Preface

This new midwifery textbook is the first to reflect Australasian historical and socio-political contexts for midwifery practice and the first to frame content within the philosophy and standards of the New Zealand and Australian Colleges of Midwives. This text is intended to provide an up-to-date evidence- and practice-based resource for midwives who work in partnership with women in women-centred models of midwife-led care.

As such this text is designed for midwifery students and practising midwives in New Zealand and Australia, and will also be relevant to midwives in other parts of the world where midwifery autonomy is acknowledged and emerging, such as Canada, Europe, Scandinavia, Japan and the United Kingdom.

We acknowledge that not all contexts in Australia and elsewhere currently support midwifery autonomy as we have described it. However, the primary purpose of this text is to equip midwives to practise autonomously and in partnership with women once contextual constraints to midwifery autonomy have been removed through political action. This text provides a model of midwifery to which midwives can aspire and for which they can be prepared. We hope that this knowledge will strengthen midwives' determination to find ways to work with women and with each other that will enhance midwifery autonomy and women-centred midwifery practice.

Philosophical framework

The philosophical framework of this text is shaped by our vision for maternity services: that each woman should have access to a midwife of her choice and that each midwife should be able to work within the full scope of midwifery practice. The context within which midwives practise may either support or limit the individual midwife's ability to practise in a way that is congruent with this philosophy. A primary purpose of this textbook is to articulate and exemplify the way in which midwifery partnership is, or can be, actualised in practice.

We believe that midwifery is both an art and a science. It occurs within historical, social, cultural, political and legal contexts. Midwifery knowledge is derived from the wisdom of women and experienced midwives, and from scientific research. The individual midwife's knowledge develops by scholarship and praxis.

A midwife forms a partnership with a woman as she experiences the life process of childbearing and early parenting. Midwifery care is woman-centred; however, care of the woman includes those she considers to be her family. The midwife shares knowledge, experience and wisdom reciprocally with the woman and her family. The midwife protects and promotes the dignity of each woman and accepts her culture, beliefs, values, expectations and previous experiences. The midwife and the woman make decisions together through a process of negotiation.

Midwives are autonomous health practitioners who, like other health practitioners, have a social mandate to practise within legally defined professional boundaries. The scope of midwifery practice involves care of the woman and her family pre-pregnancy and during all phases of childbearing and early parenting up until six weeks after the birth. The midwife works on her own responsibility, but in partnership with the woman, as long as the woman and her baby remain well and healthy.

When there is an indication that the woman or the baby requires the service of another healthcare provider, the midwife works collaboratively with the other healthcare provider. The midwife maintains her relationship with the woman and her family even if referral to another health provider is needed, and in most cases continues to provide care in collaboration with the other provider.

Structure of the textbook

Aim

The overall aim of this textbook is to support the development of competent and confident midwifery practitioners who are able to make professional judgements, in partnership with women, on their own responsibility. These practitioners will:

- have a women-centred approach
- work in partnership with women as autonomous practitioners in all settings
- have a sound knowledge base
- be critical thinkers
- be reflective practitioners
- be ethical decision-makers
- critically appraise the literature and provide evidence-based midwifery care
- be accountable and responsible for their practice
- contribute to the development of midwifery knowledge and the profession.

Structuring concepts

The text is broadly structured around the following concepts derived from its philosophical framework:

- *Context*—a reflection of the history of colonisation and the impact on the Indigenous peoples of Australia and New Zealand, our current bicultural and multicultural societies, our laws and legal systems, our political structures and processes, our healthcare systems, the organisation of maternity services and payment of maternity care providers. Childbirth and midwifery practice have been constructed within these different contexts. Each person involved in childbearing is affected by the context from which they have emerged and brings with them their individual life histories and culturally moulded attitudes, values and beliefs.
- *Woman*—includes the self of each woman and encompasses the baby that each woman carries within her body and to which she gives birth. This concept also includes each woman's partner, family/whanau, and cultural and subcultural group, and incorporates each woman's experience(s) of childbearing.
- *Midwife*—includes the self of each midwife, her knowledge, attitudes and beliefs, her partner and/or family/whanau, her cultural or subcultural group and her professional role as midwife. A midwife cares for and supports a woman as she grows and nurtures her baby, and strengthens the woman in her role as a mother.
- *Partnership*—implies a relationship of trust, reciprocity and equity through which both partners are strengthened. Each midwife strives to ensure that she does not impose her professional and personal power onto women; rather, through negotiation a midwife seeks to establish relationships in which each woman is the primary decision-maker. (*Note*: because most midwives are women we have chosen to use the feminine pronoun throughout this text.)
- *Autonomous practice*—occurs when a midwife provides care to a woman and her baby on her own responsibility. As autonomous practitioners, midwives have the knowledge and skills to provide care independently without a requirement to refer to another health professional. This does not mean that midwives practise alone; rather, midwives work in partnership with midwifery colleague(s). Nor are midwives independent of women, because all midwifery professional judgements emerge from midwife/women relationships.
- *Collaborative practice*—means working with other healthcare professionals/providers when the health of a woman or baby is outside the scope of midwifery practice. The relationship and responsibilities of each woman, each midwife and other health professionals needs to be negotiated.

Sections of the textbook

These structuring concepts are reflected in the ordering of the chapters. Part A focuses on the two partners within a midwifery partnership—the woman and the midwife, and the context within which their partnership relationship establishes and develops.

Part B focuses on midwifery practice. Section one explores the notion of midwifery partnership, while sections two and three explore midwifery practice from the perspectives of midwifery autonomy and collaborative practice.

Because midwifery practice is an integration of knowledge, skills and attitudes, the following strands are articulated within each of the three sections in Part B:

- physiology
- assessment
- evidence for practice
- professional judgements and decision-making.

We acknowledge that a number of disciplines contribute to the knowledge, attitudes and skills that a midwife needs, but the focus of this book is on midwifery-specific knowledge and the application of knowledge from other disciplines where it directly relates to the scope of midwifery practice. Where additional depth is required, readers are referred to more specific texts from other disciplines.

Each chapter provides:

- learning outcomes
- clinical scenarios to contextualise practice issues
- reflective and critical thinking exercises
- questions for review
- a list of online resources.

This text provides a new approach to midwifery education. In focusing on the midwife as an autonomous practitioner with a specific scope of practice, we have endeavoured to show how professional judgements and practice decisions rely on strong assessment skills, knowledge and understanding of physiology, application of evidence-based practice knowledge, and integration of attitudes and philosophy within a professional framework for practice. Midwives who approach practice in this way will be able to provide individualised and women-centred care. They will be able to identify when they have reached their level of expertise and when it is necessary to consult and collaborate with others to ensure that the needs of women and their babies are met. It is this awareness and midwifery 'thinking' that ensures midwives are competent and safe practitioners.

We hope you enjoy using this textbook.

About the editors

Sally Pairman

DMid, MA, BA, RM, RGON is Head of School of Midwifery and Health Group Manager at Otago Polytechnic, Dunedin, New Zealand. Actively involved in the New Zealand College of Midwives in various roles, including President, and currently inaugural Chairperson of the Midwifery Council of New Zealand, Sally has been at the forefront of establishing midwifery autonomy and degree-level direct-entry midwifery education in New Zealand.

Sally is co-author with Karen Guilliland of *The Midwifery Partnership: A Model for Practice*, a monograph describing a theoretical model of midwifery as a partnership between a woman and a midwife. Sally's master's research resulted in refinement of the model. Her professional doctorate in midwifery further analysed midwifery partnership in relation to midwifery leadership, midwifery education and midwifery regulation in her exploration of New Zealand midwifery's professionalising strategies from 1986 to 2005. Sally has published and presented extensively on these topics.

Sally is married to Michael Lucas and they have two sons, Oscar and Felix.

Jan Pincombe

PhD, MAppSc, PGDipEd, BA, RM, RIN, RN, FACMI is Professor of Midwifery, University of South Australia, Adelaide, and has extensive teaching and research experience. Over the past three years she held the position of Joint Professor of Midwifery between the University of South Australia and the Women's and Children's Hospital, Adelaide, where she has clinical teaching privileges.

More recently Jan was appointed Program Director of Midwifery for undergraduate and postgraduate programs at the University of South Australia, where she has taught and researched since 1992. She has successfully supervised PhD, masters and honours students in midwifery, alternative therapies and maternal and childcare topics over the past ten years and has taught a variety of courses in the midwifery programs.

Jan is a member of the Australian College of Midwives and the Australian National Education Standards Taskforce. She is married to Adrian, has two children, Brandon and Shauna, and two grandchildren, Will and Emma.

Carol Thorogood

PhD, MPhil, BAppSc, DipEd, PGDipArts, RN, RM, FACMI is the coordinator of midwifery programs in the School of Nursing, Midwifery and Postgraduate Medicine at Edith Cowan University in Perth, Western Australia. She is a Fellow of the Australian College of Midwives and a member of the Education Committee and Instructor for the Australian chapter of the Advanced Life Support in Obstetrics© programs. A member of the Board of Community Midwives Western Australia, the State's only publicly funded caseload, home birth program, Carol has a long-term research and clinical interest in home birth and autonomous midwifery practice.

Carol has considerable expertise in curriculum development, implementation and evaluation, including the design and evaluation of competency standards in midwifery. Her current research is concerned with the design of midwifery education programs for qualified midwives beginning tertiary study that embed generic skills such as critical thinking, reflection and written expression into clinically focused curricula.

Sally K Tracy

DMid, MA, BNurs, ADN, RM, RGON was appointed Associate Professor of Midwifery Practice Development at Northern Sydney and Central Coast Area Health Service in 2003. During that year she led the implementation and evaluation of one of the first Australian free-standing caseload midwifery units, the Ryde Midwifery Group Practice. In 2004, as part of her research program, she became a postdoctoral Research Fellow on the NH&MRC-funded Health Research and Outcomes Network (HERON), a collaborative program of the Institute for Health Research and the University of Sydney, the University of New South Wales, University of Technology Sydney, the Cancer Council NSW and NSW Health. She is based at the Australian Institute of Health and Welfare National Perinatal Statistics Unit at the University of New South Wales, where she is Associate Professor (Conjoint) in the School of Women's and Children's Health.

Sally was educated as a midwife in New Zealand and the United Kingdom, and has extensive community and hospital experience in New Zealand and Australia.

Sally was awarded the world's first professional doctorate in midwifery at the University of Technology Sydney in 2003 and has published widely on the epidemiology of obstetric intervention in labour and birth. She is married to Mark and has four children, Gabriel, Raphael, Amy and Imogen.

Foreword

'Midwifery knowledge is derived from the wisdom of women'—these words, contained in the preface, take us to the heart of this wonderful, useful, groundbreaking book. The words contain a world of meaning. The essence is crucial. In countries like New Zealand and Australia (and Canada too), midwifery is being transformed in a way that contains the ancient meaning and traditional ways of working of midwifery, being with the woman, while meeting the needs of modern-day health services and society.

It is no accident, I believe, that fresh approaches not only to practice but also to developing knowledge and skills are finding fertile soil in countries that are conscious not only of the general effect of colonisation on their societies, but also of the effect that colonisation has had on the midwifery profession. Awareness of the powerlessness that arises among the colonised is finding translation into an awareness of the effect of unequal power structures in the health services and the way that this affects childbearing women. The conscious intention to work in partnership with women, through a relationship that seeks to redress the power imbalance between each midwife and each woman, changes every aspect of midwifery practice, and calls for new knowledge and skills, and a new perspective on life and the world.

This is the first textbook to be written to reflect Australasian historical and socio-political contexts for midwifery practice and the first to frame content within the philosophy and standards of the New Zealand and Australian Colleges of Midwives. It will be invaluable to midwives and students in Australasia. However, it will also be invaluable to any midwife wherever she lives and practises. The kind of midwifery that is defined by this book, working in partnership, practising autonomously, in a way that gives mothers and their families the best start in life, requires deep knowledge and skills. It requires the ability to think critically and creatively, to be able to practise not only in partnership with women but also with a passion for developing skill, intellect and knowledge.

Midwifery is the partnership between the woman and her midwife, and the midwife in practice draws on the childbearing woman's knowledge. Working with the woman, rather than working with the institution, which is where many midwives find themselves in today's world, gives us an entirely new view, and requires an entirely new way of developing, using and transmitting knowledge. This book is the kind of rich resource that midwives need when they face the world from a position alongside a woman and her family, rather than from the institution looking on.

The position of 'being with' rather than 'doing to', of working in partnership, requires much of us but brings huge rewards. We need good resources to practise midwifery well in this way. This book is a goldmine for the modern midwife wherever she may be.

Lesley Page
Joint Head of Midwifery Guy's and St Thomas' NHS Trust and Visiting Professor of Midwifery
Nightingale School of Nursing and Midwifery
King's College London

Foreword

It is not often that one comes across a midwifery textbook like this one. This volume brings together a team of midwives from both Australia and New Zealand who are leaders in their field and who share in these pages a wealth of knowledge and expertise in midwifery practice, education, research and regulation.

Yet the credentials of the authors, while impressive, are not the only reason this book is a 'must have' for every student of midwifery. This book's unique contribution is its focus on both the universal principle that underpins midwifery philosophy and practice—that of partnership with women—and midwifery autonomy in practice.

The midwifery partnership between a woman and midwife working together to achieve the best outcome for that mother and baby differentiates it from other models of care, where the health professional assumes expertise over the mother. It is this point of difference that gives society the body of knowledge called midwifery.

Drawing on midwifery partnership, this book approaches midwifery care from the perspective of a midwife as a primary health practitioner, based in the community but interfacing with hospitals and specialists as necessary to meet the needs of individual women. It explores both autonomous practice and collaborative practice, and is the first textbook to discuss midwifery practice in the context of community and primary health rather than hospital-based maternity services.

Just as childbirth is far more than a physiological process, the art and science of midwifery is more than a study of the female human body and its reproductive powers. Like childbirth, midwifery occurs in a social, political and historical context that shapes the practice of midwifery in any given time and place. It is therefore essential that all would-be midwives have a sound understanding of this context, and an awareness of how it may influence their own practice in providing care to women. This book provides a clear and accessible introduction to the historical and contemporary context of midwifery practice in Australia and New Zealand, and examines practice within the professional frameworks of the philosophy and standards of both the Australian and New Zealand Colleges of Midwives.

Midwifery care in Australia and New Zealand is currently provided to women in very different maternity care systems. In Australia, most midwives work in public or private hospitals, providing professional care to women as best they can without the benefit of being able to get to know the women they care for. Lacking prescribing rights, independent access to public funding, and professional indemnity insurance, midwives are mostly obliged to work within services that segment women and their midwives into antenatal, labour and postnatal wards and limit the opportunities for relationship building. Midwives in New Zealand, by contrast, are free to practise in either hospitals or the community. All can access public funding for their professional services, have prescribing rights, and work in partnership with women and with each other if they choose to.

The freedom to practise in partnership with women cannot be taken for granted. Policy and legislative change in New Zealand has been achieved through twenty years of sustained political advocacy by midwives and women in partnership.

Even so, twenty years ago, when New Zealand midwives and women were in the heart of their 'save the midwife campaign', they could hardly have envisaged how successful the reinstatement of the midwifery profession would be in today's health system. In focusing on midwifery autonomy and midwifery partnership, this textbook reinforces for all midwives the achievements of women and midwives in giving childbirth back to women and their whanau. It reminds us of what a struggle it was, and still is, to keep women central to the birthing process, and each chapter provides valuable knowledge and guidance to both experienced and new midwives that will help ensure that midwifery continues to keep women and their babies safely at the centre of practice decisions.

Similarly, advocacy by midwives and women has also been under way in Australia for the past decade, and is beginning to bear fruit in creating greater freedom for midwives to practise and for women to choose their own midwife. However, there remains much to be done before midwifery in Australia achieves the level of professional autonomy and responsibility that is commonplace in New Zealand and other developed nations.

Yet for all the differences between maternity services in these two countries, midwifery remains universally constant, guided by the same theoretical and practice knowledge and skills that combine to make midwifery such a vital profession for women and babies. The commonalities far outweigh the differences, and this book is rich with up-to-date and relevant information aimed at supporting all midwives to practise autonomously and ever with an eye on the needs of the women they care for.

Acknowledgements

This textbook has taken many months to prepare and would not have been completed without the support of many people. We give heartfelt thanks to the following:

- all the authors who worked so hard to complete their chapters on time despite their very busy lives and personal challenges
- our employers—Otago Polytechnic, University of South Australia, Edith Cowan University and the Australian National Perinatal Statistics Unit—who have supported us with time to write
- the manuscript reviewers, in conjunction with Elsevier Australia, for their insightful comments, including: Jenny Browne (University of Newcastle), Margaret Duff (Waikato Institute of Technology), Joanne Gray (University of Technology Sydney), Virginia King (Southern Cross University), Jan Robinson (Jan Robinson Midwifery Education Services) and Rachel Smith (University of Technology, Sydney). We would also like to thank those contributors who kindly provided valuable feedback to their peers on selected chapters, including Sally Baddock, Shea Caplice and Roslyn Donnellan-Fernandez.
- colleagues who provided particular expertise and advice: Bronwyn Hegarty, Patrice Hickey, Karen Guilliland and Hannah Dahlen
- David Vernon for use of a birth story from the book titled *Having a Good Birth in Australia*
- David Hancock for the photographs in Chapter 24
- the New Zealand College of Midwives, Archives New Zealand and the Alexander Turnbull Library (NZ) for the photographs in Chapters 6 and 20
- our professional organisations—the New Zealand College of Midwives and the Australian College of Midwives—for their support of our vision for this book
- our hard-working team from Elsevier Australia: Helena Klijn, Suzanne Hall, Amanda Simons and Kay Waters, for their diligence, perseverance and endless patience
- and, finally, our families and friends, who supported us in so many ways over the long months of writing and reviewing, and who encouraged us when the end seemed nowhere in sight.

SECTION ONE CONTEXT

CHAPTER 1

Australian and New Zealand health and maternity services

Karen Guilliland, Sally K Tracy and Carol Thorogood

Key terms

Annual Salary Agreements, federal health, funding models, health, lead maternity carer (LMC), Maternal and Newborn Information Service (MNIS), Medicare, midwifery models, Mothers and Babies Report/NPDC, New Zealand District Health Boards, primary health, public health, Section 88 funding

Chapter overview

This chapter provides an overview and explanation of the development and current structure of the New Zealand and Australian maternity systems. It discusses the role that midwives and women have played in that development and identifies how the maternity service structure in each country supports, or does not support, the provision of midwife-led maternity care. The chapter begins with an introduction to primary healthcare and makes the case that maternity care is a primary health service and needs to be recognised as such if it is to best meet the needs of women and their families.

Learning outcomes

Learning outcomes for this chapter are:

1. To define primary, secondary and tertiary healthcare
2. To explore why maternity services need to be recognised as primary healthcare rather than secondary and tertiary services
3. To describe the structure and funding of New Zealand's maternity services
4. To describe the structure and funding of Australia's maternity services
5. To explain how funding models affect the provision of services and outcomes of care
6. To discuss the role of midwives within New Zealand and Australian maternity services.

What is health?

Health is not merely the absence of disease or infirmity; it is a social phenomenon, the determinants of which cannot be separated from the social world in which we live. Health does not necessarily relate to the availability of health services. Indeed, even in industrialised nations such as Australia and New Zealand, rich in knowledge, technology and expertise, and with relatively equal access to health services, the health of some members of society remains poor. Geoffrey Rose, in his influential book, *The Strategy of Preventive Medicine* (1992), goes some way to explaining this phenomenon when he argues that 'the primary determinants of disease are mainly economic and social, and therefore its remedies must also be economic and social. Medicine and politics cannot and should not be kept apart' (p 129). Consequently, the only way to tackle health inequalities and improve health for all is to take a multipronged approach that addresses the social and economic factors in which health and illness are generated, while also providing appropriate, affordable and accessible health services aimed at ameliorating risk factors, promoting health, and combating and curing disease.

The provision of such health services involves complex social and political processes that require political decision-making not only at the sectorial level but also by the state. Health cannot be the responsibility of any single bureaucratic–administrative sector of the state; nor can it be owned by specific groups. Health is everyone's responsibility—individuals, social groups and the state.

Adequate healthcare services will only be achieved when all members of society have access to healthcare services that meet their specific needs. Access is not possible if healthcare providers, facilities and supporting healthcare system infrastructure are not in place. Even when essential health services are available, they may not be accessible. Barriers to access include language, ethnicity, culture, geography, weather, or a lack of affordable public or medical transportation services.

The traditional Western, biomedical approach to health service provision has focused on identifying those at risk of disease, diagnosis, providing treatment for individuals who request care, and assessing outcomes of these treatments. In contrast, primary healthcare takes a broader approach to supporting individuals' health and wellness through community-based services and health promotion. Primary healthcare is not the same as public health, although there are similarities. Where primary health focuses on individuals, public health is concerned with the health of populations. It focuses on protecting and improving the health of entire populations through health promotion and education, disease prevention, control of communicable diseases, and provision of the fundamental conditions and resources required for health, such as peace, shelter, education, food, income, a stable ecosystem, sustainable resources, social justice and equity. Public healthcare addresses the factors that underpin health and illness, such as income, social status, education, employment, working conditions, social and physical environments, biology and genetics, personal health practices and coping skills, child development, health services, gender and culture.

Definitions of healthcare services

Healthcare services can be loosely categorised as primary healthcare, primary medical care, secondary care, tertiary care and public healthcare.

Primary healthcare is both a philosophy and an approach to providing health services. According to the Alma-Ata Declaration of 1978, primary healthcare:

- is a practical approach to making essential healthcare universally accessible to individuals and families in the community in an acceptable and affordable way and with their full participation
- means much more than the mere extension of basic health services
- aims to use only those technologies that have really proved their worth and can be afforded
- is delivered by community health providers who understand the real health needs of the communities they serve and have the confidence of the people.

Primary healthcare is the first level of service provision. It is usually the initial point of contact that people have with the healthcare system. Primary healthcare aims to be universally accessible to individuals and families in the community. Services are coordinated, accessible to all, and accessed through a variety of providers (not all of whom are healthcare professionals) who possess the appropriate skills to meet the needs of individuals and the community they serve.

Although the terms 'primary medical care' and 'primary healthcare' are often used interchangeably they are not the same, and it is important to distinguish between the two. Primary medical care is concerned with the initial management of an individual's health problem and, in New Zealand and Australia, is mostly provided by general practitioners (GPs) supported by nurses in community practices. Primary healthcare is supporting and improving individual wellness and promoting prevention of individual health problems through community-based care. Public health is the application of similar principles to the population or community as a whole.

Secondary healthcare is healthcare to which people do not have direct access and for which they must be referred from some other part of the health system, such as a primary health practitioner. It is a specialty service that is generally provided from hospitals.

Tertiary healthcare encompasses highly specialised, complex and costly inpatient treatment services such as neonatal intensive care. Tertiary healthcare providers are highly specialised and their equipment is usually expensive. Moreover, tertiary healthcare requires a multidisciplinary team, and high levels of organisation and coordination between providers are required.

Midwifery and primary healthcare

Midwives are uniquely positioned to provide a combination of primary, public and secondary/tertiary services. As primary health practitioners, midwives provide community-based midwifery care for individual women where care is provided in women's homes or community clinics and the focus is on enhancing and supporting the normal life process of pregnancy and childbirth. Midwives provide initial responses to problems or needs and can intervene and treat conditions within their scope of practice. They also work in collaboration with obstetric and other specialists to provide secondary and tertiary care, and can provide continuous midwifery care to women even when secondary and tertiary care specialists are involved. Midwives utilise a social justice approach to service provision. In partnership with women and each other, midwives work to empower women and their families towards self-health and self-determination so they can make the best decisions for themselves, but also for their families and the wider community. In so doing they utilise public health methodologies.

This model of midwifery care requires a strong foundation of community-based services if it is to enable women and families to maintain and strengthen their own health status and enjoyment. New Zealand midwifery provides a clear example of midwifery as primary healthcare.

New Zealand midwifery's partnership model is based on the premise that primary healthcare is the cornerstone of the maternity service. Together with the government's overall primary and public health strategies, it has been accepted as the central strategy for improving the health and wellbeing of mothers and babies. A unique aspect of New Zealand's primary health model of maternity care is that primary services are seamlessly integrated with secondary and tertiary services. Secondary maternity care encompasses the provision of comprehensive specialist services which may or may not require hospitalisation. Tertiary maternity care encompasses multidisciplinary care for women and babies with complex needs such as co-morbidities. Women who experience complications during the antenatal, labour, birth and postnatal periods are referred to secondary or tertiary specialist services for either consultation or transfer on a planned or emergency basis.

While New Zealand has a well functioning and integrated model of maternity care based in primary midwifery care, Australian maternity services are still based largely in secondary care hospital facilities and in the primary medical care arena. However, many states are moving towards community and primary health models to provide maternity services, including primary midwifery care. Both countries have developed mechanisms for linkages between primary, secondary and tertiary maternity services and these services and referral guidelines are described in the relevant service specifications issued by the Ministry of Health in New Zealand or Australian state and federal departments of health.

Internationally, midwifery is increasingly being recognised as a primary health service that can operate effectively in the community and away from medical facilities and hospitals. Community interventions have the potential to improve preventive care in isolated communities, reduce delays in seeking and obtaining care, and support primary care services and referral systems (Barnett et al 2005).

As Kaufman (2002) puts it:

> public health is a natural territory for midwives . . . Midwifery sees each woman holistically, taking into account her social, psychological and emotional needs as well as her physiological status. Midwifery understands that a woman's confidence and sense of control, her relationships with those who are important to her and her home situation are as important as the clinical interventions provided her in determining her overall well-being throughout pregnancy and early motherhood.

Midwifery, then, is of fundamental importance to the enhancement and maintenance of health. Its ideological framework and holistic agenda provide a platform for community empowerment, potentially ranging along a continuum from individual development through to the collective ability to influence external policy development, legislation and an equitable distribution of resources. Midwives understand that primary healthcare is not merely about moving resources out of the hospitals and into the community; it is also concerned with equity, access, power and politics. Maternal health does not simply mean providing more obstetric services in hospitals; it is more likely achieved through community-based care directly accessed by women and appropriate to their specific needs.

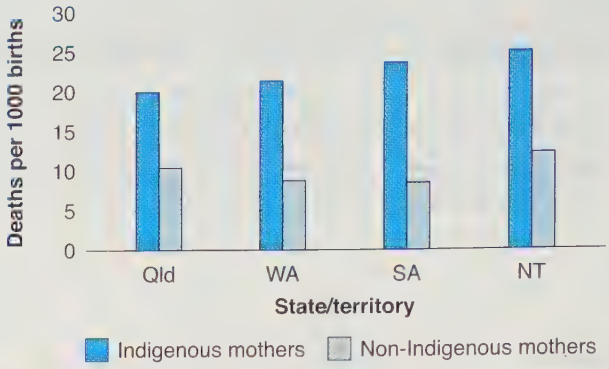
The following sections identify some basic primary health principles in more depth and provide examples from New Zealand, Australia and internationally of how—and whether—these principles have been implemented.

Principles of primary healthcare

Care should be aimed at the most needy

This principle espouses the notion of equity—resources should be distributed fairly according to need, with more directed at those who require it most. The World Bank estimates that, worldwide, 1.1 billion people live in extreme poverty; that is, they survive on less than a $1 a day. Recently, Sachs (2005), writing in *Time* magazine, said:

> Households [of people living in extreme poverty] cannot meet basic needs for survival. They are chronically hungry, unable to get healthcare, lack safe drinking water and sanitation, cannot afford education for their children and perhaps lack rudimentary shelter—a roof to keep rain out of the hut—and basic articles of clothing like shoes . . . [This is called] the poverty that kills (p 47).



In 2005, even in comparatively rich countries there are still gaping inequities and social injustice between individuals,

communities and states that leave large segments of the population without basic healthcare. Poverty is on the rise (Sachs 2005) and the few resources that societies can allocate to education and health are sometimes invested and spent in misguided and inequitable ways, so that those who need support the most do not get it.

This principle is also about reaching groups who are denied equitable access to services. In some cases, services are available but for some reason are not accessed as often or as well as they might be. In others, some population groups live so far below the poverty line that they simply cannot pay for the services they need or pay for the transport they require to get there.

Significant changes in neonatal mortality in New Zealand since 1990

Although there are still some gaps between birth outcomes for Maori, Pacific Island and Pakeha (non-Maori) babies in New Zealand, the gap is considerably less than that for Australian Aboriginal women. Examination of neonatal and perinatal statistics in Australia and New Zealand provides one indicator of the success or otherwise of maternity services in meeting the needs of those in most need of care.

Note: Perinatal deaths include fetal and neonatal deaths.

Figure 1.1 Perinatal mortality rates in Australia, 1998–2000 (based on AIHW 2004)

Research

According to the Australian Bureau of Statistics (2004), the perinatal mortality rate for Aboriginal or Torres Strait Island infants is more than twice that of the non-Indigenous population. On average, a baby of Aboriginal or Torres Strait Island descent weighs 200 g less (low birthweight) than one from another Australian background. Between 2001 and 2003, the infant death rate in both Western Australia and the Northern Territory was 16 in 1000. In contrast, the mortality rate for non-Indigenous babies was 5 in 1000 (Australian Bureau of Statistics 2004).

Lack of antenatal care is associated with a significant number of poor pregnancy outcomes. Humphrey and Keating (2004), exploring the reasons that women living in far north Queensland do not access antenatal care and their subsequent pregnancy outcomes, discovered that non-attenders were more likely to be highly parous or young Indigenous women and users of alcohol than those who did access antenatal care. Women who lived in remote communities and women with significant medical conditions complicating their pregnancies were more likely not to attend. Poor attenders had higher incidences of preterm birth and postpartum haemorrhage, and their babies were more likely to be of low birthweight, to be born with five-minute Apgar scores less than five, and had a higher incidence of perinatal death. The authors concluded that lack of antenatal care is associated with a significant number of poor outcomes, but this cannot be explained solely by the women's epidemiological characteristics. Non-attenders tended to be from the most disadvantaged or marginalised groups in society.

In New Zealand in 2000, the neonatal death rate (3.8 per 1000 live births) was 9.5% lower than in 1990. The total post-neonatal death rate (2.5 per 1000 live births) was 40.5% lower than in 1990. The total infant death rate (6.3 per 1000 live births) was 25.0% lower than in 1990 (Ministry of Health 2004).

The Sudden Infant Death Syndrome (SIDS) death rate (1.1 per 1000 live births) was 63.4% lower than in 1990 and was the lowest rate recorded since SIDS became a separate category in the International Classification of Diseases in 1979. There were 64 infant deaths under one year of age attributed to SIDS in 2000. In 2000, 40.6% of post-neonatal deaths and 17.5% of all infant deaths were attributed to SIDS (Ministry of Health 2004). It is important to note that the rate of stillbirth among Maori babies continues to fall significantly, from 7.1 per 1000 births in 1996 to 5.8 per 1000 births in 2000. For the total population this rate fell from 7.2 to 6.4 (Ministry of Health 2004).

Other outcomes measures where Maori figures are the same as or better than Pakeha include birthweight and gestational age. While 71% of Pakeha babies are fully breastfed at two weeks, Maori babies (63%) do better than Pacific (59%) or Asian babies (57%) (Ministry of Health 2004). In 2003 some 85% of Maori women had a midwife Lead Maternity Carer to provide one-on-one care (Ministry of Health 2004). Maori women are also more likely to access primary maternity units than any other ethnic group. It is reasonable to conclude that primary midwifery and maternity care does meet the needs of Maori women and that resulting improvements in health outcomes are beginning to be seen.

Primary healthcare should include essential, appropriate activities

A common concern worldwide is the lack of communication between funding bodies and consequent failure to coordinate

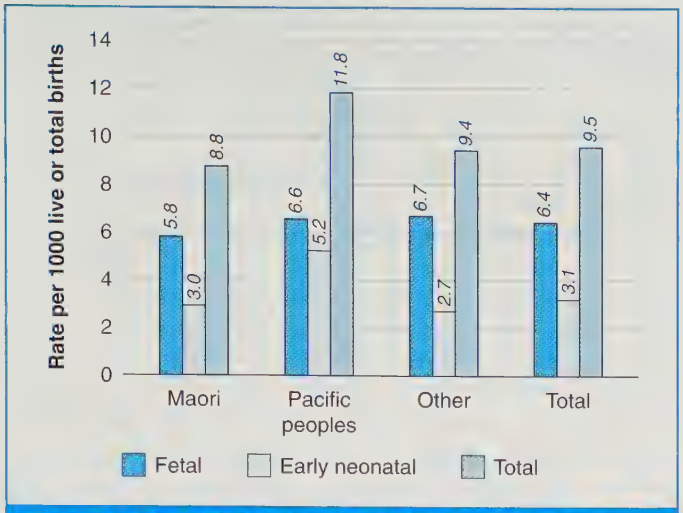


Figure 1.2 New Zealand perinatal deaths by ethnicity, 2000 (based on Ministry of Health 2004)

programs. Vertical programs may be introduced to combat a particular problem but often they are not integrated with other services. For example, immunisation programs have been introduced to reduce the number of deaths from childhood diseases. However, although this initiative has stopped infants dying from infectious diseases, in developing countries children still die of malaria or gastroenteritis from drinking contaminated water.

> In sub-Saharan Africa, malaria is estimated to cause 400,000 cases of severe maternal anaemia and between 75,000–200,000 infant deaths per year. Pregnant women in south eastern Ghana are protecting themselves and their newborns against malaria, thanks to a project funded by the Department of International Development which relies on the skills and influencing power of local midwives. The midwives provide insecticide-treated nets to women attending local clinics and encourage women to use them (Department for International Development, n.d.).

In New Zealand, midwives are the main providers responsible for referring mothers to the well child services for their babies to start their immunisation program at six weeks. Some 95% of babies receive their first vaccination, indicating an effective integration from maternity care into the next primary health service, the well child service (Ministry of Health 2004). Regretfully this level of vaccination in infants is not maintained in the well child service. Nevertheless this example demonstrates that integration from service to service is a possible consequence of a well organised one-on-one primary health maternity service.

Care should be accessible and acceptable to everybody

In general, societies dominated by one social group create health services to meet the cultural needs of that group. In Australia and New Zealand the dominant stakeholders are primarily urban-dwelling people from Anglo-European backgrounds. This means that some Australians and New Zealanders are alienated from these services because their specific cultural needs and values are not recognised. Feelings of alienation may lead to health services not being used even if they are accessible.

Dr Lowitja O'Donoghue (1999), a prominent Australian Aboriginal activist, told her audience at a rural health conference that members of remote Aboriginal communities who are ill experience triple jeopardy. First, they are Aboriginal with all the socioeconomic disadvantages that go with that; secondly, many live far from medical services. And finally, in rural and remote areas in particular, Indigenous people have little involvement in the health services they can access; and even if they do, they feel alienated from mainstream facilities.

Although the distances are much smaller in New Zealand than in Australia, the principle of establishing services within communities rather than moving women out to access services is an important consideration. New Zealand's maternity service is women-centred and aims to meet the individual needs of women and their families. Midwives visit women in their homes if necessary and state support for home birth and primary maternity unit birthing means that women can generally access services in their local community.

Primary healthcare should be affordable

Unlike countries such as the United States, all Australians and New Zealanders have access to 'free' healthcare. However, in

Reflective exercise

Imagine you are visiting a foreign country for the first time. You do not speak the language and you do not have an interpreter. You know nothing about the country's health system and very little about its culture. Imagine how it would be for you if you develop a severe urinary tract infection when you are 30 weeks pregnant and begin to have uterine contractions. You know you need urgent medical care but do not have the means to pay for it. What will you do?

Clinical point

Maternity services are often most needed by those who cannot access them. Over 12% of Aboriginal people have to travel more than 100 kilometres to get to a hospital. More than half of Indigenous people living in rural Australia have to travel more than 50 kilometres to a hospital (O'Donoghue 1999). Many do not own or have access to vehicles. It is little wonder then that Aboriginal women are 'poor attendees' at antenatal clinics; they have no means of getting there. A hallmark of quality maternity care is a good transportation system to enable referrals to a higher level of care.

Australia in particular, differences in the quality and quantity of these services, especially with regard to community-based midwifery, hospital waiting times and outpatient services, mean that many must pay extra for services that are better able to meet their needs. For example, until very recently, Western Australia was the only state to offer a publicly funded midwife-led home birth service. In other states, women who prefer this model of care are expected to pay for it, although some insurance companies will offset some of the costs associated with these services.

The picture is very different in New Zealand, where all maternity care is free. All women expect to have their own lead maternity carer (LMC) and 78% choose a midwife LMC (Ministry of Health 2004). Women can choose where they give birth and home birth is also fully funded. Women who do not require referral to specialist care can still choose a private obstetrician to be their LMC instead of the public obstetric service, although the private obstetrician is likely to charge a fee.

Primary healthcare should contribute to the self-reliance and self-determination of communities

Health bureaucrats and funding bodies often pay lip-service to the ideal of community participation in decision-making. Although structures for consultation may exist, stakeholders are rarely delegated any serious power or decision-making authority. Hence the wishes and priorities of the community are often buried in many layers of the consultation process. Moreover, a token 'consumer' on a Board of Health usually has little say in proceedings. For example, the West Australian Government consistently invites the community to join it in the identification of priority issues and to have input into the creation and implementation of programs to solve them (Thorogood 2001). However, the wishes of the community are often overruled if they are not in alignment with the needs of the powerful medical lobby.

There is good evidence (Barnett et al 2005) that community-based initiatives aimed at lowering maternal and perinatal morbidity and mortality are effective, sustainable and more likely to achieve high coverage in the poorest communities than secondary or tertiary hospital-based approaches. The Strong Women, Strong Babies, Strong Culture (SWSBSC) program (see Box 1.1) is a good example of such an approach. The SWSBSC program provides health promotion through local women's groups. This social intervention harnesses the creativity and self-organising skills of Indigenous women living in the Top End of Australia.

New Zealand has established Primary Health Organisations (PHOs) which are required to have strong community governance. However, most have struggled to overcome the dominance of GPs, and primary healthcare remains largely primary medical care. It is for this reason that the midwifery profession has recommended that maternity services remain outside PHO structures until they can demonstrate a more integrated, community-based, multidisciplinary approach.

Some non-government organisations (NGOs) that emerged from the Union health clinics and Maori provider organisations have succeeded in developing a more primary health model, and midwives have been successfully incorporated into their services without losing the midwifery/primary health focus. In 2005 the New Zealand College of Midwives initiated a proposal to the Minister of Health for a joint venture between primary health provider NGOs, Plunket (well child), the Family Planning Association, the Midwifery and Maternity Provider Organisation (MMPO) and Parents Centres (childbirth education) This joint venture is investigating the provision of an integrated well women and child health service for women, pregnant women and children up to five years old (NZCOM 2005). The joint venture would sit parallel to the PHOs and work collaboratively with them, and in this way build their understanding around the provision of primary healthcare.

Primary healthcare should be integrated with other health programs and sectors

If it is to be successful, primary healthcare has to involve horizontal, symmetrical and participatory relationships and direct, active and effective participation of the population it serves. Primary healthcare is multipronged, interdisciplinary, participatory and decentralised. Change will inevitably be slow and it will never come about by the efforts of a single sector or institution, isolated programs or specific services. As O'Donoghue (1999) remarks, none of the factors that lead to ill health, be they geographic, environmental or socio-economic, can be treated in isolation from one another. Nor can they be seen as problems of the here and now, divorced from their history (O'Donoghue 1999).

Midwifery is a primary health workforce

For the vast majority of the world's women, childbearing is a normal, physiological process influenced by culture, family traditions, religion, economics and psychosocial factors. It is a family event that requires a health-oriented approach, even in the presence of co-morbidities. In New Zealand, as in many other countries, midwifery is the primary health workforce whose specific role is to facilitate the transition to parenthood for women and their families regardless of their choices of service provider or place of birth. Australian midwifery is also working to achieve this model of care.

The underlying principles of primary healthcare provision apply to maternity services. That is, services should be provided equitably and at the most accessible level of the healthcare system capable of performing them adequately. It is considered internationally that the person best equipped to provide community-based, appropriate technology, and safe and cost-effective care to women during their reproductive lives, is the person with midwifery skills who lives in the community alongside the women she attends (WHO 1994, 2004).

Maternal health is not simply a question of providing access to technologically oriented biomedical services. It is a public

BOX 1.1 Strong women, strong babies

The Strong Women, Strong Babies, Strong Culture Program

In the 1990s the Northern Territory Department of Health and Community Services developed the first community-based intervention initiative, the Strong Women, Strong Babies, Strong Culture Program (SWSBSC). Its aim was for senior women from Aboriginal communities to help younger women prepare for pregnancy and to support pregnant Aboriginal women, by encouraging them to visit clinics for antenatal care early in pregnancy, by providing advice and encouragement about healthy pregnancy management in relation to nutrition (including bush foods), by promoting the adoption of safe practices such as refraining from alcohol and not smoking, and by reinforcing the need to seek adequate, timely medical help. Senior women delivered the program because they were better able to lead a culturally appropriate and attuned package of supporting care and education. The program's structure and content was fluid and altered according to the personal and social circumstances of the women, the available health and social services and the skill level of the SWSBSC women. An independent evaluation of the SWSBSC showed a marked increase in birthweight of the babies whose mothers attended the program. Apart from the benefits for pregnant women and their babies, the SWSBSC has had a social and economic impact in the wider community, providing opportunities for gainful and useful employment, earnings and recognition of the skills of Australian Aboriginal people tackling their own issues (d'Espaignet et al 2003).

Critical thinking exercise

Identify the strengths, weaknesses, opportunities and threats to midwifery services based on a philosophy of primary healthcare in your area. Think about acceptable solutions to problems you identify and the strategic initiatives you would put in place if the primary health midwifery service is to be sustained.

health issue, for which community interventions that are cost-effective, woman-focused, appropriate, affordable and sustainable must be implemented. In keeping with primary healthcare's philosophy of self-determination, community-controlled primary healthcare services are initiated, planned and managed by local communities. They aim to deliver high-quality, holistic and culturally appropriate healthcare and have the potential to improve health and wellbeing and reduce delays in seeking and obtaining secondary and tertiary medical services.

The next sections of this chapter provide an overview of the structure and funding of maternity services in New Zealand and Australia.

Midwifery and maternity services in New Zealand

New Zealand has a similar history to other Commonwealth colonies in the development of its maternity services. In the absence of an easily accessible health service due to a scattered, isolated geographic environment, the maternity system was built from personal experience and women helping other women. Maori had a similar history of family or whanau-centred attendance at birth. As with Pakeha, the nature and style of Maori birth attendance differed with each hapu/iwi (family or tribe), depending on their experience and belief systems. In the 1800s and early 1900s there were women (or men for some iwi) who were considered midwives, although few had structured or formal education specific to midwifery. The introduction of midwifery regulation in 1904 was an attempt to provide a more formal framework for midwifery and to give women a better standard of maternity care. This support for midwifery was not to last. A fuller discussion on the early maternity systems can be read in the historical accounts provided by Philippa Mein-Smith (1986), Joan Donley (1986), Elaine Papps and Mark Olssen (1997), Jane Stojanovich (2004) and Sally Pairman (2005).

Legislative and social changes over several decades increasingly diluted the midwifery identity to a point in the early 1980s where it was difficult to distinguish the role of midwifery from that of nursing. Parallel to the demise of midwifery was the loss of society's perception of birth as a normal life process largely belonging to the woman and her family. The struggle to reclaim both the role of midwives and birth as a family event saw women and midwives on a similar journey. This journey shaped the philosophical basis for the development of New Zealand's contemporary women-centred and midwife-led maternity services.

Historical background

As discussed earlier in this chapter, any maternity system must always be seen in the social and political context of the time, and then in the context of the health system overall. In New Zealand the 1990s was a decade notable for economic reforms and considerable changes in the health sector (Gauld 2001). These changes provided a context that was favourable to the development of the current maternity services model, and politically aware women and midwives were able to capitalise on these health sector changes or 'reforms' to create the successful maternity service that New Zealand enjoys today (Pairman & Guilliland 2003).

The health reforms were largely economically driven as New Zealand, along with most Western democracies, considered the level of demand and the spiralling costs of health services unsustainable. However, there were also other drivers for change. These included a competitive (or market model) government economic ideology, health workforce shortages

and concern about the growing and largely uncontrolled use of technology. In the maternity services another driver was the presence of a long-established and strong women's health network and consumer rights movement. It was these consumer advocates who initiated and drove the impetus that eventually brought about change in the midwifery and maternity services.

Consumer voice

From the 1920s through the 1980s, women in consumer advocacy organisations voiced their concerns over maternity care. They did not like the impersonal, hospital-controlled birthing culture and they lobbied hard over many years for a more women- and family-centred maternity service (Dobbie 1990). They identified a need for the midwife to be more visible, and demanded that she take a stronger role in providing maternity care (Tully 1999).

For most of these years the midwifery profession was submerged within the nursing profession and not well organised to use its collective voice. While some individual midwives, in particular the home birth midwives, were very clear about what midwifery was and had solid links to the consumer movement, the profession overall was slow to align itself with women. However, as women's organisations became stronger and more universal, midwives also became more organised, and by the late 1980s had become part of this women-led movement. Once politicised, women's groups and the midwifery profession worked together to make birthing services a political issue that could not be ignored (Guilliland & Pairman 1995). Helen Clark, the then Minister of Health, not only understood the foundation of the women's health movement but was also strongly focused on the essential role of primary healthcare. She was sympathetic to the view that birth was a normal life event that should be controlled by each woman and her family in their own community. She understood that in order for this to happen women would need midwives who were educated and resourced in a way that would make this care available and effective.

Maternity choices pre-1990

Prior to 1990, maternity services were almost entirely hospital based. Less than 1% of women had their babies at home, and there were a handful of domiciliary or home birth midwives and general medical practitioners who provided services for these women. General practitioners were able to claim fees from the Maternity Benefit Schedule without any cap for every service they provided, at considerably higher rates than domiciliary midwives, who were funded separately. Domiciliary midwives received funding from the Department of Health for three antenatal visits, labour and birth care, and 12–14 postnatal visits in the first two weeks post partum. As for all women and midwives at the time, they were required by law to be 'supervised' by a medical practitioner, but as home birth was frowned upon it took a brave doctor and a brave midwife to offer a home birth service, as they continually faced hostility from other health professionals.

Women accessed the maternity service mostly through the GP, who confirmed pregnancy and then directed the care in a variety of ways. Some provided the care themselves, although (according to the New Zealand Medical Association's submissions to the Maternity Benefit Tribunal in 1993) at best only about 20% ever offered a full maternity service. A larger number offered antenatal services to 28 weeks gestation before referring the woman to the hospital clinic, private obstetric specialist or a GP colleague who did provide full care.

'Teams' provided the hospital antenatal clinic service. An obstetrician, who delegated the majority of care to registrars or house surgeon trainees, led the teams. Midwives provided support to the medical team. There were very few instances of midwife-led clinics. Antenatal clinics were crowded and women waited hours to be seen. As was the case in most of the Western world, a woman could be seen by as many as 50 health professionals during pregnancy, labour, birth and the postpartum period (Flint 1986). Fathers and other family members struggled to be involved, and the information provided was heavily risk-averse and based on hospital and medical priorities.

Care was also delegated when a woman was in labour. If women were 'normal', midwives conducted the births regardless of who the client was booked under, and this was considered the midwife's role. Doctors could still claim the $300 'delivery' fee even though they were not present. In 1986, midwives, rather than GPs, medical trainees or obstetricians, conducted between 66% and 90% of normal births (NZCOM 1986). However, the rate and type of midwife-managed care depended on hospital protocols, the type of midwifery leadership, the number and availability of obstetricians and the influence that obstetrics had over service delivery. It seldom relied on women's wishes.

All midwifery care, regardless of whether it was for well, compromised or seriously sick women, was organised on a nursing framework, with midwives on rostered shifts for labour and birth and postnatal inpatient care. There was no postpartum midwifery care for women once they left the hospital. Midwives were not known to women and women had no way to access a known midwife. The exception was home birth, but only in the few areas where there was a midwife willing to provide a home-based service. However, in rural or small towns with primary maternity hospitals the care was more personalised, as the community were more likely to know each other. Women who wanted primary care from an obstetrician usually paid for that service and this remains the case today.

Secondary-level services—that is, services for complicated pregnancy, labour and birth or the postnatal period—were provided to women under the care of a hospital-based obstetrician. Although in all major cities and many provincial cities there was a parallel private obstetric system, once in the state-funded service a woman could not choose a known obstetrician, and in fact most women never saw the obstetrician who was deemed to be providing their care. Obstetric medical care was provided mostly by registrars

and house surgeons in training. The obstetrician leading the 'team' was not routinely present in the hospital, but 'on call' for registrars to contact if required. This continues in many hospitals today, although it is changing.

Medical education

By the late 1980s, many GPs had a postgraduate diploma in obstetrics, although that was not a legal requirement at the time, and some had no specific education in relation to normal birth, obstetrics or maternity care. The Diploma of Obstetrics was then a six-month course at a tertiary (teaching or base) hospital that focused on acute obstetrics, neonatal care and gynaecological services.

As the medical specialty of obstetrics developed and grew during the 1970s and 1980s, obstetricians slowly displaced the GP in maternity care, particularly in urban hospitals. By 1990 most GPs referred to obstetricians for operative procedures such as forceps and other specialised interventions, as did midwives. Rural GPs kept their obstetric skills for longer but they too eventually dropped out of intrapartum care. A 1990 report to the Canterbury Area Health Board found that GPs in Canterbury provided maternity care to an average of 10 women per year (Canterbury Area Health Board, unpublished minutes of meetings, 1990). While the style and method of service delivery may have been different, the scope of practice of most GPs was essentially the same as that of midwives by 1990. General practitioners have been reluctant to acknowledge this. Furthermore, general practice struggled to attract new graduates to maternity service provision. From 1990 onwards there was a decrease in the number of GPs providing maternity services. This exit of GPs from providing intrapartum care was a worldwide phenomenon and had similar causes in each country. Causes included doctors being less willing to provide 24-hour care (also manifested in the establishment of arrangements to provide care outside of 9 am to 5 pm, such as after-hours clinics and sports clinics) and the perception that general practice was a low-income, lower-status choice than some of the highly specialised options in medicine.

Midwifery education

Midwives' education prior to 1990 was based on a general and obstetric nursing qualification followed by the Advanced Diploma of Nursing (ADN) in which midwifery was a 12-week module. The ADN was theoretically focused on primary health and midwifery philosophy but struggled to provide clinical experience outside the tertiary hospital system (Pairman 2002). Most midwives were unhappy with their training and in 1986 an overwhelming 88% trained overseas (Guilliland 1994). Registered midwives were also disillusioned with their limited role, and increasing numbers left midwifery practice (Department of Education 1987). It had been clear to midwives for decades that midwifery education required a major review, and Sally Pairman's chapter in Papps (Pairman 2002) explains how midwifery education developed and responded to the consumer challenges and legal opportunities provided by the *Nurses Amendment Act 1990*.

The *Nurses Amendment Act 1990*

The environment in the late 1980s was therefore one of increasingly inappropriate education of the primary maternity providers (midwives and GPs), job dissatisfaction, hospitalisation or medicalisation of normal birth services, fragmented and impersonal care for the majority of women, and vociferous consumer dissatisfaction.

The first step the government of the day took to improve the situation was to strengthen the midwifery profession's ability to provide continuity of care. The *Nurses Amendment Act 1990* enabled midwives to practise all the competencies within a midwifery scope of practice. This meant that midwives could offer women the full range of antenatal, labour, birth and postnatal services from conception to six weeks post partum on their own responsibility and without the supervision of a doctor.

The Act also enabled midwives to access hospital beds—that is, to have admission rights for their clients, to prescribe if necessary and to claim for their services from the same government-funded Maternity Benefit Schedule (MBS) that funded medical practitioners. Importantly, the Act also established a pathway for an experimental education program to prepare midwives without first requiring them to undertake a nursing qualification.

Midwifery's right to claim from the MBS was challenged by the New Zealand Medical Association in 1993. The Minister of Health convened the Maternity Benefits Tribunal, and after a week-long legal hearing the Tribunal confirmed that midwives provided the same or similar services and outcomes for pregnant and birthing women as GPs. The Tribunal accepted the principle that if the work was the same then it must be of equal value and therefore midwives were entitled to claim the same payment as medical practitioners from the Maternity Benefit Schedule.

Professionalism

The 1990 Nurses Amendment Act (NAA) was the legislative vehicle for change, but importantly for midwifery its achievement enabled midwives to recognise that real change would only come if practice reflected the wish of consumers to have control over their birthing experiences. If the potential the NAA gave midwifery to develop as a profession was to be realised, fundamental change was required in the way midwifery education and practice was organised.

Midwifery had started to reclaim its identity from nursing in 1989 by separating from the Nurses Association and forming the New Zealand College of Midwives (the College). The College provided a specific focus for both midwives and women who wanted to influence the maternity services to be more women-centred and less medicalised. The College's foundation and its philosophy is that of partnership between midwives and the women for whom they provide services. Women consumers were welcomed as members of the College and were a part of all the College's decision-making structures from the beginning. The aim of the College was to replicate this partnership model within the maternity services, and consequently it was to

become a major player in the reformation of the maternity service.

The New Zealand College of Midwives

The College has a unique structure that reflects its beginnings in the women's health movement and its commitment to a partnership way of working. It is the professional organisation for midwives but it is also organised in a way that protects its professional standards and its place in ensuring that women have a safe and enabling maternity experience, without undermining its important roles as the voice of and support for midwives and midwifery. It does this by separating the professional, business and industrial functions into separate but parallel organisations. It is in effect an organisation of structural partnerships, each with their own autonomy and purpose but with midwifery in common. The College is the umbrella under which individual midwives and the profession as a whole are guided. It retains its primary functions of setting and maintaining professional standards, providing professional indemnity cover for practising midwives, and promoting to and providing New Zealand women with an effective and women-responsive midwifery service. It brings its professional voice to its other arms through representation on each structure. A midwife must be a member of the College in order to be able to access membership of the midwifery union (MERAS) or the business arm (MMPO) of the College.

Contemporary maternity services in New Zealand

The New Zealand health system

It is important to understand how the maternity system fits into the overall health services. Health services for New Zealanders are the portfolio of the Minister of Health. The minister is served by a Ministry of Health, which sets strategy and makes policy and funding decisions, which are in turn implemented by the 21 District Health Boards (DHBs) spread throughout New Zealand. Each DHB is funded on a population basis—that is, its funding reflects the numbers and make-up of its community of people, and each Board is responsible for ensuring that the population receives the best possible range, mix and types of services their funding allows. Each DHB must have Primary Health Organisations (PHOs) to manage primary care and coordinate appropriate referrals to the hospital services. People enrol with a PHO in their area if they wish to take advantage of the benefits a PHO can offer, such as subsidised prescriptions and doctors' fees, and coordinated care. Currently most PHOs are centred on GP and practice nurse services but it is envisaged that eventually all primary medical and health services, including maternity, will be coordinated through community-governed PHOs. At the time of writing, community (primary) maternity and well child services remain outside the management of the regional DHBs and the PHOs, and are funded nationally by the Ministry of Health. Other nationally operated services that affect maternity services in general include: the National Screening Unit, which directs policy for all the national screening programs (such as cervical, breast, HIV and antenatal screening); the New Zealand Health Information Service, which manages the health data provided by hospitals and health professionals (such as midwives and GPs); HealthPac, the payment arm of the Ministry, which pays health providers for services; the National Health Committee and the Health Workforce Advisory Committee, which advise the Minister on policy and workforce issues.

The maternity service

The maternity service in New Zealand takes an integrated and women-centred partnership approach. The service is placed within the primary health arena in recognition that birth is a normal life event and that women and their families should direct the care. The service specifications are explicit and within a set budget per woman. Standardised referral guidelines give the framework for consultation and transfer of care to hospital specialists if necessary.

Vision for the maternity service

The government has a vision for the maternity service. The Ministry of Health sets this vision out under Section 88 of the *Public Health and Disability Act 2000*.

> Each woman, and her whanau, will have every opportunity to have a fulfilling outcome to her pregnancy and childbirth, through the provision of services that are safe and based on partnership, information and choice. Pregnancy and childbirth are a normal life-stage for most women, with appropriate additional care available to those women who require it. A Lead Maternity Carer chosen by the woman with responsibility for assessment of her needs, planning her care with her and the care of her baby and being responsible for ensuring provision of Maternity Services, is the cornerstone of maternity care in New Zealand (Ministry of Health 2000, p 11).

The influence of New Zealand's pioneering women and midwives is obvious in this statement. The health system, including maternity, is overseen by a strong code of patient's rights and a culture of informed consent. In 2005 New Zealand has a free maternity service, with equity of access for women to all the levels of care required. These levels of care cover primary care in the community and hospital-based specialist or secondary and tertiary care. All levels of service cross the geographic boundaries of 21 different DHBs and numerous PHOs. See Figure 1.3 for the funding mechanisms of New Zealand's maternity services.

All women can have an LMC to provide and coordinate their maternity care, develop a care plan with them and attend their labour, birth and postpartum period of up to six weeks. The LMC service is a primary health one and therefore is provided mainly in the community. Most antenatal care is in women's homes or in community clinics. If not birthing at home, the majority of women in the first 12 to 48 hours following birth have their postnatal care in the hospital or birthing unit but then receive care at home for four to six weeks. This primary health service is centrally funded by the Ministry of Health, and LMCs claim directly from the Ministry for their service fees. When a woman requires additional medical or hospital

care her LMC can choose to provide the care herself, arrange additional medical or other specialist carers but continue to provide midwifery care, or transfer the care to a hospital team including obstetricians, midwives and paediatricians.

Place of birth

New Zealand women have a variety of options as to where they can give birth. Although there are no universal booking criteria for place of birth, the national consultation and referral guidelines provide a screening tool to assist women to make appropriate choices. The maternity facilities or hospitals and their associated services are funded separately from the primary LMC budget and this funding is managed by the DHBs rather than the Ministry.

Birth at home is a mainstream government-supported and funded option. The LMC is almost always a midwife. While many women are supported by consumer-led home birth associations, the majority of women today who choose home birth do so as a natural matter of course and no longer view it as a 'fringe' option. Some 6% to 10% of women have their babies at home.

There are 64 primary birthing or maternity units throughout New Zealand, most located in rural or provincial towns, although women in most big cities also have access to a primary birthing unit either via a DHB or at a privately owned but publicly funded enterprise. A primary unit provides in-house midwifery services for labour, birth and immediate postpartum care. They have no access to on-site obstetric and medical specialists. Approximately 15% of births in 2003 were in primary units. There is an ethnic difference in usage of primary, secondary and tertiary facilities, with 40% of Maori women giving birth in primary facilities—twice the national average (Ministry of Health 2004).

Secondary facilities or hospitals are generally in provincial towns or the smaller cities. The secondary service provides some additional specialist obstetric and midwifery services for women experiencing complications, but transfers women and babies with intensive care needs to tertiary facilities.

There are five tertiary facilities in New Zealand. While all services are provided, the tertiary hospitals are specialists in high-technological services such as neonatal intensive care, infertility and high-dependency obstetric care.

Section 88, *Public Health and Disability Act 2000*

As discussed above, the maternity service framework in New Zealand follows a women-centred continuity of care model. Section 88 of the *New Zealand Public Health and Disability Act 2000* is the legislative framework that outlines the model of care and gives notice of the terms and conditions for the provision of maternity services. The Ministry of Health sets these terms, conditions and fees after consultation with the New Zealand College of Midwives and the New Zealand Medical Association.

The Maternity Advice Notice, or Section 88 as it is referred to, provides a nationally consistent set of service specifications and is the practice framework for midwives, GPs, obstetricians, paediatricians, anaesthetists and radiologists. It includes 20 items that cover issues such as arrangements for antenatal care, health promotion, personal and cultural safety, education, referral, screening and planning. It does not detail or describe specific aspects of care or practice but provides a generic blueprint for service delivery. The New Zealand College of Midwives provides a detailed framework for midwifery practice (NZCOM 2005a). This includes a statement of philosophy, definition of midwifery scope of practice, a code of ethics, detailed standards of practice and decision points for midwifery care.

The Maternity Advice Notice in general:

- specifies all aspects of services to be provided by LMCs—it outlines all expected services from the woman's first contact with the maternity services until discharge and referral of her baby to the well child services. If the LMC cannot provide any aspect of care, they must ensure that others provide the care.
- identifies quality indicators and processes—the notice expects all LMCs to take part in professional quality assurance mechanisms such as NZCOM's Midwifery Standards Review.
- sets out prices and payment rates—the Notice has a comprehensive and integrated pricing structure that recognises such things as miscarriage, referral, transfer of care, place of birth, and rural and travel requirements.
- provides a set of referral guidelines—these guidelines were drawn up by all maternity providers and professionals in 1996 and are a comprehensive set of guidelines on conditions/circumstances that require referral based on a three-way conversation between the woman and her family, the LMC and the obstetrician or specialist to whom she is being referred or transferred. A Level One referral is optional; a Level Two referral requires the LMC to recommend to the woman that she consult a specialist; and a Level Three referral requires an LMC to recommend to a woman that her care be transferred to the secondary or tertiary service.
- specifies a generic access to hospital facilities agreement—this is an agreement between the hospital facility and the LMC on the conditions under which the LMC can access the hospital for their clients.
- provides claim form templates—LMCs must provide information on the service they provided, including outcomes, in order to claim their fees.

Women and their families have a range of LMC choices, including the following:

1. *Self-employed or independent midwife*—midwives specialise in attending women and their family for 'normal' or physiological pregnancy and birth. They can provide all care during pregnancy, labour, birth and post partum. Care may be in the woman's home or in the midwife's clinic rooms. Midwives can also provide care for women with complicated maternity conditions alongside a specialist in either the public or the private health system.
2. *Family doctor or GP*—GPs also provide care for normal pregnancy and birth and for some existing medical

BOX 1.2 Section 88 specifications

The service specifications of the Section 88 Notice provide that:

- LMCs receive written authorisation from the Ministry of Health to provide maternity services, as authorised practitioners, in order to be able to work under the conditions of the notice.
- Payment is made to authorised practitioners via Healthpac, the business unit of the Ministry of Health, which administers payment for primary care services.
- Each women chooses an LMC, who works with the woman to assess, plan and provide her primary maternity care, coordinate and arrange access to additional care as required. This allows for continuity of carer throughout the maternity care episode.
- An LMC can be either a midwife, a GP with a diploma in obstetrics, or an obstetrician.
- Care is from the woman's registration with an LMC to four to six weeks post partum according to clinical need. There are four modules of care, with the expectation that all four will be provided by the same carer.
- In the first trimester prior to registration with an LMC and for all consultations with obstetric specialists, the service is funded on a fee-for-service basis.
- After the first trimester, the payment structure is modular and based on: the second and third pregnancy trimester; labour and birth; and postnatal care. Each module of care is capped at a set price but there are a variety of mechanisms to enable LMC work to be recompensed if it falls outside these module definitions.
- Childbirth education other than the usual information provided by the woman's individual LMC also has a separate budget, and a variety of educators contract with the Ministry to provide this service.
- A woman can only have one LMC at a time but there is provision for her to change at any time.

The choice of LMC depends to some extent on where a woman lives, as the full range of options is not available in all areas. There is a nationwide government-funded telephone service that provides women with information on LMCs available in their area. This is the 0800 MUM2BE number. The College also provides this service nationally. A full copy of the Maternity Advice Notice is accessible from the Ministry of Health website (www.moh.govt.nz) and more information about midwifery practice in New Zealand is available from the NZCOM website (www.midwife.org.nz).

problems that may complicate pregnancy, such as diabetes or asthma. General practitioners provide care in their practice rooms/surgery, attend labour when needed and are present for the birth with an independent midwife or a core/staff midwife. They share postnatal care with hospital- or self-employed midwives.

3 *Private obstetrician*—obstetricians specialise in complications during pregnancy and birth but can also provide medical care for women experiencing a normal pregnancy. They attend labour as needed and are present for the birth with a core/staff or self-employed midwife. They share care with hospital or self-employed midwives. Care provided by private obstetricians usually involves a cost to the woman.

4 *Hospital LMC midwives*—some maternity hospitals offer primary LMC services. They do this in a variety of ways, including:
   - 'Know Your Midwife', sometimes referred to as KYM, Domino, continuity of care, or one-on-one, schemes. All or most visits will be with the same midwife, who will also attend the labour, birth and postpartum visits in hospital and at home.
   - midwifery teams, where women receive care from a small team of midwives, generally no more than three or four, but possibly up to six. The woman usually gets to meet them all. Team care has decreased over the years as women have become accustomed to one-on-one care from a known LMC.

5 *Hospital specialists*—hospital specialists provide care for women whose pregnancies and births involve complications. Other hospital staff (such as midwives, registrars and house surgeons) will be involved in the care. Pregnancy care is usually provided by the hospital team at hospital antenatal clinics but is often also in collaboration or a shared care arrangement with the LMC midwife or GPs in the community, particularly if the woman lives rurally. Care during labour and birth is provided by hospital staff or an independent midwife under the supervision of the specialist who is on duty at the time.

6 *Core or hospital staff midwives*—if women are having their babies in a hospital with their own LMC, their LMCs all rely on the core midwife to facilitate the experience for them as they move from a community to hospital service. The core midwife is on rostered duties for either 8 or 12 hours depending on hospital employment practices. She provides support and back-up for the LMC midwife and full midwifery care for the women with doctor LMCs.

LMCs have a range of experience. Some will continue to provide care in all situations and some will transfer the care of the women to the hospital obstetric team because of the women's need for more intensive obstetric care. The core midwife can then provide the secondary or tertiary midwifery services for those women, with the LMC midwife remaining in a support role.

Midwives have for several years consistently represented over 78% of the LMCs in New Zealand. As LMCs they have a contractual relationship not only with the women for whom they provide care, but also with the Ministry of Health, which provides payment for the services provided under the Notice.

In order for midwives to provide care as LMCs within the continuity-of-care model, and meet the conditions of the Section 88 Notice, most choose to work as self-employed

practitioners. Midwives generally work in with a midwife partner who provides back-up, and these pairs of midwives often work within larger group practices for further collegial support.

Midwifery practice management systems

Because the maternity service in New Zealand is fully funded by the government, the midwives and doctors who provide the service require a system to claim their fees. The Ministry of Health, via Health Pac, provides a system for all medical benefits claims, including maternity. However, it is a very big organisation and claiming is complex. As a result the midwifery profession and some individual businesses have developed a more midwifery-focused payment system. The College practice management system, the Midwifery and Maternity Provider Organisation (MMPO), is the largest of these and is underpinned by the belief that payment systems should be integrated with quality control mechanisms.

The Midwifery and Maternity Provider Organisation (MMPO)

The concept of the MMPO was initiated by the College and formed in 1997 as a separate limited liability company with its own governance structure. The purpose of the MMPO is to support the business side of midwifery and it is essentially a practice management system for midwives who carry caseloads and provide continuity of care based in the community. In 2005 there were 550 midwives throughout New Zealand using this service and it is now the largest non-government maternity provider in the country. Some midwife members are employed by District Health Boards or Community Trusts and the MMPO also manages the midwife claims for these employers. However, most members are self-employed and the MMPO manages all their fee claims from the MBS and deals with Health Pac directly on their behalf.

The claiming system works from a set of maternity notes held by each woman that the midwife uses for day-to-day care. All data is in triplicate, so one copy remains with the woman as her birth story, one is kept by the midwife as her clinical and legal record and the third is sent to the MMPO for fee-claiming purposes and for clinical data entry into the NZCOM midwifery database. Increasingly, midwives are choosing to enter their own data electronically. Midwives receive their fee payment together with a report on their clinical outcomes and statistics, which they take to their annual Midwifery Standards Review.

The New Zealand College of Midwives contracts the MMPO to enter the clinical data for its midwifery database. It then uses the database to produce a national report on midwife practice outcomes. Any themes or issues that result from the analysis of the aggregated and anonymous data form the basis of the College's continuing education program.

Other practice management or fee-claiming systems

There are other midwifery or maternity provider organisations that provide business services to self-employed midwives. In Auckland, New Zealand's largest city, there are alternative options. The Mothers and Midwives Association (MAMA) is a consumer and midwife organisation that also provides the College with midwife outcome data for the national database. South Auckland Maternity Collective Association Ltd (SAMCAL) is a business organisation directed by midwives and obstetricians providing their members with payment management services. River Ridge and Waterford Birthing Centres in Hamilton are midwifery owned and run businesses that also operate maternity birthing units. There are also privately owned but government-funded maternity-led birthing units scattered throughout the country that both employ midwives and give access to self-employed LMCs. Birthcare in Auckland, and Huntley and Charlotte Jean in Alexandra, are examples of early entrepreneurial thinking that established midwifery-led units for women to access midwifery care in a primary health setting.

Midwifery workforce

The midwife of today can choose a range of working roles. She (over 99% of midwives are women) can use her full scope of practice and accompany the woman into whatever service she requires wherever she requires it. As an LMC she can provide primary, secondary and tertiary midwifery services (often to the same woman) if she feels she has the capability.

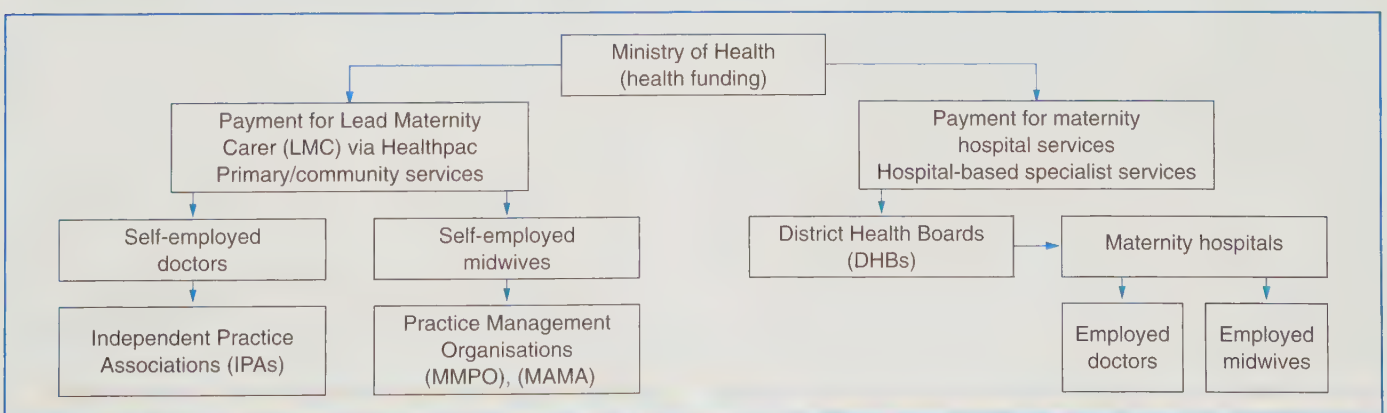

Figure 1.3 Funding mechanisms for New Zealand's maternity services

However, she has the choice of which level of care she provides, and can transfer care or ask for support if necessary. She can provide birthing support to women in hospital and/or home births across DHB and PHO boundaries. The hospital or core midwife is the essential link between the primary and secondary interface and in the LMC partnership with women clients. The core midwife provides advice and consultation to midwife LMCs when extra care is required, and full midwifery services for women with medical LMCs and secondary care needs.

This integrated service is the result not only of the professional changes enabled by the NAA as discussed above, but also the health reforms and the way in which services were funded. Understanding the funding and contractual nature of the service is essential to understanding why midwives succeeded in giving women and midwives the service they have today.

Midwifery was New Zealand's first workforce 'redesign'—that is, the first non-medical discipline in New Zealand to get practice autonomy, full prescribing rights, referral to diagnostics and access to hospital facilities and government fees for services. Midwives have many work options. In 2002, Nursing Council (which regulated midwifery prior to 2004) workforce statistics stated that 52.9% of midwives reported working in core midwifery, 39.9% in caseload midwifery, 2.9% in administration and management, 3.3% in education, 0.6% in professional advice/policy development, and 0.4% in research (Nursing Council of New Zealand 2004). There were 2107 actively practising in midwifery in total for that year. Although only 24% of midwives identified as self-employed to the Nursing Council, claiming patterns in 2002 to the Ministry of Health's payment organisation (Health Pac) for service fees identify that some 42% of the midwifery workforce were self-employed for at least some of their working time (NZCOM 2005b).

These 42% of midwives provided LMC services for 73% of birthing women in that same year. General practitioners provided LMC services for 9% of women and obstetricians provided 14% (NZHIS 2004). This is a complete reversal of the workforce picture since the 1980s, where doctors were reported as the main provider of maternity care. In 2003 the workforce picture was still changing and midwives were 78% of LMCs, GPs 7.9% and obstetricians 7.8% (NZHIS 2005). In 2005 the impression was that even more midwives are now the LMC, and as a result midwifery is under considerable stress, as midwife numbers have not increased to keep up with this phenomenal growth in demand (NZCOM 2005b). Furthermore, the fees and structure in Section 88 have not been reviewed for three years and therefore none of this changing pattern of workloads has received remuneration or recognition.

Industrial representation

Since 2003 midwives have had their own midwifery union, the Midwifery Employee Representation and Advisory Service (MERAS). The formation of the union enabled negotiation specifically for midwifery-centred services and in 2005 the union had its own collective agreement for midwives only. This agreement was a national multi-employer collective agreement (MECA) involving all DHBs. Prior to this, employed midwives relied on the Nurses Organisation to negotiate on their behalf under a variance to the collective nursing agreement. The MERAS presence in negotiations immediately influenced the way in which the midwifery workforce was seen and described, as it insisted on a more professionally based agreement reflecting standards of practice and quality assurance policies.

Outcomes of midwifery care in New Zealand

For 15 years, tens of thousands of New Zealand women have had a midwife as their primary caregiver. Contrary to the expected view and much to the dismay of midwives, this continuity of midwifery care model doesn't appear, on the face of it, to have stopped the increasing caesarean rates experienced throughout the Western world. It is not clear why this is so but there are several theories. Six possibilities are proposed below.

1. In 1996, just five years after midwives had gained autonomy, the model of maternity care was changed at a national level to introduce the LMC model. These changes were introduced without any supportive structures provided to the midwives, who were expected to completely change their way of practice from a tertiary/secondary facility-based service to a community-based, women-centred model. Consequently, some midwives simply moved their hospital practice habits into the women's homes.
2. The public was given very little information or education on the new systems—both the implications of midwifery autonomy and the structure and functioning of the LMC system—which would have boosted public confidence in the changes.
3. While midwifery was given access to claiming fees for service from the same schedule as doctors, unlike general medical practice (a similar model of practice with which it is reasonable to compare) midwifery did not receive postgraduate or continuing education funding, information technology (IT) grants or practice management system support. Nor were there any subsidies for locum relief or allowances for rural inequities.
4. Hospitals used the new LMC system to cost shift expensive secondary care services onto the community LMC without any supportive systems for collaborative care.
5. As more midwives in the community took on normal births at the request of women, the obstetrician's private source of income from these women started to decrease. Even GPs, who had previously enjoyed largely uncontested dominance of maternity care, particularly antenatal care, also started to lose clients as women chose midwives as their LMCs.

6 Probably most importantly, relationships between GPs, obstetricians and midwives were deliberately set up to be in competition under the newly competitive health environment of that time, and without any thought about the effect this would have on service delivery. Hostility from doctors was directed at midwives as the 'newcomers'. This had the effect of compromising doctors' trust in midwives' opinions and referrals. There was an obvious conflict of interest when, on the one hand, obstetricians lost clients to midwives and on the other hand, midwives consulted with obstetricians over some of those same women. This made working relationships stressful. Stressful environments influence decision-making and clinical judgement, so it is not surprising that all practitioners resorted to the use of technology (Degeling et al 1998).

In addition, the way in which outcome data are published in New Zealand does not allow for examination of the long-term impact of midwifery's primary and public health focus. Intervention rates are presented as rising annually but trends over several years are not explored. When all data are examined together, a different picture emerges. For example, there was a 5.2% increase in caesarean sections between 1988 and 1996 and before the advent of LMC care. Following the introduction of LMC care, the rise to 2003 (the latest data available) is slightly higher at 6.2%. However, the largest percentage increase in caesareans was likely to have been even earlier, between the 1970s and the 1980s. St Helens Hospital in Auckland published its caesarean section rates for the Jubilee celebrations in 1981, and these showed that from 1970 to 1981 there was an increase of 11.2% (Donley 1986). Obviously this rise had nothing to do with midwife LMCs, since there were none.

It is reasonable to assume from New Zealand's history that the rising caesarean rate cannot be laid at midwifery's door alone. It is also reasonable to assume that midwifery today may have had an influence in keeping intervention rates contained. In the debate on rising rates of caesarean section, commentators have failed to notice that over the past few years intervention rates in other areas have been contained or decreased (Ministry of Health 1999a,b; NZHIS 2005). Instrumental vaginal births have decreased from 11.8% in 1988 to 9.9% in 2003; inductions have decreased from 22.1% in 1997 to 20.1% in 2003; and epidurals have only marginally increased from 23.3% in 1997 to 24.4% in 2003 (MOH 1999a,b; NZHIS 2005). As discussed previously, exclusive breastfeeding continues to improve and immunisation rates at six weeks are high.

The Maternal and Newborn Information System (MNIS) has been collecting data on LMC provider type since 1999 (Ministry of Health 2001; NZHIS 2003, 2004, 2005). The data show that where New Zealand's intervention rate has increased, it has increased for all provider types. Furthermore, the outcome data are highly variable from region to region—further evidence that birth outcomes have multifactorial influences (NZHIS 2005). All published data where LMCs are identified by profession both prior to and post 1996 confirm that midwifery outcomes are similar to or better than those of GPs (Ministry of Health 1999, 2001; NZHIS 2003, 2004, 2005; National Women's Hospital 2000; Wellington Women's Hospital 1998).

Ministry of Health and DHB data on outcomes also indicate continuing improvement in the following:

- decrease in perinatal mortality
- significant decrease in SIDS
- decreased antenatal admissions for serious complications
- sustained decrease in admissions of very sick babies to neonatal intensive care.

Furthermore, recent trend research from 1980 to 2001 confirmed markedly decreased rates of small for gestational age babies for Maori, Pacific Island and lower socio-economic groups of women (Mantell et al 2004). Although the gap between Maori and Pakeha baby outcomes in relation to prematurity remain unacceptably large, it appears that Maori rates have improved. Teenage pregnancy is slowly decreasing, and outcomes for young Maori women have improved over

Clinical point

In 2003, birth rates in New Zealand were as follows:

	Rate (%)		
Type of birth/procedure	**LMC midwife**	**LMC GP**	**LMC obstetrician**
Normal birth	73.5	70.5	52.7
Stillbirth		(identical rates)	
Total caesarean	16.8	17.6	31.4
Forceps ventouse	8.6	11.4	15.1
Epidural	22.9	31.3	43.4
Episiotomy	9.5	17.0	18.0

(Source: NZHIS 2005)

TABLE 1.1 Comparative rates of caesarean section and unassisted vaginal birth between primary units in New Zealand and overall hospital rates for New Zealand and Australia, 2002

Hospitals	Unassisted vaginal birth (%)	Caesarean section (%)
New Zealand primary* (15% of births 2002)	71.0	8.03
Overall national hospital rates		
New Zealand (n = 53,039)	67.7	22.7
Australia (n = 250,758)	61.7	27.0

* Excluded St George Private Hospital New Zealand.

Critical thinking exercise

1. How can women's voices be heard within the maternity service in general and by the midwifery profession specifically? What influences do you think society itself brings to bear on the way birth is experienced and midwifery is practised?
2. Do you think the way maternity services are funded can influence the practice of midwifery? If so, how can we ensure this influence is used in a positive way? Imagine you are a self-employed midwife about to set up practice. What can you do to ensure you utilise your income potential while providing optimal care?

these years also. Maori, young women and women from lower socio-economic groups are more likely to choose a midwife for their LMC (NZHIS 2003). Women's satisfaction with maternity services has increased over three national surveys (MOH 1999b, 2003), as has the intensity of that satisfaction.

The intangible effects of these positive experiences on women are hard to quantify. It is not unreasonable to postulate that healthy, informed and happy women are also empowered women and that empowerment has a positive influence on both women's mothering and society in general (Guilliland 2005).

Health funding: Australia and New Zealand

Some similarities exist today between the health systems of Australia and New Zealand. For example, both countries meet the cost of publicly funded health through taxation rather than social insurance; government provides for both secondary and tertiary care. General practitioners act as 'gatekeepers' to control access to general medical secondary services, and specialist staff work in both the public and the private sphere (Davies & Hindle 1999). However, major differences have also emerged between Australia and New Zealand in the funding of the health systems, and these have influenced the way in which maternity services can be provided.

New Zealand has a unique constitutional relationship between the Crown and the Maori people—the Treaty of Waitangi, signed in 1840. No such treaty exists in Australia between the Aboriginal and Torres Strait Island people and the Crown. The Treaty of Waitangi has, over time, fostered innovative approaches to healthcare, resulting in greater autonomy for Indigenous people over their own healthcare and lowering disparities in health status (Davies & Hindle 1999). Davies and Hindle (1999) outline five other important differences:

- New Zealand has a unitary national system of funding, whereas Australia divides responsibilities between the state and Commonwealth governments.
- From 1993 New Zealand distinguished between purchaser and provider agencies but this changed in 2000, when removing this split between purchaser and provider was one of the focal points of that year (Devlin et al 2001).
- Private health insurance in New Zealand is not subsidised or regulated by government, as it is in Australia.
- New Zealand makes greater use of co-payments, in particular with respect to GPs. However, there is no provision for co-payments in maternity, except for private obstetricians, who can charge women in addition to the government maternity payment.
- New Zealand's publicly owned hospitals are constrained in their ability to deliver services to private patients.

Whether by virtue of its isolation, or the fact that it has a smaller, less cumbersome economy than Australia without the two-tier confusion of state and Commonwealth divisions in funding, New Zealand embarked on cutting-edge health reform 20 years ago. It led the charge in forging market-based health reforms in the 1980s, and also led the way in rejecting the same model of economic rationalism in health (Ham 1997b; Hornblow 1997; Malcolm 1998). Over the past decade, New Zealand's health sector has undergone a series of structural reforms and rollbacks: first an area health board system, then a competitive internal market system with regional health authorities and crown health enterprises (1993–96), a centralised purchasing system (1997–2000), and from 2002, a system of DHBs.

Health funding in Australia

A 1999 World Health Organization (WHO) report suggested that Australia was going the wrong way by limiting government

funding of healthcare in favour of 'user pays', by retaining fee-for-service payment of providers, and by promoting markets in the private sector (WHO 1999b). Many of the leaders in health policy in Australia are also highly critical of Australia's stance on health funding (Baum et al 1998; Deeble 2002; Duckett 1997; Gray 2004; Leeder 1998; Nelson 1998; Smith 1998a, b).

According to one well-known health economist, Australia's health sector is characterised by government intervention limiting and constraining, through regulation, the size and behaviour of the market. Transactions are characterised by asymmetrical information, and asymmetrical power. Service provision is dominated by politically effective individuals and organisations, and private health insurance is 'bizarre' (Richardson 2002, p 10). The former Dean of Australia's largest medical faculty agrees when he claims that: 'The decision to subsidise all private health insurance may have other negative effects. It is plausible that the Commonwealth will seek to recover the billions it pays for private health insurance by decreasing the support it offers public hospitals' (Leeder 2002, p 7).

In addition to undermining the extent to which Medicare covers the costs of services, the system has generated significant health inflation since 1999, and the policies that are in place ensure a continuation of this trend. The indications are that Australia is on the road to becoming one of the higher spenders among OECD countries, compared with being an average spender a decade ago (Gray 2004).

Medicare is an insurance system. It is not a health delivery system. Over time Medicare has come to be seen by the public, politicians and providers as encompassing *everything* in relation to Australian healthcare—in other words, that it *is* the whole healthcare system. It is a financial arrangement for ensuring universal access to services on equitable terms. It does not *provide* those services—that is the job of the health services themselves and the health professionals (Deeble 2002).

In single-payer systems, governments generally have the capacity and the will to regulate and control budget outlays and to keep overall costs under control. In multi-payer systems, no one is in charge and no single agency has the power to control total expenditures. Funders are usually interested in their own costs, not the costs of the system as a whole. Under these circumstances, the easiest way of reducing costs is to shift them to other payers. Cost shifting replaces cost control, with expensive and regressive results (Gray 2004).

The situation in 2005 is continuing to cause concern, as illustrated on the front cover of the *Australian Doctors Reform Society Journal* 2005 (see Fig 1.4).

A national review of the role of primary healthcare in health promotion in Australia concluded that in areas of effectiveness, efficiency and equity of disease prevention and health promotion in Australia, there have been significant limitations caused by the lack of a more coherent, adequately resourced primary healthcare sector (NCEPH 1992). The same review found the 'four basic principles of primary health (collaborative networking; consumer and community involvement; a balancing of healthcare priorities between the micro and immediate on one hand, and the macro and long term on the other; a partnership relationship with the secondary and tertiary sectors)' to be seriously lacking in primary care in Australia (Baum et al 1998).

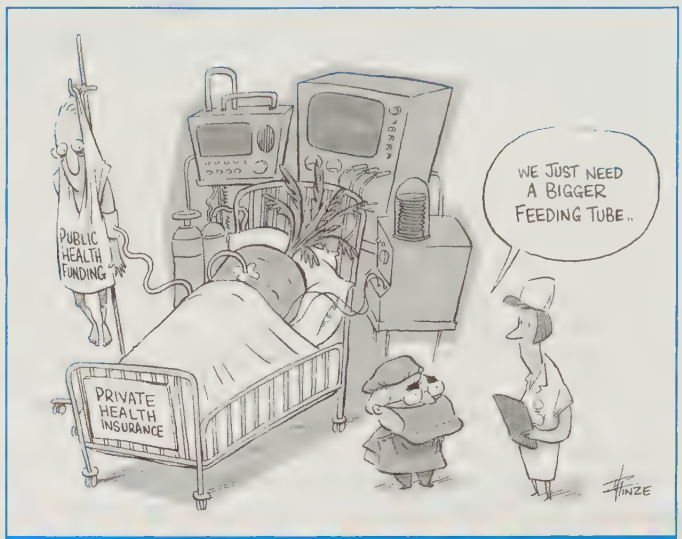

Figure 1.4 Cartoon depicting the state of health funding in favour of private health in Australia, 2005 (Doctors Reform Society 2005) © Hinze/Scratch! Media (www.scratch.com.au)

The problems facing Australia in the new millennium were outlined by the Director General for Health in New South Wales in Sydney in July 1999 (Reid 1999), who stressed that his views applied to Australia in a general sense. The eight major issues in his address are summarised below in an effort to give an overview of the extent of the problems facing Australia today. Seven years later these issues are as important and as urgent as they were in 1999:

- providing a better balance between acute care, community care and prevention. In changing the focus from supply issues to demand benefits, a long-term efficiency in health spending would be guaranteed.
- addressing the neglect of three groups within the population, namely Aboriginal people, people with mental illness, and rural and regional communities. This would involve trying to decrease the widening gap in health status between the Indigenous and non-Indigenous populations, reducing the rate of suicide of the young, and funding and a level of commitment by the public sector to give a degree of certainty to the continuation of appropriate services to rural and regional areas.
- integrating healthcare services. This can be improved by linking various service providers.
- refocusing attention on the effectiveness of care and assessing the most effective way of providing quality in healthcare. This involves the development and use of clinical indicators, clinical governance, and credentialling and accreditation processes.
- improving the funding arrangements in Australia. Currently, funds are spent more on the basis of functional responsibility than true need. To address

the problem of cost shifting between states and Commonwealth, a single pool of dollars for health is called for.
- clarifying the role of private health insurance, taking account of the increased Commonwealth investment, the real ability of people to choose within the system, and the increasing demands being placed on public hospitals
- improving workforce planning, addressing in particular restrictive trade practices, and the undersupply and multiskilling of health professionals
- managing the location, range and mix of tertiary services, and the management and monitoring of the introduction of technology (Reid 1999).

In 2005 declining bulk billing through Medicare and increasing user charges had serious implications for access and equity, while current policies ensure that health costs continue to outpace inflation. While Australian policy makers and interest groups argue counterproductively about financing channels, overseas debates have moved to the question of long-term sustainability. The central challenge for the health systems of all OECD countries is how to provide high-quality, appropriate healthcare to all citizens at an affordable price in the face of rapid technological advance. Radical reforms, involving much higher levels of public management and control, are being suggested (Gray 2004).

The split between Commonwealth and state and territory health funding

In 1946 the Australian Constitution was amended to enable the Commonwealth to provide health services and benefits without changing the status of the states and territories in this regard. Consequently, two levels of government have overlapping responsibilities in the area of funding healthcare. The states and territories are responsible for: delivering public health services; regulating health professionals; public acute and psychiatric hospital services and community services such as school health, dental health, maternal and child health, and environmental health programs. The Commonwealth funds most medical services out of hospital via the Medical Benefits Schedule (MBS) and Medicare, and the Pharmaceutical Benefits Schedule (PBS) in addition to most health research. It also finances and regulates care for older people and the disabled.

In 1999 a non-means-tested rebate of 30% of the cost of private health insurance premiums was introduced in Australia. The initial cost to the public was $1.6 billion, an amount that could have financed approximately 10,000 new public hospital beds. Unfortunately, this measure failed to significantly increase private health insurance coverage. In fact, by March 2000, the insured population had increased by only 2.1% (Gray 2004). (Private health insurance can cover private and public hospital charges and a portion of medical costs for inpatient services. Private insurance can also cover allied health and paramedical services as well as some aids and appliances.)

In July 2000, the Commonwealth Government made a further bid to encourage Australians to take out private health insurance, running a public publicity campaign called *Run for Cover*, at a cost of $8.7 million. It was suggested that people joined up because they were afraid their access to healthcare would be jeopardised if they did not have private insurance (Deeble 2002). Also, there was to be an economic incentive of a 2% tax penalty for those who did not join. This campaign for Lifetime Health Cover (LHC) increased private insurance

TABLE 1.2 Medicare spending increases from 2003–2004 after the introduction of the Commonwealth Government's Medicare 'safety net'

	Spending Jul–Sep 2004 ($ m)	Rise on same quarter 2003 (%)
TOTAL Medicare	2,440.0	12.8
Professional attendances		
General practice	1,120.0	6.1
Therapeutic procedures		
Specialist doctors	411.0	15.1
Radiology	373.0	9.7
Pathology	380.0	11.4
Obstetrics	32.1	71.1
Ophthalmology	28.5	14.8
Orthopaedics	26.4	6.9

(Source: Quinlivan 2004, *BRW*, 11–17 November, p 26; based on Australian HIC data.)

coverage by 50% to 45.8% of the population by September 2000 (Gray 2004).

In an effort to increase the public uptake of private health insurance and promote bulk billing rates in Australia, the Commonwealth Government introduced a series of policy changes beginning in 2000. (Bulk billing is a foundational pillar of Medicare because it is the mechanism through which citizens can access services without being required to pay at the point of service.)

In August 2000, 'Gap' insurance for in-hospital medical services was reintroduced. And in March 2004 the Medicare 'safety net' came into being. This was designed to protect the public from heavy non-hospital out-of-pocket health costs after these costs had reached $300 per annum for low- and middle-income families and $700 per annum for high-income earners. It was also intended to increase the rate of bulk billing. When yearly costs had reached the levels stated above, the government was to pay 80% of the gap between the normal Medicare rebate refund and the actual medical care fee. This 'safety net' policy was so badly designed and so severely misused by doctors that in November 2004 the Health Insurance Commission (HIC) reported the blowout in expenditure shown in Table 1.2. Note the extraordinary increases in Medicare spending in relation to obstetrics.

Health funding in Australia is a very complex business, due to several factors. There is a level of Commonwealth funding and a level of state funding. Within these two funding systems there is the partial funding of private health services, as described above. Figure 1.5 is a simplified representation of the current Australian model for health funding.

Funding midwifery

Midwifery in Australia is similar to midwifery in New Zealand pre-1990, although a few 'cracks' are beginning to appear and small examples of system change are beginning to emerge. Australia's funding model, outlined above, affects the development of midwifery services in the following ways:

- The only access to funding for midwifery is through each state acute health services budget (except the WACMP; Thiele & Thorogood 1998, 2001 (see below), and the Northern Women's Community Midwifery Program, Adelaide, SA (Church & Nixon 2002)). This means that women don't have the opportunity to choose a midwife as their LMC as they do in New Zealand. Where continuity-of-care models have been implemented in Australia, the area health services may draw up an annualised salary agreement for the midwives in the Midwifery Group Practices and their funding continues to come out of the acute services budget for public hospitals. In addition to this, there is not an agreed 'salary' for midwives offering these midwifery models of care, and even within states the salary package differs in terms of 'on call' costs between 25% and 29% both between and within states (SA and NSW and within NSW). There are also different levels of base rates, again between and within states. For example, some Midwifery Group Practitioners are paid a base rate for Level 8 midwifery and others a Clinical Midwifery Consultant base rate (NSWNA 2005, personal communication).
- The governments in Australia do not recognise women's choice of home birth and therefore there is no rebate or subsidy that these women can access. In general, this service saves the government at least $3000 per birth; however, women who wish to have a home birth pay

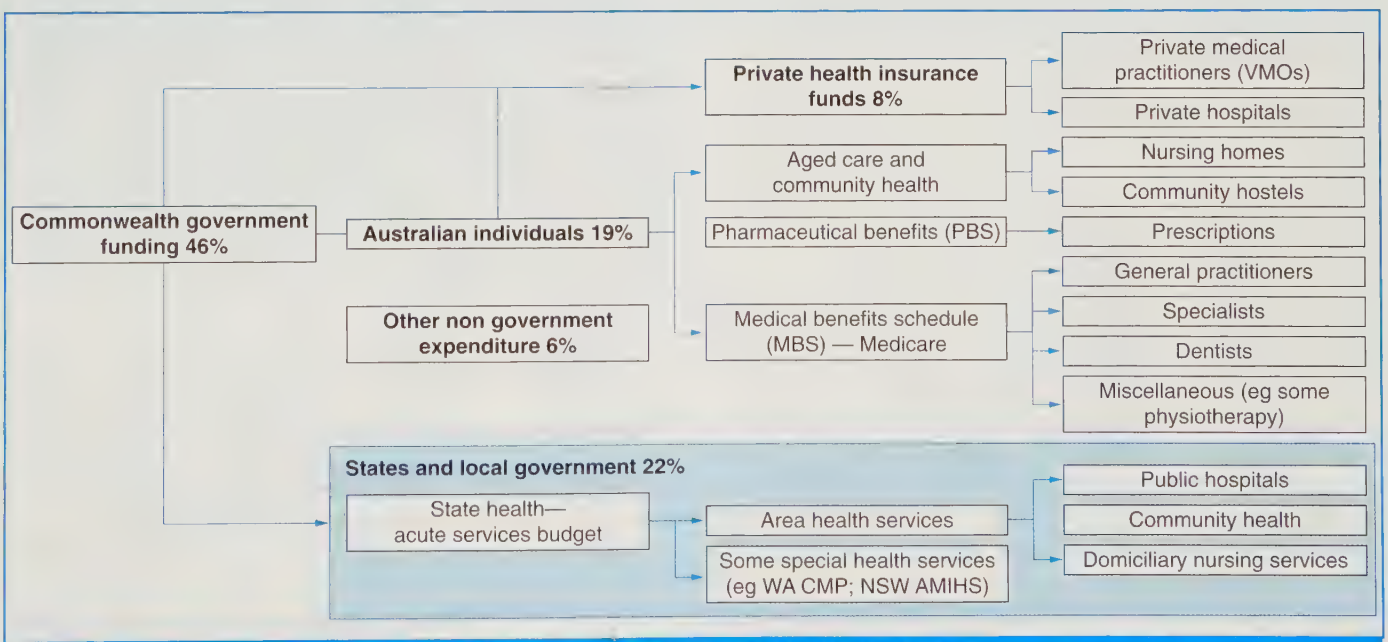

Figure 1.5 A 'simplified' representation of the current Australian model for health funding

for the privilege out of their own pockets. Some private health insurance companies are currently reviewing their policies to possibly include home birth within the next couple of years (private health insurance companies 2005, personal communication).

- Professional indemnity cover for independently practising midwives was lost in July 2001. This means that home birth is offered by midwives who do not have access to professional indemnity cover. This situation may change with the introduction of home birth within publicly funded Midwifery Group Practice Models. (There are a small number of home birth services available in the Northern Territory, Western Australia and South Australia, and a publicly funded home birth service commenced in Sydney at the time of writing in 2005.)

The Community Midwifery Program in Western Australia (WACMP) and the Northern Women's Midwifery Program in Adelaide, South Australia, have both struggled to cement a secure funding source with the health departments who fund them in those respective states.

Urgent reform is required in Australia to allow midwives to access Medicare provider numbers, so that women can choose for themselves to have a midwife caregiver for pregnancy, labour and birth. So far the negotiations for Medicare provider numbers have hit huge resistance from all sectors of the Australian medical profession. Until midwives in Australia have the same status as their medical counterparts offering the same service in maternity care, they will not achieve equal pay for equal work.

The success of the South Australian Midwifery Group Practices within the Women's and Children's Hospital in Adelaide, and the Ryde and Belmont Midwifery Group Practices in New South Wales, offer a ray of hope in the bid to offer women the opportunity to book with a midwife and have more continuity of midwifery care in Australia (at the time this book goes to press).

The impact of funding on maternal and infant outcomes

Medicare is the universal taxpayer-funded health insurance system that offers subsidised private medical services and free public hospital care for all Australians. Its guiding principles are equal access to equal care for equal need.

Having a baby in Australia is by any standards a safe event.[1] Consequently, the measure of a safe and effective outcome for childbirth in Australia (as in other affluent industrialised countries) has shifted its focus from a measure of maternal mortality to measures of maternal morbidity.

Notwithstanding, there are some women—Indigenous women, those of culturally and linguistically diverse backgrounds, and those living in remote and rural areas—who are more likely to experience poorer outcomes in terms of both maternal and perinatal mortality than the community generally (AIHW 2004).

Morbidity associated with birth interventions (Waterstone et al 2001) and long-term effects of operative and caesarean birth include increased risk of hospitalisation with infective morbidities (Lydon-Rochelle et al 2000; Lui et al 2005), increased risk of unexplained stillbirth in a subsequent pregnancy among women who have had a previous caesarean section (Smith et al 2003), and increased rates of severe postpartum bleeding with placental complications following previous caesarean sections (Armstrong et al 2004).

International comparisons show Australia to have among the highest rates of obstetric intervention in labour and birth compared with those in other resource-rich nations. The caesarean section rate appears to be rising markedly in comparison with the New Zealand rate, which appears to have

BOX 1.3 Community midwifery

The WA Community Midwifery Program, 1996–2005

In terms of a national strategy, the Community Midwifery Program in Western Australia (WACMP) provides a proven template of excellence in maternity care, and is a readily adaptable model for duplication in both urban and regional/rural locations. The WACMP was specifically established to provide a publicly funded home birth service.

The Community Midwifery Program (CMP) has been providing one-to-one continuous care from community midwives since 1996, primarily for women who meet the criteria for home birthing.

Two evaluations so far have shown it to be both a successful model of care with good outcomes, and highly valued by the women who utilise the service.

The CMP's guiding philosophy is that childbirth is, in the majority of cases, a normal life event, which, left to nature, will proceed to an uncomplicated outcome. This is underpinned by providing expert midwifery care that respects the individual needs of women and their families by supporting their emotional, social and cultural needs.

The CMP is fully government funded and offers primary community midwifery care to women in the Perth metropolitan area. The service provides women with the option of continuity of care and carer throughout their pregnancy, labour/birth and postnatal phases. Currently funding allows for the service to be offered to 150 women per annum; demand for 'places', however, exceeds this number.

The CMP is managed by Community Midwifery WA Inc, a not-for-profit community organisation that aims to improve the availability of choices in childbirth. The success of the CMP is assisted by the close working relationship between the Program's management and the Department of Health. For example, in response to the withdrawal of professional indemnity insurance, the Department of Health took over employment of the midwives to ensure their access to indemnity cover.

The fact that the program is based in the community, i.e. is community managed, has contributed to its flexibility, appropriateness, ongoing success and growth.

(Source: Thiele & Thorogood 1998, 2001)

reached a plateau over the past five years. Future research will determine whether we are at last seeing the positive results of 15 years of midwifery-led maternity care on the population outcomes in New Zealand.

Interestingly, no midwifery-led care appears to be able to withstand the seduction of opiates offered during labour in tertiary hospital care, and the only places where women seem to be able to escape the seduction of drugs is in the stand-alone and primary-level birth units and home birth in both Australia and New Zealand.

Data from the Australian Institute of Health and Welfare (AIHW 2004) reported that more than one in four women in Australia gave birth by caesarean section and that nearly 80% of mothers with a history of caesarean section were likely to have another caesarean section, while less than 20% had a spontaneous vaginal birth in the next pregnancy (AIHW 2004). The report also showed that labour was induced in 25% of births and augmented in a further 19.2% of births, and that almost one in five women had an elective caesarean section with no labour at all (AIHW 2004).

Obstetric intervention is life-saving when serious complications arise during pregnancy or labour. However, previous population-based research from Australia (Roberts et al 2000) showed that private obstetric care in Australia was a stronger risk factor for intervention in childbirth than either age or risk status (Roberts et al 2000). When women are offered interventions in labour, such as induction and epidurals, they may not be informed of the cascade of interventions in birth that inevitably follow. There is a possibility that if women have information on the extent of the association between interventions in labour and birth this may ultimately influence their choice of caregiver and place of birth. Morbidity is costly in monetary, social and emotional health terms, for both families and funders of healthcare.

Research by Tracy and Tracy (2003) into the antecedents of operative birth showed through cost modelling that the introduction of interventions during labour for women who were otherwise 'low risk' increased the expenditure incrementally in association with the introduction of each labour intervention (see Fig 1.6).

In 1996 and 1997, the rate of normal birth in low-risk primiparous women studied by Roberts et al (2000) was 66%, with 36% of women having private health insurance. The hypothetical model suggests that as the proportion of low-risk primiparous women with private health insurance increases, the rate of normal birth decreases.

This was also demonstrated by Homer (2002) in her paper commenting on the increased levels of private health insurance rates in Australia. She argued that recent Australian government policy has encouraged large numbers of women of childbearing age to enter private health insurance and that this increased uptake of private health insurance affects the rate of normal birth, caesarean section and the costs of providing maternity care for low-risk primiparous women in New South Wales. Private providers and hospitals are heavily subsidised by government and so the additional costs are costs to the Australian community, not merely additional costs to women and their families (Homer 2002, p 36).

Homer and colleagues (2000) randomised 1089 women into 'standard' hospital-based care at St George Hospital in Sydney and community-based collaborative care involving a small team of midwives and hospital obstetricians. The emphasis of the study was on continuity. They found a significant reduction in caesarean rates, their primary outcome of interest (OR 0.6, CI 0.4–0.9).

A later paper reviewed the costs achieved in this reduction in caesarean rates and found a saving of at least $1000 in the community midwifery (STOMP) group. Overall, the mean cost of providing care per woman was lower in the STOMP group than in the control group ($2579 vs. $3483) (Homer et al 2001).

Recent history

Variations in government funding schemes in the past 15 years in Australia have had a serious impact on the provision of midwifery services.

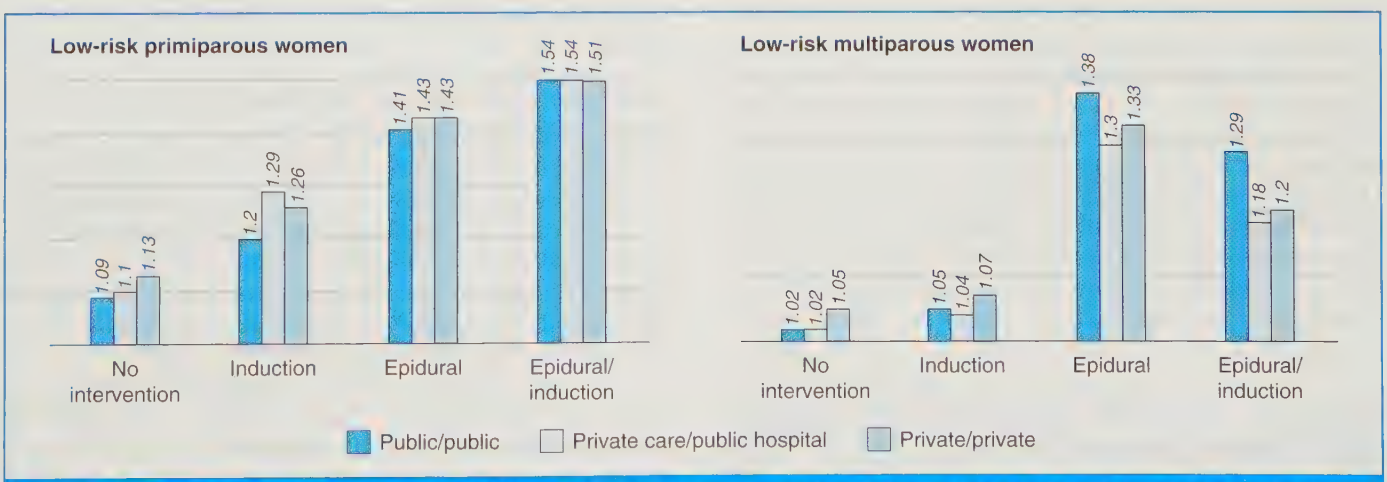

Figure 1.6 Costing the cascade: a model of the cost units per woman that are incurred with the introduction of interventions in labour, Australia 1996–97 (based on Tracy & Tracy 2003)

TABLE 1.3 Type of hospital (private or public) where women in Australia gave birth, by state and territory, 2002

(Source: AIHW 2004b)

In September 2000 the Hunter Valley Team Midwifery Project was closed due to inadequate funding levels. This was a public hospital funded team midwifery service that had been operating successfully for 10 years and had been found to be safe and accessible to women. At the John Hunter Hospital in Newcastle, NSW, continuity of care provided by midwives was evaluated by Rowley et al (1995) through a randomised, controlled study with 814 women, and found to be as safe as routine care. It also reduced the need for medical interventions including induction of labour, analgesia use, and need for neonatal resuscitation. Women receiving team care were significantly more satisfied with their experience and there was a significant reduction in cost (Rowley et al 1995).

The Alternative Birthing Program introduced as a Labor Government incentive in the 1990s was lost to Australian women when that party was elected out of government. Other midwifery models of care similarly face a bleak future as targeted funds run out and they remain, in general, 'on the edge' rather than integrated into routine services. For example, the Alternative Birthing Service funded models of care in Western Australia were all but lost. The WACMP still faces an uncertain future (Reibel 2005, personal communication). The project evaluation unanimously supported midwifery models of care for all the women who took part (Thiele & Thorogood 1998, 2001).

Similarly in Victoria, the six alternative birthing services funded by the Commonwealth, and found to offer all women from a range of socioeconomic groups benefit from continuity of care and carer, were not continued and will not replace the current fragmented arrangements that exploit rather than protect women's vulnerability during childbirth (Lane 1999). Despite the proven safety, high levels of satisfaction and reduced costs, these services have remained marginal to the mainstream services offered within most institutions and separate from their funding base. An important exception is the St George Hospital Sydney, where a community midwifery team service was developed out of regular funding and became a normal part of options available for women.

A report from the Centre for the Study of Mothers' and Children's Health in Victoria found that the constraints in budget expenditure in public hospitals in Victoria had a very real impact on the quality of care for women during labour and birth. The research also found that recommendations from previous research in 1993 calling for the introduction of team midwifery care and multidisciplinary team care for women 'at risk' had not been implemented and in fact had been reduced in some instances (Brown & Lumley 1998).

The effect of fee-for-service

Australia has developed an ad hoc 'fee-for-service' model of maternity care rather than one led by outcomes and driven by research evidence. The consequence is rapidly escalating costs and accelerating cost shifting between state and Commonwealth as the consequences are felt within both systems. There is no overarching system to monitor these costs, align them with best practice evidence, or link outcomes of current models of care according to morbidity data. For example, an editorial in the *Medical Journal of Australia* in 2002 (Wallace & Oates 2002) reported that spending in antenatal care was between $75 and $100 million. They stated that 'it is of concern that there is considerable variation in routine antenatal testing in our hospitals, and that practice is often at odds with available evidence. These inconsistencies are

not only indicative of inequalities in care, but also suggest wastage of precious and limited resources' (Wallace & Oates 2002, p 468).

The Senate Inquiry in 1999 (Rocking the Cradle, Commonwealth of Australia 1999) heard that the total Medicare benefit paid for obstetric ultrasound (MBS category 5, diagnostic imaging, item numbers 55040 and 55041) for the financial year 1997/98 was $34,888,421. This accounted for more than half of the entire obstetric Medicare rebate, $54,865,447 for the same financial year (Medicare tables 1999).

One of the unfortunate legacies of the funding system's bias towards bed day funding is the relative underdevelopment of non-inpatient services. The challenge, in attempting to provide evidence-based improvement in maternity care within the 'casemix' model, is to fund services that extend beyond the hospital bed and provide effective services in the community. At present there are disincentives for hospital services to provide what research evidence shows to be 'best care'. Midwives, most often salaried hospital staff, not only cost less on an hourly rate, but the indirect costs attached to interventionist care such as increased bed days and use of equipment and tests are reduced when they provide care to healthy women.

Current research into the high rates of obstetric intervention for otherwise 'low-risk' women indicates a very large commitment of Commonwealth and state budgets to tertiary-level maternity care among those who might least need such expensive medical support. These rates have an impact across all levels of the system, affecting resource usage at state-funded hospital level and fee-for-service costs at Commonwealth level.

The most recent research by one of the authors of this chapter (ST) shows that paying for a private obstetrician and giving birth in a private hospital is still the greatest risk factor among low-risk women for having an operative or instrumental birth with an episiotomy. Given the number of women who think that having private maternity care is desirable, this information should be more accessible in the public domain.

Within the Medicare funding system, public hospital expenditure is capped. Although prices are controlled for general and specialist services, there is less limitation on volume and hence a 'perverse incentive to over service'. The generally uncoordinated nature of the system allows for major deficiencies at this level, with patients moving from one professional to another (Leeder 1998).

One area of absolute certainty, however, is the model for home birth. Home birth saves the taxpayer money in that it uses none of the resources funded by state or Commonwealth health funds. In this respect the woman and her family are disadvantaged in that they do not qualify for any of the benefits of the health system. The onus falls entirely on the woman and her family to engage and pay the midwives who attend the birth. Some private health funds have agreed to privately insure women for home birth, because they can see the cost saving when compared to an elective caesarean birth, for example (Sprague 1999).

Options for change to general funding mechanisms

According to one of the co-founders of the original Medicare agreement, part of the strategic response to the long-term solution to the funding of Australia's health will be found in structural reform rather than incremental change (Scotton 1999). He advocates a model of managed competition that is specifically designed to induce profound changes in provider arrangements, in the way they are paid, what they deliver and how they are structured (Scotton 1999). The equity objective remains a government function and is even more apparent today due to growing health costs, and widening gaps between those with income and those without, and requires governments to subsidise both health status and income. The structural problems, according to Scotton and others, are: fragmentation of programs; payment incentives which not only lack incentives but in many cases involve perverse incentives; jurisdictional and functional overlap; and conflict between levels of government and between the private and public sectors (Leeder 1998; Owens 1999; Scotton 1999).

Having turned their backs on competition, countries such as the United Kingdom, Sweden, the Netherlands and New Zealand have stressed the need to focus on achieving health outcomes and improving the health status of the population, developing an approach based on family health teams for delivering some primary care services. 'The importance of integrated care is being emphasised as both politicians and health professionals recognise the need for team working and coordination of delivery of services after a period in which competition has militated against such an approach' (Ham 1997c, p 1845).

Increasingly, funding bodies and consumers are calling for evidence to demonstrate the effectiveness of health services, and the need for healthcare is both increasing and changing. Organisations and people need to become increasingly interdependent, willing to question existing values and beliefs in order to adapt to change. Public sector healthcare organisations have a particular need for an external orientation to identify new ways of doing more with less while maintaining quality standards (Perkins & Powell 1999).

New models of maternity care will eventually require cooperation between Commonwealth and state funding systems. At the moment, however, the new stand-alone units do not have access to Commonwealth monies because they are funded within existing area health services (state budgets), and therefore within the existing funding patterns. It is imperative that Commonwealth funding be accessed in the future, otherwise this will impinge on the ability and enthusiasm of area health services to introduce such models. The consequence of not collaborating is the extensive cost shifting that is occurring now and reducing the quality of care for women.

Data retrieval

Maternity systems in Australia and New Zealand rely on adequate and appropriate data retrieval and analysis in

order to evaluate processes, outcomes and costs in relation to maternity care. Systems for the collection of a minimum dataset are in place in both countries, although the data retrieved is not uniform across all states and territories in Australia and complete data was not available in New Zealand until 2003 and is not yet reported (Sullivan 2005, personal communication; NZHIS 2005).

