen synthesis, as described earlier. Hence, disrupting the association of

phosphorylase with the G_L would render it a substrate for PP1. Glycogen degradation would decrease and glucose release into the blood would be inhibited.

Self-Check Question

What pathway, in addition to the cAMP-induced signal-transduction pathway, is used in the liver to maximize glycogen breakdown?

Biochemists have uncovered the biochemical basis of multiple glycogen-storage diseases

In 1929, Edgar von Gierke described the first glycogen-storage disease, which subsequently bore his name. Patients with von Gierke disease have a distended abdomen, caused by a massive enlargement of the liver, and pronounced hypoglycemia (low blood glucose) between meals. Furthermore, the blood-glucose concentration does not rise on administration of epinephrine and glucagon. In 1952, Gerty and Carl Cori discovered the mechanism for this disease: the liver lacks glucose 6-phosphatase (Figure 21.4). This finding was the first demonstration of an inherited deficiency of a liver enzyme.

The absence of glucose 6-phosphatase in the liver causes hypoglycemia because glucose cannot be formed from glucose 6-phosphate, which cannot cross the plasma membrane to leave the liver. Thus, the glycogen in the liver of a patient with von Gierke disease is normal in structure but is present in abnormally large amounts. The presence of excess glucose 6-phosphate also triggers an increase in glycolysis in the liver, leading to high concentrations of lactate and pyruvate in the blood. This disease can also be produced by a mutation in the gene that encodes the glucose 6-phosphate transporter. Recall that glucose 6-phosphate must be transported into the lumen of the endoplasmic reticulum to be hydrolyzed by phosphatase (Section 16.4). Mutations in the other three essential proteins of this system can likewise lead to von Gierke disease.

Seven other glycogen-storage diseases have been characterized (**Table 21.2**). In Pompe disease (type II), lysosomes become engorged with glycogen because they lack α-1,4-glucosidase, a hydrolytic enzyme confined to these organelles (**Figure 21.25**). There are several subtypes of glycogen-storage disease III, affecting either muscle or liver. Regardless of subtype, the outer branches of the glycogen are very short. Patients with type III lack the debranching enzyme (α-1,6-glucosidase), and so only the outermost branches of glycogen can be effectively utilized. Thus, only a small fraction of this abnormal glycogen is functionally active as an accessible store of glucose.

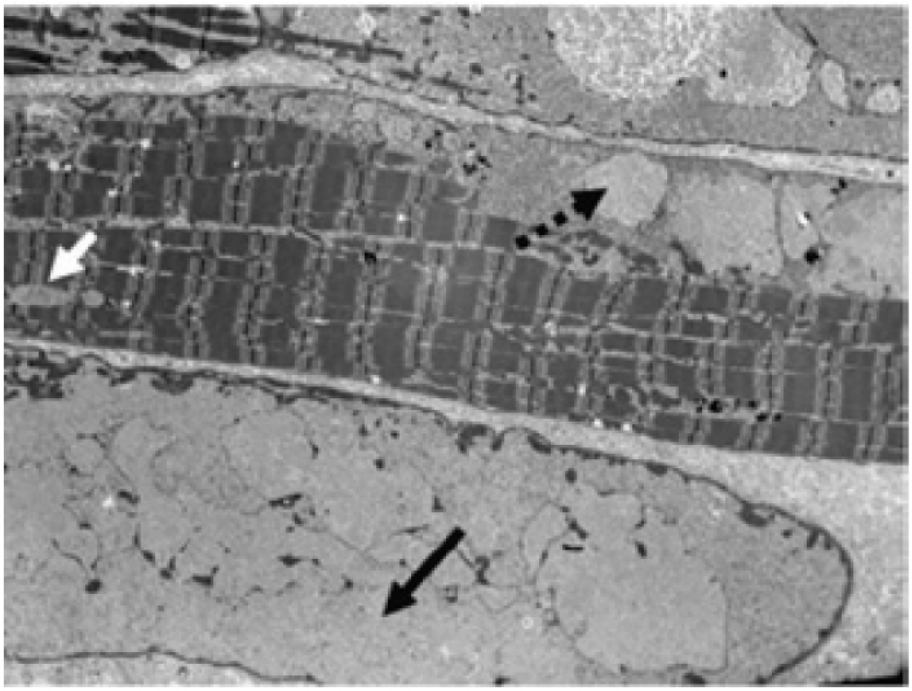

TABLE 21.2 Glycogen-storage diseases

Type	Defective enzyme	Organ affected	Glycogen in the affected organ	Clinical features

I von Gierke	Glucose 6-phosphatase or transport system	Liver and kidney	Increased amount; normal structure	Massive enlargement of the liver; failure to thrive; severe hypoglycemia, ketosis, hyperuricemia, hyperlipemia
II Pompe	α-1,4-glucosidase (lysosomal)	All organs	Massive increase in amount; normal structure	Cardiorespiratory failure causes death, usually before age 2
III Cori	α-1,6-glucosidase (debranching enzyme)	Muscle and liver	Increased amount; short outer branches	Like type I, but milder course
IV Andersen	Branching enzyme $(\alpha-1,4 \rightarrow \alpha-1,6)$	Liver and spleen	Normal amount; very long outer branches	Progressive cirrhosis of the liver; liver failure causes death, usually before age 2
V McArdle	Phosphorylase	Muscle	Moderately increased amount; normal structure	Limited ability to perform strenuous exercise because of painful muscle cramps; otherwise patient is normal and well developed
VI Hers	Phosphorylase	Liver	Increased amount	Like type I, but milder course
VII	Phosphofructokinase	Muscle	Increased amount;	Like type V

			normal structure	
VIII	Phosphorylase kinase	Liver	Increased amount; normal structure	Mild liver enlargement; mild hypoglycemia

Note: Types I through VII are inherited as autosomal recessives. Type VIII is sex-linked.

Credit: Reproduced with permission of the author, from Thurberg, B.L., et al., Characterization of pre- and post-treatment pathology after enzyme replacement for pompe disease. *Lab. Invest*, 2006 Dec: 86(12):1208–20.

FIGURE 21.25 An electron micrograph of a muscle cell from a patient with Pompe disease reveals enlarged lysosomes. Glycogen-engorged lysosomes are seen throughout the cell, including in the myofibrils (white arrow) and at the cell periphery (dashed black arrow). As the disease progresses, lysosomes may rupture, releasing large amounts of glycogen into the cytoplasm. Such accumulations of cytoplasmic glycogen are called *glycogen lakes* (solid black arrow).

A defect in glycogen metabolism confined to muscle is found in McArdle disease (type V) when muscle phosphorylase activity is

absent, limiting the capacity to perform strenuous exercise. Despite this limitation, patients with McArdle disease are otherwise normal and well developed, illustrating that effective utilization of muscle glycogen is not essential for life. We will examine McArdle disease further in Chapter 24.

Chapter 21 Summary

21.1 Glycogen Metabolism Is the Regulated Release and Storage of Glucose in Multiple Tissues

- Glycogen, a readily mobilized fuel store, is a branched polymer of glucose residues with α-1,4-glycosidic linkages and branches approximately every 12th residue created by an α-1,6-glycosidic bond.
- Glycogen is present to some extent in nearly all tissues but found in large amounts in muscle cells and in liver cells, where it is stored in the cytoplasm in the form of hydrated granules.

21.2 Glycogen Breakdown Requires the Interplay of Several Enzymes

- Most of the glycogen molecule is degraded to glucose 1-phosphate by the action of glycogen phosphorylase, which uses orthophosphate to split the α-1,4-glycosidic linkages; glucose 1-phosphate can then be reversibly converted into glucose 6-phosphate.
- Branch points are degraded by the combined actions of an oligosaccharide transferase and an α-1,6-glucosidase, both part of the bifunctional enzyme called *debranching enzyme*.

21.3 Phosphorylase Is Regulated by Allosteric Interactions and Controlled by Reversible Phosphorylation

- Phosphorylase *b*, which is usually inactive, is converted into active phosphorylase *a* by the phosphorylation of a single serine residue by phosphorylase kinase.

- In the liver, phosphorylase *a* liberates glucose for export to other organs, such as skeletal muscle and the brain; phosphorylase *a* is inhibited by the presence of glucose.
- In muscle, phosphorylase *b* can be activated by the binding of AMP to generate glucose for use inside the cells as a fuel for contractile activity. The effect of AMP is counteracted by ATP and glucose 6-phosphate.

21.4 Glucagon and Epinephrine Signal the Need for Glycogen Breakdown

- Epinephrine and glucagon stimulate glycogen breakdown through specific 7TM receptors.
- Muscle is responsive to epinephrine, whereas the liver is responsive to both epinephrine and glucagon.
- Both signal molecules initiate a kinase cascade that leads to the activation of phosphorylase kinase, which in turn converts glycogen phosphorylase *b* to the phosphorylated *a* form.

21.5 Glycogen Synthesis Requires Several Enzymes and Uridine Diphosphate Glucose

- The pathway for glycogen synthesis differs from that for glycogen breakdown: Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to the C-4 hydroxyl group of a terminal residue in the growing glycogen molecule.
- Synthesis is primed by glycogenin, an autoglycosylating protein that contains a covalently attached oligosaccharide unit on a specific tyrosine residue.
- Branching enzyme converts some of the α-1,4 linkages into α-1,6 linkages, thus increasing the number of ends and allowing glycogen to be made and degraded more rapidly.

21.6 Glycogen Breakdown and Synthesis Are Reciprocally Controlled by Hormones

- Glycogen synthesis and degradation are coordinated by several amplifying reaction cascades: epinephrine and glucagon stimulate glycogen breakdown and inhibit its synthesis by increasing the cytoplasmic concentration of cyclic AMP, which activates PKA.
- PKA activates glycogen breakdown by attaching a phosphate to phosphorylase kinase, and it inhibits glycogen synthesis by phosphorylating glycogen synthase. Glycogen synthase kinase also inhibits synthesis by phosphorylating the synthase.
- The glycogen-mobilizing actions of PKA are reversed by PP1, which is regulated by several hormones: epinephrine inhibits PP1, while insulin triggers a cascade that phosphorylates and inactivates glycogen synthase kinase. Hence, glycogen synthesis is decreased by epinephrine and increased by insulin.

Key Terms

glycogen phosphorylase
phosphorolysis
pyridoxal phosphate (PLP)
glucagon
epinephrine (adrenaline)
phosphorylase kinase
protein phosphatase 1 (PP1)
uridine diphosphate glucose (UDP-glucose)
glycogen synthase
glycogenin
glycogen synthase kinase

Problems

1. What are the three steps in glycogen degradation, and what enzymes are required? 1

2. Which molecule is the immediate product of glycogen phosphorylase? 1

a. Glucose 6-phosphate
b. Glucose 1-phosphate
c. Fructose 1-phosphate
d. Glucose 1,6-bisphosphate

3. Which of the following is a substrate for glycogen synthase? 3

a. UTP-glucose
b. Glucose 1-phosphate
c. CDP-glucose
d. UDP-glucose

4. α-Amylose is an unbranched glucose polymer. Why would this polymer not be as effective a storage form of glucose as glycogen?

5. Compare the allosteric regulation of phosphorylase in the liver and in muscle, and explain the significance of the difference. 2, 5

6. Why is water excluded from the active site of phosphorylase? Predict the effect of a mutation that allows water molecules to enter. 1

7. Outline the signal-transduction cascade for glycogen degradation in muscle. 2

8. There must be a way to shut down glycogen breakdown quickly to prevent the wasteful depletion of glycogen after energy needs have been met. What mechanisms are employed to turn off glycogen breakdown?

9. Phosphorylation has opposite effects on glycogen synthesis and breakdown. What is the advantage of its having opposing effects? 4

10. What enzymes are required for the synthesis of a glycogen particle starting from glucose 6-phosphate? 3

11. The following reaction accounts for the synthesis of UDP-glucose. This reaction is readily reversible. How is it made irreversible in vivo?

$$\text{Glucose 1-phosphate} + \text{UTP} \rightleftharpoons \text{UDP-glucose} + \text{PP}_i$$

12. Why does activation of the phosphorylated *b* form of glycogen synthase by high concentrations of glucose 6-phosphate make good biochemical sense? 4

13. Write a balanced equation showing the effect of simultaneous activation of glycogen phosphorylase and glycogen synthase. Include the reactions catalyzed by phosphoglucomutase and UDP-glucose pyrophosphorylase. 4

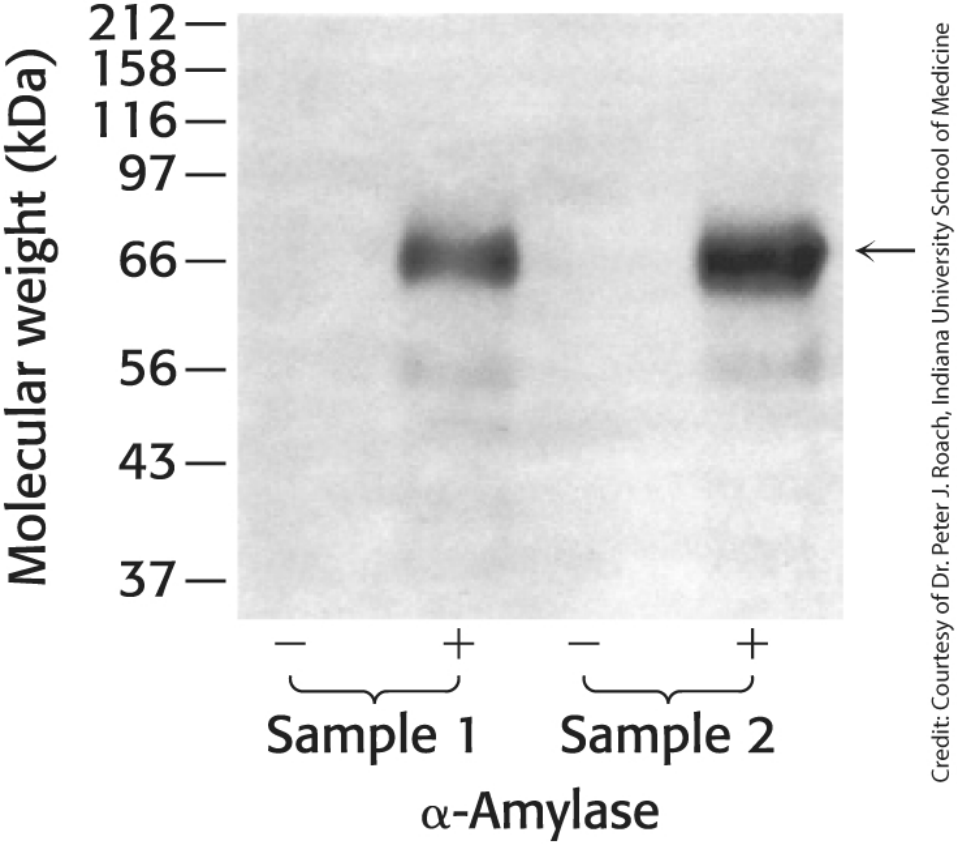
14. How does insulin stimulate glycogen synthesis? 4

15. Write a balanced equation for the formation of glycogen from galactose. 3

16. In exercising muscle, glycogen degradation supplies the muscle with glucose 6-phosphate. In order to stimulate muscle

glycogen degradation, protein phosphatase 1 (PP1) must be inhibited. Four of the five following events are involved in the inactivation of PP1 in exercising muscle. Which are they? 2, 4

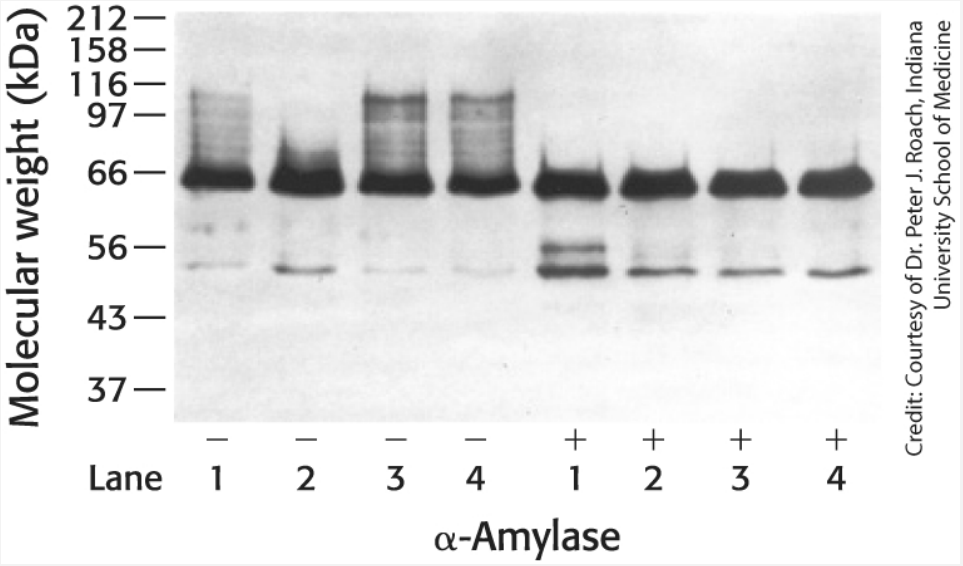
a. PKA phosphorylates an inhibitor of PP1.
b. Phosphorylated PP1 inhibitor binds to PP1, facilitating glycogen degradation by phosphorylase *a*.
c. PKA phosphorylates G_M in the $G_M - PP1$ complex, resulting in its dissociation.
d. Epinephrine initiates a cAMP signal-transduction cascade that utilizes PKA.
e. Insulin initiates a protein kinase cascade that utilizes glycogen synthase kinase.



17. Suggest another mutation in glucose metabolism that causes symptoms similar to those of von Gierke disease.

18. Experiments were performed in which serine (S)14 of glycogen phosphorylase was replaced by glutamate (E). The V_{max} of the mutant enzyme was then compared with the wild-type phosphorylase in both the *a* and the *b* form.

V_{max} μmoles of glucose $1-PO_4$ released min^{-1} mg^{-1}	
Wild-type phosphorylase *b*	25 ± 0.4
Wild-type phosphorylase *a*	100 ± 5
S to E mutant	60 ± 3

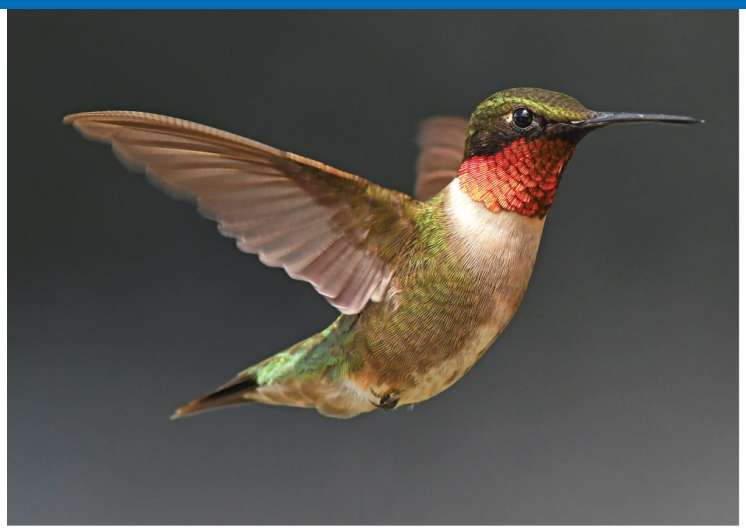


a. Explain the results obtained with the mutant.
b. Predict the effect of substituting aspartic acid for the serine.

19. The liver is a major storage site for glycogen. Purified from two samples of human liver, glycogen was either treated or not treated with α-amylase and subsequently analyzed by SDS-PAGE and western blotting with the use of antibodies to glycogenin (see Chapter 4 to review these techniques). The results are presented below.

a. Why are no proteins visible in the lanes without amylase treatment?
b. What is the effect of treating the samples with α-amylase? Explain the results.
c. List other proteins that you might expect to be associated with glycogen. Why are other proteins not visible?

20. The gene for glycogenin was transfected into a cell line that normally stores only small amounts of glycogen. The cells were then manipulated according to the following protocol, and glycogen was isolated and analyzed by SDS-PAGE and western blotting by using an antibody to glycogenin with and without α-amylase treatment. The results are presented below.



The protocol: Cells cultured in growth medium and 25 mM glucose (lane 1) were switched to medium containing no glucose for 24 hours (lane 2). Glucose-starved cells were refed with medium containing 25 mM glucose for 1 hour (lane 3) or 3

hours (lane 4). Samples (12 μg of protein) were either treated or not treated with α-amylase, as indicated, before being loaded on the gel. 3

a. Why did the western analysis produce a “smear” — that is, the high-molecular-weight staining in lane $1(-)$?
b. What is the significance of the decrease in high-molecular-weight staining in lane $2(-)$?
c. What is the significance of the difference between lanes $2(-)$ and $3(-)$?
d. Suggest a plausible reason why there is essentially no difference between lanes $3(-)$ and $4(-)$.
e. Why are the bands at 66 kDa the same in the lanes treated with amylase, despite the fact that the cells were treated differently?

Chapter 22
Fatty Acid and Triacylglycerol Metabolism

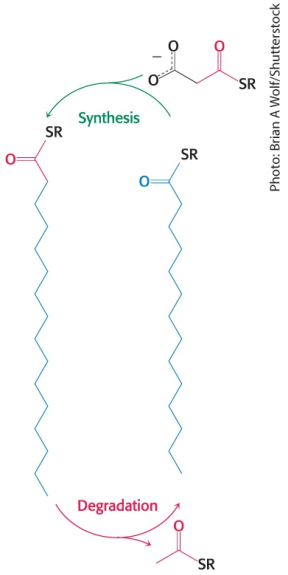


Photo: Brian A Wolf/Shutterstock

Like mammals, birds such as the ruby-throated hummingbird store energy for later use in the most weight-efficient way using fats. This bird beats its wings approximately 50 times per second nonstop to fly across the Gulf of Mexico using the energy stored in its tiny body as fat. Shown at right, the processes of fatty acid synthesis (preparation for energy storage) and fatty acid degradation (preparation for energy use) are, in many ways, the reverse of each other.

Outline

22.1 Triacylglycerols Are Highly Concentrated Energy Stores
22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing

22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation
22.4 Ketone Bodies Are a Fuel Source Derived from Fats
22.5 Fatty Acids Are Synthesized by Fatty Acid Synthase
22.6 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems
22.7 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

Learning Goals

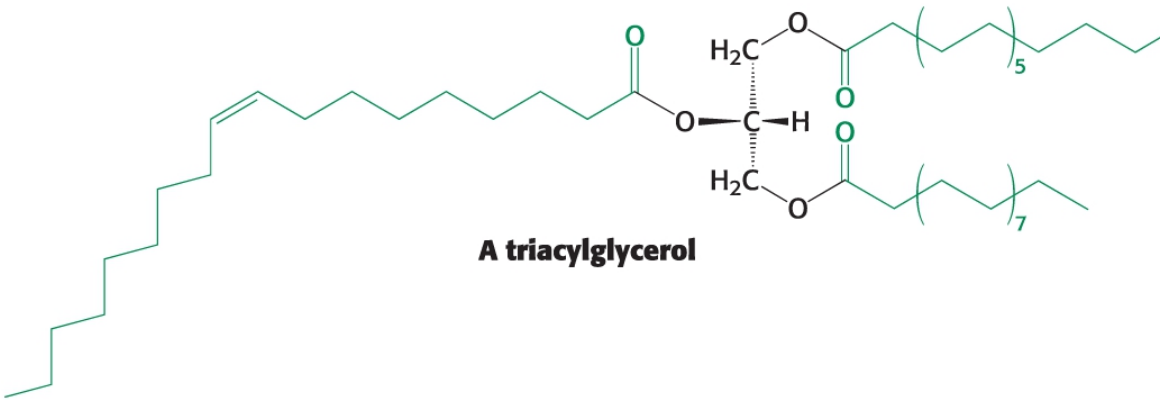
By the end of this chapter, you should be able to:

1. Identify the repeated steps of fatty acid degradation.
2. Describe ketone bodies and their role in metabolism.
3. Explain how fatty acids are synthesized.
4. Explain how fatty acid metabolism is regulated.

We turn now from the metabolism of carbohydrates to that of fatty acids, which have four major physiological roles:

1. *Fatty acids are fuel molecules.* Fatty acids are mobilized from storage in fat tissue and oxidized to meet the energy needs of a cell or organism. During rest or moderate exercise, such as walking, fatty acids are our primary source of energy.

2. *Fatty acids are building blocks of phospholipids and glycolipids.* These amphipathic molecules are important components of biological membranes, as discussed in Chapter 12.



3. *Many proteins are modified by the covalent attachment of fatty acids.* The attached fatty acids target proteins to membrane locations (Section 12.4).

4. *Fatty acid derivatives serve as hormones and intracellular messengers.*

In this chapter, we focus on the degradation and synthesis of fatty acids.

22.1 Triacylglycerols Are Highly Concentrated Energy Stores

Fatty acids are stored as **triacylglycerols** (also called **neutral fats** or **triglycerides**), which are uncharged esters of fatty acids with glycerol.

Triacylglycerols are stored mainly in adipose tissue, composed of cells called *adipocytes* (**Figure 22.1**). Triacylglycerols are highly concentrated stores of metabolic energy because they are reduced and anhydrous (containing no water). The yield from the complete oxidation of fatty acids is about $38\ kJ\ g^{-1}\ (9\ kcal\ g^{-1})$, in contrast with about $17\ kJ\ g^{-1}\ (4\ kcal\ g^{-1})$ for carbohydrates and proteins. The basis of this large difference in caloric yield is that fatty acids are much more reduced than carbohydrates or proteins. Furthermore, triacylglycerols are nonpolar, and so they are stored in a nearly anhydrous form, whereas much more polar carbohydrates are more highly hydrated. In fact, 1 g of dry glycogen binds about 2 g of water. Consequently, a gram of nearly anhydrous fat stores 6.75 times as much energy as a gram of

hydrated glycogen, which is likely the reason that triacylglycerols rather than glycogen were selected in evolution as the major energy reservoir.

Biophoto Associates/Science Source

FIGURE 22.1 An electron micrograph of an adipocyte reveals an enormous intracellular lipid droplet. A small band of cytoplasm surrounds the large deposit of triacylglycerols.

Consider a typical 70-kg man, who has fuel reserves of 420,000 kJ (100,000 kcal) in triacylglycerols, 100,000 kJ (24,000 kcal) in protein (mostly in muscle), 2500 kJ (600 kcal) in glycogen, and 170 kJ (40 kcal) in glucose. Triacylglycerols constitute about 11 kg of his total body weight. If this amount of energy were stored in glycogen, his total body weight would be 64 kg greater. The glycogen and glucose stores provide enough energy to sustain physiological function for about 24 hours, whereas the triacylglycerol stores allow survival for several weeks.

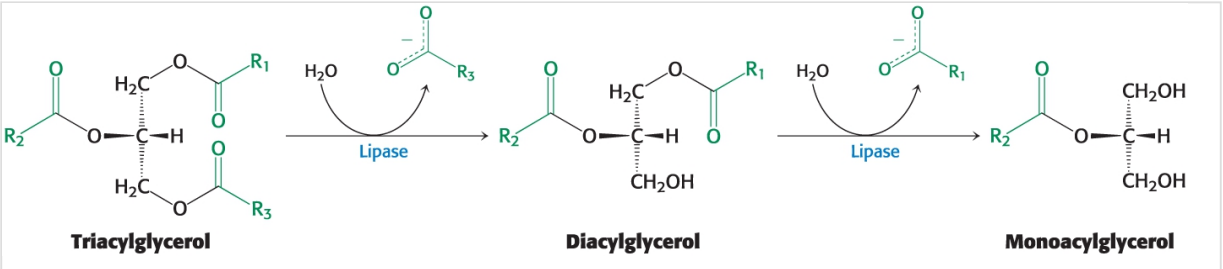
In mammals, the major site of triacylglycerol accumulation is the cytoplasm of adipocytes (fat cells). This fuel-rich, white adipose tissue is located throughout the body, notably under the skin (subcutaneous fat) and surrounding the internal organs (visceral fat). Triacylglycerols coalesce to form a large globule, called a *lipid droplet*, which may occupy most of the cell volume (Figure 22.1). The lipid droplet is surrounded by a monolayer of phospholipids and numerous proteins required for triacylglycerol metabolism. Originally believed to be inert-lipid deposits, lipid droplets are now understood to be dynamic organelles essential for the regulation of lipid metabolism. Adipose cells are specialized for the synthesis and storage of triacylglycerols and for their mobilization into fuel molecules, which are transported in the blood to other tissues. Muscle also stores triacylglycerols for its own energy needs. Indeed, triacylglycerols are evident as the "marbling" of expensive cuts of beef.

It's generally well known that many mammals like mice and bears hibernate over the long winter months. Although their metabolism slows during hibernation, the energy needs of the animal must still be met, primarily by fat metabolism. However, the utility of triacylglycerols as an energy source is perhaps most dramatically illustrated by the abilities of migratory birds like the ruby-throated hummingbird featured on the first page of the chapter, which can fly great distances without eating. Another example is the American golden plover, which flies from Alaska to the southern tip of South America; a large segment of the flight (3800 km, or 2400 miles) is over open ocean, where the birds

cannot feed. Fatty acids provide the energy source for these prodigious feats.

Dietary lipids are digested by pancreatic lipases

Most lipids are ingested in the form of triacylglycerols and must be degraded to fatty acids for absorption across the intestinal epithelium. Intestinal enzymes called **lipases**, secreted by the pancreas, degrade triacylglycerols to free fatty acids and monoacylglycerol (Figure 22.2). Lipids present a special problem because, unlike carbohydrates and proteins, these molecules are not soluble in water. They exit the stomach as an emulsion — particles with a triacylglycerol core surrounded by cholesterol and cholesterol esters.



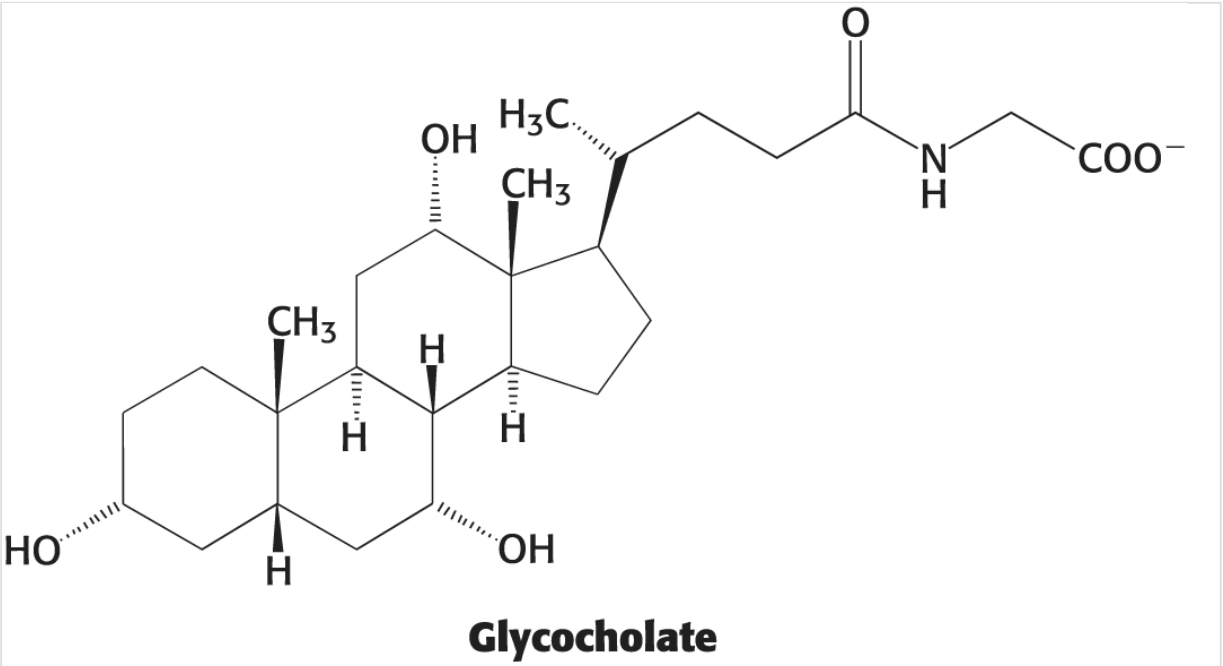


FIGURE 22.2 Pancreatic lipases convert triacylglycerols into fatty acids and monoacylglycerol for absorption into the intestine.

How are the lipids made accessible to the lipases, which are in aqueous solution? First, the particles are coated with bile acids (Figure 22.3), amphipathic molecules synthesized from cholesterol in the liver and secreted from the gallbladder. The ester bonds of each lipid are oriented toward the surface of the bile salt-coated particle, rendering the bond more accessible to digestion by lipases in aqueous solution. However, in this form, the particles are still not substrates for digestion. The protein

colipase (another pancreatic secretory product) must bind the lipase to the particle to permit lipid degradation. If the production of bile salts is inadequate due to liver disease, large amounts of fats (as much as $30\ g\ day^{-1}$) are excreted in the feces. This condition is referred to as *steatorrhea,* after stearic acid, a common fatty acid.

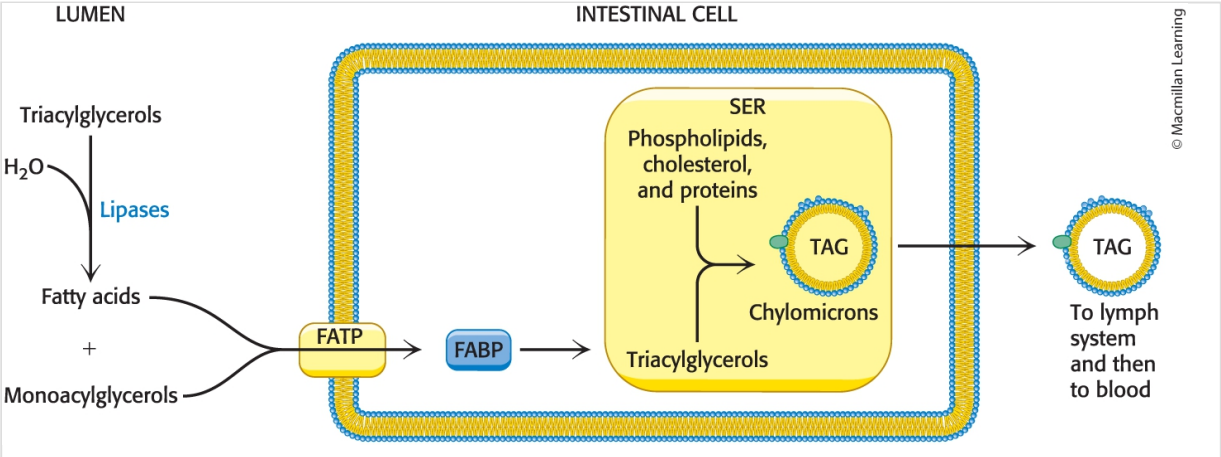
Glycocholate

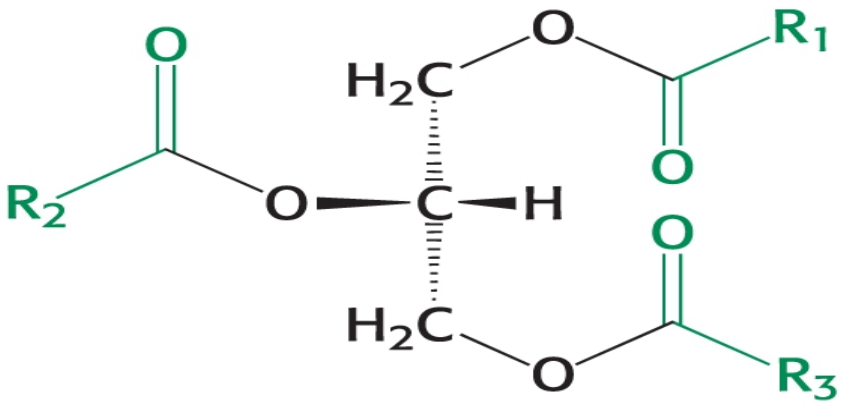
FIGURE 22.3 Bile acids, such as glycocholate, facilitate lipid digestion in the intestine.

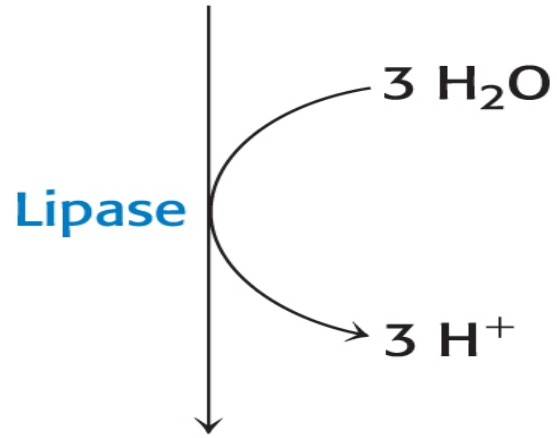
Dietary lipids are transported in chylomicrons

The final digestion products of intestinal lipases, free fatty acids and monoacylglycerol, are carried in micelles to the plasma membrane of intestinal epithelial cells where they are transported inside by membrane proteins such as fatty-acid transport proteins (FATPs)

(**Figure 22.4**). Once inside the cell, fatty-acid binding proteins (FABPs) ferry them to the cytosolic face of the smooth endoplasmic reticulum (SER), where triacylglycerols are resynthesized. After transport into the lumen of the SER, newly synthesized triacylglycerols associate with specific proteins, phospholipids, and cholesterol to form lipoprotein transport particles called **chylomicrons**. Chylomicrons are stable particles approximately 2000 Å (200 nm) in diameter that are composed of 98% triacylglycerols, with the proteins, phospholipids, and cholesterol on the surface (Figure 22.4).







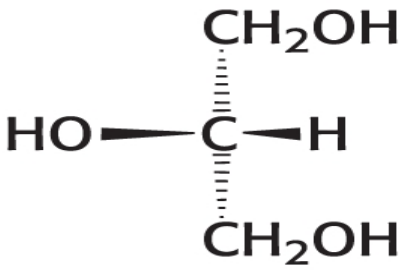


FIGURE 22.4 Fat absorption and transport is a complex process involving multiple proteins. Free fatty acids and monoacylglycerols are absorbed by intestinal epithelial cells through the action of protein transporters. Triacylglycerols are resynthesized in the cytosol and then transported into the smooth endoplasmic reticulum (SER) where they are packaged with other lipids and proteins to form chylomicrons. Finally, chylomicrons are released into the lymph system and then the blood to transport dietary triacylglycerols to various tissues.

Chylomicrons, which also transport fat-soluble vitamins and cholesterol, are next released into the lymph system and then into the blood. These particles bind to membrane-bound lipases, primarily at adipose tissue and muscle, where the triacylglycerols are once again degraded into free fatty acids and monoacylglycerols for transport into the tissue. The triacylglycerols are then resynthesized inside the cell and stored. In the muscle, they can be oxidized to provide energy.

Self-Check Question

Assuming you start in the intestinal lumen with a dietary triacylglyceride that will go directly to storage, how many times will this molecule be hydrolyzed and resynthesized before it is finally stored in an adipocyte?

22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing

Tissues throughout the body gain access to the lipid energy reserves stored in adipose tissue through three stages of processing.

1. *Mobilization.* Lipids must first be mobilized. In this process, triacylglycerols are degraded to fatty acids and glycerol, which are released from the adipose tissue and transported to the energy-requiring tissues.

2. *Activation and transport.* In the energy-requiring tissues, the fatty acids must be activated and transported into mitochondria for degradation.

3. *Breakdown into acetyl CoA.* Third, the fatty acids are broken down in a step-by-step fashion into acetyl CoA, which is then processed in the citric acid cycle.

Mobilization: Triacylglycerols are hydrolyzed by hormone-stimulated lipases

Consider someone who has just awakened from a night's sleep and begins a bout of exercise. Glycogen stores will be low, but lipids are readily available. How are these lipid stores mobilized?

Before fats can be used as fuels, the triacylglycerol storage form must be hydrolyzed to yield isolated fatty acids. This reaction is catalyzed by hormonally controlled lipases. Under the physiological conditions facing an early-morning runner, glucagon and epinephrine will be present. In adipose tissue, these hormones trigger 7TM receptors that

activate adenylate cyclase (Section 14.2). The increased level of cyclic AMP then stimulates protein kinase A, which phosphorylates two key proteins: perilipin, a fat-droplet-associated protein, and hormone-sensitive lipase (**Figure 22.5**). The phosphorylation of perilipin has two crucial effects. First, it restructures the fat droplet so the triacylglycerols are more accessible to the mobilization. Second, the phosphorylation of perilipin triggers the release of a coactivator for adipose triglyceride lipase (ATGL). Once bound to the coactivator, ATGL initiates the mobilization of triacylglycerols by releasing a fatty acid from triacylglycerol, forming diacylglycerol. Diacylglycerol is converted into a free fatty acid and monoacylglycerol by the hormone-sensitive lipase. Finally, a monoacylglycerol lipase completes the mobilization of fatty acids with the production of a free fatty acid and glycerol. Thus, epinephrine and glucagon induce lipolysis. Although their role in muscle is not as firmly established, these hormones probably also regulate the use of triacylglycerol stores in that tissue.

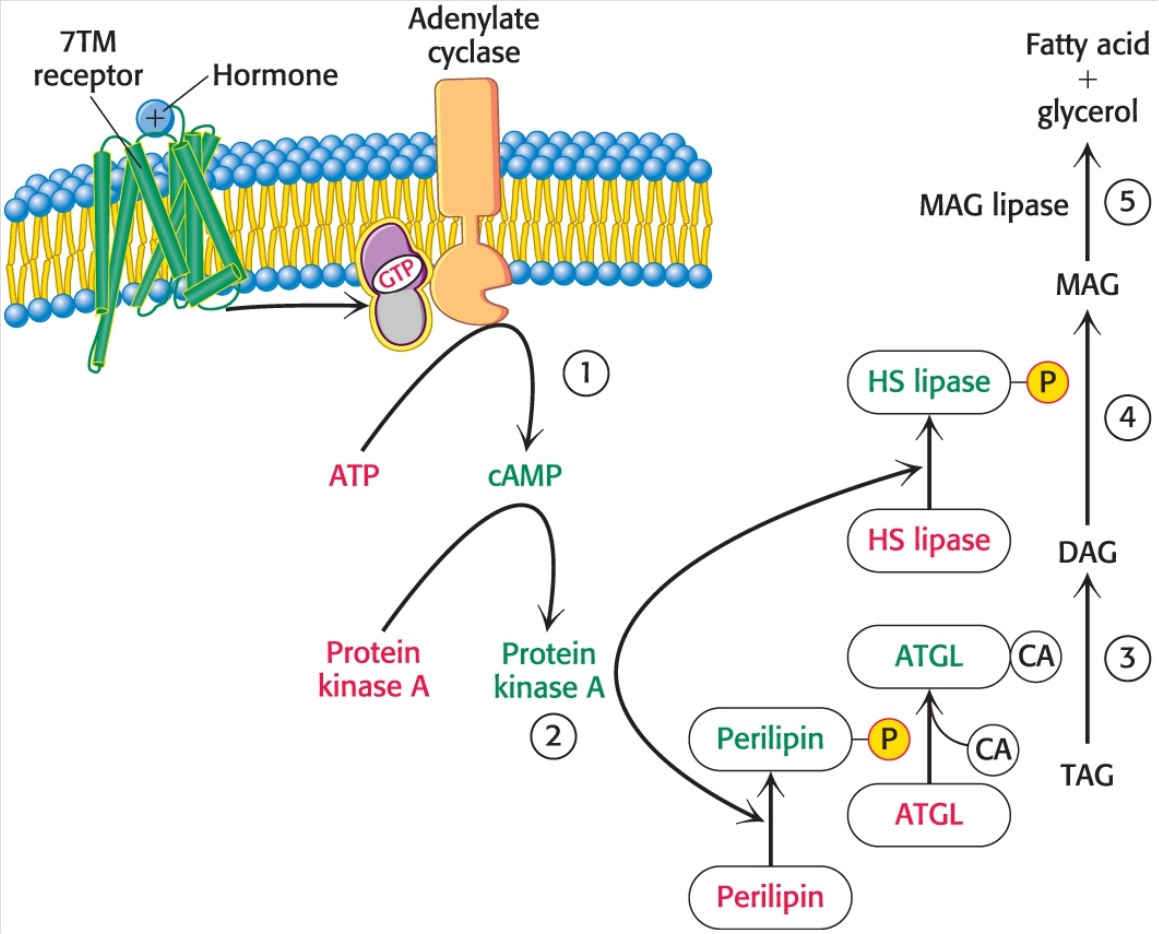

FIGURE 22.5 Triacylglycerols in adipose tissue are converted into free fatty acids in response to hormonal signals. (1) The hormones activate protein kinase A through the cAMP cascade. (2) Protein kinase A phosphorylates perilipin, resulting in the restructuring of the lipid droplet and release of the coactivator of ATGL, thereby activating ATGL. (3) ATGL converts triacylglycerol int diacylglycerol. (4) Hormone-sensitive lipase releases a fatty acid from diacylglycerol, generating monoacylglycerol. (5) Monoacylglycerol lipase completes the mobilization process. Abbreviations: 7TM, seven transmembrane receptor; ATGL, adipose triglyceride lipase; CA, coactivator; HS lipase, hormone-sensitive lipase; MAG lipase, monoacylglycerol lipase; DAG, diacylglycerol; TAG, triacylglycerol.

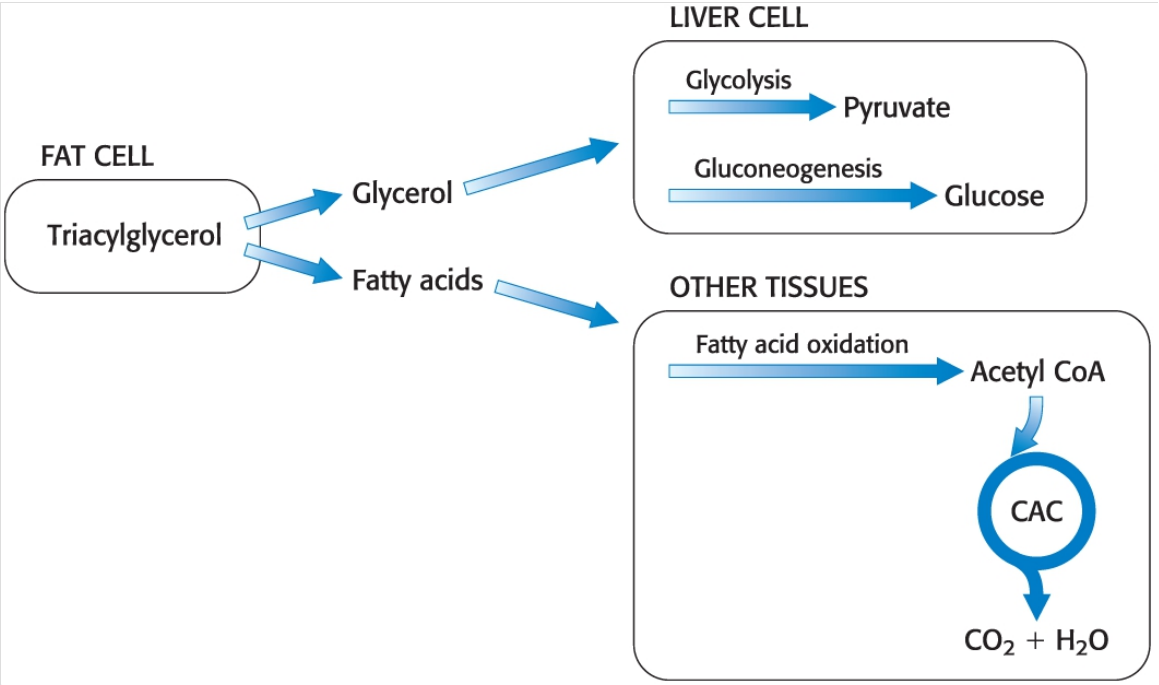
Although adipocytes are the primary site of triacylglycerol metabolism, the liver plays a crucial role in lipid metabolism, as we will examine in more detail in Chapters 24 and 27. Hepatocytes are the most common type of liver cells, and these cells function in all aspects of lipid

metabolism, including import, synthesis, storage, and secretion of lipids. These processes are responsive to diet and energy needs of the liver and other tissues. Recent research suggests that the epinephrine/cAMP pathway also regulates lipolysis from lipid droplets in cultured hepatocytes. Interestingly, this signaling pathway is disrupted by ethanol, and this disruption may play a role in the development of fatty liver, a risk factor for obesity and diabetes (Section 24.3).

Mobilization continues: Free fatty acids and glycerol are released into the blood

Fatty acids are not soluble in aqueous solutions. In order to reach tissues that require fatty acids, the released fatty acids bind to the blood protein albumin, which has seven binding sites for fatty acids of varying affinity, and delivers them to tissues in need of fuel.

Glycerol formed by lipolysis is absorbed by the liver and phosphorylated. It is then oxidized to dihydroxyacetone phosphate, which is isomerized to glyceraldehyde 3-phosphate. This molecule is an intermediate in both the glycolytic and the gluconeogenic pathways. Hence, glycerol can be converted into pyruvate or glucose in the liver, which contains the appropriate enzymes (**Figure 22.6**).



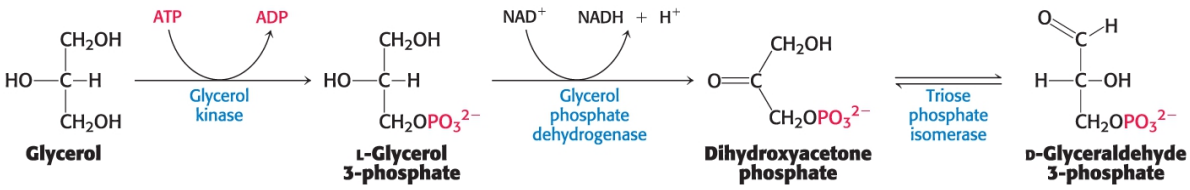


FIGURE 22.6 Lipolysis generates fatty acids and glycerol. The fatty acids are used as fuel by many tissues. The liver processes glycerol by either the glycolytic or the gluconeogenic pathway depending on its metabolic circumstances. Abbreviation: CAC, citric acid cycle.

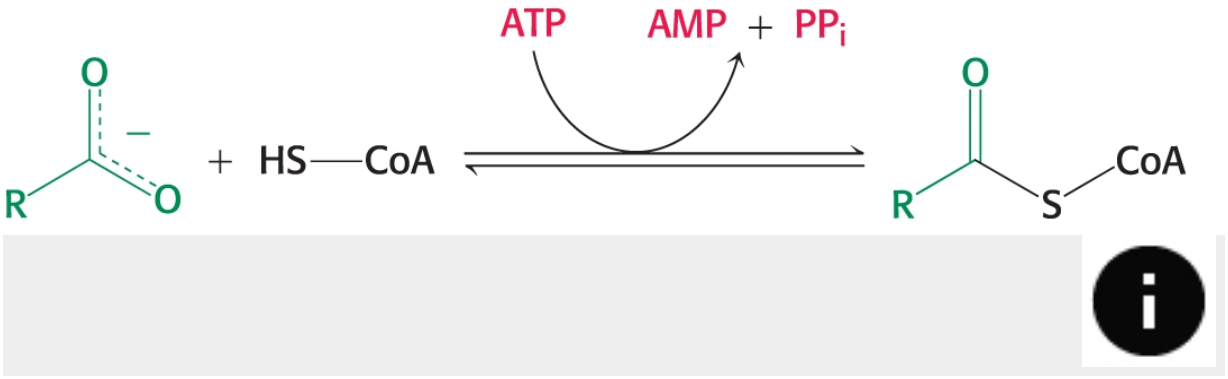
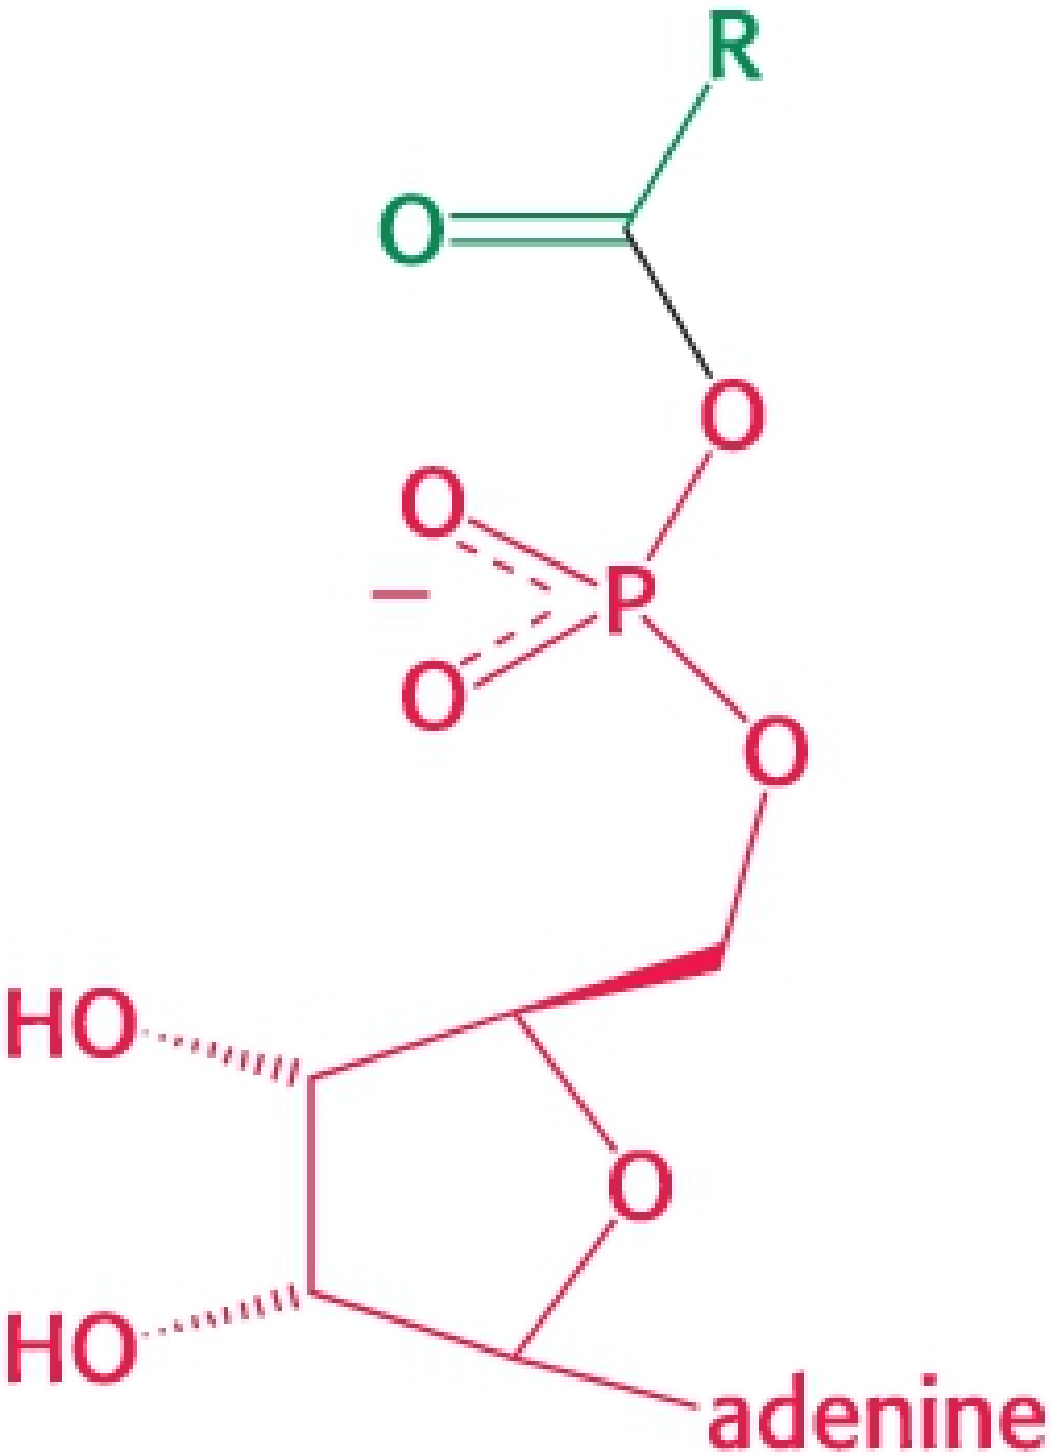
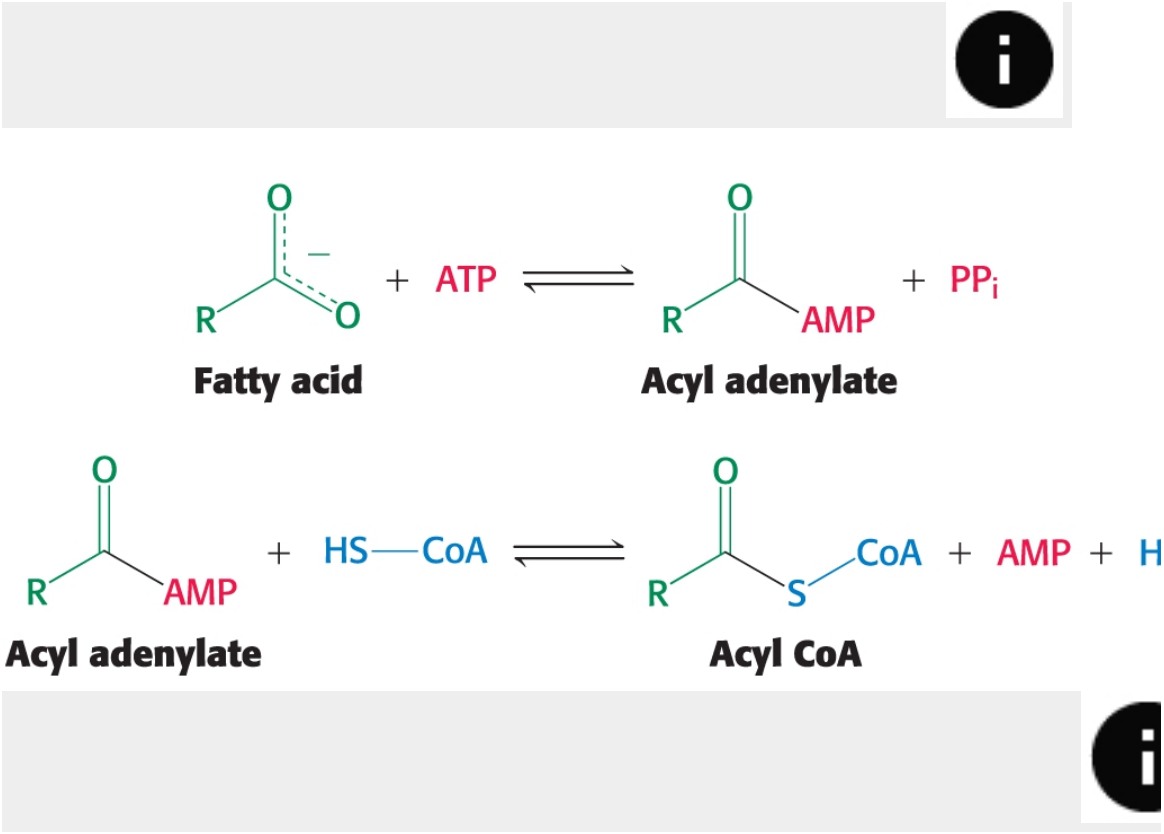


The reverse process can take place by the reduction of dihydroxyacetone phosphate to glycerol 3-phosphate. Hydrolysis by a phosphatase then gives glycerol. Thus, glycerol and glycolytic intermediates are readily interconvertible.



Activation: Fatty acids are linked to coenzyme A before they are oxidized

Fatty acids separate from the albumin in the blood stream and diffuse across the cell membrane with the assistance of fatty-acid transport proteins, the same proteins that facilitate their uptake into intestinal cells (Figure 22.4). Within the cell, fatty acids are transported while bound to fatty-acid binding proteins.



Fatty acid oxidation occurs in the mitochondrial matrix, but in order to enter the mitochondria, the fatty acids are first activated through the formation of a thioester linkage to coenzyme A. ATP drives the formation of the thioester linkage between the carboxyl group of a fatty acid and the sulfhydryl group of coenzyme A. This activation reaction takes place on the outer mitochondrial membrane, where it is catalyzed by acyl CoA synthetase.

Acyl CoA synthetase accomplishes the activation of a fatty acid in two steps. First, the fatty acid reacts with ATP to form an **acyl adenylate**. In this mixed anhydride, the carboxyl group of a fatty acid is bonded to the phosphoryl group of AMP. The other two phosphoryl groups of the ATP substrate are released as pyrophosphate. In the second step, the sulfhydryl group of coenzyme A attacks the acyl adenylate, which is tightly bound to the enzyme, to form acyl CoA and AMP.

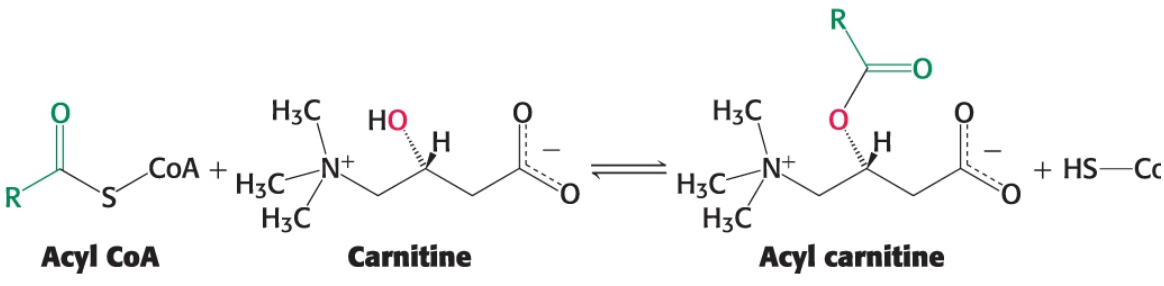
Acyl adenylate

These partial reactions are freely reversible. In fact, the equilibrium constant for the sum of these reactions is close to 1. One high-transfer-potential compound is cleaved (between PP_i and AMP), and one high-transfer-potential compound is formed (the thioester acyl CoA). How is the overall reaction driven forward? The answer is that pyrophosphate is rapidly hydrolyzed by a pyrophosphatase. The complete reaction is

$$RCOO^- + CoA + ATP + H_2O \rightarrow RCO{-}CoA + AMP + 2\ P_i + 2\ H^+$$

This reaction is quite favorable because the equivalent of two molecules of ATP is hydrolyzed, whereas only one high-transfer-potential compound is formed. We see here another example of a recurring theme in biochemistry: many biosynthetic reactions are made irreversible by the hydrolysis of inorganic pyrophosphate.

Another motif recurs in this activation reaction. The enzyme-bound acyl adenylate intermediate is not unique to the synthesis of acyl CoA. Acyl adenylates are frequently formed when carboxyl groups are activated in biochemical reactions. Amino acids are activated for protein synthesis by a similar mechanism (Section 30.2), although the enzymes that catalyze this process are not homologous to acyl CoA synthetase. Thus, activation by adenylation recurs in part because of convergent evolution.



Self-Check Question

Suppose that a promoter mutation leads to the overproduction of protein kinase A in adipose cells. How might fatty acid metabolism be altered by this mutation?

Transport: Carnitine carries long-chain activated fatty acids into the mitochondrial matrix

Fatty acids are activated on the outer mitochondrial membrane, whereas they are oxidized in the mitochondrial matrix. A special transport mechanism is needed to carry activated long-chain fatty acids across the inner mitochondrial membrane. These fatty acids must be conjugated to **carnitine**, an alcohol with both a positive and a negative charge (a zwitterion). The acyl group is transferred from the sulfur atom of coenzyme A to the hydroxyl group of carnitine to form acyl carnitine. This reaction is catalyzed by carnitine acyltransferase I (CATI), which is bound to the outer mitochondrial membrane.

Acyl carnitine is then shuttled across the inner mitochondrial membrane by a translocase (Figure 22.7). The acyl group is transferred back to coenzyme A on the matrix side of the membrane. This reaction, which is catalyzed by carnitine acyltransferase II (CATII), is simply the reverse of the reaction that takes place in the cytoplasm. The reaction is thermodynamically feasible because of the zwitterionic nature of carnitine. The *O*-acyl link in carnitine has a high group-transfer potential, apparently because, being zwitterions, carnitine and its esters are solvated differently from most other alcohols and their esters. Finally, the translocase returns carnitine to the cytoplasmic side in exchange for an incoming acyl carnitine.

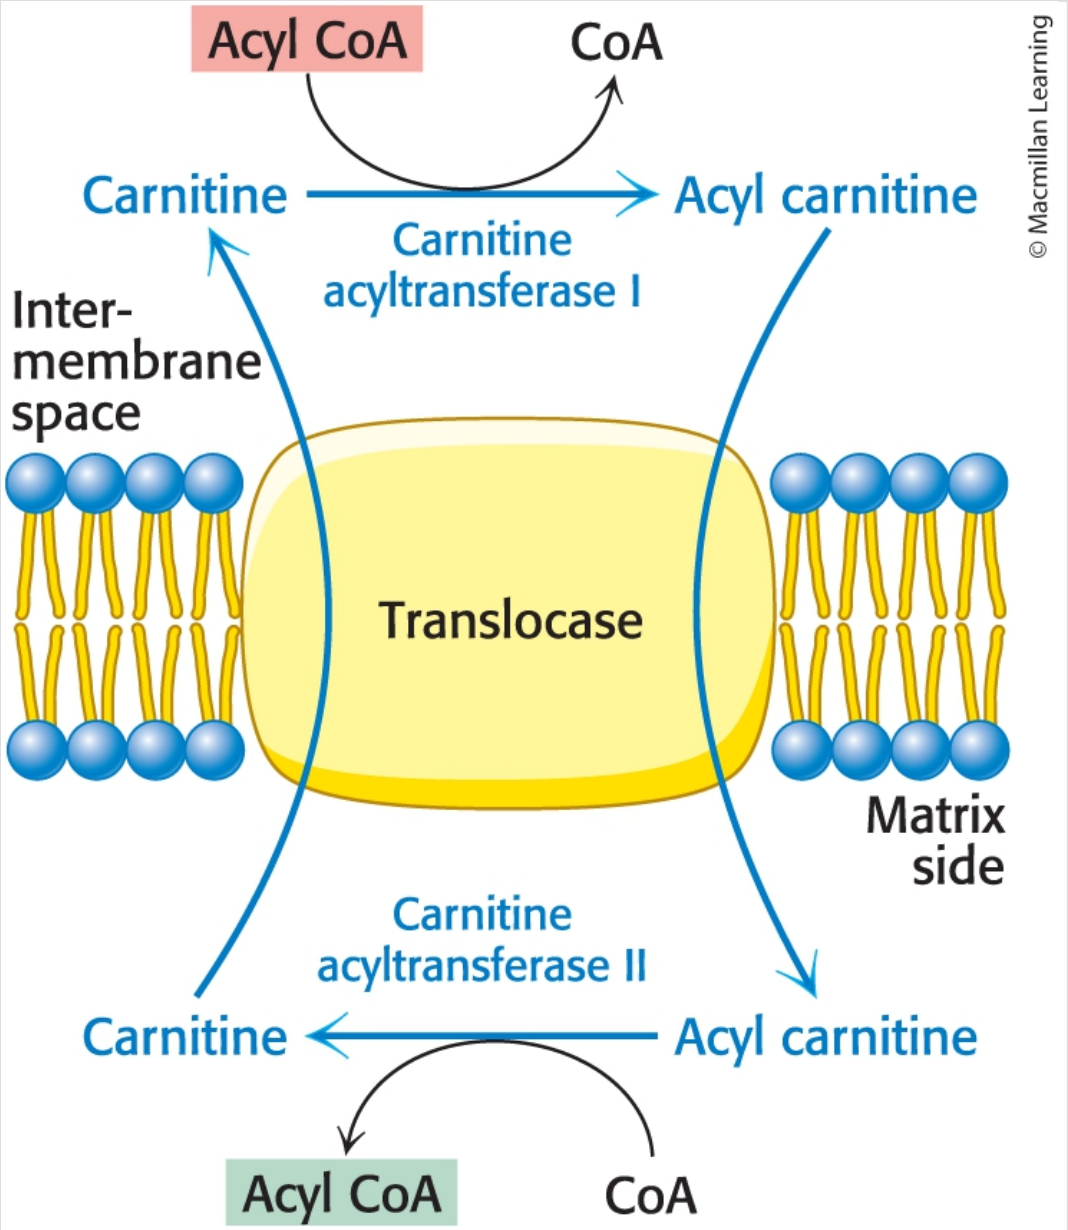


FIGURE 22.7 Acyl carnitine translocase mediates the entry of acyl carnitine into the mitochondrial matrix. Carnitine returns to the cytoplasmic side of the inner mitochondrial membrane in exchange for acyl carnitine.

A number of diseases have been traced to a deficiency of carnitine, the transferase, or the translocase. Inability to synthesize

carnitine may be a contributing factor to the development of autism in some people. The symptoms of carnitine deficiency range from mild muscle cramping to severe weakness and even death. In general, muscle, kidney, and heart are the tissues primarily impaired. Muscle weakness during prolonged exercise is a symptom of a deficiency of carnitine acyltransferases because muscle relies on fatty acids as a long-term source of energy. Medium-chain $(C_8 - C_{10})$ fatty acids are oxidized normally in these patients because these fatty acids can enter the mitochondria, to some degree, in the absence of carnitine. These diseases illustrate that the impaired flow of a metabolite from one compartment of a cell to another can lead to a pathological condition.

Breakdown: Acetyl CoA, NADH, and $FADH_2$ are generated in each round of fatty acid oxidation

A saturated acyl CoA is degraded by a recurring sequence of four reactions: oxidation by flavin adenine dinucleotide (FAD), hydration, oxidation by NAD^+, and thiolysis by coenzyme A (**Figure 22.8**). The fatty acid chain is shortened by two carbon atoms as a result of these reactions, and $FADH_2$, NADH, and acetyl CoA are generated. Because oxidation takes place at the β carbon atom, this series of reactions is called the **β-oxidation pathway**. The four reactions of each round of β-oxidation are described below and summarized in **Table 22.1**.

EXPLORE this pathway further in the Metabolic Map in Achieve

TABLE 22.1 Principal reactions in fatty acid oxidation

Step	Reaction	Enzyme
Activation	$\text{Fatty acid} + \text{CoA} + \text{ATP} \rightleftharpoons \text{acyl CoA} + \text{AMP} + \text{PP}_i$	Acyl CoA synthetase (also called fatty acid thiokinase and fatty acid:CoA ligase)*
Transport	$\text{Carnitine} + \text{acyl CoA} \rightleftharpoons \text{acyl carnitine} + \text{CoA}$	Carnitine acyltransferase (also called carnitine palmitoyl transferase)
1st Oxidation	$\text{Acyl CoA} + \text{E}-\text{FAD} \rightarrow \textit{trans}-\Delta^2-\text{enoyl CoA} + \text{E}-\text{FADH}_2$	Acyl CoA dehydrogenases (several isozymes having different chain-length specificity)
Hydration	$\textit{trans}\text{-}\Delta^2\text{-Enoyl CoA} + \text{H}_2\text{O} \rightleftharpoons \text{L-3-Hydroxyacyl CoA}$	Enoyl CoA hydratase (also called crotonase

		or 3-hydroxyacyl CoA hydrolyase)
2nd Oxidation	L-3-Hydroxyacyl CoA + NAD^+ ⇌ 3-ketoacyl CoA + NADH + H^+	L-3-Hydroxyacyl CoA dehydrogenase
Cleavage	3-Ketoacyl CoA + CoA ⇌ acetyl CoA + acyl CoA (shortened by C_2)	β-Ketothiolase (also called thiolase)

*An AMP-forming ligase.

1. *Oxidation of acyl CoA, generating* $FADH_2$. This reaction is catalyzed by acyl CoA dehydrogenase to give an enoyl CoA with a trans double bond between C-2 and C-3.

$$\text{Acyl CoA} + \text{E}-\text{FAD} \rightarrow \textit{trans}-\Delta^2-\text{enoyl CoA} + \text{E}-\text{FADH}_2$$

As in the dehydrogenation of succinate in the citric acid cycle, FAD rather than NAD^+ is the electron acceptor because the ΔG for this reaction is insufficient to drive the reduction of NAD^+. Electrons from the $FADH_2$ prosthetic group of the reduced acyl CoA dehydrogenase are transferred to a second flavoprotein called *electron-transferring flavoprotein* (ETF). In turn, ETF donates electrons to ETF: ubiquinone reductase, an iron–sulfur protein. Ubiquinone is thereby reduced to ubiquinol, which delivers its high-potential electrons to the second proton-pumping site of the respiratory chain (Section 18.3). Consequently, 1.5 molecules of ATP are generated per molecule of $FADH_2$ formed in this dehydrogenation step, as in the oxidation of succinate to fumarate.

2. *Hydration of enyol CoA*. The next step is the hydration of the double bond between C-2 and C-3 by enoyl CoA hydratase.

$$\textit{trans}\text{-}\Delta^2\text{-Enoyl CoA} + H_2O \rightleftharpoons \text{L-3-hydroxyacyl CoA}$$

The hydration of enoyl CoA is stereospecific. Only the L isomer of 3-hydroxyacyl CoA is formed when the *trans*-Δ^2 double bond is hydrated. The enzyme also hydrates a *cis*-Δ^2 double bond, but the product then is the D isomer. We shall return to this point shortly in considering how unsaturated fatty acids are oxidized. The hydration of enoyl CoA is a prelude to the next reaction.

3. *Second oxidation, generating NADH*. This reaction converts the hydroxyl group at C-3 into a keto group and generates NADH. This oxidation is catalyzed by L-3-hydroxyacyl CoA dehydrogenase, which is specific for the L isomer of the hydroxyacyl substrate.

$$\text{L-3-Hydroxyacyl CoA} + NAD^+ \rightleftharpoons \text{3-ketoacyl CoA} + NADH + H^+$$

The preceding reactions have oxidized the methylene group at C-3 to a keto group, setting up the final step.

4. *Cleavage, generating a shortened acyl CoA and acetyl CoA*. The final step is the cleavage of 3-ketoacyl CoA by the thiol group of a second molecule of coenzyme A, which yields acetyl CoA and an acyl CoA shortened by two carbon atoms. This thiolytic cleavage is catalyzed by β-ketothiolase.

$$\underset{(n \text{ carbons})}{\text{3-Ketoacyl CoA}} + \text{CoA} \rightleftharpoons \text{acetyl CoA} + \underset{(n-2 \text{ carbons})}{\text{acyl CoA}}$$

The shortened acyl CoA then undergoes another cycle of oxidation, starting with the reaction catalyzed by acyl CoA dehydrogenase (**Figure 22.9**). Fatty acid chains containing from 12 to 18 carbon atoms are oxidized by the long-chain acyl CoA dehydrogenase. The medium-chain acyl CoA dehydrogenase oxidizes fatty acid chains having from 4 to 14 carbons, whereas the short-chain acyl CoA dehydrogenase acts only on 4- and 6-carbon fatty acid chains. In contrast, β-ketothiolase, hydroxyacyl dehydrogenase, and enoyl CoA hydratase act on fatty acid molecules of almost any length.

FIGURE 22.9 Each round of fatty acid degradation removes two carbons. The first three rounds in the degradation of palmitate are shown. Notice that two-carbon units are sequentially removed from the carboxyl end of the fatty acid.

The complete oxidation of palmitate yields 106 molecules of ATP

We can now calculate the energy yield derived from the oxidation of a fatty acid. In each reaction cycle, an acyl CoA is shortened by two carbon atoms, and one molecule each of $FADH_2$, NADH, and acetyl CoA are formed.

$$C_n\text{–acyl CoA} + FAD + NAD^+ + H_2O + CoA \rightarrow$$

$$C_{n-2}\text{–acyl CoA} + FADH_2 + NADH + \text{acetyl CoA} + H^+$$

The degradation of palmitoyl CoA (C_{16}-acyl CoA) requires seven reaction cycles. In the seventh cycle, the C_4-ketoacyl CoA is thiolyzed to two molecules of acetyl CoA. Hence, the stoichiometry of the oxidation of palmitoyl CoA is

$$\text{Palmitoyl CoA} + 7\ FAD + 7\ NAD^+ + 7\ CoA + 7\ H_2O \rightarrow$$

$$8\ \text{acetyl CoA} + 7\ FADH_2 + 7\ NADH + 7\ H^+$$

Approximately 2.5 molecules of ATP are generated when the respiratory chain oxidizes each of these NADH molecules, whereas 1.5 molecules of ATP are formed for each $FADH_2$ because their electrons enter the chain at the level of ubiquinol. Recall that the oxidation of acetyl CoA by the citric acid cycle yields 10 molecules of ATP. Hence, the number of ATP molecules formed in the oxidation of palmitoyl CoA is 10.5 from the seven $FADH_2$, 17.5 from the seven NADH, and 80 from the eight acetyl CoA molecules, which gives a total of 108. The equivalent of 2 molecules of ATP is consumed in the activation of palmitate, in which ATP is split into AMP and 2 molecules of orthophosphate. Thus, the complete oxidation of a molecule of palmitate yields 106 molecules of ATP.

Self-Check Question

Explain why people with a hereditary deficiency of carnitine acyltransferase II have muscle weakness. Why are the symptoms more severe during fasting?

22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation

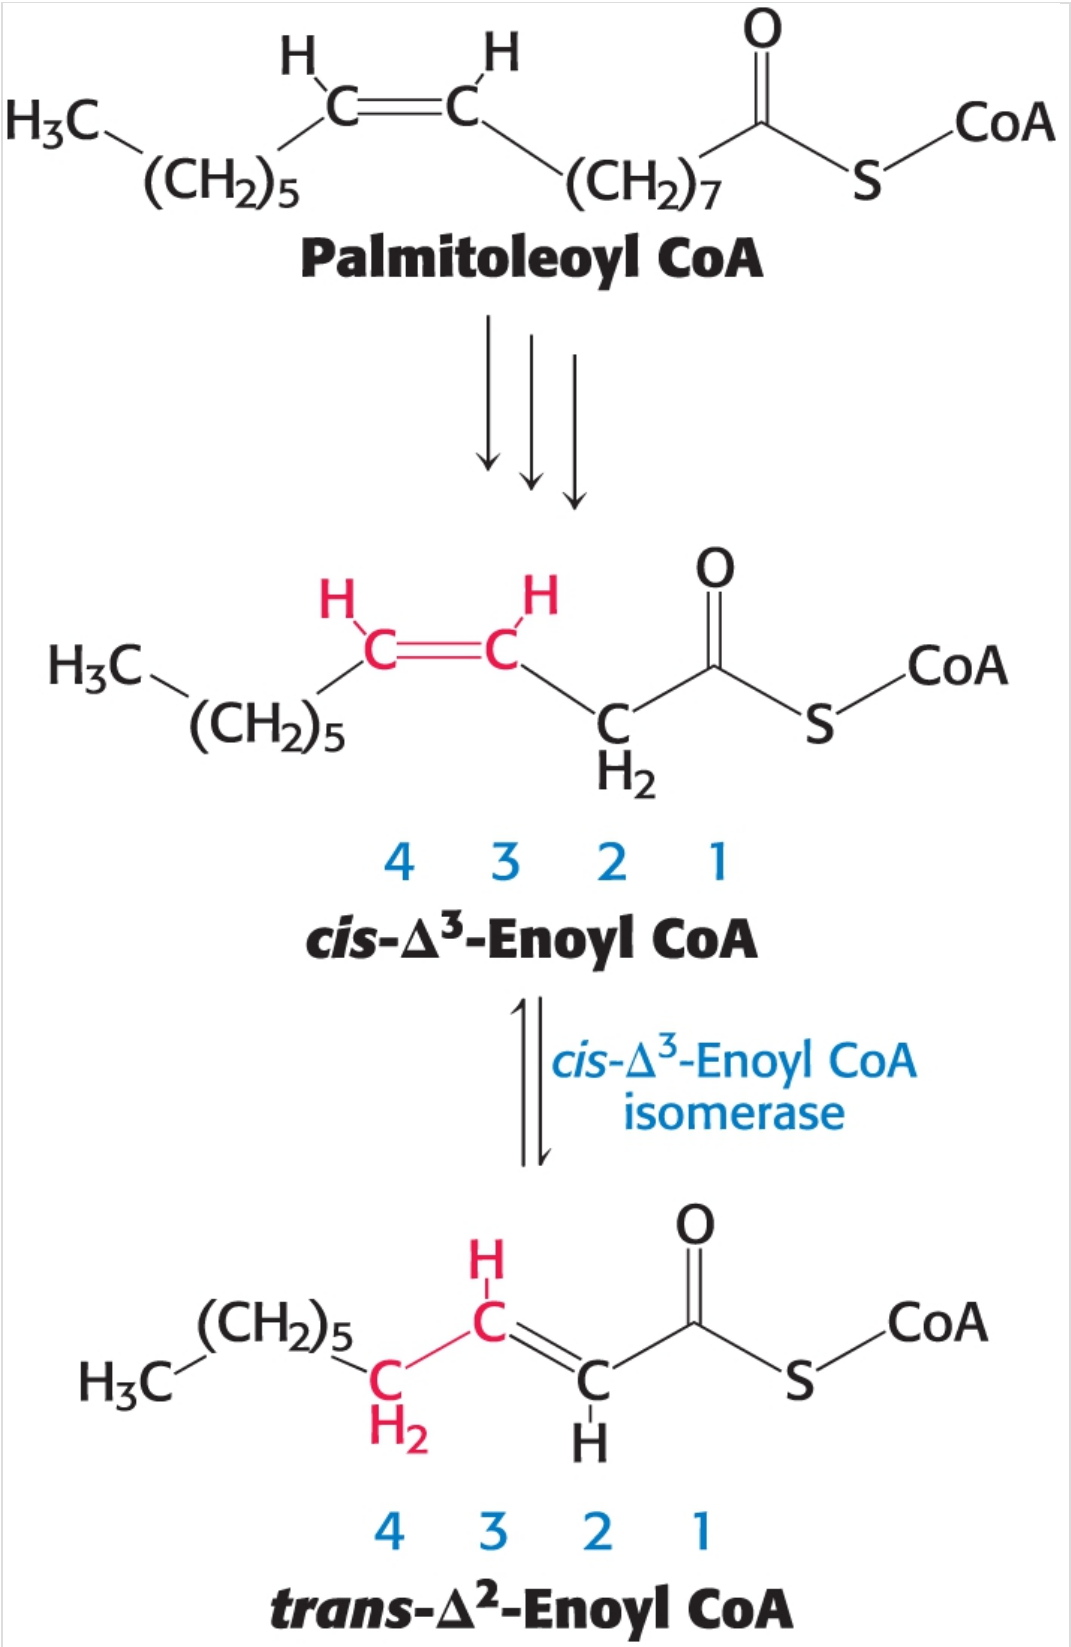
The β-oxidation pathway accomplishes the complete degradation of saturated fatty acids having an even number of carbon atoms. Most fatty acids have such structures because of their mode of synthesis (to be addressed later in this chapter). However, not all fatty acids are so simple. The oxidation of fatty acids containing double bonds requires additional steps, as does the oxidation of fatty acids containing an odd number of carbon atoms.

An isomerase and a reductase are required for the oxidation of unsaturated fatty acids

The oxidation of unsaturated fatty acids presents some difficulties, yet many such fatty acids are available in the diet. Most of the reactions are the same as those for saturated fatty acids. In fact, only two additional enzymes — an isomerase and a reductase — are needed to degrade a wide range of unsaturated fatty acids.

Consider the oxidation of palmitoleate (**Figure 22.10**). This C_{16} unsaturated fatty acid, which has one double bond between C-9 and C-10, is activated and transported across the inner mitochondrial membrane in the same way as saturated fatty acids are. Palmitoleoyl CoA then undergoes three cycles of degradation, which are carried out by the same enzymes as those in the oxidation of saturated fatty acids. However, the *cis*-Δ^3-enoyl CoA formed in the third round is not a substrate for acyl CoA dehydrogenase. The presence of a double bond

between C-3 and C-4 prevents the formation of another double bond between C-2 and C-3. This impasse is resolved by a new reaction that shifts the position and configuration of the *cis*-Δ^3 double bond. *cis*-Δ^3-Enoyl CoA isomerase converts this double bond into a trans-Δ^2 double bond (Figure 22.10). The double bond is now between C-2 and C-3. The subsequent reactions are those of the saturated fatty acid oxidation pathway, in which the *trans*-Δ^2-enoyl CoA is a regular substrate.



Palmitoleoyl CoA
4 3 2 1
cis-Δ3-Enoyl CoA
cis-Δ3-Enoyl CoA isomerase
4 3 2 1
trans-Δ2-Enoyl CoA

FIGURE 22.10 The degradation of a monounsaturated fatty acid involves an additional enzymatic step. *Cis*-Δ^3-Enoyl CoA isomerase allows continued β-oxidation of fatty acids with a single double bond.

Human beings require polyunsaturated fatty acids (Section 22.6), which have multiple double bonds, as important precursors for signal molecules. Excess polyunsaturated fatty acids are degraded by β-oxidation. However, another problem arises with the oxidation of polyunsaturated fatty acids. Consider linoleate, a C_{18} polyunsaturated fatty acid with *cis*-Δ^9 and *cis*-Δ^{12} double bonds (**Figure 22.11**). The *cis*-Δ^3 double bond (between carbons 3 and 4) formed after three rounds of β-oxidation is converted into a *trans*-Δ^2 double bond (between carbons 2 and 3) by the aforementioned isomerase. The acyl CoA produced by another round of β-oxidation contains a *cis*-Δ^4 double bond. Dehydrogenation of this species by acyl CoA dehydrogenase yields a 2,4-dienoyl intermediate (double bond between carbons 2 and 3 and carbons 4 and 5), which is not a substrate for the next enzyme in the β-oxidation pathway. This impasse is circumvented by 2,4-dienoyl CoA reductase, an enzyme that uses NADPH to reduce the 2,4-dienoyl intermediate to *trans*-Δ^3-enoyl CoA. *cis*-Δ^3-Enoyl CoA isomerase then converts *trans*-Δ^3-enoyl CoA into the *trans*-Δ^2 form, a customary intermediate in the β-oxidation pathway (Figure 22.11). These catalytic strategies are elegant and economical. Only two extra enzymes are needed for the oxidation of *any* polyunsaturated fatty acid. Odd-numbered double bonds are handled by the isomerase, and even-numbered ones by the reductase and the isomerase.

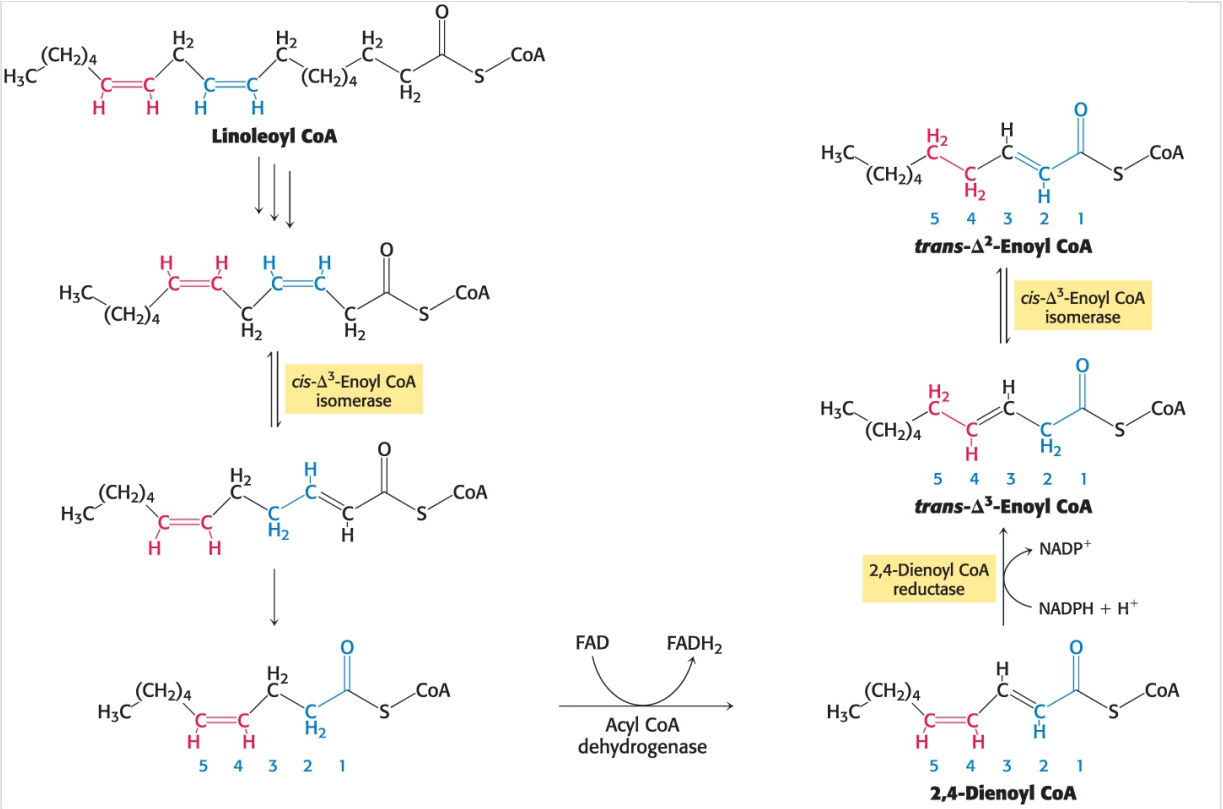


FIGURE 22.11 Multiple additional enzymes are necessary to oxidize polyunsaturated fatty acids. The oxidation of linoleoyl CoA is shown. The complete oxidation of the diunsaturated fatty acid linoleate is facilitated by the activity of enoyl CoA isomerase and 2,4-dienoyl CoA reductase. Eventually, the action of *cis*-Δ^3-enoyl CoA isomerase shifts the double bond to the Δ^2 position, making the molecule identical to an intermediate of saturated fatty acid degradation.

Odd-chain fatty acids yield propionyl CoA in the final thiolysis step

Fatty acids having an odd number of carbon atoms are minor species. They are oxidized in the same way as fatty acids having an even number, except that propionyl CoA and acetyl CoA, rather than two molecules of acetyl CoA, are produced in the final round of degradation. The

activated three-carbon unit in propionyl CoA enters the citric acid cycle after it has been converted into succinyl CoA (Figure 22.12). Interestingly, this is the only product of fatty acid catabolism that can serve as a gluconeogenic substrate. Succinyl CoA can be converted into oxaloacetate to provide carbon for glucose biosynthesis, a unique benefit of odd-numbered fatty acids.

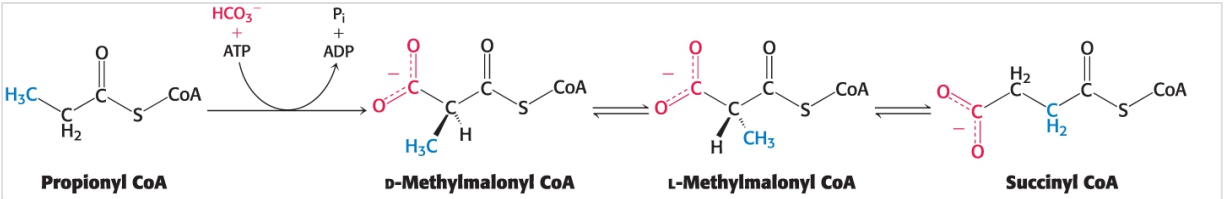

FIGURE 22.12 The final product of odd-numbered fatty acid degradation is converted into a CAC intermediate. Propionyl CoA, generated from fatty acids with an odd number of carbons as well as some amino acids, is converted into the citric acid cycle intermediate succinyl CoA, which can be a substrate for gluconeogenesis.

The pathway from propionyl CoA to succinyl CoA is especially interesting because it entails a rearrangement that requires vitamin B_{12} (also known as cobalamin). Propionyl CoA is carboxylated at the expense of the hydrolysis of a molecule of ATP to yield the D isomer of methylmalonyl CoA (Figure 22.12). This carboxylation reaction is catalyzed by propionyl CoA carboxylase, a biotin enzyme that has a catalytic mechanism like that of the homologous enzyme pyruvate carboxylase (Section 16.4). The D isomer of methylmalonyl CoA is racemized to the L isomer, the substrate for a mutase that converts it into succinyl CoA by an intramolecular rearrangement. The $-CO-S-CoA$ group migrates from C-2 to a methyl group in exchange for a hydrogen atom. This very unusual isomerization is catalyzed by methylmalonyl CoA mutase, which contains a derivative of cobalamin as its coenzyme.

Vitamin B_{12} contains a corrin ring and a cobalt atom

Cobalamin enzymes, which are present in most organisms, catalyze three types of reactions: (1) intramolecular rearrangements; (2) methylations, as in the synthesis of methionine (Section 25.2); and (3) the reduction of ribonucleotides to deoxyribonucleotides (Section 26.3). In mammals, only two reactions are known to require coenzyme B_{12}. The conversion of L-methylmalonyl CoA into succinyl CoA is one, and the formation of methionine by the methylation of homocysteine is the other (Section 25.2). The latter reaction is especially important because methionine is required for the generation of coenzymes that participate in the synthesis of purines and thymine, which are needed for nucleic acid synthesis. Interestingly, vitamin B_{12} is a molecule that is made only by prokaryotic organisms; all animals obtain coenzyme B_{12} either from diet or absorption from gut microorganisms, and plants and algae obtain it via their symbiosis with prokaryotes.

The core of cobalamin consists of a corrin ring with a central cobalt atom (**Figure 22.13**). The corrin ring, like a porphyrin, has four pyrrole units. Two of them are directly bonded to each other, whereas the others are joined by methine bridges, as in porphyrins. The corrin ring is more reduced than that of porphyrins, and the substituents are different. A cobalt atom is bonded to the four pyrrole nitrogens. The fifth substituent linked to the cobalt atom is a derivative of dimethylbenzimidazole that contains ribose 3-phosphate and aminoisopropanol. One of the nitrogen atoms of dimethylbenzimidazole is linked to the cobalt atom. In coenzyme B_{12}, the sixth substituent linked to the cobalt atom is a $5'$-deoxyadenosyl unit or a methyl group. This position can also be occupied by a cyano group. Cyanocobalamin is the form of the coenzyme administered to treat B_{12} deficiency. In all of these compounds, the cobalt is in the $+3$ oxidation state. Our knowledge of vitamin B_{12}, and countless other molecules

including pepsin, penicillin, and insulin, was made possible by the pioneering work of Prof. Dorothy Hodgkin, sometimes called the "Queen of Crystallography" for the numerous advances she made over a six-decade career.

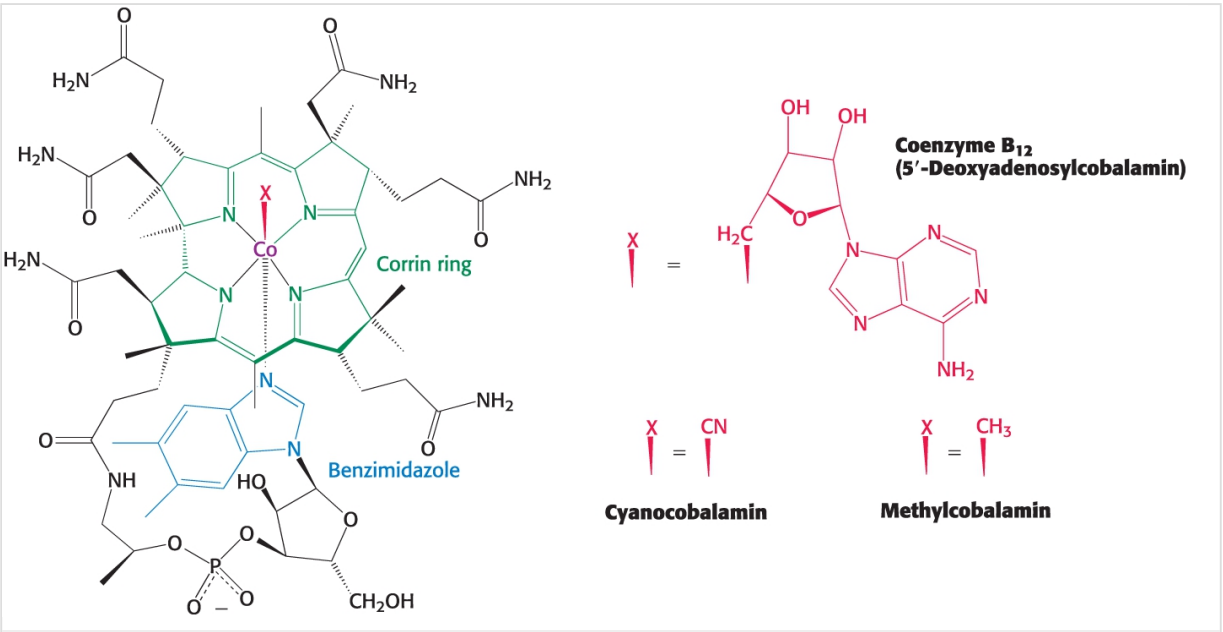

FIGURE 22.13 Coenzyme B_{12} (cobalamin) is a class of molecules with a complex structure.

Forms of coenzyme B_{12} vary depending on the component designated X in the left-hand structure. 5′-Deoxyadenosylcobalamin is the form of the coenzyme in methylmalonyl mutase. Substitution of methyl and cyano groups for X creates methylcobalamin and cyanocobalamin, respectively.

Harold Clements/Hulton Archive/Getty Images

DOROTHY HODGKIN As a teenager in England in the mid-1920s, Dorothy Hodgkin petitioned her grammar school to be educated in chemistry along with her male peers. During her PhD training she published the first data from hydrated protein crystals in 1934, and then captured the first images of insulin in her own lab in 1935. She went on to determine the structure of penicillin, which paved the way for its mass production. In 1956, she determined the structure of vitamin B_{12}, by far the most complex structure ever solved, an accomplishment that Nobel laureate Sir Lawrence Bragg likened to "breaking the sound barrier." Dr. Hodgkin was nominated for a Nobel Prize 32 times in either Physics or Chemistry before finally winning in Chemistry in 1964. Five years later, she solved the structure of insulin, after 34 years of work. She accomplished this, and much more, all while suffering from rheumatoid arthritis since the age of 28. Despite her arthritis dramatically affecting her hands later in life, she worked until age 84 and died in 1994. One of her former students,

Margaret Thatcher, famously hung a picture of Prof. Hodgkin in her office while serving as Prime Minister of the UK.

Mechanism: Methylmalonyl CoA mutase catalyzes a rearrangement to form succinyl CoA

The rearrangement reactions catalyzed by coenzyme B_{12} are exchanges of two groups attached to adjacent carbon atoms of the substrate (Figure 22.14).

FIGURE 22.14 Cobalamin enzymes catalyze specific rearrangement reactions. A group on one carbon is exchanged with a proton on an adjacent carbon. The R group can be an amino group, a hydroxyl group, or a substituted carbon.

A hydrogen atom migrates from one carbon atom to the next, and an R group (such as the $-CO-S-CoA$ group of methylmalonyl CoA) concomitantly moves in the reverse direction. The first step in these intramolecular rearrangements is the cleavage of the carbon–cobalt bond of $5'$-deoxyadenosylcobalamin to generate the Co^{2+} form of the coenzyme and a $5'$-deoxyadenosyl radical, $-CH_2\cdot$ (Figure 22.15). In this homolytic cleavage reaction, one electron of the Co–C bond stays

with Co (reducing it from the $^{+3}$ to the $^{+2}$ oxidation state), whereas the other electron stays with the carbon atom, generating a free radical. In contrast, nearly all other cleavage reactions in biological systems are heterolytic: an electron *pair* is transferred to one of the two atoms that were bonded together.

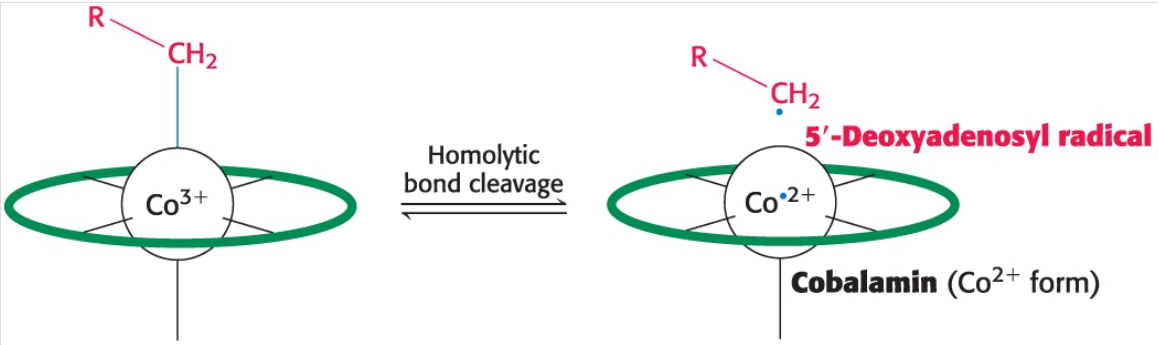

FIGURE 22.15 Cobalamin enzymes accomplish homolytic bond cleavage to form a radical. Th methylmalonyl CoA mutase reaction begins with the homolytic cleavage of the bond joining Co^{3+} of coenzyme B_{12} to a carbon atom of the ribose of the adenosine moiety of the enzym The cleavage generates a $5'$-deoxyadenosyl radical and leads to the reduction of Co^{3+} to Co^{2+}. The letter R represents the $5'$-deoxyadenosyl component of the coenzyme, and the green oval represents the remainder of the coenzyme.

What is the role of this very unusual $-CH_2\cdot$ radical? This highly reactive species abstracts a hydrogen atom from the substrate to form $5'$-deoxyadenosine and a substrate radical (Figure 22.16). This substrate radical spontaneously rearranges: the carbonyl CoA group migrates to the position formerly occupied by H on the neighboring carbon atom to produce a different radical. This product radical abstracts a hydrogen atom from the methyl group of $5'$-deoxyadenosine to complete the rearrangement and return the deoxyadenosyl unit to the radical form.

The role of coenzyme B_{12} in such intramolecular migrations is to serve as a source of free radicals for the abstraction of hydrogen atoms.

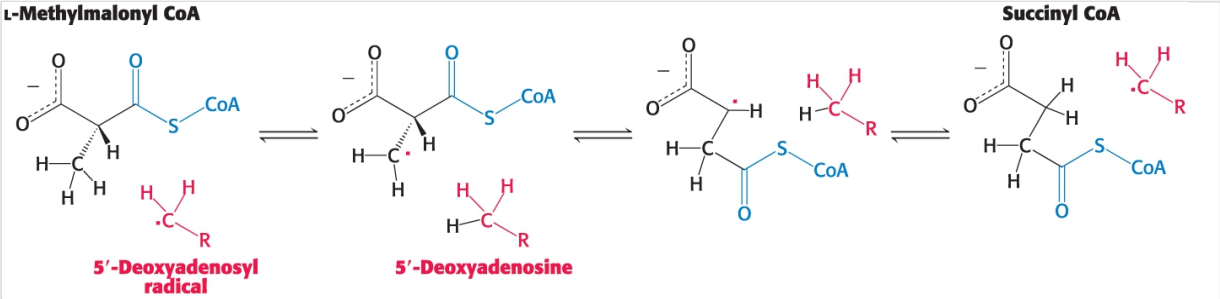

FIGURE 22.16 Succinyl CoA is formed from methylmalonyl CoA by a rearrangement reaction. A free radical abstracts a hydrogen atom in the rearrangement of methylmalonyl CoA to succinyl CoA.

An essential property of coenzyme B_{12} is the weakness of its cobalt–carbon bond, which is readily cleaved to generate a radical. To facilitate the cleavage of this bond, enzymes such as methylmalonyl CoA mutase displace the benzimidazole group from the cobalamin and bind to the cobalt atom through a histidine residue (Figure 22.17). The steric crowding around the cobalt–carbon bond within the corrin ring system contributes to the bond weakness.

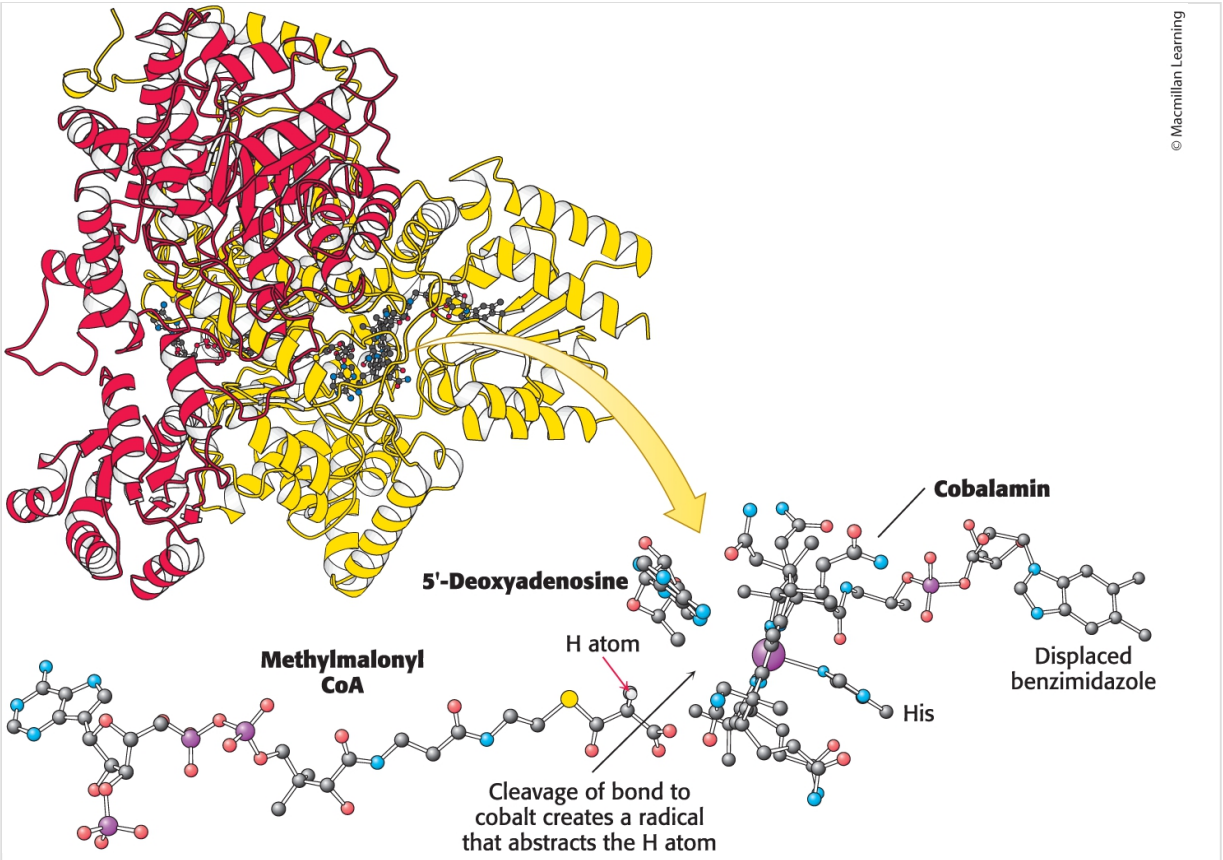

FIGURE 22.17 The active site of methylmalonyl CoA mutase reveals how radical formation is accomplished. Notice that a histidine residue from the enzyme binds to cobalt in place of benzimidazole. This arrangement of substrate and coenzyme in the active site facilitates the cleavage of the cobalt–carbon bond and the subsequent abstraction of a hydrogen atom from the substrate.

INTERACT with this model in Achieve

Fatty acids are also oxidized in peroxisomes

Although most fatty acid oxidation takes place in mitochondria, oxidation of long-chain and branched fatty acids takes place in cellular

organelles called **peroxisomes**. These organelles are small membrane-bounded compartments that are present in the cells of most eukaryotes. Fatty acid oxidation in these organelles, which halts at octanoyl CoA, serves to shorten very long chains (C_{26}) to make them better substrates of β-oxidation in mitochondria. Peroxisomal oxidation differs from β-oxidation in the initial dehydrogenation reaction (**Figure 22.18**). In peroxisomes, acyl CoA dehydrogenase — a flavoprotein — transfers electrons from the substrate to FAD and then to O_2 to yield H_2O_2. In mitochondrial β-oxidation, the high-energy electrons would be captured as $FADH_2$ for use in the electron-transport chain. Because H_2O_2 is produced instead of $FADH_2$, peroxisomes contain high concentrations of the enzyme catalase to degrade H_2O_2 into water and O_2. Subsequent steps are identical with those of their mitochondrial counterparts, although they are carried out by different isoforms of the enzymes.

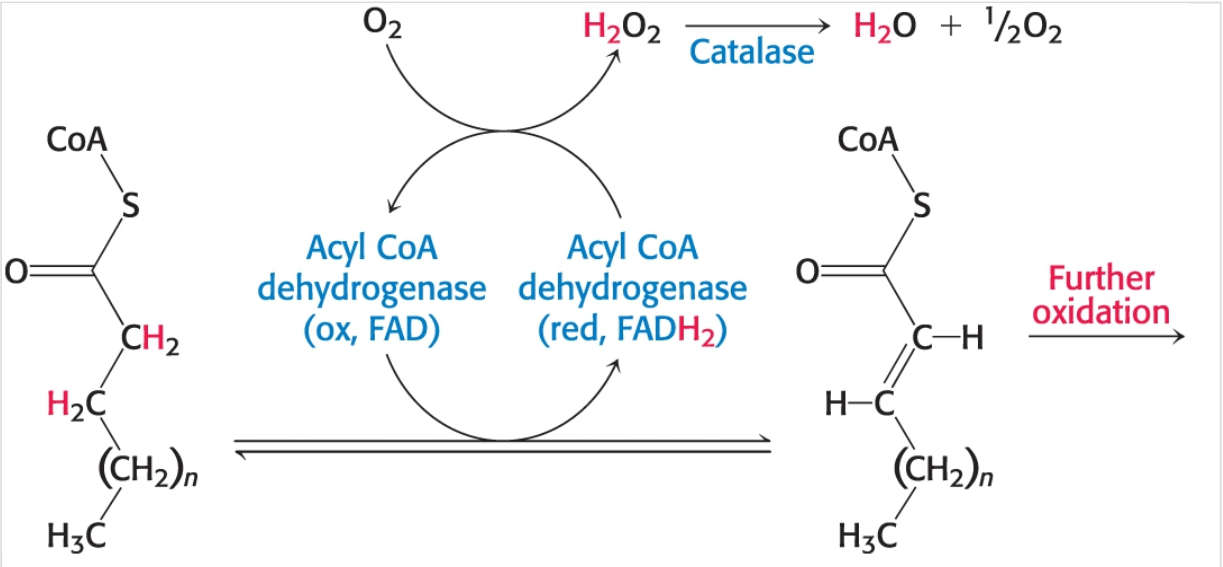

FIGURE 22.18 Initiation of peroxisomal fatty acid degradation requires a flavoprotein. The first dehydrogenation in the degradation of fatty acids in peroxisomes requires a flavoprotein dehydrogenase that transfers electrons from its $FADH_2$ moiety to O_2 to yield H_2O_2.

 Peroxisomes do not function in patients with Zellweger syndrome. Liver, kidney, and muscle abnormalities usually lead to death by age 6 years. The syndrome is caused by a defect in the import of enzymes into the peroxisomes. Here we see a pathological condition resulting from an inappropriate cellular distribution of enzymes.

Some fatty acids contribute to the development of pathological conditions

As we will see shortly (Section 22.5), certain polyunsaturated fatty acids are essential for life, serving as precursors to various signal molecules. Vegetable oils, used commonly in food preparation, are rich in polyunsaturated fatty acids. However, polyunsaturated fatty acids are unstable and are readily oxidized. This tendency to become rancid reduces their shelf life and renders them undesirable for cooking. To circumvent this problem, polyunsaturated fatty acids are sometimes hydrogenated, converting them to saturated and monounsaturated fats. However, the conditions of hydrogenation also cause an undesirable isomerization of some cis-double bonds, resulting in the unwanted production of trans unsaturated fatty acids (popularly known as “trans fats”), a variety of fat that is rare in nature.

Epidemiological evidence suggests that consumption of large amounts of saturated fatty acids and trans fat promotes obesity, type 2 diabetes, and atherosclerosis. The mechanism by which these fats exert these effects is under active investigation. Some evidence suggests that they slow β-oxidation directly, while other evidence suggests that they promote an inflammatory response and may mute the action of insulin and other hormones.

22.4 Ketone Bodies Are a Fuel Source Derived from Fats

The acetyl CoA formed in fatty acid oxidation enters the citric acid cycle only if fat and carbohydrate degradation are appropriately balanced. Acetyl CoA must combine with oxaloacetate to gain entry to the citric acid cycle. The availability of oxaloacetate, however, depends on an adequate supply of carbohydrate. Recall that oxaloacetate is normally formed from pyruvate, the product of glucose degradation in glycolysis, by pyruvate carboxylase (Section 16.4). If carbohydrate is unavailable or improperly utilized, the concentration of oxaloacetate is lowered and acetyl CoA cannot enter the citric acid cycle.

In fasting or diabetes, oxaloacetate is consumed to form glucose by the gluconeogenic pathway (Section 16.4) and hence is unavailable for condensation with acetyl CoA. Under these conditions, acetyl CoA is diverted to the formation of acetoacetate and D-3-hydroxybutyrate. Acetoacetate, D-3-hydroxybutyrate, and acetone are often referred to as **ketone bodies**. Abnormally high levels of ketone bodies are present in the blood of untreated diabetics.

Acetoacetate is formed from acetyl CoA in three steps (**Figure 22.19**). Two molecules of acetyl CoA condense to form acetoacetyl CoA. This reaction, which is catalyzed by thiolase, is the reverse of the thiolysis step in the oxidation of fatty acids. Acetoacetyl CoA then reacts with acetyl CoA and water to give 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) and CoA. This condensation resembles the one catalyzed by citrate synthase (Section 17.3). This reaction, which has a favorable equilibrium owing to the hydrolysis of a thioester linkage, compensates for the unfavorable equilibrium in the formation of acetoacetyl CoA. 3-Hydroxy-3-methylglutaryl CoA is then cleaved to acetyl CoA and acetoacetate. The sum of these reactions is

$$2\ \text{Acetyl CoA} + H_2O \rightarrow \text{acetoacetate} + 2\ \text{CoA} + H^+$$

D-3-Hydroxybutyrate is formed by the reduction of acetoacetate in the mitochondrial matrix by D-3-hydroxybutyrate dehydrogenase. The ratio of hydroxybutyrate to acetoacetate depends on the $NADH/NAD^+$ ratio inside mitochondria.

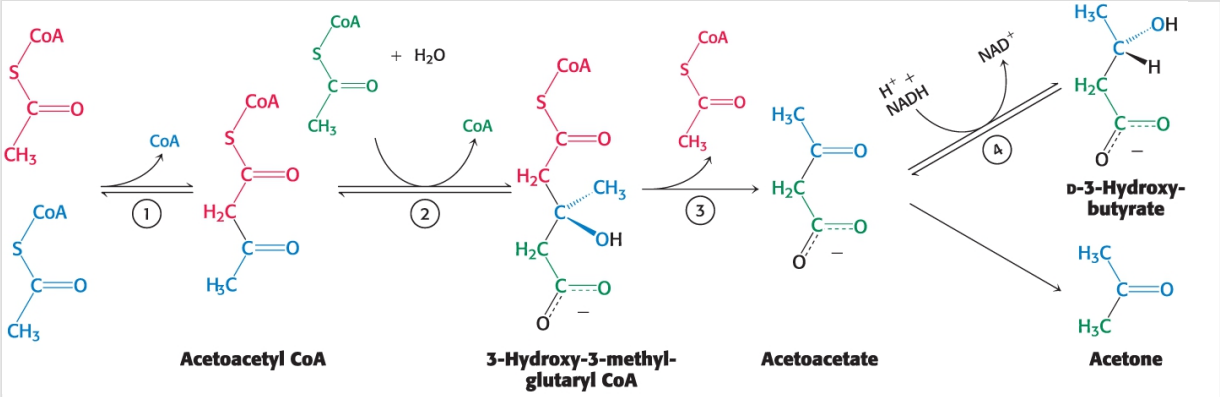

FIGURE 22.19 Ketone bodies are formed from acetyl CoA primarily in the liver. Three molecules are known as ketone bodies: acetoacetate, D-3-hydroxybutyrate, and acetone. Liver enzymes catalyzing the ketone body formation reactions are (1) 3-ketothiolase, (2) hydroxymethylglutaryl CoA synthase, (3) hydroxymethylglutaryl CoA cleavage enzyme, and (4) D-3-hydroxybutyrate dehydrogenase. Acetoacetate spontaneously decarboxylates to form acetone.

Because it is a β-ketoacid, acetoacetate also undergoes a slow, spontaneous decarboxylation to acetone. The odor of acetone may be detected in the breath of a person who has a high level of acetoacetate in the blood. Under starvation conditions, some of the acetone may be captured to synthesize small amounts of glucose.

Ketone bodies are a major fuel in some tissues

The liver is the major site of the production of acetoacetate and 3-hydroxybutyrate. These molecules are carried from the liver mitochondria into the blood by transport proteins and are conveyed to other tissues such as heart and kidney (**Figure 22.20**). Acetoacetate and 3-hydroxybutyrate are normal fuels of respiration and are quantitatively important as sources of energy. Indeed, heart muscle and the renal cortex use acetoacetate in preference to glucose. In contrast, glucose is the major fuel for the brain and red blood cells in well-nourished people on a balanced diet. However, the brain adapts to the utilization of acetoacetate during starvation and diabetes. In prolonged starvation, 75% of the fuel needs of the brain are met by ketone bodies (Section 24.5).

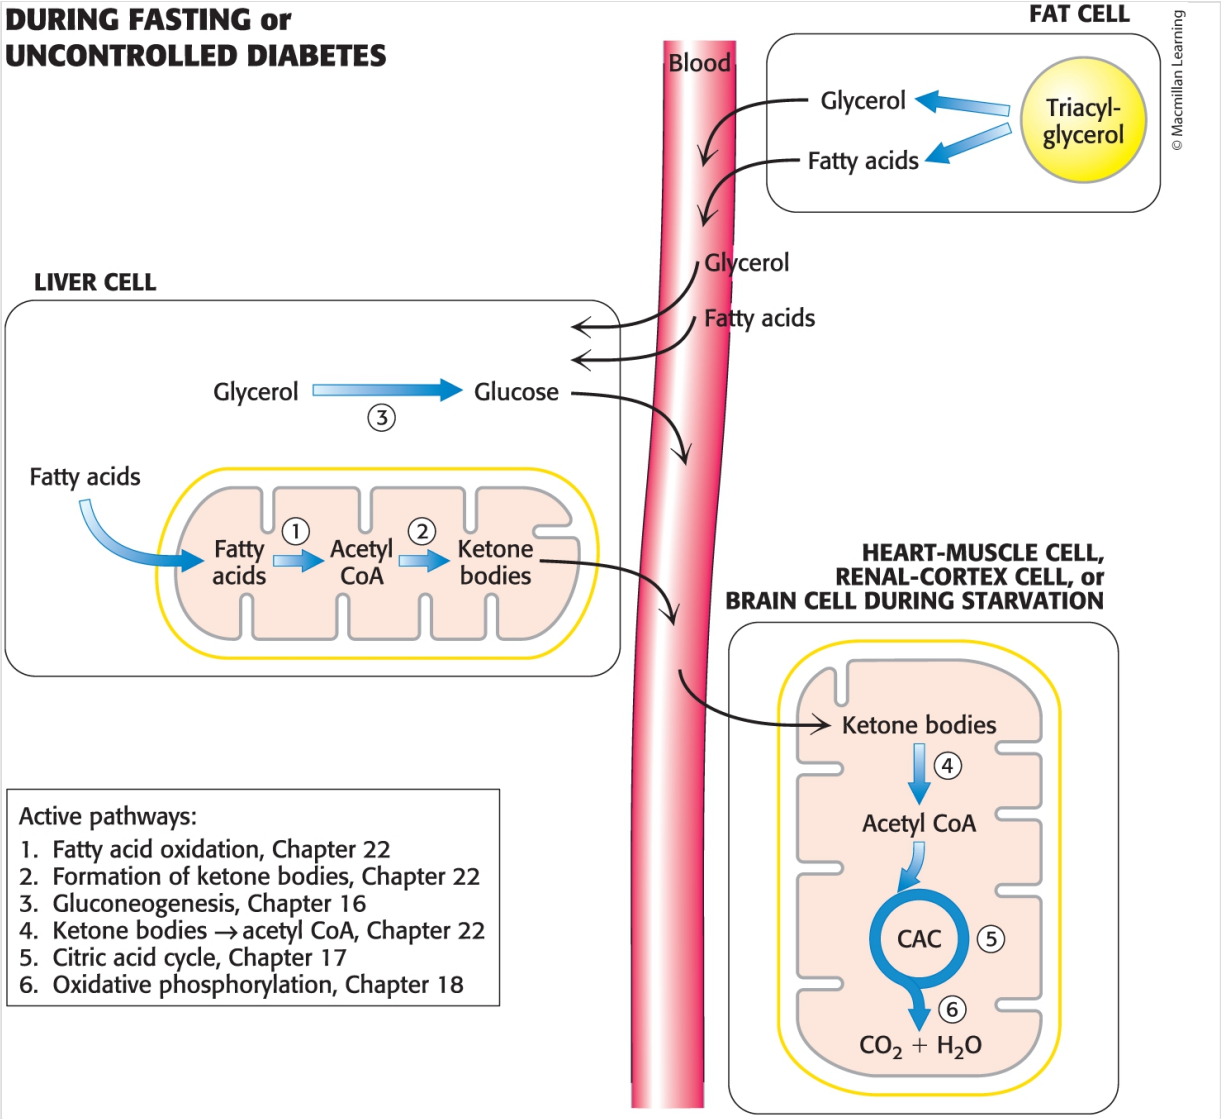

FIGURE 22.20 Pathway Integration: The liver supplies ketone bodies to the peripheral tissues. During fasting or in untreated diabetics, the liver converts fatty acids into ketone bodies, which are a fuel source for a number of tissues. Ketone-body production is especially important during starvation, when ketone bodies are the predominant fuel.

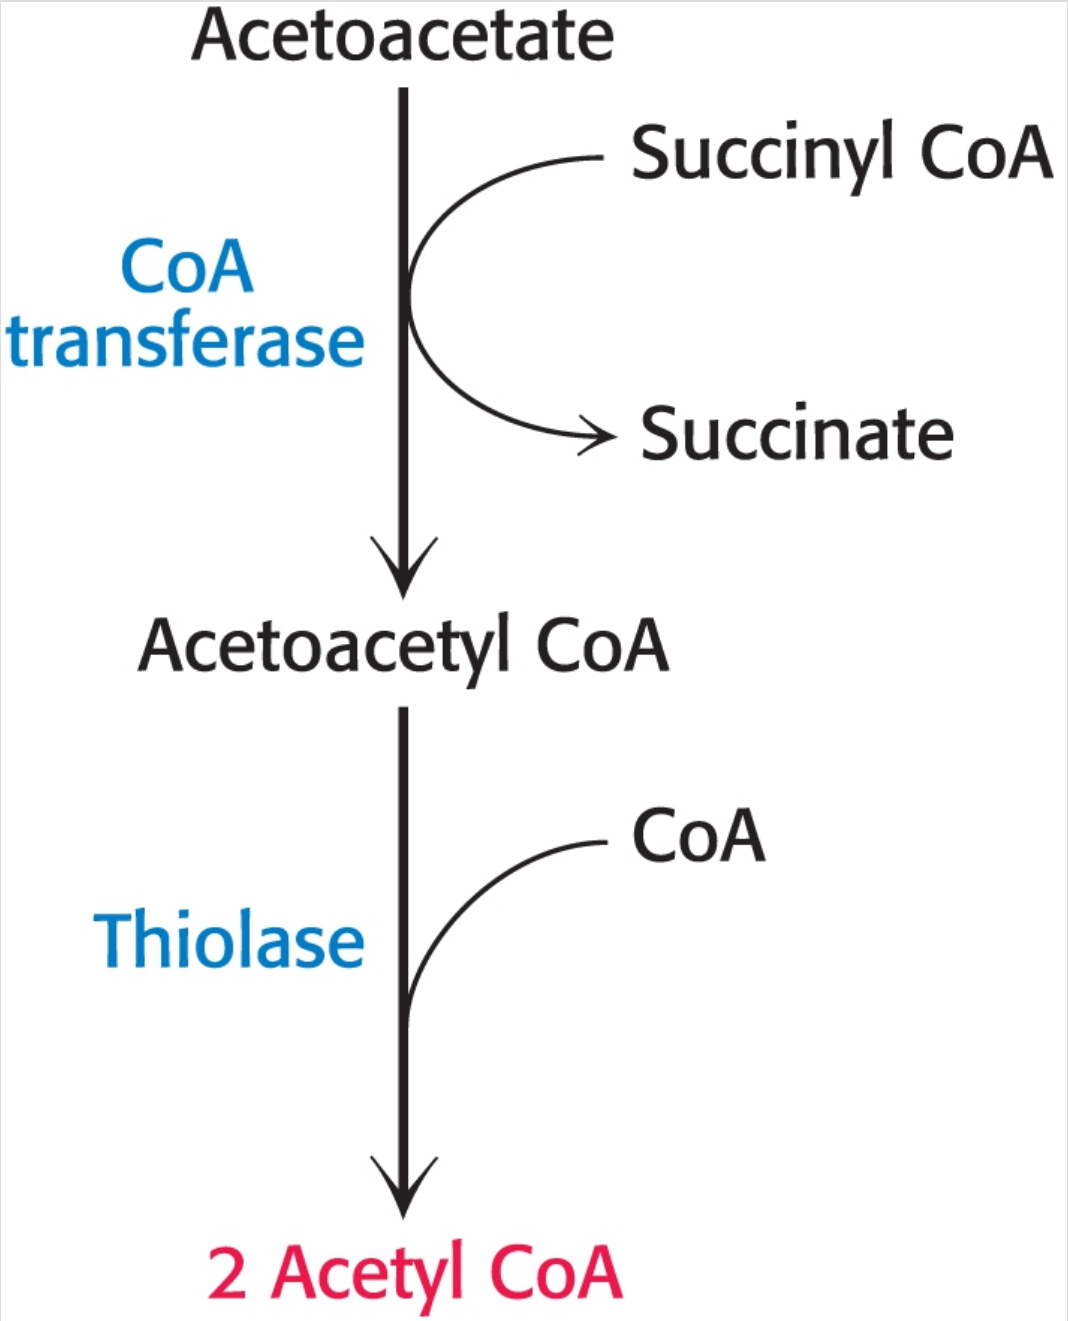
Acetoacetate is converted into acetyl CoA in two steps. First, acetoacetate is activated by the transfer of CoA from succinyl CoA in a reaction catalyzed by a specific CoA transferase. Second, acetoacetyl

CoA is cleaved by thiolase to yield two molecules of acetyl CoA, which can then enter the citric acid cycle (Figure 22.21).



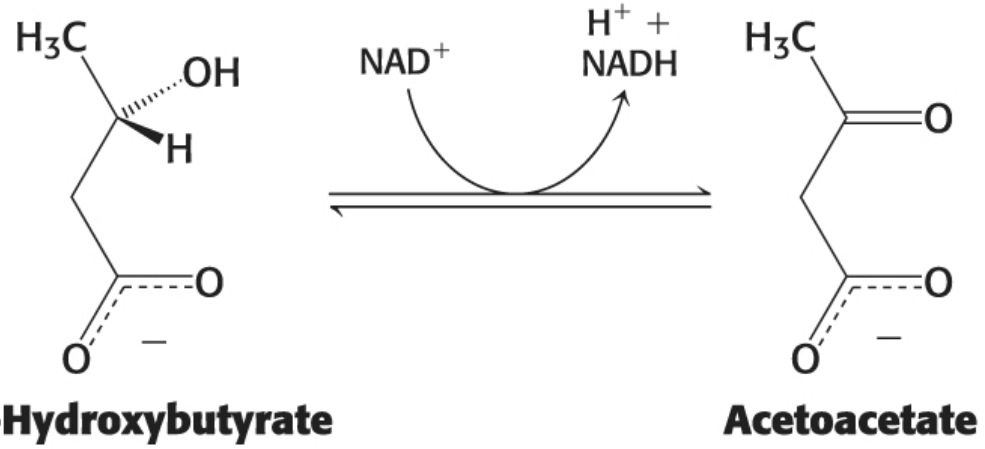


FIGURE 22.21 Acetoacetate can be used as a fuel to drive ATP formation.
Acetoacetate can be converted into two molecules of acetyl CoA, which then enter the citric acid cycle.

The liver has acetoacetate available to supply to other organs because it lacks this particular CoA transferase. 3-Hydroxybutyrate requires an additional step to yield acetyl CoA. It is first oxidized to produce acetoacetate, which is processed as described up to this point, and NADH for use in oxidative phosphorylation.

Ketone bodies can be regarded as a water-soluble, transportable form of acetyl units. Fatty acids are released by adipose tissue and converted into acetyl units by the liver, which then exports them as acetoacetate. As might be expected, both acetoacetate and 3-hydroxybutyrate also have regulatory roles. A high concentration of each in the blood signifies an abundance of acetyl units and leads to a decrease in the rate of lipolysis in adipose tissue. Although the liver produces ketone bodies for other tissues to use, it also gains energy in the process of synthesizing and releasing ketone bodies, because the production of acetyl CoA from fatty acids by β-oxidation produces both NADH and $FADH_2$ for ATP production by oxidative phosphorylation.

Interestingly, diets that promote ketone-body formation, called *ketogenic diets*, are frequently used as a therapeutic option for children with drug-resistant epilepsy. Ketogenic diets are rich in fats and low in carbohydrates, with adequate amounts of protein. In essence, the body is forced into starvation mode, where fats and ketone bodies become the main fuel source (Section 24.5). Remarkably, recent research in mice suggests that ketogenic diets alter the intestinal flora — the microbiome — and it is this alteration in the microbiome that is responsible for the therapeutic effects of the diet. The altered microbiome in some fashion regulates the levels of certain neurotransmitters, thereby reducing seizures.

Recent research in mice has also established that ketogenic diets extend lifespan, improve memory, and maintain long-term health. It will be interesting to learn if these effects apply to human beings, although gathering such data from humans is much more difficult than experiments with mice.

Diabetic ketoacidosis is a dangerous pathological condition caused by excessive ketone body formation

A high concentration of ketone bodies in the blood, the result of certain pathological conditions, can be life threatening. The most common of these conditions is diabetic ketoacidosis in patients with insulin-dependent diabetes. These patients are unable to produce insulin, which would normally be released after meals, signaling tissues to take up glucose and curtailing fatty acid mobilization by adipose tissue. The absence of insulin has two major biochemical consequences (**Figure**

22.22). First, the liver cannot absorb glucose and consequently cannot provide oxaloacetate to process fatty acid-derived acetyl CoA. Second, adipose cells continue to release fatty acids into the bloodstream; these fatty acids are then taken up by the liver and converted into ketone bodies. The liver thus produces large amounts of ketone bodies, which are acids, resulting in severe acidosis. The decrease in pH impairs tissue function, most importantly in the central nervous system.

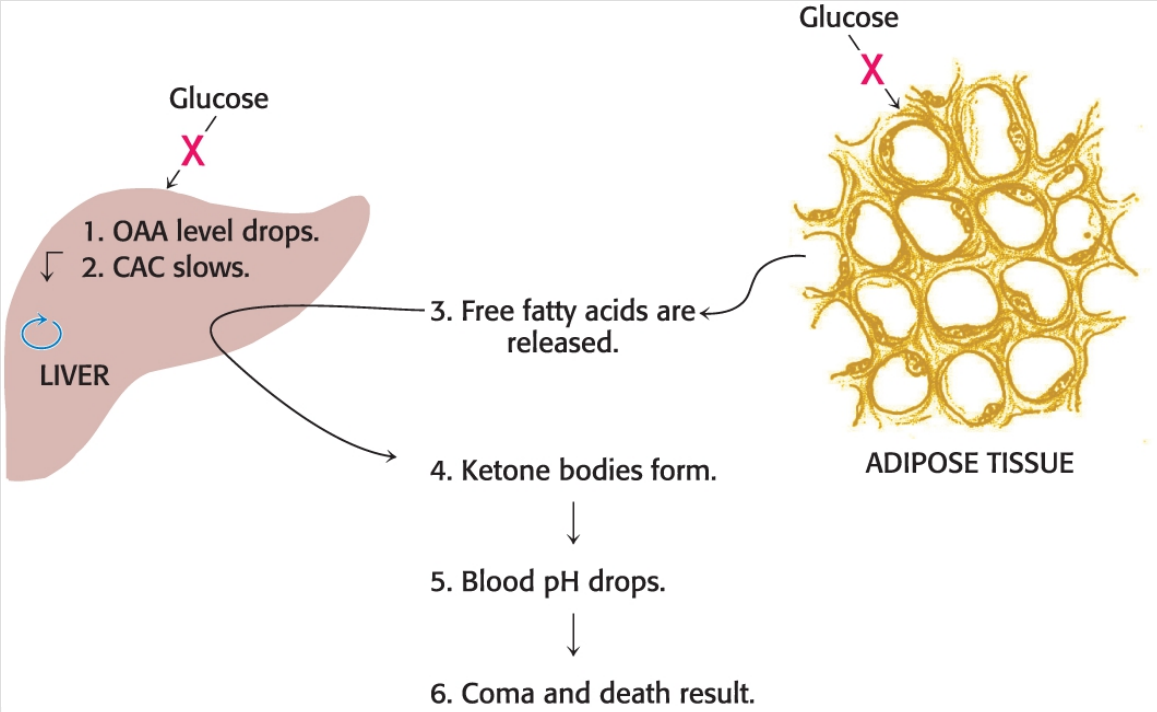

FIGURE 22.22 Diabetic ketosis results when insulin signaling is impaired. In the impairment of insulin signaling, fats are released from adipose tissue, and glucose cannot be absorbed by the liver or adipose tissue. The liver degrades the fatty acids by β-oxidation but cannot process the acetyl CoA, because of a lack of glucose-derived oxaloacetate (OAA). Excess ketone bodies are formed and released into the blood.

Self-Check Question

Calculate the number of molecules of ATP generated by the liver in the conversion of palmitate, a C_{16} fatty acid, into acetoacetate.

Animals cannot convert fatty acids into glucose

A typical human being has far greater fat stores than glycogen stores. However, glycogen is necessary to fuel very active muscle, as well as the brain, which normally uses only glucose as a fuel. When glycogen stores are low, why can't the body make use of fat stores and convert fatty acids into glucose? Because animals are unable to accomplish the net synthesis of glucose from fatty acids. Specifically, acetyl CoA cannot be converted into gluconeogenic substrates — pyruvate or oxaloacetate — in animals.

Recall that the reaction that generates acetyl CoA from pyruvate, catalyzed by the pyruvate dehydrogenase complex, is irreversible (Section 17.2). Additionally, when the two carbon atoms of the acetyl group of acetyl CoA enter the citric acid cycle, two carbon atoms also leave the cycle in the two decarboxylation reactions catalyzed by isocitrate dehydrogenase and α-ketoglutarate dehydrogenase (Section 17.3). Consequently, oxaloacetate is regenerated, but it is not formed de novo when the acetyl unit of acetyl CoA is oxidized by the citric acid cycle. In essence, two carbon atoms enter the cycle as an acetyl group, but two carbons leave the cycle as CO_2 before oxaloacetate is generated. As a result, no net synthesis of oxaloacetate is possible, and thus humans have no way of using the carbon in an acetyl group to synthesize glucose.

Also recall that, in contrast, plants and many microorganisms have the glyoxylate cycle; they have two additional enzymes that enable them to

convert the carbon atoms of acetyl CoA into oxaloacetate (Section 17.6). In conclusion, although a tremendous amount of human metabolism consists of reactions that are interconnected such that the carbon from one molecule can be used to make most anything else, this inability to convert acetyl groups into glucose can be viewed as the central disconnect in animal metabolism. We will explore the consequences of this inability more in Chapter 24.

22.5 Fatty Acids Are Synthesized by Fatty Acid Synthase

Fatty acids are synthesized by a complex of enzymes that together are called **fatty acid synthase**. Because eating most typical diets meets our physiological needs for fats and lipids, adult human beings have little need for de novo fatty acid synthesis. However, many tissues, such as liver and adipose tissue, are capable of synthesizing fatty acids, and this synthesis is required under certain physiological conditions. For instance, fatty acid synthesis is necessary during embryonic development and during lactation in mammary glands. Inappropriate fatty acid synthesis in the liver from excess caloric consumption or alcohol contributes to liver failure.

Acetyl CoA, the end product of fatty acid degradation, is the precursor for virtually all fatty acids. The biochemical challenge is to link the two carbon units together and reduce the carbons to produce palmitate, a C_{16} fatty acid. Palmitate then serves as a precursor for the variety of other fatty acids.

Fatty acid degradation and synthesis mirror each other in their chemical reactions

Fatty acid degradation and synthesis each consist of four steps that are the reverse of each other in their basic chemistry (**Figure 22.23**). As we have already seen, degradation is an oxidative process that converts a fatty acid into a set of activated acetyl units. Fatty acid synthesis is essentially the reverse of this process. The process starts with the individual units to be assembled — in this case, with an activated acyl group (most simply, an acetyl unit) and a malonyl unit (Figure 22.23). The malonyl unit condenses with the acetyl unit to form a four-carbon

fragment. To produce the required hydrocarbon chain, the carbonyl group is reduced to a methylene group in three steps: a reduction, a dehydration, and another reduction, exactly the opposite of degradation. The product of the reduction is butyryl CoA. Another activated malonyl group condenses with the butyryl unit, and the process is repeated until a C_{16} or shorter fatty acid is synthesized.

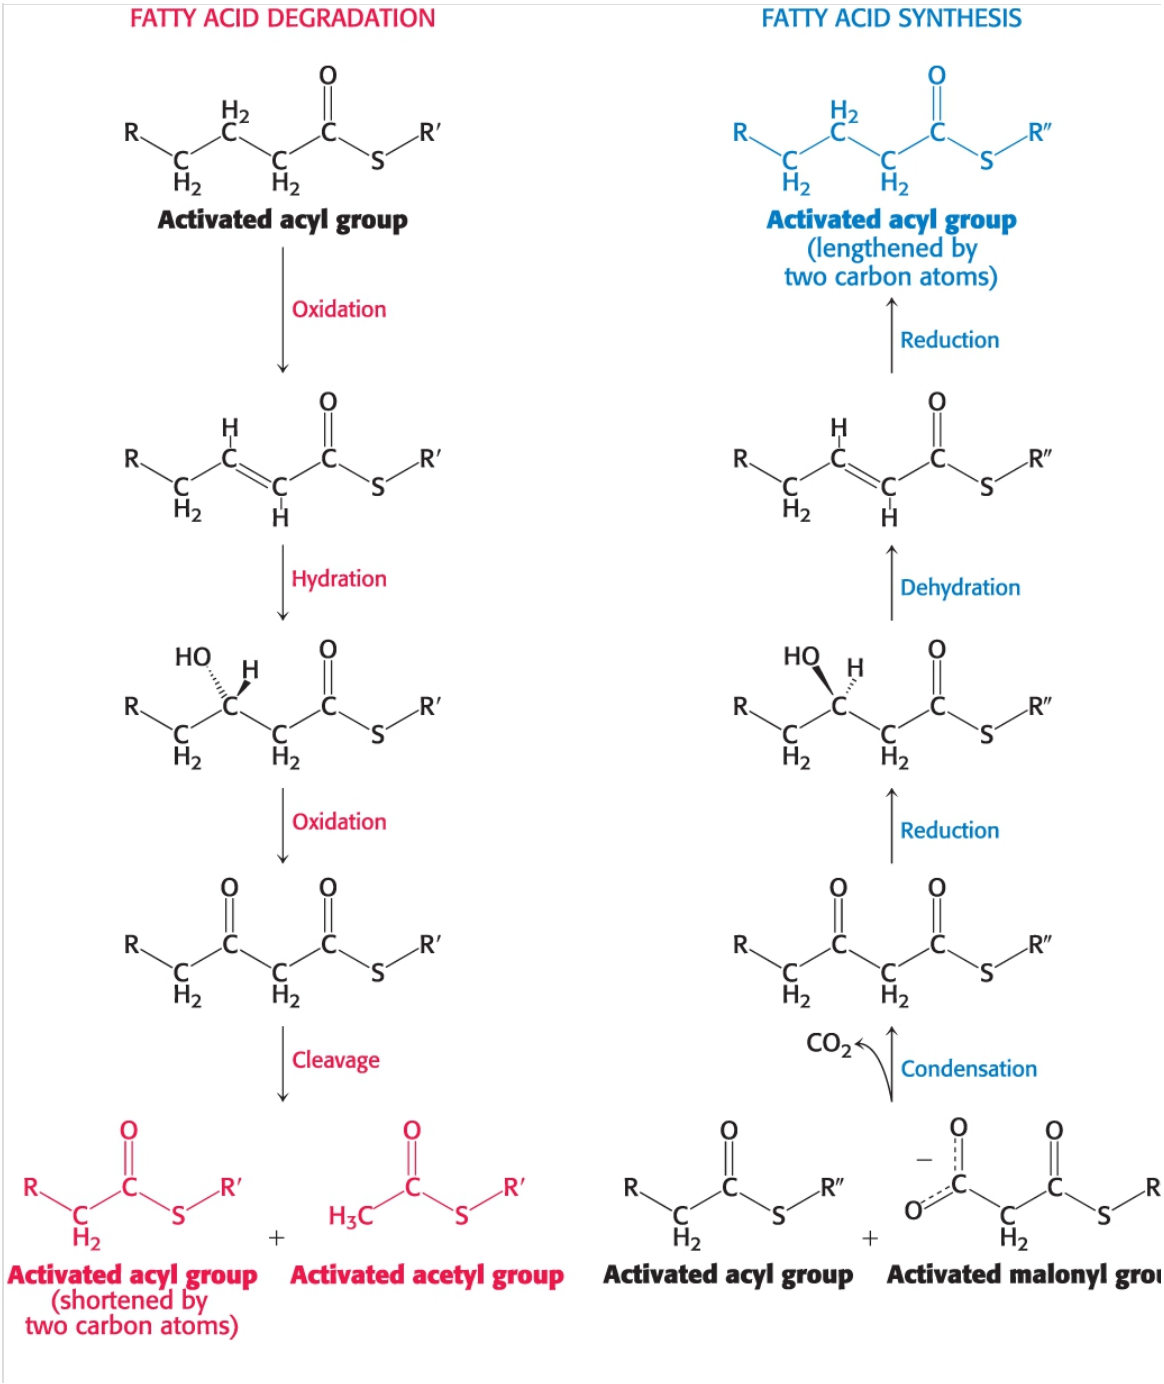

FIGURE 22.23 The steps in fatty acid degradation and synthesis are chemically similar. The tw
processes are in many ways mirror images of each other.

EXPLORE this pathway further in the Metabolic Map in Achieve

Fatty acids are synthesized and degraded by different pathways

Although fatty acid synthesis is the reversal of the degradative pathway in regard to basic chemical reactions, the synthetic and degradative pathways are different mechanistically, again exemplifying the principle that synthetic and degradative pathways are almost always distinct. Some important differences between the pathways are as follows:

1. Synthesis takes place in the cytoplasm, in contrast with degradation, which takes place primarily in the mitochondrial matrix.

2. Intermediates in fatty acid synthesis are covalently linked to the sulfhydryl groups of an **acyl carrier protein (ACP)**, whereas intermediates in fatty acid breakdown are covalently attached to the sulfhydryl group of coenzyme A.

3. The enzymes of fatty acid synthesis in higher organisms are joined in a single polypeptide chain called fatty acid synthase. In contrast, the degradative enzymes are not linked covalently.

4. The growing fatty acid chain is elongated by the sequential addition of two-carbon units derived from acetyl CoA. The activated donor of

two-carbon units in the elongation step is malonyl ACP. The elongation reaction is driven by the release of CO_2.

5. The reductant in fatty acid synthesis is NADPH, whereas the oxidants in fatty acid degradation are NAD^+ and FAD.

6. The isomeric form of the hydroxyacyl intermediate in degradation is L, while the D form is used in synthesis.

The formation of malonyl CoA is the committed step in fatty acid synthesis

Fatty acid synthesis starts with the carboxylation of acetyl CoA to **malonyl CoA**. This irreversible reaction is the committed step in fatty acid synthesis.

The synthesis of malonyl CoA is catalyzed by the cytosolic isozyme of a critical regulatory enzyme, **acetyl CoA carboxylase (ACC)**. ACC contains a biotin prosthetic group, with the carboxyl group of biotin covalently attached to the ε amino group of a lysine residue, as in pyruvate carboxylase (Figure 16.28) and propionyl CoA carboxylase (Section 22.3). As with these other enzymes, a carboxybiotin intermediate is formed at the expense of the hydrolysis of a molecule of ATP. The activated CO_2 group in this intermediate is then transferred to acetyl CoA to form malonyl CoA.

$$\text{Biotin-enzyme} + \text{ATP} + HCO_3^- \rightleftharpoons CO_2\text{-biotin-enzyme} + \text{ADP} + P_i$$

$$CO_2\text{-biotin-enzyme} + \text{acetyl CoA} \longrightarrow \text{malonyl CoA} + \text{biotin-enzyme}$$

ACC has two isozymes — ACC1, the cytosolic form, and ACC2, which is located in the mitochondria. We will discuss the regulatory roles of these proteins in Section 22.7.

Intermediates in fatty acid synthesis are attached to an acyl carrier protein

The intermediates in fatty acid synthesis are linked to an acyl carrier protein. Specifically, they are linked to the sulfhydryl terminus of a phosphopantetheine group. In the degradation of fatty acids, this unit is present as part of coenzyme A, whereas, in their synthesis, it is attached to a serine residue of the acyl carrier protein (Figure 22.24). Thus, ACP — a single polypeptide chain of 77 residues — can be regarded as a giant prosthetic group, a "macro CoA."

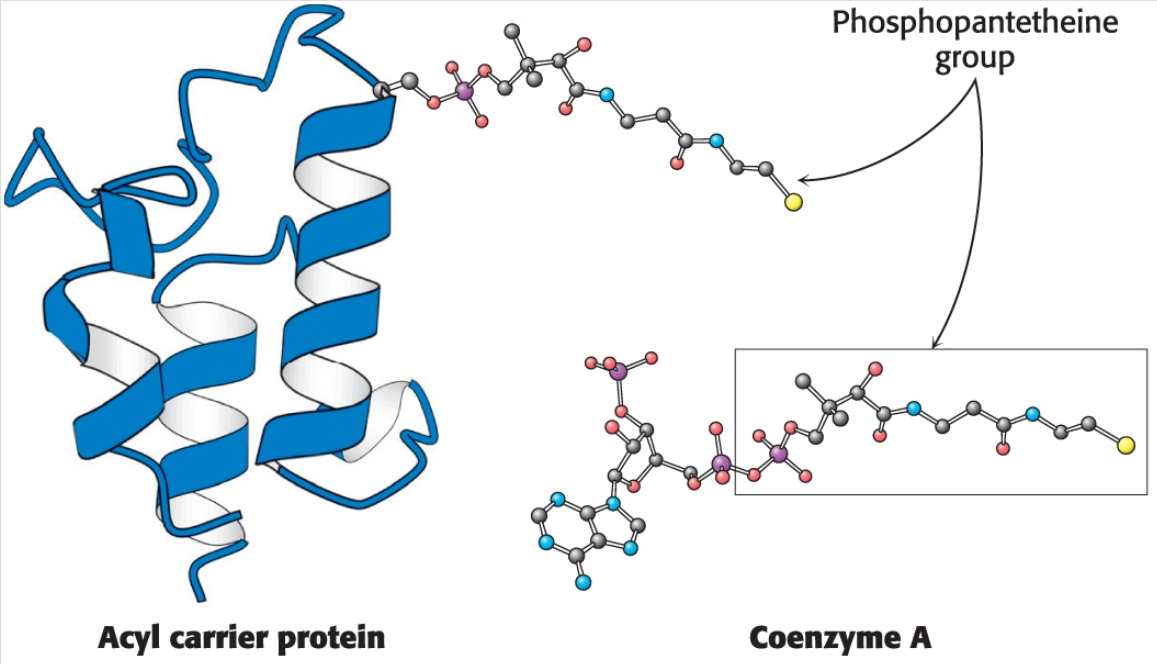

FIGURE 22.24 Both acyl carrier protein and coenzyme A include phosphopantetheine as their reactive units.

[Drawn from 1ACP.pdb.]

Fatty acid synthesis consists of a series of condensation, reduction, dehydration, and reduction reactions

The enzyme system that catalyzes the synthesis of saturated long-chain fatty acids from acetyl CoA, malonyl CoA, and NADPH is called *fatty acid synthase*. The synthase is actually a complex of distinct enzymes. The fatty acid synthase complex in bacteria is readily dissociated into individual enzymes when the cells are broken apart. The availability of these isolated enzymes has helped biochemists elucidate the steps in fatty acid synthesis (Table 22.2). In fact, the reactions leading to fatty acid synthesis in higher organisms are very much like those of bacteria.

TABLE 22.2 Principal reactions in fatty acid synthesis in bacteria

Step	Reaction	Enzyme
1	$\text{Acetyl CoA} + HCO_3^- + \text{ATP} \rightarrow \text{malonyl CoA} + \text{ADP} + P_i + H^+$	Acetyl CoA carboxylase
2	$\text{Acetyl CoA} + \text{ACP} \rightleftharpoons \text{acetyl ACP} + \text{Co A}$	Acetyl transacylase
3	$\text{Malonyl CoA} + \text{ACP} \rightleftharpoons \text{malonyl ACP} + \text{CoA}$	Malonyl transacylase
4	$\text{Acetyl ACP} + \text{malonyl ACP} \rightarrow \text{acetoacetyl ACP} + \text{ACP} + CO_2$	β-Ketoacyl synthase

5	$\text{Acetoacetyl ACP} + \text{NADPH} + \text{H}^+ \rightleftharpoons \text{D-3-hydroxybutyryl ACP} + \text{NADP}^+$	β-Ketoacyl reductase
6	$\text{D-3-Hydroxybutyryl ACP} \rightleftharpoons \text{crotonyl ACP} + \text{H}_2\text{O}$	3-Hydroxyacyl dehydratase
7	$\text{Crotonyl ACP} + \text{NADPH} + \text{H}^+ \rightarrow \text{butyryl ACP} + \text{NADP}^+$	Enoyl reductase

The elongation phase of fatty acid synthesis starts with the formation of acetyl ACP and malonyl ACP. Acetyl transacylase and malonyl transacylase catalyze these reactions.

$$\text{Acetyl CoA} + \text{ACP} \rightleftharpoons \text{acetyl ACP} + \text{CoA}$$

$$\text{Malonyl CoA} + \text{ACP} \rightleftharpoons \text{malonyl ACP} + \text{CoA}$$

Malonyl transacylase is highly specific, whereas acetyl transacylase can transfer acyl groups other than the acetyl unit, though at a much slower rate. The synthesis of fatty acids with an odd number of carbon atoms starts with propionyl ACP, which is formed from propionyl CoA by acetyl transacylase.

Acetyl ACP and malonyl ACP react to form acetoacetyl ACP (**Figure 22.25**). The β-ketoacyl synthase, also called the condensing enzyme, catalyzes this condensation reaction.

$$\text{Acetyl ACP} + \text{malonyl ACP} \rightarrow \text{acetoacetyl ACP} + \text{ACP} + \text{CO}_2$$

FIGURE 22.25 Like β-oxidation, saturated fatty acid synthesis consists of four steps. Saturated fatty acid synthesis begins with the condensation of malonyl ACP and acetyl ACP to form acetoacetyl ACP. Acetoacetyl ACP is then reduced, dehydrated, and reduced again to form butyryl ACP. Another cycle begins with the condensation of butyryl ACP and malonyl ACP. The sequence of reactions is repeated until the final product palmitate is formed.

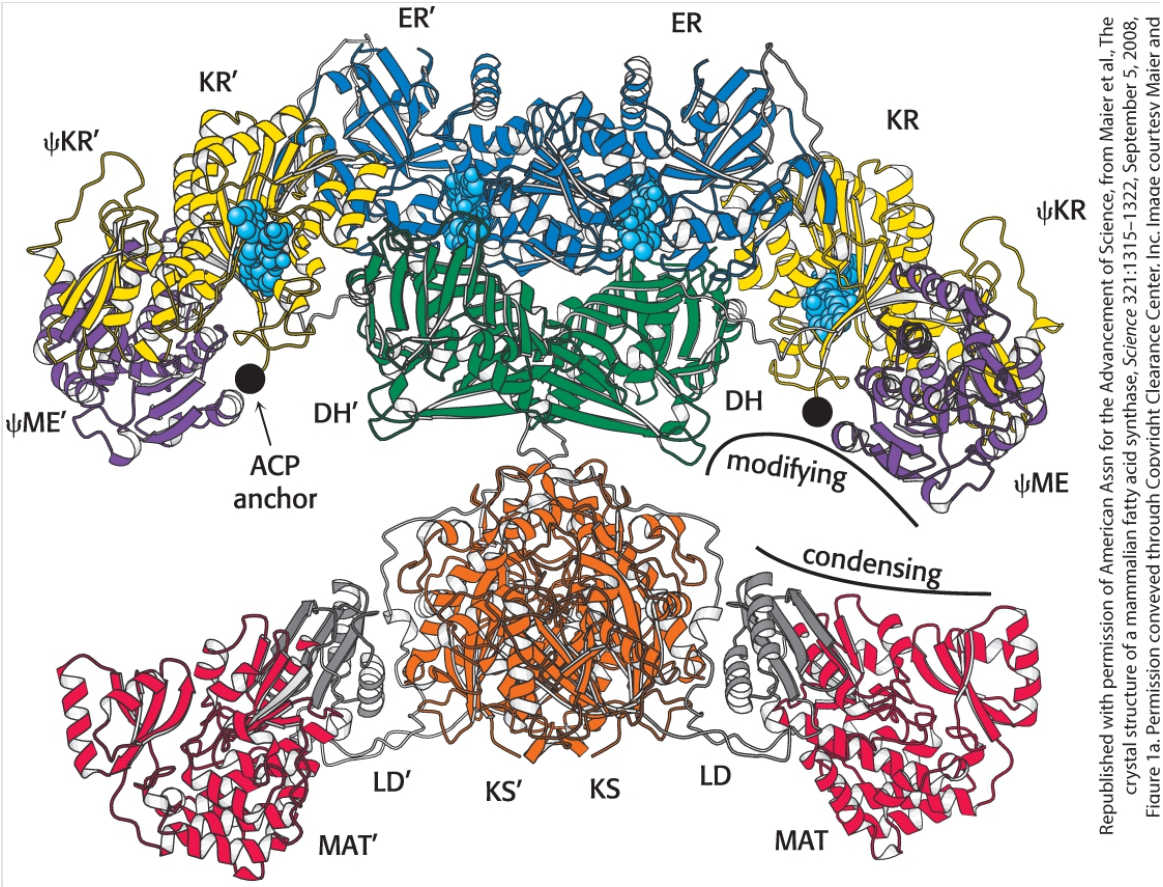
In the condensation reaction, a four-carbon unit is formed from a two-carbon unit and a three-carbon unit, and CO_2 is released. Why is the four-carbon unit not formed from two 2-carbon units — say, two molecules of acetyl ACP? The answer is that the equilibrium for the synthesis of acetoacetyl ACP from two molecules of acetyl ACP is highly unfavorable. In contrast, the equilibrium is favorable if malonyl ACP is a reactant because its decarboxylation contributes a substantial release of free energy. In effect, ATP drives the condensation reaction, though ATP does not directly participate in the condensation reaction. Instead, ATP is used to carboxylate acetyl CoA to malonyl CoA. The free energy thus stored in malonyl CoA is released in the decarboxylation accompanying the formation of acetoacetyl ACP. Although HCO_3^- is required for fatty acid synthesis, its carbon atom does not appear in the product because it is released in the subsequent decarboxylation. Rather, all the carbon atoms of fatty acids containing an even number of carbon atoms are derived only from acetyl CoA.

The next three steps in fatty acid synthesis reduce the keto group at C-3 to a methylene group (Figure 22.25). First, acetoacetyl ACP is reduced to D-3-hydroxybutyryl ACP by β-ketoacyl reductase. This reaction differs from the corresponding one in fatty acid degradation in two respects: (1) the D rather than the L isomer is formed; and (2) NADPH is the reducing agent, whereas NAD^+ is the oxidizing agent in β-oxidation. This difference exemplifies the general principle that NADPH is typically consumed in biosynthetic reactions, whereas NADH is typically generated in energy-yielding reactions. Then, D-3-

hydroxybutyryl ACP is dehydrated to form crotonyl ACP, which is a *trans*-Δ^2-enoyl ACP by 3-hydroxyacyl dehydratase. The final step in the cycle reduces crotonyl ACP to butyryl ACP. NADPH is again the reductant, whereas FAD is the oxidant in the corresponding reaction in β-oxidation. The bacterial enzyme that catalyzes this step, enoyl reductase, can be inhibited by triclosan, a broad-spectrum antibacterial agent that is added to a variety of products such as toothpaste, soaps, and skin creams. These last three reactions — a reduction, a dehydration, and a second reduction — convert acetoacetyl ACP into butyryl ACP, which completes the first elongation cycle.

In the second round of fatty acid synthesis, butyryl ACP condenses with malonyl ACP to form a C_6-β-ketoacyl ACP. This reaction is like the one in the first round, in which acetyl ACP condenses with malonyl ACP to form a C_4-β-ketoacyl ACP. Reduction, dehydration, and a second reduction convert the C_6-β-ketoacyl ACP into a C_6-acyl ACP, which is ready for a third round of elongation. The elongation cycles continue until C_{16}-acyl ACP is formed. This intermediate is a good substrate for a thioesterase that hydrolyzes C_{16}-acyl ACP to yield palmitate and ACP. The thioesterase acts as a ruler to determine fatty acid chain length. The synthesis of longer-chain fatty acids is discussed in Section 22.6.

Self-Check Question



Although HCO_3^- is required for fatty acid synthesis, its carbon atom does not appear in the product. Explain how this omission is possible.

Fatty acids are synthesized by a multifunctional enzyme complex in animals

Although the basic biochemical reactions in fatty acid synthesis are very similar in *E. coli* and eukaryotes, the structure of the synthase varies considerably. The component enzymes of animal fatty acid synthases, in contrast with those of *E. coli* and plants, are linked in a large polypeptide chain.

The structure of a large part of the mammalian fatty acid synthase has been determined, with the acyl carrier protein and thioesterase remaining to be resolved. The enzyme is a dimer of identical 270-kd subunits. Each chain contains all of the active sites required for activity, as well as an acyl carrier protein tethered to the complex (**Figure 22.26**). Despite the fact that each chain possesses all of the enzymes required for fatty acid synthesis, the monomers are not active. A dimer is required.

Republished with permission of American Assn for the Advancement of Science, from Maier et al., The crystal structure of a mammalian fatty acid synthase, *Science* 321:1315–1322, September 5, 2008, Figure 1a. Permission conveyed through Copyright Clearance Center. Inc. Image courtesy Maier and

FIGURE 22.26 Mammalian fatty acid synthase is a large, dimeric, multidomain protein complex. The complex is a dimer of two multidomain monomers and can be described as consisting of two main parts: the body of the lower part is the β-ketosynthase (KS), while the malonylacetyl transferase (MAT) domains comprise the legs. These structures are joined by a linker domain (LD). The lower part is connected at the waist to the upper part, which consists of dehydratase (DH) and enoyl reductase (ER), which together comprise the upper body. The ketoreductase (KR) domains form the arms. The noncatalytic domains are ψKR and ψME Bound $NADP^+$ cofactors are shown as blue spheres and the attachment site for the acyl carrier protein, and thioesterase is shown as a black sphere. The domains of the second chain are indicated by the abbreviation followed by a prime.

The two component chains interact such that the enzyme activities are partitioned into two distinct compartments, a lower body and an upper body, joined by a waist. The lower body contains the β-ketosynthase, while the legs comprise the malonylacetyl transferase domains which

are joined to the body by a linker domain. The body and the legs catalyze the condensing reactions. The upper body contains dehydratase and enoyl reductase, and the arms contain the ketoreductase domains. The upper body and the arms catalyze the modification reactions, the reduction and dehydration activities that result in the saturated fatty acid product. Interestingly, the mammalian fatty acid synthase has one active site — malonyl/acetyl transacylase — that adds both acetyl CoA and malonyl CoA. In contrast, most other fatty acid synthases have two separate enzyme activities — one for acetyl CoA and one for malonyl CoA. The enzyme also contains noncatalytic domains, designated by symbol ψ. The ψKR resembles the ketoreductase domain, and the ψME domain is homologous to methyltransferase enzymes. Both the ψKR and ψME domains play a role in maintaining enzyme structure.

Let us consider one catalytic cycle of the fatty acid synthase complex (**Figure 22.27**). An elongation cycle begins after malonyl/acetyl transacylase (MAT) moves an acetyl unit from coenzyme A to the acyl carrier protein (ACP). β-Ketosynthase (β-KS) accepts the acetyl unit, which forms a thioester with a cysteine residue at the β-KS active site. The vacant ACP is reloaded by MAT, this time with a malonyl moiety. Malonyl ACP visits the active site of β-KS where the condensation of the two 2-carbon fragments takes place on the ACP with the concomitant release of CO_2. The selecting and condensing process concludes with the β-ketoacyl product attached to the ACP.

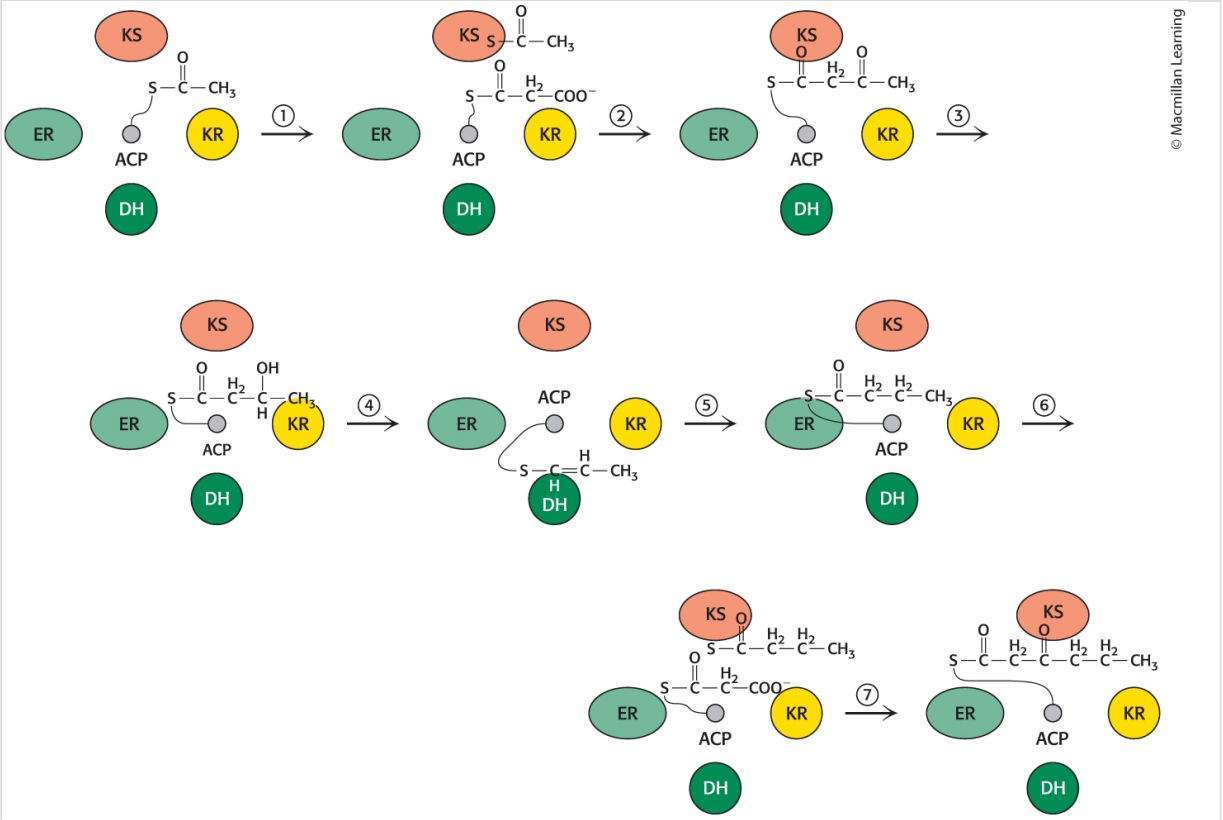


FIGURE 22.27 One catalytic cycle of mammalian fatty acid synthase consists of seven steps. The cycle begins after MAT (not shown) attaches an acetyl unit to ACP. (1) ACP delivers the acetyl unit to KS, and MAT then attaches a malonyl unit to ACP. (2) ACP visits KS again, which condenses the acetyl and malonyl units to form the β-ketoacyl product, attached to the ACP. (3) ACP delivers the β-ketoacyl product to the KR enzyme, which reduces the keto group to an alcohol. (4) The β-hydroxyl product then visits DH, which introduces a double bond with the loss of water. (5) The enoyl product is delivered to the ER enzyme, where the double bond is reduced. (6) ACP hands the reduced product to KS and is recharged with malonyl CoA by MAT. (7) KS condenses the two molecules on ACP, which is now ready to begin another cycle. See Figure 22.26 for abbreviations.

The loaded ACP then sequentially visits the active sites of the modification compartment of the enzyme. Here, the β-keto group of the substrate is reduced to — OH, dehydrated, and finally reduced to yield the saturated acyl product, still attached to the ACP. With the completion of the modification process, the reduced product is transferred to the β-KS while the ACP accepts another malonyl unit. Condensation takes place and is followed by another modification cycle.

The process is repeated until the thioesterase releases the final C_{16} palmitic acid product.

Many eukaryotic multienzyme complexes are multifunctional proteins in which different enzymes are linked covalently. Multifunctional enzymes such as fatty acid synthase seem likely to have arisen in eukaryotic evolution by fusion of the individual genes of evolutionary ancestors.

The synthesis of palmitate requires 8 molecules of acetyl CoA, 14 molecules of NADPH, and 7 molecules of ATP

The stoichiometry of the synthesis of palmitate is

$$\text{Acetyl CoA} + 7\ \text{malonyl CoA} + 14\ \text{NADPH} + 20\ H^+ \rightarrow$$

$$\text{palmitate} + 7\ CO_2 + 14\ NADP^+ + 8\ \text{CoA} + 6\ H_2O$$

The equation for the synthesis of the malonyl CoA used in the preceding reaction is

$$7\ \text{Acetyl CoA} + 7\ CO_2 + 7\ \text{ATP} \rightarrow 7\ \text{malonyl CoA} + 7\ \text{ADP} + 7\ P_i + 14\ H^+$$

Hence, the overall stoichiometry for the synthesis of palmitate is

$$8\ \text{Acetyl CoA} + 7\ \text{ATP} + 14\ \text{NADPH} + 6\ H^+ \rightarrow$$

$$\text{palmitate} + 14\ NADP^+ + 8\ CoA + 6\ H_2O + 7\ ADP + 7\ P_i$$

Citrate carries acetyl groups from mitochondria to the cytoplasm for fatty acid synthesis

Fatty acids are synthesized in the cytoplasm, whereas acetyl CoA is formed from pyruvate in mitochondria. Hence, acetyl CoA must be transferred from mitochondria to the cytoplasm for fatty acid synthesis. Mitochondria, however, are not readily permeable to acetyl CoA. Recall that carnitine carries only long-chain fatty acids. How is this obstacle overcome?

The barrier to acetyl CoA is bypassed by citrate, which carries acetyl groups across the inner mitochondrial membrane. As you will recall from Chapter 17, citrate is formed in the mitochondrial matrix by the condensation of acetyl CoA with oxaloacetate (**Figure 22.28**). When present at high levels, citrate is transported to the cytoplasm, where it is cleaved by ATP-citrate lyase.

$$\text{Citrate} + ATP + CoA + H_2O \rightarrow \text{acetyl CoA} + ADP + P_i + \text{oxaloacetate}$$

This reaction occurs in three steps: (1) The formation of a phospho-enzyme with the donation of a phosphoryl group from ATP; (2) binding of citrate and CoA followed by the formation of citroyl CoA and release of the phosphate; and (3) cleavage of citroyl CoA to yield acetyl CoA and oxaloacetate. As we will see shortly (Section 22.6), citrate stimulates acetyl CoA carboxylase, the enzyme that regulates fatty acid metabolism. Recall also, the presence of citrate in the cytoplasm

inhibits phosphofructokinase, the enzyme that controls the glycolytic pathway.

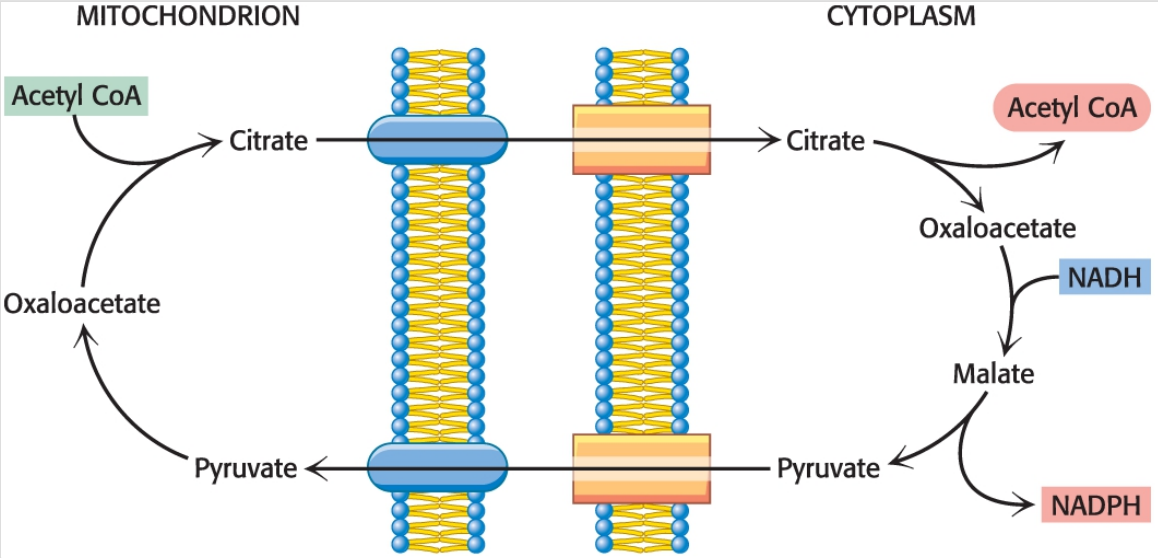

FIGURE 22.28 Acetyl CoA can be transferred from the mitochondrial matrix to the cytoplasm. Acetyl CoA is transferred from mitochondria to the cytoplasm, and the reducing potential of NADH is concomitantly converted into that of NADPH by this series of reactions.

ATP-citrate lyase is stimulated by insulin, which initiates a signal transduction pathway that ultimately results in the phosphorylation and activation of the lyase by protein kinase B (also called Akt).

Several sources supply NADPH for fatty acid synthesis

Oxaloacetate formed in the transfer of acetyl groups to the cytoplasm must now be returned to the mitochondria. The inner mitochondrial membrane is impermeable to oxaloacetate. Hence, a series of bypass reactions are needed. These reactions also generate much of the

NADPH needed for fatty acid synthesis. First, oxaloacetate is reduced to malate by NADH. This reaction is catalyzed by a malate dehydrogenase in the cytoplasm.

$$\text{Oxaloacetate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{malate} + \text{NAD}^+$$

Second, malate is oxidatively decarboxylated by $^{\text{NADP}^+}$-linked malate enzyme (also called *malic enzyme*).

$$\text{Malate} + \text{NADP}^+ \rightarrow \text{pyruvate} + \text{CO}_2 + \text{NADPH}$$

The pyruvate formed in this reaction readily enters mitochondria, where it is carboxylated to oxaloacetate by pyruvate carboxylase.

$$\text{Pyruvate} + \text{CO}_2 + \text{ATP} + \text{H}_2\text{O} \rightarrow \text{oxaloacetate} + \text{ADP} + \text{P}_i + 2\text{H}^+$$

The sum of these three reactions is

$$\text{NADP}^+ + \text{NADH} + \text{ATP} + \text{H}_2\text{O} \rightarrow \text{NADPH} + \text{NAD}^+ + \text{ADP} + \text{P}_i + \text{H}^+$$

Thus, one molecule of NADPH is generated for each molecule of acetyl CoA that is transferred from mitochondria to the cytoplasm. Hence, eight molecules of NADPH are formed when eight molecules of acetyl CoA are transferred to the cytoplasm for the synthesis of palmitate. The additional six molecules of NADPH required for this process come from the pentose phosphate pathway (Section 20.3).

The accumulation of the precursors for fatty acid synthesis is a wonderful example of the coordinated use of multiple pathways. The

citric acid cycle, transport of oxaloacetate from the mitochondria, and pentose phosphate pathway provide the carbon atoms and reducing power, whereas glycolysis and oxidative phosphorylation provide the ATP to meet the needs for fatty acid synthesis (Figure 22.29).

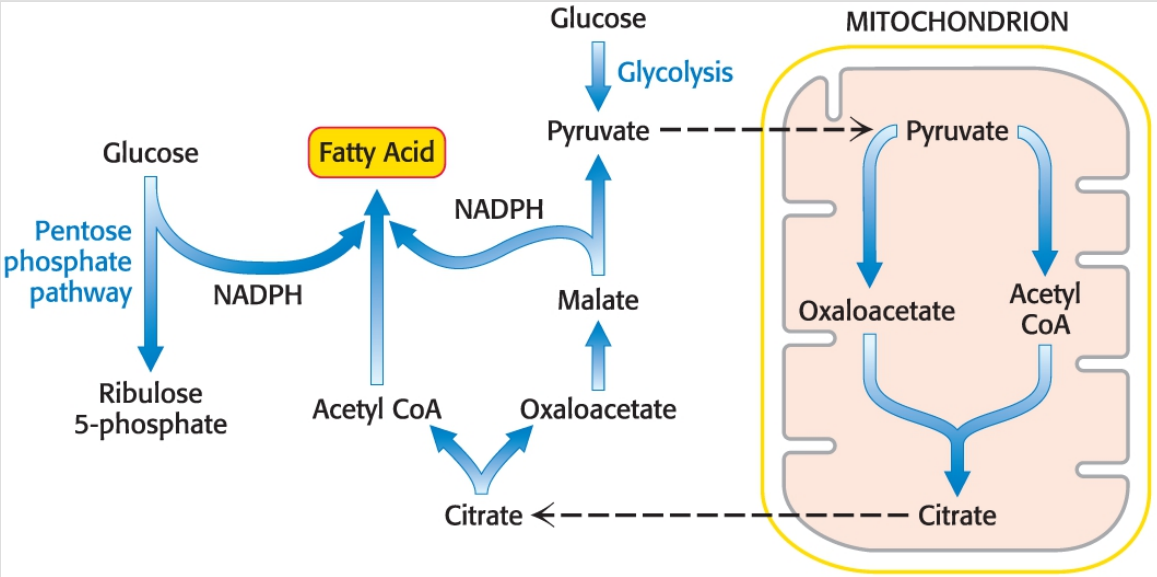

FIGURE 22.29 Pathway Integration: Fatty acid synthesis requires the cooperation of various pathways in different cellular compartments. The combination of glycolysis, the citric acid cycle, and the pentose phosphate pathway can be used to efficiently convert glucose into fatty acids.

EXPLORE this pathway further in the Metabolic Map in Achieve

Fatty acid metabolism is altered in tumor cells

We have previously seen that cancer cells alter glucose metabolism to meet the needs of rapid cell growth. Cancer cells must also increase fatty acid synthesis for use as signal molecules, as well as for incorporation into membrane phospholipids for the construction of new cell membranes in rapidly dividing cells. Many of the enzymes of fatty acid synthesis are overexpressed in most human cancers, and this expression is correlated with tumor malignancy. Recall that normal cells do little de novo fatty acid synthesis, relying instead on dietary intake to meet their fatty needs.

The dependence of de novo fatty acid synthesis provides possible therapeutic targets to inhibit cancer cell growth. Inhibition of β-ketoacyl ACP synthase — the enzyme that catalyzes the condensation step of fatty acid synthesis — does indeed inhibit phospholipid synthesis and subsequent cell growth in some cancers, apparently by inducing apoptosis. However, another startling observation was made: mice treated with inhibitors of the β-ketoacyl ACP synthase showed remarkable weight loss because they ate less. Thus, fatty acid synthase inhibitors are exciting candidates both as antitumor and as anti-obesity drugs.

ACC is also being investigated as a possible target for inhibiting cancer cell growth. Inhibition of the carboxylase in prostate and breast cancer cell lines induces apoptosis in the cancer cells, and yet is without effect in normal cells. Understanding the alteration of fatty acid metabolism in cancer cells is a developing area of research that holds promise of generating new cancer therapies.

Triacylglycerols may become an important renewable energy source

Work is underway to develop efficient means of generating triacylglycerols for use as renewable biodiesel fuel. Briefly, CO_2, CO,

and H_2 (collectively called *syngas* because they can be used to make synthetic natural gas) are captured from municipal waste or generated from other waste sources and fed to anaerobic acetogenic bacteria. Acetogenic bacteria contain a complex pathway, called the *Wood-Ljungdahl pathway*, that can synthesize acetate from syngas. In this pathway, CO_2 and CO are reduced to a methyl group which then reacts with CO and coenzyme A to form acetyl CoA. The acetate can be harvested from the bacteria, then used as a carbon source for oleaginous yeast, which can synthesize and accumulate triacylglycerols to 20% to 70% of their cell mass, depending on culture conditions. Using large fermenters and complex algorithms to control bacterial and yeast growth, triacylglycerols can be synthesized in sufficient quantities for biodiesel and other renewable products.

22.6 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems

The major product of the fatty acid synthase is palmitate. In eukaryotes, longer fatty acids are formed by elongation reactions catalyzed by enzymes on the cytoplasmic face of the endoplasmic reticulum membrane. These reactions add two-carbon units sequentially to the carboxyl ends of both saturated and unsaturated fatty acyl CoA substrates. Malonyl CoA is the two-carbon donor in the elongation of fatty acyl CoAs. Again, condensation is driven by the decarboxylation of malonyl CoA.

Membrane-bound enzymes generate unsaturated fatty acids

Endoplasmic reticulum enzymes also introduce double bonds into long-chain acyl CoAs. For example, in the conversion of stearoyl CoA into oleoyl CoA, a *cis*-Δ^9 double bond is inserted by an oxidase that employs molecular oxygen and NADH (or NADPH).

$$\text{Stearoyl CoA} + \text{NADH} + \text{H}^+ + \text{O}_2 \rightarrow \text{oleoyl CoA} + \text{NAD}^+ + 2\ \text{H}_2\text{O}$$

This reaction is catalyzed by a complex of three membrane-bound proteins: NADH-cytochrome b_5 reductase, cytochrome b_5, and stearoyl CoA desaturase (**Figure 22.30**). First, electrons are transferred from

NADH to the FAD moiety of NADH-cytochrome b_5 reductase. The heme iron atom of cytochrome b_5 is then reduced to the Fe^{2+} state. The nonheme iron atom of the desaturase is subsequently converted into the Fe^{2+} state, which enables it to interact with O_2 and the saturated fatty acyl CoA substrate. A double bond is formed and two molecules of H_2O are released. Two electrons come from NADH and two from the single bond of the fatty acyl substrate.

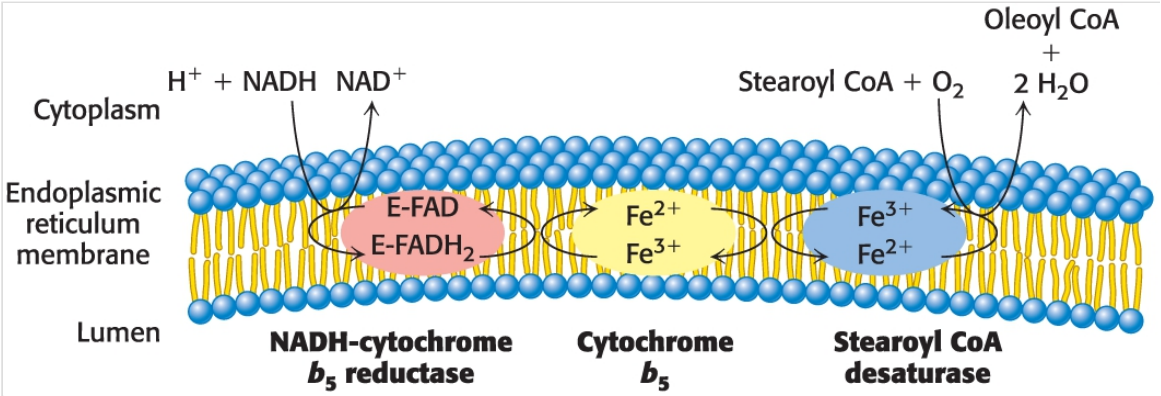

FIGURE 22.30 Fatty acids are desaturated by an electron-transport chain in the ER membran

A variety of unsaturated fatty acids can be formed from oleate by a combination of elongation and desaturation reactions. For example, oleate can be elongated to a 20:1 *cis*-Δ^{11} fatty acid. Alternatively, a second double bond can be inserted to yield an 18:2 *cis*-Δ^{6}, Δ^{9} fatty acid. Similarly, palmitate (16:0) can be oxidized to palmitoleate (16:1 *cis*-Δ^{9}), which can then be elongated to *cis*-vaccenate (18:1 *cis*-Δ^{11}).

Unsaturated fatty acids in mammals are derived from either palmitoleate (16:1 *cis*-Δ^{9}), oleate (18:1 *cis*-Δ^{9}), linoleate (18:2 *cis*-

Δ^{9}, Δ^{12}), or linolenate (18:3 *cis*-$\Delta^{9}, \Delta^{12}, \Delta^{15}$). However, mammals lack the enzymes to introduce double bonds at carbon atoms beyond C-9 in the fatty acid chain. Because mammals cannot synthesize linoleate and linolenate, these are essential fatty acids in human metabolism. The term *essential* means that they must be supplied in the diet because they are required by an organism and cannot be synthesized by the organism itself. It should be noted that this terminology has no relationship to the term *essential oil*, which has no specific chemical definition. Linoleate and linolenate furnished by the diet are the starting points for the synthesis of a variety of other unsaturated fatty acids.

Eicosanoid hormones are derived from polyunsaturated fatty acids

A 20:4 fatty acid derived from linoleate called *arachidonate* (20:4 *cis*-$\Delta^{5}, \Delta^{8}, \Delta^{11}, \Delta^{14}$) is the major precursor of several classes of signal molecules: prostaglandins, prostacyclins, thromboxanes, and leukotrienes (**Figure 22.31**).

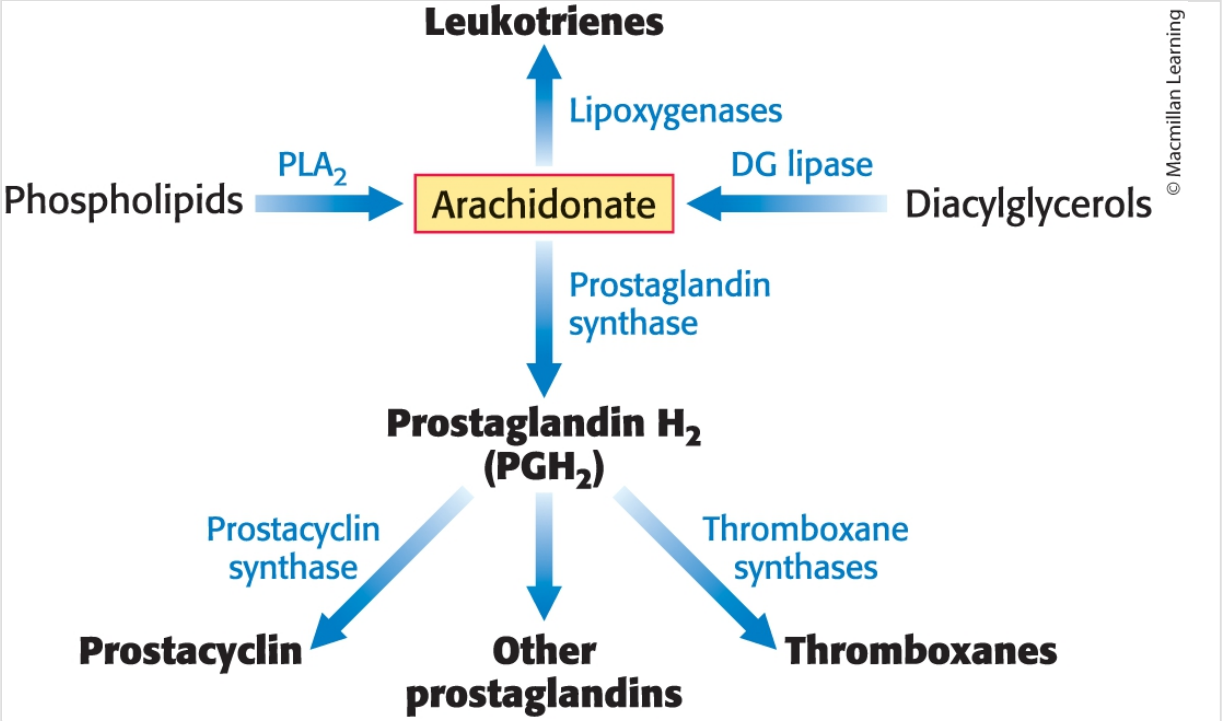

FIGURE 22.31 Several eicosanoid hormones are produced from arachidonate by distinct enzymatic pathways. Prostaglandin synthase catalyzes the first step in a pathway leading eventually to all prostaglandins, prostacyclins, and thromboxanes. Lipoxygenase catalyzes the initial step in a separate pathway leading to leukotrienes.

A **prostaglandin** is a 20-carbon fatty acid containing a 5-carbon ring (**Figure 22.32**). This basic compound is modified by reductases and isomerases to yield nine major classes of prostaglandins, designated PGA through PGI; a subscript denotes the number of carbon–carbon double bonds outside the ring. Prostaglandins with two double bonds, such as PGE_2, are derived from arachidonate; the other two double bonds of this precursor are lost in forming a 5-membered ring. Prostacyclin and thromboxanes are related compounds that arise from a nascent prostaglandin. They are generated by prostacyclin synthase and thromboxane synthase, respectively. Alternatively, arachidonate can be converted into leukotrienes by the action of lipoxygenase. Leukotrienes, first found in leukocytes, contain three conjugated double bonds —

hence the name. Prostaglandins, prostacyclin, thromboxanes, and leukotrienes are called **eicosanoids** (from the Greek *eikosi*, "twenty") because they contain 20 carbon atoms.

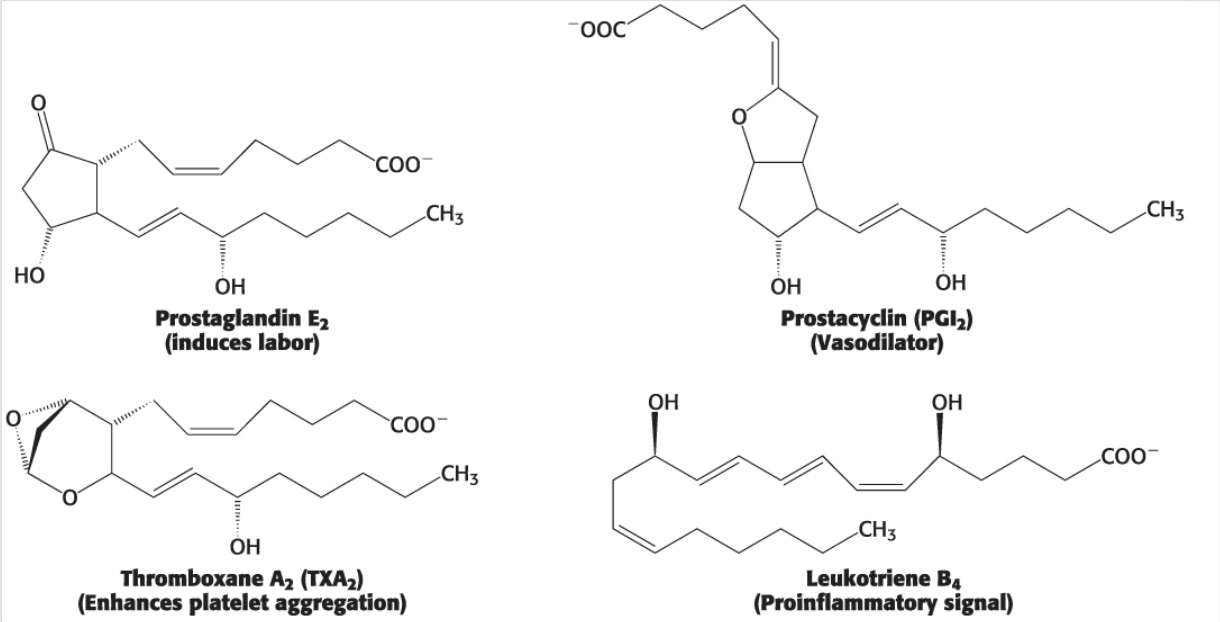

FIGURE 22.32 Eicosanoids have diverse functions but similar 20-carbon structures.

Prostaglandins and other eicosanoids are local hormones because they are short-lived. They alter the activities both of the cells in which they are synthesized and of adjoining cells by binding to 7TM receptors. Their effects may vary from one cell type to another, in contrast with the more-uniform actions of global hormones such as insulin and glucagon. Prostaglandins stimulate inflammation, regulate blood flow to particular organs, control ion transport across membranes, modulate synaptic transmission, and induce sleep.

Recall that aspirin (acetylsalicylate) blocks access to the active site of the enzyme that converts arachidonate into prostaglandin H_2

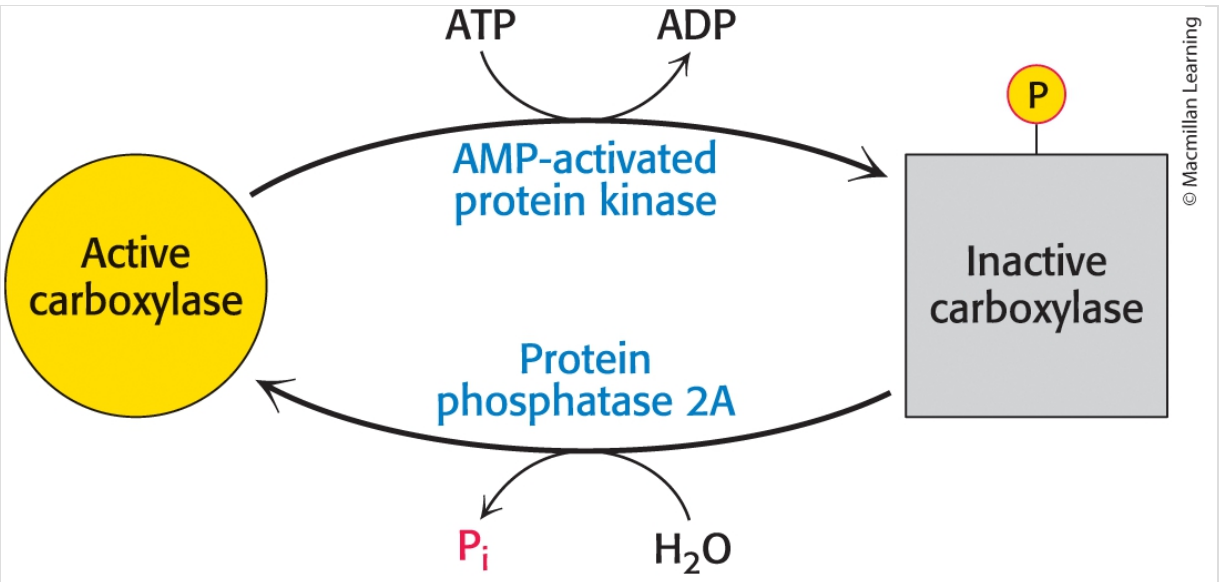
(Section 12.4). Because arachidonate is the precursor of other prostaglandins, prostacyclin, and thromboxanes, blocking this step interferes with many signaling pathways. Aspirin's ability to obstruct these pathways accounts for its wide-ranging effects on inflammation, fever, pain, and blood clotting.

22.7 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

Fatty acid metabolism is stringently controlled so that synthesis and degradation are highly responsive to physiological needs. Fatty acid synthesis is maximal when carbohydrates and energy are plentiful and when fatty acids are scarce. Both ACC1 and ACC2 play essential roles in regulating fatty acid synthesis and degradation. Recall that this enzyme catalyzes the committed step in fatty acid synthesis: the production of malonyl CoA (the activated two-carbon donor). This important enzyme is subject to both local and hormonal regulation. We will examine each of these levels of regulation in turn.

Acetyl CoA carboxylase is regulated by conditions in the cell

ACC1 responds to changes in the cytosol; it is switched off by phosphorylation and activated by dephosphorylation (**Figure 22.33**). **AMP-activated protein kinase (AMPK)** converts the carboxylase into an inactive form by modifying three serine residues. AMPK is essentially a cellular fuel gauge; it is activated by AMP and inhibited by ATP.



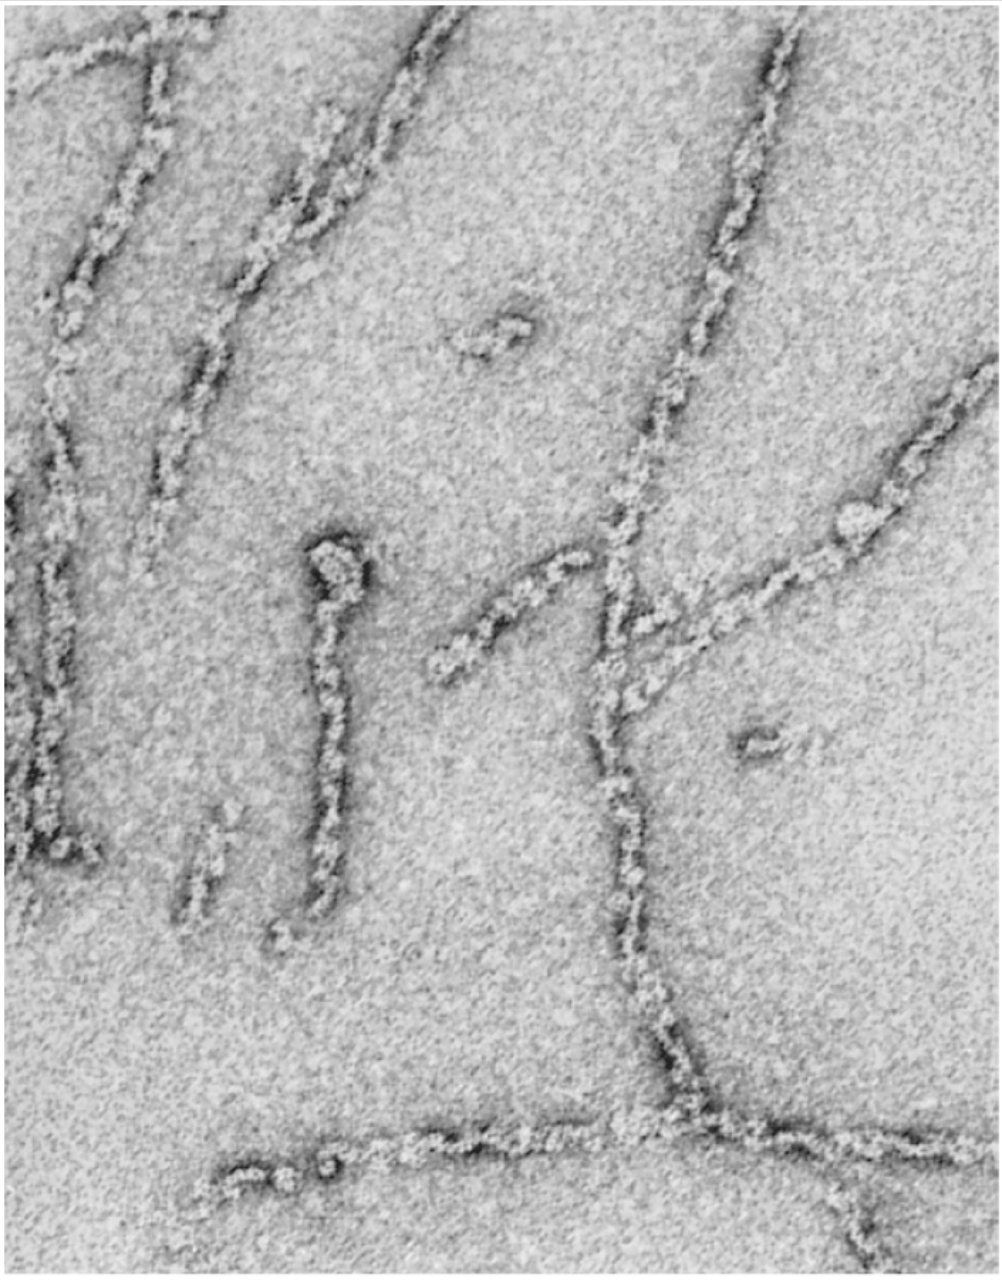


FIGURE 22.33 Acetyl CoA carboxylase is inhibited by phosphorylation by AMPK.

The carboxylase is also allosterically stimulated by citrate. The level of citrate is high when both acetyl CoA and ATP are abundant, signifying that raw materials and energy are available for fatty acid synthesis. Citrate acts in an unusual way on inactive ACC1, which exists as isolated inactive dimers. Citrate facilitates the polymerization of the inactive dimers into active filaments (Figure 22.34).

Courtesy of Dr. M. Daniel Lane.

FIGURE 22.34 Filaments of acetyl CoA carboxylase are enzymatically active. The electron micrograph shows the enzymatically active filamentous form of acetyl CoA carboxylase from chicken liver. The inactive form is a dimer of 265-kDa subunits.

However, polymerization by citrate alone requires supraphysiological concentrations. In the cell, citrate-induced polymerization is facilitated by the protein MIG12, which greatly reduces the amount of citrate required. Polymerization can partly reverse the inhibition produced by phosphorylation (**Figure 22.35**). The stimulatory effect of citrate on the carboxylase is counteracted by palmitoyl CoA, which is abundant when there is an excess of fatty acids. Palmitoyl CoA causes the filaments to disassemble into the inactive subunits. Palmitoyl CoA also inhibits the translocase that transports citrate from mitochondria to the cytoplasm, as well as glucose 6-phosphate dehydrogenase, which generates NADPH in the pentose phosphate pathway.

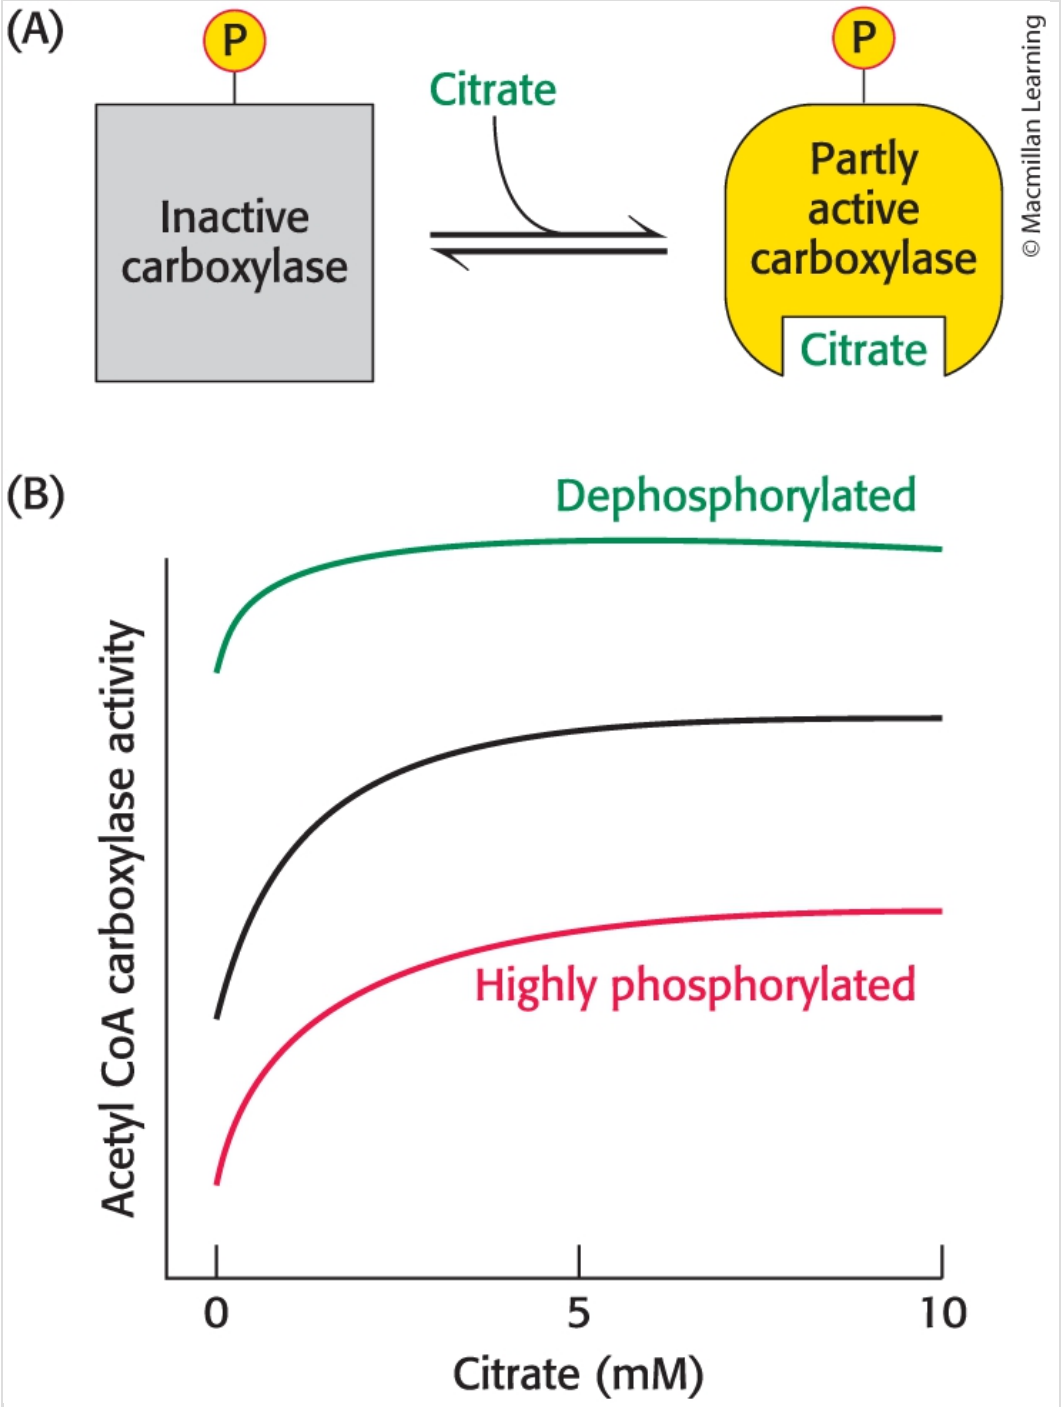

FIGURE 22.35 The catalytic activity of acetyl CoA carboxylase depends upon the concentration of citrate. (A) Citrate can partly activate the phosphorylated carboxylase. (B) The dephosphorylated form of the carboxylase is highly active even when citrate is absent. Citrate partly overcomes the inhibition produced by phosphorylation.

[Information from G. M. Mabrouk, I. M. Helmy, K. G. Thampy, and S. J. Wakil. *J. Biol. Chem.* 265:6330–6338, 1990.]

The isozyme ACC2, located in the mitochondria, plays a role in the regulation of fatty acid degradation. Malonyl CoA, the product of the carboxylase reaction, is present at a high level when fuel molecules are abundant. Malonyl CoA inhibits CATI, preventing the entry of fatty acyl CoAs into the mitochondrial matrix in times of plenty. Malonyl CoA is an especially effective inhibitor of CATI in heart and muscle, tissues that have little fatty acid synthesis capacity of their own. In these tissues, ACC2 may be a purely regulatory enzyme. ACC2 is also phosphorylated and inhibited by AMPK. The reduction in the amount of mitochondrial malonyl CoA following the inhibition of AMPK allows fatty acid transport into the mitochondria for β-oxidation. Thus, AMPK inhibits fatty acid synthesis while stimulating fatty acid oxidation. Activators of AMPK are being investigated to treat nonalcoholic fatty liver disease (NAFLD), a condition due to overnutrition where fats accumulate in the liver. Untreated NAFLD is often a precursor to type 2 diabetes (Section 24.3).

Acetyl CoA carboxylase is controlled by a variety of hormones

ACC is controlled by the hormones glucagon, epinephrine, and insulin, which denote the overall energy status of the organism. Insulin stimulates fatty acid synthesis by activating the carboxylase, whereas glucagon and epinephrine have the reverse effect.

Regulation by glucagon and epinephrine

Consider, again, a person who has just awakened from a night's sleep and begins a bout of exercise. As mentioned, glycogen stores will be low, but lipids are readily available for mobilization.

As stated earlier, the hormones glucagon and epinephrine, present under conditions of fasting and exercise, will stimulate the mobilization of fatty acids from triacylglycerols in fat cells, which will be released into the blood, and probably from muscle cells, where they will be used immediately as fuel. These same hormones will inhibit fatty acid synthesis by inhibiting ACC. Although the exact mechanism by which these hormones exert their effects is not known, the net result is to augment the inhibition by the AMPK. This result makes sound physiological sense: when the energy level of the cell is low, as signified by a high concentration of AMP, and the energy level of the organism is low, as signaled by glucagon, fats should not be synthesized. Epinephrine, which signals the need for immediate energy, enhances this effect. Hence, these catabolic hormones switch off fatty acid synthesis by keeping the carboxylase in the inactive phosphorylated state.

Regulation by insulin

Now consider the situation after the exercise has ended and the runner has had a meal. In this case, the hormone insulin inhibits the mobilization of fatty acids and stimulates their accumulation as triacylglycerols by muscle and adipose tissue. Insulin also stimulates fatty acid synthesis by activating ACC. Insulin activates the carboxylase by enhancing the phosphorylation and inactivation of AMPK by protein kinase B. Insulin also promotes the activity of a protein phosphatase that dephosphorylates and activates ACC. Thus, the signal molecules glucagon, epinephrine, and insulin act in

concert on triacylglycerol metabolism and acetyl CoA carboxylase to carefully regulate the utilization and storage of fatty acids.

Response to diet

Long-term control is mediated by changes in the rates of synthesis and degradation of the enzymes participating in fatty acid synthesis. Animals that have fasted and are then fed high-carbohydrate, low-fat diets show marked increases in their amounts of ACC and fatty acid synthase within a few days. This type of regulation is known as *adaptive control*. This regulation, which is mediated both by insulin and by glucose, is at the level of gene transcription.

Self-Check Question

Consider citrate's role as a regulator of fatty acid metabolism and recall another regulatory connection we saw in Chapter 16 but could not fully explain at that point: citrate is an inhibitor of phosphofructokinase. Explain now why this is appropriate.

AMP-activated protein kinase is a key regulator of metabolism

As we have already seen, AMPK inhibits fatty acid synthesis while simultaneously stimulating fatty acid oxidation. However, this ubiquitous trimeric enzyme (αβγ), which exists in several isozymic

forms, regulates a number of other metabolic processes. As in fatty acid metabolism, AMPK in general activates ATP-generating pathways and inhibits pathways that require ATP. Thus, AMPK stimulates glucose uptake and mitochondria biogenesis, while inhibiting cholesterol synthesis and protein synthesis. In some immune cells AMPK moderates the inflammatory response. AMPK also helps initiate nonshivering thermogenesis in brown adipose tissue (Section 18.6). Finally, its importance to growth is illustrated by the observation that its absence is lethal in mouse embryogenesis, suggesting that AMPK is crucial for early development. Interestingly, the isozymic forms of this key enzyme are themselves regulated by phosphorylation by a number of kinases. Understanding the intricacies of this enzyme will surely keep biochemists engaged for years to come.

Chapter 22 Summary

22.1 Triacylglycerols Are Highly Concentrated Energy Stores

- Fatty acids are physiologically important as (1) fuel molecules, (2) components of phospholipids and glycolipids, (3) hydrophobic modifiers of proteins, and (4) hormones and intracellular messengers.
- Fatty acids are stored as triacylglycerols in lipid droplets within adipocytes of adipose tissue.
- Dietary triacylglycerols are coated with bile acids, rendering them more easily digested by pancreatic lipases. The digestion products are transported inside intestinal cells where triacylglycerols are resynthesized. New triacylglycerols are packaged into chylomicrons which are released into the lymph system and then the blood for transport.

22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing

- Triacylglycerols can be mobilized by the action of hormonally controlled lipases. Glucagon and epinephrine stimulate triacylglycerol breakdown, while insulin inhibits it.
- Fatty acids are activated to acyl CoAs, transported across the inner mitochondrial membrane while bound to carnitine, and degraded in the mitochondrial matrix by a recurring sequence of four reactions: oxidation by FAD, hydration, oxidation by NAD^+, and thiolysis by coenzyme A.
- The $FADH_2$ and NADH formed in the oxidation steps transfer their electrons to O_2 by means of the ETC, whereas the acetyl CoA formed in the thiolysis step normally enters the citric acid cycle.

22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation

- Fatty acids that contain double bonds or odd numbers of carbon atoms require ancillary steps to be degraded.
- An isomerase and a reductase are required for the oxidation of unsaturated fatty acids, whereas propionyl CoA derived from chains with odd numbers of carbon atoms requires a vitamin B_{12}-dependent enzyme to be converted into succinyl CoA.

22.4 Ketone Bodies Are a Fuel Source Derived from Fats

- Ketone bodies are an important fuel source for some tissues. The primary ketone bodies — acetoacetate and β-hydroxybutyrate — are formed in the liver by condensation of acetyl CoA units.
- Mammals are unable to convert fatty acids into glucose because they lack a pathway for the net production of oxaloacetate, pyruvate, and other gluconeogenic intermediates from acetyl CoA.

22.5 Fatty Acids Are Synthesized by Fatty Acid Synthase

- Fatty acids are synthesized in the cytoplasm by fatty acid synthase. Synthesis starts with the carboxylation of acetyl CoA to malonyl CoA, the committed step. This ATP-driven reaction is catalyzed by acetyl CoA carboxylase (ACC), a biotin enzyme.
- The intermediates in fatty acid synthesis are linked to an acyl carrier protein (ACP). Acetyl ACP and malonyl ACP condense to form acetoacetyl ACP, with the release of CO_2. NADPH is used as a reductant in subsequent reactions which mirror the reverse of β-oxidation. Additional two-carbon units from malonyl ACP are added, typically ending at palmitoyl ACP, which is hydrolyzed to palmitate.

- A reaction cycle based on the formation and cleavage of citrate carries acetyl groups from mitochondria to the cytoplasm, while the NADPH needed for synthesis is generated in the transfer of reducing equivalents from mitochondria.

22.6 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems

- Fatty acids are elongated and desaturated by enzyme systems in the ER membrane. Desaturation requires NADH and O_2 and is carried out by a complex consisting of a flavoprotein, a cytochrome, and a nonheme iron protein.
- Mammals lack the enzymes to introduce double bonds distal to C-9, and so they require linoleate and linolenate in their diets.
- Arachidonate is the precursor of several classes of signal molecules — prostaglandins, prostacyclins, thromboxanes, and leukotrienes — that act as messengers and local hormones because of their transience and are called *eicosanoids* because they contain 20 carbon atoms.
- Aspirin (acetylsalicylate), an anti-inflammatory and antithrombotic drug, irreversibly blocks the synthesis of some of these eicosanoids.

22.7 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

- Fatty acid synthesis and degradation are reciprocally regulated so that both are not simultaneously active. Acetyl CoA carboxylase (ACC), the essential control site, is phosphorylated and inactivated by AMPK. The phosphorylation is reversed by a protein phosphatase.
- Citrate, which signals an abundance of building blocks and energy, partly reverses the inhibition by phosphorylation. Carboxylase activity is stimulated by insulin and inhibited by glucagon and epinephrine.

- In times of plenty, fatty acyl CoAs do not enter the mitochondrial matrix, because malonyl CoA inhibits carnitine acyltransferase I.

Key Terms

triacylglycerol (neutral fat, triglyceride)
lipase
chylomicron
acyl adenylate
carnitine
β-oxidation pathway
vitamin B_{12} (cobalamin)
peroxisomes
ketone bodies
fatty acid synthase
acyl carrier protein (ACP)
malonyl CoA
acetyl CoA carboxylase (ACC)
prostaglandin
eicosanoid
AMP-activated protein kinase (AMPK)

Problems

1. Write a balanced equation for the conversion of glycerol into pyruvate. Which enzymes are required in addition to those of the glycolytic pathway?

2. Place the following list of reactions or relevant locations in the β-oxidation of fatty acids in the proper order. 1

a. Reaction with carnitine
b. Fatty acid in the cytoplasm
c. Activation of fatty acid by joining to CoA
d. Hydration
e. NAD^+-linked oxidation
f. Thiolysis
g. Acyl CoA in mitochondrion
h. FAD-linked oxidation

3. We have encountered reactions similar to the oxidation, hydration, and oxidation reactions of fatty acid degradation earlier in our study of biochemistry. What other pathway employs this set of reactions? 1

4. Compare the ATP yields from palmitic acid and palmitoleic acid. 1

5. Stearic acid is a C_{18} fatty acid component of chocolate. Suppose you had a depressing day and decided to settle matters by gorging on chocolate. How much ATP would you derive from the complete oxidation of stearic acid to CO_2? 1

6. Write a balanced equation for the conversion of stearate into acetoacetate. 2

7. The β-oxidation pathway degrades activated fatty acids (acyl CoA) to acetyl CoA, which then enters the citric acid cycle. Additional enzymes are required to oxidize unsaturated, odd–chain, long–chain, and branched fatty acids. Which of the following statements is/are true?

a. Even–chain saturated fatty acids are oxidized to acetyl CoA in the β–oxidation pathway.
b. Complete catabolism of the three–carbon remnant of a 15–carbon fatty acid requires some citric acid cycle enzymes.
c. Enoyl–CoA isomerase, an enzyme that converts cis double bonds to trans double bonds in fatty acid metabolism, bypasses a step that reduces Q, resulting in a higher ATP yield.
d. The final round of β–oxidation for a 13–carbon saturated fatty acid yields acetyl CoA and propionyl–CoA, a three–carbon fragment.
e. A 14–carbon monounsaturated fatty acid with cis configuration yields more ATP than a 14–carbon saturated fatty acid.
f. Trans double bonds in unsaturated fatty acids are not well recognized by β–oxidation enzymes.

8. Which of the following statements regarding the body's inability to convert fat to carbohydrates is/are true?

a. The acetyl CoA that is produced from the oxidation of fatty acids enters the citric acid cycle but does not lead to a net gain of oxaloacetate.
b. The decarboxylation steps of the citric acid cycle prevent the net synthesis of glucose precursors from acetyl CoA in animal tissues.
c. Metabolism of odd-chain fatty acids yields propionyl CoA, which is converted to succinyl CoA and can enter the citric acid cycle.
d. Acetyl CoA that is produced from the oxidation of fatty acids and enters the citric acid cycle is used in the *de novo* synthesis of pyruvate.

e. Acetoacetate is a normal, major energy source for the brain, heart muscle, and renal cortex.

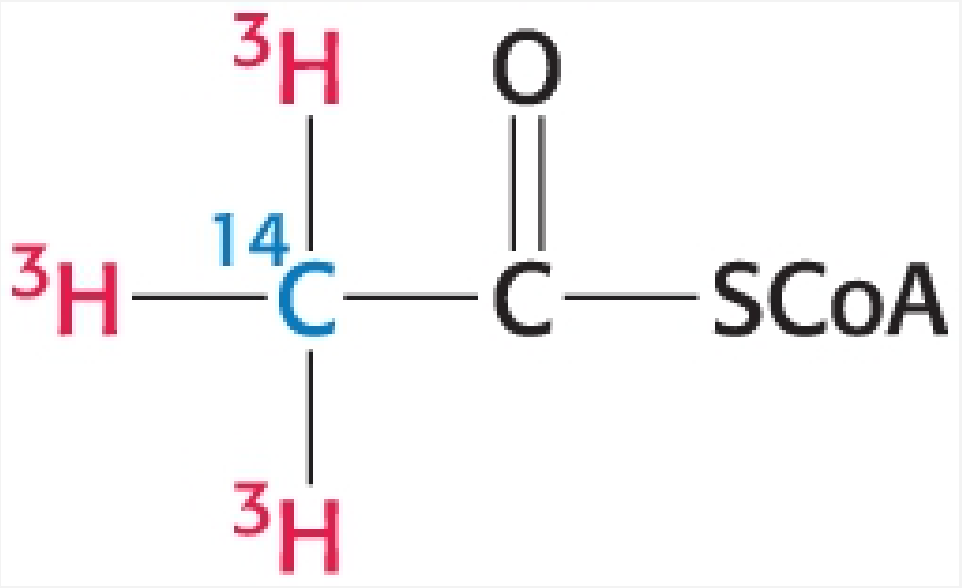
9. What is the committed step in fatty acid synthesis, and which enzyme catalyzes the step? 3

10. Compare and contrast fatty acid oxidation and synthesis with respect to

a. site of the process
b. acyl carrier
c. reductants and oxidants
d. stereochemistry of the intermediates
e. direction of synthesis or degradation
f. organization of the enzyme system

11. Lauric acid is a 12-carbon fatty acid with no double bonds. The sodium salt of lauric acid (sodium laurate) is a common detergent used in a variety of products, including laundry detergent, shampoo, and toothpaste. How many molecules of ATP and NADPH are required to synthesize lauric acid? 3

12. Arrange the following steps in fatty acid synthesis in their proper order. 3



a. Dehydration
b. Condensation
c. Release of a C_{16} fatty acid
d. Reduction of a carbonyl group
e. Formation of malonyl ACP

13. True or False? If false, explain. 3

a. Biotin is required for fatty acid synthase activity.
b. The condensation reaction in fatty acid synthesis is powered by the decarboxylation of malonyl CoA.

c. Fatty acid synthesis does not depend on ATP.
d. Palmitate is the end product of fatty acid synthase.
e. All of the enzyme activities required for fatty acid synthesis in mammals are contained in a single polypeptide chain.
f. Fatty acid synthase in mammals is active as a monomer.
g. The fatty acid arachidonate is a precursor for signal molecules.
h. Acetyl CoA carboxylase is inhibited by citrate.

14. Suppose that you had an in vitro fatty acid–synthesizing system with all of the enzymes and cofactors required for fatty acid synthesis except for acetyl CoA. To this system, you added acetyl CoA that contained radioactive hydrogen $(^3H, \text{tritium})$ and carbon $14(^{14}C)$, as shown here.

The ratio of $^{3}H/^{14}C$ is 3. What would the $^{3}H/^{14}C$ ratio be after the synthesis of palmitic acid (C_{16}) with the use of the radioactive acetyl CoA? 3

15. The serine residues in acetyl CoA carboxylase that are the target of the AMP-activated protein kinase are mutated to alanine. What is a likely consequence of this mutation? 4

16. For each of the following unsaturated fatty acids, indicate whether the biosynthetic precursor in animals is palmitoleate, oleate, linoleate, or linolenate.

a. 18:1 $cis-\Delta^{11}$

b. 18:3 $cis-\Delta^{6}, \Delta^{9}, \Delta^{12}$

c. 20:2 $cis-\Delta^{11},\Delta^{14}$

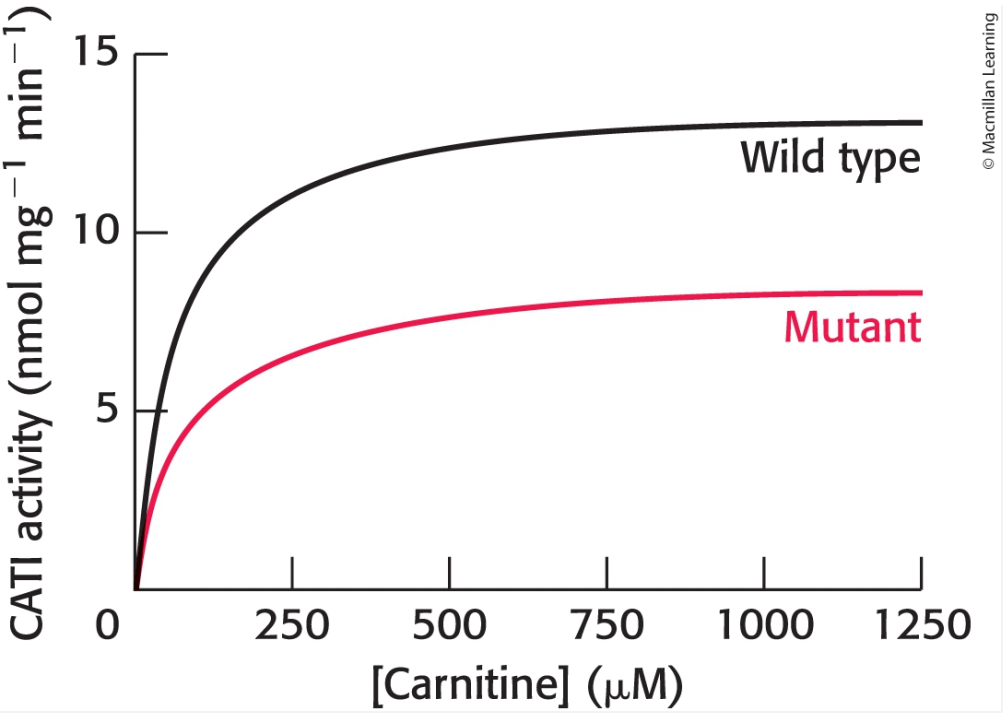
d. 20:3 $cis-\Delta^{5},\Delta^{8},\Delta^{11}$

e. 22:1 $cis-\Delta^{13}$

f. 22:6 $cis-\Delta^{4}, \Delta^{7}, \Delta^{10}, \Delta^{13}, \Delta^{16}, \Delta^{19}$

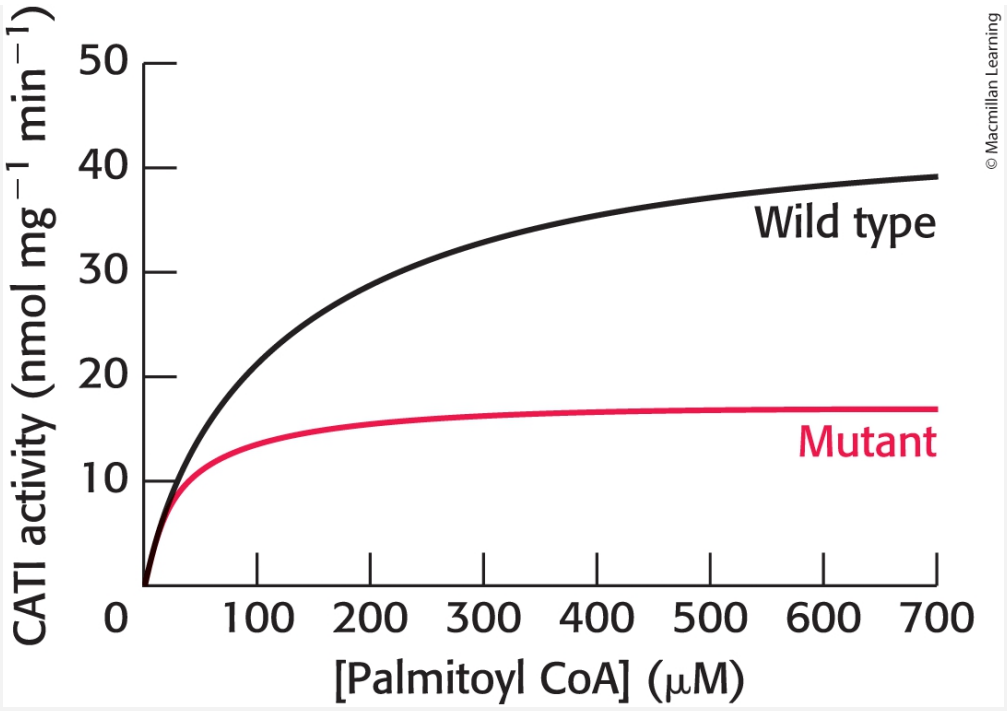
17. Figure 22.35 shows the response of acetyl CoA carboxylase to varying amounts of citrate. Explain this effect in light of the allosteric effects that citrate has on the enzyme. Predict the effects of increasing concentrations of palmitoyl CoA. 4

18. Classify each event involved in the regulation of fatty acid metabolism as an outcome of hormonal regulation by insulin or by glucagon and epinephrine:



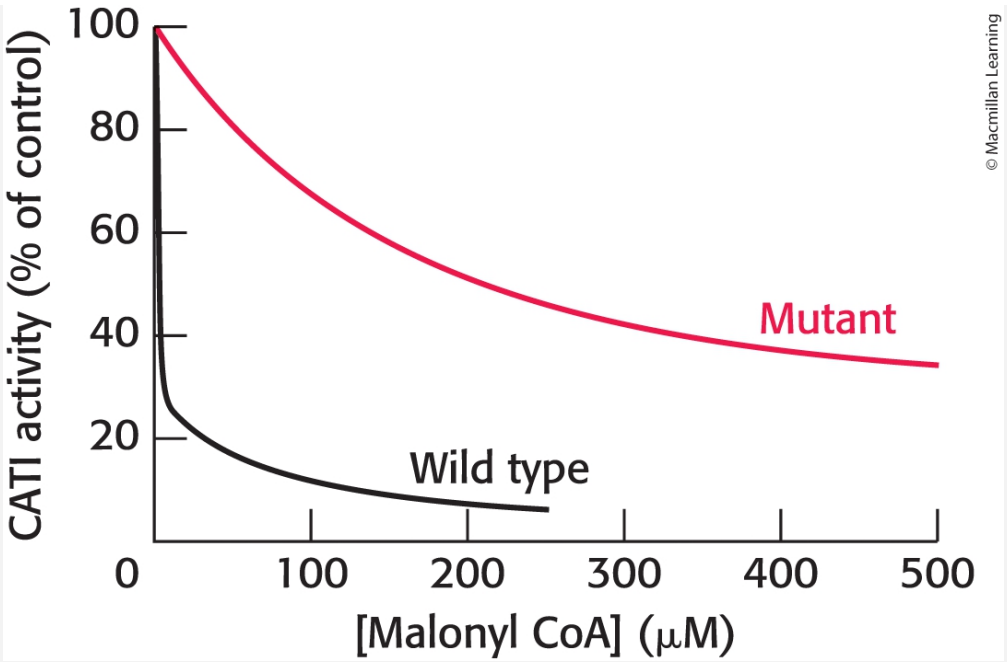
a. Stimulates fatty acid synthesis
b. Activates acetyl CoA carboxylase
c. Inhibits fatty acid synthesis

d. Inhibits acetyl CoA carboxylase
e. Stimulates protein phosphatase activity
f. Increases activity of AMPK



19. What are the three reactions that allow the conversion of cytoplasmic NADH into NADPH? What enzymes are required? Show the sum of the three reactions. 3

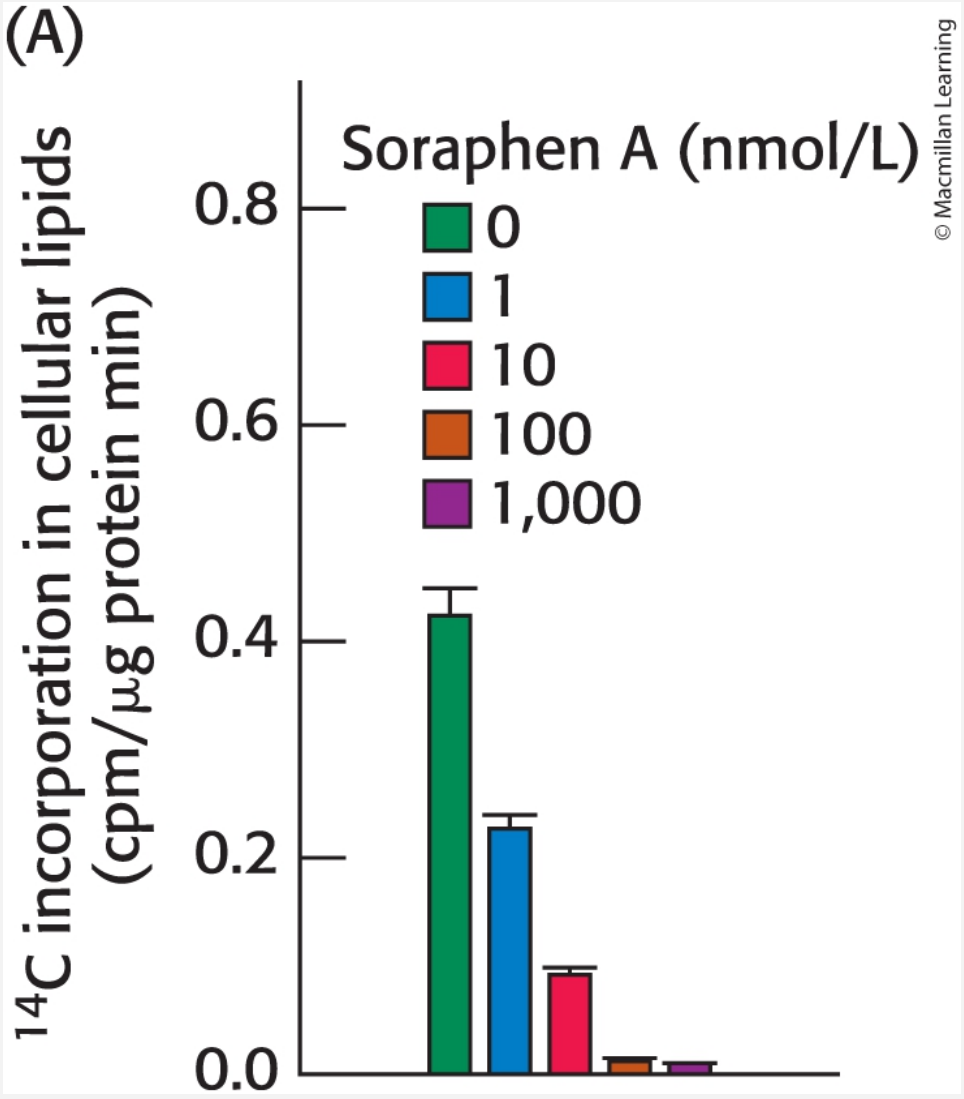
20. Carnitine acyltransferase I (CATI) catalyzes the conversion of long-chain acyl CoA into acyl carnitine, a prerequisite for transport into mitochondria and subsequent degradation. A mutant enzyme was constructed with a single amino acid change at position 3 of glutamic acid for alanine. Graphs A through C show data from studies that were performed to identify the effect of the mutation. 1

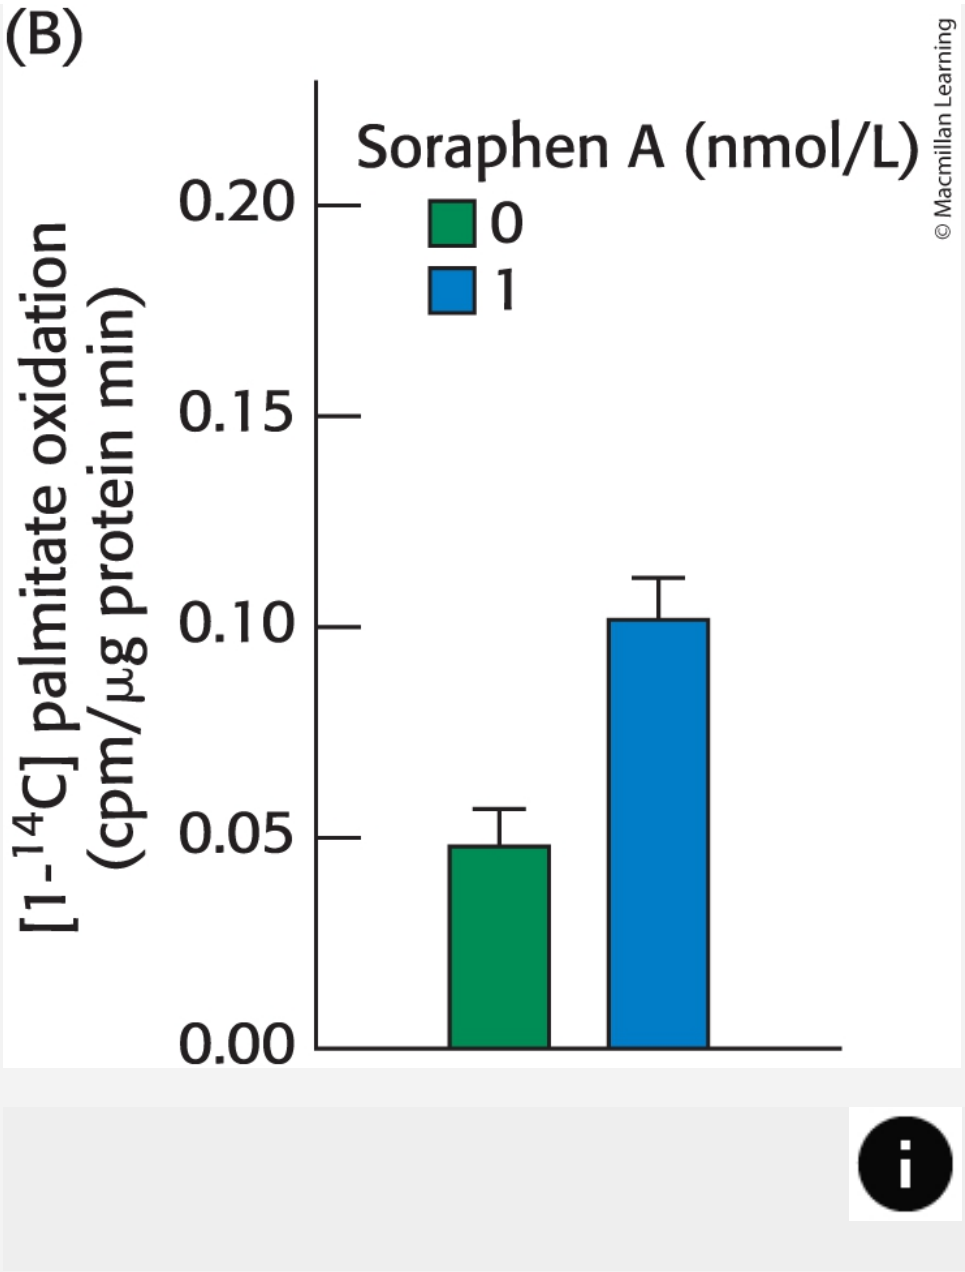


a. What is the effect of the mutation on enzyme activity when the concentration of carnitine is varied? (Results are shown below.) What are the K_M and V_{max} values for the wild-type and mutant enzymes?

b. What is the effect when the experiment is repeated with varying concentrations of palmitoyl CoA? What are the K_M and V_{max} values for the wild-type and mutant enzymes?

c. The next graph shows the inhibitory effect of malonyl CoA on the wild-type and mutant enzymes. Which enzyme is more sensitive to malonyl CoA inhibition?



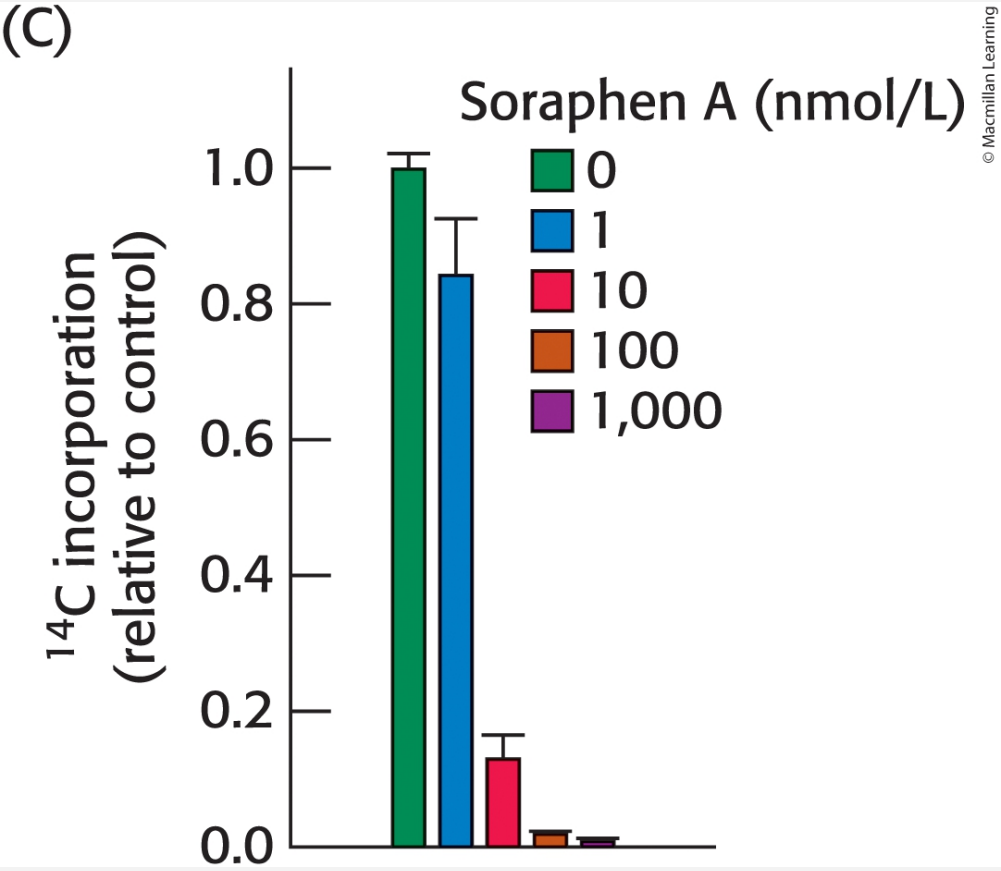


d. Suppose that the concentration of palmitoyl CoA = 100 μM, that of carnitine = 100 μM, and that of malonyl CoA = 10 μM. Under these conditions, what is the most prominent effect of the mutation on the properties of the enzyme?
e. What can you conclude about the role of glutamate 3 in CATI function?

21. Soraphen A is a natural antifungal agent isolated from a myxobacterium. Soraphen A is also a potent inhibitor of acetyl CoA carboxylase, the regulatory enzyme that initiates fatty acid synthesis. As discussed in Section 22.5, cancer cells must produce a large amount of fatty acids to generate phospholipids for membrane synthesis. Thus, acetyl CoA carboxylase might be a target for anticancer drugs. Below are

the results of experiments testing this hypothesis on a cancer line. 4

Figure A shows the effect of various amounts of soraphen A on fatty acid synthesis as measured by the incorporation of radioactive acetate (^{14}C) into fatty acids.

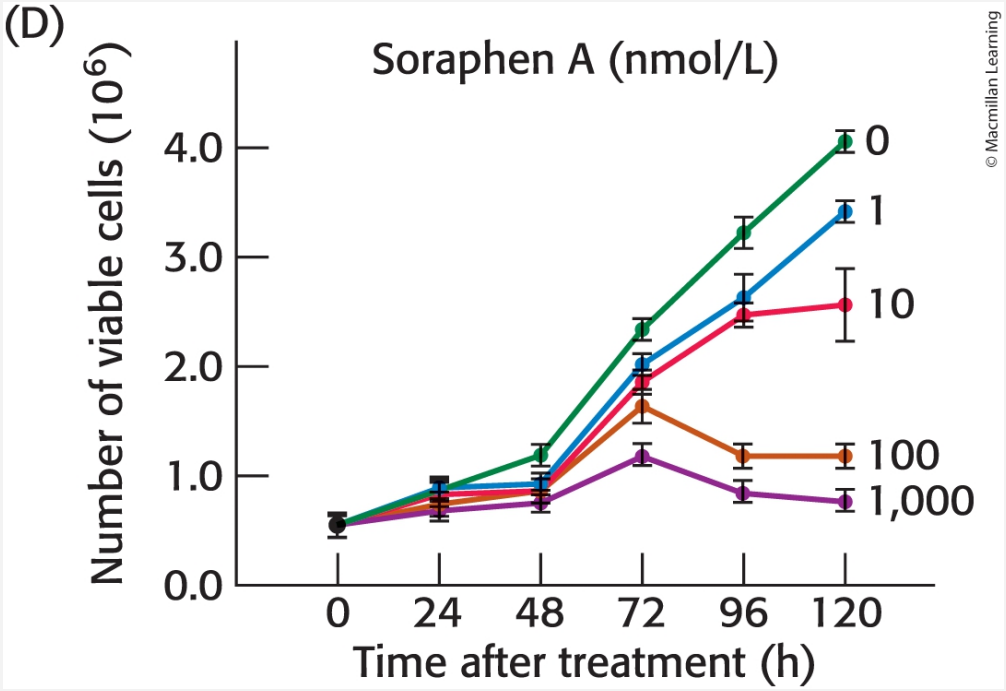


a. How did soraphen A alter fatty acid synthesis? How was synthesis affected by increasing concentrations of soraphen A?

Figure B shows the results obtained when fatty acid oxidation was measured, as the release of radioactive

CO_2 from added radioactive (^{14}C) palmitate, in the presence of soraphen A.

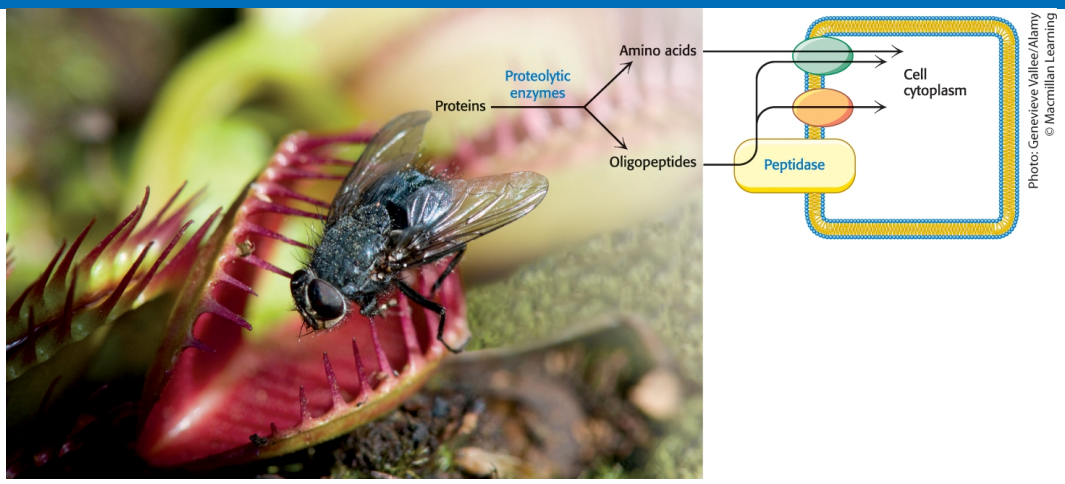
b. How did soraphen A alter fatty acid oxidation?
c. Explain the results obtained in B in light of the fact that soraphen A inhibits acetyl CoA carboxylase.



More experiments were undertaken to assess whether carboxylase inhibition did indeed prevent phospholipid synthesis. Again, cells were grown in the presence of radioactive acetate, phospholipids were subsequently isolated, and the amount of ^{14}C incorporated into the phospholipid was determined. The effect of soraphen A on phospholipid synthesis is shown in Figure C.

d. Did the inhibition of carboxylase by the drug alter phospholipid synthesis?
e. How might phospholipid synthesis affect cell viability?

Finally, as shown in Figure D, experiments were performed to determine if the drug inhibits cancer growth in vitro by determining the number of cancer cells surviving upon exposure to soraphen A.



f. How did soraphen A affect cancer cell viability?

[Data from: Beckers, A., Organe, S., Timmermans, L., Scheys, K., Peeters, A., Brusselmans, K., Verhoeven, G., and Swinnen, J. V., Chemical inhibition of acetyl-CoA carboxylase induces growth arrest and cytotoxicity selectively in cancer cells, *Cancer Res.* 67:8180–8187, 2007.]

Chapter 23
Protein Turnover and Amino Acid Catabolism

Nitrogen is a critical component of countless biomolecules. Some plants have adapted to live in nitrogen-depleted soil by capturing and digesting insects. The biochemical mechanisms used by such plants to degrade proteins into amino acids mirror those used by animals and highlight the important role of nitrogen in biochemical biosynthesis.

Outline

23.1 Proteins Are Degraded to Amino Acids
23.2 Protein Turnover Is Tightly Regulated

23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

Learning Goals

By the end of this chapter, you should be able to:

1. Explain the importance of the regulation of protein turnover.
2. Identify the primary role of ubiquitin and describe the enzymes required for ubiquitination.
3. Explain the function of the proteasome.
4. Describe the fate of nitrogen that is removed when amino acids are used as fuels.
5. Explain how the carbon skeletons of the amino acids are metabolized after nitrogen removal.
6. Identify metabolic errors in amino acid degradation.

Our study of metabolism has, up to this point, focused on carbohydrates and lipids that contain only carbon, oxygen, and hydrogen. We now turn to the subject of nitrogen metabolism, focusing first on catabolic pathways involving proteins and amino acids. In animals, the digestion of dietary proteins in the intestine and the degradation of proteins within the cell provide a steady supply of amino acids for the biosynthesis of new proteins and nucleotide bases. Cellular proteins are also constantly degraded in response to changing metabolic demands or due to misfolding or damage. Excess amino acids can neither be stored nor excreted; instead, they must be used as metabolic fuel. In this chapter we will

also consider several genetic errors of amino acid degradation. The study of amino acid metabolism is especially rewarding because it is rich in connections between basic biochemistry and clinical medicine.

23.1 Proteins Are Degraded to Amino Acids

Dietary protein is a vital source of amino acids. Especially important dietary proteins are those containing the essential amino acids — amino acids that cannot be synthesized and must be acquired in the diet (Table 23.1). Proteins ingested in the diet are digested into amino acids or small peptides that can be absorbed by the intestine and transported in the blood. Another crucial source of amino acids is the degradation of cellular proteins.

TABLE 23.1 Essential amino acids in human beings

Histidine	Phenylalanine
Isoleucine	Threonine
Leucine	Tryptophan
Lysine	Valine
Methionine	

The digestion of dietary proteins begins in the stomach and is completed in the intestine

Protein digestion begins in the stomach, where the acidic environment denatures proteins into random coils. Denatured proteins are more accessible as substrates for proteolysis than are native proteins. The primary proteolytic enzyme of the stomach is pepsin, a nonspecific protease that, remarkably, is maximally active at pH 2. Thus, pepsin can function in the highly acidic environment of the stomach that disables other proteins.

The partly digested proteins then move from the acidic environment of the stomach to the beginning of the small intestine, called the *duodenum*. The low pH of the food as well as the polypeptide products of pepsin digestion stimulate the release of hormones that promote the secretion from the pancreas of sodium bicarbonate ($NaHCO_3$), which neutralizes the pH of the food, and a variety of pancreatic proteolytic enzymes. Recall that these enzymes are secreted as inactive zymogens that are then converted into active enzymes (Sections 6.1 and 7.4). The battery of enzymes displays a wide array of specificity, and so the substrates are degraded into free amino acids as well as di- and tripeptides (**Figure 23.1**). Digestion is further enhanced by proteolytic enzymes, such as aminopeptidase N, that are located in the plasma membrane of the intestinal cells. Aminopeptidases digest proteins from the amino-terminal end, and the resulting free amino acids — as well as di- and tripeptides — are transported into the intestinal cells.

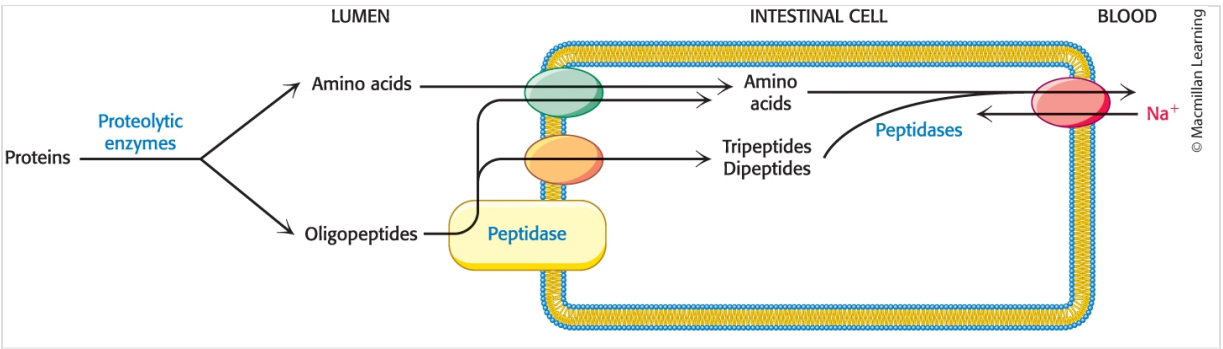

FIGURE 23.1 The products of protein digestion are absorbed by the small intestine. Protein digestion is primarily a result of the activity of enzymes secreted by the pancreas. Aminopeptidases associated with the intestinal epithelium further digest proteins. The amino acids and di- and tripeptides are absorbed into the intestinal cells by specific transporters (green and orange ovals). Free amino acids are then released into the blood by transporters (red oval) for use by other tissues.

At least seven different transporters exist, each specific to a different group of amino acids. A number of inherited disorders result from mutations in these transporters. For example, Hartnup disease, a rare disorder characterized by rashes, ataxia (lack of muscle control), delayed mental development, and diarrhea, results from a defect in the transporter for tryptophan and other nonpolar amino acids. The absorbed amino acids are subsequently released into the blood by a number of Na^+–amino acid antiporters for use by other tissues (Figure 23.1).

Cellular proteins are degraded at different rates

Protein turnover — the degradation and resynthesis of proteins — takes place constantly in cells. Although some proteins are very

stable, many proteins are short lived, particularly those that participate in metabolic regulation. These proteins can be quickly degraded to activate or shut down a signaling pathway. In addition, cells must eliminate damaged proteins. A significant proportion of newly synthesized protein molecules are defective because of errors in translation or misfolding. Even proteins that are normal when first synthesized may undergo oxidative damage or be altered in other ways with the passage of time. These proteins must be removed before they accumulate and aggregate. Indeed, a number of pathological conditions, such as certain forms of Parkinson's disease and Huntington's disease, are associated with protein aggregation.

The half-lives of proteins range over several orders of magnitude. Ornithine decarboxylase, at approximately 11 minutes, has one of the shortest half-lives of any mammalian protein. This enzyme participates in the synthesis of polyamines, which are cellular cations essential for growth and differentiation. The life of hemoglobin, however, is limited only by the life of the red blood cell, and the lens protein crystallin is limited by the life of the organism.

Self-Check Question

Where are dietary amino acids absorbed, and what is the primary fate of both dietary and cellular derived amino acids?

23.2 Protein Turnover Is Tightly Regulated

How can a cell distinguish proteins that should be degraded? **Ubiquitin**, a small, 76-amino-acid protein, is so named because it is ubiquitously present in all eukaryotic cells. Ubiquitin serves many functional roles, but its primary role is to serve as a tag that marks proteins for destruction (**Figure 23.2**). Ubiquitin, in this role then, is the cellular equivalent of the "black spot" of Robert Louis Stevenson's *Treasure Island* — the signal for death.

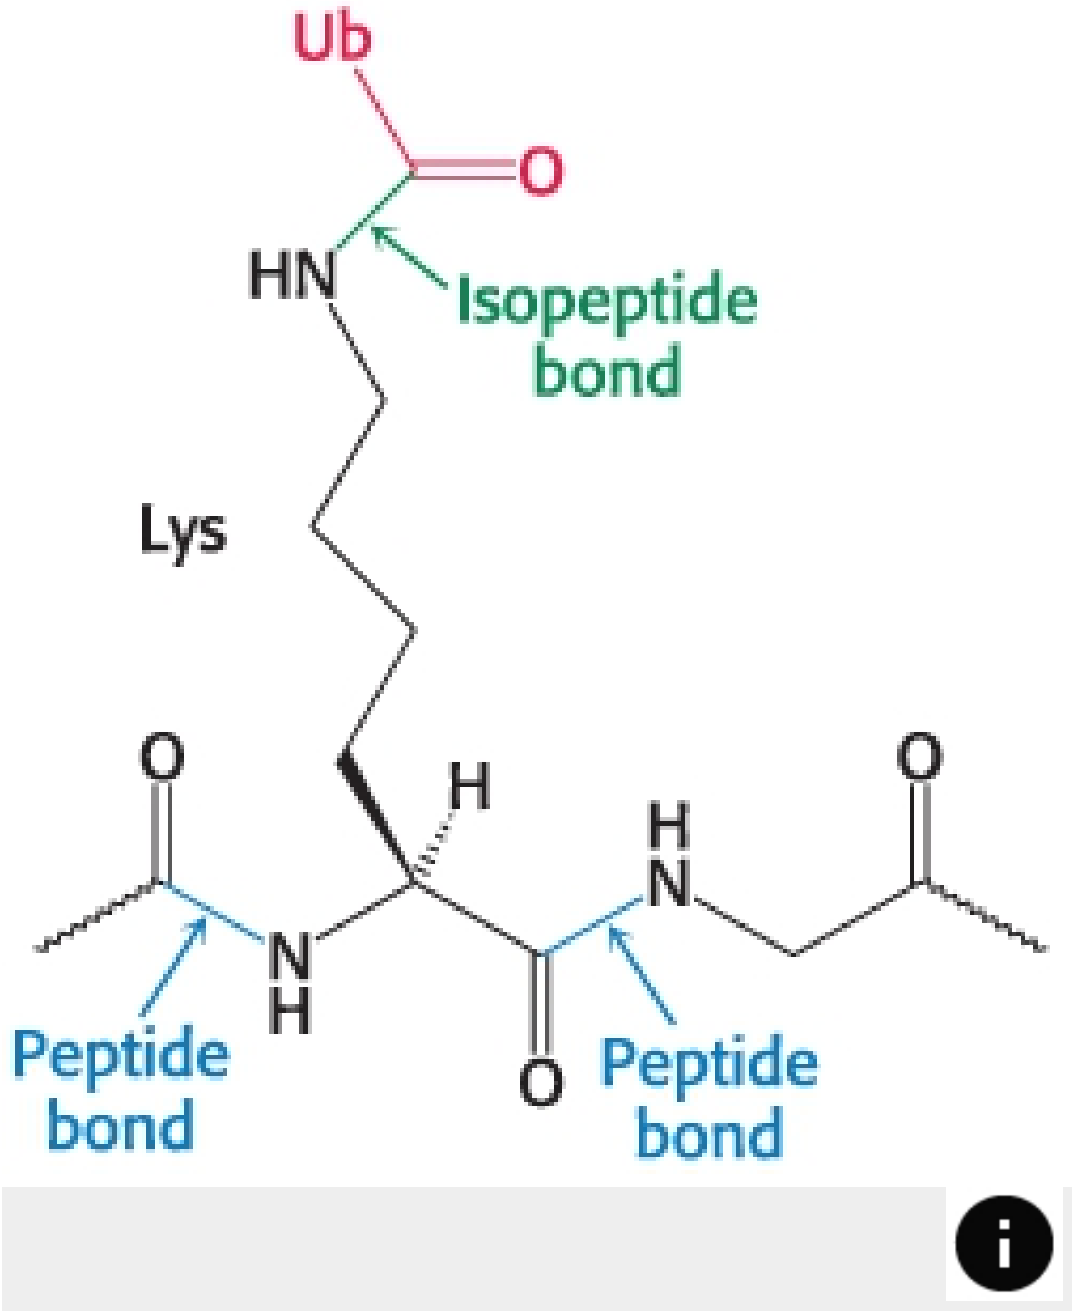

FIGURE 23.2 Ubiquitin is a small, compact protein with seven lysines. Notice that ubiquitin has an extended carboxyl terminus, which is activated and linked to proteins targeted for destruction. Lysine residues, including lysine 48, the major site for linking additional ubiquitin molecules, are shown as ball-and-stick models.

INTERACT with this model in Achieve

Ubiquitin tags proteins for destruction

Ubiquitin is highly conserved in eukaryotes: yeast and human ubiquitin differ at only 3 of 76 residues. A protein destined to be degraded will be covalently modified by the attachment of ubiquitin — by its carboxyl-terminal glycine residue — to the ε-amino groups of one or more lysine residues on the target protein. The energy for the formation of these *iso*peptide bonds (*iso* because ε- rather than α-amino groups are targeted) comes from ATP hydrolysis.

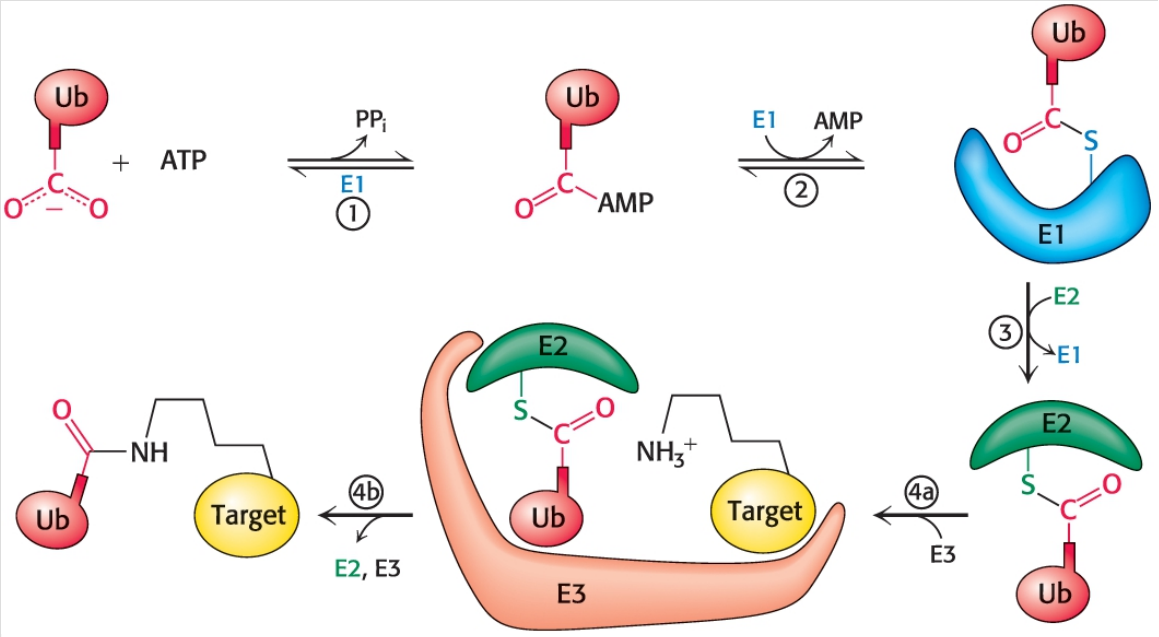
Three enzymes participate in the attachment of ubiquitin to a protein (**Figure 23.3**):

- *Ubiquitin-activating enzyme* (E1). First, the C-terminal carboxylate group of ubiquitin becomes linked to a sulfhydryl group of E1 by a thioester bond. This ATP-driven reaction is reminiscent of fatty acid activation (Section 22.2). In this reaction, an acyl adenylate is

formed at the C-terminal carboxylate of ubiquitin with the release of pyrophosphate, and the ubiquitin is subsequently transferred to a sulfhydryl group of a key cysteine residue in E1.

- *Ubiquitin-conjugating enzyme* (E2). The activated ubiquitin is then shuttled to a sulfhydryl group of E2, a reaction catalyzed by E2 itself.

- *Ubiquitin–protein ligase* (E3). Finally, E3 catalyzes the transfer of ubiquitin from E2 to an ε-amino group on the target protein. E3 does this by bringing E2 and the target protein together. In some cases, the ubiquitin is passed to a cysteine residue of E3 first, whereas in other cases it is transferred directly from the E2 to the target protein.



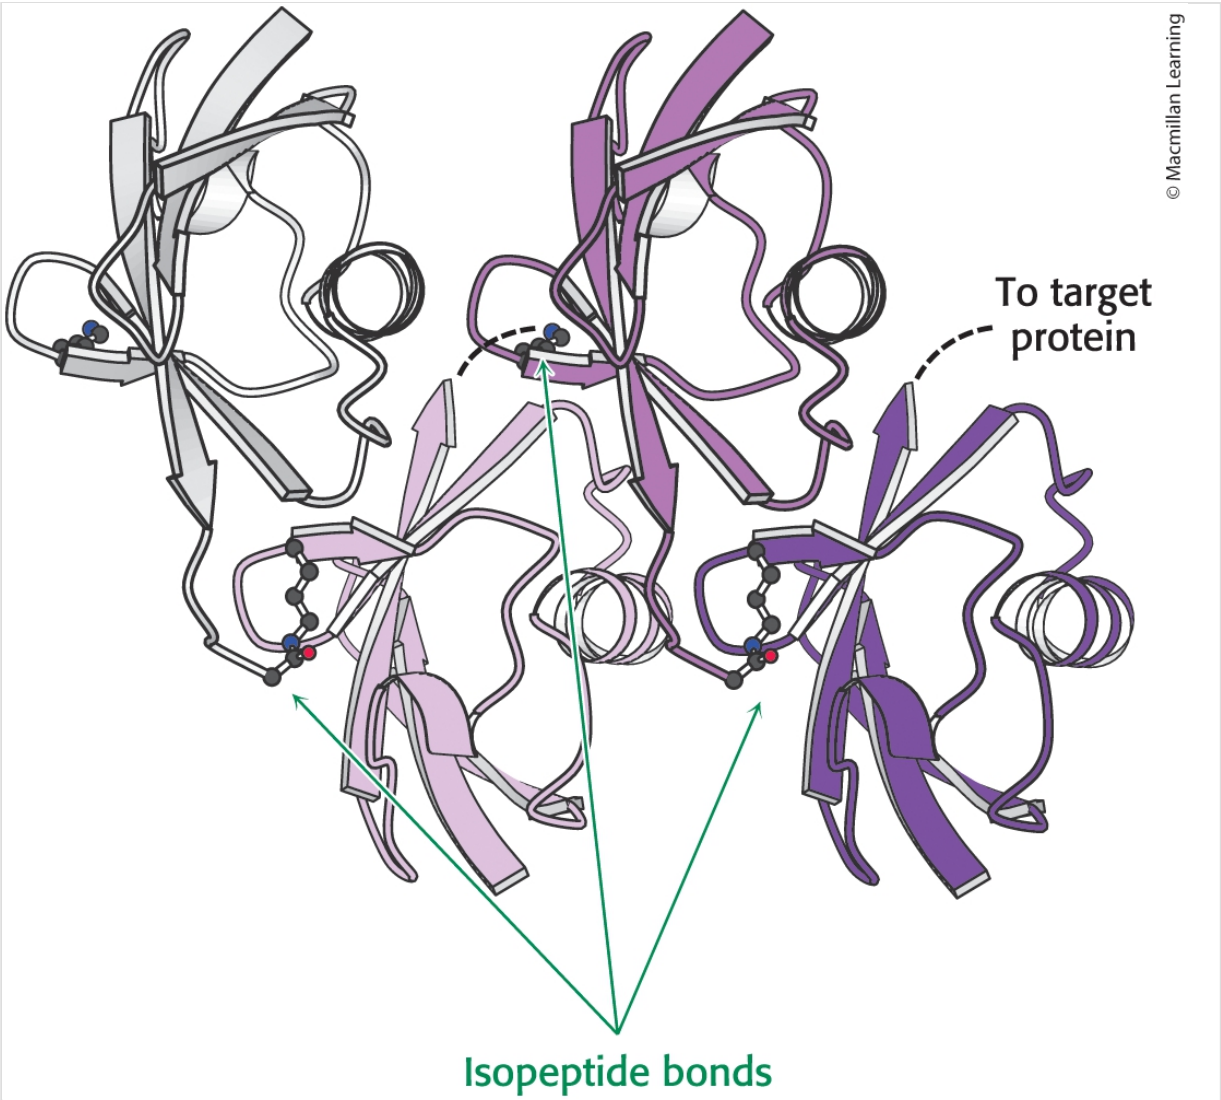


FIGURE 23.3 Ubiquitin conjugation requires three enzymes. The ubiquitin-activating enzyme E adenylates ubiquitin (Ub) (1) and transfers the ubiquitin to one of its own cysteine residues (2). Ubiquitin is then transferred to a cysteine residue in the ubiquitin-conjugating enzyme E2 by th E2 enzyme (3). Finally, the ubiquitin–protein ligase E3 transfers the ubiquitin to a lysine residue on the target protein (4a and 4b).

The ubiquitination reaction can be processive: E3 can remain bound to the target protein and generate a chain of ubiquitin molecules by linking the ε-amino group of a lysine residue of one ubiquitin molecule to the terminal carboxylate of another. Alternatively, in some cases E3 will dissociate after the first ubiquitin addition, and a chain can be extended by another E2/E3 pair. Importantly, ubiquitin can be added onto any of the seven lysines or the N-terminus of the previous ubiquitin, forming chains with different linkages, lengths, and degrees of branching. Some of the linkages signal for proteasomal degradation, while others do not; although the outcome may be context-dependent in different cells. For example, a chain of four or more ubiquitin molecules linked via lysine 48 of ubiquitin has long been known to be an especially effective signal for protein degradation (**Figure 23.4**).

© Macmillan Learning

FIGURE 23.4 In a tetraubiquitin chain, four ubiquitin molecules are linked by isopeptide bonds. Notice that each isopeptide bond is formed by the linkage of the carboxylate group at the end of the extended C terminus with the ε-amino group of a lysine residue, in this case lysine 48. Dashed lines indicate the positions of the extended C-termini that were not observed in the crystal structure. This unit is the primary signal for degradation when linked to a target protein.

[Drawn from 1TBE.pdb.]

INTERACT with this model in Achieve

What determines whether a protein becomes ubiquitinated? A specific sequence of amino acids, termed a **degron**, indicates that a protein should be degraded. One such signal appears to be quite simple: the half-life of a cytoplasmic protein is determined to a large extent by its amino-terminal residue (Table 23.2). This dependency is referred to as the *N-end rule* or the *N-degron*. A yeast protein with methionine at its N terminus typically has a half-life of more than 20 hours, whereas one with arginine at this position has a half-life of about 2 minutes. A highly destabilizing N-terminal residue such as arginine or leucine favors rapid ubiquitination, whereas a stabilizing residue such as methionine or proline does not.

TABLE 23.2 Dependence of the half-lives of cytoplasmic yeast proteins on the identity of their amino-terminal residues

Highly stabilizing residues ($t_{1/2} > 20$ hours)			
Ala	Cys	Gly	Met
Pro	Ser	Thr	Val
Intrinsically destabilizing residues ($t_{1/2} = 2$ to 30 minutes)			
Arg	His	Ile	Leu
Lys	Phe	Trp	Tyr
Destabilizing residues after chemical modification ($t_{1/2} = 3$ to 30 minutes)			
Asn	Asp	Gln	Glu

Data from J. W. Tobias, T. E. Schrader, G. Rocap, and A. Varshavsky, *Science* 254(5036):1374–1377, 1991.

Why is the N-end rule only *apparently* simple? Sometimes the N-degron is exposed only after the protein is proteolytically cleaved. Such degrons are called *pre-N-degrons* or *pro-N-degrons*, in analogy to proenzymes (Section 7.4), because the protein must be cleaved to expose the signal. In other cases, the destabilizing amino acid is added to the protein after the protein is synthesized. Other modifications, notably N-terminal acetylation, can also activate a degron. Additional degrons thought to identify proteins for degradation include cyclin destruction boxes, which are amino acid sequences that mark cell-cycle proteins for destruction, and PEST sequences, which are rich in the amino acids proline (P, single-letter abbreviation), glutamic acid (E), serine (S), and threonine (T).

E3 enzymes are the readers of N-terminal residues. Although most eukaryotes have only one or a small number of distinct E1 enzymes, all eukaryotes have many distinct E2 enzymes and even more E3 enzymes. For example, in baker's yeast there is only one E1 but 10-12 E2 enzymes and 60-100 E3 enzymes. Indeed, the E3 family is one of the largest gene families in human beings, with over 600 predicted E3 ligases in the human genome. The diversity of target proteins that must be tagged for destruction requires a large number of E3 proteins as readers.

Three examples demonstrate the importance of E3 proteins to normal cell function. First, proteins that are not degraded because of a defective E3 may accumulate, causing a disease of protein aggregation such as juvenile or early-onset Parkinson's disease. Second, a defect in another member of the E3 family causes Angelman syndrome, a severe neurological disorder characterized by an unusually happy disposition, cognitive disability, absence of speech, uncoordinated movement, and hyperactivity. Fascinatingly, if the same ligase is overexpressed, the result is autism. Third, inappropriate protein turnover also can lead to cancer. For example, human papillomavirus (HPV) encodes a protein

that activates a specific E3 enzyme. The enzyme ubiquitinates the tumor suppressor p53 and other proteins that control DNA repair, which are then destroyed. The activation of this E3 enzyme is observed in more than 90% of cervical carcinomas. Thus, the inappropriate marking of key regulatory proteins for destruction can trigger further events, leading to tumor formation.

As noted above, the role of ubiquitin is much broader than merely marking proteins for destruction. Ubiquitination also regulates proteins involved in DNA repair, chromatin remodeling, innate immunity, membrane trafficking, and autophagy, among other biochemical processes.

The proteasome digests the ubiquitin-tagged proteins

If ubiquitin is the mark of death, what is the executioner? A large protease complex called the **proteasome** (more precisely, the *26S proteasome*) digests the ubiquitinated proteins. This ATP-driven multisubunit protease spares ubiquitin, which is then recycled. The 26S proteasome is a complex of two components: a 20S catalytic unit and a 19S regulatory unit.

The 20S unit is composed of 28 subunits, encoded by 14 genes, arranged into 4 heteroheptameric rings stacked to form a structure resembling a barrel (**Figure 23.5**). The outer two rings of the barrel are made up of α-type subunits and the inner two rings of β-type subunits. The 20S catalytic core is a sealed barrel. Access to its interior is controlled by a 19S regulatory unit, itself a 700-kDa complex made up of 19 subunits. Two such 19S complexes bind to the 20S proteasome core, one at each end, to form the complete 26S proteasome (**Figure 23.6**).

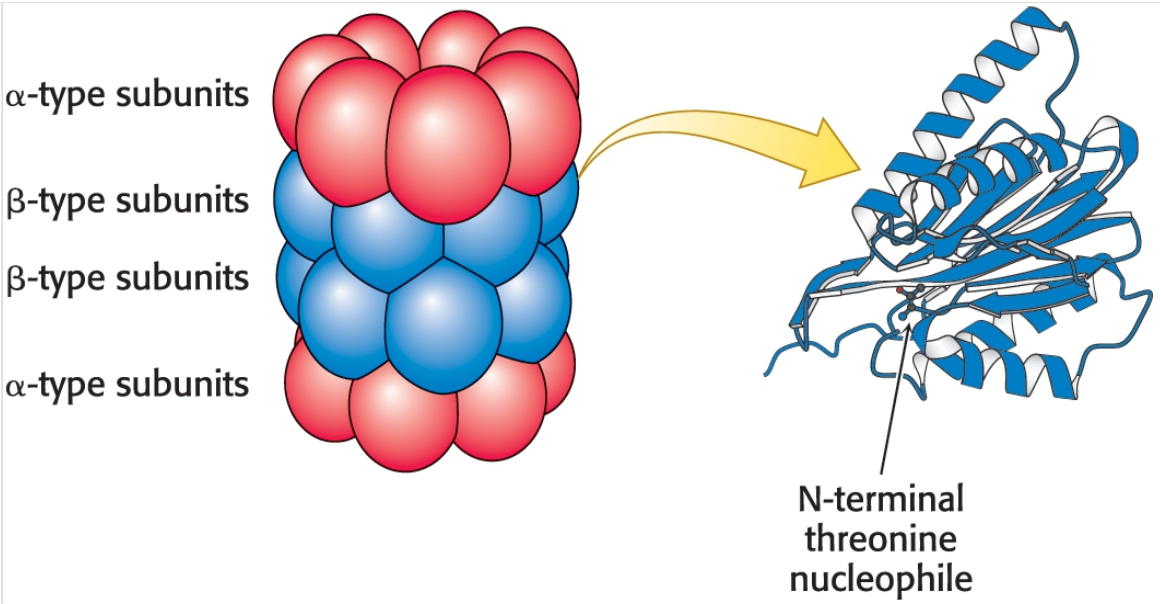

FIGURE 23.5 The 20S proteasome is barrel-shaped and made up of 28 homologous subunits. The subunits (α-type, red; β-type, blue) are arranged in four rings of 7 subunits each. Some of th β-type subunits (right) include protease active sites at their amino termini.

[Subunit drawn from 1RYP.pdb.]

INTERACT with this model in Achieve

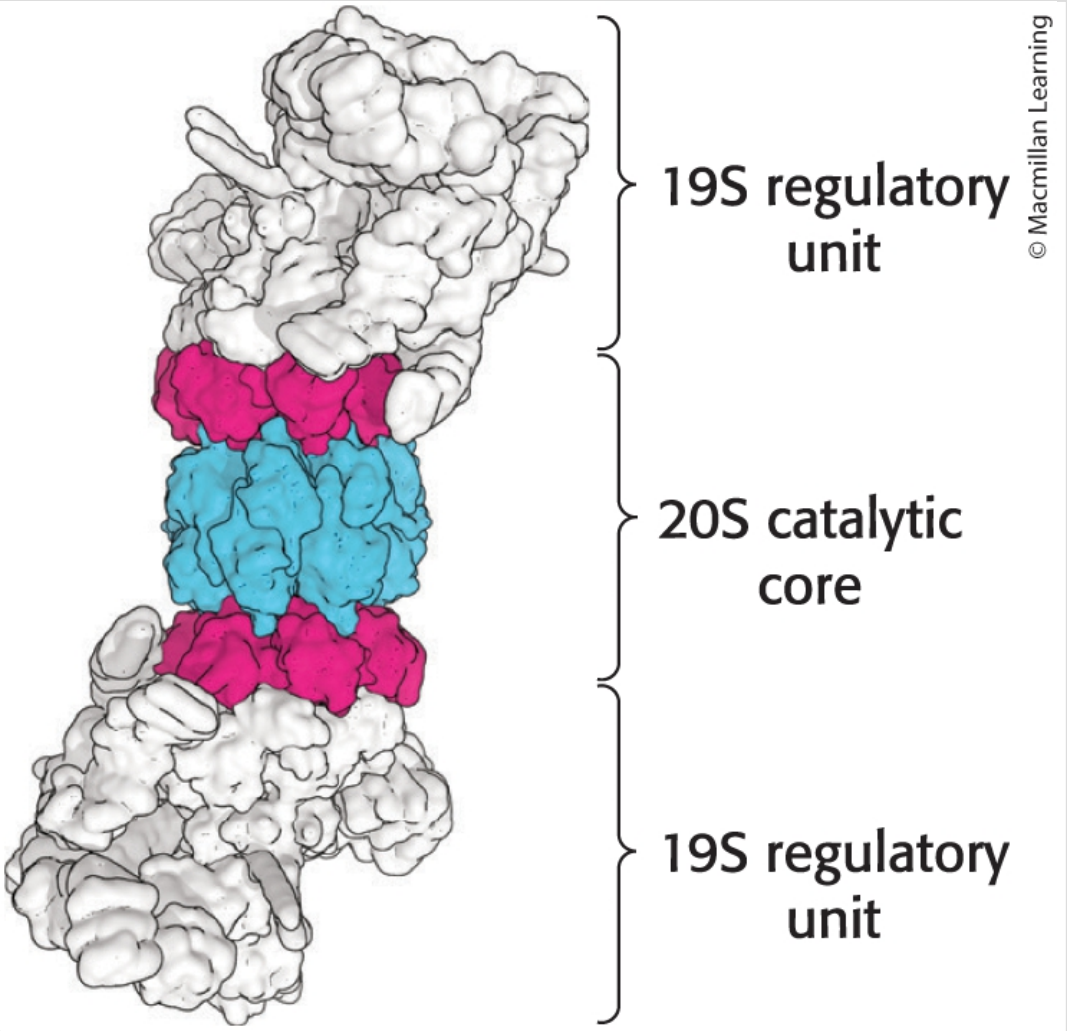

FIGURE 23.6 The 26S proteasome consists of one 20S and two 19S subunits. The 19S are regulatory and each attached at either end of the 20S catalytic unit.

The 19S regulatory unit has three functions. First, components of the 19S unit are ubiquitin receptors that bind specifically to polyubiquitin chains, thereby ensuring that only ubiquitinated proteins are degraded. Second, the doomed protein is unfolded and directed into the catalytic core. Finally, an isopeptidase in the 19S unit cleaves off intact ubiquitin molecules from the proteins so that they can be reused. Key components of the 19S complex are six ATPases of a type called the

AAA + class (ATPases associated with various cellular activities). ATP hydrolysis assists the 19S complex to unfold the substrate and induce conformational changes in the 20S catalytic core (called *gate opening*) so that the substrate can be passed into the center of the complex. Alternative ways to enter the 20S barrel have also been discovered. In some cases, partially unfolded proteins can themselves induce gate opening without the 19S, and there are alternative proteasome caps that also allow the degradation of unstructured proteins.

The proteolytic active sites are sequestered in the interior of the 20S barrel to protect potential substrates until they are directed into the barrel. There are three types of active sites in the β subunits, each with a different specificity, but all employ an N-terminal threonine. The hydroxyl group of the threonine residue is converted into a nucleophile that attacks the carbonyl groups of peptide bonds to form acyl-enzyme intermediates. Substrates are degraded in a processive manner without the release of degradation intermediates, until the substrate is digested to peptides ranging in length from seven to nine residues. These peptide products are released from the proteasome and further degraded by other cellular proteases to yield individual amino acids. Thus, the ubiquitination pathway and the proteasome cooperate to degrade unwanted proteins. **Figure 23.7** presents an overview of the fates of amino acids following proteasomal digestion. A separate process called *autophagy* serves as a second mechanism for protein turnover, although the details of that system are beyond the scope of this chapter.

FIGURE 23.7 The proteasome and other proteases generate free amino acids. Ubiquitinated proteins are processed to peptide fragments. Ubiquitin is removed and recycled prior to protein degradation. The peptide fragments are further digested to yield free amino acids, which can be used for biosynthetic reactions, most notably protein synthesis. Alternatively, the amino group can be removed and processed to urea (Figure 23.15) and the carbon skeleton can be used to synthesize carbohydrate or fats or used directly as a fuel for cellular respiration (Section 23.5).

The ubiquitin pathway and the proteasome have prokaryotic counterparts

Both the ubiquitin pathway and the proteasome appear to be present in all eukaryotes. Homologs of the proteasome are also found in some prokaryotes. The proteasomes of some archaea are quite similar in overall structure to their eukaryotic counterparts and similarly have 28 subunits (**Figure 23.8**). In the archaeal proteasome, however, all α outer-ring subunits and all β inner-ring subunits are identical; in eukaryotes, each α or β subunit is one of seven different isoforms. This specialization provides distinct substrate specificity.

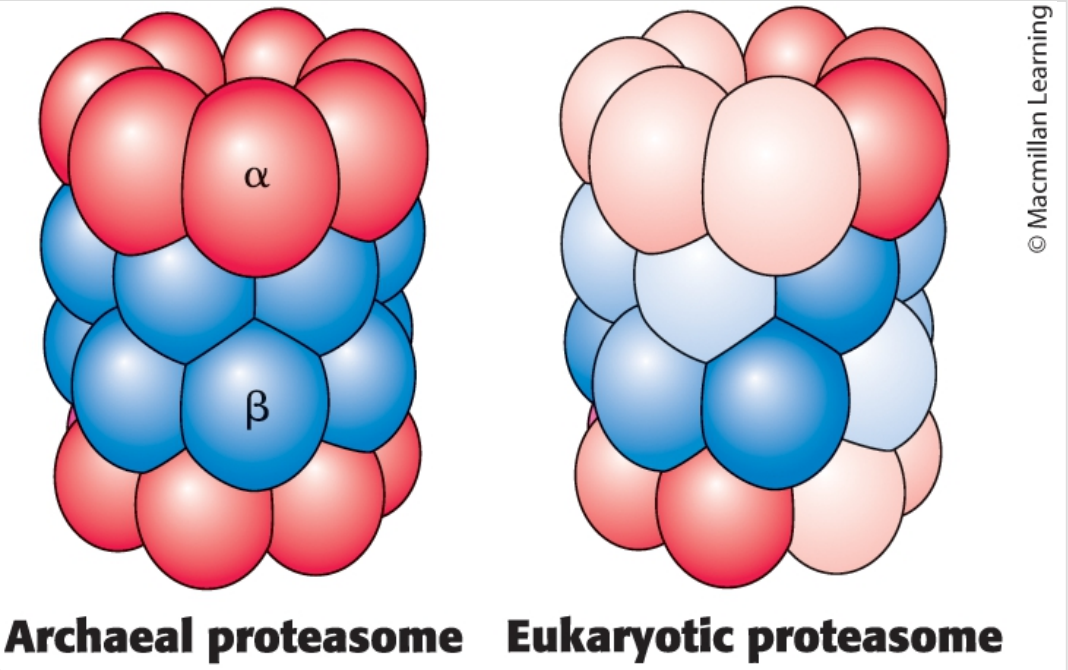

FIGURE 23.8 Proteasomes have become more complex in eukaryotes. The archaeal proteasome consists of 14 identical α subunits and 14 identical β subunits. In the eukaryotic proteasome, gene duplication and specialization has led to 7 distinct subunits of each type. The overall architecture of the proteasome is conserved.

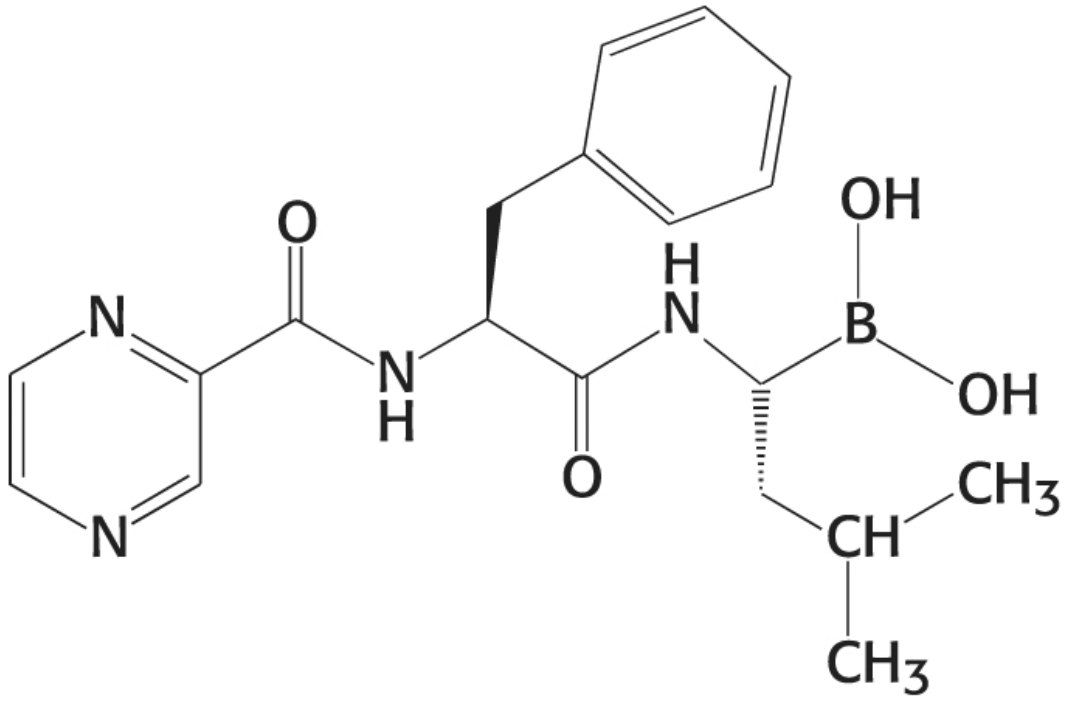
Protein degradation can be used to regulate biological function



A number of physiological processes are controlled at least in part by protein degradation through the ubiquitin–proteasome pathway (Table 23.3). In each case, the proteins being degraded are regulatory proteins.

TABLE 23.3 Processes regulated by protein degradation

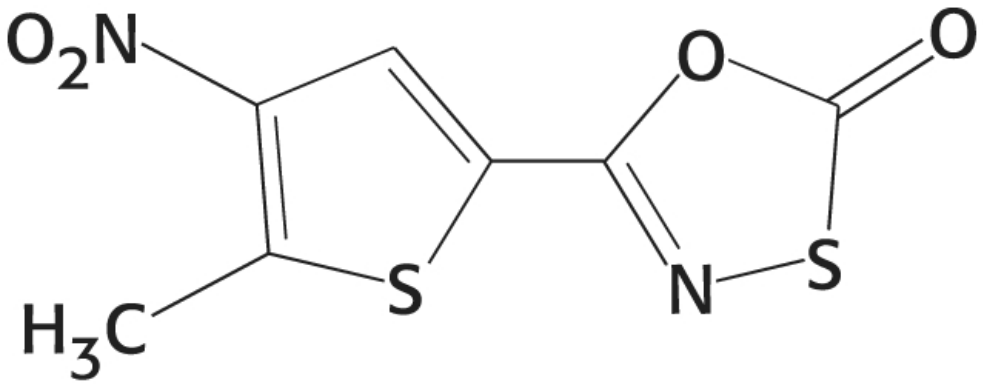
Gene transcription

Cell-cycle progression
Organ formation
Circadian rhythms
Inflammatory response
Tumor suppression
Cholesterol metabolism
Antigen processing

Consider, for example, control of the inflammatory response. A transcription factor, NF-κB (NF for nuclear factor), initiates the expression of a number of the genes that take part in this response. This factor is itself activated by the degradation of an attached inhibitory protein, I-κB (I for inhibitor). In response to inflammatory signals that bind to membrane-bound receptors, I-κB is phosphorylated at two serine residues, creating an E3 binding site. The binding of E3 leads to the ubiquitination and degradation of I-κB, unleashing NF-κB. The liberated transcription factor migrates from the cytoplasm to the nucleus to stimulate the transcription of the target genes. The NF-κB–I-κB system illustrates the interplay of several key regulatory motifs: receptor-mediated signal transduction, phosphorylation, compartmentalization, controlled and specific degradation, and selective gene expression. The importance of the ubiquitin–proteasome system for the regulation of gene expression is highlighted by the use of bortezomib (Velcade), a potent inhibitor of the proteasome, as a therapy for multiple myeloma. Bortezomib is a dipeptidyl boronic acid inhibitor of the proteasome.

Bortezomib
(a dipeptidyl boronic acid)

Degrons are also used as regulatory mechanisms for protein expression. For example, degradation signals are commonly located in protein regions that also facilitate protein–protein interactions. Why might the coexistence of these two functions in the same region be useful? Exposure of such a region to solvent, and therefore to the binding of E3 enzyme, suggests that a component of a multiprotein complex has failed to form properly or that one component has been synthesized in excess. This exposure leads to rapid degradation and the restoration of appropriate stoichiometries.



Keith Weller/Johns Hopkins Medicine

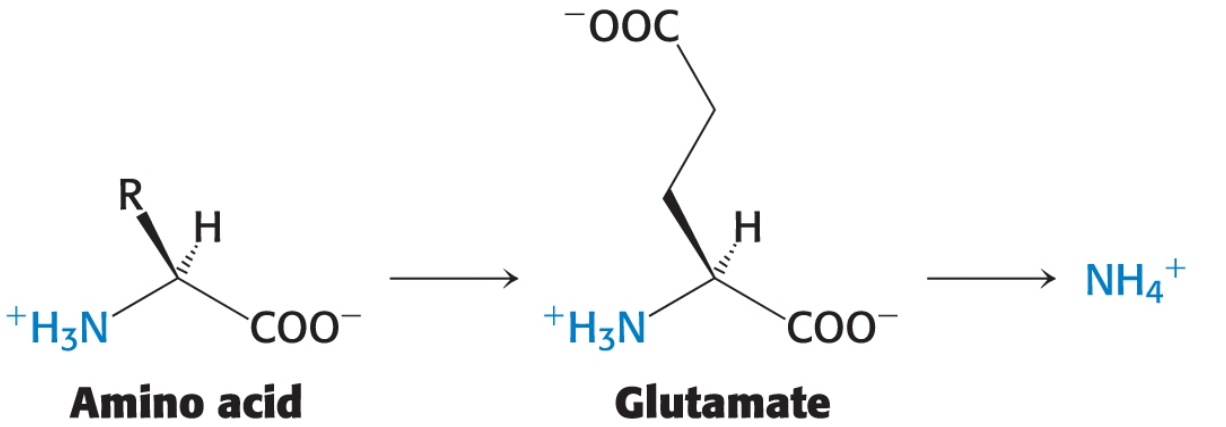
CECILE PICKART The observation that some protein degradation processes required ATP hydrolysis suggested that a novel enzymatic system was at work. Several research teams set to work to characterize this system, one of which included Dr. Cecile Pickart. Dr. Pickart had completed her PhD at Brandeis University, working with a leading enzymologist. As a postdoctoral fellow, she worked with Dr. Irwin Rose at Fox Chase Cancer, where she helped characterize the ubiquitin-based protein degradation system. She was so sure-footed that several of her colleagues agreed with the statement by another that she "described the enzymes to the world as though she had obtained the answer sheet." Later, as an independent researcher at SUNY-Buffalo and then Johns Hopkins, she focused completely on various aspects of ubiquitin biochemistry. She was an outstanding mentor to students, both in her own laboratory and throughout the university, helping students through challenges in their research, with deep insights and attention to even seemingly minor details. It was fitting that Dr. Rose and two colleagues shared the Nobel Prize in 2004 based, in

part, on her research. The field of biochemistry lost a great scientist with her untimely death in 2006 at the age of 51.

The evolutionary studies of proteasomes described previously have also yielded potential clinical benefits. The bacterial pathogen *Mycobacterium tuberculosis*, the cause of tuberculosis, harbors a proteasome that is very similar to the human counterpart. Nevertheless, recent work has shown that it is possible to exploit the differences between the human and the bacterial proteasomes to develop specific inhibitors of the *M. tuberculosis* complex. Oxathiazol-2-one compounds such as HT1171 are suicide inhibitors (Section 5.6) of the proteolytic activity of the *M. tuberculosis* proteasome, but have no effect on the proteasomes of the human host. This is especially exciting because these drugs kill the nonreplicating form of *M. tuberculosis*, and thus may not require the prolonged treatment required with conventional drugs, thereby reducing the likelihood of drug resistance due to interruption of the treatment regime.

HT1171
5-(2-methyl-3-nitrothiophen-2-yl)-1,3,4-oxathiazol-2-one

Self-Check Question



Degrons are often found in parts of proteins that facilitate protein complex formation. Explain why this might be useful.

23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen

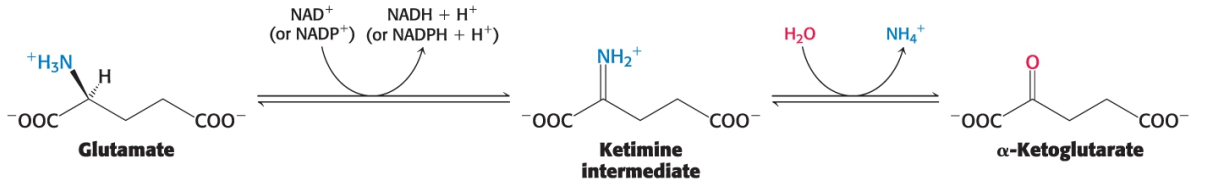
What is the fate of amino acids released on protein digestion or turnover? The first call is for their use as building blocks for biosynthetic reactions. However, any amino acids not needed as building blocks are degraded to compounds able to enter the metabolic mainstream. The amino group is first removed, and then the remaining carbon skeleton is metabolized to a glycolytic intermediate, to one of several citric acid cycle intermediates, or to acetyl CoA. The major site of amino acid degradation in mammals is the liver, although muscles also readily degrade the branched-chain amino acids (Leu, Ile, and Val). The fate of the α-amino group will be considered first, followed by that of the carbon skeleton (Section 23.5).

Alpha-amino groups are converted into ammonium ions by the oxidative deamination of glutamate in the liver

The α-amino group of many amino acids is transferred to α-ketoglutarate to form glutamate, which is then oxidatively deaminated in the liver to yield ammonium ion (NH_4^+).

[Aminotransferases] (also called **transaminases**) catalyze the transfer of an α-amino group from an α-amino acid to an α-ketoacid.

Aminotransferases generally funnel α-amino groups from a variety of amino acids to α-ketoglutarate for conversion into NH_4^+. Aspartate aminotransferase, one of the most important of these enzymes, catalyzes the transfer of the amino group of aspartate to α-ketoglutarate.



$$\text{Aspartate} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{oxaloacetate} + \text{glutamate}$$

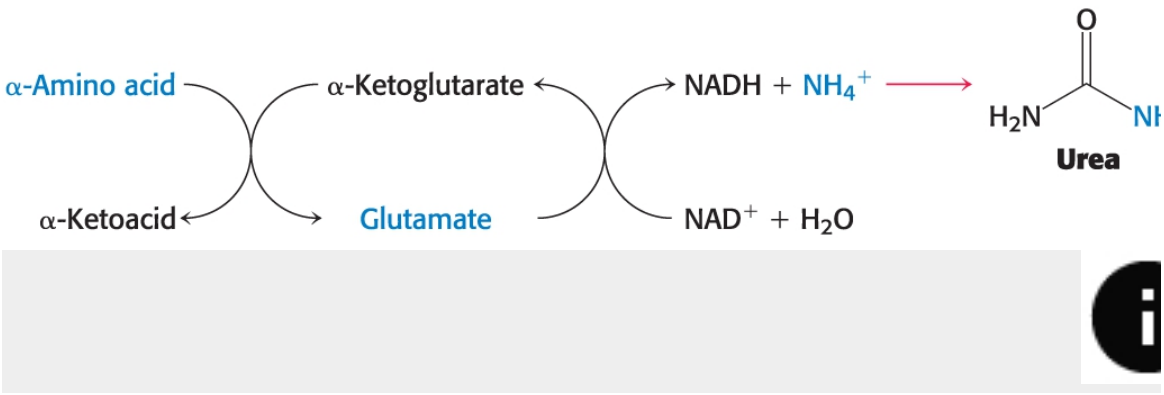
Alanine aminotransferase catalyzes the transfer of the amino group of alanine to α-ketoglutarate.

$$\text{Alanine} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{pyruvate} + \text{glutamate}$$

Transamination reactions are reversible and can thus be used to synthesize amino acids from α-ketoacids, as we shall see in Section 25.2

The nitrogen atom in glutamate is converted into free ammonium ion by oxidative deamination, a reaction catalyzed by **glutamate dehydrogenase**. This enzyme is unusual in being able to utilize either NAD^+ or $NADP^+$, at least in some species. The reaction proceeds by dehydrogenation of the $C-N$ bond, followed by hydrolysis of the resulting ketimine.

This reaction equilibrium constant is close to 1 in the liver, so the direction of the reaction is determined by the concentrations of reactants and products. Normally, the reaction is driven forward by the rapid removal of ammonium ion. Ammonium ions are toxic, and particularly detrimental to the brain, so ammonium is formed only in large amounts in the liver, where it is immediately eliminated by its conversion to urea. Thus, glutamate dehydrogenase is essentially a liver-specific enzyme. To further prevent the release of free ammonium, glutamate dehydrogenase is located in mitochondria along with some of the other enzymes required for the production of urea.



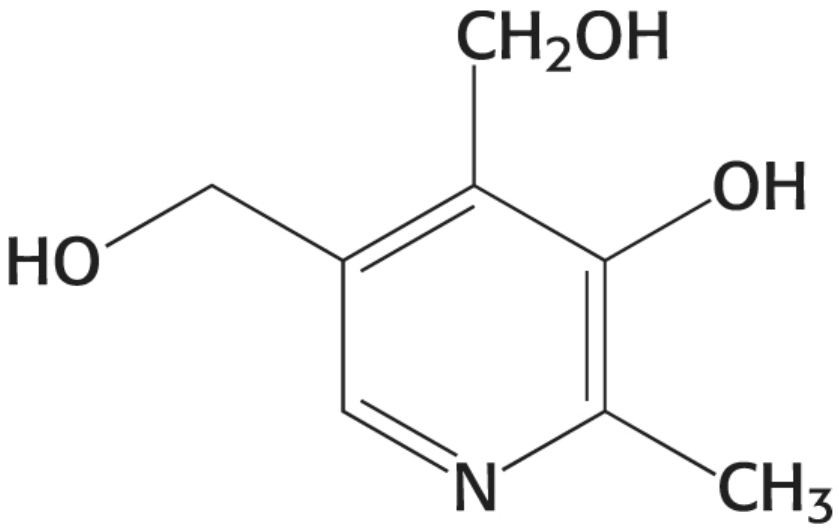
In mammals, but not in other organisms, glutamate dehydrogenase is allosterically inhibited by GTP and stimulated by ADP. These nucleotides exert their regulatory effects in a unique manner: an

abortive complex, a set of molecules bound to the enzyme that cannot move forward toward the final products, is formed when a product is replaced by substrate in the active site before the reaction is complete. For instance, the enzyme bound to glutamate and NAD(P)H is an abortive complex. GTP facilitates the formation of such complexes while ADP destabilizes them.

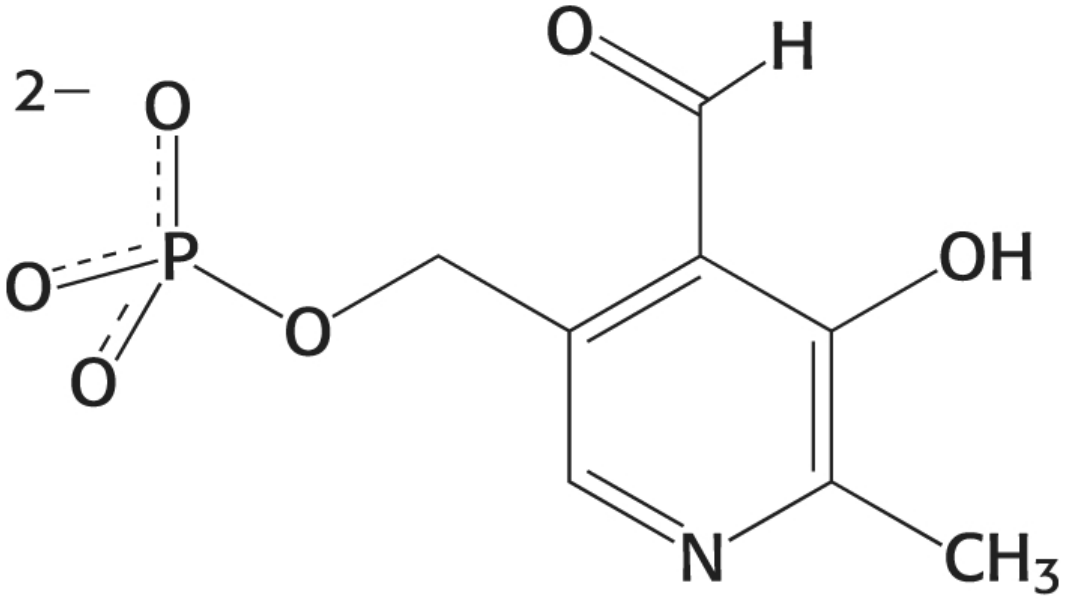
The sum of the reactions catalyzed by aminotransferases and glutamate dehydrogenase is

$$\alpha\text{-Amino acid} + \underset{(\text{or } NADP^+)}{NAD^+} + H_2O \rightleftharpoons \alpha\text{-ketoacid} + NH_4^+ + \underset{(\text{or } NADPH)}{NADH} + H^+$$

In most terrestrial vertebrates, NH_4^+ is converted into urea, which is excreted.

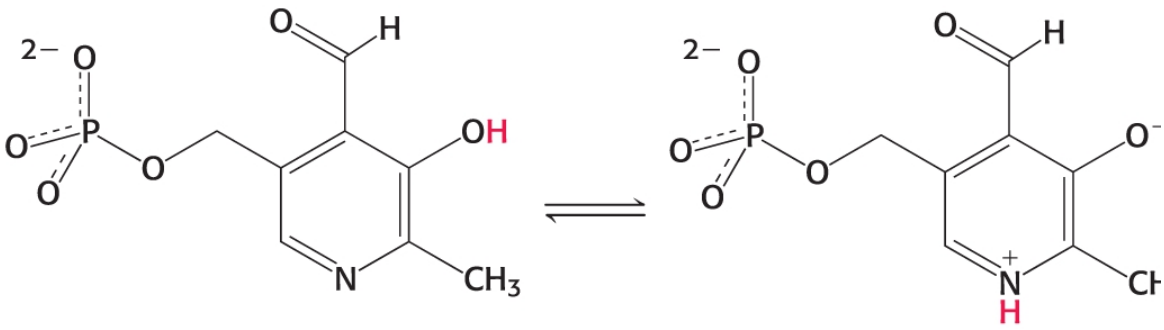


Self-Check Question

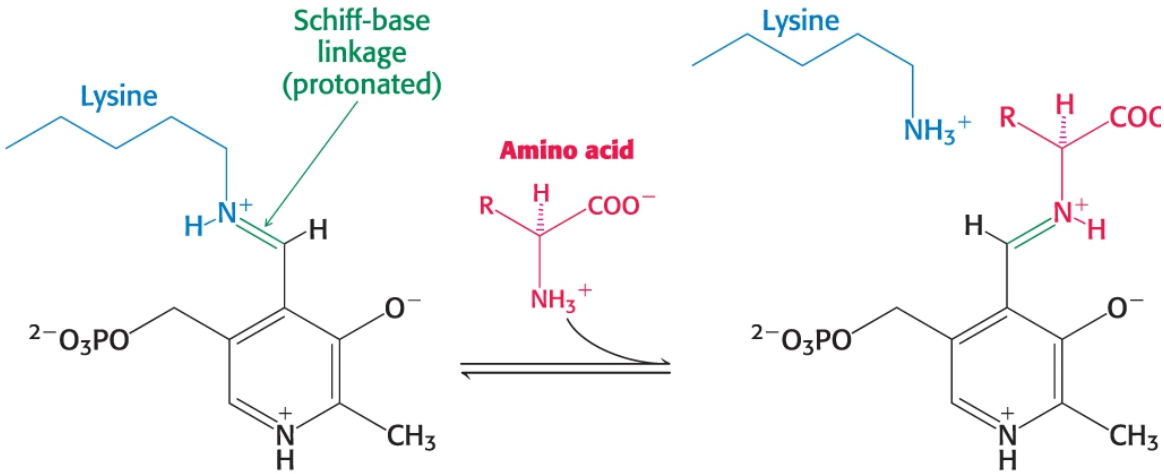


How do aminotransferases and glutamate dehydrogenase cooperate in the metabolism of the amino group of amino acids?

Mechanism: Pyridoxal phosphate forms Schiff-base intermediates in aminotransferases



All aminotransferases contain the prosthetic group **pyridoxal phosphate (PLP)**, which is derived from pyridoxine (vitamin B_6). Pyridoxal phosphate includes a slightly basic pyridine ring to which a slightly acidic OH group is attached. Thus, pyridoxal phosphate derivatives can form a stable tautomeric form in which the pyridine nitrogen atom is protonated (hence, positively charged), while the OH group loses a proton and hence is negatively charged, forming a phenolate.



Pyridoxine
(vitamin B_6)

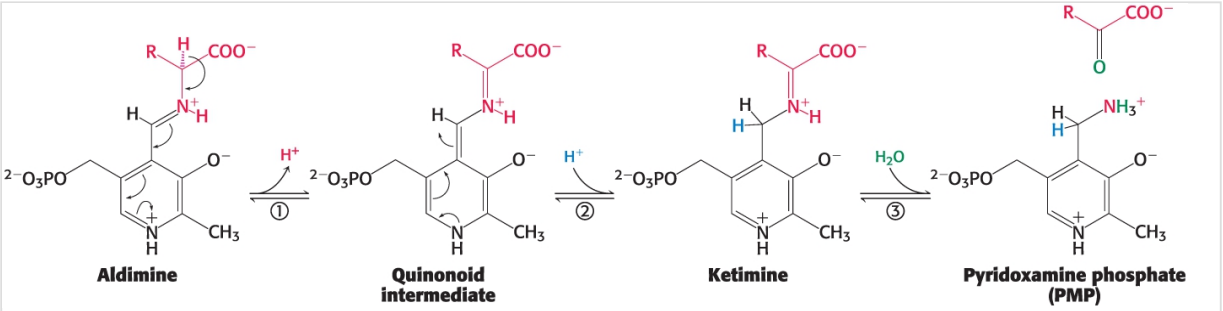
Pyridoxal phosphate
(PLP)

The most important functional group on PLP is the aldehyde. This group forms covalent Schiff-base intermediates with amino acid substrates. Indeed, even in the absence of substrate, the aldehyde group of PLP usually forms a Schiff-base linkage with the ε-amino group of a specific lysine residue at the enzyme's active site. A new Schiff-base linkage is formed on addition of an amino acid substrate.

The α-amino group of the amino acid substrate displaces the ε-amino group of the active-site lysine residue. In other words, an *internal* aldimine becomes an *external* aldimine. The amino acid–PLP Schiff base that is formed remains tightly bound to the enzyme by multiple noncovalent interactions. The Schiff-base linkage often accepts a proton at the nitrogen of the pyridine ring, with the positive charge stabilized by interaction with the negatively charged phenolate group of PLP.

The Schiff base between the amino acid substrate and PLP, the external aldimine, loses a proton from the α-carbon atom of the amino acid to form a quinonoid intermediate (**Figure 23.9**). Reprotonation of this intermediate at the aldehyde carbon atom yields a ketimine, which is then hydrolyzed to an α-ketoacid and pyridoxamine phosphate (PMP). These steps constitute half of the transamination reaction.

$$\text{Amino acid}_1 + \text{E-PLP} \rightleftharpoons \alpha\text{-ketoacid}_1 + \text{E-PMP}$$



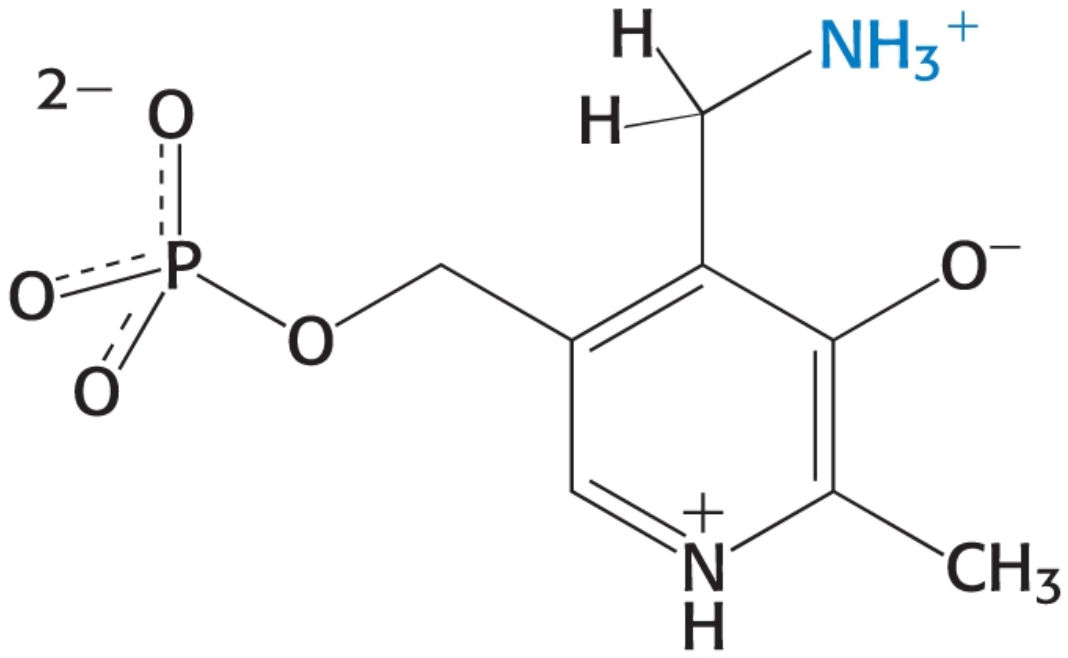


FIGURE 23.9 Transaminations proceed through three steps to form PMP. (1) The external aldimine loses a proton to form a quinonoid intermediate. (2) Reprotonation of this intermediate at the aldehyde carbon atom yields a ketimine. (3) This intermediate is hydrolyzed to generate the α-ketoacid product and pyridoxamine phosphate.

Pyridoxamine phosphate (PMP)

The second half takes place by the reverse of the preceding pathway. A second α-ketoacid reacts with the enzyme–pyridoxamine phosphate complex (E-PMP) to yield a second amino acid and regenerate the enzyme–pyridoxal phosphate complex (E-PLP).

$$\alpha\text{-Ketoacid}_2 + \text{E-PMP} \rightleftharpoons \text{amino acid}_2 + \text{E-PLP}$$

The sum of these partial reactions is

$$\text{Amino acid}_1 + \alpha\text{-ketoacid}_2 \rightleftharpoons \text{amino acid}_2 + \alpha\text{-ketoacid}_1$$

Aspartate aminotransferase is an archetypal pyridoxal-dependent transaminase

The mitochondrial enzyme aspartate aminotransferase provides an especially well-studied example of PLP as a coenzyme for transamination reactions. X-ray crystallographic studies have provided detailed views of how PLP and substrates are bound, confirming much of the proposed catalytic mechanism. Each of the identical 45-kDa subunits of this dimer consists of a large domain and a small one (**Figure 23.10**). PLP is bound to the large domain, in a pocket near the domain interface. In the absence of substrate, the aldehyde group of PLP is in a Schiff-base linkage with lysine 258, as expected. Adjacent to the coenzyme's binding site is a conserved arginine residue that interacts with the α-carboxylate group of the amino acid substrate, helping to orient the substrate appropriately in the active site. A base is necessary to remove a proton from the α-carbon group of the amino acid and to transfer it to the aldehyde carbon atom of PLP (Figure 23.9, steps 1 and 2). The lysine amino group that was initially in Schiff-base linkage with PLP appears to serve as the proton donor and acceptor.