A National Minimum Dataset (NMDS) is a core set of data elements agreed to and endorsed by the health departments of each country for mandatory collection and reporting at a national population level. An NMDS depends on national agreements to collect uniform data. A perinatal NMDS includes data items relating to the mother, including demographic characteristics and factors relating to the pregnancy, labour and birth, and data items relating to the baby including birth status, sex and birth weight.

The Australian National Perinatal Data collection (NPDC) is a collection of national data based on notifications to the perinatal data collection in each state and territory. Midwives and other staff using information obtained from mothers and from hospital and other records complete notification forms for each birth in each state and territory. Information is included in the NPDC for all births of at least 400 grams birthweight or at least 20 weeks gestation. Each year the Australian Institute of Health and Welfare National Perinatal Statistics Unit (AIHW NPSU) produces a report using the NPDC known as the Mothers and Babies Report.

National maternity data has been collected in New Zealand for some years but reports have been limited and data incomplete. The Maternal and Newborn Information System (MNIS) was established to collect perinatal information amalgamating data from both the Lead Maternity Carer payment claims through HealthPac and the data collected at hospital discharge through the NMDS. Now that all LMCs work under the Section 88 Notice, effective from July 2002, data for all births will be available for the first time in the report on the 2003 data. When New Zealand established its NMDS it was based on the Australian NPDC in order to facilitate comparison between both countries; it also includes data for all births of at least 400 grams birthweight or at least 20 weeks gestation. The quality relies on data being accurately entered by LMC practitioners and hospital coders. The New Zealand Health Information Service (NZHIS) is responsible for producing the Report on Maternity.

In both countries it takes approximately two years to analyse each year's data and therefore the most recent report available in Australia is based on data collected in 2003 (Laws & Sullivan 2005). At the time of writing, the 2003 report is still in draft form in New Zealand (NZHIS 2005).

New Zealand midwives also contribute to another data collection developed by the New Zealand College of Midwives and administered through the Midwifery and Maternity Provider Organisation (MMPO). Collected directly from a standard set of Maternity Notes, midwives report on the clinical outcomes of their care as part of the process of making claims for payment for midwifery care. The data from this practice management system provides information in relation to the health of mothers and babies—including pregnancy and birth conditions, procedures and outcomes, and neonatal morbidity—relating to every episode of care undertaken by midwife members. The proposed reports from the MMPO database will provide a benchmark for individual midwife LMCs against which they can measure their own activities and care outcomes. It will also provide the midwifery profession with valuable data to guide planning and the improvement of care outcomes.

Evaluation of maternity care in particular needs to consider both the value of health interventions to the wider population, and the value of the expected outcomes of the intervention to the individual. Data fields for economic evaluation can be designed to respond to the growing need to recognise the value of the intervention both to the individual and to society at large (Viney 1999).

Each perinatal data collection has the potential to inform both women and practitioners about the results of practice.

Conclusion

In Western societies such as Australia and New Zealand, all women should have access to a publicly funded and integrated maternity service that meets their individual needs.[2] Such a service begins with strengthening its community-based primary care provisions while also ensuring easy access to secondary and tertiary care when required. There is strong evidence that a midwife-led maternity service and stand-alone primary units provide a safe service and meet the needs of women and their families (Walsh & Downe 2004; Sandall et al 2001).

In 1990, the New Zealand Government took an unprecedented lead in making women the central focus of its maternity services reform. A comparison of the rates of access to midwifery care between Australia and New Zealand (see Fig 1.7) demonstrates the potential of such reform.

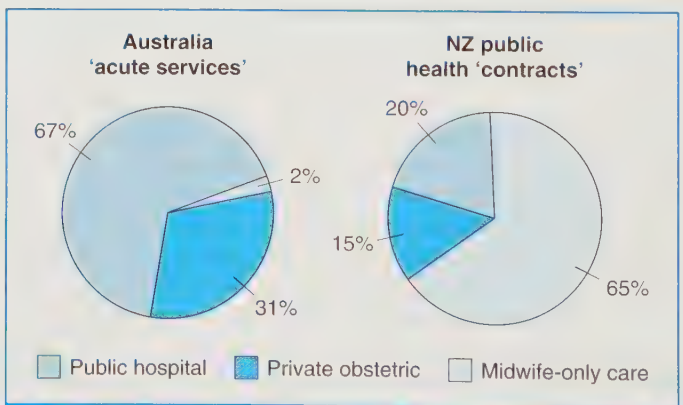

Figure 1.7 Percentage of women who access midwives under the funding models for New Zealand and Australia, 2002 (based on Ministry of Health 1999b; Roberts et al 2000; Laws & Sullivan 2004)

For 10 to 15 years now, midwives in New Zealand have been funded to provide a primary care service, to provide care for the entire maternity experience, and provide the majority of care by being present during labour and birth. In 2005 at least 78% of women booked with a midwife, compared with Australia's 1.0% of women (Tracy et al 2006, unpublished data).

The funding mechanisms that govern the provision of maternity care in Australia are in urgent need of reform. Current funding that is costed solely on acute hospital casemix models does not fund care to be undertaken in the community. Where caseload midwifery models have been implemented in Australia, and evaluated, the outcomes show they are of benefit to women and babies (Homer et al 2000; Kenny et al 1994; Rowley et al 1995; Thiele & Thorogood 1998, 2001; Tracy & Hartz 2005). Until funding encourages non-intervention by providers, probably through some form of capped prospective allowance for each woman attended, mothers and babies will continue to be disadvantaged by not having access to proven practices of safety and comfort in childbirth. Such a system is based on 'collaboration' and 'cooperation' across all levels of service provision.

The service itself must cross both acute hospital and community boundaries to achieve a balance between hospital-based and community-based care. This, coupled with funding a lead maternity carer through a capped maternity allowance allocated in terms of a maternity benefit for every pregnant woman, is known to contribute significantly to the welfare of childbearing populations.

Review questions

1. What is the difference between public, primary, secondary and tertiary healthcare?
2. List six reasons why midwifery can be defined as primary healthcare.
3. Identify four principles of primary healthcare.
4. Define the terms 'lead maternity carer' and 'continuity of care'.
5. Identify the key mechanism by which New Zealand's maternity service funding supports midwifery professional autonomy.
6. Identify four main differences between the maternity services and maternity service funding mechanisms in Australian and New Zealand.
7. How do funding mechanisms affect maternity outcomes for mothers and babies?
8. How does private obstetric care pose a risk to women and babies?
9. Why is the collection of data important for midwifery and what is the best way to collect information about birth outcomes?
10. How would you describe the most cost-effective maternity services in New Zealand and Australia?

Notes

1 However, the latest maternal mortality report for the triennium 1994–1996 shows a worrying change in rates (AIHW 2001; NHMRC 2001).

2 As this chapter highlights, there is no universally agreed model of maternity care. Most health systems in most countries have not achieved a model of care that fully recognises and adapts to the needs of women and their babies in a way that allows all women and their babies to meet their health and wellbeing potential. Nor is there a model that completely enables midwives to practise in an environment that strengthens their potential to keep birth normal.

Scrutiny of the antecedents of normal birth will possibly reveal that women should be encouraged to birth in units where intrathecal and epidural opioids and other invasive technology is not routinely on hand and is not used unless the condition of the mother and baby require intervention.

CHAPTER 2

The Australian and New Zealand context

Jill White

Key terms

Anglo-Celtic, Australian Aboriginal, Indigenous, mana, Maori, multiculturalism, Pakeha, tapu, Treaty of Waitangi, utu

Chapter overview

Other chapters of this book introduce the philosophical contexts of midwifery and maternity services generally, and the specific contexts of women in the world. This chapter seeks to situate this understanding of women, mothers and their babies, and maternity services within the social, historical and cultural contexts of Australia and New Zealand.

Having lived as woman, mother, midwife and nurse in both countries I am approaching this chapter as I lived in these countries. My approach was to accept that despite their geographic closeness they are as different as France and Germany, or the United States and Mexico. It is, I believe, important to try to understand their separateness and then to be surprised by the similarities rather than, as many do, think of them as the same and only gradually, after episodes that can only be seen as culturally insensitive, come to understand the differences. Appreciating such difference, this chapter will look at each country in turn.

In exploring the social, historical and cultural contexts of any country, looking first at the history provides an explanatory backdrop for the current relationships and attitudes as played out socially and culturally. The brief histories presented here are by no means historians' histories. The social and cultural comments are those of neither sociologists nor anthropologists. They are practitioner histories, and social and cultural commentaries: stories that highlight some salient social and historical events that give colour to a picture of a past that inevitably influences the present and the people with whom we work as midwives, and the values the women and their families express in our interactions with them in practice.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe the cardinal elements of the histories of Australia and New Zealand
2. To analyse the effects of European colonisation on the indigenous peoples of both countries
3. To discuss the importance of the Treaty of Waitangi to Maori and Pakeha in contemporary New Zealand society
4. To discuss the place of women in contemporary New Zealand and Australian societies, and the influence of history on this positioning
5. To explain the key social and cultural similarities and differences between Australia and New Zealand.

Australia

Early Australia

Australia has been home to its Aboriginal population for more than 50,000 years, and to Europeans for a mere 200 years. For Aborigines this represents 2000 generations of living, hunting and gathering in this often harsh environment. There are estimated to have been about 300,000 Aborigines living in Australia in 1788 when Europeans arrived. This population was spread across over 500 tribes, each with its own dialect, history, culture and territory. While all tribes were semi-nomadic hunters and gatherers moving across their specific territory with seasonal purpose, the size of their tribal grounds varied from 500 square kilometres in generous coastal areas to 100,000 square kilometres in desert areas (Broome 2001). Land connection was and is fundamental to Aboriginal being and features in their stories, songs and paintings. In particular, 'the lives of the Aborigines were shaped by their Dreamtime stories which were both an explanation of how the world came to be, and how people must conduct their behaviour and social relations' (Broome 2001, p 19).

From the time the Dutch navigated to what is now known as Indonesia in the sixteenth century there had been tales of rich southern lands, and ships from many countries sought these lands. A Spaniard, de Torres, navigated the straits between northern Australia and New Guinea in 1606. In 1616 the Dutch commander Hartog found the western Australian coast. There followed many more ships from Holland finding and naming land along the southern Australian coast. Tasman found what was to become Tasmania and named it van Dieman's Land after the Governor of the East Indies in Java, then a Dutch colony. Then, rather than travelling north along the Australian coast, Tasman sailed further east and found the coast of New Zealand. But as these ships were in search of gold and spices, their discoveries of land that appeared undeveloped and lacking in riches was not valued by their home countries.

At the end of the seventeenth century an Englishman, Dampier, voyaged to western Australia but again reported he had found little of value, little water and little available food. Some signs of European life were found on the edges of the continent but were the flotsam and jetsam of wrecked ships and sailors who had perished.

So Australia became known to the European world piece by piece in multiple voyages from many different countries, but was coveted mainly by the British. When the British government sent Captain Cook to the South Seas, ostensibly to study an eclipse from the oceans near Tahiti in order to help problems of navigation, the opportunity presented itself to search for the southern land and to take possession of it for Britain. International law at the time required a 'new' country to be taken only after permission was sought from the 'natives', that is, unless the land was either uninhabited or inhabited by a people who did not appear to use the land. In 1770 James Cook 'discovered' Australia's eastern coast and he and his party landed in what has become known as Botany Bay. The ship's name and date were carved on a tree and the British flag planted on the soil. After many reported attempts to engage peacefully with the 'natives' Cook recorded in his diary, 'All they seem'd to want was for us to be gone' (Clark et al 2000, p 20). He recorded the lack of interest of the Aborigines in the trinkets, ribbons and cloth that he had left for them, and their lack of clothing, organised housing or land usage, thus attempting to justify, according to the law of the time, his taking of the land, as it had no organised system of government with whom to negotiate. Cook arrived back in England in 1771 and the government, far from being uninterested in his 'discovery', began to make plans to use this new land as a penal colony as England's gaols were overcrowded and they could no longer sell their prisoners to America, as had been their most recent solution to their social problem (Clark et al 2000).

Here we have the first of many of the significant differences in the development of Australia and New Zealand as neighbouring but distinctly different countries. The organised system of Maori living, recognised by the Europeans as familiar, led to the development and signing of a treaty, rather than just a taking of 'empty' lands.

In January 1788 the eleven ships of the First Fleet entered the harbour in Botany Bay carrying 759 convicts and 200 marine guards, the chaplain and the captain who was to govern them, Captain Arthur Phillip. This was the place Cook had detailed in his week-long visit in a wet autumn eighteen years earlier. But as any antipodean knows, Sydney in January is quite a different picture to the cool of autumn, and the harsh reality of what they had before them in setting up a colony must have been a terrifying thought. They quickly realised the place they had landed would not support them and moved just north to Sydney Cove with its fresh water source and more fertile plains. But accidents of history are amazing. Within days of the English landing, a French ship under Captain La Perouse landed. What would have happened had storms or winds delayed the First Fleet and La Perouse attempted to claim the land for France we will never know. How different might the outcome for the Indigenous population have been? Again we cannot know, but given the similar patterns of constructing European communities one can imagine a contest would still have occurred for the best and most productive lands and for sources of fresh water.

Accounts of the early days of the settlement are of Aborigines being frightened off their lands by musket-discharging soldiers, and convicts and soldiers being frightened by spear-throwing 'natives'. Two groups of people thrust together in a harsh environment, with no understanding of the way of life of the other, no common language and each with a determination and need to survive. The early 1800s saw the senior members of the European colony discussing the 'native problem' and seeing 'civilising' the natives as the only solution. But these discussions concerned a relatively small colony around the area of Sydney. The rest of Australia remained relatively untouched by European settlement. That is, until the stroke of a pen on the other side of the world resulted in the slashing of duty for Australian wool compared to that of European wool producers. By 1850 200,000 migrants had moved from the United Kingdom to fell trees, clear land and graze sheep.

By 1860 4000 Europeans with 20 million sheep occupied the prime river-fed land from southern Queensland to South Australia (Broome 2001). An itinerant male workforce working in rough country with a male to female ratio of 40 men to every woman framed the beginnings of the nation that 'grew on the sheep's back' as it was colloquially described. A nation of burly men, of mateship and of women being seen as 'damned whores and God's police', a situation so colourfully captured by Anne Summers (1994) in the title of her book chronicling women's lives in early Australia. The small number of women compared to men throughout the early days of European settlement had predictable consequences for the Aboriginal people, as the Indigenous women became 'useful' to white men as domestic servants and at times in sexual relationships, both consensual and non-consensual.

As white men moved further away from the coast, they increasingly disrupted the tribal grounds of individual Aboriginal groupings and forced them onto the traditional grounds of others. This progressively disrupted the seasonal movements across the lands and brought Aboriginal tribal groups into conflict with each other as well as with the white 'settlers'. But far more devastatingly it disturbed a way of life that had existed for thousands of years, with rules of kinship and community and spirituality that were difficult to sustain out of the more nomadic lifestyle. Nutrition and infection control in the form of sanitation were adversely affected by a static form of living and resulted in poor diet, ear, eye and chest infections and diarrhoea. Also negatively affected was the sense of purpose in what were the daily rituals associated with hunting and gathering. European infections of smallpox, influenza, measles and even the common cold also damaged the Indigenous communities, who had no resistance to these new and foreign organisms. Fighting was particularly intense on the frontiers, with many deaths on both sides, but the balance of musket and spear was irrevocably disturbed by the introduction of the repeating rifle in 1870.

Aborigines were forced to live either in distant government-controlled reserves, on church-run 'missions' or close to but on the edges of white settlements in order to provide their families with safety, food and shelter. It is estimated that by the early 1900s, the population was only a quarter of that of 1788.

Variations on the New South Wales experience were repeated throughout the country. In 1829 Captain Fremantle annexed 7000 kilometres of the western Australian coast for Britain and settlement began. By 1830 over 1500 British immigrants had landed in the Swan River region of western Australia. However, unlike the beginnings in New South Wales, the Western Australian experience was of young people and families coming to start new lives, not of convicts and soldiers and a virtually all-male environment. In 1836 a further colony was begun, this time in South Australia at a site close to the mouth of the river Murray. This too was a settlement of 'free settlers'. Settlement by families had the potential to create very different societies to those dominated by men and may hold some explanation of the more 'cultured' reputation of Adelaide.

Other settlements that were to become state capitals grew at around the same time. They all experienced similar hardships and conflicts with those Aboriginal tribes who had also valued the land where rivers meet the sea and which are the most fertile. But there are stories of settlements with better race relations than others. Captain George Grey, for example, had developed a genuine respect for and understanding of the Aborigines after having experienced an accident in the north of Western Australia. He had been sheltered and fed by the 'natives' there and had come to hold them in higher esteem than his predecessor British colonial officers. Captain George Grey's 'success' with the natives resulted in several of his subsequent government postings, first to Adelaide as Governor and then to New Zealand, as the Maori Wars were causing British nervousness about the stability of the new country. We will meet up with Governor Grey later, in New Zealand, as he was to very nearly play an interesting role in Maori health and wellbeing post colonisation.

Darwin's 1859 *On the Origin of Species* and his notion of 'survival of the fittest' was well known in Australia by the late 1800s and provided what was at the time an acceptable, 'logical' and 'scientific' explanation for the racism that had come to dominate Australian attitudes to its Indigenous people by the latter part of the 1800s and early 1900s.

Broome (2001, pp 92–93) paints this picture of misunderstanding:

> The cultural and physical differences between the Aborigines and the Europeans created basic misunderstandings and a lack of sympathy between the two groups. Racism thrived on this gulf of ignorance. The first Europeans viewed Aboriginal society in terms of European values and thus saw it negatively. They stressed Aborigines did not wear clothes, build houses, till the soil or have recognizable religions, kings or forms of government. It never occurred to them that a hunter-gatherer society in a warm climate had no use for clothes, permanent houses or agriculture. The Europeans were also clearly wrong when they thought the Aborigines had no religion, law, leaders or forms of government. Seeing the world as they did, the Europeans rated their own society as the highest on the scale of human development and Aboriginal society as one of the lowest. Yet Aboriginal society was not 'primitive' as Europeans claimed, but simply different. There is no doubt that Aborigines in turn did not understand why the Europeans wore heavy clothing in a warm climate or bothered to build homes or grow crops when there were hundreds of varieties of food in the bush for the taking. Aboriginal philosophers would have rated European society low, and much European activity as valueless.
>
> Also both groups were generally unimpressed by the physical appearance of the other. The Aborigines were shocked by the pale eyes, thin noses, fair hair and white skins of the European, so much so that they first thought them to be spirits of the dead. The Europeans in turn were startled by the ritual ornamentation . . . applied to Aboriginal bodies, their flat noses, their black skin and their nakedness. Not all on both sides were repulsed as the frequent sexual contacts between the two groups revealed.

The paternalistic attitude and the overt racism that such attitudes brought forth were a feature of Australian society until the 1970s, and many would say are still present.

Federation of the colonies into a nation: a Commonwealth of Australia

On 1 January 1901 the six colonies that had developed around the coastline of Australia became a federated nation: the Commonwealth of Australia. Its population was recorded at the time as 3.75 million. Aborigines were not counted as part of this census; nor, when the parliament was set up, were they permitted to vote. Indeed it was not until 1962 that Aborigines were allowed to vote.

The perception of many Australians is of politics as having been male-dominated from its inception but a study of the political history of Australia tells a different story. From the beginning of Federation, women nominated for parliament, with three women nominating for the senate as early as 1903, although it was 41 years before a woman was elected to federal parliament (Sawer & Simms 1993). Clearly, women were anxious for the role but not elected into it. Thus parliament may have been male-dominated but politics was not—women used the elections as opportunities to voice their concerns and lobby for change.

The new Australia was seen as full of promise and potential wealth, and as the dominant view was that the Aborigines would soon die out, it was seen to be a country for and of white people. Two of the first pieces of legislation passed in the new federal parliament were restricting immigration to white people (the language used at the time to describe what is now referred to as Anglo-Celtic or European). Unofficially this legislation became known as the 'White Australia Policy'. This was not the first legislation to keep out or restrict the rights of those who were not white. In the mid-1800s, gold had been found in New South Wales and the gold rush began, doubling the population in less than 10 years. With wool and gold, Australia looked like the land of opportunity. People began to come not only from Europe—Chinese people flooded in, in their tens of thousands, for gold. Consequently, legislation was passed to limit Chinese immigration; those who were already here were not permitted to be naturalised and were to be regarded for generations as 'foreigners'. This dismissal of the Chinese as legitimate citizens occurred in spite of the fact that in the Northern Territory by 1879 there were only 400 Europeans but 3500 Chinese.

Federation was seen as a mechanism for integrating the whole of Australia under a British parliamentary structure and hence ensuring its 'white' future. This situation is perplexing when one looks at the already existing ethnic mix. Manning Clark et al (2000, p 127) quote the following demographics at the time of Federation:

> Three-quarters had been born in Australia, the greatest majority were of English, Irish or Scottish descent. But there were also 30,000 people born in China, 4,000 in Japan, 7,600 in India, 38,400 in Germany, 10,000 in Sweden, 5,600 in Italy, 6,300 in Denmark, 7,500 in the United States and 5,200 born at sea.

The World Wars

The First World War was important in the formation of a sense of a national Australian identity and an identity separate from Britain. By 1914 more than 20,000 men had joined the armed forces and had landed in Egypt for training. The Australians landed at the same time as the troops from New Zealand and collectively they became known as the ANZACs (the Australian and New Zealand Army Corps). Together they met some of the most ferocious fighting, particularly at Gallipoli, in Turkey. The way in which these men dealt with their dire and tragic situation led to the development of what became known as the ANZAC spirit; more than 26,000 Australians and over 7500 New Zealanders died at Gallipoli, but the stories of the determination, mateship and bravery are now legend. Following the debacle of Gallipoli, many of the survivors were taken to Europe to fight at the Western Front against the German army in different but equally atrocious conditions. The conditions faced on the Western Front are graphically represented by Sebastian Faulks (1993) in his book *Birdsong: A Novel of Love and War*, a harrowing but accessible account of the kinds of hardships the Australians and New Zealanders would have faced.

Many Australian women joined the war effort as nurses, but women were not allowed to be part of the war in any other formal capacity. They were left to undertake all the everyday jobs that had previously been the province of men, particularly in the country, with fencing, shearing and heavy farm work.

As we have seen, Australia, while choosing to see itself as racially Anglo-Celtic, was already a very multicultural country. Many Germans had settled in the areas around Adelaide and had begun Australia's winemaking industry as early as the 1840s. With Australia, through its ties to Britain, now at war with Germany, internment camps were set up to house the over 6000 German, Austrian and Turkish people living in Australia in 1916–17 (Eshuys et al 1996). Yet again, racial divisions across the country raised their ugly heads as people were rounded up and placed behind barbed wire in guarded compounds, many miles away from homes, work and friends.

Following the war, the 1920s were prosperous and exciting. Women began to enter state parliaments, with Western Australia first in 1921, New South Wales in 1925, Queensland in 1929 and South Australia last in 1959. But the joys of the post-war twenties were followed quickly by the depression of the 1930s. People were evicted from their houses and many men went 'on the long road with their swag'—in other words, walked from town to town in search of whatever work they could find and sleeping in the open on bedding carried rolled on their backs.

Reflective exercise

Imagine yourself a convict woman arriving on one of the early ships to settle in Port Jackson. What would be your hopes and fears?

Imagine yourself as an Aboriginal woman and mother in the early 1800s in south-eastern Australia. What would be your hopes and fears?

Reflective exercise

What complex and conflicting emotions might you have felt at the end of the war with the men in your life returning, and you having to relinquish a job you have enjoyed?

In 1939 Australia was once more at war. This time the immediate threat to Australia was from the Japanese. Internment camps were again set up, this time for Italians, Germans and Japanese. Women moved again out of the home and into industry and were relied upon to keep not only the 'home fires burning' but also the furnaces of industry.

Unlike the First World War, the Second World War was also fought in the Pacific, and therefore posed a significant threat to Australia directly. This war was more about fighting for Australia than for any notion of the 'Mother Land'.

The 1950s and beyond

The situation following the Second World War was different from that of the previous post-war experience. The direct threat to Australia had made politicians acutely aware of the vastness of the country, its small population and the potential threat this presented from the 'teeming hordes from Asia', a popular phrase at the time. This time the government knew there was a need for workers for factories, farms and service industries. Government policy was 'populate or perish' and the first waves of post-war immigration began. British immigrated on a very heavily assisted passage for a mere ten pounds. These people became known as the 'ten quid Poms'. Italians, Greeks, Germans and Dutch were also encouraged to come to Australia.

In the 1950s the economy grew, unemployment was low and the birth rate soared as a result of the 'baby boomers', babies born between the end of the war and 1960. Women's place was again seen as predominantly in the home, and outside work returned to being the province of the men. Australia experienced a period of domestic 'harmony' through the 1950s and 1960s as a 'miniature England', with beginning influences of the United States, following its interaction with Australia in the Second World War. It was a time reminiscent of scenes in the movie of *The Stepford Wives*—domestic bliss with men as Men and women as their contented domestic servants.

Australia was to change profoundly with the international winds of change of the early seventies, with the growing peace movement, calls for the end of war and nuclear weapons, demands for civil rights for all citizens, demands for equal rights for women by groups like the newly formed Women's Electoral Lobby, and a questioning of traditional 'family values'. The Whitlam government came to power in 1972 and quickly Australia was challenged with respect to its racist and sexist complacency. In its first fortnight in power, Whitlam's government abolished conscription, moved towards equal pay for women, increased spending on Aboriginals, abolished British knighthoods and introduced Australian honours, increased spending on education, the arts and health; race was no longer a consideration in immigration, and sporting teams who selected on colour or race were banned from Australia. Unfortunately, a slump in the world economy, rising oil prices and a hostile Senate led to the curtailment of these radical changes.

Whitlam's changes to foreign policy and immigration policy changed Australia's ethnic mix forever. The Whitlam government was dismissed by the governor-general, John Kerr, and the leader of the opposition was installed as caretaker prime minister until an election could be called. Whitlam lost in a Liberal landslide. By then, Australia had changed. There was now a different understanding of the place of women, Aborigines, land rights, and attitudes to non-European immigrants.

The next significant immigration wave was of South-East Asian people after the Vietnam War, followed in the 1970s and 1980s by an influx from Middle-Eastern countries and South America. By the end of the 1980s Australia was one of the most multicultural countries in the world.

Australian 'identity'

The Australian 'identity' has long been a contradictory one. Described by Ward in *The Australian Legend* nearly 50 years ago as 'the rough, honest, easy-going bushman, laconic, resourceful, loyal to his mates, uncomfortable with parsons and women, facing adversity with a stoical joke' (summarised in Hudson & Bolton 1997, p 1), to which could be added 'Anglo-Celtic bloke', this view still permeates society despite the multicultural nature of the population and the fact that more than three-quarters of the population live an urban life in coastal cities.

Hudson and Bolton (1997) exhort us to look to Australia's multiple personalities rather than find attachment in a single, perhaps only briefly existing, 'rural ideal' and to be cognisant of the amazing diversity that is the essence of the different regions within Australia. What it is to be Australian and live in Australia is very different if one is in inner-city Sydney or in Bourke or Broken Hill, and different again if one is in Perth or Broome. Even within the large cities there are now suburbs with such ethnic homogeneity that the shop signs are in Vietnamese or Arabic or Greek, and the norms of behaviour and identity vary in each.

The single Australian story may have been male, with the female either absent or as the shadow behind the man, but the women's history is a varied one too. Early attempts to tell a women's story, such as Miriam Dixon's (1976) *The Real Matilda*, paint a picture of an oppressed group. The introduction to Dixon's book begins, 'In this exploratory book I propose that Australian women, women in the land of mateship, "the Ocker", keg-culture, come pretty close to top rating as the "Doormats of the Western World"' (Dixon 1993, p 11). But the women's story is populated also by gutsy feminists at the turn of the century standing for parliament, fighting for peace, for pensions for the aged and invalided.

These women broke down the barriers to women's entry to medicine (1897), law (1903) and architecture (1889), but had to wait until after the Second World War to enter the other male bastions of the Church, the armed forces and engineering. Vida Goldstein in 1902 went to Washington to the founding conference of what was to become the International Women's Suffrage Alliance and served as its secretary. Women were also internationally published authors, such as Miles Franklin, who gives us a glimpse into a gutsy heroine in Sybylla Melvyn in *My Brilliant Career*. Jesse Street in 1946 was the Australian delegate to the United Nations. These women were part of the first wave of feminism. The second wave was to come in the 1970s.

But if there was one constant in the interruption to the development of women and their voices in Australian history, it is war. War created the ANZAC legend, reinforcing the mateship ethic as central to being 'dinky-di' Australian. It gave women the unsung role of keeping the urban and rural productivity going while the men were overseas, but they were expected to relinquish these positions when the men returned and to adjust to living with a generation of men brutalised by their experiences of the inhumanity of war. Following the Second World War, women again left the jobs they had managed but this time they were not only child-bearing but were also expected to join the workforce without the advantage of the same educational, occupational and economic opportunities as men.

The need for the country to have a single common image to relate to is seen by White (1981, 1997) to be a construction of a market that had products to sell. He writes of the relationship between the market and a sense of being a nation, citing as examples the Heidelberg school of painting's need to be iconic, as they had to be saleable to galleries rather than private collectors, the *Bulletin*'s need for a single popular market, and latterly in the 1980s and 1990s, the advertising agencies' need to sell beer, collectively contributing to over a hundred years of image reinforcement. Women did not control the spending power and were thus rendered invisible in all but domestic commercials and image portrayals.

So the quintessential Australian became a construction that was male, of mateship, exhibiting a laconic sense of humour, and while predominantly white, of 'tolerance' to others.

The Anglo-Celtic Australian notion of multicultural tolerance is questioned by Curthoys (1997, p 35). 'Tolerance' suggests two elements: the tolerators and the tolerated.

> Tolerance may be better than intolerance but it does not guarantee equality. Anglo-Celtic Australians, in their enthusiasm for multiculturalism and thereby the new inclusive Australian identity, are, then, still expressing power relations, still speaking from a self-confident centre, the Australian nation. They are doing the including, not being included. The politics of inclusion, based on notions of community and identity absorbs difference within a pre-given and predefined space.

Taking the argument a step further, Curthoys says: 'Everyone in Australia who is non-Indigenous, the "tolerators" and the "tolerated" alike, still share in and are advantaged by a history of colonialism'. In speaking also of tolerance and diversity, Don Watson, in his now famous speech, 'A Toast to the Postmodern Republic', said:

> I'm only just game enough to say it: it might be the first postmodern republic, and I mean that in the nicest possible way. I mean a republic that exalts the nation less than the way of life. Whose principal value is tolerance rather than conformity, difference rather than uniformity (quoted in Wark 1997, p 152).

Watson's 1997 speech pre-dated the move to the Right and the resurgence of sexism and racism in Australian society that has occurred under the Liberal Howard government.

A very interesting and easily readable book that traverses Australia from the 1950s to the beginning of the twenty-first century is the autobiography of Wendy McCarthy (2000), *Don't Fence Me In*.

Anne Summers (2003) again became the conscience of Australia with her powerful recent book *The End of Equality: Work, Babies and Women's Choices in 21st Century Australia.* In the introduction, Summers (2003, pp 2–3) says:

> Yet although the language of equality is still used, and despite the successes of so many individual women, the actual experience of far too many women in Australia today suggests that the promise of equality has not been met. Sadly, we are actually going in the opposite direction. If we look at the economic, physical and social markers of women's well-being, the picture that is revealed is in grim contrast to the rhetoric of equality and accomplishment ... Despite appearances to the contrary, the proportion of women in full-time employment has not increased in thirty years. More Australian women work part-time than in any other country in the industrialized world ... not from choice ... but because of a lack of childcare or other support ... Equal pay is a myth ... The number of women totally dependent on welfare has increased to an unprecedented degree ... As a result of all these factors, there are more women living at the economic margin, or actual poverty than ever before.

In contradiction to a self-image of tolerance, the plight of refugees and asylum seekers in Australia has shocked many in the Australian community. The Australian government's agreement to assist the United States in a war 'against terrorism' in Iraq again divided the nation. Any notion of being a nation with a single voice has recently been seriously challenged. Australia's stance on both these issues is in stark contrast to the stance of New Zealand, again reinforcing the separateness of the two countries.

Modern Aboriginal society

I position myself in writing this section as a middle-class Anglo-Celtic, fifth-generation Australian woman and do not presume to be able to authentically tell an Aboriginal and

Reflective exercise

What are the issues that affect you as a woman in contemporary Australian society, and in what way have these issues been influenced by the history of this country?

Torres Strait Islander story. I will distill some of what writers have seen as the cardinal events in Aboriginal society for you here so you can form a schema from which to do your own further reading.

No version of modern Australian Aboriginal and Torres Strait Islander society can make sense without an understanding of the effects of European colonisation. We were briefly introduced to this earlier in the chapter. What we did not focus on at that time is the collision of paternalistic intentions to try to 'save a dying race' and the removal of children from their parents and families, to become known in Australian history as 'The Stolen Generation'.

In 1906 Bishop Frodsman was reported to have said:

> The Aborigines are disappearing. In the course of a generation or two, at the most, the last Australian blackfellow will have turned his face to warm mother earth . . . Missionary work then may be only smoothing the pillow of a dying race, but I think if the Lord Jesus came to Australia he would be moved with great compassion for these poor outcasts, living by the wayside, robbed of their land, wounded by the lust and passion of a stronger race, and dying (Broome 2001, p 105).

Thinking of the adults as 'lost causes', the missionaries and the government determined to 'save the children'. The main strategy used was to separate the children from their parents. Some parents agreed to this separation as they saw it as a means to enhance and protect their children's health and wellbeing, despite the grief of separation; some children were forcibly removed from their parents. The children were removed to either government reserves or church missions.

Mission or reserve schooling and life left the children between two worlds, belonging to neither. Restricting the children and young adults to life on the missions or reserves not only introduced them to European foods and language but disturbed their learning of bush ways and independence in being able to hunt and gather their own foods, increasing their dependency and depriving them of traditional rituals such as initiations, which were often banned. Most missions introduced the notion of matrimonial monogamy and marriage without respect for traditional relationship rules that had stood for generations. In 1953 the Australian Government financed the provision of medical and educational facilities on the missions, further entrenching their function in the assimilation of Aboriginal children into the lifestyle of white Australia.

But such a loss can remain submerged for only so long. The stories of the lives dislodged began to be recorded and the cry for self-determination for Aboriginal people became louder through the 1960s and 1970s, with several government inquiries into the treatment received on the missions and reserves, which had at times included severe physical punishment as well as family dislocation. To generalise on the experience of all missions and reserves is to do an injustice to some who valued and upheld the traditional language and customs but they do appear to have been in the minority.

The mission story and experience dominated the northern Aboriginal settlements but the story of south-eastern Aboriginals was of fringe settlement around the edges of the towns and cities or on government reserves, of which there were 49 in 1960 (Broome 2001). The people on the reserves were rigidly controlled under the *Aboriginal Protection Act* of 1909 and later amendments. In 1936, amendments to the Act gave the Aboriginal Protection Board powers to carry out compulsory medical checks and remove people to government settlements. Aboriginal children were not permitted in state schools until 1949.

Discrimination and racism caused poverty and lack of political power, which reinforced the cycle of poverty and discrimination. The flow-on effects of poverty, being of course poorer health and education status, led to further cycles of alienation and despair, confusion and loss of purpose, but with growing defiance for some. Alcohol became an increasing problem for some old enough to obtain it, and, for some younger Aborigines, glue and petrol sniffing. Although local group identity was strong, there had not been a history of a broader sense of national Aboriginal solidarity. Sport and art were two of the few areas in which Aboriginal young people had had opportunities to excel, as they did in boxing, football, tennis, dance and painting.

Movements for Aboriginal rights had existed sporadically since the 1920s. One of the most public and decisive movements came from William Cooper, who in 1937 led a campaign for the 150th anniversary of the landing of the First Fleet to be proclaimed a day of mourning, commemorating instead the 150th anniversary of misery and degradation of the original inhabitants by white invaders (Broome 2001). This was to resurface 50 years later, when the Bicentennial created a focus for national Aboriginal cohesion, and a questioning of Australia Day as a cause for celebration as opposed to a recognition of it as a day of mourning for the Indigenous people of Australia.

In 1961 the Federal Council for the Advancement of Aborigines was formed, changing its name in 1964 to include Torres Strait Islanders. In 1967, 89% of voters voted for Aboriginal citizenship, and the federal government, rather than the states, was given power to legislate on Aboriginal affairs, and the Department of Aboriginal Affairs was created. In 1972 the first Aboriginal tent embassy was set up on the lawns of Parliament House and was a symbol of a new Aboriginal determination. In 1973 a federal inquiry into Aboriginal land rights was established. Aboriginal stories began to be recorded and in the 1980s there was an explosion of oral history recording.

But it was not until 1992 that the fiction of the empty land, *terra nullius*, was overturned by the Mabo High Court decision after 222 years of European colonisation. Native title was enshrined in the *Native Title Act 1993* and required proof of continuous relationship to the land. The national focus of the 1990s and into the early 2000s is on Aboriginal and Torres Strait Islander health—physical, mental and spiritual.

The Human Rights and Equal Opportunity Commission in 1995 explored, amongst other matters, the removal of children from their parents and families. The inquiry heard that since 1911 in Queensland alone, over 6000 children had been

removed. Some thought this to be a gross underestimation. The Stolen Generation and its sequelae are now an acknowledged part of Australian history, and their impact on current social and cultural life are recognised. The Commission's report, *Bringing Them Home*, estimated that 40,000 Aboriginal children had been removed from their families in the 1900s (HREOC 1997). In the decade from 1919, up to one-third of children were taken in the southern states.

The complex and troublesome issue for a generation of European Australians in attempting to come to terms with the consequences of the actions of their forebears has been explored in a highly readable book, *Being Whitefella*, edited by Duncan Graham (1994). This book is a compilation of 16 well-known and respected 'whitefellas' exploring their relationship with Aboriginal Australia.

In 1996 the Premier of New South Wales, Bob Carr, formally apologised in parliament, saying:

> I affirm in this place, formally and solemnly as Premier, on behalf of the government and people of New South Wales, our apology to Aboriginal people.

The federal government is yet to say 'Sorry', the word called for by Indigenous Australians. It has, however, committed to the 'process of reconciliation with Aboriginal and Torres Strait Islander people, in the context of redressing their profound social and economic disadvantage'. It appeared that Australia was beginning to take the necessary steps to atone for its past injustices. However, the 1996 federal election saw the election of Queensland Senator Pauline Hanson. Her maiden speech in parliament was a blatant attack on Aboriginal people and ignited racism again in Australia.

Poor health in the form of diabetes, renal disease, mental health problems, violence, alcoholism and domestic violence are difficulties still facing many Aboriginal families, for whom poverty is still the fundamental issue of discrimination. Half the deaths of Aboriginal men occur before they are 50, compared to only 13% in non-Indigenous men. The 1997 Census revealed that a smaller proportion of Aboriginal people than non-Aboriginal Australians drink alcohol—33% compared to 45%—but those Aborigines who drink do so more publicly and heavily than their non-Aboriginal counterparts. Twelve per cent of all drinkers drank harmful levels of alcohol; 80% of Aboriginal drinkers did so (Broome 2001). The Aboriginal health statistics still show an unacceptable discrepancy in life expectancy and maternal and perinatal mortality. This will be addressed in detail later in the text.

This section would not, however, be complete without acknowledgement of the extraordinary accomplishment of many Aboriginal and Torres Strait Islander people, in business, parliament, sport, art, academia and indeed all aspects of life in Australia, in spite of two hundred years of colonisation.

Reflective exercise

If you were an Aboriginal woman whose child was taken to a mission, how might you have consoled yourself and what effect might this have had on your life?

If you were a young Aboriginal woman brought up on a mission with little contact with your family, how might this have affected your life physically, socially, culturally and spiritually? What are the positives, what are the negatives, and how do you heal and move forward?

New Zealand

Early New Zealand

New Zealand too is an ancient land, separating as its own land mass 80 million years ago. Yet, even in their geological and ecological foundations, Australia and New Zealand are profoundly different. The New Zealand land mass is turbulent and shaky, with large earthquakes a constant possibility and small tremors part of everyday life. The vegetation looks different, to an Australian eye, and vice versa—different green, different scrub or bush; and as flat and solid as Australia is, New Zealand is mountainous and forever shifting its footing.

By the time of British settlement in New Zealand, Maori had been living in New Zealand for at least a thousand years, having come from Polynesia in canoes ('waka'). Belich (1996, p 18) suggests that three cardinal features of Maori society that are still prized today were strongly present even at this time: mana, utu and tapu.

> Mana was a kind of spiritual capital, often translated as prestige or authority, inherited, acquired and lost by both individuals and groups. Utu was not simply revenge, but reciprocity, obliging one to return gifts as well as a blow. It was particularly important in relations between groups: the exchange of gifts and hospitality were positive utu. Tapu, a system of sanctity, social constraint and sacred laws, was complemented by its opposite—noa, which can be translated as normal, ordinary or unrestricted.

Maori were and are a tribal people with specific land affiliation. These lands they cultivated for root crops, supplementing their diet through fishing and hunting. Belich (1986, p 19) describes the first Maori–European interaction thus: 'The first Maori reaction to contact with Europeans was, unambiguously enough, to kill and eat them'. Tasman, the Dutch explorer spoken of earlier, visited the New Zealand coast in 1642, and his boats were attacked and several of his crew killed. When Cook visited in 1769, similarly violent incidents occurred. However, there is evidence of trade with Pakeha (non-Maori New Zealanders, a name already in use by 1814), particularly in whaling, sealing and as missionaries (King 2003). And there is evidence of significant movement between Port Jackson, the New South Wales colony, and the Maori world, particularly in trade for timber and flax (King 2003). The return trade was in metals and tools and, devastatingly, muskets. Belich (1986, p 19) summarised the interactions in the following way:

> If Europeans mistreated Maori(s), they would be killed. If Maori(s) mistreated Europeans, trade would stop.

King puts a slightly different complexion on these interactions:

> Where Europeans took the trouble to try to understand Maori codes of behaviour and to identify Maori expectations Maori–Pakeha relations in the nineteenth century were generally harmonious ... Where they did not, there were severe disappointments on the European side, accusations of Maori unreliability and treachery, and bloodshed (King 1988, p 205).

The key to successful interaction clearly was the effort or ability to understand the importance and place of mana, utu and tapu.

As indicated above, from the early 1800s there had been small numbers of Europeans in New Zealand as missionaries, whalers and traders. Missionaries began to teach the writing of Maori languages, which until that time had been exclusively oral, as well, of course, as trying to convert the 'natives' to their God. Prior to 1840, the time of the establishment of the Treaty of Waitangi, there were only approximately 2000 non-Maori living in New Zealand.

Tribal warfare was part of New Zealand history, with the North Island in internal warfare from 1818 to 1833. This inter-tribal warfare was made worse by the phenomenon of the musket brought to them by Europeans, giving rise to the naming of these as the Musket Wars.

The interactions of Maori with the British colonies in eastern Australia brought them into increasing contact with Europeans and eventually to the attention of London. In 1832 a formal link was established, with James Busby being sent to New Zealand as a representative of the British Crown. This appointment was to protect the interests of New Zealand trade with the Australian colonies. According to King (2003), Busby's instruction from London, via the NSW Governor, 'was to protect "well disposed" settlers and traders, guard against the exploitation of Maori by Europeans and outrages committed against them, and recapture escaped convicts' (King 2003, p 153).

The British, keen to prevent expansion of the French in the southern oceans and to control the sale of land to Europeans, planned to annex and then colonise parts of New Zealand. Given that the country was clearly 'owned, governed and used' by its Indigenous people, unlike Australia, some form of negotiated settlement was required by international law. Relationships with Maori chiefs had been cultivated for about 50 years of contact through New South Wales and Busby had moved these further since coming to live in New Zealand. In 1839 William Hobson was sent from London to take the constitutional steps necessary to establish a British colony. This was to be in the form of a treaty.

The original plan was to annex small portions of land only. However, the behaviour of the New Zealand Company, a British company set up to establish trading colonies, together with the threat of the French, who had set up a colony on the South Island at Akaroa and who were planning further colonisation of the rich pastoral lands of the Canterbury plains, and Baron de Thierry's attempts to establish himself at Hokianga, caused Hobson to proclaim sovereignty over the whole country in the Treaty of Waitangi, discussed more fully later.

In everyday life, British annexation had relatively little obvious effect outside the towns of Auckland, Wellington, Wanganui, New Plymouth and Nelson. Although Maori dominated the country areas, the way in which Maori tribes interacted with each other had been irrevocably disturbed by European contact and resulted in what are known as the New Zealand Wars of 1845 to 1872 (until the 1980s these were referred to as the Maori Wars). These were wars of Maori tribes against each other and the British, and resulted in an enormous influx of British military. These wars are well documented in the book *The New Zealand Wars* by James Belich (1988), if you are interested in further reading, or Chapter 15 of King's (2003) *The Penguin History of New Zealand*.

Governor George Grey was sent to New Zealand as Governor in 1845 at a time of great unrest between Maori and Maori, and Maori and Pakeha. He had had contact with Australian Aborigines and was seen as 'good with natives'. He was particularly influential in New Zealand, attempting to ensure that the Treaty conditions were observed and Maori land rights respected. Governor Grey learned the Maori language and assisted in having Maori legends and traditions written down. His papers eventually became one of the most important repositories of Maori language in the country. Governor Grey was also concerned with Maori health and built several hospitals, and also wrote to Florence Nightingale asking how to improve the deteriorating health of the Maori people. Unfortunately, Florence Nightingale's response was not received until shortly before Grey left for South Africa and was never to be influential in New Zealand. The document that influenced health and education policy at the time was a book by Dr AS Thompson, who advocated separation of Maori into English housing and compulsory attendance at European schools. The advice was completely contrary to that suggested by Nightingale, whose letter was eventually found decades later in Grey's South African papers. Nightingale warned against too quickly seeking to educate Maori, to increase the separations between beds in Marae and not to remove the people to individual English-style houses. The advice was not dissimilar to public health advice that may be given today, and if attended to at the time may have changed the course of Maori health history (Keith 1988). Grey also left a legacy of a draft of the constitution that was to become the foundation for governance for 150 years. Under this constitution, Maori men were given the vote in 1867 and all women given the vote in 1893.

The 1860s were dominated by further flare-ups of the New Zealand Wars and by the gold rush with discoveries on both Islands, in the Coromandel Peninsula and in the south, in Nelson and Otago. By 1860 the European population had surpassed that of Maori.

In the towns, European development continued as if a subset of England, or, in the south, Scotland. In 1848, Dunedin was established as a Scottish Free Church settlement and Christchurch in 1850 as a Canterbury Association (Church of England) settlement, both based on New Zealand Company

settlement models. Dunedin and Christchurch today display visible signs of their respective Scottish and English heritages. In 1874 Dunedin had a population of 29,832, Auckland 27,840, Wellington 15,941 and Christchurch 14,270 (King 2003, p 209). But the landscape of the South Island was dominated not by people, but by sheep, of which there were 13 million by 1878.

Again, unlike the experience in Australia, the coexistence of the two dominant cultures moved in a virtually parallel existence until after the Second World War, when the numbers of Maori seeking to live an urban lifestyle grew exponentially.

The Treaty of Waitangi and British 'annexation' in 1840

The Treaty of Waitangi is a foundational document for all New Zealanders and is the basis for the claim that New Zealand is a bicultural country. It is a statement of intent by two very different groups to live equitably and harmoniously together. It was, however, drawn up hastily and by non-lawyers, and translated into Maori by people other than the original authors. On 5 February 1840, copies of the Treaty in both languages were put before a gathering of Northern Chiefs at Busby's house near Waitangi.

There were three articles to the Treaty. The first declared that the chiefs would 'cede to her Majesty the Queen of England absolutely and without reservation all rights and powers of Sovereignty . . . over their respective Territories' (as quoted in King 2003, p 159).

The second article in English held a guarantee from the Queen to the chiefs and tribes and their families 'full exclusive and undisturbed possession of their lands and Estates Forests Fisheries and other properties . . . So long as it is their wish and desire to retain the same in their possession' (as quoted in King 2003, p 159). In return, chiefs would give exclusive right of any sale to the Crown.

The third article extends to the 'Natives of New Zealand Her royal protection and imparts to them all the Rights and Privileges of British Subjects' (as quoted in King 2003, p 153). How one explained to different groups of people with different languages and cultural background the subtle meaning of these words, especially a word such as 'sovereignty', leaves significant questions of informed consent, which have been played out in courts over the past three decades. These misunderstandings were further complicated by the translation into Maori, where the word 'sovereignty' was translated as 'kawanatanga', which to Maori means 'governorship'—vastly different from sovereignty. This misunderstanding was to be reinforced in the wording of article two, which assured the retention of 'the unqualified exercise of their chieftainship over their lands, villages and all their treasures' (King 2003, p 160). These discrepancies were, however, not obvious to anyone at the signing of the Treaty. As part of the Treaty negotiations there was a commitment also that all land transactions that had taken place prior to 1840 were to be investigated by a Land Claims Commissioner.

The Treaty of Waitangi was signed on 6 February 1840 by Hobson and by many, but not all, of the Maori chiefs. Hobson then travelled the country, acquiring the signatures of most of the remaining chiefs, and the document was completed on 3 September that year. Five hundred chiefs signed the Treaty, although a number of important chiefs would not, including Te Wherewhero of Waikato, Tairaia of Thames, Tupaea of Tauranga, the Te Arawa of Rotorua, and the Ngati Tuwharetoa of Taupo. Land purchases began, with land in the South Island becoming readily available as Te Rauparaha and his warring tribe had seriously depleted the number of Maori in the south. This included the purchase by the New Zealand Company of the Canterbury Plains, the most fertile pastoral land in New Zealand. The gold rush also led to the European settlement of the South Island, with gold found in Nelson and large finds on Otago, leading to a doubling of the Otago population in six months in the 1860s.

From 1840 to 1914, 90% of those migrating to New Zealand were from Britain or Ireland, most on assisted passage either from the five New Zealand Company settlements, by assisted passage to the South Island to settle Canterbury or Otago, or as military persons brought in in their thousands to protect the colony.

Despite the existence of the treaty, the mechanisms for purchasing land were by no means straightforward, as often several different chiefs were involved and negotiation with one did not mean permission of the other. These complicated land contestations led to what have become known as the New Zealand Land Wars. Following these wars there was significant confiscation of lands in the North Island and even though this was deemed unjust by a Royal Commission 60 years later, the return of the lands was by then impossible. Maori retreated to their rural communities and Pakeha lived predominantly in the towns, and this segregation continued until the Second World War, when rural economic difficulties and growing job availability in the cities lured young Maori to the towns.

War and beyond

The New Zealand and Australian experiences were often shared experiences in the First World War, and this has already been explored. A major part of New Zealand's Second World War campaign took place in Greece and in Crete. As noted by King (2003, p 398), 'Of all the New Zealand battles in World War II, none engraved itself more deeply on the national consciousness than that for Crete. It was the Gallipoli of its era'. The other major theatre of war was North Africa and included the well known battle of El Alamein in 1942. The New Zealand armed forces also moved to Italy to continue the fight with the Germans. With the fall of Singapore to the Japanese in 1942, New Zealand also dispatched troops to the Pacific. As with the Australian experience, war appeared to unify the nation. But the post-war time was the catalyst for a disruption of the seemingly cohesive nation of parallel lives of Maori and Pakeha. The movement of Maori from the rural areas to the city grew from a 'trickle to a torrent' (King 2003, p 417).

In the 1920s, New Zealand's Pakeha population was 95% 'British'. Those not British but European fitted quickly into the dominant culture. Those who did not, like the Chinese who had migrated with the gold rush, suffered similar discrimination as they had in Australia, relegated to market gardening and never really seen as part of the identity of the nation. It took until the 1990s for an apology to be offered by Helen Clark to the New Zealand Chinese for the discrimination shown towards them for over a century.

For women, both Maori and Pakeha, freedom was much more limited than for men. Having moved on abruptly from its anachronistic British civilisation of the period up until the 1980s, when shops had shut early and never opened on weekends, and the cars looked like they belonged in the 1950s and 1960s, New Zealand in the 1980s caught up three decades in a very short period once international travel became faster and affordable, and when tariffs and industrial relations policies changed to bring New Zealand business into closer alignment with other OECD countries. New Zealand's small size as a country had ensured a history of intellectuals, artists and writers going overseas to further their talents and creativity. From the 1970s it became possible to remain in New Zealand and still participate actively in the international community. Painters such as McCahon, Woolaston and Hotere stayed in New Zealand to work.

Contemporary New Zealand society

The beginnings of change to the steady and time-warped New Zealand Britishness began in the latter part of the 1960s, with the coming together of television, the Vietnam War, to which New Zealand had committed troops, and the collapse of wool prices with its flow-on effect on the economy. The late 1960s and 1970s saw protests related to land, women's issues, Maori issues and issues of sexuality. These immediately became national issues because they could be played out on television. Perhaps the most insightful and accessible writing on the change in the life of Pakeha growing up in the 1940s and 1950s in New Zealand and living through the turbulence of the 1970s and 1980s is the book by Michael King (1985), *Being Pakeha*.

New Zealand women began organising themselves through the early 1970s, having had their consciousness raised by the US women's movement and the growing movements in Australia, of which Germaine Greer's book *The Female Eunuch* was influential. One advantage of the smallness of New Zealand is that change can happen quickly and critical mass is relatively easily reached. New Zealand had a group of articulate, well-educated women who, when they began to speak and write, tilled the soil for New Zealand to become a world force in Women's Studies. Sandra Coney, Phillida Bunkle and Marilyn Waring became household names for several decades. In some ways this is not surprising, as New Zealand European settlement was by families, and New Zealand women appear to have been more equal participants in public life than their eastern coast Australian sisters. They have a history of working with and beside, rather than in service to, the men since colonisation.

Between 1984 and 1990 the Labour government of the time was sympathetic to women's issues and in 1984 it established the Ministry of Women's Affairs. It passed legislation important to raising women's status, including the *Parental Leave and Employment Protection Act 1987*, the *State Sector Act 1988*, which required equal employment opportunities, and the *Employment Equity Act 1990*. Under Helen Clark, the then Minister for Health, the *Nurse Amendment Act 1990* was passed with the full support of all women in parliament of both parties. This Act separated midwifery from nursing and hence from direct control of doctors. It enabled midwives to practise as independent practitioners and has changed the face of childbirth in New Zealand in less than a decade.

Much of the political awareness of women's issues had been raised through the Cartwright Inquiry of 1987–89. The inquiry exposed the mistreatment of women's cervical cancer in Auckland for 20 years from 1966. The experience was captured in the book by Sandra Coney (1988), *The Unfortunate Experiment*. The inquiry resulted in a strong and vocal consumer movement in New Zealand, a disillusionment with the medical profession and a call for cultural sensitivity in healthcare (Guilliland & Pairman 1995).

The late 1980s to the mid-1990s saw an economic revolution in New Zealand that disturbed the whole country. It was economic rationalism on a scale not witnessed anywhere in the world. All understandings of New Zealand's caring, socialist society were shed and a user-pays, individualistic, contractually based, privatised society dominated. Introduced by the Labour government but taken to an increased pitch by the Nationals, the country's assets were restructured and many jobs were lost. Many would contend that this revolution was necessary for New Zealand's economic survival; others would say there was no need for the haste or brutality of what occurred. This tumultuous time has since subsided and a new era of 'collaboration, cooperation and consultation' has taken over as 'the New Zealand way of doing business'.

The progress of women in New Zealand is demonstrated in an unparalleled way with, at the beginning of the twenty-first century, a woman governor-general, woman prime minister and woman minister for health, attorney-general and chief justice.

Michael King (2003, pp 519–20) ends *The Penguin History of New Zealand* with the following words:

> The Maori culture of the twenty-first century is not Maori culture frozen at 1769, nor at 1840. Nor should it be. It changed and grew dynamically according to changing needs and circumstances prior to the eighteenth century, and it continues to do so in the twenty-first century.
>
> Similarly, Pakeha culture continues to borrow and to learn from Maori. That was one of the features that made it different from its European cultures of origin. It took words and concepts (mana, tapu, whanau, taonga, haka, turangawaewae), attitudes (the traditional hospitality which, in the early nineteenth century, was so much more visible from the Maori side of the frontier than the Pakeha), ways of doing business (an increasing willingness to talk issues through to consensus in preference to dividing groups 'for' and 'against' a given motion), and rites of passage

Reflective exercise

What are the issues that affect you as a woman in contemporary New Zealand society, and in what way have these issues been influenced by the history of this country?

(loosening up of formerly formal and highly structured funeral services)...

And most New Zealanders, whatever their cultural backgrounds, are good-hearted, practical, commonsensical and tolerant. Those qualities are part of the national cultural capital that has in the past saved the country from the worst excesses of chauvinism and racism seen in other parts of the world. They are as sound a basis as any for optimism about the country's future.

Modern Maori society

The caveat with which I introduced the section on modern Aboriginal society holds even more deeply for this section. I had the privilege of living in New Zealand for four years in the 1990s and travel frequently to that country, but I do not presume to do more here than highlight some respected texts and again attempt to assist in the development of a conceptual framework from which to further develop your personal understanding.

Unlike the circumstance of the Australian Aboriginal and Torres Strait Islander people, New Zealand Maori had, as we have seen, the benefit of having had a system of living recognisable to the European colonisers, leading to the existence of a founding document of living together, the Treaty of Waitangi, and until after the Second World War there was a prevailing sense of racial harmony, mainly related to the separation of Maori, predominantly to rural areas of the North Island. Post-war industrial development brought young Maori to the cities. In little over a generation, Maori had became a predominantly urban people.

> For the first time since the nineteenth century, the country's two major cultural traditions collided and generated the white water of confusion and hostility. Nobody was prepared for this outcome. Maori experienced discrimination in accommodation, employment and hotel bars. They were confronted with a world that was aggressively European in orientation at the very time that they had severed bonds with many sources of their own culture—traditional marae, hapu and extended families. Many of them became marginal people, weakened both by what they had relinquished and what confronted them. They were soon disproportionately represented in the ranks of convicted criminals, problem drinkers and the unemployed (King 1988, p 12).

In 1936, 11.2% of Maori were urban; in 1945, 25.7% and in 1996 over 81% (King 2003, p 473). Distress and dislocation of urban Maori grew, Maori protest groups formed, and with the assistance of media attention their claims that the Treaty had not been honoured were heard. Maori were insisting

Reflective exercise

Your mother believed that the best upbringing she could give you was to leave behind as much Maori culture as she could, in order for you to 'fit in' more easily. Imagine a conversation with your mother in which you try to balance your respect for her decision with your position as a proud young Maori person for whom language and culture are paramount.

on and gaining major changes in government departmental operations, and language nests—'Kohanga reo'—were set up to teach preschoolers Maori language. A Maori renaissance was being witnessed. The difficulties emerging from the dislocation of people and culture was graphically depicted in Alan Duff's novel *Once Were Warriors*, later made into a harrowing but illuminative film. This brought the issues of alcohol abuse and domestic violence into the open to be addressed by Maori themselves. Perhaps the most momentous of all the changes was the establishment of the Waitangi Tribunal in 1975, which over the next decade explored breaches of the Treaty retrospectively to 1840.

The 1980s resurgence of Maori pride and power has resulted in New Zealand being, and being seen to be, a bicultural country. Maori language infuses the national public communication. A recent film, *Whale Rider*, provides a compelling contemporary view of New Zealand Maori and their challenges.

Pacific Islands people in New Zealand

No snapshot of New Zealand would be complete without acknowledgement of the dramatic increase in the number of Pacific Islands people who have made their home in New Zealand since the 1960s and 1970s. Sitting somewhere outside the bicultural notions of either Maori or Pakeha, the Pacific Islands people have become an integral part of New Zealand identity, art, music and culture. By 2001 there were 232,000 Pacific Islands people in New Zealand, representing 6.5% of the population, 58% of whom are New Zealand born. They have predominantly settled in South Auckland and North-west Wellington, and while they have made a significant contribution to rugby, they are disproportionately represented in manual labouring jobs. They experience significant health problems related to obesity and its sequelae. The six major cultural groups represented are Samoan, Cook Islanders, Tongan, Niuean, Tokalauan and Fijian.

In celebration of similarity and difference

As we have seen, there are similarities between Australia and New Zealand in that their non-Indigenous antecedents were predominantly British. This inevitably brings some

Reflective exercise

You are a Pacific Islands woman living in South Auckland. You are asked by your teenage child how you see yourself in relation to New Zealand and your Pacific Island country of origin. How would you respond?

commonality of culture. These bonds provide a facade of sameness in the countries but, as we have seen, the differences are significant.

The difference, for me, is symbolised in the flatness and solidity of one compared to the mountainous and unstable nature of the other, where green in one country is a very different colour to the green in the other. These differences are paralleled in the differing histories. New Zealand is a bicultural country with a recent history of immigration bringing it very much into the Pacific. This compares to Australia's recent history of immigration and trade, which positions it clearly as part of Asia.

The relationship between the Indigenous and non-Indigenous people is also a strong contrast, and the modern impacts of the Indigenous cultures have been played out in very different ways. Australia describes itself as multicultural, New Zealand as bicultural. New Zealand everyday language is infused with Maori words; the Australian vernacular is barely touched by Aboriginal languages.

Perhaps the two countries are at this time at a point further away from each other than at any time since European colonisation. Australia faces Asia, New Zealand faces the Pacific; metaphorically they stand with their backs to each other. Australia has taken an international position aligned with the United States, New Zealand an independent stance. The temptation of Australians to view New Zealand as a ninth state or territory of Australia could never be more deceptive. The richness of the multiple cultures in both countries is a cause for celebration and exploration, and for practitioners is essential if cultural inappropriateness is to be avoided and culturally appropriate and safe practice is to be achieved. I hope this chapter has helped your understanding of these two countries, their similarities and differences.

Review questions

1. Summarise the impact that history and culture have on health in general and maternity services in particular.
2. Identify strategies that will improve the health and wellbeing of either Australian Aboriginal or Maori women and their babies.
3. Why is the health of Australian Aboriginals and Maori generally poorer than that of non-Indigenous peoples? What can you, as a midwife, do about this situation?
4. Indigenous women in Australia and New Zealand begin childbearing at a much younger age than their non-Indigenous peers. Once socio-economic status has been taken into account, teenage pregnancy is not a risk factor for poor obstetric outcomes. How can midwives provide a culturally safe environment for young mothers while they prepare for parenting and at the same time continue their education?
5. What impact does history have on the conduct of midwifery in New Zealand and Australia?
6. In what ways has the Treaty of Waitangi affected policy development and midwifery in New Zealand?
7. How can midwives work in partnership with Indigenous women to develop strategies for health gain and appropriate health and maternity services?
8. Compared to women from European backgrounds, Maori and Australian Indigenous women do not have the same levels of participation in decision-making, planning, development and delivery of health and maternity services. How can midwives work in partnership with Indigenous women to remedy these inequities?
9. Do midwives have a responsibility to work with women to help safeguard their nations' heritage, cultural concepts, values and practices? If so, how should they go about this and why is it important?
10. From the 1800s to 1969, part-Australian Aboriginal babies and children were taken from their mothers and families and placed into government-run institutions or fostered or adopted by white families. Should all midwifery education programs include compulsory units of study aimed at increasing midwives' understanding of the effects of the Stolen Generation on Aboriginal culture, history and health? If so, why?

CHAPTER 3

Understanding world views for midwifery

Karen Lane

Key terms

biological-reductionist theory, biomechanical/biomedical model of disease, discourse, essentialism, foundationalism, generativity, individualism, interpretive theories, materialism, medical dominance, medicalisation, micro-capillaries of power, narratology, objectivist, partnership, positivism, post-structuralism, professionalisation, psychologism, reflexive self, self, self-narrative, social model of health, sociological imagination, structuralism

Chapter overview

Midwifery entails:

> working with women throughout the continuum of childbirth, which extends from preconception to early parenting. In the provision of care, which ideally is provided within a continuity of care model, the midwife is cognisant of the woman's physical, psychological, social, cultural, spiritual needs and expectation . . . The philosophy for this care is women-centred . . . (Victorian Midwifery Code of Practice, Nurses Board of Victoria 1999)

Midwives understand that in order to sustain the health of the woman through pregnancy and birth, they need to look at the social context and to factor in the distinct identity of the woman—that is, her particular orientation to herself and broader society. Like the WHO (1946) definition of health as 'a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity', midwifery has stepped outside the boundaries of conventional healthcare, or the *biomechanical/biomedical model of disease*. I argue in this chapter that midwifery practised in the above mode will be instrumental in facilitating a positive self-identity or self-narrative for the woman and that this, in turn, is pivotal in creating the intergenerational health of women and babies.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain the difference between the biomechanical or medical model of illness and disease, and the social model of health
2. To describe the relationship between the individual and their social context
3. To differentiate structuralist theories of health from social constructionist theories of health
4. To examine the relationship between discourses and resistance
5. To discuss discourses of the self
6. To highlight the relevance of 'professional generativity' in securing the intergenerational health of women and their babies.

The biomechanical model of medicine and disease

According to the biomechanical model:

- Disease is an organic condition—psychological or social conditions are ignored on the assumption that the causes of disease or illness can be found within the body or biology.
- Disease makes individuals sick; they then report their malaise and take on the sick role (Parsons 1951), while the medical practitioner assumes the role of expert whose object of practice is the sick body.
- The diseased state can be cured by medical intervention.
- The medical intervention is reactive; it treats symptoms of the disease.
- Disease is treated in a medical setting (Bilton et al 2002, p 356).

In the traditional medical model, the 'patient' submits patiently to the expertise of the practitioner, whose exclusive knowledge authorises her or him to judge the causes and treatment of the diseased part of the body without recourse to the social milieu or interior status of the patient. For doctors, the relationship is one of subject/object. The patient becomes the object of the professional medical 'gaze'; there is no reason for the patient to be drawn into more than a formative and cursory discussion of the treatment or its causes, because the expert possesses knowledge about the body independently of the knowledge conveyed by the patient. Although the patient may be able to describe their symptoms accurately, they cannot know the causes because the causes have a pathological origin within the body. The model is inherently expansionary in that it constantly recruits new domains for exclusive jurisdiction. This is what is meant by medicalisation or a situation where ordinary social problems are turned into medical problems and then quarantined as the province of accredited medical practitioners who control the entry, practice and use of equipment and treatment regimes through strategies of professionalisation (Foucault 1973). Examples include homosexuality, alcoholism and childbirth. The outcome is broad-based medical dominance. For example, midwives often argue that birth has been medicalised—that a normal physiological event in the social lives of many Western women in different cultures has been reconceptualised as a dangerous event best undertaken in an acute-care setting under the care of specialist obstetricians. They then claim exclusive legal authority over women by virtue of their exclusive use of special equipment (forceps, scalpels or drugs) or accredited skills to undertake special procedures (surgical, chemical and physiological).

In summary, we could call this model of care 'objectivist' because it assumes that there is an objective reality that can be studied, learned and applied to solving problems, like disease (Rothfield 1995, pp. 174–80). This is sometimes called positivism (reality is posited rather than constructed). It does not accept that the world is a socially constructed world—that reality is culturally mediated. In other words, the medical model fails to acknowledge that how we understand ourselves (including our diseases and our health) cannot be separated from the social, political, historical and cultural contexts in which we live. These social forces form us (our 'self'/our identity/our bodies/our diseases/our health) and our knowledge about the world, including our knowledge about diseases, how we define them and what we label as 'disease'.

The biomechanical model remains the dominant model of the body in the twenty-first century and it is acknowledged here that the above outline is a rather stylised and wooden version. In reality, medical practitioners do attend to factors in the patient's social environment, they do elicit information from the patient about their preferences, and they do share information about the disease. However, the basic premise is sustained—the biomechanical model may be categorised as a biological-reductionist theory that seeks causes primarily within the body and treats the symptoms rather than the larger social causes. An illustration of the causation of disease may be seen in the following:

social conditions → psychological state → biological condition

Obviously the further back we go, the earlier we can prevent the condition (Eckerman 2000, p 55).

There are substantial critiques that challenge the efficacy of the biomechanical model. First, if social forces did not affect physical health, then placebo drugs would not work, yet there is substantial evidence that they do. Second, non-Western health practices are often very effective even though the principle and philosophy behind them are antipathetic to the Western medical model. Third, there is macro statistical evidence that every major health problem, including cancer, coronary heart disease, stroke and diabetes (and we can include birth) varies with the physical, social, economic and physical environments (AIHW 2001; Synnott 1992, p 102).

A social model of health, illness and the body

Such evidence is persuasive that our health status is sensitive to issues of social identity such as gender, ethnicity, education, occupational status, wealth and geographical location. Therefore, explaining why people are healthy or unhealthy demands a social model of the body.

> A social model of the body is one that can incorporate social, cultural, political and economic factors (both micro and macro) that impinge upon health status. This model does not reject the importance of pathogens as causes of disturbance of the efficient functioning of the body but it does enlarge the landscape of causative factors. Further, this model adds another layer of complexity in recognising the interaction of social factors in either causing ill-health or in alleviating or deepening the effects of an existing malaise or disease (Brown 1996, pp 302–3).

Going back to the definition of midwifery quoted earlier, it is evident that the midwifery definition stands as the antithesis

of the biomechanical model, at least as it is related to birth. For professional midwives, midwifery is more than just providing skills. The midwifery profession and midwifery practice are defined in relation to the woman. Further, this relationship is not a distant, objective one but 'a partnership' (Davis-Floyd 1992; Guilliland & Pairman 1995; Wagner 1994). In short, it is a dialogic relationship characterised by trust, reciprocity and integrity (Lane 2000). Further, unlike conventional medical practice, midwives attribute to the woman 'needs and expectations'. In other words, midwifery recognises that the woman possesses agency—she harbours 'physical, psychological, social, cultural, spiritual needs and expectations' and it is the midwife's role to assist her to achieve them. Thus, the woman has a self that has been fashioned by the sum total of the social forces she has experienced and negotiated. Giddens (1987, p 11) calls this the 'double involvement of individuals and institutions' ('institutions' here means patterns of human action over time). What he implies is that human beings create social systems or institutions and those institutions (social, economic, political and historical forces including scientific and medical knowledge) are constantly being changed by the ongoing actions of social individuals—individuals who have themselves been formed and re-formed over time by those very forces. This is a dynamic model of social life and social knowledge. It asserts that the ideas, beliefs, values and institutions we engage with are constantly undergoing reinterpretation in the light of ongoing social changes.

Taking pregnancy and birth as cases in point, we can argue that how a woman progresses in her pregnancy and how she gives birth will reflect the way she processes those social forces. This is what it means to have a 'self'.

> Having a self refers to 'a person's *own* understandings, opinions, stocks of knowledge, cognition and . . . practical knowledge or consciousness' (Elliott 2001, p 5; Taylor 1989). Since every woman has a self, she is entitled to be treated as the final authority on how to proceed and how to achieve outcomes for herself and her baby. (my italics)

We can say, therefore, that professional midwifery (read 'midwifery practice that eclipses the subsidiary role of medical assistant') stands in contradistinction to the conventional biomechanical model of disease in every important way—ways that will affect the progress and outcomes of pregnancy and birth. Comparative trials of midwifery and obstetric models of care typically reflect better outcomes for midwifery care precisely because women are given due recognition for the uniqueness of the self in addition to the usual medical concerns.

In an ideal sense, midwifery embraces a social model of health, one that recognises the social bases of health and illness. In so doing, midwives recognise that in order to achieve competence in their professional practice they must attend carefully to the ways in which the complexity of the social forces in the environment has a variable effect on the woman's/consumer's health status. The diagram in Figure 3.1 (Germov 1998, p 11) depicts a schema whereby the social model of health may be applied to women-centred midwifery care.

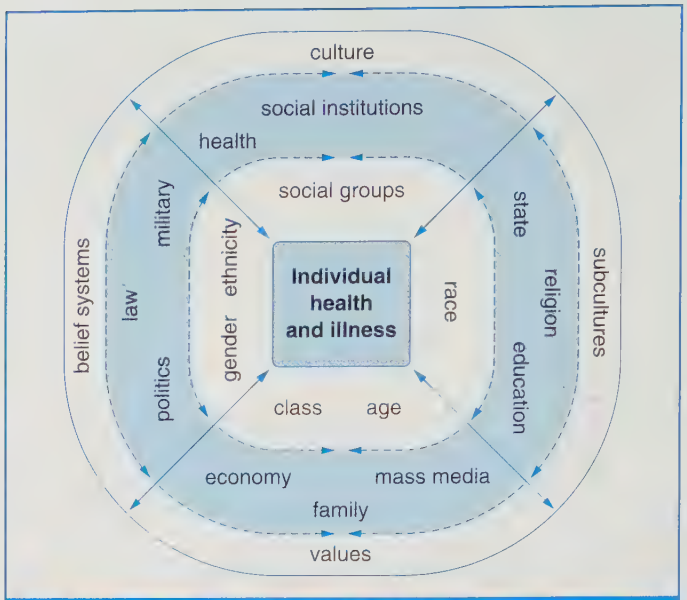

Figure 3.1 Social structure: the links between personal health and social factors (based on Germov 1998, p 11)

We need to stress that the individual is not a pre-social, 'natural' or isolated subject but one that is irreducibly social and must therefore be seen in a given social and cultural context. Individual values are socially acquired values. They change according to different cultures, within subcultures and over time.

C. Wright Mills (1970) called this 'the sociological imagination'. It refers to the idea that we should see the individual as being socialised by the multiplicity of social forces, or the product of interactions within primary social groups such as friends and family as well as major institutions including cultural groups, the education system, health system, political system, the media and economic system, including global political and economic forces. The term 'socialisation' is not used here to imply that social forces are all-determining or that we learn the rules and then placidly obey them. Wrong (1998) called this 'the oversocialised conception of man'. Rather, we want to see individuals as self-reflexive—they have the ability to reflect on their lives, their actions, their own values and where they come from, and with this knowledge are able to reinterpret the world, change their own actions, values and the 'self' and, ultimately, even to change institutions and dominant prevailing attitudes or values.

While professional midwifery practice embraces a social model of birth—since it begins with complex needs and expectations of the woman—there remain substantial questions about how to conceptualise the 'woman' and the 'self' in relation to the social milieu. Failure to be clear about these concepts will ultimately compromise the 'needs and expectations' of the woman and, therefore, the very practice of midwifery itself and its claim to provide a service different from the 'objectivist' model of medical care. An example of

this would be ignoring the substantial disadvantages borne by Aboriginal women who travel long distances from their family, cultural traditions and social supports to deliver their babies without incident in Western hospitals. Another example would be asking a woman within her own culture to deliver a baby without impediment without soliciting her preferences for procedures and support. The questions we need to ask ourselves relate to the diagram in Figure 3.1. How do we understand the impact of all of the social forces upon the woman? Do we prioritise some social forces, like gender, class or ethnicity, as being more important in their effects than others and generalise these to all women? How do we gauge the responses of the woman to those social forces, bearing in mind the 'double involvement of individuals and institutions' outlined by Giddens (above). This means that we understand social individuals as not merely passive recipients of the forces in the social universe. Rather, we actively negotiate their effects upon us according to our sense of who we are—our 'self' or identity. In the diagram, the 'double involvement of individuals and institutions' is depicted by the movement of the arrows outwards as well as inwards.

Structuralism and health

Theories of health that deny the ability of the individual to negotiate structures are called structuralist. These assume that people are victims of their historical and social circumstances. Structuralist theories give exclusive weight to social forces or institutions in determining health status, individual identity and social actions. The person is accorded little or no power to impose their own interpretation on events or to resist a dominant ethos. Structuralism is a form of positivism within the social sciences.

Like natural science, these theories tend to view reality as static and as external to the actor. In research terms they refer to the respondent as the 'subject'. In clinical settings, the person becomes the 'patient'. Positivism changes the person into an object of analysis that is transparent to the (elitist) gaze of the researcher/clinician. Under a positivist framework, the task of the researcher/obstetrician/midwife is to develop better and more sophisticated tools to discover what this reality is. Scientists might develop more powerful telescopes or more sophisticated technological apparatus to uncover DNA. Clinicians/midwives might apply apparatus to the woman's body to obtain a tracing of the baby's and woman's heart rates. Let me hasten to say that this is not a dictum to avoid technological aids. Rather, it is a caution that to rely only on technologies without inquiring into the ways in which women make sense of their social world through their own value framework would be considered positivist or objectivist. Positivism assumes that one can reveal the truth by delving deeper and deeper until you find the smallest and most basic element, which will then reveal the causes of the larger whole. These explanations are then extrapolated to social events, behaviours and patterns. For example, the Human Genome Project currently seeks to discover the relevant gene associated with every labelled biological and social 'disorder' or behaviour, including sexual preferences. Natural science may also try to establish macro causal relationships, such as the relationship between genetic inheritance and criminality, or the relationship between gender and personality traits. Social scientists who subscribe to this view of social reality also try to develop more sophisticated methods of revealing the essence of the world, or the 'natural' or the 'normal'. Their principal methodologies include covert and overt observational techniques, data analysis, large-scale surveys and laboratory experiments.

Consider the theories of health devised by structuralist sociologists and feminists. All assume that one can locate a major explanatory cause to explain the entire course of human history. Structuralist theories assume that knowledge can be posed in terms of a series of dualisms (structure/agency, social structure/culture, social/psychological, family/society, individual/society, subjective/objective, reason/emotion), and that power relations comprise hierarchical orderings such as state/civil, individual/society, men/women, management/worker. We also call this view of history 'modernism'. All modernist theories reflect a yearning to find a single source of power and authority—a 'truth' that is posited outside the everyday social intercourse of humans, a point of reference from which all other things may be measured or assessed or valued. In this sense they follow the path of Enlightenment theorists of the sixteenth century onwards, who courageously challenged the traditional, pre-modernist notion of the absolute authority of God channelled through the King and his minions. Modernists discharged the authority of God, but not the idea of a single authority (Yeatman 1990, pp 286–9). The significant part of their theories for understanding individuals and individual health is that the major source of reference for the truth was a single vantage point from which structuralist/modernist theorists rewrote human history and from which they deduced individual thoughts, beliefs, values and actions. It was assumed that individuals (the 'self' or subjectivity) could be understood according to a single, unitary identity like class (Marx), rationalisation (Weber) or sex/gender (modernist feminisms). From now on I will call this foundationalism. In the following theories we find either biological or social foundationalism. They are not exhaustive of structuralist theories of health, but they are included to demonstrate the nature and range of application and to provide a point of comparison with interpretive explanations of social life. I will deal with this approach later. Interpretive theories assume that there are no such reference points because social individuals construct meaning through interactions with each other. Meanings change over time and across cultures. We may share some commonality of meanings within the same culture perhaps but we cannot predict how social individuals will employ meanings to construct their own identity or to make sense of the external world.

Marxist theories of class and health

Theories of health using a conflict Marxist perspective assume that one's location within the capitalist labour market will largely determine one's health status.

Capitalism is a system of class conflict between the property-owning class and the class of wage-labourers. These differential social locations confer different advantages and disadvantages in terms of education, housing, wealth, cultural attributes (manners and individual aspirations), social networks and health. White collar workers enjoy better health generally because they enjoy higher incomes and can afford better education, food, holidays, safer cars and better healthcare. Several studies comparing perinatal mortality rates of working-class and middle-class areas of Melbourne, Sydney and Adelaide confirm that class is a major factor in health outcomes. For example, one study found that low birthweight infants were born 1.6 times more frequently to women who were considered to be 'socially disadvantaged' (working-class women). Social factors pertaining to low birthweight and perinatal morbidity and mortality include smoking, drug and alcohol consumption and diet, factors that are more prevalent in working-class populations. Other studies have found that mortality rates from diseases such as heart disease, cancers, strokes, bronchitis, pneumonia, cirrhosis, suicide and accidents are higher in some socially disadvantaged local government areas than others (George & Davis 1998, pp 58–61). Other sites of conflict may include ethnicity. Indeed, studies have forged a close correlation between ethnicity, class and mortality rates. In Australia, Aboriginal and Torres Strait Islander people suffer lower life expectancies, higher age-specific death rates at every age, and higher rates of mortality from circulatory diseases, infections, injuries, diabetes and mental illness. In 1991, Aboriginal women were twice as likely to produce low birthweight babies as white women. Aboriginal maternal deaths accounted for 30% of the overall maternal mortality rate in Australia even though their childbirth rates are only 3% of total births (George & Davis 1998, p 63). Within the conflict perspective also, theorists are likely to point to the crucial role of the capitalist state in legislating for individualist models of healthcare—in accrediting doctors as small businesspeople serving their own economic interests on a fee-for-service basis rather than allocating scarce resources to a public infrastructure, including public housing and public health. It also means that small practices are increasingly open to corporatisation, where profit-seeking takes precedence over universal systems of access to healthcare and health becomes a commodity to be sold on a market like any other good or service (Germov 1998, pp 15, 34).

Weberian theories of health

For theorists taking a Weberian perspective on health, the major thread running through their analyses of health systems is the increasing tendency of industrialised societies to be bureaucratised, or governed by rules (Germov 1998, pp 15–18). This approach tends to focus on professions and rules governing practice, to the detriment of patient-centred care. For example, casemix funding focuses on categorising health conditions in order to rationalise costs. Critics argue that this may compromise the type of care that a provider is willing to offer a patient. This might occur when a woman is encouraged to return home from hospital sooner than she should because the hospital is only funded by the state for a certain number of bed-days for parturient women. (The opposite would be a process-dominated approach, where individual parts of the health service are not measured in terms of comparative cost (Leeder 1999, p 76). It would be accepted that some benefits cannot be measured accurately, like the importance to a woman of having continuity of care from one midwife. The service is provided because it is of immense benefit to the woman and her family.) Weberian approaches also use class as a macro social indicator of health status but, unlike Marxian analyses, classes are not seen as necessarily in conflict. Different classes (upper, middle, lower and the self-employed) experience differential access to the health system premised on property ownership or non property ownership and also according to their marketable skills. That is, some workers may not own property but still enjoy high incomes, social status and expansive life chances because they possess valuable skills. Examples would be an airline pilot, an accountant or a scientist.

Feminist theories of health

For modernist feminists, the major social division in society is based on gender differences (as opposed to class in the case of Marx, or class and rationality in the case of Weber). The larger, structural framework that is invoked to explain power differences between men and women is not capitalism (at least in the first instance) but patriarchy, or the dominance of some men over other men and all women.

Much has now been written about structuralist feminisms and I will not attempt to reproduce all the theories in detail. A clear and basic overview of all theories may be found in Wearing (1996, pp 3–30). A more challenging text is Weedon (1992) and a more difficult but exhilarating text is Nicholson (1999), especially Chapter 4. I will deal with structuralist theories here in terms of how they may be distinguished from interpretive or social constructionist theories of gender. Basically, modernist and postmodernist/poststructuralist (meaning 'after the structures') theories diverge in how they conceive of the sex/gender distinction. For modernist feminists, the body was a biological given (the basic point of reference) and 'gender' was the cultural layering that formed on top of the biological foundation (Nicholson 1999, pp 53–55). They therefore recognised some degree of social constructionism in the concept of 'gender' (the social construction of biological sex differences) but the backbone of the theory was foundationalist. That is, like the (male) classical theorists from which they drew much of their theory, they did not question the law-like property of the body as a foundation for theorising about women's consciousness or subjectivity (the self). I will now review some of the major streams of modernist feminisms and offer critiques

of each, before moving on to social constructionist theories of health.

Liberal feminism

Liberal feminists argued that women should be able to choose to forgo domesticity in favour of competing fairly with men for public sector roles. Given equal opportunities guaranteed through law, individual women could achieve equally with men. Domestic tasks could be contracted out on a commercial basis, freeing women for the more interesting and demanding tasks in the full-time public sphere workforce. The problems with this theory are as follows:

- It conceptualises women as free-floating individuals divorced from domestic ties and traditional responsibilities and relationships with dependants. It does not recognise that men and women are located within different relationships within the family as a result of socialisation, particularly with regard to the bearing, rearing and socialisation of children. These are not entirely optional relationships because some women construct their own identities primarily in relation to intimate relationships and family life, while many men seem to perceive a robust masculine identity as based on competing successfully against others in the public sphere. The 'stickiness' of cultural identities explains why women working full-time in the public sphere continue to shoulder 70% of all domestic tasks (Bittman & Pixley 1997).
- It fails to appreciate that gender distinctions are reconstructed constantly in the public sphere, to the detriment of women's ascendancy (Wearing 1996, pp 9–11). The 'glass ceiling' is the obvious example.
- It therefore gives no credence to the importance of the differential effects of cultural understandings on the self-identification of women. For example, some women do not wish to take the corporate road and those who do so often report a residual angst about straddling two realms and managing competently in both, especially in relation to their families.

Marxist feminism

Marxist feminists do acknowledge the wider social, political and economic parameters that shape women's identities. Women are structured by their relationship to the means of production. Women exchanged sexual and reproductive services in return for economic subsistence from their husbands. Under socialism, women would be free to produce their own living in the wider public sphere. Gender inequality was a symptom of class oppression that made women slaves within the family, where they became the proletariat to the bourgeoisie status of their husbands. The criticisms of this approach are that:

- gender inequality precedes capitalism. In so-called socialist countries in Eastern Europe before the fall of the Berlin wall, there was ample evidence that women remain clustered in the low-income, low-status jobs that mimicked their domestic lives.
- although gender is accepted as a social construction of biological sex differences, there is an assumption that the larger social forces affect men and women uniformly (Wearing 1996, pp 11–14). It is, therefore, a form of social foundationalism.

Radical feminism

Radical feminists did address the sex–gender nexus, arguing either that women's oppression was rooted in the biological capacity for reproduction or that male aggression accounted for the subordination of women. The proposition that women have an essential creativity that is threatened by male jealousy and resolved through violence and economic, social and political domination is the mantra of radical feminism. The only solution for this kind of cultural imperialism was for women to separate from men and wrest control of technology away from male-dominated institutions. The major problem here is biological reductionism/biological foundationalism—the assumption that female and male identity are linked to biology and that biological differences between men and women yield universal behaviours, one being an aggressive quest for power and domination by men, and the other an essential procreative ability in women (Weedon 1992, p 17). The problems here are that:

- it assumes that sex and gender are merged, producing universal behaviours for men and women, one of which is essentially positive and the other essentially negative
- it fails to appreciate cultural and social differences among women and among men.

Social feminism

Socialist feminists also adopt a Marxist framework of capitalist class relations but add the importance of understanding patriarchy and racism in the oppression of women. They accept that these intersections are variable throughout history. Thus gender (female or male identity) is not reduced directly to biology. On the other hand, all institutions, including the family, the workplace and leisure, are patriarchal and produce an acceptance among men and women of the naturalness of patriarchy. How we think about our relationships must change and all existing institutions must be abolished because they are the expression of male domination (Weedon 1992, pp 18–19). Ultimately, then, socialist feminists do not resort to biological reductionism/foundationalism but they do resort to sociological foundationalism—a framework that subscribes to the idea of the overwhelming pressure of social forces having a uniform impact upon all women. They give no credence to individual self-reflexivity in both accepting and rejecting male-dominated structures at work and home or to the notion that the female psyche is formed by women's conscious and unconscious sifting through the mass of social influences to form their own position in relation to their intimate and formal relationships.

The summary so far

In summary, structuralist or foundationalist theories posit a fundamental point of departure that can be used to explain the

wider social world. For Marx it was class, for Weber it was class and rationalisation. The classical theorists ignored the body or biology but earlier feminists, particularly radical feminists, turned to biology as a way of explaining the widespread exclusion of women from structures of power. However, in so doing they denied 'the reflexive self' or the ability of women (and men) to actively interpret and negotiate the complex social forces circulating and interacting in the social milieu and, in this way, to create and re-create their own identities.

For midwives and other health practitioners who make a leap from sexual, biological foundations to gender or cultural overlay, this same critique would apply. We need, therefore, a theory that allows for differences among women and among men, and between men and women, so that in considering any health treatment regimen, practitioners take into account individual constructions of the social world. Indeed, any treatment regimen that ignored the ways in which individuals idiosyncratically negotiate their social world in order to construct a 'self' would almost certainly fail or at least earn the disrespect and ire of those at the receiving end.

A final postscript to this discussion is necessary, to acknowledge the validity of some aspects of structuralist theories of health. For example, statistical evidence attests to the causal importance of gender and class as determining variables in the uneven distribution of health and illness. However, the overriding shortcoming of such theories is their biological or sociological foundationalism (Nicholson 1999, p 56). They deny the capacity of individuals for self-reflexivity, which means a conscious awareness of what we do and why we do it (Giddens 1995). Individuals in contemporary societies constantly examine and monitor their daily practices in the light of knowledge available to them, and in so doing create and re-create the self as an ongoing project (Elliott 2001, p 154). By contrast, in eschewing the existence of a robust self, the modernist theorists discussed above (excluding Weber, who did accept some form of reflexivity in his concept of *Verstehen)* explained social action by recourse to the concept of a false consciousness, either due to the suffocating power of a dominant class ideology or, for feminists, a patriarchal ideology. People were unable to know what their 'true' interests were, and so the charter of a revolutionary social movement (feminism, socialism) was to liberate the victim of history from the oppressor (capitalism, the capitalist state, men or the capitalist class).

Interpretive theories of health

Phenomenology, symbolic interactionism and post-structuralism/postmodernism fall under the rubric of interpretive sociologies because they deny that macrostructures solely cause and explain the actions of individuals. They assume that individuals are meaning-conferring, or impose their own meaning on events. All focus upon:

- microsocial relations, or interactions between individuals, rather than macro structural relations
- multiple, local knowledges rather than grand theorising or grand narratives (social forces such as gender, class or rationality or a physical basis, such as biology) as a way of explaining the entire course of human history and action.

Postmodern and poststructuralist interpretative sociologies introduce the idea of:

- complex, multiple identities rather than the autonomous, rational and unitary individual of Western individualism (the idea that you can understand the social world by reference to single individuals)
- power relations as a resource available to everyone, not just single or peak institutions of power like the 'state', 'biology' or 'class struggle'.

The objective here is to provide an explanatory framework that can grasp who it is that midwives (and obstetricians) are dealing with when they engage with the 'woman'. To assume that 'woman' may be defined by her biological capacities alone, or by gender (the social construction of biological sex characteristics), would be to fall into the same essentialist trap (the assumption that human action can be explained by reference to one cause, such as biology or genetic inheritance) as the structuralist feminists. The woman's sense of self would be derived solely from her surrounding political influences or from a biological essence. The self would be a kind of blotting paper where, for example, women would all share the same experiences because they share the same biological characteristics. This would ignore the importance of differences between women based on intersecting social influences (namely class, gender, ethnicity and subculture) as well as biological differences. Note that here we are using biology not as a fact but as a culturally variable entity. In other words, biology is itself a social construction. Under interpretive or social constructionist theories, biology ceases to be a point of departure, or an indisputable fact of analysis, to explain social behaviour (notably gender differences between men and women). This does not mean that the body is unimportant; quite the reverse. It does mean that the body and sexuality may be fashioned and changed in order to construct a self. The body becomes a cultural resource. Gallagher and Laqueur (cited in Lupton 1995, p 21) have noted that throughout history the body has 'been perceived, interpreted, and represented differently in different epochs, but it has also been lived differently, brought into being within widely dissimilar material cultures, subjected to various technologies and means of control and incorporated into different rhythms of production and consumption, pleasure and pain'. The body is thus a mixture of a materialism (the physical sentient base) and discourses (the way it has been moulded by social discourses). As Grosz (1994) says, the body is 'plastic'— it bends and forms according to the discourses that shape it. For example, the performance of the body during childbirth is closely related to the way in which women construct ideas about birth and mothering from a range of competing discourses, as well as how they perceive the immediate social environment. If they are fearful of birth and lack confidence in their body and then encounter practitioners in a high-technology setting who endorse their feelings of

incompetence through their language and actions, women are much more likely to experience delays and obstructions, which then demand increasing types of intervention. The outcome is the now well-documented 'cascade of intervention' charted in hospital births.

To take a social constructionist approach to the body and sexual identity would be to point out that over time different cultures do recognise genital differences as the basis of similar or different identities (Nicholson 1999, p 74), but this feature does not guarantee similar social experiences. Nor does it determine sexuality. For example, people in dominant heterosexual cultures may adopt homosexual behaviours because of their circumstances (men in prison), but consider themselves and identify to others as predominantly heterosexual. Formerly heterosexual women and men may also change their sexual identity in the course of a lifetime, even after having been married for years and having children. Sometimes they change back again. Sexual preference is better conceptualised as a matter of identity, rather than a biological imperative ruled by genetic or any other anatomical causes. This identity may take many years to take coherent form. For example, Plummer (1995, p 54) describes the construction of a homosexual identity as being 'a journey, engaging in a contest, enduring suffering, pursuing consummation, establishing a home'. It is a difficult journey because it takes place in a homophobic and dominant heterosexual culture. For most homosexuals it is a process (of 'coming out') taking varying amounts of time, sometimes years, to admit to themselves and to others that they are homosexual. Within dominant heterosexual cultures, there is also variation over generations about what is considered 'normal' sexual behaviour (Rubin, cited in Giddens 1995, pp 9–16). If there are no solid foundations such as genetic material, sexual impulses, social conflict between classes or between men and women or social harmony to explain human behaviour and social history, then what is there? How can we have a political agenda if the very cement that pulls it together and defines its cause (in our case, the universal category 'woman') disappears as a solid conceptual grounding for clinical decision-making and collective political action?

Nicholson (1999, pp 74–75) suggests we use the word 'game' originally coined by the philosopher Wittgenstein to depict a social entity that shares some characteristics but also differs within cultures over time and between different cultures. As Nicholson says, having a vagina may be one of the similar characteristics but there are exceptions, like the person who identifies as a woman before a sex-change operation. 'Woman' can also mean different kinds of behaviours and preferences or orientations depending on the intersection of other social influences, or discourses, about reality. For example, a black, working-class woman from a rural area will have different experiences of what it is to be a woman than a white, middle-class female executive. Neither can speak for the experiences of the other about what it is like to be a woman.

'Woman', then, is 'a map of intersecting similarities and differences' where the body becomes socially variable according to the discourses that are used to describe it (Nicholson 1999, p 74). Political action need not discard the term 'woman' as the organising principle but it would need to be cognisant of the diverse needs of women, and their complex and shifting identities, and couch their political claims in sufficiently abstract terms to encompass diversity (Nicholson 1999, p 75).

For example, no one is ever just a woman or a man. I would describe myself as a Western, middle-aged, heterosexual mother and lecturer with a small physical build. All of these parts of the identity or the self come from categories which themselves arise from different ideas about social reality, or discourses. The different parts of my 'self' are not equally dominant all of the time. Different characteristics become more or less significant depending on my interpretation of the social context, my own objectives and how I perceive the response from my audience.

The point about the diversity of the self and its fluid nature is important for health practitioners because large-scale research surveys often claim to know 'what women want'. For example, macro surveys of women's needs and expectations during pregnancy and birth (Darcy et al 2001) have been charted to arrive at a set of dictums that privilege some models of maternity care over others. At best this kind of exercise produces a set of aggregate figures that reflect an ambiguous and fairly arbitrary response to a question that would have been interpreted in a number of ways by respondents and where the results may be interpreted in a number of ways by researchers and other readers. We need to accept that women have diverse identities or selves and that to know what they want demands asking each and every one of them not once but constantly. As Nicholson (1999, p 76) says:

> it is time that we explicitly acknowledge that our claims about 'women' are not based on some given reality but emerge from our own places within history and culture; they are political acts that reflect the contexts out of which we emerge and the futures we would like to see.

For midwives, whose own political and professional identities are based on being 'with women', it is vital that they are clear about individual idiosyncrasy. First, it means they need to be in constant dialogue with each woman at each point of her pregnancy and stage of birth because her needs may well change, depending on the circumstances in which she finds herself, including additional knowledge, surprising events and other pressures. We need to put all of this on a viable theoretical basis. That is, to avoid the pitfalls outlined in the foregoing discussion of structuralism, we need to employ a social constructionist framework that does not slip into biological or social foundationalism, that institutes a self that is capable of changing over time in relation to the wider social milieu, that is complex in its constitution and cannot be 'read off' a single social, biological or psychic base, and, importantly, that recognises the power of individuals to negotiate their social world.

Discourses of the self

Individuals negotiate complex social influences from their own unique social location to form a unique self. Yet, in saying

this, I am not arguing for a completely different social universe for everyone because a great deal of our social environment is shared in common. We need to understand, however, how culture is forged and modified. What are the transmission mechanisms? For post-structuralists and postmodernists, the starting point for a 'politics of transformative recognition'[1] is language and discourse. To my mind, Foucault's (1981) determination of 'discourse' is preferable to Lacan's use of the term. As it has been interpreted, Lacan's meaning of 'discourse' commonly devolves into structuralism in assuming that gender identity is determined by a pre-existing, male-dominated symbolic order, where women's subordination is inevitable. This symbolic order is conveyed through a particular view of language as a system of static meanings.[2] Lacan's theory therefore succumbs to 'psychologism'—a causal explanation that relies upon a single, underlying reference point (in this case a psychology of male domination) from which the course of human history may be explained. Its insistence on a static symbolic order of male domination cannot account for shifts in the self over time, the challenge to male domination or other forms of domination, alternative and multiple perspectives and struggles over social meanings (Fraser 1997, p 159).

We need a theory that links language with society and social change. In this way we can see how power is maintained but also how it may be challenged, that is, how to account for resistance at the macro level (including collective social struggles and social movements) as well as at the micro level of the self. Importantly, discourse provides this link to understanding how we confer meaning on social and non-social physical events and how meanings change over time.

Discourse is defined as:

> a pattern of words, figures of speech, concepts, values and symbols. A discourse is a coherent way of describing and categorizing the social and physical worlds. Discourses gather around an object, person, social group or event of interest, providing a means of 'making sense' of that object, person and so on. All discourses are textual, or expressed in texts, inter-textual, drawing upon other texts and their discourses to achieve meanings, and contextual, embedded in historical, political and cultural settings (Lupton 1995, p 18).

Discourses convey knowledge of the world through language. They influence us to see the world in one way rather than another. Thus language is never neutral; it would be a mistake to see language as just a transparent tool for describing the world. It is a mechanism for constructing reality. This is why it is disempowering to say to women that 'their cervix has failed to dilate', or to say, even innocently, 'I can't find the baby's heartbeat'. These words create a reality. This is why Foucault calls the power of discourse 'constitutive power'—it constitutes realities, subjectivities (how we see ourselves and others). Discourses are thus inevitably bound up with the exercise of power. It is not that knowledge produces power, but that power produces knowledge. This is why the medical discourse is powerful—because the institutionalised power of medicine in law, via government policy and in systems of knowledge, conveys an aura of truth. Yet medicine is only a discourse. It is accepted within medical circles that all concepts are contested, often vigorously, among researchers, clinicians and across different specialties. For poststructuralists also there is no undisputed or singular 'truth', only competing discourses. Their juxtaposition allows us to challenge the authenticity of any discourse and thereby to resist social dominance (Weedon 1992, p 111). Note that exercising power will be an uneven process across individuals and across events: not all people will feel powerful all the time in all situations, but the point remains that individuals do possess some power at all times, even if it is just the power to silently disagree. Repressive political regimes inherently know this, which is why the Berlin Wall was constructed and why it had to be pulled down.

This puts the concept of power in a very different light than a structuralist theory of power, where power is conceptualised as a system of top-down domination on the part of, say, a capitalist ideology (Marx) or a patriarchal ideology (feminism). For Foucault, power is exercised at all levels—within institutions at the macro level but also at the level of interpersonal relations. Foucault refers to this as the micro-capillaries of power. Take, for example, the discourse that birth is a dangerous event and that women should deliver in a high-technology, acute-care unit in a hospital with access to obstetric care. This is a dominant medical discourse that exercises power over many individuals because it meshes with other discursive networks, such as the idea that science is only ever conducted in the benign interests of progress and the benefit of patients. Some discourses are suppressed, such as the discourse that obstetrics is at least partially conducted in the economic interests of obstetricians to secure a viable financial base against competitors. We could include the fact that, historically, science and medicine have constituted the body in ways that allow for few alternative constructions, or at least render alternatives as dangerous or foolish or 'unscientific' (for example, homeopathy, naturopathy, midwifery and home birth). Historically also, medical practices have colluded with other institutions such as governments, prisons, hospitals, the military and schools in monitoring, regulating and disciplining bodies (Lupton 1995, p 23).

The body may be conceived, therefore, as the site of competing discourses of sexuality, health, disease and childbirth. The political effects of these discourses include the co-opting of people into their mesh-like nature. For example, people begin to extend the 'medical gaze' to monitor and discipline themselves through dietary practices, health regimens and forms of abstinence. Foucault called this 'docile bodies'. It resonates with the current fashion for the perfect body and the popular cult of the 'extreme makeover'. However, taken on its own, this view is far too structuralist—it presents a view of the self that is passive and reactive, rather than proactive in constructing alternative discourses to challenge the status quo, including dominant medical discourses.

Discourses and resistance

Foucault's theory of power proposes that power is not top-down, as discussed above, and nor is it exercised in a binary fashion, as in a zero-sum game where if one person has power another must lose it. As Foucault (1981, p 101) says:

> There is not, on the one side, a discourse of power, and opposite it another discourse that runs counter to it. Discourses are tactical elements or blocks operating in the field of force relations; there can run different and even contradictory discourses within the same strategy; they can, on the contrary, circulate without changing their form from one strategy to another, opposing strategy.

Although not fully developed as a tool of resistance, Foucault's concept of 'constitutive power' is promising because it conceives of power as creating subjectivities or social positions, which could include resistant positions. Thus, Foucault (1981, p 101) proposes that:

> Discourse transmits and produces power; it reinforces it *but it also undermines and exposes it, renders it fragile and makes it possible to thwart it.* In like manner, silence and secrecy are a shelter for power, anchoring its prohibitions, but they also loosen its hold and provide for relatively obscure areas of tolerance. (italics mine)

In his later work, Foucault (1985) shifted his focus from 'technologies of domination' to 'technologies of the self' that declared a parallel shift in his thinking about the body. Bodies were no longer docile effects of dominant discourses but potentially reflexive in the shaping of the self. However, Foucault did not provide a solid foundation for understanding exactly how resistance may occur, because he was mainly concerned with emphasising the political effects of changes in social organisations (Turner 1990, p 222). We do need to theorise resistance, however, because it looms large in understanding changes in maternity arrangements. For example, the consumer movement of the 1980s is an example of a broadly based rejection of a very powerful medical discourse. So too the professionalisation of midwifery as the guardianship of the 'normal' (Kent 2000, p 28) may be interpreted as a critique of the abstract, scientific and dehumanising practices of obstetrics epitomised by 'the Dublin method'.

The idea of midwifery partnership is the implicit recognition that the consumer possesses power to make decisions and that they may do this by weighing up various discourses from a range of sources, including the midwife and the obstetrician. They will undoubtedly, given adequate information, sift through others circulating via the popular media, their friends, their families and other literature to come to a final decision. I argued earlier that this is how the self emerges. We need to understand the self and the creative ability of the individual to resist dominant discourses, because midwives would want to challenge Foucault's claim that as members of the 'helping professions' they are acting as instruments of social control.

The postmodern self

At this point it is important to qualify the concept of individual autonomy or 'voluntarism' in relation to self-identity and thus the power of resistance. Postmodernists insist that the self in the post-industrial, postmodern, consumption-oriented, communication society of global capitalism produces a highly reflexive self, but one that is also highly fragmented and fluid. How is it then that women could manage to resist dominant discourses when the self is so malleable? Many explanations of the self turn to psychoanalysis but, as argued earlier, these typically resort to rigid symbolic orders where individual resistance and social change is theoretically negated or becomes an incidental outcome of the slippage of meanings between signifiers (words, pictures or sounds) over time. I am suggesting that the self is produced and reproduced much more proactively through engagement with various discourses over time. Thus the self is always shifting according to one's position historically and socially, but to do this the individual needs a sense of consistency and continuity, especially at the level of emotion. The way in which individuals do this is by harvesting elements from sometimes competing discourses where the outcome is a coherent self-narrative. This allows them to act in the world in a relatively autonomous fashion. Theoretically, poststructuralism (the construction of reality through language) is married with narratology (the way in which people give meaning to their lives by constructing stories about their experiences) (Gergen 1994) to provide a solid theoretical grounding to explain women's agency. Let me provide an example of how one woman reported her home birth to construct a narrative of good mothering in the future:

> ***Q*** So how was home birth for you?
>
> ***A*** Extremely good. I am a very strong believer as well that a positive launch into motherhood, into parenthood, into the world for the baby is like the crest of a wave that helps to carry you along for quite a long time. And I think if you don't have that, for those who've had difficult and traumatic births, I think they are struggling. They haven't got that crest of a wave and they are struggling for a long time afterwards, sometimes forever. It colours their whole attitude towards their child or children and parenthood. And I think that I had that crest of a wave. OK, I had ups and downs afterwards, but I really feel that on the crest of the wave I was launched.

Self-narrative represents the outcome of a process of imposing order on a random set of events in the external world over which people have limited or no control. People construct a life history through embellishing and promoting some aspects of their lived experience in order to forge coherence between the past, present and future. This is an interesting strategy because it intuitively balances the uncertainty and risk that defines contemporary social existence. It grounds the postmodern self, not from a universal vantage point (as in structuralist theorising) but from the individual author's own lived, embodied experience and interpretive practice (Gubrium & Holstein 1994). In the example above, the woman

decided to claim some events over others that happened in her birth to conclude that it had been successful and that this was an auspicious beginning to motherhood. In so doing, the woman's self-narrative depended on a range of other discourses from which she also drew. Hers was what Gergen (1994) terms a progressive narrative—'Life is in every way getting better'. The regressive narrative is where life goes backwards or downwards—'Life is just one damned thing after another'. The stability narrative links events in such a way that things go on the same. All recount the past in terms of how to make decisions to steer the future. Constructing a self-narrative is what it means to be self-reflexive. However, our choice of events to harvest is not arbitrary but draws upon certain culturally sanctioned archetypes appropriate for one's age, gender, social class and so on. For example, a 'getting older' narrative for women means dressing and acting in a certain way. Women want to avoid being perceived as 'mutton dressed as lamb', whatever that means to them. Some teenagers want to avoid being perceived as 'nerds', whatever that means to their subcultural group. We are sensitive, then, to the prevailing discourses around us that position professionals as key figures in the construction of either progressive or regressive narratives. It would be helpful, therefore, to think about how professionals can position themselves so that women may more readily construct a progressive self-narrative.

Generativity

Generativity is a term coined by Erikson (1963) to refer to a life-stage in the middle post-marriage years when people are ready to orient their energies to others and to the larger social sphere. The opposite is self-absorption. Multidisciplinary scholarship has spawned variants on the original concept but all refer to social practices that are intended to contribute to the wellbeing of the next generation and the common good. If a woman has experienced a lack of power in many dimensions of her past life (and many feminists would argue that women typically do experience political subordination in a range of spheres), a birth that mimics loss of control and respect is likely to reinforce a regressive self-narrative. Conversely, a maternity career that is interpreted by the woman as positive and life-enhancing for herself and her baby will galvanise a positive self-narrative and this narrative will re-form the self and be projected onto the future relationship with her child and onto other aspects of her life and other relationships.

Clinical generativity

Clinical generativity is described as:

> a way of conceiving of and conducting the clinical process such that emphasis is given to community and temporal context, choice and capability, and spiritual and moral dimensions in relation to sustaining and strengthening intergenerational relationships. Generative counselling explicitly and systematically seeks to transcend the medical model in these contexts (Dollahite et al 1998, p 453).

We might see generativity as revitalising Foucauldian and sociological critiques of professionalism defined by power and pecuniary self-interest, market domination of competitors through limitation, subordination and exclusion and the infantilisation of clients to ensure their ignorance and ongoing need for the service (Turner 1990; Willis 1983). Clinical generativity may go some way to neutralising the market competitiveness and cultural dominance that has in the past characterised obstetrics, and it may prevail over the clinical timidity of some midwives. It would underpin a genuine partnership approach to the care of pregnant woman by highlighting the 'spiritual and moral dimensions in relation to sustaining and strengthening intergenerational relationships' by focusing on the woman's needs rather than the narrow professional needs of either midwifery or obstetrics. Clinical generativity challenges a medical model of determinism; that is, that events could not have happened otherwise because of some pathology of the mind or body. Clinical generativity does accept a quasi-determinism—that people's actions are embedded in their history and family dynamics—but it does not dwell on deficiencies. It assumes that people may choose generative actions given sufficient individual self-reflexivity about the past to redirect the future. Events are not entirely outside the individual's control (Dollahite et al 1998, pp 464–5). For example, a person who has been the victim of child abuse need not necessarily repeat that behaviour with their own children, and a person who has been a perpetrator of violence may, with sufficient professional help and self-determination, be able to reform their behaviour.

Professional generativity

However, we need to go one step further. Because clinical generativity has been applied to individual counsellors it is less applicable to situations such as childbirth, where women may see different kinds of professional carers over the period of their maternity career. Under these conditions, generativity needs to be institutionalised into a social model of care that systematically recognises the importance of women's agency and self-reflexivity.

We could call this professional generativity. This model of care would also endorse the importance of providing appropriate care for women, that is, care that may require more than one professional. It follows that the professionals involved would be focusing on the woman's needs. A collaborative model of care is indicated here, one in which professionals genuinely value the respective skills and competencies of the other and minimise traditional tensions and anxieties. Like generative counselling (Dollahite et al 1998, p 471), it could encompass a spiritual dimension in transcending a limited concern with professional self-interest and placing a premium upon affirming the values and beliefs of women and their families.

The following self-narrative is an example of a transcendent experience of childbirth that followed a first, unhappy birth.

> My mother had five babies and had a horrendous time with every one of them and she brought my sister and me up to believe

that having children was a curse and that you didn't want to go through that. I was determined that it wasn't going to be like that. Yes, it is a major life event, isn't it? It's something that you do two, maybe three or four times in your life and it's the most important thing. It's also natural; it needn't be a conflict and surrounded by technologies . . . I felt clever, very self-satisfied and special. Somehow after that I respected my body so much more. The half stone overweight didn't seem to matter very much after that.

The mother put this progressive self-narrative down to continuity of care with the midwife. As she said, 'Because you've got a relationship with someone then you're not just a patient'.

Conclusion

I have argued that midwifery represents a social model of healthcare, one that recognises the social bases of health and illness. I critiqued structuralist theories of health that explain disease or other events by recourse to a single point of reference. I argued that interpretive theories explain health as the outcome of individual negotiation of complex and contradictory discourses. Foucauldian theory inserts the importance of power relations in understanding the greater influence of some discourses over others. Foucault was less explicit about how to conceptualise individual agency. Yet this is important because partnership is pivotal in definitions of good midwifery practice. Partnership assumes an egalitarian relationship between rational equals. In order to act as an autonomous entity, individuals need to have a sense of self or self-reflexivity. I have argued that we can use the idea of self-narratives to clarify the processes whereby women harvest events from the past to explain the present and direct their actions in the future. Self-reflexivity through the construction of a self-narrative explains how resistance against powerful discourses of the body is possible, especially medical discourses relating to birth. Although discourses do not determine self-narrative, they do shape it. I have suggested 'professional generativity' as an umbrella term that imparts a vision of collaborative practice within continuity of care models to enable women to construct a progressive (that is, healthy and assertive) self-narrative.

Review questions

1. What is meant by medicalisation?
2. What is meant by a social model of health, illness and the body?
3. How does the social context affect the physical body?
4. How could you explain your choice to do midwifery by using 'the sociological imagination'?
5. What is the one characteristic shared by all structuralist theories of health?
6. What is the difference between biological foundationalism and social foundationalism?
7. What is meant by 'partnership' between the woman and her carers?
8. What is the difference between 'top-down' (structuralist) theories of power and 'bottom-up' (social constructionist or constitutive) theories of power?
9. What is a discourse?
10. How are discourses related to self-narrative?
11. Is generativity a useful concept for thinking about midwifery practice?

Notes

1 This term is derived from Nancy Fraser's (1997) essay on a viable political culture and future direction for political groups. She argues that some groups need economic redistribution and some need cultural recognition but most political groups, including women, need both. Political remedies such as 'affirmative recognition' solidify group identities and cast them into the rejected side of the accepted 'other' (e.g. marginal homosexuality against a dominant heterosexuality) but the effect is to polarise them around fixed sexualities and identities. Political remedies such as 'transformative recognition', by contrast, as in queer politics, aim to destabilise all sexual identities to make sexual preference 'a sexual field of multiple, debinarized fluid, ever-shifting differences' (p 24). That is, it accepts a diversity of experiences and orientations.

2 There is not the space here to interrogate Lacan's theory further but interested readers may go to Fraser (1997, pp 154–157) for a more sustained critique.