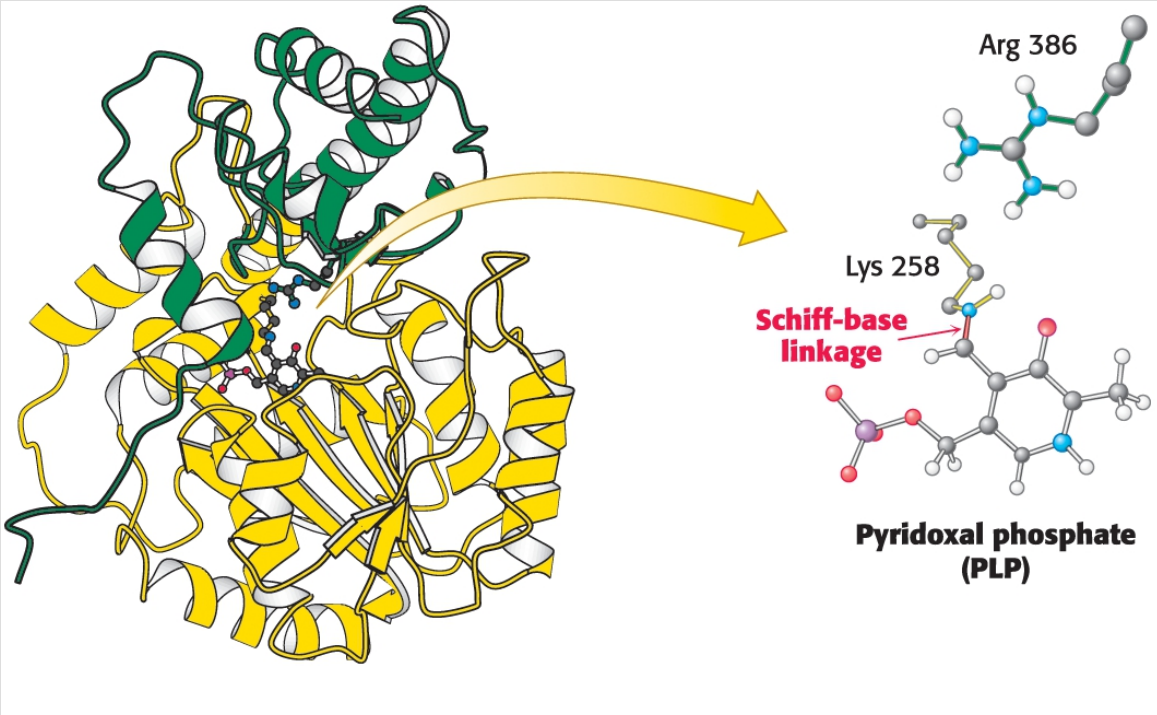

FIGURE 23.10 The active site of aspartate aminotransferase reveals PLP bound to a lysine through a Schiff-base linkage. Aspartate aminotransferase, a prototypical PLP-dependent enzyme, includes pyridoxal phosphate attached to the enzyme by a Schiff-base linkage with lysine 258. An arginine residue in the active site helps orient substrates by binding to their α-carboxylate groups. Only one of the enzyme's two subunits is shown.

[Drawn from 1AAW.pdb.]

INTERACT with this model in Achieve

Blood levels of aminotransferases serve a diagnostic function

The presence of alanine and aspartate aminotransferase in the blood is an indication of liver damage. Liver damage can occur for a number of reasons, including viral hepatitis, long-term excessive alcohol consumption, and reaction to drugs such as acetaminophen (Section 32.3). Under these conditions, liver cell membranes are damaged, and some cellular proteins — including the aminotransferases — leak into the blood. Normal blood values for alanine and aspartate aminotransferase activity are 5–30 units/l and 40–125 units/l, respectively. Depending on the extent of liver damage, the values will reach 200–300 units/l.

Pyridoxal phosphate enzymes catalyze a wide array of reactions

Transamination is just one of a wide range of amino acid transformations that are catalyzed by PLP enzymes. The other reactions catalyzed by PLP enzymes at the α-carbon atom of amino acids are decarboxylations, deaminations, racemizations, and aldol cleavages (Figure 23.11). In addition, PLP enzymes catalyze elimination and replacement reactions at the β-carbon atom (e.g., tryptophan synthetase in the synthesis of tryptophan) and the γ-carbon atom (e.g., cystathionine β-synthase in the synthesis of cysteine) of amino acid substrates. Three common features of PLP catalysis underlie these diverse reactions.

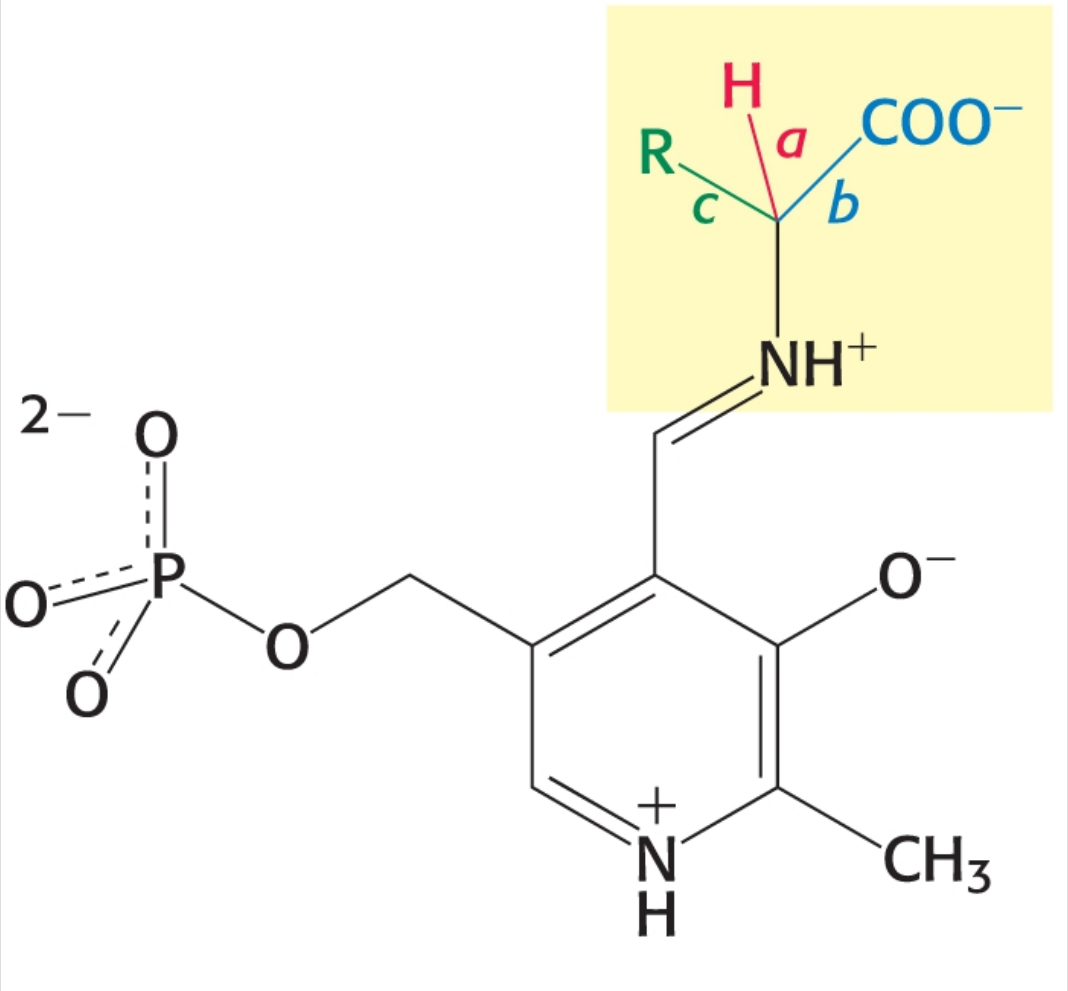

FIGURE 23.11 PLP enzymes labilize one of three bonds at the α-carbon atom of an amino acid substrate. For example, bond *a* is labilized by aminotransferases, bond *b* by decarboxylases, and bond *c* by aldolases (such as threonine aldolases). PLP enzymes also catalyze reactions at the β- and γ-carbon atoms of amino acids.

1. A Schiff base is formed by the amino acid substrate (the amine component) and PLP (the carbonyl component).
2. The protonated form of PLP acts as an electron sink to stabilize catalytic intermediates that are negatively charged. Electrons from these intermediates are attracted to the positive charge on the ring nitrogen atom.
3. The product Schiff base is cleaved at the completion of the reaction.

How does an enzyme selectively break a particular one of three bonds at the α-carbon atom of an amino acid substrate? An important principle is that the bond being broken must be perpendicular to the π bonds of the electron sink (Figure 23.12).

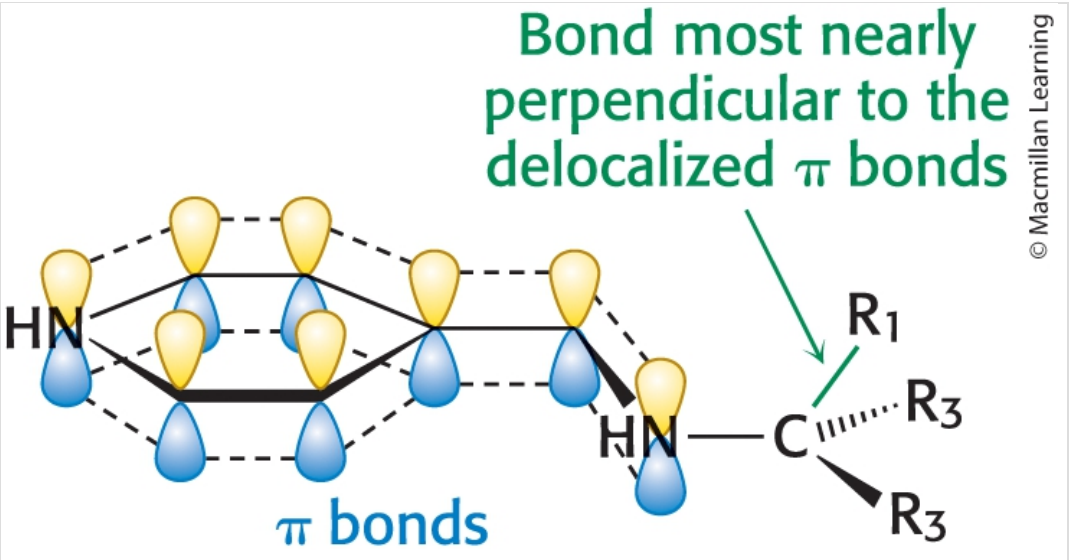

FIGURE 23.12 Stereoelectronic effects determine specific bond cleavage. The orientation about the $N-C_{\alpha}$ bond determines the most favored reaction

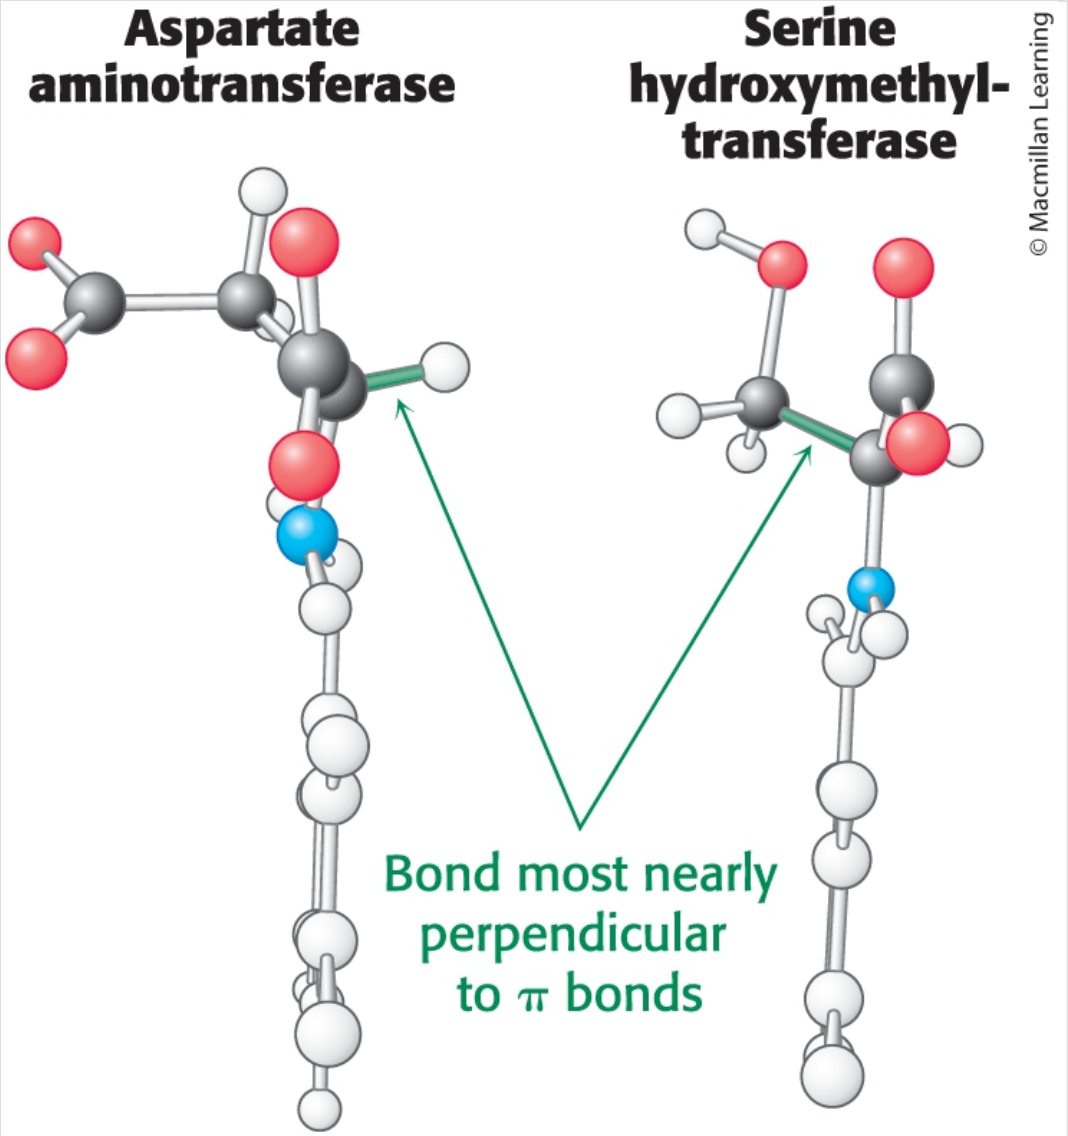
catalyzed by a pyridoxal phosphate enzyme. The bond that is most nearly perpendicular to the plane of delocalized π bonds (represented by dashed lines) of the pyridoxal phosphate electron sink is most easily cleaved.

An aminotransferase, for example, binds the amino acid substrate so that the $C_\alpha - H$ bond is perpendicular to the PLP ring (**Figure 23.13**). In serine hydroxymethyltransferase, the enzyme that converts serine into glycine, the $N - C_\alpha$ bond is rotated so that the $C_\alpha - C_\beta$ bond is most nearly perpendicular to the plane of the PLP ring, favoring its cleavage. This means of choosing one of several possible catalytic outcomes is called *stereoelectronic control*.



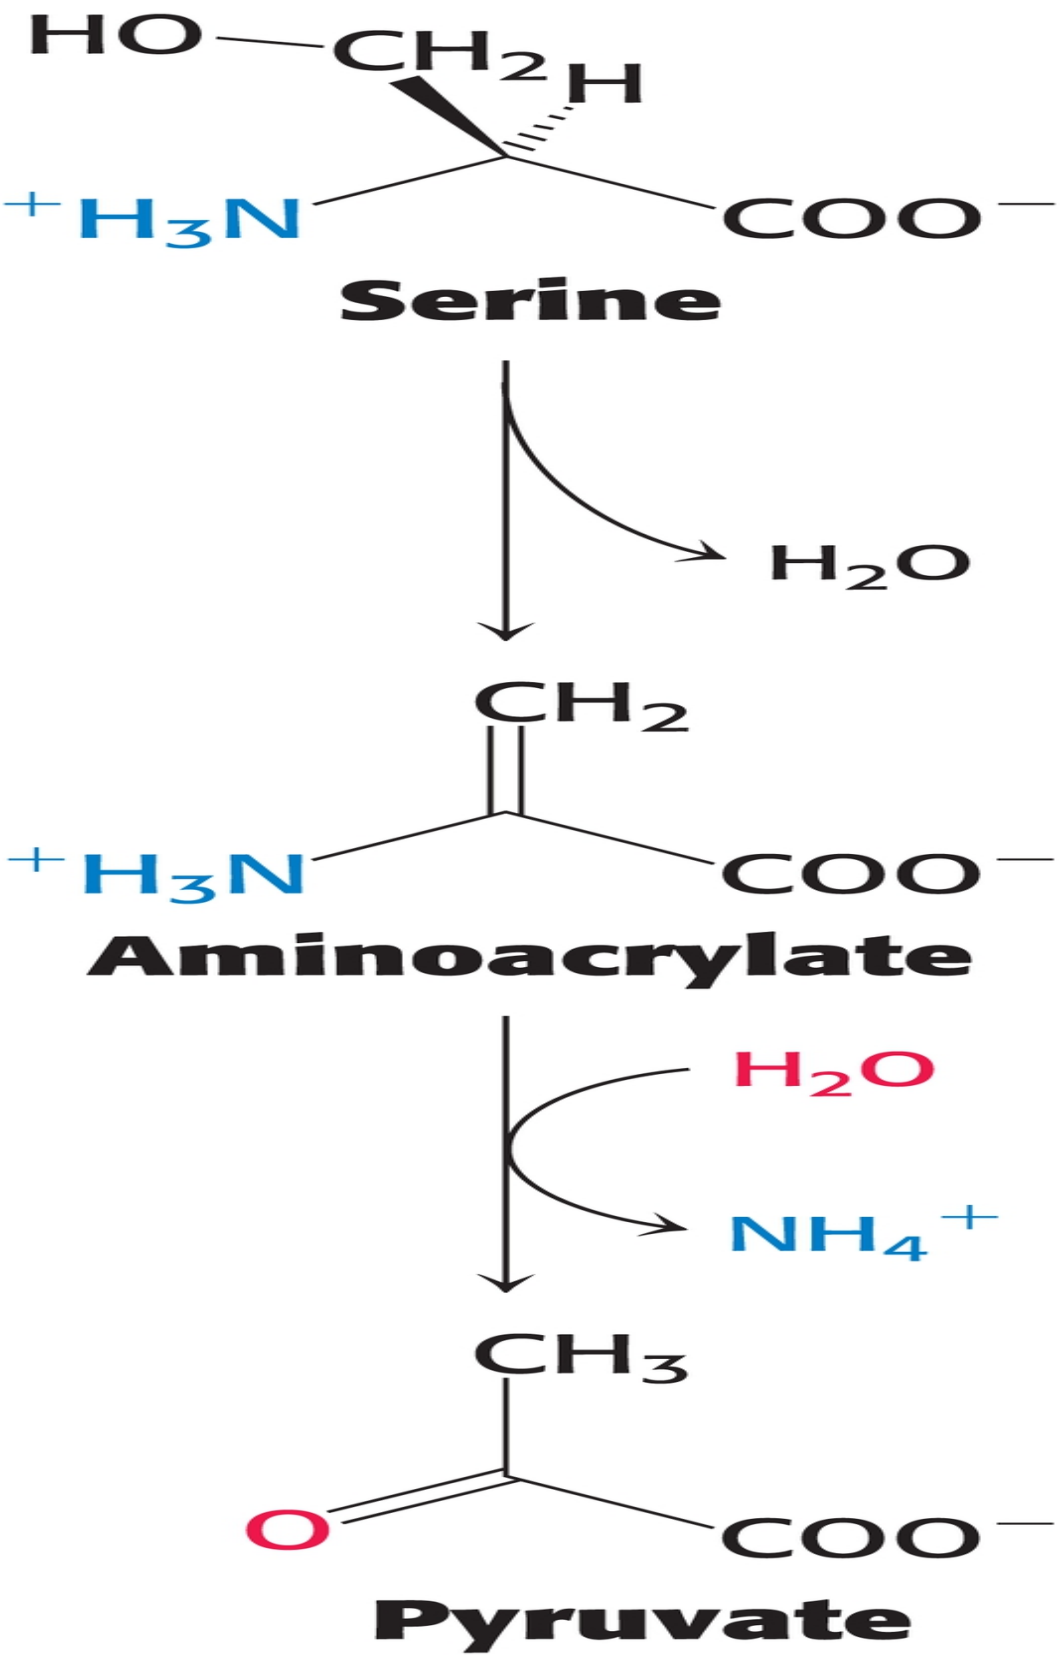


FIGURE 23.13 Bond orientation in the active site determines bond cleavage in different PLP enzymes. In aspartate aminotransferase, the $C_\alpha - H$ bond is most nearly perpendicular to the π-bond system and is cleaved. In serine hydroxymethyltransferase, a small rotation about the $N - C_\alpha$ bond places the $C_\alpha - C_\beta$ bond perpendicular to the π system, favoring its cleavage.

Serine and threonine can be directly deaminated

The α-amino groups of serine and threonine can be directly converted into NH_4^+ without first being transferred to α-ketoglutarate. These direct deaminations are catalyzed by serine dehydratase and threonine dehydratase, in which PLP is the prosthetic group.

$$\text{Serine} \rightarrow \text{pyruvate} + NH_4^+$$

$$\text{Threonine} \rightarrow \alpha\text{-ketobutyrate} + NH_4^+$$

COO−
Pyruvate

These enzymes are called *dehydratases* because dehydration precedes deamination. Serine loses a hydrogen ion from its α-carbon atom and a hydroxide ion group from its β-carbon atom to yield aminoacrylate. This unstable compound reacts with H_2O to give pyruvate and NH_4^+. Thus, the presence of a hydroxyl group attached to the β-carbon atom in each of these amino acids permits the direct deamination.

Peripheral tissues transport nitrogen to the liver

Although most amino acid degradation takes place in the liver, other tissues can degrade amino acids. For instance, muscle uses branched-chain amino acids as a source of fuel during prolonged exercise and fasting. How is the nitrogen processed in these other tissues? As in the liver, the first step is the removal of the nitrogen from the amino acid. However, muscle lacks the enzymes of the urea cycle, and so the nitrogen must be released in a nontoxic form that can be absorbed by the liver and converted into urea.

Nitrogen is transported from muscle to the liver in two principal transport forms: alanine and glutamine. To form alanine, first, glutamate is formed by transamination reactions, but the nitrogen is then transferred to pyruvate. Alanine is then released into the blood (**Figure 23.14**). The liver takes up the alanine and, by transamination, converts it back into pyruvate that can be used for gluconeogenesis; the amino group eventually appears as urea. This transport is referred to as the **glucose–alanine cycle**. It is reminiscent of the Cori cycle discussed earlier (Figure 16.36). However, in contrast with the Cori cycle, pyruvate is not reduced to lactate by NADH, and thus more high-energy electrons

are conserved for oxidative phosphorylation in the muscle by using alanine.

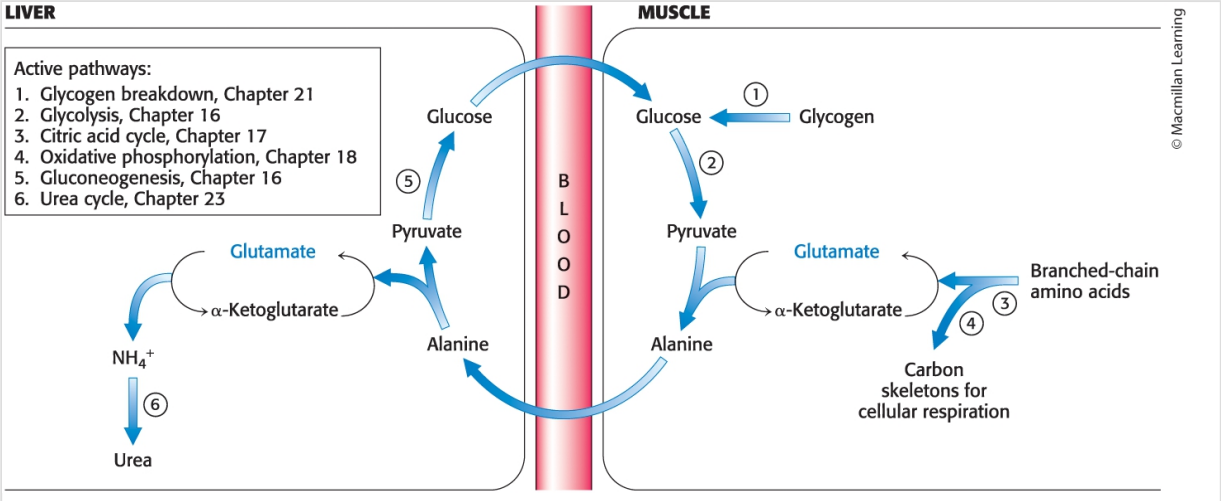

FIGURE 23.14 PATHWAY INTEGRATION: The glucose–alanine cycle allows muscle cells to use amino acids as fuel. During prolonged exercise and fasting, muscle uses branched-chain amino acids as fuel. The nitrogen removed is transferred (through glutamate) to alanine, which is released into the blood stream. In the liver, alanine is taken up and converted into pyruvate for the subsequent synthesis of glucose.

EXPLORE this pathway further in the Metabolic Map in Achieve

Glutamine is also a key transport form of nitrogen. Glutamine synthetase catalyzes the synthesis of glutamine from glutamate and NH_4^+ in an ATP-dependent reaction:

$$NH_4^+ + \text{glutamate} + ATP \xrightarrow{\text{Glutamine synthetase}} \text{glutamine} + ADP + P_i$$

The nitrogens of glutamine can be eliminated by incorporation into urea in the liver.

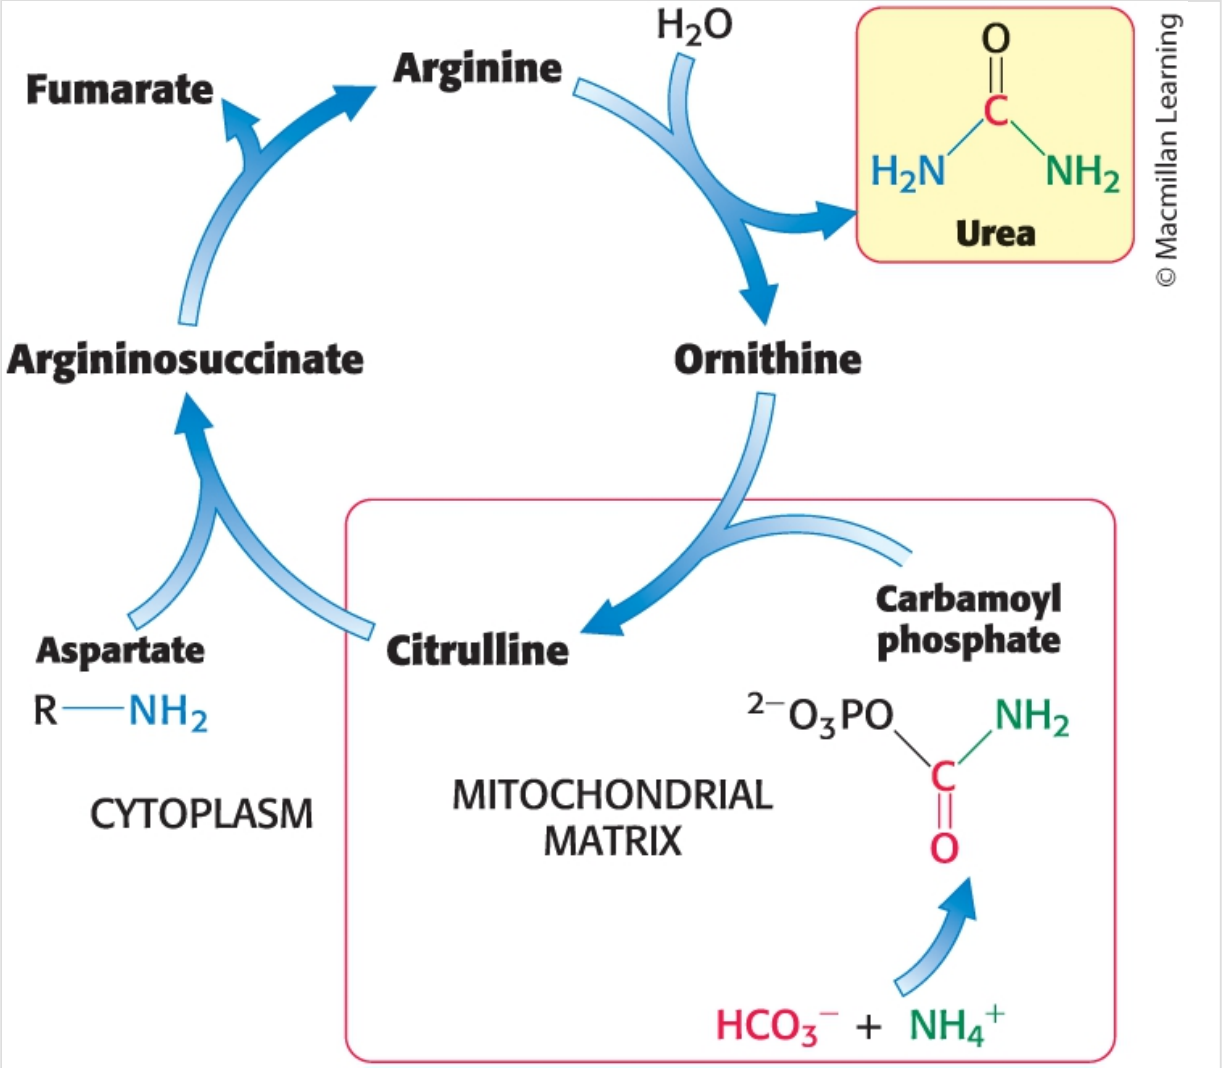
Self-Check Question

What amino acids can be deaminated directly to produce ammonium without the use of glutamate dehydrogenase, and what structural feature makes this possible?

23.4 Ammonium Ions Are Converted into Urea in Most Terrestrial Vertebrates

Some of the NH_4^+ formed in the breakdown of amino acids is consumed in the biosynthesis of nitrogen compounds. What happens to the rest of it? In most terrestrial vertebrates, the excess NH_4^+ is converted into urea and then excreted. Such organisms are referred to as *ureotelic*.

In terrestrial vertebrates, urea is synthesized by the **urea cycle** (**Figure 23.15**). One of the nitrogen atoms of urea is transferred from an amino acid, aspartate. The other nitrogen atom is derived directly from free NH_4^+, and the carbon atom comes from HCO_3^- (derived by the hydration of CO_2 through the action of carbonic anhydrase).



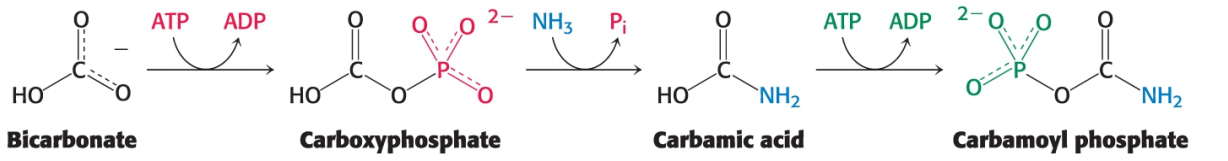


FIGURE 23.15 The urea cycle eliminates both nitrogen and carbon waste products. Two nitrogen atoms enter the cycle and leave as urea. Carbon dioxide is simultaneously eliminated as it is hydrated to bicarbonate, which then enters the cycle.

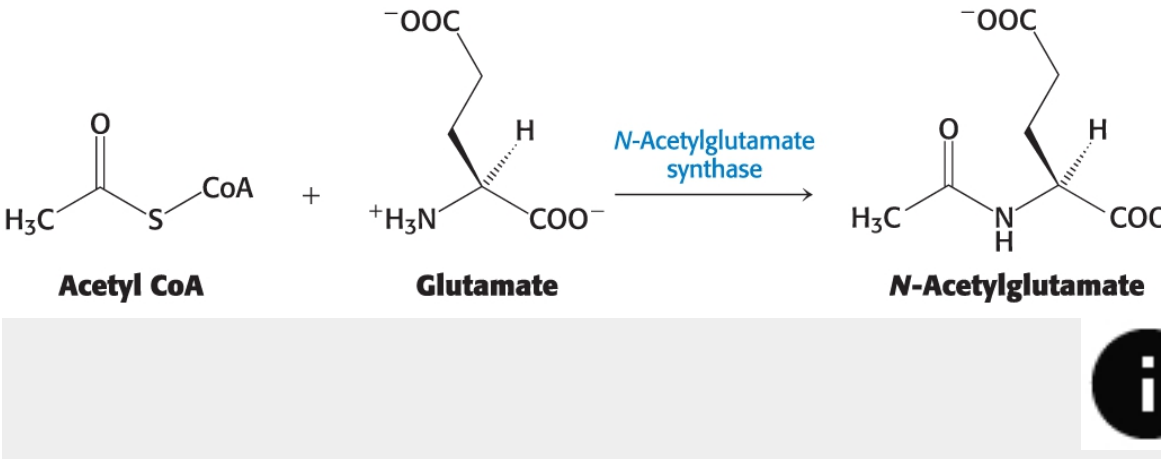
EXPLORE this pathway further in the Metabolic Map in Achieve

The urea cycle begins with the formation of carbamoyl phosphate

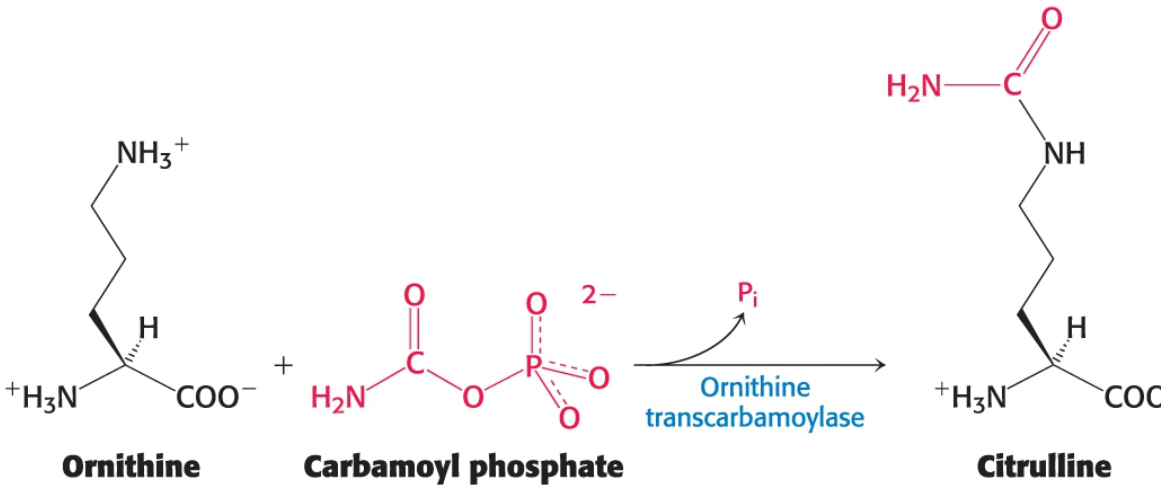
The urea cycle begins with the coupling of free NH_3 with HCO_3^- to form carbamoyl phosphate; this is the committed reaction of the urea cycle, which is catalyzed by **carbamoyl phosphate synthetase I**. In mammals, two distinct isozymes of carbamoyl phosphate synthetase are present. Carbamoyl phosphate synthetase I generates carbamoyl phosphate for both the urea cycle and the first step in pyrimidine biosynthesis (Section 26.1). Carbamoyl phosphate synthetase II is active in other steps of pyrimidine biosynthesis.



Carbamoyl phosphate is a simple molecule, but its synthesis is complex, requiring three steps.

Note that NH_3, because it is a base, normally exists as NH_4^+ in aqueous solution. However, carbamoyl phosphate synthetase I uses only NH_3 as a substrate. The reaction begins with the phosphorylation of HCO_3^- to form carboxyphosphate, which then reacts with NH_3 to form carbamic acid. Finally, a second molecule of ATP phosphorylates carbamic acid to form carbamoyl phosphate. The structure and mechanism of the enzyme that catalyzes these reactions will be presented in Chapter 26. The consumption of two molecules of ATP makes this synthesis of carbamoyl phosphate essentially irreversible.

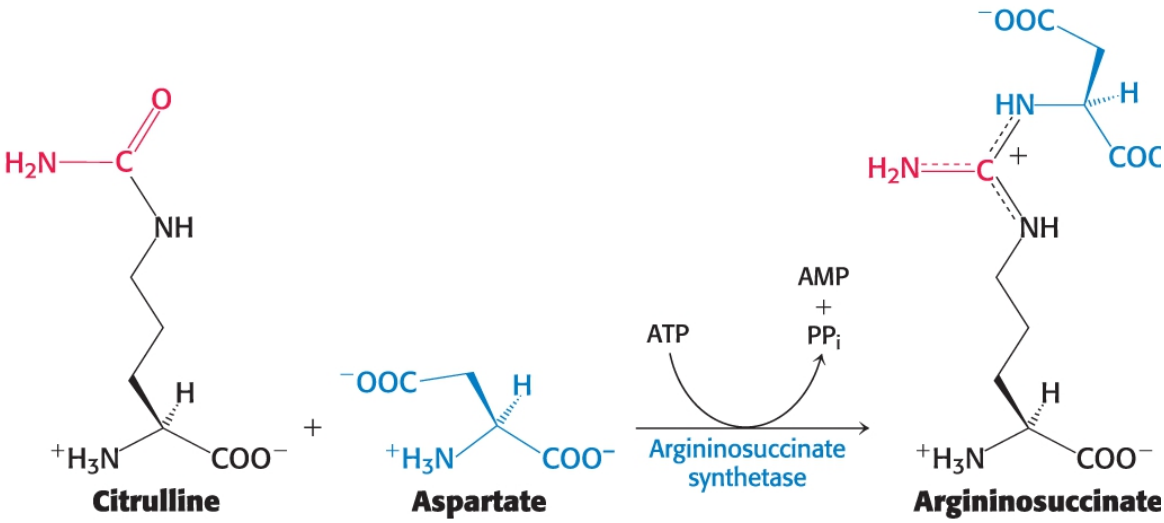
Carbamoyl phosphate synthetase I is the key regulatory enzyme for urea synthesis



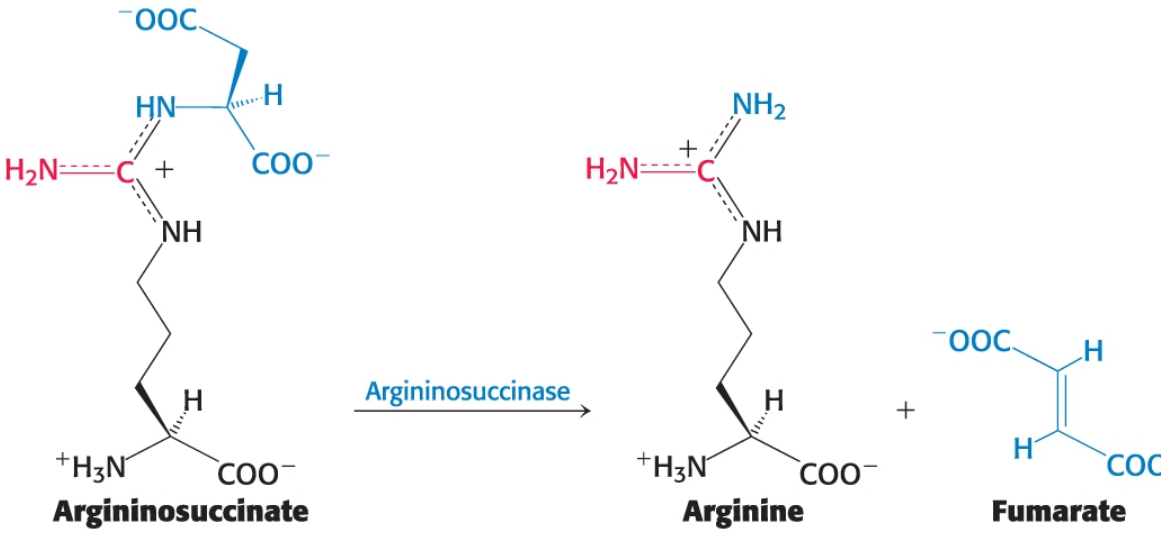
Carbamoyl phosphate synthetase I is regulated both allosterically and by covalent modification so that it is maximally active when amino acids are being metabolized for fuel use. The allosteric regulator *N*-acetylglutamate is required for synthetase activity. This molecule is synthesized by *N*-acetylglutamate synthase.

N-acetylglutamate synthase is itself activated by arginine, an intermediate in the urea cycle. Thus, *N*-acetylglutamate is synthesized when amino acids, as represented by arginine and glutamate, are readily available, and carbamoyl phosphate synthetase I is then activated to process the generated ammonia. When ammonia is not being generated, the synthetase is inhibited by acetylation. A rise in the concentration of mitochondrial NAD^+, indicative of an energy-poor state, stimulates a deacetylase that removes the acetyl group, activating the synthetase and readying the enzyme for processing ammonia from protein degradation. Biochemists have not yet determined how synthetase acetylation is controlled, serving again as a reminder that many discoveries are yet to be made in biochemistry.

Carbamoyl phosphate reacts with ornithine to begin the urea cycle

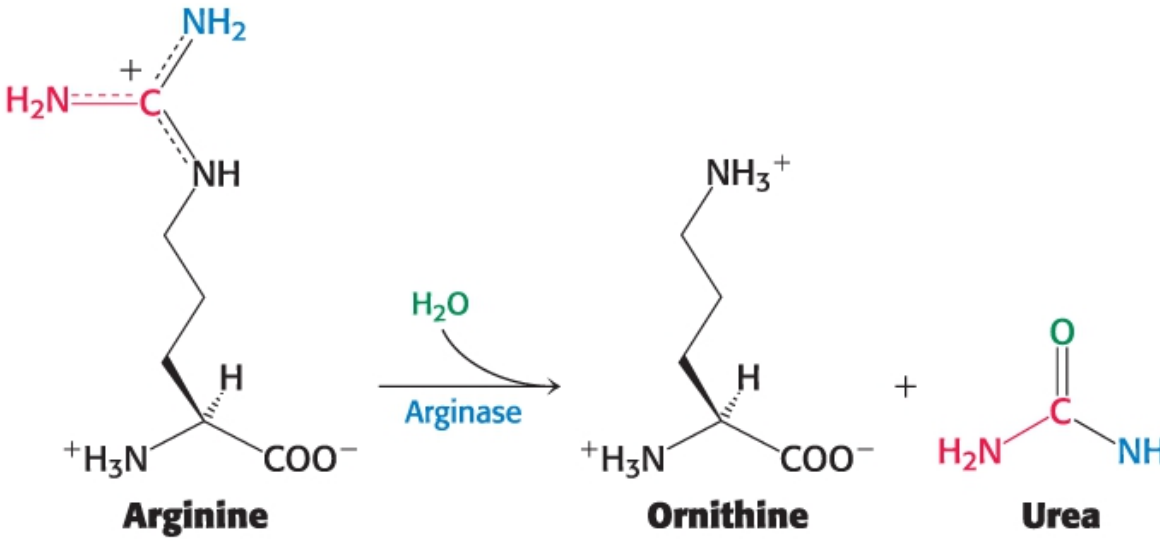


The carbamoyl group of carbamoyl phosphate has a high transfer potential because of its anhydride linkage. The carbamoyl group is transferred to ornithine to form citrulline, in a reaction catalyzed by ornithine transcarbamoylase.



Ornithine and citrulline are amino acids, but they are not proteogenic, meaning they are not used as building blocks of proteins. The formation of NH_4^+ by glutamate dehydrogenase, its incorporation into carbamoyl phosphate as NH_3, and the subsequent synthesis of citrulline take place in the mitochondrial matrix. In contrast, the next three reactions of the urea cycle, which lead to the formation of urea, take place in the cytoplasm.

Citrulline is transported to the cytoplasm, where it condenses with aspartate, the donor of the second amino group of urea. This synthesis of argininosuccinate, catalyzed by argininosuccinate synthetase, is



driven by the cleavage of ATP into AMP and pyrophosphate and by the subsequent hydrolysis of pyrophosphate.

Argininosuccinase (also called *argininosuccinate lyase*) cleaves argininosuccinate into arginine and fumarate. Thus, the carbon skeleton of aspartate is preserved in the form of fumarate.

Finally, arginine is hydrolyzed to generate urea and ornithine in a reaction catalyzed by arginase. Ornithine is then transported back into the mitochondrion to begin another cycle, and the urea is excreted. Indeed, human beings excrete about 10 kg (22 pounds) of urea per year.

The urea cycle is linked to gluconeogenesis

The stoichiometry of urea synthesis is

$$CO_2 + NH_4^+ + 3ATP + aspartate + 2H_2O \rightarrow urea + 2ADP + 2P_i + AMP + PP_i + fumarate$$

Pyrophosphate is rapidly hydrolyzed, and so the equivalent of four molecules of ATP are consumed in these reactions to synthesize one

molecule of urea. The synthesis of fumarate by the urea cycle is important because it is a precursor for glucose synthesis (Figure 23.16). Fumarate is hydrated to malate, which is in turn oxidized to oxaloacetate, producing one NADH that can be used to generate 2.5 ATP molecules; thus, the actual energetic cost of urea synthesis is not as great as it may appear. Oxaloacetate can be converted into glucose by gluconeogenesis or transaminated to aspartate for another round of urea synthesis.

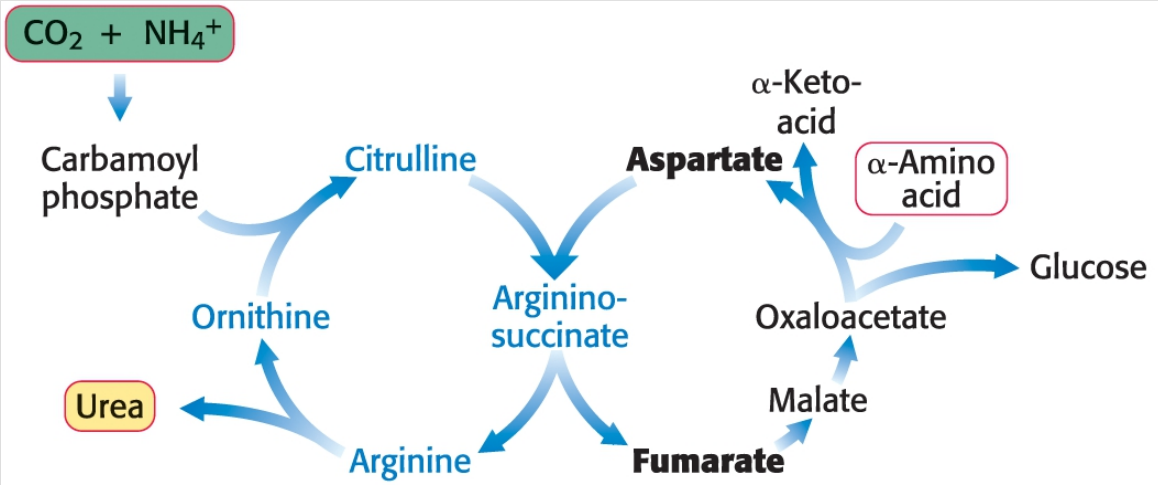


FIGURE 23.16 Nitrogen metabolism is integrated with other pathways. The urea cycle, gluconeogenesis, and the transamination of oxaloacetate are linked by fumarate and aspartate

Inherited defects of the urea cycle cause hyperammonemia and can lead to brain damage

Genetic disorders of the urea cycle that block carbamoyl phosphate synthesis or of any of the four steps of the urea cycle have devastating consequences. The synthesis of urea in the liver is the major route for the removal of NH_4^+; thus, any defect in the urea cycle leads to an elevated level of NH_4^+ in the blood (a condition called *hyperammonemia*). Urea cycle disorders occur with a prevalence of about 1 in 15,000, with some cases becoming evident a day or two after birth, when the afflicted infant becomes lethargic and vomits periodically. Coma and irreversible brain damage may soon follow.

Why are high levels of NH_4^+ toxic? Biochemists do not yet know for certain, but recent work suggests that NH_4^+ may inappropriately activate a sodium-potassium-chloride cotransporter. This activation disrupts the osmotic balance of the nerve cell, causing swelling that damages the cell and results in neurological disorders. Other studies have found that ammonium disrupts neurotransmitter systems, which is reasonable since many neurotransmitters either are amino acids or are derived from amino acids. Additionally, ammonium has been found to impact energy metabolism, levels of oxidative stress, nitric oxide synthesis, and signal-transduction pathways. Due to these many impacts, the effects of ammonium on the brain are probably complex.

Ingenious strategies for coping with deficiencies in urea synthesis have been devised on the basis of a thorough understanding of the underlying biochemistry. Consider, for example, argininosuccinase deficiency. This disorder can be partly bypassed by providing a surplus of arginine in the diet and restricting the total protein intake. In the liver, arginine is split into urea and ornithine, which then reacts with carbamoyl phosphate to form citrulline (**Figure 23.17**). This urea-cycle intermediate condenses with aspartate to yield argininosuccinate, which is then excreted. Note that two nitrogen atoms — one from carbamoyl phosphate and the other from aspartate — are eliminated from the body per molecule of arginine provided in the diet. In essence,

argininosuccinate substitutes for urea in carrying nitrogen out of the body.

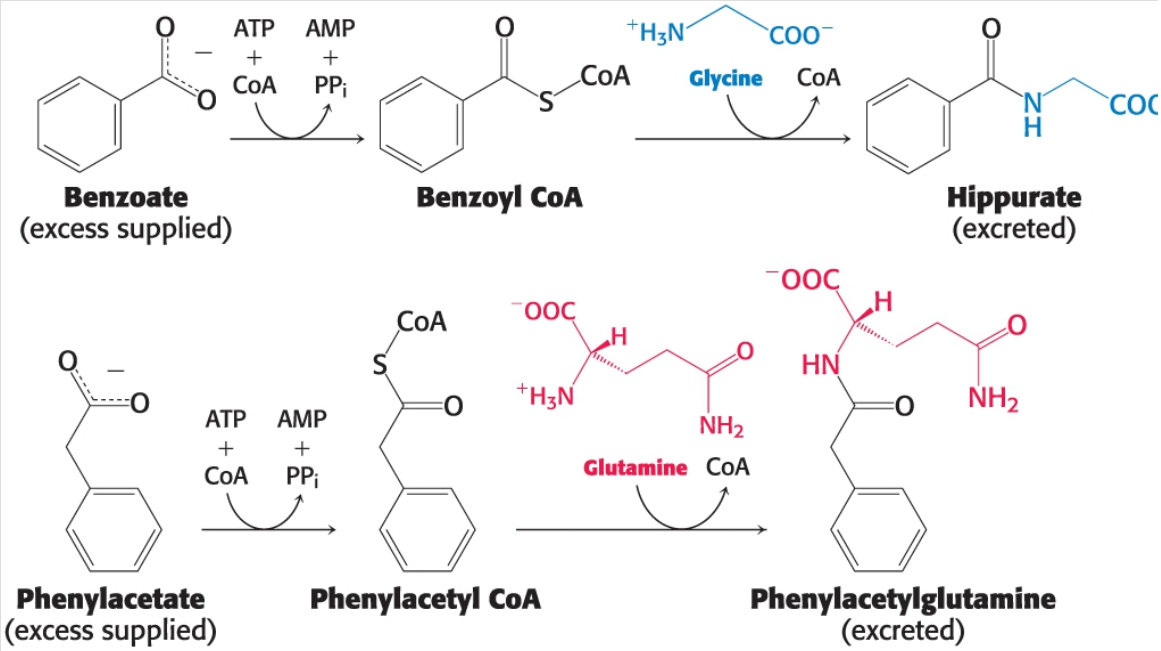
FIGURE 23.17 Argininosuccinase deficiency can be managed by supplementing the diet with arginine. Nitrogen is excreted in the form of argininosuccinate in the absence of functional argininosuccinase.

The treatment of carbamoyl phosphate synthetase deficiency or ornithine transcarbamoylase deficiency illustrates a different strategy for circumventing a metabolic block. Citrulline and argininosuccinate cannot be used to dispose of nitrogen atoms because their formation is impaired. Under these conditions, excess nitrogen accumulates in glycine and glutamine. The challenge then is to rid the body of the nitrogen accumulating in these two amino acids. That goal is accomplished by supplementing a protein-restricted diet with large amounts of benzoate and phenylacetate. Benzoate is activated to benzoyl CoA, which reacts with glycine to form hippurate, which is excreted (Figure 23.18). Likewise, phenylacetate is activated to phenylacetyl CoA, which reacts with glutamine to form phenylacetylglutamine, which is also excreted. These conjugates substitute for urea in the disposal of nitrogen. Thus, latent biochemical pathways can be activated to partly bypass a genetic defect.



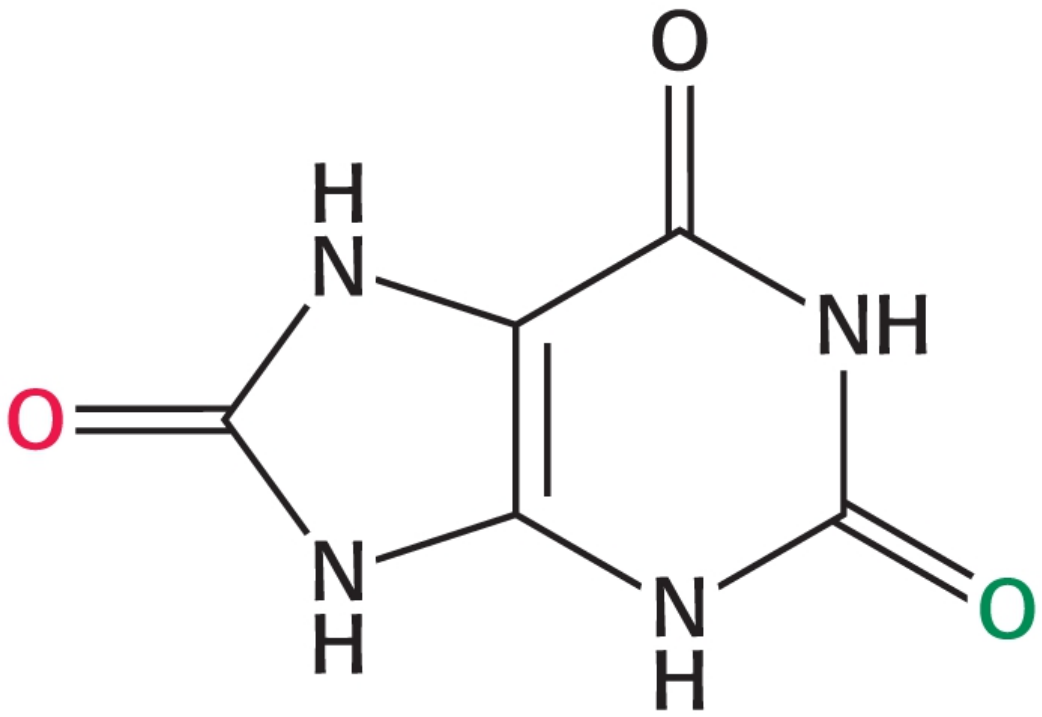


FIGURE 23.18 Both carbamoyl phosphate synthetase and ornithine transcarbamoylase deficiencies can be treated the same way. By supplementing the diet with benzoate and phenylacetate, excess nitrogen can be excreted in the form of hippurate and phenylacetylglutamine.

Urea is not the only means of disposing of excess nitrogen

As stated earlier, most terrestrial vertebrates are *ureotelic*; they excrete excess nitrogen as urea. However, urea is not the only excretable form of nitrogen. *Ammonotelic* organisms, such as aquatic vertebrates and invertebrates, release nitrogen as NH_4^+ and rely on the aqueous environment to dilute this toxic substance. Interestingly, lungfish, which are normally ammonotelic, become ureotelic in time of drought, when they live out of the water.

While both ureotelic and ammonotelic organisms require water (to varying degrees) for nitrogen excretion, *uricotelic* organisms, such as birds and reptiles, secrete nitrogen in an almost-solid slurry, as the purine uric acid. Besides requiring very little water, the secretion of uric acid also has the advantage of removing four atoms of nitrogen per molecule. The pathway for nitrogen excretion observed in different organisms developed over the course of evolution, depending on the habitat of each organism.

Uric acid

Self-Check Question

What are the immediate biochemical sources for the two nitrogen atoms in urea?

23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates

We now turn to the fates of the carbon skeletons of amino acids after the removal of the α-amino group. The strategy of amino acid degradation is to transform the carbon skeletons into major metabolic intermediates that can be converted into glucose or oxidized by the citric acid cycle. The conversion pathways range from extremely simple to quite complex. In fact, some amino acids can be degraded by alternate pathways. For instance, threonine can be metabolized to succinyl CoA or pyruvate. In all cases, however, the carbon skeletons of the diverse set of 20 fundamental amino acids are funneled into only seven molecules: pyruvate, acetyl CoA, acetoacetyl CoA, α-ketoglutarate, succinyl CoA, fumarate, and oxaloacetate. We see here an example of the remarkable economy of metabolic conversions.

Amino acids that are degraded to acetyl CoA or acetoacetyl CoA are termed **ketogenic amino acids** because they can give rise to ketone bodies or fatty acids. Amino acids that are degraded to pyruvate, α-ketoglutarate, succinyl CoA, fumarate, or oxaloacetate are termed **glucogenic amino acids**, because they can be used to produce glucose. For example, oxaloacetate, generated from pyruvate and other citric acid cycle intermediates, can be converted into phosphoenolpyruvate and then into glucose (Section 16.4). Recall from Chapters 17 and 22 that mammals lack a pathway for the net synthesis of glucose from acetyl CoA or acetoacetyl CoA; thus, any amino acid that produces only these molecules cannot be used to produce glucose.

Of the basic set of 20 amino acids, only leucine and lysine are solely ketogenic (**Figure 23.19**). Isoleucine, phenylalanine, tryptophan, and

tyrosine are both ketogenic and glucogenic. Some of their carbon atoms emerge in acetyl CoA or acetoacetyl CoA, whereas others appear in potential precursors of glucose. The other 14 amino acids are classed as solely glucogenic. We will identify the degradation pathways by the entry point into metabolism.

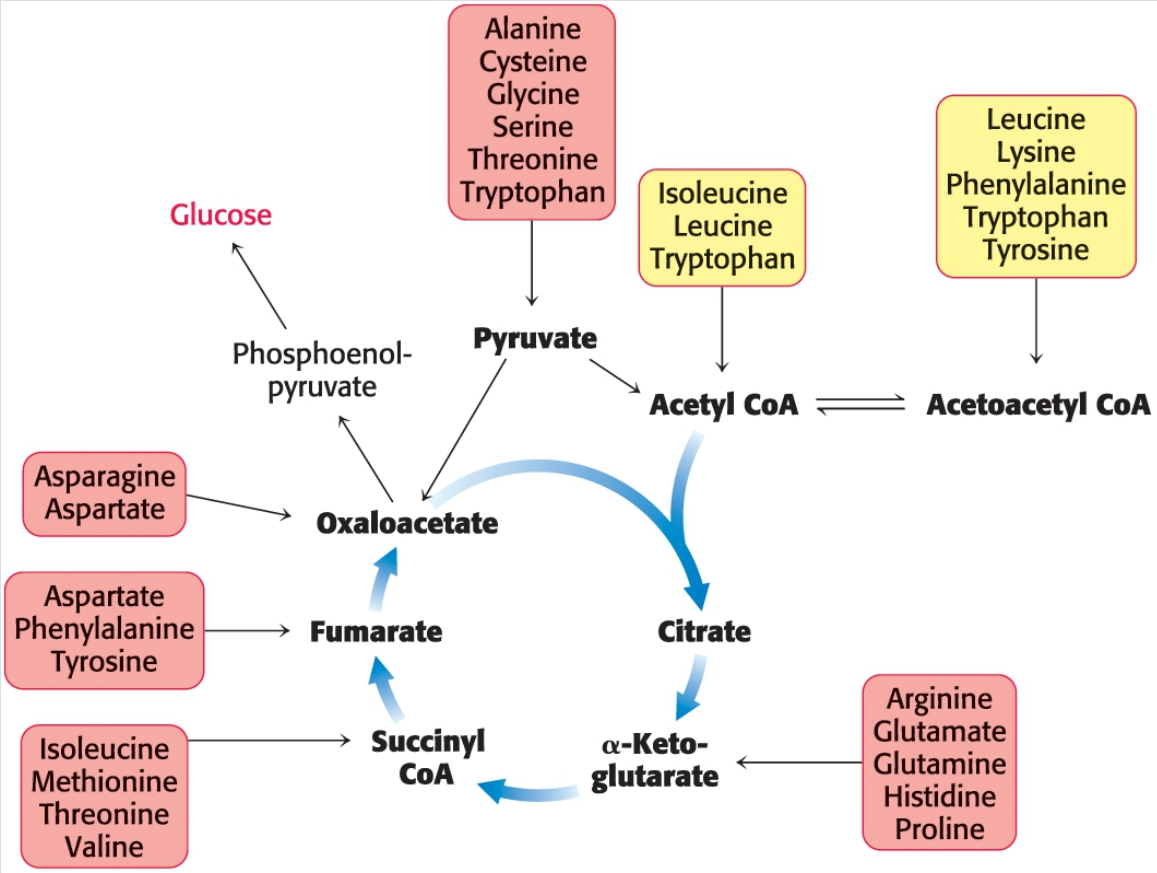

FIGURE 23.19 The carbon skeletons of all 20 proteogenic amino acids enter central metabolism as just seven different molecules. Glucogenic amino acids are shaded red, and ketogenic amino acids are shaded yellow. Several amino acids are both glucogenic and ketogenic.

Pyruvate is an entry point into metabolism for a number of amino acids

Pyruvate is the entry point of the three-carbon amino acids — alanine, serine, and cysteine — into the metabolic mainstream (Figure 23.20). The transamination of alanine directly yields pyruvate.

$$\text{Alanine} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{pyruvate} + \text{glutamat}$$

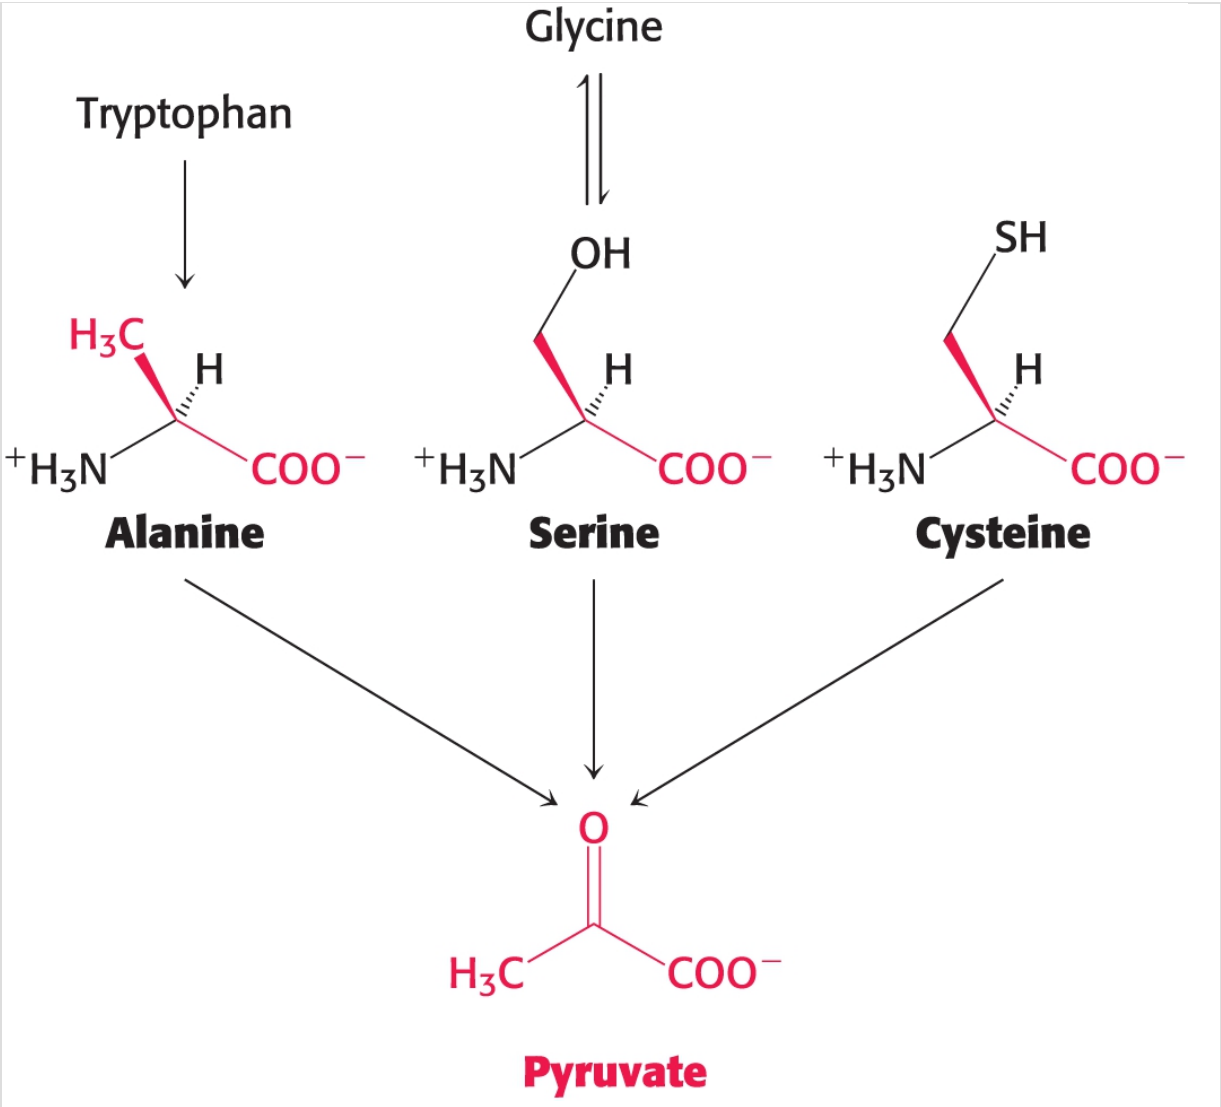

FIGURE 23.20 Pyruvate is the metabolic entry point for the carbon skeletons from three-carbon amino acids. Pyruvate is the point of entry for alanine, serine, cysteine, and glycine. Note

that alanine is eventually produced in the degradation of tryptophan, and that carbon skeleton can then be used to form pyruvate.

As mentioned earlier in the chapter, glutamate is then oxidatively deaminated in the liver, yielding NH_4^+ and regenerating α-ketoglutarate. The sum of these reactions is

$$\text{Alanine} + \text{NAD(P)}^+ + H_2O \rightleftharpoons \text{pyruvate} + NH_4^+ + \text{NAD(P)H} + H$$

Another simple reaction in the degradation of amino acids is the deamination of serine to pyruvate by serine dehydratase (Section 23.3).

$$\text{Serine} \rightarrow \text{pyruvate} + NH_4^+$$

Cysteine can be converted into pyruvate by several pathways, with its sulfur atom emerging in H_2S, SCN^-, or SO_3^{2-}.

The carbon atoms of three other amino acids can be converted into pyruvate. Glycine can be converted into serine by the enzymatic addition of a hydroxymethyl group, or it can be cleaved to give CO_2, NH_4^+, and an activated one-carbon unit. Threonine can give rise to pyruvate through the intermediate 2-amino-3-ketobutyrate. Three carbon atoms of tryptophan can emerge in alanine, which can be converted into pyruvate.

Oxaloacetate is an entry point into metabolism for aspartate and asparagine

Aspartate and asparagine are converted into oxaloacetate, a citric acid cycle intermediate. Aspartate, a four-carbon amino acid, is directly transaminated to oxaloacetate.

$$\text{Aspartate} + \alpha\text{-ketoglutarate} \rightleftharpoons \text{oxaloacetate} + \text{glutamat}$$

Asparagine is hydrolyzed by asparaginase to NH_4^+ and aspartate, which is then transaminated.

Recall that aspartate can also be converted into fumarate by the urea cycle (Figure 23.16). Fumarate is a point of entry for half the carbon atoms of tyrosine and phenylalanine, as will be discussed shortly.

Alpha-ketoglutarate is an entry point into metabolism for amino acids with five-carbon chains

The carbon skeletons of several amino acids with five-carbon chains enter the citric acid cycle as α-ketoglutarate. These amino acids are first converted into glutamate, which is then oxidatively deaminated by glutamate dehydrogenase to yield α-ketoglutarate (**Figure 23.21**).

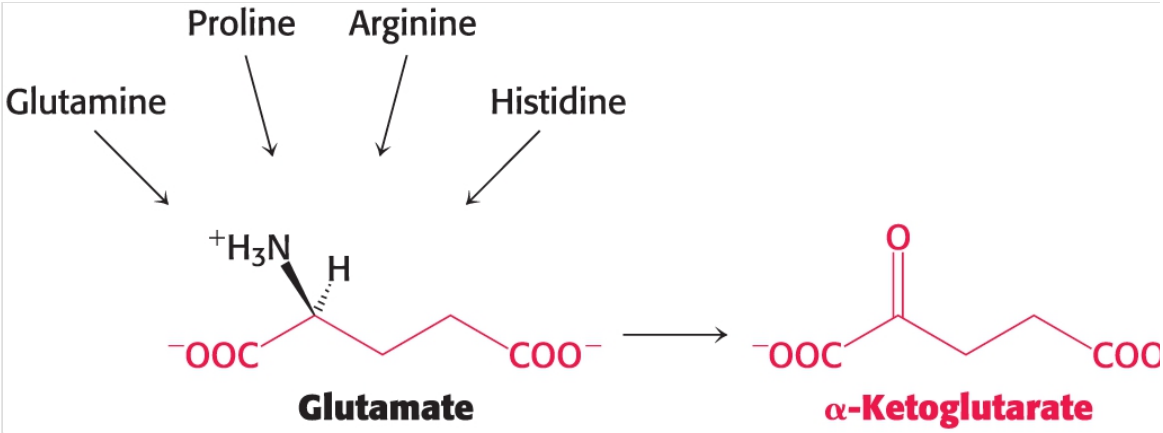

FIGURE 23.21 Four amino acids produce carbon skeletons that enter central metabolism as α-ketoglutarate. These amino acids with five-carbon chains are first converted into glutamate.

Histidine is converted into 4-imidazolone 5-propionate (Figure 23.22). The amide bond in the ring of this intermediate is hydrolyzed to the *N*-formimino derivative of glutamate, which is then converted into glutamate by the transfer of its formimino group to tetrahydrofolate, a carrier of activated one-carbon units (Section 25.2).

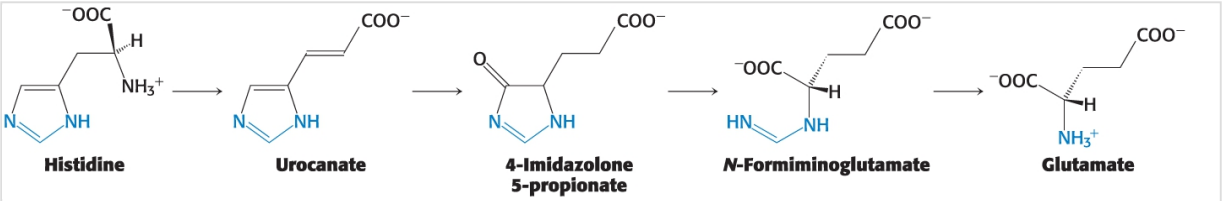

FIGURE 23.22 Histidine is converted to glutamate in four steps. The glutamate produced here is then deaminated to form α-ketoglutarate.

Glutamine is hydrolyzed to glutamate and NH_4^+ by glutaminase. Proline and arginine are each converted into glutamate γ-semialdehyde,

which is then oxidized to glutamate (Figure 23.23).

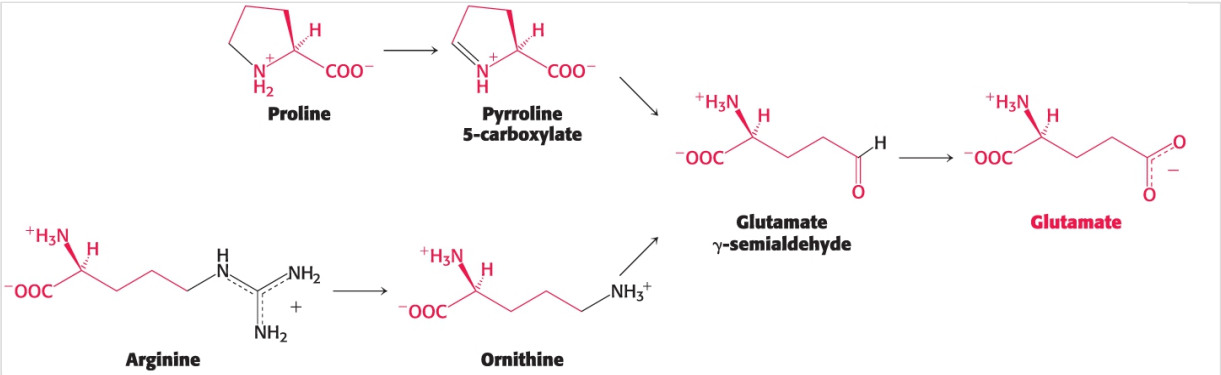

FIGURE 23.23 The degradation pathways for proline and arginine converge on a common intermediate. As with histidine and glutamine, the glutamate produced is deaminated to form α-ketoglutarate.

Succinyl coenzyme A is a point of entry for several amino acids

Succinyl CoA is a point of entry for some of the carbon atoms of methionine, isoleucine, threonine, and valine. Propionyl CoA and then methylmalonyl CoA are intermediates in the breakdown of these four amino acids (Figure 23.24). This pathway from propionyl CoA to succinyl CoA is also used in the oxidation of fatty acids that have an odd number of carbon atoms. The mechanism for the interconversion of propionyl CoA and methylmalonyl CoA was presented in Section 22.3.

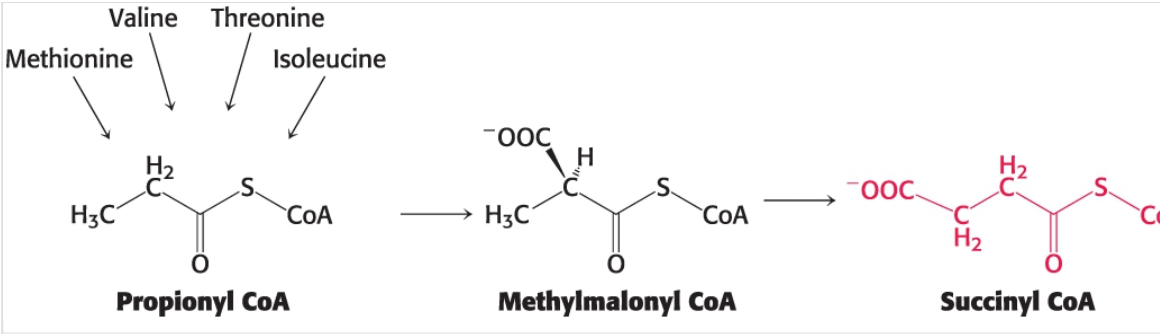

FIGURE 23.24 Succinyl CoA is formed from methionine, isoleucine, threonine, and valine.
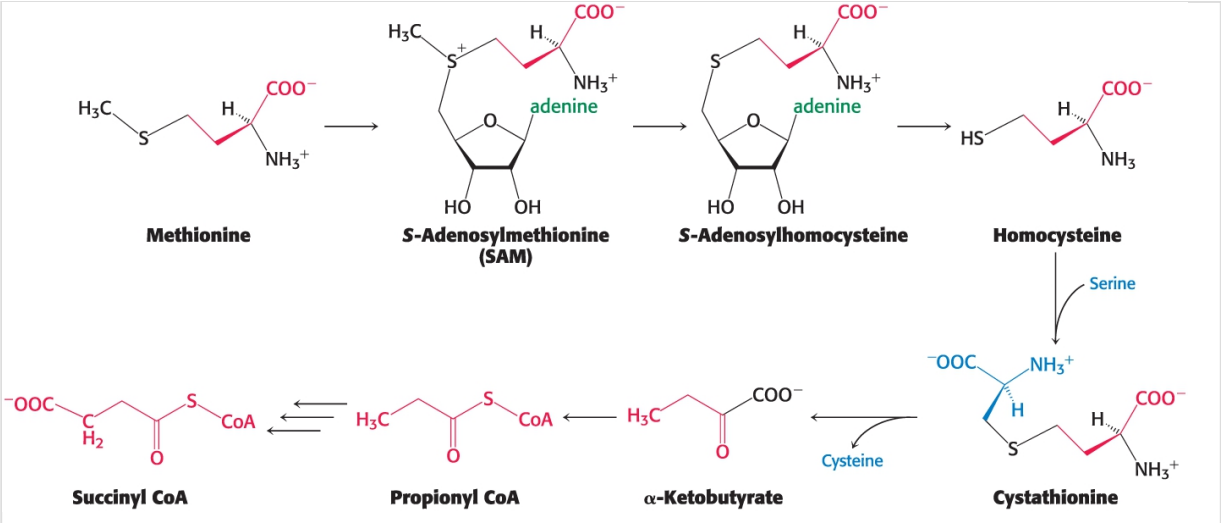
Propionyl CoA is a common intermediate in all four pathways.

Methionine degradation requires the formation of a key methyl donor, *S*-adenosylmethionine

Methionine is converted into succinyl CoA in nine steps (**Figure 23.25**). The first step is the adenylation of methionine to form *S*-adenosylmethionine (SAM), a common methyl donor in the cell (Section 25.2). Loss of the methyl and adenosyl groups yields homocysteine, which is eventually processed to α-ketobutyrate. This α-ketoacid is oxidatively decarboxylated by the α-ketoacid dehydrogenase complex to propionyl CoA, which is processed to succinyl CoA, as described in Section 22.3.



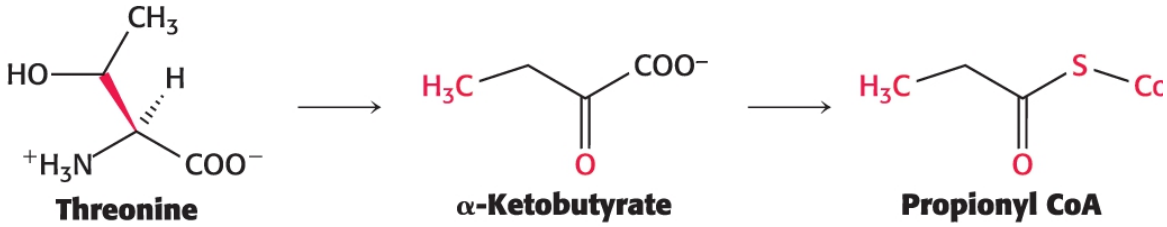


FIGURE 23.25 Methionine catabolism proceeds through the formation of SAM. The pathway for the conversion of methionine into succinyl CoA forms *S*-adenosylmethionine (SAM), an important methyl donor.

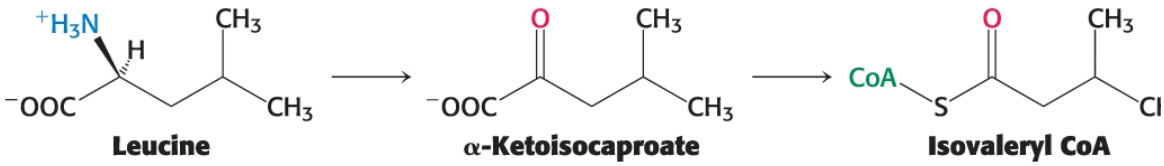
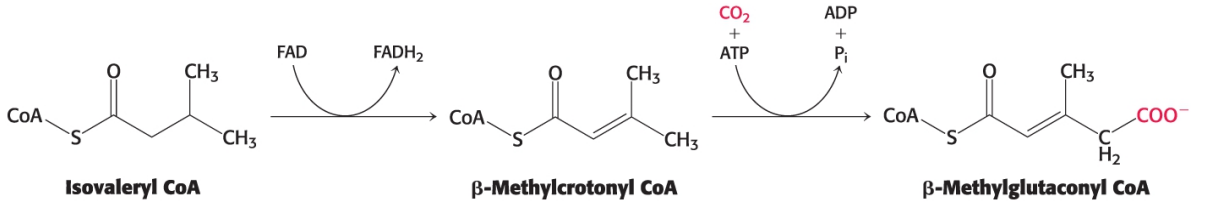
Threonine deaminase initiates the degradation of threonine



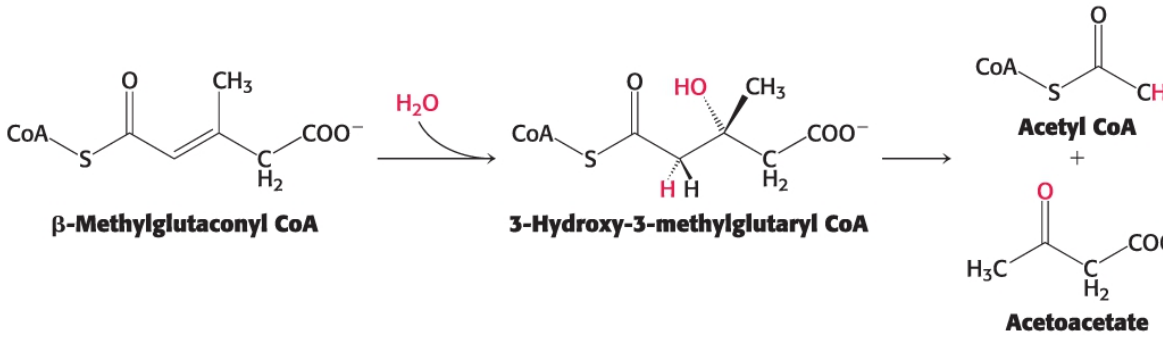
Threonine can be degraded by a number of pathways. One requires the enzyme threonine deaminase, also known as threonine dehydratase. This pyridoxal-dependent enzyme converts threonine into α-ketobutyrate.

α-Ketobutyrate then forms propionyl CoA, which is subsequently metabolized to succinyl CoA, as shown in Figure 23.24.



The branched-chain amino acids yield acetyl CoA, acetoacetate, or propionyl CoA

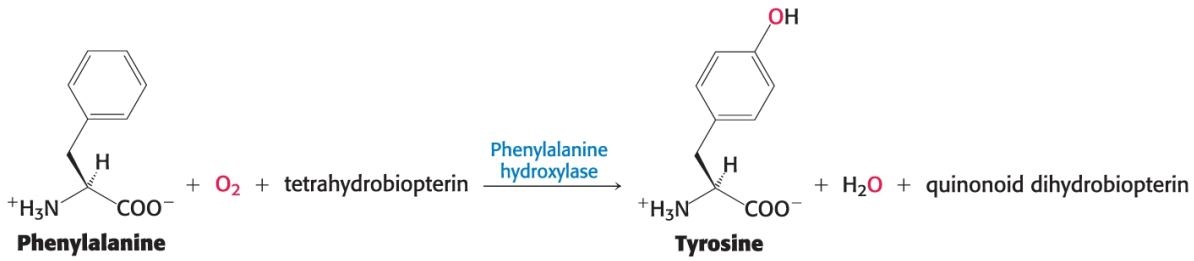
The branched-chain amino acids are degraded by reactions that we have already encountered in the citric acid cycle and fatty acid oxidation. Leucine is transaminated to the corresponding α-ketoacid, called α-*ketoisocaproate*, which is oxidatively decarboxylated to isovaleryl CoA by the branched-chain α-ketoacid dehydrogenase complex.



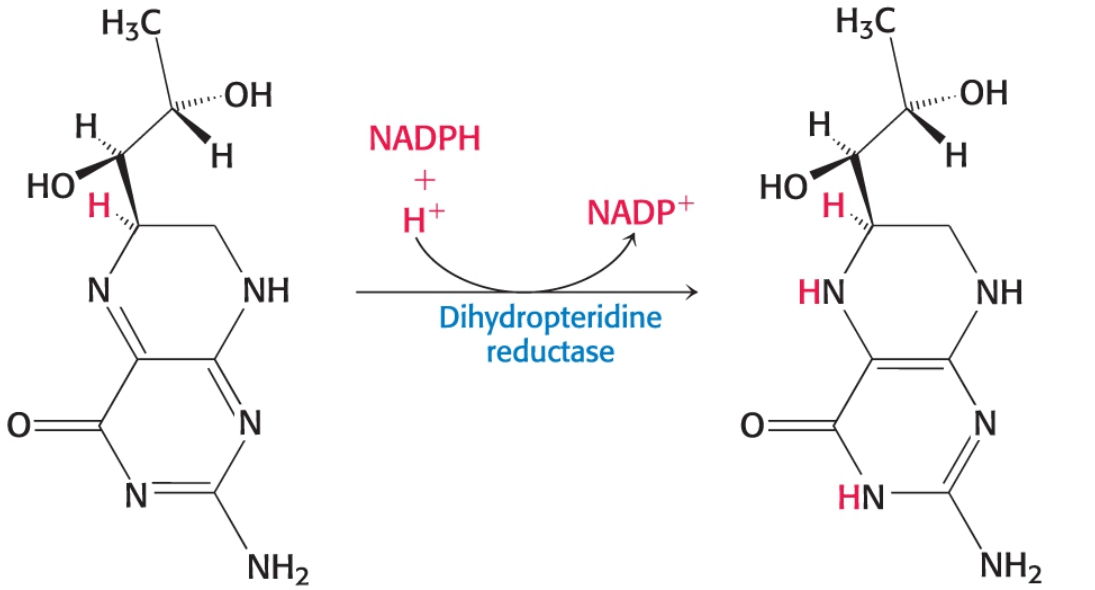
The α-ketoacids of valine and isoleucine, the other two branched-chain aliphatic amino acids, also are substrates (as is α-ketobutyrate derived from methionine). The oxidative decarboxylation of these α-ketoacids is analogous to that of pyruvate to acetyl CoA and of α-ketoglutarate to succinyl CoA. The branched-chain α-ketoacid dehydrogenase, a multienzyme complex, is a homolog of pyruvate dehydrogenase complex (Section 17.2) and α-ketoglutarate dehydrogenase complex (Section 17.3). Indeed, the E3 components of these enzymes, which regenerate the oxidized form of lipoamide, are identical.

The isovaleryl CoA derived from leucine is dehydrogenated to yield β-methylcrotonyl CoA. This oxidation is catalyzed by isovaleryl CoA dehydrogenase, with FAD as the hydrogen acceptor, as in the analogous reaction in fatty acid oxidation that is catalyzed by acyl CoA dehydrogenase. β-Methylglutaconyl CoA is then formed by the carboxylation of β-methylcrotonyl CoA at the expense of the hydrolysis of a molecule of ATP. As might be expected, the carboxylation mechanism of β-methylcrotonyl CoA carboxylase is analogous to that of pyruvate carboxylase and acetyl CoA carboxylase.

β-Methylglutaconyl CoA is then hydrated to form 3-hydroxy-3-methylglutaryl CoA, which is cleaved into acetyl CoA and acetoacetate. This reaction has already been discussed in regard to the formation of ketone bodies from fatty acids (Section 22.4).



The degradative pathways of valine and isoleucine resemble that of leucine. After transamination and oxidative decarboxylation to yield a CoA derivative, the subsequent reactions are like those of fatty acid oxidation. Isoleucine yields acetyl CoA and propionyl CoA, whereas valine yields CO_2 and propionyl CoA. The degradation of leucine, valine, and isoleucine validate a point made in Chapter 15: the number of reactions in metabolism is large, but the number of *kinds* of reactions is relatively small. The degradation of leucine, valine, and isoleucine provides a striking illustration of the underlying simplicity and elegance of metabolism.



Oxygenases are required for the degradation of aromatic amino acids

The degradation pathways of the aromatic amino acids, which yield the common intermediates acetoacetate, fumarate, and pyruvate, are not as straightforward as that of the amino acids previously discussed. For the aromatic amino acids, molecular oxygen is used to break the aromatic ring.

The degradation of phenylalanine begins with its hydroxylation to tyrosine, a reaction catalyzed by phenylalanine hydroxylase. This enzyme is called a *monooxygenase* (or *mixed-function oxygenase*) because *one* atom of O_2 appears in the product and the other atom in H_2O.

The reductant here is tetrahydrobiopterin, an electron carrier that has not been previously discussed and is derived from the cofactor biopterin, which human beings synthesize de novo. The quinonoid form of dihydrobiopterin is produced in the hydroxylation of phenylalanine. It is reduced back to tetrahydrobiopterin by NADPH in a reaction catalyzed by dihydropteridine reductase.

The sum of the reactions catalyzed by phenylalanine hydroxylase and dihydropteridine reductase is

$$\text{Phenylalanine} + O_2 + \text{NADPH} + H^+ \rightarrow \text{tyrosine} + \text{NADP}^+ + H_2O$$

Note that these reactions can also be used to synthesize tyrosine from phenylalanine.

The next step in the degradation of phenylalanine and tyrosine is the transamination of tyrosine to *p*-hydroxyphenylpyruvate (Figure 23.26). This α-ketoacid then reacts with O_2 to form homogentisate. The enzyme catalyzing this complex reaction, *p*-hydroxyphenylpyruvate hydroxylase, is called a *dioxygenase* because both atoms of O_2 become incorporated into the product, one on the ring and one in the carboxyl group. The aromatic ring of homogentisate is then cleaved by O_2, which yields 4-maleylacetoacetate. This reaction is catalyzed by homogentisate oxidase, another dioxygenase. 4-Maleylacetoacetate is then isomerized to 4-fumarylacetoacetate by an enzyme that uses glutathione as a cofactor. Finally, 4-fumarylacetoacetate is hydrolyzed to fumarate and acetoacetate.

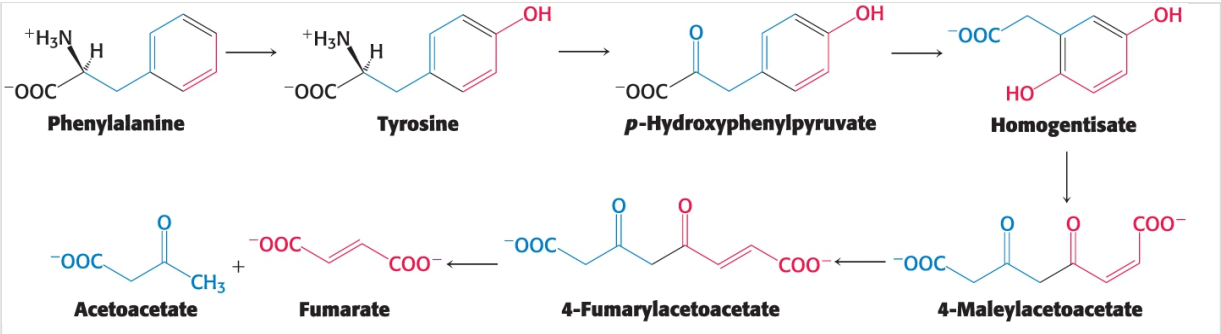


FIGURE 23.26 Phenylalanine and tyrosine degradation produce both acetoacetate and fumarate. This process requires both dioxygenases and monooxygenases.

Tryptophan degradation requires several oxygenases (Figure 23.27). Tryptophan 2,3-dioxygenase cleaves the pyrrole ring, and kynurenine 3-monooxygenase hydroxylates the remaining benzene ring, a reaction similar to the hydroxylation of phenylalanine to form tyrosine. Alanine is removed and the 3-hydroxyanthranilate is cleaved by another

dioxygenase and subsequently processed to acetoacetate. Note that nearly all cleavages of aromatic rings in biological systems are catalyzed by dioxygenases. The active sites of these enzymes contain iron that is not part of heme or an iron–sulfur cluster.

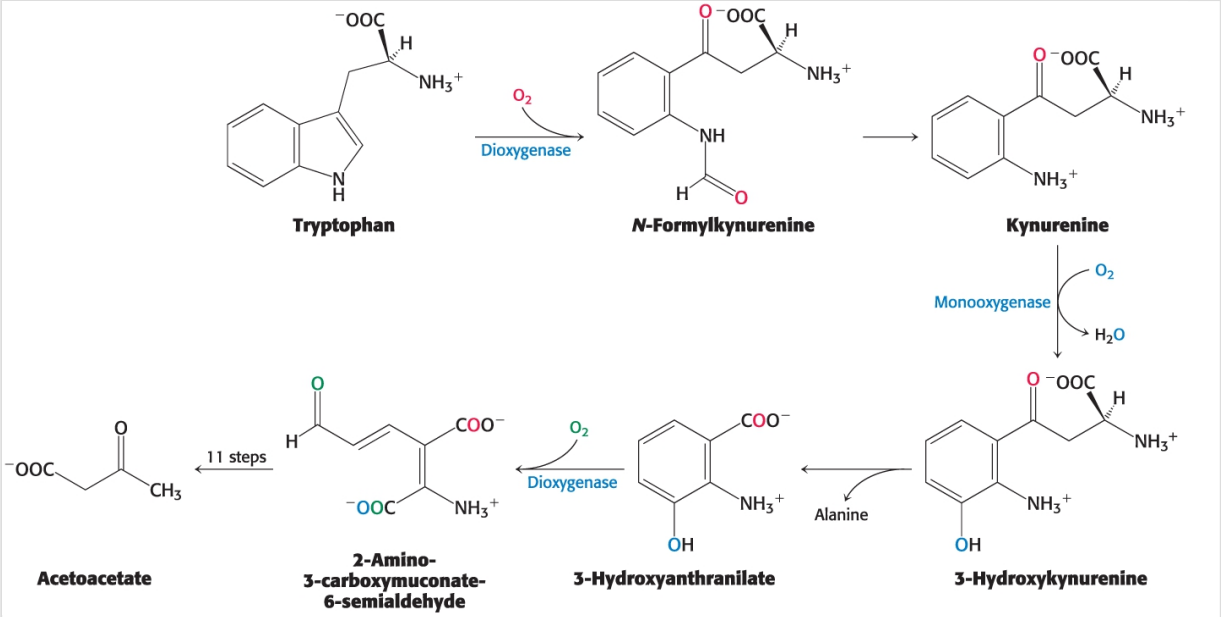

FIGURE 23.27 Tryptophan degradation requires multiple oxygenases and numerous steps.
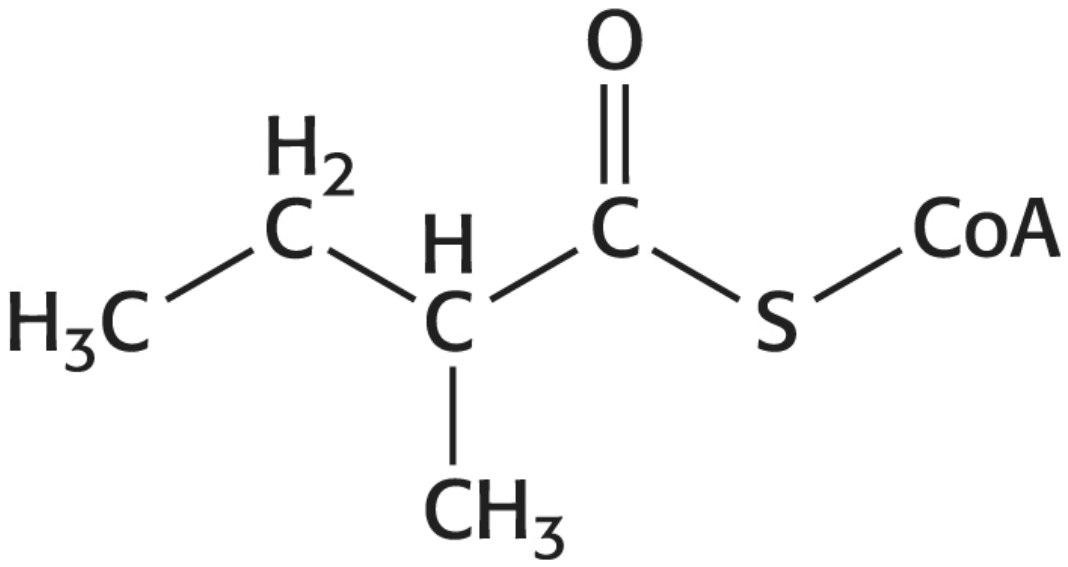
Note that both alanine and acetoacetate are ultimately formed.

Protein metabolism helps to power the flight of migratory birds

Earlier we learned that fats are the primary fuel for migratory birds that fly great distances without feeding (Section 22.1). Proteins are also degraded to contribute fuel for these impressive feats of endurance. Why would proteins be degraded? There are several likely reasons. First, since the birds are not feeding, proteins involved with digestion and transport of nutrients from the gut are not needed and thus can be

degraded. Second, gluconeogenesis is required to provide glucose for the central nervous system, and the glucogenic amino acids will meet this need. Moreover, some amino acid carbon skeletons can replenish citric acid cycle intermediates to facilitate fat metabolism. Third, the reduction in body mass resulting from protein degradation will reduce the energy cost of flight. There is one final benefit. In addition to not feeding during flight, the migratory birds cannot hydrate, yet they still require water. While the catabolism of fats yields little water — $0.029\ g\ H_2O\ kJ^{-1}$ — protein provides fivefold more water than fats — $0.155\ g\ H_2O\ kJ^{-1}$ — and may be a vital source of water for migratory flights.

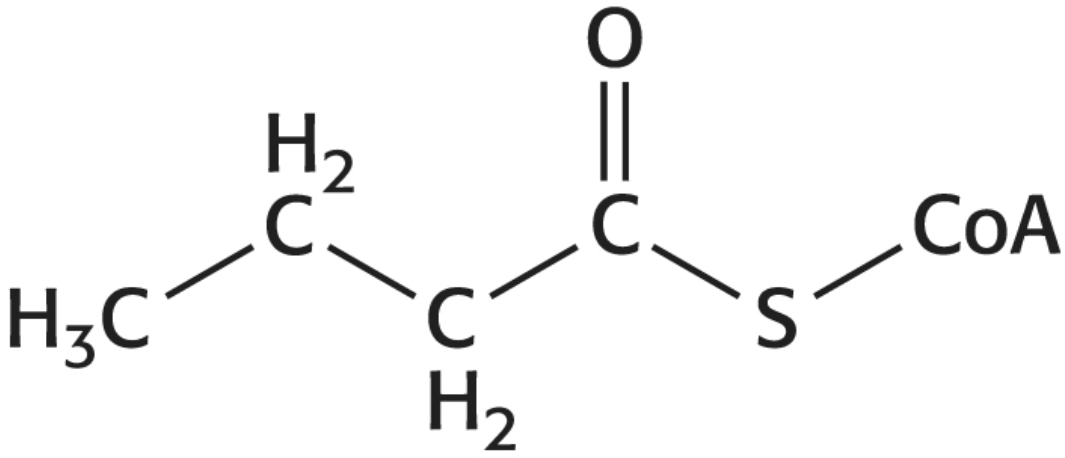
Example



Determining Metabolic Products of Amino Acid Degradation

Problem:

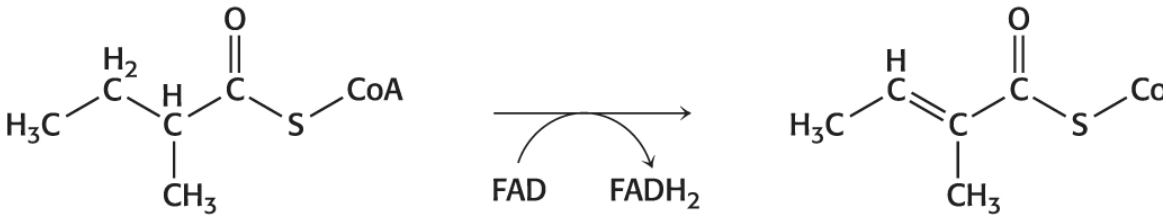
Isoleucine is said to be both a ketogenic and glucogenic amino acid. Starting from 2-methylbutyryl CoA, a degradation intermediate of isoleucine, show that it is both ketogenic and glucogenic.



Getting Started:

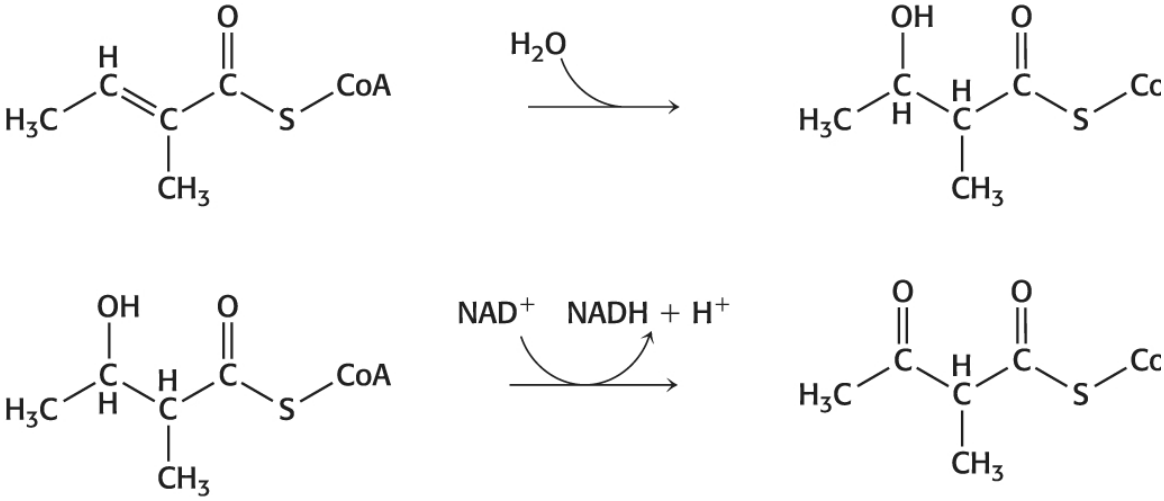
Let's begin by thinking about the structure of 2-methylbutyryl CoA. We have seen similar molecules before. What general type of biochemical does this look like?

2-Methylbutyryl CoA



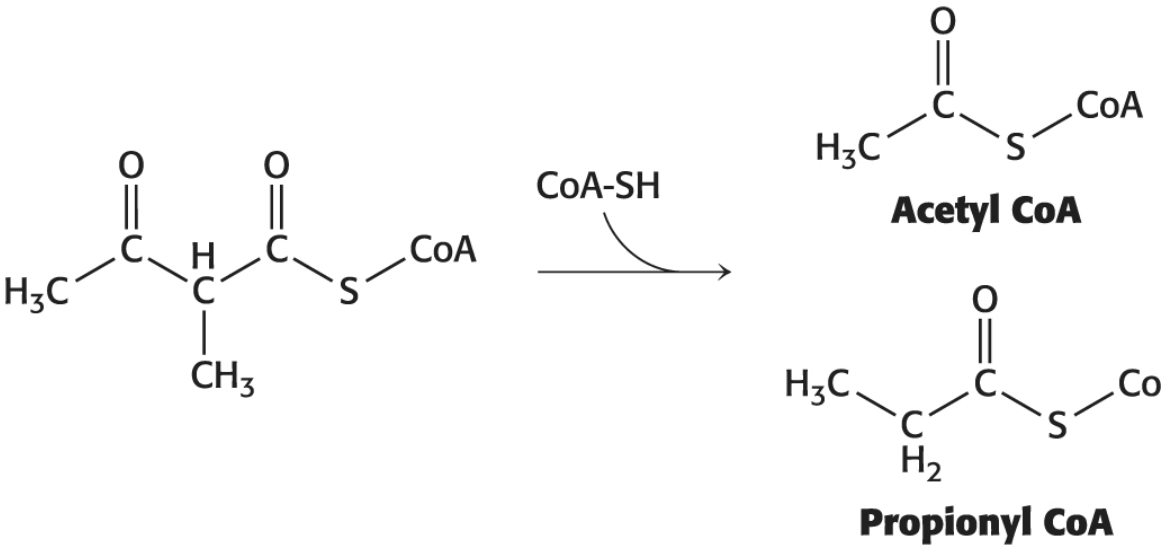
It looks like a fatty acyl CoA, except that there is a methyl group where a hydrogen would be in a fatty acyl CoA. To see this more clearly, let's look at the molecule with the substitution of a hydrogen for the methyl group, butyryl CoA.

Butyryl CoA



Analyze:

Thinking back to Chapter 22, how would you degrade butyryl CoA? β-Oxidation would be the way to go. So, let's apply β-oxidation to 2-methylbutyryl CoA. Recall that the first step in the β-oxidation is the introduction of a double bond at the β-carbon, accompanied with reduction of FAD. Recall that we saw the reaction in the conversion of succinate into fumarate in the citric acid cycle as well as in β-oxidation.

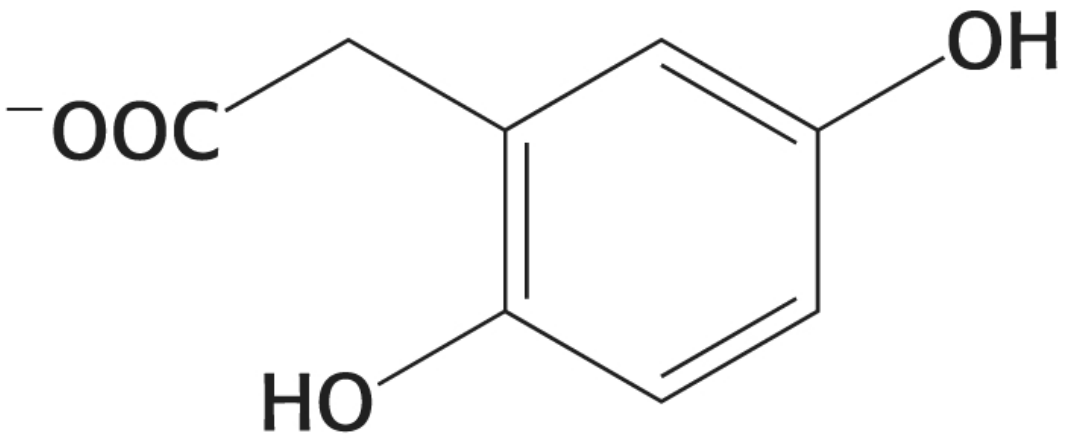


2-Methylbutyryl CoA

Next, recall that the next two reactions of β-oxidation are a hydration followed by an oxidation, with the concomitant reduction of NAD^+.

Finally, the last reaction is thiolysis by addition of CoA.

Thiolysis yields acetyl CoA and propionyl CoA.



Reflect:

Acetyl CoA can be used for ketone body production, accounting for the fact that isoleucine is a ketogenic amino acid. What is the metabolic fate of propionyl CoA? As we saw in Section 22.3, propionyl CoA is converted into the citric acid intermediate succinyl CoA, which can be metabolized to oxaloacetate, a gluconeogenic substrate (Section 16.4). So we have shown that isoleucine is, in fact, both a ketogenic and a glucogenic amino acid.

23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

Many unusual biochemical products are produced or overproduced in a disease state, and can be detected in the urine. Additionally, errors in amino acid metabolism provided some of the first examples of biochemical defects linked to pathological conditions. For instance, *alkaptonuria*, an inherited metabolic disorder caused by the absence of homogentisate oxidase, was described in 1902. Homogentisate, a normal intermediate in the degradation of phenylalanine and tyrosine (Figure 23.26), accumulates in alkaptonuria because its degradation is blocked. Homogentisate is excreted in the urine, which turns dark on standing as homogentisate is oxidized and polymerizes into a dark pigment. Urine has been used as a marker for disease for centuries (**Figure 23.28**).

Homogentisate

Air

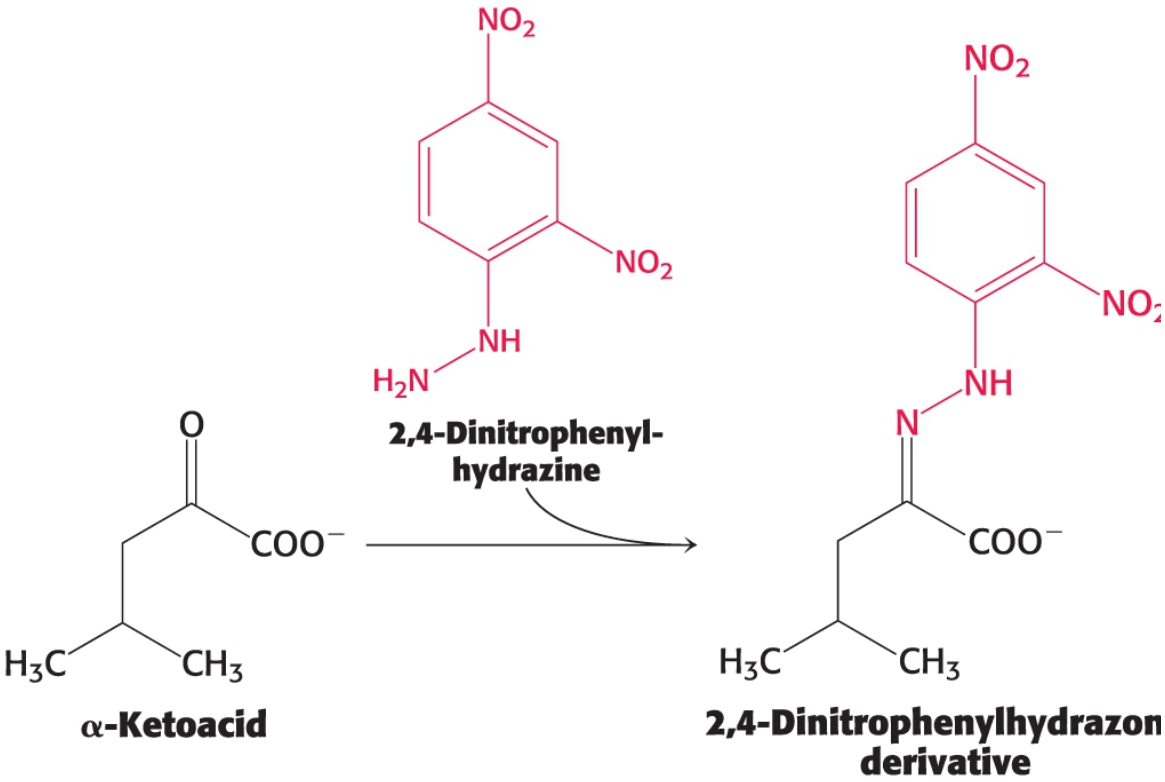
FIGURE 23.28 Urine has long been used to diagnose diseases due to the excretion of unusual biochemical products. This fourteenth-century hand-colored woodcut from Germany depicts a wheel that classifies urine samples according to their color and consistency. In the middle of the wheel, a doctor inspects a patient's urine by sight, smell, and taste. The vials on the wheel aided physicians in diagnosing diseases.

Branched-chain ketoaciduria is a serious disorder of branched-chain amino acid degradation

Although alkaptonuria is a relatively harmless condition, such is not the case with other errors in amino acid metabolism. In branched-chain ketoaciduria, most commonly called *maple syrup urine disease*, the oxidative decarboxylation of α-ketoacids derived from valine, isoleucine, and leucine is blocked because the branched-chain dehydrogenase is missing or defective. Hence, the levels of these α-ketoacids and the branched-chain amino acids that give rise to them are markedly elevated in both blood and urine. The urine of patients has the odor of maple syrup, hence the common name of the disease. The disease usually leads to cognitive and physical disabilities unless the patient is placed on a diet low in valine, isoleucine, and leucine early in life. Thankfully, the disease can be readily detected in newborns by screening urine samples with 2,4-dinitrophenylhydrazine, which reacts with α-ketoacids to form 2,4-dinitrophenylhydrazone derivatives. A definitive diagnosis can be made by mass spectrometry. **Table 23.4** lists some other diseases of amino acid metabolism.



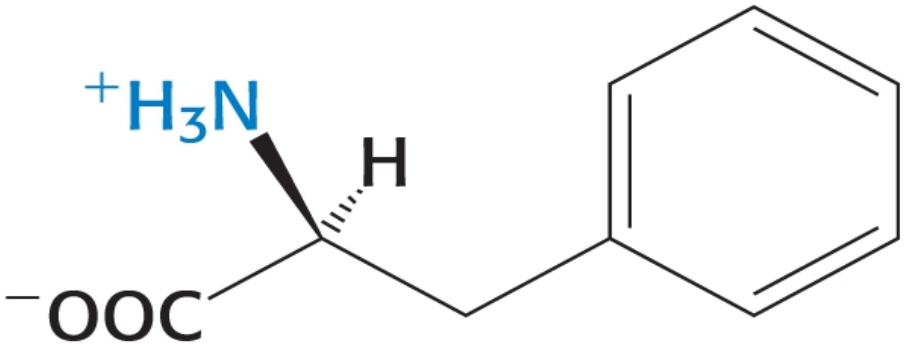


TABLE 23.4 Inborn errors of amino acid metabolism

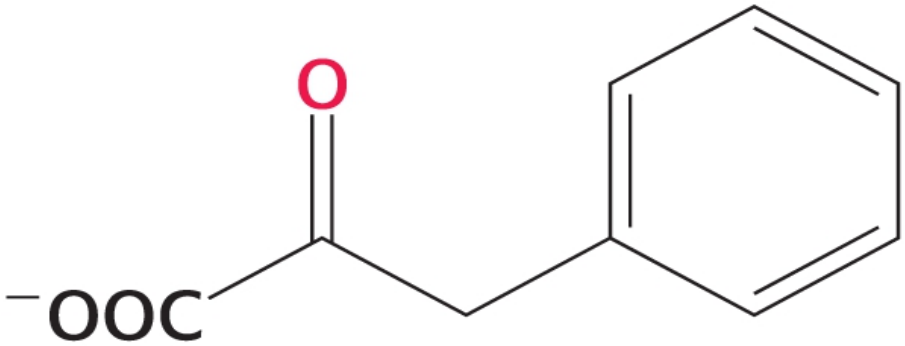
Disease	Enzyme deficiency	Symptoms
Citrullinemia	Arginosuccinate lyase	Lethargy, seizures, reduced muscle tension
Tyrosinemia	Various enzymes of tyrosine degradation	Weakness, liver damage, cognitive disability
Albinism	Tyrosinase	Absence of pigmentation
Homocystinuria	Cystathionine β-synthase	Scoliosis, muscle weakness, cognitive disability, thin blond hair

Hyperlysine mia	α-Aminoadipic semialdehyde dehydrogenase	Seizures, cognitive disability, lack of muscle tone, ataxia

Phenylketonuria is one of the most common metabolic disorders



Perhaps the best known of the diseases of amino acid metabolism is **phenylketonuria**, which occurs with a prevalence of 1 in 10,000 births. Phenylketonuria is caused by an absence or deficiency of phenylalanine hydroxylase or, more rarely, of its tetrahydrobiopterin cofactor. Phenylalanine accumulates in all body fluids because it cannot be converted into tyrosine. Normally, three-quarters of phenylalanine molecules are converted into tyrosine, and the other quarter become incorporated into proteins. Because the major outflow pathway is blocked in phenylketonuria, the blood level of phenylalanine is typically at least 20-fold as high as in unaffected people. Minor fates of phenylalanine in people who process phenylalanine normally, such as the formation of phenylpyruvate which is a phenyl ketone, become major products which are then excreted in the urine. Indeed, the initial description of phenylketonuria in 1934 was made by observing the reaction of phenylpyruvate in the urine of phenylketonurics with $FeCl_3$, which turns the urine olive green.

Phenylalanine

α-Ketoacid

α-Amino acid

Phenylpyruvate

Untreated phenylketonuria results almost inexorably in severe cognitive disabilities. Babies with phenylketonuria do not show symptoms at birth but are severely affected by the disease by age 1 if untreated, and if they remain untreated, life expectancy is between 20 and 30 years. The therapy for phenylketonuria is a low-phenylalanine diet supplemented with tyrosine, because tyrosine is normally synthesized from phenylalanine. The aim is to provide just enough phenylalanine to meet the needs for growth and replacement. Proteins that have a low content of phenylalanine, such as casein from milk, are hydrolyzed and phenylalanine is removed by adsorption.

Early diagnosis of phenylketonuria is essential and has been accomplished by mass screening programs of all babies born in the United States and Canada. The phenylalanine level in the blood is the preferred diagnostic criterion because it is more sensitive and reliable than the $FeCl_3$ test. Prenatal diagnosis of phenylketonuria with DNA probes has become feasible because the gene has been cloned and the exact locations of many mutations have been discovered in the protein.

The biochemical basis of the cognitive disabilities is not firmly established, but one hypothesis suggests that the lack of hydroxylase reduces the amount of tyrosine, an important precursor to neurotransmitters such as dopamine. Moreover, high concentrations of phenylalanine prevent amino acid transport of any tyrosine present as well as tryptophan, a precursor to the neurotransmitter serotonin, into the brain. Because all three of the amino acids are transported by the same carrier, phenylalanine will saturate the carrier, preventing access to tyrosine and tryptophan. Lack of these amino acids will impair protein synthesis in the brain. Finally, high blood levels of phenylalanine result in higher levels of phenylalanine in the brain, and evidence suggests this elevated concentration inhibits glycolysis at

pyruvate kinase, disrupts myelination of nerve fibers, and reduces the synthesis of several neurotransmitters.

Self-Check Question

The end products of tryptophan degradation are acetyl CoA and acetoacetyl CoA, yet tryptophan is a gluconeogenic amino acid in animals. Explain.

Chapter 23 Summary

23.1 Proteins Are Degraded to Amino Acids

- Dietary protein is digested in the intestine, producing amino acids that are transported throughout the body.
- Cellular proteins are degraded at widely variable rates, ranging from minutes to the life of the organism. The turnover of cellular proteins is a regulated process requiring complex enzyme systems.

23.2 Protein Turnover Is Tightly Regulated

- Proteins to be degraded by the proteasome are conjugated with ubiquitin, a small conserved protein. The ubiquitin-conjugating system is composed of three distinct enzymes.
- The proteasome is a large, barrel-shaped complex that digests ubiquitinated proteins at the expense of ATP. The resulting amino acids provide a source of precursors for protein, nucleotide bases, and other nitrogenous compounds.

23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen

- Surplus amino acids are used as building blocks and as metabolic fuel. The first step in their degradation is the removal of their α-amino groups by transamination to yield α-ketoacids. Transamination is catalyzed by aminotransferases that all use pyridoxal phosphate as a coenzyme.
- The α-amino group funnels into α-ketoglutarate to form glutamate, which is then oxidatively deaminated in the liver by glutamate dehydrogenase to yield NH_4^+ and α-ketoglutarate.

23.4 Ammonium Ions Are Converted into Urea in Most Terrestrial Vertebrates

- The first step in the synthesis of urea is the formation of carbamoyl phosphate, which is synthesized from HCO_3^-, NH_3, and two molecules of ATP by carbamoyl phosphate synthetase I.
- A second reaction in the mitochondria produces citrulline, which leaves the mitochondrion and condenses with aspartate, which provides the second nitrogen of what will become urea. Two subsequent reactions in the cytosol produce urea and regenerate the intermediates of the cycle.

23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates

- The carbon atoms of degraded amino acids are converted into pyruvate, acetyl CoA, acetoacetate, or an intermediate of the citric acid cycle.
- Most amino acids are solely glucogenic, two are solely ketogenic, and a few are both ketogenic and glucogenic.
- Carbon skeletons of glucogenic amino acids enter major metabolic pathways as pyruvate, oxaloacetate, α-ketoglutarate, or succinyl CoA. Ketogenic amino acids produce acetoacetate or acetyl CoA.
- The rings of aromatic amino acids are degraded by oxygenases. Phenylalanine hydroxylase, a monooxygenase, uses tetrahydrobiopterin as the reductant. One of the oxygen atoms of O_2 emerges in tyrosine and the other in water.
- Subsequent steps in the degradation of these aromatic amino acids are catalyzed by dioxygenases, which catalyze the insertion of both atoms of O_2 into organic products.

23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

- Errors in amino acid metabolism were sources of some of the first insights into the correlation between pathology and biochemistry.
- Phenylketonuria, the best known of the many hereditary errors of amino acid metabolism, results from the accumulation of high levels of phenylalanine in the body fluids. This accumulation leads to cognitive disabilities unless the patient is placed on low-phenylalanine diets immediately after birth.

Key Terms

ubiquitin
degron
proteasome
aminotransferases (transaminases)
glutamate dehydrogenase
pyridoxal phosphate (PLP)
glucose–alanine cycle
urea cycle
carbamoyl phosphate synthetase I
ketogenic amino acid
glucogenic amino acid
phenylketonuria

Problems

1. What are the steps required to attach ubiquitin to a target protein? 1, 2

2. Protein hydrolysis is an exergonic process, yet the 26S proteasome is dependent on ATP hydrolysis for activity. 1, 3

a. Explain why ATP hydrolysis is required by the 26S proteasome.
b. Small peptides can be hydrolyzed without the expenditure of ATP. How does this information concur with your answer to part (a)?

3. Aminotransferases require which of the following cofactors?

a. $NAD^+ / NADP^+$
b. Pyridoxal phosphate
c. Thiamine pyrophosphate
d. Biopterin

4. Which of the following compounds readily accepts amino groups from amino acids?

a. Glutamine
b. Isocitrate
c. Malate
d. α-Ketoglutarate

5. The immediate donors of the nitrogen atoms of urea are:

a. Aspartate and glutamate
b. Glutamate and carbamoyl phosphate
c. Aspartate and carbamoyl phosphate
d. Glutamine and aspartate

6. Which compound of the urea cycle is synthesized in the mitochondria and transported into the cytoplasm?

a. Ornithine

b. Citrulline
c. Argininosuccinate
d. Arginine

7. Name the α-ketoacid that is formed by the transamination of each of the following amino acids: 4, 5

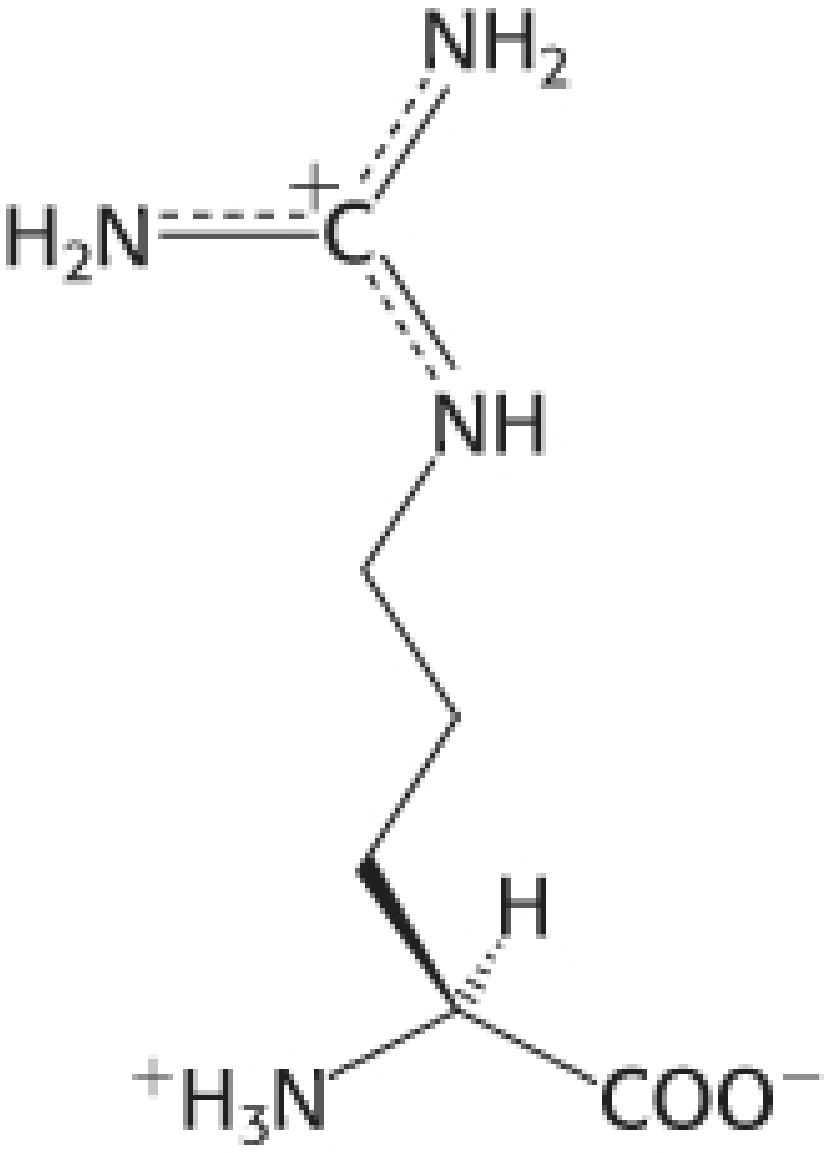
a. Alanine
b. Aspartate
c. Glutamate
d. Leucine
e. Phenylalanine
f. Tyrosine

8.

a. Write a balanced equation for the conversion of aspartate into glucose through the intermediate oxaloacetate. Which coenzymes participate in this transformation?
b. Write a balanced equation for the conversion of aspartate into oxaloacetate through the intermediate fumarate.

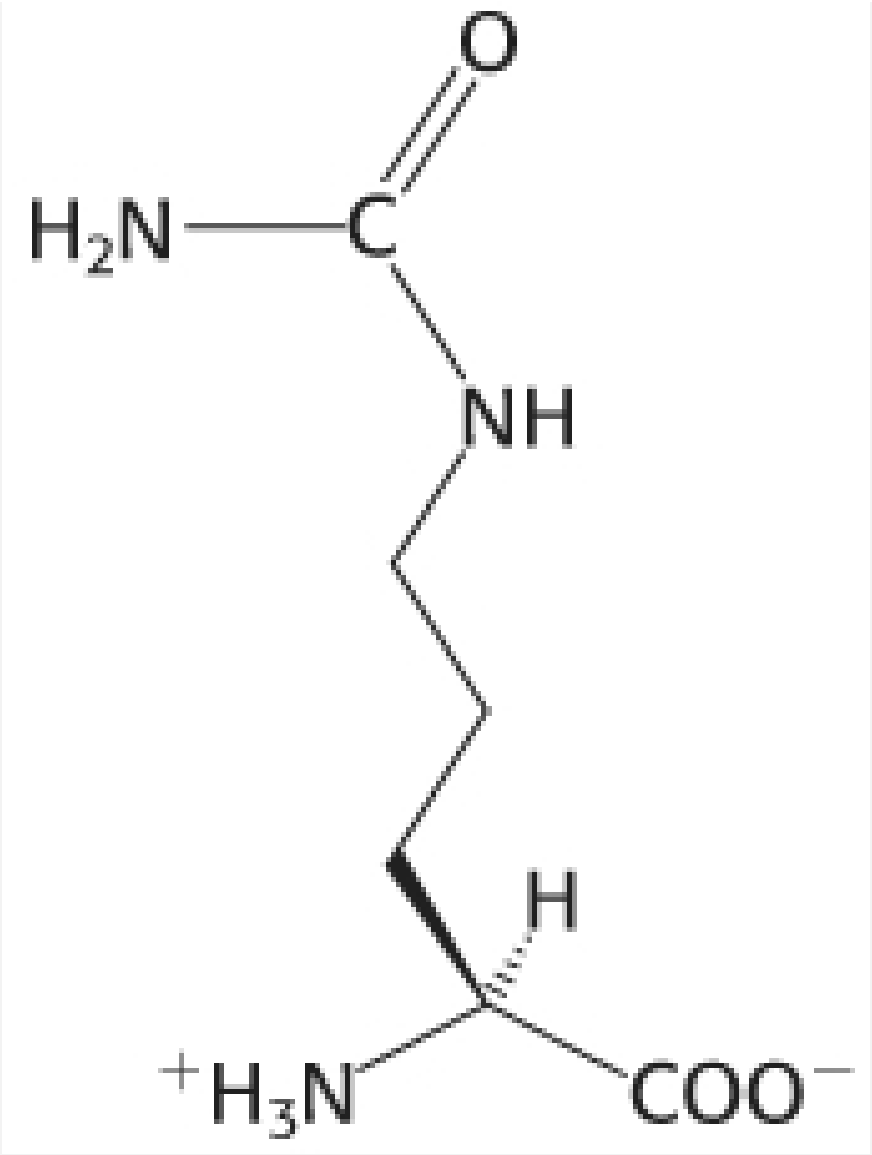
9. What amino acids yield citric acid cycle components and glycolysis intermediates when deaminated? 4, 5

10. Match the property on the left with the biochemical on the right. 4



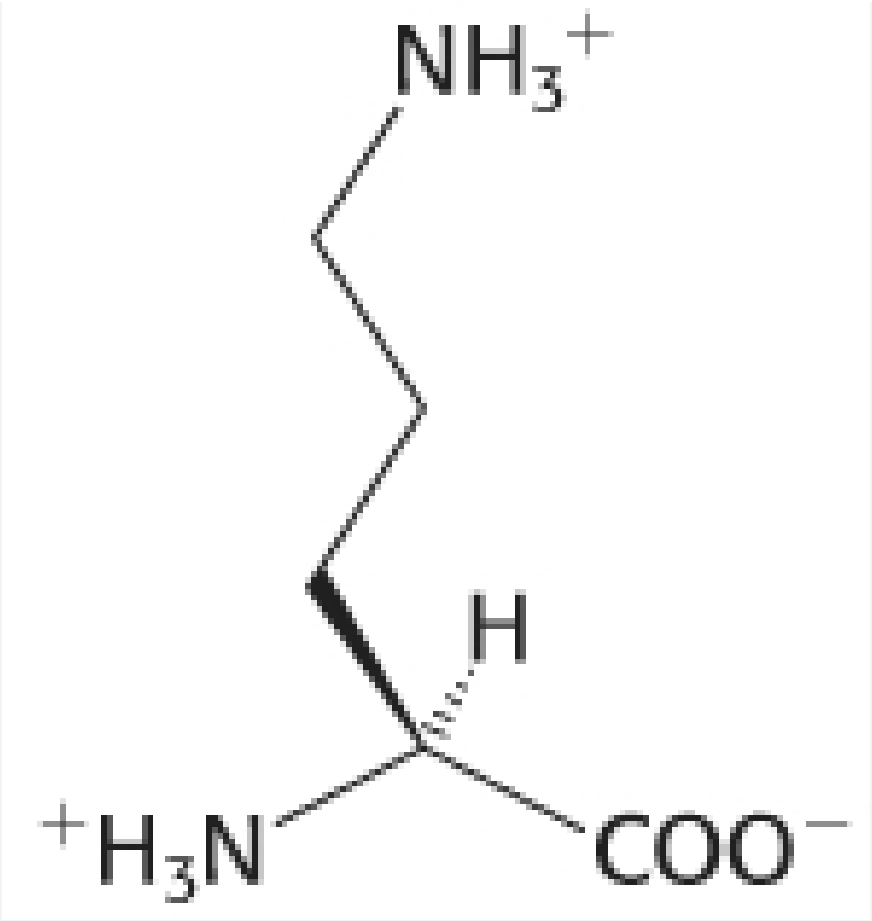
1. Formed from NH_4^+	1. Aspartate
2. Hydrolyzed to yield urea	2. Urea
3. A second source of nitrogen	3. Ornithine

4. Reacts with aspartate	4. Carbamoyl phosphate
5. Cleavage yields fumarate	5. Arginine
6. Accepts the first nitrogen	6. Citrulline
7. Final product	7. Argininosuccinate

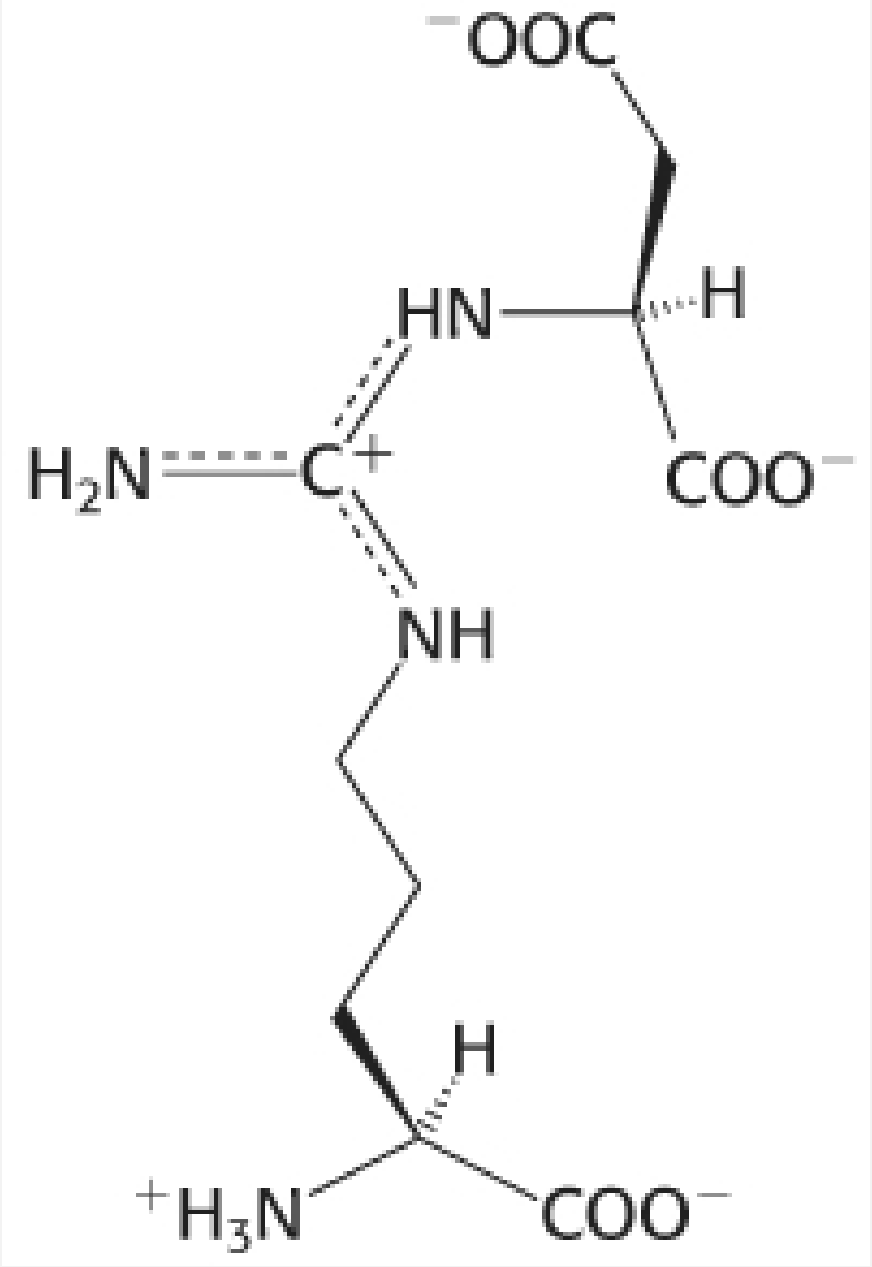


---

11. Identify structures A–D, and place them in the order that they appear in the urea cycle. 4



A.



B.

C.

D.

12. Four high-transfer-potential phosphoryl groups are consumed in the synthesis of urea according to the stoichiometry given in Section 23.4. In this reaction, aspartate is

converted into fumarate. Suppose that fumarate is converted into oxaloacetate. What is the resulting stoichiometry of urea synthesis? How many high-transfer-potential phosphoryl groups are spent?

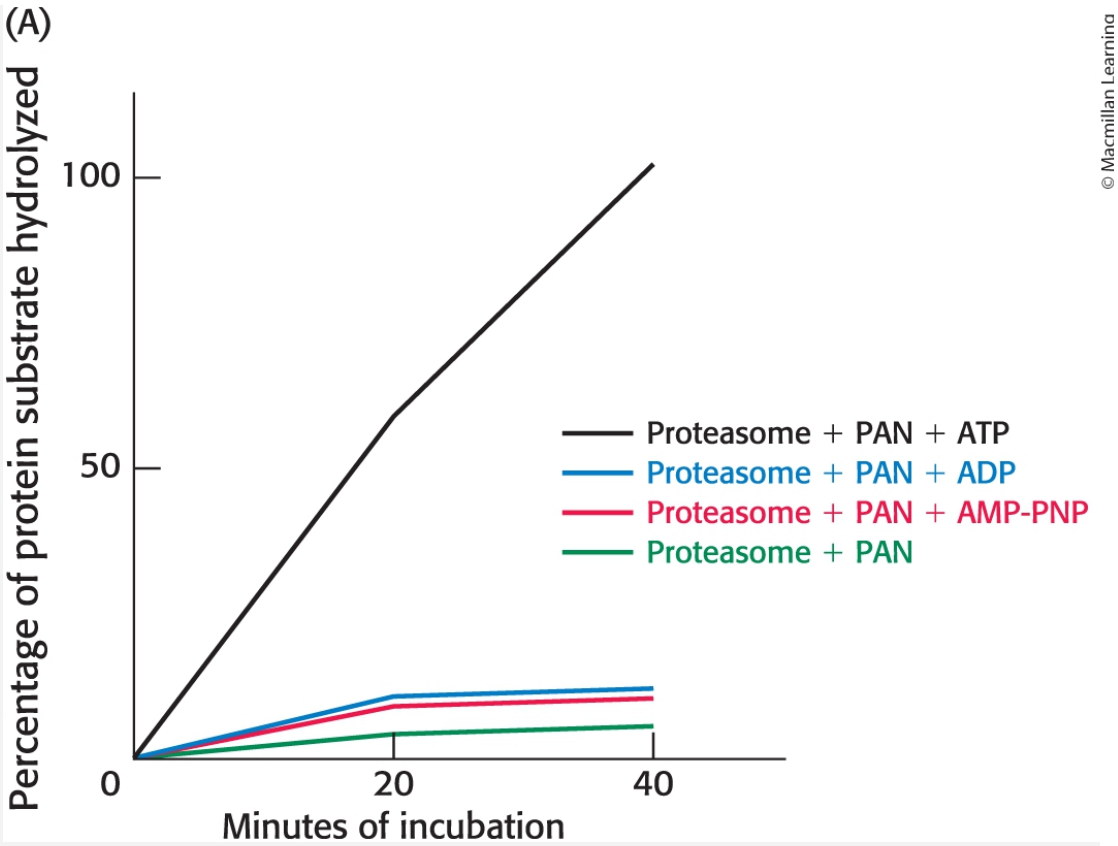
13. A friend bets you a million dollars that you can't prove that the urea cycle is linked to the citric acid cycle and other metabolic pathways. Can you prove it?

14. Why should phenylketonurics avoid using aspartame, an artificial sweetener? (Hint: Aspartame is L-aspartyl-L-phenylalanine methyl ester.) 6

15. What is meant by the terms *ketogenic amino acids* and *glucogenic amino acids*? 5

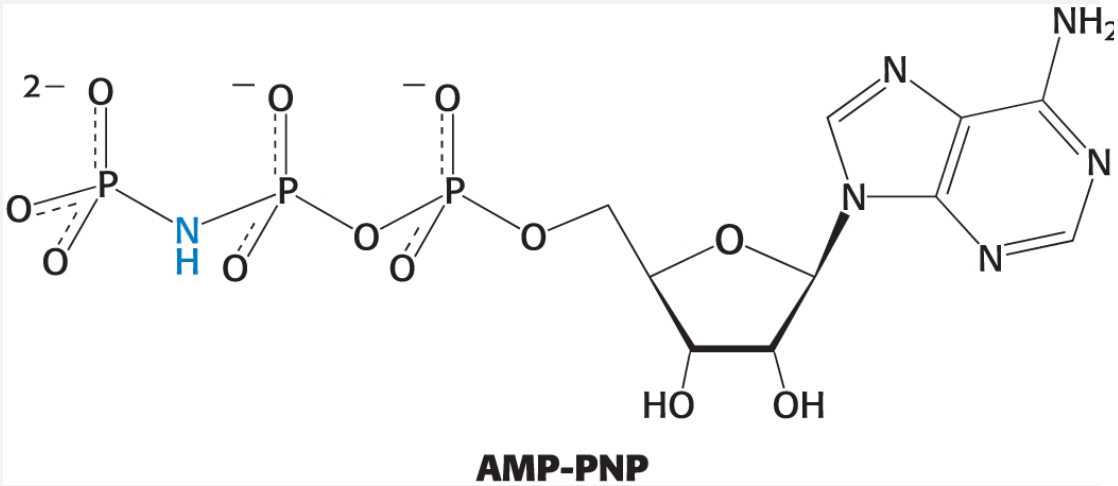
16. Pyruvate dehydrogenase complex and α-ketoglutarate dehydrogenase complex are huge enzymes consisting of three discrete enzymatic activities. Which amino acids require a related enzyme complex, and what is the name of the enzyme?

17. The carbon skeletons of the 20 common amino acids can be degraded into a limited number of end products. What are the end products, and in what metabolic pathway are they commonly found? 5



18. In Chapter 5, we learned that there are two types of bisubstrate reactions, sequential and double-displacement. Which type characterizes the action of aminotransferases? Explain your answer.

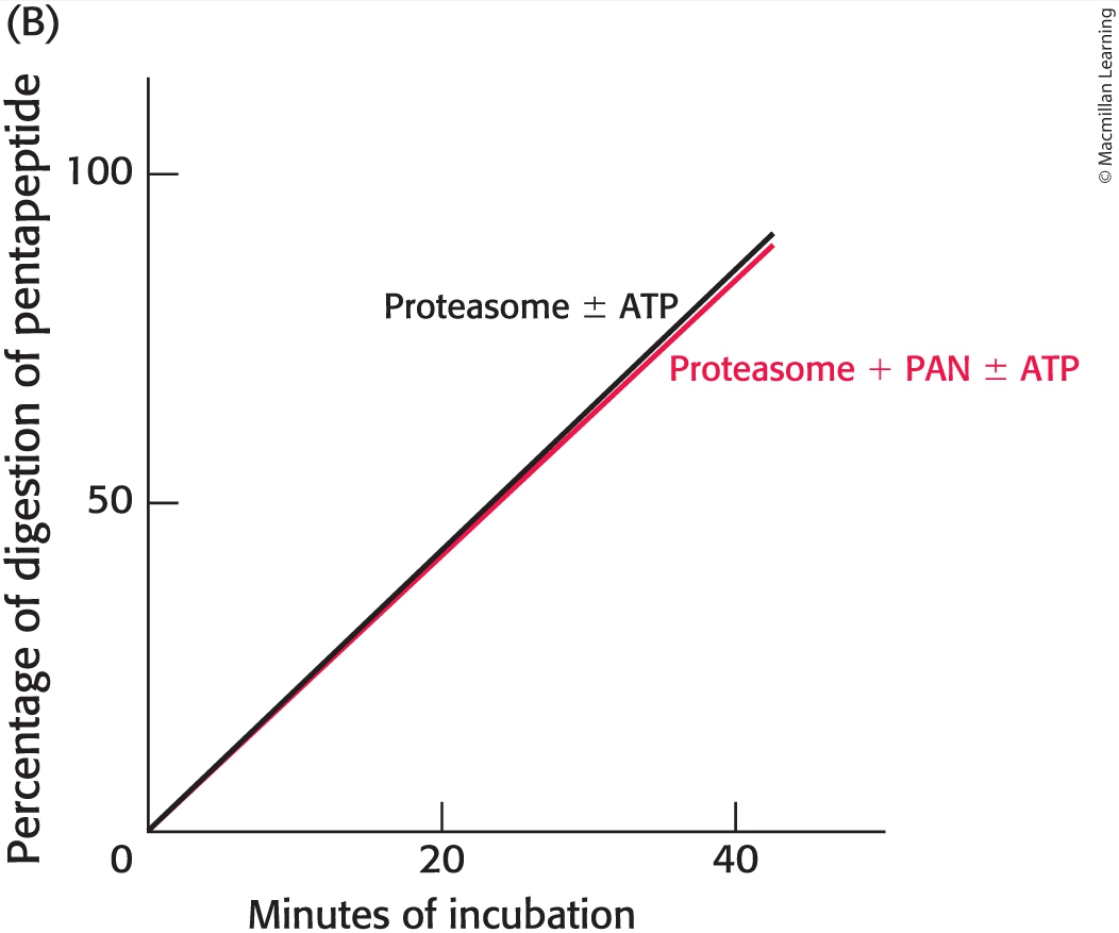
19. Within a few days after a fast begins, nitrogen excretion accelerates to a higher-than-normal level. After a few weeks, the rate of nitrogen excretion falls to a lower level and continues at this low rate. However, after the fat stores have been depleted, nitrogen excretion rises to a high level. 4, 5



a. What events trigger the initial surge of nitrogen excretion?
b. Why does nitrogen excretion fall after several weeks of fasting?
c. Explain the increase in nitrogen excretion when the lipid stores have been depleted.

20. In eukaryotes, the 20S proteasome component in conjunction with the 19S component degrades ubiquitinated proteins with the hydrolysis of a molecule of ATP. Archaea lack ubiquitin and the 26S proteasome but do contain a 20S proteasome. Some archaea also contain an ATPase that is homologous to the ATPases of the eukaryotic 19S component. This archaeal ATPase activity was isolated as a 650-kDa complex (called PAN) from the archaeon *Thermoplasma*, and experiments were performed to determine if PAN could enhance the activity of the 20S proteasome from *Thermoplasma* as well as other 20S proteasomes.

Protein degradation was measured as a function of time and in the presence of various combinations of components. Graph A shows the results. 1, 2, 3



© Macmillan Learning

AMP-PNP

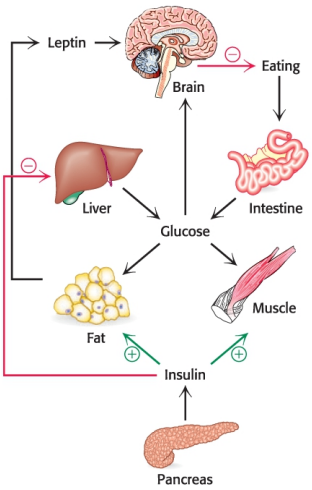
a. What is the effect of PAN on archaeal proteasome activity in the absence of nucleotides?
b. Which nucleotide stimulates protein digestion?
c. What evidence suggests that ATP hydrolysis, and not just the presence of ATP, is required for digestion?

A similar experiment was performed with a small peptide as a substrate for the proteasome instead of a protein. The results obtained are shown in graph B.

d. How do the requirements for peptide digestion differ from those of protein digestion?
e. Suggest some reasons for the difference.

The ability of PAN from the archaeon *Thermoplasma* to support protein degradation by the 20S proteasomes from the archaeon

Methanosarcina and rabbit muscle was then examined.



Percentage of digestion of protein substrate (Source of the 20S proteasome)

Additions	Thermoplasma	Methanosarcina	Rabbit muscle
None	11	10	10
PAN	8	8	8
PAN + ATP	100	40	30
PAN + ADP	12	9	10

[Data from P. Zwickl, D. Ng, K. M. Woo, H.-P. Klenk, and A. L. Goldberg, An archaebacterial ATPase, homologous to ATPase in the eukaryotic 26S proteasome, activates protein breakdown by 20S proteasomes, *J. Biol. Chem.* 274(37):26008–26014, 1999.]

f. Can the *Thermoplasma* PAN augment protein digestion by the proteasomes from other organisms?
g. What is the significance of the stimulation of rabbit muscle proteasome by *Thermoplasma* PAN?

Chapter 24
Integration of Energy Metabolism

Debbie Eckert/Alamy
© Macmillan Learning

The maintenance of blood-glucose levels requires the integration of many elaborate metabolic pathways. Disorders affecting the principal organs, hormones, and pathways involved can lead to disease. Type 1 diabetes, for example, results from the dysfunction of specific pancreatic cells that normally release the hormone insulin after meals. Fundraising events support research for better treatments for the approximately 9 million people worldwide who are affected by type 1 diabetes.

Outline

24.1 Caloric Homeostasis Is a Means of Regulating Body Weight
24.2 The Fasted–Fed Cycle Is a Response to Eating and Sleeping Behaviors
24.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity

24.4 Exercise Beneficially Alters the Biochemistry of Cells
24.5 Starvation Induces Protein Wasting and Ketone Body Formation
24.6 Ethanol Alters Energy Metabolism in the Liver

Learning Goals

By the end of this chapter, you should be able to:

1. Describe caloric homeostasis and its biochemical importance.
2. Explain the role of the neurotransmitters and hormones in maintaining caloric homeostasis.
3. Differentiate between type 1 and type 2 diabetes, and explain how each develops.
4. Explain how different forms of exercise alter cellular biochemistry.
5. Contrast the biochemical responses to the nightly fasted–fed cycle with those of prolonged starvation.
6. Explain how ethanol alters metabolism in the liver.

So far we have examined metabolism one pathway at a time and have seen how energy is extracted from fuels and used to power biosynthetic reactions. In Chapters 25 through 31, we will extend our study of biosynthetic reactions to the synthesis of nucleic acids, diverse lipids, and proteins. First, however, in this chapter we will take a step back to examine large-scale biochemical interactions that constitute the physiology of the organism and the regulation of energy at the organismal level. We will examine how various biochemical pathways and tissues interact with one another in both resting metabolism and in a variety of states of metabolic perturbation, namely: obesity, fasting, diabetes, intense exercise, starvation, and excessive alcohol consumption.

24.1 Caloric Homeostasis Is a Means of Regulating Body Weight

In this section we will address an apparently simple but actually quite complex question: at the biochemical level, how does an organism know when to eat and when to refrain from eating? The ability to maintain adequate, but not excessive, energy stores is called **caloric homeostasis** or **energy homeostasis**. By now in our study of biochemistry, we are well aware of the fact that carbohydrates, lipids, and the carbon skeletons of amino acids are sources of energy (**Figure 24.1**). We consume these energy sources as foods and capture free energy by re-forming ATP, which we use to power our lives. As illustrated in Figure 24.1, to do this requires an incredible amount of coordination among numerous metabolic pathways that we have explored in Chapters 16 through 23.

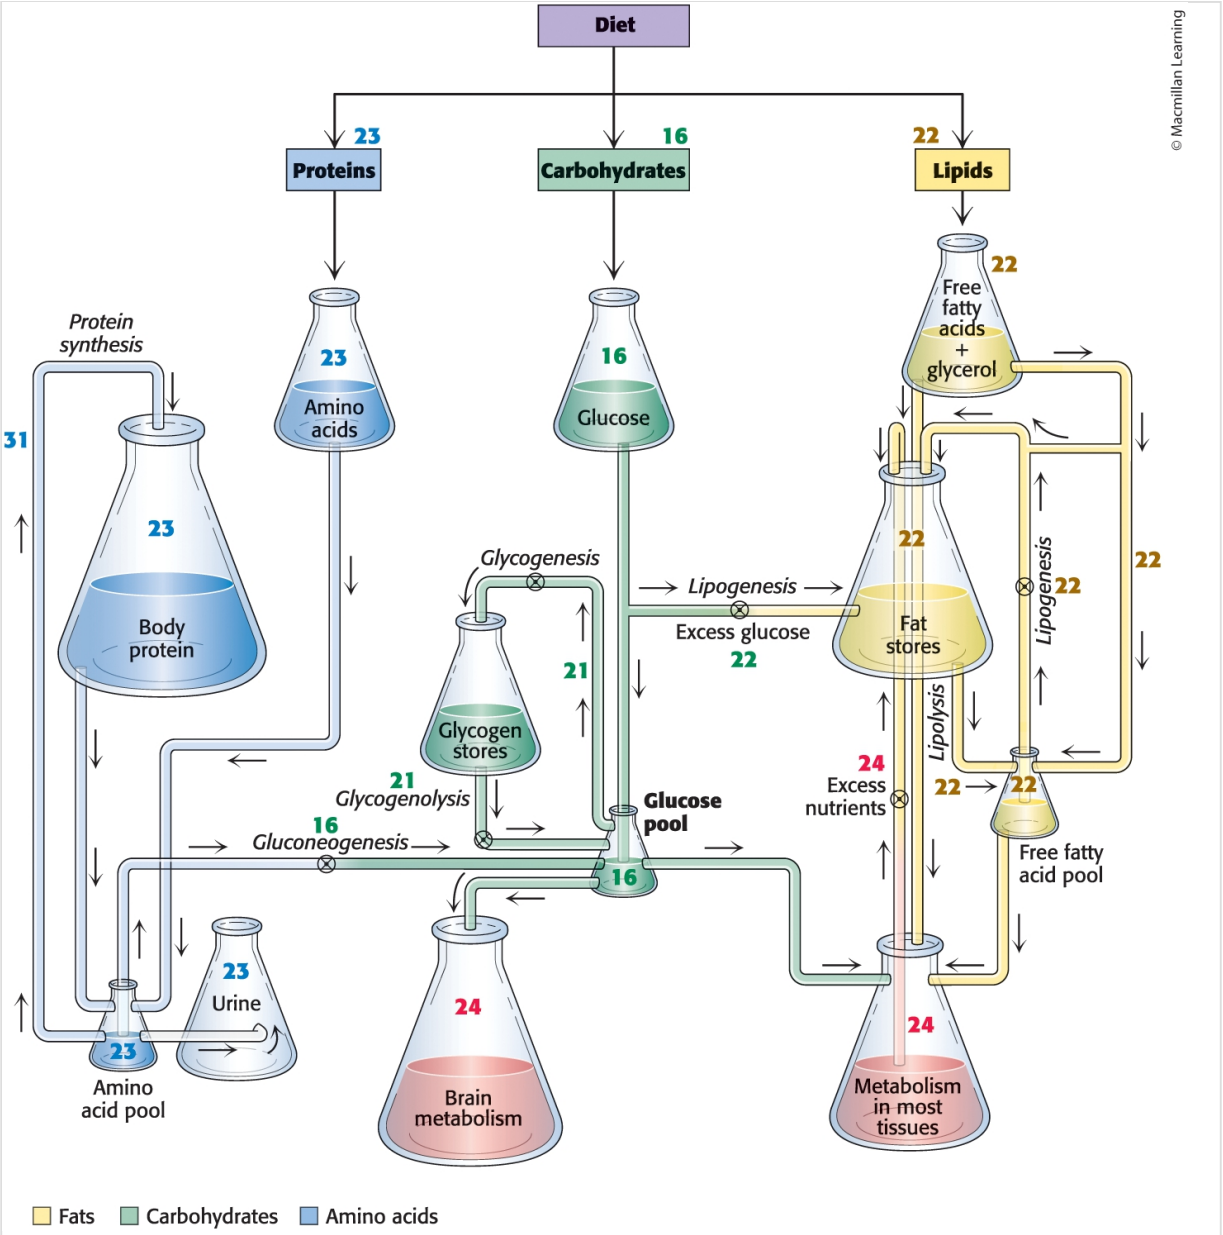


FIGURE 24.1 Maintaining homeostasis requires complex metabolic regulation that coordinates the use of nutrient pools. The numbers indicate the chapters in which the topics are discussed.

[Information from D. U. Silverthorn, *Human Physiology: An Integrated Approach,* 3rd ed. (Pearson, 2004), Fig. 22-2.]

However, despite this mechanistic complexity, like all energy transformations our energy consumption and expenditure are governed

by the laws of thermodynamics. Recall that the First Law of Thermodynamics states that energy can neither be created nor destroyed. Translated into the practical terms of our diets:

$$\text{Energy consumed} = \text{energy expended} + \text{energy stored}$$

This simple equation has severe physiological and health implications: according to the First Law of Thermodynamics, if we consume more energy than we expend, we will eventually become overweight or obese. Regardless of the original source, any excess energy molecules are ultimately converted to triacylglycerols which are stored in adipocytes. The number of adipocytes becomes fixed in adults, and so obesity results in engorged adipocytes. Indeed, the cells may increase as much as 1000-fold in size. Obesity is generally defined as a body mass index (BMI) of more than $30\ \text{kg m}^{-2}$, whereas overweight is defined as a BMI of more than $25\ \text{kg m}^{-2}$.

Obesity is a worldwide problem that is now considered a pandemic, with the number of people considered obese having tripled since 1975 and totaling 650 million people. Obesity is identified as a risk factor in a host of pathological conditions, including diabetes mellitus, hypertension, and cardiovascular disease (Table 24.1). We will consider the biochemical basis of pathologies caused by obesity later in the chapter.

TABLE 24.1 Health consequences of obesity

Coronary heart disease
Type 2 diabetes
Cancers (endometrial, breast, colon, and others)

Hypertension (high blood pressure)
Dyslipidemia (disruption of lipid metabolism)
Stroke
Liver and gallbladder disease
Sleep apnea and respiratory problems
Osteoarthritis (degeneration of joint cartilage/bone)
Gynecological problems (abnormal menses, infertility)
Male infertility problems

Information from Centers for Disease Control and Prevention website (www.cdc.gov).

Before we undertake a biochemical analysis of the results of overconsumption, let us consider why the obesity pandemic is occurring in the first place. There are several overlapping explanations. The first is a commonly held view that our bodies are programmed to rapidly store excess calories in times of plenty, an evolutionary adaptation to the scarcity of food. Consequently, we store calories as if a fast might begin tomorrow, regardless of whether it actually does. We are also no longer subject to predation, which once would have applied selective pressure to maintain low body fats so that our ancestors could more easily flee from an attack.

Another factor is that calorie-dense, highly palatable foods — rich in sugar and fats — are now more readily accessible, stimulating the same reward pathways in the brain that are triggered by drugs such as cocaine. Such reward pathways can be strong enough to override appetite-suppressing signals. These foods, along with other environmental factors such as pollution, can also affect our intestinal

microbiome — the bacteria and other microbes that inhabit our guts — that play a significant role in how we process our food.

Finally, although genetics cannot explain the obesity pandemic affecting vast amounts of the entire human *population*, it is evident that *individuals* respond differently to obesity-inducing environmental conditions, and that this difference has a large genetic component. Various studies have indicated the heritability of fat mass to be between 30% and 70%, making it extra difficult for some people to lose weight.

Regardless of why we may have a propensity to gain weight, this predisposition can be counteracted behaviorally — by eating less and exercising more. It also appears that it is easier to prevent weight gain than it is to lose weight. Clearly, caloric homeostasis is a complicated biological phenomenon that will engage biomedical research scientists for some time to come.

The brain plays a key role in caloric homeostasis

As disturbing as the obesity pandemic is, an equally intriguing observation is that many people are able to maintain an approximately constant weight throughout adult life, despite consuming literally tons of food over a lifetime. Although willpower, exercise, and a bathroom scale often play a role in this homeostasis, some favorable biochemical signaling must also be behind this remarkable physiological feat. What makes this balance of energy input and output possible? As one might imagine, the answer is complicated, entailing many biochemical signals as well as a host of behavioral factors. We will focus on a few key biochemical signals and divide our discussion into two parts: short-term signals that are active during a meal, and long-term signals that report on the overall energy status of the body. These signals originate in the gastrointestinal tract, the β cells of the pancreas, and fat cells. The

primary target of these signals is the brain, in particular a group of neurons in a region of the hypothalamus called the *arcuate nucleus*.

Short-term signals from the gastrointestinal tract induce feelings of satiety

Short-term signals relay feelings of satiety (fullness) from the gut to various regions of the brain and thus reduce the urge to eat during what is known as the *postprandial period*, or the time right after a meal (Figure 24.2).

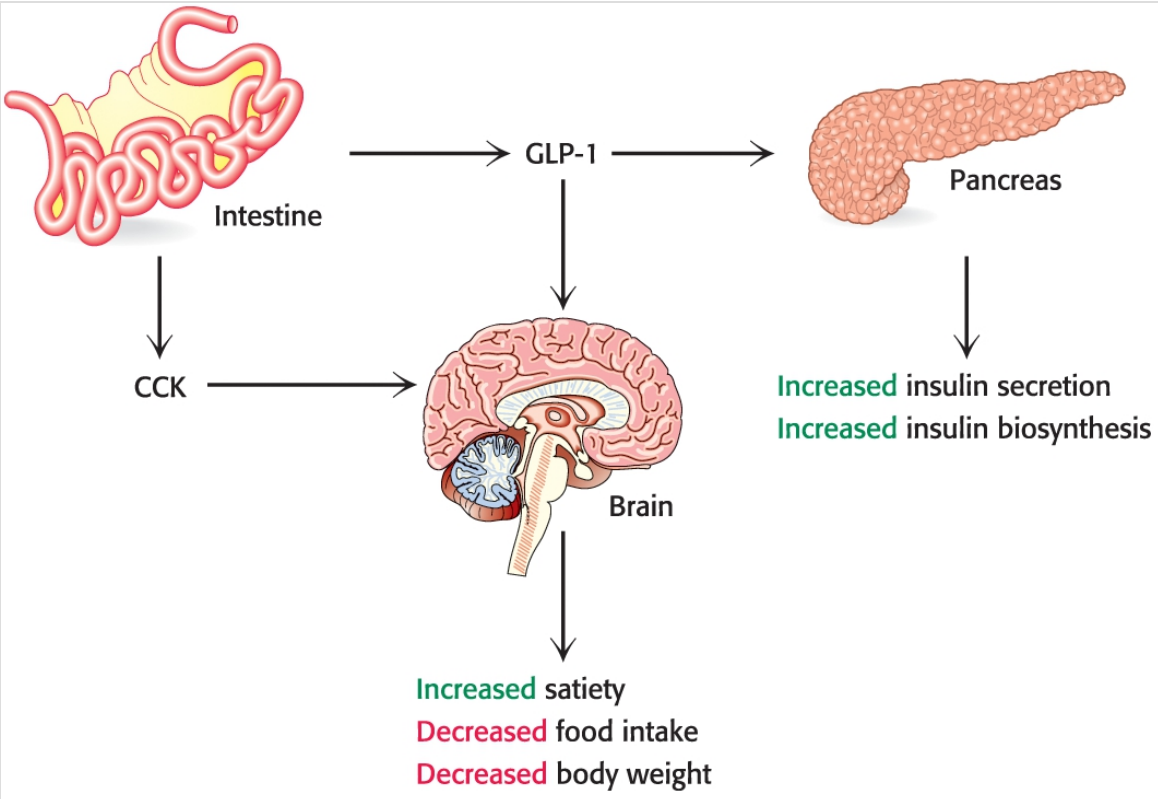

FIGURE 24.2 Signal molecules originating from the gut induce feelings of satiety in the brain. Cholecystokinin (CCK) is secreted by specialized cells of the small intestine in response to a mea and activates satiation pathways in the brain. Glucagon-like peptide 1 (GLP-1), secreted by L cel in the intestine, also activates satiation pathways in the brain and potentiates insulin action in the pancreas.

[Information from S. C. Wood, *Cell Metab*. 9:489–498, 2009, Fig. 1.]

The best-studied short-term signals are cholecystokinin (CCK) and glucagon-like peptide 1 (GLP-1). Both are small peptide hormones secreted into the blood by cells in the upper part of the small intestine as postprandial satiation signals. Both bind to their respective G-protein-coupled receptors (Section 14.2) in peripheral neurons, relaying signals to the brain that generate feelings of satiety. CCK and GLP-1 also play important roles in digestion; CCK stimulates the secretion of pancreatic enzymes and bile salts from the gallbladder, while GLP-1 enhances glucose-induced insulin secretion and inhibits glucagon secretion. Recall that **insulin** causes glucose to be removed from the blood and stimulates the synthesis of glycogen and lipids, while **glucagon** has effects opposite those of insulin.

Although we have examined only two short-term signals, many others are believed to exist (**Table 24.2**). Most of the short-term signals thus far identified are appetite suppressants. However, another small peptide hormone called *ghrelin* — secreted by the stomach — acts on regions of the hypothalamus to stimulate appetite through its G-protein-coupled receptor. Ghrelin secretion increases before a meal and decreases afterward.

Leptin and insulin regulate long-term control over caloric homeostasis

Two key signal molecules regulate energy homeostasis over the time scale of hours or days: **leptin**, which is secreted by the adipocytes, and insulin, which is secreted by the pancreatic β cells. Leptin communicates the status of the triacylglycerol stores, whereas insulin communicates the status of glucose in the blood — in other words, carbohydrate availability. We will consider leptin first.

Adipose tissue was formerly considered an inert storage form of triacylglycerols. However, later work showed that adipose tissue is an active endocrine tissue, secreting signal molecules called *adipokines*, such as leptin, that regulate a host of physiological processes. Leptin is

secreted by adipocytes in direct proportion to the amount of fat present: the more fat in a body, the more leptin is secreted. Leptin binding to its receptor throughout the body increases the sensitivity of muscle and the liver to insulin, stimulates β oxidation of fatty acids, and decreases triacylglycerol synthesis.

Let us consider the effects of leptin in the brain. Leptin binds to its receptor, thereby activating a signal-transduction pathway. The leptin receptor is found in various regions of the brain, but particularly in the arcuate nucleus of the hypothalamus. There, one population of neurons expresses appetite-stimulating (orexigenic) peptides, called neuropeptide Y (NPY) and agouti-related peptide (AgRP). Leptin inhibits the production and release of NPY and AgRP, thus repressing the desire to eat (**Figure 24.3**).

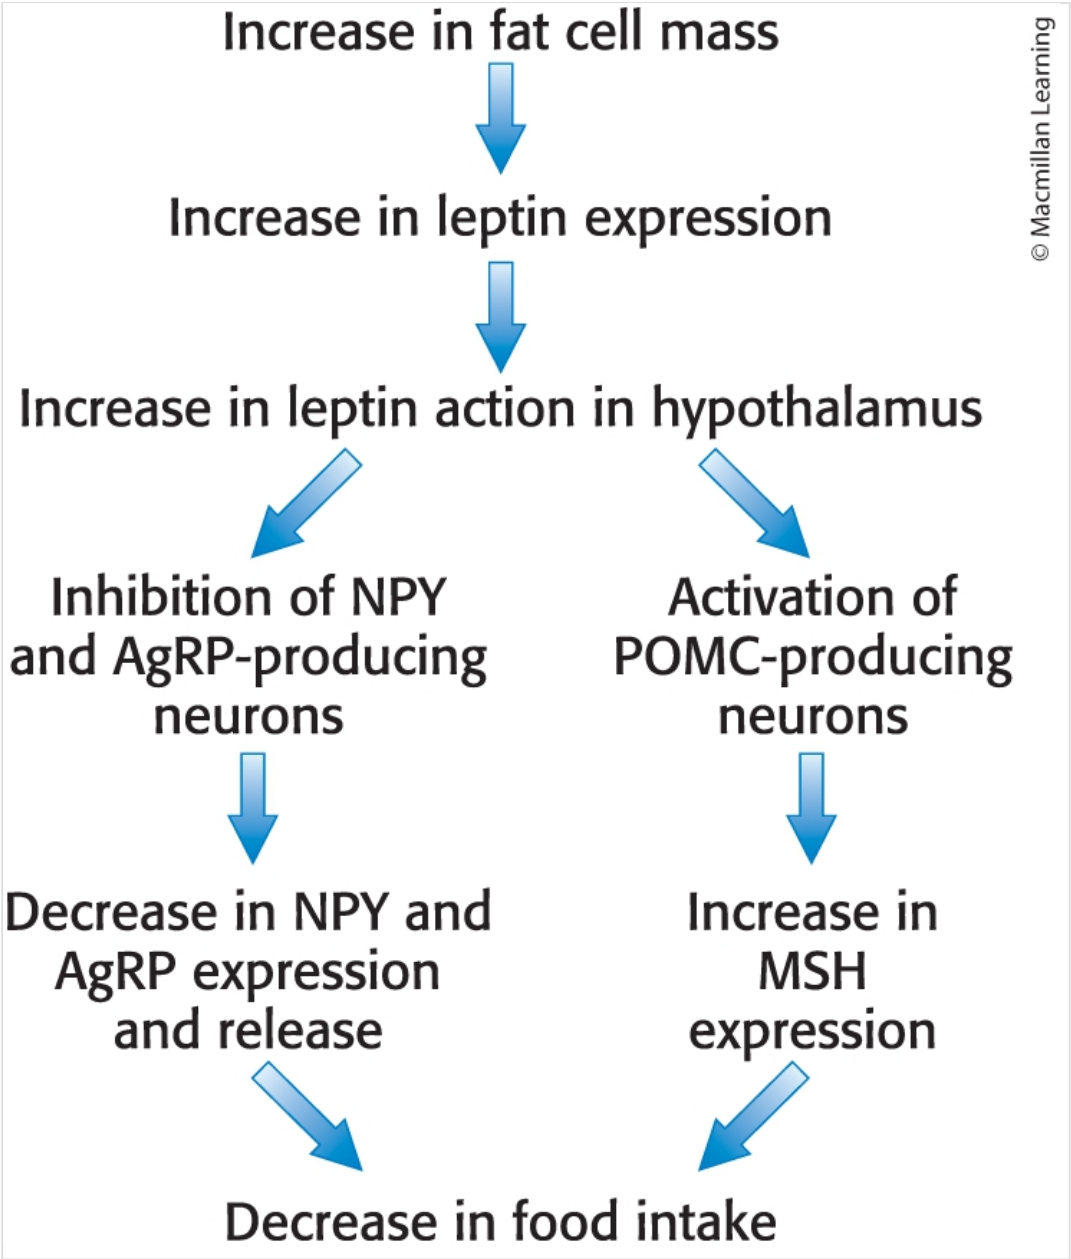

FIGURE 24.3 Leptin suppresses appetite by affecting the brain. Leptin is an adipokine secreted by adipose tissue in direct relation to fat mass. When fat mass increases, leptin inhibits NPY and AgRP secretion while stimulating the release of appetite-suppressing hormone MSH.

[Information from M. H. Stipanuk, *Biochemical, Physiological, & Molecular Aspects of Human Nutrition*, 2nd ed. (Saunders/Elsevier, 2006), Fig. 22-2.]

The second population of neurons containing leptin receptors expresses a large precursor polypeptide, proopiomelanocortin (POMC). Leptin binding to its receptor on POMC neurons causes POMC to be proteolytically processed to yield a variety of signal molecules, one of which is melanocyte-stimulating hormone (MSH). MSH, originally discovered as a stimulator of melanocytes (cells that synthesize the pigment melanin), activates appetite-suppressing (anorexigenic) neurons and thus inhibits food consumption. AgRP also inhibits MSH activity by acting as an antagonist, binding to the MSH receptor but failing to activate the receptor (Figure 24.3). Thus, the net effect of leptin binding to its receptor is the initiation of a complex signal-transduction pathway that ultimately curtails food intake. Insulin receptors are also present in the hypothalamus, although the mechanism of insulin action in the brain is less clear than that of leptin. Insulin appears to inhibit NPY/AgRP-producing neurons, thus inhibiting food consumption.

Self-Check Question

Name two short-term signals that are appetite-suppressing (anorexigenic) and one that is appetite-stimulating (orexigenic).

Leptin is one of several hormones secreted by adipose tissue

Leptin was the first adipokine discovered because of the dramatic effects of its absence. Researchers discovered a strain of mice called ob/ob mice, which completely lack leptin and, as a result, are extremely obese. These mice display hyperphagia (overeating), hyperlipidemia (accumulation of triacylglycerols in muscle and liver), and an

insensitivity to insulin. Since the discovery of leptin, other adipokines have been detected. For instance, adiponectin is another signal molecule produced by the adipocytes; but, unlike leptin, secretion of adiponectin increases in proportion to decreases in fat mass.

A key function of adiponectin appears to be increasing the sensitivity of the organism to insulin. Both leptin and adiponectin exert their effects through the key regulatory enzyme, AMP-activated protein kinase (AMPK) (**Figure 24.4**). Recall that this enzyme is active when AMP levels are elevated and ATP levels are diminished, and this activation leads to a decrease in anabolism and an increase in catabolism, most notably an increase in fatty acid oxidation (Section 22.7). In insulin-resistant obese animals, leptin levels increase while those of adiponectin decrease.

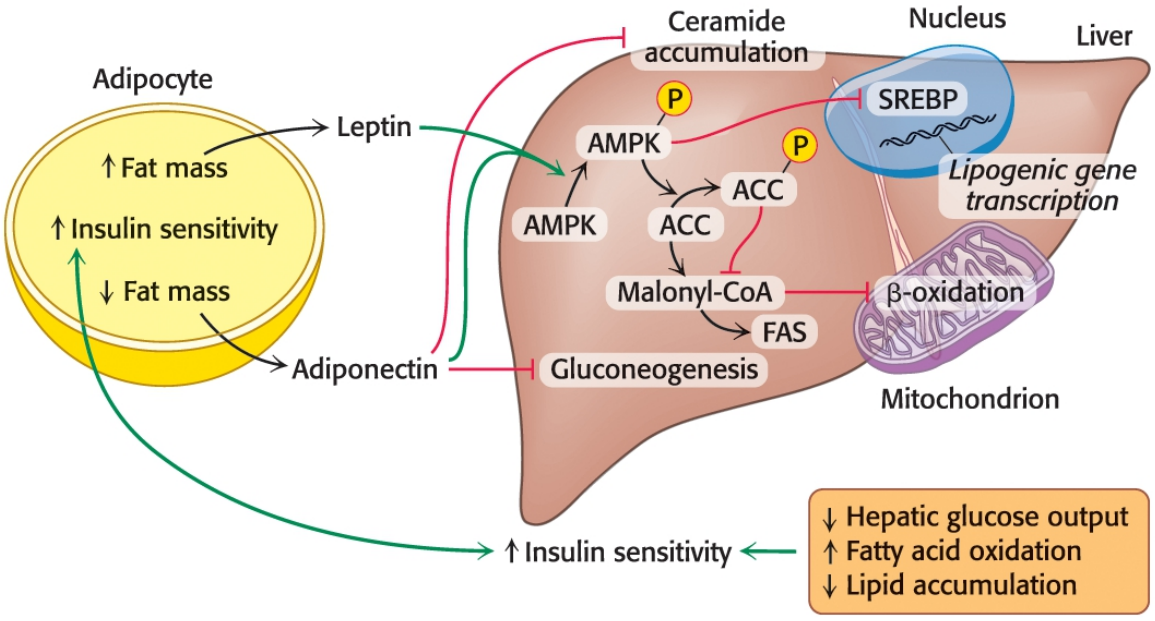

FIGURE 24.4 Adipokines help to maintain systemic lipid and glucose homeostasis. Both leptin and adiponectin act to prevent lipid accumulation in the liver and stimulate fatty acid oxidation by activating AMPK, which decreases the expression of lipogenic transcription factors such as SREBP and inactivates acetyl CoA carboxylase 1 (ACC). Inactivating ACC reduces the concentration of malonyl CoA, which normally inhibits oxidation and stimulates lipogenesis. Adiponectin also inhibits gluconeogenesis and reduces ceramide accumulation, which would otherwise further reduce insulin action. The combined action of leptin and adiponectin on the liver results in decreased glucose output, decreased lipid accumulation, and increased fatty acid oxidation in the liver, all of which enhance insulin sensitivity for the liver and other tissues.

Adipocytes produce two additional hormones, RBP4 (originally discovered as a retinol binding protein) and resistin, that promote insulin resistance. Although it is unclear why adipocytes secrete hormones that facilitate insulin resistance, a pathological condition, we can speculate on the reason. These signal molecules may help to fine-tune the actions of leptin and adiponectin or perhaps to act as "brakes" on the action of leptin and adiponectin to prevent hypoglycemia in the fasted state. Some evidence indicates that enlarged adipocytes that result from obesity may secrete higher levels of insulin-antagonizing hormones and thus contribute to insulin resistance. Resistin has recently been implicated as a causal factor in the increased incidence of cardiovascular disease associated with obesity.

Leptin resistance may be a contributing factor to obesity

If leptin is produced in proportion to body-fat mass and leptin inhibits eating, why do people become obese? Obese people, in most cases, have both functioning leptin receptors and a high blood concentration of leptin. The failure to respond to the anorexigenic effects of leptin is called *leptin resistance*. What is the basis of leptin resistance?

As for most questions in the exciting area of energy homeostasis, the answer is not well worked out, but recent evidence suggests that a group of proteins called *suppressors of cytokine signaling* (SOCS) may take part. These proteins fine-tune some hormonal systems by inhibiting receptor action. SOCS proteins inhibit receptor signaling by a number of means. Consider, for example, the effect of SOCS proteins on the insulin

receptor. Recall that insulin stimulates the autophosphorylation of tyrosine residues on the insulin receptor, which in turn phosphorylates IRS-1, initiating the insulin-signaling pathway (**Figure 24.5A**). SOCS proteins bind to phosphorylated tyrosine residues on receptors or other members of the signal-transduction pathway, thereby disrupting signal flow and thus altering the cell's biochemical activity (**Figure 24.5B**). In other cases, the binding of SOCS proteins to components of the signal-transduction pathway may also enhance proteolytic degradation of these components by the proteasome (Section 23.2).

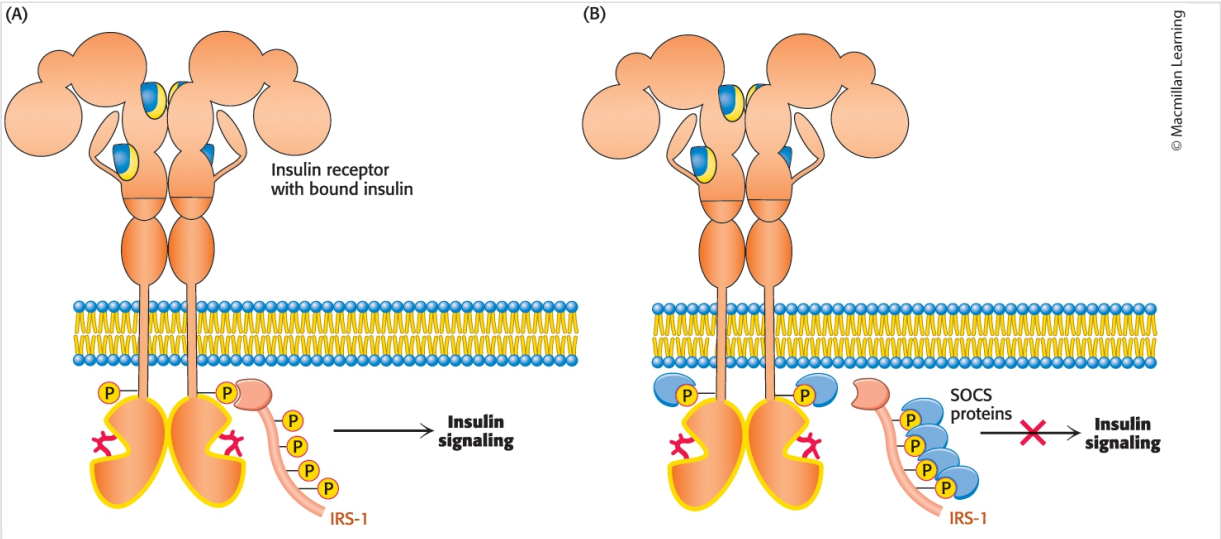

FIGURE 24.5 Suppressors of cytokine signaling (SOCS) regulate insulin receptor function. (A) Insulin binding results in phosphorylation of the receptor and subsequent phosphorylation of IRS-1. These processes initiate the insulin-signaling pathway. (B) SOCS proteins disrupt interactions of components of the insulin-signaling pathway by binding phosphorylated proteins and thereby inhibiting the pathway. The binding of a signal component by SOCS results in proteasomal degradation in some cases. (IRS-1, insulin-receptor substrate 1; SOCS, suppressor of cytokine signaling.)

Evidence in support of a role for SOCS in leptin resistance comes from mice that have had SOCS selectively deleted from POMC-expressing neurons. These mice display an enhanced sensitivity to leptin and are resistant to weight gain even when fed a high-fat diet. The reason why

the activity of SOCS proteins increases, leading to leptin resistance, remains to be determined. Alternatively, leptin resistance can arise by means unrelated to SOCS. For example, to have systemic effects, leptin must enter the brain. Mutations in proteins that transport leptin into the brain or in the brain leptin receptors could also result in leptin resistance.

24.2 The Fasted–Fed Cycle Is a Response to Eating and Sleeping Behaviors

Next, let's examine the natural cycles of human metabolism in a resting and nonpathological state. We begin with a physiological condition called the **fasted–fed cycle**, which we all experience in the hours after an evening meal and through the night's fast. This nightly fasted–fed cycle has three stages: the well-fed (postprandial) state after a meal, the early fasting (postabsorptive) state during the night, and the refed state after breakfast. A major goal of the many biochemical alterations in this period is to maintain **glucose homeostasis** — that is, a constant blood-glucose concentration. Maintaining glucose homeostasis is crucial because glucose is normally the only fuel source for the brain. The two primary signals regulating the fasted–fed cycle are insulin and glucagon.

The postprandial state follows a meal

After we consume and digest a meal, glucose and amino acids are transported from the intestine to the blood. The dietary lipids are packaged into chylomicrons and transported to the blood by the lymphatic system. This fed condition leads to the secretion of insulin, which signals the postprandial state. Insulin stimulates glycogen synthesis in both muscle and the liver, suppresses gluconeogenesis by the liver, and stimulates protein synthesis. Insulin also accelerates glycolysis in the liver, which in turn increases the synthesis of fatty acids.

The liver helps to limit the amount of glucose in the blood during times of plenty by storing it as glycogen, so as to be able to release glucose in

times of scarcity. How is the excess blood glucose present after a meal removed? The liver is able to trap large quantities of glucose because it possesses an isozyme of hexokinase called *glucokinase* that converts glucose into glucose 6-phosphate, which cannot be transported out of the cell. Recall that glucokinase has a high K_M value and is thus highly active only when blood-glucose concentration is high (Section 16.3). Furthermore, glucokinase is not inhibited by glucose 6-phosphate as hexokinase is. Consequently, the liver forms glucose 6-phosphate more rapidly as the blood-glucose concentration rises. The increase in glucose 6-phosphate, which activates glycogen synthase, coupled with the effects of insulin leads to a buildup of glycogen stores.

The hormonal effects on glycogen synthesis and storage are reinforced by a direct action of glucose itself. Phosphorylase *a* is a glucose sensor in addition to being the enzyme that cleaves glycogen. When the glucose level is high, the binding of glucose to phosphorylase *a* renders the enzyme susceptible to the action of a phosphatase that converts it into phosphorylase *b*, which does not readily degrade glycogen (Figure 21.24). Thus, glucose allosterically shifts the glycogen system from a degradative to a synthetic mode.

The high insulin level in the fed state also promotes the entry of glucose into muscle and adipose tissue. Insulin stimulates the synthesis of glycogen by muscle as well as by the liver. The entry of glucose into adipose tissue provides glycerol 3-phosphate for the synthesis of triacylglycerols. The action of insulin also extends to amino acid and protein metabolism. Insulin promotes the uptake of branched-chain amino acids (valine, leucine, and isoleucine) by muscle. Indeed, insulin has a general stimulating effect on protein synthesis, which favors a building up of muscle protein. In addition, it inhibits the intracellular degradation of proteins.

The postabsorptive state occurs at the beginning of a fast

The blood-glucose concentration begins to drop several hours after a meal, leading to a decrease in insulin secretion and a rise in glucagon secretion by the α cells of the pancreas. This period is called the *fasted state* or *postabsorptive state* because it immediately follows the absorption of glucose from the blood that resulted from the previous meal. The regulation of glucagon secretion is poorly understood, but when glucose is abundant, β cells inhibit glucagon secretion. When glucose concentration falls, the inhibition is relieved, and glucagon is secreted by the α cells of the pancreas. Just as insulin signals the fed state, glucagon signals the fasted state, serving to mobilize glycogen stores when there is no dietary intake of glucose.

The main target organ of glucagon is the liver. Glucagon stimulates glycogen breakdown and inhibits glycogen synthesis by triggering the cyclic AMP cascade; this leads to the phosphorylation and activation of phosphorylase and the inhibition of glycogen synthase (Section 21.6). Glucagon also inhibits fatty acid synthesis by diminishing the production of pyruvate and by maintaining the inactive phosphorylated state of acetyl CoA carboxylase. In addition, glucagon stimulates the gluconeogenic state in the liver and blocks glycolysis by decreasing in the amount of fructose 2,6-bisphosphate (F-2,6-BP), which normally stimulates glycolysis and inhibits gluconeogenesis (Section 16.5). Hence, the decrease in F-2,6-BP results in a decrease in glycolytic activity and an increase in gluconeogenesis because of the opposing effects of F-2,6-BP on phosphofructokinase and fructose-1,6-bisphosphatase (Section 16.5; **Figure 24.6**).

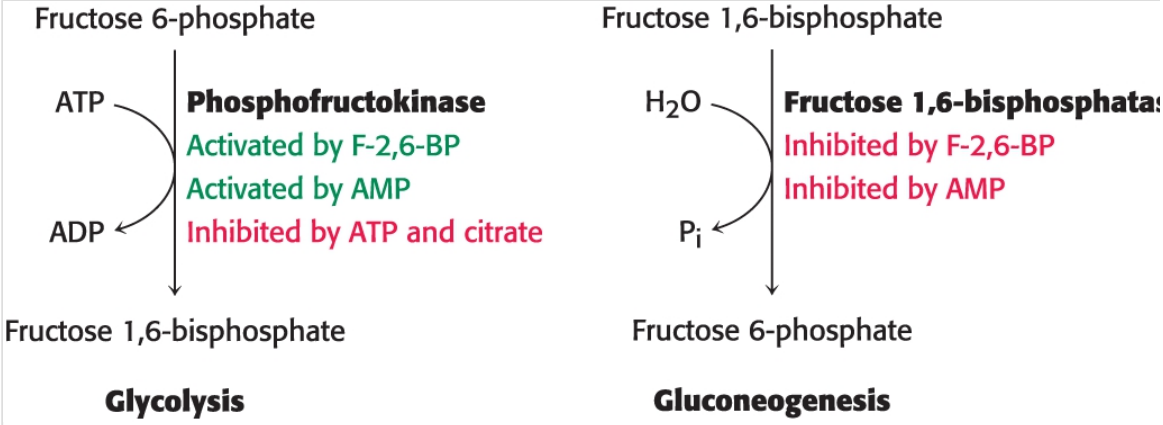

FIGURE 24.6 Glycolysis and gluconeogenesis are reciprocally regulated. Phosphofructokinase is the key enzyme in the regulation of glycolysis, whereas fructose 1,6-bisphosphatase is the principal enzyme controlling the rate of gluconeogenesis. Note the reciprocal relationship between the pathways and the signal molecules.

EXPLORE these pathways further in the Metabolic Map in Achieve

All known actions of glucagon are mediated by protein kinases that are activated by cyclic AMP. The activation of the cyclic AMP cascade results in a higher level of phosphorylase *a* activity and a lower level of glycogen synthase *a* activity. Glucagon's effect on this cascade is reinforced by the low concentration of glucose in the blood. The diminished binding of glucose to phosphorylase *a* makes the enzyme less susceptible to the hydrolytic action of the phosphatase. Instead, the phosphatase remains bound to phosphorylase *a*, and so the synthase stays in the inactive phosphorylated form. Consequently, there is a rapid mobilization of glycogen.

The large amount of glucose formed by the hydrolysis of glucose 6-phosphate derived from glycogen is then released from the liver into the blood. The entry of glucose into muscle and adipose tissue decreases in response to a low insulin level. The diminished utilization of glucose by muscle and adipose tissue also contributes to the maintenance of the blood-glucose concentration. The net result of these actions of glucagon

is to markedly increase the release of glucose by the liver. Both muscle and the liver use fatty acids as fuel when the blood-glucose concentration drops, saving the glucose for use by the brain and red blood cells. Thus, the blood-glucose concentration is kept at or above 4.4 mM by three major factors: (1) the mobilization of glycogen and the release of glucose by the liver, (2) the release of fatty acids by adipose tissue, and (3) the shift in the fuel used by muscle from glucose to fatty acids.

What is the result of the depletion of the liver's glycogen stores? Gluconeogenesis from lactate and alanine continues, but this process merely replaces glucose that had already been converted into lactate and alanine by tissues such as muscle and red blood cells. Moreover, the brain oxidizes glucose completely to CO_2 and H_2O. Thus, for the net synthesis of glucose to take place, another source of carbon is required. Glycerol released from adipose tissue on lipolysis provides some of the carbon atoms, with the remaining carbon atoms coming from the hydrolysis of muscle proteins.

The refed state occurs at the end of a long fast

What are the biochemical responses to a large breakfast? Fat is processed exactly as it is processed in the normal fed state. However, that is not the case for glucose. The difference between the refed state and other postprandial states is the length of the fast. In the case of the first morning meal or any other meal after a long fast, the liver does not initially absorb glucose from the blood, but instead leaves it for the other tissues. Moreover, the liver remains in a gluconeogenic mode. Now, however, the newly synthesized glucose is used to replenish the liver's glycogen stores. As the blood-glucose concentration continues to rise, the liver completes the replenishment of its glycogen stores and begins to process the remaining excess glucose for fatty acid synthesis.

Self-Check Question

What are the three primary sources of glucose 6-phosphate in liver cells?

24.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity

Having considered the regulation of body weight and glucose homeostasis, we now examine the biochemical results when regulation fails because of behavior, genetics, or a combination of the two. The most common result of such a failure is obesity. Humans maintain about a day's worth of glycogen and, after these stores have been replenished, excess carbohydrates are converted into fatty acids and then into triacylglycerols. Amino acids are not stored at all, and so excess amino acids are also ultimately converted into triacylglycerols. Thus, regardless of the type of food consumed, excess consumption results in increased fat stores.

We begin our consideration of the effects of disruptions in caloric homeostasis by looking at diabetes mellitus, a complex disease characterized by grossly abnormal fuel usage and named for the excessive urination that is a classic symptom (*diabetes*, from Greek, means "to pass through"). Glucose is overproduced by the liver and underutilized by other organs. As a result, glucose accumulates in the blood and is excreted in the urine when its concentration exceeds the reabsorptive capacity of the renal tubules (*mellitus*, from Latin, means "sweetened with honey"). Water accompanies the excreted glucose, and so an untreated diabetic in the acute phase of the disease is hungry and thirsty. *Mellitus* distinguishes this disease from diabetes *insipidus*, which is caused by impaired renal reabsorption of water. While diabetes insipidus is relatively rare, the incidence of diabetes mellitus is about 6% of the world population, hence it is usually referred to simply as *diabetes*.

Type 1 diabetes is caused by the destruction of the insulin-secreting β cells in the pancreas, usually due to an autoimmune disorder and beginning before age 20. Type 1 diabetes is also referred to as *insulin-dependent diabetes*, meaning that the affected person requires the administration of insulin to live. Most diabetics, in contrast, have a normal or even higher level of insulin in their blood, but they are poorly responsive to the hormone, a characteristic called **insulin resistance**. This form of the disease, known as **type 2 diabetes**, typically arises later in life than does the insulin-dependent form. Although there is a significant genetic component, obesity is a significant predisposing factor for the development of insulin resistance and type 2 diabetes.

In our discussion of diabetes in this chapter, we will consider type 2 first, which accounts for approximately 90% of the diabetes cases throughout the world and is the most common metabolic disease in the world. In the United States, where 10% of the population is affected, it is the leading cause of blindness, kidney failure, and amputation.

Self-Check Question

People who consume little fat but excess carbohydrates can still become obese. How is this result possible?

Insulin initiates a complex signal-transduction pathway in muscle

What is the biochemical basis of insulin resistance? How does insulin resistance lead to failure of the pancreatic β cells that results in type 2 diabetes? How does obesity contribute to this progression? To answer these questions and begin to unravel the mysteries of metabolic

disorders, let us reexamine the mechanism of action of insulin in muscle, the largest tissue target of insulin. Indeed, muscle uses about 85% of the glucose ingested during a meal.

In a normal cell, insulin binds to its receptor, which then autophosphorylates on tyrosine residues, with each subunit of the receptor phosphorylating its partner. Phosphorylation of the receptor generates binding sites for insulin-receptor substrates (IRSs), such as IRS-1 (**Figure 24.7**). Subsequent phosphorylation of IRS-1 by the tyrosine kinase activity of the insulin receptor engages the insulin-signaling pathway (1). Phosphorylated IRS-1 binds to phosphoinositide 3-kinase (PI3K) and activates it. PI3K catalyzes the conversion of phosphatidylinositol 4,5-bisphosphate (PIP_2) into phosphatidylinositol 3,4,5-trisphosphate (PIP_3), a second messenger (2). PIP_3 activates the phosphatidylinositol-dependent protein kinase (PDK) (3), which in turn activates several other kinases, most notably Akt (4), also known as protein kinase B (PKB).

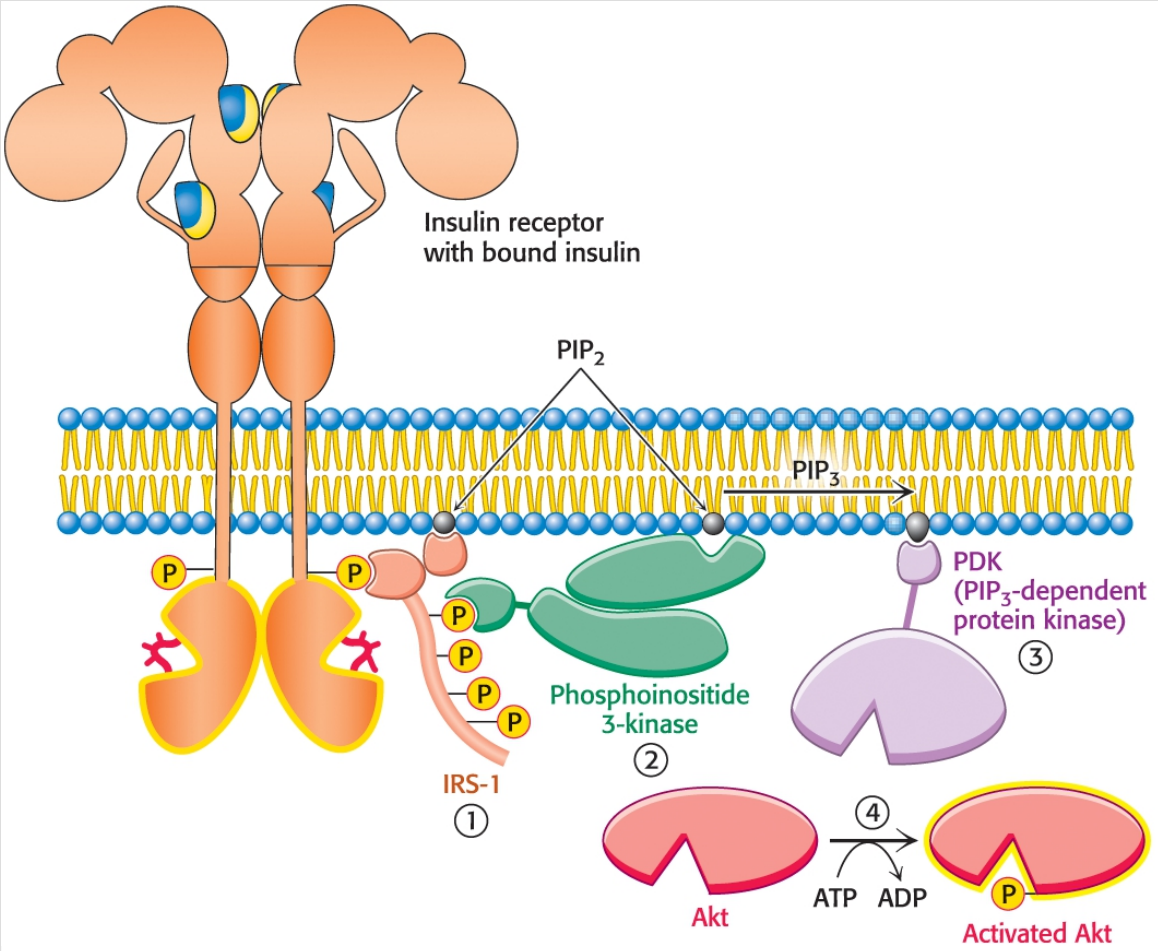

FIGURE 24.7 Insulin signaling activates Akt using the second messenger PIP_3. The binding o insulin results in the cross-phosphorylation and activation of the insulin receptor. Phosphorylated sites on the receptor act as binding sites for insulin-receptor substrates such as IRS-1 (1). The lipid kinase phosphoinositide 3-kinase binds to phosphorylated sites on IRS-1 through its regulatory domain and then converts PIP_2 into PIP_3 (2). Binding to PIP_3 activates PIP_3-dependent protein kinase (3), which phosphorylates and activates kinases such as Akt (4). Activated Akt can then diffuse throughout the cell and continue the signal-transduction pathway.

Akt facilitates the translocation of the glucose transporter (GLUT4)-containing vesicles to the cell membrane, which leads to a more robust absorption of glucose from the blood. Moreover, Akt phosphorylates

and inhibits glycogen synthase kinase (GSK3). Recall that GSK3 inhibits glycogen synthase (Section 21.6). Thus, insulin leads to the absorption of glucose from the blood, activation of glycogen synthase, and enhanced glycogen synthesis.

Like all signal pathways, the insulin-signaling cascade must be capable of being turned off. In addition to the breakdown of insulin itself, three different processes notably contribute to the down-regulation of insulin signaling. First, phosphatases deactivate the insulin receptor and destroy a key second messenger. PTP1B (protein tyrosine phosphatase 1B) removes phosphoryl groups from the receptor, thus inactivating it. The second messenger PIP_3 is inactivated by the phosphatase PTEN (phosphatase and tensin homolog), which dephosphorylates it, forming PIP_2, which is not a second messenger.

Second, the IRS protein can be inactivated by phosphorylation on serine residues by specific Ser/Thr kinases. These kinases are activated by stress signals and may play a role in the development of insulin resistance. Finally, SOCS proteins, the regulatory proteins discussed earlier, interact with the insulin receptor and IRS-1 and apparently facilitate their proteolytic degradation by the proteasome complex.

Metabolic syndrome often precedes type 2 diabetes

With our knowledge of the key components of energy homeostasis, let us begin our investigation of the biochemical basis of insulin resistance and type 2 diabetes. A cluster of pathologies — including insulin resistance, hyperglycemia, and dyslipidemia (characterized by high blood levels of triacylglycerols, cholesterol, and low-density lipoproteins) — often develop together. This clustering, called **metabolic syndrome**, is thought to be a predecessor of type 2 diabetes.

A consequence of obesity is that the amount of triacylglycerols consumed exceeds the adipose tissue's storage capacity. As a result, other tissues begin to accumulate fat, most notably muscle (myosteatosis), and the liver, a condition called *hepatic steatosis* (Figure 24.8). This accumulation results in insulin resistance and ultimately in pancreatic failure. We will focus on muscle and the pancreatic β cells.

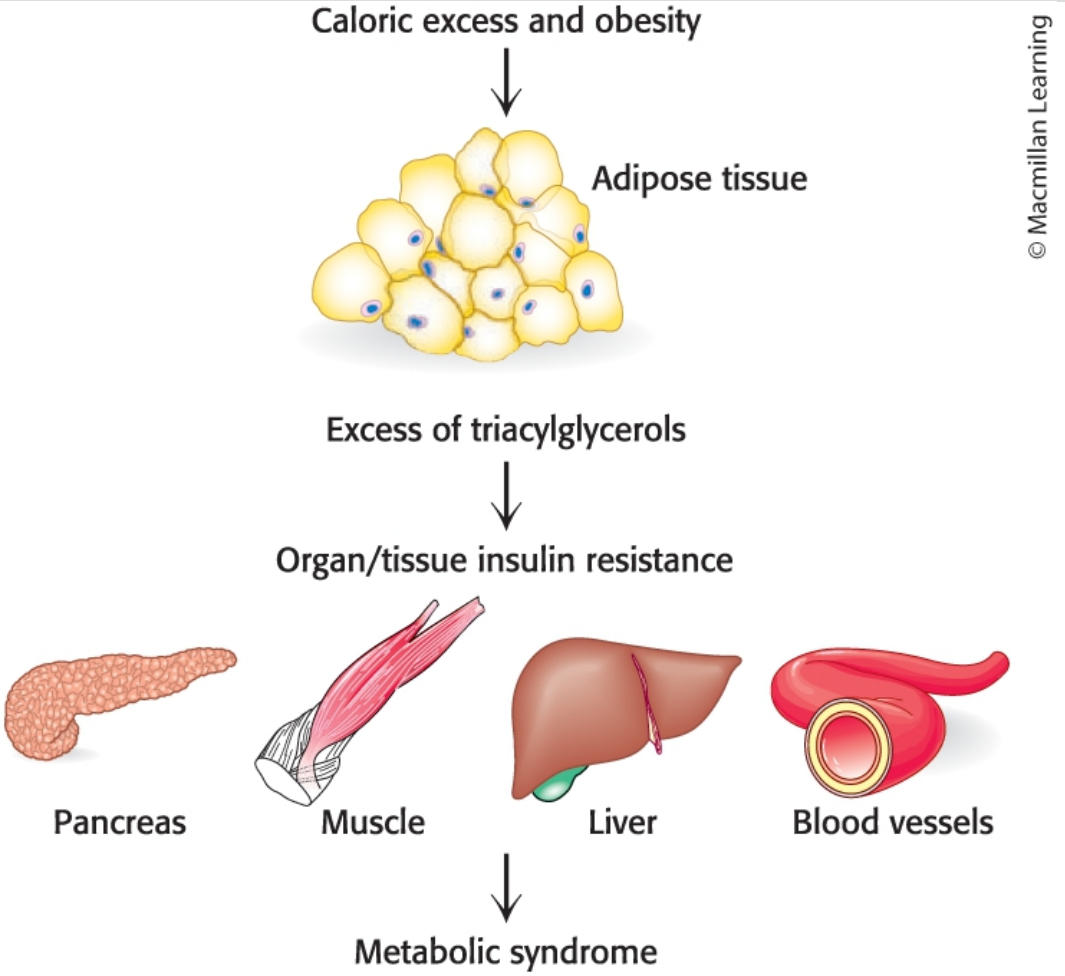

FIGURE 24.8 The storage capacity of fat tissue can be exceeded in obesity. In caloric excess, the storage capacity of adipocytes can be exceeded with deleterious results. The excess fat accumulates in other tissues, resulting in biochemical malfunction of the tissues. When the pancreas, muscle, liver, and cells lining the blood vessels are affected, metabolic syndrome, a condition that often precedes type 2 diabetes, may result.

[Information from S. Fröjdö, H. Vidal, and L. Pirola, *Biochim. Biophys. Acta* 1792:83–92, 2009, Fig. 1.]

Self-Check Question

What would be the effect of a mutation in the gene for PTP1B (protein tyrosine phosphatase 1B) that inactivated the enzyme in a person who has type 2 diabetes?

Excess fatty acids in muscle modify metabolism

Myosteatosis and insulin resistance do not always develop with obesity; however, the pathology begins when more fats are present than can be processed by muscle. Although the rate of β oxidation increases in response to the high concentration of fats, the mitochondria are not capable of processing all of the fatty acids by β oxidation; fatty acids accumulate in the mitochondria and eventually spill over into the cytoplasm. The unprocessed fatty acids are reincorporated into triacylglycerols, resulting in the accumulation of fat in the cytoplasm.

In the cytoplasm, levels of diacylglycerol and ceramide (a component of sphingolipids) also increase. Diacylglycerol is a second messenger that activates protein kinase C (PKC) (Section 14.2). When active, PKC and other Ser/Thr protein kinases are capable of phosphorylating IRS and reducing the ability of IRS to propagate the insulin signal. Saturated and trans unsaturated fatty acids may also activate kinases that block the insulin signal. Ceramide or its metabolites inhibit glucose uptake and glycogen synthesis, apparently by inhibiting PDK and Akt (Section 14.3).

The result is a diet-induced insulin resistance that can, but does not always, develop over time in obese individuals (Figure 24.9).

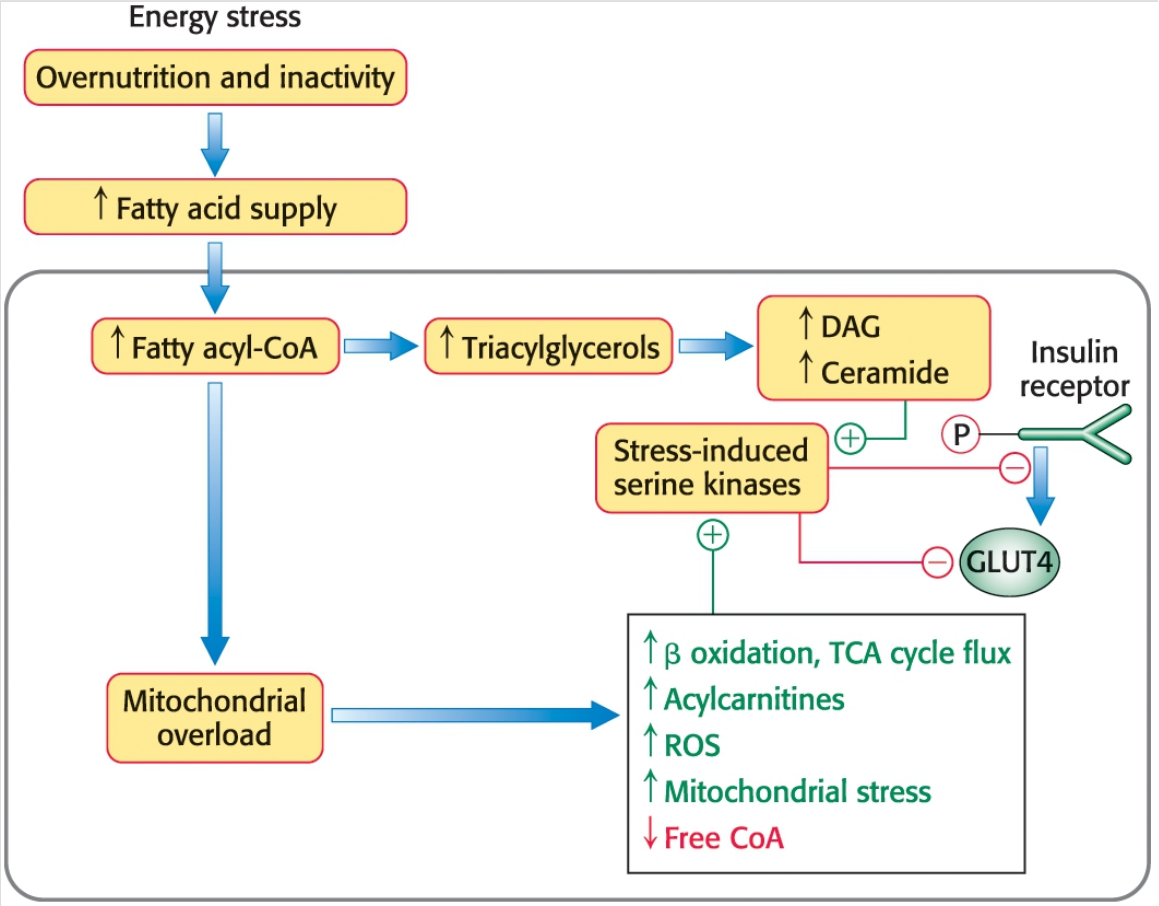

FIGURE 24.9 Excess fat can disrupt signal-transduction pathways and lead to insulin insensitivity. Excess fat accumulation in peripheral tissues, most notably muscle, can disrupt some signal-transduction pathways and inappropriately activate others. In particular, diacylglycerols and ceramide activate stress-induced pathways that interfere with insulin signaling, resulting in insulin resistance. (Abbreviations: DAG, diacylglycerol; GLUT4, glucose transporter 4; TCA, tricarboxylic acid cycle; ROS, reactive oxygen species.)

Insulin resistance in muscle facilitates pancreatic failure

What is the effect of overnutrition on the pancreas? This question is important because a primary function of the pancreas is to respond to the presence of glucose in the blood by secreting insulin. Indeed, the β cell is an insulin factory. The mRNA that encodes proinsulin, the precursor to insulin, constitutes 20% of the total mRNA in the pancreas, and proinsulin itself constitutes 50% of the total protein synthesized in the pancreas.

Glucose enters the pancreatic β cells through the glucose transporter GLUT2. Recall that GLUT2 will allow rapid glucose transport only when blood glucose is plentiful, ensuring that insulin is secreted only when glucose is abundant, such as after a meal (Section 16.1). Likewise, pancreatic glucokinase, with its relatively high K_M value, traps large amounts of glucose within the cell only when blood-glucose concentrations are high. These two proteins, in concert, act as a pancreatic glucose sensor.

The β cell metabolizes glucose to CO_2 and H_2O through cellular respiration, generating ATP. The resulting increase in the ATP/ADP ratio closes an ATP-sensitive K^+ channel that, when open, allows potassium to flow out of the cell (**Figure 24.10**). The resulting alteration in the cellular ionic environment opens a voltage-sensitive Ca^{2+} channel, and the resulting influx of Ca^{2+} causes insulin-containing secretory vesicles to fuse with the cell membrane and release insulin into the blood. Thus, the increase in ATP resulting from the metabolism of glucose has been translated by the membrane proteins into a physiological response — the secretion of insulin and the subsequent removal of glucose from the blood.

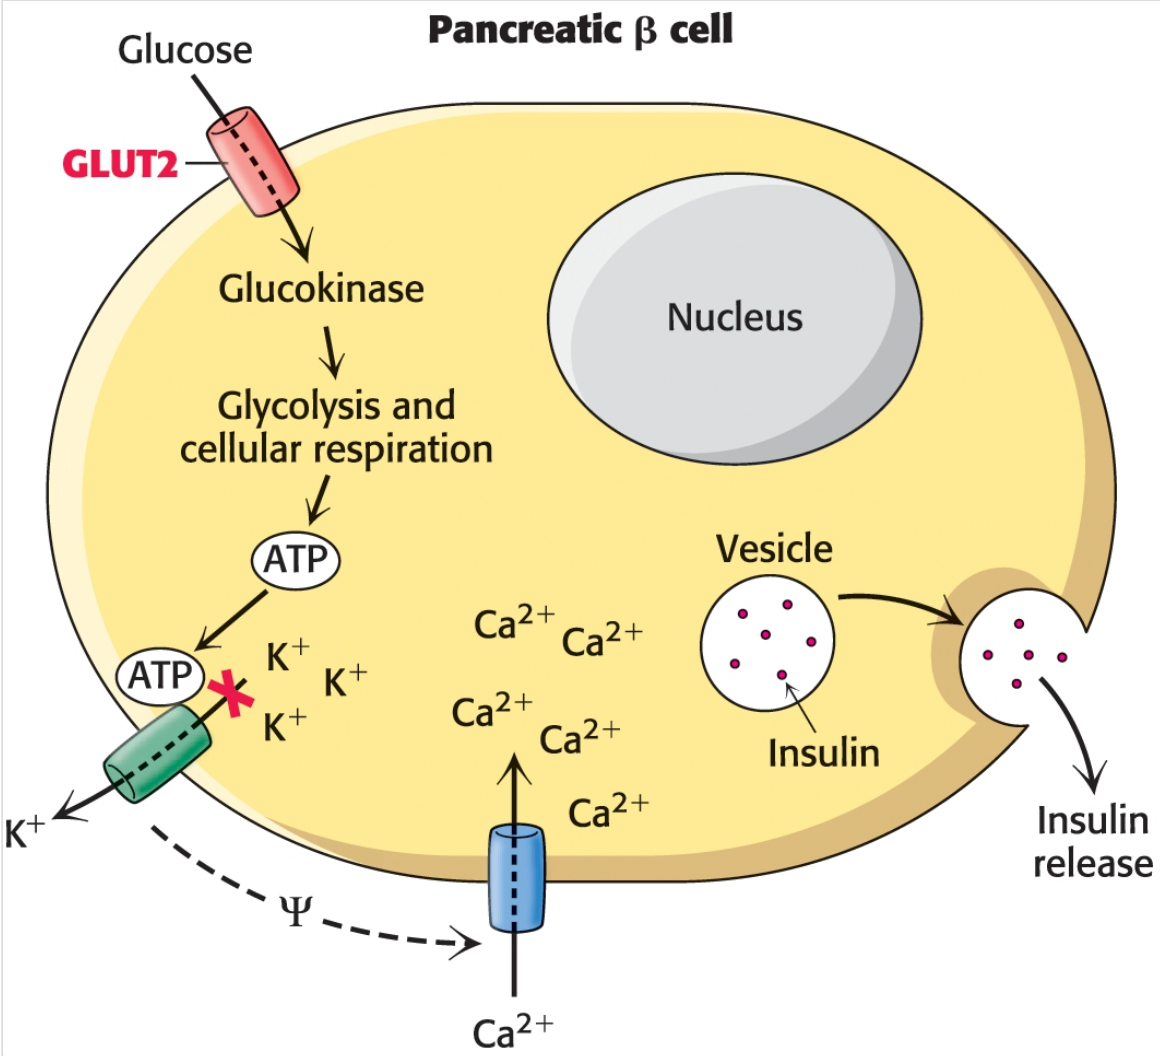

FIGURE 24.10 Insulin release by the pancreas is regulated by blood-glucose concentration, using ATP as a second messenger. The metabolism of glucose by glycolysis and cellular respiration increases the concentration of ATP, which causes an ATP-sensitive potassium chann to close. The closure of this channel alters the charge across the membrane (ψ) and causes a calcium channel to open. The influx of calcium causes insulin-containing granules to fuse with the plasma membrane, releasing insulin into the blood.

What aspect of β cell function ultimately fails, causing the transition from insulin resistance to full-fledged type 2 diabetes? Under normal circumstances, proinsulin synthesized by β cells folds into its three-dimensional structure in the endoplasmic reticulum, is processed to

insulin, and is subsequently packaged into vesicles for secretion. As insulin resistance develops in the muscle, the β cells respond by synthesizing yet more insulin in a futile attempt to drive insulin action. The ability of the endoplasmic reticulum to process all of the proinsulin and insulin becomes compromised, a condition known as **endoplasmic reticulum (ER) stress**, and unfolded or misfolded proteins accumulate.

ER stress initiates a signal pathway called the **unfolded protein response (UPR)**, a pathway intended to save the cell. UPR consists of several steps. First, general protein synthesis is inhibited so as to prevent more proteins from entering the ER. Second, chaperone synthesis is stimulated. Recall that chaperones are proteins that assist the folding of other proteins (Section 2.7). Third, misfolded proteins are removed from the ER and are subsequently delivered to the proteasome for destruction. Finally, if the described response fails to alleviate the ER stress, programmed cell death is triggered, which ultimately leads to β cell death and full-fledged type 2 diabetes.

What are the treatments for type 2 diabetes? Most are behavioral in nature. Type 2 diabetics are advised to count calories, making sure that energy intake does not exceed energy output; to consume a diet rich in vegetables, fruits, and grains; and to get plenty of aerobic exercise. Note that these guidelines are the same as those for healthy living, even for those not suffering from type 2 diabetes. Monitoring of blood-glucose concentration is important (normal is 3.6 to 6.1 mM) and for patients who are not able to maintain proper glucose levels with behavioral modifications, drug treatments are required. The administration of insulin may be necessary upon β cell failure, and/or treatment with metformin (Glucophage), which activates AMPK, may be effective. Recall that AMPK promotes the oxidation of fats while inhibiting fat synthesis and storage. It also stimulates glucose uptake and storage by muscle while inhibiting gluconeogenesis in the liver.

Self-Check Question

What is the relationship between fatty acid oxidation and insulin resistance in the muscle?

Metabolic alterations in type 1 diabetes result from insulin insufficiency and glucagon excess

We now turn to the more-straightforward type 1 diabetes. Recall that in type 1 diabetes, insulin production is usually insufficient because of autoimmune destruction of the pancreatic β cells. Consequently, the glucagon/insulin ratio is always higher than normal. In essence, the diabetic person is in biochemical fasting mode (Section 24.2) despite a high concentration of blood glucose. Because insulin is deficient, the entry of glucose into adipose and muscle cells is impaired, and the liver becomes stuck in a gluconeogenic and ketogenic state. Essentially, the cells' response to a lack of insulin amplifies the amount of glucose in the blood. The high glucagon/insulin ratio in diabetes also promotes glycogen breakdown. Hence, as with type 2 diabetes, an excessive amount of glucose is produced by the liver, released into the blood, and excreted in the urine.

Because carbohydrate utilization is impaired, a lack of insulin leads to the uncontrolled breakdown of lipids and proteins, resulting in the ketogenic state. Large amounts of acetyl CoA are then produced by β oxidation. However, much of the acetyl CoA cannot enter the citric acid cycle because there is insufficient oxaloacetate for the condensation step. Recall that mammals can synthesize oxaloacetate from pyruvate, a

product of glycolysis, but not from acetyl CoA; instead, they generate ketone bodies (Section 22.4). A striking feature of diabetes is the shift in fuel usage from carbohydrates to fats; glucose, more abundant than ever, is unable to be used. In high concentrations, ketone bodies overwhelm the kidney's capacity to maintain acid–base balance. The untreated diabetic can go into a coma because of a lowered blood-pH level and dehydration. Interestingly, diabetic ketosis is rarely a problem in type 2 diabetes because, in most cases, insulin signaling is still active enough to prevent excessive lipolysis in liver and adipose tissue.

What is the treatment for type 1 diabetes? As noted earlier, the regular administration of insulin is required for survival. Likewise, blood-glucose concentration must be monitored. Although the behaviors recommended for type 2 diabetes — watching calories, exercising, and eating a healthy diet — do not treat type 1 diabetes, they are beneficial to managing it and to maintaining a healthy lifestyle.

Self-Check Question

Insulin-dependent diabetes is often accompanied by hypertriglyceridemia, which is an excess blood level of triacylglycerols. Suggest a biochemical explanation.

24.4 Exercise Beneficially Alters the Biochemistry of Cells

Thus far, we have been considering metabolism in the context of excess calorie consumption, as in obesity. We now look at the physiological response when there is an extreme caloric need, as occurs during exercise.

Fuel choice during exercise is determined by the intensity and duration of activity

Skeletal muscle accounts for $\approx 40\%$ of total body mass and $\approx 35\%$ of resting metabolic activity. Moreover, skeletal muscle is the largest target tissue for insulin. Given its biochemical prominence, increased muscle activity — exercise — coupled with a healthy diet is one of the most effective treatments for diabetes as well as a host of other pathological conditions. These include coronary disease, hypertension, depression, age-related muscle wasting (sarcopenia), and a variety of cancers. With regard to type 2 diabetes, exercise increases insulin sensitivity and is in fact more effective than pharmacological interventions. What is the basis of this beneficial effect? To answer this question, we must first consider what energy sources muscles use during exercise.

The fuels used in anaerobic exercises — sprinting, for example — differ from those used in aerobic exercises — such as distance running. The selection of fuels during these different forms of exercise illustrates many important facets of energy transduction and metabolic integration. ATP directly powers myosin, the protein immediately responsible for converting chemical energy into movement (Section 6.4). However, the amount of ATP in muscle is small. Hence, the power

output and, in turn, the velocity of running depend on the rate of ATP production from other fuels.

As shown in **Table 24.3**, creatine phosphate (phosphocreatine) can swiftly transfer its high-potential phosphoryl group to ADP to generate ATP. However, the amount of creatine phosphate, like that of ATP itself, is limited. Creatine phosphate and ATP can power intense muscle contraction for 5 to 6 s. Maximum speed in a sprint can thus be maintained for only 5 to 6 s (Figure 15.6). Thus, the winner in a 100-meter sprint is the runner who both achieves the highest initial velocity and then slows down the least.

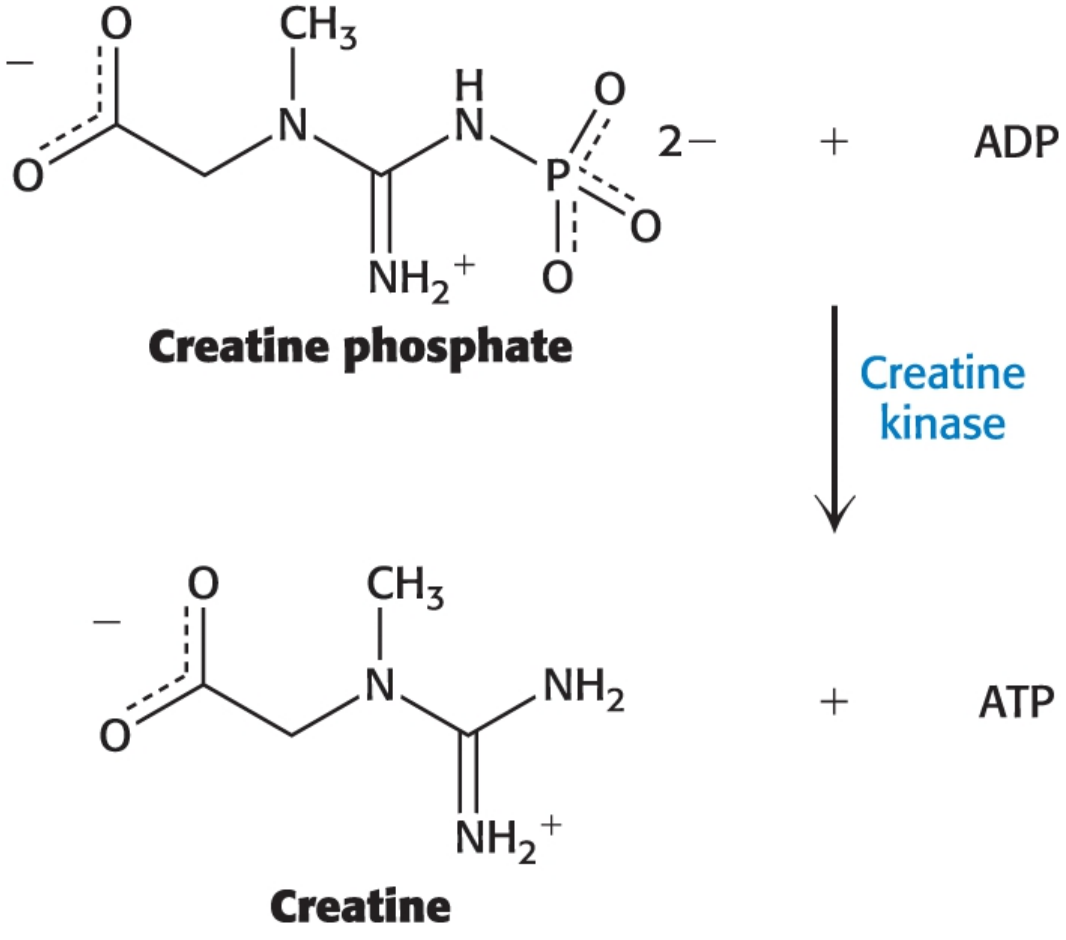

TABLE 24.3 Fuel sources for muscle contraction

Fuel source	Maximal rate of ATP production ($mmol\ s^{-1}$)	Total $\sim P$ available (mmol)
Muscle ATP		223
Creatine phosphate	73.3	446
Conversion of muscle glycogen into lactate	39.1	6700
Conversion of muscle glycogen into CO_2	16.7	84,000
Conversion of liver glycogen into CO_2	6.2	19,000
Conversion of adipose-tissue fatty acids into CO_2	6.7	4,000,000

Note: Fuels stored are estimated for a 70-kg person having a muscle mass of 28 kg.
Data from E. Hultman and R. C. Harris, in *Principles of Exercise Biochemistry,* edited by J. R. Poortmans (Karger, 2004), pp. 78–119.

Sprinting

A 100-meter sprint is powered by stored ATP, creatine phosphate, and the anaerobic glycolysis of muscle glycogen. During a ~ 10-second sprint, the concentration of ATP in muscle drops from 5.2 to 3.7 mM, and that of creatine phosphate decreases from 9.1 to 2.6 mM. Anaerobic glycolysis provides fuel to make up for the loss of ATP and creatine phosphate. The conversion of muscle glycogen into lactate can generate a good deal more ATP, but the rate is slower than that of phosphoryl-

group transfer from creatine phosphate. Because of anaerobic glycolysis, the blood-lactate concentration is increased from 1.6 to 8.3 mM. The release of H^+ from the intensely active muscle concomitantly lowers the blood pH from 7.42 to 7.24. Sprinting is powered by fast-twitch muscle fiber (type IIb) specialized for anaerobic glycolysis. One of the effects of high-intensity training is to increase the amount of lactate transporters in the membranes of slow-twitch fibers (type I), which remove lactate from the blood and slow the fall in blood pH. Nonetheless, the pace of a 100-meter sprint cannot be sustained in a 1000-meter run $(\sim 132\ s)$ for two reasons. First, creatine phosphate is consumed within a few seconds. Second, the lactate produced contributes to acidosis. Thus, alternative fuel sources are needed.

Middle-distance running

Let's examine the fuel use of a middle-distance runner. The complete oxidation of muscle glycogen to CO_2 by aerobic respiration substantially increases the energy available to power the 1000-meter run, but this aerobic process is a good deal slower than anaerobic glycolysis. Because ATP is produced more slowly by oxidative phosphorylation than by glycolysis (Table 24.3), the runner's pace is necessarily slower than in a 100-meter sprint. The championship velocity for the 1000-meter run is about $7.6\ m\ s^{-1}$, compared with approximately $10.4\ m\ s^{-1}$ for the 100-meter event (**Figure 24.11**).

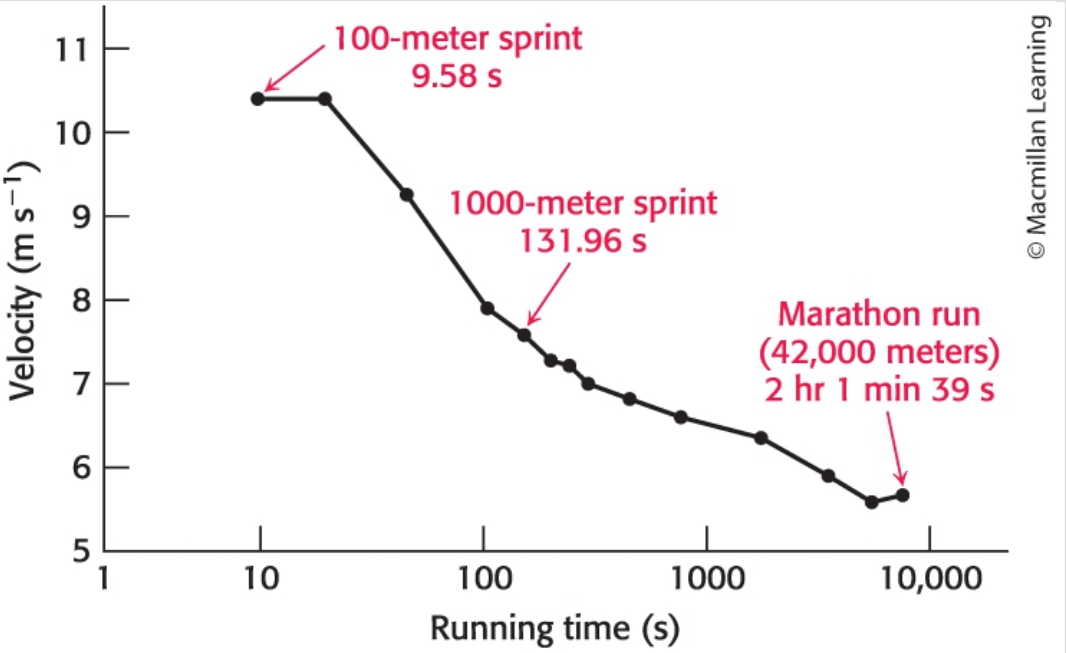

FIGURE 24.11 Running velocity decreases dramatically as a function of the duration of the race. The values shown are world track records.

[Data from trackandfieldnews.com.]

Long-distance running

Running a marathon (26.2 miles or 42,000 meters) requires a different selection of fuels and is characterized by cooperation (depending on the capabilities of the runner) between muscle, liver, and adipose tissue. Liver glycogen complements muscle glycogen as an energy store that can be tapped. Elite marathoners can use the aerobic combustion of glucose to power the entire race, provided they consume fuels during the race. However, for most of us, the total body glycogen stores (103 mol of ATP at best) are insufficient to provide the 150 mol of ATP needed for this grueling event. Much larger quantities of ATP can be obtained by the oxidation of fatty acids derived from the breakdown of fat in adipose tissue, but the maximal rate of ATP generation is slower

yet than that of glycogen oxidation and is more than 10-fold slower than that with creatine phosphate. Thus, ATP is generated much more slowly from high-capacity stores than from limited ones, accounting for the different velocities of anaerobic and aerobic events. Fats are rapidly consumed in activities such as distance running, explaining why extended aerobic exercise is beneficial for people who are insulin resistant.

Is it possible to determine the contribution of each fuel as a function of exercise intensity? The percentage contribution of each fuel can be measured with the use of a respirometer, which measures the **respiratory quotient (RQ)**, the ratio of CO_2 produced to O_2 consumed. Consider the complete combustion of glucose:

$$\underset{\text{Glucose}}{C_6H_{12}O_6} + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$$

The RQ for glucose is 1. Now consider the oxidation of a typical fatty acid, palmitate:

$$\underset{\text{Palmitate}}{C_{16}H_{32}O_2} + 23\,O_2 \rightarrow 16\,CO_2 + 16\,H_2O$$

The RQ for palmitate oxidation is 0.7. Thus, as aerobic exercise intensity increases, the RQ will rise from 0.7 (only fats are used as fuel) to 1.0 (only glucose is used as fuel). Between these values, a mixture of fuels is used (**Figure 24.12**).

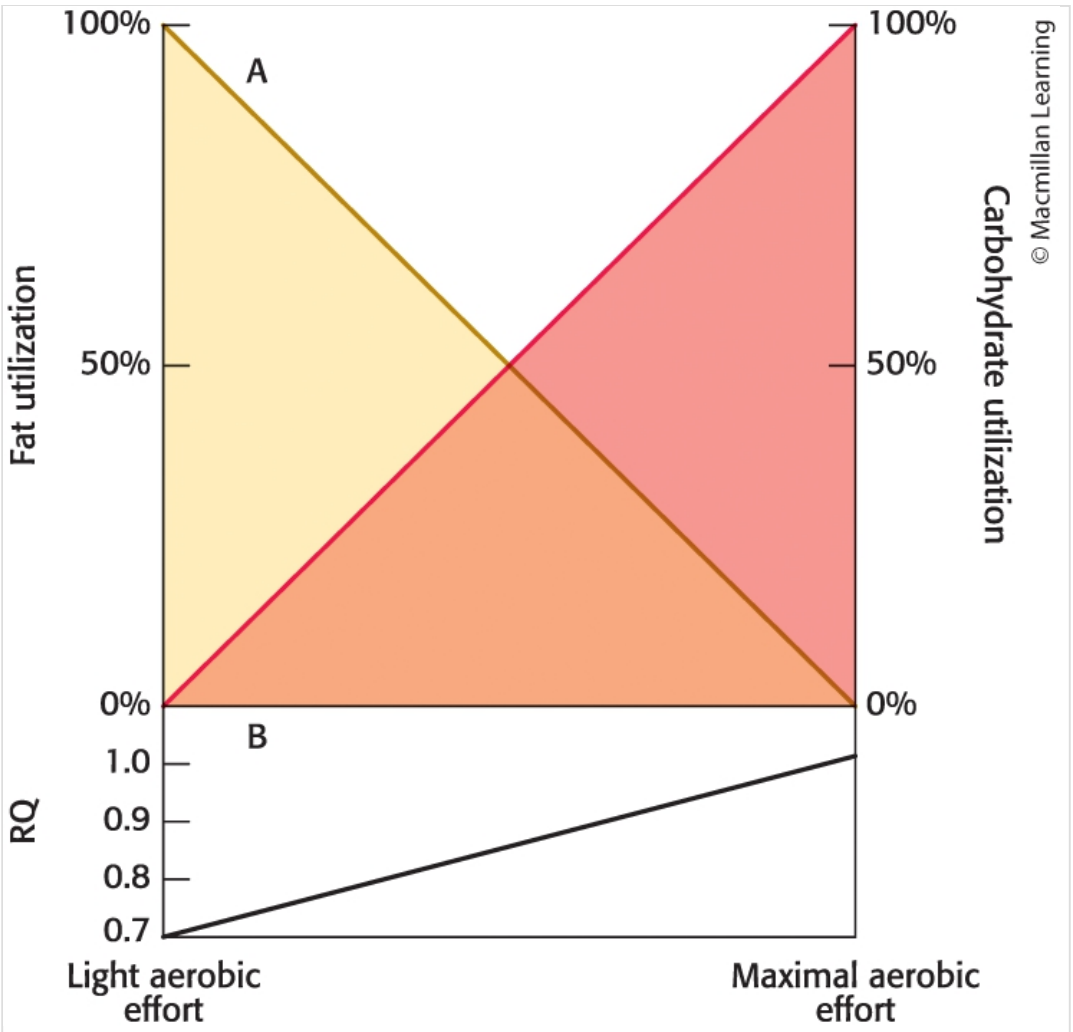

FIGURE 24.12 An idealized representation of fuel use and RQ illustrates major changes as a function of aerobic exercise intensity. (A) With increased exercise intensity, the use of fats as fuels falls as the utilization of carbohydrates increases. (B) The respiratory quotient (RQ) measures the alteration in fuel use.

What is the optimal mix of fuels for use during a marathon? As suggested above, this is a complex question that varies with the athlete and level of training. Studies have shown that, when muscle glycogen has been depleted, the power output of the muscle falls to approximately 50% of maximum. Power output decreases despite the fact that ample supplies of fat are available, suggesting that fats can

supply only about 50% of maximal aerobic effort. Indeed, depletion of glycogen stores during a race is referred to as “bonking” or “hitting the wall,” with the result that the athlete must greatly reduce the pace.

How is an optimal mix of these fuels achieved? A low blood-sugar level leads to a high glucagon/insulin ratio, which in turn mobilizes fatty acids from adipose tissue. Fatty acids readily enter muscle, where they are degraded by β oxidation to acetyl CoA and then to CO_2. The elevated acetyl CoA level decreases the activity of the pyruvate dehydrogenase complex to block the conversion of pyruvate into acetyl CoA. Hence, fatty acid oxidation decreases the funneling of glucose into the citric acid cycle and oxidative phosphorylation. Glucose is spared so that just enough remains available at the end of the marathon to increase the pace as the finish line draws near. The simultaneous use of both fuels gives a higher mean velocity than would be attained if glycogen were totally consumed before the start of fatty acid oxidation. It is important to bear in mind that fuel use is only one of many factors that determine running ability.

The perplexing symptoms of McArdle disease result from the distinct ways skeletal muscle produces ATP

In Section 21.6 we discussed several glycogen storage diseases. We can now explain the complex symptoms of McArdle disease (Type V glycogen storage disease), a rare condition affecting approximately 1 in 100,000 people. Affected individuals experience painful muscle fatigue and have burgundy-colored urine following an attempt at vigorous exercise. The coloration is due to rhabdomyolysis (rapid breakdown of

skeletal muscle), which results in myoglobinuria (myoglobin in the blood and urine) as damaged tissue leaks myoglobin into the blood, which is passed to the urine. Two additional observations are interesting: resting and moderate exercise do not induce the symptoms, and vigorous exercise causes an increase in blood pH, rather than the usually observed decrease in pH. What is the biochemical basis for these symptoms?

As discussed in the previous section, during vigorous exercise, skeletal muscle contractions are powered by glycogen mobilization by glycogen phosphorylase. Patients with McArdle disease lack functional muscle glycogen phosphorylase, leading to the inability to rapidly mobilize glucose from glycogen. In an unaffected individual, intracellular and blood pH fall as lactic acid is produced during anaerobic glycolysis (Section 16.2). Because McArdle patients cannot mobilize glucose, lactic acid will not be produced and there will be no fall in pH; rather, it rises. To explain this, recall again that an immediate source of ATP in skeletal muscle is the phosphorylation of ATP at the expense of creatine phosphate (Section 15.2). In a futile attempt to power exercise, skeletal muscles of an affected individual rapidly synthesize ATP at the expense of creatine phosphate. However, the guanidinium group of creatine is a base, leading to an increase in pH.

Finally, why don't affected individuals experience symptoms at rest or when performing leisurely exercise? As was discussed previously in this chapter, under these conditions, skeletal muscle derives most of its energy from fatty acid oxidation rather than from glycogen mobilization.

Mitochondrial biogenesis is stimulated by muscular activity

Hopefully it is now apparent that muscles must utilize a variety of fuel sources for optimal activity. Now let's consider what biochemical changes exercise induces to optimize athletic performance.

When muscle is stimulated to contract during exercise by receiving nerve impulses from motor neurons, calcium is released from the sarcoplasmic reticulum (**Figure 24.13**). Calcium induces muscle contraction, but recall that calcium is also a potent second messenger and frequently works in association with the calcium-binding protein calmodulin (Section 14.1). In its capacity as a second messenger, calcium stimulates various calcium-dependent enzymes, such as calmodulin-dependent protein kinase. The calcium-dependent enzymes, as well as AMPK, subsequently activate particular transcription-factor complexes.

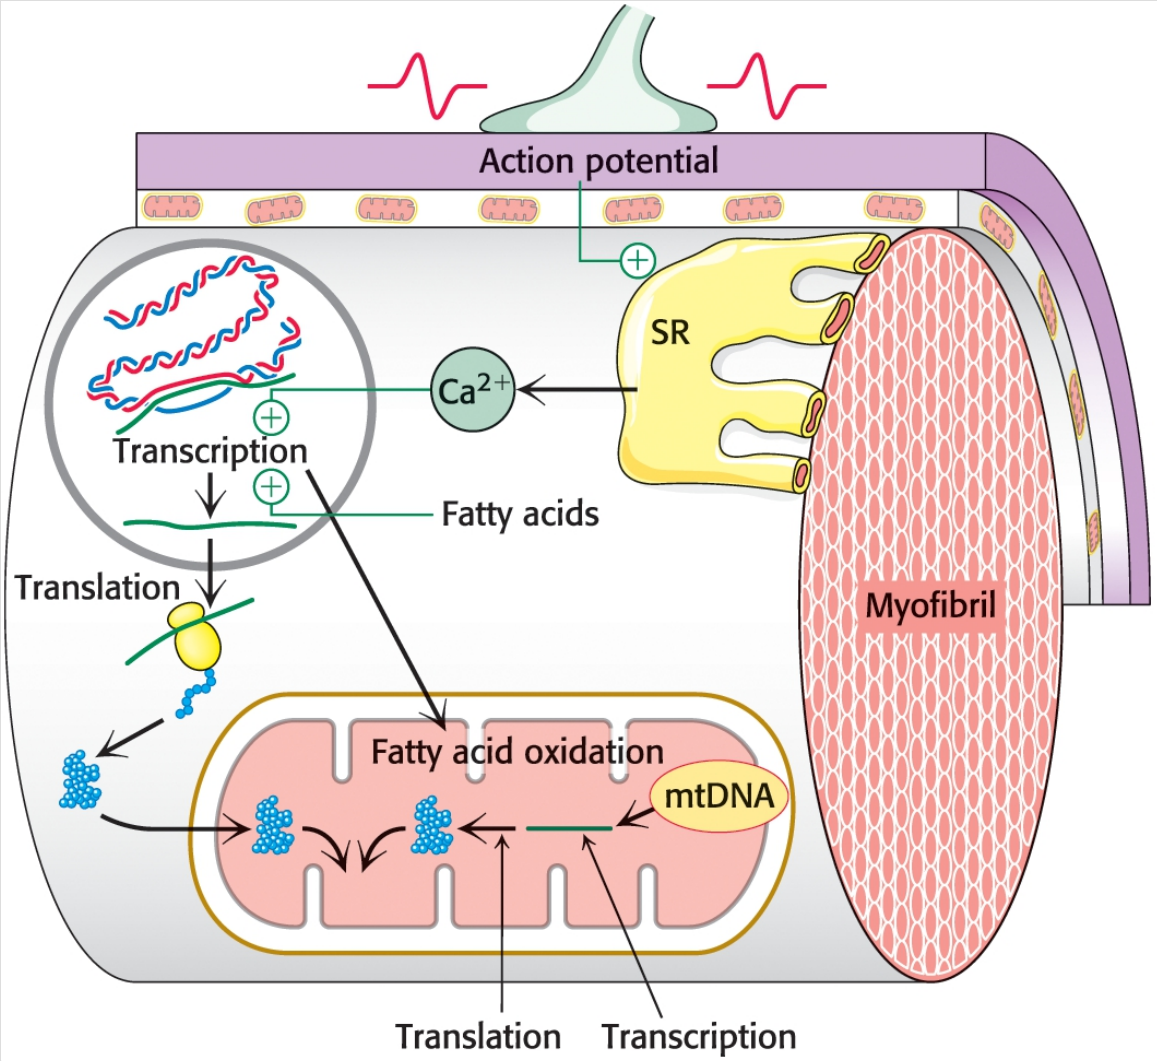

FIGURE 24.13 Exercise results in mitochondrial biogenesis and enhanced fat metabolism. An action potential causes Ca^{2+} release from the sarcoplasmic reticulum (SR), the muscle-cell equivalent of the endoplasmic reticulum. The Ca^{2+}, in addition to instigating muscle contraction, activates nuclear transcription factors that stimulate the expression of specific genes. The products of these genes, in conjunction with the products of mitochondrial genes, a responsible for mitochondrial biogenesis. Fatty acids activate a different set of genes that increase the fatty acid oxidation capability of mitochondria.

[Information from D. A. Hood, *J Appl. Physiol.* 90:1137–1157, 2001, Fig. 2.]

Two patterns of gene expression, in particular, change in response to regular exercise (Figure 24.13). Regular exercise enhances the production of proteins required for fatty acid metabolism, such as the enzymes of β oxidation. Interestingly, fatty acids themselves function as signal molecules to activate the transcription of enzymes involved in fatty acid metabolism. Additionally, another set of transcription factors activated by the calcium signal cascade initiates a signal pathway that increases mitochondrial biogenesis. In concert, the increase in fatty acid oxidizing capability and additional mitochondria allow for the efficient metabolism of fatty acids. Because an excess of fatty acids results in insulin resistance (Section 24.3), efficient metabolism of fatty acids results in an increase in insulin sensitivity. Indeed, muscles of well-trained athletes may contain high concentrations of triacylglycerols yet still maintain exquisite sensitivity to insulin. These alterations of muscle biochemistry are some of the molecular manifestations of the training effects of exercise.

Exercise alters muscle and whole-body metabolism

In addition to the changes to mitochondrial biogenesis and fatty acid metabolism in muscle tissue, exercise has additional biochemical effects on muscle and other tissues. These effects also vary depending on the type and duration/frequency of the exercise. Here we will give a brief overview of the molecular adaptations to exercise, and then we will compare the effects of endurance and resistance training on muscle and whole-body biochemistry.

Regardless of the type of exercise, the timing of the metabolic response, in general, is the same (**Figure 24.14**). The first response to exercise is an alteration in the patterns of gene expression: a variety of transcription factors are activated, and all of these transcription factors stimulate genes encoding proteins that facilitate exercise similar to the

changes described above. In addition to those changes, recall that hypoxia (low oxygen) activates the hypoxia inducible factor (HIF-1), which stimulates the genes encoding glycolytic enzymes, glucose transporters, and angiogenesis-stimulating factors (Section 16.3). Remarkably, as shown in Figure 24.14, even a single bout of exercise can stimulate gene expression several-fold, with levels returning to normal in 24 hours. However, it takes repeated bouts of exercise to accumulate enough mRNA to enhance the synthesis of proteins responding to exercise. In addition to the proteins mentioned above, other examples of such proteins include muscle contractile and structural proteins, and the oxygen-binding proteins hemoglobin and myoglobin (Chapter 3). When these and other proteins accumulate to a sufficient extent, the physiological effects of exercise become apparent. You can run longer and faster, or you can do more repetitions with heavier weights.

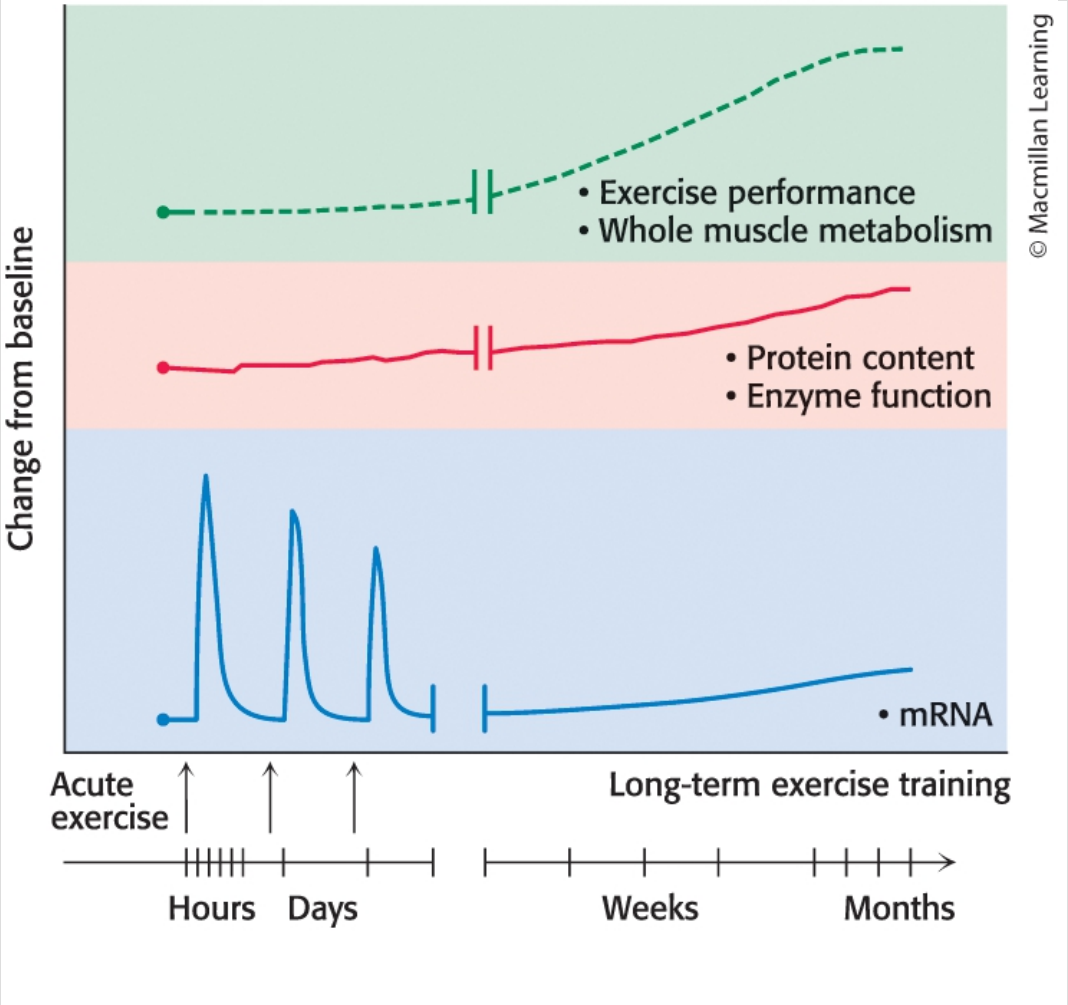

FIGURE 24.14 Biochemical adaptations to exercise vary over a range of time scales. Changes as a function of duration of exercise are shown for mRNA synthesis (bottom), protein synthesis (middle), and exercise performance (top).

[From B. Egan and J. R. Zierath, Exercise metabolism and the molecular regulation of skeletal muscle adaptation, *Cell Metab*. 17:162–184, 2013, Fig. 1.]

Table 24.4 shows some of the molecular adaptations and health benefits accruing from endurance and resistance training. For most of us, some combination of the two will result in maximal health benefits. The American Medical Association and the American College of Sports Medicine launched a global initiative several years ago called *Exercise is Medicine*. As Table 24.4 illustrates, and as we have learned throughout our study of biochemistry, this is indeed the case: exercise *is* medicine.

TABLE 24.4 Biochemical adaptations and health benefits of aerobic and resistance training

	Aerobic (endurance) training	Resistance (strength) training

Example

Measuring the Impact of a Single Athletic Activity on Caloric Homeostasis

Problem:

Estimate how long a person has to jog to offset the calories obtained from eating just 10 macadamia nuts, each with a mass of about 2 g.

Getting Started:

Let's make some assumptions about both the energy captured and energy used. First, because a macadamia nut consists mainly of fats ($\sim 37\ \mathrm{kJ\ g^{-1}}$, $\sim 9\ \mathrm{kcal\ g^{-1}}$), we can assume that each nut provides approximately 75 kJ, or 18 kcal. Second, let's assume that jogging has an incremental power consumption of 400 W.

Solve:

The ingestion of 10 nuts results in an intake of about 753 kJ (180 kcal). A watt (W) is equal to 1 joule (J) per second (0.239 calorie per second), so running with a typical power consumption rate of 400 W requires 0.4 kJ per second, or $0.4\ \mathrm{kJ\ s^{-1}}$ ($0.0956\ \mathrm{kcal\ s^{-1}}$). Dividing the total energy captured, 753 kJ, by the rate of energy use, $0.4\ \mathrm{kJ\ s^{-1}}$, gives us 1883 s, the time one would need to run.

Reflect:

So, a person would have to run just over 31 minutes to expend the calories provided by just 10 small nuts! This calculation illustrates why it can be very difficult to offset increased eating with exercise alone and why caloric homeostasis is primarily maintained by hormonal controls on appetite.

24.5 Starvation Induces Protein Wasting and Ketone Body Formation

What happens when the human body becomes deprived of energy sources? This condition, known as starvation, is a circumstance affecting nearly a billion people worldwide. Typically, a well-nourished 70-kg person has fuel reserves totaling about 670,000 kJ (161,000 kcal; Table 24.5). The energy need for a 24-hour period ranges from about 6700 kJ (1600 kcal) to 25,000 kJ (6000 kcal), of course depending on the extent of activity, as we have just examined. Thus, stored fuels suffice to meet caloric needs during starvation for 1 to 3 months. However, the carbohydrate reserves are exhausted in only a day.

TABLE 24.5 Typical fuel reserves in a 70-kg person

	Available energy in kilojoules (kcal)					
Organ	**Glucose or glycogen**		**Triacylglycerols**		**Mobilizable proteins**	
Blood	250	(60)	20	(45)	0	(0)
Liver	1700	(400)	2000	(450)	1700	(400)
Brain	30	(8)	0	(0)	0	(0)
Muscle	5000	(1200)	2000	(450)	100,000	(24,000)

Adipose tissue	330	(80)	560,000	(135,000)	170	(40)

Data from G. F. Cahill, Jr., *Clin. Endocrinol. Metab.* 5:398, 1976.

The first priority during starvation is the maintenance of blood-glucose concentration

Even under starvation conditions, the blood-glucose concentration must be maintained above 2.2 mM. The first priority of metabolism in starvation is to provide sufficient glucose to the brain and other tissues (such as red blood cells) that are absolutely dependent on this fuel. However, precursors of glucose are not abundant. Most energy is stored in the fatty acyl moieties of triacylglycerols. Moreover, recall that fatty acids cannot be converted into glucose, because acetyl CoA resulting from fatty acid breakdown cannot be transformed into pyruvate (Section 22.4). The glycerol moiety of triacylglycerol can be converted into glucose, but only a limited amount is available. The only other potential source of glucose is the carbon skeletons of amino acids derived from the breakdown of proteins. However, proteins are not stored, and so any breakdown will necessitate a loss of function. Thus, the second priority of metabolism in starvation is to preserve protein, which is accomplished by shifting the fuel being used from glucose to fatty acids and ketone bodies (**Figure 24.15**).

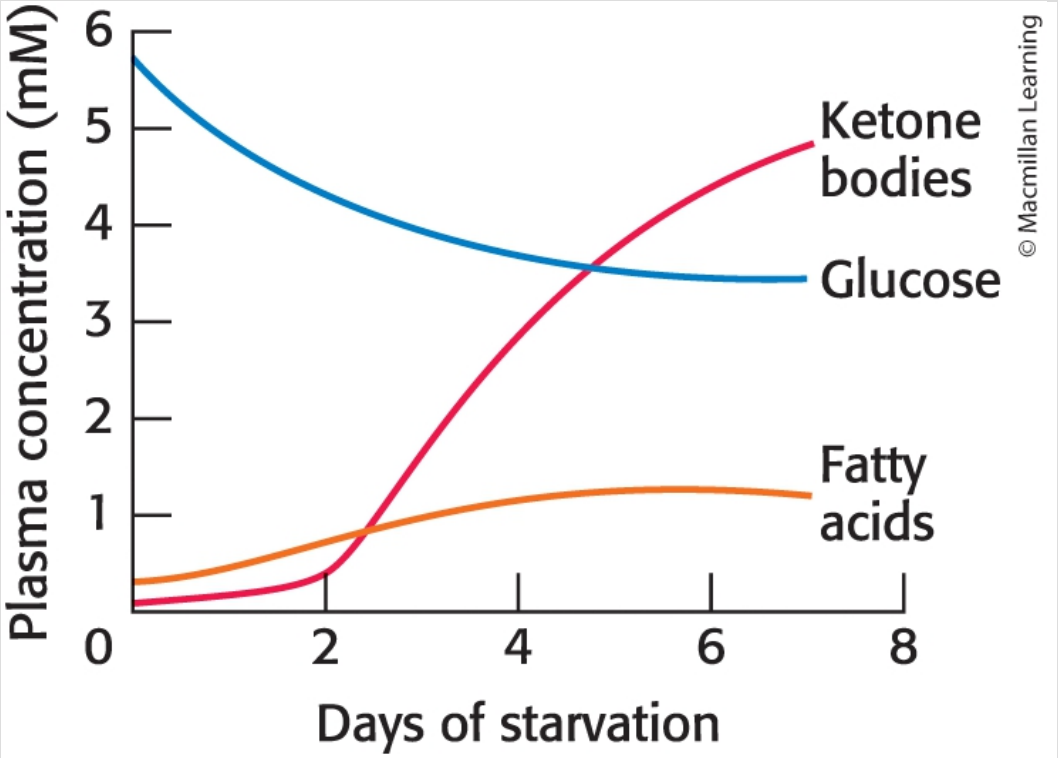

FIGURE 24.15 The blood concentrations of fatty acids and ketone bodies increase in starvation, while glucose decreases.

The metabolic changes on the first day of starvation are like those after an overnight fast. The low blood-sugar level leads to decreased insulin secretion and increased glucagon secretion. The dominant metabolic processes are the mobilization of triacylglycerols in adipose tissue and gluconeogenesis by the liver. The liver obtains energy for its own needs by oxidizing fatty acids released from adipose tissue. The concentrations of acetyl CoA and citrate consequently increase, which switches off glycolysis. The uptake of glucose by muscle is markedly diminished because of the low insulin level, whereas fatty acids enter freely. Consequently, muscle uses almost no glucose and relies nearly exclusively on fatty acids for fuel. The β oxidation of fatty acids by muscle halts the

conversion of pyruvate into acetyl CoA, because acetyl CoA stimulates the phosphorylation of the pyruvate dehydrogenase complex, which renders it inactive (Section 17.4). Hence, any available pyruvate, lactate, and alanine are exported to the liver for conversion into glucose. Glycerol derived from the cleavage of triacylglycerols is another raw material for the synthesis of glucose by the liver.

Proteolysis provides a major source of carbon skeletons for gluconeogenesis. During starvation, degraded proteins are not replenished and instead serve as carbon sources for glucose synthesis. Initial sources of protein are those that turn over rapidly, such as proteins of the intestinal epithelium and the secretions of the pancreas. Proteolysis of muscle protein can provide large amounts of amino acids for gluconeogenesis. However, survival for most animals depends on being able to move rapidly, which requires a large muscle mass, and so muscle protein loss must be minimized.

Self-Check Question

The hormone glucagon signifies the fasted state, yet it inhibits glycolysis in the liver. How do we benefit from this inhibition of an energy-production pathway?

Metabolic adaptations in prolonged starvation minimize protein degradation

How is the loss of muscle and other proteins curtailed? After about 3 days of starvation, the liver forms large amounts of the ketone

bodies, acetoacetate, and D-3-hydroxybutyrate (Section 22.4). Their synthesis from acetyl CoA increases markedly because the citric acid cycle is unable to oxidize all the acetyl units generated by fatty acid degradation. Gluconeogenesis depletes the supply of oxaloacetate, which is essential for the entry of acetyl CoA into the citric acid cycle. Consequently, the liver produces large quantities of ketone bodies, which are released into the blood. At this time, the brain begins to consume significant amounts of acetoacetate in place of glucose. After 3 days of starvation, about a quarter of the brain's energy needs are met by ketone bodies (**Table 24.6**). The heart also uses ketone bodies as fuel.

TABLE 24.6 Fuel metabolism during starvation

	Amount formed or consumed in 24 hours (grams)	
Fuel exchanges and consumption	**3rd day**	**40th day**
Fuel use by the brain		
Glucose	100	40
Ketone bodies	50	100
All other use of glucose	50	40
Fuel mobilization		
Adipose-tissue lipolysis	180	180
Muscle-protein degradation	75	20

Fuel output of the liver		
Glucose	150	80
Ketone bodies	150	150

After several weeks of starvation, ketone bodies become the major fuel of the brain. Acetoacetate is activated by the transfer of CoA from succinyl CoA to give acetoacetyl CoA (Section 22.4). Cleavage by thiolase then yields two molecules of acetyl CoA, which enter the citric acid cycle. In essence, ketone bodies are equivalents of fatty acids that are an accessible fuel source for the brain. Only 40 g of glucose is then needed per day for the brain, compared with about 120 g in the first day of starvation (**Figure 24.16A**). The effective conversion of fatty acids into ketone bodies by the liver and their use by the brain markedly diminishes the need for glucose. Hence, less muscle is degraded than in the first days of starvation. The breakdown of 20 g of muscle daily compared with 75 g early in starvation is most important for survival. How are the amino acids released by muscle processed? The amino acids are transported to the liver where nitrogen is removed as urea, gluconeogenic amino acids are metabolized into glucose, and ketogenic amino acids are used as fuel for the liver or processed to ketone bodies.

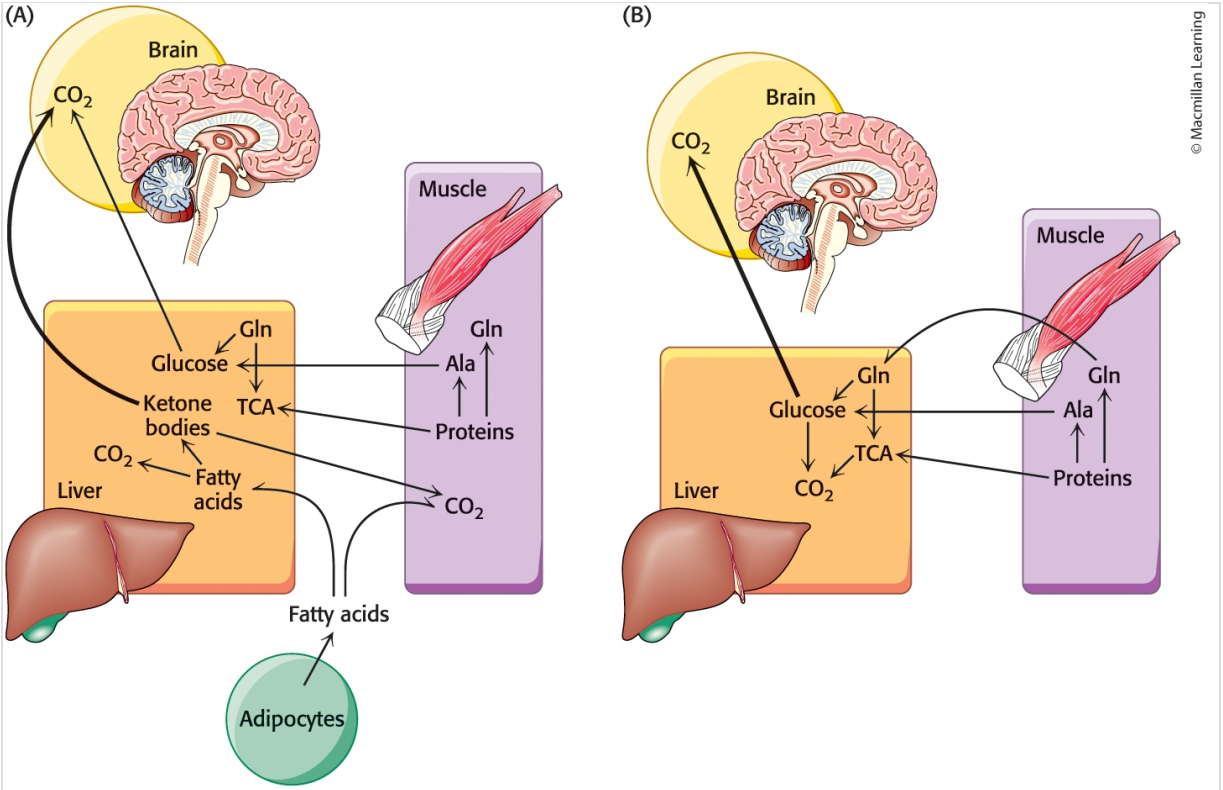

FIGURE 24.16 Fuel use during prolonged starvation changes after fat mass is depleted. A simplified depiction of the relation of adipose tissue, liver, muscle, and brain is shown. (A) Fat mass is adequate. (B) Fat mass is depleted. Only the amino acids alanine and glutamine are shown since they are also important for nitrogen transport.

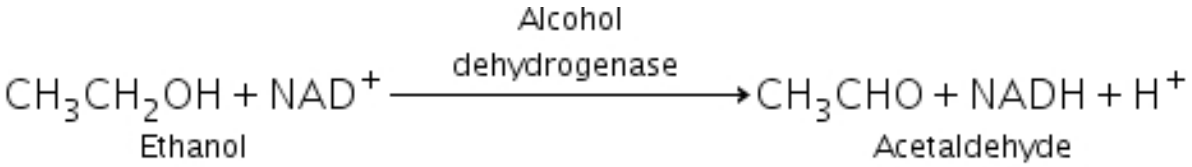
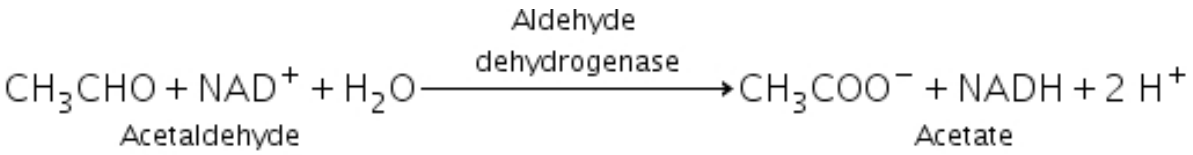
What happens after depletion of the triacylglycerol stores? The ketone body contribution disappears, and the only source of fuel that remains is protein (Figure 24.16B). Protein degradation accelerates, and a loss of heart, liver, or kidney function inevitably causes death. A person's survival time is mainly determined by the size of the triacylglycerol depot. Examinations of people who have starved themselves to death as a political protest show that lean individuals succumb after about 70 days, whereas obese individuals can survive for 6 or 7 months.

Self-Check Question



What tissue provides the largest energy supply in a well-nourished human being? What other tissues also store large amounts of energy and in what form?

24.6 Ethanol Alters Energy Metabolism in the Liver



Ethanol has been a part of the human diet for centuries, partly because of its intoxicating effects and partly because alcoholic beverages provided a safe means of hydration when uncontaminated water was scarce. However, its consumption in excess can result in a number of health problems, most notably liver damage. What is the biochemical basis of these health problems?

Ethanol metabolism leads to an excess of NADH

Ethanol cannot be excreted and must be metabolized, primarily by the liver. This metabolism is accomplished by two pathways. The first pathway comprises two steps. The first step, catalyzed by the enzyme *alcohol dehydrogenase,* takes place in the cytoplasm:

The second step, catalyzed by *aldehyde dehydrogenase*, takes place in mitochondria:

Note that ethanol consumption leads to an accumulation of NADH. This high concentration of NADH inhibits gluconeogenesis by preventing the oxidation of lactate to pyruvate. In fact, the high concentration of NADH will cause the reverse reaction to predominate, and lactate will accumulate. The consequences may be hypoglycemia and lactic acidosis.

The overabundance of NADH also inhibits fatty acid oxidation. An important metabolic purpose of fatty acid oxidation is to generate NADH for ATP generation by oxidative phosphorylation, but an alcohol consumer's NADH needs are met by ethanol metabolism. In fact, the excess NADH signals that conditions are right for fatty acid synthesis. Hence, triacylglycerols accumulate in the liver, leading to a condition known as "fatty liver" that is exacerbated in obese persons.

The second pathway for ethanol metabolism uses cytochrome P450 enzymes. This means of ethanol metabolism is also called the *microsomal ethanol-oxidizing system* (MEOS). This cytochrome P450-dependent pathway (Section 27.4) generates acetaldehyde and subsequently acetate while oxidizing biosynthetic reducing power, NADPH, to $NADP^+$. Because it uses oxygen, this pathway generates free radicals that damage tissues. Moreover, because the system consumes NADPH, the antioxidant glutathione cannot be regenerated (Section 20.5), exacerbating the oxidative stress.

Ethanol metabolites cause liver damage

What are the effects of the other metabolites of ethanol? Liver mitochondria can convert acetate into acetyl CoA in a reaction requiring ATP. The enzyme is the acyl CoA synthetase that normally activates short-chain fatty acids.

$$\text{Acetate} + \text{coenzyme A} + \text{ATP} \rightarrow \text{acetyl CoA} + \text{AMP} + PP_i$$

$$PP_i \rightarrow 2\ P_i$$

However, further processing of the acetyl CoA by the citric acid cycle is blocked, because NADH inhibits two important citric acid cycle regulatory enzymes — isocitrate dehydrogenase and α-ketoglutarate dehydrogenase.

The accumulation of acetyl CoA has several consequences. First, ketone bodies will form and be released into the blood, aggravating the acidic condition already resulting from the high lactate concentration. The processing of the acetate in the liver becomes inefficient, leading to a buildup of acetaldehyde. This very reactive compound forms covalent bonds with many important functional groups in proteins, impairing protein function. If ethanol is consistently consumed at high levels, the acetaldehyde can significantly damage the liver, eventually leading to cell death.

Ethanol also alters gene transcription, further exacerbating liver damage. Ethanol in some fashion stimulates the synthesis of sterol regulatory-element binding proteins (SREBPs) (Section 27.3), a family of transcription factors that upregulates the genes that promote fatty acid synthesis. At the same time, acetaldehyde derived from ethanol inactivates another transcription factor, PPARα (peroxisome proliferator-activated receptor), which normally stimulates the genes

involved in fatty acid oxidation. The biochemical effects of ethanol consumption can be quite rapid. For instance, fat accumulates in the liver within a few days of moderate alcohol consumption.

Liver damage from excessive ethanol consumption occurs in three stages. The first stage is the aforementioned development of fatty liver. In the second stage — alcoholic hepatitis — groups of cells die and inflammation results. This stage can itself be fatal. In stage three — cirrhosis — fibrous structure and scar tissue are produced around the dead cells. Cirrhosis impairs many of the liver's biochemical functions. The cirrhotic liver is unable to convert ammonia into urea, and blood levels of ammonia rise. Ammonia is toxic to the nervous system and can cause coma and death. Cirrhosis of the liver arises in about 25% of alcoholics, and about 75% of all cases of liver cirrhosis are the result of alcoholism. Viral hepatitis is a nonalcoholic cause of liver cirrhosis.

Excess ethanol consumption disrupts vitamin metabolism

The adverse effects of ethanol are not limited to the metabolism of ethanol itself. Vitamin A (retinol) is converted into retinoic acid, an important signal molecule for growth and development in vertebrates, by the same dehydrogenases that metabolize ethanol. Consequently, this activation does not take place in the presence of ethanol, which acts as a competitive inhibitor. Moreover, the P450 enzymes induced by ethanol inactivate retinoic acid. These disruptions in the retinoic acid signaling pathway are believed to be responsible, at least in part, for fetal alcohol syndrome as well as the development of a variety of cancers.

The disruption of vitamin A metabolism is a direct result of the biochemical changes induced by excess ethanol consumption. Other disruptions in metabolism result from another common characteristic

of alcoholics — malnutrition. Alcoholics will frequently drink instead of eating. A dramatic neurological disorder, referred to as *Wernicke–Korsakoff syndrome*, results from insufficient intake of the vitamin thiamine. Symptoms include mental confusion, unsteady gait, and lack of fine motor skills.

The symptoms of Wernicke–Korsakoff syndrome are similar to those of beriberi (Section 17.5) because both conditions result from a lack of thiamine. Thiamine is converted into the coenzyme thiamine pyrophosphate, a key constituent of the pyruvate dehydrogenase complex. Recall that this complex links glycolysis with the citric acid cycle. Disruptions in the pyruvate dehydrogenase complex are most evident as neuromuscular disorders because the nervous system is normally dependent on glucose for energy generation.

Alcoholic scurvy is occasionally observed because of an insufficient ingestion of ascorbate (vitamin C). Ascorbate is required for the formation of stable collagen fibers. The symptoms of scurvy include skin lesions and blood-vessel fragility. Most notable are bleeding gums, the loss of teeth, and periodontal infections. Gums are especially sensitive to a lack of ascorbate because the collagen in gums turns over rapidly.

What is the biochemical basis for scurvy? Ascorbate is required for the synth-esis of 4-hydroxyproline, an amino acid necessary for collagen stability. To form this unusual amino acid, proline residues on the amino side of glycine residues in nascent collagen chains become hydroxylated. One oxygen atom from O_2 becomes attached to C-4 of proline, while the other oxygen atom is taken up by α-ketoglutarate, which is converted into succinate (**Figure 24.17**).

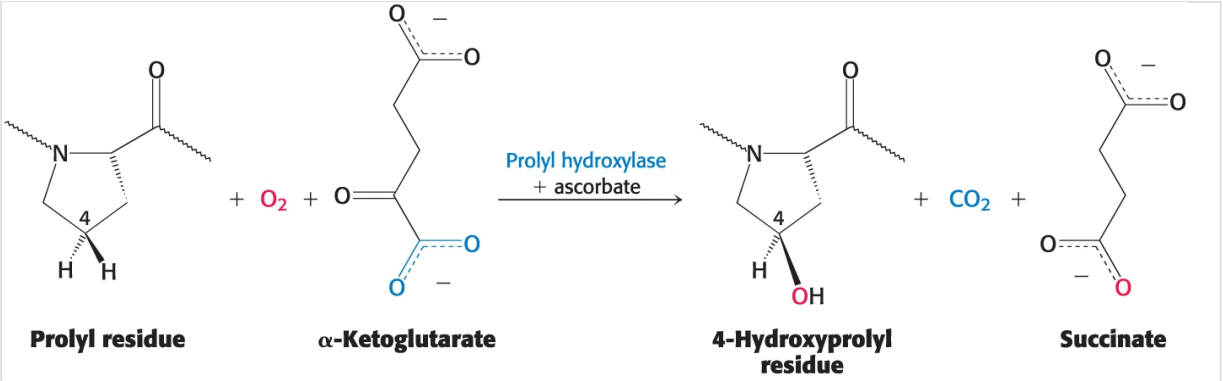


FIGURE 24.17 Formation of 4-hydroxyproline requires ascorbate. Proline is hydroxylated at C-4 by the action of prolyl hydroxylase, an enzyme that activates molecular oxygen.

This reaction is catalyzed by prolyl hydroxylase, a dioxygenase (Section 23.5), which requires an Fe^{2+} ion to activate O_2. The enzyme also converts α-ketoglutarate into succinate without hydroxylating proline. In this partial reaction, an oxidized iron complex is formed, which inactivates the enzyme. How is the active enzyme regenerated? Ascorbate comes to the rescue by reducing the ferric ion of the inactivated enzyme. In the recovery process, ascorbate is oxidized to dehydroascorbic acid (**Figure 24.18**). Thus, ascorbate serves here as a specific antioxidant.

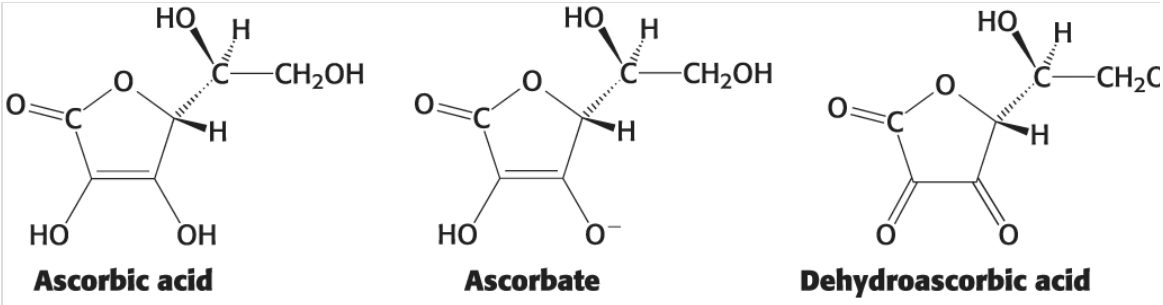

FIGURE 24.18 Ascorbate is the ionized form of vitamin C, and dehydroascorbic acid is the oxidized form of ascorbate.

Why does impaired hydroxylation have such devastating consequences? Collagen synthesized in the absence of ascorbate is less stable than the normal protein. Hydroxyproline stabilizes the collagen triple helix by forming interstrand hydrogen bonds. The abnormal fibers formed by insufficiently hydroxylated collagen account for the symptoms of scurvy. In the next section, we will see that prolyl hydroxylase also plays a critical role in the development of some cancers.

Self-Check Question

What are the two primary means of processing ethanol?

Ethanol and defects in central energy metabolism contribute to the development of cancer

In addition to the numerous detrimental effects outlined above, ethanol is also a well-known carcinogen, although the mechanisms and tissues affected are too numerous to list, and many remain poorly established. There are many other connections between biochemical defects in the enzymes of central metabolism and cancer, some of which are exacerbated by ethanol consumption. For example, mutations that alter

the activity of succinate dehydrogenase, fumarase, or pyruvate dehydrogenase kinase all enhance aerobic glycolysis (Section 16.3). Recall that in aerobic glycolysis, cancer cells preferentially metabolize glucose to lactate even in the presence of oxygen. Defects in these enzymes share a common biochemical link: the transcription factor HIF-1 and its regulation by prolyl hydroxylase.

Normally, HIF-1 upregulates the enzymes and transporters that enhance glycolysis only when oxygen concentration falls, a condition called *hypoxia*. Under aerobic conditions, HIF-1 is hydroxylated by prolyl hydroxylase and is subsequently destroyed by the proteasome (Section 23.2). The degradation of HIF-1 prevents the stimulation of glycolysis. As noted previously (Figure 24.17), prolyl hydroxylase requires α-ketoglutarate, ascorbate, and oxygen for activity. Thus, when ascorbate is unavailable — due to excessive alcohol consumption or when oxygen concentration falls — prolyl hydroxylase is inactive, HIF-1 is not hydroxylated and not degraded, and the synthesis of proteins required for glycolysis is stimulated. As a result, the rate of glycolysis is increased.

Recent research suggests that defects in the enzymes of the citric acid cycle may significantly affect the regulation of prolyl hydroxylase. When either succinate dehydrogenase or fumarase is defective, succinate and fumarate accumulate in the mitochondria and spill over into the cytoplasm. Both succinate and fumarate are competitive inhibitors of prolyl hydroxylase. The inhibition of prolyl hydroxylase results in the stabilization of HIF-1, since HIF-1 is no longer hydroxylated. Lactate, the end product of glycolysis, also appears to inhibit prolyl hydroxylase by interfering with the action of ascorbate. These multiple factors reducing prolyl hydroxylase activity are likely exacerbated by the effects of ethanol consumption described previously.

In addition to increasing the amount of the proteins required for glycolysis, HIF-1 also stimulates the production of pyruvate dehydrogenase kinase (PDK). The kinase inhibits the pyruvate

dehydrogenase complex, preventing the conversion of pyruvate into acetyl CoA. The pyruvate remains in the cytoplasm, further increasing the rate of aerobic glycolysis. Moreover, mutations in PDK that lead to enhanced activity contribute to increased aerobic glycolysis and the subsequent development of cancer. By enhancing glycolysis and increasing the concentration of lactate, the mutations in PDK result in the inhibition of prolyl hydroxylase and the stabilization of HIF-1.

One additional and particularly fascinating example of the manipulation of cellular control by cancer cells comes from recent findings on the mitochondrial enzyme acetyl CoA acetyltransferase. Under normal circumstances, this enzyme synthesizes ketone bodies; however, in certain cancers, acetyl CoA acetyltransferase is phosphorylated, causing it to form active tetramers. Interestingly, the enzyme then acts as a protein acetyltransferase, adding acetyl groups to pyruvate dehydrogenase and pyruvate dehydrogenase phosphatase. The acetylation inhibits the two enzymes and facilitates the metabolic switch from oxidative phosphorylation to aerobic glycolysis, thereby enhancing the Warburg effect (Section 16.3). In essence, the enzyme is hijacked from its normal role in ketone body formation to further cancer growth.

These observations linking central metabolic enzymes to cancer suggest that cancer is also a metabolic disease, not simply a disease of mutant growth factors and cell cycle control proteins. This realization opens the door to new thinking about cancer treatments. Indeed, preliminary experiments suggest that if cancer cells undergoing aerobic glycolysis are forced by pharmacological manipulation to use oxidative phosphorylation, the cancer cells lose their malignant properties. It seems that even in metabolic pathways as well known as the citric acid cycle, which has been studied for the better part of a century, there are still secrets to be revealed by future biochemists.

Chapter 24 Summary

24.1 Caloric Homeostasis Is a Means of Regulating Body Weight

- Maintaining near-constant body weight throughout adult life is accomplished by caloric homeostasis. When energy intake is greater than expenditure, weight gain results, which may lead to obesity. Obesity is at pandemic levels and is implicated as a contributing factor in a host of pathological conditions.
- Various signal molecules act on the brain to control appetite, including short-term signals like CCK and GLP-1, which relay satiety signals to the brain, and signals like leptin and insulin, which regulate appetite over longer periods.
- Leptin is secreted by adipose tissue in proportion to mass and reduces hunger by binding to receptors in the brain. Obesity can develop even with normal amounts of leptin and leptin receptor, suggesting that such individuals are leptin-resistant. Suppressors of cytokine signaling may inhibit leptin signaling, leading to leptin resistance and obesity.

24.2 The Fasted–Fed Cycle Is a Response to Eating and Sleeping Behaviors

- Insulin signals the fed state; it stimulates the formation of glycogen and triacylglycerols. In contrast, glucagon signals a low blood-glucose concentration, i.e., the fasted state; it stimulates glycogen breakdown and gluconeogenesis by the liver, and triacylglycerol hydrolysis by adipose tissue.
- After a meal, the rise in the blood-glucose concentration leads to increased insulin and decreased glucagon secretions, leading to glycogen synthesis in muscle and the liver.
- When the blood-glucose concentration falls, glucose is formed by glycogen degradation and gluconeogenesis, and fatty acids

are released by the hydrolysis of triacylglycerols.
- As a fast continues, the liver and muscle increasingly use fatty acids to meet their own energy needs so that glucose is conserved for use by the brain and the red blood cells.

24.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity

- Diabetes is the most common metabolic disease in the world, with type 2 being far more common than type 1.
- Type 1 diabetes results when insulin is absent due to destruction of the pancreatic β cells. The body is still responsive to insulin, which is used to treat the disease.
- Type 2 diabetes is characterized by insulin resistance, in which tissues do not respond normally to insulin. Obesity is a significant predisposing factor for type 2 diabetes.
- Excess fats accumulate in the muscle tissue of an obese individual. These fats are processed to second messengers that activate signal-transduction pathways, which inhibit insulin signaling, leading to insulin resistance.
- Insulin resistance ultimately leads to pancreatic β-cell failure. Increased insulin production to compensate for resistance results in endoplasmic reticulum stress and subsequent activation of apoptotic pathways that lead to β cell death.
- Lack of insulin signaling leads to elevated blood-glucose levels, the mobilization of triacylglycerols, and excessive ketone body formation. Accelerated ketone body formation can lead to acidosis, coma, and death in untreated diabetics.

24.4 Exercise Beneficially Alters the Biochemistry of Cells

- Exercise is a useful treatment for insulin resistance and type 2 diabetes. Muscle activity stimulates mitochondrial biogenesis in a calcium-dependent manner. The increase in the number of

mitochondria facilitates fatty acid oxidation in the muscle, resulting in increased insulin sensitivity.
- Fuel choice in exercise is determined by the intensity and duration of the bout of exercise. Sprinting is powered by stored ATP, creatine phosphate, and anaerobic glycolysis, while running a marathon requires the oxidation of both muscle glycogen and fatty acids derived from adipose tissue.

24.5 Starvation Induces Protein Wasting and Ketone Body Formation

- The metabolic adaptations during starvation serve to prioritize blood glucose yet minimize protein degradation.
- Ketone bodies are formed by the liver from fatty acids within a few days after the onset of starvation and, after several weeks, they become the major fuel of the brain. The diminished need for glucose decreases the rate of muscle breakdown, prolonging survival.

24.6 Ethanol Alters Energy Metabolism in the Liver

- The oxidation of ethanol results in an unregulated overproduction of NADH, which has several consequences. A rise in the blood concentration of lactic acid and ketone bodies causes acidosis. The liver is damaged because the excess NADH causes excessive fat formation as well as the generation of acetaldehyde, a reactive molecule.
- Alterations in the activity of several transcription factors due to ethanol consumption also contribute to liver pathology. Severe liver damage can result with prolonged ethanol use.
- Ethanol disrupts vitamin absorption and is carcinogenic. Numerous defects in central metabolism lead to cancer by a variety of unexpected mechanisms, indicating that in many cases cancer can be viewed as a metabolic disease.

type 2 diabetes
metabolic syndrome
endoplasmic reticulum (ER) stress
unfolded protein response (UPR)
respiratory quotient (RQ)

Problems

1. Pick one answer for each question: Under normal circumstances, what is the most commonly used fuel by the brain? Which becomes a substantial source of energy for the brain after a week of fasting?

a. Glycerol
b. Glucose
c. Fatty acids
d. Ketone bodies

2. Which of the following pathways is not stimulated by epinephrine?

a. Glycogen degradation
b. Mobilization of fatty acids from adipose tissue
c. Glycogen synthesis
d. Glycolysis in muscle

3. As disturbing as the obesity pandemic is, an equally intriguing, almost amazing observation is that many people are able to maintain an approximately constant weight throughout adult life. A few simple calculations of a simplified situation illustrate how remarkable this feat is. Consider a 120-pound woman whose weight does not change significantly between the ages of 25 and 65. Let's say that the woman requires 8400 kJ $(2000\ \text{kcal})\ \text{per day}^{-1}$. For simplicity's sake, let us assume the woman's diet consists predominantly of fatty acids derived from lipids. The energy density of fatty acids is $38\ \text{kJ}\ (9\ \text{kcal})\ \text{g}^{-1}$. How much food has she consumed over the 40 years in question? 1

4. Suppose that our test subject from problem 3 gained 55 pounds between the ages of 25 and 65 (a common occurrence), and that her weight at 65 years of age is 175 pounds. Calculate how many excess calories she consumed per day to gain the 55 pounds over 40 years. Assume that our test subject is 5 feet, 6 inches tall. What is her BMI? Would she be considered obese at 175 pounds? 1

5. Adipose tissue was once only considered a storage site for fat. Why is this view no longer considered correct?

6. What are the two key hormones responsible for long-term maintenance of caloric homeostasis? 2

7. What two biochemical roles does CCK play? GLP-1? 2

8. Match the characteristic (a–i) with the appropriate hormone (1–6). 2

1. Secreted by adipose tissue	1. leptin
2. Stimulates liver gluconeogenesis	2. adiponectin
3. GPCR pathway	3. GLP-1
4. Satiety signal	4. CCK
5. Enhances insulin secretion	5. insulin
6. Secreted by the pancreas during a fast	6. glucagon
7. Secreted after a meal by the pancreas	
8. Stimulates glycogen synthesis	
9. Missing in type 1 diabetes	

---

9. Differentiate between type 1 and type 2 diabetes. 3

10. The typical human adult uses about 160 g of glucose per day, 120 g of which is used by the brain. The available reserve of glucose ($\sim 20\ g$ of circulating glucose and $\sim 190\ g$ of glycogen) is adequate for about one day. After the reserve has been depleted during starvation, what other sources can be used to produce glucose?

a. Glycerol from triacylglycerols
b. Glucogenic amino acids from muscle protein

c. Pyruvate by carboxylation to form oxaloacetate
d. Fatty acids from triacylglycerols
e. Ketogenic amino acids from muscle protein

11. The rate of energy expenditure of a typical 70-kg person at rest is about 70 watts (W), like that of a light bulb.

a. Express this rate in kilojoules per second and in kilocalories per second.
b. How many electrons flow through the mitochondrial electron-transport chain per second under these conditions?
c. Estimate the corresponding rate of ATP production.
d. The total ATP content of the body is about 50 g. Estimate how often an ATP molecule turns over in a person at rest.

12. Recall that the respiratory quotient (RQ) is defined as the volume of CO_2 released divided by the volume of O_2 consumed.

a. Calculate the RQ values for the complete oxidation of glucose and of tripalmitoylglycerol.
b. What do RQ measurements reveal about the contributions of different energy sources during intense exercise? (Assume that protein degradation is negligible.) 4

13. Ingesting large amounts of glucose immediately before a marathon might seem to be a good way of increasing the fuel stores. However, experienced runners do not ingest glucose before a race. What is the biochemical reason for their avoidance of this potential fuel? (Hint: consider the effect of glucose ingestion on the level of insulin.) 2, 4

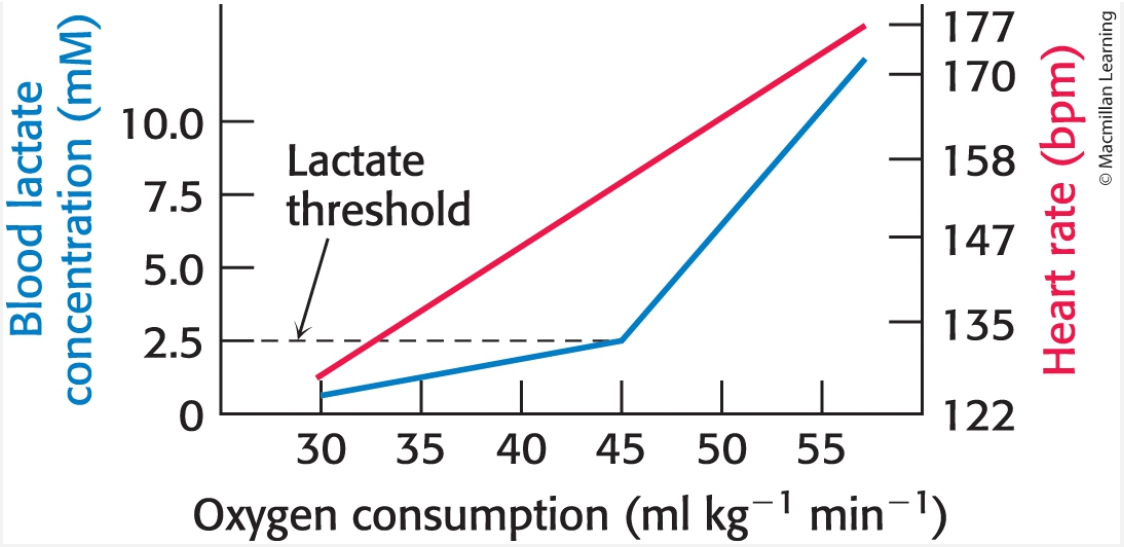
14. The most common form of malnutrition in children in the world, kwashiorkor, is caused by a diet having ample calories but little protein. The high levels of carbohydrate result in high levels of insulin. 5

a. What is the effect of high levels of insulin on lipid utilization? On protein metabolism?
b. Children suffering from kwashiorkor often have large distended bellies caused by water from the blood leaking into extracellular spaces. Suggest a biochemical basis for this condition.

15. How is the metabolism of the liver coordinated with that of skeletal muscle during strenuous exercise? What is the advantage of converting pyruvate into lactate in skeletal muscle? 4

16. What is the major fuel for resting muscle? What is the major fuel for muscle under strenuous work conditions? 4

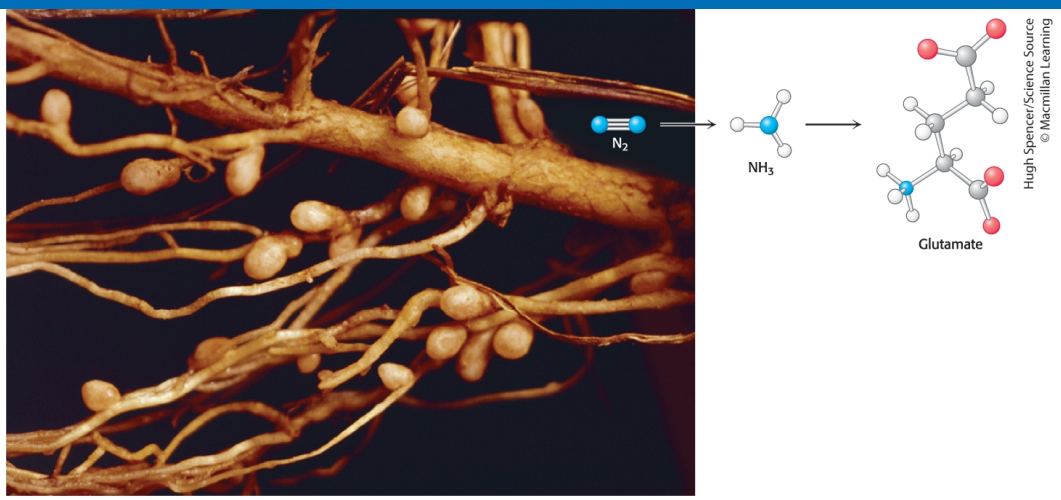
17.



a. After light exercise, the oxygen consumed in recovery is approximately equal to the oxygen deficit, which is the amount of additional oxygen that would have been consumed had oxygen consumption reached steady state immediately. How is the oxygen consumed in recovery used?
b. The oxygen consumed after strenuous exercise stops is significantly greater than the oxygen deficit and is termed *excess post-exercise oxygen consumption* (EPOC). Why is so much more oxygen required after intense exercise? 4

18. Alcohol consumption on an empty stomach results in some interesting biochemical as well as embarrassing behavioral alterations. We will ignore the latter. Gluconeogenesis falls; there are increases in intracellular ratios of lactate to pyruvate, of glycerol 3-phosphate to dihydroxyacetone phosphate, of glutamate to α-ketoglutarate, and of D-3-hydroxybutyrate to acetoacetate. Hypoglycemia develops rapidly. Blood pH also falls. Alcohol consumption by a well-fed individual does not lead to hypoglycemia or alteration in blood pH. 6

a. Why does ethanol consumption result in the altered ratios?
b. Why does hypoglycemia and blood acidosis result in the hungry individual?
c. Why does a well-fed person not experience hypoglycemia?



19. Recall that pyruvate carboxylase is the enzyme that catalyzes the most important anaplerotic reaction, which restores CAC intermediates by converting pyruvate into oxaloacetate (Section 17.5). Pyruvate carboxylase deficiency is a fatal disorder. Patients with pyruvate carboxylase deficiency sometimes display some or all of the following symptoms: lactic acidosis, hyperammonemia (excess NH_4^+ in the blood), hypoglycemia, and demyelination of the regions of the brain due to insufficient lipid synthesis. Provide a possible biochemical rationale for each of these symptoms.

20. The graph shows the relation between blood-lactate levels, oxygen consumption, and heart rate during exercise of increasing intensity. The values for oxygen consumption and heart rate are indicators of the degree of exertion. 4

a. Why is some lactate produced even when exercise is moderate?
b. Biochemically, what is taking place when the lactate concentration begins to rise rapidly, a point called the lactate threshold?
c. Endurance athletes will sometimes measure blood-lactate levels during training so that they know their lactate threshold. Then, during events, they will race just at or below their lactate threshold until the late stages of the race. Biochemically, why is this practice wise?
d. Training can increase the lactate threshold. Explain.

CHAPTER 25
Biosynthesis of Amino Acids

While nitrogen, as N_2 gas, makes up the majority of Earth's atmosphere, most organisms cannot directly access it for use in amino acids. They rely on nitrogen-fixing microorganisms, such as bacteria that live in nodules on the roots of yellow clover, to convert N_2 to ammonia (NH_3). Ammonia can then be used to synthesize, first, glutamate, and then other amino acids.

OUTLINE

25.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia
25.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways
25.3 Feedback Inhibition Regulates Amino Acid Biosynthesis

25.4 Amino Acids Are Precursors of Many Biomolecules

Learning Goals

By the end of this chapter, you should be able to:

1. Explain the centrality of nitrogen fixation to life and describe how atmospheric nitrogen is converted into biologically useful forms of nitrogen.
2. Identify the sources of carbon atoms for amino acid synthesis.
3. Describe the role of feedback inhibition in controlling amino acid synthesis.
4. Identify important biomolecules that are derived from amino acids.

The assembly of biological macromolecules, including proteins and nucleic acids, requires the generation of appropriate starting materials. In this chapter, we will consider the biosynthesis of amino acids — the building blocks of proteins and the nitrogen source for many other important molecules, including nucleotides, neurotransmitters, and prosthetic groups such as porphyrins.

Amino acid biosynthesis is intimately connected with nutrition because many higher organisms, including human beings, have lost the ability to synthesize some amino acids and must therefore obtain adequate quantities of these essential amino acids in their diets. Furthermore, because some amino acid biosynthetic enzymes are absent in mammals but present in plants and microorganisms, they are useful targets for herbicides and antibiotics.

25.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia

One of the most challenging biochemical problems organisms face is obtaining nitrogen in a usable form. The nitrogen in amino acids, purines, pyrimidines, and other biomolecules ultimately comes from atmospheric nitrogen, N_2. The extremely strong $N \equiv N$ bond, which has a bond energy of $940\ kJ\ mol^{-1}\ (225\ kcal\ mol^{-1})$, is highly resistant to chemical attack. Indeed, Antoine Lavoisier named nitrogen gas "azote," from Greek words meaning "without life," because it is so unreactive. Nevertheless, the conversion of nitrogen and hydrogen to form ammonia is thermodynamically favorable; the reaction is difficult kinetically because of the activation energy required to form intermediates along the reaction pathway.

Although higher organisms are unable to fix nitrogen, this conversion is carried out by some bacteria and archaea. The biosynthetic process starts with the reduction of N_2 to NH_3 (ammonia), a process called **nitrogen fixation**. For example, symbiotic *Rhizobium* bacteria invade the roots of leguminous plants and form root nodules in which they fix nitrogen, supplying both the bacteria and the plants. The importance of nitrogen fixation by diazotrophic (nitrogen-fixing) microorganisms to the metabolism of all higher eukaryotes cannot be overstated: the amount of N_2 fixed by these species has been estimated to be 10^{11} kilograms per year, about 60% of Earth's newly fixed nitrogen. Lightning and ultraviolet radiation fix another 15%; the other 25% is fixed by

industrial processes. The industrial process for nitrogen fixation devised by Fritz Haber in 1910 is still being used in fertilizer factories.

$$N_2 + 3H_2 \rightleftharpoons 2NH_3$$

The fixation of N_2 is typically carried out by mixing it with H_2 gas over an iron catalyst at about 500°C and a pressure of 300 atmospheres.

Biological nitrogen fixation is catalyzed by the nitrogenase complex

To meet the kinetic challenge, the biological process of nitrogen fixation requires a complex enzyme with multiple redox centers. The **nitrogenase complex**, which carries out this fundamental transformation, consists of two proteins: a *reductase* (also called the iron protein or Fe protein), which provides electrons with high reducing power, and *nitrogenase* (also called the molybdenum–iron protein or MoFe protein), which uses these electrons to reduce N_2 to NH_3. The transfer of electrons from the reductase to the nitrogenase component is coupled to the hydrolysis of ATP by the reductase (**Figure 25.1**).

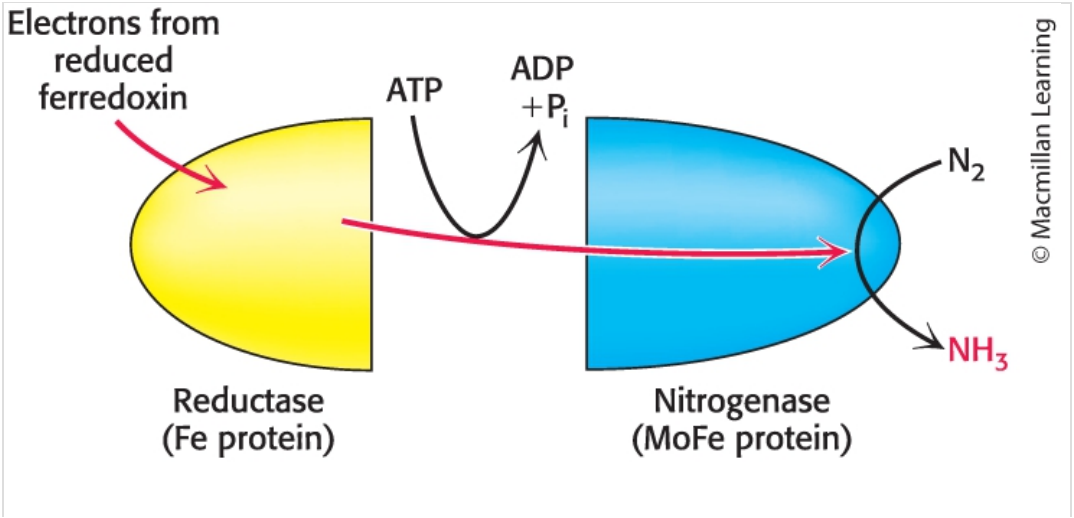


FIGURE 25.1 The nitrogenase complex fixes nitrogen to ammonia. Electrons flow from ferredoxin to the reductase (iron protein, or Fe protein) to nitrogenase (molybdenum–iron protein, or MoFe protein) to reduce nitrogen to ammonia. ATP hydrolysis within the reductase drives conformational changes necessary for the efficient transfer of electrons.

In principle, the reduction of N_2 to NH_3 is a six-electron process.

$$N_2 + 6\,e^- + 6\,H^+ \rightarrow 2\,NH_3$$

However, the biological reaction always generates at least 1 mol of H_2 in addition to 2 mol of NH_3 for each mol of $N \equiv N$. Hence, an input of two additional electrons is required.

$$N_2 + 8\,e^- + 8\,H^+ \rightarrow 2\,NH_3 + H_2$$

In most nitrogen-fixing microorganisms, the eight high-potential electrons come from reduced ferredoxin, generated by oxidative processes. Two molecules of ATP are hydrolyzed for each electron transferred. Thus, at least 16 molecules of ATP are hydrolyzed for each molecule of N_2 reduced.

$$N_2 + 8\,e^- + 8\,H^+ + 16\,ATP + 16\,H_2O \rightarrow 2\,NH_3 + H_2 + 16\,ADP + 16\,P_i$$

Recall that O_2 is required for oxidative phosphorylation to generate the ATP necessary for nitrogen fixation. However, the nitrogenase complex

is exquisitely sensitive to inactivation by O_2. To allow ATP synthesis and nitrogenase to function simultaneously, leguminous plants maintain a very low concentration of free O_2 in their root nodules, the location of the nitrogenase. This is accomplished by binding O_2 to leghemoglobin, a homolog of hemoglobin (Figure 10.13).

The iron–molybdenum cofactor of nitrogenase binds and reduces atmospheric nitrogen

Both the reductase and the nitrogenase components of the complex are iron–sulfur proteins, in which iron is bonded to the sulfur atom of a cysteine residue and to inorganic sulfide. Recall that iron–sulfur clusters act as electron carriers (Section 18.3). The reductase is a dimer of identical 30-kDa subunits bridged by a 4Fe–4S cluster (**Figure 25.2**).

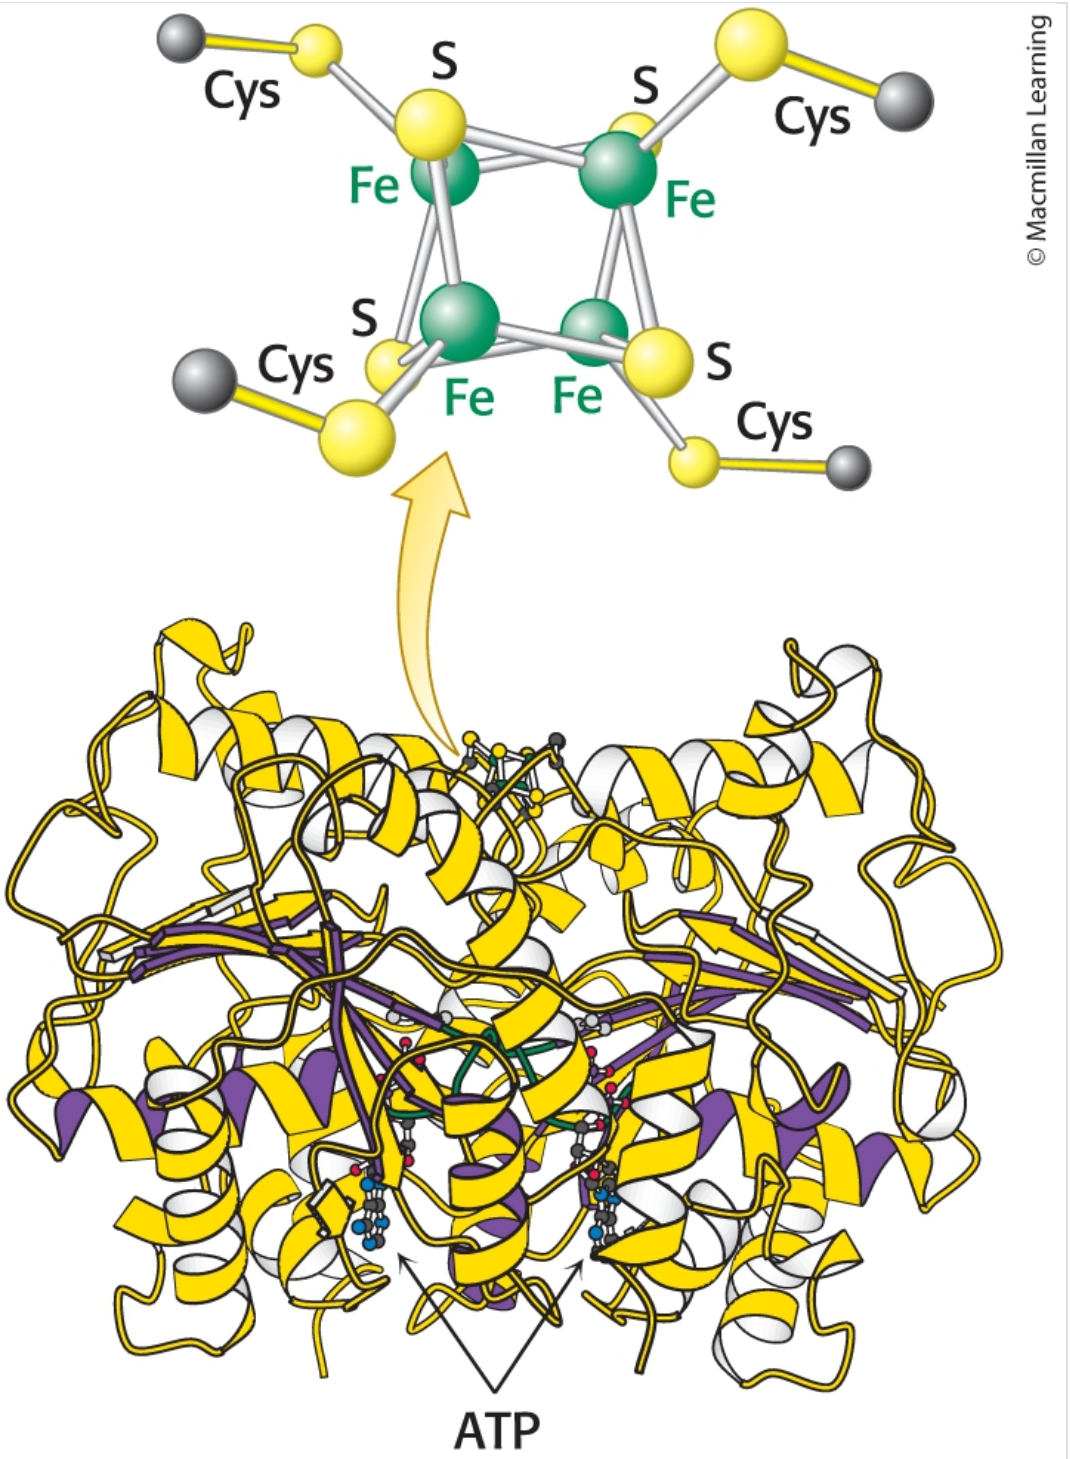

FIGURE 25.2 The Fe protein, or reductase, transfers elections of high reducing power. This protein is a dimer composed of two polypeptide chains linked by a 4Fe–4S cluster. Each monomer is a member of the P-loop NTPase family and contains an ATP-binding site.

[Drawn from 1N2C.pdb.]

INTERACT with this model in Achieve

The role of the reductase is to transfer electrons from a suitable donor, such as reduced ferredoxin, to the nitrogenase component. The 4Fe–4S cluster carries the electrons, one at a time, to nitrogenase. The binding and hydrolysis of ATP triggers a conformational change that moves the reductase closer to the nitrogenase component, whence it is able to transfer its electron to the center of nitrogen reduction.

The nitrogenase component is an $\alpha_2\beta_2$ tetramer (240-kDa), in which the α and β subunits are homologous to each other and structurally quite similar (**Figure 25.3**). The nitrogenase requires the FeMo cofactor, which consists of $[Fe_4\text{-}S_3]$ and $[Mo\text{-}Fe_3\text{-}S_3]$ subclusters joined by three disulfide bonds. A carbon atom (the interstitial carbon), donated by S-adenosylmethionine (Section 23.5), sits between the iron atoms of the FeMo cofactor. The FeMo cofactor is also coordinated to a homocitrate moiety and to the α subunit through one histidine residue and one cysteinate residue.

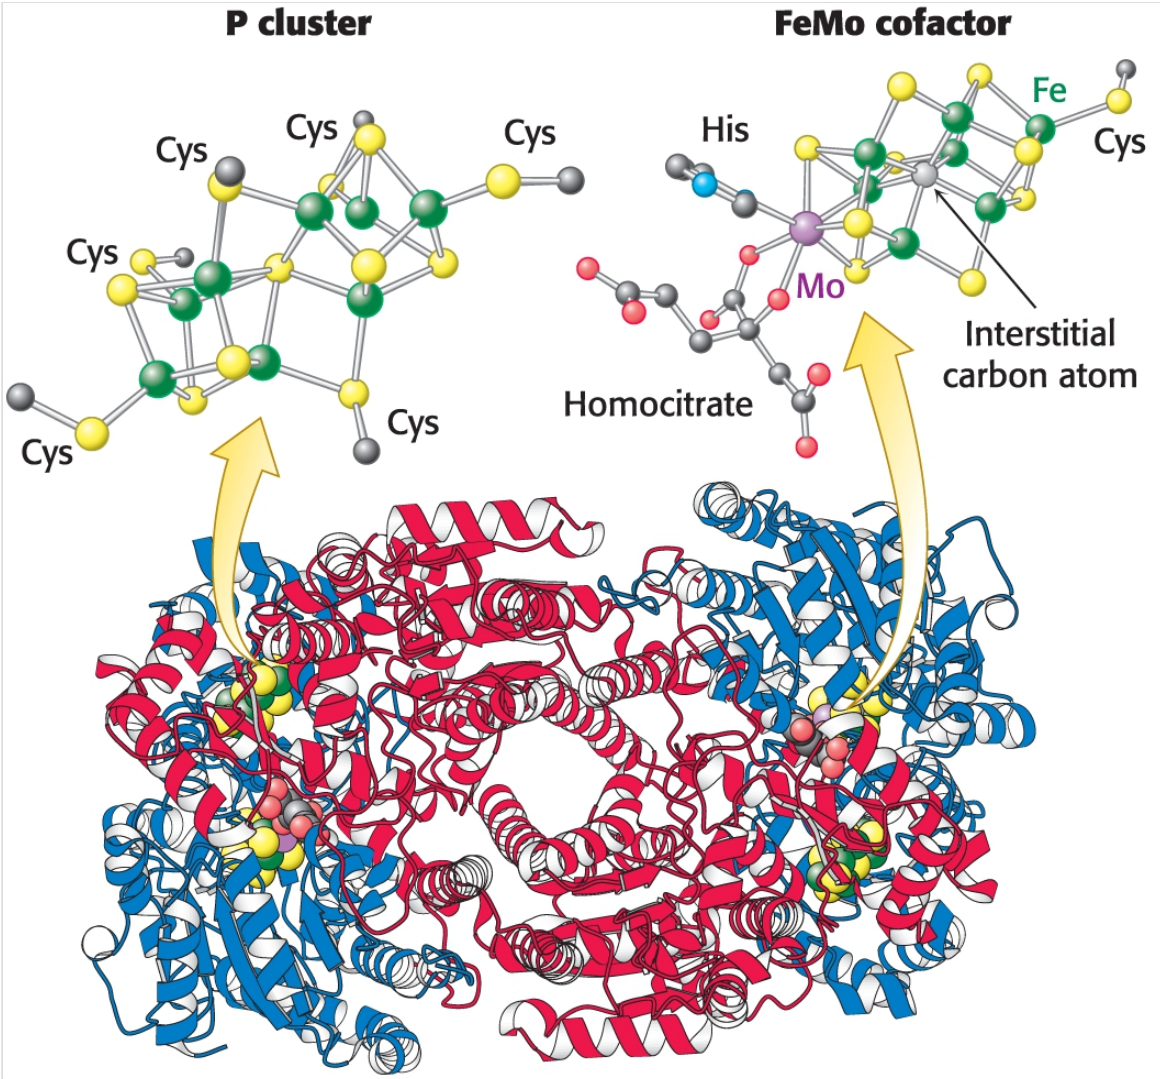

FIGURE 25.3 The MoFe protein, or nitrogenase, catalyzes the reduction of N_2 to NH_3. This protein is a heterotetramer composed of two α subunits (red) and two β subunits (blue). The complex contains two copies each of two types of clusters: P clusters and FeMo cofactors. Each cluster contains eight iron atoms (green) and seven sulfides linked to the protein by six cysteine residues. Each FeMo cofactor contains one molybdenum atom, seven iron atoms, nine sulfides, the interstitial carbon atom, and a homocitrate, and is linked to the protein by one cysteinate residue and one histidine residue.