CHAPTER 4

Risk and safety

Joan Skinner

Key terms

accountability, normality, referral, risk, safety, techno-rational discourse, values

Chapter overview

This chapter aids in the understanding of why risk is such an important concept. It begins by presenting the techno-rational or scientific approach and goes on to provide interpretations from social and cultural perspectives. What becomes clear is that the understanding and management of risk and the promotion of safety are not simple matters. However, the concerns related to risk and safety need not always engender fear and anxiety. The second part of this chapter provides a framework that the midwife can use to support safe, effective and life-affirming care within this risk environment. The framework acknowledges the complex and often paradoxical nature of midwifery practice and provides a way for the midwife to put the management of risk and safety into practice and into perspective.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain the concepts of risk and safety
2. To discuss the scientific and sociocultural contexts in which risk is manifest
3. To highlight the centrality of the relationship with the woman in the provision of safe care
4. To discuss the importance of skilled midwifery care
5. To discuss the place of accountability for the use or misuse of midwifery skills
6. To discuss the place of referral and the importance of collaborative relationships
7. To acknowledge the complexity of the environment in which safe midwifery care is provided.

Introduction

The assessment of risk and the promotion and protection of safe childbirth are key elements of the provision of maternity care. Risk and safety are strongly related concepts that the midwife must come to terms with as she works alongside women as they become mothers. Safe practice minimises and 'manages' risk; risks are assessed, avoided or managed in order to provide a safe environment in which to give birth. Risk affects the lives of midwives, both in the assessment of risk in the childbearing woman, and in the management of their own risk within the medico-legal context. Yet there is something about how risk is currently constructed, not only in maternity care but also throughout the Western world, that reflects rising levels of anxiety. This increased anxiety about risk and safety is reflected in maternity care and is occurring despite a growing understanding of the causes, incidence and prevention of negative outcomes. This has been accompanied by increasing levels of intervention, accountability and surveillance, with significant implications for the way midwifery is practised (Skinner 2003). It challenges the model of birth as a normal part of human life and thus presents challenges for midwives attempting to enact in practice this model of normality. Midwives are faced with a significant paradox in attempting to work a 'birth is normal' perspective within a 'birth is risky' context. Working in this context requires the midwife to have a sophisticated understanding of the meanings of risk aversion and of safe practice.

In a sense, risk and safety have become opposing positions. There is little acceptance that taking risks is not only a normal part of life but is also essential. Without it humans do not develop. We can miss valuable and life-changing opportunities. In order to achieve safety we might sometimes put ourselves at risk of unforeseen and unknown risks. Sometimes you have to take risks to be safe, yet safe action may have unforeseen negative outcomes. Complete safety cannot be assured and there is no such thing as a risk-free birth. Risk in the current environment has become associated with the possibility of negative outcome rather than with the possibility of positive experience (Tulloch & Lupton 2003). It is the fear of negative outcome that is most often expressed. One rarely (if ever) reads reports of the risks of a positive outcome of a planned action. For example, how often is it expressed that if you plan a home birth you risk having a birth with no intervention? It is important then for the midwife practising in this environment to have an understanding of how and why risk has become so prominent and to have some tools to deal with the reality of how this affects safe practice.

Science: sourcing the evidence

The first place to investigate, and the one that holds the dominant position in current risk discourse, is the techno-rational or scientific approach. It is here that we see research dominated by epidemiology and by the randomised controlled trial and the use of this research in informing practice. These approaches to risk are focused on the mathematical calculations of risk associated with the probability of events occurring. Their main concerns are in the measurement of risks and effects. These approaches provide valuable information for the midwife in the provision of safe care and are an essential part of her knowledge base. For example, the meta-analysis of the randomised controlled trials on continuous fetal monitoring (CFM) indicates that for low-risk women, CFM increases the risk of unnecessary intervention (Thacker et al 2004). However, the application of the scientific evidence in the management of risk and the promotion of safety are seldom simple. There are several challenges that midwives face in assessing and managing risk from a science or evidence-based framework.

For the individual health practitioner there is a fundamental difficulty in extrapolating knowledge from large studies and applying it to individual situations. For example, the early identification of risk is notoriously imprecise in predicting adverse outcome for the individual (Enkin et al 2000). Once the complexity of the individual situation is identified, the ability to know what the quantified risks of an adverse event occurring are may be further eroded. The quantification of risk must take into account not only the rate of adverse outcome but also the possible benefits, and must ensure that there is some consistency in how the risks are framed (Guise 2004). The identification of risk is also tied up with control. Heyman (1998) contends that where health practitioners claim to predict the probability of an outcome for individuals, there is a tendency to attempt to make decisions on their behalf. He states: 'The health professionals' crystal ball, although providing only cloudy, probabilistic glimpses of possible futures, through the methodology of epidemiology, leads them into attempting to manage risks on behalf of their clients' (p 22). Skilled, clinical assessment and effective communication therefore remain core competencies for the midwife in assisting the client in decision-making around safe care. The scientific evidence is one important tool to inform this practice.

The techno-rational model of maternity care also has particular implications for the understanding of what is normal and so has a special importance for midwifery, which claims expertise in 'normal' birth. Understandings of what is risky and what is normal both dominate and delineate midwifery practice and yet are often seen as juxtaposed positions. Normality has changed from being a social to a scientific concept, as we have come to accept the idea that one can't know something unless it can be measured (Hacking 1990). Being normal therefore has come to mean both having no measurable risk factors and also being 'average'. This search for measurable regularity and thus quantifiable normality has given rise to rules about childbirth that have not undergone in-depth analysis (Murphy-Lawless 1998). An example of this is the decision about what constitutes a normal labour. This needed to be measurable, so statistical data of the length of labour has been applied to individual women's progress.

Deviations from the measurable, statistically assessed norm are then seen as needing to be managed and controlled. In essence, then, science in the guise of medicine has re-created and redefined 'normal' and has seen pregnancy as normal only in retrospect (Cartwright & Thomas 2001; Symon 1998; Wagner 1994).

It is within this dominant techno-rational discourse that midwifery stays firm in its claim to expertise in normal childbearing. It is a precarious position to take, given who is defining normality and who is defining risk. The challenge for midwifery is to look beyond the techno-rational definitions of normal and to claim its own. Midwifery sees birth as a normal process, not only physiologically but also socially, culturally and spiritually (NZCOM 2005). This is reflected in the commitment that midwifery has to partnership and to women-centred care. One of the risks of this perspective, however, is the possibility of decreased emphasis on the physical aspects of what we currently call normal birth—that is, birth with no intervention.

The techno-rational approach has also tended to make safety into a commodity, one that professionals are meant to be able to provide. Symon (1998), in his study of midwives' and obstetricians' attitudes to litigation, found that both midwives and obstetricians agreed that women had been given the impression that science (in the form of obstetric intervention) can achieve more than it actually can. The techno-rational model focuses on making danger visible (technology) and measurable (epidemiology) (Cartwright & Thomas 2001). But as Smythe (1998) points out, this is not always possible. There is, she says, unsafeness that is unknown. Some things can appear unannounced, suddenly and without warning. The normal and the abnormal can 'mimic' each other. She also comments that being safe or being unsafe (being at risk) is, in a sense, already there. Some women could give birth safely with no professional input and others will not give birth safely even with all the help that professionals can provide. So the midwife is there not to 'sell' a safe birth as some sort of objective measurable commodity but to support safety and to uncover, as much as she can, the risks that might threaten this safety. This unknowable nature of risk and safety means that the midwife must be skilled and vigilant.

The techno-rational approach also implies that decision-making should be made by rational experts rather than by the 'insignificant others' (Stapleton 1997). Davis-Floyd (2002) describes this approach as technocratic. Based on the pre-eminence of technology and of mind–body separation, the technocratic approach, she says, treats the 'patient' as object and sees responsibility and authority as being held by the practitioner. This approach also presupposes that both the assessment of risk and the experts themselves are objective and rational and that people will make rational decisions about what is risky and what is safe (Lupton 1999). It is based on assumptions that the evidence provides clear answers so that choices will be also be clear and self-evident. However, this is not often the case. Take, for example, clinical practice guidelines that recommend induction of labour for pregnancies that go past 41 weeks gestation. Menticoglou and Hall (2002), on close examination of the research on which these guidelines are based, estimated that it would take 1000 inductions of uncomplicated pregnancies at 41 weeks gestation to possibly save the life of one baby. The decision about whether this is a justifiable intervention will inevitably be based on what is valued or what is feared and is therefore not a rational process. Menticoglou and Hall also highlight the possible harm caused to women and their babies by the 999 unnecessary inductions, and also to other labouring women being cared for in a maternity unit busy doing these unnecessary inductions. The use of such clinical practice guidelines, they state, also has considerable implications for litigation when they are not strictly adhered to. How midwives assist mothers to make such decisions can therefore be fraught. Who has the power to decide whether these risks are worth taking? Decisions about risk and safety are therefore not as simple as one might think.

Heyman (1998) summarises the difficulties related to the application of science and technology by saying that although the techno-rational approach has made a huge contribution to human development, it:

> cannot accurately predict most biographical outcomes, answer questions about values, or provide convincing solutions to the mind–body problem. Many of these issues come to a head in the management of health risks. [The] notion of probability, which underpins the idea of risk, does not provide a rigorous scientific tool, but only a heuristic, rule-of-thumb device which had both utility and limitations; and that the assessment of 'adversity' entails weighing up values in ways which sometimes are contested (p 2).

Heyman points out that however helpful epidemiology may be, risk decisions are not made rationally and must be understood within their social and cultural context.

Society, culture and the role of values

The management of the risks associated with childbirth then are not only understood in physical terms but must be understood within their societal and cultural contexts. As stated earlier, the current social context has highlighted risk as a central concern. This is not peculiar to maternity care. Beck (1999), a foremost sociologist in risk theory, has proposed that we now live in a 'risk society'. Modern life, he asserts, has been based on the idea that technology and science can provide the answers to our problems. Progress and controllability have been fundamental beliefs in the search for safety and security. The success of modernity, as represented by science and technology, has led to globalisation and thus to a growing understanding of the multiple ways of living and viewing the world. Modernity has also led to individualisation and a sense of self-determination. This in turn has challenged traditional social understandings including the role of women and the place of the family, leading to increasing uncertainty. This uncertainty is also reflected in the undermining of faith in

science and technology, by the growing understanding that not only does technology not solve all our problems, it actually creates some of them. This uncertainly about societal roles and loss of faith in technology have led to a generalised insecurity and anxiety, along with a loss of faith in professionals and in technology. We are in a state on being 'in between', where we have not yet created social and cultural forms that replace the tenets of modernity. We are, according to Beck, not yet postmodern but are living in what he calls 'late modern' society, where we live with, among other things, the paradox of losing faith in experts while at the same time still expecting that their work will be free of negative outcomes. The levels of anxiety that are produced become counterproductive. In terms of maternity care this reflexive culture means that maternity practitioners can be constantly questioned, challenged and increasingly restricted in their practice. The accountability that results causes fear and stress not only in the practitioners but also in the consumers of maternity care, as they themselves are required to make choices with risks attached that are difficult or impossible to quantify.

Ironically this desire to avoid or control all risk in itself creates its own problems. Annandale (1996) comments that the consumerism and managerialism that have emerged as part of the risk society have tended to further increase the levels of anxiety and, paradoxically, to have undermined the quality of care that is provided. It is this combination of managerialism in the form of protocols and guidelines, and consumerism in the form of informed choice and consent, that provides the current background for midwifery practice. One needs only to reflect on the increase in caesarean section rates in light of the 'risk society' to see how this can be applied to maternity care and to midwifery. In the effort to control for all risk, both for the mother and baby and for the maternity practitioner, caesarean sections are an increasingly used intervention. Yet this intervention comes with its own risks. The dilemma for the midwife is to work in this increasingly constrained environment while providing care that is flexible and truly women-centred. And all this in an environment focused on risk aversion. The risk society as manifest in maternity care reflects the tension between both the acceptance and the rejection of modern biomedicine. Davis-Floyd (2002) accepts the valuable knowledge that biomedicine has provided but also contests its dominance. The anxiety associated with risk and safety can be seen then as having its origins in the movement beyond an uncritical acceptance of biomedicine. The resurgence of midwifery and the increase in the valuing of humanistic or holistic care could be seen as part of the movement towards a new, more postmodern way of viewing the world. We certainly seem to be in a state of transition.

Another way to view risk and safety is to take a cultural view. Cultural perspectives attend not so much to the way in which current social forms are reflective of risk (as in Beck's 'risk society') but to the way in which societal forms themselves affect the way decisions about risk are made. One of the most influential thinkers in this field is the anthropologist Mary Douglas (Douglas 1992; Douglas & Wildavsky 1982). Douglas points to the lack of uniformity in opinions about what makes something risky, how risky it might be and what should be done about it. She rejects both the scientific, objectivist approach and an individual rational choice approach to risk decision-making. Instead, she proposes that risks are decided upon according to the cultural meaning associated with them, and is critical of experts' attempts to get to the objective truth of risk by protecting it from the 'dirty' side of politics and morals. People, she proposes, do not make decisions about risk according to individualised circumstances and beliefs, but are culturally conditioned to prefer some types of decisions over others. Their beliefs and actions therefore are culturally constructed. Within any culture there will be subgroups and communities who have varied value bases and ethical systems. These ethical systems too are culturally constructed and may vary. This variety is not related to any misguided perception, as objectivists would propose, but to different political, moral and aesthetic positions (Lupton 1999).

Values and uncertainties are an integral part of these choices and Douglas proposes that the choices between risky alternatives are not value-free. Choice in the end, therefore, is essentially based on social rather than scientific knowledge. This decision-making process can also been seen as political. Who should make decisions, who and what should matter, are related to whose knowledge is regarded as authoritative. Douglas's position does acknowledge that dangers and risks are real but proposes that it is impossible to rank them in any rational sense. There are simply too many of them (Douglas & Wildavsky 1982). A cultural approach therefore helps us see risk decision-making as a result of community consensus, rather than rational individual choice. It is this community consensus that gives preference to some risks over others. We see this clearly in the decision-making processes around birth. Take, for example, a woman's decision to deliver her breech baby without intervention, compared with an obstetrician's wish to deliver her baby by caesarean section, or a woman's choice to have an epidural anaesthetic despite her midwife's commitment to normal birth. How do the women's decisions reflect their cultural and community perspectives? Whose knowledge is authoritative? How is fear being expressed? And of course, who is at risk?

Both the social and cultural interpretations of the current risk discourse speak to how blame is apportioned. Both see blame as a reflection of societal and cultural forms that have some basis in controllability. Where adverse outcomes eventuate, someone must be held accountable for the mis-management of risk. Blame then is a deflection onto someone else. Accountability for adverse outcome is required and is usually punitive. This is reflected in the 'name, blame and shame' approach that is manifest not just in maternity care or even just in healthcare but increasingly in every sphere of life. This has significant implications for health practitioners in the risk of litigation. Health practitioners, including those in maternity care, express considerable anxiety related to this risk of litigation (Aslam 1999; Cunningham 2004; Keaney 1996; Ruston 2004; Skinner 2005; Symon 1998).

Risk and safety then can be seen not only as core business for the midwife but have been made even more dominant in

current maternity care by the 'risk society' in which we now live and work. The techno-rational approach to maternity care still dominates despite a growing understanding of the place of values and cultural understandings of risk and safety. The midwife must provide care that incorporates these different ways of knowing and acknowledges and deals with the complex and often conflicting perspectives inherent in these approaches. The following model offers the midwife a framework to support and assist her in this work.

Working with risk and safety: a birth stool for the midwife

This model has been developed from my research into how caseloading midwives in New Zealand manage risk in practice. The research was a mixed method study conducted in 2001 and examined the referral for obstetric consultation as a place where the expression of risk was most evident. The first part of the study was a national, total population survey of caseloading midwives and described the referral for obstetric consultation patterns. It also included an assessment of the midwives' attitudes to risk management, to referral and to the medico-legal environment. The second part of the study consisted of a series of six focus groups with midwives in a variety of New Zealand settings. The settings were selected to provide a range of perspectives and included regions across the country, both rural and urban, and small and large cities. The midwives discussed the challenges and opportunities they faced in the management of risk. The survey data were analysed with descriptive statistics and the focus group data were analysed thematically. The two data sets were then interpreted together in the development of the model. It is a model for practice focused on how midwives deal with risk.

Models can be very useful as they provide a framework for understanding the complexity of the real world and can guide our actions by defining what is important (Stewart et al 2003). What became evident during the development of this model was that dealing with risk and safety is no simple matter. It is not just about identifying risk factors and referring, or about good documentation, nor can it be compartmentalised into one aspect of midwifery practice. What also became apparent is that there is no quick fix for risk. Being a safe practitioner comes from being an effective midwife in every area of practice. The model therefore is a representation of the midwife's work. Its origins come from studying how risk is expressed in practice and it is placed within current understandings of the 'risk society'. It can also therefore be interpreted as a model for practice as a whole. The framework represents midwifery practice as a simple three-legged stool (Fig 4.1). It is a birth stool, not this time for the woman, but for the midwife. It is a tool that she can take with her and use wherever she practices. Many aspects of this 'stool' are covered in detail later in this text. The following section describes the stool and provides a framework for putting the whole of practice together in order to become a safe and effective midwife.

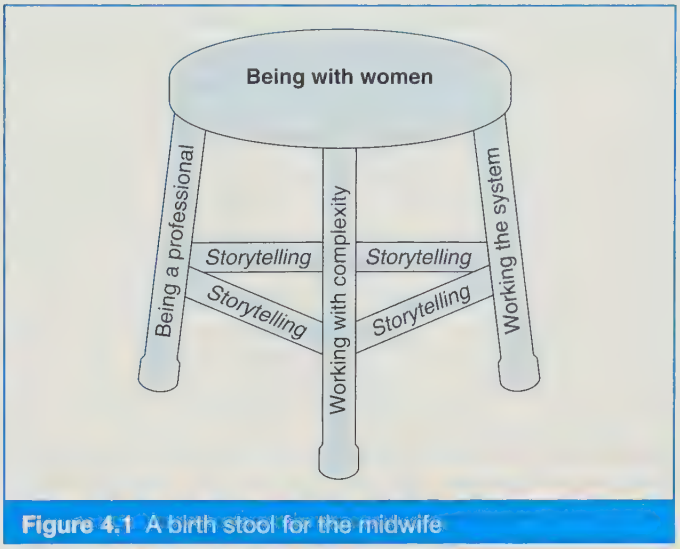

Figure 4.1 A birth stool for the midwife

Being 'with women'

The most important part of a stool is of course the seat. The seat of this stool I have called 'being with women'. It represents the centrality of the midwife–woman relationship and the importance of being alongside the woman in her journey to motherhood. It is the quality both of the relationship and of the communication that is the critical factor in the maintenance of safe and appropriate care (Edwards 2000; Symon & Wilson 2002; Wilkins 2000). Relationships matter. It is within this relationship that trust is formed, information is shared, options are offered and decisions are made. Continuity of carer is important for these relationships to be formed. Being 'with women' provides the space and time for the midwife to know the woman, to understand her perspectives and to anticipate her needs. Smythe (1998), in her study of maternity practitioners' and women's understandings of the meaning of safety, comments that the relationships the midwife forms with the women are embedded in a particular social and cultural milieu that the midwife enters and uncovers. These relationships the woman has are with family, friends, other practitioners, medicine and even the media. Smythe describes the relationship as one of 'concernfulness' (Smythe 1998, p 188). It is within this concernfulness that the midwife can most effectively discern what is safe and what is not. In my research, this relationship was manifest as a sense of protection, as the midwives assisted and supported the women to make decisions and to negotiate both different forms of knowledge and the expectations of the institution. The woman's autonomy was not acknowledged in a distanced way but was protected and encouraged. Smythe describes the climate of trust and knowing that is generated in the relationship. She says that it can free the midwife to 'leap ahead, discerning what she perceives lies in the darkness' (Smythe 1998, p 188).

Pairman (2000) describes the relationship as one of professional friendship, where notions of 'being equal',

'sharing common interests', 'involving the family', building trust', 'reciprocity', 'taking time' and 'sharing power and control' are all valued (p 210). Being with women also means being with the *whole* woman. In a risk and safety context this means that the midwife doesn't separate out the physical aspects of risk from the social and cultural realities of the woman and her family. It also means that the midwife stays in connection with the woman who becomes 'at risk'. She continues to provide midwifery care and support where possible. Her care is holistic. The idea of partnership with the women can be seen as embedded within the seat of the birth stool. Central to partnership are the concepts of negotiation, equality, shared responsibility, empowerment and informed choice and consent (Guilliland & Pairman 1995). In 'being with' the woman, the midwife works towards this partnership with her. Where the relationship is new and developing, or where it is challenging and difficult, being and staying with the woman sensitively and respectfully are key factors of being a midwife. It is within this relationship that the midwife must learn to balance trust and anxiety,

Being with the woman then is a central and critical aspect of managing risk and promoting safety, yet as Smythe (1998) says, these relationships are necessary but not sufficient. Partnership is incorporated into the seat, yet this on its own is not sufficient in helping to understand the complex and challenging work of midwifery. It is, in a sense, a seat without legs. It doesn't lift the midwife off the ground. The legs of the stool provide the other aspects of practice that are vital in the provision of safe care in the current sociocultural context. Being a professional, knowing how to work the system and understanding and working with complexity, provide the stability required to stay 'with women' and to work towards partnership with them. It the legs of the midwife's birth stool that give support; the legs help to lift the midwife above the 'messy swamp' of practice (Schon 1983).

Being a professional

The first leg of the stool I have called 'being a professional'. It includes being both a skilled and an accountable practitioner. For the midwives in my study, having the skills needed to assess risk was important. The skills required are diverse and rely on a sound knowledge base. Midwifery incorporates knowledge from many different sources. It comes from within its own discipline and from other fields such as physiology, pharmacology, epidemiology and medicine. It also sources knowledge from the humanities, such as sociology and psychology. This knowledge then informs practice in the provision of safe care. A safe midwife is attentive to sound research and seeks answers to problems. However, in Smythe's (2000) study the midwives acknowledged that not all risk is assessable. Much of it is unknown and hidden. It is the midwife's task to uncover risk as much as she can, but always to remain alert and attentive, anticipating what might be lying underneath.

A skilled midwife is also a skilled communicator and listener, attentive not only to the physical factors of the woman but also to her social and cultural milieu. She seeks to understand what the woman and her family value and thus to understand how they themselves see risk and safety. She communicates her own understanding of risk and safety in a way that promotes the woman's autonomous decision-making and minimises unnecessary fear and anxiety. She is reflective of her own position and attempts to provide care that is not dominated by it. Communication with the woman and her family is based in the quality of the relationship that she develops. It is fundamental to her 'being with' the woman.

Current constructions of professional practice are also very attentive to accountability. Accountability does not necessarily mean always accepting responsibility for adverse outcome but it does mean that the midwife must be accountable for her decisions and her actions. This accountability is primarily to the woman, but also to the profession and to the public (NZCOM 2005). Accountability is a valuable tool for the midwife and she should not be afraid of it. Accountability facilitates an honest, reflective relationship. It helps to keep the midwife attentive and motivates her to maintain her knowledge and skills. It helps to keep the woman at the centre of practice.

However, it does sometimes mean that the midwife must be accountable to the public and to the profession within the medico-legal context and it is this aspect of practice that is most feared. As discussed earlier, the current state of the 'risk society' means that professionals can be blamed when an adverse outcome has eventuated. It is here that we see the midwife as being 'at risk'. She is at risk of litigation. What must be pointed out, however, is that just as the general public seem to be becoming increasingly anxious about very small probabilities of risk, so too do health professionals themselves. The risk of being held accountable within the medico-legal processes are very small and must be kept in perspective lest practice be paralysed.

There are several ways in which the midwife can protect her own safety in this context. Accurate and complete documentation will provide evidence of the care that was provided. This should include documentation of the decision-making processes, including noting the information that was provided. The midwife needs to understand and implement her professional code of ethics and the standards for care (ACMI 2006; NZCOM 2005). Safety for the midwife includes attending to the whole of practice, to all the parts of this midwife's birth stool. It remains based in the sound development of the relationship with the woman, in providing skilled care, and also in an understanding of and connection with the systems that are in place. It is supported by an understanding of, and negotiation between, the complex and often contradictory environment in which she works.

Working the system

The next leg of the stool has been called 'working the system' and is an important part of providing safe care, care that continues to be based on staying connected with the woman and her experience. I have called it 'working the system'

as it is a reminder that the focus remains on being 'with women'. Midwives work the system in order to meet the needs of the woman. This leg reminds us that we do not provide care in isolation. We provide care within a system, and it is important not only to understand how the system works but also to participate in it. Three aspects of knowing the system are important. The first, and possibly the most crucial, is the development and maintenance of successful collaborative relationships with others in the system. Within my research, not only was the quality of the relationship with the woman important but the quality of the relationships with obstetricians and other midwives was also seen as crucial. The midwives felt that both they and the women were much safer where respectful, trusting relationships had been developed with those with whom they needed to collaborate. These relationships cannot be assumed but must be actively sought and maintained. They also include relationships with work partners and other midwives in the local community. It includes those who provide the secondary maternity services, the obstetricians and the midwives in the hospital. It includes forming collaborative relationships with those in the community whose services the women may also require: the GPs, the childbirth educators, the practice nurses and the local pharmacists, to name just a few. Smythe (2000) also found this in her study. She commented that trusting, collaborative relationships facilitated the sharing of what she described as concernfulness. This trust is developed within the relationship. One cannot assume or presume trust either with the woman or with other professionals. It is not automatic and must be earned. In order to do this, personal knowing is important.

The second aspect of 'working the system' relates to understanding and working with the processes that the system puts in place. The most obvious processes are guidelines and policies, but can also be extended to an understanding of the funding and contractual arrangements, of professional standards and of the required competencies. Risk management systems most clearly related to risk are the referral guidelines (Australian College of Midwives 2004; Ministry of Health 2002). These guidelines provide a framework for the midwife to use in the decision-making related to complex or 'at risk' pregnancies. No research has been undertaken as to the efficacy of these guidelines. However, there has been a wealth of evidence that risk screening processes in general suffer from low sensitivity and low specificity (Alexander & Keirse 1989; Rohde 1995; Rooney 1992). The referral guidelines could be seen as a risk-screening process and therefore can be critiqued as lacking validity as a useful tool to improve safety. However, they are also about delineating the boundaries of professional practice and attempt to facilitate inter-professional collaboration by establishing a process for the interaction. These referral guidelines (ACMI 2004; Ministry of Health 2002) can be seen as an indication of the scope of practice of a midwife, and can be used as a guide to indicate the appropriate level of care. Within my research (Skinner 2005), although some midwives found that the guidelines restricted their practice, most found that they were a useful tool in indicating when to seek obstetric assistance. There was also a statistically significant relationship between the midwives' positive attitudes to the referral guidelines, and whether they worked in a supportive and collaborative environment.

As most midwives realise, guidelines are not always appropriate in individual circumstances and there will always be some women who do not want to follow them. Sixty-four per cent of the midwives in Symon's (1998) study of midwives and obstetricians in the United Kingdom said that they had cared for women who did not want to follow guidelines for practice. The midwives in my study also discussed this as a frequent and normal part of practice. Risk may or may not be increased when this happens. What is important, though, is that the midwife understands that this is happening and so can assess whether measures need to be put in place for added protection either for the woman or for herself. This may be as simple as keeping careful documentation.

Working the system also involves participating in organisational risk management and clinical governance processes (Cooper 2000; Wilson 2002). It is important not only to know what the organisational expectations are but also to be involved in developing them. For the midwife, managing risk and promoting safety are also about being part of the local community and being aware of the range of resources available to help. It is about knowing what is going on and participating in change processes such as research and policy development, and about taking a leadership role where needed.

This leads to the third part of working the system. It would be naive to talk about the midwife's relationship with the system without acknowledging the existence of power relationships and the need to managing the power disparities. There is a considerable play of power in the ability to define who and what is risky and what should matter (DeVries 1996; Stapleton 1997). For the midwife, the power of the institutions and the power of obstetrics are real and challenging (Freeman et al 2004). There exists a hierarchy of authoritative knowledge within maternity care in which the technical expertise of medicine is dominant (Jordan 1997). The risk discourse as it is currently constructed, principally by medicine, can be viewed and used as a tool of control and surveillance of both midwives and mothers. Power can be hidden within this risk discourse but may also be open to challenge. The midwife needs to know, however, that confronting this medical power is in itself a risky strategy and must be approached with caution (Fahy 2002).

The midwife is not only a subject of power in terms of obstetrics but can act as an agent of power. The discourse of equality central to the notion of partnership can obscure the power relations inherent in the midwife–mother relationship (Freeman et al 2004; Leap 2000; Skinner 1999; Smythe 2000). The research by Freeman and colleagues looked at how power is expressed within this relationship and investigated where expertise, experience, knowledge and legal requirements fit into a partnership model of care. Their research found that in 85% of instances where decision-making involved high-risk situations, it was the midwife who primarily made the care decisions. As a result of this finding they developed a

model of decision-making in which, as risk increased, so too did the dominance of the decision-making by the midwife. The midwife, then, needs to understand the power relations that exist and work to claim her own power in the context both of providing safe care and of protecting and enhancing the power of the women. She needs to be mindful of the rhetoric of equality within what is called 'collaborative relationships' with doctors and within 'partnership relationships' with women. (See also Pairman 2005, pp 66–68, for a critique of Freeman et al 2004.)

In order to manage risk and safety, then, the midwife must learn to 'work the system'. She should keep connected and keep involved, actively participating in building collaborative relationships and in the planning of guidelines and policy. Safe practice is connected practice. Midwives need to build solid and collaborative relationships and to be involved in policy making and in research. They need to be active members of their professional organisation and develop a system for their own practice that is safe and sustainable. They need to both claim and share their power, and challenge power systems that are unjust. When midwives work in isolation they put themselves and the women for whom they care at risk.

Working with complexity

Complexity is such an integral part of midwifery care that it deserves a leg of the birth stool of its own. In being alongside women, things are often complex and unclear. The midwives in my study, in reflecting on how they managed risk, frequently talked about working in the 'grey areas', not only in the physical processes of birthing but also in the relationships that they developed with women, with medicine and with the system. There was a good deal of unknowing and uncertainty. The more experienced midwives described how these grey areas of practice became even bigger the more experienced they became. Yet as they became more experienced they also became more comfortable. Uncertainty and complexity became less disturbing. They accepted that risk and uncertainty were normal parts of practice. They accepted the need to understand and accommodate many different perspectives reflecting the differing underlying cultural and value systems in which both they and the women lived.

Midwifery practice is not simple. Developing relationships with women is not simple, being a professional is not simple, maintaining collaborative relationships is not simple, and managing risk is not simple. As Heyman (1998, p 9) states:

> Difficult decisions about risks entail weighing-up and trading-off qualitatively different values, for example autonomy versus safety, or quality of life against longevity. Such trade-offs of finely balanced but incompatible ends require value judgements which individuals and social groups make differently, and which cannot be meaningfully aggregated or anticipated. The persons most directly concerned in a health decision may have difficulty in deciding or even predicting what they would do. Health professionals who wish to help clients to manage risk need to grasp the complexities involved in such reasoning.

Dealing with risk, then, is complex and challenging work, done in the context of the primacy of 'being with the woman' and alongside astute, professional care. If it is so complex, how might the midwife go about it? Understanding some of the theory about how complex systems work might be of assistance. Complexity theory tells us that tension and paradox are natural phenomena. Problems are often not resolvable through simple cause-and-effect processes. Instead they occur in ways that are non-linear. Unpredictability is inherent in complex systems, although patterns emerge through inherent self-organisation. There always remain things that are unknowable (Plsek & Greenhalgh 2001). Paradox and uncertainty, however, are not necessarily negative. They can be used as sources of change and improvement. Complexity theory rejects the machine model of the human body and of health systems, where the whole is broken down into smaller and smaller parts for treatment or intervention. Action, then, requires a holistic approach, accepting unpredictability yet building on the emergent forces and processes that become evident. It requires careful observation and the application of astute, involved, creative and intuitive care.

The birth stool provides a framework for dealing with risk and safety, complex concepts embedded within and between complex systems. It provides a holistic approach and challenges the midwife to attend to each aspect of her practice in ways that acknowledge this. It is clear that there is no one truth about what is risky and what is safe, that truth is viewed through multiple lenses. It is the task of the midwife to understand these multiple lenses. To some extent, she can be seen as a 'paradigm broker', mediating between different ways of knowing and understanding (Skinner 1999).

Story-telling

The last part of the birth stool is the struts. Struts connect the legs with each other and with the seat, and help to hold the stool together firmly. I have called the struts of this midwife's birth stool 'story-telling'. Midwives are great story-tellers. We tell stories to share and connect with each other. The stories can be both healing and sense-making. Stories express and create the norms of practice. We tell stories in our documentation and in our formal practice review. We tell stories to the women we care for and sometimes we have to tell the story to the disciplinary bodies and to our professional organisation. Story-telling is probably the most valuable tool in the teaching and development of midwifery, as it is in story-telling that the messy and real complexity of practice is revealed and understood. Sharing stories keeps us connected with each other, helps us to understand the complexities of practice and provides a way of understanding what is expected. Stories can both challenge us and affirm us. Story-telling keeps us mindful and reflective. It brings to our attention that which we may have let go, and offers us other possibilities for action. It helps to keep our practice connected and safe.

Reflective exercise

Take some time to reflect on your own perspective on risk and safety. What is the level of tolerance for risk in your own life? How do you think this affects the way you practise, especially the way you communicate risk and safety to the woman? What are your tactics when risk becomes evident? How do you balance the evidence of risk with the woman's values? What does your birth stool look like? How would you like it to look?

Using the birth stool: putting theory into practice

Although I have described the parts of the stool separately, they are not separate at all. You will find that the themes are interconnected and are found embedded in the whole stool. In this way the stool embraces the complex and messy world of practice. The realities of real-world midwifery mean that we seldom if ever have a perfect stool. However, the good thing about a three-legged stool is that it remains stable even if it is a bit 'out of kilter'. The legs do not have to be exactly the same shape and size to be secure and sturdy. For example, where the relationship with the woman is challenging and difficult, strong, well-connected legs will support it. Where the new practitioner is still developing her skills and expertise, her relationship with the woman and the connections and involvement she develops with the system will ensure that she is supported. Where deficiencies in the system challenge the ability of the midwife in her work, an astute midwife who understands the power dynamics and the variety of apparent worldviews, and who is skilled and accountable in the context of a strong relationship with the women, can still provide safe care.

The birth stool is easily transportable and sturdy. The midwife can take it with her wherever she practises. She does, however, have to sit on the whole stool and be attentive to all its parts. If any of the parts give way, it will not provide support. It is also sometimes important to get off it to give it a polish or even just to give your legs a bit of a stretch (doing some more study or just having a holiday). It is also useful to have others looking on to warn of cracks appearing or to ensure that it is placed in the right position (professional standards or practice review). If any of the legs get too out of kilter or the glue comes unstuck, the midwife will fall off her seat—being with women will not be an option. Some of the midwives in my research were about to give up practice. For one, being with the women had become intolerable, as she found the demands too overwhelming and was unable to work the system to meet her own needs. For another, the pressure of the medico-legal environment had spoiled practice and she wished to be free of it. She no longer had trust in either her medical colleagues or the women for whom she cared. She herself felt unsafe. The demands of being a professional had become overwhelming and isolating. Another was a very new midwife who had found that 'working the system' as a new practitioner was just too difficult and too scary. She lacked the support of others around her. Yet for most of the midwives there was a great deal of satisfaction, sustained by the quality of the relationships they had with the women giving birth. They were confident and safe practitioners, challenged but not overwhelmed by the complexity of their work.

Being a safe practitioner is about connectedness. It is about sitting on the birth stool: being connected with up-to-date knowledge and skills, being connected to the complex systems and processes that guide practice, being connected to co-workers, and above all, being connected with the women.

Reflective exercise

Use each part of the birth stool to reflect on the following stories.

- Suzy is 34 and is expecting her first baby, conceived by IVF. She works as a program manager for a computer company and her husband is a lawyer. On her first visit with you she asks you whether she could have a home birth and how safe it would be. How would you approach this question?
- Karen is expecting her second baby and is now a week past her due date. She had a long labour with her first baby and had an epidural and a forceps delivery. Although this pregnancy is normal she has become increasingly anxious about the birth, and when you visit her she states that she wants an induction and another epidural, as she has heard that babies sometimes die when they are overdue. How do you manage these concerns and how do you negotiate and support Karen's final decision?
- Marg is expecting her fourth baby. She has had three normal births before and is relaxed and confident about this birth, although the baby is currently a breech presentation. She was shocked to be told by the obstetrician that she should have a caesarean section and is determined to have a vaginal birth with no intervention. She says she will just have you and not the doctors. How do you manage this?
- Beth is in labour with her first baby. She is now at the birthing unit and has been actively pushing for two hours. Although progress has been slow, Beth is coping well and the baby's heart rate has been stable. You can just see the baby's head appearing but the fetal heart rate is beginning to drop during contractions. What do you do and what do you say to Beth and her family?

Review questions

1. How are the concepts of risk and safety related?
2. How has the techno-rational or scientific approach to birth affected the way risk is perceived?
3. How can one consider normality when risk is identified?
4. How does the 'risk' society affect the provision of maternity care?
5. What role do cultural values play in risk decisions?
6. How does the quality of the relationship that the midwife has with the woman support safe practice?
7. What else in the midwife's practice supports safe care?
8. What role does accountability play?
9. How does the midwife ensure her own safety?
10. Why is it important to have good collaborative relationships with other health providers?
11. What place do clinical guidelines play in decision making?
12. How can the 'birth stool' model of midwifery support the midwife in dealing with risk and safety?

CHAPTER 5

Ways of looking at evidence and measurement

Sally K Tracy

Key terms

case control study, cohort study, contextual scan, critical appraisal, cross-sectional study, epidemiology, ethics committee, ethnography, evidence-based midwifery, grounded theory, historical method, intervention study, levels of evidence, measurement, narrative, phenomenology, randomised controlled trial, research methodology, systematic review

Chapter overview

Measurement is crucial to the way we practise. It provides us with the basics for learning about and improving our understanding of what we do. It helps us to assess the safety and effectiveness of our practice. The purpose of this chapter is to provide an introduction to the use of measurement and seeking truth in midwifery practice and decision-making. Much of our current practice rests on both the evidence of epidemiological research and the findings of qualitative studies. You will be introduced to some of the most common epidemiological methods of research as well as some of the methods used to understand the quality and meaning of the practice of midwifery and the quality and meaning of childbirth for women. These examples of the way we measure our experiences appear, on the surface, to contradict each other. On the one hand, quantitative research such as epidemiology provides the story of populations or groups of people in the language of averages and statistically derived measures. Qualitative research, on the other hand, provides us with the story of the individual who is inextricably connected to the influences of their own context, and is only one individual in the population sample of the epidemiologist. In midwifery, both quantitative and qualitative exploration enriches our understanding of what we do. This chapter provides a summary of and an introduction to the many ways of measuring experience. It is intended to be used as an introductory tool for understanding the basics of evidence-based practice. In measuring anything, it is always important to be aware that simply through quantifying something we are in danger of disregarding, devaluing or even denying the very thing we are trying to measure.

Learning outcomes

Learning outcomes for this chapter are:

1. To explore the dimensions of evidence and measurement in midwifery
2. To introduce some of the common terms used in research, in both qualitative and quantitative methods
3. To outline the use of epidemiology in gathering evidence
4. To identify some of the pitfalls in the evidence-based movement.

Introduction

> Some ways of knowing have traditionally occupied spaces at the edge of the dominant vision, the same kinds of spaces as are filled by the lives and experiences of the socially marginalised, including women. Thus, neither methods nor methodology can be understood except in the context of gendered social relations. Understanding this involves a mapping of how gender, women, nature and knowledge have been constructed both inside and outside all forms of science (Oakley 2000, p 4).

Inquiry is based on the recognition of certain connections. It is important always to be mindful that separating the knower from what is known implies a separation of one's self from another person and also implies the separation of the researcher from the subject of research (Reason 1988). The connection between understanding in the scientific and biological domain, and the experience we bring from our family, our practice, our social and political contexts, together with our use of language, is the reason we can expect to have different and multiple understandings of the world. We make sense of facts and select and organise all our observations based on the influences of previous learning and practice. Drawing stories from our reservoir of experiences and social contexts connects us through language and metaphor to understand the science behind midwifery. Understanding biological systems depends on a multiplicity of understandings, explanations and connections (Fox Keller 2002).

Seeking truth

Although there are several methods of seeking truth that may conflict or coexist with each other at various times, it is generally accepted that, in midwifery as well as medicine, some ways of arriving at the truth are more acceptable than others. The following examples will help provide you with an understanding of how many of the interventions and actions in practice have been arrived at. After reaching the end of this chapter, I hope you will return to this section and be able to discern whether or not the following methods are entirely acceptable.

Let's look at the safety of believing in something or having faith in an authoritative expert opinion. For example, many women and midwives believe that having an epidural during labour is both safe and effective. They believe that if the departments of anaesthesia and obstetrics so wholly endorse the procedure, then it is unlikely that having an epidural will have any adverse side-effects. Similarly, having a continuous CTG monitor running and recording the baby's heartbeat for the whole of labour will surely be seen as the safest way to detect anything going wrong as soon as it happens. Both these procedures were introduced as routine interventions without prior scientific validation, and are still supported by the fact that because so many women like them and they are so comforting, there seems little reason to question their routine use and safety.

Then there is the *feeling* that something is right. For years, midwives have done certain rituals because they had a gut feeling it was the right thing to do. How does this come about? For many it is the wisdom gained through the experience of looking after many women in childbirth. It may be something as simple as recommending a salt bath for the relief of the perineum, or wanting to give a baby extra fluid to complement the mother's milk supply when it seems that neither can settle happily. These are interventions that for some just feel like the right thing to suggest, even though the midwife may have no knowledge of the benefits or safety of such measures.

Very close to the feeling that something is right is the knowing through personal experience that this is the way to do something. We have seen something or heard it so often that our personal experience of the event leads us to believe it must be true. In both midwifery and obstetrics, much of what is practised is based on personal experience and learning from past mistakes. Personal experience is often characterised as being anecdotal, ungeneralisable, and a poor basis for making scientific decisions. However, it is often a more powerful persuader than scientific publications in changing clinical practice. In fact, midwives constantly use their personal judgement to affirm what they believe to be true in certain situations—the non-scientific 'rule of thumb'. This is also one of the most contentious areas in which to change attitudes and practice because it challenges one of the most strongly held methods for seeking truth—the knowledge gained through the personal experience of doing things a certain way.

Legal methods of arriving at the truth need little explanation. Here something is deemed to be true because it can be substantiated through authoritative testimony. The expert witness is seen as an authority and an expert in the subject under examination. Up until the past 15 years we were familiar with the use of the word evidence in relation to legal method. However, with the widely accepted move in medicine to evidence-based medicine, the word 'evidence' has taken a much more prominent position in the scheme of things. Box 5.1 walks you through an ethical argument in addressing the question: 'Is evidence the same as research?'

One of the most widely accepted methods of searching for truth in midwifery is through scientific method or research. Searching for truth using scientific research methods involves the systematic study of phenomena and the relations between and among phenomena using agreed rules or accepted methodologies. The systematic collection, analysis and interpretation of data minimises the contamination of results from external factors (known as bias) (Kirkevold 1997).

There are several schools of thought on how scientific method should proceed. On the one hand, it is believed that the theory and hypothesis should be developed before the research is undertaken. This is known as deductive method. It follows the thinking of Karl Popper (1972) that scientific knowledge is gained through the development of ideas and the attempt to refute them with empirical research. The dominant philosophy underlying quantitative scientific method is positivism. Positivism assumes that phenomena are measurable using the deductive principles of the scientific method. That is, the investigator starts with a theory and a hypothesis that is tested by the data (deduction).

BOX 5.1 Is evidence research?

Is evidence the same as research?

- In order for something (e.g. data) to be construed as 'evidence' it must be judged to be relevant and have a strong conclusion. This requires subjective interpretation, from the viewpoints of several individuals.
- Evidence itself does not constitute truth; rather, evidence plays a role in determining what is believed to be true. For example, in legal terms the evidence used to support various theories of what actually happened at the time of a crime is compared until one of the theories begins to hold more weight than the others, and, on the basis of the available evidence, is considered the most likely to be true.
- Consider how the selection of evidence to support conclusions is negotiated and debated. It is affected by social and other forces such as power, coercion and self-interest of one negotiator, or group of negotiators, vis-à-vis another. These forces then may have an impact on which conclusions or theories are ultimately selected as most likely to be true.
- Now consider the common practice of applying research data from studies conducted exclusively on male research participants, to female patients. The idea that data from men can be applied directly to women reflects a reductionist view of human physiology and a previously held social bias that took women's health to be an offshoot of men's health.
- Hence, *evidence* is a status conferred upon a fact, reflecting, at least in part, a subjective and social judgement that the fact increases the likelihood of a given conclusion being true. For any given set of phenomena, there may be many available facts that could count as evidence for more than one conclusion or theory. However, only some facts will be deemed as evidence for one successful conclusion or theory, which itself is chosen from among several options.
- Thus, evidence is not, as EBM implies, simply research data or facts but a series of interpretations that serve a variety of social and philosophical agendas.

(Based on an argument proposed by Gupta M 2003.)

The other school of thought is that research should precede theory and not be limited to a passive role of verifying and testing theory; rather, it should help to shape the development of theory (Bowling 2002) by the process of induction.

Both these strategies are used to develop the knowledge of midwifery.

Whichever method we use to try and find answers to a certain problem or situation, there are certain things that help us measure how successful the research is in answering our question. Research is measured in terms of its rigour of scientific inquiry by concepts known as reliability (the repeatability of the research) and validity (the extent to which the instruments measure what they set out to measure).

Seeking truth through empirical research involves both experimental and non-experimental research. In non-experimental designs, the observations are recorded without having first manipulated the variables. In contrast to this, in experimental method there is a systematic manipulation of and control of variables. Evidence-based healthcare, or the practice of basing clinical decisions on the best available scientific evidence, is predominantly derived from experimental method. All research, whether inductive or deductive, follows the broad pattern of the research cycle.

Regardless of the method of research, this basic formula sets out the cycle of events that occur in a research process (Fig 5.1).

Qualitative research methods

Qualitative research contributes to the understanding of social aspects of health issues, through direct observation of the nuances of social behaviour (Green & Britten 1998; Pope & Mayes 2000). Qualitative research can investigate practitioners' and patients' attitudes, beliefs and preferences, and the whole question of how evidence is turned into practice. The value of qualitative methods lies in their ability to pursue systematically the kinds of research questions that are not easily answerable by experimental methods. Rigorously conducted qualitative research is based on explicit sampling strategies, systematic analysis of data, and a commitment to examining counter-explanations. Ideally, methods should be transparent, allowing the reader to assess the validity and the extent to which the results might be applicable to their own clinical practice. Qualitative research does not usually produce numerical rates and measures (Green & Britten 1998). Researchers who use qualitative methods seek a deeper truth (Greenhalgh & Taylor 1997). They aim to make sense of, or interpret, phenomena using a holistic perspective that preserves the complexities of human behaviour (Black 1994). The research often provides

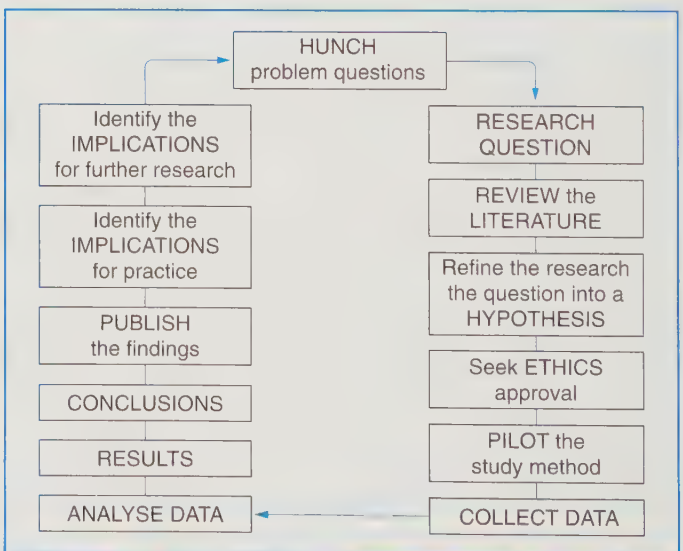

Figure 5.1 The research cycle

us with a picture of 'behind the scenes', how people are feeling, or what other forces are at work that may not be discovered in a quantitative investigation of facts.

An example of the 'behind the scenes' behaviour that affected the introduction of evidence-based leaflets into maternity hospitals in the United Kingdom was recorded by Stapleton et al (2002) when they undertook a qualitative study beside a randomised controlled trial (RCT) by O'Cathain et al (2002). In the experimental study, the researchers concluded that in everyday practice, evidence-based leaflets were not effective in promoting informed choice for women using maternity services (O'Cathain et al 2002). The qualitative study (Stapleton et al 2002) mounted alongside this RCT provided a rich insight into what was happening with the information leaflets, and found that the way in which the leaflets were disseminated affected promotion of informed choice in maternity care. The qualitative study provided the evidence for 'behind the scenes' and the bullying and coercive behaviours that had become a normal way of doing things in these maternity units. The culture into which the leaflets were introduced supported existing normative patterns of care and this ensured informed compliance rather than informed choice (Stapleton et al 2002).

Overview of qualitative methods

As a midwife you will be intimately involved in finding the answers to many questions through research evidence. However, the scope of this textbook permits only a very brief overview of some of the terms and methods you will encounter. The following summary of some of the qualitative research methods used in scientific research will give you a very brief introduction to the terminology and concepts used in qualitative research.

Phenomenology

Phenomenology is a method of constructing the meaning of (a phenomenon from) someone's experience—for example, the 'lived experience'.

- Data are gathered though interviews.
- The sample is taken from those who have experienced the phenomenon.
- The analysis follows a path of information from the research question; that is, the participant's significant phrases illustrate the researcher's interpretation.

Ethnography

Ethnography is used by the researcher to construct the meaning of culture; that is, the researcher tries to understand the insider's 'emic' view of the world. The researcher enters an unknown world and tries to make sense of it from the insider's point of view.

- Data are gathered through participant observation and interviews, and the researcher interprets the cultural patterns observed.
- The sample is taken from a cultural group living in the phenomenon. These are known as the key informants and the general informants. The key informants are those with special knowledge who are prepared to teach the researcher.
- The analysis is undertaken on field notes and observations, and meaning is sought from cultural symbols in the informants' language.

Narrative

Narrative is a linguistic form. The narrative provides information that does not pertain simply or directly to the unfolding events. The same sequence of events told by another person to another audience might be presented differently without being any less 'true'. First, it has a finite and longitudinal time sequence—that is, it has a beginning, a series of unfolding events, and (we anticipate) an ending. Secondly, it presupposes both a narrator and a listener, whose different viewpoints affect how the story is told. Thirdly, the narrative is concerned with individuals—rather than simply reporting what they do or what is done to them, it concerns how those individuals feel and how people feel about them.

Narratives help to set a person-centred agenda and challenge received wisdom, and they may generate new hypotheses. Narratives offer a method for addressing existential qualities such as inner hurt, despair, hope, grief and moral pain, which frequently accompany, and may even constitute, people's illnesses (Greenhalgh & Hurwitz 1999).

- Data-gathering involves collecting the story the respondent has to tell.
- The sample is a convenience sample.
- The analysis of the narrative is an interpretive act; that is, interpretation (the discernment of meaning) is central to the analysis of narratives. Actual transcripts are presented in the results of narrative research.

Historical research

Historical research is mainly narrative rather than numerical. Much conventional scholarship continues to focus on the search for a single, knowable, verifiable past.

- The data consist of a systematic compilation of data regarding people, events and occurrences in the past.
- The sample tries to identify all data sources.
- The analysis involves the validity of external criticism; reliability delineates data sources by internal criticism. The reader 'hears' the narrator's 'voice' and 'sees' the actions in the story with the eyes of an 'internal' or 'external' focaliser, who may or may not be identical to the narrator (Norku 2004).

Grounded theory

Grounded theory aims to find underlying social forces that shape human behaviour. The theory emerges or is generated from the data in a manner that means most hypotheses and concepts not only come from the data, but are systematically worked out in relation to the data during the course of research (Strauss & Corbin 1998).

- Data consist of interviews and skilled observations of individuals interacting in a social setting.

- The sample is purposive—the researcher deliberately samples a particular group or setting of people who are experiencing the circumstance.
- During analysis, the researcher's task is to sift and decode the data to make sense of the situation, events and interactions observed. Often this analytical process starts during the data-collection phase. Variants of content analysis involve an iterative process of developing categories from the transcripts or field notes, testing them against hypotheses, and refining them (Mays & Pope 1995; Strauss & Corbin 1998).

Other methods

Other qualitative research methods include:

- *documents*—study of documentary accounts of events, such as meetings
- *passive observation*—systematic watching of behaviour and talk in naturally occurring settings
- *participant observation*—observation in which the researcher also occupies a role or part in the setting, in addition to observing
- *in-depth interviews*—face-to-face conversation for the purpose of exploring issues or topics in detail. Does not use preset questions, but is shaped by a defined set of topics.
- *focus groups*—method of group interview that explicitly includes and uses the group interaction to generate data (Greenhalgh & Taylor 1997).

Questions to ask

Mays and Pope (1995) suggest the following questions to ask of qualitative studies:

- Has the study contributed to our knowledge?
- Was the research question clear?
- Would a different method have been more appropriate? Was the design appropriate for the question?
- Is the context adequately described?
- Was the sampling strategy clearly described and justified?
- How was the fieldwork undertaken? Was it described in detail? Could the evidence (fieldwork notes, interview transcripts, recordings, documentary analysis, etc) be inspected independently by others; if relevant, could the process of transcription be independently inspected?
- Were the procedures for data analysis clearly described and theoretically justified? Did they relate to the original research questions? How were themes and concepts identified from the data? Was the analysis repeated by more than one researcher to ensure reliability?
- Was there an audit trail, so that another researcher could repeat each stage of the research?
- Was enough of the original evidence presented systematically in the written account to satisfy the sceptical reader of the relation between the interpretation and the evidence? (For example, were quotations numbered and sources given?)

Critical thinking exercise

Search the literature for a study that uses each of the above methodologies, and compare the written studies to see what questions are asked and how these are answered. Could the same question be answered by each of the different methodologies?

BOX 5.2 How to search

How to search for a paper on Medline or the Cochrane library:

1. To look for an article you know exists, search by text words (in title, abstract, or both) or use filed suffixes for author, title, institution, journal and publication year.
2. For a maximally sensitive search on a subject, search under both MESH headings (exploded) and text words (title and abstract), then combine the two by using the Boolean operator 'or'.
3. For a focused (specific) search on a clear-cut topic, perform two or more sensitive searches as in step 2, and combine them by using the Boolean operator 'and'.
4. To find articles that are likely to be of high methodological quality, insert an evidence-based quality filter for therapeutic interventions, aetiology, diagnostic procedures or epidemiology, and/or use maximally sensitive search strategies for randomised trials, systematic reviews, and meta-analyses.
5. Refine your search as you go—for example, to exclude irrelevant material, use the Boolean operator 'not'.
6. Use subheadings only when this is the only practicable way of limiting your search, as manual indexers are fallible and misclassifications are common.
7. When limiting a large set, browse through the last 50 or so abstracts yourself rather than expecting the software to pick the best half dozen.

(Source: Greenhalgh 1996)

Evidence-based practice

The aim of evidence-based practice, to quote from Professor David Sackett, is 'the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients . . . the integration of individual clinical expertise with the best available external clinical evidence from systematic research' (Sackett & Cooke 1996, p 535). In other words, it is the combination of clinical judgement and clinical practical experience with information we gather to help us learn.

The following five steps in putting evidence into practice are based on the work of Sackett et al (1996):

BOX 5.3 Definitions

Some common terms used in research:

- *case studies*—focus on one or a limited number of settings; used to explore contemporary phenomena, especially where complex interrelated issues are involved. Can be exploratory, explanatory or descriptive, or a combination of these.
- *consensus methods*—include Delphi and nominal group techniques and consensus development conferences. They provide a way of synthesising information and dealing with conflicting evidence, with the aim of determining the extent of agreement within a selected group.
- *constant comparison*—iterative method of content analysis where each category is searched for in the entire data set and all instances are compared until no new categories can be identified.
- *content analysis*—systematic examination of text (field notes) by identifying and grouping themes and coding, classifying, and developing categories.
- *epistemology*—theory of knowledge; scientific study which deals with the nature and validity of knowledge.
- *field notes*—collective term for records of observation, talk, interview transcripts, or documentary sources. Typically includes a field diary which provides a record of the chronological events and development of research as well as the researcher's own reactions to, feelings about, and opinions of the research process.
- *Hawthorne effect*—impact of the researcher on the research subjects or setting, notably in changing their behaviour.
- *naturalistic research*—non-experimental research in naturally occurring settings.
- *purposive or systematic sampling*—deliberate choice of respondents, subjects or settings, as opposed to statistical sampling, concerned with the representativeness of a sample in relation to a total population. Theoretical sampling links this to previously developed hypotheses or theories.
- *reliability*—extent to which a measurement yields the same answer each time it is used.
- *social anthropology*—social scientific study of peoples, cultures, and societies; particularly associated with the study of traditional cultures.
- *triangulation*—use of three or more different research methods in combination; principally used as a check of validity.
- *validity*—extent to which a measurement truly reflects the phenomenon under scrutiny.

(Source: Pope & Mayes 1995)

1 Fit what you want to know into a question that can be answered.
2 Go looking for the best research to answer it.
3 Critically estimate the research for how close it is to the truth and whether it could be clinically useful.
4 Try to use the suggestions in practice.
5 Reflect on, or evaluate, what happens.

BOX 5.4 Page's five steps

1 Find out what is important to the woman and her family.
2 Use information from the clinical examination.
3 Seek and assess evidence to inform decisions.
4 Talk it through.
5 Reflect on outcomes, feelings and consequences (Page 2002).

In *The New Midwifery*, Professor Lesley Page describes evidence in terms of 'a process of involving women in making decisions about their care and of finding and weighing up information to help make those decisions' (Page 2002, p 9). The five steps to evidence-based midwifery (Box 5.4) were adapted by Professor Page from the original work in this area undertaken by Sackett and colleagues in 1996 (Sackett et al 1996).

In step 3, seeking and assessing evidence, the original authors added that it is important to decide how *valid* something is. In other words, how close to the truth is it? It is also important to find out how *useful* it is—that is, how applicable to practice is the evidence? One thing to remember is that evidence-based midwifery should never be a 'cookbook' approach to what we do. The evidence that we bring to practice from the literature or from research should only ever inform our practice, not replace it; and it should always be taken along with a woman's individual preference for a clinical decision (Page 2002; Sackett & Cooke 1996). One of the ways of checking whether a research paper addresses the area of inquiry you are interested in is to see whether the question the research seeks to answer applies to the area of interest. To do this, we divide the question into its components to make sure it is relevant. For example:

- Does it involve a population of interest, or does the population closely resemble the one you want to understand?
- Is the intervention or treatment relevant for your area of interest?
- Is the comparison group appropriate?
- Is the outcome one that you are interested in?

This is known as the PICO method (see Box 5.5).

The appendix at the end of this chapter lists questions to ask in evaluating a clinical guideline.

Evidence-based everything

Evidence-based obstetric care is a relatively new concept, which had its origins in the early 1970s . . . this was a shift away from

BOX 5.5 The PICO method

PICO is a way of breaking a question into its components.

P Population or patients
I Intervention or indication
C Comparison group or Control
O Outcome

opinion-based obstetrics, which up until then had been the dominant paradigm (King 2005).

The 'evidence-based' (EB) prefix moved with discreet political correctness over the years and attached itself not only to medicine, but more inclusively to EB practice, EB decision-making and EB healthcare. As the originators of the evidence-based movements concede, 'it engenders enthusiasm, anger, ridicule and indifference amongst people' (Sackett & Cooke 1996). Some have even suggested that evidence-based medicine (EBM) demonstrates the 'scientific chauvinism of the English' (Halliday 2000).

There are many claims for and against EBM. It is important for students of midwifery to spend some time reflecting on its pros and cons. Evidence-based care features very strongly in our search for evidence and measurement in practice (Chalmers 1989).

Those who question the authority of EBM believe that only studies with positive results get published, or that the *art* of patient care is threatened. Some critics say that systematic reviews may be 'pooling ignorance as much as distilling wisdom' (Naylor 1995), that 'medical muddling' is a profitable business and that the proliferation of new tests, devices and drugs continues at an unprecedented pace (Naylor 1995). Others concede that life would be very much simpler if new technologies could be appraised in rigorous studies with clinically relevant endpoints and data to guide practice (Chalmers 1989). Imagine if the question of the safety of hospital over home birth had been tested with relevant, well-designed studies of safety and satisfaction before women were expected to move from home to hospital for birth.

Many midwives claim that EBM has been used to increase the subordination and powerlessness of those practising in the hospital system—in the form of extravagant claims for the basis of interventions. Or, as Mary Stewart found in her research into 'Whose evidence counts?', the 'definitions of evidence vary widely among health practitioners . . . and are affected by the individual's own beliefs and give rise to a hierarchy in which some types of evidence are valued above others' (Stewart 2000). Many midwives would agree with the statement that 'The power of authoritative knowledge is not that it is correct but that it counts' (Jordan 1993, p 58).

BOX 5.6 EBM

One opinion on the EBM movement is that:

Evidence-based medicine (EBM) became the buzzword of the 1990s. Proponents of the method often recommend it with the zealousness of those who have received religious enlightenment (Traynor 2000).

Some followers of EBM have even stated that:

medicine has continued on a very dark and ill-informed path over the centuries, in fact, when the teachings of Galen superseded Hippocrates' first aphorism, 'life is short', sixteen centuries of dogma followed, and scientific rigour was not applied to medicine again until the appearance of Archie Cochrane and his contemporaries in the 1950's! (Halliday 2000).

Epidemiological method

The foundation and primary focus of evidence-based care is within the specialty of medical epidemiology, 'to ensure the practice of effective medicine, in which the benefits to an individual patient or population outweigh any associated harm to that same patient or population' (Muir Gray 1997, p 3). The underlying belief is that meaning can be discerned from population patterns and that a relation exists between mathematics and material reality. The epidemiologist's focus of study is the whole population, in which outcomes are described in averages and percentages, rates and risks. Then the science of chance is applied in the form of a statistical framework that gives the reader an indication of the measurement error or the uncertainty with which the result is believed to be true. This is better known as the 'confidence interval' (Jolley 1993). Epidemiology seeks to provide answers though the analysis of accumulated results of hundreds or thousands of comparable cases in population samples. The language of mathematics is used to describe the findings in terms of 'probability' and 'risk'. Such answers, arrived at through studying population samples in randomised trials and cohort studies, cannot be mechanistically applied to the individual. 'In large research trials the individual participant's unique and multidimensional experience is expressed as (say) a single dot on a scatter plot to which we apply mathematical tools to produce a story about the sample as a whole' (Greenhalgh 1999, p 324).

In other words, the answers that we gain from doing research at a population level tell us about the general population in averages and frequency measures. They do not tell us the story of the individuals who took part. In asking 'What works?', we are suggesting that research will show us how to do things the best way. The danger here is that we may unwittingly focus on very narrow 'evaluative' studies—that is, studies that demonstrate the effectiveness of an intervention, such as the randomised controlled trial (RCT), when in fact information from a whole range of types of studies, answering a variety of questions, may be more useful. (See the story of the information leaflets earlier.) In reality we practise within a complex and mostly unpredictable reality in which learning from trial and error may be an important way to make progress.

At the turn of the twentieth century, epidemiological research began to explicitly incorporate social science perspectives related to health data that could inform public policy. One of the first substantial prospective epidemiological analyses to be undertaken was a study of the socio-economic and nutritional determinants of infant mortality in the United States in 1912, by Julia Lathrop (Kreiger 2000). As sociologist Ann Oakley pointed out, the history of experimentation and social interventions is 'conveniently overlooked by those who contend that randomised controlled trials have no place in evaluating social interventions. It shows clearly that prospective experimental studies with random allocation to generate one or more control groups is perfectly possible in social settings' (Oakley 1998a, p 1240). The usefulness of the

population-based results of an RCT depends on the translation of the concepts and measures used to describe groups of people into a language that can inform the decisions of an individual (Steiner 1999). The RCT is currently considered to be the orthodox and 'gold standard' scientific experimental method for evaluating new treatments. The ethical basis for entering patients in RCTs, however, is under debate. Some doctors espouse the uncertainty principle whereby randomisation to treatment is acceptable when an individual doctor is genuinely unsure which treatment is best for a patient. Others believe that clinical equipoise, reflecting collective professional uncertainty over treatment, is the most sound ethical criterion (Weijer et al 2000). The scientific principles that are applied to the design and conduct of primary research, such as the RCT, are also applied to secondary research, such as the systematic review (Chalmers et al 1992). Many regard epidemiology as 'an arcane quantitative science penetrable only by mathematicians' (Grimes & Schulz 2002). However, it must be pointed out that 'statistics is at most complementary to the breadth and judgement' of the knowledge gained from epidemiological research (Jolley 1993, p 28).

Figure 5.2 outlines the kinds of studies you will encounter in the scientific literature, both medical and midwifery, that are based on epidemiological method.

In order to find where the 'best evidence' is to support our practice we are encouraged to give research studies a ranking from the highest level, or the 'gold standard', to the lowest level of research evidence. These rankings are made explicitly on the ranking of research methods from the most reliable to the least reliable. This 'evidence hierarchy' provides an initial screening test as to whether data from research studies are derived from methods that are more or less likely to guide readers towards truthful conclusions (Gupta 2003). (Further discussion on this topic, and current debates, definitions and controversies, can be found on the Centre for Evidence-based Medicine website at http://www.cebm.net/.)

Experimental trials are limited when the study size is too small to detect rare or infrequent adverse outcomes, or when the outcome of interest is long-term and the trial would need to continue for an improbable length of time. In all these cases, observational studies may be considered more practical (Black 1996). Observational studies may be most valuable where randomising people to an intervention is inappropriate (Black 1996)—for example, randomising women to having water for birth or to having an elective caesarean section is inappropriate and also disregards the 'effect that choice itself has on therapeutic outcome' (McPherson 1994).

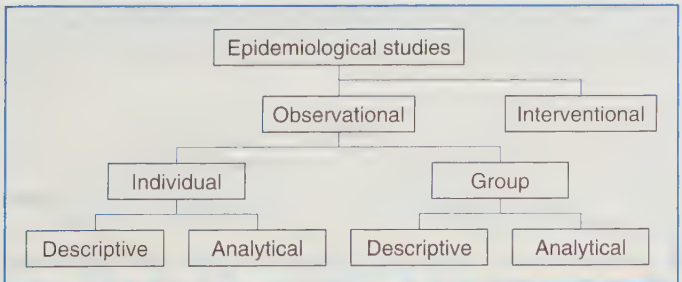

Figure 5.2 Types of epidemiological studies

BOX 5.7 Research ethics

The ethical principle governing research is that respondents should not be harmed as a result of participating in research, and they should always be asked for their informed consent to participate.

This principle is widely agreed amongst researchers. Participants should be asked to give their consent in writing after they have had written information about the aims, risks, discomforts, benefits, procedures, questionnaires and the way confidentiality and anonymity will be preserved. Hospitals and universities have ethics committees to oversee the operations of research projects from an ethical and scientific standpoint.

Before you undertake any research you must undertake to satisfy the ethics committee at the hospital or university where you work by submitting an ethics application for approval before any research begins.

There is no doubt that there are limitations of empiricism as a value-neutral truth, and as the only structure for analysing our decision-making. As one physician put it, 'Evidence-based decision models may be very powerful, but are like computer generated symphonies in the style of Mozart—correct but lifeless' (Saunders 2000, p 22). From the sociologist's viewpoint, the implementation of RCTs in real-life settings causes some hazards, such as low participation and high attrition rates, problems with informed consent, unanticipated side-effects of the intervention, and possible problematic relations between research and policy. Ann Oakley, a very well-known sociologist, asks, 'What may a society obsessed with quantification have lost in terms of the value of more intimate knowledge, intuition, emotions and all the other qualities that (we) soft social scientists are renowned for going on about?' (Oakley 1998, p 1242).

Experimental method allows the investigator to have control over the population group she or he is studying, by deciding which groups will be exposed to a factor under study and which groups will become the control group. A feature of the experimental method is that the investigator can randomly allocate a subject to the experimental or the control group (Lilienfeld & Lilienfeld 1980).

- Data may consist of questionnaires, biophysical measures, structured observations and clinical trials.
- In the sample, the subjects may be randomly allocated to the experimental or the control group.
- Analysis includes inferential statistics provided in tables, which give the significance of findings in terms of a *p* value, or the confidence intervals.

Quasi-experimental method is similar to the above but there may be no control or randomisation. Non-experimental methods are used to gather data to describe events as they occur. These may consist of surveys, for example. The data are analysed and presented using descriptive statistics such

as frequency distributions and histograms. Relationships and associations may be inferred, but not cause and effect. These methods will be covered in more detail later in this chapter.

The randomised controlled trial

Randomised controlled trials (RCTs) are often referred to as clinical trials. The difference is that each person in the trial is randomised to either receive or not receive the intervention. The clinical trial is defined as: 'any research project that prospectively assigns human subjects to intervention and comparison groups to study the cause-and-effect relationship between a medical intervention and a health outcome' (CONSORT group 2005). By 'medical intervention' we mean any intervention used to modify a health outcome. This definition includes drugs, surgical procedures, devices, behavioural treatments and process-of-care changes. A trial must have at least one prospectively assigned *concurrent* control or comparison group (International Committee of Medical Journal Editors, *JAMA* 2005; CONSORT group 2005). The rationale for conducting an RCT is to compare the outcomes of treatment given to different groups of people, while at the same time preventing the effect of systematic 'bias' on the results. The application of randomisation is the logical way to control bias in assessing the effects of certain treatments (Chalmers 1989).

> The idea is not to worry about the characteristics of the patients, but to be sure that the division of the patients into two groups is done by some method independent of human choice . . . i.e. by the use of random numbers (Cochrane 1971, p 10).

In controlling the selection bias, the aim is to be able to distinguish the effect of a certain treatment on a group of people that is separate from and not affected by the individual characteristics of that group of people. In the RCT, the logical application of controlling bias is to allocate the people who will be part of the trial by randomising them to either the treatment or the control group.

> The term random does not mean the same as haphazard but has a precise technical meaning. By random allocation we mean that each person has a known chance, usually an equal chance, of being given each treatment, but the treatment to be given cannot be predicted. If there are two treatments the simplest method of random allocation gives each patient an equal chance of getting either treatment; it is equivalent to tossing a coin. In practice most people use either a table of random numbers or a random number generator on a computer. This is simple randomisation. Possible modifications include block randomisation, to ensure closely similar numbers of patients in each group, and stratified randomisation, to keep the groups balanced for certain prognostic patient characteristics (Altman & Bland 1999, p 1209).

There are points to consider here in midwifery, however. When data are derived exclusively from randomised trials or meta-analysis, the results give us a clear idea of the efficacy of the intervention for an 'average' randomised patient. We will not be able to deduce, from the data we receive, any information on 'psychosocial factors and support, personal preferences of patients, and strategies for giving comfort and reassurance' (Feinstein & Horwitz 1997).

Randomised controls offer 'the protection of the public from potentially damaging uncontrolled experimentation and a more rational knowledge about the benefits to be derived from professional interventions' (Oakley 1998a, p 1242).

Definition

CONSORT

Have you seen this word when reading about randomised controlled trials? It stands for: Consolidated Standards of Reporting Trials.

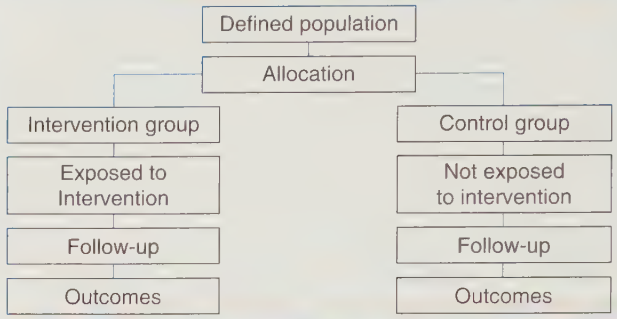

Figure 5.3 Allocation of a treatment group and a control group in an intervention study (including the randomised controlled trial)

BOX 5.8 The 'average' patient

One immediate problem in using the results of RCTs is that the conclusions refer to an 'average patient' who fulfilled the criteria for admission. When transferred to clinical medicine from an origin in agricultural research, randomised trials were not intended to answer questions about the treatment of individual patients. The trials have almost always been used to offer an average value for efficacy in groups of patients receiving the compared therapies.

(Source: Feinstein & Horwitz 1997, p 534)

The systematic review

A systematic review is a concise summary of the best available evidence that addresses a sharply defined clinical question (Sackett et al 2000). In a world where more and more research findings are being published, there is a dizzying array of information for the practitioner to wade through in deciding what is best. Systematic reviews of the effects of healthcare attempt to bring together the relevant evidence on a particular intervention or treatment, so that people choosing between

different interventions are more informed and can make better decisions. Regardless of whether a review is broad or narrow, the reviewer tries to identify as many of the eligible studies as possible, so that these can be included as fully as possible in the review. If appropriate, the reviewer might conduct a meta-analysis, in which the results of different trials are combined to provide a more precise estimate of the average difference between the effects of the interventions being compared. In all systematic reviews, the evidence being brought together for a particular intervention needs to be as free from bias and as reliable as possible. This is why most reviews of the effects of interventions rely exclusively on randomised trials. The process of bringing together the evidence also needs to minimise bias, and be rigorous and robust. The ultimate aim of any systematic review of randomised trials should be to ensure that relevant data on all randomised participants from all relevant trials are included (Clarke 2005).

The value of systematic reviews depends greatly on the availability and quality of the results of primary research. 'Knowledge development must be cumulative in the sense that related knowledge generated from separate research studies is integrated into a more comprehensive understanding of the topic at hand' (Kirkevold 1997, p 977).

One of the key parts of any review is to consider how similar or different the available primary studies are and what impact any differences have on the studies' results. Between-study differences or heterogeneity in results can result from chance, from errors in calculating accuracy indices, or from true heterogeneity—that is, differences in design, conduct, participants, tests and reference tests.

The steps required to undertake a systematic review are as follows:

1. The problems to be addressed are specified in the form of well-structured questions.
2. Literature searches are conducted to identify potentially relevant studies that shed light on the questions.
3. The quality of the selected studies is assessed.
4. The evidence concerning study characteristics and results is summarised, and differences between studies are explored and, when feasible and appropriate, meta-analysis helps in collating results.
5. Inferences and recommendations for practice are generated from interpretation and exploration of clinical relevance of the findings (Khan 2005).

A systematic review of the literature allows for estimations of the effects of healthcare interventions by identifying the individual, clinical and contextual factors that influence the effectiveness of that care. Overall conclusions are drawn from many studies that are believed to address the same or similar research hypotheses. An overview provides a broader look at the subject in question, as it is based on a number of studies in different settings and includes a variety of participants. Overviews are also useful in identifying the uncertainties and gaps in the research. The specific purpose of meta-analysis is to: increase statistical power for primary endpoints and for subgroups; resolve uncertainty where reports disagree; improve on estimates of effect size; and answer questions not posed at the start of individual trials (Sacks et al 1987). The systematic review differs from meta-analysis in that it does not necessarily statistically combine the results of studies that are critically reviewed.

BOX 5.9 Reading a Cochrane table

- See Fig 5.4 for an example of a Cochrane table.
- The 'forest plot' is the diamond at the bottom. It depicts the pooled odds ratios.
- The horizontal line corresponds with each trial included and shows the difference between groups—best single—and the width of the line demonstrates the 95% confidence interval of this estimate.
- The black line down the middle of the picture is known as the 'line of no effect'.
- If the confidence interval (the horizontal line) crosses the line of no effect (the vertical line), this means either that there is no significant difference between the interventions or that the sample size was too small for us to be confident of where the true result lies.
- The various individual studies give point estimates of the relative risks, and the confidence intervals are so wide on some studies that they go off the page. This is depicted as an arrow.
- The tiny diamond below all the horizontal lines represents the pooled data from the trials, with a new, much narrower confidence interval.
- If the diamond overlaps the line of no effect, we can say there is probably little difference between the two interventions in terms of the primary endpoint (defined at the top of the graph).
- Heterogeneity can involve some serious statistics. However, the question to ask is whether there is greater variation between the results of the trials than would be conceivable through chance.

You need to think how you would interpret these results in practice.

Specific characteristics of a systematic review include:

- formal criteria on which studies are eligible for inclusion—this is done in order to avoid selection bias regarding inclusion or exclusion of studies
- expression of the statistical uncertainties inherent in each study by appropriate use of the confidence interval
- recognition that studies have adopted different design strategies
- in the interpretation of results, taking into account the limitation of some studies in inferring causality (Pocock et al 1994).

The systematic review is an important tool, for a number of reasons. Progress in midwifery care is achieved through research that refines, extends or refutes prior theoretical concepts to build onto that system of scientific knowledge. Knowledge that is cumulative can then be integrated into

one systematic review to achieve a more comprehensive understanding (Chalmers et al 1992; Kirkevold 1997). Research must be accessible to clinicians if research-based practice is to become a reality. The value of systematic review has been demonstrated by the success of such commercial systematic review providers as the Cochrane Database.

Meta-analysis

The *Cochrane Handbook for Systematic Reviews of Interventions* lists the following reasons for considering a meta-analysis:

1. To increase power. Power is the chance of detecting a real, statistically significant effect, if it exists. Many individual studies are too small to detect small effects, but when several are combined there is a higher chance of detecting an effect.
2. To improve precision. The estimation of a treatment effect can be improved when it is based on more information.
3. To answer questions not posed by the individual studies. Primary studies often involve a specific type of patient and explicitly defined interventions. A selection of studies in which these characteristics differ can allow investigation of the consistency of effect and, if relevant, allow reasons for differences in effect estimates to be investigated.
4. To settle controversies arising from apparently conflicting studies or to generate new hypotheses. Statistical analysis of findings allows the degree of conflict to be formally assessed, and reasons for different results to be explored and quantified.

Warning: Of course, the use of statistical methods does not guarantee that the results of a review are valid, any more than it does for a primary study. Moreover, like any tool, statistical methods can be misused . . . Meta-analyses of poor-quality studies may be seriously misleading. If bias is present in each (or some) of the individual studies, meta-analysis will simply compound the errors, and produce a 'wrong' result that may be interpreted as having more credibility (Deeks et al 2005, p 78).

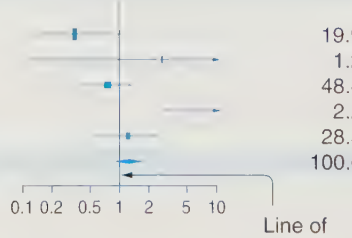
The methods used for meta-analysis generally follow these basic principles:

(1) Meta-analysis is typically a two-stage process. In the first stage, a summary statistic is calculated for each study. For controlled trials, these values describe the treatment effects observed in each individual trial. For example, the summary statistic may be a risk ratio if the data are dichotomous or a difference between means if the data are continuous.

(2) In the second stage, a summary (pooled) treatment effect estimate is calculated as a weighted average of the treatment effects estimated in the individual studies (Cochrane Handbook 2005, p 158).

You will no doubt be familiar with the Cochrane Library graphs illustrating the probability of an outcome between two groups who have been treated differently (the treatment group and the control group). When deciding what this shows—that is, the treatment effects—the questions to ask are:

1. What is the direction of effect?
2. What is the size of effect?
3. Is the effect consistent across studies?
4. What is the strength of evidence for the effect?



See if you can work out the answers to these questions when looking at Figure 5.4.

Figure 5.4 demonstrates the outcome in terms of having to manually remove the placenta between a group of women (treatment group) who were given IM Syntometrine as the oxytocic of choice and comparing this outcome with the group of women (control group) who had been randomly allocated *not* to receive this treatment. Remember: the line that passes down the middle of the graph is called the 'line of no effect'. (This will be explained more fully later in the chapter.) To go back to our four questions:

1. *Answer*: The effect is very minimally on the positive side (the right hand side) of 1. This tells us that the treatment had a mildly positive effect—that is, having an active management of the third stage of labour was associated with having to have a manual removal of the placenta.

Review: Active versus expectant management in the third stage of labour
Comparison: Active vs expectant management (all women)
Outcome: Manual removal of placenta

Study	Treatment *n/N*	Control *n/N*	Relative Risk (Fixed) 95% CI	Weight %	Relative Risk (Fixed) 95% CI
Abu Dhabi 1997	3/827	9/821		19.9	0.33 [0.09, 1.22]
Brighton 1993	1/103	0/90		1.2	2.63 [0.11, 63.64]
Bristol 1988	16/846	22/849		48.4	0.73 [0.39, 1.38]
Dublin 1990	19/705	1/724		2.2	19.51 [2.62, 145.36]
Hinchingbrooke 1998	15/748	13/764		28.3	1.18 [0.56, 2.46]
Total	3229	3248		100.0	1.21[0.82, 1.78]

Total events: 54 (Treatment), 45 (Control)
Test for heterogeneity chi-square = 13.80 df = 4 p = 0.008 I^2 = 71.0%
Test for overall effect z = 0.95 p = 0.3

Figure 5.4 Example of a systematic review and meta-analysis (based on Prendiville et al 2000)

This is called the *direction* of the effect.

2 *Answer*: The size of the effect is very small as well, because we can see that the confidence intervals of four of the studies and the pooled result all cross the line of no effect.

3 *Answer*: No, the effect is not consistent across all studies.

4 *Answer*: The confidence interval crosses 1, or the line of no effect, and therefore the strength of the evidence is not strong. The outcome may have occurred due to *chance*.

The hierarchy of evidence

According to the Oxford Centre for Evidence-based Medicine (2005):

> a systematic review documenting homogeneity in the results of a large number of high-quality RCTs (randomised with concealment, double-blinded, complete follow-up, intention-to-treat analysis) provides the least-biased estimate of the effect of an intervention. This becomes Level 1 evidence, and recommendations based on it are designated Grade A. Then, because we can document progressively increasing distortions of Level 1 results as we move to systematic reviews with heterogeneity, then to individual high-quality RCTs, then to less rigorous RCTs, then to cohort studies, then to case-control studies, then to case-series, and then to expert opinion, we formed a hierarchy of levels based on this progression (CEBM Oxford 2005).

The levels of evidence in the hierarchy are listed in Table 5.1.

To recap, the results of RCTs are considered to be evidence of the highest grade, whereas observational studies are viewed as having less validity because they reportedly overestimate treatment effects (Concato et al 2000).

> [Studies are] classified according to grades of evidence on the basis of the research design, using internal validity (that is, the correctness of the results) as the criterion for hierarchical ranking. The highest grade is reserved for research involving properly randomised controlled trials, and the lowest grade is applied to descriptive studies (such as case series) and expert opinion. Observational studies, both cohort studies and case-control studies, fall at intermediate levels. Although the quality of studies is sometimes evaluated within each grade, each category is considered methodologically superior to those below it. This hierarchical approach to study design has been promoted widely in individual reports, meta-analyses, consensus statements, and educational materials for clinicians (Concato et al 2000, p 1887).

Critical thinking exercise

What are the differences between the following?

- bad science based on poor evidence
- inadequate science based on insufficient evidence
- no science based purely on dogma.

(Source: Sharpe 2000, p 29.)

TABLE 5.1 The hierarchy of evidence

Level	Treatment/prevention
1a	Systematic review (with homogeneity) of randomised controlled trials (RCTs)
1b	Individual RCT (with narrow confidence interval)
1c	All or none of the above
2a	Systematic review (with homogeneity) of cohort studies
2b	Individual cohort study (including low quality RCT, e.g. < 80% follow-up)
2c	'Outcomes' research; ecological studies
3a	Systematic review (with homogeneity) of case-control studies
3b	Individual case-control study
4	Case-series (and poor-quality cohort and case-control studies)
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'

(Source: Phillips et al 2005)

Reflective exercise

What do you think of the hierarchical system for ranking evidence?

Culpepper and Gilbert (1999) point out that because the evidence hierarchy privileges certain types of data and certain types of research methodologies, phenomena not easily amenable to investigation by these privileged methods may be neglected or presumed less worthy of inquiry than those interventions best suited to the preferred methods.

Intervention studies

The RCT is an example of an intervention study. In such a study, we do not just observe exposures and outcomes in a population. We actively allocate an exposure (or intervention) to one of the study groups. The group that does not receive the intervention acts as a control group. We then follow the groups over a period of time. We compare the frequency of the outcome in the experimental group—those receiving the intervention—with the frequency of the outcome in the group not allocated the intervention. See, for example, the RCTs into continuity of midwifery care (Flint & Poulengeris 1989; Homer et al 2001; Rowley et al 1995).

BOX 5.10 Semmelweis

The story of Semmelweis is well known. In 1848 he published his findings that the rate of fatal postpartum sepsis was 12% for obstetricians attending women in childbirth after having performed an autopsy and not washing their hands, compared to 3% for those attended by midwives who did not perform autopsies. The medical fraternity totally and unequivocally rejected his probability-based evidence. He was denounced and driven from his job, his country, and perhaps his mind, dying in a mental institution at the age of 47 (Goodman 1999).

Before accountability was determined by 'best evidence', the collective medical tradition in these years was to leave the job of clinical evaluation to the individual. The American Medical Association (AMA) code of ethics (1847) contended that character was as important a qualification as knowledge:

> . . . character must be the foundation upon which ethical action is to be built. Proper conduct among men and affairs must be left to the man, his tact, his judgement, his education and his experience.

The AMA at the turn of the century further counselled discretion and silence with regard to the practice of colleagues. No ethical alarm bells rang, then, when Charles Meigs, chairman of midwifery at Jefferson Medical College in Philadelphia, in 1859 (eleven years following the disclosure by Semmelweis) stated:

> I have practiced midwifery for many long years; I have attended some thousands of women in labour . . . passed through repeated epidemics of childbed fever, both in town and in hospital . . . After all this experience however, I do not, upon careful reflection and self-examination, find the least reason to suppose I have ever conveyed the disease from place to place in any single instance . . . a gentleman's hands are clean (Sharpe 2000, p 30).

Cohort studies

In a cohort study, we:

1 Select a study population or cohort of people who do not initially have the outcome of interest.
2 Classify the members of the cohort according to whether they have been *exposed* to the potential risk factor or not.
3 Follow the entire cohort over time and compare the incidence of the *outcome(s)* in the exposed individuals with the incidence in those not exposed.

Cohort studies are particularly useful for rare exposures and in situations where we are interested in studying more than one outcome. However, they are generally slow and expensive to carry out. They are also inefficient in investigating rare outcomes—that is why we do case control studies where we select all cases with a rare outcome and match them for variables of interest.

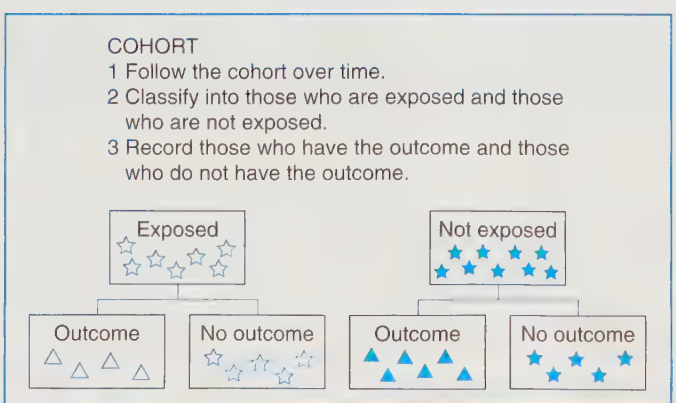


Figure 5.5 Cohort studies

Case control studies

In a case control study, we:

1 Identify individual cases of the *outcome* of interest.
2 Identify a representative group of individuals who do not have the outcome. These individuals act as controls.
3 Compare cases and controls to assess whether there were any differences in their past exposure to one or more possible risk factors.

Cross-sectional studies

In a cross-sectional study, we measure the frequency of a particular exposure(s) and/or outcome(s) in a defined population *at a particular time*. Cross-sectional studies can be either descriptive or analytical.

- In a descriptive cross-sectional study, we simply describe the frequency of the exposure(s) or outcome(s) in a defined population.
- In an analytical cross-sectional study:
  1 We simultaneously collect information on both the *outcome* of interest and the *exposure* to the potential risk factor(s).
  2 We then *compare* the frequency of the outcome in the people exposed to each risk factor with the frequency in those not exposed.

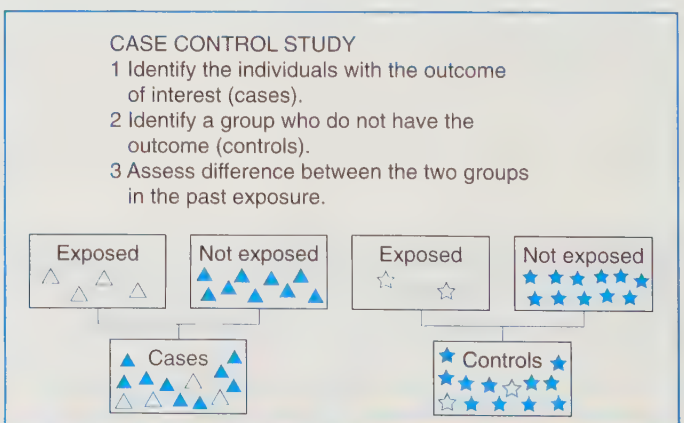

Figure 5.6 Case control studies

To determine the prevalence of an outcome at a certain time
Prevalence = number of cases/study population

Prevalence of outcome = sum of ○ plus ●
divided by the study population ☆ + ★ + ○ + ●

● Exposed with outcome ○ Unexposed with outcome
★ Exposed without outcome ☆ Unexposed without outcome

Figure 5.7 Analytical cross-sectional study design

The *prevalence* is the proportion of persons in a defined population that have the outcome under study at a specific point in time. Prevalence = the number of cases divided by the total number of people in the study population at a given time. The *incidence* of an outcome refers to the number of new cases with the outcome in a population in a defined time period.

Ecological studies

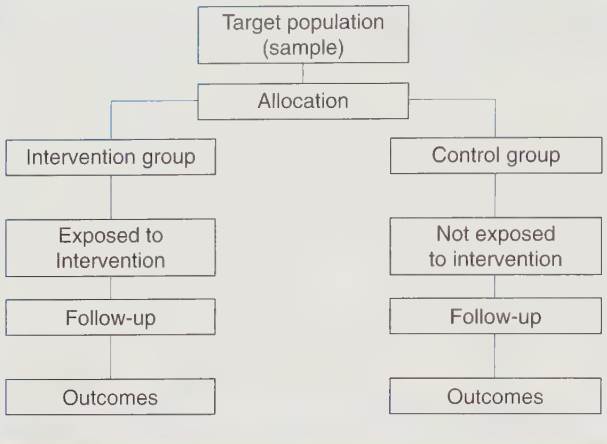
Ecological studies compare the exposure status and outcome status of *groups* rather than individuals. An ecological study thus looks for an association between an exposure and an outcome at the group level. In other words, we look to see whether the outcome is more frequent in groups where the exposure is more frequent. For each group, the exposures and outcomes are measured for the group as a whole. So, it is not possible to link the exposure of any particular individual to his or her outcome.

Bias in research studies

Bias refers to any errors in the design or conduct of a study that result in a conclusion that is different from the truth. It is particularly important that potential sources of bias are identified at the stage of study design, because you cannot usually adjust or make allowance for bias at the analysis stage. To put it very simply, if you study the wrong people, or get the wrong data from them, no amount of analysis will put it right. So, bias can ruin a study irretrievably.

The subject of bias is hotly debated in the evidence-based movement. Technical bias, publication bias and source-of-funding bias are all potential sources of systematic bias that affect the total pool of evidence and skew it in favour of experimental and commercially profitable interventions (Song et al 2000).

- *Technical bias* favours research that we know how to do, and therefore is towards phenomena that we know how to investigate. Technical bias creates a systematic bias that influences what kinds of data are created.
- *Publication bias* refers to the differential publication by medical journals of positive and/or statistically significant results (Song et al 2000). The purpose of this practice is to make the medical literature more interesting by publishing studies where new interventions are shown to be effective. However, through publication bias, clinicians may be exposed to a group of studies that misleadingly suggests the superiority of new interventions. Furthermore, publication bias, like technical bias, can ultimately lead to the neglect of certain types of phenomena. Because getting published counts significantly in researchers' career advancement (Miettinen 1998), the researchers may choose to study a restricted group of topics that are most likely to yield publishable results, that is, topics that do not fall in the 'grey zones' of clinical practice (practices whose usefulness is uncertain or for which older research data have been equivocal) (Naylor 1995). Together, these scientific and social constructionist arguments undermine the assumption in EBM that EBM-preferred data are a representative body of data most likely to lead to truthful conclusions about the medical interventions they represent (Gupta 2003).
- *Source-of-funding bias*:



Another area for ethical concern is the effect that EBM has on the authority and power of doctors vis-à-vis other groups. EBM prioritizes certain types of clinical research and thus increases the pressure for this research to be *conducted and funded*. This results in several particular outcomes. Research funding decisions are made in the context of competing priorities so that decisions to fund clinical research are also decisions not to fund other things. As the majority of evidence-based research is conducted by physicians, EBM becomes a way of entrenching medical

BOX 5.11 Types of bias

Definitions of *interpretation biases*:

- *confirmation bias*—evaluating evidence that supports one's preconceptions differently from evidence that challenges these convictions
- *rescue bias*—discounting data by finding selective faults in the experiment
- *auxiliary hypothesis bias*—introducing ad hoc modifications to imply that an unanticipated finding would have been otherwise had the experimental conditions been different
- *mechanism bias*—being less sceptical when underlying science furnishes credibility for the data
- *'time will tell' bias*—when different scientists need different amounts of confirmatory evidence
- *orientation bias*—the possibility that the hypothesis itself introduces prejudices and errors and becomes a determinant of experimental outcomes.

(Source: Kaptchuk 2003)

Potential sources of bias and where it may occur:

Selection bias
There may be systematic differences in the comparison groups
Solution: randomise

Performance bias
There may be systematic differences in the care apart from that being evaluated

Attrition bias
There may be systematic differences in the withdrawals from the trial
Solution: account for all the subjects

Detection bias
There may be systematic differences in the outcome assessment
Solution: 'blinding' of participants and/or observers

Figure 5.8 Potential sources of bias (based on sources of bias in trials of healthcare interventions in the Cochrane Handbook 2005, p 58)

authority in determining to what degree research will be funded, what questions will be researched, by whom, and thus, which results will be given priority in clinical decision-making. This occurs at the expense of those who might wish to contribute to setting the research agenda and to determining what research should be funded (Gupta 2003, p 118).

Confidence intervals

The confidence interval does as the name suggests—it allows us to feel confident (or not!) that we can apply the results we have found in our sample to the whole population. Another way of saying this is that we can *infer* the results from research to the population at large if certain situations exist (such as when we are dealing with a 'normal distribution' and are able to take a 'random sample' from the same population we are studying). Let's say we calculate from a sample of 100 healthy pregnant women that the mean weight gain (the average number of kilograms) they will gain during pregnancy will be 12 kilograms. Let's say this will be a close approximation to the average weight gained. If we were then to repeat this experiment 100 times over, with randomly selected women from the same population, we would be able to say with more certainty that the result we got (say it is 12 kilograms) is the average weight we would expect healthy pregnant women to gain in pregnancy. Of course you can see that this is a large undertaking—this is where the confidence interval comes in. Using fairly complicated statistics, we can calculate the 95% confidence interval for the average weight gain in healthy women in pregnancy. Then we can say (without having to physically repeat the experiment 100 times) that if we repeated the experiment 100 times we could be sure that 95% of the time, the mean weight gain would be somewhere around 12 kilograms. The two numbers on either side of the confidence interval tell us where the true value lies in the population. Going back to our example, we might record our finding in the following way:

> Average weight gained in pregnancy = 12.0 kg (95% CI 10.5–14.2)
> (Our sample was randomly selected from a population of healthy pregnant women in Sydney in 2005.)

This tells us that in our study the average was 12 kg, and we can infer that 95 out of 100 times, the true value in the population will be somewhere between 10.5 and 14.2 kg. (The statistics have saved us from having to do the study 100 times and record all the weights!) Another way of saying this is that once we construct a confidence interval, we have a range of values that we can be confident includes the true value of the mean. You will meet confidence intervals when you read any quality research papers. This is an introductory guide to help you understand the very basics about confidence intervals. I have recommended further reading at the end of this chapter.

Odds ratios

One of the ways in which we can understand how an exposure or an intervention is associated with the outcome we are interested in observing, is to calculate the odds ratio. The odds ratio could be loosely described as the probability of an event happening in two groups. If the odds of an event are greater than one, then the event is said to be more likely to occur. Conversely, if the odds ratio is less than one, then the event is less likely to occur. This is a very simplistic description of a very complex statistical measure.

You are most likely to come across odds ratios in reading the Cochrane graphs in systematic reviews, so I will illustrate how to read the odds ratio using a Cochrane graph.

The graph in Fig 5.9 illustrates the odds of continuity of care during pregnancy and childbirth on the likelihood of not feeling well prepared for child care. As you can see, the odds ratio is 0.57, which is less than 1, and therefore we can deduce that continuity of care is less likely to be associated with *not* feeling well prepared for child care.

Another example of the odds (in this case the risk ratio) being less than 1 is shown in Fig 5.10. (A slightly confusing issue arises here, where the authors have used the measure 'relative risk' rather than an odds ratio. For our purposes at this stage of critical analysis they are interchangeable. At an advanced level of statistics, the meanings are slightly different.

Let's turn to Figure 5.11. Can you say in your own words what Figure 5.11 is telling us?

Now for an example of the odds being greater than 1. Figure 5.12 tells us that when comparing active versus expectant management of the third stage of labour when women in the treatment group were given IM Syntometrine as the oxytocic of choice, and comparing this outcome with the group of women (control group) who had been randomly allocated *not* to receive this treatment, there is a greater likelihood of vomiting between delivery of the baby and discharge from the labour ward. The pooled risk ratio is 2.19 with a 95%

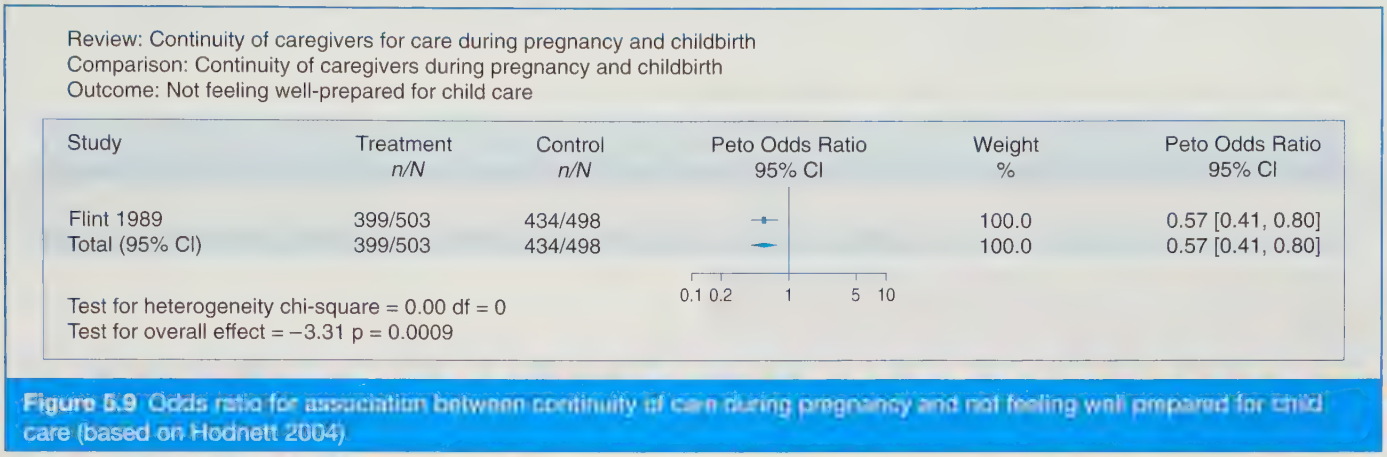


Figure 5.9 Odds ratio for association between continuity of care during pregnancy and not feeling well prepared for child care (based on Hodnett 2004)

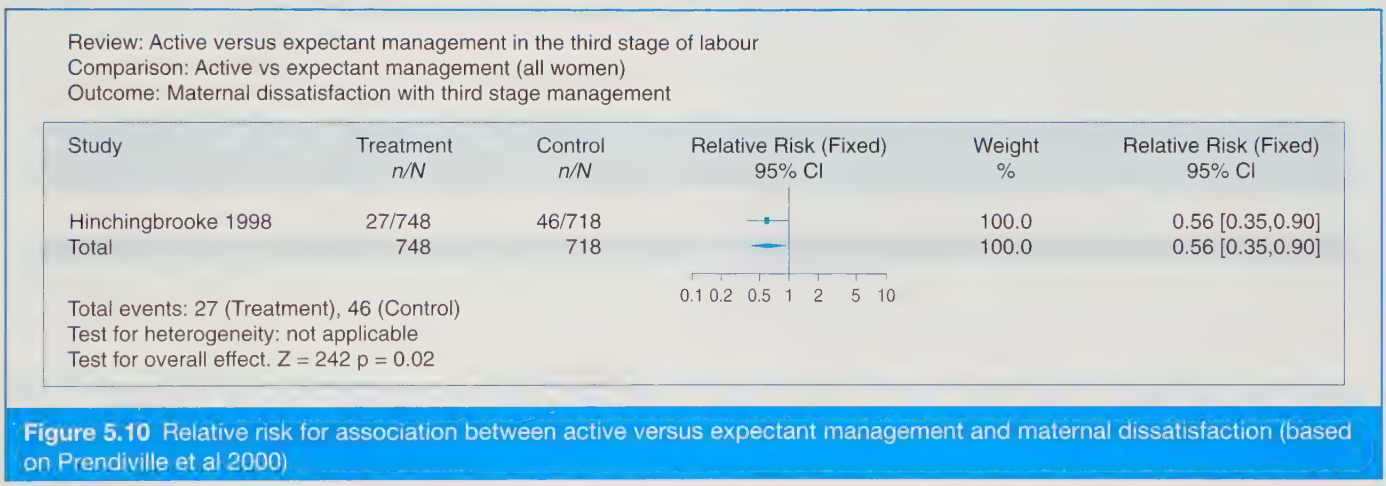

Figure 5.10 Relative risk for association between active versus expectant management and maternal dissatisfaction (based on Prendiville et al 2000)

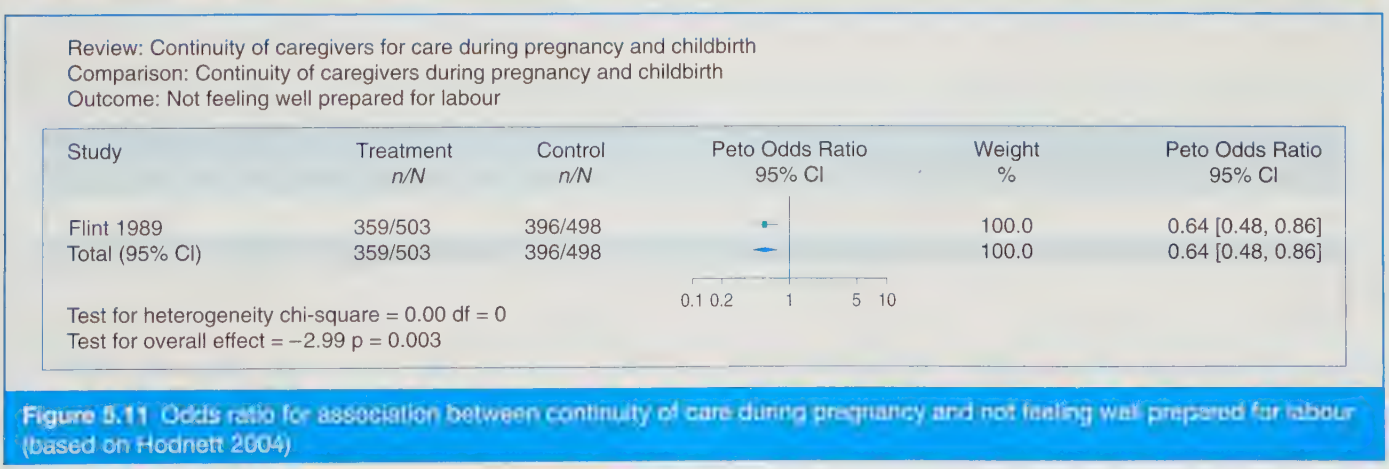

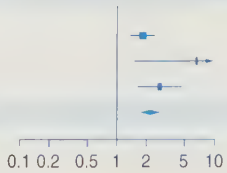

Figure 5.11 Odds ratio for association between continuity of care during pregnancy and not feeling well prepared for labour (based on Hodnett 2004)

Review: Active versus expectant management in the third stage of labour
Comparison: Active vs expectant management (all women)
Outcome: Vomiting between delivery of baby and discharge from labour ward

Study	Treatment *n/N*	Control *n/N*	Relative Risk (Fixed) 95% CI	Weight %	Relative Risk (Fixed) 95% CI
Bristol 1988	102/846	55/849		74.8	1.86 [1.36, 2.55]
Dublin 1990	10/86	2/114		2.3	6.63 [1.49, 29.47]
Hinchingbrooke 1998	47/748	17/764		22.9	2.82 [1.64, 4.87]
Total	1680	1727		100.0	2.19 [1.68, 2.86]

Total events: 159 (Treatment), 74 (Control)
Test for heterogeneity chi-square = 3.99 df = 2 p = 0.14 I^2 = 49.8%
Test for overall effect z = 5.80 p < 0.00001

Figure 5.12 Odds ratio for association between active or expectant management, and vomiting (based on Prendiville et al 2000)

BOX 5.12 Optimality

The concept of 'optimality' offers an alternative approach to evaluating the outcomes of clinical care. Optimality looks for the desired best possible outcome, rather than the occurrence of undesired adverse (and rare) events. In essence, it replaces the focus on risk and adverse outcomes with a focus on measuring the frequency of 'optimal' (good, desired) outcomes.

Optimality is different from the concept of 'normality'. 'Normal' is frequently defined in healthcare as the absence of abnormalities or adverse events. However, definitions of what is normal must be based on decisions about what constitutes the broad range of normal. The Dutch authors (Wiegers et al 1996) who originally used the 'optimality' approach for measuring patient care stressed that the index is not a static one, but requires close evaluation of its internal validity as it applies to different practice situations. The tool must be adapted to accommodate different or changed insights into maternity care.

(Sources: Murphy & Fullerton 2001; Wiegers et al 1996)

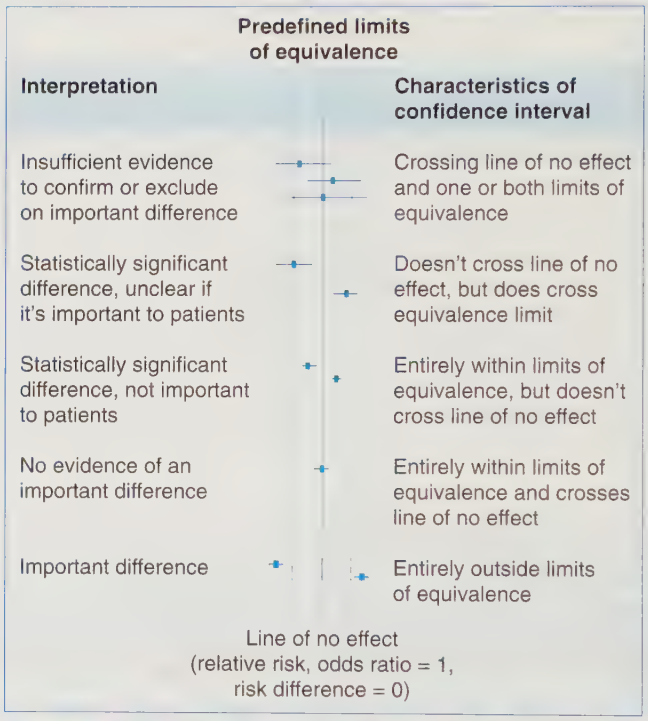

Figure 5.13 Relation between confidence interval, line of no effect, and thresholds for important differences (based on Alderson 2004)

confidence interval of 1.68–2.86. This tells us that the women who were given an oxytocic in the third stage had a greater likelihood of vomiting after birth than those who did not receive the treatment.

In summary, this has been a whistle-stop introduction to odds and risk ratios. You are advised to look at the reading list at the end of the chapter for more information.

One of the ways in which we can discern whether the results of research are going to be useful to us in clinical practice is to consider the relationship between the odds ratios, the line of no effect and another measure called the line of equivalence (which will not be explained here).

Likelihood ratios

A likelihood ratio is the percentage of ill people with a given test result divided by the percentage of well individuals with the same result. Ideally, abnormal test results should be much more typical in ill individuals than in those who are well (high likelihood ratio) and normal test results should be more frequent in well people than in sick people (low likelihood ratio). Likelihood ratios near unity have little effect on decision-making; by contrast, high or low ratios can greatly shift the clinician's estimate of the probability of disease (Grimes & Schultz 2005).

Conclusion

Turning the phrase 'evidence-based' into 'evidence-informed' was the subject of a debate in the *Midwifery Digest* (MIDIRS 2000). The author claimed that by using the word 'informed' we are more likely to be mindful of the process of midwifery knowledge that midwives understand to originate from the way women themselves understand their bodies and the process of giving birth. Lesley Page in her paper 'The backlash against evidence-based care', contends that 'evidence-based' does not necessarily mean practice based on a positivist, reductionist knowledge generated solely from within the scientific medical paradigm (Page, 1996). Others such as Mavis Kirkham claim that through research we can question the status quo, that research is also the means with which we can move from being 'expert, professional and oppressed' to an alliance with women giving birth (Kirkham 2000).

A strategic relationship between women and midwives can challenge both the economically driven imperative for research, and the legislation and control of accepted practice, and in doing so it may promote the care of previously excluded groups of women. Midwives have the opportunity to show leadership in undertaking research that is relevant to women and makes judicious use of precious research funds. To quote from Mary Stewart's research, 'the technocratic paradigm has become authoritative and highly valued, whereas a more holistic model, incorporating concepts of intuition and shared knowledge, has less credence' (Stewart 2000).

There is no doubt that evidence-based healthcare in its broadest meaning has the potential to better the lives of all women in childbirth, simply because it claims to be based in 'science' as opposed to 'authority'. It is a powerful tool with which to question the authority of obstetric practice and intervention. It is also the means with which we offer accountable and responsible care to women through informed decision-making. The RCT is currently regarded as a highly effective methodology for investigating the introduction of new technologies and treatments before they become introduced routinely. What a pity, then, that the introduction of epidurals and other highly interventionist technology was never evaluated by any rigorous, or for that matter even second-rate, scientific investigation before wholesale introduction into routine practice. In the arena of 'evidence-based everything' the RCT is an immensely valuable tool. But there is room for other methodologies and there is also room for improvement. The RCT is a relatively new and evolving method of seeking truth in maternity care that has helped to change the lives of midwives and women so far. As Chalmers noted recently, 'the greatest potential for improving research may lie in greater public involvement. Partly because of perverse incentives to pursue particular research projects researchers often seem to design trials to address questions that are of no interest to patients' (Chalmers 1989, p 1168).

BOX 5.13 Let's have SECs

As well as being vigilant in ensuring that research is ethical and meaningful to those who are researched, the use of appropriate language is something that cannot be underestimated. Ann Oakley wrote:

> Over a few commiserative drinks one evening a clinical colleague and I decided that if randomised controlled trials were renamed socially equitable comparison tests social scientists might like them better. It does not exactly run off the tongue, I know, but then neither does randomised controlled trial. Are there any takers out there? (Oakley 1998).

Count me in. Renaming the things 'socially equitable comparisons' (SECs) would locate the research language in a place much closer to the language of birth if we were to suggest having SECs rather than undertaking an RCT!

Review questions

1. What are the essential elements of a well-designed epidemiological study?
2. Name one intervention used in midwifery care that has not been researched. How would you research its effectiveness?
3. List five interventions you routinely use in your practice. Is there any published evidence to support these interventions? Is so, what level of evidence are they?
4. Using an example from practice, describe the steps you would take in applying the five steps of evidence-based practice.
5. Find an example of two areas of practice where the research underlying the practice is based on trials with a large crossover rate. How can you justify using this evidence?
6. If a study is analysed using an 'intention to treat' methodology, would you be more likely to believe the results of this trial than a population-based descriptive study? Why? What bias is likely to be evident?
7. Are randomised controlled trials meant to answer questions about the care of an individual woman? Why or why not?
8. Name some 'grey zones' of clinical practice where there is no evidence or very little evidence to support your actions.

9 What is the goal of qualitative research? Is it useful? Give an example of qualitative research that has influenced your practice.

10 How can qualitative methods complement quantitative ones?

APPENDIX: Evaluating a guideline

Who developed the guidelines?