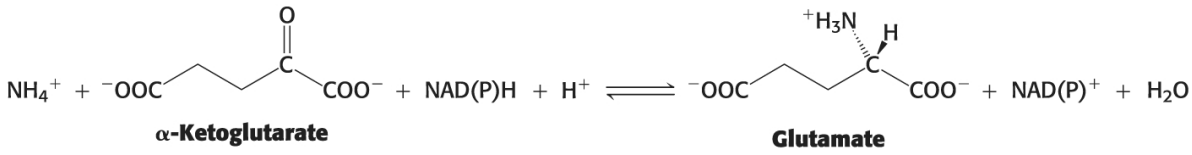
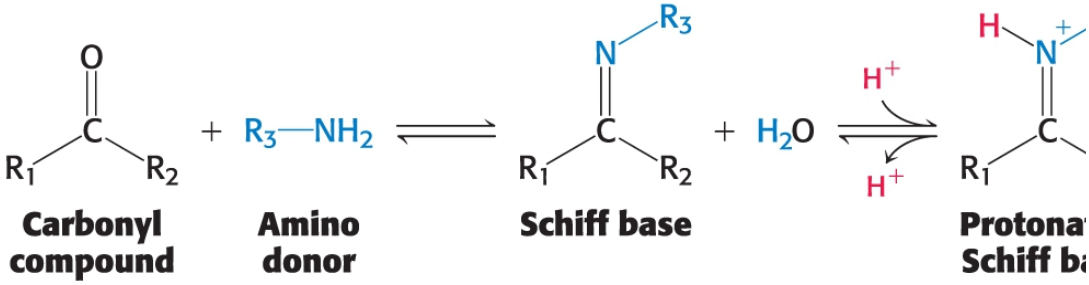


[Drawn from 1M1N.pdb.]

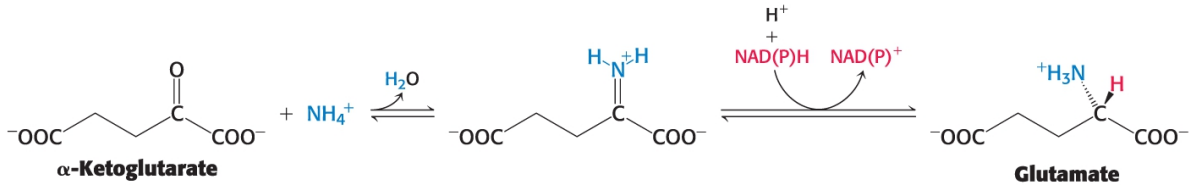
Electrons from the reductase enter at the *P clusters*, which are located at the α–β interface. The role of the P clusters is to store electrons until they can be used productively to reduce nitrogen at the FeMo cofactor. The FeMo cofactor is the site of nitrogen fixation. One face of the FeMo cofactor is likely to be the site of nitrogen reduction. The electron-transfer reactions from the P cluster take place in concert with the binding of hydrogen ions to nitrogen as it is reduced. The mechanism of this remarkable reaction remains an active focus of biochemical research.

Ammonium ion is assimilated into an amino acid through glutamate and glutamine



The NH_3 generated by the nitrogenase complex is a base, and becomes NH_4^+ in aqueous solutions. The next step in the assimilation of nitrogen into biomolecules is the entry of NH_4^+ into amino acids. The amino acids glutamate and glutamine play pivotal roles in this regard, acting as nitrogen donors for most amino acids. The α-amino group of most amino acids comes from the α-amino group of glutamate by transamination (Section 23.3). Glutamine, the other major nitrogen donor, contributes its side-chain nitrogen atom in the biosynthesis of a wide range of important compounds, including the amino acids tryptophan and histidine.

Glutamate is synthesized from NH_4^+ and α-ketoglutarate, a citric acid cycle intermediate, by the action of glutamate dehydrogenase. We have already encountered this enzyme in the degradation of amino acids (Section 23.3). Recall that NAD^+ is the oxidant in catabolism, whereas NADPH is the reductant in biosyntheses. Glutamate dehydrogenase is unusual in that it does not discriminate between NADH and NADPH, at least in some species.

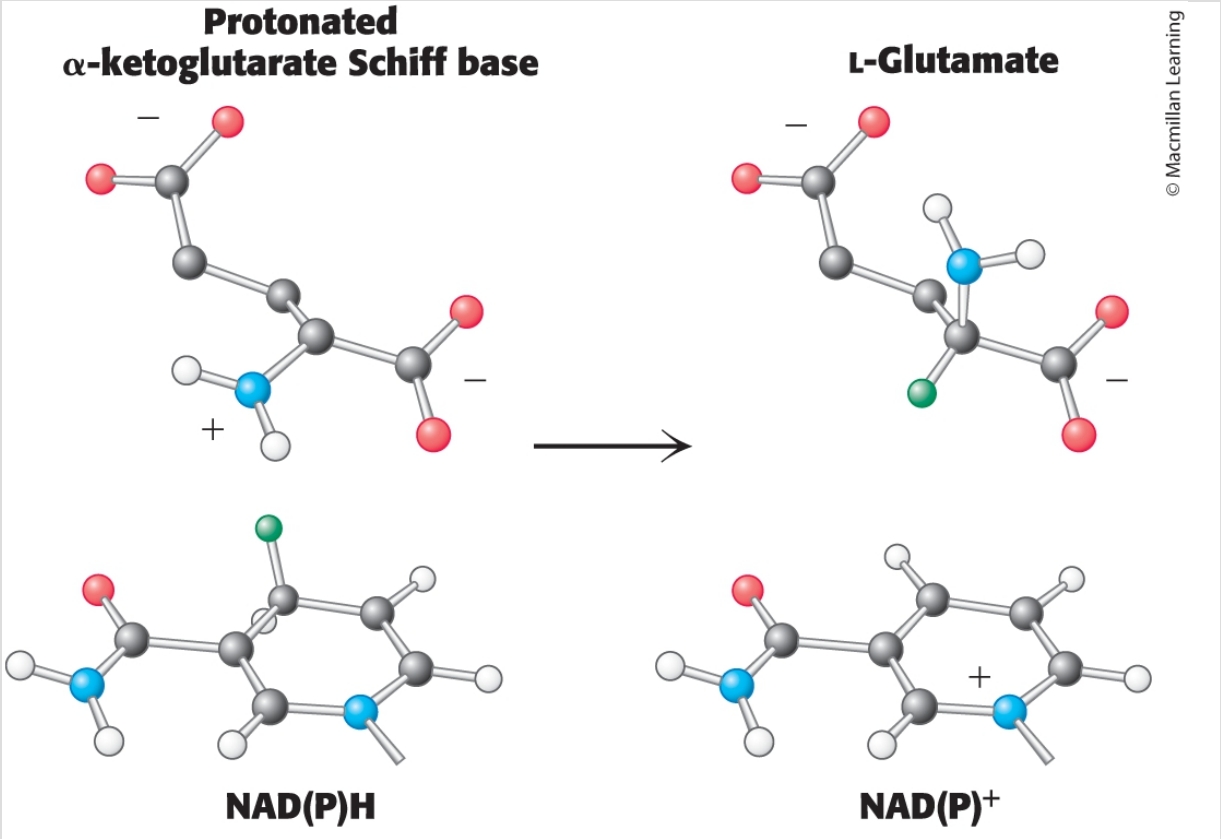


The reaction proceeds in two steps:

1. A Schiff base forms between ammonium ion and α-ketoglutarate. The formation of a Schiff base between an amine and a carbonyl compound is a key reaction that takes place at many stages of amino acid biosynthesis and degradation. Schiff bases are easily protonated.

2. The protonated Schiff base is reduced by the transfer of a hydride ion from NAD(P)H to form glutamate.

The reaction catalyzed by glutamate dehydrogenase is crucial because it establishes the stereochemistry of the α-carbon atom (*S* absolute configuration) in glutamate. The enzyme binds the α-ketoglutarate substrate in such a way that hydride transferred from NAD(P)H is added to form the L isomer of glutamate (Figure 25.4). As we shall see, this stereochemistry is established for other amino acids by transamination reactions that rely on pyridoxal phosphate. Establishing the correct stereochemistry is one of the fundamental challenges of nitrogen incorporation into biomolecules.



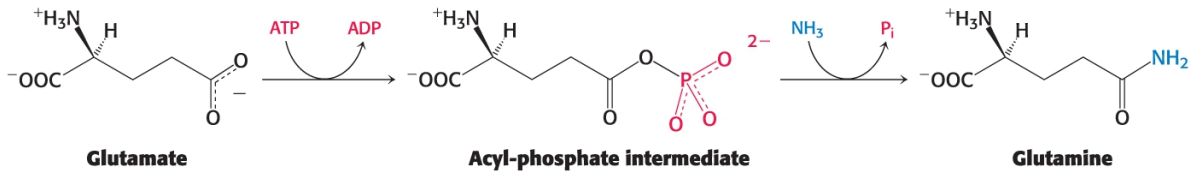


FIGURE 25.4 Glutamate chirality is established by hydride transfer to the Schiff base. In the active site of glutamate dehydrogenase, hydride transfer (green) from NAD(P)H to a specific face of the achiral protonated Schiff base of α-ketoglutarate establishes the L configuration of glutamate.

A second ammonium ion is incorporated into glutamate to form glutamine by the action of glutamine synthetase. This amidation is driven by the hydrolysis of ATP. ATP participates directly in the reaction by phosphorylating the side chain of glutamate to form an acyl-phosphate intermediate, which then reacts with ammonia to form glutamine.

NH_4^+ initially binds to the enzyme, but upon formation of the acyl-phosphate intermediate, ammonium ion is deprotonated as a high-affinity ammonia-binding site is formed. A specific site for ammonia binding is required to prevent attack by water from hydrolyzing the intermediate and wasting a molecule of ATP. As we shall soon see, the regulation of glutamine synthetase plays a critical role in controlling nitrogen metabolism (Section 25.3).

Glutamate dehydrogenase and glutamine synthetase are present in all organisms. Many organisms also contain an evolutionarily unrelated enzyme, glutamate synthase, which catalyzes the reductive amination of α-ketoglutarate to glutamate. Glutamine is the nitrogen donor.

$$\alpha\text{-Ketoglutarate} + \text{glutamine} + \text{NADPH} + \text{H}^+ \rightleftharpoons 2\ \text{glutamate} + \text{NADP}^+$$

The side-chain amide of glutamine is hydrolyzed to generate ammonia within the enzyme, a recurring theme throughout nitrogen metabolism. When NH_4^+ is limiting, most of the glutamate is made by the sequential action of glutamine synthetase and glutamate synthase. The sum of these reactions is

$$NH_4^+ + \alpha\text{-ketoglutarate} + NADPH + ATP \rightarrow \text{glutamate} + NADP^+ + ADP + P_i \quad \textbf{(1)}$$

Note that this stoichiometry differs from that of the glutamate dehydrogenase reaction in that ATP is hydrolyzed. Why do organisms sometimes use this more expensive pathway? The answer is that the value of K_M of glutamate dehydrogenase for NH_4^+ is high $(\sim 1\ mM)$, and so this enzyme is not saturated when NH_4^+ is limiting. In contrast, glutamine synthetase has very low K_M for NH_4^+. Thus, ATP hydrolysis is required to capture ammonia when it is scarce.

Self-Check Question

Write out the balanced reactions for glutamine synthetase and glutamate synthase. Show that the sum of these two reactions matches equation 1.

25.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways

Thus far, we have considered the conversion of N_2 into NH_4^+ and the assimilation of NH_4^+ into glutamate and glutamine. We turn now to the biosynthesis of the other amino acids, the majority of which obtain their nitrogen from glutamate or glutamine. The pathways for the biosynthesis of amino acids are diverse. However, they have an important common feature: their carbon skeletons come from intermediates of glycolysis, the pentose phosphate pathway, or the citric acid cycle. On the basis of these starting materials, amino acids can be grouped into six biosynthetic families (Figure 25.5).

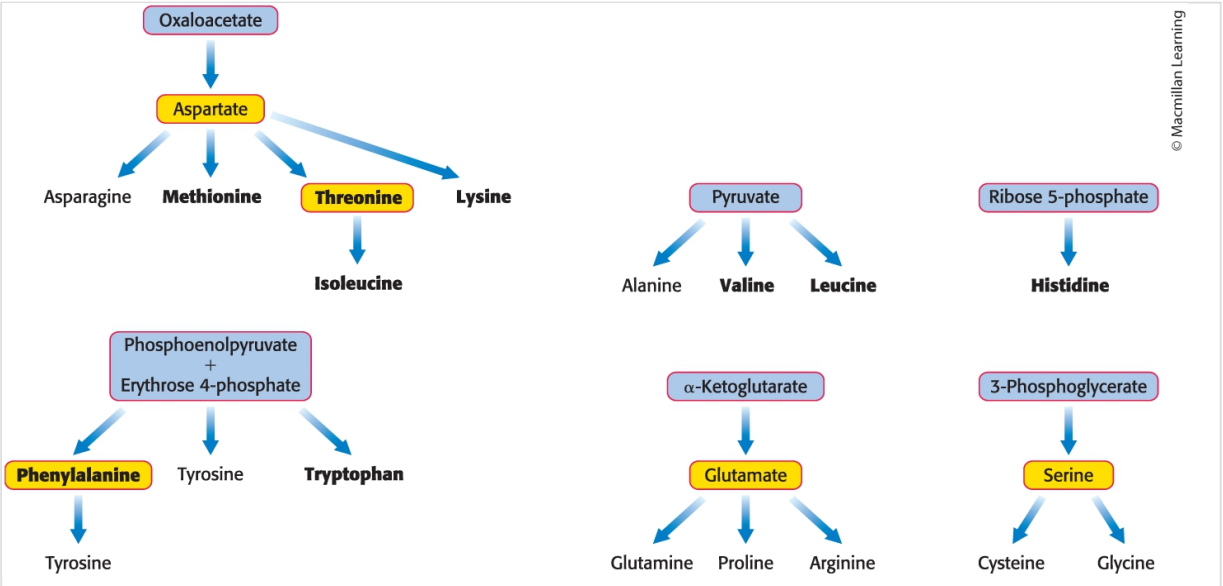

FIGURE 25.5 Amino acids can be sorted into biosynthetic families. Major metabolic precursors are shaded blue. Amino acids that give rise to other amino acids are shaded yellow. Essential amino acids for humans are in boldface type.

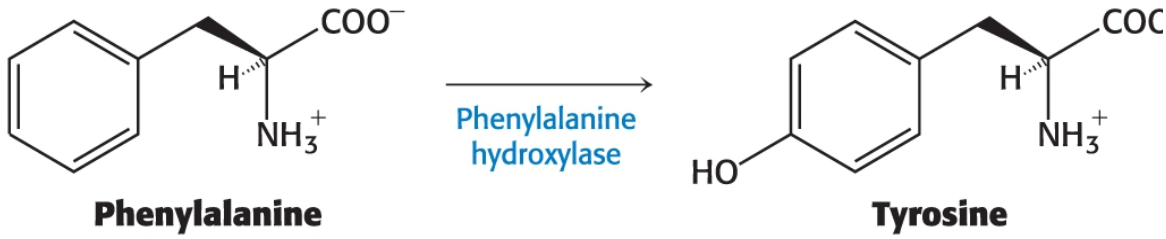

Human beings can synthesize some amino acids but must obtain others from their diet

Most microorganisms, such as *E. coli*, can synthesize the entire set of 20 amino acids, whereas human beings cannot make 9 of them. The amino acids that must be supplied in the diet are called **essential amino acids**, whereas the others, which can be synthesized if dietary content is insufficient, are termed **nonessential amino acids** (Table 25.1).

TABLE 25.1 Basic set of 20 amino acids

Nonessential	Essential
Alanine	Histidine
Arginine	Isoleucine
Asparagine	Leucine
Aspartate	Lysine
Cysteine	Methionine
Glutamate	Phenylalanine
Glutamine	Threonine
Glycine	Tryptophan
Proline	Valine
Serine	

These designations refer to the needs of an organism under a particular set of conditions. For example, enough arginine is synthesized by the urea cycle to meet the needs of an adult, but perhaps not those of a growing child. Likewise, tyrosine is sometimes designated as an essential amino acid, but is not if phenylalanine is present in adequate amounts. In mammals, tyrosine can be synthesized from phenylalanine in one step.

Phenylalanine **Tyrosine**

A deficiency of even one amino acid results in a negative nitrogen balance. In this state, more protein is degraded than is synthesized, and so more nitrogen is excreted than is ingested.

The nonessential amino acids are synthesized by quite simple reactions, whereas the pathways for the formation of the essential amino acids are quite complex. For example, the nonessential amino acids alanine and aspartate are synthesized in a single step from pyruvate and oxaloacetate, respectively. In contrast, the pathways for the essential amino acids require from 5 to 16 steps (**Figure 25.6**). The sole exception to this pattern is arginine, inasmuch as the synthesis of this nonessential amino acid de novo requires 10 steps. Typically, however, it is made in only 3 steps from ornithine as part of the urea cycle. Tyrosine, classified as a nonessential amino acid because it can be synthesized in 1 step from phenylalanine, requires 10 steps to be

synthesized from scratch and is essential if phenylalanine is not abundant.

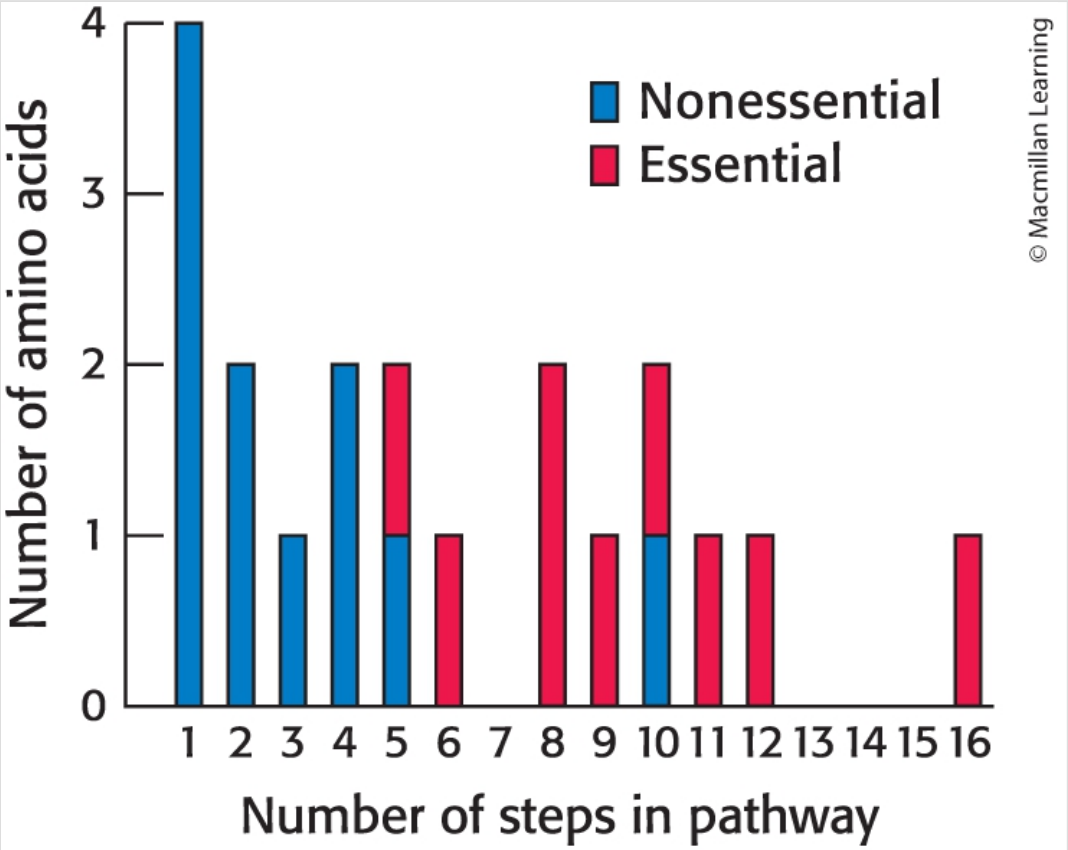

FIGURE 25.6 Essential and nonessential amino acids can be distinguished by the required number of biosynthetic steps. Some amino acids are nonessential to human beings because they can be biosynthesized in a small number of steps. Those amino acids requiring a large number of steps for their synthesis are essential in the diet because some of the enzymes for these steps have been lost in the course of evolution.

Aspartate, alanine, and glutamate are formed by the addition of an amino group to

an alpha-ketoacid

Let us begin with the biosynthesis of nonessential amino acids. Three α-ketoacids — α-ketoglutarate, oxaloacetate, and pyruvate — can be converted into amino acids in one step through the addition of an amino group. We have seen that α-ketoglutarate can be converted into glutamate by reductive amination (Section 23.3). The amino group from glutamate can be transferred to other α-ketoacids by transamination reactions. Thus, aspartate and alanine can be made from the addition of an amino group to oxaloacetate and pyruvate, respectively.

$$\text{Oxaloacetate} + \text{glutamate} \rightleftharpoons \text{aspartate} + \alpha\text{-ketoglutarat}$$

$$\text{Pyruvate} + \text{glutamate} \rightleftharpoons \text{alanine} + \alpha\text{-ketoglutarate}$$

These reactions are carried out by pyridoxal phosphate-dependent aminotransferases. Transamination reactions are required for the synthesis of most amino acids.

In Section 23.3, we considered the mechanism of aminotransferases as applied to the metabolism of amino acids. Let us review the aminotransferase mechanism as it operates in the biosynthesis of amino acids. The reaction pathway begins with **pyridoxal phosphate (PLP)** in a Schiff-base linkage with lysine at the aminotransferase active site, forming an internal aldimine (**Figure 25.7**).

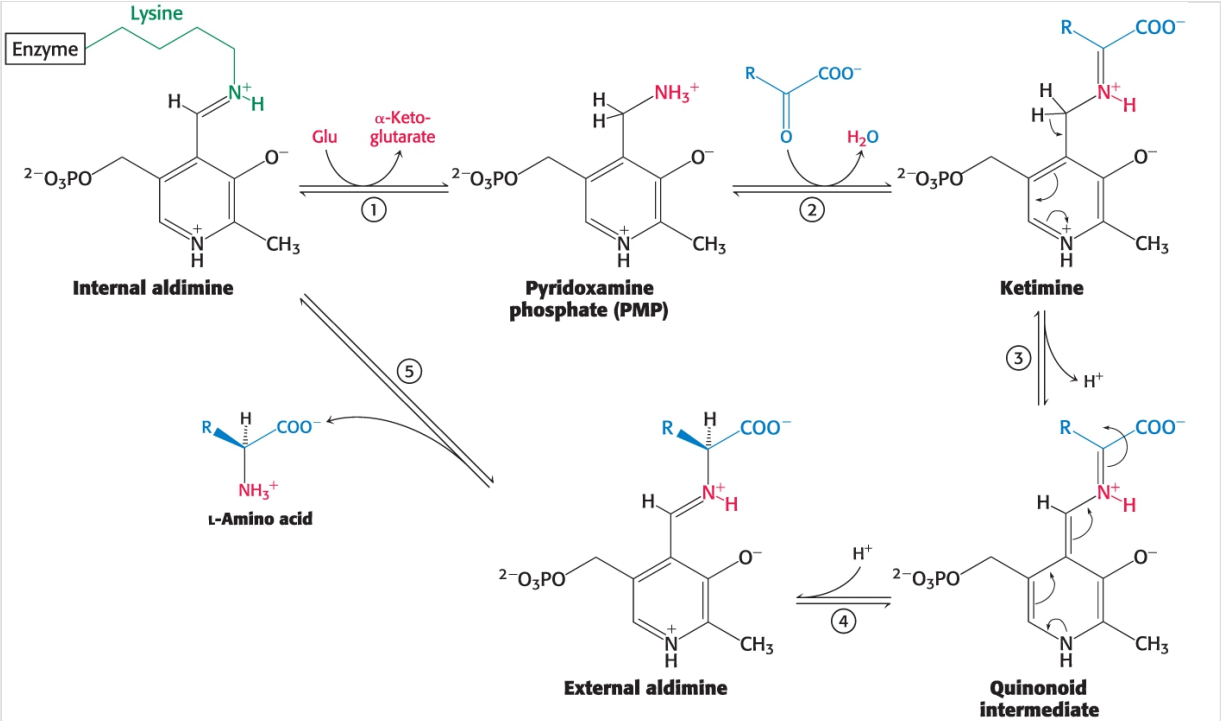

FIGURE 25.7 Transamination is a critical step in the biosynthesis of most amino acids. (1) Within an aminotransferase, the internal aldimine is converted into pyridoxamine phosphate (PMP) by reaction with glutamate in a multistep process not shown. (2) PMP then reacts with an α-ketoacid to generate a ketimine. (3) This intermediate is converted into a quinonoid intermediate (4), which in turn yields an external aldimine. (5) The aldimine is cleaved to release the newly formed amino acid to complete the cycle.

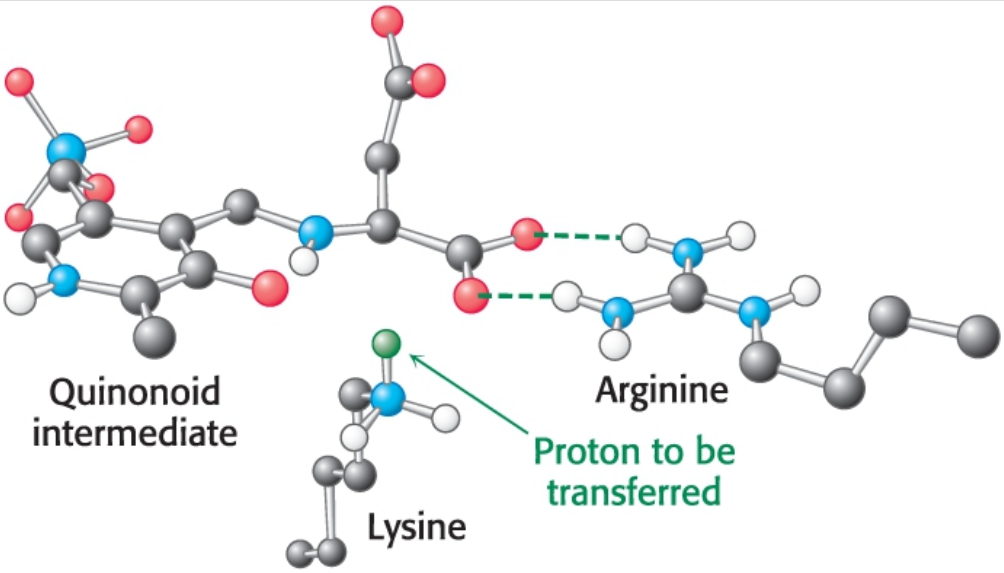
1. An amino group is transferred from glutamate to form pyridoxamine phosphate (PMP), the actual amino donor, in a multistep process.

2. PMP then reacts with an incoming α-ketoacid to form a ketimine.

3. Proton loss forms a quinonoid intermediate.



4. Proton addition at a different site forms an external aldimine.

5. The newly formed amino acid is released with the concomitant re-formation of the internal aldimine.

A common step determines the chirality of all amino acids

Aspartate aminotransferase is the prototype of a large family of PLP-dependent enzymes. Comparisons of amino acid sequences as well as several three-dimensional structures reveal that almost all aminotransferases having roles in amino acid biosynthesis are related to aspartate aminotransferase by divergent evolution. An examination of the aligned amino acid sequences reveals that two residues are completely conserved. These residues are the lysine residue that forms the Schiff base with the PLP cofactor (lysine 258 in aspartate aminotransferase) and an arginine residue that interacts with the α-carboxylate group of the ketoacid (Figure 23.10).

An essential step in the transamination reaction is the protonation of the quinonoid intermediate to form the external aldimine. The chirality of the amino acid formed is determined by the direction from which this proton is added to the quinonoid intermediate (**Figure 25.8**). The interaction between the conserved arginine residue and the α-carboxylate group helps orient the substrate so that the lysine residue transfers a proton to the bottom face of the quinonoid intermediate, generating an aldimine with an L configuration at the C_α center.

© Macmillan Learning

FIGURE 25.8 Proton addition during transamination establishes amino acid stereochemistry. In an aminotransferase active site, the addition of a proton from the lysine residue to the bottom face of the quinonoid intermediate determines the L configuration of the amino acid product. The conserved arginine residue interacts with the α-carboxylate group and helps establish the appropriate geometry of the quinonoid intermediate.

BEVERLY GUIRARD A key contributor to the isolation and characterization of different forms of vitamin B_6, including pyridoxal phosphate, was Dr. Beverly Guirard. Dr. Guirard grew up in St. Martinville, Louisiana, received her BS and MS degrees from Southwestern Louisiana Institute and Louisiana State University, respectively, and went on to receive her PhD from the University of Texas, Austin, in 1945. She identified acetate and several forms of vitamin B_6 working under the supervision of Professors Roger Williams and Esmond Snell. After completing her doctorate, she worked with Professor Fritz Lipmann. During this time, she made a key contribution to the elucidation of the structure of coenzyme A, research for which Dr. Lipmann would share the Nobel Prize. In 1951, she moved back to the University of Texas, where she continued her work with Dr. Snell until her retirement in 1990. She was an accomplished scientist on her own, characterizing several pyridoxal-dependent enzymes, and she played an important role in furthering significant research from many graduate students and postdoctoral fellows over many decades.

The formation of asparagine from aspartate requires an adenylated intermediate

The formation of asparagine from aspartate is chemically analogous to the formation of glutamine from glutamate. Both transformations are amidation reactions, and both are driven by the hydrolysis of ATP. The actual reactions are different, however. In bacteria, the reaction for asparagine synthesis is

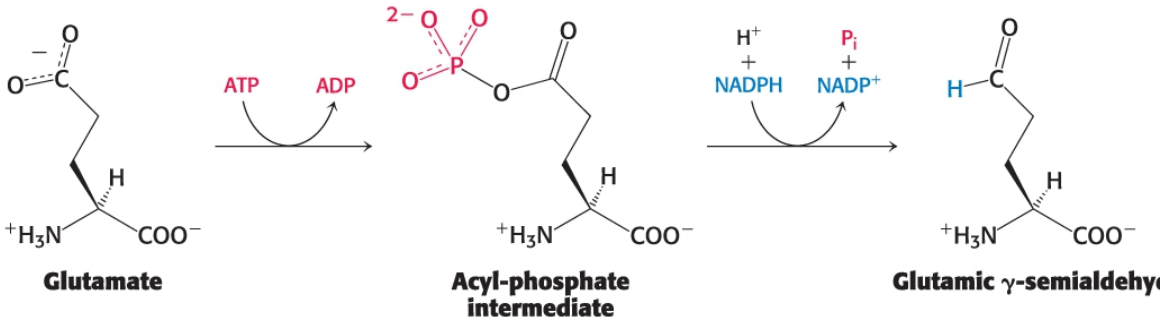
$$\text{Aspartate} + NH_4^+ + ATP \longrightarrow \text{asparagine} + AMP + PP_i + H^+$$

Thus, the products of ATP hydrolysis are AMP and PP_i rather than ADP and P_i. Aspartate is activated by adenylation rather than by phosphorylation.

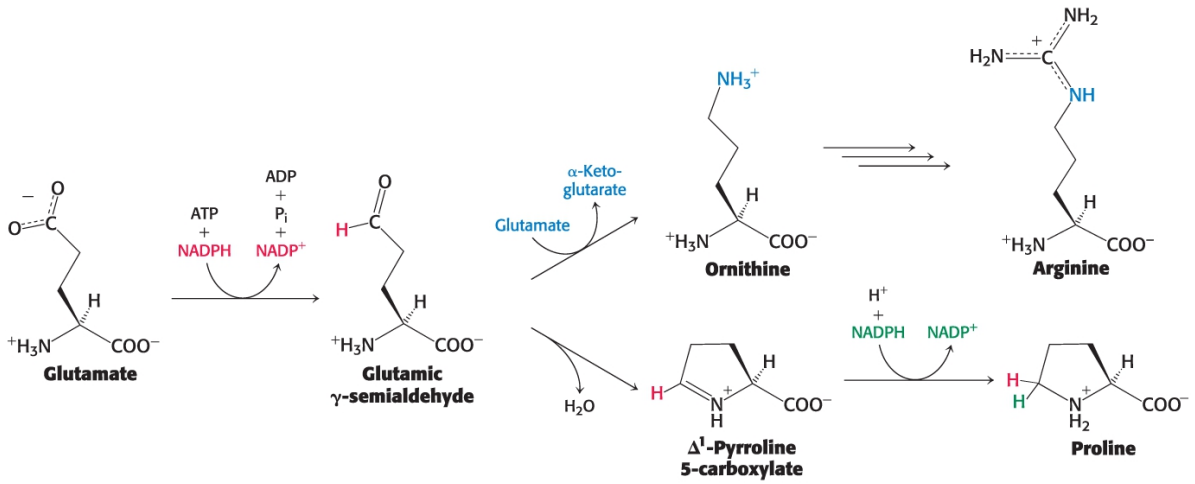
We have encountered this mode of activation in fatty acid degradation and will see it again in lipid and protein synthesis.

In mammals, the nitrogen donor for asparagine is glutamine rather than ammonia as in bacteria. Ammonia is generated by hydrolysis of the side chain of glutamine and directly transferred to activated aspartate, bound in the active site. An advantage is that the cell is not

directly exposed to NH_4^+, which is toxic at high levels to human beings and other mammals. The use of glutamine hydrolysis as a mechanism for generating ammonia for use within the same enzyme is a motif common throughout biosynthetic pathways.



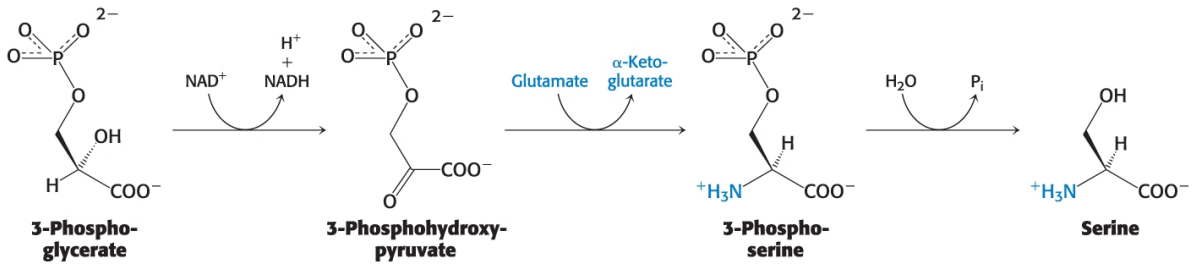
Self-Check Question



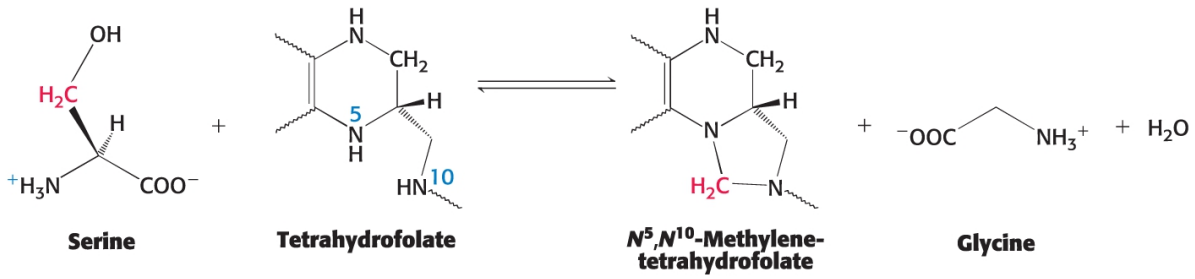
Consider the conversion of glutamate to glutamine and aspartate to asparagine in humans. Name two ways in which these reactions are similar, and two ways in which they differ.

Glutamate is the precursor of glutamine, proline, and arginine

The synthesis of glutamate by the reductive amination of α-ketoglutarate has already been discussed, as has the conversion of glutamate into glutamine (Section 25.1). Glutamate is the precursor of two other nonessential amino acids: proline and arginine. First, the γ-carboxyl group of glutamate reacts with ATP to form an acyl phosphate. This mixed anhydride is then reduced by NADPH to an aldehyde.



Glutamic γ-semialdehyde cyclizes with a loss of H_2O in a nonenzymatic process to give Δ^1-pyrroline 5-carboxylate, which is reduced by NADPH to proline. Alternatively, the semialdehyde can be transaminated to ornithine, which is converted in several steps into arginine in the urea cycle (Figure 23.16).



3-Phosphoglycerate is the precursor of serine, cysteine, and glycine

Serine is synthesized from 3-phosphoglycerate, an intermediate in glycolysis. The first step is an oxidation to 3-phosphohydroxypyruvate. This α-ketoacid is transaminated to 3-phosphoserine, which is then hydrolyzed to serine.

Serine is the precursor of *cysteine* and *glycine*. As we shall see, the conversion of serine into cysteine requires the substitution of a sulfur atom derived from methionine for the side-chain oxygen atom. In the formation of glycine, the side-chain methylene group of serine is transferred to tetrahydrofolate, a carrier of one-carbon units that will be discussed shortly.

This interconversion is catalyzed by serine hydroxymethyltransferase, a PLP enzyme that is homologous to aspartate aminotransferase. The formation of the Schiff base of serine renders the bond between its α- and β-carbon atoms susceptible to cleavage, enabling the transfer of the β-carbon to tetrahydrofolate and producing the Schiff base of glycine.

Tetrahydrofolate carries activated one-carbon units at several oxidation levels

Tetrahydrofolate is a highly versatile carrier of activated one-carbon units. This cofactor consists of three groups: a substituted pteridine, *p*-aminobenzoate, and a chain of one or more glutamate residues (Figure 25.9). Mammals can synthesize the pteridine ring, but they are unable to conjugate it to the other two units. They obtain tetrahydrofolate from their diets or from microorganisms in their intestinal tracts.

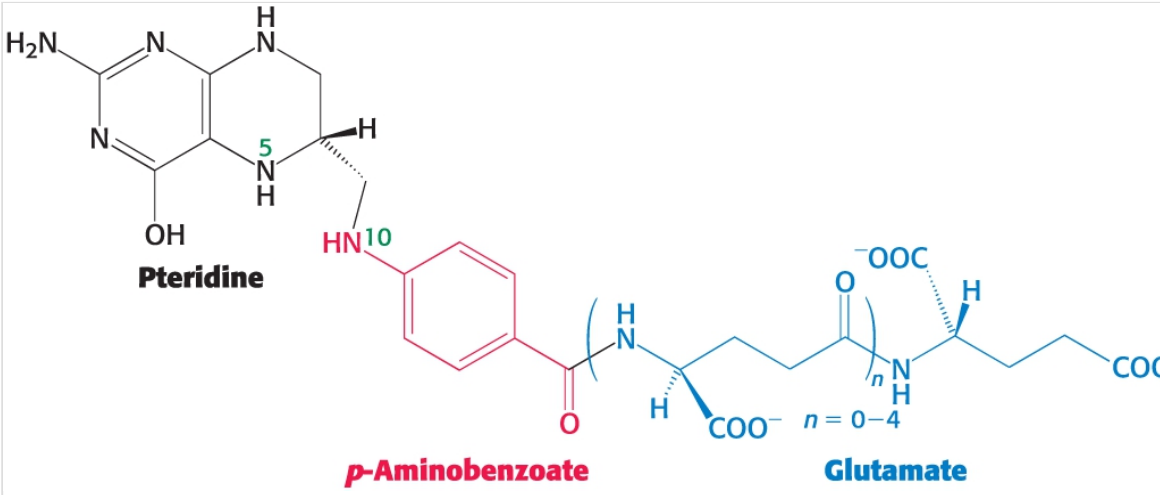


FIGURE 25.9 Tetrahydrofolate is an important carrier of activated one-carbon units. This cofactor includes three components: a pteridine ring, *p*-aminobenzoate, and one or more glutamate residues.

The one-carbon group carried by tetrahydrofolate is bonded to its N-5 or N-10 nitrogen atom (denoted as N^5 and N^{10}) or to both. This unit can exist in three oxidation states (Table 25.2). The most-reduced form carries a *methyl* group, whereas the intermediate form carries a *methylene* group. More-oxidized forms carry a *formyl*, *formimino*, or

methenyl group. The fully oxidized one-carbon unit, CO_2, is carried by biotin rather than by tetrahydrofolate.

TABLE 25.2 One-carbon groups carried by tetrahydrofolate

	Group	
Oxidation state	**Formula**	**Name**
Most reduced (= methanol)	$-CH_3$	Methyl
Intermediate (= formaldehyde)	$-CH_2-$	Methylene
Most oxidized (= formic acid)	$-CHO$ $-CHNH$ $-CH=$	Formyl Formimino Methenyl

The one-carbon units carried by tetrahydrofolate are interconvertible (Figure 25.10). N^5,N^{10}-*Methylene*tetrahydrofolate can be reduced to N^5-*methyl*tetrahydrofolate or oxidized to N^5,N^{10}-*methenyl*tetrahydrofolate. N^5,N^{10}-Methenyltetrahydrofolate can be converted into N^5-*formimino*tetrahydrofolate or N^{10}-*formyl*tetrahydrofolate, both of which are at the same oxidation level. N^{10}-Formyltetrahydrofolate can also be synthesized from tetrahydrofolate, formate, and ATP. N^5-Formyltetrahydrofolate can be reversibly isomerized to N^{10}-formyltetrahydrofolate, or it can be converted into N^5,N^{10}-methenyltetrahydrofolate.

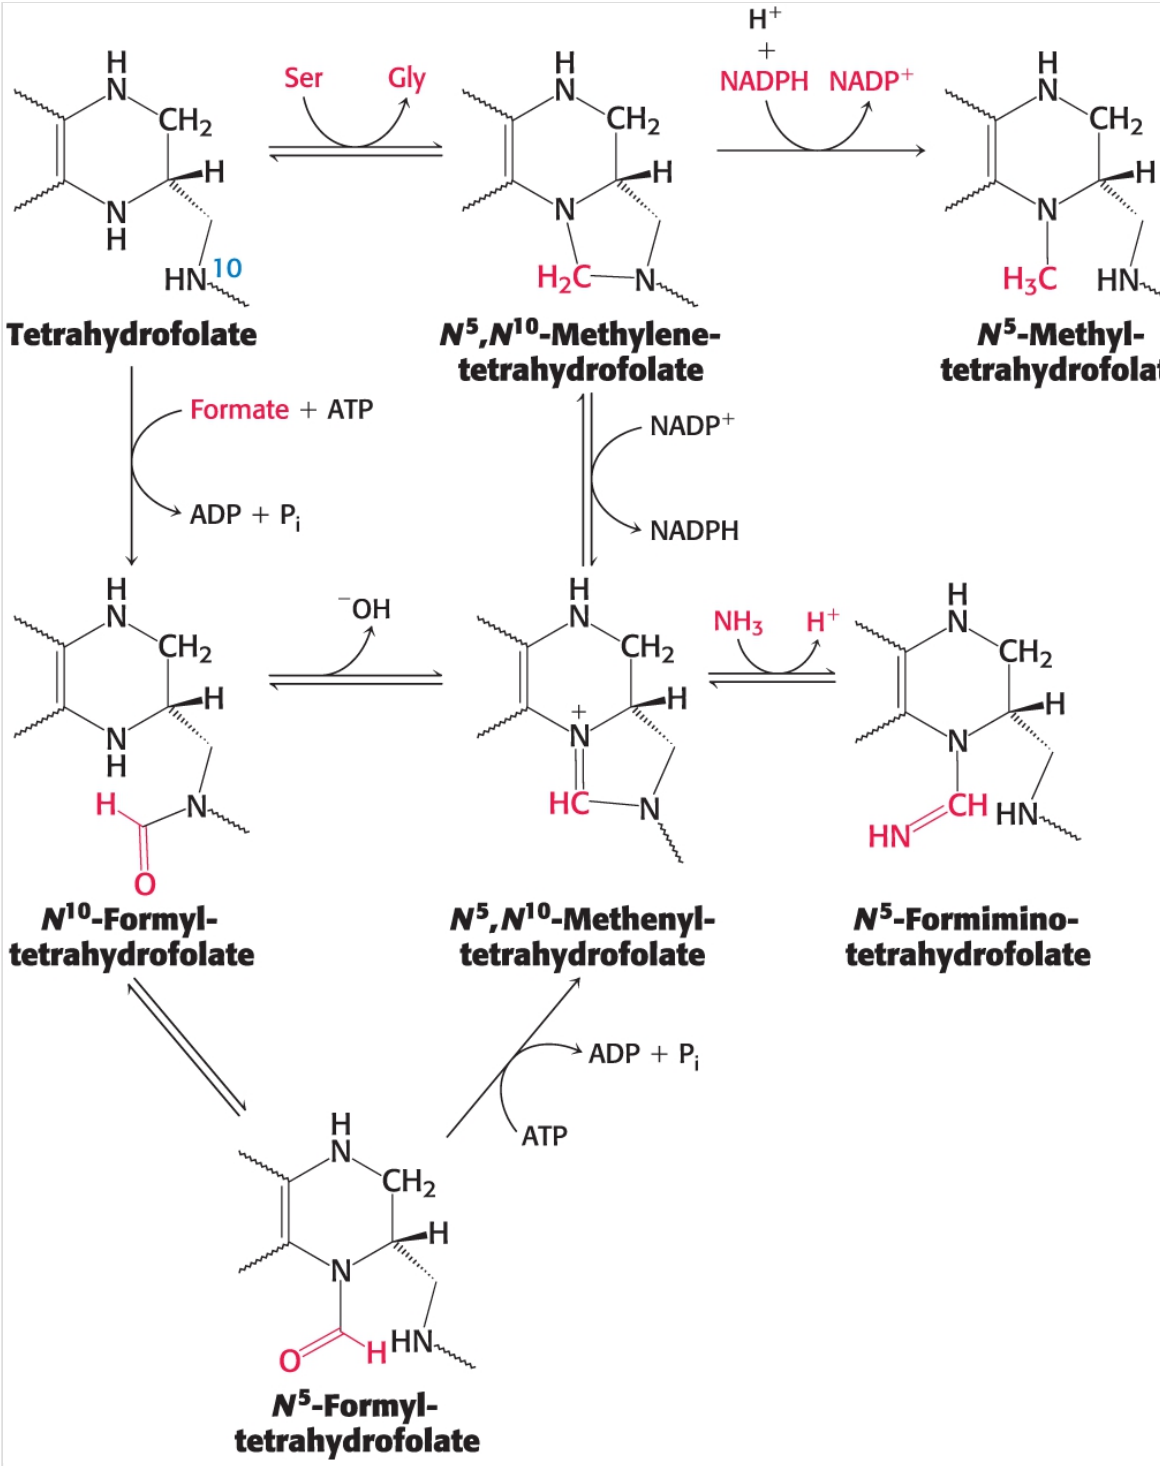

FIGURE 25.10 The one-carbon units attached to tetrahydrofolate are interconvertible.

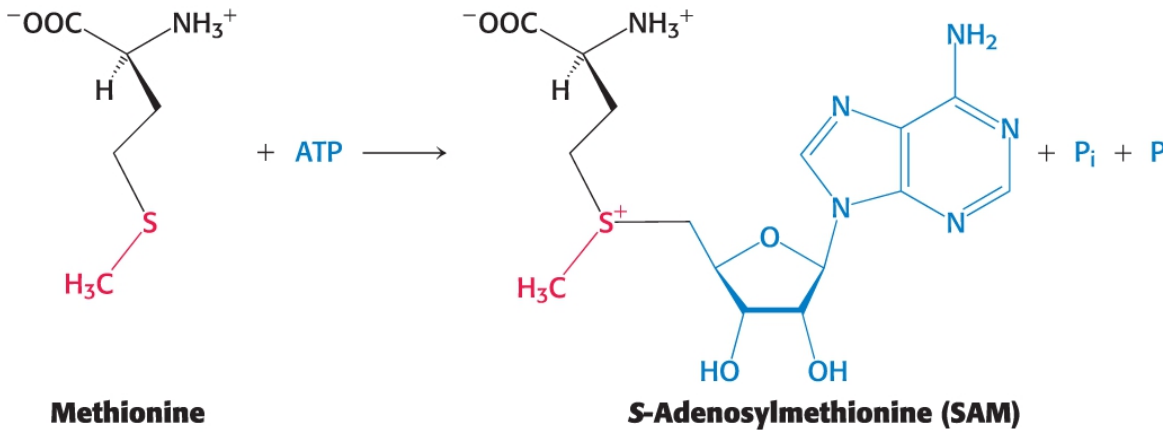
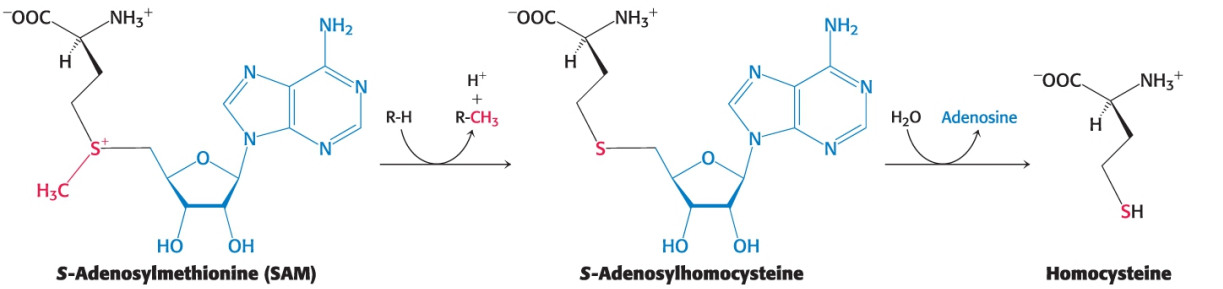
These tetrahydrofolate derivatives serve as donors of one-carbon units in a variety of biosyntheses. Methionine is regenerated from homocysteine by transfer of the methyl group of N^5-methyltetrahydrofolate, as will be discussed shortly. We shall see in Chapter 26 that some of the carbon atoms of purines are acquired from derivatives of N^{10}-formyltetrahydrofolate. The methyl group of thymine, a pyrimidine, comes from N^5,N^{10}-methylenetetrahydrofolate. This tetrahydrofolate derivative can also donate a one-carbon unit in an alternative synthesis of glycine that starts with CO_2 and NH_4^+, a reaction catalyzed by glycine synthase (called the *glycine cleavage enzyme* when it operates in the reverse direction).



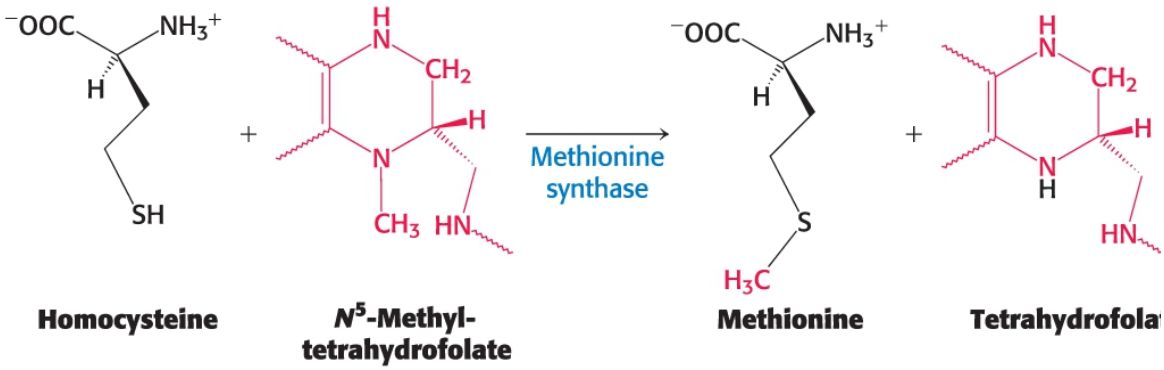
$$CO_2 + NH_4^+ + N^5,N^{10}\text{-methylenetetrahydrofolate} + NADH \rightleftharpoons \text{glycine} + \text{tetrahydrofolate} + NAD^+$$

Thus, one-carbon units at each of the three oxidation levels are utilized in biosyntheses.



Furthermore, tetrahydrofolate serves as an acceptor of one-carbon units in degradative reactions. The major source of one-carbon units is the facile conversion of serine into glycine by serine hydroxymethyltransferase, which yields N^5, N^{10}-methylenetetrahydrofolate. Serine can be derived from 3-phosphoglycerate, and so this pathway enables one-carbon units to be formed de novo from carbohydrates.

S-Adenosylmethionine is the major donor of methyl groups



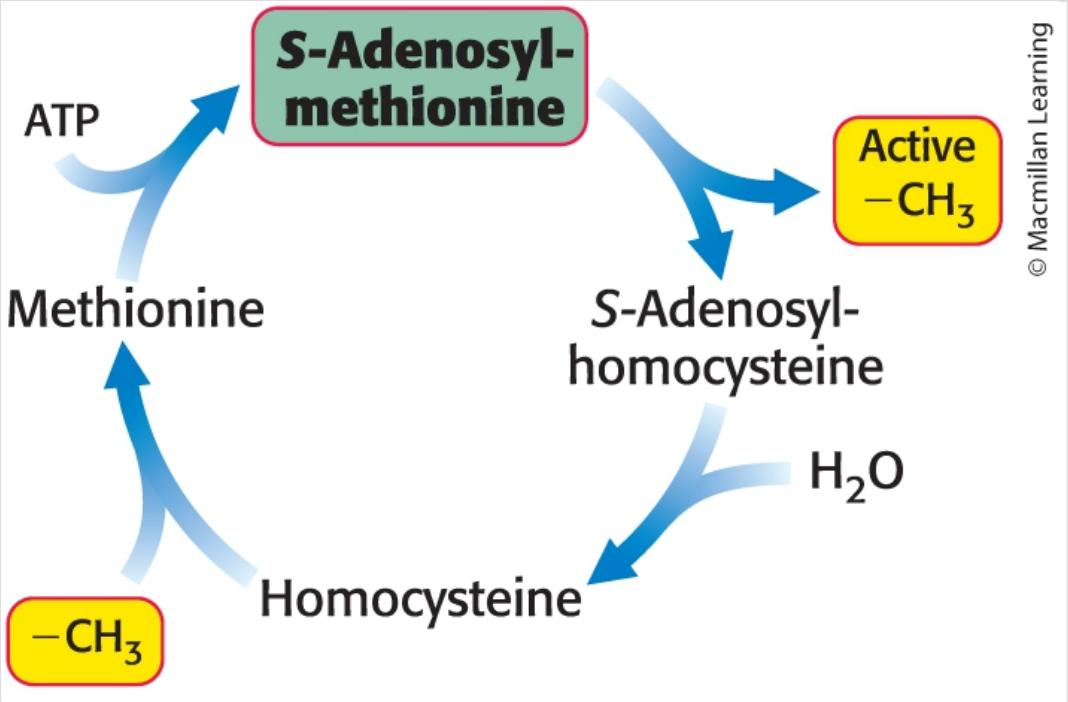
Tetrahydrofolate can carry a methyl group on its N-5 atom, but its transfer potential is not sufficiently high for most biosynthetic methylations. Rather, the activated methyl donor is usually **S-adenosylmethionine (SAM)**, which is synthesized by the transfer of an adenosyl group from ATP to the sulfur atom of methionine.

The methyl group of the methionine unit is activated by the positive charge on the adjacent sulfur atom, which makes the molecule much more reactive than N^5-methyltetrahydrofolate. The synthesis of *S*-adenosylmethionine is unusual in that the triphosphate group of ATP is split into pyrophosphate and orthophosphate; the pyrophosphate is subsequently hydrolyzed to two molecules of P_i. *S*-Adenosylhomocysteine is formed when the methyl group of *S*-adenosylmethionine is transferred to an acceptor. *S*-Adenosylhomocysteine is then hydrolyzed to homocysteine and adenosine.

Methionine can be regenerated by the transfer of a methyl group to homocysteine from N^5-methyltetrahydrofolate, a reaction catalyzed by methionine synthase.

The coenzyme that mediates this transfer of a methyl group is methylcobalamin, derived from vitamin B_{12}. In fact, this reaction and the rearrangement of L-methylmalonyl CoA to succinyl CoA (Section 22.3), catalyzed by a homologous enzyme, are the only two B_{12}-dependent reactions known to take place in mammals. Another enzyme that converts homocysteine into methionine without vitamin B_{12} is also present in many organisms.

These reactions constitute the **activated methyl cycle** (**Figure 25.11**). Methyl groups enter the cycle in the conversion of homocysteine into methionine and are then made highly reactive by the addition of an adenosyl group, which makes the sulfur atoms positively charged and the methyl groups much more electrophilic. The high transfer potential of the *S*-methyl group enables it to be transferred to a wide variety of acceptors. Among the acceptors modified by *S*-adenosylmethionine are specific bases in bacterial DNA. For instance, the methylation of DNA protects bacterial DNA from cleavage by restriction enzymes (Section 6.4). Methylation is also important for the synthesis of phospholipids (Section 27.1).



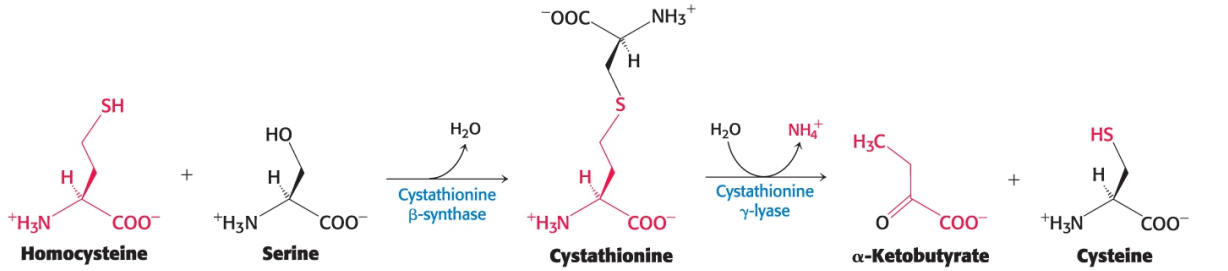


FIGURE 25.11 The activated methyl cycle enables regeneration of methionine. The methyl group of methionine is activated by the formation of *S*-adenosylmethionine.

Self-Check Question

Which derivative of folate is a reactant in the conversion of **(a)** glycine into serine? **(b)** homocysteine into methionine?

Cysteine is synthesized from serine and homocysteine

In addition to being a precursor of methionine in the activated methyl cycle, homocysteine is an intermediate in the synthesis of cysteine. Serine and homocysteine condense to form cystathionine. This reaction is catalyzed by cystathionine β-synthase. Cystathionine is then deaminated and cleaved to cysteine and α-ketobutyrate by cystathionine γ-lyase or cystathionase.

Both of these enzymes utilize PLP and are homologous to aspartate aminotransferase. The net reaction is

$$\text{Homocysteine} + \text{serine} \rightleftharpoons \text{cysteine} + \alpha\text{-ketobutyrate} + NH_4$$

Note that the sulfur atom of cysteine is derived from homocysteine, whereas the carbon skeleton comes from serine.

High homocysteine levels correlate with vascular disease

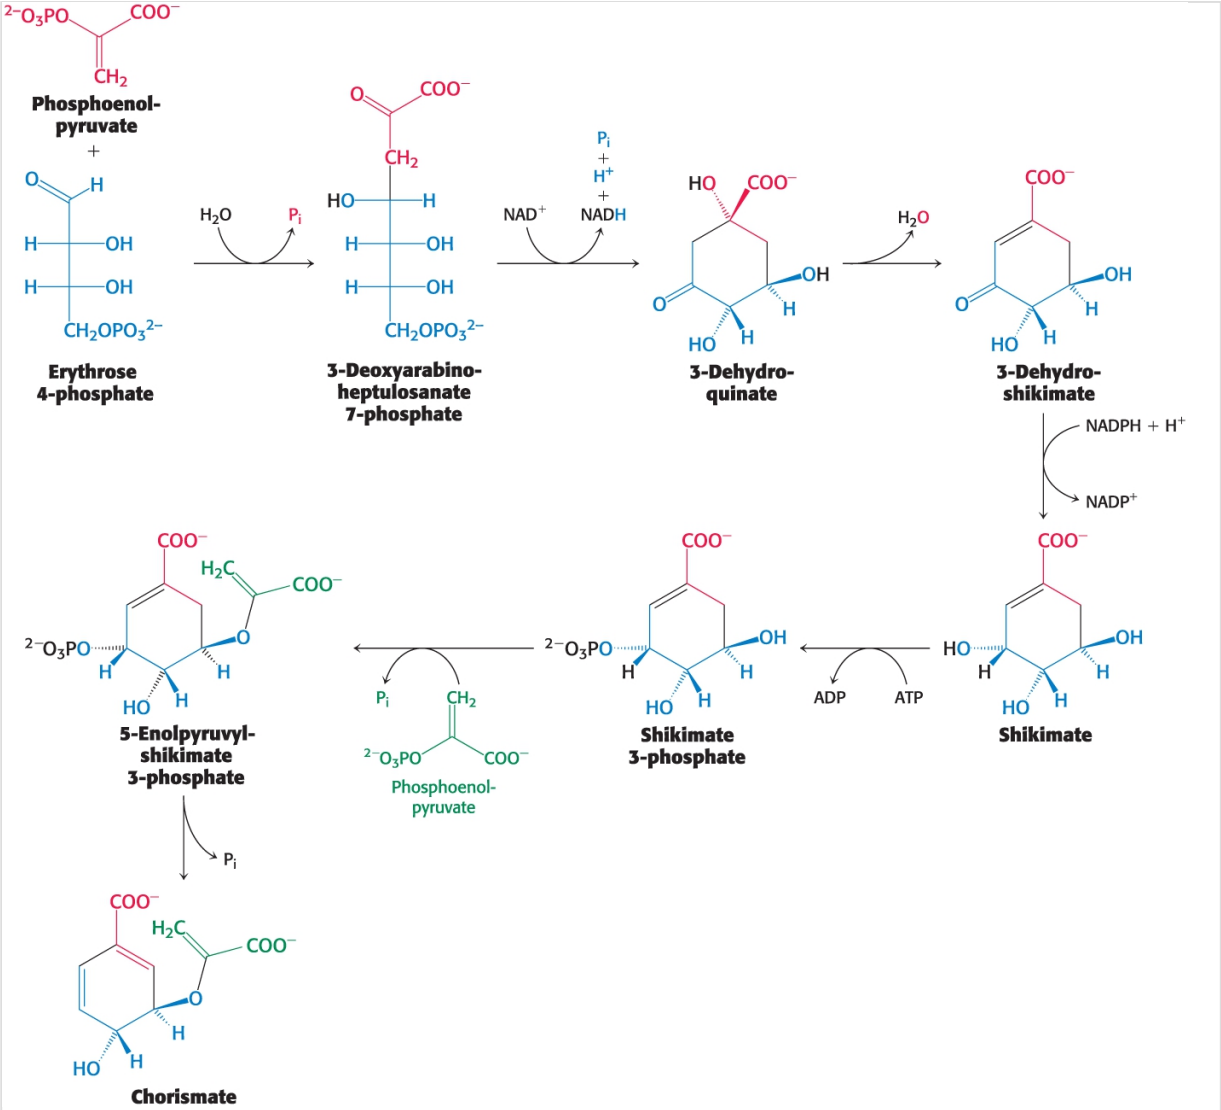
People with elevated serum levels of homocysteine (homocysteinemia) or the disulfide-linked dimer homocystine (homocystinuria) have an unusually high risk for coronary heart disease and arteriosclerosis. The most common genetic cause of high homocysteine levels is a mutation within the gene encoding cystathionine β-synthase. High levels of homocysteine appear to damage cells lining blood vessels and to increase the growth of vascular smooth muscle. The amino acid raises oxidative stress as well and has also been implicated in the development of type 2 diabetes.

The molecular basis of homocysteine's action has not been clearly identified, but it may result from stimulation of the inflammatory response. Vitamin treatments are sometimes effective in reducing homocysteine levels in some people. Treatment with vitamins maximizes the activity of the two major metabolic pathways processing homocysteine. Pyridoxal phosphate, a vitamin B_6 derivative, is necessary for the activity of cystathionine β-synthase, which converts homocysteine into cystathionine; tetrahydrofolate, as well as vitamin B_{12}, supports the methylation of homocysteine to methionine.

Shikimate and chorismate are intermediates in the biosynthesis of aromatic amino acids

We turn now to the biosynthesis of essential amino acids. These amino acids are synthesized by plants and microorganisms, and those in the human diet are ultimately derived primarily from plants. The essential amino acids are formed by much more complex routes than are the nonessential amino acids. The pathways for the synthesis of aromatic amino acids in bacteria have been selected for discussion here because they are well understood and exemplify recurring mechanistic motifs.

Phenylalanine, tyrosine, and tryptophan are synthesized by a common pathway in *E. coli* (**Figure 25.12**). The initial step is the condensation of phosphoenolpyruvate (a glycolytic intermediate) with erythrose 4-phosphate (a pentose phosphate pathway intermediate). The resulting seven-carbon open-chain sugar is oxidized, loses its phosphoryl group, and cyclizes to 3-dehydroquinate. Dehydration then yields 3-dehydroshikimate, which is reduced by NADPH to shikimate. The phosphorylation of shikimate by ATP gives shikimate 3-phosphate, which condenses with a second molecule of phosphoenolpyruvate. The resulting 5-enolpyruvyl intermediate loses its phosphoryl group, yielding chorismate, the common precursor of all three aromatic amino acids.



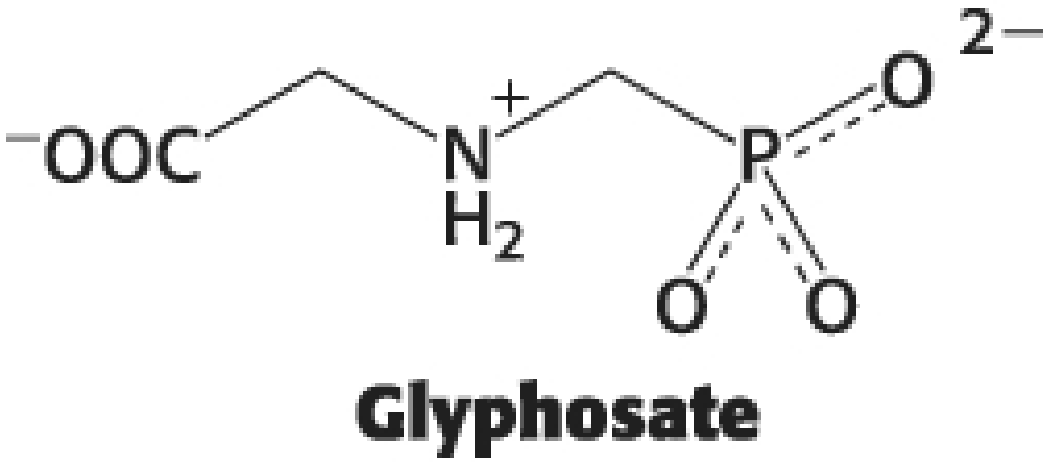


FIGURE 25.12 Chorismate is formed from phosphoenolpyruvate and erythrose 4-phosphate. Chorismate is an intermediate in the biosynthesis of phenylalanine, tyrosine, and tryptophan.

The importance of this pathway is revealed by the effectiveness of glyphosate, a broad-spectrum herbicide. This compound is an uncompetitive inhibitor of the enzyme that produces 5-enolpyruvylshikimate 3-phosphate. It blocks aromatic amino acid biosynthesis in plants but is fairly nontoxic in animals because they lack the enzyme. Recently, there have been claims that glyphosate may

cause cancer, although most scientific evidence does not support the claims.

The pathway bifurcates at chorismate. Let us first follow the *prephenate branch* (**Figure 25.13**). The enzyme chorismate mutase converts chorismate into prephenate, the immediate precursor of the aromatic ring of phenylalanine and tyrosine. This fascinating conversion is a rare example of an electrocyclic reaction in biochemistry, mechanistically similar to the well-known Diels–Alder reaction in organic chemistry. Dehydration and decarboxylation yield phenylpyruvate. Alternatively, prephenate can be oxidatively decarboxylated to *p*-hydroxyphenylpyruvate. These α-ketoacids are then transaminated to form phenylalanine and tyrosine.

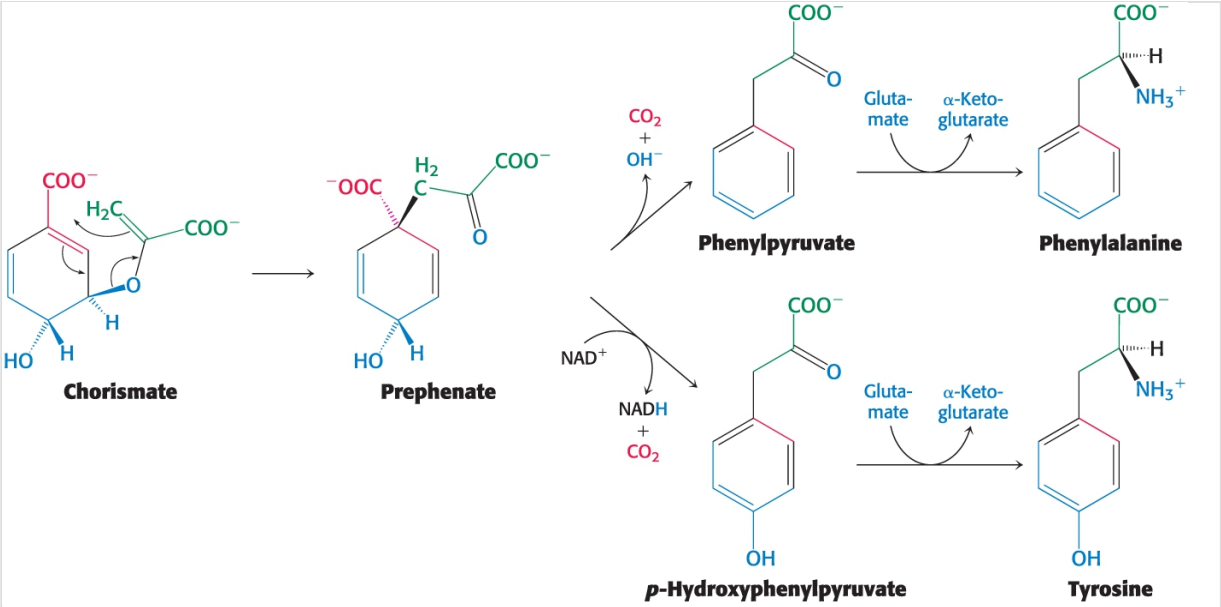

FIGURE 25.13 Phenylalanine and tyrosine are formed in the prephenate branch. Chorismate can be converted into prephenate, which is subsequently converted into phenylalanine and tyrosine.

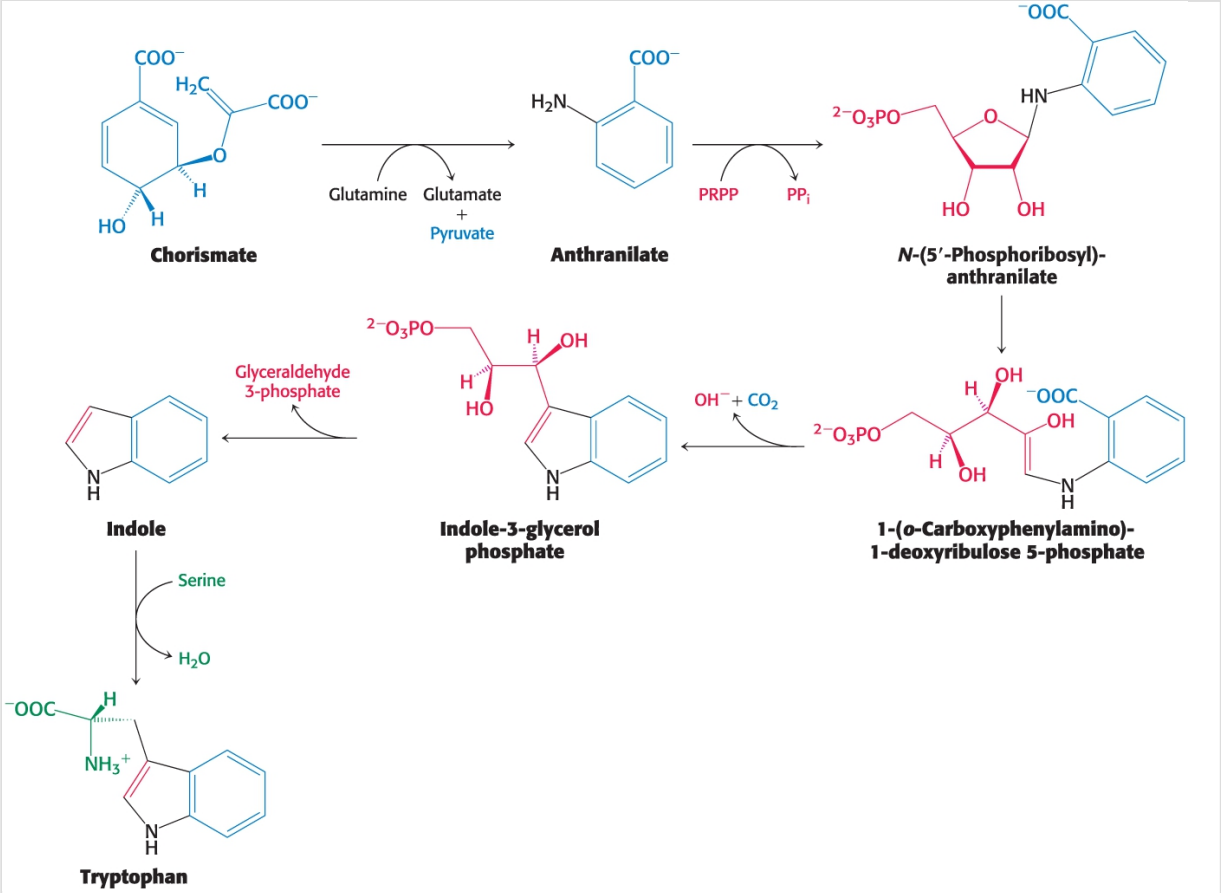
The *anthranilate branch* leads to the synthesis of tryptophan (Figure 25.14).



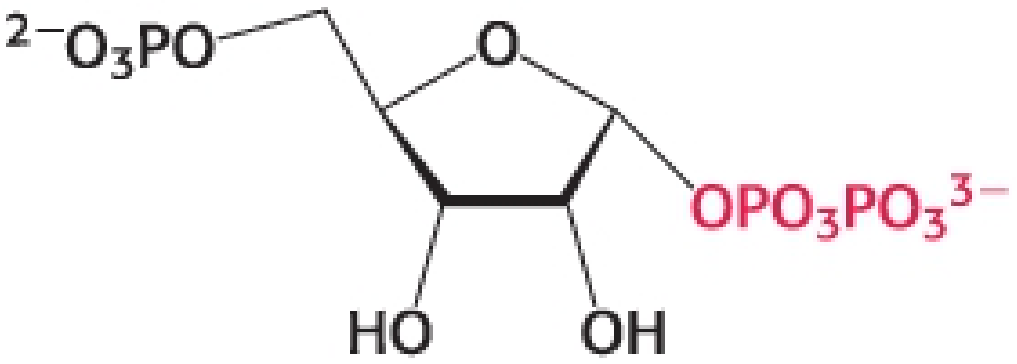


FIGURE 25.14 Tryptophan is formed in the anthranilate branch. Chorismate can be converted into anthranilate, which is subsequently converted into tryptophan.

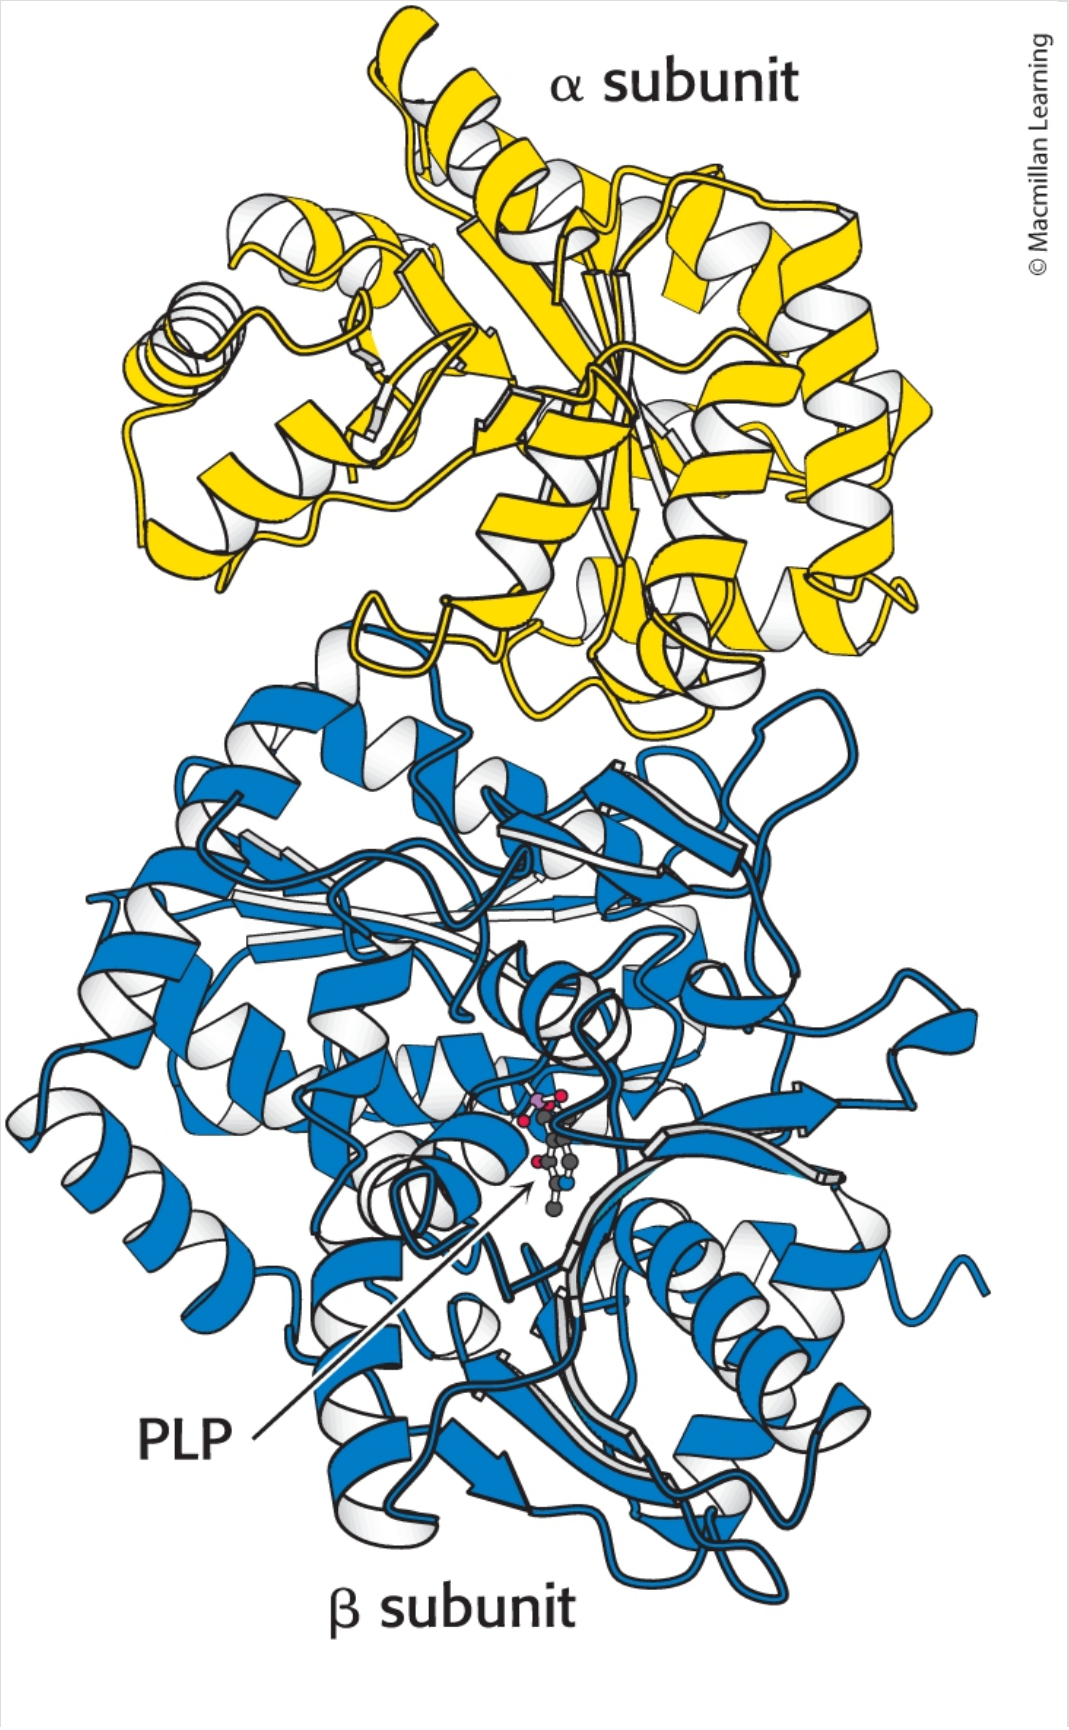
Chorismate acquires an amino group derived from the hydrolysis of the side chain of glutamine and releases pyruvate to form anthranilate. Anthranilate then condenses with 5-phosphoribosyl-1-pyrophosphate (PRPP), an activated form of ribose phosphate.

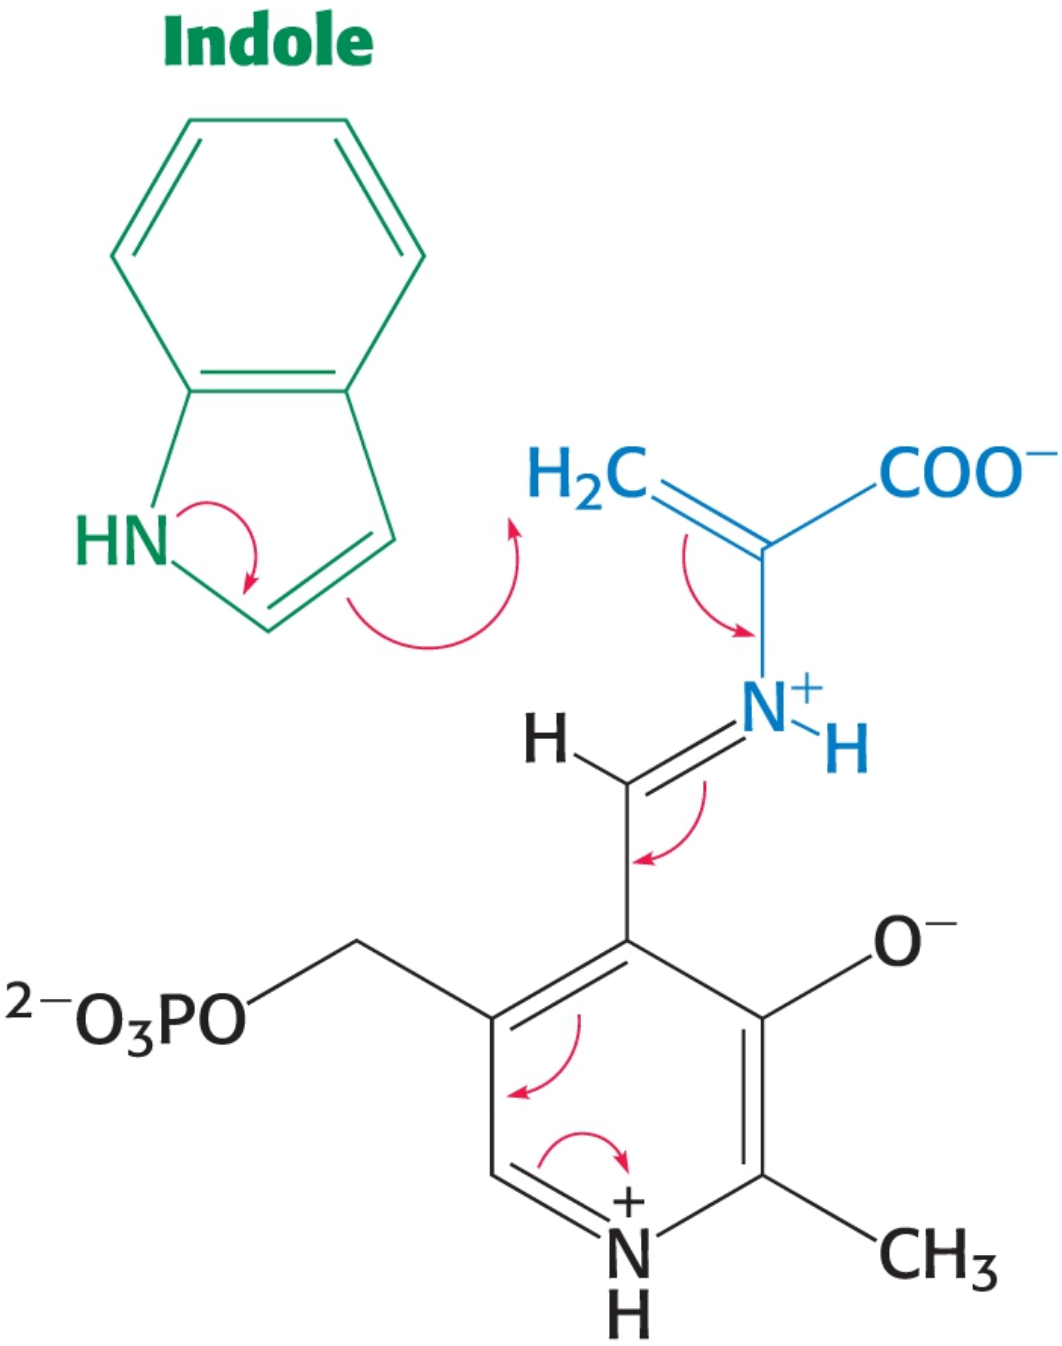


5-Phosphoribosyl-1-pyrophosphate (PRPP)

PRPP is also an important intermediate in the synthesis of histidine, pyrimidine nucleotides, and purine nucleotides (Sections 26.1 and 26.2). The C-1 atom of ribose 5-phosphate becomes bonded to the nitrogen atom of anthranilate in a reaction that is driven by the release and hydrolysis of pyrophosphate. The ribose moiety of phosphoribosylanthranilate undergoes rearrangement to yield 1-(*o*-carboxyphenylamino)-1-deoxyribulose 5-phosphate. This intermediate is dehydrated and then decarboxylated to indole-3-glycerol phosphate. Tryptophan synthase completes the synthesis of tryptophan with the removal of the side chain of indole-3-glycerol phosphate, yielding glyceraldehyde 3-phosphate, and its replacement with the carbon skeleton of serine.

Tryptophan synthase illustrates substrate channeling in enzymatic catalysis

The *E. coli* enzyme tryptophan synthase, an $\alpha_2\beta_2$ tetramer, can be dissociated into two α subunits and a β_2 dimer (**Figure 25.15**).



© Macmillan Learning

FIGURE 25.15 Tryptophan synthase contains two remotely positioned catalytic domains. The complex is formed by one α subunit (yellow) and one β subunit (blue). Pyridoxal phosphate (PLP) is bound deeply inside the β subunit, a considerable distance from the α subunit.

[Drawn from 1BKS.pdb.]

INTERACT with this model in Achieve

The α subunit catalyzes the formation of indole from indole-3-glycerol phosphate, whereas each β subunit has a PLP-containing active site that catalyzes the condensation of indole and serine to form tryptophan. Serine forms a Schiff base with this PLP, which is then dehydrated to give the Schiff base of aminoacrylate. This reactive intermediate is attacked by indole to give tryptophan.

Schiff base of aminoacrylate
(derived from serine)

The synthesis of tryptophan poses a challenge. Indole, a hydrophobic molecule, readily traverses membranes and would be lost from the cell if it were allowed to diffuse away from the enzyme. This problem is solved in an ingenious way. A 25-Å-long channel connects the active site of the α subunit with that of the adjacent β subunit in the $\alpha_2\beta_2$ tetramer (**Figure 25.16**). Thus, indole can diffuse from one active site to the other without being released into bulk solvent. Isotope-labeling experiments showed that indole formed by the α subunit does not leave the enzyme when serine is present. Furthermore, the two partial reactions are coordinated. Indole is not formed by the α subunit until the highly reactive aminoacrylate is ready and waiting in the β subunit.

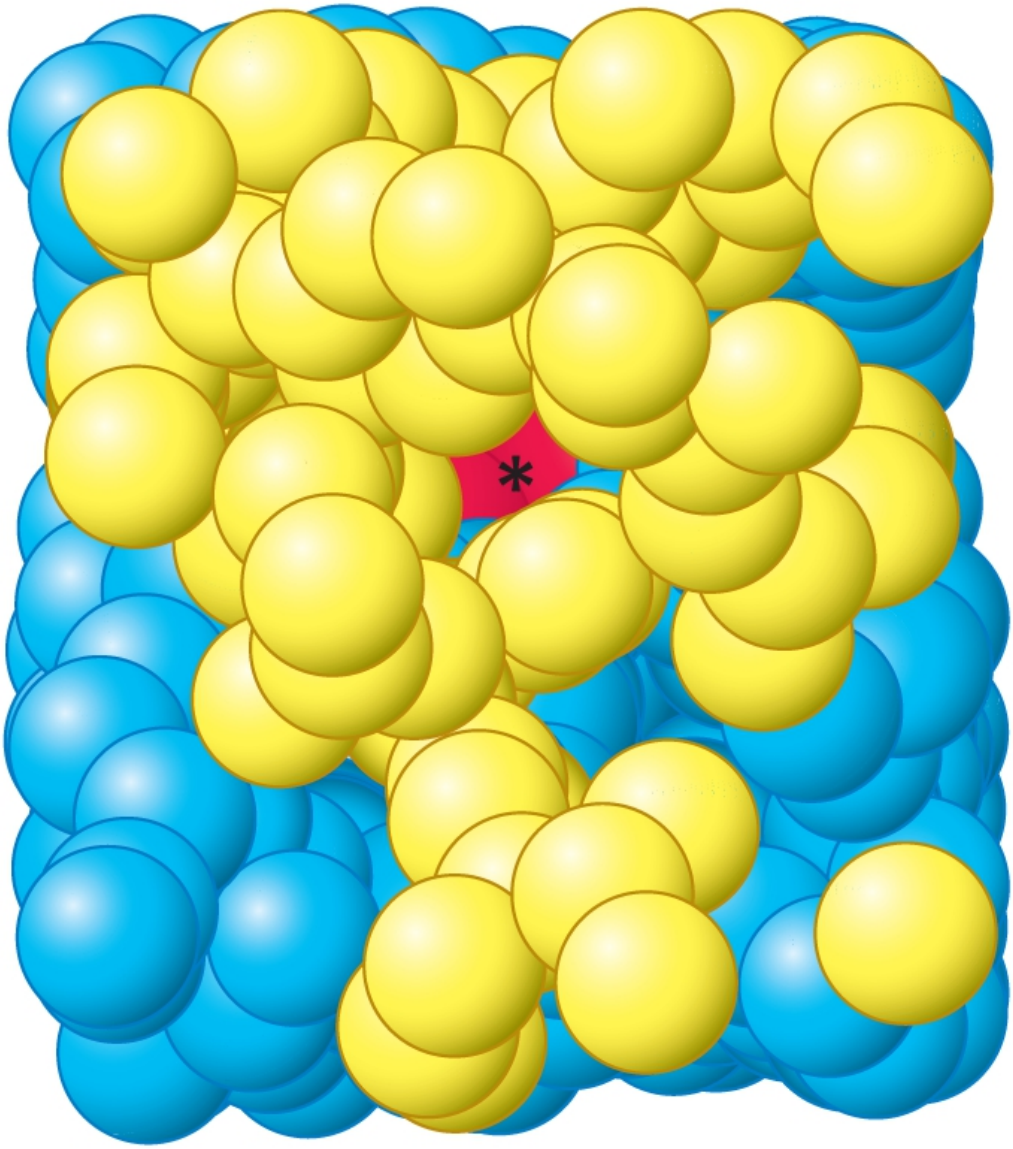


FIGURE 25.16 Tryptophan synthase uses substrate channeling to prevent loss of the indole intermediate. A 25-Å tunnel runs from the active site of the α subunit of tryptophan synthase (yellow) to the PLP cofactor (red) in the active site of the β subunit (blue). The asterisk indicates the center of the tunnel.

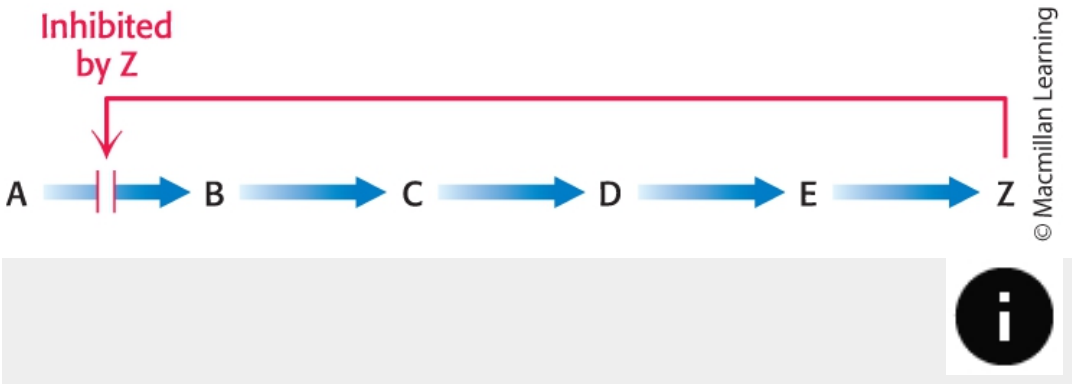

We see here a clear-cut example of **substrate channeling** in catalysis by a multienzyme complex. Channeling substantially increases the catalytic rate. Furthermore, a deleterious side reaction — in this case,

the potential loss of an intermediate — is prevented. We shall encounter other examples of substrate channeling in Chapter 26.

25.3 Feedback Inhibition Regulates Amino Acid Biosynthesis

The rate of synthesis of amino acids depends mainly on the *amounts* of the biosynthetic enzymes and on their *activities*. We now consider the control of enzymatic activity. The regulation of enzyme synthesis in eukaryotes will be discussed in Chapter 31.

In a biosynthetic pathway, the first irreversible reaction is usually an important regulatory site. As we have seen in Section 7.1, this reaction is referred to as the *committed step*. The final product of the pathway (*Z*) often inhibits the enzyme that catalyzes the committed step $(A \rightarrow B)$.

This kind of control is essential for the conservation of building blocks and metabolic energy. Consider the biosynthesis of serine (Section 25.2). The committed step in this pathway is the oxidation of 3-phosphoglycerate, catalyzed by the enzyme 3-phosphoglycerate dehydrogenase. The *E. coli* enzyme is a tetramer of four identical subunits, each comprising a catalytic domain and a serine-binding regulatory domain (**Figure 25.17**). The binding of serine to a regulatory site reduces the value of V_{max} for the enzyme; an enzyme bound to four molecules of serine is essentially inactive. Thus, if serine is abundant in

the cell, the enzyme activity is inhibited, and so 3-phosphoglycerate, a key building block that can be used for other processes, is not wasted.

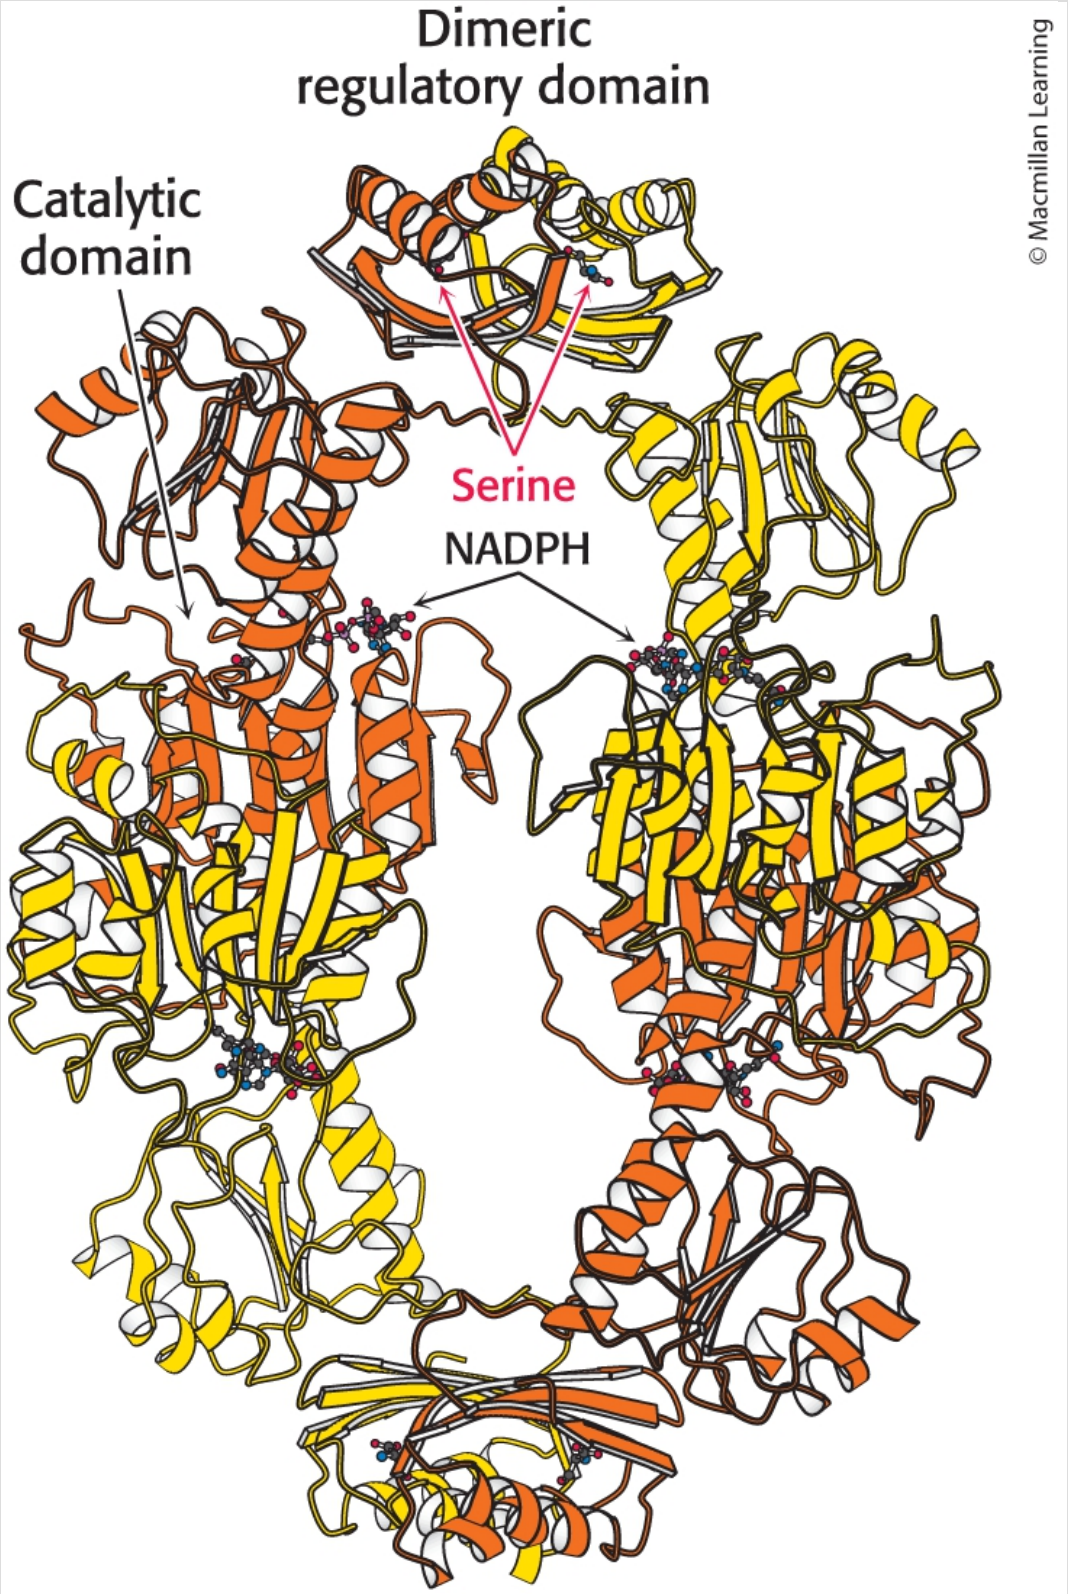

FIGURE 25.17 3-Phosphoglycerate dehydrogenase is a homotetramer. This enzyme, which catalyzes the committed step in the serine biosynthetic pathway, is inhibited

by serine. There are two serine-binding dimeric regulatory domains — one at the top and the other at the bottom of the structure.

[Drawn from 1PSD.pdb.]

Branched pathways require sophisticated regulation

The regulation of branched pathways is more complicated because the concentration of two products must be taken into account. In fact, several intricate feedback mechanisms have been found in branched biosynthetic pathways.

Feedback inhibition and activation

Two pathways with a common initial step may each be inhibited by its own product and activated by the product of the other pathway. Consider, for example, the biosynthesis of the branched chain amino acids valine, leucine, and isoleucine. A common intermediate, hydroxyethyl thiamine pyrophosphate (hydroxyethyl-TPP; Section 17.2), initiates the pathways leading to all three of these amino acids. Hydroxyethyl-TPP reacts with α-ketobutyrate in the initial step for the synthesis of isoleucine. Alternatively, hydroxyethyl-TPP reacts with pyruvate in the committed step for the pathways leading to valine and leucine. Thus, the relative concentrations of α-ketobutyrate and pyruvate determine how much isoleucine is produced compared with valine and leucine.

Threonine deaminase, the PLP enzyme that catalyzes the formation of α-ketobutyrate, is allosterically inhibited by isoleucine (**Figure 25.18**). This enzyme is also allosterically activated by valine. Thus, this enzyme is inhibited by the end product of the pathway that it initiates and is

activated by the end product of a competitive pathway. This mechanism balances the amounts of different amino acids that are synthesized.

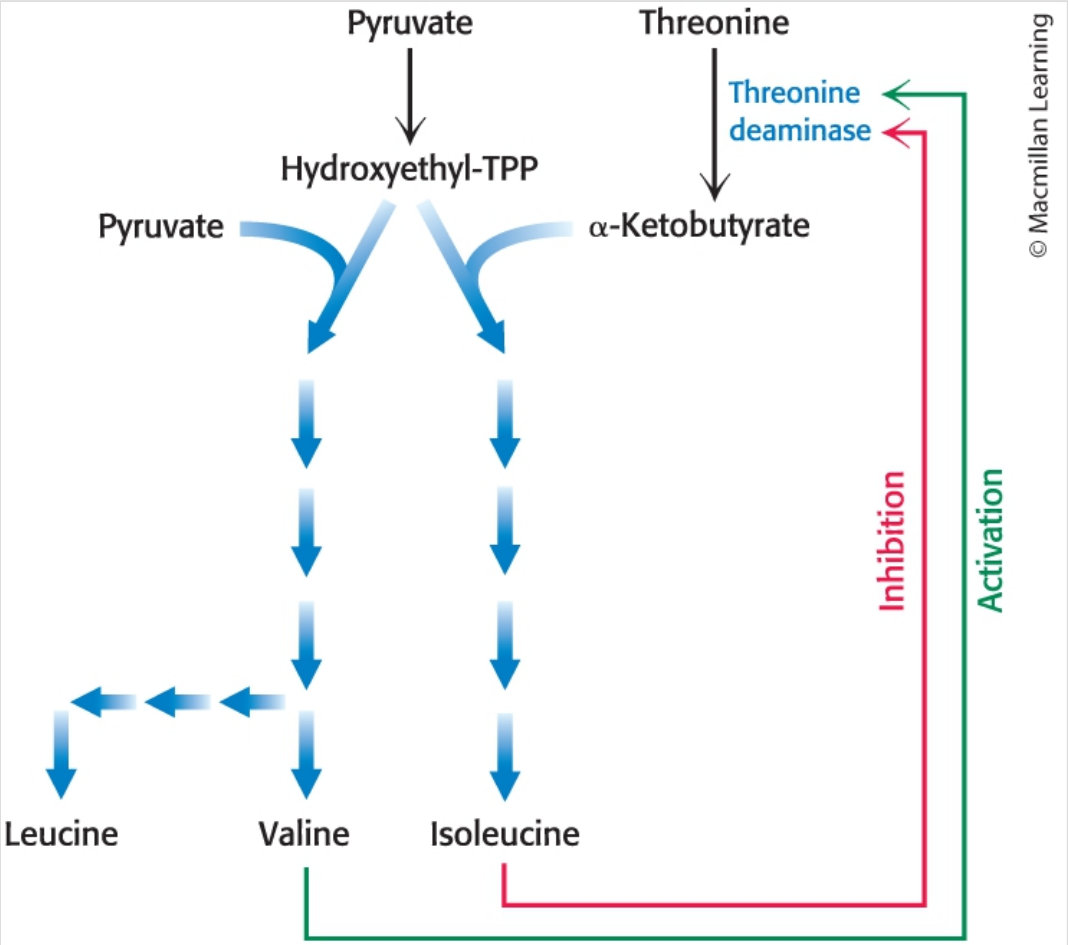

FIGURE 25.18 Threonine deaminase is regulated by feedback inhibition and activation. Threonine is converted into α-ketobutyrate in the committed step, leading to the synthesis of isoleucine. The enzyme that catalyzes this step, threonine deaminase, is inhibited by isoleucine and activated by valine, the product of a parallel pathway.

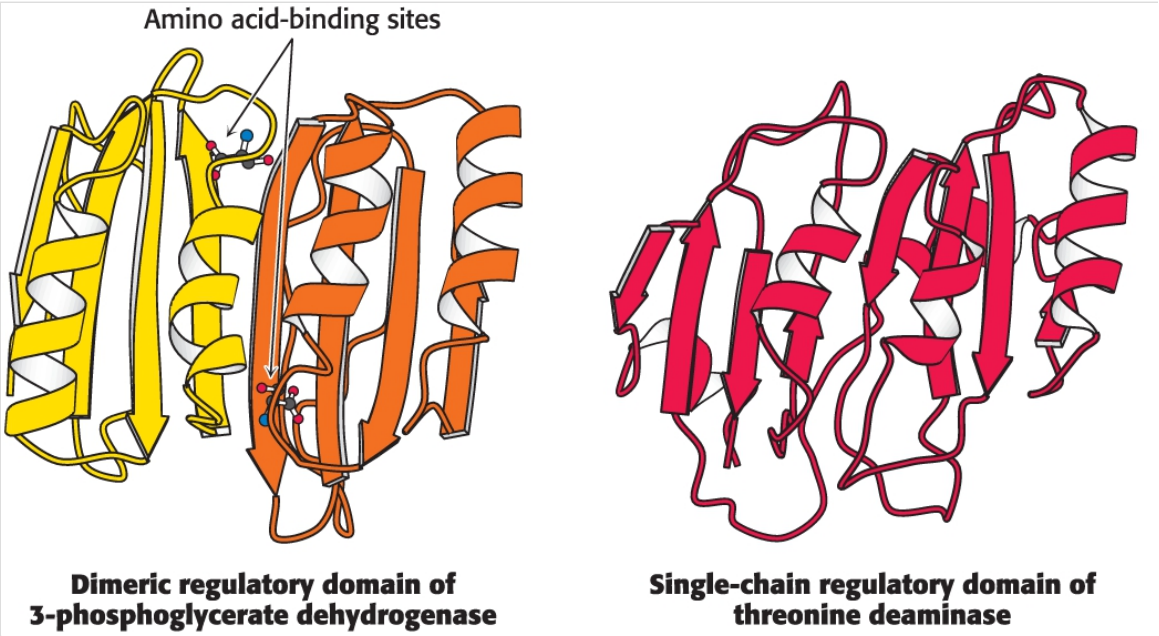
The regulatory domain in threonine deaminase is very similar in structure to the regulatory domain in 3-phosphoglycerate dehydrogenase (Figure 25.19). In the latter enzyme, regulatory domains of two subunits interact to form a dimeric serine-binding regulatory

unit, and so the tetrameric enzyme contains two such regulatory units. Each unit is capable of binding two serine molecules. In threonine deaminase, the two regulatory domains are fused into a single unit with two differentiated amino acid-binding sites, one for isoleucine and the other for valine. Sequence analysis shows that similar regulatory domains are present in other amino acid biosynthetic enzymes. The similarities suggest that feedback-inhibition processes may have evolved by the linkage of specific regulatory domains to the catalytic domains of biosynthetic enzymes.



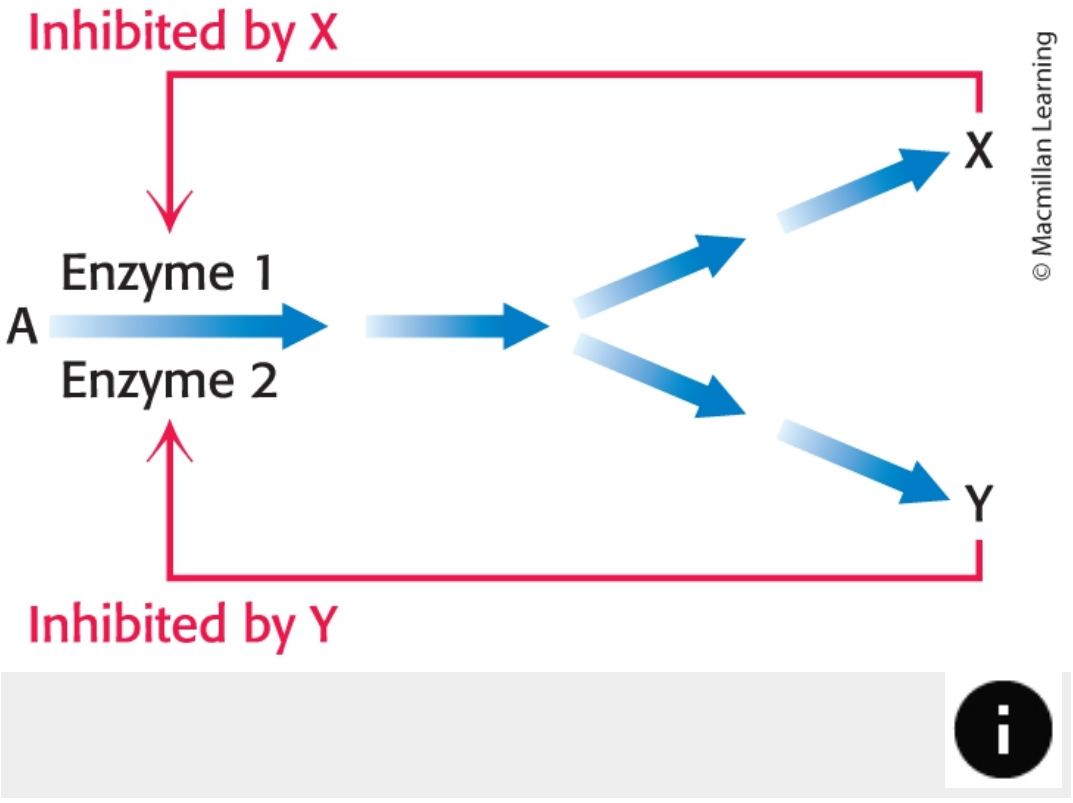


FIGURE 25.19 The regulatory domains of 3-phosphoglycerate dehydrogenase and threonine deaminase are related structurally. The regulatory domain of 3-phosphoglycerate dehydrogenase is comprised of two subunits, while the corresponding domain of threonine deaminase is comprised of a single chain. Both overall structures have four α helices and eight β strands in similar locations. Sequence analyses have revealed this amino acid-binding regulatory domain to be present in other enzymes as well.

[Drawn from 1PSD.pdb and 1TDJ.pdb.]

Enzyme multiplicity

In a process known as **enzyme multiplicity**, the committed step can be catalyzed by two or more isozymes, enzymes with essentially identical catalytic mechanisms but different regulatory properties (Section 7.2). For example, the phosphorylation of aspartate is the committed step in the biosynthesis of threonine, methionine, and lysine. Three distinct aspartokinases, which evolved by gene duplication, catalyze this reaction in *E. coli* (**Figure 25.20**). The catalytic domains of these enzymes show approximately 30% sequence identity. Although the mechanisms of catalysis are the same, their activities are regulated differently: one enzyme is not subject to feedback inhibition, another is inhibited by threonine, and the third is inhibited by lysine.

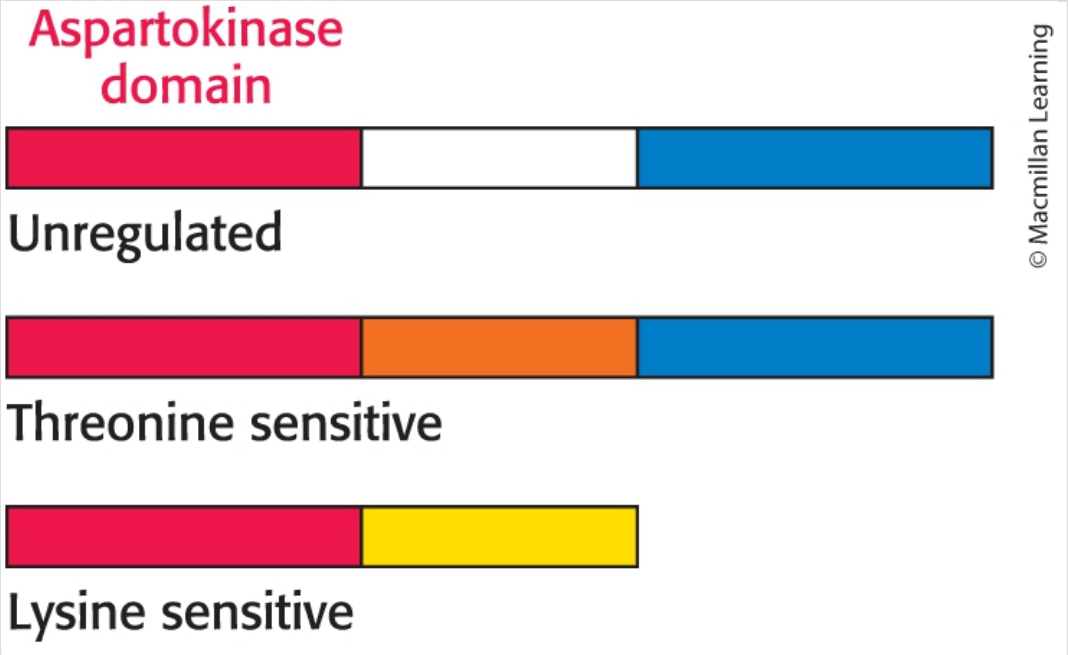

FIGURE 25.20 The three aspartokinases from *E. coli* have different regulatory domains. Each catalyzes the committed step in the biosynthesis of a different amino acid: (top) methionine, (middle) threonine, and (bottom) lysine. They have a catalytic domain in common (red) but differ in their regulatory domains (yellow and orange). The blue domain represents another enzyme (homoserine dehydrogenase) involved in aspartate metabolism. Thus, the top two aspartokinases are bifunctional enzymes.

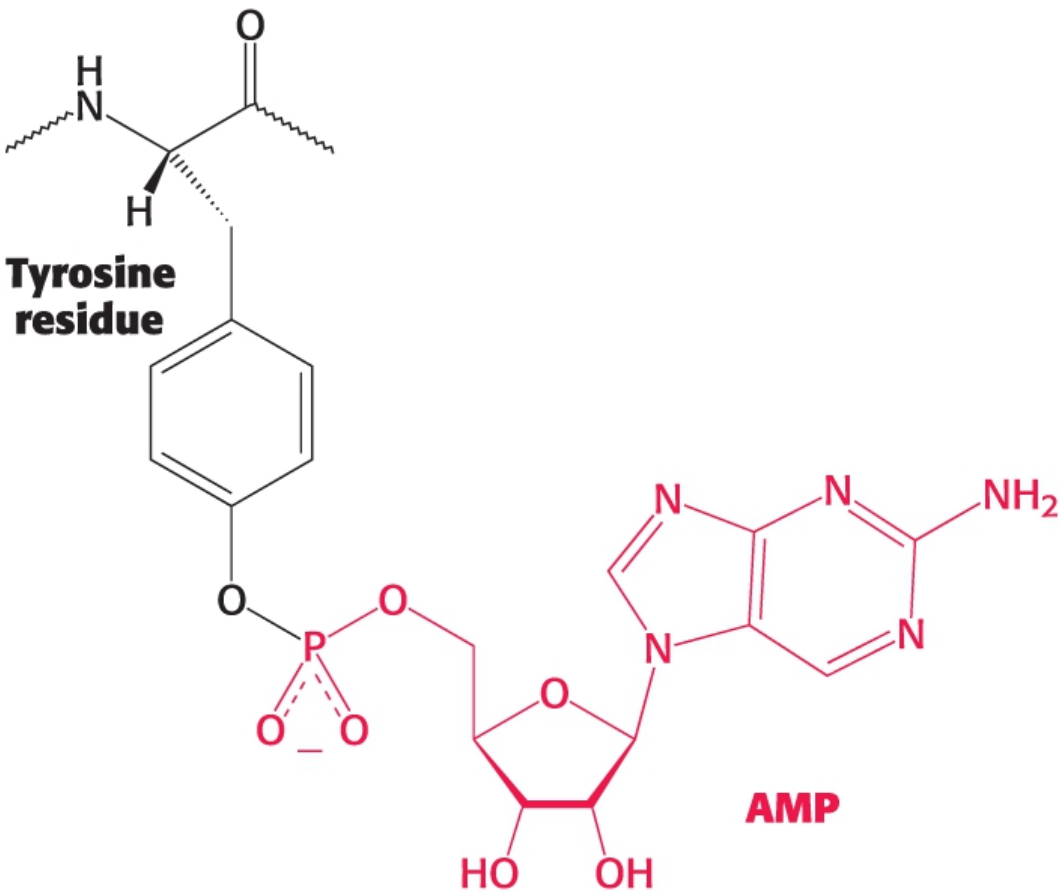

Cumulative feedback inhibition

A common step is partly inhibited by multiple final products, each acting independently. The regulation of glutamine synthetase in *E. coli* is a striking example of **cumulative feedback inhibition**. Recall that glutamine is synthesized from glutamate, NH_4^+, and ATP. Glutamine synthetase consists of 12 identical 50-kDa subunits arranged in two hexagonal rings that face each other. This enzyme regulates the flow of nitrogen and hence plays a key role in controlling bacterial metabolism. The amide group of glutamine is a source of nitrogen in the

biosyntheses of a variety of compounds, such as tryptophan, histidine, carbamoyl phosphate, glucosamine 6-phosphate, cytidine triphosphate, and adenosine monophosphate. Glutamine synthetase is cumulatively inhibited by each of these final products of glutamine metabolism, as well as by alanine and glycine. In cumulative inhibition, each inhibitor can reduce the activity of the enzyme, even when other inhibitors are bound at saturating levels. The enzymatic activity of glutamine synthetase is switched off almost completely when all final products are bound to the enzyme.

The sensitivity of glutamine synthetase to allosteric regulation is altered by covalent modification

The activity of glutamine synthetase is also controlled by reversible covalent modification — the attachment of an AMP unit by a phosphodiester linkage to the hydroxyl group of a specific tyrosine residue in each subunit. This adenylylated enzyme is less active and more susceptible to cumulative feedback inhibition than is the deadenylylated form. The covalently attached AMP unit is removed from the adenylylated enzyme by phosphorolysis.

Tyrosine residue modified by adenylylation

The adenylylation and phosphorolysis reactions are catalyzed by the same enzyme, adenylyl transferase. This enzyme is composed of two homologous halves, one half catalyzing the adenylylation reaction and the other half the phosphorolytic deadenylylation reaction. What determines whether an AMP unit is added or removed? The specificity of adenylyl transferase is controlled by a regulatory protein P_{II}, a trimeric protein that can exist in two forms, unmodified (P_{II}) or covalently bound to UMP (P_{II}-UMP). The complex of P_{II} and adenylyl transferase catalyzes the attachment of an AMP unit to glutamine synthetase, which reduces its activity. Conversely, the complex of P_{II}-

UMP and adenylyl transferase removes AMP from the adenylylated enzyme (Figure 25.21).

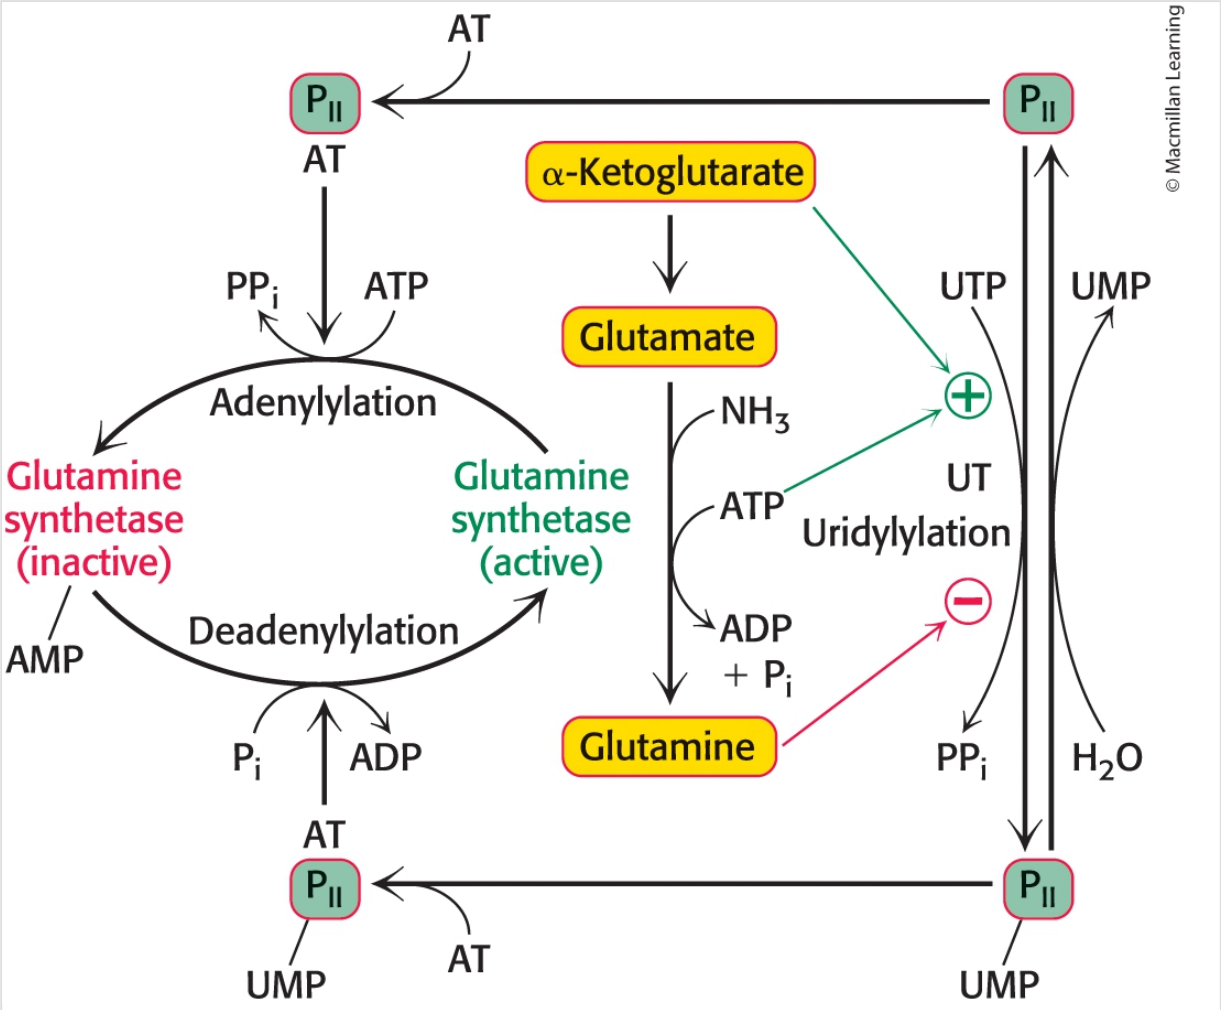

FIGURE 25.21 Glutamine synthetase is regulated by covalent modification. Adenylyl transferase (AT), in association with the regulatory protein P_{II}, adenylylates and inactivates the synthetase. When associated with P_{II} bound to UMP, AT deadenylylates the synthetase, thereby activating the enzyme. Uridylyl transferase (UT), the enzyme that modifies P_{II}, is allosterically regulated by α-ketoglutarate, ATP, and glutamine.

[Information from D. L. Nelson and M. M. Cox, Lehninger Principles of Biochemistry, 7th ed. (W. H. Freeman and Company, 2013), Fig. 22.9.]

This scheme of regulation immediately raises the question, how is the modification of P_{II} controlled? P_{II} is converted into P_{II}-UMP by the attachment of uridine monophosphate to a specific tyrosine residue (Figure 25.21). This reaction, which is catalyzed by uridylyl transferase, is stimulated by ATP and α-ketoglutarate, whereas it is inhibited by glutamine. In turn, the UMP units on P_{II} are removed by hydrolysis, a reaction promoted by glutamine and inhibited by α-ketoglutarate. These opposing catalytic activities are present on a single polypeptide chain and are controlled so that the enzyme does not simultaneously catalyze uridylylation and hydrolysis. In essence, if glutamine is present, the covalent modification system favors adenylylation and inactivation of glutamine synthetase. If glutamine is absent, as indicated by the presence of its precursors α-ketoglutarate and ATP, the control system results in the deadenylylation and activation of the synthetase.

The integration of nitrogen metabolism in a cell requires that a large number of input signals be detected and processed. In addition, the regulatory protein P_{II} also participates in regulating the transcription of genes for glutamine synthetase and other enzymes taking part in nitrogen metabolism. The evolution of covalent regulation superimposed on feedback inhibition provided many more regulatory sites and made possible a finer tuning of the flow of nitrogen in the cell. We have previously seen such a dual regulatory format in the regulation of glycogen metabolism (Section 21.6).

25.4 Amino Acids Are Precursors of Many Biomolecules

In addition to being the building blocks of proteins and peptides, amino acids serve as precursors of many kinds of small molecules that have important and diverse biological roles. Let us briefly survey some of the biomolecules that are derived from amino acids (**Figure 25.22**).

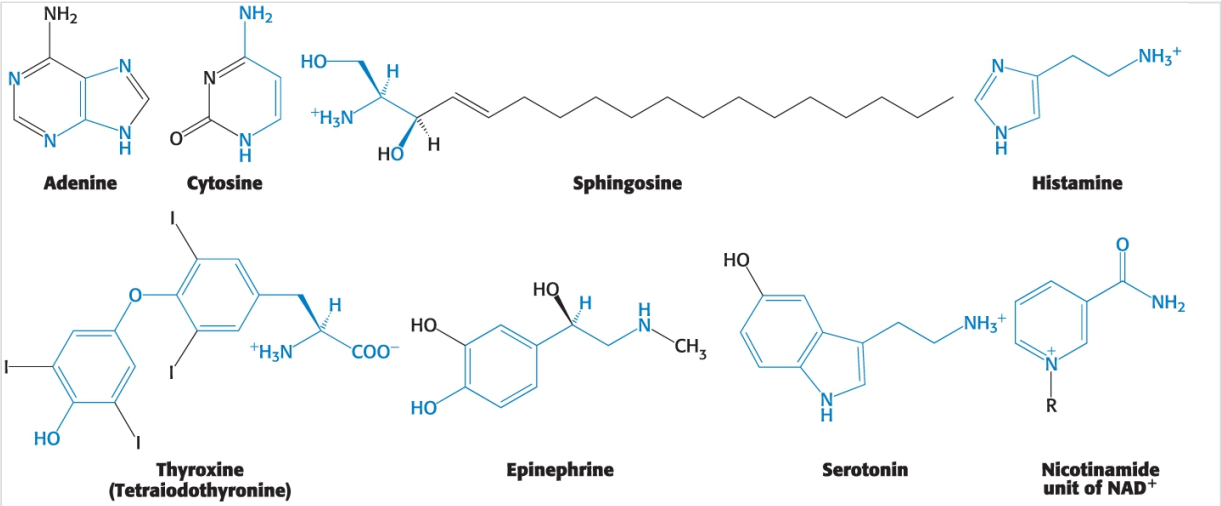

FIGURE 25.22 A diverse array of biomolecules are derived from amino acids. The atoms contributed by amino acids are shown in blue.

Purines and pyrimidines are derived largely from amino acids. The biosynthesis of these precursors of DNA, RNA, and numerous coenzymes will be discussed in detail in Chapter 26. The reactive terminus of sphingosine, an intermediate in the synthesis of sphingolipids (Section 12.2), comes from serine. Histamine, a potent vasodilator, is derived from histidine by decarboxylation. Tyrosine is a precursor of thyroxine (tetraiodothyronine, a hormone that modulates

metabolism), epinephrine (Section 14.2), and melanin (a complex polymeric molecule responsible for skin pigmentation). The neurotransmitter serotonin (5-hydroxytryptamine) and the nicotinamide ring of NAD^+ are synthesized from tryptophan. Let us now consider in more detail three particularly important biochemicals derived from amino acids.

Glutathione, a gamma-glutamyl peptide, serves as a sulfhydryl buffer and an antioxidant

Glutathione, a tripeptide containing a sulfhydryl group, is a highly distinctive amino acid derivative with several important roles (**Figure 25.23**).

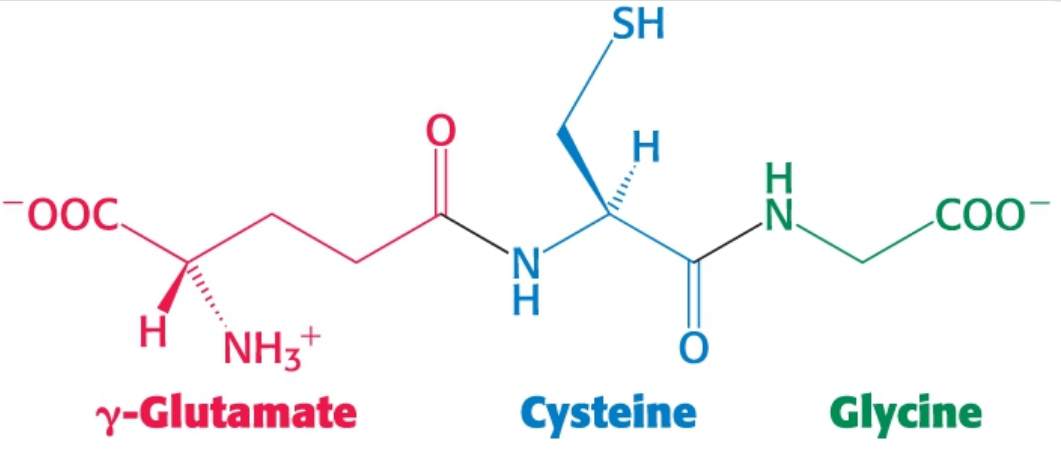

FIGURE 25.23 Glutathione is an important sulfhydryl buffer and antioxidant. This tripeptide consists of a cysteine residue flanked by a glycine residue and a glutamate residue that is linked to cysteine by an isopeptide bond between glutamate's side-chain carboxylate group and cysteine's amino group.

For example, glutathione, present at high levels $(\sim 5\ \text{mM})$ in animal cells, protects red blood cells from oxidative damage by serving as a sulfhydryl buffer (Section 20.5). It cycles between a reduced thiol form (GSH) and an oxidized form (GSSG) in which two tripeptides are linked by a disulfide bond.

$$2\,\text{GSH} + \text{RO—OH} \rightleftharpoons \text{GSSG} + \text{H}_2\text{O} + \text{ROH}$$

GSSG is reduced to GSH by glutathione reductase, a flavoprotein that uses NADPH as the electron source. The ratio of GSH to GSSG in most cells is greater than 500. Glutathione plays a key role in detoxification by reacting with hydrogen peroxide and organic peroxides, the harmful by-products of aerobic life (Section 20.5).

Glutathione peroxidase, the enzyme catalyzing the reaction of GSH with peroxides, is remarkable in having a modified amino acid containing a selenium (Se) atom (**Figure 25.24**). Specifically, its active site contains the selenium analog of cysteine, in which selenium has replaced sulfur.

FIGURE 25.24 Glutathione peroxidase contains a selenocysteine residue in its active site.

[Drawn from 1GP1.pdb.]

INTERACT with this model in Achieve

The selenolate $(E-Se^-)$ form of this residue reduces the peroxide substrate to an alcohol and is in turn oxidized to selenenic acid (E-SeOH). Glutathione then comes into action by forming a selenosulfide adduct (E-Se-S-G). A second molecule of glutathione then regenerates the active form of the enzyme by attacking the selenosulfide to form oxidized glutathione (Figure 25.25).

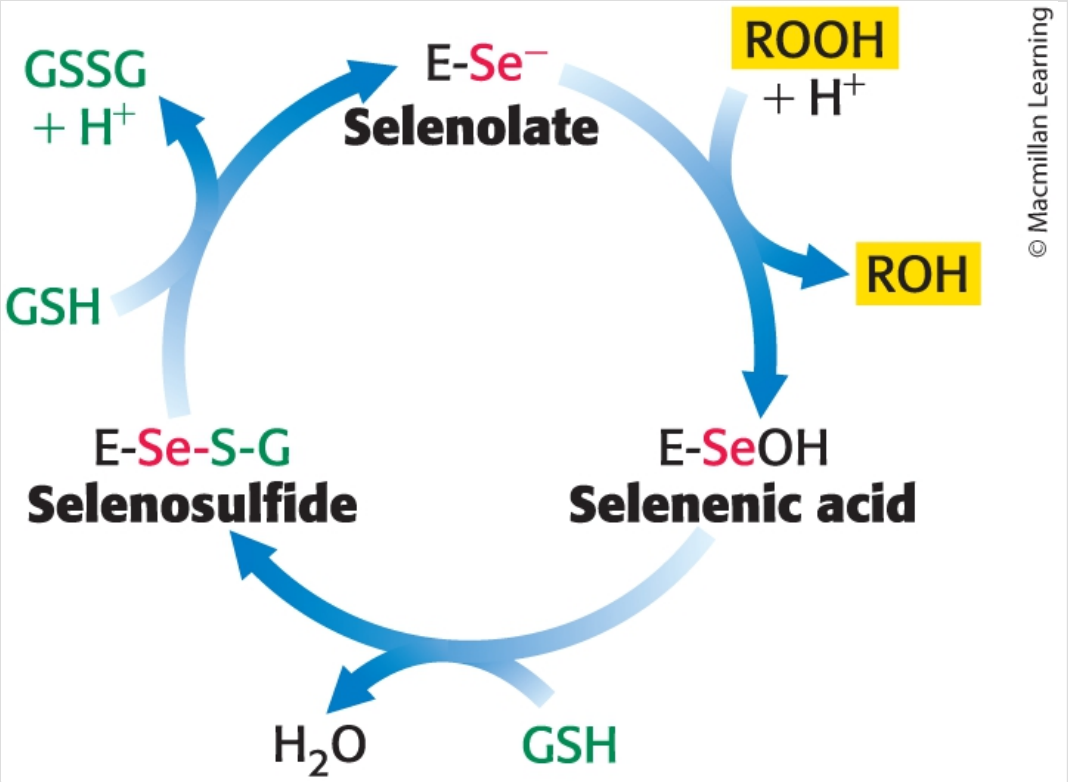

FIGURE 25.25 Glutathione peroxidase uses two molecules of glutathione to regenerate the selenolate active site after peroxide cleavage.

[Information from O. Epp, R. Ladenstein, and A. Wendel. *Eur. J. Biochem.* 133:51–69, 1983.]

Nitric oxide, a short-lived signal molecule, is formed from arginine

Nitric oxide (NO) is an important messenger in many vertebrate signal-transduction processes, identified first as a relaxing factor in the cardiovascular system. It is now known to have a variety of roles not only in the cardiovascular system, but also in the immune and nervous systems (Table 25.3)

TABLE 25.3 Some functions of nitric oxide

Reduces blood pressure by relaxing vascular muscle
Increases blood flow to the kidney
Acts as a neurotransmitter to increase cerebral blood flow
Dilates pulmonary vessels
Mediates erectile function
Controls peristalsis of the gastrointestinal tract
Regulates inflammation

NO has also been shown to stimulate mitochondrial biogenesis. This free-radical gas is produced endogenously from arginine in a complex reaction that is catalyzed by nitric oxide synthase. NADPH and O_2 are required for the synthesis of nitric oxide (**Figure 25.26**). Nitric oxide acts by binding to and activating soluble guanylate cyclase, an important enzyme in signal transduction. Soluble guanylate cyclase is homologous to adenylate cyclase (Section 14.2) but includes a heme-containing domain that binds NO.

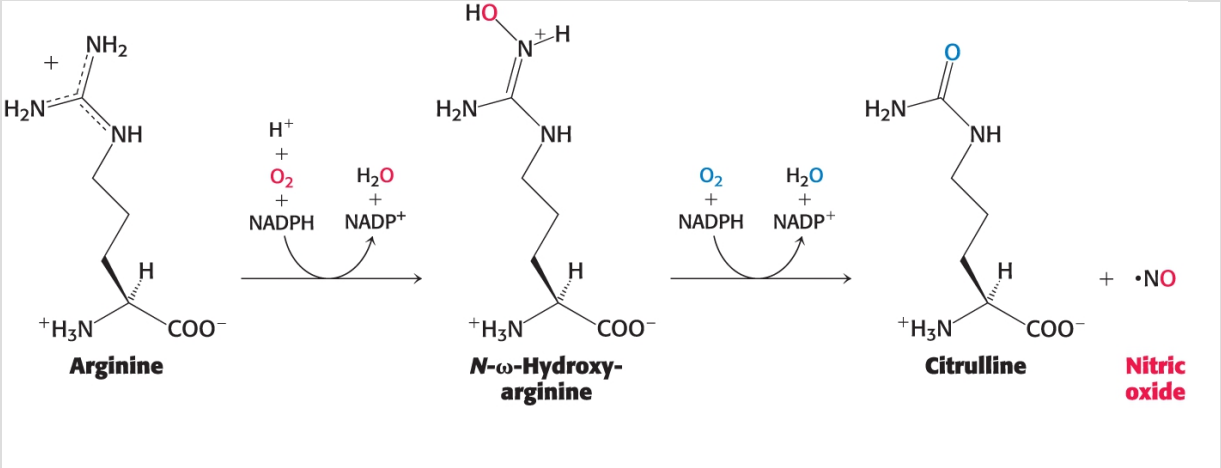

FIGURE 25.26 Nitric oxide is generated by the oxidation of arginine.

Amino acids are precursors for a number of neurotransmitters

Catecholamines, signal molecules with a variety of biological roles, are derived from tyrosine (**Figure 25.27**). Norepinephrine and dopamine are neurotransmitters, and epinephrine is familiar to us for the regulation of fuel use, stimulating glycogen breakdown and lipid mobilization (Section 14.2). In general, the catecholamines are associated with stress and play a role in the "fight or flight" response.

Tryptophan is a precursor for two neurotransmitters (Figure 25.28A). Serotonin functions in several ways. Most notably, serotonin regulates moods and may be involved in alleviating depression. Serotonin is also found in the gastrointestinal tract, where it regulates intestinal contraction, and platelets, where it facilitates vasoconstriction. Serotonin can be metabolized to another hormone, melatonin, which functions to maintain our natural sleep-wake cycle (Figure 25.28B).

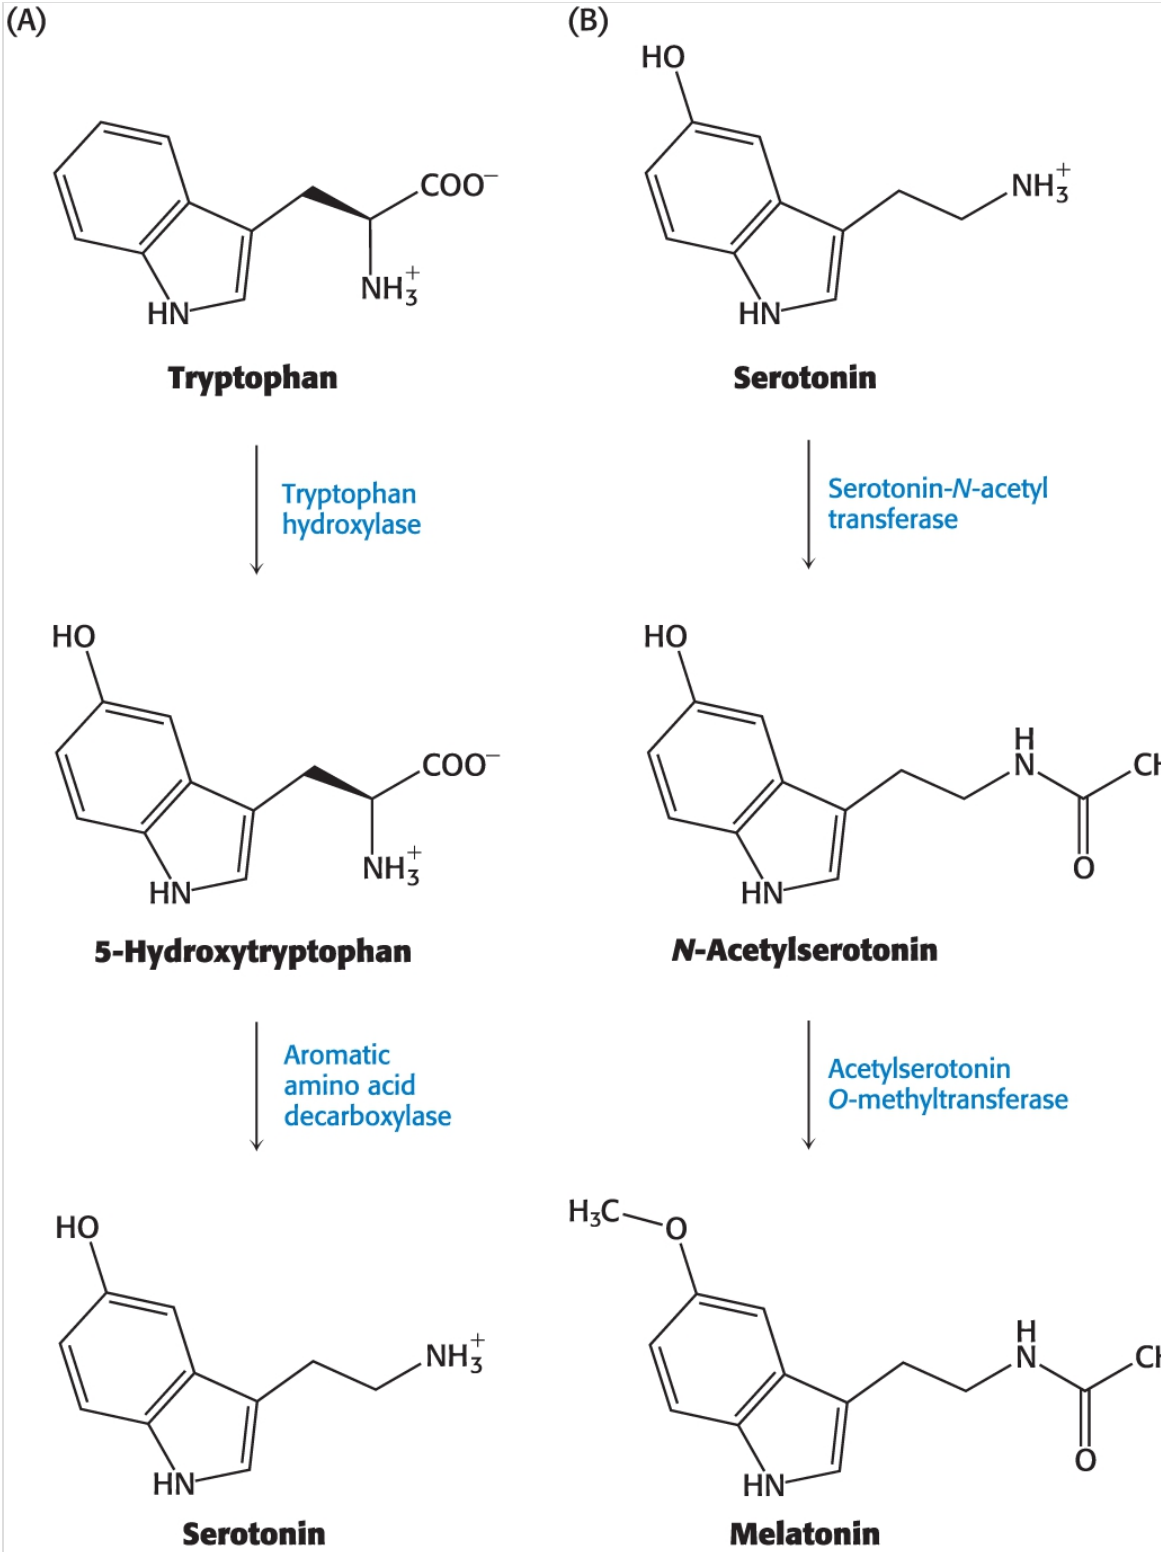

FIGURE 25.28 The neurotransmitters serotonin and melatonin are synthesized from tryptophan. (A) Serotonin is synthesized from tryptophan in two enzymatic steps. (B) Melatonin, in turn, is generated from serotonin in two additional steps.

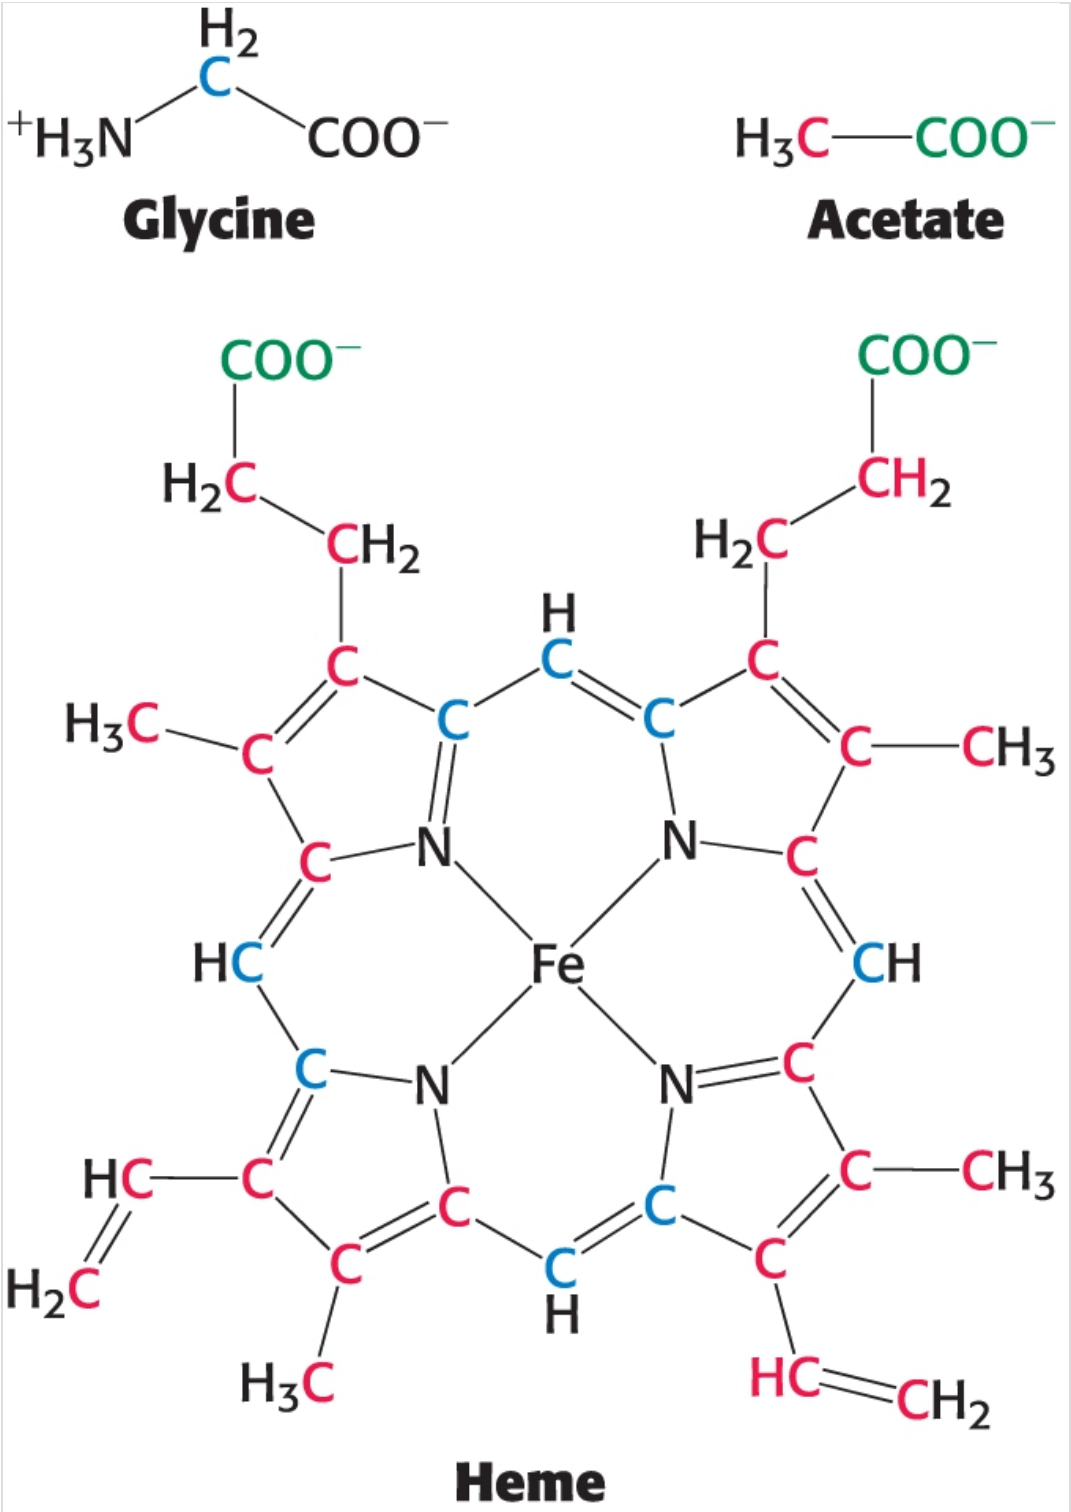
Porphyrins are synthesized from glycine and succinyl coenzyme A

The participation of an amino acid in the biosynthesis of the porphyrin rings of hemes and chlorophylls was first revealed by isotope-labeling experiments carried out by David Shemin and his colleagues. In 1945, they showed that the nitrogen atoms of heme were labeled after the feeding of $[^{15}N]$ glycine to human subjects, whereas the ingestion of $[^{15}N]$ glutamate resulted in very little labeling.

Experiments using ^{14}C, which had just become available, revealed that 8 of the carbon atoms of heme in nucleated duck erythrocytes are derived from the α-carbon atom of glycine and none from the carboxyl carbon atom. Subsequent studies demonstrated that the other 26 carbon atoms of heme can arise from acetate. Moreover, the ^{14}C in methyl-labeled acetate emerged in 24 of these carbon atoms, whereas the ^{14}C in carboxyl-labeled acetate appeared only in the other 2 (**Figure 25.29**).



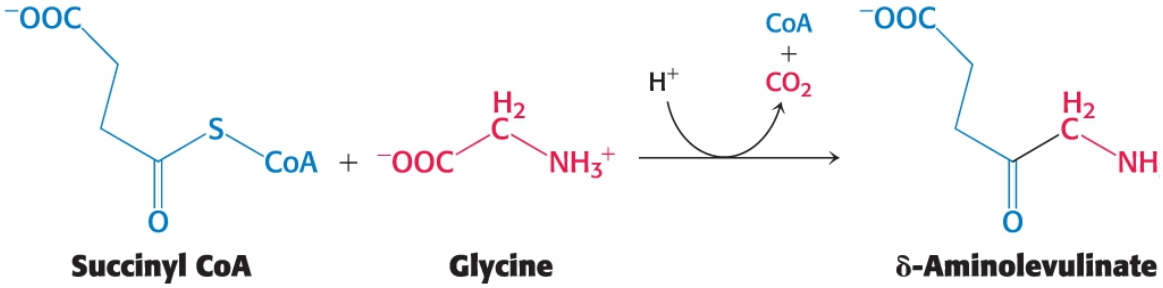


FIGURE 25.29 The origins of atoms in heme were revealed by isotope-labeling studies. The final structure of heme contains 8 carbons from the a-carbon of glycine (blue), 24 carbons from the methyl group of acetate (red), and two carbons from the carboxyl group of acetate (green).

This highly distinctive labeling pattern suggested that acetate is converted to succinyl-CoA through enzymes from the citric acid cycle (Section 17.3) and that a heme precursor is formed by the condensation of glycine with succinyl-CoA. Indeed, the first step in the biosynthesis of porphyrins in mammals is the condensation of glycine and succinyl CoA to form δ-aminolevulinate.

This reaction is catalyzed by δ-aminolevulinate synthase, a PLP enzyme present in mitochondria. Consistent with the labeling studies described earlier, the carbon atom from the carboxyl group of glycine is lost as carbon dioxide, while the α-carbon remains in δ-aminolevulinate.

The reactions required for heme synthesis take place in both the mitochondria and the cytoplasm (**Figure 25.30**), revealing another example of intercompartmental cooperation (Figure 16.30). δ-Aminolevulinate is generated in the mitochondria and is then transported into the cytoplasm, where two molecules of δ-aminolevulinate condense to form porphobilinogen, the next intermediate. Four molecules of porphobilinogen then condense head to tail to form a linear tetrapyrrole in a reaction catalyzed by

porphobilinogen deaminase. The enzyme-bound linear tetrapyrrole then cyclizes to form uroporphyrinogen III, which has an asymmetric arrangement of side chains. This reaction requires a cosynthase. In the presence of synthase alone, uroporphyrinogen I, the nonphysiological symmetric isomer, is produced. Uroporphyrinogen III is also a key intermediate in the synthesis of vitamin B_{12} by bacteria and that of chlorophyll by bacteria and plants.

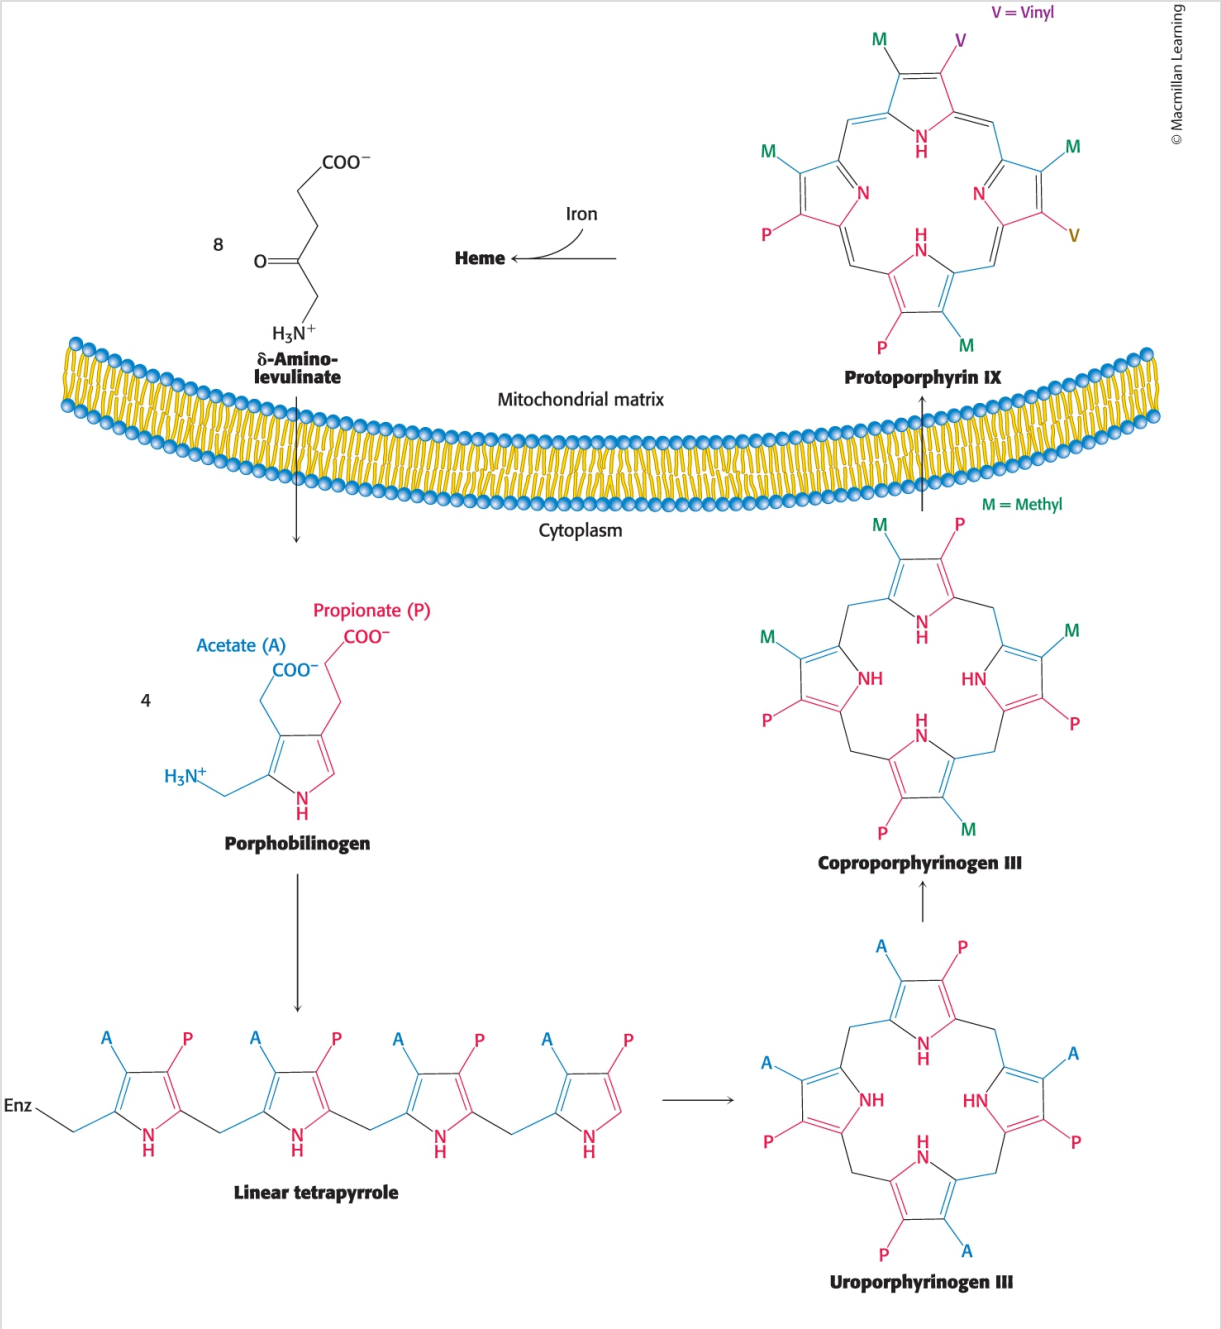

FIGURE 25.30 Heme is synthesized from eight molecules of δ-aminolevulinate. The biosynthetic pathway involves intercompartmental cooperation between the cytoplasm and the mitochondrial matrix.

The porphyrin skeleton is now formed. Subsequent reactions alter the side chains and the degree of saturation of the porphyrin ring (Figure 25.30). Coproporphyrinogen III is formed by the decarboxylation of the acetate side chains and then transported into the mitochondria. There, the desaturation of the porphyrin ring and the conversion of two of the propionate side chains into vinyl groups yield protoporphyrin IX. The chelation of iron finally gives heme, the prosthetic group of proteins such as myoglobin, hemoglobin, catalase, peroxidase, and cytochrome *c*. The insertion of the ferrous form of iron is catalyzed by ferrochelatase. Iron is transported in the plasma by transferrin, a protein that binds two ferric ions, and is stored in tissues inside molecules of ferritin (Section 31.6).

Studies with ^{15}N-labeled glycine revealed that the normal human erythrocyte has a life span of about 120 days. The first step in the degradation of the heme group is the cleavage of its α-methine bridge to form the green pigment biliverdin, a linear tetrapyrrole (**Figure 25.31**). This reaction is catalyzed by heme oxygenase. The central methine bridge of biliverdin is then reduced by biliverdin reductase to form bilirubin, an orange-yellow pigment. The changing color of a bruise is a highly graphic indicator of these degradative reactions.

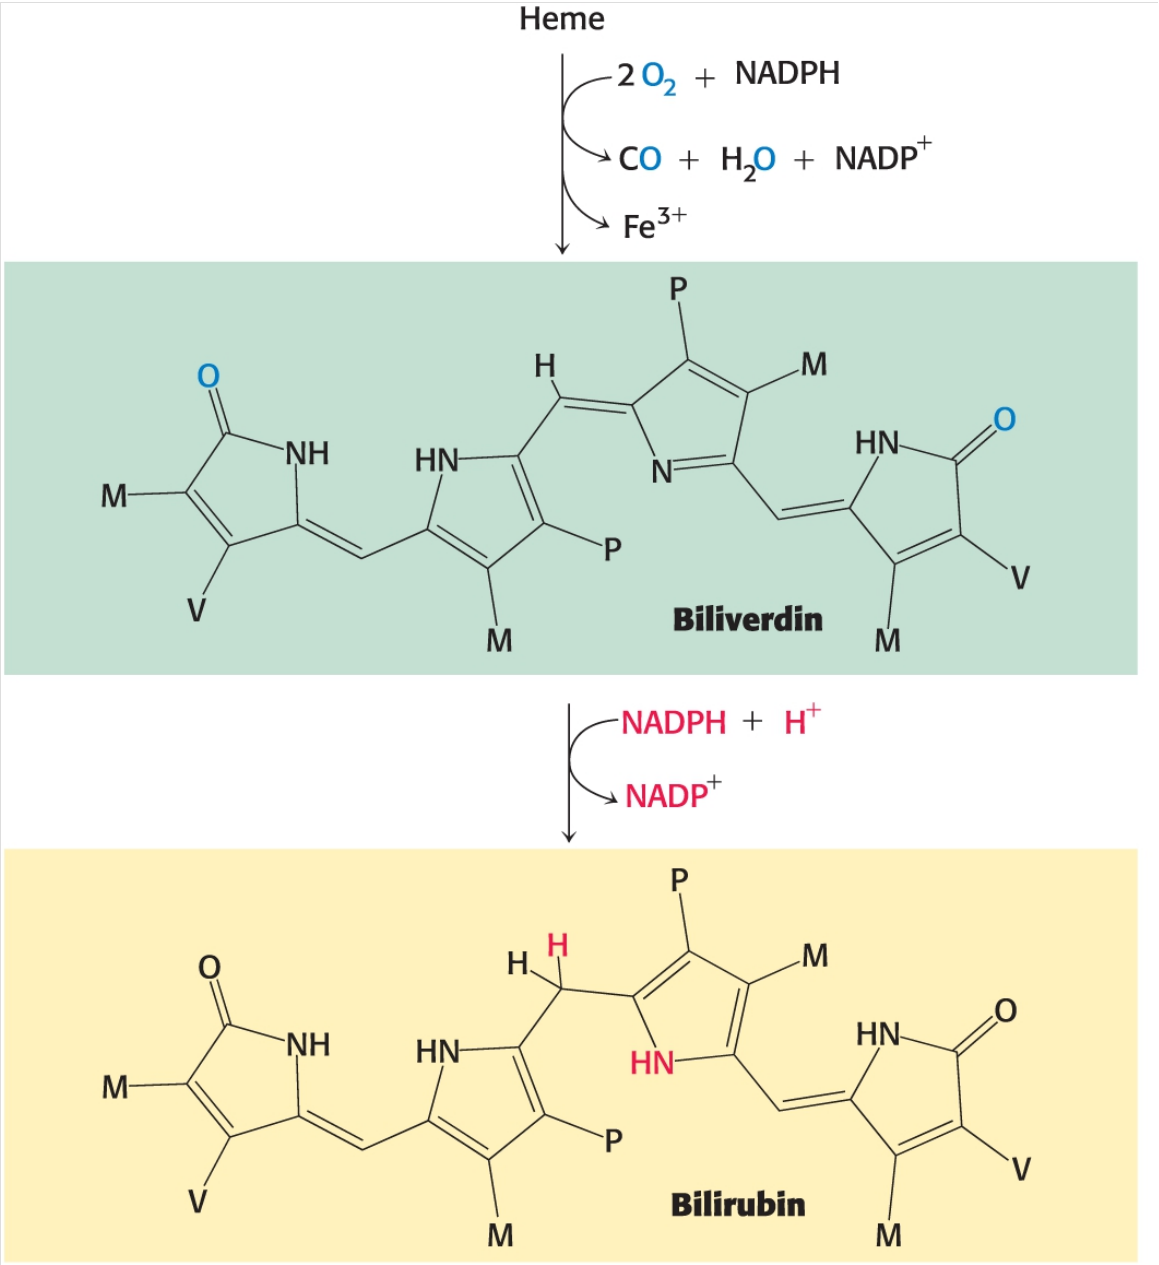

FIGURE 25.31 Heme is degraded into biliverdin and bilirubin. These products are the pigment responsible for the color of bruises. Abbreviations: M, methyl; V, vinyl.

Self-Check Question

The synthesis of δ-aminolevulinate takes place in the mitochondrial matrix, whereas the formation of porphobilinogen takes place in the cytoplasm. Propose a reason for the mitochondrial location of the first step in heme synthesis.

Porphyrins accumulate in some inherited disorders of porphyrin metabolism

Porphyrias are inherited or acquired disorders caused by a deficiency of enzymes in the heme biosynthetic pathway. Porphyrin is synthesized in both the erythroblasts and the liver, and either one may be the site of a disorder. Congenital erythropoietic porphyria, for example, prematurely destroys erythrocytes. This disease results from insufficient cosynthase. In this porphyria, the synthesis of the required amount of uroporphyrinogen III is accompanied by the formation of very large quantities of uroporphyrinogen I, the useless symmetric isomer. Uroporphyrin I, coproporphyrin I, and other symmetric derivatives also accumulate. The urine of patients having this disease is red because of the excretion of large amounts of uroporphyrin I. Their teeth exhibit a strong red fluorescence under ultraviolet light because of the deposition of porphyrins. Furthermore, their skin is usually very sensitive to light because photoexcited porphyrins are quite reactive.

Acute intermittent porphyria is the most prevalent of the porphyrias affecting the liver. This porphyria is characterized by the overproduction of porphobilinogen and δ-aminolevulinate, which

results in severe abdominal pain and neurological dysfunction. The "madness" of George III, king of England during the American Revolution, may have been due to this porphyria.

Chapter 25 Summary

25.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia

- Nitrogen fixation is the process by which N_2 is reduced to NH_3.
- Using ATP and reduced ferredoxin, microorganisms use the nitrogenase complex to catalyze nitrogen fixation.
- Higher organisms use the fixed nitrogen in the form of NH_4^+ to synthesize amino acids, nucleotides, and other nitrogen-containing biomolecules.
- The major points of entry of NH_4^+ into metabolism are glutamine or glutamate.

25.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways

- Human beings can synthesize 11 of the basic set of 20 amino acids. These amino acids are called *nonessential*.
- The *essential* amino acids must be supplied in the diet.
- The pathways for the synthesis of nonessential amino acids are quite simple, while those of the essential amino acids tend to contain greater than 5 catalytic steps.
- A transamination reaction takes place in the synthesis of most amino acids. At this step, the chirality of the amino acid is established.
- Alanine, aspartate, and glutamate are synthesized in one step by the addition of an amino group to pyruvate, oxaloacetate, and α-ketoglutarate, respectively.
- Glutamine is synthesized from NH_4^+ and glutamate, and asparagine is synthesized similarly in bacteria. In mammals,

the nitrogen donor for asparagine is glutamine.
- Proline and arginine are derived from glutamate.
- Serine, formed from 3-phosphoglycerate, is the precursor of glycine and cysteine.
- Tyrosine is synthesized by the hydroxylation of phenylalanine, an essential amino acid.
- In many of these pathways, tetrahydrofolate serves as an important carrier of one-carbon units, while *S*-adenosylmethionine acts as a donor of methyl groups.

25.3 Feedback Inhibition Regulates Amino Acid Biosynthesis

- Most of the pathways of amino acid biosynthesis are regulated by feedback inhibition in which the committed step is allosterically inhibited by the final product.
- The regulation of branched pathways requires extensive interaction among the branches that includes both negative and positive regulation.
- The regulation of glutamine synthetase in *E. coli* is a striking demonstration of cumulative feedback inhibition and of control by a cascade of reversible covalent modifications.

25.4 Amino Acids Are Precursors of Many Biomolecules

- Amino acids are precursors of a variety of biomolecules.
- Glutathione (γ-Glu-Cys-Gly) serves as a sulfhydryl buffer and detoxifying agent.
- Nitric oxide, a short-lived messenger, is formed from arginine.
- Porphyrins, the iron-binding groups in heme, are synthesized from glycine and succinyl CoA.

Key Terms

nitrogen fixation
nitrogenase complex
essential amino acids
nonessential amino acids
pyridoxal phosphate (PLP)
tetrahydrofolate
S-adenosylmethionine (SAM)
activated methyl cycle
substrate channeling
enzyme multiplicity
cumulative feedback inhibition
glutathione
nitric oxide (NO)
porphyrias

Problems

1. Identify the two components of the nitrogenase complex and describe their specific tasks. 1

2. Which of the following statements about nitrogen fixation are correct? 1

a. Atmospheric nitrogen is reduced to the biologically useful form NH_3 (or NH_4^+).
b. Nitrogen fixation in nature and in the lab requires a metal cofactor or catalyst.

c. Nitrogen fixation is energetically neutral, using a negligible amount of ATP.
d. The enzyme nitrogenase, which takes part in nitrogen fixation, is inactivated by oxygen.
e. Ammonium from the atmosphere is fixed to more usable forms of nitrogen, such as nitrate (NO_3^-).
f. The availability of fixed nitrogen limits biological productivity.

3. The first step in the incorporation of NH_4^+ into amino acids is catalyzed by glutamate dehydrogenase, in which an α-keto acid is converted to glutamate by transamination. 1

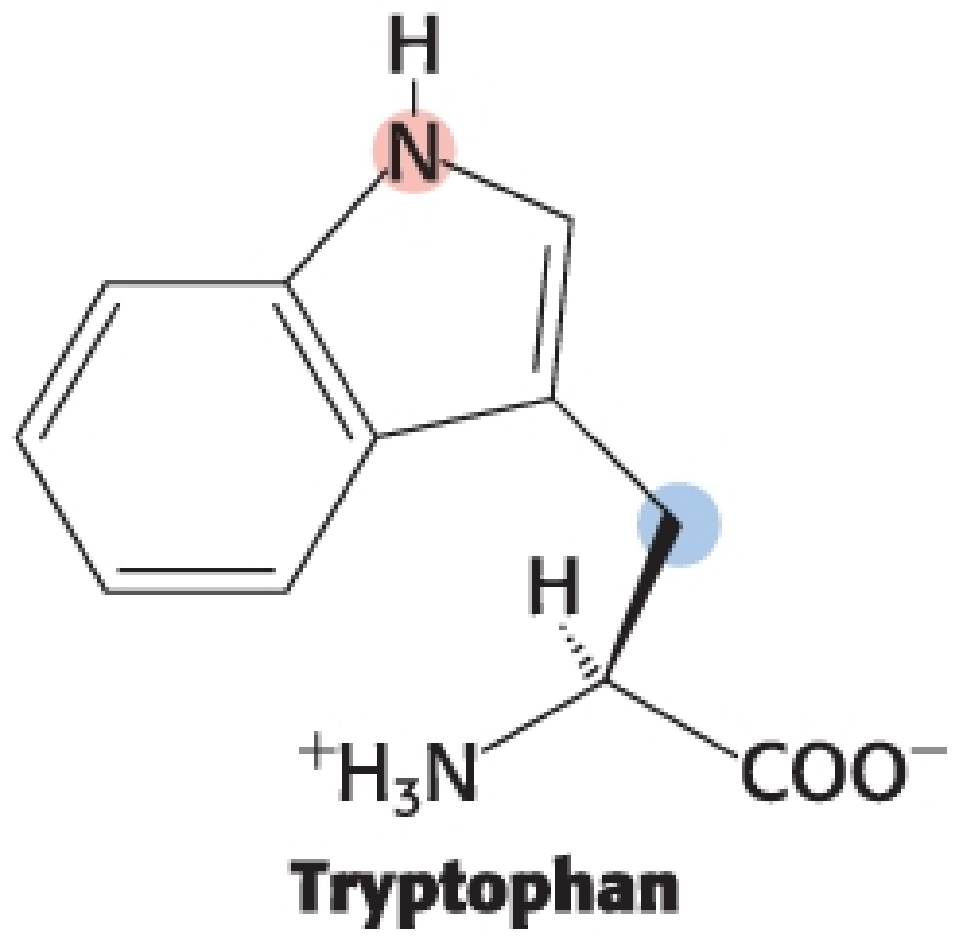
a. Draw the structure of the α-keto acid precursor to glutamate.
b. Besides glutamate, what are the other products of this reaction?

4. The entry of nitrogen into the biosphere is not an energetically cheap process. How many molecules of ATP must be hydrolyzed per N_2 molecule fixed? 1

5. The nitrogenase complex consists of two protein components: the reductase and the nitrogenase. What is the function of each of these proteins? 1

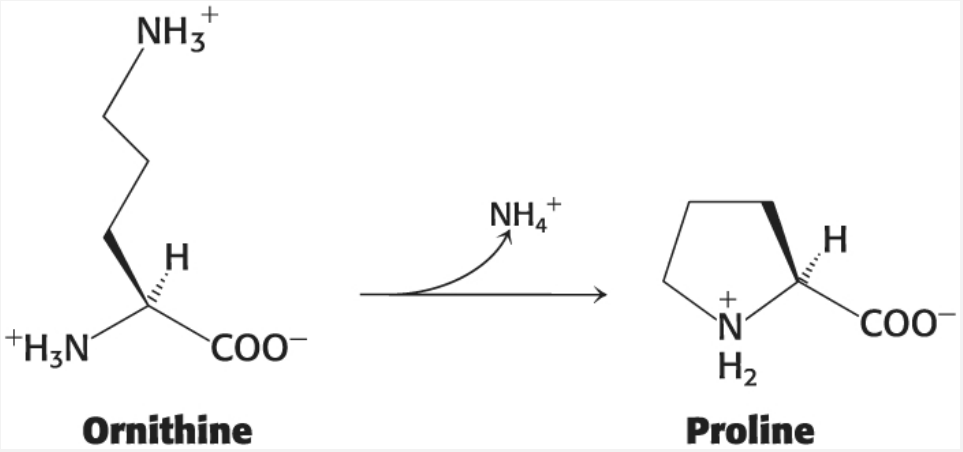
6. What are the seven precursors of the 20 amino acids? 2

7. Write a balanced equation for the synthesis of alanine from glucose. 2



8. Which of the 20 amino acids can be synthesized directly from a common metabolic intermediate by a transamination reaction? 2

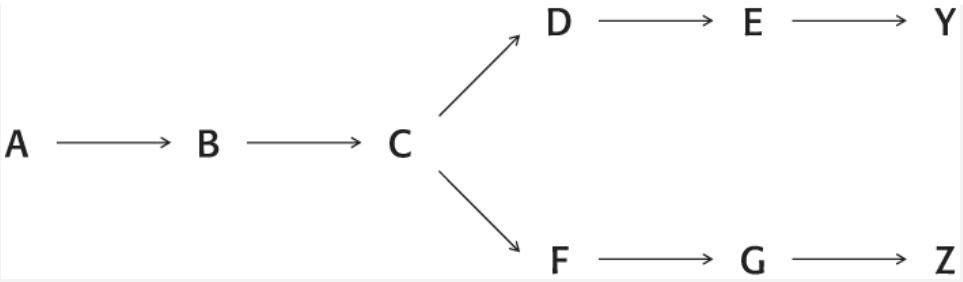
9. Which amino acids are formed from the glycolysis intermediate 3-phosphoglycerate? 2



10. Which of the following molecules is the most direct source for the sulfur atom in the sulfur-containing amino acids in human beings? 2

a. Biotin
b. Homocysteine
c. Glutathione
d. Tetrahydrofolate
e. Coenzyme A

11. The atoms from tryptophan shaded below are derived from two other amino acids. Name them. 2



12. Certain species of bacteria possess an enzyme, ornithine cyclodeaminase, that can catalyze the conversion of L-ornithine into L-proline in a single catalytic cycle.

The enzyme lysine cyclodeaminase has also been identified. Predict the product of the reaction catalyzed by lysine cyclodeaminase.

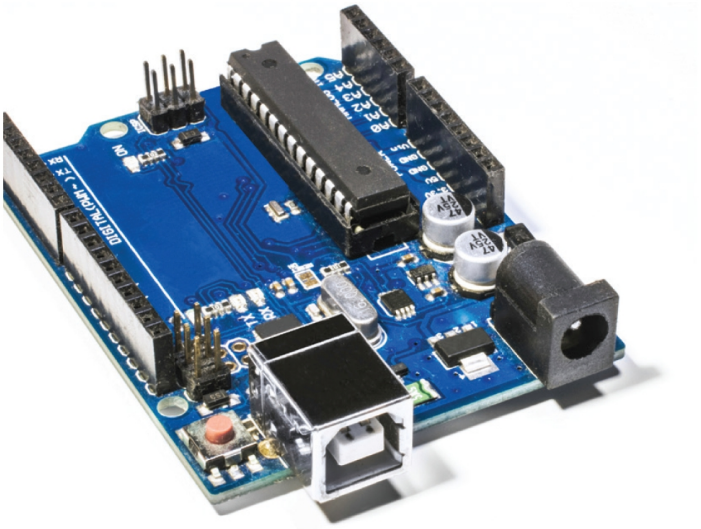
13. For the following example of a branched pathway, propose a feedback inhibition scheme that would result in the production of equal amounts of Y and Z. 3

14. Consider the branched pathway in problem 13. The first common step $(A \rightarrow B)$ is partly inhibited by both of the final products, each acting independently of the other. Suppose that a high level of Y alone decreased the rate of the $A \rightarrow B$ step from 100 to $60\ s^{-1}$ and that a high level of Z alone decreased the rate from 100 to $40\ s^{-1}$. What would the rate be in the presence of high levels of both Y and Z? 3

15. What are the intermediates in the flow of nitrogen from N_2 to heme? 4

16. David Shemin and coworkers used acetate-labeling experiments to conclude that succinyl-CoA is a key intermediate in the biosynthesis of heme. Identify the intermediates in the conversion of acetate into succinyl-CoA. 4

17. Which of the following statements about heme are correct? 4



a. Phenylalanine is a precursor to heme.
b. Heme is found in trypsin.

c. Heme is found in cytochrome *c*.
d. Heme contains a magnesium ion.
e. Succinyl-CoA is a precursor to heme.
f. Heme contains an iron ion.

18. In this chapter, we considered three different cofactors/cosubstrates that act as carriers of one-carbon units. Name them.

19. Individuals with an inactivating mutation in phenylalanine hydroxylase require an additional amino acid in their diet which is not an essential amino acid in the ordinary human diet. Which one?

CHAPTER 26
Nucleotide Biosynthesis

An Arduino board is a versatile electronics component that can be modified to perform a variety of functions. The ability to be adjusted allows this component to participate in many related processes. Similarly, the ATP grasp domain depicted at right is found in many enzymes that participate in nucleotide biosynthesis; evolutionary modifications have allowed enzymes containing such domains to catalyze a range of related reactions.

OUTLINE

26.1 Nucleotides Can Be Synthesized by de Novo or Salvage Pathways
26.2 The Pyrimidine Ring Is Assembled from CO_2, Ammonia, and Aspartate

26.3 Purine Bases Can Be Synthesized from Glycine, Aspartate, and Other Components
26.4 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides
26.5 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition
26.6 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

Learning Goals

By the end of this chapter, you should be able to:

1. Describe how pyrimidine nucleotides are synthesized.
2. Describe the pathway for purine nucleotide synthesis.
3. Explain how deoxyribonucleotides are formed.
4. Name the regulatory steps in nucleotide synthesis.
5. Identify the pathological conditions resulting from impaired nucleotide synthesis.

In this chapter, we describe the biosynthesis of nucleotides, continuing along the path begun in Chapter 25, which described the incorporation of nitrogen into amino acids from inorganic sources such as nitrogen gas. The amino acids glycine and aspartate are the scaffolds on which the ring systems present in nucleotides are assembled. Furthermore, aspartate and the side chain of glutamine serve as sources of NH_2 groups in the formation of nucleotides.

Nucleotide biosynthetic pathways are tremendously important as intervention points for therapeutic agents. Many of the most widely

used drugs in the treatment of cancer block steps in nucleotide biosynthesis, particularly steps in the synthesis of DNA precursors.

26.1 Nucleotides Can Be Synthesized by de Novo or Salvage Pathways

Nucleotides are key biomolecules required for a variety of life processes.

- Nucleotides are the activated precursors of nucleic acids, necessary for the replication of the genome and the transcription of the genetic information into RNA.
- An adenine nucleotide, ATP, is the universal currency of energy.
- A guanine nucleotide, GTP, also serves as an energy source for a more select group of biological processes.
- Nucleotide derivatives such as UDP-glucose participate in biosynthetic processes.
- Nucleotides such as cyclic AMP and cyclic GMP are essential components of signal-transduction pathways.
- ATP acts as the donor of phosphoryl groups transferred by protein kinases in a variety of signaling pathways.

The pathways for the biosynthesis of nucleotides fall into two classes: *de novo* pathways and *salvage* pathways (**Figure 26.1**). In **de novo pathways**, the nucleobases are assembled from scratch; meaning, from simpler compounds. The framework for a pyrimidine base is assembled first and then attached to ribose. In contrast, the framework for a purine base is synthesized piece by

piece directly onto a ribose-based structure. These de novo pathways each comprise a small number of elementary reactions that are repeated with variations to generate different nucleotides, as might be expected for pathways that appeared very early in evolution. In **salvage pathways**, preformed bases are recovered and reconnected to a ribose unit.

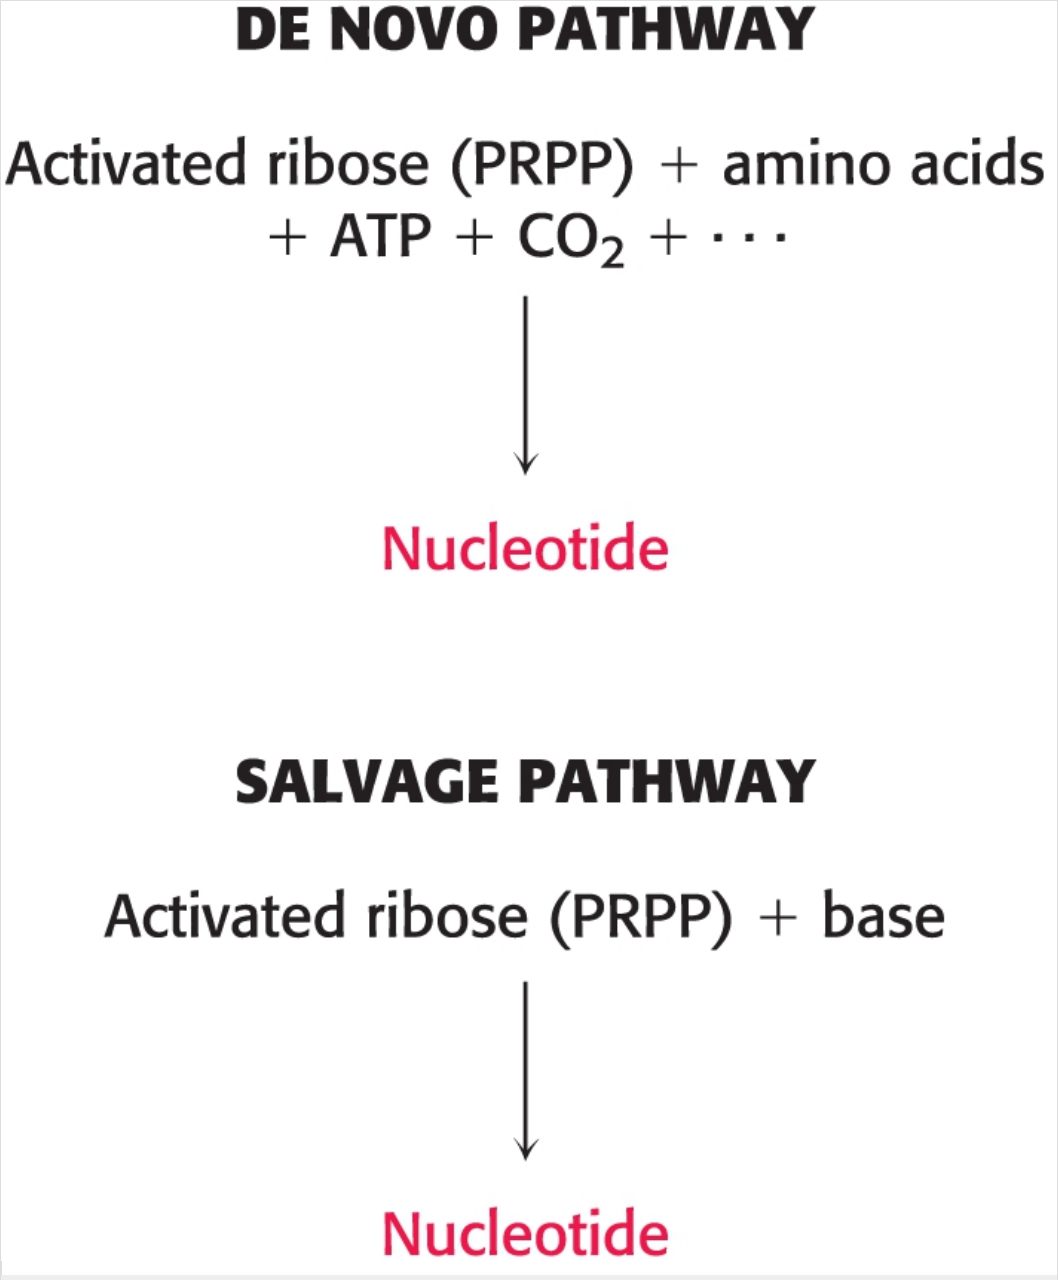

FIGURE 26.1 Nucleotides can be synthesized by de novo and salvage pathways. In de novo synthesis, the base itself is synthesized from simpler

starting materials, including amino acids. ATP hydrolysis is required for de novo synthesis. In a salvage pathway, a base is reattached to a ribose, activated in the form of 5-phosphoribosyl-1-pyrophosphate (PRPP).

De novo pathways lead to the synthesis of *ribo*nucleotides. However, DNA is built from *deoxyribo*nucleotides. Consistent with the notion that RNA preceded DNA in the course of evolution, all deoxyribonucleotides are synthesized from the corresponding ribonucleotides. The deoxyribose sugar is generated by the reduction of ribose within a fully formed nucleotide. Furthermore, the methyl group that distinguishes the thymine of DNA from the uracil of RNA is added at the last step in the pathway.

Recall from Chapter 8 that a *nucleoside* is a purine or pyrimidine base linked to a sugar and that a *nucleotide* is a phosphate ester of a nucleoside. The names of the major bases of RNA and DNA, and of their nucleoside and nucleotide derivatives, are given in **Table 26.1**.

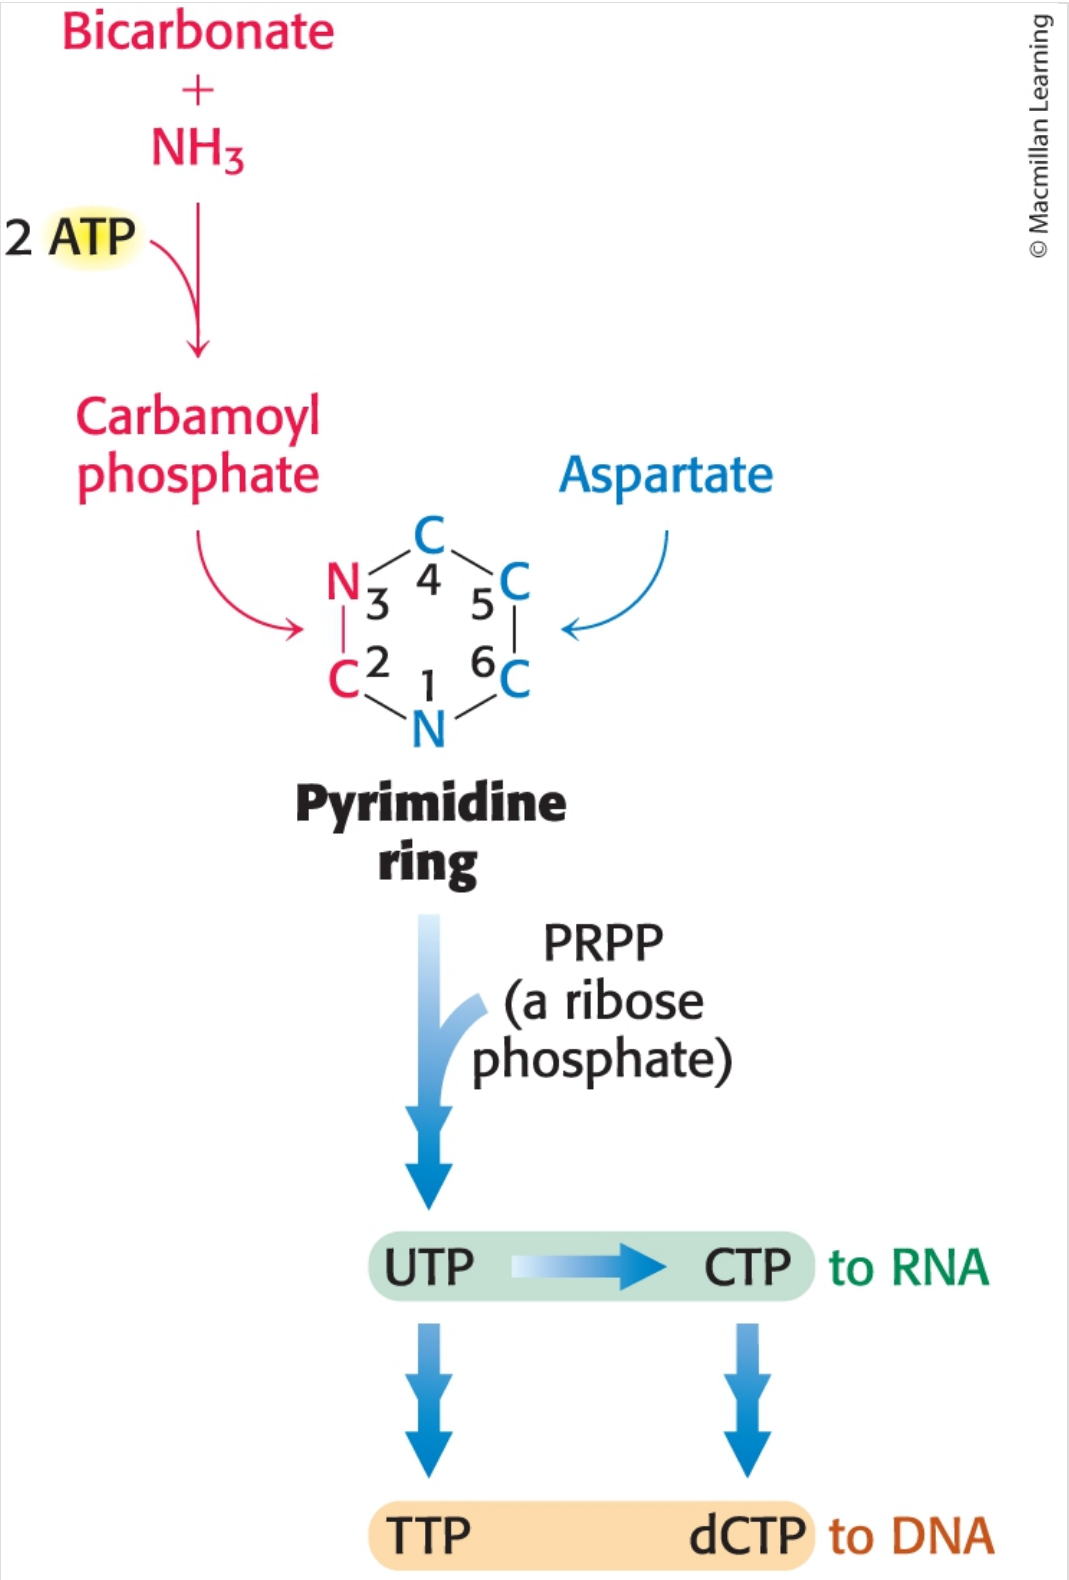

TABLE 26.1 Nomenclature of bases, nucleosides, and nucleotides

RNA		
Base	**Ribonucleoside**	**Ribonucleotide** (5′-monophosphate)
Adenine (A)	Adenosine	Adenylate (AMP)
Guanine (G)	Guanosine	Guanylate (GMP)

Uracil (U)	Uridine	Uridylate (UMP)
Cytosine (C)	Cytidine	Cytidylate (CMP)
DNA		
Base	**Deoxyribonucleoside**	**Deoxyribonucleotide (5′−monophosphate)**
Adenine (A)	Deoxyadenosine	Deoxyadenylate (dAMP)
Guanine (G)	Deoxyguanosine	Deoxyguanylate (dGMP)
Thymine (T)	Thymidine	Thymidylate (TMP)
Cytosine (C)	Deoxycytidine	Deoxycytidylate (dCMP)

26.2 The Pyrimidine Ring Is Assembled from CO_2, Ammonia, and Aspartate

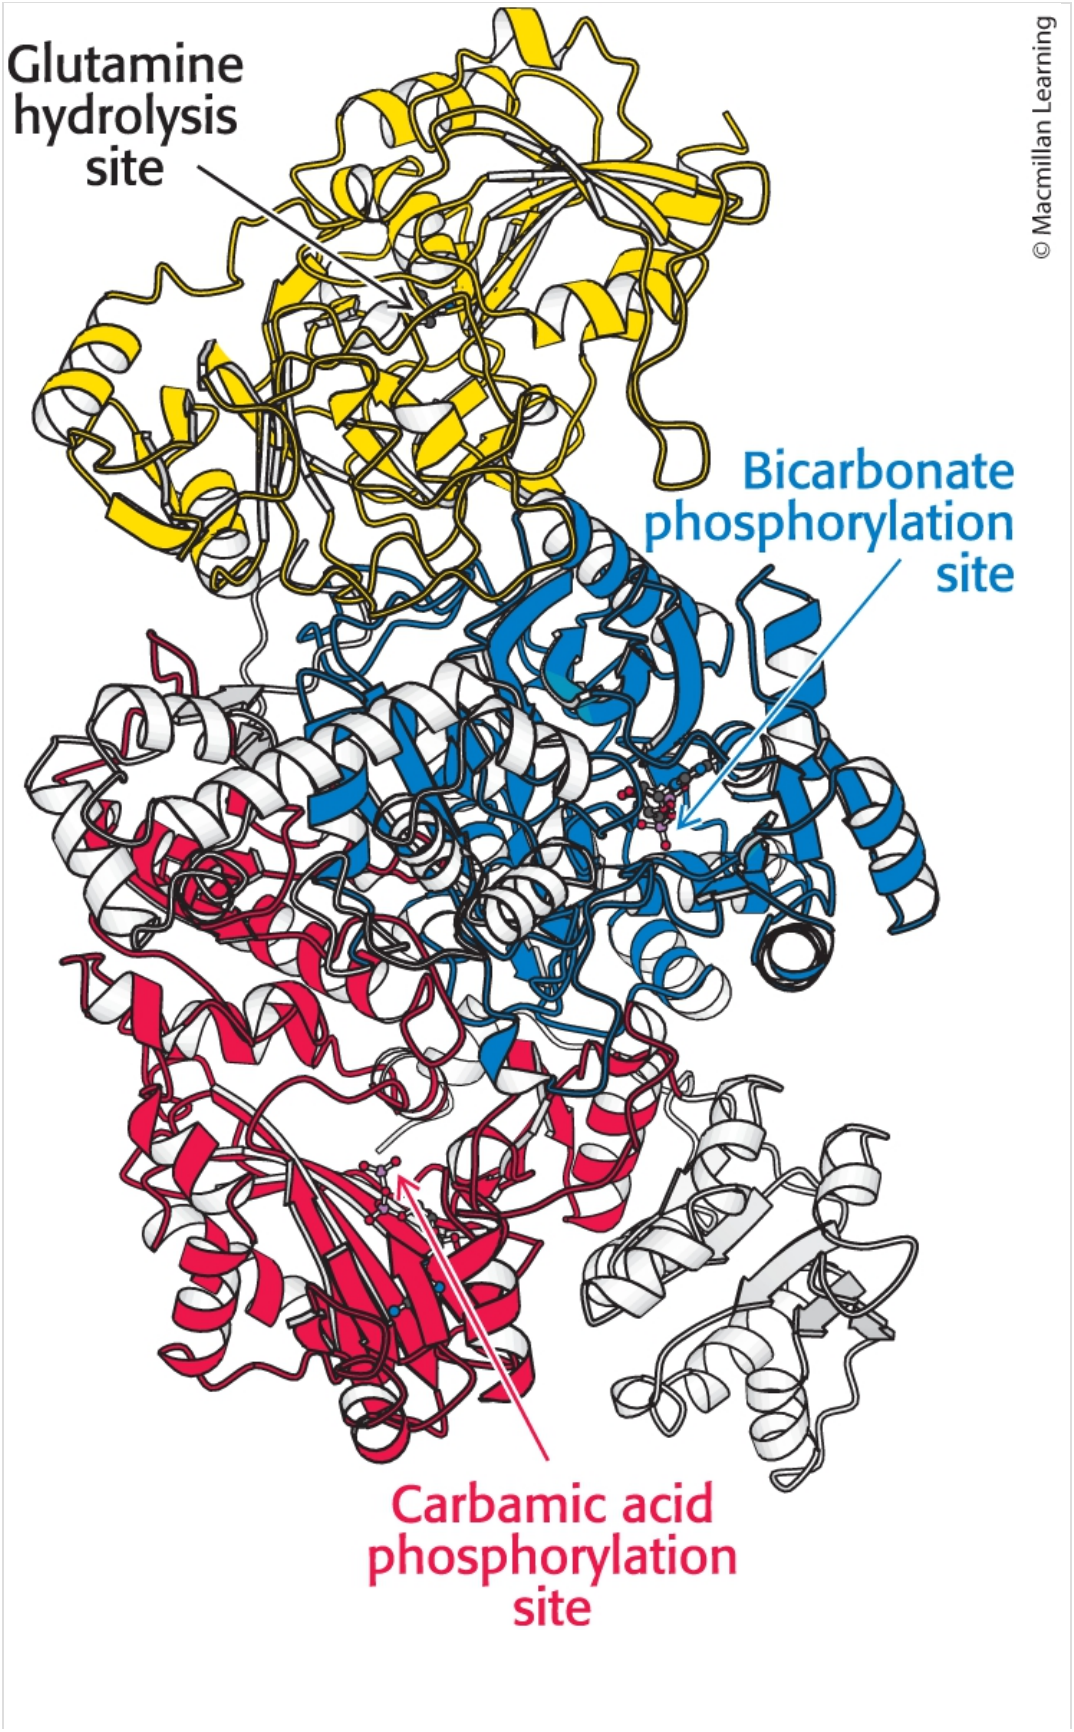
In de novo synthesis of pyrimidines, the ring is synthesized first and then attached to a ribose phosphate to form a pyrimidine nucleotide (Figure 26.2). Pyrimidine rings are assembled from bicarbonate, aspartate, and ammonia. Although an ammonia molecule already present in solution can be used, the ammonia is usually produced from the hydrolysis of the side chain of glutamine.

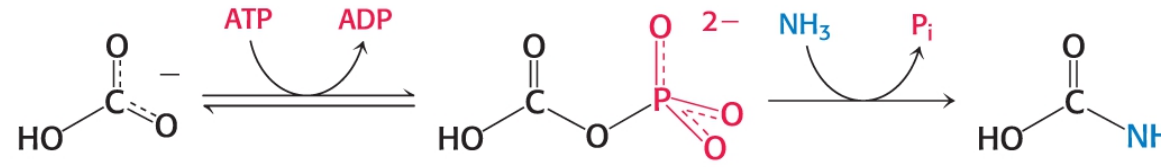
© Macmillan Learning

FIGURE 26.2 Pyrimidine nucleotides can be synthesized de novo. The C-2 and N-3 atoms in the pyrimidine ring come from carbamoyl phosphate, whereas the other atoms of the ring come from aspartate.

Bicarbonate and other oxygenated carbon compounds are activated by phosphorylation

The first step in de novo pyrimidine biosynthesis is the synthesis of carbamoyl phosphate from bicarbonate and ammonia in a multistep process, requiring the cleavage of two molecules of ATP. This reaction is catalyzed by carbamoyl phosphate synthetase II (CPS II). Recall that carbamoyl phosphate synthetase I facilitates ammonia incorporation into urea (Section 23.4). Carbamoyl phosphate synthetase II is a dimer composed of a small subunit that hydrolyzes glutamine to form NH_3 and a large subunit that completes the synthesis of carbamoyl phosphate. Analysis of the structure of the large subunit reveals two homologous domains, each of which catalyzes an ATP-dependent step (**Figure 26.3**).





Glutamine hydrolysis site
Bicarbonate phosphorylation site
Carbamic acid phosphorylation site

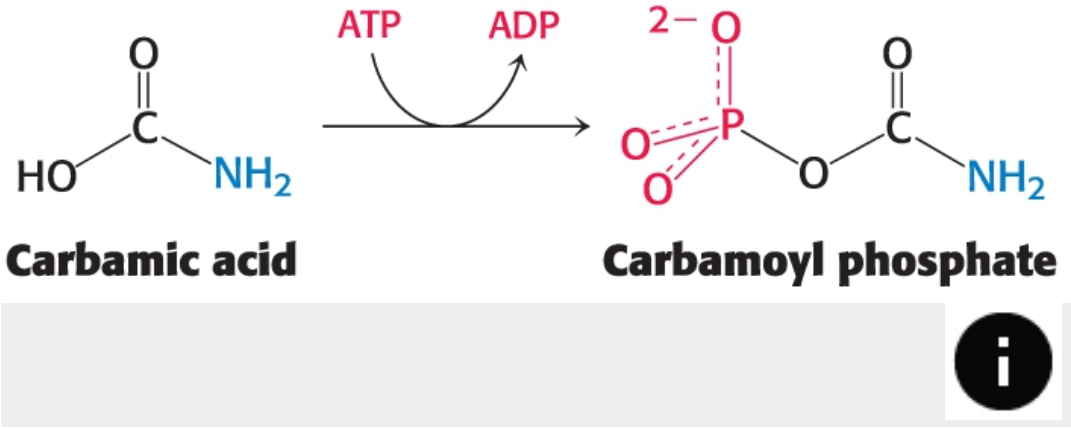
FIGURE 26.3 Carbamoyl phosphate synthetase II includes sites for three reactions. This enzyme consists of two chains. The smaller chain (yellow) contains a site for glutamine hydrolysis to generate ammonia. The larger chain includes two ATP-grasp domains (blue and red). In one ATP-grasp domain (blue), bicarbonate is phosphorylated to carboxyphosphate, which then reacts with ammonia to generate carbamic acid. In the other ATP-grasp domain, the carbamic acid is phosphorylated to produce carbamoyl phosphate.

[Drawn from 1JDB.pdb.]

INTERACT with this model in Achieve



In the first step, bicarbonate is phosphorylated by ATP to form carboxyphosphate and ADP. Ammonia then reacts with carboxyphosphate to form carbamic acid and inorganic phosphate.

The active site for this reaction lies in a domain formed by the amino-terminal third of CPS. This domain forms a structure called an **ATP-grasp fold**, which surrounds ATP and holds it in an orientation suitable for nucleophilic attack at the γ phosphoryl group. Proteins containing ATP-grasp folds catalyze the formation of carbon–nitrogen bonds through acyl-phosphate intermediates. Such ATP-grasp folds are widely used in nucleotide biosynthesis.

In the second step catalyzed by carbamoyl phosphate synthetase II, carbamic acid is phosphorylated by another molecule of ATP to form

carbamoyl phosphate.

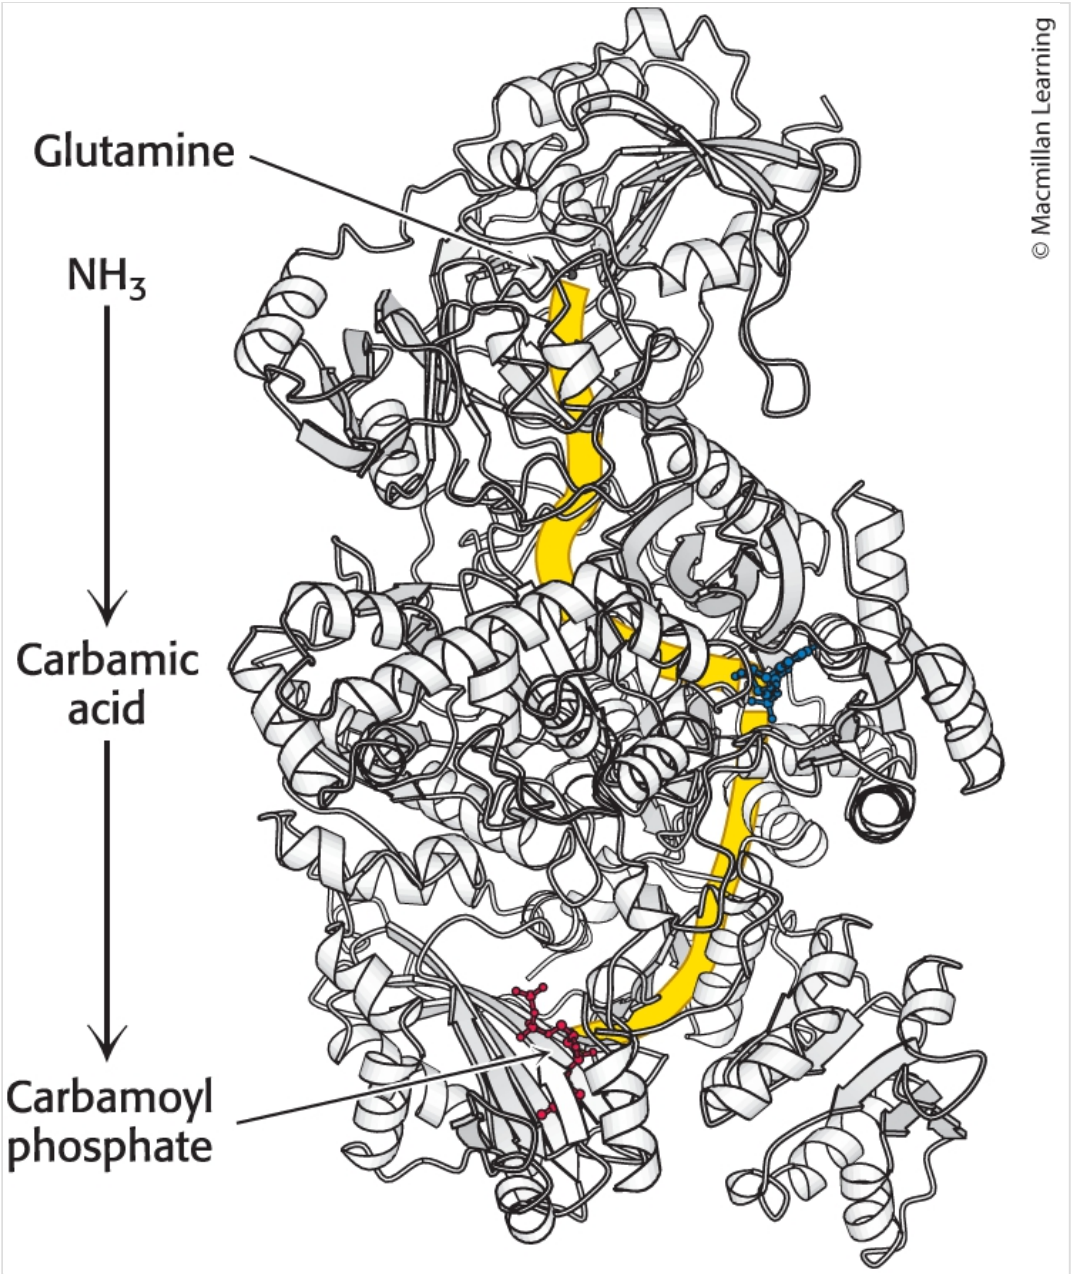
This reaction takes place in a second ATP-grasp domain within the enzyme. The active sites leading to carbamic acid formation and carbamoyl phosphate formation are very similar, revealing that this enzyme evolved by a gene duplication event. Indeed, duplication of a gene encoding an ATP-grasp domain followed by specialization was central to the evolution of nucleotide biosynthetic processes, as we shall see.

The side chain of glutamine can be hydrolyzed to generate ammonia

Glutamine is the primary source of ammonia for carbamoyl phosphate synthetase II. The small subunit of the enzyme hydrolyzes glutamine to form ammonia and glutamate. The active site of the glutamine-hydrolyzing component contains a catalytic dyad comprising a cysteine and a histidine residue. Such a catalytic dyad, reminiscent of the active site of cysteine proteases (Figure 6.16A), is conserved in a family of amidotransferases, including CTP synthetase and GMP synthetase.

Carbamoyl phosphate synthetase II contains three different active sites (Figure 26.3), separated from one another by a total of 80 Å.

Intermediates generated at one site move to the next without leaving the enzyme by means of substrate channeling, which is similar to the process described for tryptophan synthetase (**Figure 26.4**; also Figure 25.16). The ammonia generated in the glutamine-hydrolysis active site travels 45 Å through a channel within the enzyme to reach the site at which carboxyphosphate has been generated. The carbamic acid generated at this site then diffuses an additional 35 Å through an extension of the channel to reach the site at which carbamoyl phosphate is generated. This channeling serves two roles: (1) intermediates generated at one active site are captured with no loss caused by diffusion; and (2) labile intermediates, such as carboxyphosphate and carbamic acid (which decompose in less than 1 s at pH 7), are protected from hydrolysis. We will see additional examples of substrate channeling later in this chapter.



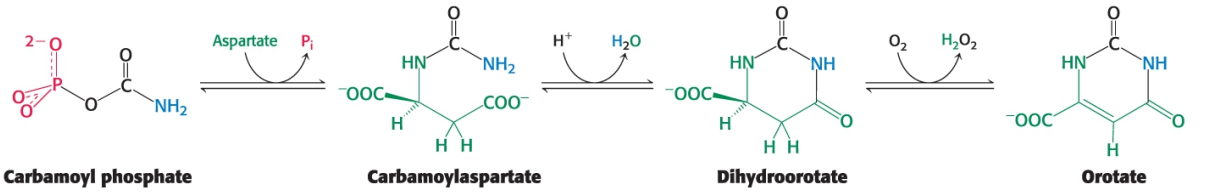


FIGURE 26.4 The three active sites of carbamoyl phosphate synthetase II are linked by a channel through which intermediates pass. The channel is shown in yellow. Glutamine enters one active site, and carbamoyl phosphate, which includes the nitrogen atom from the glutamine side chain, leaves another 80 Å away.

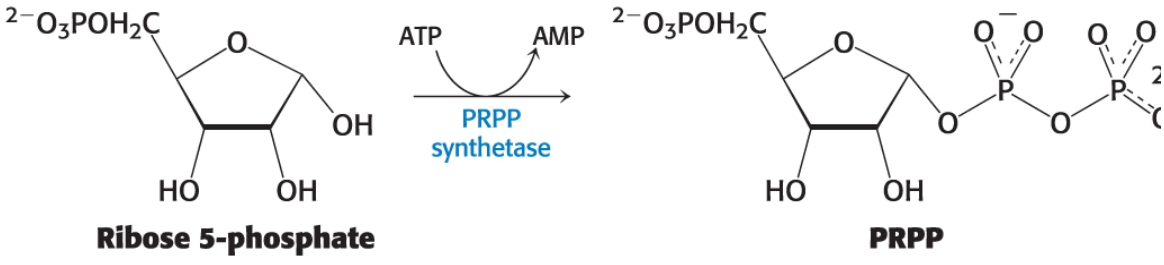
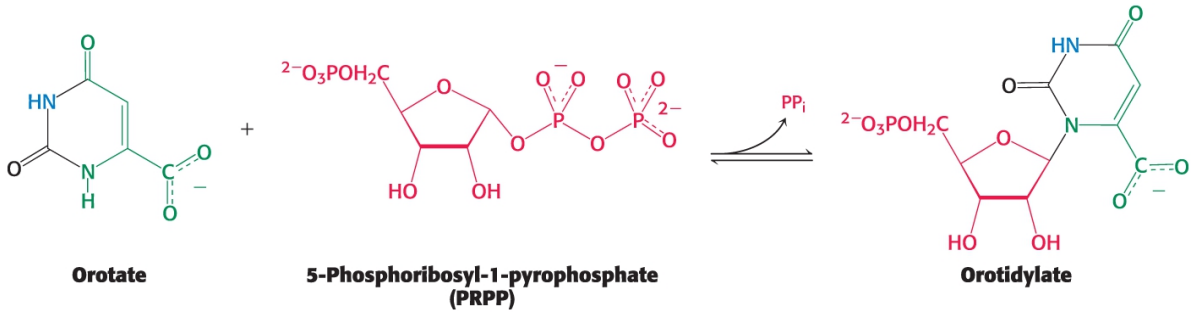
[Drawn from 1JDB.pdb.]

INTERACT with this model in Achieve

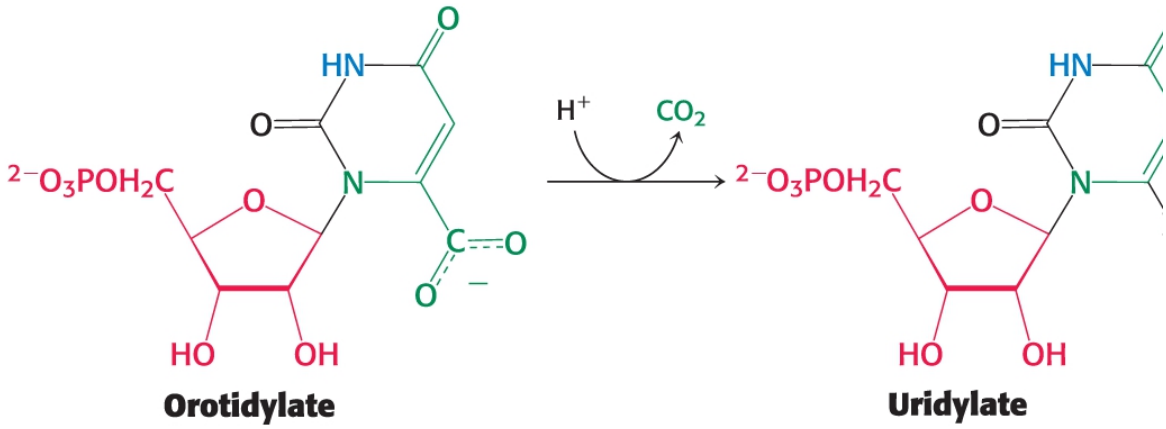


The pyrimidine ring is completed and coupled to ribose

Carbamoyl phosphate reacts with aspartate to form carbamoylaspartate in a reaction catalyzed by aspartate transcarbamoylase. Carbamoylaspartate then cyclizes to form dihydroorotate, which is then oxidized to form orotate.



In mammals, the enzymes that form orotate are part of a single large polypeptide chain called CAD, for carbamoyl phosphate synthase, aspartate transcarbamoylase and dihydroorotase.



At this stage, orotate couples to ribose, in the form of [5-phosphoribosyl-1-pyrophosphate (PRPP)](), a form of ribose activated to accept nucleobases. 5-Phosphoribosyl-1-pyrophosphate synthetase synthesizes PRPP by adding a pyrophosphate from ATP to ribose-5-phosphate, which is formed by the pentose phosphate pathway.

Orotate reacts with PRPP to form **orotidylate**, a pyrimidine nucleotide. This reaction is driven by the hydrolysis of pyrophosphate. The enzyme that catalyzes this addition, orotate phosphoribosyltransferase, is homologous to a number of other phosphoribosyltransferases that add different groups to PRPP to form the other nucleotides.

Orotidylate is then decarboxylated to form uridylate (UMP), a major pyrimidine nucleotide that is a precursor to RNA. This reaction is catalyzed by orotidylate decarboxylase, also called orotidine 5′-phosphate decarboxylase.

Orotidylate decarboxylase is one of the most proficient enzymes known. In its absence, decarboxylation is extremely slow and is estimated to take place once every 78 million years; with the enzyme present, it takes place approximately once per second, a rate enhancement of 10^{17}-fold.

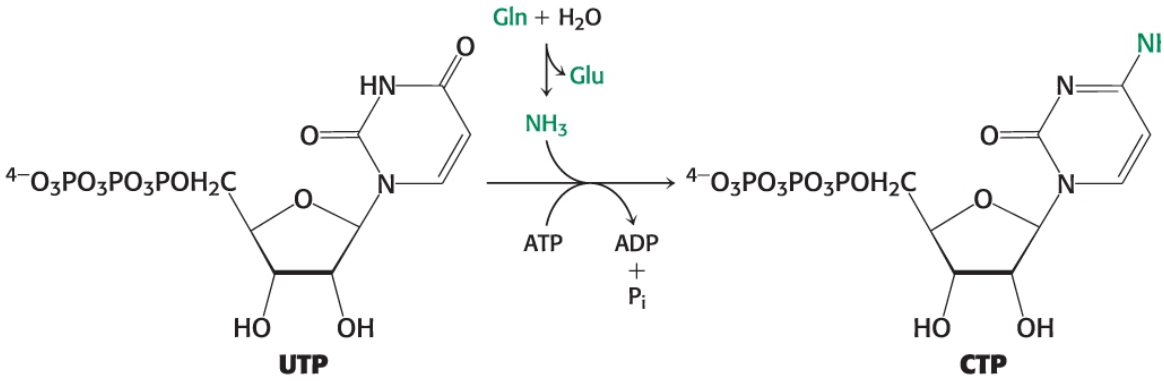
The phosphoribosyltransferase and decarboxylase activities are located on the same polypeptide chain, providing another example of a bifunctional enzyme. The bifunctional enzyme is called *uridine monophosphate synthetase*.

Self-Check Question

Identify the sources of the atoms that form the pyrimidine ring.

Nucleotide mono-, di-, and triphosphates are interconvertible

How is the other major pyrimidine ribonucleotide, cytidine, formed? It is synthesized from the uracil base of UMP, but the synthesis can take place only after UMP has been converted into UTP. Recall that the diphosphates and triphosphates are the active forms of nucleotides in biosynthesis and energy conversions. Nucleoside monophosphates are converted into nucleoside triphosphates in stages. First, nucleoside monophosphates are converted into diphosphates by specific nucleoside monophosphate kinases that utilize ATP as the phosphoryl-group donor. For example, UMP is phosphorylated to UDP by UMP kinase.



$$UMP + ATP \rightleftharpoons UDP + ADP$$

Nucleoside diphosphates and triphosphates are interconverted by nucleoside diphosphate kinase, an enzyme that has broad specificity, in contrast with the monophosphate kinases. X and Y represent any of several ribonucleosides or even deoxyribonucleosides:

$$XDP + YTP \rightleftharpoons XTP + YDP$$

CTP is formed by amination of UTP

After uridine triphosphate has been formed, it can be transformed into cytidine triphosphate by the replacement of a carbonyl group by an amino group, a reaction catalyzed by cytidine triphosphate synthetase.

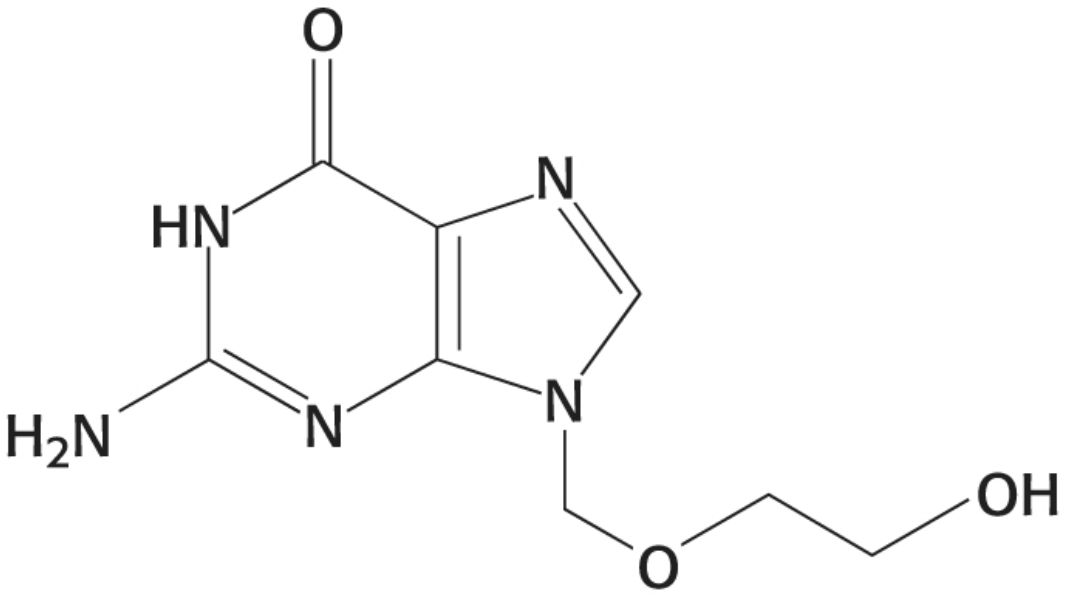
Like the synthesis of carbamoyl phosphate, this reaction requires ATP and uses glutamine as the source of the amino group. The reaction proceeds through an analogous mechanism in which the O-4 atom is

phosphorylated to form a reactive intermediate, and then the phosphate is displaced by ammonia, freed from glutamine by hydrolysis. CTP can then be used in many biochemical processes, including lipid and RNA synthesis.

Salvage pathways recycle pyrimidine bases

In adding to production by de novo pathways, pyrimidine bases can also be recovered from the breakdown products of DNA and RNA through salvage pathways, as noted earlier. In these pathways, a preformed base is reincorporated into a nucleotide. We will consider the salvage pathway for the pyrimidine base thymine. Thymine is found in DNA and base-pairs with adenine in the DNA double helix. Thymine released from degraded DNA is salvaged in two steps. First, thymine is converted into the nucleoside thymidine by thymidine phosphorylase.

$$\text{Thymine} + \text{deoxyribose-1-phosphate} \rightleftharpoons \text{thymidine} + \text{I}$$



Thymidine is then converted into a nucleotide by thymidine kinase.

$$\text{Thymidine} + \text{ATP} \rightleftharpoons \text{TMP} + \text{ADP}$$

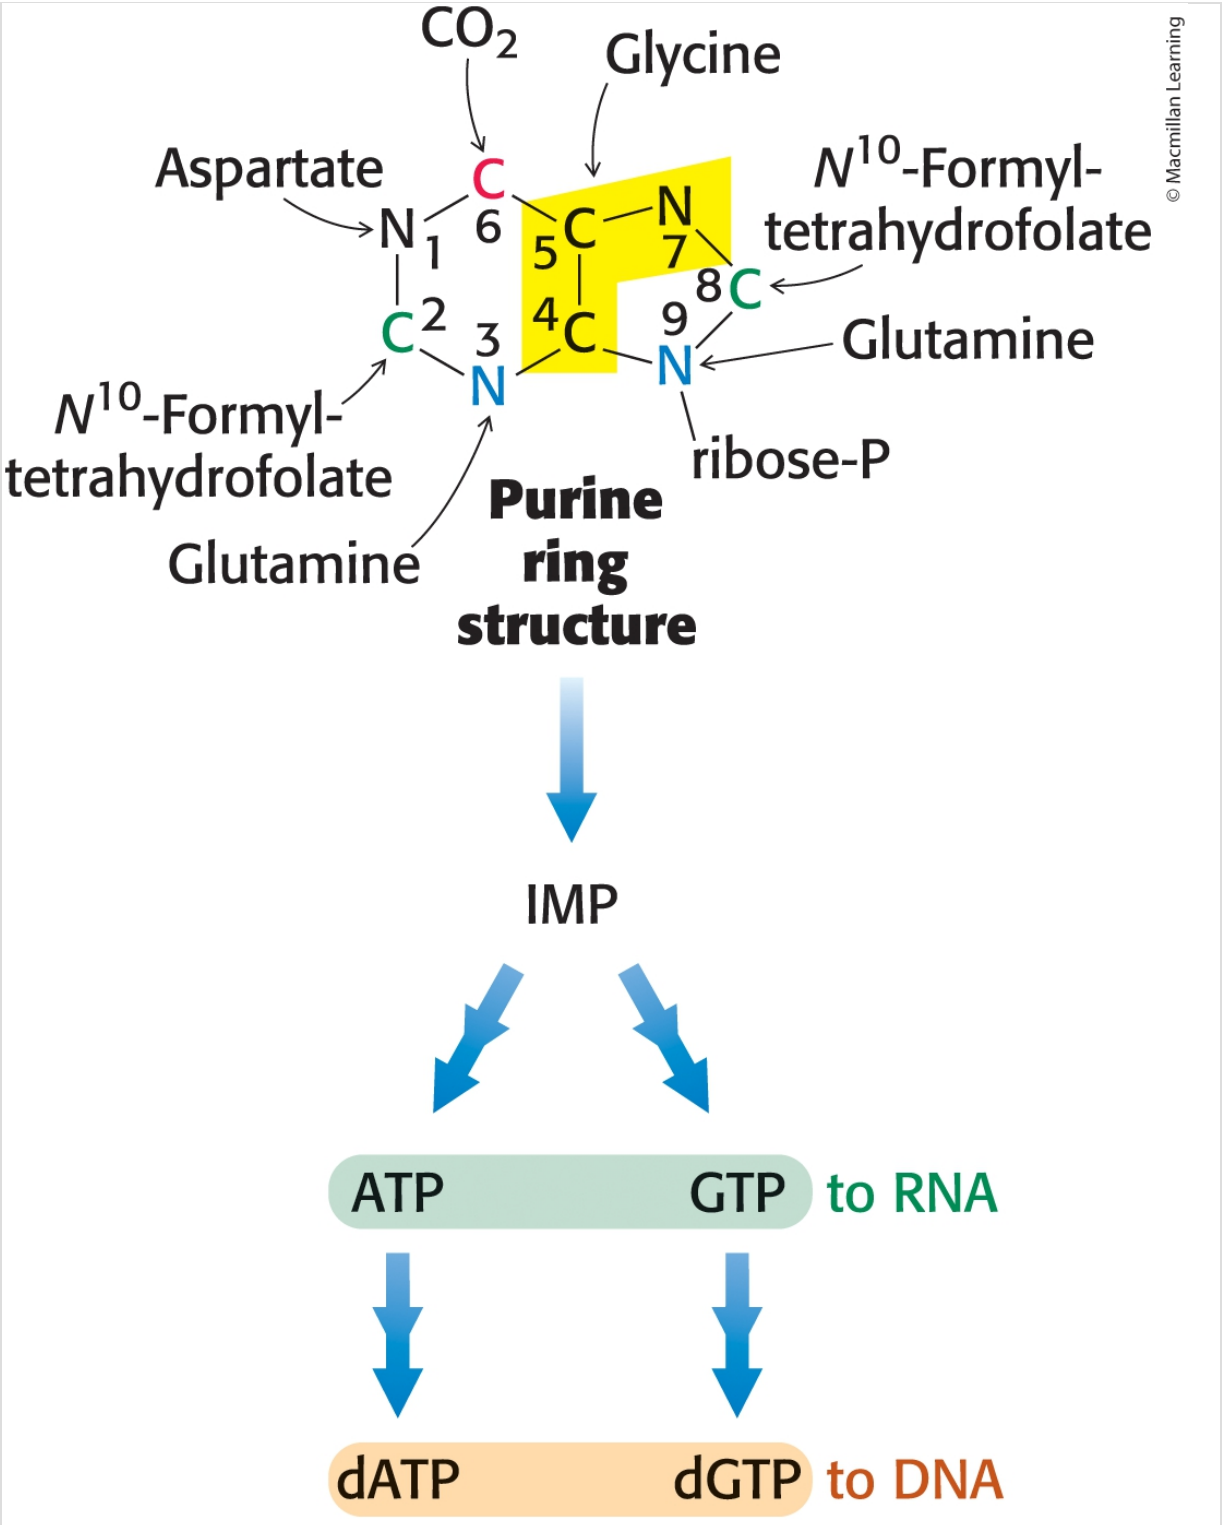
Viral thymidine kinase differs from the mammalian enzyme and thus provides a therapeutic target. For instance, herpes simplex infections are treated with acyclovir (acycloguanosine), which viral thymidine kinase converts into acyclovir monophosphate by adding a phosphate to the hydroxyl group of acyclovir. Viral thymidine kinase binds acyclovir more than 200 times as tightly as cellular thymidine kinase, accounting for its effect on infected cells only. Acyclovir monophosphate is phosphorylated by cellular enzymes to yield acyclovir triphosphate, which competes with dGTP for DNA polymerase.

Once incorporated into viral DNA, acyclovir triphosphate acts as a chain terminator since it lacks a $3'$-hydroxyl required for chain extension. As we will see shortly, thymidine kinase also plays a role in the de novo synthesis of thymidylate.

Acyclovir

26.3 Purine Bases Can Be Synthesized from Glycine, Aspartate, and Other Components

Like pyrimidine nucleotides, purine nucleotides can be synthesized de novo or by salvage pathways. When synthesized de novo, purine synthesis begins with simple starting materials such as amino acids and bicarbonate (**Figure 26.5**). Unlike the bases of pyrimidines, the purine bases are assembled already attached to the ribose ring. Alternatively, purine bases released by the hydrolytic degradation of nucleic acids and nucleotides can be salvaged and recycled. Purine salvage pathways are especially noted for the energy that they save and the remarkable effects of their absence.



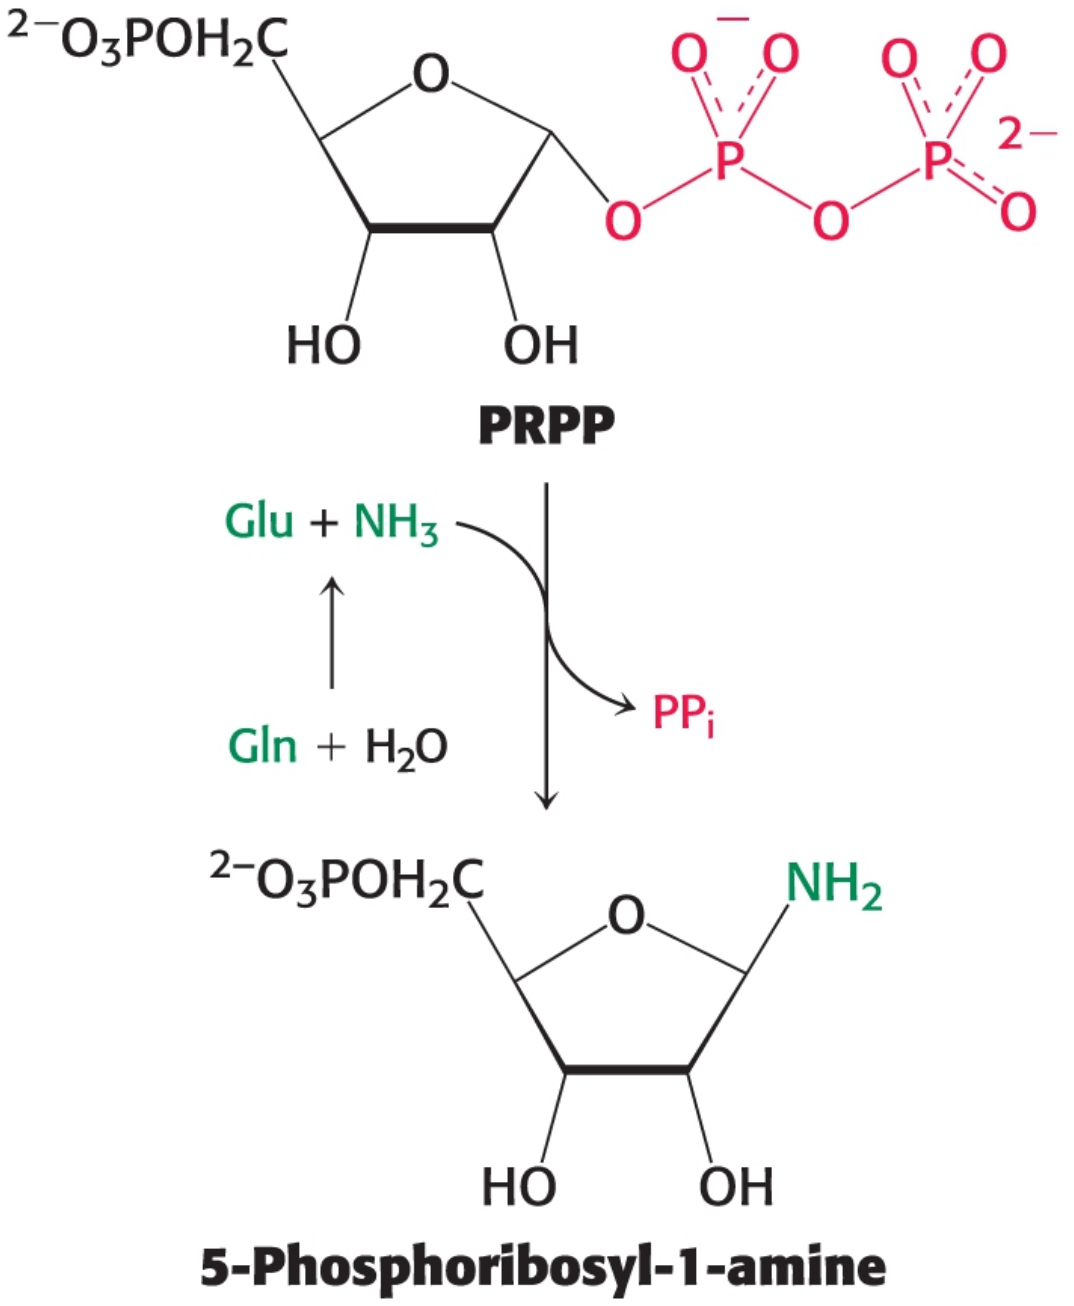


FIGURE 26.5 Purine nucleotides can be synthesized de novo. The origins of the atoms in the purine ring are indicated.

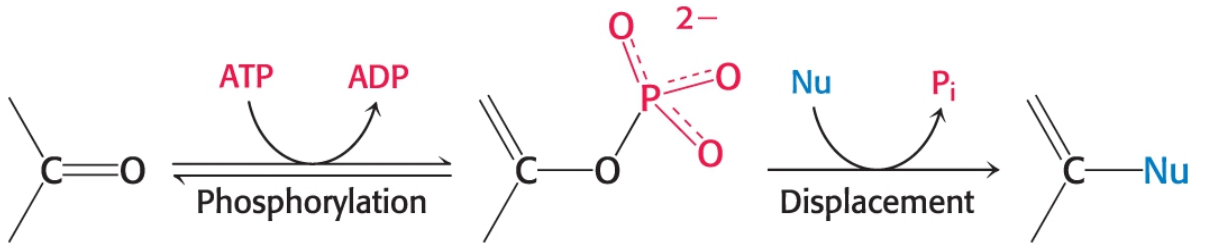
The purine ring system is assembled on ribose phosphate

De novo purine biosynthesis, like pyrimidine biosynthesis, requires PRPP. However, for purines, PRPP provides the foundation on which the bases are constructed. This process is started by the introduction of a nitrogen atom onto the ribose structure. This process, catalyzed by glutamine phosphoribosyl amidotransferase, is the displacement of pyrophosphate by ammonia. This reaction, the committed step in purine biosynthesis, produces 5-phosphoribosyl-1-amine, with the amine in the β configuration.



Glutamine phosphoribosyl amidotransferase comprises two domains: the first is homologous to the phosphoribosyltransferases in purine salvage pathways, whereas the second produces ammonia from glutamine by hydrolysis. To prevent wasteful hydrolysis of either

substrate, the amidotransferase assumes the active configuration only on binding of both PRPP and glutamine. As is the case with carbamoyl phosphate synthetase II, the ammonia generated at the glutamine-hydrolysis active site passes through a channel to reach PRPP without being released into solution.

The purine ring is assembled by successive steps of activation by phosphorylation followed by displacement

Nine additional steps are required to assemble the purine ring. Remarkably, the first six steps are analogous reactions. Most of these steps are catalyzed by enzymes with ATP-grasp domains that are homologous to those in carbamoyl phosphate synthetase. Each step consists of the activation of a carbon-bound oxygen atom (typically a carbonyl oxygen atom) by phosphorylation, followed by the displacement of the phosphoryl group by ammonia or an amine group acting as a nucleophile (Nu). The hydrolysis of ATP provides the thermodynamic driving force to favor synthesis over degradation.

De novo purine biosynthesis proceeds as shown in Figure 26.6. Table 26.2 lists the enzymes that catalyze each step of the reaction.

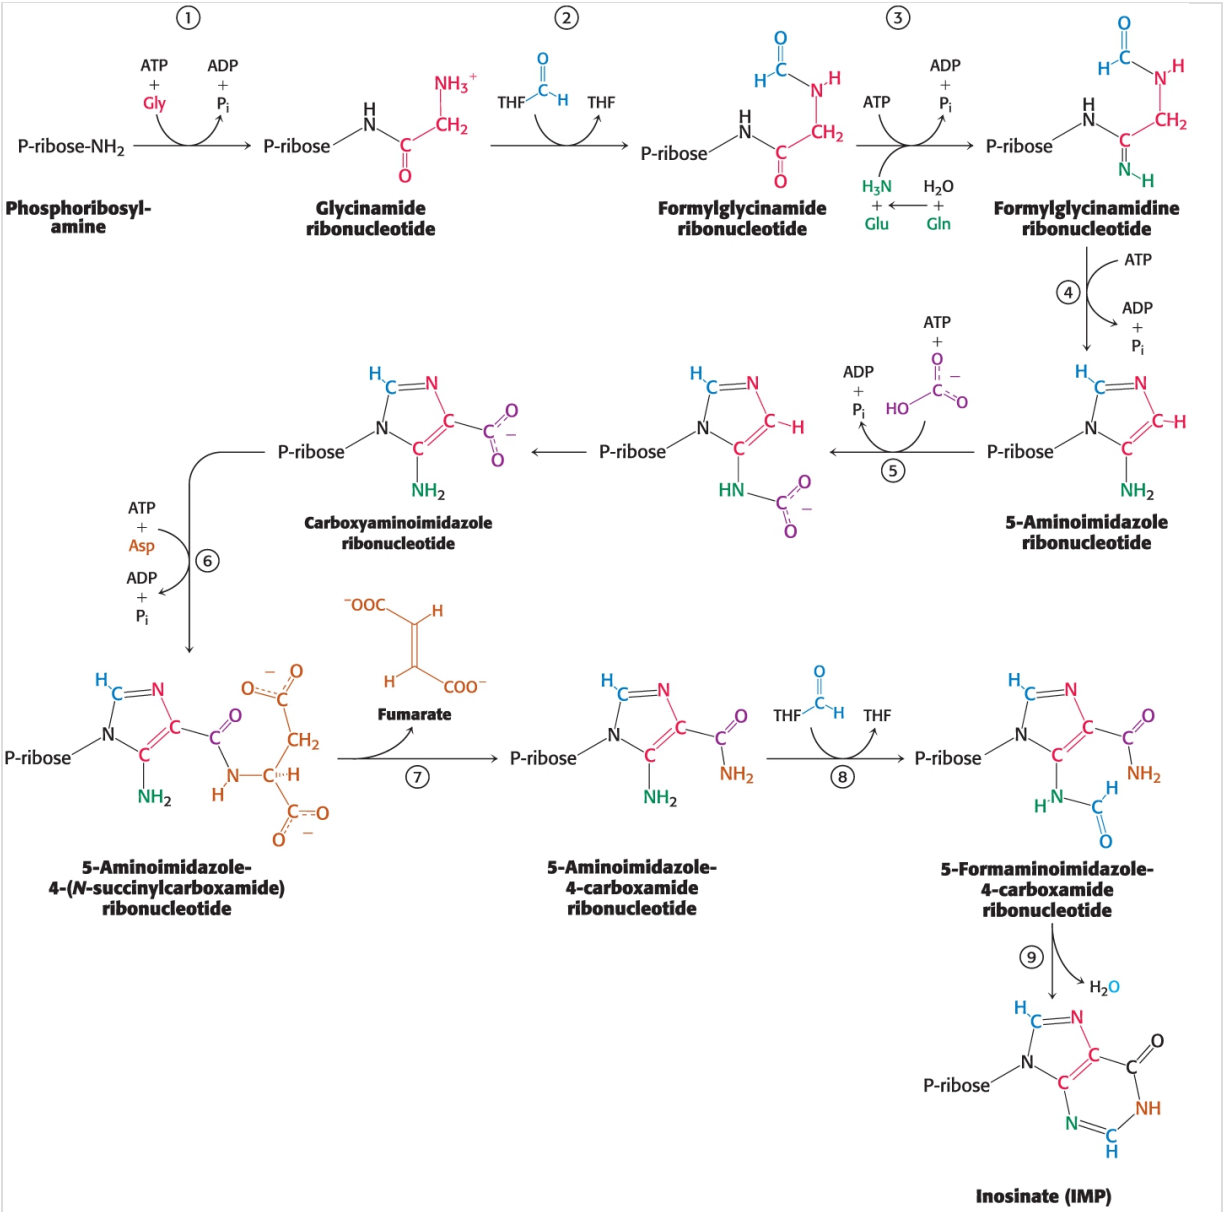


FIGURE 26.6 The de novo purine biosynthesis pathway involves nine steps. (1) Glycine is coupled to the amino group of phosphoribosylamine. (2) N^{10}-Formyltetrahydrofolate (THF) transfers a formyl group to the amino group of the glycine residue. (3) The inner amide group is phosphorylated and converted into an amidine by the addition of ammonia derived from glutamine. (4) An intramolecular coupling reaction forms the five-membered imidazole ring. (5) Bicarbonate adds first to the exocyclic amino group and then to a carbon atom of the imidazole ring. (6) The imidazole carboxylate is phosphorylated, and the phosphate is displaced by the amino group of aspartate. (7) Fumarate is released. (8) A second formyl group is donated from N^{10}-formyltetrahydrofolate (THF). (9) Cyclization completes the synthesis of inosinate, a purine nucleotide.

TABLE 26.2 The enzymes of de novo purine synthesis

Step	Enzyme
1	Glycinamide ribonucleotide (GAR) synthetase
2	GAR transformylase
3	Formylglycinamidine synthase
4	Aminoimidazole ribonucleotide synthetase
5	Carboxyaminoimidazole ribonucleotide synthetase
6	Succinylaminoimidazole carboxamide ribonucleotide synthetase
7	Adenylosuccinate lyase
8	Aminoimidazole carboxamide ribonucleotide transformylase
9	Inosine monophosphate cyclohydrolase

1. The carboxylate group of a glycine residue is activated by phosphorylation and then coupled to the amino group of phosphoribosylamine. A new amide bond is formed, and the amino group of glycine is free to act as a nucleophile in the next step.

2. N^{10}-formyltetrahydrofolate donates a formyl moiety to this amino group to form formylglycinamide ribonucleotide.

3. The inner carbonyl group is activated by phosphorylation and then converted into an amidine by the addition of ammonia derived from glutamine.

4. The product of this reaction, formylglycinamidine ribonucleotide, cyclizes to form the five-membered imidazole ring found in purines. Although this cyclization is likely to be favorable thermodynamically, a molecule of ATP is consumed to ensure irreversibility. The familiar pattern is repeated: a phosphoryl group from the ATP molecule activates the carbonyl group and is displaced by the nitrogen atom attached to the ribose molecule. Cyclization is thus an intramolecular reaction in which the nucleophile and phosphate-activated carbon atom are present within the same molecule. In higher eukaryotes, the enzymes catalyzing steps 1, 2, and 4 (Table 26.2) are components of a single polypeptide chain.

5. Bicarbonate is activated by phosphorylation and then attacked by the exocyclic amino group. The product of the reaction in step 5 rearranges to transfer the carboxylate group to the imidazole ring. Interestingly, mammals do not require ATP for this step; bicarbonate apparently attaches directly to the exocyclic amino group and is then transferred to the imidazole ring.

6. The imidazole carboxylate group is phosphorylated again and the phosphate group is displaced by the amino group of aspartate. Once again, in higher eukaryotes, the enzymes catalyzing steps 5 and 6 (Table 26.2) share a single polypeptide chain.

7. Fumarate, an intermediate in the citric acid cycle, is eliminated, leaving the nitrogen atom from aspartate joined to the imidazole ring. The use of aspartate as an amino-group donor and the concomitant release of fumarate are reminiscent of the conversion

of citrulline into arginine in the urea cycle, and these steps are catalyzed by homologous enzymes in the two pathways (Section 23.4).

8. A formyl group from N^{10}-formyltetrahydrofolate is added to this nitrogen atom to form a final 5-formaminoimidazole-4-carboxamide ribonucleotide.
9. 5-Formaminoimidazole-4-carboxamide ribonucleotide cyclizes with the loss of water to form inosine monophosphate (inosinate).

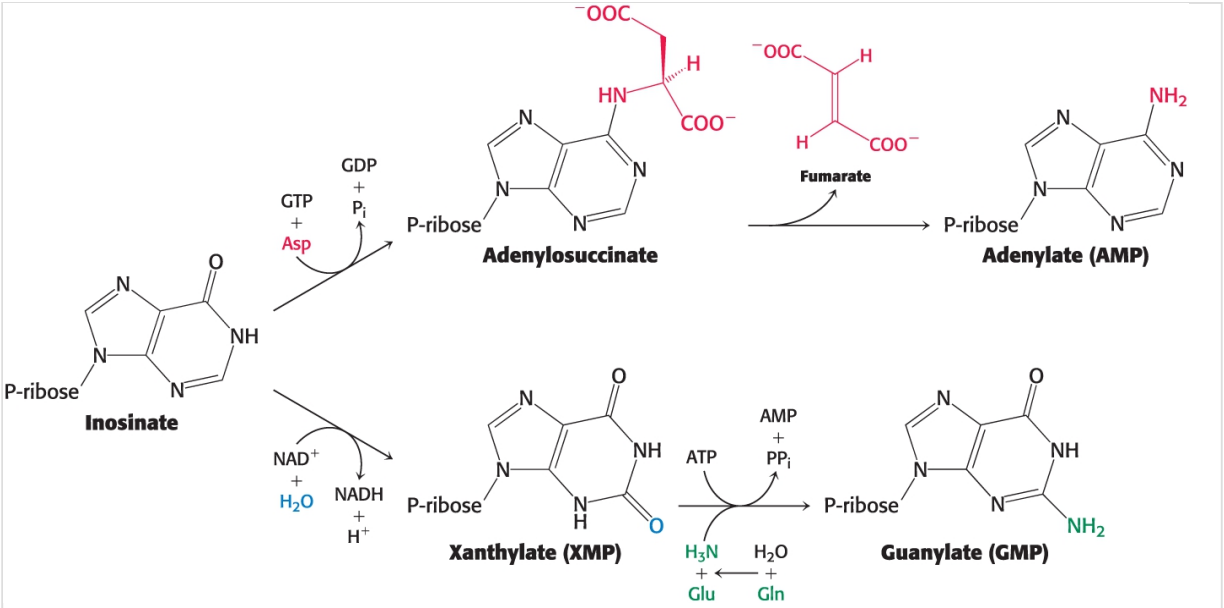
This pathway completes the formation of the purine ring system.

Self-Check Question

Identify the sources of the atoms that form the purine ring.

AMP and GMP are formed from IMP

A few steps convert inosinate into either AMP or GMP (**Figure 26.7**). Adenylate is synthesized from inosinate by the substitution of an amino group for the carbonyl oxygen atom at C-6. Again, the addition of aspartate followed by the elimination of fumarate contributes the amino group. GTP, rather than ATP, is the phosphoryl-group donor in the synthesis of the adenylosuccinate intermediate from inosinate and aspartate. In accord with the use of GTP, the enzyme that promotes this conversion, adenylosuccinate synthetase, is structurally related to the G-protein family and does not contain an ATP-grasp domain.



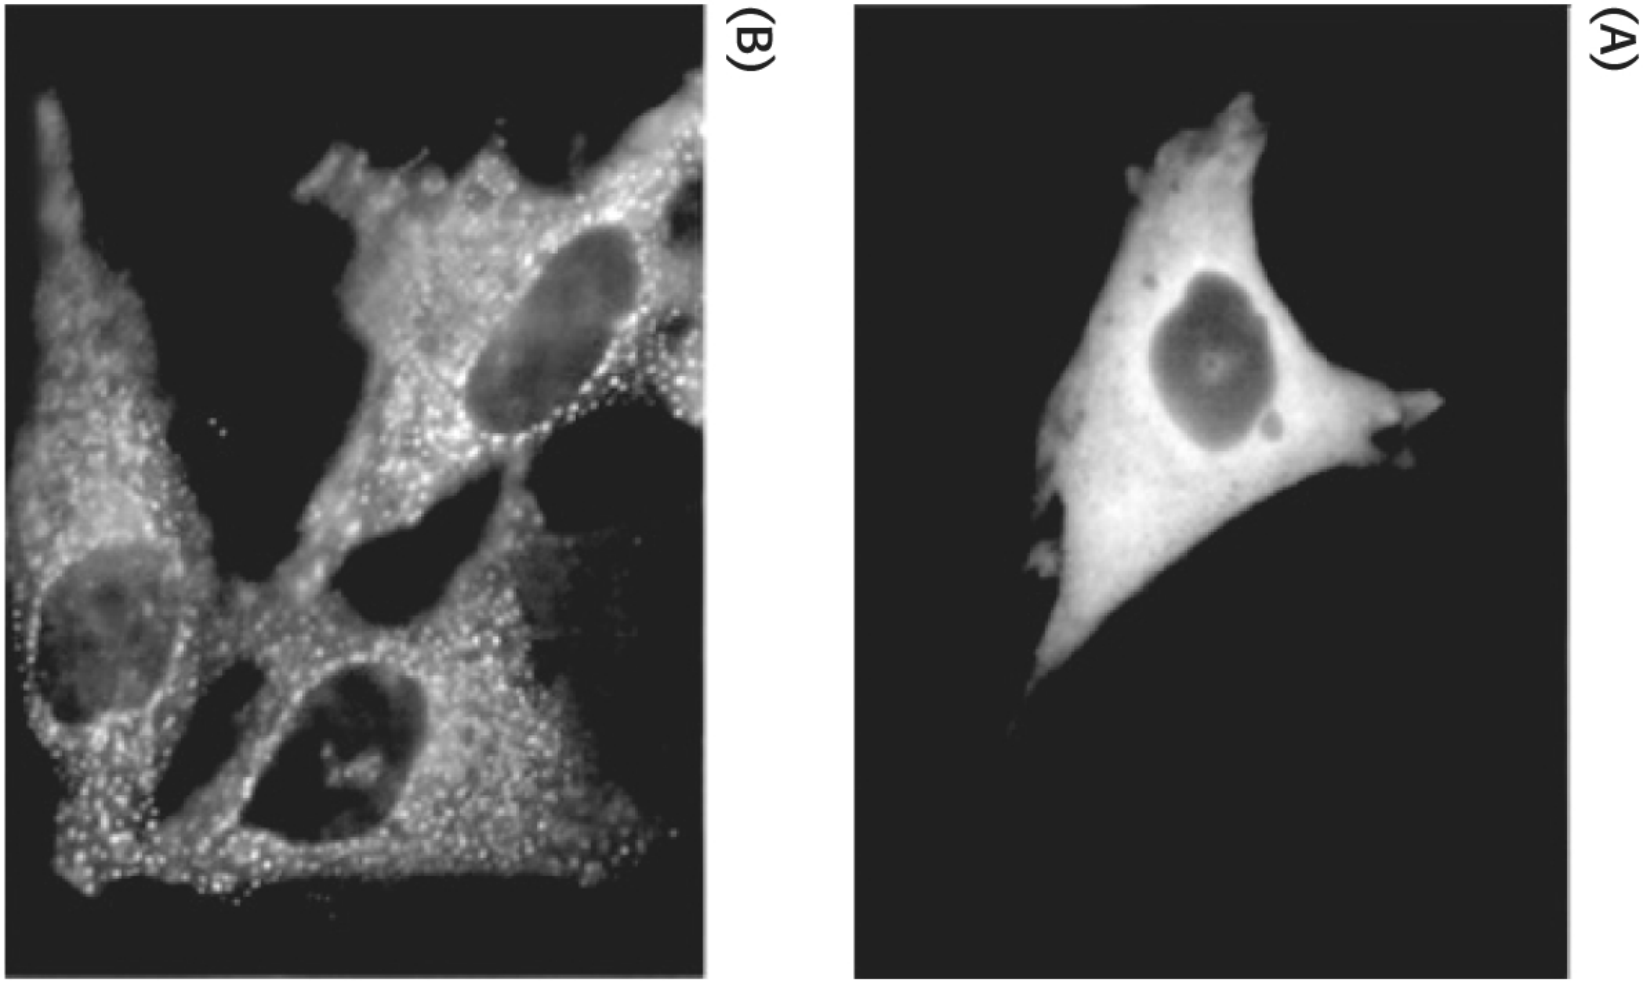


FIGURE 26.7 Inosinate can be converted to AMP and GMP. AMP is formed by the addition of aspartate followed by the release of fumarate. GMP is generated by the addition of water, dehydrogenation by NAD^+, and the replacement of the carbonyl oxygen atom by $-NH_2$ derived by the hydrolysis of glutamine.

Guanylate is synthesized by the oxidation of inosinate to xanthylate (XMP), followed by the incorporation of an amino group at C-2. NAD^+ is the hydrogen acceptor in the oxidation of inosinate, and xanthylate is activated by the transfer of an AMP group (rather than a phosphoryl group) from ATP to the oxygen atom in the newly formed carbonyl group. Ammonia, generated by the hydrolysis of glutamine, then displaces the AMP group to form guanylate, in a reaction catalyzed by GMP synthetase. Note that the synthesis of adenylate requires GTP, whereas the synthesis of guanylate requires ATP. This reciprocal use of nucleotides by the pathways creates an important regulatory opportunity.

Enzymes of the purine biosynthesis pathway associate with one another

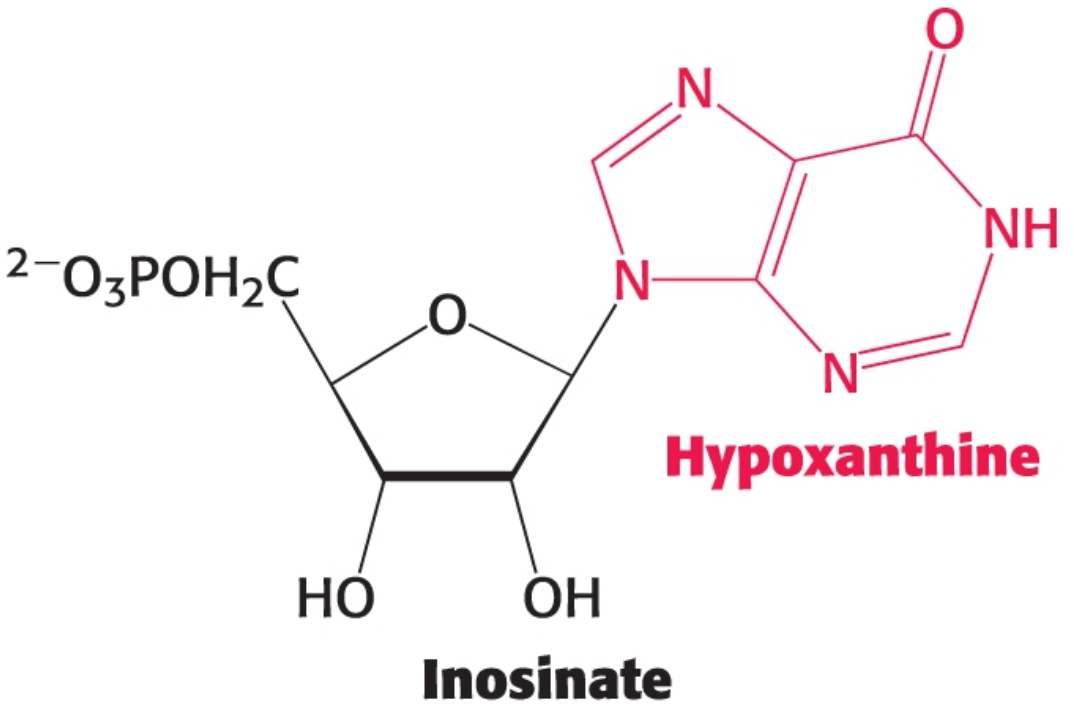
Many of the intermediates in the de novo purine biosynthesis pathway degrade rapidly in water, suggesting that the product of one active site might be channeled directly to the next enzyme along the pathway in a manner similar to that described for carbamoyl phosphate synthetase II. In some bacteria, enzymes catalyzing consecutive steps in the purine biosynthetic pathway are fused into single polypeptide chains, likely promoting such channeling.

A more intricate process occurs in human cells. In the presence of sufficient levels of purines, the enzymes of the purine biosynthetic pathway do not appear to be associated with one another. However, when grown under conditions with low concentrations of purines, granules termed **purinosomes** form (**Figure 26.8**). The core of the purinosome comprises the enzymes catalyzing the first six steps of the pathway, with the remaining enzymes more loosely associated. The reversible formation of these large assemblies provides a powerful mode of regulation of purine biosynthesis. The assembly and disassembly of the purinosome is controlled by phosphorylation, enabling the linkage of these processes to the cell cycle and to other events through signal transduction pathways. Thus, the biosynthesis of purines, so central to DNA replication but also to other processes, can be regulated in response to a range of signals other than the concentrations of purines present.

Republished with permission of AAAS, from An, S., Kumar, R., Sheets, E. D., and Benkovic, S. J. 2. Reversible compartmentalization of de novo purine biosynthetic complexes in living cells. *Science* 320: 103–106, 2008; permission conveyed through Copyright Clearance Center, Ltd.

FIGURE 26.8 Purinosomes form when purine synthesis is required. A gene construct encoding a fusion protein consisting of formylglycinamidine synthase and GFP was transfected into and expressed in Hela cells, a human cell line. (A) In the presence of purines (the absence of purine synthesis), the GFP was seen as a diffuse stain throughout the cytoplasm. (B) When the cells were shifted to a purine-free medium, purinosomes formed, seen as cytoplasmic granules, and purine synthesis occurred.

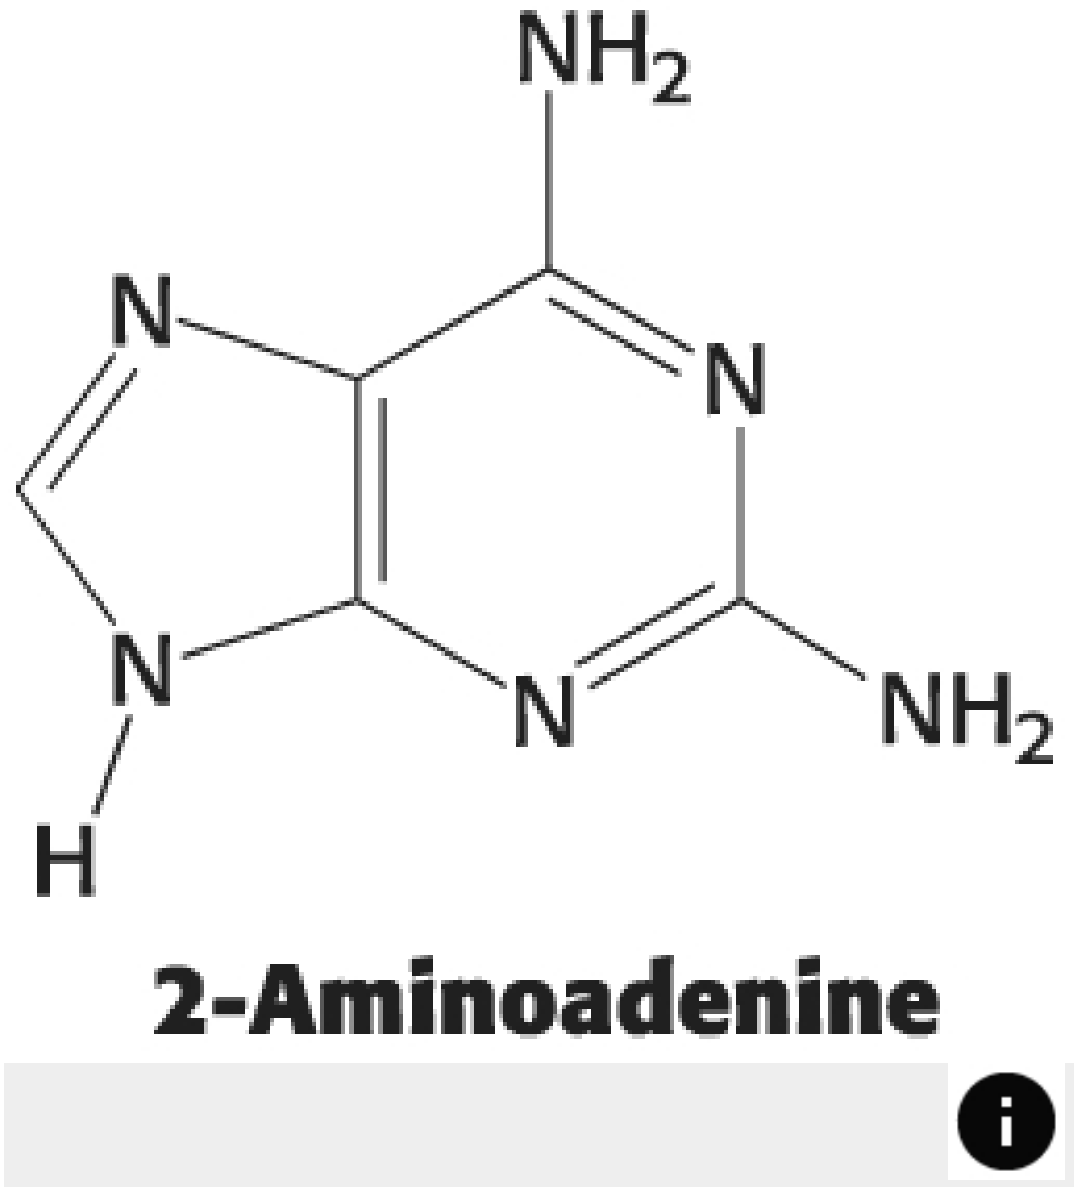
Salvage pathways economize intracellular resource consumption



As we have seen, the de novo synthesis of purines requires a substantial investment of ATP as well as starting materials that play roles in many other pathways. Purine salvage pathways provide a more economical means of generating purines. Free purine bases, derived from the turnover of nucleotides or from the diet, can be attached to PRPP to form purine nucleoside monophosphates, in a reaction analogous to the formation of orotidylate. Two salvage enzymes with different specificities recover purine bases. Adenine phosphoribosyltransferase catalyzes the formation of adenylate (AMP):

$$\text{Adenine} + \text{PRPP} \rightarrow \text{adenylate} + PP_i$$

whereas hypoxanthine-guanine phosphoribosyltransferase (HGPRT) catalyzes the formation of guanylate (GMP) as well as inosinate (inosine monophosphate, IMP), a precursor of guanylate and adenylate.



$$\text{Guanine} + \text{PRPP} \rightarrow \text{guanylate} + PP_i$$

$$\text{Hypoxanthine} + \text{PRPP} \rightarrow \text{inosinate} + PP_i$$

An alternative to adenine is used by some viruses

When we first encountered the DNA double helix, you may have noticed that G–C base pairs are held together by three hydrogen bonds, whereas A–T base pairs have only two. However, if one of the hydrogens on adenine were replaced with an amino group, then this alternative could form three hydrogen bonds with T.

2-Aminoadenine

The genomes of certain bacterial viruses contain this nucleobase, termed *2-aminoadenine*, in place of adenine. Nucleotides containing this base are biosynthesized by a pathway that is analogous to that for the conversion of inosinate to adenylate (Figure 26.7) but differs in important details (**Figure 26.9**). The pathway begins with deoxyguanylate. In a first step, aspartate replaces the carbonyl oxygen in a process coupled to the hydrolysis of ATP in reaction catalyzed by the enzyme PurZ. Fumarate is then released to form deoxy 2-aminoadenylate in a subsequent step catalyzed by adenylosuccinate

lyase, the same enzyme that catalyzes the removal to fumarate to form adenylate.

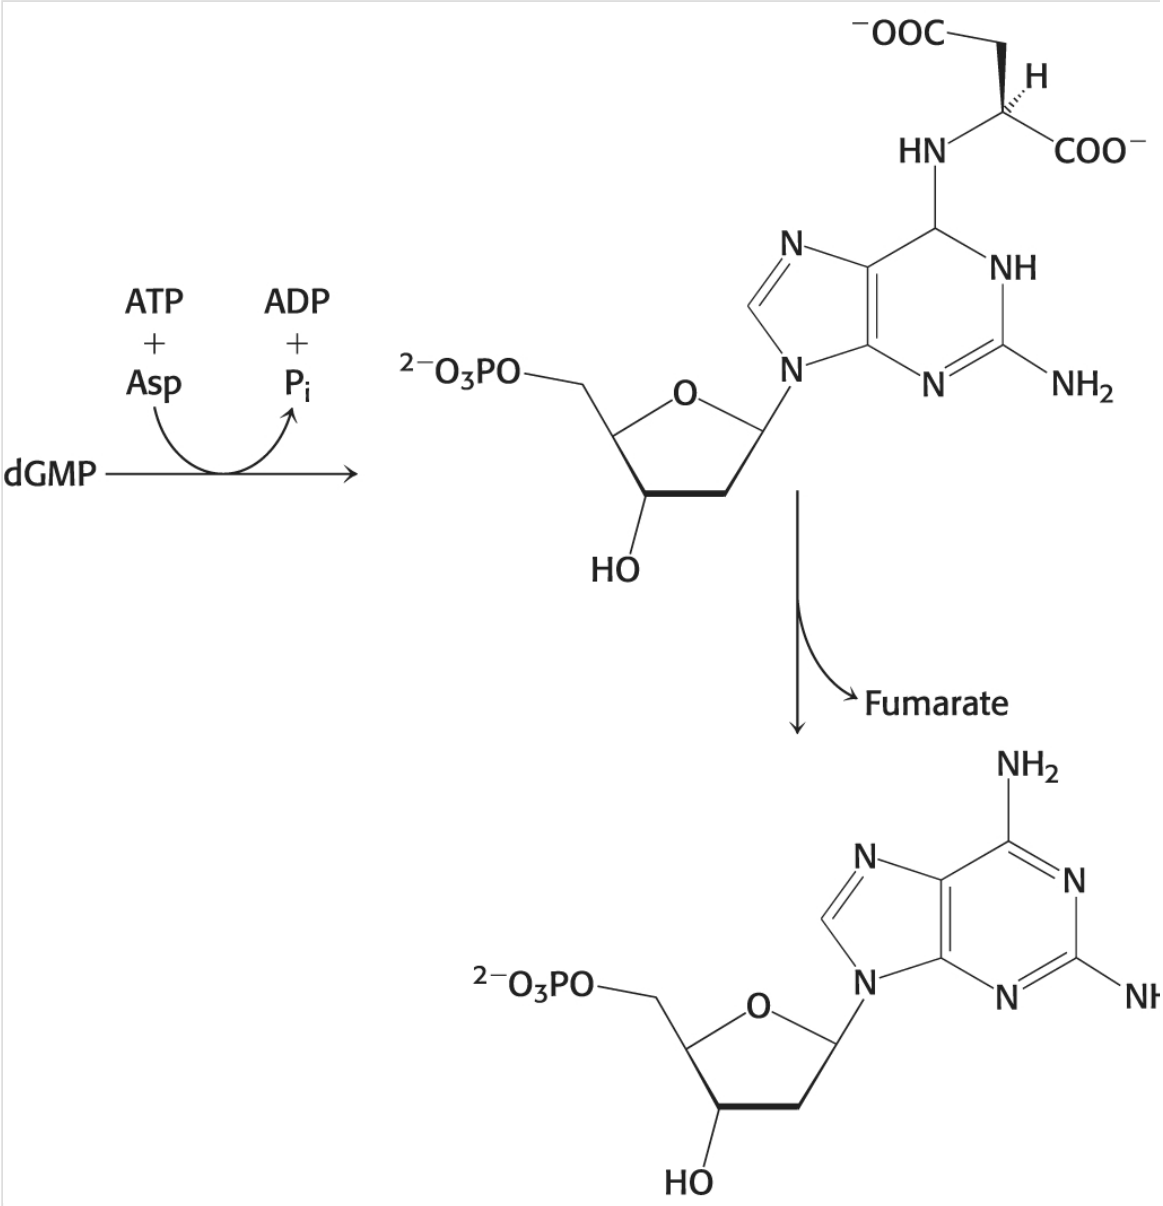


FIGURE 26.9 The nucleotide containing 2-aminoadenine is synthesized from deoxyguanylate
PurZ catalyzes the ATP-coupled replacement of the carbonyl oxygen on dGMP with aspartate. In the second step, catalyzed by adenylosuccinate lyase, fumarate is released, yielding the 2-aminoadenine-containing deoxyribonucleotide.

The identification of the gene encoding PurZ in other viral genomes indicates the likely presence of this pathway, without the need for characterizing the base composition of purified viral DNA. Upon the discovery of this bioinformatic approach, the number of bacterial viruses with evidence of 2-aminoadenine in their genomes increased from less than five to more than 50. As anticipated, DNA containing this base is more thermally stable, consistent with the formation of the additional hydrogen bonds. More important, the unusual base protects the viral genomes from bacterial endonucleases.

26.4 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides

We turn now to the synthesis of deoxyribonucleotides. These precursors of DNA are formed by the reduction of ribonucleotides; specifically, the $2'$-hydroxyl group on the ribose moiety is replaced by a hydrogen atom. The substrates are ribonucleoside diphosphates, and the ultimate reductant is NADPH. The enzyme **ribonucleotide reductase** is responsible for the reduction reaction for all four ribonucleotides.

The ribonucleotide reductases of different organisms are a remarkably diverse set of enzymes. Yet detailed studies have revealed that they have a common reaction mechanism, and their three-dimensional structural features indicate that these enzymes are homologous.

Ribonucleotide reduction occurs via a radical mechanism

The active sites of ribonucleotide reductases include three conserved cysteine residues and a glutamate residue, all four of which participate in the reduction of ribose to deoxyribose. In the synthesis of a deoxyribonucleotide, the OH bonded to $C-2'$ of the ribose ring is replaced by H, with retention of the configuration at the $C-2'$ carbon atom (**Figure 26.10**).

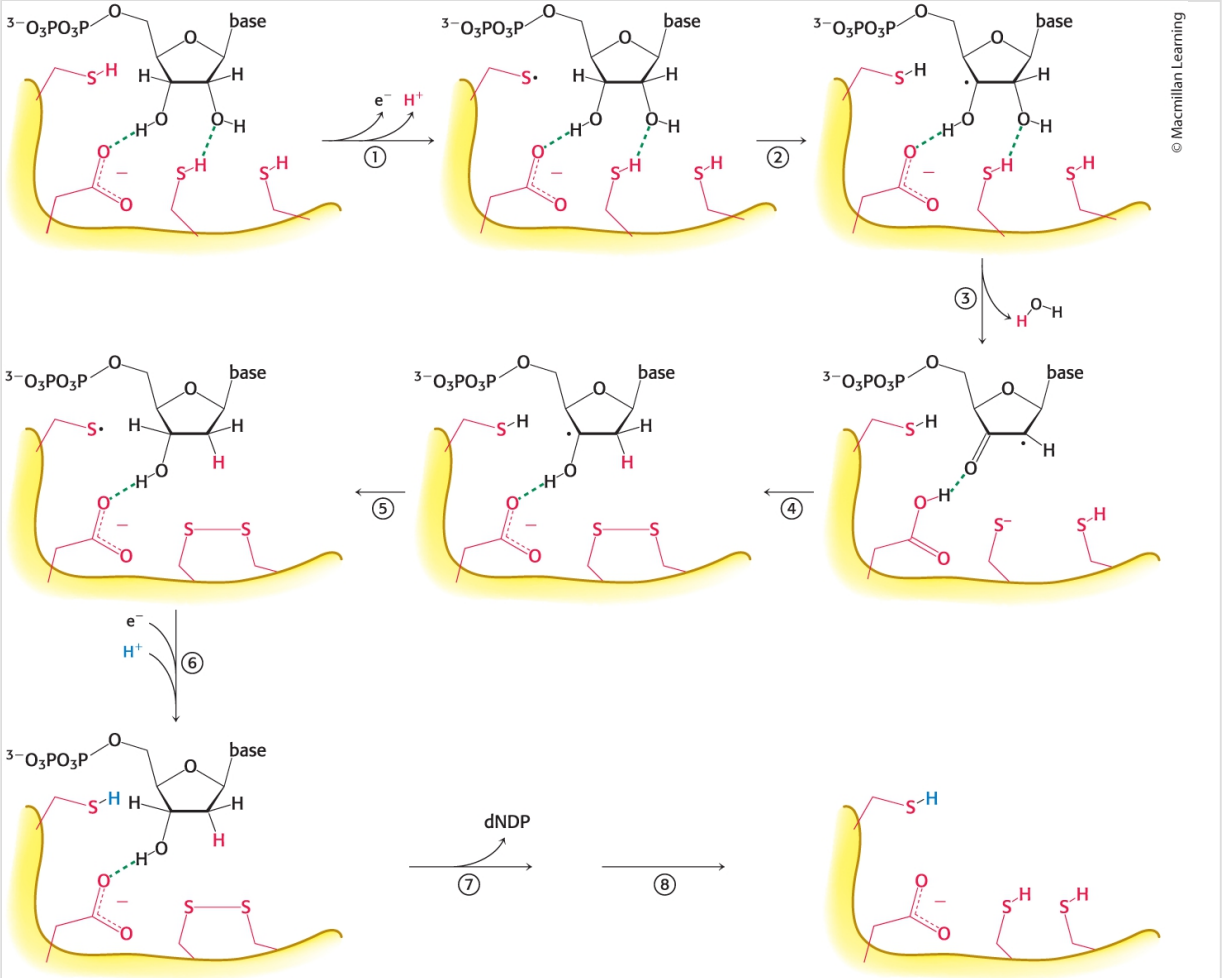

FIGURE 26.10 Ribonucleotide reductase uses a radical mechanism to produce deoxyribonucleotides. (1) An electron is transferred from a cysteine residue on R1 to a tyrosine radical on R2, generating a highly reactive cysteine thiyl radical. (2) This radical abstracts a hydrogen atom from $C-3'$ of the ribose unit. (3) The radical at $C-3'$ releases OH^- from the $C-2'$ carbon atom. Combined with a proton from a second cysteine residue, the OH^- is eliminated as water. (4) A hydride ion is transferred from a third cysteine residue, with the concomitant formation of a disulfide bond. (5) The $C-3'$ radical recaptures the originally abstracted hydrogen atom. (6) An electron is transferred from R2 to reduce the thiyl radical, which also accepts a proton. (7) The deoxyribonucleotide leaves R1. (8) The disulfide formed in the active site is reduced to begin another cycle.

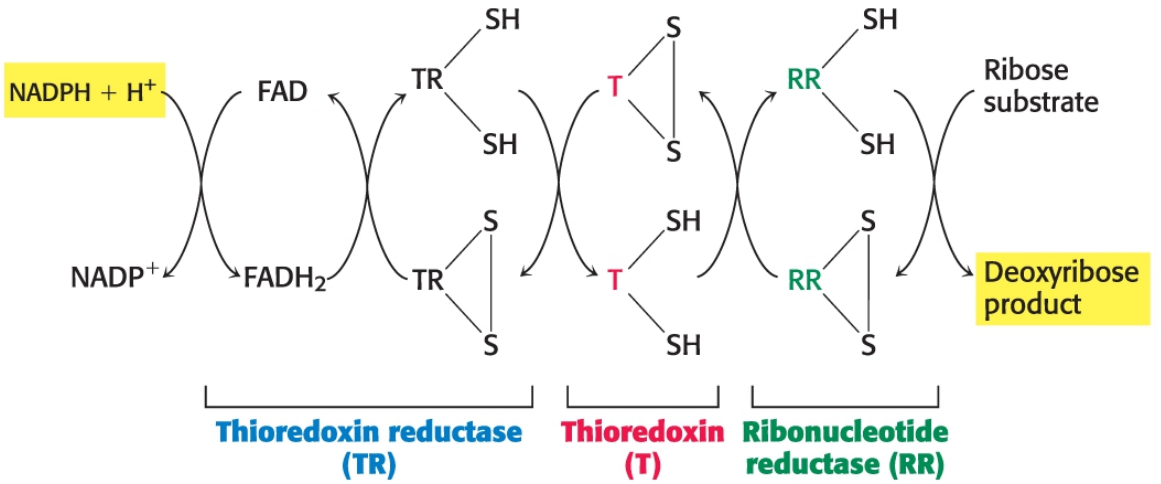
1. The reaction begins with the transfer of an electron from a cysteine residue in the active site of ribonucleotide reductase to an electron acceptor on a second subunit of the enzyme. The loss of an electron generates a highly reactive cysteine thiyl radical.

2. This radical then abstracts a hydrogen atom from $C-3'$ of the ribose unit, generating a radical at that carbon atom.

3. The radical at $C-3'$ promotes the release of the OH^- from the $C-2'$ carbon atom. Protonated by a second cysteine residue, the departing OH^- leaves as a water molecule.

4. A hydride ion (a proton with two electrons) is then transferred from a third cysteine residue to complete the reduction of the position, form a disulfide bond, and regenerate the radical at the $C-3'$ carbon.

5. This $C-3'$ radical recaptures the same hydrogen atom originally abstracted by the first cysteine residue, and the deoxyribonucleotide is free to leave the enzyme.



6. An electron from the second subunit of ribonucleotide reductase is transferred to reduce the thiyl radical.

7. The newly synthesized deoxyribonucleotide exits the active site.

8. The disulfide bond generated in the enzyme's active site is reduced to regenerate the active enzyme.

The electrons for this reduction come from NADPH, but not directly. One carrier of reducing power linking NADPH with the reductase is thioredoxin, a 12-kDa protein with two exposed cysteine residues near each other. These sulfhydryls are oxidized to a disulfide in the reaction catalyzed by ribonucleotide reductase itself. In turn, reduced thioredoxin is regenerated by electron flow from NADPH. This reaction is catalyzed by thioredoxin reductase, a flavoprotein. Electrons flow

from NADPH to bound FAD of the reductase, to the disulfide of oxidized thioredoxin, and then to ribonucleotide reductase, and finally to the ribose unit.

Stable radicals are present in ribonucleotide reductases

The most well-studied ribonucleotide reductase is that from *E. coli* grown under aerobic conditions. This enzyme consists of two subunits: R1 (an 87-kDa dimer) and R2 (a 43-kDa dimer). The R1 subunit contains the active site as well as two allosteric control sites (Section 26.5). Each R2 chain contains a tyrosyl radical with an unpaired electron delocalized onto its aromatic ring, generated by a nearby iron center consisting of two ferric (Fe^{3+}) ions bridged by an oxide (O^{2-}) ion (**Figure 26.11**). This very unusual free radical is remarkably stable, with a half-life of 4 days at 4°C. By contrast, free tyrosine radicals in solution have microsecond lifetimes.

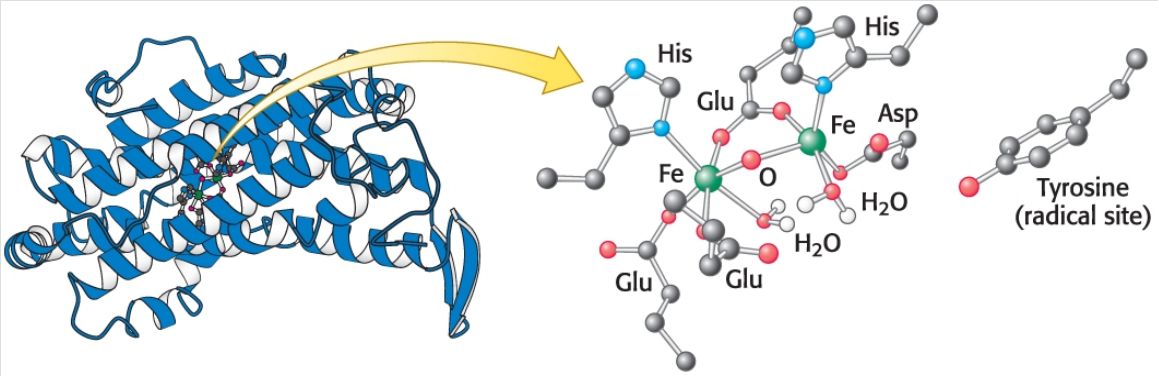


FIGURE 26.11 The ribonucleotide reductase R2 subunit contains a stable free radical on a tyrosine residue. This radical is generated by the reaction of oxygen (not shown) at a nearby sit containing two iron atoms. Two R2 subunits come together to form a dimer.

[Drawn from 1RIB.pdb.]

INTERACT with this model in Achieve

The ribonucleotide reductases from many other organisms, including human beings, are similar to the *E. coli* enzyme, in that they contain the tyrosine radical and the iron center. However, ribonucleotide reductases that do not contain tyrosyl radicals have been characterized in other prokaryotes. Instead, these enzymes contain distinct stable radicals that are generated by other processes. For example, in one class of reductases, the coenzyme adenosylcobalamin (from vitamin B_{12}) is the radical source (Section 22.3). Despite differences in the stable radical employed, the active sites of these enzymes are similar to that of the *E. coli* ribonucleotide reductase, and they appear to act by the same mechanism, based on the exceptional reactivity of cysteine radicals. Thus, these enzymes have a common ancestor but evolved a range of mechanisms for generating stable radical species that function well under different growth conditions. The primordial ribonucleotide reductases appear to have been inactivated by oxygen, whereas the one found in *E. coli* makes use of oxygen to generate the initial tyrosyl radical. Note that the reduction of ribonucleotides to

deoxyribonucleotides is a difficult reaction, likely to require a sophisticated catalyst. The existence of a common protein enzyme framework for this process strongly suggests that proteins joined the RNA world before the evolution of DNA as a stable storage form for genetic information.

Justin Knight

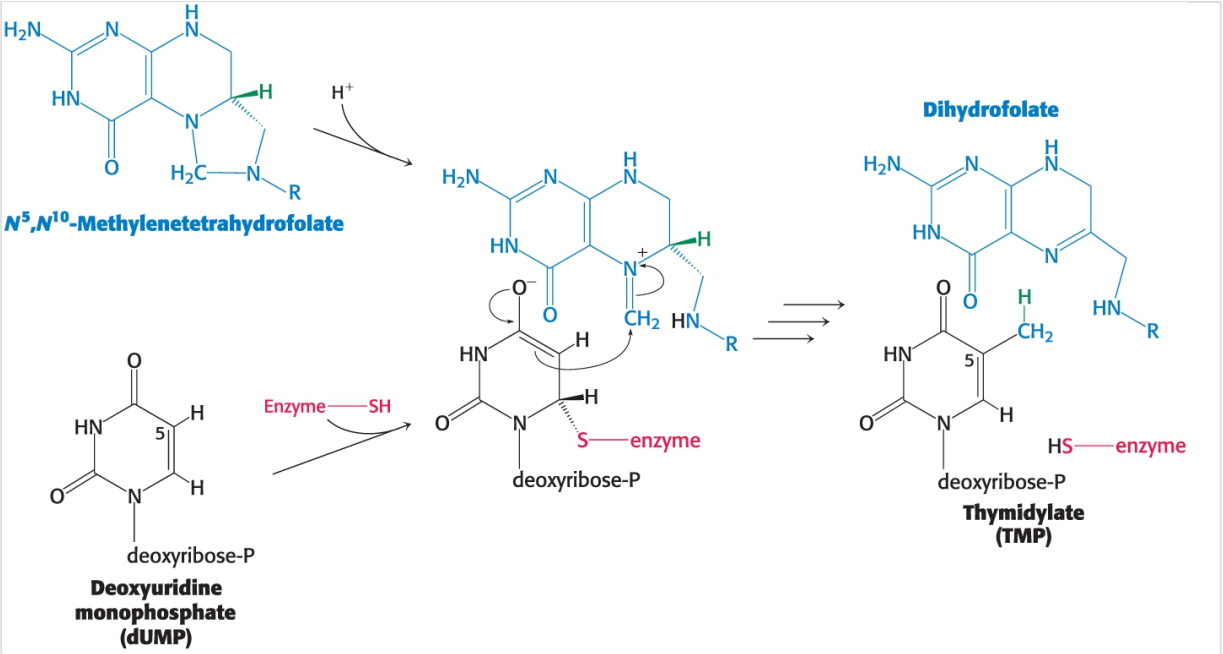
JOANNE STUBBE Trained in chemistry at the University of California, Berkeley, JoAnne Stubbe developed a deep interest in biochemistry and enzyme reaction mechanisms. Dr. Stubbe began her independent career on the faculty of Williams College, teaching and performing research with undergraduate student coworkers. As her interest and accomplishments in research grew, she took a leave of absence to work with a leading enzymologist at Brandeis University. She did not return to Williams but moved to more research-intensive departments, eventually ending up in the Chemistry Department at the Massachusetts Institute of Technology. There, with PhD students and postdoctoral fellows, she elucidated the mechanisms of several important biochemical processes, more notably the radical-based mechanism for ribonucleotide reductases. Her accomplishments have been recognized by important

honors, including the National Medal of Science and the Priestley Medal from the American Chemical Society.

Thymidylate is formed by the methylation of deoxyuridylate

Uracil, produced by the pyrimidine synthesis pathway, is not a component of DNA. Rather, DNA contains *thymine*, a methylated analog of uracil. Another step is required to generate thymidylate from uracil. **Thymidylate synthase** catalyzes this finishing touch: deoxyuridylate (dUMP) is methylated to thymidylate (TMP).

The methyl group becomes attached to the C-5 atom within the aromatic ring of dUMP, but this carbon atom is not a good nucleophile and cannot itself attack the appropriate group on the methyl donor. Thymidylate synthase promotes methylation by adding a thiolate from a cysteine side chain to this ring to generate a nucleophilic species that can attack the methylene group of N^5,N^{10}-methylenetetrahydrofolate (**Figure 26.12**). This methylene group, in turn, is activated by distortions imposed by the enzyme that favor opening the five-membered ring. The attack of the activated dUMP on the methylene group forms the new carbon–carbon bond. The intermediate formed is then converted into product. First a hydride ion is transferred from the tetrahydrofolate ring to transform the methylene group into a methyl group, and then a proton is abstracted from the carbon atom bearing the methyl group to eliminate the cysteine and regenerate the aromatic ring. The tetrahydrofolate derivative loses both its methylene group and a hydride ion and, hence, is oxidized to dihydrofolate.



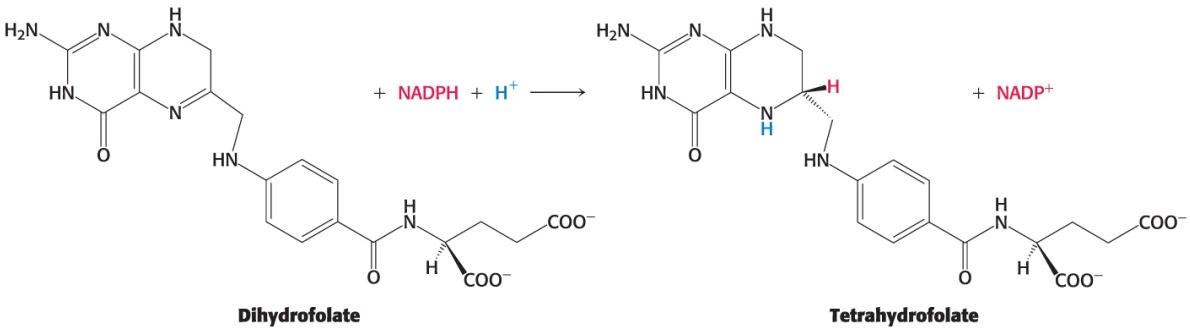


FIGURE 26.12 Thymidylate synthase catalyzes the addition of a methyl group to dUMP to form TMP. The methyl group is derived from N^5,N^{10}-methylenetetrahydrofolate. The addition of a thiolate from the enzyme activates dUMP. Opening the five-membered ring of the THF derivative prepares the methylene group for nucleophilic attack by the activated dUMP. The reaction is completed by the transfer of a hydride ion to form dihydrofolate.

For the synthesis of more thymidylate, tetrahydrofolate must be regenerated. This is achieved by [dihydrofolate reductase] with the use of NADPH as the reductant.

A hydride ion is directly transferred from the nicotinamide ring of NADPH to the pteridine ring of dihydrofolate. The bound dihydrofolate and NADPH are held in close proximity to facilitate the hydride transfer.

Self-Check Question

Describe the path for the synthesis of TTP from UTP.

Several valuable anticancer drugs block the synthesis of thymidylate

Rapidly dividing cells require an abundant supply of thymidylate for the synthesis of DNA. The vulnerability of these cells to the inhibition of TMP synthesis has been exploited in the treatment of cancer. Thymidylate synthase and dihydrofolate reductase are choice targets of chemotherapy (Figure 26.13).

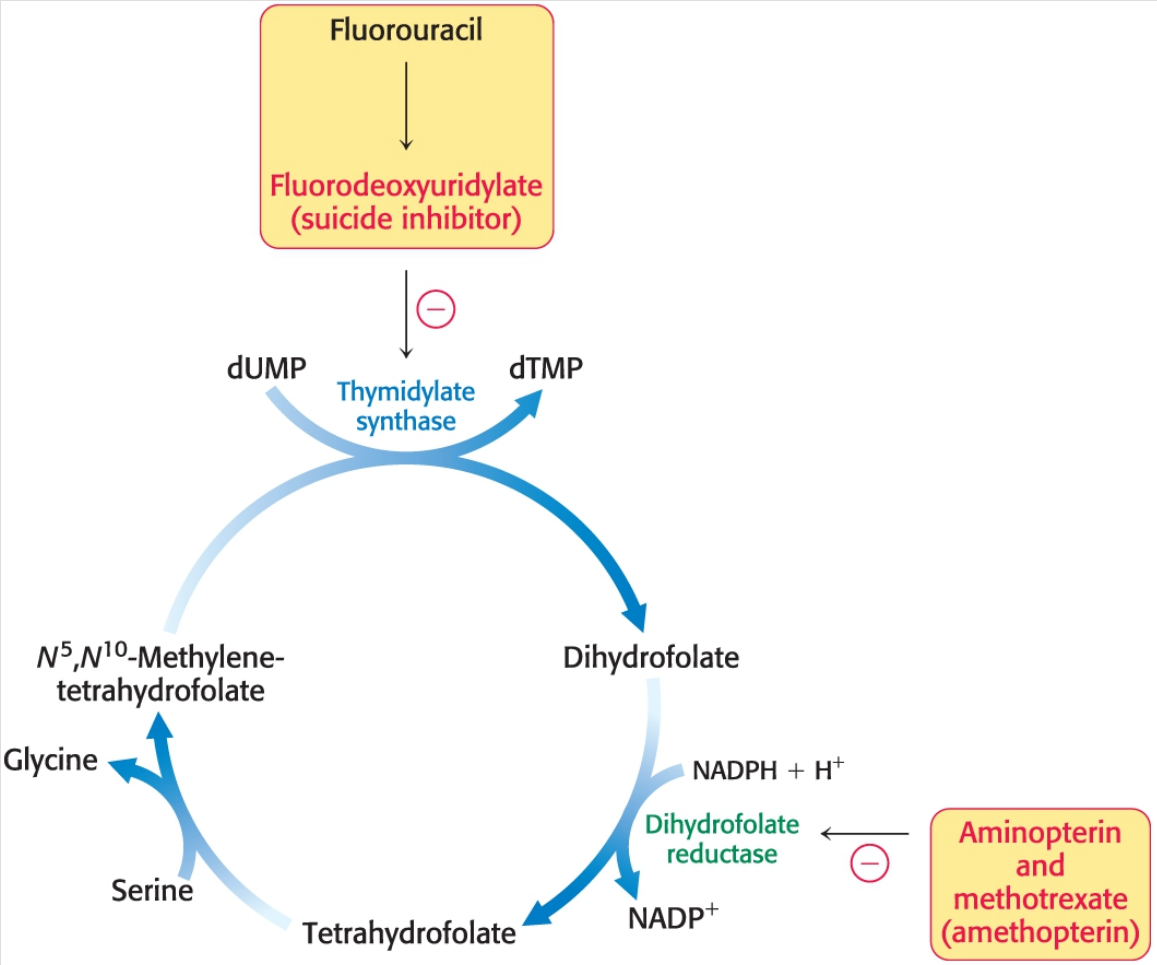

FIGURE 26.13 Enzymes crucial for nucleotide synthesis are anticancer drug targets.
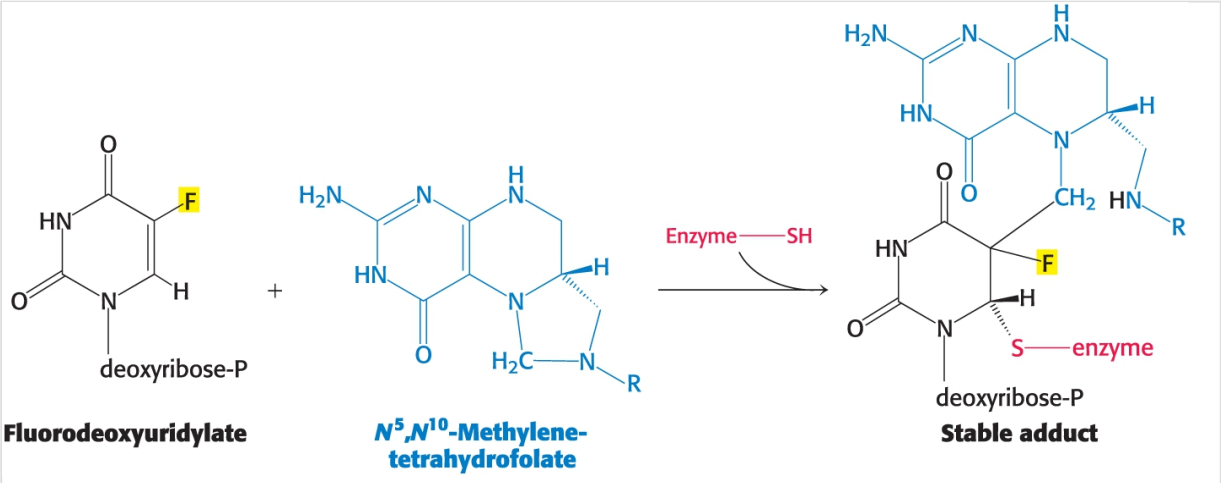
Thymidylate synthase and dihydrofolate reductase are choice targets in cancer chemotherapy because the generation of large quantities of precursors for DNA synthesis is required for rapidly dividing cancer cells.

Fluorouracil, an anticancer drug, is converted in vivo into fluorodeoxyuridylate (F-dUMP). This analog of dUMP irreversibly inhibits thymidylate synthase after acting as a normal substrate through part of the catalytic cycle. Recall that the formation of TMP requires the removal of a proton (H^+) from C-5 of the bound nucleotide (Figure 26.12). However, the enzyme cannot abstract F^+ from F-dUMP, and so

catalysis is blocked at the stage of the covalent complex formed by F-dUMP, methylenetetrahydrofolate, and the sulfhydryl group of the enzyme (Figure 26.14). We see here an example of suicide inhibition, in which an enzyme converts a substrate into a reactive inhibitor that halts the enzyme's catalytic activity.



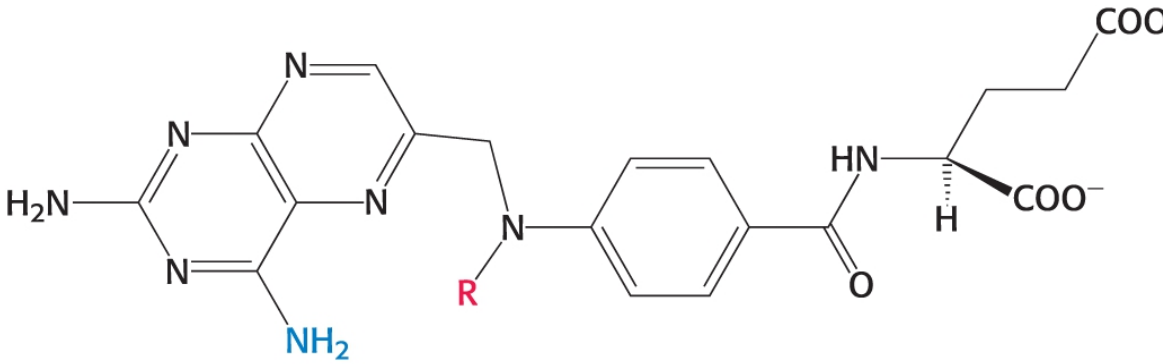


FIGURE 26.14 Fluoruracil acts by suicide inhibition. Fluorodeoxyuridylate (generated from fluorouracil) forms an adduct with tetrahydrofolate that traps thymidylate synthase in a form that cannot proceed down the reaction pathway.

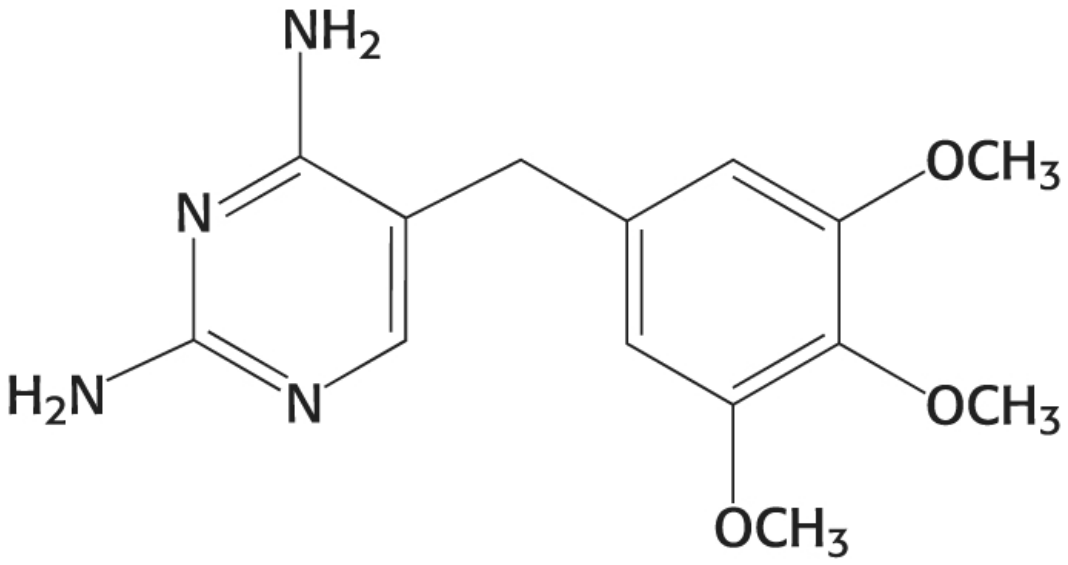
The synthesis of TMP can also be blocked by inhibiting the regeneration of tetrahydrofolate. Analogs of dihydrofolate, such as aminopterin and methotrexate (amethopterin), are potent competitive inhibitors ($K_i < 1$ nM) of dihydrofolate reductase.



Aminopterin (R = H) or methotrexate (R = CH_3)

Methotrexate is a valuable drug in the treatment of many rapidly growing tumors, such as those in acute leukemia and choriocarcinoma, a cancer derived from placental cells. However, methotrexate kills rapidly replicating cells whether they are malignant or not. Stem cells in bone marrow, epithelial cells of the intestinal tract, and hair follicles are vulnerable to the action of this folate antagonist, accounting for its toxic side effects, which include weakening of the immune system, nausea, and hair loss.

Folate analogs such as trimethoprim have potent antibacterial and antiprotozoal activity. Trimethoprim binds 10^5-fold less tightly to

mammalian dihydrofolate reductase than it does to reductases of susceptible microorganisms. Small differences in the active-site clefts of these enzymes account for the highly selective antimicrobial action. The combination of trimethoprim and sulfamethoxazole (an inhibitor of folate synthesis) is widely used to treat infections such as bronchitis, traveler's diarrhea, and urinary tract infections.

Trimethoprim

26.5 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition

Nucleotide biosynthesis is regulated by feedback inhibition in a manner similar to the regulation of amino acid biosynthesis. These regulatory pathways ensure that the various nucleotides are produced in the required quantities.

Pyrimidine biosynthesis is regulated by aspartate transcarbamoylase

Aspartate transcarbamoylase (ATCase), one of the key enzymes for the regulation of pyrimidine biosynthesis in bacteria, was described in detail in Chapter 7. Recall that ATCase is inhibited by CTP, the final product of pyrimidine biosynthesis, and stimulated by ATP.

The synthesis of purine nucleotides is controlled by feedback inhibition at several

sites

The regulatory scheme for purine nucleotides is more complex than that for pyrimidine nucleotides (Figure 26.15).

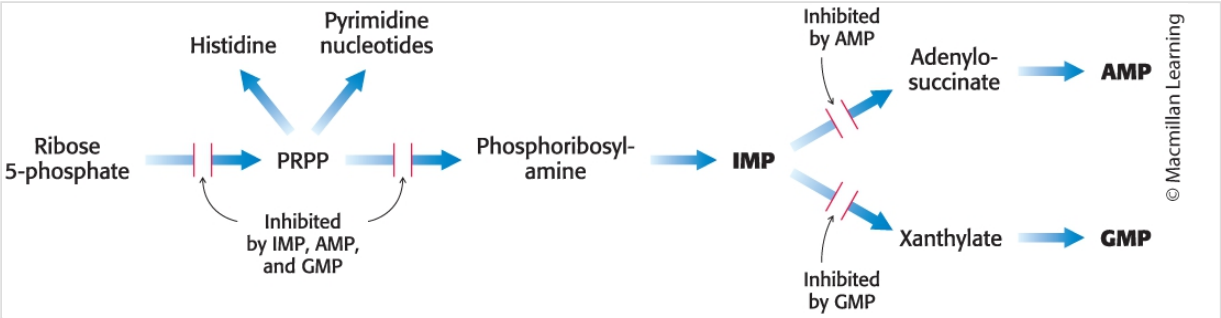


FIGURE 26.15 Purine biosynthesis is regulated at many steps. Feedback inhibition controls both the overall rate of purine biosynthesis and the balance between AMP and GMP production.

1. The committed step in purine nucleotide biosynthesis is the conversion of PRPP into phosphoribosylamine by glutamine phosphoribosyl amidotransferase. This important enzyme is feedback-inhibited by many purine ribonucleotides. It is noteworthy that AMP and GMP, the final products of the pathway, synergistically inhibit the amidotransferase.

2. Inosinate is the branch point in the synthesis of AMP and GMP. The reactions leading away from inosinate are sites of feedback inhibition. AMP inhibits the conversion of inosinate into adenylosuccinate, its immediate precursor. Similarly, GMP inhibits the conversion of inosinate into xanthylate, its immediate precursor.

3. As already noted, GTP is a substrate in the synthesis of AMP, whereas ATP is a substrate in the synthesis of GMP (Figure 26.7). This reciprocal substrate relation tends to balance the synthesis of adenine and guanine ribonucleotides.

Note that the synthesis of PRPP by PRPP synthetase is highly regulated even though it is not the committed step in purine synthesis. Mutations have been identified in PRPP synthetase that result in a loss of allosteric response to nucleotides without any effect on catalytic activity of the enzyme. A consequence of this mutation is an overabundance of purine nucleotides that can result in gout, a pathological condition discussed in Section 26.5.

Self-Check Question

Which enzyme catalyzes the committed step in the synthesis of pyrimidines? Which enzyme catalyzes the committed step in the synthesis of purines?

The synthesis of deoxyribonucleotides is controlled by the regulation of ribonucleotide reductase

The reduction of ribonucleotides to deoxyribonucleotides is precisely controlled by allosteric interactions. Each polypeptide of the R1 subunit of the aerobic *E. coli* ribonucleotide reductase contains two allosteric sites (**Figure 26.16**). One of them controls the overall activity of the enzyme, and the other regulates substrate specificity. The overall catalytic activity of ribonucleotide reductase is diminished by the binding of dATP, which signals an abundance of deoxyribonucleotides. The binding of ATP reverses this feedback inhibition.

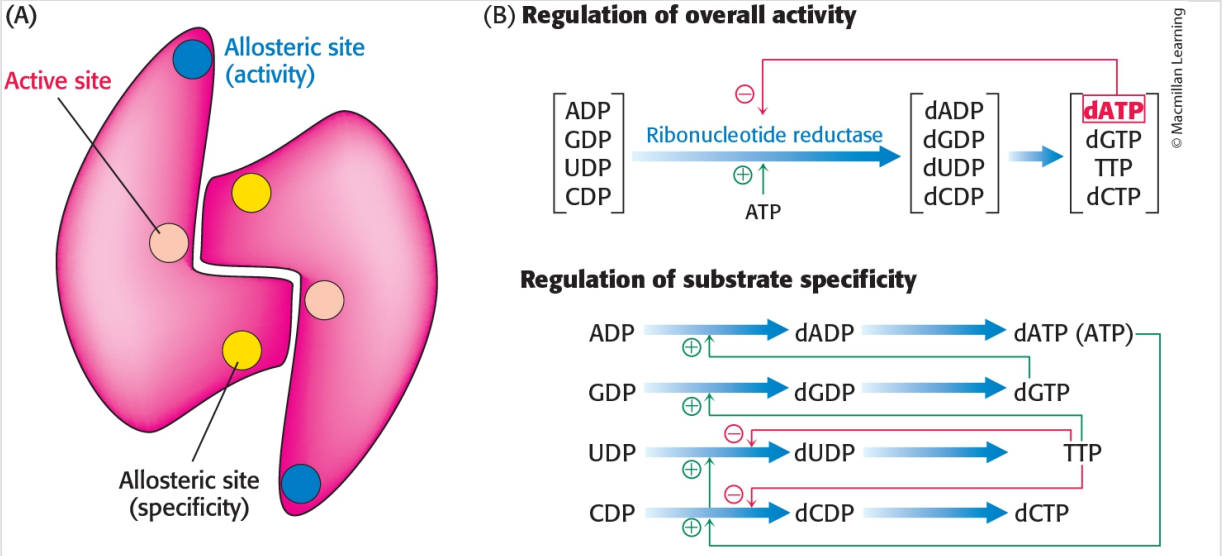

FIGURE 26.16 Ribonucleotide reductase is highly regulated to balance the pool of deoxyribonucleotides. (A) Each subunit in the R1 dimer contains two allosteric sites in addition to the active site. One site regulates the overall activity, and the other site regulates substrate specificity. (B) The patterns of regulation with regard to different nucleoside diphosphates are demonstrated by ribonucleotide reductase.

The binding of dATP or ATP to the substrate-specificity control site enhances the reduction of UDP and CDP, the pyrimidine nucleotides. The binding of thymidine triphosphate (TTP) promotes the reduction of GDP and inhibits the further reduction of pyrimidine ribonucleotides. The subsequent increase in the level of dGTP stimulates the reduction of ATP to dATP. This complex pattern of regulation supplies the appropriate balance of the four deoxyribonucleotides needed for the synthesis of DNA.

26.6 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

The nucleotides of a cell undergo continual turnover. This turnover facilitates the proper balance between ribo- and deoxyribonucleotides as well as the removal of damaged bases (Figure 26.17). This turnover begins with the hydrolytic conversion of nucleotides to nucleosides by nucleotidases. The sugars and bases are separated from one another by nucleoside phosphorylases in a reversible process. The free bases are then either reused to form nucleotides by salvage pathways or degraded to products that are excreted.

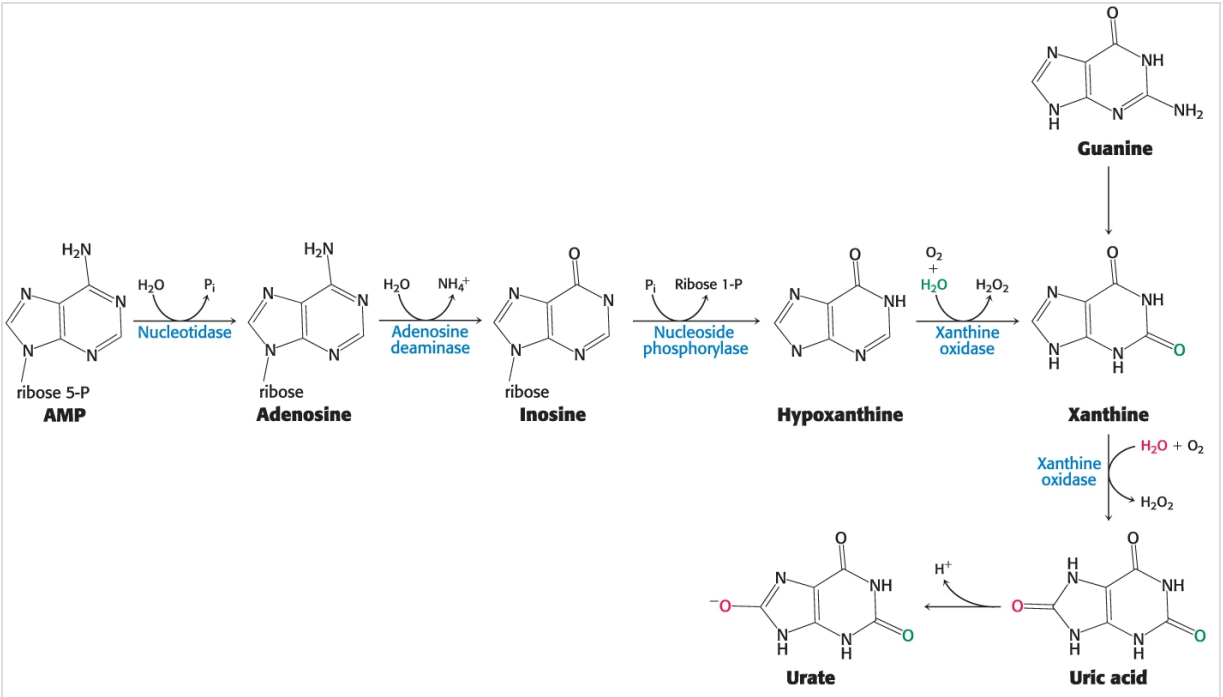

FIGURE 26.17 Purines are catabolized for excretion. Purine bases are converted first into xanthine and then into urate. Xanthine oxidase catalyzes two steps in this process.

The loss of adenosine deaminase activity results in severe combined immunodeficiency

Adenosine is not a substrate for nucleoside phosphorylases in eukaryotes, so that adenosine turnover requires an additional step compared to the turnover of guanosine. In the extra step, adenosine is deaminated by adenosine deaminase to form inosine (Figure 26.17).

A deficiency in adenosine deaminase activity is associated with some forms of **severe combined immunodeficiency (SCID)**, an immunological disorder. Persons with the disorder have acute recurring infections, often leading to death at an early age. SCID is characterized by a loss of T cells, which are crucial to the immune response. A lack of adenosine deaminase results in an accumulation of 50 to 100 times the normal level of dATP, which is toxic to many cells through a variety of mechanisms. Adenosine deaminase deficiency is one of the first conditions to be treated by gene therapy, and recent progress is encouraging.

Gout is induced by high serum levels of urate

Inosine generated by adenosine deaminase is subsequently metabolized by nucleoside phosphorylase to hypoxanthine, which is oxidized by xanthine oxidase — a molybdenum- and iron-containing flavoprotein — to xanthine, and then to uric acid. Uric acid loses a proton at physiological pH to form urate which, in human beings, is the final product of purine degradation and is excreted in the urine.

High serum levels of urate induce the painful joint disease **gout** as the sodium salt of urate crystallizes in the fluid and lining of the joints. The small joint at the base of the big toe is a common site for sodium urate buildup, although the salt also accumulates at other joints. Painful inflammation results when cells of the immune system engulf the sodium urate crystals. The kidneys, too, may be damaged by the deposition of urate crystals. Gout is a common medical problem, affecting 1% of the population of Western countries.

Administration of allopurinol, an analog of hypoxanthine, is one treatment for gout. The mechanism of action of allopurinol is interesting: it acts first as a substrate and then as an inhibitor of xanthine oxidase. The oxidase hydroxylates allopurinol to alloxanthine (oxipurinol), which then remains tightly bound to the active site. The binding of alloxanthine keeps the molybdenum atom of xanthine oxidase in the $^{+4}$ oxidation state instead of it returning to the $^{+6}$ oxidation state as in a normal catalytic cycle, another example of suicide inhibition. The synthesis of urate from hypoxanthine and xanthine decreases soon after the administration

of allopurinol. The serum concentrations of hypoxanthine and xanthine rise, and that of urate drops.

Allopurinol

The average serum level of urate in human beings is close to the solubility limit and is higher than levels found in other primates.

What is the selective advantage of a urate level so high that it teeters on the brink of gout in many people? It turns out that urate has a markedly beneficial action. Urate is a highly effective scavenger of reactive oxygen species. Indeed, urate is about as effective as ascorbate (vitamin C) as an antioxidant. The increased level of urate in human beings may protect against reactive oxygen species that are implicated in a host of pathological conditions.

Lesch–Nyhan syndrome is a dramatic consequence of mutations in a salvage-pathway enzyme

Mutations in genes that encode nucleotide biosynthetic enzymes can reduce levels of needed nucleotides and can lead to an accumulation of intermediates. A nearly total absence of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) has unexpected and devastating consequences. The most striking expression of this inborn error of metabolism, called **Lesch–Nyhan syndrome**, is compulsive, self-destructive behavior. At age 2 or 3, children with this disease begin to bite their fingers and lips and will chew them off if unrestrained. These children also behave aggressively toward others and often show cognitive disabilities and spasticity. Elevated levels of urate in the serum lead to the formation of kidney stones early in life, followed by the symptoms of gout years later. The disease is inherited as a sex-linked recessive disorder.

What is the connection between the absence of HGPRT activity and the behavioral characteristics of Lesch–Nyhan syndrome? The

answer has not been established, but several explanations may contribute. The brain has limited capacity for de novo purine synthesis. Consequently, lack of HGPRT results in a deficiency of purine nucleotides. ATP and ADP, formed from inosinate, are important in the brain as signal molecules. These nucleotides bind to and activate G-protein coupled receptors, which require guanine nucleotides to function. Finally, a cofactor required for dopamine biosynthesis is biosynthesized from GTP. Thus, the lack of HGPRT may result in an imbalance of key neurotransmitters and the pathways they stimulate. Lesch–Nyhan syndrome demonstrates that the salvage pathway for the synthesis of IMP and GMP is not of minor importance. Moreover, Lesch–Nyhan syndrome reveals that abnormal behavior such as self-mutilation and extreme hostility can be caused by the absence of a single enzyme. Psychiatry will no doubt benefit from the unraveling of the molecular basis of such disorders.

Chapter 26 Summary

26.1 Nucleotides Can Be Synthesized by de Novo or Salvage Pathways

- Nucleotide biosynthesis can be divided into either de novo pathways or salvage pathways.
- In de novo pathways, the nucleobases are synthesized from simpler compounds.
- In salvage pathways, pre-formed bases are recovered and reconnected to a ribose unit.

26.2 The Pyrimidine Ring Is Assembled from CO_2, Ammonia, and Aspartate

- In de novo synthesis, pyrimidine rings are first assembled, then attached to a ribose phosphate.
- 5-Phosphoribosyl-1-pyrophosphate is the donor of the ribose phosphate moiety.
- The synthesis of the pyrimidine ring starts with the formation of carbamoylaspartate from carbamoyl phosphate and aspartate, catalyzed by aspartate transcarbamoylase.
- Dehydration, cyclization, and oxidation yield orotate, which reacts with PRPP to give orotidylate, which serves as the precursor to the pyrimidine nucleotides.
- Nucleotide mono-, di-, and triphosphates are interconvertible by the action of nucleoside monophosphate kinases and nucleoside diphosphate kinase.

26.3 Purine Bases Can Be Synthesized from Glycine, Aspartate, and Other Components

- In the de novo pathway, the purine ring is assembled on ribose phosphate from glutamine, glycine, aspartate, N^{10}-formyltetrahydrofolate, and CO_2.
- The committed step in the de novo synthesis of purine nucleotides is the formation of 5-phosphoribosylamine from PRPP and glutamine.
- The purine ring is assembled over nine synthetic steps, predominantly using the activation of a carbon-bound oxygen atom by phosphorylation and subsequent displacement of an amino group.
- AMP and GMP are formed from IMP.

26.4 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides

- Deoxyribonucleotides, the precursors of DNA, are formed by the reduction of ribonucleoside diphosphates.
- These reactions are catalyzed by ribonucleotide reductases through a radical mechanism.
- TMP is formed by the methylation of dUMP by thymidylate synthase. This reaction oxidizes N^5,N^{10}-methylenetetrahydrofolate to dihydrofolate, which is regenerated by dihydrofolate reductase.
- Thymidylate synthase and dihydrofolate reductase are targets of various anticancer drugs.

26.5 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition

- Pyrimidine biosynthesis is regulated by the feedback inhibition of aspartate transcarbamoylase.
- Regulation of purine biosynthesis is more complex and includes the feedback inhibition of glutamine-PRPP amidotransferase by

purine nucleotides.
- The synthesis of deoxyribonucleotides is controlled by the regulation of ribonucleotide reductase at two allosteric sites: one controls overall enzyme activity, and another regulates substrate specificity.

26.6 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

- Severe combined immunodeficiency results from the absence of adenosine deaminase, an enzyme in the purine degradation pathway.
- Purines are degraded to urate in human beings. Gout, a disease that affects joints and leads to arthritis, is associated with an excessive accumulation of urate.
- Lesch–Nyhan syndrome, a genetic disease characterized by self-mutilation, cognitive disabilities, and gout, is caused by the absence of hypoxanthine-guanine phosphoribosyltransferase. This enzyme is essential for the synthesis of purine nucleotides by the salvage pathway.

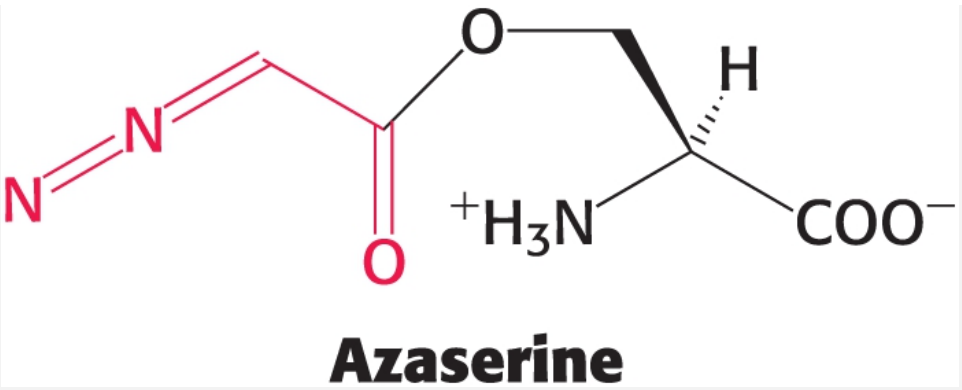
Key Terms

de novo pathway
salvage pathway
ATP-grasp fold
5-phosphoribosyl-1-pyrophosphate (PRPP)
orotidylate
purinosome
ribonucleotide reductase
thymidylate synthase
dihydrofolate reductase
severe combined immunodeficiency (SCID)

gout
Lesch–Nyhan syndrome

Problems

1. Differentiate between the de novo synthesis of nucleotides and salvage-pathway synthesis. 1



2. How many molecules of ATP are required to synthesize one molecule of CTP from scratch? 1

3. Write a balanced equation for the synthesis of orotate from glutamine, CO_2, and aspartate. 1

4. What is the activated reactant in the biosynthesis of each of the following compounds?

a. Phosphoribosylamine
b. Carbamoylaspartate
c. Orotidylate (from orotate)
d. Phosphoribosylanthranilate

5. Amidotransferases are inhibited by the antibiotic azaserine (*O*-diazoacetyl-L-serine), which is an analog of glutamine. 2

Azaserine

Which intermediates in purine biosynthesis would accumulate in cells treated with azaserine?

6. What intermediate in purine synthesis will accumulate if a strain of bacteria is lacking each of the following biochemicals? 2

a. Aspartate
b. Tetrahydrofolate
c. Glycine
d. Glutamine

7. What major biosynthetic reactions utilize PRPP?

8. Purine biosynthesis is allowed to take place in the presence of $[^{15}N]$ aspartate, and the newly synthesized GTP and ATP are isolated. What positions are labeled in the two nucleotides? 2

9. Write a balanced equation for the synthesis of TMP from dUMP that is coupled to the conversion of serine into glycine. 3

10. Arrange the steps to outline the mechanism by which ribonucleotide reductase converts a ribonucleotide to a deoxyribonucleotide. 3

a. $C-2'$ of the substrate releases an OH^-.
b. The tyrosyl radical on R2 accepts an electron from a cysteine on R1.
c. $C-2'$ accepts a hydride ion from a cysteine residue.
d. A hydrogen atom binds to $C-3'$ of the substrate.
e. The cysteine radical abstracts a hydrogen atom from $C-3'$ of the substrate, forming a radical.

11. Which of the following molecules are substrates of the ribonucleotide reductase reaction? Which are products? 3

a. ADP
b. CDP
c. dADP
d. dCTP

12. Both side-chain oxygen atoms of aspartate 27 at the active site of dihydrofolate reductase form hydrogen bonds with the pteridine ring of folates. The importance of this interaction was assessed by studying two mutants at this position, Asn 27 and Ser 27. The dissociation constant of methotrexate was 0.07 nM for the wild type, 1.9 nM for the Asn 27 mutant, and 210 nM for the Ser 27 mutant, at 25°C. Calculate the standard free energy of the binding of methotrexate by these three proteins. What is the decrease in binding energy resulting from each mutation? 3

13. Which nucleoside triphosphate regulates aspartate transcarbamoylase (ATCase) by feedback inhibition? Which one acts as an allosteric activator of ATCase? 4

14. Which of the following statements correctly describe the regulatory steps of purine synthesis? 4

a. The committed step in purine synthesis is the conversion of PRPP into phosphoribosylamine.
b. Inosinate is the branch point in the synthesis of inhibitors AMP and GMP.
c. The final reaction in purine synthesis, the generation of either AMP or IMP, is the rate-limiting step.
d. AMP is a feedback inhibitor, regulating the conversion of inosinate into xanthylate, its immediate precursor.
e. ATP is not required for the synthesis of GMP.

15. Which two nucleoside triphosphates bind to the allosteric site of the ribonucleotide reductase R1 subunit that controls overall enzyme activity? 4

16. Identify the correct statements about Lesch–Nyhan syndrome. 5

a. This deficiency does not allow purine nucleotide production via the salvage pathway.
b. This syndrome is caused by a deficiency in PRPP.
c. Some symptoms of Lesch–Nyhan syndrome include involuntary movements and self-mutilation.
d. Gout causes Lesch–Nyhan syndrome.

17. In humans, the multifunctional enzyme uridine 5′-monophosphate (UMP) synthase has orotate phosphoribosyltransferase and orotidylate decarboxylase activity. Both enzymatic functions are impaired in patients

with orotic aciduria. Which substance is present in high levels in the urine of these patients? 5

a. Carbamate
b. Carbamoyl phosphate
c. Uridylate (UMP)
d. Orotate
e. Orotidylate

18. Suppose that a person is found who is deficient in an enzyme required for IMP synthesis. How might this person be treated? 5

19. Mutant cells unable to synthesize nucleotides by salvage pathways are very useful tools in molecular and cell biology. Suppose that cell A lacks thymidine kinase, the enzyme catalyzing the phosphorylation of thymidine to thymidylate, and that cell B lacks hypoxanthine-guanine phosphoribosyl transferase.

a. Cell A and cell B do not proliferate in a HAT medium containing hypoxanthine, aminopterin or amethopterin (methotrexate), and thymine. However, cell C, formed by the fusion of cells A and B, grows in this medium. Why?
b. Suppose that you want to introduce foreign genes into cell A. Devise a simple means of distinguishing between cells that have taken up foreign DNA and those that have not.

CHAPTER 27
Biosynthesis of Membrane Lipids and Steroids

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the relationship between triacylglycerol synthesis and phospholipid synthesis.
2. Describe the three stages of cholesterol biosynthesis.
3. Identify the regulatory processes controlling cholesterol synthesis.
4. Describe some important molecules synthesized from cholesterol precursors and from cholesterol.

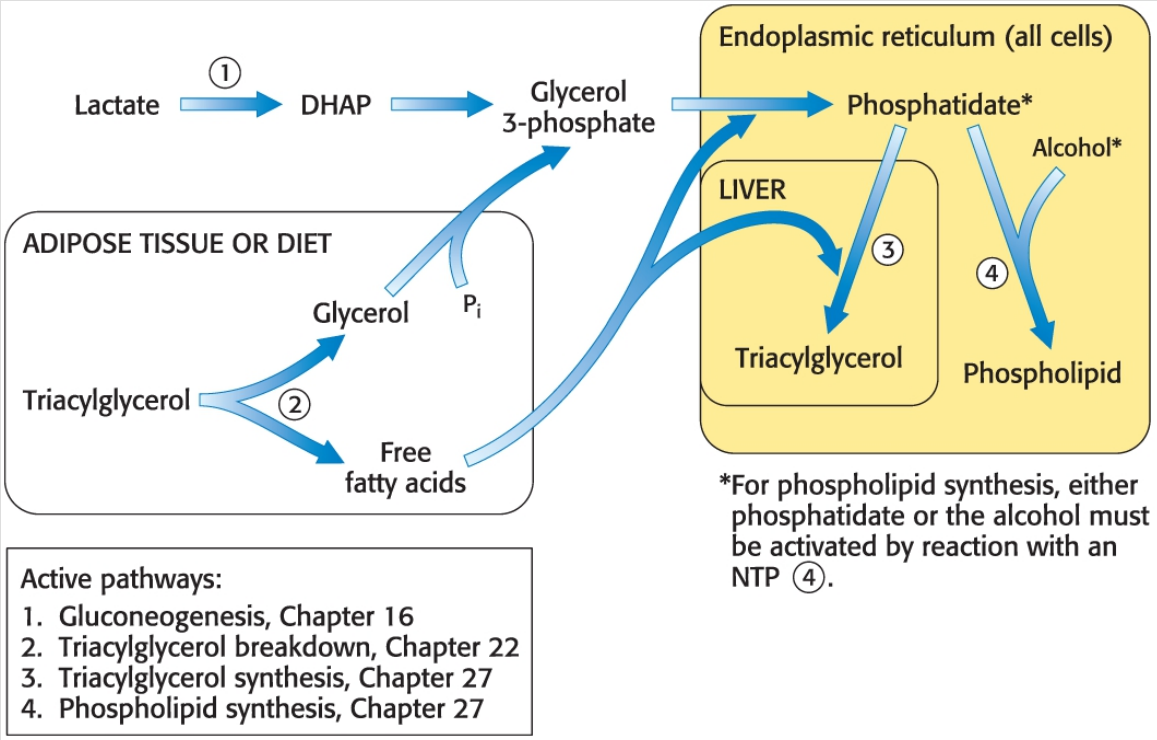
Living cells must replenish their cell membranes and enlarge them when growing and dividing. Furthermore, even seemingly minor variations in lipid structure are associated with participation in different functions, including intracellular and intercellular signaling. Thus, the pathways by which lipids are made and interconverted are of considerable interest.

This chapter examines the biosynthesis of three important components of biological membranes — phospholipids, sphingolipids, and cholesterol. Triacylglycerols also are considered here because the pathway for their synthesis overlaps that of phospholipids. Cholesterol is of interest both as a membrane component and as a precursor of potent signaling molecules, such as the steroid hormones estradiol, testosterone, progesterone, and cortisol. Knowledge of these biosynthetic pathways, particularly that

for cholesterol, has been of great importance for drug development and understanding the mechanisms of drug action.

27.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols

Lipid synthesis requires the coordinated action of gluconeogenesis and fatty acid metabolism (Figure 27.1). The common step in the synthesis of both phospholipids for membranes and triacylglycerols for energy storage is the formation of **phosphatidate** (diacylglycerol 3-phosphate). In mammalian cells, phosphatidate is synthesized in the endoplasmic reticulum and the outer mitochondrial membrane.



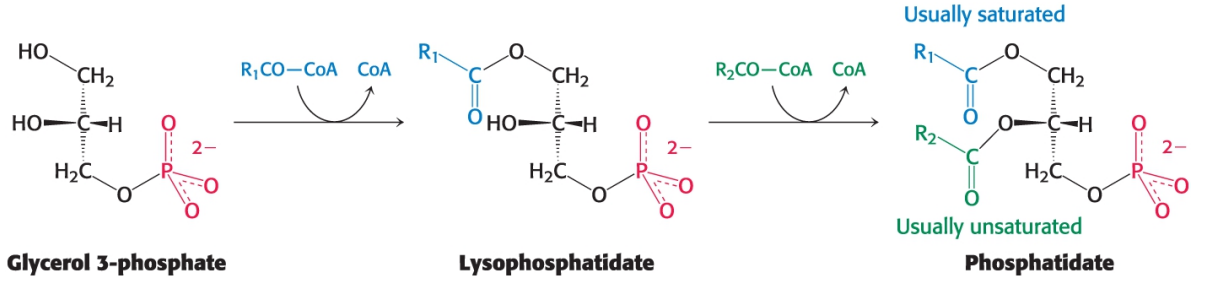


FIGURE 27.1 Phosphatidate is a key intermediate in lipid biosynthesis. Phosphatidate, synthesized from dihydroxyacetone phosphate (DHAP) produced in gluconeogenesis and fatty acids, can be further processed to produce triacylglycerol or phospholipids. Phospholipids and other membrane lipids are continuously produced in all cells.

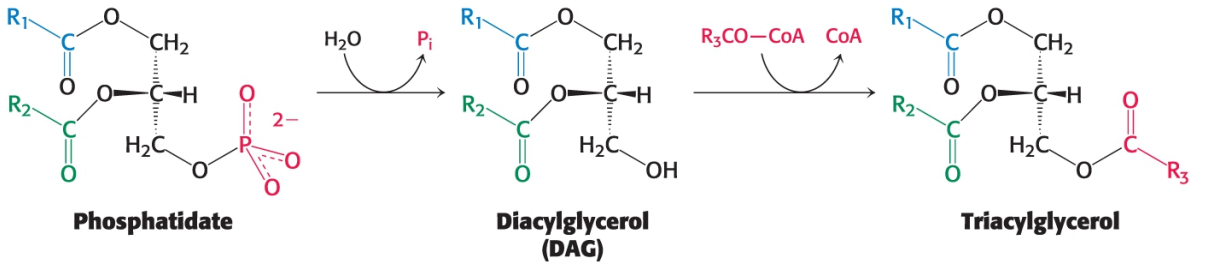
EXPLORE this pathway further in the Metabolic Map in Achieve



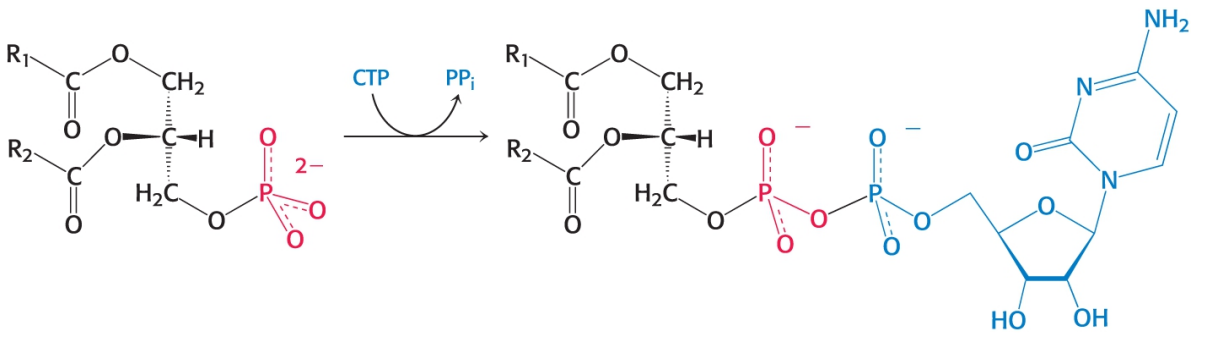
The pathway for the biosynthesis of phosphatidate begins with glycerol 3-phosphate, which is formed primarily by the reduction of dihydroxyacetone phosphate (DHAP) synthesized by the gluconeogenic pathway, and to a lesser extent by the phosphorylation of glycerol. The addition of two fatty acids to glycerol-3-phosphate yields phosphatidate. First, acyl coenzyme A contributes a fatty acid chain to form lysophosphatidate, and then a second acyl CoA contributes a fatty acid chain to yield phosphatidate.

These acylations are catalyzed by glycerol phosphate acyltransferase. In most phosphatidates, the fatty acid chain attached to the C-1 atom is saturated, whereas the one attached to the C-2 atom is unsaturated. Phosphatidate can also be synthesized from diacylglycerol (DAG), in what is essentially a salvage pathway, by the action of diacylglycerol kinase:

Diacylglycerol + ATP → phosphatidate + ADP

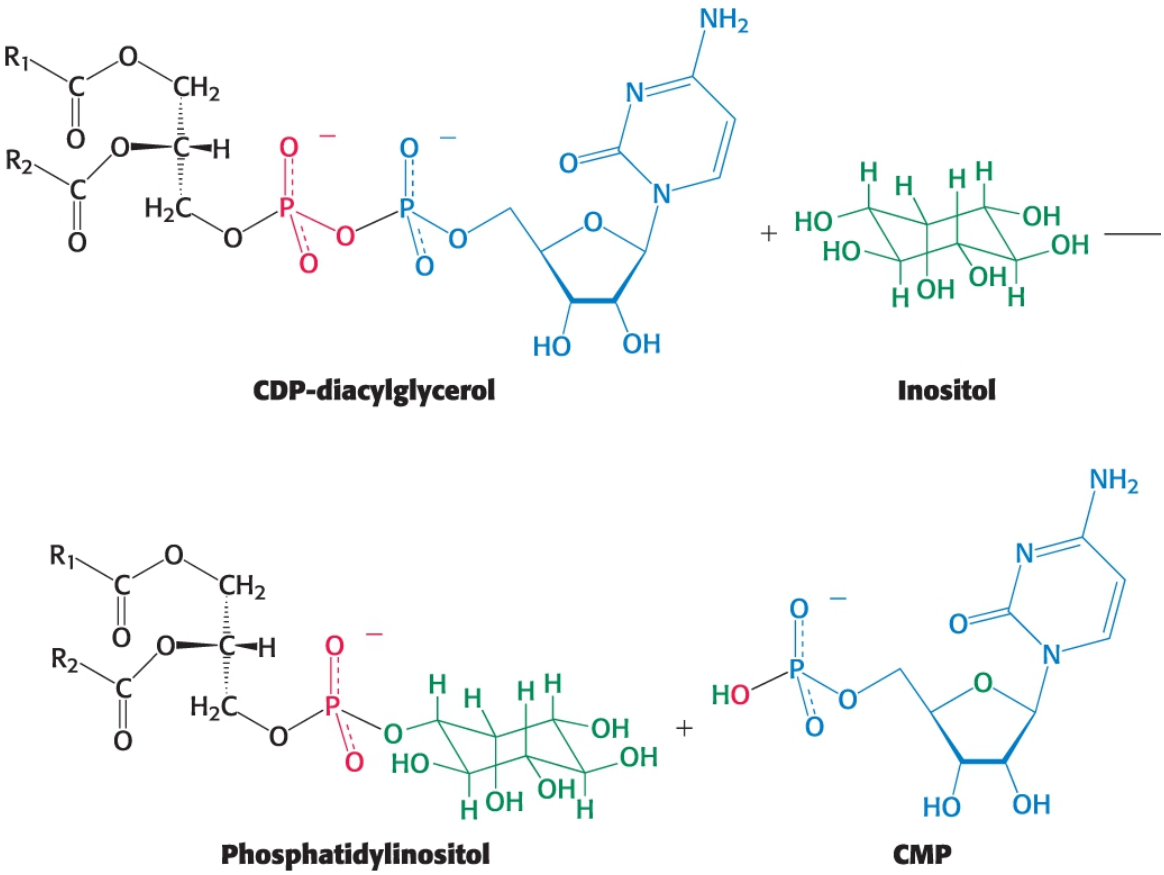
The phospholipid and triacylglycerol pathways diverge at phosphatidate. In the synthesis of triacylglycerols, a key enzyme in the regulation of lipid synthesis, phosphatidic acid phosphatase, hydrolyzes phosphatidate to give a diacylglycerol. This intermediate is acylated to a **triacylglycerol** through the addition of a third fatty acid chain in a reaction that is catalyzed by diglyceride acyltransferase. Both enzymes are associated in a triacylglycerol synthetase complex that is bound to the endoplasmic reticulum membrane.

The liver is the primary site of triacylglycerol synthesis. From the liver, the triacylglycerols are transported to the muscles for energy conversion or to the adipose cells for storage.



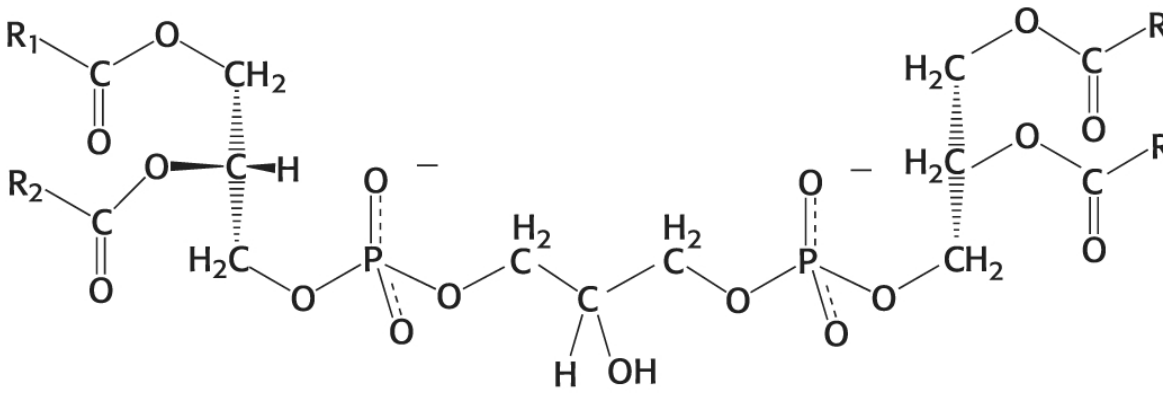
Self-Check Question

You find two samples labeled “Pure phosphatidic acid” but discover that the two samples have slightly different properties including different molecular weights. Explain.



The synthesis of phospholipids requires an activated intermediate

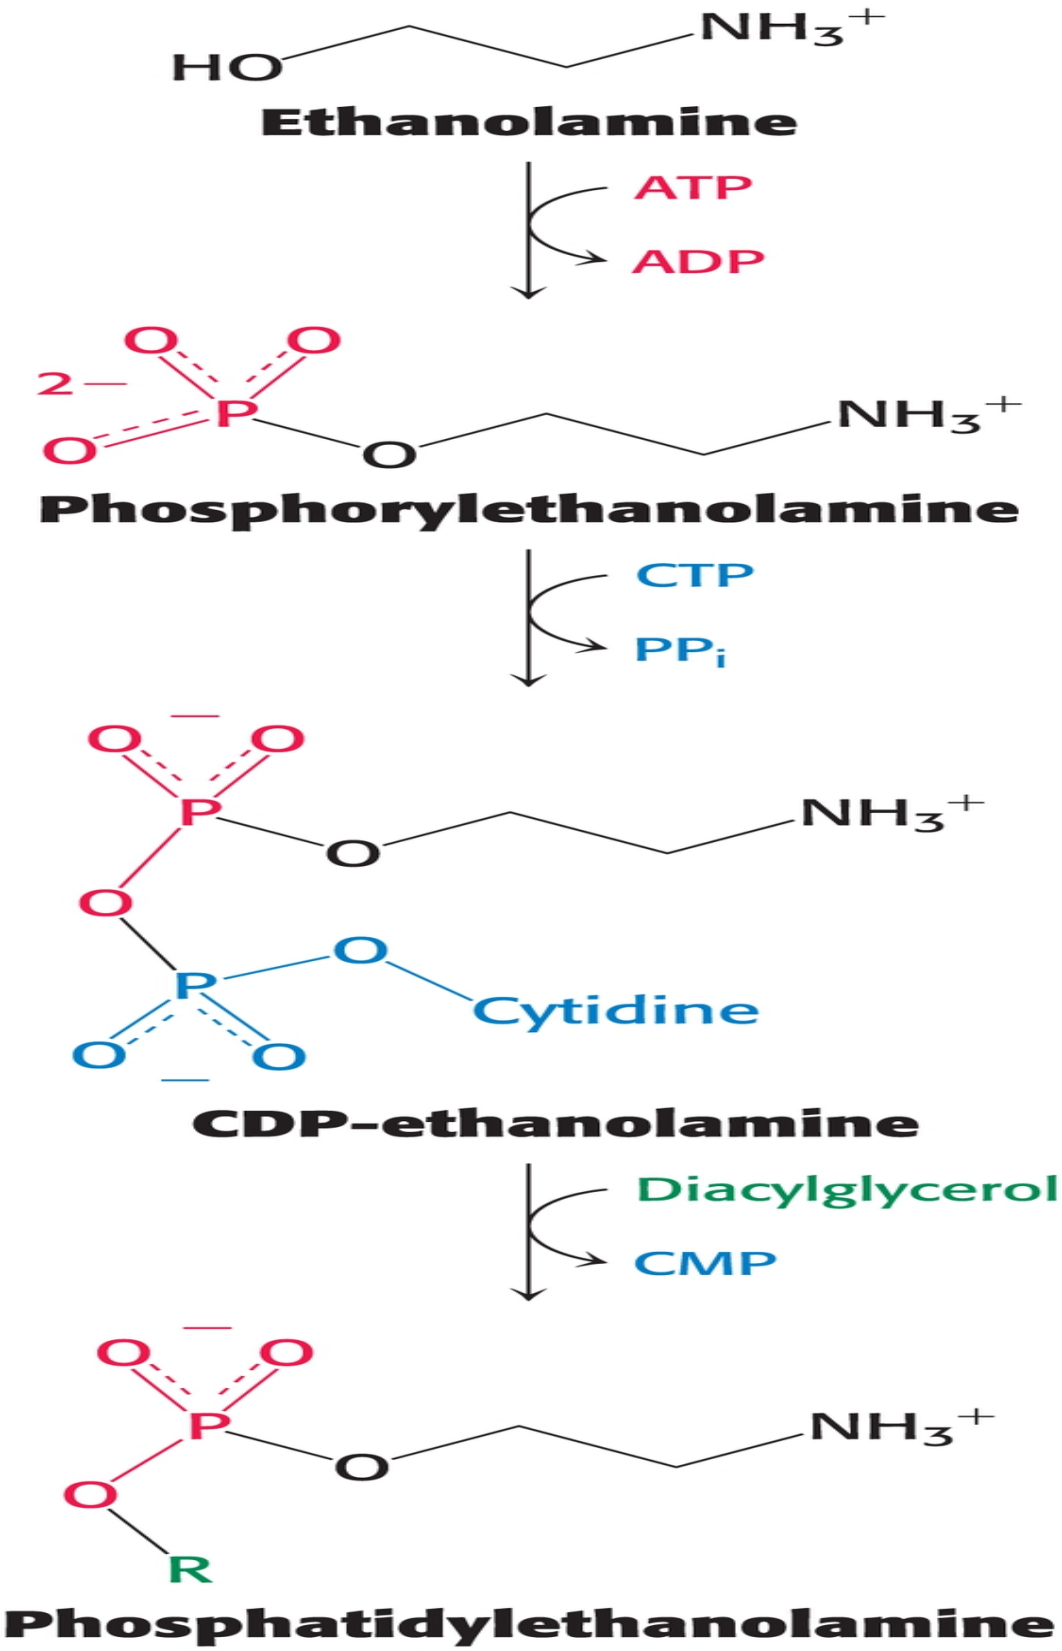
Membrane-lipid synthesis continues in the endoplasmic reticulum and in the Golgi apparatus. Phospholipid synthesis requires the combination of a diacylglycerol with an alcohol. As in most anabolic reactions, one of the components must be activated. In this case, either the diacylglycerol or the alcohol may be activated, depending on the source of the reactants.



The synthesis of some phospholipids begins with the reaction of phosphatidate with cytidine triphosphate (CTP) to form the activated diacylglycerol, **cytidine diphosphodiacylglycerol (CDP-diacylglycerol)**. This reaction, like those of many biosyntheses, is driven forward by the hydrolysis of pyrophosphate.

The activated phosphatidyl unit then reacts with the hydroxyl group of an alcohol to form a phosphodiester linkage. If the alcohol is inositol, the products are phosphatidylinositol and cytidine monophosphate (CMP).

Subsequent phosphorylations catalyzed by specific kinases lead to the synthesis of phosphatidylinositol 4,5-bisphosphate, the precursor of two intracellular messengers — diacylglycerol and inositol 1,4,5-trisphosphate. If the alcohol is phosphatidylglycerol, the products are diphosphatidylglycerol (cardiolipin) and CMP. In eukaryotes, cardiolipin is synthesized in the mitochondria and is located exclusively in inner mitochondrial membranes.

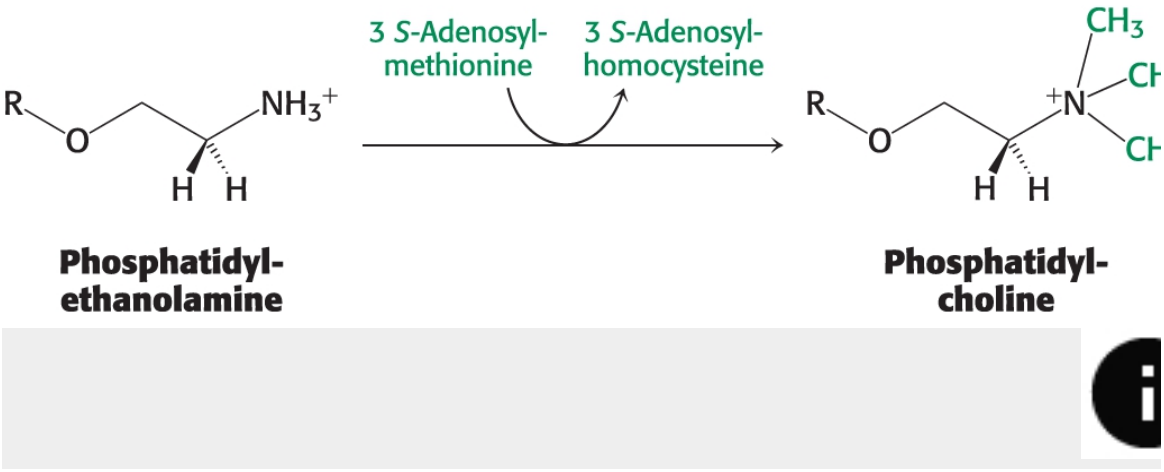


Diphosphatidylglycerol (Cardiolipin)

Cardiolipin is abundant in the inner membrane of mitochondria and plays an important role in the organization of the protein components participating in oxidative phosphorylation. Scientists have also discovered that cardiolipin facilitates the proper folding of α-synuclein in nerve cells. Misfolding of α-synuclein causes the formation of aggregates that are toxic. These α-synuclein deposits are believed to play a role in the development of Parkinson's disease.

The fatty acid components of phospholipids may vary, and thus cardiolipin, as well as most other phospholipids, represents a class of molecules rather than a single species. As a result, a single mammalian cell may contain thousands of distinct phospholipids. Phosphatidylinositol is unusual in that it has a nearly fixed fatty acid composition. Stearic acid usually occupies the C-1 position and arachidonic acid the C-2 position.

Some phospholipids are synthesized from an activated alcohol



Phosphatidylethanolamine, the major phospholipid of the inner leaflet of cell membranes, is synthesized from the alcohol ethanolamine. To activate the alcohol, ethanolamine is phosphorylated by ATP to form the precursor, phosphorylethanolamine. This precursor then reacts with CTP to form the activated alcohol, CDP-ethanolamine. The phosphorylethanolamine unit of CDP-ethanolamine is transferred to a diacylglycerol to form phosphatidylethanolamine.

Phosphatidylcholine is an abundant phospholipid

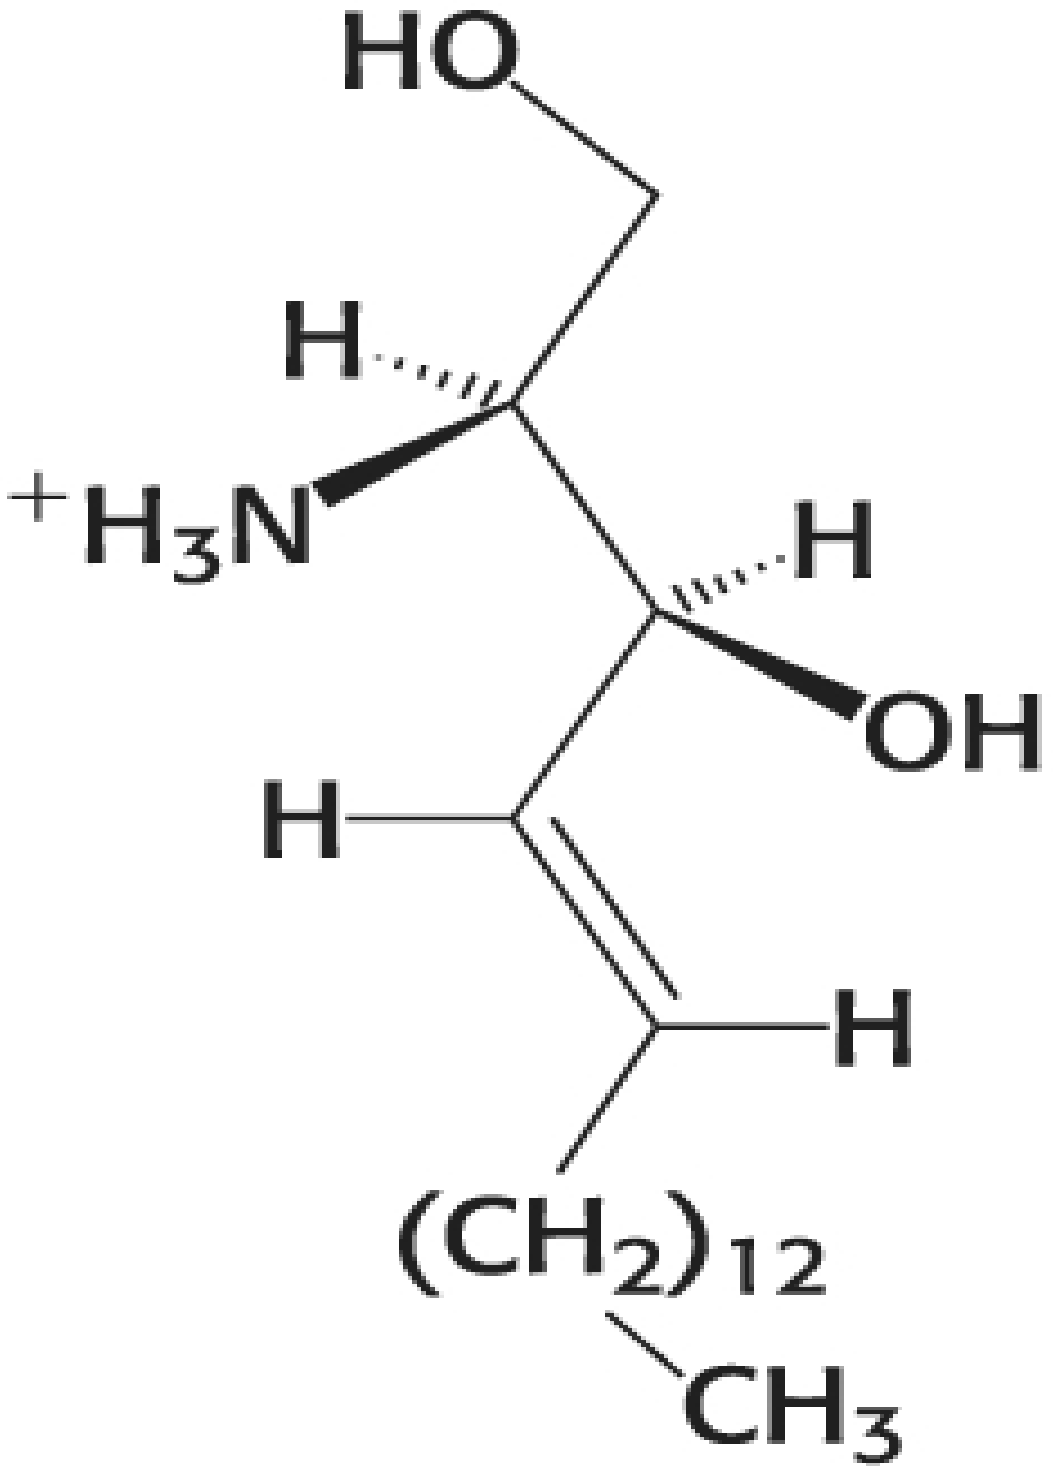
The most common phospholipid in mammals is phosphatidylcholine, comprising approximately 50% of the membrane mass. Dietary choline is activated in a series of reactions analogous to those in the activation of ethanolamine. CTP-phosphocholine cytidylyltransferase (CCT) catalyzes the formation of CDP-choline, the rate-limiting step in phosphatidylcholine synthesis. CCT is termed an *amphitropic enzyme* — a class of enzymes whose regulator ligand is the membrane itself. A portion of the enzyme, normally associated with the membrane, is sensitive to a decrease in phosphatidylcholine concentration as an alteration in the physical properties of the membrane. When this occurs, another portion of the enzyme inserts into the membrane, leading to enzyme activation. Indeed, the k_{cat}/K_M value increases by three orders of magnitude upon activation, contributing to the restoration of phosphatidylcholine levels.

The liver also possesses an enzyme, phosphatidylethanolamine methyltransferase, which synthesizes phosphatidylcholine from phosphatidylethanolamine when dietary choline is insufficient, a testament to the importance of this vital phospholipid. The amino group of this phosphatidylethanolamine is methylated three times to form phosphatidylcholine. *S*-adenosylmethionine is the methyl donor.

Thus, phosphatidylcholine can be produced by two distinct pathways in mammals, ensuring that this phospholipid can be synthesized even if the components for one pathway are in limited supply.

Base-exchange reactions can generate phospholipids

Phosphatidylserine makes up 10% of the phospholipids in mammals. This phospholipid is synthesized in a base-exchange reaction of serine with phosphatidylcholine or phosphatidylethanolamine. In the reaction, serine replaces choline or ethanolamine.



Phosphatidylcholine + serine → choline + phosphatidylserine
Phosphatidylethanolamine + serine → ethanolamine + phosphatidylserine

Phosphatidylserine is normally located in the inner leaflet of the plasma membrane bilayer but is moved to the outer leaflet in apoptosis. There, it serves to attract phagocytes to consume the cell remnants after apoptosis is complete. Phosphatidylserine is translocated from one side of the membrane to the other by an ATP-binding cassette translocase.

Note that a cytidine nucleotide plays the same role in the synthesis of these phosphoglycerides as a uridine nucleotide does in the formation of glycogen (Section 21.4). In all of these biosyntheses, an activated intermediate (UDP-glucose, CDP-diacylglycerol, or CDP-alcohol) is formed from a phosphorylated substrate (glucose 1-phosphate, phosphatidate, or a phosphorylalcohol) and a nucleoside triphosphate (UTP or CTP). The activated intermediate then reacts with a hydroxyl group (the terminus of glycogen, an alcohol, or a diacylglycerol).

Sphingolipids are synthesized from ceramide

We now turn from glycerol-based phospholipids to another class of membrane lipid — the **sphingolipids**. These lipids are found in the plasma membranes of all eukaryotic cells, although the concentration is highest in the cells of the central nervous system. The backbone of a sphingolipid is sphingosine rather than glycerol.

Sphingosine

Palmitoyl CoA and serine condense to form 3-ketosphinganine. The serine–palmitoyl transferase catalyzing this reaction is the rate-limiting step in the pathway and requires pyridoxal phosphate; this reveals again the dominant role of this cofactor in transformations that include amino acids. Ketosphinganine is then reduced to dihydrosphingosine before conversion into **ceramide**, a lipid consisting of a fatty acid chain attached to the amino group of a sphingosine backbone (**Figure 27.2**).

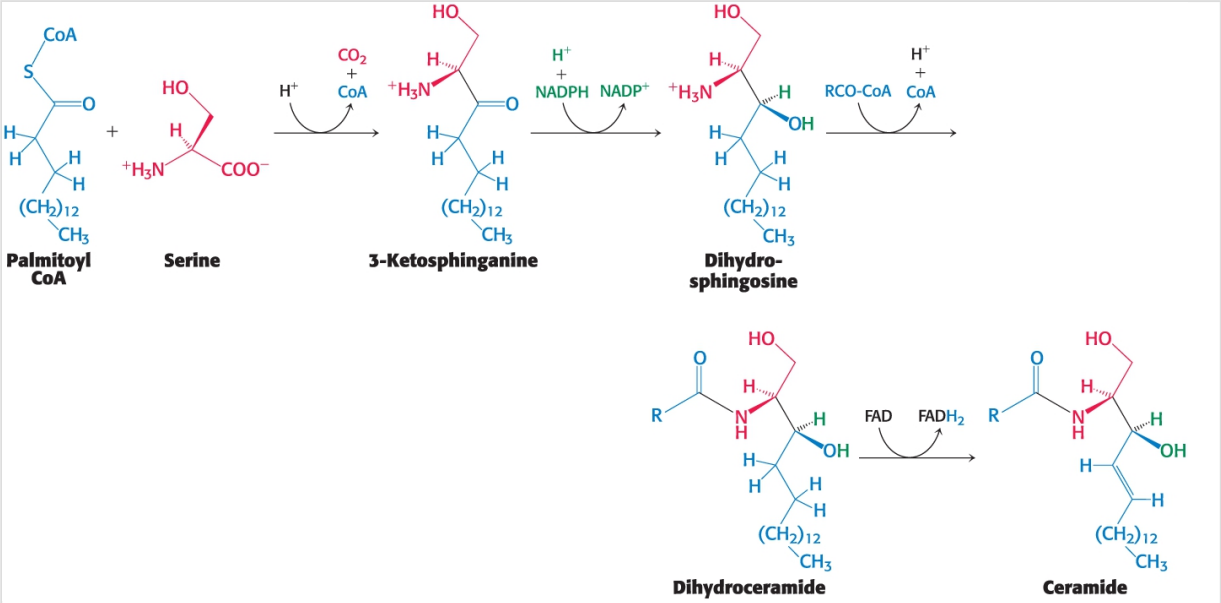


FIGURE 27.2 Biosynthesis of ceramide involves four steps. Palmitoyl CoA and serine combine to initiate the synthesis of ceramide. The product is further elaborated with the incorporation of an additional fatty acid chain and the introduction of a carbon–carbon double bond.

In all sphingolipids, the amino group of ceramide is acylated. The terminal hydroxyl group also is substituted. In sphingomyelin, a component of the myelin sheath covering many nerve fibers, the substituent is phosphorylcholine, which comes from

phosphatidylcholine. In a cerebroside, the substituent is glucose or galactose. UDP-glucose or UDP-galactose is the sugar donor.

Gangliosides are the most complex sphingolipids. In a ganglioside, an oligosaccharide chain is linked to the terminal hydroxyl group of ceramide by a glucose residue (Figure 27.3). This oligosaccharide chain contains at least one acidic sugar, either *N*-acetylneuraminate or *N*-glycolylneuraminate. These acidic sugars are called *sialic acids*. Their nine-carbon backbones are synthesized from phosphoenolpyruvate (a three-carbon unit) and *N*-acetylmannosamine 6-phosphate (a six-carbon unit).

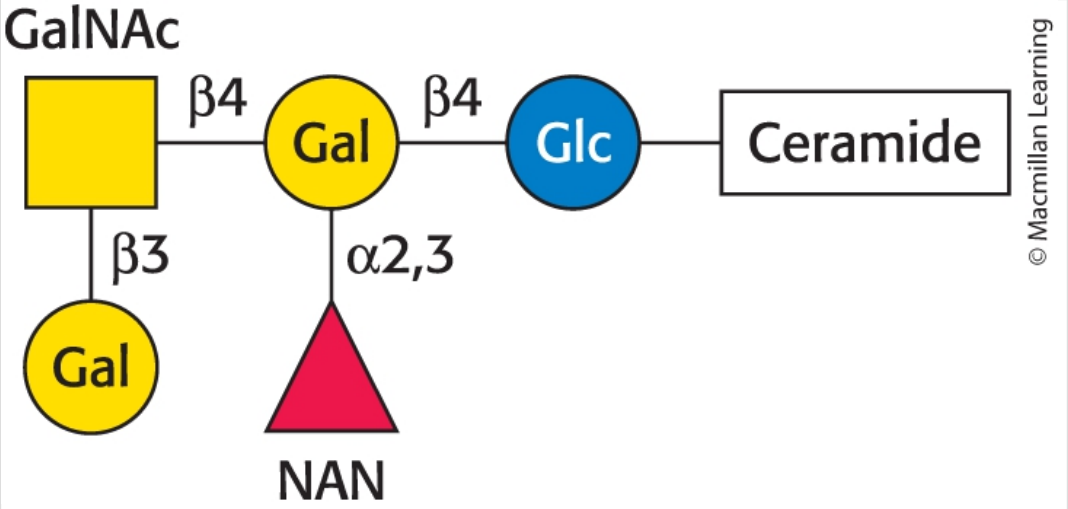

FIGURE 27.3 The ganglioside G_{M1} consists of five monosaccharides linked to ceramide. These sugars include one glucose (Glc) molecule, two galactose (Gal) molecules, one *N*-acetylgalactosamine (GalNAc) molecule, and one *N*-acetylneuraminate (NAN) molecule.

Gangliosides are synthesized by the ordered, step-by-step addition of sugar residues to ceramide (Figure 27.4). The synthesis of these complex lipids requires the activated sugars UDP-glucose, UDP-galactose, and UDP-*N*-acetylgalactosamine, as well as the CMP

derivative of *N*-acetylneuraminate. CMP-*N*-acetylneuraminate is synthesized from CTP and *N*-acetylneuraminate. The sugar composition of the resulting ganglioside is determined by the specificity of the glycosyltransferases in the cell. Almost 200 different gangliosides have been characterized.

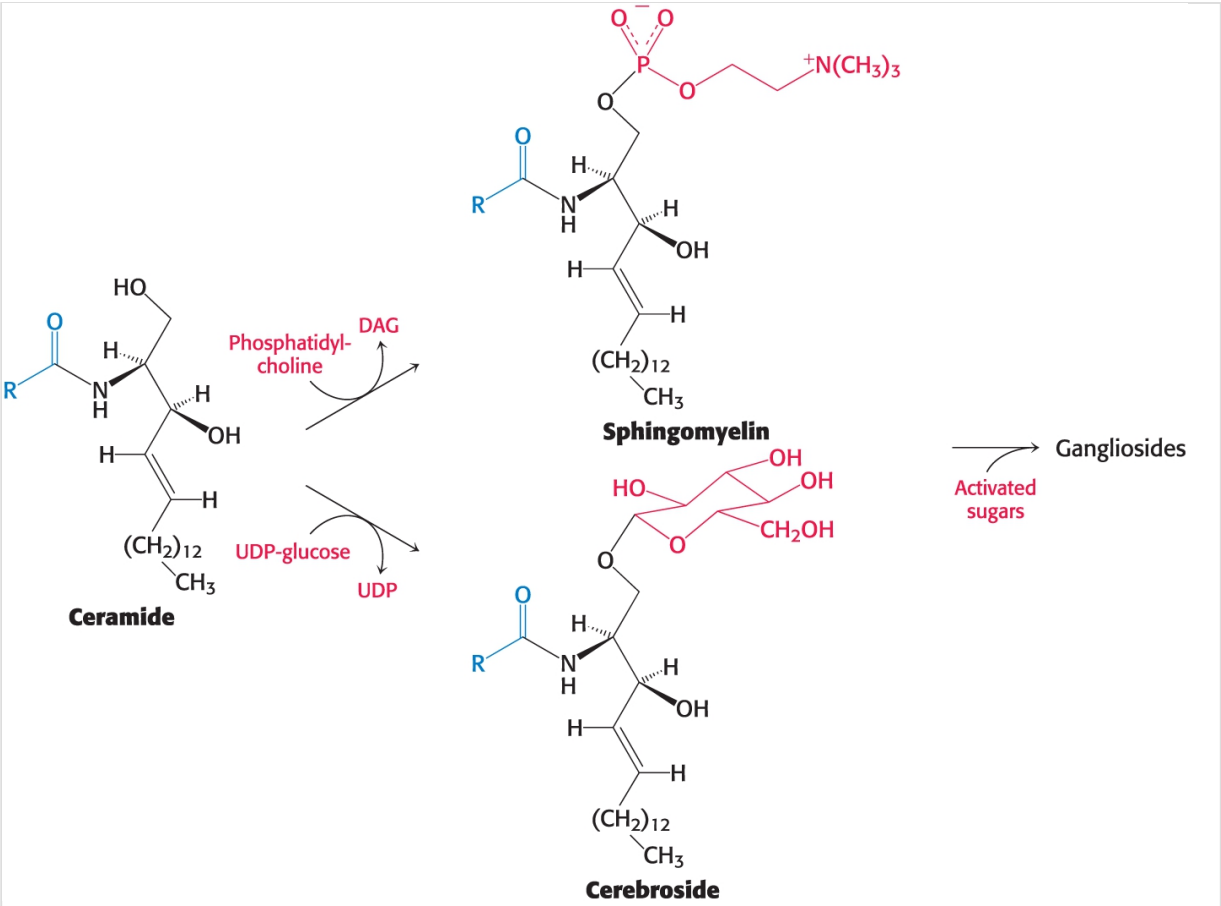

FIGURE 27.4 Ceramide can be converted into sphingomyelin, cerebroside, and gangliosides.

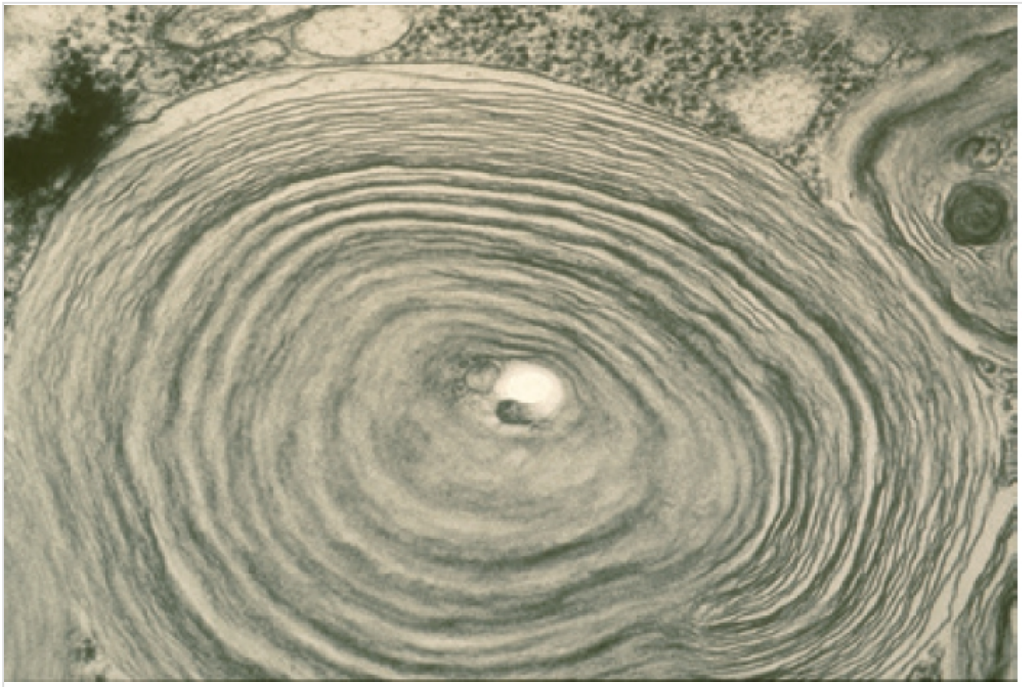
Tay–Sachs disease results from the disruption of lipid metabolism

Tay–Sachs disease is caused by a failure of lipid degradation: an inability to degrade gangliosides. Gangliosides are found in highest concentration in the nervous system, particularly in gray matter, where they constitute 6% of the lipids. Gangliosides are normally degraded inside lysosomes by the sequential removal of their terminal sugars, but in Tay–Sachs disease this degradation does not take place. As a consequence, neurons become significantly swollen with lipid-filled lysosomes (Figure 27.5). An affected infant displays weakness and limited psychomotor skills before 1 year of age and usually dies before age 3.



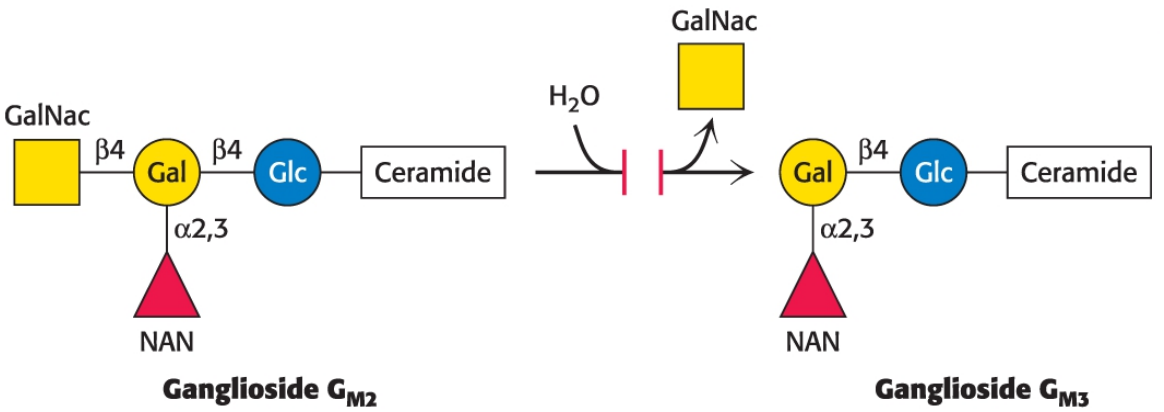


Photo Credit: Science Photo Library/Science Source

FIGURE 27.5 Lysosome sometimes will fill up with lipids. An electron micrograph shows a lysosome engorged with lipids. Such lysosomes are sometimes described as being “onion-skin” like because the layers of undigested lipids resemble a sliced onion.

The ganglioside content of the brain of an infant with Tay–Sachs disease is greatly elevated. The concentration of ganglioside G_{M2} is many times higher than normal because its terminal *N*-acetylgalactosamine residue is removed very slowly or not at all. The missing or deficient enzyme is a specific β-*N*-acetylhexosaminidase.

Carriers of Tay–Sachs can be identified by genetic testing. Moreover, Tay–Sachs disease can be diagnosed in the course of fetal development. Cells obtained from either the villi of the placenta (chorionic villus sampling) or from the amniotic fluid (amniocentesis) are tested for the presence of the defective gene. Tay–Sachs disease was especially prominent among Ashkenazi Jews (descendants of Jews from central and eastern Europe). Genetic testing programs, initiated in the early 1970s upon the development of a simple blood test to identify carriers, have dramatically reduced the incidence of the disease in this population.

Phosphatidic acid phosphatase is a key regulatory enzyme in lipid metabolism

The enzyme phosphatidic acid phosphatase (PAP), working in concert with diacylglycerol kinase, plays a key role in the regulation of lipid synthesis. PAP, also called *lipin 1* in mammals, controls the extent to which triacylglycerols are synthesized relative to phospholipids and regulates the type of phospholipid synthesized (Figure 27.6). For instance, when PAP activity is high, phosphatidate is dephosphorylated and diacylglycerol is produced, which can react with the appropriate activated alcohols to yield phosphatidylethanolamine, phosphatidylserine, or phosphatidylcholine. Diacylglycerol can also be converted into triacylglycerols. Evidence suggests that the formation of triacylglycerols may act as a fatty acid buffer. This buffering helps to regulate the levels of diacylglycerol and sphingolipids, which serve signaling functions.

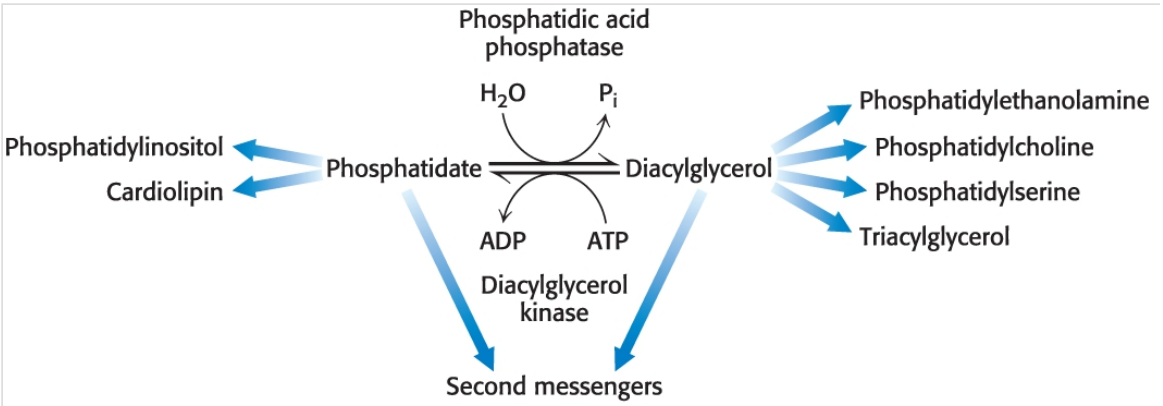

FIGURE 27.6 Phosphatidic acid phosphatase is a key regulatory enzyme in lipid synthesis. When active, PAP generates diacylglycerol (DAG), which can react with activated alcohols to for phospholipids or with fatty acyl CoA to form triacylglycerols. When PAP is inactive, phosphatidate is converted into CMP-DAG for the synthesis of different phospholipids. PAP also controls the amount of DAG and phosphatidate, both of which function as second messengers.

EXPLORE this pathway further in the Metabolic Map in Achieve

When PAP activity is lower, phosphatidate is used as a precursor for different phospholipids, such as phosphatidylinositol and cardiolipin. Moreover, phosphatidate is a signal molecule itself. Phosphatidate regulates the growth of endoplasmic reticulum and nuclear membranes and acts as a cofactor that stimulates the expression of genes in phospholipid synthesis.

27.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages

We now turn our attention to the synthesis of the fundamental lipid **cholesterol**. This steroid modulates the fluidity of animal cell membranes and is the precursor of steroid hormones such as progesterone, testosterone, estradiol, and cortisol. All 27 carbon atoms of cholesterol are derived from acetyl CoA in a three-stage synthetic process (**Figure 27.7**). The first stage takes place in the cytoplasm, and the next two in the endoplasmic reticulum.

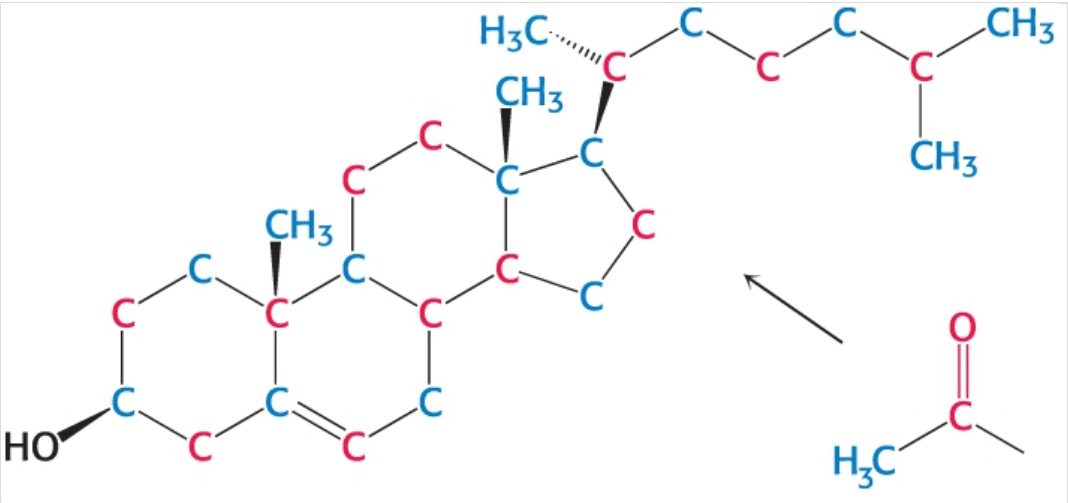

FIGURE 27.7 Isotope-labeling experiments have revealed the source of carbon atoms in cholesterol synthesized from acetate. In this depiction, the source of carbons from acetate's methyl group are shown in blue; carbons from acetate's carboxylate group are shown in red.

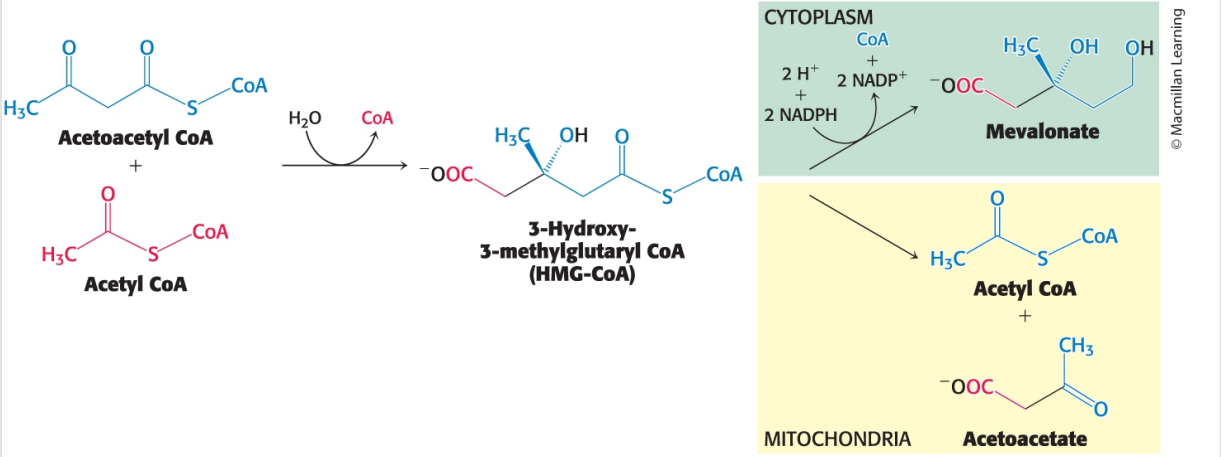
Stage 1: The synthesis of mevalonate initiates the synthesis of cholesterol

The first stage in the synthesis of cholesterol is the formation of isopentenyl pyrophosphate from acetyl CoA. This set of reactions starts with the formation of 3-hydroxy-3-methylglutaryl CoA (HMG CoA) from acetyl CoA and acetoacetyl CoA. This intermediate is reduced to **mevalonate** for the synthesis of cholesterol (**Figure 27.8**). Recall that, alternatively, 3-hydroxy-3-methylglutaryl CoA may be generated in the mitochondria and processed to form ketone bodies, which are subsequently secreted to provide fuel for other tissues, notably the brain under starvation conditions.



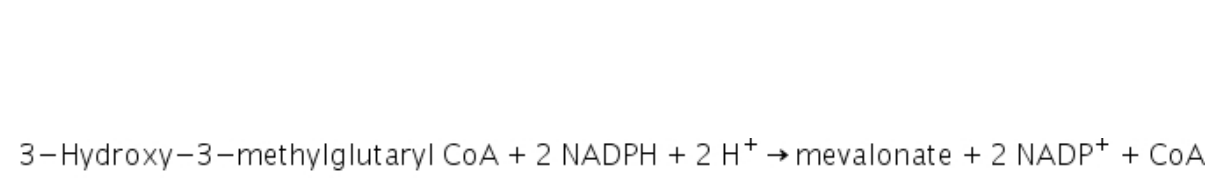


FIGURE 27.8 3-Hydroxy-3-methylglutaryl CoA has different fates. In the cytoplasm, HMG-CoA is converted into mevalonate. In mitochondria, it is converted into acetyl CoA and acetoacetate.

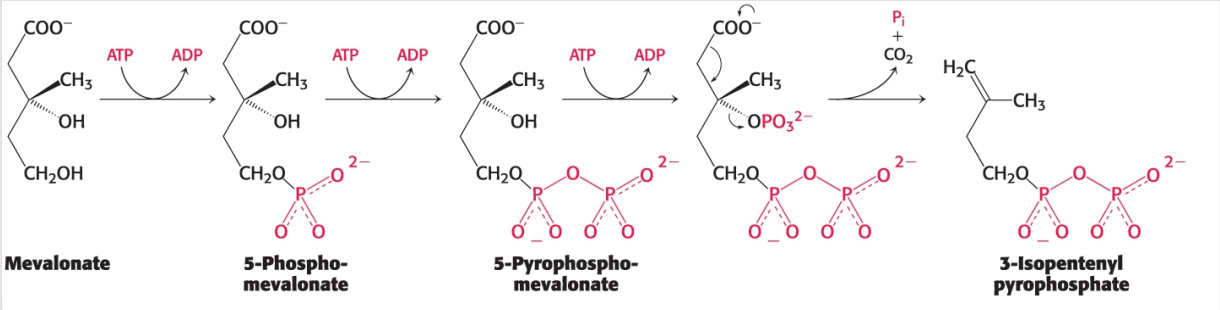
The synthesis of mevalonate is the committed step in cholesterol formation. The enzyme catalyzing this irreversible step, **3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase)**, is an important control site in cholesterol biosynthesis, as will be discussed shortly.

HMG-CoA reductase is an integral membrane protein in the endoplasmic reticulum.

Mevalonate is converted into 3-isopentenyl pyrophosphate in three consecutive reactions requiring ATP (**Figure 27.9**).



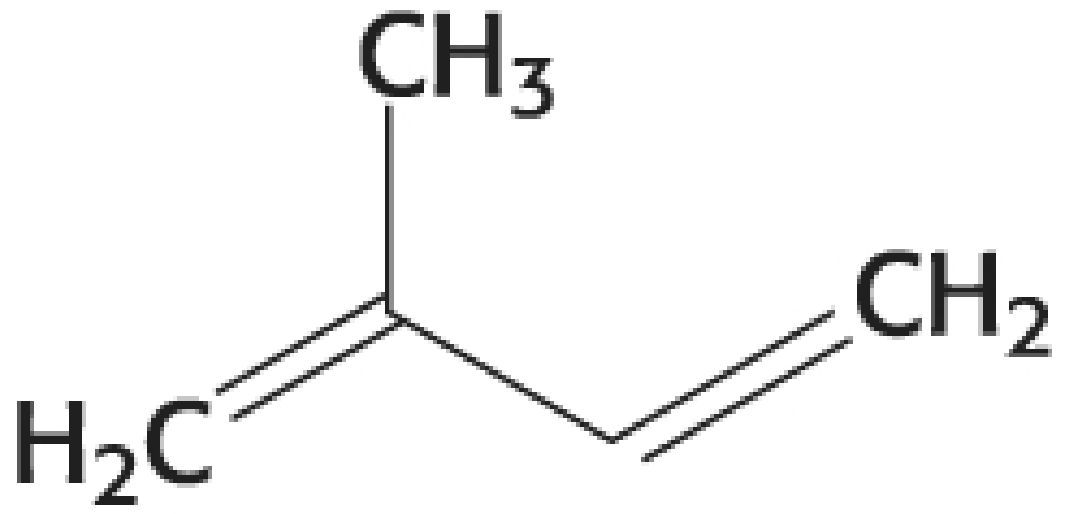


FIGURE 27.9 Mevalonate is converted into isopentenyl pyrophosphate. This activated intermediate is formed from mevalonate in three steps requiring ATP, followed by a decarboxylation.

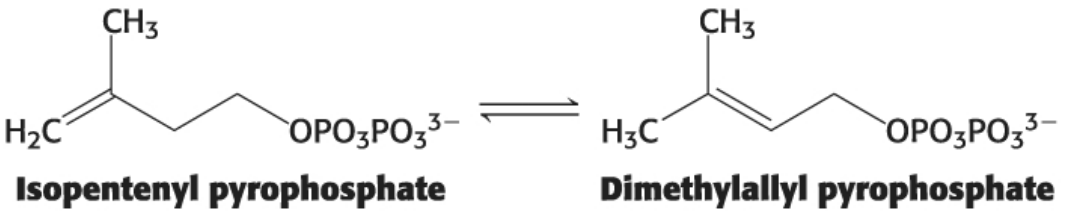
In the last step, the release of CO_2 yields isopentenyl pyrophosphate, an activated isoprene unit that is a key building block for many important biomolecules throughout the kingdoms of life.



Isoprene

Stage 2: Squalene (C_{30}) is synthesized from six molecules of isopentenyl pyrophosphate (C_5)

Squalene is synthesized from isopentenyl pyrophosphate by the reaction sequence

$$C_5 \rightarrow C_{10} \rightarrow C_{15} \rightarrow C_{30}$$

This stage in the synthesis of cholesterol starts with the isomerization of isopentenyl pyrophosphate to dimethylallyl pyrophosphate.

These two isomeric C_5 units (one of each type) condense to form a C_{10} compound: isopentenyl pyrophosphate attacks an allylic carbocation formed from dimethylallyl pyrophosphate to yield geranyl pyrophosphate (Figure 27.10). The same kind of reaction takes place again: geranyl pyrophosphate is converted into an allylic carbonium ion, which is attacked by isopentenyl pyrophosphate. The resulting C_{15} compound is called farnesyl pyrophosphate. The same enzyme, geranyl transferase, catalyzes each of these condensations.

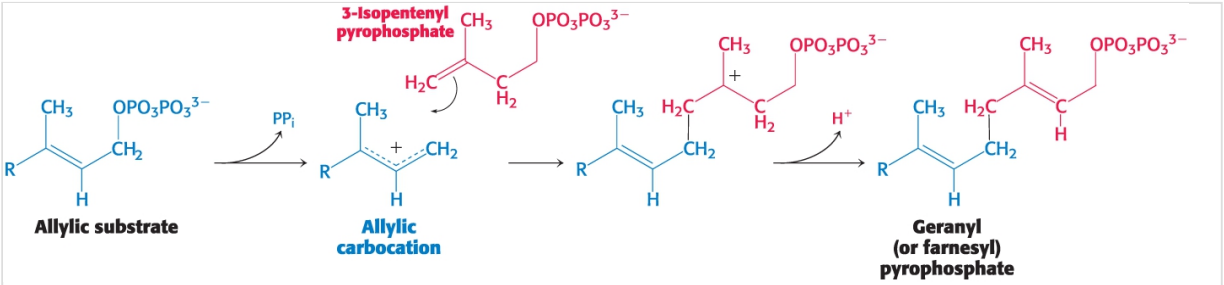


FIGURE 27.10 Condensation reactions build carbon–carbon bonds that eventually form the cholesterol skeleton. The isomeric C_5 units dimethylallyl pyrophosphate and isopentenyl pyrophosphate join to form geranyl pyrophosphate. The same mechanism is used to add an additional isopentenyl pyrophosphate to form farnesyl pyrophosphate.

The last step in the synthesis of squalene is a reductive tail-to-tail condensation of two molecules of farnesyl pyrophosphate catalyzed by the endoplasmic reticulum enzyme squalene synthase.

The reactions leading from C_5 units to squalene, a C_{30} isoprenoid, are summarized in **Figure 27.11**.

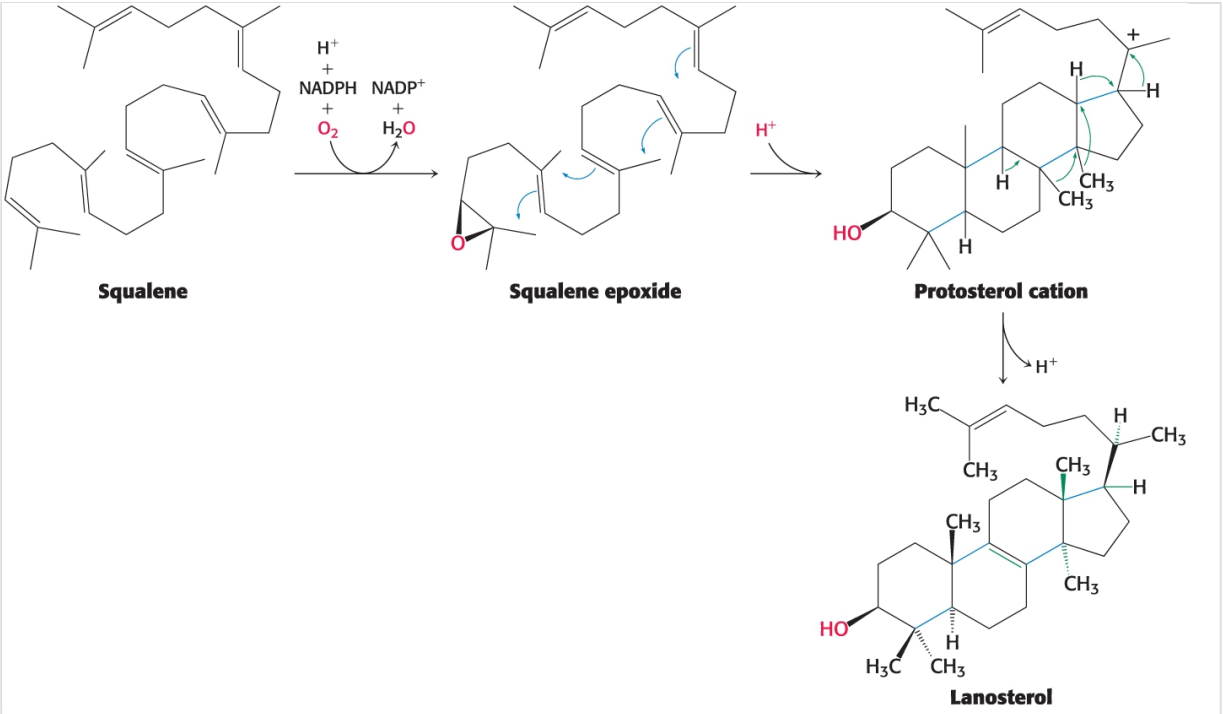
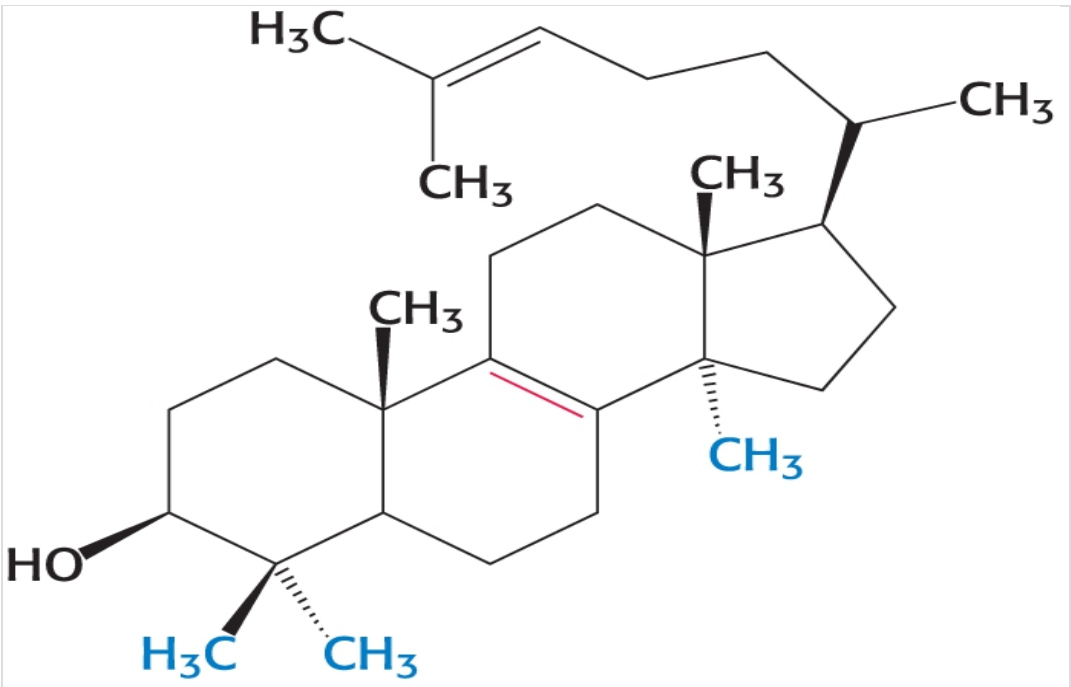
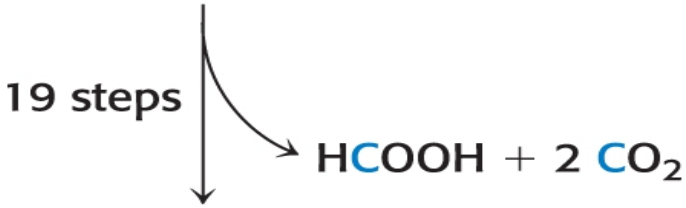
One molecule of dimethylallyl pyrophosphate and two molecules of isopentenyl pyrophosphate condense to form farnesyl pyrophosphate. The tail-to-tail coupling of two molecules of farnesyl pyrophosphate yields squalene.

Stage 3: Squalene cyclizes to form cholesterol

The final stage of cholesterol biosynthesis starts with the cyclization of squalene (Figure 27.12). Squalene is first activated by conversion into squalene epoxide (2,3-oxidosqualene) in a reaction that uses O_2 and NADPH. Squalene epoxide is then cyclized to lanosterol by oxidosqualene cyclase. The enzyme holds squalene epoxide in an appropriate conformation and initiates the reaction by protonating the epoxide oxygen. The carbocation formed spontaneously rearranges to produce lanosterol.







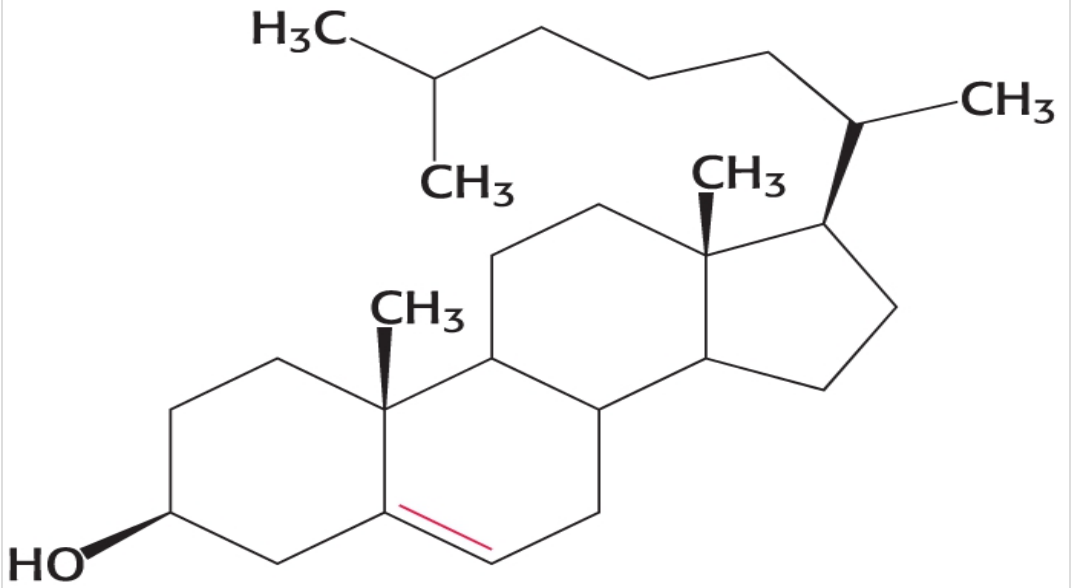


FIGURE 27.12 Squalene cyclization leads to the steroid skeleton in the form of lanosterol. The formation of the steroid nucleus from squalene begins with the formation of squalene epoxide. This intermediate is protonated to form a carbocation that cyclizes to form a tetracyclic structure, which rearranges to form lanosterol.

This is a remarkable chemical transformation, forming the four rings that are characteristic of steroids through four new carbon–carbon bonds. In addition, six new chiral centers are generated. In contrast to this remarkably efficient step, the conversion of lanosterol to cholesterol — which involves the removal of three methyl groups, the reduction of a double bond, and the migration of a different double bond — requires 19 steps and 9 different enzymes (Figure 27.13).

Lanosterol

Cholesterol

FIGURE 27.13 Cholesterol is formed from lanosterol. This complex transformation involves 19 steps and 9 different enzymes.

Self-Check Question

The biosynthesis of cholesterol requires 20 steps and 10 different enzymes. Which enzyme is responsible for the formation of the five-membered ring in the cholesterol structure?

27.3 The Regulation of Cholesterol Biosynthesis Takes Place at Several Levels

Cholesterol can be obtained from the diet or cells can synthesize it de novo, using one of the most highly regulated metabolic pathways known. Biosynthetic rates may vary several hundred-fold, depending on how much cholesterol is consumed in the diet. An adult on a low-cholesterol diet typically synthesizes about 800 mg of cholesterol per day. The liver is the major site of cholesterol synthesis in mammals, although the intestine also forms significant amounts.

The rate of cholesterol formation by the liver and intestine is highly responsive to the cellular level of cholesterol. This feedback regulation is mediated primarily by changes in the amount and activity of 3-hydroxy-3-methylglutaryl CoA reductase. As described earlier, this enzyme catalyzes the formation of mevalonate, the committed step in cholesterol biosynthesis. HMG CoA reductase is controlled in multiple ways:

1. *The rate of synthesis of reductase mRNA is controlled by a transcription factor called SREBP.* **Sterol regulatory element binding protein (SREBP)** is a member of a family of transcription factors that regulate the proteins required for lipid synthesis. SREBP binds to a short DNA sequence called the sterol regulatory element (SRE) on the $5'$ side of the reductase gene when cholesterol levels are low, enhancing transcription of the gene. In its inactive state, SREBP resides in the endoplasmic reticulum membrane, where it is associated with the SREBP cleavage activating protein (SCAP), an integral membrane protein. SCAP is the cholesterol sensor.

When cholesterol levels fall, SCAP escorts SREBP in small membrane vesicles to the Golgi complex, where it is released from the membrane by two specific proteolytic cleavages (Figure 27.14). The first cleavage frees a fragment of SREBP from SCAP, whereas the second cleavage releases the regulatory domain from the membrane. The released protein migrates to the nucleus and binds the SRE of the HMG-CoA reductase gene, as well as several other genes in the cholesterol biosynthetic pathway, to enhance transcription. When cholesterol levels rise, the proteolytic release of the SREBP is blocked, and the SREBP in the nucleus is rapidly degraded by proteasomes located in the nucleus. These two events halt the transcription of genes of the cholesterol biosynthetic pathways.

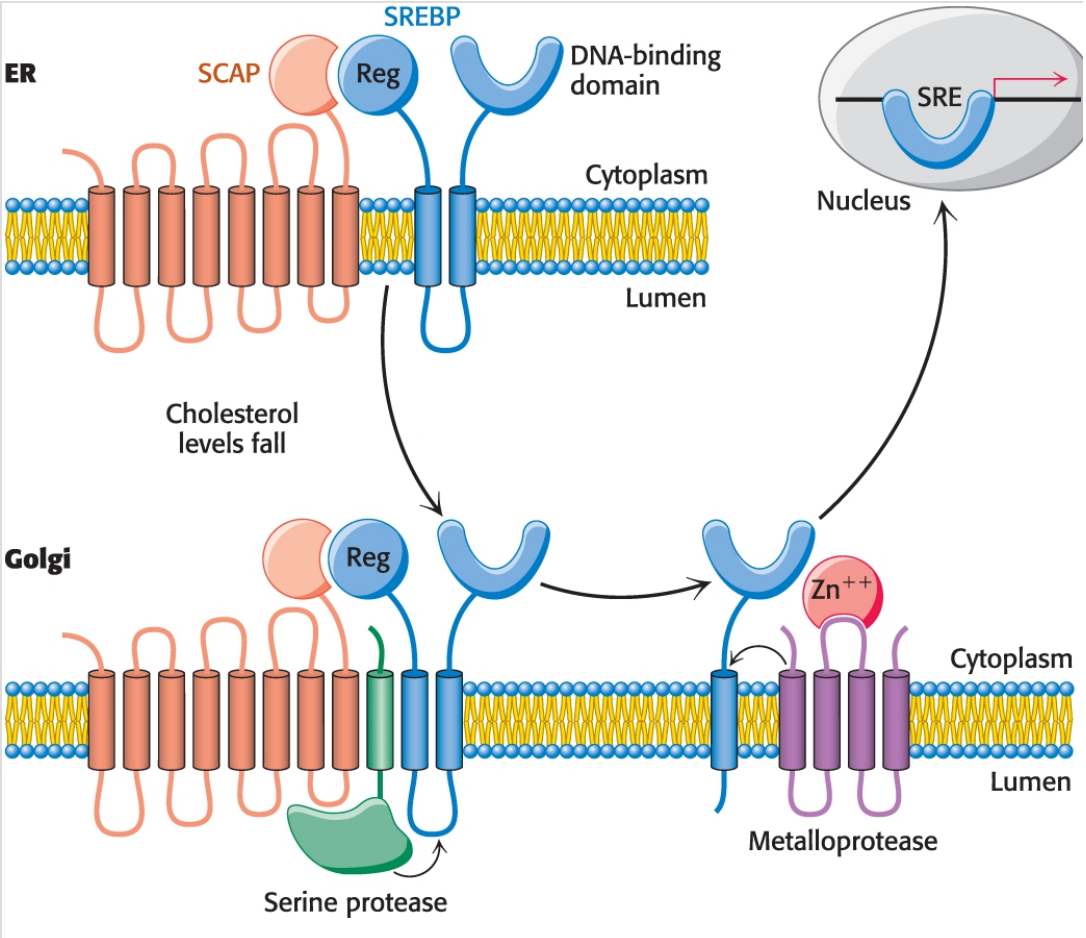

FIGURE 27.14 SREBP regulates gene expression in response to cholesterol levels. Stero regulatory element binding protein (SREBP) resides in the endoplasmic reticulum (ER),

where it is bound to SCAP by its regulatory (Reg) domain. When cholesterol levels fall, SCAP and SREBP move to the Golgi complex, where SREBP undergoes successive proteolytic cleavages by a serine protease and a metalloprotease. The released DNA-binding domain moves to the nucleus to alter gene expression.

[Information from an illustration provided by Dr. Michael Brown and Dr. Joseph Goldstein.]

What is the molecular mechanism that retains SCAP–SREBP in the ER when cholesterol is present but allows movement to the Golgi complex when cholesterol concentration is low? When cholesterol is low, SCAP binds to vesicular proteins that facilitate the transport of SCAP–SREBP to the Golgi apparatus. When cholesterol is present, SCAP binds cholesterol, which causes a structural change in SCAP so that it binds to another endoplasmic reticulum protein called Insig (insulin-induced gene) (Figure 27.15). Insig is the anchor that retains SCAP and thus SREBP in the endoplasmic reticulum in the presence of cholesterol. The interactions between SCAP and Insig can also be forged when Insig binds 25-hydroxycholesterol, a metabolite of cholesterol. Thus, two distinct steroid–protein interactions prevent the inappropriate movement of SCAP–SREBP to the Golgi complex.

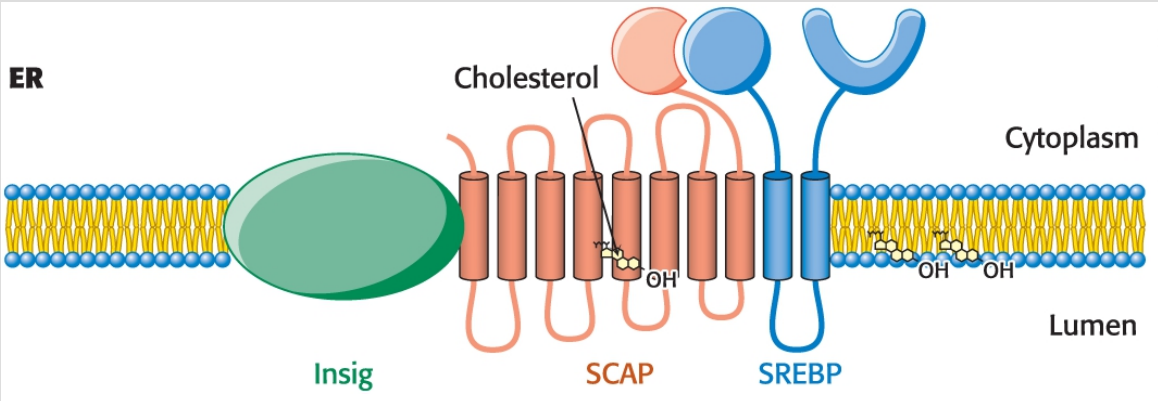

FIGURE 27.15 Insig regulates SCAP–SREBP movement. In the presence of cholesterol, Insig interacts with SCAP–SREBP and prevents the activation of SREBP. Cholesterol binding to SCAP 25-hydroxycholesterol binding to Insig facilitates the interaction of Insig and SCAP, retaining SCAP–SREBP in the endoplasmic reticulum.

2. *The rate of translation of reductase mRNA is inhibited by nonsterol metabolites derived from mevalonate.* This results in an 80% reduction in the rate of reductase protein production.

3. *The degradation of the reductase is stringently controlled.* The enzyme is bipartite: its cytoplasmic domain carries out catalysis, and its membrane domain senses signals that lead to its degradation. The membrane domain may undergo structural changes in response to increasing concentrations of sterols such as lanosterol and 25-hydroxycholesterol. Under these conditions, the reductase appears to bind to a subset of Insigs that are also associated with the ubiquitinating enzymes (Figure 27.16). The reductase is polyubiquitinated and subsequently extracted from the membrane in a process that requires geranylgeraniol. The extracted reductase is then degraded by the proteasome. The combined regulation at the levels of transcription, translation, and degradation can alter the amount of enzyme in the cell more than 200-fold.

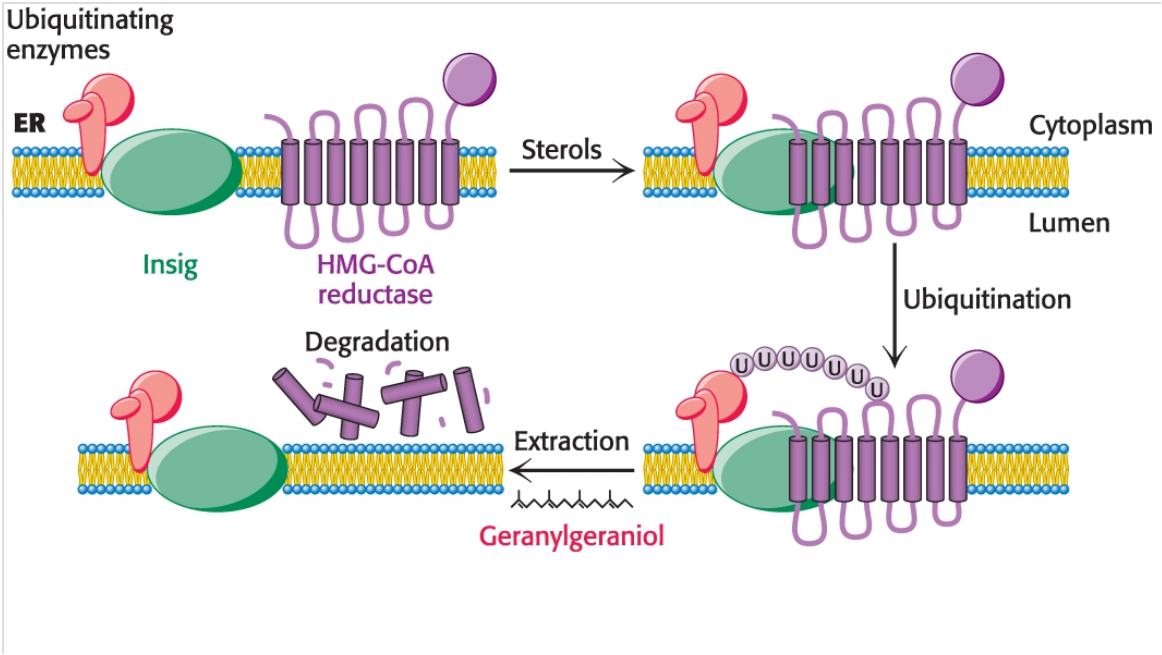

FIGURE 27.16 Insig facilitates the degradation of HMG-CoA reductase. In the presence of sterols, a subclass of Insig associated with ubiquitinating enzymes binds HMG-CoA reductase. This interaction results in the ubiquitination of the enzyme. This modification and the presence of geranylgeraniol results in extraction of the enzyme from the membrane and degradation by the proteasome.

4. *Phosphorylation decreases the activity of the reductase.* This enzyme, like acetyl CoA carboxylase, which catalyzes the committed step in fatty acid synthesis, is switched off by an AMP-activated protein kinase. Thus, cholesterol synthesis ceases when the ATP level is low.

Lipoproteins transport cholesterol and triacylglycerols throughout the organism

Cholesterol and triacylglycerols are transported in body fluids in the form of **lipoprotein particles**, which are important for a number of reasons. First, lipoprotein particles are the means by which triacylglycerols are delivered to tissues, from the intestine or liver, for use as fuel or for storage. Second, the fatty acid constituents of the triacylglycerol components of the lipoprotein particles are incorporated into phospholipids for membrane synthesis. Likewise, cholesterol is a vital component of membranes and is a precursor to the powerful signal molecules — the steroid hormones. Finally, cells are not able to degrade the steroid nucleus. Consequently, the cholesterol must be used biochemically or excreted by the liver. Excess cholesterol plays a role in the development of atherosclerosis. Lipoprotein particles function in cholesterol homeostasis, transporting the molecule from sites of synthesis to sites of use, and finally to the liver for excretion.

Each lipoprotein particle consists of a core of hydrophobic lipids surrounded by a shell of more-polar lipids and proteins. The protein

components of these macromolecular aggregates, called apoproteins, have two roles: they solubilize hydrophobic lipids and contain cell-targeting signals. Apolipoproteins are synthesized and secreted by the liver and the intestine.

Lipoprotein particles are classified according to increasing density (Table 27.1). Lipoprotein particles can shift between classes as they release or pick up cargo, thereby changing their density.

lipoprotein

Abbreviations: TAG, triacylglycerol; CE, cholesteryl ester; C, free cholesterol; PL, phospholipid; P, protein.

Chylomicrons

Triacylglycerols, cholesterol, and other lipids obtained from the diet are carried away from the intestine in the form of large chylomicrons. These particles have a very low density because triacylglycerols constitute about 90% of their content. Apolipoprotein B-48 (apo B-48), a large protein (240 kDa), forms an amphipathic spherical shell around the fat globule; the external face of this shell is hydrophilic.

The triacylglycerols in chylomicrons are released through hydrolysis by lipoprotein lipases. These enzymes are located on the lining of blood vessels in muscle and other tissues that use fatty acids as fuels or in the synthesis of lipids. The liver then takes up the cholesterol-rich residues, known as *chylomicron remnants.*

Very low-density lipoprotein

Lipoprotein particles are also crucial for the transport of lipids from the liver, which is a major site of triacylglycerol and cholesterol synthesis, to other tissues in the body (**Figure 27.17**). Triacylglycerols and cholesterol in excess of the liver's own needs are exported into the blood in the form of very low-density lipoproteins (VLDL). These particles are stabilized by two apolipoproteins — apo B-100 (513 kDa) and apo E (34 kDa).

FIGURE 27.17 The liver is the major site of cholesterol synthesis. An electron micrograph shows a part of a liver cell actively engaged in the synthesis and secretion of very low-density lipoprotein (VLDL). The arrow points to a vesicle that is releasing its content of VLDL particles.

Intermediate-density lipoprotein

Triacylglycerols in very low-density lipoproteins, as in chylomicrons, are hydrolyzed by lipases on capillary surfaces, with the released fatty acids being taken up by the muscle and other tissues. The resulting remnants, which are rich in cholesteryl esters, are intermediate-density lipoproteins (IDL). These particles have two fates. Half of them are taken up by the liver for processing, and half are converted into low-density lipoprotein by the removal of more triacylglycerol by tissue lipases that absorb the released fatty acids.

Low-density lipoprotein

The major carrier of cholesterol in blood is **low-density lipoprotein (LDL)** (**Figure 27.18**). It contains a core of some 1500 cholesterol molecules esterified to fatty acids. The most common fatty acid chain in these esters is linoleate, a polyunsaturated fatty acid. A shell of phospholipids and unesterified cholesterol molecules surrounds this highly hydrophobic core. The shell also contains a single copy of apo B-100, which is recognized by target cells. In addition to transporting cholesterol to peripheral tissues, LDL regulates de novo cholesterol synthesis at these sites.

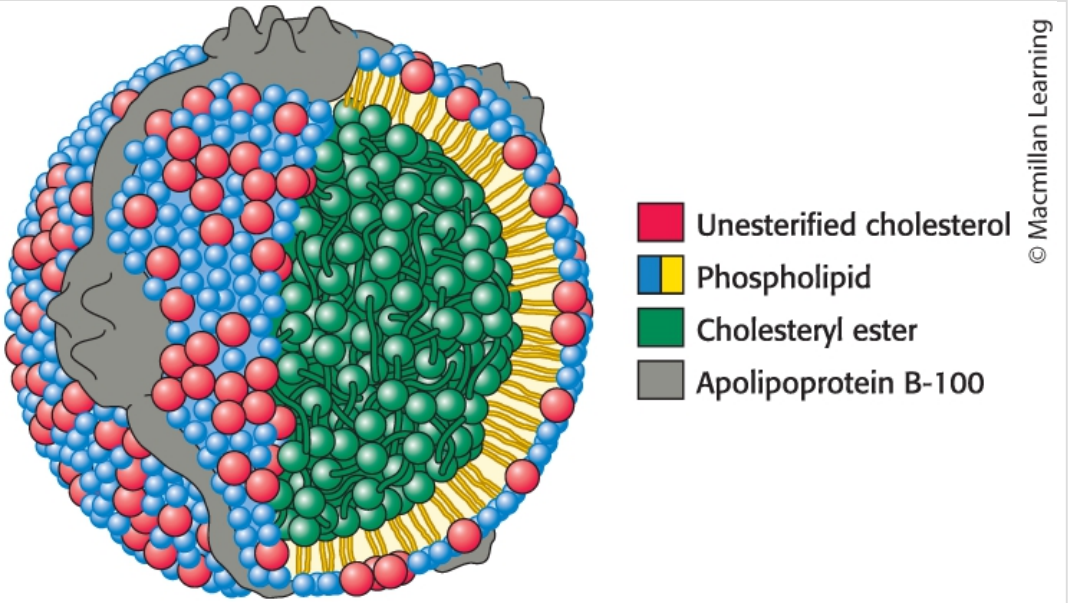

FIGURE 27.18 LDL consists of a core of cholesterol esters surrounded by a single molecule of apolipoprotein B-100. A low-density lipoprotein (LDL) particle is approximately 22 nm (220 Å) in diameter.

High-density lipoprotein

A different purpose is served by **high-density lipoprotein (HDL)**, which picks up cholesterol released into the plasma from dying cells and from membranes undergoing turnover and delivers the cholesterol to the liver for excretion. An acyltransferase in HDL esterifies these cholesterols, which are then returned by HDL to the liver.

Low-density lipoproteins play a central role in cholesterol metabolism

Cholesterol metabolism must be precisely regulated to prevent atherosclerosis. The mode of control in the liver, the primary site of cholesterol synthesis, has already been considered: dietary cholesterol reduces the activity and amount of 3-hydroxy-3-methylglutaryl CoA reductase, the enzyme catalyzing the committed step. In general, cells outside the liver and intestine obtain cholesterol from the plasma rather than synthesizing it de novo. Specifically, their primary source of cholesterol is the low-density lipoprotein. The process of LDL uptake, called **receptor-mediated endocytosis**, serves as a paradigm for the uptake of many molecules (**Figure 27.19**).

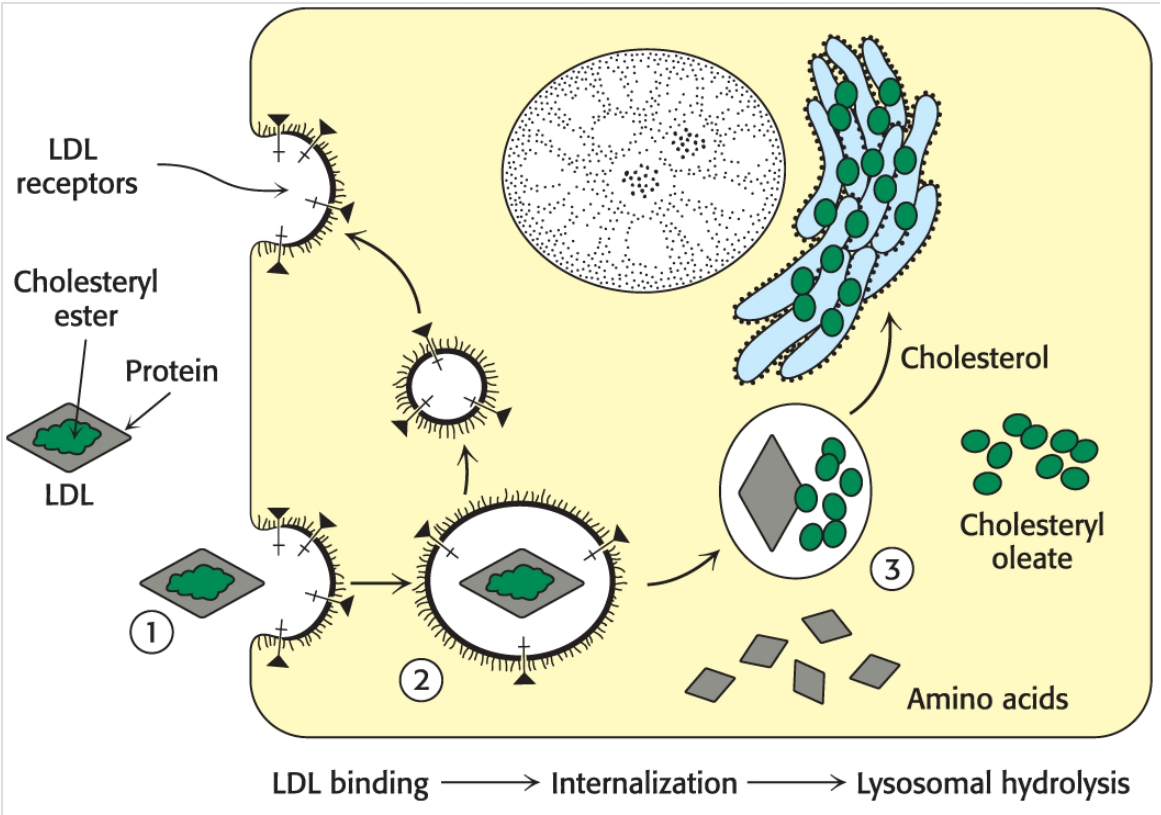

FIGURE 27.19 LDL enters cells through receptor-mediated endocytosis. (1) LDL binds to a specific receptor, the LDL receptor. (2) This complex invaginates to form an endosome. (3) After separation from its receptor, the LDL-containing vesicle fuses with a lysosome, leading to the degradation of the LDL and the release of the cholesterol.

Endocytosis begins when apolipoprotein B-100 on the surface of an LDL particle binds to a specific receptor protein on the plasma membrane of nonhepatic cells. The receptors for LDL are localized in specific regions called *coated pits*, which contain a protein called *clathrin*. The receptor–LDL complex is then internalized by endocytosis; that is, the plasma membrane in the vicinity of the complex invaginates and then fuses to form an endocytic vesicle called an *endosome*. The endosome is acidified by an ATP-dependent proton pump homologous to the Na^+/K^+ ATPase, which causes the receptor to release its cargo. Some of the receptor is returned to the cell membrane in a recycling vesicle, while a portion is degraded along with its cargo. The round-trip time for a receptor is about 10 minutes; in its lifetime of about a day, each receptor may bring hundreds of LDL particles into the cell.

The vesicles containing LDL, and in some cases the receptor, subsequently fuse with *lysosomes*, acidic vesicles that carry a wide array of degradative enzymes. The protein component of LDL is hydrolyzed to free amino acids, while the cholesteryl esters in LDL are hydrolyzed by a lysosomal acid lipase. The released unesterified cholesterol can then be used for membrane biosynthesis. Alternatively, it can be reesterified for storage inside the cell. In fact, free cholesterol activates acyl CoA:cholesterol acyltransferase (ACAT), the enzyme catalyzing this reaction.

Reesterified cholesterol contains mainly oleate and palmitoleate, which are monounsaturated fatty acids, in contrast with the cholesteryl esters in LDL, which are rich in linoleate, a polyunsaturated fatty acid (Table 12.1). It is imperative that the cholesterol be reesterified, because high concentrations of unesterified cholesterol disrupt the integrity of cell membranes.

The synthesis of the LDL receptor is itself subject to feedback regulation. Studies of cultured fibroblasts show that, when cholesterol is abundant inside the cell, new LDL receptors are not synthesized, and so the uptake of additional cholesterol from plasma LDL is blocked. The gene for the LDL receptor, like that for the reductase, is regulated by SREBP, which binds to a sterol regulatory element that controls the rate of mRNA synthesis.

The absence of the LDL receptor leads to hypercholesterolemia and atherosclerosis

The pioneering studies of familial hypercholesterolemia by Michael Brown and Joseph Goldstein revealed the physiological importance of the LDL receptor. The total concentration of cholesterol and LDL in the blood plasma is markedly elevated in this genetic disorder, which results from a mutation at a single autosomal locus. The cholesterol level in the plasma of homozygotes is typically $680\ \mathrm{mg\ dl^{-1}}$, compared with $300\ \mathrm{mg\ dl^{-1}}$ in heterozygotes (clinical assay results are often expressed in milligrams per deciliter, which is equal to milligrams per 100 milliliters). A value of $< 200\ \mathrm{mg\ dl^{-1}}$ is regarded as desirable, but many people have higher levels. In familial hypercholesterolemia, cholesterol is deposited in various tissues because of the high concentration of LDL cholesterol in the plasma. LDL accumulates under the endothelial cells lining the blood vessels, and nodules of cholesterol called *xanthomas* are prominent in skin and tendons.

Of particular concern is the oxidation of the excess LDL to form oxidized LDL (oxLDL), which can instigate the inflammatory response by the immune system, a response that has been implicated in the

development of cardiovascular disease. The oxLDL is taken up by immune system cells called macrophages, which become engorged to form foam cells. These foam cells become trapped in the walls of the blood vessels and contribute to the formation of atherosclerotic plaques that cause arterial narrowing and lead to heart attacks (Figure 27.20). In fact, most people who are homozygous for the hypercholesterolemia allele die of coronary artery disease in childhood. The disease in heterozygotes (1 in 500 people) has a milder and more variable clinical course.

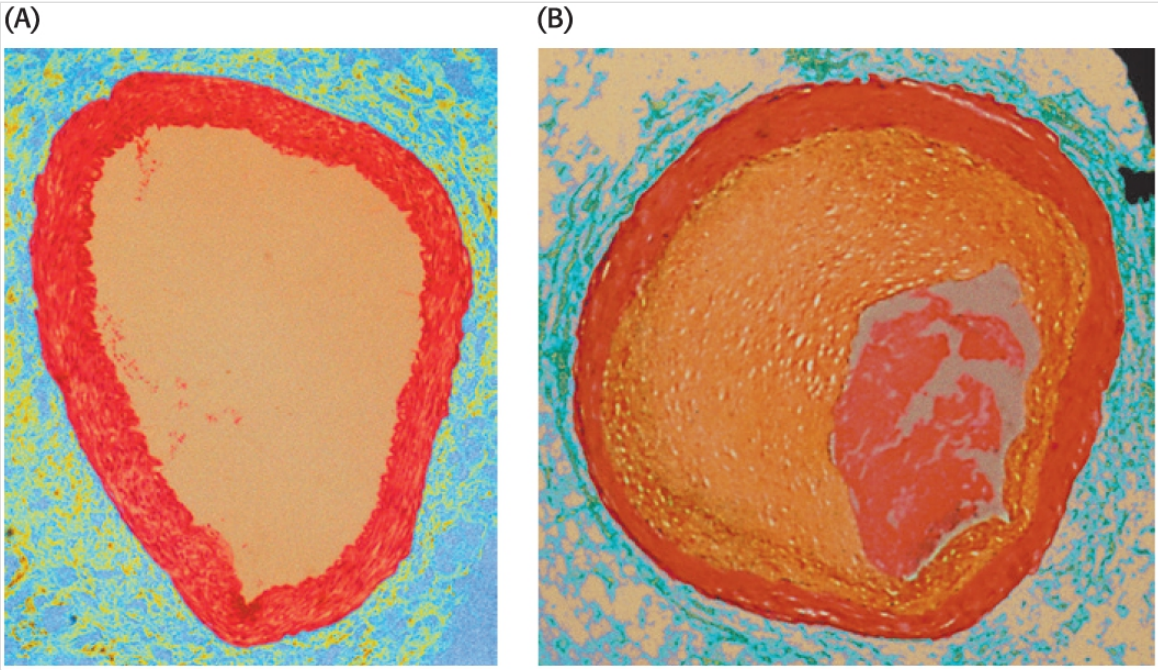

FIGURE 27.20 Arterial plaques are one of the effects of excess cholesterol. Cross sections of (A a normal artery and (B) an artery blocked by a cholesterol-rich plaque are shown.

The molecular defect in most cases of familial hypercholesterolemia is an absence or deficiency of functional receptors for LDL. Receptor mutations that disrupt each of the stages in the endocytotic pathway have been identified. Homozygotes have almost no functional receptors for LDL, whereas heterozygotes have about half the normal number.

The entry of LDL into liver and other cells is impaired, leading to an increased level of LDL in the blood plasma. Furthermore, less IDL enters liver cells because IDL entry, too, is mediated by the LDL receptor. Consequently, IDL stays in the blood longer in familial hypercholesterolemia, and more of it is converted into LDL than in normal people. All deleterious consequences of an absence or deficiency of the LDL receptor can be attributed to the ensuing elevated level of LDL cholesterol in the blood.

Mutations in the LDL receptor prevent LDL release and result in receptor destruction

One class of mutations that results in familial hypercholesterolemia generates receptors that are reluctant to give up the LDL cargo. Let us explore why this is by examining the makeup of the receptor. The human LDL receptor is a 160-kDa glycoprotein with a complicated modular structure (**Figure 27.21**). The receptor exists in two interconvertible states: an extended or open state, capable of binding LDL, and a closed state that results in release of the LDL in the endosome. The receptor maintains the open state while in the plasma membrane, on binding LDL, and throughout its journey to the endosome. The conversion from the open state into the closed state takes place on exposure to the acidic environment of the endosome.

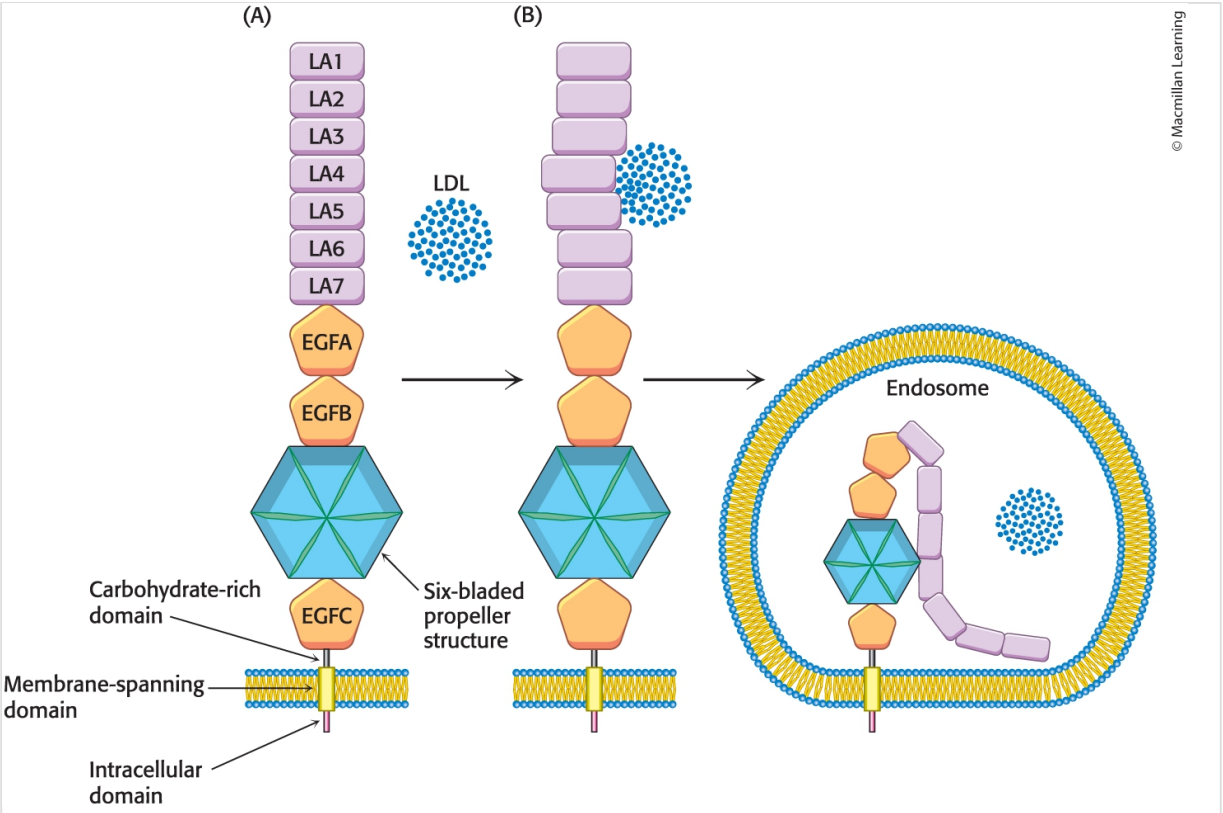

FIGURE 27.21 The LDL receptor releases LDL in the endosome. (A) A schematic representation of the domain structure of the LDL receptor. (B) In the endosome, the receptor converts from the open structure into the closed structure, resulting in the release of the LDL into the endosome.

The importance of this process is highlighted by the fact that more than half of the point mutations that result in familial hypercholesterolemia are due to disruptions in the interconversion between the open state and the closed state. These mutations result in a failure to release the LDL cargo and loss of the receptor by degradation.

Cycling of the LDL receptor is regulated

PCSK9 (proprotein convertase subtilisin/kexin type) is a protease, secreted by the liver, that plays a crucial role in the regulation of cycling

of the LDL receptor. However, despite the fact that PCSK9 is a protease, enzymatic activity of the protein is not required for cycling regulation. PCSK9 in the blood binds to the LDL receptor and locks it in the open conformation even under the acidic conditions of the endosome. Failure to adopt the closed conformation prevents the receptor from returning to the plasma membrane, and it is degraded in the lysosome along with its cargo.

 Individuals having a mutation that reduces the amount of PCSK9 in the blood have greatly reduced levels of LDL in the blood and display an almost 90% reduction in the rate of cardiovascular disease. Presumably, reduced levels of PCSK9 allow more receptor cycling and more efficient removal of LDL from the blood. Several monoclonal antibodies to PCSK9 have been approved for treatment for high LDL levels, but their use has been limited by their high cost.

HDL appears to protect against atherosclerosis

Although the events that result in atherosclerosis take place rapidly in familial hypercholesterolemia, a similar sequence of events takes place in people who develop atherosclerosis over decades. In particular, the formation of foam cells and plaques are especially hazardous occurrences. HDL and its role in returning cholesterol to the liver appear to be important in mitigating these life-threatening circumstances.

HDL has a number of antiatherogenic properties, including the inhibition of LDL oxidation. However, HDL's best-characterized property is the removal of cholesterol from cells, especially macrophages. Earlier, we noted that HDL retrieves cholesterol from other tissues in the body to return the cholesterol to the liver for

excretion as bile or in the feces. This transport, called *reverse cholesterol transport*, is especially important in regard to macrophages. Indeed, when the transport fails, macrophages become foam cells and facilitate the formation of plaques. Macrophages that collect cholesterol from LDL normally transport the cholesterol to HDL particles. The more HDL, the more readily this transport takes place and the less likely that the macrophages will develop into foam cells. Presumably, this robust reverse cholesterol transport accounts for the observation that higher HDL levels confer protection against atherosclerosis.

Until recently, high levels of HDL-bound cholesterol ("good cholesterol") relative to LDL-bound cholesterol ("bad cholesterol") were believed to protect against cardiovascular disease. This belief was based on epidemiological studies. However, a number of recent clinical trials revealed that increased levels of HDL-bound cholesterol may have little protective effect. These studies do not discount the protective effects of HDL alone, but they illustrate the danger of equating free HDL and cholesterol-bound HDL.

Self-Check Question

List three differences between low-density lipoprotein and high-density lipoprotein.

The clinical management of cholesterol levels can be understood at the biochemical level

Homozygous familial hypercholesterolemia can be treated only by a liver transplant. A more generally applicable therapy is available for heterozygotes and others with high levels of cholesterol. The goal is to reduce the amount of cholesterol in the blood by stimulating the synthesis of more than the customary number of LDL receptors. We have already observed that the production of LDL receptors is controlled by the cell's need for cholesterol. The therapeutic strategy is to deprive the cell of ready sources of cholesterol. When cholesterol is required, the amount of mRNA for the LDL receptor rises, and more receptors are found on the cell surface. This state can be induced by a two-pronged approach. First, the reabsorption of **bile salts** — cholesterol derivatives that promote the absorption of dietary cholesterol and dietary fats — from the intestine is inhibited. Second, de novo synthesis of cholesterol is blocked.

The reabsorption of bile is impeded by oral administration of positively charged polymers, such as cholestyramine, that bind negatively charged bile salts and are not themselves absorbed. Cholesterol synthesis can be effectively blocked by a class of compounds called *statins*. A well-known example of such a compound is lovastatin, which is also called mevacor (**Figure 27.22**). Statins are potent competitive inhibitors $(K_i = 1\ \text{nM})$ of HMG-CoA reductase, the essential control point in the biosynthetic pathway. Plasma cholesterol levels decrease by 50% in many patients given both lovastatin and inhibitors of bile-salt reabsorption. Lovastatin and other inhibitors of HMG-CoA reductase are widely used to lower the plasma-cholesterol level in people who have atherosclerosis, which is the leading cause of death in industrialized societies.

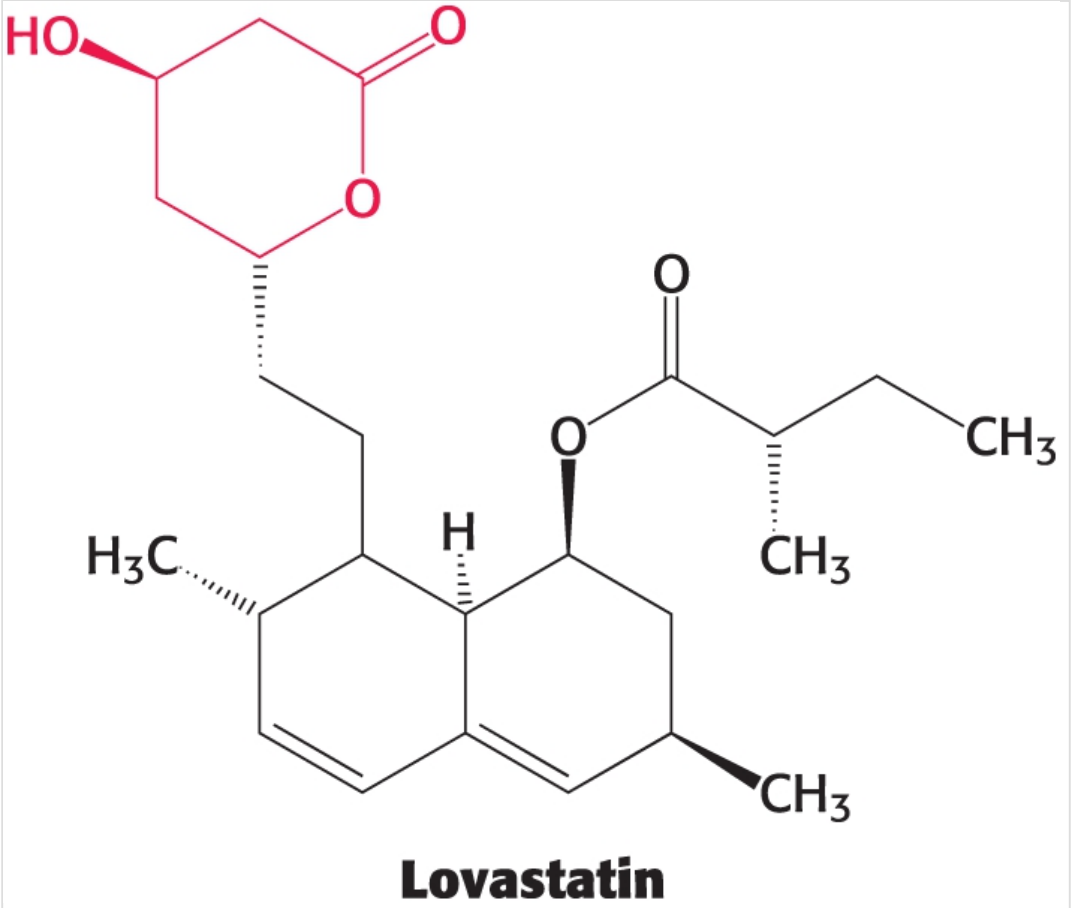

FIGURE 27.22 The statin lovastatin is a competitive inhibitor of HMG-CoA reductase. The part of the structure that resembles the 3-hydroxy-3-methylglutaryl moiety is shown in red.

27.4 Important Biochemicals Are Synthesized from Cholesterol and Isoprene

Cholesterol is the precursor of several other important classes of compounds. Bile salts, the major constituent of bile, are synthesized in the liver, stored and concentrated in the gallbladder, and then released into the small intestine. Bile salts are highly effective at solubilizing dietary lipids because they contain both polar and nonpolar regions. Solubilization increases the effective surface area of lipids with two consequences: (1) more surface area is exposed to the digestive action of lipases and (2) lipids are more readily absorbed by the intestine. Bile salts are also the major breakdown products of cholesterol. The bile salts glycocholate, the primary bile salt, and taurocholate are shown in Figure 27.23.

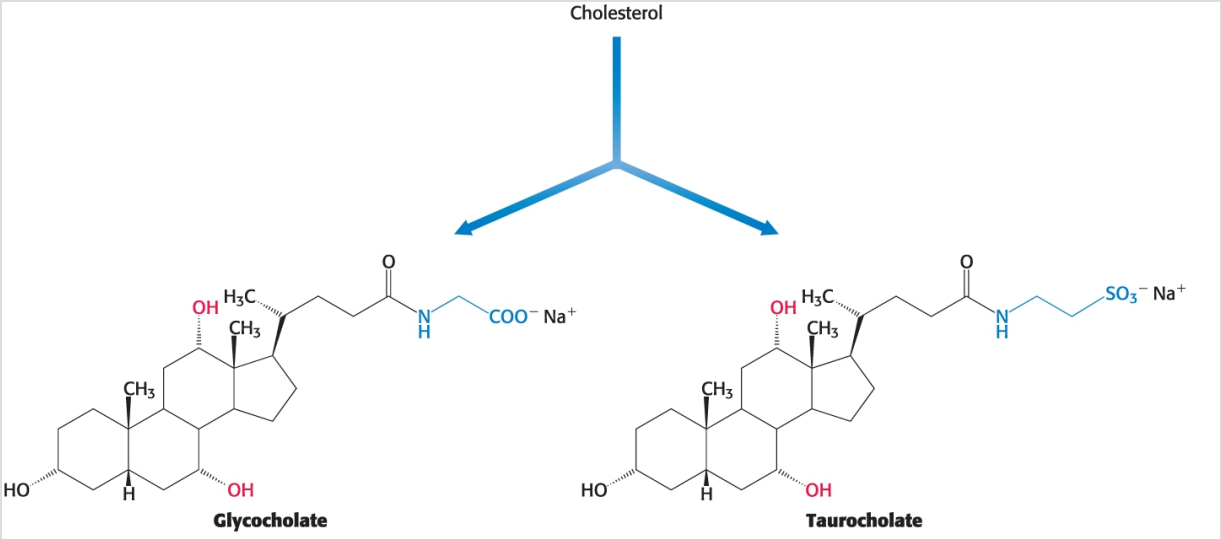

FIGURE 27.23 Bile salts are synthesized from cholesterol. The OH groups in red are added to cholesterol, as are the groups shown in blue. These polar groups make bile salt effective in detergents.

Cholesterol is also the precursor of the five major classes of steroid hormones — progestogens, glucocorticoids, mineralocorticoids, androgens, and estrogens (Figure 27.24). These hormones are powerful signal molecules that regulate a host of organismal functions.

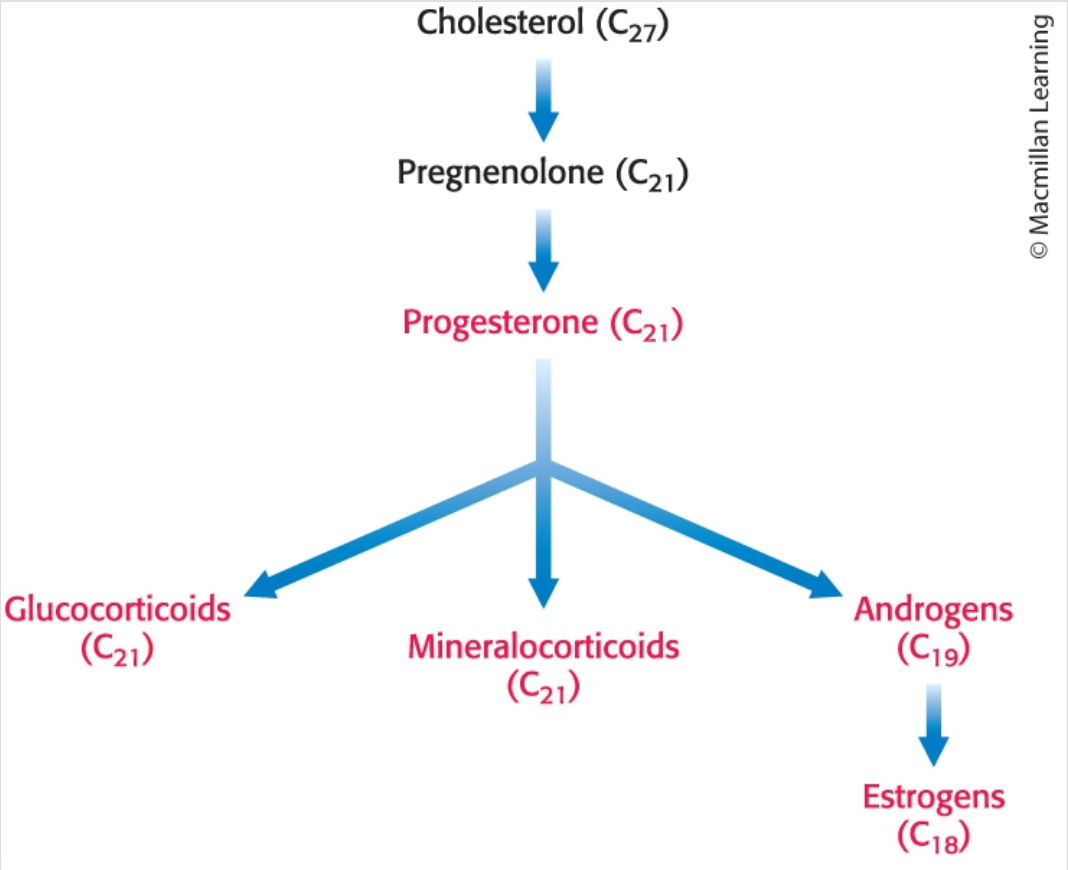

FIGURE 27.24 Different classes of steroid hormones are derived from cholesterol.

- Progesterone, a progestogen, prepares the lining of the uterus for the implantation of an ovum. Progesterone is also essential for the

maintenance of pregnancy by preventing premature uterine contractions.

- Glucocorticoids (such as cortisol) promote gluconeogenesis and glycogen synthesis, enhance the degradation of fat and protein, and inhibit the inflammatory response. They enable animals to respond to stress; indeed, the absence of glucocorticoids can be fatal.
- Mineralocorticoids (primarily aldosterone) act on the distal tubules of the kidney to increase the reabsorption of Na^+ and the excretion of K^+ and H^+, which leads to an increase in blood volume and blood pressure.
- Androgens (such as testosterone) are responsible for the development of male secondary sex characteristics.
- Estrogens (such as estradiol) are required for the development of female secondary sex characteristics. Estrogens, along with progesterone, also participate in the ovarian cycle.

These steroids are described using a common numbering and lettering system (Figure 27.25). The carbons are numbered 1–27 and the rings are denoted by the letters A–D.

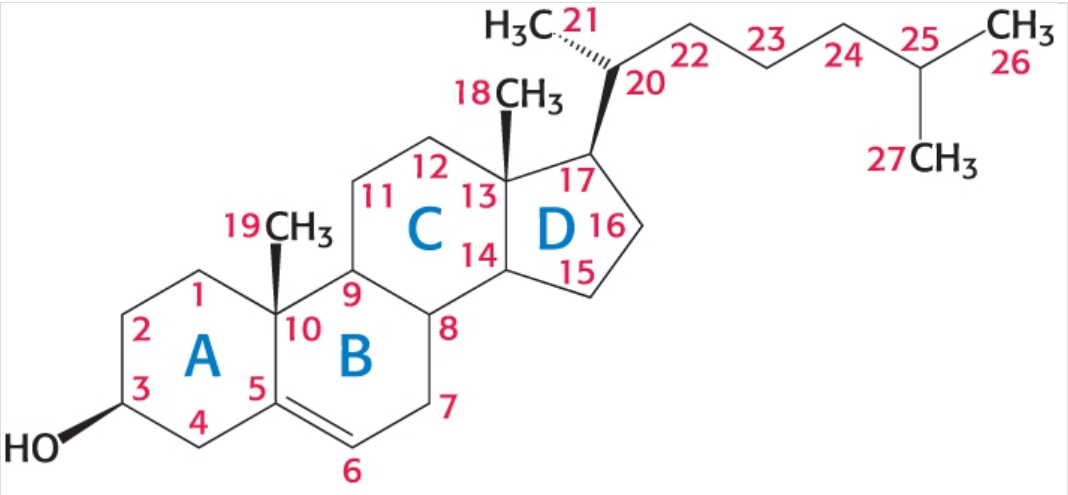

FIGURE 27.25 A common numbering system is used for cholesterol and other steroids. The numbering scheme for the carbon atoms and the naming system for

rings are shown.

The major sites of synthesis of these classes of hormones are the corpus luteum, for progestogens; the testes, for androgens; the ovaries, for estrogens; and the adrenal cortex, for glucocorticoids and mineralocorticoids.

Steroid hormones bind to and activate receptor molecules that serve as transcription factors to regulate gene expression. Despite their relatively similar structures, these compounds are able to have greatly differing physiological effects because the structural variations among them allow each class to be recognized by specific receptor molecules.

Steroids are hydroxylated by cytochrome P450 monooxygenases that use NADPH and O_2

The addition of oxygen atoms plays an important role in the synthesis of cholesterol from squalene and in the conversion of cholesterol into steroid hormones. These oxidation reactions require O_2 but, also, the reducing agent NADPH. One oxygen atom of the O_2 molecule goes into the substrate, while the other is reduced to water. The enzymes catalyzing these reactions are called *monooxygenases* (or *mixed-function oxygenases*). The general form of the most common type of reaction catalyzed by these enzymes is

$$RH + O_2 + NADPH + H^+ \rightarrow ROH + H_2O + NADP^+$$

In the synthesis of steroid hormones and bile salts, these reactions are catalyzed by members of the cytochrome P450 family, a family of heme-containing enzymes that absorb light maximally at 450 nm when complexed in vitro with exogenous carbon monoxide. Oxygen is activated through its binding to the iron atom in the heme group.

The catalytic mechanism for P450 enzymes is shown in **Figure 27.26**. NADPH transfers its high-potential electrons to a flavoprotein, which transfers them, one at a time, to adrenodoxin, a nonheme iron protein. Adrenodoxin transfers one electron to reduce the ferric (Fe^{3+}) form of P450 to the ferrous (Fe^{2+}) form. Without the addition of this electron, P450 will not bind oxygen. Recall that only the ferrous form (Fe^{2+}) of myoglobin and hemoglobin binds oxygen. The binding of O_2 to the heme is followed by the acceptance of a second electron from adrenodoxin. This second electron leads to cleavage of the $O—O$ bond. One of the oxygen atoms is then protonated and released as water. The remaining oxygen atom forms a highly reactive ferryl $(Fe^{4+})Fe{=}O$ intermediate with an additional electron removed from the porphyrin ring of the heme group. This intermediate removes a hydrogen atom from the substrate RH to form R•. This transient free radical captures the OH group from the iron atom to form ROH, the hydroxylated product, returning the iron atom to the ferric state.

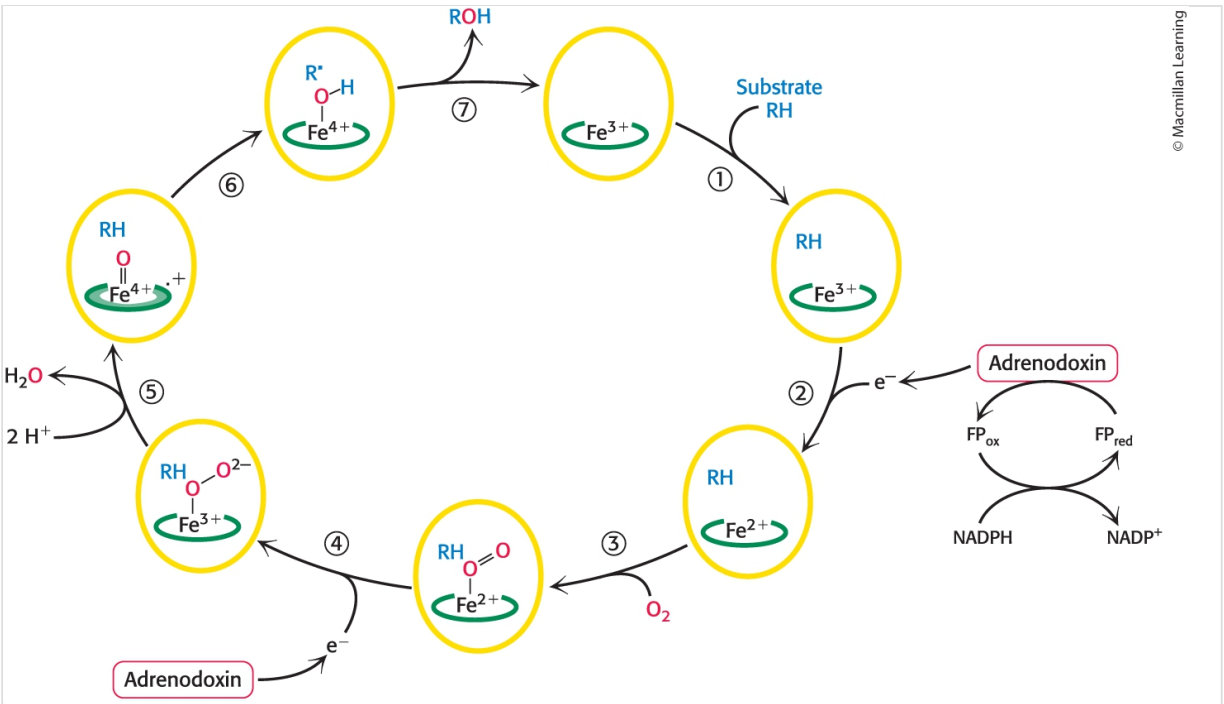

FIGURE 27.26 The reaction mechanism for cytochrome P450 enzymes reveals how oxygen is inserted into R-H bonds. (1) Substrate binds to the enzyme. (2) Adrenodoxin donates an electron, reducing the heme iron. (3) Oxygen binds to Fe^{2+}. (4) Adrenodoxin donates a second electron. (5) The bond between the oxygen atoms is cleaved, a molecule of water is released, and an intermediate with an $Fe^{4+}=O$ group and one electron removed from the porphyrin ring (indicated by shaded ring) is formed. (6) The $Fe^{4+}=O$ intermediate abstracts a hydrogen atom from the substrate to form a substrate radical. (7) The $Fe^{4+}-OH$ intermediate combines with the radical through the oxygen atom to form the hydroxylated product and return the iron to the Fe^{3+} state, ready for another reaction cycle.

Cytochrome P450s are widespread and perform many functions

The human genome encodes 57 members of the cytochrome P450 family, many of which have relatively broad substrate preferences. In addition to their roles in lipid and other biosynthetic pathways, members of the cytochrome P450 family are also important in the metabolism of foreign substances (xenobiotic compounds) including most drugs. For example, the hydroxylation of phenobarbital, a barbiturate, increases its solubility and facilitates its excretion. The duration of action of many drugs depends on their rate of metabolism by cytochrome P450 enzymes.

Some compounds are not active as drugs until they are modified by cytochrome P450 enzymes. These are referred to as *prodrugs*. For example, the anticoagulant clopidogrel (Plavix®) is inactive until it is oxidized by a cytochrome P450 family named cytochrome P450 2C19 (**Figure 27.27**). This requirement is particularly important because the genes encoding this enzyme are variable in the population, with more than 20% of human beings having variants that lead to reduced activity. Clopidogrel does not function well in these individuals. In some settings, a simple genetic is used prior to prescribing clopidogrel, and alternative drugs are used if clopidogrel activation is likely to be inefficient. The appreciation and use of the roles of genomic variations on drug action, a field referred to as *pharmacogenomics*, is of increasing importance.

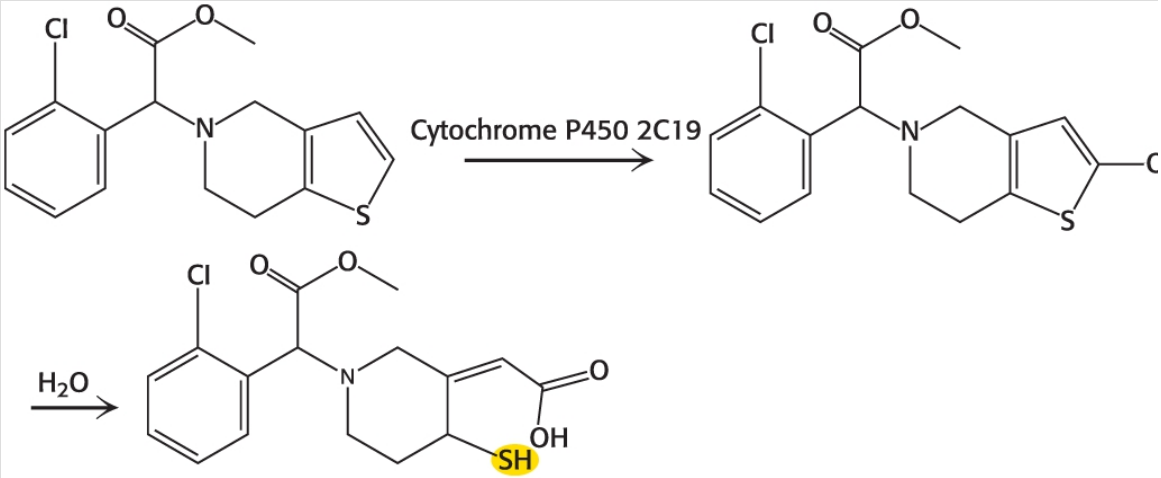

FIGURE 27.27 Cytochrome P450 2C19 converts the prodrug clopidogrel to an active form. The substance taken as clopidogrel is not active. The molecule is hydroxylated by cytochrome P450 2C19, and the product spontaneously hydrolyzes to produce a compound with a reactive thiol group (yellow).

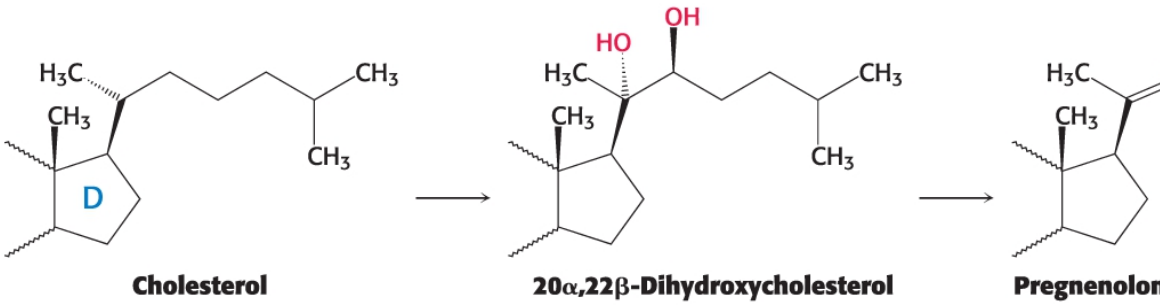
Despite its general protective role in the removal of foreign chemicals, the action of the cytochrome P450 system can also do harm. Some of the most powerful carcinogens are generated from harmless compounds by the cytochrome P450 system in vivo in the process of metabolic activation. In plants, the cytochrome P450 system plays a role in the synthesis of toxic compounds as well as the pigments of flowers.



Keith Weller/Johns Hopkins Medicine

NAMANDJÉ BUMPUS After developing an interest in science from tinkering with chemistry sets as a child, Namandjé Bumpus (shown seated in the photo above) now pursues research at the interface between chemistry and medicine. After majoring in biology and becoming the first person in her family to graduate from college in 2003, she went on to earn a PhD in pharmacology that focused on a member of the cytochrome P450 family, a group of enzymes that has remained a primary interest throughout her career. She has also pursued research on the metabolism of drugs used for the treatment of HIV infections, including the importance of variations in genes for drug-metabolizing genes in determining individual responses to drugs. In 2020, Dr. Bumpus was appointed director of the Department of Pharmacology and Molecular Sciences at Johns Hopkins University School of Medicine, becoming the first Black woman to chair a department in the 128-year history of this prestigious

institution. She has received numerous awards including, appropriately enough, the John J. Abel Award in Pharmacology, named for the biochemist and pharmacologist who, in 1893, founded the department she now leads. In 2022, she was named Chief Scientist of the U.S. Food and Drug Administration (FDA).

Pregnenolone is a precursor of many other steroids

Steroid hormones contain 21 or fewer carbon atoms, whereas cholesterol contains 27. Thus, the first stage in the synthesis of steroid hormones is the removal of a six-carbon unit from the side chain of cholesterol to form the steroid pregnenolone. The side chain of cholesterol is hydroxylated at C-20 and at C-22, and then a third time resulting in cleavage of the bond between these atoms. Each of these steps is catalyzed by cytochrome $P450_{scc}$ (for side-chain cleavage), also known as desmolase and cytochrome P450 11A1.

Progesterone and corticosteroids

Progesterone is synthesized from pregnenolone in two steps. The 3-hydroxyl group of pregnenolone is oxidized to a 3-keto group, and the Δ^5 double bond is isomerized to a Δ^4 double bond (Figure 27.28).

Cortisol, the major glucocorticoid, is synthesized from progesterone by hydroxylations at C-11, C-17, and C-21; C-17 must be hydroxylated before C-21 is hydroxylated, whereas C-11 can be hydroxylated at any stage.

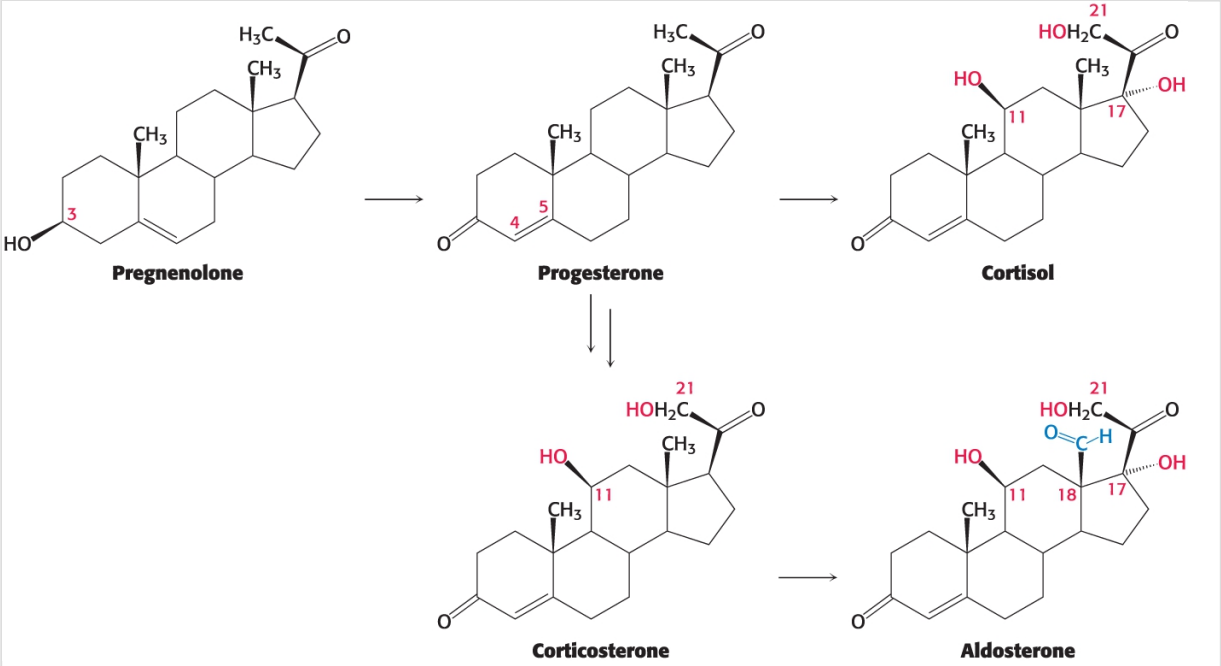


FIGURE 27.28 Pregnenolone is converted into progesterone, cortisol, and aldosterone.

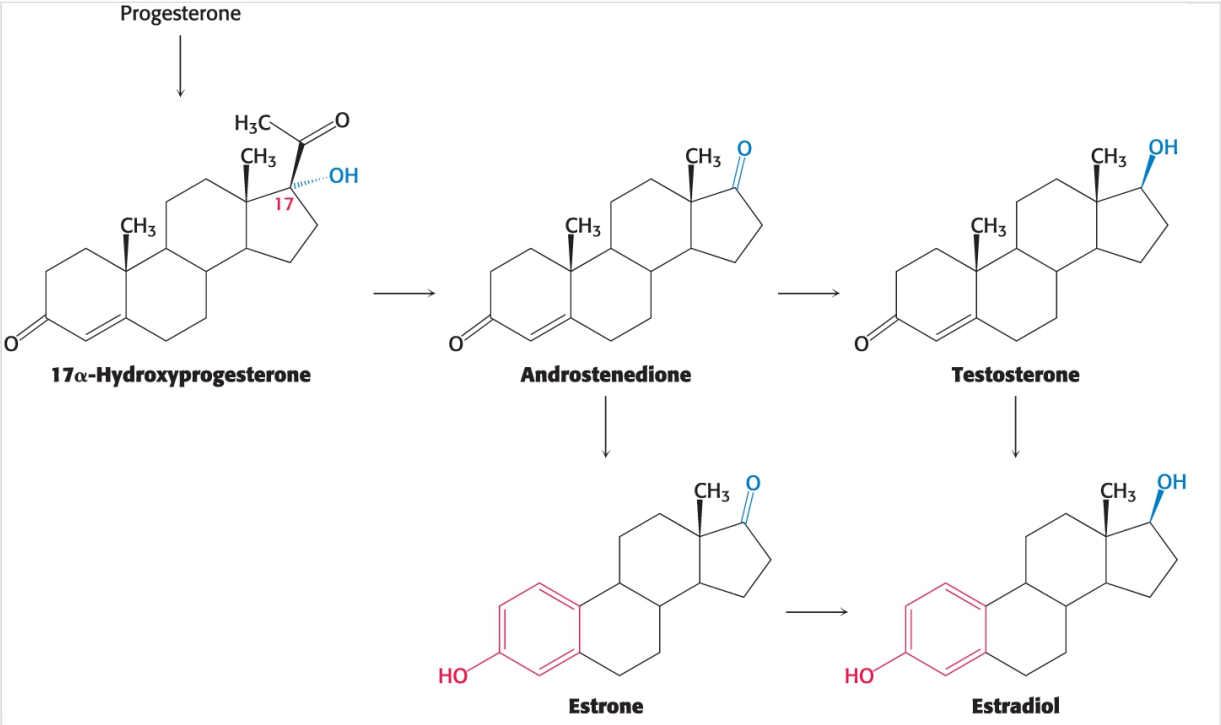
The enzymes catalyzing these hydroxylations are highly specific. The initial step in the synthesis of aldosterone, the major mineralocorticoid, is the hydroxylation of progesterone at C-21. The resulting deoxycorticosterone is hydroxylated at C-11. The oxidation of the C-18 angular methyl group to an aldehyde then yields aldosterone.

Androgens and estrogens

Androgens and estrogens also are synthesized from pregnenolone through the intermediate progesterone. Androgens contain 19 carbon

atoms. The synthesis of androgens starts with the hydroxylation of progesterone at C-17 (Figure 27.29). The side chain consisting of C-20 and C-21 is then cleaved to yield androstenedione, an androgen. Testosterone, another androgen, is formed by the reduction of the 17-keto group of androstenedione.



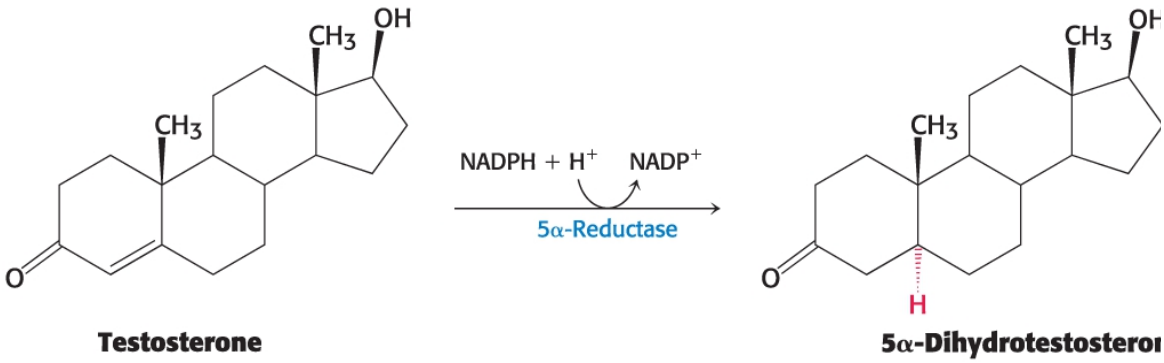


FIGURE 27.29 Progesterone is converted into testosterone and estradiol.

Testosterone is reduced by 5α-reductase to yield dihydrotestosterone, a potent androgen that instigates the development and differentiation of the male phenotype.

Testosterone **5α-Dihydrotestosteron**

Estrogens, the steroid hormones we introduced in Chapter 2, are synthesized from androgens by the loss of the C-19 angular methyl group and the formation of an aromatic A ring. Estrone, an estrogen, is derived from androstenedione, whereas estradiol, the biologically most potent estrogen, is formed from testosterone. Estradiol can also be formed from estrone. The formation of the aromatic A ring is catalyzed by the cytochrome P450 enzyme aromatase.

Because breast and ovarian cancers frequently depend on estrogens for growth, aromatase inhibitors are often used as a treatment for these cancers. Anastrozole (Arimidex) is a competitive inhibitor of the enzyme, whereas exemestane (Aromasin) is a suicide inhibitor that covalently modifies and inactivates the enzyme (**Figure 27.30**). The development of these drugs again reveals how the understanding of biosynthetic pathways can yield important medical and other applications.

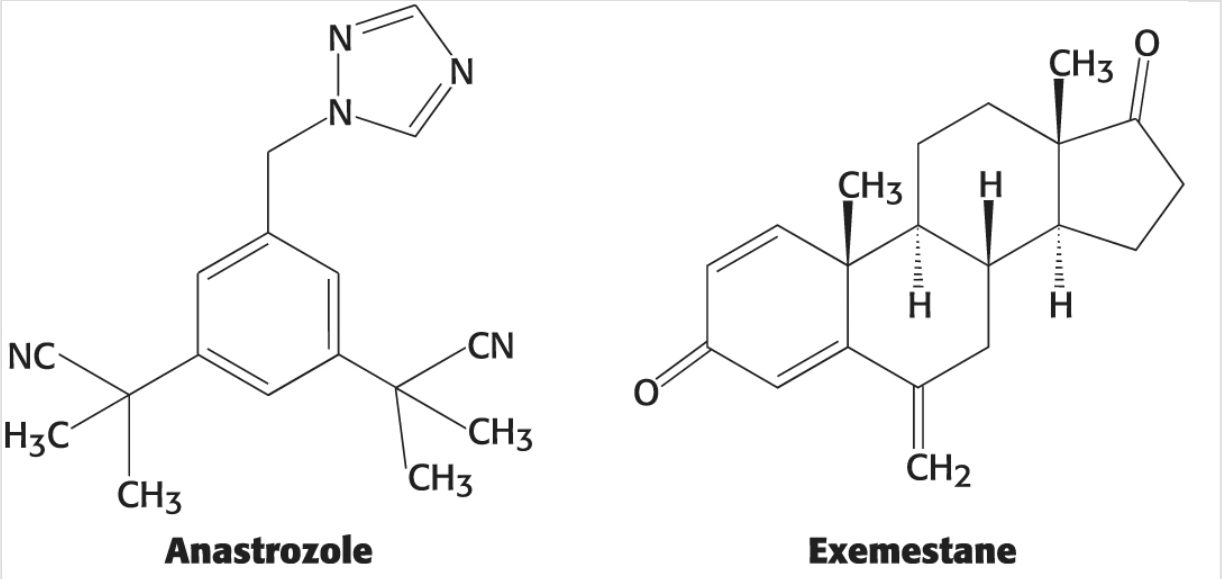

FIGURE 27.30 Drugs such as these for breast cancer can be developed based on knowledge of biosynthetic pathways.

Vitamin D is derived from cholesterol by the ring-splitting activity of light

Cholesterol is also the precursor of vitamin D, which plays an essential role in the control of calcium and phosphorus metabolism. 7-Dehydrocholesterol (provitamin D_3) is photolyzed by the ultraviolet light of sunlight to previtamin D_3, which spontaneously isomerizes to vitamin D_3 (Figure 27.31). Vitamin D_3 (cholecalciferol) is converted into the hormone calcitriol (1,25-dihydroxycholecalciferol), the active form of vitamin D, by hydroxylation reactions in the liver and kidneys. Although not a steroid hormone, vitamin D acts in an analogous fashion. It binds to receptors, homologous to the steroid receptors, to

form complexes that function as transcription factors, regulating gene expression.

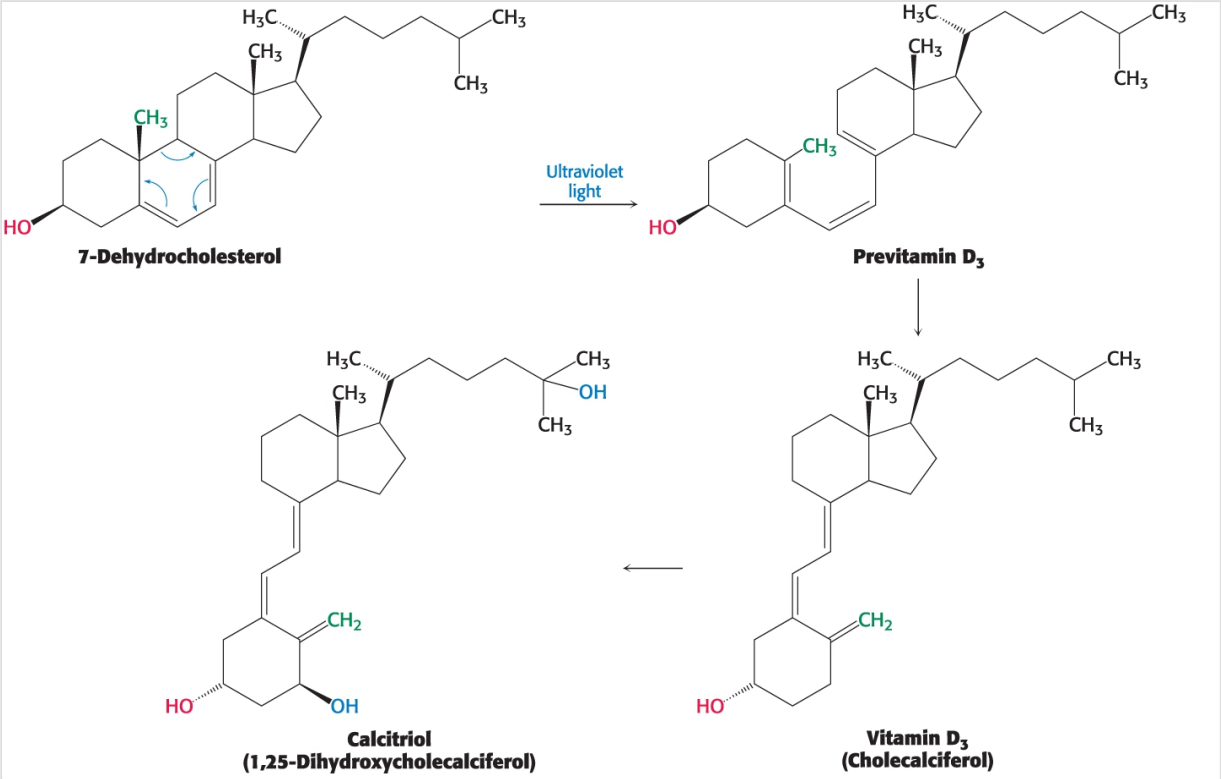

FIGURE 27.31 Vitamin D is synthesized from 7-dehydrocholesterol in a process initiated by absorption of ultraviolet light. The pathway for the conversion of 7-dehydrocholesterol into vitamin D_3 and then into calcitriol (vitamin D) is shown.

Self-Check Question

Label the carbon atoms from 1 to 27 in calcitriol using the numbering scheme from Figure 27.25.

 Vitamin D deficiency in childhood produces rickets, a disease characterized by inadequate calcification of cartilage and bone. Rickets was so common in 17th-century England that it was called the "children's disease of the English." In the typically overcast weather of England, the 7-dehydrocholesterol in the skin of these children was not sufficiently photolyzed to previtamin D_3. Furthermore, their diet provided little vitamin D, because most naturally occurring foods have a low content of this vitamin. Fish-liver oils are a notable exception. Cod-liver oil, abhorred by generations of children because of its unpleasant taste, was used in the past as a rich source of vitamin D. Today, the most reliable dietary sources of vitamin D are fortified foods. Milk, for example, is fortified to a level of 400 international units per quart (10 μg per quart). The recommended daily intake of vitamin D is 200 international units until age 50, after which it increases with age as the skin becomes less able to manufacture previtamin D_3 in response to sunlight; this is a striking reminder that vitamin D is needed by adults as well as by children.

Five-carbon units are joined to form a wide variety of biomolecules

We have seen that a remarkable array of compounds are formed from isopentenyl pyrophosphate, the basic five-carbon building block. The first step, the synthesis of squalene (C_{30}) from isopentenyl pyrophosphate (C_5), exemplifies a fundamental mechanism for the assembly of carbon skeletons of biomolecules. We will end this chapter by looking at a few more biologically important compounds produced from C_5 units.

The fragrances of many plants arise from volatile C_{10} and C_{15} compounds, which are called *terpenes*. For example, myrcene $(C_{10}H_{16})$ from bay leaves, hops, and cannabis, among other plants, consists of two isoprene units, as does limonene $(C_{10}H_{15})$ from lemon oil (**Figure 27.32**). Zingiberene $(C_{15}H_{24})$, from the oil of ginger, is made up of three isoprene units. Some terpenes, such as geraniol from geraniums and menthol from peppermint oil, are alcohols, and others, such as citronellal, are aldehydes. Natural rubber is a linear polymer of *cis*-isoprene units.

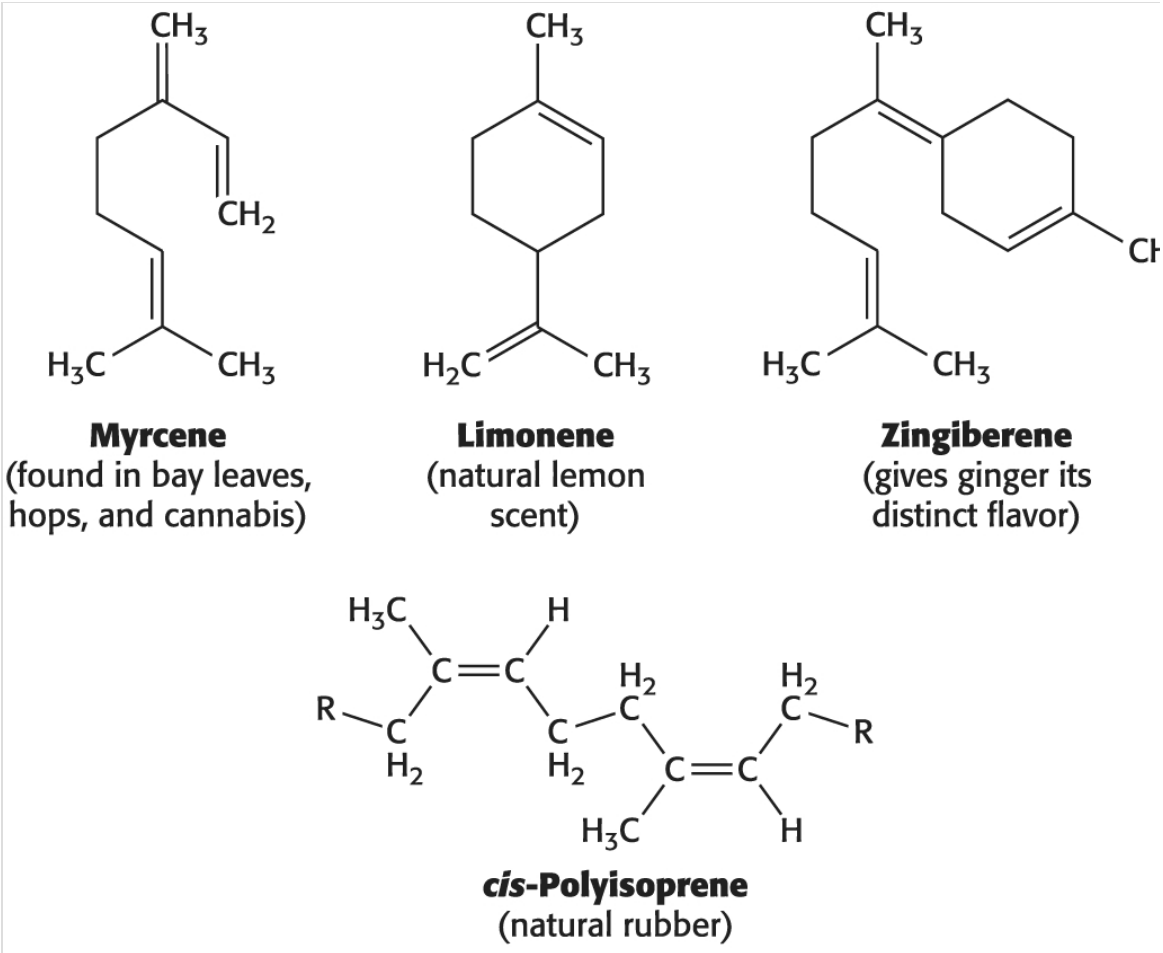

FIGURE 27.32 Some terpenes are familiar from everyday life.

We have already encountered several molecules that contain isoprenoid side chains. The C_{30} hydrocarbon side chain of vitamin K, a key molecule in clotting, is built from six C_5 units. Coenzyme Q_{10} in the mitochondrial respiratory chain has a side chain made up of 10 isoprene units. Yet another example is the phytol side chain of chlorophyll, which is formed from four isoprene units.

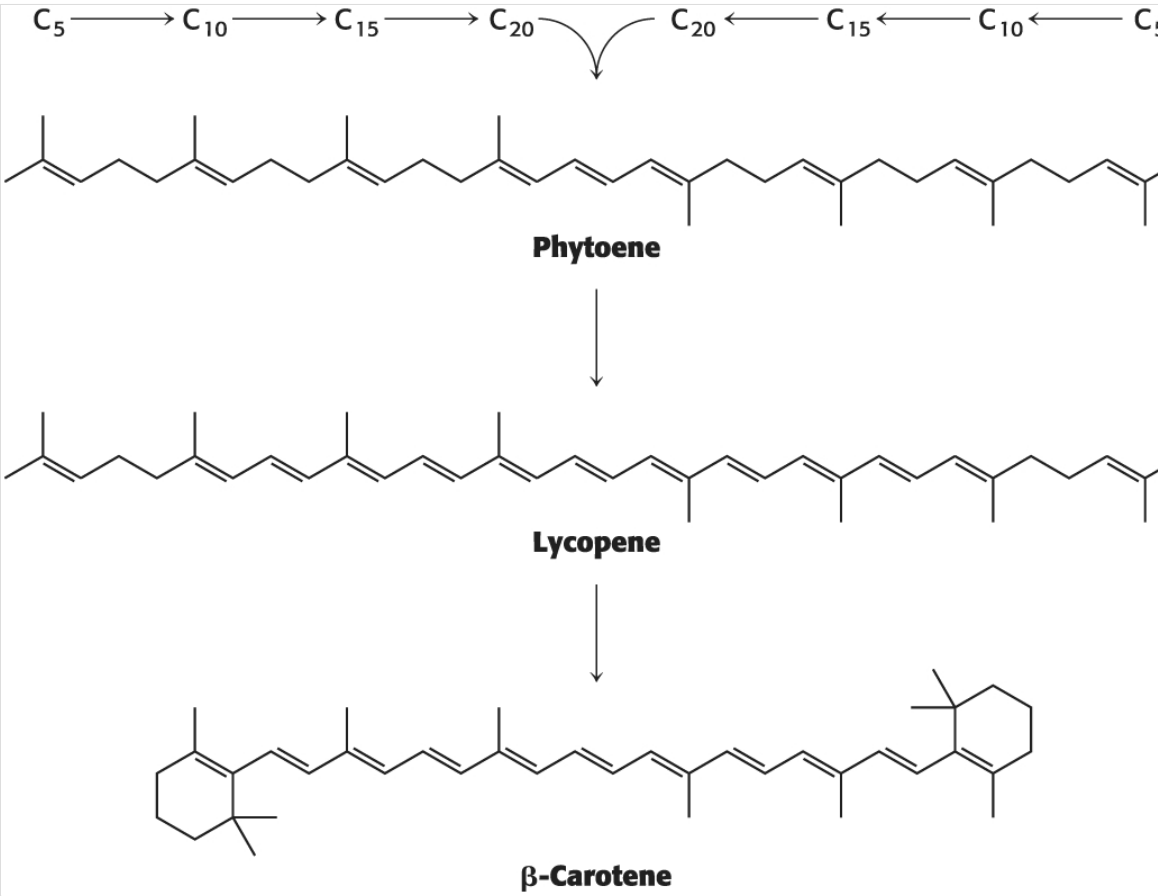
Isoprenoids can delight by their color as well as by their fragrance. The color of tomatoes and carrots comes from *carotenoids*, specifically from lycopene and β-carotene, respectively. These compounds absorb light because they contain extended networks of single and double bonds — that is, they are *polyenes*. Their C_{40} carbon skeletons are built by the successive addition of C_5 units to form geranylgeranyl pyrophosphate, a C_{20} intermediate, which then condenses tail-to-tail with another molecule of geranylgeranyl pyrophosphate. This biosynthetic pathway is like that of squalene, except that C_{20} rather than C_{15} units are assembled and condensed.

$$C_5 \rightarrow C_{10} \rightarrow C_{15} \rightarrow C_{30} \qquad \text{(Squalene)}$$

$$C_5 \rightarrow C_{10} \rightarrow C_{15} \rightarrow C_{20} \rightarrow C_{40} \qquad \text{(Phytoene)}$$

Phytoene, the C_{40} condensation product, is dehydrogenated to yield lycopene. Cyclization of both ends of lycopene gives β-carotene (**Figure 27.33**). Carotenoids serve as light-harvesting molecules in photosynthetic assemblies and also play a role in protecting bacteria from the deleterious effects of light. Carotenoids are also essential for

vision. β-Carotene is the precursor of retinal, the chromophore in visual pigments.



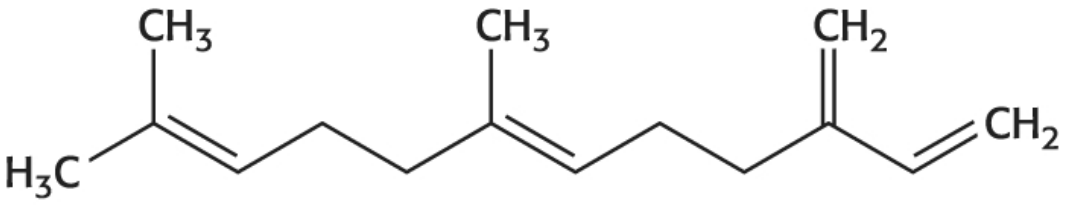


FIGURE 27.33 Two carotenoids responsible for the color of tomatoes and carrots are large isotrenes. Lycopenes give ripe tomatoes their red color, and **b**-carotene gives carrots their orange hue.

Some isoprenoids have industrial applications

Farnesene is an isoprenoid that has potential to meet a wide variety of practical needs (Table 27.2).

Farnesene

TABLE 27.2 Uses of farnesene and its derivatives

As a high-energy density biofuel
As sealants and adhesives
As solvents and lubricants
To make automobile tires that yield improved gas mileage and wet road grip
As a component of cosmetics
To make flavors and fragrances

However, to meet these potential uses in an economical manner, large amounts of farnesene are produced in modified baker's yeast, with genes for four enzymes that were not native to yeast introduced. These genes enable the yeast to ferment sugar cane syrup to farnesene, and

then to secrete the farnesene. The secreted farnesene is 93% pure, and distillation enhances the purity to 98%. This process can be scaled up to industrial levels, thus generating a versatile, renewable biomolecule with a variety of applications.

Chapter 27 Summary

27.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols

- Phosphatidate is formed by successive acylations of glycerol 3-phosphate by acyl CoA.
- Hydrolysis of the phosphoryl group from phosphatidate followed by acylation yields triacylglycerol.
- CDP-diacylglycerol is formed from phosphatidate and CTP. The activated phosphatidyl unit is then transferred to the hydroxyl group of a polar alcohol to form a phospholipid.
- In mammals, phosphatidylethanolamine is formed by CDP-ethanolamine and diacylglycerol. Phosphatidylethanolamine is methylated by *S*-adenosylmethionine to form phosphatidylcholine. Phosphatidylcholine can also be synthesized by a pathway that utilizes dietary choline.
- Sphingolipids are synthesized from ceramide, which is formed by the acylation of sphingosine.

27.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages

- Cholesterol is a steroid component of animal cell membranes and is also a precursor of steroid hormones.
- The committed step in its synthesis is the formation of mevalonate from 3-hydroxy-3-methylglutaryl CoA. Mevalonate is converted into farnesyl pyrophosphate, which condenses with itself to form squalene.
- Squalene cyclizes to lanosterol, which is modified to form cholesterol.

27.3 The Regulation of Cholesterol Biosynthesis Takes Place at Several Levels

- In the liver, cholesterol synthesis is regulated by changes in the amount and activity of 3-hydroxy-3-methylglutaryl CoA reductase. Transcription of the gene, translation of the mRNA, degradation of the enzyme, and enzyme activity are stringently controlled.
- Triacylglycerols exported by the intestine are carried by chylomicrons and then hydrolyzed by lipases lining the capillaries of target tissues. Cholesterol and other lipids in excess of those needed by the liver are exported in the form of very low-density lipoprotein.
- After delivering its content of triacylglycerols to adipose tissue and other peripheral tissue, very-low density lipoprotein is converted into intermediate-density lipoprotein (IDL) and then into low-density lipoprotein (LDL). IDL and LDL carry cholesteryl esters, primarily cholesteryl linoleate.
- Liver and peripheral tissue cells take up LDL by receptor-mediated endocytosis. The LDL receptor, a protein spanning the plasma membrane of the target cell, binds LDL and mediates its entry into the cell.
- Absence of the LDL receptor in the homozygous form of familial hypercholesterolemia leads to a markedly elevated plasma level of LDL cholesterol and the deposition of cholesterol on blood-vessel walls.
- High-density lipoproteins transport cholesterol from the peripheral tissues to the liver.

27.4 Important Biochemicals Are Synthesized from Cholesterol and Isoprene

- Hydroxylations by cytochrome P450 monooxygenases that use NADPH and O_2 play an important role in the synthesis of

steroid hormones and bile salts from cholesterol.

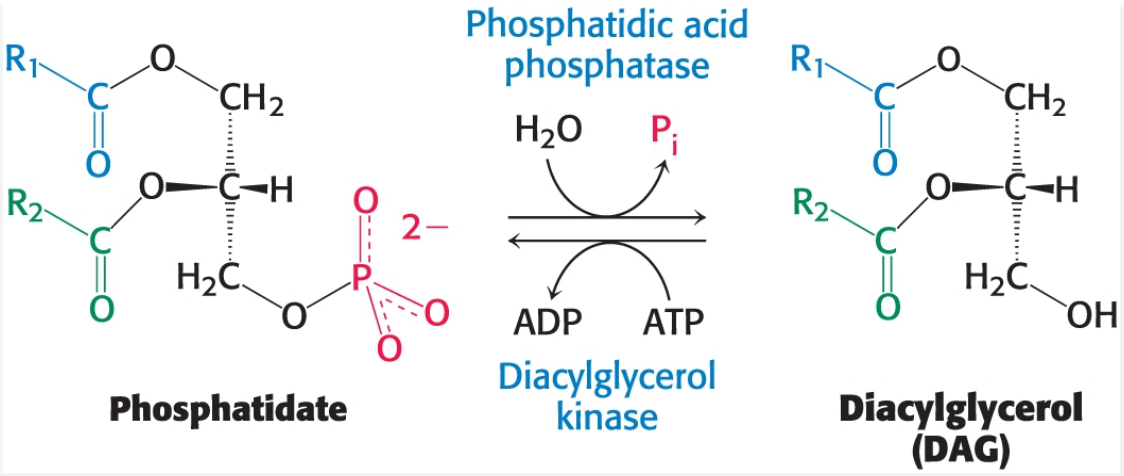
- Five major classes of steroid hormones are derived from cholesterol: progestogens, glucocorticoids, mineralocorticoids, androgens, and estrogens.
- Cytochrome P450 enzymes participate in the detoxification of drugs and other foreign substances.
- Pregnenolone is an essential intermediate in the synthesis of steroids.
- Estrogens are synthesized from androgens by the loss of an angular methyl group and the formation of an aromatic A ring.
- Vitamin D, which is important in the control of calcium and phosphorus metabolism, is formed from a derivative of cholesterol by the action of light.
- A remarkable array of biomolecules in addition to cholesterol and its derivatives are synthesized from isopentenyl pyrophosphate, the basic five-carbon building block.

Key Terms

phosphatidate
triacylglycerol
cytidine diphosphodiacylglycerol (CDP-diacylglycerol)
sphingolipid
ceramide
cholesterol
mevalonate
3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase)
squalene
sterol regulatory element binding protein (SREBP)
lipoprotein particles
low-density lipoprotein (LDL)
high-density lipoprotein (HDL)

receptor-mediated endocytosis
bile salt

Problems

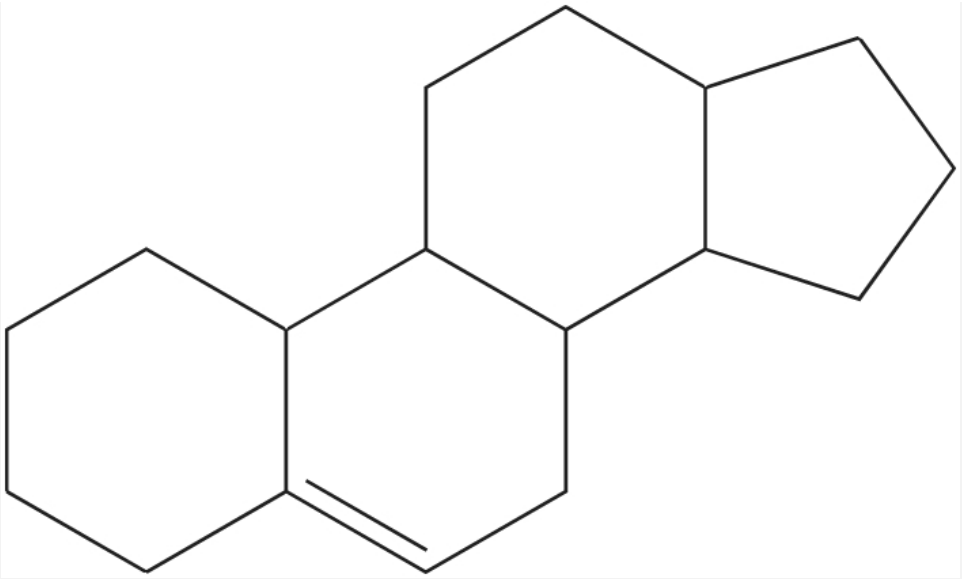


1. How many high-phosphoryl-transfer-potential molecules are required to synthesize phosphatidylethanolamine from ethanolamine and diacylglycerol? Assume that the ethanolamine is the activated component. 1

2. What is the activated reactant in each of the following biosyntheses? 1

a. Phosphatidylinositol from inositol
b. Phosphatidylethanolamine from ethanolamine
c. Ceramide from sphingosine
d. Sphingomyelin from ceramide
e. Cerebroside from ceramide
f. Ganglioside G_{M1} from ganglioside G_{M2}
g. Farnesyl pyrophosphate from geranyl pyrophosphate

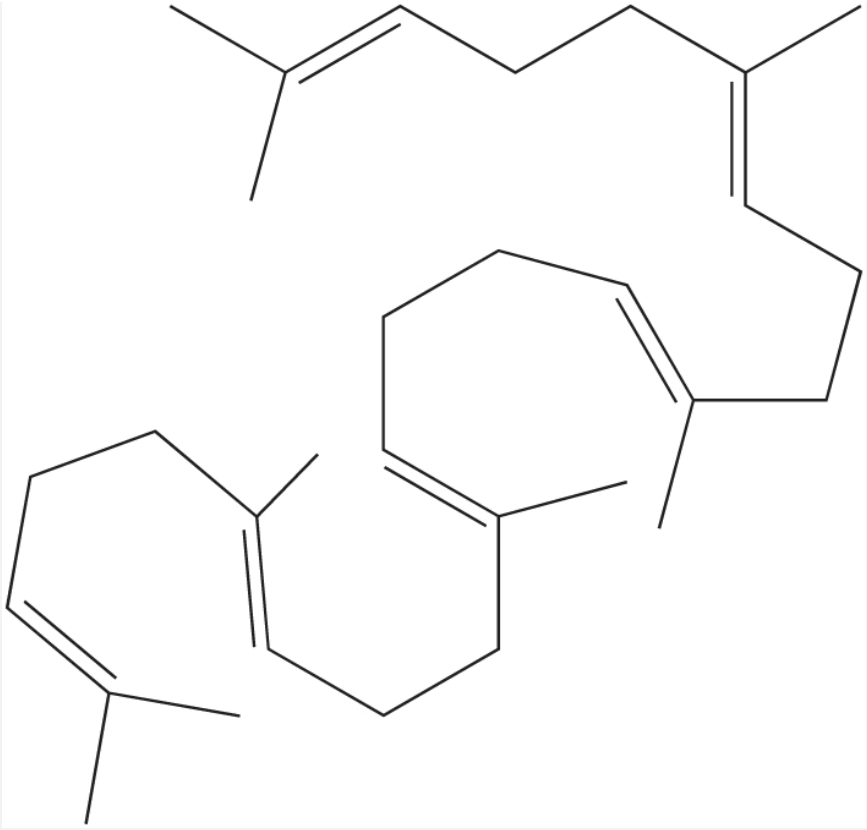
3. Write a balanced equation for the synthesis of a triacylglycerol, starting from glycerol and fatty acids. 1



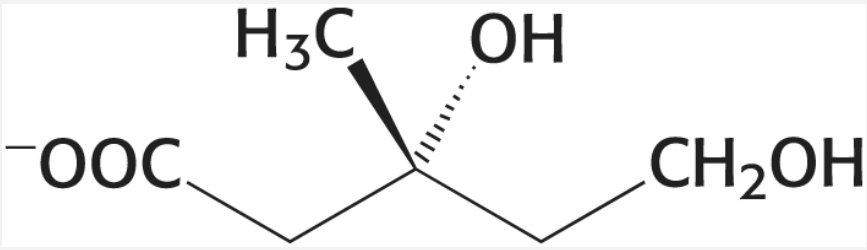
4. Phosphatidic acid phosphatase (PAP) converts phosphatidate to diacylglycerol (DAG). Diacylglycerol kinase converts DAG to phosphatidate.

Consider the effect of an inactivating mutation in the gene encoding PAP on triacylglycerol and phospholipid synthesis. Classify each lipid based on whether its concentration will increase or decrease when the PAP carries this mutation.

a. Phospholipids generated from DAG and activated head groups
b. Triacylglycerols
c. Phospholipids generated from CDP-DAG and a polar head group
d. Phosphatidate
e. Phosphatidylinositol
f. Phosphatidylethanolamine

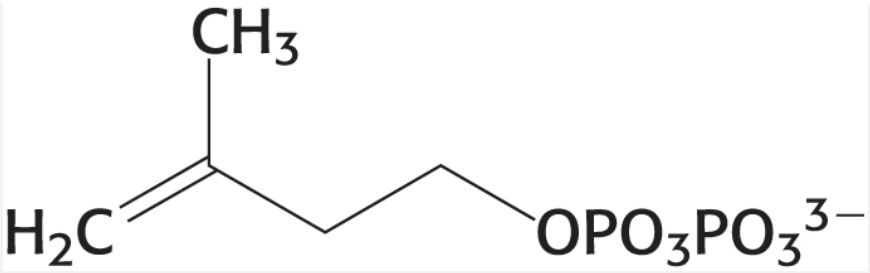


5. Below is the characteristic fused-ring core structure of a steroid. Add atoms as necessary to show the entire structure of cholesterol. 2

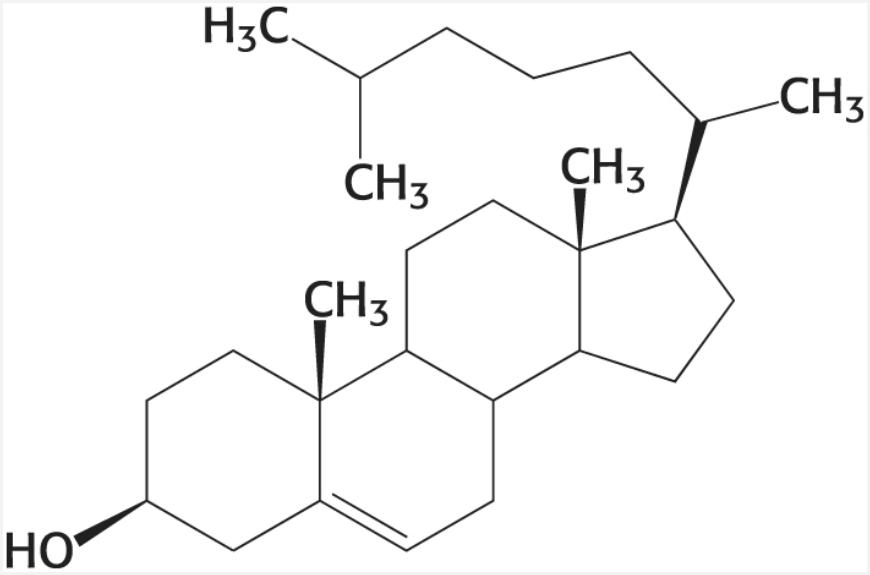


6. What are the three stages required for the synthesis of cholesterol? 2

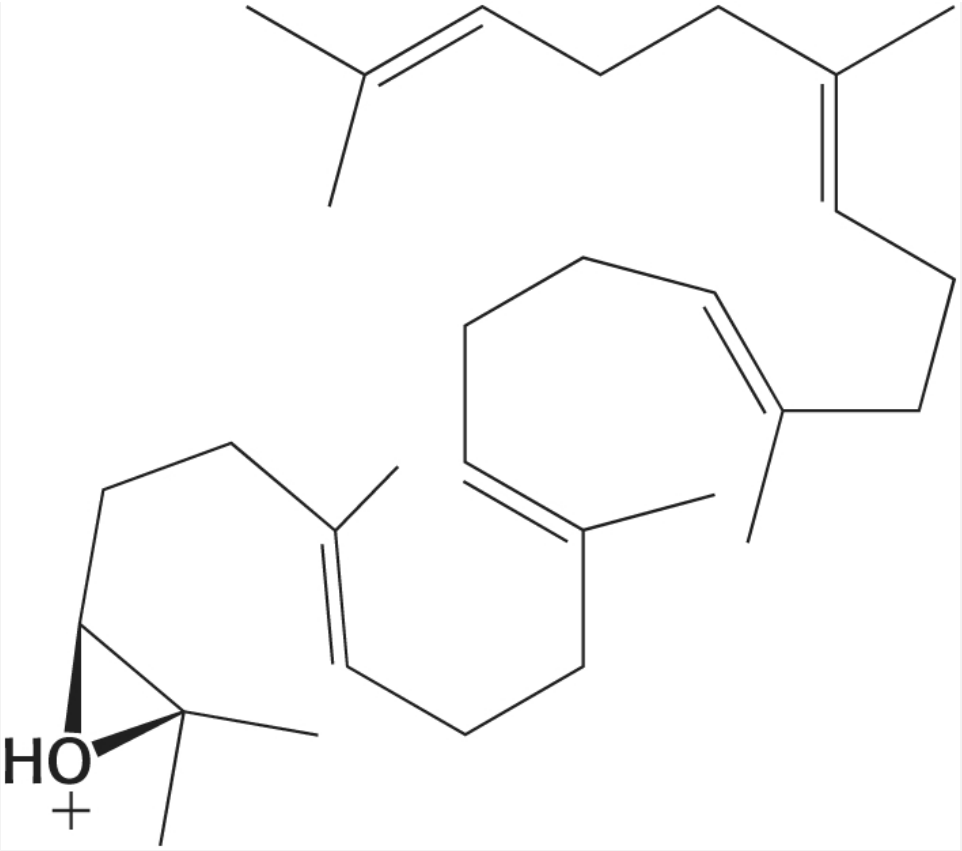
7. Arrange the molecules in the order they appear in cholesterol synthesis. Note that there may be intermediate steps between these molecules. 2



a.



b.



c.

d.

8. A key intermediate in the cyclization of squalene epoxide (in which the epoxide oxygen atom has been protonated) is shown below. Draw arrows indicating the movement of electrons to form the protosterol cation.

9. Arrange the following intermediates in the biosynthesis of cholesterol into their correct order: 2

a. Geranyl pyrophosphate
b. Lanosterol
c. Acetyl CoA
d. Mevalonate
e. Cholesterol
f. Squalene epoxide
g. HMG-CoA
h. Isopentenyl pyrophosphate
i. Farnesyl pyrophosphate

j. Squalene

10. Identify the atoms in mevalonate and isopentenyl pyrophosphate that will be labeled from acetyl CoA labeled with ^{14}C in the carbonyl carbon. 2

11. Outline the mechanisms of the regulation of cholesterol biosynthesis. 3

12. The synthesis of cholesterol is a process that involves over 30 different steps. Which step is the rate-determining step of cholesterol synthesis? 3

13. What are statins? What is their pharmacological function? 3

14. Describe the process of receptor-mediated endocytosis by using LDL as an example. 3

15.

a. Which lipoprotein is the least dense?
b. Which lipoprotein is the most soluble? (Hint: Use Table 27.1 for this question.) 3

16. Match each description to either low-density lipoproteins (LDL) or high-density lipoproteins (HDL): 3

a. Are known as the “bad” cholesterol
b. Have levels that increase with regular exercise
c. Help to remove cholesterol from arteries
d. Can invade artery walls and trigger an inflammatory response

17. At a biochemical level, vitamin D functions like a steroid hormone. Therefore, it is sometimes referred to as an honorary

steroid. Why is vitamin D not an actual steroid? 4

18. Match the steroid or steroid class with its respective function 4

1. Bile salts	1. Regulation of electrolytes (e.g., Na^+, K^+)
2. Androgens	2. Development of female secondary sex characteristics
3. Glucocorticoids	3. Solubilizing dietary lipids
4. Mineralocorticoids	4. Development of male secondary sex characteristics
5. Estrogens	5. Regulation of blood glucose

---

19. 3-Hydroxy-3-methylglutaryl CoA is on the pathway for cholesterol biosynthesis. It is also a component of another pathway. Name the pathway. What determines which pathway 3-hydroxy-3-methylglutaryl CoA follows?

Chapter 28
DNA Replication, Repair, and Recombination

Lou Linwei/Alamy
© Macmillan Learning

Faithful copying is essential to the storage of genetic information. With the precision of a careful artisan copying an exemplar, a DNA polymerase (above) copies DNA strands, preserving the precise sequence of bases with very few errors.

Outline

28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template
28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases
28.3 DNA Replication Is Highly Coordinated
28.4 Many Types of DNA Damage Can Be Repaired

28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

---

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the reactions catalyzed by DNA polymerase, DNA primase, and DNA ligase and the roles of the template, the primer, and Okazaki fragments.
2. Discuss the reaction catalyzed by helicases and key aspects of their mechanisms.
3. Define topoisomers of circular DNA molecules and explain the relationship between twist and writhe in determining the linking number.
4. Describe how different activities of DNA replication are coordinated to faithfully copy and maintain the genome of an organism.
5. Compare and contrast prokaryotic and eukaryotic replication.
6. Define telomeres and describe how they are synthesized.
7. Discuss types of DNA damage and how such lesions can be repaired.
8. Discuss the mechanism of DNA recombination and its role in a variety of biological processes.

Perhaps the most exciting aspect of Watson and Crick's deduction of the structure of DNA was their realization "that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." A double helix separated into two single strands can be replicated because each strand serves as a template on which its complementary sequence can be assembled. To preserve the information encoded in DNA through many cell divisions, copying of the genetic information must be extremely faithful. Although DNA is remarkably robust, ultraviolet light and a range of chemical species can damage DNA, introducing changes in the sequence (mutations) or lesions that can block further DNA

replication. All organisms contain DNA-repair systems that detect DNA damage and act to preserve the original sequence.

28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template

To preserve the information encoded in DNA through many cell divisions, the base sequences of newly synthesized DNA must faithfully match the sequences of parent DNA. To replicate the human genome without mistakes, an error rate of less than 1 bp per 6×10^9 bp must be achieved. Such remarkable precision is achieved through a multilayered system of accurate DNA synthesis (which has an error rate of 1 per 10^3 - 10^4 bases inserted), proofreading during DNA synthesis (which reduces that error rate to approximately 1 per 10^6 - 10^7 bp), and postreplication mismatch repair (which reduces the error rate to approximately 1 per 10^9 - 10^{10} bp).

To achieve faithful replication, each strand within the parent double helix acts as a **template** for the synthesis of a new DNA strand with a complementary sequence, as discussed in Section 8.3. The building blocks for the synthesis of the new strands are deoxyribonucleoside triphosphates. They are added, one at a time, to the $3'$ end of an existing strand of DNA.

Although this reaction is in principle quite simple, it is significantly complicated by specific features of the DNA double helix. First, the two strands of the double helix run in opposite directions. Because DNA strand synthesis always proceeds in the $5'$-to-$3'$ direction, the DNA

replication process must have specific mechanisms to accommodate the oppositely directed strands. Second, the two strands of the double helix interact with one another in such a way that the bases, key templates for replication, are on the inside of the helix. Thus, the two strands must be separated from each other to generate appropriate templates. Finally, the two strands of the double helix wrap around each other. Thus, strand separation also entails the unwinding of the double helix. This unwinding creates supercoils that must themselves be resolved as replication continues. We begin by considering the chemistry that underlies the formation of the phosphodiester backbone of newly synthesized DNA.

DNA polymerases require a template and a primer

Polynucleotide chains are catalyzed by enzymes called **DNA polymerases**. Each incoming nucleoside triphosphate first forms an appropriate base pair with a base in the template. Only then does the DNA polymerase link the incoming base with the predecessor in the chain. Thus, DNA polymerases are template-directed enzymes.

DNA polymerases cannot start synthesis from scratch by adding nucleotides to a single-stranded DNA template — they can only add nucleotides to an existing hydroxyl group at the $3'$ end of a polynucleotide chain. This free hydroxyl group is presented by a **primer** — an initial polynucleotide chain that is already base-paired to the template. The polymerase catalyzes the nucleophilic attack by the $3'$-hydroxyl-group terminus of the polynucleotide chain on the α-phosphoryl group of the nucleoside triphosphate to be added (Figure 8.24). Primers are made by RNA polymerases, which, in contrast to DNA polymerases, can initiate RNA synthesis from scratch (as we shall see in Chapter 29).

DNA polymerases have common structural features

The three-dimensional structures of a number of DNA polymerase enzymes are known. The first such structure was elucidated by Thomas Steitz and coworkers, who determined the structure of the Klenow fragment of DNA polymerase I from *E. coli* (**Figure 28.1**). This fragment comprises two main parts of the full enzyme, including the polymerase unit. This unit approximates the shape of a right hand with domains that are referred to as the fingers, the palm, and the thumb. In addition to the polymerase unit, the Klenow fragment includes a domain with $3' \rightarrow 5'$ **exonuclease** activity that participates in proofreading and correcting the polynucleotide product.

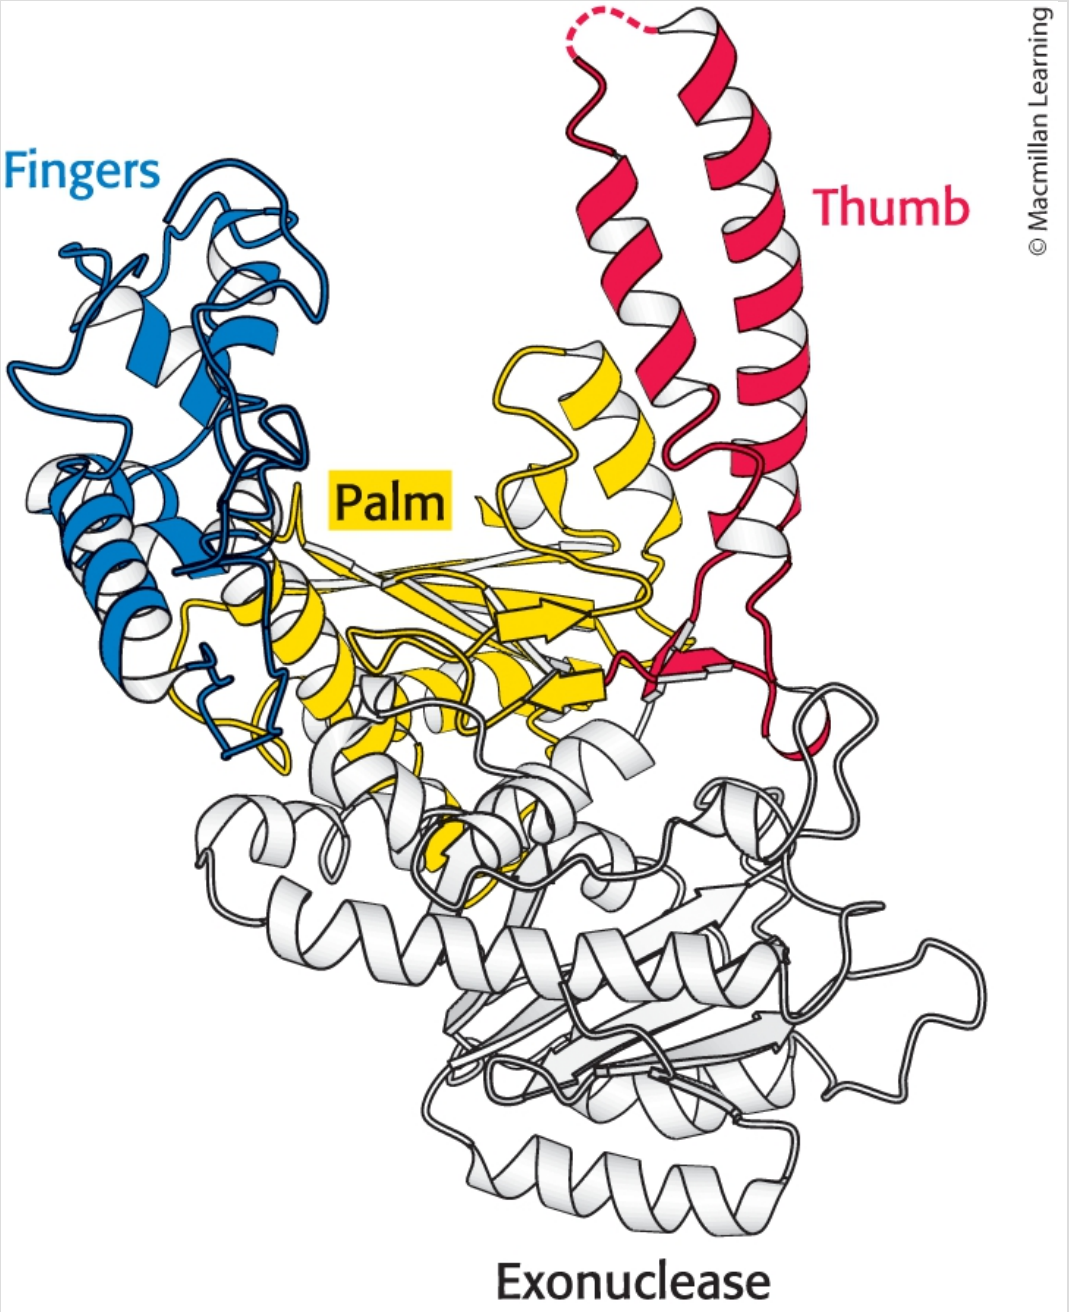


FIGURE 28.1 The structure of the *E.coli* DNA polymerase I Klenow fragment resembles a hand. This was the first DNA polymerase structure to be determined; like the structures of other DNA polymerases determined later, it resembles a right hand with fingers (blue), palm (yellow), and thumb (red). The Klenow fragment also includes an exonuclease domain that removes incorrect nucleotide bases.

[Drawn from 1DPI.pdb.]

INTERACT with this model in Achieve

DNA polymerases are remarkably similar in overall shape, although they differ substantially in detail. At least five structural classes have been identified; some of them are clearly homologous, whereas others appear to be the products of convergent evolution. In all cases, the finger and thumb domains wrap around DNA and hold it across the enzyme's active site, which comprises residues primarily from the palm domain. Furthermore, all DNA polymerases use similar strategies to catalyze the polymerase reaction, making use of a mechanism in which three metal ions take part.

Bound metal ions participate in the polymerase reaction

Like all enzymes with nucleoside triphosphate substrates, DNA polymerases require metal ions for activity. Examination of the structures of DNA polymerases with bound substrates and substrate analogs initially revealed the presence of two metal ions in the active site, but recent data supports a three-metal-ion model. One metal ion binds both the deoxyribonucleoside triphosphate (dNTP) and the $3'$-hydroxyl group of the primer, while the other two interact only with the dNTP (**Figure 28.2**). Two of the three metal ions are bridged by the carboxylate groups of two aspartate residues in the palm domain of the polymerase. These side chains hold the metal ions in the proper positions and orientations. The metal ion bound to the primer activates the $3'$-hydroxyl group of the primer, facilitating its attack on the α-phosphoryl group of the dNTP substrate in the active site. The three metal ions together help stabilize the negative charge that accumulates on the pentacoordinate transition state. The two metal ions initially

bound to the dNTP stabilize the negative charge on the pyrophosphate product.

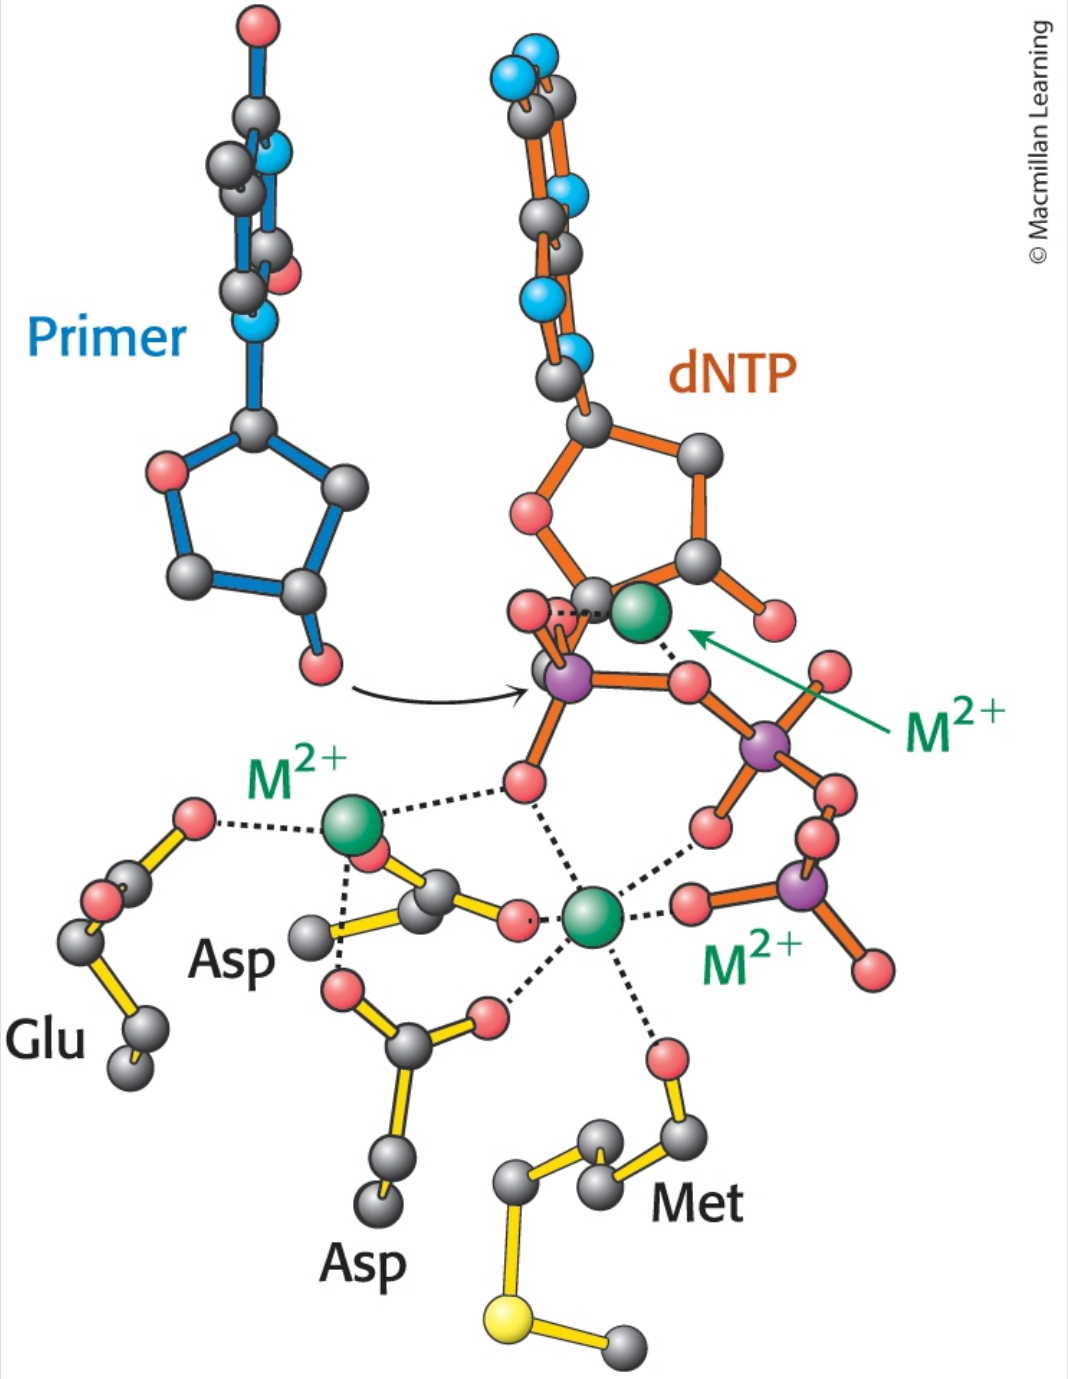

FIGURE 28.2 Three metal ions (typically, Mg^{2+}) participate in the DNA polymerase reaction. One metal ion coordinates the $3'$-hydroxyl group of the

primer, whereas the other two metal ions interact only with the dNTP. The phosphoryl group of the nucleoside triphosphate bridges all three metal ions. Two of the three metal ions are also bridged by the carboxylate groups of two aspartate residues in the polymerase. The hydroxyl group of the primer attacks the phosphoryl group to form a new $O-P$ bond.

Self-Check Question

Provide a chemical explanation of why DNA synthesis proceeds in a $5'$-to-$3'$ direction.

The specificity of replication is dictated by complementarity of shape between bases

Since DNA must be replicated with high fidelity, each base added to the growing chain should, with high probability, be the Watson–Crick complement of the base in the corresponding position in the template strand. The binding of the dNTP containing the proper base is favored by the formation of a base pair with its partner on the template strand. Although hydrogen bonding contributes to the formation of this base pair, overall shape complementarity is crucial. Studies show that a nucleotide with a base that is very similar in shape to adenine but lacks the ability to form base-pairing hydrogen bonds can still direct the incorporation of thymidine, both in vitro and in vivo (Figure 28.3).

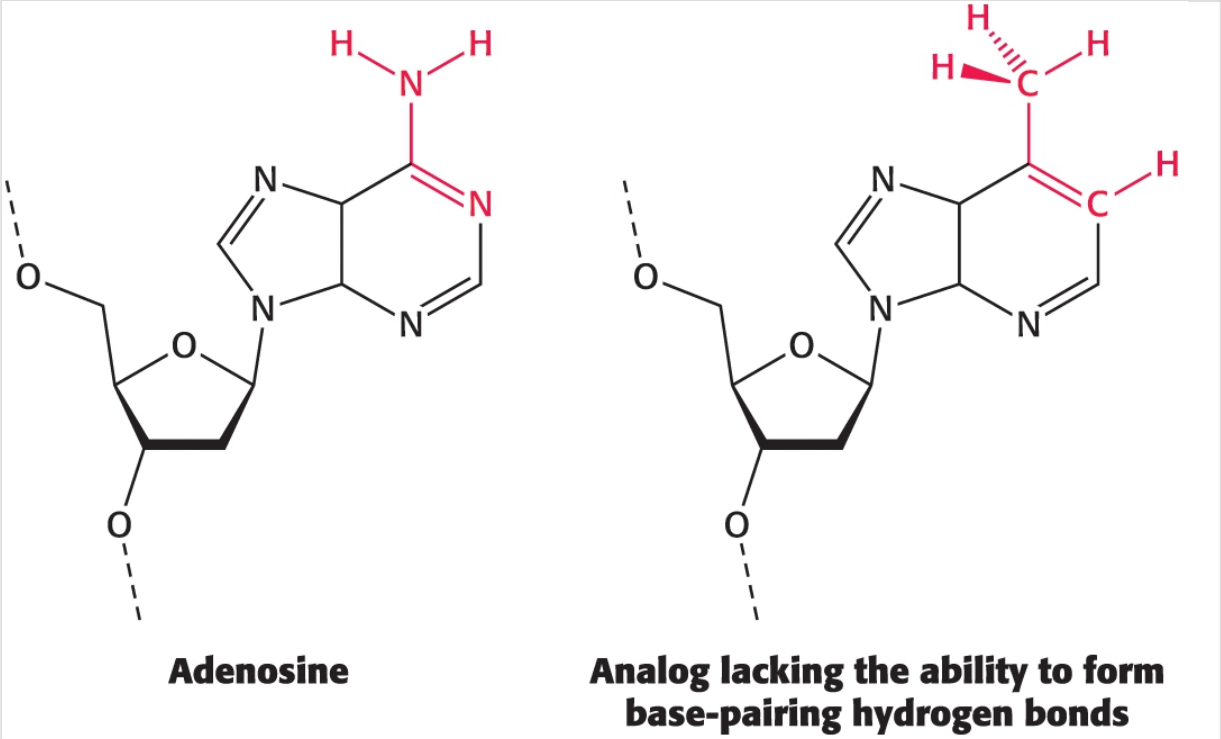

FIGURE 28.3 Base analogs that have the same shape as normal bases can participate in DNA replication. The base analog on the right has the same shape as adenosine, but groups that form hydrogen bonds between base pairs have been replaced by groups not capable of hydrogen bonding (shown in red). Nonetheless, studies reveal that when this analog is incorporated into the template strand, it directs the insertion of thymidine in DNA replication.

An examination of the crystal structures of various DNA polymerases reveals why shape complementarity is so important. First, residues of the enzyme form hydrogen bonds with the minor-groove side of the base pair in the active site (Figure 28.4). In the minor groove, hydrogen-bond acceptors are present in the same positions for all Watson–Crick base pairs. These interactions act as a "ruler" that measures whether a properly spaced base pair has formed in the active site.

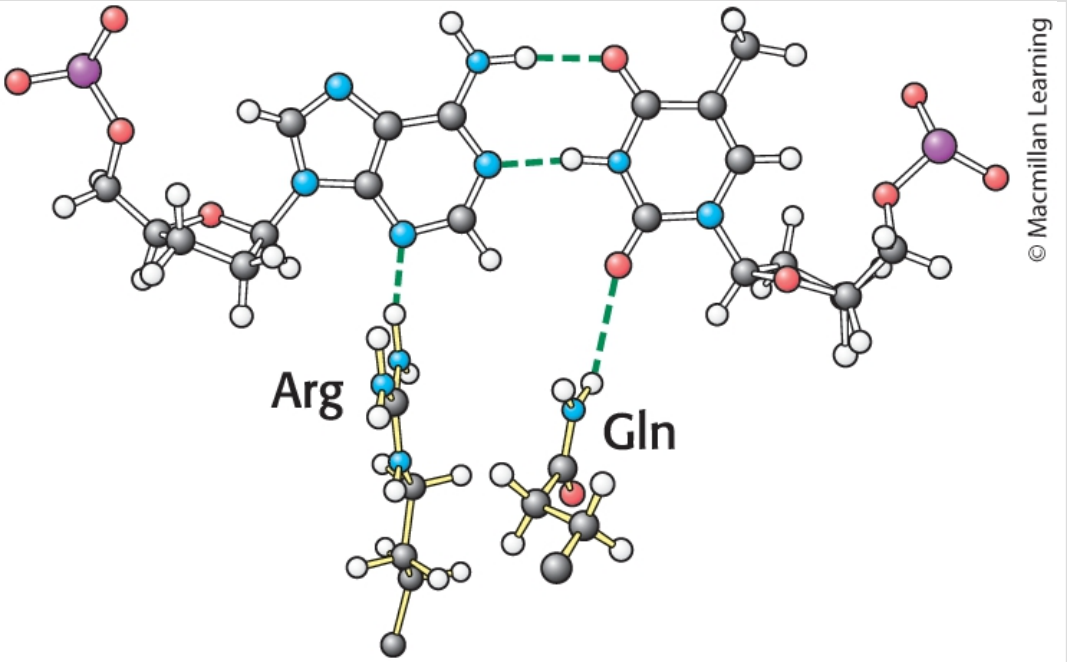

FIGURE 28.4 Minor-groove interactions promote the specificity of DNA replication. DNA polymerases donate two hydrogen bonds to base pairs in the minor groove. Hydrogen-bond acceptors are present in these two positions for all Watson–Crick base pairs, including the A–T base pair shown.

Second, the binding of a dNTP in the active site of a DNA polymerase triggers a conformational change: the finger domain rotates to form a tight pocket into which only a properly shaped base pair will readily fit (Figure 28.5). Many of the residues lining this pocket are important to ensure the efficiency and fidelity of DNA synthesis. For example, mutation of a conserved tyrosine residue that forms part of the pocket results in a polymerase that is approximately 40 times more error prone as the parent polymerase.

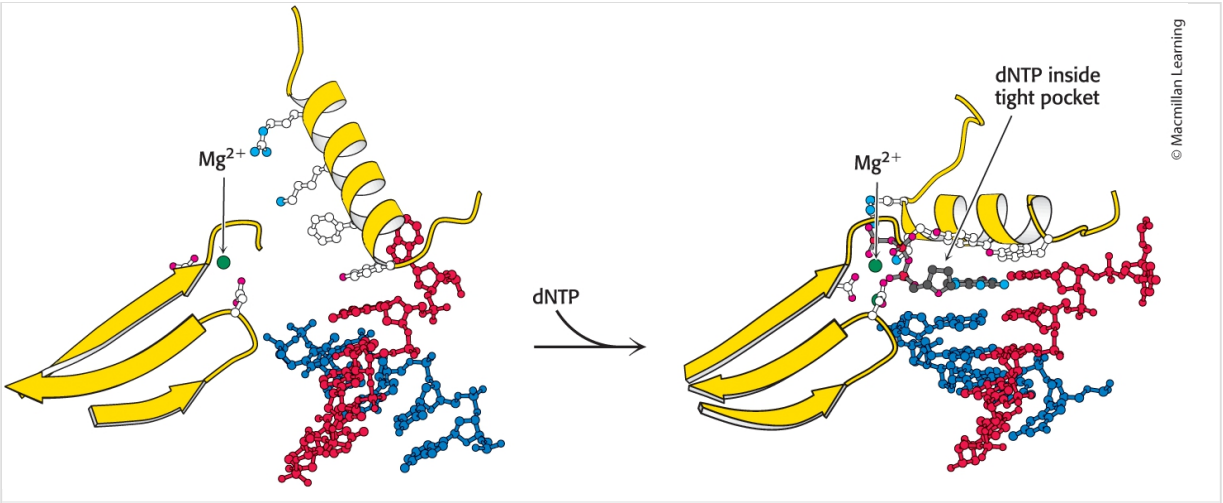

FIGURE 28.5 Shape selectivity promotes the specificity of DNA replication. The binding of a deoxyribonucleoside triphosphate (dNTP) to DNA polymerase induces a conformational change, generating a tight pocket for the base pair consisting of the dNTP and its partner on the template strand. Such a conformational change is possible only when the dNTP corresponds to the Watson–Crick partner of the template base. Only one of the three coordinating metal ions at the active site is shown.

[Drawn from 2BDP.pdb and 1T7P.pdb.]

INTERACT with these models in Achieve

An RNA primer enables DNA synthesis to begin

As discussed above, DNA polymerases require a primer with a free $3'$ end to initiate DNA synthesis. How is this primer formed? An important clue came from the observation that RNA synthesis is essential for the initiation of DNA synthesis. In fact, RNA primes the synthesis of DNA. An RNA polymerase called **primase** synthesizes a short stretch of RNA (about five nucleotides) that is complementary to the template DNA strands (Figure 28.6). Primase, like other RNA polymerases, can initiate

synthesis without a primer. After DNA synthesis has been initiated, the short stretch of RNA is removed by hydrolysis and replaced by DNA.

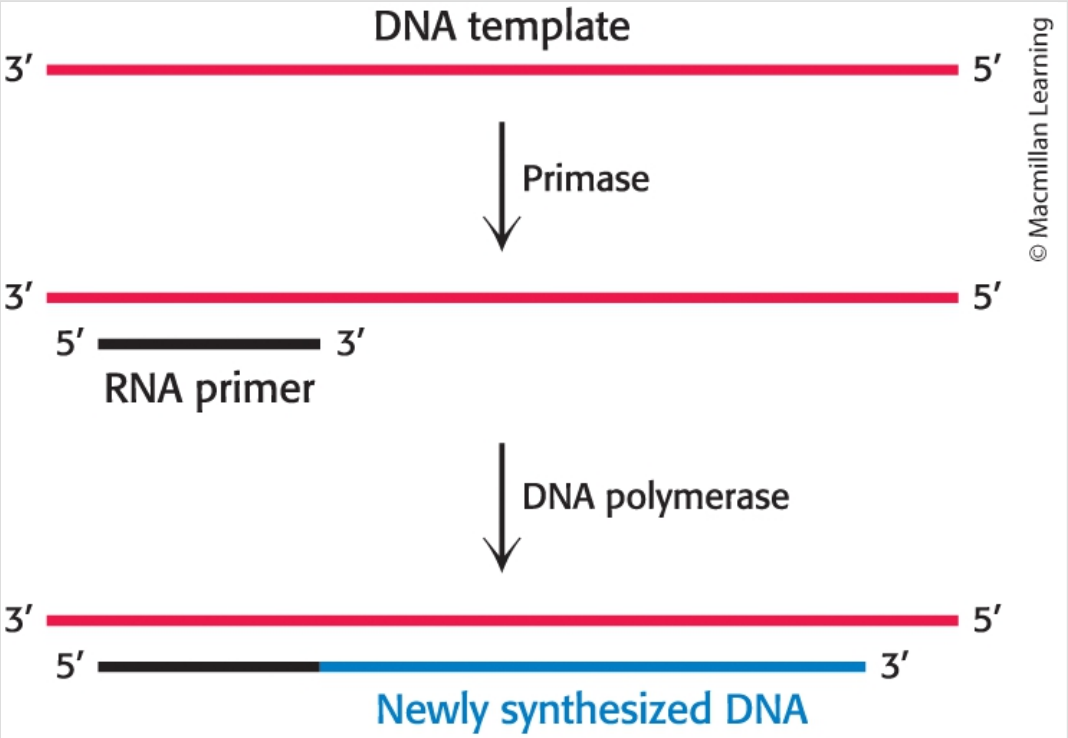

FIGURE 28.6 DNA polymerases require a primer. DNA replication is primed by a short stretch of RNA that is synthesized by primase, an RNA polymerase. The RNA primer is removed at a later stage of replication.

Self-Check Question

DNA replication does not take place in the absence of the ribonucleotides ATP, CTP, GTP, and UTP. Propose an explanation.

One strand of DNA is made continuously, whereas the other strand is synthesized in fragments

Both strands of parental DNA serve as templates for the synthesis of new DNA. The site of DNA synthesis is called the **replication fork** because the complex formed by the newly synthesized daughter helices arising from the parental duplex resembles a two-pronged fork. Recall that the two template strands are antiparallel; that is, they run in opposite directions. Since all known DNA polymerases synthesize DNA only in the $5' \rightarrow 3'$ direction, the two daughter strands must be synthesized in opposite directions: one away from the fork, and one toward the fork. How exactly does this work?

An answer to this question was provided by Reiji Okazaki and his wife Tsuneko Okazaki, who found that a significant proportion of newly synthesized DNA exists as small fragments. These units of about a thousand nucleotides (called **Okazaki fragments**) are present briefly in the vicinity of the replication fork (**Figure 28.7**). As replication proceeds, these fragments become covalently joined, forming a continuous daughter strand. The other new strand is synthesized continuously. The strand formed from Okazaki fragments is termed the **lagging strand**, whereas the one synthesized without interruption is the **leading strand**.

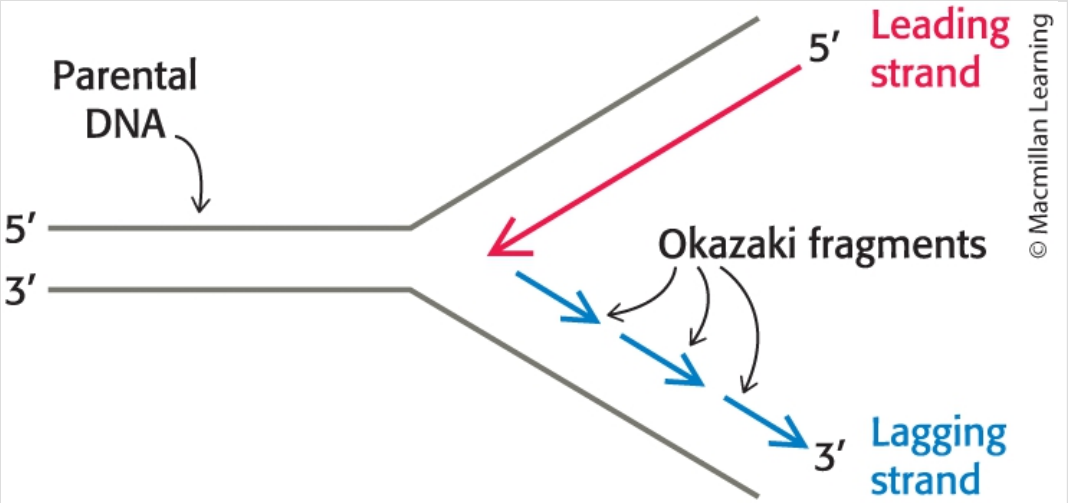

FIGURE 28.7 The lagging strand is made in short pieces called Okazaki fragments.

At a replication fork, both strands are synthesized in the $5' \rightarrow 3'$ direction, but only the leading strand is synthesized continuously

Tsuneko Okazaki, University Professor, Nagoya University

TSUNEKO AND REIJI OKAZAKI Growing up in Japan during World War II, Tsuneko and Reiji Okazaki persevered in their studies despite wartime hardships. Tsuneko's father wanted her to pursue medicine, but she was more interested in biology and became a researcher at a time when it was a very rare career path for women. Tsuneko met and married Reiji while they were both at Nagoya University, and in the early 1960s they briefly worked at Stanford University in the lab of Arthur Kornberg, who had recently extracted DNA polymerase activity from *E.coli*. Back at Nagoya University, they continued to investigate how DNA polymerase could be replicating antiparallel strands of DNA in only one direction, eventually leading to their discovery of the

short-lived DNA fragments that now carry their name. In 1975 Reiji died of leukemia, a consequence of his exposure to intense radiation in Hiroshima as a teenager. Dr. Tsuneko Okazaki continued in research while also raising two children, and she went on to have a distinguished academic career.

DNA ligase seals breaks in double-stranded DNA

The joining of Okazaki fragments requires an enzyme that can connect the ends of two DNA chains. The existence of circular DNA molecules also points to the existence of such an enzyme. In 1967, scientists in several laboratories simultaneously discovered **DNA ligase**, the enzyme that catalyzes the formation of a phosphodiester linkage between the $3'$-hydroxyl group at the end of one DNA chain and the $5'$-phosphoryl group at the end of the other (**Figure 28.8**). An energy source is required to drive this thermodynamically uphill reaction. In eukaryotes and archaea, ATP is the energy source. In bacteria, NAD^+ typically plays this role.

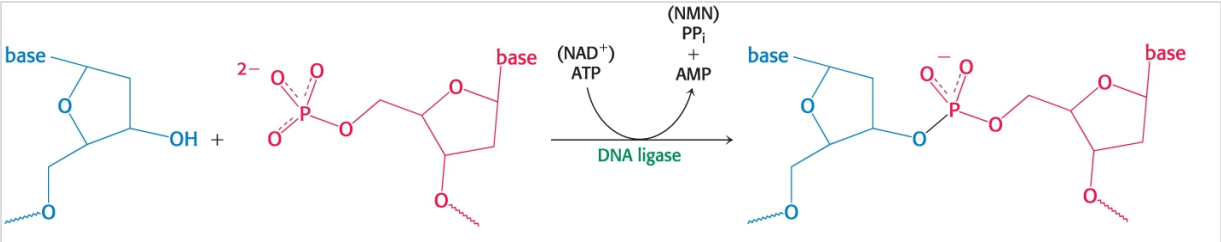

FIGURE 28.8 DNA ligase catalyzes the joining of two DNA strands. In this reaction, one DNA strand with a free $3'$-hydroxyl group is joined to another with a free $5'$-phosphoryl group. In eukaryotes and archaea, ATP is cleaved to AMP and PP_i to drive this reaction. In bacteria, NAD^+ is cleaved to AMP and nicotinamide mononucleotide (NMN).

DNA ligase cannot link two single-stranded DNA molecules or circularize single-stranded DNA. Rather, ligase seals breaks in double-stranded DNA molecules. The enzyme from *E. coli* ordinarily forms a phosphodiester bridge only if there are at least a few bases of single-stranded DNA on the end of a double-stranded fragment that can come together with those on another fragment to form base pairs. Ligase encoded by T4 bacteriophage can link two blunt-ended double-helical fragments, a capability that is exploited in recombinant DNA technology.

The separation of DNA strands requires specific helicases and ATP hydrolysis

For a double-stranded DNA molecule to replicate, the two strands of the double helix must be separated from each other, at least locally. This separation allows each strand to act as a template on which a new polynucleotide chain can be assembled. Specific enzymes, termed **helicases**, harness the energy of ATP hydrolysis to power strand separation.

While helicases are a large and diverse family of enzymes taking part in many biological processes, the helicases in DNA replication are typically oligomers containing six subunits that form a ring structure. The structure of one such helicase, that from bacteriophage T7, has been a source of considerable insight into the helicase mechanism (**Figure 28.9**).

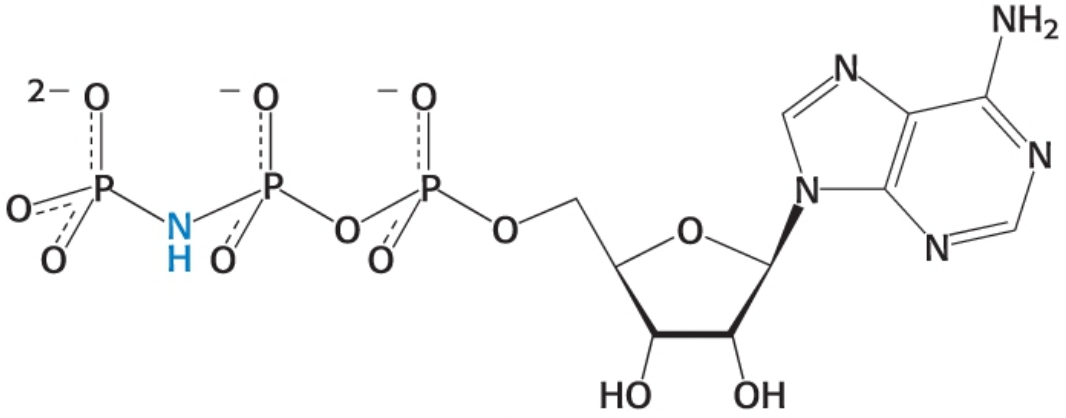

FIGURE 28.9 Helicases are hexamers. The structure of the hexameric helicase from bacteriophage T7 is shown. The loops that participate in DNA binding are highlighted by a yellow oval in one of the subunits. Each subunit interacts closely with its neighbors, and the DNA-binding loops line the hole in the center of the structure.

[Drawn from 1E0K.pdb.]

Each of the subunits within this hexameric structure has two loops that extend toward the center of the ring structure and interact with DNA. Each subunit interacts closely with its two neighbors within the ring structure. Closer examination of this structure reveals that the ring deviates significantly from sixfold symmetry, a deviation that is even

more apparent when helicase is crystallized in the presence of the nonhydrolyzable ATP analog AMP-PNP.

AMP-PNP

The AMP-PNP binds to only four of the six subunits within the ring (**Figure 28.10**). Furthermore, the four nucleotide binding sites are not identical but fall into two classes. One class appears to be well positioned to bind ATP but not catalyze its hydrolysis, whereas the other class is more well-suited to catalyze the hydrolysis but not release the hydrolysis products. The classes are analogous to myosin's two different conformations — one for binding ATP and one for hydrolyzing it (Section 6.4). Finally, the six subunits fall into three classes with regard to their orientation within the overall ring structure, with differences in rotation around an axis in the plane of the ring of approximately 30°. These differences in orientation affect the positions of the two DNA-binding loops in each subunit.

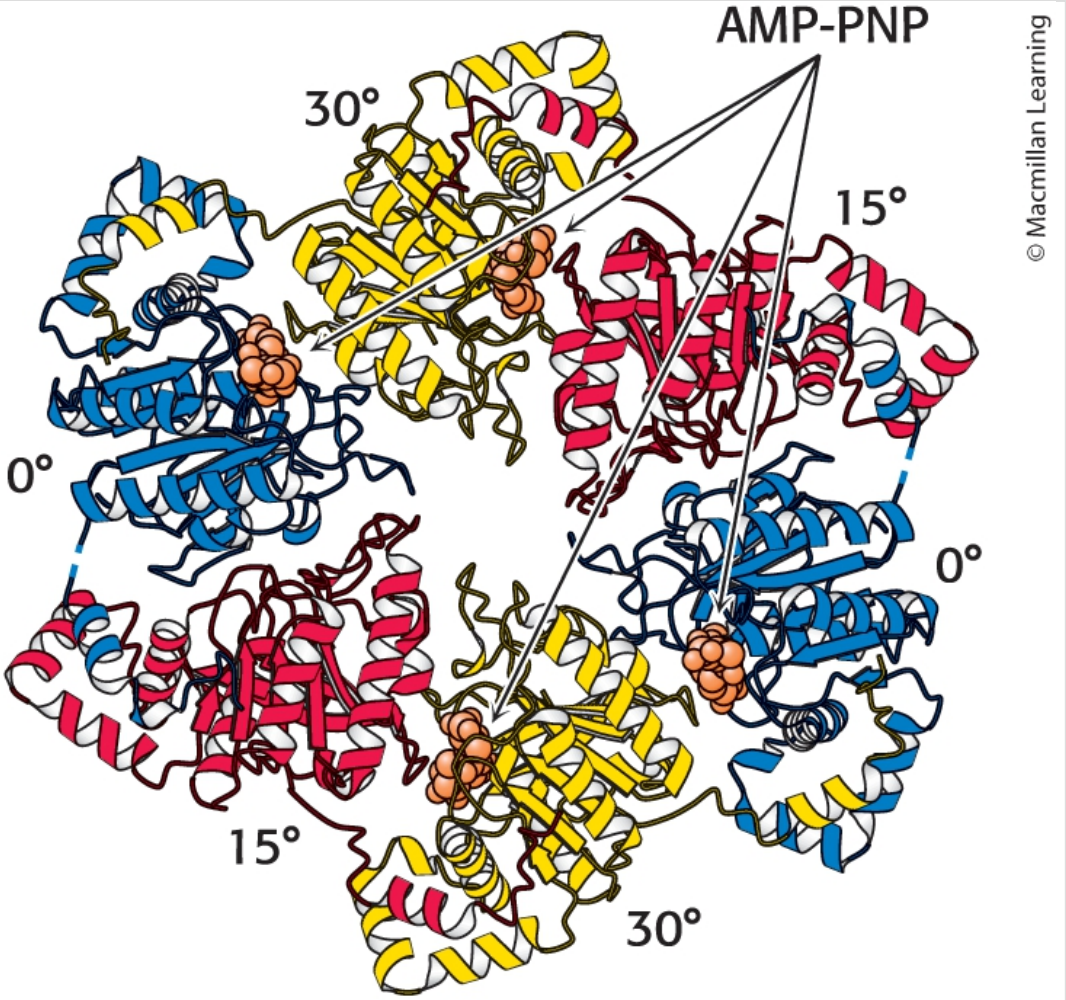

FIGURE 28.10 Helicases have intrinsic asymmetry. The structure of the T7 helicase complexed with the ATP analog AMP-PNP is shown. The three classes of helicase subunits are shown in blue, red, and yellow. The rotation relative to the plane of the hexamer is shown for each subunit. Notice that only four of the subunits, those shown in blue and yellow, bind AMP-PNP.

[Drawn from 1E0K.pdb.]

These observations are consistent with the following mechanism for the helicase (Figure 28.11):

1. Only a single strand of DNA can fit through the center on the ring. This single strand binds to loops on two adjacent subunits, one of

which has bound ATP and the other of which has bound $ADP + P_i$.

2. The binding of ATP to the domains that initially had no bound nucleotides causes a conformational change within the entire hexamer, leading to the release of $ADP + P_i$ from two subunits and the binding of the single-stranded DNA by one of the domains that just bound ATP. This conformational change pulls the DNA through the center of the hexamer.

3. The protein acts as a wedge, forcing the two strands of the double helix apart.

4. This cycle then repeats itself, moving two bases along the DNA strand with each cycle.

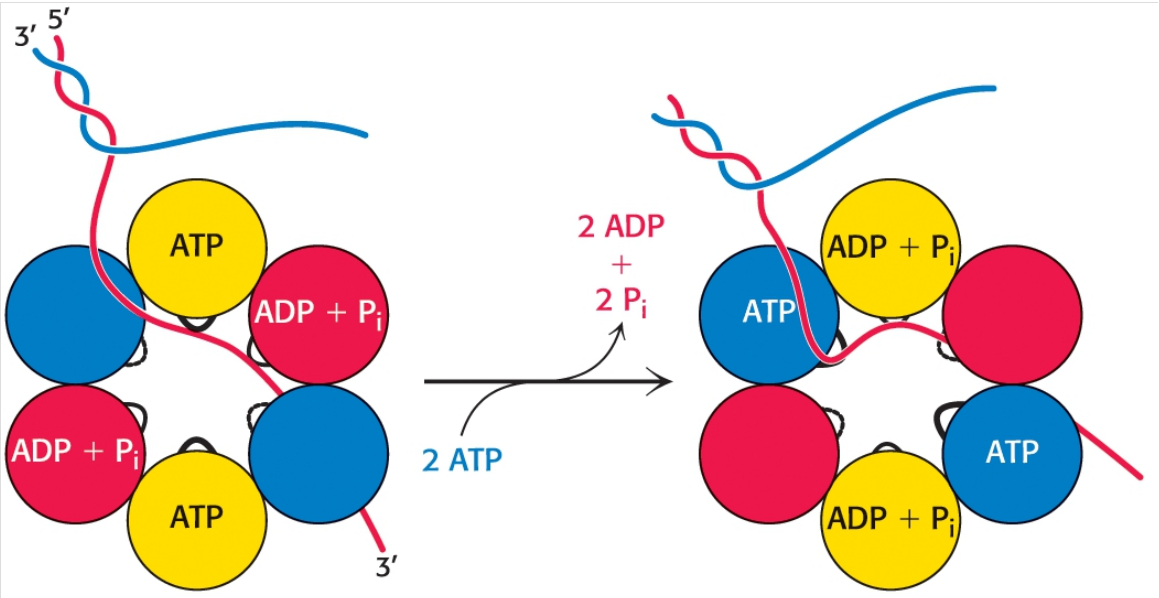

FIGURE 28.11 Helicases unwind DNA. One of the strands of the double helix passes through the hole in the center of the helicase, bound to the loops of two adjacent subunits. Two of the subunits do not contain bound nucleotides. On the binding of ATP to these two subunits and the release of $ADP + P_i$ from two other subunits, the helicase hexamer undergoes a conformational change, pulling the DNA through the helicase. The helicase acts as a wedge to force separation of the two strands of DNA.

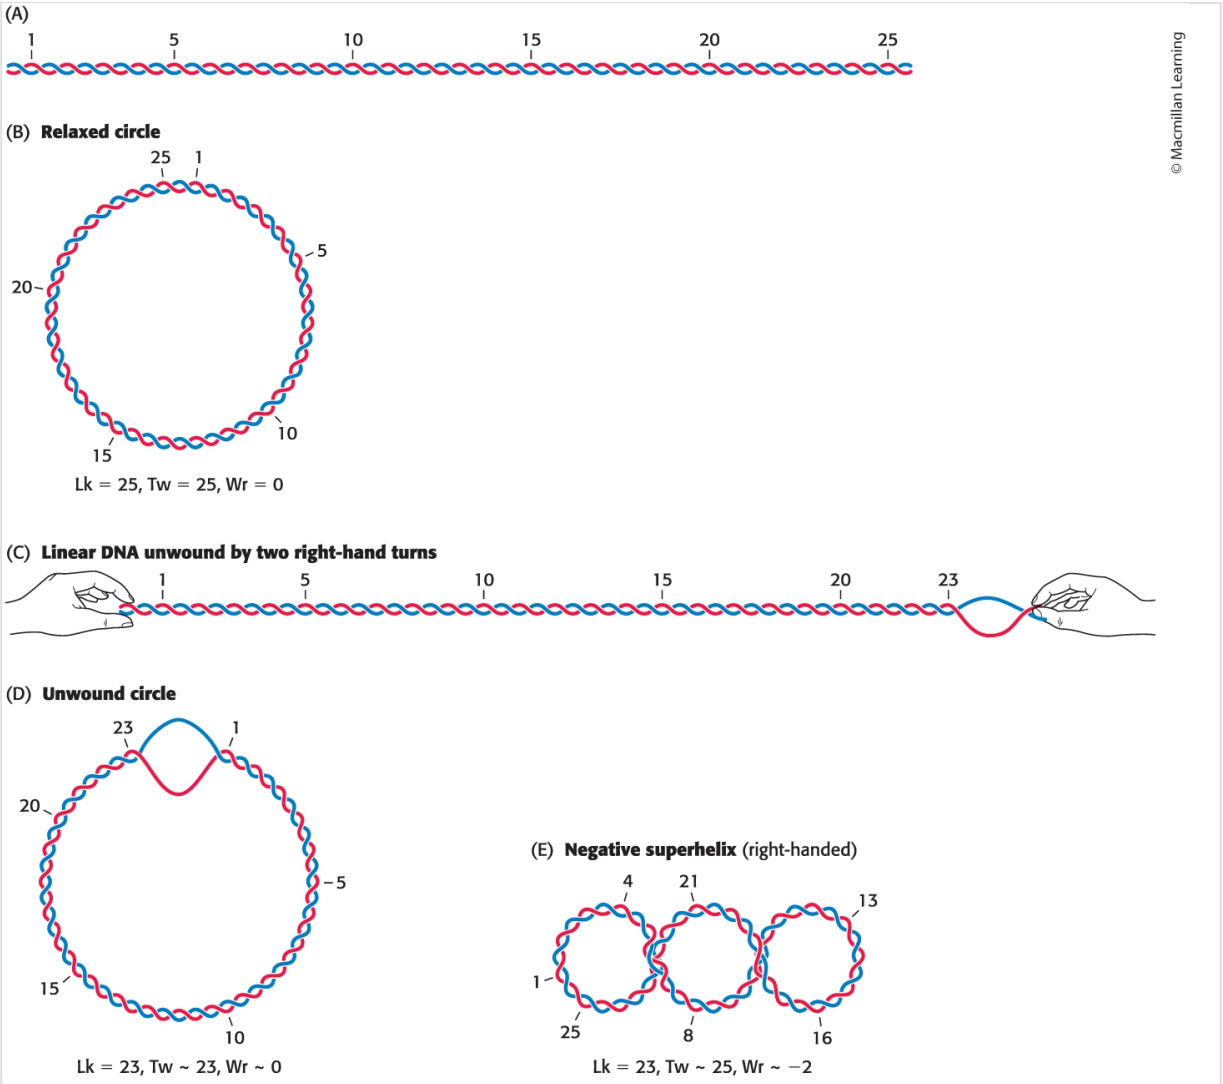
28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases

As a helicase moves along unwinding DNA, the DNA in front of the helicase will become overwound in the absence of other changes. DNA double helices that are torsionally stressed tend to fold up on themselves to form tertiary structures created by **supercoiling**. Supercoiling is most readily understood by considering circular DNA molecules, but it also applies to linear DNA molecules constrained to be in loops by other means. In fact, most DNA molecules inside cells are subject to supercoiling. We will first consider the supercoiling of DNA in quantitative terms and then turn to topoisomerases, enzymes that can directly alter DNA winding and supercoiling.

Consider a linear 260-bp DNA duplex in the B-DNA form (**Figure 28.12A**). Because the number of base pairs per turn in an unstressed DNA molecule averages 10.4, this linear DNA molecule has 25 (260/10.4) turns. The ends of this helix can be joined to produce what is called a *relaxed* circular DNA (**Figure 28.12B**). A different circular DNA can be formed by unwinding the linear duplex by two turns before joining its ends (**Figure 28.12C**). What is the structural consequence of unwinding before ligation? Two limiting conformations are possible. The DNA can fold into a structure containing 23 turns of B helix and an unwound loop (**Figure 28.12D**). Alternatively, the double helix can undergo supercoiling, in which it folds up to cross itself. In this example, a supercoiled structure with 25 turns of B helix and 2 turns of right-handed (termed *negative*) supercoils can be formed (**Figure 28.12E**). Unwinding will cause supercoiling in circular DNA molecules, whether covalently closed or constrained in closed configurations by other means.



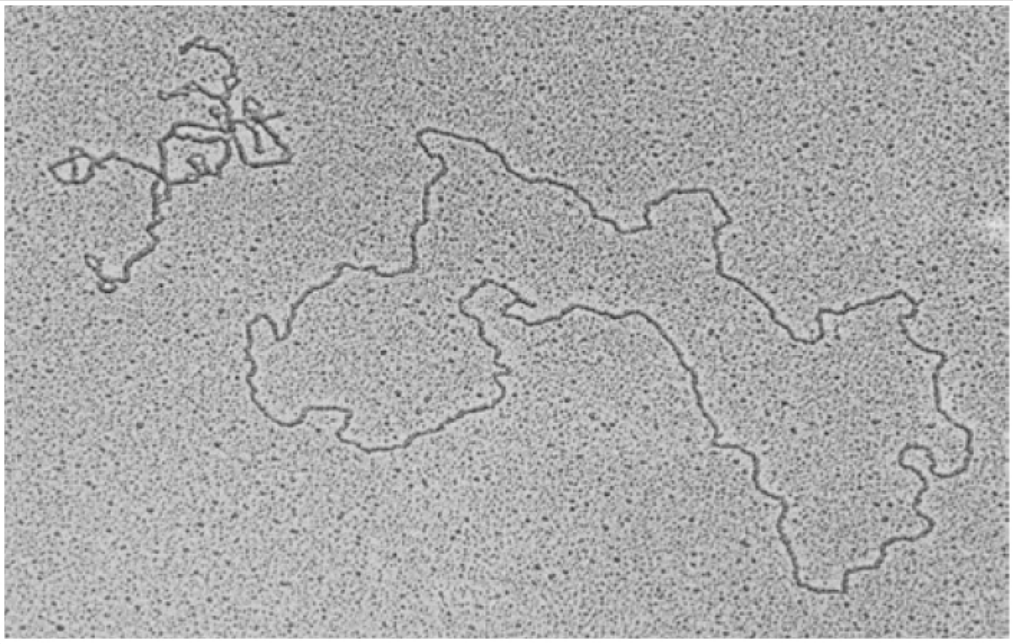


FIGURE 28.12 The linking number (Lk), twist (Tw), and writhe (Wr) of circular DNA are related.

[Information from W. Saenger, *Principles of Nucleic Acid Structure* (Springer Verlag, 1984), p. 452.]

Supercoiling markedly alters the overall form of DNA, because it makes the DNA more compact than a relaxed DNA molecule of the same length. Hence, supercoiled DNA moves faster than relaxed DNA when analyzed by centrifugation or electrophoresis (Figure 28.13).

Courtesy of Dr. Jack Griffith

FIGURE 28.13 Supercoiling condenses DNA topoisomers. An electron micrograph showing negatively supercoiled and relaxed DNA.

The linking number, a topological property, determines the degree of supercoiling

Our understanding of the conformation of DNA is enriched by concepts drawn from topology, a branch of mathematics dealing with structural properties that are unchanged by deformations such as stretching and bending. A key topological property of a circular DNA molecule is its **linking number (Lk)**, which is equal to the number of times that a strand of DNA winds in the right-handed direction around the helix axis when the axis lies in a plane, as shown in Figure 28.12A. For the relaxed DNA shown in Figure 28.12B, $Lk = 25$. For the partly unwound molecule shown in part D and the supercoiled one shown in part E, $Lk = 23$ because the linear duplex was unwound two complete turns before closure. Molecules differing only in linking number are topological isomers, or **topoisomers**, of one another. Topoisomers of DNA can be interconverted only by cutting one or both DNA strands and then rejoining them.

The unwound DNA and supercoiled DNA shown in Figure 28.12D and E are topologically identical but geometrically different. They have the same value of Lk but differ in two measurements: twist and writhe. Although the rigorous definitions of twist and writhe are complex, **twist (Tw)** is a measure of the helical winding of the DNA strands around each other, whereas **writhe (Wr)** is a measure of the coiling of the axis of the double helix — that is, supercoiling. A right-handed coil is assigned a negative number (negative supercoiling), and a left-handed coil is assigned a positive number (positive supercoiling).

Is there a relation between Tw and Wr? Indeed, there is. Topology tells us that the sum of Tw and Wr is equal to Lk:

$$Lk = Tw + Wr$$

In Figure 28.12, the partly unwound circular DNA has $Tw \sim 23$, meaning the helix has 23 turns, and $Wr \sim 0$, meaning the helix has not crossed itself to create a supercoil. The supercoiled DNA, however, has $Tw \sim 25$ and $Wr \sim -2$. These forms can be interconverted without cleaving the DNA chain because they have the same value of Lk — namely, 23.

Topoisomerases prepare the double helix for unwinding

Most naturally occurring DNA molecules are negatively supercoiled. What is the basis for this? As already stated, negative supercoiling arises from the unwinding or underwinding of the DNA. In essence, negative supercoiling prepares DNA for processes requiring separation of the DNA strands, such as replication. Positive supercoiling condenses DNA as effectively, but it makes strand separation more difficult.

The action of the helicase at the replication fork causes the DNA ahead of the fork to be overwound with positive supercoils, making unwinding difficult. Therefore, negative supercoils must be continuously introduced to relax the DNA as the double helix unwinds. Specific enzymes called **topoisomerases** that introduce or eliminate supercoils were discovered by James Wang and Martin Gellert. Type I topoisomerases catalyze the relaxation of supercoiled DNA, a thermodynamically favorable process, while Type II topoisomerases use free energy from ATP hydrolysis to add negative supercoils to DNA. Both type I and type II topoisomerases play important roles in DNA replication as well as in transcription and recombination.

Topoisomerases alter the linking number of DNA by catalyzing a three-step process: (1) the cleavage of one or both strands of DNA, (2) the passage of a segment of DNA through this break, and (3) the resealing of the DNA break. Type I topoisomerases cleave just one strand of DNA, whereas type II enzymes cleave both strands. The two types of enzymes have several common features, including the use of key tyrosine residues to form covalent links to the polynucleotide backbone that is transiently broken.

Type I topoisomerases relax supercoiled structures

The three-dimensional structures determined for several type I topoisomerases reveal many features of the reaction mechanism (**Figure 28.14**). For example, human type I topoisomerase comprises four domains, which are arranged around a central cavity having a diameter of 20 Å, just the correct size to accommodate a double-stranded DNA molecule. This cavity also includes a tyrosine residue (Tyr 723), which acts as a nucleophile to cleave the DNA backbone in the course of catalysis.

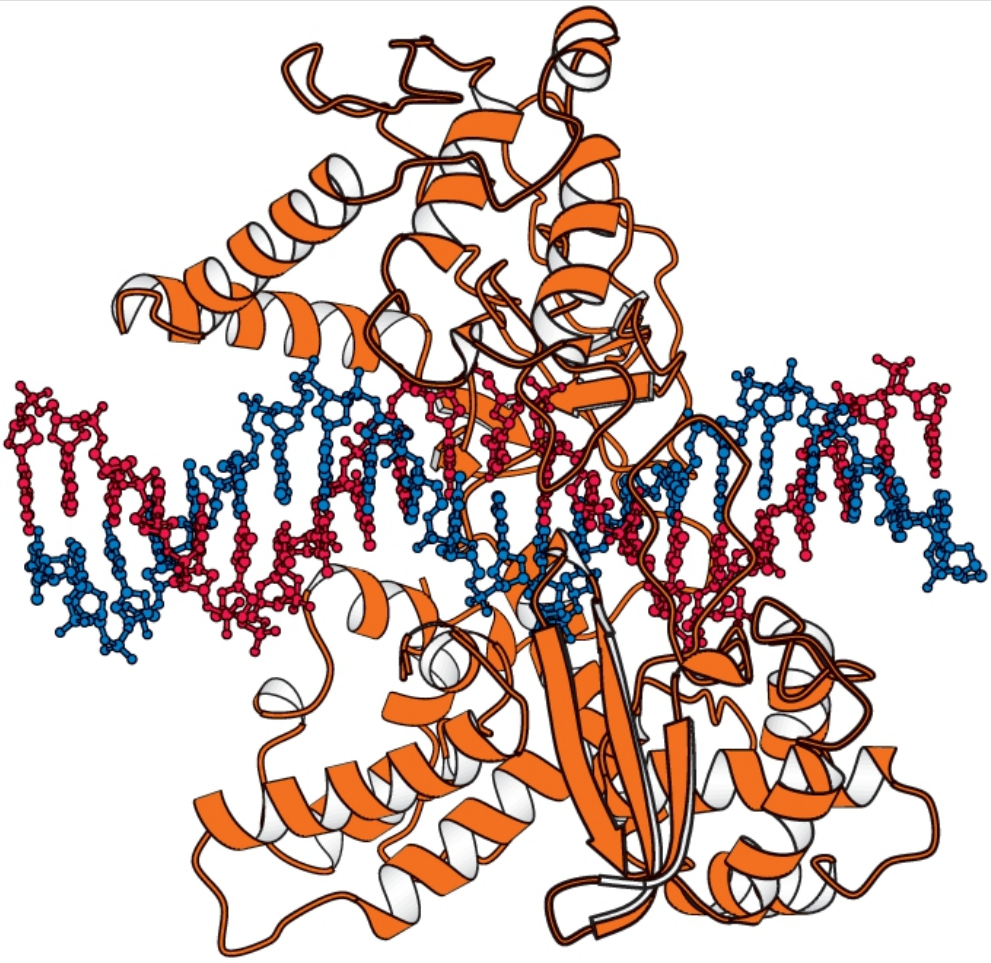

FIGURE 28.14 Topoisomerase I binds to DNA. The structure of a complex between a fragment of human topoisomerase I and DNA is shown. The DNA occupies a central cavity within the enzyme.

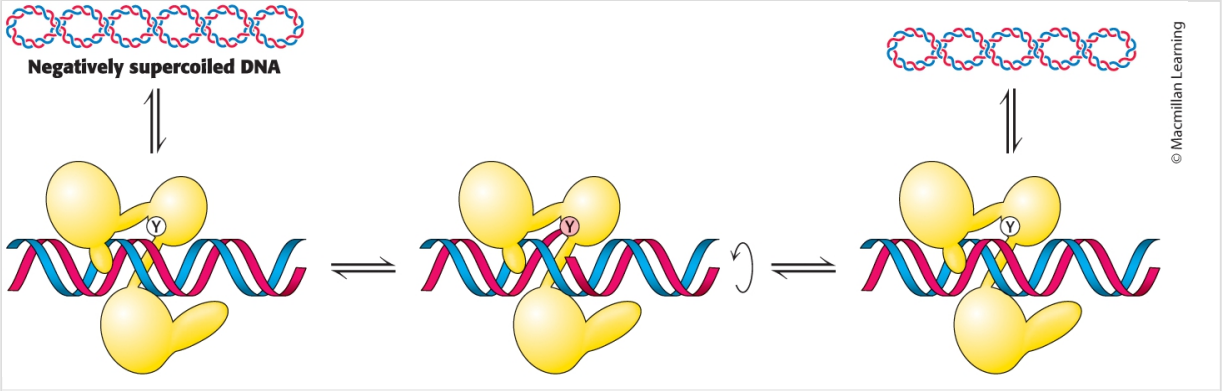
[Drawn from 1EJ9.pdb.]

INTERACT with this model in Achieve

From analyses of topoisomerases and the results of other studies, the relaxation of negatively supercoiled DNA molecules is known to proceed in the following manner (Figure 28.15):



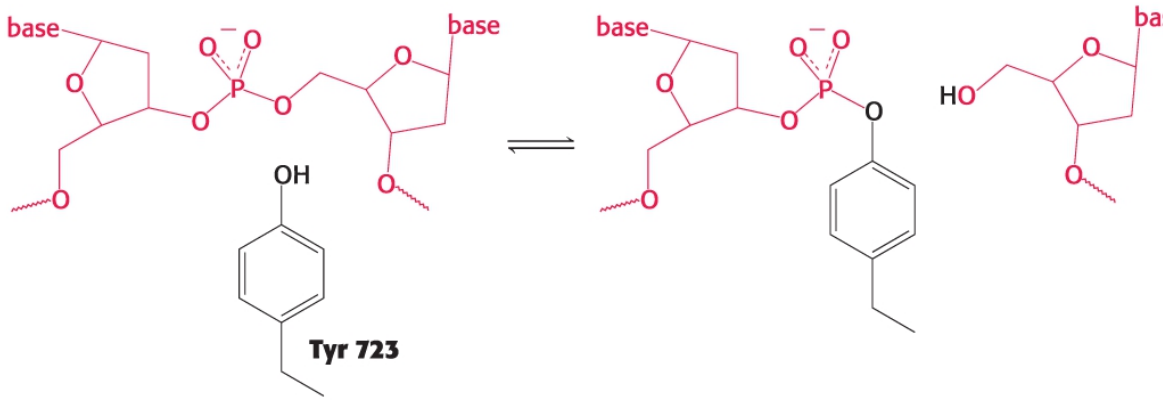


FIGURE 28.15 Topoisomerase I relaxes supercoiled DNA. On binding to DNA, topoisomerase I cleaves one strand of the DNA by means of a tyrosine (Y) residue attacking a phosphoryl group. When the strand has been cleaved, it rotates in a controlled manner around the other strand. The reaction is completed by re-ligation of the cleaved strand. This process results in partial or complete relaxation of a supercoiled plasmid.

1. First, the DNA molecule binds inside the cavity of the topoisomerase. The hydroxyl group of tyrosine 723 attacks a phosphoryl group on one strand of the DNA backbone to form a phosphodiester linkage between the enzyme and the DNA, cleaving the DNA and releasing a free 5′-hydroxyl group.

2. With the backbone of one strand cleaved, the DNA can now rotate around the remaining strand, its movement driven by the release of energy stored because of the supercoiling. The rotation of the DNA unwinds the supercoils. The enzyme controls the rotation so that the unwinding is not rapid.

3. The free hydroxyl group of the DNA attacks the phosphotyrosine residue to reseal the backbone and release tyrosine. The DNA is then free to dissociate from the enzyme. Thus, reversible cleavage of one strand of supercoiled DNA allows controlled rotation to partly relax the supercoils.

Type II topoisomerases introduce negative supercoils through coupling to ATP hydrolysis

Supercoiling requires an input of energy because a supercoiled molecule, in contrast to its relaxed counterpart, is torsionally stressed. The introduction of an additional supercoil into a 3000-bp plasmid typically requires about $30\ \text{kJ mol}^{-1}$ ($7\ \text{kcal mol}^{-1}$).

Supercoiling is catalyzed by type II topoisomerases. These elegant molecular machines couple the binding and hydrolysis of ATP to the directed passage of one DNA double helix through another, temporarily cleaved DNA double helix. These enzymes have several mechanistic features in common with the type I topoisomerases.

Topoisomerase II molecules are dimeric with a large internal cavity (**Figure 28.16**). The large cavity has gates at both the top and the bottom that are crucial to topoisomerase action:

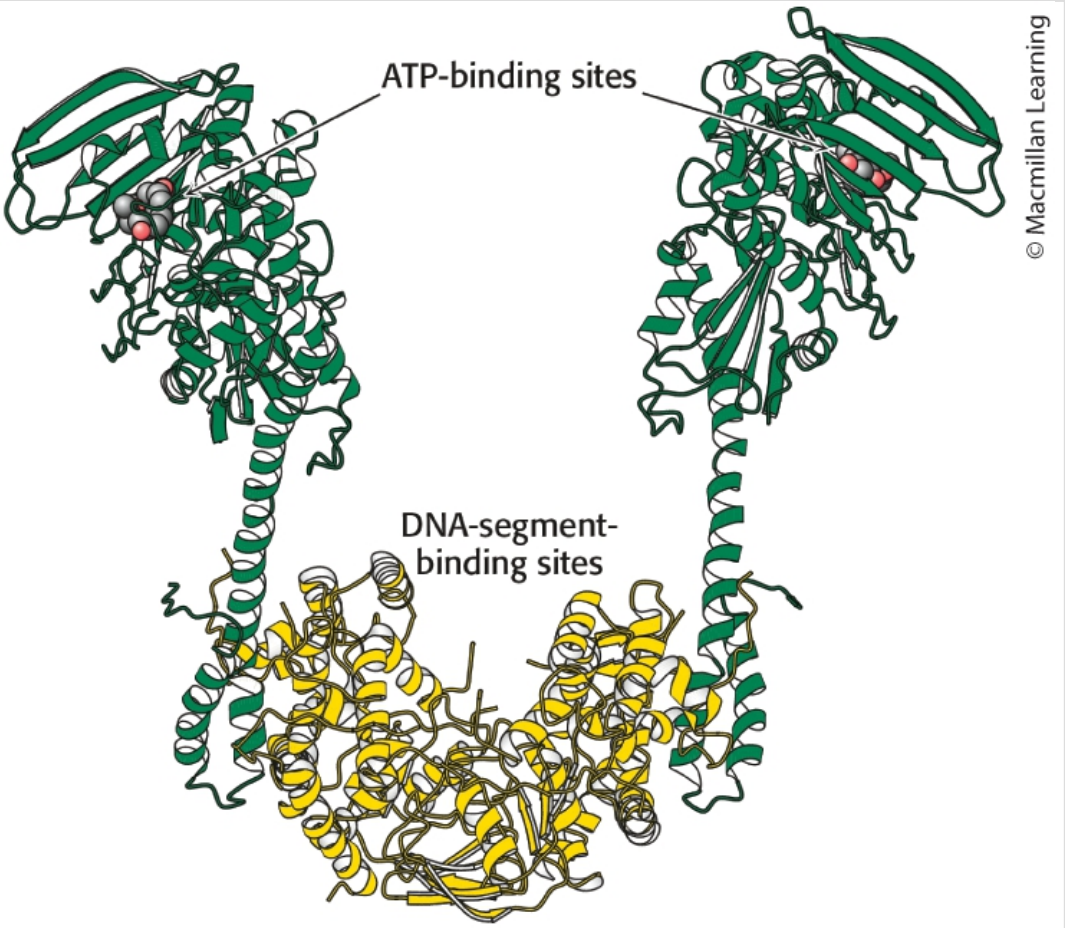

FIGURE 28.16 Topoisomerase II is a dimer. The structure of a typical topoisomerase II, this one from the archaeon *Sulfolobus shibatae*, is shown. Each half of the enzyme has one domain (shown in yellow) that contains a region for binding a DNA double helix and another domain (shown in green) that contains ATP-binding sites.

[Drawn from 2ZBK.pdb.]

INTERACT with this model in Achieve

1. The reaction begins with the binding of one double helix (hereafter referred to as the *G*, for gate, segment) to the enzyme (Figure 28.17). Each strand is positioned next to a tyrosine residue, one from each monomer, capable of forming a covalent linkage with the DNA backbone.

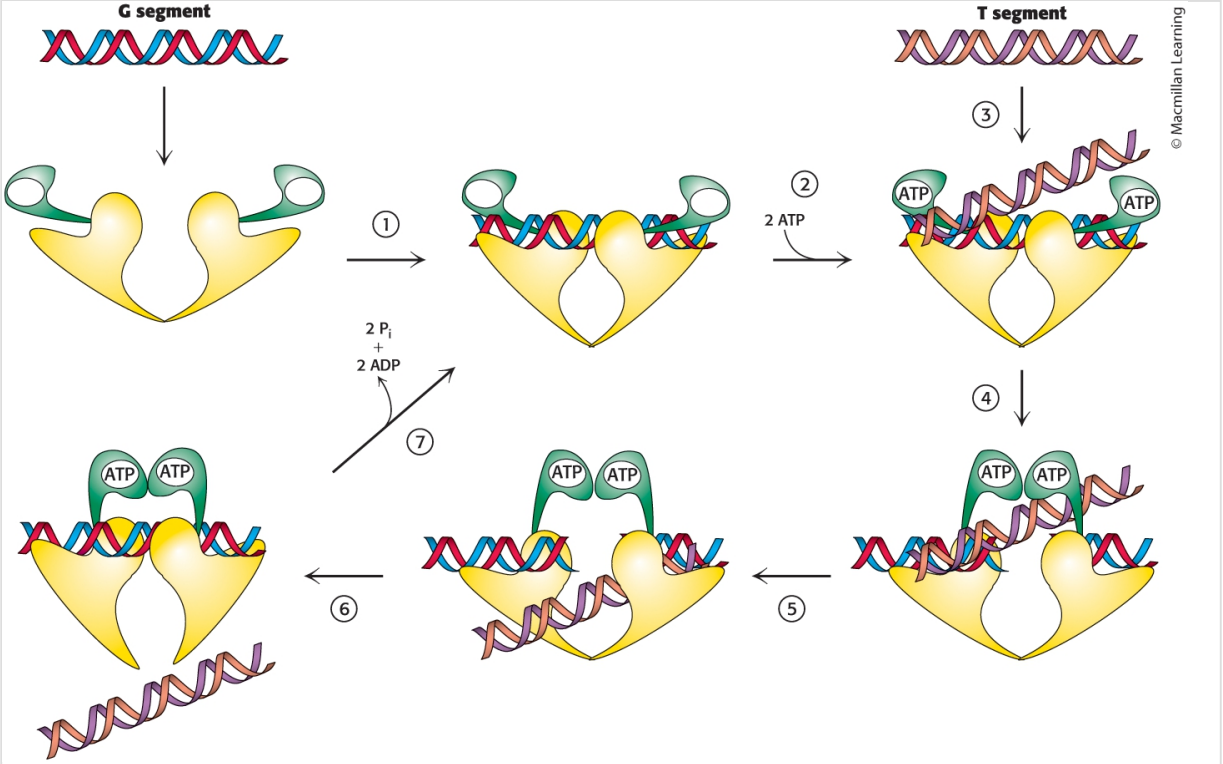

FIGURE 28.17 Topoisomerase II uses ATP hydrolysis to introduce negative supercoils into DNA. Topoisomerase II first binds one DNA duplex termed the G (for gate) segment (1). The binding of ATP to the two N-terminal domains brings these two domains together (2). This conformational change leads to the cleavage of both strands of the G segment and the binding of an additional DNA duplex, the T segment (3). This T segment then moves through the break in the G segment and out the bottom of the enzyme (4 through 6). The hydrolysis of ATP resets the enzyme with the G segment still bound (7). The orientation of the entering T segment results in the introduction of negative supercoils.

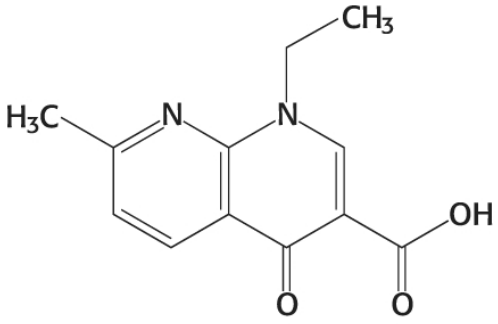
2. Each monomer of the enzyme has a domain that binds ATP, eventually leading to a conformational change that strongly favors the coming together of the two domains.

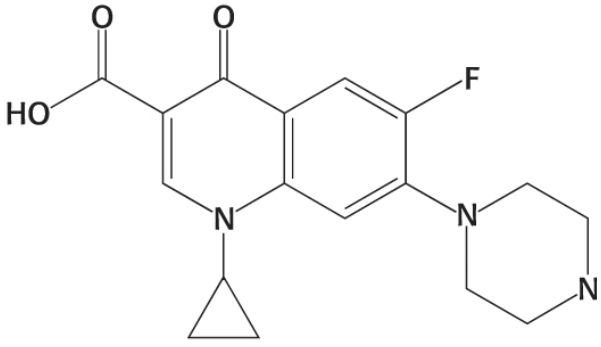
3. This complex then loosely binds a second DNA double helix (hereafter referred to as the *T*, for transported, segment). As the ATP-binding domains come closer together, they trap the bound T segment.

4. This conformational change also forces the separation and cleavage of the two strands of the G segment. Each strand is linked to the enzyme by a tyrosine–phosphodiester bond. Unlike the type I enzymes, the type II topoisomerases hold the DNA tightly so that it cannot rotate.



5. The T segment then passes through the cleaved G segment and into the large central cavity.

6. The ligation of the G segment leads to the release of the T segment through the gate at the bottom of the enzyme.



7. The hydrolysis of ATP and the release of ADP and orthophosphate allow the ATP-binding domains to separate, preparing the enzyme to bind another T segment. The overall process leads to a decrease in the linking number by two.

The bacterial topoisomerase II (often called DNA gyrase) is the target of several antibiotics that inhibit the prokaryotic enzyme much more than the eukaryotic one. Novobiocin blocks the binding of ATP to gyrase. Nalidixic acid and ciprofloxacin, in contrast, interfere with the breakage and rejoining of DNA chains. These two gyrase inhibitors are widely used to treat urinary tract and other infections including those due to *Bacillus anthracis* (anthrax). Camptothecin, an antitumor agent, inhibits human topoisomerase I by stabilizing the form of the enzyme covalently linked to DNA.

28.3 DNA Replication Is Highly Coordinated

DNA replication must be very rapid, given the sizes of the genomes and the rates of cell division. The *E. coli* genome contains 4.6 million base pairs and is copied in less than 40 minutes. Thus, 2000 bases are incorporated per second. Enzyme activities must be highly coordinated to replicate entire genomes precisely and rapidly.

We begin our consideration of the coordination of DNA replication by looking at *E. coli*, which has been extensively studied. For this organism with a relatively small genome, replication begins at a single site and continues around the circular chromosome. The coordination of eukaryotic DNA replication is much more complex because there are many initiation sites throughout the genome and an additional enzyme is needed to replicate the ends of linear chromosomes.

DNA replication requires highly processive polymerases

Replicative polymerases are characterized by their very high catalytic potency, fidelity, and processivity. **Processivity** refers to the ability of an enzyme to catalyze many consecutive reactions without releasing its substrate. These polymerases are assemblies of many subunits that have evolved to grasp their templates and not let go until many nucleotides have been added.

The source of the processivity was revealed by the determination of the three-dimensional structure of the β_2 subunit of the *E. coli* replicative polymerase called DNA polymerase III (**Figure 28.18**). This unit, which has the form of a star-shaped ring, keeps the polymerase associated

with the DNA double helix. A 35 Å-diameter hole in its center can readily accommodate a duplex DNA molecule (around 20 Å in diameter) and leaves enough space between the DNA and the protein to allow rapid sliding during replication. A polymerization rate of 1000 nucleotides per second requires that 100 turns of duplex DNA (a length of 3400 Å, or 0.34 μm) slide through the central hole of β_2 per second. Thus, β_2 plays a key role in replication by serving as a **sliding DNA clamp**.

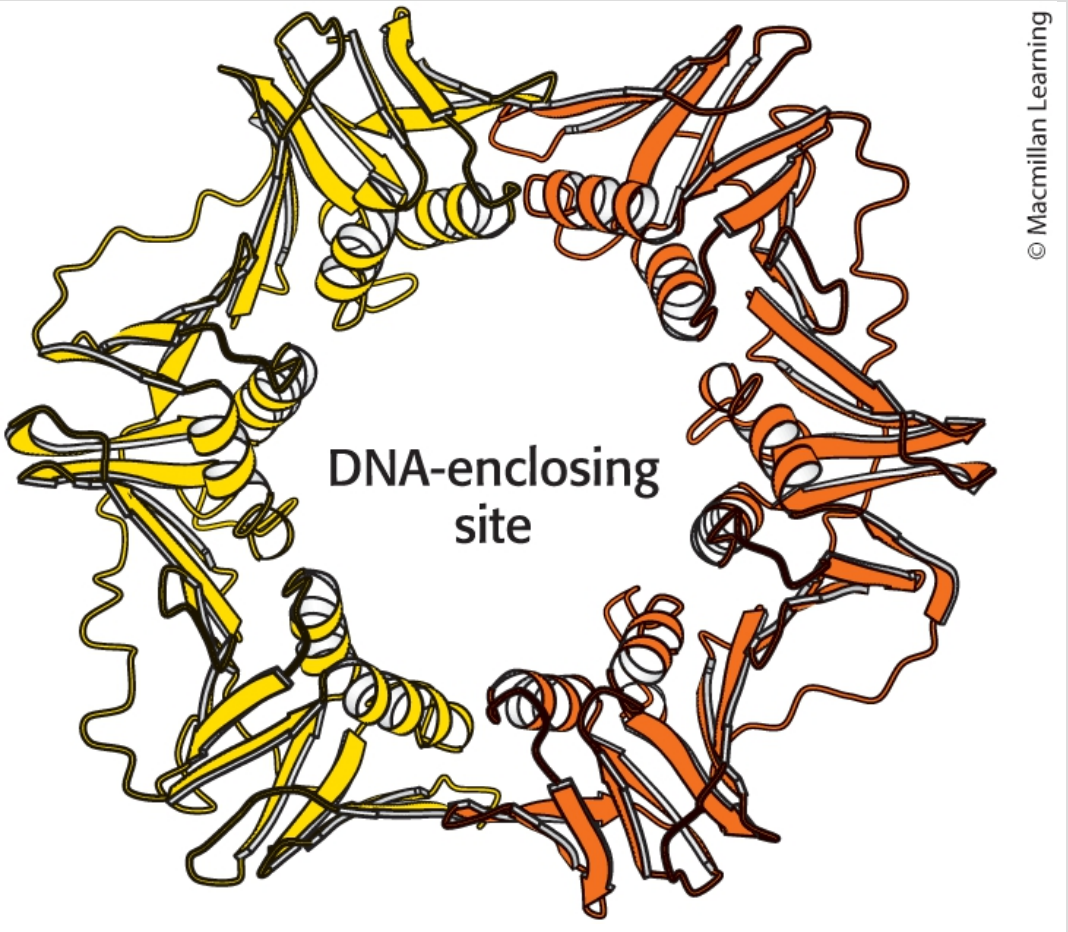

FIGURE 28.18 The sliding clamp subunit of DNA polymerase III is a dimer. The β subunit of DNA polymerase III forms a ring that surrounds the DNA duplex. The DNA template slides through the central cavity. Clasping the DNA molecule in the ring, the polymerase enzyme is able to move without falling off the DNA substrate.

[Drawn from 2POL.pdb.]

INTERACT with this model in Achieve

How does DNA become entrapped inside the sliding clamp? Replicative polymerases also include assemblies of subunits that function as clamp loaders by grasping the sliding clamp and, using the energy of ATP binding, pulling apart one of the interfaces between the two subunits of the sliding clamp. DNA can move through the gap, inserting itself through the central hole. ATP hydrolysis then releases the clamp, which closes around the DNA.

The leading and lagging strands are synthesized in a coordinated fashion

Replicative polymerases such as DNA polymerase III synthesize the leading and lagging strands simultaneously at the replication fork (Figure 28.19). Let's first look at how DNA polymerase III begins the synthesis of the leading strand starting from the RNA primer formed by primase. While the duplex DNA ahead of the polymerase is unwound by a hexameric helicase called DnaB, copies of single-stranded-binding protein (SSB) bind to the unwound strands, keeping the strands separated so that both strands can serve as templates. The leading strand is synthesized continuously by polymerase III, as topoisomerase II concurrently introduces right-handed (negative) supercoils to avert a topological crisis.

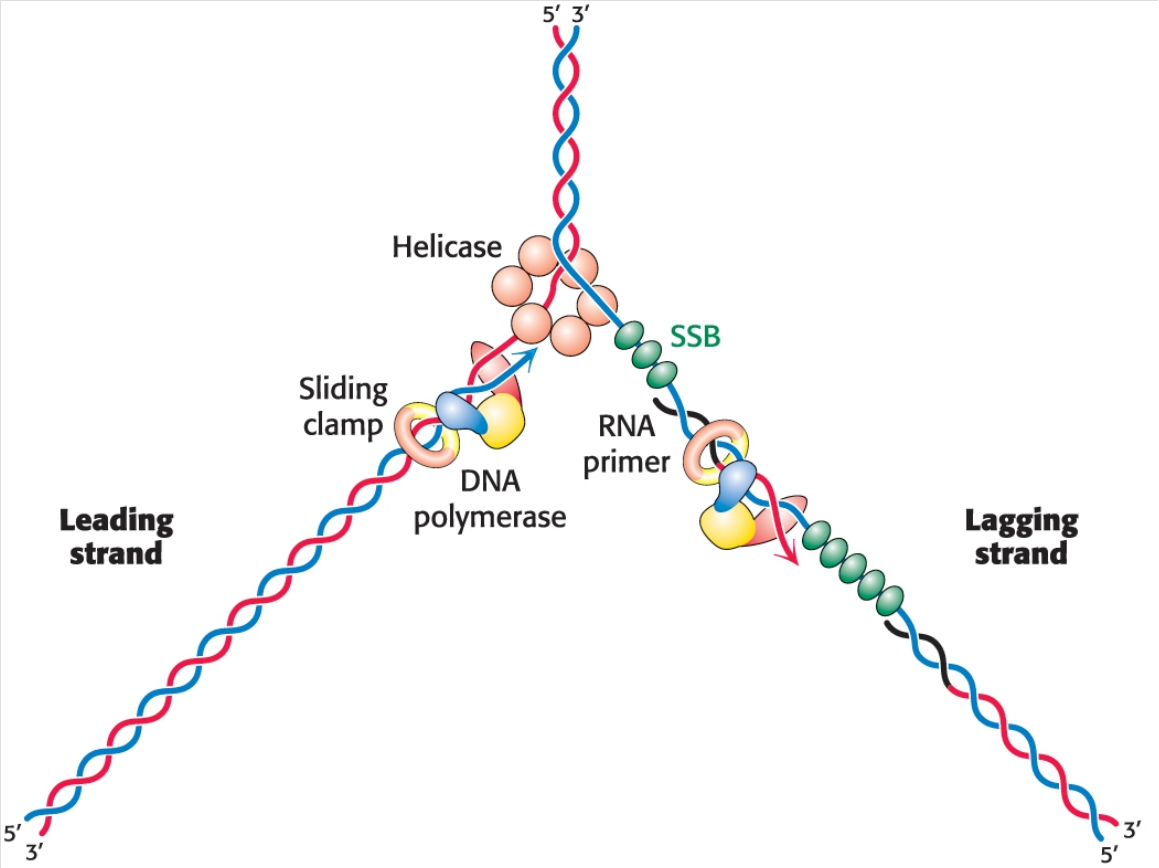

FIGURE 28.19 DNA synthesis at the replication fork is highly coordinated. A schematic view of the arrangement of DNA polymerase III and associated enzymes and proteins involved in the replication of DNA is shown. The helicase separates the two strands of the parent double helix, allowing DNA polymerases to use each strand as a template for DNA synthesis. Abbreviation: SS single-stranded-binding protein.

As mentioned earlier, the lagging strand is synthesized in fragments, so its synthesis is necessarily more complex. Yet the synthesis of the lagging strand is coordinated to be simultaneous with the synthesis of the leading strand. How is this coordination accomplished?

Examination of the subunit composition of the DNA polymerase III holoenzyme reveals an elegant solution for synthesis of the lagging strand (Figure 28.20). The holoenzyme includes two copies of the

polymerase core enzyme, which consists of the DNA polymerase itself (the α subunit); the ε subunit, a 3′-to-5′ proofreading exonuclease; another subunit called θ; and two copies of the dimeric β-subunit sliding clamp. The core enzymes are linked to a central structure having the subunit composition $\gamma\tau_2\delta\delta'\chi\phi$. The $\gamma\tau_2\delta\delta'$ complex serves as the clamp loader, and the χ and ϕ subunits interact with the single-stranded-DNA–binding protein; meanwhile, the entire apparatus interacts with the hexameric helicase DnaB. Eukaryotic replicative polymerases have similar, albeit slightly more complicated, subunit compositions and structures.

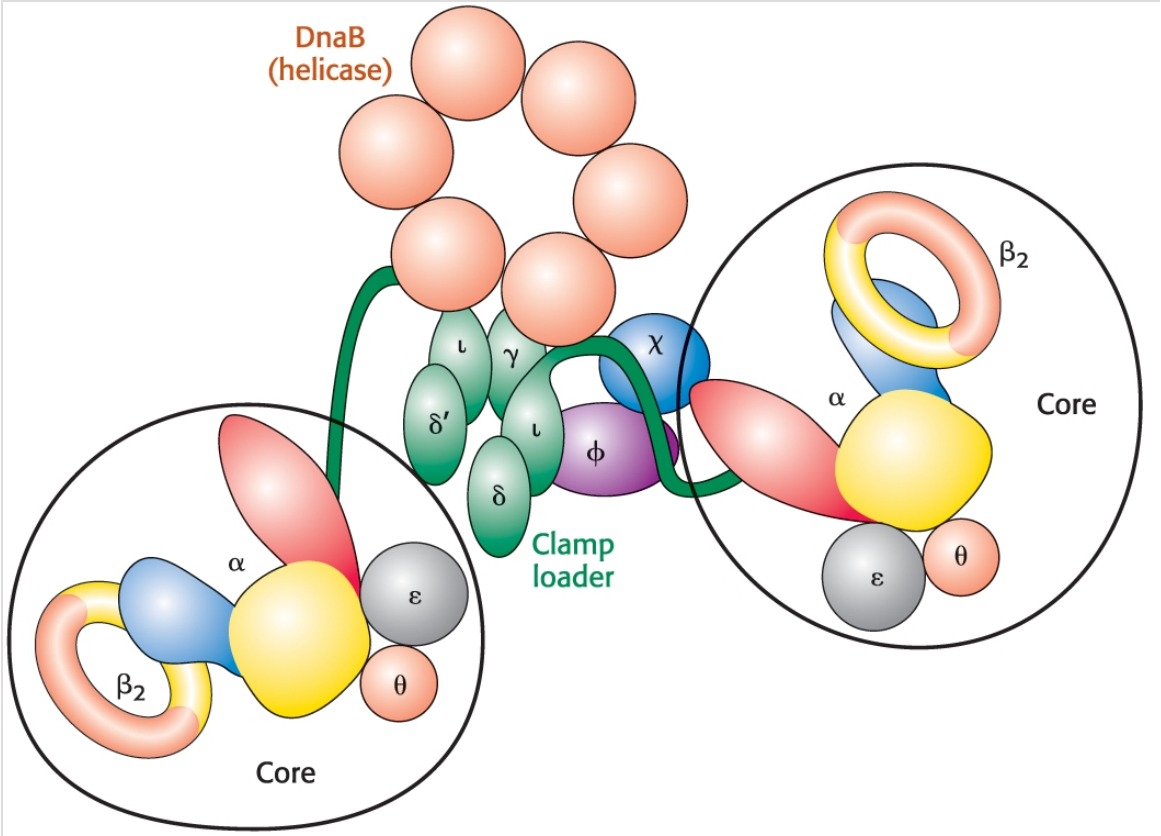

FIGURE 28.20 The DNA polymerase holoenzyme consists of multiple subunits. Each holoenzyme consists of two copies of the polymerase core enzyme, which comprises the α, ε, a θ subunits and two copies of the β subunit, linked to a central structure. The central structure includes the clamp-loader complex and the hexameric helicase DnaB.

The lagging-strand template is looped out so that it passes through the polymerase site in one subunit of a dimeric DNA polymerase III in the same direction as that of the leading-strand template in the other subunit. DNA polymerase III lets go of the lagging-strand template after adding about 1000 nucleotides by releasing the sliding clamp. A new loop is then formed, a sliding clamp is added, and primase again synthesizes a short stretch of RNA primer to initiate the formation of another Okazaki fragment. This mode of replication has been termed the **trombone model** because the size of the loop lengthens and shortens like the slide on a trombone (**Figure 28.21**).

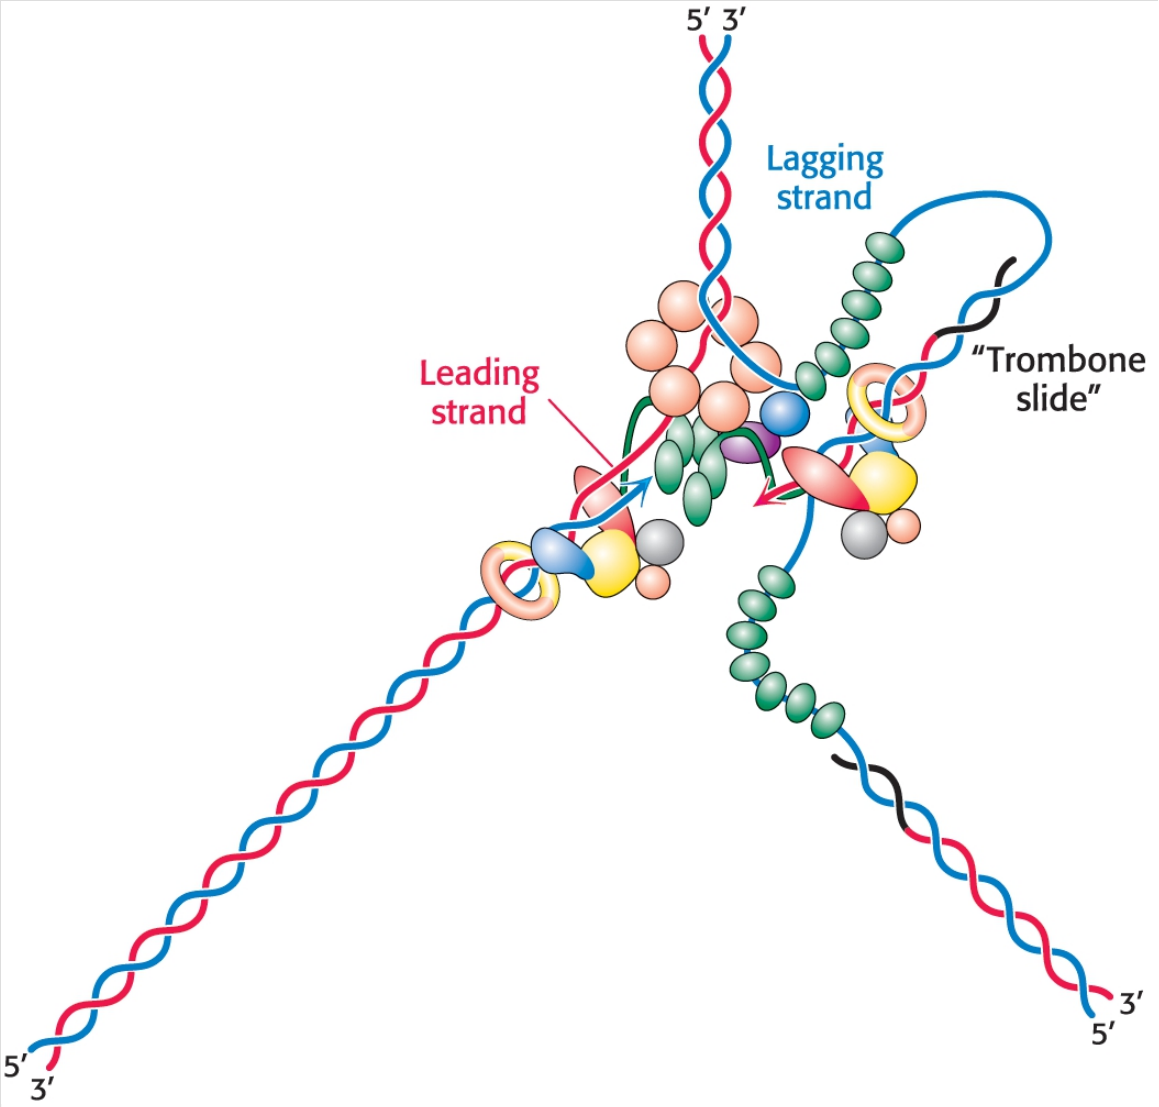

FIGURE 28.21 The trombone model describes the coordination of DNA synthesis at the replication fork. The replication of the leading and lagging strands is coordinated by the loopin out of the lagging strand to form a structure that acts somewhat as a trombone slide, growing a the replication fork moves forward. When the polymerase on the lagging strand reaches a regio that has been replicated, the sliding clamp is released and a new loop is formed.

The gaps between fragments of the nascent lagging strand are filled by DNA polymerase I. This essential enzyme also uses its $5' \rightarrow 3'$ exonuclease activity to remove the RNA primer lying ahead of the

polymerase site. The primer cannot be erased by DNA polymerase III because the enzyme lacks $5' \rightarrow 3'$ editing capability. Finally, DNA ligase connects the fragments.

DNA replication in *E. coli* begins at a unique site

In *E. coli*, DNA replication starts at a unique site within the entire 4.6×10^6 bp genome. This **origin of replication**, called the *oriC locus*, is a 245-bp region that has several unusual features (**Figure 28.22**). The *oriC* locus contains five copies of a sequence that is the preferred binding site for the origin-recognition protein DnaA. In addition, the *oriC* locus contains a tandem array of 13-bp sequences that are rich in AT base pairs.

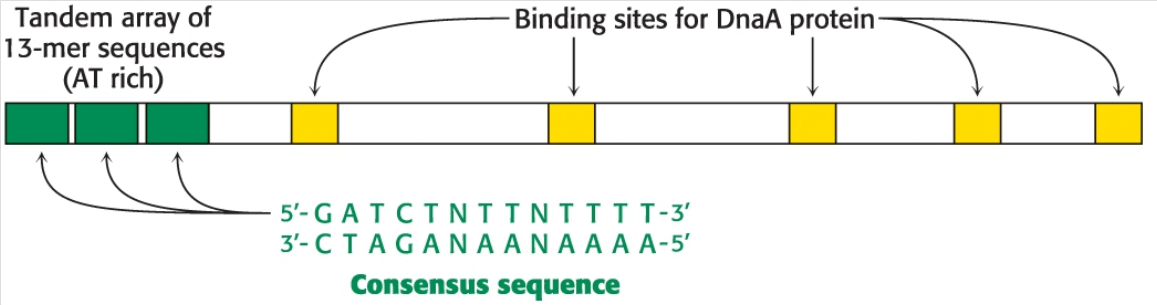

FIGURE 28.22 The *E. coli* chromosome has a single origin of replication. The *oriC* locus has a length of 245 bp and contains a tandem array of three nearly identical 13-nucleotide sequences (green) and five binding sites (yellow) for the DnaA protein.

Several steps are required to prepare for the start of replication:

1. *DnaA proteins bind to the* oriC. DnaA proteins are related to the hexameric helicases. Each DnaA monomer comprises an ATPase domain linked to a DNA-binding domain at its C-terminus. DnaA molecules are able to bind to each other through their ATPase domains; a group of bound DnaA molecules will break apart on the binding and hydrolysis of ATP. The DnaA proteins bind to the five high-affinity sites in *oriC* and then come together with other DnaA molecules bound to lower-affinity sites to form an oligomer, possibly a cyclic hexamer. The DNA is wrapped around the outside of the DnaA hexamer (**Figure 28.23**).

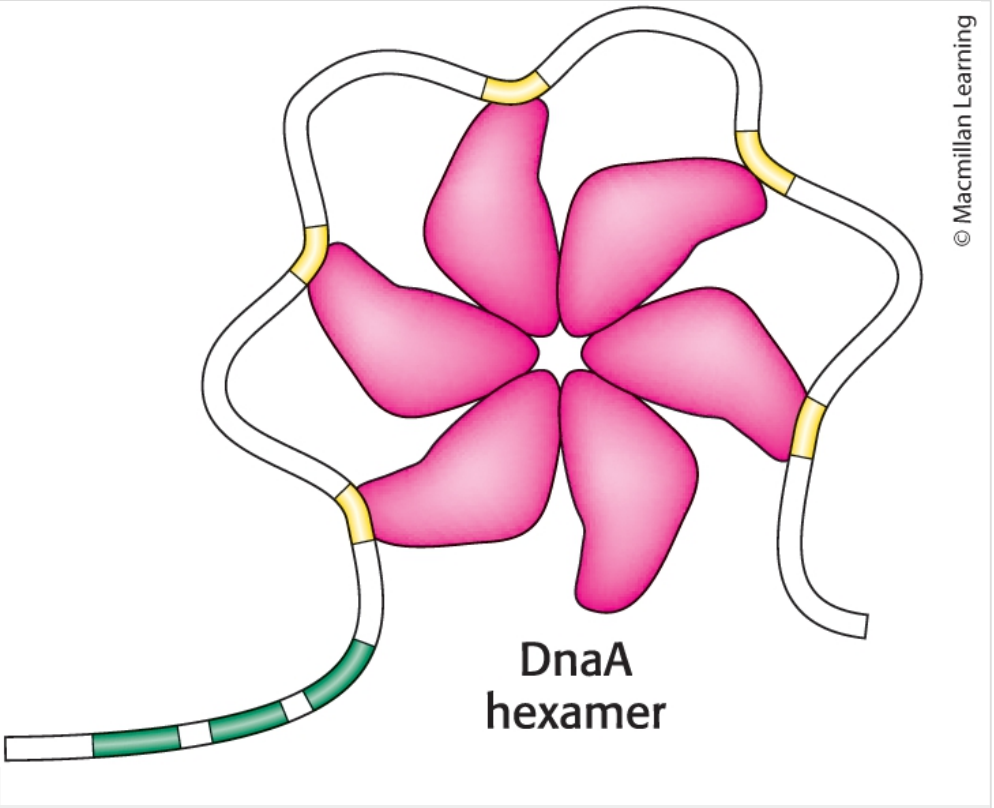

FIGURE 28.23 The assembly of DnaA proteins initiates DNA replication. Monomers of DnaA bind to their binding sites (shown in yellow) in *oriC* and come together to form a complex structure, possibly the cyclic hexamer shown here. This structure marks the origin of replication and favors DNA strand separation in the AT-rich sites (green).

2. *Single DNA strands are exposed in the prepriming complex*. With DNA wrapped around a DnaA hexamer, additional proteins are brought into play. The hexameric helicase DnaB is loaded around the DNA with the help of the helicase loader protein DnaC. Then, local regions of *oriC*, including the AT regions, are unwound and trapped by the single-stranded-DNA–binding protein. The result of this process is the creation of a structure called the *prepriming complex*, which makes single-stranded DNA accessible to other proteins (Figure 28.24). Significantly, the primase, DnaG, is now able to insert the RNA primer.

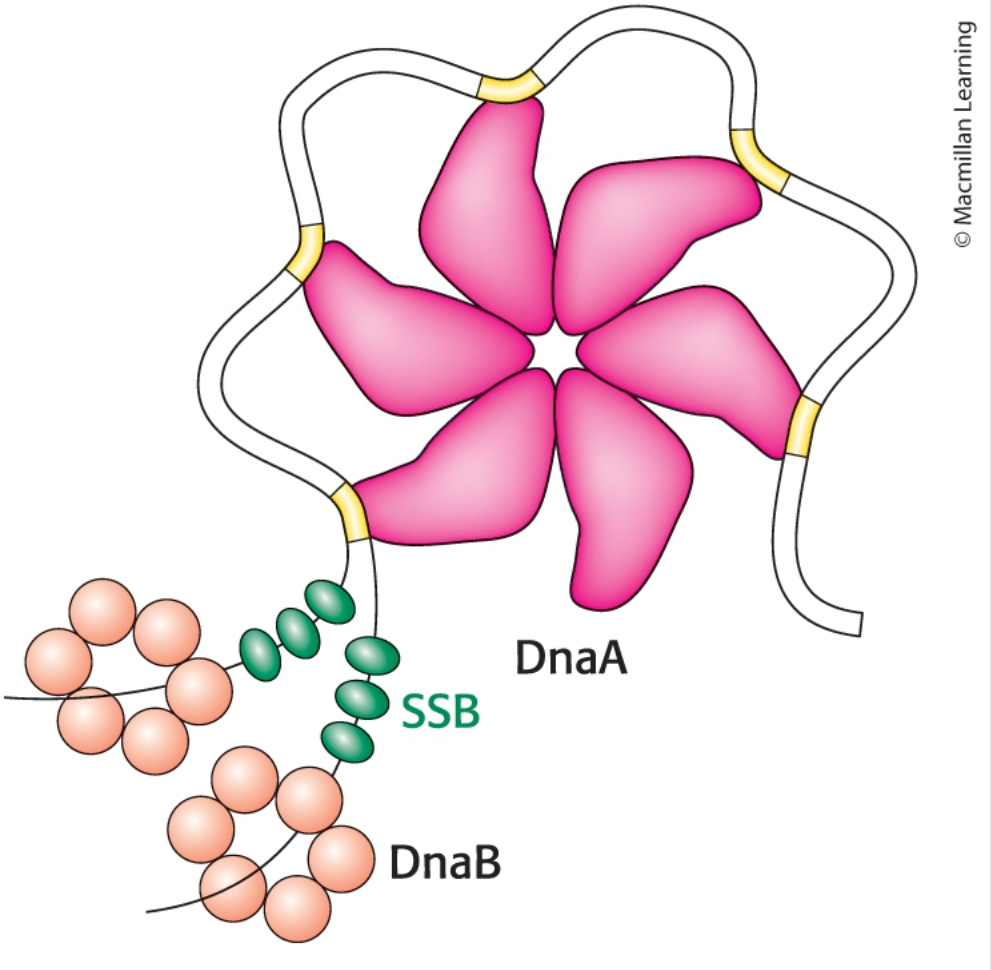

FIGURE 28.24 The prepriming complex prepares the template strands for DNA synthesis. The AT-rich regions are unwound and trapped by the single-stranded-binding protein (SSB). The hexameric DNA helicase DnaB is loaded on each strand. At this stage, the complex is ready for the synthesis of the RNA primers and assembly of the DNA polymerase III holoenzyme.

3. *The polymerase holoenzyme assembles*. The DNA polymerase III holoenzyme assembles on the prepriming complex, initiated by interactions between DnaB and the sliding-clamp subunit of DNA polymerase III. These interactions also trigger ATP hydrolysis within the DnaA proteins, causing them to break up. The breakup of the DnaA assembly prevents additional rounds of replication from beginning at the *oriC*, signaling the end of the preparatory phase.

Once initiated, DNA replication continues around the circular chromosome. To efficiently terminate replication, the *E. coli* chromosome includes specific termination sites (or *Ter* sites) that act as binding sites for a protein called *termination utilization substance*, or *Tus* (**Figure 28.25**). The complexes that form when Tus binds to the Ter sites are not symmetrical, and this asymmetry is central for its function: when a replication fork, led by the helicase DnaB, reaches a Ter–Tus complex from one direction, it can move past it, but when it reaches it from the opposite direction, the Ter–Tus complex effectively blocks the replication fork. The positions and orientations of the Ter sites within the *E. coli* genome facilitate efficient termination when one cycle of termination is complete.

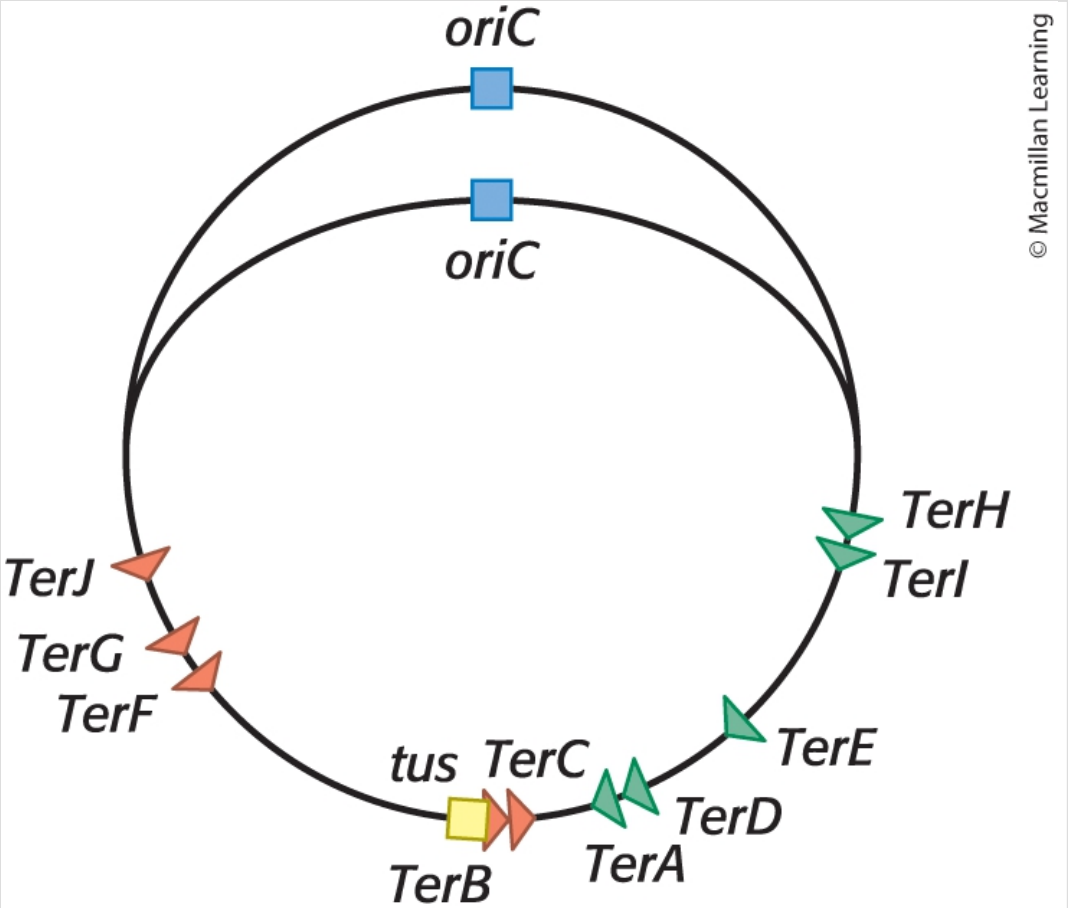

FIGURE 28.25 Replication termination in *E. coli* occurs at Ter sites. The *E. coli* genome includes 10 Ter sites that bind the termination utilization substance (Tus) protein. The Ter–Tus complexes block incoming replication forks in a unidirectional manner (indicated by the orientation of the triangles representing the Ter sites), facilitating termination of replication after a single cycle.

DNA replication in eukaryotes is initiated at multiple sites

Replication in eukaryotes is mechanistically similar to replication in prokaryotes but is more challenging for a number of reasons. One of them is sheer size: *E. coli* must replicate 4.6 million base pairs, whereas

a human diploid cell must replicate more than 6 billion base pairs. Second, the genetic information for *E. coli* is contained on one chromosome, whereas, in human beings, 23 pairs of chromosomes must be replicated. Finally, whereas the *E. coli* chromosome is circular, human chromosomes are linear. Unless countermeasures are taken, linear chromosomes are subject to shortening with each round of replication.

The first two challenges are met by the use of multiple origins of replication. In human beings, replication requires about 30,000 origins of replication, with each chromosome containing several hundred. Each origin of replication is the starting site for a replication unit, or *replicon*. DNA replication can be monitored by single-molecule methods, revealing bidirectional synthesis from different sites (Figure 28.26). In contrast with *E. coli*, the origins of replication in human beings do not have sharply defined sequences. Instead, more broadly defined AT-rich sequences are the sites around which the origin of replication complexes (ORCs) are assembled.

FIGURE 28.26 Eukaryotic chromosomes have multiple origins of replication. The image shows a single molecule of DNA containing two origins of replication. The origins were identified by labeling newly replicated DNA in human cells first with one thymine analog (iodo-deoxyuridine, IdU) and then another (chloro-deoxyuridine, CldU). DNA molecules from these cells were then extended on a microscope slide and labeled with antibodies to IdU (green) and CldU (red) to visualize the DNA. This method allows the detection of replication origins as well as determination of the rate of DNA synthesis.

[Data from: Conti et al., Replication fork velocities at adjacent replication origins are coordinately modified during DNA replication in human cell, *Molecular Biology of the Cell* 18:3059–3067, 2007.]

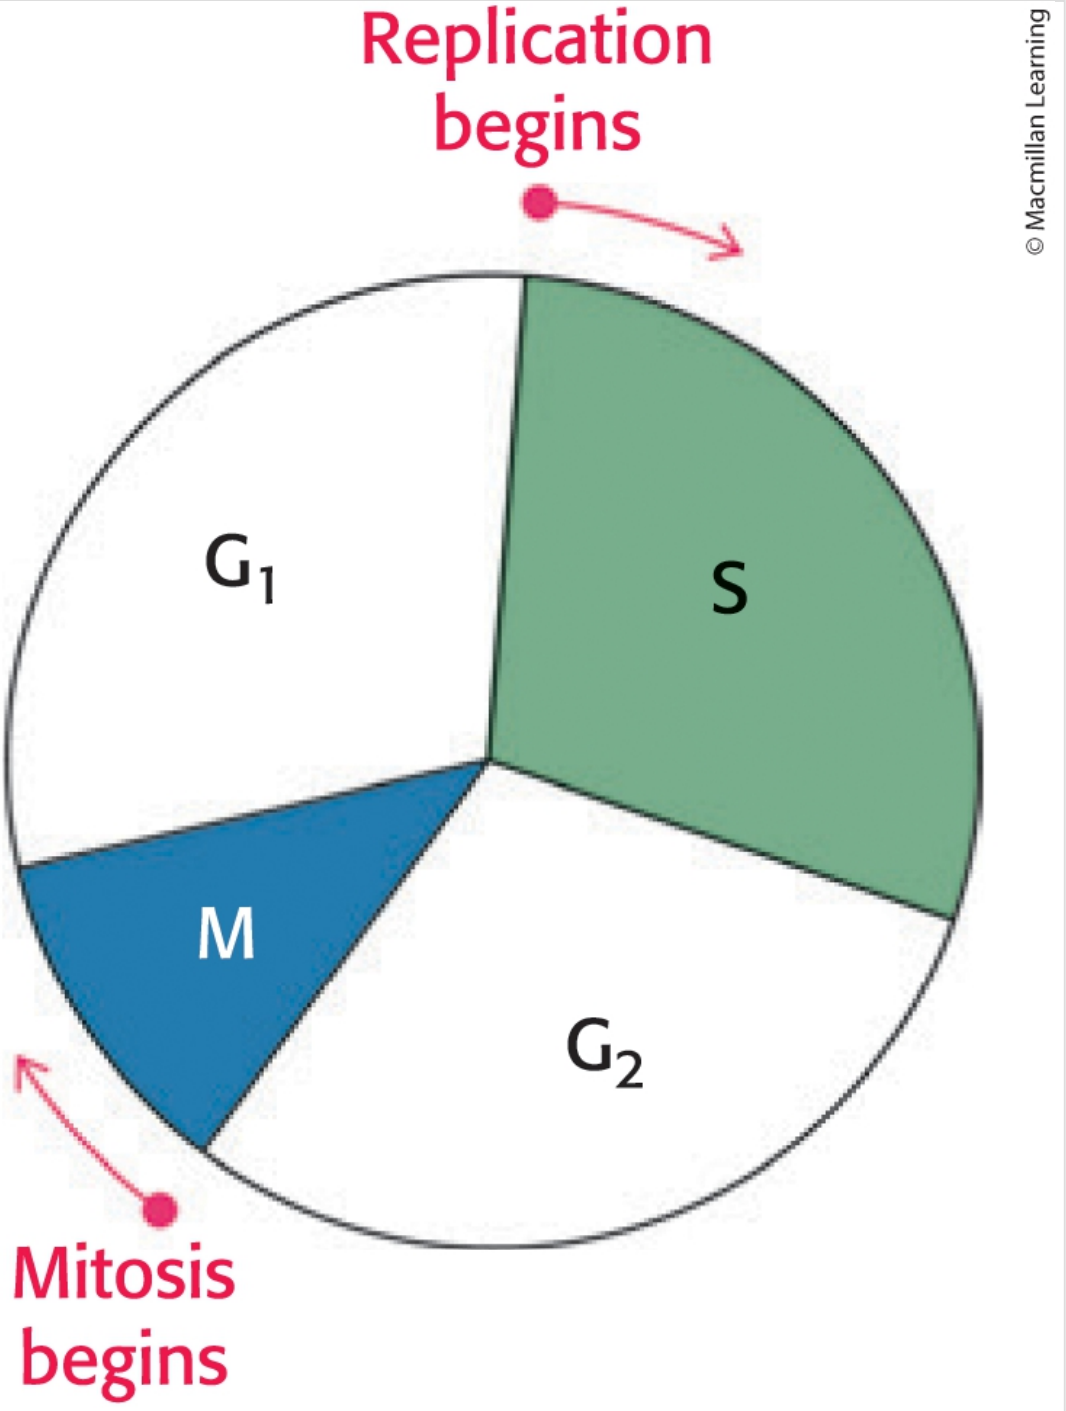
Initiation of replication in eukaryotes proceeds as follows:

1. *The ORC is assembled.* In human beings, the ORC is composed of six different proteins, each homologous to DnaA in *E. coli.* These proteins come together to form a hexameric structure analogous to the assembly formed by DnaA.