- Are the members of the guideline development team identified?
- Are all clinical perspectives represented?
- Are all cultural perspectives represented (e.g. African-American, Pacific Islander)?
- Is patient input or participation documented?
- Are the sponsors of the guideline identified?
- Are there potential conflicts of interest?

Why did they develop the guideline?

- Is there a clear statement of the guideline objective?
- Is the gap between current practice and outcomes and the recommended practice and outcomes clearly stated?
- Is the guideline development process described? (If so, what process was used?)
  - explicit evidence-based (includes projections of healthcare outcomes for a defined population)
  - evidence-based
  - consensus process
  - process of development not described.
- What is the strength of the evidence?
- Is there a description of the strategy used to obtain information from the medical literature?
- Is there a description of the strategy used to critically appraise and synthesise the evidence?
- Is the evidence presented in terms of absolute differences in outcome (as compared to relative differences)?
- Are the major recommendations of the guideline based on high-quality evidence?

Does the guideline possess the attributes of a good guideline?

- Are the patients that the guideline applies to clearly described and are exceptions stated?
- Is the guideline clear and brief?
- Does it provide genuine clinical guidance?
- Is it flexible (does it allow for clinical judgement)?
- Can the change in care be measured?
- Can it be implemented in your care delivery system?
- Is the information the guideline is based on current?
- Has the guideline been successfully piloted or implemented?

CHAPTER 6

The place of birth

Maralyn Foureur and Marion Hunter

Key terms

birth centre, maternity unit, primary birth unit[1]

Chapter overview

This chapter focuses on the power of the place of birth to influence the behaviour of women and their midwives during childbirth. We propose that neither the type of care provider nor the model of care delivery *alone* is able to affect outcomes without sufficient attention paid to the physical and psychological environment for birth. Through exploring the complex nature of modern maternity care, with its focus on hospital birth and the use of technology to guarantee 'safety', we discover that the influence of 'environment' may be so pervasive that the full, potential benefits of 'new' systems or models, such as continuity of midwifery care, fail to be easily realised in hospital settings. Important insights into why this might occur are provided through the lens of one New Zealand study comparing the practices of midwives who move between small and large birthing units. The midwives' own words will be used to clearly illustrate what they have come to know as 'real midwifery'. The chapter begins with a brief historical account of childbirth history in Australia and New Zealand, to explore the reasons why women moved from their homes to hospitals for birth at the turn of the twentieth century and why they continue to go to hospital to give birth over a hundred years later. This will provide a context for considering what has been lost in the process and how the modern birth environment affects outcomes for women and babies, as well as midwives. This chapter aims to reveal what midwives can do to ensure that the potential benefits of midwifery-led care are optimised, no matter where the place of birth.

Learning outcomes

Learning outcomes for this chapter are:

1. To explore the impact of the place of birth on women and midwives
2. To explore different perspectives on why women moved from home to hospital for birth at the turn of the twentieth century, and to discuss what was lost in the process
3. To explore the risks and benefits of the three locations for place of birth: home, birth centre or hospital
4. To discuss the 'fear cascade', a plausible theoretical model that explains why the birth environment may affect birth outcomes
5. To describe some of the physiological consequences of birth in an unfamiliar or fearful environment
6. To describe the key competencies required for practising 'real midwifery' no matter where the place of birth.

Introduction

In the twenty-first century, birth takes place in the intimate spaces provided in women's homes, in small birth centres or primary birth units which aim to provide a home-like atmosphere, and in large hospitals surrounded by an array of technology and personnel. This chapter argues that each location exerts a powerful influence on how the woman's labour unfolds and how she will give birth and greet her baby. Importantly, each location also exerts a powerful influence on, and is influenced by, the midwife who accompanies the woman. Therefore, a comprehensive understanding of the influence of 'environment' on the physiological processes controlling labour and birth is essential for all midwives. We will endeavour to provide a point of entry into that knowledge by exploring the answers to two important questions: why did women move from home to hospital for birth, and what was lost in the process? In addition, some of the many studies that have explored the complex relationships between environment and physiology of birth will be examined in order to offer support for the proposal that this is essential knowledge for midwives. Finally, the chapter provides an in-depth discussion of the way in which one group of midwives discovered this knowledge in what they described as doing 'real midwifery'.

Birth moves from home to hospital

The turn of the nineteenth century marked the beginning of the move of childbirth into institutions throughout Britain, Europe, North America, and Australia and New Zealand. Therefore an examination of the past two hundred years of the history of childbirth in any of those countries will reveal the complex interplay of human and social forces which ultimately dislocated childbearing women from their homes and families, and moved apparent responsibility for childbirth to the medical profession based in hospitals (Graham 1997). Far from being the rational sequential scientific development that one might expect, such an examination reveals that the systems have been shaped and moulded by class and gender, fashion and fallacy, and professional and economic competition (Rowley 1998).

This chapter begins with a very brief glimpse into that history in Australia and New Zealand. While there are parallels between the development of maternity care and midwifery in Britain and Europe and among the non-Indigenous populations of Australia and New Zealand, there are also important differences emerging from Australia's initial role as a penal colony and the later development of both Australia and New Zealand as nations with booming economies where a vigorous medical profession was seeking to establish itself (Tew 1995). Mein Smith claims that in these two colonies, the revolution in the organisation of childbirth began earlier and progressed faster than in either Britain or Europe (Mein Smith 1986). However, it should first be acknowledged that most historical accounts in both Australia and New Zealand have largely ignored the childbirth experiences and expertise of the original occupants of the land. Since we must rely on secondary sources of information, this account will do the same, in order not to misrepresent the birth traditions of either the Maori of New Zealand or the Aboriginal peoples of Australia.

The origins of midwifery in Australia

The ships of the First Fleet, which landed in Sydney in 1788, carried several women who were free settlers as well as numbers of convict women. The ships' logs record that during the long voyage to Australia, several women gave birth, allowing others to gain midwifery experience (Adcock et al 1984). The military and ship's surgeons accompanying the colonising forces probably had little or no midwifery expertise, and there were no midwives listed among either the free settlers or the convict women. Therefore it appears that midwifery in Australia began with women helping each other as best they could, accessing medical help where it was available and when it was required. Some of the women who found themselves in the role of midwife continued to assist women in childbirth and became well known, loved and respected for their abilities.

Female convicts were transported to Australia for the next fifty years in an attempt to empty English prisons of 'hardened cases' but covertly to provide sexual services for men (who outnumbered the women six to one) and ultimately to stabilise the economy of the new colony (Rowley 1998). Early census records reveal that by 1806, two per cent of women were in skilled trades, which included two women who listed their occupation as midwife, although with every woman under the age of forty-two producing a baby each year, there were clearly more than two 'midwives' in the colony (Adcock et al 1984). No 'learned' midwives were recorded among those early settlers until forty years later, when Mrs McTavish, identified as the first 'trained' midwife to settle in Australia, advertised her services in a Hobart newspaper (Barclay 1993, cited in Rowley 1998). Therefore it is reasonable to propose that the midwifery traditions of Australia were established by community-based, 'lay' midwives, without access to any theoretical knowledge or teaching other than what they had gleaned from observation and experience. These were the 'accidental' or empirical midwives of the convict era assisting women to give birth in whatever place constituted 'home'.

The first maternity hospitals in Australia

In 1820, a midwife or 'fingersmith' was appointed to the Female Factory at Parramatta, which was built to house female convicts. Some midwives chose to work in the Female Factory for short periods to gain experience before moving out into the community and private practice. Convicts in domestic service who became pregnant were sent to Parramatta for punishment and confinement. Once delivered, the women returned to their employer, often leaving the baby behind, where their infants were wet-nursed by thirty convict 'nurses' who resided there.

The Female Factory became the first maternity hospital, as the pregnancy rate among convicts was high. Soon, poor and destitute women also sought to be confined there, since the authorities were reluctant to build hospitals for the general populace. The Female Factory was eventually closed due to an epidemic of puerperal sepsis. Following the closure, convict women continued to give birth at home, as did the free settlers, attended by relatives, neighbours, or a midwife if they could afford one or find one, but rarely by a doctor.

The transportation of convicts ended in 1848 just before the discovery of gold near Bathurst in 1851. The new colony prospered. The government of the day encouraged the immigration of young single women to redress the imbalance in the sexes and to populate the country. As settlers moved out into rural areas, even neighbours were sparse, and there are numerous accounts of women being attended by Aboriginal women during childbirth (Willis 1989). Learned midwives who had received midwifery training in England and Scotland were also among the new immigrants. As the settlements grew into towns, some midwives began taking women into their own homes for 'confinement', and thus began the first private maternity homes, which were eventually to become community or primary hospitals (Shephard 1989, 1991). Later, concern over the deplorable conditions under which poor and destitute women were 'confined' in their homes led to the establishment of (initially) charitable and (ultimately) State-funded women's hospitals in the cities of Melbourne (1886) and Sydney (1893) just prior to the turn of the twentieth century (Forster 1965).

The origins of midwifery in New Zealand

Childbirth for Pakeha[2] women in New Zealand prior to the 1904 *Midwives Act* was described by Donley (1986) as a neighbourhood affair conducted in homes. Women were attended by either (English or Scottish) trained or lay midwives, who took charge of domestic responsibilities as well as supporting the woman in labour, delivering the baby and getting breastfeeding established. As in Australia, these early midwives were loved and respected for their competence and care, and there are several accounts of the good records of the pioneering midwives in terms of maternal and perinatal mortality (Donley 1986). As the towns grew and cities evolved, many midwives set up their own small, private maternity homes. It is estimated that by the turn of the twentieth century, there were over two hundred one- or two-bed maternity homes run by midwives or by doctors, located throughout the towns and cities of New Zealand (Mein Smith 1986).

The first maternity hospitals in New Zealand

Several events coalesced just after the turn of the century that initiated major changes in the way childbirth was managed, and changed it forever from a relatively private family affair into a concern of the State. Reports to Parliament had for some time recorded the fluctuating maternal and infant mortality rates in the new colony and, in particular, the rate of maternal deaths from puerperal sepsis. In 1903, a peak in the maternal mortality rate caused alarm in government circles. At the same time a Royal Commission set up in New South Wales in 1904 to investigate falling birth rates in both Australia and New Zealand found that the decline was highest among the 'better classes' and that 'while the "unfit" were having many children ... [they] had a higher rate of infant mortality' (Donley 1986, p 32). The Premier, Richard Seddon, demanded action and a champion emerged in the person of Grace Neill,[3] who was easily able to persuade him that the way to increase the birth rate and improve the appalling rates of maternal and infant mortality was to register all midwives and establish State-subsidised hospitals, where the wives of working-class men (the deserving poor) could give birth in comfort and safety. This saw the setting up of St Helens Hospitals in the major centres of New Zealand, with the first established in a rented cottage in Rintoul Street, Wellington, in 1905 (Donley 1986). The hospitals provided midwifery training for both nurses and women without a nursing qualification, and offered either hospital or domiciliary care (without prejudice).

Why did women move from home to hospital?

Over the next twenty years, simultaneously in both countries, women started to move from home to hospital in increasing numbers. Why this happened is an intriguing question. A simple answer would be to find that mothers and babies died in large numbers at home in the care of midwives, and that women chose to move into hospital, where medically managed birth was safe. This is not the case, however. Different authors quote a variety of maternal and infant mortality rates, all purporting to provide evidence of either a dramatic improvement in, or worsening of, mortality as a consequence of the move (Ehrenreich & English 1973; Shorter 1983). Gaining a clear picture of what was happening at the time is difficult, and this allows different interpretations of the

St Helens Hospital, Dunedin, New Zealand c. 1923. Reproduced with the permission of Alexander Turnbull Library, Wellington, New Zealand. Photo from the S C Smith Collection

significant events to emerge. What motivated women to move from birth at home to hospital can never be known for certain, but the parallel movement in Australia and New Zealand suggests that the motivators for the change may have been similar, and several issues can be identified which may have played a part.

The first is the issue of falling birth rates at the turn of the twentieth century and the intervention of both colonial governments in childbirth, with the aim of increasing the size of their respective populations and ensuring their health and vigour (Donley 1986). The Health Departments in both countries promoted the hospitalisation of birth in order to decrease the rate of maternal deaths particularly from puerperal sepsis, and to ensure women accessed antenatal care that would lead to the birth of a healthy baby. Both governments were disturbed by the parlous physical state of many of the men recruited into the armed forces during World War I, and saw the birth of a healthy baby as essential to the health of the nation in the event of another war (Mein Smith 1986).

Other themes relate to the views of women themselves and what they may have been seeking. Some may have sought increased material comfort around the time of the birth, because many homes in both New Zealand and Australia were described as lacking in all but the barest of necessities (Mein Smith 1986; Rowley 1998; Tew 1995). Other women may have found the promise of a temporary release from domestic burdens attractive (Tew 1995). Still others may have been seeking the support and company of other women, which had been dislocated by the Industrial Revolution (Wilson 1995), or greater access to doctors and their forceps (Loudon 1992; Rowley 1998; Tew 1995), or greater access to midwives since the lay midwife had largely disappeared from the community following the setting up of registration and hospital-based training. Added to these issues were the promises of a pain-free labour (Loudon 1992) and increased safety for themselves and their infants, largely and falsely promoted by the medical profession (Tew 1995). In New Zealand, the medical profession actively encouraged women's groups in political activity to persuade the government to build more maternity hospitals, which then became a focus for the growing power of the emerging medical specialty of obstetrics (Mein Smith 1986). All these issues have been debated in the literature cited, and the student of history is encouraged to pursue particular lines of inquiry using the references and further reading lists at the end of this chapter as a guide. It is interesting to note, for instance, that both forceps and the pain relief offered by twilight sleep were liberally administered by doctors attending women in childbirth at home, so these two reasons alone do not seem to be convincing arguments for the move to hospital (Forster 1965; Mein Smith 1986).

Far from increasing safety as promised, deaths from puerperal sepsis increased with hospital birth, in all but the St Helens Hospitals (Wood & Foureur 2005; Mein Smith 1986), but this appeared to go unnoticed by women as they started to move into hospitals in increasing numbers. Mein Smith (1986) asserts that by 1920, most New Zealand women continued to give birth at home, while approximately 35% of deliveries occurred in hospitals. In Australia, 'births in public institutions . . . increased from 3% in 1907 to 7% in 1920 but then leapt ahead to 55% in 1929' (Tew 1995, p 65), with one account quoting a rate as high as 67% for hospital deliveries in 1925 in the State of Victoria (Loudon 1992).

By 1935, deaths from puerperal sepsis were rarely seen, due to the advent of the drugs Prontosil and, later, sulphanilamide (Tew 1990). Perinatal mortality also began to decline between the world wars, due to dramatic improvements in the general health of women and raised living standards (Johanson et al 2002). However, in the minds of many, moving to hospital for birth had improved safety for women and babies, and it was not until 1990 that a critical history of maternity care undertaken by Marjorie Tew (1990) was able to convincingly demonstrate the fallacy of this belief. Today the vast majority of women in either country will give birth in hospital, be it a birth centre, primary birth unit or secondary/tertiary hospital. Home birth occurs in less than one per cent of the population of childbearing women in Australia, and although the estimated rate may be higher in New Zealand, at approximately six per cent (Pairman & Guilliland 2003), birth at home is the choice of few women. Or, paradoxically, is it that there is no choice?

What was lost in the move?

Several important things were lost in the move from home to hospital. The first was the opportunity to labour in a familiar environment. The second was the close personal and trusting relationship between the woman and her midwife and the continuous support in labour that the midwife provided. The third was the belief in the concept of birth as a normal physiological event. These were and are still universal aspects of home birth provision, and the whole package of care provides clear benefits for women (Walsh 2004). Let us explore these ideas a little more.

The concept of 'environment' is multifaceted and encompasses much more than the geographical or physical bricks and mortar of the location for birth. It is important to consider that 'environment' also includes the spiritual and emotional space and place in the mind and heart of the woman (Simkin & Ancheta 2001). We must also acknowledge that the environment too exerts a powerful influence on the midwife and that, in the future, new areas of research in what some have termed 'neuroarchitecture' (or 'psycho-geography') will improve our understanding of this concept (Foureur 2002; Lepori 1994; Newburn 2003; Page 2002; Walsh et al 2004).

In their calls for more home-like environments for birth, more continuity and more choice and involvement in decision-making, women may have unknowingly articulated their longing to replicate the idealised birth environment of home. Policy makers have attempted to put back components of the package, and researchers have undertaken numerous studies to explore the safety and impact of differences in location for birth (home, birth centre, primary unit, hospital), type of care provider (medical, midwife, doula), models of care (fragmented versus continuity of care and carer) and philosophies of care (belief in birth as a normal physiological event or only normal in retrospect; risk-embracing or risk-averse). However, if the three components of birth at home are an integrated and inseparable package, it becomes apparent that most studies to date have focused on either one or another part of the package. As a consequence, most studies are limited in what they can contribute to our understanding of this complex event. Hodnett realised the synergistic nature of caregiver and location for birth when she wrote that the environment may favourably influence caregivers' attitudes towards the care of labouring women, and that therefore it may be the influence of the caregiver *more* than just the location for birth that leads to good obstetric outcomes (Hodnett 2004). We will return to this idea later in the chapter.

Birth at home or in hospital: which is safer?

The debate concerning the safety of the home as the place of birth has been in progress for over one hundred years and no doubt will continue into the future, unless it becomes possible to conduct an extremely large trial where women are randomly allocated to either a home or a hospital birth. One such study involving only eleven women was identified during the process of systematic review published by the Cochrane Collaboration (Olsen & Jewell 1998). Because of the small size of the study, the reviewers were forced to conclude that there is no strong evidence to favour either planned hospital birth or planned home birth for low-risk women. Many other studies using less robust designs (such as observational, case control or cohort studies and audit of maternity services) have been conducted internationally, but few of these have been within Australia or New Zealand (for example, Chamberlain et al 1997; Rooks et al 1989; Young & Hey 2000). Most studies of this nature suffer from a lack of 'denominator data', meaning that the researcher cannot be certain that all women giving birth at home in their particular data set have been accounted for. Therefore, studies may under- or over-estimate the risks. However, the most recent and largest prospective cohort study of homebirth published in 2005 accurately identified all births and concluded that outcomes for homebirth women were substantially better than for low-risk American women having hospital births (Johnson & Daviss 2005). Among the 5418 women who planned to give birth at home when labour began, there was a 12.1% transfer rate at the beginning of labour. Intervention rates were significantly reduced, with epidural (4.7%), episiotomy (2.1%), instrumental delivery (1.06%) and caesarean section (3.7%). The intrapartum and neonatal mortality was 1.7 deaths per 1000 planned homebirths when congenital anomalies were excluded. This is the largest study so far to confirm the safety of homebirth.

But for mothers with a twin, breech or post-term pregnancy, the current state of evidence asserts that there is an increased risk of perinatal death at home (Bastian & Keirse 1998; Young & Hey 2000). The Johnson and Daviss (2005) paper supports the findings of the comprehensive UK study *Where to be born?*, which concluded that, given the current state of knowledge, 'there is no evidence to support the claim that the safest policy is for all women to give birth in hospital' (Macfarlane et al 2000, p 798).

However, the rhetoric that began over one hundred years ago persists, and society still views birth at home as a poor choice. Indeed, Tew (1995) identified that data had been deliberately misinterpreted in UK studies between 1958 and 1970 to support the claim that 'the family home is the most dangerous place for birth' (p 29). Tew stated that an impartial observer could clearly see that the perinatal mortality rate was higher in hospitals, yet this fact was distorted in reports of the time. Obstetricians throughout the world used the false interpretation of these statistics to influence the future development of maternity services. Midwives may also be influenced by the rhetoric and either refuse to provide a home birth option for women or unconsciously bias the way it is discussed, leading women to 'choose' a hospital birth (Walsh 2004).

The birth centre: a halfway house?

Moves to address the loss of the familiar home environment for birth appeared in the late 1970s with the call for more

Reflective exercise

Imagine that you are a midwife who cares for women wherever they want to give birth (indeed, this might be a reality for many midwives). Some women want to be at home, others want to be at the small, local birth unit, and still others want to be in the hospital. Ask yourself the following questions.

1. How do I feel about supporting women in each of these locations?
2. Are the feelings different depending on the location?
3. Where do these feelings come from?
4. How do I react when a woman asks me to support her in planning a home birth?
5. How do others react to her decision for a home birth?
6. Why is this so?
7. How inconvenient/uncomfortable/scary is it for me to have to travel to the woman's home? Do I have to support her choice?
8. How inconvenient is it for me to have to travel to the birth centre rather than the hospital?
9. Do we (women and midwives) have any real choices of where to birth in our region?
   - Is there a need to change anything?
   - How can I do that?
   - Who will help me?

humanised or home-like birth spaces, culminating in the development of the birth centre in many locations throughout Australia and New Zealand (as elsewhere). Birth centres may be free-standing or located within hospitals, either adjacent to or within high-technology and medically staffed labour wards, thus enabling immediate consultation or rapid transfer if the need arises. Primary birth units may be located in urban or rural settings and share many of the attributes of birth centres. Although birth centres may differ in their structure, location, furnishings and staffing, all share a strong philosophical orientation towards assisting women to achieve normal physiological birth (Coyle et al 2001; Kirkham 2003). They are intended only for women classified as 'low risk', the very women who would fulfil criteria for birth at home. However, even in this low-risk population, numbers of women are transferred out for medical assistance or pain-relieving drugs before, during or after labour. Transfer rates vary from as low as 12% (Rooks et al 1989) to more commonly around 20% but even up to 63% in some settings (Hodnett 2004). In Australia, around 5% of women give birth in primary birth units (Griew 2003)—this includes 5379 births in birth centres in 2003, 'representing 2.1% of all confinements' (Laws & Sullivan 2005). In New Zealand the combined birth centre/primary birth unit rate in 2001 was 1% (Pairman & Guilliland 2003) and in 2003 was 15% (NZHIS 2005).

Numerous randomised controlled trials and observational studies examining the effectiveness and safety of birth centres/primary birth units have been conducted worldwide, and have demonstrated that birth for low-risk women is at least as safe in small low-risk maternity units as it is in hospitals (Kirkham 2003; Walsh & Downe 2004). In addition, a recent consumer satisfaction survey conducted in New Zealand has revealed that women 'are more likely to be satisfied with maternity services if they birth at a primary maternity facility' (Ministry of Health 2002, p 4). In a Cochrane Systematic Review, Hodnett (2004) included evidence from six trials involving almost 9000 women, and concluded that there appear to be some benefits from home-like settings for birth. However, one recent study has raised concerns about the safety of out-of-hospital births, and it needs to be considered here (Gottvall et al 2004).

A ten-year retrospective review of the Stockholm Birth Centre undertaken by Gottvall et al (2004) revealed a trend to higher perinatal mortality in primigravid women.[4] Following scrutiny of each perinatal death by an obstetrician, Gottvall and colleagues (2004) claimed that a potential risk of birth centre care is the 'philosophy that emphasises a strong belief in the natural process' (p 77). Hodnett (2004) echoed concerns regarding the emphasis on normal birth and stated that this belief might delay recognition of imminent complications or the ability of the midwife to take averting action. However, concluding comments from Gottvall et al (2004) indicate a potential bias in the study introduced through an underlying concern with intrapartum care that does not include technology and medical assistance. Many of the perinatal deaths in the original Stockholm trial (Waldenstrom et al 1997) occurred after transfer and were associated with clearly documented suboptimal care in the receiving hospital. Gottvall and colleagues did not comment on this. On the other hand, Walsh (2004) refuted any suggestion that birth centre midwives are over-orientated to normal birth and therefore may delay recognition of complications. Walsh asserts that birth centre midwives are highly skilled practitioners with an astute awareness of normal labour and that these midwives are particularly diligent in updating their skills in emergency care. Walsh acknowledged that it might very well be the midwife's belief in physiological labour, especially for primigravid women, that enables such women to achieve normal birth in birth centres. In his most recent ethnographic study, Walsh

Reflective exercise

Think about the place of birth in which you work and ask yourself the following questions. (It may be helpful to write down your responses.)

1. What do I honestly think about safety and place of birth?
2. What is the underlying belief system that I take with me to a birth?
3. What does the physical environment say about birth in this place and our beliefs about birth?
   - Is there a need to change anything?
   - How can I do that?
   - Who will help me?

(2006) asserts that very little attention has been paid to organisational dimensions of childbirth care until recently. He claims that free-standing birth centres 'subvert' the processing mentality of modernist organisations such as large maternity hospitals. Birth centres demonstrate greater flexibility in labour care so as to accommodate women's preferences and enhance the autonomy of midwives and women, such that a self-managing and self-regulating ethos flourishes (Walsh 2006).

Sociologists who have paid particular attention to childbirth also show concern regarding interpretations of safety. Annandale (1988) used both quantitative and qualitative methods to study the structure of birth in a North American birthing centre. Her study included eighteen months of observation, repeated focus group interviews and content analysis of 900 women's records over a five-year period. Obstetricians did not see women unless a risk factor arose; however, Annandale commented that midwives and obstetricians disagreed about what constituted a risk factor. Midwives tended to disagree with the assertion that a post-term induction was high risk, and that intervention was required after twelve hours of rupture of membranes. Annandale found that birth centre midwives adopted strategies to maintain the 'normal', such as encouraging women to stay at home until active labour was well established. This strategy reduced the likelihood of transfer to a large hospital for perceived prolonged labour. However, Hodnett (2004) cautioned that 'just as an over emphasis on risk and intervention can lead to unnecessary interventions and avoidable complications for healthy childbearing women and their families, an over-emphasis on normality may lead to delayed recognition of or action regarding complications' (p 5).

The return of a familiar caregiver

The second component of the care package to be lost in the move was the familiar caregiver and the continuous support she provided. This has been addressed through calls for increased continuity of care, which midwives have provided, first in experimental models tested in numerous randomised controlled trials, and more latterly in New Zealand following the changes to the *Nurses Act* in 1990 leading to midwifery autonomy.

Auscultation of baby's heart with Pinard stethoscope. Reproduced with the permission of the New Zealand College of Midwives

There now exists overwhelming evidence, from nearly twenty randomised controlled trials conducted in Australia, Canada, Sweden, Hong Kong, the United Kingdom, Scotland and the United States of America, that continuous labour support for women during childbirth should be the norm, rather than the exception (Biro et al 2003; National Institute for Clinical Excellence 2004; Rowley 1998; Rowley et al 1995; Waldenstrom & Turnbull 1998). It is clear that any maternity care system that is not founded on this model of care places women at increased risk of interventions such as epidural analgesia and operative birth by forceps, vacuum extraction or caesarean section. Although the short-term effects of such procedures are well documented, it is becoming increasingly apparent that these are all major interventions with potential for unanticipated, adverse, long-term physical and behavioural effects on both mothers and babies (Bahl et al 2004; Beech 1998; Carter et al 2001; DiMatteo et al 1996; Gottvall & Waldenstrom 2002; Jacobsen & Bygdeman 1998; Jacobsen et al 1990; Mayberry et al 2002). Some effects may be permanent.

The financial costs of the long-term consequences of intervention in childbirth have received less scrutiny, but even the increased costs of the procedures themselves must lead health care planners to consider more carefully the models of care to which women are subjected (Roberts et al 2000; Tracy & Tracy 2003). These findings cannot be ignored, and many maternity care systems have focused attention on ways and means of increasing opportunities for women to experience continuous labour support, with varying degrees of success.

However, while continuous labour support is a form of maternity care that should be available for all women, it is clearly not sufficient, in and of itself, to enable normal birth. Three issues will be explored here. First we will examine the New Zealand maternity care system, which has successfully embraced a model of care that provides continuous labour support for all women, but still sees women experience high and rising rates of intervention, although the rise is notably less than in other Western countries (NZHIS 2004). Second, we will consider what it is about continuity of care and continuous labour support that influences outcomes, by exploring the concept of the fear cascade (Rowley 1998). Finally, we will consider whether a better understanding of the physiology of birth contributes to keeping birth normal.

What is a 'normal birth'?

Continuous labour support aims to decrease intervention in childbirth and thereby increase the numbers of women who experience 'normal' birth. Much debate has arisen around the concept of 'normal' birth, and for the purposes of this chapter

it is defined as follows: labour occurs at term, is spontaneous in onset, and there is no requirement for augmentation or analgesia; the birth occurs spontaneously, vaginally, and the mother and baby are healthy. Some authors have estimated that in the twenty-first century, fewer than one-third of women in 'developed' countries will be enabled to give birth as nature intended (Conference Reports 2001; Sandall 2004). Many women are fearful of the process and shocked by their experiences. Rates of intervention vary between and within countries, between different locations for birth (hospital, birth centre and home birth), and between different models of maternity care in the same settings (public and private, fragmented care and continuity of care). Even the rates of intervention found in randomised controlled trials of continuous labour support and continuity of care reveal differences depending on the location of the trial—whether in a labour ward or a birth centre. However, very few trials and even fewer national data collection systems report birth outcomes in terms of the numbers of women who experience normal birth. Therefore the extent (or disappearance) of normal birth has been unintentionally hidden from our gaze until very recently.

'Continuity of care' versus 'continuous labour support'

Continuity of care describes the actual provision of care by the same caregiver or small group of caregivers throughout pregnancy, during labour and birth, and in the postnatal period. This model usually implies, but may not always include, continuous one-to-one support throughout labour. Continuous labour support describes the process of one-to-one supportive care from a companion throughout labour. It is apparent from at least one systematic review that continuous labour support provided by a non-hospital caregiver is more effective at reducing interventions than support provided by members of the hospital staff (Hodnett 2004). This raises interesting questions as to why the impact of continuous labour support differs depending on the type of caregiver. Hodnett (2004) proposes that the difference results from the ability of non-hospital caregivers to give greater attention to the mother's needs, since such companions are not distracted by the diverse responsibilities of hospital employees and organisational issues such as shift changes and staff shortages. We propose that this explanation is too simplistic. If Hodnett's proposal was valid, we could expect to find low rates of intervention in maternity care systems where both continuity of care and continuous one-to-one support throughout labour from non-hospital caregivers was the norm. Arguably this is the situation that has emerged in New Zealand over the past ten years. However, while it is apparent that New Zealand women are overwhelmingly satisfied with their experiences of midwifery-led continuity of care since their emotional/social needs are well met (Ministry of Health 2002), there exists some disquiet about decreasing rates of birth without intervention (Strid 2000). Let us examine this more closely.

The New Zealand experience

Around 57,000 women give birth annually in New Zealand at tertiary and primary care hospitals, in birth centres and at home. There are approximately 2500 qualified midwives currently practising in New Zealand and they are almost evenly divided between those who work as hospital (or core) midwives and those who work as independent (or caseloading) midwives. While core midwives are employed and generally work on shifts in maternity facilities, caseloading midwives may be employed or self-employed and provide continuity of care to an identified caseload of women. All women are required to have a known caregiver or 'Lead Maternity Carer' (LMC) throughout their childbirth experience. Although a general practitioner or specialist obstetrician can be chosen by the woman as her LMC, over 78% of women choose a midwife (NZHIS 2005). If the LMC is a midwife, she will usually provide continuity of care throughout pregnancy, one-to-one continuous labour and birth support and postnatal care. The research evidence suggests that this model of care will result in low rates of intervention. However, no conclusions can be drawn at present from the emerging (and as yet incomplete) population data collections published by the New Zealand Ministry of Health (NZHIS 2003, 2004, 2005). It appears that the rates of some interventions in childbirth are continuing to climb, with the national rate of caesarean section rising from 20.8% in 2000 to 23.1% in 2003 (NZHIS 2003, 2004, 2005). However, these rates compare favourably to Australia's caesarean section rate, which increased from 20.6% in 2000 to 28.5% in 2003 (Laws & Sullivan 2002, 2005). Additionally, if LMC midwife care is compared with LMC medical care for a similar cohort of women, the intervention rates are lower (MMPO, in press). In New Zealand, the rate of unassisted vaginal birth or non-operative vaginal birth fell from 68.4% in 2000 to 67.4% in 2003, while in Australia the rate of unassisted vaginal birth fell from 68.4% in 2000 to 60.3% in 2003 (Laws & Sullivan 2005, 2002; NZHIS 2005).

What outcome statistics do not yet address is the question of whether midwifery may make a much more subtle difference to maternity outcomes than is apparent through annual statistics and trend data. While 15 years of a midwife-led and women-centred maternity service in New Zealand has not shown a dramatic change in outcome measures such as caesarean section and 'normal' birth, there is emerging evidence that New Zealand's intervention rates are slowing and appear to be reaching a plateau compared with other Western countries (Laws & Sullivan 2004; NZHIS 2005). Midwifery care may have a greater impact on primary and public health measures than has been appreciated and therefore may be more significant in bringing about social change. This means that its effects are long-term and difficult, but not impossible, to quantify in the future (Guilliland 2005). Recognised public health measures in New Zealand include outcome measures for Maori, breastfeeding rates and immunisation rates.

A recent New Zealand study into the outcomes of a million births between 1980 and 2001 showed a marked decrease in numbers of low birthweight babies born to Maori women, Pacific Island women and women from low socio-economic groups, and decreasing numbers of premature babies (Mantell et al 2004)). These groups of women are all more likely to have midwifery care and less likely to have obstetric caregivers. Over 85% of Maori women chose a midwife in 2003, versus 76% of Pakeha, and 40% chose to give birth in a primary unit, which is twice the national average (NZHIS 2005). The latest breastfeeding data also shows a very encouraging trend upwards, with an overall 4% increase in exclusive breastfeeding over three years and in some areas increases of up to 30% (NZHIS 2005). Some 95% of babies received their six-week vaccination, the highest cover for all vaccination contacts, indicating a successful midwifery transfer to the well child service that is not sustained within the next service. These measures indicate the need for a more comprehensive approach to research into outcomes in relation to type of caregiver, place of birth and trends over time.

Until then it is useful to consider a plausible explanation provided by Kitson and colleagues (Kitson et al 1998). In exploring the problems encountered in implementing research evidence in practice, Kitson et al developed a useful model described as SI = f(E,C,F). In essence this means that the successful implementation of research (SI) is a function (f) of the type of evidence (E), the context (C) in which the research was produced and to which it will be applied, and the facilitation (F) that occurs to enable research implementation. It is important to consider the contexts within which the evidence of effectiveness for both continuity of care and continuous labour support was produced. The evidence in both cases is a product of numerous randomised controlled trials. Such trials usually occur in settings that are openly supportive of innovation and exploration, because they are required to invest resources to carry out such studies. They are potentially more likely to have a high awareness of evidence of effectiveness for many aspects of maternity care which may influence processes and outcomes not measured in trials. They are special places and attract staff interested in exploring the evidence base for practice.

Arguably this is not the situation in the messy everyday world of real-life maternity care. In reality, midwifery care in New Zealand is mainstream rather than experimental, as in most other countries, but midwives still work mostly in highly medicalised environments, which can clearly override the potential benefits of continuity of care and continuous labour support. They also provide care to women with a full range of risk factors, not only those considered to be 'low risk'. This in itself may be a contributing factor to the way in which midwives consider the role of intervention, given that their clients are almost never 'risk' free. The model itself may not be powerful enough to provide benefits no matter what the setting, since the setting is imbued with the power of a risk-averse belief system. We propose that increasing our understanding of how the 'package of care' actually influences the physiology of birth will provide a means to address the environmental constraints. If midwives (and others) had a greater understanding of the physiology of birth, fearful belief systems would be overcome.

What do we know about birth physiology?

During birth, 'a range of physiological adaptations' (Ginesi & Niescierowicz 1998a) are coordinated by a delicately balanced cascade of interrelated hormones such as oxytocin, endorphins, prolactin, ACTH and more, which flood the body and brain (Ginesi & Niescierowicz 1998b; Vose 2003). This is a largely unconscious process controlled by the part of our brain that initiates and responds to emotions—the hypothalamus or primal brain. Although the process has evolved over millennia to ensure the survival of the human species and is therefore relatively robust and successful, it is clearly possible to disrupt it by stimulating the neocortex of our brain into counter-active mode. Bright lights, harsh noises, foreign smells, strange and unfamiliar surroundings, loneliness, lack of trust in companions, loss of control, invasive procedures, pain and fear are just some of the phenomena that will stimulate the neocortex. This can be more fully appreciated by examining a process named the 'fear cascade' (Figure 6.1) explored by one of the authors (MF, nee Rowley) as part of a randomised controlled trial of team midwifery in Australia (Naaktgeboren 1989; Rowley 1998; Rowley et al 1995). The fear cascade provides one plausible theoretical explanation of why the two main reasons for all interventions in childbirth—uterine inertia (failure to progress) and fetal distress—occur. This is what it suggests: A healthy increase in maternal anxiety (eustress) can be expected as labour commences and the birth approaches. Nature has intended this as a signal to find a safe place to give birth so that a helpless newborn infant can be hidden from dangerous predators. However, the fear cascade may be initiated if the level of maternal anxiety increases to the extent that high levels of the catecholamine, adrenaline, are produced. This is a component of the well-described 'fight or flight' response. Adrenaline has an impact on the continued release of oxytocin, which has a major role to play

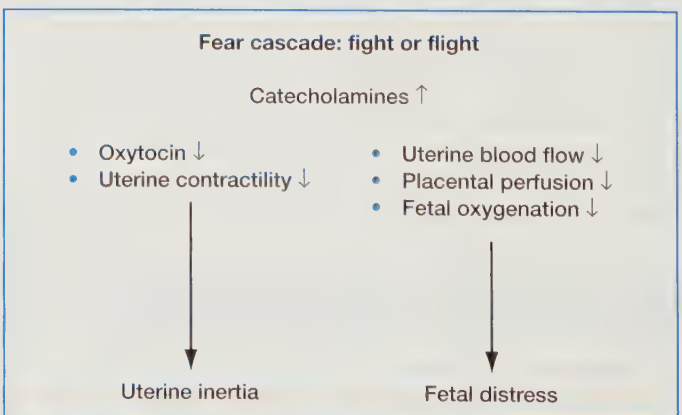

Figure 6.1 The fear cascade (Rowley 1998)

in uterine contractions (as well as many others). Disrupting the rhythmical release of oxytocin can result in incoordinate or absent contractions. This can both slow the progress of labour and increase the amount of pain experienced by the woman. The result is uterine inertia or failure to progress. On the other side of the fear cascade, the effect of adrenaline on uterine blood flow and placental perfusion can be seen. During the 'fight or flight' response, blood is diverted away from non-essential organs to the brain and limbs, and in this case the uterus is considered a non-essential organ. This may result in shifts in the amount of blood to the uterus. Even a small decrease in the volume of blood passing through the placenta can have an impact on fetal wellbeing and, thus, fetal distress may become apparent.

Finding supporting evidence for the fear cascade requires an eclectic approach to searching the literature, because the research has largely been conducted in animals and has occurred across a thirty-year span. Although results from animal research are not directly transferable to women, they do need to be given due attention. As Naaktgeboren says:

> Extrapolation from studies of parturient animals to human reproduction is inherently unwise since we assume human behaviour is much more complex than that of animals . . . but comparative obstetrics has demonstrated that . . . different species have made specific adaptations to the ecology of which they form a part; however common mechanisms which have a fundamental value, are observed in all mammals. This is just as true for the behavioural as for the physiological, endocrinological, anatomical (and many other aspects) of parturition (Naaktgeboren 1989).

Labouring undisturbed

In a classic work in 1978, perinatal psychologist Niles Newton noted the neuro-hormonal similarities between human sexual response, un-drugged birth and the let-down reflex in breastfeeding (Newton 1978). Newton suggested that all three processes were mediated by oxytocin, and that the pleasurable feelings they promoted had evolved to ensure the continuation of the species. Newton also observed that each could be inhibited by environmental disturbances, which she explored in a series of elegant experiments on mice (Newton et al 1966).

Newton randomly selected labouring mice from a laboratory mouse population and moved them from their secure nest into the hostile environment of a nest containing bedding contaminated with cat urine. She then compared the length of labour for each group of mice and found that the disturbed mice had longer labours, to the point where many did not give birth until moved back into their safe nest. Significantly fewer mice gave birth in the hostile environment. What was even more disturbing was that the newborn pups of the disturbed mice were more likely to be found dead soon after birth, suggesting that fetal damage had occurred in utero. Newton hypothesised that fear generated by the hostile environment had disturbed the production of oxytocin, slowed labour and interfered with the supply of blood to the uterus. She questioned whether the same mechanism might operate in labouring women subjected to the variations between home and hospital environments.

Newton's work offers much support for the fear cascade, at least in mice. Other research conducted with rhesus monkeys also adds some weight to the case for a fear cascade (Adamsons et al, cited in Rowley 1998). Adamsons and colleagues were also interested in the role of catecholamines and uterine blood flow. They discovered that catecholamines such as adrenaline injected directly into the fetus of a pregnant rhesus monkey had no effect on the fetus other than raising its heart rate. However, when catecholamines were injected into the mother, fetal asphyxia and acidosis could be induced, and it was postulated that this was due to the vasoconstrictor effect of catecholamines leading to impaired uterine blood flow.

There is now much more evidence concerning the impact of fear on the physiology of pregnancy in human studies, including those using ultrasound to examine uterine artery resistance in response to maternal anxiety (Teixeira et al 1999). It is now possible to demonstrate that maternal anxiety increases the uterine artery resistance index, and reduces blood flow to the baby, affecting fetal development and leading to small-for-gestational-age infants and the possibility of premature birth. All of these studies offer support for the fear cascade and suggest a role for reducing maternal anxiety through ensuring undisturbed labour as an essential

Reflective exercise

Take a careful look at the birth spaces in your local unit and ask yourself the following questions.

1. Can women labour *undisturbed* in this environment?
2. How can I ensure that no one disturbs the woman unnecessarily?
3. Am I disturbing her by talking too much?
4. Is there a sign on the door asking people to knock and wait for a reply if they want to come in?
5. Do unknown staff walk in unannounced?
6. Are there locks on the door?
7. Can we hear the woman next door giving birth?
8. How private is the space?
9. Who 'owns' the space when a woman is in labour and giving birth here?
10. Is the woman free to move around—to sit, stand, walk, squat, lean, lie down?
11. Are there en suite facilities for her to shower or use a bath during labour or birth?
12. Where is the bed located and what kind of bed is it?
13. Is there a space for her family/support people?
14. How welcoming is it for them?
15. Are food and drink available?

- Is there a need to change anything?
- How can I do that?
- Who will help me?

aspect of keeping birth normal. Continuity of care that also includes one-to-one support throughout labour provides one way of achieving this. What 'support' should entail is well described in *The Labor Progress Handbook* by Simkin and Ancheta (2001), which provides midwives with a myriad of practical and seemingly simple ways to apply this theoretical understanding to clinical practice. The reader is urged to find a copy of this valuable publication and to share it with women and colleagues alike.

Continuity of care provides opportunities for a close and trusting relationship to develop between the woman and her midwife. Continuous one-to-one support in labour provides an opportunity to ensure that labour is undisturbed and the fear cascade is not initiated (Buckley 2003). Adding this component to the package that already includes a familiar or home-like place for birth increases the likelihood that birth will be normal. However, there is one other component of the package that appears to be essential—the belief in birth as a normal physiological process.

Belief in birth as a normal physiological process

A recent study conducted by one of the authors (MH) in New Zealand provides important insights into the power of the place of birth to influence the midwife's belief in birth as a normal physiological process (Hunter 2000, 2003). In a series of in-depth interviews conducted with caseloading midwives who cared for women in both large (secondary/tertiary) and small (primary) maternity facilities, Hunter discovered that the midwives overwhelmingly preferred to provide labour care in small maternity units, where they felt they were more able to attend to women, as opposed to attending to machines, and where they had developed additional midwifery skills. This they named as practising 'real midwifery'. In the small unit, the midwives felt truly autonomous, able to take time to let labour unfold rather than rush women along as if on a conveyor belt, able to give the woman time to settle into her labour before intruding with a vaginal examination to assess progress, and more able to tolerate the woman making noise without fear that they would be regarded as a less than competent midwife. Importantly, the midwives revealed how the additional responsibility of being alone in the small unit caused them to reflect carefully on their skills and ability to manage any challenge, keeping them alert and watchful. Despite the additional responsibility and feeling that they would 'carry the can' if anything went wrong, they were unshaken in their belief in the normal process of birth and had the confidence to enable the process to occur with minimal intervention. Hunter (2003) proposed that the following skills are necessary for midwives who practise in primary maternity units:

- the confidence to provide intrapartum care in a low-technology setting
- being comfortable with using embodied knowledge and skills to assess a woman and her baby, as opposed to using technology
- being able to let labour 'be' and not interfere unnecessarily
- the confidence to avert or manage problems that might arise
- the confidence to trust the process of labour and be flexible with respect to time
- being willing to employ other options to manage pain, without access to epidurals
- being solely responsible for outcomes without access to on-site specialist assistance
- being a midwife who enjoys practising 'real midwifery'.

'Real midwifery' was articulated by one of the participants, named Elizabeth, as follows:

> At [the small maternity unit] it's like real midwifery in a way, because you're not interfering . . . When you are using the synto and the epidural, a lot of it's taken away from the woman and, in a lot of respects, probably taken away from you a little bit as well.
>
> . . . I think with real midwifery, a lot of it is not doing, in a way letting it happen, being there, but you're still there and you still want to make sure that things are happening as they should . . . And I think real midwifery can be not being that overpowering person there.

Midwives in primary maternity units need to have a belief in normal birth and the skills to be unobtrusive while still ensuring that labour is progressing normally. Women also need to believe that they are able to labour and give birth in a primary facility (Coyle et al 2001). Antenatal visits and childbirth education classes held at primary units generally foster women's confidence and enhance their commitment to labouring in a primary facility. In this study the midwives endeavoured to influence women with regard to place of birth, as evidenced by the following words from one of the participants:

> With first-time mums when they come to me, we talk about who has actually influenced them into thinking they need to be at a large hospital. We talk about the statistics that show women are actually safer in a smaller hospital, and a good percentage of them will end up coming to the smaller hospital (Rosemary).

Rosemary could be referring to a number of studies, including a landmark study undertaken by Rosenblatt and colleagues (1985), which showed that New Zealand women had good outcomes in primary facilities and that such facilities had an important place within a population that is dispersed throughout urban and remote rural areas.

Being confident to provide intrapartum care in a low-technology setting

Most of the participants interviewed stated that they were proficient with the technology in the large hospital. Yet they preferred practising in primary units, where there is low use of technology. Participant Elizabeth emphasises this point:

> The technology has got its place. I can go from having a woman on a syntocinon infusion and an epidural pump, to the next day,

at the small unit, and the woman is squatting in the corner, or whatever, and it is totally different.

For the midwife, being hands-off and just being there for the woman is often more challenging than being constantly busy attending to equipment and machines.

Being comfortable to use embodied knowledge and skills to assess a woman and her baby, as opposed to using technology

The ability to be attuned to embodied knowledge grows with midwifery experience, and includes the ability to listen to one's gut feelings. Using embodied knowledge does not preclude the use of technology. For example, the woman might elect to have the fetal heart monitored by Doppler to enable flexibility with positions during labour. The use of the Pinard stethoscope might require her to change position to enable the baby's heart sounds to be heard. A waterproof Doppler is a useful tool when the woman elects to have a water birth, as this enables her to remain in the water as long as she chooses.

There are times during a woman's labour when the midwife needs to step back and acknowledge the feelings and signals that arise from her own body. Embodied knowledge recognises that the mind and body are inextricably linked. Guiver (2004) undertook a grounded theory study about midwifery knowledge in relation to normal birth. Participants talked about their gut instinct, which assisted them as midwives to know whether the labour was normal. Participants in Hunter's (2000) study stated that over-use of equipment and machines meant less use of the midwife's internal senses. One participant said that switching on the cardiotocograph machine was almost simultaneous with switching off her own assessment skills related to fetal wellbeing. Another spoke of how mild tachycardia may indicate that something could be astray.

The following examples show midwives using their own assessment skills and knowledge:

> You need your eyes and your hands more than any equipment. That will tell you more than any monitors. In the large hospital you're actually thinking more in the high risk, using all the instrumentation you have, or all the technology, rather than using your own ideas or what you are seeing yourself (Cluain Meala).

> When the woman's lying there with her epidural, you're watching machines. Whereas, at the small unit, it's sort of like watching and waiting . . . and you have to have confidence in women's bodies just to let it flow (Bronnie).

The midwives talk of using their hands, eyes and own ideas through observation with the woman, as opposed to a total reliance upon equipment. Observations might entail watching and waiting. The midwife needs to have confidence that the labour will flow and progress normally. Experienced midwives know that the art of palpating contractions provides a vast amount of information, including the strength and characteristics of contractions. This is in contrast with the limited diagrammatic representation of contractions on cardiotocograph machines, which really only show the frequency of contractions.

Being able to let labour 'be' and not interfere unnecessarily

Midwives described 'real midwifery' as 'being there and letting it happen'. Sometimes it consists of 'not doing' and just letting the labour unfold. But the midwife is always watching to make sure things are progressing, without being obtrusive. Working in primary units and attending home births fosters learning about real midwifery and fosters confidence in one's own practice. High-technology settings might hinder the development of low-technology midwifery skills. Other participants echo Bronnie's words of being able to 'go with the flow' of labour in small units:

> Looking after women in the small units, there is this expectation of going with the flow. I think you have to believe that birth is normal and that women's bodies are built for the job and the majority of births are normal (Kirsty).

> You need confidence in birth as being normal and I think it's something that grows. When you leave someone alone and don't interfere, then the risk of a problem is even less (Joyce).

Being able to let labour 'be' requires a belief in normal birth and the ability to care for women without intervening unnecessarily. Guiver (2004) criticised the rhetoric that birth is only normal in hindsight and stated that birth without interventions is eminently possible with midwife-led care and a faith in normal birth.

Being confident to trust the process of labour and be flexible with respect to time

Midwives opposed the discourse of a fixed time frame for women in labour. One way in which midwives showed flexibility regarding time was through limited use of vaginal assessments. Midwives commented that an immediate vaginal assessment might not be necessary (at a primary unit) if you were very sure of presentation and engagement, if the woman was obviously contracting well and had not been in labour for too long, and if the fetal heart was normal and the woman did not want to know her dilatation:

> Sometimes women will request to have a VE just to reassure them that they are actually in established labour. I'll probably do a VE then, but if they don't request one, I'll just sit and watch for a couple of hours (Rosemary).

Coyle et al (2001) showed that women appreciated a non-interventionist approach, such as midwives keeping vaginal examinations to a minimum. In order to do this, midwives need to be adept at palpation of the presenting part, and descent and flexion of the head (Sookho & Biott 2002). Midwives also need to be willing to silently pose the question: Is it a head or could it be a breech? The presentation of the baby assumes more importance in free-standing primary units, where it might take several hours to transfer a woman with a breech presentation diagnosed in labour.

Midwives also stressed the importance of continuity of care and mutual trust where women stayed at home until labour was well established. When a woman telephoned the midwife

in early labour, the midwife might offer to attend the woman at home and undertake an initial assessment that might or might not include a vaginal examination. This process reassured the woman and the midwife that labour had started, and progress was likely as the hours unfolded. The midwives placed great importance on education antenatally about the latent stage of labour and the time needed for the cervix to efface:

> This first-time mum that I am thinking of, she did have a long labour in the small unit—20 hours. It's a balance between the woman feeling relaxed in the small unit and maybe using the bath and knowing that she is coping, to going to the large hospital where we have got to use active management of labour (Kirsty).

Kirsty shows the art of midwifery in allowing the woman time, and the sense of not rushing or interfering. She also gave the woman the choice of remaining in the primary unit, as the woman and the baby were coping with the process of labour.

Most of the midwives who offered intrapartum care in small maternity units also offered women the option of having a home birth. There seemed to be similarities when the midwives described practising in small units and attending women for home birth:

> I just feel a little bit freer at the small maternity unit. It's like being at a home birth in a way really—not quite, but in a way it can be (Elizabeth).

Although all the midwives were autonomous lead maternity carers, they still felt compelled to 'do' when in a large obstetric hospital:

> The difference between a small and large hospital is that once you get into the large obstetric hospital, you feel like you've got a time frame to get out of there. Whereas, at the small unit, you don't want to interfere, you don't want to rush things (Bronnie).

The sense of a time frame appears to pervade the ambience of large obstetric hospitals and, in turn, even autonomous midwives are affected by the busyness of large hospitals and become acutely aware of time.

Being willing to employ other options to manage pain without access to epidurals

Managing pain during labour is a major challenge to women and midwives, and Leap (2000) has contributed her expertise to assist midwives. In primary maternity units, midwives have no access to epidural analgesia, and the midwives in the study preferred not to use pethidine analgesia. The key to managing pain was multifaceted, but one aspect was that the midwives tolerated noise from women during labour, as opposed to silencing them with analgesia. It is important that women are allowed to make noise during labour and to express their pain if this assists them to cope through each contraction.

Not having access to epidural analgesia taught participant Elizabeth how to work with women in labour. If epidural analgesia is on site, it is too easy to resort to this to relieve pain. Midwives in primary facilities employed all the usual things like mobilisation, a hot pack on the woman's back, massage, homeopathy, shower, bath, pool, different positions, sitting on the toilet, rocking, squeezing the top of the hipbones and other manoeuvres. Being with the woman, going through every contraction with her, talking her through, were all viewed as methods of pain relief.

Practising as an independent midwife also changed how some of the midwives worked with women and their pain. A big difference in continuity of care is that the woman and the midwife know each other and therefore there is a sense of trust. The midwife is generally working on a one-to-one basis with that particular woman and is totally focused on her, as compared with being focused on the needs of a busy delivery unit. The 'education factor' that occurs antenatally enables a platform for working with women and their pain:

> I think that the support that you give women at one of these smaller units is more intensive. You know that if the woman has that support all the way through her labour, she is going to cope a little bit better (Rosemary).

As discussed earlier in this chapter, intensive support seems to be critical in assisting women to cope with their pain, along with trying a variety of strategies to meet the woman's needs. A calm environment creates the ambience for birth to proceed. Appropriate background music and the woman's family or supporters help to (re)create an atmosphere of normality and enable the woman to proceed with the birth process. Understanding the physiological impact of an epidural on the physiology of labour, and the potential long-term consequences of in utero exposure to narcotics for the baby may inspire both the woman and her midwife to work with the pain productively (Robinson 2001).

Being confident to avert or manage problems that might arise, and being solely responsible for outcomes without access to on-site specialist assistance

Situations arise in the course of midwifery practice where the midwife must promptly avert or manage problems. As practising midwives, we all carry memories of emergency occasions that we have been involved in and those that we have managed. It is important that practice is not coloured by a problem focus. However, our memory tends to occlude the numerous occasions when we have driven our car without incident, yet we vividly recall the one time that we had an accident. Midwives admitted that the responsibility for outcomes was greater when they practised intrapartum care in free-standing primary maternity units. Sometimes it would take hours before the woman was transferred via ambulance to the large hospital and assessed by a specialist obstetrician. In the interlude, it is the midwife who assesses the emergency situation, provides interim care and organises the urgent transfer to the large hospital.

In order to provide intrapartum care in primary units, midwives stressed the need for acute senses, awareness, alertness and the skills to react in a timely manner. A midwife

in a primary unit has to know what to do immediately—there are no doctors to respond to an emergency bell.

The following participant gives an example of responding to an emergency situation:

> I had a postpartum haemorrhage the other night of 1000 ml in the small unit. I gave intramuscular syntometrine and intravenous syntocinon and I ended up putting up a drip. I knew the placenta was complete and knew the uterus wasn't contracting well. Her pulse didn't accelerate, her blood pressure never wavered, the blood had clotted; so she was able to stay there. So you just do what you would do. You don't wait and see (Mary).

Mary's assessment skills are evident in vocalising her actions. She had checked the placenta thoroughly and thus ruled out retained products. The woman had been administered two oxytocic drugs—intravenous syntocinon ensures rapid uterine contractility and intramuscular syntometrine is used to obtain a longer-acting contraction of the uterus. Mary then inserted an intravenous line to administer fluids and to provide access for an ongoing syntocinon infusion. She did not waste precious minutes trying to insert the intravenous line initially. A tourniquet can be applied to give rapid intravenous access for syntocinon administration. The woman's pulse did not accelerate and, hence, Mary was reassured that the woman was not becoming hypovolaemic and potentially shocked.

Reflective exercise

Think about the hospital labour ward with which you are most familiar and imagine that you are greeting a woman in early labour who has never been here before. Ask yourself the following questions.

1. What makes this place familiar to me—is it the smell when I walk in the door? Do I even notice it any more? I wonder what it smells like to this woman—safe and comforting, or antiseptic and scary?
2. I wonder what it sounds like to her. Is it noisy right now? What kinds of noises are there—clanking sounds of metal on metal and harsh surfaces, lots of voices, telephones and beeping machinery?
3. What does it look like—bright lights, bright, busy people, paperwork on the desk, equipment lining the corridor, signs on the wall, businesslike, efficient? Is this comforting to her? I wonder how her family (who are with her) feel right now.
4. What do I see when we walk into her room together? I wonder what she sees first and what impression it has on her and how she feels.

Remember, 'environment' encompasses all five senses—sight, hearing, touch, taste and smell—and each of these senses has an impact on the mind and heart, and therefore the physiology of childbirth.

- Is there a need to change anything?
- How can I do that?
- Who will help me?

Are all midwives practising real midwifery?

In a survey administered to midwives who were not already working in a midwifery-run unit in the United Kingdom, Symon (1998) asked midwives if they would be happy to do so, taking full responsibility for a woman's care. Replies were received from 1522 midwives. The majority of midwives (76%) stated that they would happily do so, and 24% said they would not. Midwives with more than twenty years of experience, and those working in units with 2000 to 2999 deliveries per year were least likely to say 'yes'. Reasons for not wanting to work in a midwifery-run unit included: preference for consultant cover and full facilities; not having enough experience (although most of these midwives had twenty or more years' experience!); not having enough confidence; fear of complications; and fear of litigation. Symon (1998) reported the following comments from a midwife participant:

> I strongly believe that these units are an excellent means by which midwives (particularly junior ones) can develop their true midwifery skills and practice—working in an obstetric or consultant unit should be seen as a different type of practice altogether. Many of today's midwives do not seem to know the difference or care for that matter (p 45).

Graham (1997) indicated that it might be a certain type of midwife who prefers to work in settings away from the dominance of obstetricians:

> It is intuitively obvious that systems of care which give the practitioner more independence in decision making, a homely environment in which to work, continuity of involvement with women, and a focus on normality and natural childbirth will attract particular individuals (p 396).

These statements suggest that 'true' midwifery skills develop best when a midwife practises in small maternity units, whereas a different type of practice is apparent in a consultant obstetric unit. Graham concluded that more independence and a focus on normality might be more enjoyable for some midwives. It seems likely that the midwives' personal beliefs and length of time practising in a large hospital influence their choice of venue for provision of intrapartum care. There was an inverse relationship between the desire to practise in a small maternity unit and the number of years of experience the midwife had in practising in a large hospital.

Is it possible to practise real midwifery in a large hospital?

Kirkham (2003) argues that the birth centre is the place where 'the complex skills underpinning normal birth can be developed, nurtured and learned' (p 12). Whether the birth centre needs to be free-standing or whether these same skills can be nurtured in a birth centre that is part of a hospital remains to be seen (Johanson & Newburn 2001). As a space between home and hospital, birth centres may offer the greatest opportunity for both women and midwives

to rediscover a profound belief in the inherently normal physiological process of birth. As with birth at home, birth centres are founded on a belief in the normality of birth, which appears to be the most influential aspect of the birth environment to consider.

Global strategies to centralise childbirth into large tertiary centres on the grounds of safety pose a serious threat not only to homebirth and birth centres but also to rural communities, who are faced with the loss of primary maternity units as locations for birth. The challenge facing maternity services today in countries like Australia and New Zealand is how to balance the need for safety with the preservation of primary-level birth facilities. A recent population-based Australian study of all women who gave birth from 1999 to 2001 showed that for low-risk women, small maternity units were not associated with higher rates of perinatal mortality, regardless of parity (Tracy et al 2006).

Conclusion

The three components of women's care that were lost when the place of birth changed from home to hospital were the familiar environment, the close personal and trusting relationship with a midwife who provided continuous care throughout labour, and a strong belief in the normal physiology of birth. All three components of the care 'package' function together, to keep birth normal. The environment for birth not only includes the geographical space where the event will unfold, but is influenced by less visible but no less powerful forces that include relationships with midwives and the beliefs, knowledge and skills they bring to practising real midwifery. The challenge for all midwives is to consider these three elements in their own practice location.

Review questions

1. What does the theoretical model known as the fear cascade contribute to our understanding of how the place of birth affects birth outcomes?
2. What role(s) does oxytocin play in birth outcomes?
3. What were the reasons for women moving from home to hospital at the turn of the twentieth century?
4. Why do different accounts of childbirth explain these events differently?
5. How similar are the childbirth histories of women and midwives in New Zealand and Australia?
6. What three things were lost when women moved from home to hospital for birth?
7. What are the potential consequences of intervention in childbirth?
8. How many women choose home birth in Australia or New Zealand?
9. Do midwives and other providers enable 'choice' for women regarding place of birth?
10. What midwifery skills are needed in order to provide care to women either at home or in primary maternity settings?

Notes

1 These terms are used interchangeably, and mean a low-technology maternity facility that does not have available epidural analgesia, operating theatres for caesarean section or on-site obstetricians, anaesthetists or paediatricians.
2 Pakeha refers to the non-Maori population of New Zealand.
3 Grace Neill was a Scottish-trained nurse and midwife who was the Chief Inspector of Hospitals in New Zealand at the turn of the twentieth century.
4 This trend was not statistically significant but has been used to discredit birth centre care and has since been critiqued by Fahy and Colyvas (2005) as having several methodological flaws.

SECTION TWO

THE WOMAN

CHAPTER 7

Challenges to women's health

Caroline Homer

Key terms

alcohol, anxiety, bipolar disorder, blood-borne viruses, cannabis, chlamydia, depression, domestic violence, environmental tobacco smoke, family violence, female genital mutilation, fetal alcohol syndrome, genital herpes, gonorrhoea, hepatitis B, hepatitis C, heroin, HIV/AIDS, infibulation, legislation, mental health, methadone, schizophrenia, screening, smoking, smoking cessation programs, standard drink, STI, syphilis, universal precautions

Chapter overview

This chapter covers some of the main challenges for women during pregnancy. The following topics are discussed in detail as they are of particular relevance to midwives: mental health illnesses; smoking; alcohol and drug use; sexually transmitted diseases; blood-borne viruses; domestic violence; female genital mutilation. At the end of each topic is a critical thinking exercise and a reflective exercise. You are encouraged to undertake these as they will enhance your learning.

There are many other challenges to women's health that are of relevance to midwives. Some of these are addressed in other chapters. Others may not be directly addressed in this textbook; however, it is part of the responsibility of all midwives to learn how to seek information. Public libraries, the internet, hospital or university library databases and journals are all excellent sources of information.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe the main mental health conditions and outline their effect on pregnancy
2. To describe the adverse effects related to smoking cigarettes in pregnancy
3. To describe the adverse effects related to environmental tobacco smoke on a newborn baby
4. To describe the adverse effects related to alcohol and drug use in pregnancy
5. To explain why it is advisable for women to be on methadone rather than heroin during pregnancy
6. To describe four main sexually transmitted infections, including signs and symptoms, diagnosis and management
7. To explain the risks, prevalence, effects and management of women with blood-borne viruses (HIV, hepatitis B, hepatitis C) during pregnancy
8. To compare the epidemiology and transmission rates of HIV and hepatitis C
9. To explain the prevalence of domestic violence and the specific adverse effects for women, babies and families
10. To assess some of the issues related to routine screening for domestic violence, and make suggestions for the practice setting
11. To discuss female genital mutilation (FGM) and the implications for women
12. To outline the main types of FGM and the implications for practice.

Mental health and pregnancy

Mental health disorders are common in women of childbearing age. This section discusses some of the effects of existing mental health disorders on pregnancy. Postnatal depression and psychosis are specific topics that are covered in detail in Chapter 37.

Anxiety disorders

Anxiety disorders include generalised anxiety disorder, obsessive compulsive disorder, social anxiety disorder, panic disorder, and phobias. In all of these there is an anxiety that is so overwhelming that it can interfere with a person's ability to function from day to day. A person may experience more than one anxiety disorder. Some may also experience depression with the anxiety, or have problems with alcohol or drug use (SANE Australia 2004a).

Anxiety disorders can emerge or re-emerge during pregnancy and there is an increased risk of susceptibility in the postnatal period (Altshuler et al 1998).

Initial management should include assessment, reassurance, support, cognitive behavioural therapy and social changes (Rampono 2004). Medications may be necessary if these strategies are ineffective.

Schizophrenia

Schizophrenia is a condition that affects the normal functioning of the brain, interfering with a person's ability to think, feel and act. Some people recover completely, and, with time, most find that their symptoms improve. For many, though, it is a prolonged illness that can involve years of distressing symptoms and disability (SANE Australia 2004b).

Women with schizophrenia do not have an increased risk of relapse during pregnancy if they are well before the pregnancy (Rampono 2004).

Bipolar mood disorder

Bipolar disorder is sometimes called 'manic-depression'. It affects the normal functioning of the brain, so that the person experiences extreme moods—very high and over-excited or very low and depressed. The person may be affected so much that he or she experiences the symptoms of psychosis, and is unable to distinguish what is real (SANE Australia 2004c).

Hormonal changes result in an increased risk of relapse of bipolar mood disorder during pregnancy and in the postpartum period (Rampono 2004). Little is known of the effects of bipolar disorder on pregnancy; however, the postnatal period is a time of highest risk. Postpartum relapse rates in women not treated with prophylactic mood stabilisers are 30% to 50%. Initiation of treatment with a mood stabiliser during pregnancy or immediately postpartum reduces this risk (Ward & Zamorski 2002).

The medications used to treat this disorder are complex, particularly in the first trimester. Lithium, the most commonly used medication, increases the risk of cardiovascular abnormalities in the baby. Other drugs used, such as sodium valproate and carbamazepine, are associated with spina bifida (Rampono 2004).

Women who are prescribed mood-stabilising medications should also be offered folate supplementation and prenatal screening for cardiac and neural tube defects, as indicated (Ward & Zamorski 2002).

Issues for midwives

Management of these complex mental health disorders falls beyond the scope of usual practice for midwives. Collaboration with mental health specialists, including psychiatrists, psychologists, mental health nurses and social workers, is essential to ensure that these women receive appropriate care and support. Decisions around the most appropriate management and medications need to be made with the woman and her family. Case conferences, where the woman and all those involved in her care help plan the management, are useful.

Achieving a balance between the usefulness and effectiveness of medications and the effects on the growing baby is sometimes very challenging for midwives and other clinicians. These decisions need to be made carefully in partnership with the woman and her family and the people involved in providing her care. A management plan is a useful way of disseminating this information to all concerned.

Midwives also need to ensure that women have appropriate support, especially in the postnatal period. Planning for this should occur during pregnancy and involve health and non-government organisations in partnership with the woman.

Critical thinking exercise

You are caring for a woman who tells you that she has anxiety about many issues in her life and was once labelled as having an anxiety disorder. She has never received any treatment for this; however, she seems very anxious during her pregnancy.

1. What other information should you try to obtain about this condition?
2. What resources might be useful?
3. What should be your management now?
4. What should you be putting in place for after the baby is born?

Reflective exercise

Take some time to reflect on your own experiences with mental health conditions, whether in a personal or professional capacity. How do you think your experiences might affect the way you practise and how you work in partnership with women?

Smoking and pregnancy

The relationship between smoking and pregnancy has been widely studied. Smoking during pregnancy and exposure to environmental tobacco smoke have serious health consequences for both mother and baby (English et al 1995; US Department of Health and Human Services 1990; Walsh et al 2001). Smoking in the second half of pregnancy poses the greatest risk to the health of both mother and baby. A summary of some of the negative outcomes is given in Table 7.1.

Fortunately, many of these outcomes are reasonably uncommon (e.g. placenta previa, SIDS), but the increased risks due to smoking remain a concern and are therefore important for midwives to consider carefully.

Rates of smoking in pregnancy

In one Australian state, the proportion of women smoking during pregnancy has decreased over the past five years. In 1998, almost 20% of women reported smoking in pregnancy. By 2002, the rate had decreased to 16%. Over the five-year period, among those who smoked in the second half of pregnancy, there was a trend towards smoking fewer cigarettes per day (NSW Health 2003). It is likely that these rates are similar to those reported in other Australian states and territories.

In Australia, Indigenous women have particularly high rates of smoking in pregnancy. In New South Wales in 2002, 58% of Aboriginal and Torres Strait Islander women reported smoking at some time during pregnancy, compared with 15% of non-Indigenous women (NSW Health 2003).

In New Zealand, the rates of smoking in pregnancy have also been higher in Indigenous than non-Indigenous women (Pakeha). For example, in 1999, one in two Maori women smoked during pregnancy, compared with one in four Pakeha (National Health Committee 1999).

TABLE 7.1 Estimated relative risk of negative outcomes associated with smoking in pregnancy

Negative outcomes	Relative risk (95% CI)
Spontaneous abortion	1.36 (1.32–1.40)
Ectopic pregnancy	1.46 (1.23–1.72)
Placental abruption	1.62 (1.46–1.77)
Placenta previa	1.58 (1.04–2.21)
Antepartum haemorrhage	1.62 (1.56–1.69)
Premature rupture of membranes	1.93 (1.79–2.08)
Low birthweight	2.04 (2.03–2.05)
Perinatal mortality	1.27 (1.21–1.32)
Sudden infant death syndrome	2.76 (2.66–2.86)

(Source: Walsh et al 2001)

Environmental tobacco smoke

Exposure to environmental tobacco smoke (ETS), or passive smoking, also poses risks for pregnant woman and their babies. Children are especially vulnerable to passive smoking and it is a risk factor for SIDS (NHMRC 1997).

Women often receive advice during the antenatal period about smoking cessation, but their partners or others who live in their home are often not targeted for education. Research conducted in south-west Sydney indicated that almost none of the men attending antenatal classes had received quit smoking suggestions or advice (Mabbutt et al 2002).

Reducing smoking in pregnancy

Reducing smoking during pregnancy and exposure to ETS are important aims of antenatal care. Women are known to be more motivated to stop smoking during pregnancy and are usually in regular contact with health services and midwives (Moore et al 2002). Midwives are ideally placed to provide information and support around smoking cessation or reduction to women and their partners.

Smoking cessation programs

The most recent review in the Cochrane Library suggests that smoking cessation programs in pregnancy appear to reduce smoking, low birthweight and preterm birth, but no effect was detected for perinatal mortality (Lumley et al 2004).

'Social support is known to be an important determinant of success in smoking cessation efforts therefore ... an intervention designed to increase support from a partner might lead to greater rates of successful smoking cessation' (Park et al 2004). Unfortunately, the systematic review of partner support interventions did not show an increase in quit rates and does not allow conclusions about the impact of partner support on smoking cessation (Park et al 2004).

Smoking cessation is much more complicated than merely presenting women or their partners with information, even at a time when they are probably most motivated to quit. As there is an association between social inequality and continued smoking (Oliver et al 2001), the social and cultural circumstances of women need to be considered when discussing smoking cessation in pregnancy.

Despite the challenges, the evidence in favour of routine discussions with pregnant women about smoking cessation is strong. The *Three Centres Consensus Guidelines on Antenatal Care* from Victoria in Australia recommend that smoking cessation interventions should be offered to all pregnant women who smoke or who have recently quit (Victorian Health 2001). The guidelines recommend that midwives and doctors ask women about their smoking at every antenatal visit and document this on the antenatal records. Women should be asked this question in an open-ended way, such as 'Can you tell me about your smoking?' rather than 'Do you smoke?', which will give a yes or no response.

A number of interventions have been shown to be effective once smoking is identified. These are outlined in the next section.

What works?

The review in the Cochrane Library suggests that multifaceted approaches—that is, more than one intervention—are the most effective (Lumley et al 2004). Table 7.2 summarises what is known about effective and ineffective quit smoking interventions for pregnant women (Walsh et al 2001).

Four main components of smoking cessation interventions are recommended (Walsh et al 2001): assessment, advice, assistance with quitting, and follow-up. These are outlined in Table 7.3. In New Zealand, the NZCOM provides training for midwives to assist pregnant women to change their smoking habits.

Nicotine replacement therapy, using gum and patches, is widely used in many non-pregnant populations. Some pregnant women will be using this as you can buy it over the counter in Australia and New Zealand. Its use in pregnancy, however, remains controversial as its safety is still under question. One trial of nicotine replacement therapy in pregnancy showed an overall reduction in quit rate that was the same for both intervention and placebo groups. The group who had the intervention, however, had a higher mean birthweight of 186 grams (Wisborg et al 2000).

TABLE 7.2 Effective and ineffective quit-smoking interventions for pregnant women

	Intervention
Effective	Medical, midwifery, nursing or other counselling Self-help materials developed for the target population
Ineffective	Risk information alone Group behaviour therapy—very low attendance Self-help materials developed for different population
Insufficient evidence	Hypnosis Nicotine replacement therapy
Untested	Acupuncture Antidepressants Aversive smoking therapy

(Source: Walsh et al 2001)

Clinical scenario

You are a midwife seeing a woman, Evelyn, for her first antenatal appointment. Evelyn is having her third baby. During the visit you find out that she smokes 10 to 20 cigarettes per day. She tells you that she did this with her other babies and there were no problems.

1. How would you discuss smoking in pregnancy with Evelyn?
2. What strategies would you use through her pregnancy in relation to her smoking?
3. How would you discuss the issue of smoking around a new baby?

TABLE 7.3 Four main components of smoking cessation interventions

Component	Suggested interventions
Assessment	Avoiding questions about smoking that have simple 'yes/no' responses increases smoking disclosure.
Advice	Specific risk information tailored to the woman's current knowledge should be provided. Record in the clinical notes that advice to quit smoking has been provided.
Assistance	Check whether the woman has attempted to quit or is contemplating quitting. If she is not thinking about quitting, an attempt should be made to identify why and to respond and discuss this response. It may be necessary to dispel myths such as 'It will be easier to give birth to a smaller baby'. It is valuable to negotiate a target quit date as this seems to help people make a serious attempt to quit. Subsequent discussions should involve some behavioural tips. These need to be tailored to individual women. The five D's may be useful to use: • Delay—even for a short while • Drink water • Deep breathing • Do something different • Discuss your craving with another person. Involve the woman's partner and other members of her household in these discussions.
Follow-up	Ongoing discussions with women, reinforcing these behavioural tips, may be useful. Postnatal follow-up and discussion is also important to reduce ETS exposure for the baby.

(Source: Walsh et al 2001)

Critical thinking exercise

When you are next discussing smoking with a woman during pregnancy or in the postnatal period, think about the kind of language that might be useful in your discussion. Can you think about a time recently when the discussion went well? What was good about the way you handled the conversation?

In a small group, discuss strategies for discussing smoking with women in ways that do not alienate them or make them feel that you are being judgemental.

Reflective exercise

Take some time to reflect on your own attitudes on smoking in pregnancy, particularly if you are a smoker yourself. How do you think your attitudes affect the way you practise, especially the way you communicate smoking cessation information to women?

Alcohol and pregnancy

Concerns about alcohol use in pregnancy and its effects on the baby have existed since Biblical times (O'Leary 2002). In the 1800s there were documented concerns that the children of alcoholic mothers were more likely to die prior to their second birthday than those of non-alcoholic women (Overholser 1990).

The first reported association between maternal alcoholism and a characteristic pattern of cranio-facial, limb and cardiovascular defects in the baby, which came to be known as fetal alcohol syndrome (FAS), was published in 1973 (Jones et al 1973). Since then there have been thousands of papers published that have raised concerns about the link between excessive alcohol consumption in pregnancy and FAS.

However, controversy surrounds the debate about what is considered 'excessive' alcohol intake and what quantity and frequency of consumption is required to produce adverse effects in babies (O'Leary 2002). This controversy comes from difficulties associated with measuring alcohol intake in pregnancy and making an accurate diagnosis.

Measuring and monitoring alcohol intake

Alcohol is measured in standard drinks and grams. A standard drink contains 10 grams of alcohol. One small glass of beer, wine, spirits or mixed drinks equals approximately one standard drink. Alcoholic cider and cans of premixed spirits equal at least one-and-a-half standard drinks (Alcohol Advisory Council of New Zealand 2004; National Alcohol Campaign 2002).

The *Australian Alcohol Guidelines* state that to minimise health risks, in both the short and the long term, and to gain any longer-term health benefits, the recommended alcohol intake for women (who are not pregnant or breastfeeding) is:

- no more than two standard drinks a day on average and
- no more than four standard drinks on any one day, and
- one or two alcohol-free days per week.

These guidelines are similar in New Zealand (Alcohol Advisory Council of New Zealand 2004).

Alcohol and adverse effects in pregnancy

The Royal College of Obstetricians and Gynaecologists in the United Kingdom has developed guidelines relating to the consumption of alcohol during pregnancy (Table 7.4).

Despite the lack of evidence at less than 12 standard drinks per week, it is recommended that women be careful about alcohol consumption in pregnancy and limit this to no more than one standard drink per day.

Fetal alcohol syndrome

A recent literature review on FAS provides evidence supporting the biological plausibility of alcohol as a teratogen and the link between excessive consumption of alcohol and FAS (O'Leary 2002). It is probably during the first eight weeks of the pregnancy that the primary teratogenic effects occur. Exposure later in pregnancy may affect growth and be associated with behavioural and cognitive disorders. The intellectual impairment associated with FAS is permanent, and FAS is now regarded as the leading preventable cause of non-genetic intellectual handicap (O'Leary 2002).

Overall, there appears to be no sound evidence that low levels of alcohol consumption produce FAS or other adverse effects.

The diagnosis of FAS can be difficult. This is because the syndrome can be easily confused with other disorders; there is no one clinical sign that will give the diagnosis and there is no laboratory test (O'Leary 2002). A paediatrician, preferably one with experience in this area, should make the diagnosis. Support and referral to such a health professional are the most appropriate strategies for the midwife to undertake.

Recommendations for practice

Asking women about their alcohol consumption during pregnancy is important. Women who disclose excessive

Critical thinking exercise

Women who do have problems with alcohol in pregnancy may be secretive about their consumption, especially if they think their midwife will be judgemental. Can you think of strategies that might be effective in developing a trusting relationship with women so that these issues can be discussed in a safe way?

TABLE 7.4 Consumption of alcohol during g pregnancy

Consumption of alcohol per week	Adverse effects
Consumption of 120gms (15 units) or more per week has been associated with a reduction in birthweight (Evidence Level III)	There are inconsistent data about the effect of social alcohol consumption on many pregnancy outcomes. Alcohol consumption of more than three drinks per week during the first trimester increases the risk of spontaneous abortion7 (O.R.=2.3; 95% C.I. ±1.1-4.5) but any effect on gestational length remains controversial. There is good evidence that social alcohol consumption does have a small negative effect on intrauterine fetal growth. Mills et al8 reported an 83gm decrement of birthweight per one to two drinks per day very similar to that found by Florey et al in the Euromac Study,9 i.e. a deficit of 66gms of birthweight per 120gms of alcohol (15 units) per week.
Consumption of 160gms (20 units) or more per week has been associated with intellectual impairment in children. (Evidence Level III)	Any impairment of neurodevelopment appears to occur at higher levels of alcohol consumption. The best information in this area comes from the Seattle Pregnancy and Health Study.10 The Seattle Group reported a decrement of five IQ points in children of mothers drinking greater than 250gms of alcohol per week, whilst at seven years of age, children of mothers drinking greater than 165gms per week had a decrement of seven IQ points. Other impairments included attention and memory deficits, arithmetic and reading difficulties.
There is no conclusive evidence of adverse effects in either growth or IQ at levels of consumption below 120gms (15 units) per week. Nonetheless it is recommended that women should be careful about alcohol consumption in pregnancy and limit this to no more than one standard drink per day. In pregnancy excessive alcohol consumers will require specific counselling and possible referral for specialist treatment. Clinics should consider providing a telephone contact number for women seeking advice and support for alcohol problems.	

Source: RCOG 1999. Reproduced from Alcohol consumption in pregnancy. Guideline no. 9, December 1999, with permission of the Royal College of Obstetricians and Gynaecologists.

Clinical scenario

A woman you are seeing in the antenatal period tells you that she is having a couple of glasses of wine each night and a beer for lunch on the weekend. You need to work out how many grams of alcohol she is consuming per week. How would you do this? Look on the internet for descriptions of the Standard Drink to help you work it out.

Reflective exercise

Providing midwifery care to women who have problems with alcohol can often challenge our own values and beliefs. How do you feel when you see a pregnant woman drinking alcohol in a social situation? Reflect on your attitudes towards pregnant women drinking alcohol. How do you see these values affecting your capacity to provide midwifery care to these women?

consumption should be supported and referred to specific counselling for specialist treatment. Antenatal services should provide a telephone contact number for women seeking advice and support for alcohol problems (RCOG 1999).

The *Australian Alcohol Guidelines* (National Alcohol Campaign 2002) state that:

> If you are pregnant, or are planning to become pregnant:
> - you should consider not drinking at all
> - most importantly, you should never become intoxicated
> - if you choose to drink, you should have less than 7 standard drinks over a week, AND no more than 2 standard drinks (spread over at least two hours) on any one day
> - you should note that the risk is highest in the earlier stages of pregnancy, including the time from conception to the first missed period

The Consensus Statement produced by the NZ College of Midwives (NZCOM 2001) states that:

> There is no known safe level of alcohol consumption during pregnancy. Therefore parents planning a pregnancy and women who are pregnant should be advised not to drink alcohol.

Other drugs and pregnancy

Other drugs of relevance to pregnant women include cannabis, heroin and methadone. Midwives need to have an understanding of the issues related to these drugs in pregnancy, and the referral networks and support groups that exist. An important principle in the care of women who use these drugs and others that may be harmful is to develop strong networks with other services and non-government organisations that work in this area. Midwives cannot, and should not, try to be experts in this area. It is our role to identify women with these issues and provide them with support to enable them to access

other services and agencies who may be able to help. Other services will include drugs and alcohol networks, counsellors and peer support groups.

Cannabis

Cannabis comes from the *Cannabis sativa* plant. There are three main forms of cannabis: marijuana, hashish and hash oil.

Cannabis is a depressant drug. This class of drugs affects the central nervous system by slowing down the messages going to and from the brain to the body. Cannabis can also have mild hallucinogenic effects (Australian Drug Foundation 2003).

Little is known about the effects of cannabis on the unborn child. However, the use of cannabis during pregnancy is not recommended. If cannabis is used during pregnancy the baby may be low birthweight. Again, little is known about the effects of cannabis on breastfeeding. It is believed that some of the drug will pass through the breast milk to the baby, and the baby may become unsettled (Australian Drug Foundation 2003). The decision about whether to recommend that women who are smoking cannabis breastfeed depends on a number of factors. These include access to safe alternatives and the risks of not breastfeeding.

Heroin

Heroin is an 'opiate'. Other opiates include opium, morphine, codeine, pethidine and methadone. Pregnant women who are using heroin are encouraged to enter a methadone program as early as possible in their pregnancy. There are fewer complications associated with the use of methadone than with heroin in pregnancy (Australian Drug Foundation 2003). Reasons for this include the following:

- The unexpected periods of drug withdrawal experienced using other opiates (that can be harmful to the baby) do not occur when on a daily dose of methadone.
- The lifestyle of women is often enhanced when on methadone treatment, resulting in improved nutrition and less stress.
- Methadone supplied by a pharmacy or treatment centre has not been 'cut' or mixed with any other potentially harmful substance that may be passed on to the baby.

Heroin crosses the placenta and can cause drug dependence in the baby. This means that these babies may experience withdrawal symptoms in the first few days. These babies need careful observation in a special care nursery using a neonatal abstinence scale or a similar method to monitor withdrawal. Injecting heroin also increases the risk of the woman contracting blood-borne viral infections such as hepatitis B, C or HIV (Australian Drug Foundation 2003).

Critical thinking exercise

One of the most important principles in the care of women with drug or alcohol addiction is appropriate referral and multidisciplinary team work. If you provide midwifery care to a woman with these challenges, where would you obtain advice from and to whom could you refer her?

Write a list of all the people/agencies or services that might be useful.

Reflective exercise

Take some time to reflect on your own attitudes on drug and alcohol use, especially in pregnancy. How do you think your attitudes affect the way you practise, especially the way you communicate the risks to women?

Methadone

Pregnant women who are dependent on opiates are encouraged to enter a methadone program as early as possible in their pregnancy.

As small amounts of methadone may be passed on through breast milk, women who are on a methadone program are often encouraged to breastfeed in order to help ease the baby's withdrawal from methadone. Methadone has been found to reach its maximum level in breast milk between two and four hours after a dose, and therefore feeding the baby just before a dose or taking the methadone just before the baby has a long sleep will reduce the amount available to the baby (Australian Drug Foundation 2003).

Sexually transmitted infections and pregnancy

Sexually transmitted infections (STI) are common, although often underestimated. They have been called the 'hidden epidemic' because their scope and consequences are under-recognised by the public and healthcare professionals. The rates of STIs are increasing in most countries including Australia and New Zealand (Ministry of Health 2001; NCHECR 2004).

This section reviews the common STIs, including pathophysiology, signs and symptoms, diagnosis and management. The common STIs that will be covered are genital herpes, chlamydia, gonorrhoea and syphilis (Erian et al 2004).

Consultation and/or referral to an infectious diseases physician or sexual health nurse or doctor are important if an STI is suspected or diagnosed. Midwives must work collaboratively with other healthcare providers to ensure that STIs are recognised and treated effectively. If one STI is diagnosed, it is often wise to recommend that the woman be tested for other common STIs as well as the human immunodeficiency virus (HIV). These infections often occur together, as the modes of transmission are similar.

Notification

In Australia, chlamydia, gonorrhoea and syphilis are notifiable conditions in all states and territories This means diagnoses of these infections are notified by state/territory health authorities to the National Notifiable Disease Surveillance System, maintained by the Australian Government Department of Health and Ageing (NCHECR 2004).

In Australia, the population rates of diagnosis of chlamydia, gonorrhoea and syphilis continue to be substantially higher in the Northern Territory than elsewhere in the country. Substantially higher rates of diagnosis of chlamydia, gonorrhoea and syphilis have also been recorded among Indigenous people than in non-Indigenous people (NCHECR 2004).

Information on STIs in New Zealand is difficult to obtain as national statistics on people diagnosed are not collected and some laboratories do not provide information for population-based estimates to be made. With the exception of HIV/AIDS, STIs are not notifiable infectious diseases.

Women who are diagnosed with an STI should be counselled about referring their sexual partners for testing and treatment (Centers for Disease Control and Prevention 2002). Depending on the infection, tracing partners can go back months and even years.

Genital herpes

Genital herpes is a common infection caused by the herpes simplex virus (HSV). There are two types of HSV:

- Type 1 is usually found around the lips and is commonly referred to as a 'cold sore'.
- Type 2 is usually found around the genitals or anus.

HSV is transmitted by close skin-to-skin contact with someone who has the infection. This usually occurs during vaginal, anal or oral intercourse. However, transmission can also occur if there is skin-to-skin contact without penetrative sex. Transmission of herpes may also occur through asymptomatic shedding. This is where someone infected with herpes sheds the virus from the skin without any visible signs of herpes. Similarly, transmission may occur when people are unaware they are infected with HSV because they have no symptoms, or very minor ones that are often unnoticed (NSW Health 2004a).

TABLE 7.5 Causative agent, signs and symptoms, diagnosis and management of STIs that are most important in pregnancy

	Genital herpes	Chlamydia	Gonorrhoea	Syphilis
Causative agent	Herpes simplex virus type 2	*Chlamydia trachomatis*	*Neisseria gonorrhoeae*	*Treponema pallidum*
Signs and symptoms	Blistering and ulceration of the directly affected areas (may include labia majora, labia minor, clitoris and urethra). These can be painful, tingling or itchy.	In 70–90% of women, the infection is asymptomatic. When there are symptoms, these may include dysuria, abnormal vaginal discharge, abnormal vaginal bleeding, pelvic pain or pain during sex.	In more than 60% of women the infection is asymptomatic. Where there are symptoms, these include cervicitis and a discoloured vaginal discharge.	A primary chancre (painless sore) develops at the site after an incubation period of approximately 21 days. In the secondary stage, a rash on the palms of the hands or soles of the feet, and on other parts of the body may be seen. Second stage symptoms, if they develop, usually occur from 7 to 10 weeks after infection.
Diagnosis	A laboratory test (PCR test) is undertaken from a swab of the lesion.	Detected by swabs collected from the cervix, urethra or anus or by a urine sample. PCR test or culture is undertaken.	Detected by swabs collected from the cervix, urethra or anus and cultured for the organism.	A sample of the chancre is taken for examination. Blood tests are used to diagnose primary and secondary syphilis.
Management	Acyclovir in different doses and length of time depending on whether it is the first episode or a recurrence.	Azithromycin, doxycycline or erythromycin generally for 10 days is effective treatment.	Penicillin most commonly is used but ceftriaxone may also be prescribed. Follow-up cultures are recommended one week after completing treatment to ensure cultures are negative.	Injections of penicillin is the most common treatment. Other drugs include erythromycin and doxycycline.

The risk of transmission to the baby is high (30–50%) in women who acquire genital herpes near the time of birth, but low (< 1%) among women with a history of recurrent herpes at term or who acquire genital HSV during the first half of pregnancy. Prevention of neonatal herpes depends both on preventing acquisition of genital HSV infection during late pregnancy and on avoiding exposure of the infant to herpetic lesions during birth. In some cases, this may mean avoiding a vaginal birth (Centers for Disease Control and Prevention 2002).

Women without known genital herpes should be advised to avoid intercourse during the third trimester with partners known or suspected to have genital herpes, to reduce the chance of an episode around the time of birth.

Chlamydia

In Australia, chlamydia is the most frequently reported notifiable condition in Australia (NCHECR 2004) and its incidence is likely to be high in New Zealand. Chlamydia can affect future fertility if not treated appropriately.

Chlamydia is often referred to as 'the silent STI' because the majority of people infected do not have symptoms. Chlamydia can affect the urethra, cervix, rectum, throat and eyes and is most often transmitted through unprotected vaginal and anal sex (NSW Health 2004).

Chlamydia in newborn babies occurs because of exposure to infected cervical fluids. The infection is most often recognised by conjunctivitis that develops 5–12 days after birth. Chlamydia is the most frequent identifiable infectious cause of ophthalmia neonatorum but can also be a common cause of subacute, afebrile pneumonia at 1–3 months of age (Centers for Disease Control and Prevention 2002).

Gonorrhoea

Gonorrhoea can infect the urethra, anus, cervix, throat and eyes of both men and women. It can be transmitted through oral, anal and vaginal sex without a condom. Condoms are highly effective in preventing gonorrhoea (NSW Health 2004a).

Gonococcal infections can also be present in newborns if they have been exposed to infected cervical fluids. It is usually an acute illness than presents two to five days after birth. The infection can cause ophthalmia neonatorum, rhinitis, vaginitis, urethritis, and inflammation at sites of fetal monitoring (Centers for Disease Control and Prevention 2002).

Syphilis

Syphilis is no longer very common in Australia or New Zealand. Congenital syphilis has considerable long-term effects on babies, including deafness, and so early diagnosis and treatment are important.

In Australia and New Zealand, routine antenatal tests often include a syphilis blood test. These tests are usually the venereal disease reference laboratory (VDRL) test and the rapid plasma reagin (RPR) test. The test that is specific for syphilis is called the *T. pallidum* haemagglutination assay (TPHA). Once someone has been infected with syphilis, the infection will always show up on the TPHA test even if they have been successfully and adequately treated (Erian et al 2004).

Critical thinking exercise

Contact tracing is the term used to describe the process of finding and notifying sexual partners when a person has been diagnosed with an STI. This can be a difficult and sensitive topic and confidentiality is important. Can you think of some strategies that would assist the contact tracing process? Look on the website for your health department to find out information about notifications and contact tracing.

Reflective exercise

Many people have very negative connotations and stereotypes attached to STIs. Take some time to reflect on your own attitude to STIs. How do you think your attitude might affect the way you practise?

Blood-borne viruses and childbearing

Blood-borne viruses (BBV) are increasingly important for midwives to understand. The BBVs that have particular significance for childbearing women are the human immunodeficiency virus (HIV), hepatitis B (HBV) and hepatitis C (HCV). This section will address issues for women and midwives in relation to these three BBVs.

While each virus has distinct transmission patterns, HIV, HBV and HCV can all be transmitted parenterally through the sharing of injecting equipment, needle-stick injuries, or piercing and tattooing with contaminated equipment. The efficiency of sexual transmission is significantly different between the viruses. This has implications for midwifery practice and mother-to-child transmission (Sasadeusz et al 2004).

Midwifery and BBVs

Midwives should institute universal or standard precautions when caring for all women, not just those who are known to be living with a BBV. This will ensure that midwives are adequately protected and that discrimination does not occur. Universal precautions include wearing protective equipment (gloves, eye shields etc) when exposed to body fluids, especially blood.

When considering the most appropriate protective equipment, it is useful to remember exactly how these

infections are transmitted, and avoid 'over-reacting' when the risk is either minimal or non-existent.

Vaccination for HBV is recommended to all healthcare workers as part of an occupational screening program.

HIV/AIDS

The language of HIV/AIDS is important to understand at the outset so that the correct terminology can be used. HIV refers to the actual agent, that is, the human immunodeficiency virus. AIDS is the name of the syndrome that occurs as a result of the immune problems caused by HIV. AIDS refers to acquired immunodeficiency syndrome and includes around 26 illnesses. These are called AIDS-defining conditions—for example, invasive cervical cancer, oesophageal candidiasis, tuberculosis, recurrent pneumonia and lymphoma. Therefore, it is inaccurate to talk about 'someone having the AIDS virus'. There is no such virus.

The global picture

The number of people around the world who are, or have been, affected by HIV/AIDS is staggering. Table 7.6 reports the global summary of the epidemic to December 2004 (UNAIDS 2004). The ranges around the estimates in this table define the boundaries within which the actual numbers lie, based on the best available information.

In some parts of the world, more than half of those infected are women. For example, in sub-Saharan Africa, women and girls make up almost 57% of adults living with HIV. Young women in particular are more likely to be infected than older women. For example, in South Africa, Zambia and Zimbabwe, young women (aged 15–24 years) are three to six times more likely to be infected than young men (UNAIDS 2004).

TABLE 7.6 Global summary of the HIV epidemic to December 2004

	Number*
People living with HIV	
Total	*39.4 million (35.9–44.3 m)*
Adults	37.2 million (33.8–41.7 m)
Women	17.6 million (16.3–19.5 m)
Children under 15 years	2.2 million (2.0–2.6 m)
People newly infected with HIV	
Total	*4.9 million (4.3–6.4 m)*
Adults	4.3 million (3.7–5.7 m)
AIDS deaths in 2004	
Total	*3.1 million (2.8–3.5 m)*
Adults	2.6 million (2.3–2.9 m)

*Range is shown in brackets
(Source: UNAIDS 2004, www.unaids.org)

Some of Australia's and New Zealand's closest neighbours are struggling with an increasing HIV epidemic. For example, Papua New Guinea, which shares an island with one of Indonesia's worst-affected provinces, Papua, has the highest prevalence of HIV infection in the Pacific (UNAIDS 2004). More than twice as many young women (aged 15–24 years) as men have been diagnosed with HIV. In 2003, 1.4% of pregnant women at antenatal clinics in the capital, Port Moresby, tested HIV-positive, while in Lae, in the central highlands, 2.5% of pregnant women were HIV-positive (UNAIDS 2004).

A number of other nations in our region have reported high rates of sexually transmitted infections (gonorrhoea, syphilis, chlamydia), including Vanuatu, Samoa and East Timor. High rates of STIs are often predictors of sexual behaviour that puts women at risk of HIV. These rates are a warning sign of potential HIV epidemics in the future.

HIV/AIDS in Australia and New Zealand

In Australia, an estimated 13,630 people were living with HIV/AIDS in 2003, including around 1100 adult/adolescent women (NCHECR 2004). The annual number of new HIV diagnoses declined from around 930 in 1994 to 690 in 1999 and 780 in 2003. The annual number of HIV diagnoses in women has stayed relatively stable, but more of those diagnosed infections occurred through heterosexual intercourse—either in a high-prevalence country or with a partner from a high-prevalence country (UNAIDS 2004).

In New Zealand, to the end of June 2004 a total of 819 people (754 males and 65 females) have been notified with AIDS, and 2154 (1823 males, 313 females, and 18 sex not stated) have been found to be infected with HIV (Ministry of Health 2004).

Mode of transmission

HIV is transmitted through sexual contact, blood-to-blood contact and mother-to-child transmission.

In Australia and New Zealand, transmission of HIV continues to be mainly through sexual intercourse between men (UNAIDS 2004). In developing countries, however, transmission is primarily through heterosexual intercourse.

Blood-to-blood contact can occur during sharing of needles used in injecting drug use, blood transfusion and needle-stick injuries. Transmission through injecting drug use is uncommon in Australia and New Zealand because of early strategies to reduce the incidence of needle-sharing. Transmission through injecting drug use is particularly common in parts of Europe, Asia and the United States. In Australia and New Zealand, transmission via blood transfusion occurred before blood products were universally screened (in 1985). In countries where all blood products are screened for HIV, transmission is exceedingly rare. Needle-stick injuries rarely result in transmission. It has been reported that only 0.03% of exposures from HIV-positive individuals result in HIV transmission (Sasadeusz et al 2004).

Mother-to-child-transmission can occur during pregnancy, labour and birth and through breastfeeding. The rates of mother-to-child transmission range from 20% to 45%, depending on the context. Transmission rates have been shown to be reduced significantly (to around or less than 5%) with the use of antiretroviral therapy during pregnancy, labour and after birth, and other interventions such as elective caesarean sections and avoidance of breastfeeding (Sasadeusz et al 2004).

Issues for midwives

Although HIV/AIDS is uncommon in women in Australia and New Zealand, midwives need to be aware of the infection and the implications for screening and treatment.

1 Testing for HIV in pregnancy

The first issue to address is the identification of those women with HIV infection. Treatment options during pregnancy and birth significantly reduce the risk of mother-to-child transmission of HIV. Early identification is advantageous to the baby. Identification also may mean that women can access treatments that prolong the immune deficiency effects of the virus and delay the onset of an AIDS-related condition.

Screening policies for HIV vary greatly. A survey of private obstetricians, general practitioners and directors of public maternity units found great disparity in antenatal testing policies. A policy of universal offering of antenatal testing for HIV was reported from 47% of private obstetricians, 62% of general practitioners and 23% of public maternity units (Spencer et al 2003).

Routine screening for HIV is controversial, but many are now recommending routine screening with pre- and post-test counselling and consent. The Royal Australian and New Zealand College of Obstetricians and Gynaecologists (RANZCOG) and the NSW Health Department recommend that all pregnant women be offered HIV screening at their first antenatal visit (NSW Health 2004a; RANZCOG 2004). The NZCOM discussed the issue in 2002 and stated that:

> No consensus was reached in relation to the draft statement that had been circulating prior to the July 2002 AGM. The statement issued from the AGM was: On current evidence the New Zealand College of Midwives (NZCOM) does not support the routine screening of all pregnant women for HIV (NZCOM 2002a).

The New Zealand Ministry of Health appears to support the recommendation made by the Australian National Council on AIDS and Related Diseases (ANCARD):

> In general, women identified through their medical history as being at higher risk of HIV infection should be encouraged to be tested. No pregnant woman should be pressured into HIV testing or be tested without informed consent. Conversely, no pregnant woman seeking HIV testing should be discouraged from being tested (ANCARD 1998).

This recommendation was made in 1998. The document goes on to say 'in the light of rapidly changing testing and treatment, there should be a regular (two yearly) review of antenatal testing policies and practice' (ANCARD 1998). In 2006 the New Zealand Ministry of Health announced that all pregnant women will be offered routine antenatal screening for HIV.

Routine screening is a complex matter. Midwives must consider the risks and benefits associated with both HIV infection and screening in order to decide on policy and practice.

2 A multidisciplinary approach

HIV/AIDS is complex, and so a multidisciplinary approach is necessary. An approach where continuity of carers is provided is highly beneficial. The team should consist of a midwife, obstetrician, HIV physician and HIV nurse. The team may also include a social worker or counsellor.

As the baby will require ongoing testing during the first 18 months, a paediatrician and paediatric nurse with expertise in HIV infection are also important. It is useful for the woman to meet, or have contact with, the paediatric team prior to the birth of the baby to discuss the testing and monitoring process.

3 Support and confidentiality

Pregnant women who have HIV infection experience a number of additional fears and worries in addition to the normal concerns of pregnancy. This is particularly so for women who discover in pregnancy that they have HIV infection. The diagnosis is a shock, with the whole gamut of emotions including disbelief, anger, fear and concerns for the future and the baby. These women need time and support in order to make decisions about the pregnancy and their ongoing care and use of treatments.

Non-government organisations, such as the AIDS Council in each Australian state and territory and the New Zealand

BOX 7.1 Global Coalition on Women and AIDS

The Global Coalition on Women and AIDS was launched by UNAIDS in early 2004 to highlight the effects of AIDS on women and girls and to stimulate effective action to reduce that impact. The Global Coalition on Women and AIDS is not a new organisation but a movement of people, networks and organisations supported by activists, leaders, government representatives, community workers and celebrities. Its work is focused on seven areas:

- preventing HIV infection among adolescent girls
- reducing violence against women
- protecting the property and inheritance rights of women and girls
- ensuring equal access by women and girls to care and treatment
- supporting improved community-based care, with a special focus on women and girls
- promoting access to new prevention options, including female condoms and microbicides
- supporting ongoing efforts towards universal education for girls.

AIDS Foundation, have support groups, counsellors, resources and information that may be useful for women and families to access.

Confidentiality is essential. Some women choose to tell their family about their infection; others do not. Midwives and others involved in the care of women need to be very conscious of this when providing care, especially in a hospital ward setting. For example, if a woman's family does not know about her infection they may question why she has chosen an elective caesarean section or is not breastfeeding. These decisions must be made by the woman and respected by all those involved in her care. Other simple issues should be addressed, like removing medication charts from the end of the bed or cot, as they may have antiretroviral medications ordered, indicating the infection.

Hepatitis C

In 2003, an estimated 242,000 people living in Australia had been exposed to hepatitis C virus (HCV). Of these, 25% were estimated to have cleared their infection, 59% had chronic hepatitis C infection and early liver disease, 13% had chronic hepatitis C infection and moderate liver disease, and 3% were living with hepatitis C related cirrhosis (NCHECR 2004). In 2000, it was estimated that in New Zealand the prevalence of hepatitis C was 25,200 people, with an incidence of 1300 new cases per year. Both the prevalence and incidence are lower than Australia on a per capita basis (Nesdale et al 2000).

The test for hepatitis C only became available in 1990. Currently, there is no vaccine available for hepatitis C.

While HCV and HIV are similar is some ways, in many others they are very different. Table 7.7 illustrates some of these differences. While this comparison is in Australia, the essential differences remain the same in the New Zealand population.

Mode of transmission

The transmission of HCV mainly occurs when infected blood enters the bloodstream of another person. The most common mode of transmission in Australia and New Zealand remains injecting drug use.

The role of sexual transmission, if any, is still controversial. If sexual transmission of HCV does occur, it is at a very low level, which makes it inappropriate to routinely recommend safe sex among long-term monogamous couples.

Mother-to-child transmission occurs in approximately 5% of births. This rate may be higher in women who also have HIV infection (Sasadeusz et al 2004). Mode of birth does not appear to affect the risk of transmission. As the infection is passed parenterally, care should be taken not to damage the skin integrity of the baby (e.g. avoid scalp clips).

Mother-to-child transmission is more likely to occur if women have high levels of circulating virus; that is, the more virus the more the chance of transmission. The amount of circulating virus is measured using a test called a polymerase chain reaction (PCR). The rate of mother-to-child transmission is 6% when women have positive PCR and 0% when the PCR is negative (Dore et al 2001). Therefore, a PCR test during pregnancy is very useful to women and their care providers.

Breastfeeding is not thought to be a risk factor for transmission. No cases of transmission via breast milk have been reported (ASHM 2003).

Issues for midwives

In Australia and New Zealand, HCV is far more common than HIV, although it has received considerably less interest from the popular media and health sectors in general. Midwives are far more likely to care for a woman with HCV infection than HIV.

1 Testing for HCV in pregnancy

Routine antenatal screening for HCV in pregnancy is also controversial. The Australian National Council on AIDS, Hepatitis C and Related Diseases currently does not recommend universal screening for pregnant women (ANCAHRD 2003). It recommends that testing be offered based on risk factors.

Women are considered to be at increased risk for HCV if they have:

TABLE 7.7 Comparison of the HIV and HCV epidemics in Australia

	HIV	HCV
Commencement of epidemic	early 1980s	1960s
Peak of new infections	1984	1999
Estimated current infection	13,630	242,000
Male:female ratio	17:1	1.7:1
Estimated current infection p.a.	780	14,499
Cumulative attributable deaths	6,372	unknown
Predominant transmission	Male homosexual (85%)	Injecting drug use (80%)

(Source: NCHECR 2004)

- a history of injecting drug use
- a partner (past or present) who has injected drugs
- a tattoo or piercing
- been in prison
- received blood which later tested positive for HCV
- been on long-term dialysis
- received an organ transplant prior to July 1992 (Victorian Health 2001).

RANZCOG recommends that all pregnant women be offered hepatitis C screening at the first antenatal visit.

The issues around screening are similar to those discussed earlier in this chapter around HIV and include the need for pre-test counselling and consent (Victorian Health 2001).

2 A multidisciplinary approach

As with HIV infection, a multidisciplinary approach is essential when caring for women with HCV. An infectious diseases physician or gastroenterologist with expertise in HCV will be the most appropriate physician. Longer-term follow-up of the woman and her baby, especially to monitor liver function, needs to be offered.

3 Support and confidentiality

The issues around support and confidentiality are equally similar to the ones discussed earlier in relation to HIV. There is probably less stigma attached to an HCV diagnosis, although the recognised risk factor being injecting drug use may be difficult for some women and their families. Again, the wishes of the woman must be respected and strategies put in place to ensure confidentiality.

Hepatitis B

Hepatitis B infection is the last BBV to be considered in this section. Of those infected, 5–10% become chronic carriers, and they remain infectious to others for life.

Hepatitis B is a huge health issue around the world. More than a third of the world's population have been infected with HBV, with an estimated 350 million chronic carriers worldwide. About 25% of chronic carriers develop serious liver disease (chronic hepatitis, cirrhosis, liver cancer). HBV results in 1–2 million deaths per year (Zuckerman 1999).

Mode of transmission

Hepatitis B infection is transmitted mainly by contact with an infected person's blood or sexual fluids, or from an infected woman to her baby (NSW Health 2004b).

Prevention of hepatitis B infection depends on immunisation of all children and immunisation of household contacts of infectious cases. Infectious people should avoid exposing others to their blood or sexual fluids. Hepatitis B immunoglobulin given with vaccine to babies born to infectious mothers is also effective.

Issues for midwives

1 Testing for HBV in pregnancy

It is recommended that all women be offered screening for HBV at their first antenatal visit (RANZCOG 2004; Victorian Health 2001). There is no evidence to support a repeat test later in pregnancy (Victorian Health 2001).

The results can be interpreted using the information presented in Table 7.8. It is essential to be very clear about the interpretation of the results (see Ch 32).

2 A multidisciplinary approach

As in the other BBVs, collaboration and a multidisciplinary approach is needed in hepatitis B. Consultation with an infectious diseases physician is important so that women and families receive accurate information. In addition, long-term follow-up, similar to that for hepatitis C, is recommended.

3 Support and confidentiality

The issues around support and confidentiality are equally similar to the ones discussed earlier in relation to HIV and HCV. There is probably less stigma attached to an HBV diagnosis, as it is even more common. Nevertheless, care needs to be taken to ensure that confidentiality is maintained and that women and their families receive appropriate support.

4 Prevention of neonatal infection

Neonates whose mothers are HbsAg positive are at greatest risk of hepatitis B acquisition. Of babies infected at birth, 90% will develop chronic hepatitis B infection.

Therefore, all babies born to mothers who are HbsAg positive should be offered hepatitis B immunoglobulin (HBIG) within 12 hours plus hepatitis B vaccination. Hepatitis

Reflective exercise

Take some time to reflect on your own attitudes on BBV, especially HIV and hepatitis C. How do you think your attitudes affect the way you practise, especially the way you discuss the infections with women?

Critical thinking exercise

1. Appropriate referral and having a multidisciplinary team approach are essential in the care for women with a BBV. Write a list of all the people/agencies or services that might be useful in your setting.
2. Review the antenatal blood tests of a woman with HBV infection and a woman who does not have the infection. What are the features of the test that are important to understand?
3. Your manager has a policy of putting women who have hepatitis B infection in a single room for postnatal care. What are the issues in relation to this policy? Name and discuss one advantage and one disadvantage of the policy.
4. Find your hospital or health setting's policy on universal precautions. Does this reflect best practice? What is the action in the case of a needle-stick injury?

TABLE 7.8 Interpretation of hepatitis serology testing

HBsAg: surface antigen	HBeAg: e antigen	Anti-HBc: core antibody	Anti-HBe: e antibody	Anti-HBs: surface antibody	Interpretation
0	0	0	0	0	Never had HBV infection or is in the early incubation period of the infection
0	0	0	0	+	Either passive temporary immunisation with HBV infection or long-term immunisation with hepatitis B vaccine. Non-infectious
+	0	0	0	0	Late incubation period or early stages of acute infection. Infectious
+	+	0	0	0	Early stage of acute infection. Infectious
0	0	+	0	+	Indicates a past resolved HBV infection. Suggests immunity to subsequent infections. Non-infectious
0	0	+	+	+	Indicates a past resolved HBV infection. Suggests immunity to subsequent infections. Non-infectious
+	+	+	0	0	Acute or chronic infection. Infectious
+	0	+	0	0	Acute or chronic infection: stage after HBeAg has disappeared but anti-HBe not yet detected. Follow-up serology indicated. Infectious
+	+	+	+	0	Mid to late stage of acute infection or chronic carrier state. Period of seroconversion from HBeAg to anti-HBe. Follow-up serology indicated. Infectious
+	0	+	+	0	Mid to late stage of acute infection or chronic carrier state. Follow-up serology indicated. Potentially infectious
0	0	+	0	0	Resolved infection with selective loss of anti-HBs. May also represent the window phase of an acute infection with HBsAg below level of detection. Remotely potentially infectious
0	0	+	+	0	This may represent resolved infection. Remotely potentially infectious
0	+	0	0	0	A rare profile that most likely represents erroneous test result. Repeat serology.
0	0	0	+	0	Probably an erroneous test result. Repeat serology.
+	0	+	+	+	A profile observed occasionally. Infectious

BOX 7.2 Discussing BBVs

Language to consider when talking with women about BBVs:

Avoid the terms:

- addict
- addiction
- drug addict
- drug abuse
- drug abuser
- intravenous.

Use the terms:

- injecting (rather than intravenous)
- drug use, not abuse
- injecting equipment, not needles
- reused, not shared (e.g. Have you ever reused someone else's injecting equipment?)
- withdrawal symptoms and/or dependence, not addiction
- new, rather than clean, equipment.

(Source: ASHM 2003)

B vaccine should be administered at the same time as HBIG but in a different site.

Language

The language used is very important when discussing BBV infections with women. The National Hepatitis Education Program has developed some hints to consider when talking with women about possible or real infections (see Box 7.2).

Domestic violence and pregnancy

Domestic violence (also known as intimate partner violence or family violence) is a significant issue for women whether they are pregnant or not. A number of terms are used to refer to domestic violence in government documents and in the literature. These include 'family violence', 'intimate partner violence' and 'spousal violence'. In this chapter the term 'domestic violence' is used.

Violence against women is increasing in all cultures, societies and socio-economic groups (WHO 2000). In Australia, New Zealand and elsewhere, government and health providers have developed policies on domestic violence.

Domestic violence in pregnancy is a significant issue, as there are immediate and long-term effects on both the woman and her baby. This section discusses the prevalence of violence in pregnancy, the risks and dangers to women and their babies, and issues relating to screening, support and referral.

Challenges to determining prevalence rates

Defining and measuring domestic violence in pregnancy is challenging. Definitions include 'only physical violence' and 'physical and sexual violence', or expand to take in other forms of violence, including emotional abuse and harassment (Hegarty et al 1999; Taft 2002).

One of the other challenges is related to how women are asked about violence. Whether women are asked in person, by telephone or on a self-reporting questionnaire affects the reported prevalence rates (Taft 2002). Women who speak little English may also not disclose violence, especially if the interpreter is from their community and confidentiality is not assured. Women whose partners do not leave their sides when seeking healthcare, for example in antenatal visits, often do not disclose because of lack of opportunity (Taft 2002).