2. *Licensing factors expose single strands of DNA.* After the ORC has been assembled, additional proteins are recruited, including Cdc6, a homolog of the ORC subunits, and Cdt1. These proteins, in turn, recruit a hexameric helicase with six distinct subunits called Mcm2-7. These proteins, including the helicase, are sometimes called *licensing factors* because they permit the formation of the initiation complex. After the initiation complex has formed, Mcm2-7 separates the parental DNA strands, and the single strands are stabilized by the binding of replication protein A, a single-stranded-DNA–binding protein.

3. *Two distinct polymerases are needed to copy a eukaryotic replicon.* An initiator polymerase called *polymerase* α begins replication but is soon replaced by a more processive enzyme. This process is called *polymerase switching* because one polymerase has replaced another. This second enzyme, *DNA polymerase* δ, is the principal replicative polymerase in eukaryotes (**Table 28.1**).

TABLE 28.1 Some types of DNA polymerases



Name	Function
Prokaryotic Polymerases	
DNA polymerase I	Removes primer and fills in gaps on lagging strand
DNA polymerase II (error-prone	DNA repair

polymerase)	
DNA polymerase III	Primary enzyme of DNA synthesis
Eukaryotic Polymerases	
DNA polymerase α	Initiator polymerase
Primase subunit	Synthesizes the RNA primer
DNA polymerase unit	Adds stretch of about 20 nucleotides to the primer
DNA polymerase β (error-prone polymerase)	DNA repair
DNA polymerase δ	Primary enzyme of DNA synthesis

Once initiated, replication proceeds with the binding of DNA polymerase α. This enzyme includes a primase subunit, used to synthesize the RNA primer, as well as an active DNA polymerase. After this polymerase has added a stretch of about 20 deoxynucleotides to the primer, another replication protein, called *replication factor C* (RFC), displaces DNA polymerase α. Replication factor C attracts a sliding clamp called *proliferating cell nuclear antigen* (PCNA), which is homologous to the β_2 subunit of *E. coli* DNA polymerase III. The binding of PCNA to DNA polymerase δ renders the enzyme highly processive and suitable for long stretches of replication. Replication continues in both directions from the origin of replication until adjacent replicons meet and fuse. At this stage the RNA primers are removed and the DNA fragments are ligated by DNA ligase.

The eukaryotic cell cycle ensures coordination of DNA replication and cell division

The use of multiple origins of replication requires mechanisms for ensuring that each sequence is replicated once and only once. Thus, the processes of DNA synthesis and cell division are coordinated in the eukaryotic **cell cycle** so that the replication of all DNA sequences (which occurs during S phase) is complete before the cell progresses into the next phase of the cycle (**Figure 28.27**). This coordination requires several so-called *checkpoints* that control the progression along the cycle. Checkpoints are managed by a family of small proteins termed *cyclins*, which are synthesized and degraded by proteasomal digestion in the course of the cell cycle. Cyclins act by binding to specific cyclin-dependent protein kinases and activating them. One such kinase, cyclin-dependent kinase 2 (cdk2), binds to assemblies at origins of replication and regulates replication through a number of interlocking mechanisms.

© Macmillan Learning

FIGURE 28.27 Eukaryotic DNA replication and cell division are highly coordinated. Mitosis (M) takes place only after DNA synthesis (S). Two gap phases (G_1 and G_2) separate the two processes.

The complexity of the eukaryotic genome includes the three-dimensional organization of chromosomes in specific compartments within the nucleus, a concept referred to as the *3D genome*. This level of organization is related to the fact that certain sections of the genome are replicated at distinct times during the S phase of the cell cycle. Moreover, regions of the genome that are replicated early in S phase also tend to be more highly expressed.

Telomeres are protective structures at the ends of linear chromosomes

Recall that whereas the genomes of essentially all prokaryotes are circular, the chromosomes of human beings and other eukaryotes are linear. The free ends of linear DNA molecules introduce several complications that must be resolved by special enzymes. In particular, complete replication of DNA ends is difficult because polymerases act only in the $5' \rightarrow 3'$ direction. Thus, without some kind of intervention, the lagging strand would have an incomplete $5'$ end after the removal of the RNA primer, and each round of replication would further shorten the chromosome.

The first clue to how this problem is resolved came from sequence analyses of the ends of chromosomes, called **telomeres** (from the Greek *telos*, "an end"). Telomeric DNA contains hundreds of tandem repeats of a six-nucleotide sequence. One of the strands is G rich at the $3'$ end, and it is slightly longer than the other strand. In human beings, the repeating G-rich sequence is AGGGTT.

Extensive investigation of the structure adopted by telomeres suggests that they may form large duplex loops (**Figure 28.28**). The single-stranded region at the very end of the structure has been proposed to

loop back to form a DNA duplex with another part of the repeated sequence, displacing a part of the original telomeric duplex. This loop-like structure is formed and stabilized by specific telomere-binding proteins. Such structures would nicely mask and protect the end of the chromosome.

FIGURE 28.28 Telomeres may form duplex loops. A single-stranded segment of the G-rich strar extends from the end of the telomere. In one model for telomeres, this single-stranded region invades the duplex to form a large duplex loop.

Telomeres are replicated by telomerase, a specialized polymerase that carries its own RNA template

How are these repeated sequences generated? An enzyme, termed **telomerase**, that executes this function has been purified and characterized. When a primer ending in GGTT is added to human telomerase in the presence of dNTPs, the sequences GGTTAGGGTT and GGTTAGGGTTAGGGTT, as well as longer products, are generated. Elizabeth Blackburn and Carol Greider (Chapter 1) discovered that the enzyme adding the repeats contains an RNA molecule that serves as the template for the elongation of the G-rich strand (**Figure 28.29**). Thus, telomerase carries the information necessary to generate the repeated telomeric sequences. Subsequently, a protein component of telomerases also was identified. This component is related to reverse

transcriptases, enzymes first discovered in retroviruses that copy RNA into DNA (Section 8.4). Thus, telomerase is a specialized reverse transcriptase that carries its own template.

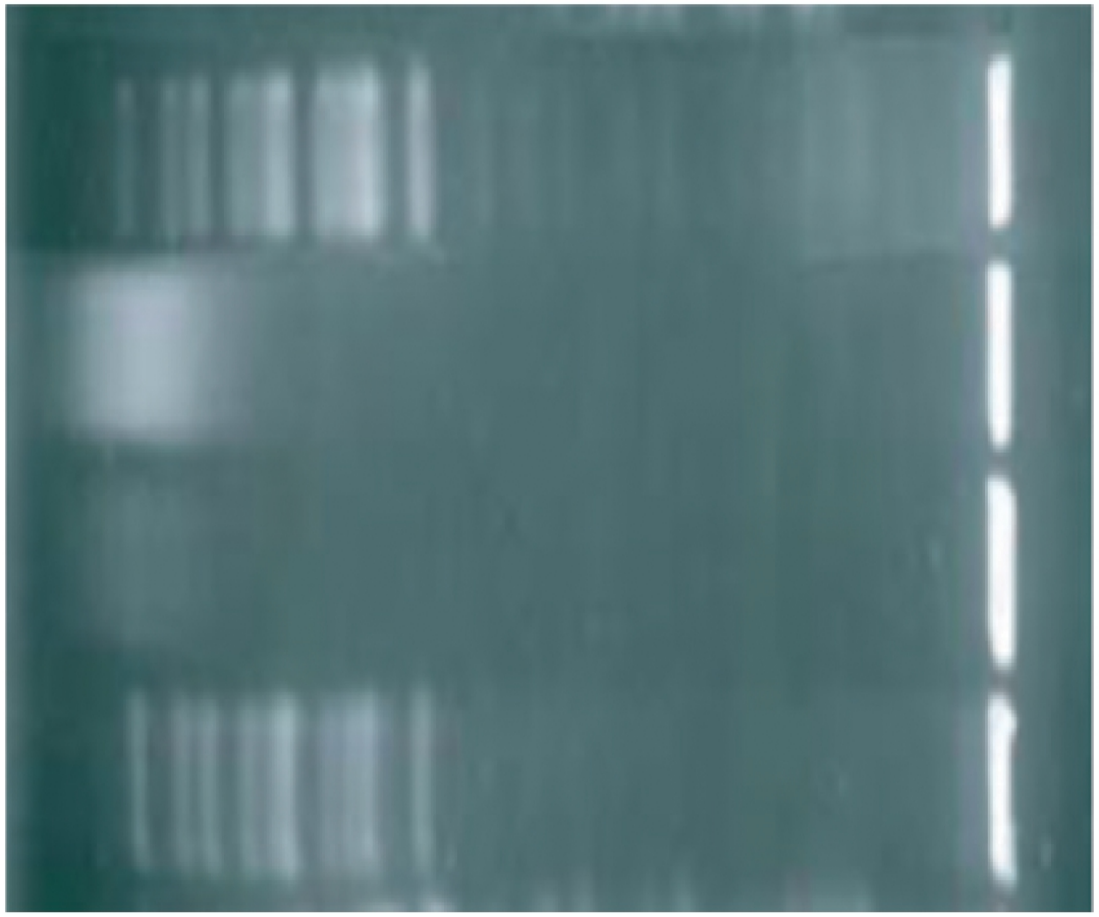
FIGURE 28.29 Telomerase uses its RNA template to synthesize the G-rich strand of telomeres. The RNA template of telomerase is shown in blue and the nucleotides added to the G-rich strand of the primer are shown in red.

[Information from E. H. Blackburn, *Nature* 350:569–573, 1991.]

Telomerase is generally expressed at high levels only in rapidly growing cells, including cancer cells. Thus, telomerase is a potential target for anticancer therapy. A variety of approaches for blocking telomerase expression or blocking its activity are under investigation for cancer treatment and prevention.

Self-Check Question



Telomerase is not active in most human cells. Some cancer biologists have suggested that activation of the telomerase gene would be a requirement for a cell to become cancerous. Explain why this might be the case.

28.4 Many Types of DNA Damage Can Be Repaired

We have examined how even very large and complex genomes can, in principle, be replicated with considerable fidelity. However, DNA does become damaged, both in the course of replication and through other processes. Although DNA is remarkably robust, ultraviolet light as well as a range of chemical species can damage DNA, introducing changes in the DNA sequence (mutations) or lesions that can block further DNA replication. DNA damage can also take more complex forms such as the chemical modification of bases, chemical cross-links between the two strands of the double helix, or breaks in one or both of the phosphodiester backbones. The results may be cell death or cell transformation, changes in the DNA sequence that can be inherited by future generations, or blockage of the DNA replication process itself. While a variety of DNA-repair systems have evolved that can recognize DNA damage and, in many cases, restore the DNA molecule to its undamaged form, mutations in genes that encode components of DNA-repair systems are key factors in the development of cancer.

The bacterium *Deinococcus radiodurans* illustrates the extraordinary power of DNA-repair systems. This bacterium was discovered in 1956 when scientists were studying the use of high doses of gamma radiation to sterilize canned meat. In some cases, the meat still spoiled due to the growth of a bacterial species that withstood doses of gamma radiation more than 1000 times larger than those that would kill a human being. Each *D. radiodurans* cell contains between 4 and 10 copies of its genome. Even when these bacterial chromosomes are broken into many fragments by the ionizing radiation, they can reassemble and recombine to regenerate the intact genome with essentially no loss of information (**Figure 28.30**). These cells can also survive extreme desiccation — that is, drying out — much better than other organisms.

This ability is believed to be the selective advantage that favored the evolution of this and related species.

FIGURE 28.30 The bacterium *Deinococcus radiodurans* repairs DNA damage quickly. After irradiation with gamma rays, the fragmented genome of this bacterium is repaired and reassembled within 3 hours. To aid analysis, the genomic DNA samples were digested with a restriction enzyme that cuts at only a few sites within the genome. C = control

Before we discuss various DNA-repair systems, let's begin with some of the sources of DNA damage.

Errors can arise in DNA replication

Errors introduced in the replication process are the simplest source of damage in the double helix. With the addition of each base, there is the possibility that an incorrect base might be incorporated, forming a non-Watson–Crick base pair. These non-Watson–Crick base pairs can locally distort the DNA double helix. Furthermore, such mismatches can be mutagenic; that is, they can result in permanent changes in the DNA sequence. When a double helix containing a non-Watson–Crick base pair is replicated, the two daughter double helices will have different sequences, because the mismatched base is very likely to pair with its Watson–Crick partner. Errors other than mismatches include insertions, deletions, and breaks in one or both strands. Furthermore, replicative polymerases can stall or even fall off a damaged template entirely, causing replication of the genome to halt before it is complete.

A variety of mechanisms have evolved to deal with such interruptions, including specialized DNA polymerases that can replicate DNA across many lesions. A drawback is that such polymerases are substantially more error-prone than are normal replicative polymerases. Nonetheless, these translesion or error-prone polymerases allow the completion of a draft sequence of the genome that can be at least partly repaired by DNA-repair processes. DNA recombination (Section 28.5)

provides an additional mechanism for salvaging interruptions in DNA replication.

DNA can be damaged by oxidizing agents, alkylating agents, and light

A variety of chemical and physical agents, called **mutagens**, can alter specific bases within DNA after replication is complete. Let's look in depth at some of these mutagens.

Reactive oxygen species

For example, hydroxyl radical reacts with guanine to form 8-oxoguanine. 8-Oxoguanine is mutagenic because it often pairs with adenine rather than cytosine in DNA replication. Its pairing partner differs from that of guanine because it uses a different edge of the base to form base pairs (**Figure 28.31**).

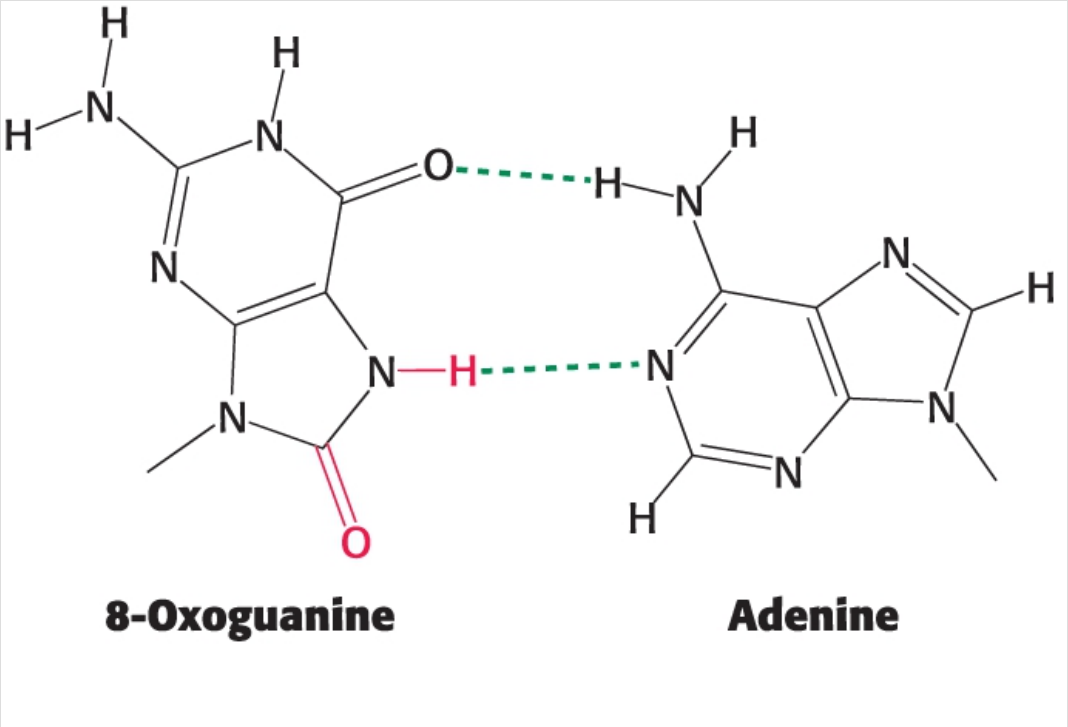

FIGURE 28.31 Damaged DNA bases can form base pairs. When guanine is oxidized to 8-oxoguanine, the damaged base can form a base pair with adenine through an edge of the base that does not normally participate in base-pair formation.

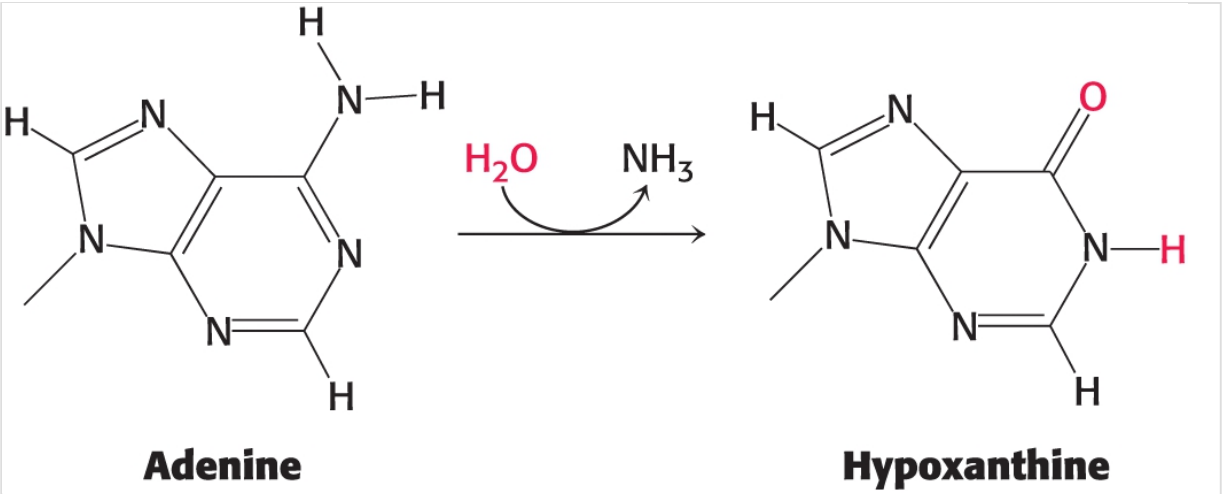
Deaminating agents

Deamination is another potentially deleterious process. For example, nitrous acid will deaminate adenine to form hypoxanthine (Figure 28.32). This process is mutagenic because hypoxanthine pairs with cytosine rather than thymine. Guanine and cytosine can also be deaminated to yield bases that pair differently from the parent base.



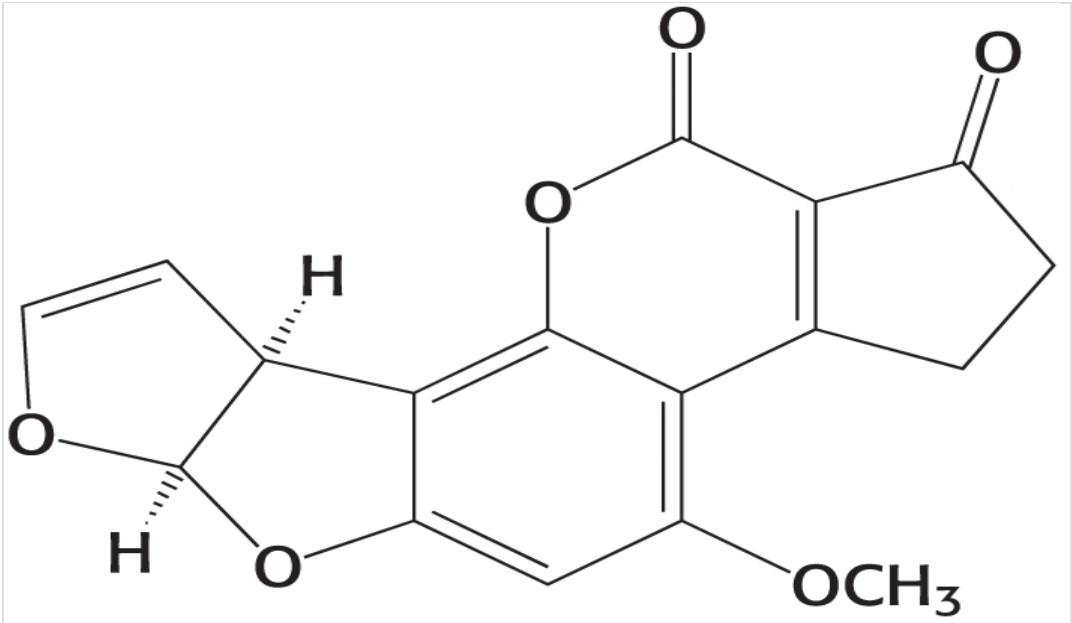


FIGURE 28.32 Adenine can be deaminated to form hypoxanthine. Hypoxanthine forms base pairs with cytosine in a manner similar to that of guanine, and so the deamination reaction can result in mutation.

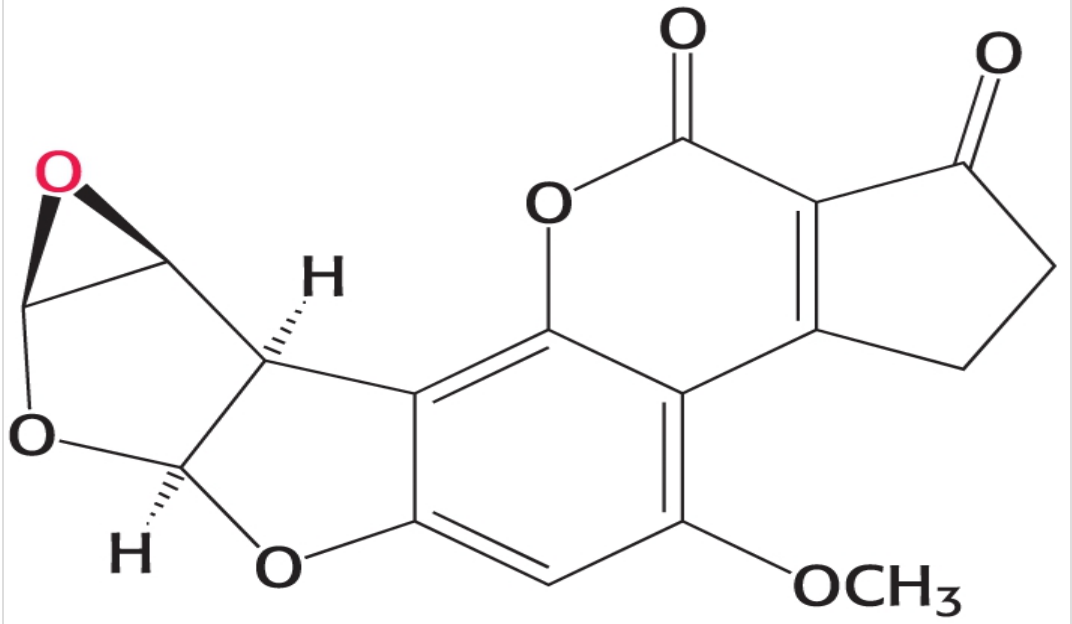

Alkylating agents

In addition to oxidation and deamination, nucleotide bases are subject to alkylation, in which electrophilic centers are attacked by nucleophiles such as N-7 of guanine and adenine to form alkylated adducts. Some compounds are converted into highly active electrophiles through the action of enzymes that normally play a role in detoxification. A striking example is aflatoxin B_1, a compound produced by molds that grow on peanuts and other foods. A cytochrome P450 enzyme (Section 26.4) converts this compound into a highly reactive epoxide (**Figure 28.33**). This agent reacts with the N-7 atom of guanosine to form a mutagenic adduct that frequently leads to a G–C-to-T–A transversion.

Active DNA-modifying agent

FIGURE 28.33 Aflatoxin can be activated into a mutagen. Aflatoxin is activated by cytochrome P450 to form a highly reactive species that modifies bases such as guanine in DNA, leading to mutations.

UV light and other cross-linking agents

The ultraviolet component of sunlight is a ubiquitous DNA-damaging agent. Its major effect is to covalently link adjacent pyrimidine residues along a DNA strand (Figure 28.34). Such a pyrimidine dimer cannot fit into a double helix, and so replication and gene expression are blocked until the lesion is removed. A thymine dimer is an example of an *intra*strand cross-link because both participating bases are in the same strand of the double helix. In contrast, *inter*strand cross-links between bases on opposite strands disrupt replication because they prevent strand separation. Interstrand cross-links can be introduced by various agents, including compounds called *psoralens* (Figure 28.35) that are produced by a number of plants, including the common fig. When consumed in high doses and combined with exposure to UV light, psoralens can be mutagenic; but in lower doses, the combination of psoralens and UV light is an approved treatment method for a variety of skin conditions such as psoriasis and eczema.

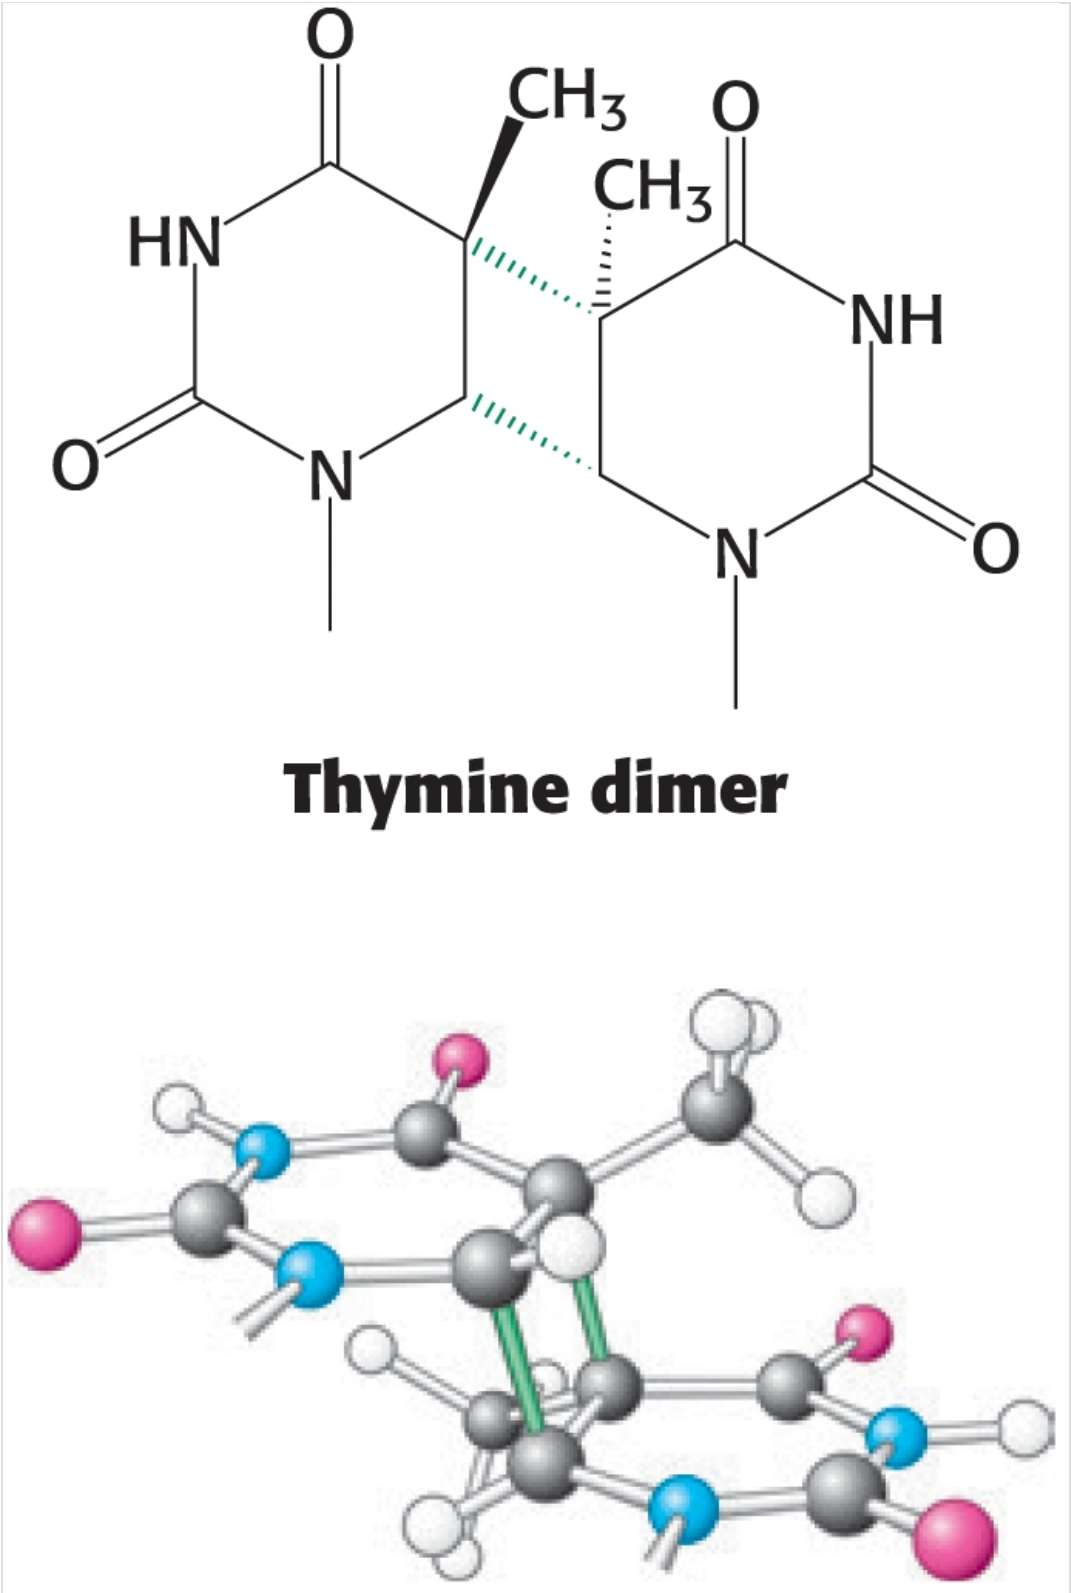

FIGURE 28.34 Ultraviolet light induces cross-links between adjacent pyrimidines along one strand of DNA.

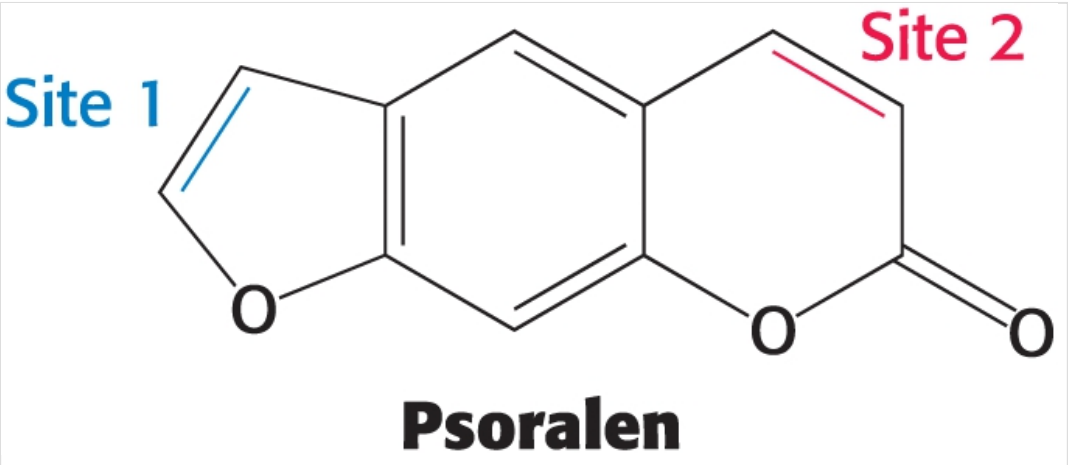

FIGURE 28.35 Psoralen is a cross-linking agent. The compound psoralen and its derivatives can form interstrand cross-links through two reactive sites that can form adducts with nucleotide bases.

High-energy electromagnetic radiation such as x-rays

X-rays can damage DNA by producing high concentrations of reactive species in solution. X-ray exposure can induce several types of DNA damage, including single- and double-stranded breaks in DNA. This ability to induce such DNA damage led Hermann Muller to discover the mutagenic effects of x-rays in *Drosophila* in 1927. This discovery contributed to the development of *Drosophila* as one of the premier organisms for genetic studies.

DNA damage can be detected and repaired by a variety of systems

To protect the genetic message, a wide range of DNA-repair systems are present in most organisms. Many systems repair DNA by using sequence information from the uncompromised strand. Such single-strand replication systems follow a similar mechanistic outline:

1. Recognize the offending base(s).
2. Remove the offending base(s).
3. Repair the resulting gap with a DNA polymerase and DNA ligase.

We will briefly consider examples of several repair pathways. Although many of these examples are taken from *E. coli*, corresponding repair systems are present in most other organisms, including human beings.

Proofreading and repair by DNA polymerases

The replicative DNA polymerases themselves are able to correct many DNA mismatches produced in the course of replication. For example, the ε subunit of *E. coli* DNA polymerase III functions as a $3'$-to-$5'$ exonuclease. This domain removes mismatched nucleotides from the $3'$ end of DNA by hydrolysis. How does the enzyme sense whether a newly added base is correct? As a new strand of DNA is synthesized, it is, in a sense, proofread (**Figure 28.36**). If an incorrect base is inserted, then DNA synthesis slows down, owing to the difficulty of threading a non-Watson–Crick base pair into the polymerase. In addition, the mismatched base is weakly bound and therefore able to fluctuate in position. The delay from the slowdown allows time for these fluctuations to take the newly synthesized strand out of the polymerase active site and into the exonuclease active site. There, the DNA is

degraded, one nucleotide at a time, until it moves back into the polymerase active site and synthesis continues.

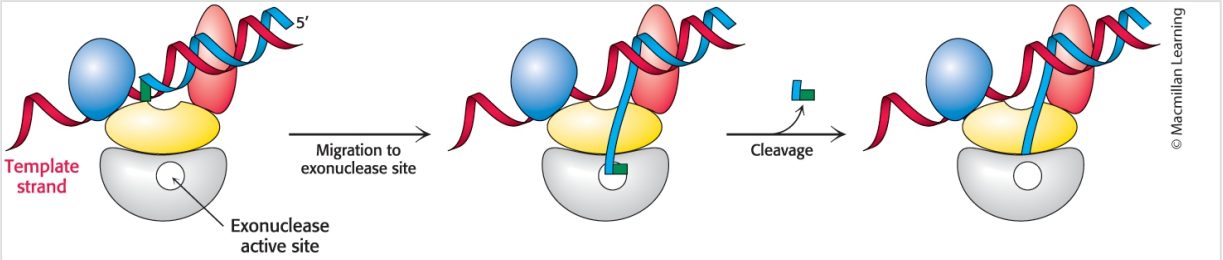

FIGURE 28.36 DNA polymerases have proofreading activities. The growing polynucleotide chain occasionally leaves the polymerase site and migrates to the active site of the exonuclease. There, one or more nucleotides are excised from the newly synthesized chain, removing potentially incorrect bases.

Mismatch repair

A second mechanism is present in essentially all cells to correct errors made in replication that are not corrected by proofreading (Figure 28.37). **Mismatch repair** is achieved by systems of at least two proteins, one for detecting the mismatch and the other for recruiting a restriction endonuclease that cleaves the newly synthesized DNA strand close to the lesion to facilitate repair. In *E. coli*, these proteins are MutS and MutL, and the endonuclease is MutH.

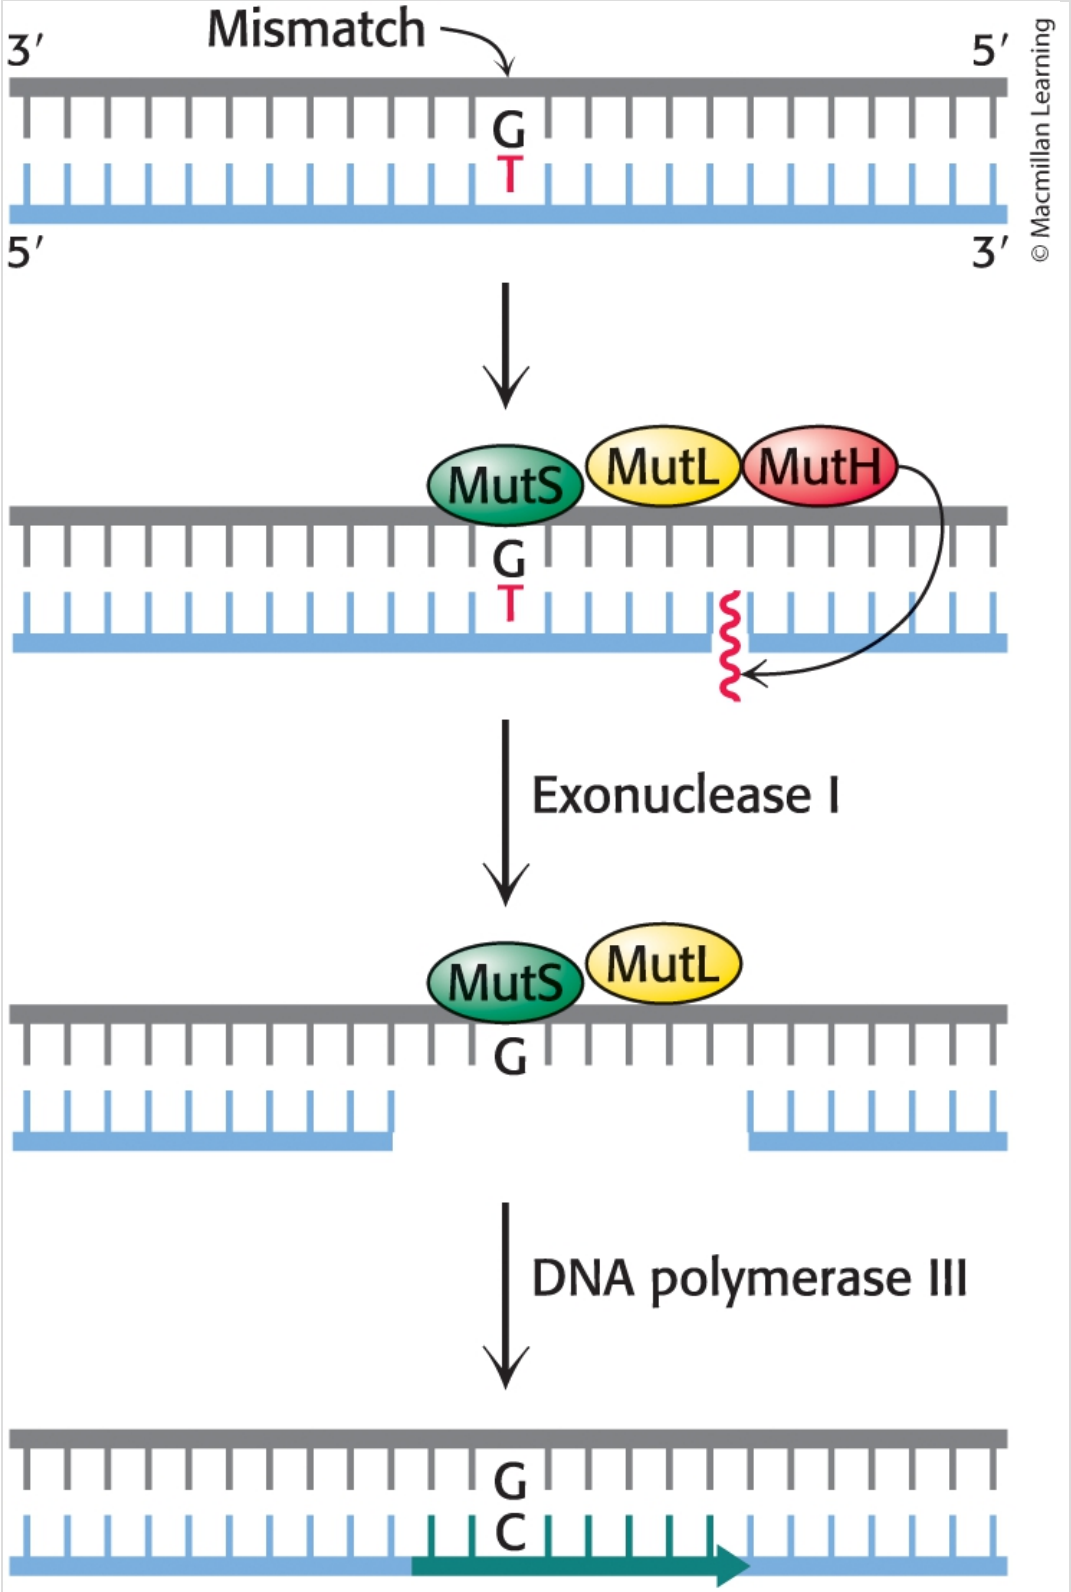

FIGURE 28.37 DNA mismatch repair in *E. coli* involves multiple proteins. First, a G–T mismatch is recognized by the MutS–MutL complex, and then MutH cleaves the

backbone in the vicinity of the mismatch. Subsequently, a segment of the DNA strand containing the erroneous T is removed by exonuclease I and synthesized anew by DNA polymerase III.

[Information from R. F. Service, *Science* 263:1559–1560, 1994.]

Direct repair

Another mechanism of DNA repair is **direct repair**, one example of which is the photochemical cleavage of pyrimidine dimers. Nearly all cells contain a photoreactivating enzyme called *DNA photolyase*. The *E. coli* enzyme, a 35-kDa protein that contains bound N^5, N^{10}-methenyltetrahydrofolate and flavin adenine dinucleotide (FAD) cofactors, binds to the distorted region of DNA. The enzyme uses light energy — specifically, the absorption of a photon by the N^5, N^{10}-methenyltetrahydrofolate coenzyme — to form an excited state that cleaves the dimer into its component bases.

Base-excision repair

Erroneous bases may also be removed. The excision of modified bases such as 3-methyladenine by the *E. coli* enzyme AlkA is an example of **base-excision repair**. The binding of this enzyme to damaged DNA flips the affected base out of the DNA double helix and into the active site of the enzyme (**Figure 28.38**). The enzyme then acts as a glycosylase, cleaving the glycosidic bond to release the damaged base. At this stage, the DNA backbone is intact, but a base is missing. This hole is called an *AP site* because it is apurinic (devoid of A or G) or apyrimidinic (devoid of C or T). An AP endonuclease recognizes this defect and nicks the backbone adjacent to the missing base. Then, deoxyribose

phosphodiesterase excises the residual deoxyribose phosphate unit, and DNA polymerase I inserts an undamaged nucleotide, as dictated by the base on the undamaged complementary strand. Finally, the repaired strand is sealed by DNA ligase.

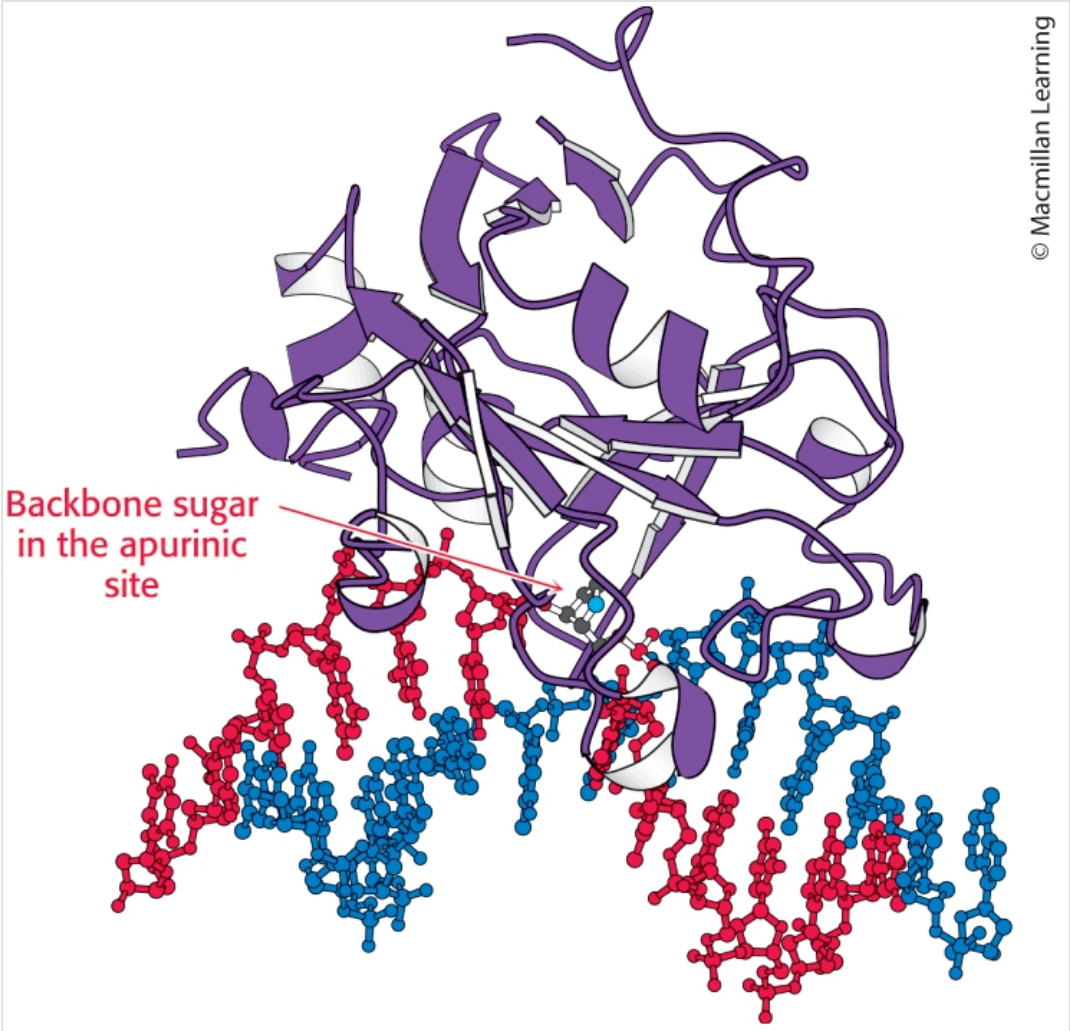

FIGURE 28.38 Base-excision repair enzymes remove damaged bases. A complex between the DNA-repair enzyme AlkA and an analog of a DNA molecule missing a purine base (an apurinic site) is shown. The backbone sugar in the apurinic site is flipped out of the double helix into the active site of the enzyme.

[Drawn from 1BNK.pdb.]

INTERACT with this model in Achieve

Nucleotide-excision repair

Sometimes, more than just the erroneous base is excised; the entire nucleotide may be removed. One of the best-understood examples of **nucleotide-excision repair** is utilized for the excision of a pyrimidine dimer. Three enzymatic activities are essential for this repair process in *E. coli* (**Figure 28.39**). First, an enzyme complex consisting of the proteins encoded by the *uvrABC* genes detects the distortion produced by the DNA damage. The UvrABC enzyme cuts the damaged DNA strand at two sites, 8 nucleotides away from the damaged site on the $5'$ side and 4 nucleotides away on the $3'$ side, and the 12-residue oligonucleotide excised by this highly specific *excinuclease* (from the Latin *exci*, "to cut out") then diffuses away. Second, DNA polymerase I enters the gap to carry out repair synthesis. The $3'$ end of the nicked strand is the primer, and the intact complementary strand is the template. Third, the $3'$ end of the newly synthesized stretch of DNA and the original part of the DNA chain are joined by DNA ligase.

Repair of breaks in both strands

While DNA ligase can seal simple breaks in one strand of the DNA backbone, alternative mechanisms are required to repair breaks on both strands that are close enough together that they would otherwise separate the DNA into two double helices. Several distinct mechanisms are able to repair such damage.

One mechanism, **non-homologous end joining (NHEJ)**, does not depend on other DNA molecules in the cell (see Section 9.4). In NHEJ, the free double-stranded ends are bound by a heterodimer of two proteins, Ku70 and Ku80. These proteins stabilize the ends and mark them for subsequent manipulations. Through mechanisms that are not yet well-understood, the Ku70/80 heterodimers act as handles used by other proteins to draw the two double-stranded ends close together so that enzymes can seal the break. Alternative mechanisms of double-stranded-break repair can operate if an intact stretch of double-stranded DNA with an identical or very similar sequence is present in the cell. These repair processes use homologous recombination, presented in Section 28.5.

As noted in Section 9.4, researchers can now take advantage of double-stranded-break repair mechanisms for executing targeted changes in eukaryotic genomes, using techniques such as CRISPR. Specific engineered nucleases are used to introduce double-stranded

breaks in particular locations within the genome. The DNA-repair machinery in the targeted cells will then repair the break, through either NHEJ to disrupt the gene or homologous recombination-based repair with added double-stranded DNA fragments to introduce more elaborate modifications. For example, mutations associated with human diseases can be specifically introduced into the genomes of model organisms such as mice or zebrafish to examine the consequences.

Self-Check Question

Summarize the various ways in which the sequence of DNA is verified or corrected. Why are there so many pathways?

The presence of thymine instead of uracil in DNA permits the repair of deaminated cytosine

The presence in DNA of thymine rather than uracil, as in RNA, was an enigma for many years. Both bases pair with adenine; the only difference between them is a methyl group in thymine in place of the C-5 hydrogen in uracil. Why is a methylated base employed in DNA and not in RNA? The existence of an active repair system to correct the deamination of cytosine provides a convincing solution to this puzzle.

Cytosine in DNA spontaneously deaminates at a perceptible rate to form uracil. The deamination of cytosine is potentially mutagenic because uracil pairs with adenine, and so one of the daughter strands will contain a U–A base pair rather than the original C–G base pair. This

mutation is prevented by a repair system that recognizes uracil to be foreign to DNA (**Figure 28.40**). The repair enzyme, uracil DNA glycosylase, which is homologous to AlkA, hydrolyzes the glycosidic bond between the uracil and deoxyribose moieties but does not attack thymine-containing nucleotides. The AP site generated is repaired to reinsert cytosine.

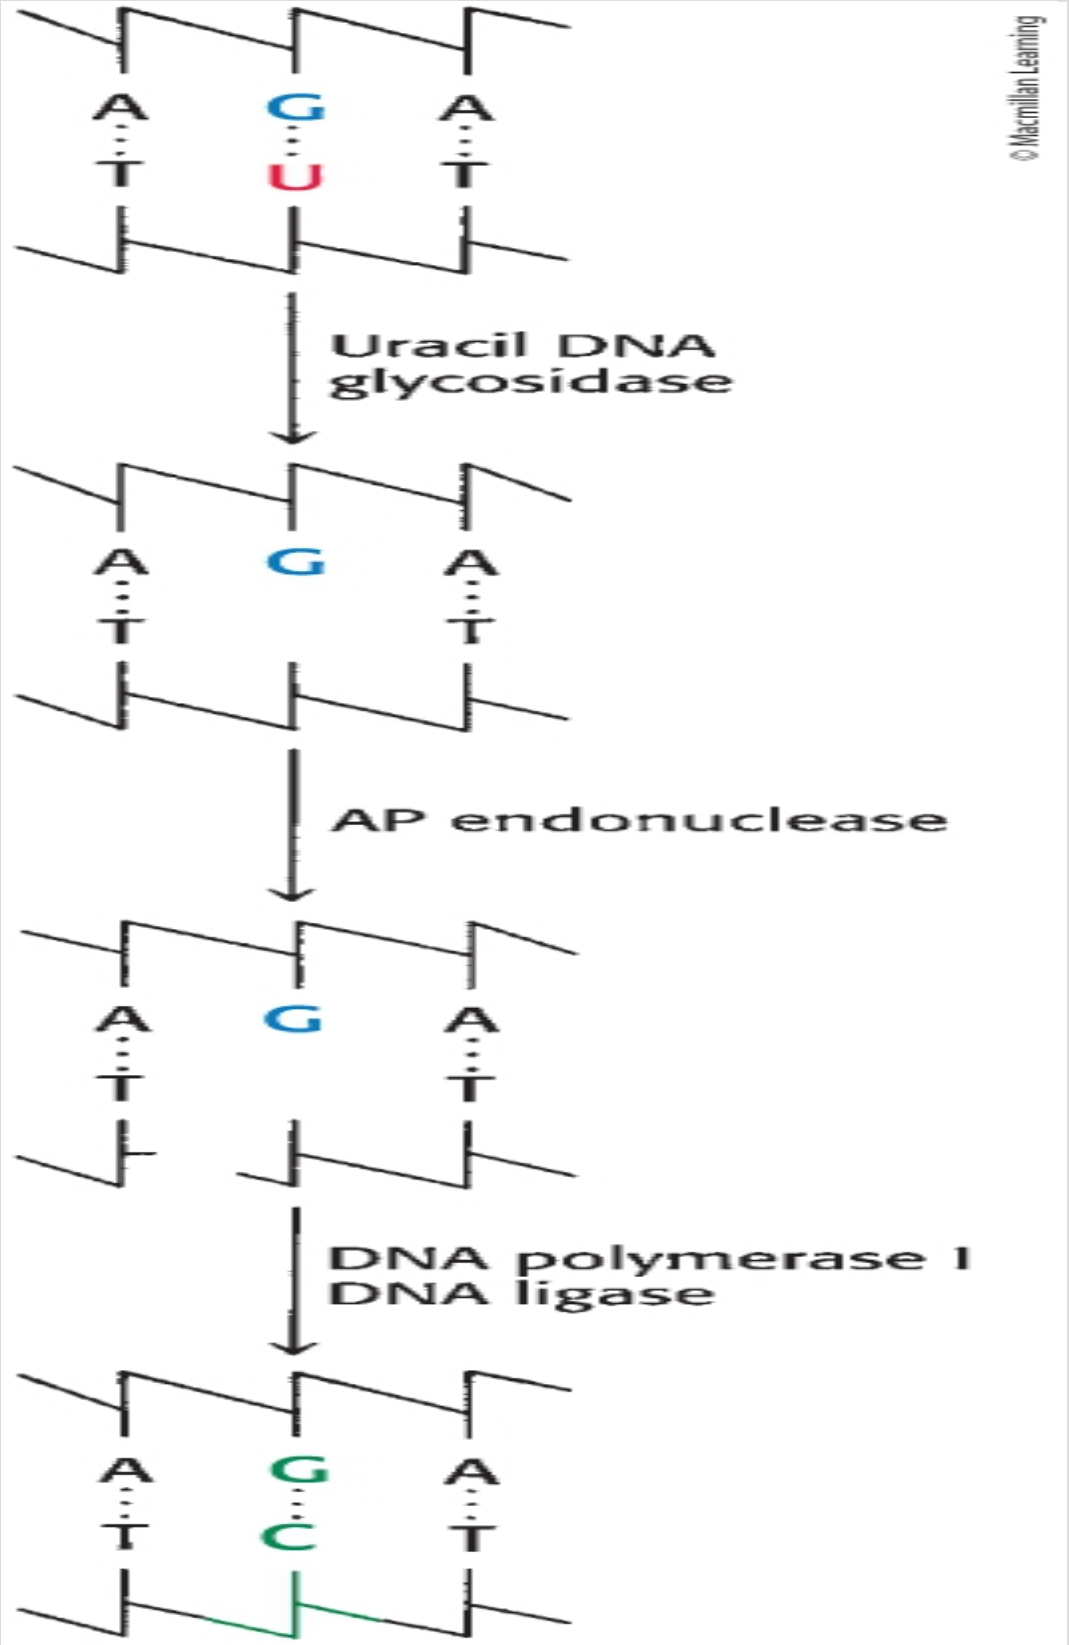

FIGURE 28.40 Uridine bases in DNA are excised and replaced by cytidine.

Thus, we can conclude that the methyl group on thymine acts like a tag that distinguishes thymine from deaminated cytosine. If uracil instead of thymine were used in DNA, correctly placed uracil would be indistinguishable from uracil formed by deamination of cytosine. The defect would persist unnoticed, and so a C–G base pair would necessarily be mutated to U–A in one of the daughter DNA molecules. This mutation is prevented by a DNA-repair system that searches for uracil and leaves thymine alone. In summary, the use of thymine instead of uracil in DNA enhances the fidelity of the genetic message.

Some genetic diseases are caused by the expansion of repeats of three nucleotides

Some genetic diseases are caused by the presence of DNA sequences that are inherently prone to errors during replication and repair. A particularly important class of such diseases is characterized by the presence of long tandem arrays of multiple copies of a particular sequence of three nucleotides, called **trinucleotide repeats**. An example is Huntington's disease, an autosomal dominant neurological disorder with a variable age of onset. The mutated gene in this disease expresses a protein in the brain called *huntingtin*, which contains a stretch of consecutive glutamine residues encoded by a tandem array of CAG sequences within the gene. In unaffected persons, this array is between 6 and 31 repeats, whereas in those with the disease, the array is between 36 and 82 repeats or longer. Moreover, the array tends to become longer from one generation to the next. The consequence is a

phenomenon called *anticipation* in which the children of an affected parent tend to show symptoms of the disease at an earlier age than did the parent.

The tendency of trinucleotide repeats to expand over time is explained by the formation of alternative structures in the course of DNA replication or repair. For example, part of the repeat can loop out without disrupting base-pairing outside this region. Then, in replication, DNA polymerase extends this strand through the remainder of the repeat, leading to an increase in the number of copies of the trinucleotide sequence (**Figure 28.41**).

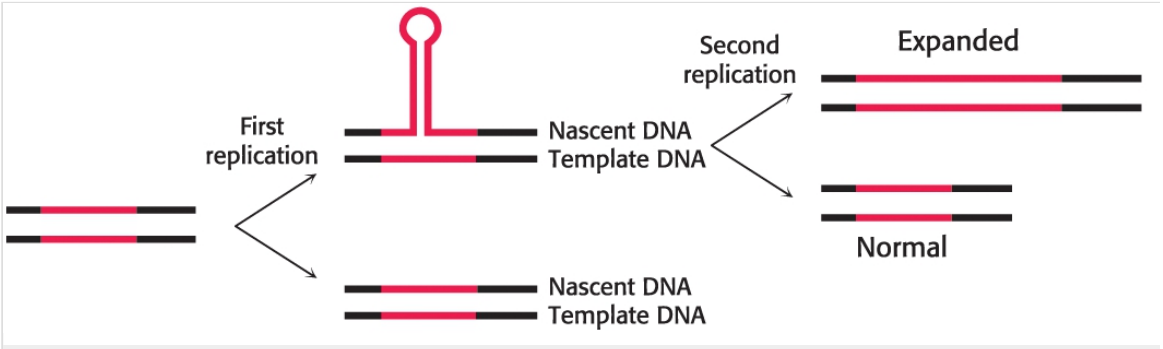

FIGURE 28.41 Trinucleotide repeats can form structures that lead to their expansion during DNA replication. In this example, a hairpin structure forms that results in the expansion of the trinucleotide repeat segment (red) in one of the daughter strands after two rounds of replicatio

How do these long stretches of repeated amino acids cause disease? For huntingtin, it appears that the polyglutamine stretches become increasingly prone to aggregate as their length increases; the additional consequences of such aggregation are still under investigation.

Many cancers are initiated by the defective repair of DNA

As described in Chapter 14, cancers are caused by mutations in genes associated with growth control. Defects in DNA-repair systems increase the overall frequency of mutations and, hence, the likelihood of cancer-causing mutations. Indeed, the synergy between studies of mutations that predispose people to cancer and studies of DNA repair in model organisms has been tremendous in revealing the biochemistry of DNA-repair pathways.

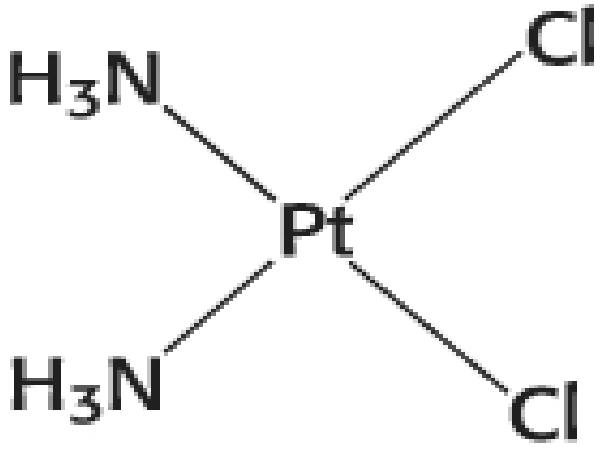
Genes for DNA-repair proteins are often **tumor-suppressor genes**; that is, they suppress tumor development when at least one copy of the gene is free of a deleterious mutation. When both copies of a gene are mutated, however, tumors develop at rates greater than those for the population at large. People who inherit defects in a single tumor-suppressor allele do not necessarily develop cancer but are susceptible to developing the disease because only the one remaining normal copy of the gene must develop a new defect to further the development of cancer. **Table 28.2** lists selected proteins involved in DNA-repair processes that, when mutated, can contribute to certain diseases, including cancers.

TABLE 28.2 Examples of diseases caused by mutations in repair proteins

Disease	Selected Proteins	Affected Repair Pathway
Xeroderma pigmentosum (skin)	XPA, XPB, XPC	Nucleotide-excision repair
Lynch syndrome (colorectal cancer)	MSH2, MLH1	Mismatch repair
Breast and ovarian cancer	BRCA1 and	Double-strand break repair

	BRCA2	
Renal and lung cancer	OGG1	Base-excision repair

- *Xeroderma pigmentosum.* In the rare human skin disease xeroderma pigmentosum, the skin of an affected person is extremely sensitive to sunlight or ultraviolet light. Studies of xeroderma pigmentosum patients have revealed that mutations occur in genes for a number of proteins that are components of the human nucleotide-excision-repair pathway, including homologs of the UvrABC subunits. Severe changes in the skin start in infancy and worsen with time, usually resulting in the development of skin cancers at several sites. Many patients die before age 30 from metastases of these malignant skin tumors.



- *Hereditary nonpolyposis colorectal cancer.* As many as 1 in 200 people develop hereditary nonpolyposis colorectal cancer (HNPCC, or Lynch syndrome) resulting from defective DNA mismatch repair. Mutations in two genes, called *hMSH2* and *hMLH1*, account for most cases. The striking finding is that these genes encode the human counterparts of MutS and MutL of *E. coli.* Mutations in *hMSH2* and *hMLH1* likely allow other mutations to accumulate throughout the genome; in time, genes important in controlling cell proliferation become altered, resulting in the onset of cancer.

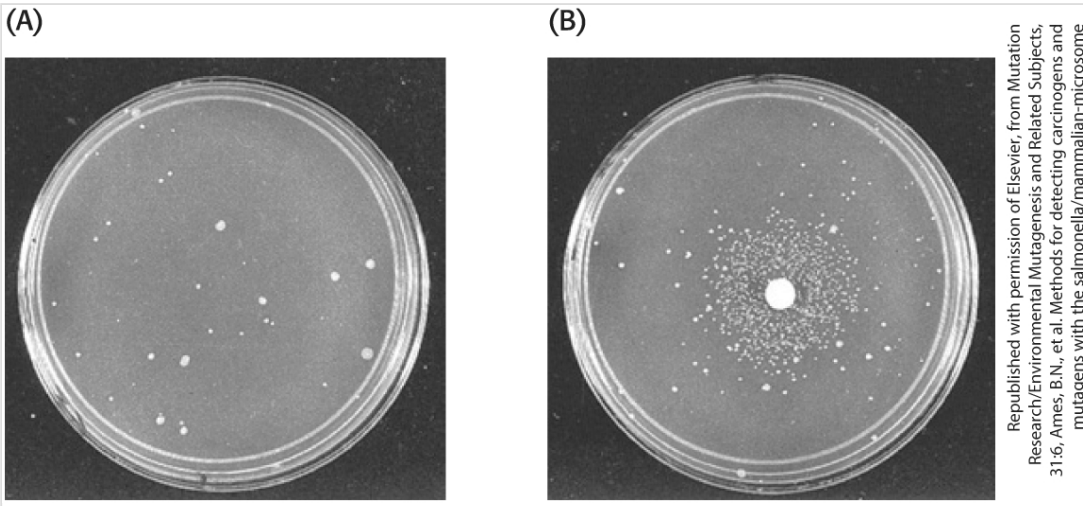
- *Cancers caused by mutations to* p53. Not all tumor-suppressor genes are specific to particular types of cancer. For example, the *p53* gene is mutated in more than half of all tumors. This gene codes for a protein that helps control the fate of damaged cells, p53. First, the p53 protein plays a central role in sensing DNA damage, especially double-stranded breaks. Then, after sensing damage, the protein either promotes a DNA-repair pathway or activates the apoptosis pathway, leading to cell death. Most mutations in the *p53* gene are sporadic; that is, they occur in somatic cells rather than being inherited, but the mutation can also be inherited. People who

inherit a deleterious mutation in one copy of the *p53* gene have a high probability of developing several types of cancer.

Cyclophosphamide

Cisplatin

Cancer cells often have two characteristics that make them especially vulnerable to agents that damage DNA molecules. First, they divide frequently, and so their DNA replication pathways are more active than they are in most cells. Second, as already noted, cancer cells often have defects in DNA-repair pathways. Several agents widely used in cancer chemotherapy, including cyclophosphamide and cisplatin, act by damaging DNA. Cancer cells are less able to avoid the effect of the induced damage than are normal cells, providing a therapeutic window for specifically killing cancer cells.



Many potential carcinogens can be detected by their mutagenic action on bacteria

Many human cancers are caused by exposure to chemicals that are mutagens; therefore, it is important to identify such compounds and to ascertain their potency so that exposure to them can be minimized. Bruce Ames devised a simple and sensitive test, called the **Ames test**, for detecting chemical mutagens.

1. A thin layer of agar containing about 10^9 bacteria of a specially constructed tester strain of *Salmonella* is placed on an agar plate. These bacteria are unable to grow in the absence of histidine, because a mutation is present in one of the genes for the biosynthesis of this amino acid.

2. A chemical mutagen is added to the center of the plate, resulting in many new mutations. A small proportion of these mutations reverse the original mutation, allowing the bacteria to synthesize histidine.

3. These so-called *revertants* multiply in the absence of an external source of histidine and appear as discrete colonies after the plate has been incubated at 37°C for 2 days (Figure 28.42). For example, 0.5 μg of 2-aminoanthracene gives 11,000 revertant colonies, compared with only 30 spontaneous revertants in its absence.

Republished with permission of Elsevier, from Mutation Research/Environmental Mutagenesis and Related Subjects, 31:6, Ames, B.N., et al. Methods for detecting carcinogens and mutagens with the salmonella/mammalian-microsome

FIGURE 28.42 The Ames test determines the mutagenicity of various compounds. Two results are shown: (A) an agar plate containing about 10^9 *Salmonella* bacteria that cannot synthesize histidine, and (B) an agar plate containing a filter-paper disc with a mutagen, which produces a large number of revertants that can synthesize histidine. After 2 days, the revertants appear as rings of colonies around the disc. The small number of visible colonies in plate A are spontaneous revertants.

4. A series of concentrations of the chemical mutagen that caused the reversion can be readily tested to generate a dose-response curve.

Different tester strains of *Salmonella* used in the Ames test are sensitive to different kinds of mutations. For example, some of the tester strains are responsive to base-pair substitutions, whereas others detect deletions or additions of base pairs (frameshifts). These specially

designed strains are particularly sensitive to mutations because the genes of their excision-repair systems have been deleted. In addition, potential mutagens enter the tester strains easily because the lipopolysaccharide barrier that normally coats the surface of *Salmonella* is incomplete in these strains. A key feature of this detection system is the inclusion of a mammalian liver homogenate, which promotes the conversion of some potential carcinogens into their active forms. Bacteria lack the enzymes required for this conversion.

The *Salmonella* test is extensively used to help evaluate the mutagenic and carcinogenic risks of a large number of chemicals. This rapid and inexpensive bacterial assay for mutagenicity complements epidemiological surveys and animal tests that are necessarily slower, more laborious, and far more expensive. The *Salmonella* test for mutagenicity is an outgrowth of studies of gene–protein relations in bacteria. It is a striking example of how fundamental research in molecular biology can lead directly to important advances in public health.

28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

Most processes associated with DNA replication function to copy the genetic message as faithfully as possible. However, several biochemical processes require **genetic recombination**, the exchange of genetic material between two DNA molecules that results in the reassortment of DNA sequences present on two different double helices (**Figure 28.43**).

FIGURE 28.43 Recombined DNA molecules have segments from both parent molecules.

Recombination is essential in the following processes:

1. When replication stalls, recombination processes can reset the replication machinery so that replication can continue.

2. Some double-stranded breaks in DNA are repaired by recombination.

3. In meiosis, the limited exchange of genetic material between paired chromosomes provides a simple mechanism for generating genetic diversity in a population.

4. Recombination plays a crucial role in generating molecular diversity for antibodies and some other molecules in the immune system.

5. Some viruses employ recombination pathways to integrate their genetic material into the DNA of a host cell.

6. Recombination is used to manipulate genes in, for example, the generation of gene knockout mice and other targeted genome modifications (Section 9.4).

Recombination is most efficient between DNA sequences that are homologous. In homologous recombination, parent DNA duplexes align at regions of sequence similarity, and new DNA molecules are formed by the breakage and joining of homologous segments.

RecA can initiate recombination by promoting strand invasion

In many recombination pathways, a DNA molecule with a free end recombines with a DNA molecule having no free ends available for interaction. DNA molecules with free ends are the common result of double-stranded DNA breaks, but they may also be generated in DNA replication if the replication complex stalls. Double-stranded breaks are among the most potentially devastating types of DNA damage. With both strands of the double helix broken in a local region, neither strand is intact to act as a template for future DNA synthesis. Repairing such lesions relies on DNA recombination.

This type of recombination has been studied extensively in *E. coli*, but it also takes place in other organisms through the action of proteins homologous to those of *E. coli*. Often dozens of proteins participate in the complete recombination process. However, the

key protein is RecA, the homolog of which is Rad51 in human cells. To accomplish the exchange, the single-stranded DNA first displaces one of the strands of the double helix (Figure 28.44). The resulting three-stranded structure is called a *displacement loop* or *D-loop*, and the process is often referred to as *strand invasion*. Because a free $3'$ end is now base-paired to a contiguous strand of DNA, the $3'$ end can act as a primer to initiate new DNA synthesis.

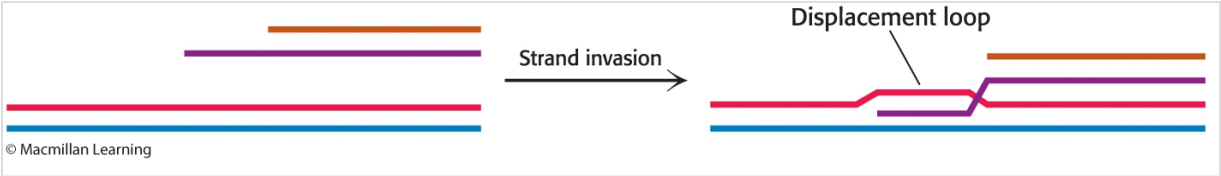


FIGURE 28.44 Strand invasion can initiate recombination. This process is promoted by proteins such as RecA.

Strand invasion can initiate many processes, including the repair of double-stranded breaks and the reinitiation of replication after the replication apparatus has come off its template. In the repair of a break, the recombination partner is an intact DNA molecule with an overlapping sequence.

Some recombination reactions proceed through Holliday-junction intermediates

In recombination pathways for meiosis and some other processes, intermediates form that are composed of four polynucleotide chains in a cross-like structure. Intermediates with these cross-like

structures are referred to as **Holliday junctions**, after Robin Holliday, who proposed their role in recombination in 1964. Such intermediates have been characterized by a wide range of techniques, including x-ray crystallography.

Specific enzymes, termed **recombinases**, bind to these structures and resolve them into separated DNA duplexes. The Cre recombinase from bacteriophage P1 has been extensively studied. The mechanism begins with the recombinase binding to the DNA substrates (**Figure 28.45**).

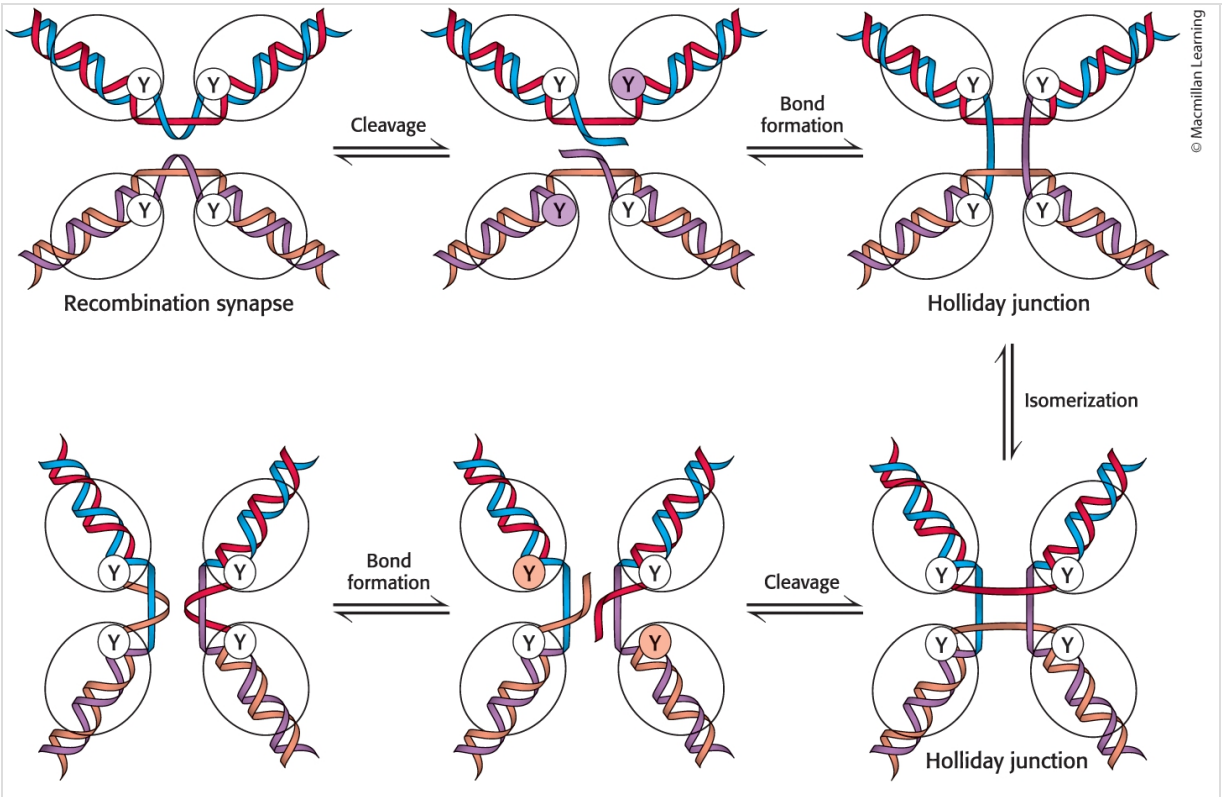

FIGURE 28.45 Holliday junctions are formed and resolved by recombinases. Recombination begins as two DNA molecules and four recombinases come together to form a recombination synapse. One strand from each duplex is cleaved by transesterification with the 3′ end of each of the cleaved strands linked to a tyrosine residue on the recombinase enzyme. New phosphodiester bonds are formed when a 5′ end of the other cleaved strand in the complex attacks these tyrosine–DNA adducts. After isomerization, these steps are repeated to form the recombined products.

1. Four molecules of the enzyme and two DNA molecules come together to form a **recombination synapse**. The reaction begins with the cleavage of one strand from each duplex via transesterification reactions with the $3'$-phosphoryl groups becoming linked to specific tyrosine residues in the recombinase while the $5'$-hydroxyl group of each cleaved strand remains free.

2. The free $5'$ ends invade the other duplex and participate in transesterification reactions to form new phosphodiester bonds and free the tyrosine residues. These reactions result in the formation of a Holliday junction.

3. This junction can then isomerize to form a structure in which the polynucleotide chains in the center of the structure are reoriented.

4. From this junction, the processes of strand cleavage and phosphodiester-bond formation repeat. The result is a synapse containing the two recombined duplexes. Dissociation of this complex generates the final recombined products.

Cre catalyzes the formation of Holliday junctions as well as their resolution. In contrast, other proteins bind to Holliday junctions that have already been formed by other processes and resolve them into separate duplexes. In many cases, these proteins also promote the process of branch migration whereby a Holliday junction is moved along the two component double helices. Branch migration

can affect which segments of DNA are exchanged in a recombination process.

While most recombination events are between homologous sequences, recombination can also occur between different, non-homologous chromosomes. Nonhomologous recombination during cell division leads to genetic translocations, where parts of some chromosomes are moved to or exchanged with other chromosomes. Chromosomal translocations can be harmless or can result in diseases, depending on the chromosomes involved and the genes that are modified or disrupted. The formation of the *bcr-abl* gene, which leads to chronic myelogenous leukemia, was discussed in Section 14.5. During CRISPR manipulations of genomes, gene insertions occur primarily via homologous recombination, but, more rarely, sequences can also be inserted into non-homologous positions.

Chapter 28 Summary

28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template

- DNA polymerases are template-directed enzymes that catalyze the formation of phosphodiester bonds.
- DNA polymerases require a primer with a free $3'$-hydroxyl group to initiate strand synthesis.
- DNA polymerases always synthesize a DNA strand in the $5'$-to-$3'$ direction.
- For both daughter strands to be synthesized simultaneously, one strand is made continuously while the other is synthesized in fragments, called *Okazaki fragments*.

28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases

- A key topological property of DNA is its linking number, which is the number of times one strand of DNA winds around the other in the right-hand direction.
- Molecules differing in linking number can be interconverted only by cutting one or both DNA strands; these reactions are catalyzed by topoisomerases.
- Supercoiled DNA can be relaxed by either topoisomerase I, which acts by transiently cleaving one strand of DNA in a double helix, or by topoisomerase II, which transiently cleaves both strands simultaneously.

28.3 DNA Replication Is Highly Coordinated

- The DNA polymerase holoenzyme comprises two DNA polymerase enzymes (one to act on each template strand) and other subunits.
- As a replicative polymerase moves along a DNA template, the leading strand is copied smoothly while the lagging strand forms loops.
- DNA replication is initiated at the origin of replication, a single site within the *E. coli* genome, where a set of specific proteins assembles the enzymes needed for DNA synthesis.
- The initiation of replication in eukaryotes is more complex than in prokaryotes; DNA synthesis is initiated at thousands of sites throughout the genome.
- Telomerase synthesizes specialized structures called telomeres at the ends of linear chromosomes.

28.4 Many Types of DNA Damage Can Be Repaired

- Different types of DNA damage include mismatched bases incorporated during DNA replication, individual bases damaged by oxidation or alkylation after replication, cross-linked bases, and single- or double-stranded breaks in the DNA backbone.
- Several different repair systems detect and repair DNA damage: the exonuclease activity of the DNA polymerase excises mismatches bases; specific enzymes reverse some DNA lesions such as thymine dimers; still other DNA-repair pathways act through the excision of single damaged bases or short segments of nucleotides.
- Double-stranded breaks in DNA can be repaired by homologous or non-homologous end-joining processes.
- Defects in DNA-repair components are associated with susceptibility to many different types of cancer.

28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

- Genetic recombination is important in some types of DNA repair.
- Some recombination pathways are initiated by strand invasion, where a single strand at the end of a DNA double helix forms base pairs with one strand of DNA in another double helix and displaces the other strand.
- In other recombination pathways a Holliday junction (a cross-like structure of four DNA strands) is formed.
- Recombinases promote recombination reactions through the introduction of specific DNA breaks and the formation and resolution of Holliday-junction intermediates.

Problems

1. A nucleotide pairing between A (adenine) and T (thymine) in the original DNA strand is miscopied during DNA replication. On one strand of DNA, A correctly pairs with T. However, on the other strand, T pairs with G (guanine) instead of A. This mistake is not corrected, and the double strand with the mistake is incorporated into a new cell during cell division. The double strand with the G–T mistake is later replicated without additional mistakes. What nucleotide pairs will be

found in the two new double strands at the site of the G–T mistake? 4

Original DNA sequence	Mistake during replication
A–T	A–T G–T

2. The oxidation of guanine bases in the context of triplet repeats such as CAGCAGCAG can lead to the expansion of the repeat. Explain. 4

3. DNA polymerase I, DNA ligase, and topoisomerase I use an activated intermediate to catalyze the formation of phosphodiester bonds with the release of a leaving group. Match the activated intermediate and the leaving group to each enzyme. 1

5. Pyrophosphate
6. DNA-tyrosyl

4. Draw a replication fork. Label the template strands and identify their $5'$ and $3'$ ends. Draw in and add labels for the leading strand, lagging strand, RNA primer(s), and Okazaki fragments. Add $5'$ and $3'$ labels to the daughter strands. Then place the following proteins on your diagram: SSBs, helicase (DnaB), DNA topoisomerase II (gyrase), primase. 1

5. Under standard conditions, the free energy of ATP hydrolysis is about $-30\ \mathrm{kJ\ mol^{-1}}$. Assuming that the energy required to break an average base pair within double-stranded DNA is $10\ \mathrm{kJ\ mol^{-1}}$, estimate the maximum number of base pairs that could be broken per ATP hydrolyzed by a helicase operating under standard conditions. 2

6. Circular DNA from SV40 virus was isolated and subjected to gel electrophoresis. The results are shown in lane A (the control) of the adjoining gel patterns shown below. 3

From W. Keller. PNAS 72(1975):2553.

a. Why does the DNA separate in agarose gel electrophoresis? How does the DNA in each band differ?
b. The DNA was then incubated with topoisomerase I for 5 minutes and again analyzed by gel electrophoresis, with the results shown in lane B. What types of DNA do the various bands represent?
c. Another sample of DNA was incubated with topoisomerase I for 30 minutes and again analyzed as shown in lane C. What is the significance of the fact that more of the DNA is in slower-moving forms?

7. Answer the following questions about supercoiling and linking number (Lk). 3

a. What is Lk for a relaxed, closed-circular DNA with 4784 base pairs?
b. What is Lk for a negatively supercoiled 4784 bp DNA if it is underwound by 4 complete turns?
c. How does Lk change when there is a break in one strand?
d. What is Lk for a negatively supercoiled 4784 bp DNA after treatment with one molecule of topoisomerase II (DNA gyrase) and adequate ATP?

8. Which of the sequences below represents newly synthesized DNA that can be repaired by the proofreading activity of DNA polymerases? For the segments shown, the top strand represents the template strand; the bottom strand represents the newly synthesized strand. 4

a. $3'-GATCAGAATG-5'$
$5'-CTAGGCTTAC-3'$

b. $3'-GATCAGAATG-5'$
$5'-TTAGTCTTAC-3'$

c. $3'-GATCAGAATG-5'$
$5'-CTAGTCTTAT-3'$

d. $3'-GATCAGAATG-5'$
$5'-CTAGTCTTAC-3'$

9. What of the following strategies do cells use to ensure that newly replicated DNA does not contain errors? Select all that apply. 4

a. Enzymes repair mistakes in the new DNA double helix after the new double helix separates from the original double helix.
b. As DNA polymerase synthesizes new DNA, the DNA polymerase finds and corrects misplaced nucleotides.
c. Enzymes proofread the DNA after the DNA has been replicated and replace any mismatched nucleotides.
d. DNA polymerase replaces the newly replicated DNA on any chromosomes on which there are mistakes.
e. Enzymes remove and resynthesize any misshapen sequences in the DNA prior to replication.

10. Place the following steps of prokaryotic DNA replication in order, starting with the bacterium initiating DNA replication, and ending with DNA replication being terminated. 5

a. The bacterium initiates DNA replication.
b. DNA replaces RNA and lagging strands are joined.
c. Tus protein stops replication forks from crossing each other and ends synthesis.
d. The upstream region melts, and helicase binds and unwinds DNA.
e. RNA primers are added to provide a $3'$ end for elongation.
f. DNA replication is terminated.
g. $5'$-to-$3'$ synthesis of the leading strand and short lagging strand is carried out by DNA polymerase.
h. The DnaA protein binds to the single origin of replication.

11. Place the following steps of eukaryotic DNA replication in order, starting from when a germ cell enters gap 1 (G_1) phase and ending with the termination of one cell cycle. 5

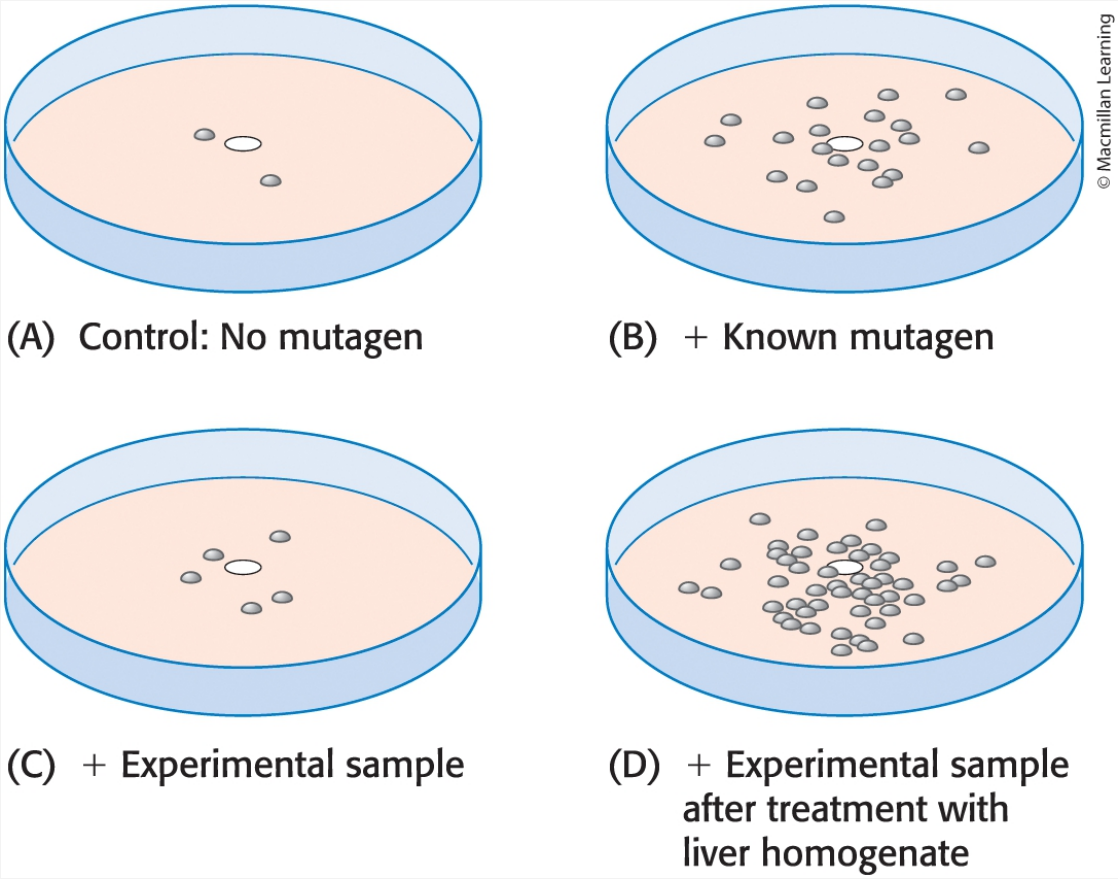
a. The cell enters G_1.
b. Each genomic origin of replication assembles a pre-replication complex.
c. RNA primers are added to provide a $3'$ end for elongation.
d. Active telomerase can extend the lost telomere region.
e. One round of the cell cycle terminates.
f. $5'$-to-$3'$ synthesis of the leading and lagging strands is carried out by DNA polymerase.
g. The initiation complex creates an active replication fork as helicase unwinds DNA.
h. RNA is replaced with DNA, and lagging strands are joined.

12. Place the events in which telomerase maintains chromosomal ends during replication in order. 6

a. Additional nucleotides are added to the $3'$ end of the parental DNA strand.
b. Telomerase moves along the newly elongated DNA strand toward its $3'$ end.
c. Nucleotides that are complementary to the RNA component of telomerase are added to the $3'$ end of the DNA overhang.
d. Telomerase is removed from the DNA strand entirely, making way for a DNA polymerase.
e. The RNA component of telomerase binds to a complementary sequence on the $3'$ overhang of the parental DNA strand.
f. DNA polymerase adds bases complementary to the elongated overhang created by telomerase.

13. In contrast to prokaryotes, which have circular chromosomes, eukaryotes have linear chromosomes. A potential problem arises because DNA polymerase cannot replicate the $5'$ ends of linear chromosomes. As a result, the lagging strands of eukaryotic chromosomes shorten with repeated rounds of replication.

Telomerase, an enzyme implicated in aging and cell lifespan, helps overcome this problem. Telomerase adds more deoxynucleotides to the end of the chromosome, lengthening it. This DNA sequence, or telomere, prevents the loss of essential DNA from the ends of chromosomes.



Which of the following statements accurately describe telomeres and the actions of telomerase? Select all that apply. 6

a. Telomerase contains a G-rich template sequence that adds a C-rich DNA sequence to the lagging strand of the chromosome.
b. Inappropriate activation of telomerase can result in cellular immortality, one of the cellular changes implicated in the development of cancer.
c. A telomere forms a loop with a section of the complementary DNA strand, protecting the chromosome from degradation by endonucleases.
d. Telomerase activity is turned off in most human cells, causing the telomeres to gradually shorten as the individual ages.
e. Telomerase consists of an RNA template and a protein component that adds complementary nucleotides to the 3′ end of DNA.

14. The following illustration shows four agar plates used for the Ames test. A piece of filter paper (white circle in the center of each plate) was soaked in one of four preparations and then placed on an agar plate. The four preparations contained (A) purified water (control), (B) a known mutagen, (C) a chemical whose mutagenicity is under investigation, and (D) the same chemical after treatment with liver homogenate. The number of revertants, visible as colonies on the plates, was determined in each case. 7

a. What was the purpose of the control plate, which was exposed only to water?
b. Why was it wise to use a known mutagen in the experimental system?

c. How would you interpret the results obtained with the experimental compound?
d. What liver components would you think are responsible for the effects observed in preparation D?

15. Classify each statement on the right as describing DNA replication in prokaryotes, eukaryotes, both, or neither. 5

1. DNA replication in prokaryotes
2. DNA replication in eukaryotes
3. Both
4. Neither

1. Several origins of replication per chromosome
2. Bidirectional replication
3. Several types of DNA polymerases
4. Occurs during M phase of cell cycle
5. One origin of replication per chromosome

---

16. Determine whether each phrase on the right describes recombination that enables replication with a single-stranded gap, a double-stranded break, or both. Each phrase may only be used once. 8

1. Single-stranded gap
2. Double-stranded break
3. Both

1. Produces two DNA segments with no breaks
2. Occurs between arms of a replication fork
3. A free $3'$ end invades another DNA segment
4. Occurs between homologous DNA segments

5. Involves removal of the $5'$ end(s) of the broken DNA

6. Involves a gap in one strand of a DNA segment

---

17. DNA that contains a gap in a single strand can be replicated through recombination. Place the steps in order from when replication stops to when replication continues. 8

a. The replication fork encounters a single-stranded gap.
b. The crossed-over strands are resolved; a gap remains in one duplicated strand.
c. Replication continues as the lesion is bypassed.
d. The $3'$ end of the unwound DNA is displaced.
e. The displaced $3'$ end is a primer for DNA polymerase, and replication continues in the crossed-over strands.
f. The displaced DNA aligns itself with the complementary bases on the other arm of the replication fork.
g. A helicase unwinds the newly synthesized DNA at the break.

18. Match each key term to its appropriate definition:**3**

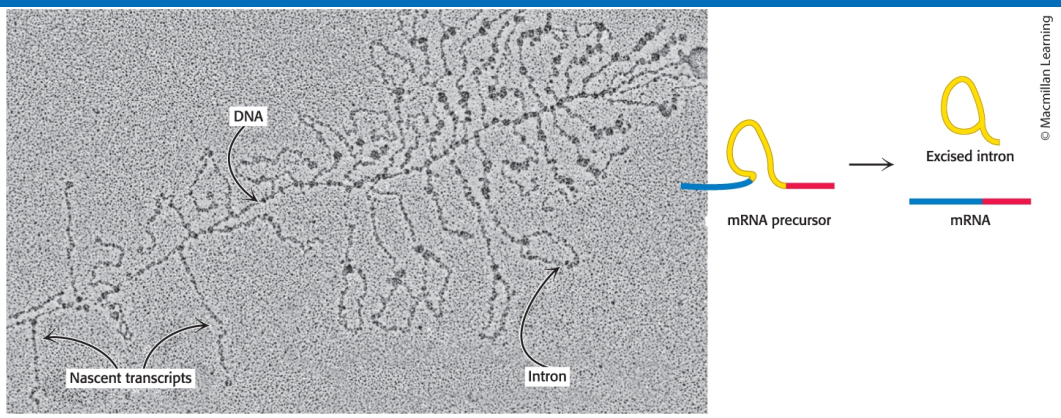
1. Positive supercoiling	1. The coiling, or looping, of the double helix around its axis
2. Twist	2. Results from the partial unwinding (right-handed, or underwinding) of the double helix; represents the topology of DNA in vivo; and permits easier strand separation

3. Writhe	3. The winding of two DNA strands around each other
4. Negative supercoiling	4. Permits DNA to maintain a relatively stable conformation when the helix is slightly underwound or overwound
5. Supercoiling	5. Results from the overwinding of the DNA and double helix

---

19. The end-replication problem (telomere problem) exists in eukaryotic chromosomes and is characterized by the chromosomes shortening with each round of DNA replication. Select the statements that best explain why the end-replication problem exists in eukaryotic chromosomes. 6

a. DNA ligase links the $5'$-OH group of one fragment to the $3'$ phosphate group of an adjacent fragment.



b. DNA polymerase synthesizes DNA from the $5'$ end to the $3'$ end.

c. The lagging strand is synthesized from the $3'$ end to the $5'$ end.

d. DNA polymerase requires a primer for DNA synthesis.

e. The RNA primer is removed in a $3'$-to-$5'$ direction.

CHAPTER 29
RNA Functions, Biosynthesis, and Processing

RNA synthesis is a key step in the expression of genetic information. This electron micrograph shows a DNA template from a fruit fly in the genus *Drosophila* (the center "stem") being actively transcribed into RNAs (the "branches"). In eukaryotic organisms such as fruit flies, the initial RNA transcript often contains sections that do not encode protein sequence (introns). These sections are removed by splicing; proteins associated with RNA splicing can be seen as dark blobs on the mRNA transcripts in the image on the left.

Data from *Does the pachytene checkpoint, a feature of meiosis, filter out mistakes in double-strand DNA break repair and as a side-effect strongly promote adaptive speciation?* Foe, Victoria E, Integrative Organismal Biology, 10 Apr 2022, Vol. 4, Issue 1 Oxford University Press, Open Access article distributed under the terms of the Creative Commons Attribution License (https://creativecommons.org/licenses/by/4.0/)

OUTLINE

29.1 RNA Molecules Play Different Roles, Primarily in Gene Expression

29.2 RNA Polymerases Catalyze Transcription
29.3 Transcription Is Highly Regulated
29.4 Some RNA Transcription Products Are Processed
29.5 The Discovery of Catalytic RNA Revealed a Unique Splicing Mechanism

Learning Goals

By the end of this chapter, you should be able to:

1. Discuss the primary function of RNA polymerases, the reaction they catalyze, and the chemical mechanism of that reaction.
2. Describe transcription, including the processes of initiation, elongation, and termination.
3. Compare the roles of eukaryotic RNA polymerases I, II, and III in producing ribosomal, transfer, and messenger RNAs.
4. Recognize the significance of transcription factors and enhancers in the regulation of transcription in eukaryotes.
5. Describe the process of RNA splicing, including the roles of the spliceosome and self-splicing RNA molecules.
6. Understand some of the differences between transcription in bacteria and in eukaryotes.

DNA stores genetic information in a stable form that can be readily replicated. The expression of this genetic information requires its flow from DNA to RNA and, usually, to protein, as was introduced in Chapter 8. This chapter examines transcription, which, you will recall, is the process of synthesizing an RNA transcript from a DNA template, transferring the sequence information within the DNA to the new RNA molecule. We begin with a brief discussion of the diverse types of RNA molecules; then we will turn to RNA polymerases, the large and complex enzymes that carry out the

synthetic process. This will lead into a discussion of transcription in bacteria and focus on the three stages of transcription: promoter binding and initiation, elongation of the nascent RNA transcript, and termination. We then examine transcription in eukaryotes, focusing on the distinctions between bacterial and eukaryotic transcription.

29.1 RNA Molecules Play Different Roles, Primarily in Gene Expression

While the function of some RNAs has been known for some time, other classes of RNAs have only recently been discovered. The investigation of some of these RNA molecules has been one of the most productive areas of biochemical research in recent years.

RNAs play key roles in protein biosynthesis

As we will explore in Chapter 30, the long-known ribosomal and transfer RNA molecules, along with messenger RNAs, are central to protein synthesis. Ribosomal RNAs are critical components of ribosomes (the sites of protein synthesis), and transfer RNAs play a role in delivering amino acids (the building blocks of proteins) to the ribosome. Messenger RNAs carry the information that ribosomes use for the production of specific protein sequences.

Some RNAs can guide modifications of themselves or other RNAs

In eukaryotes, one of the most striking examples of RNA modification is the splicing of mRNA precursors, a process that is catalyzed by large complexes composed of both proteins and small nuclear RNAs. These small nuclear RNAs play a crucial role in guiding the splicing of messenger RNAs.

Remarkably, some RNA molecules can splice themselves in the absence of other proteins and RNAs. This landmark discovery of self-splicing introns, which we will discuss later in this chapter, revealed that RNA molecules can serve as catalysts, which greatly influenced our view of molecular evolution. Many other types of RNAs, such as small regulatory RNAs and long noncoding RNAs, have been discovered more recently, and while their functions are still under active investigation, our understanding is rapidly expanding.

Some viruses have RNA genomes

While DNA is the genetic material in most organisms, some viruses have genomes made of RNA (Section 8.4). RNA viruses are responsible for several diseases, such as influenza, polio, mumps, Ebola, the common cold, and — of particular note — COVID-19. The coronavirus SARS-CoV-2, which causes COVID-19, belongs to a family of coronaviruses that have an unusually large, single-stranded RNA genome. Coronaviruses cause a variety of diseases in mammals and birds that have a wide range of symptoms, including respiratory distress in humans that can potentially be lethal.

RNA viruses vary in their genome organization. They have either single- or double-stranded RNA molecules arranged in single or multiple fragments. Inside their hosts, RNA viruses replicate their genomes with a virus-encoded RNA polymerase that uses RNA as a template. In some viruses, a complementary RNA molecule is made from the single-stranded viral RNA genome, while in other viruses, a double-stranded DNA copy is made that can integrate itself into the host's genome. Viral RNA polymerases do not have the same proofreading ability of other polymerases, which leads to high mutation rates of RNA viruses.

Messenger RNA vaccines provide protection against diseases

Messenger RNA (mRNA) vaccines take advantage of the fact that cells can be tricked into making proteins they don't usually make, even those from other organisms such as viruses. Unlike other vaccines that use parts of a weakened or inactivated pathogen to trigger an immune response, mRNA vaccines — including those available for the SARS-CoV-2 virus — use sections of pathogenic (usually viral) mRNA that have been generated in the laboratory. When human cells are injected with this mRNA, they will produce the corresponding protein from this set of instructions. This "foreign" protein will be presented on the surface of the cells, trigger an immune response, and provide some level of protection if and when the actual pathogen invades. Even though research on mRNA vaccines had been going on for many years, the COVID-19 pandemic accelerated the development, approval, and distribution of mRNA vaccines to the public.

Self-Check Question

Compare the biological roles of RNA and DNA. What aspects of the structure and chemistry of RNA make it so versatile?

29.2 RNA Polymerases Catalyze Transcription

Transcription, the synthesis of RNA molecules from a DNA template, is catalyzed by large enzymes called **RNA polymerases**. The basic biochemistry of RNA synthesis is shared by all organisms, a commonality that has been beautifully illustrated by the three-dimensional structures of representative RNA polymerases from prokaryotes and eukaryotes (**Figure 29.1**). Despite substantial differences in size and number of polypeptide subunits, the overall structures of these enzymes are quite similar, revealing a common evolutionary origin.

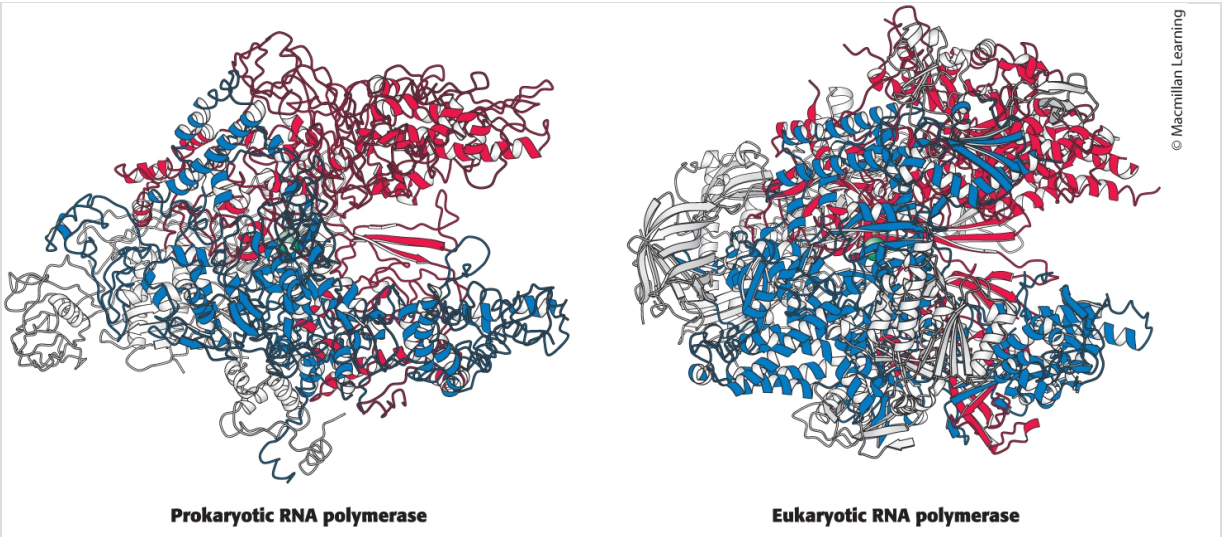


FIGURE 29.1 RNA polymerase structures in prokaryotes and eukaryotes resemble each other. In these three-dimensional models of RNA polymerases from a prokaryote (*Thermus aquaticus*) and a eukaryote (*Saccharomyces cerevisiae*), the two largest subunits for each structure are shown in dark red and dark blue. Both structures contain a central metal ion (green) in their active sites, near a large cleft on the right. The similarity of these structures reveals that these enzymes have the same evolutionary origin and have many mechanistic features in common.

[Drawn from 1I6V.pdb and 1I6H.pdb.]

INTERACT with these models in Achieve

RNA polymerases are very large, complex enzymes. For example, the core of the RNA polymerase of *E. coli* consists of five kinds of subunits with the composition $\alpha_2\beta\beta'\omega$ (Table 29.1). A typical eukaryotic RNA polymerase is larger and more complex, having 12 subunits and a total molecular mass of more than 500 kDa. Despite this complexity, the detailed structures of RNA polymerases have been determined by x-ray crystallography in work pioneered by Roger Kornberg and Seth Darst. The structures of many additional RNA polymerase complexes have been determined by cryo-electron microscopy.

TABLE 29.1 Subunits of RNA polymerase from *E. coli*

Subunit	Gene	Number	Mass (kDa)
α	*rpoA*	2	37
β	*rpoB*	1	151
β'	*rpoC*	1	155
ω	*rpoZ*	1	10
σ^{70}	*rpoD*	1	70

RNA synthesis comprises three stages: initiation, elongation, and termination

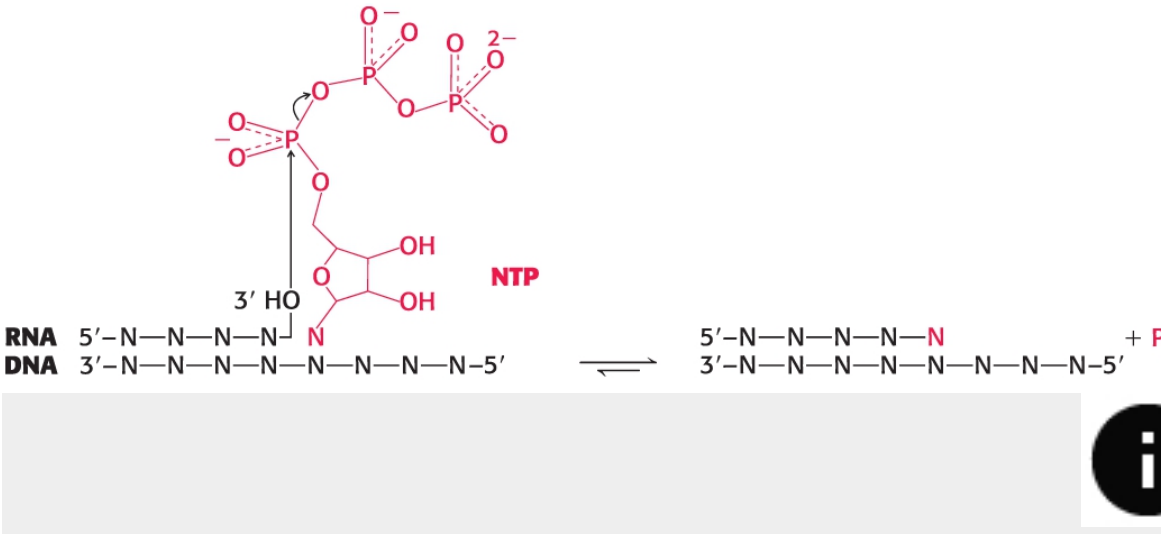
RNA synthesis, like all biological polymerization reactions, takes place in three stages: *initiation*, *elongation*, and *termination*. RNA polymerases perform multiple functions in this process:

1. They search DNA for initiation sites, also called *promoter sites* or simply **promoters**. For instance, *E. coli* DNA has about 2000 promoters in its 4.6×10^6 bp genome.

2. They unwind a short stretch of double-helical DNA to produce single-stranded DNA templates from which the sequence of bases can be easily read out.

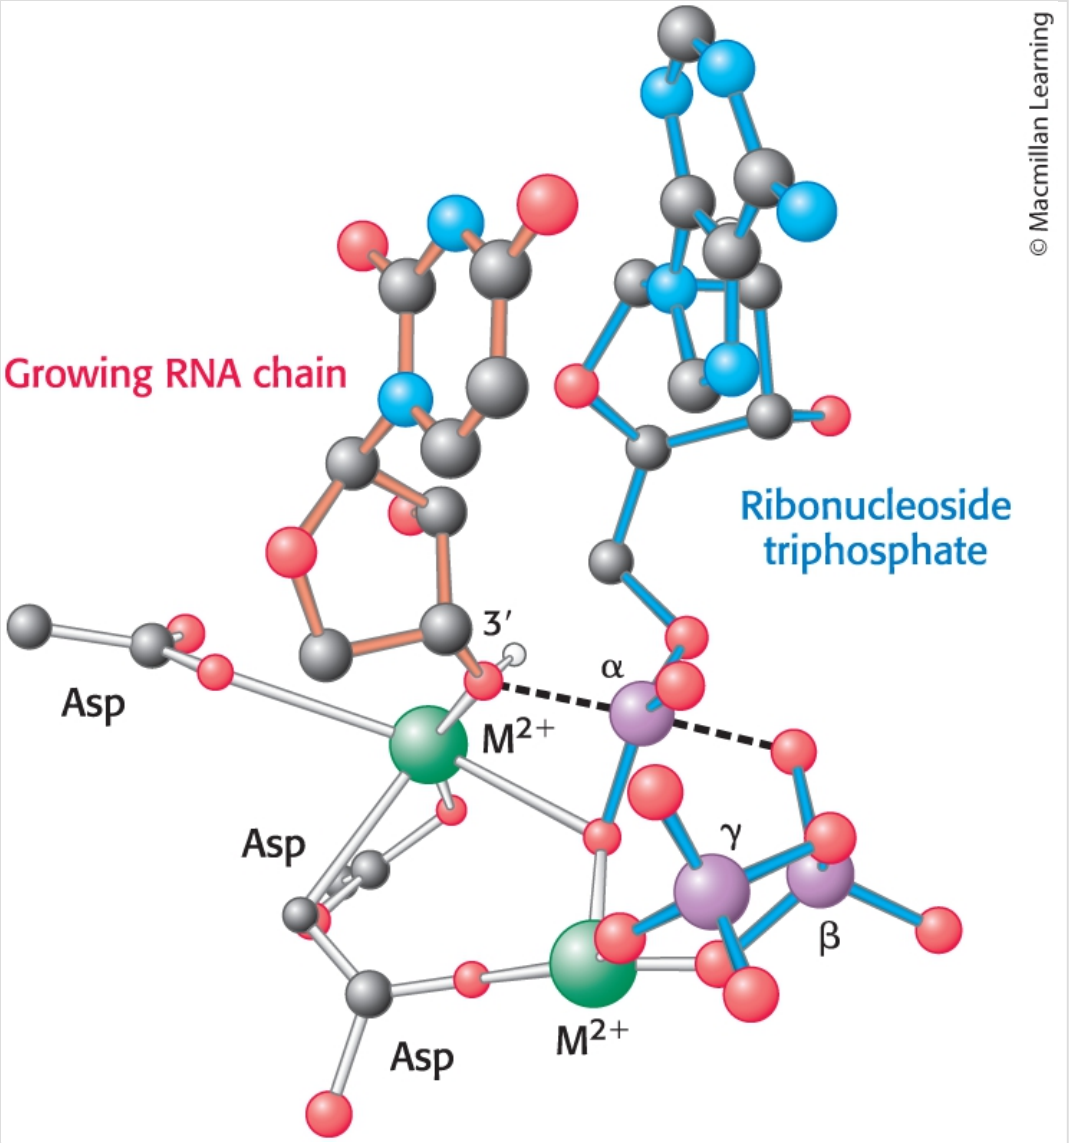
3. They select the correct ribonucleoside triphosphate and catalyze the formation of a phosphodiester bond. This process is repeated many times as the enzyme moves along the DNA template. RNA polymerase is completely processive — a transcript is synthesized from start to end by a single RNA polymerase molecule.

4. They detect termination signals that specify where a transcript ends.



5. Their activity is regulated by activator and repressor proteins that interact with the promoter and modulate the ability of the RNA polymerase to initiate transcription. Gene expression is controlled substantially at the level of transcription, as will be discussed in detail in Chapter 31.

The chemistry of RNA synthesis is identical for all forms of RNA, including messenger RNAs, transfer RNAs, ribosomal RNAs, and small regulatory RNAs, so the basic steps just outlined apply to all forms. Their synthetic processes differ mainly in regulation, the specific RNA polymerase that creates them, and their posttranscriptional processing.



RNA polymerases catalyze the formation of a phosphodiester bond

The fundamental reaction of RNA synthesis, like that of DNA synthesis, is the formation of a phosphodiester bond. The 3′-hydroxyl group of the

last nucleotide in the chain makes a nucleophilic attack on the α-phosphoryl group of the incoming nucleoside triphosphate, releasing a pyrophosphate.

The catalytic sites of all RNA polymerases include two metal ions, normally magnesium ions (**Figure 29.2**). One ion remains tightly bound to the enzyme, whereas the other ion comes in with the nucleoside triphosphate and leaves with the pyrophosphate. Three conserved aspartate residues participate in binding these metal ions. Given the recent appreciation of the role of a third metal ion in the active site of DNA polymerases (see Section 28.1), it will be interesting to see if RNA polymerases show similarities to that model.

© Macmillan Learning

FIGURE 29.2 The RNA polymerase active site contains metal ions. In this model of the transition state for phosphodiester-bond formation in the active site of RNA polymerase, the 3′-hydroxyl group of the growing RNA chain attacks the α-phosphoryl group of the incoming nucleoside triphosphate, resulting in the release of pyrophosphate. This transition state is structurally similar to that in the active site of DNA polymerase (see Figure 28.2).

The polymerization reactions that are catalyzed by both prokaryotic and eukaryotic RNA polymerases take place within a complex in DNA termed a **transcription bubble** (**Figure 29.3**). This complex consists of double-stranded DNA that has been locally unwound in a region of approximately 17 base pairs. The edges of the bases that normally take part in Watson–Crick base pairs are exposed in the unwound region. We will begin with a detailed examination of the elongation process, including the role of the DNA template read by RNA polymerase and the reactions catalyzed by the polymerase, before returning to the more complex processes of initiation and termination.

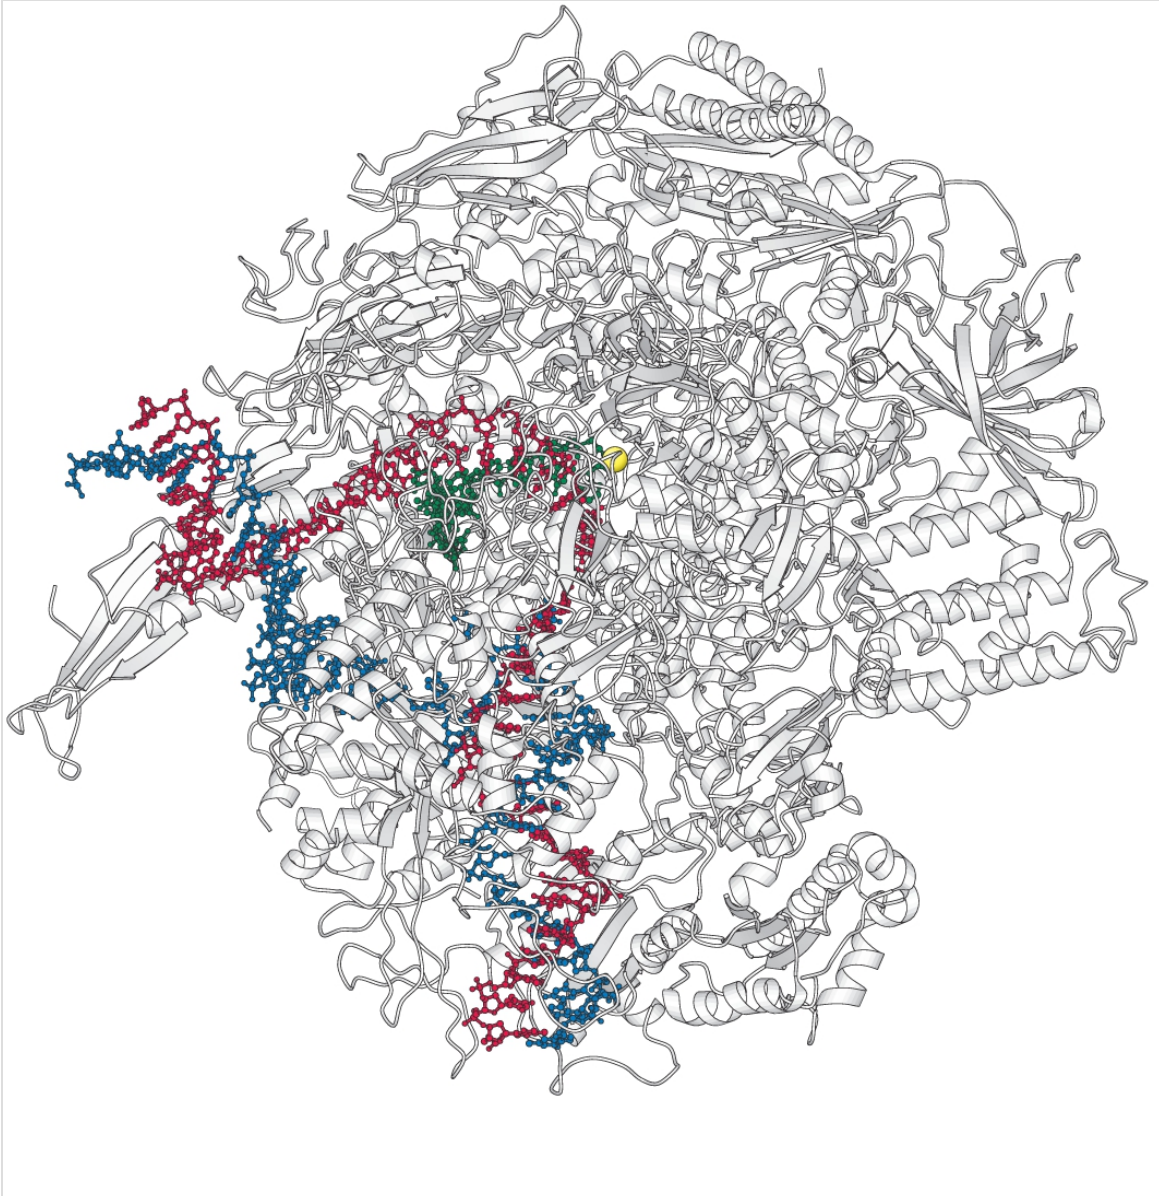


FIGURE 29.3 RNA polymerase separates a region of the double helix to form the transcription bubble. The red (template) and blue (nontemplate) strands of DNA are shown along with the RN molecule being synthesized (shown in green). The position of the active site magnesium is indicated (yellow sphere). The DNA enters from the left and exits at the bottom.

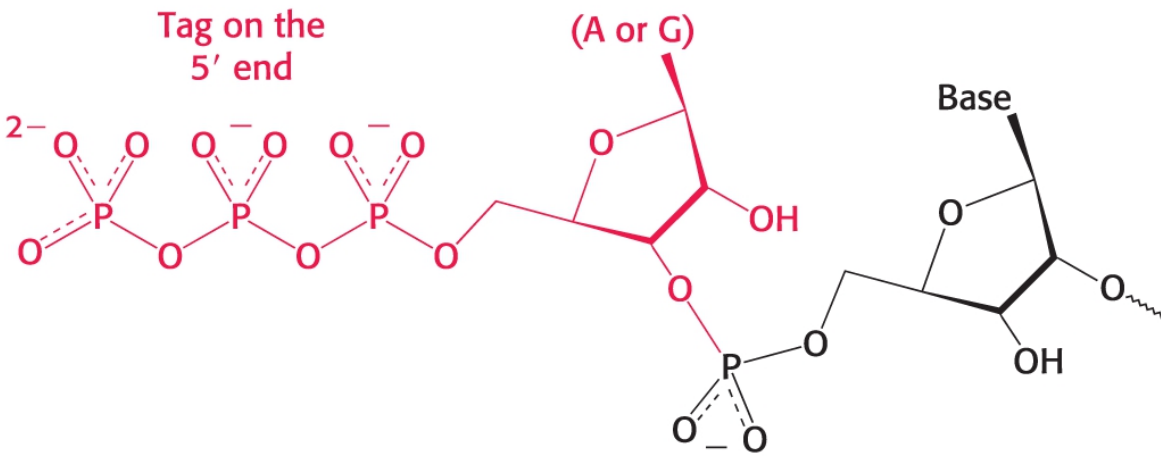

RNA chains are formed de novo and grow in the 5′-to-3′ direction

Let us begin our examination of transcription by considering the DNA template. The first nucleotide (the start site) of a DNA sequence to be transcribed is denoted as $+1$ and the second one as $+2$; the nucleotide preceding the start site is denoted as -1. These designations refer to the coding strand of DNA. Recall that the sequence of the *template strand* of DNA is the complement of that of the RNA transcript (Figure 29.4). In contrast, the *coding strand* of DNA has the same sequence as that of the RNA transcript except for thymine (T) in place of uracil (U). The coding strand is also known as the *sense* $(+)$ *strand*, and the template strand as the *antisense* $(-)$ *strand*.

FIGURE 29.4 The RNA transcript is complementary to the template, or antisense $(-)$, strand

In contrast with DNA synthesis, RNA synthesis can start de novo, without the requirement for a primer. Most newly synthesized RNA chains carry a highly distinctive tag on the 5′ end: the first base at that end is either pppG or pppA.

The presence of the triphosphate moiety confirms that RNA synthesis starts at the 5′ end.

The dinucleotide shown above is synthesized by RNA polymerase as part of the complex process of initiation, which will be discussed later in the chapter. After initiation takes place, RNA polymerase elongates the nucleic acid chain as follows (Figure 29.5).

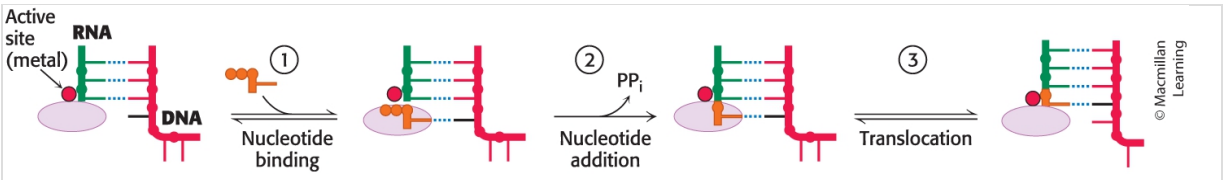

FIGURE 29.5 The elongation mechanism involves a series of steps. A ribonucleoside triphosphate binds adjacent to the growing RNA chain and forms a Watson–Crick base pair with a base on the DNA template strand (1). The 3′-hydroxyl group at the end of the RNA chain attacks

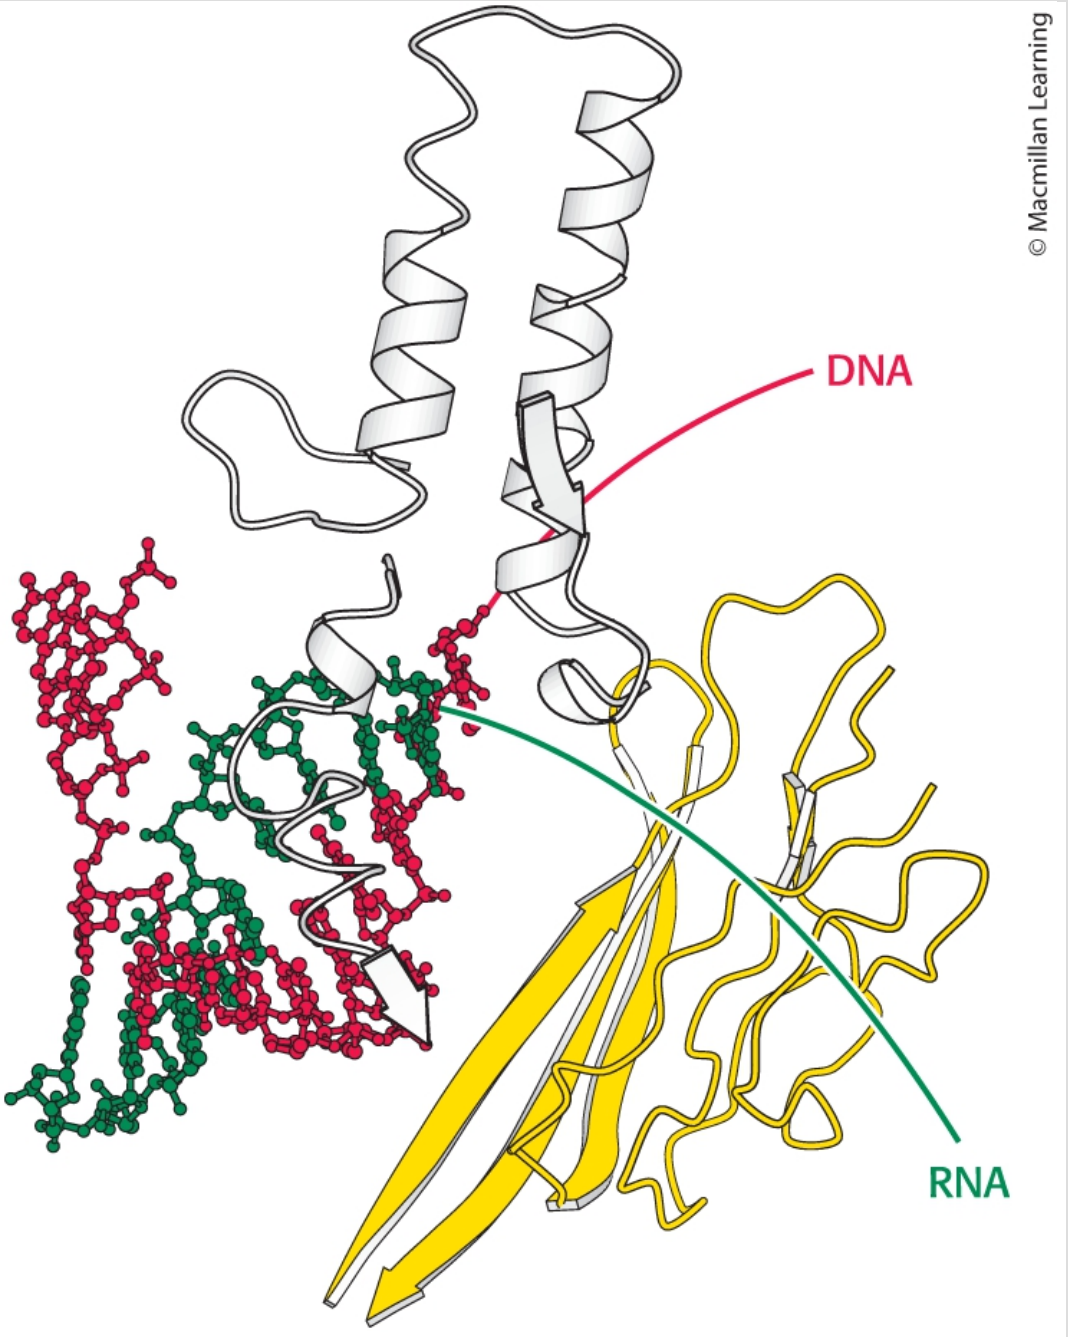
the newly bound nucleotide and forms a new phosphodiester bond, releasing pyrophosphate (2). After nucleotide addition, the RNA–DNA hybrid can translocate through the RNA polymerase (3), bringing a new DNA base into position to base-pair with an incoming nucleoside triphosphate.



1. A ribonucleoside triphosphate binds in the active site of the RNA polymerase directly adjacent to the growing RNA chain, and it forms a Watson–Crick base pair with the template strand.

2. The $3'$-hydroxyl group of the growing RNA chain, which is oriented and activated by the tightly bound metal ion, attacks the α-phosphoryl group to form a new phosphodiester bond, displacing pyrophosphate.

3. Next, the RNA–DNA hybrid must move relative to the polymerase to bring the $3'$ end of the newly added nucleotide into proper position for the next nucleotide to be added. This translocation step does not include breaking any bonds between base pairs and is reversible; but, once it has taken place, the addition of the next nucleotide, favored by the triphosphate cleavage and pyrophosphate release and cleavage, drives the polymerization reaction forward.

The lengths of the RNA–DNA hybrid and of the unwound region of DNA stay rather constant as RNA polymerase moves along the DNA template. The length of the RNA–DNA hybrid is determined by a structure within the enzyme that forces the RNA–DNA hybrid to separate, allowing the RNA chain to exit from the enzyme and the DNA chain to rejoin its DNA partner (**Figure 29.6**).

© Macmillan Learning

FIGURE 29.6 A structure within RNA polymerase forces the separation of the RNA–DNA hybrid. Notice that the DNA strand exits in one direction and the RNA product exits in another.

[Drawn from 1I6H.pdb.]

INTERACT with this model in Achieve

RNA polymerases backtrack and correct errors

The RNA–DNA hybrid can also move in the direction opposite that of elongation (Figure 29.7). This backtracking is energetically less favorable than moving forward because it breaks the bonds between a base pair. However, backtracking is very important for *proofreading*. The incorporation of an incorrect nucleotide introduces a non-Watson–Crick base pair. In this case, breaking the bonds between this base pair and backtracking is energetically less costly.

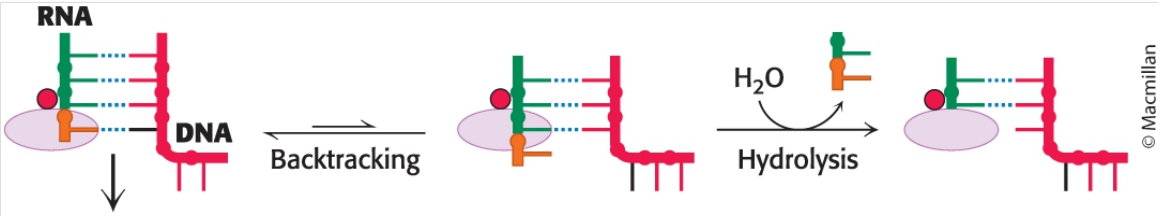


FIGURE 29.7 The RNA–DNA hybrid can occasionally backtrack within the RNA polymerase. In the backtracked position, hydrolysis can take place, producing a configuration equivalent to tha after translocation. Backtracking is more likely if a mismatched base is added, facilitating proofreading.

After the polymerase has backtracked, the phosphodiester bond one base pair before the one that has just formed is adjacent to the metal ion in the active site. In this position, a hydrolysis reaction in which a water molecule attacks the phosphate can result in the cleavage of the

phosphodiester bond and the release of a dinucleotide that includes the incorrect nucleotide.

Studies of single molecules of RNA polymerase have confirmed that the enzymes pause and backtrack to correct errors. Furthermore, these proofreading activities are often enhanced by accessory proteins.

The final error rate of the order of one mistake per 10^4 or 10^5 nucleotides is higher than that for DNA replication, including all error-correcting mechanisms. The lower fidelity of RNA synthesis can be tolerated because mistakes are not transmitted to progeny. For most genes, many RNA transcripts are synthesized; a few defective transcripts are unlikely to be harmful.

Self-Check Question

List some ways in which RNA polymerases are similar to DNA polymerases, and how they are different.

RNA polymerase binds to promoter sites on the DNA template in bacteria to initiate transcription

While the elongation process is common to all organisms, the processes of initiation and termination differ substantially in bacteria and eukaryotes. We begin with a discussion of these processes in bacteria, starting with initiation of transcription.

The bacterial RNA polymerase discussed earlier with the composition $\alpha_2\beta\beta'\omega$ is referred to as the *core enzyme*. The inclusion of an additional subunit (σ) produces the *holoenzyme* with composition $\alpha_2\beta\beta'\omega\sigma$. The **σ subunit** helps find the promoters, sites on DNA where transcription begins. At these sites, the σ subunit participates in the initiation of RNA synthesis and then dissociates from the rest of the enzyme.

Sequences upstream of the promoter site are important in determining where transcription begins. A striking pattern is evident when the sequences of bacterial promoters are compared: Two common motifs are present on the upstream side of the transcription start site. They are known as the -10 *sequence* and the -35 *sequence* because they are centered at about 10 and 35 nucleotides upstream of the start site. The region containing these sequences is called the *core promoter*. The -10 and -35 sequences are each 6 bp long. Their **consensus sequences**, deduced from analyses of many promoters (**Figure 29.8**), are:

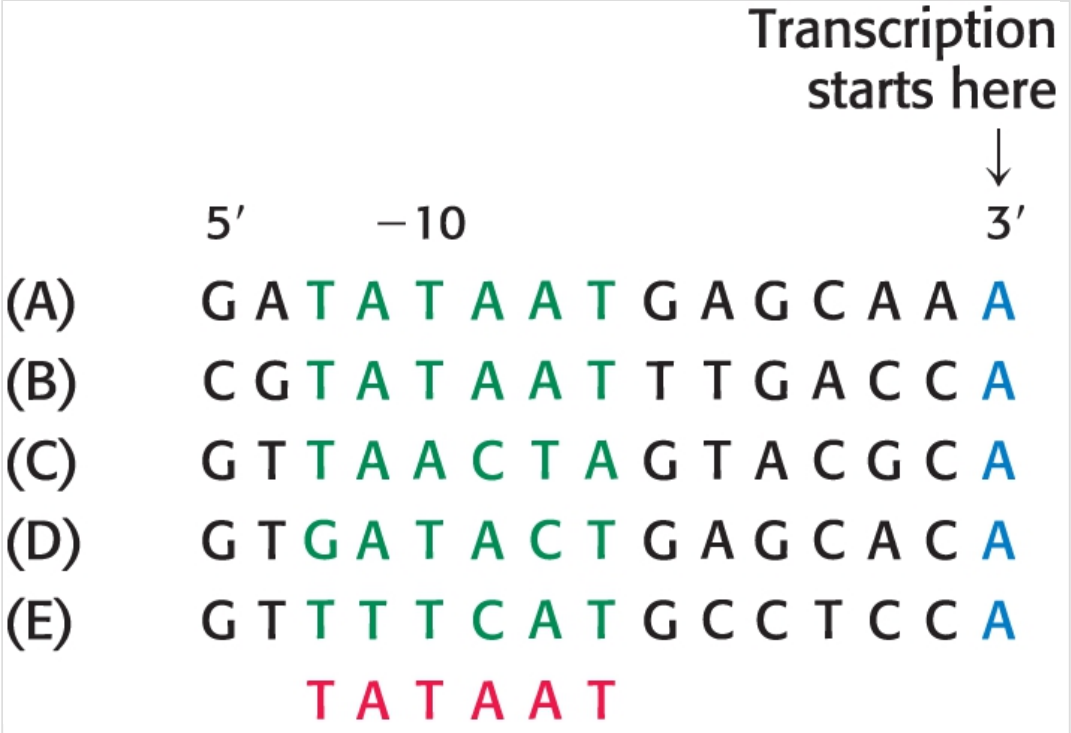

FIGURE 29.8 Bacterial promoters contain conserved sequences. A comparison of five sequences from prokaryotic promoters reveals a recurring sequence of TATAAT centered on position -10. The -10 consensus sequence (in red) was deduced from a large number of promoter sequences. The sequences are from the (A) *uvrD*, (B) *uncI*, and (C) *trp* operons of *E. coli*, from (D) λ phage, and from (E) ϕX174 phage.

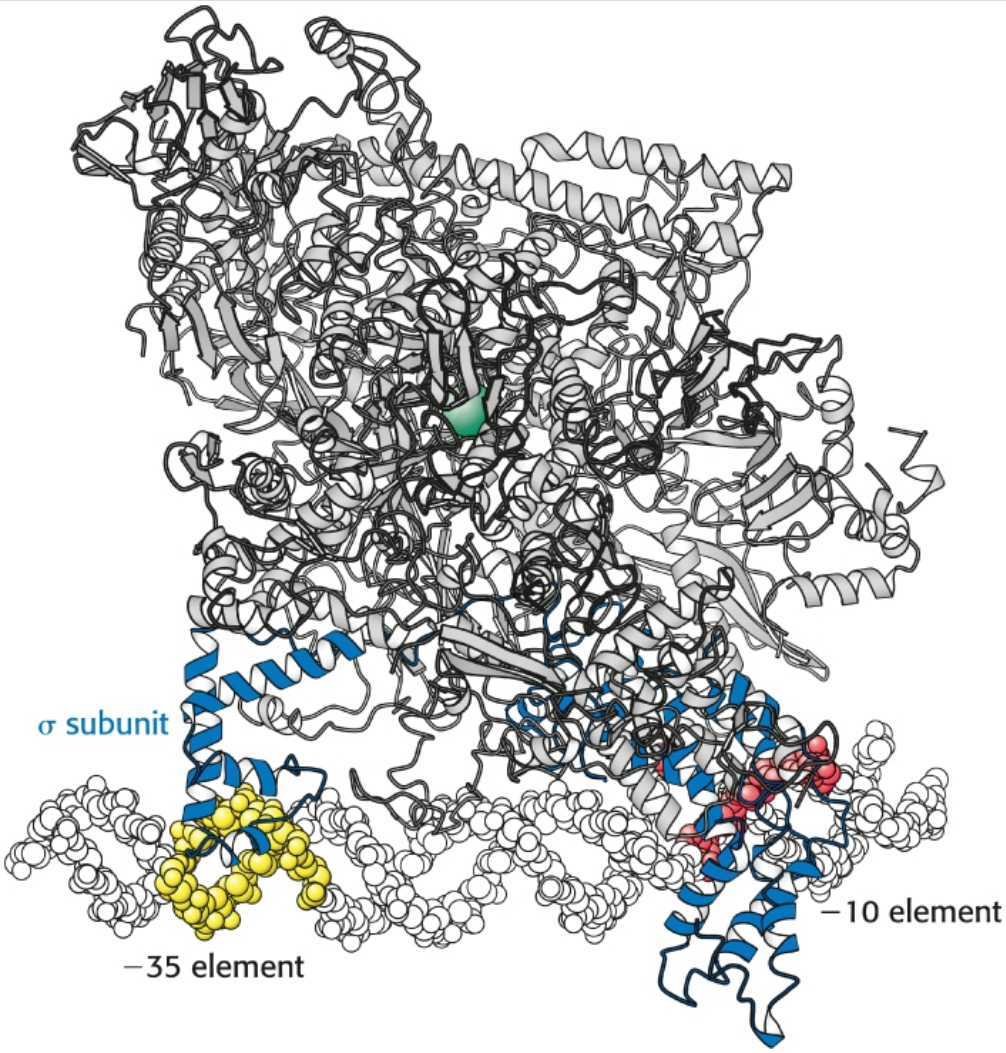

Promoters differ markedly in their efficacy. Some genes are transcribed frequently — as often as every 2 seconds in *E. coli*. The promoters for these genes are referred to as *strong promoters*. In contrast, other genes are transcribed much less frequently, about once in 10 minutes; the promoters for these genes are *weak promoters*. The -10 and -35 regions of most strong promoters have sequences that correspond closely to the consensus sequences, whereas weak promoters tend to have multiple substitutions at these sites. Indeed, mutation of a single base in either the -10 sequence or the -35 sequence can diminish promoter activity.

The distance between these conserved sequences also is important; a separation of 17 nucleotides is optimal. Thus, the efficiency or strength of a promoter sequence serves to regulate transcription. Regulatory proteins that bind to specific sequences near promoter sites and interact with RNA polymerase (Chapter 31) also markedly influence the frequency of transcription of many genes.

Outside the core promoter in a subset of highly expressed genes is the *upstream element* (also called the UP element). This sequence is present from 40 to 60 nucleotides upstream of the transcription start site. The UP element is bound by the α subunit of RNA polymerase and serves to increase the efficiency of transcription by creating an additional interaction site for the polymerase.

Sigma subunits of RNA polymerase in bacteria recognize promoter sites

To initiate transcription, the $\alpha_2\beta\beta'\omega$ core of RNA polymerase must bind the promoter. However, it is the σ subunit that makes this binding possible by enabling RNA polymerase to recognize promoter sites. In the presence of the σ subunit, the RNA polymerase binds weakly to the DNA and slides along the double helix until it dissociates or encounters a promoter. The σ subunit recognizes the promoter through several interactions with the nucleotide bases of the promoter DNA. The structure of a bacterial RNA polymerase holoenzyme bound to a promoter site shows the σ subunit interacting with DNA at the -10 and -35 regions essential to promoter recognition (**Figure 29.9**). Therefore, the σ subunit is responsible for the specific binding of the RNA polymerase to a promoter site on the template DNA. The σ subunit is generally released when the nascent RNA chain reaches 9 or 10 nucleotides in length. After its release, it can associate with another core enzyme and assist in a new round of initiation.

© Macmillan Learning

FIGURE 29.9 *E. coli* RNA polymerase holoenzyme complex binds to conserved promoter sequences. The σ subunit (blue) of the bacterial RNA polymerase holoenzyme makes sequence-specific contacts with the -10 (red) and -35 (yellow) promoter elements. The active site of the polymerase is revealed by a bound metal ion (purple).

[Drawn from 1L9Z.pdb].

INTERACT with this model in Achieve

The template double helix must be unwound for transcription to take place

Although the bacterial RNA polymerase can search for promoter sites when bound to double-helical DNA, a segment of the DNA double helix must be unwound before synthesis can begin. The transition from the closed promoter complex (in which DNA is double helical) to the open promoter complex (in which a DNA segment is unwound) is an essential event in both bacterial and eukaryotic transcription. In bacteria it is the RNA polymerase itself that accomplishes this (Figure 29.10), while in eukaryotes additional proteins are required to unwind the DNA template.

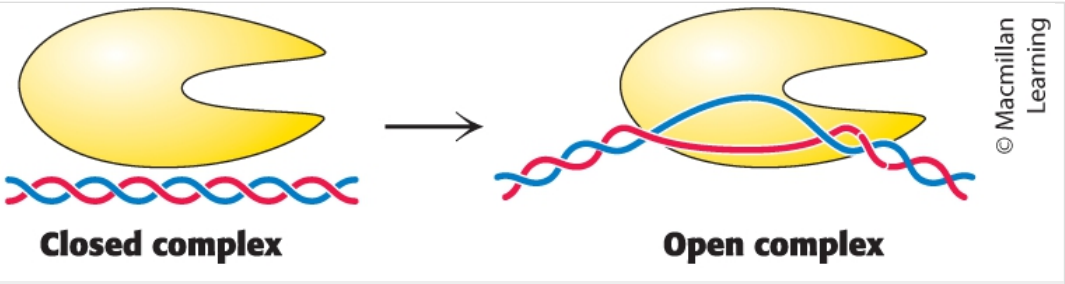

FIGURE 29.10 *E. coli* RNA polymerase binds to a promoter sequence. The transition from the closed promoter complex to the open promoter complex requires the unwinding of approximately 17 base pairs of DNA.

We know that, in bacteria, the free energy necessary to break the bonds between approximately 17 base pairs in the double helix is derived from additional interactions between the template and the bacterial RNA polymerase. These interactions become possible when the DNA distorts to wrap around the RNA polymerase; they also occur between the single-stranded DNA regions and other parts of the enzyme. These interactions stabilize the open promoter complex and help pull the template strand into the active site. The -35 element remains in a double-helical state, whereas the -10 element is unwound. The stage is

now set for the formation of the first phosphodiester bond of the new RNA chain.

Elongation takes place at transcription bubbles that move along the DNA template

The elongation phase of RNA synthesis begins with the formation of the first phosphodiester bond, after which repeated cycles of nucleotide addition can take place. However, until about 10 nucleotides have been added, RNA polymerase sometimes releases the short RNA, which dissociates from the DNA and gets degraded. Once RNA polymerase passes this point, the enzyme stays bound to its template until a termination signal is reached.

The region containing the unwound DNA template and nascent RNA corresponds to the transcription bubble (**Figure 29.11**). The newly synthesized RNA forms a hybrid helix with the template DNA strand. This RNA–DNA helix is about 8 bp long, which corresponds to nearly one turn of a double helix. The $3'$-hydroxyl group of the RNA in this hybrid helix is positioned so that it can attack the α-phosphorus atom of an incoming ribonucleoside triphosphate. The core bacterial RNA polymerase also contains a binding site for the coding strand of DNA.

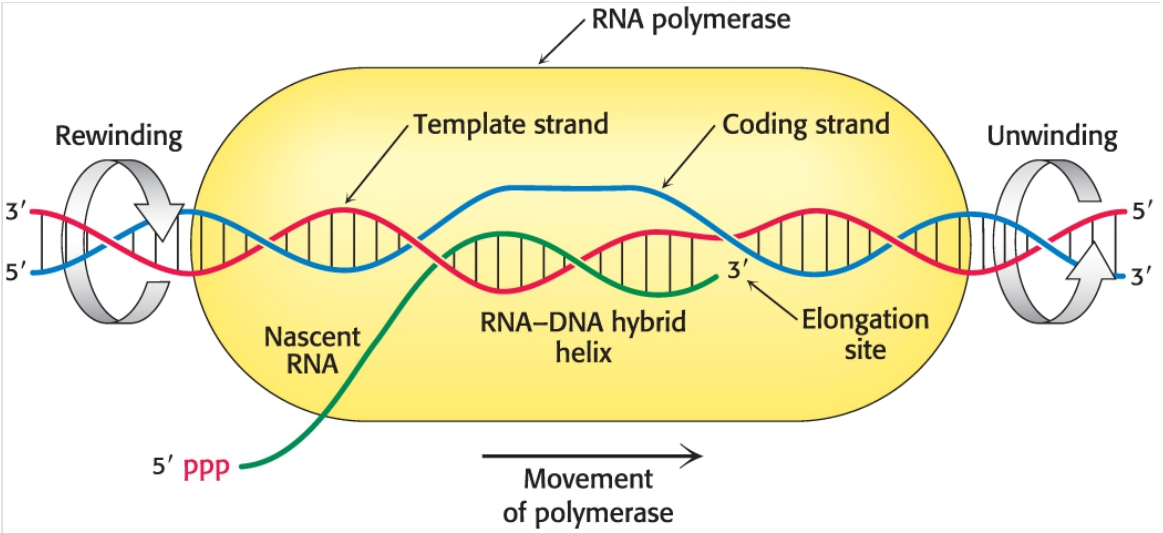

FIGURE 29.11 The transcription bubble moves with the RNA polymerase during elongation. I this schematic representation of a transcription bubble in the elongation of an RNA transcript, duplex DNA is unwound at the forward end of RNA polymerase and rewound at its rear end. The RNA–DNA hybrid rotates during elongation.

As in the initiation phase, about 17 bp of DNA are unwound throughout the elongation phase. The transcription bubble moves a distance of 170 Å (17 nm) in a second, which corresponds to a rate of elongation of about 50 nucleotides per second. Although rapid, it is much slower than the rate of DNA synthesis, which is 800 nucleotides per second.

Sequences within the newly transcribed RNA signal termination

How does the RNA polymerase know where to stop transcription? In the termination phase of transcription, the formation of phosphodiester bonds ceases, the RNA–DNA hybrid dissociates, the unwound region of DNA rewinds, and RNA polymerase releases the DNA. This process is as precisely controlled as initiation. So what determines where

transcription is terminated? In both eukaryotes and bacteria, the transcribed regions of DNA templates contain so-called *intrinsic* termination signals.

In bacteria, the simplest intrinsic termination signal is a palindromic GC-rich region followed by an AT-rich region. The RNA transcript of this DNA palindrome is self-complementary (**Figure 29.12**). Hence, its bases can pair to form a hairpin structure with a stem and loop, a structure favored by its high content of G and C residues. Guanine–cytosine base pairs are more stable than adenine–thymine pairs, primarily because of the preferred base-stacking interactions in G–C base pairs (Section 1.3). This stable hairpin is followed by a sequence of four or more uracil residues, which also are crucial for termination. The RNA transcript ends within or just after them.

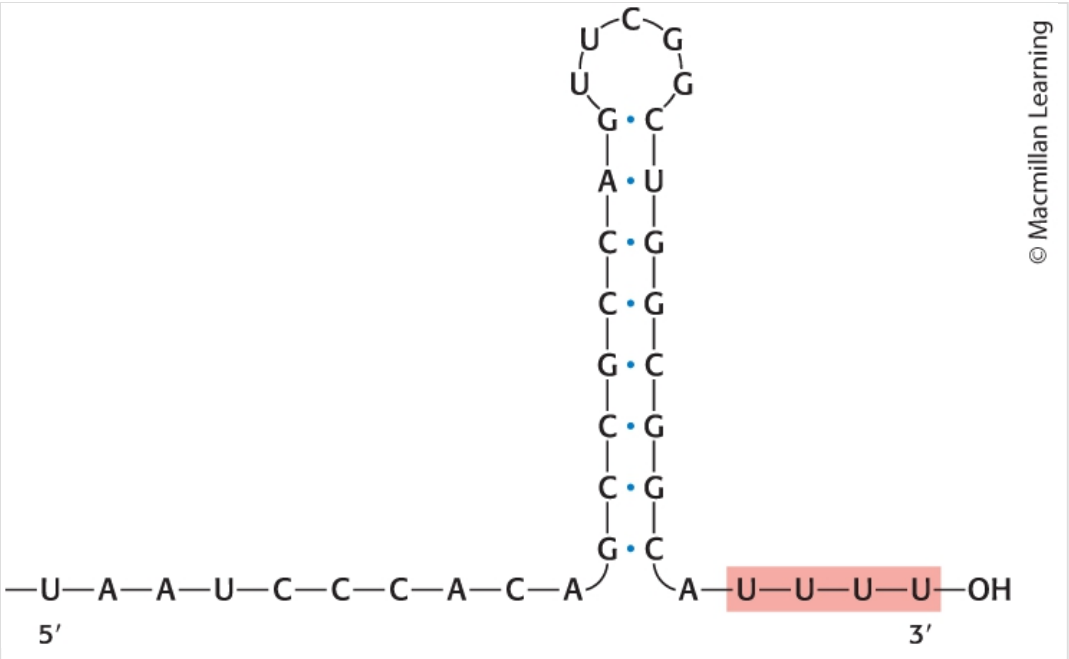

FIGURE 29.12 Some genes contain intrinsic termination signals. A typical intrinsic termination signal found at the 3′ end of an mRNA transcript consists of a series of bases that form a stable stem-loop structure followed by a string of U residues.

How does this combination hairpin–oligo(U) structure terminate transcription? First, RNA polymerase likely pauses immediately after it has synthesized a stretch of RNA that folds into a hairpin. Furthermore, the RNA–DNA hybrid helix produced after the hairpin is unstable because its rU–dA base pairs are the weakest of the four kinds. Hence, the pause in transcription caused by the hairpin permits the weakly bound nascent RNA to dissociate from the DNA template and then from the enzyme. The solitary DNA template strand rejoins its partner to re-form the DNA duplex, and the transcription bubble closes.

In bacteria, the rho protein helps to terminate the transcription of some genes

Bacterial RNA polymerase needs no help to terminate transcription at the intrinsic sites described above. At other sites, however, termination requires the participation of an additional factor. This discovery was prompted by the observation that some RNA molecules synthesized in vitro by RNA polymerase acting alone are longer than those made in vivo. The missing factor, a protein that caused the correct termination, was isolated and named **rho (ρ)**.

Additional information about the action of ρ was obtained by adding this termination factor to an incubation mixture at various times after the initiation of RNA synthesis (**Figure 29.13**). RNAs with sedimentation coefficients of 10S, 13S, and 17S were obtained when ρ was added at initiation, a few seconds after initiation, and 2 minutes after initiation, respectively. If no ρ was added, transcription yielded a 23S RNA product. It is evident that the template contains at least three termination sites that respond to ρ (yielding 10S, 13S, and 17S RNA) and one termination site that does not (yielding 23S RNA). Thus, specific termination at a site producing 23S RNA can take place in the absence of ρ. However, ρ detects additional termination signals that are not recognized by RNA polymerase alone.

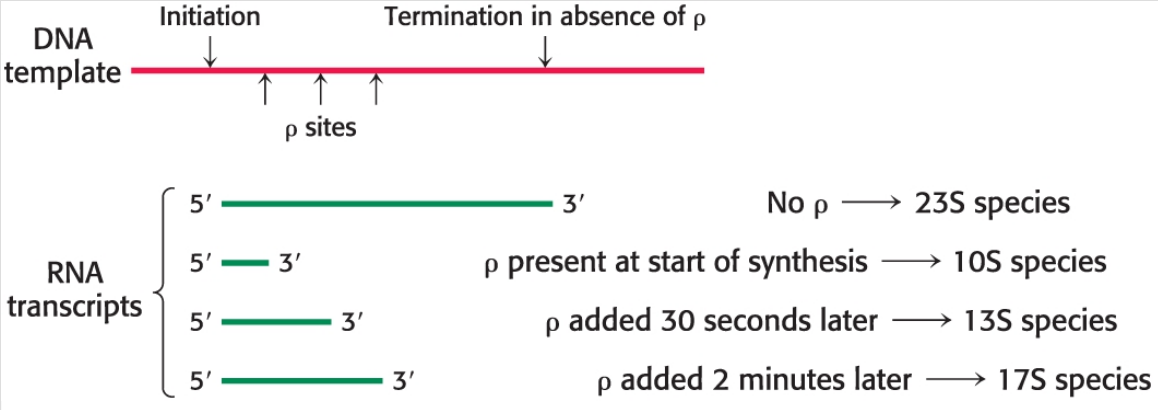

FIGURE 29.13 ρ protein promotes the termination of transcription. The DNA template shown here contains three ρ-dependent termination sites and one site that does not require the actior of the ρ protein.

The ρ protein promotes about 20% of termination events in bacteria, but exactly how it selects its target termination signals is not clear. Unlike the hairpin–oligo(U) sequence of intrinsic termination sites, the identification of conserved patterns in ρ-dependent terminators has proven more difficult.

How does ρ promote the termination of RNA synthesis? A key clue is the finding that ρ is hexameric and hydrolyzes ATP in the presence of single-stranded RNA but not in the presence of DNA or duplex RNA. Thus ρ is a helicase, homologous to the hexameric helicases that we encountered in our discussion of DNA replication (Section 28.1). The role of ρ in the termination of transcription in bacteria is as follows (**Figure 29.14**):

- The ρ protein is brought into action by sequences located in the nascent RNA that are rich in cytosine and poor in guanine.
- A stretch of nucleotides is bound in such a way that the RNA passes through the center of the structure.

- The helicase activity of ρ enables the protein to pull the nascent RNA while pursuing RNA polymerase.
- When ρ catches RNA polymerase at the transcription bubble, it breaks the RNA–DNA hybrid by functioning as an RNA–DNA helicase.

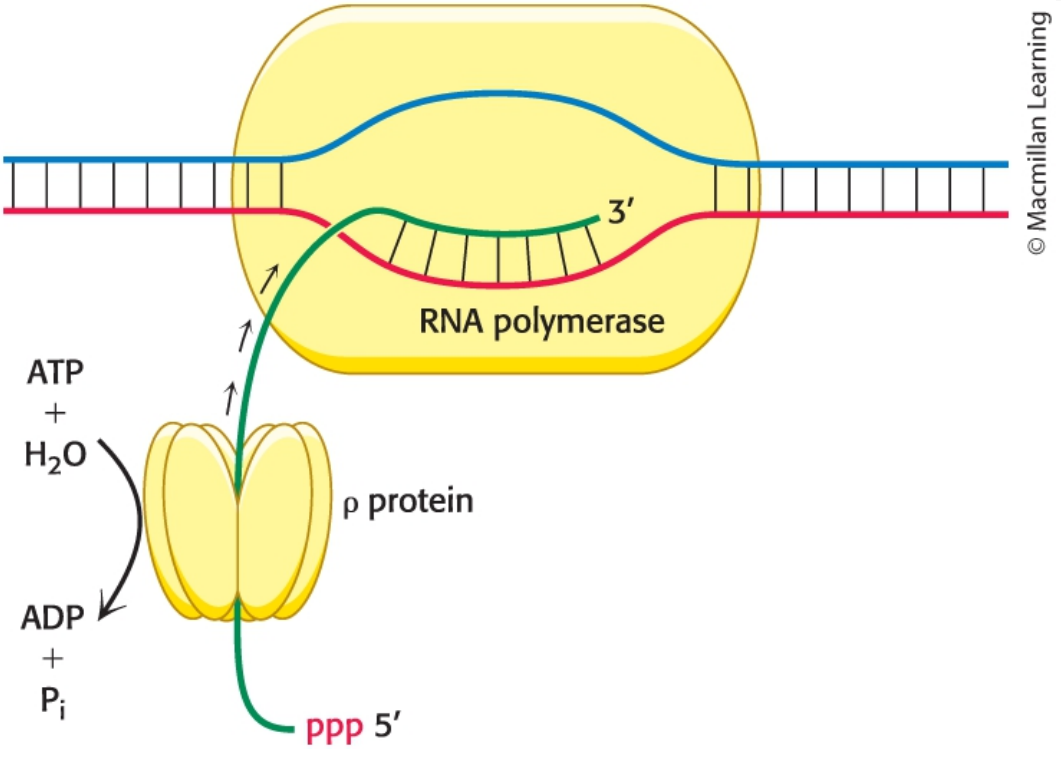

FIGURE 29.14 ρ protein is an ATP-dependent helicase. ρ promotes the termination of transcription by binding the nascent RNA chain and pulling it away from the RNA polymerase and the DNA template. The small arrows represent the movement of ρ protein along the transcript.

Proteins in addition to ρ may promote termination. For example, the NusA protein enables RNA polymerase in *E. coli* to recognize a characteristic class of termination sites. A common feature of transcription termination, whether it relies on a protein or not, is that

the functioning signals lie in newly synthesized RNA rather than in the DNA template.

29.3 Transcription Is Highly Regulated

As we will see in Chapter 31, the level at which different genes are transcribed is highly regulated. Regulated gene expression is critical for the development of multicellular organisms, the differentiation of various cell types, and the response of bacteria to changes in their environment. Here, we will discuss a few examples of how transcription can be controlled.

Alternative sigma subunits in bacteria control transcription in response to changes in conditions

As noted above, the σ factor allows for the specific binding of the bacterial RNA polymerase to a promoter site on the template DNA. *E. coli* has seven distinct σ factors for recognizing several types of promoter sequences in *E. coli* DNA. The type that recognizes the consensus sequences described earlier is called σ^{70} because it has a mass of 70 kDa. A different σ factor comes into play when the temperature is raised abruptly. *E. coli* responds by synthesizing σ^{32}, which recognizes the promoters of so-called *heat-shock genes*. These promoters exhibit -10 sequences that are somewhat different from the -10 sequence for standard promoters (**Figure 29.15**). The increased transcription of heat-shock genes leads to the coordinated synthesis of a series of protective proteins. Other σ factors respond to environmental conditions, such as nitrogen starvation. These findings demonstrate

that σ plays the key role in determining when and where RNA polymerase initiates transcription.

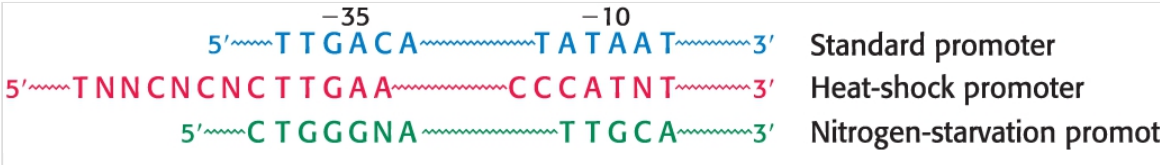

FIGURE 29.15 Alternative promoters vary in their consensus sequences at conserved sites. A comparison is shown of the consensus sequences of standard, heat-shock, and nitrogen-starvation promoters of *E. coli.* These promoters are recognized by σ^{70}, σ^{32}, and σ^{54}, respectively.

Some other bacteria contain a much larger number of σ factors. For example, the genome of the soil bacterium *Streptomyces coelicolor* encodes more than 60 σ factors recognized on the basis of their amino acid sequences. This repertoire allows these cells to adjust their gene-expression programs to the wide range of conditions, with regard to nutrients and competing organisms, that they may experience.

Some messenger RNAs directly sense metabolite concentrations

As we shall explore in Chapter 31, the expression of many genes is controlled in response to the concentrations of metabolites and signaling molecules within cells. One set of control mechanisms found in both prokaryotes and eukaryotes depends on the remarkable ability of some mRNA molecules to form secondary structures that are capable of directly binding small molecules. These structures are termed **riboswitches**.

Consider a riboswitch that controls the synthesis of genes that participate in the biosynthesis of riboflavin in the bacterium *Bacillus subtilis* (Figure 29.16). When flavin mononucleotide (FMN), a key intermediate in riboflavin biosynthesis, is present at high concentration, it binds to the RNA transcript. Binding of FMN to the transcript induces a hairpin structure that favors premature termination. By trapping the RNA transcript in this termination-favoring conformation, FMN prevents the production of functional full-length mRNA. However, when FMN is present at low concentration, it does not readily bind to the mRNA. Without FMN bound, the transcript adopts an alternative conformation without the terminator hairpin, allowing the production of the full-length mRNA. The occurrence of riboswitches serves as a vivid illustration of how RNAs are capable of forming elaborate, functional structures, though in the absence of specific information we tend to depict them as simple lines.

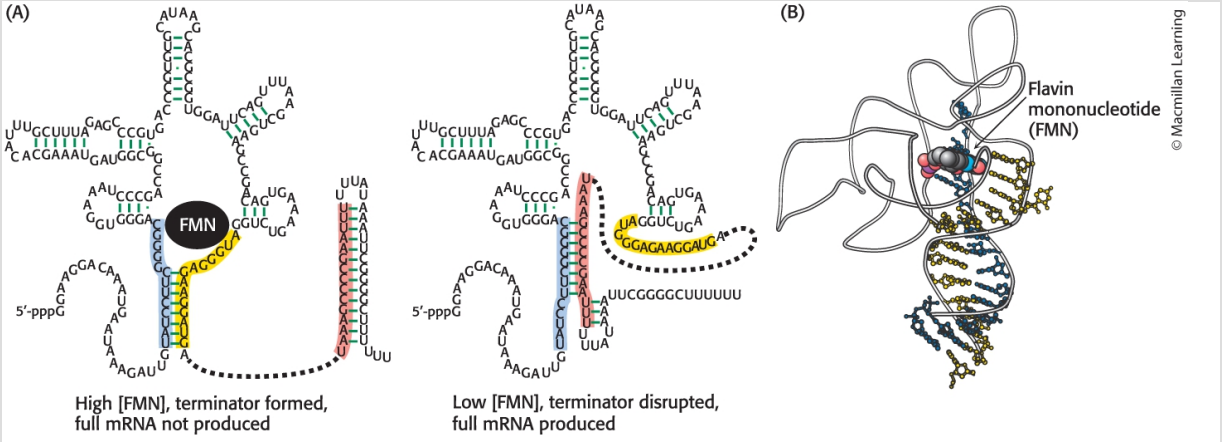

FIGURE 29.16 Riboswitches use metabolite concentrations to regulate transcription. (A) The 5′ end of an mRNA that encodes proteins engaged in the production of flavin mononucleotide (FMN) folds to form a structure that is stabilized by binding FMN. This structure includes a terminator that leads to premature termination of the mRNA. At lower concentrations of FMN, an alternative structure that lacks the terminator is formed, leading to the production of full-length mRNA. (B) In the three-dimensional structure of a related FMN-binding riboswitch bound to FMN, the blue and yellow stretches correspond to regions highlighted in the same colors in part A. The yellow strand contacts the bound FMN, stabilizing the structure.

[Drawn from 3F2Q.pdb].

INTERACT with this model in Achieve

Control of transcription in eukaryotes is highly complex

We turn now to transcription in eukaryotes, a much more complex process than in bacteria. Eukaryotic cells have a remarkable ability to regulate precisely the time at which each gene is transcribed and how much RNA is produced. This ability led to the evolution of multicellular eukaryotes with distinct tissues. That is, multicellular eukaryotes use differential transcriptional regulation to create different cell types.

Gene expression is influenced by three important characteristics unique to eukaryotes: the nuclear membrane, complex transcriptional regulation, and RNA processing.

1. *The nuclear membrane allows transcription and translation to take place in different cellular compartments.* Transcription takes place in the membrane-bound nucleus, whereas translation takes place outside the nucleus in the cytoplasm. In bacteria, the two processes are closely coupled (**Figure 29.17**). Indeed, the translation of bacterial mRNA begins while the transcript is still being synthesized. The spatial and temporal separation of transcription and translation enables eukaryotes to regulate gene expression in much more intricate ways, contributing to the richness of eukaryotic form and function.

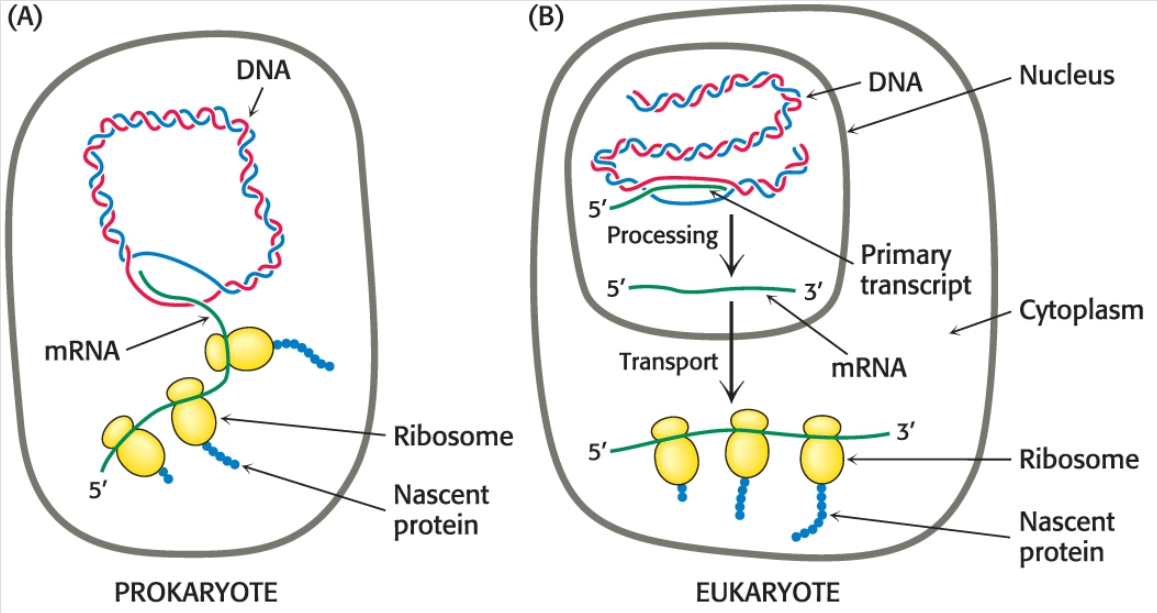

FIGURE 29.17 Transcription and translation are closely coupled in prokaryotes, whereas they are spatially and temporally separate in eukaryotes. (A) In prokaryotes, the primary transcript serves as mRNA and is used immediately as the template for protein synthesis. (B) In eukaryote mRNA precursors are processed and spliced in the nucleus before being transported to the cytoplasm for translation into protein.

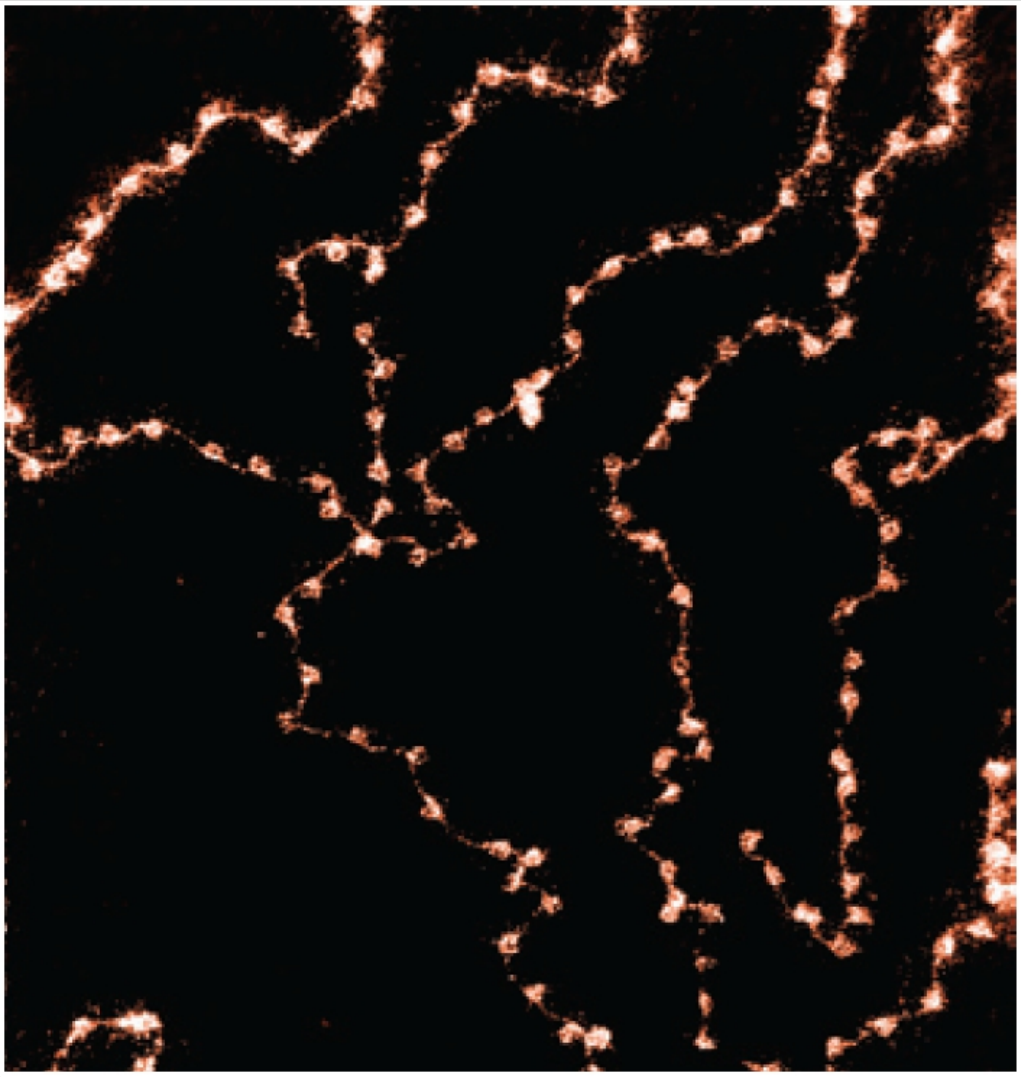
[Information from J. Darnell, H. Lodish, and D. Baltimore. *Molecular Cell Biology*, 2nd ed. (Scientific American Book 1990), p. 230.]



2. *A variety of types of promoter elements enables complex transcriptional regulation*. Like bacteria, eukaryotes rely on conserved sequences in DNA to regulate the initiation of transcription. But bacteria have only three promoter elements (the -10, -35, and UP elements), whereas eukaryotes use a variety of types of promoter elements, each identified by its own conserved sequence. Not all possible types will be present together in the same promoter. In eukaryotes, elements that regulate transcription can be found upstream or downstream of the start site and sometimes at distances much farther from the start site than in prokaryotes. For example, enhancer elements located on DNA far from the start site increase the promoter activity of specific genes.

3. *The degree of RNA processing is much greater in eukaryotes than in bacteria*. Although both bacteria and eukaryotes modify RNA, eukaryotes very extensively process nascent RNA destined to become mRNA. This processing includes modifications to both ends and, most significantly, splicing out segments of the primary transcript. RNA processing is described in Section 29.4.

Eukaryotic DNA is organized into chromatin

Whereas bacterial genomic DNA is relatively accessible to the proteins involved in transcription, eukaryotic DNA is packaged into **chromatin**, a complex formed between the DNA and a particular set of proteins. Chromatin compacts and organizes eukaryotic DNA, and its presence has dramatic consequences for gene regulation. Although the principles for the construction of chromatin are relatively simple, the chromatin structure for a complete genome is quite complicated. Importantly, in any given eukaryotic cell, some genes and their associated regulatory regions are relatively accessible for transcription and regulation, whereas other genes are tightly packaged, less accessible, and therefore inactive. Eukaryotic gene regulation frequently requires the manipulation of chromatin structure.

Chromatin viewed with the electron microscope has the appearance of beads on a string (**Figure 29.18**). Partial digestion of chromatin with DNase exposes these particles, which consist of fragments of DNA (the "string") wrapped around octamers of proteins called *histones* (the "beads"). The complex formed by a histone octamer and a 145-bp DNA fragment is called the **nucleosome** (**Figure 29.19**).

Don. W. Fawcett/Science Source.

FIGURE 29.18 Eukaryotic chromatin structure resembles beads on a string. In this electron micrograph of chromatin, the “beads” correspond to DNA complexed with specific proteins into nucleosomes. Each bead has a diameter of approximately 100 Å.

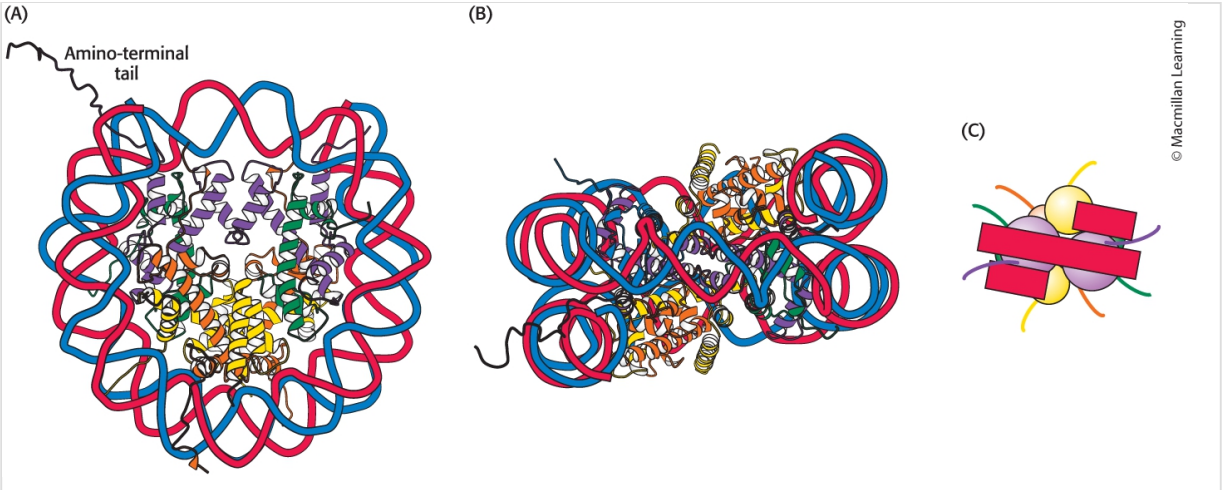


FIGURE 29.19 The structure of the nucleosome consists of eight histone proteins surrounded by DNA. (A) A view showing the DNA wrapping around the histone core. (B) A 90-degree rotation of the view in part A. The DNA forms a left-handed superhelix as it wraps around the core. (C) A schematic view.

[Drawn from 1AOI.pdb.]

The overall structure of the nucleosome was revealed through electron microscopic and x-ray crystallographic studies pioneered by Aaron Klug and his colleagues. More recently, the three-dimensional structures of reconstituted nucleosomes have been determined to higher resolution by x-ray diffraction methods. The histone octamer is a complex of four different types of histones (H2A, H2B, H3, and H4) that are homologous and similar in structure.

The eight histones in the core are arranged into a $(H3)_2(H4)_2$ tetramer and a pair of H2A–H2B dimers. The tetramer and dimers come together to form a left-handed superhelical ramp around which the DNA wraps. In addition, each histone has an amino-terminal tail that extends out from the core structure. These tails are flexible and contain many lysine and arginine residues. As we shall see in Chapter 31, covalent modifications of these tails play an essential role in regulating gene expression.

Three types of RNA polymerase synthesize RNA in eukaryotic cells

In bacteria, RNA is synthesized by a single kind of polymerase. In contrast, the nucleus of a typical eukaryotic cell contains three types of RNA polymerase differing in template specificity and location in the nucleus (Table 29.2). The three polymerases are named for the order in which they were discovered, which has no bearing on the relative importance of their function. We will discuss them in an order that reflects their similarities in localization, function, and regulation. We will emphasize RNA polymerase II, since it transcribes all of the protein-coding genes and has therefore been the focus of much research investigating transcriptional mechanisms.

TABLE 29.2 Eukaryotic RNA polymerases

Type	Location	Cellular transcripts	Effects of α-amanitin
I	Nucleolus	18S, 5.8S, and 28S rRNA	Insensitive
II	Nucleoplasm	mRNA precursors and snRNA	Strongly inhibited
III	Nucleoplasm	tRNA and 5S rRNA	Inhibited by high concentrations

RNA polymerase I is located in specialized structures within the nucleus called nucleoli, where it transcribes the tandem array of genes for 18S, 5.8S, and 28S rRNA. The other rRNA molecule (5S rRNA) and all the tRNA molecules are synthesized by *RNA polymerase III*, which is located in the nucleoplasm rather than in nucleoli. *RNA polymerase II*, which

also is located in the nucleoplasm, synthesizes the precursors of mRNA as well as several small RNA molecules, such as those of the splicing apparatus and many of the precursors to small regulatory RNAs. All three of the polymerases are large proteins, containing from 8 to 14 subunits and having total molecular masses greater than 500 kDa (or 0.5 MDa), and it is likely that they evolved from a single enzyme that was present in a common ancestor of eukaryotes, bacteria, and archaea. In fact, many components of the eukaryotic transcriptional machinery evolved from those in a common ancestor.

Although all eukaryotic RNA polymerases are homologous to one another and to prokaryotic RNA polymerases, RNA polymerase II contains a unique **carboxyl-terminal domain** (CTD) on the 220-kDa subunit; this domain is unusual because it contains multiple repeats of a YSPTSPS consensus sequence. The activity of RNA polymerase II is regulated by phosphorylation, mainly on the serine residues of the CTD.

The different polymerases were originally distinguished through their variable responses to the toxin α-amanitin, a cyclic octapeptide that contains several modified amino acids and is produced by a genus of poisonous mushroom (**Figure 29.20**). α-Amanitin binds very tightly ($K_d = 10$ nM) to RNA polymerase II and thereby blocks the elongation phase of RNA synthesis. Higher concentrations of α-amanitin (1 μM) inhibit RNA polymerase III, whereas RNA polymerase I is insensitive to this toxin. This pattern of sensitivity is highly conserved throughout the animal and plant kingdoms.

Tisha Razumovsky/Shutterstock

α-Amanitin

FIGURE 29.20 α-Amanitin is produced by poisonous mushrooms in the genus *Amanita*. Pictured is *Amanita phalloides*, also called the *death cap* or the *destroying angel*.

Finally, eukaryotic polymerases differ from each other in the promoters to which they bind. Eukaryotic genes, like prokaryotic genes, require promoters for transcription initiation. Like prokaryotic promoters, eukaryotic promoters consist of conserved sequences that attract the polymerase to the start site. However, eukaryotic promoters differ distinctly in sequence and position, depending on the type of RNA polymerase that binds to them (**Figure 29.21**).

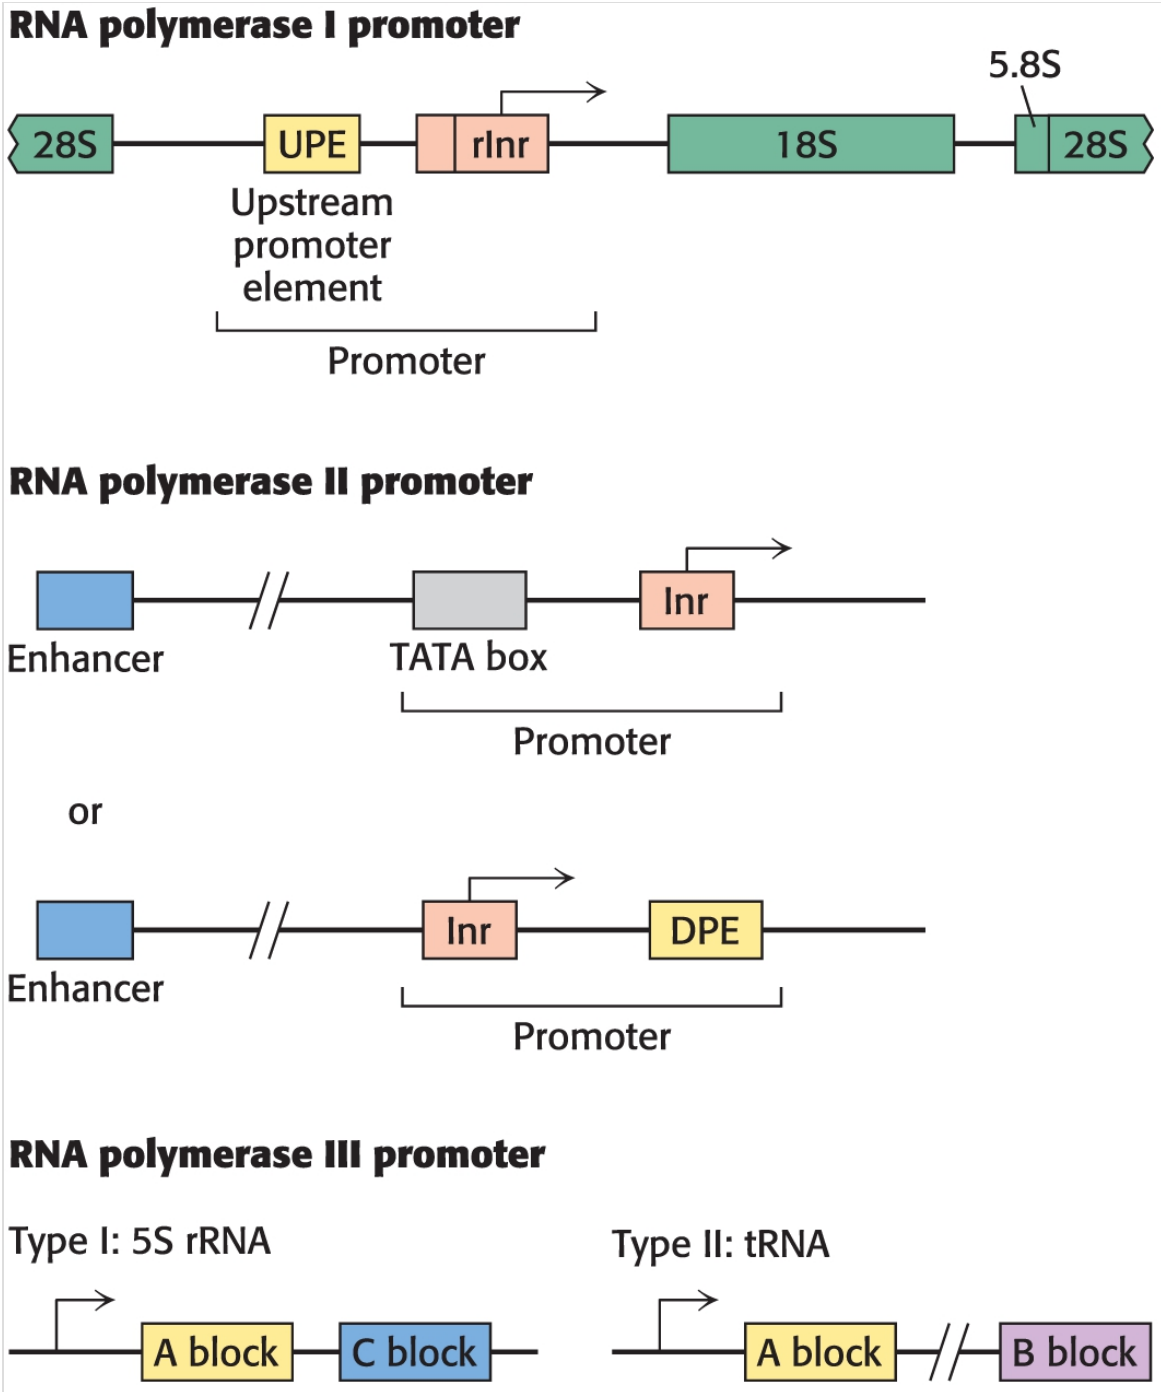

FIGURE 29.21 Eukaryotic promoters share common elements. Each eukaryotic RNA polymera recognizes a set of promoter elements — sequences in DNA that promote transcription. The RN polymerase I promoter consists of a ribosomal initiator (rInr) and an upstream promoter eleme (UPE). The RNA polymerase II promoter likewise includes an initiator element (Inr) and may als include either a TATA box or a downstream promoter element (DPE). Separate from the promot region, enhancer elements bind specific transcription factors. RNA polymerase III promoters consist of conserved sequences that lie within the transcribed genes.

- *The promoter sequences for RNA polymerase I are located in stretches of DNA separating the ribosomal DNA (rDNA) it transcribes.* These rRNA genes are arranged in several hundred tandem repeats, each containing a copy of each of three rRNA genes. At the transcriptional start site lies a TATA-like sequence called the *ribosomal initiator element* (rInr). Farther upstream, 150 to 200 bp from the start site, is the *upstream promoter element* (UPE). Both elements aid transcription by binding proteins that recruit RNA polymerase I.

- *Promoters for RNA polymerase II, like prokaryotic promoters, include a set of consensus sequences that define the start site and recruit the polymerase.* However, the promoter can contain any combination of a number of possible consensus sequences. Unique to eukaryotes, they also include enhancer elements that can be more than 1 kb from the start site.

- *Promoters for RNA polymerase III are within the transcribed sequence, downstream of the start site*. This is contrast to promoters for RNA polymerase I and II, which are *upstream* of the transcription start site. There are two types of intergenic promoters for RNA polymerase III. Type I promoters, found in the 5S rRNA gene, contain two short, conserved sequences, the A block and the C block. Type II promoters, found in tRNA genes, consist of two 11-bp sequences, the A block and the B block, situated about 15 bp from either end of the gene.

Three common elements can be found in the RNA polymerase II promoter region

RNA polymerase II transcribes all of the protein-coding genes in eukaryotic cells. Promoters for RNA polymerase II, like those for bacterial polymerases, are generally located upstream of the start site for transcription. Because these sequences are on the *same* molecule of DNA as the genes being transcribed, they are called *cis-acting elements*.

1. The most commonly recognized cis-acting element for genes transcribed by RNA polymerase II is called the **TATA box** on the basis of its consensus sequence (**Figure 29.22**). The TATA box is usually found between positions -30 and -100. Note that the eukaryotic TATA box closely resembles the prokaryotic -10 sequence (TATAAT) but is farther from the start site. The mutation of a single base in the TATA box markedly impairs promoter activity. Thus, the precise sequence, not just a high content of AT pairs, is essential.

FIGURE 29.22 The sequence of the TATA box is highly conserved.
Comparisons of the sequences of more than 100 eukaryotic promoters led to the consensus sequence shown. The subscripts denote the frequency (%) of the base at that position.

2. The TATA box is often paired with an *initiator element* (Inr), a sequence found at the transcriptional start site, between positions -3 and $+5$. This sequence defines the start site because the other

promoter elements are at variable distances from that site. Its presence increases transcriptional activity.

3. A third element, the *downstream core promoter element* (DPE), is commonly found in conjunction with the Inr in transcripts that lack the TATA box. In contrast with the TATA box, the DPE is found downstream of the start site, between positions $+28$ and $+32$.

Regulatory cis-acting elements are recognized by different mechanisms

Additional regulatory sequences are located between -40 and -150. Many promoters contain a *CAAT box*, and some contain a *GC box* (**Figure 29.23**). Constitutive genes (genes that are continuously expressed rather than regulated) tend to have GC boxes in their promoters. The positions of these upstream sequences vary from one promoter to another, in contrast with the quite constant location of the -35 region in prokaryotes. Another difference is that the CAAT box and the GC box can be effective when present on the template (antisense) strand, unlike the -35 region, which must be present on the coding (sense) strand.

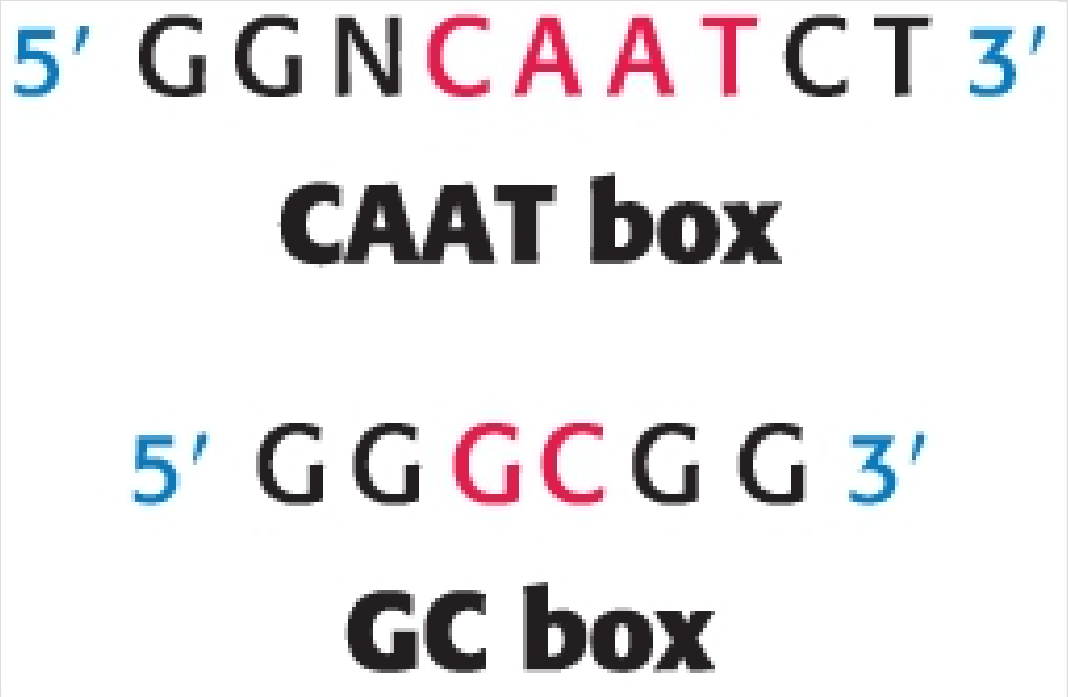

FIGURE 29.23 The sequences of the CAAT box and GC box are also highly conserved. Consensus sequences are shown for the CAAT and GC boxes of eukaryotic promoters for mRNA precursors.

These differences between prokaryotes and eukaryotes correspond to fundamentally different mechanisms for the recognition of cis-acting elements. The -10 and -35 sequences in prokaryotic promoters are binding sites for RNA polymerase and its associated σ factor. In contrast, the TATA, CAAT, and GC boxes and other cis-acting elements in eukaryotic promoters are recognized by proteins other than RNA polymerase itself.

The TFIID protein complex initiates the assembly of the active transcription complex in eukaryotes

Cis-acting elements constitute only part of the puzzle of eukaryotic gene expression. **Transcription factors** that bind to these elements also are required. For example, RNA polymerase II is guided to the start site by a set of transcription factors known collectively as *TFII* (*TF* stands for transcription factor, and *II* refers to RNA polymerase II). Individual TFII factors are called TFIIA, TFIIB, and so on.

In TATA-box promoters, the key initial event is the recognition of the TATA box by the TATA-box-binding protein (TBP), a 30-kDa component of the 700-kDa TFIID complex. In TATA-less promoters, other proteins in the TFIID complex bind the core promoter elements; however, because less is known about these interactions, we will consider only the TATA-box–TBP binding interaction. TBP binds 10^5 times as tightly to the TATA box as to nonconsensus sequences; the dissociation constant of the TBP–TATA-box complex is approximately 1 nM.

The TATA box of DNA binds to the concave surface of TBP, inducing large conformational changes in the bound DNA (**Figure 29.24**). The double helix is substantially unwound to widen its minor groove, enabling it to make extensive contact with the antiparallel β strands on the concave side of TBP. Hydrophobic interactions are prominent at this interface. Four phenylalanine residues, for example, are intercalated between base pairs of the TATA box. The flexibility of AT-rich sequences is generally exploited here in bending the DNA. Immediately outside the TATA box, classical B-DNA resumes. The TBP–TATA-box complex is distinctly asymmetric, a property that is crucial for specifying a unique start site and ensuring that transcription proceeds unidirectionally.

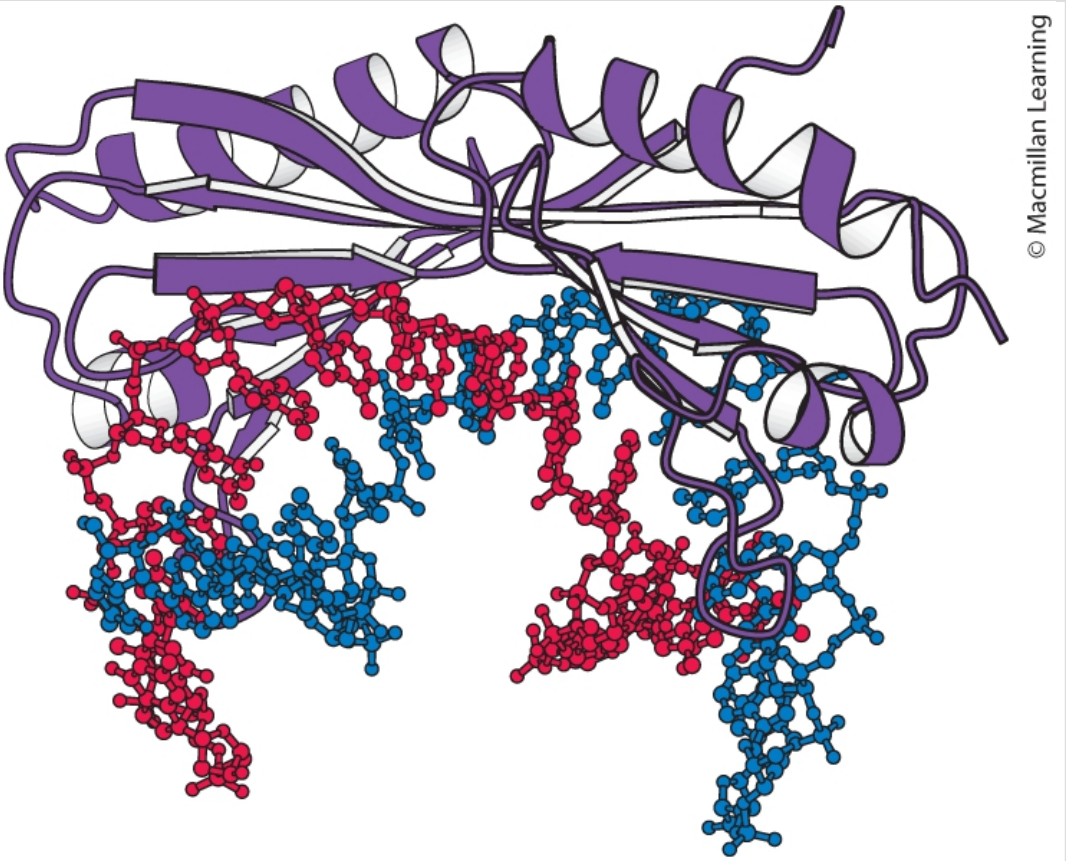

FIGURE 29.24 The TATA-box-binding protein binds to DNA. TBP is a saddle-shaped protein consisting of two similar domains. The saddle-like structure of the protein sits atop a DNA fragment, which is significantly unwound and bent.

[Drawn from 1CDW.pdb.]

INTERACT with this model in Achieve

TBP bound to the TATA box is the heart of the initiation complex (Figure 29.25). The surface of the TBP saddle provides docking sites for the binding of other components, with additional transcription factors assembling on this nucleus in a defined sequence. TFIIA is recruited, followed by TFIIB; then TFIIF, RNA polymerase II, TFIIE, and TFIIH join the other factors to form a complex called the *pre-initiation complex* (PIC).

FIGURE 29.25 General transcription factors are essential in initiating transcription by RNA polymerase II. The step-by-step assembly of these general transcription factors begins with the binding of TFIID (purple) to the TATA box. [The TATA-box-binding protein (TBP), a component of TFIID, recognizes the TATA box.] After assembly, TFIIH opens the DNA double helix and phosphorylates the carboxyl-terminal domain (CTD), allowing the polymerase to leave the promoter and begin transcription. The red arrow marks the transcription start site.

These additional transcription factors play specific roles in this complex. As we saw above, TFIID recognizes core promoter elements and is central to the assembly process. While TFIIA is not essential for the assembly or function of the PIC in vitro, it may aid in the binding of TFIID to the DNA. TFIIB is a DNA-binding protein that recognizes specific cis-acting promoter elements called *B recognition elements*, which are often found near the TATA box. TFIIF aids in the recruitment of polymerase II, while TFIIE brings TFIIH to the complex. TFIIH is a multisubunit complex with helicase and protein kinase activities, both of which are critical in the initiation of transcription. The helicase activity unwinds the DNA template, and the kinase activity phosphorylates specific amino acids in the CTD of polymerase II.

During the formation of the PIC, the carboxyl-terminal domain (CTD) is unphosphorylated and plays a role in transcription regulation through its binding to an enhancer-associated complex called *mediator* (Section 31.4). Phosphorylation of the CTD by TFIIH marks the transition from initiation to elongation. The phosphorylated CTD stabilizes transcription elongation by RNA polymerase II and recruits RNA-processing enzymes that act during the course of elongation. The importance of the carboxyl-terminal domain is highlighted by the finding that yeast cells containing mutant polymerase II with fewer than 10 repeats in the CTD are not viable.

The PIC described above initiates transcription at a low (basal) frequency, and the transcription factors associated with it are referred

to as *basal* or *general* transcription factors. Additional transcription factors that bind to other sites are required to achieve a high rate of mRNA synthesis. Their role is to selectively stimulate *specific* genes. In summary, transcription factors and other proteins that bind to regulatory sites on DNA can be regarded as passwords that cooperatively open multiple locks, giving RNA polymerase access to specific genes.

Self-Check Question

The function of the σ subunit of *E. coli* RNA polymerase is analogous to the function of general transcription factors in eukaryotes. Briefly describe their common function.

Enhancer sequences can stimulate transcription at start sites thousands of bases away

The activities of many promoters in higher eukaryotes are greatly increased by another type of cis-acting element called an **enhancer**.

- Enhancer sequences have no promoter activity of their own yet can exert their stimulatory actions over distances of several thousand base pairs.
- Enhancers can be upstream, downstream, or even in the middle of a transcribed gene.
- Enhancers are effective when present on either the coding or noncoding DNA strand.

- A particular enhancer is effective only in certain cells; for example, the immunoglobulin enhancer functions in B lymphocytes but not elsewhere.

 Cancer can result if the relation between genes and enhancers is disrupted. In Burkitt lymphoma and B-cell leukemia, a chromosomal translocation brings the proto-oncogene *myc* (a transcription factor itself) under the control of a powerful immunoglobulin enhancer. The consequent dysregulation of the *myc* gene is hypothesized to play a role in the progression of the cancer.

The discovery of promoters and enhancers has allowed us to gain a better understanding of how genes are selectively expressed in eukaryotic cells. The regulation of eukaryotic gene transcription, discussed in Chapter 31, is the fundamental means of controlling gene expression.

29.4 Some RNA Transcription Products Are Processed

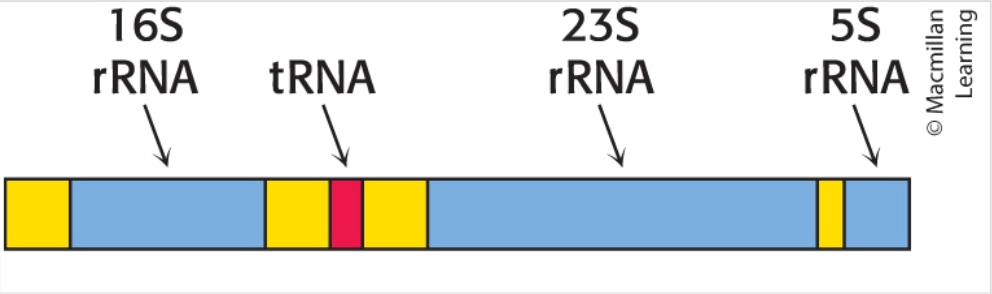
Virtually all the initial products of eukaryotic transcription are further processed, and even some prokaryotic transcripts are modified. As we will see next, the particular processing steps and the factors taking part vary according to the type of RNA precursor and the type of RNA polymerase that produced it.

Precursors of transfer and ribosomal RNA are cleaved and chemically modified after transcription

In bacteria, messenger RNA molecules undergo little or no modification after synthesis by RNA polymerase. Indeed, many mRNA molecules are translated while they are being transcribed. In contrast, transfer RNA (tRNA) and ribosomal RNA (rRNA) molecules are generated by modifications of nascent RNA chains.

- *The transcript can be cleaved at specific sites along its sequence.* For example, in *E. coli*, the three rRNAs and a tRNA are excised from a single primary RNA transcript that also contains spacer regions (**Figure 29.26**). Other transcripts contain arrays of several kinds of tRNA or several copies of the same tRNA. The nucleases that cleave and trim these precursors of rRNA and tRNA are highly precise. *Ribonuclease P* (RNase P), for example, generates the correct $5'$ terminus of all tRNA molecules in *E. coli.* Sidney Altman and his coworkers showed that this interesting enzyme contains a catalytically active RNA molecule. *Ribonuclease III* (Rnase III) excises 5S, 16S, and 23S rRNA precursors from the primary

transcript by cleaving double-helical hairpin regions at specific sites.



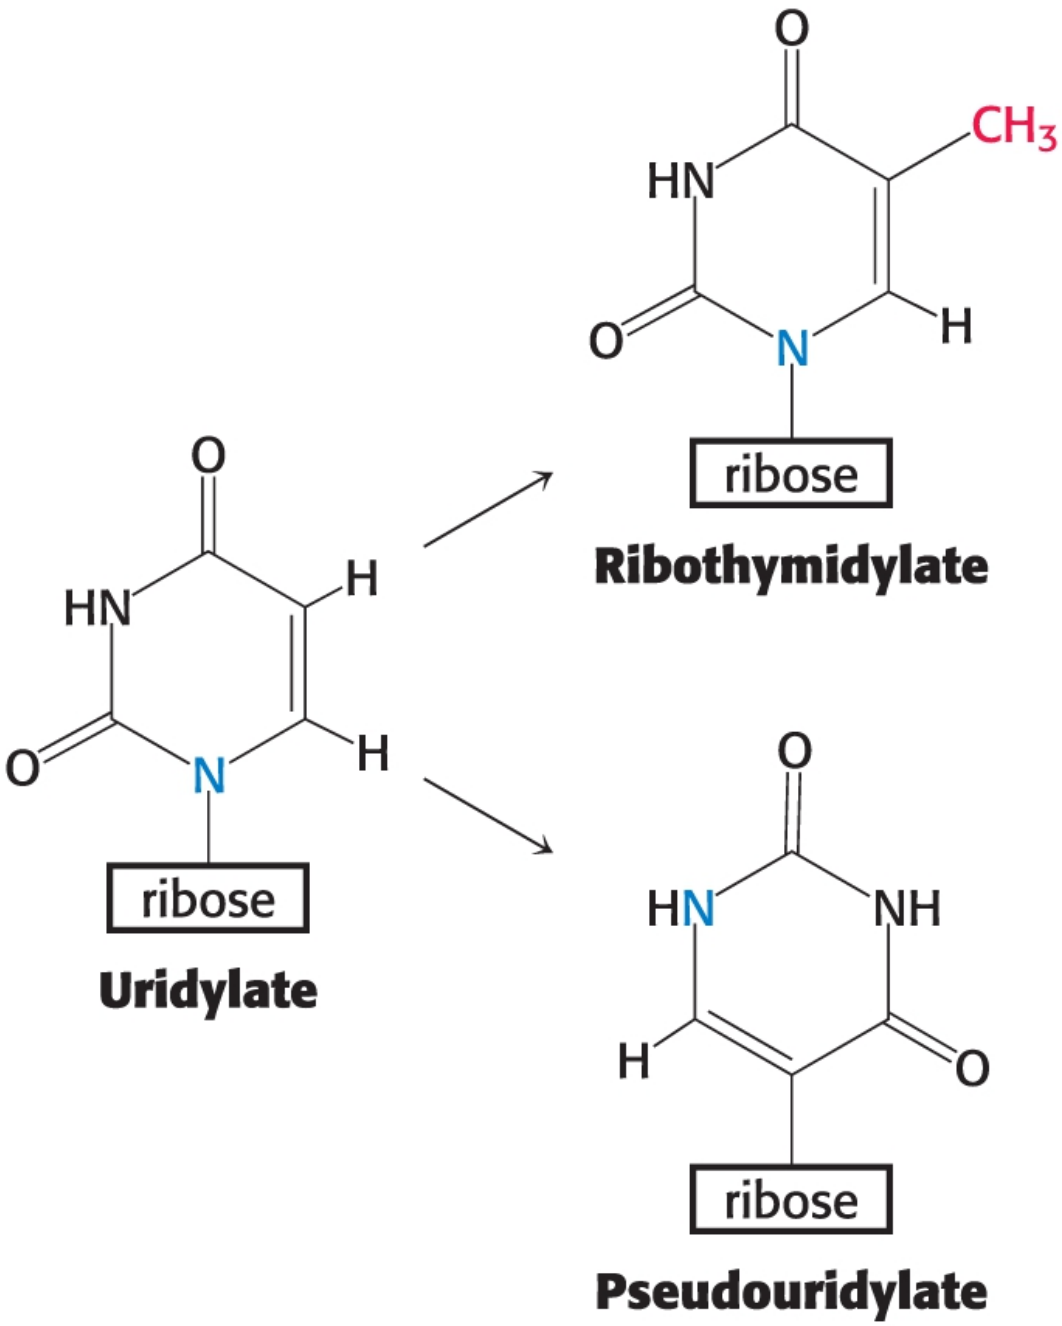


FIGURE 29.26 Cleavage of a primary RNA transcript in *E. coli* produces 5S, 16S, and 23S rRNA molecules and a tRNA molecule. Spacer regions are shown in yellow.

- *Nucleotides can be added to the termini of some RNA chains.* For example, CCA, a terminal sequence required for the function of all tRNAs, is added to the $3'$ ends of tRNA molecules for which this terminal sequence is not encoded in the DNA. The enzyme that catalyzes the addition of CCA is atypical for an RNA polymerase in that it does not use a DNA template.

- *Bases and ribose units of RNAs can be modified.* For example, some bases of rRNA are methylated. Furthermore, all tRNA molecules contain unusual bases formed by the enzymatic modification of a standard ribonucleotide in a tRNA precursor. For example, uridylate residues are modified after transcription to form ribothymidylate and pseudouridylate. These modifications generate diversity, allowing greater structural and functional versatility.

RNA polymerase I produces three ribosomal RNAs

Several RNA molecules are key components of ribosomes. In eukaryotes, RNA polymerase I transcription produces a single precursor (45S in mammals) that encodes three RNA components of the ribosome: the 18S rRNA, the 28S rRNA, and the 5.8S rRNA (Figure 29.27).

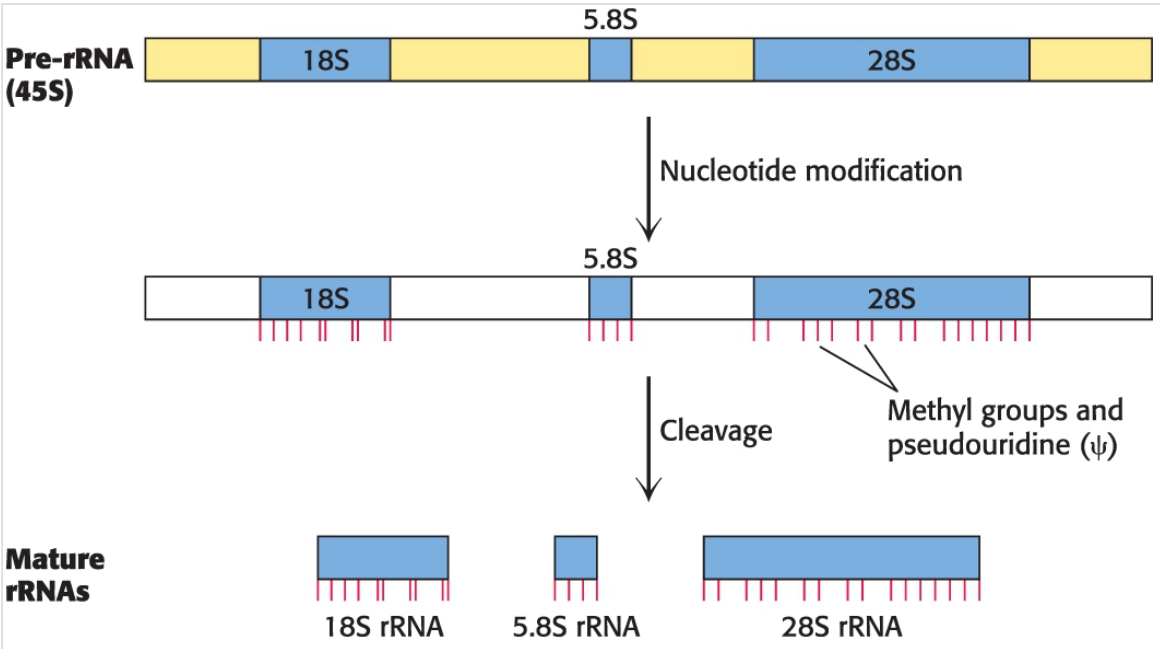

FIGURE 29.27 The processing of eukaryotic pre-rRNA produces mature rRNAs. The mammalia pre-rRNA transcript contains the RNA sequences destined to become the 18S, 5.8S, and 28S rRNAs of the small and large ribosomal subunits. First, nucleotides are modified: small nucleola ribonucleoproteins methylate specific nucleoside groups and convert selected uridines into pseudouridines (indicated by red lines). Next, the pre-rRNA is cleaved and packaged to form mature ribosomes, in a highly regulated process in which more than 200 proteins take part.

The 18S rRNA is the RNA component of the small ribosomal subunit (40S), and the 28S and 5.8S rRNAs are two RNA components of the large ribosomal subunit (60S). The other RNA component of the large

ribosomal subunit, the 5S rRNA, is transcribed by RNA polymerase III as a separate transcript. Processing of the precursor proceeds as follows:

- First, the nucleotides of the pre-rRNA sequences destined for the ribosome undergo extensive modification, on both ribose and base components, directed by many **small nucleolar ribonucleoproteins (snoRNPs)**, each of which consists of one snoRNA and several proteins.
- The pre-rRNA is then assembled with ribosomal proteins, as guided by processing factors, to form a large ribonucleoprotein. For instance, the small-subunit (SSU) processome is required for 18S rRNA synthesis and can be visualized in electron micrographs as a terminal knob at the $5'$ ends of the nascent rRNAs (**Figure 29.28**).

Reprinted by permission from Macmillan Publishers Ltd, from Dragon, F., Gallagher, J., Compagnone-Post, P. et al. A large nucleolar U3 ribonucleoprotein required for 18S ribosomal RNA biogenesis. Nature 417, 967–970 (2002); permission conveyed through Copyright Clearance Center, ltd.

FIGURE 29.28 Electron microscopy gives a window into rRNA transcription and processing in eukaryotes. The assemblies of transcribed rRNA into precursor ribosomes resemble fir trees: the trunk is the rDNA, and each branch is a pre-rRNA transcript. Transcription starts at the top of the tree, where the shortest transcripts can be seen, and progresses down the rDNA to the end of the gene. The terminal knobs visible at the end of some pre-rRNA transcripts likely correspond to the SSU processome, a large ribonucleoprotein required for processing the pre-rRNA.

- Finally, rRNA cleavage (sometimes coupled with additional processing steps) releases the mature rRNAs assembled with ribosomal proteins as ribosomes. Like those of RNA polymerase I transcription itself, most of these processing steps take place in the cell's nucleolus.

RNA polymerase III produces transfer RNAs

Eukaryotic tRNA transcripts are among the most processed of all RNA polymerase III transcripts. Like those of prokaryotic tRNAs, the $5'$ leader is cleaved by RNase P, the $3'$ trailer is removed, and CCA is added by the CCA-adding enzyme (Figure 29.29). Eukaryotic tRNAs are also heavily modified on base and ribose moieties; these modifications are important for function. In contrast with prokaryotic tRNAs, many eukaryotic pre-tRNAs are also spliced by an endonuclease and a ligase to remove an intron.

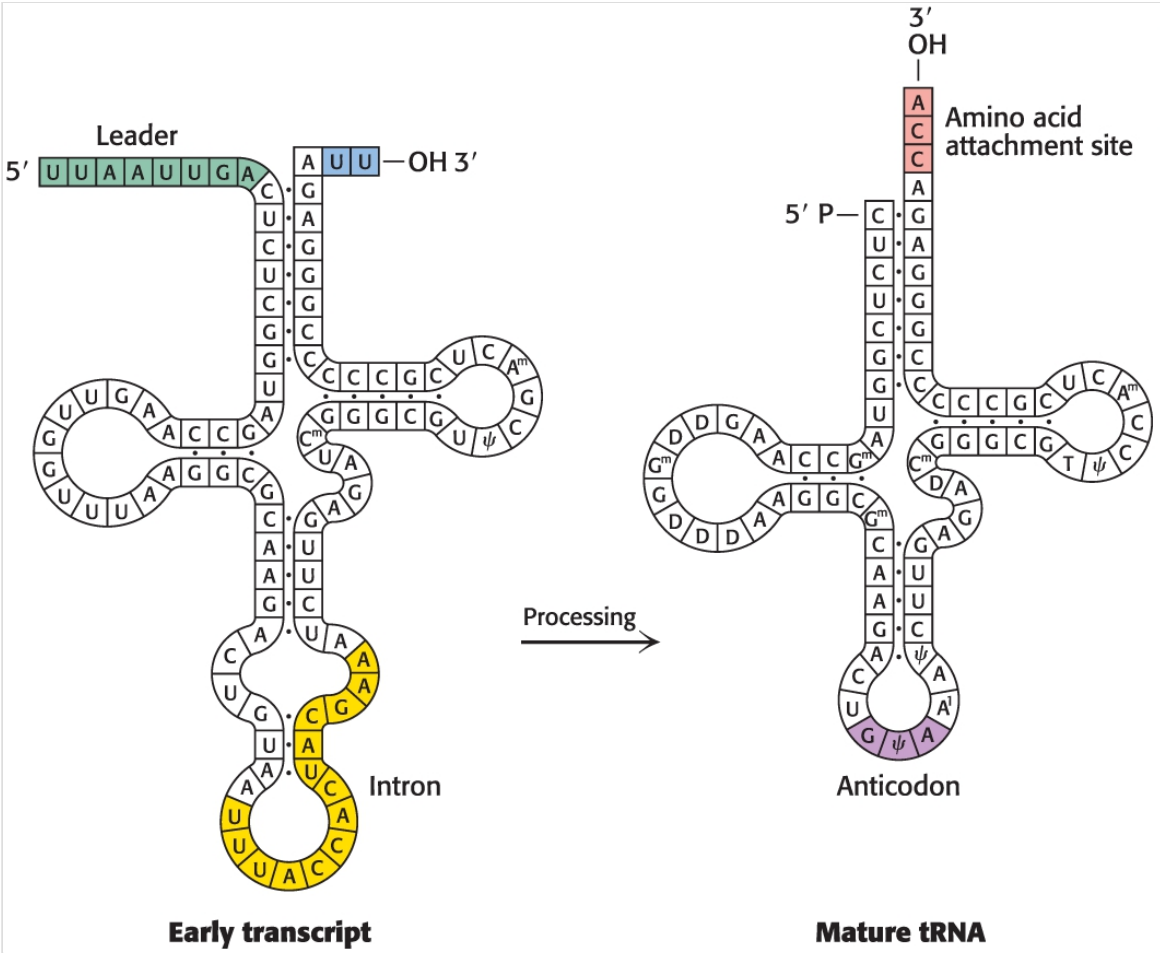

FIGURE 29.29 Transfer RNA precursors are processed. The conversion of a yeast tRNA precurso into a mature tRNA requires the removal of a 14-nucleotide intron (yellow), the cleavage of a 5′ leader (green), and the removal of UU and the attachment of CCA at the 3′ end (red). In additio several bases are modified.

The product of RNA polymerase II, the pre-mRNA transcript, acquires a 5′ cap and a 3′

poly(A) tail

Perhaps the most extensively studied transcription product is the product of RNA polymerase II: most of this RNA will be processed to mRNA. The immediate product of RNA polymerase II is sometimes referred to as precursor-to-messenger RNA, or **pre-mRNA**. Most pre-mRNA molecules are spliced to remove the introns, which we will discuss in greater detail below. In addition, both the $5'$ and the $3'$ ends are modified, and both modifications are retained as the pre-mRNA is converted into mRNA.

As in prokaryotes, eukaryotic transcription usually begins with A or G. However, the $5'$ triphosphate end of the nascent RNA chain is immediately modified:

- First, a phosphoryl group is released by hydrolysis.
- The diphosphate $5'$ end then attacks the α-phosphorus atom of GTP to form a very unusual $5'-5'$ triphosphate linkage. This distinctive terminus is called a **$5'$ cap** (**Figure 29.30**).

FIGURE 29.30 The 5′ ends of eukaryotic mRNAs are capped. Caps at the 5′ end of eukaryotic mRNA include 7-methylguanylate (red) attached by a triphosphate linkage to the ribose at the 5′ end. None of the riboses are methylated in cap 0, one is methylated in cap 1, and both are methylated in cap 2.

- The N-7 nitrogen of the terminal guanine is then methylated by *S*-adenosylmethionine to form cap 0. The adjacent riboses may be methylated to form cap 1 or cap 2.

Caps contribute to the stability of mRNAs by protecting their 5′ ends from phosphatases and nucleases. In addition, caps enhance the translation of mRNA by eukaryotic protein-synthesizing systems. Transfer RNA and ribosomal RNA molecules, in contrast with messenger RNAs and with small RNAs that participate in splicing, do not have caps.

As mentioned earlier, pre-mRNA is also modified at the 3′ end. Most eukaryotic mRNAs contain a string of adenine nucleotides — a **poly(A) tail** — at that end. This poly(A) tail is added *after* transcription has ended, since the DNA template does not encode this sequence. Indeed, the nucleotide preceding poly(A) is not the last nucleotide to be transcribed. Some primary transcripts contain hundreds of nucleotides beyond the 3′ end of the mature mRNA.

How is the 3′ end of the pre-mRNA given its final form? Eukaryotic primary transcripts are cleaved by a specific endonuclease that recognizes the sequence AAUAAA (**Figure 29.31**). Cleavage does not take

place if this sequence or a segment of some 20 nucleotides on its 3′ side is deleted. The presence of internal AAUAAA sequences in some mature mRNAs indicates that AAUAAA is only part of the cleavage signal; its context also is important. After cleavage of the pre-RNA by the endonuclease, a *poly(A) polymerase* adds about 250 adenylate residues to the 3′ end of the transcript; ATP is the donor in this reaction.

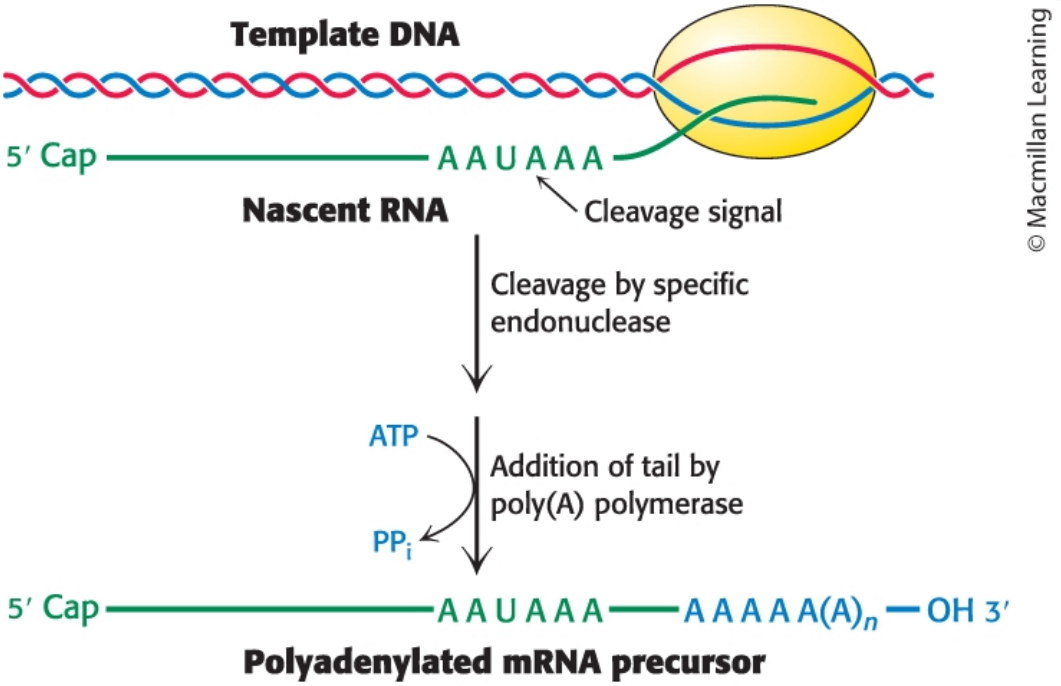

FIGURE 29.31 Primary transcripts in eukaryotes are polyadenylated. A specific endonuclease cleaves the RNA downstream of AAUAAA. Poly(A) polymerase then adds about 250 adenylate residues.

The role of the poly(A) tail is still not firmly established despite much effort. However, evidence is accumulating that it enhances translation efficiency and the stability of mRNA. Blocking the synthesis of the poly(A) tail by exposure to 3′-deoxyadenosine (cordycepin) does not interfere with the synthesis of the primary transcript. Messenger RNA

without a poly(A) tail can be transported out of the nucleus. However, an mRNA molecule without a poly(A) tail is usually much less effective as a template for protein synthesis than one with a poly(A) tail. Indeed, some mRNAs are stored in an unadenylated form and receive the poly(A) tail only when translation is imminent. The half-life of an mRNA molecule may be determined in part by the rate of degradation of its poly(A) tail.

Sequences at the ends of introns specify splice sites in mRNA precursors

Most genes in higher eukaryotes are composed of exons and introns (Section 8.7). The introns must be excised and the exons linked to form the final mRNA in a process called **RNA splicing**. This splicing must be exquisitely sensitive; splicing just one nucleotide upstream or downstream of the intended site would create a one-nucleotide shift, which would alter the reading frame on the $3'$ side of the splice to give an entirely different amino acid sequence, likely including a premature stop codon. Thus, the correct splice site must be clearly marked.

Does a particular sequence denote the splice site? The sequences of thousands of intron–exon junctions within RNA transcripts are known. In eukaryotes from yeast to mammals, these sequences have a common structural motif: the intron begins with GU and ends with AG. The consensus sequence at the $5'$ splice in vertebrates is AGGUAAGU, where the GU is invariant (**Figure 29.32**). At the $3'$ end of an intron, the consensus sequence is a stretch of 10 pyrimidines (U or C; termed the *polypyrimidine tract*), followed by any base, then by C, and ending with the invariant AG. Introns also have an important internal site located between 20 and 50 nucleotides upstream of the $3'$ splice site; it is called

the *branch site* for reasons that will be evident shortly. In yeast, the branch-site sequence is nearly always UACUAAC, whereas in mammals a variety of sequences are found.

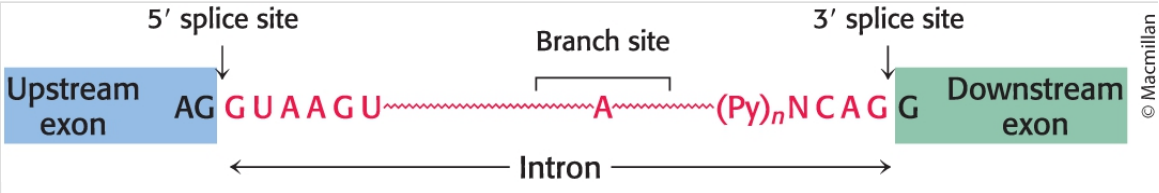

FIGURE 29.32 Splice sites are identified by conserved sequences. Consensus sequences for th 5′ splice site and the 3′ splice site are shown. Py stands for pyrimidine.

The 5′ and 3′ splice sites and the branch site are essential for determining where splicing takes place. Mutations in each of these three critical regions lead to aberrant splicing. Introns vary in length from 50 to 10,000 nucleotides, and so the splicing machinery may have to find the 3′ site several thousand nucleotides away. Specific sequences near the splice sites (in both the introns and the exons) play an important role in splicing regulation, particularly in designating splice sites when there are many alternatives. Researchers are currently attempting to determine the factors that contribute to splice-site selection for individual mRNAs. Despite our knowledge of splice-site sequences, predicting pre-mRNAs and their protein products from genomic DNA sequence information remains a challenge.

Splicing consists of two sequential transesterification reactions

The splicing of nascent mRNA molecules is a complicated process. It requires the cooperation of several small RNAs and proteins that form a large complex called a **spliceosome**. However, the chemistry of the splicing process is simple. Splicing begins with the cleavage of the phosphodiester bond between the upstream exon (exon 1) and the $5'$ end of the intron (**Figure 29.33**). The attacking group in this reaction is the $2'\text{–OH}$ group of an adenylate residue in the branch site. A $2'\text{–}5'$ phosphodiester bond is formed between this A residue and the $5'$ terminal phosphate of the intron in a transesterification reaction.

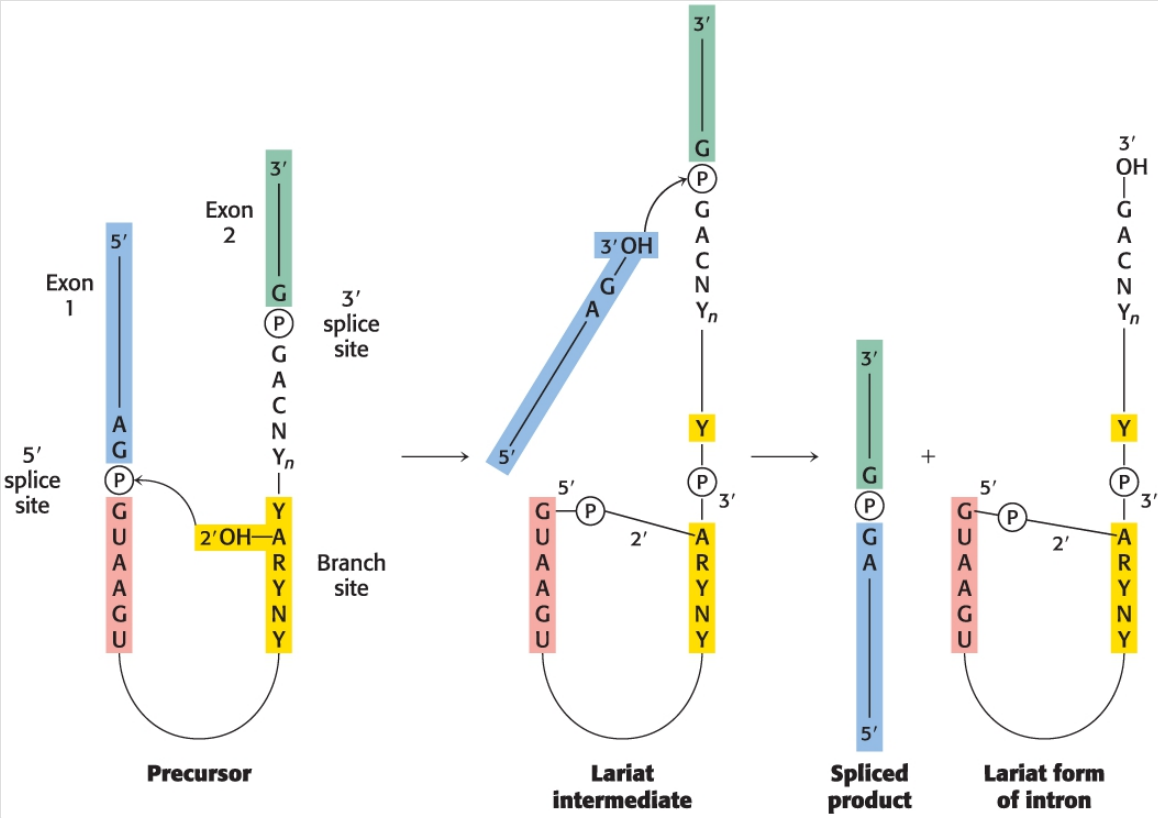

FIGURE 29.33 The splicing mechanism for mRNA precursors involves a lariat intermediate. Th upstream $(5')$ exon is shown in blue, the downstream $(3')$ exon in green, and the branch site i yellow. Y stands for a pyrimidine nucleotide, R for a purine nucleotide, and N for any nucleotide The $5'$ splice site is attacked by the $2'-OH$ group of the branch-site adenosine residue. The $3'$ splice site is attacked by the newly formed $3'-OH$ group of the upstream exon. The exons are joined, and the intron is released in the form of a lariat.

[Information from P. A. Sharp, *Cell* 42:397–408, 1985.]

Note that this adenylate residue is also joined to two other nucleotides by normal $3'-5'$ phosphodiester bonds (Figure 29.34). Hence, a branch is generated at this site, and a lariat (loop) intermediate is formed.

FIGURE 29.34 The splicing branch point has a unique structure. The structure of the branch point in the lariat intermediate in which the adenylate residue is joined to three nucleotides by phosphodiester bonds. The new $2'$-to-$5'$ linkage is shown in red, and the usual $3'$-to-$5'$ linkages are shown in blue.

The $3'-OH$ terminus of exon 1 then attacks the phosphodiester bond between the intron and exon 2. In another transesterification reaction, exons 1 and 2 become joined, and the intron is released in lariat form. Splicing is thus accomplished by two transesterification reactions rather than by hydrolysis followed by ligation.

Both transesterification reactions are promoted by the pair of bound magnesium ions, in reactions reminiscent of those for DNA and RNA polymerases. The first reaction generates a free $3'-OH$ group at the $3'$ end of exon 1, and the second reaction links this group to the $5'$-phosphate of exon 2. The number of phosphodiester bonds stays the same during these steps, which is crucial because it allows the splicing reaction itself to proceed without an energy source such as ATP or GTP.

Small nuclear RNAs in spliceosomes catalyze the splicing of mRNA precursors

The nucleus contains many types of small RNA molecules with fewer than 300 nucleotides, referred to as **small nuclear RNAs (snRNAs)**. A few of them — designated U1, U2, U4, U5, and U6 — are essential for splicing mRNA precursors. The secondary structures of these RNAs are highly conserved in organisms ranging from yeast to human beings.

snRNA molecules are associated with specific proteins to form complexes termed **small nuclear ribonucleoproteins (snRNPs)**; investigators often speak of them as "snurps" (**Table 29.3**). SnRNPs and their role in RNA splicing were discovered by Joan Steitz and Michael Lerner in 1980. One major piece of evidence suggesting a role for snRNPs in splicing was the base complementarity between portions of the U1 snRNA and the splice sites found in the unprocessed mRNAs.

TABLE 29.3 Roles of small nuclear ribonucleoproteins (snRNPs) in the splicing of mRNA precursors

snRNP	Size of snRNA (nucleotides)	Role
U1	165	Binds the 5′ splice site
U2	185	Binds the branch site
U5	116	Binds the 5′ splice site and then the 3′ splice site
U4	145	Masks the catalytic activity of U6
U6	106	Catalyzes splicing

SnRNPs associate with hundreds of other proteins (called *splicing factors*) and the mRNA precursors to form the large (60S) spliceosomes. The large and dynamic nature of the spliceosome made the determination of the detailed three-dimensional structure a great challenge. However, with the maturation of cryo-electron microscopy (Section 4.5), the structures of spliceosomes from several species in a number of different stages of their function have been determined (**Figure 29.35**). These structures have added to our understanding of the splicing process (**Figure 29.36**).

FIGURE 29.35 The spliceosome consists of proteins and RNAs. This three-dimensional structur displays one form of the spliceosome from a yeast determined by high-resolution cryo-electron microscopy. The key RNA components U2, U5, and U6 are shown in red, yellow, and blue, respectively.

FIGURE 29.36 The spliceosome promotes the splicing of some genes. (1) U1 binds the 5′ splice site and (2) U2 binds to the branch point. (3) A preformed U4-U5-U6 complex then joins the assembly to form the complete spliceosome. (4) The U6 snRNA re-folds and binds the 5′ splice site, displacing U1. Extensive interactions between U6 and U2 displace U4. (5) Then, in the first transesterification step, the branch-site adenosine attacks the 5′ splice site, making a lariat intermediate. (6) U5 holds the two exons in close proximity, and the second transesterification takes place, with the 5′ splice-site hydroxyl group attacking the 3′ splice site. These reactions result in the mature spliced mRNA and a lariat form of the intron bound by U2, U5, and U6.

[Information from T. Villa, J. A. Pleiss, and C. Guthrie, *Cell* 109:149–152, 2002.]

1. Splicing begins with the recognition of the 5′ splice site by the U1 snRNP. U1 snRNA contains a highly conserved six-nucleotide sequence, not covered by protein in the snRNP, that base-pairs to the 5′ splice site of the pre-mRNA. This binding initiates spliceosome assembly on the pre-mRNA molecule.

2. U2 snRNP then binds the branch site in the intron by base-pairing between a highly conserved sequence in U2 snRNA and the pre-mRNA. U2 snRNP binding requires ATP hydrolysis.

3. A preassembled U4-U5-U6 tri-snRNP joins this complex of U1, U2, and the mRNA precursor to form the spliceosome. This association also requires ATP hydrolysis. Experiments with a reagent that cross-links neighboring pyrimidines in base-paired regions revealed that in this assembly U5 interacts with exon sequences in the $5'$ splice site and subsequently with the $3'$ exon.

4. Next, U6 disengages from U4 and undergoes an intramolecular rearrangement that permits base-pairing with U2 as well as interaction with the $5'$ end of the intron, displacing U1 and U4 from the spliceosome. U4 serves as an inhibitor that masks U6 until the specific splice sites are aligned. The catalytic center includes two bound magnesium ions bound primarily by phosphate groups from the U6 RNA (**Figure 29.37**).

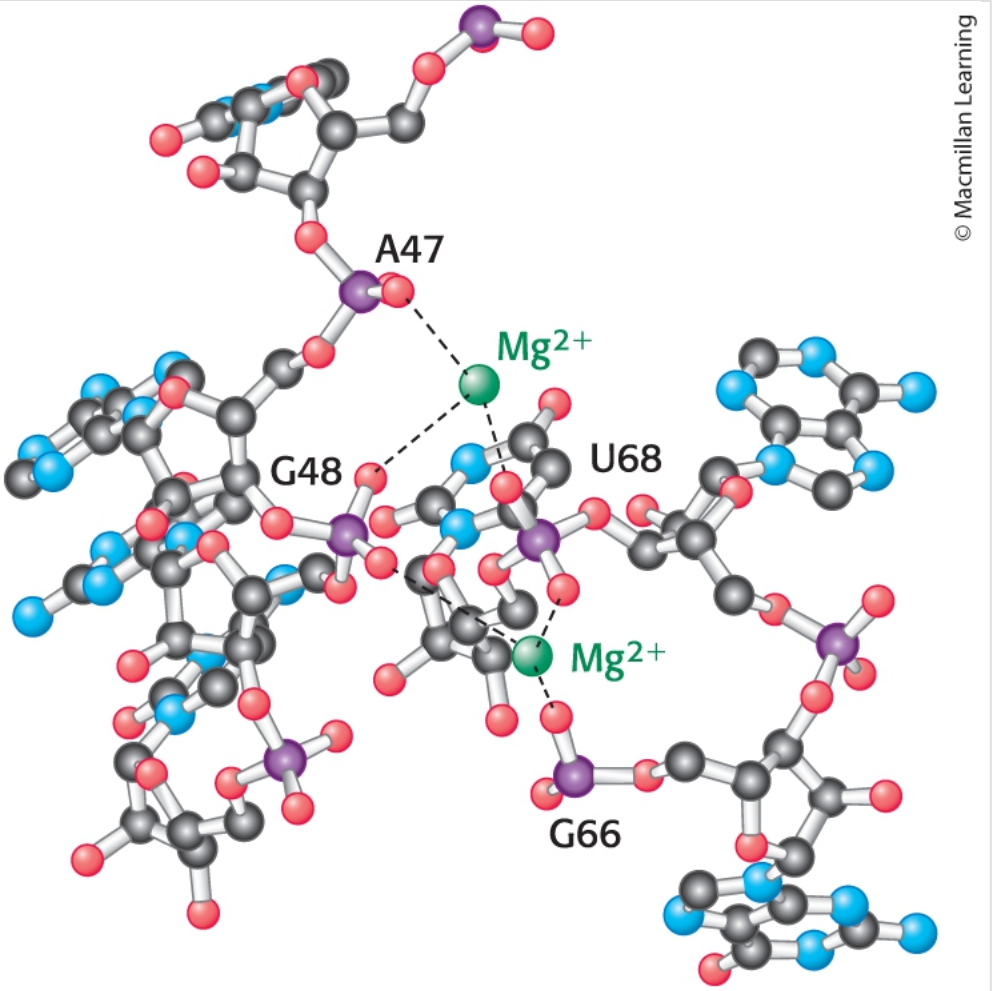

FIGURE 29.37 The spliceosome's catalytic center includes two key magnesium ions. These ions bind to the U6 RNA and promote the two transesterification reactions that are central to RNA splicing.

5. These rearrangements result in the first transesterification reaction, cleaving the 5′ exon and generating the lariat intermediate.

6. Further rearrangements of RNA in the spliceosome facilitate the second transesterification. In these rearrangements, U5 aligns the

free $5'$ exon with the $3'$ exon such that the $3'$-hydroxyl group of the $5'$ exon is positioned to make a nucleophilic attack on the $3'$ splice site to generate the spliced product. U2, U5, and U6 bound to the excised lariat intron are released, completing the splicing reaction.

Many of the steps in the splicing process require ATP hydrolysis. How is the free energy associated with ATP hydrolysis used to power splicing? To achieve the well-ordered rearrangements necessary for splicing, ATP-powered RNA helicases must unwind RNA helices and allow alternative base-pairing arrangements to form. Thus, two features of the splicing process are noteworthy. First, RNA molecules play key roles in directing the alignment of splice sites and in carrying out catalysis. Second, ATP-powered helicases unwind RNA duplex intermediates that facilitate catalysis and induce the release of snRNPs from the mRNA.

Mutations that affect pre-mRNA splicing cause disease

Mutations in either the pre-mRNA (cis-acting) or the splicing factors (trans-acting) can cause defective pre-mRNA splicing that manifests in disease. In fact, mutations affecting splicing have been estimated to cause at least 15% of all genetic diseases. We will look at two examples here.

First, we will consider the possible effects of cis-acting mutations on hemoglobin function. Mutations in the pre-mRNA cause some forms of thalassemia, a group of hereditary anemias characterized by the defective synthesis of hemoglobin (Section 3.3). Cis-acting mutations that cause aberrant splicing can occur at the $5'$ or $3'$ splice sites in

either of the two introns of the hemoglobin β chain or in its exons. Typically, mutations in the 5′ splice site alter that site such that the splicing machinery cannot recognize it, forcing the machinery to find another 5′ splice site in the intron and introducing the potential for a premature stop codon. The defective mRNA is normally degraded rather than translated. Alternatively, mutations in the intron itself may create a new 5′ splice site; in this case, either one of the two splice sites may be recognized (Figure 29.38). Consequently, some normal protein can be made, and so the disease is less severe.

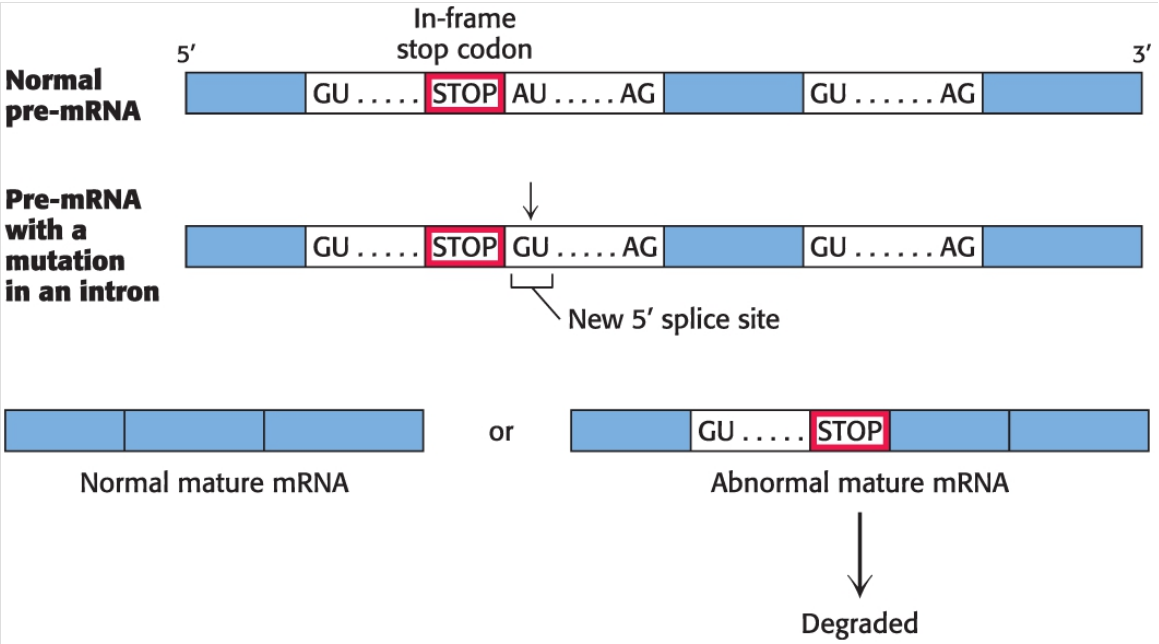

FIGURE 29.38 Mutations in splice sites can cause diseases such as thalassemia. An A-to-G mutation within the first intron of the gene for the human hemoglobin β chain creates a new 5′ splice site (GU). Both 5′ splice sites are recognized by the U1 snRNP; thus, splicing may sometimes create a normal mature mRNA and an abnormal mature mRNA that contains intron sequences. The normal mature mRNA is translated into a hemoglobin β chain. Because it includes intron sequences, the abnormal mature mRNA now has a premature stop codon and is degraded.

Second, we will consider the possible effects of trans-acting mutations on eyesight. Disease-causing mutations may also appear in splicing factors. Retinitis pigmentosa is a disease of acquired blindness, first described in 1857, with an incidence of 1/3500. About 5% of the autosomal dominant form of retinitis pigmentosa is likely due to mutations in the hPrp8 protein, a pre-mRNA splicing factor that is a component of the U4-U5-U6 tri-snRNP. How a mutation in a splicing factor that is present in all cells causes disease only in the retina is not clear; nevertheless, retinitis pigmentosa is a good example of how mutations that disrupt spliceosome function can cause disease.

Most human pre-mRNAs can be spliced in alternative ways to yield different proteins

As a result of **alternative splicing**, different combinations of exons from the same gene may be spliced into a mature RNA, producing distinct forms of a protein for specific tissues, developmental stages, or signaling pathways. What controls which splicing sites are selected? The selection is determined by the binding of trans-acting splicing factors to cis-acting sequences in the pre-mRNA. Most alternative splicing leads to changes in the coding sequence, resulting in proteins with different functions.

Alternative splicing provides a powerful mechanism for generating protein diversity. It expands the versatility of genomic sequences through combinatorial control. Consider a gene with five positions at which splicing can take place. With the assumption that these

alternative splicing pathways can be regulated independently, a total of $2^5 = 32$ different mRNAs can be generated.

Sequencing of the human genome has revealed that most pre-mRNAs are alternatively spliced, leading to a much greater number of proteins than would be predicted from the number of genes. An example of alternative splicing leading to the expression of two different proteins, each in a different tissue, is provided by the gene encoding both calcitonin and calcitonin-gene-related peptide (CGRP; Figure 29.39). In the thyroid gland, the inclusion of exon 4 in one splicing pathway produces calcitonin, a peptide hormone that regulates calcium and phosphorus metabolism. In neuronal cells, the exclusion of exon 4 in another splicing pathway produces CGRP, a peptide hormone that acts as a vasodilator. A single pre-mRNA thus yields two very different peptide hormones, depending on cell type.

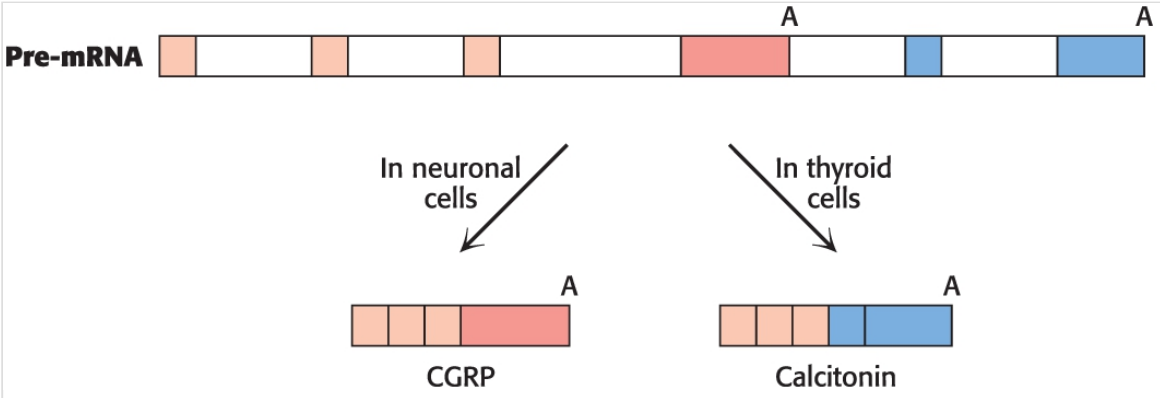

FIGURE 29.39 Alternative splicing produces different mRNAs. In human beings, two very different hormones are produced from a single calcitonin/CGRP pre-mRNA. Alternative splicing produces the mature mRNA for either calcitonin or CGRP (calcitonin-gene-related protein), depending on the cell type in which the gene is expressed. Each alternative transcript incorporates one of two alternative polyadenylation signals (A) present in the pre-mRNA.

In the above example, only two proteins result from alternative splicing; however, in other cases, many more can be produced. An extreme

example is the *Drosophila* pre-mRNA that encodes DSCAM, a neuronal protein affecting axon connectivity. Alternative splicing of this pre-mRNA has the potential to produce 38,016 different combinations of exons, a greater number than the total number of genes in the *Drosophila* genome. However, only a fraction of these potential mRNAs appear to be produced, owing to regulatory mechanisms that are not yet well understood.

Several human diseases that can be attributed to defects in alternative splicing are listed in **Table 29.4**. Further understanding of alternative splicing and the mechanisms of splice-site selection will be crucial to understanding how the proteome represented by the human genome is expressed.

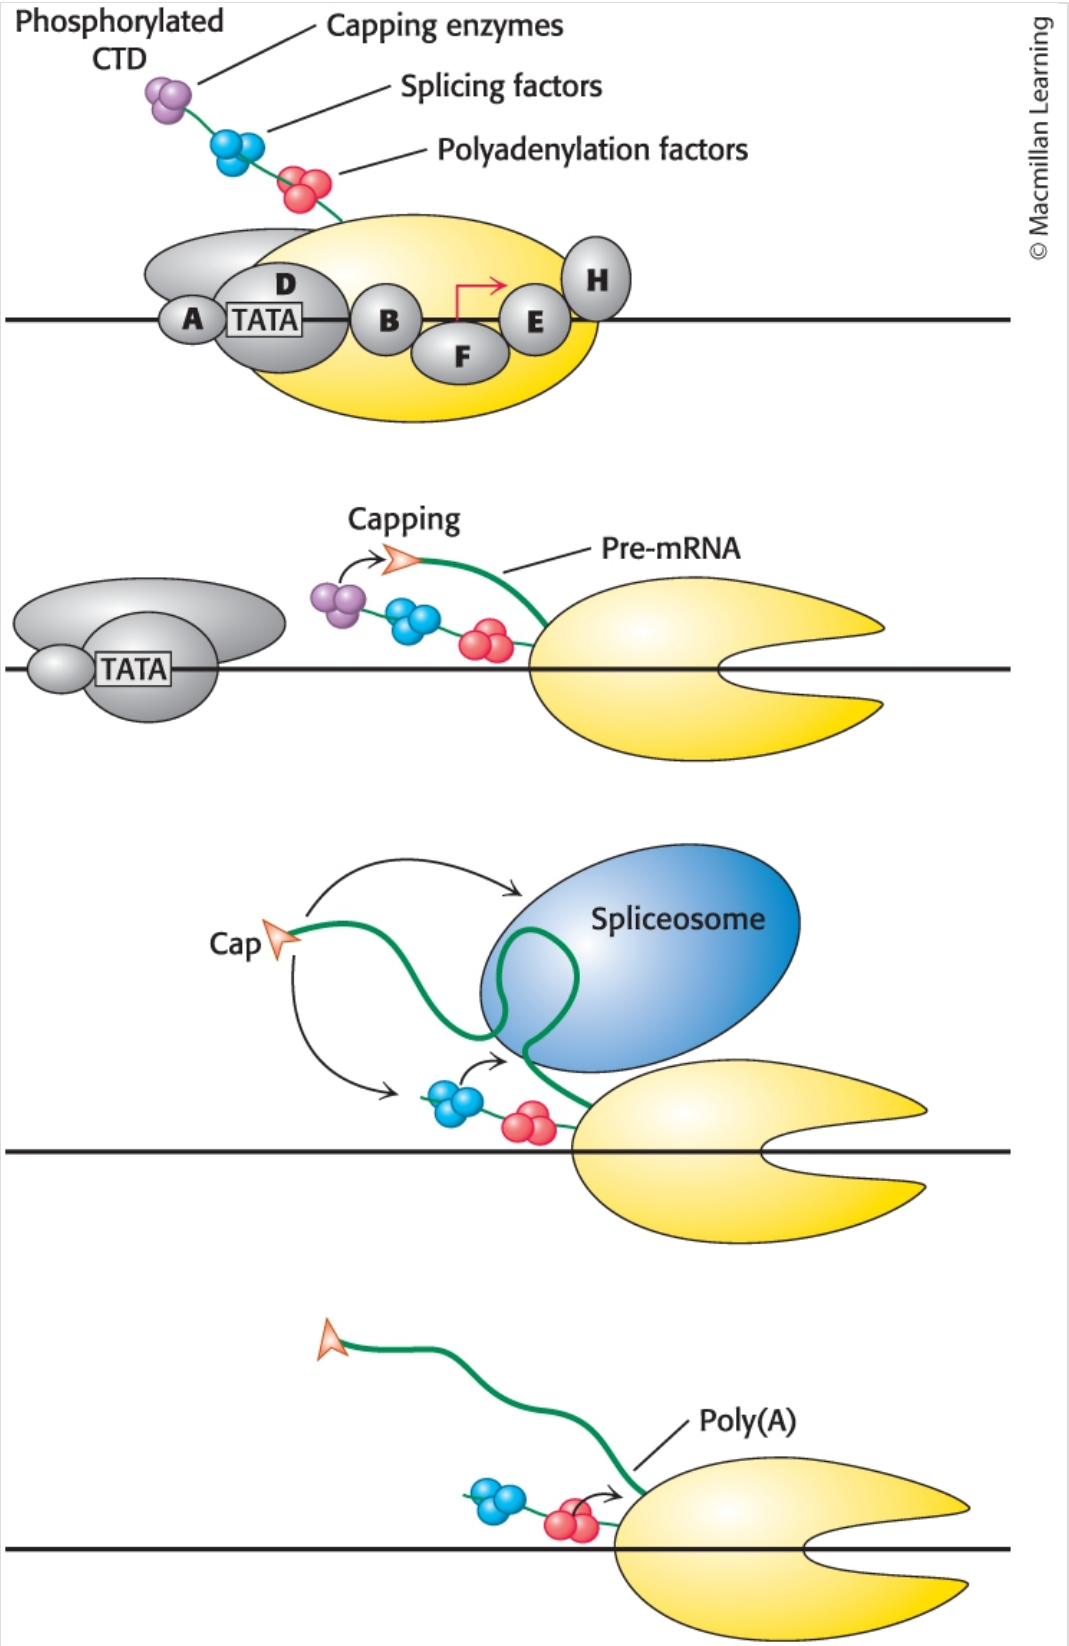

TABLE 29.4 Selected human disorders attributed to defects in alternative splicing

Disorder	Gene or its product
Acute intermittent porphyria	Porphobilinogen deaminase
Breast and ovarian cancer	*BRCA1*
Cystic fibrosis	*CFTR*
Frontotemporal dementia	T protein
Hemophilia A	Factor VIII
HGPRT deficiency (Lesch–Nyhan syndrome)	Hypoxanthine-guanine phosphoribosyltransferase
Leigh encephalomyelopathy	Pyruvate dehydrogenase E1 α

Severe combined immunodeficiency	Adenosine deaminase
Spinal muscle atrophy	*SMN1* or *SMN2*

Transcription and mRNA processing are coupled

Although we have described the transcription and processing of mRNAs as separate events in gene expression, experimental evidence suggests that the two steps are coordinated by the carboxyl-terminal domain of RNA polymerase II. We have seen that the CTD consists of a unique repeated seven-amino-acid sequence, YSPTSPS. Either S_2, S_5, or both may be phosphorylated in the various repeats. The phosphorylation state of the CTD is controlled by a number of kinases and phosphatases and leads the CTD to bind many of the proteins having roles in RNA transcription and processing. The CTD contributes to efficient transcription by recruiting certain proteins to the pre-mRNA (**Figure 29.40**). These proteins include:

© Macmillan Learning

FIGURE 29.40 The CTD couples transcription to pre-mRNA processing. The transcription factor TFIIH phosphorylates the carboxyl-terminal domain (CTD) of RNA polymerase II, signaling the transition from transcription initiation to elongation. The phosphorylated CTD binds factors required for pre-mRNA capping, splicing, and polyadenylation. These proteins are brought in close proximity to their sites of action on the nascent pre-mRNA as it is transcribed during elongation.

[Information from P. A. Sharp, *Trends in Biochemical Sciences* 30:279–281, 2005.]

1. Capping enzymes, which methylate the $5'$ guanine on the pre-mRNA immediately after transcription begins
2. Components of the splicing machinery, which initiate the excision of each intron as it is synthesized
3. An endonuclease that cleaves the transcript at the poly(A) addition site, creating a free $3'-OH$ group that is the target for $3'$ adenylation

These events take place sequentially, directed by the phosphorylation state of the CTD.

Small regulatory RNAs are cleaved from larger precursors

Cleavage plays a role in the processing of small single-stranded RNAs (approximately 20–23 nucleotides) called **microRNAs**. MicroRNAs play key roles in gene regulation in eukaryotes, as we shall see in Chapter 31. They are generated from initial transcripts produced by RNA polymerase II and, in some cases, RNA polymerase III. These transcripts fold into hairpin structures that are cleaved by specific nucleases at various stages (**Figure 29.41**). The final single-stranded

RNAs are bound by regulatory proteins, where the RNAs help target the regulation of specific genes.

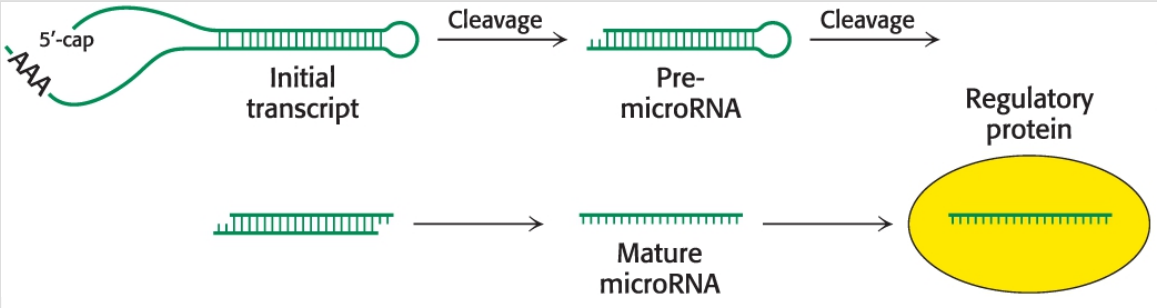

FIGURE 29.41 Small regulatory RNAs are involved in gene regulation. The initial transcription product is first cleaved to a small double-stranded RNA called a pre-microRNA. One of the strands of the pre-microRNA, the mature microRNA, is then bound by a regulatory protein.

RNA editing can lead to specific changes in mRNA

Remarkably, the amino acid sequence information encoded by some mRNAs is altered after transcription. This phenomenon is referred to as **RNA editing**, a posttranscriptional change in the nucleotide sequence of RNA that is caused by processes other than RNA splicing. RNA editing is prominent in some systems; next, we will consider three examples.

RNA editing is key to the process of lipid transport by apolipoprotein B (apo B). Apo B plays an important role in the transport of triacylglycerols and cholesterol by forming an amphipathic spherical shell around the lipids carried in lipoprotein particles (Section 27.3). Apo B exists in two forms, a 512-kDa *apo B-100* and a 240-kDa *apo B-48*. The larger form, synthesized by the liver, participates in the transport of lipids synthesized in the cell. The smaller form, synthesized by the

small intestine, carries dietary fat in the form of chylomicrons. Apo B-48 contains the 2152 N-terminal residues of the 4536-residue apo B-100. This truncated molecule can form lipoprotein particles but cannot bind to the low-density-lipoprotein receptor on cell surfaces.

What is the relationship between these two forms of apo B? Experiments revealed that a totally unexpected mechanism for generating diversity is at work: the changing of the nucleotide sequence of mRNA *after* its synthesis (**Figure 29.42**). A specific cytidine residue of mRNA is deaminated to uridine, which changes the codon at residue 2153 from CAA (Gln) to UAA (stop). The deaminase that catalyzes this reaction is present in the small intestine, but not in the liver, and is expressed only at certain developmental stages.

FIGURE 29.42 RNA editing alters the coding sequence of mRNAs. Enzyme-catalyzed deamination of a specific cytidine residue in the mRNA for apolipoprotein B-100 changes a codon for glutamine (CAA) to a stop codon (UAA). Apolipoprotein B-48, a truncated version of the protein lacking the LDL receptor-binding domain, is generated by this posttranscriptional change in the mRNA sequence.

[Information from P. Hodges and J. Scott, *Trends in Biochemical Sciences* 17:77, 1992.]

RNA editing also plays a role in the regulation of postsynaptic receptors. Glutamate opens cation-specific channels in the vertebrate central nervous system by binding to receptors in postsynaptic membranes. RNA editing changes a single glutamine codon (CAG) in the mRNA for the glutamate receptor to the codon for arginine (CGG). The substitution of Arg for Gln in the receptor prevents Ca^{2+}, but not Na^{+}, from flowing through the channel.

In trypanosomes (parasitic protozoans), a different kind of RNA editing markedly changes several mitochondrial mRNAs. Nearly half the uridine residues in these mRNAs are inserted by RNA editing. A guide RNA molecule identifies the sequences to be modified, and a poly(U) tail on the guide RNA donates uridine residues to the mRNAs undergoing editing.

DNA sequences evidently do not always faithfully represent the sequence of encoded proteins; crucial functional changes to mRNA can take place. RNA editing is likely much more common than was formerly thought. The chemical reactivity of nucleotide bases — including the susceptibility to deamination that necessitates complex DNA-repair mechanisms — has been harnessed as an engine for generating molecular diversity at the RNA and, hence, protein levels.

29.5 The Discovery of Catalytic RNA Revealed a Unique Splicing Mechanism

RNAs form a surprisingly versatile class of molecules. As we have seen, splicing is catalyzed largely by RNA molecules, with proteins playing a secondary role. RNA is also a key component of ribonuclease P, which catalyzes the maturation of tRNA by endonucleolytic cleavage of nucleotides from the $5'$ end of the precursor molecule. Finally, as we shall see in Chapter 30, the RNA component of ribosomes is the catalyst that carries out protein synthesis.

Some RNAs can promote their own splicing

The versatility of RNA first became clear from observations of the processing of ribosomal RNA in a single-cell eukaryote, a ciliated protozoan in the genus *Tetrahymena*. In *Tetrahymena*, a 414-nucleotide intron is removed from a 6.4-kb precursor to yield the mature 26S rRNA molecule.

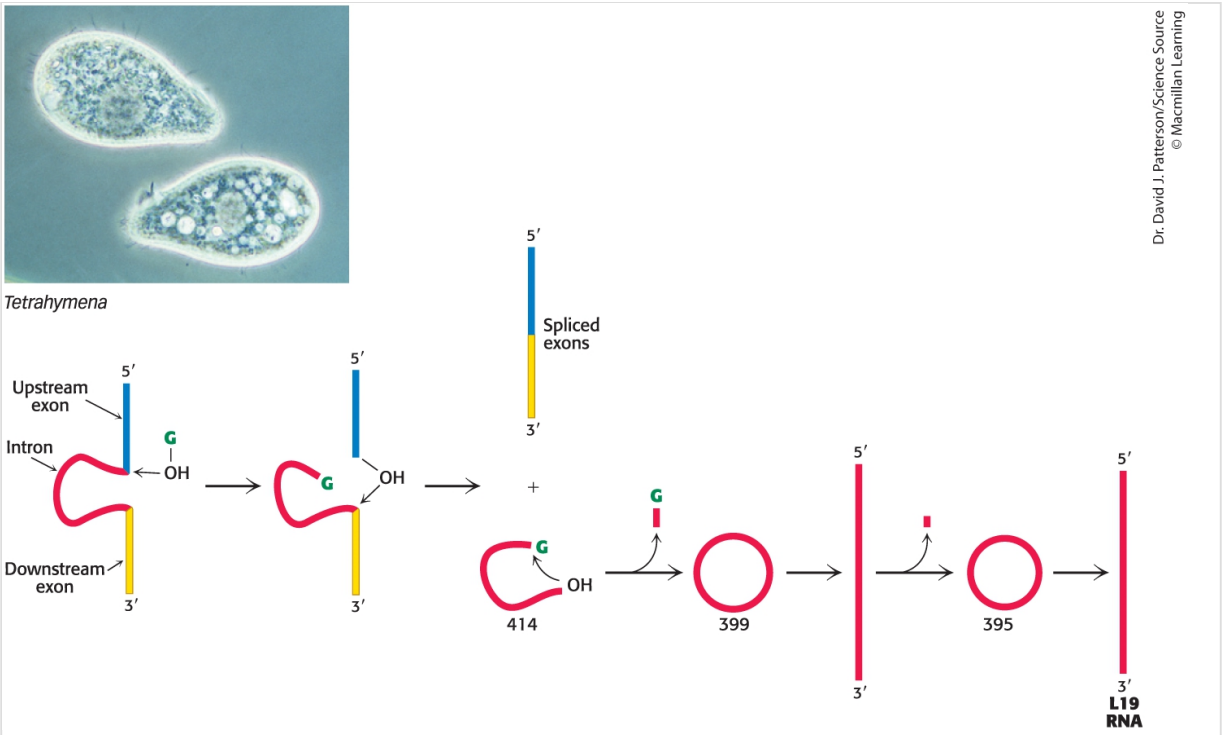
In an elegant series of studies of this splicing reaction, Thomas Cech and his coworkers established that, in the absence of protein, the RNA spliced itself to precisely excise the intron. Indeed, the RNA alone is catalytic and, under certain conditions, is thus a **ribozyme**. More than 1500 similar introns have since been found in species as widely dispersed as bacteria and eukaryotes, though not in vertebrates. Collectively, they are referred to as group I **self-splicing introns**.

Glenn Asakawa, University of Colorado Boulder

THOMAS CECH Fascinated by the structure of chromosomes, Thomas Cech pursued this topic as a graduate student and postdoctoral fellow. He then accompanied his wife, Dr. Carol Cech, to the University of Colorado in Boulder (UCB), where they had both been offered faculty positions. They had met in chemistry class while they were undergraduate students at Grinnell College. At UCB, Dr. Cech set out to purify enzymes involved in the splicing of a particular RNA molecule, but he and his

coworkers soon discovered that the RNA molecule spliced itself. This fundamental discovery of RNA catalysis, which changed our view of both modern biochemistry and our evolutionary past, was recognized with the Nobel Prize in Chemistry in 1989. Dr. Cech has remained at UCB, teaching with infectious enthusiasm throughout his career. He also served as an investigator (and president from 2000 to 2009) of the Howard Hughes Medical Institute (HHMI), a leading private funder of biomedical research.

The self-splicing reaction in the group I intron requires an added guanosine nucleotide (**Figure 29.43**). Nucleotides were originally included in the reaction mixture because it was thought that ATP or GTP might be needed as an energy source. Instead, the nucleotides were found to be necessary as cofactors. The required cofactor proved to be a guanosine unit, in the form of guanosine, GMP, GDP, or GTP. G (denoting any one of these species) serves not as an energy source but as an attacking group that becomes transiently incorporated into the RNA. G binds to the RNA and then attacks the $5'$ splice site to form a phosphodiester bond with the $5'$ end of the intron. This transesterification reaction generates a $3'-OH$ group at the end of the upstream exon. This $3'-OH$ group then attacks the $3'$ splice site in a second transesterification reaction that joins the two exons and leads to the release of the 414-nucleotide intron.



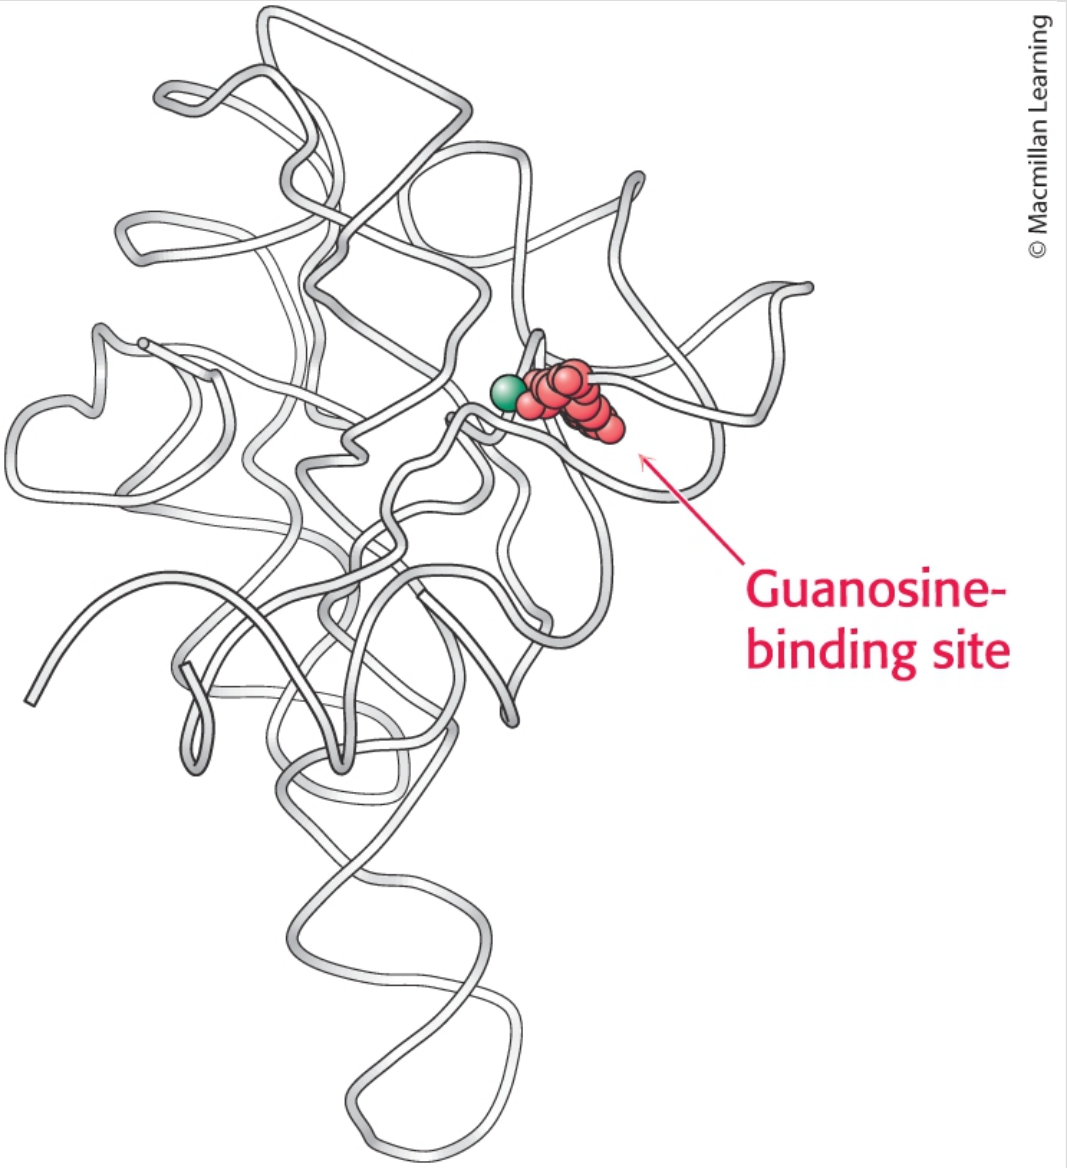


FIGURE 29.43 Some introns are capable of self-splicing. A ribosomal RNA precursor representative of the group I introns, from the protozoan *Tetrahymena*, splices itself in the presence of a guanosine cofactor (G, shown in green). A 414-nucleotide intron (red) is released in the first splicing reaction. This intron then splices itself twice again to produce a linear RNA that has lost a total of 19 nucleotides. This L19 RNA is catalytically active.

[Information from T. Cech, RNA as an enzyme. Copyright © 1986 by Scientific American, Inc. All rights reserved.]

Self-splicing depends on the structural integrity of the RNA precursor. Much of the group I intron is needed for self-splicing. This molecule, like many RNAs, has a folded structure formed by many double-helical stems and loops (Figure 29.44), with a well-defined pocket for binding the guanosine. Examination of the three-dimensional structure of a catalytically active group I intron determined by x-ray crystallography reveals the coordination of magnesium ions in the active site analogous to that observed in protein enzymes such as DNA polymerase.

INTERACT with this model in Achieve

Analysis of the base sequence of the rRNA precursor suggested that the splice sites are aligned with the catalytic residues by base-pairing

between the *internal guide sequence* (IGS) in the intron and the $5'$ and $3'$ exons (**Figure 29.45**). The IGS first brings together the guanosine cofactor and the $5'$ splice site so that the $3'-OH$ group of G can make a nucleophilic attack on the phosphorus atom at this splice site. The IGS then holds the downstream exon in position for attack by the newly formed $3'-OH$ group of the upstream exon. A phosphodiester bond is formed between the two exons, and the intron is released as a linear molecule. Like catalysis by protein enzymes, self-catalysis of bond formation and breakage in this rRNA precursor is highly specific.

FIGURE 29.45 The catalytic mechanism of the group I self-splicing intron includes a series of transesterification reactions.

[Information from T. Cech, RNA as an enzyme. Copyright © 1986 by Scientific American, Inc. All rights reserved.]

The finding of enzymatic activity in the self-splicing intron and in the RNA component of RNase P has opened new areas of inquiry and changed the way in which we think about molecular evolution. As mentioned in an earlier chapter, the discovery that RNA can be a catalyst as well as an information carrier suggests that an RNA world may have existed early in the evolution of life, before the appearance of DNA and protein.

Messenger RNA precursors in the mitochondria of yeast and fungi also undergo self-splicing, as do some RNA precursors in the chloroplasts of unicellular organisms such as *Chlamydomonas*. Self-splicing reactions can be classified according to the nature of the unit that attacks the upstream splice site. Group I self-splicing is mediated by a guanosine cofactor, as in *Tetrahymena*. The attacking moiety in group II splicing is the $2'-OH$ group of a specific adenylate of the intron (**Figure 29.46**).

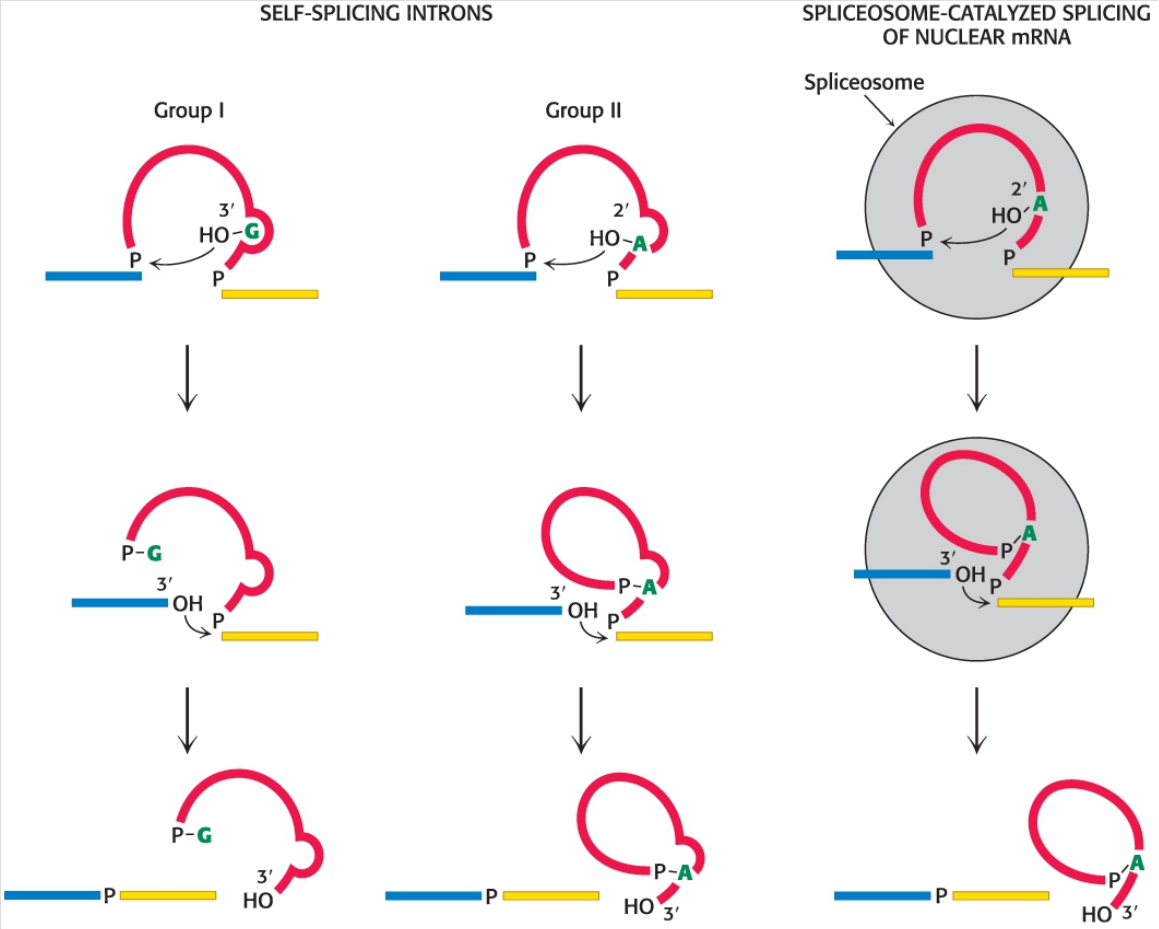

FIGURE 29.46 In self-splicing mechanisms, the catalytic site is formed by the intron itself. The exons being joined are shown in blue and yellow, and the attacking unit is shown in green. The catalytic site is formed by the intron itself (red) in group I and group II splicing. In contrast, the splicing of nuclear mRNA precursors is catalyzed by snRNAs and their associated proteins in the spliceosome.

[Information from P. A. Sharp, *Science* 235:766–771, 1987.]

Group I and group II self-splicing resembles spliceosome-catalyzed splicing in two respects. First, in the initial step, a ribose hydroxyl group attacks the $5'$ splice site. The newly formed $3'\text{–OH}$ terminus of the upstream exon then attacks the $3'$ splice site to form a phosphodiester bond with the downstream exon. Second, both reactions are

transesterifications in which the phosphate moieties at each splice site are retained in the products. The number of phosphodiester bonds stays constant.

Group II splicing is like the spliceosome-catalyzed splicing of mRNA precursors in several additional ways. First, the attack at the $5'$ splice site is carried out by a part of the intron itself (the $2'-OH$ group of adenosine) rather than by an external cofactor (G). Second, the intron is released in the form of a lariat. Third, in some instances, the group II intron is transcribed in pieces that assemble through hydrogen bonding to the catalytic intron, in a manner analogous to the assembly of the snRNAs in the spliceosome.

The similarities in mechanism have led to the suggestion that the spliceosome-catalyzed splicing of mRNA precursors evolved from RNA-catalyzed self-splicing. Group II splicing may well be an intermediate between group I splicing and the splicing in the nuclei of higher eukaryotes. A major step in this transition was the transfer of catalytic power from the intron itself to other molecules. The formation of spliceosomes gave genes a new freedom because introns were no longer constrained to provide the catalytic center for splicing. Another advantage of external catalysts for splicing is that they can be more readily regulated.

However, it is important to note that similarities do not establish ancestry. The similarities between group II introns and mRNA splicing may be a result of convergent evolution. Perhaps there are only a limited number of ways to carry out efficient, specific intron excision. The determination of whether these similarities stem from ancestry or from chemistry will require expanding our understanding of RNA biochemistry.

Self-Check Question

Compare and contrast the three different splicing mechanisms that have been identified.

RNA enzymes can promote many reactions, including RNA polymerization

In this chapter, we have discussed the role of many different RNA molecules, including those that promote reactions such as splicing. In Chapter 30, we will discuss the key roles that RNAs play in protein biosynthesis, and we will see that ribosomal RNAs have a significant role in the catalysis of peptide bonds.

While the ribosomal RNAs have a role in the polymerization of amino acids into proteins, some RNAs are also capable of catalyzing the polymerization of other RNA molecules or even themselves. In vitro experiments have identified the possibility of self-ligating ribozymes: RNA molecules capable of joining other, short RNAs to their own end. The ability of RNAs to direct the synthesis of other catalytic molecules gives us a glimpse into how, in a primordial RNA world, ribozymes may have accelerated chemical reactions critical for life.

Chapter 29 Summary

29.1 RNA Molecules Play Different Roles, Primarily in Gene Expression

- RNA molecules are integral to many different cellular functions; for example, protein biosynthesis.
- Some RNAs can direct their own modification.

29.2 RNA Polymerases Catalyze Transcription

- RNA polymerases synthesize all cellular RNA molecules according to instructions given by DNA templates.
- The direction of RNA synthesis is $5' \rightarrow 3'$, as in DNA synthesis.

  RNA polymerases, unlike DNA polymerases, do not need a primer.
- RNA polymerase in *E. coli* is a multisubunit enzyme. The subunit composition of the $\sim 500\text{-kDa}$ holoenzyme is $\alpha_2\beta\beta'\omega\sigma$ and that of the core enzyme is $\alpha_2\beta\beta'\omega$.
- Transcription is initiated at promoter sites.
- The σ subunit enables the holoenzyme to recognize promoter sites. The σ subunit usually dissociates from the holoenzyme after the initiation of the new chain.
- Elongation takes place at transcription bubbles that move along the DNA template at a rate of about 50 nucleotides per second.
- The nascent RNA chain contains stop signals that end transcription. One stop signal is an RNA hairpin, which is followed by several U residues. A different stop signal is read by the *rho* protein, an ATPase.
- In *E. coli,* precursors of transfer RNA and ribosomal RNA are cleaved and chemically modified after transcription, whereas

messenger RNA is used unchanged as a template for protein synthesis.

29.3 Transcription Is Highly Regulated

- Bacteria use alternate σ factors to adjust the transcription levels of various genes in response to external stimuli.
- Some genes are regulated by riboswitches, structures that form in RNA transcripts and bind specific metabolites.
- Eukaryotic DNA is tightly bound to basic proteins called histones; the combination is called chromatin. DNA wraps around an octamer of core histones to form a nucleosome.
- There are three types of eukaryotic RNA polymerases in the nucleus, where transcription takes place: RNA polymerase I makes ribosomal RNA precursors, II makes messenger RNA precursors, and III makes transfer RNA precursors.
- Eukaryotic promoters are composed of several different elements. The activity of many promoters is greatly increased by enhancer sequences that have no promoter activity of their own.

29.4 Some RNA Transcription Products Are Processed

- The $5'$ ends of mRNA precursors become capped and methylated during transcription.
- A $3'$ poly(A) tail is added to most mRNA precursors after the nascent chain has been cleaved by an endonuclease.
- The splicing of mRNA precursors is carried out by spliceosomes, which consist of small nuclear ribonucleoproteins. Splice sites in mRNA precursors are specified by sequences at ends of introns and by branch sites near the $3'$ ends of introns.

- RNA editing alters the nucleotide sequence of some mRNAs, such as the one for apolipoprotein B.

29.5 The Discovery of Catalytic RNA Revealed a Unique Splicing Mechanism

- Some RNA molecules undergo self-splicing in the absence of protein.
- Spliceosome-catalyzed splicing may have evolved from self-splicing.
- The discovery of catalytic RNA has opened new vistas in our exploration of early stages of molecular evolution and the origins of life.

Problems

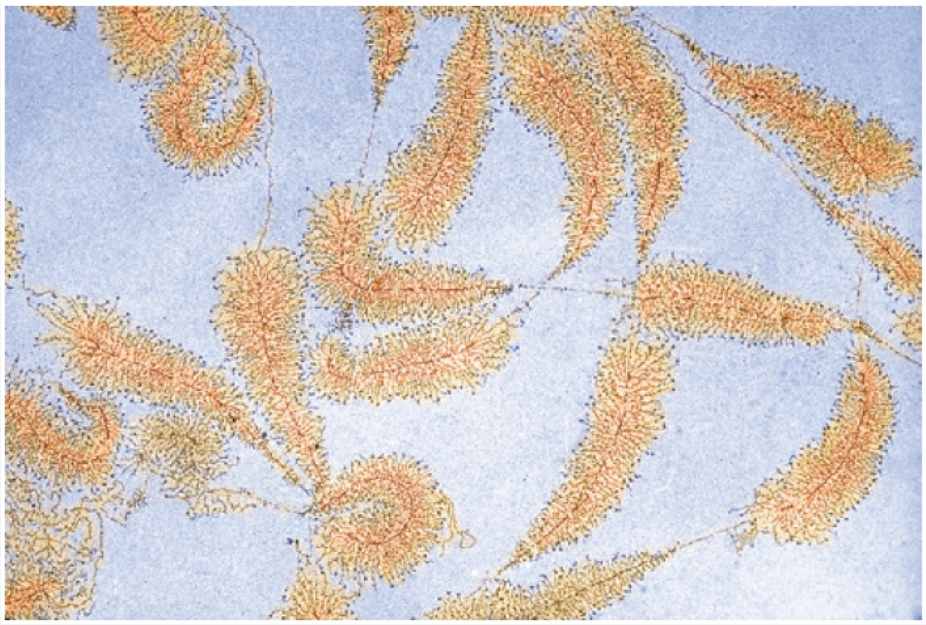
1. Why is RNA synthesis not as carefully monitored for errors as is DNA synthesis? 1, 2

2. What are the functions of RNA polymerases? Select all that apply. 1, 3

a. Polymerization of polypeptides from RNA transcripts
b. Elongation of ribosomal RNA (rRNA)
c. Initiation of transcription at promoter sites
d. Elongation of messenger RNA (mRNA) transcripts
e. Initiation of translation from RNA transcripts

3. The overall structures of RNA polymerase and DNA polymerase are very different, yet their active sites show considerable similarities. What do the similarities suggest about the evolutionary relationship between these two important enzymes? 1

4. The sequence of part of an mRNA transcript is



$$5'-\text{AUGGGGAACAGCAAGAGUGGGGCCCUGUCCAAGGAG}-3'$$

What is the sequence of the DNA coding strand? Of the DNA template strand? 1

5. Sigma protein by itself does not bind to promoter sites. Predict the effect of a mutation enabling σ to bind to the -10 region in the absence of other subunits of RNA polymerase. 2

6. The molecular weight of an amino acid is approximately 110 Da, and *E. coli* RNA polymerase has a transcription rate of approximately 5050 nucleotides per second. What is the minimum length of time required by *E.coli* polymerase for the synthesis of an mRNA encoding a 100-kDa protein? Round your answer to the nearest whole number. 1

7. The autoradiograph below depicts several bacterial genes undergoing transcription. Identify the DNA. What are the strands of increasing length? Where is the beginning of transcription? The end of transcription? What can you conclude about the number of enzymes participating in RNA synthesis on a given gene? 2

8. Fill in the blanks to complete the statements about the capping process: Capping occurs at the **(a)** _____ end of the mRNA. The nucleoside that is added is **(b)** _____. The nucleoside is connected to the mRNA through a **(c)** _____ linkage. The added nucleoside is modified by methylation at **(d)** _____ atom. The mRNA is further modified by methylation of ribose residues at the **(e)** _____ -hydroxyl position. 3

9. Suppose that RNA polymerase was transcribing a eukaryotic gene with several introns all contained within the coding region. In what order would the RNA polymerase encounter the elements in the DNA sequence of the gene, from earliest to latest? 2

a. Splice donor site
b. 3′ untranslated region (UTR)
c. Transcription start site
d. Translation start codon

e. 5′ untranslated region (UTR)

f. Translation termination codon

10. For the three genes shown below, transcription occurs from right to left for gene *A* and gene *B*, whereas transcription occurs from left to right for gene *C*. Identify which strand (top or bottom) is the template strand for each gene. 1

11. Which would you expect to have more types of **σ** factors: a free–living prokaryote in a fluctuating environment, or a prokaryote in a relatively stable environment with adequate nutrients? Why? 2

12. The three different eukaryotic RNA polymerases perform different functions and can be distinguished experimentally by their sensitivity to the toxin α–amanitin. Match the appropriate function and α–amanitin sensitivity to each RNA polymerase. Each function and sensitivity will be used only once. 3

Type of polymerase	Function and sensitivity
1. RNA polymerase I	1. Inhibited by high concentrations of α-amanitin

2. RNA polymerase II	2. Not inhibited by α-amanitin
	3. Synthesizes pre-ribosomal RNA
3. RNA polymerase III	4. Synthesizes primarily tRNA and small RNAs
	5. Synthesizes mostly pre-messenger RNA
	6. Inhibited by low concentrations of α-amanitin

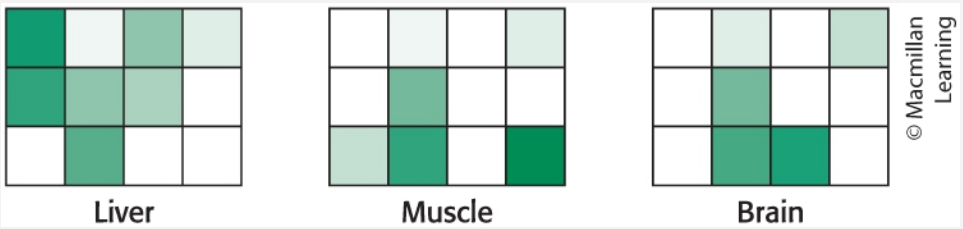
---

13. Fill in the blanks to complete the statements about ribosomal RNA processing in eukaryotes: RNA polymerase I generates the **(a)** _____ kb rRNA transcript, which has a sedimentation coefficient of **(b)** _____. The RNA transcript is processed in a series of steps to yield three smaller rRNA molecules: **(c)** _____. The **(d)** _____ rRNA assembles with the **€** _____ rRNA, the **(f)** _____ rRNA, and proteins into **(g)** _____ ribosomal subunits. The 5S rRNA genes are transcribed by **(h)** _____. The 18S rRNA is associated with **(i)** _____ ribosomal subunits. 3

14. Which of the following statements regarding promoters is correct? Select all that apply. 1, 4, 6

a. In prokaryotes, the promoter is recognized by general transcription factors, which recruit the RNA polymerase holoenzyme.
b. In both prokaryotes and eukaryotes, the promoter is located in the 5′ direction, upstream from the transcription start site.
c. In eukaryotes, the promoter attracts the small and large ribosomal subunits with the help of initiation factors.

d. In prokaryotes, the promoter contains a -35 and -10 region upstream of the transcription start site.
e. In eukaryotes, the promoter recruits the preinitiation complex, which includes the TATA–binding protein.



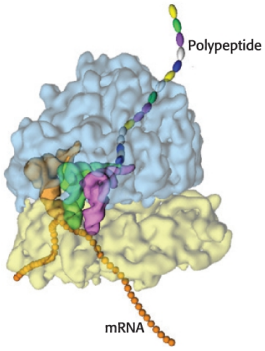
15. Match each RNA type with its appropriate function. Each function will be used only once. 3

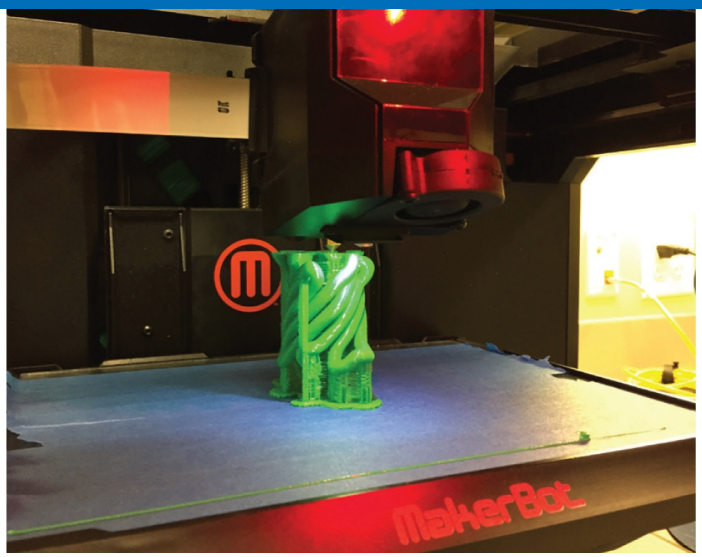
Type of RNA	Function
1. small nuclear RNA (snRNA)	1. Helps to regulate the expression of specific genes
2. ribosomal RNA (rRNA)	2. Carries genetic information to ribosomes for protein synthesis
3. transfer RNA (tRNA)	3. Combines with proteins to form ribosomes
4. messenger RNA (mRNA)	4. Brings amino acids to sites of mRNA during protein synthesis
5. microRNA (miRNA)	5. Involved in the splicing process when mRNA is formed

16. A gene contains eight sites where alternative splicing is possible. Assuming that the splicing pattern at each site is independent of that at all other sites, how many splicing products are possible? 5

17. What processes considered in this chapter make the proteome more complex than the genome? What processes might further enhance this complexity? 5

18. Nuclei were isolated from brain, liver, and muscle. The nuclei were then incubated with $\alpha-[^{32}P]$ UTP under conditions that allow RNA synthesis, except that an inhibitor of RNA initiation was present. The radioactive RNA was isolated and annealed to various DNA sequences that had been attached to a gene chip. In the adjoining graphs, the intensity of the shading indicates roughly how much mRNA was attached to each DNA sequence. 4





a. Why does the intensity of hybridization differ between genes?
b. What is the significance of the fact that some of the RNA molecules display different hybridization patterns in different tissues?
c. Some genes are expressed in all three tissues. What is the nature of these genes?
d. Suggest a reason why an initiation inhibitor was included in the reaction mixture.

19. Eukaryotic messenger RNA can undergo postsynthetic processing after transcription and before translation. One of the processing steps is splicing, where portions of the RNA are removed and the remaining RNA are joined together. Classify the statements regarding mRNA splicing as true or false. 5

a. Splicing occurs while the mRNA is attached to the nucleosome.
b. One mRNA can sometimes code for more than one protein by splicing at alternative sites.
c. Splicing occurs while the mRNA is still in the nucleus.
d. In splicing, intron sequences are removed from the mRNA in the form of lariats (loops) and are degraded.
e. Splicing of mRNA does not involve any proteins.

Chapter 30
Protein Biosynthesis

© Jess Petree
© Macmillan Learning

The ribosome, shown above, is a cellular machine that is not unlike a 3D printer. The ribosome follows specific instructions in mRNA to create a polypeptide from amino acids. Each amino acid is connected to a transfer tRNA molecule and brought to the ribosome, one at a time, to be joined to the growing polypeptide chain. Once complete, the polypeptide chain detaches from the ribosome and adopts a three-dimensional structure.

Outline

30.1 Protein Biosynthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences
30.2 Aminoacyl-tRNA Synthetases Establish the Genetic Code
30.3 The Ribosome Is the Site of Protein Biosynthesis

30.4 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins
30.5 A Variety of Antibiotics and Toxins Inhibit Protein Biosynthesis

Learning Goals

By the end of this chapter, you should be able to:

1. Explain how nucleic acid information is translated into amino acid sequence and define the role of aminoacyl tRNA synthetases in this process.
2. Define the role of ribosomes in protein biosynthesis.
3. Compare and contrast bacterial and eukaryotic protein biosynthesis.
4. Describe the pathway for the biosynthesis of secretory and membrane proteins.
5. Describe how certain chemicals can inhibit protein biosynthesis.

Einstein is reported to have said, “The more I learn, the more I realize how much I don’t know.” He might as well have been talking about ribosomes, enormous molecular complexes containing several large RNA molecules and dozens of proteins. What makes ribosomes so fascinating? Ribosomes are responsible for protein biosynthesis, and since proteins play most of the functional roles in cells, ribosomes are therefore critical to cell survival. Any errors in this process can have detrimental effects on cells by interfering with normal cellular functions. In addition, toxins and antibiotics that bind to the ribosome and prevent its ability to make proteins can cause cell death. As we will see in this chapter, protein biosynthesis depends not just on the ribosome, but also on many additional nucleic acid and protein factors. There is still much to discover about this intricate process, and “ribosomology” is certain to keep biochemists busy for years to come.

30.1 Protein Biosynthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences

In this chapter we discuss the mechanism of protein biosynthesis, a process called **translation** because the 4-letter alphabet of nucleic acids is translated into the entirely different 20-letter alphabet of proteins. Because of this conversion of one alphabet into another, translation is a conceptually more complex process than either replication or transcription, both of which take place within the framework of a common base-pairing language. The basics of protein biosynthesis are the same across all kingdoms of life — evidence that the protein-biosynthesis system arose very early in evolution. An mRNA is translated, or decoded, in the $5'$-to-$3'$ direction one codon at a time, and the corresponding protein is synthesized in the amino-to-carboxyl direction by the sequential addition of amino acids to the carboxyl end of the growing peptide chain (**Figure 30.1**). Amino acids are delivered to the ribosome attached to specific tRNAs. Once the tRNA has delivered its amino acid, it is released from the ribosome and can be linked to another amino acid, and the cycle of peptide chain elongation continues. For each amino acid there is at least one kind of tRNA, and specific enzymes link amino acids to their corresponding tRNAs. This linking is essential to the accurate translation of the language of nucleic acids to that of proteins and thus to the accuracy of the genetic code.

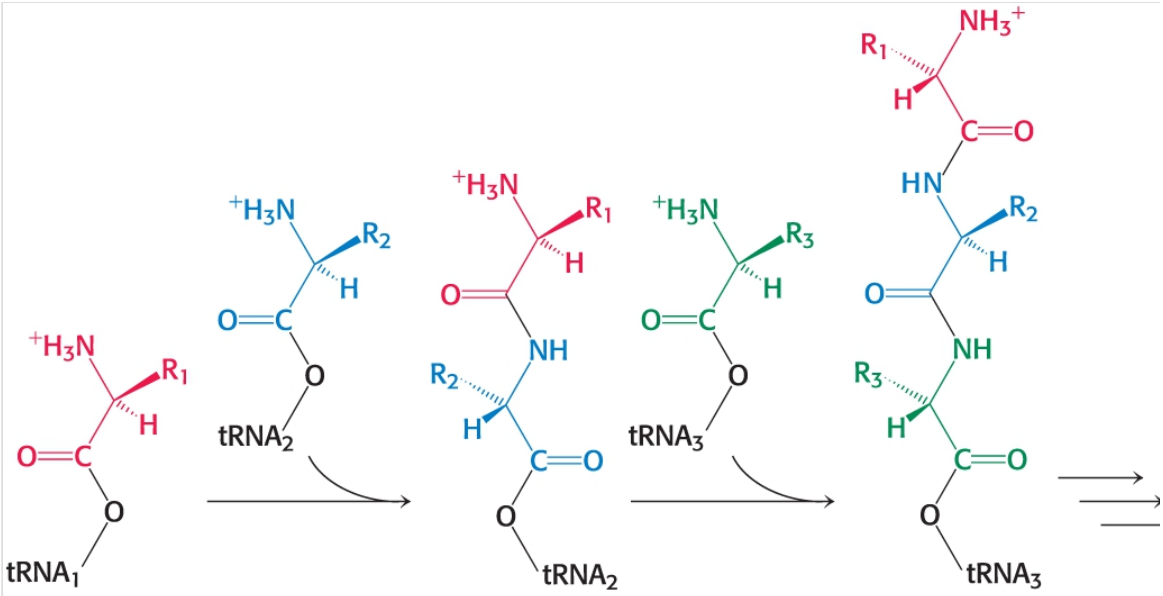


FIGURE 30.1 Polypeptides are synthesized by the successive addition of amino acids to the carboxyl terminus.

The biosynthesis of long proteins requires a low error frequency

The process of transcribing DNA into mRNA is analogous to copying, word for word, a page of a book. There is no change of alphabet or vocabulary, so the likelihood of a change in meaning is small. In contrast, translating the base sequence of an mRNA molecule into a sequence of amino acids is analogous to translating the page of a book into another language. Translation is a complex process, entailing many steps and dozens of molecules, and a potential for error exists at each step. The complexity of translation creates a conflict between two requirements: the process must be accurate yet fast enough to meet a cell's needs. In *E. coli*, translation can take place at a rate of 20 amino acids per second, a truly impressive speed considering the complexity of the process.

How accurate must protein biosynthesis be? Let us consider error rates. The probability of forming a protein with no errors depends on the number of amino acid residues and on the frequency (ε) of insertion of a wrong amino acid. As Table 30.1 shows, an error frequency of 10^{-2} is intolerable, even for quite small proteins $(\sim 100 \text{ residues})$. An ε value of 10^{-3} usually leads to the error-free synthesis of an average-sized 300-residue protein $(\sim 33 \text{ kDa})$ but not of a large 1000-residue protein $(\sim 110 \text{ kDa})$; the error frequency must not exceed approximately 10^{-4} to produce the larger proteins effectively. While lower error frequencies are conceivable, they will not dramatically increase the percentage of proteins with accurate sequences, except for really large proteins $(> 1000 \text{ residues})$. In addition, such lower error rates are likely to be possible only by a reduction in the rate of protein biosynthesis because additional time for proofreading is required. In fact, the observed values of ε are close to 10^{-4}, allowing for the accurate production of proteins consisting of as many as 1000 amino acids while maintaining a remarkably rapid rate for protein biosynthesis.

TABLE 30.1 Accuracy of protein synthesis

Frequency of inserting an incorrect amino acid	Probability of synthesizing an error-free protein		
	Number of amino acid residues		
	100	300	1000
10^{-2}	0.366	0.049	0.000
10^{-3}	0.905	0.741	0.368

10^{-4}	0.990	0.970	0.905
10^{-5}	0.999	0.997	0.990

Note: The probability p of forming a protein with no errors depends on n, the number of amino acids, and ε the frequency of insertion of a wrong amino acid: $p = (1 - \epsilon)^n$.

Transfer RNA (tRNA) molecules have a common design

The fidelity of protein biosynthesis requires accurate recognition of three-base **codons** on mRNA (Section 8.5). An amino acid cannot itself recognize a codon. Consequently, an amino acid is attached to a specific tRNA molecule that recognizes the codon by Watson–Crick base-pairing. **Transfer RNA** serves as the adapter molecule: not only does the tRNA contain an **anticodon** that binds to a specific codon, but it also brings with it an amino acid for incorporation into the polypeptide chain.

Thousands of tRNA sequences are known. All tRNA molecules must be able to interact in nearly the same way with the ribosomes, mRNAs, and protein factors that participate in translation. So, it's not surprising that tRNA molecules have many shared structural features and underlying commonalities in their sequences:

- Each tRNA is a single chain containing between 73 and 93 ribonucleotides.
- Each tRNA sequence can be arranged in a cloverleaf pattern in which about half the residues are base-paired (**Figure 30.2**).

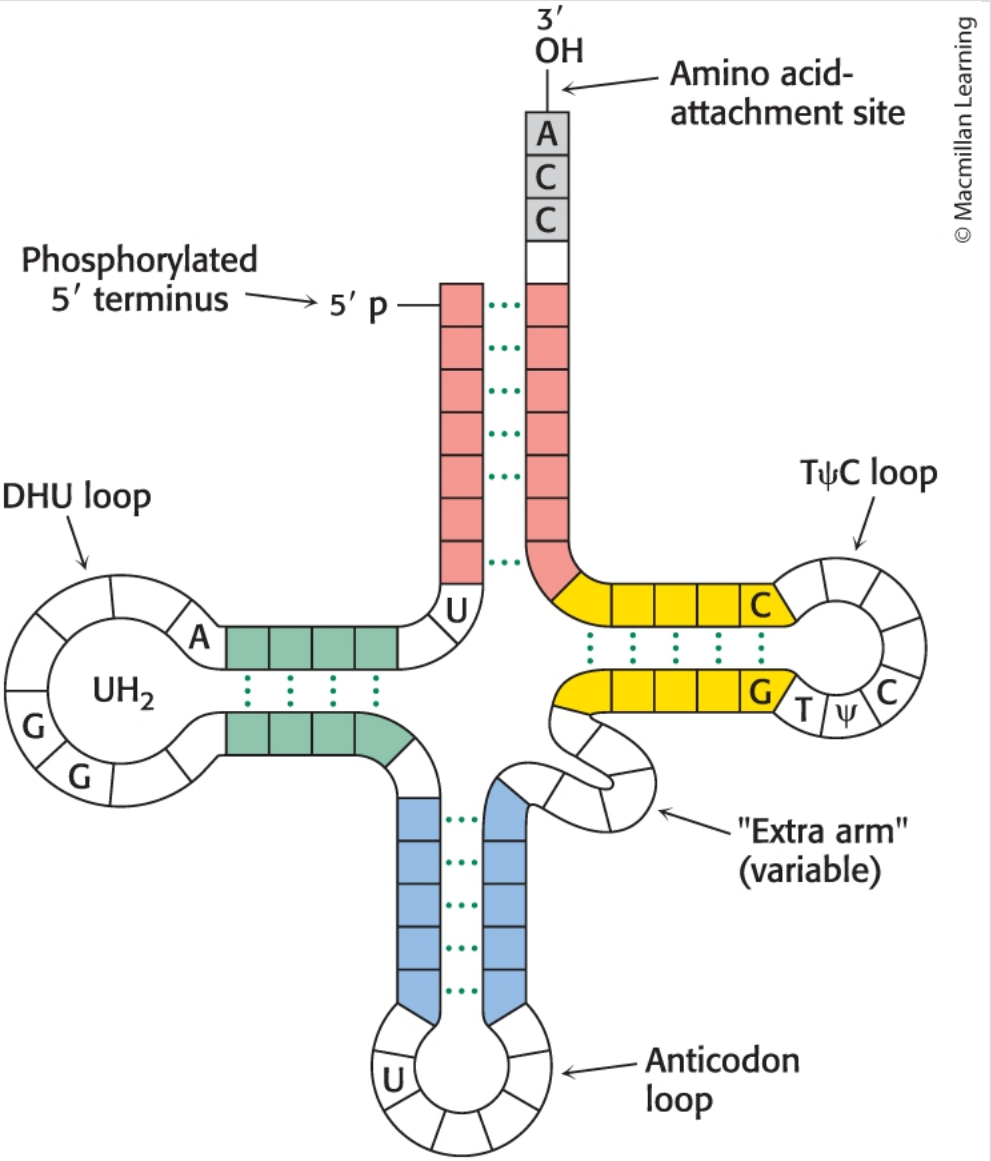

FIGURE 30.2 The secondary structure of all transfer RNAs resembles a cloverleaf. Comparison of the base sequences of many tRNAs reveals a number of conserved features.

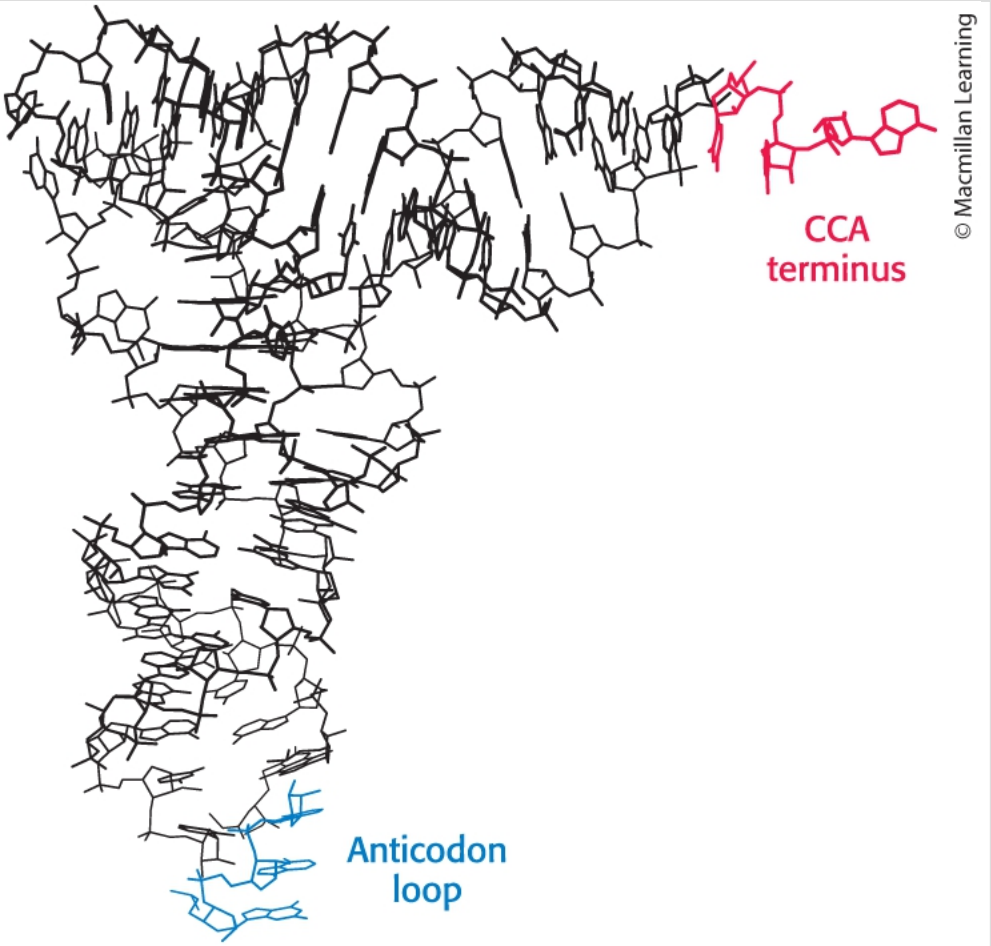
- The molecule is L-shaped (Figure 30.3).



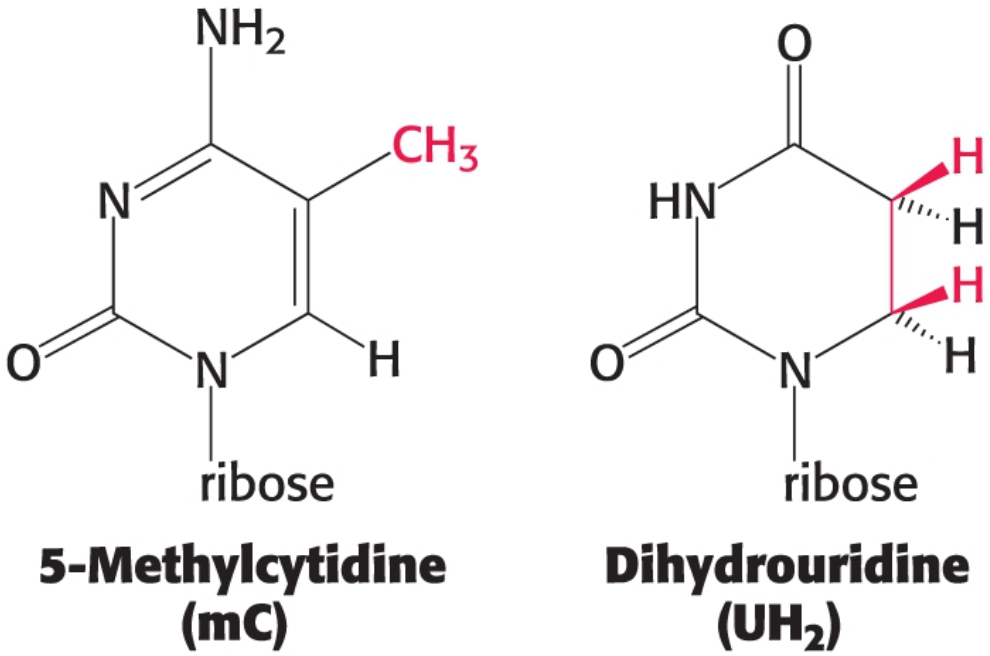


FIGURE 30.3 Transfer RNAs have an L-shaped tertiary structure. The L-shaped structure is revealed by this skeletal model of yeast phenylalanyl-tRNA. The CCA region is at the end of one arm, and the anticodon loop is at the end of the other.

[Drawn from 1EHZ.pdb.]

INTERACT with this model in Achieve

- They contain many unusual bases, typically between 7 and 15 per molecule. Some of these bases are methylated or dimethylated derivatives of A, U, C, and G formed by enzymatic modification of a precursor tRNA. Two examples of such modified bases are 5-

methylcytidine (mC) and dihydrouridine (UH_2). Methylation imparts a hydrophobic character to some regions of tRNAs, which may be important for their interaction with synthetases and ribosomal proteins. Some methylations also prevent bases from forming proper base pairs, allowing them to interact with other bases. Other modifications alter codon recognition, as will be described shortly.

- About half the nucleotides in tRNAs are base-paired to form double helices. The four helical regions are arranged to form two apparently continuous segments of double helix. These segments are like A-form DNA, as expected for an RNA helix (Section 4.2). One helix contains the 5′ and 3′ ends and runs horizontally in the model shown in **Figure 30.4**; it forms one arm of the L. The other helix, which contains the anticodon and runs vertically in Figure 30.4, forms the other arm of the L.

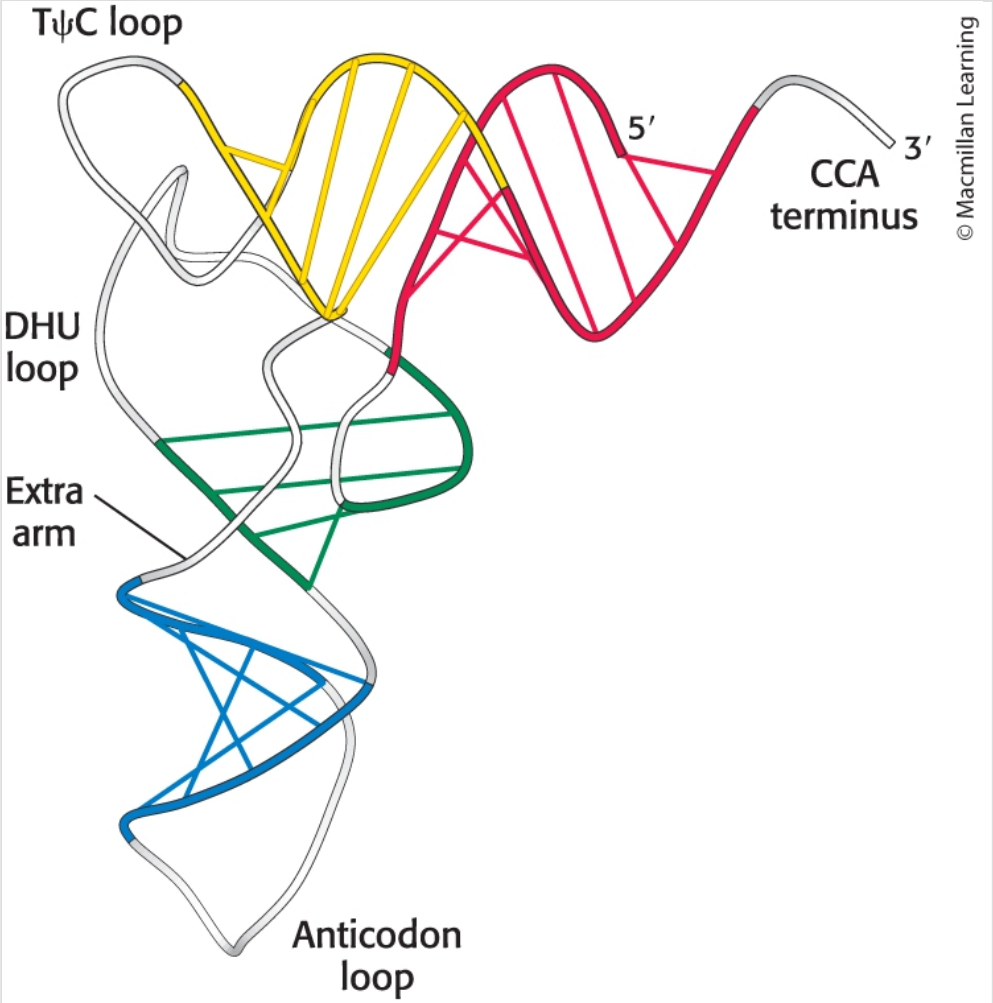

FIGURE 30.4 The four double-stranded regions of a tRNA stack to form an L-shaped structure.

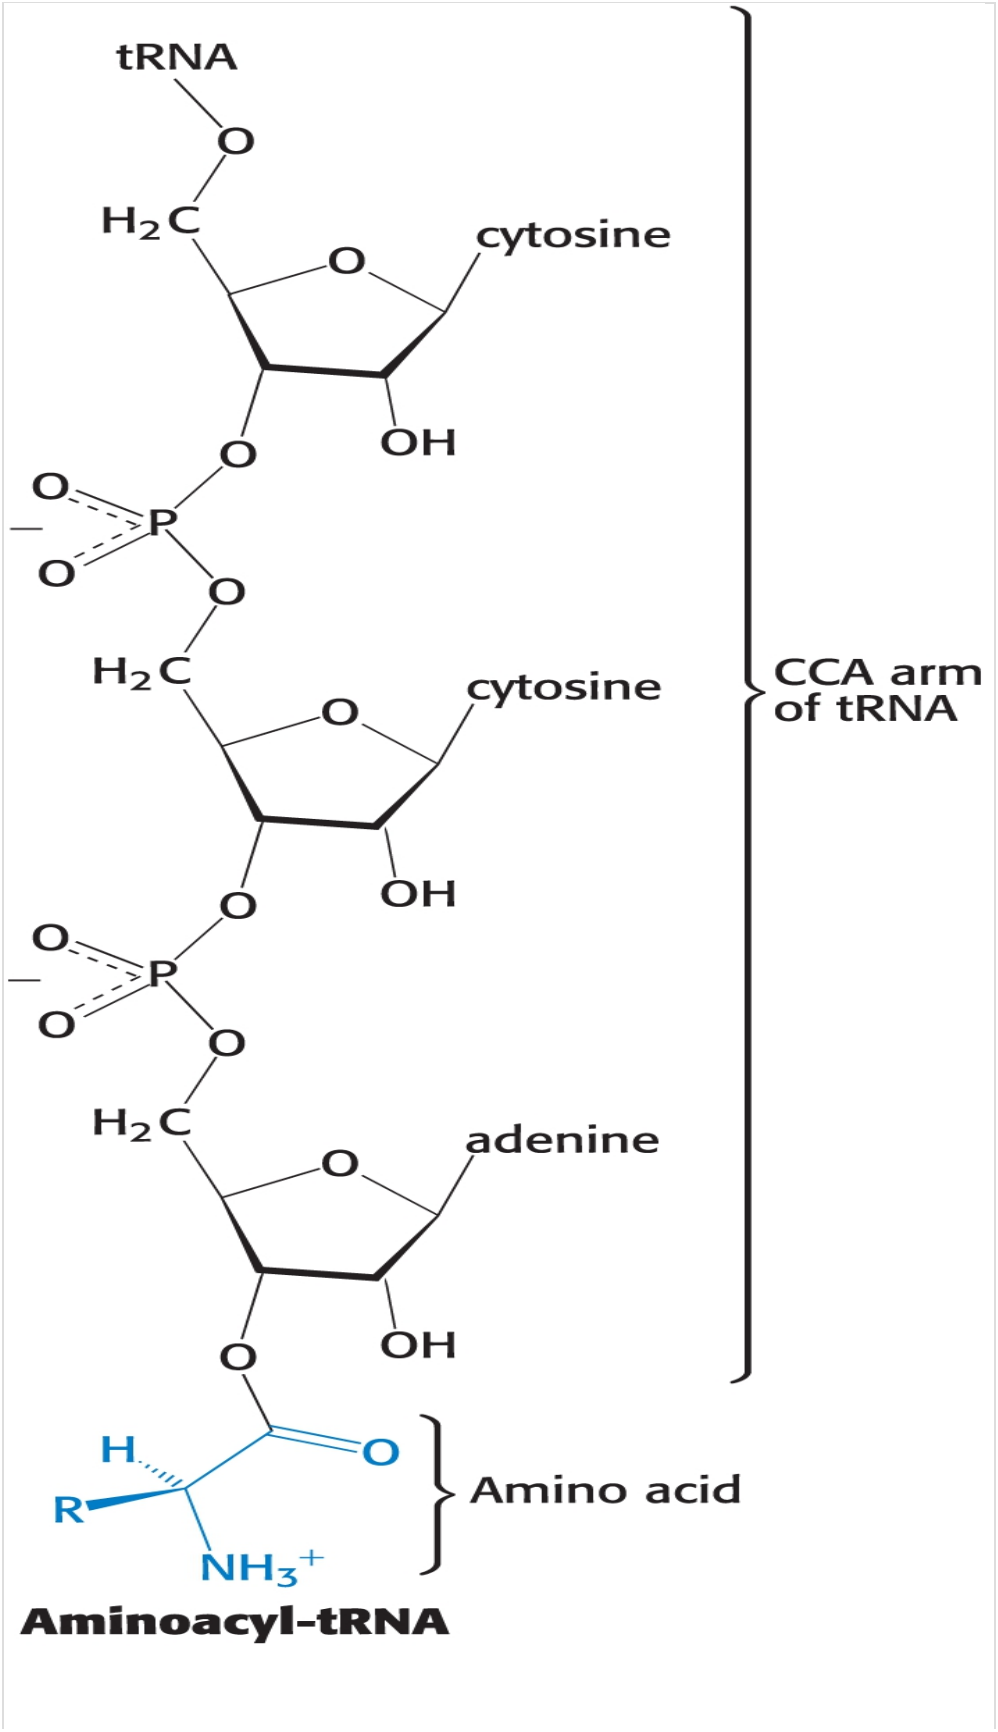


[Drawn from 1EHZ.pdb.]

INTERACT with this model in Achieve

Five groups of bases are not base-paired in this way: the 3′ CCA terminal region, which is part of a region called the *acceptor stem*; the TψC *loop*, which is named for its ribothymidine-pseudouracil-cytosine; the "*extra arm*," which contains a variable number of

residues; the *DHU loop*, which contains several dihydrouracil residues; and the *anticodon loop*. Most of the bases in the nonhelical regions participate in hydrogen-bonding interactions, even if the interactions are not like those in Watson–Crick base pairs. Although they are structurally similar overall, the structural diversity generated by this combination of helices and loops containing modified bases ensures that the tRNAs can be uniquely distinguished.

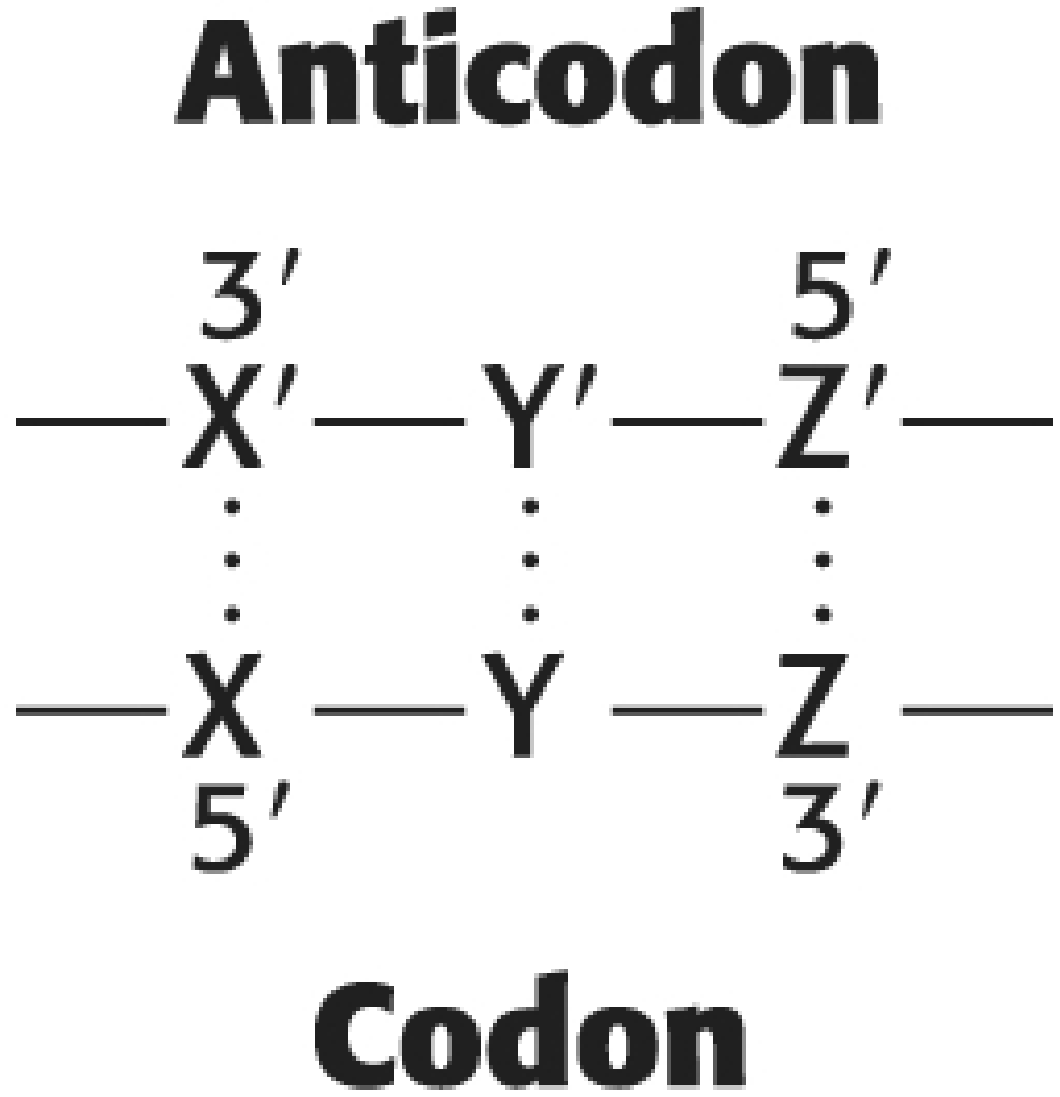
- The $5'$ end of a tRNA is phosphorylated. The $5'$ terminal residue is usually pG.
- An activated amino acid is attached to a hydroxyl group of the adenosine residue in the amino-acid-attachment site, located at the end of the $3'$ CCA component of the acceptor stem (**Figure 30.5**).

Aminoacyl-tRNA

FIGURE 30.5 Ester linkages couple amino acids to tRNAs. While a linkage to the $3'$-hydroxyl group is shown here, these bonds can be to either the $2'$- or the $3'$-hydroxyl group of the $3'$-adenosine residue on the tRNA.

- The anticodon loop, which is present in a loop near the center of the sequence, is at the other end of the L, making the three bases that constitute the anticodon accessible for interaction with a codon.

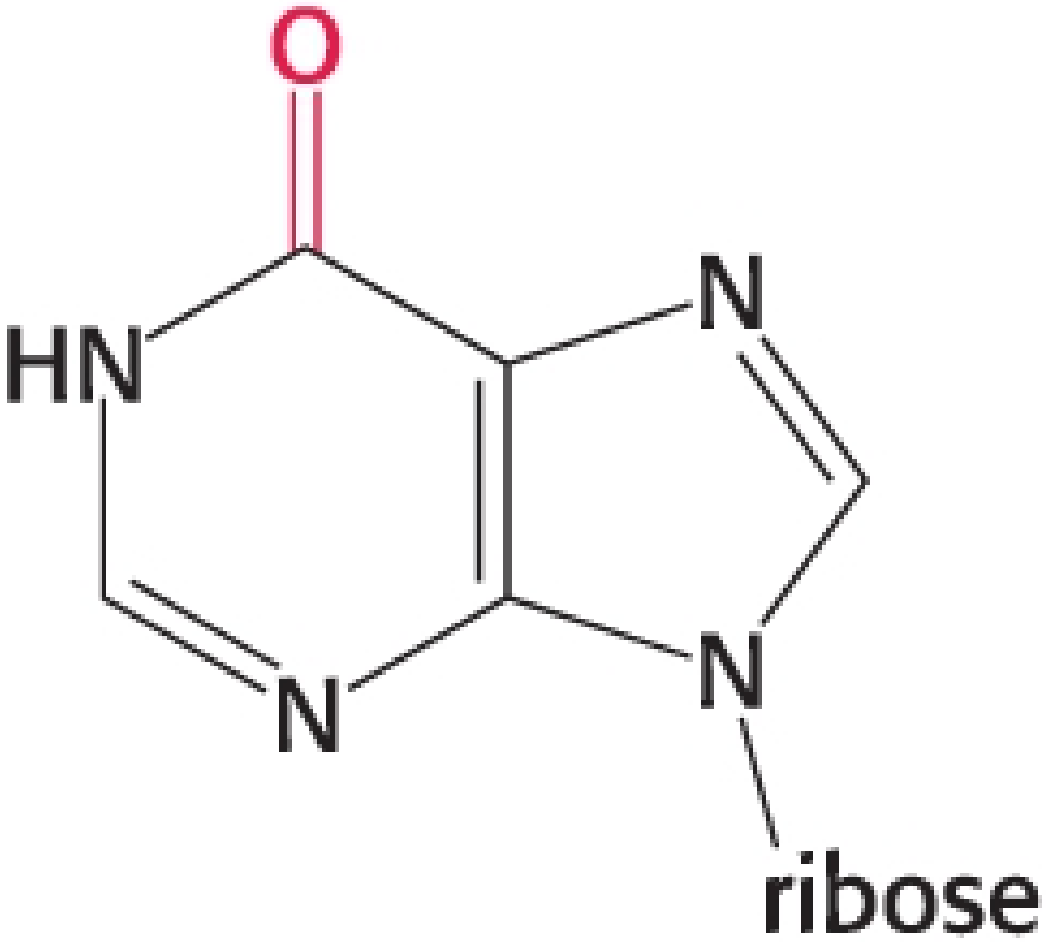
Thus, the architecture of the tRNA molecule is well suited to its role as adaptor: the anticodon is available to interact with an appropriate codon on mRNA, while the end that is linked to an amino acid is well positioned to participate in peptide-bond formation.



Self-Check Question

What features are common to all tRNA molecules?

Some transfer RNA molecules recognize more than one codon because of wobble in base-pairing



What are the rules that govern the recognition of a codon by the anticodon of a tRNA? A simple hypothesis is that each of the bases of the codon forms a Watson–Crick base pair with a complementary base on the anticodon of the tRNA. The codon and anticodon would then be lined up in an antiparallel fashion, where the prime denotes the complementary base in the anticodon. Thus X and X' would be either A and U (or U and A) or G and C (or C and G). According to this model, a particular anticodon can recognize only *one* codon.

Experiments show, however, that some tRNA molecules can recognize more than one codon. For example, the yeast alanyl-tRNA binds to *three* codons: GCU, GCC, and GCA. The first two bases of these codons are the same, whereas the third is different. Could it be that recognition of the third base of a codon is sometimes less discriminating than recognition of the other two? The redundancy, or degeneracy, of the genetic code indicates that it might be so. XYU and XYC always encode the same amino acid; XYA and XYG usually do. These data suggest that the steric

criteria might be less stringent for pairing of the third base than for the other two. In other words, there is some steric freedom ("wobble") in the pairing of the third base of the codon.

The **wobble hypothesis** is now firmly established (**Table 30.2**). The anticodons of tRNAs of known sequence bind to the codons predicted by this hypothesis; for example, the anticodon of yeast alanyl-tRNA is IGC (*I* is the purine base inosine). This tRNA recognizes the codons GCU, GCC, and GCA. Recall that, by convention, nucleotide sequences are written in the $5' \rightarrow 3'$ direction unless otherwise noted. Hence, I (the $5'$ base of this anticodon) pairs with U, C, or A (the $3'$ base of the codon), as predicted.

Inosine

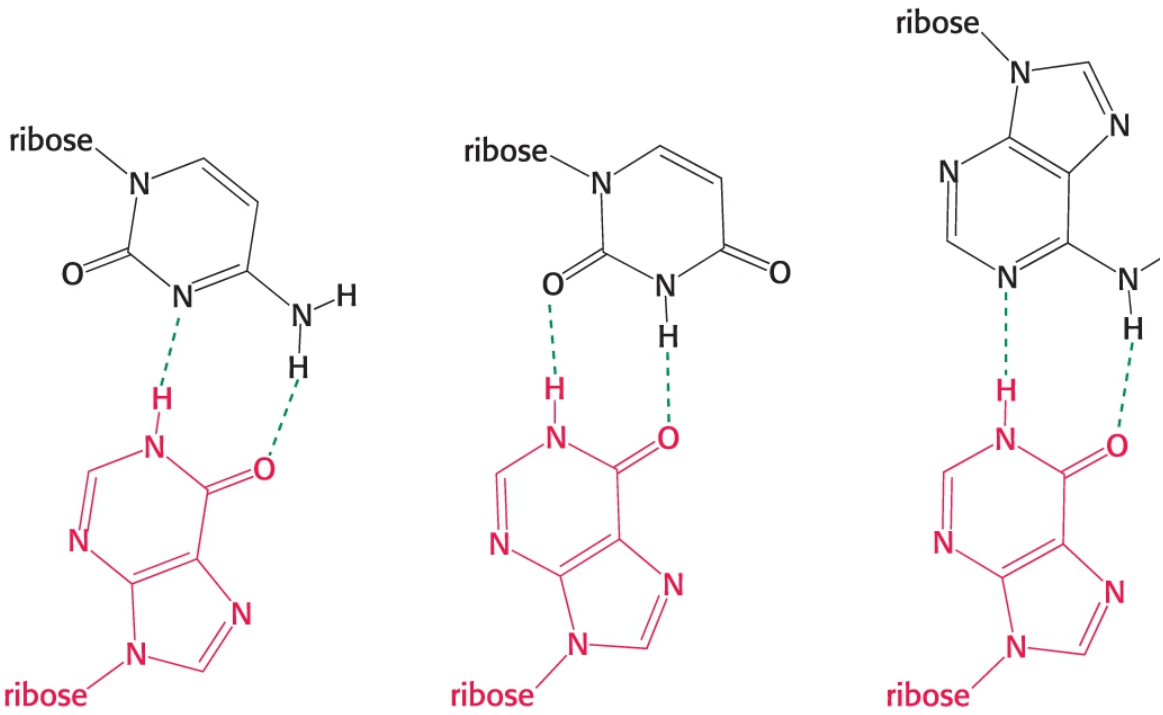


TABLE 30.2 Allowed pairings at the third base of the codon according to the wobble hypothesis

First base of anticodon	Third base of codon
C	G
A	U
U	A or G
G	U or C
I	U, C, or A

Two generalizations concerning the codon–anticodon interaction can be made:

1. *Codons that differ in either of their first two bases must be recognized by different tRNAs.* The first two bases of a codon pair in the standard way, and recognition is precise. For example, both UUA and CUA encode leucine but are read by different tRNAs.

2. *Part of the degeneracy of the genetic code arises from imprecision (wobble) in the pairing of the third base of the codon with the first base of the anticodon.* The first base of an anticodon determines whether a particular tRNA molecule reads one, two, or three kinds of codons: C or A (one codon), U or G (two codons), or I (three codons).

We see here a strong reason for the frequent appearance of inosine, one of the unusual nucleosides, in anticodons: inosine maximizes the number of codons that can be read by a particular tRNA molecule. The inosine bases in tRNA are formed by the deamination of adenosine after the synthesis of the primary transcript.

Why is wobble tolerated in the third position of the codon but not in the first two? This question is answered by considering the interaction of the tRNA with the ribosome. As we will soon examine in greater detail, **ribosomes** are huge RNA–protein complexes consisting of two subunits. One of these subunits has three universally conserved bases in its RNA molecule that form hydrogen bonds only with correctly formed base pairs in the codon–anticodon duplex (**Figure 30.6**). These interactions ensure that Watson–Crick base pairs are present in the first two positions of the codon–anticodon duplex, but not the third position, so more varied base pairs are tolerated. Thus, the ribosome plays an active role in decoding the codon–anticodon interactions.

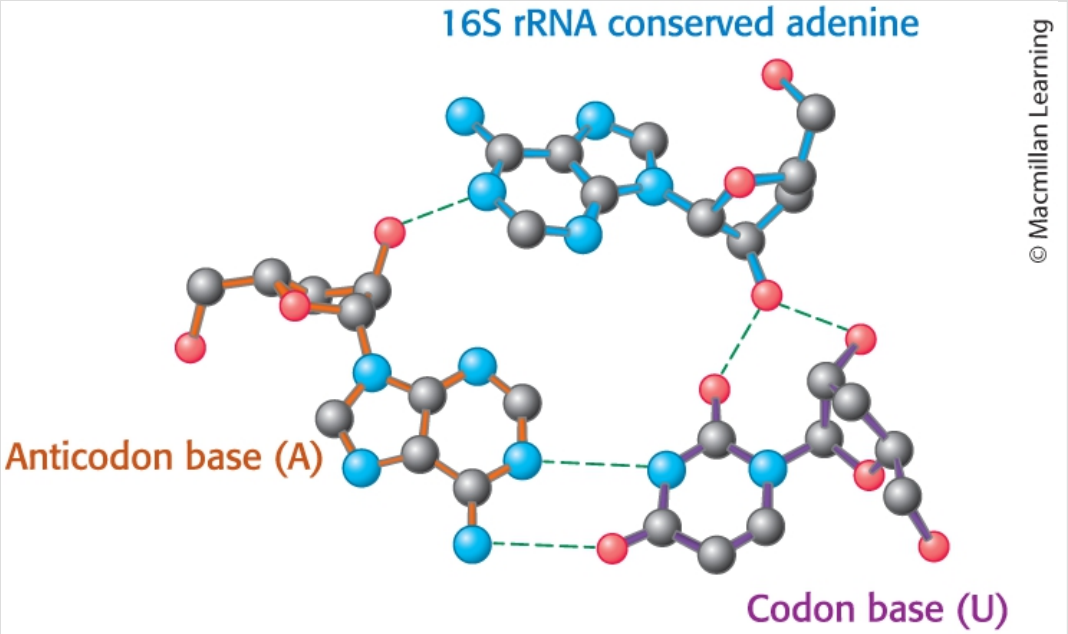

FIGURE 30.6 16S rRNA monitors base-pairing between the codon and the anticodon. One of three universally conserved bases in 16S rRNA (an adenine) forms hydrogen bonds with the bases in both the codon and the anticodon only if the codon and anticodon are correctly paired. Only one anticodon base (adenine) and one codon base (uracil) are shown. Hydrogen atoms are omitted for clarity.

Self-Check Question

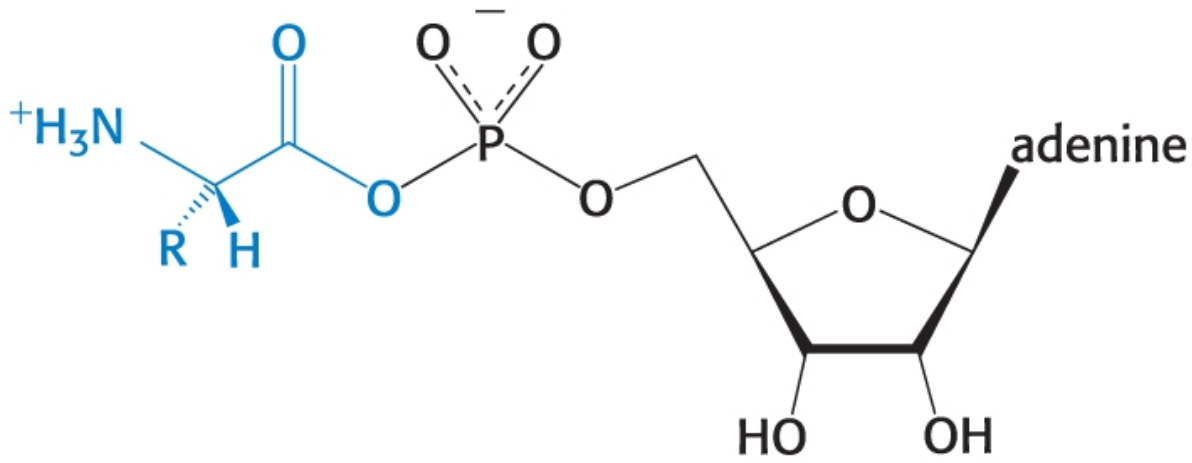
Explain how it is possible that some tRNA molecules recognize more than one codon.

30.2 Aminoacyl-tRNA Synthetases Establish the Genetic Code

Before codon and anticodon meet, the amino acids required for protein biosynthesis must first be attached to specific tRNA molecules, linkages that are crucial for two reasons:

- *The attachment of a given amino acid to a particular tRNA establishes the genetic code.* When an amino acid has been linked to a tRNA, it will be incorporated into a growing polypeptide chain at a position dictated by the anticodon of the tRNA.

- *Because the formation of a peptide bond between free amino acids is not thermodynamically favorable, the amino acid must first be activated for protein biosynthesis to proceed.* The activated intermediates in protein biosynthesis are amino acid esters, in which the carboxyl group of an amino acid is linked to either the $2'$- or the $3'$-hydroxyl group of the ribose unit at the $3'$ end of tRNA. An amino acid ester of tRNA is called an **aminoacyl-tRNA** or sometimes a *charged tRNA* (Figure 30.6). For a specific amino acid attached to its cognate tRNA — for instance, threonine — the charged tRNA is designated $\mathrm{Thr{-}tRNA}^{\mathrm{Thr}}$.



Amino acids are first activated by adenylation

The activation reaction is catalyzed by specific **aminoacyl-tRNA synthetases**. These enzymes activate an amino acid and then link it to

its corresponding tRNA in a two-step reaction. The first step is the formation of an aminoacyl adenylate from an amino acid and ATP.

$$\text{Amino acid} + \text{ATP} \rightleftharpoons \text{aminoacyl-AMP} + \text{PP}_\text{i}$$

This activated species is a mixed anhydride in which the carboxyl group of the amino acid is linked to the phosphoryl group of AMP; hence, it is also known as *aminoacyl-AMP*.

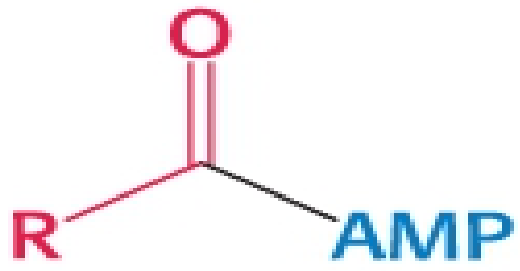
Aminoacyl-AMP

The next step is the transfer of the aminoacyl group of aminoacyl-AMP to a particular tRNA molecule to form aminoacyl-tRNA.

$$\text{Aminoacyl-AMP} + \text{tRNA} \rightleftharpoons \text{aminoacyl-tRNA} + \text{AMP}$$

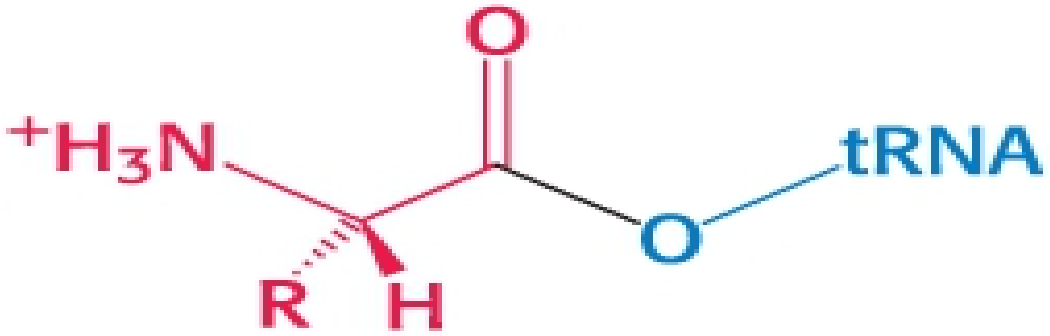
The sum of these activation and transfer steps is

$$\text{Amino acid} + \text{ATP} + \text{tRNA} \rightleftharpoons \text{aminoacyl-tRNA} + \text{AMP} + \text{PP}_\text{i}$$



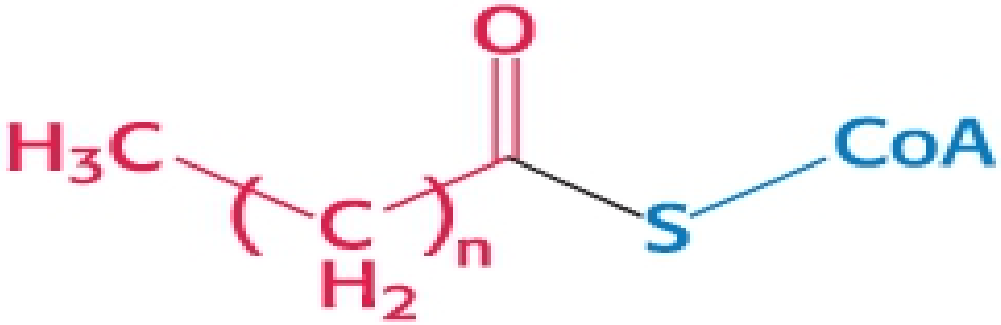
The $\Delta G^{\circ\prime}$ of this reaction is close to 0, because the free energy of hydrolysis of the ester bond of aminoacyl-tRNA is similar to that for the hydrolysis of ATP to AMP and PP_i. As we have seen many times, the reaction is driven by the hydrolysis of pyrophosphate. The sum of these three reactions is highly exergonic:

$$\text{Amino acid} + \text{ATP} + \text{tRNA} + H_2O \rightarrow \text{aminoacyl}-\text{tRNA} + \text{AMP} + 2P_i$$

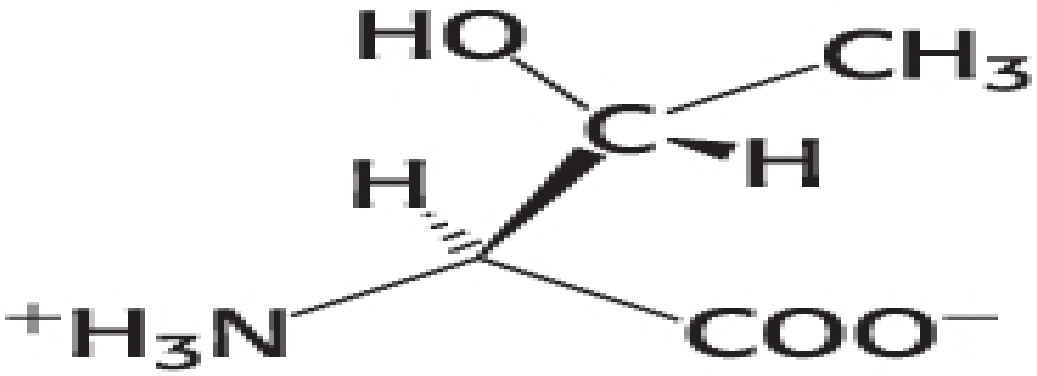


There are two key points to note about this reaction:

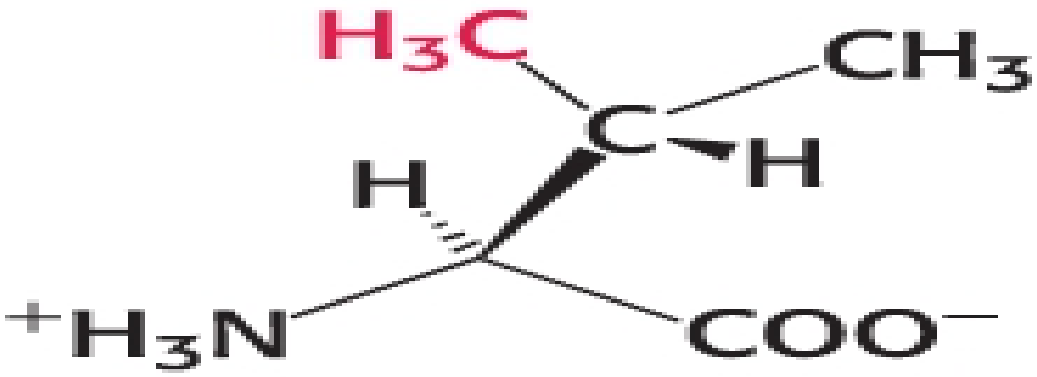
- *The equivalent of two molecules of ATP is consumed in the synthesis of each aminoacyl-tRNA*. One of them is consumed in forming the ester linkage of aminoacyl-tRNA, whereas the other is consumed in driving the reaction forward.



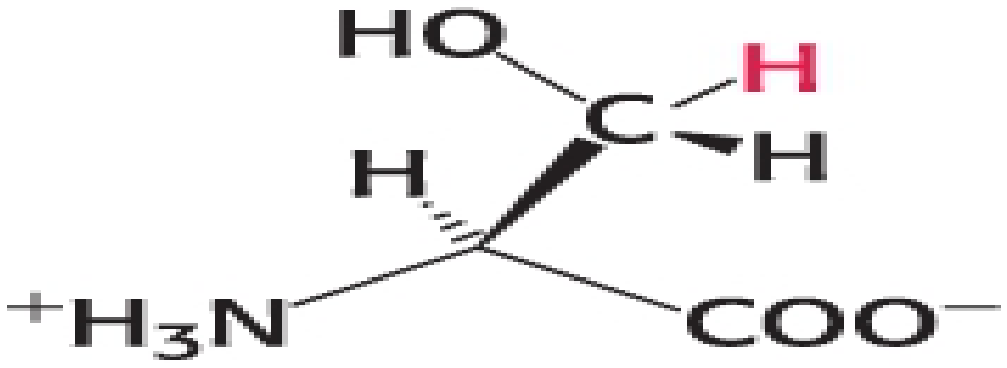
- *The aminoacyl-AMP intermediate does not dissociate from the synthetase*. Rather, it is tightly bound to the active site of the enzyme by noncovalent interactions. This means that the activation and transfer steps for a particular amino acid are catalyzed by the same aminoacyl-tRNA synthetase.



Acyl adenylate intermediate



Aminoacyl-tRNA



Fatty acyl CoA

Threonine

Valine

Serine

We have already encountered an acyl adenylate intermediate in fatty acid activation (Section 22.2). The major difference between these reactions is that the acceptor of the acyl group is CoA in fatty acid activation and tRNA in amino acid activation. The energetics of these biosyntheses are very similar: both are made irreversible by the hydrolysis of pyrophosphate.

Aminoacyl-tRNA synthetases have highly discriminating amino acid activation sites

Each aminoacyl-tRNA synthetase is highly specific for a given amino acid. Indeed, a synthetase will link an incorrect amino acid to a tRNA only once in 10^4 or 10^5 reactions. How is this level of specificity achieved? Each aminoacyl-tRNA synthetase takes advantage of the properties of its amino acid substrate. Consider the challenge faced by threonyl-tRNA synthetase. Threonine is especially similar to two other amino acids: valine and serine. Valine has almost exactly the same shape as that of threonine, except that valine has a methyl group in place of a hydroxyl group. Serine has a hydroxyl group, as does threonine, but lacks the methyl group. How can the threonyl-tRNA synthetase avoid coupling these incorrect amino acids to threonyl-tRNA (abbreviated $tRNA^{Thr}$)?

The structure of the amino acid-binding site of threonyl-tRNA synthetase reveals how valine is avoided (**Figure 30.7**). The synthetase contains a zinc ion bound to the enzyme by two histidine residues and one cysteine residue, with the remaining coordination sites available for substrate binding. The use of a zinc ion appears to be unique to threonyl-tRNA synthetase; other aminoacyl-tRNA synthetases have different strategies for recognizing their cognate amino acids.

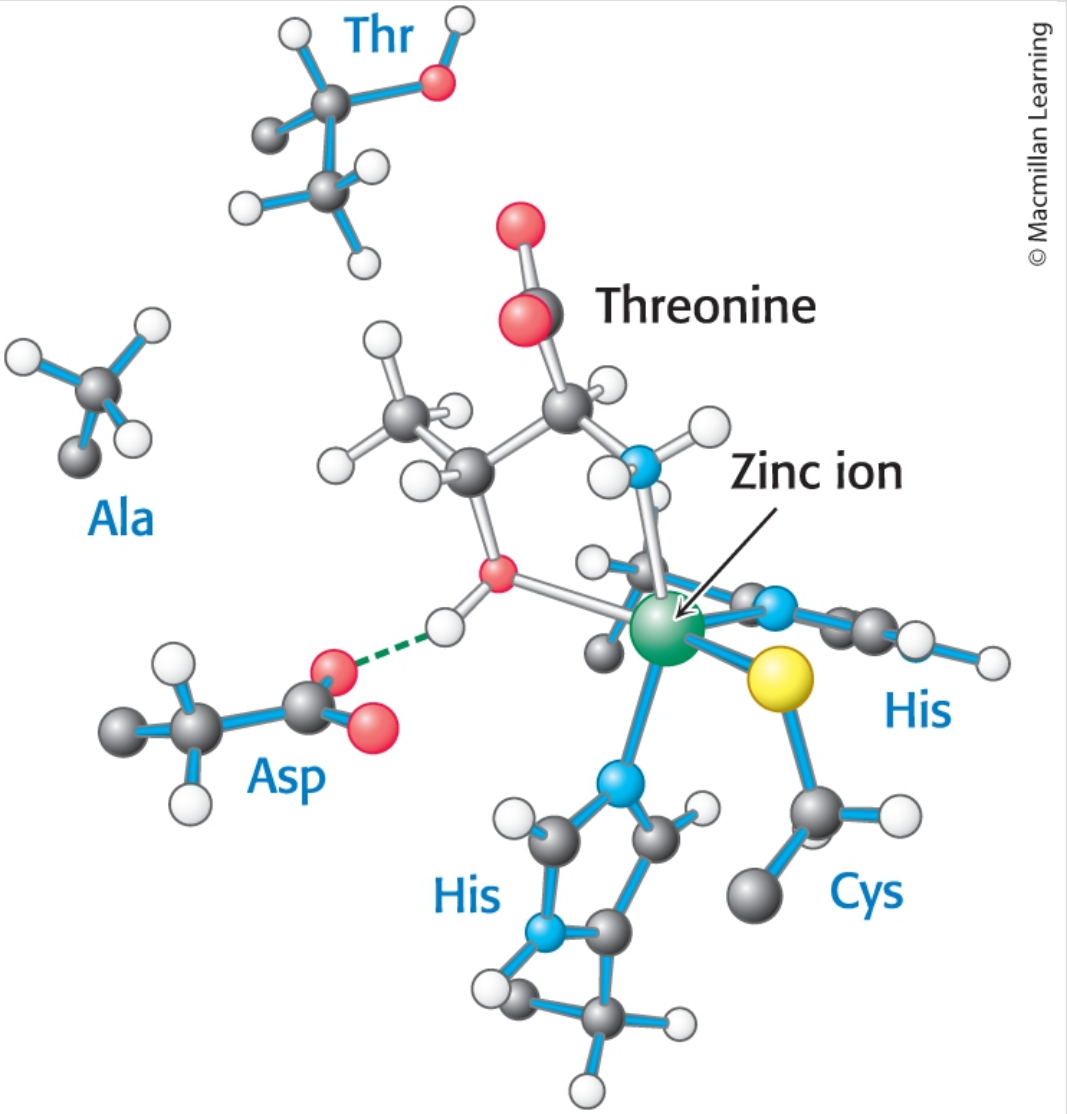


FIGURE 30.7 The amino acid-binding site of threonyl-tRNA synthetase contains a zinc ion. This zinc ion (green ball) binds to the amino and hydroxyl groups of threonine (white). Selected amino acids from the synthetase are shown in blue.

Threonine binds to the zinc ion through its amino group and its side-chain hydroxyl group. The side-chain hydroxyl group is further recognized by an aspartate residue that hydrogen-bonds to it. The methyl group present in valine in place of this hydroxyl group cannot participate in these interactions; it is excluded from this active site and,

hence, does not become adenylated and transferred to $tRNA^{Thr}$. The carboxylate group of the correctly positioned threonine is available to attack the α-phosphoryl group of ATP to form the aminoacyl adenylate.

The zinc site is less able to discriminate against serine because this amino acid does have a hydroxyl group that can bind to the zinc ion. Indeed, with only this mechanism available, threonyl-tRNA synthetase does mistakenly couple serine to $tRNA^{Thr}$ at a rate 10^{-2} to 10^{-3} times that for threonine. This error rate is likely to lead to many translation errors, so how is a higher level of specificity achieved?

Proofreading by aminoacyl-tRNA synthetases increases the fidelity of protein biosynthesis

Threonyl-tRNA synthetase can be incubated with $tRNA^{Thr}$ that has been covalently linked with serine ($Ser-tRNA^{Thr}$); the tRNA has been "mischarged." The reaction is immediate: a rapid hydrolysis of the aminoacyl-tRNA forms serine and free tRNA. In contrast, incubation with correctly charged $Thr-tRNA^{Thr}$ results in no reaction. Thus, threonyl-tRNA synthetase contains an additional functional site that hydrolyzes $Ser-tRNA^{Thr}$ but not $Thr-tRNA^{Thr}$. This editing site provides an opportunity for the synthetase to correct its mistakes and improve its fidelity to less than one mistake in 10^4.

The results of structural and mutagenesis studies revealed that the editing site for threonyl-tRNA synthase is more than 20 Å from the activation site (**Figure 30.8**). This editing site readily accepts and cleaves

$Ser-tRNA^{Thr}$ but does not cleave $Thr-tRNA^{Thr}$. The discrimination of serine from threonine is easy because threonine contains an extra methyl group; a site that conforms to the structure of serine will sterically exclude threonine. The structure of the complex between threonyl-tRNA synthetase and its substrate reveals that the aminoacylated CCA can swing out of the activation site and into the editing site (**Figure 30.9**). Thus, the aminoacyl-tRNA can be edited without dissociating from the synthetase. This proofreading depends on the conformational flexibility of a short stretch of polynucleotide sequence.

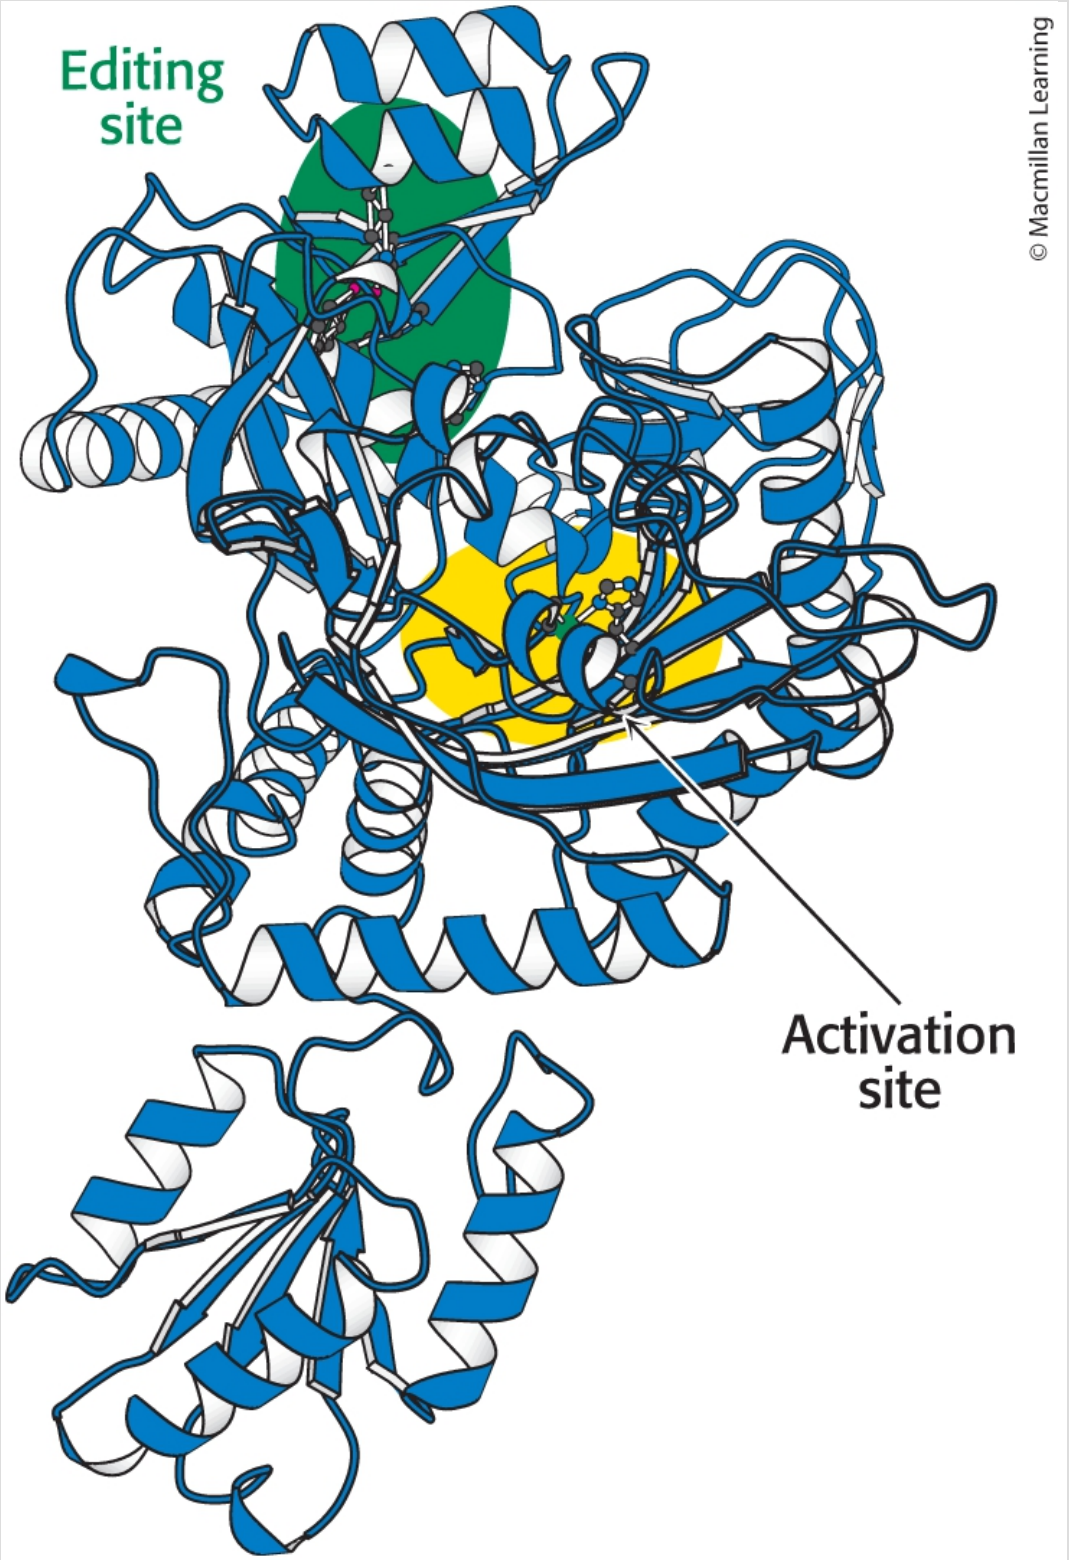

FIGURE 30.8 Threonyl-tRNA synthetase also contains an editing site. Mutagenesis studies revealed the position of the editing site (shown in green) in threonyl-tRNA

synthetase. The activation site is shown in yellow. Only one subunit of the dimeric enzyme is shown here and in subsequent illustrations.

[Drawn from 1QF6.pdb.]

INTERACT with this model in Achieve

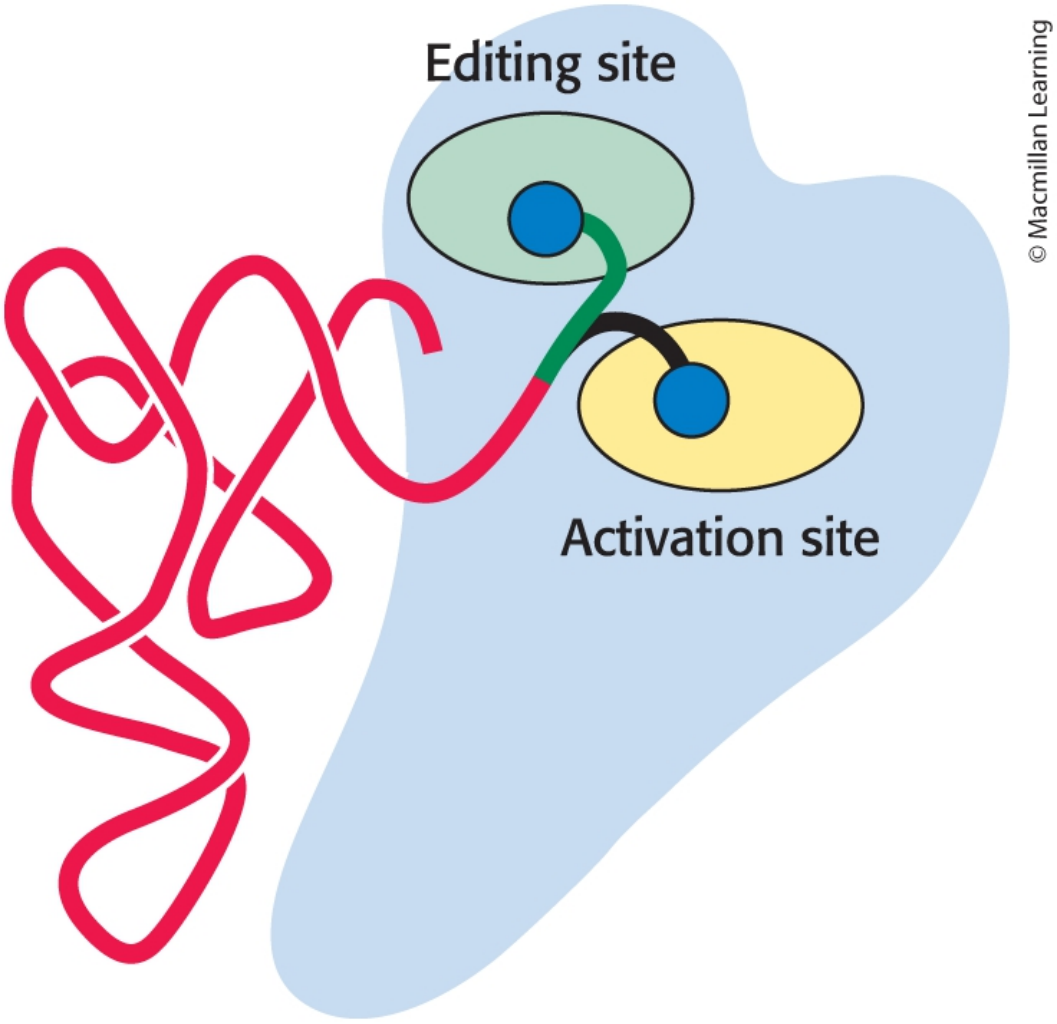

FIGURE 30.9 Amino acids move between the activation site and the editing site of an aminoacyl-tRNA synthetase. The flexible CCA arm of an aminoacyl-tRNA can swing the attached amino acid from the activation site (yellow) to the editing site (green). If the amino acid fits well into the editing site, the amino acid is removed by hydrolysis. Only one amino acid is attached to the tRNA at a time, and this amino acid can only occupy either the editing site or the activation site.

Most aminoacyl-tRNA synthetases contain editing sites in addition to activation sites. Together, these complementary sites ensure very high fidelity. In general, the acylation site rejects amino acids that are *larger* than the correct one because there is insufficient room for them, whereas the hydrolytic site cleaves activated species that are *smaller* than the correct one.

A few synthetases achieve high accuracy without editing. For example, tyrosyl-tRNA synthetase has no difficulty discriminating between tyrosine and phenylalanine; the hydroxyl group on the tyrosine ring enables tyrosine to bind to the enzyme 10^4 times as strongly as phenylalanine. In conclusion, proofreading has evolved only when fidelity must be enhanced beyond what can be obtained through an initial binding interaction.

Kinetic proofreading increases the fidelity of protein biosynthesis

As noted above, the integrity and validity of the genetic code depends on the fidelity with which tRNAs are linked to their cognate amino acids. The free energy difference of binding an incorrect versus a correct substrate is often too small to explain the accuracy of protein biosynthesis. So how is it possible? Aminoacyl-tRNA synthetases prevent many mistakes by introducing an irreversible step that facilitates their removal. This mechanism, called *kinetic proofreading*, locks in the equilibrium favoring the correct product, then selectively removes incorrect products to increase specificity further (**Figure**

30.10). For aminoacyl-tRNA synthetases, this results in additional hydrolysis of ATP, but it increases specificity.

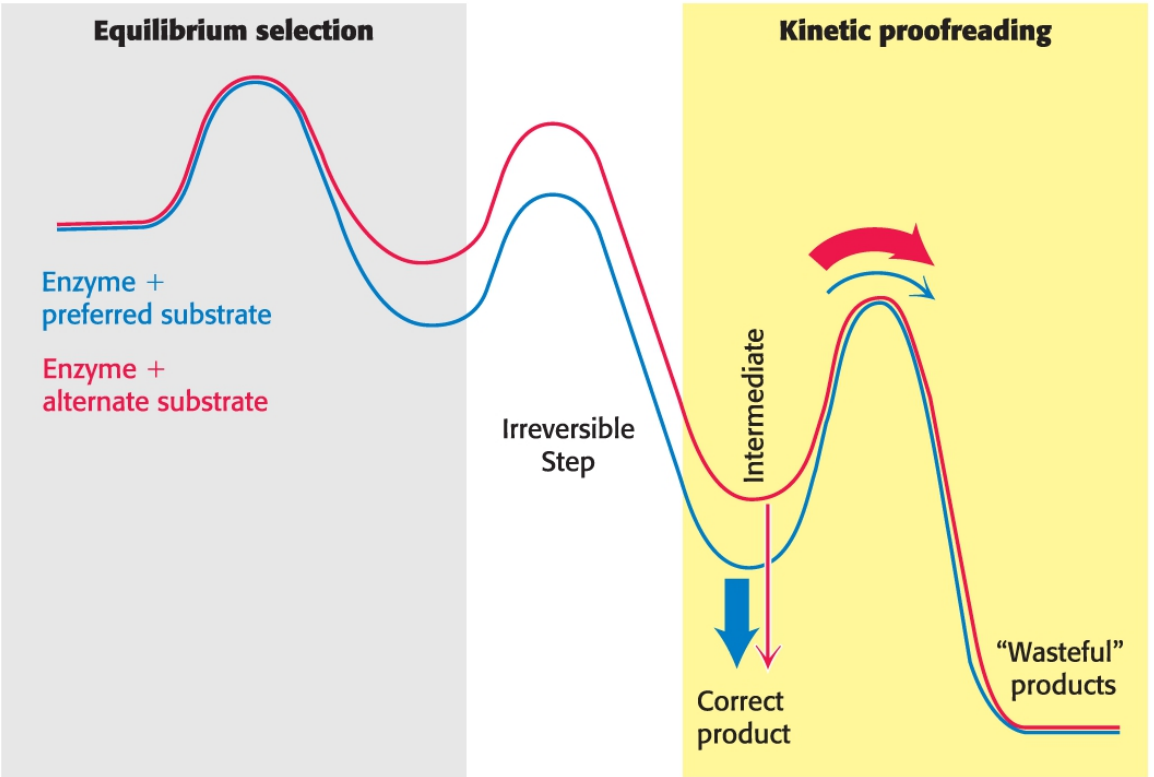

FIGURE 30.10 Kinetic proofreading can increase reaction specificity. Consider a substrate that binds to an enzyme more tightly (curve shown in blue) than an alternate substrate (curve shown in red). The preferred substrate is selected by the binding equilibrium to the enzyme. This selected equilibrium can be locked in place by an irreversible step to produce an intermediate that can either go on to the final product or undergo a side reaction to produce wasteful products. This side reaction is likely to be faster for the alternate substrate, resulting in an increased ratio of the preferred-to-alternate products. For aminoacyl-tRNA synthetases, the intermediate is an aminoacyl adenylate and the wasteful products are free amino acids and AM

Kinetic proofreading benefits other processes as well: aminoacyl-tRNA synthetases use it to discriminate between cognate and noncognate amino acids as well as tRNAs, and ribosomes use it during codon–anticodon recognition, thereby further adding to the integrity of the genetic code. Kinetic proofreading is employed by many additional

molecular processes (including DNA replication) to ensure the faithful selection of substrates.

Synthetases recognize various features of transfer RNA molecules

How do synthetases choose their tRNA partners? This enormously important step is the point at which the actual "translation" takes place: when the correlation between the amino acid and the nucleic acid worlds is made. In a sense, aminoacyl-tRNA synthetases are the only molecules in biology that "know" the genetic code. Their precise recognition of tRNAs is as important for high-fidelity protein biosynthesis as is the accurate selection of amino acids, and this recognition is sometimes referred to as the "second genetic code." In general, tRNA recognition by the synthetase is different for each synthetase and tRNA pair:

- *Some synthetases recognize their tRNA partners primarily on the basis of their anticodons*. The most direct evidence comes from crystallographic studies of complexes formed between synthetases and their cognate tRNAs. Consider, for example, the structure of the complex between threonyl-tRNA synthetase and $tRNA^{Thr}$ (**Figure 30.11**). As expected, the CCA arm extends into the zinc-containing activation site, where it is well-positioned to accept threonine from threonyl adenylate. The enzyme interacts extensively not only with the acceptor stem of the tRNA, but also with the anticodon loop. The interactions with the anticodon loop are particularly revealing. Each base within the sequence $5'-CGU-3'$ of the anticodon participates in hydrogen bonds with the enzyme; those with the second two bases (G and U) appear to be more important because the synthetase interacts just as efficiently with the anticodons GGU and UGU.

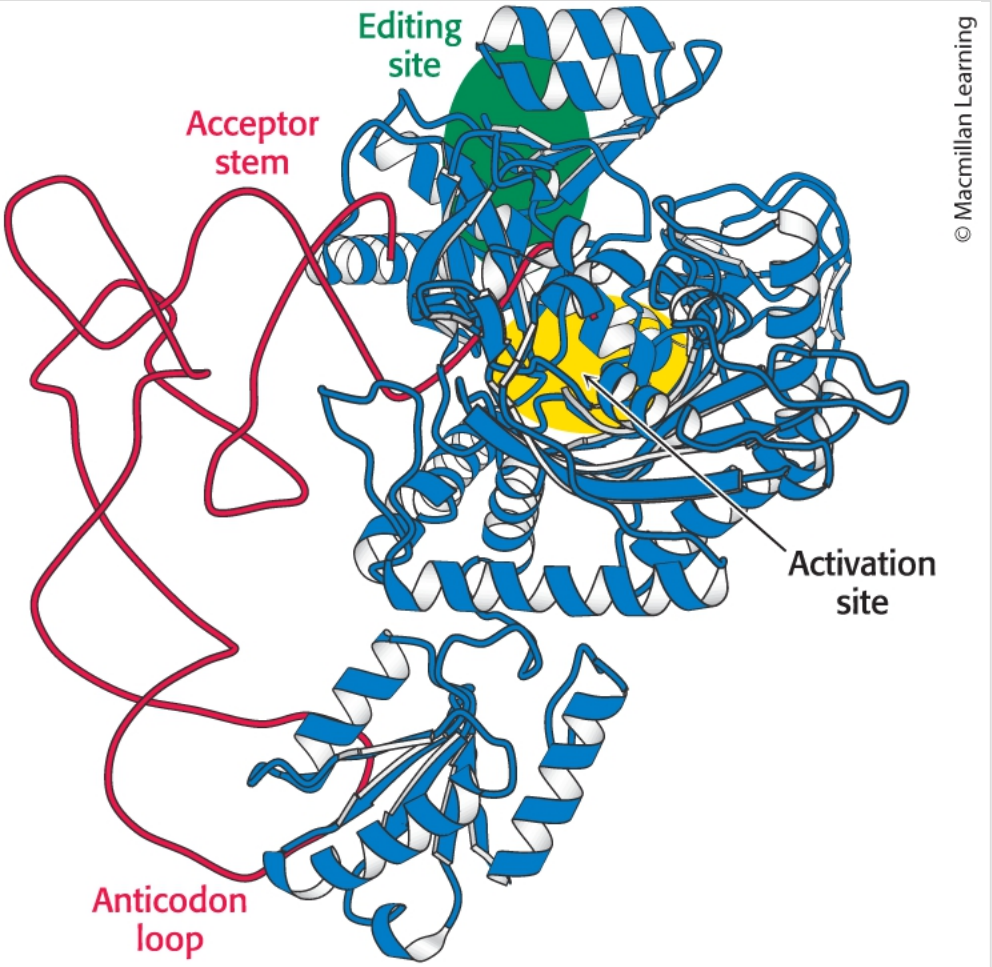

FIGURE 30.11 Aminoacyl-tRNA synthetases bind to both the acceptor stem and the anticodon loop of a tRNA. This structure shows the complex between threonyl-tRNA synthetase (blue) and $tRNA^{Thr}$ (red).

[Drawn from 1QF6.pdb.]

INTERACT with this model in Achieve

- *Synthetases may also recognize other aspects of tRNA structure that vary among different tRNAs.* Although interactions between the enzyme and the anticodon are often crucial for correct recognition, Figure 30.12 shows that many aspects of tRNA molecules are recognized

by synthetases. Note that many of the recognition sites are loops rich in unusual bases that can provide structural identifiers.

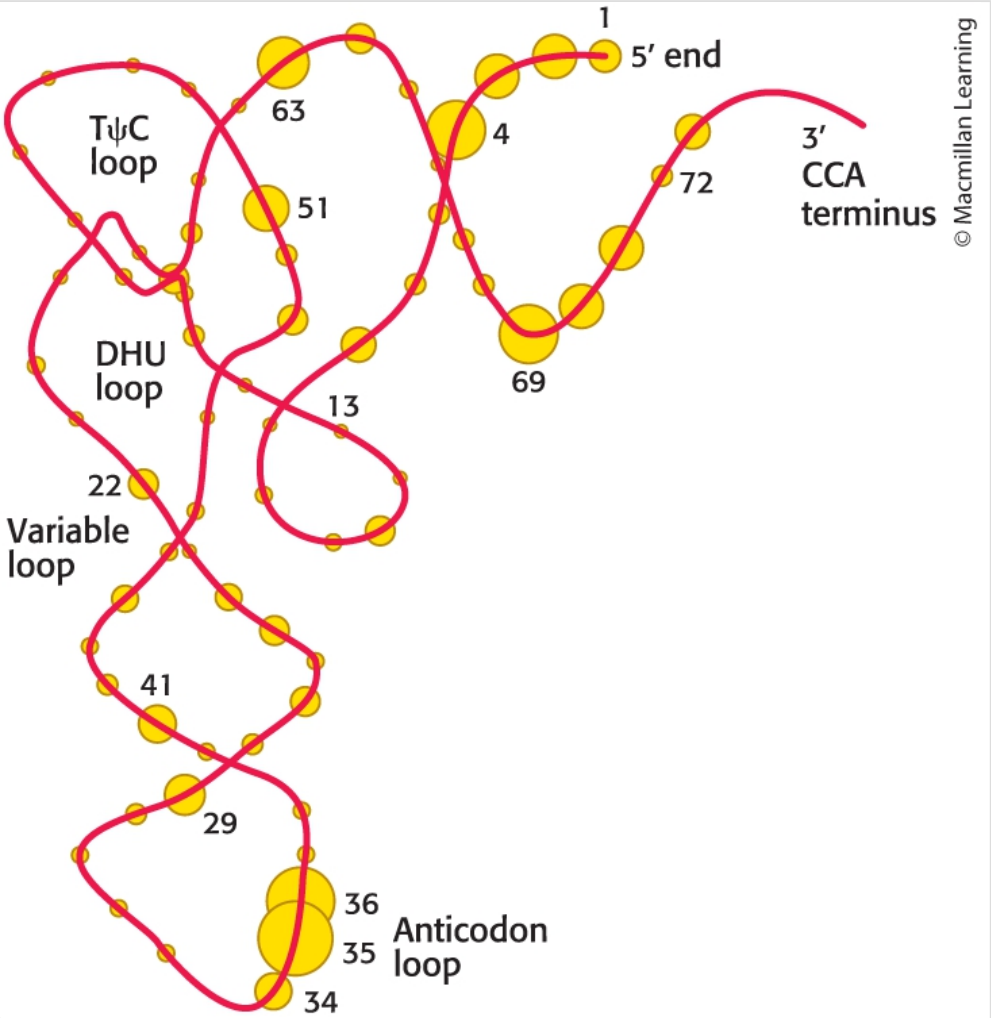

FIGURE 30.12 tRNAs have multiple recognition sites for aminoacyl-tRNA synthetases. Circles represent nucleotides, and the sizes of the circles are proportional to the frequency with which they are used as recognition sites by aminoacyl-tRNA synthetases. The numbers indicate the positions of the nucleotides in the base sequence, beginning from the 5′ end of the tRNA molecule.

[Information from M. Ibba and D. Söll, *Annu. Rev. Biochem*. 69:617–650, 1981, p. 636.]

Aminoacyl-tRNA synthetases are divided into two classes

The diverse sizes, subunit composition, and sequences of aminoacyl-tRNA synthetases were bewildering for many years. Could it be that essentially all synthetases evolved independently? The determination of the three-dimensional structures of several synthetases followed by more refined sequence comparisons revealed that different synthetases are, in fact, related.

Specifically, synthetases fall into two classes, termed *class I* and *class II*, each of which includes enzymes specific for 10 of the 20 amino acids (**Table 30.3**). Intriguingly, synthetases from the two classes bind to different faces of the tRNA molecule (**Figure 30.13**). The CCA arm of tRNA adopts different conformations to accommodate these interactions; the arm is in the helical conformation observed for free tRNA (Figures 30.3 and 30.4) for class II enzymes and in a hairpin conformation for class I enzymes. These two classes also differ in other ways:

TABLE 30.3 Classification and subunit structure of aminoacyl-tRNA synthetases in *E. coli*

Class I	Class II
Arg (α)	Ala (α_4)
Cys (α)	Asn (α_2)
Gln (α)	Asp (α_2)
Glu (α)	Gly ($\alpha_2\beta_2$)
Ile (α)	His (α_2)

Leu (α)	Lys (α2)
Met (α)	Phe (α2β2)
Trp (α2)	Ser (α2)
Tyr (α2)	Pro (α2)
Val (α)	Thr (α2)

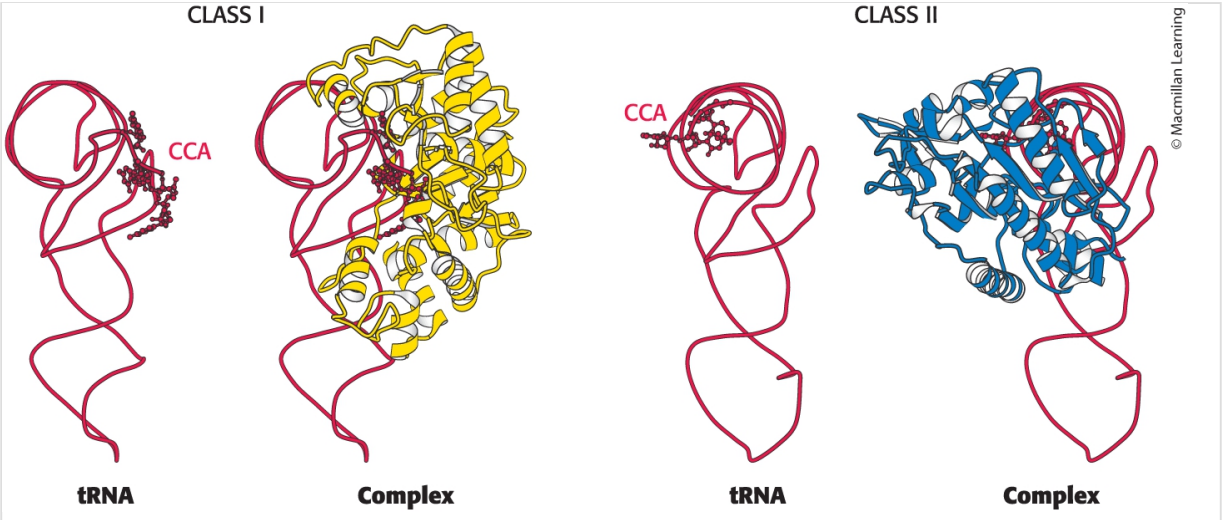

FIGURE 30.13 Class I and class II aminoacyl-tRNA synthetases recognize different faces of the tRNA molecule. The CCA arm of tRNA adopts different conformations in complexes with the two classes of synthetase. Note that the CCA arm of the tRNA is turned toward the viewer (as compared to Figures 30.3 and 30.4). Only the CCA-binding domains of the aminoacyl-tRNA synthetases are shown.

[Drawn from 1EUY.pdb and 1QF6.pdb.]

INTERACT with these models in Achieve

- Class I enzymes acylate the $2'$-hydroxyl group of the terminal adenosine of tRNA, whereas class II enzymes (except the enzyme

for $tRNA^{Phe}$) acylate the $3'$-hydroxyl group.

- The two classes bind ATP in different conformations.
- Most class I enzymes are monomeric, whereas most class II enzymes are dimeric.

Why did two distinct classes of aminoacyl-tRNA synthetases evolve? The observation that the two classes bind to distinct faces of tRNA suggests a possibility. Recognition sites on both faces of tRNA may have been required to allow the recognition of 20 different tRNAs.

30.3 The Ribosome Is the Site of Protein Biosynthesis

We turn now to ribosomes, the molecular machines that coordinate the interplay of aminoacyl-tRNAs, mRNA, and proteins that leads to protein biosynthesis. We will focus our discussion first on ribosomes and protein biosynthesis in bacteria, then discuss the differences observed in eukaryotes.

The 20,000 ribosomes in a bacterial cell constitute nearly a quarter of its mass. An *E. coli* ribosome is a ribonucleoprotein assembly with a mass of about 2300 kDa, a diameter of approximately 250 Å, and a sedimentation coefficient (Section 4.1) of 70S.

A 70S ribosome can dissociate into a **large subunit (50S)** and a **small subunit (30S)**, each of which can be further split into their constituent proteins and RNAs. The 30S subunit contains 21 different proteins (referred to as S1 through S21) and a 16S RNA molecule. The 50S subunit contains 34 different proteins (L1 through L34) and two RNA molecules, a 23S and a 5S species. A 70S ribosome contains one copy of each RNA molecule, two copies each of the L7 and L12 proteins, and one copy of each of the other proteins. The L7 protein is identical to L12 except that its amino terminus is acetylated (Section 7.3).

Both the 30S and the 50S subunits can be reconstituted in vitro from their constituent proteins and RNA. This reconstitution is an outstanding example of the principle that supramolecular complexes can form spontaneously from their macromolecular constituents.

The structures of both the 30S and the 50S subunits as well as the complete 70S ribosome have been determined (**Figure 30.14**). The features of these structures are in remarkable agreement with

interpretations of less-direct experimental analyses of the structure and function of the ribosome. These structures provide an invaluable framework for examining the mechanism of protein biosynthesis.

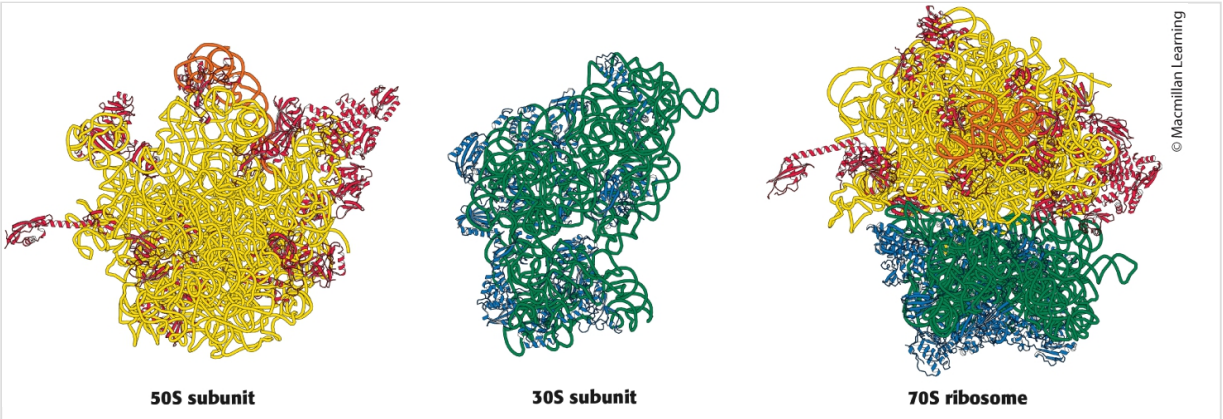

FIGURE 30.14 The ribosome consists of a large subunit and a small subunit. These detailed models of a bacterial ribosome are based on high-resolution x-ray crystallographic data of the 70S ribosome and the 30S and 50S subunits. (Left) View of the part of the 50S subunit that interacts with the 30S subunit. (Center) View of the part of the 30S subunit that interacts with the 50S subunit. (Right) View of the 70S ribosome (note that this view is rotated with respect to the other two views). 23S rRNA is shown in yellow, 5S rRNA in orange, 16S rRNA in green, proteins of the 50S subunit in red, and proteins of the 30S subunit in blue. The interface between the 50S and the 30S subunits consists primarily of RNA.

[Drawn from 1GIX.pdb and 1GIY.pdb.]

Ribosomal RNAs (5S, 16S, and 23S rRNA) play central roles in protein biosynthesis

The prefix *ribo* in the name *ribosome* is apt because RNA constitutes nearly two-thirds of the mass of these large molecular assemblies. The three RNAs present — 5S, 16S, and 23S — are critical for ribosomal architecture and function. They are formed by the cleavage of primary 30S transcripts and further processing. These molecules fold into structures that allow them to form internal base pairs. Their base-pairing patterns were deduced by comparing the nucleotide sequences

of many species to detect conserved sequences as well as conserved base pairings. For instance, the 16S RNA of one species may have a G–C base pair, whereas another may have an A–U base pair, but the location of the base pair is the same in both molecules. Chemical modification and digestion experiments supported the structures deduced from sequence comparisons (Figure 30.15). The striking finding is that across all species, ribosomal RNAs (rRNAs) are folded into defined structures that have many short intramolecular duplex regions.

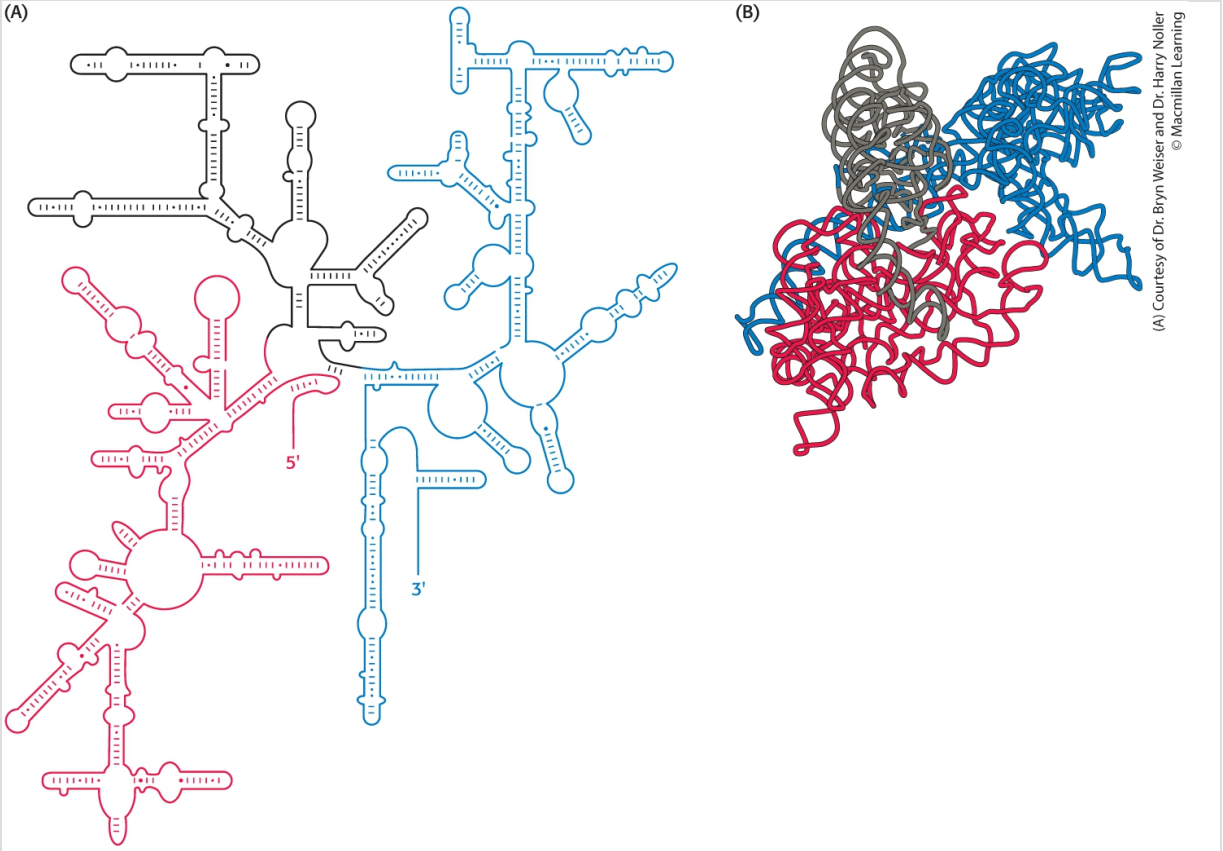

FIGURE 30.15 Ribosomal RNAs form intramolecular base pairs. (A) The secondary structure of 16S rRNA deduced from sequence comparison and the results of chemical studies. Dashes represent standard Watson–Crick base pairs, and dots represent non-Watson–Crick base pairs. (B) The tertiary structure of 16S rRNA determined by x-ray crystallography.

[(B) drawn from 1FJG.pdb.]

INTERACT with this model in Achieve

For many years, ribosomal proteins were presumed to orchestrate protein biosynthesis and ribosomal RNAs were presumed to serve primarily as structural scaffolding. The current view is almost the reverse. The discovery of catalytic RNA (Section 29.5) made biochemists receptive to the possibility that RNA plays a much more active role in ribosomal function. In fact, bacterial ribosomes can be stripped of most of their protein components in vitro and still retain their ability to catalyze peptide-bond formation. In addition, the detailed structures show that the key sites in the ribosome, such as those that catalyze the formation of the peptide bond and those that interact with mRNA and tRNA, are composed almost entirely of rRNA. Contributions from the proteins are minor. The almost inescapable conclusion is that the ribosome initially consisted only of RNA and that the proteins were added later to fine-tune its functional properties. This conclusion has the pleasing consequence of dodging a "chicken and egg" question: How can complex proteins be synthesized if complex proteins are required for protein biosynthesis?

Ribosomes have three transfer RNA-binding sites that bridge the 30S and 50S subunits

Three tRNA-binding sites in ribosomes are arranged to allow the formation of peptide bonds between amino acids encoded by the codons on mRNA (**Figure 30.16**). The mRNA fragment being translated at a given moment is bound within the 30S subunit. Each of the tRNA molecules is in contact with both the 30S subunit and the 50S subunit. At the 30S end, two of the three tRNA molecules are bound to the mRNA through anticodon–codon base pairs. These binding sites are called the

A site (for aminoacyl) and the P site (for peptidyl). The third tRNA molecule is bound to an adjacent site called the E site (for exit).

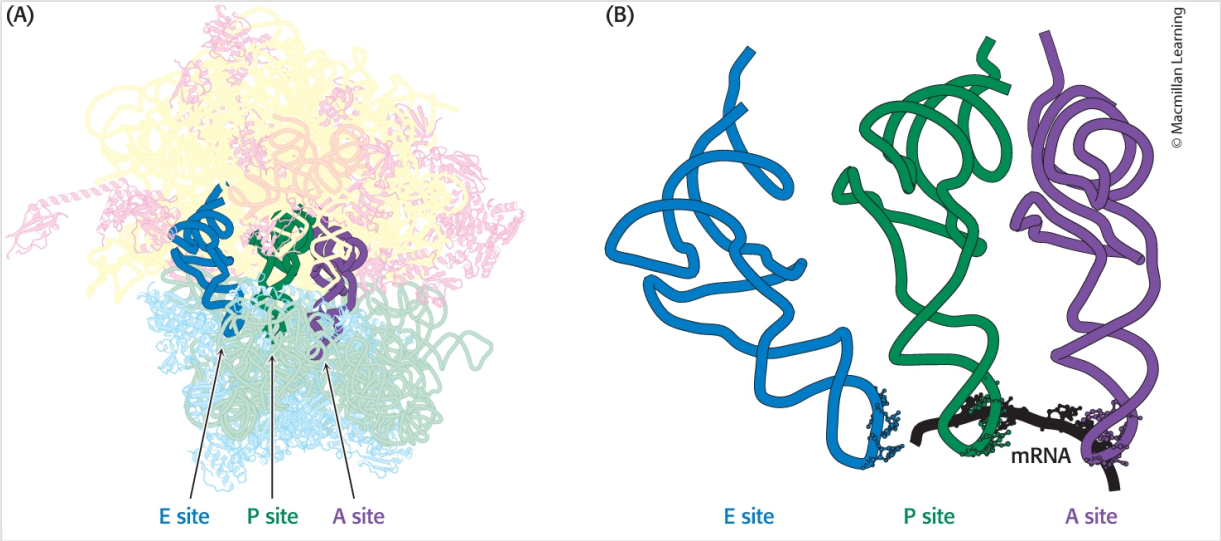

FIGURE 30.16 The ribosome has three binding sites for transfer RNAs. (A) The three tRNA binding sites on the 70S ribosome are called the A (for aminoacyl), P (for peptidyl), and E (for exit) sites. Each tRNA molecule contacts both the 30S and the 50S subunit. (B) The tRNA molecules in sites A and P are base-paired with mRNA.

[(B) Drawn from 1JGP.pdb.]

INTERACT with this model in Achieve

The other end of each tRNA molecule, the end without the anticodon, interacts with the 50S subunit. The acceptor stems of the tRNA molecules occupying the A site and the P site converge at a site where a peptide bond is formed. A tunnel connects this site to the back of the ribosome, through which the polypeptide chain passes during synthesis (Figure 30.17).

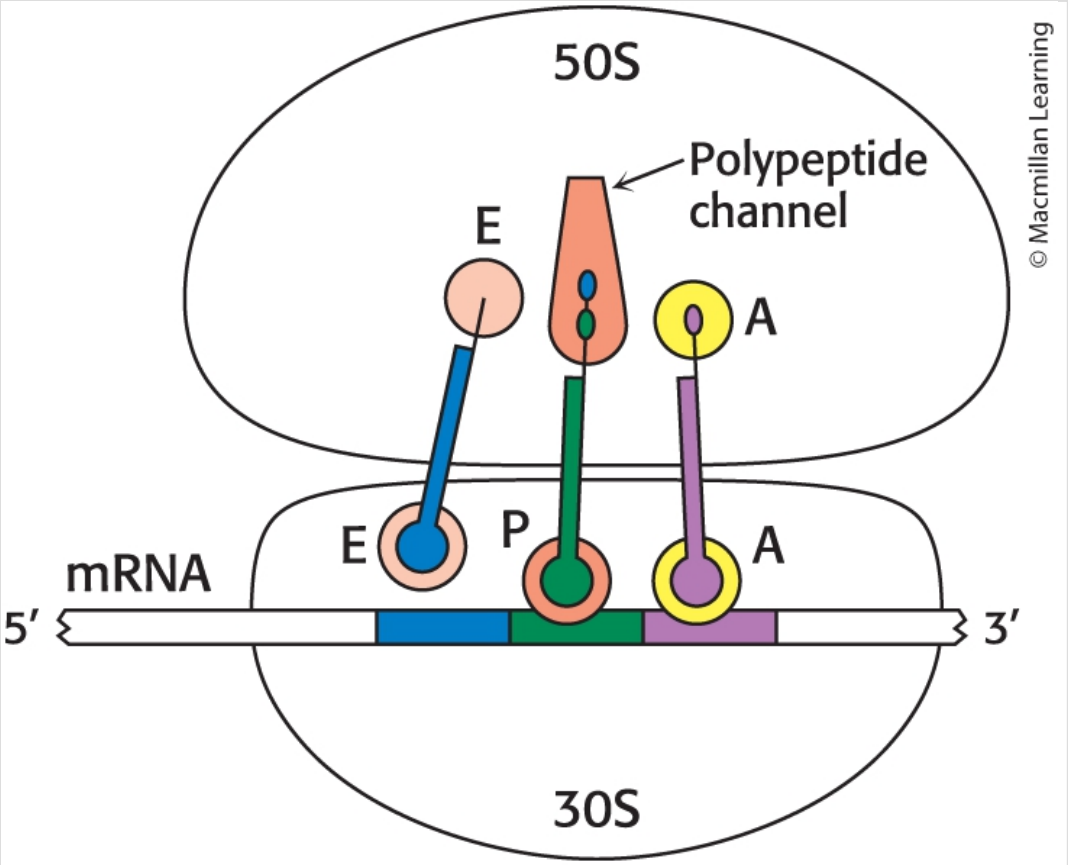

FIGURE 30.17 The key components of the translation machinery interact on an active ribosome. This schematic representation shows the relationship between the ribosomal subunits, tRNAs, and mRNA.

The start signal is usually AUG preceded by several bases that pair with 16S rRNA

How does protein biosynthesis start? The simplest possibility would be for the first three nucleotides of each mRNA to serve as the first codon; no special start signal would then be needed. However, experiments show that translation in bacteria does not begin immediately at the 5′

terminus of mRNA. Indeed, the first translated codon is nearly always more than 25 nucleotides away from the $5'$ end. Furthermore, in bacteria, many mRNA molecules encode two or more polypeptide chains. For example, a single mRNA molecule about 7000 nucleotides long specifies five enzymes in the biosynthetic pathway for tryptophan in *E. coli.* Each of these five proteins has its own start and stop signals on the mRNA. In fact, all known mRNA molecules contain signals that define the beginning and end of each encoded polypeptide chain.

A clue to the mechanism of initiation was the finding that nearly half the amino-terminal residues of proteins in *E. coli* are methionine. In fact, the initiating codon in mRNA is AUG (methionine) or, less frequently, GUG (valine) or, rarely, UUG (leucine). What additional signals are necessary to specify a translation start site? The first step toward answering this question was the isolation of initiator regions from a number of mRNAs. This isolation was accomplished by using ribonuclease to digest mRNA–ribosome complexes (formed under conditions in which protein biosynthesis could begin but elongation could not take place). As expected, each initiator region usually displays an AUG codon (**Figure 30.18**). In addition, each initiator region contains a purine-rich sequence centered about 10 nucleotides on the $5'$ side of the initiator codon.

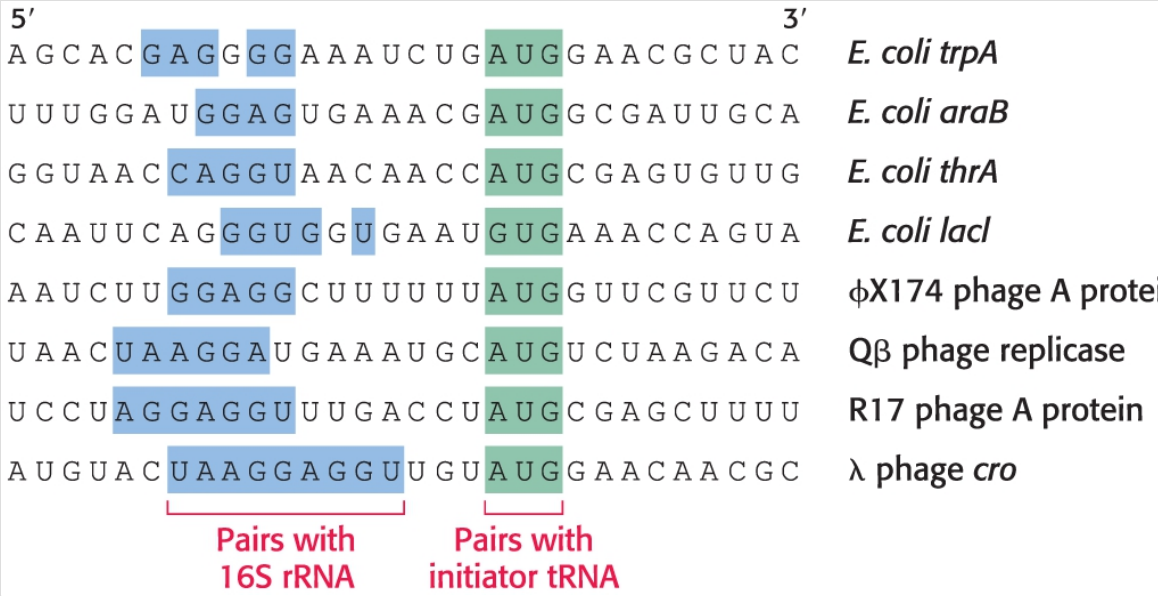

FIGURE 30.18 Initiator regions in mRNA determine where protein biosynthesis starts. This sequence alignment of mRNA initiation sites in some bacterial and viral mRNA molecules revea some recurring features. The purine-rich sequence on the 5′ side of the initiator codon pairs wi a conserved sequence on the 16S rRNA. The first downstream AUG, GUG (less frequent), or UUG (rare) codon acts as the initiator codon for protein biosynthesis.

The role of this purine-rich region, called the **Shine–Dalgarno sequence** (after John Shine and Lynn Dalgarno, who first described the sequence), became evident when the sequence of 16S rRNA was determined. The 3′ end of this rRNA component of the 30S subunit contains a sequence of several bases that is complementary to the Shine–Dalgarno sequence in the mRNA. Mutagenesis of the CCUCC sequence near the 3′ end of 16S rRNA to ACACA markedly interferes with the recognition of start sites in mRNA. This result and other evidence show that the initiator region of mRNA binds very near the 3′ end of the 16S rRNA. The number of base pairs linking mRNA and 16S rRNA ranges from three to nine. This interaction between the 5′ end of

the mRNA and the $3'$ end of the 16S rRNA positions the initiator codon of the mRNA in the P site of the ribosome, ready for recognition by the anticodon of an initiator tRNA molecule.

Bacterial protein biosynthesis is initiated by *N*-formylmethionyl-transfer RNA

As stated earlier, methionine is the first amino acid in many *E. coli* proteins. However, the methionine residue found at the amino-terminal end of *E. coli* proteins is usually modified. In fact, protein biosynthesis in bacteria starts with the modified amino acid *N*-formylmethionine (fMet). A distinct tRNA brings *N*-formylmethionine to the ribosome to initiate protein biosynthesis. This tRNA, called *initiator tRNA* (abbreviated as $tRNA^{fMet}$), differs from the tRNA that inserts methionine in internal positions (abbreviated as $tRNA^{Met}$). The superscript "fMet" indicates that methionine attached to the initiator tRNA can be formylated, whereas it cannot be formylated when attached to $tRNA^{Met}$. Although virtually all proteins synthesized in *E. coli* begin with *N*-formylmethionine, in approximately one-half of the proteins, *N*-formylmethionine is removed when the nascent, or growing, chain is 10 amino acids long.

Methionine is linked to these two kinds of tRNAs by the same aminoacyl-tRNA synthetase. A specific enzyme then formylates the amino group of the methionine molecule that is attached to $tRNA^{fMet}$ (Figure 30.19). The activated formyl donor in this reaction is N^{10}-formyltetrahydrofolate, a folate derivative that carries activated one-

carbon units (Section 25.2). Free methionine and methionyl-$tRNA^{Met}$ are not substrates for this transformylase.

N-Formylmethionyl-$tRNA^{fMet}$ is placed in the P site of the ribosome in the formation of the 70S initiation complex

Messenger RNA and *N*-formylmethionyl-$tRNA^{fMet}$ must be brought to the ribosome for protein biosynthesis to begin. How is this task accomplished? Three protein **initiation factors** (IF1, IF2, and IF3) are essential. The 30S ribosomal subunit first forms a complex with IF1 and IF3 (**Figure 30.20**). The binding of these factors to the 30S subunit prevents it from prematurely joining the 50S subunit to form a dead-end 70S complex, devoid of mRNA and $fMet-tRNA^{fMet}$. IF1 binds near the A site and directs the $fMet-tRNA^{fMet}$ to the P site. IF2, a member of the G-protein family, binds GTP, and the concomitant conformational change enables IF2 to associate with $fMet-tRNA^{fMet}$. The IF2–GTP–initiator-tRNA complex binds with mRNA (correctly positioned by the interaction of the Shine–Dalgarno sequence with the 16S rRNA) and the 30S subunit to form the 30S initiation complex. Structural changes then lead to the ejection of IF1 and IF3. IF2 stimulates the association of the 50S subunit to the complex. The GTP bound to IF2 is hydrolyzed upon arrival of the 50S subunit, releasing IF2. The result is a 70S initiation complex. The

formation of the 70S initiation complex is the rate-limiting step in protein biosynthesis.

FIGURE 30.20 Prokaryotic initiation factors aid the assembly of initiation complexes. These factors first aid assembly of the 30S initiation complex, and then of the 70S initiation complex. IF1 interacts with the 30S near the A site and prevents any tRNAs from binding there. IF3 also binds to the 30S and prevents the 50S from prematurely interacting with the 30S. IF2 delivers the initiator tRNA (or *N*-formylmethionyl-$tRNA^{fMet}$) to the P site as a ternary complex with GTP.

When the 70S initiation complex has been formed, the ribosome is ready for the elongation phase of protein biosynthesis. The $fMet-tRNA^{fMet}$ molecule occupies the P site on the ribosome, positioned so that its anticodon pairs with the initiating codon on mRNA. The other two sites for tRNA molecules, the A site and the E site, are empty. This interaction establishes what is termed the *reading frame* for the translation of the entire mRNA (Section 8.6). After the initiator codon has been located, groups of three nonoverlapping nucleotides are decoded by the ribosome to create the polypeptide chain.

Elongation factors deliver aminoacyl-tRNAs to the ribosome

At this point, $fMet-tRNA^{fMet}$ occupies the P site, and the A site is vacant. The particular aminoacyl-tRNA inserted into the empty A site depends on the mRNA codon in the A site. However, the appropriate aminoacyl-tRNA does not simply leave the synthetase and diffuse to the A site. Rather, it is delivered to the A site in association with a 43-kDa protein called **elongation factor Tu (EF-Tu)**, another member of the G-protein family. EF-Tu, the most abundant bacterial protein, binds aminoacyl-tRNA only in its GTP form (**Figure 30.21**).

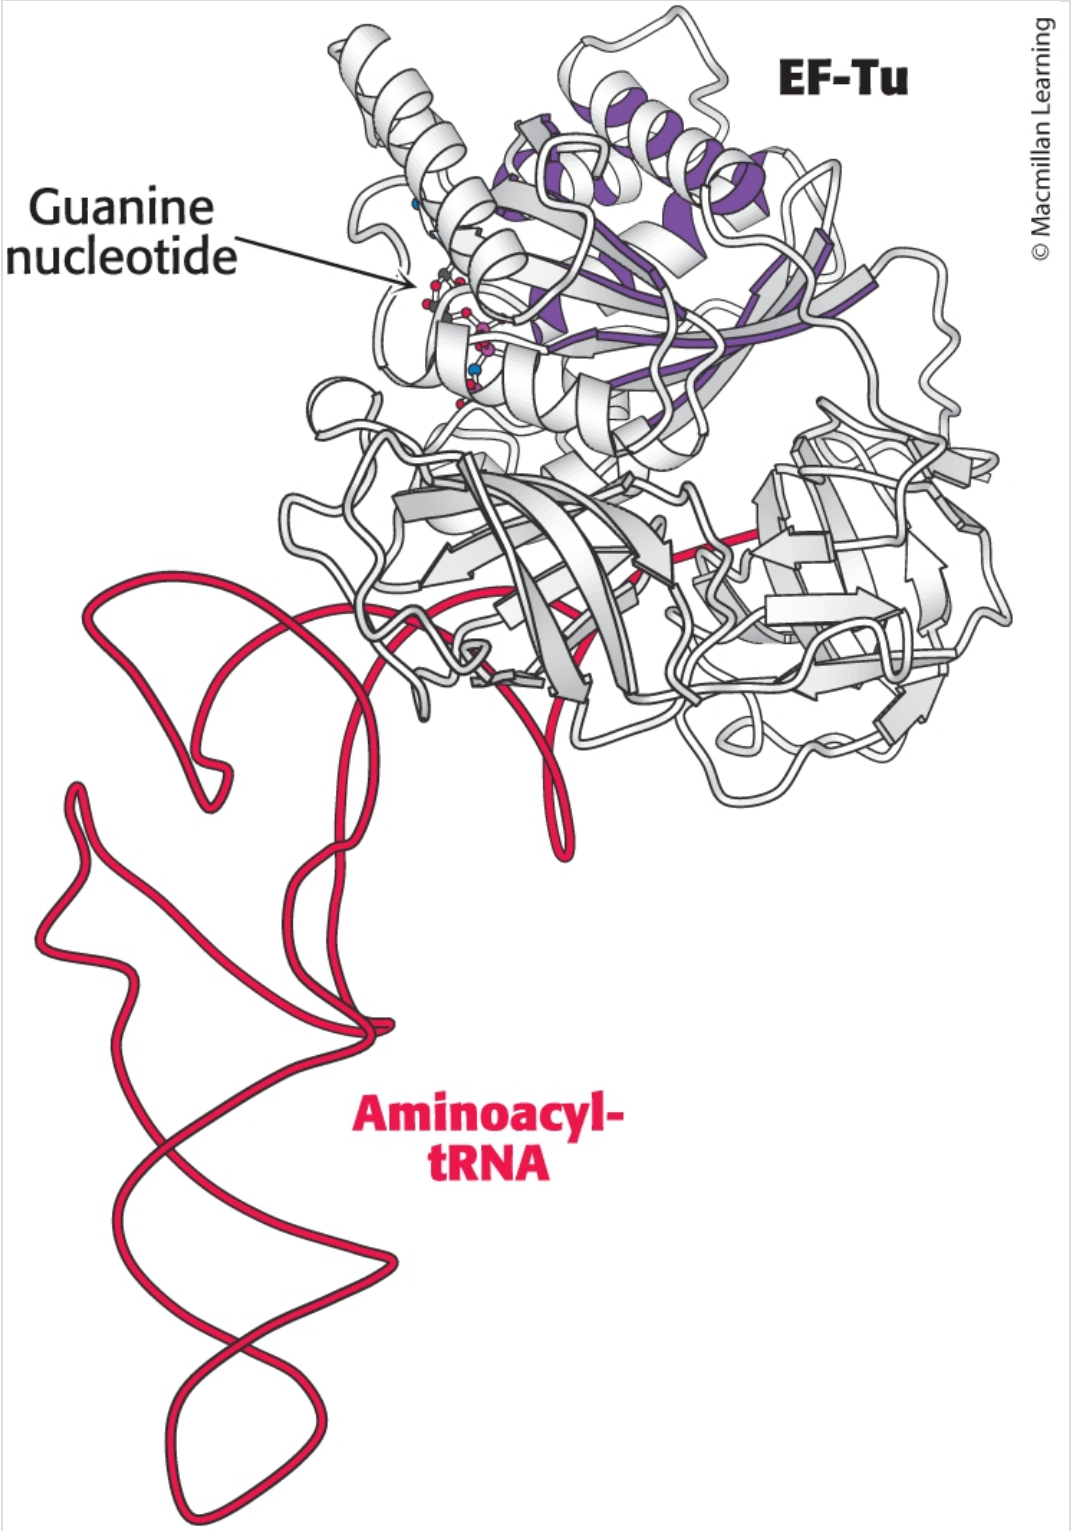

FIGURE 30.21 The structure of elongation factor Tu (EF-Tu) and an aminoacyl-tRNA resembles those of other G proteins. The P-loop NTPase domain (purple shading) at the amino-terminal end of EF-Tu is also found in other G proteins.

[Drawn from 1B23.pdb.]

INTERACT with this model in Achieve

The binding of EF-Tu to aminoacyl-tRNA serves two functions. First, EF-Tu protects the delicate ester linkage in aminoacyl-tRNA from hydrolysis. Second, EF-Tu contributes to the accuracy of protein biosynthesis because GTP hydrolysis and expulsion of the EF-Tu-GDP complex from the ribosome occurs only if the pairing between the anticodon and the codon is correct. EF-Tu interacts with the 16S rRNA, which monitors the accuracy of the base pairing at positions 1 and 2 of the codon (Figure 30.6).

Correct codon recognition induces structural changes in the 30S subunit that move the EF-Tu to a highly conserved site in the 23S rRNA in the 50S subunit called the sarcin-ricin loop (SRL). The interaction with the SRL of the 50S subunit activates the GTPase activity of EF-Tu, releasing EF-Tu-GDP from the ribosome. These same structural changes also rotate the aminoacyl-tRNA in the A site so that the amino acid is brought into proximity with the aminoacyl-tRNA in the P site on the 50S subunit, a process called *accommodation*. Accommodation aligns the amino acids for peptide-bond formation.

Released EF-Tu is then reset to its GTP form by a second elongation factor, **elongation factor Ts** (**Figure 30.22**). EF-Ts induces the dissociation of GDP. GTP binds to EF-Tu, and EF-Ts concomitantly departs. It is noteworthy that EF-Tu does not interact with $\mathrm{fMet-tRNA^{fMet}}$. Hence, this initiator tRNA is not delivered to the A site. In contrast, $\mathrm{Met-tRNA^{Met}}$, like all other aminoacyl-tRNAs, does bind to EF-Tu. These findings account for the fact that internal AUG codons are not read by the initiator tRNA. Conversely, IF2 recognizes $\mathrm{fMet-tRNA^{fMet}}$ but no other tRNA.

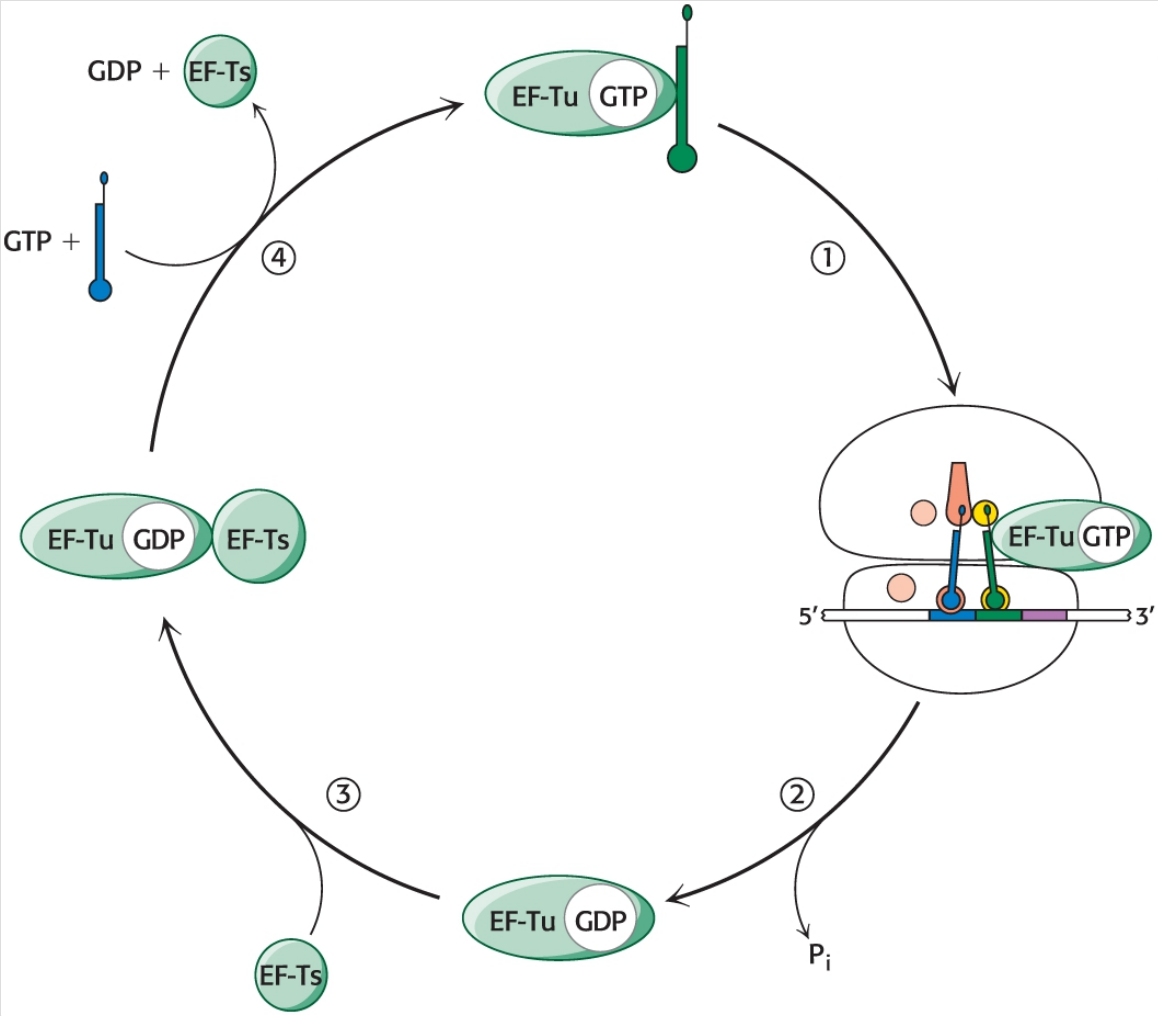

FIGURE 30.22 The GTPase EF-Tu binds aminoacyl-tRNA only in its GTP form. (1) EF-Tu-GTP binds aminoacyl-tRNA and delivers it to the A site on the ribosome. (2) Correct codon recognitic stimulates the GTPase activity of EF-Tu, which leaves it in its GDP form. (3) EF-Ts binds to EF-Tu-GDP. (4) EF-Ts induces release of GDP. EF-Ts departs as another GTP and aminoacyl-tRNA bind t EF-Tu-GTP, and the complex is ready for another delivery to the ribosome.

This GTP–GDP cycle of EF-Tu is reminiscent of those of the heterotrimeric G proteins in signal transduction (Section 14.2) and the Ras proteins in growth control (Section 14.4). This similarity is due to their shared evolutionary heritage, seen in the homology of the amino-terminal domain of EF-Tu to the P-loop NTPase domains in the other G

proteins. In all these related enzymes, the change in conformation between the GTP and the GDP forms leads to a change in interaction partners. A further similarity is the requirement that an additional protein catalyzes the exchange of GTP for GDP; EF-Ts catalyzes the exchange for EF-Tu, just as an activated receptor does for a heterotrimeric G protein.

Peptidyl transferase catalyzes peptide-bond formation

With both the P site and the A site occupied by aminoacyl-tRNA, the stage is set for the formation of a peptide bond: the *N*-formylmethionine molecule linked to the initiator tRNA will be transferred to the amino group of the amino acid in the A site. The formation of the peptide bond, one of the most important reactions in life, is a thermodynamically spontaneous reaction catalyzed by a site on the 23S rRNA of the 50S subunit called the **peptidyl transferase center**. This catalytic center is located deep in the 50S subunit near the tunnel that allows the nascent peptide to leave the ribosome.

The ribosome, which enhances the rate of peptide-bond synthesis by a factor of 10^7 over the uncatalyzed reaction $(\sim 10^{-4}\,M^{-1}\,s^{-1})$, derives much of its catalytic power from catalysis by proximity and orientation. The ribosome positions and orients the two substrates so that they are situated to take advantage of the inherent reactivity of an amine group (on the aminoacyl-tRNA in the A site) with an ester (on the initiator tRNA in the P site). The amino group of the aminoacyl-tRNA in the A site, in its unprotonated state, makes a nucleophilic attack on the ester linkage between the initiator tRNA and the *N*-formylmethionine molecule in the P site (**Figure 30.23A**). The nature of the transition state that follows the attack is not established, and several models are plausible. One model proposes roles for the $2'$ OH of the adenosine of

the tRNA in the P site and a molecule of water at the peptidyl transferase center. The nucleophilic attack of the α-amino group generates an eight-membered transition state in which three protons are shuttled about in a concerted manner. The proton of the attacking amino group hydrogen bonds to the $2'$ oxygen of ribose of the tRNA. The hydrogen of $2'$ OH in turn interacts with the oxygen of the water molecule at the center, which then donates a proton to the carbonyl oxygen. Collapse of the transition state with the formation of the peptide bond allows protonation of the $3'$ OH of the now-empty tRNA in the P site (Figure 30.23B). The stage is now set for translocation and formation of the next peptide bond.

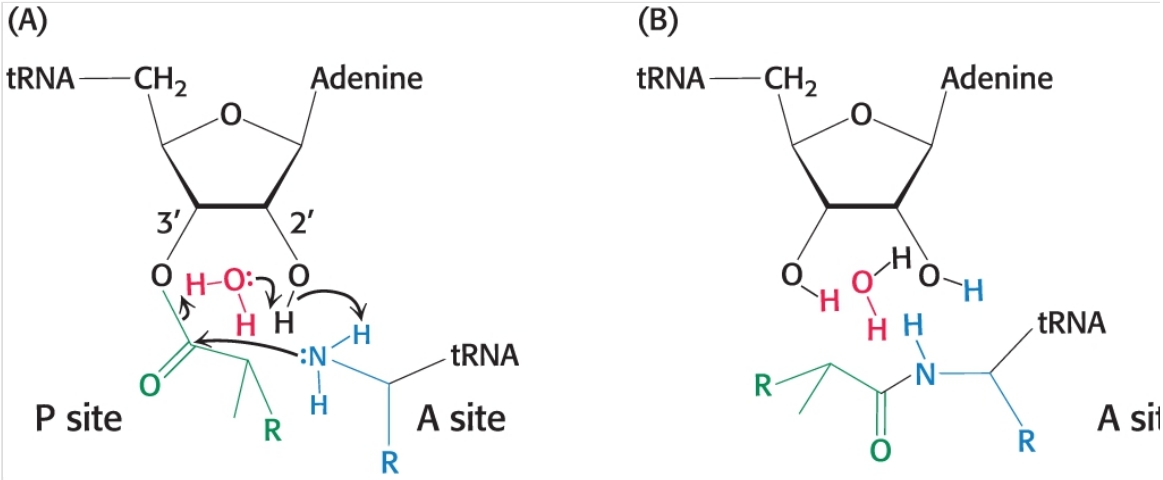

FIGURE 30.23 Peptide-bond formation links amino acids. (A) The amino group of the aminoacyl-tRNA in the A site attacks the carbonyl group of the ester linkage of the peptidyl-tRN in the P site. An eight-membered transition state is formed with the addition of a molecule of water. Notice that not all atoms are shown, and some bond lengths are exaggerated for clarity. (B) This transition state collapses to form the peptide bond and release the deacylated tRNA.

Self-Check Question

Why is the ribosome considered to be a ribozyme?

GTP hydrolysis-driven translocation of tRNAs and mRNA follows peptide-bond formation

With the formation of the peptide bond, the peptide chain is now attached to the tRNA whose anticodon is in the A site on the 30S subunit. The two ribosomal subunits rotate with respect to one another. This structural change places the acceptor end of the same tRNA and its peptide in the P site of the large subunit while its anticodon end is still in the A site (Figure 30.24). However, protein biosynthesis cannot continue unless the next codon is presented in the A site and the site is open for the next aminoacyl-tRNA to be delivered. This requires the translocation of the mRNA and the tRNAs within the ribosome.

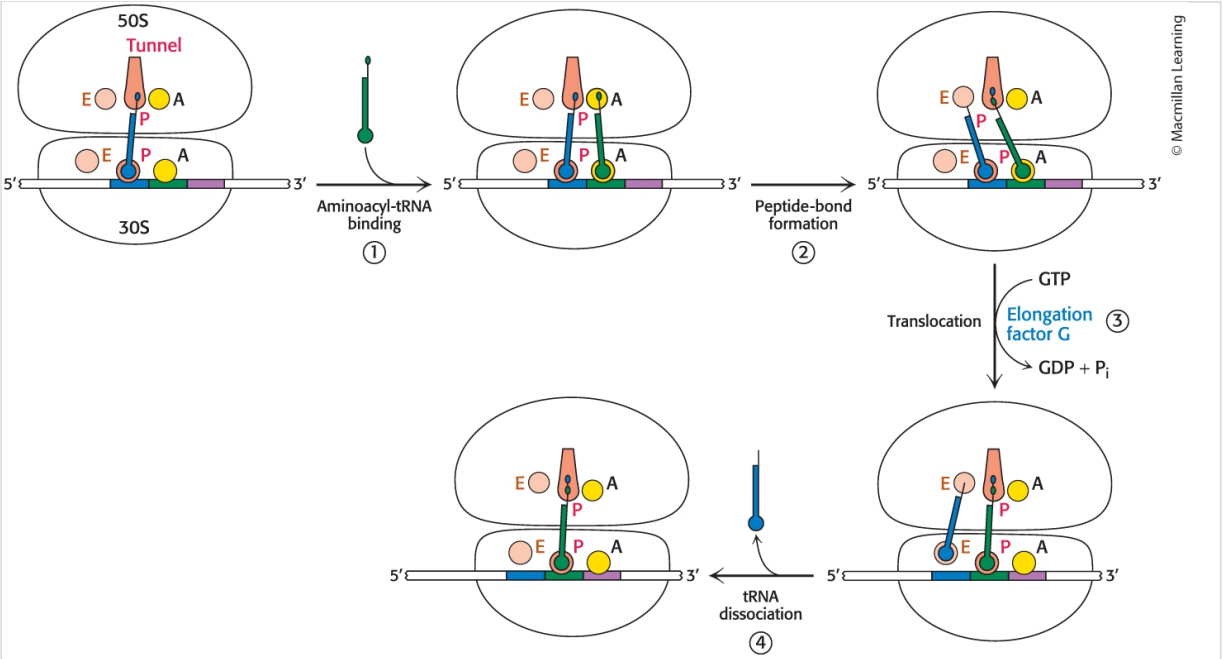

FIGURE 30.24 Protein biosynthesis is a cyclical process. The cycle begins with peptidyl-tRNA in the P site. (1) An aminoacyl-tRNA binds in the A site. (2) With both sites occupied, a new peptide bond is formed. (3) The tRNAs and the mRNA are translocated through the action of elongation factor G, which moves the deacylated tRNA to the E site. (4) Once there, the tRNA is free to dissociate to complete the cycle.

Elongation factor G (**EF-G**, also called **translocase**) catalyzes the movement of mRNA, at the expense of GTP hydrolysis, by a distance of three nucleotides. Now, the next codon is positioned in the A site for interaction with the incoming aminoacyl-tRNA-EF-Tu-GTP complex. Simultaneously, the anticodon end of the peptidyl-tRNA moves out of the A site into the P site on the 30S subunit and the anticodon end of the deacylated tRNA moves out of the P site into the E site. This deacylated tRNA is subsequently released from the ribosome. The movement of the peptidyl-tRNA into the P site shifts the mRNA by one codon, exposing the next codon to be translated in the A site.

The three-dimensional structure of the ribosome undergoes significant change during translocation, and evidence suggests that translocation

may result from properties of the ribosome itself. However, EF-G accelerates the process. A possible mechanism for accelerating the translocation process is shown in **Figure 30.25**. First, EF-G in the GTP form binds to the ribosome near the A site, interacting with the 23S rRNA of the 50S subunit. The binding of EF-G to the ribosome stimulates the GTPase activity of EF-G. On GTP hydrolysis, EF-G undergoes a conformational change that displaces the peptidyl-tRNA in the A site to the P site, which carries the mRNA and the deacylated tRNA with it. The dissociation of EF-G leaves the ribosome ready to accept the next aminoacyl-tRNA into the A site. This cycle of elongation is repeated, with mRNA translation taking place in the $5' \rightarrow 3'$ direction. As new aminoacyl-tRNAs move into the A site, the polypeptide is elongated until a termination codon is met. Note that the peptide chain remains in the P site on the 50S subunit throughout this cycle, growing into the exit tunnel.

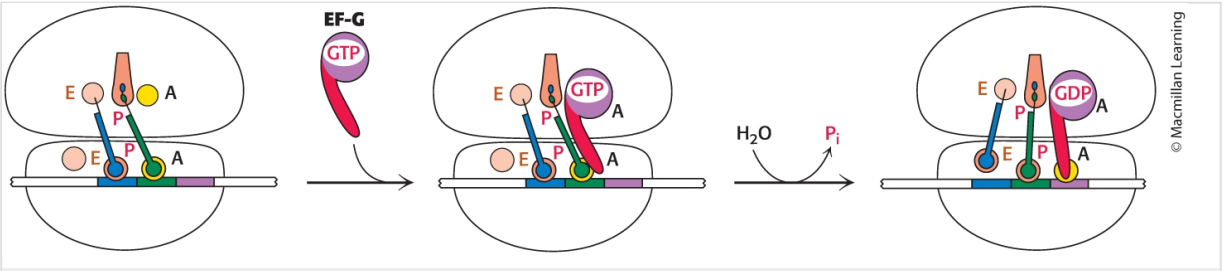

FIGURE 30.25 Translocation repositions tRNAs and mRNA with respect to the ribosome. In the GTP form, EF-G binds to the A site on the 50S subunit. This binding stimulates GTP hydrolysis, inducing a conformational change in EF-G that forces the tRNAs and mRNA to move through the ribosome by a distance corresponding to one codon.

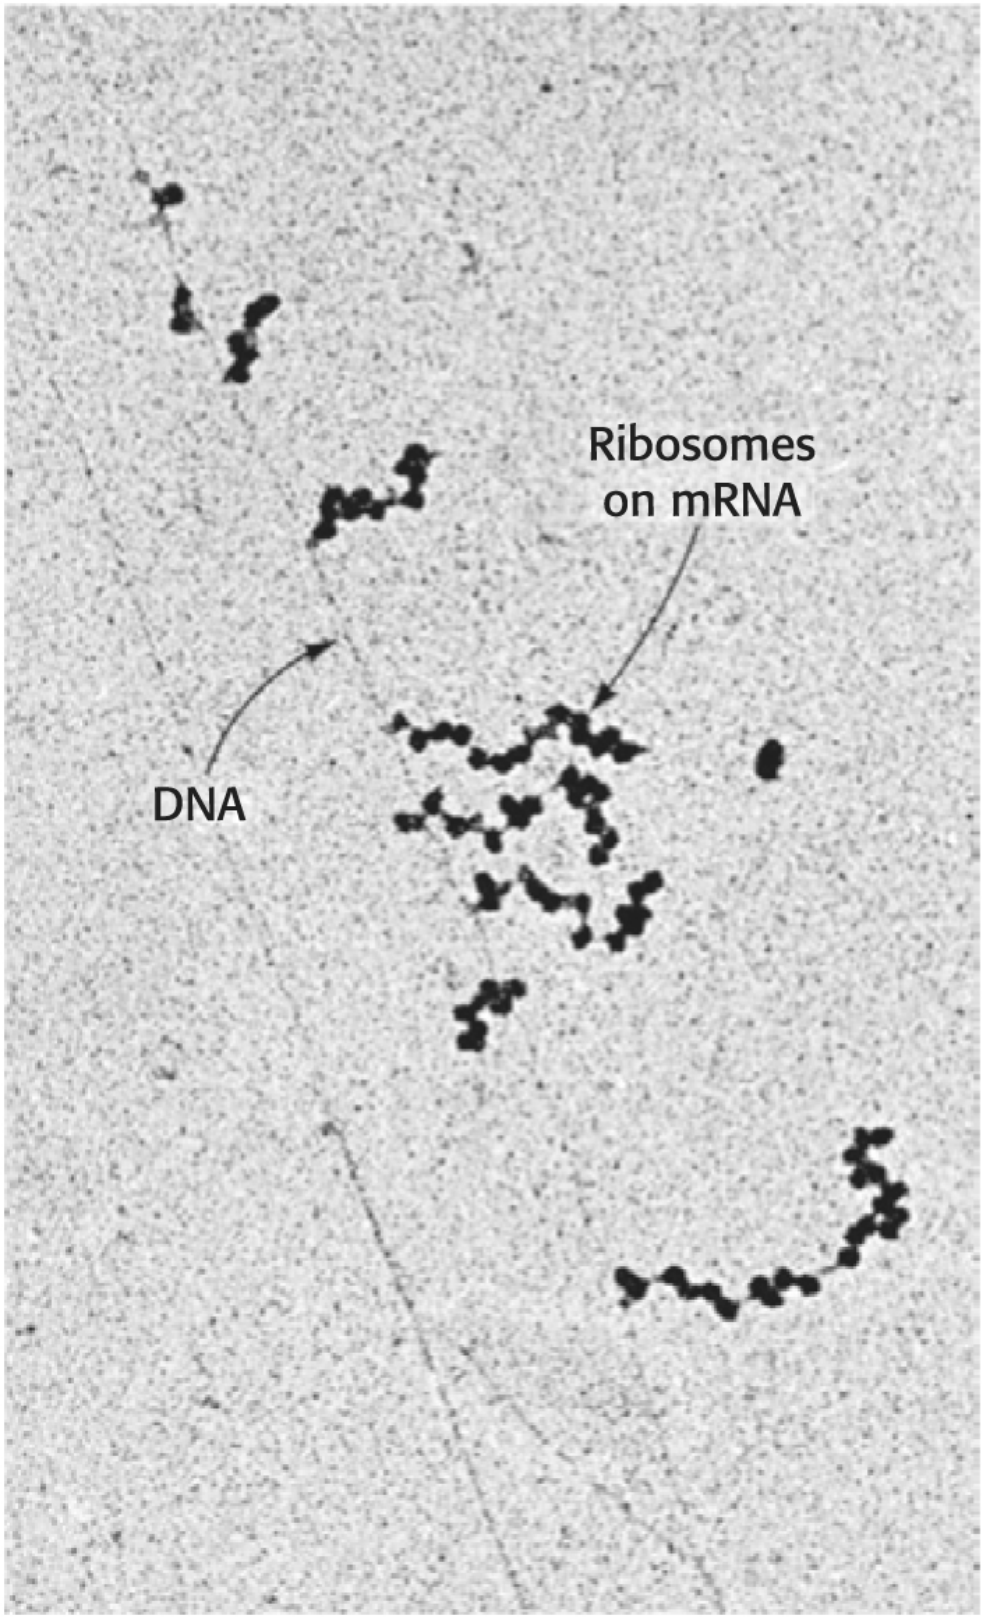
The direction of translation has important consequences. Recall that transcription is also in the $5' \rightarrow 3'$ direction (Section 29.2). If the direction of translation were opposite that of transcription, only fully synthesized mRNA could be translated. Since the directions of synthesis

are the same, translation can occur while an mRNA is being synthesized.

Self-Check Question



Summarize the role of G proteins and GTP hydrolysis in translation initiation and elongation in bacteria.

In bacteria, transcription and translation are coupled in space and time

In bacteria, almost no time is lost between transcription and translation. The $5'$ end of mRNA interacts with ribosomes very soon after it is made, well before the $3'$ end of the mRNA molecule is finished. Recent experiments with *E. coli* using cryo-electron microscopy (Section 4.5) have established the existence of an expressome, a transcribing and translating complex consisting of RNA polymerase and the 70S ribosome. The interaction of the polymerase with the ribosome occurs at the carboxyl-terminal domain of the polymerase.

Many ribosomes can be translating an mRNA molecule simultaneously. A group of ribosomes bound to an mRNA molecule is called a *polyribosome* or a **polysome** (**Figure 30.26**). Recent work shows that the ribosomes are arranged so as to protect the mRNA and to facilitate easy exchange of the substrates and products with the cytoplasm. The ribosomes in the polysome are in a helical array around the mRNA with

the tRNA binding sites and peptide exit tunnel exposed to the cytoplasm.

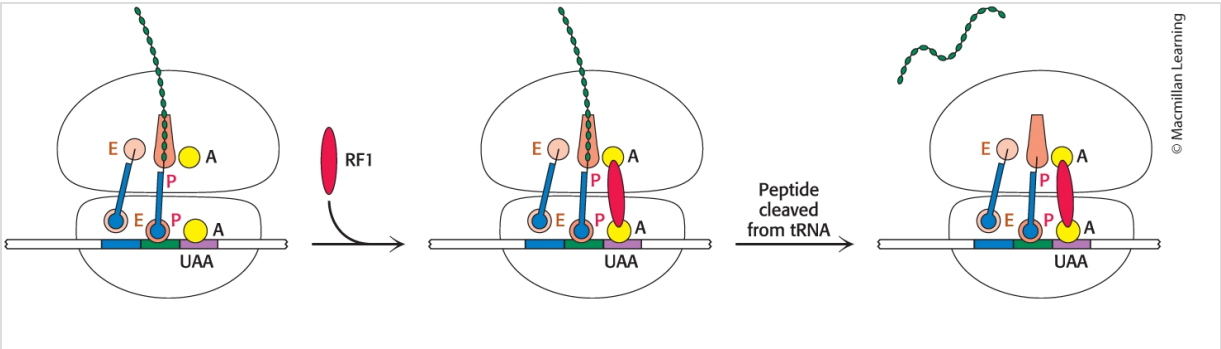
FIGURE 30.26 In prokaryotes, polysomes can simultaneously translate one mRNA. Transcription of a segment of DNA from *E. coli* generates mRNA molecules that are

immediately translated by multiple ribosomes (polysomes).

Protein biosynthesis is terminated by release factors that read stop codons

The final phase of translation is termination. How does the synthesis of a polypeptide chain come to an end when a stop codon is encountered? No tRNAs with anticodons complementary to the stop codons — UAA, UGA, or UAG — exist in normal cells. Instead, these stop codons are recognized by proteins called **release factors (RFs)**. One of these release factors, RF1, recognizes UAA or UAG. A second factor, RF2, recognizes UAA or UGA. A third factor, RF3, another GTPase, catalyzes the removal of RF1 or RF2 from the ribosome upon release of the newly synthesized protein.

RF1 and RF2 are compact proteins that resemble a tRNA molecule. When bound to the ribosome, the proteins unfold to bridge the gap between the stop codon on the mRNA and the peptidyl transferase center on the 50S subunit (**Figure 30.27**). The RF interacts with the peptidyl transferase center using a loop containing a highly conserved glycine-glycine-glutamine (GGQ) sequence, with the glutamine methylated on the amide nitrogen atom of the R group. This modified glutamine (assisted by the peptidyl transferase) is crucial in promoting a water-molecule attack on the ester linkage between the tRNA and the polypeptide chain, freeing the polypeptide chain.



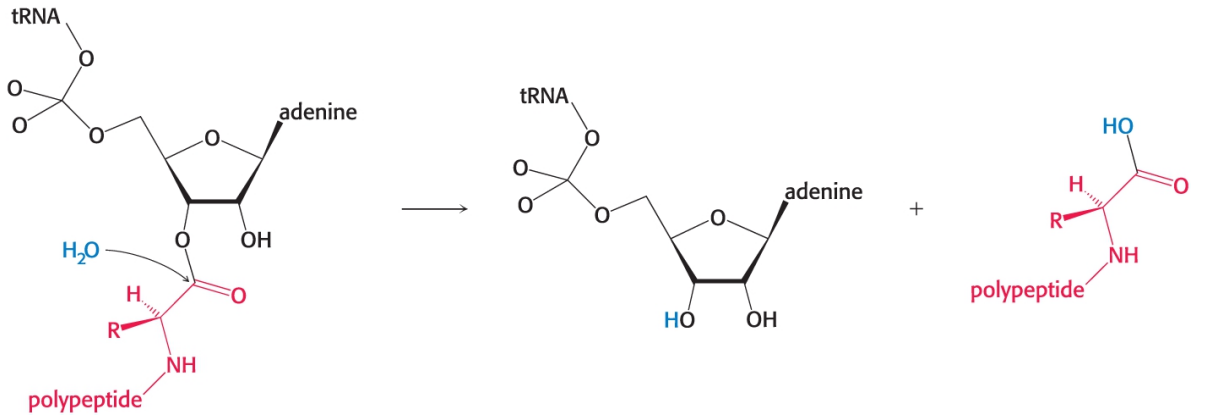


FIGURE 30.27 Release factors facilitate the termination of protein biosynthesis. A release factor recognizes a stop codon in the A site and stimulates the release of the completed protein from the tRNA in the P site.

Next, the detached polypeptide leaves the ribosome. Transfer RNA and mRNA remain briefly attached to the 70S ribosome until the entire complex is dissociated through the hydrolysis of GTP in response to the binding of EF-G and another factor, called the *ribosome release factor* (RRF).

Eukaryotic protein biosynthesis differs from bacterial protein biosynthesis primarily in translation initiation

The basic plan of protein biosynthesis in eukaryotes and archaea is similar to that in bacteria. The major structural and mechanistic themes

recur in all domains of life. However, eukaryotic protein biosynthesis entails more protein components than does bacterial protein biosynthesis, and some steps are more intricate. Some noteworthy similarities and differences include:

- *Eukaryotic ribosomes are larger than those of bacteria*. They consist of a 60S large subunit and a 40S small subunit, which come together to form an 80S particle having a mass of 4200 kDa, compared with 2300 kDa for the bacterial 70S ribosome. The 40S subunit contains an 18S rRNA that is homologous to the bacterial 16S rRNA. The 60S subunit contains three RNAs: the 5S rRNA, which is homologous to the bacterial 5S rRNA; the 28S rRNA, which is homologous to the bacterial 23S molecule; and the 5.8S rRNA, which is homologous to the $5'$ end of the 23S rRNA of bacteria.

- *In eukaryotes, the initiating amino acid is methionine rather than N-formylmethionine*. However, as in bacteria, a special tRNA participates in initiation. This aminoacyl-tRNA is called $\mathrm{Met-tRNAi^{Met}}$ ("i" stands for *initiation*).

- *In eukaryotes, the initiating codon in eukaryotes is almost always AUG (sometimes it is CUG), while in bacteria it can infrequently be GUG or UUG in addition to AUG.* Eukaryotes, in contrast with bacteria, do not have a Shine–Dalgarno sequence on the $5'$ side to distinguish initiator AUGs from internal ones. Instead, the AUG nearest the $5'$ end of mRNA is usually selected as the start site. Eukaryotes use many more initiation factors than do bacteria, and the interplay of these factors is much more complex. The prefix *eIF* denotes a eukaryotic initiation factor.

Initiation begins with the formation of a ternary complex consisting of the 40S ribosome and $\mathrm{Met-tRNAi^{Met}}$ in association with eIF-2. This

complex is called the *43S preinitiation complex* (PIC). The PIC binds to the $5'$ end of mRNA and begins searching for an AUG codon by moving step-by-step in the $3'$ direction. Meanwhile, initiation factor eIF-4E binds to the $5'$ cap of the mRNA (Section 29.3) and facilitates binding of the PIC to the mRNA (**Figure 30.28**). This scanning process is catalyzed by helicases that move along the mRNA powered by ATP hydrolysis. When the anticodon of $\text{Met}-\text{tRNAi}^{\text{Met}}$ finds and pairs with the AUG codon of mRNA, it signals that the target has been found. In almost all cases, eukaryotic mRNA has only one start site and hence is the template for only a single protein. In contrast, a bacterial mRNA can have multiple start sites and can serve as a template for the synthesis of several proteins.

FIGURE 30.28 Translation initiation differs in eukaryotes as compared with prokaryotes. In eukaryotes, translation initiation starts with the assembly of a complex on the $5'$ cap that includes the 40S subunit and $\text{Met}-\text{tRNAi}^{\text{Met}}$. Driven by ATP hydrolysis, this complex scans the mRNA until the first AUG is reached. The 60S subunit is then added to form the 80S initiation complex.

The difference in initiation mechanism between bacteria and eukaryotes is, in part, a consequence of the difference in RNA processing. The $5'$ end of mRNA is readily available to ribosomes immediately after transcription in bacteria. In contrast, in eukaryotes, pre-mRNA must be processed and transported to the cytoplasm before translation is initiated. The $5'$ cap provides an easily recognizable starting point. In addition, the complexity of eukaryotic translation initiation provides another mechanism for regulation of gene expression that we shall explore further in Chapter 31.

Although most eukaryotic mRNA molecules rely on the $5'$ cap to initiate protein biosynthesis, recent work has established that some mRNA molecules can recruit ribosomes for initiation without the use of a $5'$ cap and cap-binding proteins. In these mRNAs, highly structured RNA sequences called *internal ribosome entry sites* (IRES) facilitate 40S ribosome binding to the mRNA. IRES were first discovered in the genomes of RNA viruses and have since been found in other viruses, as well as in a subset of cellular mRNA that appears to take part in development and stress responses (such as to a viral infection). The molecular mechanism by which IRES function to initiate protein biosynthesis remains to be determined.

- *Eukaryotic mRNAs adopt a unique structure.* Soon after the PIC binds the mRNA, eIF-4G links eIF-4E to a protein associated with the

poly(A) tail, called *the poly(A)-binding protein 1* (PABP1; **Figure 30.29**). Cap and tail are thus brought together to form a circle of mRNA. One benefit of circularization of eukaryotic mRNAs is that it may prevent translation of mRNA molecules that have lost their poly(A) tails (Section 29.3).

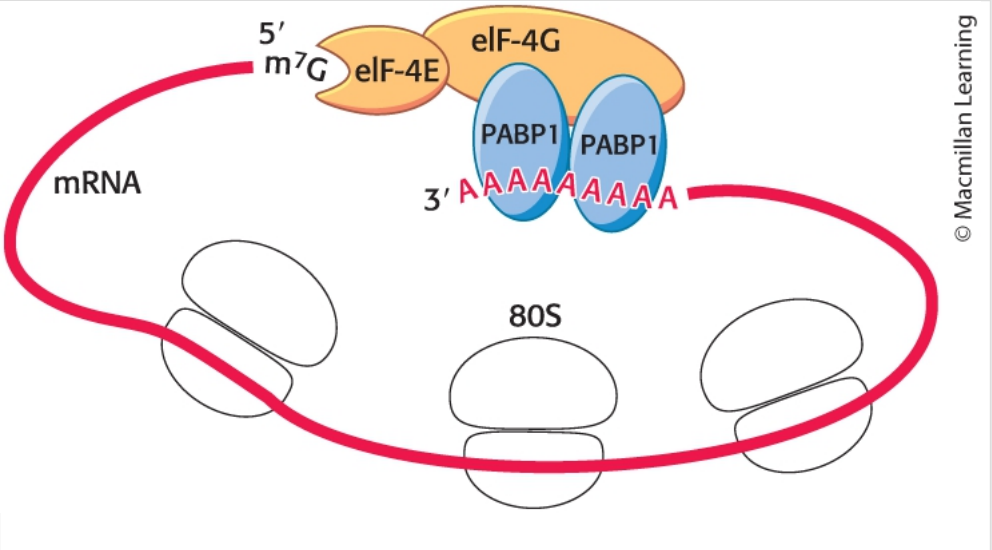

FIGURE 30.29 Protein interactions circularize eukaryotic mRNA. Eukaryotic IFs bound to the 5′ cap and PABP1 bound to the 3′ poly(A) tail come together to create a circular mRNA. This circularization may regulate translation of certain mRNAs.

[Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004), Fig. 4.31.]

- *Bacterial elongation and release factors have structural and functional counterparts in eukaryotes.* Eukaryotic elongation factors EF1α and EF1βγ are the counterparts of bacterial EF-Tu and EF-Ts. The GTP form of EF1α delivers aminoacyl-tRNA to the A site of the ribosome, and EF1βγ catalyzes the exchange of GTP for bound GDP. Eukaryotic EF2 mediates GTP-driven translocation in much the same way as does bacterial EF-G. Termination in eukaryotes is

carried out by a single release factor, eRF1, compared with two in bacteria. Release factor eIF-3 accelerates the activity of eRF-1.

- *The components of the translation machinery in higher eukaryotes are organized into large complexes associated with the cytoskeleton*. This association is believed to facilitate the efficiency of protein biosynthesis. Recall that organization of elaborate biochemical processes into physical complexes is a recurring theme in biochemistry (for example, the ATP synthasome in Section 18.5 and purine biosynthesis in Section 26.2).

Ribosomes selectively control gene expression

Ribosomes were once thought to all be the same, regardless of cell type or physiological state. Recent evidence suggests otherwise and points to a more significant role for ribosomes in the regulation of gene expression.

First, the composition of ribosomes has been shown to change in a cell-specific manner. For instance, mutations in certain ribosomal proteins result in Diamond-Blackfan anemia, which is characterized by bone marrow failure in blood stem-cell differentiation. Although protein biosynthesis is impaired in the blood stem cells, protein biosynthesis in other tissues is apparently normal. If mutations in ribosomal proteins lead to loss of ribosomal function in a tissue-specific manner, might changes to ribosomal protein amounts or posttranslational modifications also regulate ribosomal function in a tissue-specific manner? This question remains to be answered.

Second, nonribosomal proteins can also control ribosome activity. One example is FMRP (fragile X mental retardation protein), which is essential for human cognitive development and also for reproductive

function in women. FMRP, an RNA-binding protein, binds to the 80S ribosome to inhibit the translation of specific mRNAs. Mutations in FMRP result in cognitive disabilities, ovarian failure, and other pathologies. In another startling example, an isozyme of the glycolytic enzyme pyruvate kinase, pyruvate kinase M (Section 16.3), binds to the ribosome to control the translation of proteins destined for the endoplasmic reticulum.

How else might ribosomes regulate translation? Ribosome concentration, which varies 3- to 10-fold among different tissues, may play a role. For instance, a low ribosome concentration might discriminate against certain mRNAs that do not initiate well. This might be the case if mRNA has a complex three-dimensional structure in the $5'$ untranslated region, the part of the mRNA upstream of the initiator codon. Indeed, an insufficient ribosome concentration that results in the impaired translation of a specific subset of mRNA is hypothesized to cause some cases of Diamond-Blackfan anemia. What determines ribosome concentration in different cell types remains unknown.

ADA YONATH Jerusalem-born Ada Yonath and her family experienced poverty and grief, but her parents always supported her desire for understanding the world. In 1970, after completing her postdoctoral work in the United States, Dr. Yonath returned to Israel and set up the country's first biological x-ray crystallography lab at the Weizmann Institute. Fascinated by genetic code translation, she began structural studies on ribosomes but, like many others, failed to arrive at a solution, owing to the ribosomes' complexity and marked instability. She continued only a few years later, after she read about how the ribosomes of hibernating polar bears are arranged in an ordered fashion within their cells, indicating to her the natural tendency to maintain stability. This inspired her to pursue the crystallization of ribosomes from bacteria that live under pressure. Then she confronted another problem: extreme damage to the ribosomal crystals by the x-rays used to visualize them, which prevented structure determination. Her novel solution — taking measurements of frozen crystals of ribosomes at sub-zero temperatures, called *cryo-crystallography* — became popular immediately and has allowed the determination of more than

100,000 structures of various biological materials. Dr. Yonath was awarded the Nobel Prize in Chemistry with Drs. Venkatraman Ramakrishnan and Thomas Steitz in 2009.

Scientists have manipulated protein biosynthesis pathways to incorporate unnatural amino acids in preselected positions

Knowledge of how aminoacyl-tRNA synthetases charge tRNAs with amino acids, and how the ribosome decodes the information in mRNA, has allowed biochemists to synthesize modified proteins with unnatural amino acids (amino acids that are not normally found in nature). These unnatural amino acids can be incorporated at specific positions within the polypeptide chain. Examples of unnatural amino acids include those that have been modified to contain a fluorescent moiety (Figure 30.30), heavy atoms, or other reactive groups, providing the protein that contains them with new and useful chemical and biological properties.

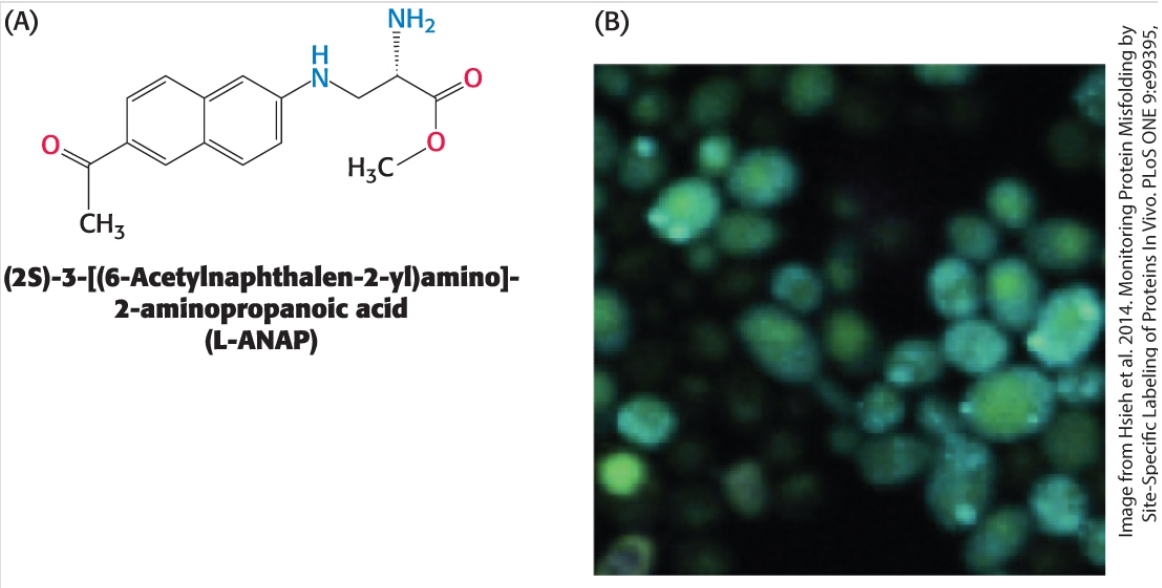

FIGURE 30.30 Unnatural amino acids can be incorporated into proteins. Unnatural amino acid give proteins novel characteristics that are useful for experimental studies. (A) The structure of

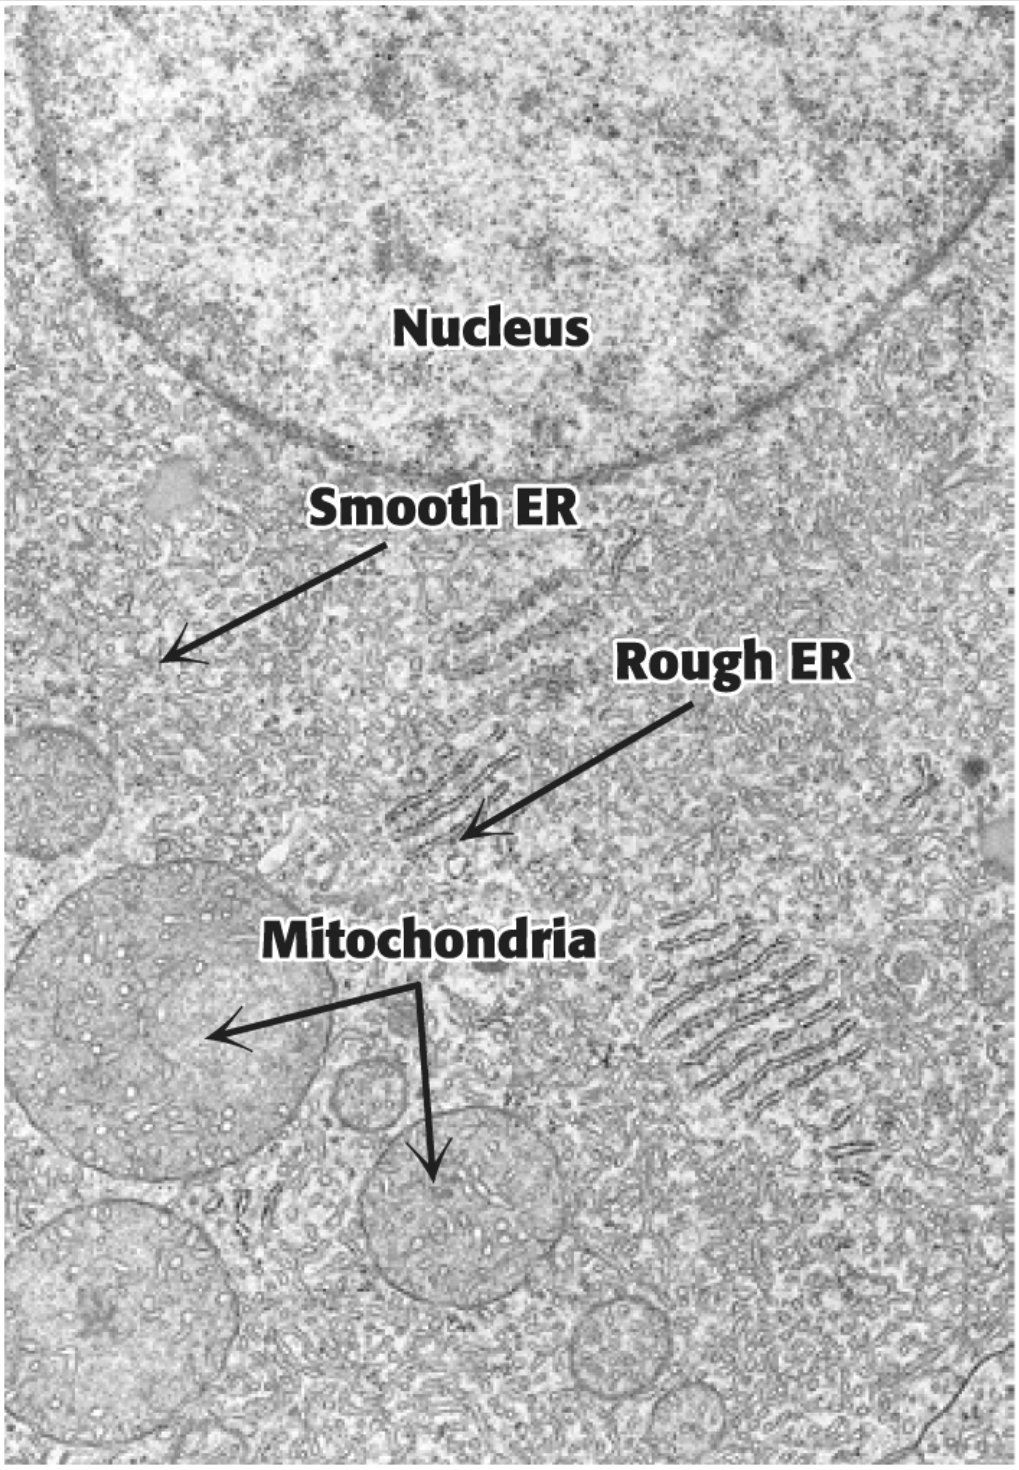
ANAP ((2S)-3-[(6-Acetylnaphthalen-2-yl)amino]-2-aminopropanoic acid), a fluorescent unnatura
amino acid, is shown. (B) Fluorescent proteins are easy to visualize and thus localize, as seen in
this image of yeast cells that express a protein containing L-ANAP.

How are unnatural amino acids introduced into proteins? There are multiple strategies to accomplish this, but in all cases the three key players involved are a tRNA, the unnatural amino acid itself, and the aminoacyl-tRNA synthetase that charges the particular tRNA with the unnatural amino acid. In addition to these players, it is often necessary to usurp one of the three termination codons to introduce the unnatural amino acid into the polypeptide chain (since all other mRNA codons are already set to code for the 20 natural amino acids). Recall that termination codons are not recognized by any cellular tRNAs. To introduce an unnatural amino acid into a protein, the tRNA is engineered to recognize a termination codon, and the aminoacyl-tRNA synthetase is engineered to charge that tRNA with the unnatural amino acid. All of these components can be introduced into a living cell for in vivo protein production. More recent research focuses on creating unnatural proteins in vitro.

Modifying proteins through the incorporation of unnatural amino acids is likely less disruptive to overall protein function than posttranslational modification or labeling. These “designer” proteins can be used in experimental studies of protein folding, localization, and many other characteristics, both in vitro and in vivo. Consider, for example, a synthetic protein with fluorescent unnatural amino acids incorporated near its surface: the exact in vivo sub-cellular localization of this protein can be easily determined via fluorescent microscopy. If the functions of this protein are largely undetermined, knowing where it is located, and what other factors it colocalizes with, might give some insights into what its functions might be.



30.4 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

Not all newly synthesized proteins are destined to function in the cytoplasm. Eukaryotic cells can direct proteins to internal sites such as mitochondria, the nucleus, and the endoplasmic reticulum, a process called *protein targeting* or *protein sorting*. How is this sorting accomplished? There are two general mechanisms by which sorting takes place. In one mechanism, the protein is synthesized in the cytoplasm, and then the completed protein is delivered to its intracellular location posttranslationally. Proteins destined for the nucleus, chloroplasts, mitochondria, and peroxisomes are delivered by this general process. The other mechanism, termed the *secretory pathway*, directs proteins into the endoplasmic reticulum (ER), the extensive membrane system that comprises about half the total membrane of a cell. This mechanism delivers the proteins to the ER cotranslationally — that is, while the protein is being synthesized. Approximately 30% of all proteins are sorted by the secretory pathway, including secreted proteins, residents of the ER, the Golgi complex, lysosomes, and integral membrane proteins of these organelles as well as integral plasma membrane proteins. We will focus our attention on the secretory pathway only.

Protein biosynthesis begins on ribosomes that are free in the cytoplasm

In eukaryotic cells, a ribosome remains free in the cytoplasm unless it is directed to the ER. The region of the ER that ribosomes bind to is called the *rough ER* because of its studded appearance in contrast with the

smooth ER, which is devoid of ribosomes (**Figure 30.31**). The synthesis of proteins sorted by the secretory pathway begins on free ribosomes that soon associate with the ER. Free ribosomes that are synthesizing proteins for use in the cell are apparently identical with those attached to the ER, so ribosomes synthesizing proteins destined to enter the ER need to bind to the ER. How is this accomplished?

Don W. Fawcett/Science Source.

FIGURE 30.31 Ribosomes are bound to the endoplasmic reticulum. In this electron micrograph, ribosomes appear as small black dots binding to the cytoplasmic side of the endoplasmic reticulum to give a rough appearance. In contrast, the smooth endoplasmic reticulum is devoid of ribosomes.

Signal sequences mark proteins for translocation across the endoplasmic reticulum membrane

The synthesis of proteins destined to leave the cell or become embedded in the plasma membrane begins on a free ribosome. However, shortly after synthesis begins, the process is halted until the ribosome is directed to the cytoplasmic side of the ER. When the ribosome docks with the ER membrane, protein biosynthesis begins again. As the newly forming peptide chain exits the ribosome, it is transported — while being translated — through the membrane into the lumen of the ER. The translocation consists of four components:

1. *The signal sequence*. The **signal sequence** is a sequence of 9 to 12 hydrophobic amino acid residues, sometimes containing positively charged amino acids (**Figure 30.32**). This sequence, which adopts an α-helical structure, is usually near the amino terminus of the nascent polypeptide chain. The presence of the signal sequence identifies the nascent peptide as one that must cross the ER membrane. Some signal sequences are maintained in the mature protein, whereas others are cleaved by a **signal peptidase** on the lumenal side of the ER membrane.

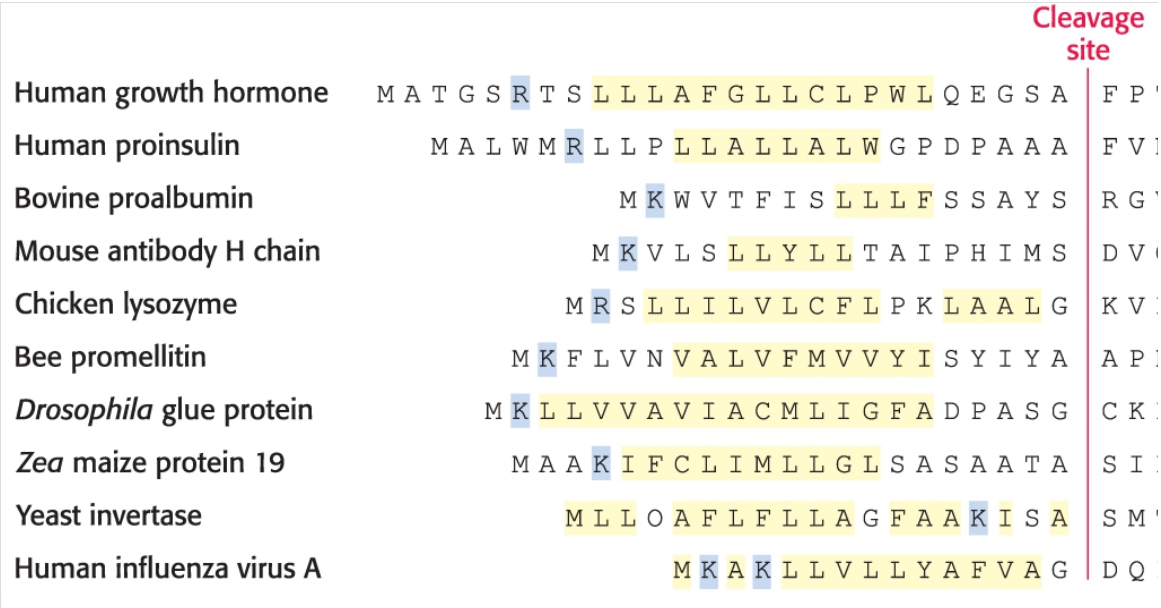


FIGURE 30.32 The signal sequences of eukaryotic secretory and plasma membrane proteins contain hydrophobic residues. This alignment of the amino-terminal signal sequences of some eukaryotic secretory and plasma membrane proteins highlights the hydrophobic core (yellow), which is preceded by basic residues (blue) and followed by a cleavage site (red) for signal peptidase.

2. *The signal-recognition particle*. The **signal-recognition particle (SRP)** recognizes the signal sequence and binds the sequence and the ribosome as soon as the signal sequence exits the ribosome. SRP then shepherds the ribosome and its nascent polypeptide chain to the ER membrane. SRP is a ribonucleoprotein consisting of a 7S RNA and six different proteins (**Figure 30.33**). One protein, SRP54, is a GTPase that is crucial for SRP function. SRP samples all ribosomes until it locates one exhibiting a signal sequence. After SRP binds to the signal sequence, interactions between the ribosome and the SRP block the elongation-factor-binding site, thereby halting protein biosynthesis.

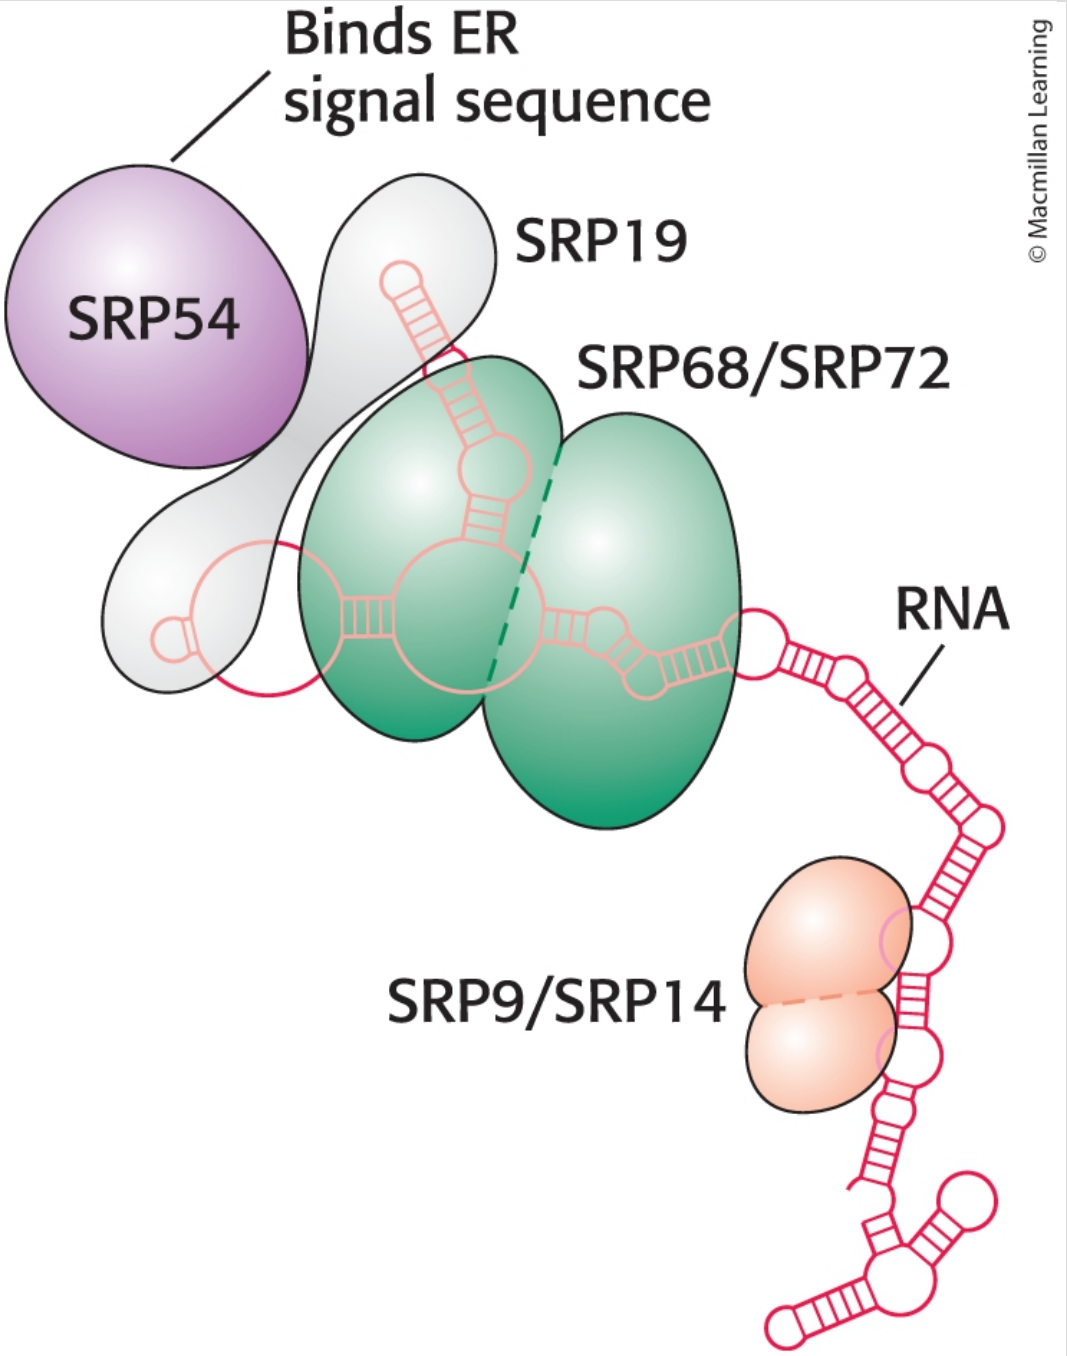

FIGURE 30.33 The signal-recognition particle (SRP) consists of six proteins and one 300-nucleotide RNA. The RNA has a complex structure with many double-helical stretches punctuated by single-stranded regions, shown as circles.

[Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004). Data from K. Strub et al., *Mol. Cell Biol*. 11:3949–3959, 1991, and S. High and B. Dobberstein, *J. Cell Biol*. 113:229–233, 1991.]

3. *The SRP receptor*. The SRP–ribosome complex diffuses to the ER, where SRP binds the **SRP receptor (SR)**, an integral membrane protein consisting of two subunits, SRα and SRβ. SRα is, like SRP54, a GTPase.

4. *The translocon*. The SRP–SR complex delivers the ribosome to the translocation machinery, called the **translocon**, a multisubunit assembly of integral and peripheral membrane proteins. The translocon is a protein-conducting channel that opens when the translocon and ribosome bind to each other. Protein biosynthesis resumes with the growing polypeptide chain passing through the translocon channel into the lumen of the ER.

The interactions of the components of the translocation machinery are shown in **Figure 30.34**. Both the SRP54 and the SRα subunits of SR must bind GTP to facilitate the formation of the SRP–SR complex. For the SRP–SR complex to then deliver the ribosome to the translocon, the two GTP molecules — one in SRP and the other in SR — are aligned in what is essentially an active site shared by the two proteins. The formation of the alignment is catalyzed by the 7S RNA of the SRP. After the ribosome has been passed along to the translocon, the GTPs are hydrolyzed, SRP and SR dissociate, and SRP is free to search for another signal sequence to begin the cycle again. Thus, SRP acts catalytically. The signal peptidase, which is associated with the translocon in the lumen of the ER, removes the signal sequence from most proteins.

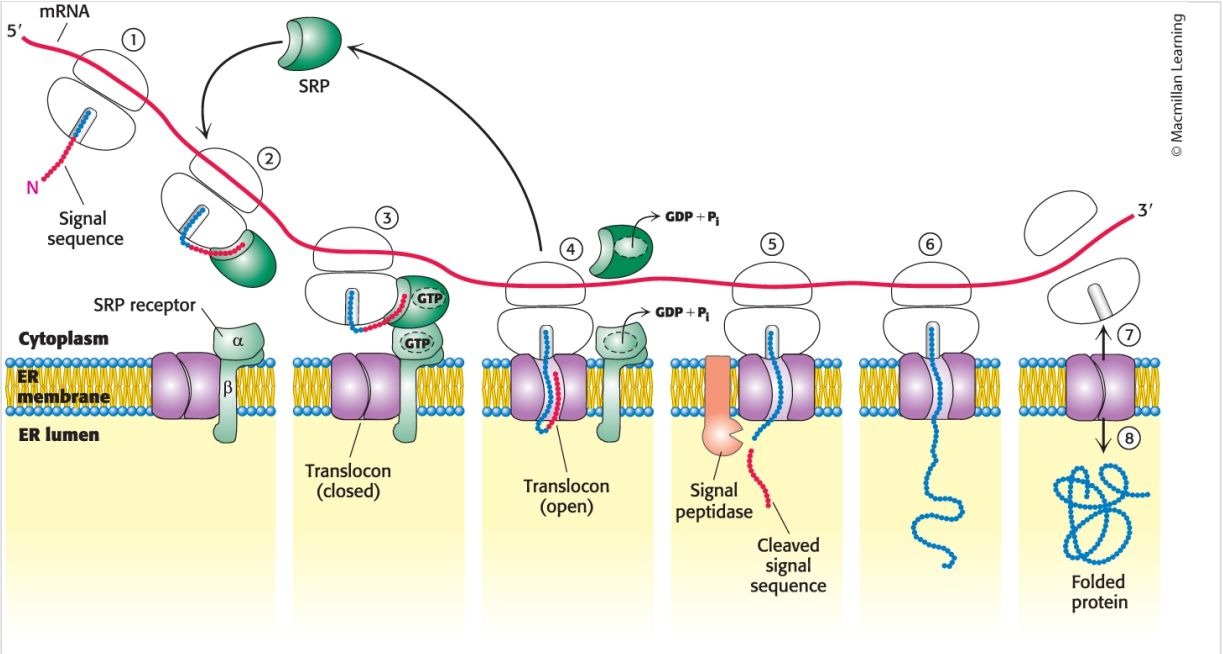

FIGURE 30.34 The SRP targeting cycle delivers nascent proteins containing a signal sequence to the ER. (1) Protein biosynthesis begins on free ribosomes. (2) After the signal sequence has exited the ribosome, it is bound by the SRP, and protein biosynthesis halts. (3) The SRP–ribosome complex docks with the SRP receptor in the ER membrane. (4) The SRP and the SRP receptor simultaneously hydrolyze bound GTPs. Protein biosynthesis resumes and the SRP is free to bind another signal sequence. (5) The signal peptidase may remove the signal sequence as it enters the lumen of the ER. (6) Protein biosynthesis continues as the protein is synthesized directly into the ER. (7) On completion of protein biosynthesis, the ribosome is released. (8) The protein tunnel in the translocon closes.

[Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004), Fig. 16.6.]

Transport vesicles carry cargo proteins to their final destinations

As the proteins are synthesized, they fold into their three-dimensional structures in the lumen of the ER. Some proteins are modified by the attachment of N-linked carbohydrates (Section 11.3). Finally, the proteins must be sorted and transported to their final destinations.

Regardless of the destination, the principles of transport are the same. Transport is mediated by **transport vesicles** that bud off the ER (**Figure 30.35**). Transport vesicles from the ER carry their cargo (the proteins) to the Golgi complex, where the vesicles fuse and deposit the cargo inside the complex. There the cargo proteins are further modified — for instance, by the attachment of O-linked carbohydrates. From the Golgi complex, transport vesicles carry the cargo proteins to their final destinations, as shown in Figure 30.35.

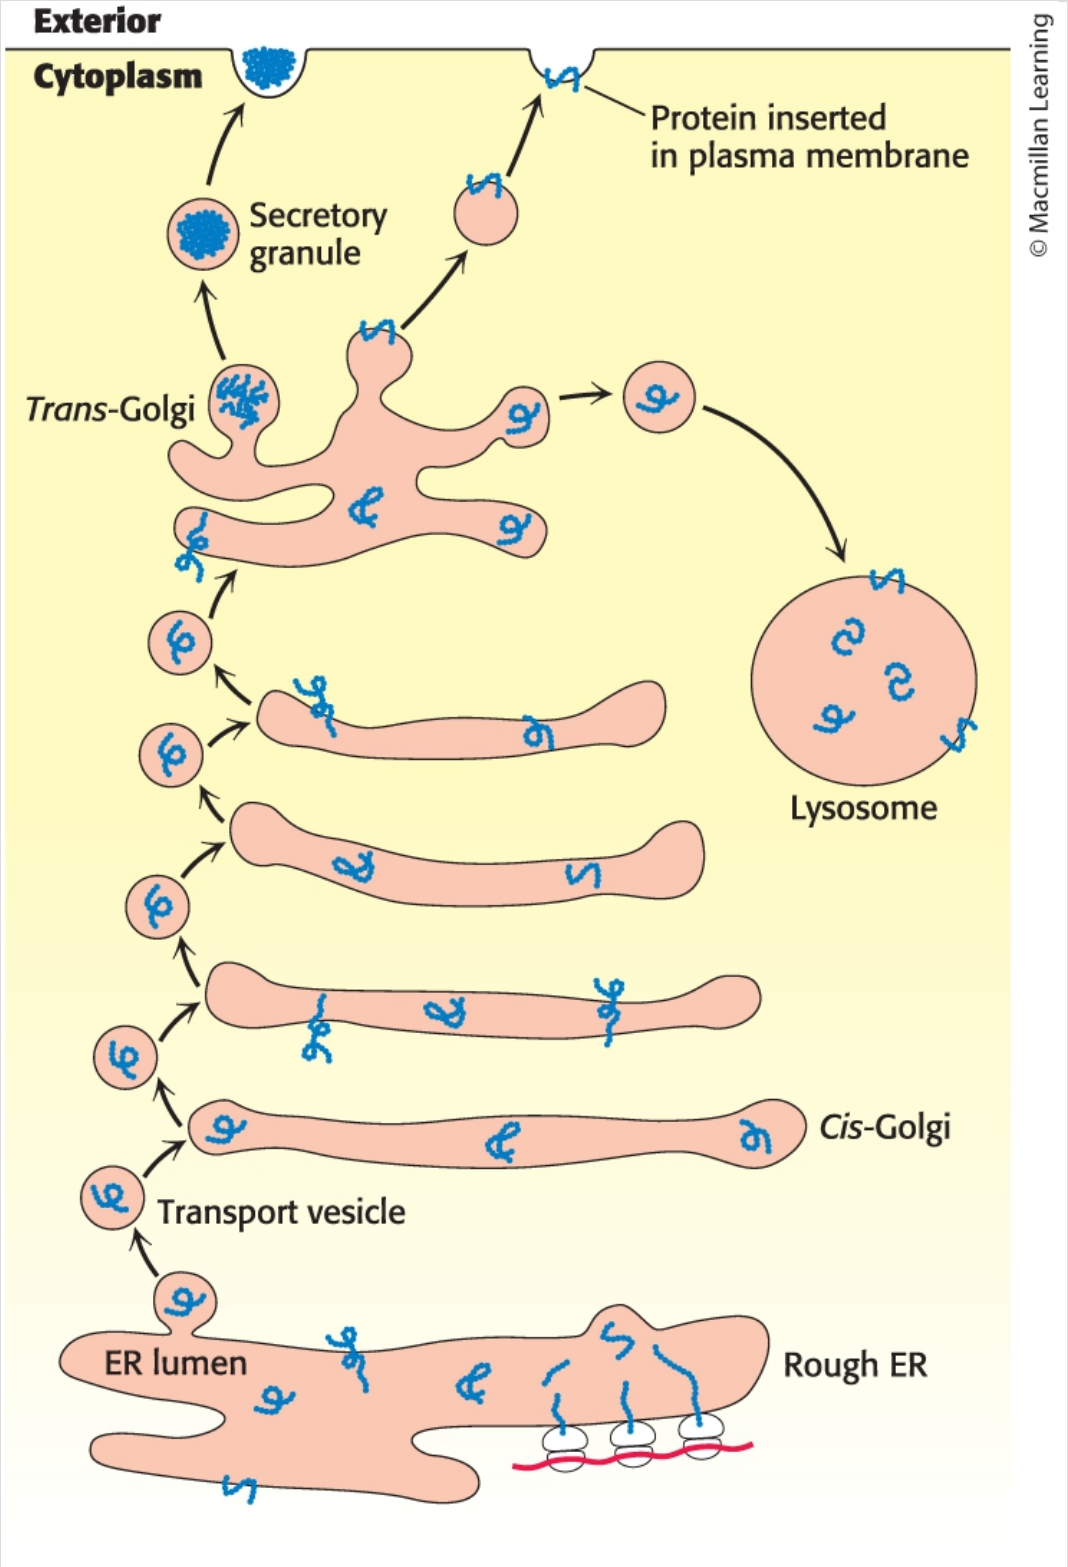

FIGURE 30.35 Protein-sorting pathways deliver proteins to their final destinations. Newly synthesized proteins in the lumen of the ER are collected into membrane buds. These buds pinch off to form transport vesicles. The transport vesicles carry

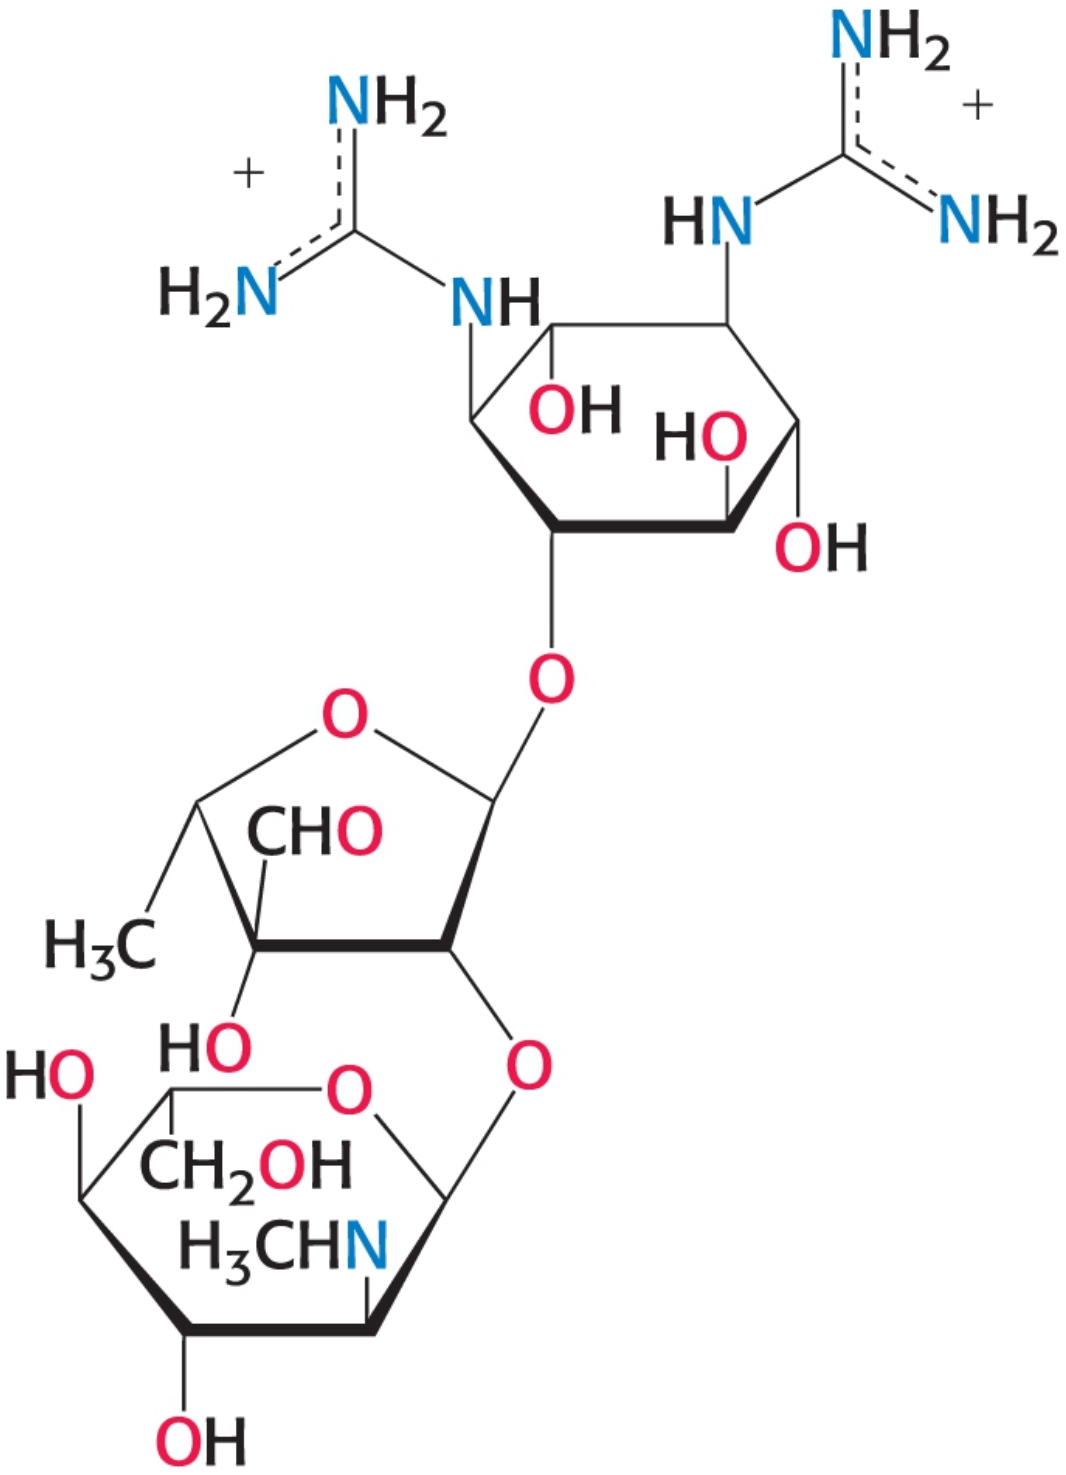
the cargo proteins to the Golgi complex, where the cargo proteins are modified. Transport vesicles then carry the cargo to the final destination as directed by the v-SNARE and t-SNARE proteins.

How does a protein end up at the correct destination? A newly synthesized protein will float inside the ER lumen until it binds to an integral membrane protein called a *cargo receptor*. This binding sequesters the cargo protein into a small region of the membrane that can subsequently form a membrane bud. The bud will carry the protein to a specific destination — plasma membrane, lysosome, or cell exterior. The key to ensuring that the protein reaches the proper destination is that the protein must bind to a receptor in the ER region associated with the protein's destination. To ensure the proper match of protein with ER region, cargo receptors recognize various characteristics of the cargo protein, such as a particular amino acid sequence or an added carbohydrate.

The formation of buds is facilitated by the binding of coat proteins to the cytoplasmic side of the bud. The coat proteins associate with one another to pinch off the vesicle. After the transport vesicle has formed and is released, the coat proteins are shed to reveal another integral protein, called **v-SNARE** ("v" for vesicle) (Section 12.6). The binding of v-SNARE to a particular **t-SNARE** ("t" for target) in the target membrane leads to the fusion of the transport vesicle to the target membrane, and the cargo is delivered. Thus, the assignment of identical v-SNARE proteins to the same region of the ER membrane causes an ER region to be associated with a particular destination.

Self-Check Question



What is the role of the signal-recognition particle in protein translocation?

30.5 A Variety of Antibiotics and Toxins Inhibit Protein Biosynthesis

Many chemicals that inhibit various aspects of protein biosynthesis have been identified. These chemicals are powerful experimental tools and clinically useful drugs.

Some antibiotics inhibit protein biosynthesis

The differences between eukaryotic and bacterial ribosomes can be exploited for the development of antibiotics (Table 30.4). For example, the antibiotic streptomycin, a highly basic trisaccharide, interferes with the binding of fMet-$tRNA^{fMet}$ to ribosomes in bacteria and thereby prevents the correct initiation of protein biosynthesis. Other aminoglycoside antibiotics such as neomycin, kanamycin, and gentamycin interfere with the interaction between tRNA and the 16S rRNA of the 30S subunit of bacterial ribosomes. Chloramphenicol acts by inhibiting peptidyl transferase activity. Erythromycin binds to the 50S subunit and blocks translocation. Cycloheximide, another antibiotic, blocks translocation in eukaryotic ribosomes, making it a useful laboratory tool for blocking protein biosynthesis in eukaryotic cells.

Streptomycin

TABLE 30.4 Antibiotic inhibitors of protein biosynthesis

Antibiotic	Action
Streptomycin and other aminoglycosides	Inhibit initiation and cause the misreading of mRNA (bacteria)
Tetracycline	Binds to the 30S subunit and inhibits the binding of aminoacyl-tRNAs (bacteria)
Chloramphenicol	Inhibits the peptidyl transferase activity of the 50S ribosomal subunit (bacteria)
Cycloheximide	Inhibits translocation (eukaryotes)
Erythromycin	Binds to the 50S subunit and inhibits translocation (bacteria)
Puromycin	Causes premature chain termination by acting as an analog of aminoacyl-tRNA (bacteria and eukaryotes)

The antibiotic puromycin inhibits protein biosynthesis in both bacteria and eukaryotes by causing nascent polypeptide chains to be released before their synthesis is completed. Puromycin is an analog of the terminal part of aminoacyl-tRNA (**Figure 30.36**) that binds to the A site on the ribosome and blocks the entry of aminoacyl-tRNA. Furthermore, puromycin contains an α-amino group. This amino group, like the one on aminoacyl-tRNA, forms a peptide bond with the carboxyl group of the growing peptide chain. The product, a peptide having a covalently attached puromycin residue at its carboxyl end, dissociates from the ribosome. While no longer used medicinally, puromycin remains an experimental tool for the investigation of protein biosynthesis.

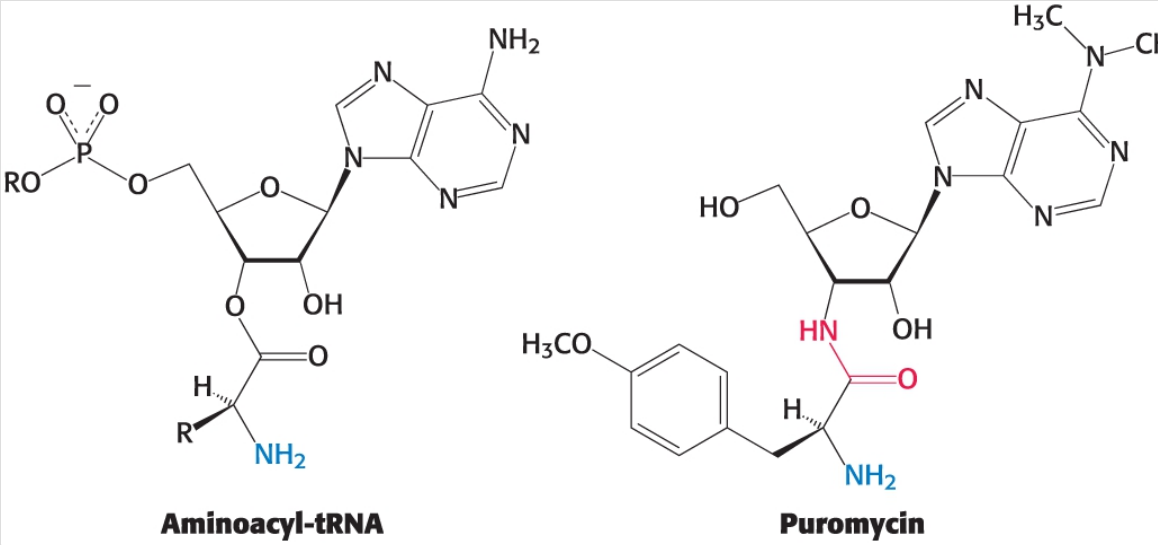


FIGURE 30.36 The antibiotic puromycin resembles the aminoacyl terminus of an aminoacyl-tRNA. The amino group of puromycin joins the carboxyl group of the growing polypeptide chain to form peptidyl-puromycin that dissociates from the ribosome. Peptidyl-puromycin is stable because puromycin has an amide (shown in red) rather than an ester linkage.

Diphtheria toxin blocks protein biosynthesis in eukaryotes by inhibiting translocation

Many antibiotics, harvested from bacteria for medicinal purposes, are inhibitors of bacterial protein biosynthesis. However, some bacteria produce compounds that inhibit eukaryotic protein biosynthesis, leading to diseases such as diphtheria, which was a major cause of childhood death before the advent of effective immunization.

Pathogenic strains of *Corynebacterium diphtheriae*, a bacterium that grows in the upper respiratory tract of an infected person, have a prophage inserted into their genomes that produces the diphtheria

toxin. The toxin consists of a single polypeptide chain that is cleaved into a 21-kDa A fragment and a 40-kDa B fragment shortly after entering the target cell. The role of the B fragment in the intact protein is to bind to the cell, enabling the toxin to enter the cytoplasm of its target cell. The A fragment catalyzes the covalent modification of EF2, the elongation factor catalyzing translocation in eukaryotic protein biosynthesis.

A single A fragment of the toxin in the cytoplasm can kill a cell. Why is it so lethal? EF2 contains diphthamide, an unusual amino acid residue that enhances the fidelity of codon shifting during translocation. Diphthamide is formed by a highly conserved complicated pathway that posttranslationally modifies histidine. The A fragment of the diphtheria toxin catalyzes the transfer of the ADP ribose unit of NAD^+ to the diphthamide ring (**Figure 30.37**). This ADP ribosylation of a single side chain of EF2 blocks EF2's capacity to carry out the translocation of the growing polypeptide chain. Protein biosynthesis ceases, accounting for the remarkable toxicity of diphtheria toxin. A few micrograms of diphtheria toxin are usually lethal in an unimmunized person.

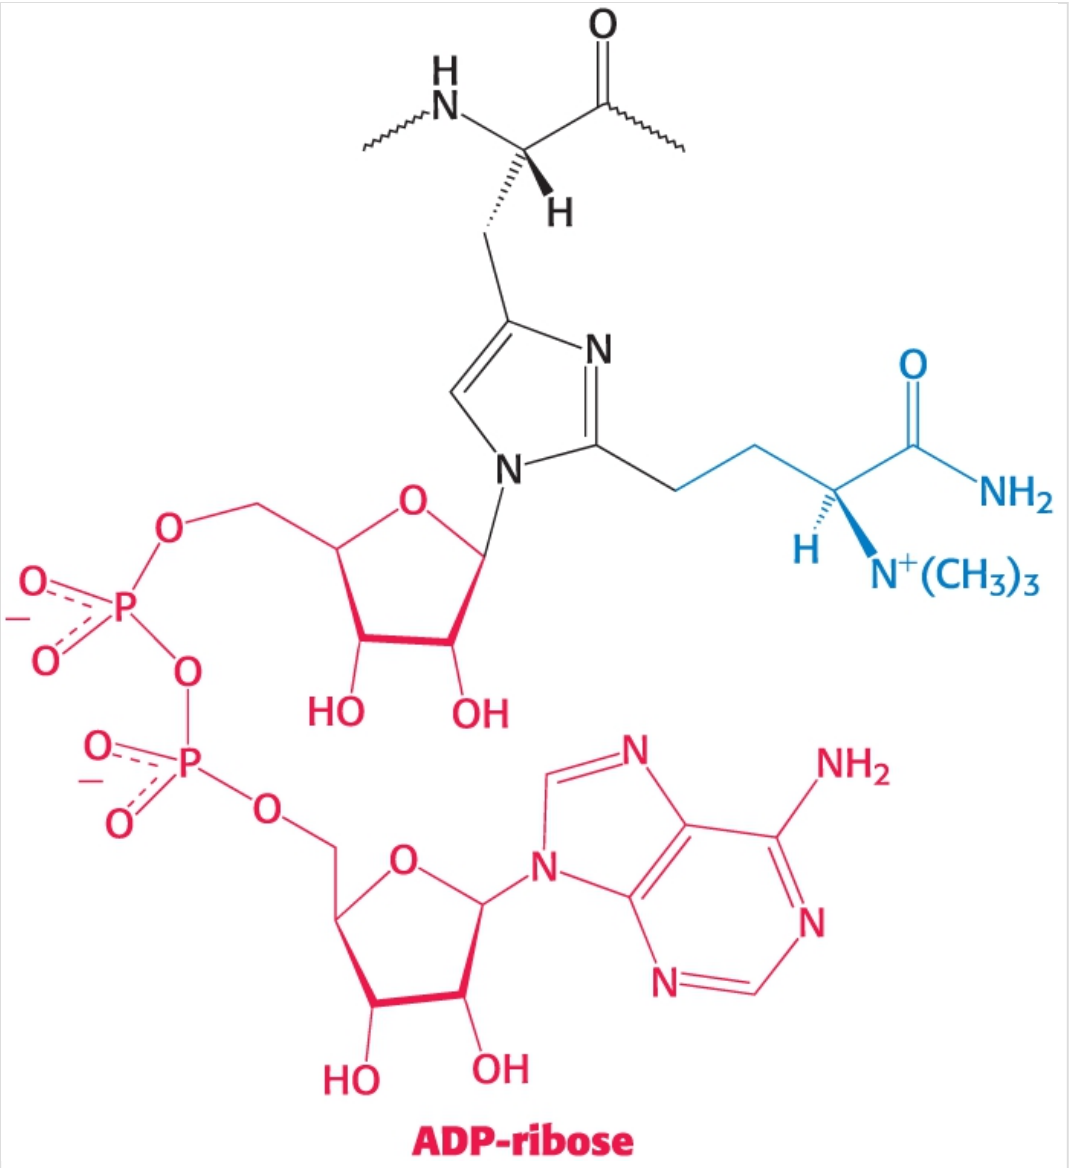

FIGURE 30.37 Diphtheria toxin inhibits protein biosynthesis in eukaryotes.
Diphtheria toxin blocks translocation by catalyzing the transfer of an ADP-ribose unit from NAD^+ to diphthamide, a modified amino acid residue in EF2 (translocase). Diphthamide is formed by the posttranslational modification (blue) of a histidine residue.

Some toxins modify 28S ribosomal RNA

α-Sarcin is a 17kDa ribonuclease secreted by filamentous fungi. It penetrates cells by interacting with membrane lipids and cleaves a specific single phosphodiester linkage in the 28S rRNA of the large ribosomal subunit. This cleavage completely inhibits protein biosynthesis.

Another toxin, ricin, also affects the 28S rRNA in the same region as α-sarcin (the sarcin-ricin loop; Section 30.3) but is a glycoside hydrolase, not a ribonuclease. Ricin is a small protein (65 kDa) found in the seeds of the castor oil plant, *Ricinus communis*. It is indeed a deadly molecule because as little as 500 μg is lethal for an adult human being, and a single molecule can inhibit all protein biosynthesis in a cell, resulting in cell death.

Ricin is a heterodimeric protein composed of a catalytic A chain joined by a single disulfide bond to a B chain. The B chain allows the toxin to bind to the target cell, and this binding leads to an endocytotic uptake of the dimer and the eventual release of the A chain into the cytoplasm. The A chain is an N-glycoside hydrolase that cleaves adenine from a particular adenosine nucleotide on the 28S rRNA that is found in all eukaryotic ribosomes. Removal of the adenine base completely inactivates the ribosome by preventing the binding of elongation factors.

Thus, diphtheria toxin, α-sarcin, and ricin all act by inhibiting protein-synthesis elongation; ricin and α-sarcin do so by covalently modifying rRNA, and diphtheria toxin does so by covalently modifying the elongation factor. Interestingly, attempts are underway to modify α-sarcin for use as an antitumor drug.

Chapter 30 Summary

30.1 Protein Biosynthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences

- Protein biosynthesis is called translation because information in a nucleic acid sequence is translated into a different language, the sequence of amino acids in a protein.
- This complex process is mediated by the coordinated interplay of more than a hundred macromolecules, including mRNA, rRNAs, tRNAs, aminoacyl-tRNA synthetases, and protein factors.
- Transfer RNAs are the adaptors that make the link between a nucleic acid and an amino acid.

30.2 Aminoacyl-tRNA Synthetases Establish the Genetic Code

- Each amino acid is activated and linked to a specific tRNA by an aminoacyl-tRNA synthetase. There is at least one specific aminoacyl-tRNA synthetase and at least one specific tRNA for each amino acid.
- By specifically recognizing both amino acids and tRNAs, aminoacyl-tRNA synthetases implement the instructions of the genetic code.
- The codons of mRNA recognize the anticodons of transfer RNAs rather than the amino acids attached to the tRNAs. A codon on mRNA forms base pairs with the anticodon of the tRNA.
- Some tRNAs are recognized by more than one codon because pairing of the third base of a codon is less crucial than that of the other two (the wobble mechanism).

30.3 The Ribosome Is the Site of Protein Biosynthesis

- Protein biosynthesis takes place on ribosomes, which are huge ribonucleoprotein particles consisting of large and small subunits.
- In *E. coli*, the 70S ribosome (2300 kDa) is made up of 30S and 50S subunits.
- The ribosome includes three sites for tRNA binding, called the A (aminoacyl) site, the P (peptidyl) site, and the E (exit) site.
- Protein biosynthesis takes place in three phases: initiation, elongation, and termination.
- In bacteria, mRNA, *N*-formylmethionyl-$tRNA^{fMet}$ and a 30S ribosomal subunit come together with the assistance of initiation factors to form a 30S initiation complex. A 50S ribosomal subunit then joins this complex to form a 70S initiation complex, in which $fMet-tRNA^{fMet}$ occupies the P site of the ribosome.
- During elongation, an EF-Tu-GTP complex delivers the appropriate aminoacyl-tRNA to the ribosome's A site as a ternary complex.
- A peptide bond is formed when the amino group of the aminoacyl-tRNA nucleophilically attacks the ester linkage of the peptidyl-tRNA.
- After peptide-bond formation, the tRNAs and mRNA are translocated for the next cycle to begin. The deacylated tRNA moves to the E site and then leaves the ribosome, and the peptidyl-tRNA moves from the A site into the P site.
- Protein biosynthesis is terminated by release factors, which recognize the termination codons UAA, UGA, and UAG and cause the hydrolysis of the ester bond between the polypeptide and tRNA.
- Eukaryotic ribosomes (80S) consist of a 40S small subunit and a 60S large subunit.
- The initiation of protein biosynthesis is more complex in eukaryotes than in bacteria.

- The regulation of translation in eukaryotes provides a means for regulating gene expression.

30.4 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

- Proteins contain signals that determine their ultimate destination. The synthesis of all proteins begins on free ribosomes in the cytoplasm.
- In eukaryotes, protein biosynthesis continues in the cytoplasm unless the nascent chain contains a signal sequence that directs the ribosome to the endoplasmic reticulum.
- The signal-recognition particle recognizes signal sequences and brings ribosomes bearing them to the ER. The nascent chain is then translocated across the ER membrane.

30.5 A Variety of Antibiotics and Toxins Inhibit Protein Biosynthesis

- Many clinically important antibiotics function by inhibiting protein biosynthesis.
- All steps of protein biosynthesis are susceptible to inhibition by antibiotics or toxins.

Key Terms

translation

t-SNARE

Problems

1. Which of the following reaction steps are required to form an aminoacyl-tRNA? (Select all that apply.) 1

a. Formation of an aminoacyl adenylate from an amino acid and ATP
b. Transfer of an aminoacyl group to a tRNA molecule
c. Formation of an acyl adenylate from a fatty acid and ATP
d. Attack of the ester linkage of a peptidyl-tRNA by an amino group

2. Ribosomes were isolated from bacteria grown in a “heavy” medium (^{13}C and ^{15}N) and from bacteria grown in a “light” medium (^{12}C and ^{14}N). These 70S ribosomes were then added to an in vitro system engaged in protein synthesis. Several hours later, an aliquot was removed and analyzed by density-gradient centrifugation. How many bands of 70S ribosomes would you expect to see in the density gradient? 2

3. A tRNA with a UGU anticodon is enzymatically conjugated to ^{14}C-labeled cysteine. The cysteine unit is then chemically modified to alanine. The altered aminoacyl-tRNA is added to a protein-synthesizing system containing normal components except for this tRNA. The mRNA added to this mixture contains the following sequence:

$$5'-UUUUGCCAUGUUUGUGCU-3'$$

What is the sequence of the corresponding radiolabeled peptide? 1

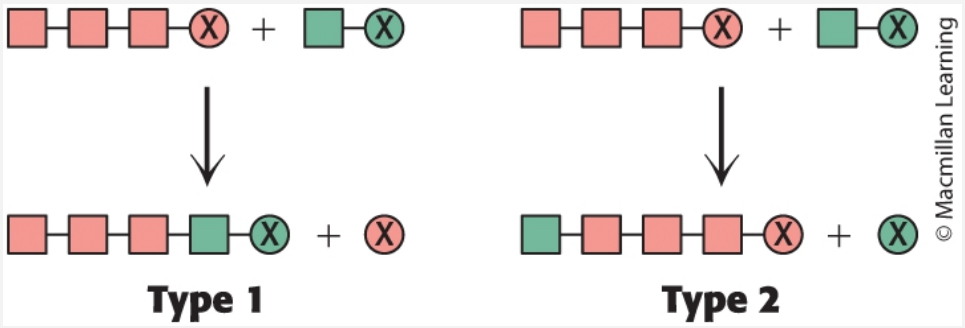
4. Match each factor with its associated phase of translation in prokaryotes. Factors can be used more than once. 2

1. Initiation	1. GTP
2. Elongation	2. AUG
3. Termination	3. fMet
	4. RRF

5. IF2

6. Shine–Dalgarno

7. EF-Tu



8. Peptidyl transferase

9. UGA

10. Transformylase

---

5. The two basic mechanisms for the elongation of biomolecules are represented in the adjoining illustration. In type 1, the activating group (X) is released from the growing chain. In type 2, the activating group is released from the incoming unit as it is added to the growing chain. Indicate whether each of the following biosyntheses is by means of a type 1 or a type 2 mechanism: 1

a. Glycogen synthesis
b. Fatty acid synthesis

c. $C_5 \rightarrow C_{10} \rightarrow C_{15}$ in cholesterol synthesis
d. DNA synthesis
e. RNA synthesis
f. Protein synthesis

6. What is the smallest number of molecules of ATP and GTP consumed in the synthesis of a 200-residue protein, starting from amino acids? Assume that the hydrolysis of PP_i is equivalent to the hydrolysis of ATP for this calculation. 1, 2

7. Compare and contrast protein biosynthesis by ribosomes with protein synthesis by the solid-phase method (Section 4.4). 1, 2

8. Suppose that you have a protein-synthesis system that is synthesizing a protein designated A. Furthermore, you know that protein A has four trypsin-sensitive sites, equally spaced in the protein, that, on digestion with trypsin, yield the peptides A_1, A_2, A_3, A_4, and A_5. Peptide A_1 is the amino-terminal peptide, and A_5 is the carboxyl-terminal peptide. Finally, you know that your system requires 4 minutes to synthesize a complete protein A. At $t = 0$, you add all 20 amino acids, each carrying a ^{14}C label. 2

a. At $t = 1$ minute, you isolate intact protein A from the system, cleave it with trypsin, and isolate the five peptides. Which peptide is most heavily labeled?
b. At $t = 3$ minutes, what will be the order of the labeling of peptides from greatest to least?
c. What does this experiment tell you about the direction of protein synthesis?

9. Every ribosome has three tRNA binding sites: the A site, the P site, and the E site. For the given sentences, identify whether it refers to the P site, A site, or E site. 2

a. This site binds the tRNA molecule that is attached to the growing peptide chain.
b. This site binds the aminoacyl-tRNA.
c. This site may bind deacylated (uncharged) tRNA.
d. This site binds the peptidyl-tRNA.

10. EF-Tu, a member of the G-protein family, plays a crucial role in the elongation process of translation. Suppose that a slowly hydrolyzable analog of GTP were added to an elongating system. What would be the effect on the rate of protein synthesis? 2

11. List the differences between bacterial and eukaryotic protein biosynthesis. 3

12. Match each label or component with its associated ribosomal subunit. Some labels can be used more than once. 3

1. Prokaryotic large ribosomal subunit	1. 30S subunit
2. Prokaryotic small ribosomal subunit	2. 40S subunit
3. Eukaryotic large ribosomal subunit	3. 50S subunit
4. Eukaryotic small ribosomal subunit	4. 60S subunit

5. 5S rRNA

6. 5.8S rRNA

7. 16S rRNA

8. 18S rRNA

9. 23S rRNA

10. 28S rRNA

---

13. There are several key differences between prokaryotic and eukaryotic ribosomes which have been exploited by some antibiotics to selectively target bacterial ribosomes. Match each antibiotic with the best description of how it inhibits translation. Not all descriptions will be used. 5

1. Streptomycin is an aminoglycoside. It binds to the 16S rRNA, which interferes with the proofreading function of the 30S subunit.

2. Tetracyclines bind to and distort the A site.

3. Puromycin has a structure similar to the 3′ end of an aminoacyl-tRNA. It binds to the A site and reacts with the peptidyl-tRNA to form peptidylpuromycin, which cannot be translocated to the P site and has a weak affinity for the A site.

1. Prevents initiation

2. Causes dissociation of covalently modified polypeptide

3. Prevents binding of aminoacyl-

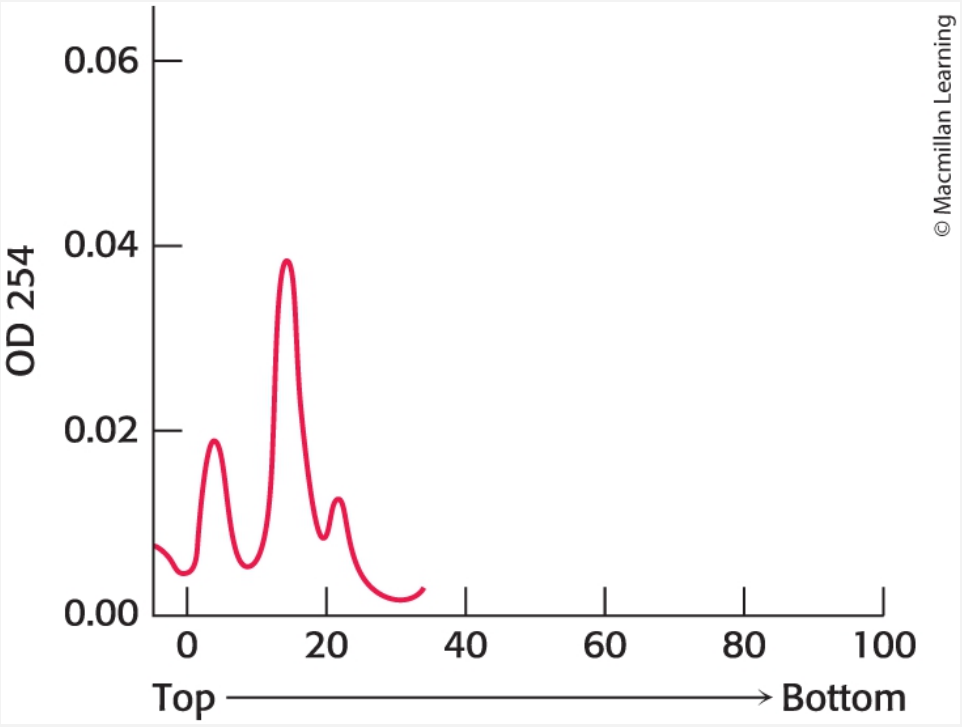
4. Azithromycin is a macrolide. It binds to the 50S subunit and interferes with the exit of the growing polypeptide chain from the ribosome.

tRNA at the A site

4. Causes misreading of mRNA codons

5. Prevents termination

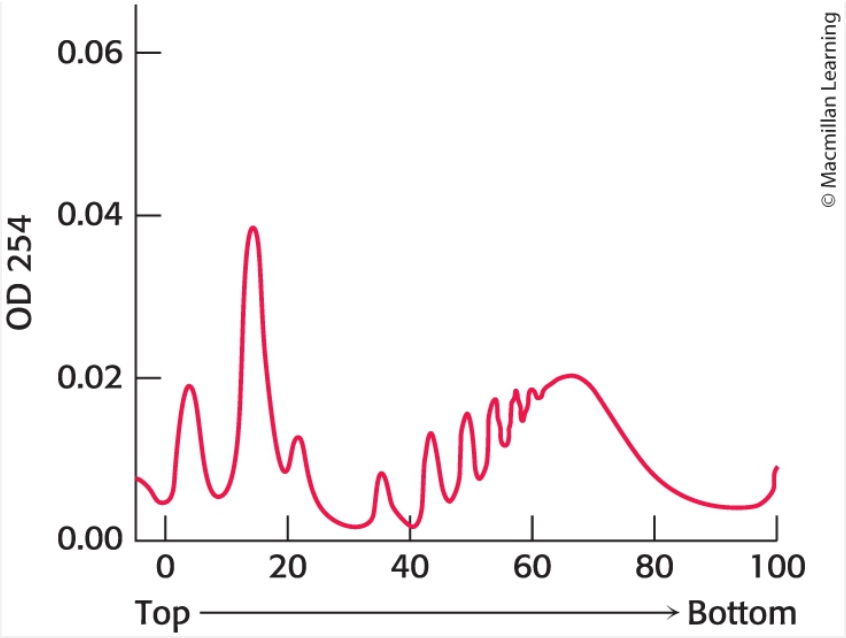
6. Causes premature termination



---

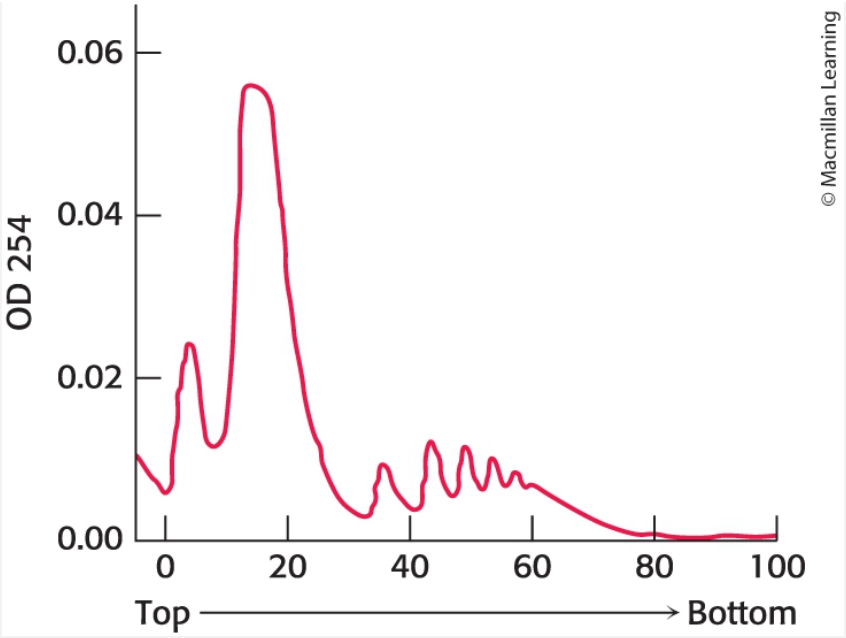
14. Fill in the blanks in the following paragraph:

Transcription in prokaryotes begins as promoter sites bind RNA polymerase. Prokaryotic cells have two sites that function as promoters: the **(a)** _____, which has the consensus sequence TTGACA, and the **(b)** _____, which is centered at -10 and has the consensus sequence TATAAT. Transcription starts at position **(c)** _____. Transcription ends when RNA polymerase transcribes a **(d)** _____, which in *E. coli* is a hairpin loop. In translation, ribosomal RNA pairs with the **(e)** _____, a purine-rich region of the mRNA molecule upstream from the start codon. Translation starts as the first tRNA recognizes the start codon, **(f)** _____, on mRNA.



15. The protein-synthesizing machinery was isolated from eukaryotic cells and briefly treated with a low concentration of RNase. The sample was then subjected to sucrose density-gradient centrifugation. The gradient was fractionated, and the

absorbance, or optical density (OD), at 254 nm was recorded for each fraction. The following plot was obtained. 3



a. What do the three peaks of absorbance represent?

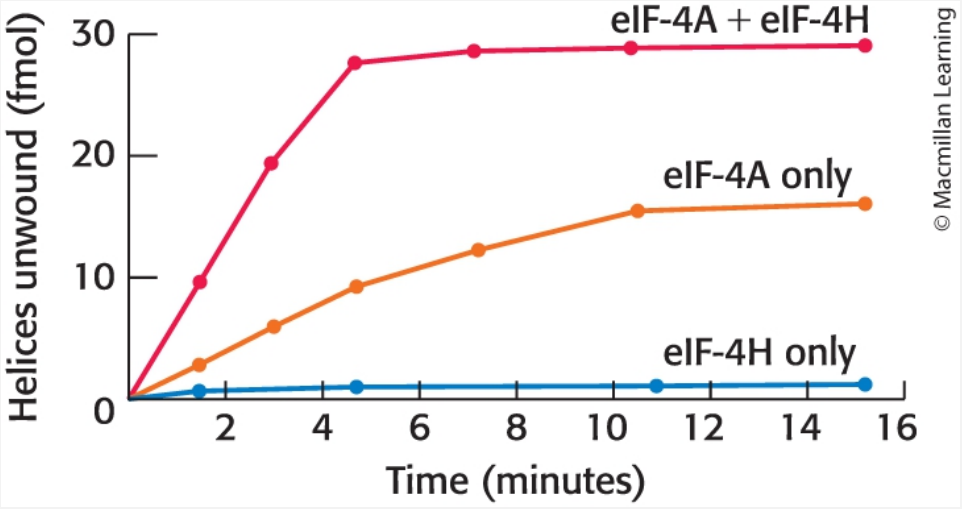
The experiment was repeated except that, this time, the RNase treatment was omitted.

b. Why is the centrifugation pattern now more complex? What does the series of peaks near the bottom of the centrifuge tube represent?

Before the isolation of the protein-synthesizing machinery, the cells were grown in low concentrations of oxygen (hypoxic conditions). Again the experiment was repeated without RNase treatment. The next graph shows the results.

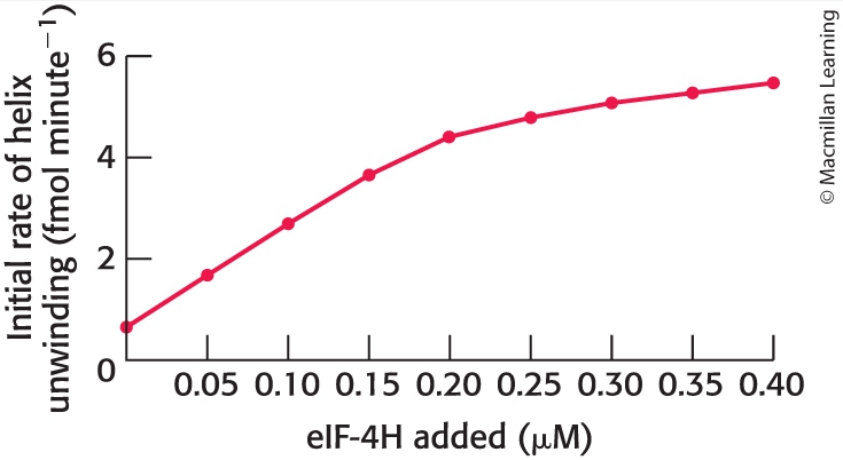
c. What happens to cells grown in hypoxic conditions?

16. Place the following steps of the membrane translocation of eukaryotic secretory proteins in order, starting with the signal peptide exiting the ribosome during translation, and ending with the protein being transported by vesicles out of the ER.
4



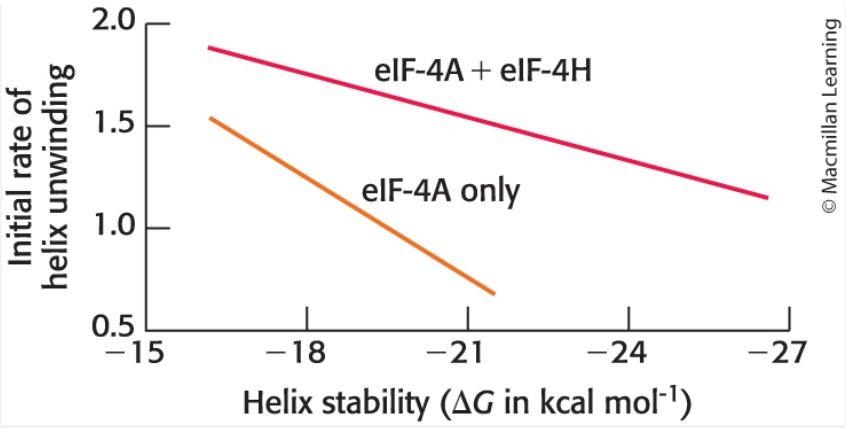
a. The signal peptide exits the ribosome during translation.
b. Signal peptidase removes the signal peptide from the growing polypeptide.
c. Translation resumes.
d. SRP binds to the signal peptide and translation stops.
e. Protein is transported out of the ER.

f. The growing polypeptide crosses the ER membrane through the translocon.
g. The remainder of the polypeptide is moved into the ER lumen.
h. Ribosome docks to a translocon.
i. SRP moves the ribosome to the ER membrane.



17.

a. What four components are required for the translocation of proteins across the endoplasmic reticulum membrane? 4
b. What is the energy source that powers the cotranslational movement of proteins across the endoplasmic reticulum? 4



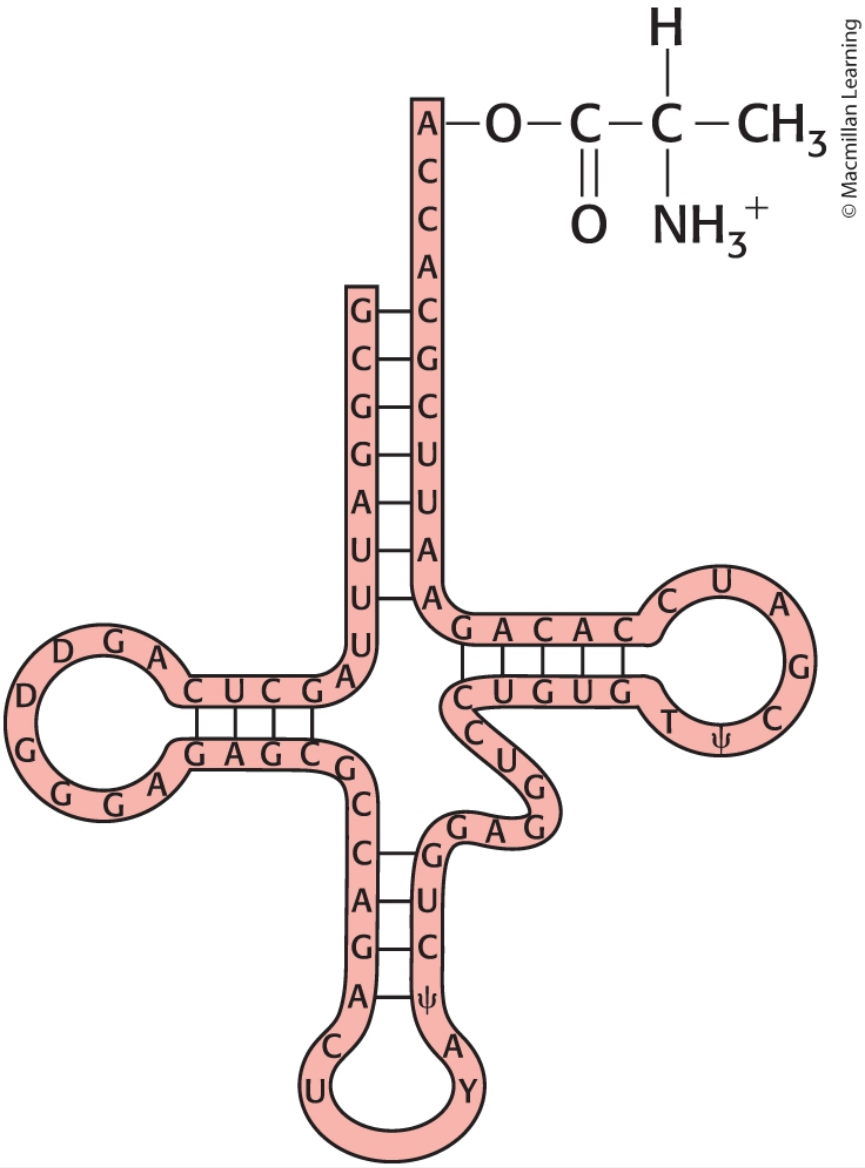
18. The initiation factor eIF-4 displays ATP-dependent RNA helicase activity. Another initiation factor, eIF-4H, has been proposed to assist the action of eIF-4. The graph shows some of the experimental results from an assay that can measure the activity of eIF-4 helicase in the presence of eIF-4H. 3

a. What are the effects on eIF-4 helicase activity in the presence of eIF-4H?
b. Why did measuring the helicase activity of eIF-4H alone serve as an important control?
c. The initial rate of helicase activity of 0.2 μM of eIF-4 was then measured with varying amounts of eIF-4H. What ratio of eIF-4H to eIF-4 yielded optimal activity?

d. Next, the effect of RNA–RNA helix stability on the initial rate of unwinding in the presence and absence of eIF-4H was tested. How does the effect of eIF-4H vary with helix stability?

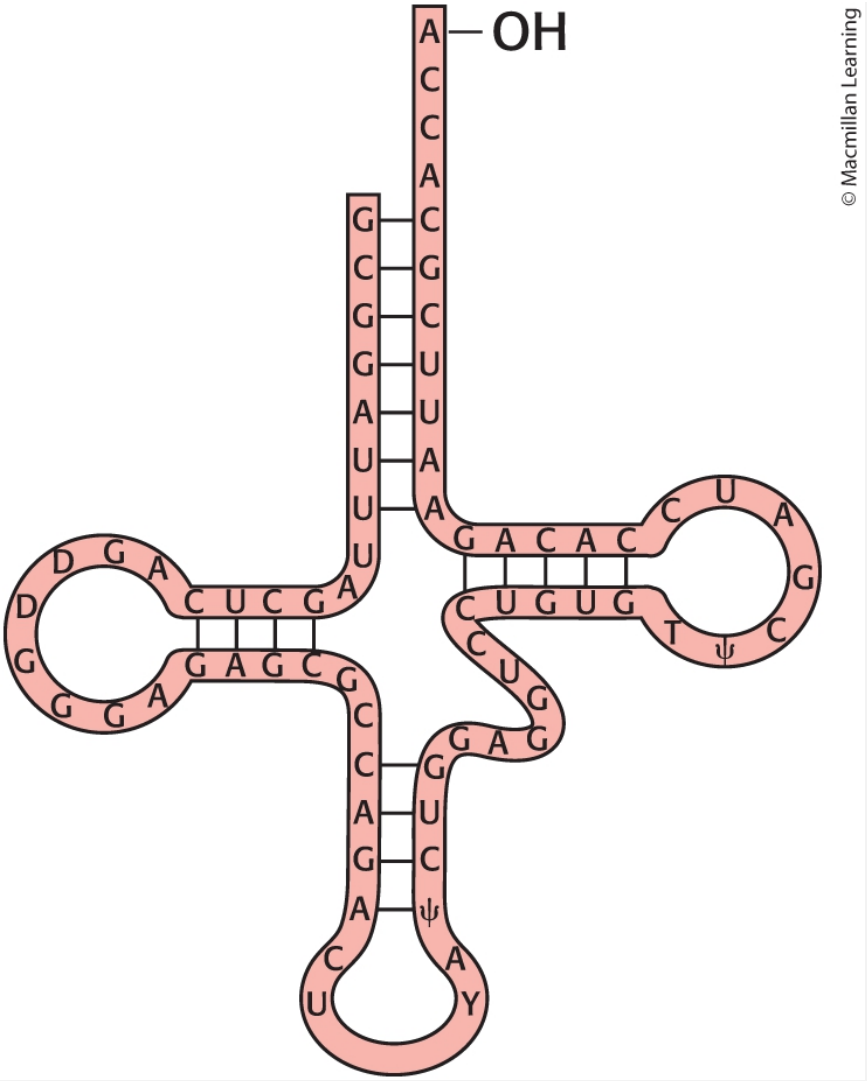
e. How might eIF-4H affect the helicase activity of eIF-4A?

19. Consider the 5′-to-3′ DNA sequence of three consecutive codons below.



5′–TTAGAGCGC–3′

Determine the following sequences: 1



a. The complementary DNA strand (3′ to 5′)
b. The transcribed mRNA
c. The tRNA anticodons
d. The amino acids

20. Consider the following tRNA molecules. **(a)** Which tRNA is the activated version? **(b)** What is the name of the amino acid side chain? 1

A.

B.

Chapter 31
Control of Gene Expression

Oxford Scientific/The Image Bank/Getty Images
© Macmillan Learning

Complex biological processes often require coordinated control of the expression of many genes. The maturation of a tadpole into a frog is largely controlled by thyroid hormone. This hormone regulates gene expression by binding to a protein, the thyroid-hormone receptor, as shown at the right. In response to the hormone's binding, this protein binds to specific DNA sites in the genome and modulates the expression of nearby genes.

Outline

31.1 Bacterial DNA-Binding Proteins Bind to Specific Regulatory Sites
31.2 In Bacteria, Genes Are Often Arranged into Clusters Under the Control of a Single Regulatory Sequence

31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression
31.4 Regulation of Gene Expression Is More Complex in Eukaryotes
31.5 The Control of Gene Expression in Eukaryotes Can Require Chromatin Remodeling
31.6 Gene Expression Can Be Controlled at the Posttranscriptional Level

Learning Goals

By the end of this chapter, you should be able to:

1. Evaluate the control of transcription by bacterial and eukaryotic DNA-binding proteins.
2. Analyze the common structural features of bacterial and eukaryotic DNA-binding proteins that allow them to recognize specific DNA sequences.
3. Understand the roles of the various components in the *E. coli lac* operon.
4. Describe how genetic switches work, using the lytic versus lysogenic path in bacteriophage lambda as an example.
5. Discuss the role of chromatin modifications in controlling eukaryotic gene expression.
6. Contrast the control of gene expression in bacteria and in eukaryotes.
7. Understand examples of mechanisms of posttranscriptional gene regulation.

The development of multicellular organisms; the changes that distinguish normal cells from cancer cells; bacteria responding to changes in their environment — all of these intriguing phenomena have one thing in common: they rely on the regulation of gene expression. A gene is expressed when it is transcribed into RNA and, for most genes, translated into proteins. While some of the thousands of genes that make up a genome are expressed all the time, many other genes are expressed only under some

circumstances. For example, the level of expression of some genes in bacteria may vary more than a thousand-fold in response to the supply of nutrients or to environmental challenges. In this chapter, we will learn about several strategies that allow for the coordinated regulation of gene expression, both in bacteria and eukaryotes.

31.1 Bacterial DNA-Binding Proteins Bind to Specific Regulatory Sites

How do regulatory systems distinguish the genes that need to be activated or repressed from genes that are *constitutive*, or expressed all the time? The DNA sequences of genes themselves do not have any distinguishing features that would allow regulatory systems to recognize them. Instead, gene regulation depends on other sequences in the genome. In bacteria, these regulatory sites are close to the region of the DNA that is transcribed. Regulatory sites are usually binding sites for specific DNA-binding proteins, which can either stimulate or repress gene expression.

Many DNA-binding proteins match the symmetry in their target DNA sequences

Regulatory sites were first identified in *E. coli* through experiments that looked at changes in gene expression in response to nutrient availability. For example, if the usual energy source (the sugar glucose) is not available to the bacterium, but lactose *is* available, the bacterium starts to express a gene encoding **β-galactosidase**, an enzyme that can process lactose for use as a carbon and energy source. The sequence of the regulatory site for this gene is shown in **Figure 31.1**. The nucleotide sequence of this site shows a nearly perfect inverted repeat, indicating that the DNA in this region has an approximate twofold axis of symmetry. Recall that cleavage sites for restriction enzymes such as EcoRV have similar symmetry properties (Section 9.2). Symmetry in such regulatory sites usually corresponds to symmetry in the protein that binds the site. Symmetry matching is a recurring theme in protein–DNA interactions.

FIGURE 31.1 The sequence of the *lac* regulatory site is a nearly perfect inverted repeat. This leads to twofold rotational symmetry in the DNA. Parts of the sequences that are related by this symmetry are shown in the same color.

To understand these protein–DNA interactions in detail, scientists determined the structure of the complex between the regulatory site for the gene encoding β-galactosidase and the DNA-binding unit from the protein that binds to it (Figure 31.2). The protein that recognizes this particular regulatory site is called the *lac repressor*, because it represses the expression of the lactose-processing gene when bound to the regulatory site.

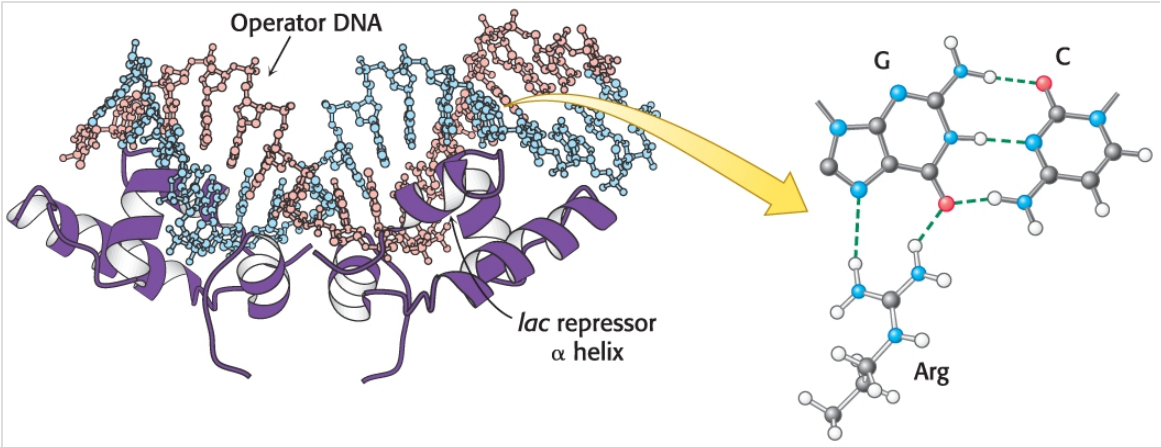

FIGURE 31.2 The *lac* repressor binds to operator DNA. The DNA-binding domain from the *lac* repressor binds to a DNA fragment containing its preferred binding site by inserting an α helix into the major groove of operator DNA. A specific contact forms between an arginine residue of the repressor and a G–C base pair in the binding site.

[Drawn from 1EFA.pdb.]

INTERACT with this model in Achieve

As expected, the DNA-binding unit from the *lac* repressor binds as a dimer, and the twofold axis of symmetry of the dimer matches the symmetry of the DNA. An α helix from each monomer of the protein is inserted into the major groove of the DNA, where amino acid side chains make specific contacts with exposed edges of the base pairs. For example, the side chain of an arginine residue of the protein forms a pair of hydrogen bonds with a guanine residue of the DNA, which would not be possible with any other base. This interaction and similar ones allow the *lac* repressor to bind more tightly to this site than to the wide range of other sites present in the *E. coli* genome.

The helix-turn-helix motif is common to many bacterial DNA-binding proteins

Do other bacterial DNA-binding proteins use similar strategies? The structures of many such proteins have now been determined, and amino acid sequences are known for many more. Strikingly, the DNA-binding surfaces of many, but not all, of these proteins consist of a pair of α helices separated by a tight turn, called a **helix-turn-helix motif** (**Figure 31.3**). In complexes with DNA, the second of these two helices (often called the *recognition helix*) lies in the major groove, where amino acid side chains make contact with the edges of base pairs. In contrast, residues of the first helix participate primarily in contacts with the DNA backbone. Helix-turn-helix motifs are present in many proteins that bind DNA as dimers, and thus two of the units will be present, one in each monomer.

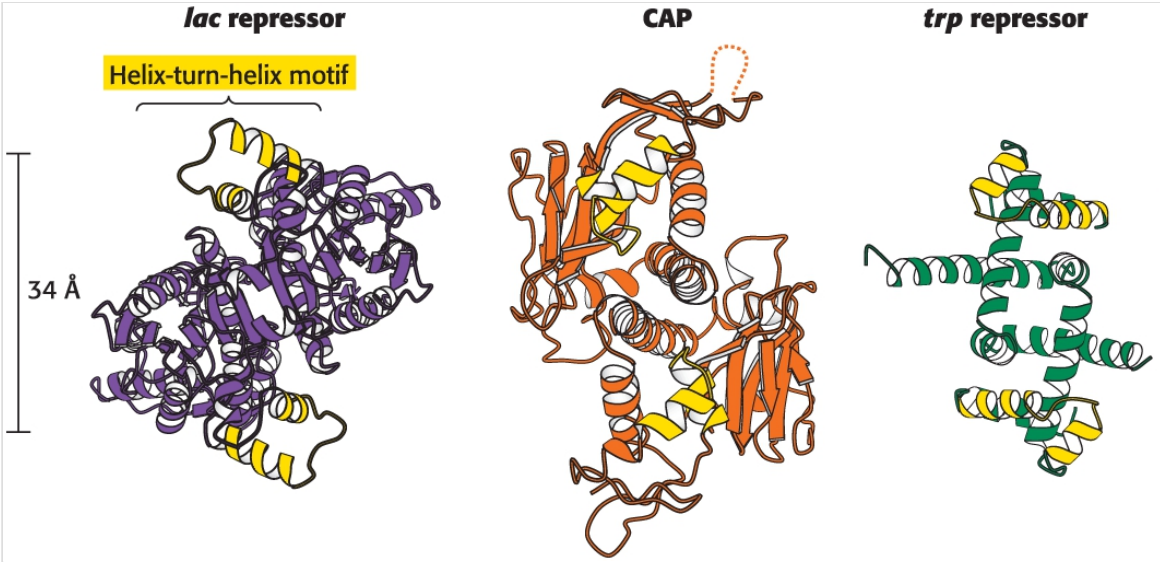

FIGURE 31.3 Sequence-specific DNA-binding proteins interact with DNA through a helix-turn-helix motif. In each case, the helix-turn-helix units (highlighted in yellow) within a protein dime are approximately 34 Å apart, corresponding to one full turn of DNA.

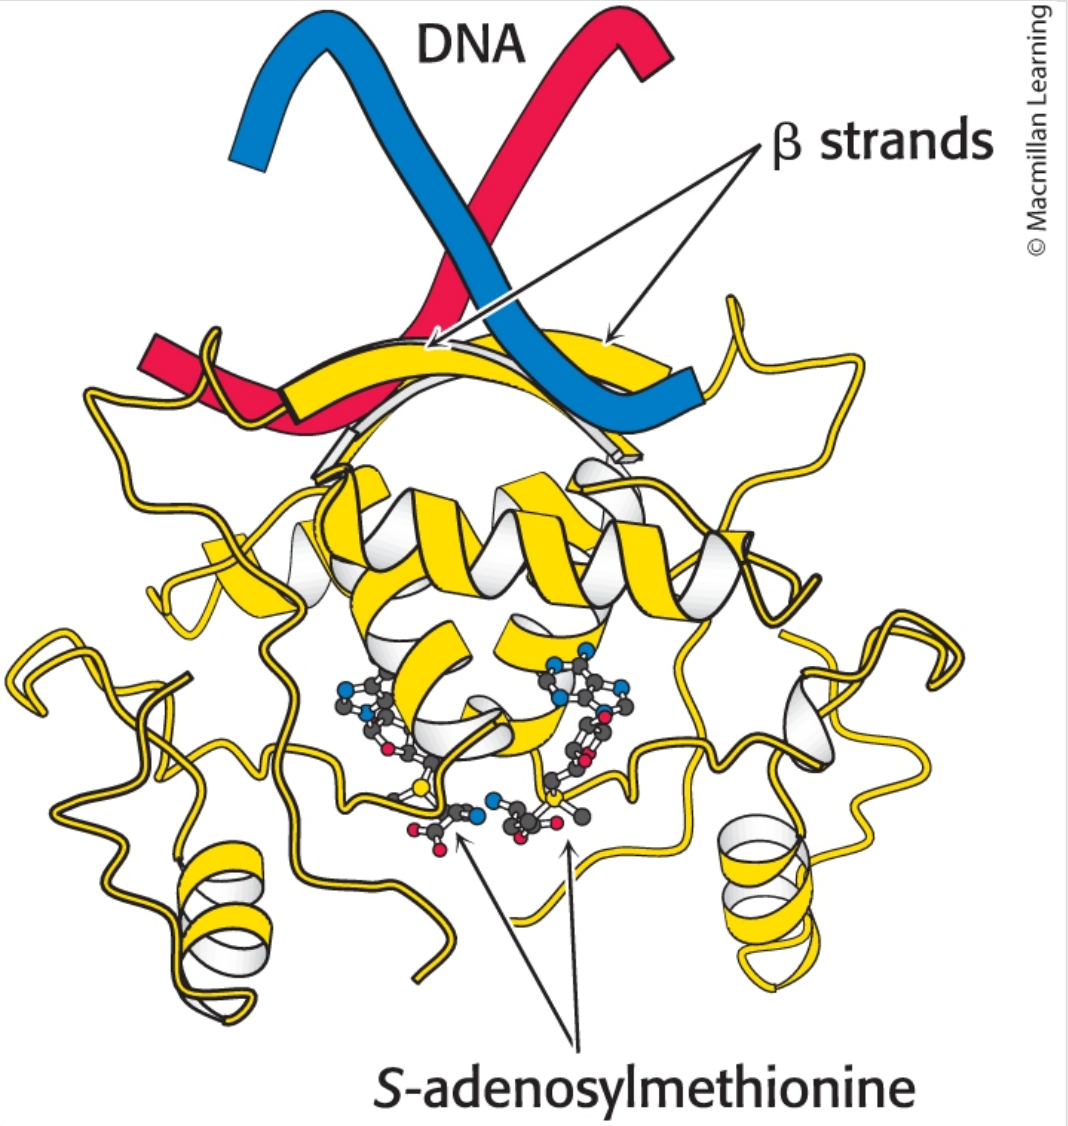
[Drawn from 1EFA.pdb, 1RUN.pdb, and 1TRO.pdb.]

Although the helix-turn-helix motif is the most commonly observed DNA-binding unit in bacteria, not all regulatory proteins bind DNA through such units. The *E. coli* methionine repressor (Figure 31.4), for example, binds DNA through the insertion of a pair of β strands into the major groove. A historically important example for gene regulation in *E. coli*, discussed next, reveals many common principles and elucidates the role of DNA-binding proteins in controlling transcription.



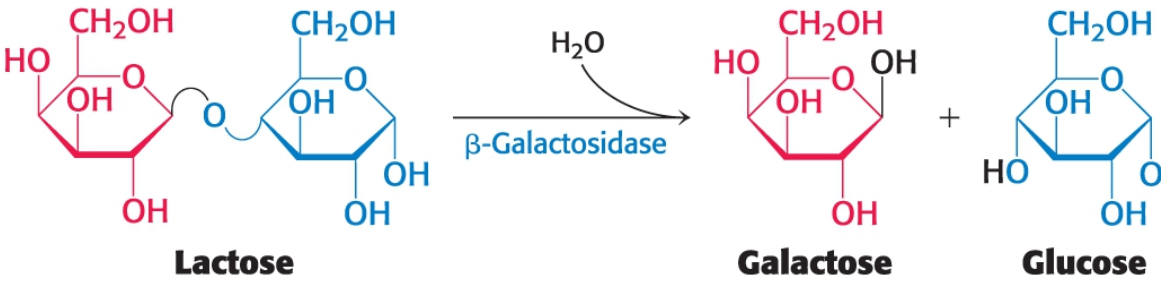


FIGURE 31.4 Some DNA-binding proteins recognize specific DNA sequences through β strands. The methionine repressor complexed with its co-repressor *S*-adenosylmethionine is shown bound to DNA (blue and red ribbon). In this example residues in β strands, rather than in α helices, participate in the crucial interactions between the protein and the DNA.

[Drawn from 1CMA.pdb.]

INTERACT with the models shown in Figure 31.3 and Figure 31.4 in Achieve

31.2 In Bacteria, Genes Are Often Arranged into Clusters Under the Control of a Single Regulatory Sequence

As noted above, bacteria such as *E. coli* usually rely on glucose as their source of carbon and energy, even when other sugars are available. However, when glucose is scarce, *E. coli* can use lactose as their carbon source, even though this disaccharide does not lie on any major metabolic pathways. β-Galactosidase is an essential enzyme in the metabolism of lactose because it hydrolyzes lactose into galactose and glucose. These products are then metabolized by pathways discussed in Chapter 16.

This reaction can be conveniently followed in the laboratory through the use of alternative galactoside substrates, such as X-Gal, that form colored products (**Figure 31.5**).

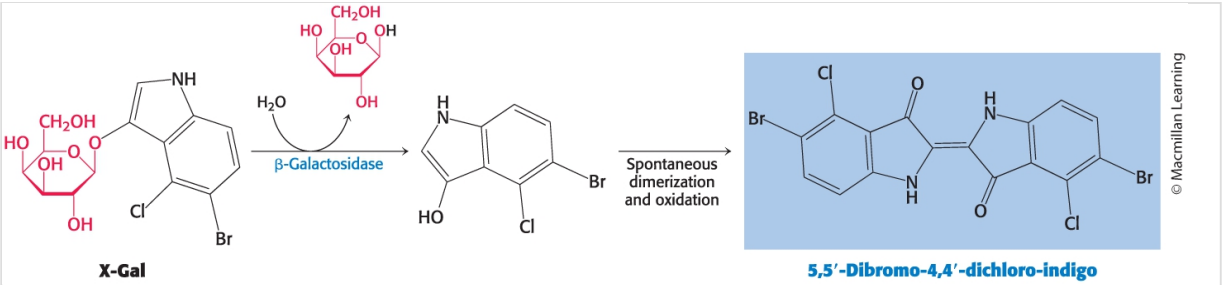

FIGURE 31.5 The β-galactosidase reaction can be monitored using a colored indicator. The galactoside substrate X-Gal produces a colored product when cleaved by β-galactosidase. The appearance of this colored product provides a convenient means for monitoring the amount of the enzyme both in vitro and in vivo.

An *E. coli* cell growing on a carbon source such as glucose or glycerol contains fewer than 10 molecules of β-galactosidase. In contrast, the same cell will contain several thousand molecules of the enzyme when grown on lactose (Figure 31.6). The presence of lactose in the culture medium induces the large increase in the amount of β-galactosidase by up-regulating the gene that codes for it, resulting in the synthesis of new enzyme molecules.

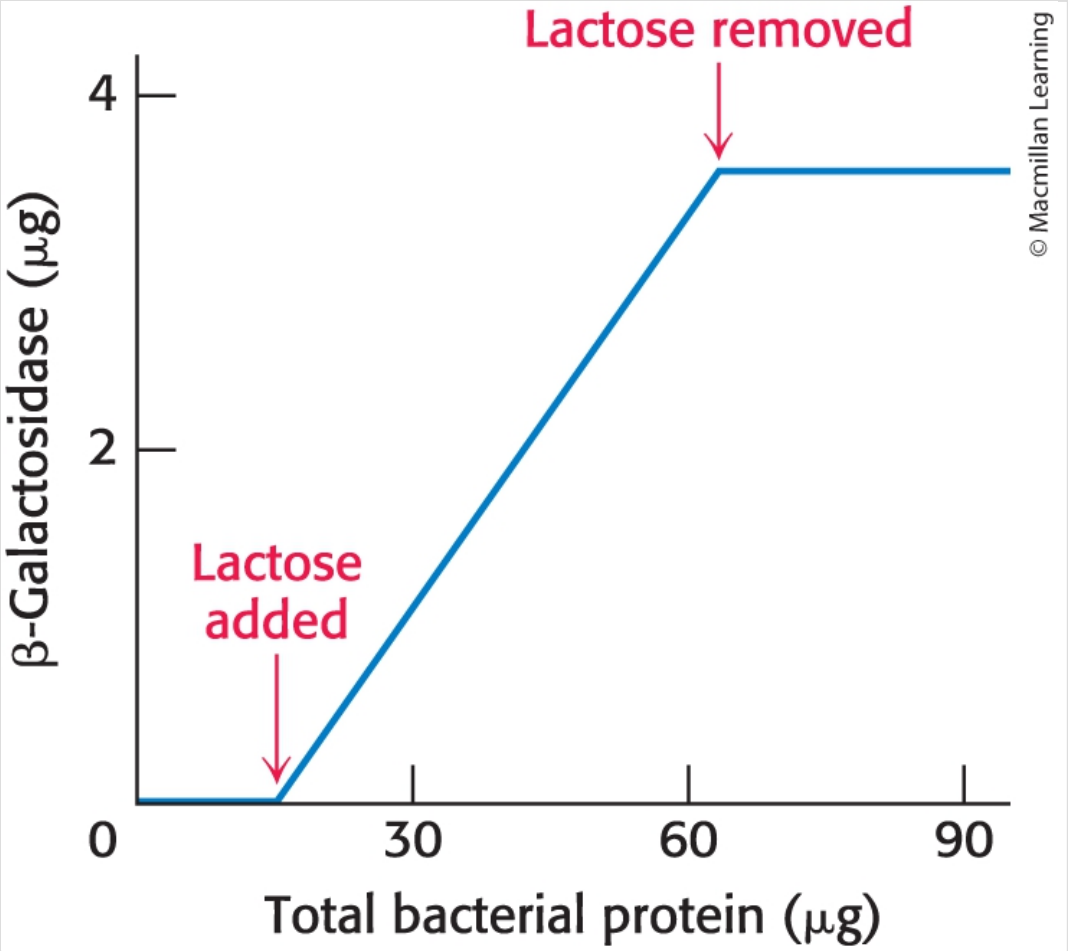

FIGURE 31.6 The production of β-galactosidase can be increased by the addition of lactose. The addition of lactose to an *E. coli* culture causes the production of β-galactosidase to increase from very low amounts to much larger amounts. The increase in the amount of enzyme parallels the increase in the number of cells in the growing culture. β-Galactosidase constitutes 6.6% of the total protein synthesized in the presence of lactose.

A crucial clue to the mechanism of gene regulation was the observation that two other proteins are synthesized in concert with β-galactosidase — namely, galactoside permease and thiogalactoside transacetylase. The permease is required for the transport of lactose across the bacterial cell membrane (Section 13.3). The transacetylase is not essential for lactose metabolism but appears to play a role in the detoxification of

compounds that also may be transported by the permease. Thus, the expression levels of a set of enzymes that all contribute to the adaptation to a given change in the environment are regulated together. Such a coordinated unit of gene expression is called an **operon**.

An operon consists of regulatory elements and protein-encoding genes

The parallel regulation of β-galactosidase, the permease, and the transacetylase suggested that the expression of genes encoding these enzymes is controlled by a common mechanism. François Jacob and Jacques Monod proposed the so-called *operon model* to account for this parallel regulation as well as the results of other genetic experiments. The genetic elements of the model are a regulator gene that encodes a regulatory protein (with its promoter), a regulatory DNA sequence called an **operator site**, and a set of structural genes with a separate promoter (**Figure 31.7**).

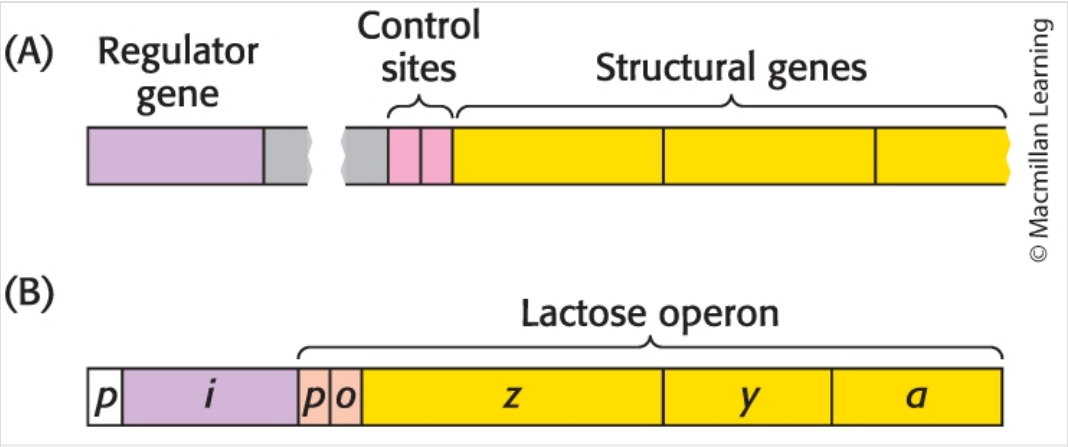

FIGURE 31.7 Operons are clusters of genes under a common control. (A) The general structure of an operon as conceived by Jacob and Monod. In some cases, the regulator gene may be some distance away from the structural genes, as indicated by the break. (B) The structure of the lactose operon. In addition to the promoter, *p*, in the operon, a second promoter is present in front of the regulator gene, *i*, to drive the synthesis of the regulator.

The regulator gene encodes a **repressor** protein that binds to the operator site. The binding of the repressor to the operator prevents transcription of the structural genes. The operator and its associated structural genes constitute the operon. For the *lactose (lac) operon*, the *i* gene encodes the repressor, *o* is the operator site, and the *z*, *y*, and *a* genes are the structural genes for β-galactosidase, the permease, and the transacetylase, respectively. The operon also contains a promoter site (denoted by *p*), which directs the RNA polymerase to the correct transcription initiation site. The *i* gene is under the control of a separate promoter (also denoted *p*). The *z*, *y*, and *a* genes are transcribed to give a single mRNA molecule that encodes all three proteins. An mRNA molecule encoding more than one protein is known as a *polygenic* or *polycistronic* transcript.

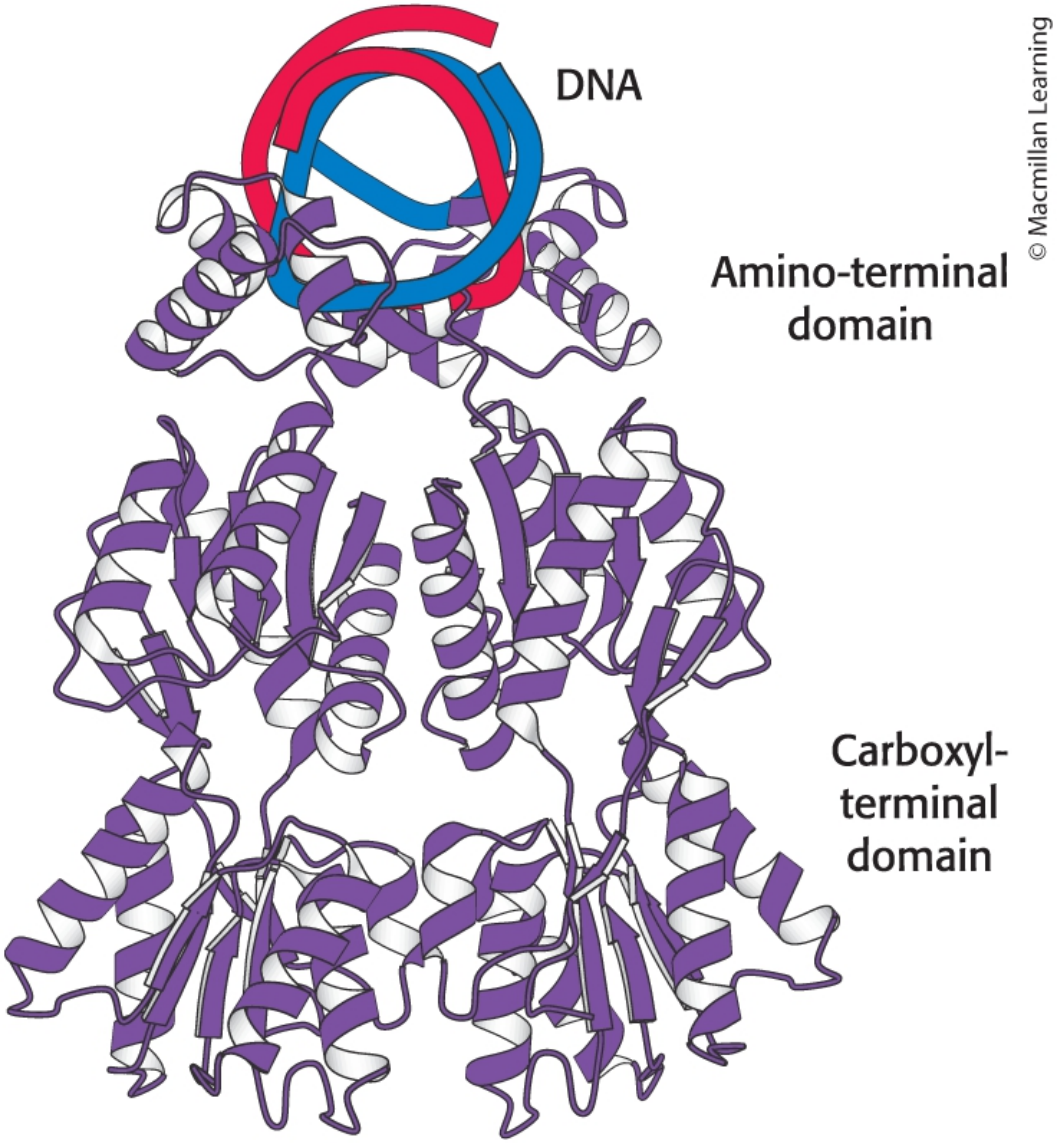
The *lac* repressor protein can block transcription

In the absence of lactose, the lactose operon is repressed. How does the *lac* repressor mediate this repression? The *lac* repressor exists as a tetramer of 37-kDa subunits with two pairs of subunits coming together to form the DNA-binding unit previously discussed. In the absence of lactose, the repressor binds very tightly and rapidly to the operator, which is directly downstream of the promoter. When the *lac* repressor is bound to the operator DNA, it prevents transcription of the protein-coding genes because it blocks the progress of RNA polymerase along the DNA template.

How does the *lac* repressor locate the operator site in the *E. coli* chromosome? The *lac* repressor binds 4×10^6 times as strongly to operator DNA as it does to random sites in the genome. This high degree of selectivity allows the repressor to find the operator efficiently even with a large excess of other sites within the *E. coli* genome. The dissociation constant for the repressor–operator complex is approximately $0.1\ \text{pM}\ (10^{-13}\ \text{M})$. The rate constant for association $(\approx 10^{10}\ \text{M}^{-1}\ \text{s}^{-1})$ is strikingly high, indicating that the repressor finds the operator primarily by diffusing along a DNA molecule (a one-dimensional search) rather than encountering it from the aqueous medium (a three-dimensional search). This diffusion has been confirmed by studies that monitored the behavior of fluorescently labeled single molecules of *lac* repressor inside living *E. coli* cells.

Inspection of the complete *E. coli* genome sequence reveals two sites within 500 bp of the primary operator site that approximate the sequence of the operator. When one dimeric DNA-binding unit binds to the operator site, the other DNA-binding unit of the *lac* repressor tetramer can bind to one of these sites with similar sequences. The DNA between the two bound sites forms a loop. No other sites that closely match the sequence of the *lac* operator site are present in the rest of the *E. coli* genome sequence. Therefore, the DNA-binding specificity of the *lac* repressor is sufficient to target two closely related sites within the *E. coli* genome.

The three-dimensional structure of the *lac* repressor has been determined in various forms. Each monomer consists of a small amino-terminal domain that binds DNA and a larger domain that mediates the formation of the dimeric DNA-binding unit and the tetramer (**Figure 31.8**). A pair of the amino-terminal domains come together to form the functional DNA-binding unit. Each monomer has a helix-turn-helix unit that interacts with the major groove of the bound DNA.



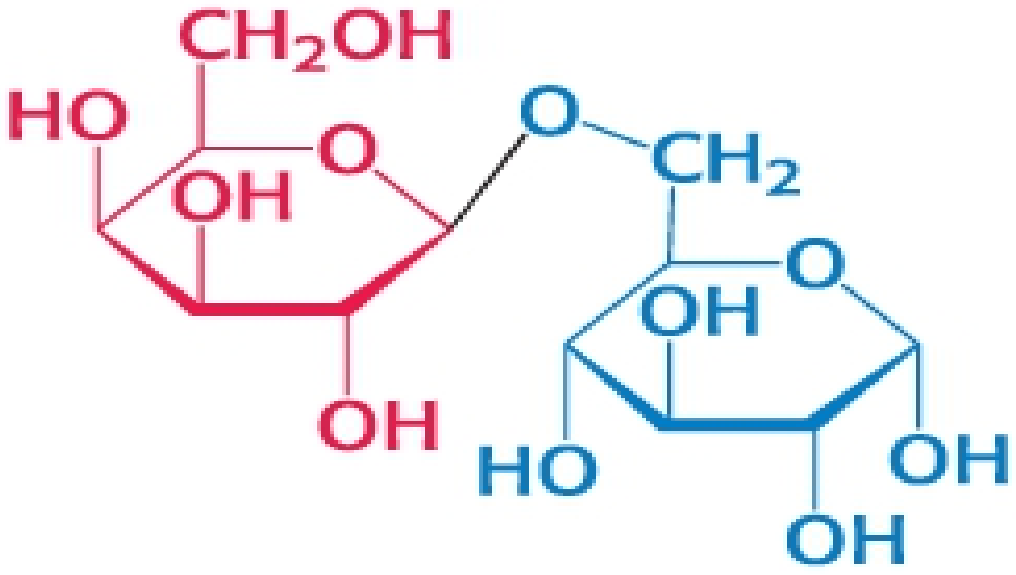


FIGURE 31.8 The *lac* repressor binds to DNA as a dimer. The amino-terminal domain binds to DNA, whereas the carboxyl-terminal domain forms a separate structure. A part of the structure that mediates the formation of *lac* repressor tetramers is not shown.

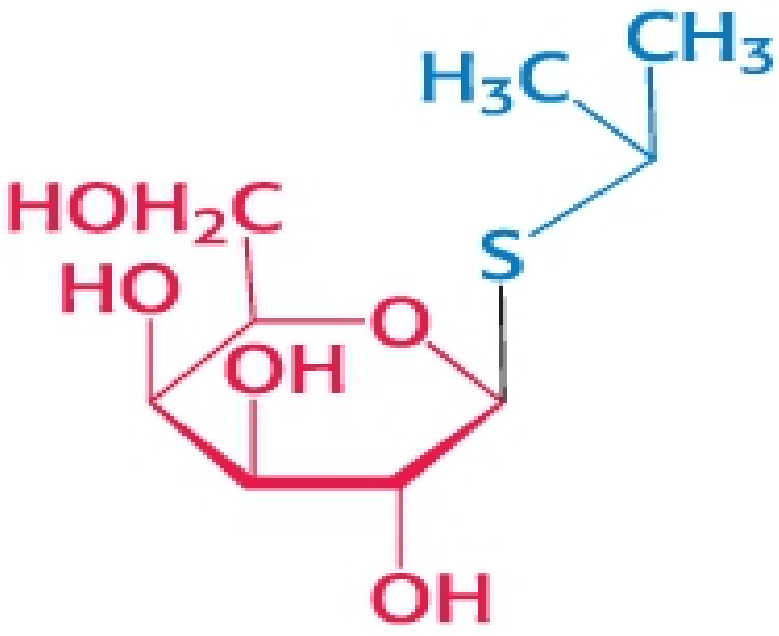

[Drawn from 1EFA.pdb.]

Ligand binding can induce structural changes in regulatory proteins

In the situation just described, glucose is present, lactose is absent, and the *lac* operon is repressed. How does the presence of lactose trigger the relief of this repression and, hence, the expression of the *lac* operon? Interestingly, lactose itself does not have this effect; rather, allolactose, a combination of galactose and glucose with an α-1,6 rather than an α-1,4 linkage, does. Allolactose is thus referred to as the **inducer** of the *lac* operon. Allolactose is a side product of the β-galactosidase reaction and is produced at low levels by the few molecules of β-galactosidase that are present before induction. Some other β-galactosides such as isopropylthiogalactoside (IPTG) are potent inducers of β-galactosidase expression, although they are not substrates of the enzyme. IPTG is useful in the laboratory as a tool for inducing gene expression in engineered bacterial strains.

1,6-Allolactose

Isopropylthiogalactoside (IPTG)

The inducer triggers gene expression by preventing the *lac* repressor from binding the operator. The inducer binds to the *lac* repressor and thereby greatly reduces the repressor's affinity for operator DNA. An inducer molecule binds in the center of the large domain within each monomer. This binding leads to subtle conformational changes that modify the relation between the two small DNA-binding domains (Figure 31.9). These domains can no longer easily contact DNA simultaneously, leading to a dramatic reduction in DNA-binding affinity.

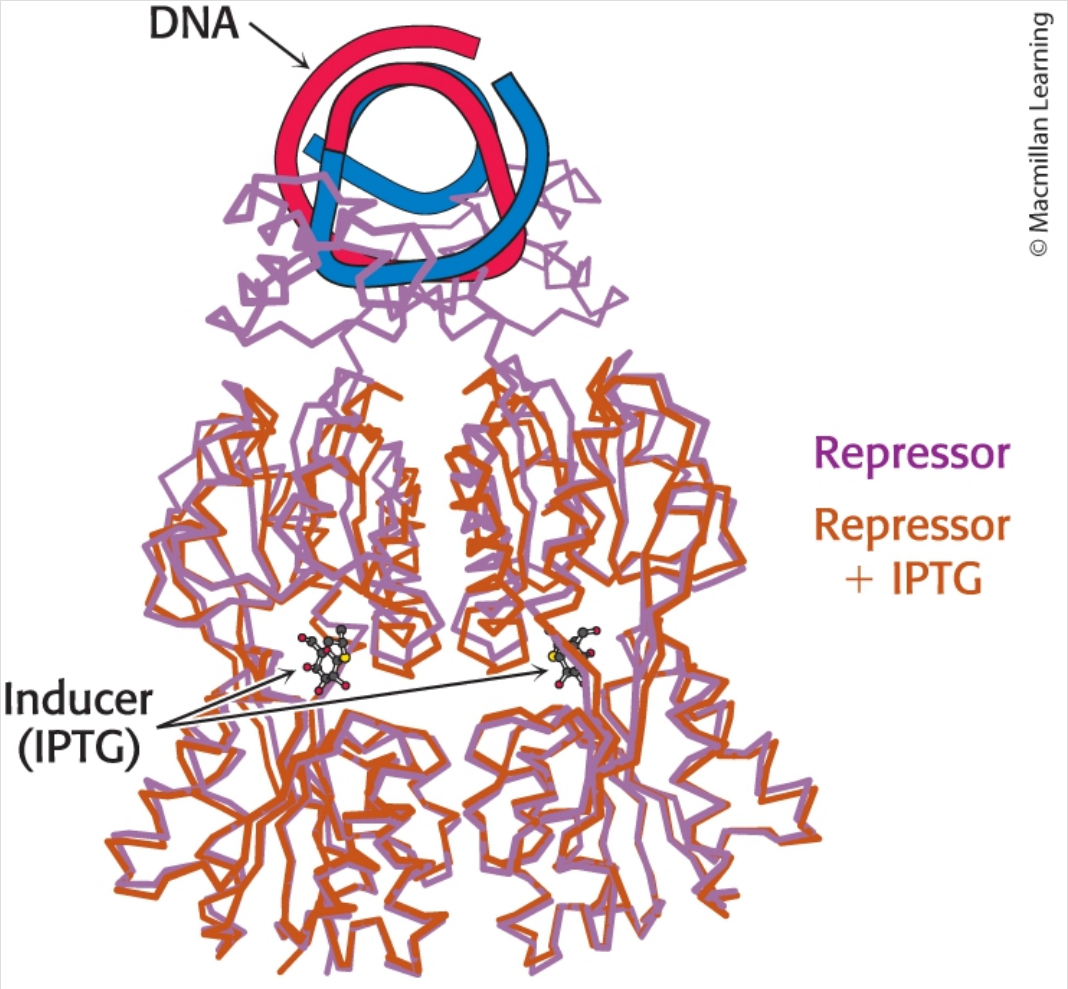

FIGURE 31.9 Binding of IPTG alters the *lac* repressor structure and affects its ability to bind DNA. The structure of the *lac* repressor bound to the inducer isopropylthiogalactoside (IPTG), shown in orange, is superimposed on the structure of the *lac* repressor bound to DNA, shown in purple. The binding of IPTG induces only subtle structural changes, but these are large enough near the interface of the DNA-binding domains that the repressor cannot interact effectively with DNA. The DNA-

binding domains of the *lac* repressor bound to IPTG are not shown, because these regions are not well ordered in the crystals studied.

How does this fit in with the regulation of gene expression in the lactose operon? Let's review the process (**Figure 31.10**). In the absence of inducer, the *lac* repressor is bound to DNA in a manner that blocks RNA polymerase from transcribing the *z*, *y*, and *a* genes. Thus, very little β-galactosidase, permease, or transacetylase is produced. The addition of lactose to the environment leads to the formation of allolactose. This inducer binds to the *lac* repressor, leading to conformational changes and the release of DNA by the *lac* repressor. With the operator site unoccupied, RNA polymerase can then transcribe the other *lac* genes and the bacterium will produce the proteins necessary for the efficient use of lactose.

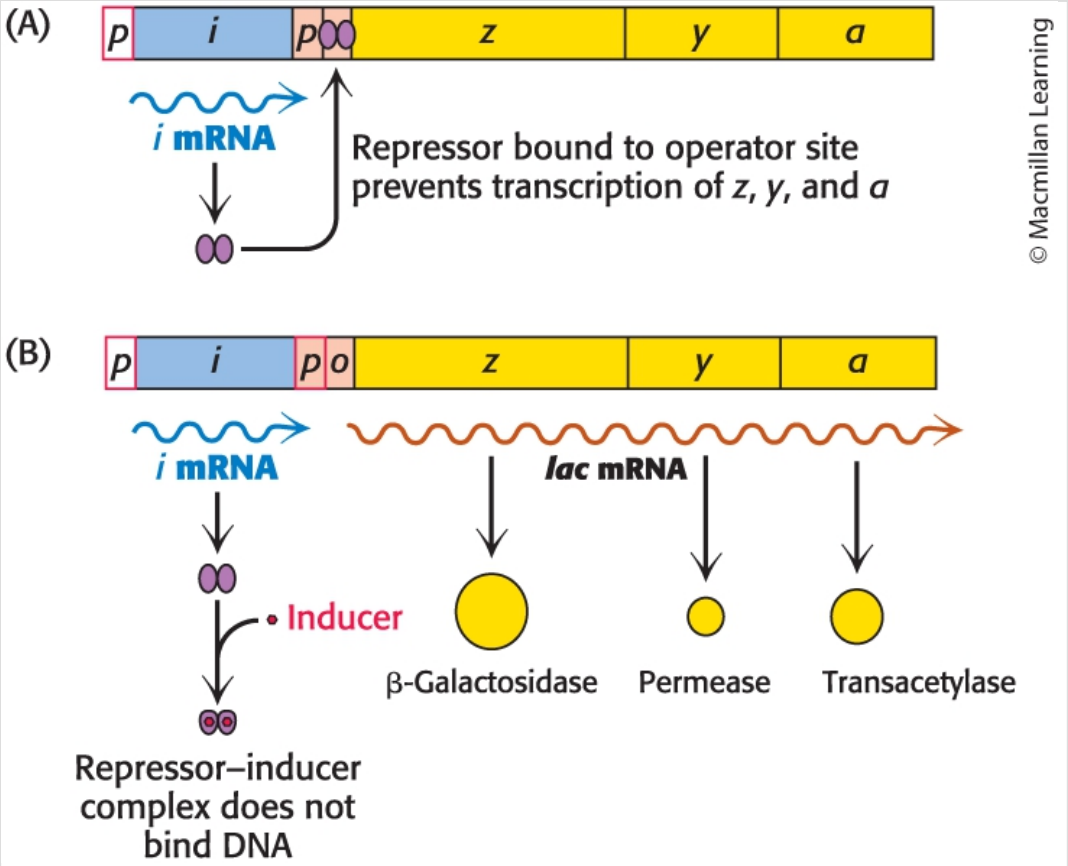

FIGURE 31.10 The *lac* operon can be induced. (A) In the absence of lactose, the *lac* repressor binds DNA and represses transcription from the *lac* operon. (B) Allolactose or another inducer binds to the *lac* repressor, leading to its dissociation from DNA and to the production of *lac* mRNA.

The operon is a common regulatory unit in bacteria

The lac operon is just one well-studied example of an operon in *E. coli*. In fact, there are an estimated 600–700 operons in *E. coli*, all of which contain genes that are connected via a common metabolic function or pathway. Clustering genes in operons provides the clear advantage of a

coordinated regulatory mechanism for enzymes that are functionally related.

Many other gene-regulatory networks are controlled in ways analogous to those of the *lac* operon. For example, genes taking part in purine and, to a lesser degree, pyrimidine biosynthesis are repressed by the *pur* repressor. This dimeric protein is 31% identical in sequence with the *lac* repressor and has a similar three-dimensional structure. However, the behavior of the *pur* repressor is opposite that of the *lac* repressor: whereas the *lac* repressor is released from DNA by binding to a small molecule, the *pur* repressor binds DNA specifically, blocking transcription, only when bound to a small molecule. Such a small molecule is called a **corepressor**. For the *pur* repressor, the corepressor can be either guanine or hypoxanthine.

The dimeric *pur* repressor binds to inverted-repeat DNA sites of the form $5'-$AN**G**C**AA**N**CG**N**TT**N**C**NT$-3'$, in which the bases shown in boldface type are particularly important. Examination of the *E. coli* genome sequence reveals the presence of more than 20 such sites, regulating 19 operons and including more than 25 genes (**Figure 31.11**).

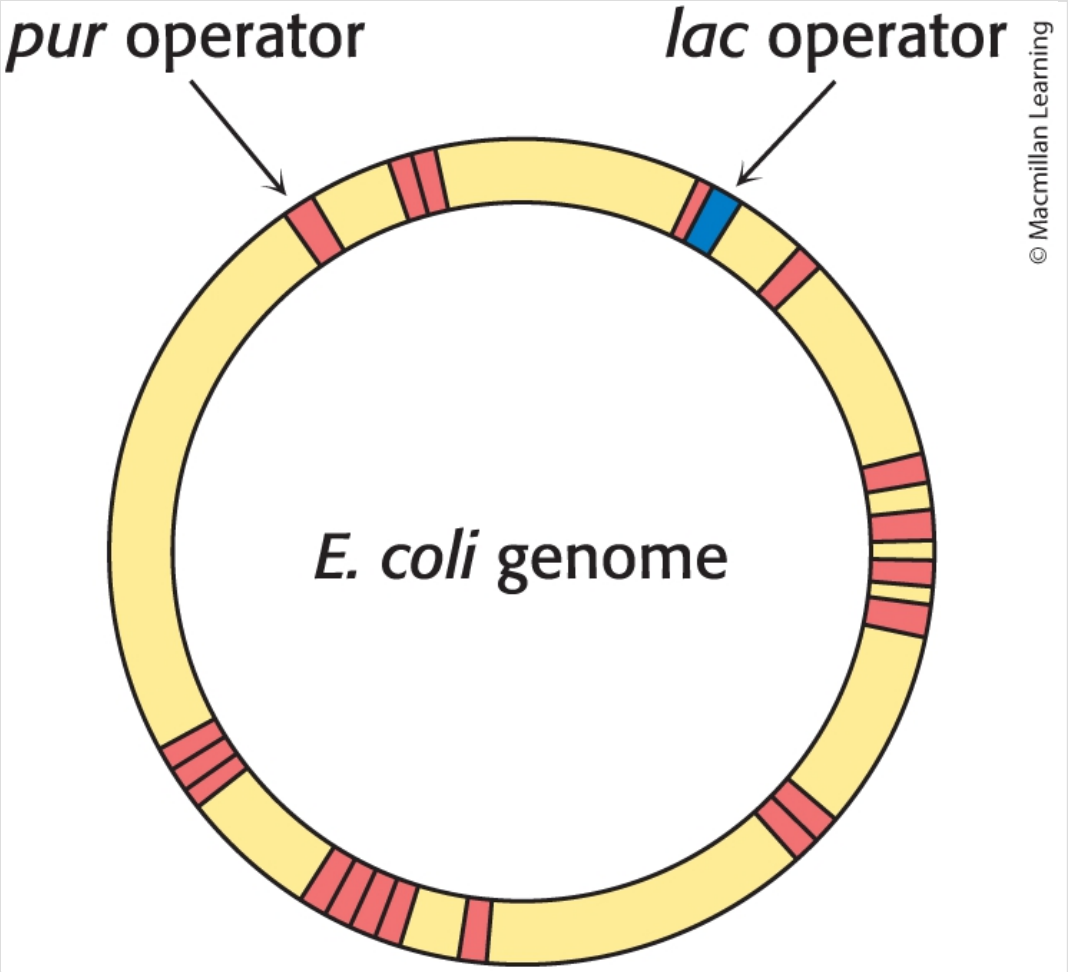

FIGURE 31.11 Operator sites are not distributed evenly across the E. *coli* genome. The *E. coli* genome contains only a single region that closely matches the sequence of the *lac* operator (shown in blue). In contrast, 19 sites match the sequence of the *pur* operator (shown in red). Thus, the *pur* repressor regulates the expression of many more genes than does the *lac* repressor.

Because the DNA-binding sites for these regulatory proteins are short, it is likely that they evolved independently and are not related by divergence from an ancestral regulatory site. Once a ligand-regulated DNA-binding protein is present in a cell, binding sites for the protein may arise by mutation adjacent to additional genes. Binding sites for the *pur* repressor have evolved in the regulatory regions of a wide range of

genes taking part in nucleotide biosynthesis. All such genes can then be regulated in a concerted manner.

The organization of bacterial genes into operons is useful for the analysis of completed genome sequences. Sometimes a gene of unknown function is discovered to be part of an operon containing well-characterized genes. Such associations can provide powerful clues to the biochemical and physiological functions of the uncharacterized gene.

Some DNA-binding proteins stimulate transcription

All the DNA-binding proteins discussed thus far function by inhibiting transcription until some environmental condition, such as the presence of lactose, is met. There are also DNA-binding proteins that stimulate transcription. One particularly well-studied example is a protein in *E. coli* that stimulates the expression of catabolic enzymes.

E. coli grown on glucose, a preferred energy source, have very low levels of catabolic enzymes for metabolizing other sugars. Synthesizing these enzymes when glucose is abundant would be wasteful. In fact, glucose has an inhibitory effect on the genes encoding these enzymes, an effect called **catabolite repression**. How does this work? Glucose achieves this inhibitory effect by lowering the concentration of cyclic AMP in *E. coli*. To understand the consequences of this, let us first consider the role of cAMP in the regulation of transcription.

High concentrations of cAMP stimulate the concerted transcription of many catabolic enzymes by acting through a protein called the **catabolite activator protein (CAP)**, also known as the *cAMP receptor protein* (CRP). When bound to cAMP, CAP stimulates the transcription of

lactose- and arabinose-catabolizing genes. CAP is a sequence-specific DNA-binding protein. Within the *lac* operon, CAP binds to an inverted repeat that is centered near position -61 relative to the start site for transcription (**Figure 31.12**). This site is approximately 70 base pairs from the operator site. As expected from the symmetry of the binding site, CAP functions as a dimer of identical subunits. CAP binding also bends DNA in a manner that favors interactions with RNA polymerase.

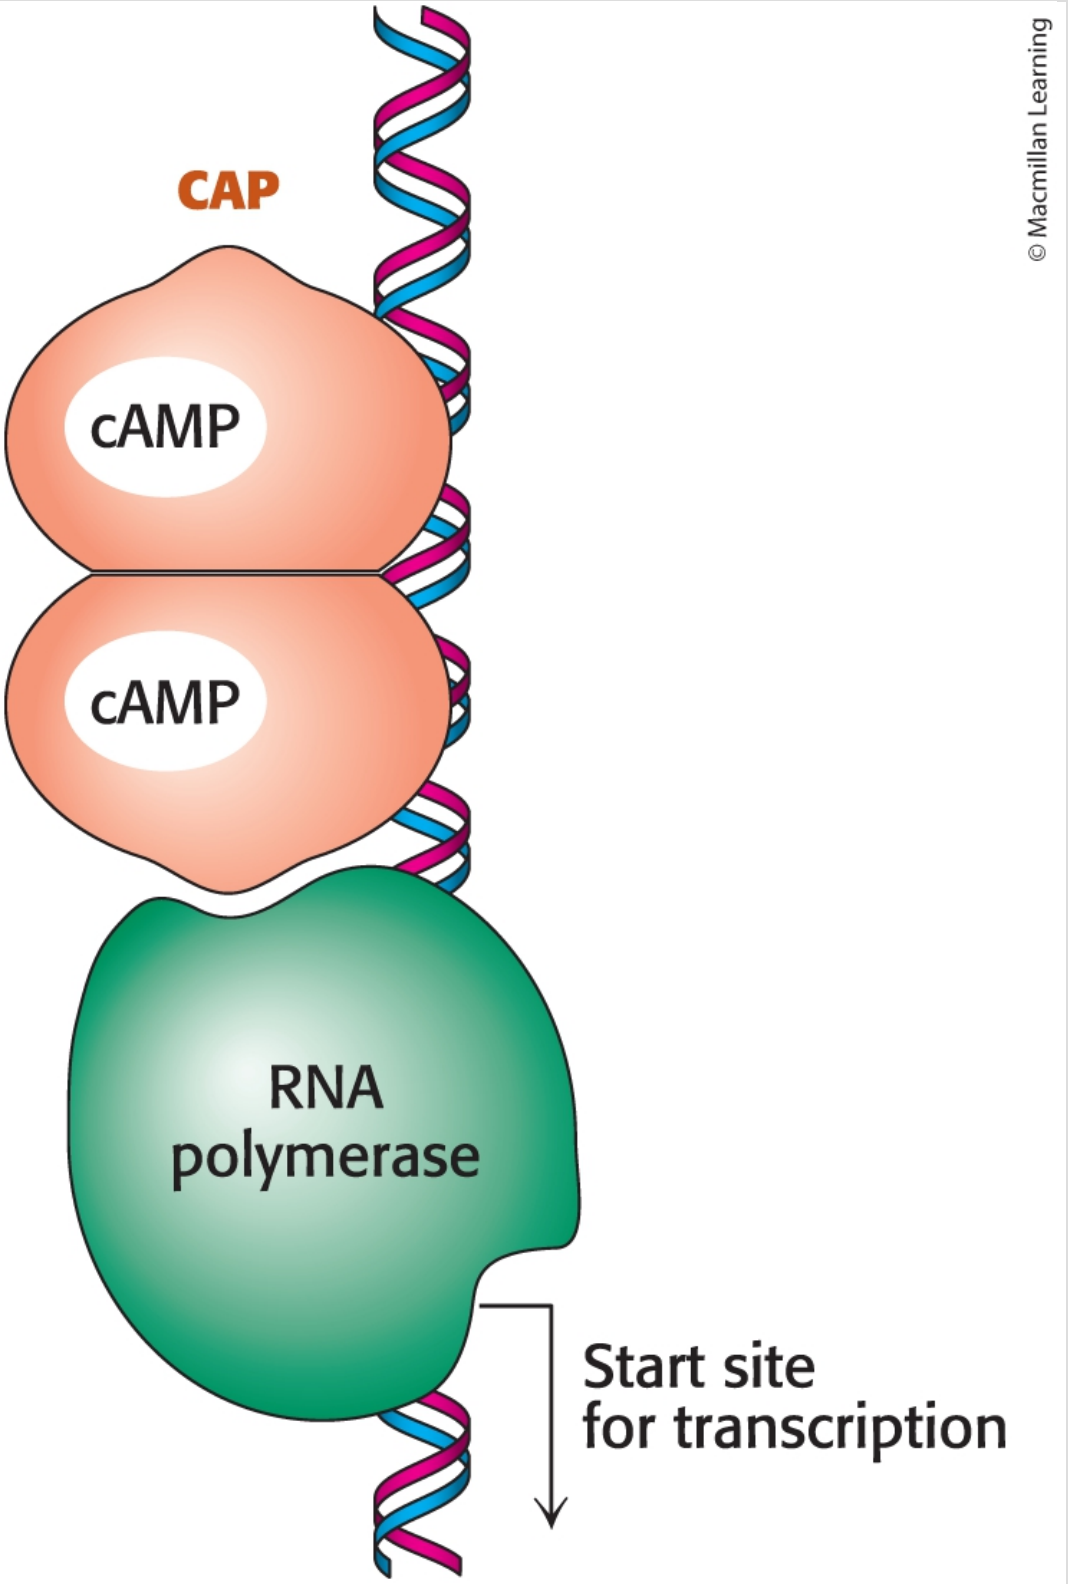

FIGURE 31.12 The catabolite activator protein (CAP) binds to DNA as a dimer. This protein binds to an inverted repeat that is at position −61 relative to the start site

of transcription. The CAP-binding site on DNA is adjacent to the position at which RNA polymerase binds.

The CAP–cAMP complex stimulates the initiation of transcription by approximately a factor of 50. Energetically favorable contacts between CAP and RNA polymerase increase the likelihood that transcription will be initiated at sites to which the CAP–cAMP complex is bound (Figure 31.13). Thus, for the *lac* operon, gene expression is maximal when the binding of allolactose relieves the inhibition by the *lac* repressor and the CAP–cAMP complex stimulates the binding of RNA polymerase.

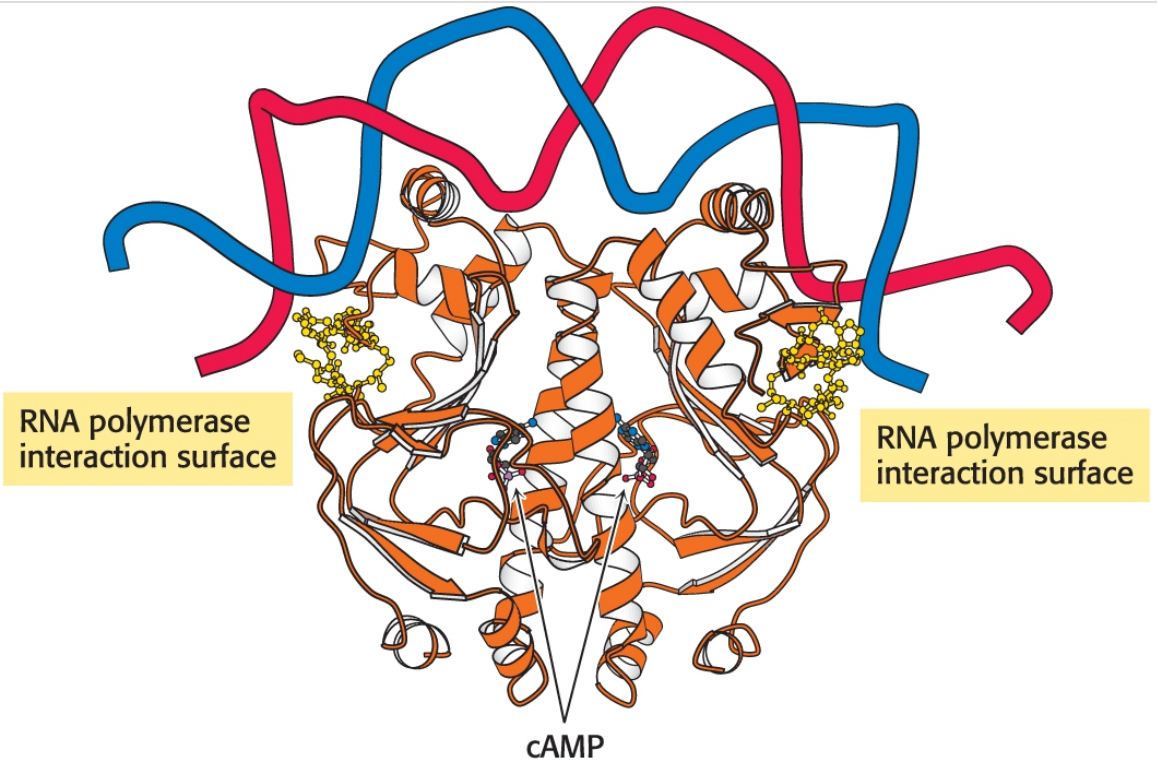

FIGURE 31.13 The CAP dimer binds to DNA and to RNA polymerase. The residues shown in yellow in each CAP monomer have been implicated in direct interactions with RNA polymerase.

[Drawn from 1RUN.pdb.]

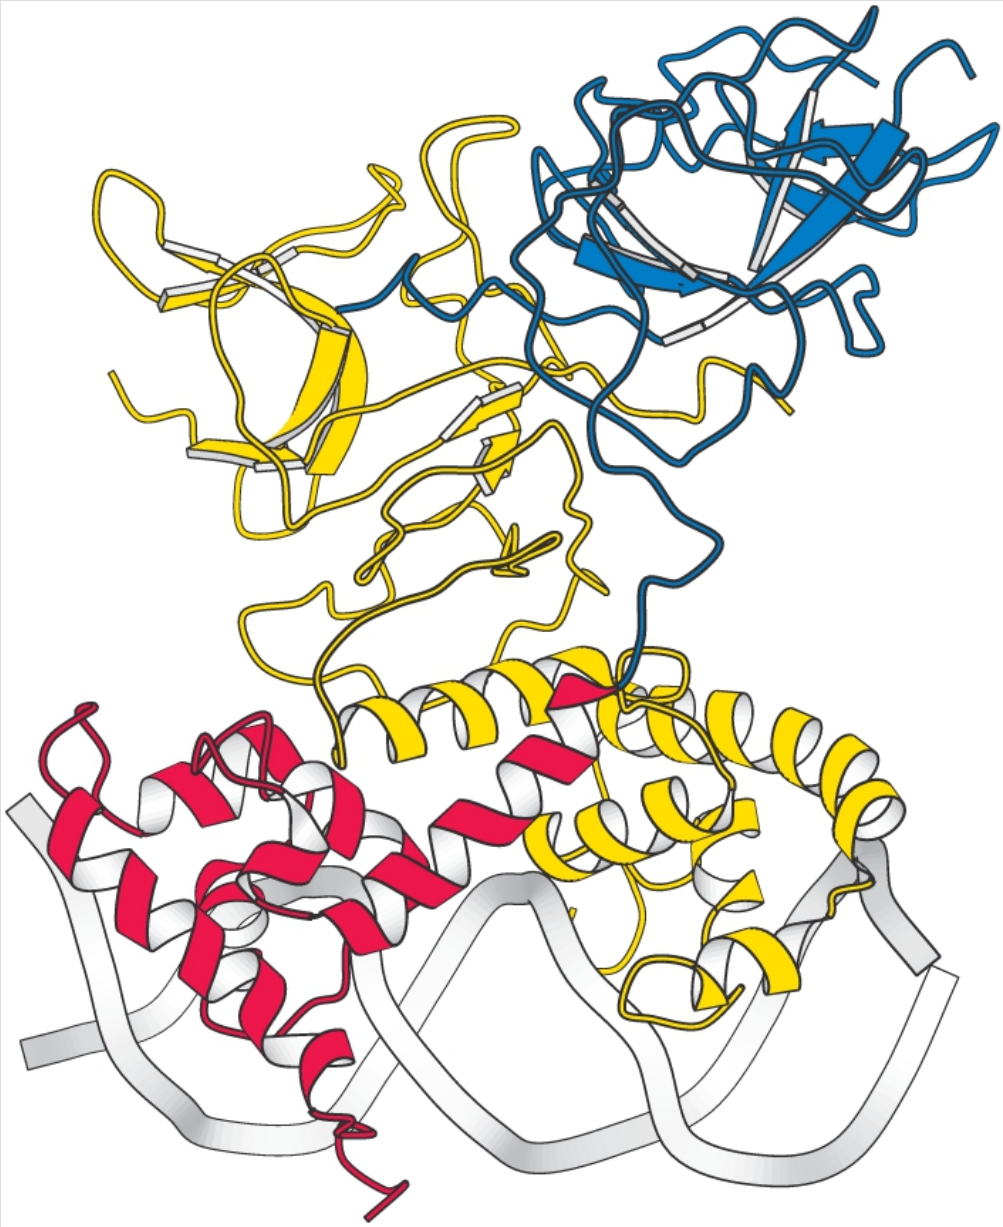
The *E. coli* genome contains many CAP-binding sites in positions appropriate for interactions with RNA polymerase. Thus, an increase in the cAMP level inside an *E. coli* bacterium results in the formation of CAP–cAMP complexes that bind to many promoters and stimulate the transcription of genes encoding a variety of catabolic enzymes. Conversely, as noted above, when glucose levels are high, the concentration of cAMP is low. This results in fewer CAP–cAMP complexes and reduced expression of the genes encoding the catabolic enzymes.

Self-Check Question

Under conditions of high glucose and high lactose, *E. coli* will first metabolize glucose before switching to lactose. How do you explain this?

31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression

The study of viruses that infect bacteria has led to significant advances in our understanding of the processes that control gene expression. Again, sequence-specific DNA-binding proteins play key roles in these processes. Investigations of bacteriophage λ have been particularly revealing.



We examined the alternative infection modes of λ phage in Chapter 9. In the lytic pathway, most of the genes in the viral genome are transcribed, initiating the production of many virus particles and leading to the eventual lysis of the bacterial cell with the concomitant release of approximately 100 virus particles. In the lysogenic pathway, the viral genome is incorporated into the bacterial DNA where most of the viral genes remain unexpressed, allowing the viral genome to be carried along as the bacteria replicate. Two key proteins and a set of regulatory sequences in the viral genome are responsible for the switch that determines which of these two pathways is followed.

The λ repressor regulates its own expression

The first protein that we will discuss is the **λ repressor**, sometimes known as the λ cI protein. This protein is key because it blocks, either directly or indirectly, the transcription of almost all genes

encoded by the virus. The one exception is the gene that encodes the λ repressor itself.

The λ repressor consists of an amino-terminal DNA-binding domain and a carboxyl-terminal domain that participates in protein oligomerization (**Figure 31.14**). This protein binds to a number of key sites in the λ phage genome. The sites of greatest interest for our present discussion are in the so-called *right operator* (**Figure 31.15**). This region includes three binding sites for the λ repressor dimer, as well as two promoters within a section of approximately 80 base pairs. One promoter drives the expression of the gene for the λ repressor itself, whereas the other drives the expression of several other viral genes.

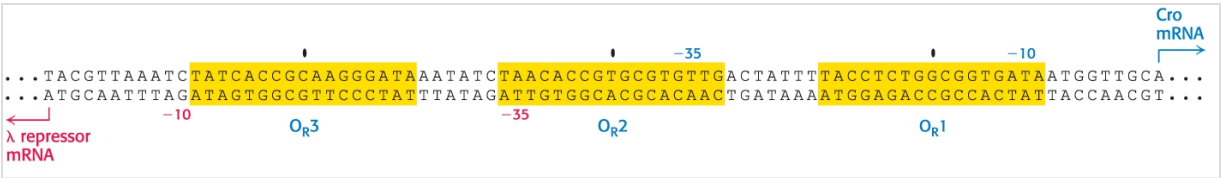
FIGURE 31.14 The λ repressor binds to DNA as a dimer. The amino-terminal domain of one subunit is shown in red and the carboxyl-terminal domain is shown in blue. In the other subunit, both domains are shown in yellow. Notice how α helices on the amino-terminal domains fit into the major groove of the DNA.

[Drawn from 3BDN.pdb.]

INTERACT with the models in Figure 31.13 and Figure 31.14 in



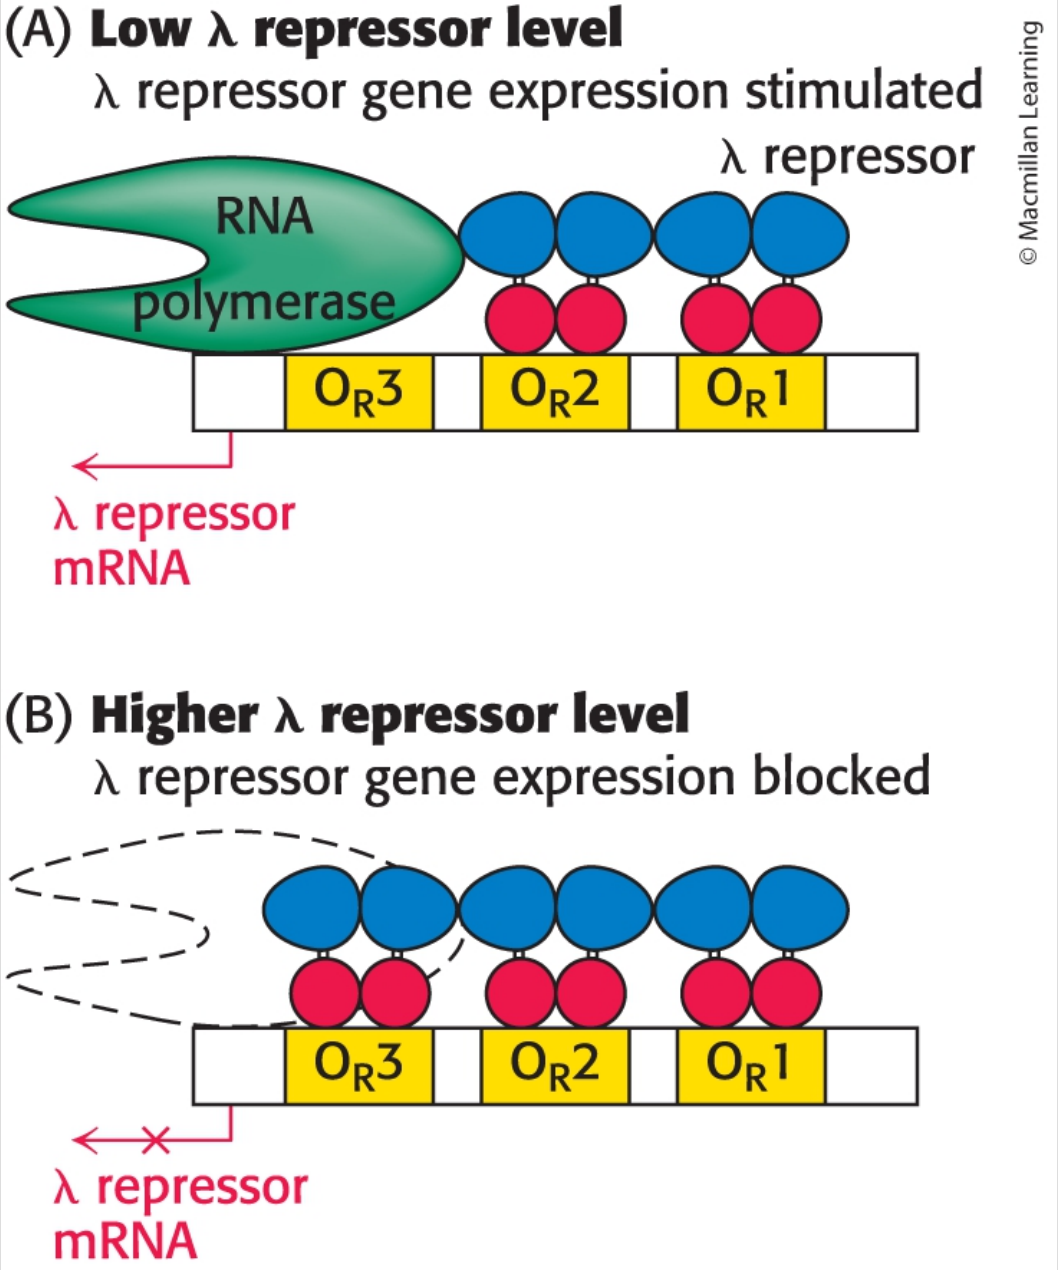


FIGURE 31.15 The sequence of the λ right operator is a binding target for regulatory proteins. The three operator sites (O_R1, O_R2, and O_R3) are shaded yellow with their centers indicated. The start sites for the λ repressor mRNA and the Cro mRNA are indicated, as are the -10 and -35 positions of their respective promoters.

The λ repressor does not have the same affinity for the three sites; it binds the site O_R1 with the highest affinity. In addition, the binding to adjacent sites is cooperative so that, after a λ repressor dimer has bound at O_R1, the likelihood that a protein will bind to the adjacent site O_R2 increases by approximately 25-fold. Thus, when the λ repressor is present in the cell at moderate concentrations, the most likely configuration has the λ repressor bound at O_R1 and O_R2, but not at O_R3. In this configuration, the λ repressor dimer bound at O_R1 blocks access to the promoter on the right side of the operator sites. This represses transcription of the adjacent gene, which encodes a protein termed **Cro** (controller of repressor and others), while the repressor dimer at O_R2 can be in contact with RNA polymerase and stimulate transcription of the promoter that controls the transcription of the gene that encodes the λ repressor itself.

Thus, the λ repressor stimulates its own production. As the concentration of the λ repressor increases further, an additional repressor dimer can bind to the O_R3 site, blocking the other promoter and repressing the production of additional repressor. Thus, the O_R3 site serves to maintain the λ repressor in a narrow, stable concentration range (**Figure 31.16**). The λ repressor also blocks other promoters in the λ phage genome so that the repressor is the only phage protein produced, maintaining the lysogenic state.

© Macmillan Learning

FIGURE 31.16 The λ repressor controls its own synthesis. (A) When λ repressor levels are relatively low, the repressor binds to sites O_R1 and O_R2 and stimulates the transcription of the gene that encodes the λ repressor itself. (B) When λ repressor levels are higher, the repressor also binds to site O_R3, blocking access to its promoter and repressing transcription from this gene.

A circuit based on the λ repressor and Cro forms a genetic switch

What stimulates the switch to the lytic pathway? Changes such as DNA damage initiate the cleavage of the λ repressor at a specific bond between the DNA-binding and oligomerization domains. This process is mediated by the *E. coli* RecA protein (Section 28.5). After this cleavage has taken place, the affinity of the λ repressor for DNA is reduced. After the λ repressor is no longer bound to the O_R1 site, the Cro gene can be transcribed. Cro is a small protein that binds to the same sites as the λ repressor does, but with a different order of affinity for the three sites in the right operator. In particular, Cro has the highest affinity for O_R3. Cro bound at this site blocks the production of new λ repressor. The absence of λ repressor activates the expression of other phage genes, leading to the production of virus particles and the eventual lysis of the host cells.

Thus, this genetic circuit acts as a switch with two stable states: (1) λ repressor high, Cro low, corresponding to the lysogenic state; and (2) Cro high, λ repressor low, corresponding to the lytic state (**Figure 31.17**). Regulatory circuits with two stable states are often referred to as being *bistable*. In these bistable circuits, positive and negative transcriptional control are tightly linked, with different DNA-binding proteins controlling the expression of each other's genes. This is a common motif for controlling gene expression in all systems, from viruses to eukaryotes. In eukaryotes, for example, genetic switches can determine distinct cellular fates, analogous to the lysogenic and lytic infection modes of λ phage.

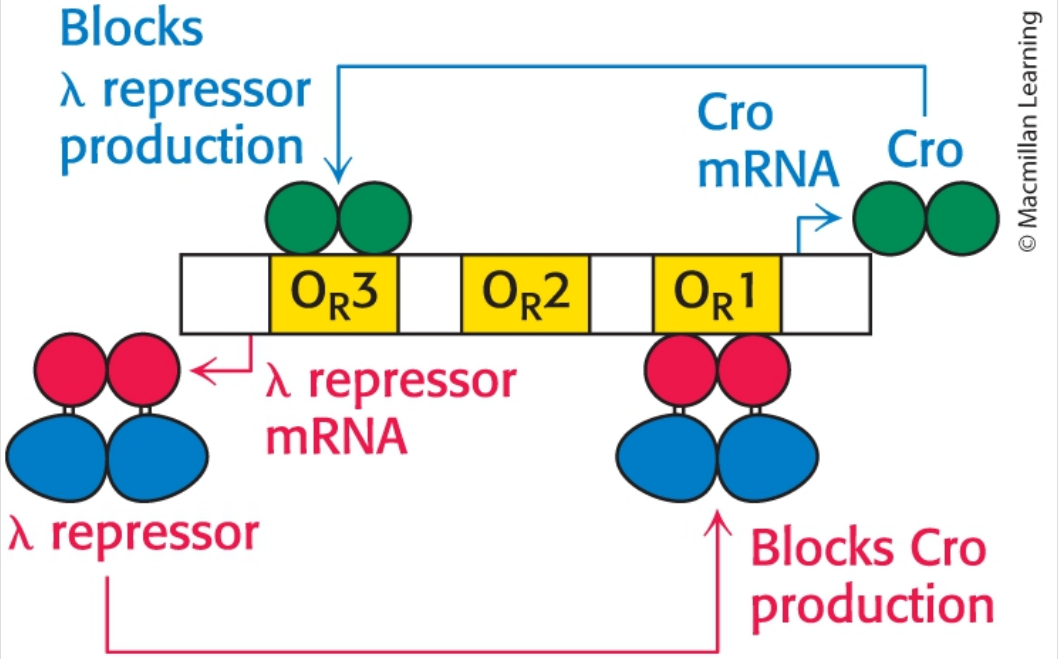

FIGURE 31.17 The λ repressor and Cro form a genetic circuit. The λ repressor blocks the production of Cro by binding most favorably to site O_R1, whereas Cro blocks the production of the λ repressor by binding most favorably to site O_R3. This circuit forms a switch that determines whether the lysogenic or the lytic pathway is followed.

31.4 Regulation of Gene Expression Is More Complex in Eukaryotes

Gene regulation in eukaryotes is significantly more complex than in bacteria in several ways. First, the genomes being regulated are significantly larger. The *E. coli* genome consists of a single, circular chromosome containing 4.6 megabases (Mb). This genome encodes approximately 2000 proteins. In comparison, one of the simplest eukaryotes, *Saccharomyces cerevisiae* (baker's yeast), contains 16 chromosomes ranging in size from 0.2 to 2.2 Mb. The yeast genome totals 12 Mb and encodes approximately 6000 proteins. The genome within a human cell contains 23 pairs of chromosomes ranging in size from 50 to 250 Mb. Approximately 20,000 protein-coding genes are present within the 3000 Mb of human DNA. Second, recall from Section 29.3 that eukaryotic DNA is packaged into chromatin. Third, eukaryotic genes are not generally organized into operons. Instead, genes that encode proteins for steps within a given pathway are often spread widely across the genome. This characteristic requires that other mechanisms function to regulate genes in a coordinated way.

Despite these differences, some aspects of gene regulation in eukaryotes are quite similar to those in bacteria. In particular, proteins that recognize specific DNA sequences are central to many gene-regulatory processes. Eukaryotic transcription factors — DNA-binding proteins similar in many ways to the bacterial proteins that we encountered earlier — can act directly by interacting with the transcriptional machinery, or indirectly by influencing chromatin structure. Key features of eukaryotic promoters, transcription factors, and enhancer sequences that can act far away from transcription start sites were introduced in Section 29.3.

A range of DNA-binding motifs are employed by eukaryotic DNA-binding proteins

The structures of many eukaryotic DNA-binding proteins have been determined and a range of structural motifs have been observed, but we will focus on three that reveal the common features and the diversity of these motifs. The first type of eukaryotic DNA-binding motif that we will consider is the **homeodomain** (**Figure 31.18**). The structure of the homeo-domain and its mode of recognition of DNA are very similar to those of the bacterial helix-turn-helix proteins. In eukaryotes, homeodomain proteins often form heterodimeric structures, sometimes with other homeodomain proteins, that recognize asymmetric DNA sequences.

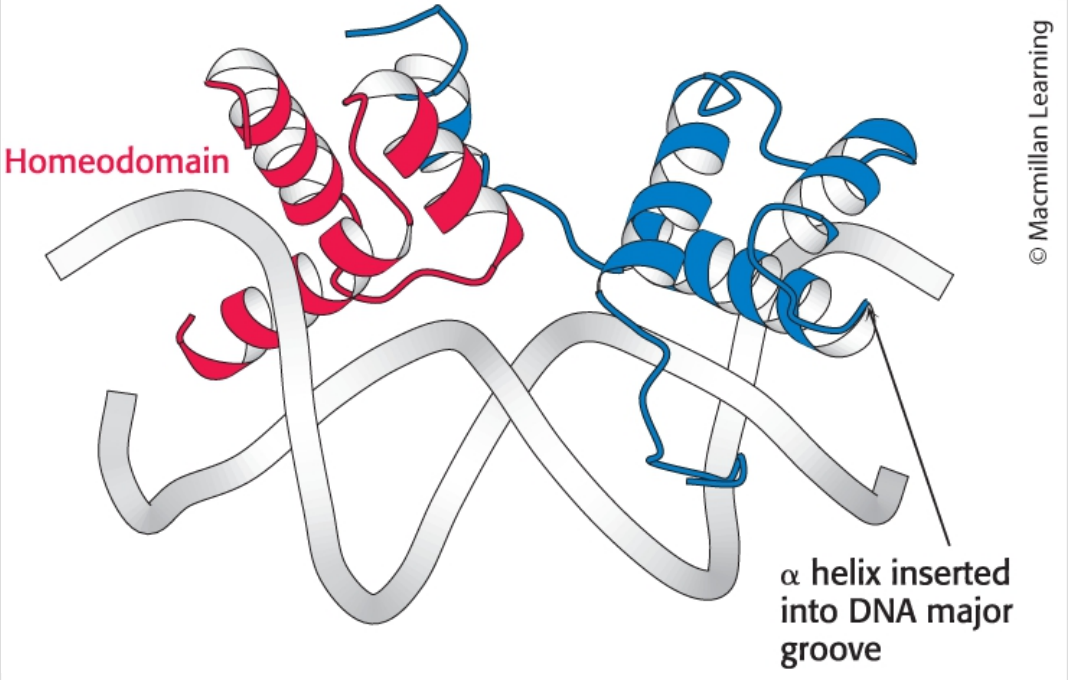

FIGURE 31.18 Two different DNA-binding homeodomains can form a heterodimer. Each homeodomain has a helix-turn-helix motif with one helix inserted into the major groove of DNA.

[Drawn from 1AKH.pdb.]

Another class of eukaryotic DNA-binding motif comprises the **basic-leucine zipper (bZip) proteins** (**Figure 31.19**). This DNA-binding motif consists of a pair of long α helices. The first part of each α helix is a basic region that lies in the major groove of the DNA and makes contacts responsible for DNA-site recognition. The second part of each α helix forms a coiled-coil structure with its partner. When these units are stabilized by appropriately spaced leucine residues, they are referred to as *leucine zippers*.

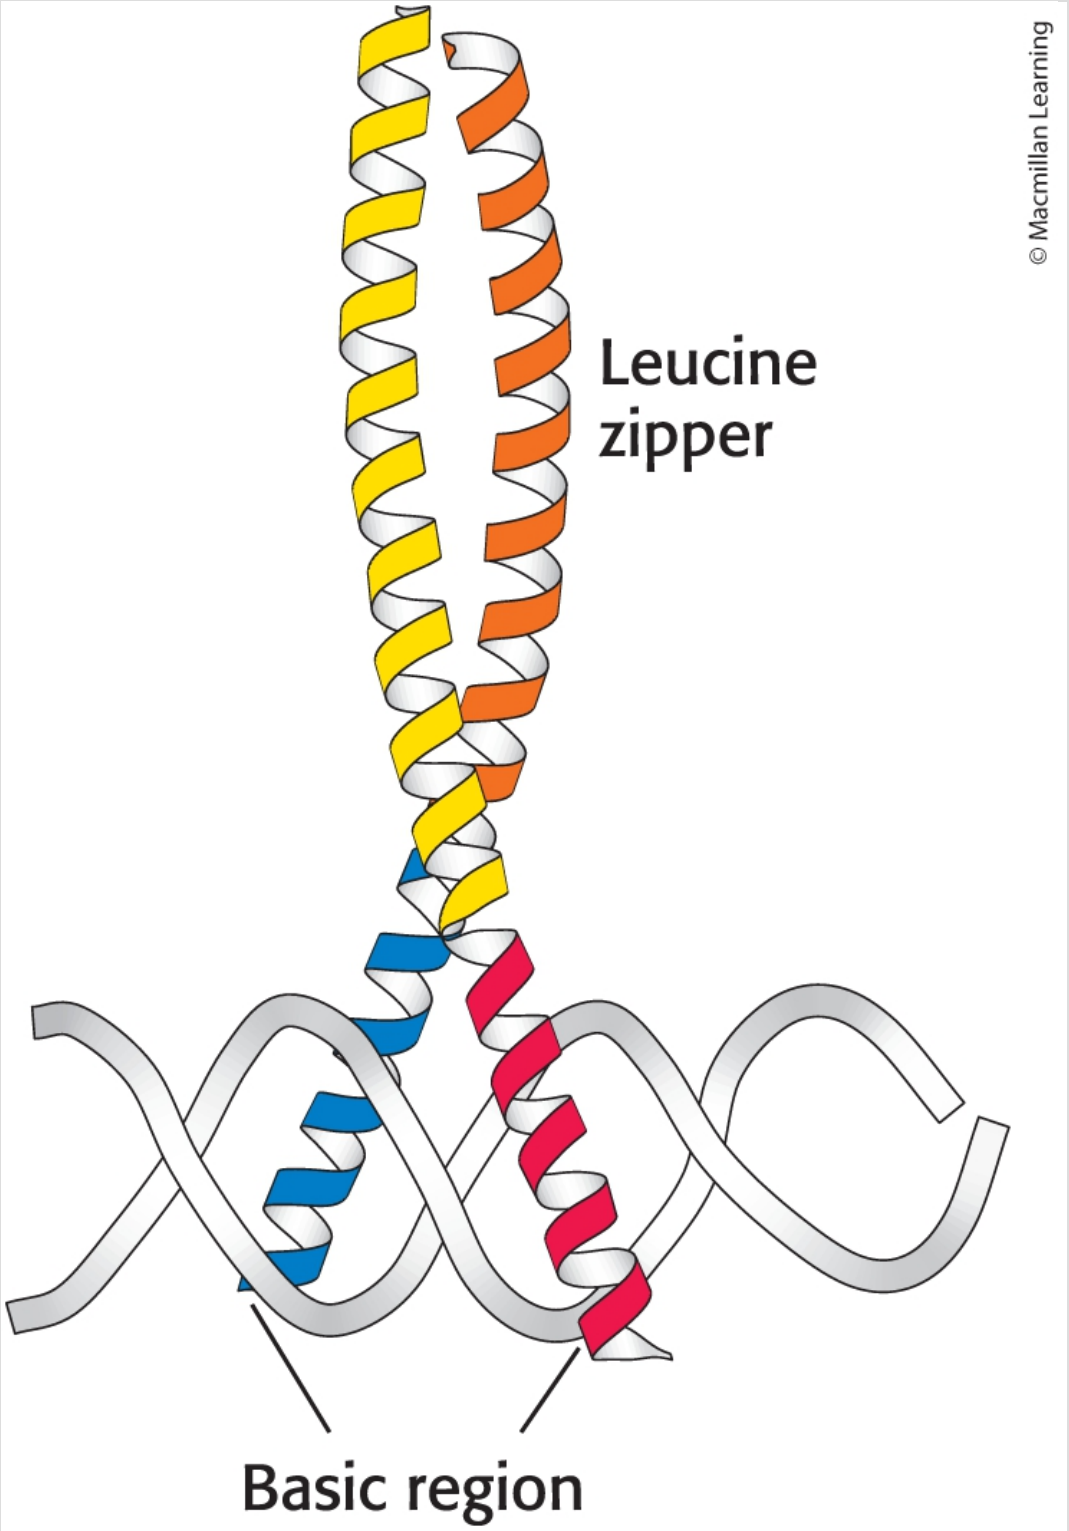

FIGURE 31.19 Two basic-leucine zipper proteins can form a heterodimer. The basic region lies in the major groove of DNA. The leucine zipper stabilizes the protein dimer.

[Drawn from 1FOS.pdb.]

The final class of eukaryotic DNA-binding motifs that we will consider here are the Cys_2His_2 **zinc-finger domains** (**Figure 31.20**). This motif comprises tandem sets of small domains, each of which binds a zinc ion through conserved sets of two cysteine and two histidine residues. These structures, often just called zinc-finger domains, form a string that follows the major groove of DNA. An α helix from each domain makes specific contacts with the edges of base pairs within the groove. Some proteins contain arrays of 10 or more zinc-finger domains, potentially enabling them to contact long stretches of DNA. The human genome encodes several hundred proteins that contain zinc-finger domains of this type. We will encounter another class of zinc-based DNA-binding domain when we consider nuclear hormone receptors in Section 31.5.

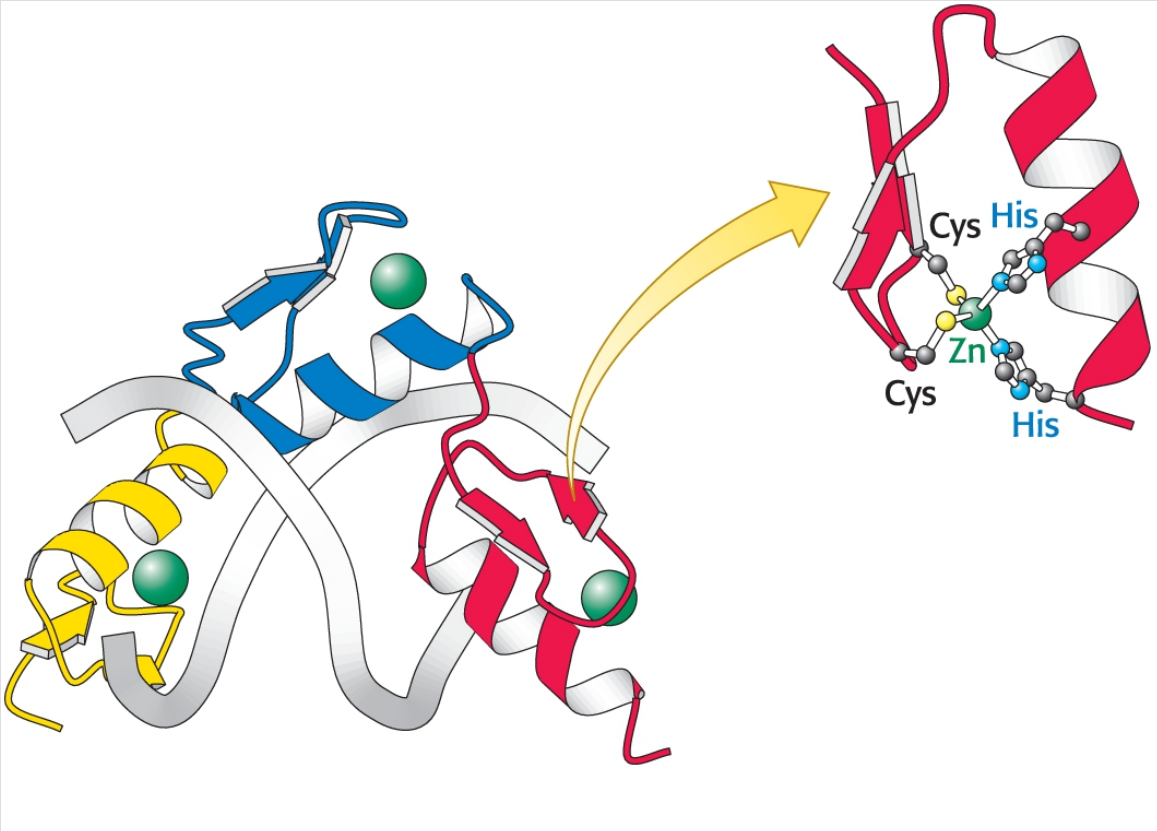

FIGURE 31.20 Zinc-finger domains bind to DNA. A DNA-binding domain comprising three Cys_2His_2 zinc-finger domains (shown in yellow, blue, and red) is shown in a complex with DNA. Each zinc-finger domain is stabilized by a bound zinc ion (shown in green) through interactions with two cysteine residues and two histidine residues. Notice how the protein wrap around the DNA in the major groove.

Self-Check Question

The α helix is the most common element used by both bacterial and eukaryotic DNA-binding motifs. Why is this?