Prevalence of domestic violence in pregnancy

The prevalence of domestic violence varies depending on the context, population and measurement instruments. A review of 14 studies of violence against pregnant women reported prevalence rates between 1% and 20% (Gazmarian et al 1996). More recently, a study conducted in antenatal clinics in the United Kingdom reported prevalence rates of 2% at booking, 6% at 34 weeks of pregnancy and 5% at 10 days post partum (Bacchus et al 2004). In the United States, a study in low-risk pregnant women reported that abuse during pregnancy was reported by 6% of women (Neggers et al 2004).

An early important Australian study of more than 1000 women found that almost 30% reported a history of abuse, with around 6% reporting being abused during pregnancy. The proportion of women admitting to abuse rose over the duration of pregnancy to 9% at 36 weeks (Webster et al 1994). Women who were adolescent, single, separated, divorced or in a de facto relationship, not working outside the home or with lower levels of education, were more likely to have experienced abuse.

In New Zealand, there is evidence that domestic violence also affects a significant number of women. Research suggests that between 15% and 21% of women report having experienced physical or sexual abuse, and 44% to 53% report having experienced psychological abuse in the previous 12 months (Leibrich et al 1995; Morris 1996). While these rates are not specifically for women during pregnancy, one could hypothesise that these would translate to similar levels in pregnancy as reported elsewhere.

Effects of domestic violence

Women who suffer abuse are at risk of physical injury, gynaecological problems, complications during pregnancy and childbirth, depression, anxiety, sexually transmitted infections and eating disorders (Taft 2002).

Domestic violence can also have catastrophic effects. In the most recent report of *Maternal Deaths in Australia* there were two deaths as a result of domestic violence (Slaytor et al 2004). One was an 18-year-old woman, 18 weeks pregnant with a past history of intravenous drug use. There had been noted concerns for her regarding domestic violence. The second death occurred following a domestic dispute, in a 25-year-old woman who was nine weeks pregnant.

Avoidable factors were thought to have played a role in both deaths.

The *Confidential Enquiry into Maternal Deaths* in the United Kingdom (2001) reported that 12% of the 378 women whose deaths were investigated from 1997 to 1999 had self-reported a history of domestic violence to a health worker. Of these women, eight were subsequently murdered by a partner or close relative.

Domestic violence also affects children in the family. Exposure to violence between parents has been reported to result in higher levels of physical and psychosomatic disorders, behavioural problems, post-traumatic stress and poor educational achievements in children and young people (Taft 2002).

Implications for midwives

All health professionals, including midwives, need to be aware of the significance of domestic violence. They need to adopt a non-judgemental and supportive response to women who have experienced physical, sexual or psychosocial abuse. Midwives need to provide women with basic information about where to get help and provide continuing support whatever decision she makes about her future (Confidential Enquiry into Maternal Deaths 2001).

The New Zealand College of Midwives has a Consensus Statement about the responsibility of midwives in relation to domestic violence (NZCOM 2002b). It also provides training for midwives in relation to routine screening for family violence, and referral processes for women who disclose their exposure to violence.

Screening for violence in pregnancy

Routine screening for domestic violence has been advocated in a number of countries including New Zealand, the United States and some Australian states. The aim of screening is to enable women to disclose to healthcare providers so they can receive appropriate referral and support.

Women generally do not disclose without direct questioning unless the abuse has reached a serious level (Hegarty & Taft 2001). There are a number of barriers to women's disclosure about domestic violence (Taft 2002). These include:

- shame and/or embarrassment
- fear of the abuser and retribution
- belief that the abuse is normal and common among couples
- fear of judgemental attitudes
- her partner's presence
- believing that the abuse is her responsibility and that no one else can help.

Risks and benefits of screening

There is controversy about routine screening for domestic violence in antenatal care.

Women respond differently to the screening questions, depending on their level of fear, their degree of trust in the person asking the questions and their sense that anything can be done. Therefore, screening may not detect all women who are experiencing abuse. The screening questions are also not always acceptable to women. A study in the United States asked women about their attitudes to being screened for physical and sexual abuse (Gielen et al 2000). When asked whether healthcare providers should routinely screen women for physical and sexual abuse, only 54% of women who reported abuse, and 42% of women who did not, agreed. A study in Sweden reported high levels of acceptability in both abused and non-abused women, with 82 and 72% respectively of these groups finding screening acceptable (Stenson et al 2001). In Australia, a pilot study reported that feedback from the 159 women who were screened over a 12-week period was very positive (Jones & Bonner 2002).

Many health settings are not well equipped to provide adequate support and referral networks, and in many places acceptable services for women do not exist. There are concerns that if undue emphasis is placed on screening and disclosure in places where effective services are in place to guarantee confidentiality and safety, women may suffer harm (Taft 2002). If screening is implemented, it is essential that the maternity service staff are aware of the available resources and support networks accessible to women.

Midwives as women

The rates of domestic violence in the community are high. It is likely, therefore, that some midwives will have been subjected to domestic violence. Midwives could be past or current victims of domestic violence. This may mean that it is difficult for these midwives to undertake screening for domestic violence. This issue needs to be acknowledged in any screening program.

It is essential that midwives who undertake screening are provided with training and ongoing support and clinical

BOX 7.3 NZCOM Consensus Statement

The New Zealand College of Midwives Consensus Statement on family violence is as follows.

Midwives:

- require support to address the issue of violence against women within the national family violence strategy/framework
- undertake screening of all pregnant women for violence as part of a comprehensive health assessment
- understand the effect of violence against pregnant women and in particular in relation to sexual and reproductive health
- acknowledge that the woman has the right to define choice of action/referral or support
- are familiar with referral agencies that provide support, counselling and emergency services for survivors of violence
- can provide information resources to pregnant women on local emergency support services
- do not support mandatory referral when violence has been disclosed.

(Source: NZCOM 2002)

supervision. The training should discuss the implications of screening for both women and midwives and the practicalities of screening (Jones & Bonner 2002). Ongoing support and clinical supervision are necessary for staff who are undertaking screening.

Child protection issues

Child protection must be at the forefront of concerns in relation to domestic violence. In many states and territories in Australia and in New Zealand, mandatory reporting is required if there are any concerns about children at risk, including those in domestic violence situations. Midwives need to be clear about their role and responsibilities in this area and need to work with other healthcare and non-government providers to ensure that children receive appropriate protection.

Poor communication between healthcare workers is known to be a concern in cases involving the protection of children. Appropriate referral, follow-up and documentation are therefore essential to ensure that children in potentially volatile situations have quality care and access to services and support.

Screening questions

A number of different styles of screening questions have been developed and implemented. An example is presented in Box 7.4 (Jones & Bonner 2002). The screening is only undertaken when the woman is alone with the midwife. The preamble is read out before the questions are asked. The reasons for not screening and the outcome of screening are documented.

Recommendations

A number of key recommendations have been made by the Confidential Enquiries into Maternal Deaths in the United Kingdom in relation to domestic violence (Lewis 2001):

- All health professionals should be aware of the importance of domestic violence in their practice. They should adopt a non-judgemental and supportive response to women who have experienced physical, psychological or sexual abuse and must be able to give basic information to women about where to get help. They should be able to provide continuing support, whatever decision the woman makes concerning her future.
- When a woman discloses violence this must be taken seriously. Women who are poor clinic-attenders need active outreach services.
- Local health services and community teams should develop guidelines for the identification of, and provision of further support for, these women, including developing multi-agency working to enable appropriate referrals or provision of information on sources of further help.
- Information about local sources of help and emergency help lines should be displayed in suitable places in antenatal clinics, for example, in the woman's toilets or printed as a routine at the bottom on the hand-held maternity records.
- Enquiries about violence should be routinely included when taking a social history. This may be at the booking visit.
- When routine screening is introduced, this should be accompanied by the development of local strategies for referral. This should be accompanied by an educational program for health professionals in consultation with local groups.
- Where a woman is unable to speak English, an interpreter should be provided. A partner, friend or family member should not be used for interpreting.

BOX 7.4 Preamble and screening questions

Preamble:

- In this health service we routinely ask all women the same questions about violence at home.
- This is because violence in the home is very common and can be serious and we want to improve our response to women experiencing domestic violence.
- You don't have to answer the questions if you don't want to.
- All answers to the questions will remain confidential to the health service except where you give us information that indicates that you or your children are at immediate risk of serious harm. We would discuss this with you.

Screening questions:

1. Within the last year have you been hit, slapped or hurt in any way by your partner or ex-partner?
2. Are you frightened of your partner or ex-partner?
3. Are you safe to go home when you leave here?
   - If domestic violence has been identified in any of the above questions, continue to Question 4.
4. Would you like any assistance with this?

(Source: Jones & Bonner 2002)

Reflective exercise

Take some time to reflect on your own experiences with domestic violence whether in a personal or professional capacity. How do you think your experiences might affect the way you practise and how you communicate with women?

Critical thinking exercise

1. Screening for domestic violence should never occur with the woman's partner or family members present. What are some strategies you could use to ensure that this can occur?
2. The legislation relating to child protection and mandatory reporting varies across Australia and New Zealand. Find out what it is in your area. How will this affect your practice when asking women about domestic violence?

- Every woman should be seen on her own at least once during pregnancy to enable the disclosure of such information (Lewis 2001).

Female genital mutilation and pregnancy

The World Health Organization (WHO) has defined female genital mutilation as comprising 'all procedures involving partial or total removal of the female external genitalia or other injury to the female genital organs whether for cultural or other non-therapeutic reasons' (WHO 1997). An estimated 135 million of the world's girls and women have undergone genital mutilation, and two million girls a year are at risk of mutilation—approximately 6000 per day (Amnesty International 1997).

This definition encompasses the diversity of procedures performed by different cultural groups. The classification of FGM (see Table 7.9) provides a technical description of the types of procedures that this definition covers. Within each of the types of FGM there will be variation with respect to the amount of tissue removed.

The term 'female genital mutilation' may cause offence to some who have experienced it. Although Western societies may view the practice as mutilation, within the cultures who practise FGM it is performed with the good of the child in mind. The use of the term 'female genital mutilation' in midwifery practice has the potential to be counterproductive to the establishment of effective relationships with women. Without the development of such relationships, it may not be possible to meaningfully address the difficult and sensitive issues with which a woman affected by these practices may need assistance (RANZCOG 1997). Sometimes terms like 'traditional female surgery', 'cutting' and 'ritual female surgery' are more useful.

Classification and terminology

Midwives need to be aware that different women may refer to the extent of the FGM differently. The WHO has devised a classification system that will be useful to define the level of FGM and to assist clarity. This will also help in the planning of the woman's care, especially for the birth.

An estimated 15% of all mutilations in Africa are infibulations. The procedure consists of clitoridectomy (where all, or part of, the clitoris is removed), excision (removal of all, or part of, the labia minora), and cutting of the labia majora to create raw surfaces, which are then stitched or held together in order to form a cover over the vagina when they heal. A small hole is left to allow urine and menstrual blood to escape. In some less conventional forms of infibulation, less tissue is removed and a larger opening is left. The vast majority (85%) of genital mutilations performed in Africa consist of clitoridectomy or excision. The least radical procedure consists of removal of the clitoral hood (Amnesty International 1997).

In some traditions a ceremony is held, but no mutilation of the genitals occurs. The ritual may include holding a knife next to the genitals, pricking the clitoris, cutting some pubic hair, or light scarification in the genital or upper thigh area (Amnesty International 1997).

Complications of FGM

A wide range of complications associated with FGM are reported, including short- and long-term physical, sexual and psychosocial problems. Some women do not experience any problems that they attribute to FGM (RANZCOG 1997).

TABLE 7.9 WHO classification of female genital mutilation

Type I	Excision of the prepuce, with or without excision of part or all of the clitoris Other terms used to describe Type I procedures include circumcision, ritualistic circumcision, sunna, clitoridectomy.
Type II	Excision of the clitoris with partial or total excision of the labia minora Other terms used to describe Type II procedures include clitoridectomy, sunna, excision and circumcision.
Type III	Excision of part or all of the external genitalia and stitching/narrowing of the vaginal opening (infibulation) Other terms used to describe Type III procedures include infibulation, Pharaonic circumcision and omalian circumcision.
Type IV	Unclassified: includes • pricking, piercing or incising of the clitoris and/or labia • stretching of the clitoris and/or labia • cauterisation by burning of the clitoris and surrounding tissue • scraping of tissue surrounding the vaginal orifice (angurya cuts) or cutting of the vagina (gishiri cuts) • introduction of corrosive substances or herbs into the vagina to cause bleeding or for the purposes of tightening or narrowing it • any other procedure which falls under the definition of female genital mutilation given above.

(Source: WHO 1997)

TABLE 7.10 Complications associated with FGM	
Immediate	• pain • bleeding • infections • injuries • urinary obstruction • death
Longer term	• vulval scarring and pain • pelvic and urinary tract infection • obstructed menstrual and urinary flow • urinary and faecal fistulae • obstructed miscarriage and childbirth • vaginal and perineal damage at childbirth
Sexual	• non-consummation due to dyspareunia, obstruction, vaginismus or painful scar tissue • trauma on deinfibulation by partner • impaired sexual response and enjoyment • problematic sexual expression or relationship conflict, if vaginal intercourse is precluded
Psychological	• reactions to the trauma of FGM itself • anxiety and depressive symptoms • effects on sexuality • conflict within family and community • responses of host communities, including health professionals • inter-generational issues regarding continuity of the practice • post-immigration anxiety and regret regarding FGM

(Source: RANZCOG 1997)

Legislation surrounding FGM

Specific legislation banning FGM has been enacted in almost all Australian states and territories and in New Zealand. Where legislation has been passed, it has the following features:

- A person who intentionally performs female genital mutilation on a person is guilty of a serious offence with a maximum penalty of at least seven years imprisonment.
- A person must not take a child from a jurisdiction, or arrange for a child to be taken from it, with the intention of having female genital mutilation performed on the child. A child is defined as someone under the age of 18 years. Again there is a maximum penalty of at least seven years imprisonment.
- There are exceptions for the performance of medical procedures that have a genuine therapeutic purpose.

Child protection legislation often also exists to protect girl children who might be deemed to be at risk of FGM. Healthcare professionals are therefore required to report incidents of FGM including situations where they believe a girl to be at risk. Reports should be made to the relevant child welfare authority (RANZCOG 1997).

Midwives and FGM

Midwives and other healthcare professionals have an important role in the prevention of FGM, and the care of women who are affected by this practice.

Considerable time is required with women who are affected by FGM to discuss all the issues and to develop trust and rapport. If possible, these women should have care from a small group of midwives throughout the antenatal, labour and birth and postnatal periods. Continuity of caregiver is important, as is knowledge about FGM and the cultural and social issues related to it.

Midwifery care

Table 7.11 presents the best practice principles for the care of women through pregnancy, labour and birth and the postnatal period. These principles are developed from work undertaken by the Royal Australian and New Zealand College of Obstetricians and Gynaecologists (RANZCOG 1997), the NSW Education Program on FGM (NSW Education Program on Female Genital Mutilation 2000) and the South Eastern Sydney Area Health Service's Women's Health Unit (South East Health 2002). These resources should be used for more information when caring for these women.

Culturally sensitive care

Female genital mutilation is a significant health issue for women and girls around the world. With increased migration and movement, midwives in Australia and New Zealand will be increasingly exposed to women who have undergone this procedure. It is essential that midwives develop skills in supporting both the physical and the psychosocial needs of this group of women. Culturally sensitive care is important if women are to feel well supported.

Critical thinking exercise

1. The legislation relating to FGM varies across Australia and New Zealand. Find out the legislation in your state or country regarding FGM.
2. Are there any national or state policies about the care of women who have experienced FGM? How can you ensure that these are incorporated into practice in your setting?

Reflective exercise

Take some time to reflect on your own attitudes on the practice of FGM. How do you think your attitudes affect the way you practise?

TABLE 7.11 Best practice principles for care of women who have undergone FGM

Antenatal	• Women with FGM should be managed by a small team of midwives and doctors to ensure continuity of caregivers, information and support • The use of sensitive language is important for women affected by FGM. • Information relating to FGM should always be given in the women's language. The depth of discussion will depend on the grading of FGM and the receptiveness of the woman and her family. Diagrams can be used to help the woman understand how she will be affected during childbirth. • After gaining consent for examination, the woman needs to be examined by the medical officer or midwife to determine the type of FGM. This can occur at a visit during the pregnancy once the midwife has developed the trust of the woman. • If she is classified as Type III or when the introitus is inadequate, then she will need deinfibulation antenatally or during the intrapartum period (see below). • Decision about deinfibulation needs to be made in consultation with the woman and her partner and undertaken between 20 and 28 weeks gestation. It can be performed as a day case, preferably under spinal or local anaesthetic. • Ensure the woman and her partner understand that reinfibulation will not be undertaken. • Communication between all involved in the care of the woman needs to be ongoing and further counselling may be needed. • Encourage the woman to have her partner/support person come to the visits. • All interventions and decisions must be documented clearly and fully in the clinical records.
Labour and birth	• Each woman will have been assessed in the antenatal period. Review the clinical notes. • Vaginal examination can be difficult. Use of one finger only may make it tolerable. • Bladder management: encourage frequent urination. Insertion of a catheter can be difficult. Urethral meatus may need to be palpated digitally prior to insertion. If a urinary catheter is inserted, leave it indwelling. • Women with Type I or II normally do not require deinfibulation. Division of adhesions normally occurs as the fetal head emerges, but on occasions deinfibulation may need to be attended.
Postnatal	• Women who have Type I or II FGM should have usual postnatal care. • Women who have Type III or if deinfibulation has occurred: individual assessment is required. – Women need to be aware that voiding will be quicker and noisier than before. – Offer urine alkaliser and analgesia. – Watch for urinary retention in first 24 hours. – The scar should be checked prior to discharge by the practitioner who did the deinfibulation. • Provide information regarding ongoing genital hygiene. • The midwife should become aware of cultural practices surrounding the postnatal period for individual women. • If the baby is a girl, there should be a discussion about FGM. Ongoing education and support needs to involve the woman's GP, social worker and child and family health nurse.

(Sources: NSW Education Program on Female Genital Mutilation 2000; RANZCOG 1997; South East Health 2002)

Conclusion

This chapter has covered a number of challenges to women's health, specifically during pregnancy.

Midwives face these challenges and many others every day in their practice. While the specifics of the challenges are different, the principles of providing woman-centred, evidence-based care always remain the same. Working with women through these challenges means listening to their stories, understanding their experiences and supporting them to make choices and decisions that are right for them. This should always be done in a non-judgemental and collaborative manner, utilising other workers and non-government agencies as appropriate. In addressing these challenges, midwives should be mindful of the need to respect and support the needs of women to be self-determining in promoting their own health and wellbeing.

Some of the issues addressed in this chapter fall beyond the scope of midwifery practice. Collaboration with others therefore is essential. Women should be provided with clear information about accessing community support agencies that are available during pregnancy, in the postnatal period and after, when the midwifery relationship is concluded. An important part of the role of the midwife is to ensure that women have developed links and networks that enable them to make connections and receive appropriate support.

Review questions

1 Which strategies may be useful for women with an anxiety disorder in pregnancy?
2 What are the major risks for the baby associated with medication used to treat bipolar disorder in the first trimester?
3 Name three adverse effects related to smoking cigarettes in pregnancy for (a) the mother and (b) the baby
4 Which two strategies have been found to result in smoking cessation in pregnancy?
5 What strategies might you use in an antenatal setting to support women who want to stop or reduce smoking?
6 What is the maximum number of standard drinks recommended for (a) non-pregnant women and (b) pregnant women?
7 What are some of the adverse effects of using heroin in pregnancy?
8 What is the management of babies whose mothers have used opiates during late pregnancy?
9 What are the signs and symptoms of chlamydia infection in women?
10 What organisms cause ophthalmia neonatorum?
11 What is the risk of mother-to-child transmission of HIV infection? How can this risk be reduced?
12 What are two issues to consider when deciding on a policy of routine screening for HIV and/or hepatitis C infections?
13 What are the estimated rates of domestic violence in pregnant women in Australia and New Zealand?
14 Why are they only 'estimated'?
15 Give two benefits and two disadvantages of routine screening for domestic violence.
16 What are three ways in which midwives can support women who have experienced domestic violence?
17 Women from which cultures are most likely to be affected by female genital mutilation?
18 Outline the features of Type III FGM.
19 What are the implications for labour and birth for women affected by Type III FGM?
20 What are some of the midwifery strategies to support women who have been affected by FGM during pregnancy and birth?

CHAPTER 8

Making decisions about fertility

Sally K Tracy

Key terms

biological clock, fecundity rates, gamete intrafallopian transfer (GIFT), intracytoplasmic sperm injection (ICSI), in vitro fertilisation (IVF), infertility, luteal support, older women, protecting fertility

Chapter overview

This chapter offers a brief introduction to fertility and reproductive issues faced by women who may not achieve pregnancy without assistance. It will introduce you to some of the physical methods of assisted reproduction, and some of the ethical dilemmas associated with fertility and reproduction technology.

Learning outcomes

The aims of this chapter are:

1. To explore the meaning of fertility and infertility
2. To identify key aspects of assisted reproduction
3. To discuss the importance of age and motherhood.

Introduction

Demographic, economic, social and administrative changes have all had a role in fertility transition (Caldwell 1999). A sustained fall in fertility is a relatively recent phenomenon. In the late eighteenth century a sustained fall in fertility began in France, and fertility declines became general in western and central Europe, as well as in English-speaking settlement countries, in the last quarter of the nineteenth century (Caldwell 1999). The reasons were complex (Caldwell 1999). Fertility decline has never been an unconscious social process; advocacy and organisation have been important. From 1950 to 1965, the world population increased by 34% and that of developing countries by 39% (Caldwell 1999). In developing countries, in the 15 years from the early 1950s until the late 1960s, life expectancy at birth had risen from under 41 years to over 52 years and the annual population growth rate had climbed from 2.0 to 2.5%, while the total fertility rate (the average number of lifetime births per woman at the age-specific birth rates at a specified date) had remained at just over six. Social theorists began to proclaim that it was unique characteristics of the Western family that had allowed or ordained fertility control, and others suggested that the socio-economic gap between the late nineteenth century West and the mid-twentieth century Third World was greater than had been thought. But by 1970 it was clear that there had been a widespread fall in fertility from about 1965 in both Latin America and Asia (Caldwell 1999).

In the three decades from 1965–70 to 1995–2000, the total fertility rate of the developing world halved from 6.0 to 3.0 births per woman. What has been less frequently noted is that between the early 1960s and the late 1990s the total fertility rate of developed countries fell by 37%, from 2.7 to 1.7. Fertility in the West fell because married women were entering the labour force in larger numbers than before, but undoubtedly the change was facilitated by the same forces that assisted the Third World: there were better contraceptives and their use had become respectable. Thus the world's annual number of births in the late 1990s was only 129 million, well below the 206 million that would have been the situation if the fertility levels of the early 1960s had been maintained.

The choice of delaying pregnancy has become the norm for many women in developed countries. Among some women, however, achieving pregnancy may be difficult or impossible at a later time. Australian and New Zealand women, like women in most developed countries, are delaying childbirth until their thirties and forties. In 1971 the average age of Australian and New Zealand women at delivery was 25.4 years, but has consistently increased since then, reaching a peak of 30.5 years in 2003 (Laws & Sullivan 2004; NZHIS 2004). Since 1971, birth rates among women in their thirties have increased while decreasing for the younger age groups. Several causative factors have been identified, such as delayed partnering, higher education, increased employment opportunities for women, longer life expectancy and improved access to and availability of contraception. At the same time, advances in assisted reproductive technologies have improved pregnancy rates among infertile couples, adding to the growing group of primiparous women aged 35 years and older.

Women's ability to conceive declines with age. Data have shown that the proportion of women who tried but did not succeed in conceiving their first child within one year increased from 6% in the 15–24 years age group to more than 30% in the 35–44 years age group (te Velde et al 1998). Adverse neonatal outcomes such as preterm birth, low birthweight, stillbirth and neonatal deaths are higher among assisted-conception births (Helmerhorst et al 2004). Infertility treatment is also an independent risk factor for caesarean section among primiparous women aged 40 and above (Sheiner et al 2001). Over half (54.3%) of all assisted reproductive technique (ART) cycles in Australia in 2002 involved women aged 35 years and over (Sullivan et al 2005, unpublished work).

Fertility

The total fertility rate refers to the number of babies a woman could expect to bear, on average, during her lifetime if she experienced current age-specific fertility rates throughout her childbearing life. In Australia, since 1961, when each woman averaged 3.55 babies, the total fertility rate has declined to 1.75 births per woman in 2002 (ABS 2003). This is notably below the replacement fertility level of 2.1 babies per woman—the number of babies a woman would need to have during her lifetime to replace both herself and her partner. This trend for fertility to drop below replacement level is occurring in most developed, and some developing, countries. Aided by effective and available methods of fertility control, Australian and New Zealand women are increasingly delaying childbearing for a number of social, economic and cultural reasons.

In 2002, the highest fertility occurred in women aged 30–34 years, at a rate of 111.2 babies per 1000 women, continuing the trend of the previous two years. This group experienced slightly higher fertility than the 25–29 year age group (104.2 babies per 1000 women). The main decline in the fertility rate over the past 20 years has occurred among the 20–24 and 25–29 age groups. Meanwhile, fertility has continued to increase in women aged 40 and over (ABS 2003), and ART has played a role in this. Recent years have seen some notable trends in reproduction. Numbers of births in Australia and New Zealand have been generally decreasing, as have fertility rates and perinatal deaths. In contrast, the proportion of multiple births has been increasing (Laws & Sullivan 2004).

'Fertility' in the colloquial sense of the word denotes reproductive capacity (rather than the demographic sense of number of live births). Aside from some medically determined causes of sterility, the reproductive capacity of a couple cannot be measured directly. Rather, it has to be assessed stochastically, by whether pregnancy occurs and how long it takes the couple to conceive (Sallmen et al 2005, p 494).

The ability to preserve fertility with various methods has become a key issue for some women. Although the need is most pressing among women with cancer, the same therapeutic

options may be available for many other women who are reaching an advanced reproductive age. However, in this group, the use of the available techniques is controversial and should be considered experimental (Lobo 2005, p 64).

The peak number of oocytes in the female infant occurs at about 20 weeks gestation, when there are somewhere between 6 and 7 million oocytes. Then, by the time of birth, the number has reduced to 1 to 2 million oocytes. By the time a woman is 37 years old, she reportedly has approximately 25,000. This number drops over the years until at menopause (around 50 years for most women) she will have about 1000 oocytes left in her body (Lobo 2005, p 65). The mechanism underlying this process is poorly understood and involves multiple factors encoded by genes on the X chromosome, as well as on autosomes (Simpson 2000). Although environmental factors may be important, genetic factors predict 44% to 87% of the variance in the age at menopause (de Bruin et al 2001; van Asselt 2004). In normal women, at approximately 37.5 years of age, an accelerated atresia of the oocytes begins (Gougeon et al 1994).

This accelerated loss is poorly understood and is often associated with a small monotropic rise in the level of follicle-stimulating hormone (FSH) and decreased fecundity (Scott et al 1989; Wood et al 1992), as well as an increased risk of aneuploidy. The subtle increase in the level of FSH is thought to increase atresia, which is coupled with an accelerated loss of follicles and a further increase in FSH, thus resulting in a positive-feedback loop (Erickson et al 2000).

Accordingly, women who are destined to go through menopause at the age of 45 years (10% of the population) might be expected to have accelerated atresia and reduced fecundity beginning at the age of 32 years; however, this hypothesis has not been proved. Although it is clear that women with a strong family history of early menopause would be at risk for reduced fecundity at an earlier age, no data suggest at what age fecundity decreases. As atresia continues, both the number and the quality of oocytes fall below a critical level, and the rate of aneuploidy increases—a finding that is related at least in part to problems of the meiotic spindle resulting in nondisjunction. This process leads to a greater risk of spontaneous abortion once pregnancy occurs.

Ageing is a significant factor influencing the ability to conceive. As stated earlier, in normal women, fecundity begins to decline at a more rapid pace after the age of 37.5 years.

Premature ovarian failure, which is defined as menopause before the age of 40 years or hypergonadotrophic amenorrhea, occurs in up to 0.9% of women in the general population and has multiple causes, including the involvement of several genes. Once premature ovarian failure has been established, fertility is usually lost, although spontaneous pregnancies may occur. Familial premature ovarian failure and environmental factors that may deplete ovarian follicles define this risk category. Various environmental factors and toxic exposures may also affect the age at menopause.

Pelvic diseases—such as endometriosis, neoplasms and infection—may require surgery, which by removing and destroying cortical tissue depletes the follicular or oocyte reservoir and may lead to early menopause. In addition, pelvic surgery may lead to the formation of adhesions, which may affect the ability to conceive naturally. Among the women at greatest risk for the inability to reproduce are those undergoing treatment for cancer due to the effects of multi-drug chemotherapy.

The body fat connection

That excessive exercise or under-nutrition can postpone puberty, reduce fertility or prevent menstruation was first discovered by Rose Frisch in her pioneering studies beginning in the late 1960s. Her work describing the reproductive consequences of an altered mass of fat were largely ignored or treated with scepticism. Her hypothesis—that a critical mass of body fat is the crucial trigger of gonadotrophin secretion, both in developing girls and in mature women during reproductive life—was initially based on detailed analysis of worldwide demographic data and was later supported by highly focused clinical investigation (Reichlin 2003).

In otherwise healthy young women, a critical mass of body fat is the essential trigger of cyclical pituitary–ovarian function. A successful pregnancy requires approximately 50,000 calories stored in the form of fat. A critical body-fat mass determines the onset of menses. Excessive leanness, as in people with anorexia nervosa and some competitive athletes and professional dancers, delays the onset of puberty; after menarche has been established, excessive leanness can cause impaired ovulation, infertility and amenorrhea. Oestrogen deficiency induced by excessive exercise (and decreased fat mass) is associated with premature osteoporosis, even in runners in whom bone formation has been stimulated by exercise. On the positive side, women who have been extremely active athletically have a much reduced risk of breast cancer, presumably because they have been exposed to lower levels of oestrogen over time. These insights have been invaluable for the evaluation of women with delayed puberty and amenorrhea, and they have important social and medical implications for dancers and athletes. Though less well documented, critical body-fat mass is probably also

BOX 8.1 Weight and onset of menarche

Rose Frisch was the scientist who discovered, during her studies on weight gain in populations around the world, that poor rural girls had their peak rate of growth at an older age than did well-nourished urban girls. Since it was known at the time that a period of rapid growth precedes the onset of menarche, she analysed several large population studies in the United States in which the rate of growth and the age of menarche had been assessed and found that the average weight at menarche was 47 kg, whether girls matured early or late. She realised that body weight was a more accurate predictor of the age at the onset of menstruation than was chronological age.
(Source: Reichlin 2003)

important in determining pituitary gonadal activity in men (Reichlin 2003, p 870).

Time to pregnancy refers to the number of menstrual cycles it takes a couple to conceive. Fecundability, in turn, is a couple-specific probability of conceiving a recognised pregnancy per menstrual cycle, given no contraception (Sallmen et al 2005, p 494). The characteristics of 'infertile' and 'infertility' refer to couples who try for more than a year to conceive. Many infertile couples will eventually conceive, but a sterile subset cannot conceive without medical intervention (Sallmen et al 2005, p 495).

Given the irreversible nature of women's emancipation and their presence in the labour workforce, there is a relationship between public policies (maternity leave, income tax regulations), workplace conditions (part-time opportunities and the flexibility of work hours) and the availability of affordable non-parental child care that enables mothers to participate in the labour force (Hank et al 2003).

A growing body of research suggests a changing, now positive, relationship between women's education or employment and fertility with the advent of social contexts that allow women to combine childrearing and employment. Access to affordable child care is essential for this to occur (Hank & Kreyenfeld 2003).

Older women and childbirth

Most women over age 35 have healthy pregnancies and healthy babies. According to US data, the number of first births per 1000 women aged 35 to 39 years increased by 36% between 1991 and 2001, and the rate among women age 40 to 44 years leapt by a remarkable 70%. In 2002, 263 births were reported in women between 50 and 54 years of age (Heffner 2004).

Very advanced maternal age, defined as maternal age of 45 years or greater at the time of delivery, has important consequences for both mother and baby. Currently, 0.1% of all Australian and New Zealand women giving birth are in this age category (ABS 2000; NZHIS 2004). Given the trend towards delayed childbearing and the increasing availability of assisted reproductive techniques, women aged 45 and over may increasingly seek advice about the risks of embarking on a pregnancy (Callaway et al 2005).

The effect of maternal age on the outcome of pregnancy may be best assessed by examining five specific factors (Heffner 2004) that can negatively affect the desired outcome of a pregnancy—a healthy mother and baby. These are:

- declining fertility
- miscarriage
- chromosomal abnormalities
- hypertensive complications
- stillbirth.

It is not unusual for a woman in her mid-thirties or older to take longer to conceive than a younger woman. Age-related decline in fertility may be due, in part, to less frequent ovulation, or to problems such as endometriosis, in which tissue similar to that lining the uterus attaches to the ovaries or fallopian tubes and interferes with conception. While women over age 35 may have more difficulty conceiving, they also have a greater chance of bearing twins. The likelihood of naturally conceived (without fertility treatment) twins peaks between ages 35 and 39, then declines.

Miscarriage is defined as spontaneous pregnancy loss before the twentieth week of gestation. Karyotyping of the products of conception after miscarriage indicates that about two-thirds are chromosomally abnormal (Heffner 2004). There is a strong relationship between maternal age and miscarriage rates. At 20 years of age, the rate is about 10%. It increases to a high of more than 90% among women 45 years of age or older. This high miscarriage rate contributes significantly to decreasing fertility among older women (Heffner 2004, p 1927).

The success rate using donor eggs from younger women for in vitro fertilisation supports the hypothesis that deterioration occurs in the quality of the ova with advancing maternal age (Heffner 2004).

Both chronic hypertension (that antedates pregnancy) and pregnancy-induced hypertension usually occur during the second half of a pregnancy and include both hypertension without proteinuria and the many variants of the disorder pre-eclampsia. All forms of hypertension can complicate pregnancies by restricting fetal growth and may necessitate premature delivery when the health of either the mother or the fetus is in jeopardy. The risk of hypertensive complications of pregnancy increases steadily as women age; such complications are twice as likely among women 40 years of age or older as among younger women (Heffner 2004, p 1928).

How should we counsel young women when they ask about their reproductive choices? Generally speaking, the decade between 25 and 35 years of age would seem to be ideal. A woman's education is typically complete, she has usually gained some experience in her professional arena, and pregnancy is at its safest. For women between 35 and 45 years

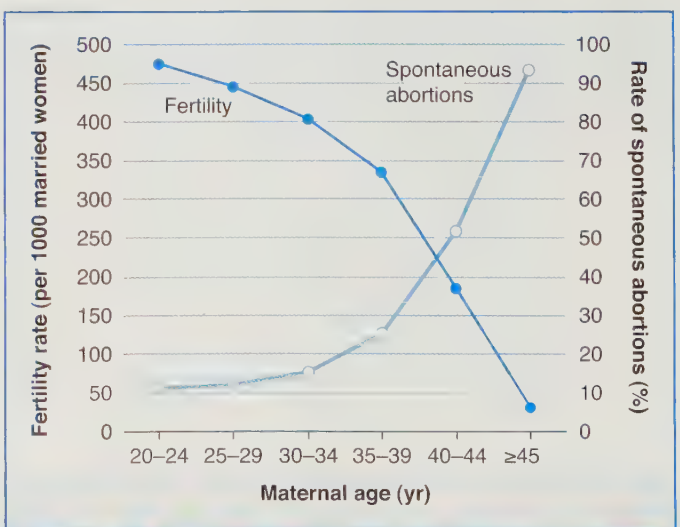

Figure 8.1 Fertility and miscarriage rates as a function of maternal age (based on Heffner 2004)

of age for whom earlier childbearing is not an option, this decade remains safe enough that maternal age alone should not be a contraindication to childbearing. However, women do face decreasing fertility and a moderate increase in the risks of miscarriage and chromosomal abnormalities as they pass 40 years of age. Perimenopausal and postmenopausal pregnancy remains an option for those women who are lucky enough to find themselves healthy and sufficiently wealthy to pursue it (Heffner 2004, p 1929).

The risk of bearing a child with certain chromosomal disorders increases as a woman ages. The most common of these disorders is Down syndrome, a combination of mental retardation and physical abnormalities caused by the presence of an extra chromosome 21 (humans have 23 pairs of chromosomes). At age 25, a woman has about a 1 in 1250 chance of having a baby with Down syndrome; at age 30, a 1 in 1000 chance; at age 35, a 1 in 400 chance; at age 40, a 1 in 100 chance; and at 45, a 1 in 30 chance. Most pregnant women who are 35 or older are offered the option of prenatal testing (with amniocentesis or chorionic villus sampling) to diagnose or, more likely, rule out Down syndrome and other chromosomal abnormalities. About 95% of women who undergo prenatal testing find that their baby does not have one of these disorders. If prenatal testing rules out chromosomal defects and the mother is healthy, the baby probably is at no greater risk of birth defects than if the mother were in her twenties.

Most miscarriages occur in the first trimester for women of all ages. The rate of miscarriage in older women is significantly greater than that in younger women. A recent Danish study found that about 9% of recognised pregnancies for women aged 20 to 24 ended in miscarriage. The risk rose to about 25% at age 35 to 39, and more than 50% by age 42 (Nyobo Anderson et al 2000).

While women in their late thirties and forties are very likely to have a healthy baby, they do face more complications along the way. Besides the increased risk of diabetes and high blood pressure, women over 35 have an increased risk of placental problems. The most common placental problem is placenta praevia, in which the placenta covers part or all of the opening of the cervix. First-time mothers over age 40 were up to eight times as likely as women in their twenties to have this complication. Some studies suggest that women having their first baby at age 35 or older are at increased risk of having either a low birthweight or preterm baby (born at less than 37 full weeks of pregnancy). These risks rise modestly but progressively with a woman's age, even if she does not have age-related chronic health problems such as diabetes and high blood pressure. The Danish study also found that women over age 35 had an increased risk of ectopic pregnancy (in which the fertilised egg implants in the fallopian tube) (Nyobo Anderson et al 2000).

Teenage pregnancies

Among teenage mothers in Australia and New Zealand the birth rate continues to decline. In Australia the birth rate for women aged 15–19 years declined from 27.4 births per 1000 women in 1982 to 17.1 in 2002. Even in the last few years, the decline has been large, down from 22.0 in 1992 to 17.7 in 2000. Compared with the 1982 rate, the 2002 rate represents an overall decline of 38% (ABS 2003).

Thirty years ago, a study of 37 developed countries including Denmark, Finland, Norway and Sweden showed a relationship between low fertility rates and openness about sexual matters, government policy for providing contraceptives to young unmarried women, well-organised teaching about contraception in schools, and a high percentage of the population living in large cities (Jones et al 1985). It is believed that the main reason for a drop in abortion rates worldwide is increased use of contraceptive methods (Henshaw 1999) and in the Netherlands a national emphasis on the importance of contraceptive methods, ongoing positive sex education in schools, and easily accessible, low-cost and friendly contraceptive services are the main reasons for low fertility and abortion rates (Ketting & Visser 1994).

In Sweden, contraceptive services for young people were introduced and are run by midwives (Bender et al 2003). The greater accessibility of contraceptive methods in Sweden was made possible through the immediate development of teenage clinics, which now comprise over 200 nationwide (Bender et al 2003). The link between fertility and use of contraception was considered important, and its preventive effect regarding abortion was recognised. Sweden also developed an effective link between sex education in schools and contraceptive services for young people (Bender et al 2003).

In industrialised countries, *Chlamydia trachomatis* is the predominant infectious agent causing pelvic inflammatory disease and, as a result of damage to the fallopian tubes, accounts for up to half of all ectopic pregnancies. The substantial financial costs of genital chlamydial infections result from hospital treatment for pelvic inflammatory disease, ectopic pregnancy and infertility, which may include in vitro fertilisation.

World population trends

Since 1968, when the UN Population Division predicted that the world population, now 6.3 billion, would grow to at least 12 billion by 2050, the agency has regularly revised its estimates downwards. It now expects world population to plateau at 9 billion. We are experiencing a profound demographic shift as a result of two forces: increasing longevity and declining fertility. The best-known example of shrinkage is in Italy, where women were once symbols of fecundity. By 2000, Italy's fertility rate was Western Europe's lowest, at 1.2 births per woman. Its population is expected to drop 20% by mid-century. Denmark was below population replacement level in 1970 at 2.0 births per woman, and slid to 1.7 by 2001 (Kurjak & Carrera 2005).

Demographics of New Zealand women

The age of mothers has changed over the past 20 years, with the number of women giving birth over 30 years of age

TABLE 8.1 Projected population growth

Location	Total population, 2004 (billions)	Projected population, 2050 (billions)	Average growth, 2000–2005 (billions)
World	6.378	8.919	1.2
More developed regions	1.206	1.220	0.2
Less developed regions	5.172	7.699	1.5
Least developed countries	0.736	1.675	2.4

Data are from the United Nations Population Fund. More developed regions comprise North America, Japan, Europe, Australia and New Zealand. Less developed regions comprise all regions of Africa, Latin America, the Caribbean, Asia (excluding Japan), Melanesia, Micronesia and Polynesia. The least developed countries are defined according to the standard United Nations designations.

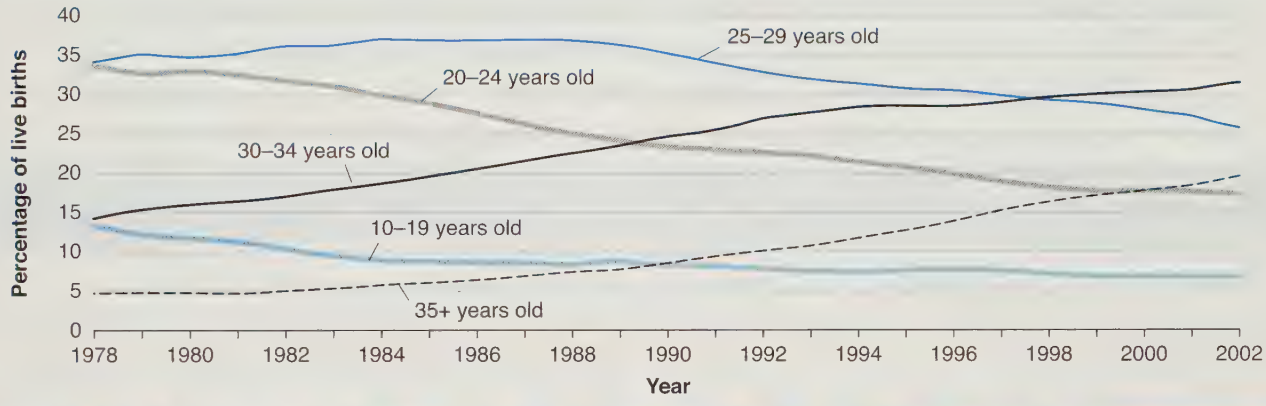

Figure 8.2 Age of mothers at the time of giving birth in New Zealand, 1978–2002 (based on NZHIS 2004)

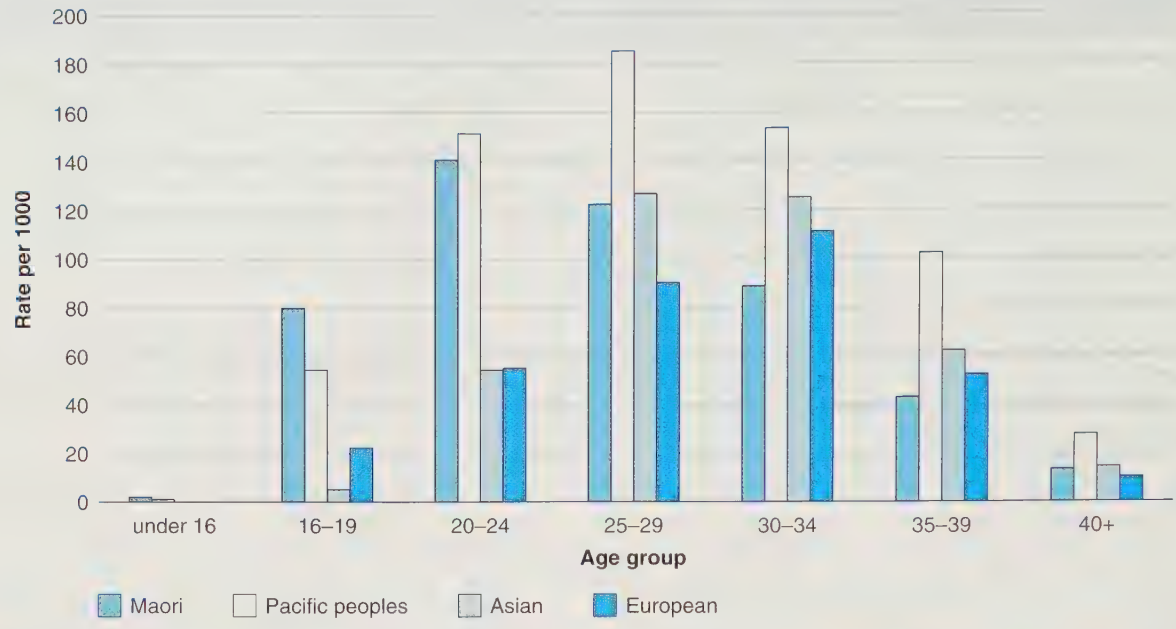
steadily increasing, while births among younger women have decreased. The reducing rate for teenage women is a result not of a declining fertility rate but of an increasing abortion rate, and the birth rate in women under the age of 19 remains high by international standards. Young pregnant women—especially those without sufficient family support—require significant support from health and social services. In the 2002 Maternity Services Consumer Survey, women aged 15–19 years were less likely than older mothers to have been satisfied with maternity services (New Zealand Ministry of Health 2004).



Although the age distribution of mothers may have changed over time (Fig 8.2), the percentage of births by each ethnic group has changed very little.

In 2002 the average age for New Zealand women to have a baby was 29.7 years, and 56.3% of New Zealand births were to women between the ages of 25 and 34 years. Seven per cent of births were to those under 20 years (3697/53,037), 19.5% (10,338/53,037) to Maori women, 10.8% to Pacific women (5714/53,037), and 7.7% to Asian women (4082/53,037).

In 2002, Maori women tended to have children at a younger age than women in other ethnic groups (Fig 8.3). The most common age for a Maori woman to give birth was 20–24 years. Of all births to teenage mothers (under 20 years of age), 44.1% (1629/3697) were to Maori women. Asian women most commonly gave birth between 25 and 34 years of age, and accounted for 1.7% (64/3697) of the teenage births.

Methods of assisted reproduction

Conception depends on a woman releasing an egg each month. The egg enters the fallopian tube where it meets the sperm. A sperm cell penetrates the egg in the process known as fertilisation. The resulting embryo is transported down the tube to the uterus, where it implants into the uterine lining (endometrium) a few days later. In general, 75% of couples will achieve a spontaneous pregnancy within six months of exposure, 90% by a year and 95% by two years. Three major factors determine the chances of a natural conception: female age, sperm quality and duration of exposure. It is well known that the risk of an adverse outcome after in vitro fertilisation (IVF) is attributable in large part to the greatly increased rate of multiple births. The rates of multiple gestation after IVF in Europe and the United States are 26.4% and 35.4%, respectively (Thurin et al 2004), underscoring the magnitude

Note: The 'Other' and 'Not reported' ethnic groups have been excluded from this graph.

Figure 8.3 Age group and ethnicity of mothers in New Zealand giving birth in hospital in 2002 (based on NZ Ministry of Health 2004)

of the problem. However, higher risks of preterm delivery and low birthweight have also been observed for singletons conceived by IVF and have been attributed at least in part to parental characteristics associated with infertility, such as high maternal age and nulliparity; these, of course, would not be influenced by the use of single-embryo transfer. Nevertheless, a substantial reduction in multiple births after IVF would dramatically decrease the risks associated with prematurity and low birthweight for children born after IVF (Thurin et al 2004).

In vitro fertilisation

In vitro fertilisation involves four basic steps: ovarian stimulation, egg recovery, insemination and, finally, embryo replacement. Couples with less than two years exposure need only consider IVF with proven tubal disease, significant semen abnormalities and moderate to severe endometriosis. Couples with unexplained infertility of less than two years, in women aged less than 35, need only consider IVF after two or more years of trying, and after a year in women older than 35. Minimal endometriosis is unlikely to be the cause of a delay in conception. Although IVF was originally devised for women with tubal damage or dysfunction, in combination with intracytoplasmic sperm injection (ICSI) it is a very effective method to treat male factor infertility. In vitro fertilisation treatment may be used in selected instances with donated eggs, sperm or embryos.

It is important to establish the cause of infertility before proceeding to IVF. Investigations would usually include checks of ovulation, tubal patency and an ultrasound for the female partner. A semen analysis is required for the male partner.

Ovarian stimulation

During a natural unstimulated cycle, a follicle containing a single egg develops to maturity. To produce more eggs it is necessary to stimulate the ovaries with a group of drugs known as gonadotrophins. Ovarian hyperstimulation (an excessive response) is a major and potentially life-threatening complication associated with gonadotrophins.

It is safest to monitor the response of the ovaries by daily oestrogen measurements and ultrasound. Ultrasound scans are used to see the number and size of the follicles and to judge when to do the egg recovery. The oestrogens are necessary to determine the ovarian response to stimulation. By interpreting the results of ultrasound and oestrogen, the specialist will determine the best time to perform the egg collection. About 36 hours before the egg collection is due, an injection of human chorionic gonadotrophin (hCG) is given to initiate the final process of egg maturation. Precise timing is necessary, as the eggs will be suitable for recovery 34 to 36 hours after the hCG injection.

Egg collection

This is done under sedation or general anaesthetic using a vaginal ultrasound probe. A needle is guided through the top of the vagina into the ovary. Each follicle is aspirated through the needle using a suction device.

Insemination and fertilisation

The eggs are identified in the laboratory and placed in culture medium. They are then placed in dishes in an incubator. The male partner produces a semen sample by masturbation and this is prepared in the laboratory. A number of motile sperm are extracted and used to inseminate the eggs some hours later. It takes about 18 hours for fertilisation to be completed, and about 12 hours later the embryo starts to divide. Two or three days after egg collection, when the embryos have reached the 2–6 cell stage, they are ready to be replaced into the woman's uterus.

Embryo transfer

This is a most important step and is best performed under ultrasound guidance. A maximum of two embryos may be replaced. Couples should consider the replacement of a single embryo to prevent a twin pregnancy. There is no evidence that bed rest makes a difference to the outcome and most units recommend resuming normal activities.

Luteal support

Hormone supplementation in the form of hCG injections, progesterone pessaries or injections is usually recommended after embryo transfer, to support the uterine lining.

Embryo freezing

Most IVF clinics offer embryo freezing and storage for spare embryos. However, not all surplus embryos are suitable for freezing, not all survive the procedure, and the implantation rate after transfer is lower than with fresh embryo transfer.

Abandoned cycles

The abandoned cycle rate varies considerably between units. Cycles may be abandoned before egg recovery as the ovarian response is either inadequate or excessive, and before embryo replacement if no eggs are recovered, or the eggs fail to fertilise or the embryos don't divide. In many instances it will be possible to try again using alternative drugs or methods, such as intracytoplasmic sperm injection (ICSI) for failed fertilisation.

Occasionally IVF cycles are abandoned because of a high risk of ovarian hyperstimulation. (The risk of ovarian hyperstimulation is increased in women with polycystic ovaries.) In these circumstances the cycle may be cancelled during ovarian stimulation and restarted with a lower dose of drugs, or allowed to proceed but all the embryos are frozen and replaced when the ovaries have returned to normal.

The ovarian hyperstimulation syndrome is potentially life-threatening. This syndrome occurs in about 2% to 3% of cases and consists of severe nausea and vomiting, a rapid gain in weight, abdominal swelling and shortness of breath. The fluid and electrolyte imbalance needs careful management in experienced centres. It starts a week after the hCG injection and is made worse by pregnancy.

Support when undergoing treatment

It is well recognised that undergoing assisted conception treatment, particularly IVF, is stressful both emotionally and physically. It is essential that patients fully understand the proposed treatment program and the commitment in time required for monitoring the cycle. Most clinics have information sheets and some have support groups to help in times of stress. All licensed centres are obliged to offer independent counselling to patients considering IVF treatment. This may prove helpful, as it gives the opportunity for a couple to discuss their infertility and treatment confidentially with an impartial person.

Gamete intrafallopian transfer

Gamete intrafallopian transfer (GIFT) can be considered both a sophisticated form of artificial insemination and a simplified form of IVF. The management of a patient in a GIFT treatment cycle is usually exactly the same as for an IVF cycle, up until the point at which the oocytes (eggs) have been recovered. A number of drug regimens are used to stimulate the ovaries to produce multiple oocytes, and these are always discussed with the couple at the time the treatment is started.

The growth of the ovarian follicles in which the eggs are developing is always monitored with a combination of serial ultrasound scans and often blood or urine tests. When the follicles are considered to be mature enough, arrangements are made for the patient to receive an injection of hCG and the egg recovery procedure is planned some 34–36 hours later.

Most clinics now will recover the oocytes by the transvaginal ultrasound directed technique, as for IVF. Some clinics will, however, recover the eggs laparoscopically. Once the oocytes have been collected and identified, the best two or three are selected. A preparation of the husband's sperm is taken into a fine catheter, together with the eggs, the tube is gently inserted under direct vision through the laparoscope into the outer ends of one or both fallopian tubes and the egg/sperm mixture is injected into the tube(s). At the end of this procedure, the patient is returned to the ward to recover, and will go home the same day.

Most patients are given either injections or pessaries of the hormone progesterone and some 15 days later a pregnancy test is carried out to determine whether there is early evidence of a pregnancy.

GIFT is generally found to be slightly more successful than IVF in most clinics. This is probably because the fallopian tube is a more physiological environment for fertilisation to occur in than in a laboratory culture dish. However, the procedure does require a laparoscopy, and most clinics now do not generally believe that the extra inconvenience of and potential discomfort of a laparoscopy makes the slightly increased pregnancy rates worthwhile. If a clinic is achieving good results with IVF, then it will generally not do GIFT. Clinics achieving poorer success rates with IVF may find that GIFT is considerably more successful and therefore recommend it.

Pregnancy rates for IVF are commonly quoted as being in the range of 15–30% and for GIFT, 25–30%.

Intracytoplasmic sperm injection

Intracytoplasmic sperm injection (ICSI) was introduced into clinical treatment for certain types of infertility in 1992. It is a type of IVF treatment that involves the injection of a single sperm straight into each egg. The fertilised egg (embryo) can then be transferred into the womb of the woman as in a normal IVF cycle.

The live birth rates for ICSI and conventional IVF are similar—about 23% per cycle, in the most recently published Human Fertilisation and Embryology Authority (HFEA) data from the United Kingdom (2005).

What does ICSI involve?

Intracytoplasmic sperm injection is similar to conventional IVF in that gametes (eggs and sperm) are collected from each partner. To achieve fertilisation, a single sperm is taken up in a fine glass needle and is injected directly into an egg. The eggs are then incubated and examined. Usually one or two embryos may then be transferred back into the womb of the woman two or three days after fertilisation. Some eggs may not survive the injection process and not all eggs collected will be of a high-enough quality or mature enough to be suitable for injection.

When is ICSI used?

In conventional IVF the eggs and the sperm are mixed together in a dish and the sperm fertilise the eggs naturally. ICSI bypasses the natural processes involved in a sperm penetrating an egg, and is therefore used when there are problems that make it difficult to achieve fertilisation naturally or by conventional IVF. It is used when:

- the sperm count is very low
- the sperm cannot move properly or are in other ways abnormal
- the sperm have been retrieved directly from the epididymis (PESA) or the testicles (TESA/TESE), from the urine, or by electro ejaculation
- there are high levels of antibodies in the semen
- there have been previous fertilisation failures.

Men who have very few sperm (oligozoospermia) or no sperm (azoospermia) in their semen, or who have high numbers of abnormal sperm that are unable to fertilise an egg, would previously have had little or no chance of fathering their own genetic offspring.

Like IVF, ICSI is an invasive procedure. However, unlike IVF, ICSI involves injecting a sperm directly into an egg, therefore allowing the use of sperm that may not otherwise be able to fertilise an egg. For these reasons, concerns about the potential risks to children born as a result of ICSI have been raised, and several follow-up studies have been published.

ICSI is still a relatively new technique, and all children conceived using ICSI are still very young. Consequently, follow-up studies involve relatively small numbers of children and do not include effects that may only be seen in older children or in the next generation. Follow-up studies are extremely important. The complexity of the process of egg and sperm production means that even if an individual possesses a normal number of chromosomes, their gametes could potentially have an abnormal number. It is not possible to detect beforehand which eggs or sperm have chromosomal abnormalities, and gametes that might not have been able to participate in natural fertilisation could therefore be used in ICSI. Babies born after ICSI have been reported to have new chromosomal abnormalities in up to 3% of cases. The rate in the general population is around 0.6% (HFEA 2005).

BOX 8.2 Terms used in ART

- *PESA*—percutaneous epididymal sperm aspiration, involving sperm being retrieved directly from the epididymis using a needle.
- *TESA*—testicular sperm aspiration, involving sperm being retrieved directly from the testes using a needle.
- *TESE*—testicular sperm extraction, involving sperm being retrieved from a biopsy of testicular tissue.

The procedure

The woman is stimulated for follicle (the tiny sack in the ovary that carries the egg) production, as in conventional IVF. Egg recovery is identical to that for routine IVF, but sperm treatment differs according to individual patient circumstances and, even if obtained from the ejaculate, often requires a modification of the procedures used for IVF. This modification uses a high centrifugation method to concentrate the contents of the seminal plasma into the size of a tiny fraction of a teardrop from which just a few sperm can be obtained and extracted. In certain circumstances micro-injection needles are used (approximately 12 times thinner than a strand of human hair) to isolate single sperm from the seminal plasma.

Whichever method is used—centrifugation or single sperm isolation—it is essential that the sperm be washed free of the seminal plasma. The human egg aspirated from the follicle is surrounded by thousands of spacialised cells—the cumulus cells (these perform a 'nursing' role while the egg is in the follicle). These cumulus cells are removed by treatment with hyaluronidase, a natural enzyme that is produced by the sperm during its passage through the cumulus cells while in the fallopian tube. In less than a couple of minutes the enzyme digests away the cells, leaving the egg encased in a few layers in another type of specialised cells. These are mechanically removed by the embryologist using gentle suction into a very finely pulled glass tube. The egg denuded of almost all its surrounding cells is then accessible for ICSI.

The ICSI procedure per se begins by first immobilising the sperm. This is often performed by transferring the sperm into a viscous solution, which dramatically slows down its motility. In its sluggish state the single sperm has its tail permanently immobilised—this has been shown to be an extremely important part of the process. The sperm is then

aspirated into the tiny micro-needle and carefully maintained at its tip. The micro-injection needle is manipulated using a micro-manipulator, which has extremely fine control capabilities. The egg itself is held onto another micro-tool by gentle suction to keep it firmly positioned. The micro-needle containing the sperm is pushed gently up against the outer shell (zone pellucida) and carefully pushed through the shell, through the outer membrane of the egg and directly into the centre of the egg itself—in the egg's cytoplasm.

Once the needle is inside the egg, a tiny amount of cytoplasm is aspirated into the micro-needle to mix with the sperm and ensure that the egg has been properly penetrated. Despite the tiny size of the egg (approximately seven times smaller than the average full stop), the membrane is a very elastic structure and can be extensively stretched without actually being ruptured. Once the embryologist is certain that the egg has been penetrated, the sperm and cytoplasmic mixture is injected back into the egg. This procedure rarely causes residual damage to the egg, and has no lasting effects on further development. The whole procedure is performed under a high-powered microscope. In some cases, immotile but living sperm is used. It is therefore important for the embryologists to be able to distinguish between dead and living immotile sperm. In this situation a solution is used that causes the tail of a living but immotile sperm to curl. The curled tail indicates that the sperm is actually living. It is these that the embryologist selects with the micro-needle.

Once isolated, the sperm can then be transferred to the viscous solution and treated in the same way for the ICSI procedure. At the end of the injection procedure the micro-injection needle is carefully withdrawn and suction on the egg is released. The egg is washed through a few changes of normal culture medium, and left overnight in an incubator at 37°C in conditions similar to routine IVF culture. The subsequent culture procedures, checking for fertilisation, cleavage of the fertilised egg and transfer of any embryos to the womb, occur in the same routine manner as for conventional IVF.

Laws about donation

In New Zealand and parts of Australia, the identity of donors is recorded. Knowing about our genetic heritage can help us to understand who we are. This can be important:

- for the psychological and emotional wellbeing of donor-conceived people. Many of them, like people who have been adopted, are naturally curious about their genetic origins.
- for medical reasons. Inherited characteristics may predispose the offspring to certain medical conditions. Knowing the medical history may help to get an early diagnosis and effective treatment for an inherited disease.
- for family relationships. Family secrets can undermine trust and lead to conflict and stress. They can also suggest to children (and others) that their parents are ashamed of how they were conceived.
- for donor-conceived people's future relationships. There is a small but real risk that two people who are genetic siblings could have children together without realising they were related. If parents tell their children they were donor-conceived they will be able to check this out.
- for donors. Donors are often curious about the children they may have created. Under the law they are able to find out from the clinic how many children were born as a result of their donation. They will not be able to identify them by name, however, although children will be able to find out who the donor was and may wish to contact them.

Critical thinking exercise

1. What are some of the ethical dilemmas around knowing the identity of a donor:
   - for the offspring?
   - for the donor parent?
2. Do you think this is the right way to approach egg donation? Or should the process be anonymous? Why?

Demographics of assisted reproduction

Following the introduction of assisted reproductive technologies (ART), including intracytoplasmic sperm injection (ICSI), in vitro fertilisation (IVF) and ovulation induction (OI) with clomiphene citrate or follicle-stimulating hormone (FSH), the past 20 years have seen a steady increase in multiple pregnancy rates (Bolton et al 2003). Rates for twins are increased by approximately 20 times and higher-order multiple pregnancies by 400 times in women undergoing treatment with ART. When compared with singleton births, twins have a six-fold increased risk of mortality and for triplets the risk is 10- to 20-fold higher. The proportion of multiple births that are the result of fertility treatments is unknown in New Zealand, as a result of inadequacies in birth record information (Bolton et al 2003).

In Australia

In Australia, among babies born in 2002, 2.3% were following the use of ART. These babies had a lower average birthweight than all Australian babies, with 20.9% of pregnancies being preterm. Almost half the women with ART pregnancies gave birth via caesarean section (49.4%). Of ART pregnancies there were 3845 singletons (79.1%), 988 sets of twins (20.3%) and 26 sets of triplets (0.5%). In total, 20.9% were multiple pregnancies.

Since 1979, assisted reproductive technology (ART) has been used in Australia to help couples achieve pregnancy. The main procedures used in ART treatment cycles include IVF, ICSI and GIFT. Data on treatment cycles and outcomes of pregnancy are collected annually from all 25 ART centres in Australia and four in New Zealand and collated into

an Australian and New Zealand assisted conception data collection. The data collection is funded by the Fertility Society of Australia and is maintained at the National Perinatal Statistics Unit (NPSU). Results of treatments and outcomes of pregnancies in previous years' treatments were reported annually in the past, from the Assisted Conception Data Collection (ACDC). With the implementation of the new Australian and New Zealand Assisted Reproduction Database (ANZARD) collection in 2002, the results of the treatments and their pregnancy outcomes can be reported as a single cohort in the same year in the AIHW Assisted Conception series (Laws & Sullivan 2004, p 61).

In 2002, the average age of women giving birth after ART treatment was 33.7 years, 4.3 years older than the average age of all Australian and New Zealand mothers (29.4 years). In 2002, the average duration of ART pregnancies was 37.6 weeks. Of all ART confinements, 20.9% were preterm, reflecting a much larger proportion of preterm births compared with all Australian births (7.0% preterm). The proportion of ART singleton babies that were preterm was 10.9%, compared with 58.2% for ART twins. For all Australian singletons, the proportion of preterm babies was 6.3% and for twins 52.9% (Laws & Sullivan 2004).

Mothers of ART babies had a higher incidence of caesarean section (49.4% of all ART births) compared with all Australian deliveries (27.0%). Since 1997, the caesarean section rate has been steadily increasing, from 41.9% to 49.4%. The average caesarean section rate between 1993 and 2002 was 44.4%, twice that of all Australian pregnancies during the same period (21.6%). In 2002, the average birthweight of all ART babies was 2943 grams, 415 grams lower than the average birthweight of all Australian babies (3358 grams). The proportion of ART babies of low birthweight (less than 2500 grams) was 24.1%, and of very low birthweight (less than 1500 grams), 5.3%. The proportions for all Australian babies in 2002 were 6.9% and 1.5%, respectively. The average birthweight for singleton ART babies was 3263 grams, 130 grams lower than the average birthweight of all singleton Australian babies (3393 grams) (Laws & Sullivan 2004, p 62).

Birth outcomes following ART

In vitro fertilisation was introduced into practice with little formal evaluation of its effects on the health of the children conceived with this procedure. Following the introduction of intracytoplasmic sperm injection in 1992, there was a concern that infants conceived with the use of assisted reproductive technology might have an increased risk of birth defects (Hansen et al 2002; te Velde et al 1998). A study published in the *New England Journal of Medicine* in 2002 (Hansen et al 2002) found that infants conceived with assisted reproductive technology were more than twice as likely as naturally conceived infants to have major birth anomalies diagnosed during the first year of life, and were also more likely to have multiple major anomalies. The increase in the risk of a major birth anomaly associated with assisted conception remained significant when only singleton or term singleton infants were

Scenario

Issues in assisted reproduction

The first case involved Lu and John B. who used in vitro fertilisation (IVF) with donor eggs and donor sperm. The embryos were subsequently implanted in a genetically unrelated woman (the 'surrogate' mother) for gestation and birth. The Bs intended to rear the resulting child as their own. Before the child, Jay, was born, the couple separated and John wanted to have nothing to do with the child.

In the first trial in this case the judge found that Jay was parentless [regardless of the fact that six adults had been involved in her 'production'].

This decision was reversed on appeal, and the appeals court decided that because, under California law, a husband who consents to his wife's artificial insemination becomes the legal father of the child, a husband and wife [should be] deemed the lawful parents of a child after a surrogate bears a biologically unrelated child on their behalf . . . [since] in each instance a child is procreated because a medical procedure was initiated and consented to by intended parents. Thus, the court concluded that Lu and John were Jay's legal parents. To make sure no one missed the analogy, the court expanded on it, stating that gestational surrogacy and artificial insemination are exactly analogous in this crucial respect: both contemplate the procreation of a child by the consent to a medical procedure of someone who intends to raise the child but who otherwise does not have any biological tie. The court did not like the idea of people who are responsible for the creation of a child turning around and disclaiming any responsibility after the child is born. Since the court believed that John 'caused' the birth of Jay simply by signing a contract, the court had no problem concluding that the same logic that made him the legal father made Lu (his wife at the time the contract with the surrogate mother was signed) the legal mother, since she agreed to the 'procreative project' at the start. The appeals court nonetheless concluded that 'things might work out for the best'. The court conceded that John may have agreed to the surrogate-mother arrangement simply 'as an accommodation to allow Lu to surmount a formality' but observed that 'human relationships are not static; things done merely to help one individual overcome a perceived legal obstacle sometimes become much more meaningful'.

There is no legal basis for such musings, according to George J Annas, writing in the *New England Journal of Medicine* (1998).

(Sources: Annas 1998; Buzzanca v. Buzzanca, 61 Cal. App. 4th 1410 1998)

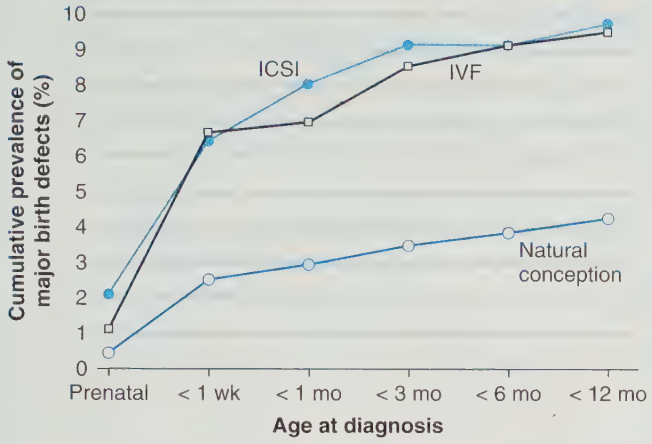


Figure 8.4 Cumulative prevalence of diagnosed major birth anomalies in singleton infants, according to age at diagnosis (based on Hansen et al 2002)

considered, as well as after adjustment for maternal age and parity, the sex of the infant, and correlation between siblings. Furthermore, the estimates of the prevalence of anomalies reported to the registry by one year of age in the assisted-conception groups were well in excess of the 6% prevalence of major birth anomalies (Hansen et al 2002, p 729).

An excess risk of major birth anomalies in infants conceived with assisted reproductive technology is plausible due to the older age of the couple concerned as well as the underlying cause of their infertility. The risk of anomalies may be associated with medications used to induce ovulation or to maintain the pregnancy in the early stages and factors associated with the procedures themselves. These procedures may involve freezing and thawing of embryos, the potential for polyspermic fertilisation, and the delayed fertilisation of the oocyte (Hansen et al 2002).

Complication rates

Complication rates in subfertile women have been ascribed to increased maternal age, lower parity and multiple births resulting from fertility treatment. A large population cohort of women attending a fertility clinic between 1989 and 1999 who subsequently delivered singletons were more likely to develop complications of pregnancy including pre-eclampsia and antepartum haemorrhage than the general obstetric population after adjustment for confounders such as age and parity (Thomson et al 2005). While the calculated relative risks for abruption and placenta praevia are high for subfertile women, the absolute increase in risks is extremely small. Only 0.5% more subfertile women had abruption and 0.7% more had placenta praevia than control women, indicating the importance of considering both the statistical and the clinical significance of any findings. Fertility treatment did not seem to affect the rate of maternal complications or the rates of obstetric intervention. The researchers found that subfertility did increase the risk of delivering by caesarean section, although this could be partially attributed to the anxiety surrounding these pregnancies, which may lower obstetricians' thresholds for intervention. The association between rates of complications and obstetric intervention by obstetricians has been noted before (Bell et al 2001).

Conclusion

Wide disparities exist in the availability, quality and delivery of infertility services between the resource-rich and resource-poor nations of the world. Approximately 80 million people worldwide are infertile. Most countries in the industrialised West have declining fertility rates marked by late marriage, postponed childbearing and primary infertility. In contrast, in the developing world, there is little voluntary effort to postpone childbearing, and early first marriage is common. However, a high prevalence of sexually transmitted infections and infections acquired as a result of inadequate healthcare result in increased rates of secondary infertility (Nachtigall 2006). In developing societies, childlessness is often highly stigmatised and leads to profound social suffering for infertile women in particular, yet most infertile people in the developing world have virtually no access to effective fertility treatment.

In countries such as New Zealand and Australia, however, in just over two decades, assisted reproduction techniques have evolved from a laboratory curiosity to a commercialised, industrialised technology responsible for thousands of births. Human reproduction has always been a matter of philosophical debate and social controversy. In resource-rich nations, the debate has grown more complicated through continued technical evolution. Both hopes and concerns have been raised simultaneously about the legitimacy of pre-embryo research, the slippery slope of pre-implantation embryo diagnostic testing and eugenic implications, and the fundamental and philosophical problem of the status of the embryo.

Among the resource-poor women of the world, an estimated 250 million years of productive life are lost every year as a result of reproductive health problems. The inability to determine when and how many children to have limits a woman's life choices (UN 2005). More than a decade after the 1994 Cairo International Conference on Population and Development (ICPD), and a global consensus that reproductive rights are central to human rights, sustainable development, gender equality and the empowerment of women (UN 2005), millions of women still do not have access to contraceptive services. Maternal mortality rates remain essentially unchanged and many women still die from complications of unsafe abortions. Both fertility and reproductive health problems remain the greatest burden of the world's poorest women.

Review questions

1. Name four reasons for infertility in women.
2. Name five major reasons for 'subfertility' or infertility in men.
3. What is ovulation induction (hormone treatment)? How would you describe this treatment to women?
4. What is artificial insemination (AI) using the partner's sperm and intra-uterine insemination (IUI)? How would you describe these processes?
5. What is the difference between gamete intra-fallopian transfer (GIFT), in vitro fertilisation (IVF) and intra-cytoplasmic sperm injection (ICSI)?
6. Do you think there should be a register of sperm donors? If so, what are the ethical issues associated with donor insemination?
7. Describe the issues identified in question 6 from the point of view of a male donor (father's point of view).
8. Describe the issues from the point of view of an adolescent wanting to trace her biological parents. Address the implications of the importance of genetic information.
9. What are some of the adverse outcomes of assisted reproduction for women? Have these changed over the past 10 years? If so, what has changed?
10. What are the risks of multiple births following assisted reproduction? Are these significantly different from those of multiple births following unassisted reproduction?

CHAPTER 9

Transitions

Jan Pincombe

Key terms

attachment theory, bonding, family health, life transitions, transition to fatherhood, transition to motherhood, transition to parenthood

Chapter overview

Having a baby is a life-changing event, and transition to the role of mother, parent or father has been described as both exhilarating and exhausting. This chapter explores some of the main aspects of life transitions to motherhood, family health and the transition to parenthood and fatherhood.

Learning outcomes

Learning outcomes for this chapter are:

1. To discuss the main theories concerning life transitions with respect to the birth of a baby
2. To highlight the importance of maternal–infant attachment and bonding
3. To provide information for expectant women on admission to maternity units or midwifery-led models of care
4. To discuss the role of men's transition to fatherhood.

Introduction

In this section we see that life transitions, including birth, becoming a mother, a parent or father, are generally accompanied by ritual, and that the rituals vary from society to society.

In the past, the birth of a baby was recognised as a major life transition. According to Levy-Shiff (1994) and Ball (1994), researchers have theorised that this time in a woman's life represents a period of crisis and a watershed in her life. However, more recently they have conceptualised birth in terms of developmental phases with associated 'personal, familial, social and more often professional changes' (Levy-Shiff 1994, p 591).

Draper (2003) examined the history of the development of transition, or what has been referred to as ritual theory, and discusses the theory of 'rites of passage' in her paper exploring men's transition to fatherhood. The seminal work carried out by anthropologist van Gennep (1960) argues that 'rites of passage' represent a way of understanding traditional societies' rituals and rites. He describes customary behaviour in these rituals and rites that go with 'changes of place, state, social position and age' (Froggat 1997, p 124) van Gennep (1960) proposes that common life cycle events include childbirth as well as puberty, marriage and death. He suggests that these customary behaviours consist of three main groups and that 'all rites of passage have a similar tripartite form of separation, transition and incorporation' (Froggatt 1997, p 124).

van Gennep's (1960) work analyses particular ceremonies that took place around pregnancy and childbirth in different cultures from writings during the 1880s, and as a consequence his work reflects the attitudes of that time. He writes how, in some cultures, the woman during her pregnancy is separated from her society, her family and at times even members of her own gender. He describes the period of pregnancy as one of transition, and ultimately with the birth of the child, the associated 'rites' that take place, the woman being reintegrated back into her society, often with an elevated place, often depending to some extent on the gender of her baby, with the birth of a son in many communities providing additional status for the woman. According to van Gennep (1960), transitional rites and ceremonies vary according to particular cultures. He also refers to the transition period as 'limen'. The limen 'constituted a boundary in its own right and time (and place) where the people passing through the rite are cut off from the wider structure of society' and represented 'a time and a place of withdrawal from the normal mode of social action' (Froggatt 1997, p 125). van Gennep's work was extended by Turner (1969, 1977, 1987). Turner differentiated between traditional and small-scale societies and suggested that 'liminial' be reserved for 'ritual and myth telling' and the term 'liminoid' be reserved to mean 'modern symbolic inversions and expressions of disorder' (Froggatt 1997, pp 125, 127).

In current writings, the theory of transition has also been linked to structural-functionalist roots by Draper (2003, p 66), who argues that despite this, transition theory can be seen to be useful as a framework for 'illuminating contemporary transitions across the life course'. Rituals are common in all cultures and are written about extensively by anthropologists, who associate rituals with transitional periods in life. Hospital culture is well known for its rituals. Midwifery researchers and scholars suggest that hospital rituals surrounding birth often do not support birthing women and their families, but rather favour hospital rules and regulations (Hunt & Symonds 1995; Kirkham 2000).

Philpin (2002, p 144) suggests that 'ritual' has been used in a negative way to refer to 'unthinking, routinised action by nurses, which lacks any empirical foundation'. She carried out an electronic data-based literature search from 1960 to 2000 to explore the term 'ritual', which revealed two broad themes: 'First, the complex issues surrounding the definition of ritual, including the relationship between rational and irrational action; and second, the purposes served by ritual' (Philpin 2002, p 144). Any exploration of the transition to motherhood must take into account these myths and rituals surrounding birth.

Transition to motherhood

Becoming a mother is recognised as a significant transition in the life of a woman, often giving rise to ambivalent feelings and emotions (Barclay et al 1997; Mercer 2004; Percival & McCourt 2000; Rogan et al 1997), and feelings of being ill prepared for the role (Schmied & Everitt 1996). Feminist Rich (1976), writing during the 1970s, promoted the idea that motherhood had the potential to provide a source of creativity and joy, although she also raised the issue that birth in contemporary industrial societies is often dominated by men.

Rogan and colleagues (1997) propose that there are three broad theories that underpin research and practice in the transition to early motherhood and the postpartum period. They assert that role attainment and its cognitive aspects reflect one theoretical approach (Rubin 1967a,b, 1984). Rubin's work encompasses two main aspects, namely attaining the maternal role and the recognition of the baby. She articulates the importance of the changes that take place when becoming a mother, and her work has been influential for some scholars in their approach to research on the postpartum period.

Another theoretical approach according to Rogan et al (1997, p 878) involves 'behavioural and psychosocial aspects of transition' and is illustrated in the work by Burr (1972) and Rossi (1968). Their sociological frameworks have been largely adopted by nursing and midwifery researchers and is typified by the work carried out by Mercer (1981, 1985, 2004), who examined aspects of parenthood that are impeded or enhanced by behavioural and psychological conditions that affect the transition to motherhood.

The third area described by Rogan et al (1997) encompasses 'emotional ties between mother and her infant' (Ainsworth

1962; Gottlieb 1978; Klaus & Kennel 1976, 1982; Rogan et al 1997, p 878). Essentially this work concerns attachment theories and bonding between mother and child.

Attachment and bonding with the baby

What is attachment?

Attachment theories provide a theoretical understanding of the importance of the bonding between mother and newborn. Attachment has been defined as 'the tendency of the young organism to seek closeness to particular individuals and to feel more secure in their presence' (Atkinson et al 1993, p A-31). What became known as attachment theory has antecedents in animal studies. One of the first recorded studies in the psychology literature to test out attachment was an experiment to investigate whether contact comfort was more important than feeding. Harlow and Zimmerman (1959) raised baby rhesus monkeys with surrogate mothers. Each baby had two 'mothers', one a food source and made of wire, the other with no food and made of cloth. The mothers were always available to the baby monkeys. The researchers found that the baby monkeys spent decreasing time with the wire mother monkey and increasing time with the cloth-covered mother. They also found that baby monkeys showed a tendency to use the 'cloth mother' from which to explore the environment, and when they were afraid they clung to the cloth mother. These findings were in contrast to the current theories of the time, which predicted that the babies would develop a stronger bond with the wire mother because it fed them. These experiments demonstrated the importance of bonding and the importance of the mother in being able to provide comfort to their offspring.

John Bowlby's work also built on the idea of attachment. He hypothesised a control systems model of attachment and provided, for the time, a very different approach to understanding the development of the mother (caregiver) and infant relationship (Broberg 2000). The aim of the system was to enhance survival and reproduction of the species (Bowlby 1969). To achieve this, the infant needed to maintain close proximity to the caregiver for protection against real or feared danger. Bowlby (1969) suggested that all infants who receive basic care from their caregiver developed some level of attachment. However, not all infants were able to access their caregiver as a secure base from which to explore their world, and the caregiver needed to be able to respond to the infant's attachment requirements. This came to be known as the caregiving system. More recently, research on the capacity of babies and young children to adapt positively to changed circumstances has been published and consistent. It is understood that children need kind, supportive care from one or more caregivers who may or may not be the mother. Bowlby (1980) later acknowledged that an infant may form selective attachments to a number of caregivers. Moreover, once established, the security of the parent/infant bond remains stable over time.

Ainsworth and colleagues (1978) were the first to provide descriptions of the caregiving system that is essential to the development of the attachment relationship. Ainsworth's work was based on the idea that parental stimulation, especially in response to the infant's signals, was critical in developing attachment. Further, she hypothesised that in developing maternal responsiveness between infant and mother, a secure base was established that allowed the infant to explore her or his environment and create an emotionally stable attachment. These studies were carried out in the context of a 'strange situation'. Infants separated or reunited with their primary caregiver responded in a particular pattern categorised as securely attached, avoidance behaviour or anxious/ambivalent behaviours. Those infants who were securely attached to their primary caregiver confidently explored their environment and used their caregiver as a secure base. The infants who were judged to be 'avoidant' explored their environment but ignored their caregiver on reunion. Anxious/ambivalent infants became anxious when separated and were reluctant to explore their environment (Ainsworth et al 1978).

More recently, animal studies in rats have demonstrated the positive effects of maternal care on baby rats. Specifically,

> i) a causal relationship between maternal behaviour and stress reactivity in the offspring and ii) the transmission of such individual differences in maternal behaviour from one generation of females to the next (Francis et al 1999, p 1155)

has been found. An earlier study by some members of this team (Lui et al 1997, p 1659) established, from their research, that those adult rats whose mothers demonstrated more licking and grooming of their pups in the first 10 days of life showed:

> reduced plasma adrenocorticotropic hormone and corticosterone responses to acute stress, increased hippocampal glucocorticoid receptor RNA expression, enhanced glucocorticoid feedback sensitivity and decreased levels of hypothalamic corticotropin-releasing hormone messenger RNA. Each measure was significantly correlated with the frequency of maternal licking and grooming (all r's > –0.6).

Studies of non-human mammals have been important as they have allowed examination of ways of promoting secure attachment between human mothers and infants in conditions that would have made observation difficult or experimentation unethical had humans been used. One study referring to the importance of animal experiments examined the effects of home visiting after the birth of a baby (Armstrong et al 1999), specifically looking at maternal–infant bonding during work on early home-based interventions. This work was predicated on the importance of the first few years of a child's life as a 'critical period' in the child's brain development (Wynder 1998). A randomised controlled trial (RCT) was carried out to investigate the effect of a home-visiting program in 181 families classified as vulnerable (Armstrong et al 1999). Recruitment to the trial was carried out using a self-report questionnaire called the Brisbane Evaluation of Needs Questionnaire (BENQ). This tool contained questions that identified families at risk. Two levels of risk identification were used. The first level consisted of 'physical domestic violence, identified childhood abuse of parent, sole parenthood, or ambivalence to the pregnancy

(sought termination, no antenatal care)' and the second level consisted of:

> maternal age of less than 18 years, unstable housing (three or more moves in the preceding 2 years), financial stress (often concerned about having adequate food, or making ends meet), less than 10 years of maternal education, low family income (< A$16,000 per annum), social isolation, history of mental health disorder, drug, or alcohol abuse (either parent) and domestic violence other than physical abuse; the presence of three or more of these risk factors enabled selection (Armstrong et al 1999, p 238).

Those families that met the inclusion criteria and gave informed written consent were randomised to a control group ($n = 91$) or the intervention group ($n = 90$). The intervention group received weekly home visits from a child health nurse for six weeks, fortnightly up to three months and then monthly up to six months. The intervention was multifaceted and consisted of the following aims:

> i) establish a relationship of trust with the infant's family; ii) enhance parenting self-esteem and confidence by reinforcement of success; iii) provide anticipatory guidance for normal child development problems such as crying or sleep behaviour variants; iv) promote preventative child healthcare; and v) facilitate access to appropriate community services (Armstrong et al 1999, p 238).

In addition to this, the child health nurse met with a social worker and paediatrician in a weekly case conference for the planning of care for the family and child. A variety of instruments were used to measure maternal and child health outcomes in this study group at six weeks postnatally. A 30-item self-report questionnaire called the Parent Questionnaire, the Edinburgh Post Natal Depression Scale (PNDS) (Cox et al 1987), Parent Domain (PD), which is a subset of the Parenting Stress Index (Abidin 1990), The HOME Inventory (Caldwell & Bradley 1984) and the Modified Patient Satisfaction Questionnaire (Ware et al 1976) were administered to both groups at six weeks. Significant differences were found between groups for postnatal depression, with the intervention group demonstrating better (lower) levels ($F1,169 = 7.35$, $p < 0.050$) than the control group. The scores for the PSI subscale that measured perception of parent–child interaction showed a statistically significant main effect ($F1,169 = 8.72$, $p < 0.05$), showing that there were better scores in the intervention group, illustrating higher levels of confidence among this group. The HOME inventory scores were better on all but one subscale for the intervention group ($p < 0.001$ to $p < 0.003$). Also, greater satisfaction levels were statistically significant in the intervention group for all subsets of the Modified Patient Satisfaction scale. The findings for this study showed the overall good effects of this targeted home-based intervention for vulnerable families.

Armstrong and colleagues (2000) carried out a follow-up of the RCT with participants at four months. The intervention group and the control group each consisted of 80 families. There were significant differences between the intervention group infants' immunisation status and the control group, with higher levels of completed immunisation in the intervention group ($p < 0.05$). The intervention group also self-reported fewer bruises and injuries.

The EPND scores at six weeks were better (lower) for the intervention group but were not maintained at the four months assessment interval. The total HOME score for the intervention group on all subscales showed better scores (statistically significant) than the control group. The researchers pointed out the positive effects of this intervention but argued for longer-term follow-up studies to confirm the results collected at six weeks and four months post partum.

A volunteer home-visiting program in the outer metropolitan area of Sydney using a phenomenological approach was carried out by Taggart et al (2000). The emphasis of this program was on implementing a volunteer home-visiting program to prevent child abuse and neglect. Interviews were carried out with the coordinator of the project, 10 volunteers and 15 mothers involved in the project. The descriptions of the experiences of the three groups were reported, with excerpts from the mothers' interviews. Emotional support was one of the main issues identified as being a critical issue. One example quoted in the paper consisted of the following:

> I had no family support, three children at home and was totally incapacitated after a traumatic birth, and my husband had to go interstate with work. It's really hard. I thought that I'd have to rely on friends, who have their own families. Both our Mums are old and live far away (M12) (Taggart et al 2000, p 5).

Friendship and motherhood was also one of the main themes, and it was important to these mothers that they were helped emotionally by being able to talk about their worries and having someone who would listen to them.

Involvement of midwives

Midwives have the opportunity to be intimately involved with promoting best midwifery practice in the following way. Immediately after the birth of their baby, mothers can be encouraged by midwives to hold their babies directly against their skin, thus encouraging bonding, maintaining the baby's optimum temperature and promoting the initiation of breast feeding within one hour of the baby's birth (Ashmore 2001).

Kangaroo mother care, or skin-to-skin contact, has been found to have beneficial effects for both mother and baby. It has been described in the following way: the baby is held in an upright position by the mother, with skin-to-skin and chest-to-chest contact, and held between her breasts for approximately one to two hours (Ludington-Hoe 1993). In

Reflective exercise

Reflect on what you can do as a midwife to promote bonding between the woman and her baby immediately after birth. This may require providing strategies to encourage the maintenance of a quiet and secure environment in what is a sometimes a noisy place for having a baby.

a RCT with low birthweight babies randomised to kangaroo mother care versus traditional care 'kangaroo care' has been found to be safe to use with low birthweight babies whose diagnosis is considered clinically stable (Charpak et al 1997; Ruiz-Pelaez et al 2004).

Maternal role attainment and adjustment

Maternal role attainment and adjustment has a history of development that is recorded in the North American literature and has also been adopted by some Australian midwifery researchers. In this section the North American background, followed by Australian studies and their relevance to midwifery, is reviewed.

According to Rubin (1975), a consistent American view of motherhood expressed during the 1960s and 1970s was that after the birth of a baby everyone lived happily ever after. Rubin (1975) argued that this attitude was responsible for shorter hospital stays for birthing women during the period from 1960 to 1986. Reviews of the effects of early discharge during this time reflected mainly the experiences of women who had had extensive prenatal education and postnatal follow-up, with little research into 'the needs and experiences of low-risk puerperal women' (Ruchala & Halstead 1994, p 83).

Ruchala and Halstead (1994) point out that a complication of reduced length of hospital stay after birth was that little time was available for mother–infant relationships to be assessed by midwifery staff. They reported that women experiencing uncomplicated births were discharged from 12 to 48 hours after the birth of their baby. They carried out interviews with 50 women in their homes two weeks after discharge from the maternity unit. The results from the coding of the interview data demonstrated that the majority of the women indicated that postnatally their experiences were 'hectic' and consisted of 'a time of adjustment' (Ruchala & Halstead 1994, p 85). Postnatal fatigue was also reported as a major part of their experiences, with 22 (44%) of the women expressing this view and how it adversely affected their relationship with their partner and other family members. Six (24%) of the primiparous women and 8 (32%) multiparous women stated that they experienced 'crying' episodes. The authors concluded that many mothers reported fatigue and still had emotional and physical concerns connected to the birth of their baby to deal with. They suggested that mothers should be supported with follow-up telephone calls and to encourage women to participate in support groups.

The relationship between maternal role attainment and postpartum depression was explored by Fowles (1997). She recruited 168 primiparous women during the last trimester of their antenatal period, with 136 of those women participating in her study and completing standardised questionnaires 9–14 weeks after the birth of their baby. Each of the women completed four questionnaires—the Edinburgh Postnatal Depression Scale (EPDN) and three questionnaires that investigated maternal role attainment, namely the 'Myself as Mother Scale'.

The 'My Baby Scale' reported re-test reliability estimates ranging from 0.64 to 0.77 and estimated each mother's evaluation of her infant. The Perceived Competence Scale, which assessed mothers' views of their competence in feeding and infant care, demonstrated a Cronbachs' Alpha ranging from 0.83 to 0.93. Fowles found that 'maternal depression had a negative relationship with women's confidence in the mothering role' (Fowles 1997, p 90).

The implications for practice were that most mothers felt confident by four months in their mothering, supporting the earlier work by Mercer (1985). However, she suggested that 2–3 months after the birth of their baby, women should be evaluated for postnatal depression. She also indicated the importance of role models for women so that they can be exposed to appropriate parenting behaviours to instill feelings of confidence in the new mother.

This section has explored the work of theorists who have supported a maternal role attainment approach. However, Mercer (2004) recently expressed the view that perhaps the term 'becoming a mother' more completely reflects the transition to motherhood theory. This is demonstrated in one of her recent articles, where she writes:

> Women's descriptions of the life-transforming experience in becoming a mother with concomitant growth, development and new self-definition are not adequately encompassed in MRA terminology. The maternal persona continues to evolve as the child's developmental challenges and life's realities lead to disruptions in the mother's feelings of competence and self-confidence. The argument is made to replace 'maternal role attainment' with 'becoming a mother' to connote the initial transformation and continuing growth of the mother identity (Mercer 2004, p 231).

The view Mercer reflects in this most recent article is more aligned with Australian midwifery researchers and scholars, such as the work by Barclay et al (1997), who support the 'becoming a mother' theoretical stance.

Studies examining mothers' readiness to assume their role

Various research studies have explored women's readiness to assume their mothering role. The functional status of first-time mothers was investigated by McVeigh (2000) in an Australian-based study. McVeigh and Charboyer (2002, p 107) defined 'functional status' in a later study as 'mothers' readiness to assume infant care responsibilities and resume self-care, household, social and community, and occupational activities'.

McVeigh (2000) explored the relationship between anxiety and functional status in first-time mothers. Her work was based on earlier research by Fawcett et al (1988), who developed a multidimensional measurement instrument they called Functional Status After Childbirth (IFSAC). The tool consisted of a 36-item scale and was found to have an inter-rater reliability estimate of 97% and a Cronbach's alpha of 0.70 (Fawcett et al 1988).

McVeigh (2000) sent the IFSAC questionnaire to 200 first-time mothers residing in a regional health area of New

South Wales, who attended maternal child health centres. The Speilberger State Anxiety Inventory (Speilberger 1983) and a short socio-demographic questionnaire were also included in the package sent to each participant. The response rate was 86% ($n = 173$) at six weeks, with 73% ($n = 146$) responding at three months and 71% ($n = 142$) at six months. At six weeks the results showed a 'significant inverse relationship between total functional status score and maternal anxiety ($p = 0.015$), social and community activities and maternal anxiety ($r = -0.234$, $p = 0.002$) and self-care and maternal anxiety ($r = -0.226$, $p = 0.003$)' (McVeigh 2000, p 16).

Although the statistical results were slightly different at three months and six months, they were also significant at these points. Also, mothers who were found to be highly anxious were also found to have babies who were more likely to be unsettled ($p < 0.001$) and babies who were more likely to sleep less at night ($p < 0.001$). These mothers were also more dissatisfied with their role ($p < 0.0001$). McVeigh (2000) suggested that the implementation of continuity midwifery-led models of care may offer midwives a better opportunity to identify women at risk of maternal anxiety. She also recommended that midwives be involved in the design and introduction of programs to identify maternal anxiety in expectant and postpartum women in order to improve satisfaction with being a mother.

Applications to midwifery practice

Midwives can support women after the birth of their baby by listening to what women have to say. Gamble and colleagues (2004) discuss counselling processes that can assist those women who experience psychological distress following childbirth. In their study they investigated strategies used by 16 midwives during counselling with women after the birth of their baby. The analysis of the interviews revealed three main themes. The first consisted of 'opportunities to talk about the birth'. Midwives indicated that although they were familiar with the term 'debriefing' they preferred to use an approach that consisted of a 'woman-led discussion' (Gamble et al 2004, p 18). This technique allowed for input from the midwife as required. Midwives also suggested that women should have the opportunity to discuss their birthing experience when they are ready to, and more than once if required. The second theme was 'developing an understanding of events', and midwives suggested that going though the 'labour record with them' was a useful approach (Gamble et al 2004, p 18). They also suggested that, in the event of an operative procedure, the medical officer should debrief the woman. The third theme was that of 'minimising feelings of guilt', and midwives strongly supported the view that women should not see themselves as 'failing' and that positive affirmations and suggestions should be given to women, such as, 'I think that was a very good decision' (Gamble et al 2004, p 18).

Transition to parenthood

Vimpani (2001) has claimed that parenting is a vital public health priority facing Western societies. The transition to parenthood, according to de Montigny and Lacharite (2003), has been a focus for study for more than 50 years, with most studies concentrating on the role of the mother.

Education for parenthood

Evidence from the literature suggests that, in preparation for parenthood, information about parenthood provided by health professionals during prenatal classes is oriented around the birth of the baby. This has resulted in postnatal issues being insufficiently covered (Nolan 1997; O'Meara 1993). Nolan (1997, p 26) recommends that pregnant women be given more information about practical baby-care skills and opportunities to discuss 'postnatal emotional issues' during antenatal classes. Collington (1998) discusses the importance of midwives being able to provide educational advice to parents about all aspects of pregnancy care, so that parents can make informed choices about care and thereby be empowered.

Coming in for the birth of the baby

Maternity hospitals provide literature for pregnant women and their partners during the antenatal period, and information about when women should contact their midwife. For example, women who book into one of the maternity hospitals in Adelaide, South Australia, are advised that:

- if more than 20 weeks pregnant, the woman should contact her midwife if in a Midwifery Group Practice (MGP) or the midwife in the delivery suite
- if less than 20 weeks pregnant she should contact the midwife in the Women's Assessment Service (WAS).

Women are provided with information about signs or feelings that they might experience which should lead them to come into the maternity unit. For example, the maternity teaching hospital in Adelaide also encourages women to contact the hospital if they experience any of the following:

- Their water breaks (even though they may not be experiencing contractions).
- The contractions are regular.
- They are experiencing increasing abdominal discomfort.
- There is any blood loss.
- The baby's movements reduce.
- They are uncertain of what is happening.
- They are concerned or anxious.

Women are also given a list of suggested requirements for their baby, which they are advised to bring in with them (see Box 9.1). They are also requested to bring their pregnancy health record with them. This 'hand held record' contains confidential information about their progress during pregnancy. In some states of Australia this data is now entered into an electronic database.

BOX 9.1 Advice given to expectant mothers

Things to bring to hospital:

- your Pregnancy Hand Held Record
- your birth plan
- things you might choose to use in labour (discussed in antenatal classes), e.g. a selection of music tapes or CDs
- casual clothes to wear during the day if desired
- 2 night dresses (minimum)
- dressing gown and slippers
- 2 maternity bras
- plenty of comfortable underpants
- cordial if desired
- pen
- toiletries, e.g. soap, shampoo, toothbrush and toothpaste
- 1 large box of tissues
- 1 box of nipple pads/washable nursing pads
- 4 packets of sanitary pads
- your own pillow if desired.

For your baby:

- 40 disposable nappies or
- fasteners/nappy pins if you are going to use cloth nappies (Cloth nappies are provided by the hospital if you do not wish to use disposable nappies.)
- 6 pilchers (not plastic) if using cloth nappies
- baby care products for your baby while in hospital—for example, baby wipes and gentle lotions or creams (optional)
- mittens (optional).

(Source: *Having your Baby at the Women's and Children's Hospital* 2003, pp 16, 17)

In New Zealand all women hold their own notes and there are moves to standardise these notes based on the New Zealand College of Midwives Maternity Notes. These documents will provide three records within the one set of notes—one for the woman, one for the midwife and one for data collection and payment purposes.

Mothers' postnatal needs not being met

Research into women's transition to motherhood has demonstrated that many women are often unprepared for the transition to parenthood, and particularly for postnatal self-care and baby care. Several studies have also found that women's postnatal needs are not being met (Cook & Stacey 2003; Henderson 2000; McKellar et al 2002). The National Health and Medical Research Council (1996) suggests that many women feel abandoned during the postpartum period.

Dissatisfaction with postnatal experiences was voiced by women in a study carried out in the United Kingdom (Ockelford et al 2004). An at-home interview conducted with 39 multiparous and primiparous 'white' and Indian women 13 weeks after the birth of their babies was carried out to investigate women's views about their postnatal experiences at two time points retrospectively. The first time point for women's views about their experiences was their immediate postnatal stay, and the second was as they were leaving to go home. The most mentioned problem for women during their early postpartum stay was shortages of midwifery staff and the resultant lack of attention to the care of their baby and their own wellbeing. Some women indicated that that was a reason for leaving the postnatal ward earlier than they had planned. Their recorded experiences of leaving hospital and going home reflected their feelings of difficulties with the transition from postnatal stay to home with a new baby.

Teaching mothering skills

Postnatal research in Australia has shown that women experience feelings of exhaustion, often linked to shorter length of postnatal stay in traditional care situations. This trend, according to Maloni (1994), has provided fewer opportunities for teaching mothering skills. Other reasons for new mothers to be less exposed to mothering are the greater percentage of women working until the birth of their baby, and growing mobility leading to greater geographic distance from relatives.

In most states of Australia, postnatal early discharge is common after childbirth and in some states, 'mothers in the public healthcare system undergo mandatory early discharge' (Emmanuel et al 2001, p 16). Various reasons have been proposed, that have been associated with encouraging early postnatal discharge. They have included economically driven requirements (Buist 1997). In some cases it has been due to women's choice (Nolan 1997). Buist (1997) reported in an article published in the *Australian Medical Journal* that early discharge rates had increased to 32% of mothers in 1994 from 20.2% in 1991.

Some studies have found that early discharge is as safe as traditional postnatal stays (Grullon & Grimes 1997). Women's satisfaction with early postnatal stays has been investigated by Carty and Bradley (1990), who found that the group of women discharged early at 12–24 hours were more satisfied with midwifery care than those in the four-day postnatal stay group. The first group was designated to 12–24 hour early discharge with four home visits, the second group was discharged at 25–48 hours with three home visits, and the third group had a four-day stay and received one home visit. The variation in the number of home visits and the small sample size ($n = 131$) may have confounded the results, so caution needs to be exercised with these findings.

The influence of shorter length of postnatal stay on women's breastfeeding duration at six weeks post partum and maternal depression at five to eight months has been investigated by Brown et al (2004) in three population-based surveys. They studied women who birthed in Victoria, Australia, during '1 week in 1989, 2 weeks in 1993 and 2 weeks in 1999' (Brown et al 2004, p 202). The response rate for each survey point was 71.4% (790/1107) for 1989, 62.5% (1336/2138) for 1993 and 67% (1616/2412) in 1999. They found that at the end of the 1990s, the standard length of stay was two to three days for a public patient, although women with private health insurance had five days or longer postnatal stays. Only 27% of privately

insured women in the survey were discharged earlier than five days postnatally. There were no significant differences between women's responses in the three surveys for shorter length of stay, depression and breastfeeding duration at six weeks.

A systematic review of the literature by Brown et al (2005) examined eight trials with 3600 women who were discharged early from maternity hospitals. Their results were inconclusive. There was no evidence to support any adverse findings with respect to early discharge, but due to limitations caused by methodological problems this could not be entirely ruled out. They also indicated that the importance of the effect of support at home by a midwife was as yet unclear. They recommended that large trials investigating the effect of early discharge be carried out (Brown et al 2005).

Early discharge from maternity services was one aspect reported in the *Review of Maternity Services in New Zealand* (National Health Committee 1999). A postal survey was completed by 11,511 women and a telephone survey was conducted with 1000 women who had recently had a baby in New Zealand . Results from the survey showed that 'nearly 10% of mothers in New Zealand are now discharged home on the day of delivery', and that 'two thirds of respondents had hospital stays of between two and five days, with 22% having a stay of one day or less' (National Health Committee 1999, p 24). Although 82% of women reported that they had a choice with respect to how long they stayed in hospital, most women indicated that there was pressure to leave quickly or the 'understaffed postnatal wards provided incentives to leave' (National Health Committee 1999, p 24). The quality of the hospital environment and postnatal hospital care left room for considerable improvement, according to women who responded to the surveys. However, those women who had a lead maternity caregiver (LMC) and rural women recorded higher satisfaction levels with their hospital care than other women who did not have an LMC or came from a non-rural area.

In 2003, the Ministry of Health published the outcomes of the Maternity Services Consumer Satisfaction Survey, a follow-up to the 1999 survey. This evaluation adopted similar methods to the 1999 survey for comparative purposes. It included some minor changes which incorporated three new questions and some improvements to several existing survey questions (Ministry of Health 2003).

The 2003 survey reported on the views of 2909 New Zealand women who gave birth between February and March 2002. The findings from the survey indicated that although the maternity services framework had not changed since the 1999 survey, responses from women confirmed that it was essential that they choose an LMC. Women also indicated the importance of having a vital role in decision-making about their care as well as opportunities for choices about their care.

The importance of parent group support has been heightened due to early discharge of women and their babies from maternity units (Hanna et al 2002). Notwithstanding the contribution of community-based midwifery services, parent groups are particularly important for first-time parents, according to these writers. In Australia, various levels of government funding are provided for formal parenting courses, through which informal groups can be formed, or for directly arranging or expediting meetings of new parents. For example, in Victoria, Australia, women are provided with eight sessions concentrating on 'parenting skills, relationship development and social support in order to increase confidence and skills in parenting' (Hanna et al 2002, p 209).

Family health

Policies to improve family health have been legislated by Australian state governments (for example, in South Australia, 'Every chance for every child. Making the early years count. A framework for early childhood services in South Australia 2003–2004', Department of Human Services 2003). The Australian federal government has also developed legislation to improve family health (see 'Participation Support for a More Equitable Society', Department of Family and Community Services 2000; and in Sydney, '"Families first" outcomes evaluation framework', Fisher et al 2002).

New Zealand also has extensive legislative reforms articulated in various reports to advocate and support New Zealand families (for example, see 'New Zealand Families Today', Ministry of Social Development 2004).

Improving family health through education

A Cochrane Review that investigated postnatal parental education for improving family health was carried out by Gagnon and Barkum (2003). They acknowledged that the transition to parenthood was both exciting and overwhelming, and suggested that parents may receive an overload of information during prenatal classes and may not assimilate postnatal information during this time. They also suggested that early discharge from maternity units may also contribute to deficits in new parents' knowledge about self-care and care for their newborns.

McKellar and colleagues (2002), using action research methods, investigated a strategy to enhance postnatal education for new mothers. Focus groups were carried out with six midwives and seven first-time mothers to find out their views about how information to improve postnatal information could be presented to new mothers. From the thematic analysis of the focus groups, a written educational resource was designed. One theme indicated that respondents believed that consistent and relevant information was important. Mothers indicated that developing knowledge and confidence in caring for their baby—that is, baby-care and self-care—were the most important aspects. The educational resource was designed from this information. Women also revealed that because midwives did not have sufficient time to spend with first-time mothers, this presented a significant factor in preventing women from being able to effectively learn to care for their baby and to learn about their own care.

A questionnaire was then developed to find out women's views about the effectiveness of the resource. Seventeen

mothers were surveyed and the results indicated that they believed that the resource was easy to read and contained clear and helpful information without the need to read through an extensive amount of literature. Importantly, 81.70% of women felt that the education resource had contributed to their confidence in providing baby-care and self-care (McKellar et al 2002). It should be noted, however, that the number of women surveyed was very small and therefore caution should be exercised regarding any generalisation to other populations.

According to Brown et al (2002), after the birth of a baby, education and interventions vary considerably, with birth mainly taking place in institutional settings in Western countries. However, globally, for most women birth takes place in the home, where education is provided mainly by informal structures, which can be immediate female members of the family and extended family (Moran et al 1997).

Maternity payment

Family health has been linked to socio-economic status and historically the maternity payment provided to women in Australia for having a baby was referred to as a 'baby bonus'. It was first introduced in Australia by the federal government in 1912 at the sum of five pounds (Thompson 2004). The authorities at the time believed that:

> It would increase the declining birthrate; diminish maternal and infantile mortality, and make childbearing safer for women. In the nine years following its introduction, the birth rate steadily decreased. There was no substantial reduction in the maternal or infantile death rates, and the number of women attended in childbirth by a doctor greatly increased—medical attendance was greater in the State of Victoria despite the Midwives' Act in Victoria (Kingston 1977, cited in Thompson 2004, p 17).

Maternity payment guidelines in Australia are outlined on the Australian Government, Family Assistance, website (see the list of online resources at the end of this chapter). The purpose is outlined and it is stated that maternity payment is not income-tested, can be made as a lump-sum payment and replaces the 'existing maternity allowance and the Baby Bonus'. Eligibility for maternity payment is outlined on the website as:

> A parent of a baby if the parent meets all other eligibility criteria at any time within 13 weeks of the baby's birth; or
>
> A parent of a stillborn baby if the parent would have met all the other criteria if the baby had not been stillborn; or
>
> A claimant who is entrusted with the care of a newborn baby if the claimant meets all other eligibility criteria within 13 weeks of the baby's birth and if the claimant is likely to continue to have care of the child for no less than 12 weeks; or
>
> A claimant who, before a baby is 26 weeks of age, has the baby entrusted to their care because the claimant will be adopting the baby, provided the claimant meets all other eligibility criteria within 13 weeks of the baby coming into the care of the claimant.
> (http://www.familyassist.gov.au/Internet/fao/fao.nsf/content/publications-factsheets-m...4/12/2005, p 1)

Further eligibility criteria:

> the claimant and the baby must meet Australian residency requirements
>
> the claimant must be legally responsible, either alone or with another adult, for the day-to-day care, welfare and development of the baby; and
>
> the claimant must satisfy tax file number requirements; and
>
> the claimant must lodge an effective claim within 26 weeks of the baby's birth or, in the case of adopting parents, within 26 weeks of the baby coming into their care.

These eligibility criteria change from time to time and midwives should encourage women to check the website for up-to-date information. This is particularly important, as documentation is required to be submitted to government agencies in a timely manner in order to register for benefits.

Maternity care is free to all New Zealand women, although private obstetricians are entitled to charge women for care.

In New Zealand, a 'maternity payment' is not provided to parents but a variety of possible benefits are available to women and families who meet certain criteria. For example, the Domestic Purposes Benefit is available to sole parents (mothers or fathers). A sickness benefit is available for those who have had to stop working or reduce their working hours due to sickness, injury, pregnancy or disability. Low- and middle-income families can access the Childcare Subsidy program and the OSCAR Subsidy to help pay for early childcare and after-school programs. Working for Families is a package of financial support designed to assist low- and middle-income families to work and raise a family. Further details about available subsidies can be found through the New Zealand Ministry of Social Development website (see online resources at the end of this chapter).

Men's transition to parenthood

Draper (2003) writes about the importance of men's transition to fatherhood as being an integral part of their partners' transition to motherhood. She suggests that this transition needs to be viewed within the context of understanding that it is represented as a matrix and encompasses the baby, siblings and grandparents as well as the father.

Fathers' attendance at their babies' birth

According to Dellman (2004, p 20), during the early 1900s, anthropologists recorded various instances of fathers' 'bizarre behaviour' during their wives' labour, with the husbands not attending the actual birth but participating in ceremonies. For example, in one reported ceremony this behaviour involved 'building bridges for the infant's soul'.

In Western societies in the late twentieth and early twenty-first centuries, men's attendance at the birth of their baby has been shown to be high—approximately 96% of men are reported to have attended their partner giving birth (Dellman

2004). Interestingly, Odent (1996), who is well known for his early work on encouraging the presence of the father at birth, has more recently suggested that 'men should be kept away from the birth' as in his view they increase the levels of stress in their partner and slow down their partner's labour (Neile 1997, p 120). Odent has also commented that 'the labouring woman doesn't need support' (Odent 1996, p 46). Odent (cited in Walters & Kirkham 1997, p 105) also states that:

> Men sometimes find it hard to observe, accept and understand a woman's instinctive behaviour during childbirth. Instead they often try to keep her from slipping out of a rational, self controlled state . . . it is not mere coincidence that in all traditional societies women in labour are assisted not by men but by other women who have had children themselves.

However, Vehvilainen-Julkunen & Liukkonen (1998, pp 10–11) report in their paper on transformation from man to father that 'fathers appreciate being asked about their experiences and opinions' and that 'the presence of fathers at childbirth has been shown to be a highlight in the life of both parents'.

Walters and Kirkham (1997) also write about the father's presence at birth, and indicate that major changes have occurred since the 1950s when, they argue, it would have been a radical event if the father had been present at the birth. They suggest that by the 1980s, the father's attendance at the birth was expected. However, by the 1990s there were reports of the experience of birth being 'overwhelming' and suggestions that a doula can provide positive strategies to the partner so the partner can assist the woman and be supported as well (Walters & Kirkham 1997, p 105).

Studies examining the transition to fatherhood

Researchers claim that studies have focused more on the role of the mother, with little research addressing men's attitudes to their partner's pregnancy (Thomas & Upton 2000). However, due to changes in society, with more men attending antenatal classes with their partners and the birth, there has been a small trend towards examining the role of the father (Dellman 2004). This is reflected in the following studies.

A qualitative study was carried out by Barclay and Lupton (1999) into the experiences of 15 first-time Australian fathers in a series of semi-structured interviews carried out over four time-points. The first interview was done just prior to the birth of the baby and three interviews were carried out post birth over five to six months. Although the majority of the men interviewed looked forward to fatherhood, some men found it 'more uncomfortable than rewarding' (Barclay & Lupton 1999, p 1013). Discourse analysis was applied to the textual data and some themes were revealed in their comments about bonding. For example, one father reported that bonding with his infant did not occur immediately. The following is an extract of comments by 'Juan' (Barclay & Lupton 1999, p 1017):

> I thought as a father there would be a bond there straight away with the child. I thought it would just come naturally. I thought because he was mine I was going to be immediately attracted to this child and love would come naturally. I was surprised I wasn't overcome with feelings for him straight away.

A change in the relationship between partners was also a theme. Positive and negative aspects from the participants' interviews were recorded by researchers. However, 'Peter's' comments demonstrated simple pleasures in being involved in his changed role. He indicated that:

> We'll go down to . . . a local park and take the baby and the dog with us. We try to do this every second, if not each weekend. We usually go about lunch time when there is no one else around, we just take some sandwiches and water for the dog and enjoy ourselves' (Barclay & Lupton 1999, p 1018).

Barclay and Lupton (1999, p 1019) stated how, in the future, the 'new fatherhood' might be achieved, and that structural and societal changes would be needed in Western society in order for this change to occur. In their view, 'mutually supportive and enriching early parenting is currently unachievable' (Barclay & Lupton 1999, p 1019). Further, they argued that this was not due to men not wishing to be involved in 'close, caring relationships with their infants' but more about how 'fatherhood is represented and understood' (Barclay & Lupton 1999, pp 1019–1020).

A survey carried out by Vehvilainen-Julkunen and Liukkonen (1998) with 137 fathers attending the birth of their baby in a university hospital in Finland showed a response rate of 81% (n = 107). Younger fathers reported feeling uncomfortable during the birth more often than others.

A grounded theory approach was used by Barclay et al (1996) to study 53 first-time fathers who attended antenatal clinics with their partners. The resultant analysis of the textual data revealed five categories—'anxiety, ambivalence, adjustment, separation and need to know'—and the core category was defined as 'development' (Barclay et al 1996, p 14). 'Development' represented one of the more positive categories, and the authors indicated that in their interviews, the men stated concepts such as 'excitement, growth of self and of relationships with partner, expected child and their family involvement and closeness' (Barclay et al 1996, p 20).

Baafi and colleagues (2001) argued that midwives should be encouraged to understand the impact that a new baby has on the father, and that men should be afforded greater recognition during this period. They suggested that during the transition to fatherhood, men should be encouraged to develop strategies to deal with their role. The authors administered a quantitative survey to 204 men residing in a regional area health service in New South Wales. Data were collected at three and six months, and a response rate of 63% (n = 128) was recorded. Early results showed that 94% of men who responded were satisfied most of the time with their role of fatherhood.

First-time fathers' adjustment to their role and factors affecting their transition were investigated by Buist et al (2002). Two hundred and twenty men were recruited from a large maternity teaching hospital in Melbourne, Australia. The researchers used a longitudinal repeated measures design that included questionnaires assessing 'parity history, social support, marital satisfaction, anger, anxiety and gender

role stress' at a prenatal interview, followed by interviews postnatally at four months after the birth of their baby (Buist et al 2002, p 172). Prenatal and postnatal distress was measured using the EPDS. The most distressing time for men was experienced at the time of their first interview, which was held during their partners' prenatal period; this was especially so for those men who were younger, employed part-time and who had been in shorter relationships. Distress was reported to become less during the postnatal period, although it was shown to negatively affect the attachment of men to their infant. However, the transition to fatherhood for most men was dealt with effectively. The authors suggested that problems with transition to parenthood could be reduced if attention was paid to men's anxieties antenatally.

These studies suggest that the transition to fatherhood represented profound changes in men's lives. This was particularly so for first-time fathers, who experienced issues relating to changes in their relationship with their partner.

Ways in which midwives can involve fathers

Midwives can facilitate the establishment of communication between father and baby by suggesting the use of baby massage (Whitehouse 2001). Mackereth (2003) writes about teaching fathers baby massage, and although only one father took part in the study, the case study that is reported suggested that 'Mike' (the father) found good effects from the first time he used the massage technique. These good effects had benefits for all members in the family. This was demonstrated when their baby, who also had eczema, slept through the night after the massage for the first time.

With Mike, the only father, in the four case studies, his overwhelming concerns were problems with the baby waking frequently during the night and her eczema, which was being treated with a cream containing 1% hydrocortisone. Both the parents and the infant were not resting fully. Mike reported that this had left both their baby and themselves tired and irritated during the day—this was their first child. Mike reported that following the first massage session his baby slept through the night for the first time. In the group sessions he reported that she had slept every night without disturbance since massage had become part of the daily routine. Importantly, he also reported that her eczema had also improved, possibly from a combination of the massage with oil and the improved sleep. Mike said that carrying out the massage session was their quality time, doing something together, which was not centred on changing nappies or feeding, it was also a time to interact, notice developmental changes and play. Joining the baby massage classes also provided opportunities to meet other parents and see his baby start to play with others (Mackereth 2003, p 150).

Conclusion

This chapter has presented some of the main aspects of life transitions—transition to motherhood, transition to parenthood, family health and men's transition to fatherhood. The evidence suggests that this is a time of great change for women, their babies and families. The challenge for midwives is to ensure that women, their babies and families are supported and provided with information that will assist them to be competent and confident mothers.

Review questions

1. Explain the role of rites and rituals in childbirth and the transition to parenthood.
2. Describe the major attachment theories relating to maternal and infant bonding.
3. Discuss how kangaroo mother care can assist in bonding between mother and newborn.
4. Briefly list the main maternal role and attainment theories.
5. Describe actions that midwives can apply when women experience psychological distress after the birth of their baby.
6. Describe the signs and feelings that women experience that should lead them to come into the maternity unit.
7. Discuss the importance of teaching mothering skills to women in the immediate postpartum period.
8. Discuss the effects of shorter length of stays for mothers on breastfeeding outcomes.
9. Describe eligibility for maternity payments for Australian and New Zealand women.
10. Discuss strategies that midwives can use to include men in the parenting role.

SECTION THREE THE MIDWIFE

CHAPTER 10

Professional frameworks for practice in Australia and New Zealand

Sally Pairman and Roslyn Donnellan-Fernandez

Key terms

Australian College of Midwives, Australian Midwifery Action Project, code of ethics, code of practice, competencies, New Zealand College of Midwives, maternity services, medicalisation, midwifery regulation, professionalism, Register of Midwives, regulatory framework, standards of practice

Chapter overview

This chapter outlines current and evolving professional and regulatory frameworks guiding midwifery practice in Australia and New Zealand. While professional frameworks for midwifery arise from the profession itself, regulatory frameworks reflect societal understandings of midwifery and wider interests than those of midwifery alone. Regulatory frameworks provide the statutory boundaries for midwifery practice and define the extent of professional autonomy each state affords to midwifery. This chapter explains the relationships between regulatory and professional frameworks in both countries and how these frameworks affect midwifery practice.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe current and evolving professional frameworks that guide midwifery practice in Australia and New Zealand
2. To describe the links between definition and scope of practice of a midwife, philosophy, code of ethics, and standards for practice with midwifery standards review and recertification (NZ), and continuing professional development (Australia)
3. To articulate an understanding of the term 'professionalism' and differentiate between 'old' and 'new' professions
4. To articulate differentiations in the development of the midwifery profession in New Zealand and Australia, with respect to history, role, functions and structure
5. To differentiate between midwifery regulation in New Zealand and midwifery regulation in Australia, and express an understanding of regulatory principles in common
6. To describe the role and function of the Midwifery Council of New Zealand and the various regulatory authorities for midwifery in Australia
7. To explain the relationship between regulatory and professional frameworks and their application to midwifery practice.

Introduction

As a health profession, midwifery in both Australia and New Zealand is governed by legislation that determines, to a greater or lesser extent, the scope of midwifery practice, the level of midwifery autonomy, processes for entering the profession (registration), expected standards for practice (competencies), and mechanisms for accountability and regulatory control. The purpose of this regulatory framework is to ensure the safety of the public by ensuring that midwives are appropriately qualified, competent and safe to practise midwifery. The legislation reflects society's understanding of and assumptions about midwifery at the time the legislation was enacted. The effect of such legislation is to determine how midwifery interfaces with other providers of maternity services, how midwifery fits within the structures of maternity and health services, and the extent of its professional jurisdiction. Particularly in the case of Australia, regulatory legislation does not necessarily reflect current midwifery practice or, indeed, women's views of the kinds of midwifery services they wish to receive. It may well reflect the interests of other professional groups such as medicine, or of the state, in determining the direction of maternity services. Indeed, 'as both a licensing authority and a source of funding, the state can enhance or diminish the control that an occupation or profession has at any given time over the provision of particular services' (Tully 1999, p 3).

While legislation provides a regulatory framework for midwifery practice, midwives in both Australia and New Zealand also operate under professional frameworks that guide and determine practice. The New Zealand College of Midwives (NZCOM) and the Australian College of Midwives (ACM, formerly ACMI) are the midwifery professional organisations in their respective countries. Both provide direction for midwifery practice through setting philosophy, standards for practice, and ethics and practice guidelines that midwife members are expected to follow. Both organisations also have a political role in working on behalf of midwives to strengthen and protect midwifery and in working to ensure that maternity services meet the needs of childbearing women.

These two frameworks are complementary. Regulation focuses on public safety, while professions focus primarily on midwifery and midwives. Both are concerned with ensuring a competent and safe midwifery workforce but the profession generally has wider concerns and can undertake political action, whereas regulation is constrained by the limits of the legislation.

The way in which regulatory and professional frameworks have developed in each country reflects their unique historical, social, political, cultural and economic contexts. Australia and New Zealand share a common history of colonial settlement from Britain in the early nineteenth century and both countries have Indigenous peoples who have suffered and continue to suffer the effects of colonisation. However, for all their commonalities, Australia and New Zealand have evolved differently into the modern nations they are today. So too have their professions of midwifery. This chapter briefly traces the historical development of midwifery in both countries and then provides an overview of the regulatory and professional frameworks that determine the practice of midwifery in Australia and New Zealand.

Professions and professionalism: what do they mean?

The *Concise English Dictionary* defines a profession as 'an occupation involving high educational or technical qualifications' or 'the body of persons engaged in such a vocation'. Further, 'a professional' is defined as 'one who has skill or proficiency in an art or science, and who makes their living by the practice of this knowledge, as distinguished from one who engages in it for pleasure'.

Professionalisation can be considered 'the process by which an occupation moves toward a special form of control called a profession' (Aydelotte 1985, p 127). In addition to laying claim to a special knowledge base that is socially sanctioned, and deriving economic benefit from the application of this knowledge, there is also an active political dynamic and legal legitimation of any claim to professional status that has led to the assertion that professions are the creation of a ruling class. The sociologist Elliot Friedson, in defining the attributes and characteristics required for full professional status in relation to the medical profession, advanced this view, stating:

> A profession attains and maintains its position by virtue of the protection and patronage of some elite segment of society which has been persuaded that there is some special value in its work (Friedson, cited in Ehrenreich & English 1973, p 47).

Ehrenreich and English, building on Friedson's work, show how professional groups maintain political and economic monopolisation of their field by exercising 'control over their institutional organisations, their theory and practice, their profits and prestige' (1973, p 20). Additionally, they establish that:

> An occupational group doesn't gain a professional monopoly on the basis of technical superiority alone. A recognised profession is not just a group of self-proclaimed experts; it is a group which has authority in the law to select its own members and regulate their practice, i.e. to monopolise a certain field without outside interference (1973, p 47).

In other words, a profession uses its knowledge base as 'an ideological cover in its struggle for power and status' (Tully 1999, p 30). A profession's knowledge base is contingent on the complex interactions that take place between professions, the state and client or consumer groups and thus is highly variable (Tully 1999).

Abbot picked up on the dynamics of interactions between professions in his development of what he called the 'system' of professions (Abbott 1988). Abbott identified professionalism

as a system of interprofessional competition that focuses on disputes over jurisdiction. He defined 'jurisdiction' as the link between a profession and its work and argued that it 'is the history of jurisdictional disputes that is the real, the determining history of professions' (Abbott 1988, p 20). A profession's work is the control of tasks.

> The tasks themselves are defined in the profession's cultural work. Control over them is established by competitive claims in public media, in legal discourse and in workplace negotiation. A variety of settlements, none of them permanent, but some more precarious than others, create temporary stabilities in this process of competition (Abbott 1988, p 84).

Gendered professions

Divinity, law and medicine are three longstanding and traditional professions. Each group has a long and entrenched history of patriarchal tradition in Western societies and has attained the attributes of a profession described above. It is well documented that throughout their histories each has sought to exclude women from entry or from the professional societies and organisations in which members exercise political influence, or marginalised women to non-lucrative and less prestigious areas of practice. This behaviour needs to be considered in the context of the historical control and cultural views of defined sex roles in Western industrialised societies, whereby the female sex role was considered to be incompatible with that required for professional achievement (Speedy 1987). For instance, medicine extended its social and legal legitimacy as the dominant health profession during the nineteenth and twentieth centuries, aided by the ideals and activities of Western imperialism, the rational doctrines of the Enlightenment and the principles of modern mechanisation (Grimshaw et al 1996; Willis 1983). Synchronously, midwifery was downgraded and/or made illegal in many Western societies, in the face of the new licensed professional (predominantly male), specialist medical practitioner, the obstetrician and gynaecologist (Anderson 2002; Donley 2002; Finklestein 1990).

While the improved status of women in contemporary Western society has enabled some to be admitted into the traditional professions, issues around sex differences and power dynamics remain. Men continue 'to control the means by which their particular perspectives are privileged, through their control of political, religious, and literary discourses' (Torres 1992, cited in Shachar 2001, p 4). In relation to childbearing, Lane (2002) and Reiger (2001, 2003) show that the scientific paradigm and its attendant consequences is now firmly institutionalised in law, medical recruitment and clinical practice in contemporary Australian society, including mainstream models of care sponsored by the funding mechanisms of the modern nation state. While the medical discourse of childbirth is being challenged in New Zealand by the development of a midwife-led and women-centered maternity system, it is still deeply entrenched, and the maternity service still reflects the global phenomena of medicalisation and technological intervention that characterise every Western society (Pairman & Guilliland 2003).

Tully (1999) argues that a more useful way of understanding the relations between gender and professionalising activity is to conceptualise gender as a resource rather than a relation of social domination or inequality. Her examination of midwifery in New Zealand shows how midwifery was able to use the gender of its practitioners as a resource in a context where women were demanding more 'women-centred' care and the state had given priority to this women's agenda. Tully contends that New Zealand midwifery deliberately reconstituted itself as a feminist form of professional practice. Central to this practice is the concept of a 'partnership' between midwives, as female health professionals, and women who share their understanding of birth as a normal life event.

> In positioning midwives and birthing women as 'partners' who shared responsibility for the pregnancy/birth, midwifery leaders drew on feminist understandings of the importance of women taking control over their lives and health in general, and their reproductive experiences in particular. Feminist concerns about issues of responsibility, control, empowerment and choice were put at the centre of midwifery's definition of itself as a profession with a 'moral obligation to work in partnership with women' (Tully 1999, p 49).

'Old' and 'new' styles of professionalism

The attributes that characterise a profession have been described as

- a strong level of commitment;
- long and disciplined educational process;
- unique body of knowledge and skill;
- discretionary authority and judgement;
- active and cohesive professional organization;
- acknowledged social worth and contribution (Speedy 1987, p 20).

However, a profession's social power is even more important than its expertise or knowledge, or the commitment of its members. This social power is achieved through a social mandate for practice, and the social mandate comes from political action.

> An occupation becomes a profession not because of the good work of its individual members, but because the occupation as a whole wins a state or social mandate to practise.

> When a class recognises itself as a class, it can organise itself politically . . . professionalism in this sense is quite simply not something that can be achieved by hard work or study. Professional status comes from political action (Katz Rothman 1984, p 300).

Ehrenreich and English reminded us of the contradictions inherent in professional status when they stated:

> We must never confuse professionalism with expertise. Expertise is something to work for and to share: professionalism is—by definition—elitist and exclusive, sexist, racist and classist (Ehrenreich & English 1973, p 42).

These notions of professions as 'expert' with a rational, scientific and masculinist approach to knowledge characterise 'old' style professionalism, which continues to define

dominant professions in Western industrialised societies. For many midwives, the characteristics of 'old' professions are antithetical to midwifery because they are seen as separating midwives and women from each other, and midwives have asked why midwifery would want or need to be a profession (Cronk 2000; Wilkins 2000). In contrast, the New Zealand midwifery model of midwifery partnership provides an example of 'new' professionalism (Guilliland & Pairman 1995; Pairman 2005; Tully 1999). This latter model has been described as characterising the 'new midwifery' of the future, in which knowledge about the body is constructed as the outcome of relationships and interactions between people (Lane 2002; Page 2003). The characteristics of old and new professionalism can be differentiated as: mastery of knowledge versus reflective practice; unilateral decision processes (patient as dependent, colleagues as differential) versus interdependent decision processes (patient empowered, colleagues engaged as equals); autonomy and self-management versus supported practice teamwork; individual accountability versus collective learning, responsibility and accountability; and detachment versus engagement (Health Workforce Advisory Committee 2005).

We move on now to explore midwifery's approach to professionalism in both Australia and New Zealand.

Midwifery as a profession in Australia

Midwifery in Australia is in a state of transition and at this stage does not reflect the attributes of either 'old' or 'new' professions (Barclay et al 2003).

Influences of competing discourses of childbearing

Understanding the evolution of a professional framework for midwifery practice in Australia in the twenty-first century is contingent on examining and understanding the historical, political, cultural, economic and race relations of Australia's early foundation as a colonial settlement of the United Kingdom and its subsequent development into a modern nation state. These developments encompass the socio-political, professional and economic arrangements and relationships that underpin the evolution of its current health infrastructure (Anderson 2002; Duckett 2000; Grimshaw et al 1996; Reiger 2003). Additionally, understanding recent critique of contemporary economic, political and cultural forces that have influenced government policy, including competing trends towards both market-driven health services and institutionalised state-sponsored health services, consumer and professional activism, and the women's movement during the twentieth century, is also vital in understanding influences on the future framework for professional midwifery practice in Australia (Barclay et al 2003; Donnellan-Fernandez & Eastaugh 2003; Maternity Coalition 2002; Reiger 2001).

Mainstream Australian maternity services are fragmented into antenatal, intrapartum and postnatal spheres, and maternity care has been constructed within an industrial nursing framework whereby the midwife's role is confined to a set roster and specified hours. This historical structural division of labour has created conflict among groups advocating an elitist, specialist, professionalising route for midwifery, and those that place women at the centre of the decision-making process, such as 'partnership' models of midwifery, in which care is part of the continuum of an established relationship (Reiger 2001). Within such a context, continuing questions need to be asked about how and where professionalisation as a strategy for midwifery sits in relation to current discourses of birth as a social construct. This includes consideration of the emerging ethos of relationship between women and midwives being articulated as 'partnership' models of birth in countries such as New Zealand, where midwifery autonomy has been actualised in practice and is visibly regulated (Pairman 2000; Guilliland & Pairman 1995).

In examining the Australian history of childbearing, Reiger (2003) and Lane (2002) have analysed the evolution and construction of birth as the medicalisation of the body and of social life. Both authors propose that professionalisation has been a response to the state-sanctioned medical practice monopoly in childbearing, including the historical subordination of midwifery as a branch of specialist nursing practice. This is supported by contemporary Australian midwifery researchers' claims of the practice of medical obstetrics on normal, healthy women as a form of 'occupational imperialism' to ensure ongoing medical strategic control and financial monopoly of maternity services. Twofold effects have been a national lack of access for consumers to midwifery-based services and continuing lack of midwifery autonomy and job satisfaction, resulting in deskilling and increasing attrition rates from the midwifery workforce (Brodie 2002; Tracy et al 2000).

The sites where midwives have been able to practise autonomously in Australia, such as birth centres and home birth, have been limited and marginalised by barriers that include: a lack of state-sponsored policy frameworks and funding mechanisms; interprofessional rivalry and philosophical clashes with medical and nursing groups; and, since mid-2001, national withdrawal of professional indemnification arrangements for self-employed midwives despite continuing state-subsidised arrangements for the medical profession (Donnellan-Fernandez 1996, 2000; Donnellan-Fernandez & Eastaugh 2003). Although midwifery claims to be a profession, its professionalisation strategy is still in its infancy (Lane 2002). Lane (2002, p 30) suggests that 'Midwives need to ask themselves how much autonomy they wish to exercise in their practice and how they understand the relationship between the body and society'. In common with the findings of Sandall (1997) in the United Kingdom and Lazarus (1997) in North America, her research leads her to advocate for diversity in models of midwifery practice, to suit 'both women and a range of women's needs' (Lane 2002, p 39).

Australian Midwifery Action Project (AMAP)

The most recent comprehensive report on midwifery in Australia is that of the Australian Midwifery Action Project (AMAP) (Barclay et al 2003). This project facilitated the collaboration of industry partners, researchers, relevant

organisations and the wider community through an action-oriented research process. Over the life of the project, the primary outcome has been a series of publications investigating the service delivery, educational, policy and regulatory environments affecting midwifery nationally. Important secondary outcomes have been 'to analyse and facilitate collaboration and communication across all of these sectors', in addition to 'informing the development of national and state initiatives to improve maternity services' (Barclay et al 2003, p 61). The findings of AMAP are a legacy of the history of many of the forces identified above, and the report is significant in that it underlines barriers to the future of midwifery in Australia. Particularly problematic at the beginning of the twenty-first century is the national status of the midwife. In summary this includes:

> the lack of a coherent approach to the role of the midwife—the invisibility of midwives in policy, planning and regulation, and problems in contemporary midwifery education offered by schools of nursing. These include lack of symmetry between various stakeholders with regard to the role of the midwife; her sphere of practice, her skills, degree of professional autonomy and legal responsibilities forms a singular and monolithic barrier to the emergence of a fully functional midwifery profession. The future potential of midwifery as a provider of primary healthcare to all women, regardless of designated medical risk status, rests on the capacity of educational, regulatory and service institutions to mobilise a unified vision of midwifery practice and the requisite skills and legal framework to achieve it (Barclay et al 2003, p 57).

Professional status

Specific challenges have recently been mounted to midwifery's capacity to fulfil its professional status in Australia, in the areas of educational process, body of knowledge, discretionary authority and judgement, and cohesive professional organisation.

Educational process

While a unique body of knowledge and skills in midwifery is asserted in the 'International Definition of a Midwife' (ICM 1990) and accepted by the Australian College of Midwives Inc., recent mapping and critique of inconsistencies and minimum practice standards in midwifery education programs in Australia have highlighted both a lack of opportunities for students to participate in midwifery models, and the fact that current assessment regulations for midwifery fall well short of those required by the regulation bodies of other industrialised countries (ANMC 2004; Leap et al 2002). These findings are hardly surprising, given Australian midwifery's history, education infrastructure, resources and industry/labour force expectations of a skill set and accompanying set of socialised relationships that are constructed as 'add-ons' to specialist nursing practice (Donnellan-Fernandez 2000).

Body of knowledge

Recent interviews by Lane (2002) with Australian midwives showed that midwifery is not a static, discrete body of knowledge, and that midwives cannot be classified into discrete obstetric assistant/medical models or professional/independent midwifery models. Rather, most could be classified as 'hybrid' and reflecting the needs of a variety of practice settings rather than a model determined by midwifery.

Discretionary authority and judgement

While the Australian College of Midwives (ACM), as the peak 'professional' body for midwives in Australia, has articulated national standards for midwifery practice and education, it currently has no statutory mandate to enforce these standards in law in all Australian states and territories. At present there are no nationally consistent midwifery educational or practice standards that are either universally endorsed or are statutorily enforceable by the Australian nursing regulatory authorities in each of the eight states and territories of the nation—that is, there is no 'discretionary authority' or professional regulatory jurisdiction that is legally sanctioned. Rather, midwives in most Australian states and territories are ambiguously licensed as nurses, a position that is not legislatively consistent with professional midwifery practice or regulation in other areas of the Western world, or consistent with the principle of regulation in the public interest (Brodie & Barclay 2001; Donnellan-Fernandez 2001).

Cohesive professional organisation

Until the late 1970s, midwives in Australia were largely subsumed within nursing organisations. In 1979 a National Midwives Association was formed concurrent with an emerging professional consciousness. Subsequent incorporation and membership of the International Confederation of Midwives (ICM) has seen the ACM develop over the past 20 years to become the accepted national organisation for midwives. In addition to shaping standards for professional midwifery practice it has developed educational programs, participated in health policy development and provided a significant information network for its members (Barclay et al 2003).

However, despite ACM articulation of comprehensive objectives (see the discussion of the role and function of the ACM later in this chapter), recent analysis indicates that the ACM has not yet achieved the same cohesion, public profile or political influence as some of its international sister organisations, such as the New Zealand College of Midwives and the Royal College of Midwives UK. Membership consists of less than a quarter of midwives estimated to be currently practising, with the majority (who are employed by state and territory governments in public sector hospitals) remaining members of the principal industrial body for nursing in Australia, the Australian Nursing Federation (Reiger 2003).

Birth culture and institutionalisation

Despite current global evidence that supports universal access for all healthy childbearing women to midwifery-led care (WHO 1996), the dominant, state-sanctioned birth culture in Australian society at the beginning of the twenty-first century remains that of institutionalised medicine (CDHAC 1999;

Maternity Coalition 2002). This culture is characterised by state sponsorship of medicine, including over-representation of techno-industrial models of 'professional' practice, which view the birthing body as a 'machine' and generate profits or health-funding outcomes that are defined in a market-driven economy (Davis-Floyd & Sarjeant 1997; De Vries et al 2001). In common with many other affluent, industrialised Western nations, in Australia this culture is entrenched at the level of government policy, funding and existing health infrastructure (AGPC 2004; Donnellan-Fernandez & Eastaugh 2003; Reiger 2003).

Despite two decades of state, territory and national inquiries into birthing services in Australia, including accompanying recommendations expressing women's repeated requests for 'choice, continuity and control', there is a vacuum in national government policy and political will to enable the funding, infrastructure and service reform recommendations of these reports to be implemented (Maternity Coalition 2002).

With three exceptions (Victoria, New South Wales and Western Australia), no state or territory government in the past decade has articulated a comprehensive policy for maternity services reform based on primary health principles that enables the midwife to work to the full scope of practice as defined in the International Definition of the Midwife. Maternity policy in Victoria, New South Wales and Western Australia envisage restoring midwifery to a primary health role in the delivery of state-based maternity services (New South Wales Health Department 2000; State of Victoria, Department of Human Services 2004; Western Australian Government 2004). Despite recent evidence that rates of obstetric intervention in labour and birth are lowest among women experiencing care from midwives in public-sector facilities, a culture of expensive medicalised childbirth is the norm for the majority of women in Australia (Homer et al 2001a; Roberts et al 2000, 2002). Maternity care options for women living in regional, rural and remote areas of Australia are limited to state-funded medical providers, and in many instances access to local services and culturally appropriate services, particularly for Indigenous women, are either non-existent or in short supply (Maternity Coalition 2002). While this is the current context for childbearing women and midwifery practice in Australia, some models of midwifery continuity of care are beginning to evolve (Homer et al 2001b).

Redefining professionalism in New Zealand

The current status of midwifery as a profession in New Zealand is somewhat different to that in Australia. New Zealand midwives are an autonomous and distinct professional group. They were granted a social mandate for autonomous practice in 1990 through the Nurses Amendment Act and over the subsequent 15 years have established midwifery as the main provider of maternity services based on a model of autonomous caseload practice and midwifery partnership. Largely through the influence of midwifery, New Zealand's maternity service has been reshaped to a women-centred and midwife-led service in which each woman can access one-to-one continuity of midwifery care from early pregnancy through to six weeks post partum, no matter what the course of her childbirth experience and which other providers need to be involved, and no matter where she chooses to give birth (Pairman & Guilliland 2003). New Zealand midwifery, perhaps more than any other, most closely meets the International Definition of the Midwife by practising within the full scope of midwifery practice (International Confederation of Midwives 1990; Midwifery Council of New Zealand 2004a).

For New Zealand midwifery, these achievements are the culmination of years of planned political and professional activity to bring about the necessary changes to legislation, to societal understandings of birth and midwifery, and to midwifery's understanding of itself as a profession that is deeply intertwined with women. The central tenet of New Zealand midwifery's professional identity is that midwifery *is* the partnership between women and midwives (Guilliland & Pairman 1995; New Zealand College of Midwives 2005). By constituting midwifery as 'midwifery partnership', New Zealand midwifery has sought to replace traditional notions of professionalism with one in which relationships between midwives and women are negotiated and where power differentials are acknowledged and actively shifted from the midwife to the childbearing woman.

This recognition that midwifery is a partnership between a woman and a midwife resulted from the combined political activity of maternity consumer groups and the New Zealand College of Midwives, which led to the *Nurses Amendment Act 1990* and the one-to-one caseload model of midwifery practice that developed subsequently.

Although New Zealand has had a regulated midwifery workforce since the *Midwives Act 1904*, the scope of midwifery practice diminished as a result of increasing hospitalisation and medicalisation of childbirth from the early 1920s onwards (Donley 1986; Mein Smith 1986; Pairman 2002, 2005; Pairman & Guilliland 2003; Papps & Olssen 1997). Women were encouraged to birth in hospitals to avoid the risks of puerperal infection in the home, to access 'pain-free' birth and because of unfounded claims that hospitals were safer than home. That hospitalisation led to fragmented maternity care, loss of control for women and their families, increased medical intervention and use of technology, loss of confidence in women's bodies, and increased fear of birth, has been well documented and is reflected throughout the Western world (Donley 1986; Donnison 1988, Kitzinger 1988; Mein Smith 1986; Papps & Olssen 1997; Tew 1990). Institutional organisation and power structures also affected midwives, who lost their one-to-one community-based practice with women to become 'doctor assistants' and 'specialists' in aspects of maternity care. By 1971, midwifery was no longer visible as a separate profession and was incorporated into nursing as 'specialist nursing practice'. Legislative changes in 1983 and 1986 further undermined the definition and scope of practice of midwifery, which reached an all-time low, where only a handful of home birth midwives remained practising in a way that bore any resemblance to the International Definition of Midwifery (Donley 1986; International Confederation of Midwives 1990).

It was this near-demise of midwifery that led to its rebirth. In reclaiming their identity as separate from nursing, midwives used their professional group, the Midwives Section of the New Zealand Nurses Association, as a vehicle for political action. Initially this activity was focused on reclaiming the International Confederation of Midwives (ICM) definition of a midwife as a 'person' rather than a 'nurse' (as the Nurses Association had redefined it) and on separating midwifery education from nursing (Pairman 2002). However, midwives soon realised that their interests were divergent from those of nursing and could never be served by the (larger) nursing professional organisation. Midwives disbanded the Midwives Sections and in 1989 formed a separate midwifery professional organisation, the New Zealand College of Midwives (Donley 1989; Guilliland 1989).

Maternity consumer groups were also active at this time, seeking to gain control over their birth experiences and to decrease the dominance of the medical model over maternity services (Strid 1987). These women had faith in midwifery and argued for a return of the autonomous midwife, who they believed would be more likely to share power with women through a more women-centered and normal-birth philosophy of practice (Dobbie 1990; Strid 1987).

Recognising that their aims were mutual, midwives and women joined together in a combined political strategy that would first reinstate midwifery autonomy, secondly enable women to have a choice of midwifery care, and thirdly enable the development of direct entry midwifery education to produce the new type of midwife that would be required for this autonomous scope of practice.

A key outcome was that midwives recognised the benefit to themselves and to women of their political partnership, and they gave meaning to this partnership by incorporating partnership constitutionally into every aspect of the New Zealand College of Midwives. Midwifery 'consciously recognises that the only real power base we have rests with the women we attend' (Guilliland 1989, p 14). The active involvement of women in the New Zealand College of Midwives has continued to strengthen midwifery. 'Women's participation in the midwifery profession has given midwives a public, legal and socially sanctioned mandate for practice' (Guilliland & Pairman 1995, p 19). This social mandate carries with it a moral obligation for the midwifery profession to provide the kind of service women want. The continued involvement of women (consumers) in the policy formation and processes of the College ensures that midwives uphold the needs and wishes of women.

It was this understanding of the link between professional autonomy and women's need to have control over their birthing experiences that was the basis of New Zealand midwifery's determination to redefine professionalism.

Although not attracted by the traditional 'power over' model of professionalism, it recognised the potential benefit of professional autonomy. As Oakley and Houd (1990, p 114) contend, 'the exclusion from childbirth of autonomous midwifery restricts the care options available to childbearing women and inevitably promotes the definition of childbearing as a pathological medicalised event'. New Zealand midwives and women believed that if midwifery autonomy were reinstated, then midwives would have the ability to once again practise within their traditional role as a guardian of normal birth (Strid 1987). Each midwife who worked in this way would be a 'positive presence who focuses on the childbearing woman and the baby, with the knowledge and skills required, but also with a sensitivity and respect for the individuality and uniqueness of each woman and her choices for birthing' (Strid 1987, p 15). Writers such as Barbara Katz Rothman supported these beliefs when she stated:

> I have come to see that it is not that birth is managed the way it is because of what we know about birth. Rather, what we know about birth has been determined by the way it has been managed. And the way childbirth has been managed has been based on the underlying assumptions, beliefs and ideology of medicine as a profession (Katz Rothman 1984, p 304).

The determination to provide women and midwives with the opportunity to co-create new knowledge and understandings of childbirth that would lead to women regaining control and choice in childbirth and to society once again recognising childbirth as a normal life event rather than an illness was the impetus for political activity to reinstate midwifery autonomy. Through the experience of this political partnership, midwives were able to conceptualise a 'new' model of professionalism.

> By redefining the professional–client relationship as one of 'partnership' in which each partner contributes knowledge and experience, it also embraces feminist criticisms of the hierarchical power relations inherent in the doctor–patient relationship and the consequent devaluing of women's knowledge (Tully & Mortlock 1999, p 175).

In recognising the knowledge and experience of women/clients as well as midwives, Midwifery partnership does not afford midwifery expertise and knowledge the same epistemological priority it held in the 'old' model of professionalism (Tully 1999). In midwifery partnership both midwives and women have recognised authority and the midwife's role moves from 'expert' to 'reflective practitioner' whose task is to support, guide and accompany a woman within a more equitable, interdependent and empowering relationship (Tully 1999). In redefining its practice as partnership, midwifery has differentiated its services from those offered by other providers and claimed jurisdiction over 'normal' birthing services. Thus partnership with women is an effective professionalising strategy for midwives (Tully 1999).

The challenge for midwifery is to maintain its partnership relationships with women; and, as will be discussed, the professional and regulatory frameworks of New Zealand midwifery both aim to ensure that this occurs. By articulating midwifery as a partnership, New Zealand midwives have redefined traditional notions of professionalism. However, midwives need to understand this definition and midwifery needs to reinforce the implications of this 'new' style of professionalism for midwifery practice so that midwives do not abuse their power and authority.

Instead of seeking to control childbirth, midwifery seeks to control midwifery, in order that woman can control childbirth. Midwifery must maintain its women-centered philosophy to ensure that its control of midwifery never leads to control of childbirth (Guilliland & Pairman 1995, p 49).

Development of the midwifery profession in New Zealand

Structure and functions of the New Zealand College of Midwives

The New Zealand College of Midwives (NZCOM; the College) is the professional organisation for midwifery in New Zealand. Established in 1989, the College has provided a focus for midwifery's understanding of itself as a profession separate from nursing, and now represents over 80% of all practising midwives in New Zealand. Its commitment to midwifery partnership has meant that from its inception, women consumers have been members as of right and the constitution provides for regional and national membership by individual women and consumer groups. The consumer membership votes for four representatives to the National Committee from consumer organisations such as Parents Centre New Zealand, Home Birth Aotearoa, La Leche League and The Plunket Society. As the voice for midwifery in New Zealand, the College is involved in a wide variety of activities, both professional and political, to meet the needs of individual midwives, the profession as a whole, and birthing women as its partners and the focus of its interests, by working to maintain a strong and autonomous midwifery profession. The role and functions of the College are summarised in Box 10.1.

The College structure is simple (see Fig 10.1). New Zealand is divided into 10 regions, each with its own regional committee and governance responsibility. The chairpersons (all midwives) of each of the 10 regions are members of the National Committee, along with the four consumer representatives, two midwifery student representatives and

BOX 10.1 NZCOM role and functions

The role and functions of the New Zealand College of Midwives are listed below.

Professional practice advice and information
- for all midwives
- for District Health Boards (DHBs)
- for Ministry of Health/government ministries
- for regulatory body/other statutory authorities
- for consumers and consumer organisations
- for other professions
- for the public

Professional development/standards
- for all midwives
- Midwives Handbook
- liaison with DHBs
- expert witness training
- professional development program
- portfolio development and support
- Section 88 negotiations/interprofessional liaison
- contractual advice and policy development

Quality assurance
- Midwifery Standards Review Process for all midwives
- complaints resolution committees for women
- training programs

Education
- NZCOM continuing education workshops/programs
- consensus statements/practice guidelines
- DHB practice workshops
- smoke change workshops
- family violence workshops
- liaison with midwifery education providers
- liaison with DHB midwifery educators

Liaison
- with consumers
- with Maori
- with government/statutory bodies/ health organisations/non governmental organisations
- international midwifery organisations
- other professional groups

Research
- Secretariat for Joan Donley Midwifery Research Collaboration
- Biennial Research Forum

Communication and promotion
- journal
- midwifery news
- biennial conference
- publications
- website
- promotional material
- media

Legal advice and representation
- professional indemnity insurance
- legal representation

Financial management/membership management

two Maori midwife representatives. Two Kuia or elders (Maori and Pakeha), the President and Chief Executive lead the Committee. The National Committee meets three times a year to fulfil its governance role. It works in a non-hierarchical and women-centred model that includes extensive consultation processes and consensus decision-making. The National Committee employs the Chief Executive, who in turn employs the staff of the National Office. These staff, some of whom are midwives, carry out the day-to-day work of the College as represented in Box 10.1.

As it has evolved, the College has recognised the need for other midwifery-specific organisations to meet the business and industrial needs of midwives. Considerable thought went into the establishment of these organisations to ensure that their structure, functions and governance mechanisms did not become blurred with the College and dissipate the overall strength and unity of the midwifery voice. As shown in Fig 10.1, the College has created three separate but parallel organisations: the Midwifery and Maternity Provider Organisation (MMPO), the Midwifery Employment Representation and Advice Service (MERAS), and the Joan Donley Midwifery Research Collaboration (JDMRC). Each organisation has its own governance structure and specific role and functions, and its links to the College are maintained through College representation to its governance structure and through the requirement for midwives to first be members of the College before they can access services from any of these organisations.

The Midwifery and Maternity Provider Organisation (MMPO)

The College established the MMPO in 1997 as a separate limited-liability company with its own governance structure. Its purpose is to support the business practices of midwives who carry caseloads and are remunerated through the Maternity Benefit Schedule. It does this through managing the claiming of fees on behalf of midwives and through provision of standardised midwifery notes that facilitate compliance with data provision and reporting.

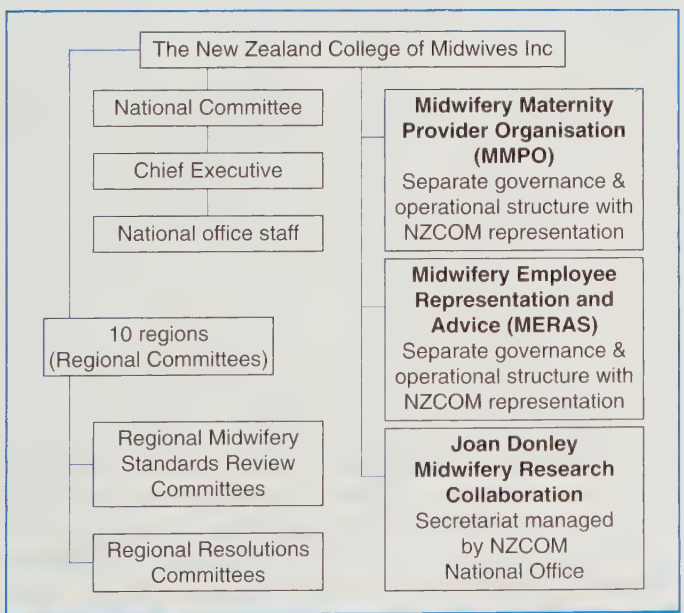

Figure 10.1 Structure of the New Zealand College of Midwives

Each page of the Maternity Notes is in triplicate: one copy remains with the woman as her birth story and personal record, one is kept by the midwife as her clinical and legal record, and the third is sent to the MMPO for fee-claiming purposes and for clinical data entry into the NZCOM midwifery database. Midwives receive their fee payment together with a report on their clinical outcomes and statistics, which they take to their annual Midwifery Standards Review.

The majority of self-employed midwives throughout New Zealand use this service, and the MMPO also manages the midwife claims for some DHB and Community Trust employers.

NZCOM contracts the MMPO to enter the clinical data from the maternity notes for its midwifery database. It then uses the database to produce a national report on midwife outcomes that analyses the aggregated and anonymous data.

Midwifery Employee Representation and Advisory Service (MERAS)

MERAS is the union for employed midwives. Its formation arose from the wish of College members for a more midwifery-focused representation in the workplace. Until 2003, industrial representation for midwives was only available through the New Zealand Nurses Organisation (NZNO), and salaries and conditions to meet the needs of employed midwives and their various practice models could only be recognised through a variation of the nursing agreement.

In 2005, MERAS achieved a collective agreement specifically for midwives. This agreement covered midwives in all 21 District Health Boards. It not only improved conditions and pay levels for employed midwives but also framed the industrial document within a professional midwifery model and reflected the need for all midwives to focus on professional codes and practice standards. It paved the way for a new midwifery professional development model for employed midwives that is distinct from nursing.

The Joan Donley Midwifery Research Collaboration (JDMRC)

The Collaboration is housed in the College and is named after midwife Joan Donley, the founder of the NZCOM and midwife author and researcher. It is the evidence-based arm of the New Zealand College of Midwives. Its purpose is to encourage and facilitate research cooperation between all midwifery education providers. It hosts a research forum once every two years, specifically for postgraduate midwifery students and hospital midwifery educators to develop research ideas and proposals or present the results of work carried out.

Professional activities

The leadership of the NZCOM has been a major driver in the development of the midwife-led and women-centered

maternity service that New Zealand enjoys today (Pairman 2005; Pairman & Guilliland 2003). Its leadership has also been essential in the development of midwifery as a strong and autonomous profession. There have been many processes through which the College has worked and continues to work with midwives to build their professional identity and enhance professional standards. These include:

- developing its philosophy and setting standards for practice and an ethical framework (NZCOM 2005)
- producing consensus statements about practice, an education framework and breastfeeding guidelines
- providing education for midwives on family violence and how to screen for and refer women in situations of violence (on contract from the Ministry of Health (MOH))
- providing education for midwives on smoking in pregnancy and how to assist women to change their smoking habits (on contract from MOH)
- publishing resources to guide practice and professional development (e.g. *Midwives Handbook for Practice*, Midwives Portfolio)
- convening disciplinary forums to build practice consensus
- developing mentoring frameworks
- promoting rural networks and locum support
- advising and monitoring pre-registration midwifery education programs.

Perhaps one of the College's most innovative and important professional developments is its Midwifery Standards Review (MSR) process. This, together with its Resolutions process, provides a quality assurance process for midwifery practice in New Zealand that aims to improve and maintain professional midwifery standards. Each region of the College has standing committees for its MSR process and its Resolutions process. As will be discussed later, the College's MSR process is an essential feature of the Recertification Program established in 2005 by the Midwifery Council of New Zealand for all midwives.

Midwifery Standards Review

The Domiciliary Midwives Society initially established Midwifery Review in 1988 to review the practice of home birth midwives. This was in response to moves by obstetric and hospital management to try and impose hospital practices and protocols on the home birth service. As more midwives moved into independent practice after 1990, the College realised that it needed to provide a similar quality assurance mechanism for all midwives. Consequently, in 1992, the College adopted the domiciliary review process and modified it to include the College's standards of practice. Eventually the Domiciliary Midwives Society dissolved and became part of the College, and all midwives are now reviewed under the same criteria.

Midwifery Standards Review committees comprise two midwives, nominated from the region, and two consumers, nominated from consumer organisations. The region endorses all members. All reviewers attend a College-run national training program that seeks to ensure a standardised approach to MSR throughout the country and to help reviewers develop the personal and communication skills necessary for the reviewer role.

Midwives prepare for review by examining their previous year's work, analysing their annual birth outcomes (statistics), considering feedback from women clients (collected via client evaluations by a third party and provided to the midwife for her review), and undertaking a self-assessment against the NZCOM Standards for Practice.

Midwives meet individually with the Review Committee and have the opportunity to explore and discuss their midwifery practice through a supportive and educative process. A main outcome is the joint development of a Professional Development Plan that is revisited at the next review.

It was caseloading midwives who initially undertook MSR and usually presented for review each year. In 2003, NZCOM began encouraging core midwives (hospital midwives not working in caseload models) to undertake review, and since 2005 the Midwifery Council has made MSR mandatory for these midwives every three years, while it expects caseloading midwives to continue with annual review.

Resolution Committees

While the review process is consciously midwife-centered, the College's commitment to partnership with women is reflected in the establishment of Resolution Committees. These committees focus on consumers, and any woman who has concerns about the midwifery care she has received can use this process. One midwife and one consumer make up the committee and also participate in a national training program. The committee helps a woman to resolve her issues, sometimes through facilitating a meeting with the midwife or by providing a forum in which a woman can have her concerns heard and discussed. If resolution is not possible, the committee assists the woman to access other available avenues.

Midwifery as a profession in New Zealand

The New Zealand College of Midwives displays a strong level of commitment to midwifery and to ensuring a midwife-led and women-centred maternity service. Midwifery in New Zealand claims a unique body of knowledge and skill as a guardian of normal birth that arises from its model of midwifery partnership, and it is this experiential knowledge that may be its greatest contribution to the discipline.

The contribution midwifery makes to society is recognised by the authority it has been granted over midwifery, and thus 'normal birth', through legislative changes. As a result, midwives have wide jurisdiction to make midwifery judgements and provide midwifery care on their own responsibility. Legislative authority means that midwifery as a profession is self-regulating and must therefore ensure that midwives provide appropriate standards of care and are accountable for their midwifery judgements. The control of a sphere of practice is never static, and the College must be constantly vigilant to maintain midwifery's position as the main provider of primary maternity services.

While midwifery in New Zealand can claim to have achieved a great deal, it still faces challenges in consolidating its status as a profession and in ensuring that its service really does make a positive difference to the lives of New Zealand women, particularly in a global context of increasing medicalisation and technology. An important ongoing role of the profession is to encourage and assist midwives to act on their personal and professional autonomy and use their midwifery knowledge with confidence in an endeavour to reduce the impact of these global ideologies on childbearing women and their families (Guilliland 2004).

Development of the midwifery profession in Australia

Challenges to a professional framework for midwifery practice in Australia

Australian midwifery has evolved beside and in relation to medical dominance, and the emergence of medical dominance parallels the development of the nation state (Grimshaw et al 1996). Although most births still took place at home at the beginning of the twentieth century, the first half of the century saw birth shifted to hospital and a well-established culture of medical birth (Reiger 2003). Hospitalisation for birth has led to fragmented and episodic care, confined to sites dominated by medicine and where funding, resources and labour force have been concentrated. Within many of these environments, application of complex medical technologies and procedures, implemented by multiple providers, are prioritised over human relationships and basic primary healthcare measures. This distortion is common in many Western industrialised societies and is reinforced by vested market interests in health, 'as it complements and abets continuing fragmentation and colonisation of women and babies' bodies by expensive Western science, practice, products and "health systems" across their life span' (Donley 2002; Donnellan-Fernandez & Eastaugh 2003; Shachar 2001).

Australian midwifery reflects this same history of erosion and colonisation by powerful 'others', including medicine, nursing and the nation state, and 'this has resulted in the erosion of women's birthing power, and state and statutory endorsement of the "invisible" midwife' (Donnellan-Fernandez & Eastaugh 2003).

The Australian Midwifery Action Project (Barclay et al 2003) makes 21 specific recommendations for reform in education, regulation, sphere of practice, cultural safety, maternity service funding mechanisms, industry expectations and community interest in order to achieve community-orientated maternity services and midwifery-led, women-centered care. Synchronously, the formation and replication of grassroots, state, territory and national organisations calling for implementation of reforms in maternity care have been steadily increasing their profile, strategic planning and political activity in the Australian community over the past decade, supporting a social mandate and political platform for increased midwifery autonomy (Donnellan-Fernandez & Eastaugh 2003; Johnston & Newman 2005; Reibel 2004). The ACM, in collaboration with women, is a significant stakeholder in this discourse.

Structure of the Australian College of Midwives

The Australian College of Midwives (ACM) was established from the National Midwives Association (formed in 1979), whose membership broke away from the Australian Nursing Federation, the chief federal industrial body for nurses in Australia. Membership of the ACM across all states and territories of Australia comprises approximately 3000 midwives. National midwifery workforce data suggest that this figure comprises approximately 30% of all practising midwives (Tracy et al 2002).

The ACM is governed by a constitution and by-laws that outline the aims and objectives of the College, the terms and categories of membership status, the functions and powers of the National Executive Committee, and provide for a federated structure with equal representation from each of the eight state and territory ACM Branches (New South Wales, South Australia, Tasmania, Queensland, Victoria, Western Australia, Northern Territory and Australian Capital Territory). Membership of the National Executive (NEC) comprises one delegate from each state and territory, who is elected and nominated by each branch for two years prior to each Biennial Conference. Office bearers for the positions of President, Vice-President, Secretary and Treasurer are nominated and elected by delegates comprising the NEC.

The eight state and territory branches of the ACM operate as autonomous bodies charged with the responsibility of fulfilling the aims and objectives of the College. Each is governed by its own articles of association (which must be in harmony with the national constitution), and branch executives can authorise the formation of sub-branches within their region. Although the ACM has always sought to establish alliances and effective working relationships with women and maternity consumer groups, it is only in the past five years that amendment of the inaugural national constitution and articles of association of state and territory branches have enabled women consumers as members of right.

The National Executive meets up to four times per year to fulfill its governance role, and there is a Biennial General Meeting that is usually held in conjunction with the Biennial National Midwifery Conference. The NEC employs the Chief Executive Officer, who employs the staff of the National Office. In 2003 the National Office was relocated from Melbourne to Canberra.

The cooperative federalism model of governance that dictates the current structure of the ACM has both strengths and challenges in a country as large as Australia, and replicates the Westminister model on which the Australian system of government is based—that is, an overarching national constitution with two tiers of governance that enables state

and territory, in addition to federal, debate and input into decision-making.

Role and functions

College membership is through membership of a state or territory branch. The NEC carries out certain duties at the request of the International Confederation of Midwives (ICM), as a member association. The NEC acts in response to issues raised at branch level, and may delegate tasks to the various branches for research and action. See Box 10.2 for a summary of the College's vision and purpose, key strategic goals and functions.

While state sponsorship of autonomous midwifery practice in New Zealand is currently guaranteed via legislated funding (Maternity Benefit Schedule) and regulatory process (Midwifery Council of New Zealand), this is not the case in Australia. Consequently, unlike MMPO and MERAS, which represent the business and industrial interests of midwives in New Zealand, there has been no development of parallel organisations in the Australian context, apart from the Australian Society of Independent Midwives, whose membership of self-employed midwives remains small. There are currently no equivalent structures within the ACM, which to date, despite vigorous government lobbying, has been unable to secure professional indemnification arrangements for self-employed midwives since this was withdrawn nationally in mid-2001. In public health facilities in Australia, the majority of midwives, as employees of the state, have had no collective salary agreements that are independent of the eight state-based Nursing Awards under whose conditions, terms and pay structures they are employed. Recent introduction of an Annualised Salary Agreement for Midwives (as a variation to a state-based Nurses Award) took four years to negotiate in one state, and in 2005 has been expanded to all public sector sites in that state (Nurses South Australian Public Sector Enterprise Agreement: 2004, Midwifery Caseload Practice Agreement). Negotiations continue in other states individually, between Area Health Services and the Nurses Union.

Australian College of Midwives Framework for Midwifery

In March 2004, the ACM established the Australian National Education Standards Taskforce (ANEST) to undertake a national review of current ACM philosophy, codes of ethics and practice, education standards and position statements,

BOX 10.2 ACM role and functions

The role and functions of the Australian College of Midwives are as listed below.

Vision and purpose:

- To be the leading organisation shaping Australian maternity care
- To provide a unified political voice for the midwifery profession
- To support midwives to reach their full potential
- To ensure all childbearing women have access to continuity of care by a known midwife
- To set professional practice and education standards.

Key strategic goals:

- To be an accessible, efficient, transparent organisation providing valued services to members
- Consistent and timely political representation to influence policy development and decision making Australia wide
- To make midwifery a public health strategy
- To achieve National Standards for midwifery education and practice that are internationally recognised.

Functions:

- To act as the political voice of the midwifery profession in Australia
- To further the professional, educational and social interests of midwives in Australia
- To promote and maintain high standards of maternity care
- To set national professional practice and education standards that are internationally recognised. (An accreditation process for Independently Practising Midwives has been established since 1990. Current ACM negotiations with the Australian Council of Safety and Quality are working towards a proposal for funding to support development of a Continuing Professional Development process for all midwives that is linked to the new national midwifery standards framework. It is envisaged that the CPD process will closely parallel the Standards Review system adopted by NZ Midwifery (ACMI 2005).)
- To provide continuing education programs for midwives
- To act as a consultant to government bodies in the development of health policy that makes midwifery a public health strategy
- To provide an information network for midwives throughout Australia and all organisations affiliated with the International Confederation of Midwives
- To provide a forum for professional midwifery discussion and debate
- To disseminate current information via the ACM journal, national newsletter, Biennial National Midwifery Conferences, and through state Branches and the media
- To provide scholarships for midwives to undertake research and to assist in the promotion of the education and practice of midwifery through administration of the Australian Midwifery Scholarship Foundation Biennial National Midwifery Conferences, and through state branches and the media
- To provide scholarships for midwives to undertake research and to assist in the promotion of the education and practice of midwifery through administration of the Australian Midwifery Scholarship Foundation.

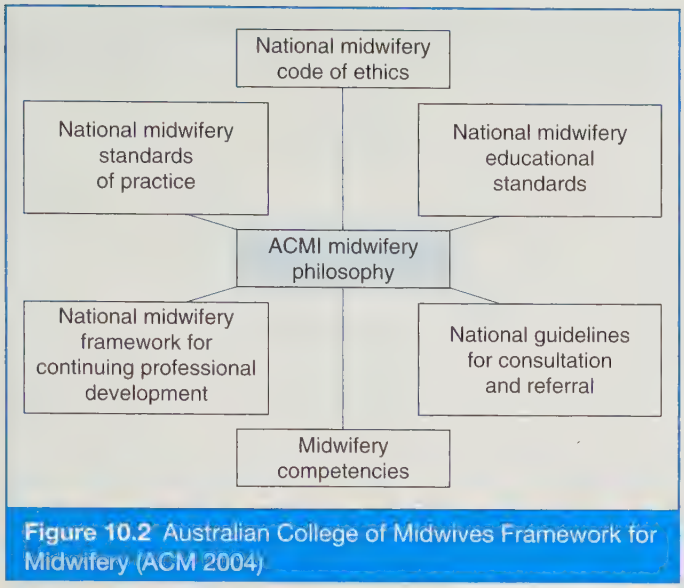

Figure 10.2 Australian College of Midwives Framework for Midwifery (ACM 2004)

and to propose a Professional Development Framework (see Fig 10.2). At the same time, the Australian Nursing and Midwifery Council (established in 1992 and changing its name to include midwifery in 2005), whose stated brief is to lead a national approach with state and territory regulatory authorities in developing statutory standards for nursing and midwifery, funded a project to research the role and scope of practice of midwives and to develop national competency standards for midwifery. This project was completed in late 2005 and ANMC National Competency Standards for the Midwife (ANMC 2005a) will replace the ACM Midwifery Competency Standards (2002).

Australian National Standards for Midwifery Practice

It is currently a time of significant change, challenge and upheaval for diverse factions and groups of midwives in Australia with regard to developing a cohesive national framework for professional standards.

Attempts to meet international standards in the education of Australian midwives have seen the introduction of three-year Bachelor of Midwifery Degree programs at several universities in two Australian states in 2002, with further states and universities commencing these courses in 2006, in alignment with the ACM National Standards for three-year Bachelor of Midwifery courses. This strategy, projected to help address current industry shortages and an ageing midwifery workforce, comprises a professional paradigm shift in midwifery education in Australia, and has undoubtedly advanced the agenda of developing a national midwifery framework that is compatible with international standards. It has also heightened tensions with industry, professional and industrial groups in nursing, and highlighted gaps in current regulatory frameworks, particularly with regard to the absence of endorsed national regulatory standards against which to measure continuing competence in midwifery.

The ACM national website currently hosts a variety of endorsed professional publications, including:

- ACM Midwifery Philosophy Statement (2004)
- National Midwifery Guidelines on Consultation and Referral (2004)
- National Position Statement on Midwifery Education (2004)
- Code of Practice for Midwives (2000)
- Code of Ethics (2001)
- Midwifery Competency Standards (2002) (www.acmi.org.au).

Newly developed National Competency Standards for the Midwife (ANMC 2005a) were released by the Australian Nursing and Midwifery Council in January 2006, following extensive consultation with midwives around Australia. Members from the Australian National Education Standards Taskforce of the ACM acted as Reference Group for the Project Management Group at the University of Technology, Sydney, which undertook development of the midwifery standards on behalf of the ANMC. The standards have been approved by each state and territory nursing and midwifery regulatory body to provide a nationally consistent framework by which the performance of midwives can be measured. The Code of Practice for Midwives (2000) and Code of Ethics (2001) are under review, with the ANMC in late 2005 tendering a joint project of a National Review of the Code of Ethics and Code of Conduct for Nurses in Australia, and the development of a National Code of Ethics and Code of Conduct for Midwives in Australia. The project, announced in January 2006, will involve collaboration between regulatory, professional and industrial bodies including the ANMC, the ACM, the ANF and the Royal College of Nursing. The project is due for completion in 2007.

Midwifery regulation in New Zealand

In December 2003, a new regulatory authority, the Midwifery Council of New Zealand, was established with the passing of the *Health Practitioners Competence Assurance Act 2003* (HPCAA). This historic event provided final recognition that midwifery is a profession in its own right, as the Midwifery Council took over all regulatory functions and responsibilities from the Nursing Council.

The Midwifery Council comprises six midwives and two lay members, and its focus is on protecting the public and ensuring that they receive safe and competent midwifery care. It does this by carrying out a number of statutory functions that came into force on 18 September 2004 (see Ch 11).

Midwifery Scope of Practice

The HPCAA required each profession to define its scope(s) of practice. The Midwifery Scope of Practice (see Box 10.3) further amended previous modifications made by NZCOM to the ICM definition of a midwife in order to ensure that the Midwifery Scope of Practice statement appropriately

BOX 10.3 Midwifery Scope of Practice

The midwife works in partnership with women, on her own professional responsibility, to give women the necessary support, care and advice during pregnancy, labour and the postpartum period up to six weeks*, to facilitate births and to provide care for the newborn.

The midwife understands, promotes and facilitates the physiological processes of pregnancy and childbirth, identifies complications that may arise in mother and baby, accesses appropriate medical assistance, and implements emergency measures as necessary. When women require referral midwives provide midwifery care in collaboration with other health professionals.

Midwives have an important role in health and wellness promotion and education for the woman, her family and the community. Midwifery practice involves informing and preparing the woman and her family for pregnancy, birth, breastfeeding and parenthood and includes certain aspects of women's health, family planning and infant well-being.

The midwife may practise in any setting, including the home, the community, hospitals, or in any other maternity service. In all settings, the midwife remains responsible and accountable for the care she provides.

(*In relation to a preterm baby the Midwifery Council defines the six-week postpartum period as commencing from the expected date of birth rather than the actual date of birth. That is, Council recognises that the postpartum midwifery role for preterm babies *may* extend beyond six calendar weeks.)

(Source: Midwifery Council of New Zealand 2004a)

reflected current midwifery practice in New Zealand (ICM 1990; NZCOM 1993, 2002).

The Midwifery Scope of Practice provides a broad statement of the boundaries of what a New Zealand midwife can do *on her own professional responsibility*. It provides a legal definition of New Zealand midwifery practice. It does not mean that every midwife must practise the full scope all the time. Rather, it is expected that all midwives can demonstrate that they are *able* to practise the full scope, even if their daily practice is more restricted. The Midwifery Scope of Practice reflects what the public expects from anyone holding the title of 'midwife' (Midwifery Council of New Zealand 2004b).

Competencies for entry to the Register of Midwives

In setting the competencies required of midwives in order to gain registration in New Zealand, Council amended competencies initially developed in 1996 by the Nursing Council in collaboration with NZCOM. The competencies for entry to the Register of Midwives (see Box 10.4) provide the detail of the skills, knowledge and attitudes expected of a midwife working within the Midwifery Scope of Practice. Where the Midwifery Scope of Practice provides the broad boundaries of midwifery practice, the competencies provide the detail of how a registered midwife is expected to practise and what she is expected to be capable of doing. These are minimum competence standards required of all midwives who register in New Zealand. Again, not all midwives will necessarily demonstrate all competencies all the time in their everyday practice. However, the Council requires all midwives to make an annual declaration that they are *able* to meet these competencies (Midwifery Council of New Zealand 2004b).

Registration as a midwife in New Zealand

The Midwifery Council is responsible for setting policy and managing the process for registration in New Zealand of its own midwifery education graduates, overseas registered midwives, and midwives applying from Australia.

All applicants must provide evidence of fitness for registration, specified qualifications, and competence to practise in the Midwifery Scope of Practice as measured by the Competencies for Entry to the Register of Midwives. Midwives applying from Australia under the *Trans Tasman Mutual Recognition Act 1997* (see Ch 11) are deemed to be registered, but along with other overseas applicants are likely to have conditions placed on their practice.

Common conditions that apply to Australian and other overseas midwives are that they work in peer-supported contexts such as maternity hospitals or group practices, and that they cannot prescribe medications until they have completed courses that orientate them to New Zealand's maternity and midwifery services and a course in pharmacology and prescribing.

Midwives educated in New Zealand must complete an approved three-year Bachelor of Midwifery program. These programs are mainly 'direct entry' for women without a previous nursing qualification, although there is a slightly shorter route for the few nurses who still wish to change careers and become midwives. The Bachelor of Midwifery programs began in 1992 and have been the only route to midwifery registration since 1996.

Continuing competence as a midwife

A central tenet of the HPCAA (2003) is that all health practitioners must demonstrate ongoing competence to practise in order to be issued with an annual practising certificate. The Midwifery Council makes this assessment through its Recertification Program.

All midwives make a declaration of their competence each year. Over each subsequent three-year period they must: work across all aspects of the Midwifery Scope of Practice; undertake certain compulsory education to update skills in cardiopulmonary resuscitation (CPR), infant resuscitation and certain other clinical skills identified by the Midwifery Council; undertake a certain amount of elective continuing education; and complete a certain amount of professional activity (Midwifery Council of New Zealand 2004d).

A key element of the recertification program is that every midwife is required to undergo the NZCOM's Midwifery

BOX 10.4 Revised competencies for entry to the Register of Midwives

Competency 1
'The midwife works in partnership with the woman throughout the maternity experience.'
Explanation
The word 'midwife' has an inherent meaning of being 'with woman'. The midwife acts as a professional companion to promote each woman's right to empowerment to make informed choices about her pregnancy, birth experience and early parenthood. The midwifery relationship enhances the health and well-being of the woman, the baby and their family/whanau. The onus is on the midwife to create a functional partnership. The balance of 'power' within the partnership fluctuates but it is always understood that the woman has control over her own experience.

Competency 2
'The midwife applies comprehensive theoretical and scientific knowledge with the affective and technical skills needed to provide effective and safe midwifery care.'
Explanation
The competent midwife integrates knowledge and understanding, personal, professional and clinical skills within a legal and ethical framework. The actions of the midwife are directed towards a safe and satisfying outcome. The midwife utilises midwifery skills that facilitate the physiological processes of childbirth and balances these with the judicious use of intervention when appropriate.

Competency 3
'The midwife promotes practices that enhance the health of the woman and her family/whanau and which encourage their participation in her healthcare.'
Explanation
Midwifery is a primary health service in that it recognises childbirth as a significant and normal life event. The midwife is therefore responsible for supporting this process through health promotion, education and information sharing, across all settings.

Competency 4
'The midwife upholds professional midwifery standards and uses professional judgement as a reflective and critical practitioner when providing midwifery care.'
Explanation
As a member of the midwifery profession the midwife has responsibilities to the profession. The midwife must have the skills to recognise when midwifery practice is safe and satisfactory to the woman and her family/whanau.

Each of the above competencies has a number of criteria that provide detailed measures of how a midwife would demonstrate her competence against each competency statement. The full list of competencies and criteria can be found on the Midwifery Council of New Zealand website (www.midwiferycouncil.org.nz).
(Source: Midwifery Council of New Zealand 2004c)

Standards Review process either annually or every three years. As part of the review, the MSR committee focuses on the midwife's ability to meet the NZCOM standards for practice and the Midwifery Council Competencies and assists the midwife to identify a personal development plan for the forthcoming year(s).

Midwives are randomly audited to ensure they comply with the requirements of the Recertification Program.

Competence review

Where it has reason to be concerned about a midwife's competence to practise, the Council can carry out a competence review. It establishes a Competence Review Panel to make an assessment of a midwife's competence. If concerns are identified, the Council has various powers, such as requiring the midwife to complete a specific competence program, undertake further education or work under certain conditions. If Council believes that a midwife poses a risk of serious harm to the public, it has the power to suspend a midwife from practice.

Disciplinary functions

All complaints made by consumers about midwives are investigated by the Health and Disability Commissioner and assessed in relation to the Code of Health and Disability Services Consumers' Rights, and findings are reported to the Midwifery Council. If the Commissioner decides the matter is a serious professional matter, he or she may refer it on to the Director of Proceedings, who may then decide to lay charges against the midwife. The HPCAA established a separate tribunal, the Health Practitioners Disciplinary Tribunal (HPDT), to hear allegations of professional misconduct. The HPDT can impose various penalties, including suspension, fines and cancellation of registration.

The Midwifery Council has established a Professional Conduct Committee (PCC) to which it can refer matters for investigation. Such matters may include notifications of practice below required standards of competence and conduct, and notification of convictions for certain offences or against certain legislation. The PCC can investigate, call for evidence and receive evidence or submissions. It can make recommendations to the Council and can lay charges before the HPDT.

Other functions

The Midwifery Council has powers to seek information about any midwife who is notified as being unable to practise appropriately because of some physical or mental condition and to apply conditions to that midwife's practice in order to protect both the public and the midwife. The Council also has

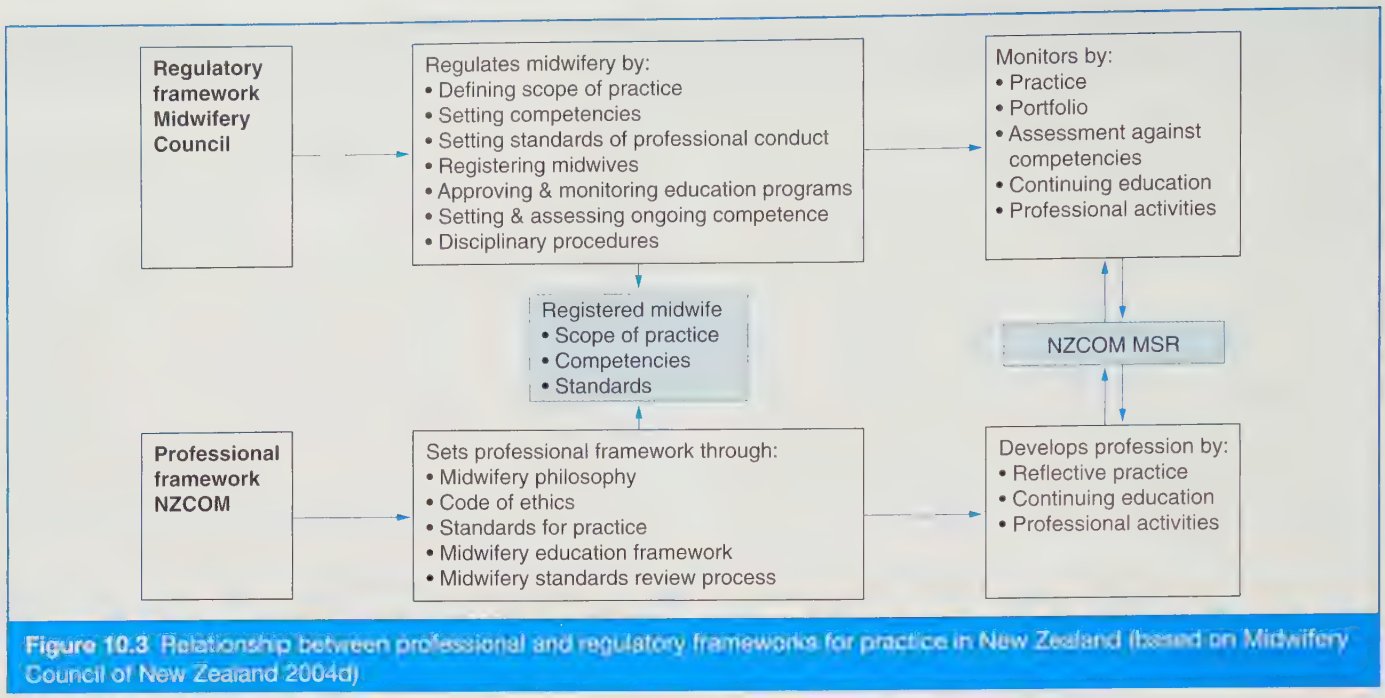

Figure 10.3 Relationship between professional and regulatory frameworks for practice in New Zealand (based on Midwifery Council of New Zealand 2004d)

an important role in approving and accrediting midwifery education providers, programs and courses.

Relationship between the New Zealand College of Midwives and the Midwifery Council

Although they are separate organisations, the roles of the Council and NZCOM are complementary. The Council provides the regulatory framework within which midwives must practise, and it sets the minimum standards required for public safety. NZCOM provides the professional framework in which midwives practise, and it aims to develop and support high standards of midwifery practice. Both organisations have an interest in ensuring that the regulatory processes for midwives are integrated in a professional framework and that appropriate standards of midwifery practice are maintained so that the public can be assured of safe and competent midwifery care. Figure 10.3 shows the interface of these professional and regulatory frameworks.

Midwifery regulation in Australia

Midwifery Scope of Practice

The International Definition of the Midwife has been recognised as the basis for the definition of the role and scope of practice in many Western industrialised countries, including Australia, where it has been used to develop various local and national standards and underpins all curriculum documents for entry to practise midwifery. The midwife's primary role and responsibility is to understand, support and facilitate the physiological processes of pregnancy, labour and the postnatal period with women, within parameters of cultural safety. Additionally, midwives are responsible for identifying deviations from normal and consulting, referring and working collaboratively with other health professionals where required (ACM 2004).

Recent consultations undertaken by the Australian Midwifery Competencies Project: Round Three (Homer 2004) on the role and scope of practice of midwives in Australia have seen the National Executive Committee of the ACM affirm its commitment to the current ICM Definition of the Midwife, including the requirement that this definition be included in any review of standards for practice in Australia (ACM National Executive 2004). Other areas for discussion have related to the timeframe surrounding the woman/midwife partnership postpartum, the inclusion of pre-pregnancy care in the midwife's scope of practice, and midwifery's relationship to sexual and reproductive health, encompassing areas such as family planning. During the course of these discussions the Technical Working Group of WHO (1999) definition of the postnatal period has been acknowledged (i.e. one hour after delivery of the placenta until the first six weeks after giving birth). In the main, debates have focused on existing tensions in maintaining international comparability and alignment while ensuring that the role and scope of practice remains broad, including the attendant consequences for regulation, education and overlap with other professional groups (ACM National Executive 2004).

National midwifery competencies

Competencies for midwives serve as the minimum requirement for licensure/registration to practise. In the Australian context, competencies 'provide details of the skills, knowledge and attitudes expected of a midwife to work within the midwifery scope of practice' (ANMC 2005b, p 6). They detail how a

BOX 10.5 Domains and competencies

Domains and competencies for Australian midwifery are listed below.

Domain 1: Legal and professional practice

- *Competency 1*—Functions in accordance with legislation and common law affecting midwifery practice
- *Competency 2*—Accepts accountability and responsibility for own actions within midwifery practice

Domain 2: Midwifery knowledge and practice

- *Competency 3*—Communicates information to facilitate decision-making by the woman
- *Competency 4*—Promotes safe and effective midwifery care
- *Competency 5*—Assesses, plans, provides and evaluates safe and effective midwifery care
- *Competency 6*—Assesses, plans, provides and evaluates safe and effective midwifery care for the woman and/or baby with complex needs

Domain 3: Midwifery as primary healthcare

- *Competency 7*—Advocates to protect the rights of women, families and communities in relation to the provision of maternity care
- *Competency 8*—Develops effective strategies to implement and support collaborative midwifery practice
- *Competency 9*—Actively supports midwifery as a public health strategy
- *Competency 10*—Ensures midwifery practice is culturally safe

Domain 4: Reflective and ethical practice

- *Competency 11*—Bases midwifery practice on ethical decision-making
- *Competency 12*—Identifies personal beliefs and develops these in ways that enhance midwifery practice
- *Competency 13*—Acts to enhance the professional development of self and others
- *Competency 14*—Uses research to inform midwifery practice

(Source: ANMC 2005)

provider is to practise and what they are expected to be capable of doing, in contrast to definition and scope of practice, which provide the 'broad boundaries' of midwifery practice (ANMC 2005b, p 6).

Domains and competencies deemed relevant for Australian midwifery are those indicated in Box 10.5. A domain is defined as 'a cluster of competency standards that characterise a central aspect of midwifery practice,' and a competency is 'a combination of attributes underlying some aspect of successful professional performance' (Homer et al 2004, pp 7–16). Within each competency are elements that contain examples of competent performance known as cues (Homer et al 2004).

States and territories: legislation

Brodie and Barclay (2001) have recently undertaken a comprehensive analysis of state and territory statutory regulation of midwifery education and practice standards as part of AMAP research. A systematic content analysis of each of the eight nursing statutes purporting to regulate midwifery in Australia was undertaken. Serious deficiencies in the current regulatory system were identified and reflected concerns about midwifery practice, regulation and education in Australia that have been expressed over the previous two decades in relation to issues of international parity, power and outcomes for childbearing women and their infants (Barclay 1985, 1986; Barclay & Haddon 1993; Bogossian 1998; Chamberlain 1998; Donnellan-Fernandez et al 2001; Hancock 1992; Summers 1995; Tracy et al 2000; Waldenstrom 1996, 1997). Midwifery continues to be regulated by nursing and is not recognised as a separate profession to nursing, a position that continues to be contested by women, midwives, the ACM and some regulatory authorities in Australia. Most recently, the Australian Nursing and Midwifery Council added midwifery to its name to indicate recognition of the separate nature of midwifery by that organisation (AMALG 2000; Barclay et al 2003; Donnellan-Fernandez & Eastaugh 2003; Phelan 2005; Reiger 2003).

Registration, continuing competence and disciplinary functions

In the Australian context, 'midwife' describes a registered/regulated health professional who has undertaken either a nursing degree with subsequent postgraduate 'midwifery' education, or, more recently, a comprehensive three-year Bachelor of Midwifery Degree (i.e. direct entry route). Midwifery in Australia continues to experience inconsistent and de facto regulation under the auspice of nursing legislation in most of the eight states and territories. This position has historically been contingent on social and professional acceptance of a legislated identity that has classified midwifery as a branch of specialist nursing practice. Lying within this regulatory misappropriation is a series of anomalies and ambiguities that vary among the states and territories and includes: varying educational requirements in midwifery curricula; declaration of competence in accordance with national nursing competencies in some states and territories; an annual declaration of continuing competence in midwifery when the practising certificate renewal is issued by the regulator, but no mandated requirement for demonstration of midwifery standards review; professional misconduct committees and disciplinary tribunal and process constituted under nursing frameworks. These anomalies call into question the credibility of assessment and regulation processes for midwives in Australia at the national level and create further difficulties and inconsistencies with respect to Mutual Recognition legislation. Urgent legislative ambiguities currently exist for students graduating from three-year Bachelor of Midwifery Degree programs who have not undertaken nursing studies or clinical competencies in nursing. Similarly, midwives arriving from overseas and seeking employment in Australia who have not been educated via nursing pathways are confronted with the same inconsistencies.

Recent developments

Beginning in 2003, and subsequent to National Competition Policy Review of professional regulation over the previous decade (COAG 1999) and intense lobbying by women and midwives, amendments to the Nurses Acts in New South Wales, the Northern Territory and the Australian Capital Territory are now naming midwifery as a discrete field alongside nursing in the titles of their Boards. Western Australia currently also has a Nurses and Midwives Bill before the WA Parliament, to replace the existing WA Nurses Act 1992 (ANF 2006). It may be naive, however, to assume that, without further direct lobbying and pressure from midwifery organisations and consumers, nationally consistent standards for statutory midwifery regulation will be prominent on the government's agenda. Much work remains to be done if a comprehensive, nationally consistent approach to regulating the midwifery profession, as has recently occurred in New Zealand, is to be achieved in all Australian states and territories. Recent recommendations in the National Productivity Report, chaired by Mike Woods, advocate the merging of Australia's 90 existing registration boards for health professionals into one national entity (AGPC 2004; Cresswell 2006).

National legislation and regulation

Regulated labour force arrangements that construct and distort midwifery as a branch of specialist nursing practice ensure a continuing division of labour to serve the interests of institutionalised medical birthing practice in Australia. Vigorous consumer activism in the second half of the twentieth century has highlighted tensions between medicalised mainstream maternity services available in the Australian context and a rising identity crisis in midwifery practice and education (NMAP 2002). This climate has implications for regulation of the midwifery workforce. Ongoing sponsorship of the medical model of childbirth by the modern nation state via health funding, infrastructure support, and maintenance of current regulatory arrangements makes the continuing relationship between nursing and the regulation of midwifery practice highly significant, and open to critique in both the social and the professional domains (Donnellan-Fernandez & Eastaugh 2003).

Friedson's assertion that 'a profession is a group that has authority *in the law* to select its own members and to regulate their practice'(cited in Ehrenreich & English 1973, p 47) requires nationally consistent education requirements for midwifery and nationally consistent practice standards that are universally endorsed by Australian nursing and midwifery regulatory authorities, including the Australian Nursing and Midwifery Council. Although the ACM is appropriately engaged in articulating national standards for midwifery practice and education, it currently has no statutory mandated authority on behalf of midwives or women, to ensure in the public interest that these standards are being met.

The first principle of professional regulation through legislation is that it should be in the public interest (COAG Committee on Regulatory Reform 1999). The public interest of naming *what* is being regulated cannot be overstated. Reform and innovation that acknowledges a discrete legislated identity and mandate for regulation of the midwifery profession in Australia is supported by current scientific evidence and policy directives of the World Health Organization that recognise midwives as the most appropriate, cost-effective providers for women experiencing healthy pregnancy and childbirth (WHO 1996). Although national midwifery legislation is precluded by the Australian constitution and cooperative federalism model in which state and territory governments retain responsibility for legislating with respect to provision of services and regulation of trade and commerce, national consistency in midwifery regulation across state and territory borders is possible, desirable and expected under the terms of Mutual Recognition. This aim has been articulated in the Vision Statement and Terms of Reference of the Australia Midwives Act Lobby Group (AMALG) since 2000 (AMALG 2000) (see Box 10.6).

BOX 10.6 AMALG Vision Statement

- Women and midwives work in partnership to ensure culturally appropriate care that is safe, affordable and accessible.
- Midwives are autonomous practitioners who provide woman-centred care.
- Midwifery legislation will protect and strengthen the woman and midwife partnership.

(Source: AMALG 2000)

Encompassed within a mandate for national regulation is the agenda to legitimise and fund, through legislative reform, authorisation of services already undertaken by midwives, such as test ordering for normal pregnancy and childbearing, diagnostic imaging, prescribing and referral practices (NHMRC 1998). Unlike New Zealand, where midwives are reimbursed for services via the Maternity Benefit Schedule, in Australia, midwives are excluded from federal funding mechanisms provided through Medicare and HIC (Health Insurance Commission) Agreements via which medical practitioners providing midwifery services maintain their state-supported monopoly on maternity care (Australian Government Productivity Commission (AGPC) 2004; Maternity Coalition 2003). These current economic and legislative arrangements deny Australian women equity in accessing midwifery-based care.

Relationship between professional and regulatory frameworks in Australia

The national professional framework for midwifery and current regulatory jurisdictions in each state and territory demonstrate inconsistency and a lack of integration. However,

political alliances between the community and midwives are beginning to drive a reform agenda that demands consistency and integration of these areas, in the interest of public safety. This includes the need for a discrete legislated identity for the midwifery profession in Australia (www.maternitycoalition.org.au; www.amalg.asn.au). Kahn articulated the notion of language as an instrument of control, describing it as 'the repository of all power relations' (cited in White 1999). That midwifery is a contested site is evident both in the discourses on childbirth in Australia and in the historical regulation of midwifery as specialist nursing practice. How midwives name themselves and their practice is significant, with the importance of naming in nursing and midwifery having been well described by White (1999), Leap (1999) and Brodie & Barclay (2001).

The process of emancipation for midwifery in Australia within a context of dominance by the nursing profession is evolving and gaining momentum through multiple paradigm shifts, including: introduction of a national professional standards framework for midwives in Australia; introduction of direct, comprehensive three-year university degree programs for midwifery education; implementation of continuity of midwifery care services in mainstream health settings across the nation; legislative amendment of state and territory Nurses Acts to recognise the discrete discipline of midwifery; increasing professional awareness of interdisciplinary practice domains; and public demand for greater accountability from providers of healthcare.

A professional framework underpinned by the International Definition of the Midwife, based on national standards for midwifery education and practice, and linked to continuing professional development and competence, is articulated by ACM (2005). Uniform endorsement and adoption of these national midwifery standards by the Australian Nursing and Midwifery Council and current regulators is essential to protect the public interest, to promote and maintain high standards of maternity care in Australia, and to underpin and further the goal of realising nationally consistent midwifery legislation in all states and territories within the next five years.

Conclusion

This chapter has provided a brief overview of the professional and regulatory frameworks for midwifery practice in Australia and New Zealand. While midwifery in both countries is claimed to be a profession, New Zealand midwifery has a legal and professional framework that supports this claim. Australian midwifery faces a number of challenges to bring about legislated change that will recognise midwifery as separate from nursing, through regulation and to change funding, insurance and other institutional processes that will support midwifery's professional framework and aspirations. Although professional frameworks are extremely important, legislated changes are essential if midwifery is truly to be self-determining as a profession.

Review questions

1. What are the main characteristics of a profession and why is it important for midwifery to be a profession?
2. What does the concept of 'professionalism' mean for midwifery?
3. How do current social/partnership models of birth affect the notion and development of midwifery as a profession in Australia and New Zealand?
4. How is the midwifery scope of practice (as defined in the WHO definition and by the NZ Midwifery Council) enabled or constrained in both the Australian and New Zealand contexts?
5. What is the relationship between scope of practice and competencies?
6. What is the purpose of regulation of midwifery and how does it work?
7. What has been the influence of history, role, functions and structure on the midwifery profession in both Australia and New Zealand, and how is this manifest currently in delivery of maternity services in each country?
8. How does the relationship between the professional and regulatory frameworks influence midwifery practice in Australia and New Zealand?
9. How does New Zealand's Midwifery Standards Review process work to improve standards of midwifery practice?
10. What might be the impact of deregulation of midwifery?

CHAPTER 11

Legal frameworks for practice in Australia and New Zealand

Helen Newnham and Jackie Pearse

Key terms

common law, regulation, statute[1]

Chapter overview

The law regulates and controls the practice of midwifery and provides legal redress for clients who have been injured after contact with a member of the midwifery profession. This chapter provides an overview of the main statutes from Australia and New Zealand that affect midwifery practice. An understanding of the law and how it operates is essential for safe practice and so that midwives can fulfil their legal responsibilities both to clients and to the midwifery profession.

Learning objectives

Learning outcomes for this chapter are:

1. To summarise key legislation affecting midwives in Australia and New Zealand as they relate to regulation and control of the midwifery practice
2. To examine the role and function of nursing/midwifery regulatory authorities
3. To discuss the legal responsibilities of midwives when undertaking midwifery practice
4. To examine privacy issues as they pertain to midwifery practice and patient access to information
5. To discuss the legislative requirements for the notification of births and deaths in midwifery practice
6. To explain the avenues of complaint for clients following an adverse incident
7. To examine the role and the function of the Coroner's Court as it relates to midwifery practice.

Introduction to the law

The primary functions of the law are to provide protection to citizens, to administer and regulate entitlements, and to sanction those who offend against the norms and values of any society, as those norms and values are expressed within its legal system. In Australasia the generic term 'law' refers to the Acts of Parliament (statutes), regulations, and the common law, each of which govern the lives and actions of citizens within our respective societies.

Why is the law important to midwives?

All midwives must be aware of the legislative context in which they practise and they must be sufficiently cognisant of 'the law' to enable them to fulfil their legal and professional obligations to their clients, profession and society. The law confers duties on practitioners and provides for the protection of the fundamental rights of health consumers. There may be significant consequences for a midwife where harm results from an act or omission in the delivery of health care. Following an incident a midwife may face a civil action brought by the mother or parents of a newborn, or a criminal action brought by the authorities, or a disciplinary hearing brought by the regulatory authority. Ignorance of the law is no excuse. Every midwife should be aware of the law in the jurisdiction in which she practises.

Midwifery practice in both Australia and New Zealand is governed by a large number of statutes. This chapter summarises key Australian and New Zealand statutes to help midwives understand the breadth of their legal responsibilities.

Australia, unlike New Zealand, is a federation with six states and two territories, each with a legislative body making laws that affect the practice of midwives. In a chapter such as this it is impossible to cover all the laws governing the practice of midwifery in Australia; instead, it provides an overview of certain key pieces of legislation and professional issues governing midwives. Midwives are encouraged to be aware of the laws of the jurisdiction in which they practise.

The chapter is divided into sections addressing the laws that pertain to midwifery regulation, public safety, privacy and personal information, and midwifery practice. Each section provides information first for Australia and then for New Zealand. As New Zealand midwives may prescribe drugs on their own responsibility there is a section on specific legislation pertaining to this. It is understood that Australian midwives are involved in the administration of medications and need to be familiar with relevant legislation in their jurisdictions. However, specific information on that legislation is not provided in this chapter. In the final section, the role of the coroner is addressed for Australia and New Zealand together, as the function and purpose of a coronial inquest is similar in both countries.

Key statutes on regulation of midwifery practice

Midwifery regulation in Australia

Overview

In 1901 the Federation of Australia came into existence. The Commonwealth of Australia consists of six states and two territories, each with its own statutory authority to regulate the practice of nursing and midwifery. Section 51 of the Australian Constitution gives the federal or Commonwealth legislature certain powers to make laws for the 'peace, order and good government of the Commonwealth'. Therefore, the Commonwealth Government has power to pass laws in the national interest but this does not include the regulation of professions. Until such time as the states and territories concede that power to the Commonwealth, or the Constitution is changed, Australia will remain with eight jurisdictions—six states and two territories—regulating the practice of nursing and midwifery. Although similarities exist between the states and territories, there are also differences. It is not possible to provide a comprehensive review of all the legislation in the area in a chapter such as this, and midwives are encouraged to familiarise themselves with the legislation in the jurisdiction in which they practise.

Mutual recognition legislation

Prior to the introduction of mutual recognition legislation, a nurse or midwife who wished to practise in another state or territory had to apply for registration. Each case was assessed individually and required the submission of evidence of registration in the first state. Mutual recognition legislation first introduced by the Commonwealth in 1992 and subsequently adopted by the states and territories has in part facilitated the process of registration from one state to another but is well short of a national registering authority. The main principle of the legislation is that a person registered in one state is entitled to be registered in another state for the equivalent occupation (section 17 *Mutual Recognition Act 1992* (Commonwealth (Cth))). If any conditions are placed on practice, or the registration of a nurse or midwife is cancelled or suspended in one state following a disciplinary hearing, the person's registration in another state is similarly affected. However, the other state may vary or waive any conditions set in the first state if this is considered appropriate given the circumstances (section 33 *Mutual Recognition Act 1992* (Cth)).

All states and territories, with the exception of Western Australia and Tasmania, have Trans-Tasman mutual recognition legislation allowing for registration of nurses and midwives between Australia and New Zealand.

Midwifery regulation

Until the early twentieth century, midwives mostly practised independently and without regulation. Tasmania was the first

state in Australia to regulate midwives with the *Midwifery Nurses Act 1901*. Victoria regulated midwives with the *Victorian Midwives Act 1915*, followed by South Australia in 1920 and New South Wales in 1923 (www.nursesreg.nsw.gov.au/). All midwives in Australia are now registered and regulated by nursing and midwifery registering authorities in their respective states or territories.

Professional regulatory authorities

Each state has a Nurses Act or Nurses and Midwives Act and accompanying Regulations. The names of the Acts and governing bodies vary from jurisdiction to jurisdiction (see Table 11.1).

The legislation sets out the role and function of the regulatory authorities including the composition of the Board or Council and the procedure for disciplinary hearings.

The ACT, NSW and the Northern Territory, in addition to Australia's peak nursing body, the Australian Nursing and Midwifery Council (ANMC), have incorporated 'midwifery/midwives' into the title of their legislation and nursing regulatory authorities in recognition of midwifery as a separate discipline.

Generally the legislation has a common purpose, namely to maintain acceptable standards within the practice of nursing and midwifery and to ensure that clients are not misled as to whether their health carer has met the requirements of the state (Wallace 2001). By registering nurses and midwives, setting and maintaining standards, and inquiring into alleged misconduct, the public is protected. The wording of the Acts varies from jurisdiction to jurisdiction and while some specifically state in the objects that the purpose of the Act is the protection of the public, others do not. By way of example, the *Nurses and Midwives Act 1991* (NSW) states the following:

> Section 2A of the Nurses and Midwives Act 1991, NSW
> (1) the objects of the this Act are:
> (a) to protect the health and safety of the public by providing mechanisms to ensure that nurses and midwives are fit to practise, and
> (b) to provide mechanisms to enable the public and employers to readily identify nurses and midwives who are registered or enrolled under the Act.
> (2) The Board must exercise its functions under the Act in a manner that is consistent with these objects.

The titles of 'nurse' and 'midwife' are protected under the legislation with penalties for unauthorised use. Generally there are two divisions of the register for nurses and midwives in the various states and territories. Comprehensive and general nurses are recorded in Division 1 and enrolled nurses in Division 2. On successful completion of an accredited course, midwives are endorsed or recorded in Division 1 of the register. Once registered, a midwife must notify the appropriate authority of her intention to practise as an independent or private midwife. The notification is usually in a prescribed form, such as the Health (Notifications By Midwives) Regulations 1994, WA.

In New South Wales, the Nurses and Midwives Board will recognise courses leading to a Bachelor of Midwifery without the previous requirement of a nursing qualification. Midwives who are nurses will remain on the register for nurses with an endorsement for midwifery.

Powers and functions of the regulatory authorities

Although the boards and council have expressed their powers and duties differently, in essence they have a common purpose. Section 16(1) of the *Nurses Act 1999* (SA) identifies the functions of the Nurses Board of SA as follows:

> (a) to regulate the practice of nursing in the public interest;
> (b) to determine the scope of nursing practice;
> (c) to approve courses of education or training that provide qualifications for registration or enrolment as a nurse under this Act;

TABLE 11.1 Statutes regulating the practice of nursing and midwifery in Australia

State/territory	Name of the Act	Board/Council
Australian Capital Territory	*Nurses Act 1988* *Health Professionals Act 2004*	ACT Nursing and Midwifery Board
New South Wales	*Nurses and Midwives Act 1991*	Nurses and Midwives Board of NSW
Northern Territory	*Health Practitioners Act 2004*	The Nursing and Midwifery Board of the Northern Territory
Queensland	*Nursing Act 1992*	Queensland Nursing Council
South Australia	*Nurses Act 1999*	Nurses Board of SA
Tasmania	*Nurses Act 1995*	Nursing Board of Tasmania
Victoria	*Nurses Act 1993*	Nurses Board of Victoria
Western Australia	*Nurses Act 1992*	Nurses Board of WA

(d) to determine the requirements necessary for registration or enrolment under the Act;
(e) to investigate the fitness of persons to practise as nurses in this State, and to investigate the professional conduct of nurses who are registered or enrolled under this Act;
(f) to endorse codes of conduct for nurses;
(g) to endorse professional standards, including definitions and titles;
(h) to authorise areas of specialist nursing practice for inclusion on the register or roll under this Act;
(i) to determine and recognise special practice areas for the purposes of this Act;
(j) to exchange information with other registering authorities for nurses;
(k) to provide advice to the Minister as may be appropriate;
(l) to carry out other functions assigned to the Board by or under this Act, or by the Minister.

Midwives should consult the relevant legislation in their jurisdiction.

Disciplinary action

As part of its role in protecting the public, each board or council has the power to investigate professional misconduct by a nurse or midwife and recommend that a disciplinary hearing take place. The process is initiated by a complaint, which may be from a patient, a member of the public or another health professional, often a Director of Nursing. The complaint is then investigated and the matter may or may not proceed to a disciplinary hearing. If the complaint is considered frivolous or vexatious it may not be pursued.

Most states have a two-tiered system where, for instance in New South Wales, a Professional Standards Committee is set up to review complaints, and should a finding of professional misconduct be made the matter is referred to the Nurses and Midwives Tribunal. Following an enquiry, the name of the midwife may be removed from the Register or Roll. In Western Australia, an informal or formal inquiry may be held. A nurse or midwife can only be de-registered following a formal inquiry.

Section 4(1) of the *Nurses and Midwives Act 1991*, NSW defines 'professional misconduct' as 'Unsatisfactory professional conduct of a sufficiently serious nature to justify the removal of the nurse's name from the Register or Roll'. The NSW *Nurses and Midwives Act 1991* distinguishes 'unsatisfactory professional conduct' as less serious than 'professional misconduct' and defines the term in section 4(2) as:

(a) any conduct that demonstrates lack of adequate:
  (i) knowledge,
  (ii) experience,
  (iii) skill,
  (iv) judgement, or
  (v) care
  by the nurse or midwife in the practice of nursing or midwifery.

The onus of proof is on the board or council to prove the allegation against the nurse according to the civil standard of proof, which is on the balance of probabilities.

Under section 61 the Nurses Board of Western Australia has further powers to conduct a disciplinary hearing where: registration has been obtained by fraud; a nurse has been convicted of an offence, is addicted to or misuses alcohol, any deleterious drug or suffers from a mental or physical disorder that renders the person unfit to practise as a nurse.

Section 61(g) of the *Nurses Act 1992*, WA provides that the Board may take action against a person who is guilty of unethical conduct as a nurse by reason of:

(i) carelessness
(ii) incompetence
(iii) impropriety
(iv) misconduct
(v) a breach of this Act; or
(vi) non-compliance with any condition or restriction imposed under this Act.

The purpose of a disciplinary hearing is not to punish the nurse or midwife but to protect the public. While many nurses who appear before a disciplinary hearing no doubt consider the process punitive, that is not its main purpose. While an aggrieved patient may notify the Board or Council of the alleged misconduct, the hearing does not provide for a compensation payment to be paid to the patient. Should a patient wish to be compensated for the loss incurred, a civil action must be brought through the courts. The Boards or Council have the power to set up an independent committee of enquiry, which conducts a hearing into the alleged misconduct. The names of the committees, procedure and composition of the committee hearing the disciplinary matter varies but each jurisdiction provides for a process designed to protect the public by ensuring that nurses and/or midwives are fit to practise. Some proceedings are open to the public.

In the ACT, the complaint process is controlled by the *Nurses Act 1988*, the *Health Professionals Boards (Procedures) Act 1981* and the *Community Health Services Complaints Act 1993*. It is anticipated that from 2005 in Western Australia, the state Administrative Tribunals will conduct hearings into what were previously formal hearings dealt with by the Professional Standards Committee of the Nurses Board. The Board will continue to conduct informal hearings but it will no longer have the power to suspend or de-register a nurse or midwife.

While the procedure and composition of the committees investigating the alleged misconduct varies from jurisdiction to jurisdiction, most are informal. The rules of evidence do not apply, with the exception of formal enquires in Western Australia. However, a hearing is governed by rules set out in the relevant legislation and incorporates the principles of natural justice. The main principles are that the accused must know of the allegations, and must be able to state their case, and that 'no one may sit in judgement of another who has a vested interest in the outcome' (Wallace 2001, p 16). Following a disciplinary hearing, a right of appeal exists within the respective legislation. By way of example, a breach in the rules of natural justice would give a midwife the right to appeal to another judicial body according to the specific legislation.

The penalties imposed by the Boards or Council following a finding of guilty vary but in general range from a censure to de-registration. By way of example, the Nurses Board of Victoria may, under section 41 of the *Nurses Act 1993*, impose the following penalties after an informal hearing where a nurse or midwife has been found guilty of unprofessional conduct which is not of a serious nature:

(a) that the nurse undergo counselling;
(b) that the nurse be cautioned;
(c) that the nurse be reprimanded;
(d) that the nurse undertake further education of the kind stated in the determination and complete it within the period specified in the determination.

The Nurses Board of Victoria can, under section 48 of the *Nurses Act 1993*, Vic, impose the following penalties after a formal hearing:

(a) require the nurse to undergo counselling;
(b) caution the nurse;
(c) reprimand the nurse;
(d) require the nurse to undertake further education of the kind stated in the determination and to complete it within the period specified in the determination;
(e) impose conditions, limitations or restrictions on the registration or endorsement of registration of the nurse;
(f) impose a fine on the nurse of not more than 10 penalty units;
(g) suspend the registration or endorsement of registration of the nurse for the period specified in the determination; or
(h) cancel the registration or endorsement of registration of the nurse.

The number of complaints received in 2002–03 represents a substantial increase in the number of complaints received by the Nurses Board of Western Australia from the previous year. In the same period, nine formal hearings were conducted with three pending, and 13 informal hearings with two pending (Nurses Board of Western Australia 2003, p 13).

Midwifery regulation in New Zealand

Nurses Act 1977

The *Nurses Act 1977* was the governing legislation for nurses and midwives in New Zealand until 2003 and it established the Nursing Council of New Zealand as the statutory body. It was the role of the Nursing Council, amongst other things, to regulate registration of local and overseas nurses and midwives, issue annual practising certificates, approve educational programs, and investigate and hear complaints against nurses and midwives as part of its disciplinary function.

The regulation of midwives was transferred from the Nursing Council to the Midwifery Council of New Zealand as a result of the *Health Practitioners Competence Assurance Act 2003* (HPCAA). This legislation repealed the *Nurses Act 1977*, and other health professional legislation, and established the Midwifery Council as the responsible authority to regulate the practice of midwifery.

Nurses Amendment Act 1990

Before considering the HPCAA in more detail, it is useful to briefly reflect on the enactment of the *Nurses Amendment Act 1990*, as the passing of this Act represented a major victory for midwives and women in New Zealand. Prior to this Amendment Act, the requirement for a doctor to oversee maternity care and be present at every birth meant that women were limited in the type of care they could access. Women who wanted to birth at home struggled to find a doctor willing to attend the birth. The 1990 Amendment removed the medical monopoly on maternity care and as a consequence enabled greater choice for women about who cared for them during pregnancy and birth, and where they gave birth.

For midwives, the advantages accompanying the Amendment Act were equally significant. As a profession, midwifery regained its professional autonomy and midwives were given a socially mandated right to practise independently of medical practitioners and medical oversight. In her introduction to an information booklet for providers, the Honorable Helen Clark, then Minister of Health, stated:

> Statistics reflect the benefit of a commitment to natural childbirth, of continuity of care of the client and the rejection of unnecessary intervention. The majority of women have been socialized to perceive birth as an illness. The challenge of this legislation is to change this perception (Department of Health 1990, p 1).

This was a socially and internationally unique statement. It represented an affirmation by government of the importance of natural childbirth and provided a statutory recognition that midwives were appropriate caregivers for women experiencing normal birth.

The Amendment Act also enabled midwives (through changes to other legislation) to provide a full range of maternity services, including the right to order laboratory tests and ultrasound scans, to prescribe drugs for antenatal, intrapartum and postnatal care, including the controlled drug pethidine, to refer clients to specialists, and to admit women to public hospitals under midwifery care.

The Amendment Act enabled experimental midwifery education programs to be established and paved the way for direct entry midwifery education, which is now the most common route to midwifery registration in New Zealand. The Amendment Act was also a key step in the attainment of pay equity for midwives. This equity was reinforced through a ruling of the 1993 Maternity Tribunal, which stated that general medical practitioners and midwives provided the same level of maternity care and should be paid the same amount for providing that service.

Health Practitioner's Competence Assurance Act 2003 (HPCAA)

A key aim of this omnibus Act was to bring all registered health practitioners under one regulatory framework rather than enact a separate piece of legislation for each professional group. The HPCAA was highly significant for New Zealand midwives as it established what may be the world's first solely midwifery council—a council completely separate from

nursing and medicine. Its establishment has removed the final barrier to full professional autonomy for midwives.

The HPCAA (2003) sets out the functions of the various professional councils, or, as they are termed, Responsible Authorities. In summary, each authority is required to:

- maintain a public register
- authorise registration
- set standards of clinical, cultural and ethical competence
- monitor and accredit educational institutions, programs and degree courses
- review and promote the competence of practitioners
- issue annual practising certificates
- notify appropriate persons or bodies, where the practice of a health practitioner may pose a risk of harm to the public
- establish health and disability procedures for practitioners whose health or habits are affecting their practice.

Each council or authority will additionally establish a 'scope of practice' for the profession it regulates, and identify any health services that are to be termed 'restricted activities' and therefore only able to be performed by health practitioners who are competent to practise such activities.

The HPCAA (2003) gives the Midwifery Council a wide scope to establish Professional Conduct Committees and Competence Review Committees to investigate and review the conduct and/or competence of any midwife. If valid concerns are identified, the Council may require that midwife to undergo a competence program to ensure that she is practising to a safe and reasonable standard, and may impose restrictions on the midwife's practice to ensure protection of the public while improving her standard of practice.

The HPCAA (2003) also divides the disciplinary and regulatory functions of the councils and establishes a new Health Practitioner's Disciplinary Tribunal (HPDT), which will hear all professional misconduct charges against all professionals. The Tribunal has a legal chair and among its members are one lay person and three peers from the same profession as the respondent practitioner. The process of investigation and the hearing procedures are contained on the HPDT website (see list of online resources later in this chapter). If, following a hearing, there is a finding of professional misconduct against a midwife, the penalties that may be imposed include censure, suspension or restrictions on practice, such as the requirement for supervision or that the midwife work in a specific area, for up to three years, a fine of up to $30,000, or removal of the midwife's name from the register. Part of the penalty would include an award of costs against the midwife and there would normally be publication of the midwife's name and details of the HPDT decision in the media and practice journals. Any midwife who is unhappy with a decision of the tribunal may appeal to the High Court of New Zealand.

Other statutes that protect public safety

Complaint procedures and professional negligence in Australia

Unlike New Zealand, Australia does not have a no-fault liability scheme to compensate injured clients. Following an adverse event, a client may choose to seek redress in a number of ways. They may go directly to the healthcare provider, which may be an institution or midwife. Alternatively, they may sue the midwife for negligence or they may take their grievance to a health complaints authority.

Professional negligence

Negligence is part of tort law, which seeks to compensate persons injured through an act or omission of another. The purpose of this is to put the person in the position they would have been in had they not been injured (Forrester & Griffiths 2001). Damages are intended to compensate the injured party, not to punish—that is the role of criminal law (Skene 2004).

Civil liabilities legislation has been enacted in the states and territories in response to the so-called medical insurance crisis (Skene 2004). Legislation now provides for a statutory basis for the principles of negligence, which were based on common law principles. It is presumed that in interpreting the statutory provisions, the courts will apply the general principles of negligence evolved through the common law (Balkin & Davis 2004).

In negligence, the plaintiff must prove that a duty of care was owed, that there was a breach in the duty of care, that is, the standard of care fell below that of an ordinary reasonable midwife given the circumstances, and that the damage or injury was a reasonably foreseeable consequence of that breach.

There is no question that a midwife owes a client a duty of care. To successfully argue otherwise would in most cases be extremely difficult. Lord Atkin, in the now famous case of *Donoghue v Stevenson* [1932] AC 562 at 580, established to whom a duty of care is owed.

> You must take reasonable care to avoid acts or omissions which you can reasonably foresee would be likely to injure your neighbour. Who then in law is my neighbour? The answer seems to be persons who are so closely affected by my act that I ought reasonably to have them in contemplation as being so affected when I am directing my mind to the acts or omissions which are called in question.

The statutory duty of care is identified in section 5B of the *Civil Liability Act 2002*, WA Similar provisions exist in other jurisdictions within Australia.

> Section 5B
>
> (1) A person is not liable for harm caused by that person's fault in failing to take precaution against a risk of harm unless–
>
> (a) the risk was foreseeable (that is, it is a risk of which the person knew or ought to have known);

(b) the risk was not insignificant; and
(c) in the circumstances, a reasonable person in the person's position would have taken those precautions.

(2) In determining whether a reasonable person would have taken precautions against a risk of harm, the court is to consider the following (amongst other relevant things)–
(a) the probability that the harm would occur if care were not taken;
(b) the likely seriousness of the harm;
(c) the burden of taking precautions to avoid the risk of harm;
(d) the social utility of the activity that creates the risk of harm.

Once a duty is established, the plaintiff must prove that the midwife breached her duty of care or that it was her fault that the injury occurred. The test used to establish a breach is one of reasonableness. The standard required of a midwife is an objective test according to what a 'reasonable midwife' would or would not have done in the circumstances. In determining whether the standard has been met, the court will consider not only expert evidence but various documents such as appropriate statutes, hospital policy and the midwife's case notes.

In proving causation, the traditional test in Australia has been the 'but for' test. The 'but for' test is expressed as, but for the actions of the defendant the plaintiff would not have been injured. However, it is not an exclusive test (Skene 2004, p 230). Civil liabilities legislation now requires a factual causation, that is, whether the harm was caused by the negligence and whether 'it is appropriate to extend the scope of the tortfeasor's (defendant's) liability to the harm so caused (scope of liability)' (s 5C *Civil Liability Act 2002*, WA).

The plaintiff always bears the onus of proof, according to the civil standard of proof, namely, on the balance of probabilities (s 5D *Civil Liability Act 2002*, WA). The defendant does not have to prove that he or she was not negligent but rather raise sufficient evidence to throw doubt on the plaintiff's case (Wallace 2001).

Health complaints authorities in Australia

Each state and territory has an independent health care complaints body, set up under specific legislation to deal with complaints about health care providers and services (see Table 11.2). The health complaints authorities are in recognition of an increase in patients' rights (Wallace 2001) and acknowledgement that it may not be appropriate to take every grievance through the courts. Forrester and Griffiths (2001) suggest that while the aim of tort law is to maintain quality health care through the threat of litigation, this is not always the case.

An aggrieved patient may choose not to purse litigation through the courts. The process is time-consuming, expensive and stressful whether or not the case proceeds to court. An alternative means of resolution is through a health complaints authority, where the patient can make a complaint about the health care provider. The legislation varies from jurisdiction to jurisdiction but in general the aim of the legislation is to provide an independent body for the resolution of complaints between health consumers and providers.

TABLE 11.2 Australian health complaints authorities

Legislation	Complaints body
Community Health Services Complaints Act 1993, ACT	Community and Health Service Complaints Office
Health and Community Services Complaints Act 1998, NT	Health and Community Services Complaints Commission
Health Rights Commission Act 1991, Qld	Health Rights Commission
Health and Community Services Complaints Act 2004, SA	Health and Community Services Complaints Commision
Health Complaints Act 1995, Tas	Health Complaints Commissioner
Health Care Complaints Act 1993, NSW	Health Care Complaints Commission (HCCC)
Health Services (Conciliation and Review) Act 1987, Vic	Health Services Commissioner
Health Services (Conciliation and Review) Act 1995, WA	Office of Health Review

In general a complaint must allege that the health service provider acted unreasonably in one or more areas, such as: not providing a health service; in the manner of providing a health service; denying or restricting the user's access to the records kept by the health provider; in disclosing or using the user's health records or confidential information or in the fee charged (s 25 *Health Services (Conciliation and Review) Act* 1995 WA). There is an expectation that the patient will have attempted to resolve the issue with the health care provider before making a complaint (s 30 *Health Services (Conciliation and Review) Act 1995* WA).

The commissioner or director of the health complaints authority has the power to investigate and conciliate a matter arising from a complaint. For a matter to be conciliated requires the consent of both parties. If appropriate, the matter can be referred to the registering authority of the professional involved for investigation (s 32 *Health Services (Conciliation and Review) Act 1995*, WA).

Complaint procedures and professional negligence in New Zealand

Health and Disability Commissioner Act 1994 (HDCA)

Part of the impetus for the appointment of a Health and Disability Commissioner (HDC) was calls from consumer groups for an independent person or watchdog that could investigate complaints against health professionals. Another driver for the establishment of the office of the HDC was the

abject failure of health professionals to regulate themselves and prevent the occurrences that lead to inquiries such as that which became known as the 'Cartwright Inquiry' (Cartwright 1998).

Despite initial government support for a Health Commissioner, it was almost a decade before the first Health and Disability Commissioner was appointed. The Commissioner's first task was to draft a Code of Health and Disability Services Consumers' Rights ('the Code'). This Code sets out 10 fundamental rights for any person receiving a health or disability service. These include the right to:

- respect
- fair treatment
- dignity and independence
- proper standards
- communication
- information
- make informed decisions
- support
- teaching and research protections
- complain.

The Code is a regulation under the substantive Act and is enforceable by law.

The HDCA requires all midwives to practise according to the Code, and it provides an avenue for complaint and prosecution of any midwife who is found in breach of its provisions. The HDC is now the primary complaints organisation in New Zealand and the Office filters and manages almost all complaints against all health practitioners.

A lesser-known requirement of the Code is that any midwife who personally receives a complaint must respond to the complainant within five working days. This is in keeping with the aim of the Act, which is to deal with complaints in a simple, speedy and efficient way, and its underpinning philosophy of early mediation and resolution. Where such resolution cannot be achieved, or is unrealistic given the seriousness of the complaint, the matter will be investigated, the midwife notified of the allegations against her, and statements of witnesses and evidence will be gathered. It is usual for the Commissioner to refer the complaint, and responses, to midwifery experts, who will assist the Commissioner in the consideration of the clinical issues and who will provide an opinion on the reasonableness or otherwise of the midwife's practice and decision-making during the relevant events. Eventually a decision will be made as to whether, in the Commissioner's opinion, the midwife's conduct constitutes a breach of the Code.

During this process the midwife is given at least two opportunities to respond and comment on the case against her, although unfortunately she may not be aware of much of the evidence until very late in the investigation. The first opportunity is following initial notification of the complaint, where she is requested to provide a full report on her involvement to the Commissioner. The second opportunity is upon receipt of the Commissioner's Provisional Opinion, which will set out the evidence and proposed finding. Often it is only at this point that the midwife becomes aware of the full extent of the complaint against her, and it is important that she fully address any adverse evidence before the Commissioner's Opinion is finalised.

If the Commissioner finds the midwife in breach, she or he may make a range of recommendations including written apology, further education, and mentoring. Since the establishment of the Midwifery Council, the Commissioner has begun to recommend that the Council consider whether or not to conduct a competence review of the midwife's practice.

In serious cases the Commissioner will notify the midwife that he or she is referring the matter to the Director of Proceedings. The Director is an independent statutory officer and will determine whether the complaint reaches the threshold of seriousness to warrant laying a charge of professional misconduct before the Health Practitioner's Disciplinary Tribunal and whether, additionally, damages should be sought before the Human Rights Review Tribunal.

Once the Commissioner has finalised his or her Opinion, an anonymous version is circulated to the professional bodies, the complainant, the practitioner(s), to employers and sometimes to external bodies such as the Minister of Health or the police. It may also be placed, for educational purposes, on the Commissioner's website in the hope that similar complaints can be averted. An identifiable copy of the Final Opinion is sent to the Midwifery Council. The Council can decide to take action on the matter, if it decides that it raises professional issues that need to be addressed, even if the Commissioner is not taking the complaint further.

In some cases the Commissioner may liaise with the Midwifery Council earlier in the process. This might occur if the Commissioner had serious concerns about the safety of the midwife's ongoing practice. Alternatively, if the Commissioner came to the view that the midwife had health or disability issues and that these were affecting her ability to practise safely, then the Commissioner might refer the matter to the Health Committee of the Midwifery Council.

The most common areas of complaint against midwives under the HDC jurisdiction relate to poor communication, poor documentation, lack of informed consent, failure to recognise and act on deviations from normal, particularly with respect to fetal heart patterns and failure to progress in labour, and failure to refer women to a specialist in a timely and appropriate manner. These same themes occur in obstetric or maternity complaints across almost all international jurisdictions.

Human Rights Act 1993 / Human Rights Amendment Act 2001

This Human Rights Act is notable for midwives as it established the Human Rights Review Tribunal (HRRT) (previously known as the Complaints Review Tribunal). If a practitioner is found in breach of the *Human Rights Act 1993*, the *Privacy Act 1993* or the *Health and Disability Commissioner's Act 1994*, an 'aggrieved person' or someone acting on their behalf can seek damages of up to $200,000. The claim may cover pecuniary (monetary) loss and expenses reasonably incurred by the complainant and any loss of benefit the person might

reasonably have expected to obtain, but for the breach that occurred.

Under the HDCA it was only the Director of Proceedings who could lay proceedings before this Tribunal. With the advent of the HPCAA, where there is a finding of breach of the Code, any aggrieved person may seek damages before the HRRT, irrespective of whether or not the Director of Proceedings considers that the threshold of seriousness has been met.

The usual HRRT process is that a charge is laid alleging that the breach of the Code has caused humiliation, loss of dignity and injury to the feelings of the complainant or, as the case may be, to the aggrieved person. Once this is received, the Tribunal notifies the parties and sets down a date for a formal hearing. The Human Rights Review Tribunal is made up of a minimum of three people, one of whom is legally trained. The hearings are held in public and witnesses may be summonsed to give evidence. Witnesses have the same privileges and immunities as in court proceedings. Parties may be legally represented and the procedure is similar to that of District Court hearings or disciplinary tribunals. Decisions of the Tribunal must be in writing and be properly reasoned. An Appeal may be lodged against any decision of the Tribunal to the High Court.