DNA-binding transcription factors are key to gene regulation in eukaryotes, just as they are in bacteria. However, the roles of eukaryotic transcription factors are different in several ways:

- Whereas the DNA-binding sites crucial for the control of gene expression in bacteria are usually quite close to promoters, those in eukaryotes can be farther away from promoters and can exert their action at a distance.
- Most bacterial genes are regulated by single transcription factors, and multiple genes in a pathway are expressed in a coordinated fashion because such genes are often transcribed as part of a polycistronic mRNA. In eukaryotes, the expression of each gene is typically controlled by multiple transcription factors, and the coordinated expression of different genes depends on having similar transcription-factor-binding sites in each gene in the set.

- In bacteria, transcription factors usually interact directly with RNA polymerase. In eukaryotes, while some transcription factors interact directly with RNA polymerase, many others act more indirectly, interacting with other proteins associated with RNA polymerase or modifying chromatin structure.

Eukaryotic transcription factors usually consist of several domains. As discussed above, the **DNA-binding domain** binds to regulatory sequences that can either be adjacent to the promoter or at some distance from it. Most commonly, transcription factors include additional domains that help activate transcription. When a transcription factor is bound to the DNA, its **activation domain** promotes transcription by interacting with RNA polymerase, by interacting with other associated proteins, or by modifying the local structure of chromatin.

Activation domains interact with other proteins

The activation domains of transcription factors generally recruit other proteins that promote transcription. In some cases, these activation domains interact directly with RNA polymerase. In other cases, the activation domains bind to closely associated proteins that bridge the transcription factors and the polymerase.

One example of an important bridge between transcription factors and promoter-bound RNA Polymerase II is **mediator**, a protein complex of 25 to 30 subunits that is conserved from yeast to human beings (**Figure 31.21**). Studies using cryo-electron microscopy are revealing the details of mediator structure and its interactions with RNA polymerase II and transcription factors. These structures provide insights into how mediator facilitates the phosphorylation of the carboxyl-terminal domain of RNA polymerase to promote the transition from transcription initiation to elongation.

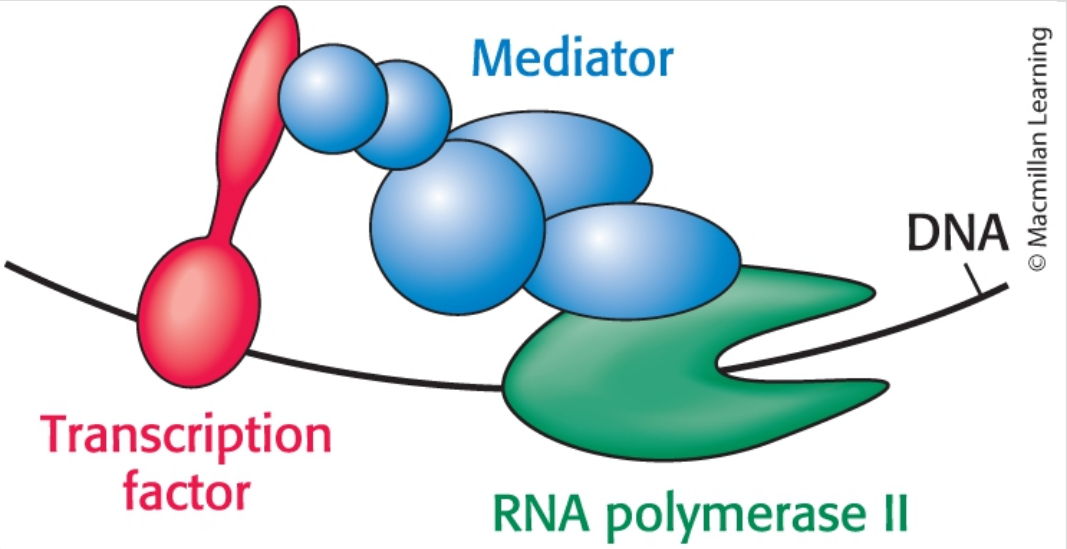

FIGURE 31.21 The mediator complex binds to transcription factors and to RNA polymerase II. Mediator acts as a bridge between transcription factors bearing activation domains and RNA polymerase II. These interactions help recruit and stabilize RNA polymerase II near specific genes that are then transcribed.

Interestingly, despite their critical role in the regulation of transcription, activation domains are quite diverse and share very little sequence similarity. For example, they may be acidic, hydrophobic, glutamine rich, or proline rich. However, they do have certain features in common. First, they are often redundant; that is, a part of the activation domain can be deleted without loss of function. Second, they are modular and can activate transcription when paired with a variety of DNA-binding domains. Third, they can act synergistically: two activation domains acting together create a stronger effect than either of them acting separately.

We have been considering the case in which gene control increases the expression level of a gene. In many cases, the expression of a gene must be decreased by blocking transcription. The agents in such cases are *transcriptional repressors*. In many cases, transcriptional repressors act by altering chromatin structure.

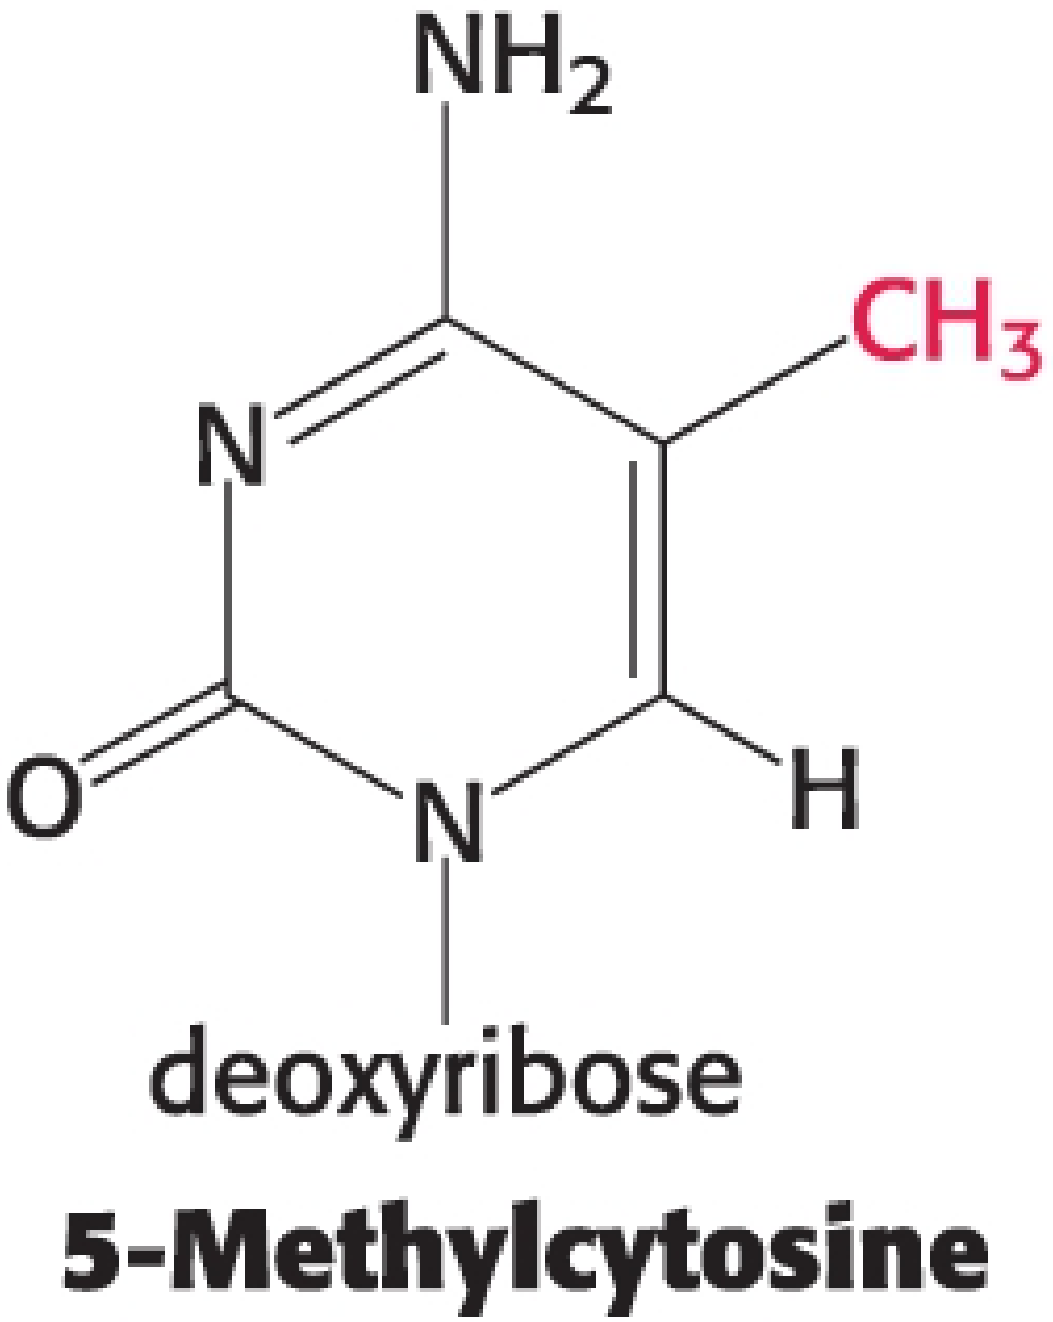
Multiple transcription factors interact with eukaryotic regulatory regions

The pre-initiation complex described in Chapter 29 initiates transcription at a low frequency. Recall that several general transcription factors join with RNA polymerase II to form the pre-initiation complex (PIC). Additional transcription factors must bind to other sites that can be near the promoter or quite distant for a gene to achieve a higher rate of mRNA synthesis. In contrast with the regulators of bacterial transcription, few eukaryotic transcription factors have any effect on their own. Instead, each factor recruits other proteins to build up large complexes that interact with the transcriptional machinery to activate transcription.

A major advantage of this mode of regulation is that a given regulatory protein can have different effects, depending on what other proteins are present in the same cell. This phenomenon, called *combinatorial control*, is crucial to multicellular organisms that have many different cell types. Even in unicellular eukaryotes such as yeast, combinatorial control allows for the generation of distinct cell types.

31.5 The Control of Gene Expression in Eukaryotes Can Require Chromatin Remodeling

Recall from Section 29.3 that to fit inside the nucleus, eukaryotic DNA is compacted into chromatin, a complex of DNA and a special set of proteins. One of the fundamental features of chromatin is the nucleosome, where DNA is wrapped around an octamer of histone proteins H2A, H2B, H3, and H4. In this section we will discuss how chromatin modifications affect gene expression.



Early studies investigating the effect of nucleases on chromatin suggested a correlation between chromatin structure and gene expression. DNA that is densely packaged into chromatin is less susceptible to cleavage by the nonspecific DNA-cleaving enzyme DNase I. Regions adjacent to genes that are being transcribed are more sensitive to cleavage by DNase I than are other sites in the genome, suggesting that the DNA in these regions is less compacted than it is elsewhere and is thus more accessible to regulatory proteins.

In addition, some sites, called *hypersensitive sites,* are extremely sensitive to DNase I and other nucleases. These sites are usually within 1 kb of the start site of an active gene and correspond to regions that have few nucleosomes or contain nucleosomes in an altered conformation. Hypersensitive sites are cell-type specific and developmentally regulated. For example, globin genes in the precursors of erythroid cells from 20-hour-old chicken embryos are insensitive to DNase I. However, when hemoglobin synthesis begins at 35 hours, regions adjacent to these genes become highly susceptible to digestion. In tissues such as the brain that produce no hemoglobin, the globin genes remain resistant to DNase I throughout development and into adulthood. These

studies and additional lines of evidence suggest that chromatin structure is altered in active genes compared with inactive ones and that one prerequisite for gene expression is a relaxing of the chromatin structure.

Chromatin remodeling and DNA methylation regulate access to DNA-binding sites

If, as mentioned above, the relaxing of chromatin structure allows for gene expression, then it makes sense that the packaging of DNA into nucleosomes will inhibit gene expression. Another mechanism of regulating gene expression is provided by the degree of methylation of DNA, especially at cytosines. Specific methyltransferases methylate carbon 5 of cytosine, converting it into 5-methylcytosine.

About 70% of the $5'-CpG-3'$ sequences (where “p” represents the phosphate residue in the DNA backbone) in mammalian genomes are methylated. This modification is associated with gene silencing because

the methyl group of 5-methylcytosine protrudes into the major groove of DNA where it may interfere with the binding of proteins that stimulate transcription.

The distribution of these methylated CpG sequences in mammalian genomes is not uniform. Many CpG sequences have been converted into TpG through mutation by the deamination of 5-methylcytosine to thymine. In addition, some regions contain primarily *non-methylated* CpG dinucleotides, referred to as **CpG islands**. The promoters of ca. 70% of mammalian genes are associated with CpG islands, making them more accessible by transcription factors. The relative absence of 5-methylcytosines near gene promoters is referred to as *hypomethylation*.

The distribution of methylated CpG sequences may also depend on the cell type. Consider the β-globin gene. In cells that are actively expressing hemoglobin, the region from approximately 1 kb upstream of the start site to approximately 100 bp downstream of the start site is less methylated than the corresponding region in cells that do not express this gene.

These observations suggest that methylation of CpG sequences may block DNA recognition by transcription factors, thus influencing gene expression. Recent evidence suggests that non-methylated CpG sequences are specifically bound by certain transcription factors. These transcription factors may also recruit histone-modifying enzymes that alter the chromatin structure. We will discuss histone modifications in more detail below.

Epigenetic modifications influence gene expression

DNA methylation and histone modification (to be discussed below) are two mechanisms associated with **epigenetics** — modifications to the

genome that affect gene expression but do not alter the DNA sequence. A third mechanism involves RNA-mediated silencing, which we will discuss in Section 31.6. Several human disorders, including Fragile X syndrome, Angelman's syndrome, and various forms of cancer, are thought to be caused by epigenetic modifications and influenced by diet, exercise, age, or exposure to environmental toxins.

Cancer was the first human disease to be linked to epigenetics when it was discovered that cancerous cells had abnormally high levels of methylation as compared to normal cells. Further investigations showed that in cancer cells, many CpG islands become methylated, silencing genes such as tumor-suppressor genes that are critical for the control of cell division and should not be turned off.

PBH Images/Alamy

SARAH STEWART Dr. Sarah Stewart was born in Mexico in 1905 to an American father and a Mexican mother. Her family relocated to the United States in 1911, and she pursued her interests in bacteriology and chemistry, earning a PhD in microbiology in 1939. Dr. Stewart wanted to research the possible link between cancer and viruses at a time when that idea was considered preposterous, even though research as early as 1911 suggested such a link. Unable to obtain funding for her research, she instead pursued a medical degree. In 1949 she was the first woman to ever receive an MD

from Georgetown University School of Medicine, having completed that degree in only two years. She was 43 at the time. Dr. Stewart returned to research, and in 1953 she isolated a small agent from cancerous tissue that is also capable of causing cancer in healthy tissue, thus pioneering the field of viral oncology. Sadly, Dr. Stewart succumbed to the same disease she was investigating; she died of cancer in 1976.

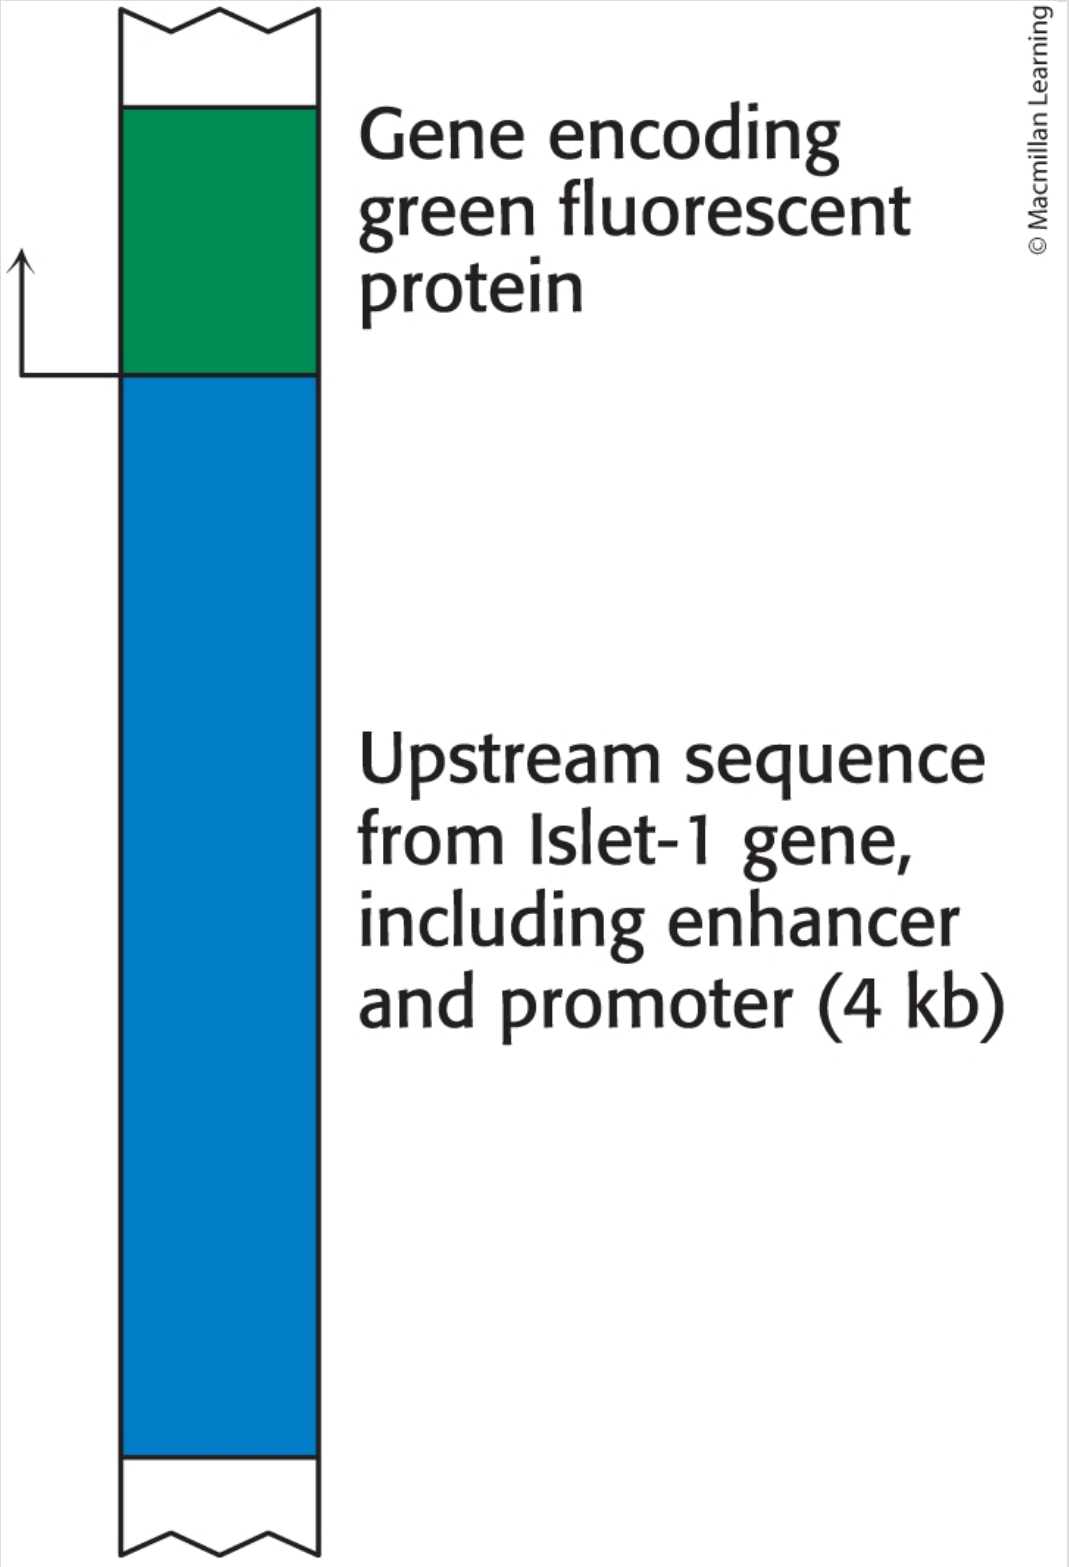
Enhancers stimulate transcription by recruiting activator proteins that alter chromatin structure

Let us now turn to the action of enhancers, which were introduced in Section 29.3. Recall that enhancers are DNA sequences that have no promoter activity of their own but greatly increase transcription, even when they are located several thousand base pairs from the gene being expressed.

Enhancers function by serving as binding sites for specific transcription factors. An enhancer is effective only in the specific cell types in which appropriate regulatory proteins are expressed. In many cases, these DNA-binding proteins influence transcription initiation by altering the local chromatin structure to expose a gene or its regulatory sites rather than by direct interactions with RNA polymerase. This mechanism accounts for the ability of enhancers to act at a distance.

The properties of enhancers are illustrated by studies of the enhancer controlling the gene Islet-1. This gene encodes a homeodomain-containing protein that plays important roles in the developing nervous system. DNA fragments were constructed by connecting the promoter and enhancer regions associated with the Islet-1 gene to a gene expressing green fluorescent protein (GFP; **Figure 31.22**). When this DNA construct was introduced into zebrafish, an organism useful for imaging studies because of its size and transparency, the expression of green fluorescent protein could be visualized by microscopy. The green

fluorescence of GFP was only seen in motor neurons and only during one stage of zebrafish development (**Figure 31.23**), revealing the power of the enhancer in limiting gene expression to particular cells.



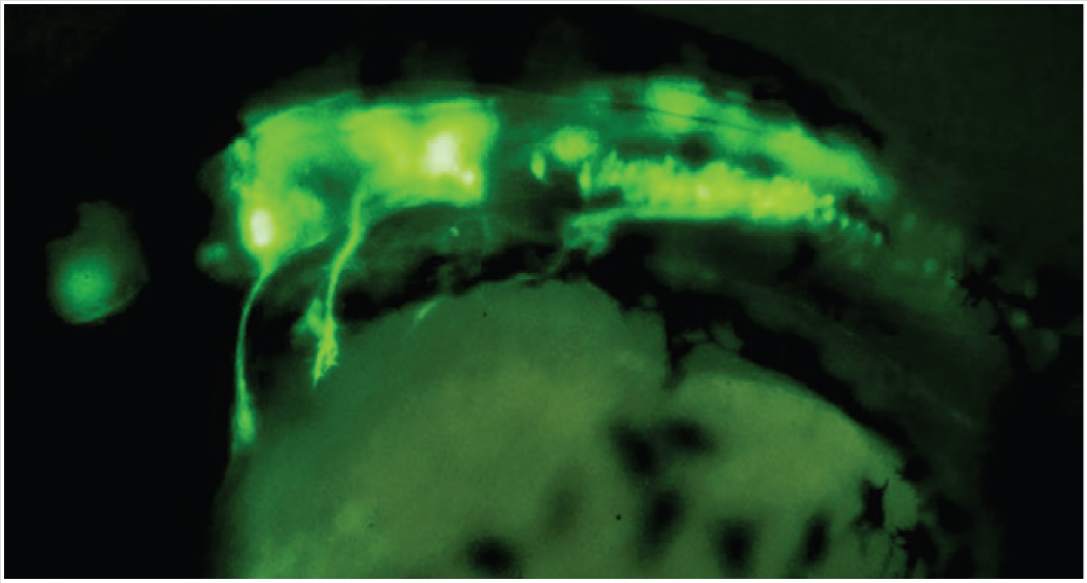


FIGURE 31.22 Enhancer function can be assayed with a reporter construct. A DNA construct that includes a gene encoding green fluorescent protein adjacent to 4 kilobases of the DNA upstream of the start site for the Islet-1 gene. If this construct is

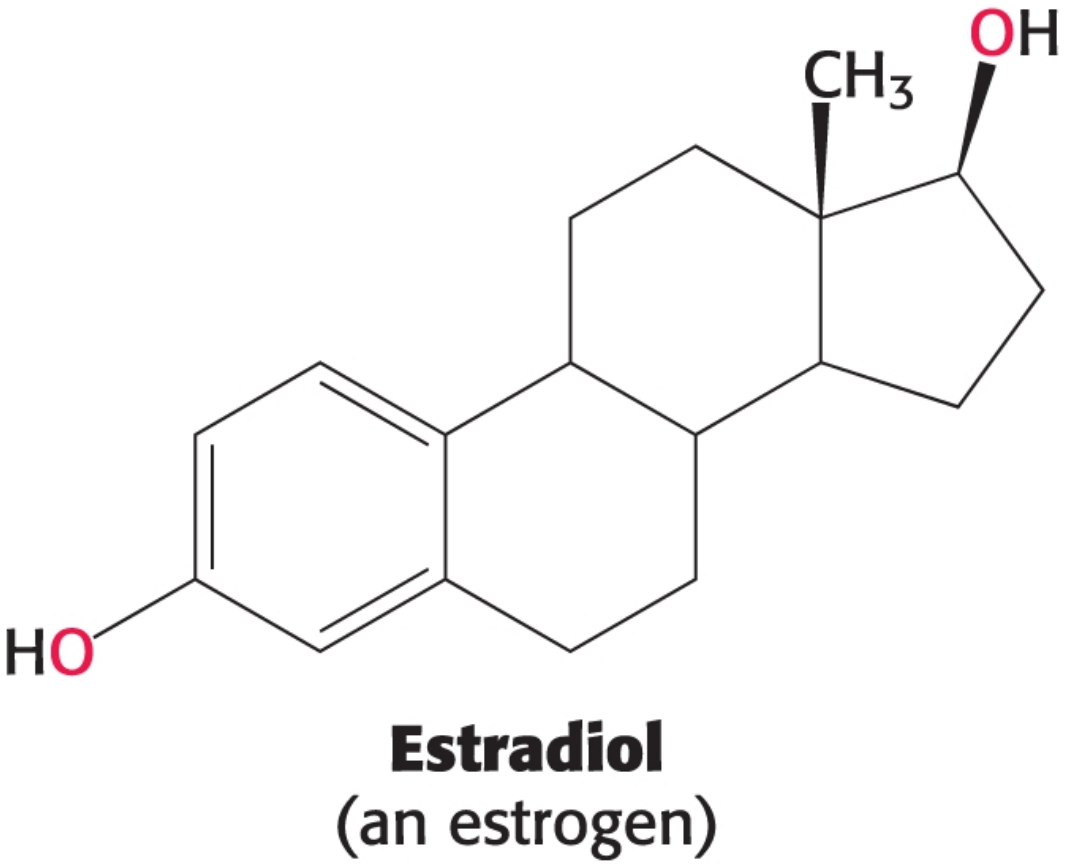
introduced into cells in which Islet-1 is expressed, then the enhancer and promoter should lead to the production of green fluorescent protein.

Republished with permission of Society for Neuroscience, from Higashijima S., Hotta Y., Okamoto H., Visualization of Cranial Motor Neurons in Live Zebrafish. *J. Neurosci.*, January 1, 2000, 20(1):206–218;

FIGURE 31.23 Enhancer function can be demonstrated in vivo. This microscopic image shows developing zebrafish embryo into which the probe for enhancer function (Figure 31.22) has bee introduced. The green fluorescence reveals that green fluorescent protein is expressed only in a subset of cells, shown to be cranial motor neurons.

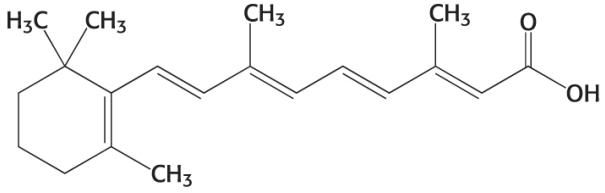


Self-Check Question

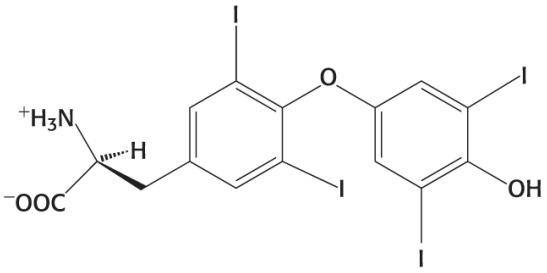
Why is eukaryotic DNA compacted into chromatin? How does this impact the activation or repression of gene expression? What must happen to chromatin in order for genes to be transcribed or silenced?

Nuclear hormone receptors are transcription factors that cause changes in chromatin

structure



How do transcription factors stimulate changes in chromatin structure and thus influence gene expression? To illustrate this, let's discuss the system that detects and responds to estrogens, cholesterol-derived steroid hormones (Section 27.4). Synthesized and released by the ovaries, estrogens, such as estradiol, are required for the development of female secondary sex characteristics and, along with progesterone, participate in the ovarian cycle.



Estradiol
(an estrogen)

Because they are hydrophobic molecules, estrogens easily diffuse across cell membranes. When inside a cell, estrogens bind to highly specific, soluble receptor proteins. Estrogen receptors are members of a large

family of proteins that act as receptors for a wide range of hydrophobic molecules, including other steroid hormones, thyroid hormones, and retinoids.

All-*trans*-retinoic acid
(a retinoid)

Thyroxine
(L-3,5,3′,5′-Tetraiodothyronine)
(a thyroid hormone)

The human genome encodes approximately 50 members of this family of receptors, often referred to as **nuclear hormone receptors**. The genomes of other multicellular eukaryotes encode similar numbers of nuclear hormone receptors, although they are absent in yeast.

All these receptors have a similar mode of action. On binding of the signal molecule (called, generically, a *ligand*), the ligand–receptor complex modifies the expression of specific genes by binding to control elements in the DNA. Estrogen receptors bind to specific DNA sites (referred to as estrogen response elements or EREs) that contain the consensus sequence $5'-AGGTCANNNTGACCT-3'$. As expected from the symmetry of this sequence, an estrogen receptor binds to such sites as a dimer.

A comparison of the amino acid sequences of members of this family reveals two highly conserved domains: a DNA-binding domain and a ligand-binding domain (**Figure 31.24**). The DNA-binding domain lies toward the center of the molecule and consists of a set of zinc-based domains different from the Cys_2His_2 zinc-finger proteins introduced in

Section 31.4. These zinc-based domains bind to specific DNA sequences by virtue of an α helix that lies in the major groove in the specific DNA complexes formed by estrogen receptors.

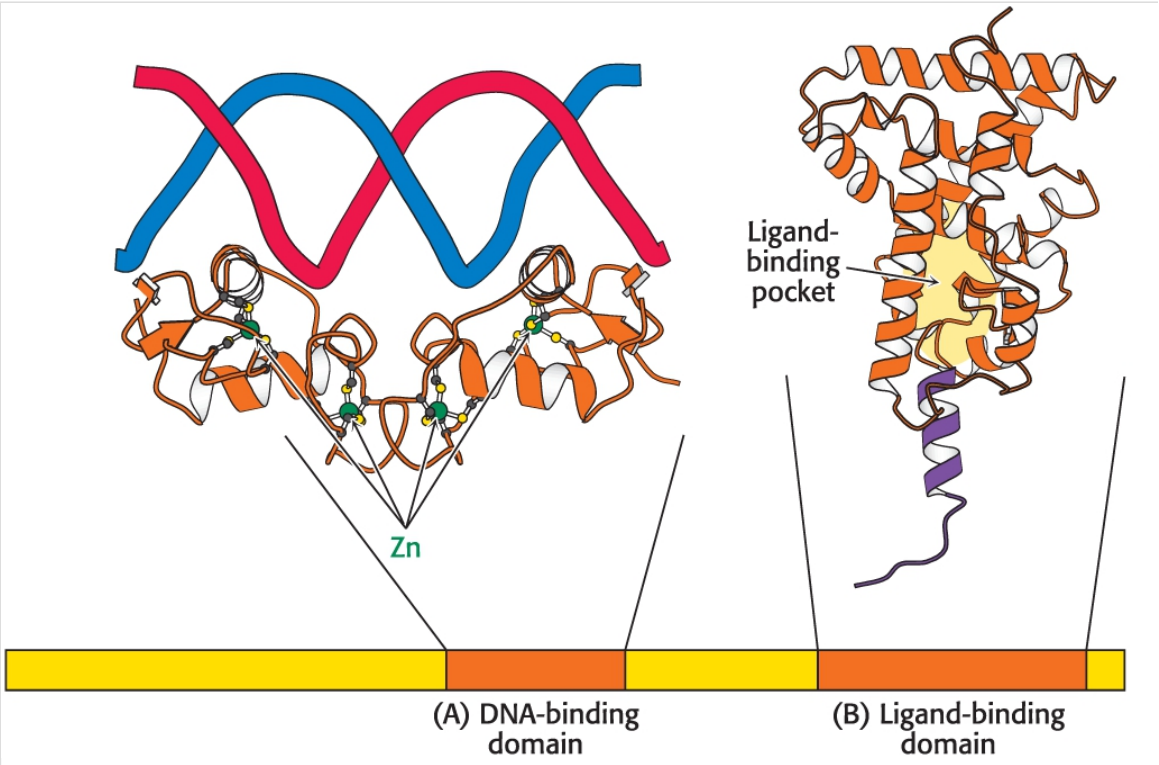


FIGURE 31.24 Nuclear hormone receptors contain two important conserved domains. These domains are: (A) a DNA-binding domain toward the center of the protein sequence, and (B) a ligand-binding domain toward the carboxyl terminus. The structure of a dimer of the DNA-binding domain bound to DNA is shown, as is one monomer of the normally dimeric ligand-binding domain.

[Drawn from 1HCQ.pdb and 1LBD.pdb.]

INTERACT with these models in Achieve

The second highly conserved domain of the nuclear receptor proteins is the ligand-binding site, which lies near the carboxyl terminus. This domain folds into a structure that consists almost entirely of α helices, arranged in three layers. The ligand binds in a hydrophobic pocket that

lies in the center of this array of helices (Figure 31.25). This domain changes conformation when it binds its ligand, estrogen.

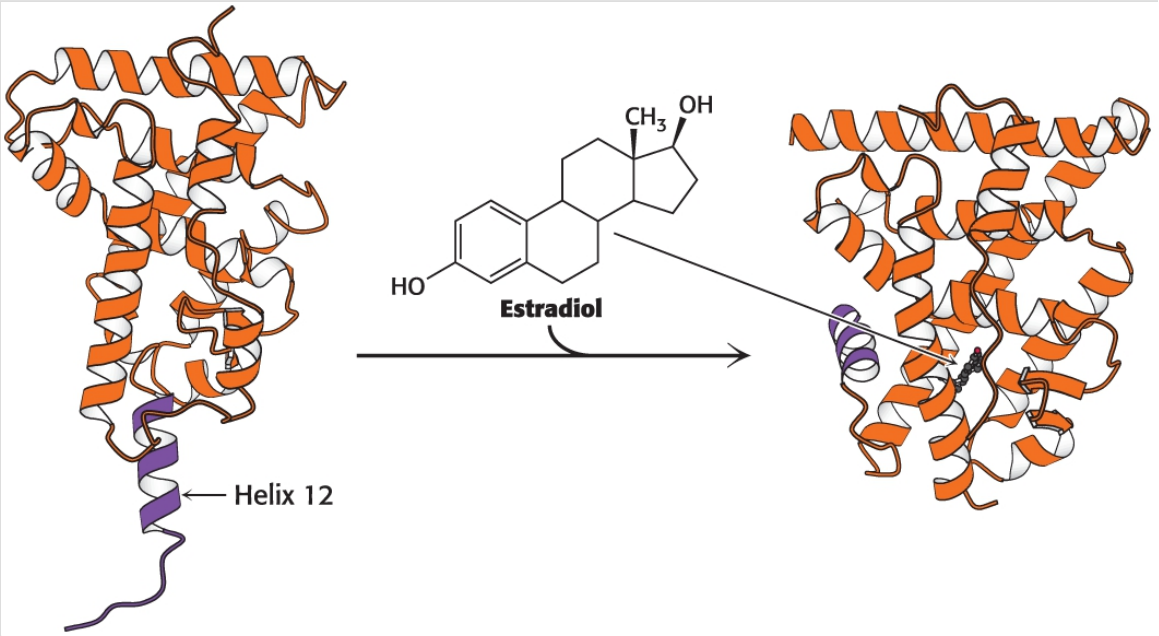

FIGURE 31.25 Nuclear hormone receptors interact with ligands. The ligand lies completely surrounded within a pocket in the ligand-binding domain. Notice that the last α helix, helix 12 (shown in purple), folds into a groove on the side of the structure once the ligand binds.

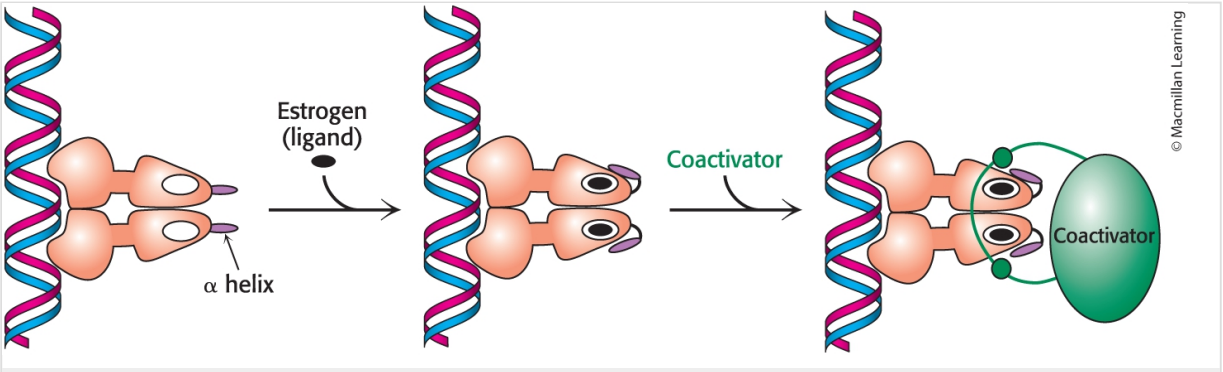
[Drawn from 1LDB.pdb and 1ERE.pdb.]

INTERACT with this model in Achieve

How does ligand binding lead to changes in gene expression? The simplest model would have the binding of ligand alter the DNA-binding properties of the receptor, much like the *lac* repressor in bacteria. However, experiments with purified nuclear hormone receptors revealed that ligand binding does *not* significantly alter DNA-binding affinity and specificity. The effect must be due to a different mechanism.

Nuclear hormone receptors regulate transcription by recruiting coactivators to the transcription complex

Is it possible that nuclear hormone receptors interact with specific proteins only in the presence of a ligand? Experiments to answer this question led to the identification of several related proteins called **coactivators**, such as SRC-1 (steroid receptor coactivator-1), GRIP-1 (glucocorticoid receptor interacting protein-1), and NcoA-1 (nuclear hormone receptor coactivator-1). These coactivators are referred to as the p160 family because of their size. The binding of ligand to the receptor induces a conformational change that allows the recruitment of a coactivator (**Figure 31.26**). In many cases, these coactivators are enzymes that catalyze reactions that lead to the modification of chromatin structure.



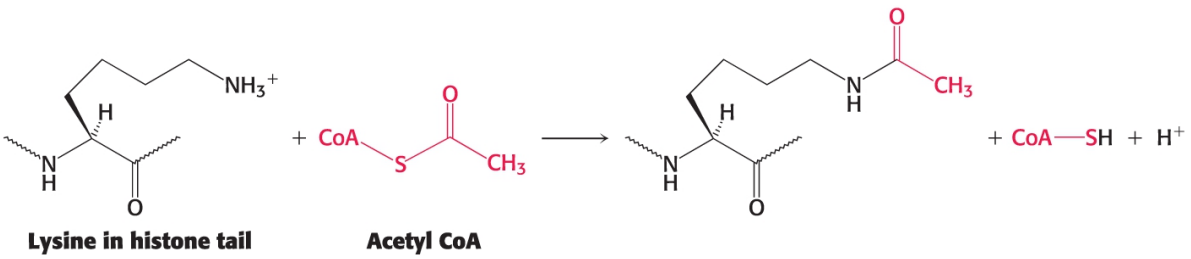


FIGURE 31.26 Nuclear hormone receptors recruit coactivators upon ligand binding. The binding of ligand to a nuclear hormone receptor induces a conformational change in the ligand-binding domain. This change in conformation generates favorable sites for the binding of a coactivator.

Chromatin structure is modulated through covalent modifications of histone tails

We have seen that nuclear receptors respond to signal molecules by recruiting coactivators. So now the question is: how do coactivators modulate transcriptional activity? The answer is that these proteins act to loosen the histone complex from the DNA, exposing additional DNA regions to the transcription machinery.

Much of the effectiveness of coactivators appears to result from their ability to covalently modify the amino-terminal tails of histones as well as regions on other proteins. Some of the p160 coactivators and the proteins that they recruit catalyze the transfer of acetyl groups from acetyl CoA to specific lysine residues in these amino-terminal tails.

Enzymes that catalyze such reactions are called **histone acetyltransferases (HATs)**. The histone tails are readily extended so they can fit into the HAT active site and become acetylated (**Figure 31.27**).

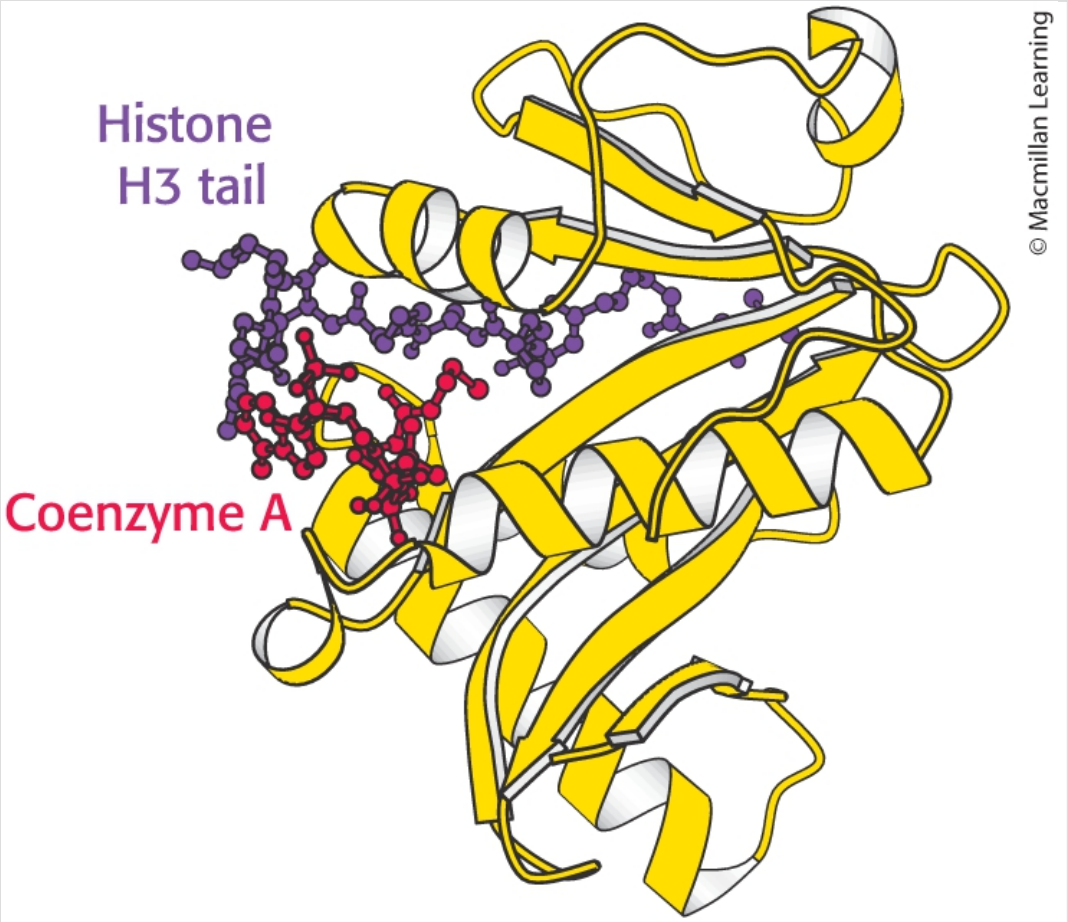

FIGURE 31.27 Histone acetyltransferase modifies histone tails. In this structure, the amino-terminal tail of histone H3 extends into a pocket in the histone acetyltransferase enzyme (yellow). A lysine side chain on the histone tail can accept an acetyl group from acetyl Coenzyme A bound in an adjacent site on the enzyme.

[Drawn from 1QSN.pdb.]

INTERACT with this model in Achieve

What are the consequences of histone acetylation? Lysine bears a positively charged ammonium group at neutral pH. The addition of an acetyl group generates an uncharged amide group. This change dramatically reduces the affinity of the histone tail for DNA and modestly decreases the affinity of the entire histone complex for DNA,

loosening the histone complex from the DNA and relaxing the chromatin structure.

In addition, the acetylated lysine residues interact with a specific acetyllysine-binding domain that is present in many proteins that regulate eukaryotic transcription. This domain, also termed a **bromodomain**, comprises approximately 110 amino acids that form a four-helix bundle containing a peptide-binding site at one end (**Figure 31.28**).

FIGURE 31.28 Bromodomains interact with acetyllysine. In this structure, the four-helix-bundle bromodomain binds an acetylated peptide from histone H4.

[Drawn from 1E6I.pdb.]

INTERACT with this model in Achieve

Bromodomain-containing proteins are components of two large complexes essential for transcription. One is a complex of more than 10 polypeptides that binds to the TATA-box-binding protein (TBP). Recall that TBP is an essential transcription factor for many genes (Section 29.3). Proteins that bind to the TATA-box-binding protein are called **TAFs** (for **TATA-box-binding protein associated factors**), and together with TBP they form TFIID (Section 29.3). In particular, TAF1 contains a pair of bromodomains near its carboxyl terminus. The two domains are oriented such that each can bind one of two acetyllysine residues at positions 5 and 12 in the histone H4 tail. Thus, acetylation of the histone tails provides a mechanism for recruiting other components of the transcriptional machinery.

Bromodomains are also present in some components of large complexes known as **chromatin-remodeling complexes**. These complexes, which also contain domains homologous to those of helicases, use the free energy of ATP hydrolysis to shift the positions of nucleosomes along the DNA and to induce other conformational changes in chromatin (**Figure 31.29**). Histone acetylation can lead to a reorganization of the chromatin structure via these ATP-dependent remodeling complexes, potentially exposing binding sites for other factors. Thus, histone acetylation can activate transcription through a combination of three mechanisms: by reducing the affinity of the histones for DNA, by recruiting other components of the transcriptional machinery, and by initiating the remodeling of the chromatin structure.

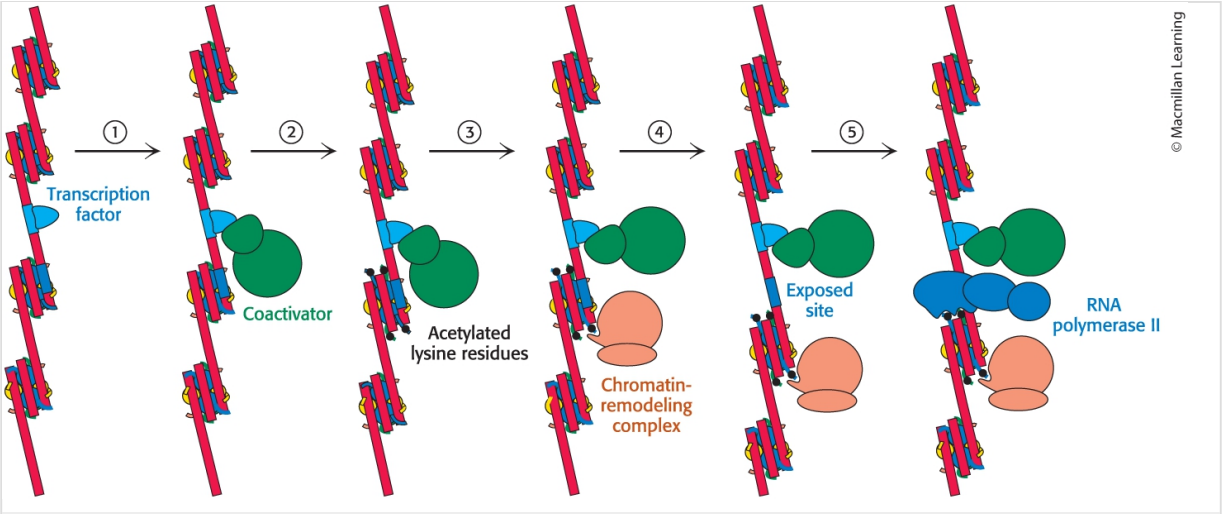

FIGURE 31.29 Gene regulation can involve chromatin remodeling. Eukaryotic gene regulation begins with an activated transcription factor bound to a specific site on DNA. One scheme for the initiation of transcription by RNA polymerase II requires five steps: (1) recruitment of a coactivator, (2) acetylation of lysine residues in the histone tails, (3) binding of a remodeling-engine complex to the acetylated lysine residues, (4) ATP-dependent remodeling of the chromatin structure to expose a binding site for RNA polymerase II or for other factors, and (5) recruitment of RNA polymerase II. Only two subunits are shown for each complex, although the actual complexes are much larger. Other schemes are possible.

Nuclear hormone receptors also include regions that interact with components of the mediator complex. Thus, two mechanisms of gene regulation can work in concert. Modification of histones and chromatin remodeling can open up regions of chromatin into which the transcription complex can be recruited through protein–protein interactions.

Transcriptional repression can be achieved through histone deacetylation and other modifications

Just as in bacteria, some changes in a cell's environment lead to the repression of genes that had been active. The modification of histone tails again plays an important role. However, in repression, a key reaction appears to be the *deacetylation* of acetylated lysine, catalyzed by specific **histone deacetylase** enzymes.

In many ways, the acetylation and deacetylation of lysine residues in histone tails (and, likely, in other proteins) is analogous to the phosphorylation and dephosphorylation of serine, threonine, and tyrosine residues in other stages of signaling processes. Like the addition of phosphoryl groups, the addition of acetyl groups can induce conformational changes and generate novel binding sites. Without a means of removal of these groups, however, these signaling switches will become stuck in one position and lose their effectiveness. Like phosphatases, deacetylases help reset the switches.

Acetylation is not the only modification of histones and other proteins in gene-regulation processes. The methylation of specific lysine and arginine residues also can be important. Some of the more common modifications are shown in Table 31.1.

TABLE 31.1 Selected histone modifications

Modification	Effect
H3 K9 acetylation	Activation
H3 K27 acetylation	Activation

H4 K16 acetylation	Activation
H3 K4 monomethylation	Activation
H3 K9 trimethylation	Repression
H3 K27 trimethylation	Repression
H3 R17 methylation	Activation
H2B S14 phosphorylation	DNA repair
H2B K120 ubiquitination	Activation

The elucidation of the roles of these modifications is a very active area of research. The relation between various histone modifications and their roles in controlling gene expression is sometimes referred to as "the histone code," and important generalizations have been elucidated. For example, trimethylation of lysine 27 on histone H3 (H3 K27) is associated with repression of gene expression. This modification is promoted by a protein complex termed *polycomb repressive complex-2* (PRC-2). PRC-2 both binds to histones containing the trimethylated H3 K27 and catalyzes the addition of methyl groups to other H3 K27 substrates. This allows an initial modification to spread to adjacent histone octamers, facilitating gene repression.

The development and application of methods that allow probing of histone modifications on a genome-wide scale in a range of cell types has provided large data sets that can be examined to test and refine models of transcription regulation via chromatin modifications.

Self-Check Question

Summarize the various aspects of chromatin modifications discussed above and how they affect gene expression.

31.6 Gene Expression Can Be Controlled at the Posttranscriptional Level

The modulation of the rate of transcription initiation is the most common mechanism of gene regulation. However, other stages of transcription also can be targets for regulation. In addition, the process of translation provides other points of intervention for regulating the level of a protein produced in a cell. In Chapter 29, we considered riboswitches that control transcription termination (Section 29.3). Other riboswitches control gene expression by other mechanisms, such as the formation of structures that inhibit translation. Additional mechanisms for posttranscriptional gene regulation have been discovered in both bacteria and eukaryotes, some of which will be described here.

Attenuation regulates transcription in bacteria through the modulation of nascent RNA secondary structure

A different mechanism for regulating transcription in bacteria was discovered by Charles Yanofsky and his colleagues as a result of their studies of the tryptophan operon. This operon encodes five enzymes that convert chorismate into tryptophan. Analysis of the 5′ end of *trp* mRNA revealed the presence of a leader sequence of 162 nucleotides before the initiation codon of the first enzyme.

The next striking observation was that bacteria produced a transcript consisting of only the first 130 nucleotides when the tryptophan level was high, but they produced a 7000-nucleotide *trp* mRNA, including the

entire leader sequence, when tryptophan was scarce. Thus, when tryptophan is plentiful and the biosynthetic enzymes are not needed, transcription is abruptly broken off before any mRNA coding for the enzymes is produced. The site of termination is called the attenuator, and this mode of regulation is called **attenuation**.

Attenuation depends on features at the 5′ end of the mRNA product (**Figure 31.30**). The first part of the leader sequence encodes a 14-amino-acid leader peptide. Following the open reading frame for the peptide is the attenuator, a region of RNA that is capable of forming several alternative structures. Recall that transcription and translation are tightly coupled in bacteria. Thus, the translation of the *trp* mRNA begins soon after the ribosome-binding site has been synthesized.

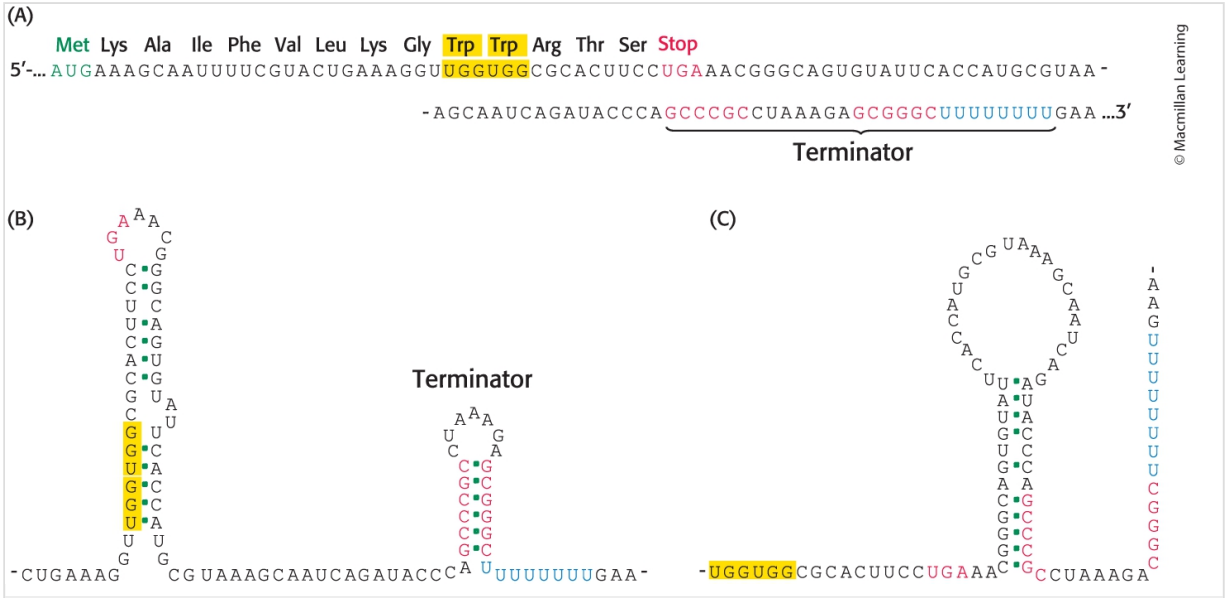

FIGURE 31.30 The leader region of *trp* mRNA includes tryptophan codons. (A) The nucleotide sequence of the 5′ end of *trp* mRNA includes a short open reading frame that encodes a peptide comprising 14 amino acids; the leader encodes two tryptophan residues and has an untranslated attenuator region that includes a region that can form a terminator structure (red and blue). (B and C) The attenuator region can adopt either of two distinct stem-loop structures.

How does the level of tryptophan alter transcription of the *trp* operon? An important clue was the finding that the 14-amino-acid leader peptide includes two adjacent tryptophan residues. A ribosome is able to translate the leader region of the mRNA product only in the presence of adequate concentrations of tryptophan. When enough tryptophan is present, a stem-loop structure forms in the attenuator region, which leads to the release of RNA polymerase from the DNA (Figure 31.31). However, when tryptophan is scarce, transcription is terminated less frequently. Little tryptophanyl-tRNA is present, and so the ribosome stalls at the tandem UGG codons encoding tryptophan. This delay leaves the adjacent region of the mRNA exposed as transcription continues. An alternative RNA structure that does not function as a terminator is formed, and transcription continues into and through the coding regions for the enzymes. Thus, attenuation provides an elegant means of sensing the supply of tryptophan required for protein synthesis.

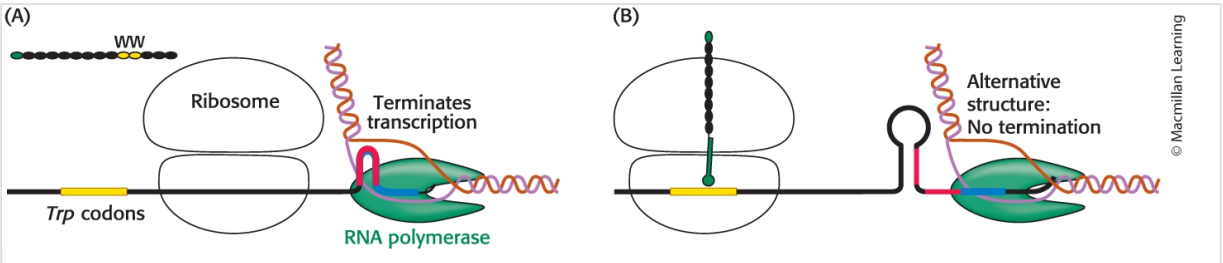

FIGURE 31.31 Attenuation regulates transcription. (A) In the presence of adequate concentrations of tryptophan (and, hence, Trp-tRNA), translation proceeds rapidly and an RNA structure forms that terminates transcription. (B) At low concentrations of tryptophan, translation stalls while awaiting Trp-tRNA, giving time for an alternative RNA structure to form that prevents the formation of the terminator and allows transcription to proceed.

Several other operons for the biosynthesis of amino acids in *E. coli* also are regulated by attenuator sites. The leader peptide of each contains an abundance of the amino acid residues of the type synthesized by the operon (Figure 31.32). For example, the leader peptide for the phenylalanine operon includes 7 phenylalanine residues among 15

residues. The threonine operon encodes enzymes required for the synthesis of both threonine and isoleucine; the leader peptide contains 8 threonine and 4 isoleucine residues in a 16-residue sequence. The leader peptide for the histidine operon includes 7 histidine residues in a row. In each case, low levels of the corresponding charged tRNA cause the ribosome to stall, trapping the nascent mRNA in a state that can form a structure that allows RNA polymerase to read through the attenuator site. Evolution has apparently converged on this strategy repeatedly as a mechanism for controlling amino acid biosynthesis.

FIGURE 31.32 The leader sequences of several operons contain codons for the specific amino acid that they regulate. Shown here are the amino acid sequences and the corresponding mRNA nucleotide sequences of the (A) threonine operon, (B) phenylalanine operon, and (C) histidine operon. In each case, an abundance of one amino acid in the leader peptide sequence leads to attenuation.

This example of posttranscriptional gene regulation that we have been describing comes from bacteria, as opposed to archaea. The transcriptional apparatus present in archaea shares many features with that found in eukaryotes. This commonality is frequently interpreted to suggest that eukaryotes evolved after a cell fusion event in which a bacterial cell was engulfed by an archaeal cell. Nonetheless, the key principles of gene regulation such as the occurrence of operons and the roles of DNA-binding proteins in directly blocking or stimulating RNA polymerase are the same in bacteria and archaea, perhaps because of

similar genome sizes. As we shall see next, eukaryotic cells with larger genomes and, often, many distinct cell types, use quite different strategies.

Eukaryotes use different mechanisms to control gene expression at the posttranscriptional level

Just as in bacteria, gene expression in eukaryotes can be regulated subsequent to transcription. We shall consider two examples. The first is the regulation of genes taking part in iron metabolism through key features in RNA secondary structure, similar in many ways to attenuation in bacteria. The second entails an entirely new mechanism, in which certain small regulatory RNA molecules allow the regulation of gene expression through interaction with a range of target mRNAs. Remarkably, this mechanism, discovered relatively recently, affects the expression of approximately 60% of all human genes.

Genes associated with iron metabolism are translationally regulated in animals

RNA secondary structure plays a role in the regulation of iron metabolism in eukaryotes. Iron is an essential nutrient, required for the synthesis of hemoglobin, cytochromes, and many other proteins. However, excess iron can be quite harmful because, untamed by a suitable protein environment, iron can initiate a range of free-radical reactions that damage proteins, lipids, and nucleic acids.

Animals have evolved sophisticated systems for the accumulation of iron in times of scarcity and for the safe storage of excess iron for later

use. Key proteins include **transferrin**, a transport protein that carries iron in the serum, **transferrin receptor**, a membrane protein that binds iron-loaded transferrin and initiates its entry into cells, and **ferritin**, an impressively efficient iron-storage protein found primarily in the liver and kidneys. Twenty-four ferritin polypeptides form a nearly spherical shell that encloses as many as 2400 iron atoms, a ratio of one iron atom per amino acid (**Figure 31.33**).

FIGURE 31.33 The structure of ferritin forms a sphere. (A) Twenty-four ferritin polypeptides form a nearly spherical shell. (B) A cutaway view reveals the core that stores iron as an iron oxide–hydroxide complex.

[Drawn from 1IES.pdb.]

Ferritin and transferrin receptor expression levels are reciprocally related in their responses to changes in iron levels. When iron is scarce, the amount of transferrin receptor increases and little or no new ferritin is synthesized. Interestingly, the extent of mRNA synthesis for these proteins does not change correspondingly. Instead, regulation takes place at the level of translation.

Consider ferritin first. Ferritin mRNA includes a stem-loop structure termed an *iron-response element* (IRE) in its $5'$ untranslated region (**Figure 31.34**). A 90 kDa protein, the IRE-binding protein (IRP), binds to this stem-loop and blocks the initiation of translation at the downstream coding region. When the iron level increases, the IRP binds iron as a 4Fe–4S cluster. The IRP bound to iron cannot bind RNA, because the binding sites for iron and RNA substantially overlap. Thus, in the presence of iron, ferritin mRNA is released from the IRP and translated to produce ferritin, which sequesters the excess iron.

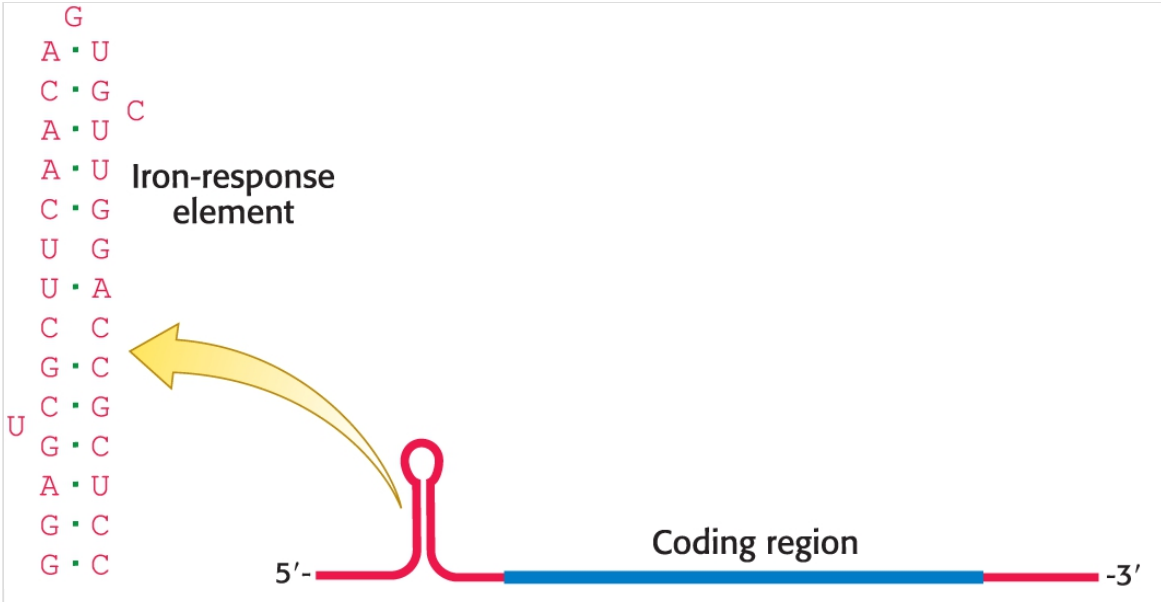

FIGURE 31.34 Ferritin mRNA includes an iron-response element in its 5′ untranslated region

A specific protein binds to the IRE stem-loop structure in the 5′ untranslated region of the mRN and blocks the translation of this mRNA under low-iron conditions.

An examination of the nucleotide sequence of transferrin receptor mRNA reveals the presence of several IRE-like regions. However, these regions are located in the 3′ untranslated region rather than in the 5′ untranslated region (Figure 31.35). Under low-iron conditions, IRP binds to these IREs. However, given the location of these binding sites, the transferrin receptor mRNA can still be translated.

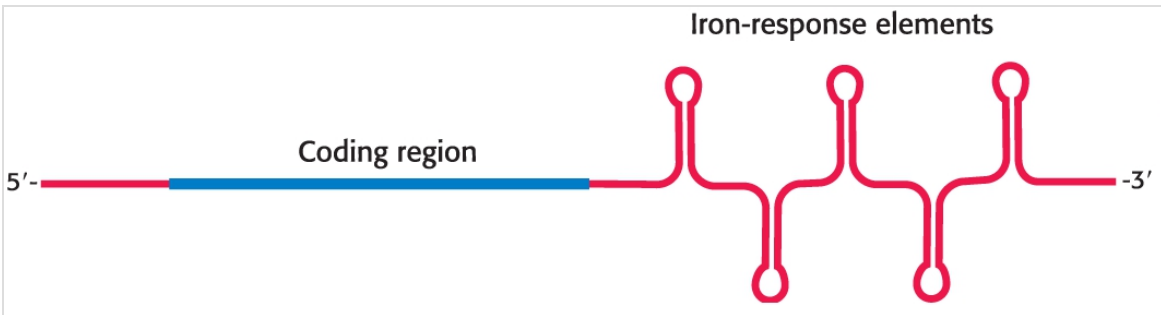

FIGURE 31.35 Transferrin receptor mRNA has a set of iron-response elements (IREs) in its 3′ untranslated region. The binding of the IRE-binding protein to these elements stabilizes the mRNA but does not interfere with translation.

What happens when the iron level increases and the IRP no longer binds transferrin receptor mRNA? Freed from the IRP, transferrin receptor mRNA is rapidly degraded. Thus, an increase in the cellular iron level leads to the destruction of transferrin receptor mRNA and, hence, a reduction in the production of transferrin receptor protein.

The purification of the IRP and the cloning of its cDNA were sources of truly remarkable insight into evolution. The IRP was found to be approximately 30% identical in amino acid sequence with the citric acid cycle enzyme aconitase from mitochondria. Further analysis revealed that the IRP is, in fact, an active aconitase enzyme; it is a cytoplasmic aconitase that had been known for a long time, but its function was not well understood (Figure 31.36). The iron–sulfur center at the active site of the IRP is rather unstable, and loss of the iron triggers significant changes in protein conformation. Thus, this protein can serve as an iron-sensing factor.

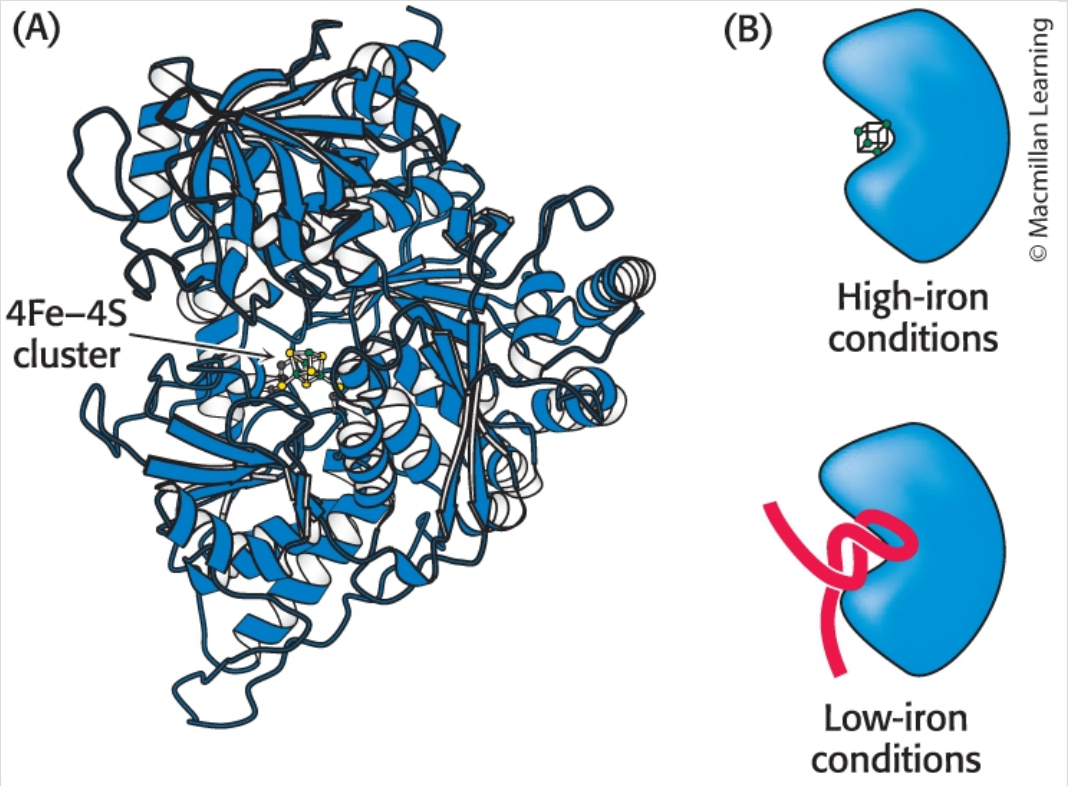

FIGURE 31.36 The IRP is an aconitase. (A) Aconitase contains an unstable 4Fe–4S cluster at its center. (B) Under conditions of low iron, the 4Fe–4S cluster dissociates and appropriate RNA molecules can bind in its place.

[Drawn from 1C96.pdb.]

INTERACT with this model in Achieve

Other mRNAs, including those taking part in heme synthesis, have been found to contain IREs. Thus, genes encoding proteins required for iron metabolism acquired sequences that, when transcribed, provided binding sites for the iron-sensing protein. An environmental signal — the concentration of iron — controls the translation of proteins required for the metabolism of this metal. Thus, mutations in the untranslated region of mRNAs have been selected for beneficial regulation by iron levels.

Small RNAs are involved in posttranscriptional gene regulation in eukaryotes

Other mechanisms of posttranscriptional gene regulation, particularly silencing, involve small regulatory RNAs, most of which were only recently discovered. These small RNAs represent an important class of gene-regulatory molecules.

One prominent mechanism of gene silencing is known as **RNA interference (RNAi)**, in which small RNAs interact with a protein complex and guide it to a target mRNA. Subsequently, the target mRNA will either be degraded or its translation will somehow be inhibited.

How was RNAi discovered? Genetic studies of development in *C. elegans* revealed that a gene called *lin-4* encodes an RNA molecule 61 nucleotides long that can regulate the expression of certain other genes. The 61-nucleotide *lin-4* RNA does not encode a protein, but rather is cleaved into a 22-nucleotide RNA that possesses the regulatory activity. This discovery was the first view of a large class of regulatory RNA molecules known as microRNAs (miRNAs), which were briefly introduced in Section 29.4. The key to the activity of microRNAs and their specificity for particular genes is their ability to form Watson–Crick base-pair-stabilized complexes with the mRNAs of those genes.

MicroRNAs do not function on their own, however. They bind to members of a highly conserved family of proteins called **Argonaute** (**Figure 31.37**). Argonaute–miRNA complexes bind target mRNAs due to sequence complementarity between the miRNA and the mRNA. Thus, the miRNAs serve as guide RNAs that determine the specifi-city of the Argonaute protein, which will cleave the target mRNA through its intrinsic RNase activity (**Figure 31.38**). Argonaute proteins form part of

a larger complex called the *RNA-induced silencing complex* (RISC), which is central to the process of RNAi.

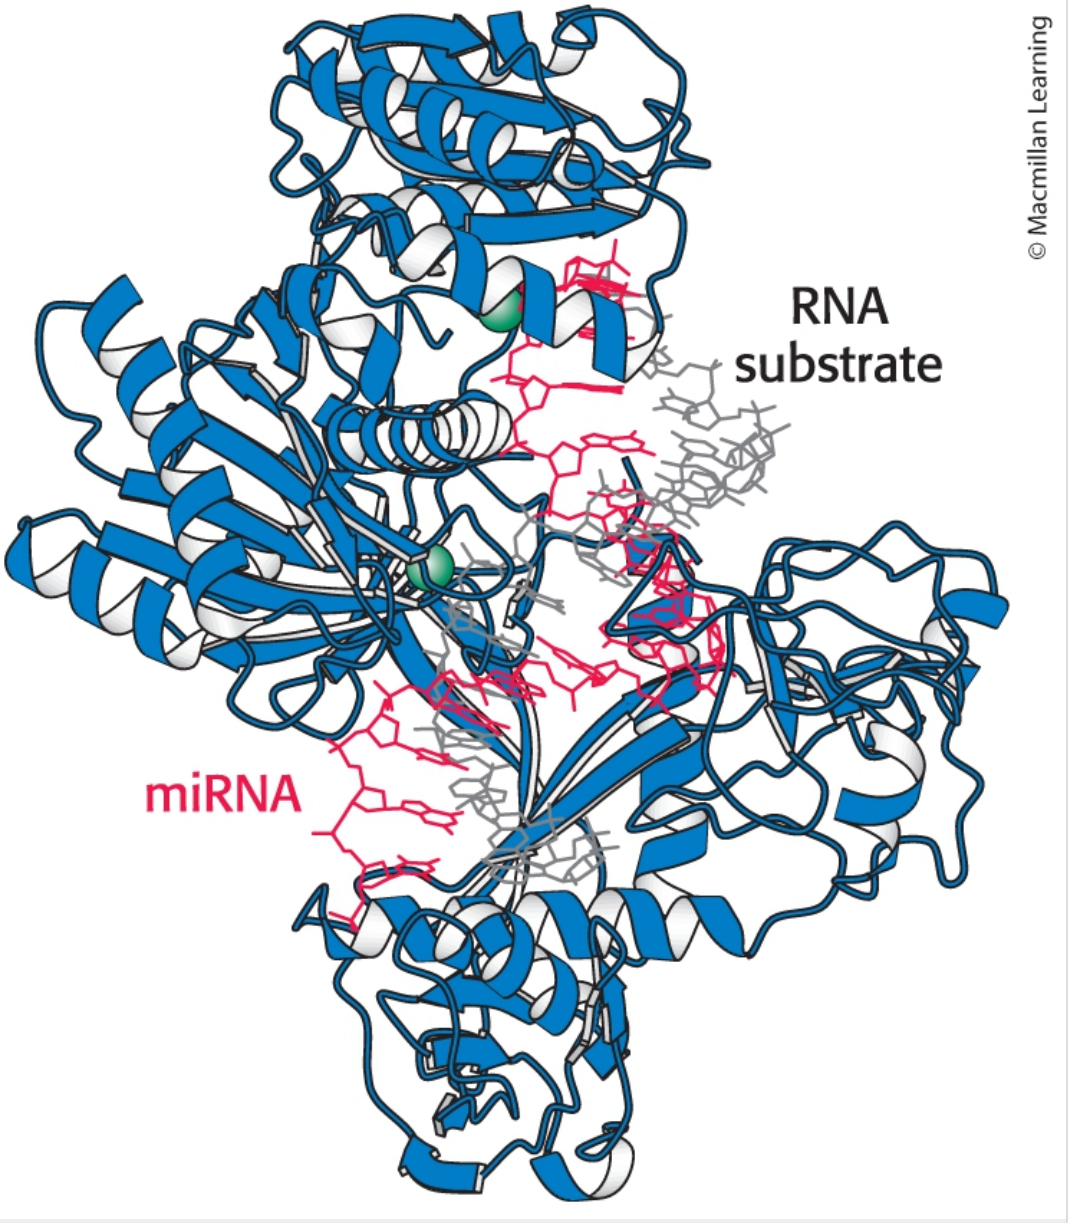

FIGURE 31.37 MicroRNAs bind to the Argonaute complex. The miRNA (shown in red) is bound by the Argonaute protein. The miRNA serves as a guide that binds the RNA substrate (shown in gray) through the formation of a double helix. Two magnesium ions are shown in green.

[Drawn from 3HK2.pdb.]

INTERACT with the above model in Achieve

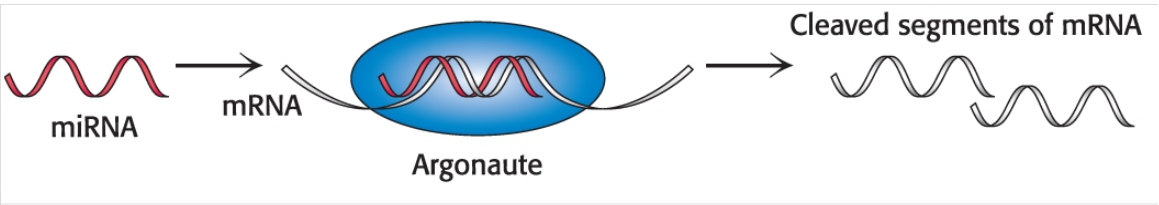

FIGURE 31.38 MicroRNA–Argonaute complexes target specific mRNA molecules for cleavage.

Interestingly, Argonaute proteins can bind to other types of small noncoding RNAs, including small interfering RNAs (siRNAs). Both siRNAs and miRNAs are generated through cleavage by an RNA endonuclease called *Dicer*, but they differ from each other in that they originate from different sources. MicroRNAs are generated from large, genetically encoded, single-stranded pri-microRNA precursors transcribed in the cell, as described in Figure 29.41. These miRNA precursors adopt a stem-loop structure which is cleaved and processed into mature miRNAs by Dicer. In contrast, siRNAs are derived from longer double-stranded extra-cellular RNAs, many of which might be invading viral sequences. It is also possible to produce siRNAs in vitro and introduce them into cells experimentally. This approach provides researchers with the opportunity to examine the phenotypic effects of controlled targeted gene silencing.

The occurrence of gene regulation by small noncoding RNAs was originally thought to be limited to a relatively small number of species. However, subsequent studies have revealed that this mode of gene regulation is nearly ubiquitous in eukaryotes. Indeed, more than 1900 miRNAs encoded by the human genome have been identified. Each miRNA can regulate many different genes because many different target

sequences are present in each mRNA. An estimated 60% of all human genes are regulated by one or more miRNAs.

As one example, consider the human miRNA called miR-206. This miRNA down-regulates the expression of one isoform of the estrogen receptor. In addition, it appears to down-regulate the expression of several different coactivators that interact with the estrogen receptor. Thus, this miRNA can mute the influence of estrogen by blocking the estrogen-initiated signaling pathway at several different steps.

The microRNA pathway has tremendous implications for the evolution of gene-regulatory pathways. Most of the target sites for miRNAs are present in the 3′-untranslated regions of mRNAs. These sequences are

quite free to mutate because they do not encode proteins and are not required to fold into any specific structures. Thus, in the context of a set of expressed miRNAs, mutations in this region of any particular gene could, in principle, increase or decrease the affinity for one or more miRNAs and, hence, alter the regulation of the gene.

Self-Check Question

Gene expression in all systems involves the conversion of information present in a genomic DNA sequence into a functional protein. Give general examples of the control of gene expression at different steps along this pathway.

Chapter 31 Summary

31.1 Bacterial DNA-Binding Proteins Bind to Specific Regulatory Sites

- In bacteria, specific DNA-binding proteins recognize regulatory sites that usually lie adjacent to the genes whose transcription is regulated by these proteins.
- The helix-turn-helix motif is a common DNA-binding motif.

31.2 In Bacteria, Genes Are Often Arranged into Clusters Under the Control of a Single Regulatory Sequence

- In bacteria, many genes are clustered into operons, which consist of control sites (an operator and a promoter) and a set of structural genes.
- Regulator genes encode proteins that interact with the operator and promoter sites in an operon to stimulate or inhibit transcription.
- The treatment of *E. coli* with lactose induces an increase in the production of β-galactosidase and two additional proteins that are encoded in the lactose operon.
- In the absence of lactose, the *lac* repressor protein binds to an operator site on the DNA and blocks transcription.
- The binding of allolactose, a derivative of lactose, to the *lac* repressor induces a conformational change that leads to dissociation from DNA. RNA polymerase can then move through the operator to transcribe the *lac* operon.
- The binding of the cAMP–CAP complex to a specific site in the promoter region of an inducible catabolic operon enhances the binding of RNA polymerase and the initiation of transcription.

31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression

- Bacteriophage λ can maintain either a lytic or a lysogenic life cycle.
- A key regulatory protein, the λ repressor, regulates its own expression, promoting transcription of the gene that encodes the repressor when repressor levels are low and blocking transcription of the gene when levels are high.
- The Cro protein binds to the same sites as does the λ repressor, but with reversed affinities. When Cro is present at sufficient concentrations, it blocks the transcription of the gene for the λ repressor while allowing the transcription of its own gene.

31.4 Regulation of Gene Expression Is More Complex in Eukaryotes

- In eukaryotes, transcription factors are required to activate the expression of most genes. Transcription factors bind DNA and interact directly or indirectly with RNA polymerases.
- Eukaryotic transcription factors are modular: they consist of separate DNA-binding and activation domains.
- Important classes of DNA-binding domains include the homeodomains, the basic-leucine zipper proteins, and Cys_2His_2 zinc-finger proteins.
- Activation domains interact with RNA polymerases or their associated factors, or with other protein complexes such as mediator.
- Enhancers are DNA elements that can modulate gene expression from more than 1000 bp away from the start site of transcription.

31.5 The Control of Gene Expression in Eukaryotes Can Require Chromatin Remodeling

- Chromatin structure is crucial to the control of gene expression; it is more open and the DNA is less methylated near the

transcription start sites of actively transcribed genes.
- Steroids such as estrogens bind to eukaryotic transcription factors called nuclear hormone receptors. The binding of ligands to the receptors induces a conformational change that allows the recruitment of additional proteins called coactivators.
- Coactivators can catalyze the addition of acetyl groups to lysine residues in the tails of histone proteins. Histone acetylation decreases the affinity of the histones for DNA, making additional genes accessible for transcription.
- In addition, acetylated histones are targets for proteins containing specific binding units called bromodomains. Bromodomains are components of two classes of large complexes that open up sites on chromatin and initiate transcription.

31.6 Gene Expression Can Be Controlled at the Posttranscriptional Level

- In bacteria, many operons important in amino acid biosynthesis are regulated by attenuation, a process that depends on the formation of alternative structures in mRNA.
- In eukaryotes, genes encoding proteins that transport and store iron are regulated at the translational level.
- RNA interference (RNAi) is a common gene-silencing mechanism that involves small noncoding RNAs. These small regulatory RNAs function as guides to identify specific target mRNA molecules for cleavage by nucleases.

Key Terms

β-galactosidase

Problems

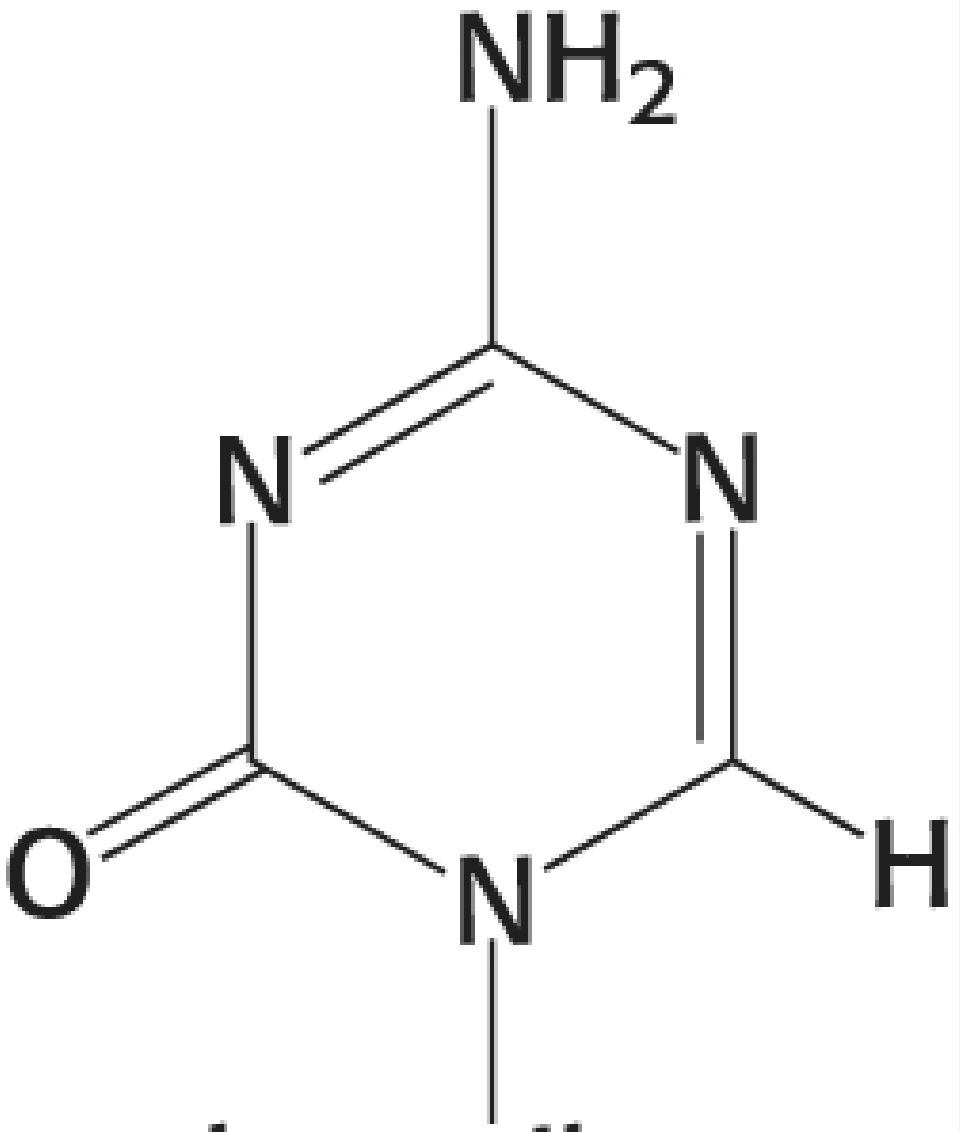
1. Predict the effects of deleting the following regions of DNA:

a. The gene encoding *lac* repressor
b. The *lac* operator
c. The gene encoding CAP 1, 3

2. The *lac* repressor and the *pur* repressor are homologous proteins with very similar three-dimensional structures, yet they have different effects on gene expression. Describe two important ways in which the gene-regulatory properties of these proteins differ. 2

3. Which types of mutation in the *lac* operon stop *E. coli* from using lactose as a carbon source? Select all that apply. 3

a. Operator deletion
b. Promoter deletion
c. Lactose-binding site mutation
d. Repressor DNA-binding site mutation

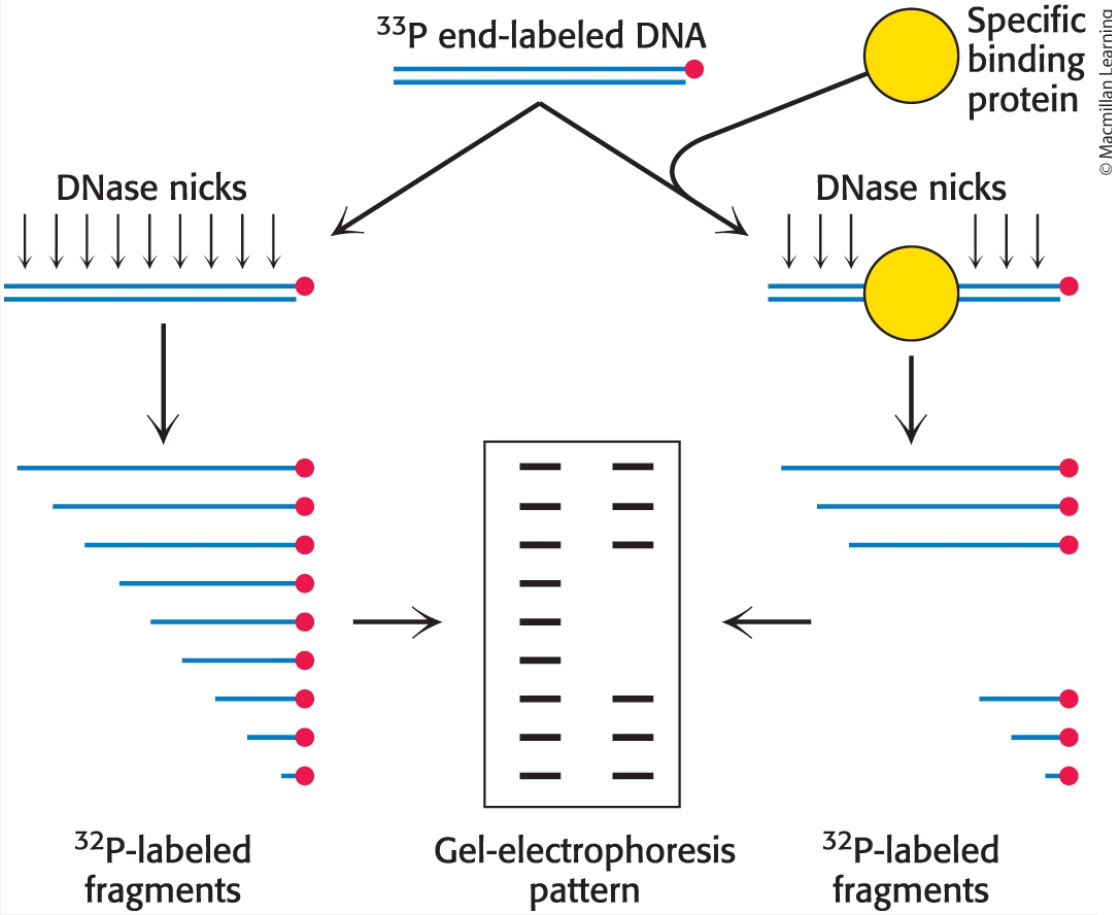


4. Consider a hypothetical mutation in O_R2 that blocks both λ repressor and Cro binding. How would this mutation affect the likelihood of bacteriophage λ entering the lytic phase? 4

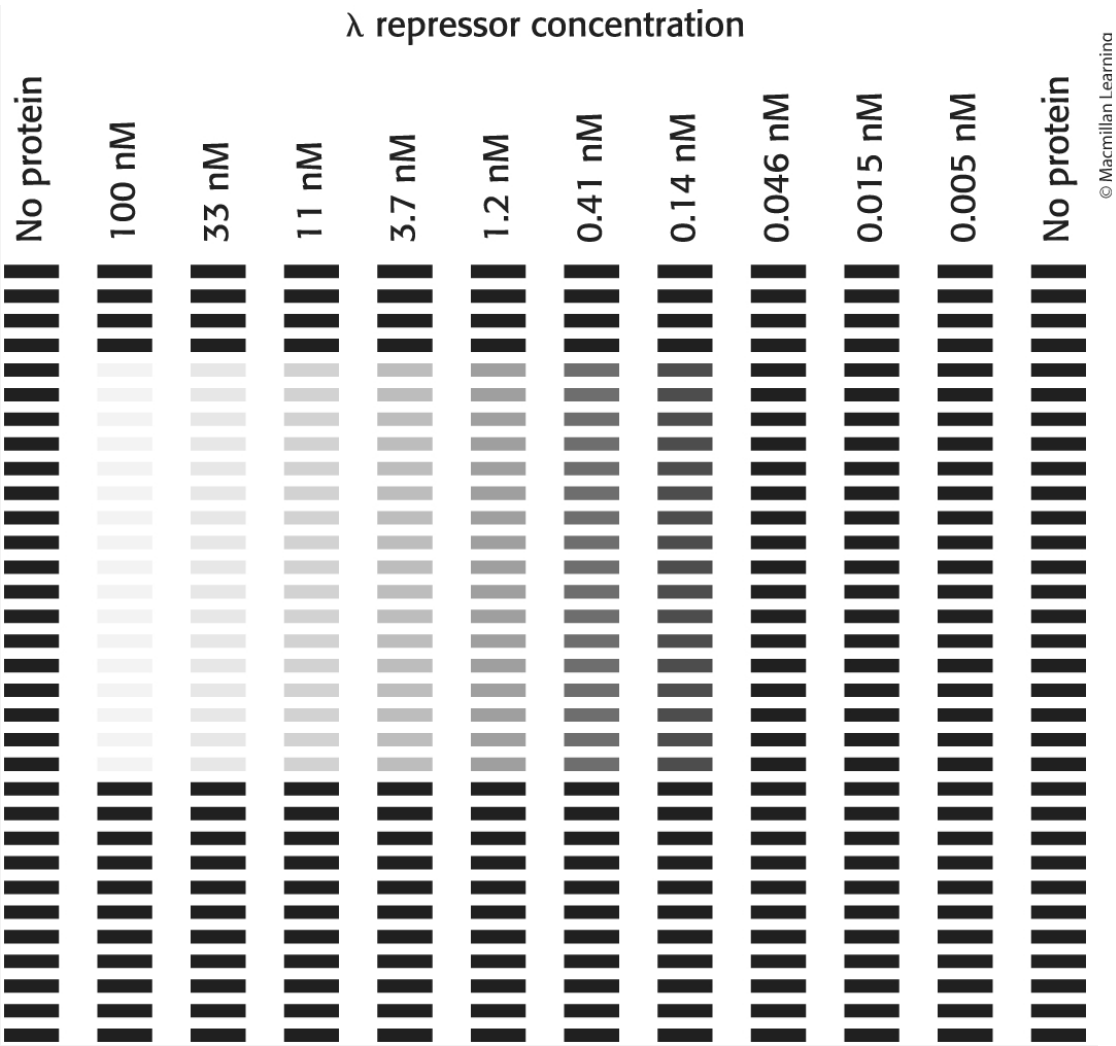
5. Place the events of gene regulation by the *lac* operon in order of their occurrence, starting with the introduction of lactose into the environment, and ending with the cell digesting lactose. 3

a. The repressor is inactivated by allolactose.
b. RNA polymerase binds to the promoter region.
c. The repressor is removed from the operator.

d. The cell begins to digest lactose.
e. Lactose is introduced into the environment.
f. Lactose enzyme genes are expressed by the operon.



6. Growth of mammalian cells in the presence of 5-azacytidine results in the activation of some normally inactive genes. Propose an explanation.  5

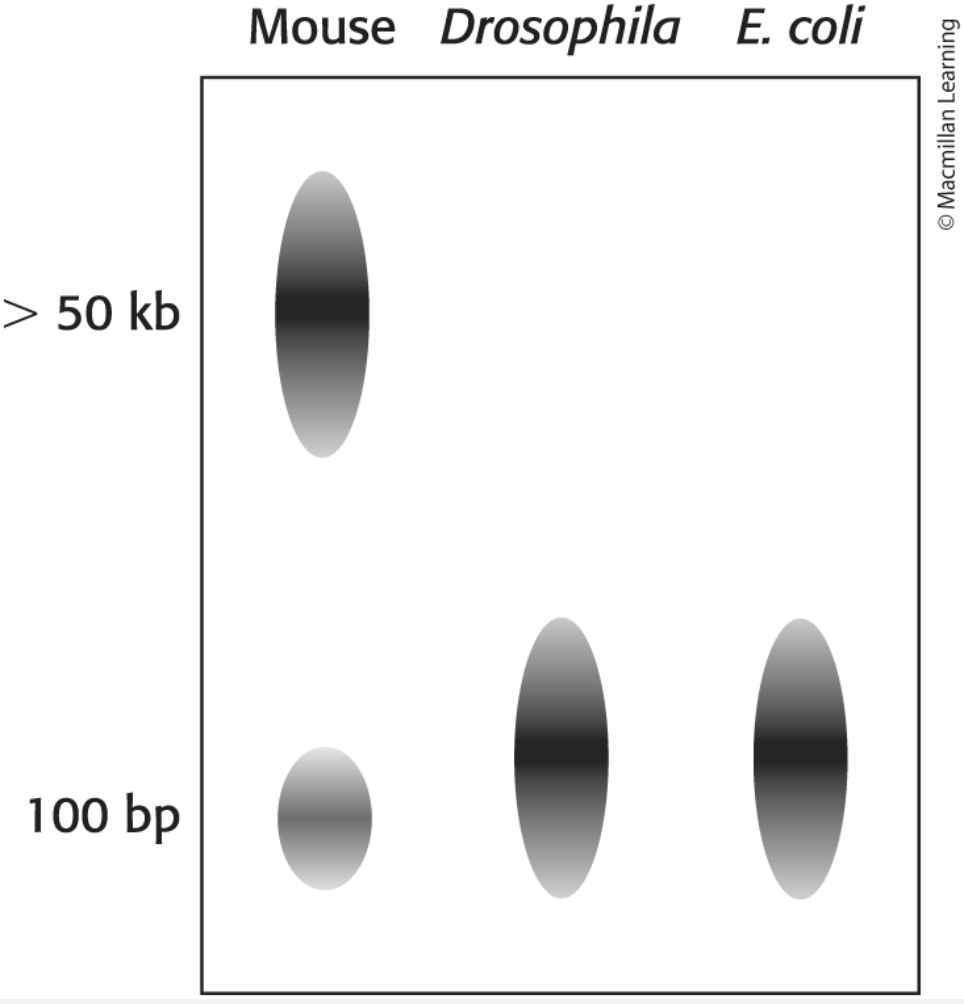


5-Azacytidine

7. What is the effect of an increased Cro concentration on the expression of the gene for the λ repressor? Of an increased concentration of λ repressor on the expression of the Cro gene? Of an increased concentration of λ repressor on the expression of the λ repressor gene? 1, 4

8. A powerful method for examining protein–DNA interactions is called *DNA footprinting*. In this method, a DNA fragment containing a potential binding site is radiolabeled on one end. The labeled DNA is then treated with a DNA-cleaving agent such as DNase I such that each DNA molecule within the population is cut only once. The same cleavage process is carried out in the presence of the DNA-binding protein. The bound protein protects some sites within the DNA from cleavage. The patterns of DNA fragments in the cleaved pool of DNA molecules are then examined by electrophoresis followed by autoradiography.

This method is applied to a DNA fragment containing a single binding site for the λ repressor in the presence of different concentrations of the λ repressor. The results are shown below:



Estimate the dissociation constant for the λ repressor–DNA complex and the standard free energy of binding. 4

9. Which of the following statements about miRNAs and RNA interference are true? 7

a. miRNAs suppress gene expression by interfering with transcription.

b. Small RNAs interfere with gene expression by interacting with mRNA, bringing about mRNA degradation.
c. siRNAs and miRNAs are produced by the Dicer enzyme complex from various precursors.
d. miRNAs are about 45 nucleotides long.

10. The restriction enzyme HpaII is a powerful tool for analyzing DNA methylation. This enzyme cleaves sites of the form $5'-CCGG-3'$ but will not cleave such sites if the DNA is methylated on any of the cytosine residues. Genomic DNA from different organisms is treated with HpaII, and the results are analyzed by gel electrophoresis (see below). Provide an explanation for the observed patterns. 5

11. Which of the following statements are true? (Select all that apply.) 6

a. Chromatin packaging occurs in eukaryotes.
b. The structure of adenine is different in eukaryotic DNA compared with prokaryotic DNA.
c. Eukaryotic DNA contains enhancers.
d. Multiple general transcription factors are found in eukaryotes.
e. Nuclear export of RNA occurs in bacteria.

12. A protein domain that recognizes 5-methylcytosine in the context of double-stranded DNA has been characterized. What role might proteins containing such a domain play in regulating gene expression? Where on a double-stranded DNA molecule would you expect such a domain to bind? 1, 2

13. What is the effect of acetylation of a lysine residue on the charge of a histone protein? Of lysine methylation? 5

14. Place the events in the order necessary for an epigenetic modification to be inherited in the next generation, starting with methylated CpG sites present on one inherited DNA strand, and ending with the epigenetic silencing being passed to the offspring. 5

a. A methyl group is added to the cytosine residue of the DNA sequence.
b. Certain CpG methylation sites are not erased during gametogenesis or embryogenesis.
c. Epigenetic silencing is passed to the offspring.

d. Methylated CpG sites are present on one inherited DNA strand.
e. DNA methyltransferase maintains the methylation pattern on both DNA strands.
f. DNA methyltransferase recognizes and binds CpG sites on DNA.

15. Through recombinant DNA methods, a modified steroid hormone receptor was prepared that consists of an estrogen receptor with its ligand-binding domain replaced by the ligand-binding domain from the progesterone receptor. Predict the expected responsiveness of gene expression for cells treated with estrogen or with progesterone. 1

16. What effect would you expect from the addition of an IRE to the $5'$ end of a gene that is not normally regulated by iron levels? To the $3'$ end? 7

17. The following is the amino acid sequence of a eukaryotic transcription factor that belongs to one of the three structural classes discussed in Section 31.4. Identify the class. 2

HTCDYAGCGKTYTKSSHLKAHLRTHTGEKPYHCDWDGC GWKFARSDELTRHYRKHTGHRPFQCQKCDRAFSRSDHL ALHMKRHF

18. Modifications to chromatin can affect transcriptional activity by changing the accessibility of DNA to the transcription machinery. The given descriptions are examples of various processes that cause remodeling of chromatin. Match each description to the effect it has on transcriptional activity. 5

Chromatin modification description	Effect on transcriptional activity via chromatin

	remodeling
1. Histone methylation occurs at different amino acids. 2. Histone acetyltransferases attach acetyl groups to the N-terminus of histones. 3. Methylated CpG regions are found close to transcription start sites.	1. Activates 2. Inactivates 3. Activates and inactivates

19. Nuclear hormone receptors form a complex with their ligands, other proteins, and DNA control elements in order to regulate the expression of specific genes. Match each nuclear hormone receptor domain to the characteristic(s) with which it is associated. 2

Nuclear hormone receptor domain	Characteristic
1. Activation domain 2. DNA-binding domain 3. Ligand-binding domain	1. Zinc-finger domain 2. Binds coactivators 3. Center of the receptor 4. Carboxyl-terminal end 5. Steroid-binding hydrophobic pocket

20. Classify the following examples of gene expression as positive or negative regulation. 6

a. In the presence of lactose and low glucose, the *lac* operon is expressed 20-fold higher than in the absence of lactose.
b. In the absence of lactose, the *lac* repressor binds to the *lac* operator.
c. Low levels of tryptophan in *E. coli* result in the production of the full-length *trp* mRNA.
d. Elevated iron levels in eukaryotes prevent the IRP from binding to the transferrin receptor mRNA, allowing it to be translated.
e. miRNAs direct the Argonaute nuclease to a target mRNA.

Chapter 32
Principles of Drug Discovery and Development

Many drugs are based on natural products. Paclitaxel (marketed as Taxol) is a molecule isolated from the bark of the Pacific yew tree (*Taxus brevifolia*) that potently inhibits cell division and is used to treat various forms of cancer. Recently, methods have been developed to synthesize paclitaxel without destruction of the Pacific yew, significantly reducing the ecological impact of drug preparation.

Outline

32.1 Drug Discovery Begins with Target Identification and Validation
32.2 Lead Molecules Can Be Discovered in Many Ways
32.3 Compounds Must Meet Stringent Criteria to Be Developed into Drugs
32.4 Biologics are a Growing Family of Drugs

32.5 The Clinical Development of Medicines Proceeds Through Several Phases

---

Learning Goals

By the end of this chapter, you should be able to:

1. Describe the importance of target validation and tractability in the early drug discovery process.
2. List some ways in which lead molecules are identified.
3. Explain the criteria the compounds must meet in order to be developed into drugs.
4. Describe the processes by which the body interacts with drug molecules.
5. Describe how structural information can be used to assist in drug development.
6. Differentiate small molecule drugs and biologics.
7. Distinguish the clinical phases of drug development.

The development of drugs is among the most important interfaces between biochemistry and medicine. In most cases, drugs act by binding to proteins and inhibiting or otherwise modulating their activities. An effective drug is much more than a potent modulator of its target, however. Drugs must be readily administered to patients and must persist within the body long enough to reach their targets. Furthermore, to prevent unwanted physiological effects, drugs must not modulate the properties of biomolecules other than the intended targets. These requirements tremendously limit the number of compounds that have the potential to be clinically useful drugs.

32.1 Drug Discovery Begins with Target Identification and Validation

In this chapter, we will explore the science of **pharmacology**, which encompasses the discovery, chemistry, composition, identification, biological and physiological effects, uses, and manufacture of drugs. The journey from knowledge of a biochemical pathway to a clinically approved medicine is long, laborious, and expensive. This process is typically divided into two phases (Figure 32.1). In the **discovery phase**, molecules with the desired physiological effects are identified and optimized such that they can be introduced into humans; in the **development phase**, clinical trials are conducted with the optimal candidate molecule. Each of these phases is subdivided into stages. At the transition point from one stage to the next, the data are evaluated and a decision is made to approve the investment required to progress into the next stage.

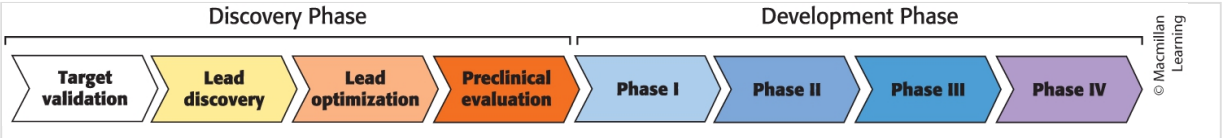


FIGURE 32.1 The journey to an approved drug is divided into a discovery phase and a development phase. Each phase is subdivided into stages. At the end of each stage, the data obtained up to that point are evaluated, and a decision is made on whether to progress to the next step.

Drug targets must be validated and tractable

The initial steps of the discovery phase first require the identification of a **target** — a protein or an oligonucleotide whose activity, when

modulated by a drug, will alter the progression of a human disease process. Throughout the previous chapters in this book, we have encountered a number of types of proteins — enzymes, receptors, and transporters — that serve as targets for a majority of the drugs in clinical use (**Figure 32.2**). Before embarking on the process of developing a drug against a particular target, researchers must first establish confidence that the target exhibits two critical properties.

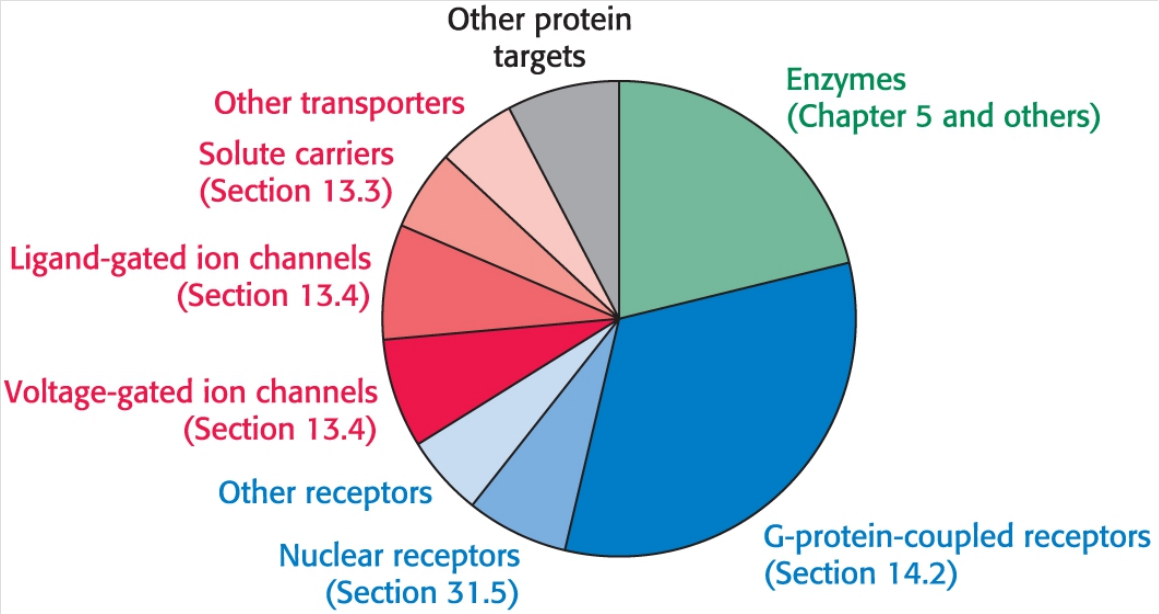

FIGURE 32.2 Drug targets span a variety of protein classes. In this pie chart, currently used drugs that modulate human proteins are sorted by target type: enzymes in green, receptors in blue, transporters in red, and other targets in gray.

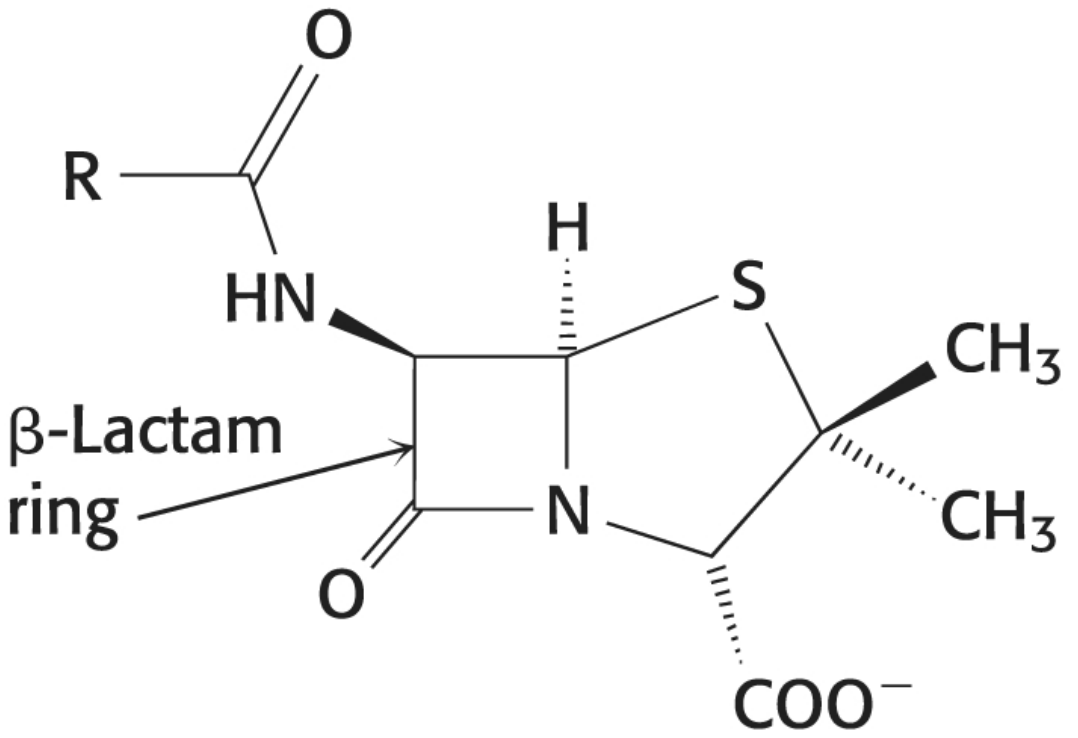
[Data from M. Rask-Andersen et al., *Nat. Rev. Drug Discov.* 10:579–590, 2011.]

There should be sufficient evidence that the target plays an important role in disease progression in humans. The process of obtaining this evidence is referred to as **target validation**. Researchers achieve validation of a target from a variety of experiments, such as human genetic analyses, RNA interference, or transgenic or knockout animal models (Section 9.4); they may also conduct studies with *tool compounds* — molecules

that are usable in cellular or animal experiments but not necessarily suitable as drugs for humans.

There should be sufficient evidence that a molecule can be designed to interact with the target in a potent and specific manner. This property is referred to as a drug's **tractability**, or **druggability**. Assessment of target tractability is made significantly easier if the structure of the target, or a closely related protein, is known. A tractable target contains structural features, such as ligand-binding pockets, with which drug-like molecules can interact with a high degree of potency and specificity.



In practice, very few targets are known to be well-validated and highly tractable during the early stages of the discovery phase. As the target proceeds through the further investigation, additional data are obtained that either support or refute initial projections of the target's validation and tractability. One of the primary goals of the pharmaceutical scientist is to design experiments which can provide this information as early as possible. If the data do not lend support for a particular target, it can be abandoned in favor of more attractive targets.

Serendipitous observations can drive drug development

One cannot recount the history of drug discovery without acknowledging the role played by serendipity, or chance observations. Perhaps the most well-known example is Alexander Fleming's observation in 1928 that colonies of the bacterium *Staphylococcus aureus* died when they were adjacent to colonies of the mold *Penicillium notatum*, after spores of the mold had landed accidentally on plates growing the bacteria. Fleming determined that the mold produced a

substance that could kill disease-causing bacteria. This discovery led to a fundamentally new approach to the treatment of bacterial infections. Howard Florey and Ernest Chain developed a powdered form of the substance, termed penicillin, that became a widely used antibiotic in the 1940s. When the structure of penicillin was elucidated in 1945, it was found to contain a four-membered β-lactam ring. This unusual feature is key to the antibacterial function of penicillin, as noted in Section 5.6.

Penicillin

Three steps were crucial to fully capitalize on Fleming's discovery. First, an industrial process was developed for the production of penicillin from *Penicillium* mold on a large scale. Second, penicillin and its derivatives were chemically synthesized. The availability of synthetic penicillin derivatives opened the way for scientists to explore the

relationship between structure and function. Finally, in 1965, Jack Strominger and James Park independently determined that penicillin exerts its antibiotic activity by blocking a critical transpeptidase reaction in bacterial cell-wall biosynthesis (Figure 32.3). Many penicillin derivatives remain widely used today.

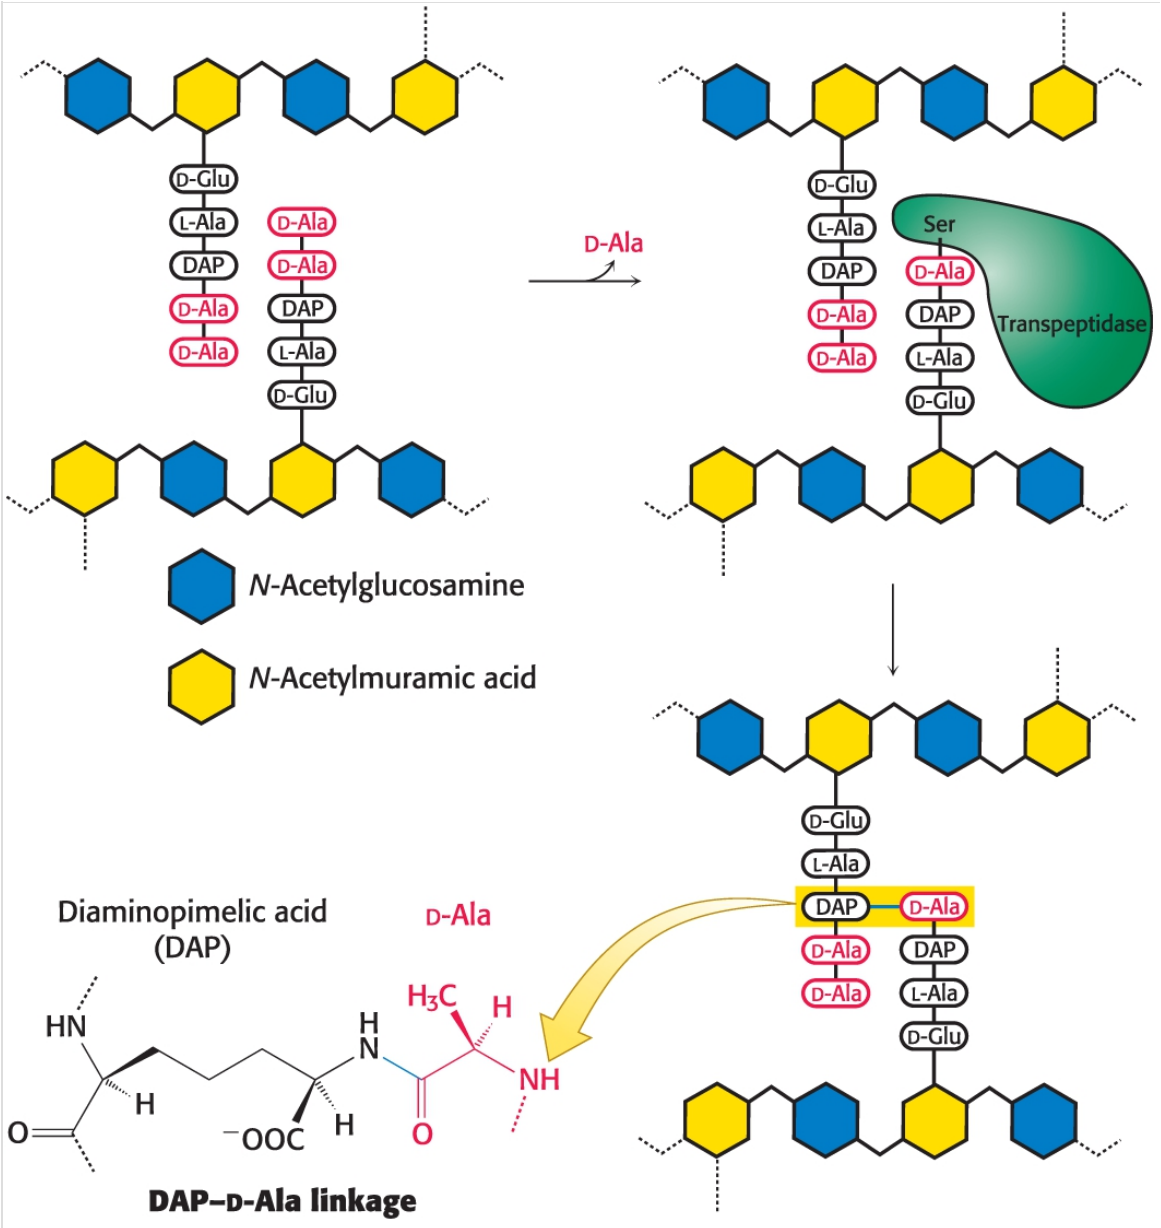


FIGURE 32.3 Penicillin disrupts the biosynthesis of the bacterial cell wall. A transpeptidase enzyme catalyzes the formation of cross-links between peptidoglycan groups. In the case show the transpeptidase catalyzes the linkage of D-alanine at the end of one peptide chain to the amino acid diaminopimelic acid (DAP) on another peptide chain. The diaminopimelic acid linkage (bottom left) is found in Gram-negative bacteria such as *E. coli.* Linkages of glycine-rich

peptides are found in Gram-positive bacteria. Penicillin inhibits the action of the transpeptidase so bacteria exposed to the drug have weak cell walls that are susceptible to lysis.

A more recent example of a drug discovered by serendipity is sildenafil. This compound was developed as an inhibitor of phosphodiesterase 5 (PDE5), an enzyme that catalyzes the hydrolysis of cGMP to GMP (Figure 32.4). The compound was intended as a treatment for hypertension and angina because cGMP plays a central role in the relaxation of smooth-muscle cells in blood vessels (Figure 32.5). The inhibition of PDE5 was expected to increase the concentration of cGMP by blocking the pathway for its degradation. In the course of early clinical trials in Wales, some men reported unusual penile erections, but whether this chance observation by a few men was due to the compound or to other effects was unclear. However, the observation made some biochemical sense because smooth-muscle relaxation due to increased cGMP levels had been previously discovered to play a role in penile erection.

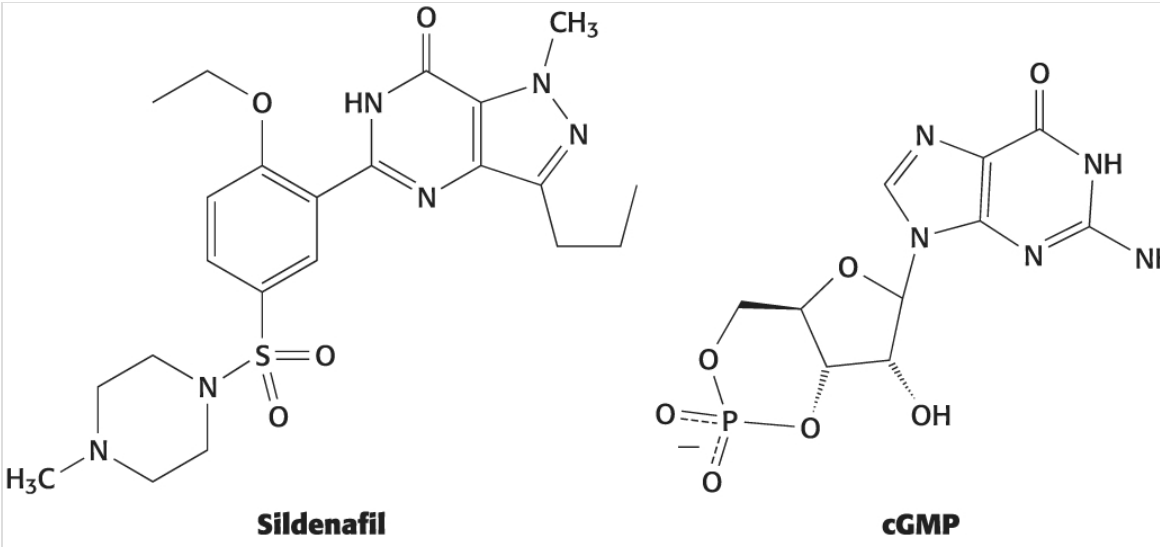

FIGURE 32.4 Sildenafil was designed to resemble cGMP, the substrate of phosphodiesterase 5 (PDE5).

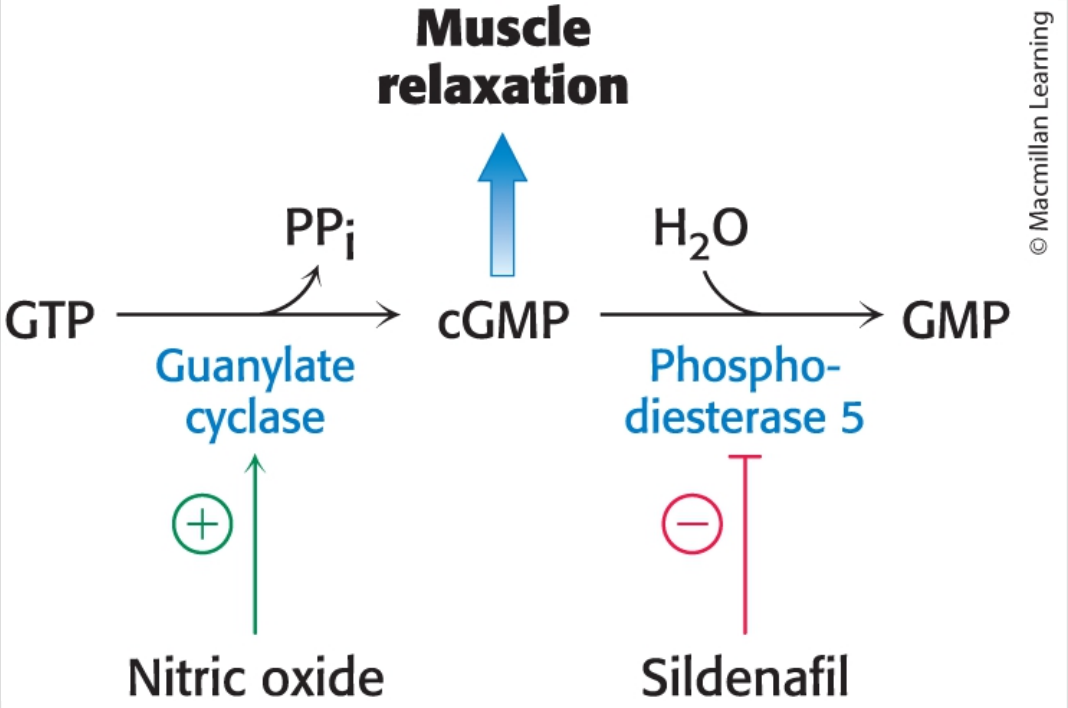

FIGURE 32.5 cGMP stimulates muscle relaxation. Increases in nitric oxide levels stimulate guanylate cyclase, which produces cGMP. PDE5 hydrolyzes cGMP, which lowers the cGMP concentration. The inhibition of PDE5 by sildenafil maintains elevated levels of cGMP.

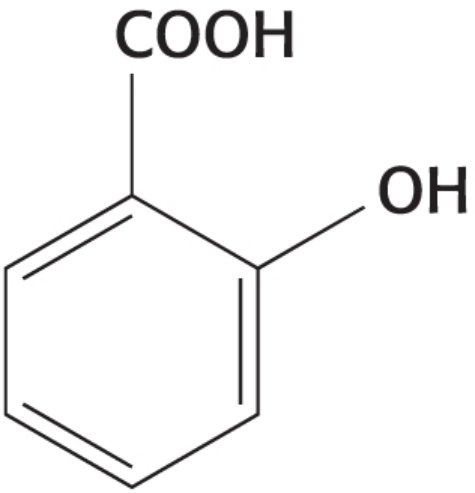
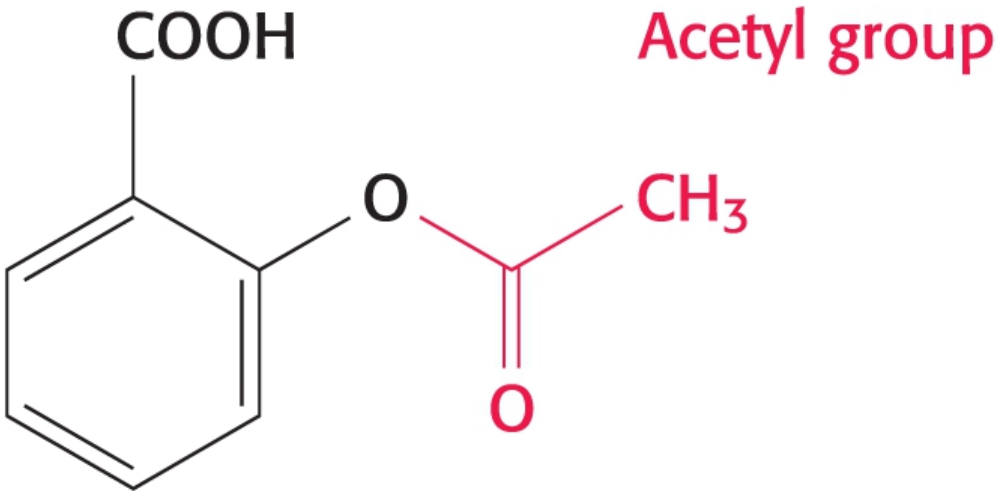
Subsequent clinical trials directed toward the evaluation of sildenafil for erectile dysfunction were successful. This account testifies to the importance of collecting comprehensive information from clinical-trial participants. In this case, incidental observations led to a new treatment for erectile dysfunction and a multibillion-dollar-per-year drug market.



32.2 Lead Molecules Can Be Discovered in Many Ways

Once a target has been selected, molecules which interact with the target and impact its activity must be identified. Initial drug-like molecules, also called **lead molecules** or **leads**, are the starting points for optimization into drug candidates that can be tested in humans. How are lead molecules identified? As we have seen, there are many examples where drugs were discovered by serendipity, or chance observation. Despite these successes, scientists have sought more reliable methods for lead identification. More recently, leads have been discovered by screening collections of natural products or large compound libraries for molecules that have desired biochemical properties. We will examine several examples of each of these pathways to reveal common principles.



Natural products are a valuable source of lead molecules

No drug is as widely used as aspirin. Observers at least as far back as Hippocrates (~400 B.C.E.) have noted the use of extracts from the bark and leaves of the willow tree for pain relief. In 1829, a mixture called *salicin* was isolated from willow bark, and subsequent analysis identified salicylic acid as the active component. Although it was used to treat pain, salicyclic acid often irritated the stomach. Several investigators attempted to find a means to neutralize salicylic acid. Felix Hoffmann, a chemist working at the German company Bayer, developed a less irritating derivative by treating salicylic acid with a base and acetyl chloride. This derivative, acetylsalicylic acid, was named *aspirin* from “a” for acetyl chloride, “spir” for *Spiraea ulmaria* (meadowsweet, a flowering plant that also contains salicylic acid), and “in” (a common

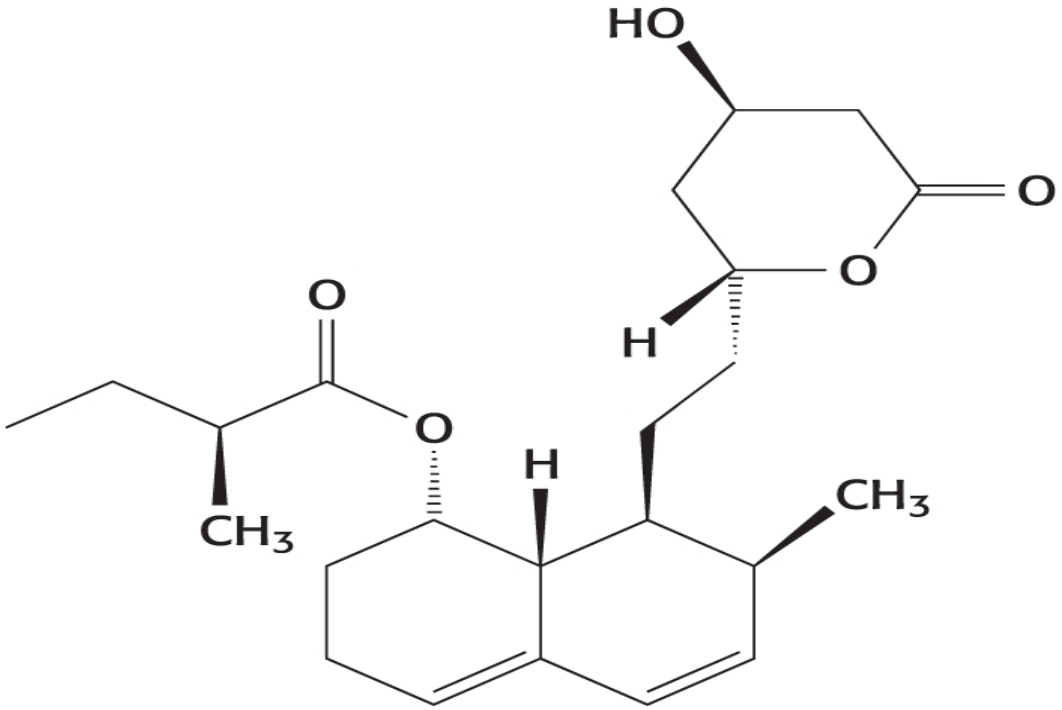
ending for drugs). Each year, approximately 35,000 tons of aspirin (nearly the weight of the *Titanic*) are taken worldwide.

Salicylic acid

Aspirin (acetylsalicylic acid)

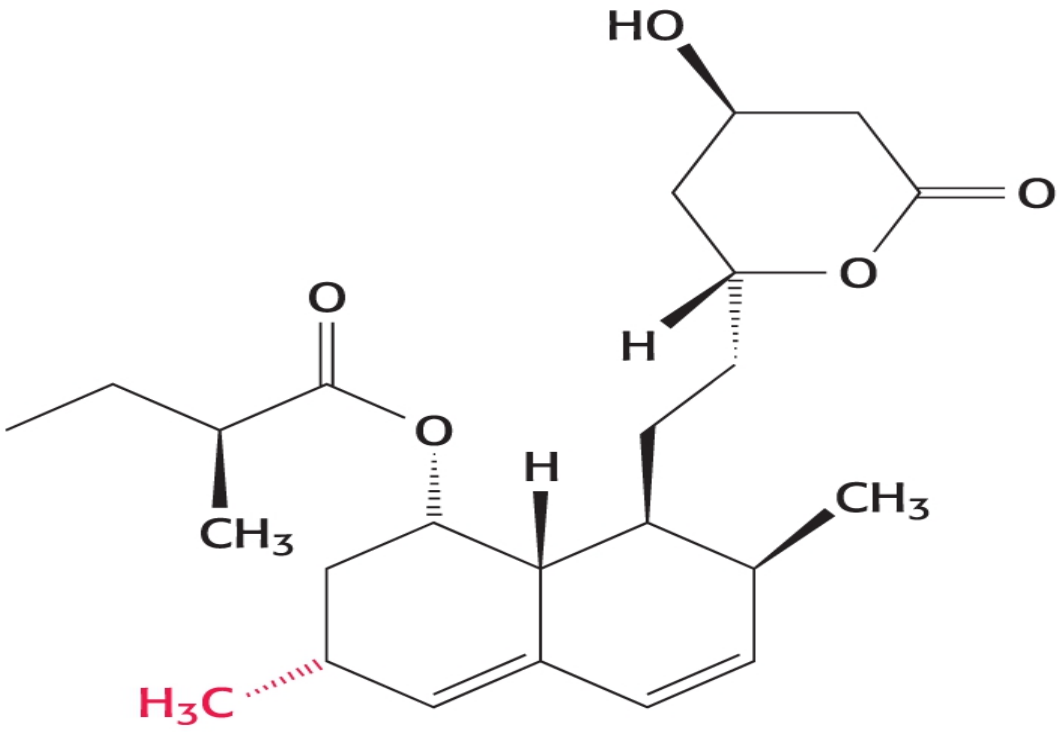
As discussed in Section 12.4, the acetyl group in aspirin is transferred to the side chain of a serine residue that lines the hydrophobic channel from the membrane to the active site of the cyclooxygenase component of prostaglandin H_2 synthase (Figure 12.24). In this position, the acetyl

group blocks access to the active site. Thus, even though aspirin binds in the same pocket on the enzyme as salicylic acid, the acetyl group of aspirin dramatically increases its effectiveness as a drug. This account illustrates the value of screening extracts from plants and other materials that are believed to have medicinal properties for active compounds. The large number of herbal and folk medicines are a treasure trove of new drug leads.



Let us consider another example, which has also had a significant impact on the clinical management of individuals with cardiovascular disease. More than 100 years ago, a fatty, yellowish material was discovered on the arterial walls of patients who had died of vascular disease. The presence of the material was termed *atheroma* from the Greek word for porridge. This material proved to be cholesterol. The Framingham Heart Study, initiated in 1948, documented a correlation between high blood-cholesterol levels and high mortality rates from heart disease. This observation led to the notion that blocking cholesterol synthesis might lower blood-cholesterol levels and, in turn, lower the risk of heart disease.

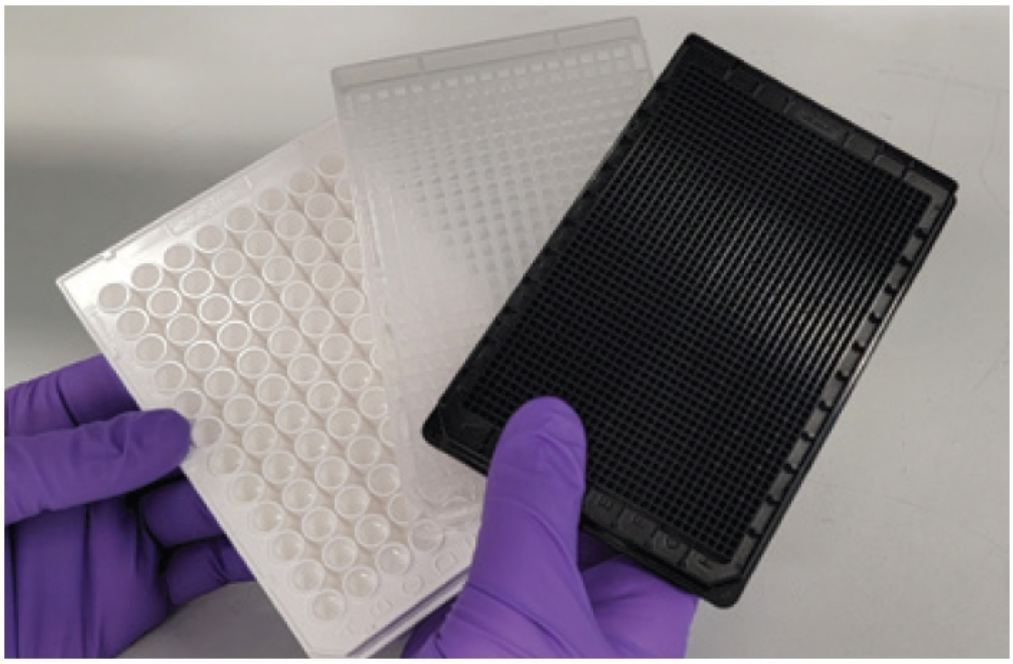
Initial attempts at blocking cholesterol synthesis focused on targets near the end of the pathway. However, these efforts were abandoned because the accumulation of the insoluble substrate for the inhibited enzyme led to the development of cataracts and other side effects. Investigators eventually identified a more favorable target — namely, the enzyme HMG-CoA reductase (Section 27.2). This enzyme acts on a substrate, HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A), that does not accumulate, because it is water-soluble and can be utilized by other pathways.



A promising natural product, called *compactin*, was discovered in a screen of compounds from a fermentation broth from *Penicillium citrinum* in a search for antibacterial agents. In some animal studies, compactin was found to inhibit HMG-CoA reductase and to lower serum

cholesterol levels. In 1982, a new HMG-CoA reductase inhibitor was discovered in a fermentation broth from another mold, *Aspergillus terreus*. This compound, now called *lovastatin*, was found to be structurally very similar to compactin, bearing one additional methyl group. After many studies, the Food and Drug Administration (FDA) approved lovastatin for treating high serum cholesterol levels. A structurally related HMG-CoA reductase inhibitor was later shown to cause a statistically significant decrease in deaths due to coronary heart disease, validating the clinical benefits of lowering serum cholesterol levels.

Compactin



Lovastatin

High-throughput screening expands the opportunity for lead identification

Drug developers can screen large libraries of either natural products or purely synthetic compounds to identify lead molecules with desired activities. Under favorable circumstances, millions of compounds can be tested in this process, termed **high-throughput screening (HTS)**.

The success of a high-throughput screen depends on the development of a robust and sensitive assay. Earlier, we introduced the necessity of a specific assay to assess the progress of a protein purification scheme (Section 4.1). A similar assay is needed to rapidly and sensitively detect molecules that have a desired activity such as the ability to inhibit an enzyme or block an ion channel. Since a high-throughput screen will assess a large number of compounds, screening assays are typically run in very small volumes (usually between 1 and 100 µl) in microtiter plates that contain hundreds, if not thousands, of wells (**Figure 32.6**). Additionally, screening is often conducted using automation equipment to handle the repetitive workload and ensure precise timing.

Gregory J. Gatto, Jr.

FIGURE 32.6 High-throughput screens are conducted in microtiter plates. Shown here are plates that contain 96, 384, and 1536 wells. As the number of wells increases, the maximum volume that each well can hold is reduced.

To achieve the required level of assay sensitivity, methods that rely on fluorescence or luminescence detection are often employed. While numerous methods are available, let us consider one approach to introduce a sensitive detection method into an enzyme assay. Recall the reaction of a protein kinase (Section 7.3), an enzyme which uses ATP to attach phosphoryl groups to the side chains of serine, threonine, or tyrosine residues.

$$\text{Protein-OH} + \text{ATP} \xrightleftharpoons{\text{Protein kinase}} \text{Protein-OPO}_3^{2-} + \text{ADP}$$

Neither the substrates (ATP or the unphosphorylated protein) nor the products (ADP or the phosphorylated protein) of this reaction are inherently fluorescent. However, by including additional enzymes (pyruvate kinase, pyruvate oxidase, and peroxidase) and the necessary substrates in the reaction, the production of ADP by the kinase can be coupled to the generation of the fluorescent dye resorufin (**Figure 32.7**). The successive actions of multiple enzymes to detect a reaction product is referred to as a **coupled assay**. Such assays can be quite effective for use in high-throughput screening. Follow-up assays, also called *secondary assays*, must be run on any hits from a coupled assay screen to ensure that the hits are not blocking the activity of the coupling enzymes, rather than the target kinase.

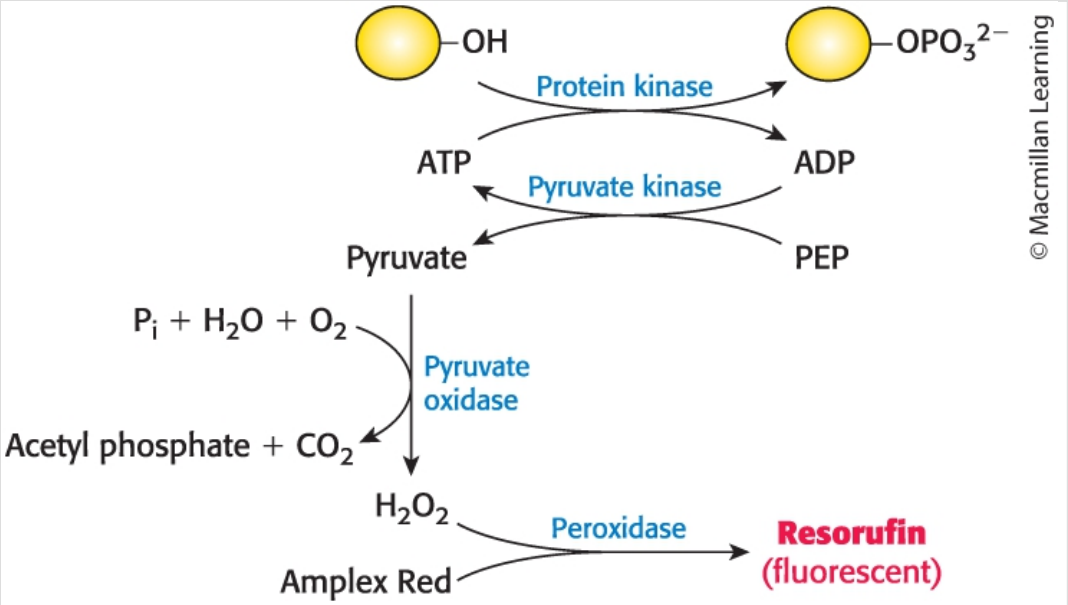


FIGURE 32.7 Coupled assays link the activity of an enzyme to the production of a fluorescent product. In this example, the hydrolysis of ATP to ADP by a protein kinase is linked via the successive action of three enzymes — pyruvate kinase, pyruvate oxidase, and peroxidase — to the production of the fluorescent dye resorufin.

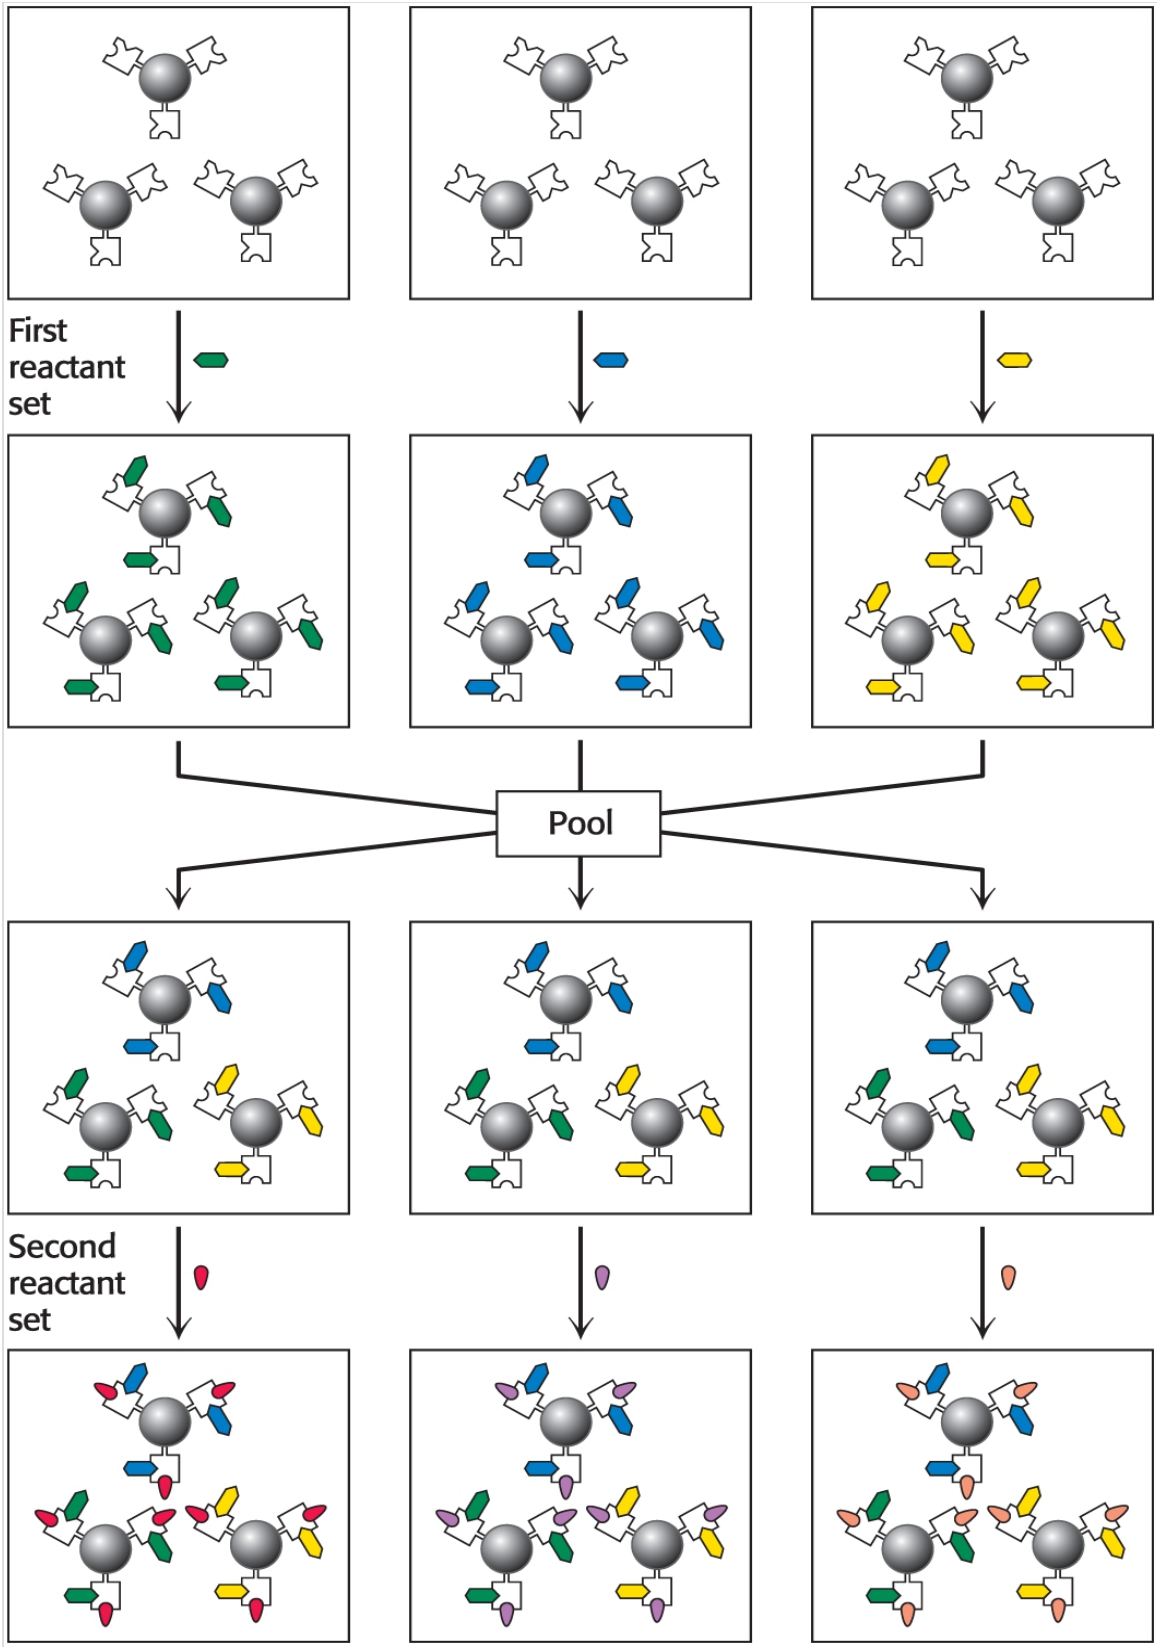
Self-Check Question

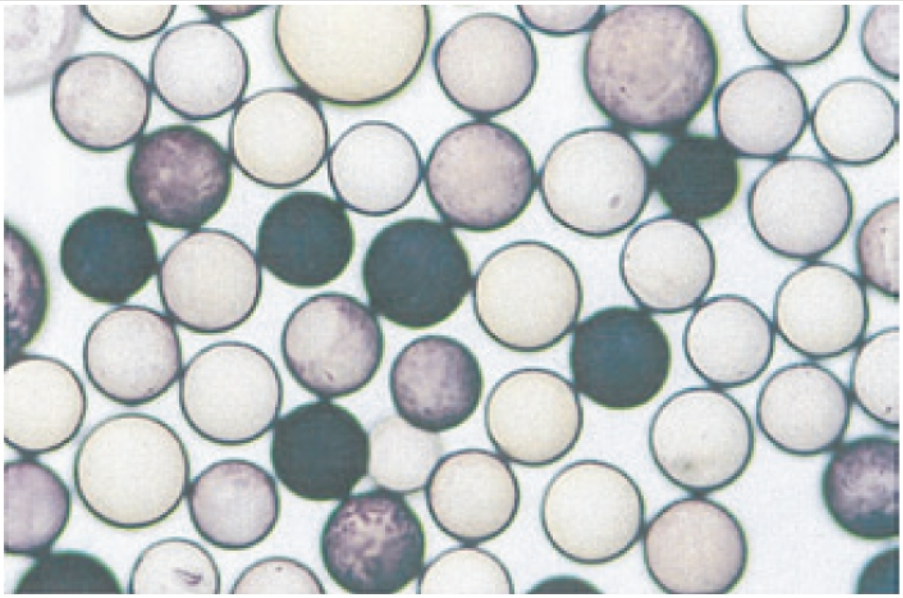
Some compounds in a screening library are themselves fluorescent. Why might they be problematic in a high-throughput screening experiment?

Screening libraries can be prepared using combinatorial chemistry

The final component needed for a high-throughput screen is a diverse chemical library. While compounds in these libraries can be synthesized one at a time for testing, an alternative approach is to synthesize all at once a large number of structurally related compounds that differ from one another at only one or a few positions. This approach is termed **combinatorial chemistry**. Here, compounds are synthesized with the use of the same chemical reactions but a variable set of reactants, enabling the generation of thousands of possible compounds over a few chemical steps.

A key method in combinatorial chemistry is **split-pool synthesis** (**Figure 32.8**). The method depends on solid-phase synthetic methods, first developed for the synthesis of peptides (Section 4.4). Compounds are synthesized on small beads. Beads containing an appropriate starting scaffold are produced and divided (split) into n sets, with n corresponding to the number of building blocks to be used at one site. Reactions adding the reactants at the first site are run, and the beads are isolated by filtration. The n sets of beads are then combined (pooled), mixed, and split again into m sets, with m corresponding to the number of reactants to be used at the second site. Reactions adding these m reactants are run, and the beads are again isolated. The important result is that each bead contains only one compound, even though the entire library of beads contains many. Furthermore, although only $n + m$ reactions were run, $n \times m$ compounds are produced. Suppose that a molecular scaffold is constructed with two reactive sites and that $n = 20$ reactants can be used in the first site and $m = 40$ reactants can be used in the second site. Over two synthetic steps, $20 + 40 = 60$ reactions produce $20 \times 40 = 800$ compounds.





First reactant set
Pool
Second reactant set

FIGURE 32.8 Compound libraries can be generated by split-pool synthesis. Reactions are performed on beads, shown in gray, that have the same initial structural scaffold, shown in white. Each of the reactions with the first set of reactants is performed on a separate set of bead The beads are then pooled, mixed, and split into sets. The second set of reactants is then added Many different compounds will be produced, but all of the compounds on a single bead will be identical.

In some cases, assays can be performed directly with the compounds still attached to the bead to find compounds with desired properties (Figure 32.9). Alternatively, each bead can be isolated and the compound cleaved from the bead to produce free compounds for analysis. After an interesting compound has been identified, analytical methods of various types must be used to identify which of the $n \times m$ compounds are present.

From Figure 3 in Liang et al., "Polyvalent binding to carbohydrates immobilized on an insoluble resin," Proceedings of the National Academy of Sciences, USA, vol. 94, pp. 10554–10559. Copyright 1997 National Academy of Sciences, USA.

FIGURE 32.9 A library of synthesized carbohydrates can be screened using an "on-bead" assay. A small combinatorial library of carbohydrates synthesized on the surface of 130-mm beads is screened for carbohydrates that are bound tightly by a lectin from peanuts. Beads that have such carbohydrates are darkly stained through the action of an enzyme linked to the lectin.

DNA-encoded libraries provide very large compound libraries for lead identification

The "universe" of drug-like compounds is vast. More than an estimated 10^{40} compounds are possible with molecular weights less than 750. So, even with a library of millions of compounds, only a tiny fraction of the chemical possibilities, referred to as **chemical space**, is represented in a particular compound collection.

In an effort to develop libraries that encompass even greater regions of chemical space, scientists have developed **DNA-encoded libraries (DELs)**. In a DEL, compounds are synthesized using split-pool methods directly on a short sequence of DNA. At each synthetic step, a new synthetic oligonucleotide is also ligated to the DNA portion of the molecule. The sequence of this oligonucleotide is unique to the identity of the building block added. Essentially, the synthetic DNA tag acts as a bar code. In this manner, a vast array of compounds can be generated, each with its own uniquely identifying DNA sequence (**Figure 32.10**).

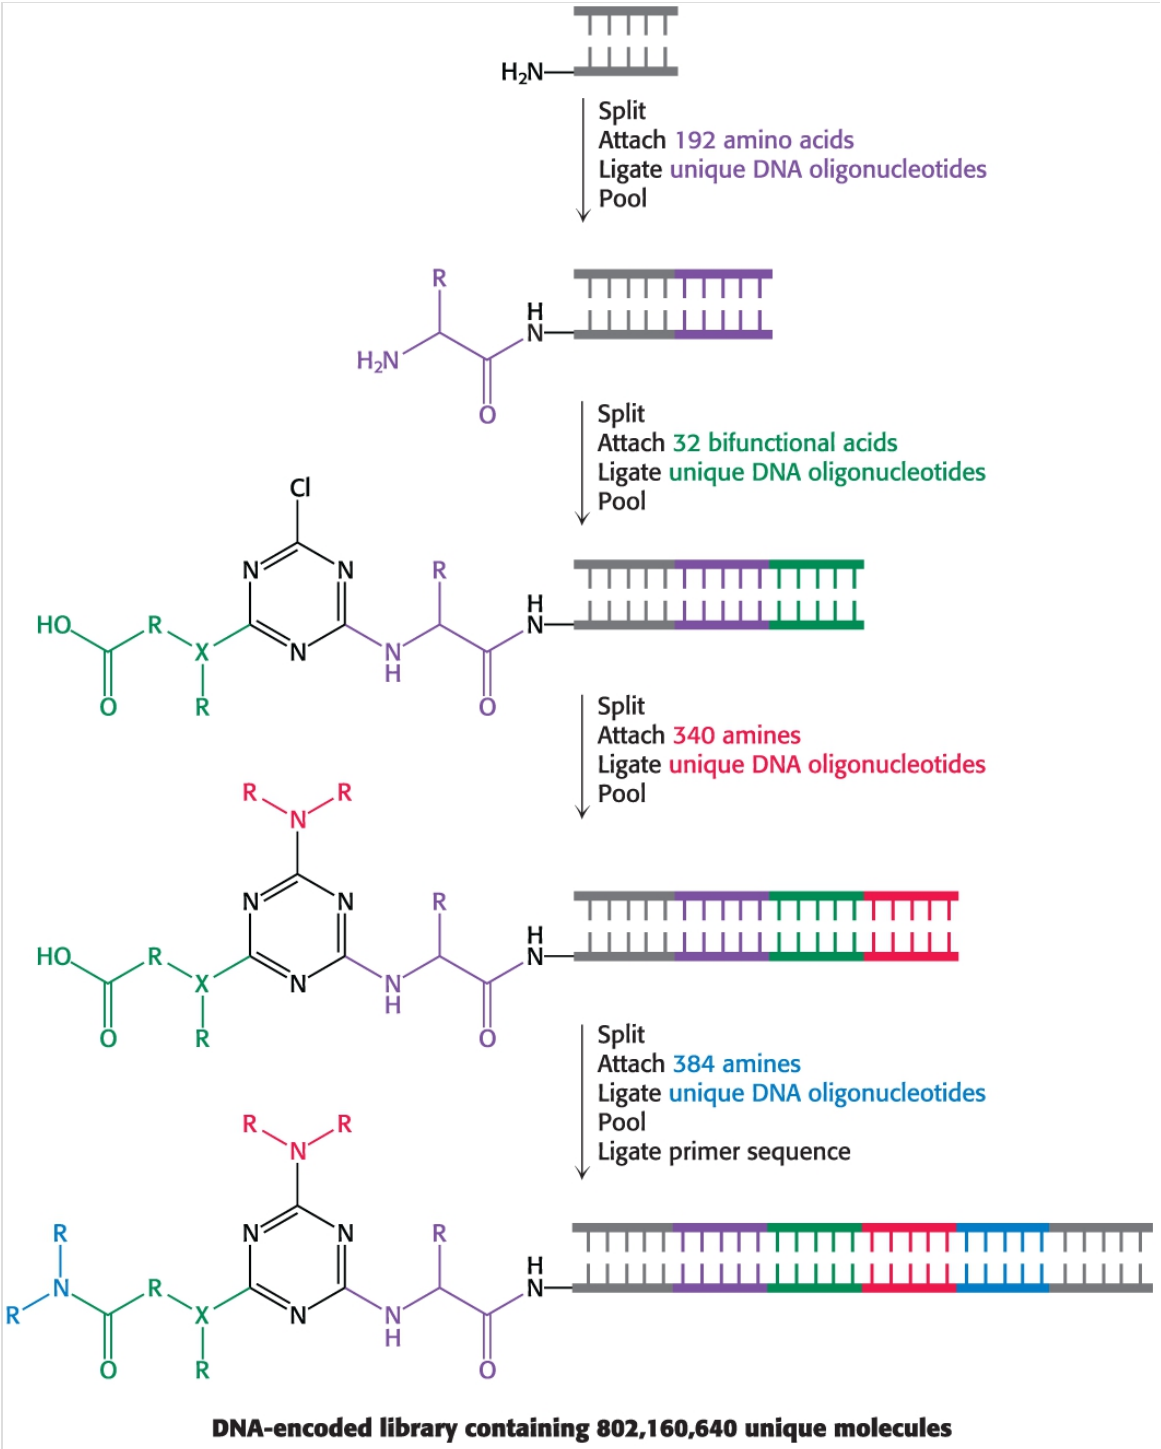


FIGURE 32.10 Diverse DNA-encoded libraries are generated by split pool synthesis. In the construction of a DNA-encoded library (DEL), compounds are synthesized directly on a short strand of double-stranded DNA. At each step, the pool of compounds is split, and different building blocks are added. Before pooling, a short oligonucleotide is ligated to the DNA strand. The sequence of this oligonucleotide is unique to the particular chemical building block that wa added. In this example, after four steps, a library containing over 800 million unique molecules

constructed, each linked to a DNA sequence that specifically encodes the reaction history of tha molecule.

[Information from P. A. Harris et al., *Nature Chem. Biol.* 5:647–654, 2009, Fig. 1.]

How are DELs then screened? In one approach reminiscent of affinity chromatography, the target of interest is attached to a solid resin support, usually through a recombinantly added affinity tag (Section 4.1). The DEL is then passed over the resin; molecules with high affinity for the target will remain bound to the target, while the others pass through unbound. The protein is then denatured, and the bound molecules are eluted. The DNA tags are then amplified by PCR and sequenced using next-generation methods (Section 9.3), revealing the identity of the hits. Since DELs are tested in a single pool, as opposed to individual compounds each dispensed into separate wells in a standard HTS, much larger libraries can be screened over a shorter period of time. The PCR amplification step enables identification of very small amounts of the hit compounds.

A number of follow-up studies must be performed to confirm the hits and explore their properties. For example, once the structures of the positive hits are inferred by DNA sequencing, the compounds must be prepared "off-DNA" to ensure that their affinity to the target was driven solely by the compound, and not influenced by any region of the attached DNA. Furthermore, this screening approach identifies only compounds that *bind* to the target; separate experiments must be conducted to determine if these molecules have *functional impact* on the activity of the target. Despite these challenges, leads have been identified by DEL screening for a number of protein targets, and several of these have been further optimized into highly potent candidates that have entered clinical testing, as we will explore in Section 32.3.

Phenotypic screening provides an alternative to the target-centered approach

Thus far, we have discussed a path to drug discovery that starts with the identification and validation of desired targets. Then, assays specific for these targets are used to screen compound libraries for chemical starting points for further optimization. This approach, called **target-based screening** (Figure 32.11A), is widely applied throughout the pharmaceutical industry. However, target-based screening presents significant challenges that must be overcome: compelling validation evidence for the target must be accumulated; assays specific to the target must be developed; and, as we shall see, compounds must be chemically optimized to be functional in physiological environments.

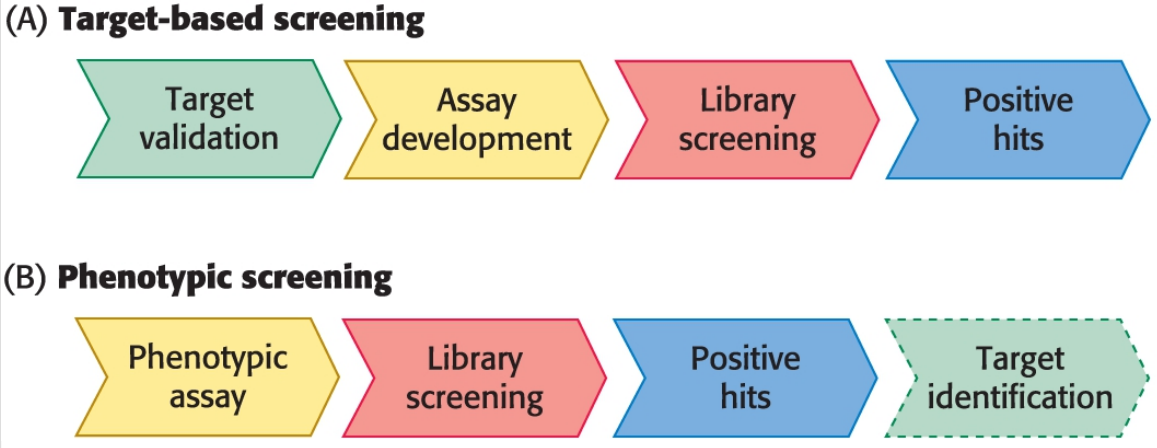

FIGURE 32.11 Target-based screening and phenotypic screening are two paths to early drug discovery. (A) In target-based screening, a molecular target is identified and validated. An assay for this target's activity is used to screen a compound library. Hits can then be tested for their physiological effects and optimized into drug candidates. (B) In phenotypic screening, an assay for a disease-relevant phenotype is developed in a cellular or animal model system. This assay is used to screen a compound library, from which hits can be optimized into drug candidates. These compounds can also be used to identify the molecular target.

Alternatively, leads may be identified by **phenotypic screening** (**Figure 32.11B**). In this approach, libraries of compounds are screened in an assay designed to detect a desired phenotype in a cellular system or animal model. For example, compounds may be tested for their ability to promote cellular survival or enhance resistance to specific toxic stimuli. In phenotypic screening, a biological effect is known before the target is identified. One advantage to this method is that any positive screening hits are already known to have the desired pharmacological effect in a physiological setting.

A significant challenge to phenotypic screening is that the target is not always obvious. As we have seen in our discussions on signal transduction (Chapter 14), a physiological phenotype could be modulated at a wide variety of potential points. Hence, the mode of action of the compound, including the identity of its target or targets, must be identified later. These target identification experiments typically require a substantial amount of effort.

Self-Check Question

Propose an experiment that could enable identification of a target, using the knowledge of a phenotypic screening hit.

32.3 Compounds Must Meet Stringent Criteria to Be Developed into Drugs

In the previous section, we described the process by which leads are identified. During the next stage, **lead optimization**, numerous molecules related to the leads are synthesized to identify those which meet the strict criteria for further development into a **candidate**, a molecule suitable for testing in humans. Many compounds have significant effects when taken into the body, but only a very small fraction of them have the potential to be useful drugs. A foreign compound, not adapted to its role in the cell over the course of evolution, must have a range of special properties to function effectively without causing serious harm. Let us consider some of the challenges faced by drug developers.

Drugs must be potent and selective

Most drugs bind to specific proteins, usually receptors or enzymes, within the body. To be effective, a drug should bind a sufficient number of its target proteins when taken at a dose that can be reasonably administered to patients. One factor in determining drug effectiveness is the strength of the interaction between the drug and its target. Recall from Section 3.1 that a molecule that binds to some target protein is often referred to as a *ligand*. A prototypical ligand-binding curve is shown in **Figure 32.12**. The tendency of a ligand to bind to its target is measured by the dissociation constant, K_d, defined by the expression

$$K_d = [R][L]/[RL]$$

where [R] is the concentration of the free receptor, [L] is the concentration of the free ligand, and [RL] is the concentration of the receptor–ligand complex. The dissociation constant is a measure of the strength of the interaction between the drug candidate and the target; the lower the value, the stronger the interaction. The concentration of free ligand at which one-half of the binding sites are occupied equals the *dissociation constant*, as long as the concentration of binding sites is substantially less than the dissociation constant.

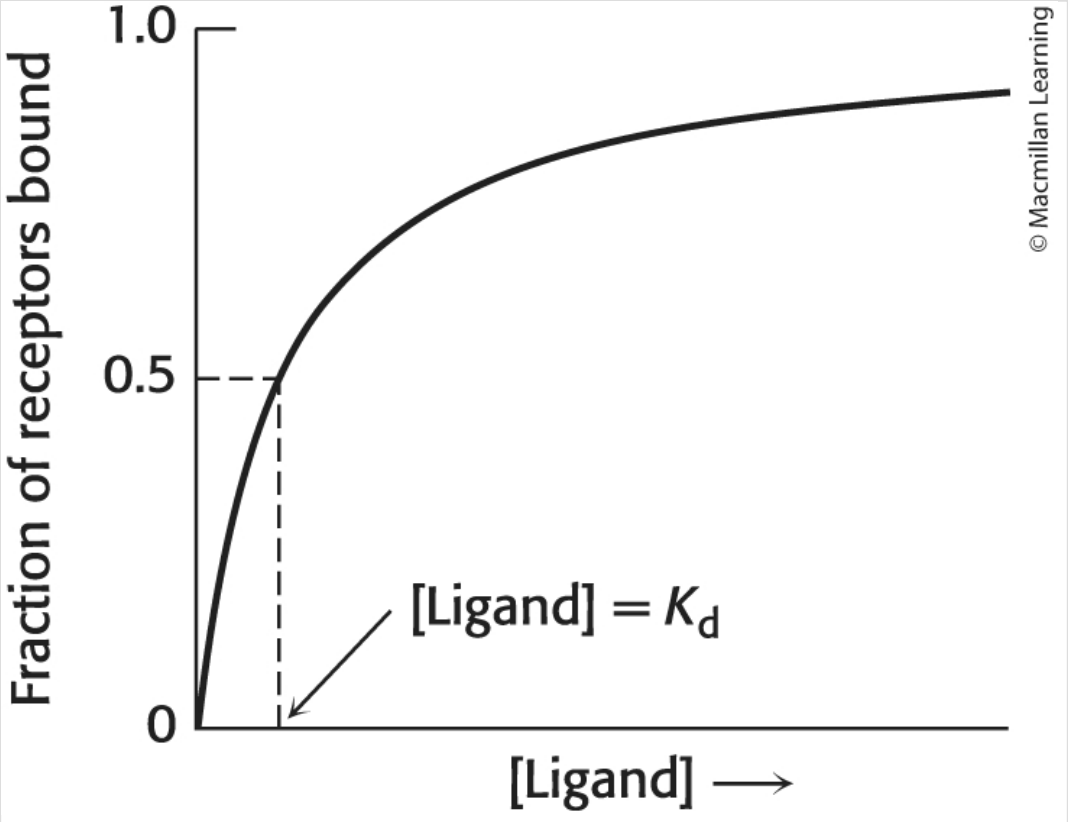

FIGURE 32.12 Simple ligand binding results in a hyperbolic curve. The titration of a receptor, R, with a ligand, L, results in the formation of the complex RL. In uncomplicated cases, the binding reaction follows a simple saturation curve. Half of the receptors are bound to ligand when the ligand concentration equals the dissociation constant, K_d, for the RL complex.

In many cases, biological assays using living cells or tissues (rather than direct enzyme or binding assays) are employed to examine the potency of drug candidates. More potent molecules exert their effects at a lower concentration than less potent ones. For example, the fraction of bacteria killed by a drug might indicate the potency of a potential antibiotic. In these cases, values such as EC_{50} are used. EC_{50}, where EC stands for *effective concentration*, is the concentration of the drug candidate required to elicit 50% of the maximal biological response (**Figure 32.13**). Similarly, EC_{90} is the concentration required to achieve 90% of the maximal response. In the example of an antibiotic, EC_{90} would be the concentration required to kill 90% of bacteria exposed to the drug. For drug candidates that are inhibitors, the corresponding terms IC_{50} and IC_{90}, where IC stands for *inhibitory concentration*, are often used to describe the concentrations of the inhibitor required to reduce a response by 50% or 90%, respectively.

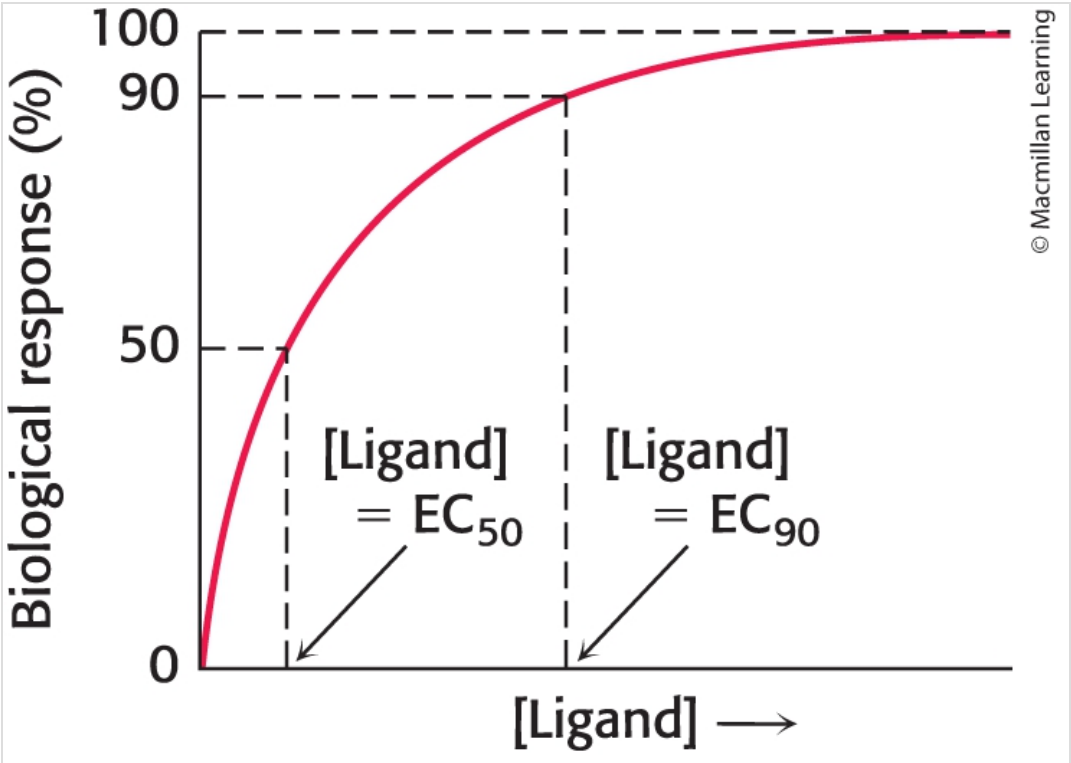

FIGURE 32.13 Effective concentration (EC) describes the amount of compound required to elicit a particular biological response. The EC_{50} value describes the

concentration required to elicit 50% of the maximum response, while the EC_{90} describes that required to elicit 90% of the maximum response.

Values such as the EC_{50} and IC_{50} are measures of the potency of a drug candidate in modulating the activity of the desired biological target. Additionally, to prevent unwanted effects, often called **side effects**, ideal drug candidates should be selective. That is, they should not bind biomolecules other than the target to any significant extent. The degree of selectivity can be described in terms of the ratio of the K_d values for the binding of the drug candidate to any other molecules to the K_d value for the binding to the desired target.

Under physiological conditions, achieving potent and selective binding of a target site by a drug can be quite challenging. Most drug targets also bind ligands normally present in tissues; often, the drug and these ligands will compete for binding sites on the target. We encountered this scenario when we considered competitive inhibitors in Section 5.6. Suppose that the drug target is an enzyme and the drug candidate is competitive with respect to the enzyme's natural substrate. The concentration of the drug candidate necessary to inhibit the enzyme will depend on the physiological concentration of the normal substrate (**Figure 32.14**). Biochemists Yung-Chi Cheng and William Prusoff described the relationship between the IC_{50} of an enzyme inhibitor and its inhibition constant K_i (analogous to the dissociation constant, K_d, of a ligand). For a competitive inhibitor,

$$IC_{50} = K_i(1 + [S]/K_M)$$

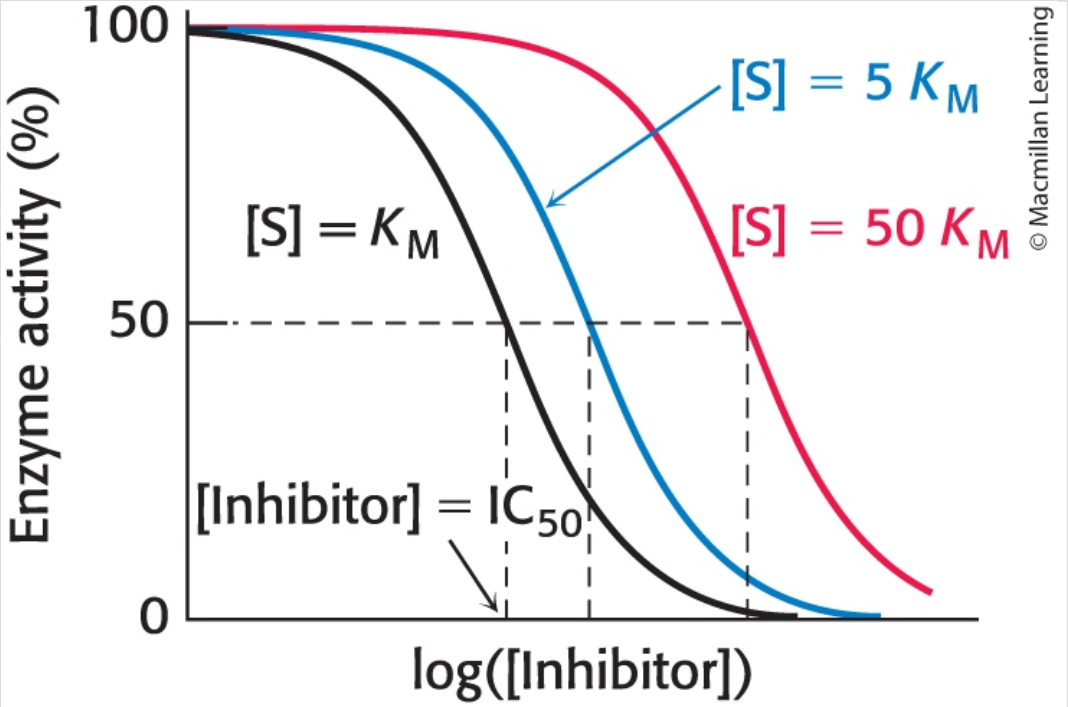

FIGURE 32.14 Inhibitors compete with substrates for enzyme active sites. The measured IC_{50} of a competitive inhibitor to its target enzyme depends on the concentration of substrate present.

This relationship, referred to as the Cheng–Prusoff equation, demonstrates that the IC_{50} of a competitive inhibitor will depend on the concentration and the Michaelis constant (K_M) for the substrate S. The higher the concentration of the natural substrate, the higher the concentration of drug needed to inhibit the enzyme.

Example

Determining the IC_{50} for an Inhibitor

PROBLEM:

The activity of an enzyme was measured in the presence of varying concentrations of Compound A and reported in the table shown. Estimate the IC_{50} for this compound. If Compound A is known to be a competitive inhibitor with respect to the enzyme substrate and the assay was run at a concentration of substrate equal to its K_M, what is the K_i of Compound A?

Compound A (nM)	Percent enzyme activity
0	100
45	90
140	84
410	65
800	51
3700	22
11,200	8
33,100	4

Getting Started:

The IC_{50} is defined as the concentration at which the activity of an enzyme is inhibited by 50%. Reassuringly, the first row of the table confirms that the activity of the enzyme in the absence of Compound A is 100%. Hence, a good first approximation for the IC_{50} would be close to the concentration where the enzyme activity is 50%. From the table, this is about 800 nM.

Calculate:

Since we know that Compound A is competitive with respect to substrate, and the assay was run at a substrate concentration equal to its K_M, we can use the Cheng–Prusoff equation to estimate the K_i:

$$IC_{50} = K_i\left(1 + \frac{[S]}{K_M}\right)$$

$$IC_{50} = K_i\left(1 + \frac{K_M}{K_M}\right) = 2K_i$$

$$K_i = \frac{IC_{50}}{2} = \frac{800\ \text{nM}}{2} = 400\ \text{nM}$$

Reflect:

Pharmacologists describe inhibitor potency in a variety of ways. Note that while IC_{50} values are commonly used, they are dependent upon assay conditions, whereas K_i values are reflective of the intrinsic affinity of the inhibitor for its target. Also, be careful when applying the Cheng–

Prusoff equation! The equation provided in the text is specific for competitive inhibitors with respect to the substrate S. More complicated equations are needed to describe this relationship for other inhibitory modalities.

Drugs must have suitable properties to reach their targets

Thus far, we have focused on the ability of molecules to act on specific target molecules. However, an effective drug also has other requisite characteristics. It must be easily administered and must reach its target at sufficient concentration to be effective. After a drug molecule has entered the body, it is acted upon by several processes — absorption, distribution, metabolism, and excretion — that will determine its effective concentration over time (**Figure 32.15**). A drug's response to these processes is referred to as its **ADME** (pronounced "add-me") **properties**.

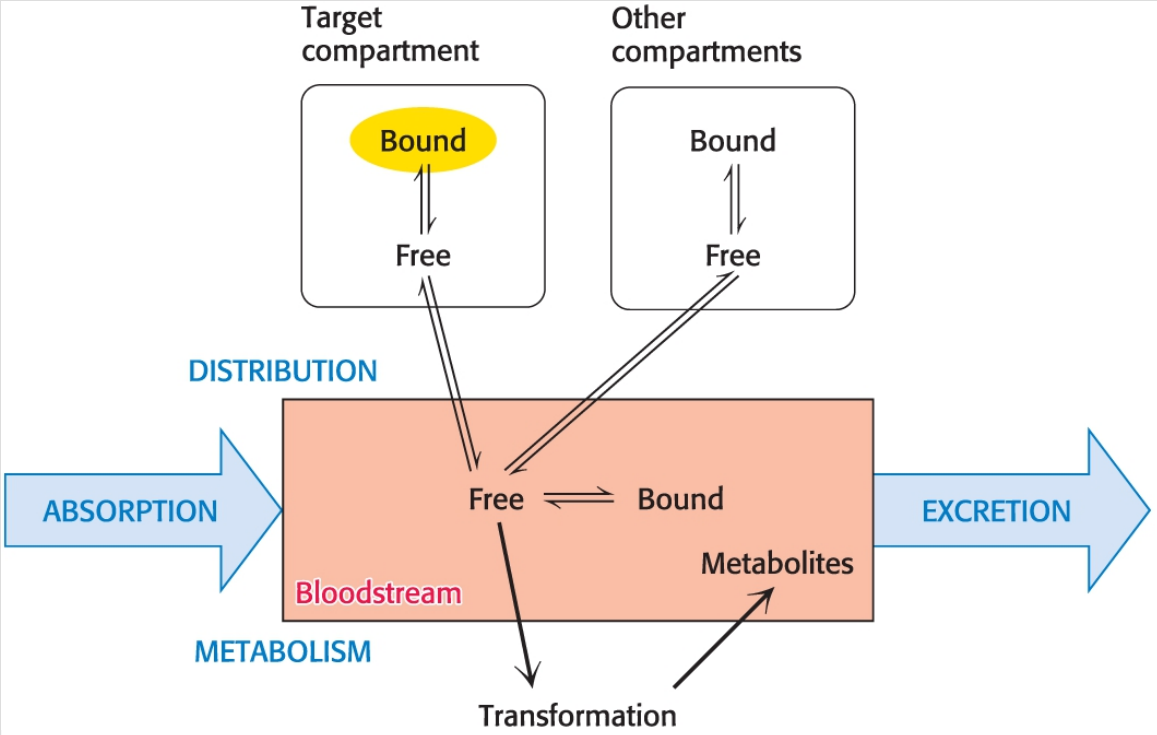

FIGURE 32.15 The pharmacokinetics of a compound in a living organism is described by its absorption, distribution, metabolism, and excretion (ADME) properties. The concentration of compound at its target site (yellow) is affected by the magnitudes and rates of absorption, distribution, metabolism, and excretion.

Administration and absorption

Ideally, a drug can be taken orally as a small tablet. An orally administered active compound must be able to survive the acidic conditions in the gut and then be absorbed through the intestinal epithelium. Thus, the compound must be able to pass through cell membranes at a significant rate. Larger molecules such as proteins cannot be administered orally, because they often cannot survive the acidic conditions in the stomach and, if they do, they are not readily absorbed. Even many small molecules are not absorbed well; they may be too polar and unable to pass through cell membranes easily, for example. The ability to be absorbed is often quantified in terms of the

oral bioavailability. This quantity is defined as the ratio of the peak concentration of a compound given orally to the peak concentration of the same dose injected directly into the bloodstream. Bioavailability can vary considerably from species to species, so results from animal studies may be difficult to apply to human beings. Despite this variability, some useful generalizations have been made. One powerful set consists of Lipinski's rules, developed by the pharmaceutical chemist Christopher A. Lipinski.

Lipinski's rules tell us that poor absorption is likely when

1. The molecular weight is greater than 500 daltons.
2. The number of hydrogen-bond donors is greater than 5.
3. The number of hydrogen-bond acceptors is greater than 10.
4. The partition coefficient [measured as log(*P*)] is greater than 5.

The partition coefficient is a way to measure the tendency of a molecule to enter lipid membranes, which correlates with its ability to dissolve in organic solvents. It is determined by allowing a compound to equilibrate between water and an organic phase, *n*-octanol. The log(*P*) value is defined as $\log_{10}$ of the ratio of the concentration of a compound in *n*-octanol to the concentration of the compound in water:

$$\log(P) = \log\left(\frac{[\text{compound}]_{\text{n-octanol}}}{[\text{compound}]_{\text{water}}}\right)$$

For example, if the concentration of the compound in the *n*-octanol phase is 100 times that in the aqueous phase, then log(*P*) is 2. Although the ability of a drug to partition in organic solvents is ideal, as it implies that the compound can penetrate membranes, a log(*P*) value that is too

high suggests that the molecule may be poorly soluble in an aqueous environment.

Morphine, for example, satisfies all of Lipinski's rules and has moderate bioavailability (Figure 32.16). Still, a drug that violates one or more of these rules may also have satisfactory bioavailability. Nonetheless, these rules, and other similar guidelines that have since been developed, serve as useful principles for evaluating new drug candidates.

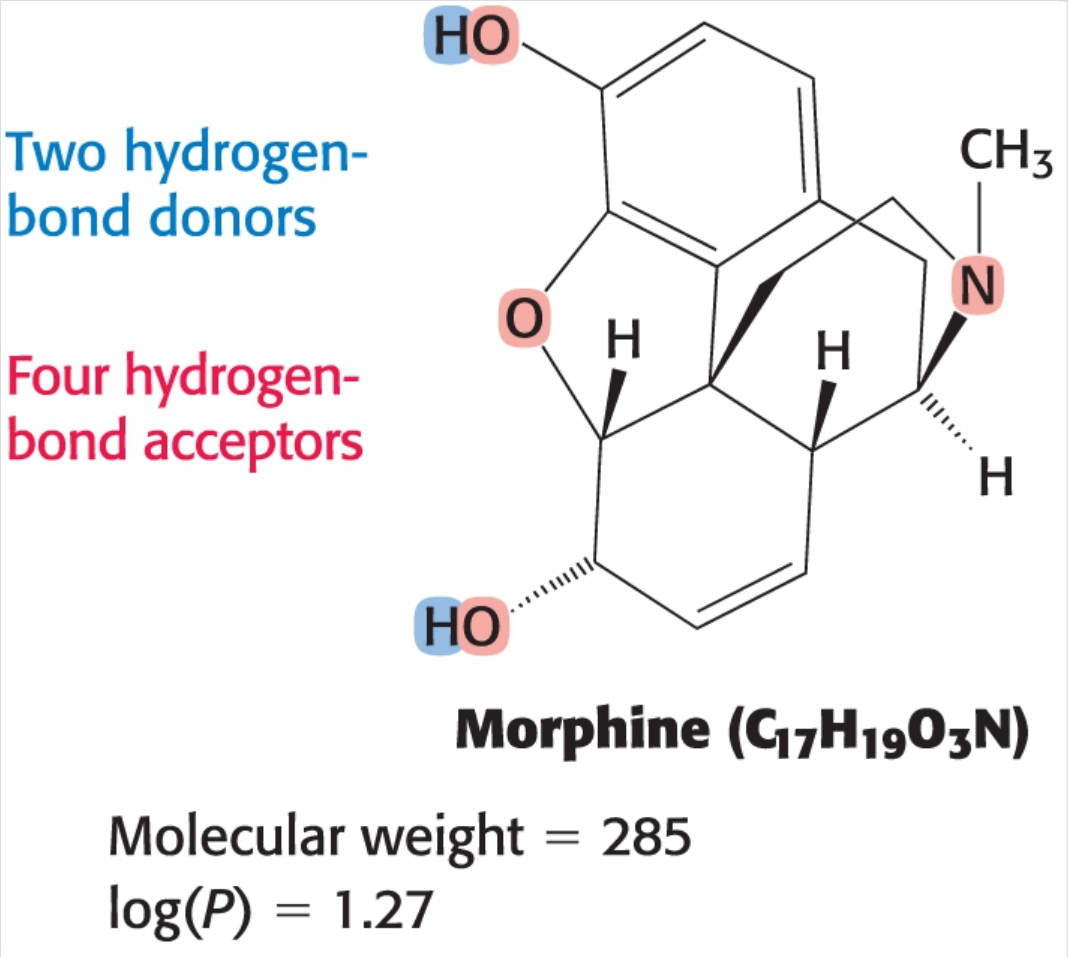

FIGURE 32.16 Lipinski's rules serve as a guide to predict oral bioavailability. Morphine satisfies all of Lipinski's rules and has an oral bioavailability in human beings of 33%.

Distribution

Compounds taken up by intestinal epithelial cells can pass into the bloodstream. However, hydrophobic compounds and many others do not freely dissolve in the bloodstream. These compounds bind to proteins, such as albumin (Figure 32.17), that are abundant in the blood serum. Because albumin is present in the circulation at high concentrations (nearly 0.7 mM) and can bind a wide variety of compounds, it can dramatically affect the free concentration of drug in the bloodstream. Nevertheless, the binding capacity of albumin enables transport of the drug throughout the circulatory system.

FIGURE 32.17 Albumin is abundant in the bloodstream and binds hydrophobic compounds. Seven hydrophobic molecules (in red) are shown bound to a single molecule of serum albumin.

[Drawn from 1BKE.pdb.]

When a compound has reached the bloodstream, it is distributed to different fluids and tissues, which are often referred to as *compartments*. Some compounds are highly concentrated in their target compartments, either by binding to the target molecules themselves or by other mechanisms. Other compounds are distributed more widely (Figure 32.18). An effective drug will reach the target compartment in sufficient quantity; the concentration of the compound in the target compartment is reduced whenever the compound is distributed into other compartments.

FIGURE 32.18 Once absorbed, compounds distribute to various organs within the body. The distribution of the antifungal agent fluconazole has been monitored through the use of positron emission tomography (PET) scanning. These images were taken of a healthy human volunteer 9

minutes after injection of a dose of $5\ mg\ kg^{-1}$ of fluconazole containing trace amounts of fluconazole labeled with the positron-emitting isotope ^{18}F.

Some target compartments are particularly hard to reach. For example, many compounds are excluded from the central nervous system by the tight junctions between endothelial cells that line blood vessels within the brain and spinal cord, referred to as the *blood-brain barrier*.

Metabolism

A potential drug molecule must evade the body's defenses against foreign compounds, also called **xenobiotics**. Many compounds are released from the body in the urine or stool, often after having been metabolized to aid in excretion. This **drug metabolism** poses a considerable threat to drug effectiveness, because the concentration of the desired compound decreases as it is metabolized. Thus, a rapidly metabolized compound must be administered more frequently or at higher doses.

Drug metabolism takes place primarily in the liver. Because blood flows from the intestine directly to the liver through the portal vein, xenobiotic metabolism often alters drug compounds before they ever reach full circulation. This process, referred to as *first-pass metabolism*, can substantially limit the availability of compounds taken orally.

Two of the most common pathways in xenobiotic metabolism are oxidation, often referred to as **phase I transformations**, and conjugation (which are called **phase II transformations**). Oxidation reactions can aid excretion in at least two ways: by increasing water

solubility, and thus ease of transport, and by introducing functional groups that participate in subsequent metabolic steps. These reactions are often promoted by cytochrome P450 enzymes in the liver (Section 27.4). The human genome encodes more than 50 different P450 isozymes, many of which participate in xenobiotic metabolism. A typical reaction catalyzed by a P450 isozyme is the hydroxylation of ibuprofen (**Figure 32.19**).

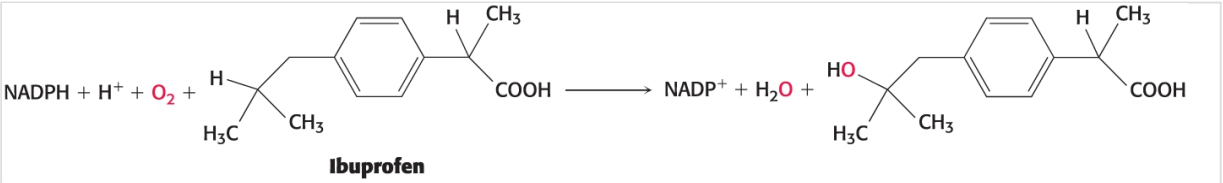

FIGURE 32.19 Cytochrome P450 isozymes catalyze xenobiotic metabolic reactions such as hydroxylation. In this example, one P450 isozyme introduces an oxygen atom derived from molecular oxygen into the anti-inflammatory drug ibuprofen.

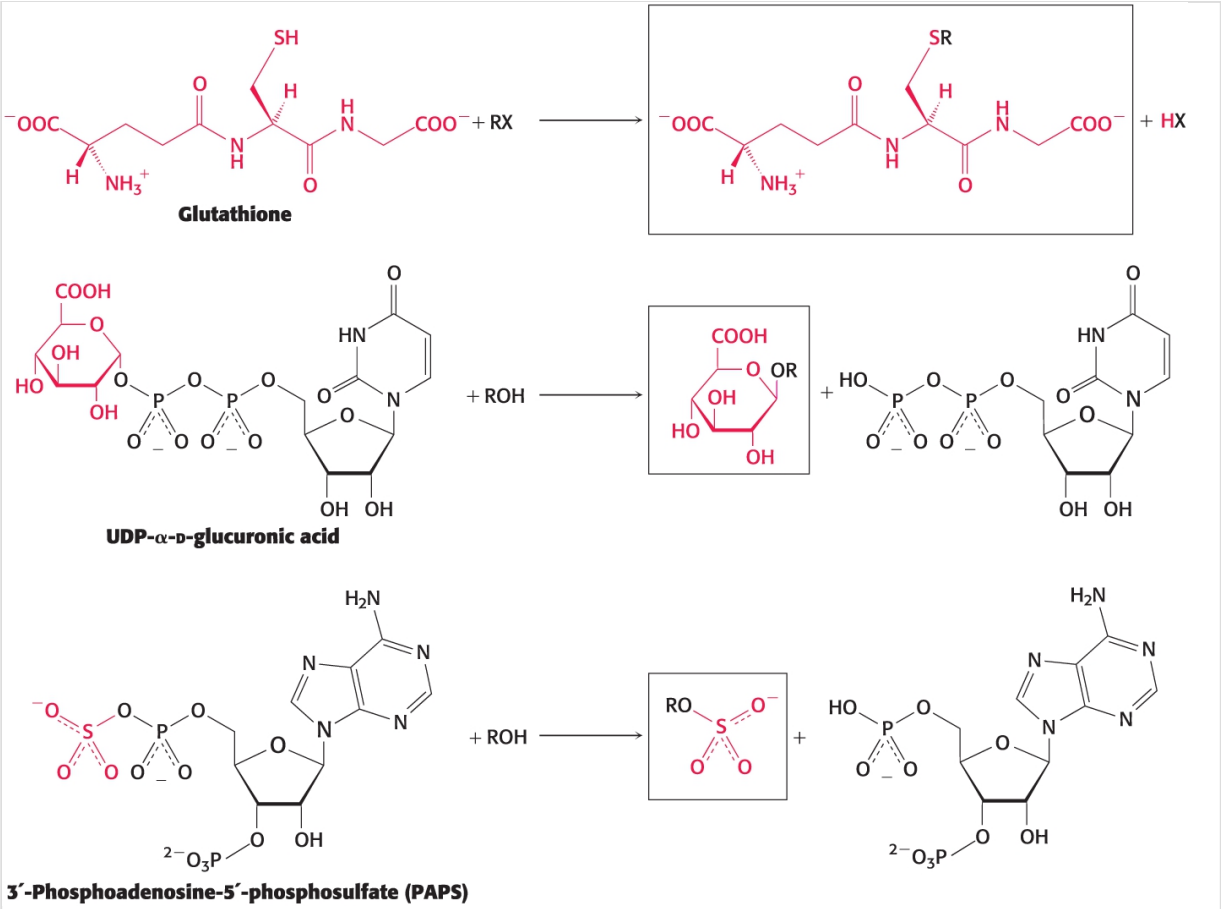
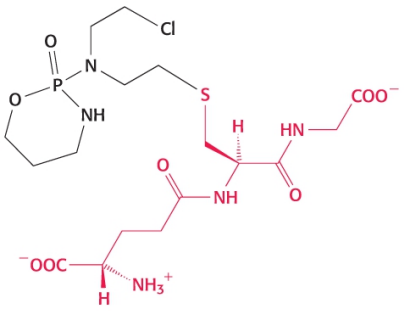
Conjugation is the addition of particular groups to the xenobiotic compound. Common groups added are glutathione (Section 20.5), glucuronic acid, and sulfate (**Figure 32.20**). These additions often increase water solubility and promote excretion. Note that an oxidation reaction often precedes conjugation because the oxidation reaction can generate modifications, such as the hydroxyl group, to which groups such as glucuronic acid can be attached.





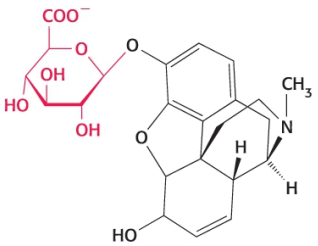


FIGURE 32.20 Compounds that have certain functional groups are often modified by conjugation reactions. Such reactions include the addition of glutathione (top), glucuronic acid (middle), or sulfate (bottom). The conjugated product is shown boxed.

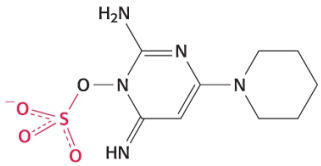

Examples of conjugation include the addition of glutathione to the anticancer drug cyclophosphamide, the addition of glucuronidate to the analgesic morphine, and the addition of a sulfate group to the hair-growth stimulator minoxidil. While the metabolic products of a drug are usually less active than the drug itself, there are notable exceptions. For example, the sulfation of minoxidil produces a compound that is more active in stimulating hair growth than is the unmodified compound.

Cyclophosphamide-glutathione conjugate

Morphine glucuronidate

Minoxidil sulfate

Excretion

After compounds have entered the bloodstream, they can be removed from circulation and excreted from the body by two primary pathways. First, they can be absorbed through the kidneys and excreted in the urine. In this process, the blood passes through networks of fine capillaries, called *glomeruli*, in the kidney that act as filters. Compounds with molecular weights less than approximately 60,000 pass though the glomeruli. Many of the water molecules, glucose molecules, nucleotides, and other low-molecular-weight compounds that pass through the glomeruli are reabsorbed into the bloodstream, either by transporters that have broad specificities or by the passive transfer of hydrophobic molecules through membranes. Drugs and metabolites that pass through the first filtration step and are not reabsorbed are subsequently excreted.

Second, compounds can be actively transported into bile by a process that takes place in the liver. After concentration in the gallbladder, bile flows into the intestine. In the intestine, the drugs and metabolites can be reabsorbed into the bloodstream, further degraded by digestive enzymes, or excreted through the stool. Sometimes, compounds are recycled from the bloodstream into the intestine and back into the bloodstream, a process referred to as *enterohepatic cycling* (**Figure**

32.21). This process can significantly decrease the rate of excretion of some compounds, because they escape from an excretory pathway and reenter the circulation.

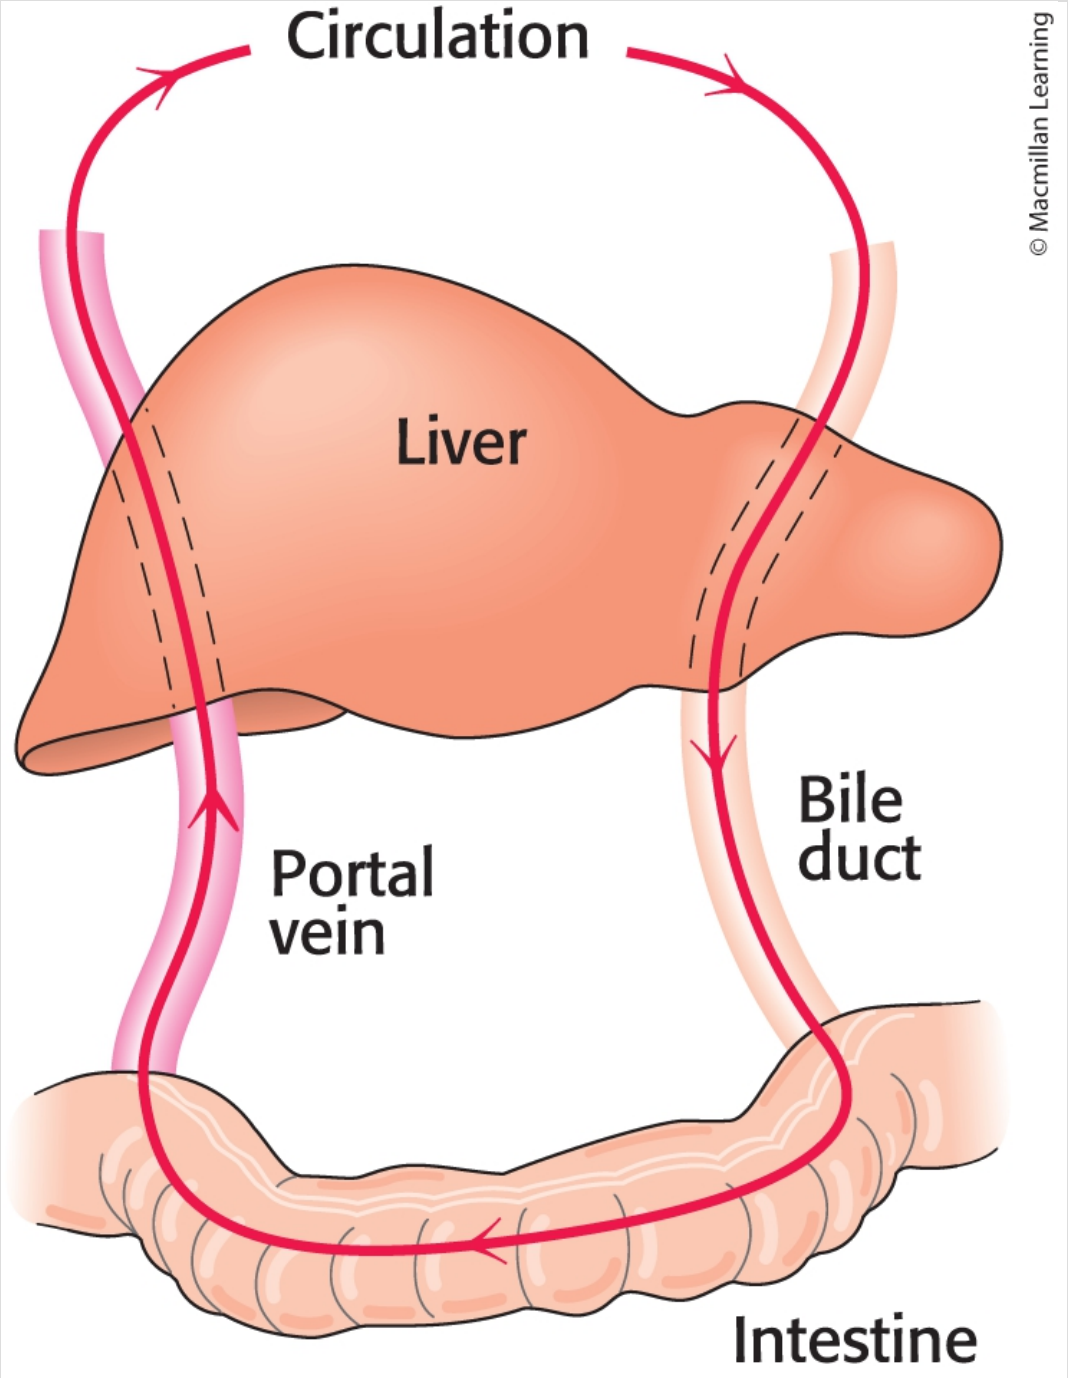

FIGURE 32.21 Drugs can move between the intestine and the circulation via enterohepatic cycling. In this pathway, some drugs can move from the blood

circulation to the liver, into the bile, into the intestine, to the liver, and back into circulation. This cycling decreases the rate of drug excretion.

The kinetics of compound excretion is often complex. In some cases, a fixed percentage of the remaining compound is excreted over a given period of time (Figure 32.22). This pattern of excretion results in exponential loss of the compound from the bloodstream that can be characterized by a half-life $(t_{1/2})$. The half-life is the fixed period of time required to eliminate 50% of the remaining compound. It is a measure of how long an effective concentration of the compound remains in the system after administration. As such, the half-life is a major factor in determining how often a drug must be taken. A drug with a long half-life might need to be taken only once per day, whereas a drug with a short half-life might need to be taken three or four times per day.

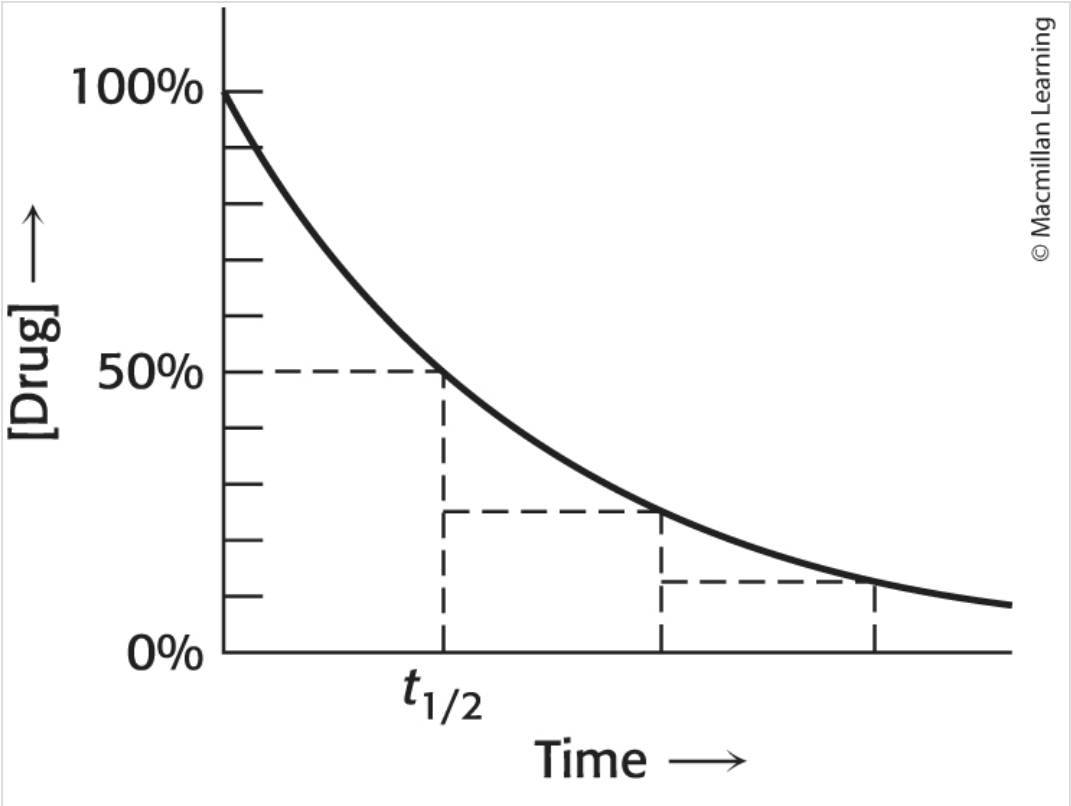

FIGURE 32.22 Drug excretion may be measured by its half-life. The concentration of a drug in the bloodstream decreases to one-half of its value in a period of time, $t_{1/2}$, referred to as its half-life.

Toxicity can limit drug effectiveness

An effective drug must not be so toxic that it seriously harms the person who takes it. A drug may be toxic for any of several reasons. First, it may modulate the target molecule itself too effectively, referred to as **mechanism-based**, or **on-target**, **toxicity**. For example, the presence of too much of the anticoagulant drug coumadin can result in dangerous, uncontrolled bleeding and death.

Second, the compound may modulate the properties of proteins that are distinct from the target molecule itself, referred to as **off-target toxicity**. Compounds that are directed to one member of a family of enzymes or receptors often bind to other family members. For example, an antiviral drug directed against viral proteases may be toxic if it also inhibits proteases that perform critical functions in the body, such as those that regulate blood pressure. A compound may also be toxic if it modulates the activity of a protein unrelated to its intended target. For example, many compounds block ion channels such as the potassium channel hERG (Section 13.4), causing potentially life-threatening disturbances of cardiac rhythm. To prevent cardiac side effects, many compounds are screened for their ability to block such channels.

Finally, even if a compound is not itself toxic, its metabolic by-products may be. Phase I metabolic processes can generate damaging reactive groups in products. An important example is liver toxicity observed with large doses of the common pain reliever acetaminophen (**Figure 32.23**).

A particular cytochrome P450 isozyme oxidizes acetaminophen to *N*-acetyl-*p*-benzoquinone imine, and the resulting compound is conjugated to glutathione. With large doses, however, the liver's supply of glutathione is exhausted, and the liver is no longer able to protect itself from the imine and other metabolites. Initial symptoms of excessive acetaminophen include nausea and vomiting. Within 24 to 48 hours, symptoms of liver failure may appear. Acetaminophen poisoning accounts for about 35% of cases of severe acute liver failure in the United States. A liver transplant is often the only effective treatment.

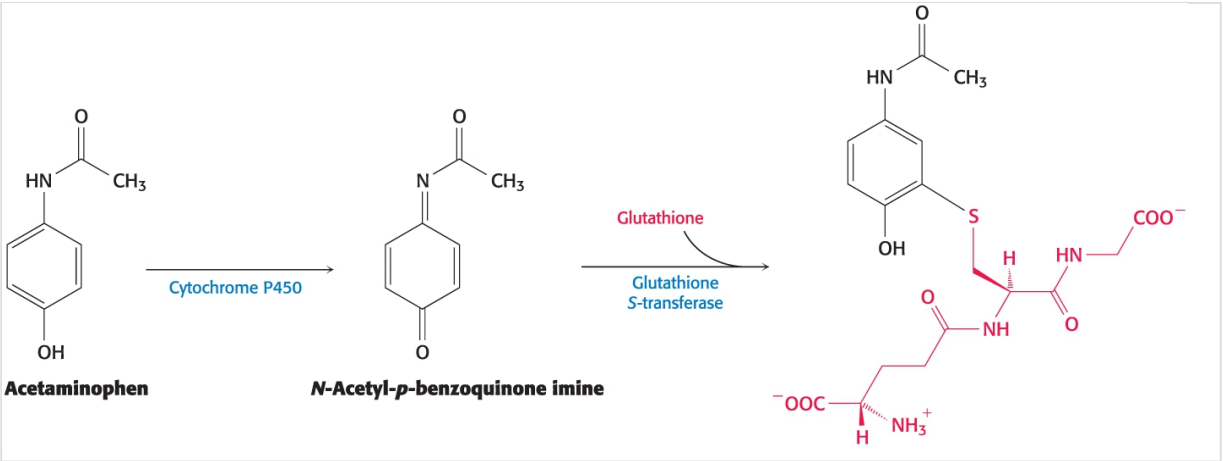

FIGURE 32.23 Acetaminophen metabolism results in its toxicity. A minor metabolic product of acetaminophen is *N*-acetyl-*p*-benzoquinone imine, which is conjugated to glutathione. Large doses of acetaminophen can thus deplete liver glutathione stores.

The toxicity of a drug candidate can be described in terms of the **therapeutic index**. This measure of toxicity is determined through animal tests, usually with mice or rats. The therapeutic index is defined as the ratio of the dose of a compound that is required to kill one-half of the animals (referred to as the LD_{50} for "lethal dose") to a comparable measure of the effective dose, usually the EC_{50}. So, if the therapeutic index is 1000, then lethality is significant only when 1000 times the

effective dose is administered. Analogous indices can provide measures of toxicity less severe than lethality.

Many compounds have favorable properties in vitro, yet they fail when administered to a living organism because of difficulties with ADME and toxicity. Expensive and time-consuming animal studies are required to verify that a drug candidate is not toxic, yet differences between animal species in their response can confound decisions about moving forward with a compound toward human studies. One hope is that, with more understanding of the biochemistry of these processes, scientists can develop computer-based models to replace or augment animal tests. Such models would need to accurately predict the fate of a compound inside a living organism from its molecular structure or other properties that are easily measured in the laboratory without the use of animals.

Lead molecules can be optimized on the basis of three-dimensional structural information about their targets

Many drugs bind to their targets in a manner reminiscent of Emil Fischer's lock-and-key model (Figure 5.8). In principle, we should be able to design a key, given enough knowledge about the shape and chemical composition of the lock. In the idealized case, we could design a small molecule that is complementary in shape and electronic structure to a target protein so that it binds effectively to the targeted site. Yet, despite our ability to determine three-dimensional structures rapidly, the achievement of this goal remains elusive. Designing stable compounds from scratch that have the correct shape and properties to fit precisely into a binding site is difficult because predicting the structure that will best fit into a binding site is difficult. Prediction of binding affinity requires a detailed understanding of the interactions between a compound and its binding partner and of the interactions

between the compound and the solvent when the compound is free in solution.

Nonetheless, **structure-based drug design** has proved to be a powerful tool in drug development. In this approach, the structure of the target complexed with compounds of interest are determined. Chemists can use these structural data to make directed changes to these molecules that are predicted to improve their affinities to the target. The structures of these new molecules can then be determined in complex with the target, and the process can be repeated over several cycles.

 One of the most prominent successes of structure-based drug design has been the development of drugs that inhibit the protease from the human immunodeficiency virus (HIV). In this case, two sets of promising inhibitors that had high potency but poor solubility and bioavailability were discovered. X-ray crystallographic analysis and molecular-modeling findings suggested that a hybrid of these two inhibitor sets might have both high potency and improved bioavailability (**Figure 32.24**). The synthesized hybrid compound did show improvements but required further optimization.

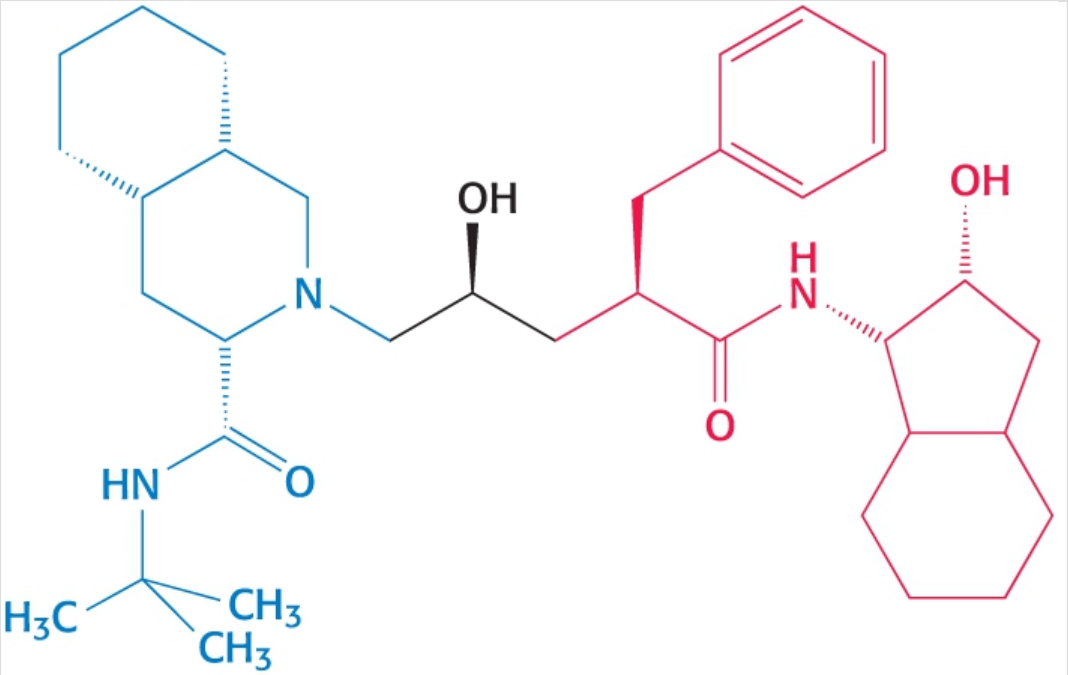

FIGURE 32.24 Structural information led to the initial design of an HIV protease inhibitor. This compound was designed by combining part of one compound with good inhibition activity but poor solubility (shown in red) with part of another compound with better solubility (shown in blue).

Guided by structural data, a series of compounds were prepared and tested for their ability to inhibit the protease (**Figure 32.25**). These data demonstrate a **structure–activity relationship (SAR)**; they provide an opportunity to correlate each compound's structure with its function to guide the design of further molecules. The most active compound showed poor bioavailability, but one of the other compounds (highlighted in yellow in Figure 32.25) showed good bioavailability and acceptable activity. The maximum serum concentration available through oral administration was significantly higher than the levels required to suppress replication of the virus. Ultimately, this molecule became the marketed HIV protease inhibitor indinavir (Section 6.2). This drug, as well as other protease inhibitors developed at about the same time, has been used in combination with other drugs to treat HIV

infection and AIDS with much more encouraging results than had been obtained previously.

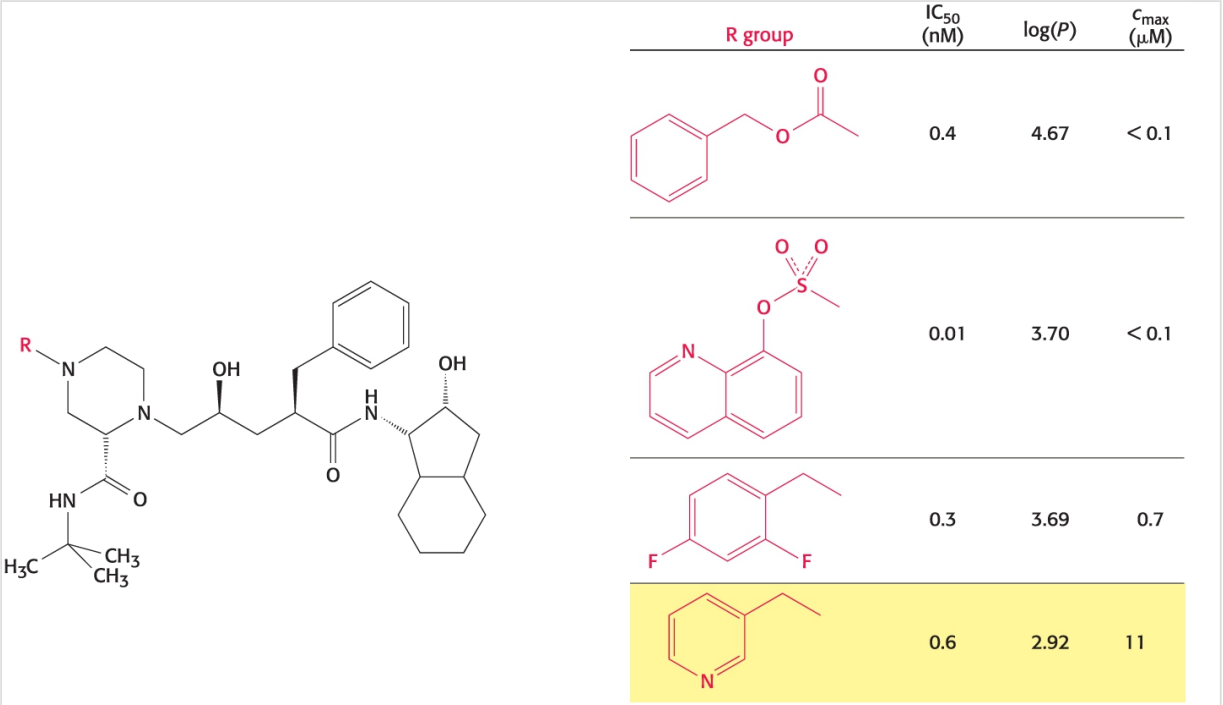

FIGURE 32.25 Optimizing lead molecules requires the balancing of multiple compound properties. Four HIV protease inhibitors were evaluated for characteristics, including the IC_{50}, log(*P*), and C_{max} (the maximal concentration of compound present) measured in the serum of dogs. The compound shown at the bottom (highlighted in yellow) has the weakest inhibitory power (measured by IC_{50}) but by far the best bioavailability (measured by C_{max}). This compound was selected for further development, ultimately leading to the drug indinavir.

The development of indinavir represents an example of the challenges faced by pharmaceutical scientists during the process of lead optimization. Potency is only one of multiple properties that must be optimized during this stage. During the course of a discovery program, thousands of compounds may be synthesized and tested. Improvements in one property may be to the detriment of other properties. The collaboration of many scientists — biochemists, pharmacologists,

chemists, and biologists, just to name a few — is required to attain a molecule suitable for testing in humans.

32.4 Biologics Are a Growing Family of Drugs

In this chapter, we have primarily focused on small molecules as drugs. These molecules are typically less than 500 Da in molecular weight (as described by Lipinski's rules), may be orally bioavailable, and bind to specific structural pockets on their targets. Many small molecule drugs are membrane-permeable, enabling them to access intracellular targets. However, they also exhibit some limitations, including short half-lives and a high susceptibility to off-target toxicity.

Over the past several decades, a new class of therapeutics has emerged. Broadly defined, **biologics** are medicines derived from living cells or through biological processes. With each scientific advancement, the number and different types of biologics have grown significantly (Table 32.1). As this is a highly diverse group of medicines, we will consider some of the more prominent examples here.

TABLE 32.1 Examples of biologics

Recombinant proteins
Monoclonal antibodies
Vaccines
Blood and blood components

Allergenics (molecules that elicit an allergic response)
Cells and tissues

The majority of biologics are recombinant proteins

Earlier, we discussed the first approved biologic: recombinant human insulin produced in *E. coli* (Section 9.2). Approved by the U.S. Food and Drug Administration (FDA) in 1982, this groundbreaking drug enabled the treatment of millions of diabetic patients without the risk of allergic reactions caused by insulins produced by other animal species.

Since the approval of insulin, a number of recombinant proteins have been approved for clinical use. For example, granulocyte colony-stimulating factor (G-CSF) is a 174-amino-acid glycoprotein that stimulates the production of granulocytes in the bone marrow. A recombinant form of G-CSF (filgrastim) was approved by the FDA in 1991 for patients suffering from low neutrophil counts due to HIV infection or some forms of chemotherapy. Similarly, other signaling proteins have been developed as biologics.

Recombinant protein biologics may be chemically modified to improve their pharmacokinetic properties. For example, filgrastim has a short half-life of around 3.5 hours, requiring once- or twice-daily dosing. Through the covalent attachment of a 20-kD polyethylene glycol (PEG) moiety to filgrastim, a process referred to as *pegylation*, its half-life can be extended to 40 hours. A single injection of the pegylated form of filgrastim, pegfilgrastim, exhibits

the same biological effect as 11 daily doses of the nonpegylated protein.

Monoclonal antibodies are highly specific and potent recombinant protein biologics

As we discussed in Section 3.4, antibody-producing cells have evolved remarkable mechanisms for generating a broad range of recognition diversity. Scientists can take advantage of nature's own combinatorial chemistry to generate numerous distinct antibodies that can bind to a specific ligand. In addition, the hybridoma method (Section 4.2) can be used to prepare large quantities of monoclonal antibodies that exhibit high affinities for their targets.

As drugs, monoclonal antibodies have unique advantages over small molecules. For example, they can recognize a broader surface of the target; they are not limited to the smaller pockets typically bound by small molecule drugs. This larger interaction surface enables the development of drugs with very high potency and specificity. Furthermore, the Fc region of monoclonal antibodies (Figure 3.40) binds to an endogenous salvage pathway receptor, the *neonatal Fc receptor* (FcRn), permitting the drug to persist in an active form for a very long half-life, on the order of weeks. Hence, monoclonal antibodies can be dosed much less frequently (e.g., weekly to monthly) than small-molecule drugs (e.g., daily).

There are some limitations to using monoclonal antibodies as drugs. First, as they are proteins, they are unable to withstand the harsh environment of the gastrointestinal tract. Hence, antibodies cannot be dosed orally and are usually administered under the skin (subcutaneously) or directly into blood vessels (intravenously).

Additionally, antibodies do not cross membranes readily, so they generally are usable only against secreted or cell-surface targets. Despite these limitations, however, over 60 monoclonal antibodies are currently in clinical use as therapeutics, with hundreds more in clinical development.

How do monoclonal antibodies exert their therapeutic effects? In many cases, they serve as antagonists, blocking receptors from interacting with their corresponding ligands. This was the case for cetuximab, the chemotherapeutic monoclonal antibody that blocks the epidermal growth factor (EGF) receptor from binding EGF (Section 14.5). Alternatively, some monoclonal antibodies bind specific circulating ligands, preventing them from exerting their cellular effects. In other cases, monoclonal antibodies can be used to target specific cell-surface proteins — such as markers specific for tumor cells — for degradation by the host's own immune system.

Another unique example is the *antibody-drug conjugate* (ADC). In this case, a small molecule drug is conjugated to an antibody specific for a particular cell type. Once the antibody-target complex is internalized by the cell, the linker between the antibody and the drug is cleaved, and the free drug can exert its effects. In this manner, the off-target toxicity of a particular drug can be limited by directing its activity to a small subset of cells within the body.

Monoclonal antibodies represent a rapidly growing and exciting drug class. These versatile molecules have been exploited in numerous creative ways to provide clinical benefit for a variety of diseases besides cancer, including inflammatory, infectious, cardiovascular, and ophthalmologic conditions.

Will & Deni McIntyre/The Chronicle Collection/Getty Images

GERTRUDE ELION At the age of 15, Gertrude Elion was inspired to pursue a career in science and medicine after her grandfather's death from stomach cancer. Her family was bankrupted by the stock market crash in 1929, but she was able to attend Hunter College for free, where she achieved great academic success. At the age of 19, she took jobs as a secretary, a chemistry teacher, and an unpaid laboratory assistant, after which she had saved enough money to enroll in the graduate program at New York University, where she obtained her Master of Science degree in chemistry in 1941. During World War II, with many male chemists serving overseas, Elion was able to secure a research position at

Burroughs Wellcome, where she began a lifelong collaboration with George Hitchings (both scientists are shown above). Together, they eschewed the “trial-and-error” approach to drug discovery, exploiting differences in metabolism between human cells and pathogens to target infectious organisms and tumors. Her work with Hitchings led to the discovery of numerous antibacterial, antiviral, immunosuppressive, and chemotherapeutic medicines, and their efforts were recognized with the Nobel Prize in Physiology or Medicine in 1988.

Self-Check Question

A number of Fc domain mutations have been discovered that enhance the affinity of an antibody for FcRn. What effect would those mutations have on the half-life of a monoclonal antibody drug?

32.5 The Clinical Development of Medicines Proceeds Through Several Phases

In the United States, the FDA requires demonstration that drug candidates be effective and safe before they may be used in human beings on a large scale. This requirement is particularly true for drug candidates that are to be taken by people who are relatively healthy. More side effects are acceptable for drug candidates intended to treat significantly ill patients such as those with serious forms of cancer, where there are clear, unfavorable consequences for not having an effective treatment.

Clinical trials are time-consuming and expensive

Clinical trials test the effectiveness and potential side effects of a candidate drug before it is approved by the FDA for general use. These trials proceed in at least three phases (Figure 32.26). In Phase I, a small number (typically from 10 to 100) of usually healthy volunteers take the drug for an initial assessment of safety. These volunteers are given a range of doses and are monitored for signs of toxicity. The efficacy of the drug candidate is not specifically evaluated.

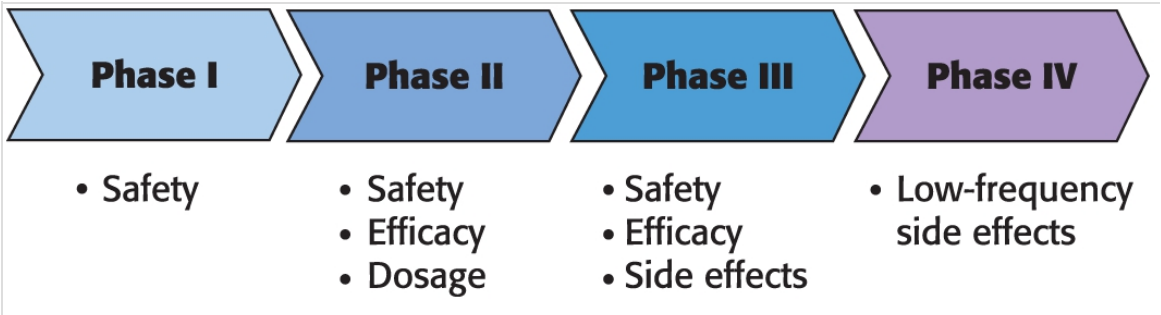

FIGURE 32.26 Clinical trials proceed in phases examining safety and efficacy in increasingly large groups.

In Phase II, the efficacy of the drug candidate is tested in a small number of persons who might benefit from the drug, and further data regarding the drug's safety are obtained. Such trials are often controlled and double-blinded. In a **controlled study**, subjects are divided randomly into two groups. Subjects in the treatment group are given the treatment under investigation. Subjects in the control group are given either a **placebo** — that is, a treatment such as sugar pills known to not have intrinsic value — or the best standard treatment available, if withholding treatment altogether would be unethical. In a **double-blinded study**, neither the subjects nor the researchers know which subjects are in the treatment group and which are in the control group. A double-blinded study prevents bias in the course of the trial. Only when the trial has been completed are the assignments of the subjects into treatment and control groups unsealed and the results for the two groups compared. A variety of doses are often investigated in Phase II trials to determine which doses appear to be free of serious side effects and which doses appear to be effective.

The power of the **placebo effect** — that is, the tendency to perceive improvement in subjects who believe that they are receiving a potentially beneficial treatment — should not be underestimated. In a study of arthroscopic surgical treatment for knee pain, for example, subjects who were led to believe that they had received surgery through the use of videotapes and other means showed the same level of improvement, on average, as subjects who actually received the procedure.

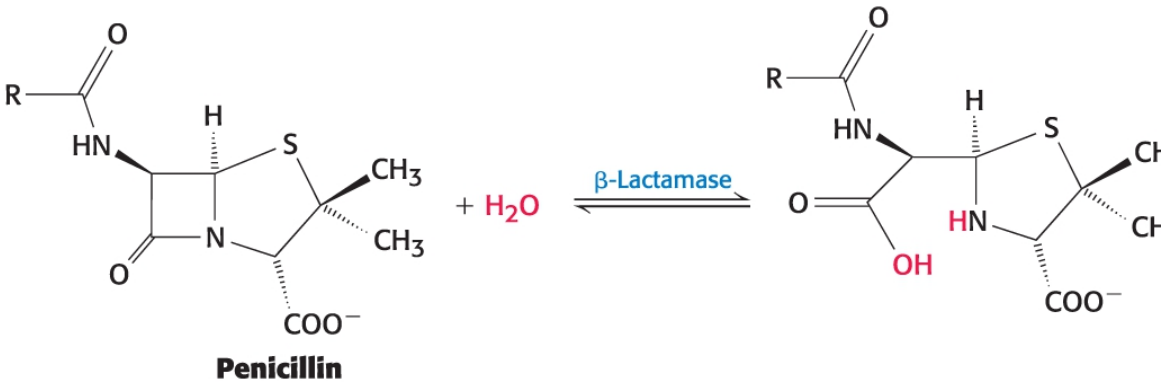
In Phase III, similar studies are performed on a larger and more diverse population. This phase is intended to more firmly establish the efficacy

of the drug candidate and to detect side effects that may develop in a small percentage of the subjects who receive treatment. Thousands of subjects may participate in a typical Phase III study.

Clinical trials can be extremely costly and time-consuming. Hundreds or thousands of patients must be recruited and monitored for the duration of the trial. Many physicians, nurses, clinical pharmacologists, statisticians, and others participate in the design and execution of the trial. Costs can run from tens to hundreds of millions of dollars. Extensive records must be kept, including documentation of any adverse reactions. These data are compiled and submitted to the FDA. Furthermore, many drugs fail to show efficacy in these larger studies where the patient population is more diverse. The full cost of developing a drug is currently estimated to be more than $800 million.

Even after a drug has been approved and is in use, difficulties can arise. Clinical trials that are run after a drug has entered the market, referred to as Phase IV or *postmarketing surveillance* studies, are designed to identify low-frequency side effects that may emerge only after widespread or long-term use. For example, the cyclooxygenase-2 inhibitor rofecoxib was withdrawn from the market after significant cardiac side effects were detected in Phase IV clinical trials. Such events highlight the necessity for doctors and patients to balance beneficial effects against potential risks for any medicine.

The evolution of drug resistance can limit the utility of drugs for infectious agents and cancer



Many drugs are used for long periods of time without any loss of effectiveness. However, in some cases, particularly for the treatment of cancer or infectious diseases, drug treatments that were initially

effective become less so. In other words, the disease becomes resistant to the drug therapy. Why does this resistance develop? Infectious diseases and cancer have a common feature — namely, that an affected person contains many cells (or viruses) that can mutate and reproduce, meeting the two conditions necessary for evolution to take place. Thus, an individual virus, microorganism, or cancer cell may, by chance, have a genetic variation that makes it more suitable for growth and reproduction in the presence of the drug. These microorganisms or cells are more fit than others in their population, and they will tend to take over the population. As the selective pressure due to the drug is continually applied, the population of microorganisms or cancer cells will tend to become more and more resistant to the presence of the drug. Note that resistance can develop by a number of mechanisms.

The HIV protease inhibitors discussed in Section 32.3 provide an important example of the evolution of drug resistance. Retroviruses such as HIV are very well suited to this sort of evolution because reverse transcriptase carries out replication without a proofreading mechanism. In a genome of approximately 9750 bases, each possible single point mutation is estimated to appear in a virus particle more than 1000 times per day in each infected person. At this mutation rate, multiple point mutations occur. While most of these mutations either have no effect or are detrimental to the virus, a few of the mutant virus particles encode proteases that are less susceptible to inhibition by the drug. In the presence of an HIV protease inhibitor, these virus particles will tend to replicate more effectively than does the population at large. With the passage of time, the less susceptible viruses will come to dominate the population and the virus population will become resistant to the drug.

Pathogens may become resistant to antibiotics by completely different mechanisms. Some pathogens contain enzymes that inactivate or degrade specific antibiotics. For example, many bacteria are resistant to β-lactams such as penicillin because they contain β-lactamase enzymes.

These enzymes hydrolyze the β-lactam ring and render the drugs inactive.

Many of these enzymes are encoded in plasmids, small circular pieces of DNA often carried by bacteria (Section 9.2). Many plasmids are readily transferred from one bacterial cell to another, transmitting the capability for antibiotic resistance. Plasmid transfer thus contributes to the spread of antibiotic resistance, a major health-care challenge.

Drug resistance commonly emerges in the course of cancer treatment. Cancer cells are characterized by their ability to grow rapidly without the constraints that apply to normal cells. Many drugs used for cancer chemotherapy inhibit processes that are necessary for this rapid cell growth. However, individual cancer cells may accumulate genetic changes that mitigate the effects of such drugs. These altered cancer cells will tend to grow more rapidly than others and will become dominant within the cancer-cell population. This ability of cancer cells to mutate quickly has been a challenge to one of the major breakthroughs in cancer treatment: the development of inhibitors for proteins specific to cancer cells present in certain leukemias (Section 14.5). For example, tumors become undetectable in patients treated with imatinib, a Bcr-Abl protein kinase inhibitor, but in many patients the tumors recur after a period of years. In many of these cases,

mutations have altered the Bcr-Abl protein so that it is no longer inhibited by the concentrations of imatinib used in therapy.

Finally, cancer patients often take multiple drugs concurrently in the course of chemotherapy, and, in many cases, cancer cells become simultaneously resistant to many or all of them. This multiple-drug resistance can be due to the proliferation of cancer cells that overexpress a number of ABC transporter proteins that pump drugs out of the cell (Section 13.2). Thus, cancer cells can evolve drug resistance by overexpressing normal human proteins or by modifying proteins responsible for the cancer phenotype.

Chapter 32 Summary

32.1 Drug Discovery Begins with Target Identification and Validation

- The process of drug discovery is divided into two phases: the discovery phase, where molecules are optimized for testing in humans, and the development phase, where clinical trials are conducted.
- A drug target is a protein or oligonucleotide whose activity, when modulated by a drug, will alter the progression of a disease process.
- Targets should be validated, in that sufficient evidence suggests that it plays an important role in disease progression.
- Targets should also be tractable, in that sufficient evidence suggests that a molecule can be designed to interact with a target.
- Serendipity has played a significant role in the history of drug discovery.

32.2 Lead Molecules Can Be Discovered in Many Ways

- Lead molecules are starting points for optimization into drug candidates.
- Natural products are often a robust source of lead molecules. For example, the first HMG-CoA reductase inhibitors were derived from compounds isolated from the broths of bacteria and fungi.
- High-throughput screening (HTS), in which up to millions of compounds can be tested for their activity against a target, is a valuable source of lead molecules.
- HTS depends on the construction of a large chemical library. Combinatorial chemistry can be used to prepare large

populations of compounds using only a few synthetic steps.
- In phenotypic screening, compounds are tested for their ability to affect a disease-relevant phenotype. The identity of the targets of hits from such screens are determined in subsequent steps.

32.3 Compounds Must Meet Stringent Criteria to Be Developed into Drugs

- Lead optimization is the process by which leads are modified into drug candidates suitable for testing in humans.
- To be effective, drugs must bind to their targets with high affinity and specificity.
- Most compounds are poorly absorbed and rapidly excreted from the body, or they are modified by metabolic pathways that target foreign compounds. Consequently, a drug's ADME properties, related to its absorption, distribution, metabolism, and excretion, must be optimized.
- A compound may also not be a useful drug because it is toxic; it may either modulate the target molecule too effectively (mechanism-based toxicity) or bind to proteins other than the target (off-target toxicity).
- Structural information on the interaction of a compound and its target can be used to drive further optimization of potency and selectivity.

32.4 Biologics Are a Growing Family of Drugs

- Biologics are a diverse class of drugs that are derived from living cells or through biological processes.
- The majority of biologics are recombinant proteins.
- Monoclonal antibodies represent a large proportion of recombinant protein biologics, as they are capable of a high degree of potency and selectivity.

- Because of their interaction with an endogenous salvage pathway, monoclonal antibodies typically exhibit very long half-lives, allowing them to be dosed weekly or monthly.

32.5 The Clinical Development of Medicines Proceeds Through Several Phases

- Before compounds can be given to human beings as drugs, they must be extensively tested for safety and efficacy.
- Clinical trials are performed in stages: first testing safety, then safety and efficacy in a small population; finally, safety and efficacy in a larger population to detect rarer adverse effects.
- With regard to infectious diseases and cancer, patients often develop resistance to a drug after it has been administered for a period of time because variants of the disease agent that are less susceptible to the drug have a selective advantage over more susceptible variants when the drug is present.

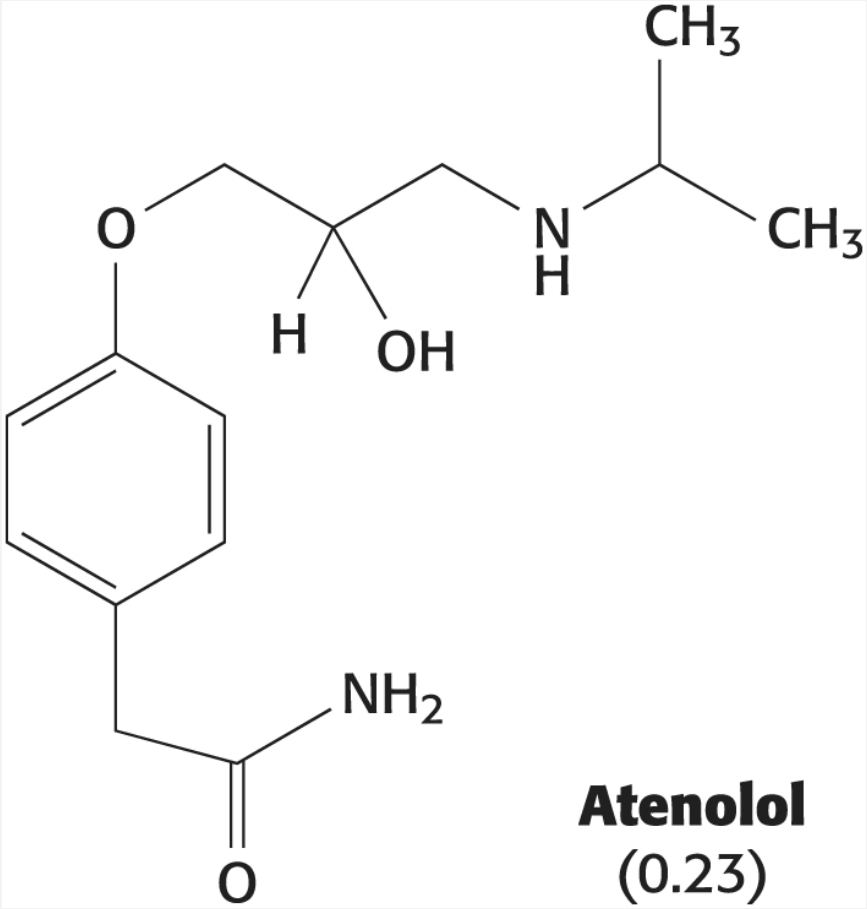
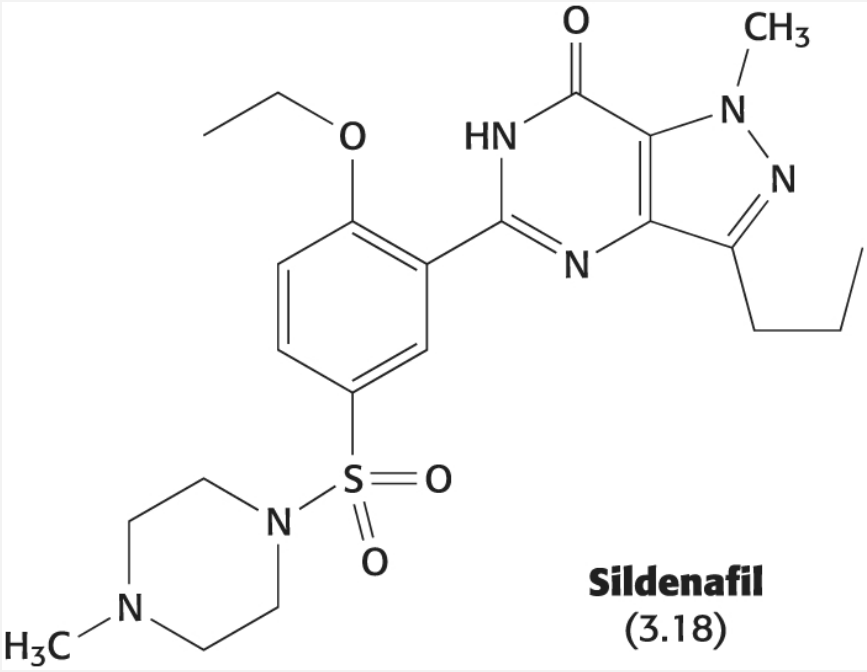
Problems



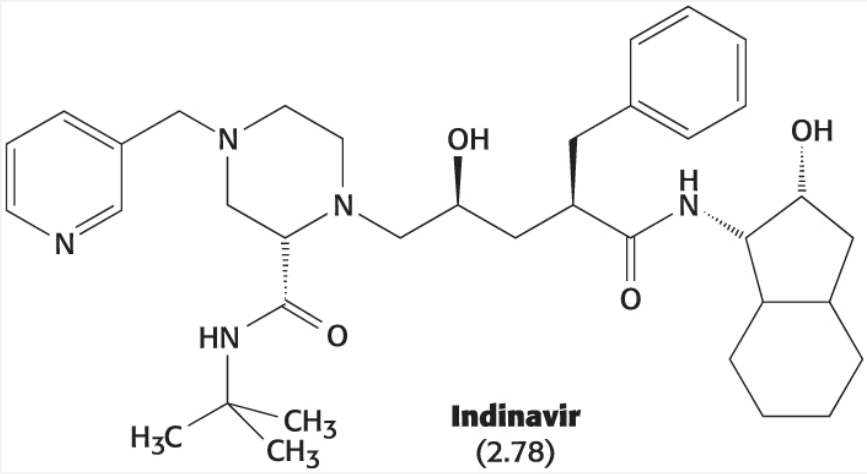
1. Sildenafil induces its physiological effects by increasing the intracellular concentrations of cGMP, leading to muscle relaxation. On the basis of the scheme shown in Figure 32.5, identify another approach for increasing cGMP levels with a small molecule. 1

2. For each of the following drugs, indicate whether the drug discovery was accidental, a result of natural product screening, or the result of targeted design. 2



a. Penicillin
b. Lovastatin
c. Sildenafil
d. Aspirin
e. Indinavir

3. Which of the following compounds satisfy all of Lipinski's rules? Note that log(*P*) values are given in parentheses. 3



A.

B.

(2.78)

4. Name one advantage of a noncompetitive inhibitor as a potential drug compared with a competitive inhibitor. 3

5. Explain why drugs that inhibit P450 enzymes may be particularly dangerous when used in combination with other medications. 4

6. Coumadin can be a very dangerous drug because too much can cause uncontrolled bleeding. Persons taking coumadin must be careful about taking other drugs, particularly those that bind to albumin. Propose a mechanism for this drug–drug interaction.

7. Compound A is one of a series that were designed to be potent inhibitors of HIV protease.

Compound A

Compound A was tested by using two assays: (1) direct inhibition of HIV protease in vitro and (2) inhibition of viral RNA production in HIV-infected cells, a measure of viral replication; results are shown in the following table. The HIV protease activity is measured with a substrate peptide present at a concentration equal to its K_M value.

Compound A (nM)	HIV protease activity (arbitrary units)	Compound A (nM)	Viral RNA production (arbitrary units)
0	11.2	1	4.0
0.2	9.9	2	2.2
0.4	7.4	10	0.9
0.6	5.6	100	0.2
0.8	4.8	0	760
		1.0	740
		2.0	380
		3.0	280
		4.0	180
		5.0	100
		10	30

	50	20

a. Estimate the values for the K_I of compound A in the protease-activity assay and for its IC_{50} in the viral-RNA-production assay.
b. Treating rats with the relatively high oral dose of $20\ mg\ kg^{-1}$ results in a maximum concentration of compound A of 0.4 μM. On the basis of this value, do you expect compound A to be effective in preventing HIV replication when taken orally? Explain.

8. Considerable effort has been expended to develop computer programs that can estimate log(*P*) values entirely on the basis of chemical structure. Why would such programs be useful? 3

9. Distinguish between Phase I and Phase II clinical trials in regard to number of persons enrolled, the state of health of the subjects, and the goals of the study. 7

10. The metabolism of amphetamine by cytochrome P450 enzymes results in the conversion shown here. Propose a mechanism, and indicate any additional products.

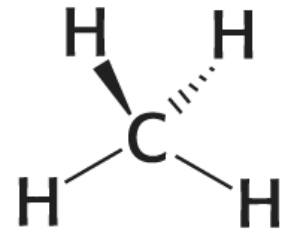
Amphetamine

11. You are studying a collection of competitive inhibitors of an exciting new enzyme. The K_M value for the natural substrate is 1 μM. One member of your team presents to you a list of IC_{50} values for these compounds using an assay that employs a substrate concentration of 20 μM. A week later, another member of your team tells you about her assay that requires a substrate concentration of only 1 μM. She presents you a list of IC_{50} values for the same set of compounds, which are consistently about 10-fold lower than those previously determined. Explain why this drop in IC_{50} is not at all surprising.

12. What are some advantages of using a monoclonal antibody as a drug, as opposed to using a small molecule? 6

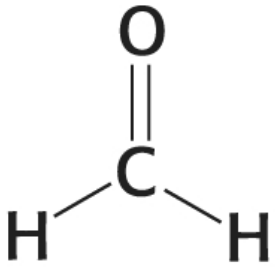
Chemistry Review Appendix

Visualizing Molecular Structures



The authors of a biochemistry textbook face the problem of trying to present three-dimensional molecules in the two dimensions available on the printed page. The interplay between the three-dimensional structures of biomolecules and their biological functions are discussed extensively throughout this book. Toward this end, we frequently use representations that, although of necessity are rendered in two dimensions, emphasize the three-dimensional structures of molecules.

Depicting Structural Formulas

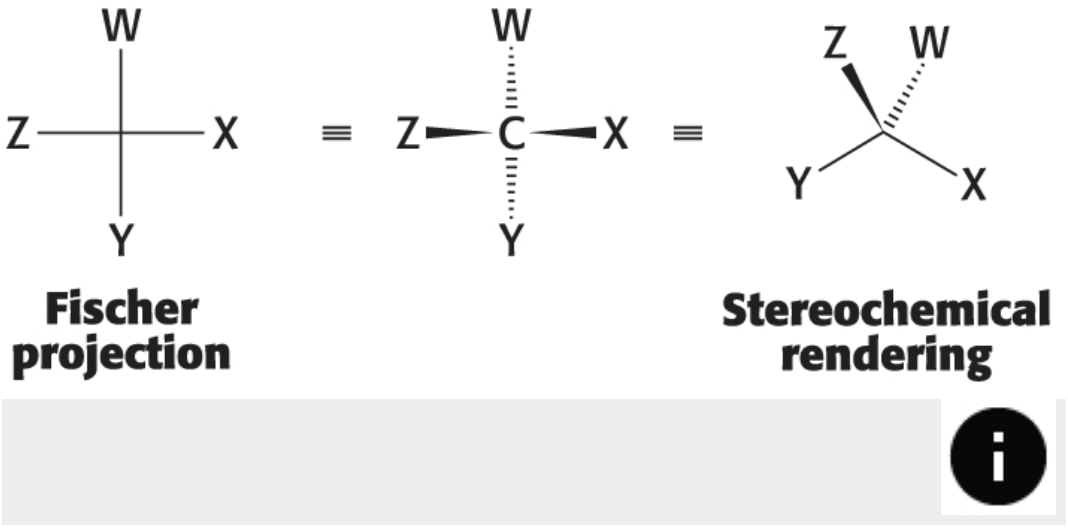


Structural formulas in this book are often shown in two different ways.

Stereochemical Renderings

Most of the chemical formulas in this book are drawn to depict the geometric arrangement of atoms — the stereochemistry — crucial to chemical bonding and reactivity, as accurately as possible. For example, the carbon atom of methane is tetrahedral, with H–C–H angles of 109.5 degrees, whereas the carbon atom in formaldehyde has bond angles of 120 degrees.

Methane



Formaldehyde

To illustrate the correct stereochemistry about tetrahedral carbon atoms, wedges are used to depict the direction of a bond into or out of the plane of the page. A solid wedge with the broad end away from the carbon atom denotes a bond coming toward the viewer out of the plane. A dashed wedge, with its broad end at the carbon atom, represents a bond going away from the viewer behind the plane of the page. The remaining two bonds are depicted as straight lines.

Fischer Projections

Although representative of the actual structure of a compound, stereochemical structures are often difficult to draw quickly. An alternative, less-representative method of depicting structures with tetrahedral carbon centers relies on the use of Fischer projections.

In a Fischer projection, the bonds to the central carbon are represented by horizontal and vertical lines from the substituent atoms to the carbon atom, which is assumed to be at the center of the cross. By convention, the horizontal bonds are assumed to project out of the page toward the viewer, whereas the vertical bonds are assumed to project behind the page away from the viewer.

Depicting Small Molecules

For depicting the molecular architecture of small molecules in more detail, two types of models are often used in this book: space filling and ball-and-stick. These models show structures at the atomic level.

Space-Filling Models

The space-filling models are the most realistic. The size and position of an atom in a space-filling model are determined by its bonding properties and van der Waals contact distance, or the van der Waals radius. The van der Waals radius describes how closely two atoms can

approach each other when they are not linked by a covalent bond. The colors of the model are set by convention.

Carbon, black	Hydrogen, white	Nitrogen, blue
Oxygen, red	Sulfur, yellow	Phosphorus, purple

Space-filling models of several simple molecules are shown in Figure 1.

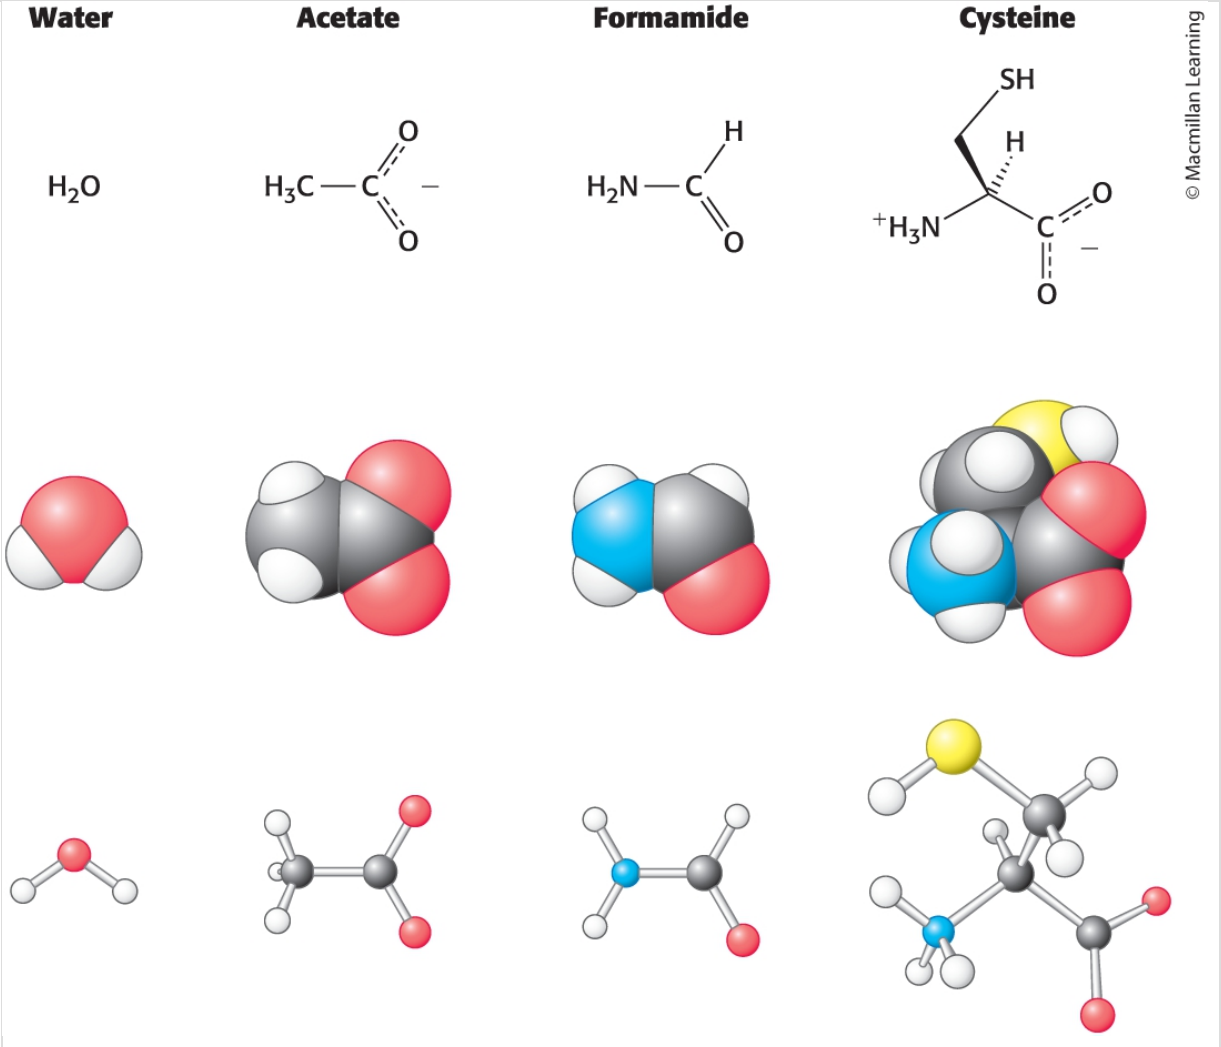


FIGURE 1 Molecules are depicted in various ways. Structural formulas (top), space-filling representations (middle), and ball-and-stick models (bottom) of several molecules are

shown.

Ball-and-Stick Models

Ball-and-stick models are not as realistic as space-filling models, because the atoms are depicted as spheres of radii smaller than their van der Waals radii. However, the bonding arrangement is easier to see because the bonds are explicitly represented as sticks. The taper of a stick helps to depict perspective and indicates which of a pair of bonded atoms is closer to the reader. Thus, a ball-and-stick model reveals a complex structure more clearly than a space-filling model does. Ball-and-stick models of several simple molecules are shown in Figure 1.

Depicting Protein Structures

Many of the powerful techniques for the determination of protein structure discussed in Chapter 4 allow the positions of the thousands of atoms within a protein to be determined. The final results include the x, y, and z coordinates for each atom in the structure. These coordinate files are compiled in the Protein Data Bank (https://www.wwpdb.org), from which they can be readily downloaded. These structures comprise thousands or even tens of thousands of atoms.

The complexity of proteins with thousands of atoms presents a challenge for the depiction of their structure. Several different types

of representations are used to portray proteins, each with its own strengths and weaknesses. The types that you will see most often in this book are space-filling models, ball-and-stick models, backbone models, and ribbon diagrams. Where appropriate, structural features of particular importance or relevance are noted in an illustration's legend.

Space-Filling Models

Space-filling models are the most realistic type of representation. Each atom is shown as a sphere with a size corresponding to the van der Waals contact distance of the atom. Bonds are not shown explicitly but are represented by the intersection of the spheres shown when atoms are closer together than the sum of their van der Waals contact distances. All atoms are shown, including those that make up the backbone and those in the side chains. A space-filling model of lysozyme is depicted in **Figure 2**.

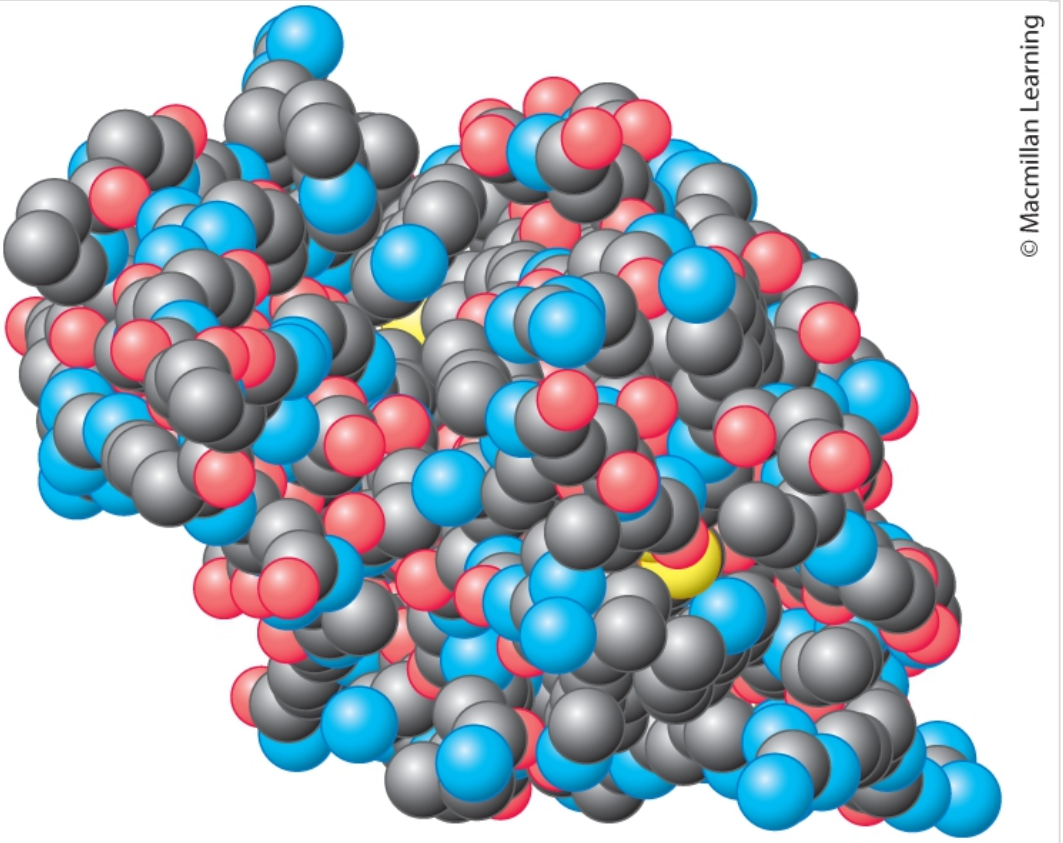

FIGURE 2 A space-filling model shows the atoms tightly packed. Hydrogen atoms are often omitted because their positions are not often readily determined and because excluding them aids visualization of the other atoms. The protein lysozyme is depicted here and in the next four figures.

Space-filling models convey a sense of how little open space there is in a protein's structure, which always has many atoms in van der Waals contact with one another. These models are particularly useful in showing conformational changes in a protein from one set of circumstances to another. A disadvantage of space-filling models is that the secondary and tertiary structures of the protein are difficult to see. Thus, these models are not very effective in distinguishing one protein from another — many space-filling models of proteins look very much alike.

Ball-and-Stick Models

Ball-and-stick models are not as realistic as space-filling models. Realistically portrayed atoms occupy more space, determined by their van der Waals contact distances, than do the atoms depicted in ball-and-stick models. However, the bonding arrangement is easier to see because the bonds are explicitly represented as sticks (Figure 3). A ball-and-stick model reveals a complex structure more clearly than a space-filling model does. Yet, the depiction is so complicated that structural features such as α helices or potential binding sites are difficult to discern.

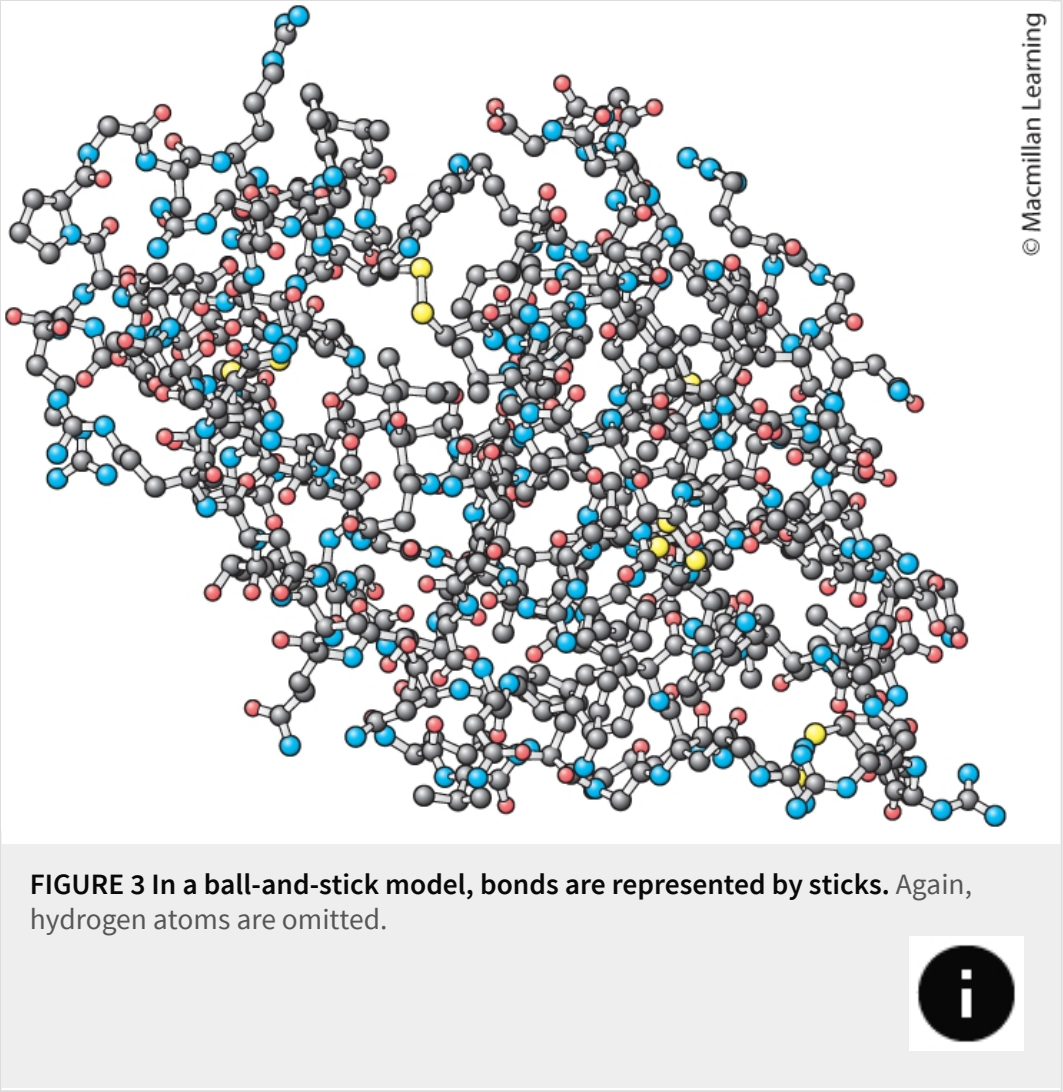

FIGURE 3 In a ball-and-stick model, bonds are represented by sticks. Again, hydrogen atoms are omitted.

Because space-filling and ball-and-stick models depict protein structures at the atomic level, the large number of atoms in a complex structure makes it difficult to distinguish the relevant structural features. Thus, representations that are more schematic — such as backbone models and ribbon diagrams — have been developed for the depiction of macromolecular structures. In these representations, most or all atoms are not shown explicitly.

Backbone Models

Backbone models show only the backbone atoms of a polypeptide chain, or sometimes only the α-carbon atom of each amino acid. Atoms are linked by lines representing bonds; if only α-carbon atoms are depicted, lines connect α-carbon atoms of amino acids that are adjacent in the amino acid sequence (**Figure 4**). While in Figure 4, the α-carbon atoms are shown, elsewhere in this book backbone models show only the lines connecting the α-carbon atom positions; bonds to other carbon atoms are not depicted.

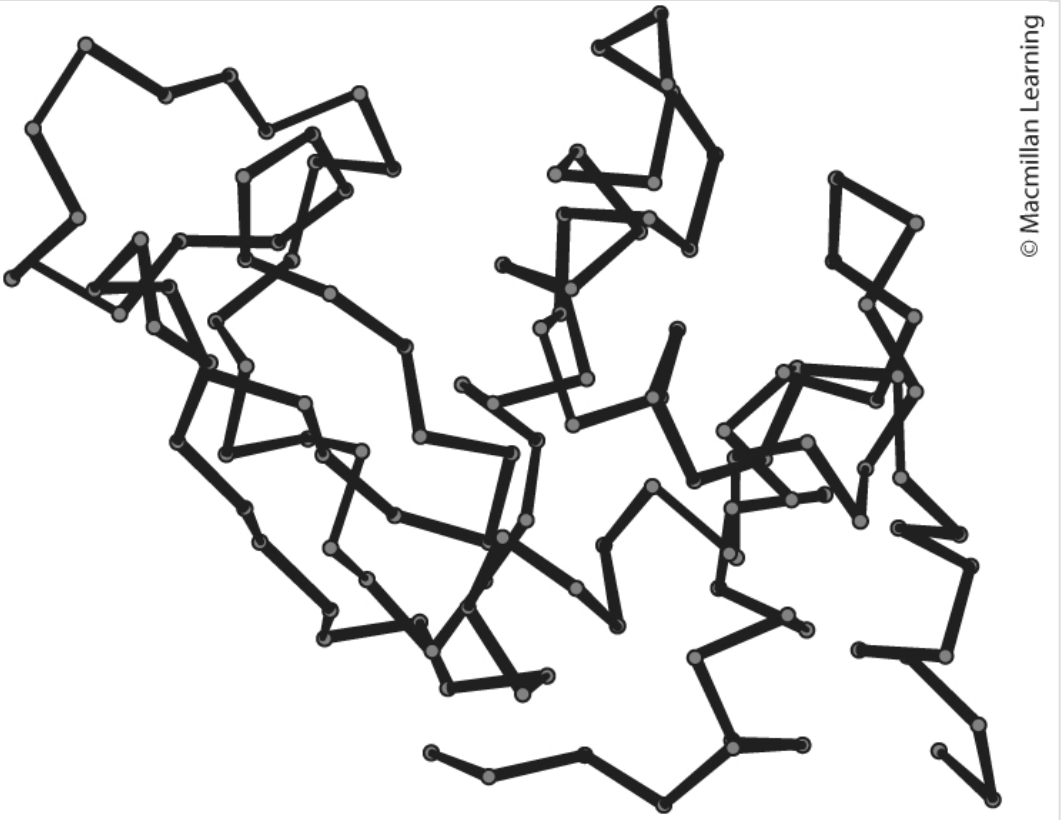

FIGURE 4 In a backbone model, only the backbone polypeptide chain is represented. In this model, the α carbons of the adjacent amino acids are shown in gray and lines relating their positions in black. Many backbone models omit the atoms and include only the lines.

A backbone model shows the overall course of the polypeptide chain much better than a space-filling or ball-and-stick model does. However, secondary structural elements are still difficult to see.

Ribbon Diagrams

Ribbon diagrams are highly schematic and most commonly used to accent a few dramatic aspects of protein structure, such as the α

helix, depicted as a coiled ribbon or a cylinder. The β strand is depicted as a broad arrow, and loops, turns, and random coil structure are all shown with thin tubes. These structural depictions provide the clearest views of the folding patterns of proteins (**Figure 5**). The ribbon diagram allows the course of a polypeptide chain to be traced and readily shows the secondary structural elements. Thus, ribbon diagrams of proteins that are related to one another by evolutionary divergence appear similar (as shown in Figure 10.13), whereas unrelated proteins are clearly distinct.

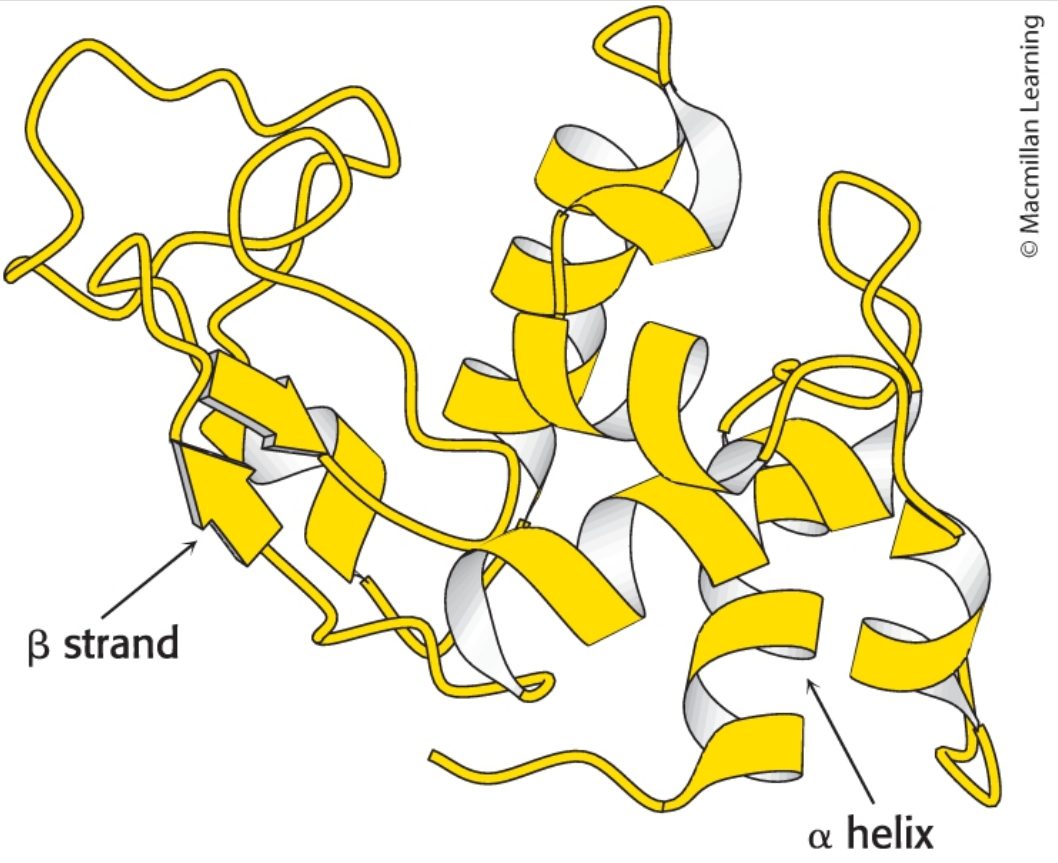

FIGURE 5 In a simple ribbon diagram, the α helices are shown as coiled ribbons and β strands are depicted as arrows. More irregular structures are shown as thin tubes.

In this book, coiled ribbons are generally used to depict α helices. However, for membrane proteins, which are often quite complex, cylinders are used rather than coiled ribbons. This convention also makes membrane proteins with their membrane-spanning α helices easy to recognize (as shown in Figure 12.18).

Bear in mind that the open appearance of ribbon diagrams is deceptive. As noted earlier, protein structures are tightly packed and have little open space. However, the openness of ribbon diagrams makes them particularly useful as frameworks in which to highlight additional aspects of protein structure. Active sites, substrates, bonds, and other structural fragments can be included in ball-and-stick or space-filling form within a ribbon diagram (**Figure 6**).

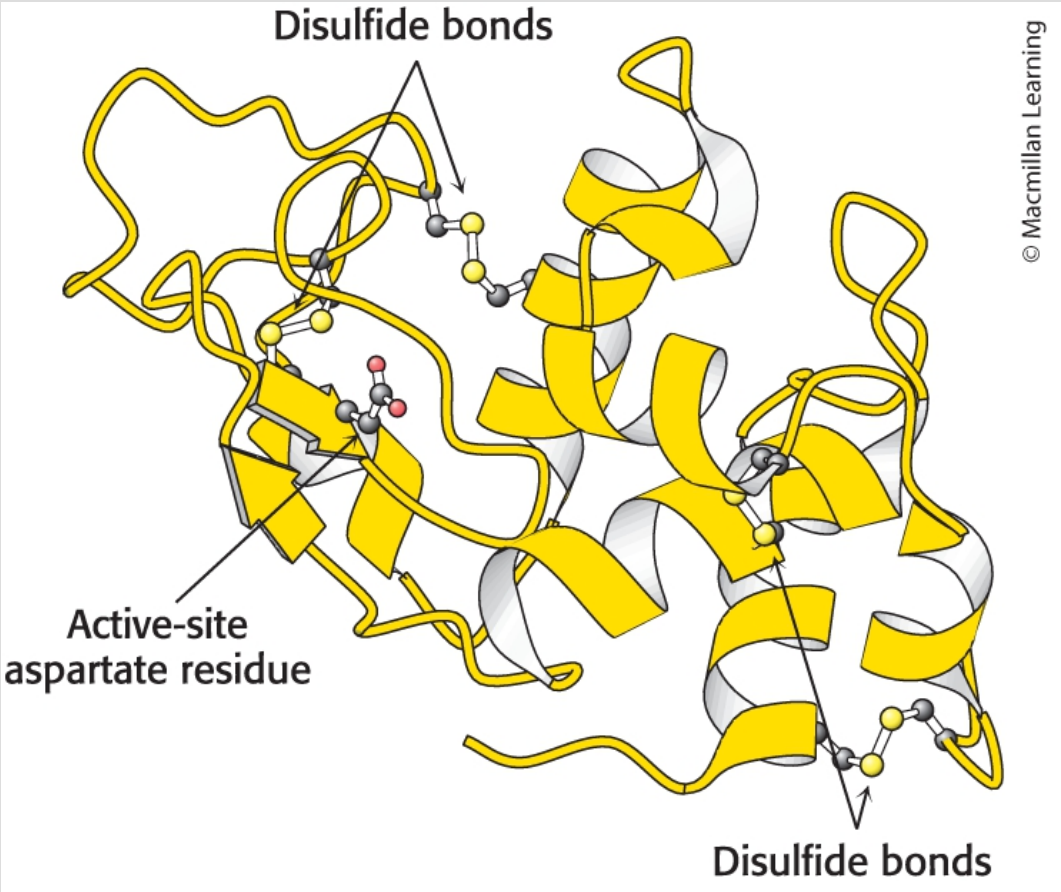

FIGURE 6 An enhanced ribbon diagram may show functionally important areas using ball-and-stick. Four disulfide bonds and a functionally important aspartate

residue of lysozyme are shown in ball-and-stick form.

Functional Groups

Biochemistry depends on many concepts and principles from organic chemistry. The properties of individual atoms are substantially affected by the other atoms to which they are bonded. Functional groups are specific combinations of a small number of atoms that often have properties that are relatively independent of other aspects of the molecules in which they are found. There are many functional groups in organic chemistry, but a relatively small number of these are central to biochemistry:

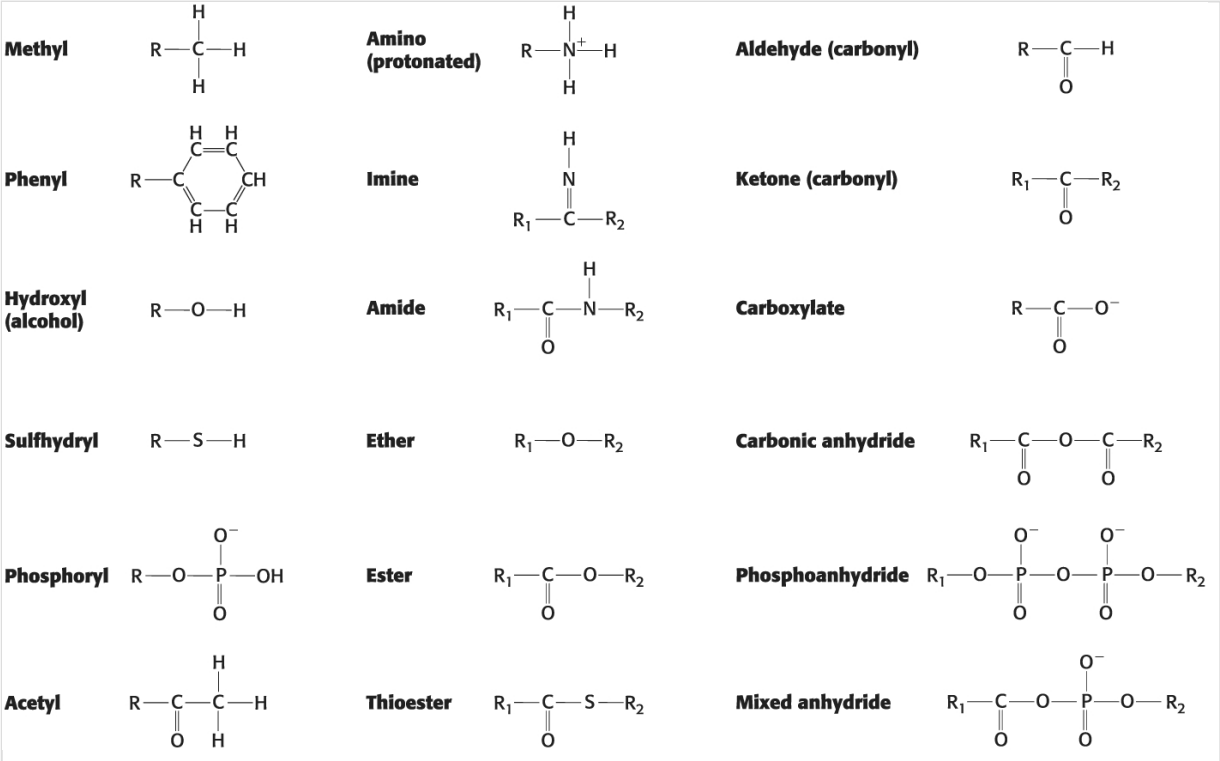
- *Hydroxyl group,* $-OH$ A hydroxyl group comprises an oxygen atom bonded to a hydrogen atom. The hydroxyl group can both donate and accept hydrogen bonds. The hydroxyl group is both a very weak acid and a very weak base.

- *Amino group,* $-NH_2$ An amino group comprises a nitrogen atom bonded to two hydrogen atoms. The amino group can both donate and accept hydrogen bonds. The amino group often behaves as a base, accepting a hydrogen ion to form an ammonium group, $-NH_3^+$.

- *Carbonyl group,* $\rangle C{=}O$ A carbonyl group comprises a carbon atom double bonded to an oxygen atom. The carbonyl group can act as a hydrogen bond acceptor but not a donor. The carbonyl

group is found in many different classes of compounds, depending on the other groups that are bonded to the carbon atom. The most important carbonyl-containing functional group in biochemistry is the amide, in which the carbonyl carbon is bonded to one carbon and one nitrogen.

It may be beneficial to review the name and structure of some common functional groups so that you can recognize them readily during your study of biochemistry. Figure 7 lists some commonly encountered groups.



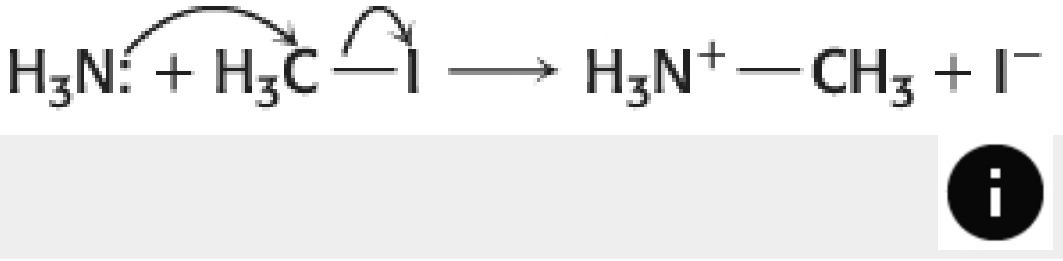


FIGURE 7 Functional groups define many important properties of macromolecules.

Reaction Mechanisms: “Arrow Pushing”

Many aspects of biochemistry depend on chemical reactions in which covalent bonds are broken and formed. These reactions involve the flow of electrons out of bonds and into spaces between atoms in which new bonds are formed. It is often useful to depict such reactions with arrows to represent this electron flow. The process of analyzing reactions in this way is sometimes referred to informally as “arrow pushing” or “electron pushing.”

Consider the reaction between ammonia, NH_3, and methyl iodide, $H_3C—I$. NH_3 has a lone pair of electrons on the nitrogen atom that can participate in bond formation. The iodine atom in $H_3C—I$ can accept electrons to form the relatively stable iodide ion, I^-. The reaction and its mechanism are shown below:

The first arrow depicts the flow of the electron pair from the nitrogen to the space between the nitrogen and the carbon to form the new nitrogen–carbon bond. The second arrow shows the flow of electrons from the carbon–iodine bond to the iodine to form the iodide ion. The initial product of this reaction is methylammonium ion, methylamine in its protonated form. In this reaction, ammonia is the nucleophile, meaning the molecule or group that donates an electron pair during a reaction.

In this book, we encounter many examples of reaction mechanisms, particularly when we discuss the actions of enzymes — the essential

catalysts that facilitate so much of biochemistry.

Answers to Self-Check Questions

Chapter 1

Page 7 TATCGGACCT
Page 14 The enthalpy change (heat released or absorbed by the system) accounts for entropy changes in the surroundings.
Page 20 15.14
Page 26 No

Chapter 2

Page 41 Isoleucine and threonine. Both these atoms feature four unique groups emerging from the first carbon atom in their side chains. These atoms are indicated by an asterisk in Figures 2.6 and 2.7.

Page 46 Proline and glycine. The cyclic side chain of proline linking the nitrogen and α-carbon atoms limits φ to a very narrow range (around -60 degrees). The lack of steric hindrance exhibited by the side chain hydrogen atom of glycine enables this amino acid to access a much greater area of the Ramachandran plot.

Page 50 There are about 3.6 amino acids per turn of an α helix, so residues three or four amino acids apart will appear on the same face. By contrast, adjacent amino acids appear on opposite faces of a β strand, so every other residue will lie on the same face.

Page 53 The amino acids would be hydrophobic in nature. An α helix is especially suited to crossing a membrane because all of the amide hydrogen atoms and carbonyl oxygen atoms of the peptide backbone take part in intrachain hydrogen bonds, thus stabilizing these polar atoms in a hydrophobic environment.

Page 57 If the protein concentration was high upon denaturation, groups from different molecules might interact to form a large, insoluble aggregate.

Chapter 3

Page 72 $50\ \text{nanograms/ml} = 2.3 \times 10^{-9}\ \text{M} = 2.3\ \text{nM}$. The $L_{1/2}$ value would be expected to be in the same range.
Page 72 The dissociation rate is equal to the association rate at equilibrium. $5\ s^{-1}$.

Page 79 b.
Page 80 Since the proximal histidine is not attached to the protein, it is free to move into the plane of the heme when oxygen binds; so, the oxygen affinity is high, similar to that of myoglobin.
Page 88 Total number, 12. Total not counting duplicates, 6; 3 from the light chain and 3 from the heavy chain.
Page 94 The association rate constant is $k_1 = 10^4\ s^{-1}/10^{-3}\ M = 10^7\ M^{-1}s^{-1}$. The dissociation rate constant is $k_{-1} = 50\ s^{-1}$. The dissociation constant is $K_d = 50\ s^{-1}/10^7\ M^{-1}s^{-1} = 5 \times 10^6\ M$.

Chapter 4

Page 107 Note in Figure 4.10 that the relative electrophoretic mobility of proteins is proportional to the *logarithm* of their individual masses. The mass of the protein is 50 kDa.

Page 116 A sandwich ELISA experiment requires both antibodies to be able to simultaneously bind the antigen. If the capture antibody on the plate and the detection antibody both recognize the same epitope, then each antibody will displace the other. Either the antigen will remain bound to the capture antibody and will not be detected, or the antigen will bind to the soluble detection antibody and will be washed away before the detection step.

Page 121 Isoleucine and leucine are isomers and, hence, have identical masses. Peptide sequencing by mass spectrometry as described in this chapter is incapable of distinguishing these two residues. Further analytical techniques are required to differentiate them.

Page 132 Protein crystal formation requires the ordered arrangement of identically positioned molecules. Proteins with flexible linkers can introduce disorder into this arrangement and prevent the formation of suitable crystals.

Chapter 5

Page 144 All three terms apply, but prosthetic group is the most specific.

Page 158 K_M is an intrinsic property of an enzyme because it is independent of the quantity of enzyme measured. In contrast, V_{max} is an extrinsic property because it does depend on the quantity of enzyme observed.

Page 159 The mutation made the enzyme a more efficient catalyst as the catalytic efficiency (k_{cat}/K_M) increased by 50%.

Page 169 Competitive.

Chapter 6

Page 180 Catalysis by approximation (since it brings two substrates together).

Page 189 The same as is shown in Figure 6.8, except that cysteine replaces serine in the active site and no aspartate is present.

Page 193 $10^4\ s^{-1}$. The maximum expected buffer-assisted rate is $10^9\ M^{-1}s^{-1} \times 10^{-6}\ M = 10^3\ s^{-1}$, but the unassisted maximum rate is $10^4\ s^{-1}$.

Page 199 EcoRV binds all sequences with approximately equal affinity but discriminates at the cleavage step.

Page 204 ATP is reversible hydrolyzed in the myosin active site with incorporation of ^{18}O. Some of this ATP is released as ATP rather than $ADP + P_i$ and this ATP will include ^{18}O.

Chapter 7

Page 216 All of the enzyme would be in the R form all of the time. There would be no cooperativity. The kinetics would look like that of a Michaelis–Menten enzyme.

Page 221 The net outcome of the two reactions is the hydrolysis of ATP to ADP and P_i, which has a ΔG of $-50\ \text{kJ mol}^{-1}\ (-12\ \text{kcal mol}^{-1})$ of under cellular conditions.

Page 226 Although quite rare, cases of enteropeptidase deficiency have been reported. The affected person has diarrhea and fails to thrive because digestion is inadequate. In particular, protein digestion is impaired.

Page 232 Antithrombin III is a very slowly hydrolyzed substrate of thrombin. Hence, its interaction with thrombin requires a fully formed active site on the enzyme.

Chapter 8

Page 242 There would be too much charge repulsion from the negative charges on the phosphoryl groups. These charges must be countered by the addition of cations.

Page 248 (a) Hydrogen bonds between base pairs and van der Waals interactions among the bases. The van der Waals interactions come into play because of the hydrophobic effect, which forces the bases to the interior of the helix. (b) One possible explanation is that GC base pairs have three hydrogen bonds compared with two for AT base pairs; the higher content of GC would mean more hydrogen bonds and greater helix stability. Another possibility is that the base stacking interactions are stronger for GC base pairs than for AT base pairs. Careful measurements support the second explanation: the favorable base-stacking energy of GC base pairs largely contributes to the increases in melting temperature.

Page 256 The genetic code is degenerate. Of the 20 amino acids, 18 are specified by more than one codon. Hence, many nucleotide changes (especially in the third base of a codon) do not alter the nature of the encoded amino acid. Mutations leading to an altered amino acid are usually more deleterious than those that do not and hence are subject to more stringent selection.

Chapter 9

Page 266 The presence of the AluI sequence would, on average, be $(1/4)^4$, or $1/256$, because the likelihood of any base being at any position is one-fourth and there are four positions. By the same reasoning, the presence of the NotI sequence would be $(1/4)^8$, or $1/65{,}536$. Thus, the average product of digestion by AluI would be 250 base pairs (0.25 kb) in length, whereas that by NotI would be 66,000 base pairs (66 kb) in length.

Page 270 At high temperatures of hybridization, only very close matches between primer and target would be stable because all (or most) of the bases would need to find partners to stabilize the primer–target helix. As the temperature is lowered, more mismatches would be tolerated; so the amplification is likely to yield genes with less sequence similarity. In regard to the yeast gene, synthesize primers corresponding to the ends of the gene, and then use these primers and human DNA as the target. If nothing is amplified at 54°C, the human gene differs from the yeast gene, but a counterpart may still be present. Repeat the experiment at a lower temperature of hybridization.

Page 278 The average frequency of EcoRI sites in the genome is $(1/4)^6 = 1/4{,}096$, or about once in every 4 kb. Because most human genes are much longer than 4 kb, this would not be a suitable cloning strategy, as most fragments would contain only a small part of a complete gene.

Page 294 Since PAM sequences are required downstream of a particular target site, variants of Cas9 that recognize different PAMs would increase the likelihood that a sgRNA could be designed against a particular target sequence.

Chapter 10

Page 305 Placement of too many gaps in an alignment could artificially increase the number of identities.
Page 309 44% identity.
Page 314 To detect pairs of residues with correlated mutations, there must be variability in these sequences. If the alignment is overrepresented by closely related organisms, there may not be enough changes in their sequences to allow the identification of potential base-pairing patterns.

Chapter 11

Page 330 D-Fructopyranose; the chair conformation of D-fructopyranose; bulky groups in equatorial positions about a ring structure; β-anomer of D-glucopyranose
Page 333 All three are reducing sugars.
Page 337 Maltose, cellulose, starch, amylose, and glycogen; cellulose and chitin.
Page 346 The genome is the least complex; the glycome is likely the most complex.

Chapter 12

Page 358 Phospholipids, glycolipids (which are a subclass of sphingolipids), and cholesterol. Examples of polar head groups include serine, ethanolamine, choline, and inositol.
Page 360 Essentially an “inside-out” membrane. The hydrophilic groups would come together on the interior of the structure, away from the solvent, whereas the hydrocarbon chains would interact with the solvent.
Page 369 In a hydrophobic environment, the formation of intrachain hydrogen bonds stabilizes the amide hydrogen atoms and carbonyl oxygen atoms of the polypeptide chain, and so an α helix forms. In an aqueous environment, these groups are stabilized by interaction with water, and so there is no energetic reason to form an α helix. Thus, the α helix would be more likely to form in a hydrophobic environment.
Page 372 The presence of a cis double bond introduces a kink in the fatty acid chain that prevents tight packing and reduces the number of atoms in van der Waals contact. The kink lowers the melting point compared with that of a saturated fatty acid. Trans fatty acids do not have the kink, and so their melting temperatures are higher, more similar to those of saturated fatty acids. Because trans fatty acids have no structural effect, they are rarely observed.

Chapter 13

Page 390 SERCA, a P-type ATPase, uses a mechanism by which a covalent phosphorylated intermediate (at an aspartate residue) is formed. At steady state, a subset of the SERCA molecules is trapped in the E_2-P state and, as a result, radiolabeled. The MDR protein is an ABC transporter and does not operate through a phosphorylated intermediate. Hence, a radiolabeled band would not be observed for MDR.

Page 392 FCCP effectively creates a pore in the bacterial membrane through which protons can pass rapidly. Protons that are pumped out of the bacteria will pass through this pore preferentially (the "path of least resistance"), rather than participate in H^+/lactose symport.

Page 398 An ion channel must transport ions in either direction at the same rate. The net flow of ions is determined only by the composition of the solutions on either side of the membrane.

Page 407 Cardiac muscle must contract in a highly coordinated manner in order to pump blood effectively. Numerous gap junctions, abundant in connexin proteins, mediate the orderly cell-to-cell propagation of the action potential through the heart during each beat.

Chapter 14

Page 424 In cardiac muscle, increased cAMP levels lead to increased protein kinase A activity, which leads to increased phosphorylation of troponin, resulting in muscle contraction. In smooth muscle, decreased cAMP levels lead to decreased protein kinase A activity, which decreases the level of phosphorylation of myosin light chains, thus decreasing the extent of muscle contraction.
Page 430 No, the substrate preference and the activation loop sequence are quite different.
Page 433 Both Ras and a heterotrimeric G protein are activated by GTP for GDP exchange. Ras is a small monomeric protein, whereas heterotrimeric G proteins are larger and exist as trimers in their inactive states. (Other answers are possible.)
Page 437 One would expect the loss of sensitivity to the odor of one or a small number of compounds detectable by most individuals.
Page 441 Olfaction: odorant molecules; vision: light in the visible range; hearing: pressure waves (vibrations) in the air. Odorant molecules bind to odorant receptors; light absorption results in isomerization of 11-cis-retinal in visual pigments; air vibrations result in relative displacement of stereocilia in hair bundles.

Chapter 15

Page 449 A can still be converted to B despite a positive $\Delta G^{\circ\prime}$ value if the concentrations of A and B are sufficiently imbalanced such that ΔG is negative. Alternatively, the reaction that converts A into B can be coupled to another reaction with a negative $\Delta G^{\circ\prime}$ value by an enzyme such that the overall reaction now has a negative $\Delta G^{\circ\prime}$ value.

Page 459 Statement 3 is the only true statement. Statement 1 is false because energy is required to break covalent bonds and is released upon bond formation with water, and Statement 2 is false because ATP has an intermediate phosphoryl transfer potential.

Page 468 Coenzyme A; $NADP^+$; Vitamins.

Chapter 16

Page 484 The 1-arseno-3-phosphoglycerate that will be formed will be rapidly hydrolyzed so no ATP can be generated by the next reaction of glycolysis by phosphoglycerate kinase. Thus, arsenate eliminates one of the two ATP-synthesizing steps in glycolysis. In fact, all enzymes that use phosphate could use arsenate, severely compromising the energy production of the cell, leading to cell damage. If the arsenate concentration were high enough, death would result.
Page 486 Two molecules of NADH and four molecules of ATP.
Page 488 Two molecules of ATP and zero molecules of NADH.
Page 492 Classic galactosemia is much more detrimental to human health. If a person was galactosemic, it would be better to be lactose intolerant so that less galactose would be absorbed when lactose is consumed in the diet.
Page 499 ATP initially stimulates PFK activity, as would be expected for a substrate, but at higher concentrations, it inhibits the enzyme. Although this effect seems counterintuitive for a substrate, recall that the function of glycolysis in muscle is to generate ATP. Consequently, high concentrations of ATP signal that the ATP needs are met and glycolysis should stop. In addition to being a substrate, ATP is an allosteric inhibitor of PFK, with the allosteric site having a lower affinity for ATP than the active site.
Page 508 The energy needs of a muscle cell vary widely, from rest to intense exercise, so the rapid regulation of phosphofructokinase by ATP and AMP is vital. In other tissues, such as the liver, ATP concentration is less likely to fluctuate and will not be a key regulator of phosphofructokinase, but rather the enzyme, and its counterpart in gluconeogenesis, fructose 1,6-bisphosphatase, are subject to hormonal control through the action of fructose 2,6-bisphosphate instead.

Page 509 Forming lactate allows tissues that are anaerobic, either temporarily, like skeletal muscle, or permanently, like some parts of the skin, to continue to produce ATP without oxygen. The burden of resynthesizing glucose from lactate at the expense of ATP can be borne by other tissues, like the liver, that are replete with oxygen and energy stores. Thus, the Cori cycle allows an important division of labor in the body.

Page 511 Fructose 2,6-bisphosphate, present at high concentration when glucose is abundant, normally slows gluconeogenesis by inhibiting fructose 1,6-bisphosphatase. In this genetic disorder, the phosphatase is active irrespective of the glucose level. Hence, substrate cycling is increased. The level of fructose 1,6-bisphosphate is consequently lower than normal. Less pyruvate is formed, and thus less ATP is generated.

Chapter 17

Page 521 The remaining steps regenerate oxidized lipoamide, which is required to begin the next reaction cycle. Moreover, this regeneration results in the production of high-energy electrons in the form of NADH.

Page 529 The fact that fluorocitrate is formed tells us something about the immediate metabolic fate of fluoroacetate: It must first be converted to fluoroacetyl CoA and enter the citric acid cycle. Fluoroacetyl CoA must react with oxaloacetate to form fluorocitrate, but while citrate is normally converted into isocitrate by the enzyme aconitase, it appears that fluorocitrate is not a substrate for aconitase, and so it accumulates.

Page 531 The enzyme nucleoside diphosphokinase transfers a phosphoryl group from GTP (or any nucleoside triphosphate) to ADP according to the reversible reaction: $\mathrm{GTP + ADP \rightleftharpoons GDP + ATP}$

Page 534 The CAC depends on a steady supply of $\mathrm{NAD^+}$ as an oxidant, generating NADH. $\mathrm{O_2}$ is never directly utilized in the cycle. However, $\mathrm{NAD^+}$ is regenerated via donation of electrons to $\mathrm{O_2}$ by way of the electron transport chain, so eventually a lack of $\mathrm{O_2}$ will cause the cycle to cease due to a lack of $\mathrm{NAD^+}$. The same is true of FAD and $\mathrm{FADH_2}$.

Chapter 18

Page 545 From the cytosol it would pass through the mitochondrial outer membrane, into the intermembrane space (IM space), then through the mitochondrial inner membrane, and finally into the mitochondrial matrix. The infoldings are called cristae, and they are formed by the mitochondrial inner membrane.
Page 549 Pyruvate accepts electrons and is thus the oxidant. NADH gives up electrons and is the reductant.
Page 552 The 10 isoprene units render coenzyme Q soluble in the hydrophobic environment of the inner mitochondrial membrane. The two oxygen atoms can reversibly bind two electrons and two protons as the molecule transitions between the quinone form and quinol form.
Page 561 The answer to all three questions is Succinate-Q reductase (Complex II).
Page 562 Complex I would be reduced, whereas Complexes II, III, and IV would be oxidized. The citric acid cycle would halt because it has no way to oxidize NADH.
Page 567 Recall from the discussion of enzyme-catalyzed reactions that the direction of a reaction is determined by the ΔG difference between substrate and products and that enzymes accelerate the rate of both the forward and the backward reactions. The hydrolysis of ATP is exergonic, and so ATP synthase will enhance the hydrolytic reaction.
Page 570 3 ATP per full rotation; $14 \text{ protons} / 3 \text{ ATP} = 4.7$ protons per ATP if there are 14 **c** subunits.
Page 573 The extra negative charge on ATP relative to that on ADP accounts for ATP's translocation out of the mitochondrial matrix toward the more positively charged side of the inner mitochondrial membrane. Mg^{2+} lessens the charge differences between ATP and

ADP, reducing the impact of charge on the directionality of transport. Additionally, by decreasing the difference between the two ligands, the metal may make ADP more readily compete with ATP for transport to the cytoplasm.

Page 579 DNOC must be an uncoupler, similar to DNP. Recall that uncouplers deplete the proton gradient, allowing the electron-transport chain to operate in the absence of ATP synthesis. In the presence of DNOC, the energy released by the electron-transport chain is released as heat instead of being used to synthesize ATP. Oxygen consumption will increase as more fuel molecules are metabolized to try to make up for the lack of ATP produced by ATP synthase.

Page 579 In the presence of poorly functioning mitochondria, the only means of generating ATP is by anaerobic glycolysis, which will lead to an accumulation of lactic acid in blood.

Page 581 A proton-motive force across the plasma membrane is necessary to drive the flagellar motor. Under conditions of starvation, this proton-motive force is depleted. In acidic solution, the pH difference across the membrane is sufficient to power the motor.

Chapter 19

Page 587 Phototrophy and autotrophy.
Page 589 Chloroplasts are descended from an ancient bacterium that was engulfed and became codependent with another organism, a phenomenon called endosymbiosis. Within chloroplasts are membrane-enclosed compartments called thylakoids. The internal compartment of the thylakoid is called the stroma.
Page 593 The special pair is a specific pair of chlorophyll molecules in the reaction center that absorb light energy and transfer an electron away, creating photoinduced charge separation, the key to photosynthesis.
Page 599 PS I generates reduced ferredoxin, a powerful reductant that reduces $NADP^+$ to NADPH. PS II activates the WOC, a powerful oxidant capable of oxidizing water, generating O_2. The WOC releases the electrons that will ultimately reduce $NADP^+$ and generates protons to form the proton gradient used to drive the synthesis of ATP.
Page 602 The two components are the chemical gradient and the charge gradient. The chemical gradient is nearly entirely responsible for ATP production in chloroplasts because the thylakoid membrane is quite permeable to Cl^- and Mg^{2+}. Thus, as H^+ is pumped into the thylakoid lumen, Mg^{2+} moves out of the lumen while Cl^- move in, dissipating any charge gradient that would otherwise form.

Chapter 20

Page 615 When ribulose 1,5-bisphosphate reacts with CO_2, it forms a six-carbon compound that splits into two molecules of 3-phosphoglycerate. Only one will have ^{14}C.

Page 618 In the dark reactions, magnesium serves to bind ribulose 1,5-bisphosphate and activate it for reaction with CO_2. In the light reactions, magnesium is present in chlorophyll.

Page 634 In the pentose phosphate pathway, erythrose 4-phosphate reacts with xylulose 5-phosphate to produce fructose 6-phosphate and glyceraldehyde 3-phosphate in a reaction catalyzed by transketolase. In the Calvin–Benson cycle, erythrose 4-phosphate reacts with dihydroxyacetone phosphate to form sedoheptulose 1,7-bisphosphate in a reaction catalyzed by aldolase.

Chapter 21

Page 646 Phosphorylase, debranching enzyme, phosphoglucomutase, and glucose 6-phosphatase.

Page 647 Free glucose must be phosphorylated at the expense of one ATP, whereas glucose 6-phosphate derived from glycogen is formed by phosphorolytic cleavage, sparing one molecule of ATP. Thus, the net yield of ATP when glycogen-derived glucose is processed to pyruvate is three molecules of ATP compared with two molecules of ATP from free glucose.

Page 649 Glucose is an allosteric inhibitor of phosphorylase *a*. Hence, crystals grown in its presence are in the T state. The addition of glucose 1-phosphate, a substrate, causes a conformational change in the enzyme toward the R state which is sufficiently large that the crystal shatters.

Page 660 In the liver, glucagon stimulates the cAMP-dependent pathway that activates protein kinase A. Epinephrine binds to a 7TM α-adrenergic receptor in the liver plasma membrane, which activates phospholipase C and the phosphoinositide cascade. This activation causes calcium ions to be released from the endoplasmic reticulum, which bind to calmodulin, and further stimulates phosphorylase kinase and glycogen breakdown.

Chapter 22

Page 668 Two times each. The triacylglycerol will be hydrolyzed in the intestinal lumen, resynthesized in the intestinal cell, hydrolyzed again in the blood, and resynthesized again in the adipocyte.
Page 671 Fat mobilization in adipocytes is activated by phosphorylation. Hence, overproduction of the cAMP-activated kinase will lead to an accelerated breakdown of triacylglycerols and a depletion of fat stores.
Page 674 Fatty acids cannot be transported into mitochondria for oxidation. The muscles cannot use fats as a fuel. Muscles could use glucose derived from glycogen. However, when glycogen stores are depleted, as after a fast, the effect of the deficiency is especially apparent.
Page 683 Eight molecules of acetyl CoA combine to form four molecules of acetoacetate for release into the blood, and so they do not contribute to the energy yield in the liver. However, the $FADH_2$ and $NADH$ generated in the preparation of acetyl CoA can be processed by oxidative phosphorylation to yield ATP.

$$1.5\ ATP/FADH_2 \times 7 = 10.5\ ATP$$
$$2.5\ ATP/NADH \times 7 = 17.5\ ATP$$

The equivalent of 2 ATP were used to form palmitoyl CoA. Thus, 26 ATP were generated for use by the liver.
Page 687 HCO_3^- is attached to acetyl CoA to form malonyl CoA. When malonyl CoA condenses with acetyl CoA to form the four-carbon ketoacyl CoA, the HCO_3^- is lost as CO_2.
Page 696 Phosphofructokinase controls the flux down the glycolytic pathway which generates ATP or building blocks for biosynthesis, depending on the tissue. The presence of citrate in the cytoplasm

means that the cell favors fatty acid synthesis over degradation, indicating that those needs are met, and there is no need to catabolize glucose.

Chapter 23

Page 703 Dietary amino acids are absorbed in the upper part of the small intestine (the duodenum). The primary fate of both dietary and cellular-derived amino acids is as building blocks for cellular proteins and other nitrogen-containing molecules.
Page 707 Exposure of such a region suggests that a component of a multiprotein complex has failed to form properly or that one component has been synthesized in excess. This exposure leads to rapid degradation and the restoration of appropriate stoichiometries.
Page 709 Aminotransferases transfer the α-amino group to α-ketoglutarate to form glutamate. Glutamate is oxidatively deaminated to form an ammonium ion in the liver by glutamate dehydrogenase.
Page 713 Ser and Thr. The presence of a hydroxyl group on the β-carbon.
Page 718 Carbamoyl phosphate and aspartate.
Page 728 As shown in Figure 23.27, alanine, a gluconeogenic amino acid, is released during the metabolism of tryptophan to acetyl CoA and acetoacetyl CoA.

Chapter 24

Page 736 Cholecystokinin (CCK) and glucagon-like peptide 1 (GLP-1) are short-term and anorexigenic. Ghrelin is short-term and orexigenic.
Page 741 Phosphorylation of dietary glucose after it enters the liver; gluconeogenesis; glycogen breakdown.
Page 742 When glycogen stores are filled, the excess carbohydrates are metabolized to acetyl CoA, which is then converted into fats. Human beings cannot convert fats into carbohydrates, but they can certainly convert carbohydrates into fats.
Page 743 Such a mutation would increase the phosphorylation of the insulin receptor and IRS in muscle and would improve insulin sensitivity. Indeed, PTP1B is an attractive therapeutic target for type 2 diabetes.
Page 745 The inability of muscle mitochondria to process all of the fatty acids leads to excessive levels of diacylglycerol (DAG) and ceramide in the muscle cytoplasm. DAG is a second messenger that activates protein kinase C, which phosphorylates IRS, reducing its ability to propagate the insulin signal. Ceramide inhibits Akt.
Page 746 In the absence of insulin, lipid mobilization will take place to an extent that it overwhelms the ability of the liver to convert the lipids into ketone bodies. The excess is re-esterified and released into the blood.
Page 753 A role of the liver is to provide glucose for other tissues. In the liver, glycolysis is used not for energy production but for biosynthetic purposes. Consequently, in the presence of glucagon, liver glycolysis stops so the glucose can be released into the blood.
Page 754 Adipose tissue. Other tissues are the liver and muscle which store glycogen, and the skeletal muscle which technically acts as a storage of energy if necessary in the form of muscle proteins.

Page 757 Ethanol is oxidized to yield acetaldehyde by alcohol dehydrogenase, which is subsequently oxidized to acetate and acetaldehyde. Ethanol is also metabolized to acetaldehyde by the P450 enzymes, with the subsequent depletion of NADPH.

Chapter 25

Page 767 Glutamine synthetase:

$$\text{Glutamate} + \text{ATP} + \text{NH}_3 \rightarrow \text{glutamine} + \text{ADP} + \text{P}_i$$

Glutamate synthase:

$$\alpha\text{–Ketoglutarate} + \text{glutamine} + \text{NADPH} + \text{H}^+ \rightarrow 2\ \text{glutamate} + \text{NADP}^+$$

The sum of these reactions is:

$$\text{NH}_4^{\ +} + 2\ \alpha\text{–ketoglutarate} + \text{NADPH} + \text{ATP} \rightarrow \text{glutamate} + \text{NADP}^+ + \text{ADP} + \text{P}_i$$

Page 771 Both conversions are amidation reactions that require ATP hydrolysis. In the conversion of glutamate to glutamine, the nitrogen donor is ammonia and the side chain carboxylate is activated by phosphorylation. In the conversion of aspartate to asparagine in human beings, the nitrogen donor is glutamine and the side chain carboxylate is activated by adenylation.

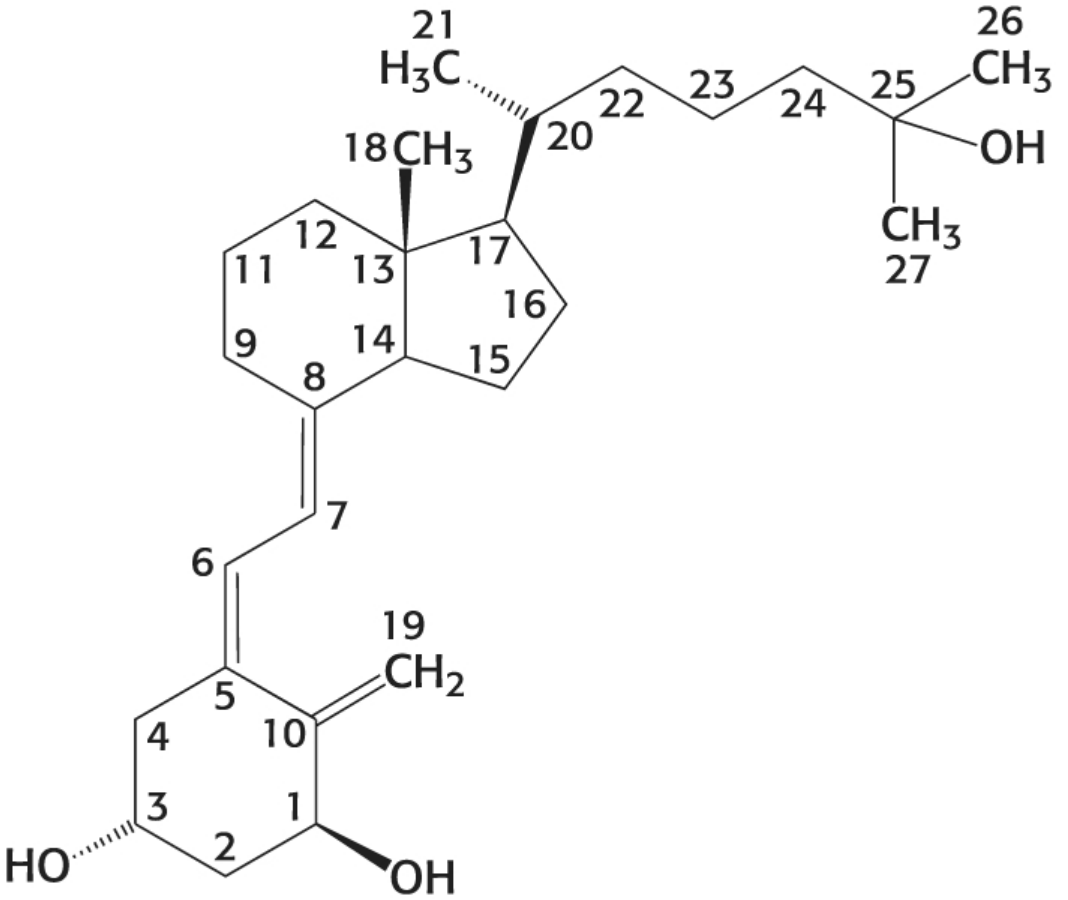
Page 775 (a) N^5,N^{10}-Methylenetetrahydrofolate; (b) N^5-methyltetrahydrofolate.

Page 788 Succinyl CoA is formed in the mitochondrial matrix as part of the citric acid cycle.

Chapter 26

Page 795 Aspartate and carbamoyl phosphate.

Page 799 Carbon dioxide, glycine, aspartate, glutamine, and N^{10}-formyltetrahydrofolate.



Page 805 UTP is first converted into UDP. Ribonucleotide reductase generates dUDP. DeoxyUDP is converted to dUMP. Thymidylate synthase generates TMP from dUMP. Monophosphate and diphosphate kinases subsequently form TTP.

Page 808 The committed step in pyrimidine biosynthesis is catalyzed by aspartate transcarbamoylase (ATCase). The committed step in purine biosynthesis is catalyzed by glutamine phosphoribosyl amidotransferase.

Chapter 27

Page 816 Phosphatidic acid includes two acyl groups that can vary in structure, leading to molecular weight differences.
Page 825 Oxidosqualene cyclase.
Page 832 Density, protein composition, lipid composition. See Table 27.1.

Page 839

Chapter 28

Page 847 The nucleotides used for DNA synthesis have the triphosphate attached to the $5'$-hydroxyl group with free $3'$-hydroxyl groups. Such nucleotides can be used only for $5'$-to-$3'$ DNA synthesis.

Page 848 DNA replication requires RNA primers. Without appropriate ribonucleotides, such primers cannot be synthesized.

Page 864 A hallmark of most cancer cells is prolific cell division, which requires DNA replication. If the telomerase were not activated, the chromosomes would shorten until they became nonfunctional, leading to cell death.

Page 868 DNA polymerase has proofreading activity, so it will immediately fix any bases that were wrongly incorporated, much like using a backspace key to correct typos. Any errors that are not fixed during replication can be repaired afterwards by mismatch repair. Damaged DNA is fixed via base-excision repair or nucleotide-excision repair. More significant damage, such as double-stranded breaks, can be repaired via recombination pathways. There are so many systems because the integrity of the DNA sequence is critically important, and it must be duplicated with fidelity. Each system provides added levels of accuracy.

Chapter 29

Page 881 RNA is mostly single-stranded, although it can form short duplexed sections, such as hairpins. The sugar in RNA is ribose, which has an extra hydroxyl group on the $2'$ carbon. This extra $2'-OH$ gives RNA its catalytic characteristics.

Page 885 RNA polymerases are similar to DNA polymerases in that they catalyze the formation of a phosphodiester bond in an active site that contains metal ions. Unlike DNA polymerases, RNA polymerases do not require an existing $3'-OH$ for this reaction and can therefore build RNA strands de novo. RNA polymerases have a greater error rate than DNA polymerases.

Page 898 The σ subunit as well as the eukaryotic transcription factors play a significant role in recruiting the RNA polymerase (bacterial or eukaryotic, respectively) to the promoter in order to facilitate the initiation of transcription at the appropriate site(s) and not randomly within the genome.

Page 912 All three reaction mechanisms involve two sequential transesterification reactions. Group I and group II self-splicing introns do not require the spliceosome. In group 1 splicing, the first reaction is an intermolecular nucleophilic attack (the $3'-OH$ group from a G). In group II and spliceosomal splicing, the first reaction is an intramolecular nucleophilic attack by the $2'-OH$ group from an adenylate within the intron.

Chapter 30

Page 920 (i) Each is a single chain. (ii) They contain unusual bases. (iii) Approximately half of the bases are base-paired to form double helices. (iv) The $5'$ end is phosphorylated and is usually pG. (v) The amino acid is attached to the hydroxyl group of the A residue of the CCA sequence at the $3'$ end of the tRNA. (vi) The anticodon is located in a loop near the center of the tRNA sequence. (vii) The molecules are l-shaped.

Page 921 The first two bases in a codon form Watson–Crick base pairs with their corresponding bases in the anticodon. These interactions are checked for fidelity by bases of the 16S rRNA. The interaction of the third base with its corresponding base in the anticodon is not inspected for accuracy, and so some variation is tolerated. This leads to the redundancy of the genetic code.

Page 933 The ribosome is a ribozyme because the peptide bond is catalyzed by rRNA. The peptidyl transferase center in the large subunit consists entirely of rRNA, with no ribosomal proteins near that active site. In addition, a ribosome stripped of its protein components is still able to catalyze peptide bond formation.

Page 935 During translation initiation in bacteria, the IF-2-GTP-initiator-tRNA complex forms part of the 30S initiation complex. Hydrolysis of GTP occurs once the 50S subunit joins this complex and will result in the release of IF2. During translation elongation, the EF-Tu-GTP complex binds the aminoacyl-tRNA and delivers it to the ribosome. Hydrolysis of GTP will release the EF-Tu-GDP complex from the ribosome.

Page 942 The SRP binds to the signal sequence and inhibits further translation. The SRP ushers the inhibited ribosome to the ER, where it interacts with the SRP receptor (SR). The $\mathrm{SRP{-}SR}$ complex binds

the translocon and simultaneously hydrolyzes GTP. On GTP hydrolysis, SRP and SR dissociate from each other and from the ribosome. Protein synthesis resumes, and the nascent protein is channeled through the translocon.

Chapter 31

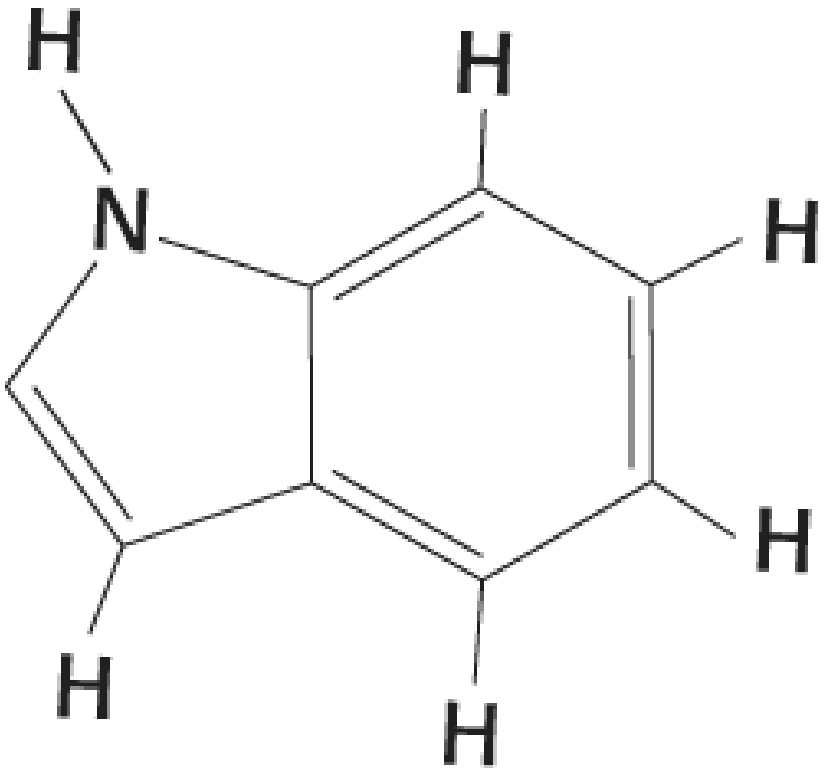
Page 956 High concentrations of lactose cause the inducer (allolactose) to prevent the repressor from binding to the operator DNA, allowing for transcription of the structural genes in the operon. High concentrations of glucose, however, result in low levels of cAMP, meaning there would be no positive regulation (activation) of the *lac* operon by CAP. Under these conditions, the lack of positive regulation results in little to no expression of the structural genes, despite the negative control (repression) having been removed. In the absence of β-galactosidase, glucose is metabolized first. Once glucose levels have been depleted, cAMP levels are high, and cAMP–CAP complexes stimulate the transcription of the operon.
Page 959 Alpha helices fit into the major groove of DNA and are able to make specific contacts with the bases presented there.
Page 962 Eukaryotic DNA must be compacted and organized into chromatin in order to fit into the nucleus. This compaction makes it difficult for RNA polymerase and other regulatory proteins to gain access to the DNA. Chromatin structure must be relaxed in order for transcription to be activated. Gene expression can also be silenced by chromatin remodeling.
Page 967 The various aspects of chromatin modification include DNA methylation, histone methylation, histone acetylation, and histone deacetylation. DNA methylation, histone methylation, and histone deacetylation typically silence gene expression by making the DNA less accessible to transcription factors. Histone acetylation activates transcription by relaxing the chromatin structure and recruiting transcription factors and other components of the transcriptional machinery.
Page 972 During transcription, regulatory proteins determine the amount of mRNA produced from certain genes. Posttranscriptionally, regulatory mechanisms can affect the stability and translatability of

mRNAs. Once a protein is made, its functionality can be regulated via covalent modifications.

Chapter 32

Page 982 If an enzyme assay used in a high-throughput screen relies on a fluorescence readout, compounds that are themselves fluorescent may interfere with the assay and appear to be hits (i.e., false positives).

Page 986 In a manner reminiscent of affinity chromatography, the compound identified as a phenotypic screening hit could be attached to a solid support, and the extract of the type of cell used in the initial screen could be passed over the resin. Proteins that bind to the resin could be potential targets for the compound. If numerous proteins are identified, then this experiment could be repeated on other screening hits, and one could look for proteins that were common to both.



Page 996 A monoclonal antibody with higher affinity for FcRn would be more likely to be salvaged and retained in the body, thus prolonging its half-life.

Answers to Problems

Chapter 1

1. The hydrogen-bond donors are the NH and NH_2 groups. The hydrogen-bond acceptors are the carbonyl oxygen atoms and those ring nitrogen atoms that are not bonded to hydrogen or to deoxyribose.

12. (a) 0.45; (b) 1.00; (c) 1.62

13.

14. (a) No; (b) Around pH 2.

15. 90 mM acetic acid; 160 mM sodium acetate, 0.18 moles acetic acid; 0.32 moles sodium acetate; 10.81 g acetic acid; 26.25 g sodium acetate.

16. (a) MOPS; (b) MES

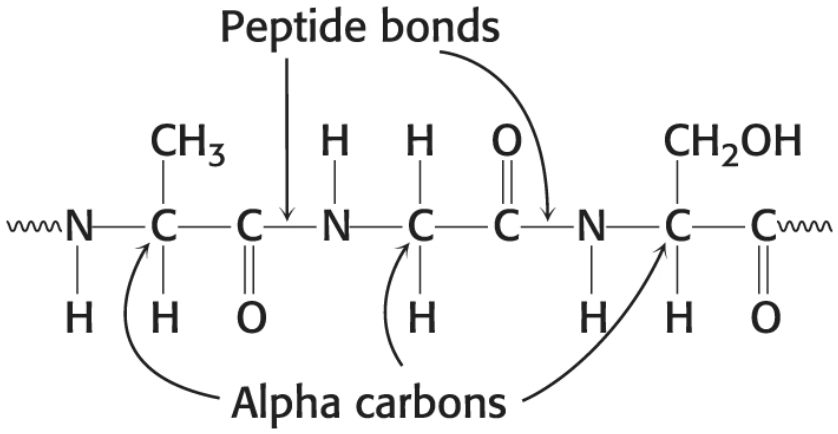
17. Buffer, because the sodium ions will shield the electrostatic repulsion between the phosphate groups.

18. $+1.45\ \text{kJ mol}^{-1}\ (+0.35\ \text{kcal mol}^{-1})$; $+57.9\ \text{kJ mol}^{-1} (+13.8\ \text{kcal mol}^{-1})$

19. The hydrophobic effect

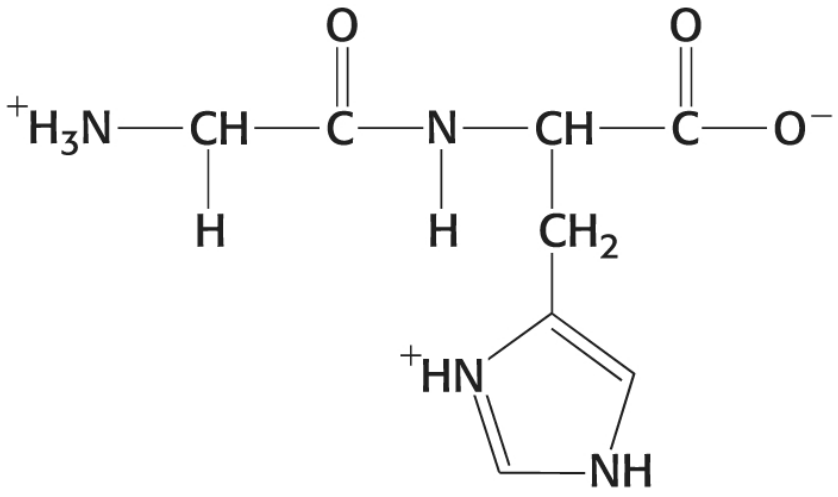
20. 100%. No, it would not be a useful clock because it changes too slowly.

21. 7.9%



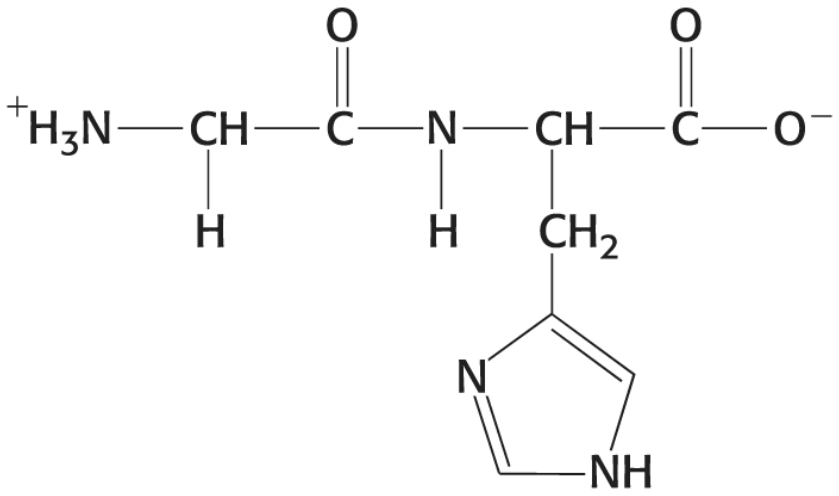
Chapter 2

1. (A) Proline, Pro, P; (B) tyrosine, Tyr, Y; (C) leucine, Leu, L; (D) lysine, Lys, K.

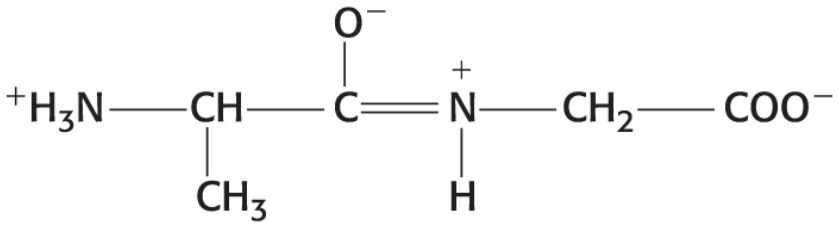


2. (a) D; (b) none; (c) A, C; (d) B.

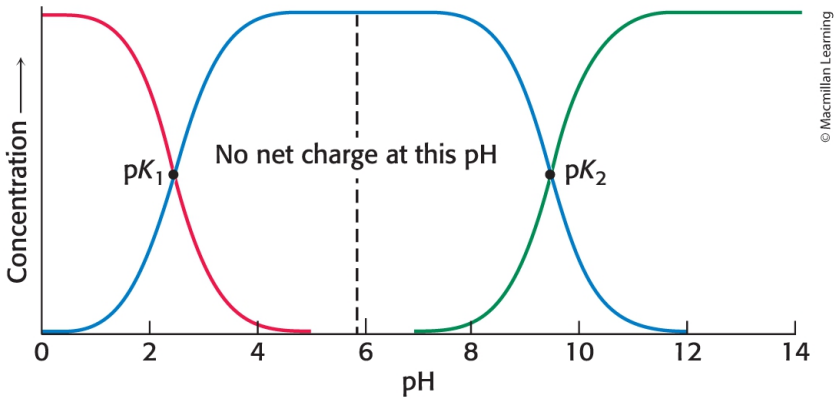
3. Ser, Glu, Tyr, Thr.



4. (a) Alanine-glycine-serine; (b) alanine; (c) 2.



5. At pH 5.5, the net charge is $^{+1}$:



At pH 7.5, the net charge is 0:

6.

7. The solution would have no net charge at the pH in the midpoint of the zwitterionic species curve (blue), effectively at the midpoint between pK_1 and pK_2:

8. (a) pH 1.5; (b) pH 3.0 and pH 4.9

9. (a) Each strand is 35 kDa and hence has about 318 residues (the mean residue mass is 110 daltons). Because the rise per residue in an α helix is 1.5 Å, the length is 477 Å. More precisely, for an α-helical coiled coil, the rise per residue is 1.46 Å; so the length is 464 Å. (b) Eighteen residues in each strand (40 minus 4 divided by 2) are in a β-sheet conformation. Because the rise per residue is 3.5 Å, the length is 63 Å.

10. The methyl group attached to the β-carbon atom of isoleucine sterically interferes with α-helix formation. In leucine, this methyl group is attached to the γ-carbon atom, which is farther from the main chain and hence does not interfere.

11. The native conformation of insulin is not the thermodynamically most stable form, because it contains two separate chains linked by disulfide bonds. Insulin is formed from proinsulin, a single-chain precursor, that is cleaved to form insulin, a 51-residue molecule, after the disulfide bonds have formed.

12. A 12 kDa single-stranded α helix contains about 109 residues:

$$12\ \text{kDa} \times \frac{1000\ \text{Da}}{1\ \text{kDa}} \times \frac{1\ \text{residue}}{110\ \text{Da}} = 109\ \text{residues}$$

A single turn of the helix (each repeating unit) extends about 5.4 Å. There are 3.6 residues per turn. Therefore, the rise per residue is 1.5 Å. The length of the segment is 164 Å

$$109\ \text{residues} \times \frac{1.5\ \text{Å}}{1\ \text{residue}} = 164\ \text{Å}$$

13. (a). This peptide has a large number of aromatic and beta-branched amino acids, which tend to be disfavored in α helices and accommodated well by β sheets.

14. (a) a; (b) a, b, c.

15. (a) All; (b) β sheets; (c) α helices; (d) reverse turn; (e) α helices.

16. Recall that hemoglobin exists as a tetramer while myoglobin is a monomer. Consequently, the hydrophobic residues on the surface of hemoglobin subunits are probably involved in van der Waals interactions with similar regions on the other subunits, and will be shielded from the aqueous environment by this interaction.

17. Using the Henderson–Hasselbalch equation, we find the ratio of alanine-COOH to alanine-COO^- at pH 7 to be 10^{-4}. The ratio of alanine-NH_2 to alanine-NH_3^+, determined in the same fashion, is 10^{-1}. Thus, the ratio of neutral alanine to the zwitterionic species is $10^{-4} \times 10^{-1} = 10^{-5}$.

18. ELVISISLIVINGINLASVEGAS

19. No, Pro—X would have the characteristics of any other peptide bond. The steric hindrance in X—Pro arises because the R group of Pro is bonded to the amino group. Hence, in X—Pro, the proline R group is near the R group of X, which would not be the case in Pro—X.

20. A, c; B, e; C, d; D, a; E, b.

21. Disulfide pairings are not positioned correctly unless weak bonding interactions are present.

Chapter 3

1. $^{1}/_{2}$

2. 1.44×10^{-2} grams; 1.44×10^{-1} grams; 128

3. No, because oxygen binding requires partial electron transfer to oxygen.

4. No. The Bohr effect requires changes in quaternary structure and myoglobin in monomeric.

5. Less tight, because n-hexyl isocyanide is likely too large to easily fit into the oxygen-binding cavity.

6. lowered; raised; raised

7. (a) 1.0, expected for a monomeric protein; (b) 2.8. This suggests substantial cooperativity but is less that 4.0 expected for full cooperativity

8. (a) 61.7%; (b) Her hemoglobin P_{50} increases, promoting oxygen delivery to tissues.

9. The two copper ions move together upon binding oxygen, and this motion could promote cooperativity.

10. (c) because of its negative charge.

11. Uracil is found in RNA, characteristic of potential viral infection.

12. Uracil to avoid the potential innate immune response.

13. Each IgG has two arms and each hemoglobin has two copies of each potential binding site. These could come together to form a large insoluble polymer. This is not possible for myoglobin because it is monomeric.

14. (a) L**L**QATYSA**V**

15. 0.17; 0.67, 0.95, 0.995

16. (a) $R_{free} = R = 1.0 - 0.14 - 0.71 = 0.15 R_{total}$. (b) $\text{Estradiol}_{free} = 1\ \text{nM} - 0.14 R_{total}$. (c) $\text{BPA}_{free} = 1\ \mu\text{M} - 0.71 R_{total}$. (d) Estradiol $K_d = (R_{free} \times \text{Estradiol}_{free})/[R\text{–Estradiol}] = (0.15\ R_{total}) \times (1\ \text{nM} - 0.14\ R_{total})/0.14 R_{total} = (0.15/0.14) \times (1\ \text{nM}$ assuming R_{total} is much less than 1 nM, BPA $K_d = (R_{free} \times \text{BPA}_{free})/[R\text{–BPA}] = (0.15\ R_{total}) \times (1\ \mu\text{M} - 0.71 R_{total})/0.71 R_{total} = (0.15/0.71) \times (1\ \mu\text{M} - 0.71 R_{tota}$.

17. $\text{Rate} = k_1 [L] = 5 \times 10^{-3}\ s^{-1}$ when $[L] = 10\ \mu\text{M}$ so that $k_1 = 5 \times 10^{8}\ M^{-1} s^{-1}$. $k_{-1} = K_d \times k_1 = (20\ \text{nM}) \times (5 \times 10^{8}\ M^{-1} s^{-1}) = 10\ s^{-1}$.

18. 0.5 nM

19. $10^{-6}\,\mathrm{M}$

20. Essentially all (100%) of the irons will be bound to carbon dioxide.

Chapter 4

1. (a), (c), (d)

2.

Purification procedure	Total protein (mg)	Total activity (units)	Specific activity (units mg^{-1})	Purification level	Yield (%)
Crude extract	20,000	4,000,000	200	1	100
$(NH_4)_2SO_4$ precipitation	5000	3,000,000	600	3	75
DEAE-cellulose chromatography	1500	1,000,000	667	3.3	25
Gel-filtration chromatography	500	750,000	1500	7.5	19
Affinity chromatography	45	675,000	15,000	75	17

3. (a) 0.4 mM; (b) 0.02 mM

4. A fluorescence-labeled derivative of a bacterial degradation product (e.g., a formylmethionyl peptide) would bind to cells containing the receptor of interest.

5. (a) Trypsin cleaves after arginine (R) and lysine (K), generating AVGWR, VK, and S. Because they differ in size, these products could be separated by molecular exclusion chromatography. (b) Chymotrypsin, which cleaves after large aliphatic or aromatic R groups, generates two peptides of equal size (AVGW) and (RVKS). Separation based on size would not be effective. The peptide RVKS has two positive charges (R and K), whereas the other peptide is neutral. Therefore, the two products could be separated by ion-exchange chromatography.

6. (a) Ion exchange chromatography will remove Proteins A and D, which have a substantially lower isoelectric point; then gel filtration chromatography will remove Protein C, which has a lower molecular weight. (b) If Protein B carries a His tag, a single affinity chromatography step with an immobilized nickel(II) column may be sufficient to isolate the desired protein from the others.

7. Mass spectrometry is highly sensitive and capable of detecting the mass difference between a protein and its deuterated counterpart. Fragmentation techniques can be used to identify the amino acids that retained the isotope label. Alternatively, NMR spectroscopy can be used to detect the isotopically labeled atoms because the deuteron and the proton have very different nuclear-spin properties.

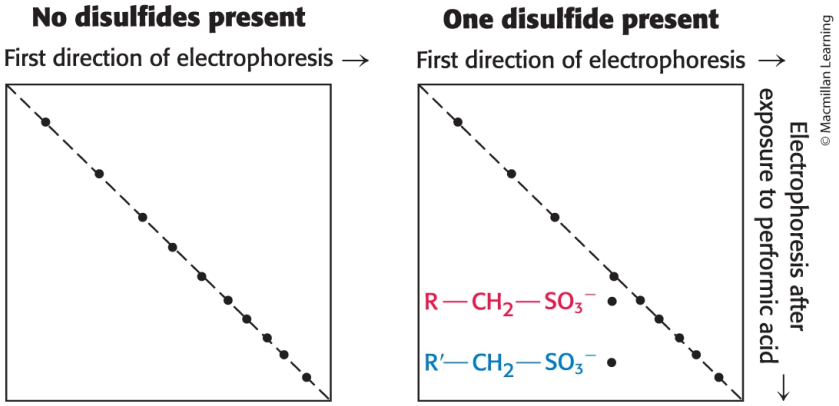
8. (c), (e), (b), (a), (d).

9. The difference between the predicted and the observed masses for this fragment equals 28.0, exactly the mass shift that would be expected in a formylated peptide. This peptide is likely formylated at its

amino terminus and corresponds to the most N-terminal fragment of the protein.

10. (b)

11. (a) Three fragments; the smallest is Ser-Arg. (b) One “fragment”; this peptide does not contain any chymotrypsin cleavage sites (no Phe, Tyr, Trp, Leu, or Met). The sequence would remain Gly-Ser-Lys-Ala-Gly-Arg-Ser-Arg.



12. (a) d and e; (b) b.

13. TRMKPAMLICWMPD

14. Met-Val-Lys-Tyr-Thr-Trp-Ala-Phe-Gly-Arg

15. (a) (A): Native PAGE; (B): Non-reducing SDS-PAGE; (C) Reducing SDS-PAGE (b) Protein X consists of two 50 kDa polypeptide chains, resulting in a total mass of 100 kDa. According to the nonreducing SDS-PAGE gel, intact protein X has a total molecular weight of 100 kDa. Therefore, the molecular weights of the protein X polypeptide chains must add up to 100 kDa. The only peptides indicated by the reducing SDS-PAGE gel that combine to yield a 100-kDa protein are two 50-kDa chains. (c) Protein Y consists of two 60-kDa chains and one 30-kDa chain, for a total mass of 150 kDa. According to the nonreducing SDS-PAGE gel, the intact protein Y has a total molecular weight of 150 kDa. Therefore, the molecular weights of the protein Y polypeptides must add up to 150 kDa. Although three 50 kDa could make up a 150-kDa polypeptide, the reducing SDS-PAGE method shows bands of 30 kDa and 60 kDa. Therefore, protein Y must include chains of 30 kDa and 60 kDa. The association of two 60-kDa chains and one 30-kDa chain would yield the 150-kDa protein Y.

16. If the protein did not contain any disulfide bonds, then the electrophoretic mobility of the trypsin fragments would be the same before and after performic acid treatment: all the fragments would lie along the diagonal of the paper. If one disulfide bond were present, the disulfide-linked trypsin fragments would run as a single peak in the first direction, and then as two separate peaks after performic acid treatment. The result would be two peaks appearing off the diagonal:

These fragments could then be isolated from the chromatography paper and analyzed by mass spectrometry to determine their amino acid composition and thus identify the cysteines participating

in the disulfide bond.

17. From top to bottom: (d), (e), (f), (a), (c), (b)

18. From low pH to high pH: (d), (e), (f), (c), (b), (a)

Chapter 5

1. A cofactor.

2. d, e, and f.

3. The energy required to reach the transition state (the activation energy) is returned when the transition state proceeds to product.

4. The product is more stable than the substrate in graph A; so ΔG is negative and the reaction is exergonic. In graph B, the product has more energy than the substrate has; ΔG is positive, meaning that the reaction is endergonic.

5. (a) $K = \dfrac{[P]}{[S]} = \dfrac{k_F}{k_R} = \dfrac{10^{-4}}{10^{-6}} = 100$. Using equation 5 in the text, $\Delta G^{\circ\prime} = -11.42\ \text{kJ mol}^{-1}\ (-2.73\ \text{kcal mol}^{-1})$. (b) $k_F = 10^{-2}\ \text{s}^{-1}$ and $k_R = 10^{-4}\ \text{s}^{-1}$. The equilibrium constant and $\Delta G^{\circ\prime}$ values are the same for both the uncatalyzed and catalyzed reactions.

6. There would be no catalytic activity. If the enzyme–substrate complex is more stable than the enzyme–transition-state complex, the transition state would not form and catalysis would not take place.

7. (a) 0; (b) $+28.53$; (c) -22.84; (d) -11.42; (e) $+5.69$.

8.

(a)
$$\Delta G^{\circ\prime} = -RT \ln K'_{eq}$$
$$+1.8 = -(1.98 \times 10^{-3}\ \text{kcal}^{-1}\ \text{K}^{-1}\ \text{mol}^{-1})(298\ \text{K})(\ln[\text{G1P}]/[\text{G6P}])$$
$$-3.05 = \ln [\text{G1P}]/[\text{G6P}]$$
$$+3.05 = \ln [\text{G6P}]/[\text{G1P}]$$
$$K'^{-1}_{eq} = 21 \text{ or } K'_{eq} = 4.8 \times 10^{-2}$$

Because $[\text{G6P}]/[\text{G1P}] = 21$, there is 1 molecule of G1P for every 21 molecules of G6P. Because we started with 0.1 M, the [G1P] is $1/22\ (0.1\ \text{M}) = 0.0045\ \text{M}$ and [G6P] must be 21/22 (0.1 M) or 0.096 M. Consequently, the reaction does not proceed as written to a significant extent. (b) Supply G6P at a high rate and remove G1P at a high rate by other reactions. In other words, make sure that the [G6P]/[G1P] is kept large.

9. $K_{eq} = 19$, $\Delta G = -7.3\ \text{kJ mol}^{-1}\ (-1.77\ \text{kcal mol}^{-1})$

10. No, K_M is not equal to the dissociation constant and thus does not measure affinity because the numerator also contains k_2, the rate constant for the conversion of the enzyme substrate complex into enzyme and product. If, however, k_2 is much smaller than k_{-1}, $K_M \approx K_d$.

11. Competitive inhibition: 2, 3, 9; uncompetitive: 4, 5, 6; noncompetitive: 1, 7, 8.

12. When $[S] = 10\ K_M, V_0 = 0.91\ V_{max}$. When $[S] = 20\ K_M, V_0 = 0.95\ V_{max}$. So, any Michaelis–Menten curves showing that the enzyme actually attains V_{max} are pernicious lies.

13. (a) $31.1\ \mu mol$; (b) $0.05\ \mu mol$; (c) $622\ s^{-1}$, a midrange value for enzymes (Table 8.5).

14. (a) Yes, $K_M = 5.2 \times 10^{-6}\ M$; (b) $V_{max} = 6.8 \times 10^{-10}\ mol\ minute^{-1}$; (c) $337\ s^{-1}$.

15. (a) V_{max} is $8.9\ \mu mol\ minute^{-1}$ K_M is $9.9 \times 10^{-5}\ M$, the same as without inhibitor. (b) Noncompetitive. (c) $2.5 \times 10^{-5}\ M$ (d) $f_{ES} = 0.73$, in the presence or absence of this noncompetitive inhibitor.

16. (a) $V_0 = V_{max} - (V_0/[S])\ K_M$; (b) $Slope = -K_M, y-intercept = V_{max}, x-intercept = V_{max}/K_M$; (c) An Eadie Hofstee plot.

17. Sequential reactions are characterized by the formation of a ternary complex consisting of the enzyme and both substrates. Double-displacement reactions always require the formation of a temporarily substituted enzyme intermediate.

18. (a) K_M is a measure of affinity *only* if k_2 is rate limiting, which is the case here. Therefore, the lower K_M means higher affinity. The mutant enzyme has a higher affinity. (b) $50\ \mu mol\ minute^{-1}$. 10 mM is K_M, and K_M yields $1/2\ V_{max}$. V_{max} is $100\ \mu mol\ minute^{-1}$, and so (c) Enzymes do not alter the equilibrium of the reaction.

19. If the total amount of enzyme $[E]_T$ is increased, V_{max} will increase, because $V_{max} = k_2[E]_T$. But $K_M = (k_{-1} + k_2)/k_1$; that is, it is independent of enzyme concentration. The middle graph describes this situation.

20. Enzyme 2. Despite the fact that enzyme 1 has a higher V_{max} than enzyme 2, enzyme 2 shows greater activity at the concentration of the substrate in the environment because enzyme 2 has a lower K_M for the substrate.

21.

Experimental condition	V_{max}	K_M
(a) Twice as much enzyme is used	Doubles	No change
(b) Half as much enzyme is used	Half as large	No change
(c) A competitive inhibitor is present	No change	Increases
(d) An uncompetitive inhibitor is present	Decreases	Decreases
(e) A pure noncompetitive is present	Decreases	No change

22. The first step will be the rate-limiting step. Enzyme E_B is operating at $\frac{1}{2}\ V_{max}$, and E_C is very close to maximum velocity, whereas the K_M for enzyme E_A is greater than the substrate concentration. E_A would be operating at approximately $10^{-2}\ V_{max}$.

23. At substrate concentrations near the K_M, the enzyme is elastic, meaning that it displays significant catalysis yet is still sensitive to changes in substrate concentration.

24. (a) This piece of information is necessary for determining the correct dosage of succinylcholine to administer. (b) The duration of the paralysis depends on the ability of the serum cholinesterase to clear the drug. If there were one-eighth the amount of enzyme activity, paralysis could last eight times as long. (c) K_M is the concentration needed by the enzyme to reach $1/2\ V_{max}$. Consequently, for a given concentration of substrate, the reaction catalyzed by the enzyme with the lower K_M will have the higher rate. The patient with the higher K_M will clear the drug at a much lower rate.

Chapter 6

1. For the amide substrate, the formation of the acyl-enzyme intermediate is slower than the hydrolysis of the acyl-enzyme intermediate, and so no burst is observed. A burst is observed for ester substrates, because the formation of the acyl-enzyme intermediate is faster, leading to the observed burst.

2. The histidine residue in the substrate can substitute to some extent for the missing histidine residue of the catalytic triad of the mutant enzyme.

3. No. The catalytic triad works as a unit. After this unit has been made ineffective by the mutation of histidine to alanine, the further mutation of serine to alanine should have only a small effect.

4. The substitution corresponds to one of the key differences between trypsin and chymotrypsin, and so trypsin-like specificity (cleavage after lysine and arginine) might be predicted. In fact, additional changes are required to affect this specificity change.

5. Imidazole is apparently small enough to reach the active site of carbonic anhydrase and compensate for the missing histidine. Buffers with large molecular components cannot do so, and the effects of the mutation are more evident.

6. No, because the enzyme would destroy the host DNA before protective methylation could take place.

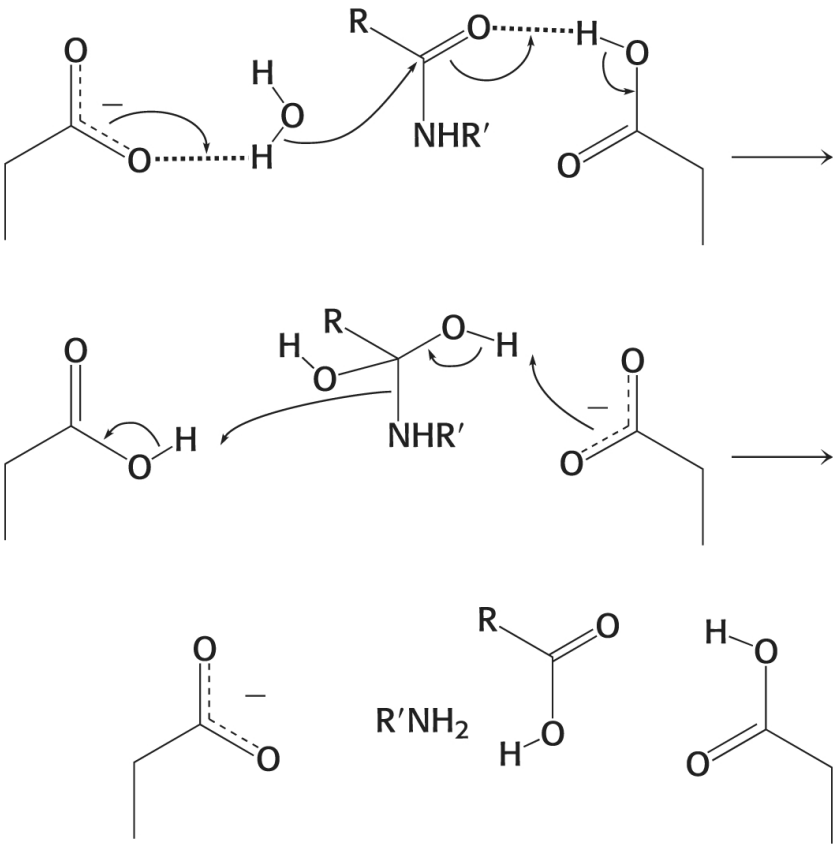
7. EDTA will bind to Zn^{2+} and remove the ion, which is required for enzyme activity, from the enzyme.

8. (a) The aldehyde reacts with the active-site serine. (b) A hemiacetal is formed.

9. lysine; trypsin; aspartate

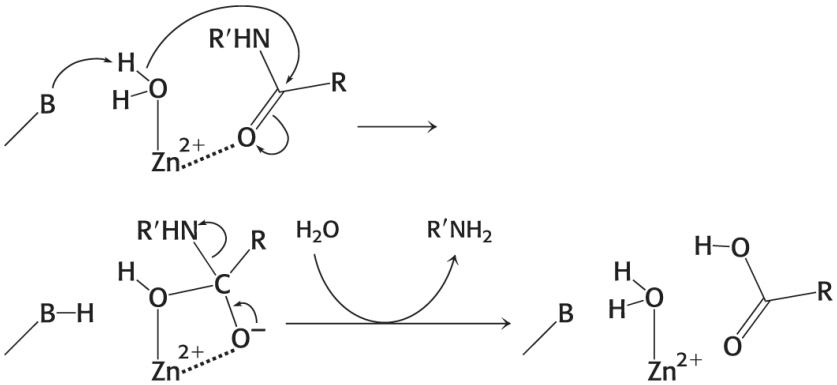
10. $k_{cat} = 60{,}000\ s^{-1}$. The reaction is expected to be slower by a factor of 10 because the rate depends on the pK_a of the zinc-bound water.

11. EDTA binds the Mg^{2+} necessary for the enzymatic reaction to proceed.



12. If the aspartate is mutated, the protease is inactive and the virus will not be viable.

13. Water substitutes for the hydroxyl group of serine 236 in mediating proton transfer from the attacking water and the γ-phosphoryl group.



14. For subtilisin, the catalytic power is approximately $30\ s^{-1}/10^{-8}\ s^{-1} = 3 \times 10^9$. For carbonic anhydrase (at pH 7), the catalytic power is approximately $500{,}000\ s^{-1}/0.15\ s^{-1} = 3.3 \times 10^6$. Subtilisin is the more powerful enzyme by this criterion.

15. The triple mutant still catalyzes the reaction by a factor of approximately 1000-fold compared to the uncatalyzed reaction. This could be due to the enzyme binding the substrate and holding it in a conformation that is susceptible to attack by water.

16. (a) Cysteine protease. The same as Figure 6.8 except that cysteine replaces serine and no aspartate is present. (b) Aspartyl protease.

(c) Metalloprotease.

17. From a biological perspective, highly specific enzymes allow control of which reactions occur at appreciable rates. From a chemical perspective, enzymes generally require a tight fit between enzyme and substrate, likely leading to high specificity. An enzyme with high catalytic activity but low specificity would require the ability to bind substrates with substantial parts of the substrate not in close contact with the enzyme.

18. Myosin will bind and hydrolyze ATP but will release the products ADP and P_i very slowly, limiting the overall rate of hydrolysis.

Chapter 7

1. a, b, and d are true.

2. a, c, and d.

3. Homotropic effectors are the substrates of allosteric enzymes. Heterotropic effectors are the regulators of allosteric enzymes. Homotropic effectors account for the sigmoidal nature of the velocity versus substrate concentration curve, whereas heterotropic effectors alter the K_M of the curve. Ultimately, both types of effectors work by altering the T/R ratio.

4. CTP is formed by the addition of an amino group to UTP. Evidence indicates the UTP is also capable of inhibiting ATCase in the presence of CTP.

5. Kinases: (a), (b), (f); Phosphatases: (c), (g); Neither: (d), (h); Both: (e).

6. (b), (d), (f).

7. (a) CTP and UTP; (b) PALA; (c) ATP.

8. (c), (d), (b), (a).

9. (a) Decrease; (b) Decrease; (c) Decrease; (d) The activity of enzyme 1 increases.

10. Replacing methionine with leucine would be a good choice. Leucine is resistant to oxidation and has nearly the same volume and degree of hydrophobicity as methionine has.

11. (b).

12. (a) Enteropeptidase and trypsin; (b) All four zymogens are directly activated by trypsin!

13. (b), (d), (f), (a), (e), (c).

14. The simple sequential model predicts that the fraction of catalytic chains in the R state, f_R, is equal to the fraction containing bound substrate, *Y*. The concerted model, in contrast, predicts that f_R increases more rapidly than *Y* as the substrate concentration is increased. The change in f_R leads to the change in *Y* on addition of substrate, as predicted by the concerted model.

15. (a) e_1, e_4, e_5, and e_7; (b) The product of e_1, B, has two possible fates, conversion to C or B'. Thus, the product is not committed to the synthesis of G. The first enzyme that catalyzes a reaction that commits the pathway to the synthesis of G is enzyme e_4. This enzyme is most likely the allosteric enzyme.

16. (a) When crowded, the control group displays gregarious behavior. (b) Inhibition of PKA appears to prevent gregarious behavior, while inhibition of PKG has no effect on the behavior. (c) The effect of PKG inhibition was investigated to establish that the effect seen with PKA inhibition is specific and not just due to the inhibition of any kinase. (d) PKA plays a role in altering behavior of insects.

17. The binding of PALA switches ATCase from the T to the R state because PALA acts as a substrate analog. PALA disrupts the equilibrium in favor of R. Thus, the limited amount of substrate can more

readily bind the R state, and the ATCase activity initially increases with increasing PALA. Once the inhibitor occupies more and more active sites, the real substrate will be unable to bind the enzyme. When PALA occupies all of the active sites, the catalytic activity falls to zero.

18. (a) 100. If the binding of the substrate is 100 times tighter for the R form, then $c = 1/100$ (recall that tighter binding means a lower dissociation constant). Thus, $\frac{[T_1]}{[R_1]} = c^1 L = \frac{1}{100} L$ and the change in $[R]/[T]$ will 100-fold. Note that the change in the $[R]/[T]$ ratio on binding one substrate molecule must be the same as the ratio of the substrate affinities of the two forms. (b) 10. With four substrates bound, we can use the equation to determine:

$$\frac{[T_4]}{[R_4]} = c^4 L = \left(\frac{1}{100}\right)^4 L = 10^{-8} \cdot 10^7 = \frac{1}{10}$$

Hence, the $[R]/[T]$ ratio in the fully liganded molecule is 10.

Chapter 8

1. Nucleosides: (c), (f); Nucleotides: (a), (e), (g); Both: (b), (d), (h)

2. (a) Guanosine $5'$-diphosphate (GDP); (b) Deoxyuridine; (c) Adenosine

3. T is always equal to A, and so these two nucleotides constitute 40% of the bases. G is always equal to C, and so the remaining 60% must be 30% G and 30% C.

4. (a) TTGATC; (b) GTTCGA; (c) ACGCGT; (d) ATGGTA.

5. DNA: (b), (c), (f); RNA: (a), (d), (e), (g)

6. (a) purine, ribose; (b) pyrimidine, ribose; (c) purine, deoxyribose

7. B-DNA: (b), (f); A-DNA: (a), (c), (i); Z-DNA: (d), (g); All three: (e), (h)

8. (a) Tritiated thymine or tritiated thymidine. (b) dATP, dGTP, dCTP, and TTP labeled with ^{32}P in the innermost (α) phosphorus atom.

9. Molecules in parts *(a)* and *(b)* would not lead to DNA synthesis, because they lack a $3'-OH$ group (a primer). The molecule in part *(d)* has a free $3'-OH$ group at one end of each strand but no template strand beyond. Only the molecule in part *(c)* would lead to DNA synthesis.

10. (a) 50%; (b) 0%

11. The diameter of DNA is 20 Å, and $1\ Å = 0.1\ nm$, so the diameter is 2 nm. Because $1\ \mu m = 10^3\ nm$, the length is $2 \times 10^4\ nm$. Thus, the axial ratio is 1×10^4.

12. There are 2 μm missing in the deletion mutant, or 20,000 Å of DNA. Given a base separation of 3.4 Å in B-DNA, this corresponds to $20000/3.4$, or about 5.88×10^3 base pairs.

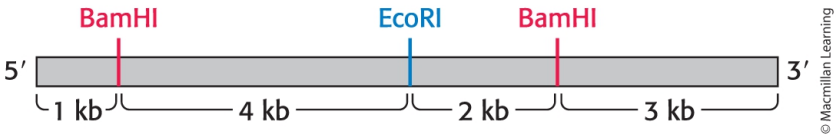
13. (a) 2, 4, 8; (b) 1, 6, 10; (c) 3, 5, 7, 9.

14. (a) $5'-UAACGGUACGAU-3'$ (b) Leu-Pro-Ser-Asp-Trp-Met (c) Poly(Leu-Leu-Thr-Tyr)

15. (a) Deoxyribonucleoside triphosphates versus ribonucleoside triphosphates. (b) $5' \rightarrow 3'$ for both. (c) Semiconserved for DNA polymerase I; conserved for RNA polymerase. (d) DNA polymerase I needs a primer, whereas RNA polymerase does not.

16. Three nucleotides encode an amino acid; the code is nonoverlapping; the code has no punctuation; the code exhibits directionality; the code is degenerate.

17. tRNA: (c), (e); mRNA: (a), (d); rRNA: (b)



18. Prokaryotic promoters: (a), (d); Eukaryotic promoters: (c), (e); Both: (b)

19. It shows that the genetic code and the biochemical means of interpreting the code are common to even very distantly related life forms. It also testifies to the unity of life: that all life arose from a common ancestor.

20. (a) 3; (b) 6; (c) 2; (d) 5; (e) 7; (f) 1; (g) 4.

Chapter 9

1.

2. A mutation in person B has altered one of the alleles for gene *X*, leaving the other intact. The fact that the mutated allele is smaller suggests that a deletion has occurred in one copy of the gene. The one functioning copy is transcribed and translated and apparently produces enough protein to render the person asymptomatic.

Person C has only the smaller version of the gene. This gene is neither transcribed (negative northern blot) nor translated (negative western blot).

Person D has a normal-size copy of the gene but no corresponding RNA or protein. There may be a mutation in the promoter region of the gene that prevents transcription.

Person E has a normal-size copy of the gene that is transcribed, but no protein is made, which suggests that a mutation prevents translation. There are a number of possible explanations, including a mutation that introduced a premature stop codon in the mRNA.

Person F has a normal amount of protein but still displays the metabolic problem. This finding suggests that the mutation affects the activity of the protein—for instance, a mutation that compromises the active site of enzyme Y.

3. Chongqing: residue 2, L → R, CTG → CGG
Karachi: residue 5, A → P, GCC → CCC
Swan River: residue 6, D → G, GAC → GGC

4. Careful comparison of the sequences reveals that there is a 7-bp region of complementarity at the 3′ ends of these two primers:

$$5'\text{–GGATCGATG}\mathbf{CTCGCGA}\text{–}3'$$
$$3'\text{–}\mathbf{GAGCGCT}\text{GGGCTAGGA–}5'$$

In a PCR experiment, these primers would likely anneal to one another, preventing their interaction with the template DNA. During DNA synthesis by the polymerase, each primer would act as a template

for the other primer, leading to the amplification of a 25-bp sequence corresponding to the overlapped primers.

5. The encoded protein contains four repeats of a specific sequence.

6. (b), (d), (a), (c)

7. EcoRI and HindIII. Cleavage with PstI would disrupt the ampicillin resistance gene in pSAP, while cleavage with EcoRI and SmaI would remove the origin of replication from pSAP. Based on the information given, the other remaining restriction enzymes do not have cleavage sites on the fragment.

8. On the basis of the comparative genome map shown in Figure 9.29, the region of greatest overlap with human chromosome 20 can be found on mouse chromosome 2.

9. The codon(s) for each amino acid can be used to determine the number of possible nucleotide sequences that encode each peptide sequence (Table 8.5):

Ala–Met–Ser–Leu–Pro–Trp:

$$4 \times 1 \times 6 \times 6 \times 4 \times 1 = 576 \text{ total sequences}$$

Gly–Trp–Asp–Met–His–Lys:

$$4 \times 1 \times 2 \times 1 \times 2 \times 2 = 32 \text{ total sequences}$$

Cys–Val–Trp–Asn–Lys–Ile:

$$2 \times 4 \times 1 \times 2 \times 2 \times 3 = 96 \text{ total sequences}$$

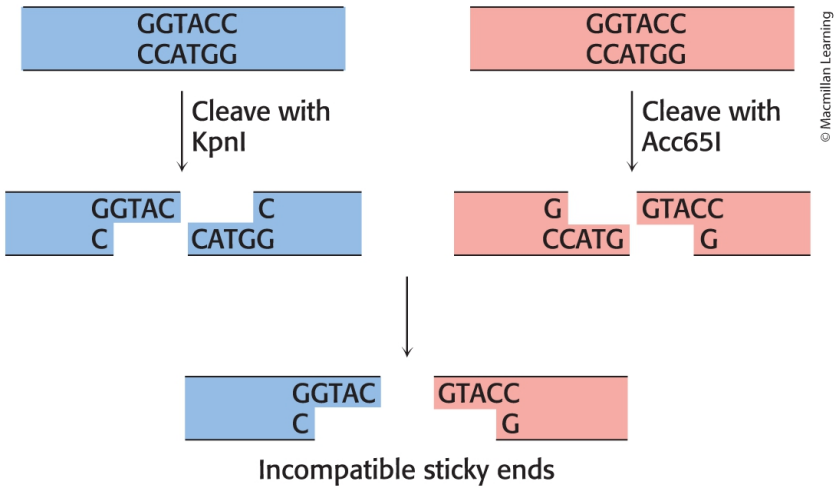
Arg–Ser–Met–Leu–Gln–Asn:

$$6 \times 6 \times 1 \times 6 \times 2 \times 2 = 864 \text{ total sequences}$$

The set of DNA sequences encoding the peptide Gly-Trp-Asp-Met-His-Lys would be most ideal for probe design because it encompasses only 32 total oligonucleotides.

10. In this sequence, the GTG codon encodes valine. To change this to an alanine codon, one should use the primer sequence: ATG–CGC–GAA–CTG–G**C**G–AAC–TAA

11. Since the N could be any one of the four bases, the presence of the NGG trinucleotide would occur with a frequency of $\frac{4}{4} \times \frac{1}{4} \times \frac{1}{4}$, or once every 16 bases, on average.



12. (a) In order to confirm the success of a knockdown experiment, one should use a method that can rapidly detect the loss of mRNA transcript. The most convenient method would be qPCR (real-time PCR) to compare the transcript levels in a knockdown study versus a control sample. One could also look for changes in the expressed protein level by western blotting if an appropriate antibody is available. (b) Whole-genome complementary DNA (cDNA) includes fully processed mRNA transcripts that have already had their introns spliced out. Therefore, cDNA represents the best source for an RNAi library because the mature mRNA is what researchers want to target and degrade in order to knock down the gene products.

13. 1: (b); 2: (c); 3: (a)

14. (a) Individual II; (b) Individual IV; (c) Cannot be determined with the current probe.

15. This particular person is heterozygous for this particular mutation: one allele is wild type, whereas the other carries a point mutation at this position. Both alleles are PCR amplified in this experiment, yielding the “dual peak” appearance on the sequencing chromatogram.

16. Although the two enzymes cleave the same recognition site, they each break different bonds within the 6-bp sequence. Cleavage by KpnI yields an overhang on the $3'$ strand, whereas cleavage by Acc65I produces an overhang on the $5'$ strand. These sticky ends do not overlap.

17. The amount of dsDNA doubles with each cycle, so the amount of dsDNA present is equal to 2^x, where x is the number of cycles. Hence, after 1 cycle, there will be 2 molecules of dsDNA; after 3 cycles, 8 molecules of dsDNA; and after 30 cycles, ~1 billion molecules of dsDNA.

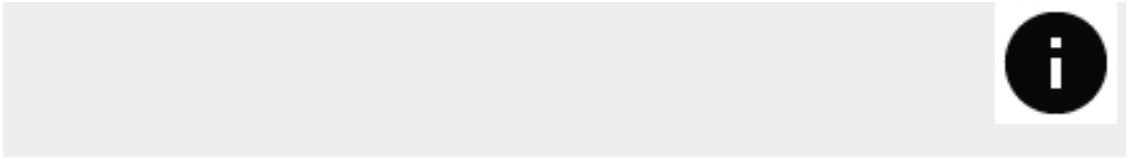
18. (c); (d); (e); (g).

19. (a): 2, 8; (b): 1, 6; (c): 3, 7; (d): 4, 5.

20. RNA-seq detects transcripts whether or not a gene is annotated in the genome, while in microarray analysis, researchers quantify expression levels based on binding to an array of oligonucleotides known to represent annotated genes, so transcripts of unannotated genes are not measured. RNA-seq has a wider dynamic range than microarray analysis, meaning it detects changes in high and low expression level genes. Another advantage of RNA-seq is its sensitivity to splice variants among mRNAs produced from the same gene. In fact, microarray analysis cannot identify splice variants unless each variant is represented and distinguishable in the oligonucleotides on the microarray.

Chapter 10

1. Paralogs are homologs that are present within one species and often differ in their detailed biochemical functions. Orthologs are homologs that are present within different species and have very similar or identical functions.



2. Orthologs: (b), (e), (f); Paralogs: (a), (c), (d)

3. There are 27 identities (highlighted in yellow) and two gaps, for a score of 220. The two sequences are approximately 27% identical. For an alignment of 27% identity over almost 100 residues, it is likely these two proteins are evolutionarily related and structurally similar.

```
WYLGKITRMDAEVLLKKPTVRDGHFLVTQCESSPGEF

SLNELVAYHRTASVSRTHTILLSDMNV
SSLQQLVAYYSKHADGLCHRLTNV
```

4. Protein shuffling involves randomly rearranging one of the protein sequences and comparing the alignment between the two sequences. Researchers repeat this process multiple times to produce a distribution plot that displays alignment scores of the randomly aligned sequences. If the alignment score for the two sequences is significantly higher than the randomly generated plot, then the sequences are likely significantly homologous.

5. Alignment score of sequences (1) and (2) is $6 \times 10 = 60$. Many answers are possible, depending on the randomly reordered sequence. A possible result is

Shuffled sequence:	(2) LYEGADKAKT
Alignment:	(1) ASNFLDKAGK (2) LYEGADKAKT
Alignment score is $3 \times 10 = 30$	

6. Replacement of cysteine, glycine, and proline never yields a positive score. Each of these residues exhibits features unlike those of its other 19 counterparts: cysteine is the only amino acid capable of forming disulfide bonds, glycine is the only amino acid without a side chain and is highly flexible, and

proline is the only amino acid that is highly constrained through the bonding of its side chain to its amine nitrogen.

7. According to the Blosum-62 matrix, substitution of an aspartate residue with a glutamate residue yields a score of $+2$.

8. (1) $\text{Identity score} = -25$; $\text{Blosum score} = 14$; (2) $\text{Identity score} = 15$; $\text{Blosum score} = 4$.

9. (a) The proteins almost certainly diverged from a common ancestor. (b) The proteins almost certainly diverged from a common ancestor. (c) The proteins may have diverged from a common ancestor, but the sequence alignment may not provide supporting evidence. (d) The proteins may have diverged from a common ancestor, but the sequence alignment is unlikely to provide supporting evidence.

10. There are 4^{40}, or 1.2×10^{24}, different molecules. Each molecule has a mass of 2.2×10^{-20} g, because 1 mol of polymer has a mass of $330 \text{ g mol}^{-1} \times 40$, and there are 6.02×10^{23} molecules per mole. Therefore, 26.4 kg of RNA would be required.

11. #1, Solvin A; #2, Solvin D; #3, Solvin C; #4, Solvin B. Solvin B and Solvin E are most similar, having diverged from each other 100 million years ago.

12. Convergent evolution: (a), (g); Divergent evolution: (d), (e), (f); Both: (b), (c)

13. (a) Divergent evolution; (b) Convergent evolution; (c) Divergent evolution.

14. Protein A is clearly homologous to protein B, given 65% sequence identity, and so A and B are expected to have quite similar three-dimensional structures. Likewise, proteins B and C are clearly homologous, given 55% sequence identity, and so B and C are expected to have quite similar three-dimensional structures. Thus, proteins A and C are likely to have similar three-dimensional structures, even though they are only 15% identical in sequence.

15. After RNA molecules have been selected and reverse transcribed, PCR is performed to introduce additional mutations into these strands. The use of this error-prone, thermostable polymerase in the amplification step would enhance the efficiency of this random mutagenesis.

Chapter 11

1. a, b, and c

2. b, c, d, and e

3. d

4. Three amino acids can be linked by peptide bonds in only six different ways. However, three different monosaccharides can be linked in a plethora of ways. The monosaccharides can be linked in a linear or branched manner, with α or β linkages, with bonds between C-1 and C-3, between C-1 and C-4, between C-1 and C-6, and so forth. In fact, the three monosaccharides can form 12,288 different trisaccharides.

5. (a) 10; (b) 6; (c) 8; (d) 9; (e) 2; (f) 4; (g) 1; (h) 5; (i) 7; (j) 3.

6. (a) aldose-ketose; (b) epimers; (c) aldose-ketose; (d) anomers; (e) aldose-ketose; (f) epimers.

7. b and c

8. Erythrose: tetrose aldose; ribose: pentose aldose; glyceraldehyde: triose aldose; dihydroxyacetone: triose ketose; erythrulose: tetrose ketose; ribulose: pentose ketose; fructose: hexose ketose.

9. The proportion of the α anomer is 0.36, and that of the β anomer is 0.64.

10. (a) Not a reducing sugar; no open-chain forms are possible; (b) D-galactose, D-glucose, D-fructose; (c) D-galactose and sucrose (glucose + fructose).

11. (a) Each glycogen molecule has one reducing end, whereas the number of nonreducing ends is determined by the number of branches, or α-1,6 linkages. (b) Because the number of nonreducing ends greatly exceeds the number of reducing ends in a collection of glycogen molecules, all of the degradation and synthesis of glycogen takes place at the nonreducing ends, thus maximizing the rate of degradation and synthesis.

12. b, c, and e

13. (a) Cellulose; (b) chitin; (c) glycogen; (d) chitin, glycogen, cellulose, and starch; (e) glycogen and starch.

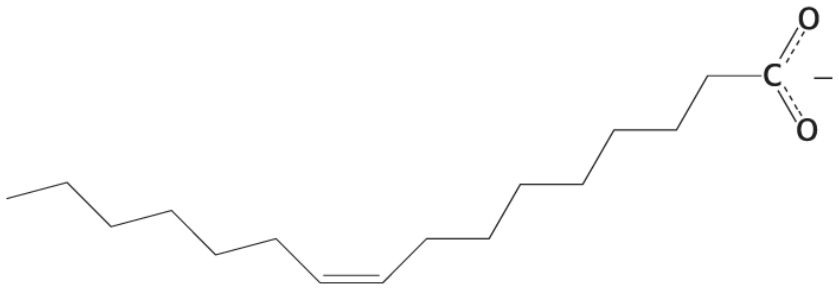
14. Simple glycoproteins are often secreted proteins and thus play a variety of roles. For example, the hormone EPO is a glycoprotein. Usually, the protein component constitutes the bulk of the glycoprotein by mass. In contrast, proteoglycans and mucoproteins are predominantly carbohydrates. Proteoglycans have glycosaminoglycans attached and play structural roles as in cartilage and the extracellular matrix. Mucoproteins often serve as lubricants and have multiple carbohydrates attached through an *N*-acetylgalactosamine moiety.

15. b and c

16. Asparagine, serine, and threonine.

17. A glycoprotein is a protein that is decorated with carbohydrates. A lectin is a protein that specifically recognizes carbohydrates. A lectin can also be a glycoprotein.

18. Each site either is or is not glycosylated, and so there are $2^6 = 64$ possible proteins.



19. If the carbohydrate specificity of the lectin is known, an affinity column with the appropriate carbohydrate attached could be prepared. The protein preparation containing the lectin of interest could be passed over the column. Indeed, the use of this method was how the glucose-binding lectin concanavalin A was purified.

20. (a) Aggrecan is heavily decorated with glycosaminoglycans. If glycosaminoglycans are released into the media, aggrecan must be undergoing degradation. (b) Another enzyme might be present that cleaves glycosaminoglycans from aggrecan without degrading aggrecan. Other experiments not shown established that glycosaminoglycan release is an accurate measure of aggrecan destruction. (c) The control provides a baseline of “background” degradation inherent in the assay. (d) Aggrecan degradation is greatly enhanced. (e) Aggrecan degradation is reduced to the background system. (f) It is an in vitro system in which not all the factors contributing to cartilage stabilization in vivo are present.

Chapter 12

1. This fatty acid contains 18 carbons and two cis double bonds, which are located at carbons 9 and 12. Hence, its designation is $18{:}2(cis, cis, -\Delta^{9,12})$. Its common name is linoleate. Counting from the distal, or ω carbon, the two double bonds are located at positions ω-6 and ω-9.

2.

The common name for this fatty acid is palmitoleate.

3. The C_{16} alkyl chain is attached by an ether linkage. The C-2 carbon atom of glycerol has only an acetyl group attached by an ester linkage instead of a fatty acid, as is the case with most phospholipids.

4. (a) Phospholipids; (b) Sphingolipids, glycolipids, cholesterol; (c) Cholesterol; (d) Sphingomyelin, glycolipids; (e) Glycolipids; (f) Archaeal lipids.

5. 2×10^{-7} cm, 6×10^{-6} cm, and 2×10^{-4} cm.

6. Phospholipids and sphingolipids. Lipid molecules capable of aligning side by side to form a lipid bilayer must be amphipathic as well as have an appropriate geometry. Cholesterol molecules are almost completely hydrophobic and are therefore not capable of forming a lipid bilayer. Fatty acids, triacylglycerols, glycerophospholipids, and sphingomyelins are all amphipathic lipid molecules; however, the geometries of fatty acids and triacylglycerols are not favorable for aligning side by side to form a lipid bilayer.

7. Integral membrane proteins: (a); Peripheral membrane proteins: (b), (d); Lipid-anchored membrane protein: (c).

8. Membrane-spanning α helix: (c); Membrane-spanning β strands: (e); Lipid-anchored membrane protein: (a); Peripheral membrane protein: (b), (d).

9. The protein plotted in part *c* is a transmembrane protein from *C. elegans.* It spans the membrane with four α helices that are prominently displayed as hydrophobic peaks in the hydropathy plot.

Interestingly, the protein plotted in part *a* also is a membrane protein, a porin. This protein is made primarily of β strands, which lack the prominent hydrophobic window of membrane helices. This example shows that, although hydropathy plots are useful, they are not infallible.

10. The protein may contain an α helix that passes through the hydrophobic core of the protein. This helix is likely to feature a stretch of hydrophobic amino acids similar to those observed in transmembrane helices.

11. The radius of this molecule is 3.1×10^{-7} cm, and its diffusion coefficient is $7.4 \times 10^{-9}\ \text{cm}^2\ \text{s}^{-1}$. The average distances traversed are 1.7×10^{-7} cm in 1 μs, 5.4×10^{-6} cm in 1 ms, and 1.7×10^{-4} cm in 1 s.

12. (a) The graph shows that, as temperature increases, the phospholipid bilayer becomes more fluid. T_m is the temperature of the transition from the predominantly less-fluid state to the predominantly more-fluid state. Cholesterol broadens the transition from the less-fluid to the more-fluid state. In essence, cholesterol makes membrane fluidity less sensitive to temperature changes. (b) This effect is important because the presence of cholesterol tends to stabilize membrane fluidity by preventing sharp transitions. Because protein function depends on the proper fluidity of the membrane, cholesterol maintains the proper environment for membrane-protein function.

13. $S = 7.2\ \mu\text{m}$.

14. From lowest melting point to highest: d, c, b, e, a. The fatty acid with the lowest melting point is the one with the highest number of double bonds, α-lineoleic acid (18:3). Palmitoleic acid (16:1) has a higher melting point than α-linoleic acid (18:3) because it only contains one double bond. Oleic acid (18:1) also contains one double bond, but it has a longer fatty acid chain than palmitoleic acid, and subsequently, a higher melting point. Fatty acids without double bonds have the highest melting points, and those that are longer have higher melting points. Thus, palmitic acid (16:0) has a higher melting point than oleic acid (18:1). Stearic acid (18:0) has the highest melting point.

15. Each of the 21 v-SNARE proteins could interact with each of 7 t-SNARE partners. Multiplication gives the total number of different interacting pairs: $7 \times 21 = 147$ different v-SNARE–t-SNARE pairs.

16. The membrane underwent a phase transition from a highly fluid to a nearly frozen state when the temperature was lowered. A carrier can shuttle ions across a membrane only when the bilayer is highly fluid. A channel, in contrast, allows ions to traverse its pore even when the bilayer is quite rigid.

17. (a) H_2O; (b) Indole; (c) H_2O. Permeability is most directly correlated with the solubility in a nonpolar solvent.

18. Hibernators selectively feed on plants that have a high proportion of polyunsaturated fatty acids with lower melting temperature.

19. Saturated phospholipids: c; Unsaturated phospholipids: a, d; Both: b.

20. (a) Prostaglandin H_2 synthase-1 recovers its activity immediately after removal of ibuprofen, suggesting that this inhibitor dissociates rapidly from the enzyme. In contrast, the enzyme remains significantly inhibited 30 minutes after removal of indomethacin, suggesting that this inhibitor dissociates slowly from its active site. (b) Aspirin covalently modifies prostaglandin H_2 synthase-1, indicating that it would dissociate very slowly (if at all). Hence, one would anticipate that very low activity would be evident in all conditions where inhibitor has been added (columns 2, 3, and 4).

Chapter 13

1. In simple diffusion, the substance in question can diffuse down its concentration gradient through the membrane. In facilitated diffusion, the substance is not lipophilic and cannot directly diffuse through the membrane. A channel or carrier is required to facilitate movement down the gradient.

2. Uniporters act as enzymes do; their transport cycles include large conformational changes, and only a few molecules interact with the protein per transport cycle. In contrast, channels, after having opened, provide a pore in the membrane through which many ions may pass. As such, channels mediate transport at a much higher rate than do uniporters.

3. Passive transport: (b), (d); Active transport: (a), (c).

4. For chloride, $z = -1$. At the concentrations given, the equilibrium potential for chloride is $-97\ \text{mV}$.

5. (a) Using $\Delta G = RT \ln (c_2 / c_1) + ZF\Delta V$, where the inside of the cell is side 2 and the outside is side 1, the free energy of sodium transport is:

$$\begin{aligned}\Delta G_{Na} &= (8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{deg}^{-1}) \times (310\ \text{deg}) \times \ln(17/155) \\ &\quad + (1) \times (96.5\ \text{kJ mol}^{-1}\ \text{V}^{-1}) \times (-0.055\ \text{V}) \\ \Delta G_{Na} &= -11.0\ \text{kJ mol}^{-1}\end{aligned}$$

Because two Na^+ ions are transported for each glucose molecule, the maximum energy available for establishing the glucose gradient is $-22.0\ \text{kJ mol}^{-1}$.

(b) For an uncharged solute like glucose, the minimum energy required to pump glucose against a concentration gradient is given by:

$$\Delta G_{gluc} = RT \ln([\text{glucose}]_{in} / [\text{glucose}]_{out})$$

Rearranging this equation, we obtain:

$$[\text{glucose}]_{in} / [\text{glucose}]_{out} = e^{\frac{\Delta G_{gluc}}{RT}} = e^{\frac{(22.0\ \text{kJ mol}^{-1})}{(8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{K}^{-1})(310\ \text{K})}} = 5100$$

6. At pH 7.4, $[H^+] = 3.98 \times 10^{-8}\ \text{M}$, and at pH 2.0, $[H^+] = 0.01\ \text{M}$. Using $\Delta G = RT \ln(c_2 / c_1) + ZF\Delta V$:

$$\begin{aligned}\Delta G &= (8.315 \times 10^{-3}\ \text{kJ mol}^{-1}\ \text{deg}^{-1}) \times (310\ \text{deg}) \times \ln\left(\frac{0.01}{3.98 \times 10^{-8}}\right) \\ &\quad + (1) \times (96.5\ \text{kJ mol}^{-1}\text{V}^{-1}) \times (0.070\text{V}) \\ \Delta G &= 38.8\ \text{kJ mol}^{-1}\end{aligned}$$

7. ABC transporters: (b), (f); P-type ATPases: (c), (d); Both: (a), (e).

8. (b), (c), (f), (g).

9. After the addition of ATP and calcium, SERCA will pump Ca^{2+} ions into the vesicle. However, the accumulation of Ca^{2+} ions inside the vesicle will rapidly lead to the formation of an electrical gradient that cannot be overcome by ATP hydrolysis. The addition of calcimycin will allow the pumped Ca^{2+} ions to flow back out of the vesicle, dissipating the charge buildup, and enabling the pump to operate continuously.

10. The three types of carriers are symporters, antiporters, and uniporters. Symporters and antiporters can mediate secondary active transport.

11. Facilitated diffusion: (e), (i); Primary active transport: (b), (g); Secondary active transport: (c), (d), (h); Both primary and secondary active transport: (a), (f).

12. When a potassium ion passes through the channel, it remains hydrated for most of the distance. However, the channel narrows after the ion passes about 22 Å into the membrane, and K^+ must relinquish its hydration shell. This is energetically costly, but it is compensated by the interaction of K^+ with the carbonyl oxygen atoms in the interior of the channel at its narrow point. Since Na^+ is small compared to K^+, it cannot interact optimally with these oxygen atoms, and can thus not adequately compensate for the high energy cost of Na^+ desolvation.

13. A mutation that impairs the ability of the sodium channel to inactivate would prolong the duration of the depolarizing sodium current, thus lengthening the cardiac action potential.

14. Batrachotoxin blocks the transition from the open to the closed state.

15. (a) Only ASIC1a is inhibited by the toxin. (b) Yes; when the toxin was removed, the activity of the acid-sensing channel began to be restored. (c) 0.9 nM.

16. The blockage of ion channels inhibits action potentials, leading to loss of nervous function. Like tetrodotoxin, these toxin molecules are useful for isolating and specifically inhibiting particular ion channels.

17. Ligand-gated ion channels: (c), (e); Voltage-gated ion channels: (a); Both: (b), (d).

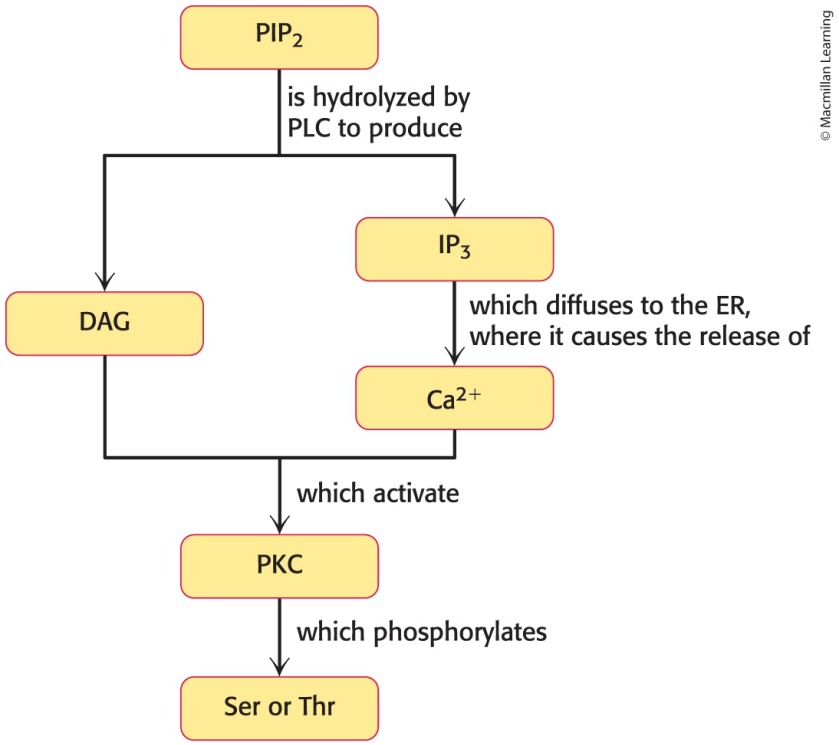
18. After repolarization, the ball domains of the ion channels engage the channel pore, rendering them inactive for a short period of time. During this time, the channels cannot be reopened until the ball domains disengage and the channel returns to the “closed” state.

19. (b), (d), (e), (c), (a), (f).

20. Compound A is TEA, Compound B is TTX.

Chapter 14

1. c, d, a, f, g, e, b



2. c, b, d, a, e, f

3. The rate of cAMP production will be 10^5 per second; in 10 seconds, 10^6 molecules of cAMP will be produced.

4. The mutated α subunit will always be in the GTP (that is, active) form; thus, it would stimulate its signaling pathway.

5. $G_{\alpha s}$ stimulates adenylate cyclase, leading to the generation of cAMP. This signal then leads to glucose mobilization (Chapter 21). If cAMP phosphodiesterase were inhibited, then cAMP levels would remain high even after the termination of the adrenaline signal, and glucose mobilization would continue.

6. (a)

© Macmillan Learning

(b) IP_3, DAG, and Ca^{2+} are considered second messengers.

7. b, c, f

8. G protein-coupled receptors: c, d, g, i

Receptor tyrosine kinases: a, e, f

Both: f

Neither: b

9. Imatinib (Gleevec) is a small molecule that targets the active site of a tyrosine kinase inside the cell; cetuximab (Erbitux) is an antibody that binds to the extracellular domain of the receptor, preventing ligand binding.

10. a, d, e

11. In the reaction catalyzed by adenylate cyclase, the $3'-OH$ group undergoes a nucleophilic attack on the α-phosphorus atom attached to the $5'-OH$ group, leading to displacement of pyrophosphate. The reaction catalyzed by DNA polymerase is similar except that the $3'-OH$ group is on a different nucleotide.

12. $GTP\gamma S$ is not hydrolyzed by the G_α subunit, leading to prolonged activation.

13. (a) Use ATP labeled at the γ (gamma) phosphate; (b) Use ATP labeled at the α (alpha) phosphate.

14. (a) $X \approx 10^{-7}\ M; Y \approx 5 \times 10^{-6}\ M; Z \approx 10^{-3}\ M$. (b) Because much less X is required to fill half of the sites, X displays the highest affinity. (c) The binding affinity almost perfectly matches the ability to stimulate adenylate cyclase, suggesting that the hormone receptor complex leads to the stimulation of adenylate cyclase. (d) Try performing the experiment in the presence of antibodies to $G_{\alpha s}$.

15. The transgenic nematode would avoid the compound. The identity of the ligand is determined by the receptor, whereas the behavioral response is dictated by the neuron in which the receptor is expressed.

16. Only a mixture of compounds $C_5\text{-}COOH$ and $HOOC\text{-}C_7\text{-}COOH$ is predicted to yield this pattern.

17. Sound travels 0.15 m in 428 μs. The human hearing system is capable of sensing time differences of close to a microsecond, and so the difference in arrival times at the two ears is substantial. A system based on G proteins is unlikely to be able to reliably distinguish between signals arriving at the two ears, because G proteins typically respond in milliseconds.

18. (a) 380 (one for each receptor); (b) there are $(380 \times 379)/2! = 72{,}010$ combinations of two receptors; (c) $(380 \times 379 \times 378)/3! = 9{,}073{,}260$ combinations of three receptors.

19. The absorption of light converts 11-*cis*-retinal into all-*trans*-retinal.

Chapter 15

1. Anabolism is the set of biochemical reactions that build new molecules and ultimately new cells and generally use energy. Catabolism is the set of biochemical reactions that break down biomolecules and generally extract energy from fuel sources.

2. Phototrophs derive energy by transforming light into chemical energy. Chemotrophs derive energy from the oxidation of chemicals, either organic such as glucose and fatty acids, or inorganic sources like iron, sulfur, or ammonia.

3. Stage 1 is digestion, where the larger molecules in food are broken into smaller molecules. No ATP is generated. In stage 2, these smaller molecules are converted to key molecules of metabolism. A small amount of ATP is generated in this stage. Stage 3 consists of the complete oxidation of fuel molecules to CO_2 and H_2O. Most of the ATP is produced in stage 3.

4. Cellular movements and the performance of mechanical work; active transport; biosynthetic reactions.

5. Charge repulsion, resonance stabilization, increase in entropy, and stabilization by hydration.

6. Increasing the concentration of ATP or decreasing the concentration of cellular ADP or P_i (by rapid removal by other reactions, for instance) would make the reaction more exergonic. Likewise, altering the Mg^{2+} concentration could raise or lower the ΔG of the reaction (see problem 20).

7. Reactions in parts (a) and (c), to the left; reactions in parts (b) and (d), to the right.

8. (a) $\Delta G^{\circ\prime} = +31.4\ \text{kJ mol}^{-1} (+7.5\ \text{kcal mol}^{-1})$ and $K'_{eq} = 3.06 \times 10^{-6}$; (b) 3.28×10^4.

9. $\Delta G^{\circ\prime} = +7.1\ \text{kJ mol}^{-1} (+1.7\ \text{kcal mol}^{-1})$. The equilibrium ratio is 17.5.

10. (a) $\text{Acetate} + \text{CoA} + H^+$ goes to acetyl $\text{CoA} + H_2O$, $\Delta G^{\circ\prime} = -31.4\ \text{kJ mol}^{-1} (-7.5\ \text{kcal mol}^{-1})$. ATP hydrolysis to AMP and PP_i, $\Delta G^{\circ\prime} = -45.6\ \text{kJ mol}^{-1} (-10.9\ \text{kcal mol}^{-1})$. Overall reaction, $\Delta G^{\circ\prime} = -14.2\ \text{kJ mol}^{-1} (-3.4\ \text{kcal mol}^{-1})$. (b) With pyrophosphate hydrolysis, $\Delta G^{\circ\prime} = -33.4\ \text{kJ mol}^{-1} (-7.98 \text{kcalmol}^{-1})$. Pyrophosphate hydrolysis makes the overall reaction even more exergonic.

11. Arginine phosphate in invertebrate muscle, like creatine phosphate in vertebrate muscle, serves as a reservoir of high-potential phosphoryl groups. Arginine phosphate maintains a high level of ATP in muscular exertion.

12. An ADP unit.

13. (a) The rationale behind creatine supplementation is that it would be converted into creatine phosphate and thus serve as a rapid means of replenishing ATP after muscle contraction. (b) If creatine supplementation is beneficial, it would affect activities that depend on short bursts of activity; any

sustained activity would require ATP generation by fuel metabolism, which, as Figure 15.7 shows, requires more time.

14. Under standard conditions, $\Delta G^{\circ\prime} = -RT \ln [\text{products}]/[\text{reactants}]$. Substituting $+23.8\ \text{kJ mol}^{-1} (+5.7\ \text{kcal mol}^{-1})$q for $\Delta G^{\circ\prime}$ and solving for $[\text{products}]/[\text{reactants}]$ yields 9.9×10^{-5}. In other words, the forward reaction does not take place to a significant extent. Under intracellular conditions, ΔG is $-1.3\ \text{kJ mol}^{-1} (-0.3\ \text{kcal mol}^{-1})$. Using the equation $\Delta G = \Delta G^{\circ\prime} + RT \ln [\text{products}]/[\text{reactants}]$ and solving for $[\text{products}]/[\text{reactants}]$ gives a ratio of 5.96×10^{-5}. Thus, a reaction that is endergonic under standard conditions can be converted into an exergonic reaction by maintaining the [products]/[reactants] ratio below the equilibrium value. This conversion is usually attained by using the products in another coupled reaction as soon as they are formed, thus artificially decreasing their concentration and driving the proceeding reaction forward (Le Chatelier's Principle).

15. Liver: $-45.2\ \text{kJ mol}^{-1} (-10.8\ \text{kcal mol}^{-1})$; muscle: $-48.1\ \text{kJ mol}^{-1} (-11.5\ \text{kcal mol}^{-1})$; brain: $-48.5\ \text{kJ mol}^{-1} (-11.6\ \text{kcal mol}^{-1})$. The ΔG is most negative in brain cells.

16. (a) Ethanol; (b) lactate; (c) succinate; (d) isocitrate; (e) malate.

17. NADH and $FADH_2$ are electron carriers for catabolism; NADPH is the carrier for anabolism.

18. Oxidation–reduction reactions; ligation reactions; isomerization reactions; group-transfer reactions; hydrolytic reactions; cleavage of bonds by means other than hydrolysis or oxidation.

19. Controlling the amount of enzymes; controlling enzyme activity; controlling the availability of substrates.

20. (a) As the Mg^{2+} concentration falls, the ΔG of hydrolysis becomes more negative. Note that pMg is a logarithmic plot, and so each number on the *x*-axis represents a 10-fold change in $[Mg^{2+}]$. (b) Mg^{2+} would bind to the phosphates of ATP and help to mitigate charge repulsion. As the $[Mg^{2+}]$ falls, charge stabilization of ATP would be less, leading to greater charge repulsion and ΔG of hydrolysis becoming more negative.

Chapter 16

1. a and e.

2. b and d.

3. (a) 4; (b) 3; (c) 1; (d) 6; (e) 8; (f) 2; (g) 10; (h) 9; (i) 7; (j) 5.

4. In both cases, the electron donor is glyceraldehyde 3-phosphate. In lactic acid fermentation, the electron acceptor is pyruvate, converting it into lactate. In ethanol fermentation, acetaldehyde is the electron acceptor, forming ethanol.

5. Glucokinase enables the liver to remove glucose from the blood when hexokinase is saturated, ensuring that glucose is captured for later use.

6. The GAP formed is immediately removed by subsequent reactions, resulting in the conversion of DHAP into GAP by the enzyme.

7. Glucose 6-phosphate must have other fates. Indeed, it can be converted into glycogen (Chapter 21) or processed to yield reducing power for biosynthesis (Chapter 20).

8. The conversion of glucose into glucose 6-phosphate by hexokinase; the conversion of fructose 6-phosphate into fructose 1,6-bisphosphate by phosphofructokinase; the formation of pyruvate from phosphoenolpyruvate by pyruvate kinase.

9. GLUT2 transports glucose only when the blood concentration of glucose is high, which is precisely the condition in which the β cells of the pancreas secrete insulin.

10. Without triose isomerase, only one of the two three-carbon molecules generated by aldolase could be used to generate ATP. Only two molecules of ATP would result from the metabolism of each glucose. But two molecules of ATP would still be required to form fructose 1,6-bisphosphate, the substrate for aldolase. The net yield of ATP would be zero, a yield incompatible with life.

11. The equilibrium concentrations of fructose 1,6-bisphosphate, dihydroxyacetone phosphate, and glyceraldehyde 3-phosphate are 7.8×10^{-4} M, 2.2×10^{-4} M, and 2.2×10^{-4} M, respectively.

12. (a) 2, 3, 6, 9; (b) 1, 4, 5, 7, 8.

13. Glucose is an important energy source for both tissues and is essentially the only energy source for the brain. Consequently, these tissues should never release glucose. Glucose release is prevented by the absence of glucose 6-phosphatase.

14. 6 NTP (4 ATP and 2 GTP); 2 NADH.

15. 50 pyruvate, 100 ATP, and 50 NADH.

16. (a) Increased; (b) increased; (c) increased; (d) decreased.

17. b and e.

18. This example illustrates the difference between the *stoichiometric* and the *catalytic* use of a molecule. If cells used NAD^+ stoichiometrically, a new molecule of NAD^+ would be required each time a molecule of lactate was produced. The synthesis of NAD^+ requires ATP. On the other hand, if the NAD^+ that is converted into NADH could be recycled and reused, a small amount of the molecule could regenerate a vast amount of lactate, which is the case in the cell. NAD^+ is regenerated by the oxidation of NADH and reused. NAD^+ is thus used catalytically.

19. Using the Michaelis–Menten equation to solve for [S] when $K_M = 50\ \mu M$ and $V_0 = 0.9V_{max}$ shows that a substrate concentration of 0.45 mM yields 90% of V_{max}. Under normal conditions, the enzyme is essentially working at V_{max}.

20. (a) If both enzymes operated simultaneously, the net result would be simply:

$$ATP + H_2O \rightarrow ADP + P_i$$

The energy of ATP hydrolysis would be released as heat. (b) Not really. For the cycle to generate heat, both enzymes must be functional at the same time in the same cell. (c) The species *B. terrestris* and *B. rufocinctus* might show some futile cycling because both enzymes are active to a substantial degree. (d) No. These results simply suggest that simultaneous activity of phosphofructokinase and fructose 1,6-bisphosphatase is unlikely to be employed to generate heat in the species shown.

Chapter 17

1. The pyruvate dehydrogenase complex catalyzes the following reaction, linking glycolysis and the citric acid cycle:

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \rightarrow \text{acetyl CoA} + \text{NADH} + \text{H}^+ + \text{CO}_2$$

2. a

3. b

4. Thiamine pyrophosphate plays a role in the decarboxylation of pyruvate. Lipoic acid (as lipoamide) transfers the acetyl group. Coenzyme A accepts the acetyl group from lipoic acid to form acetyl CoA. FAD accepts the electrons and hydrogen ions when reduced lipoic acid is oxidized. NAD^+ accepts electrons from FADH_2.

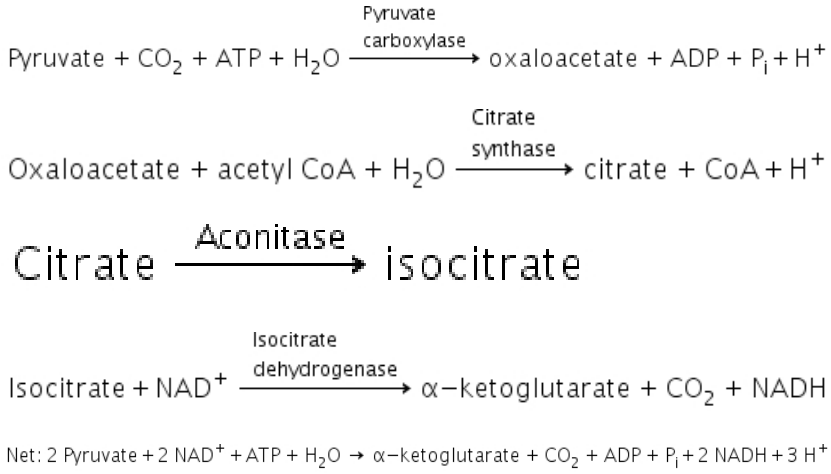
5. Catalytic coenzymes (TPP, lipoic acid, and FAD) are modified but regenerated in each reaction cycle. Thus, they can play a role in the processing of many molecules of pyruvate. Stoichiometric coenzymes (coenzyme A and NAD^+) are used in only one reaction because they are the components of products of the reaction.

6. $-41.0\ \text{kJ mol}^{-1} (-9.8\ \text{kcal mol}^{-1})$

7. (a) DCA inhibits pyruvate dehydrogenase kinase. (b) The fact that inhibiting the kinase results in more dehydrogenase activity suggests that there must be some residual activity that is being inhibited by the kinase.

8. (a) Enhanced kinase activity will result in a decrease in the activity of the PDH complex because phosphorylation by the kinase inhibits the complex. (b) Phosphatase activates the complex by removing a phosphate. If the phosphatase activity is diminished, the activity of the PDH complex also will decrease.

9. (a) 6; (b) 10; (c) 1; (d) 7; (e) 2; (f) 8; (g) 3; (h) 4; (i) 5; (j) 9.



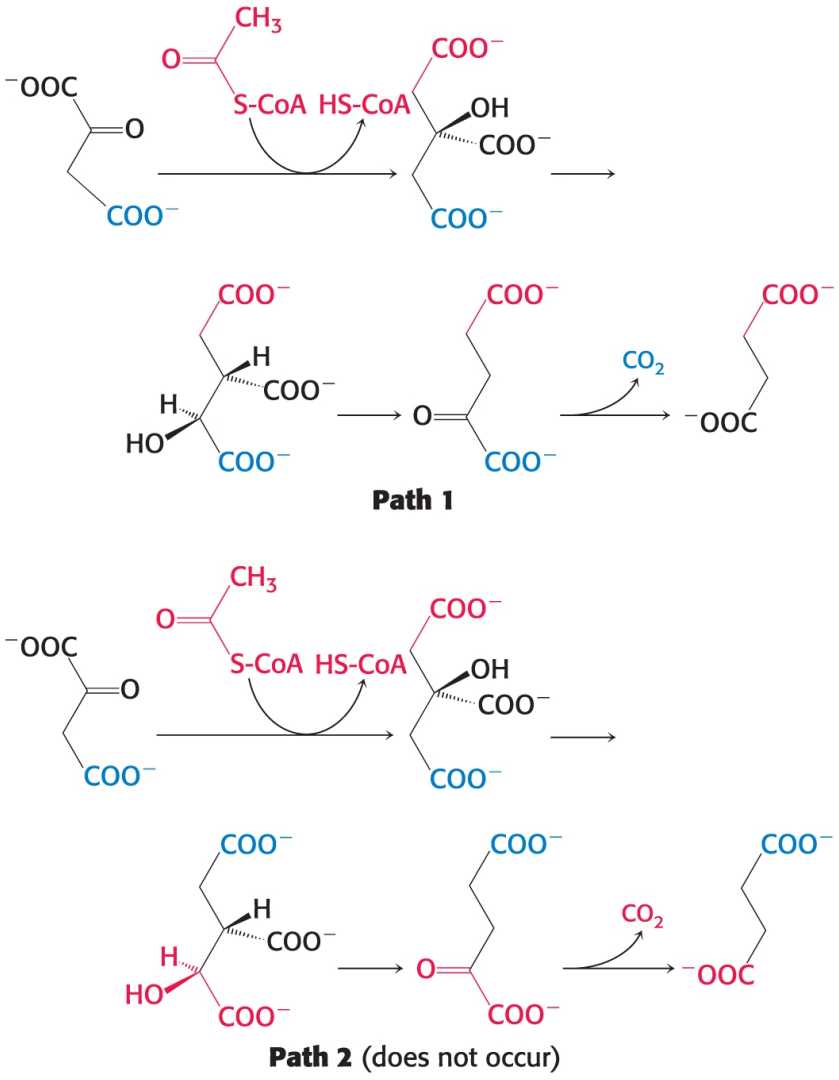
10. (a) 5; (b) 7; (c) 1; (d) 10; (e) 2; (f) 4; (g) 9; (h) 3; (i) 8; (j) 6.

11. Succinate dehydrogenase is the only enzyme in the citric acid cycle that is embedded in the mitochondrial membrane, which makes it associated with the electron-transport chain.

12. (a) The steady-state concentrations of the products are low compared with those of the substrates. (b) The ratio of malate to oxaloacetate must be greater than 1.57×10^4 for oxaloacetate to be formed.

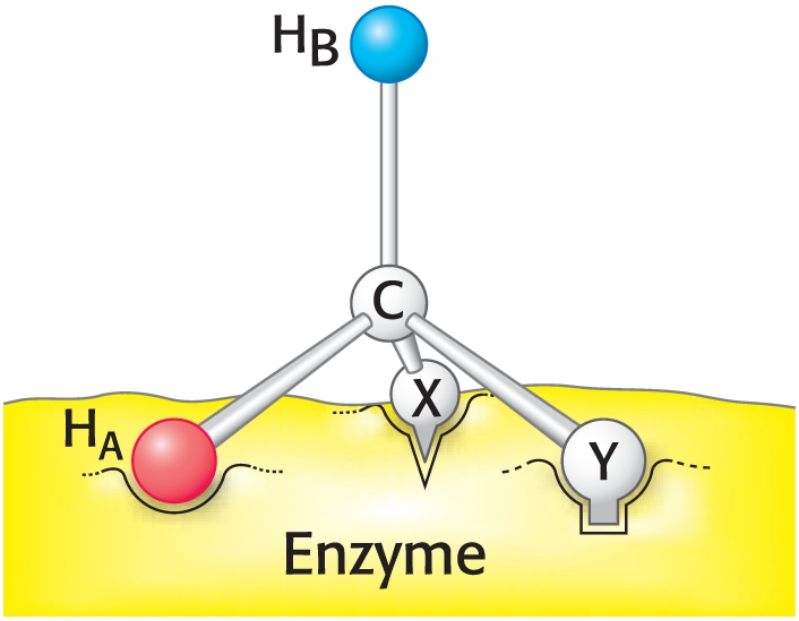
13.

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \xrightarrow[\text{complex}]{\text{Pyruvate dehydrogenase}} \text{acetyl CoA} + \text{CO}_2 + \text{NADH}$$



14. Succinate will increase in concentration, followed by α-ketoglutarate and the other intermediates "upstream" of the site of inhibition. Succinate has two methylene groups that are required for the dehydrogenation, whereas malonate has but one.

15. It enables organisms such as plants and bacteria to convert fats, through acetyl CoA, into glucose.



16. We cannot get the net conversion of fats into glucose, because the only means to get the carbon atoms from fats into oxaloacetate, the precursor of glucose, is through the citric acid cycle. However, although two carbon atoms enter the cycle as acetyl CoA, two carbon atoms are lost as CO_2 before oxaloacetate is formed. Thus, although some carbon atoms from fats may end up as carbon atoms in glucose, we cannot obtain a *net* synthesis of glucose from fats.

17. Acetyl CoA will inhibit the complex. Glucose metabolism to pyruvate will be slowed because acetyl CoA is being derived from an alternative source.

18. (a) Citrate is a symmetric molecule. Consequently, the investigators assumed that the two $-CH_2COO^-$ groups in it would react identically. Thus, for every citrate molecule undergoing the reactions shown in path 1, they thought that another citrate molecule would react as shown in path 2. If so, then only *half* the label should have emerged in the CO_2.

(b) Call one hydrogen atom A and the other B. Now suppose that an enzyme binds three groups of this substrate—X, Y, and H—at three complementary sites. The adjoining diagram shows X, Y, and H_A bound to three points on the enzyme. In contrast, X, Y, and H_B cannot be bound to this active site; two of these three groups can be bound, but not all three. Thus, H_A and H_B will have different fates.

© Macmillan Learning

Sterically nonequivalent groups such as H_A and H_B will almost always be distinguished in enzymatic reactions. The essence of the differentiation of these groups is that the enzyme holds the substrate in a specific orientation. Attachment at three points, as depicted in the diagram, is a readily visualized way of achieving a particular orientation of the substrate, but it is not the only means of doing so.

19. (a) The complete oxidation of citrate requires $4.5\ \mu mol$ of O_2 for every micromole of citrate.

$$C_6H_8O_7 + 4.5\ O_2 \rightarrow 6\ CO_2 + 4\ H_2O$$

Thus, 13.5 μmol of O_2 would be consumed by 3 μmol of citrate. (b) Citrate led to the consumption of far more O_2 than can be accounted for simply by the oxidation of citrate itself. Citrate thus facilitated O_2 consumption.

20. (a) The initial infection is unaffected by the absence of isocitrate lyase, but the absence of this enzyme inhibits the latent phase of the infection. (b) Yes. (c) A critic could say that, in the process of deleting the isocitrate lyase gene, some other gene was damaged, and it is the absence of this other gene that prevents latent infection. Reinserting the isocitrate lyase gene into the bacteria from which it had been removed renders the criticism less valid. (d) Isocitrate lyase enables the bacteria to synthesize carbohydrates that are necessary for survival, including carbohydrate components of the cell membrane.

Chapter 18

1. b

2. a

3. b

4. d

5. Biochemists use E_0', the value at pH 7, whereas chemists use E_0, the value in $1\ M\ H^+$. The prime denotes that pH 7 is the standard state.

6. The reduction potential of $FADH_2$ is less than that of NADH (Table 18.1). Consequently, when those electrons are passed along to oxygen, less energy is released. The consequence of the difference is that electron flow from $FADH_2$ to O_2 pumps fewer protons than do the electrons from NADH. The $\Delta G^{\circ\prime}$ for the reduction of oxygen by $FADH_2$ is $-200\ kJ\ mol^{-1}(-48\ kcal\ mol^{-1})$.

7. $\Delta G^{\circ\prime}$ is $+67\ kJ\ mol^{-1}(+16.1\ kcal\ mol^{-1})$ for oxidation by NAD^+ and $-3.8\ kJ\ mol^{-1}(-0.92\ kcal\ mol^{-1})$ for oxidation by FAD. The oxidation of succinate by NAD^+ is not thermodynamically feasible.

8. c, e, b, a, d.

9. (a) 4; (b) 3; (c) 1; (d) 5; (e) 2.

10. Rotenone: NADH, NADH-Q oxidoreductase will be reduced. The remainder will be oxidized. Antimycin A: NADH, NADH-Q oxidoreductase and coenzyme Q will be reduced. The remainder will be oxidized. Cyanide: All will be reduced.

11. (a) 12.5; (b) 14; (c) 32; (d) 13.5; (e) 30; (f) 16.

12. (a) It blocks electron transport and proton pumping at Complex IV. (b) It blocks electron transport and ATP synthesis by inhibiting the exchange of ATP and ADP across the inner mitochondrial membrane. (c) It blocks electron transport and proton pumping at Complex I. (d) It blocks ATP synthesis without inhibiting electron transport by dissipating the proton gradient. (e) It blocks electron transport and proton pumping at Complex IV. (f) It blocks electron transport and proton pumping at Complex III.

13. ATP synthase will from an arsenate (AsO_4^{3-}) anhydride with ADP. Such compounds are unstable and rapidly hydrolyzed. Under these conditions, no ATP synthesis can occur, but the synthase will continue catalyzing the useless reaction. Consequently, the electron-transport system will keep running, most likely at a higher than normal rate. In essence, arsenate is acting as an uncoupler.

14. (a) No effect; mitochondria cannot metabolize glucose. (b) No effect; no fuel is present to power the synthesis of ATP. (c) $[O_2]$ falls because citrate is a fuel and ATP can be formed from ADP and P_i. (d) Oxygen consumption stops because oligomycin inhibits ATP synthesis, which is coupled to the activity

of the electron-transport chain. (e) No effect, for the reasons given in part (*d*). (f) $[O_2]$ falls rapidly because the system is uncoupled and does not require ATP synthesis to lower the proton-motive force. (g) $[O_2]$ falls, though at a lower rate. Rotenone inhibits Complex I, but the presence of succinate will enable electrons to enter at Complex II. (h) Oxygen consumption ceases because Complex IV is inhibited and the entire chain backs up.

15. (a) The $P:O$ ratio is equal to the product of $(H^+/2e^-)$ and (P/H^+). Note that the $P:O$ ratio is identical with the $P:2\ e^-$ ratio. (b) 2.5 and 1.5, respectively.

16. This inhibitor (like antimycin A) blocks the reduction of cytochrome c_1 by QH_2.

17. If oxidative phosphorylation were uncoupled, no ATP could be produced. In a futile attempt to generate ATP, much fuel would be consumed. The danger lies in the dose. Too much uncoupling would lead to tissue damage in highly aerobic organs such as the brain and heart, which would have severe consequences for the organism as a whole. The energy that is normally transformed into ATP would be released as heat. To maintain body temperature, sweating might increase, although the very process of sweating itself depends on ATP.

18. In humans, the proton motive force is also used to drive the export of ATP from the matrix and the import of phosphate into the matrix. In bacteria, it drives flagellar motion.

19. (a) DNP is an uncoupler that prevents the use of the proton-motive force for ATP synthesis. Consequently, the rate of oxygen consumption rises (reflecting the rate of the electron transport chain) in a futile attempt to synthesize ATP. Because mitochondrial ATP synthesis is inhibited, the rate of glycolysis, as measured by ECAR, increases in an attempt meet the cells ATP needs. (b) Because glycolysis is now inhibited, no lactic acid will be produced, and the rate of extracellular acidification will fall. Because DNP is still present, oxygen consumption will still occur at a high rate. (c) A key step in glycolysis is the isomerization of glucose 6-phosphate to fructose 6-phosphate. 2-Deoxyglucose is incapable of undergoing the isomerization. (d) Rotenone inhibits electron flow through Complex I, the electron transport chain is inhibited, and oxygen consumption ceases.

20. (a) Succinate is oxidized by Complex II, and the electrons are used to establish a proton-motive force that powers ATP synthesis. (b) The ability to synthesize ATP is greatly reduced. (c) The goal was to measure ATP hydrolysis. If succinate had been added in the presence of ATP, no reaction would have taken place, because of respiratory control. (d) The mutation has little effect on the ability of the enzyme to catalyze the hydrolysis of ATP. (e) They suggest two things: (1) the mutation did not affect the catalytic site on the enzyme, because ATP synthase is still capable of catalyzing the reverse reaction, and (2) the mutation did not affect the amount of enzyme present, given that the controls and patients had similar amounts of activity.

Chapter 19

1. d

2. a

3. a

4. c

5. The oxygen we require is produced by photosynthesis. Moreover, most of the carbon atoms of which we are made, not just carbohydrates, enter the biosphere through the process of photosynthesis.

6. $2\ NADP^+ + 3\ ADP^{3-} + 3\ P_i^{\ 2-} + H^+ \rightarrow O_2 + 2\ NADPH + 3\ ATP^{4-} + H_2O$

7. (a) PS I; (b) PS II; (c) PS II; (d) PS II; (e) PS I.

8. Photosystem II, in conjunction with the water-oxidizing complex, powers oxygen release. The reaction center of photosystem II absorbs light maximally at 680 nm. Oxygen consumption will be maximal when photosystems I and II are operating cooperatively. Oxygen will be efficiently generated when electrons from photosystem II fill the electron holes in photosystem I, which were generated when the reaction center of photosystem I was illuminated by light of 700 nm.

9. The light reactions take place on thylakoid membranes. Increasing the membrane surface increases the number of ATP- and NADPH-generating sites.

10. These complexes absorb more light than a reaction center alone can absorb by using additional pigments. The light-harvesting complexes funnel light energy to the reaction centers using resonance energy transfer.

11. $NADP^+$ is the acceptor. H_2O is the donor. Light energy.

12. Protons released by the oxidation of water; protons pumped into the lumen by the cytochrome *bf* complex; protons removed from the stroma by the reduction of $NADP^+$ and plastoquinone.

13. $\Delta E_0' = 10.11\ V$, and $\Delta G^{\circ\prime} = -21.3\ kJ\ mol^{-1} (-5.1\ kcal\ mol^{-1})$.

14. Not at all. Chemicals other than water can donate electrons and protons as they do in anoxygenic photosynthesis on Earth today.

15. DCMU inhibits electron transfer in the link between photosystems II and I. O_2 can evolve in the presence of DCMU if an artificial electron acceptor such as ferricyanide can accept electrons from Q.

16. DCMU will have no effect, because it blocks photosystem II, and cyclic photophosphorylation uses photosystem I and the cytochrome *bf* complex.

17. (a) $+120\ kJ\ einstein^{-1} (+28.7\ kcal\ einstein^{-1})$; (b) 1.24 V; (c) One 1000-nm photon has the free-energy content of 2.4 molecules of ATP. A minimum of 0.42 photon is needed to drive the synthesis of a molecule of ATP.

18. The cristae, formed by the inner mitochondrial membrane, and the matrix.

19. In eukaryotes, both processes take place in specialized organelles. Both depend on high-energy electrons to generate ATP. In oxidative phosphorylation, the high-energy electrons originate in fuels and are extracted as reducing power in the form of NADH. In photosynthesis, the high-energy electrons are generated by light and are captured as reducing power in the form of NADPH. Both processes use redox reactions to generate a proton gradient, and the enzymes that convert the proton gradient into ATP are very similar in both processes. In both systems, electron transport takes place in membranes inside organelles.

18. Fava beans can be dangerous for individuals with glucose 6-phosphate deficiency.

19. (a) $5\ \text{Glucose 6–phosphate} + ATP \rightarrow 6\ \text{ribose 5–phosphate} + ADP + H^+$. (b) $\text{Glucose 6–phosphate} + 12\ NADP^+ + 7\ H_2O \rightarrow 6\ CO_2 + 12\ NADPH + 12\ H^+ + P_i$.

20. The C_4 pathway allows the CO_2 concentration to increase at the site of carbon fixation. High concentrations of CO_2 inhibit the oxygenase reaction of Rubisco. This inhibition is important for tropical plants because the oxygenase activity increases more rapidly with temperature than does the carboxylase activity.

21. d.

Chapter 21

1. Step 1 is the release of glucose 1-phosphate from glycogen by glycogen phosphorylase. Step 2 is the formation of glucose 6-phosphate from glucose 1-phosphate, a reaction catalyzed by phosphoglucomutase. Step 3 is the remodeling of the glycogen by the transferase and the α-1,6-glucosidase.

2. b.

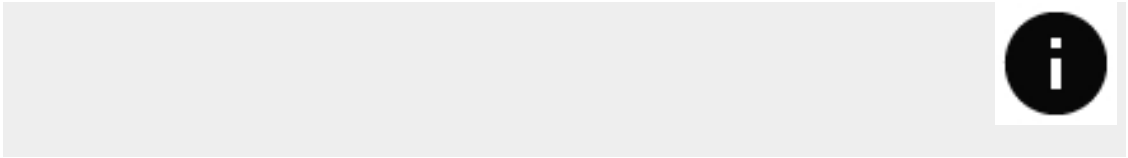
3. d.

4. As an unbranched polymer, α-amylose has only one nonreducing end. Therefore, only one glycogen phosphorylase molecule could degrade each α-amylose molecule. Because glycogen is highly branched, there are many nonreducing ends per molecule. Consequently, many phosphorylase molecules can release many glucose molecules per glycogen molecule, providing a rapid source of energy.

5. In muscle, the *b* form of phosphorylase is activated by AMP. In the liver, the *a* form is inhibited by glucose. The difference corresponds to the difference in the metabolic role of glycogen in each tissue. Muscle uses glycogen as a fuel for contraction, whereas the liver uses glycogen to maintain blood-glucose concentration.

6. Water is excluded from the active site to prevent hydrolysis. The entry of water could lead to the formation of glucose rather than glucose 1-phosphate. A site-specific mutagenesis experiment is revealing in this regard. In phosphorylase, Tyr 573 is hydrogen bonded to the $2'-OH$ group of a glucose residue. The ratio of glucose 1-phosphate to glucose product is 9,000:1 for the wild-type enzyme and 500:1 for the Phe 573 mutant. Model building suggests that a water molecule occupies the site normally filled by the phenolic OH group of tyrosine and occasionally attacks the carbocation intermediate to form glucose.

7. Epinephrine binds to its G-protein-coupled receptor. The resulting structural changes activate a G_α protein, which in turn activates adenylate cyclase. Adenylate cyclase synthesizes cAMP, which activates protein kinase A. Protein kinase A partly activates phosphorylase kinase, which phosphorylates and activates glycogen phosphorylase. The calcium released during muscle contraction also activates the phosphorylase kinase, leading to further stimulation of glycogen phosphorylase.



8. First, the signal-transduction pathway is shut down when the initiating hormone is no longer present. Second, the inherent GTPase activity of the G protein converts the bound GTP into inactive GDP. Third, phosphodiesterases convert cyclic AMP into AMP. Fourth, PP1 removes the phosphoryl group from glycogen phosphorylase, converting the enzyme into the usually inactive *b* form.

9. It prevents both from operating simultaneously, which would lead to a useless expenditure of energy.

10. Phosphoglucomutase, UDP-glucose pyrophosphorylase, pyrophosphatase, glycogenin, glycogen synthase, and branching enzyme.

11. The enzyme pyrophosphatase converts the pyrophosphate into two molecules of inorganic phosphate. This conversion renders the overall reaction irreversible.

$$\text{Glucose 1-phosphate} + \text{UTP} \rightleftharpoons \text{UDP-glucose} + PP_i$$
$$PP_i + H_2O \longrightarrow 2\ P_i$$
$$\text{Glucose 1-phosphate} + \text{UTP} + H_2O \longrightarrow \text{UDP-glucose} + 2\ P_i$$

12. The presence of high concentrations of glucose 6-phosphate indicates that glucose is abundant and that it is not being used by glycolysis. Therefore, this valuable resource is saved by incorporation into glycogen.

13. $\text{Glycogen}_n + P_i \rightarrow \text{glycogen}_{n-1} + \text{glucose 6-phosphate}$

$$\text{Glucose 6-phosphate} \rightarrow \text{glucose 1-phosphate}$$

$$\text{UTP} + \text{glucose 1-phosphate} \rightarrow \text{UDP-glucose} + 2\ P_i$$

$$\text{Glycogen}_{n-1} + \text{UDP-glucose} \rightarrow \text{glycogen}_n + \text{UDP}$$

$$\text{Sum: Glycogen}_n + \text{UTP} \rightarrow \text{glycogen}_n + \text{UDP} + P_i$$

14. Insulin binds to its receptor and activates the tyrosine kinase activity of the receptor, which in turn triggers a pathway that activates protein kinases. The kinases phosphorylate and inactivate glycogen synthase kinase. Protein phosphatase 1 then removes the phosphate from glycogen synthase and thereby activates the synthase.

15. $\text{Galactose} + \text{ATP} + \text{UTP} + H_2O + \text{glycogen}_n \longrightarrow \text{glycogen}_{n+1} + \text{ADP} + \text{UDP} + 2\ P_i + H^+$.

16. a, b, c, and d.

17. This disease can also be produced by a mutation in the gene that encodes the glucose 6-phosphate transporter. Recall that glucose 6-phosphate must be transported into the lumen of the endoplasmic reticulum to be hydrolyzed by phosphatase. Mutations in the other three essential proteins of this system can likewise lead to von Gierke disease.

18. (a) Apparently, the glutamate, with its negatively charged R group, can mimic to some extent the presence of a phosphoryl group on serine. That the stimulation is not as great is not surprising in that the carboxyl group is smaller and not as charged as the phosphate. (b) Substitution of aspartate would give some stimulation, but because it is smaller than the glutamate, the stimulation would be smaller.

19. (a) Glycogen was too large to enter the gel and, because analysis was by western blot with the use of an antibody specific to glycogenin, we would not expect to see background proteins. (b) α-Amylase degrades glycogen, releasing the protein glycogenin, which can be visualized by a western blot. (c) Glycogen phosphorylase, glycogen synthase, and protein phosphatase 1. These proteins might be visible if the gel were stained for protein, but a western analysis using only an anti-glycogenin antibody reveals the presence of glycogenin only.

20. (a) The smear was due to molecules of glycogenin with increasingly large amounts of glycogen attached to them. (b) In the absence of glucose in the medium, glycogen is metabolized, resulting in a loss of the high-molecular-weight material. (c) Glycogen could have been resynthesized and added to the glycogenin when the cells were fed glucose again. (d) No difference between lanes 3 and 4 suggests that, by 1 hour, the glycogen molecules had attained maximum size in this cell line. Prolonged incubation does not apparently increase the amount of glycogen. (e) α-Amylase removes essentially all of the glycogen, and so only the glycogenin remains.

Glycerol kinase and glycerol phosphate dehydrogenase

2. b, c, a, g, h, d, e, f.

3. The citric acid cycle. The reactions that take succinate to oxaloacetate, or the reverse, are similar to those of fatty acid metabolism (Section 17.3).

4. Palmitic acid yields 106 molecules of ATP. Palmitoleic acid has a double bond between carbons C-9 and C-10. When palmitoleic acid is processed in β-oxidation, one of the oxidation steps (to introduce a double bond before the addition of water) will not take place, because a double bond already exists. Thus, $FADH_2$ will not be generated, and palmitoleic acid will yield 1.5 fewer molecules of ATP than palmitic acid, for a total of 104.5 molecules of ATP.

5. To form stearoyl CoA requires the equivalent of 2 molecules of ATP.

$$\text{Stearoyl CoA} + 8\ FAD + 8\ NAD^+ + 8\ CoA + 8\ H_2O \rightarrow$$
$$9\ \text{acetylCoA} + 8\ FADH_2 + 8\ NADH + 8\ H^+$$

9 acetyl CoA at $10\ ATP/\text{acetyl CoA}$	+90 ATP
8 NADH at $2.5\ ATP/NADH$	+20 ATP
$8\ FADH_2$ at $1.5\ ATP/FADH_2$	+12 ATP
Activation fee	−2.0
Total	**122 ATP**

6. $\text{Stearate} + ATP + 13.5\ H_2O + 8\ FAD + 8\ NAD^+ \rightarrow$
$4.5\ \text{acetoacetate} + 14.5\ H^+ + 8\ FADH_2 + 8\ NADH + AMP + 2\ P_i$.

7. a, b, and d.

8. a, b, and c.

9. The formation of malonyl CoA from acetyl CoA by acetyl CoA carboxylase 1.

10. (a) Oxidation in mitochondria; synthesis in the cytoplasm. (b) Coenzyme A in oxidation; acyl carrier protein for synthesis. (c) FAD and NAD^+ in oxidation; NADPH for synthesis. (d) The l isomer of 3-

hydroxyacyl CoA in oxidation; the d isomer in synthesis. (e) From carboxyl to methyl in oxidation; from methyl to carboxyl in synthesis. (f) The enzymes of fatty acid synthesis, but not those of oxidation, are organized in a multienzyme complex.

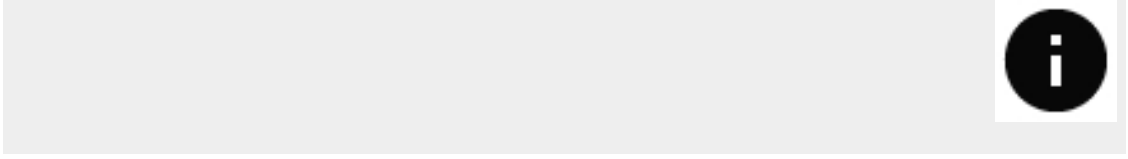
11. We will need six acetyl CoA units. One acetyl CoA unit will be used directly to become the two carbon atoms farthest from the acid end. The other five units must be converted into malonyl CoA. The synthesis of each malonyl CoA molecule costs 1 molecule of ATP; so 5 molecules of ATP will be required. Each round of elongation requires 2 molecules of NADPH, 1 molecule to reduce the keto group to an alcohol, and 1 molecule to reduce the double bond. As a result, 10 molecules of NADPH will be required. Therefore, 5 molecules of ATP and 10 molecules of NADPH are required to synthesize lauric acid.

12. e, b, d, a, c.

13. (a) False. Biotin is required for acetyl CoA carboxylase activity. (b) True. (c) False. ATP is required to synthesize malonyl CoA. (d) True. (e) True. (f) False. Fatty acid synthase is a dimer. (g) True. (h) False. Acetyl CoA carboxylase is stimulated by citrate, which is cleaved to yield its substrate acetyl CoA.

14. All of the labeled carbon atoms will be retained. Because we need 8 acetyl CoA molecules and only 1 carbon atom is labeled in the acetyl group, we will have 8 labeled carbon atoms. The only acetyl CoA used directly will retain 3 tritium atoms. The 7 acetyl CoA molecules used to make malonyl CoA will lose 1 tritium atom on addition of the CO_2 and another one at the dehydration step. Each of the 7 malonyl CoA molecules will retain 1 tritium atom. Therefore, the total retained tritium is 10 atoms. The ratio of tritium to carbon is 1.25.

15. The mutant enzyme will be persistently active because it cannot be inhibited by phosphorylation. Fatty acid synthesis will be abnormally active. Such a mutation might lead to obesity.



16. (a) Palmitoleate; (b) linoleate; (c) linoleate; (d) oleate; (e) oleate; (f) linolenate.

17. Citrate works by facilitating, in cooperation with the protein MIG12, the formation of active filaments from inactive monomers. In essence, it increases the number of active sites available, or the concentration of enzyme. Consequently, its effect is visible as an increase in the value of V_{max}. Allosteric enzymes that alter their V_{max} values in response to regulators are sometimes called V-class enzymes. The more common type of allosteric enzyme, in which K_M is altered, comprises K-class enzymes. Palmitoyl CoA causes depolymerization and thus inactivation.

18. Regulation by insulin: a, b, e; regulation by glucagon or epinephrine: c, d, f.

19. The first reaction

$$\text{Oxaloacetate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{malate} + \text{NAD}^+$$

is catalyzed by cytoplasmic malate dehydrogenase. The next reaction is catalyzed by malic enzyme:

$$\text{Malate} + \text{NADP}^+ \rightarrow \text{pyruvate} + \text{CO}_2 + \text{NADPH}$$

Finally, oxaloacetate is regenerated from pyruvate by pyruvate carboxylase.

$$\text{Pyruvate} + \text{CO}_2 + \text{ATP} + \text{H}_2\text{O} \rightarrow \text{oxaloacetate} + \text{ADP} + \text{P}_\text{i} + 2\,\text{H}^+$$

The sum of the reactions is

$$\text{NADP}^+ + \text{NADH} + \text{ATP} + \text{H}_2\text{O} \rightarrow \text{NADPH} + \text{NAD}^+ + \text{ADP} + \text{P}_\text{i} + \text{H}^+$$

20. (a) The V_{max} is decreased and the K_M is increased. $V_{max}(\text{wild type}) = 13\ \text{nmol minute}^{-1}\,\text{mg}^{-1}$; $K_M(\text{wildtype}) = 45\ \mu\text{M}$; $V_{max}(\text{mutant}) = 8.3\ \text{nmol minute}^{-1}\,\text{mg}^{-1}$; $K_M(\text{mutant}) = 74\ \text{mM}$. (b) Both the V_{max} and the K_M are decreased. $V_{max}(\text{wild type}) = 41\ \text{nmol minute}^{-1}\,\text{mg}^{-1}$; $K_M\text{wild type} = 104\ \mu\text{M}$; $23\ \text{nmol minute}^{-1}\,\text{mg}^{-1}$; $K_M(\text{mutant}) = 69\ \mu\text{M}$. (c) The wild type is significantly more sensitive to malonyl CoA. (d) With respect to carnitine, the mutant displays approximately 65% of the activity of the wild type; with respect to palmitoyl CoA, approximately 50% activity. On the other hand, 10 μM of malonyl CoA inhibits approximately 80% of the wild type but has essentially no effect on the mutant enzyme. (e) The glutamate appears to play a more prominent role in regulation by malonyl CoA than in catalysis.

21. (a) Soraphen A inhibits fatty acid synthesis in a dose-dependent manner. (b) Fatty acid oxidation is increased in the presence of soraphen A. (c) Recall that acetyl CoA carboxylase 2 synthesizes malonyl CoA to inhibit the transport of fatty acids into the mitochondria, thereby preventing fatty acid oxidation. Soraphen A apparently inhibits both forms of the carboxylase. (d) Phospholipid synthesis was inhibited in a dose-dependent manner. (e) Phospholipids are required for membrane synthesis. (f) Soraphen A inhibits cell proliferation, especially at higher concentrations.

Chapter 23

1. First, the ubiquitin-activating enzyme (E1) links ubiquitin to a sulfhydryl group on E1 itself. Next, the ubiquitin is transferred to a cysteine residue on the ubiquitin-conjugating enzyme (E2) by E2. The ubiquitin-protein ligase (E3), using the ubiquitinated E2 as a substrate, transfers the ubiquitin to the target protein.

2. (a) The ATPase activity of the 26S proteasome resides in the 19S subunit. The energy of ATP hydrolysis is used to unfold the substrate, which is too large to enter the catalytic barrel. ATP may also be required for translocation of the substrate into the barrel. (b) Substantiates the answer in part (*a*). Because they are small, the peptides do not need to be unfolded. Moreover, small peptides could probably enter all at once and not require translocation.

3. b

4. d

5. c

6. b

7. (a) Pyruvate; (b) oxaloacetate; (c) α-ketoglutarate; (d) α-ketoisocaproate; (e) phenylpyruvate; (f) hydroxyphenylpyruvate.

8. (a) $\text{Aspartate} + \alpha\text{-ketoglutarate} + \text{GTP} + \text{ATP} + 2\ H_2O + \text{NADH} + H^+ \rightarrow \frac{1}{2}\text{glucose} + \text{glutamate} + CO_2 + \text{ADP} + \text{GDP} + NAD^+ + 2\ P_i$.

The required coenzymes are pyridoxal phosphate in the transamination reaction and NAD^+/NADH in the redox reactions. (b) $\text{Aspartate} + CO_2 + NH_4^+ + 3\ \text{ATP} + NAD^+ + 4\ H_2O \rightarrow \text{oxaloacetate} + \text{urea} + 2\ \text{ADP} + 4\ P_i + \text{AMP} + \text{NADH} + H^+$.

9. Aspartate (oxaloacetate), glutamate (α-ketoglutarate), alanine (pyruvate).

10. (a) 4; (b) 5; (c) 1; (d) 6; (e) 7; (f) 3; (g) 2.

11. A, arginine; B, citrulline; C, ornithine; D, argininosuccinate. The order of appearance: C, B, D, A.

12. $CO_2 + NH_4^+ + 3\ \text{ATP} + NAD^+ + \text{aspartate} + 3\ H_2O \rightarrow \text{urea} + 2\ \text{ADP} + 2\ P_i + \text{AMP} + PP_i + \text{NADH} + H^+ + \text{oxaloacetate}$.

Four high-transfer-potential phosphoryl groups are spent. Note, however, that an NADH is generated if fumarate is converted into oxaloacetate. NADH can generate 2.5 ATP in the electron-transport chain. Taking these ATP into account, only 1.5 high-transfer-potential phosphoryl groups are spent.

13. The synthesis of fumarate by the urea cycle is important because it links the urea cycle and the citric acid cycle. Fumarate is hydrated to malate, which, in turn, is oxidized to oxaloacetate. Oxaloacetate has several possible fates: (1) transamination to aspartate, (2) conversion into glucose by

the gluconeogenic pathway, (3) condensation with acetyl CoA to form citrate, or (4) conversion into pyruvate.

14. Aspartame, a dipeptide ester (L-aspartyl-L-phenylalanine methyl ester), is hydrolyzed to L-aspartate and L-phenylalanine. High levels of phenylalanine are harmful in phenylketonurics.

15. The carbon skeletons of ketogenic amino acids can be converted into ketone bodies or fatty acids. Only leucine and lysine are purely ketogenic. Glucogenic amino acids are those with carbon skeletons that can be converted into glucose.

16. The branched-chain amino acids leucine, isoleucine, valine, and threonine. The required enzyme is the branched-chain α-ketoacid dehydrogenase complex.

17. Pyruvate (glycolysis and gluconeogenesis), acetyl CoA (citric acid cycle and fatty acid synthesis), acetoacetyl CoA (ketone-body formation), α-ketoglutarate (citric acid cycle), succinyl CoA (citric acid cycle), fumarate (citric acid cycle), and oxaloacetate (citric acid cycle and gluconeogenesis).

18. Double-displacement. A substituted enzyme intermediate is formed.

19. (a) Depletion of glycogen stores. When they are gone, proteins must be degraded to meet the glucose needs of the brain. The resulting amino acids are deaminated, and the nitrogen atoms are excreted as urea. (b) The brain has adapted to the use of ketone bodies, which are derived from fatty acid catabolism. In other words, the brain is being powered by fatty acid breakdown. (c) When the glycogen and lipid stores are gone, the only available energy source is protein.

20. (a) Virtually no digestion in the absence of nucleotides. (b) Protein digestion is greatly stimulated by the presence of ATP. (c) AMP-PNP, a nonhydrolyzable analog of ATP, is no more effective than ADP. (d) The proteasome requires neither ATP nor PAN to digest small substrates. (e) PAN and ATP hydrolysis may be required to unfold the peptide and translocate it into the proteasome. (f) Although *Thermoplasma* PAN is not as effective with the other proteasomes, it nonetheless results in threefold to fourfold stimulation of digestion. (g) In light of the fact that the archaea and eukarya diverged several billion years ago, the fact that *Thermoplasma* PAN can stimulate the rabbit muscle proteasome suggests homology not only between the proteasomes, but also between PAN and the 19S subunit (most likely the ATPases) of the mammalian 26S proteasome.

Chapter 24

1. Normal circumstances: b; after fasting: d.

2. c.

3. Over the 40 years under consideration, our test subject will have consumed

$$40\ \text{years} \times 365\ \text{days year}^{-1} \times 8400\ \text{KJ (2000 kcal) day}^{-1}$$
$$= 1.2 \times 10^8\ \text{kJ} (2.9 \times 10^7\ \text{kcals})\ \text{in 40 years.}$$

Thus, over the 40-year span, our subject has ingested

$$1.2 \times 108 (2.9 \times 10^7\ \text{kcal}) / 38\ \text{kJ} (9\ \text{kcal g}^{-1})$$
$$= 3.2 \times 10^6\ \text{g} = 3200\ \text{kg of food,}$$

which is equivalent to more than 6 tons of food!

4. $2.55\ \text{pounds} = 25\ \text{kg} = 25{,}000\ \text{g} = \text{total weight gain}$

$$40\ \text{years} \times 365\ \text{days year}^{-1} = 14{,}600\ \text{days}$$
$$25{,}000\ \text{g} / 14{,}600\ \text{days} = 1.7\ \text{g day}^{-1}$$

which is equivalent to an extra pat of butter per day. Her BMI is 26.5, and she would be considered overweight but not obese.

5. Adipose tissue is now known to be an active endocrine organ, secreting signal molecules called adipokines.

6. Leptin and insulin.

7. CCK produces a feeling of satiety and stimulates the secretion of digestive enzymes by the pancreas and the secretion of bile salts by the gallbladder. GLP-1 also produces a feeling of satiety; in addition, it potentiates the glucose-induced secretion of insulin by the β cells of the pancreas.

8. (a) 1, 2; (b) 6; (c) 3, 4; (d) 3, 4; (e) 3; (f) 6; (g) 5; (h) 5; (i) 5.

9. Type 1 diabetes is due to autoimmune destruction of the insulin-producing cells of the pancreas. Type 1 diabetes is also called insulin-dependent diabetes because affected people require insulin to survive. Type 2 diabetes is characterized by insulin resistance. Insulin is produced, but the tissues that should respond to insulin, such as muscle, do not.

10. a, b, and c.

11. (a) A watt is equal to 1 joule (J) per second (0.239 calorie per second). Hence, 70 W is equivalent to $0.07\ kJ\ s^{-1} (0.017\ kcal\ s^{-1})$. (b) A watt is a current of 1 ampere (A) across a potential of 1 volt (V). For simplicity, let us assume that all the electron flow is from NADH to O_2 (a potential drop of 1.14 V). Hence, the current is 61.4 A, which corresponds to 3.86×10^{20} electrons per second $(1A = 1coulomb\ s^{-1} = 6.28 \times 10^{18}\ charge\ s^{-1})$. (c) About 2.5 molecules of ATP are formed per molecule of NADH oxidized (two electrons). Hence, 1 molecule of ATP is formed per 0.8 electron transferred. A flow of $3.86 \times 10^{20}\ electrons$ per second therefore leads to the generation of 4.83×10^{20} molecules of ATP per second, or $0.80\ mmols^{-1}$. (d) The molecular weight of ATP is $507\ g/mol$. The total body content of ATP of 50 g is equal to 0.099 mol. Hence, ATP turns over about once in 125 seconds when the body is at rest.

12. (a) The stoichiometry of the complete oxidation of glucose is

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$$

and that of tripalmitoylglycerol is

$$C_{51}H_{98}O_2 + 72.5\ O_2 \rightarrow 51\ CO_2 + 49\ H_2O$$

Hence, the RQ values are 1.0 and 0.703, respectively. (b) An RQ value reveals the relative use of carbohydrates and fats as fuels. The RQ of an amateur marathon runner typically decreases from 0.97 to 0.77 in the course of a race. The lowering of the RQ indicates the shift in fuel from carbohydrates to fat.

13. A high blood-glucose level triggers the secretion of insulin, which stimulates removal of glucose from the blood for the synthesis of glycogen and triacylglycerols. A high insulin level would impede the mobilization of fuel reserves during the marathon.

14. (a) Insulin inhibits lipid utilization. Insulin stimulates protein synthesis, but there are no amino acids in the children's diet. Moreover, insulin inhibits protein breakdown. Consequently, muscle proteins cannot be broken down and used for the synthesis of essential proteins. (b) Because proteins cannot be synthesized, blood osmolarity is too low. Consequently, fluid leaves the blood. An especially important protein for maintaining blood osmolarity is albumin.

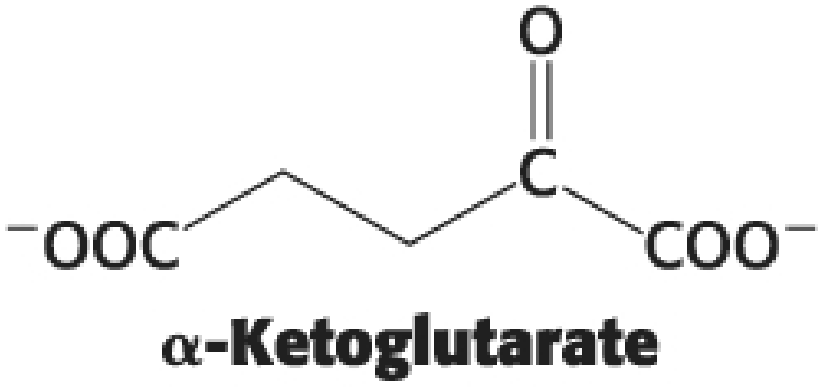
15. During strenuous exercise, muscle converts glucose into pyruvate through glycolysis. Some of the pyruvate is processed by cellular respiration. However, some of it is converted into lactate and released into the blood. The liver takes up the lactate and converts it into glucose through gluconeogenesis. Muscle may process the carbon skeletons of branched-chain amino acids aerobically. The nitrogens of these amino acids are transferred to pyruvate to form alanine, which is released into the blood and taken up by the liver. After the transamination of the amino group to α-ketoglutarate, the resulting pyruvate is converted into glucose. Finally, muscle glycogen may be mobilized, and the released glucose can be used by muscle. The conversion of pyruvate to lactate allows muscle to function anaerobically. NAD^+ is regenerated when pyruvate is reduced to lactate, and so energy can continue to be extracted from glucose during strenuous exercise. The liver converts the lactate into glucose.

16. Fatty acids and glucose, respectively.

17. (a) The oxygen consumption at the end of exercise is used to replenish ATP and creatine phosphate and to oxidize any lactate produced. (b) After strenuous exercise, oxygen is used in oxidative phosphorylation to resynthesize ATP and creatine phosphate. The liver converts lactate released by the muscle into glucose. Blood must be circulated to return the body temperature to normal, and so the heart cannot return to its resting rate immediately. Hemoglobin must be reoxygenated to replace the oxygen used in exercise. The muscles that power breathing must continue working at the same time as the exercised muscles are returning to resting states. In essence, all the biochemical systems activated in intense exercise need increased oxygen to return to the resting state.

18. (a) The increase in all of the ratios is due to the NADH glut caused by the metabolism of alcohol. (b) The increased amounts of lactate and d-3-hydroxybutyrate are released into the blood, accounting for the acidosis. (c) Drinking on an empty stomach suggests that glycogen stores are low. Because of the NADH glut, gluconeogenesis cannot occur. Consequently, hypoglycemia results. A well-fed drinker will have glucose in the blood from the meal and thus will not experience hypoglycemia.

19. The precise cause of all of the symptoms is not firmly established, but a likely explanation depends on the centrality of oxaloacetate to metabolism. A lack of pyruvate carboxylase would reduce the amount of oxaloacetate. The lack of oxaloacetate would reduce the activity of the citric acid cycle and so ATP would be generated by lactic acid formation. If the concentration of oxaloacetate is low, aspartate cannot be formed and the urea cycle would be compromised. Oxaloacetate is also required to form citrate, which transports acetyl CoA to the cytoplasm for fatty acid synthesis. Finally, oxaloacetate is required for gluconeogenesis.



20. (a) Red blood cells always produce lactate, and fast-twitch or type II muscle fibers also produce a large amount of lactate. (b) At that point, the athlete is beginning to move into anaerobic exercise, in which most energy is produced by anaerobic glycolysis. (c) The lactate threshold is essentially the point at which the athlete switches from aerobic exercise, which can be done for extended periods, to anaerobic exercise, essentially sprinting, which can be done for only short periods. The idea is to race at the extreme of his or her aerobic capacity until the finish line is in sight and then to switch to anaerobic. (d) Training increases the number of blood vessels and of muscle mitochondria. Together, they increase the ability to process glucose aerobically. Consequently, a greater effort can be expended before the switch to anaerobic energy production.

Chapter 25

1. The reductase provides electrons with high reducing power, whereas the nitrogenase, which requires ATP hydrolysis, uses the electrons to reduce N_2 to NH_3.

2. a, b, d, f.

3. (a) The α-keto acid precursor to glutamate is α-ketoglutarate:

α-Ketoglutarate

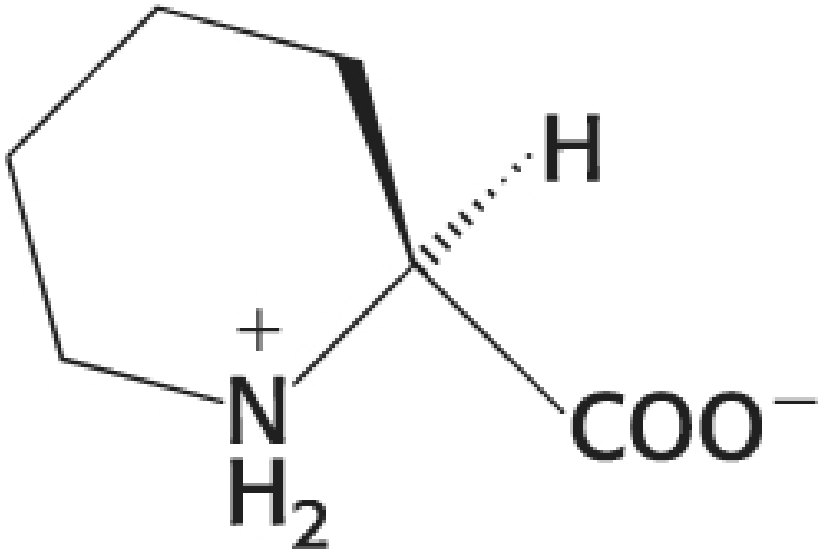
(b) $NAD(P)^+$ and H_2O

4. 16

5. The reductase protein provides electrons with high reducing power. The nitrogenase uses these electrons to reduce N_2 to NH_3.

6. Oxaloacetate, pyruvate, ribose-5-phosphate, phosphoenol-pyruvate, erythrose-4-phosphate, α-ketoglutarate, and 3-phosphoglycerate.

7. $\text{Glucose} + 2\ \text{ADP} + 2\ P_i + 2\ NAD^+ + 2\ \text{glutamate} \rightarrow$
$2\ \text{alanine} + 2\ \alpha\text{-ketoglutrate} + 2\ \text{ATP} + 2\ \text{NADH} + 2\ H_2O + 2\ H^+$



8. Alanine from pyruvate; aspartate from oxaloacetate; glutamate from α-ketoglutarate.

9. Serine, glycine, and cysteine.

10. (b). As an essential amino acid, methionine is not synthesized de novo in human beings, but it can, however, be regenerated via methylation of homocysteine to yield methionine. Homocysteine is also an intermediate in cysteine synthesis. Homocysteine condenses with serine to form cystathionine, which is deaminated and cleaved to yield α-ketobutyrate and cysteine.

11. The nitrogen atom shaded red is derived from glutamine. The carbon atom shaded blue is derived from serine.

12. Lysine cyclodeaminase converts L-lysine into the six-membered ring analog of proline, also referred to as L-homoproline or L-pipecolate:

Pipecolate

13. Y could inhibit the $C \rightarrow D$ step, Z could inhibit the $C \rightarrow F$ step, and C could inhibit $A \rightarrow B$. This scheme is an example of sequential feedback inhibition. Alternatively, Y could inhibit the $C \rightarrow D$ step, Z could inhibit the $C \rightarrow F$ step, and the $A \rightarrow B$ step would be inhibited only in the presence of both Y and Z. This scheme is called concerted feedback inhibition.

14. The rate of the $A \rightarrow B$ step in the presence of high levels of Y and Z would be $24\ s^{-1}(0.6 \times 0.4 \times 100\ s^{-1})$.

15. $N_2 \rightarrow NH_4^+$ → glutamate → serine → glycine → δ-aminolevulinate → porphobilinogen → heme

16. Acetate → acetyl-CoA → citrate → isocitrate → α-ketoglutarate → succinyl-CoA

17. c, e, f.

18. *S*-Adenosylmethionine, tetrahydrofolate, and methylcobalamin.

19. In human beings, tyrosine is synthesized from phenylalanine by phenylalanine hydroxylase. If this enzyme is defective, the biosynthetic route to tyrosine is blocked, and tyrosine must be obtained from the diet. Tyrosine is sometimes said to be “conditionally essential” because its synthesis is dependent on the essential amino acid phenylalanine.

Chapter 26

1. In de novo synthesis, the nucleotides are synthesized from simpler precursor compounds, in essence from scratch. In salvage pathways, preformed bases are recovered and attached to riboses.

2.

The synthesis of carbamoyl phosphate requires 2 ATP	2 ATP
The formation of PRPP from ribose 5-phosphate yields an AMP*	2 ATP
The conversion of UMP to UTP requires 2 ATP	2 ATP
The conversion of UTP to CTP requires 1 ATP	1 ATP
Total	**7 ATP**

*Remember that AMP is the equivalent of 2 ATP because an ATP must be expended to generate ADP, the substrate for ATP synthesis.

3. $\text{Glutamine} + \text{aspartate} + CO_2 + 2\ \text{ATP} + NAD^+ \rightarrow$
$\text{orotate} + 2\ \text{ADP} + 2\ P_i + \text{glutamate} + \text{NADH} + H^+$.

4. (a, c, and d) PRPP; (b) carbamoyl phosphate.

5. PRPP and formylglycinamide ribonucleotide.

6. (a) Carboxyaminoimidazole ribonucleotide; (b) glycinamide ribonucleotide; (c) phosphoribosyl amine; (d) formylglycinamide ribonucleotide.

7. PRPP is the activated intermediate in the synthesis of phosphoribosylamine in the de novo pathway of purine formation; of purine nucleotides from free bases by the salvage pathway; of orotidylate in the formation of pyrimidines; of nicotinate ribonucleotide; and of phosphoribosylanthranilate in the pathway leading to tryptophan.

8. N-1 in both cases, and the amine group linked to C-6 in ATP.

9. $\text{dUMP} + \text{serine} + \text{NADPH} + H^+ \rightarrow \text{TMP} + NADP^+ + \text{glycine}$.

10. b, e, a, c, d.

11. Substrates: a, b; Product: c.

12. The free energies of binding are -57.7 (wild type), -49.8 (Asn 27), and $-38.1\ (\text{Ser27})\ \text{kJ mol}^{-1}$ ($-13.8, -11.9$, and $-9.1\ \text{kcal mol}^{-1}$, respectively). The loss in binding energy is $+7.9\ \text{kJ mol}^{-1} (+1.9\ \text{kcal mol}^{-1})$ and $+19.7\ \text{kJ mol}^{-1} (+4.7\ \text{kcal mol}^{-1})$.

13. CTP is a feedback inhibitor of ATCase, while ATP is an allosteric activator.

14. a and b.

15. ATP and dATP.

16. a and c.

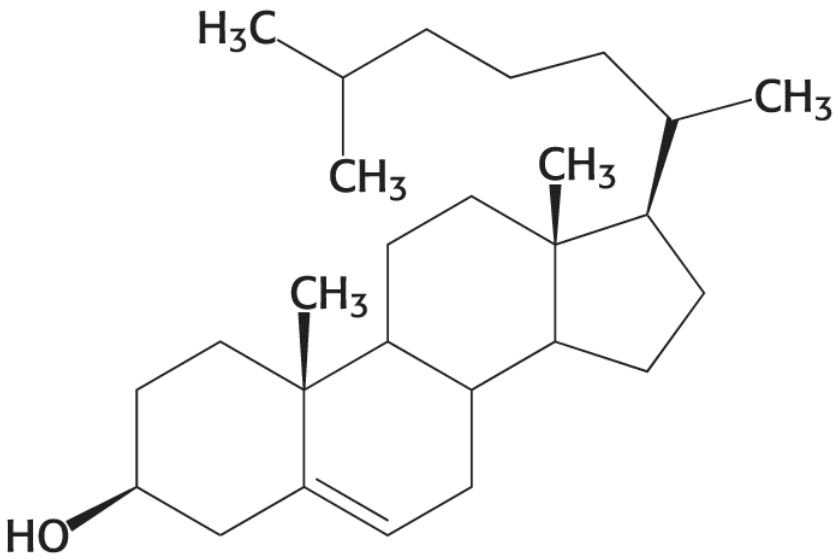
17. d.

18. Inosine or hypoxanthine could be administered.

19. (a) Cell A cannot grow in a HAT medium, because it cannot synthesize TMP either from thymidine or from dUMP. Cell B cannot grow in this medium, because it cannot synthesize purines by either the de novo pathway or the salvage pathway. Cell C can grow in a HAT medium because it contains active thymidine kinase from cell B (enabling it to phosphorylate thymidine to TMP) and hypoxanthine guanine phosphoribosyltransferase from cell A (enabling it to synthesize purines from hypoxanthine by the salvage pathway). (b) Transform cell A with a plasmid containing foreign genes of interest and a functional thymidine kinase gene. The only cells that will grow in a HAT medium are those that have acquired a thymidylate kinase gene; nearly all of these transformed cells will also contain the other genes on the plasmid.

Chapter 27

1. Three. One molecule of ATP to form phosphorylethanolamine and two molecules of ATP to regenerate CTP from CMP.

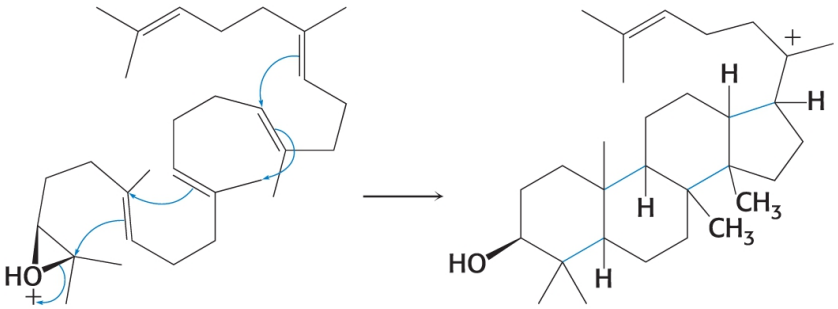


2. (a) CDP-diacylglycerol; (b) CDP-ethanolamine; (c) acyl CoA; (d) phosphatidylcholine; (e) UDP-glucose or UDP-galactose; (f) UDP-galactose; (g) geranyl pyrophosphate.

3. $\text{Glycerol} + 4\,\text{ATP} + 3\,\text{fatty acids} + 4\,H_2O \rightarrow \text{triacylglycerol} + \text{ADP} + 3\,\text{AMP} + 7\,P_i + 4\,H^+$.

4. If PAP activity were to decline due to a mutation, phosphatidate conversion to DAG would decrease. Therefore, the concentration of DAG would decline and the concentration of phosphatidate would be high. Hence, the concentrations of lipids derived from activated phosphatidate will likely increase, and the concentrations of lipids derived from DAG and an activated head group would decrease.

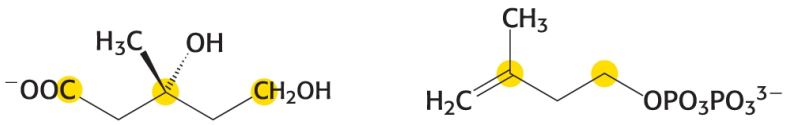
The following would decrease: a, b, f. The following would increase: c, d, e.



5.

6. (1) The synthesis of activated isoprene units (isopentyl pyrophosphate), (2) the condensation of six of the activated isoprene units to form squalene, and (3) cyclization of the squalene to form cholesterol.

7. b, c, a, d



8.

Protosterol cation

9. c, g, d, h, a, i, j, f, b, e

10.

Labeled mevalonate **Labeled isopentenyl pyrophosphate**

11. The amount of reductase and its activity control the regulation of cholesterol biosynthesis. Transcriptional control is mediated by SREBP. Translation of the reductase mRNA also is controlled. The reductase itself may undergo regulated proteolysis. Finally, the activity of the reductase is inhibited by phosphorylation by AMP kinase when ATP levels are low.

12. The conversion of HMG-CoA to mevalonate by HMG-CoA reductase is the rate-determining step.

13. Statins are competitive inhibitors of HMG-CoA reductase. They are used as drugs to inhibit cholesterol synthesis in patients with high levels of cholesterol.

14. The LDL contains apolipoprotein B-100, which binds to an LDL receptor on the cell surface in a region known as a coated pit. On binding, the complex is internalized by endocytosis to form an internal vesicle. The vesicle is separated into two components. One, with the receptor, is transported back to the cell surface and fuses with the membrane, allowing continued use of the receptor. The other vesicle fuses with lysosomes inside the cell. The cholesteryl esters are hydrolyzed, and free cholesterol is made available for cellular use. The LDL protein is hydrolyzed to free amino acids.

15. (a) Lipids are less dense than proteins. Chylomicrons, which have the highest percentage by weight of lipids, are the least dense lipoproteins. (b) In a lipoprotein, the protein components are generally

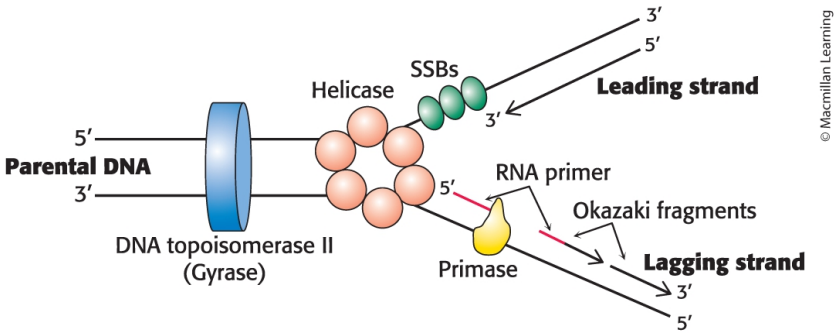
soluble and the lipid components are not. Lipoproteins with more proteins are more soluble. High-density lipoproteins (HDLs) have more protein than other lipoproteins and are the most soluble.

16. LDL: a and d; HDL: b and c

17. The core structure of a steroid is four fused rings: three cyclohexane rings and one cyclopentane ring. In vitamin D, the B ring is split by ultraviolet light.

18. (a) 3; (b) 4; (c) 5; (d) 1; (e) 2.

19. 3-Hydroxy-3-methylglutaryl CoA is also a precursor for ketone-body synthesis. If fuel is needed elsewhere in the body, as might be the case during a fast, 3-hydroxy-3-methylglutaryl CoA is converted into the ketone body acetoacetate. If energy needs are met, the liver will synthesize cholesterol. Remember also that cholesterol synthesis occurs in the cytoplasm while ketone bodies are synthesized in the mitochondria.



Chapter 28

1. One new strand will have an A–T pair, and the other strand will have a G–C pair.

2. The oxidation of guanine could lead to DNA repair: DNA strand cleavage could allow looping out of the triplet repeat regions and triplet expansion.

3. (a) 4, 5; (b) 3, 2; (c) 6, 1

4.

© Macmillan Learning

5. In principle, it could be used to break three base pairs.

6. (a) Size; the top is relaxed and the bottom is supercoiled DNA. (b) Topoisomers. (c) The DNA is becoming progressively more unwound, or relaxed, and thus slower-moving.

7. (a) $Lk = 460$ (b) $Lk = 456$; (c) Lk is undefined; (d) $Lk = 458$

8. c

9. b, c, e

10. a, h, d, e, g, b, c, f

11. a, b, g, c, f, h, d, e

12. e, c, b, a, d, f

13. b, d, e

14. (a) It was used to determine the number of spontaneous revertants—that is, the background mutation rate. (b) The known mutagen was used to firmly establish that the system was working. A known mutagen's failure to produce revertants would indicate that something was wrong with the

experimental system. (c) The chemical itself has little mutagenic ability but is apparently activated into a mutagen by the liver homogenate. (d) Components of the cytochrome P450 system.

15. (a) 5; (b) 1; (c) 2, 3; (d) 4

16. (a) 6, 4; (b) 1, 5; (c) 3, 4

17. a, g, d, f, e, b, c

18. (a) 5; (b) 3; (c) 1; (d) 2; (e) 4

19. b, d

Chapter 29

1. An error will affect only one molecule of mRNA of many synthesized from a gene. In addition, the errors do not become a permanent part of the genomic information.

2. b, c, d.

3. The active sites are related by convergent evolution.

4. The sequence of the coding ($^{+}$, sense) strand is

$5'-ATGGGGAACAGCAAGAGTGGGGCCCTGTCCAAGGAG-3'$ and the sequence of the template (–, antisense) strand is $3'-TACCCCTTGTCGTTCTCACCCCGGGACAGGTTCCTC-5'$

5. This mutant σ will competitively inhibit the binding of holoenzyme and prevent the specific initiation of RNA chains at promoter sites.

6. A 100-kDa protein contains about 910 residues, which are encoded by 2730 nucleotides. At a maximal transcription rate of 50 nucleotides per second, the mRNA would be synthesized in 55 s.

7. DNA is the single strand that forms the trunk of the tree. Strands of increasing length are RNA molecules; the beginning of transcription is where growing chains are the smallest; the end of transcription is where chain growth stops. Many enzymes are actively transcribing each gene.

8. (a) $5'$; (b) guanosine; (c) triphosphate; (d) a nitrogen; (e) $2'$.

9. c, e, d, a, f, b.

10. Gene A, top; gene B, top; gene C, bottom.

11. The organism in the fluctuating environment, because it is exposed to more extremes.

12. (a) 2, 3; (b) 5, 6; (c) 1, 4

13. (a) 13.7; (b) 45S; (c) 18S, 5.8S, and 28S; (d) 28S; (e) 5.8S; (f) 5S; (g) large (60S); (h) RNA polymerase III; (i) small (40S).

14. b, d, e.

15. (a) 5; (b) 3; (c) 4; (d) 2; (e) 1.

16. There are $2^8 = 256$ possible products.

17. Alternative splicing, RNA editing. Covalent modification of the proteins after synthesis.

18. (a) Different amounts of RNA are present for the various genes. (b) Although all of the tissues have the same genes, the genes are expressed to different extents in different tissues. (c) These genes are called housekeeping genes—genes that most tissues express all the time. They might include genes for glycolysis or citric acid cycle enzymes. (d) The point of the experiment is to determine which genes are

initiated in vivo. The initiation inhibitor is added to prevent initiation at start sites that may have been activated during the isolation of the nuclei.

19. True: b, c, d; False: a, e.

Chapter 30

1. (a) and (b) only.

2. Four bands: light, heavy, a hybrid of light 30S and heavy 50S, and a hybrid of heavy 30S and light 50S.

3. The peptide would be Phe-Cys-His-Val-Ala-Ala. The codons UGC and UGU encode cysteine but, because the cysteine was modified to alanine, alanine is incorporated in place of cysteine.

4. (a) 1, 2, 3, 5, 6, 10; (b) 1, 2, 7, 8; (c) 1, 4, 8, 9.

5. (a, d, and e) Type 2; (b, c, and f) Type 1.

6. Two hundred molecules of ATP are converted into $200\ AMP + 400\ P_i$ to activate the 200 amino acids, which is equivalent to 400 molecules of ATP. One molecule of GTP is required for initiation, and 398 molecules of GTP are needed to form 199 peptide bonds, for a total of 399 molecules of GTP.

7. Proteins are synthesized from the amino to the carboxyl end on ribosomes, whereas they are synthesized in the reverse direction in the solid-phase method. The activated intermediate in ribosomal synthesis is an aminoacyl-tRNA; in the solid-phase method, it is the adduct of the amino acid and dicyclohexylcarbodiimide.

8. (a) A_5. (b) $A_5 > A_4 > A_3 > A_2$. (c) Synthesis is from the amino terminus to the carboxyl terminus.

9. (a) P site; (b) A site; (c) E site; (d) P site.

10. The rate would fall because the elongation step requires that the GTP be hydrolyzed before any further elongation can take place.

11.

	Bacteria	**Eukaryotes**
Ribosome size	70S	80S
Initiation	Shine–Dalgarno is required	First AUG is used
Protein factors	Required	Many more required
Relation to transcription	Translation can start before transcription is completed	Transcription and translation are spatially separated
First amino acid	fMet	Met

12. (a) 3, 5, 9; (b) 1, 7; (c) 4, 5, 6, 10; (d) 2, 8.

13. (a) 4; (b) 3; (c) 2; (d) 6.

14. (a) -35 sequence; (b) Pribnow box; (c) $+1$; (d) terminator sequence; (e) Shine–Dalgarno sequence; (f) AUG.

15. (a) The three peaks represent, from left to right, the 40S ribosomal subunit, the 60S ribosomal subunit, and the 80S ribosome. (b) Not only are ribosomal subunits and the 80S ribosome present, but polysomes of various lengths also are apparent. The individual peaks in the polysome region represent polysomes of discrete length. (c) The treatment significantly inhibited the number of polysomes while increasing the number of free ribosomal subunits. This outcome could be due to inhibited protein-synthesis initiation or inhibited transcription.

16. a, d, i, h, c, f, b, g, e.

17. (a) The signal sequence, signal-recognition particle (SRP), the SRP receptor, and the translocon. (b) The formation of peptide bonds, which in turn are powered by the hydrolysis of the aminoacyl-tRNAs.

18. (a) eIF-4H has two effects: (i) the extent of unwinding is increased; and (ii) the rate of unwinding is increased, as indicated by the increased rise in activity at early reaction times. (b) To firmly establish that the effect of eIF-H4 was not due to any inherent helicase activity. (c) Half-maximal activity was achieved at 0.11 μM of eIF-4H. Therefore, maximal stimulation would be achieved at a ratio of 1:1. (d) eIF-4H enhances the rate of unwinding of all helices, but the effect is greater as the helices increase in stability. (e) The results in graph C suggest that eIF-4H increases the processivity.

19. (a) $3'-AATCTCGCG-5'$; (b) UUAGAGCGC; (c) AAU, CUC, GCG; (d) leucine, glutamic acid, arginine.

20. (a) A; (b) alanine.

Chapter 31

1. (a) and (b) Cells will express β-galactosidase, *lac* permease, and thiogalactoside transacetylase even in the absence of lactose. (c) The levels of catabolic enzymes such as β-galactosidase and arabinose isomerase will remain low even at low levels of glucose.

2. The *lac* repressor does not bind DNA when the repressor is bound to a small molecule (the inducer), whereas the *pur* repressor binds DNA only when the repressor is bound to a small molecule (the corepressor). The *E. coli* genome contains only a single *lac* repressor-binding region, whereas it has many sites for the *pur* repressor.

3. b, c.

4. Bacteriophage λ would be more likely to enter the lytic phase because the cooperative binding of the λ repressor to O_R2 and O_R1, which supports the lysogenic pathway, would be disrupted.

5. e, a, c, b, f, d.

6. 5-Azacytidine cannot be methylated. Some genes, normally repressed by methylation, will be active. 5-Azacytidine is also an inhibitor of DNA methyltransferase, resulting in lower levels of methylation and, hence, lower levels of gene repression.

7. Increased Cro concentration reduces the expression of the λ repressor gene. Increased λ repressor concentration reduces the expression of the Cro gene. At low λ repressor concentrations, increased λ repressor concentration increases the expression of the λ repressor gene. At higher λ repressor concentrations, increased λ repressor concentration decreases the expression of the λ repressor gene.

8. The footprint appears to have approximately 50% of its intensity near 3.7 nM so that the dissociation constant is approximately 3.7 nM, corresponding to a standard free energy of binding of $-48\ \text{kJ/mol}\ (-11\ \text{kcal/mol})$ at $T = 298\text{K}$.

9. b, c.

10. In mouse DNA, most of the HpaII sites are methylated and therefore not cut by the enzyme, resulting in large fragments. Some small fragments are produced from CpG islands that are unmethylated. For *Drosophila* and *E. coli* DNA, there is no methylation, and all sites are cut.

11. a, c, d.

12. Proteins containing these domains will be targeted to methylated DNA in repressed promoter regions. They would likely bind in the major groove, because that is where the methyl group is located.

13. The acetylation of lysine will reduce the charge from $+1$ to 0. The methylation of lysine will not reduce the charge.

14. d, f, a, e, b, c.

15. Gene expression is not expected to respond to the presence of estrogen. However, genes for which expression normally responds to estrogen will respond to the presence of progesterone.

16. The addition of an IRE to the $5'$ end of the mRNA is expected to block translation in the absence of iron. The addition of an IRE to the $3'$ end of the mRNA is not expected to block translation, but it might affect mRNA stability.

17. On the basis of the pattern of cysteine and histidine residues, this region appears to contain three zinc-finger domains.

18. (a) 3; (b) 1; (c) 2.

19. (a) 2; (b) 3, 1; (c) 4, 5.

20. Positive: a, c, d; negative: b, e.

Chapter 32

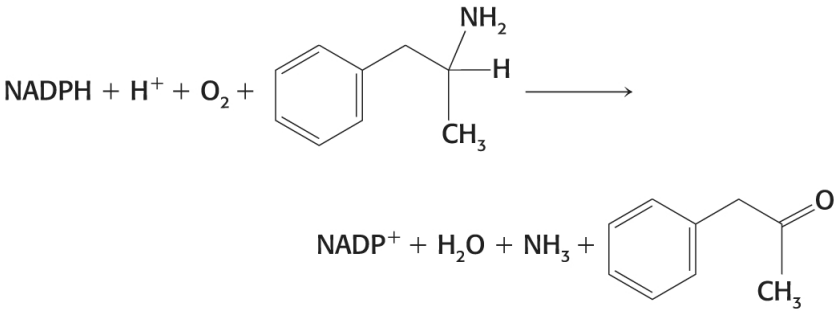
1. Sildenafil increases cGMP levels by inhibiting the phosphodiesterase-mediated breakdown of cGMP to GMP. Intracellular cGMP levels can also be increased by activating its synthesis. This activation can be achieved with the use of NO donors (such as sodium nitroprusside and nitroglycerin) or compounds that activate guanylate cyclase activity. Drugs that act by the latter mechanism are currently in clinical trials.

2. (a) Accidental; (b) natural product screening; (c) accidental; (d) natural product screening; (e) targeted design.

3. (A) Yes; (B) yes; (C) no $(MW > 600)$.

4. Unlike competitive inhibition, noncompetitive inhibition cannot be overcome with additional substrate. Hence, a drug that acts by a noncompetitive mechanism will be unaffected by changing levels of the physiological substrate.

5. A drug that inhibits a P450 enzyme may dramatically affect the disposition of another drug that is metabolized by that same enzyme. If this inhibited metabolism is not accounted for when dosing, the second drug may reach very high, and sometimes toxic, levels in the blood.



6. The binding of other drugs to albumin could cause extra coumadin to be released. (Albumin is a general carrier for hydrophobic molecules.)

7. (a) $K_I \approx 0.3\ nM$. $IC_{50} \approx 2.0\ nM$. (b) Yes, compound A should be effective when taken orally because 400 nM is much greater than the estimated values of K_I and IC_{50}.

8. The computational prediction of log(P) values on the basis of chemical structure enables a more rapid assessment of drug-like properties of a molecule, and it avoids the need for experimental phase partitioning studies. Many such algorithms are now available to pharmacologists.

9. In Phase I clinical trials, approximately 10 to 100 usually healthy volunteers are typically enrolled in a study designed to assess safety. In contrast, a larger number of subjects are enrolled in a typical Phase II trial. Moreover, these persons may benefit from the drug administered. In a Phase II trial, efficacy, dosage, and safety can be assessed.

10. A reasonable mechanism would be an oxidative deamination following an overall mechanism similar to that in Figure 32.19, with release of ammonia.

11. Recall that for a competitive inhibitor, the IC_{50} will shift depending on the substrate concentration. According to the Cheng–Prusoff equation, for an enzyme with a K_M of 1 μM the IC_{50} of a competitive inhibitor at $[S] = 20\ \mu M$ will be $21 \times K_I$, while at $[S] = K_M$, the IC_{50} will be $2 \cdot K_I$, a 10-fold shift.

12. Because monoclonal antibodies interact with a broader surface on the target, they can achieve greater potency than small molecules, as well as achieve a higher degree of selectivity versus proteins similar to the target. Also, because they are retained in the body via the FcRn receptor-mediated salvage pathway, they can maintain much longer half-lives than small molecules.

Glossary

α carbon
The central carbon of an amino acid, linked to an amino group, a carboxylic acid group, a hydrogen atom, and a side chain.

α helix
A common structural motif in proteins, in which a polypeptide main chain forms the inner part of a right-handed helix, with the side chains extending outward; the helix is stabilized by intrachain hydrogen bonds between amino and carboxyl groups of the main chain.

β pleated sheet (β sheet)
A common structural motif in proteins, in which a number of β strands are associated as stacks of chains, stabilized by interchain hydrogen bonds.

β strand
A polypeptide chain that is almost fully extended rather than being tightly coiled as in the α helix.

3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase)
A highly regulated enzyme that catalyzes the committed step in cholesterol synthesis, which is the formation of mevalonate from 3-hydroxy-3-methylglutaryl CoA.

5-phosphoribosyl-1-pyrophosphate (PRPP)
A form of ribose activated to accept nucleotide bases.

5′ cap

A structure at the $5'$ end of eukaryotic mRNA that stabilizes the mRNA and enhances its translation. The cap contains a 7-methyl guanylate residue attached by a triphosphate linkage to the sugar at the $5'$ end of the mRNA in a rare $5'$-$5'$ linkage.

ABC transporters

A class of pumps that use the ATP-binding cassette for nucleotide binding and hydrolysis.

acetyl CoA
An activated two-carbon acetyl unit formed by the thioester linkage to coenzyme A.

acetyl CoA carboxylase (ACC)
A regulatory enzyme that catalyzes the ATP-dependent synthesis of malonyl CoA from acetyl CoA and carbon dioxide, the committed step in fatty acid synthesis.

acid-base reaction
A reaction in which hydrogen ions are added to or removed from molecules.

activated carrier
A small molecule carrying activated functional groups that can be donated to another molecule. For instance, ATP carries activated phosphoryl groups and coenzyme A carries activated acyl groups.

activated methyl cycle
A series of reactions in which methyl groups from methionine are converted into a biochemically reactive form through the formation of *S*-adenosylmethionine.

activation domain
The part of eukaryotic transcription factors that interacts with RNA polymerase or other proteins, or modifies chromatin structure.

activation loop
A structure found in protein kinases that changes conformation, often in response to the phosphorylation of specific tyrosine or serine/threonine residues.

active site
A specific region of an enzyme that binds the enzyme's substrate and carries out catalysis.

active transport
The transport of an ion or a molecule against a concentration gradient, where ΔG for the transported species is positive. The process must be coupled to an input of free energy from a source such as ATP, an electrochemical gradient, or light.

acyl adenylate

A mixed anhydride in which the carboxyl group of a molecule is linked to the phosphoryl group of AMP. It serves as a means of activating carboxyl groups, such as the formation of fatty acyl CoA molecules from a free fatty acid and coenzyme A.

acyl carrier protein (ACP)
A polypeptide that is linked to phosphopantetheine and acts as a carrier of the growing fatty acyl chain in fatty acid biosynthesis.

adenosine triphosphate (ATP)
A nucleotide that is the free energy donor in most energy-requiring processes such as motion, active transport, or biosynthesis. Most of catabolism consists of reactions that extract energy from fuels such as carbohydrates and fats and convert it into ATP.

adenylate cyclase
An enzyme that converts ATP to cyclic AMP.

ADME properties
A drug's response to the absorption, distribution, metabolism, and excretion processes within a living organism.

adrenergic receptors
A cell surface receptor that signals in response to the binding of adrenaline.

aerobic glycolysis
The tendency of cancer cells to use glucose at high rates via glycolysis and lactic acid fermentation, even in the presence of molecular oxygen. Also called the *Warburg effect*.

affinity chromatography
A method of separation based on a specific interaction between a protein and a ligand. The ligand is immobilized on inert material, and a protein mixture is passed over the ligand. Only the protein with the specific interaction will bind.

affinity label (reactive substrate analog)
A substrate analog used to map the active site of an enzyme by binding to the active site and forming a covalent bond with a nearby amino acid.

agonists
A molecule that binds to and activates a receptor.

Aldolase
An enzyme that catalyzes an aldol condensation reaction.

allosteric (regulatory) site
A region of an enzyme, distinct from the active site, where a regulatory molecule binds and affects catalytic activity.

allosteric effector
A small molecule that affects the properties of a protein or enzyme by binding to a site distinct from the active site.

allosteric enzyme
An enzyme having multiple active sites and/or distinct regulatory sites that control the flux of biochemicals through a metabolic pathway. The regulation of catalytic activity is by environmental signals, often the final product of the metabolic pathway regulated by the enzyme; its kinetics are more complex than those of single subunit enzymes

alternative splicing
The generation of unique but related mRNA molecules by the differential splicing of the pre-mRNA transcript; increases the encoding potential of the genome.

Ames test
A simple, rapid means of detecting carcinogens by measuring a chemical's ability to induce mutations in *Salmonella* bacteria.

amino acids
An organic compound containing an amino group, a carboxyl group, and a unique functional group that are each bonded to a common carbon atom.

aminoacyl-tRNA
A tRNA molecule that has been covalently linked to the amino acid corresponding to its anticodon sequence.

aminoacyl-tRNA synthetases
An enzyme that activates an amino acid and then links it to transfer RNA. Each aminoacyl-tRNA synthetase is specific for a particular amino acid. It is also known as an *activating enzyme*.

Aminotransferases

A class of enzymes that transfer an α-amino group from an α-amino acid to an α-ketoacid. Also called **transaminases**.

AMP-activated protein kinase (AMPK)
A protein kinase, conserved among eukaryotes, that is activated on binding AMP and inhibited by ATP. It functions as a cellular fuel gauge, inhibiting certain processes by phosphorylating key enzymes when the energy supply is low.

amphibolic pathways
A metabolic pathway consisting of reactions that can be anabolic or catabolic, depending on the energy conditions and biosynthetic needs of the cell.

amphipathic molecules (amphiphilic molecules)
A molecule, such as a membrane lipid, that contains both a hydrophobic and a hydrophilic moiety.

amyloid fibrils (amyloid plaques)
Protein aggregates composed of insoluble fibers rich in β sheets that are found in the brains of patients with certain neurological diseases, including Alzheimer disease and Parkinson disease.

anabolism
The set of metabolic reactions that creates more complex molecules from simpler precursors, frequently requiring energy.

anaplerotic reaction
A reaction that leads to the net synthesis, or replenishment, of pathway components.

anion exchange
A form of ion-exchange chromatography where cationic beads are used to bind negatively charged proteins.

anomer
Isomers that differ at a new asymmetric carbon atom generated by intramolecular hemiacetal or hemiketal formation; that carbon atom is known as the anomeric carbon atom.

antagonists
A molecule that binds to a receptor but does not activate it and, therefore, blocks the effects of activating ligands (agonists).

antibodies (immunoglobulins)
Proteins produced by the immune system that bind specifically to particular foreign molecules and help lead to the sequestration or destruction of viruses, bacteria, or infected cells.

anticoagulant drugs
Medicines that reduce blood clot formation.

anticodon
A nucleotide triplet in tRNA that binds to a specific codon within an mRNA molecule during transcription.

Antigen
A foreign substance that induces an immune response, especially the production of antibodies.

antigenic determinant (epitope)
A specific group or cluster of amino acids on an antigen that is recognized by an antibody.

Antiporters
A secondary transporter that couples the downhill flow of one species to the uphill flow of another in the opposite direction across the membrane.

apoenzyme
An enzyme without its cofactor(s).

apoptosis
A form of programmed cell death specific to multicellular organisms. One pathway of activation involves the release of cytochrome *c* from mitochondria, leading to the activation of caspases.

aptamers
Synthetic single-stranded oligonucleotides that can specifically bind ligands.

aquaporins
A membrane transporter that facilitates the rapid transport of water molecules.

Archaea
One of the two domains of prokaryotic life forms, unicellular organisms that lack a well-defined nucleus. The existence of this second domain of prokaryotes was discovered in 1977. They differ from the other such domain, Bacteria, in several

ways, including the sequences of ribosomal RNA, the composition of cell membranes, and the use of some biochemical pathways.

Argonaute
A family of proteins that, when bound to miRNA, will cleave specific target mRNAs.

assay
Any procedure to measure the activity of a biomolecule, such as an enzyme.

ATP synthase
A molecular assembly of the inner mitochondrial membrane responsible for the respiratory-chain-driven synthesis of ATP. Also called **Complex V**.

ATP synthase of chloroplasts
Molecular assembly of the thylakoid membrane responsible for the photo-induced synthesis of ATP. Also called the CF_1-CF_0 **complex**.

ATP-ADP translocase
A transport protein in the inner mitochondrial membrane that carries ADP into the mitochondria and ATP out in a coupled fashion. Also called **adenine nucleotide translocase** or **ANT**.

ATP-binding cassettes (ABCs)
The nucleotide-binding domains found within ABC transporter proteins.

ATP-grasp fold
A structural motif found in several nucleotide biosynthesis enzymes in which ATP is held in a conformation suitable for nucleophilic attack at the γ phosphoryl group.

ATPase
An enzyme that hydrolyzes ATP to ADP plus inorganic phosphate.

attenuation
A mechanism for regulating gene expression in bacteria that involves the formation of alternative mRNA structures that alter transcription.

autotrophs
An organism that obtains the majority of its carbon for biosynthesis from the reduction of carbon dioxide, as opposed to using organic sources.

Bacteria
One of the two domains of prokaryotic life forms, unicellular organisms that lack a well-defined nucleus. Members of Bacteria differ from members of the other prokaryotic domain, Archaea, in several ways, including the sequences of ribosomal RNA, the composition of cell membranes, and the use of some biochemical pathways.

bacteriophage lambda (λ phage)
A bacterial virus that is frequently used as a cloning vector.

bacteriorhodopsin
An archaeal membrane protein that is evolutionarily related to rhodopsin. Bacteriorhodopsin uses retinal to absorb photons to drive conformational changes that pump protons across the cell membrane for the purpose of ATP generation by ATP synthase.

ball-and-chain model
A model for ion channel inactivation in which a cytoplasmic unit (the ball) at the end of a flexible polypeptide (the chain) occludes the open pore.

base pair
A specific structure that forms in nucleic acids such as DNA involving two nitrogenous bases joined by hydrogen bonds. Units with adenine form base pairs with those with thymine, and units with cytosine form base pairs with those with guanine.

base-excision repair
A means of repairing DNA in which the damaged base is removed and replaced by a base complementary to the undamaged DNA strand.

basic local alignment search tool (BLAST) search
A database query which seeks to identify homologous sequences to a submitted amino acid sequence.

basic-leucine zipper (bZip) proteins
A DNA-binding motif found in eukaryotic transcription factors, consisting of a pair of long α helices.

beriberi
A neurological and cardiovascular disorder caused by a dietary deficiency of thiamine (vitamin B_1).

bifunctional enzyme
An enzyme with two different, often opposing, catalytic activities on one polypeptide chain.

bile salts
A polar derivative of cholesterol that solubilizes dietary lipids, facilitating their digestion and absorption.

binding energy
The free energy released in the formation of the weak interactions between enzyme and substrate, some of which can facilitate the formation of the transition state for catalysis.

binding energy
The free energy released in the formation of the noncovalent interactions between enzyme and substrate that facilitate the formation of the transition state.

biochemical timescale
The timescale over which most chemical interactions and processes take place, measured in picoseconds to microseconds $(10^{-12} - 10^{-6}\ s)$.

biological macromolecules
Large organic molecules, often constructed from smaller building blocks, present within living organisms. Examples include nucleic acids such as DNA or proteins such as hemoglobin.

biologics
Medicines derived from living cells or through biological processes.

Bohr effect
The observation that H^+ and CO_2 promote the release of oxygen from oxyhemoglobin, named for Christian Bohr.

bromodomain
A domain consisting of a four-helix bundle that binds peptides containing acetyllysine. It is also called *acetyllysine-binding domain*.

buffer
A solution that resists change in pH upon the addition of acid or base.

C_4 pathway

A means by which four-carbon compounds, such as oxaloacetate and malate, carry carbon dioxide from mesophyll cells in contact with the air to bundle-sheath cells, which are the major sites of photosynthesis. The pathway accelerates photosynthesis by concentrating carbon dioxide in photosynthetic cells. Also known as the **Hatch–Slack pathway**.

calmodulin (CaM)

A protein present in many cells that binds calcium ions, changes conformation, and binds certain α-helical structures, often to activate enzymes.

caloric homeostasis

The maintenance of an adequate but not excessive amount of body fat; the balancing of caloric input and use. Also called **energy homeostasis**.

Calvin–Benson cycle

A cyclic metabolic pathway in plants, in which carbon dioxide is incorporated into ribulose 1,5-bisphosphate to yield compounds that can be used for the synthesis of hexoses.

candidate

In drug discovery, a molecule that has been optimized for potency, selectivity, pharmacokinetics, and safety such that it can be tested in humans.

carbamoyl phosphate synthetase I

An enzyme that begins the urea cycle by catalyzing the synthesis of carbamoyl phosphate from bicarbonate, ammonium ion, and ATP.

carbon monoxide

A colorless, odorless gas that can bind to heme proteins such as myoglobin and hemoglobin in competition with oxygen.

carbonic anhydrases

An enzyme that hydrates carbon dioxide to form bicarbonate HCO_3^-.

carboxyl-terminal domain

A regulatory domain in RNA polymerase II. Phosphorylation of this domain regulates aspects of transcription and splicing.

carnitine

A zwitterionic alcohol formed from lysine that acts as a carrier of long-chain fatty acids from the cytoplasm to the mitochondrial matrix.

carotenoids
An extended polyene that absorbs light between 400 and 500 nm and serves as an accessory pigment in photosynthesis by funneling the energy to the photosynthetic reaction center.

Carriers
A membrane protein that transports ions or molecules across the membrane without hydrolysis of ATP.

cassette mutagenesis
A method for introducing mutations into a target sequence where a portion of the target gene is removed by restriction digestion, and a synthetic oligonucleotide containing the mutations is ligated in its place.

catabolism
The set of metabolic reactions that breaks complex molecules into simpler ones, typically transforming fuels into cellular energy.

catabolite activator protein (CAP)
The cAMP-response protein. When bound to cyclic AMP, CAP binds to an inverted repeat in the *lac* operon to stimulate transcription.

catabolite repression
The repression by glucose of enzymes required to catabolize sugars other than glucose.

catalysis by approximation
Increases in the rate of a reaction that occur by bringing multiple substrates together along a single binding surface of an enzyme.

catalyst
An agent that enhances the rate of a chemical reaction without being permanently affected itself.

catalytic triad
A constellation of three residues, found in many proteolytic enzymes, in which two of the residues convert the remaining residue, usually a serine or cysteine residue, into a potent nucleophile.

cation exchange
A form of ion-exchange chromatography where anionic beads are used to bind positively charged proteins.

cDNA library
A collection of cDNA molecules inserted into cloning vectors; the library consists of all the mRNA molecules expressed by a particular cell.

cell
The smallest structural and functional unit of an organism, consisting of a collection of biological macromolecules and metabolites surrounded by a membrane.

cell cycle
A sequence of regulated stages that allow a cell to complete cell division. One of these stages involves the replication of the cell's genome.

Cell-mediated immunity
An adaptive immune response mediated by cytotoxic T lymphocytes and not by antibodies.

cellular respiration
The process that includes the generation of high-transfer-potential electrons by the citric acid cycle, their flow through the respiratory chain to reduce oxygen to water, and the accompanying synthesis of ATP. Also called **respiration**.

cellulose
An unbranched homopolysaccharide in plants, composed of glucose residues in β-1,4 linkage; the major structural polysaccharide in plants.

ceramide
A sphingosine with a long-chain acyl group attached to its amino group.

chemical modification reaction
A reaction in which an enzyme or proteins is covalently modified, usually by a relatively reactive reagent.

chemical shift
The frequency of electromagnetic radiation at which an intrinsically magnetic nucleus resonates. This value is dependent upon the local environment of the nucleus.

chemical space
The range of chemical possibilities for compounds within a given range of molecular weights.

chemotrophs
An organism that obtains energy by the oxidation of chemicals. Can be further subclassified as an organochemotroph or a lithotroph if the chemical energy sources are organic, or inorganic, respectively.

chiral
The property of asymmetry in which a structure and its mirror image are not superimposable.

chlorophyll *a*
A substituted tetrapyrrole that is the principal photoreceptor in plants.

chloroplasts
The organelle in plants and algae in which eukaryotic photosynthesis takes place.

cholesterol
A sterol that is an important constituent of eukaryotic membranes and lipoproteins; also a precursor of steroid hormones.

chromatin
A complex of DNA and proteins found in eukaryotes that helps to package the DNA into a more compact structure.

chromatin-remodeling complexes
Large protein complexes that utilize the free energy of ATP hydrolysis to induce changes in chromatin structure.

chromogenic substrate
A substrate that generates a colored product when acted on by an enzyme.

chylomicrons
A lipoprotein particle, composed primarily of triacylglycerol, that transports dietary triacylglycerols from the intestine to other tissues.

citric acid cycle (CAC)
A cyclic series of metabolic reactions that completely oxidize acetyl units to carbon dioxide. Also called **tricarboxylic acid (TCA) cycle**; **Krebs cycle**.

class I MHC proteins
A class of proteins found on the surfaces of many cells that present peptides in a groove for potential recognition by T-cell receptors.

cloning vectors
A class of vector, usually a plasmid, that is designed for the facile insertion and stable replication of DNA inserts.

co-immunoprecipitation
An antibody-based precipitation technique used to identify binding partners to a protein of interest.

coactivators
A protein that enhances transcription by binding to a transcription factor. Coactivators themselves do not bind to DNA.

codon
A nucleotide triplet in mRNA that encodes a particular amino acid.

codons
A nucleotide triplet in mRNA that encodes a particular amino acid.

coenzyme
A cofactor that is a small organic molecule; vitamins are often components or precursors of coenzymes.

coenzyme Q
A mobile electron carrier that is a component of the respiratory chain. It shuttles between the oxidized ubiquinone form and the reduced ubiquinol form through a semiquinone intermediate, accepting electrons from NADH-Q oxidoreductase as well as succinate-Q reductase. Also called **Q** or **ubiquinone**.

cofactor
A small molecule on which the catalytic activity of an enzyme may depend. The cofactor's precise role varies with the cofactor and the enzyme. Cofactors can be subdivided into two groups: (1) small organic molecules called coenzymes and (2) metals.

cohesive (sticky) ends
Complementary strands produced when a restriction enzyme cleaves the DNA target sequence in a staggered fashion.

combinatorial chemistry
A process by which millions of compounds are synthesized in a single process.

committed step
The first irreversible step in a metabolic pathway under physiological conditions; this step is catalyzed by an allosteric enzyme and commits the product to a particular chemical fate.

common ancestor
An individual from which all members of a group have descended.

competitive inhibition
The reduction in the rate of enzyme activity observed when a reversible inhibitor binds only to the free enzyme, not to the substrate-bound enzyme; thus, the enzyme can bind the substrate or the inhibitor, but not both. A type of reversible inhibition, many competitive inhibitors resemble the substrate and compete with it for reversible binding to the enzyme's active site. Relief from inhibition by increasing substrate concentration is a kinetic hallmark of competitive inhibition.

complementary DNA (cDNA)
DNA that is complementary to mRNA. It is synthesized by reverse transcriptase with the use of mRNA as a template.

complementary sequences
Single-stranded DNA sequences that have the potential to form double helices through base pairs. Examples include the sequences CGATTAAT and ATTAATCG.

concerted model
A model for hemoglobin oxygen-binding cooperativity where the hemoglobin tetramers undergo "all-or-none" transitions between the T and R states.

connexon
A hexagonal array of connexin proteins expressed on the surface of one cell, which joins with the corresponding array on a neighboring cell to form a gap junction. Also called a **hemichannel**.

consensus sequence
In the context of protein kinases, a group of related peptide sequences recognized by a specific protein kinase.

consensus sequences
An idealized base sequence that represents common features of a promoter site.

conservative substitution
An amino acid change in which an amino acid is replaced with another that is similar in biochemical properties.

controlled study
A clinical study in which patients are divided into two groups: one group receives the therapeutic to be tested, while the other group receives either a placebo or the current standard treatment available.

controlled termination of replication
A DNA-sequencing technique based on the generation of DNA fragments whose length depends on the last base in the sequence. Also called the **Sanger dideoxy method**.

convergent evolution
The process by which entities (species, populations, proteins, etc.) not derived from a common ancestor independently arrive at similar solutions to a particular problem.

cooperative transition
In protein folding, an "all-or-none" process where conditions that lead to the disruption of any part of a protein structure are likely to unravel the entire protein completely.

corepressor
A small molecule that binds to a repressor and promotes its interaction with an operator to block transcription.

Cori cycle
A cyclic, inter-organ metabolic pathway in which lactate from active muscle is converted into glucose by the liver, which in turn supplies newly synthesized glucose to muscle and other tissues.

coupled assay
The use of multiple enzyme steps to link the activity of an enzyme with the production of easily detectable (i.e. fluorescent) product.

covalent bond
A bond formed by the sharing of a pair of electrons between adjacent atoms; covalent bonds are the strongest bonds between atoms in biochemistry.

covalent catalysis

Catalysis in which the active site contains a reactive group that becomes temporarily covalently modified.

CpG islands
A region of a mammalian genome that contains about four times as many CpG sequences as the rest of the genome.

crassulacean acid metabolism (CAM)
An adaptation by plants living in an arid environment. The C_4 pathway concentrates carbon dioxide at night, and gas exchange with the environment is curtailed during the heat of the day by closure of the stomata.

CRISPR-Cas system
A gene editing system derived from a primitive prokaryotic immune system that uses a single guide RNA to deliver the Cas nuclease to specific sites in the genome, allowing removal and addition of new DNA sequences.

Cro
A small protein in bacteriophage λ that is expressed once the λ repressor no longer binds to the operator. Cro blocks the production of new λ repressor.

cryo-electron microscopy (cryo-EM)
A method for protein structure determination in which a protein solution is frozen very quickly and then exposed to an incident electron beam. This method is particularly suitable for the determination of very large complexes.

cumulative feedback inhibition
A regulatory strategy in which the enzyme catalyzing the committed step common to several pathways is incrementally inhibited by the products of each of the pathways.

cyclic photophosphorylation
In photosynthesis, the generation of ATP without the concomitant formation of NADPH. Electrons cycle from the reaction center of photosystem I to ferredoxin and then back to the reaction center through cytochrome *b6f* and plastoquinone, generating a proton gradient that is used to drive ATP formation.

Cys_2His_2 zinc-finger domains
A conserved sequence-specific DNA-binding domain, found in members of the nuclear hormone-receptor family.

cytidine diphosphodiacylglycerol (CDP-diacylglycerol)
An activated precursor for the synthesis of many phospholipids formed by the reaction of phosphatidate with cytidine triphosphate.

cytochrome *bf*
A cytochrome complex that links photosystem II and photosystem I in green plants; cytochrome *bf* contributes to the proton gradient by oxidizing plastoquinol to plastoquinone.

Cytochrome *c*
A water-soluble, highly conserved cytochrome component of the respiratory chain that accepts electrons from cytochrome *c* reductase and is in turn oxidized by cytochrome *c* oxidoreductase.

cytochrome *c* oxidase
The final complex of the respiratory chain, which transfers electrons from cytochrome *c* to molecular oxygen and concomitantly pumps protons across the inner mitochondrial membrane to generate the proton-motive force. Also called **Complex IV**.

Cytochromes
Heme-containing proteins that often function in oxidation-reduction reactions.

cytoskeleton
The internal scaffolding of cells, made up of actin filaments and other proteins, that enables cells to transport materials intracellularly, change shape, and migrate.

Cytotoxic T lymphocytes (killer T cells)
A class of white blood cells that promote the destruction of cells infected with viruses or perceived as damaged in other ways.

dalton
A unit of mass equal to one atomic mass unit, or very nearly equal to that of a hydrogen atom.

de novo pathways
A biosynthetic pathway in which a molecule is synthesized from simple precursors.

degron

A feature of a protein that targets it for destruction by the ubiquitin-proteasome system. Degrons can be amino acid sequences, structural motifs, or even single residues.

denatured protein
A protein that has been converted into a randomly coiled peptide that lacks its normal activity.

deoxyhemoglobin
The oxygen-carrier protein hemoglobin in its form without bound oxygen.

deoxymyoglobin
The oxygen-storage protein myoglobin in its form without bound oxygen.

deoxyribonucleic acid (DNA)
A nucleic acid, usually found in a double helical structure, that serves as the primary storage point of genetic information in essentially all organisms.

deoxyribonucleic acid (DNA)
A nucleic acid constructed of four different deoxyribonucleotides; contains the genome and exists as a double-stranded helix in all higher organisms.

deoxyribose
A five-carbon monosaccharide $(C_5H_{10}O_4)$ that constitutes the carbohydrate moiety of a deoxynucleotide; the deoxyribose commonly found in deoxynucleotides is 2-deoxyribose.

development phase
The second phase of drug discovery, in which clinical trials are conducted to determine the safety, efficacy, and side effects of a drug in humans.

dialysis
A process of removing small molecules from a mixture of solutes using a semipermeable bag through which only small molecules can diffuse.

dihydrofolate reductase
An enzyme that catalyzes the regeneration of tetrahydrofolate from dihydrofolate formed in the synthesis of thymidylate.

dipolar ion (zwitterion)
An ion carrying both a positive and a negative charge.

direct repair
A means of repairing damaged DNA in which the damaged region is corrected in place. For example, pyrimidine dimers are simply cleaved to restore the original nucleotides.

disaccharide
A carbohydrate consisting of two sugars, usually joined by an *O*-glycosidic linkage.

discovery phase
The first phase of drug discovery, in which molecules with the desired physiological effects are identified and optimized for testing in humans.

distal histidine
The histidine residue in myoglobin and hemoglobin on the opposite side of the heme group from the proximal histidine and, therefore, on the same side as the bound oxygen molecule.

disulfide bond
A covalent bond formed by the oxidation of two sulfhydryl groups; the oxidation of cysteine residues in a polypeptide yields a disulfide bond linking the two residues.

divergent evolution
The process by which entities (species, populations, proteins, etc.) derived from a common ancestor accumulate differences over time, potentially gaining new functions.

DNA ligase
An enzyme that catalyzes the formation of a phosphodiester linkage between the $3'$-hydroxyl group at the end of one DNA strand and the $5'$-phosphoryl group at the end of another strand. DNA ligase takes part in the synthesis, repair, and splicing of DNA.

DNA methylases
An enzyme that adds a methyl group to a DNA substrate.

DNA microarray
A collection of known DNA sequences attached to a specific location on a solid surface, to which fluorescently labeled cDNA is hybridized to reveal the expression level of each gene.

DNA polymerases
Enzymes that catalyze the template-directed, primer-dependent addition of deoxynucleotide units to the $3'$ end of a DNA chain; chain growth is in the $5'$-to-$3'$ direction; such enzymes replicate and repair DNA.

DNA probe
A short stretch of single-stranded DNA that contains a known base sequence.

DNA-binding domain
The part of eukaryotic transcription factors that interacts with regulatory sequences.

DNA-encoded libraries (DELs)
A combinatorial compound library in which molecules are synthesized while covalently attached to a DNA oligonucleotide; the sequence of the oligonucleotide encodes the reaction history for that particular molecule.

domain
An independently folded unit in the tertiary structure of a polypeptide chain, often connected to other similar regions by a flexible polypeptide segment.

double helix
A structure with two strands spiraling around a common axis. Double-stranded DNA forms a double helix.

double-blinded study
A clinical study in which neither the subjects nor the researchers know which subjects are in the treatment group and which are in the control group.

double-displacement (Ping-Pong) reaction
A reaction having multiple substrates in which one or more products are released before all substrates bind the enzyme. The defining feature of these reactions is the formation of a substituted-enzyme intermediate.

drug metabolism
The process by which the body alters drugs to aid in their excretion.

EF hand
A structure found in calcium-binding proteins that consists of two α helices joined by a loop.

eicosanoids
Cell signaling molecules derived from 20-carbon-long polyunsaturated fatty acids, including arachidonic acid.

elasticity
The responsiveness of the velocity of an enzyme to changes in substrate concentration. Diminishes as substrate concentrations increase significantly above the K_M value.

electric dipole (dipole)
A characteristic of a molecule or fragment due to an uneven distribution of electrons so that some regions are partially negatively charged and other regions are partially positively charged.

electrochemical potential
The energetic cost that is required to establish a concentration gradient of a charged species across a membrane. Also called **membrane potential**.

electron-density map
The output from an x-ray crystallographic experiment, which reveals the most electron-dense regions of a crystal, that is, where the atoms are located.

electron-transport chain
Four large protein complexes embedded in the inner mitochondrial membrane in which the oxidation–reduction reactions that allow the flow of electrons from NADH and FADH2 to oxygen take place. Also called **respiratory chain**.

electrophilic
Describing the tendency of a molecule or group to attract or acquire electrons.

electroporation
A method for transfection of foreign DNA in which intense electric field pulses are applied to the host cells, rendering their membranes transiently permeable to large molecules.

electrospray ionization (ESI)
A method of ionizing samples for mass spectrometry in which a solution is passed through an electrically charged nozzle into a chamber of very low pressure.

elongation factor G (EF-G) (translocase)

A member of the G-protein family required for protein synthesis in eukaryotes. By hydrolyzing GTP, EF-G causes the tRNAs and mRNA to move through the ribosome a distance corresponding to one codon.

elongation factor Ts
A protein that binds to the GDP-bound form of EF-Tu and induces the release of GDP, thereby enabling EF-Tu to participate in another elongation step.

elongation factor Tu (EF-Tu)
A member of the G-protein family that delivers aminoacyl-tRNAs to the A site of the ribosome with the concomitant hydrolysis of GTP to GDP.

endoplasmic reticulum (ER)
An extensive system of cytoplasmic membranes that comprises about half the total cell membrane. The region of the ER that binds ribosomes is called the rough ER, and the region that is devoid of ribosomes is called the smooth ER.

endoplasmic reticulum (ER) stress
stress A condition in which the ability of the ER to fold proteins becomes compromised, resulting in protein misfolding and triggering of the unfolded protein response. If unresolved, it can lead to apoptosis.

endosomes
The intracellular vesicles that are formed during receptor-mediated endocytosis.

energy charge
A means of determining and conceptualizing the energy status of the cell; equal to the concentration of ATP plus one-half the concentration of ADP, all divided by the total adenine nucleotide concentration.

enhancer
A DNA sequence that has no promoter activity itself but can greatly enhance the activity of other promoters. Enhancers can exert their stimulatory effect over a distance of several thousand nucleotides.

enthalpy
In thermodynamics, enthalpy is a quantity equivalent to the total heat content of a system.

entropy
In thermodynamics, entropy is a specific measure of the degree of randomness or disorder in a system.

enzymatic cascade
A series of zymogen activations used to achieve a rapid response, such as that observed in blood clotting pathways.

enzyme
A biological macromolecule that acts as a catalyst for a biochemical reaction; although almost all enzymes are composed of protein, some RNA molecules are catalytically active (see **ribozyme**).

enzyme multiplicity
A regulatory strategy in which the committed step common to several pathways is catalyzed by distinct enzymes that have the same catalytic properties but different regulatory properties.

enzyme-linked immunosorbent assay (ELISA)
An immunological-based means of detecting and quantifying proteins.

enzymes
A biological macromolecule that acts as a catalyst for a biochemical reaction; although almost all enzymes are composed of protein, some RNA molecules are catalytically active.

epigenetics
Modifications to the genome that do not alter the DNA sequence but may affect gene expression.

epimers
A pair of molecules, each with more than one asymmetric center, that differ in configuration at only one such center. For example, glucose and galactose are epimers, differing only in the configuration at carbon 4 (C-4).

epinephrine
A hormone released under conditions of stress that increases heart rate, blood circulation, and carbohydrate metabolism.

epinephrine (adrenaline)
A catecholamine released by the adrenal medulla in response to muscle activity or its anticipation that stimulates the breakdown of muscle glycogen. Also called **adrenaline**.

equilibrium potential

The membrane voltage at which the movement of ion down its concentration gradient is balanced by the opposite electrostatic force.

essential amino acids
Amino acids that cannot be synthesized de novo and therefore must be acquired from the diet.

ethanol fermentation
The anaerobic conversion of glucose into ethanol with the concomitant production of ATP.

Eukarya (eukaryotes)
The domain of life that includes all multicellular organisms and as well some single-celled organisms such as yeast. Members of Eukarya are characterized by the presence of a well-defined cell nucleus.

eversion
The process of interconverting conformations typically observed in membrane pumps and secondary transporters.

evolutionary tree
A branching diagram that represents the evolutionary relationships among various species or entities and indicates the time at which different populations diverged.

exon shuffling
During evolution, the rearrangement of exons encoding discrete elements, binding sites, and catalytic sites, all of which can generate novel gene sequences.

exons
Region of pre-mRNA that is retained in mature mRNA.

exonuclease
An enzyme that digests nucleic acids from the ends of the molecules, rather than at an internal site. Exonucleases can be specific for digestion from the $3'$ or $5'$ ends of the nucleic acid.

expression vectors
A class of vector, usually a plasmid, that is designed for the expression of proteins encoded in their DNA inserts.

facilitated diffusion
The transport of an ion or a molecule down a concentration gradient, where ΔG for the transported species is negative. Also called **passive transport**.

facultative anaerobes
An organism that can both utilize molecular oxygen for aerobic metabolism as well as survive and grow in its absence through fermentation pathways.

fasted–fed cycle
A series of metabolic changes, primarily involving the liver, that maintain glucose homeostasis during the changing conditions that follow meals or periods of fasting.

fatty acid synthase
An enzyme system that catalyzes the synthesis of saturated long-chain fatty acids from acetyl CoA, malonyl CoA, and NADPH.

Fatty acids
A carboxylic acid that contains a long hydrocarbon chain. Fatty acids are an important fuel source as well as a key component of membrane lipids.

feedback inhibition
The inhibition of an enzyme by the end product of the pathway.

feedforward stimulation
The activation of an allosteric enzyme in a later stage of a pathway by the product of a reaction that takes place earlier in the reaction pathway. Also called **feedforward activation**.

fermentation
A redox neutral metabolic scheme for the production of ATP from an organic chemical source. Fermentations allow ATP production without the use of oxygen, although they can still occur in its presence.

ferritin
An iron-storage protein found primarily in the liver and kidneys.

fibrous protein
A protein that adopts a long, extended structure with repeated sequences.

flavoproteins

A protein tightly associated with FAD or FMN. Flavoproteins play important roles in many oxidation–reduction reactions.

fluid mosaic model
A model that describes the overall organization of biological membranes as two-dimensional solutions of oriented lipids and globular proteins.

fluorescence microscopy
Visualization of cells and tissues using fluorescence-labeled markers, including antibodies.

fractional saturation
A measure of the fraction of a potential binding site that is occupied with ligand.

free energy (Gibbs free energy)
In thermodynamics, the free energy is a quantity that satisfies the equation $\Delta G = \Delta H_{system} - T\Delta S_{system}$ where ΔH_{system} is the change in enthalpy of the system and ΔS_{system} is the change in entropy of the system.

G protein
A signaling protein that depends on binding guanine (G)-containing nucleotides.

G-protein-coupled receptors (GPCRs)
A member of a large family of cell surface receptors with seven membrane-spanning α helices that signal through G proteins. See also **seven-transmembrane-helix (7TM) receptor**.

gap junction
A channel permeable to ions and small hydrophilic molecules. Gap junctions connect the interiors of contiguous cells. Also called a **cell-to-cell channel**.

gel electrophoresis
A technique for separating biomolecules, such as nucleic acids and proteins, on the basis of charge and size. When placed under an electric field, the biomolecules move through the gel (a cross-linked polymer such as polyacrylamide), with larger molecules moving more slowly than smaller molecules.

gel-filtration chromatography
A method of separation where porous beads are used to differentiate proteins on the basis of size. Small molecules can enter the beads and thus take longer to pass

through the column.

gene disruption (gene knockout)
The removal of a specific gene in the genome, using one of a number of gene editing techniques.

general acid–base catalysis
Catalysis in which a molecule other than water plays the role of a proton donor or acceptor.

genetic code
The relationship between nucleic acid sequence information and protein sequence information.

genetic recombination
The exchange of genetic material between two DNA molecules, resulting in the reassortment of DNA sequences.

genome editing
One of a number of techniques that allow the highly specific modification of the genome.

genomic library
A collection of DNA fragments, inserted into a cloning vector, that represents the entire genome of an organism.

Gibbs free energy of activation
The energy required to form the transition state from the substrate of a reaction when considered from a particular direction. Also called the **activation energy**.

globular protein
A protein that forms a tightly packed structure, usually water soluble and devoid of overall symmetry.

glucagon
A polypeptide hormone that is secreted by the α cells of the pancreas when the blood-glucose level is low, leading to glycogen breakdown in the liver and the release of glucose to the blood.

glucogenic amino acids
An amino acid with a carbon skeleton that can be converted, entirely or in part, into substrates for gluconeogenesis.

gluconeogenesis
The synthesis of glucose from noncarbohydrate precursors, including lactate, glycerol, and amino acids.

glucose 6-phosphate dehydrogenase
An enzyme that initiates the oxidative phase of the pentose phosphate pathway by oxidizing glucose 6-phosphate to 6-phosphoglucono-δ-lactone to generate one molecule of NADPH.

glucose homeostasis
The regulation of glucose concentrations in the blood, primarily by the liver, to maintain adequate levels for the brain and other tissues.

glucose–alanine cycle
A cyclic pathway in which nitrogen and pyruvate are transported from muscle to the liver as alanine.

glutamate dehydrogenase
An enzyme that catalyzes the oxidative deamination of glutamate in the liver, yielding ammonium ion and α-ketoglutarate.

glutathione
A tripeptide playing a role in combating oxidative stress by maintaining the reduced state of the cell. Glutathione cycles between the reduced (GSH) and oxidized (GSSG) state.

glycerol 3-phosphate shuttle
A pathway, prominent in muscle tissue, that transfers electrons from cytoplasmic NADH into the mitochondria.

glycogen
A readily mobilized storage form of glucose in which the glucose monomers are linked by α-1,4-glycosidic linkages and in which there are branches (α-1,6-glycosidic linkages) at about every 12th residue.

glycogen phosphorylase
An allosteric enzyme that catalyzes the phosphorolysis of glycogen to yield glucose 1-phosphate; it is regulated by reversible covalent modification. Commonly referred to simply as **phosphorylase**.

glycogen synthase

An allosteric enzyme that can be reversibly covalently regulated and is responsible for the synthesis of glycogen. It transfers glucose from UDP-glucose to the hydroxyl group at a C-4 terminus of glycogen.

glycogen synthase kinase
An enzyme that phosphorylates glycogen synthase, keeping glycogen synthase in its inactive state.

glycogenin
A protein that bears an oligosaccharide of α-1,4 glucose units and is the primer for glycogen synthase. Glycogenin uses UDP-glucose to catalyze autoglycosylation.

glycolipids
A sugar-containing lipid that is derived from sphingosine; the sugar moiety is attached at the alcohol on sphingosine.

Glycolysis
A sequence of reactions that convert glucose into pyruvate with the concomitant generation of energy.

glycoprotein
A protein that has a specific carbohydrate moiety attached.

glycosaminoglycan
A heteropolysaccharide made of repeating disaccharide units and containing the amino sugar glucosamine or galactosamine.

glycosidic linkage
A covalent linkage between an aldehyde or ketone of a monosaccharide and an oxygen, nitrogen, or sulfur atom of another molecule. The most common glycosidic linkages are *O*-links between the anomeric carbon atom of a sugar and a hydroxyl group of another saccharide.

glycosyltransferases
Any of a number of specific enzymes that catalyze the formation of glycosidic linkages.

glyoxylate cycle
A metabolic pathway found primarily in microorganisms and plants that converts two-carbon acetyl units into succinate for energy production and biosyntheses.

glyoxysomes

An organelle containing enzymes of the glyoxylate pathway; found only in plants and filamentous fungi.

Golgi complex
In the cytoplasm, a stack of membranous sacs that constitute the major sorting center for proteins that reside in cell membranes and the lumen of organelles.

gout
A disease characterized by inflammation of the joints and kidneys due to the precipitation of abnormally high levels of sodium urate, a breakdown product of purines.

Gram staining
A method for staining bacteria using crystal violet that can distinguish between bacteria that possess a single membrane and a thick cell wall (Gram positive), and those that have a double lipid bilayer (Gram negative).

granum
A stack of thylakoid membranes in the chloroplast.

group-specific reagent
A reagent that reacts with specific R groups (side chains) of amino acids.

helicases
An enzyme that catalyzes the ATP-driven unwinding of nucleic acids. DNA helicases are important in DNA replication.

helix-turn-helix motif
The most common type of DNA-binding motif found in bacterial DNA-binding proteins.

heme
The prosthetic group of myoglobin and hemoglobin as well as other proteins; consists of an organic constituent, protoporphyrin IX, and an iron atom.

hemoglobin
A heme-containing oxygen carrier found in the bloodstream.

hemostasis
The process of blood clot formation and dissolution.

Henderson—Hasselbalch equation

The equation relating pH, the pK_a of an acid, and the ratio of the ionized and unionized form of the acid: $pH = pK_a + \log([A^-]/[HA])$.

heterotrophs
An organism that obtains the majority of its carbon for biosynthesis from organic molecules, rather than from carbon dioxide.

heterotropic effects
The effect of nonsubstrate molecules on catalytic activity by acting at sites distinct from the enzyme active site.

high-density lipoprotein (HDL)
A lipoprotein that picks up cholesterol from dying cells and from membranes undergoing turnover, esterifies it, and then transfers the cholesterol esters to the liver and other steroid-synthesizing tissues.

high-performance liquid chromatography (HPLC)
An enhanced column chromatography technique in which the separation materials are more finely divided and thus possess more interaction sites, resulting in greater resolution.

high-throughput screening (HTS)
The testing of a large compound library to identify molecules that bind to or affect the activity of a particular target.

histone acetyltransferases (HATs)
An enzyme that catalyzes the attachment of acetyl groups from acetyl CoA to specific lysine residues in the amino-terminal domains of histones.

histone deacetylase
An enzyme that contributes to transcriptional repression by the deacetylation of acetylated lysine residues in histones.

Holliday junctions
A cross-like structure, formed by four polynucleotide chains, that is a key intermediate in the recombination process.

holoenzyme
A complete and functional enzyme that consists of the protein component forming the main body of the enzyme (the apoenzyme) and any necessary cofactors.

homeodomain
A DNA-binding motif found in eukaryotic transcription factors, similar to bacterial helix-turn-helix motifs.

homodimer
A protein complex containing two identical subunits.

homogenate
The mixture formed when a tissue is treated in such a way that the plasma membranes are disrupted.

homologous recombination
The process by which two DNA molecules with strong sequence similarity exchange segments, allowing the transfer of foreign DNA into a genome.

homologs
Molecules that are related to each other by being derived from a common ancestor.

homotropic effects
The cooperative effect of substrate binding in one active site on the affinity at the comparable active site elsewhere in the enzyme.

horizontal gene transfer
The exchange of genetic material between species that provides a selective advantage to the recipient.

hybridoma
A cell formed from the fusion of immortal myeloma cancer cells with antibody-producing cells from the spleen of an inoculated organism. These cells produce large quantities of a single monoclonal antibody and have very long life spans.

hydrogen bond
A specific type of dipole–dipole interaction in which a hydrogen atom is partially shared by two electronegative atoms such as nitrogen or oxygen. Hydrogen bonds are relatively weak, with energies ranging from 4 to $20\ \mathrm{kJ\ mol^{-1}}$ (from 1 to $5\ \mathrm{kcal\ mol^{-1}}$), but are very important for specificity in biochemical interactions.

hydrogen-bond acceptor

The atom and its lone pair of electrons within a hydrogen bond that is less tightly linked to the hydrogen atom.

hydrogen-bond donor
The group within a hydrogen bond that includes both the hydrogen atom and the atom to which the hydrogen atom is more tightly linked.

hydropathy plot
An analysis of amino acid sequence used to locate potential membrane-spanning alpha helices by identifying highly hydrophobic regions across a defined sequence window.

hydrophobic effect
The tendency of nonpolar molecules to associate with one another in water.

Hypervariable loops (complementarity-determining regions)
Loops found on one end of an antibody structure that differ greatly between antibodies and determine antigen-binding specificity.

identities
The number of matched amino acid residues between two sequences.

Immunoglobulin fold
The three-dimensional structure of domains found in antibodies and other proteins comprising a disulfide-link sandwich structure of two antiparallel beta sheets with loops on the ends.

induced fit
The modification of the shape of an active site in an enzyme, toward a structure complementary to the transition state, after the substrate has been bound.

induced fit
The modification of the shape of an active site in an enzyme that occurs upon substrate binding.

inducer
A small molecule that binds to a repressor and alters its interaction with an operator to activate transcription.

initiation factors
One of a set of proteins that assist in the association of the ribosome, mRNA, and initiator tRNA to initiate the process of protein synthesis.

innate immune system
The first line of defense against invading pathogens that recognizes molecular structures common to pathogens, such as viruses and bacteria, that are not found outside cells in our bodies.

insulin
A hormone secreted by the pancreas that promotes the absorption of glucose from the bloodstream.

insulin resistance
The gradual reduction of the signaling response to insulin, despite adequate or excessive quantities of insulin produced; part of the metabolic syndrome. This often progresses to a near complete loss of insulin responsiveness.

Integral membrane proteins
A protein found in membranes that interacts extensively with the hydrocarbon chains of the membrane lipids and usually spans the membrane.

intermembrane space (IM space)
The compartment bounded by the inner and outer mitochondrial membranes into which protons are pumped by the action of the electron-transport chain.

introns
Region of the primary transcript that is removed in the mature mRNA. Also called the *intervening sequence*.

ion channels
A passive-transport system for ions capable of very high transport rates. Ion channels often display a high degree of specificity for the transported ion.

ion-exchange chromatography
A method of separation that takes advantage of the differences in net charge among proteins.

ionic interaction
An interaction involving one charged group interacting with another charged group. Such interactions are available if the two groups have charges of opposite sign.

iron–sulfur protein

A protein containing clusters of iron and sulfur that plays a role in electron-transfer reactions; iron cycles between the Fe^{2+} and Fe^{3+} state. Also called **nonheme iron protein**.

iron–sulfur proteins
Proteins containing clusters of iron and sulfur that play a role in electron-transfer reactions; iron cycles between the Fe^{2+} and Fe^{3+} state. Also called **nonheme iron proteins**.

isoelectric focusing
A means of separating proteins electrophoretically based on the relative content of acidic and basic residues of the proteins.

isoelectric point
The pH at which the net charge of a protein is zero.

isozymes (isoenzymes)
Enzymes that are encoded by different genes and that catalyze the same reaction, yet display different kinetic parameters and respond to different regulatory molecules.

k_{cat}/K_M (specificity constant)
A single number that directly relates the rate of a reaction to the concentration of the reactant and allows comparison of the efficiency of an enzyme capable of reacting with different substrates. Also called the catalytic efficiency.

ketogenic amino acids
An amino acid with a carbon skeleton that is degraded, entirely or in part, into acetyl CoA or acetoacetyl CoA; only leucine and lysine are solely ketogenic.

ketone bodies
Acetoacetate, b-hydroxybutyrate, and acetone produced when acetyl CoA is diverted from the citric acid cycle to the formation of acetoacetyl CoA in the liver. Ketone bodies act to transport acetyl groups from one tissue to another.

Kinases
An enzyme that catalyzes the attachment or removal of a phosphoryl group to a substrate by using ATP as a phosphoryl donor or ADP as the acceptor.

K_M (Michaelis constant)
The concentration of substrate at which an enzyme is operating at one-half maximum velocity.

lactic acid fermentation
The anaerobic metabolism of glucose to yield lactic acid with the concomitant production of ATP.

lagging strand
A newly synthesized strand of DNA at the replication fork that is initially synthesized as Okazaki fragments. See also *leading strand*.

large subunit (50S)
The large subunit of the bacterial 70S ribosome. The site of peptide-bond synthesis, it contains 34 different proteins, a 5S RNA species, and a 23S RNA species.

lateral diffusion
The ability of lipid and protein molecules to move laterally in the membrane rapidly and spontaneously.

lead molecules (leads)
Initial drug-like molecules that are the starting points for optimization into a drug candidate.

lead optimization
The process by which lead compounds are optimized into molecules suitable for testing in humans.

leading strand
A newly synthesized strand of DNA at the replication fork that is synthesized continuously. See also *lagging strand*.

lectins
A protein with a high affinity for a specific sugar residue; as such, lectins are important probes of carbohydrate containing molecules.

leptin
An adipokine hormone produced by adipose tissue in proportion to mass. Leptin induces feelings of satiety to regulate body mass.

Lesch–Nyhan syndrome
A disease resulting from the loss of a single enzyme in the salvage pathway for purines. It is marked by cognitive disabilities, extreme hostility, and self-mutilation.

ligand-gated channel
An ion channel whose opening is controlled by the presence of specific ligands.

ligands
A molecule or group that binds to a receptor including a metal ion.

light reactions
In chloroplasts, the reactions in which light is used to create reducing potential, to form ATP, and to generate oxygen.

light-harvesting complexes
A complex of light-absorbing pigments and protein that completely surrounds the reaction center of photosynthesis, funneling the energy of absorbed light to the reaction center.

Lineweaver–Burk plot
A plot of $1/V_0$ versus 1/[S] yields a straight line with a *y*-intercept of $1/V_{max}$ and a slope of K_M/V_{max}. Also called a double-reciprocal plot.

linking number (Lk)
The number of times that a strand of DNA winds in the right-handed direction around the helix axis when the axis lies in a plane.

lipases
An enzyme that degrades a triacylglycerol into free fatty acids and monoacylglycerol.

lipid bilayer
A bimolecular sheet formed by amphipathic molecules in which the hydrophobic moieties are on the inside of the sheet and the hydrophilic ones are on the aqueous outside.

lipid rafts
Complexes that are formed by cholesterol and some phospholipids, notably sphingolipids. Lipid rafts may concentrate in specific regions within membranes,

forming structures that are thicker, more stable, and less fluid than the rest of the membrane.

lipids
Water-insoluble biomolecules that are highly soluble in organic solvents such as chloroform.

lipoprotein particles
Clusters of molecules, consisting of a core of hydrophobic lipids surrounded by a shell of polar lipids and specific proteins, that play a role in the transport of cholesterol and triacylglycerols.

liposome (lipid vesicle)
An artificial membrane structure that consists of an aqueous compartment enclosed by a lipid bilayer.

Long QT syndrome (LQTS)
A genetic disorder in which the recovery of the action potential from its peak potential to the resting equilibrium potential is delayed.

loop
A segment of residues where the polypeptide chain reverses direction, usually longer and more elaborate than a reverse turn.

low-density lipoprotein (LDL)
The major carrier of cholesterol in the blood, consisting of a core of esterified cholesterol molecules surrounded by a shell of phospholipids, unesterified cholesterol, and apoprotein B-100. LDL is the primary source of cholesterol for cells other than those in the liver or intestine.

main chain (backbone)
The regularly repeating part of a polypeptide, including the amino group, α-carbon, and carbonyl groups.

Major histocompatibility complex (MHC)
A group of genes that encode proteins found on the surfaces of cells that help the immune system recognize foreign substances.

malate–aspartate shuttle
A reversible shuttle, found in the liver and heart, that transports electrons from cytoplasmic NADH to mitochondrial NAD^+.

malonyl CoA
Carboxylated acetyl CoA, the activated form of acetyl CoA used in fatty acid synthesis.

mass spectrometry
A technique for determining a protein's mass and identity and for sequencing a protein.

matrix
The central compartment of a mitochondrion, bounded by the inner mitochondrial membrane.

matrix-assisted laser desorption/ionization (MALDI)
A method of ionizing samples for mass spectrometry in which laser pulses ionize a sample embedded within a volatile matrix.

mechanism-based (on-target) toxicity
Toxicity caused by actions of a drug against its intended target.

mechanism-based (suicide) inhibitor
An inhibitor that binds to an enzyme as a substrate and initiates the normal catalytic mechanism, but via a subsequent mechanism generates a chemically reactive intermediate that inactivates the enzyme irreversibly through covalent modification.

mediator
A multisubunit complex that acts as a bridge between enhancer-bound activators and promoter-bound RNA polymerase II.

melting temperature
For a DNA double helix, the temperature at which half of the helical structure is lost.

Messenger RNA (mRNA)
A class of RNA molecules that serve as templates for the synthesis of proteins.

metabolic syndrome
A spectrum of metabolic changes that typically precede the development of type 2 diabetes and are often associated with obesity. These include hyperglycemia, dyslipidemia, and insulin resistance.

metabolism

A highly integrated network of chemical pathways that enables a cell to extract energy from the environment and use this energy for biosynthetic purposes. Also called **intermediary metabolism**.

metabolites
Small organic molecules (typically with molecular weight less than 1000 gm/mol) found in biological systems. This term derives from *metabolism,* the chemical processes that occur within living cells.

metal ion catalysis
Catalysis in which a metal acts as an electrophilic catalyst by stabilizing a negative charge on a reaction intermediate, generates a nucleophile by increasing the acidity of nearby molecules, or increases the binding energy of the enzyme–substrate interaction by binding to substrates.

mevalonate
A precursor for the synthesis of cholesterol. Its formation by 3-hydroxy-3-methylglutaryl CoA reductase constitutes the committed step in cholesterol biosynthesis.

micelle
A globular structure, typically formed from free fatty acids that contain only one hydrocarbon chain, in which the polar head groups form the outside surface and the hydrocarbon tails are sequestered inside.

Michaelis–Menten equation
An equation that expresses the initial velocity (V_0) of an enzyme-catalyzed reaction in terms of maximum velocity, V_{max}, substrate concentration, [S], and the Michaelis–Menten constant, K_M. The equation accounts for the hyperbolic kinetics observed when V_0 is plotted as a function of S; the equation is

$$V_0 = V_{max}\frac{[S]}{[S] + K_M}.$$

microbiome
The microorganisms that live on or within a macroscopic organism such as a human being.

microRNAs

A type of noncoding RNAs found in plants, invertebrates, and vertebrates. These ~21-nucleotide-long RNA molecules are excised from longer double-stranded RNAs and play a role in post-transcriptional regulation.

Mismatch repair
A system of DNA repair that consists of at least two proteins, one for detecting the mismatch and the other for recruiting an endonuclease that cleaves the newly synthesized DNA strand near the lesion. An exonuclease can then excise the incorrect base, and a polymerase fills the gap.

mixed noncompetitive inhibition
The reduction in the rate of enzyme activity observed when a reversible inhibitor binds significantly to both the enzyme–substrate complex and to the free enzyme but with different affinities. Mixed noncompetitive inhibitors always decrease the turnover number; however, the effect on the apparent value of K_M depends on the inhibitor's relative affinity for either E or ES. As such, mixed noncompetitive inhibitors can either increase or decrease the apparent K_M for an enzyme.

molecular clock hypothesis
The hypothesis stating that the extent of sequence difference between the same protein from two organisms can be used to infer the amount of time that has passed since these organisms had a common ancestor.

molecular recognition
Specific complex formation between two or more molecules via noncovalent interactions.

monoclonal antibody
An antibody, produced by a cloned hybridoma cell, that binds to only one epitope on a specific antigen.

monosaccharides
A single aldehyde or ketone that has two or more hydroxyl groups; monosaccharides are the simplest carbohydrates and are also called sugars.

motif (supersecondary structure)
Certain combinations of secondary structure present in many proteins, which frequently exhibit similar functions.

mucin

One of a class of glycoproteins, consisting mainly of carbohydrate, in which the protein component is extensively glycosylated to serine or threonine by *N*-acetylgalactosamine. Also called a **mucoprotein**.

multidrug resistance
When observed in tumor cells, the development of resistance to one drug that renders cells less sensitive to a range of other compounds

mutagens
An agent that perturbs the base sequence of DNA and causes a mutation. A mutagen is often a chemical, but it can also be an energy source such as ultraviolet light.

Myelin
A specialized membrane structure that serves as an electrical insulator around certain nerve fibers.

myoglobin
A heme-containing oxygen storage protein found in muscle.

myosins
A class of molecular motor proteins that hydrolyze DNA and use the free energy of hydrolysis to move along actin filaments.

NADH-Q oxidoreductase
A large component of the respiratory chain that transfers electrons from NADH to ubiquinone and, in the process, pumps protons across the inner mitochondrial membrane to generate the proton-motive force. Also called *NADH dehydrogenase* or **Complex I**.

native protein
A protein in its original active and folded form.

nerve impulse
An electrical signal produced by the coordinated flow of ions across the plasma membrane of a neuron. Also called an **action potential**.

neurotransmitters
Small, diffusible molecules that communicate nerve impulses across synapses.

next-generation sequencing (NGS)

A family of techniques that enable the rapid sequencing of short stretches of DNA in a massively parallel fashion (i.e., millions of sequences in a single experiment).

Nitric oxide (NO)
A free radical gas that serves as an important messenger in many vertebrate signal transduction processes, including vascular relaxation and mitochondrial biogenesis.

nitrogen fixation
The reduction of nitrogen gas (N_2) into ammonia (NH_3).

nitrogenase complex
An enzyme complex that catalyzes the reduction of N_2 to ammonia (nitrogen fixation); it is found in certain bacteria and the blue-green algae (cyanobacteria).

nitrogenous bases (bases)
One of the four possible substituents on the backbone of nucleic acids such as DNA. In DNA, these bases are adenine, cytosine, guanine, and thymine.

non-homologous end joining (NHEJ)
A mechanism used to repair double-stranded breaks in DNA. It joins two free double-stranded ends that are not related in sequence.

nonconservative substitution
An amino acid change in which an amino acid is replaced with one that is structurally dissimilar.

nonessential amino acids
Amino acids that can be synthesized by an organism and are thus not a dietary requirement.

nonphotochemical quenching (NPQ)
A process in chloroplasts that, in bright sunlight, directs photons from the reaction center, releasing the energy as heat. NPQ protects against the generation of reactive oxygen species.

nonpolar molecule
A molecule that cannot participate in hydrogen bonding or ionic interactions.

northern blotting

A technique that allows the identification of a specific RNA molecule using a ^{32}P-labeled probe complementary to the RNA molecule of interest.

nuclear hormone receptors
A member of a large family of transcription factors that, on the binding of a signal molecule such as a steroid hormone, modify the expression of specific genes by binding to control elements in the DNA.

nuclear magnetic resonance (NMR) spectroscopy
A method for determining the structure of molecules in solution by measuring the chemical environment of and contacts between intrinsically magnetic nuclei (such as protons) within the sample.

nuclear Overhauser effect
An interaction between nuclei that is proportional to the inverse sixth power of the distance between them. This effect is exploited in NMR spectroscopy to identify pairs of atoms within 5 Å of each other.

nucleophilic
Describing the tendency of a molecule or group to donate electrons or react at relatively electron-poor sites.

nucleoside
A purine or pyrimidine base linked to a sugar.

nucleoside diphosphokinase
An enzyme that exchanges the gamma phosphate between a nucleoside triphosphate and nucleoside diphosphate, allowing the equilibration of pools of energetically equivalent nucleoside trisphosphates in the cell.

nucleosome
A key structure of chromatin that is formed by the wrapping of ca. 145 bp of DNA around an octamer of histone proteins.

nucleotide
A nitrogenous purine or pyrimidine base linked to a sugar, which is in turn linked to one or more phosphoryl groups.

nucleotide-excision repair
A means of repairing DNA in which a stretch of DNA around the site of damage is removed and replaced.

obligate anaerobes
An organism that cannot survive in the presence of oxygen and thus is usually dependent on fermentation as a source of cellular energy.

off-target toxicity
Toxicity caused by actions of a drug against proteins that are distinct from the intended target.

Okazaki fragments
Small fragments of DNA (approximately 1000 nucleotides) that are formed on the lagging strand at the replication fork of DNA synthesis and later joined. Okazaki fragments enable $5'$-to-$3'$ polymerization at the nucleotide level while overall growth is in the $3'$-to-$5'$ direction.

oligopeptides (peptides)
Polypeptide chains made of small numbers of amino acids.

Oligosaccharides
A carbohydrate composed of 2 to 12 monosaccharide units.

oncogenes
A gene that can initiate the development of cancer.

open reading frames (ORFs)
A protein-coding region within a genome.

operator site
A regulatory sequence found in an operon to which regulatory proteins bind.

operon
A grouping of genes in bacteria whose expression is regulated in a coordinated manner because they are transcribed into one mRNA from a single promoter.

oral bioavailability
The ability of an orally administered drug to be absorbed into the bloodstream. It is defined as the ratio of the peak concentration of a compound given orally to the peak concentration of the same dose injected directly into the bloodstream

origin of replication
A particular sequence in a genome at which replication begins.

origin of replication complexes (ORCs)
A complex of six different proteins that promotes initiation of DNA replication in eukaryotes.

orotidylate
A nucleotide precursor to uridylate and cytidylate formed by the reaction of orotate with 5-phosphoribosyl-1-pyrophosphate (PRPP).

Orthologs
Homologs that are present within different species and have very similar or identical functions.

overlap peptides
Peptides generated by a cleavage method that enable the ordering of fragments generated by an orthogonal method.

oxidative phosphorylation
The process in which ATP is formed as a result of the transfer of electrons from NADH or $FADH_2$ to O_2 by a series of electron carriers.

oxyanion hole
A region on certain proteolytic enzymes that stabilizes the oxyanion constituent of the tetrahedral intermediate of the reaction.

oxyhemoglobin
The oxygen-carrier protein hemoglobin in its form with bound oxygen.

oxymyoglobin
The oxygen-storage protein myoglobin in its form with bound oxygen.

P-type ATPases
A class of pumps whose reaction mechanism includes a phosphorylaspartate intermediate.

Paralogs
Homologs that are present within one species and often differ in their detailed biochemical functions.

patch-clamp technique
A method for the measurement of the ion conductance through a small patch of cell membrane, capable of measuring the current through a single ion channel.

pentose phosphate pathway
A metabolic pathway that generates NADPH and five-carbon sugars such as ribose 5-phosphate from glucose 6-phosphate. Also referred to as the *hexose monophosphate shunt* or the *phosphogluconate pathway*.

peptide bond (amide bond)
A covalent linkage formed between the α-carboxyl group of one amino acid and the α-amino group of another.

peptide mass fingerprinting
The use of protein cleavage, followed by chromatographic separation and mass spectrometry to rapidly identify and quantitate proteins present within a sample.

peptidyl transferase center
A region of the large ribosomal subunit that catalyzes peptide-bond formation between the aminoacyl (or peptidyl) tRNA in the P site and the aminoacyl tRNA in the A site.

Peripheral membrane proteins
A protein that is associated with the surface of a membrane by electrostatic and hydrogen-bond interactions.

peroxisomes
A membrane-bound organelle that, in plants, houses enzymes that convert glycolate to glyoxylate as part of photorespiration.

pH
A measure of the concentration of hydrogen ions in solution nd is given by the equation $\mathrm{pH} = -\log [\mathrm{H}^+]$.

pharmacology
The scientific discipline which encompasses the discovery, chemistry, composition, identification, biological and physiological effects, uses, and manufacture of drugs.

phase I transformations
The oxidation reactions of drug metabolism.

phase II transformations
The conjugation reactions of drug metabolism.

phenotypic screening
A lead identification approach to early drug discovery in which compounds are screened for their ability to affect a disease-relevant phenotype of cells or tissues.

phenylketonuria
A disease caused by the inability to convert phenylalanine into tyrosine, which results in excess phenylalanine and its secondary metabolites. If untreated, it causes severe cognitive deficiencies and reduced lifespan.

phosphatase
An enzyme that catalyzes the attachment or removal of a phosphoryl group to a substrate by using inorganic phosphate as a phosphoryl donor or water as the acceptor.

phosphatidate
A precursor to triacylglycerols and to many phospholipids.

phospholipid
An important constituent of membranes that is composed of three components: a backbone (usually glycerol or sphingosine), two fatty acid chains, and a phosphorylated alcohol.

phosphoproteome
The proteins expressed by the genome that have been phosphorylated.

phosphorolysis
The cleavage of a bond by orthophosphate, as in the degradation of glycogen to glucose 1-phosphate.

phosphoryl-transfer potential
A measure of the tendency of a phosphorylated compound to transfer a phosphoryl group to another compound, presented as the $\Delta G^{\circ\prime}$ of hydrolysis of the phosphorylated compound. The more negative the $\Delta G^{\circ\prime}$ of hydrolysis, the greater the phosphoryl-group-transfer potential.

phosphorylase kinase
An enzyme that activates phosphorylase *b* by attaching a phosphoryl group in the regulation of glycogen degradation. This kinase is itself under dual control: it is activated both by phosphorylation and by increases in Ca^{2+} levels.

photoinduced charge separation
The excitation of an electron from its ground state to a higher energy level by light absorption and the subsequent movement of the excited electron from the initial molecule to an acceptor, resulting in a positive charge on the initial molecule and a negative charge on the acceptor molecule.

photorespiration
The conversion of organic carbon into carbon dioxide without the production of energy-rich metabolites, as the result of the oxygenase reaction catalyzed by Rubisco and subsequent steps.

photosynthesis
A metabolic scheme involving both phototropy and autotrophy, in which energy from sunlight is used to drive both the production of ATP and the reduction of carbon dioxide to synthesize carbohydrate. Photosynthesis may be oxygen-forming (oxygenic) or anoxygenic.

Photosystem I
In chloroplasts, a photosynthetic unit that includes a light-harvesting complex, a reaction center, and an electron-transport chain. The system catalyzes the light-driven transfer of electrons from reduced plastoquinone to ferredoxin, which in turn drives the formation of NADPH. PS I requires light of wavelength shorter than 700 nm.

Photosystem II
In chloroplasts, a photosynthetic unit that includes a light-harvesting complex, a reaction center, and an electron-transport chain. The system catalyzes the light-driven transfer of electrons from water to plastoquinone, with the concomitant generation of oxygen. PS II requires light of wavelength shorter than 680 nm.

Phototrophs
An organism that can meet its energy needs by converting light energy into chemical energy.

pK_a value

A measure of the acidity of a group HA and is defined by $pK_a = -\log(K_a)$ where K_a is the equilibrium constant $K_a = [H^+][A^-]/[HA]$.

placebo

A treatment given in controlled clinical trials that is known to not have intrinsic value.

placebo effect
The tendency to perceive improvement in a subject who believes that he or she is receiving a potentially beneficial treatment.

Plasmids
In bacteria, a small circular DNA separate from the bacterial chromosomal DNA that can replicate independently of the chromosomal DNA and often carries genes that confer antibiotic resistance.

pleckstrin homology domain
A protein domain that can bind phosphatidylinositol lipids.

polarity
The property of an object in which one end is different than the other. A strand of DNA has polarity and so, for example, the sequence -AGC- is distinct from -CGA-.

poly(A) tail
A long (as many as 250 nucleotides) polyadenylate segment added post-transcriptionally to the 3′ end of most eukaryotic mRNA.

polyclonal antibodies
Antibodies against a single antigen that are derived from multiple antibody-producing cell populations and thus recognize multiple epitopes on the antigen.

polylinker
A portion of a vector that contains multiple overlapping unique restriction sites. The presence of a polylinker allows for many different cohesive ends to be used for DNA insertion.

polymerase chain reaction (PCR)
A technique used to amplify a target DNA sequence over several orders of magnitude. A PCR cycle consists of three steps—strand separation, hybridization of primers, and DNA synthesis—that are repeated 20 or 30 times.

polymorphisms
An instance of genetic variation found within a population.

polysaccharides

A carbohydrate composed of a large number of covalently linked monosaccharide units; homopolysaccharides are composed of large numbers of one type of sugar, whereas heteropolysaccharides contain more than one type.

polysome
A group of ribosomes bound to an mRNA molecule and simultaneously carrying out translation. It is also called a *polyribosome* or the *primary transcript*.

Porphyrias
Inherited or acquired disorders caused by a deficiency of enzymes in the heme biosynthetic pathway.

posttranslational modification
Alterations in the structure of a protein after it has been synthesized in the cell.

pre-mRNA
The unspliced immediate product of RNA polymerase II in eukaryotes. It is also called the *primary transcript*.

primary messenger
A hormone, neurotransmitter, or other molecule that carries information to a cell or tissue by binding to a receptor, usually on the cell surface.

primary structure
The linear sequence of amino acids in a protein.

primase
A specialized RNA polymerase that synthesizes the RNA primers for DNA synthesis.

primer
In the elongation of polymers, the initial segment of the polymer that is to be extended. In DNA synthesis, elongation depends on the primer.

Processivity
A property of an enzyme that enables it to catalyze multiple rounds of elongation or the digestion of a polymer while the polymer stays bound to the enzyme.

prokaryote
A unicellular organism whose cells lack a well-defined nucleus.

promoter sites

A specific sequence of DNA, usually just upstream of a gene, that specifies the start site and extent of transcription of the associated gene.

promoters
A specific sequence of DNA, usually just upstream of a gene, that specifies the start site and extent of transcription of the associated gene.

prostaglandin
A class of short-lived signal molecules that are 20-carbon fatty acids containing a five-membered ring.

prosthetic group
A coenzyme that is tightly bound or covalently linked to an enzyme such that it does not readily dissociate but instead remains continuously associated with an enzyme.

protease
A class of enzymes that hydrolyze the peptide bonds between amino acids, thus digesting proteins. Also called a *proteolytic enzyme*.

protease inhibitors
A chemical that blocks or reduces the activity of a protease enzyme; some protease inhibitors are important drugs.

Proteases
A class of enzymes that catalyze the hydrolysis of peptide bonds between amino acids, thus digesting proteins.

proteasome
A large barrel-shaped protein complex primarily responsible for protein turnover in eukaryotes. Homologous systems exist in archaea and bacteria.

protein
A member of a class of biological macromolecules built of chains of units called amino acids. There are 20 different possible amino acids.

protein kinases
An enzyme that catalyzes the attachment of a phosphoryl group to a protein substrate by using ATP as a phosphoryl donor.

Protein phosphatase 1 (PP1)

A protein phosphatase stimulated by insulin that inhibits glycogen degradation and stimulates glycogen synthesis.

Protein phosphatases
An enzyme that catalyzes the removal of a phosphoryl group from a protein substrate by hydrolysis.

proteoglycans
A protein containing one or more covalently linked glycosaminoglycan chains. Cartilage proteoglycan contains keratan sulfate and chondroitin chains linked to a polypeptide backbone.

proteome
A term that refers to the proteins expressed by the genome, encompassing the types, functions, and interactions of proteins that yield a functional unit. Unlike the genome, the proteome varies with cell type, developmental state, and environmental conditions.

proto-oncogenes
A normal gene that can be converted to an oncogene by mutation.

proton shuttle
A group that facilitates the transfer of protons into or out of the active site of an enzyme.

proton-motive force
The energy inherent in the proton gradient established during the functioning of the respiratory chain, consisting of a membrane potential as well as a chemical gradient.

proximal histidine
The histidine residue in myoglobin and hemoglobin that is bound to the heme iron atom.

pseudogenes
A formerly functional gene that has accumulated enough mutations that it no longer produces protein.

pseudosubstrate sequence
A peptide sequence that matches the consensus sequence for a particular protein kinase substrate, but lacks the hydroxyl group required for phosphoryl transfer.

Pumps
Membrane proteins that catalyze the active transport of ions against their electrochemical gradients.

pure noncompetitive inhibition
The reduction in the rate of enzyme activity observed when a reversible inhibitor binds equally well to both the enzyme–substrate complex and to the free enzyme. Pure noncompetitive inhibitors decrease the turnover number, but do not alter the K_M, for an enzyme; their effects are not overcome by increased substrate concentration.

purine
A nitrogenous base that includes a pyrimidine ring fused with a five-membered imidazole ring; the purine derivatives adenine and guanine are found in nucleotides and nucleic acids.

purinosomes
A complex formed upon the association of the enzymes of purine synthesis.

pyridoxal phosphate (PLP)
A prosthetic group derived from vitamin B_6 (pyridoxine) that plays a key role in transamination reactions.

pyrimidine
A nitrogenous base that is a six-membered heterocyclic ring containing two nitrogen atoms and four carbon atoms; the pyrimidine derivatives cytosine, uracil, and thymine are found in nucleotides and nucleic acids.

pyrosequencing
A next-generation sequencing method that measures the DNA polymerase-catalyzed addition of a nucleotide by enzymatically converting the pyrophosphate product into light.

pyruvate dehydrogenase complex
A large mitochondrial enzyme complex that catalyzes the oxidative decarboxylation of pyruvate to form acetyl CoA. This irreversible reaction is the link between glycolysis and the citric acid cycle.

Q cycle
A set of reactions in which coenzyme Q cycles between the fully reduced state and the fully oxidized state through one-electron-transfer reactions.

Q-cytochrome c oxidoreductase
A component of the respiratory chain that carries electrons from coenzyme Q to cytochrome *c*, pumping protons out of the mitochondrial matrix to generate the proton-motive force. Also called *cytochrome* c *reductase* or **Complex III**.

quantitative PCR (qPCR)
A polymerase chain reaction technique capable of determining the quantity of individual mRNA transcripts. Also called real-time PCR.

quaternary structure
In proteins containing more than one polypeptide chain, the spatial arrangements of those chains (subunits) and the nature of the contacts between them.

R state
The quaternary structure adopted by oxyhemoglobin, where "R" refers to *relaxed* compared to the T (*tense*) state adopted by deoxyhemoglobin.

Ramachandran plot
A steric contour diagram that depicts allowed ranges of the angles φ and ψ for amino acid residues in polypeptide chains.

reaction center
In a photosynthetic unit, a specialized chlorophyll molecule that collects excitation energy from other chlorophyll molecules and mediates the transformation of light into chemical energy.

receptor-mediated endocytosis
The process of importing specific proteins into a cell by their binding to plasma-membrane receptors and their subsequent endocytosis and inclusion into vesicles.

receptors
A biological macromolecule, usually a cell-surface protein, that binds a molecule such as a hormone and initiates signaling cascades.

recognition sequences
A nucleic acid sequence that acts as a preferred binding, cleavage, or modification site for a DNA binding or modification protein such as a restriction enzyme.

recombinases
Enzymes that resolve Holliday junctions into separate DNA duplexes.

recombination synapse
A structure formed when four molecules of a recombinase and two DNA double helices come together before forming a Holliday junction.

recovery
In ion channels, the process by which an inactivated channel returns to the closed state.

reducing sugars
A sugar that converts into a form with a free aldehyde group that is readily oxidized and can thus reduce another compound.

reduction potential

The electron-transfer potential, expressed symbolically as E'_0. Also called **redox potential** or **oxidation–reduction potential**.

refractory period
The time after an action potential in which a subsequent action potential cannot be induced.

release factors (RFs)
One of a set of proteins that recognize stop codons on mRNA at the A site on the ribosome, which leads to the release of the completed protein from the tRNA in the P site of the ribosome.

replication fork
The site of DNA synthesis where the parental strands are separated and daughter strands complementary to each parent are synthesized.

reporter genes
A gene that encodes an easily detectable marker such as an antibiotic-resistance enzyme or a fluorescent protein. When used in vectors, they enable the rapid identification of clones that have successfully incorporated a DNA fragment.

repressor
A protein that binds to an operator sequence and inhibits the transcription of the structural genes in the operon.

residue
An amino acid unit within a polypeptide chain.

resonance structure
A structure that represents alternative arrangements of single and double bonds within the same structural framework. The true structure is intermediate between these alternative structures and is lower in energy than the individual resonance structures.

respirasome
A supramolecular complex consisting of two copies each of Complexes I, III, and IV of the electron-transport chain.

respiratory quotient (RQ)
A commonly used metabolic index defined as the volume of CO_2 released divided by the volume of O_2 consumed at a defined pressure. RQ is used to estimate the ratio of glucose vs. fatty acids used during rest or exercise.

restriction enzyme (restriction endonuclease)
A prokaryotic enzyme that recognizes specific base sequences in DNA and cleaves, at these specific places, both strands of DNA.

restriction enzymes
A bacterial enzyme that recognizes specific base sequences in double-helical DNA and cleaves, at specific places, both strands of DNA. Also called **restriction endonuclease**.

Restriction-fragment-length polymorphisms (RFLPs)
A polymorphism within restriction sites that changes the sizes of restriction fragments produced by the appropriate restriction enzyme.

restriction-modification systems
A combination of a restriction enzyme and a methylase that allows a host cell to cleave viral or other foreign DNA while not affecting host DNA.

retroviruses
A class of RNA viruses in which genetic information flows from RNA to DNA following the insertion of a copy of the viral RNA genome into the host's DNA.

reverse turn (β turn; hairpin turn)
A short segment of residues where the polypeptide chain reverses direction, often featuring a hydrogen bond between the CO group of residue i and the NH group of $i + 3$.

rho (ρ)
An ATP-dependent bacterial helicase that breaks the RNA–DNA hybrid at the transcription bubble and thereby terminates transcription.

ribonucleic acid (RNA)
A long unbranched polymer consisting of ribonucleotides joined by $3' \rightarrow 5'$ phosphodiester linkages that plays many roles in the cell, including that of catalyst. RNA is similar to DNA in composition except that it contains the base uridine instead of thymine, its sugar component has an extra hydroxyl group, and it is single-stranded.

ribonucleotide reductase
An enzyme that catalyzes the reduction of all four ribonucleotides to deoxyribonucleotides.

ribose
A five-carbon monosaccharide $(C_5H_{10}O_5)$ that constitutes the carbohydrate moiety of ATP, other ribonucleosides and ribonucleotides, and cofactors such as NAD^+ and coenzyme A.

Ribosomal RNA (rRNA)
The RNA components of ribosomes.

ribosomes
A large ribonucleoprotein assembly that catalyzes the formation of peptide bonds; a molecular machine that coordinates protein synthesis.

riboswitches
A structural component of some bacterial mRNA molecules that can bind to specific small molecules and thereby prevent further transcription of the mRNA.

ribozyme
A member of a class of RNA molecules that display enzymatic activity.

ribulose 1,5-bisphosphate carboxylase/oxygenase
An enzyme that catalyzes the reaction of carbon dioxide with ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate.

RNA editing

A process, distinct from RNA splicing, that changes the nucleotide sequence of mRNA after transcription.

RNA interference (RNAi)
The regulation of gene expression post-transcriptionally by small molecules of RNA.

RNA polymerases
A member of a class of enzymes that synthesize RNA molecules complementary to DNA templates.

RNA splicing
The process by which introns are removed and exons are ligated from precursors of RNA to form mature RNA.

RNA-seq
A method for measuring the transcriptome of cells or tissues in which cDNA is generated from the mRNA in the sample and then sequenced by next-generation sequencing techniques.

***S*-adenosylmethionine (SAM)**
An activated methyl donor that consists of an adenosyl group linked to the sulfur atom of methionine.

salvage pathways
A biosynthetic pathway that synthesizes the final product from preformed components.

scissile bond
The bond in a molecule that is cleaved by an enzymatic reaction.

SDS–polyacrylamide gel electrophoresis (SDS-PAGE)
A form of gel electrophoresis in which protein samples are first denatured in the presence of SDS, then run through a polyacrylamide gel and separated by size.

second messengers
An intracellular signaling molecule, such as a calcium ion or cyclic AMP, whose concentration changes in response to the arrival of a primary messenger.

secondary active transport
The coupling of the thermodynamically unfavorable flow of one species of ion or molecule up a concentration gradient to the favorable flow of a different species

down a concentration gradient

secondary structure
In proteins, the spatial arrangement of amino acid residues that are near one another in the linear sequence.

secondary transporter
A transporter that uses the energy of the downhill (exergonic) flow of one ion or molecule to power the uphill (endergonic) flow of another. Also called a **cotransporter**.

selectins
A carbohydrate-binding protein that constrains immune-system cells to the site of injury in an inflammatory response by mediating cell–cell interactions.

selectivity filter
A region of ion-channel proteins that determines the specificity of a particular channel.

self-splicing introns
Introns that are able to remove themselves from precursor RNA and assist in the splicing of exons to form mature RNA.

semiconservative replication
The type of replication observed in the duplication of DNA, in which one of the strands of each daughter molecule is newly synthesized, whereas the other is unchanged from the parental DNA double helix.

sequence alignment
A method in which two sequences are systematically aligned with respect to each other to identify regions of significant overlap.

sequence template
A map of conserved residues that are structurally and functionally important and characteristic of particular families of proteins.

sequential model
A model for hemoglobin oxygen-binding cooperativity where each hemoglobin subunit undergoes a structural change upon oxygen binding.

sequential reaction

A reaction having multiple reactants, in which all substrates bind to the enzyme before any product is released. Thus, in a reaction with two substrates, a ternary complex of the enzyme and both substrates forms.

seven-transmembrane-helix (7TM) receptors
A member of a large family of cell surface receptors with seven membrane-spanning α helices that signal through G proteins. See also **G-protein-coupled receptor (GPCR)**.

severe combined immunodeficiency (SCID)
An immunological disorder characterized by a loss of T cells and severe recurring infections, often leading to death at an early age.

Shine–Dalgarno sequence
In bacterial messenger RNA, a purine-rich region of about 10 nucleotides on the $5'$ side of an initiator codon that pairs with the $3'$ end of 16S RNA in the 30S ribosomal subunit; helps to determine where translation is initiated on an mRNA molecule.

sickle-cell anemia
A blood disease associated with distortion of red blood cells into a crescent shape when deprived of oxygen caused by a single amino acid substitution in one hemoglobin chain.

side chain (R group)
The distinctive variable group bonded to the α-carbon atom of an amino acid.

side effects
Unwanted effects caused by the administration of drugs in humans.

sigmoid
A descriptor for a curve with an "S" shape that indicates something other than a simple binding process.

signal peptidase
An enzyme that cleaves signal sequences in mature proteins on the lumenal side of the endoplasmic reticulum membrane.

signal sequence
A sequence of 9 to 12 hydrophobic amino acid residues that identifies the nascent peptide as one that must cross the endoplasmic reticulum membrane.

signal-recognition particle (SRP)
A ribonucleoprotein complex that recognizes and binds the signal sequence to the ribosome and then shepherds the ribosome and its nascent polypeptide chain to the endoplasmic reticulum membrane.

simple diffusion
The movement of molecules down a concentration gradient.

single guide RNA
The RNA component of the CRISPR-Cas system that directs the nuclease activity of Cas to particular genome sequences.

site-directed mutagenesis
A method for introducing mutations into a target sequence where a primer containing the desired change is used for DNA polymerization.

sliding DNA clamp
The dimeric β2 subunit of DNA polymerase III through which the DNA template slides. By clasping the DNA molecule, it allows the polymerase to move without falling off its substrate.

small nuclear ribonucleoproteins (snRNPs)
Complexes of small nuclear RNA and specific proteins that catalyze the splicing of mRNA precursors.

small nuclear RNAs (snRNAs)
A member of the class of small RNAs confined to the nucleus, some of which play a role in splicing.

small nucleolar ribonucleoproteins (snoRNPs)
A structure, consisting of one small nucleolar RNA and several proteins, that directs the extensive modification of the ribose and base components of nucleotides of pre-rRNA sequences destined for the ribosome.

small subunit (30S)
The small subunit of the bacterial 70S ribosome, containing 21 different proteins and a 16S RNA molecule.

solid-phase method
A method for synthesizing peptides and oligonucleotides in which monomer units are added to a growing chain tethered to a solid support.

Southern blotting
A technique that allows the identification of a specific DNA sequence using a ^{32}P-labeled probe complementary to the DNA sequence of interest.

special pair
In a photosynthetic reaction center, the pair of chlorophyll molecules that collect excitation energy from antenna chlorophyll molecules and then transfer high-energy electrons to other electron acceptors.

specific activity
The ratio of the enzyme activity to the amount of protein within a sample.

sphingolipids
A lipid having sphingosine rather than glycerol as its backbone. This is found in the plasma membranes of all eukaryotic cells and at highest concentrations in the cells of the central nervous system.

Sphingomyelin
Common in brain tissue, a sphingolipid in which the terminal hydroxyl group of ceramide has a phosphorylcholine substituent.

sphingosine
An amino alcohol containing a long, unsaturated hydrocarbon chain that is a component of the phospholipid sphingomyelin and of glycolipids. Sphingosine serves a role analogous to that of glycerol in phospholipids.

spliceosome
An assembly of proteins and small nuclear RNAs that splices, or joins together, primary transcripts to form mature mRNA.

Splicing
The removal of introns and the ligation of exons from precursors of RNA to form mature RNA.

split-pool synthesis
A combinatorial chemistry method where compounds on a solid support are split into individual pools for a reaction step, then pooled and re-split before the next synthetic step.

Squalene

A 30-carbon polyunsaturated hydrocarbon that is the precursor to cholesterol and steroid hormones.

SRP receptor (SR)
An integral membrane protein consisting of two subunits to which a complex consisting of a signal-recognition particle and a ribosome binds.

starch
A homopolysaccharide that is a storage form of glucose in plant chloroplasts. Amylopectin, the branched form of starch, has approximately one α-1,6 linkage per thirty α-1,4 linkages, whereas amylose is unbranched, composed of glucose residues in α-1,4 linkage.

stem-loop
A nucleic acid structure, commonly seen in RNA, created when two complementary sequences within a single strand come together to form a double-helical structure, which constitutes the stem. The two strands of the stem are linked by the loop.

Sterol regulatory element binding protein (SREBP)
A transcription factor that binds to the sterol regulatory element of the HMG-CoA reductase gene, stimulating the gene's transcription. It also stimulates transcription of other genes involved in cholesterol and fatty acid metabolism.

Stochastic
A process is said to be stochastic if the result is randomly determined from among possible outcomes.

stop codons
In most organisms, one of three nucleotide triplets in mRNA that designate the termination of transcription.

stroma
The matrix of the chloroplast; contains thylakoids as well as soluble enzymes and is enclosed by the inner membrane of the chloroplast.

structure-based drug design
A method of drug optimization in which structural information about the target and its interaction with compounds is used to design more potent and selective molecules.

structure–activity relationship (SAR)
The relationship between the structures of compounds and their activity against a particular drug target.

substitution matrix
A scoring system for the replacement of any amino acid with each of the other 19 amino acids.

substrate
A reactant in a chemical reaction. An enzyme catalyzes a single chemical reaction or a set of closely related reactions, and the components of those reactions are called substrates.

substrate channeling
The transfer of the product of one enzyme-catalyzed reaction directly to another enzyme for which the molecule is the substrate, without the release of the molecule to the bulk solvent.

substrate cycle
A pair of thermodynamically irreversible biochemical reactions that simultaneously produce and consume a pair of metabolic intermediates; these paired pathways may amplify metabolic signals and, in some cases, can generate heat for the maintenance of temperature in tissues. Also called a *futile cycle*.

substrate-level phosphorylation
The formation of ATP from ADP in which the phosphate donor is a substrate with a higher phosphoryl-transfer potential than that of ATP.

subunit
An individual polypeptide chain within a protein that contains multiple chains.

succinate-Q reductase
An integral-membrane-protein complex of the inner mitochondrial membrane that transfers electrons from $FADH_2$ formed in the citric acid cycle to coenzyme Q. Also called **Complex II**.

sucrose
A disaccharide of glucose and fructose (commonly known as table sugar) that is readily transportable and stored in many plant cells.

supercoiling

The ability of closed, circular DNA to coil upon itself.

surface complementarity
The property relating two surfaces such that when they meet, hydrogen-bond donors align with hydrogen-bond acceptors, and nonpolar surfaces come together to maximize van der Waals interactions and minimize nonpolar surface area exposed to water.

symporters
A secondary transporter that couples the downhill flow of one species to the uphill flow of another in the same direction across the membrane.

synaptic cleft
The gap between excitable membranes across which a nerve impulse is transmitted.

synthetic biology
An emerging discipline in which engineering principles are used to produce organisms or biochemically based devices that perform desired functions.

T state
The quaternary structure adopted by deoxyhemoglobin, where "T" refers to *tense*, due to structural constraints to stabilize this structure compared to the R (*relaxed*) state adopted by oxyhemoglobin.

t-SNARE
An integral membrane protein found in target membranes. Binding of v-SNAREs to t-SNARES leads to fusion of the vesicle and target membranes and the delivery of the cargo.

tandem mass spectrometry
A method of generating ion fragments within the mass spectrometer, enabling sequencing of peptides.

target
A protein or an oligonucleotide whose activity, when modulated by a drug, will alter the progression of a human disease process.

target validation
The process of accumulating evidence that a proposed drug target plays an important role in disease progression in humans.

target-based screening
A lead identification approach to early drug discovery in which the target is first selected, then screened for chemical starting points.

TATA box
A promoter element that is found in nearly all eukaryotic genes. The TATA box is centered between 30 and 90 residues upstream of the transcription start site and has the consensus sequence $5'-TATAAAA-3'$.

TATA-box-binding protein associated factor (TAF)
One of a group of proteins, many of which contain bromodomains, that bind to the TATA-box-binding protein.

telomerase
A reverse transcriptase that contains its own template; a highly processive enzyme that elongates the $3'$-ending strand of a telomere.

telomeres
Each end of a chromosome. The DNA at the telomere consists of hundreds of repeats of a hexanucleotide sequence characteristic of the organism.

template
In DNA or RNA, a sequence that directs the production of a complementary sequence.

template strand
In DNA or RNA, a sequence that directs the production of a complementary sequence.

tertiary structure
In proteins, the spatial arrangement of amino acid residues that are far from each other in the linear sequence, as well as the pattern of disulfide bonds.

Tetrahydrofolate
A highly versatile carrier of activated one-carbon units.

therapeutic index
A measure of the toxicity of a drug relative to its effective dose.

thylakoids

In chloroplasts, a membranous sac, or vesicle, that contains the energy-transducing machinery of photosynthesis, including light-harvesting proteins, reaction centers, electron-transport chains, and ATP synthase.

Thymidylate synthase
An enzyme that catalyzes the methylation of deoxyuridylate (dUMP) to form thymidylate (TMP).

time-of-flight (TOF) mass analyzer
A method for measuring ions within a mass spectrometer in which ions are passed through an elongated chamber of fixed electrostatic potential. The amount of time needed to traverse the chamber is proportional to the mass-to-charge ratio of the ion.

titration
An experiment in which known amounts of reagent are gradually added to a solution with which the reagent reacts while monitoring the results.

topoisomerases
An enzyme that catalyzes the interconversion of topoisomers of DNA, and that can relax supercoiled DNA.

topoisomers
Molecules of DNA that differ only in their linking number. Topoisomers of DNA can be interconverted only by cutting one or both DNA strands and then rejoining them.

torsion angle
A measure of the rotation about a bond, usually taken to lie between -180 and $+180$ degrees.

tractability (druggability)
The evidence that a molecule can be designed to interact with a drug target in a potent and specific manner.

transcription
DNA-directed synthesis of RNA catalyzed by RNA polymerase.

Transcription activator-like effector nucleases (TALENs)
An artificial restriction endonuclease whose DNA binding domain consists of amino acid repeats, called TALE repeats, that direct the nuclease to specific sites

in the target DNA.

transcription bubble
The site of RNA synthesis or transcription. This site contains RNA polymerase, a locally melted "bubble" of DNA, and hybrid helices consisting of the template strand and the newly synthesized RNA.

Transcription factors
A protein that assists RNA polymerase in the initiation of RNA synthesis. It binds to a specific promoter element.

transcriptome
The pattern and level of expression of all genes in a particular cell or tissue.

transduction
The transmission of information, often with the conversion of one form of information carrier into another.

Transfer RNA
The adaptor molecule in protein synthesis. tRNA contains an amino-acid-recognition site as well as a template-recognition site, or anticodon.

Transfer RNA (tRNA)
The adaptor molecule in protein synthesis; contains an amino-acid-recognition site as well as a template-recognition site, or anticodon.

transferrin
A transport protein that carries iron in the blood serum.

transferrin receptor
A membrane protein that binds iron-loaded transferrin and initiates its entry into cells.

transgenic mice
A mouse harboring a foreign gene that has been introduced into its genome.

transition state
A chemical species that has the highest free energy and the lowest concentration of those on the pathway from a substrate to a product.

transition-state analog

A compound resembling the transition state of a catalyzed reaction; such compounds are usually potent competitive inhibitors of enzyme-catalyzed reactions.

transketolase
An enzyme that transferase a ketone-containing group from one carbohydrate to another.

translation
The process of cellular protein synthesis, so named because the four-letter alphabet of nucleic acids is translated into the different amino acids that make up proteins.

translocon
A multisubunit assembly of integral and peripheral membrane proteins that binds to the ribosome, forming a channel to translocate a nascent protein across the endoplasmic reticulum.

transport vesicles
A small, membrane-enclosed cellular compartment that facilitates the transport of cargo proteins to specific destinations within the cell.

triacylglycerol
A glycerol that has fatty acyl chains esterified to each of its hydroxyl groups; a storage form of fats.

triacylglycerol
A glycerol that has fatty acyl chains esterified to each of its hydroxyl groups; the storage form of fatty acids called *fat* or *oil*, depending on melting point. Also called **neutral fat** or **triglyceride**.

trinucleotide repeats
Many repetitions of a trinucleotide sequence found in a stretch of DNA; these segments of DNA can expand in the course of DNA replication, causing such genetic diseases as Huntington's disease.

trombone model
A model for the stage of the DNA replication process when the lagging strand loops out to form a structure that acts somewhat as a trombone slide does, growing as the replication fork moves forward. When the polymerase on the lagging strand reaches a region that has been replicated, the sliding clamp is released and a new loop is formed.

Tumor-inducing plasmids (Ti plasmids)
A plasmid carried by the soil bacterium *Agrobacterium tumefaciens* that carries instructions to switch its plant host into a tumor growth state; because a small portion of the plasmid is integrated into the host genome, it is an ideal vector for the introduction of foreign DNA into plant species.

tumor-suppressor genes
A gene that, if present in even a single copy, can suppress the development of cancer.

turnover number
The number of substrate molecules converted into product by an enzyme active site in a unit time when the enzyme is fully saturated with substrate; equal to the kinetic constant k_2 (see K_M).

twist (Tw)
A measure of the helical winding of the DNA strands around each other.

two-dimensional electrophoresis
A means of obtaining high-resolution separations of proteins in a mixture, in which the protein mixture is first separated in one dimension by isoelectric focusing and then separated in a second dimension by SDS-PAGE.

Type 1 diabetes
The form of diabetes mellitus caused by inadequate production of insulin, usually due to the destruction of the β cells of the pancreas by an autoimmune disorder. Type 1 diabetes is treated by the regular administration of insulin.

type 2 diabetes
The form of diabetes mellitus caused by inadequate insulin sensitivity, usually due to a combination of genetics and behavioral factors, and most notably obesity. This is commonly preceded by metabolic syndrome.

Ubiquitin
A small protein, ubiquitously found in all cells that is used to mark proteins by covalent addition. Its primary role is to target proteins for degradation by the proteasome; however, numerous other biological functions have now been determined.

ultracentrifugation

The process of using centrifugation at very high velocities to determine the mass, density, shape, and interactions of proteins.

uncompetitive inhibition
Reversible enzyme inhibition distinguished by the fact that the inhibitor binds only to the enzyme–substrate complex and not to the free enzyme. Uncompetitive inhibitors decrease both the turnover number and the apparent value of K_M for an enzyme; their effects are not overcome by increased substrate concentration.

uncoupling protein (UCP-1)
A mitochondrial membrane protein that forms a pathway for the flow of protons into the matrix of the mitochondria, thereby generating heat without synthesizing ATP. Also called *thermogenin*.

unfolded protein response (UPR)
An adaptive cellular stress response involving several pathways and chaperone protein families, triggered by the accumulation of misfolded proteins in the ER lumen.

Uniporters
A secondary transporter that can transport a specific species in either direction governed only by concentrations of that species on either side of the membrane.

urea cycle
A cyclic pathway that converts excess ammonia into urea for secretion; the first metabolic pathway to be discovered.

uridine diphosphate glucose (UDP-glucose)
The activated form of glucose used in the synthesis of glycogen. It is formed from glucose 1-phosphate and UTP.

v-SNARE
An integral membrane protein found in transport vesicles. It binds to a particular t-SNARE.

van der Waals contact distance
The distance at which two molecules or groups have an optimal van der Waals interaction.

van der Waals interaction

A weak interaction due to fluctuating dipoles in one group inducing complementary dipoles on a nearby group with which it interacts favorably. At shorter distances, the van der Waals interaction becomes strongly unfavorable due to repulsive interactions between the electron clouds on the two groups.

vector
A small DNA molecule that can replicate autonomously in an appropriate organism.

virus
An entity that comprises a nucleic acid genome (DNA or RNA) surrounded by a protein coat that can infect specific cells and use the components of these cells to replicate itself.

vitamin B_{12}
A water-soluble vitamin used as a cofactor for two enzymes in human metabolism, among other functions. It is composed of a cobalt atom bound by a derivatized corrin-ring heterocycle. Also called **cobalamin.**

vitamins
An organic molecule that must be consumed in small quantities by a particular organism to allow a number of essential biochemical reactions to proceed.

V_{max} (maximal rate)
The theoretical maximum velocity of an enzyme catalyzed reaction at infinite substrate concentration. The asymptote line defining the upper limit of the hyperbolic relationship of V_0 as a function of substrate concentration, i.e., the Michaelis–Menten equation.

voltage-gated channels
An ion channel whose opening is controlled by changes in the voltage across the membrane.

water-oxidizing complex (WOC)
The site of oxygen generation in photosynthesis in green plants. The complex, which includes four manganese ions, donates electrons to positively charged P680, and then oxidizes two molecules of water to replenish its electrons; it thus forms a single molecule of molecular oxygen and four protons. Also called the **manganese center**.

western blotting
A means of detecting small quantities of a protein of interest in a cell or bodily fluid using a labeled antibody specific for the protein of interest. Also called immunoblotting.

wobble hypothesis
Refers to steric freedom in the pairing of the third base of an mRNA codon with the anticodon of a tRNA molecule, which allows more than one codon to be recognized by a particular tRNA.

writhe (Wr)
A measure of the coiling of the axis of the double helix; in other words, the degree of supercoiling.

x-ray crystallography
A method for determining molecular structure in which the sample (such as a protein) is crystallized. The diffraction of an x-ray beam through the crystal can be recorded and calculated into an electron density map, indicating the atomic positions within the crystal.

xenobiotics
Foreign compounds, including drugs, introduced into a living organism.

Z scheme of photosynthesis
The pathway of electron flow between photosystem I and photosystem II; so called because the redox diagram from P680 to P700 looks like the letter Z.

Zinc-finger nucleases (ZFNs)
An artificial restriction endonuclease formed by fusing the nuclease domain of a restriction enzyme with a specific DNA-binding domain consisting of zinc-fingers.

zymogen (proenzyme)
A catalytically inactive precursor of an enzyme.

α-ketoglutarate dehydrogenase complex
A regulatory citric acid cycle enzyme that catalyzes the oxidative decarboxylation of α-ketoglutarate to yield succinyl CoA. It is structurally and mechanistically similar to the pyruvate dehydrogenase complex.

β-galactosidase

An essential enzyme in lactose metabolism that hydrolyzes lactose into galactose and glucose.

β-oxidation pathway
The primary metabolic pathway for the oxidation and degradation of fatty acids. It is a sequence of oxidation, hydration, and oxidation reactions that converts a methylene group at the C-3 carbon atom of a fatty acyl CoA molecule into a β-keto group, with subsequent cleavage yielding acetyl CoA.

λ repressor
A protein in bacteriophage λ that blocks the transcription of all viral genes.

σ subunit
A component of bacterial RNA polymerase that enables the core RNA polymerase to recognize promoter sites.

Adenylated intermediates, 770–771
Adenylation
    in amino acid activation, 921–922
    in amino acid synthesis, 782–783, 782f
    in translation, 921–922
Adenylosuccinate synthetase, 800
Adenylyl transferase, 782, 782f
Adipocytes, 666, 666f, 737
Adipokines, 736, 737f
Adiponectin, 736–737, 737f
Adipose cells (fat cells), 666
Adipose tissue
    brown, 575, 576f
    fat in, 748
    glycerol released from, 753
    leptin secretion, 736–737
    triacylglycerols in, 753
    white, 575
Adipose triglyceride lipase (ATGL), 669, 669f
Adler, Julius, 580
ADME properties of drugs, 988–989, 988f

ADP (adenosine diphosphate)
ATP hydrolyzed to, 450–451
formation of, 200
in oxidative phosphorylation, 572–573, 572f, 575f
in random sequential reaction, 160
structure of, **200**, **219**, **450f**
Adrenaline, 221, 412, 414, **414**, 650. *See also* Epinephrine
Adrenergic receptors, 415
Adrenocorticotropic hormone, 63
Advanced glycation end product (AGE), 331, 480, 510
Aequorea victoria, 63, 117
Aerobic exercise, 747
Aerobic glycolysis, 497–498, 531
Affinity chromatography, 104–105, 104f, 110
Affinity labels, 170, 170f
Affinity tags, 112, 170f
Aflatoxin activation, 865, 865f
Aggrecan, 340–341
Agonists, 415, 416f
Agouti-related peptide (AgRP), 736, 736f
Agre, Peter, 1, 27–28, 407
Agrobacterium tumefaciens, 295–296, 295f
Akt. *See* Protein kinase B (PKB)
Alanine
defined, 36
formation of, 769–770
in gluconeogenesis, 509
in muscle contraction, 509
pyruvate formation from, 719, 719f
site-directed mutagenesis and, 187–188, 187f
structure of, **37f**, 38
from tryptophan, 724f
tryptophan in, 719
Alanine aminotransferase, 708

Albinism, 727t
Albumin, **989f**
Alcaptonuria, 726
Alcohol dehydrogenase, 755
Alcoholic fermentation, 472, 486–487
Alcoholic hepatitis, 756
Alcoholic scurvy, 756–757, 757f
Alcohols
    fermentation of, 472, 486–487
    formation from pyruvate, 486–487
    metabolism of, 755–759
    monosaccharides and, 331–332
    phospholipids, synthesis of, 817–818
    toxicity of, 756–757
Aldehyde dehydrogenase, 755
Aldehydes, oxidation of energy, 480–481
Alder, Julius, 580
Aldimine, 710, **710**
Aldol cleavages, 711
Aldolase, 478
    in Calvin–Benson cycle, 616
    in transaldolase reaction, 629–630
Aldoses
    conversion to ketoses, 477
    defined, 325
    structure of, **615**
Aldosterone, 834, 837, **837f**
Alkali cations, properties of, 396t
Alkali digestion, 278
Alkylating agents, 865
Allergenics, 995t
Allolactose, 954, 956
Allopurinol, 810, **810**
Allosteric coefficient (L), 215
Allosteric control, 210–217

Allosteric effector, 81
Allosteric enzymes, 161f
concerted model, 215
control of, 468
defined, 161
homotropic effects on, 215
sequential model, 215
sigmoidal kinetics, 212, 212f
substrate concentration and, 215
threshold effects, 215f, 216
T-to-R equilibrium in, 216–217, 216f, 217f
T-to-R state transition, 215, 216f
Allosteric sites, 211
Alloxanthine, 810
All-*trans*-retinal, 439f
All-*trans*-retinoic acid, **963**
α_1-antiproteinase, 227, 228f
AlphaFold, 61, 62f
α carbon, 35
α chains, 75
α helix, 46–48
formation of, 57–59
hydrogen-bonding scheme, 47f
of membrane proteins, 368–369, 368f, 368t
pitch of, 47
as right-handed, 47, 47f
schematic view of, 48f
screw sense, 47
structure of, **47f**, 58f
α-1,4-glycosidic linkage, 333
α-1,6 linkages, 655, 655f
α-amino acids, 35, 41
α-glucosidase, 473–474
α-glucosidase inhibitors, 334

α-helical coiled coil, 53
α-hemoglobin
    alignment with gap insertion, 304f
    amino acid sequences, 303–305, 303f
α-keratin, 53
α-sarcin, 944
αβ dimers, 75
α-synuclein, 817
Alternative splicing
    defects in, 907t
    defined, 906
    example of, 907f
    pre-mRNA, 906–907
Altman, Sidney, 899
Alu sequences, 284
Alzheimer's disease, 62–63, 63f
Amanita phalloides, 894f
α-amanitin, 894, **894f**
American College of Sports Medicine, 751
American Medical Association, 751
Ames, Bruce, 871
Ames test, 871, 871f
Amide bonds. *See* Peptide bonds
Amines, monosaccharides and, 331–332
Amino acid degradation, 701–728
    acetoacetyl CoA in, 718
    acetyl CoA in, 718, 722–723
    amino acid use through, 701
    aminotransferases in, 708–711
    of aromatic amino acids, 723–724
    of branched-chain amino acids, 708–713, 722–723
    carbon atoms of as metabolic intermediates, 718–726
    digestive enzymes in, 702
    fumarate in, 718, 719f

glucose-alanine cycle in, 713, 713f
glutamate dehydrogenase in, 708–709
a-ketobutyrate in, 720
α-ketoglutarate in, 718, 719, 719f, 720, 720f
liver in, 708–709, 712–713
metabolic products of, 725b–726b
metabolism errors and, 723–728, 727t
overview of, 702–703
oxaloacetate in, 718, 719–720, 719f
oxygenases in, 723–724
propionyl CoA in, 722–723
proteasomes in, 705–707, 706f, 707f
in protein turnover, 703–705
pyridoxal phosphate (PLP) in, 709–710, 711–712
pyruvate in, 712–713, 718, 719, 719f
regulation function of, 707, 707t
Schiff-base intermediates in, 709–711, 711f
serine dehydratase in, 712
starvation and, 754, 754f
succinyl CoA in, 718, 719f, 721, 721f
threonine dehydratase in, 712
transaminases in, 708–713
ubiquitin in, 703–705, 704f
ubiquitination in, 703–705
urea cycle in, 713–718
Amino acid sequences, 33–34
alignment of, 302–309, 303f, 304f
collagen, 53–54, 54f
comparison of, 123–124
determination of, 100
directionality of, 42, 42f
in DNA probe creation, 124
DNA sequences and, 123f
evolution of, 44
evolutionary pathways and, 123

gap insertion, 303, 304f
of hemoglobin, 303–305, 303f
homologous, 308–309
identities, 303
importance of, 43–44
information provided by, 123–124
of insulin, 43, 43f
of myoglobin, 303–305, 303f
porin, 364–365, 364f, 365f
probes generated from, 277, 277f
in protein identification, 123–124
in protein structure determination, 55–64
protein structures and, 43, 43f
recombinant DNA technology and, 123
ribonuclease, 56–57, 56f, 57f
searching for internal repeats, 124, 124f
shuffled, 305, 305f
as signals, 124
statistical comparison of alignment, 305, 305f
substitution in, 305–308, 306f, 307f, 309f
transmembrane helices from, 367–369, 368f
Amino acid side chains
aliphatic, 36
aromatic, 37
charge of, 39–40, 39f, 41f
covalent modifications, 63f
defined, 35
distribution of, 51
hydrocarbon, 36
hydrophilic, 38
hydrophobic, 38
hydroxyl-containing, 38, 38f
ionizable, 40, 40t
sulfhydryl-containing, 39
thiol-containing, 39

types of, 36–40
Amino acid synthesis, 763–788
S-adenosylmethionine in, 774–775
adenylation in, 782–783, 782f
ammonia in, 764–767
aromatic amino acids, 776–779
branched pathways in, 780–782
chorismate in, 776–779, 777f
enzyme multiplicity in, 781
essential amino acids, 768–769, 769f
feedback inhibition/activation in, 780–783, 780f
glutamine synthetase in, 782–783, 782f
human, 768–769
α-ketoglutarate in, 766–767, 769
nitrogen fixation in, 764–767, 764f
nonessential amino acids, 768, 768f
overview of, 763
regulation of, 780–783
regulatory domains in, 780–782, 781f
Schiff bases in, 766, 767f
shikimate in, 776–779
tetrahydrofolate in, 772–774, 773f
threonine deaminase in, 780–781, 780f, 781f
by transamination, 767, 769–770, 769f, 770f
Amino acids. *See also* Proteins
abbreviations for, 40, 41t
activation by adenylation, 921–922
activation sites, 922–923, 923f
aromatic, 38, 723–724, 776–779
basic set of, 768t
biosynthetic families of, 768f
branched-chain, 708–713, 722–723
as building block, 25
carbon skeletons, fates of, 719f

chirality of, 35, 769f, 770
conservation across species, 40–41
D isomer, 35, 35f
defined, 25, 35
dipolar form of, 35
essential, 702, 702t, 768–769, 768f, 768t
glucogenic, 718, 719f
in gluconeogenesis, 499
hydrophilic, 38, 52
hydrophobic, 36–38, 37f, 51f, 52f
hydroxyl groups of, 38–39, 63
“inside out” distribution of, 52f
ionization state of, 36, 36f
ketogenic, 718, 719f
L isomer, 35, 35f
metabolism, 726–728, 727t
negatively charged, 39–40, 39f
nitrogen in, 764
nonessential, 768, 768f, 768t
nonproteinogenic, 126
peptide bonds, 42, 42f
polar, 38–39, 38f
positively charged, 39, 39f
as precursors, 783–788
as precursors for neurotransmitters, 785
protein folding and, 25, 25f
proteinogenic, 126
pyruvate formation from, 719, 719f
reactive, 38, 41, 41f
residue, 42, 51
in secondary structures, 58t
undesirable reactivity in, 41f
unnatural, 938–939, 938f
Amino sugar, 332
Amino-acid signal sequences, 940–941, 940f

Aminoacrylate, Schiff bases of, 779, **779**
Aminoacyl adenylate, **922**
Aminoacyl-AMP, 922
Aminoacyl-tRNA
    defined, 921
    editing of, 923–924, 923f
    elongation factors and, 931–932, 931f
Aminoacyl-tRNA synthetases
    accuracy of, 931
    activation sites of, 922–923, 923f
    amino acid activation sites, 922–923
    binding to acceptor stem and anticodon loop, 925, 925f
    classes of, 926, 926f, 926t
    defined, 921
    editing sites, 923–924, 923f
    evolution of, 926
    genetic code and, 921–926
    proofreading by, 923–925, 924f
    subunit structure, 926, 926t
2-aminoadenine, 801, 801f, **801**
Aminoglycoside antibiotics, 942
δ-aminolevulinate, 786–787, 787f
δ-aminolevulinate synthase, 786–787
Aminopeptidase N, 702
Aminopterin, 806f, 807
Aminotransferases
    in amino acid degradation, 708–711
    blood levels of, 711
    defined, 708
    Schiff-base intermediates formation in, 709–711
Ammonia
    in amino acid degradation, 708–709
    in amino acid synthesis, 764–767
    conversion to urea, 713–718
    formation of, 708–709

in glutamate synthesis, 766–767
in glutamine synthesis, 766–767
in purine synthesis, 800
in pyrimidine synthesis, 793
Ammoniotelic organisms, 718
AMP (adenosine monophosphate)
ATP hydrolyzed to, 450–451
energy charge and, 505–506
phosphofructokinase (PFK), regulation of, 493–494
in purine synthesis, 799–800, 799f
structure of, **450f**
synthesis of, 807–808, 808f
AMP-activated protein kinase (AMPK), 695, 696, 737, 737f, 745
Amphibolic pathways, 448
Amphipathic (amphiphilic) molecules, 358
Amphitropic enzyme, 818
AMP-PNP, 850–851, **850**, **851f**
α-amylase, 335, 473
Amylin, 735t
Amyloid fibrils, 62–63, 62f, 63f
Amyloid plaques, 62, 63f
Amylopectin, 335
Amylose, 335
Amyotrophic lateral sclerosis (ALS), 271, 290
Amytal, 577, 577f
Anabolic reactions, 451–452
Anabolism, 448
Anaerobic exercise, 747
Anaerobic glycolysis, 531
Analytes, 118
Anaplerotic reaction, 535
Anastrozole, 838, **839f**
Anchor residues, 90
Ancient DNA, 318–319
Anderson disease, 661t

Androgens
functions of, 834
pathways for formation of, 838f
synthesis of, 837–838, 838f
Androstenedione, 838, **838f**
Anemia, 21, 83–84, 339
Anfinsen, Christian, 56–57
Angelman syndrome, 705
Angiogenin, 302, **302f**
Animals
fatty acid synthesis in, 687–689
fatty acids and, 683
as models in drug target testing, 993
vision in, 442
Anion exchange, 104
Anomeric carbon atom, 328
Anomers, 326f, 328
Anoxygenic photosynthesis, 586
Antagonists, 424
Anthranilate branch, 778–779
Anthrax, 857
Antibiotics
aminoglycoside, 942
protein synthesis inhibition by, 942–944, 943f, 943t, 944f
resistance to, 998
translocation inhibition by, 943–944, 944f
Antibodies. *See also* Immunoglobulins
in adaptive immune system, 89
amino acid sequence data in making, 124
antibody binding of, 88–89
antigen binding of, 88–89
antigen interaction, 113f
defined, 69, 86
diversity of, 89
generation of, 112–113

monoclonal, 113–114, 113f, 114f, 434, 434f, 995–996, 995t
polyclonal, 113, 113f
primary, 116
secondary, 116
structures of, 87–88
Antibody-drug conjugate (ADC), 996
Antibody-protein interactions, 87–88
Anticancer drugs
in blocking thymidylate synthesis, 805–807, 806f
resistance to, 998–999
targets, 806f
Anticipation, 869
Anticoagulants, 231, 231f
Anticodon loop, 919, 925, 925f
Anticodons
base/base pair, 920–921, 921f
defined, 918
in translation, 919–921, 921f
Antidiuretic hormone, 126, 127f
Antigenic determinants, 113
Antigens
ABO blood group, 343–344, 343f, 344f
antibody interaction, 113, 113f
defined, 86, 112–113
synthetic peptides as, 126
Antimycin A, 577, 577f
Antiporters, 390, 390f
Antisense (-) strand, 884, 884f
Antiserum, 113
Antithrombin III, 232
AP endonuclease, 867
Apoenzyme, 144
Apolipoprotein A-IV, 735t
Apolipoprotein B (apo B), 909, 909f
Apolipoproteins, 827

Apoproteins, 827
Apoptosis, 224, 579
Apoptosome, 579
Apoptotic peptidase-activating factor 1 (APAF-1), 579
Approximation, catalysis by, 180
Aptamers, 320–321
Apyrase, 285
Aquaporins, 407, 408f
Arabidopsis thaliana, 2f, 283
Arachidonate, 693, 693f
Arachidonic acid, 366, 366f
Archaea
    defined, 3, 3f
    membranes of, 358, 358f, 373
    proteasomes of, 707
Archaeal lipid, 359f
Arcuate nucleus, 735
Arginase, 716
Arginine
    argininosuccinase and, 715, 716
    degradation of, 720, 720f
    nitric oxide from, 784–785, 784f
    structure of, 39, **39f**, **40t**
    supplementation of, 717
    synthesis of, 771
Argininosuccinase, 715, 716
Argininosuccinase deficiency, 717, 717f
Argininosuccinate, 715, **715**, 717
Argininosuccinate synthetase, 715
Argonaute complex, 971–972, 971f
Aromatase, 838
Aromatase inhibitors, 838
Aromatic amino acids
    degradation of, 723–724
    side chains, 38

synthesis of, 776–779
Arrestin, 420
Arsenate, 459
Arsenite poisoning, 535–536, 536f
Arthropods, polysaccharides of, 336–337, 337f
Artificial intelligence, 61
Artificial photosynthetic systems, 606–607, 607f, 620, 620f
Ascorbic acid (vitamin C)
deficiency, alcohol related, 756–757, 757f
forms of, 757, 757f
function of, 464t
Asparaginase, 719
Asparagine
conversion into oxaloacetate, 719–720
structure of, **38f**, 39
synthesis of, 770
Aspartate, **160**
conversion into oxaloacetate, 719–720
deamination of, 535
formation of, 769–770
phosphorylation of, 781
structure of, 39, **39f**, **160**
synthesis of, 771
Aspartate aminotransferase, 708, 711, 711f
Aspartate transcarbamoylase. *See* ATCase
Aspartic acid, 39, **40t**
Aspartokinases, 781, 781f
Aspartyl proteases, 188, 188f, **188f**
Aspergillus terreus, 981
Aspirin, 141
discovery and development of, 980–981
effect on prostaglandin H2 synthase-1, 366, 366f
as prostaglandin inhibitor, 694, 981
Assays

"on-bead," 983f
coupled, 982, 982f
defined, 101
enzyme-linked immunosorbent (ELISA), 114–115, 115f
in protein purification, 101
secondary, 982
sensitivity of, 982
ATCase (aspartate transcarbamoylase)
active site of, 213–214, **213f**, **214f**
allosteric interactions in, 212–216
catalytic subunit, 212, 212f, 213f
concerted model, 215
cooperativity, 215
defined, 211
feedback inhibition, 211
impact of CTP vs. ATP, 217f
inhibition by CTP, 807
reaction, 211, 211f
regulatory subunit, 212, 212f
separable subunits, 212
sigmoidal curve, 215, 215f
sigmoidal kinetics, 212, 212f, 215, 215f
structure of, 212–216, **213f**, **214f**
tense and relaxed states, 214f, 215
T-to-R transition, 214f, 215
Atheroma, 981
Atherosclerosis, 679, 827, 830–831, 832
ATP (adenosine triphosphate)
as activated carrier, 460
binding of, 320–321, 320f, 321f
in Calvin–Benson cycle, 618
catabolism generation, 456
in catabolism stages, 458–459, 459f
as cellular energy currency, 221
in citric acid cycle, 517, 526–531, 533, 534–535

defined, 448, 449–450
effect on ATCase kinetics, 216f, 217, 217f
electrostatic repulsion, 453
as energy source, 792
as energy-coupling agent, 452
as energy-rich molecule, 450
entropy increase in, 453
enzymes and, 145
in exercise, 454–455, 455f, 498–499, 747–749, 747t
export, inhibition of, 578
formation of, 448, 601, 601f, 602
free energy and, 449–456
generation by NADH, 461
glucose oxidation and, 573–574
hydration stabilization in, 453
hydrolysis of, 179
as immediate donor of free energy, 456
in insulin release, 744, 745f
ion gradients in, 458–459, 458f
membrane proteins and, 384–390
in mitochondria, 570–571, 572f
in muscle, 747, 749
in muscle contraction, 493, 747–749
in nitrogen fixation, 764–769
in oxidative phosphorylation, 573–574, 574t, 575f
phosphoryl-transfer potential, 453–455, 454f
in random sequential reaction, 160
resonance structures, 453, 453f
structure of, **200**, **219**, 450–451, **450f**
synthesis, 456, 543–545, 543f
ATP formation
1,3-bisphosphoglycerate (1,3-BPG) and, 482–484
citric acid cycle and, 529–531
by cyclic photophosphorylation, 601, 601f, 602
enzyme-bound, 565

fermentation in, 486
from glucose to pyruvate conversion, 484–485
from glycolysis, 485–486
from phosphoryl transfer, 482–484
proton-motive force and, 565–567, 565f
pyruvate in, 485–486
ATP hydrolysis
ABC transporters and, 388
ATP as base to promote, 202, 202f
in DNA replication, 850–851, 850f
in DNA supercoiling, 855–857, 856f
in driving metabolism, 451–452
enzyme use of, 201
as exergonic, 450–451
free energy from, 449–456
γ subunit in, 567
hydrolysis, 201
magnesium ions in, 201–202
myosin and, 200–207
myosin conformational changes, 202f, 203
reversible, within myosin active site, 204, 204f
rotational motion, 567
in transcription, 905
transition state formation for, 202–203
ATP synthase
α subunit of, 564
a subunit of, 564, 567–569, 567f
ATP synthesis and, 565–566, 565f
ATP-driven rotation in, 566, 567f
b subunit of, 564
β subunit of, 564, 566, 567, 600
bind-change mechanism for, 565–567, 566f
c ring of, 567–569, 568f
c subunit of, 566, 567–569

of chloroplasts, 600–601
cristae and, 565f
defined, 562, 563
δ subunit of, 564
dimer of, 564f
discovery, 563
efficiency of, 570f
F_0 subunit of, 564
F_1 subunit of, 564
G proteins and, 569
γ subunit of, 564, 566, 569
γε stalk, 564, 566
inhibition of, 577
in mitochondria, 564f, 570–571
nucleotide-binding sites, 566, 566f
proton flow through, 563, 565–567
proton motion across membrane in, 568f
proton path through membrane in, 568f
proton-conducting unit, 564, 567f
regulation of, 575
rotational catalysis in, 567, 567f
structure of, 564, 564f
ATP synthasome, 572
ATP synthesis
ATP synthase and, 565–566, 565f
in chloroplasts, 599–602
efficiency of, 567
as endergonic process, 562–563
mechanism, 564–567, 565f
oxidative phosphorylation uncoupling from, 575–576, 576f
proton flow around c ring in, 567–569
proton gradient across thylakoid membrane, 599–602
proton gradients in, 562–569
proton motion across membrane in, 567–569

proton path through membrane in, 567–569
uncoupling electron transport from, 577–578
ATP yield, 573–574, 574t
ATP–ADP cycle, 451, 456f
ATP-ADP translocase, 572–573, 572f, 573f, 578
ATPases, 201

Catabolism
    ATP generation by, 456
    defined, 448
    energy from, 456–459
    free energy of, 456–459, 459f
    roles of, 456
    stages of, 459, 459f
Catabolite activator protein (CAP), 955–956, 955f, 956f
Catabolite repression, 955
Catalase, 561
Catalysis
    by approximation, 180
    by ATCase, 211
    Circe effect in, 159
    covalent, 180, 181, 181f, 183f
    efficiency of, 158–159
    enzyme–substrate binding in, 151
    enzyme–substrate complex formation in, 149, 149f
    general acid–base, 180
    maximal rate, 154–155, 156
    metal ion, 180
    specificity constant, 158
    transition state formation and, 148
    velocity of, 158
    zinc activation of water molecule, 191–192, 192f
Catalysts, 142, 181
Catalytic RNA, 909–912
Catalytic strategies, 180

of carbonic anhydrases, 179, 190–194
in chymotrypsin, 181–182, 181f, 182f
of myosins, 179, 200–207
overview of, 179
of restriction endonucleases, 179, 194–200
of serine proteases, 179, 183–185
Catalytic triads
defined, 183
in elastase, 186–187
in hydrolytic enzymes, 184f, 186–187, 186f
serine in, 183–185, 183f
site-directed mutagenesis and, 187–188, 187f
of subtilisin, 186–187, 187f
in trypsin, 186–187, 186f
Cataracts, 491, 491f
Catecholamines, 785, 785f
Cation exchange, 104
cDNA library, 279
CDP-ethanolamine, 818, **818**
Cech, Carol, 912b
Cech, Thomas, 912b
Cell cycle, 862
Cell-mediated immunity, 89
Cells, 2, 114
Cell-to-cell channels, 406–407, 406f, 407f
Cellular immune response, 86
Cellular respiration
citric acid cycle in, 516–517, 517f
defined, 543
enzymes in, 144
in oxidative phosphorylation, 543–545
vs. photosynthesis, 587
regulation of, 573–579
Cellulose, 335–336, **336f**
Centrifugation

differential, 102, 102f
ultracentrifugation, 111
Cephalopods, 337
Ceramide
insulin resistance and, 743–744, 744f
as precursor, 820f
synthesis of, 819, 819f
Cerebroside, 357, **357**, 819, **820f**
CETCH cycle, 619–620
Cetuximab (Erbitux), 434, 434f, 996
cGMP, 980, **980f**
cGMP phosphodiesterase, 439, 439f
Chain, Ernest, 979
Chair form, 329–330, 329f
Changeux, Jean-Pierre, 78
Channelrhodopsin, 607, 607f
Channels, 382
Chaperones, 57
Charged tRNA, 921
Charpentier, Emmanuelle, 294b
Checkpoints, 862
Chemical modification reaction, 182
Chemical shifts, 133
Chemical space, 984
Chemiosmotic hypothesis, 562–563, 563f
Chemotroph, 447, 586
Cheng, Yung-Chi, 987
Cheng–Prusoff equation, 987
Chirality
of amino acids, 35, 769f, 770
establishment of, 767f
Chitin, 336–337, 337f
Chitosan, 337
Chlamydomonas, 911
Chloramphenicol, 942, 943t

Chlorobium thiosulfatophilum, 606
Chlorophyll *a*, 589–590, 602, 603f
absorbance spectrum, 590f
structure of, **589f**
Chlorophyll *b*, 602–603, **602**, 603f
Chlorophylls, 786
defined, 589
in photosynthesis, 589–593
light absorption by, 590, 590f
phytol, 589
structure of, 589
Chloroplasts
ATP synthase, 600–601
ATP synthesis in, 599–602
defined, 588
electron micrograph of, 588f
evolution of, 589
genome of, 589
in photosynthesis, 588–589, 588f
reaction center, 590–591, 591f
redox conditions, 601
structure of, 588, 588f
Cholecystokinin (CCK), 735, 735f, 735t
Cholera toxin, 344, 344f
Cholesterol
"bad," 832
carbon numbering, 834, 834f
defined, 355, 821
discovery of, 981
excess, effects of, 830, 830f
fatty acid chains and, 371–372, 372f
formation of, 825f
"good," 832
from lanosterol, **825f**

levels, clinical management of, 832–833
lipid rafts, 372–373, 372f
as membrane fluidity regulator, 371–372
in membrane lipid, 357–358, 821–823
as precursor, 833–841, 833f
as precursor for steroid hormones, 827, 834, 834f
as precursor for vitamin D, 839–840
structure of, 357–358, **357**
transport of, 827–829
Cholesterol homeostasis, 827
Cholesterol synthesis, 821–825, 822f
blocking of, 833, 981
condensation mechanism of, 823, 823f
defined, 822
isopentenyl pyrophosphate in, 822–823, 823f
liver in, 825, 828f
low-density (LDLs) in, 829–830
metabolism, 829–830
mevalonate in, 822, 822f, 823f, 827
as precursor for steroid hormones, 834, 834f
rate of, 825–827
regulation of, 825–833
site of, 827, 828f, 829
squalene in, 823, 824–825, 824f, 825f
stages of, 822–825
sterol regulatory element binding protein (SREBP) in, 825–827, 826f
Choline, 818
Chorismate in amino acid synthesis, 776–779, 777f
Chromatin, 961–967
defined, 893
in gene expression, 893, 961–967
higher-order, structure of, 958
histone tails and, 965–966, 965f
remodeling of, 961–967, 966f

structure of, **893f**
Chromatin-remodeling complexes, 966
Chromatography
affinity, 104–105, 104f, 110
gel-filtration, 103, 103f, 110
high-performance liquid (HPLC), 105, 105f
ion-exchange, 103–104, 104f
Chromogenic substrate, 182, 182f
Chromosomes
accessory, 272, 274
bacterial, 864, 864f
eukaryotic, 861, 861f, 863
in human genome, 283, 283f, 286f
yeast, 958
Chronic myelogenous leukemia (CML), 435, 435f
Chylomicron remnants, 828
Chylomicrons, 667–668, 668f, 828, 828t
Chymotrypsin
active site, 183f
catalysis kinetics, 182, 182f
catalytic mechanism, 181–182, 181f
catalytic triad in, 183–185
conformations of, 225, 225f
covalent catalysis in, 181, 181f, 183f
diisopropylphosphofluoridate (DIPF) and, 181–182, 182f
elastase and, 186, 186f
mammalian, 313
natural substrate for, 170, **170f**
oxyanion hole, 185, 185f
peptide hydrolysis by, 183, 184f
S_1 pockets of, 186f
serine residue, 181–182, 182f
specificity of, 181f
specificity pocket of, 185, 185f

structure of, 183–185, **313f**
substrate preferences of, 158–159, 158t
trypsin and, 186, 186f
Chymotrypsinogen
conformations of, 225, 225f
defined, 224
proteolytic activation of, 224f, 225–226
Ciproflaxin, 857, **857**
Circe effects, 159
Cirrhosis, 756
Cis configuration, peptide bonds, 44, 44f, 45f
Cis-acting elements, 896
Cisplatin, **871**
cis-Polyisoprene, **840f**
Citrate
in fatty acid metabolism, 690, 695f
in glyoxylate cycle, 537, 537f
isomerization of, 524–525, 525f
in isomerization reactions, 467
vs. phosphate, 459
phosphofructokinase inhibition by, 495
in polymerization, 695
synthesis of, 533
transport to cytoplasm, 533
Citrate synthase
in citric acid cycle, 522–523, 523f
conformational changes on binding, 523, 523f
defined, 523
mechanism of, 523–524, 524f
Citric acid cycle
acetyl CoA in, 502, 516, 518–520, 522–524, 524f, 535
aconitase in, 524–525, 525f
ADP in, 503
ATP in, 517, 526–531, 533, 534–535
biosynthetic roles of, 534–536, 534f

carbon oxidation in, 522–531
in cellular respiration, 516–517, 517f
citrate isomerization in, 524–525, 525f
citrate synthase in, 522–523, 523f
citryl CoA in, 522–524, 524f
components of, 530t
control sites of, 533, 533f
decarboxylation in, 518–519, 519f
defined, 516
entry to, 531–533
evolution of, 536
in exercise, 532
glycolysis and, 517–521, 518f
high-energy electron harvesting in, 516
illustrated, 529f
intermediates in, 534
isocitrate dehydrogenase in, 525, 533, 533f
isocitrate in, 524–525
α-ketoglutarate dehydrogenase complex in, 526, 533, 533f
α-ketoglutarate in, 525
ketone bodies in, 753–754, 754f
lipoamide in, 520–521, 522f
in mitochondria, 516, 516f
overview of, 459, 516–517, 517f
oxaloacetate in, 517, 522–523, 523f, 528–529, 534
oxidation by, 488
pathway integration, 535
pattern of, 517, 517f
phosphorylation in, 531–532, 532f
in photosynthesis. *See* dark reactions
pyruvate dehydrogenase complex in, 516, 517–521, 518f, 520f, 522f, 531–533, 531f, 532f
pyruvate dehydrogenase in, 531–533
pyruvate dehydrogenase phosphatase (PDP) in, 531

rate of the cycle, 533, 533f
reactions of, 528
regulation of, 531–532, 533, 533f
replenishment, 534–535
substrate channeling in, 530
succinate dehydrogenase in, 528–529
succinyl CoA in, 526–527, 527f
succinyl CoA synthetase in, 527
thiamine pyrophosphate (TPP) in, 518–519, 519f
Citrulline, 715–716, **715**
Citrullinemia, 727t
Citryl CoA (citryl coenzyme A), 522–524, 524f
Clamp loaders, 857–858, 859f
Clapham, David, 425b

NADH generation, 487, 487f
oxidation of, 457–458, 482
in pentose phosphate pathway, 626, **627**, **628**
structure of, **457**

Glycerol
generation by lipolysis, 670, 670f
in gluconeogenesis, 499
in liver, 669–670
in phosphoglycerides, 356
release of, 740
structure of, **2**
Glycerol 3-phosphate, 739
in lipid synthesis, 815
reoxidation of, 571
Glycerol 3-phosphate shuttle, 570–571, 570f
Glycerol phosphate acyltransferase, 815
Glycine, 719, 719f
in Calvin–Benson cycle, 614f, 615
collagen chain and, 54, 54f
conversion into serine, 719, 719f
defined, 36
in liposomes, 360, 360f
porphyrins from, 786–787
pyruvate formation from, 719, 719f
structure of, **37f**
synthesis of, 772
Glycine cleavage enzyme, 774
Glycine synthase, 774
Glycine-glycine-glutamine (GGQ) sequence, 936
Glycobiology, 347b
Glycocholate, 667f, **833f**
Glycoforms, 338
Glycogen
branch point in, 335f
defined, 335, 640
glucose storage in, 335, 335f, 640, 641–642
in glycogen metabolism, 344–345, 651f, 652f
in liver, 641, 641f, 651, 740, 741
molecules, 640, 641f, 655f

in muscle, 641, 641f
phosphorolytic cleavage of, 643–645
remodeling, 645, 645f
storage efficiency, 656
storage sites of, 641, 641f
structure of, **336f**, **641f**, **643**
Glycogen lakes, 661f
Glycogen metabolism, 640–661
branching enzyme in, 655, 655f
cAMP in, 652–653, 657f
coordinate control of, 656, 657f
degradation of, 641–642
enzyme breakdown, 642–647
epinephrine in, 651–653, 651f, 656, 657f, 658, 658f
G proteins in, 651–653
glucagon in, 651–653, 656, 657f, 658, 658f
α-1,6-glucosidase in, 645f
glycogen in, 344–345, 651f, 652f
glycogen phosphorylase in, 642–643
glycogen synthase in, 654–655, 655f
glycogen synthase kinase (GSK) in, 655–656, 657f
glycogenin in, 654
hormones in, 651–653, 651f, 656–661, 657f
insulin in, 658–659, 659f
in liver, 646–647, 659–660, 659f, 660f
overview of, 640–642
pathway integration, 652f
phosphoglucomutase in, 646, 646f, 647f
phosphoglycerate mutase in, 646
phosphorolysis in, 642–645
phosphorylase in, 642–647, 645f, 659, 659f, 660f
protein kinase A (PKA) in, 651, 652f, 656, 657f, 658f
protein phosphatase 1 (PP1) in, 653, 656–658, 657f, 659
pyridoxal phosphate (PLP) in, 643–645, 644f
regulation of, 642, 656–661, 657f

regulatory cascade for, 651–653, 652f
7TM receptors in, 652, 652f
termination of, 653
transferase in, 645–646, 645f
UDP-glucose and, 654–655
Glycogen phosphorylase
a, 647–649, **647f**, 650, 650f
allosteric regulation of, 647–651, 648f
b, 647–649, **647f**, 650, 650f
carboxyl-terminal domain of, 643, 644f
defined, 642, 646
in glycogen metabolism, 642–647
glycogen-binding site of, 643–645, 644f
in liver, 647–649, 647f, 648f, 657f
in muscle, 648, 648f, 650f
regulation of, 647–651, 653
Glycogen synthase
α-1,6 linkages, 655, 655f
defined, 654
in glycogen synthesis, 655–656
isozymes of, 654–655
Glycogen synthase kinase (GSK), 742
defined, 655–656
in glycogen metabolism, 655–656, 657f
Glycogenin, 641, 654
Glycogen-storage diseases, 661f, 661t
Glycolate, 614f, 615
Glycolipids, 355, 357, 359
N-glycolylneuraminate, 819
Glycolysis, 447f
aerobic, 497–498, 531
aldehyde oxidation in, 480–481
anaerobic mode, 531, 747, 749
ATP formation in, 482–484

1,3-bisphosphoglycerate (1,3-BPG) in, 457–458, 480–481, 483–484
in cancer, 497–498
citric acid cycle and, 517–521, 518f
control of, 492–499
covalent enzyme-bound intermediate in, 481
defined, 473
dihydroxyacetone phosphate (DHAP) in, 466, 476f, 478, 479f, 489
as Embden-Meyerhof-Parnas pathway, 473
enediol intermediate in, 479, 479f
energy charge and, 505–506
as energy-conversion pathway, 474–492
enzymes of, 474, 497
in eukaryotic cells, 473, 476–477
evolution and, 511
fermentation in, 486–487
first stage of, 475f, 476f
fructose 1,6-bisphosphate in, 466, 476f, 477
fructose 1-phosphate in, 489, 489f
fructose 2,6-bisphosphate in, 495, 496f
fructose 6-phosphate in, 477, 495
fructose in, 489–490, 489f
galactose in, 489f, 490–491
gluconeogenesis and, 499–501, 505–511, 505f
glucose 6-phosphate (G-6P) in, 476, 477, 494, 495f
glucose transporters in, 498, 498t
glyceraldehyde 3-phosphate (GAP) in, 476f, 478, 479f, 480–481, 480f
hexokinase in, 476–477, 476f, 494, 495–496, 495f
historical perspective on, 473
isomerization of carbon sugars in, 477, 478
in liver, 494–497, 495f, 496f, 497f, 506–508
in muscle, 493–494, 495f
NAD^+ in, 482, 482f, 486–488, 487f

NADH in, 482, 486–487, 486f

overview of, 473f, 475f, 476f
pathway integration, 509, 510f
pentose phosphate pathway and, 624–628
phosphofructokinase (PFK) in, 493–495, 493f, 496f
3-phosphoglycerate in, 484–485
2-phosphoglycerate in, 484–485
3-phosphoglycerate in, 485–486
phosphoglycerate mutase in, 484
pyruvate in, 473, 473f, 476f, 485–486, 486f
pyruvate kinase in, 494, 495f, 496–497, 497f
reactions of, 485t
reciprocal regulation in, 505–511, 505f
regulation of, 740f, 746
second stage of, 475f, 480–481, 480f
stages of, 474–476, 475f, 480f
thioester intermediate in, 481, 481f, 482, 483f
triose phosphate isomerase (TPI) in, 478–480, 479f
Glycolytic intermediates, 633
Glycolytic pathway
glucokinase in, 495–496
hexokinase in, 495–496
phosphofructokinase (PFK) in, 493–495, 496f
pyruvate kinase in, 496–497, 497f
Glycopeptide transpeptidase, 173
Glycophorin, 348f, 369
Glycoproteins, 337–346
Glycosaminoglycans, 338, 339–340, 340f
Glycosidic bonds, 331–332, 332f, 336, 336f, 338
Glycosidic linkage, 331–332, 332f, 335f, 336f, 338f
O-glycosidic linkage, 332, 332f
N-glycosidic linkage, 332, 332f
Glycosylation, 331, 341–342
congenital disorders of, 344–345
errors in, 344–345

location of, 341f
in nutrient sensing, 339, 339f
Glycosyltransferases, 341–342, 343f
Glyoxylate, 537, 537f, 615
Glyoxylate cycle, 536–538, 537f
Glyoxysomes, 537
Glyphosate, 777
Glyset, 334
GMP (guanosine monophosphate)
in purine synthesis, 799–800, 799f
synthesis of, 807–808, 808f
GMP synthetase, 800

Next-generation sequencing (NGS)
    defined, 284
    detection methods in, 284–286, 285f, 286f
    as highly parallel, 284
    ion semiconductor, 285, 286f
    pyrosequencing, 284
    reversible terminator method, 285
    RNA-seq, 289
NF-κB, 707
Niacin (vitamin B_3), 463t, 464f
Nicotinamide, 783, **783f**
Nitric oxide (NO)
    functions of, 784t
    synthesis of, 784–785, 784f
Nitrogen
    in amino acids, 764
    excess, disposal of, 713–718
    metabolism, 701, 716f, 783
    peripheral tissue transport of, 712–713
Nitrogen fixation
    in amino acid synthesis, 764–767, 764f
    ATP in, 765–769
    in bacteria, 764–767
    defined, 764
    FeMo cofactor in, 765, 765f

glutamate in, 766–767
glutamine in, 766–767
iron–sulfur proteins in, 765–766, 765f
P clusters in, 766
Nitrogenase, 764, 765–766, **765f**
Nitrogenase complex, 764–765
Nitrogenous bases. *See* Bases/base pairs
Nitrous acid, 865
N-linkage, 338, 338f, 341
N-linked oligosaccharides, 338, 338f, 345
Nonalcoholic fatty liver disease (NAFLD), 695
Noncompetitive inhibition. *See also* Enzyme inhibition
defined, 166
example of, 168
inhibitor binding, 168
kinetics of, 168, 168f
Nonconservative substitutions, 305, 307, 307f
Noncovalent bonds
in biological molecules, 7–11, 9f
hydrogen bonds, 5, 9, 9f, 10, 11
hydrophobic effect and, 10–11, 11f
types of, 8
van der Waals interactions, 9–10, 10f, 12
Nonessential amino acids, 768, 768f, 768t
Nonheme iron proteins, 525, 551–552
Non-homologous end joining (NHEJ), 292, 292f, 868
Nonphotochemical quenching (NPQ), 604
Nonpolar molecules, 11
Nonproteinogenic amino acids, 126
Nonshivering thermogenesis, 575, 577, 580–581
Norepinephrine, 785, 785f
Northern blotting, 267
Novobiocin, 857
Nuclear envelope, 374, 374f

Nuclear hormone receptors
defined, 963
domain structures, 964, 964f
in gene expression, 963–965
ligand-binding to, 963, 964f, 965f
Nuclear magnetic resonance (NMR) spectroscopy, 132–135, 132t
basis of, 133, 133f
chemical shifts, 133
defined, 132
NOESY and, 133–134, 134f, 135f
one-dimensional, 133, 133f
RNA structure, 320, 321f
signals, 133f
two-dimensional, 133–135
Nuclear membrane, gene expression and, 892
Nuclear Overhauser effect (NOE), 133–134
Nuclear Overhauser enhancement spectroscopy (NOESY), 134–135, 134f, 135f
Nuclear pores, 374
Nucleation-condensation model, 60, 60f
Nucleic acids, 265. *See also* DNA; RNA
Nucleophilic catalyst, 181
Nucleoside diphosphate kinase, 451, 796
Nucleoside diphosphokinase, 527
Nucleoside monophosphate, 451
Nucleoside monophosphate kinases, 451, 796
Nucleoside phosphorylases, 809
Nucleosides
defined, 792
nomenclature of, 792, 792t
Nucleosome, 893, **893f**
Nucleotidases, 809
Nucleotide synthesis, 791–812
de novo pathways in, 792, 798
deoxyribonucleotide, 801–807, 802f, 808–809, 808f

disorders of, 809–811
inosinate in, 808
overview of, 791–792
of purine, 783, 796–801, 797f, 807–808, 808f
of pyrimidine, 783, 792f, 793–797, 793f, 807
regulation of, 807–809
salvage pathways in, 792, 792f
substrate channeling in, 794
Nucleotide-excision repair, 868, 868f
Nucleotides
cyclic, 792
defined, 792
metabolism disruptions, 809–811
nomenclature of, 792, 792t
sequence of, 43
in signal transduction pathways, 792
NusA protein, 890

Obesity, 734
causes of, 734
diabetes and, 741–746
evolution and, 734
health consequences of, 734t
insulin in, 736
insulin resistance and, 743, 743f
leptin resistance in, 736f, 737–738
storage capacity of fat tissue, 743f
Obligate anaerobes, 488, 488t
Octadecanoic acid, 353
Odd-chain fatty acids, 675–676, 676f
Odorant receptors (ORs)
activation of, 436–437, 437f
evolution of, 441, 441f
in olfaction, 436–437
Off-diagonal peaks, 134

Off-target toxicity, 992
O-GlcNAc transferase, 339
Okazaki, Reiji, 849, 849b
Okazaki, Tsuneko, 849, 849b
Okazaki fragments, 849, 849f, 859
Oleate, 693
Olfaction. *See also* Sensory systems
    7TM receptors in, 436–437
    COVID-19 and, 437
    odorant receptors (ORs) in, 436–437, 437f, 441, 441f
    signal transduction in, 436–437, 436f, 437f
Olfactory neurons, 436
Oligomycin, 577
Oligopeptides. *See* Peptides
Oligosaccharide chain, 819
Oligosaccharides, 345f
    antigen structures, 343, 343f
    attached to erythropoietin, 339, 339f
    defined, 333
    enzymes responsible for assembly, 342–343
    human milk, 335
    mass spectroscopy and, 345, 345f
    N-linked, 338, 338f
    O-linked, 338, 338f
    sequencing of, 338, 339f
O-linkage, 338, 338f, 341
Omega (Ω) loop, 46
ω-carbon atom, 354
“On-bead” assays, 983f
Oncogenes, 433
One-dimensional NMR, 133, 133f
On-target toxicity, 992
Open promoter complex, 887, 887f
Open reading frames (ORFs), 309

Operator site, 952
Operon model, 952
Operons, 953f
in bacteria, 955
defined, 952
histidine, 969, 969f
lac, 953, 953f
structure of, 952, 953f
threonine, 969, 969f
trp, 968, 968f
Opsin, 438
Optogenetics, 607, 607f
Oral bioavailability, 988–989, 989f
Origin of replication complexes, 861–862
Origin of replication (oriC locus), 860, 861f
Ornithine, 715–716
Ornithine transcarbamoylase, 715, 717
Ornithine transcarbamoylase deficiency, 717f, 718–719
Orotate, 794–795
Orotate phosphoribosyltransferase, 795
Orotidylate, 795
Orotidylate decarboxylase, 795
Orthologs, 302, 302f
Orthophosphate, 453, **453f**, 482, 483f, 503, 642–643
Oseltamivir, 348
Osteoarthritis, 341
Osteogenesis imperfecta, 54
Overlap peptides, 122, 122f
Oxaloacetate, **160**
in amino acid degradation, 718, 719–720, 719f
in amino acid synthesis, 769
in Calvin–Benson cycle, 622, 622f
in citric acid cycle, 517, 522–523, 523f, 528–529, 534
conversion into phosphoenolpyruvate, 502–503

in fasting or diabetes, 680
formation of, 501–502
in gluconeogenesis, 499–503, 500f, 502f
in glyoxylate cycle, 537f
in ligation reactions, 467
in oxidation-reduction reactions, **465**
in starvation, 753–754
Oxidant, 546
Oxidation
activated carriers of electrons for, 460–461
of aldehydes, 480–481
carbon, 456–459
by citric acid cycle, 488
in drug metabolism, 990
by electron transport chain, 488
energy, 457–458
in fatty acid metabolism, 669–670, 671–674, 673t, 678–679
of fatty acids, 678–679
of glyceraldehyde 3-phosphate (GAP), 482
of membrane proteins, 674f
phase I transformations in, 990
pyruvate dehydrogenase complex and, 518–519
of succinate, 528–529
of unsaturated fatty acids, 674–675, 674f
Oxidation-reduction potential. *See* Reduction potential
Oxidation-reduction reactions
free-energy change in, 546, 547–548
in metabolism, 465, 465t
Oxidative phosphorylation, 542–581
ADP in, 572–573, 572f, 575f
ATP in, 573–574, 575f
ATP yield in, 573–574, 574t
ATP-ADP translocase in, 572–573, 572f, 573f, 578
cellular respiration in, 543–545
chemiosmotic hypothesis in, 562–563, 563f

defined, 458, 543
electron transfer in, 545–548, 561, 562f
electron-transport chain in, 543, 548–549, 569f
in eukaryotes, 543–544
in exercise, 747–749
inhibition of, 577–578
iron–sulfur clusters in, 551–552, 551f
in mitochondria, 543–544, 562–564, 563f, 564f
mitochondrial transporters in, 572–573, 572f
NADH in, 545, 547–548
overview of, 542, 543f
photosynthesis comparison, 600f
proton gradients in, 458, 458f, 543, 548–549, 562–569
proton-motive force in, 543, 562–563, 563f, 565–567, 565f
rate of, 574
reduction potential in, 545–548, 546f
respiratory chain in, 549–562
respiratory control in, 573–574, 575f
shuttles in, 570–573, 570f, 571f
transporters in, 570–573, 572f
uncoupling of, 575–576, 576f
Oxidized LDL (oxLDL), 830
Oxidized lipoamide, 520
Oxidizing agent, 546
Oxidoreductases, 143t
Oxidosqualene cyclase, 824
Oxoguanine-adenine base pair, 865, 865f
Oxyanion hole
of chymotrypsin, 185, 185f
defined, 185
of subtilisin, 186–187, 187f
Oxygen
affinity in red blood cells, 80–81, 80f, 81f, 82f
carbon monoxide and, 81, 82–83
concentration in tissues, 77, 77f

cooperative binding of, 76–77
cooperative release of, 76
hemoglobin quaternary structure and, 77–78, 77f
in hydroxylation function, 834–836
myoglobin and, 73–75
partial pressure, 76
pyruvate and, 486
reactive, 74
toxic derivatives of, 560–561
Oxygen affinity of hemoglobin, 80–81, 80f, 81f, 82f
Oxygen binding
cooperative, 76–77
by heme iron, 73–74
hemoglobin quaternary structure and, 75–76, 77f
iron and, 79f
pure hemoglobin, 80, 80f
sites, 73
Oxygenase reaction, 614–615, 614f
Oxygenases
in aromatic amino acid degradation, 723–724
mixed-function, 723
Oxygen-binding curve
defined, 73
fractional saturation, 73
for hemoglobin, 76, 76f, 77f
for myoglobin, 73f, 76
sigmoid, 76
T-to-R transition, 78, 78f, 80–81
Oxygenic photosynthesis, 586, 587f. *See also* Photosynthesis

enzymes as, 142
fibrous, 53–54
flexibility of, 35, 35f
folding of, 25, 25f
functional groups of, 34
functions of, 33–35
genetically engineered, 281
glycan-binding, 346
glycosylation of, 339
half-life of, 703, 704, 705t
interaction of, 34
internal repeats, 124, 124f
as linear polymers, 34, 41
loops, 50, 50f
membrane. *See* membrane proteins
misfolding of, 62–63
molecular weights of, 111t
native, 57
overview of, 100
phosphorylation of, 223
plasma-membrane, 940, 940f
posttranslational modifications, 63–64
properties of, 33–35

pure, 101
purification of, 101–112
refolding of, 57
regulatory, 954
repressor, 953
reverse turns, 50, 50f
ribosomal. *See* ribosomes
rigidity of, 35
S values of, 111t
secretory, 940, 940f
secretory pathway, 939