Injury Prevention, Rehabilitation and Compensation Act 2001

New Zealand has a comprehensive 'no fault' accident and insurance scheme whereby any person suffering personal injury by accident receives financial compensation and assistance. Part of this is that any claimant who receives cover under the scheme is then effectively barred from bringing suit against a registered health professional. While there are a few exceptions to this rule, the extent of this cover means that New Zealand midwives are largely protected from civil action or law suits against them.

The *Injury Prevention Rehabilitation and Compensation Act 2001* (IPRC) is the most recent version of the Accident Compensation legislation. This legislation was amended in 2005 to simplify the cover criteria and claims process for injuries arising from treatment and make this more consistent with the rest of the ACC scheme.

For a claimant to receive cover for personal injury by accident they must, where a registered health professional has been involved in their care or treatment, bring themselves under the medical misadventure provisions of the IPRC. This section was amended in 2005, replacing the two generic categories of Medical Mishap and Medical Error with a new category of Treatment Injury. Under this amendment, the ACC no longer has to find fault to consider a treatment injury claim for cover, or limit cover to injuries that are 'rare and severe'.

A treatment injury is a personal injury that has occurred within the context of treatment provided by, or at the direction of, one or more health professionals. There must be a direct causal link between the injury and the treatment. Treatment injury cover is for outcomes that are abnormal, unusual or exceptional having regard to the patient's particular circumstances, and such events are not expected to happen often. In the context of treatment injury, personal injury is defined as either the death of a person; physical injury; mental injury suffered by a person because of physical injury; and/or damage to dentures or prostheses that replace a human body part.

Treatment is defined as:

> The giving of treatment; diagnosis; choice of treatment, including a decision not to treat; failure to provide treatment, or to provide it in a timely manner; provision of prophylaxis;
>
> Obtaining or failing to obtain informed consent from the legally appropriate person;
>
> Failure of any equipment, device, or tool used as part of the treatment process, including failure of any implant or prosthesis, other than by an intervening act (e.g. a fall, which would be considered under the accident provisions of the scheme) or fair wear and tear; and
>
> The application of any relevant support systems, including policies, processes, practices and administrative systems (ACC information sheet 2005).

A key objective of the changes was to encourage health providers to make claims earlier and with more comprehensive information to facilitate the timely provision of assistance by ACC to claimants. Ideally, claims for treatment injury should be made on behalf of the patient (claimant) by the registered health professional who provided the treatment that caused the injury. With the removal of the 'fault' aspect, the health professional will be able to provide information to the ACC without fear of reprisal.

There are numerous claims for ACC cover and most New Zealand midwives will deal with a claim every three to five years. The claims are wide ranging but common examples (under the previous category of medical error) included: a failure to accurately diagnose a complication of pregnancy or labour; a tendency to normalise abnormalities, such as where the midwife does not recognise the significance of abnormal tracings, attributing reduced variability to a sleeping trace, or where she does not respond appropriately to warnings of possible fetal distress such as thick meconium, or does not recognise the signs of an obstructed labour. Another bracket of claims related to a lack of, or delays in, appropriate specialist referral. This is a frequent allegation where babies are born with severe asphyxia or are later found to have cerebral palsy.

There have also been a number of less serious claims for complications of perineal lacerations, particularly when the extent of the tear is incorrectly diagnosed by the midwife or where the laceration is left unsutured without documented evidence that the woman has consented for this to happen.

ACC claims have arisen less commonly with respect to postnatal care but may occur where a midwife fails to accurately identify haemolytic jaundice or kernicterus in a baby and the parents later make a claim for a baby's hearing loss or resultant brain damage.

Claims under the old category of medical mishap were rare and included cases where the baby was unexpectedly large or there was a malpresentation or a shoulder dystocia and Erb's palsy resulted, or where the woman sustained an injury to her coccyx or back during labour, or where there was radial nerve damage after an appropriately sited intravenous infusion.

The ACC no longer reports individual medical error decisions and trends to the HDC, registration authorities and employers unless the ACC determines that there is risk of public harm. The ACC continues to collect and make available non-identifiable trend data.

Crimes Act 1961

The Crimes Act has a number of sections, 150A–157, often dubbed the 'duty sections', which require all health professionals to meet a reasonable standard of skill and care in their practice, while operating on patients, and while doing dangerous acts such as administering surgical or medical treatment including administering complex intravenous drug therapy, epidural anaesthesia and drugs (Mellars et al 1995).

The concept of the 'reasonable standard' has been adopted from the common law and is basically linked to the question: 'What would a reasonable midwife do, or not do, in these circumstances?' Usually the adjudicating body will determine the evidence of what constitutes reasonable practice after they have heard the evidence of expert witnesses from the same professional group as the practitioner under scrutiny.

Other criminal charges

Midwives should remember that they are subject to the whole realm of law, just like any other citizens. However, unlike other citizens, a conviction for serious traffic or drug offences, assaults or dishonesty offences may have the additional result for a midwife of a professional misconduct hearing, and a loss of her right to practise.

Reflective exercise

1. There is a wide diversity of views about what drugs or equipment should reasonably be available for midwives to use. What equipment do you think should be available to you as a midwife to ensure the safety of the women and babies you care for? If this equipment is not available, what is your responsibility?
2. Hera is a 40-year-old woman pregnant with her fifth child. She has a history of severe postpartum haemorrhage and has experienced a previous obstructed labour. She has refused referral to a secondary care provider or a specialist, and chooses to birth at home
   - What issues does the midwife face?
   - What are her legal responsibilities?
   - What steps should the midwife take in relation to the legal and ethical ramifications of any decisions?

Statutes on privacy and access to personal information

Australian privacy legislation

Patients do not own their records. They are owned by the person or institution who made them, but patients have a right to access the information contained in them (Skene 2004, p 236). Patients in the public sector have access through state and federal freedom of information legislation. At common law there was no right of access to patient records in the private sector, although access could be gained through the process of litigation. In 2000 the Commonwealth *Privacy Act 1988* was amended to provide access for private patients to their records. It also provides patients with access to their personal information held by Commonwealth agencies. The ACT, New South Wales and Victoria have enacted legislation to provide private patients with access to their medical records.

The *Privacy Act 1988* (Cth) sets out Information Privacy Principles (IPPs) (s 14), which pertain to government agencies, and National Privacy Principles (NPP) (Sch 3), which pertain to private institutions and doctors.

The Principles provide instruction on the collection of information, use and disclosure of information, quality of information, security of information, type of information held, access to information, correction of information, use of unique identifiers, anonymity options, international transfer of information and circumstances in which information may be collected. Midwives should familiarise themselves with these principles.

The *Privacy Act 1988* (Cth) established the office of Privacy Commissioner to investigate and deal with complaints or breaches under the Act.

New Zealand statutes on privacy and information

Health (Retention of Health Information) Regulations 1996

These regulations impose an obligation on midwives to retain original health information about their clients, both mothers and babies, for a minimum of 10 years. The information may be retained in any form the midwife thinks fit. Health information for the purposes of the regulation may include midwifery diaries, travel logs and phone logs if clinical details are noted in such documents. In the event of retirement or a midwife ceasing practice, this information can be transferred to the client or, if the client is dead, to that individual's personal representative, or to another provider. Although such transfer is possible, this may have significant legal risk if a claim is later brought against the midwife and the midwife no longer has access to the notes in order to mount a defence.

An exception to this Regulation is that original health information may be subpoenaed in some jurisdictions, in which case the midwife is entitled to release the records to the appropriate authority.

Health Information Privacy Code 1994 / Privacy Act 1993

Although the *Privacy Act 1993* establishes certain privacy principles regarding the collection, correction, use, disclosure, storage and access to personal information, the rules with respect to the health information of identifiable individuals comes under the Health Information Privacy (HIP) Code. This Code applies to all 'agencies' providing healthcare, such as hospitals and individual practitioners. The following is summarised from the Privacy Commissioner's document 'Health Information Privacy Code 1994'. The Code consists of 12 privacy rules covering the collection (in most cases this will be from the individual concerned), storage, access to, retention and correction of any health information obtained by health professionals. The Code also sets certain limits on the use and disclosure of an individual's health information. If any information is to be shared with other agencies such as a well child provider or medical practitioner, this should be discussed with the woman.

Most midwives who practise in partnership with women will either provide a copy of any health information collected, such as clinical notes, or give the woman a summary of what has been documented at each visit. The woman should be informed of her rights in relation to provision of information and to access or correct any information gathered. Midwives must ensure that the woman comprehends the information being given. If she is unfamiliar with English or is having trouble understanding what is being said, then an appropriate family member, friend or interpreter may need to be used or the midwife may need to provide a written summary of the woman's rights under the HIP Code. Care must be made not to make unfounded assumptions regarding the ethnicity and language ability of any person.

Health information, including diaries, lab results, scan reports and phone logs, must be stored to prevent loss, unlawful access by others, or misuse of the information. All files should be safely stored, in a locked cupboard or cabinet, and not in the boots of cars, as is the practice of some community midwives. Access to the notes, including any faxed information, should be strictly limited. When a woman requests access to her information, the Code outlines the time frame in which a midwife by law must respond to the request.

The Privacy Commissioner reminds us that while health information is created to provide care and treatment, it may also be used for other purposes such as clinical or financial audit, for administration purposes and for training and education. If such additional purposes are envisaged, they should be disclosed when the information is collected, although generally if the information is to be used for collateral purposes it will be transferred to a non-identifying form. Where disclosures are made without the consent of the individual, they must be made only to the extent necessary to meet the particular purpose or permitted request.

Reflective exercise

John is the partner of Sue, a woman you cared for two years ago. He phones and says that he is in a custody and paternity dispute and wants a copy of Sue's midwifery notes to show that he was actively involved in the birth of their son.

1. Who do the notes belong to?
2. Is John entitled to a copy?
3. Is there any circumstance in which you would release the notes?

Clinical point

There may be times when a midwife will observe evidence of violence or neglect of a baby and this will lead to concern about the baby's life or safety. If the matter is not urgent then the midwife should document her concerns and involve social workers, Family Start program support, general practitioners or family or whanau to help the parents and prevent future harm. On rare occasions, however, the midwife may consider that immediate intervention should take place and she will need to urgently report the mother, father or partner to the appropriate agency. Technically this may constitute a breach of confidentiality, but the midwife who acts in good faith and has reasonable grounds to believe that her actions are necessary to prevent serious or imminent harm to a child is likely to have a defence.

Complaints

Any complaints alleging a breach of privacy may be made to the Privacy Commissioner—Te Mana Matapono Matatapu. If complaints cannot be resolved with the assistance of the Commissioner, then the complainant may seek orders, declarations or damages from the Human Rights Review Tribunal.

Legislation on midwifery practice

Australian legislation

Notification of birth

Each state and territory has legislation that requires the notification and registration of births, deaths and marriages. Under the Births, Deaths and Marriages Acts in the respective states and territories, the definitions of birth, child and whether a stillborn is registered as a birth and/or a death vary, but all agree on the gestation and weight parameters of a stillborn.

> A 'stillborn' is a child that exhibits no sign of respiration or heartbeat, or other sign of life, after birth and that:

(a) is of at least 20 weeks' gestation, or
(b) if it cannot be reliably established whether the period of gestation is more or less than 20 weeks, has a body mass of at least 400 grams at birth (s4 *Births, Deaths and Marriages Registration Act 1995*, NSW).

The South Australian legislation goes further and states that a birth 'does not include the product of a procedure for the termination of pregnancy (s 4 *Births, Death and Marriages Registration Act 1996*, SA).

In the ACT, New South Wales, South Australia, Victoria and Tasmania, a stillborn or stillbirth is registered as a birth but not a death. In Western Australia and Queensland, a stillborn is registered as a birth and a death.

In Queensland, South Australia, Tasmania and Western Australia, a birth is defined as the expulsion or extraction of a child from its mother. A child is further defined as including a stillborn. In the ACT, New South Wales, the Northern Territory and Victoria, a birth includes a stillbirth.

Failure to provide the details to the appropriate authority is an offence. The purpose of the notification is so the particulars of the birth can be entered into the Births, Death and Marriages Register of the state or territory in which the child was born. Health legislation provides for the requirement of notification of a birth whether stillborn or a live birth. Under the respective legislation, a midwife who attends a birth is required to notify the appropriate authority. A specific form for the purpose is provided in the respective legislation. The time frame for notification varies from jurisdiction to jurisdiction but ranges from 24 hours in Victoria to one month in Western Australia.

In Western Australia a neonatal death is defined as 'the death of a live-born child within 28 days after the birth'.

In Victoria a perinatal death means:

(a) the death of a live-born child within 28 days after the birth; or

(b) a stillbirth.

In Western Australia, for the purposes of burial under the *Cremation Act 1929*, WA and the *Cemeteries Act 1986*, WA, a dead body 'means the body of a deceased person (who was born alive) and includes the body of an infant of not less than 7 months gestation that was still-born'. Unless the parents wish to conduct a funeral there is no requirement in law in Western Australia to do so for a stillborn of less than 28 weeks.

Abortion laws in Australia

Each state and territory has provisions in their respective criminal legislation that make abortion unlawful. A breach of the legislation generally carries severe criminal penalties. 'An abortion can be defined as the untimely expulsion of the fetus from the uterus either spontaneously or by artificial means' (Forrester & Griffiths 2001, p 196). However, provisions do exist for a termination of pregnancy to take place in specific circumstances. Case law in Victoria and other states such as R v Davidson [1969] VR 667 allows for an abortion to be lawful in circumstances where the medical practitioners are of the view that the procedure is necessary to preserve the woman's physical and mental health. However, as Rankin (2001, pp 233–4) points out, at no stage are the views of the woman taken into account.

In South Australia, Section 82A of the *Criminal Law Consolidation Act 1835*, SA further provides that a medical practitioner must perform the abortion in a prescribed hospital. Additionally, the woman must have been a resident of South Australia for at least two months prior to the termination, and again it is a medical decision to perform the abortion.

Following an incident in Western Australia where two doctors were charged under the Criminal Code for performing an abortion in 1998, the abortion laws were changed and are now one of the most liberal in Australia. An unlawful abortion is still a crime as per section 199 of the Criminal Code 1913, WA. Previously an unlawful abortion attracted a term of 14 years' imprisonment. Under the amendments to the Criminal Code 1913, WA and the *Health Act 1911*, WA, an unlawful abortion by a medical practitioner attracts a fine of $50,000. An abortion performed by a person other than a medical practitioner is still a crime and attracts a penalty of five years' imprisonment. Provided the requirements of Section 334 of the *Health Act 1911*, WA are met, no offence has been committed. The provisions require that a woman must give 'informed consent' to the procedure. The requirements for 'informed consent' are met when the woman is advised of 'the medical risk of termination of pregnancy and of carrying a pregnancy to term' and a medical practitioner has offered to refer the woman for appropriate counselling (s 334 *Health Act 1911*, WA). Alternatively, if the pregnancy is more than 20 weeks, the matter is referred to a committee of two medical practitioners from a panel of six, who agree that the mother or unborn child has a severe medical condition that in their clinical judgement justifies the termination. The legislation changes in Western Australia do to some extent take the focus away from the criminal law. The doctor can make the decision based on a reasonable belief that if the abortion were not performed the woman would suffer serious mental or physical harm. However, it is still not abortion on demand.

New Zealand legislation

New Zealand Public Health and Disability Act 2000

Under Section 88 of the *New Zealand Public Health and Disability Act 2000* the Crown, or a District Health Board, may issue a notice of the terms and conditions on which payment will be made to those providing a public health service. One example is the Notice Pursuant to Section 88 of the *New Zealand Public Health and Disability Act 2000* for Maternity Services, which sets out the terms and conditions for the provision of maternity services. Key appendices to the Notice include the Guidelines for Consultation with Obstetric and Related Specialist Medical Services; the Standard Terms and Conditions of Access to a Maternity Facility or a Birthing Unit, and the Indications for Ultrasound Scanning. These appendices require the practitioner to consult and refer women according to the guidelines and set up the expectation

that midwives will practise according to the standards set down by their professional bodies.

The national Access Agreement is also included in the Section 88 Notice and this requires the midwife, subject to the woman's informed consent, to comply with the protocols and policies set out by the hospitals to which she admits her clients. Often midwives are unaware that as soon as they have accepted any payment under the Notice, they are deemed to have agreed to comply with all the terms and conditions and appendices of the Notice and that they are then bound to follow these protocols and policies.

A further issue for midwives claiming payment under Section 88 is that their claims may be subjected to an extensive random audit. If the midwife is audited she must be able to demonstrate that she has provided the services that she has been paid for, and be able to prove this provision through documentation. Generally the auditors take random copies of the midwife's notes and check these against what was claimed. Any failure of the midwife to substantiate claims during the investigation may lead to money being recovered from her, or, in the worst-case scenario, prosecution of the midwife for fraud in the District Court.

Births, Deaths and Marriages Registration Act 1995

The midwife has several legal responsibilities with respect to the birth of a baby. The first is to determine whether the baby is born alive or is stillborn. While this may seem an obvious distinction to make, there are times in practice where a midwife may confuse the two states, and this can lead to significant legal difficulties.

Live birth is the complete expulsion or extraction from the mother of a product of conception, irrespective of the duration of pregnancy which, after such separation, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of the voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached.

Stillbirth means the issue from its mother of a stillborn child. A stillborn child is a dead fetus which, whether or not the umbilical cord had been severed or the placenta has detached, at no time after issuing completely from its mother breathed or showed any other sign of life (such as beating of the heart, pulsation of the umbilical cord, or definite movement of the voluntary muscles), and weighed 400 grams or more when it issued from its mother or issued from its mother after the 20th week of pregnancy.

When a baby is born alive or stillborn, a Notice of birth must be completed and sent to the Registrar of Births, Deaths, and Marriages within five working days of the birth. Generally this notification is the responsibility of the occupier of the hospital where the birth took place, and a person attending the birth, such as a midwife, endorses it. Where the birth takes place at home, the midwife will usually complete the Notice.

The parents or guardians or any baby born alive or stillborn must also be registered with the Registrar of Births, Deaths and Marriages within two months of the birth. Every death must also be notified to the Registrar of Births, Deaths and Marriages within three working days after the disposal of the body. This notification is made by the person who carries out this disposal. Where an inquest has occurred, the coroner must make the notification to the registrar within three working days after the completion of the Inquest.

In most cases the coroner only becomes involved where the cause of death is unclear, or there are concerns about the circumstances surrounding the death. It is then up to the coroner to decide whether a post mortem is required to ascertain the cause of death. If a coroner does commence an investigation, a medical certificate stating the cause of death cannot be signed until after the coroner has completed his or her inquiries. This means that no one, including a funeral director or family member, can take charge of the baby's body without first obtaining the appropriate certificate, burial order or the coroner's order authorising its release. It is only once these formalities are completed that the family can bury or cremate their baby. This can be a stressful and difficult time for families, particularly Indigenous families such as New Zealand Maori, where whanau members would normally stay with the baby from the time of death to the burial or cremation.

In some stillbirth situations a doctor need not sign a certificate of stillbirth. Midwives should note that Section 46A of the *Burial and Cremation Act 1964* states that where a baby is stillborn, either a medical practitioner who was present at the birth or examined the baby after the birth, or if no doctor was present, a registered midwife who was present at the birth, may certify that the baby was born dead. The midwife must have been present at the birth and therefore in the situation of a precipitate birth where the midwife arrives just after the birth and finds a baby dead, she should not sign the certificate.

Adoption Act 1955

From time to time midwives become involved in adoptions, particularly where adoptions take place within an extended family grouping or whanau. Midwives should be aware that the New Zealand Adoption Acts set out a statutory procedure that must be followed before an adoption can legally take place. A midwife cannot act as an agent, and nor can she broker an adoption arrangement between parties. If a midwife is caring for any woman considering an adoption of her baby, the midwife should ensure that the woman is referred to the appropriate state agencies. This will usually require the early involvement of a social worker.

Contraception, Sterilisation and Abortion Act 1977

The key responsibility of midwives under this Act is to be aware of the referral requirements for any woman seeking abortion. Often it is the midwife to whom a woman will come for diagnosis or confirmation of pregnancy. It is illegal for any midwife to help a woman procure an abortion. If any woman does not want to continue a pregnancy then the role of the midwife is to refer her to a doctor for further counselling and assessment.

Legislation on drug administration and prescribing (New Zealand)

Medicines Act and Regulations

There is a plethora of Acts and Regulations relating to the prescription and administration of drugs, and this section attempts to pull together the key points of the law as it relates to midwives.

New Zealand midwives have been able to prescribe a range of drugs and medications related to antenatal, intrapartum and postnatal care since 1990. The Medicines Regulations 1984 as amended by the Medicines Regulations 1984, Amendment No 3, gave a statutory mandate for midwives to prescribe a range of medications and brought midwives under the Medicines Regulations 1984. Section 39 of the Regulations (1984/143) states that:

> (6) No registered midwife shall
> (a) Prescribe for any patient a quantity of any prescription medicine that exceeds 3 months supply; or
> (b) Prescribe any prescription medicine otherwise than for antenatal, intrapartum or postpartum care.

Although the law is a bit convoluted, this basically legislates that a midwife may prescribe for the normal conditions of pregnancy—that is, within the Scope of Midwifery Practice. Midwives should not prescribe for pre-existing medical conditions or complex pregnancy conditions.

Section 41 of the Medicines Regulations 1984 prescribes the form of any prescription, which must include:

- that it shall be legibly and indelibly printed
- the date, address and personal signature of the prescriber
- the title, surname, initial and address of the person for whom the prescription is given
- the name, strength, dose, frequency of dose, and method of administration of the medicine
- the number of occasions on which the medicine may be supplied
- the interval between dates of supply
- the period in which the medicine is to be used.

Whenever a midwife prescribes a medication, there must be a discussion about the reason for the prescription, the effects, side-effects and contraindications to that medication, an identification of any allergy or previous problems with the medication, and a clinical assessment of the appropriateness of the medication for that person, in the presenting circumstances. Ultimately where the drug is given, the practitioner must demonstrate that this was done with the informed consent of the client. An exception to this is an emergency, such as where there is a seriously depressed neonate who might be given naloxone, or where a woman is experiencing an overwhelming postpartum haemorrhage and becomes unconscious and is administered intravenous fluids and possibly blood products. In most cases, however, such scenarios will have been discussed antenatally and the woman's views ascertained prior to this occurring.

Clinical point

Requirements for prescriptions for controlled drugs. Medicines Act Amendment No 11 (1995/75)
Prescriptions should be legibly and indelibly written, signed and dated, include the midwife's address, the name of the drug, the amount of the drug, the dose and frequency of the drug, the surname, initials and address of the person for whom the drug is intended and bear the words 'for midwifery use only'.

Urgent prescriptions

Section 40A of the Medicines Amendment Regulations 2001 enables a registered midwife to request an urgent prescription orally (in person or by phone) to a pharmacist to whom he or she is known personally. She must then forward a written script of the oral communication within seven days. The schedule of this Amendment also discusses standing orders with respect to controlled drugs, although in practice it would be unusual for a midwife to use this mechanism, because if a controlled drug is required, the midwife or her back-up should either already be in attendance or should immediately attend to assess the woman.

Controlled drugs

Section 8 (2) of the *Misuse of Drugs Act 1975* as amended by the *Nurses Amendment Act 1990* enables any registered midwife to prescribe, supply and administer the controlled drug pethidine to a patient under her care but the frequency of administration is strictly regulated. The Misuse of Drugs Regulations 1977, Amendment No. 9 (1990/222) states that pethidine may be supplied to the patient of a midwife on not more than two occasions, and should be supplied at an interval specified by the midwife, the first being not more than four days after the prescription and the second being not more than four days after the termination of that interval.

Any prescription must be written on a Controlled Drug prescription form, and in hospital must be written on the drug sheet. Amendment No. 10 (1993/157) updates the requirement to keep a Controlled Drug Register in hospital wards. Midwives cannot prescribe benzodiazepines such as clonazepam, diazepam and temazepam, as they are class C Part V controlled drugs.

Coroner's Court legislation and process

The office of coroner is an ancient one and each state and territory in Australia and New Zealand has a Coroner's Act. The coroners legislation requires certain deaths to be reported

and provides for penalties for failure to inform the coroner of a 'suspicious death'. If the death has been reported to the coroner then the midwife is no longer under an obligation to do so. Home birth midwives in particular should be cognisant of the requirements for reporting a death in the jurisdiction in which they operate.

The coroner investigates those deaths where certain facts need to be established to determine how the person died. 'The office of the coroner is established to provide a means of investigation of certain situations where death results, to identify impropriety or negligent activity' (Forrester & Griffiths 2001, p 242). The wording and the requirements for an inquest vary. However, the purpose is to investigate sudden or unexplained deaths and to establish whether the death resulted from natural causes or from unlawful homicide. The coroner generally has the power to order a post mortem, investigate deaths where a person has died in custody, in a mental health facility or under the care and control of a member of the police force, while in prison or under child welfare legislation (s3 *Coroner's Act 1996*, WA).

The number of deaths referred to coroners in New Zealand and Australia is growing and it is increasingly likely that a midwife, at some time in her career, will be involved in a coronial investigation or that she will be called to give evidence at an inquest. This can be a difficult and stressful experience and it is therefore important for midwives to be aware of the procedures set out in the coroners legislation governing her practice.

When the coroner's office is notified of a death, the body should be left until such time as the coroner's office instructs the hospital that the body can be moved to the morgue. All intravenous lines, catheters and drains are left in situ or capped as necessary. The midwife or midwives involved in the care should make notes regarding the case, as these can then be used to assist in a statement given to the police.

Not all deaths fit into the category of 'suspicious circumstances' and the coroner may dispense with the inquest once satisfied that the death was from natural causes. The legislation varies—in some cases the coroner has a discretionary power to hold an inquest and in others it is mandatory to hold an inquest. For completeness and accuracy it is suggested that the relevant legislation be consulted.

In Australia and New Zealand, uniformed police officers assist the coroner in these inquiries. They gather evidence and interview or request reports from those involved. Sometimes the police will ask midwives to disclose information or the clinical records. Poor records may indicate that the care given to the patient prior to death was also inadequate. If asked for an interview or a written statement, or for originals or copies of the notes, a midwife would be well advised to seek independent legal advice. The hospital may offer legal advice from their lawyers. However, a situation may arise where the interests of the midwife and those of the institution are in conflict.

Midwives who are involved in these inquiries are witnesses, not parties, and there are fundamental protections to which they are entitled. A midwife is entitled to give a written report at a later time and she can refuse to be questioned at all by the police until she has spoken to a lawyer or taken professional advice. It is important that midwives do not give evidence when they are distressed, exhausted or worried about the woman and her family, or when they have not had access to the clinical records, as any unwitting errors that they make may later adversely affect their credibility. When she does speak with police the midwife should always retain a copy of any evidence or statement that she provides, and she should keep the contact details of any officer that she speaks to or who phones her. She should also carefully read through any statement or answers to questions that she makes before signing this as correct. If the matter goes to an inquest, the midwife's evidence may either be accepted 'on the papers', in which case she may not have to actually attend the hearing, or she may be summonsed as a witness and will then be required to be sworn in and to read her statement in open court.

In Australia, magistrates appointed as coroners do not conduct trials; they merely establish the facts as to the identity of the deceased, the cause of death and the circumstances surrounding the death, so the death can be recorded under the births, deaths and marriages legislation.

The coroner is concerned with causation, not fault. A Coroner's Court is generally more informal than an ordinary court and the rules of evidence do not apply. Nevertheless, the Coroner's Court has many of the trappings of an ordinary court. It is a public hearing, where witnesses give sworn evidence and are questioned by the coroner and may be cross-examined by lawyers representing the various parties. Witnesses can be summonsed to give evidence and the coroner can impose penalties should a witness fail to appear. Often media are present and report on what takes place.

It is not the role of the coroner to find a person or persons liable in negligence or guilty of a crime, but rather to establish how the person died. The coroner cannot frame his or her findings in a way that indicates either the guilt or negligence of a person involved with the person prior to the death. In New Zealand, if a coroner makes an 'adverse comment' about the acts or omissions of any provider, then he or she is required to give that person—or in the case of adverse comment about a dead person, to give the family—at least seven days' notice of the proposed comments. This enables the person or their representative to make submissions to the coroner in order to answer and defend the comments before the finding is released. If the coroner believes that an indictable offence has been committed, the appropriate authority, in most cases the Director of Public Prosecutions, is notified. The findings at inquest may provide relatives of the deceased with information indicative of negligence. It is then up to the relatives to pursue the matter through the civil courts.

At the conclusion of an inquest, a coroner may comment on any matter in relation to a death, including public safety or the administration of justice, and make recommendations. For instance, in New South Wales, an elderly patient died after suffering severe burns from a hot water tap in a shower. She was shocked by the rush of water and was unable to turn

the tap off. By the time help arrived, she had been severely scalded and subsequently died. The coroner recommended that the temperature of water in hospitals and nursing homes be thermostatically controlled to avoid a similar occurrence in the future. While it is a recommendation, the appropriate departments have a responsibility to act on such a recommendation (Staunton & Chiarella 2003). Under New Zealand legislation, the coroner is also charged with making recommendations to try to bring to the attention of the public the circumstances of the death, in the hope of avoiding future similar deaths.

In Western Australia, a coroner may refer the matter to the registering authority/disciplinary body if the coroner believes that they may wish to inquire into the conduct of a member of that profession (s 50 *Coroner's Act 1996*, WA). Although other legislation may not have that express provision for informing a regulatory authority, the findings of a coroner may form part of a disciplinary hearing against a midwife.

Summary

It may be surprising to find that so much law applies to midwifery practice, but midwives can be reassured that they are rarely the subject of criminal or civil proceedings. It is hoped that this chapter has provided a helpful guide to the key statutes that relate to midwifery practice in Australia and New Zealand.

Review questions

1. What is the legislation that governs the regulation of midwifery in your state/country and what are the main functions of this legislation?
2. What is the definition of 'professional misconduct' in the state/country where you practise?
3. What would you do if someone made a complaint against your practice?
4. In New Zealand, what are your responsibilities under the Code of Health and Disability Services Consumers' Rights?
5. What is the process for consumers/clients to make a complaint about their care in your state/country?
6. What privacy requirements govern your practice?
7. Where and how should health information be stored (in your state/country)?
8. Can a midwife broker an adoption in New Zealand?
9. What documentation must be completed when a baby is born (in your state or country)?
10. What is the role of the coroner?

Note

1 (Where definitions differ between Australia and New Zealand they are provided in the text.) *Statute*: a law made by an Act of Parliament passed by a majority of elected representatives. (Orsman & Wattie 2001). *Regulation*: (for the purposes of this chapter) a rule or other order issued by a ministry or (government) department under authority delegated by parliament. A regulation has the force of law in Australia and New Zealand. *Common law*: originally defined as the ancient unwritten law of England, but it has come to mean the system of law based on old customs or court decisions, as distinct from statute law or the laws enacted by parliament (Orsman & Wattie 2001).

CHAPTER 12

Ethical frameworks for practice

Lynley Anderson and Bronwen Pelvin

Key terms

autonomy, beneficence, bioethics, code of ethics, ethics, informed consent, justice, non-maleficence

Chapter overview

This chapter outlines the philosophical underpinnings of midwifery and the history of the development of bioethics. The principles adopted in order to understand moral ethical approaches and informed consent are explored. The codes of ethics of the International Confederation of Midwives (ICM), the Australian College of Midwives (ACM) and the New Zealand College of Midwives (NZCOM) are also presented and discussed.

Learning outcomes

Learning outcomes for this chapter are:

1. To explore the philosophical framework of midwifery from a bioethical perspective
2. To describe moral concepts associated with midwifery professional practice
3. To outline the development of bioethics
4. To describe the four-principle approach to ethics
5. To provide a history of the development of the international codes of ethics
6. To examine the current midwifery codes of ethics in Australia and New Zealand.

The world of the midwife

Throughout history, midwives have assisted the birthing woman with companionship, guidance, knowledge and support. Midwifery has developed out of a particular human need and to respond to women as they experience a common and universal biological and physiological process.

However, midwifery is also created and affected by the social context in which it exists. Shifts in the way society is structured and functions affect how midwifery is practised. Some of those shifts have been discussed in earlier chapters, and have had a major impact on the place of midwifery in society. Other social reforms will affect how midwives respond to women in their care. There have been a number of interesting changes in society since the Second World War. Improvements have occurred in health, education and general levels of wealth. Such improvements, along with developments in levels of information and communication, have seen a move from attention to basic concerns of life to the challenging of authority and hierarchy within our society. The civil rights movement and the women's movement were two such changes that gathered force at around this time. These created a climate of growing social awareness of the need for widening the scope of activity to groups in society that had previously been denied. There has also been an increase in inclusiveness of all members of society, and an increased focus on individuals having a say in matters that affect them. This has led to a focus on what individuals want for their own life, with much emphasis on achieving goals and outcomes for the education, work, lifestyle, material possessions and so on that the individual decides upon. Individuals also began to challenge medical authority, wanting to have more say in their own treatment and care. The move to individuals having a greater say and involvement in their care has changed the way midwives and women interact.

In the West, we have to some extent distanced ourselves from our two biological endpoints, birth and death. Medicalisation and specialisation of both of these elemental human processes have removed them from the communities in which the birthing woman or the dying person lives. Healthcare is now most often delivered to individuals away from their homes, in institutions developed specifically for the purpose of delivering complex health services, with trained health professionals or specialists providing the care. Maternity care provision has also commonly been drawn into modern styles of health service delivery, with the development of large hospital-based services providing midwifery and medical services to women at the time of birth rather than through the continuum of the woman's maternity experience.

Some midwives and women in the West may look enviously at other cultures whose day-to-day existence is closer to the reality of birth and dying, and its impact. While there might be some appeal in this, there are also harsh realities faced by these communities, including the very real risks of dying, disability and loss associated with giving birth, to which the West is able to provide many solutions. At the same time, proximity to pregnancy, giving birth and breastfeeding ensures that young women in these cultures have absorbed knowledge of the process. They learn from a young age that birth is a normal physiological process that occurs as part of the nature of life despite the individual risks and outcomes that they observe.

We have also professionalised the people who provide care to those who are birthing or dying, so the knowledge is contained within the professional person. We now live in an age of 'expert-ism', with the public expecting that the 'expert' will have the answers to their life issues and the experiences and problems they encounter in living.

The sharing of the 'expert's' knowledge with a person and their family/whanau is dependent on the professional person's desire to share knowledge and power, and that is dependent on their plan and desire for their own life—are they an ambitious person, for example, wanting to succeed in their own professional realm? Do they wish to have 'power over' others to build up their sense of their own power? Do they have a social conscience, desiring to assist others by sharing knowledge and resources with others in their immediate community?

Philosophical underpinnings of midwifery

Over the course of a midwife's working life, whether she is aware of it or not, she will be using a framework for understanding and making sense of the way in which she practises midwifery and the style of care she provides to women and babies. For example, how much the midwife shares her knowledge and the degree to which she works alongside the woman and her family will be determined by the midwife's own particular philosophy about the manner in which care should be provided. This philosophy will have come from a number of sources, including her own belief system incorporating her cultural understandings, from the society in which she lives, as well as those from the midwifery profession. This framework could be thought of as being constructed from her values or those things she considers morally important.

Ethical reasoning informs a midwife's everyday clinical practice. The way a midwife relates to and interacts with a woman and her family, and the styles of care she chooses, all have an underlying ethical basis. Recognising the ethical dimensions of clinical practice is important in meeting the needs of the woman and her family and also in meeting the professional standards laid down by midwifery bodies.

A midwife will also encounter a number of complex ethical issues during the course of her professional life. Some of these might cause her to stop and think about what is the right course of action to take in the particular situation; in others, she might be very clear about the correct course of action. How she responds to these issues will depend on the ethical factors she believes most relevant to the issue.

Applying these values is not necessarily a simple task. For example, there might be problems if her ethical values conflict

with those of the woman she is caring for, or the institution she may be working in. What if the ethical values she was raised with conflict with those of her profession? These questions raise some interesting issues for midwives, particularly with regard to the process of thinking through ethical issues arising in clinical practice.

Some examples of ethical issues that can arise in practice might include those where:

- the midwife perceives that the woman is making a decision that is not in the woman's best interests or her baby's best interests—for example, the woman may drink heavily or be taking non-prescription drugs during pregnancy
- the best interests of the baby compete with those of the mother—for example, the woman develops a life-threatening illness in pregnancy and refuses treatment to ensure her baby's survival; or the woman develops a complication of pregnancy and refuses treatment despite the fact that her baby will be severely affected or may die as a result
- a woman is limited in her ability to make decisions—this might be due to an oppressive partner, or mental disability or traumatic brain injury.

New reproductive and birthing technologies can also pose ethical issues for midwives. The rise of genetics and particularly prenatal genetic screening may stir ethical unease in many midwives, especially if abortion is involved. Because women now have fewer children, the pressure exists for each child to be the 'perfect' child, and the idea that there are now ways of ensuring that each child is 'perfect' can be enormously attractive to some people. Involving women in research also raises ethical concerns.

There is little doubt that these and many other contentious issues make midwifery an ethically interesting and sometimes challenging occupation. On reading a list of potential ethical concerns such as those listed above, many people will have a 'gut' response to some issues. And while this kind of response might be a good indicator that there is indeed an issue involved, gut instincts may be based more on our distaste for or level of discomfort with a situation. Being able to recognise an ethical issue in clinical practice is a good start, but getting to the heart of why these might be troubling, and beginning to unravel the issues requires a more systematic response. For that we begin by turning to the academic discipline of bioethics.

Bioethics is commonly described as a branch of applied moral philosophy.[1] In the midwifery context, bioethical approaches can be used to provide reasoned analysis of the array of ethical concerns. Ethical analysis can assist a midwife to untangle the issues involved in a particular situation, helping to identify and clarify the moral concerns and at times help her to find a resolution to the problem. We can explore an ethical problem using a variety of approaches. Each approach acts to highlight a different aspect of the particular problem.

Moral ideas from everyday life

All of us are familiar with moral concepts (although they might not have been identified as such) from our upbringing. As young children we are taught a range of important moral ideas. We learn, for example, the importance of telling the truth and of not hurting others, the significance of keeping our promises and respecting the views of others, and about sharing, to name a few. These concepts are reinforced by our own experiences of what it feels like to be caught telling lies or to be hurt by others.

Much of the time these ideas work well—we keep our promises and others keep their promises to us, or we are kind to others, and so on. However, problems soon arise when we discover that in order to follow one concept, we can no longer comply with another. For example, if we are asked by a friend who is trying on clothes, 'Do I look fat in this?' we might begin to question whether honesty is indeed the best policy. So while honesty is an important concept for a young child to learn, later we might learn that complete honesty might cause harm to the feelings of others and that it may be better to say nothing or modify our statements than to tell the complete truth. However, as an individual moves into professional practice it is important to know when to apply which moral idea. For example, honesty may not be best when giving clothing advice to overweight friends, but for a woman in labour who has decisions to make, honesty will be required from her caregivers in order for her to make an informed decision.

Moral concepts in professional practice

As a student trains to become a midwife, moral ideas become increasingly important. Many of these are written into professional codes of practice that establish particular ethical standards of behaviour that midwives are expected to meet. These will be discussed later in the chapter.

Law and ethics

Expectations about the quality and standards of all health professionals in their dealings with those in their care may also be expressed in legislation. For example, getting informed consent from a woman prior to undertaking any treatment or care is now an expectation under New Zealand law. For a woman to be able to make a decision about her care, she must receive information about why something is being suggested and what it might mean to make each choice, as well as the risks and benefits, and so on. And so honesty is an example of a moral idea from early life that develops new meaning and legal expectations in professional midwifery care.

However, ethical reasoning is not simply an application of legal expectations in professional life. Law and ethics have much common ground, and yet they are distinct disciplines. What is ethically acceptable might differ significantly from what is legally acceptable. For example, some laws might be ethically unacceptable. There may also be times when an activity is not illegal but could certainly be considered ethically dubious. For example, imagine a woman who says she will take her lonely friend out to the movies, but later gets invited to a party with some people she has been trying for some time to

impress. The woman then calls her friend to say she is sick, in order to break their arrangement so she can go to the party. Although she hasn't done anything illegal, we could question her standard of ethics.

A reason sometimes given by health professionals for complying with legislation put in place to protect those they care for is fear of legal reprisals for failure to do so. An example of this might be when getting informed consent from a woman. It is often heard that this is only done to avoid getting into trouble with the law. However, such a motivation—fear of legal punishment—fails to comprehend the ethical value in informing women, including acknowledging and respecting a woman's right to make decisions for herself.

The history and development of bioethics

Bioethics emerged during the last half of the twentieth century, partly in response to the revelation of unethical and unchecked action by doctors and scientists, but also in response to the exceptional clinical developments in healthcare at around that time, as well as the social changes already outlined at the beginning of this chapter. At the end of the Second World War, Nazi doctors being tried at Nuremberg revealed that horrific experiments had been carried out on prisoners of war and others. While many attributed these actions to the horrors of war and the monstrous Nazi regime, that doctors could be involved in such atrocities in the name of research was of major concern. Protection of research participants from unethical research was an important development resulting from the Nuremberg Trials.

Unethical research was found not to be limited to war when, in 1966, Henry Beecher wrote his famous article entitled, 'Ethics and clinical research'. This article uncovered 22 research studies he claimed were unethical, being carried out in US hospitals. The desire to improve clinical care had led many researchers to disregard the health and wellbeing of the research subject, many of who were vulnerable or considered to be of lower social class.[2] The Beecher article demonstrated that all was not well with medicine and science, particularly in the world of research. The need to protect the participants in research became paramount.

Developments in clinical medicine were burgeoning around this time and these also contributed to the development of ethical reflection on their use. One such clinical example of this kind of development was that of regular kidney dialysis in 1961—this provided an opportunity for lives to be extended where they previously would have ended. However, a shortage of dialysis machines meant that decisions had to be made about who should get this precious resource.

In New Zealand, the growth of bioethics can, in part, be attributed to the revelation of our own unethical research at National Women's Hospital in Auckland. In 1987, two journalists published an article in an Auckland magazine. This article detailed the research of Associate Professor Herbert Green into carcinoma in situ of the cervix (cervical cancer). A small number of doctors at the hospital collaborated with the authors after their own earlier attempts to call a halt to the study had failed. The authors claimed that Professor Green (a consultant obstetrician and gynaecologist at National Women's Hospital in Auckland) had conducted a medical experiment in which conventional treatment was withheld without the women's knowledge and consent over a period of nearly 20 years. Professor Green believed that carcinoma in situ did not lead to invasive cancer, despite this being recognised internationally at the time. The intense public interest generated by the article led to the Minister of Health appointing Judge Silvia Cartwright to head an inquiry. The Inquiry validated the allegations of the article, concluding that 'for a minority of women, their management resulted in persisting disease, the development of invasive cancer and, in some cases, death' (Cartwright 1988). The Inquiry did not limit itself solely to the research project but also explored other related issues, such as patients' rights, medical power and hierarchy, and the problems of effective problem solving in medical institutions. The Cartwright Inquiry can be understood as the first public scrutiny of medical practice, research, education and institutions in New Zealand. One of the most significant outcomes in New Zealand has been the development of the Code of Health and Disability Services Consumers' Rights, which enshrines a code of patients' rights under legislation. Another important outcome has been the development of ethical review of research through a system of ethics committees.

The Cartwright Inquiry and the subsequent developments in patient rights and ethical review of research could not simply have occurred at any time; it needed the right socio-political conditions in which to emerge. The second wave of feminism and the rise of women's health issues surrounding women's reproductive choices was one of the significant issues of this time, creating a climate ripe for the examination of the practices of those in authority. Bioethics therefore has, to some degree, developed out of a social movement that challenges traditionally held authority and has been involved in empowerment of those who are socially marginalised.

Approaches to ethics

The four-principle approach to healthcare ethics

The framework most commonly seen within the bioethics literature is that of the four principles developed by Beauchamp and Childress (2001). These include: autonomy, beneficence, non-maleficence and justice. Although originally developed with medicine in mind, many of these concepts are valuable in other health professional contexts and will be discussed here. This framework also has some shortcomings, which will be discussed later in the chapter.

Autonomy

The term 'autonomy' literally means self-rule or self-determination. It means having the freedom to make decisions in line with how we want our life to be. Autonomy is based on the idea that we all have our own experiences, identities and

significant features in our life; therefore it is thought that we will have the ability to judge what is best for us.

> Autonomy means self-determination. In any individual case, autonomy may be influenced by the cultural values and beliefs of the individual.
>
> The principle of autonomy requires that the right of each person to individual beliefs, desires, values and goals be respected and safeguarded.
>
> Healthcare involves an agreed transaction between providers and user of services. Since the relationship behind the transaction is often one of unequal value, special care is required to ensure respect for the autonomy of users.
>
> Respect for autonomy involves seven key points:
> - effective communication
> - adequate information
> - comprehension
> - competence
> - absence of coercion
> - the right to refuse proposed treatments and/or procedures
> - advocacy (Ministry of Health, New Zealand 1991, p 9).

In healthcare, the concept of autonomy involves respecting the ability of a person to make choices about their treatment and for those choices to be respected. It implies that the individual has the competence to make decisions for themselves and also that they should not be coerced or forced into making decisions.

Autonomy in healthcare is a relatively recent development in line with the social changes outlined earlier. It has come about due to a rise in individualism and a growing desire for people to have increasing involvement in their own care. It is also a direct challenge to medical paternalism, where the doctor has traditionally been held to know what is best. The rise in autonomy has meant a shift in the locus of decision-making in healthcare from the healthcare professional to the person himself or herself.

Informed consent

One of the most important ways in which we can commonly see the principle of autonomy in action is through the process of informed consent. In the midwifery context, informed consent involves providing information to the woman and allowing her to either consent or refuse the suggested course of action.

Informed consent has two main components—the providing of information, and the giving of consent. These two components can be broken down further to:

- information
- comprehension
- competence
- voluntariness.

Take the example of a woman being presented with the option of a vitamin K injection for the baby following delivery. The midwife would need to provide *information* to the woman, telling her what vitamin K is and what it does, what the procedure entailed, what risks and benefits are associated with the injection (including short- and long-term benefits and risks), how much pain the baby would be expected to experience due to the injection, any possible effective alternatives, and what if any costs the woman might be expected to incur, and so on. The information needs to be provided in a way that the woman can understand. This does not mean that the woman should to be spoken down to, but that the information should be given at a level that is comprehensible to the woman, and is jargon-free. Midwives sometimes wonder how much information to give about a particular topic. Should they give out information about very rare complications related to some procedures? There are common concerns that this kind of information could frighten some people and put them off a procedure that might otherwise be helpful. In order to answer this we need to return to the concept of autonomy. To be truly respectful of autonomy, midwives are required to give the information. The extent of the information that needs to be given has been a topic under scrutiny in recent times, particularly in the courts.

The 'consent' part of informed consent involves considering the competence of the woman to give informed consent and the voluntariness of that decision. Under New Zealand law, every person is presumed competent to consent unless proved otherwise. For some, it may take more explanation, and the use of diagrams and other methods, but the presumption should be that nearly all women are able to give consent. Questioning the competence of a woman simply because she is making a choice that the midwife doesn't agree with is not acceptable and not in line with a respect for autonomy.

Consent should also be *voluntary*, meaning that it should not be coerced. An example of coercion would be if a midwife carrying out research tells a woman that she will withdraw some element of care if the women does not agree to take part in the research. The woman who consents under these circumstances could be said to have been coerced.

Informed consent should be viewed as an ongoing conversation between the midwife and the woman, not a one-off event. In this way the midwife is always checking with the woman that care is proceeding along lines that she is comfortable with.

We all are aware that some people will not be able to be autonomous, including a person with a severe and acute psychiatric illness, or severe brain injury. In these situations we might rightly question the competency of this person. There may be times, for example when people who are normally competent temporarily lose such ability, due, for example, to the administration of an anaesthetic or due to unconsciousness. Under these circumstances care can be provided that is perceived to be in that person's best interests, until such time as they recover their competency.

Beneficence

Acting in the way described above, in a way that promotes the best interests of others, involves the principle of beneficence. The principle of beneficence determines that we act in such a way as to provide benefit to or improve the wellbeing of those we provide care for. This is one of the fundamental principles underlying the provision of healthcare. The very purpose of

healthcare in all its many forms is to improve the health and wellbeing of its recipients.

However, there are many accounts of what might constitute a benefit or an improvement in wellbeing. We know that people are different from each other—some like a life full of challenge and risk, while others prefer life to be more sedentary. Because we all differ, deciding on what a benefit is for others is a particularly difficult and dangerous task, and is best left to the individual to decide for themselves, unless they are unable to do so.

When dealing with pregnant women, the issue is compounded because caregivers might want to take into consideration the interests of the baby. How far should we go to safeguard the wellbeing of the baby? For most of the time, the best interests of both coincide: good nutrition for the mother will mean good nourishment for the dependent fetus. However, the interests of the two will diverge when a woman acts in a way that threatens the future of the unborn baby—by consuming excessive alcohol, for example, or using drugs. Should we override the wishes of the mother to defend the interests of the baby? This idea has been carried out with some pregnant women detained due to substance abuse, or forced to undergo a Caesarean section against their wishes. Some might point out that the woman has an interest not to be harmed by such detention or forced surgery, while others might claim that the interests of the baby outweigh the interests of the mother in both bodily integrity and freedom.

Non-maleficence

Non-maleficence can be understood simply as 'do no harm'. This principle requires that we do nothing that will harm or injure a person in our care. But what one person thinks as a harm may not be a harm for someone else. For example, a woman may consider that experiencing a birth without pain relief would be to suffer a great harm, whereas another woman might feel that to miss out on the birth process by taking pain relief would be harm. Given that we all differ in our preferences, the difficulty lies in how to determine what a harm is.

Justice

Within healthcare, the principle of justice dictates that healthcare services should be distributed fairly. There are two important ways in which this can be understood in healthcare. The first is with regard to providing care to people without discrimination. We need to take care that we are not discriminating against people because of their race, religion, sexual orientation, marital status and so on. Imagine two women needing midwifery care: one woman is married, has a mild heart condition and is having her third baby; the other is living in a lesbian relationship and is having her first baby. Do we provide different levels of care for each person? According to the principle of justice, both are given good quality care. However, that does not mean that we have to give out exactly the *same* care to each woman. Each will have different requirements: the woman having her first baby may require more time than the woman having her third. She may require more detailed explanation about certain tests and procedures than the other woman, who has been through it all before. The woman having her third may require a little more attention in other areas, such as support with the two other children, and care with regard to how her heart condition might be responding to pregnancy and birth. So while each woman may require different care and more of the midwife's time at certain times during pregnancy and birth, this is due to the individual needs of each of the women, and not because of their marital status or sexual orientation.

The principle of justice may also have us pay attention to the allocation of resources on a much wider scale than that facing an individual midwife. In our society, for example, many people do not have equal access to a number of social benefits and appear to carry greater social burdens than the rest of us. Some of these inequalities can be expressed in poorer health statistics related to morbidity and mortality. Most caring societies wishing to promote at least some egalitarian principles would wish to ensure a basic quality of life for its most vulnerable and disadvantaged members. Policies will therefore need careful consideration to ensure that the distribution of health services does not exacerbate any existing inequalities in health, but attempts to mitigate them.

Some criticisms of a principles approach

No solution

Many authors have identified problems associated with a principles approach to ethical issues in healthcare. One of the most commonly identified problems is that the principles do not solve our problems for us. They might highlight particular issues and supply a framework for thinking about the issues, but provide no instruction on how to balance or rank the principles when they conflict.

No single unifying theory

Another criticism in the literature is that the principles do not represent a single theory, but result from taking a bit from one theory and a bit from another. For example, autonomy is said to be a concept borrowed from a Kantian idea of respect for persons and beneficence from John Stuart Mill (a utilitarian). Because each of these concepts comes from conflicting moral theories, criticisms are made that the principles lack internal consistency and should therefore be rejected.

Feminist objections

Feminist bioethicists have also objected to a principles approach to bioethics. Their objections centre on the failure of the principles to fit the moral experiences of women, and the lack of regard to the particularities of a given situation. They also claim that there is a lack of attention to the political and social dimensions of a situation, and therefore a lack of attention to issues of power and dominance in our society. Some feminist authors also object to the principles approach, saying that because they have emerged from a Western philosophic tradition, they are therefore male-dominated and male-orientated, and at times have been misogynistic.

Having emerged from a desire to protect vulnerable research participants, it appears odd that bioethics hasn't readily taken on some of the concerns of feminism, especially as many of the concerns appear to be paralleled. However, despite this, early bioethical writing has largely neglected the views of women, even when the topic has been of central concern to women. There has also been scant understanding of the hierarchical nature of medical institutions and its exclusion of women's voices and experiences. Many feminists have identified the gender blindness that exists in standard ethical theory and analysis, and have sought to remedy this by developing and promoting a feminist approach to bioethics.

Feminist approaches to ethics in healthcare

Feminist approaches to bioethics do not speak in one voice. Just as there are different approaches to feminist thought, so too there are multiple voices in bioethics. These might include liberal, cultural, radical, Marxist and psychoanalytical approaches, each highlighting a different aspect of oppression and possible solutions that might be appropriate.[3]

Feminist approaches to bioethics have focused on the 'concern to understand and eliminate the oppression of women in all its guises'(Crosthwaite 2001, p 32). However, although feminists are primarily interested in removing oppression based on gender, their moral opposition would expand to all forms of oppression. There are a number of areas in which a feminist approach to ethics would challenge traditional approaches to bioethics. A prominent writer in feminist bioethics, Susan Sherwin, has proposed that a feminist approach to bioethics might include not only re-examining existing areas of discussion using a lens of feminism, but also widening the debate to hear from other perspectives and turning to issues that concern these groups. She also suggests that feminist approaches would also use alternative methods for analysis and reflection (Sherwin 1998).

So how would this approach differ practically from a principles approach? An example might be that of a woman undergoing cosmetic surgery to enlarge her breasts. While a principles approach might consider factors such as her competence to consent and a discussion of her autonomous right to choose, a feminist approach might raise concerns about the subordination of women to oppressive ideas of beauty and youth and how women might be forced to conform to these in order to get work or please a partner.

Objections to a feminist approach

One of the most common criticisms of a feminist approach is that it does not offer an alternative moral guide. While a feminist approach might help to open the debate to wider issues than those presented under the four principles, those advocating other approaches might argue that feminism doesn't help to resolve the issue. Feminist approaches also vary widely, and so there are vastly different ways in which to respond.

Ethic of care

The ethic of care arose from women's experiences of caring for others. This theory is commonly used in nursing and specifically values the caring work that is done predominantly by women. The ethic of care originated from the work of Carol Gilligan (1982) who, in response to claims that women were morally less developed than men, theorised that women and men reasoned differently. When she asked a group of 11-year-old boys and girls how they would respond to an ethical problem, she discovered that males used principles more frequently, relying on the principle of justice in response to the case. Girls, on the other hand, made decisions based on which response provided the best outcome for maintaining the different relationships in the case. On the basis of this, and her work on women making abortion decisions, Gilligan created her theory. She argued that because women are involved in caring relationships due to their capacity to get pregnant, give birth and mother children, they are more attuned to the nurturing role and therefore would place greater emphasis on the quality of relationships. Caring 'involves responding to the particular, concrete, physical, spiritual, intellectual, psychic, and emotional needs of others' (Tronto 1989, p 174). An ethic of care values and fosters the web of relationships that exist between people. In many ways the ethic of care provides a challenge to what is sometimes referred to as the 'masculine' way of thinking that values abstract principles over the detail and particulars of caring. It takes account of the moral dimensions of care and what it means to care for others.

Some problems with an ethic of care

One of the problems with an ethic of care most commonly identified within the literature relates to the limits it places on women and men. If caring and relationships are indeed something that women do best, then how are they to escape it? Should we therefore expect women to take on the caring role in our society? Not surprisingly, many feminists object to an ethic of care because it appears to trap women in a biologically determined role. Understanding men as less able to care could be understood as freeing them from any expectation of caring. Men may also want to be involved in caring work, but may be limited because they are not thought to have such abilities under this theory.

Midwifery codes of ethics

As a way of explaining the nature of midwifery, professional organisations and regulatory bodies produce statements reflecting what the profession believes about itself. This is usually represented by a statement of philosophy—the values and belief system that underpin the working of the profession—or a mission statement that clearly identifies the purpose for which the organisation exists. Codes of ethics are written as guides to the correct or proper way for members of the profession to conduct themselves.

Codes of ethics act as a distillation of centuries of knowledge and wisdom that guides members of a profession in the 'right' way to maintain their relationships with the client group to whom they provide services. They guide the behaviour of members of the profession in a way that ensures that individual practitioners reflect the values on which the profession is based. Codes of ethics often reflect the highest human values as identified by religious, humanitarian and philosophical systems that have developed over centuries.

The frameworks created by the midwifery Codes describe and encapsulate the world and culture of midwifery. They provide the midwife with a reference point for making decisions about appropriate midwifery conduct in everyday practice as well as in situations that require complex examination and decision-making. Codes of ethics enable the midwife to examine her own values and beliefs and her professional conduct to see whether it fits within the midwifery values and belief system. Most importantly, these Codes assist each midwife to experience herself as part of a larger world—the world of midwifery, a world within the bigger world that consistently expresses certain values and beliefs about the best way for the world to work in the interests of women and the midwives that care for them.

The midwife has a role to play in guiding and supporting women and their families through the experience of childbearing in a way that assists them to make sense of the experience and derive maximum benefit from it for their ongoing life. It is critical that the midwife has a good grasp of the values and beliefs that the profession espouses so that she can display these in her everyday interactions with all the women she has contact with. This is irrespective of the role she may be in. She may be providing one-to-one continuity of care; she may be working shifts in a maternity facility—a birthing centre, a primary unit, a secondary or tertiary facility; she may be a manager of midwifery services or a facility; she may be an educator or professional advisor. The onus is on each individual midwife to ensure that she is grounded within the ethical framework of the profession so that she expresses its values and beliefs in her everyday work.

Codes of conduct and standards of midwifery practice are a further development and expression of ethical frameworks and provide guidance to the midwife and others about the standard of care women can expect from a member of the profession. Standards of Practice assist the midwife to apply the ethical framework in her daily practice and her relationships with the woman and her family. They assist her with her relationships with other midwives and colleagues of other professions with whom she works, as well as those who determine the shape of maternity service provision. Codes of conduct and standards of midwifery practice require ongoing application so that the midwife internalises the values and beliefs they express and, in that way, the midwife herself becomes the expression of those values and beliefs in the world.

Midwifery philosophies, codes of ethics, codes of conduct and Standards of Midwifery Practice give the midwife a valuable tool to use when she is reflecting on practice and developing herself into a critically reflective midwifery practitioner by giving her a framework for the expected behaviour of the professional midwife.

Three different midwifery organisations' codes of ethics are presented here in full to give a sense of what these guiding documents say about the way in which professional midwives are expected to behave.

International Confederation of Midwives Code of Ethics

The International Confederation of Midwives (ICM) represents the world's midwives. It has 85 Member Associations in 75 countries throughout the world. It exists to 'advance worldwide the aims and aspirations of the midwives in the attainment of improved outcomes for women, their newborns and families during the childbearing cycle using the ICM midwifery philosophy and model of care' (ICM 2005).

The goals of the ICM are to:

- work to improve women's health globally
- promote and strengthen the midwifery profession
- promote the aims of the organisation internationally.

To guide the profession of midwifery worldwide, the ICM has developed its Code of Ethics (Box 12.1) through a consultative process with its member associations.

Australian College of Midwives code of ethics

The Australian College of Midwives (ACM) is the professional organisation for midwives in Australia. It has a national office in Canberra and branches in the capital cities of each state or territory. Its purpose is:

- to provide a unified political voice for the midwifery profession
- to support midwives to reach their full potential
- to set professional practice and education standards
- to ensure that all childbearing women have access to continuity of care by a known midwife.

The ACM has developed a code of ethics (Box 12.2) to guide and support the midwifery profession in Australia.

New Zealand College of Midwives philosophy and code of ethics

The New Zealand College of Midwives (NZCOM) is the professional organisation and recognised 'voice' of midwives in New Zealand. NZCOM works in partnership with maternity consumer groups such as Parents Centre New Zealand, the Home Birth Association, La Leche League and individual women to ensure high-quality maternity services in New Zealand. The organisational structure of NZCOM reflects and supports this partnership between women and midwives by ensuring a place for women as well as midwives at every level of the College and in every College process. Through working in partnership with women the College aims to ensure that midwives remain professionally autonomous and that women have the opportunity to be in control of their childbearing experiences. The College has a national office based in Christchurch.

BOX 12.1 ICM Code of Ethics

PREAMBLE

The aim of the International Confederation of Midwives (ICM) is to improve the standard of care provided to women, babies and families throughout the world through the development, education, and appropriate utilization of the professional midwife. In keeping with its aim of women's health and focus on the midwife, the ICM sets forth the following code to guide the education, practice and research of the midwife. This code acknowledges women as persons with human rights, seeks justice for all people and equity in access to healthcare, and is based on mutual relationships of respect, trust, and the dignity of all members of society.

THE CODE

I. Midwifery relationships

a. Midwives respect a woman's informed right of choice and promote the woman's acceptance of responsibility for the outcomes of her choices.
b. Midwives work with women, supporting their right to participate actively in decisions about their care, and empowering women to speak for themselves on issues affecting the health of women and their families in their culture/society.
c. Midwives, together with women, work with policy and funding agencies to define women's needs for health services and to ensure that resources are fairly allocated considering priorities and availability.
d. Midwives support and sustain each other in their professional roles, and actively nurture their own and others' sense of self-worth.
e. Midwives work with other health professionals, consulting and referring as necessary when the woman's need for care exceeds the competencies of the midwife.
f. Midwives recognize the human interdependence within their field of practice and actively seek to resolve inherent conflicts.
g. The midwife has responsibilities to her or himself as a person of moral worth, including duties of moral self-respect and the preservation of integrity.

II. Practice of midwifery

a. Midwives provide care for women and childbearing families with respect for cultural diversity while also working to eliminate harmful practices within those same cultures.
b. Midwives encourage realistic expectations of childbirth by women within their own society, with the minimum expectation that no women should be harmed by conception or childbearing.
c. Midwives use their professional knowledge to ensure safe birthing practices in all environments and cultures.
d. Midwives respond to the psychological, physical, emotional and spiritual needs of women seeking healthcare, whatever their circumstances.
e. Midwives act as effective role models in health promotion for women throughout their life cycle, for families and for other health professionals.
f. Midwives actively seek personal, intellectual and professional growth throughout their midwifery career, integrating this growth into their practice.

III. The professional responsibilities of midwives

a. Midwives hold in confidence client information in order to protect the right to privacy, and use judgement in sharing this information.
b. Midwives are responsible for their decisions and actions, and are accountable for the related outcomes in their care of women.
c. Midwives may refuse to participate in activities for which they hold deep moral opposition; however, the emphasis on individual conscience should not deprive women of essential health services.
d. Midwives understand the adverse consequences that ethical and human rights violations have on the health of women and infants, and will work to eliminate these violations.
e. Midwives participate in the development and implementation of health policies that promote the health of all women and childbearing families. Revised May 1999

IV. Advancement of midwifery knowledge and practice

a. Midwives ensure that the advancement of midwifery knowledge is based on activities that protect the rights of women as persons.
b. Midwives develop and share midwifery knowledge through a variety of processes, such as peer review and research.
c. Midwives participate in the formal education of midwifery students and midwives.

(Source: International Confederation of Midwives 1993 Code of Ethics)

The College has developed both a philosophy and a code of ethics (Box 12.3) to guide the practice of midwifery in New Zealand. The philosophy of NZCOM is as follows:

> Midwifery care takes place in partnership with women. Continuity of midwifery care enhances and helps protect the normal process of childbirth.
>
> Midwifery is holistic by nature: combining an understanding of the social, emotional, cultural, spiritual, psychological and physical ramifications of women's reproductive health experience; actively promoting and protecting women's wellness; promoting health awareness in women's significant others; enhancing the health status of the baby when the pregnancy is ongoing.
>
> Midwifery is: dynamic in its approach; based upon an integration of knowledge that is derived from the arts and sciences; tempered by experience and research; collaborative with other health professionals.

BOX 12.2 ACM Code of Ethics

I. The professional responsibilities of midwives

A Midwives in their professional capacity should at all times maintain standards of personal conduct, which reflect credit upon the profession.

B Midwives respect and maintain confidentiality of client information in order to protect the client's right to privacy, and use professional judgement when sharing information necessary to achieve healthcare goals.

C Midwives are accountable for their decisions and actions related to outcomes of their care of women.

D Midwives may refuse to participate in activities for which they hold deep moral opposition: however the emphasis on individual conscience should not deprive women of essential health services or respect for her culture.

E Midwives participate in the development and implementation of health policies that promote the health of women and childbearing families.

F Midwives are accountable for the dissemination of unbiased, current information to promote informed choice by women.

II Practice of midwifery

A Midwives provide care in partnership for women and childbearing families with respect for cultural diversity.

B Midwives encourage realistic expectations of childbirth by women within their own society.

C Midwives use their professional knowledge in collaboration with women ensuring that women are not harmed by conception, childbearing or birthing practices in all environments and cultures.

D Midwives respond to the psychological, physical, emotional and spiritual needs of women seeking healthcare whatever their circumstances.

E Midwives actively seek spiritual, intellectual and professional growth throughout their midwifery career, integrating this growth into their practice.

III Midwifery relationships

A Midwives respect a woman's right to make an informed choice and acknowledge her choice and support her in that choice.

B Midwives encourage and support women in their right to participate actively in decisions about their care. Midwives empower women to speak for themselves on issues affecting the health and welfare of women and their families in their culture/society.

C Midwives support and sustain each other in their professional roles, and actively nurture their own and others' sense of self-worth.

D Midwives liaise with other health professionals as necessary to ensure that women's needs for care are met.

E Midwives recognise the human interdependence within their field of practice and actively promote co-operation and mutual understanding.

IV Advancement of midwifery knowledge and practice

A Professional development encompasses a range of activities related to the advancement of midwifery knowledge, is based on skills, evidence based practice and inquiry that protects the rights of women.

B Midwives are responsible for maintaining a core of professional knowledge, through reflection on current practices and the initiation of new research.

C Midwives implement quality standards of practice through processes such as peer review, continuous quality improvement and research.

D Midwives support and actively participate in the education of midwifery students and each other.

(Revised 2001)

(Source: ACM, Code of Ethics)

(Currently under review)

> Midwifery is a profession concerned with the promotion of women's health. It is centred upon sexuality and reproduction and an understanding of women as healthy individuals progressing through the life cycle.
>
> Midwifery care is given in a manner that is flexible, creative, empowering and supportive (NZCOM 2005, p 3).

Despite the three Codes originating in three different midwifery organisations, there are consistent themes expressed in the statements. Broadly, there are three areas of midwifery ethical responsibility:

- the midwife's responsibility to the women she cares for
- the midwife's professional responsibilities
- the midwife's role in the wider community.

Underpinning the relationship the midwife has with the woman are respect for the woman's autonomy and culture. This is demonstrated by the need for the midwife to follow a process of giving unbiased and current information so that the woman makes informed choices and gives her consent for the care the midwife provides. The midwife has a responsibility to treat the woman's information as private and confidential. The midwife is responsible for meeting the woman's needs whatever circumstances the woman finds herself in. The word 'partnership' is used to describe the nature of the relationship between the midwife and the woman in the codes of ethics developed in Australia and New Zealand, and there is a clear expectation that the midwife will work in this way with the women for whom she cares.

Professionally, the midwife carries the responsibility and accountability for the care that she provides. This includes the necessity to recognise the limitations of her knowledge, experience and expertise and to make the necessary referrals to others. The midwife is responsible for her own ongoing education and professional development throughout her

BOX 12.3 NZCOM Code of Ethics

Responsibilities to the woman

a] Midwives work in partnership with the woman.
b] Midwives accept the right of each woman to control her pregnancy and birthing experience.
c] Midwives accept that the woman is responsible for decisions that affect herself, her baby and her family/whanau.
d] Midwives uphold each woman's right to free, informed choice and consent throughout her childbirth experience.
e] Midwives respond to the social, psychological, physical, emotional, spiritual and cultural needs of women seeking midwifery care whatever their circumstances, and facilitate opportunities for their expression.
f] Midwives respect the importance of others in the woman's life.
g] Midwives hold information in confidence in order to protect the right to privacy. Confidential information should be shared with others only with the informed consent of the woman unless there is a danger to her or her baby's life.
h] Midwives are accountable to women for their Midwifery practice.
i] Midwives have a responsibility not to interfere with the normal process of pregnancy and childbirth.
j] Midwives have a responsibility to ensure that no action or omission on their part places the woman at risk.
k] Midwives have a professional responsibility to refer to others when they have reached the limit of their expertise.
l] Midwives have a responsibility to be true to their own value system and professional judgements. However, Midwives' personal beliefs should not deprive any woman of essential healthcare.

Responsibilities to the wider community

a] Midwives recognise the Maori people as Tangata Whenua of Aotearoa and honour the principles of partnership, protection and participation as an affirmation of the Treaty of Waitangi.
b] Midwives encourage public participation in the shaping of social policies and institutions.
c] Midwives advocate policies and legislation that promote social justice, improved social conditions and a fairer sharing of the community's resources
d] Midwives acknowledge the role and expertise of community groups in providing care and support for childbearing women.
e] Midwives act as effective role models in health promotion for women throughout the life cycle, for families and for other health professionals.

Responsibilities to colleagues and the profession

a] Midwives support and sustain each other in their professional roles and actively nurture their own and others' sense of self-worth.
b] Midwives actively seek personal, intellectual and professional growth throughout their career, integrating this into their practice.
c] Midwives are responsible for sharing their Midwifery knowledge with others.
d] Midwives are autonomous practitioners regardless of the setting and are accountable to the woman and the Midwifery profession for their Midwifery practice.
e] Midwives have a responsibility to uphold their professional standards and avoid compromise just for reasons of personal or institutional expedience.
f] Midwives acknowledge the role and expertise of other health professionals providing care and support for childbearing women.
g] Midwives take appropriate action if an act by colleagues infringes accepted standards of care.
h] Midwives ensure that the advancement of Midwifery knowledge is based on activities that protect the rights of women.
i] Midwives develop and share Midwifery knowledge through a variety of processes such as peer review and research.
j] Midwives participate in education of Midwifery students and other Midwives.
k] Midwives adhere to professional rather than commercial standards in making known the availability of their services.

(Source: NZCOM 2005)

career. She has a responsibility to herself and her own moral code; she can refuse to participate in activities but she is not ethically able to deprive women of midwifery care. As a member of the midwifery profession, the midwife has a responsibility to support, sustain and nurture other midwives and to educate midwifery students and her colleagues. She also has responsibility for the advancement of midwifery knowledge while protecting the rights of women.

Within society, midwives act as role models for other women in the communities in which they live. They carry responsibility for ensuring that women and midwives have a say in the development of health policies that promote and protect the health of women and childbearing families, particularly working with women to set policy for the provision of maternity services.

The role of the midwife carries many responsibilities and these are specified in the codes of ethics for the profession. Clearly, these are not to be taken lightly. At the same time, the work of midwives is involved with the most joyous and life-affirming moments in the lives of women and their families. The ethical responsibilities that they carry need to be balanced with the satisfying role of assisting women to become mothers.

Ethics in practice

We have now explored some ethical theories and have looked at the codes of ethics for midwives; it is time to examine how the ethical frameworks work in practice. The following are real-life scenarios that midwives deal with in their everyday work. Read through the scenarios and use the following information to work out how you will deal with such matters when they arise in your practice.

Scenario 1

Mary and Phil are expecting their first baby and have engaged Trudy as their midwife. They have decided to have their baby at home and are very keen to have no intervention in the birth process. Mary goes into labour in the early hours of one morning and contacts Trudy after about four hours. Trudy visits and, during a palpation of Mary's abdomen, determines that the baby is lying in a breech position. Trudy explains the extra risks of a breech birth to Mary and Phil, and advises them that current practice recommends that they transfer to hospital for the birth and consult with an obstetrician. Mary and Phil decide that they do not want to change their plans, and they let Trudy know that they still want to go ahead with a home birth.

The midwife involved with this couple will need to be aware that Mary and Phil are making decisions from a position of little knowledge of the experience of birth but a great deal of knowledge of themselves, their capabilities and the type of birth they want to experience. One of the ethical responsibilities of the midwife is to provide Mary and Phil with the necessary and appropriate information to ensure that they are making an informed choice and understand what they are choosing. There is also the ethical issue of building up Mary's belief in herself as a birthing woman and there is a fine line between giving a woman the facts of this situation and not scaring her about the physiological process she is already embarked upon. The experience of the midwife in breech birth and the length of time she has been a practitioner are likely to have an impact on her ability to 'be with' Mary and Phil as they make this decision. It will influence the way in which she guides them through the decision-making process.

This case raises some interesting questions, such as: Are the risks to the baby from being born breech outweighed by Mary's claim to autonomy and her ability to determine the matter for herself? Irrespective of Mary and Phil's decision on where to have their baby, what is the midwife's responsibility to them? How does the midwife deal with the fact that there can be competing ethical responsibilities in dealing with an issue? Is there any overriding responsibility the midwife has in relation to Mary? Who might the midwife consult with if she is unsure of her responsibilities in this scenario? What is she entitled to do if she totally disagrees with Mary and Phil's decision to stay at home? What support mechanisms might be put in place so that additional assistance and specialist expertise is immediately available should any complications arise during the birth or should the baby need resuscitation? Would consent need to be sought from Mary and Phil in anticipation of calling for specialist assistance if required?

Scenario 2

Sheralyn is expecting her first baby. She is 36 and has a career as a partner in a law firm. She makes it clear at her booking visit with the midwife that she plans to have a caesarean section at 39 weeks and will go back to work full time when the baby is eight weeks old, employing a nanny to take care of her child. She asks the midwife to refer her to an obstetrician who will provide this care.

In responding to this case, a midwife might want to begin by examining the choice Sheralyn is making. As pointed out earlier, there are good reasons why we might wish to support a woman in her choice and not override her views—after all, Sheralyn will probably be the best judge of what might be appropriate for her. The potential harms that may result from Sheralyn's choice might also need to be clarified and discussed with her. However, she may claim that such harms may be less significant for her than those associated with vaginal delivery. Turning now to feminism to explore this case, we would find that different branches of feminism would take differing views. For example cultural feminism may highlight the gendered nature of healthcare and how women are being influenced by beliefs that women's bodies are out of control and should be taken under the care of medicine. They might argue that such beliefs detach a woman from the capabilities and power of her body to give birth naturally. However, radical feminists might argue that women can only free themselves from oppression by removing the ties to reproduction. This group would want women to have a wide variety of choices that suit a variety of women and perhaps not to be subject to traditional ideas of childbirth.

For the midwife in clinical practice, Sheralyn's decision may not fit well with her philosophical position, and she may have to make a decision about whether she will continue care or pass her on to an obstetrician and midwife who specialise in this kind of care.

Scenario 3

Jenna is 16 years old and is pregnant with her first child. She first found out she was pregnant when she was already at 22 weeks gestation. Jenna was unhappy to discover she was pregnant but was too far advanced to meet the criteria for an abortion.

(continued)

Scenario 3—cont'd

She is now 25 weeks pregnant and has been heavily involved in binge drinking and sniffing solvents. Jenna was recently picked up in the street by police for disorderly behaviour while intoxicated. Sophie is Jenna's midwife, but they have had little contact because Jenna doesn't often make it to appointments. Jenna's mother says she is at her wits end with Jenna, as Jenna won't listen to her

Using the four principles to explore this case might instruct the reader to think about how we can benefit Jenna and her baby. Getting her away from solvents and alcohol would certainly benefit both her and her baby, but does this justify detaining her? This could risk alienating her from her caregivers and her baby when she realises that this is not happening to her friends who aren't pregnant. This raises another issue: should women be subject to a loss of freedom because they are pregnant? Another way of looking at this case might be to use an ethic of care. Jenna, her baby and her mother will still have some sort of a relationship long after the involvement of health professionals. How could a midwife foster such relationships? Planning appointments to suit Jenna might be a start. However, this may require some creative work from the midwife. Involving Jenna and her mother in her own care as much as possible will also help both of them feel more connected to the process.

Scenario 4

Cherry has been a midwife for five years and has recently taken on a position as a case-loading midwife in a hospital team. She has taken over the case-load of another midwife who has gone on maternity leave. Cherry has been in the position for three months and there is one woman, Marlene, who she is finding it difficult to get along with. Marlene is very critical of Cherry and keeps referring back to the things that her previous midwife said and did. Marlene is expecting her third baby and is now 35 weeks pregnant. Cherry is feeling increasingly uncomfortable in providing care to Marlene and is thinking about what her next step needs to be to resolve the situation.

In considering this scenario, the midwife has to weigh up her ability to develop a positive relationship with the woman to whom she is providing care. The midwife has the responsibility to provide a professional standard of care to the women for whom she provides midwifery care, and at the same time there is an expectation that there will be a working partnership between the two individuals involved. There are a number of approaches that can be taken when considering this scenario.

What is the nature of the partnership when one or other of the participants does not get on with the other? How is it possible to provide effective and professional midwifery care in this circumstance? Whose role is it to make the partnership work? What steps need to be taken when the relationship is not working for the midwife? In the absence of other care being available to the woman, what are the responsibilities of the midwife who is already involved with her? One aspect of this situation to consider is the developmental challenge provided to the midwife in terms of her ability to provide care to a wide range of women.

Research ethics and midwifery

The midwifery encounter does not just begin and end with maternity services as we commonly understand them to be. There is also potential for midwives to be involved in research. Having due regard for the research participant in research is also of ethical concern.s

Many midwives have a desire to understand more about pregnancy, childbirth and the social context in which these occur. This may be partly driven by aspirations to understand more or improve their own practice and the experience for women and their families. There is also a move within healthcare to base practice on firm foundations of knowledge rather than on an unsupported belief, theory or anecdote. All these factors have meant that many healthcare providers, such as midwives, are involved in research. However, whenever people are part of a research study there is always the potential for harm.

Ethical review of research involving human participants

We know from earlier in the chapter that research participants have not always fared well, and concern for their welfare has, at times, been lacking. There has been recognition worldwide that safeguards are required to ensure that the welfare of research participants is protected. In New Zealand and Australia, a formal process of ethical review for any research involving human participants is carried out by research ethics committees.

It may be thought that the review process is sometimes an unnecessary step in research. It could be claimed that midwives have the best interests of their clients at heart and so it is not necessary for anyone other than the midwife herself to decide about the ethical status of her research. However, midwives also undertake research because of their own interests—to publish, obtain degrees and advance their own profession. But the real issue here is not so much mixed motivation as the fullest possible protection of potential and actual research participants. It is widely agreed that this requires all proposed studies to be assessed by research ethics committees who have no vested interests in the research.

Ensuring the wellbeing of research participants

Consent

The primary means by which the wellbeing of participants is ensured is through participant consent. Ethical review aims to ensure that as far as possible no research participant will ever be the subject of research without his or her full, informed and continuing agreement. Ways of achieving consent include information sheets describing the intended research written in such a way as to be readily understood by someone new to the area of study. Participants need time to think about participation, and the option to withdraw without penalty, which means that there will be no reduction in the level or quality of care provided if they decide not to take part.

But even with all this in place, consent can be subtly compromised, for example in the actual circumstances in which it may be sought. A particular problem in midwifery-based research might be the occasions where the prospective participants are the clients of the researcher. The enthusiasm of the researcher-midwife for the research or the gratitude of a woman for what the midwife has done or is doing for her may make it difficult for the woman to refuse a request to participate in research. Overcoming these problems requires careful consideration of *how* women are approached and *who* makes that approach.

Calculating harms and benefits

Ethical review of healthcare research is commonly concerned not only with whether or not the risks of taking part in research are acceptable. This issue precedes the concern with consent and places some onus on the researcher to make sure that the planned research is minimally harmful *before* consent is requested.

Here it may be argued that midwifery research is unlikely to be harmful because midwifery research is likely to involve the woman as an informant, where she is asked to take part in an interview or questionnaire. The levels of risk of such research must be low compared to being in the trial of a new drug. But harm can come from all kinds of sources, including questioning and interviewing. *What* is asked, and *how* it is asked, are of ethical interest.

In addition, some research, while not actually producing harm, is incapable of producing benefits—because the design of the study is inadequate, for example. Research that cannot meet its own aims is pointless, and in such a case if the research proceeded then any risk or even inconvenience to the participants would be unacceptable.

Confidentiality

It is common for ethics committees to demand that those who participate in research have their identities protected in any published (that is, publicly available) form of the research, unless they have agreed to being identified. Research undertaken by midwives commonly involves women telling their experiences, and care must be taken to ensure that confidentiality is maintained.

Innovative practice

In any clinical practice, such as midwifery, there is constant innovation. Midwives will become aware of new techniques and may see situations where they can try these, believing that they may be just what the woman needs. This kind of evolving innovative practice is common but raises some ethical questions, such as: Is this practice effective in the situation where I am using it? Can it cause harm? These questions cannot be addressed without proper research. Midwives, as with all healthcare professionals, need to be alert to when a developing practice requires research to validate its use before it becomes a new and accepted practice.

Research involving people automatically raises ethical issues, and there is international agreement that a process of ethical review centred on certain key issues is essential. These include consent, confidentiality and an evaluation of harms and benefits. In the midwifery context there are some specific subtle issues that arise in relation to these and to the question of what counts as, and/or needs, research.

Conclusion

This chapter has introduced the ethical constructs of the midwifery profession. It has presented codes of ethics for the midwifery profession and examined how these create the midwifery world. It has also presented the development of bioethics and critiques of the bioethical approach as an introduction to ethical thinking in the provision of healthcare. Finally, it has looked at ethical dilemmas that midwives may confront in their everyday practice and the guidance that professional codes of ethics may provide the individual midwife in exploring the dilemmas that arise.

Review questions

1. Briefly describe the philosophical underpinnings of midwifery.
2. Discuss the way in which ethical reasoning can affect the everyday clinical practice of midwives, and provide a case scenario.
3. What strategies can midwives employ in applying moral concepts to their professional midwifery practice?
4. Discuss the importance of gaining informed consent from women undergoing treatment or care.

5 Briefly discuss the history and development of international codes of bioethics.

6 List the components of the four-principle approach to healthcare ethics.

7 Discuss, in a paragraph, the idea of 'do no harm' and its application to midwifery care.

8 Describe the history of the development of international midwifery codes of ethics.

9 Briefly discuss the current code of ethics of the Australian College of Midwives Incorporated (ACMI).

10 Name three elements from the philosophy and code of ethics of the New Zealand College of Midwives.

Notes

1 Strictly speaking the term 'bioethics' is used to refer to the moral concerns in all areas of life, including human, animal, plant and environmental areas. However in this chapter we will limit this term to refer to ethical analysis of midwifery practice only.

2 Examples of such research can be seen in the Tuskegee experiments uncovered in 1972. For further discussion see McNeill, *The Ethics and Politics of Human Experimentation* (in Further reading).

3 For further detail on the different varieties of feminism see Rosemary Tong, *Feminine and Feminist Ethics* (in Further reading).

CHAPTER 13

Life skills for midwifery practice

Bronwen Pelvin

Key terms

autonomy, boldness, commitment, companionship, curiosity, decisiveness, empathy, friendliness, generosity, honesty, integrity, life skills, negotiating, organisational skills, positivity, practicality, reflectiveness, relationships, robustness, self-care, self-knowledge, self-responsibility, work–life balance

Chapter overview

This chapter identifies a number of 'life skills' that are required for midwives to fulfil their role in working 'with' women through the life experiences of pregnancy, birth and new mothering. These life skills include the development of personal attributes needed to be in relationships with women and of skills that assist midwives to sustain and maintain their midwifery practice.

This chapter is experiential, as it provides the personal perspective of one midwife with a long involvement in midwifery practice across all settings and draws on knowledge derived from practice rather than theory. Unlike other chapters in this book, this chapter is not based on research or other evidence from current literature. Instead, the author offers guidance to midwives based on her knowledge and understandings and derived from reflective midwifery practice.

Learning objectives

Learning outcomes for this chapter are:

1. To explore the role of a midwife and the nature of midwifery practice
2. To identify and explore the essential qualities of a midwife
3. To identify and explore the life skills necessary to undertake the work of a midwife
4. To identify and explore concepts of 'self-care' and 'work–life balance' in relation to sustaining midwifery practice.

Introduction

Women rarely go through their childbearing experiences totally on their own. Each woman comes with not only her own personal context but also her social context. Each woman's personal context is made up of her life stage, stage of personal development, educational background, spiritual beliefs, personal values that she holds and the nature of her relationships with those in her immediate social circle. Her social context consists of the wider community, social group, ethnic or religious community that she lives within and the values and beliefs that those groups hold and how these influence the woman's life.

Consequently, a midwife has to develop the ability to make an analysis of the total context of each woman and her family/whanau as well as the ability to develop a meaningful and purposeful working relationship with each woman as together they travel the journey of pregnancy, birth and the postnatal period. The way these working relationships develop will depend to a large extent on each individual midwife and where she is on her own professional and personal development journey. The learning she does as a midwifery student and the knowledge she gains through her practice experiences unite into her journey of development as a professional midwife.

The nature of midwifery practice requires the development of skills and abilities within each midwife to support the work that she is required to do in her working relationships with each woman and her family. It is useful for a midwife to understand the skills and abilities that will continue to develop along with her midwifery practice as she builds practice wisdom through her experiences as a midwife.

Midwifery, centered as it is in human relationships and assisting an individual through a universal, yet highly personal and intimate life experience, requires practitioners who are able to bring sensitivity, support, compassion and generosity to those for whom they are providing care. The position of midwife is one of privilege—the intimate nature of the work places a midwife in a position of close proximity, learning, noticing and observing how a woman functions at a fundamental level and in her relationships with those nearest and dearest to her, as she experiences one of life's pivotal events. Midwifery relationships, at their best, facilitate not only the physiological process of pregnancy, giving birth and the early mother–baby relationship but also the growth and development of each woman and a deepening of her relationships with those in her family/whanau.

This chapter discusses the personal qualities and skills a midwife needs in order to be able to meet the demands of her profession. Midwifery education programs can assist individuals to prepare for the role of midwife by helping students begin to develop the necessary skills and abilities. This chapter will focus on identifying some of the life skills required to carry out, support and sustain the work of a practitioner of the art and science of midwifery.

The nature of midwifery and the role of the midwife

Midwifery is concerned with the making of mothers. At the core of midwifery is the relationship between each mother and her baby. Midwives know that this relationship is critical for the baby's physical, mental, emotional and spiritual survival. Midwives know that this relationship has a profound effect on the mother's sense of her own power, her ability to give and nurture life and her core sense of herself as a woman and as a human being. Midwives understand the intensity of the feelings attached to this experience and the need for the mother to allow herself the deepest sense of love that she may yet have experienced. Midwives know that it is critical for the baby to grow and develop in a world of love, understanding, generosity and abundance, in order to lay the foundations for its ongoing development for the rest of its life.

There is also the nature of each woman's relationships with the others in her immediate family/whanau/social network to consider. Midwives facilitate the development of the necessary support systems so that family and friends will support the mother in her primary role in ensuring the wellbeing of the baby. The midwife acts as a source of information and guidance; she acts as an educator of the wider family group and the community. As life has become more technologically advanced and complex, the midwife acts as holder of some fundamental truths of human existence, the things we can and must do to ensure that our lives have depth and meaning and that we are connected with each other. This is expressed around the universal act of giving birth; the truths evident here are applicable to the rest of our lives.

The role of the midwife is a large one in whichever society the midwife lives and works. It is a role that the individuals who take up midwifery grow into. Each midwife does not emerge from her educational program 'fully formed'. As a new practitioner, each midwife cannot be expected to have the wisdom of the ages in her bones. It can be expected that she will have the competencies of a registered midwife and a willingness to go on learning through her experience.

Developing the role of the midwife

The ability to enact a particular role within a society requires development that occurs in a certain way. First it requires integration of the individual's own context and personal development with the requisite knowledge, skills and abilities of the role. Second, it requires acknowledgement that maturity and wisdom both develop over time and that therefore an individual who pursues midwifery will mature over time into a 'self-actualised' midwife, able to meet the obligations that the role and society demand.

Consequently, the focus is on developing each midwife's ability to know herself as a person and as a professional practitioner. Midwifery will make certain demands on those

who practice, demands that, in the main, will be a pleasure and a joy for the midwife to meet. However, some demands will challenge the midwife to the foundations of her own sense of herself and her belief in the purpose of life and the nature of meaningful work. Fortunately, a midwife's experience takes place over many periods of time, as midwives take on different roles within the profession and move in and out of full- and part-time work depending on their personal life circumstances. There is an interesting synergy to an individual's development as a midwife. To be a midwife requires a certain degree of personal development and maturity; but the practice of midwifery itself provides important opportunities for individuals to develop maturity and wisdom. Each midwife's professional life can be viewed as a continuous stream of learning opportunities and challenges. In so doing it is useful to identify some of the qualities that will sustain each midwife in her ongoing midwifery life and keep her open to learning from the deep and rich experiences that midwifery practice offers.

Qualities for midwives

Robustness

Being robust means being able to withstand what life presents to you, able to pick yourself up after being knocked over and carry on. The word 'robust' means strong and healthy, sturdily built, requiring and displaying physical strength. In the case of the midwife, this is translated into the mental, emotional and spiritual characteristics necessary to assist women and their families through the experience of childbearing and the number of challenges that can occur in any life experience.

Midwives deal with life 'in the raw', life as it is lived by women who rely on them for information, support and guidance. This means each midwife has to develop the ability to deal with what is happening in the 'here and now' and continue to work with each woman and her family to support them through their experiences. This requires stamina, fortitude and physical and emotional strength as well as the ability to keep thinking, assessing and planning.

Empathy

Empathy is the ability to sense and understand someone else's feelings as if they were one's own. It is necessary for midwives to develop this ability to a high degree in order that they can put themselves in each woman's position and have a sense of what it is like for her. There is a potential danger in a midwife over-identifying with a woman, and this may lead to a desire to have the woman's experience for her or to protect her from the experience that she is having. Empathy has to be tempered by the ability to set clear boundaries and have respect for each woman and her autonomy. The ability to empathise leads to acceptance of another and understanding of what their life is like for them.

Empathy is derived from communicating with each woman to discover what her feelings are about any given situation that arises in her experience. There is no room here for making assumptions about what a woman may or may not be experiencing. Whatever a midwife thinks a woman is experiencing needs to be checked out to ensure that the midwife is not projecting her own thoughts and feelings into the situation.

Companionship

The word 'midwife' is derived from the Old English *mid*, meaning 'with' and *wif*, meaning 'woman'. At the core of the word is the concept of being a companion to a person, being alongside them, journeying together. Thus a midwife takes on the role of a companion and the nature of the work requires her to be able to assist a woman to make sense of her experience bit by bit and as a whole. But it is not just being a companion; it is being a companion in a certain way.

Midwifery companionship is based on midwifery knowledge, knowledge derived and distilled from centuries of attending women in childbirth. This includes knowledge of: the anatomy and physiology underlying the physical process of reproduction; human psychology, developmental psychology and the nature of human relationships; social, cultural and spiritual contexts of each woman; and women's wellness, place in society and networks of support. Midwifery companionship is grounded in the belief of each woman's ability to give birth—to grow and nurture a baby through pregnancy; to initiate, go through labour and give birth; and to nurture and care for a newborn infant and sustain its life in the first weeks after birth. Midwifery companionship is also grounded in respect for each woman, her life experience so far, and both the woman's and the midwife's own capacities to learn from experience.

Honesty

Honesty is the quality of being truthful and trustworthy. It can be applied to relationships where openness and sincerity characterise the interactions between the participants, who present themselves as they are.

In midwifery, honesty pertains to the ability of a midwife to present herself, her way of working, her knowledge, beliefs, assessments, opinions and the available evidence about her choices for care to each woman truthfully so that meaningful discussions can occur about the care needed by each woman and her family/whanau. There is an art to presenting the midwifery 'truth' while still leaving room for a woman and her family/whanau to express the truth of the matter from their perspective. There is an art to being able to contain more truths than just one's own and to work for a way forward if the truths are different or in conflict.

Commitment

Commitment is about honouring the intended purpose of each midwife/woman relationship, and a midwife is involved in providing services that meet the maternity needs of women and their families. A midwife has to develop the ability to be committed to the work and to each woman for whom she cares. She will do this in different ways, depending on the midwifery role she is in. One of the most binding commitments a midwife can make is to provide continuity of

care to a woman throughout her childbearing experience. A midwife makes herself available to respond to a woman and the unpredictable nature of her experience, whenever and however it occurs.

Midwives working in other midwifery roles—shift work within a maternity facility, as a midwifery educator or advisor—also express commitment to their work by being available for the work at regular times and being available to others during the times of work and often outside those times of work as well. When at work, these midwives express their commitment to the profession by engaging with the women for whom they care, the students they teach and the midwives and others they advise.

The law requires commitment from registered midwives. There are regulatory requirements that midwives have to meet and, depending on how maternity services are managed, contractual obligations for service to fulfil. The midwifery profession requires commitment from midwives. The profession expects them to provide midwifery care to a professional standard, and articulates what the professional standard of care is and what midwives need to do to provide it.

Integrity

Integrity implies consistency between the spoken word and the actions of an individual. It can be defined simply as honesty, the capacity for truthfulness, but there is an extra dimension connected to being united or whole. The word can be applied to a person's functioning to describe the way in which their behaviour reflects their expressed belief system and their intentions. As a professional person, a midwife has an ethical responsibility to be consistent in what she says and does. This also applies to her words and actions being consistent with the professional expectations of her as reflected by professional regulatory requirements, codes of ethics and philosophical statements.

Decisiveness

The role of the midwife requires the ability to make decisions. Decision-making requires the midwife to take in all the information about a certain issue, practice or course of action, weigh up the information and determine what aspects of the issue are more critical or pressing, examine her own thoughts and beliefs about the information, and come to a decision about what is required or what advice to give the woman and her family. In most situations, this process can be leisurely and thoughtful, but there are also circumstances that require decisions to be made quickly because the life or wellbeing of the woman or her baby is at stake.

Curiosity

Pregnancy, labour, birth and the postnatal period are biological, physiological, mental, emotional and spiritual processes that a woman experiences. This means they are as dynamic and varied as each woman who experiences them. A midwife is involving herself in a life event and it is being lived forward, without the benefit of hindsight, until it is completed. A midwife will benefit from curiosity in her work—the eagerness to know or find out.

Despite her basic knowledge of the process of childbearing, each time a midwife encounters the experience it is with a different woman. Each time she encounters the childbearing experience with the same woman, the woman is in a different place on her developmental journey and the process is another singular event in her life—it is 'this time', not the last time or the next time. Nothing can be assumed or taken for granted.

Curiosity will enable a midwife to sustain her interest in the childbearing process. It will open her up to being responsive to what is in front of her, continuing to learn, assess and report on the event for the woman and her family/whanau.

Practicality

Midwives are often known and respected for their sense and practicality. Practicality is derived from experiences and actual use rather than from theory. The involvement of midwives with women in their everyday lives affords them a wonderful opportunity to see women coming up with practical solutions to the management of pregnancy, labour and the care of the newborn. As women, midwives have often had these experiences themselves and can report on what they have found helpful. They can also report what they have noticed in other women's childbearing experiences and contribute to the dissemination of knowledge. In this way midwives act as conduits of sensible, useful and effective responses to the situations women encounter as they journey through their childbirth experience.

Boldness

Courage, confidence and fearlessness typify the midwife's functioning in the world. This is not a profession for retiring, 'shrinking violets'! When a midwife deals with all the possibilities and variations of a physiological life event and the potential for disappointment, grief, shock and trauma as well as enormous joy, elation, love and compassion, she must develop the capacity to be bold—to go where no one else has gone, to risk uncertainty and to respond to changing and unknown situations.

Women and their families/whanau can face their deepest fears as they approach childbirth in today's risk-averse society. There is a strong drive for guarantees and perfect outcomes, not least because women have fewer babies than they have ever had before in the history of the human race. They want every baby, particularly their baby, to be perfect. The opportunity to learn about the nature of life from many different experiences is reduced and maximum learning has to be derived from the experiences that each person has. Medical dominance of the reproductive process and the reflection of that dominant view in the media has created a degree of fear in the community that the midwifery profession, coming as it does from a belief in a woman's ability to grow, nurture, give birth to and feed her own baby, has to withstand.

It is work in itself to present a different view of childbirth to women informed by magazines, newspapers, radio and

television that seem intent on sensationalising only the most dramatic and often negative stories about birth. It requires effort to sustain a belief in the physiological process and to defend women's ability to achieve their biological purpose with a minimum of intervention from any quarter. From a midwifery perspective, there is a need to support this approach to ensure that women are built up in their sense of their own competence. This is essential for the wellbeing of women, babies, families and society; and midwives, individually and collectively, have a great responsibility to contribute.

Reflectiveness

Introspection is an essential ability for a midwife in order to process and make sense of her professional experiences. She needs the ability to reflect on her practice in order to grow and develop in experience and practice wisdom. She needs to reflect on her own functioning with women and their families to learn more about ways in which she can make a positive contribution to their lives.

A midwife must be able to both reflect internally and express that reflection in the company of others, to ensure that she is maintaining practice in the way in which the profession expects. A midwife also has to be able to place her own personal, professional experience within the context and frameworks that create the midwifery world.

Friendliness

The nature of midwifery work requires midwives to move in and out of women's lives and the lives of their family/whanau members. A midwife needs to develop an open and welcoming demeanour that demonstrates goodwill towards others, a quality reflected in the word 'friendliness'. Being friendly carries the suggestion of being on the same side, disposed towards being helpful and supportive. It is this concept that is reflected in the slogan 'Midwives help people out' used in the New Zealand College of Midwives' promotional material.

Generosity

Generosity is a quality that women value highly from their midwife or the midwives who attend them while they are in hospital. Generosity means a willingness to give time, attention, knowledge; freedom from pettiness and meanness; the sense of abundance and plenty. Women appreciate midwives giving them the necessary time to deal with their concerns, to assist them through the decision-making process, attending them throughout their labour and birth, providing support and knowledge as they respond and develop as mothers in the postnatal period—all in an unhurried, stress-free and easy manner.

There will be times in every midwife's life when she finds herself unable to continue to be generous. At this time she needs to resource herself adequately through taking a break, talking with family, friends and colleagues, seeking professional guidance or assistance and other means, in order to restore her faith in herself and human nature, to enable her to again approach her work in the spirit of generosity.

Positivity

Positivity in the midwifery profession is the quality that assists women to believe in their ability to grow and develop a baby during pregnancy, to experience labour and give birth and to become a mother. This quality is grounded in a midwife's belief, knowledge, understanding and experience of a woman's physiological process and her body's ability to do what, from a biological and evolutionary point of view, she is designed and equipped to do. Positivity is characterised by affirmation of each woman and the biological process she is undergoing, as well as expressing certainty in that process and in a woman's ability to learn throughout her experience.

Midwives are fortunate that they are in touch with a life-giving process on a regular basis, and with new life as they greet each new baby along with its mother, her family and her friends. There is magic in birth and in seeing a woman in all her power and glory. There is magic in the resolution of difficult obstetrical problems to a safe outcome and a happy meeting of mother, baby and family. It is this magic that nurtures positivity in individual midwives and the profession. It can be used to replenish and restore midwives so they can support and nurture other women and families through the same process.

In summary

Naturally, these are not the only qualities that midwives will have or continue to develop. The qualities described above are some of those that a midwife will find useful for sustaining herself as a practitioner. The ongoing development of all of these qualities in a midwife will ensure that the women and the families with whom a midwife comes into contact, will benefit from her involvement with them.

The qualities described above give some indication of the expansive nature of midwifery work. As one person within a network of women, families and communities, a midwife, by the nature of her involvement in an individual's intimate life experiences, has a wide sphere of influence. Think of a pebble being dropped into a pond—the initial impact may be small but ripples spread in ever-widening circles—a midwife in her working life touches many lives.

Reflective exercise

1. Get together with one other student from your class. Discuss the preceding qualities and identify which ones you have developed well in your functioning; which ones you have but need to develop further; and which ones are absent from your functioning.
2. Identify three ways in which you can strengthen each quality that is under-developed and one way in which you can begin to develop the qualities that are absent from your functioning.
3. Write down your findings and your plan, for future reference.

Sustaining midwifery practice

Let us now move on to explore the way in which a midwife can sustain herself to be able to express these qualities within her working life and fulfil her role as a midwife.

Self-knowledge

How does a midwife come to know herself as both a person and a midwife? Every midwife needs to gain a sense of herself as a 'work in progress', on her own unique professional and personal journey. Inherent in the nature of professional practice is the concept of ongoing and continual learning from experience. Central to the professional midwifery practitioner is the idea that the learning and knowledge gained from all she experiences will be integrated into her functioning, and that her clients will benefit from the practice wisdom she develops over time.

The nature of midwifery work will assist a midwife to develop the sense of being a 'work in progress' as she accompanies the women she cares for through the dynamic life process we call 'having a baby'. The contact with many, many women, some of them other midwives, in various stages of personal and professional development, provides opportunities for a midwife to reflect on her own life stage and her own development simply through exposure to other people's lives. Throughout the span of her midwifery career, in the various roles she enacts in the midwifery world, a midwife is exposed to many ideas, personal stories, personal visions, ways of being and doing things, lifestyles and life choices that will inform and guide her when making decisions for herself.

During the process of learning about midwifery, many students are introduced to the concept of journaling as a powerful, reflective tool for their own learning. Journaling, or simply writing about what she experiences, enables a midwife to discriminate between her personal responses to what happens within her midwifery practice and her professional responses informed by what she knows and believes about midwifery along with professional midwifery knowledge and perspectives, professional ethics and standards.

Midwives also involve themselves in many opportunities to reflect on their own functioning as midwives. This can occur in informal discussions and dialogue with women and other midwifery practitioners; conversations with colleagues in passing in corridors and ward offices in hospitals; midwifery practice meetings; involvement with midwifery students; and picking up information from newspapers, magazines, television, the movies, the internet and many other sources. A midwife will also involve herself in more formal learning opportunities such as Midwifery Standards Review; peer review; formal sessions with a midwifery mentor or supervisor; formal courses and involvement in postgraduate study; preparing and giving teaching sessions; subscriptions to midwifery journals and magazines; internet searches and literature reviews on particular topics. A midwife can connect to her professional group and is likely to involve herself to a greater or lesser degree with the professional activities that occur.

Many midwives will also make use of their own life experiences to inform their practice. They may do this informally and as part of their journaling exercises. They may also participate in personal development sessions or workshops. Examining the effect of personal experience both past and present may form part of the exploration of practice behaviour undertaken with mentors, supervisors or as part of midwifery conversations with peers and colleagues. Midwives may participate in professional development processes and find that these also have personal development outcomes for them.

As her practice progresses and develops in this way, a midwife will become much clearer about herself as a practitioner. If she is involved in marketing herself or the practice she belongs to, or presenting herself to reviewers or her peers, she will need a clear sense of herself as a midwife in order to present herself well. The idealism with which she is likely to present herself at the beginning of her career will be replaced with practice knowledge and wisdom developed from her own experience, as this is integrated into the way she is as a practitioner and the way in which she works. She will develop objectivity about herself and her own behaviour as a midwife and this will assist her in assessing her own performance, as well as creating new ideas about the best way in which she can fulfil her role.

As part of her developing consciousness, a midwife also becomes aware of her capabilities and her limitations as a practitioner. As a new practitioner, a midwife is conscious of her limitations and inexperience; at the same time she is aware of the amount she has to learn and is eager to develop herself as a practitioner. Through the experience she has in providing care for women, a midwife will begin to add her own experience to the knowledge and competence she has gained as a student midwife.

Once a midwife begins to integrate her experience into her functioning, and through reflection on practice both formally and informally, she becomes more conscious of her capabilities. Developing awareness of capabilities brings awareness of limitations. A midwife then needs to discern whether her personal and professional limitations will affect her development as a practising midwife. She is also able to discriminate more easily between the effect she can have on the women to whom she provides midwifery care and the other influences on those women from their own lives, their own experience and their own value systems.

As this learning takes place within individual midwives over time, they become more able to recognise that they cannot be all things to all women. They are likely to develop a wide range of referral options for women to assist them to support their physiological processes instead of being restricted to the medical, obstetric paradigm. Midwives also become more aware of community-based support networks for women and their families/whanau. This will include local maternity consumer organisations, support groups and counselling services as well as social and government agencies that have

a role in supporting women at this time in their lives. This knowledge enables midwives to direct women to appropriate sources of information and support. Midwives learn how to use referral judiciously to benefit each woman and her individual circumstances.

There is no doubt that the development of a midwife's consciousness of her functioning is a critical factor in her ability to sustain herself as a practitioner and within the profession. Midwifery is a large role to take on and there are many demands made on a midwife, particularly when she provides continuity of care to women. Different practitioners will respond differently to the demands of midwifery and may choose to be involved in different areas of practice because, for them, that is the best way for them to manage the demands of the professional role. It is important that as midwives we are just as sensitive, understanding and appreciative of our colleagues' ways of being midwives as we are of our own.

Autonomy

Autonomy means self-determination, the ability to be self-governing. It can be applied to individuals, groups, communities, societies and states. Autonomy will be influenced by many and varied factors, including values and belief systems, cultural and ethnic origins as well as personal and professional desires and goals.

Midwifery is often described as an autonomous profession. This concept is used to declare its independent functioning, distinct from the medical profession and the nursing profession. The concept is also used to demonstrate that midwifery has its own distinct body of knowledge, its own view of the world derived from that knowledge, and that it is self-determining in its educational pathways, philosophy, ethics and standards.

There is a point at which the notion of autonomy applies to each individual midwife, bestowing on her the freedom to determine her own actions and behaviour within the midwifery context. There is also a point at which the notion of autonomy applies to the midwife's personal life. Obviously, there is integration between the personal and the professional life of any midwife, and the degree of integration will influence and inform both her professional and personal functioning and decision-making processes.

Reflective exercise

1. Consider the person you were five years ago. Write a paragraph on what sort of person you were at that point in your life—identify your character traits, the things you thought about, your dreams, goals, plans, what you thought and felt about things.
2. Now write a paragraph on yourself as you are now, describing the same things.
3. Write another paragraph identifying what is the same about you and what has changed in that period of time.

Reflective exercise

1. Think about your own degree of autonomy in your life. Are you completely self-determining and in charge of the course your life takes?
2. What influences the decisions you make about your own path in life?
3. What are the thoughts and beliefs you have that prevent you from doing what you want to?
4. Write a summary of what you have discovered and a paragraph on any steps you will take to develop the sense you have of yourself as completely autonomous.

Autonomy implies that actions are the result of deliberate and informed decisions rather than reactivity and unconscious behaviour. It is in a midwife's best interests for her to develop the ability to function as an autonomous individual, clear about what she is deciding and why, both personally and professionally. Her perception of herself as autonomous will depend on her personal development as an autonomous person in her own life. If the midwife has not developed as an individual who is free to make decisions in her own best interests, knowledgeable about her own personal circumstances and possible consequences of her actions, she *may* be able to function autonomously as a midwife but it will be much more difficult for her to do so.

Self-responsibility

Responsibility refers to the ability or authority to act or decide on one's own, without supervision. It also refers to the person who is answerable for an action. Responsibility comes from the same root as the verb 'to respond'. To every action or event, a midwife has a response and her response will be both personal and professional. Her response(s) will then influence, inform and direct the actions she takes in relation to what she encounters. Self-responsibility refers to the ability to be responsible and account for one's own thoughts, feelings, actions and decisions. It requires the individual to develop the ability to state, 'Yes, I did that, I made that decision, I gave that information, I thought that, I felt that' and, if necessary, to explain further.

Self-responsibility is closely aligned with autonomy. It adds an extra dimension to the concept of self-determination by indicating that the people who decide carry the full weight of the decision on their own shoulders. It is nicely summarised in the phrase: 'The buck stops here!'.

For a midwife, self-responsibility begins with the way in which she engages with the profession, initially as a student and then as a practitioner, whether providing hands-on midwifery care, educating midwifery students and other midwives, managing midwifery services or advising the profession. The ability to carry responsibility for one's own

Reflective exercise

1. Get together with one other person. Describe to each other a time when taking responsibility for your actions contributed to something—a relationship, a problem, an event or function—turning out well.
2. Then describe the last time you each took responsibility for a mistake that you made—an error of judgement, or something that did not go according to plan.

actions and behaviour grows exponentially with the midwife as a practitioner. From the moment of registration, each midwife is responsible in law for her professional actions. She carries that responsibility as an adjunct to all her activities, including some of her personal decisions. It will benefit her greatly to develop and practise the ability to be accountable for her actions and decisions.

A midwife is also responsible for the way in which she organises and conducts herself in the profession and for carrying out her professional activities in a professional manner—that is, as determined by the profession through its regulations, standards and ethical codes. If a midwife is employed to provide women with midwifery care, it is likely that her employer will have expectations of her professional functioning. Within her employed role, whatever it may be, there is a professional expectation that an individual midwife will be responsible for her actions and decisions.

As part of her responsibility, a midwife will also need to be able to determine and negotiate responsibilities within each midwifery partnership she forms with the women for whom she provides care. There is no need for a midwife to assume responsibility over a woman and her actions and decisions. However, there is a need to be able to negotiate who is responsible for what and to tread the fine, and sometimes difficult, line of shared responsibility and shared decision-making.

Occasionally, in a midwifery partnership, a midwife is required by professional imperatives to assert her midwifery authority. This will be a rare event, given the collaborative nature of midwifery partnerships, occurring only when a midwife believes that life is in danger. A midwife must be sure of her position and clear with the woman about why this needs to occur and discuss with her in what situations she may need to assert her professional authority.

As each midwife grows professionally throughout her career, she will learn to carry her various responsibilities with ease and lightness. When she works in true partnership with women, each midwife will have a clear understanding of what is her responsibility and what responsibilities the woman retains.

Developing and negotiating relationships

Midwifery is itself a relationship—a negotiated partnership between a woman and the midwife caring for her. This means that a midwife has to develop a way of establishing, continuing and finishing the relationships she has with women and their families; midwifery colleagues and practice partners; other professional colleagues; employers; consumer and other community groups; and members of the public and so on. Women come to the midwifery partnership in varying stages of their ability to develop working relationships with a midwife. Therefore it falls to the midwife to develop a functional partnership with each woman for whom she provides care. The midwife takes a leadership role in establishing the partnership, sustaining it throughout the life of the partnership and negotiating its completion.

Over a practice lifetime, a midwife will have contact with thousands of women and their families. She will engage with women in a variety of settings and will be working in a variety of midwifery roles. She may be 'their' midwife—providing continuity of midwifery care throughout a woman's childbearing experience and possibly over several experiences for the same woman and her family. She may be working in a hospital and meeting women briefly as they progress through the institution during an aspect of their childbearing experience. Or she may have a longer involvement with women who are in hospital several times in a pregnancy or for a long period of time. She may have fleeting involvement with women as part of a secondary care 'team' providing care in an urgent or emergency situation. She may be an educator or a manager and have involvement with women at a distance as she works with students or the midwives who are providing care.

In all these situations, a midwife has to use her ability to develop a relationship easily and sometimes quickly, as this enables her to work with a woman and her family/whanau, being alongside her to achieve the most satisfying birthing experience that she can have, given her personal circumstances, whatever they may be.

Each midwife will have her own way of developing this relationship according to the ethical principles and frameworks expressed in chapters 12 and 14. Each midwife needs to consider her own ability to do this and develop whatever skills she requires to make the process of building the relationships with women and their significant others pleasurable, effective and able to rise to the challenges that will eventuate. For the vast majority of midwives, this is learned on the job, by having

Reflective exercise

1. Identify two abilities that you have that assist you to develop good working relationships with other people. Write a paragraph about how you came to develop these abilities.
2. Now identify two abilities that you need to develop further in order to have a good working partnership with the women for whom you will provide midwifery care.
3. On a sheet of paper, list these, and beside each one, describe the next step you will take to develop that ability.

successes, making mistakes, having another go and learning the most effective way to keep working together to benefit the woman and her experience of having a baby.

Organisational skills

Every midwife must develop the ability to organise her own workload. This applies whether she is managing a caseload of women for whom she provides continuity of care or whether she is employed to work 8–12 hour shifts in a maternity facility. It applies if she is self-employed, employed, in an educator role or a managerial one, or working in a professional advisory capacity.

A midwife organises and manages the things she must do to meet the obligations she has to women and their families, her employer, the profession and within the law. She must have good organisational skills, whether she is responsible for providing all the care for women through the continuum of childbearing or only part of the care as a shift worker in a maternity facility.

A major component of the ability to organise work is the ability to plan. A midwife has to plan how she will achieve whatever she has to achieve within the time available. Because of the nature of midwifery work—it is involved with a life process that does not always follow a straightforward path—a midwife also needs the ability to change the plan and to make alternative arrangements for the work that she planned. Fortunately for midwives, they work with women who are in the main going through a healthy life event without any extra requirement for care. This often means that whatever they had planned for providing care to women can quite safely be postponed while the midwife attends to the more urgent matter. This can range from attending a birth, to an emergency situation, an urgent need or, indeed, the midwife's own illness or family situation.

Time management is a critical factor in the ability to organise. Unfortunately, lateness can become habitual, as many midwives fail to take into account the human element of midwifery work when planning their time and do not factor in the extra time needed to deal with the concerns of individual women they are scheduled to see. Obviously, part of a midwife's work is unpredictable but much of what midwives do can be planned methodically, as long as enough time is allocated to each midwifery exchange. One way to demonstrate the importance with which a midwife views an individual woman and her experience is to behave in a way that recognises that her time is as valuable as the midwife's time and to give plenty of notice when existing arrangements have to be altered.

Because midwives are, in the main, women who work with other women, there is an acceptance of how women's lives work. Consequently, there is an acceptance by women receiving care from midwives of the nature of the midwives' work and a tolerance of the situations that arise. This does not lessen the need for midwives to explain how they work and the alternative arrangements they plan for women in their own absence. Midwives should not take the goodwill of their clients for granted or use it as an excuse for poor time management and disorganisation.

Reflective exercise

1. Write a description of your organisational style and how you think it will contribute to your work as a midwife. How will it assist you? How will it hinder you?
2. What do you need to change about the way you organise and plan your life and work in order to become a successfully functioning midwife?

For midwives providing continuity-of-care to women, one of the most important considerations in organising their practice is ensuring clear back-up arrangements. Midwives often make mutually beneficial arrangements for back-up and 'cover' with one or more midwives, depending on whether they practise as a sole practitioner, in a midwifery partnership with one other midwife or in a group practice. It is common within group practices for the midwives involved to work in pairs for back-up to ensure that women do not have to meet a stream of midwives who 'might' provide their care.

Midwives working shifts in a maternity facility often care for a number of women at any one time, providing antenatal and postnatal care. This also requires organisation and planning to deliver the necessary care in a defined time period without feeling stretched or stressed.

Many of the decisions involved in organising an individual midwife's life and work come down to a matter of personal choice. As long as women understand clearly how the service is provided and who provides it, and feel that they are getting the individual attention that they need, they are usually satisfied with the way in which midwives work.

Self-care

Midwifery is an important role in any society. Midwives form part of the grass-roots systems in the community that carry information and wisdom about how people function in groups and communities over time. They also hold important knowledge about the nature of life, death, the meaning of human experiences and in particular the role of giving birth and the nature of the parenting relationship. Midwives carry a great deal of responsibility to the women they care for, to the profession through regulation and professional expectations, and to society in general for the nature of the work they do with families in their community and the contribution they make to the wellbeing of the communities in which they live.

Consequently, midwives also carry responsibility for ensuring that they are able to continue to do their work, in whichever setting they choose to work, in a way that is sustainable for them. Individual midwives have to make their own assessment of what they personally require to sustain them in the role they have chosen. What she requires may not be totally clear to a midwife when she begins practising in the profession, and the first few years of practice will be a

time for coming to understand the nature of the work, the demands it makes on her and of her, as well as working out the things she needs to sustain and develop in order to withstand the demands of working with women and their families at a profoundly intense period in their lives.

There are several areas for the midwife to consider as she determines the best way in which she can look after herself so that she can continue to work in a fresh and thoughtful way.

Work–life balance

For a midwife to be able to bring her best professional functioning to her work, she needs to ensure that she has the appropriate balance between work and other aspects of her life.

Each midwife has to find out what that appropriate balance is, and this will depend on the phase of her life. Is she a single woman with no dependants starting out in the profession? Or is she a mother with children whose needs she has to consider when planning how she will contribute to the workforce? Does she have elderly parents she needs to care for? Have her children left home now, leaving her free to work more in a job she loves? Has she worked for many years and does she now want to have more time to pursue other interests?

The answers to any or all of the above questions will depend on each midwife as she considers her own life path and the personal and professional goals she has for herself at any given time. Whatever answers each midwife comes up with will determine the way in which she becomes involved with the profession and will influence the way in which she chooses to work: case-loading midwifery and how many women she will take on in a year; working with one or two other midwives or being part of a bigger practice; working core shifts in a maternity unit; or working in some other area of practice in a different way.

There is also the matter of holidays and leisure activities. Midwives who are employed to work in maternity units on 8- or 12-hour shifts perhaps have a more ordered life, and of course some midwives choose to work this way so that they *can* have a more ordered life with scheduled time off and regular holidays from work.

Midwives who attach themselves to women and provide continuity of midwifery care have a more unpredictable life. They are responsive to the women they care for, who are caught up in a reproductive life experience that has its own timetable that often does not fit with the way in which we try to order our world. Consequently it is both more important and more difficult for midwives working in this way to ensure that they schedule regular time off and take enough holidays each year to rest and recover from the demands made on them.

Sleep is also a factor for caseloading midwives, as they can become sleep-deprived when attending long labours or many women in the same time period. The work of a midwife does not finish when the baby is born—it begins in earnest as the midwife supports and guides the women in the first days of her baby's life so that she and her baby get off to a good start with each other. It becomes critical that the midwife paces herself to cope with these demands and calls for help from her back-up colleagues when necessary, so that she gets the essential rest she needs to be able to keep going with her work.

Having fun and enjoyment

All midwives have to consider how they can work in a way that allows them to derive maximum enjoyment and satisfaction from their experience as a midwife. Without enjoyment, the work of the midwife becomes unsustainable at a personal level. The work of a midwife is sufficiently important that the individuals who work in the profession have to feel a sense of purpose and satisfaction for them to be able to continue to provide women and their families with the support, guidance and care that they require.

Fortunately, being with women when they go through pregnancy, labour and birth and as they achieve motherhood is a very positive experience that is often reward in itself, and a midwife does get a sense of her work being important to the wellbeing of the world. As midwives progress in the profession, they get a sense that they are responsible, not for what happens to women, but for their own professional functioning and the contribution that they make. A midwife begins to understand that she is part of something greater than herself and can carry the work lightly even though she is dealing with serious matters that can sometimes be life-threatening. Developing her acceptance of what is happening and her ability to respond to what is happening will free a midwife to enjoy the unpredictable nature of the work and her involvement with the women and their families, whatever role and relationship she has with them and other midwives.

Fun can be derived in many ways in the work of a midwife. Many midwives have cheerful working relationships with their midwifery colleagues and make the most of opportunities to share midwifery experiences and stories with each other. The ability to do this both at work and socially lightens the load of responsibility that many midwives feel through their involvement with women as they go through the birthing process. Midwifery conferences are particularly renowned for midwives letting their hair down and having a good time with each other. It is important for individual midwives to have colleagues with whom they can share stories of the humorous, satisfying, problematic and sometimes tragic experiences they encounter. Each midwife needs to ensure that she is connected with a group of colleagues with whom she meets regularly, as a release valve for all the responsibility she holds in relation to her work.

Obviously, there is also fun outside of midwifery and it is critical for every midwife to have other activities in which she is pursuing something she enjoys. This can be as simple as regularly organised family activities, gardening, going to the movies, tramping or bushwalking, singing, sports such as cycling, running, canoeing, karate and so on, or any other hobby or leisure pursuit. By participating in activities she enjoys completely outside of midwifery, the midwife replenishes her resources so that she can continue to provide good-quality midwifery care to women. She can bring a more rounded and balanced life perspective to her work and this

will benefit those with whom she works, both women and midwives.

Setting boundaries

The concept of boundaries comes from the self-assertiveness movement of the 1970s and 1980s, as women developed themselves to take on a fuller role in society after the second wave of feminist thinking. Boundary setting is a particularly important aspect of freeing oneself from the dependency models of human functioning and creating a strong sense of self and self-determination.

For midwives working in maternity units, this may never become an issue, or they may find it useful to consider the matter of boundaries when dealing with particularly demanding women and their families. Caseloading midwives may find that boundary issues can and do arise with some women for whom they care.

It is the role of a midwife to know the purpose of the work she does with women and to support women to become autonomous in their own lives. Midwives are also autonomous as health professionals, and tensions can arise in the relationship between a midwife and a woman if what the woman wants from the midwife and what the midwife is prepared to offer do not match up. The midwife has to have ability to make an assessment of what the woman is requesting and to determine whether it is in the best interests of the woman for the midwife to meet the request. She then needs to have a discussion with the woman and resolve the matter to the point where the relationship continues or finishes in an amicable way. This can include the midwife ensuring that the woman receives care from another midwife or maternity service.

While midwives can be a source of information and support to women, it is not the role of the midwife to provide everything a woman requires or to fix her life up for her. A midwife has a role in assisting the woman to determine what she needs, and a role in helping her find the appropriate information and develop the necessary support networks to ensure that her needs are met. Midwifery is very specific in its role—the role of the midwife is to provide maternity services to women. There are other agencies in society and other community groups to meet some of the non-maternity needs of women for whom a midwife is caring. Having a good knowledge of those agencies and groups is one way for midwives to ensure that they are not taken advantage of and can fulfil their own role in an appropriate way. Midwives need not be all things to all the women they care for and in that way protect themselves from being overburdened by the role of the midwife.

Standing strong, being in control

Midwifery teaches all of us that we are not in control of the processes of life. We are also not in control of what other people choose to do—they make their own decisions and have their own successes and mistakes. Although we have more understanding of the processes involved than ever before, having a baby remains predictably unpredictable.

Reflective exercise

1. List seven ways in which you plan to take care of yourself in the first two years of your midwifery practice.
2. Beside each item, plan the steps you will take to achieve that goal.

Midwifery, however, does hold some things to be true and it is this that contributes and informs midwifery knowledge: working in partnership with women; informed choice and consent; assessing health and wellbeing; recording and documentation; planning care with women; practising safely; accountability to women and the profession; and reflection on practice.

A midwife grounded in midwifery knowledge, tempered by her own experience that she has reflected on and made sense of within the framework of midwifery's philosophy, ethics and professional standards, will develop her own authority. This will enable her to stand strongly in the face of the challenges that will come her way. These challenges will come from women she attends and their families, as well as members of other professional groups who do not understand the nature of midwifery, and other groups in society who have different agendas than the one midwifery espouses.

The one thing a midwife does have control over is her self: the way in which she gets involved and engages with women and their families; her midwifery colleagues; her employers; the profession; members of the community and the public; and members of allied health professions. All this is in her control and will reflect how well she has internalised the midwifery philosophy. Her own functioning as a midwife will give her much material on which to reflect when she engages in the informal and formal processes that contribute to her ongoing development as a midwifery practitioner.

Conclusion

This chapter has focused on the development of some of the abilities and attributes that will assist a midwife to derive the maximum personal and professional benefit from the work she does. It has identified a wide range of qualities for midwives to consider when thinking about their work and what they need to develop to sustain them. It has provided a general and broad look at life skills needed by midwives for their work to be satisfying and educational.

As all midwives are individuals who bring their own personal life qualities, learning styles and personal/professional goals to their work, this chapter cannot provide specific advice to individuals about their career path or development required to meet particular challenges. Ideas are presented here for the reader to consider as they reflect on their own development in the profession of midwifery.

CHAPTER 14

Theoretical frameworks for midwifery practice

Sally Pairman and Judith McAra-Couper

Key terms

active participation, assimilation, being equal, being with, continuity of caregiver, control, cultural awareness, cultural safety, cultural sensitivity, culturally safe practice, culturally unsafe practice, emancipation, empowerment, equality, independent profession, individual negotiation, informed choice, informed consent, midwifery partnership, practice wisdom, professional friendship, reciprocity, 'self' in practice, self-responsibility, shared power, shared responsibility, support, theoretical frameworks, Treaty of Waitangi, trust, with woman, women-centred

Chapter overview

This chapter discusses two theoretical frameworks—cultural safety and midwifery partnership—that can be used by midwives to guide their practice. Both frameworks were developed in New Zealand and arose out of that country's unique historical, social and cultural context. However, both can be applied to midwifery practice in Australia and other countries, as the principles articulated in each theory describe values, beliefs, understandings and behaviours that any midwife can embrace.

Both theories focus on relationships. Cultural safety enables a health practitioner to examine her or his beliefs, values and culture, and to understand how these might affect the person who is the recipient of care, with their different cultural understandings. Culturally safe care is provided when the recipient of that care determines that it is safe for them. Midwifery partnership provides a model for a midwife/woman relationship. Involving trust, shared control and responsibility and shared meaning, it is a reciprocal relationship negotiated and understood by the partners—a childbearing woman and a midwife. Like cultural safety, midwifery partnership aims to shift power from the midwife to the childbearing woman and seeks to redefine accepted definitions of the midwife as 'expert'. Ultimately, cultural safety and midwifery partnership are about self-determination, whereby the childbearing woman is recognised as 'expert', able to define her own needs, to control her own experiences, and to determine the appropriateness of the midwifery care she has received.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain the origin of the term 'cultural safety' and the development of this theory
2. To describe the principles of cultural safety
3. To describe the difference between caring for a woman as the midwifery 'expert' and working with a woman as an equal partner
4. To explain the principles of midwifery partnership
5. To discuss the implications of midwifery partnership and cultural safety for professionalism

Midwifery and relationships

Midwifery is about *relationships*—between women and midwives, between women's families and midwives, between midwives, and between other health professionals and midwives. These relationships are the medium through which midwifery is practised and they take place in varying contexts and over varying periods of time.

Midwifery involves working with women and their families through the significant and universal life event of childbirth. Childbirth is a physiological process in which healthy women are able to birth healthy babies with the minimum of interference or assistance. This physiological process is also mediated by cultural and social norms and practices that strongly influence how women feel about their ability to birth, where they feel safe to birth, who they want with them during birth and what cultural practices are important to them during birth and new motherhood.

Universally, midwives understand that their role is to support and enhance this physiological and cultural process by being alongside a woman and her family as a companion or guardian (Kaitiaki), using specific expertise and knowledge to ensure a safe transition to new motherhood that meets the individual needs of each woman and family (Donley 1986). This midwifery expertise is as much about knowing when not to interfere in the physiological process of pregnancy and birth as it is about recognising when and how to intervene in a way that will facilitate and enhance the woman's ability to give birth or to confidently mother her new baby.

While midwives in Australia, New Zealand and elsewhere lost this role during the twentieth century through the hospitalisation and medicalisation of childbirth, they are now reclaiming it. In New Zealand, and increasingly in Australia, midwives work in contexts that enable them to provide continuity of midwifery care throughout the entire childbirth process from pregnancy, through labour and birth, to the completion of the postnatal period at six weeks. Working with women over this nine- to ten-month period enables women and midwives to really get to know each other in a way that is much more intimate and personal than was the case when women arrived in the maternity unit to be cared for by midwives with whom they had no prior relationship. Internationally, midwives are now exploring and claiming a more personal relationship with each childbearing woman that is based on mutual respect, shared understanding and trust, and which breaks down power inequalities previously inherent in health professional/patient relationships in favour of one that is negotiated and equitable (Kirkham 2000a; Page 2000).

To work in equal and negotiated professional relationships requires self-knowledge, personal security, integrity and maturity. The midwife can no longer rely on her professional role as 'expert' to guide her practice. Instead she must open herself as a person to each woman she works with and be willing to recognise and embrace the woman as an equal partner, as together they explore the physical, emotional, social and spiritual ramifications of childbirth for that woman. The midwife brings her midwifery knowledge and understandings to the relationship, as the woman brings her knowledge and experiences. But rather than directing care, the midwife works 'with' the woman to support her to take up her power as a woman and as a mother so that she can direct and control her own birthing experience.

Theoretical frameworks for practice

Two theoretical frameworks have been developed in New Zealand that can provide some guidance for midwives engaging in these types of relationships with women. Midwifery partnership describes and explores how midwives can work in partnership with women. Cultural safety supports partnership relationships through focusing on invisible structures of power that exist between any two partners and in wider contexts within health service institutions and society. Cultural safety, like midwifery partnership, seeks to make these power differentials visible so that both partners can negotiate how they work together and ensure that the woman, as the recipient of care, receives care that meets her needs and leaves her individuality intact and strengthened.

Cultural safety and midwifery partnership both also have a political imperative. Cultural safety challenges any personal, professional, institutional and social issues and structure that 'diminishes, demeans or disempowers the cultural identity and wellbeing of an individual' (NCNZ 2002, p 7). Midwifery partnership challenges professional power structures and medical dominance over childbirth, through recognising childbearing women as active partners of equal status in the shared experience of maternity care (Guilliland & Pairman 1995).

What is a theoretical framework?

Rosamund Bryar (1995) contends that the essence of the art of midwifery is intuition and empathy that is informed by theory, knowledge and reflective thinking. Exercising the art of midwifery requires combining the personal qualities of the midwife with reflective thinking about how theory and knowledge can best be used in the care of individual women. 'Theory provides a structure within which midwives can compare the present experiences of the woman they are caring for with the responses identified in the theory' (Bryar 1995, p 5).

Theory arises from midwifery practice and from a range of other disciplines. The thinking of midwives about this theory in relation to their daily practice with women will lead to further development of practice theories. Theory is an integrated set of defined concepts and statements that present a view of a phenomenon and can be used to describe, explain, predict and/or control that phenomenon (Burns & Grove 1995).

The relationship between concepts can sometimes be presented diagrammatically to illustrate how the author visualises the links between the concepts. It can also be presented through language that explains the relationship between concepts. Models and theories are 'mental constructs or images developed to provide greater understanding of events in the physical, psychological or social worlds . . . and are intended to be tested, modified or abandoned in the light of new evidence' (Bryar 1995, p 40). Theoretical frameworks are tools for making sense of and explaining reality, and for thinking about practice. They provide ways in which midwifery care may be examined, understood, tested and developed.

The two theoretical frameworks presented in this chapter, midwifery partnership and cultural safety, arose from practice, and describe and explain living processes (relationships) that are always engaging, challenging and changing. 'Partnership' and 'cultural safety' exist only in encounters between individuals, groups or cultures, and have a moral and ethical imperative as well as a theoretical one. Both theoretical frameworks identify a number of concepts and values, and these are described below as tools for helping midwives to think about themselves and explore how they engage with others in their professional roles as midwives.

The origins of cultural safety and midwifery partnership

Cultural safety and midwifery partnership were both developed in New Zealand and both arose out of its unique historical, cultural and social context. New Zealand's constitutional and legislative structure is founded on the Treaty of Waitangi, signed in 1840 between Maori (New Zealand's Indigenous peoples) and the British Crown. The Treaty of Waitangi articulates a particular relationship between Maori and generations of settlers who have come to New Zealand since the early 1800s. This relationship is a bicultural partnership between Maori and the Crown that recognises the unique place and status of the Indigenous people and assures the place of both Maori and the colonists in New Zealand (Ramsden 1990, 2002).

Rapid British colonial expansion in the nineteenth century meant that immigrants from Britain and the four continents as well as the Pacific rapidly outnumbered Maori. There has been ongoing debate and dispute about the meaning of the Treaty and biculturalism in a society made up of a variety of ethnicities, languages and religions. These debates have been compounded by a long-standing struggle by Maori to have the Crown recognise and meet its partnership obligations under the Treaty. The 1980s and 1990s saw increased efforts by Maori and government to address Treaty claims and construct a bicultural relationship based on the principles of partnership, protection, participation and equity. One result of this work has been that the notion of 'partnership' is culturally embedded in New Zealand society.

New Zealand women drew on this cultural understanding of partnership when they actively sought changes to the way in which maternity services were delivered, and in particular demanded the choice of a midwife as their caregiver for childbirth (Dobbie 1990; Strid 1987). In the mid-1980s, maternity consumer organisations joined with midwifery's professional organisation (at that time the Midwives Section of the New Zealand Nurses Association, now the New Zealand College of Midwives) in an organised political campaign to reinstate midwifery autonomy and enable women to have a choice of caregiver for childbirth (Donley 1989; Guilliland 1989). The campaign took place in a context in which women's issues were high on the political agenda and the Cartwright Inquiry had raised awareness of patients' rights and issues of informed consent (Guilliland & Pairman 1995). Together, women and midwives succeeded in bringing about change, and the resulting 1990 Amendment to the *Nurses Act 1977* reinstated midwives as practitioners in their own right and gave women the choice of a doctor or a midwife or both as their lead caregiver for childbirth.

Another result of this political campaign was midwifery's recognition of its political partnership with women and its determination to enact this partnership by establishing representation for women (as maternity service consumers) at every level of midwifery's professional structure, the New Zealand College of Midwives. It was then only a short step for midwives to understand that their individual relationships with women were also partnerships, or could be. Exploration of the political and professional relationships between midwives and women has led the New Zealand College of Midwives (NZCOM) to identify partnership as a philosophical stance, a standard for practice and an ethical principle (NZCOM 2005).

New Zealand midwifery is redefining midwifery professionalism to mean midwifery partnership as it seeks to replace traditional hierarchical professional relationships with relationships that are negotiated and in which power differentials are acknowledged and actively shifted from the midwife to the childbearing woman so that she can control her own birthing experience (Guilliland & Pairman 1995). New Zealand midwifery has also embraced cultural safety as developed by Irihapeti Ramsden and required of all New Zealand nurses and midwives by the Nursing Council of New Zealand (since 2003 replaced for midwives by the Midwifery Council of New Zealand) in its competencies for entry to the registers of nurses and midwives (NCNZ 2002; Ramsden 2002). The NZCOM Standards for Midwifery Practice require midwives to be 'culturally safe' and the Midwifery Council of New Zealand's (MCNZ) Competencies for Entry to the Register of Midwives require that the midwife 'apply the principles of cultural safety to the midwifery partnership' (NZCOM 2005, p 13; MCNZ 2004a).

Cultural safety and midwifery partnership in other contexts

The theoretical frameworks of cultural safety and midwifery partnership both explore relationships and therefore, although both arose out of the New Zealand context, are applicable in other countries, cultures or contexts. Indeed, the Australian Midwifery Competency Project identified that a role of the midwife is to work in partnership with women and to ensure that midwifery practice is provided in a culturally safe environment (Homer 2004).

In any context, midwifery must be concerned with relationships because, unlike any other health profession, midwifery is privileged to have the opportunity to be 'with' women throughout the life experiences of pregnancy, birth and new motherhood. In their professional roles, midwives are able to develop relationships with women that last up to 10 months (sometimes longer) and they have the opportunity to work with women in their own homes and communities, away from the influence and control of institutions. In such settings the traditional practitioner/patient relationship, where the practitioner is the 'expert' and has the authority to make decisions, is clearly inappropriate. Midwives who work within continuity-of-care models work in contexts in which relationships are valued and where midwifery care such as support, caring and enabling is recognised as skilled midwifery practice. Midwives and childbearing women in these settings need to develop relationships of equity, trust and mutual understanding. So too do midwives and women working within the constraints of hospital services with fragmented care, insufficient staffing numbers, hierarchies and organisational control. Such settings can undermine midwifery knowledge and midwifery confidence and trust, making it difficult for midwives to support women in taking control of their own birthing experiences (Kirkham 2000a). Both midwives and women need to take hold of their power in order to begin to change the culture of these institutions. The political partnership of women and midwives experienced in New Zealand offers some guidance (Guilliland & Pairman 1995; Kirkham 2000b).

No matter what the context, midwives should examine their relationships with childbearing women because these relationships are at the heart of midwifery practice. When New Zealand women fought for midwifery autonomy they did so because they believed that midwives would provide an alternative model to medicine—a model of care in which women would be in control as the decision-makers (Strid 1987). These same arguments are being made by Australian women and midwives seeking to strengthen midwifery autonomy through legislative and practice changes (Maternity Coalition 2002).

Midwifery autonomy in New Zealand brought with it a social mandate for midwives to practise independently of other health professions so that they could provide the kind of care that women wanted. This social mandate carries with it a moral obligation for midwifery to provide the service that women have called for. There is also a moral obligation to recognise and respect individual differences in those we work with as midwives, no matter what other structures encourage us to do so. For New Zealand midwives, 'there would still be a moral imperative to engage in the difficult and complex quest to achieve meaningful partnership with Maori, even if there were no Treaty of Waitangi' (Hinchcliff 1997, p 300). The same is true in Australia, where Australian midwives have a moral obligation to engage meaningfully with Aboriginal peoples in order to create maternity services that will meet their needs.

Midwives in any country and from any cultural context will work with childbearing women who are different from them. Midwives need to examine their relationships with the women they care for if women are to become active agents in their own care (Kirkham 2000b). Cultural safety and midwifery partnership provide frameworks for achieving meaningful relationships between midwives and childbearing women.

Cultural safety

Cultural safety is defined as:

> The effective nursing[1] or midwifery practice of a person or family from another culture, and is determined by that person or family. Culture includes, but is not restricted to, age or generation; gender; sexual orientation; occupation and socio-economic status; ethnic origin or migrant experience; religious or spiritual belief; and disability.
>
> The nurse or midwife delivering the nursing or midwifery service will have undertaken a process of reflection on his or her own cultural identity and will recognise the impact that his or her personal culture has on his or her professional practice. Unsafe cultural practice comprises any action which diminishes, demeans or disempowers the cultural identity and well-being of an individual (NCNZ 2002, p 7).

Intrinsic to the concept and practice of cultural safety is the notion of 'right relationship'. Whether that relationship is between two persons, two groups, two cultures or two countries, right relationship recognises and honours the rights and responsibilities of each (McAra-Couper 2005). Cultural safety seeks to establish the practice of right relationship at a personal, professional and institutional level.

What is meant by 'culture'?

> . . . we learn from the experiences of the past to correct the understanding of the present and create a future which can be justly shared (Ramsden 2002, p 182).

The understandings of culture expressed in nursing and midwifery in New Zealand today have evolved over a long period. It is important to be familiar with this evolution of understandings in order to appreciate the significance and place of cultural safety.

Historically, in New Zealand and elsewhere, culture was invisible in nursing and midwifery curricula. In part this

reflected a context in which assimilation was prevalent. Despite the existence of the Treaty of Waitangi, assimilation policy influenced the social thinking of the nineteenth and early twentieth centuries, and led to the establishment of structures and processes that denied differences between Maori and Pakeha in an attempt to make Maori like Pakeha and absorb them into Pakeha-dominated culture and society (Walker 1987).

In this context, nurses and midwives were encouraged to give care to patients 'irrespective of differences such as nationality, culture, creed, colour, age, sex, political or religious belief or social status' (Ramsden 1990, p 79). This understanding of culture informed the practice of nurses in New Zealand until the early 1970s. It was well intentioned but served only to reinforce assimilation (Spence 2001). The long-term consequences of assimilation are suppression and destruction of the culture of Indigenous people, which results in mental, physical and spiritual stress (NCNZ 1992). This stress is seen only too readily in the present-day health statistics of Indigenous peoples in New Zealand and Australia and throughout the world.

In the 1970s a new understanding of culture developed. In New Zealand, as elsewhere, anthropological understandings of culture emerged which led to greater cultural awareness and cultural sensitivity. Transcultural nursing theory, developed by nurse theorist Madeline Leininger in the early 1970s, influenced nursing education. Transcultural nursing was based on nurses having knowledge about a range of different cultures from which they could respond therapeutically to their client's needs (Papps 2005). Nurses and midwives were taught to gather information about the beliefs, patterns and behaviours of other cultures, so that they would be able to identify 'specific cultural patterns that occurred' and provide culturally sensitive care (Richardson 2000, p 32; Spence 1999). Nurses and midwives were taught about the concepts of cultural awareness (becoming aware of difference) and cultural sensitivity (sensitivity to the legitimacy of difference and the impact the midwife's own culture may have on others) (NCNZ 2002). Nursing and midwifery knowledge considered culture and race from the perspective of the nurse or midwife, as an observer, exploring and understanding what makes the other person different from themselves (Ramsden 2000; Richardson 2000). Such approaches allowed the nurse or midwife to be patronising and powerful as they identified the needs of people from other ethnic groups, and did not require any self-knowledge or change in attitude (Ramsden 2000). In New Zealand, the dominance of transcultural nursing in nursing education and practice was challenged by the alternative theory of cultural safety.

Developed in the 1980s by Maori nurse educator, Irihapeti Ramsden, cultural safety or Kawa Whakaruruhau, provided another theoretical framework for understanding culture. This socio-political definition of culture had the Treaty of Waitangi as its starting point, and involved recognition that power needed to be shared and racism de-institutionalised (Spence 1999). Cultural safety focused on the socio-political factors that affected health care (Richardson 2000).

By contrast, notions of cultural sensitivity and cultural awareness avoided the more difficult recognition of power relationships that existed in the delivery of health care and led to cultural stereotypes and simplistic notions such as cultural checklists (Ramsden 2000). Cultural safety focused not on the 'other' but on the nurse and midwife. The process of cultural safety began with self-reflection and attitude change (see Fig 14.1). This process required the nurse or midwife to recognise themselves as 'powerful bearers of their own life experience and realities and the impact this may have on others' (Ramsden 2000, p 117).

The notion of power is inherent in the concept of and processes associated with cultural safety. The nurse or midwife is challenged to recognise her or his personal power and the power of the institutions and society in which they work and live (Richardson 2000). Cultural safety is primarily about establishing trust, gaining a shared meaning of vulnerability and power, and carefully working through the legitimacy of difference (Ramsden 2000). Cultural safety makes visible the invisible structures of power (including our own) and attempts to transform anything that creates inequality and inequities in the health services. In the New Zealand context this also includes actions that do not uphold the Treaty of Waitangi in the delivery of health services.

Figure 14.1 describes the progression of students towards understanding cultural safety and the difference in meaning of the commonly used terms 'cultural safety', 'cultural sensivity' and 'cultural awareness'.

Thus cultural safety and transcultural nursing present different theoretical understandings of culture. Transcultural nursing exists in a multicultural context and focuses primarily on defining culture as race and ethnicity (Ramsden 2002). Transcultural nursing places the nurse or midwife in the position of 'external observer' for the purpose of providing culture-specific care. On the other hand, cultural safety addresses the issue of power between the client (woman) and the nurse (midwife) and interprets 'culture' in the broadest possible sense (Ramsden 2002).

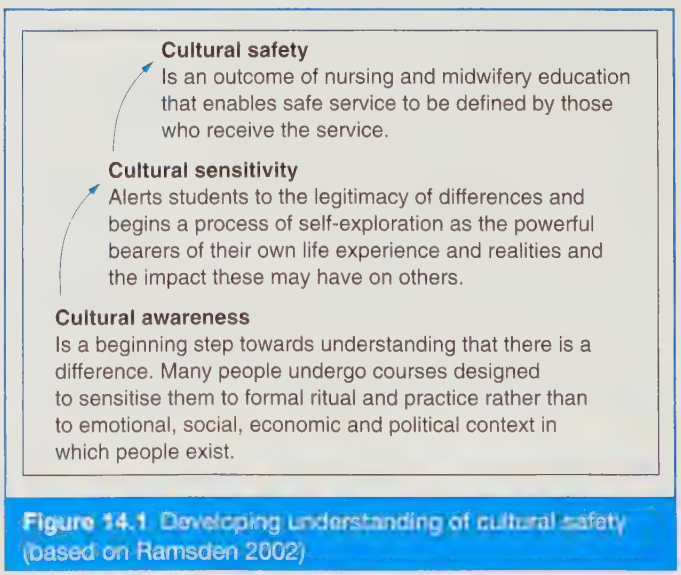

Figure 14.1 Developing understanding of cultural safety (based on Ramsden 2002)

> Leininger's culturally congruent care model is different from Cultural Safety in that nurses and midwives need to move from treating people *regardless* of colour or creed towards a model of treatment that was *regardful* of all those things that make them unique (Ramsden 1993, p 5 (our emphasis)).

This movement from 'regardless to regardful' is one of the most important contributions cultural safety makes in ensuring the safety of the care that midwives give.

The development of cultural safety

Irihapeti Ramsden's theory of cultural safety arose from her experiences in the late 1980s in teaching student nurses, and her attempts to include Maori health issues and the Treaty of Waitangi in her teaching (Ramsden 2005). Her frustrations in trying to teach about difference and racism in a context of assimilation, where culture was seen only as ethnicity, led her to develop strategies for teaching about Maori health issues in nursing. These strategies were articulated in her framework, 'A Model for Negotiated and Equal Partnership', which was adopted by all schools of nursing soon after (Ramsden 1989).

In 1988, Irihapeti Ramsden was commissioned to run a national hui (meeting), the Hui Waimanawa, which involved over 100 participants including Maori nursing students. According to Irihapeti, it was a first-year nursing student at that hui who first coined the term 'cultural safety' and permitted Irihapeti to use the term in her subsequent work. The student stood at the hui and spoke about the expectation of legal safety, ethical safety, safe clinical practice and safe knowledge bases for nurses and asked, 'What about cultural safety?' (Ramsden 2005, p 17). Irihapeti Ramsden published her document, Kawa Whakaruruhau: Cultural Safety in Nursing Education in Aotearoa' in 1990. The Nursing Council of New Zealand accepted it, along with 'A Model for Equal and Negotiated Partnership', thus legitimising the term 'cultural safety' in nursing and midwifery language (Ramsden 2005).

At several hui held in the late 1980s and early 1990s, a variety of definitions for cultural safety were debated. The hui of the Whanau Kawa Whakaruruhau defined culturally safe practice as 'actions which recognise, respect and nurture the unique cultural identity of tangata whenua and safely meet their needs, expectations and rights' (Hill, cited in Whanau Kawa Whakaruruhau 1991, p 7). This hui also defined 'culturally unsafe practice' as 'any actions which diminish, demean, or disempower the cultural identity and well being of the individual' (ibid).

Cultural safety required appropriate health services to be provided for all New Zealanders. However, the need to address Maori health as a result of the enduring effects of colonisation had become urgent (Spence 2004). Therefore, much of the early work around cultural safety was concerned first and foremost with trying to identify ways in which health services could address the poor health status of Maori (Ramsden 2002). While colonisation was primarily the reason for the poor health status of Maori, it was also the reason for the development of cultural safety, and the initial processes of teaching cultural safety needed to deal with colonial history. Therefore cultural safety teaching included analysis of the historical, political, social and economic realities that were affecting Maori Health (Ramsden 2002). Nursing and midwifery students needed a 'profound understanding of the history and social function of racism and the process of colonization' to become culturally safe practitioners (Ramsden 2002, p 180).

In 1991, the Nursing Council commissioned Irihapeti Ramsden to write guidelines that would assist schools of nursing (and midwifery) to incorporate cultural safety (Kawa Whakaruruhau) into the education curricula (Papps 2002). In the council's view it was important that such guidelines would provide a process through which students would understand difference and dominance and so 'demonstrate flexibility in their relationships with people who are different from themselves' (NCNZ 2002, p 12).

These guidelines became council policy in 1992 and required student nurses and midwives to be educated:

- to examine their own realities and the attitudes they bring to each new person they encounter in their practice;
- to be open-minded and flexible in their attitudes toward people who are different to them and to whom they offer or deliver service;
- not to blame the victims of historical and social processes for their current plight (NCNZ 1992, p 1).

In these guidelines the Nursing Council's definition of cultural safety more clearly articulated a shift in power to the client (Papps 2005). Cultural safety was now defined as:

> The effective nursing of a person/family from another culture by a nurse who has undertaken a process of reflection on [her] own cultural identity and recognises the impact of the nurse's culture on [her] own nursing practice. Unsafe cultural practice is any action which diminishes, demeans or disempowers the cultural identity and well-being of an individual (NCNZ 1992, p 1, glossary).

The incorporation of cultural safety into nursing and midwifery curricula from 1992 meant that education required:

- the nurse and midwife to acquire insight and analysis of themselves as cultural safety shifted the focus from other to self (Ramsden 2000)
- attitudinal change through reflection on self (Ramsden 2000)
- that clients be cared for regardful, not regardless, of all that makes them unique (Ramsden 2002)
- that the nurse and midwife understand that the care they provide is defined as safe by those who use their service (Ramsden 2002)
- that at the end of the educational process the 'most vulnerable in our society' can say that the nurse/midwife was safe (Ramsden 2000, p 5).

Unfortunately, few nurse educators had the educational preparation to teach cultural safety or to understand that culture was an important influence on people's health, and students were not provided with clear definitions of culture. Where culture was equated with ethnicity, students were often taught Maori language, songs and dance instead of learning

about their own cultural identity and its impact on their nursing or midwifery practice (Papps 2005).

The confusion continued in media reports that condemned the teaching of cultural safety in nursing, claiming that attention to this aspect of the curriculum was to the detriment of other more important areas such as 'medical' knowledge. Papps suggests that opposition to and confusion about cultural safety arose because it aims to do two separate but interrelated things. First it aims to address nurses' and midwives' conscious or unconscious attitudes towards any cultural differences, and second, it aims to raise awareness about imbalances in the health status of Maori (Papps 2002). Because it teaches about the effects of colonisation on the health of Maori, cultural safety has been misunderstood as being about only one culture (Papps 2002). What was not understood was that cultural safety is about addressing power relationships between nurses or midwives and the recipients of their care. Where historically nurses were taught to provide care *irrespective* of colour or creed and to treat everyone the same, cultural safety requires nurses and midwives to be '*respective* of the nationality of human beings, the culture of human beings, the age, the sex, the political and the religious beliefs of other members of the human race' (Ramsden 2005, p 7). Rather than the nurse or midwife deciding what is culturally safe, it is the patients or clients who determine whether they feel safe with the care they have received (Ramsden 1995, cited in Papps 2002).

Intense political and media scrutiny of cultural safety eventually led to an investigation by a Parliamentary Select Committee in 1995. Cultural safety was 'depicted as politically inspired while the curriculum of clinical nursing practice was apolitical and neutral' (Papps 2005, p 26). Several recommendations from this enquiry were actioned by the Nursing Council but it remained firm that the name 'cultural safety' would not change and that the Treaty of Waitangi would remain as the basis for nursing and midwifery education (Papps 2005).

In 1996, the Nursing Council published new guidelines in which the definition of cultural safety was broadened and focused less on Maori issues such as structural, political or social causes of the poor health status of Maori (Ramsden 2002). It emphasised relationships between nurses and midwives and clients who differ from them by age, gender, sexual orientation, socio-economic status, ethnicity, religious or spiritual belief and disability (NCNZ 1996). Council recognised that while cultural safety originated from the experience of Maori, its principles needed to be broad-based and apply to all people. 'Culture, in the cultural safety sense, includes all people who differ from the cultures of nursing and midwifery' (NCNZ 1996, p 8).

By 1996, the Nursing Council definition of cultural safety had evolved to include the consumer in determining 'effective nursing or midwifery care' (NCNZ 1996, p 9). The council said:

> Cultural safety is the experience of the recipient of care. Cultural safety is well beyond cultural awareness and cultural sensitivity. It gives people the power to comment on care leading to reinforcement of positive experiences. It also enables them to be involved in changes in any service experienced as negative (NCNZ 1996, p 10).

MIDWIFE'S STORY 1

It was obvious from the moment we walked in that there was a lot of tension in the room, and the night staff looked relieved to be going home. The young woman, who was a Pakeha and aged about 17, was looking straight ahead and not really acknowledging us at all. The boyfriend was sitting in the corner with his Walkman plugged in and his eyes closed, and the mother of the young woman looked as if she was about to pounce on us. You could feel the hostility and anger. The first thing the mother said was, 'I suppose you are going to tell us she is not in labour either'. The midwife pulled up a stool and sat next to the woman and reassured the mother that she was not about to say such a thing after being in the room only a short time. The midwife then did nothing except sit there with her hand on the woman's abdomen feeling for the contractions—she did this for 30 minutes. The young woman gradually looked at her and then talked to her and the mother sat down and touched her daughter and a conversation took place. I could not believe the difference in the room and in the bodies of the mother and the pregnant young woman. The boyfriend even had a peek to see if it was safe to come out. The midwife listened to the baby's heart and then sat there for another 30 minutes just feeling the contractions and talking to the woman and her mother. Eventually, after an hour, when it was clear that the contractions were not establishing the young woman into labour, the midwife talked to the family about what was happening in terms of the contractions, early labour, first babies and so on. They eventually went home and she did come back four hours later in established labour and had her baby five hours after that. I asked the midwife why she had handled it this way. She replied that when she walked into the room it was clear that everyone was upset, angry and anxious, and until she had established trust and had gained a rapport with them it was a waste of time doing anything. It was important for them to feel safe, supported and listened to before any other options were offered.

Questions

1. Describe the 'culturally unsafe' issue presented in this story.
2. Describe what the midwife did to ensure that the woman and her family were safe.
3. Identify the principle/s of cultural safety that the midwife adhered to, which ensured that her practice was culturally safe.
4. Describe ways in which midwives can ensure that their practice is culturally safe (e.g. 'listening' to what is unspoken).
5. Describe how you would have handled this situation, in order to ensure the cultural safety of the woman and her family.

Ramsden (2000) argued that this all-inclusive definition of cultural safety meant that there was a need for a new curriculum design. She believed it was time for a stand-alone course in Maori health, so that the integration of cultural safety in its broadest sense could occur without threat to the issues of Maori health and the Treaty of Waitangi (Ramsden 2000).

Guidelines released by the Nursing Council in 2002 made this distinction. Cultural safety teaching was separated from teaching of the Treaty of Waitangi and Maori health in order to avoid confusion about the nature of cultural safety (NCNZ 2002). Nursing and midwifery education is now expected to prepare nurses and midwives to face and deal with personal, professional, institutional and social issues that affect the provision of safe midwifery care to women and their families.

It was Irihapeti's view that the future evolution and direction of cultural safety will not focus on the customs, habits and cultural practices of any group, but rather will continue to be about an analysis of power and relationships of power (Ramsden 2002). Cultural safety is simply an instrument that allows the woman and her family to judge whether the health service and delivery of health care is safe for them (Ramsden 2002). Therefore, the next step in this journey of cultural safety will need to be centred on the facilitation of a process whereby women and their families can tell midwives about the safety of the care they receive (Ramsden 2002).

Principles of cultural safety

The Nursing Council of New Zealand believes that cultural safety is facilitated by communication, understanding the diversity in worldviews, and the impact of colonisation (NCNZ 2002).

It identifies four principles of cultural safety:

- Cultural safety seeks to improve the health status of all New Zealanders.
- Cultural safety seeks to enhance the delivery of health and
- disability services through a culturally safe workforce.
- Cultural safety is broad-based and broad in its application.
- Cultural safety focuses closely on 'understanding of self, the rights of others and the legitimacy of difference' (Ramsden 2002, p 200; NCNZ 2002).

Nursing and midwifery education is based on these principles and the Nursing Council expects that it will lead to a nursing and midwifery workforce that will practise in a culturally safe way as defined by recipients of the care. The learning outcomes they identify are that nursing and midwifery students will have:

- examined their own realties and attitudes that they bring to practice
- assessed how historical, political and social processes have affected people's health
- demonstrated and continue to 'demonstrate flexibility in their relationship with people who are different from themselves' (NCNZ 2002, p 12).

In her doctoral thesis, titled 'Cultural safety and nursing education in Aotearoa and Te Waipounamu', Irihapeti Ramsden (2002) makes a number of statements that may also be interpreted as principles of cultural safety:

- Care is provided within a framework of recognising and respecting the difference of every person.
- Professional trust is established between the midwife and the woman and her family or whanau.
- The differences between the woman and her family or whanau are 'identified and negotiated' (Ramsden 2002, p 118).
- The woman and her family or whanau decide the definition of safe care.

MIDWIFE'S STORY 2

I was a student midwife working on the delivery unit with a hospital midwife when at handover we were sent to Room 9. There was a woman aged 42 having her fifth baby. Her pregnancy had been uneventful and everything was progressing normally in labour and it was thought that she was close to birthing. The midwife we took over from was very anxious, as she said it was impossible to get near the woman to 'do' anything to her. I looked over and saw that the woman was surrounded by her four grown-up daughters in a semi-circle around the bed, and it was true that there was not a spare inch for any midwife to get into the birthing space. The midwife introduced herself and me to the woman and her daughters, who acknowledged us—just. The midwife then stood back and watched, and said to me, 'This baby will be born soon'. I whispered to her, 'How are you going to be part of this baby's birth?' and she said, 'I don't think I am and I don't need to be'. It soon became clear that the baby was about to be born—the daughters formed a tight circle around their mother as she birthed their new brother into the world. The midwife had a towel ready and as one of the daughters lifted the baby up and welcomed the baby with song and prayer, the midwife dried the baby and we were allowed in to 'do'. This experience has stayed with me and reminded me time and time again about to whom birth belongs and just what the role of the midwife is in the birthing process.

Questions

1. Describe the culturally safe and culturally unsafe issue in this story.
2. The night midwife felt anxious because she could 'not do anything' to the woman, while the other midwife was more relaxed because she knew the mother and baby were safe. Describe the skills that would have been needed to keep the situation culturally safe if something had had to be 'done' for the baby or the woman.
3. Identify the principle/s of cultural safety that the midwife adhered to, which ensured that her practice was culturally safe.
4. Describe the questions you would ask a woman to find out what was important to her and what would ensure a culturally safe experience for and her family.

- The power relationships between the providers and recipients of care are addressed, including the transfer of power from those who provide the service to those who receive the service (Kearns 1997).

Implications for midwifery practice

Learning about cultural safety and thinking about its implications for practice can be challenging. Students who are part of the dominant culture (such as being a white New Zealander with a European background) can be challenged by issues such as history, the Treaty of Waitangi, biculturalism and cultural safety, and may perceive these as irrelevant or unimportant. McIntosh (1988) claims that members of the dominant culture are socialised in such a way that they do not recognise their privilege in society and instead 'think of their lives as morally neutral, normative and average' (p 16). In other words, when people are part of a dominant culture, they believe that the ways in which they experience the world are natural and normal, and are the same for everyone. Understanding that this is not the case can be disturbing, challenging and alienating for students if the process of coming to awareness is not facilitated with sensitivity and care. It is important that a framework that is working towards the transformation of everything that diminishes, demeans and disempowers, does not do precisely this in working towards awareness.

Spence (2004) suggests that the process of engaging with people who differ from the nurse and midwife is unlikely to ever be free of tension. She argues that nurses (and midwives) need to learn to live with the uncertainty and paradox that difference constantly presents to them. The process of becoming culturally safe and learning to live with uncertainty and paradox takes courage, patience and kindness: courage to enter into the process, patience to stay with the process, and kindness towards self and others in the struggle with what the process requires. As Ramsden reminds us, the process of cultural safety calls for 'excellence in the service to other human beings' (Ramsden 2000, p 12).

We finish this section by acknowledging that cultural safety was 'designed as an educational process by Maori and it is given as koha [gift] to all people who are different from the service providers, whether by gender, sexual orientation, economic or educational status, age or ethnicity' (Ramsden 2002, p 181).

Critical thinking exercise

Cultural safety is not about extraordinary events but about the everyday situations midwives find themselves in. It is the handling of these ordinary situations that requires a midwife to be culturally safe.

Midwifery partnership

As described earlier, New Zealand midwifery has developed a model for practice within its unique historical, social and cultural context. The notion of midwifery as a partnership between the woman and the midwife arose from midwifery's reflection on its successful political partnership with maternity consumer groups, which had brought about the Nurses Amendment Act in 1990 and reinstated midwifery autonomy. The New Zealand College of Midwives gave primacy to this partnership relationship by ensuring that women (consumers) had a rightful place at every level in the structure of the College and in the development of all policy and decisions. Midwifery recognised that its only power base came from the women it worked with and that together they could bring about further changes to the maternity services that would benefit both (Guilliland 1989). Thus the philosophy, standards for practice and ethical statements of the College all recognised the importance of partnership to midwifery practice (NZCOM 2005).

However, it was not until 1994 that this partnership relationship was examined in depth and an attempt was made to explain what partnership meant for midwives and how it could be practised (Guilliland & Pairman 1994).

Evolving understandings of midwifery partnership

By 1994, four years after midwifery autonomy had been reinstated, many midwives were discussing and reflecting on their new understandings of childbirth and of their role as midwives, which were arising as a result of the longer-term relationships they could now have with women throughout pregnancy, labour, birth and through the postnatal period to six weeks, and in which they were now the sole or main caregiver.

In 1994, Karen Guilliland and one of us (SP) wrote *The Midwifery Partnership: a model for practice* in an attempt to explore the relationships that were developing between midwives and their clients in the new context of midwifery autonomy and continuity of care (Guilliland & Pairman 1995). In this exploration, the authors attempted to identify the common characteristics and components of these relationships, and developed a set of principles and a model to guide midwives in their practice of partnership.

The model of midwifery partnership was published in 1995 and appeared to strike a chord with many midwives in New Zealand and overseas, because it has added to the profession's understanding of the relationships between midwives and women. It has become a required text in all schools of midwifery and has been used as a framework for midwifery curricula and models of midwifery practice in both New Zealand and overseas, including Australia.

As more midwives have been able to work in continuity of care models with women, their understanding of midwifery partnership has deepened, and midwives have become more aware of the personal attributes they need to develop in order to work in partnership relationships. In 1998, one of us (SP) completed Master's research that sought to further examine the relationship between midwives and childbearing women (Pairman 1998). In this study, six independent (caseloading

MIDWIFE'S STORY 3

I was with my independent midwife at home, discharging one of the women I had followed through as part of my student midwifery case-load. Sue was 42 and had just had her sixth baby, and in the presence of all the family I was doing the discharge examination. I asked Sue what type of contraception she would use, noting that she had used contraception for the last three years. She looked away from me and even looked embarrassed. I realised that this was an embarrassing topic for her, so to make it easier I said, 'Will you take the same contraception as last time?'. The midwife who had been talking to one of the relatives looked over at me and changed the subject and went onto another part of the discharge form. We never went back to the question of contraception and when I questioned the midwife about it later, she said, 'Sue took the contraception in secret so no one knew about it because of her family's values and beliefs'. Sue had told the midwife that in taking the contraception she felt she was betraying her family, culture and religion but that she did not want to have another child and so had done it in secret. Sue had said that children were seen as a blessing from God and so the more children, the more blessed. It appeared that contraception was not something that was discussed in the way I had assumed and in fact was a taboo subject. I felt so bad about this mistake on my part—it never fails to amaze me the assumptions I have when it comes to caring for and working with women.

Questions

1. Describe the culturally unsafe issue in this story.
2. Identify and explore the principle/s of culture safety that would have ensured culturally safe practice in this instance.
3. Describe how this situation could have been handled to ensure that it was a culturally safe experience for this woman.
4. Describe your own culture and identify five things that are really important to you.
5. Describe how the assumptions, beliefs and values that you hold may affect your practice as a midwife.
6. Identify three ways in which you can ensure that your practice as a midwife will be culturally safe.
7. Explore how you might feel and what you might do if a woman or her family told you that they felt unsafe with you.

and self-employed) midwives and six of their clients were individually interviewed and also participated in two focus group meetings. The participants were actively involved in analysis of the data and identification of the emerging themes. At the final stage, participants compared the findings of the study with the model of midwifery partnership as developed by Karen and one of us (SP). Refinements were suggested and the participants 'teased out' midwifery partnership to also mean 'professional friendship' (Pairman 1998, 1999, 2000).

Subsequently, no further formal developments to the theoretical framework of midwifery partnership have been documented. However, as the context for midwifery practice has evolved it has become necessary to revisit the model and explore its application for midwives who do not work in continuity of care and independent practice models. This work is under way and is expected to be published in 2006 (Pairman 2005).

Overview of midwifery partnership: a model for practice

Midwifery partnership is defined as:

> A relationship of 'sharing' between the woman and the midwife, involving trust, shared control and responsibility and shared meaning through mutual understanding (Guilliland & Pairman 1995, p 7).

This relationship constitutes midwifery because it is the medium through which a midwife works with a woman through the shared experience of pregnancy, labour and birth and the postnatal period to six weeks that makes up the Midwifery Scope of Practice (MCNZ 2004b).

Although a single diagrammatic representation is presented here, it is important to recognise that each relationship a midwife has with each woman she works with will be different. The key to midwifery partnership is that both partners are recognised as individuals who make equally important contributions to the relationship. Both partners negotiate the relationship and how it unfolds over time to take account of and respect their differences, needs and wishes. This negotiation is overt and requires active participation by both partners, as well as clear communication. Each woman's childbirth experience is unique and the respective roles of each midwife and each woman will vary to reflect these individual experiences and needs. The negotiated outcomes of each partnership will be different for each midwife/woman pair and therefore few partnership relationships will look the same. Because it is a professional relationship, the midwife is responsible for initiating the partnership and working with the woman to achieve this. The principles outlined below provide guidance for a midwife to achieve this.

The partners

The two partners in a midwifery partnership are a midwife and a woman. They enter into a relationship for the purposes of receiving and giving midwifery care and together they share the woman's life experiences of pregnancy, labour and birth and the postnatal period. As mentioned previously, this nine- to ten-month time frame sets the boundaries of midwifery care and enables a midwife and a woman to get to know each other in a way that makes their relationship distinctly different from usual health professional/client relationships.

Each partner will bring a unique contribution to the relationship. The woman brings her beliefs, values, knowledge, expectations, experiences and fears. She is the expert on herself and knows what she wants for this birth experience. In the model, the woman's partner, children and family/whanau surround her. The woman defines who these people are and

the role they play in her life and through this birth experience. She will be influenced by the beliefs, values and culture of this group. The midwife, too, comes from her own social context and personal culture. However, because she is in this relationship in a professional role, the midwife is depicted in the model surrounded by midwifery's professional framework of standards and ethics that guide her practice. Both partners will also be shaped by the wider cultural and social context of the society in which they live. This will include the impact of socio-economic structures and environment, including health and maternity services. Both partners will also be influenced by dominant societal ideologies and historical determinants such as gender and class.

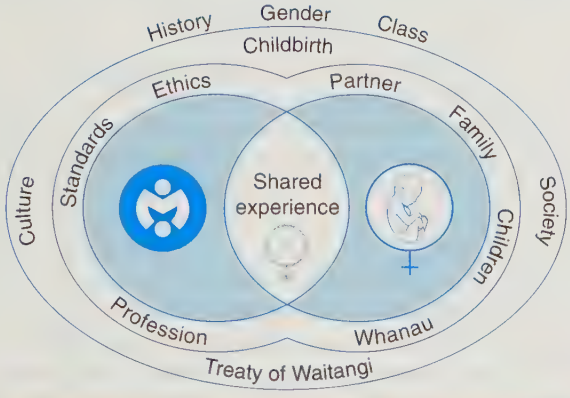

Figure 14.2 The midwifery partnership: the partners (based on Guilliland & Pairman 1995)

As the examination of cultural safety has shown us, the midwife needs to have worked through and reflected on her cultural identity, what it is that she brings with her to any midwifery relationship and how these beliefs and values could affect the woman with whom she is working. The midwife needs to recognise each woman as an individual, and respect and acknowledge her differences, working with the woman to ensure that she provides care in a way that the woman determines will meet her needs.

The model shown in Figure 14.2 depicts midwifery partnership as two equal and intertwined circles. The equal size of the circles represents the equality of both partners. The intertwined segment depicts the shared experience of pregnancy and childbirth, which provides the immediate context for each midwife–woman relationship, and the woman symbol in this section indicates the woman-centered nature of the partnership.

In Pairman's (1998) study, additional concepts were added to both the woman circle and the midwife circle to make more explicit the contributions that both make to the relationship and also to make more overt the qualities that women seek from midwives and that midwives can bring to their relationships with women (see Fig 14.3). These concepts arose from the data and were verified by the participants.

To the 'woman' circle were added the concepts of 'seeking professional care', 'seeking active participation, self-responsibility and control', 'seeking trust, respect, equality and openness' and 'being female'.

As Bizz, one woman in the study, said:

> I wanted someone that I could initially build a trust in and get to know leading right up to the birth. Just that more personal and

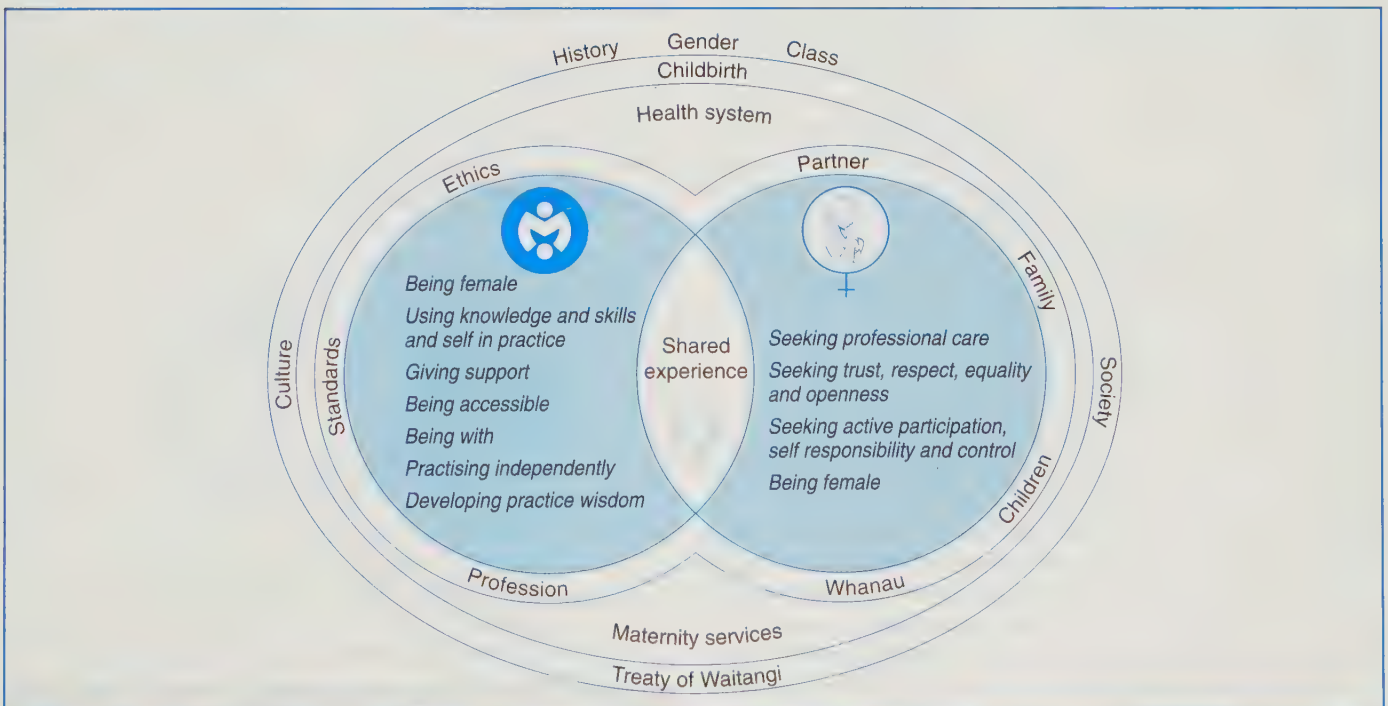

Figure 14.3 The midwifery partnership: the partners (refined) (based on Pairman 1998)

> trusting relationship. And hearing the same things from the same person . . . it was important that it was someone I could talk to quite confidently, someone approachable . . . it was important too that she was a woman . . . to have an equal relationship (BF, in Pairman 1998, p 75).

Bizz's expectations were not unusual, according to Chris, one of the midwives, although she does raise the question of whether these aspects will be so clearly articulated by women once continuity of midwifery care is easily accessible to all.

> Some people are very keen right from the beginning to be responsible for their own care and make their own decisions and they want information and can pretty much handle it themselves, making their decisions. You tend not to have women coming to you who want to be told what to do. I think the women that choose to come to midwifery care, and it's probably changing, but a lot of them come because they are already prepared to stand up and be counted and make their own choices because it's still going against the consensus, I think of society as a whole. Their mothers, aunts, husbands, society, which says, 'You must have a doctor, you know you've got to be safe', and the feeling is that a midwife isn't . . . I guess for a lot of women they are already in a place where they are wanting to and do make their own choices (CS, in Pairman 1998, p 82).

Exploration of the way in which midwives worked with women identified that midwives contributed more than just their midwifery knowledge and experiences to the relationship (Pairman 1998). Midwives also exhibited other attributes. Broadly, these were described as being 'with woman' and involved: the way a midwife used knowledge, skill and 'self' in practice; her accessibility to women; the way in which she provided emotional support to women and her specific skill in supporting women in labour; and the way she brought herself as a woman to each relationship. Thus within the midwife circle, the concepts of 'being female', 'giving support', 'being accessible', 'using knowledge, skill and "self" in practice' and 'being with' were added. In addition to her ability to be 'with woman', the midwife also brought her ability to reflect on her practice and to develop and trust her practice wisdom. Midwives recognised that practising midwifery independently was both conscious and active and extended beyond their work as midwives into their daily lives and affected their personal identities. These attributes were included in the midwife circle as 'developing practice wisdom' and 'practising independently'.

Philosophical underpinnings

Midwifery partnership relies on the midwife, and often also the woman, holding certain philosophical beliefs. These beliefs provide the supporting structure for midwifery partnership because they direct the practice of midwifery. In many ways these beliefs are what distinguish midwifery from other disciplines involved in the provision of maternity care. Midwives around the world share these philosophical positions and they are inherent in the international definition of a midwife articulated by the International Confederation of Midwives (ICM) (Association of Radical Midwives 1986; Australian Nursing and Midwifery Council 2005; Davis 1987; Flint 1986, 1993; Gaskin 1980; Houd 1993; ICM 1990; Page 1988, 1993; Midwifery Council of New Zealand 2004; Midwives Alliance of North America 1991). These philosophical beliefs are that: pregnancy and birth are normal life events; midwifery provides continuity of caregiver; midwifery is an independent profession; and midwifery is women-centered (see Fig 14.4).

Pregnancy and childbirth are normal life events

The belief that pregnancy and childbirth are normal life events is one of the fundamental differences between the midwifery and medical models of childbirth. While a myriad of definitions of 'normal' exist, in this context it is generally understood to mean that pregnancy and childbirth are unique physiological processes and critical events in women's lives that mark transitions to motherhood and create families (Beech & Phipps 2004).

In Western societies, the rise of faith in science and technology has led to the development of maternity services that tend to trust machines and technology more than physiology. Rather than seeking ways to support and enhance physiology, research has looked for ways to control childbirth in order to guarantee a healthy baby (and mother) at the end. As a result, the culture of childbirth that is constructed in Western societies is deeply entrenched in medicalisation, so that most births take place in hospitals, most women experience some form of surgical, technological or pharmacological intervention and many midwives are actively involved in implementing these interventions (Crabtree 2004). Medical management of childbirth has become the norm. In this context, both women and midwives have lost confidence in women's bodies and their belief in physiology is undermined. As Downe and others have identified, midwifery's claim to be the guardian of normal birth while apparently actively implementing a variety of interventions during pregnancy and birth is paradoxical (Downe 2004; Kirkham 2000b). Even where models of midwifery support one-to-one care from a midwife, such as in New Zealand, intervention rates in childbirth continue to rise, although they may be beginning to plateau.

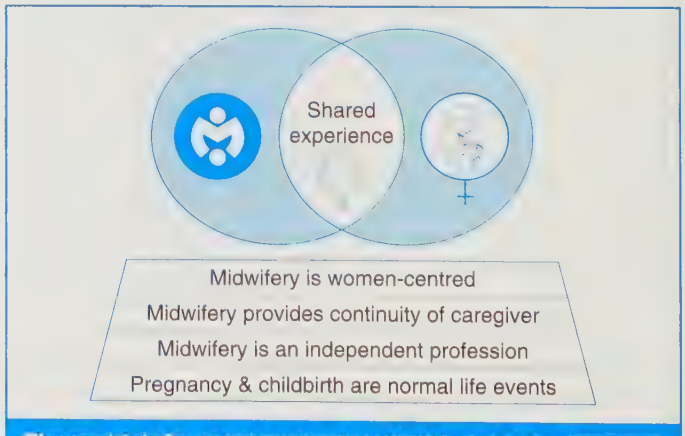

Figure 14.4 Supporting structure for the midwifery partnership (based on Guilliland & Pairman 1995)

Clearly the belief that pregnancy and childbirth are normal life events is not enough on its own, although it must be the first place to start. Downe and McCourt (2004) argue that childbirth must be understood as unique to each woman and her baby, and recognise

> the interaction and connectivity between her personal and familial history, the environment in which she labours, the attitude and response of the caregiver(s), and a multitude of other factors (Downe & McCourt 2004, p 20).

The challenge for midwives in recognising the complexity and uncertainty of childbirth is to explore personal and contextual influences on the way they practise and the way they protect and facilitate normal birth.

> By being more acutely aware of the overt and subtle ways in which medical ideology frames our practice and continues to operate, we can seek ways in which to challenge, resist and reframe this practice (Crabtree 2004, p 98).

In Chapter 6, Foureur and Hunter propose that the 'package' required to keep childbirth normal comprises three strands: a close personal and trusting relationship with a midwife who provides continuity of care throughout the childbirth experience; a strong belief in the normal physiology of childbirth; and a familiar environment for birth that enhances and supports the belief that childbirth is normal. This is supported by Pairman and Guilliland (2003), who suggest that midwives and women need locations for birth that are not dominated by the medical-model philosophy of birth, in order to strengthen their understandings of birth as a physiological process and reduce their reliance on technological interventions for routine screening and pain relief. To this end, midwives and maternity service managers need to actively promote both home and primary facilities/birthing centres as the most appropriate places for the majority of women to give birth (Pairman & Guilliland 2003). Downe and McCourt (2004) suggest that systems of care need to be reframed before any other interventions to promote normal birth can work. Instead of framing childbirth on the basis of 'simplicity, certainty and pathology', as is the case in the medical model, childbirth needs to be reframed as 'unique normality'. A maternity system that responds to women's unique normality is 'most likely to engage with complexity and uncertainty, and to maximise holistic well-being, while ensuring appropriate responses to pathology when it arises' (Downe 2004, p 174).

Midwifery partnership is about recognising each woman as uniquely normal. This belief is internalised for both women and midwives as they experience childbirth as a continuum and as women birth 'in their own way, unfettered by imposed belief systems' (Guilliland & Pairman 1995 p 35). When midwives and women work together throughout the childbirth experience and in women's own environments, midwives begin to understand the range of 'normal', which can only be defined individually for each woman (Katz Rothman 1984). The challenge for midwifery is to promote practice from these understandings so that in midwife-led care at least, childbirth really is reframed as 'uniquely normal'. Perhaps then midwifery's challenge to the medicalisation of childbirth can be truly effective.

Midwifery is an independent profession

Independent midwifery practice exists when the midwife works in partnership with the woman to provide the complete service throughout pregnancy, labour, birth and the postnatal period on her own responsibility (Guilliland & Pairman 1995, p 37). Independence relates to the way the midwife practises, not to where the woman gives birth or the employment status of the midwife.

The key aspect of independent practice is autonomy—that is, a specific philosophy and body of knowledge, together with the ability to practise without reference to another discipline. For midwifery this means being able to provide care across the scope of midwifery practice and the freedom to make decisions with the woman about care. Autonomy also requires accountability and responsibility for these midwifery judgments and actions. Autonomy does not mean practising alone. In midwifery partnership, decisions are always discussed and negotiated with each woman, and the midwife is firstly accountable to her. Midwives also work with other midwives and often discuss their midwifery judgments and uncertainties with their midwifery colleagues. When additional care is required, these judgments will include deciding when to involve an obstetrician or other specialist in a woman's care. Midwives who practise independently will take responsibility for ensuring that roles and expectations are clarified when others become involved in a woman's care, that communication is good and that the woman remains the primary decision-maker.

That midwives can practise independently is important to both midwives and to women. As will be discussed later, it is this recognition of professional autonomy that provides the foundation for the development of new understandings and knowledge that places the control of childbirth with women instead of doctors or midwives.

Midwifery provides continuity of caregiver

Continuity of caregiver means 'one midwife (and her back-up colleague) providing midwifery care throughout the entire childbirth experience' (Guilliland & Pairman 1995, p 39). Continuity of caregiver in a one-to-one relationship is fundamental to midwifery because it enables midwives to work in their full scope of practice in a way that other disciplines do not. It is what distinguishes midwifery as a profession. It gives midwives the ability to build partnerships with women because it provides them with time to get to know each other and to develop trust. In relationships that span pregnancy and beyond, there is time to work with each woman to discuss her wishes and her fears for birth and motherhood, and to build her confidence in herself. There is time to work with families to build their confidence and to uncover their fears and misconceptions. Decision-making becomes much easier because there is time for each woman to explore information and to think through options to come to decisions that are

right for her. Midwives and women have time to talk about labour, pain, the impact of the environment, uncertainty and complexity, so that, ideally, by the time a woman goes into labour she is willing and confident to 'let go' and to trust her body to give birth.

Midwives working outside the continuity model (core midwives) provide the essential link for the caseloading midwife and the woman when they require extra or supportive care. Core midwives' partnership relationship with the woman's chosen midwife ensures that the continuum of care is possible for most women regardless of their need for obstetric intervention.

There is now a significant amount of evidence that care provided by teams of midwives in continuity-of-care models is associated with a reduction in the use of some technological and pharmacological interventions, and that women prefer this type of care (Sandall 2004). Although there are no randomised controlled trials of caseloading (one-to-one) midwifery, the evidence of the importance of supportive relationships during pregnancy and continuous one-to-one support during labour is clear (Hodnett et al 2003; MIDIRS 1996; Oakley et al 1996). Despite this research knowledge, it is often not acted upon and outside New Zealand many maternity services do not enable and support midwives to develop and maintain one-to-one models of practice (Kirkham 2000b).

Midwifery is women-centred

In midwifery partnership, 'women-centredness' is important in three main ways. First, midwifery only exists 'to facilitate the optimal experience of birth for pregnant women and their babies' (Guilliland & Pairman 1995, p 41). Secondly, midwifery recognises the centrality of women's experiences by ensuring that its focus is on the woman, who defines her needs. The midwifery relationship is with the woman, who has the primary relationship with her baby. A woman-centred philosophy does not separate the needs of the mother and baby, viewing them rather as an integrated whole, where the needs of one will be the needs of the other. Women-centredness is not a denial of the important part the family plays in the woman's life, but rather acknowledges that it is she who has the primary relationship with her family, not the midwife, and it is she who decides how her family will be involved.

Finally, a women-centred philosophy ensures that women are seen as individuals, each with different needs and different cultural identities. As Bizz described, a women-centred approach takes account of each woman's particular context.

> The midwife spoke about my pregnancy as a whole thing with me, Eric and the baby, rather than just my body and my baby inside it (BF, in Pairman 1998, p 183).

And Kate explained:

> It's the whole family dynamics; it's the people who are close to her. It's not just the woman; it's everyone that affects her and everything that affects her (KS, in Pairman 1998, p 183).

Women-centredness just means working with a woman in whatever way she wants. For the women in Pairman's study (1998), the involvement of their families was crucial and their expectations were that the midwife would facilitate the involvement of their families in these shared experiences of pregnancy and childbirth.

Theoretical concepts

The philosophical beliefs outlined above provide the conditions within which midwifery partnerships can form. However, the successful establishment and maintenance of a midwifery partnership relies on the integration of certain principles in how the partners relate to each other. These principles are: individual negotiation, equality, shared responsibility and empowerment, and informed choice and consent (see Fig 14.5).

It is on this aspect of midwifery partnership that the findings from Pairman's (1998) study had the most impact, and refinements were made in order to make more explicit the way in which midwives and women 'work together' in

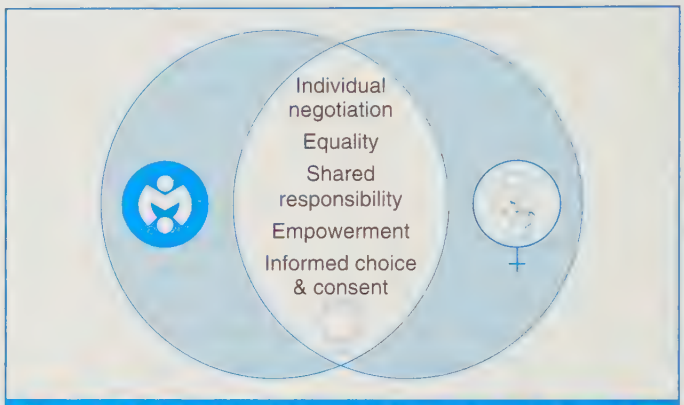

Figure 14.5 Principles inherent in the partnership (based on Guilliland & Pairman 1995)

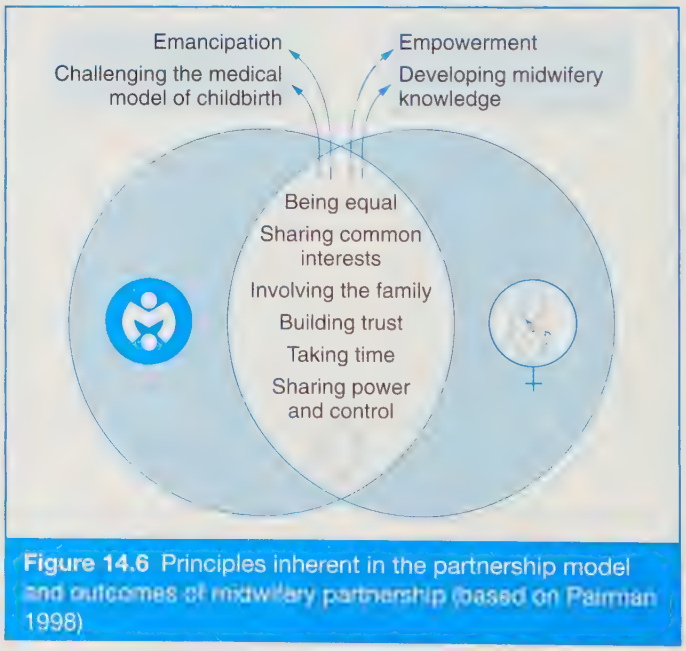

Figure 14.6 Principles inherent in the partnership model and outcomes of midwifery partnership (based on Pairman 1998)

a midwifery partnership. The refined model identified the following concepts as describing how midwives and women worked together: 'being equal', 'sharing common interests', 'involving the family', 'building trust', 'reciprocity', 'taking time' and 'sharing power and control' (see Fig 14.6).

These concepts incorporated most of the original concepts identified in the midwifery partnership model (see Fig 14.5), but were more specific and focused to a greater extent on how a midwife and a woman actually worked together.

The refined model also made the outcomes of midwifery partnership more explicit. Empowerment was identified as an outcome for both women and midwives, as was emancipation. The developments of new knowledge about midwifery and about birth and the challenge this midwifery model of care poses to the medical model of childbirth were identified as two specific outcomes that resulted from empowerment and emancipation of the midwife and woman within midwifery partnership. The refined model is presented in Figure 14.7.

The concepts discussed below are key principles from both models that exemplify the way in which midwifery partnership is enacted. In many ways these concepts overlap in their meaning, and it is their integration that characterises midwifery partnerships.

Negotiation

The underlying premise of the partnership is that it is individually negotiated, recognising the essential contribution of each (Guilliland & Pairman 1995, p 44). Each partner brings different things to the partnership, but both partners must participate and contribute if the partnership is to work. Negotiation is a process by which a midwife and a woman work though issues such as power-sharing, decision-making, and mutual rights and responsibilities, and make their expectations of each other explicit. Negotiation relies on open and effective communication and a positive sense of self. It is a process for working things out and coming to mutual understandings and agreements. It is a mutating, changing, synchronous pattern of give and take that facilitates movement towards a shared purpose (Henson 1997, p 79).

Each partnership will be different because of the unique characteristics of each partner and the way they negotiate the relationship.

Equality and reciprocity

In a partnership, both partners have equal status and must feel equal. This does not mean that a midwife and a woman are the same or that they bring the same things to their relationship

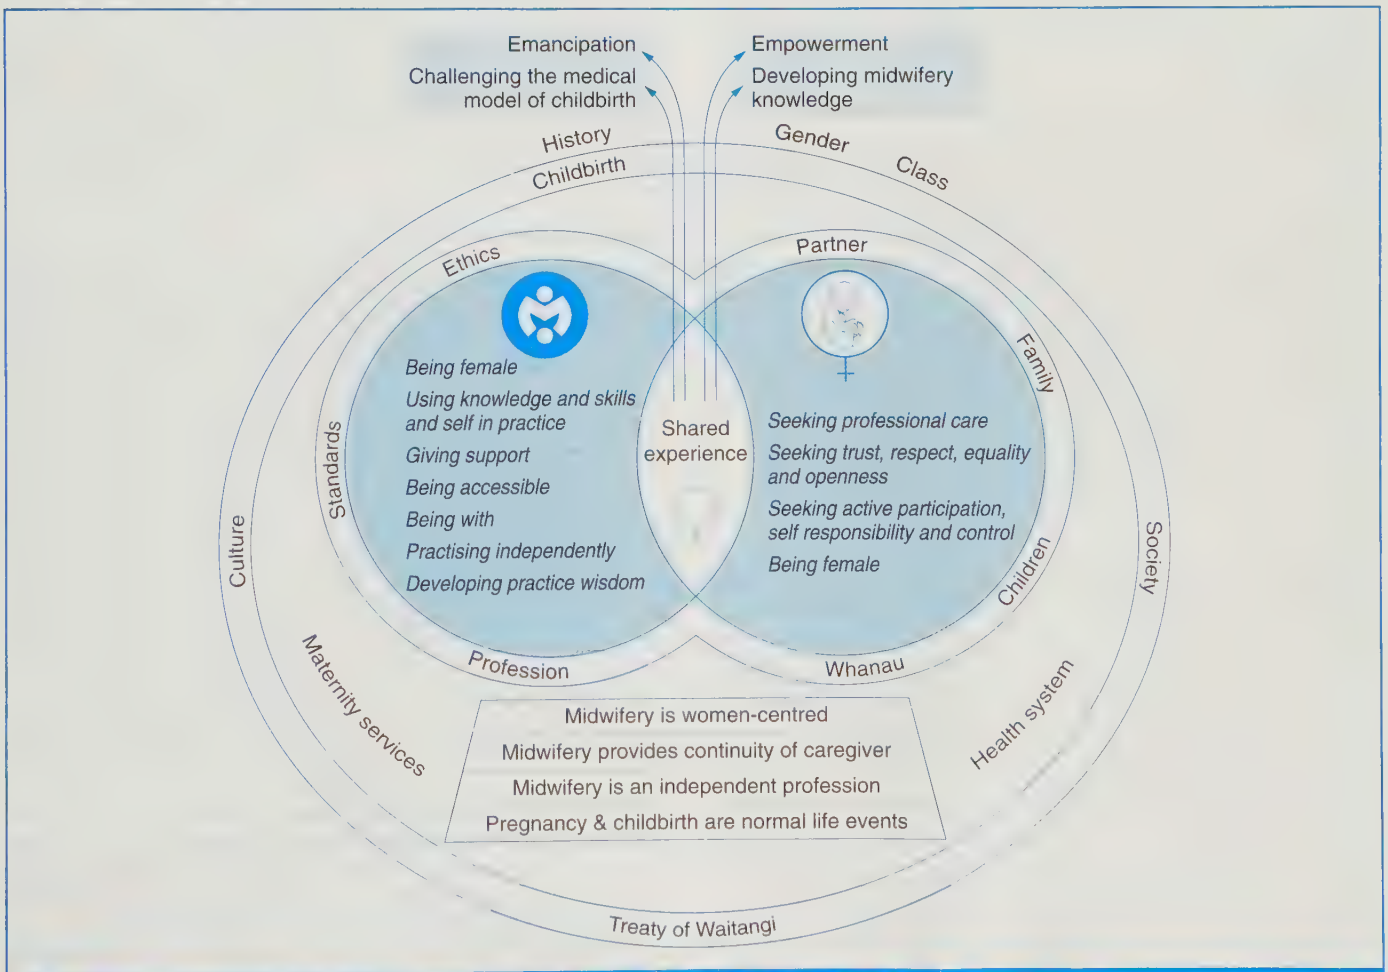

Figure 14.7 The midwifery partnership model (refined) (based on Pairman 1998)

or that they have the same roles. They are different and this difference is recognised and respected. As Amy, a woman in the study, commented: 'She was there to do her job and not be bossy and I was there to do a job and not push her around' (AA, in Pairman 1998, p 122). And Bizz said:

> I trusted her professionalism and all her knowledge, but I felt very equal with her. I needed her expertise and I was very confident in it, but I suppose her confidence built my confidence. So I didn't feel at any stage that she was in any way above me, looking down on me or anything like that (BF, in Pairman 1998, p 117).

The contributions that both make to their relationship are equally valued and the process of getting to know each other and working together is reciprocal. Reciprocity means a two-way sharing or mutual exchange that creates shared meaning and is beneficial to both. Mutual involvement of both partners strengthens and deepens their relationship and has positive effects on both partners. As Chris, one of the midwives in the study, explained:

> It's two way . . . that the woman feels relaxed and comfortable, supported . . . if she feels she can trust you with herself and particularly the vulnerability in labour . . . I think that's a real privilege for us to have that trust, and it works the other way, that you trust the woman to tell you what her needs are and if she's not happy or wants something else (CS, in Pairman 1998, p 122).

Trust and time

As women and midwives get to know each other, they learn to trust each other. Trust is essential in any healthy human relationship and in midwifery partnership trust underpins information sharing, decision-making, power sharing and empowerment. When two people trust each other they feel safe with each other and willing to expose their vulnerabilities because they know the other person will respect these. Faced with the uncertainty of childbirth, it is important for women to trust their midwives and for midwives to trust women. No amount of talking or preparation can predict how each unique birth experience will unfold and there is always a time when women and midwives have to 'let go' and trust the process—trust physiology, trust women's bodies, and trust themselves. As Linda, one of the women in the study, explained:

> I felt that if something was going wrong she'd give me plenty of advance warning and I wouldn't have to yell at her to take me . . . like she knew that I was scared, she knew how I was feeling. Because we discussed Lauren's birth quite in detail, and so she knew where I was coming from and so I felt very comfortable with her . . . after Brianna was born, the way she lifted her up . . . I felt very safe with her having Brianna as well . . . I trusted her totally . . . I trusted her to show it (the placenta) to me and it was alright. It was alright because I felt safe with her (LF, in Pairman 1998, p 121).

Trust develops over time and therefore continuity of caregiver enhances the development of trust. Midwives who visit women in their own homes during pregnancy are able to get to know each woman in her own context and in surroundings where she is comfortable and in control. Often family will be involved. In these more relaxed settings both partners have the opportunity to really get to know each other. Dianne said:

> Just the development of the relationship. It does take a while to get to know someone. And you're inviting them to partake in something that's going to happen only once or twice in your lifetime. So you want to be sure that the person who's attending you is going to respect your wishes and is going to be on the same wavelength as you (DMcD, in Pairman 1998, p 127).

There are several dimensions to time: the time that midwives give to each visit that enables full discussion; being accessible to women at other times when necessary; the length of the relationship from early pregnancy through to about six weeks after birth; and for some midwives and women, the opportunity to work with each other again in subsequent pregnancies so that their relationships can continue to develop over years. This ability to spend time is valued by both women and midwives. As Dianne said:

> She'd come and spend an hour with us . . . I was really appreciative of all the time she did spend with us, so that the experience that we had was really amazing . . . it wasn't just a five minute 'Are you OK?'. Because sometimes I think that you need longer . . . you really need that time to go through and talk about what was going on (DMcD, in Pairman 1998, p 126).

As mentioned already, the capacity of a midwife to develop a personal and trusting relationship with a woman over nine to ten months is one of the unique differences between midwifery and other health professions involved in the provision of maternity care.

Sharing power and responsibility

In midwifery partnership, both partners exercise power. The balance of power is negotiated and mutually agreed. Power is shared through sharing information, by the way decisions are made and by recognising and enhancing each woman's sense of control. Feeling in control during childbirth leads to a sense of satisfaction, fulfilment and positive wellbeing (Green et al 1990). The exercise of power and personal control is dependent on having the resources and options that allow choice, being adequately informed about choices, being involved in decision-making and being able to implement those decisions once they are made (Walker et al 1995). Midwifery partnership provides a framework within which a woman can achieve a sense of personal control. In an equal and negotiated relationship, where both partners trust each other and feel safe, midwives can actively support women to take hold of their power and make decisions without imposing their own beliefs. As Kay explained:

> I present women with all the information that's available and then they make the choices of what they want to do . . . I give them information, usually research based, about things they want to know . . . I think there is a danger that some midwives put their experiences onto women . . . sometimes that's okay and sometimes it's not, because it's not actually your experience, it's their experience so it should be totally theirs, it should be unique (KF, in Pairman 1998, p 135).

Dianne also described this kind of decision-making:

> It was at the back of my mind that she must have her own feelings about what should be done but it never came through. That's what I found really amazing about her, that I never felt in any way that whatever she carried with her (because I believe that anyone who makes a decision—there's a whole lot of other things as to why they make that decision), and I never felt she brought any of that into the situation . . . she was there but she never moved in (DMcD, in Pairman 1998, p 134).

Along with the power to make decisions and be in control comes responsibility for those decisions. While midwives are always professionally accountable for their midwifery judgements and actions, in midwifery partnership women also take responsibility for the outcomes of decisions jointly made. As Dianne described, taking responsibility and making decisions can be an empowering process:

> You've got to take responsibility and I think once you take responsibility for your life you can do so much more. It's tied up in a circle—you can evolve much beyond that. It's like taking hold of your life. If you take responsibility then if you get a bad thing out of it then you learn from your mistake. If you get a good thing out of it then you get a real buzz. It's not anyone else's—they might have contributed to it, but it's like 'yeah, I did that and I can take the credit for it' . . . even today I look at Jessica and I find it really amazing that she grew up in me. I ate really healthy and I felt whatever I did would be reflected in Jessica, and I wanted a really good healthy baby . . . then at the end we got this fantastic little baby who was really alert from day one. Even now she's raring to go. I take a wee credit for that (DMcD, in Pairman 1998, p 168).

Empowerment and emancipation

Midwives are privileged in that their professional role enables them to be alongside women and families through the important and life-changing processes of pregnancy, childbirth and early motherhood. The midwifery role is mainly to support and assist women in a way that 'recognises that the physical, emotional, and spiritual aspects of pregnancy and birth are equally important' (Page & Hutton 2000, p 1). Midwifery aims to enable women to recognise their personal power and strengths and increase women's sense of autonomy and confidence as mothers and as women. These are lofty aims but because pregnancy and birth are such life-changing events they often cause women to ask questions about themselves and their lives and seek to make changes. As Nicky Leap (2000, p 5) said, 'The question marks of pregnancy are the beginning of a process of grappling with the uncertainty and decision-making that will persist throughout the experience of raising a child'. For some women, having a midwife ask them what they want for their birth may be the first time they have had the opportunity to make any choices in their lives. Kate commented:

> It's a nice feeling to see a woman go from thinking that everyone else owns, or has a right to dictate, to deciding—and to see it spill over into other areas is really neat . . . and start questioning other areas and other things in her life . . . that's a major plus I think to work with a woman over a longer time (KS, in Pairman 1998, p 166).

Midwives can work with women in ways that facilitate empowerment for women and this in turn can be empowering for midwives. Key facilitation skills for midwives are believing in women and inspiring confidence, and knowing when to intervene and when to withdraw (Leap 2000). As Julie described:

> Every message they get is about self-responsibility . . . asking information at the beginning, saying, 'How is your baby moving? What do you notice about yourself? How have you felt?' and actually listening . . . what we're doing is checking that she's observing and aware of herself and her baby, and I believe women take that on (JR, in Pairman 1998, p 143).

Although midwives share significant life events with women, they are involved in women's lives for only short periods. Their involvement with women can be empowering if they work to facilitate independence and self-determination rather than dependence. One way to do this is to encourage women to build their own networks of support rather than relying on midwives, who will not be there for the long-term. As Chris explained:

> I like to think that the focus is that they're developing their own independence and their own networks to support them, because when you move towards leaving them at six weeks postpartum or whenever, I usually find, not quite that you're rejected, but that you're not needed anymore. By the time you finish they're competent, confident and managing and have set up networks to keep going (CS, in Pairman 1998, p 150).

Midwifery partnership can be empowering for both women and midwives. As midwives work with women in this way, their beliefs about birth and about midwifery are reinforced and strengthened. Observing the uniqueness of each woman's birth experience builds midwives' confidence about the ranges of 'normal' that are possible and builds trust in women's bodies. Sharing and negotiating power and decision-making and being able to see the outcomes of these decisions strengthens midwives' trust and confidence in women, and in themselves as autonomous practitioners.

Midwifery partnership also has emancipatory potential. Women who experience midwifery partnership often encourage other women to seek this type of care. 'Emancipation is a dynamic state of being in which self-knowledge (enlightenment) and self-advocacy (empowerment) are connected to knowledge and advocacy for others' (Henderson 1995, p 66). As most systems of maternity care in Western societies are still entrenched in the medical model, there is huge scope for women to persuade other women through the telling of their stories about the normalcy of birth and the benefits of one-to-one midwifery care. New Zealand and Canada are two examples of where political action by women has led to significant structural and philosophical changes in the way maternity services are delivered and the development of more women-centred models of care.

Professional friendship

The women in Pairman's (1998) study believed that the term 'professional friend' encompassed what they felt about the midwife/woman relationship and their experience of midwifery partnership. This term describes the relationship between midwives and women as friendship but also recognises the professional focus of the relationship and its time-limited nature (Pairman 2000). As Bizz explained:

> I think we had a really good relationship, actually. It was more of a friend relationship, but a friend you could trust in—a professional friend you could rely on (BF, in Pairman 1998, p 163).

Pairman's study teased out midwifery partnership to mean 'professional friendship'. As described, the refinements made to the partnership model in this study provided further depth and understanding of the concepts by exploring how women and midwives experienced midwifery partnerships. Further exploration of the notion of professional friendship will contribute to midwifery's understanding of the practice of partnership.

Potentials and possibilities for partnership

Midwifery partnership, then, is a relationship of sharing based on mutual respect and trust that has the potential to enrich the lives of both women and midwives. Although the partnership model arose from New Zealand's unique historical, social and cultural context, it can be applied in other settings. New Zealand midwives have claimed that 'midwifery *is* the partnership between the woman and the midwife' (Guilliland & Pairman 1995, p 33). This is because midwives work always in relationships with women (Guilliland & Pairman 1995. These relationships are the medium through which midwives provide care and have a powerful impact on how women receive this care. Midwifery partnership identifies a set of principles that enable midwives to develop relationships with women that are intrinsically different from the usual health professional/client relationships. In midwifery partnerships, women are recognised as autonomous individuals undergoing a significant and transformative but 'normal' life process. Women need midwives' specialised expertise, knowledge and wisdom to support and guide them through this process but must also contribute their own expertise, knowledge and wisdom if the experience is to meet their needs. In midwifery partnerships, midwives and women both have recognised expertise and they collaborate to ensure that the childbirth experience is safe and fulfilling for the woman. The processes of collaboration, sharing and negotiation required in midwifery partnerships strengthen and empower both midwives and women. New Zealand midwifery has redefined professionalism to mean midwifery partnership and claimed a new professional role as 'partner' rather than 'expert'.

Working in partnership is demanding. It requires self-knowledge on the part of midwives, strong and effective communication skills and a secure sense of self. It also takes time and the ability to be reflective. Like any human relationship it will not be possible to get it 'right' every time, and each new relationship with a woman can add to a midwife's understanding of herself and how she works with women, if she is willing to examine these. The model of midwifery partnership provides guidance to midwives wanting to develop partnerships with women, and the concepts discussed above are a starting place for reflective practice and learning about partnership.

Midwifery partnership is definitely enhanced when midwives work in one-to-one continuity of care models as autonomous practitioners. Even when this is not possible, midwives can incorporate some of the principles of partnership into their care of women in more fragmented settings where the midwife and the woman do not know each other. Acknowledging our professional power and finding ways to shift that power to women is challenging but still possible even in the most fleeting of encounters with women. The way midwives write in women's maternity notes and the language they use can empower or disempower women.

Midwifery partnership also provides a model for the development of political partnerships between maternity consumer groups and midwifery professional organisations. There is always the opportunity for midwives to get to know their local community and to establish relationships with maternity consumer groups. As seen in New Zealand, these women can be a force for social change. Change can happen in small steps. The successful implementation of one-to-one care in a single maternity unit can lead to further developments as more women demand this type of care and more midwives demand to work in this way.

As midwife-led maternity services are developed they need to be supported, ideally by the wider health organisations. However, even if support is not forthcoming from managers and employers, midwives can do a great deal to support each other and empower themselves as a group. Pairs of midwives working together to provide care to a caseload of women should join other pairs to create larger groups. These larger groups can provide support, friendship, mentoring and safe places to debrief and problem solve. They can also provide political strength when necessary.

Where midwives and women experience continuity-of-care relationships based on partnership, they begin to understand childbirth differently. If each woman's experience is different, then it follows that protocols, timeframes and routinised midwifery care will not enhance women's diverse childbirth processes. In such settings a midwife has to 'question many of the taken-for-granted assumptions of the medical setting and the medical model. And she finds herself constructing a new model, a new way of explaining what she sees' (Katz Rothman 1984, p 304). Midwifery partnership creates the opportunity for new knowledge (midwifery knowledge) to develop for both

Critical thinking exercise

Are midwifery partnership and cultural safety the same? If so, explain their similarities. If not, explain their differences.

midwives and women that can begin to challenge the medical model as the dominant paradigm for childbirth.

Conclusion

Midwifery partnership provides a framework for a negotiated and reciprocal relationship of equity and power sharing. Cultural safety provides a framework for recognising cultural 'difference' between a midwife and a woman, the power inherent in the professional role of a midwife and the impact that the culture of the midwife may have on her professional practice. A key aspect of cultural safety in relation to midwifery practice is that it is the childbearing woman and her family, not the midwife, who determine that the midwifery care is effective and 'safe'. Together these frameworks identify and explain the unique nature of New Zealand's midwifery and maternity practices.

Review questions

1. Describe 'culture' as defined by the New Zealand Nursing Council.
2. Describe 'cultural safety' as defined by the New Zealand Nursing Council.
3. Describe culturally safe practice.
4. Describe culturally unsafe practice.
5. Who determines whether a midwife's practice is culturally safe?
6. Describe the difference between transcultural nursing and cultural safety.
7. Describe the relationship between colonisation and cultural safety.
8. Describe the difference between cultural awareness, cultural sensitivity and cultural safety.
9. Describe the movement from 'regardless' to 'regardful' of what makes a person unique and how this relates to cultural safety.
10. Describe how power and structures of power are related to cultural safety.
11. List the principles of cultural safety.
12. Describe midwifery partnership as defined by Guilliland and Pairman (1995).
13. What are the supporting philosophical positions of midwifery partnership?
14. Identify five important concepts that describe how a midwife and a woman work together in partnership
15. How is empowerment achieved in midwifery partnership?

Note

1 This section talks of nurses and midwives because cultural safety was developed in an era when nursing and midwifery were still closely intertwined educationally and were both regulated by the Nursing Council of New Zealand, which defined cultural safety as a competency for practice for both nurses and midwives.

CHAPTER 15

Working in partnership

Nicky Leap and Sally Pairman

Key terms

continuity of care, core midwife, decision-making, partnership, persuasion, professional friend, professional judgement, midwifery role, professionalism, relationship, self-determination, women-centred care

Chapter overview

This chapter provides an overview of how midwives can work in partnerships with women and with other midwives through an exploration of key aspects of partnership practice.

Working in partnership takes maturity, self-knowledge, honesty, commitment and professionalism. It is demanding and challenging but ultimately rewarding and satisfying. It can benefit both partners. To work in partnership requires a midwife to move beyond her professional role and expose and share herself as a person with the women for whom she provides care. This chapter identifies some important aspects of partnership practice and explores how midwives can integrate these aspects into their own midwifery practice.

Learning outcomes

Learning outcomes for this chapter are:

1. To explore the meaning of 'partnership' between women and midwives
2. To identify key aspects of partnership practice
3. To understand the importance of midwifery partnership to midwifery practice and women's experiences of childbirth
4. To develop strategies for the integration of partnership into midwifery practice

Introduction

The central tenet of midwifery is that it is a relationship between a midwife and a woman and that this relationship is one of partnership (Guilliland & Pairman 1995; Kirkham 2000). The development of this partnership relationship relies on midwives being able to work in continuity-of-care models so that mutual trust and understanding between midwives and women can evolve over time. Partnership relationships provide a context from which there is potential for both women and midwives to be enriched by exploring the inherent possibilities within the self (Guilliland & Pairman 1995; Siddiqui 1991).

Promoting normal (physiological) birth is only one aim of midwifery care. Equally important is the aim of supporting women to be confident in their roles as mothers, with the consequent positive impact on families and communities. A one-to-one relationship between a midwife and a woman over nine to ten months of the childbirth process provides a unique opportunity for midwives to reinforce and support women's abilities as decision-makers and their sense of self-determination. Confidence in her body and in her self will stand a woman in good stead as she takes on the complex role of mother that is central to the healthy functioning of a family.

While personally demanding, working in partnership with women is also extremely rewarding and empowering for midwives. One-to-one continuity of care provides a context in which midwives can truly embrace their full role and scope of practice and explore what it means to 'be with' women during childbirth. This meaning will differ for each midwife, who will identify and develop her[1] own practice strategies to enhance her partnership relationships with women.

This chapter looks at some of the practicalities and issues relating to practising in partnership with women and with the aim of promoting women's confidence and sense of self-determination. The chapter also examines the partnerships that midwives form with midwifery colleagues. The philosophy and particular nature of midwifery partnership is explored, with practical references to an approach that:

- minimises disturbance, direction, authority and intervention
- maximises the potential for physiology, common sense and instinctive behaviour to prevail
- places trust in the expertise of the childbearing woman
- shifts power towards the woman (Leap 2000, p 2).

Partnership: overview of some evidence

There is a growing awareness of the benefits to women of being able to access one-to-one continuity of midwifery care (or midwifery caseload practice), which is the foundation of partnership (Benjamin et al 2001; Hodnett 2004; Homer et al 2001; Homer et al 2002a; Page et al 2001; Sandall et al 2001). Although most studies are of continuity of care from a small group of caregivers rather than one-to-one care, the benefits for women include increased satisfaction with their care and a reduced likelihood of: being admitted to hospital antenatally; having drugs for pain relief in labour; having an episiotomy; and their baby requiring resuscitation (Sandall 2004). These benefits extend to women who experience complications and need to also have care provided by obstetricians, paediatricians and other medical specialists (Farrell et al 2002; Homer et al 2002b).

A central component of midwifery caseload practice is continuous support in labour, which has a positive impact on both women's experiences and birth outcomes (Hodnett 2004). Women who have continuous support are more likely to have a spontaneous vaginal birth, less likely to use analgesia in labour, less likely to have an operative birth or caesarean section and are more likely to be satisfied with the birth experience (Hodnett 2004).

In New Zealand, where over 78% of women receive continuity of care through caseload midwifery models, the impact of this care in improving outcomes for women and babies is beginning to be recognised (NZHIS 2005). Rather than a dramatic decrease in intervention rates, it appears more likely that continuity of midwifery care may make a positive impact on outcomes and health over a longer timeframe (Guilliland 2005). For example, since the commencement of this one-to-one partnership model of midwifery care in 1996[2], perinatal mortality rates have continued to decline, antenatal admission rates for women with serious complications have declined, 95% of babies receive their six-week immunisation (a rate higher than at any other time in the immunisation schedule), rates of exclusive breastfeeding at six weeks and three months are increasing, and women's satisfaction with their maternity service is high and continues to increase (Guilliland 2005; Ministry of Health 1999, 2001, 2003; NZHIS 2003, 2004, 2005).

The picture for Maori and Pacific Island women as well as women from lower socio-economic groups is also positive. Maori and young women from lower socio-economic groups are more likely to choose midwives as their lead care providers, and Maori women are more likely to birth in primary maternity facilities than any other ethnic group (NZHIS 2005). A study of over a million births from 1980 to 2001 shows that while preterm birth rates for Maori women are still higher than for non-Maori women, there has been a slight decline in the rates for Maori and Pacific Island women, in contrast to a marked increase for European women (Craig et al 2004). While rates for small for gestational age (SGA) babies have decreased for Maori, Pacific Island and European women over this period, the rate of decline for Pacific Island and Maori women has been greater (Craig et al 2004). Despite the high rates of preterm birth and SGA among Maori women, perinatal mortality rates for Maori communities are equal to or lower than those of other ethnic groups (NZHIS 2000).

Intervention rates in childbirth continue to increase in New Zealand as elsewhere in developed countries. However, while New Zealand's caesarean section rate has slowly increased to 23.1% in 2003, the increase appears slower and lower

than in Australia, where the rate was 28.3% in 2003 (Laws & Sullivan 2005; NZHIS 2005; Ministry of Health 2001). Other measures such as instrumental births and induction of labour have declined in recent years, and epidural rates have barely increased (23.3% in 1997 to 24.4% in 2003). Midwifery care is linked to better outcomes than care with general practitioners and obstetricians, with higher normal birth rates and lower rates of caesarean section, instrumental births, episiotomies and epidural use (NZHIS 2004).

The context for childbirth in Western societies is characterised by the increasing use of intervention and technology, and the reasons for this are complex. Reducing unnecessary intervention in childbirth and reframing birth as a physiological life process is no simple matter, but providing midwifery care through one-to-one continuity of care in partnerships with women is one place to start (Page 1995). The relationship between a woman and a known midwife can ameliorate the impact of institutionalisation (Berg et al 1996; Halldorsdottir & Karlsdottir 1996; Kirkham 2000) and repeated studies demonstrate that women's feelings about this relationship and the related interactions override all other factors when women reflect on their experiences of labour (Hodnett 2002, 2004).

Partnership and the role of the midwife

The International Confederation of Midwives definition and scope of practice of a midwife (accepted in Australia and adapted in New Zealand) identifies that midwives work with women during pregnancy, labour and birth and the postnatal period—identified by the World Health Organization[3] as six weeks following birth—in the provision of 'woman-centred' midwifery care (ACMI 2005; Midwifery Council of New Zealand 2004; NZCOM 2005). The childbirth experience is a discrete period of profound significance to women and their families/whanau. Unlike any other episode where people seek healthcare, pregnancy, birth and breastfeeding are physiological processes. 'Woman-centred care' is articulated as different from the care given by other practitioners in that, throughout centuries and across cultures, women have asked midwives to be alongside them in their journey to motherhood in a relationship of mutual trust and respect embodying feminist principles and focusing on the individual needs of each childbearing woman (Guilliland & Pairman 1995; Thompson 2004).

In maternity services in New Zealand, and to a lesser extent in Australia, women can access models of care where midwives are alongside them throughout this period as primary carers. What women seek from midwives is support and skills in addressing the physical, emotional, social and spiritual aspects of a rite of passage that has far-reaching consequences for all involved and for the wellbeing of societies (Kirkham 2000; Kitzinger 1988; Thompson 2004).

Many of the currently compartmentalised components of woman-centred care are linked through relationship. The midwife becomes a 'professional friend' (Pairman 1998, 2000a; Wilkins 2000), supporting a woman to give birth in a way that she believes to be right for her and her baby. This relationship includes an emotional engagement, each party placing the other within a personal and biographical context (Wilkins 2000). Women have articulated the concept of the midwife as 'professional friend' where the following factors apply:

> The midwife and the woman work together in a particular way that integrates the notions of 'being equal', 'sharing common interests', 'involving the family', 'building trust', 'reciprocity', 'taking time' and 'sharing power and control' (Pairman 2000a, p 210).

The concept of 'professional friend' embodies characteristics of friendship within a professional relationship formed for the purpose of providing professional midwifery care and ending at completion of the childbirth process (Pairman 1998). Working with women in partnership as a 'professional friend' involves the integration of knowledge, skills and attitudes as reflected in the philosophies, competencies and other standards of the midwifery professions in both New Zealand and Australia. The midwifery role of 'being with woman' (the meaning of the Anglo-Saxon word *mid-wyf*) underpins these professional frameworks and is recognised by midwives internationally.

As identified in Chapter 14, the midwife–woman relationship was first articulated as a feminist concept involving partnership by New Zealanders Sally Pairman and Karen Guilliland in their 1995 monograph, *The Midwifery Partnership: A Model for Practice* (Guilliland & Pairman 1995). The notion of 'being with' as opposed to 'doing to' is associated with rites of passage such as birth and death (Powell Kennedy et al 2003). Fundamental to this understanding is recognition of the autonomy of the individuals involved in these significant events. The midwife's role is to 'be with' each woman and support her independence and growth through pregnancy and birth so that she feels strong and confident in her abilities as a woman and as a new mother (Katz Rothman 1991).

> At every stage of our interactions with childbearing women, as midwives, we should be adopting behaviours that will ensure that women can take up the power that will enable them to lead fulfilling lives as individuals and as mothers. This process of empowerment may have far reaching consequences in terms of women's feelings of self worth and confidence (Leap 2000, p 4).

In order to promote confidence in women, the midwife needs to be secure and confident in herself, both as a woman and as a midwife (Kirkham 2000). This often entails a mature approach to resisting the temptation to 'make things better', 'sort everything out' and take control as the 'expert'. It also means understanding how to avoid creating dependencies. There is a danger that 'needy' midwives can create 'needy women' and inadvertently create dependencies that interfere with a woman's sense of her own expertise and ability to be self-determining.

Instead of seeing themselves as the 'experts' who need to 'instruct' and 'educate' women, midwives need to conceptualise the relationship as one based on mutual learning and

Critical thinking exercise

1. Continuity of midwifery care is common in New Zealand, but not in Australia. Think about the implications for women who cannot access continuity of midwifery care. How might this affect their relationships with midwives? What impact could this have on their experiences of maternity care?
2. If you work in a setting where continuity of care is not available to women or midwives, how can you incorporate some of the principles of partnership into your midwifery practice? Think of six changes you can make to your practice that will help you to develop a more equal relationship with the women you work with and to give them a stronger sense of power and control.

reciprocity (Guilliland & Pairman 1995; Pairman 1998). This begins with the midwife asking open-ended questions and having good listening skills.

> If a relationship is such that the practitioner does not listen, does not come to know the hopes and fears of the woman, does not respond to her anxieties, then the mode of care can only ... be based on the semblance of what the practitioner thinks should be happening. It lacks attention to the things that are 'mattering'. It traps the woman into a passive role of accepting inappropriate, unsafe care, rather than freeing her to involve herself in the accomplishment of personalised care that promotes all that is safe (Smythe 1998, p 202).

If midwifery is about promoting self-determination for women, then the notion of 'advocacy'—often seen as an important part of the nursing role—needs to be questioned. Arguably women should be advocating for themselves if they are to feel powerful. In most situations this is possible, particularly where the relationship with a midwife has enabled the woman to access information and articulate her needs. Where pain in labour or severe illness interferes with this process, the midwife may have a role in presenting the woman's wishes but this is done from a position of knowledge and trust that has been established and negotiated. This is all part of being clear about expectations at the initial visit and subsequently as the relationship develops.

Valuing women's expertise

Valuing a woman's expertise in monitoring her baby's well-being throughout pregnancy and in the early weeks of motherhood is often about stepping back and sending a message of trust. The balance between 'trusting the process' and being alert to signs that there is a need to intervene—either by making suggestions or by taking action—is a core midwifery skill that is often invisible and is hard to articulate in its complexity. The individuality and unpredictability of each woman's experience means that often both women and midwives find themselves in situations where they feel they are outside their comfort zones and where they need to draw on courage as well as knowledge and experience.

Thus 'being with' encompasses the ability of midwives to trust the process of birth while using practice wisdom to guide and intervene as necessary. Because midwives cannot always be certain about their decisions or women's decisions, the balance between trusting and facilitating a process, and intervening through action, is finely balanced and individual to each woman's experience. It takes a degree of maturity on the part of the a midwife, and characteristics and skills such as honesty, integrity, decisiveness, practicality, reflectiveness, generosity, positivity and autonomy.

Working in partnership with women

The beginning of the relationship

The fundamental starting point for partnership is the recognition that women and midwives both have expertise that will contribute to an optimal experience for each woman and her family. The way in which both a midwife and a woman will contribute to the relationship needs to be individually negotiated. Each will bring different expectations and skills.

> The woman, with her knowledge of self and family...brings a willingness to participate actively in her care, sharing responsibility for her decisions and assuming control over her experience. The midwife, from her foundation of professional standards and ethics, brings her ability to be 'with woman'. In this, she utilises her knowledge, skills and self in practice and is accessible and supportive to the woman (Pairman 2000a, p 210).

Women seek midwifery care because of the knowledge and skills that midwives bring to the relationship. Indeed, the only reason for midwives to be involved with women is to bring this expertise. Safety is a priority for women and they expect midwives to act on their professional judgements.[4] At the same time, making professional judgements does not give midwives licence to deny women choices or to make decisions on their behalf under the guise of 'professional judgement'. Partnership requires each midwife and each woman to clarify their expectations of each other, to understand the philosophical base from which each works and to work out together the limits and extent of decision-making processes.

Partnership is linked to continuity of care because it takes time for midwives and women to get to know each other, to trust each other, to clarify and negotiate expectations. The best place for these discussions to occur, at least initially, is in the woman's home, where she is comfortable and the midwife is a guest. Working in partnership means working in a relationship where the power balance between the partners is equalised and negotiated. When midwives visit women in their homes for the booking visit, there is a subtle shift of power to the

woman, and midwives and women can get to know each other on a more personal level in an environment that is familiar to the woman. Generally, women feel more confident in sharing information and thus the midwife is able to get a sense of what matters to the woman as well as her social context.

During pregnancy

Subsequent visits can be negotiated according to both the woman's and the midwife's situations. There may be value in most of these being at the midwife's practice premises if this means that the woman will be able to meet other pregnant women and attend antenatal groups; however, there may be reasons why it suits both for all antenatal care to take place in the woman's home. Either way, as identified in Chapter 17, there are many benefits when the midwife carries out a visit in late pregnancy to bring together the woman's supporters and plan for labour and the early postnatal period (Kemp 2003). The woman identifies the people in her family/whanau and community who will play a role in her experience of labour, birth and mothering and, where appropriate, the midwife can facilitate situations that ensure these support structures thrive. She can talk through likely events and how the woman might react to them, and enable time to discuss everyone's roles and expectations.

The value of midwives facilitating groups as opposed to running classes is also discussed in Chapter 17. This approach is about a social model of midwifery care, one that sees bringing women together in groups as a crucial strategy to develop a forum where they can learn from each other and develop friendships and support networks (Leap 1991). As suggested by Mavis Kirkham, 'linking women with others makes them stronger' (Kirkham 1986, p 47). Where the focus of antenatal groups is on antenatal care as well as education and support, significant improvements in outcomes have been identified in disadvantaged communities in the United States (Ickovics et al 2003; Schindler Rising 1998).

Telling the story

Where midwives work in partnership with women, they tend to develop a different attitude towards how maternity records are developed and kept. This includes encouraging the woman to write in her notes, using woman-friendly, descriptive language, avoiding alienating abbreviations and enabling the woman to keep a copy of the record when the midwifery partnership ends approximately six weeks after the baby's birth. Anecdotal evidence suggests that women cherish the record of their pregnancy, labour and the early weeks following birth, particularly where a story has been told using language that does not shy away from emotions.

During pregnancy, women can record how they felt at each stage of their pregnancy where the record stays with the woman rather than with the caregiver or institution. The concept of 'woman-held' maternity records is increasingly being seen as an important principle in maternity care and is a fundamental component of the midwifery partnership model. However, there is still resistance to their use in some quarters where midwives are employed and therefore an overview of the evidence relating to this subject may prove useful.

Woman-held maternity records are popular with women and are widely used in New Zealand (Hendry 2003) and the United Kingdom (Hart et al 2003). In Australia, although their use has been encouraged by government policy (NHMRC 1996; NSW Health Department 2000), widespread introduction has been relatively slow. Freedom of information, access to and ownership of medical records are current and controversial issues in Australia, and the debate provokes emotional responses (Phipps 2001). However, it can be argued that where midwives work in partnership with women, the maternity record reflects the relationship and is one of the contributory factors in sharing power and shifting the dominant culture of professionalism that potentially disempowers women.

The advantages of women carrying their own maternity care notes were first argued in the 1980s in the United Kingdom (Draper et al 1986; Lovell & Elbourne 1987; Lovell et al 1986). Since then, numerous authors have identified that this initiative encourages women's active participation in their care, improves communication between practitioners, and enhances communication between caregivers and women. Furthermore, women who carry their own notes have an increased sense of control and are unlikely to lose their records (Brown & Smith 2004; Elbourne et al 1987; Fawdry 1994a,b; Holmes et al 2005; Homer et al 1999; Lovell et al 1987; Phipps 2001; Young 1991).

A WHO collaborative study in eight developing countries identified that a woman-held maternity record plays an important role in primary healthcare and health promotion. The WHO concluded that the concept should be widely adapted for local use due to its effectiveness in the promotion of continuity of care, the early recognition of 'at-risk' women, the promotion of self-referral and self-care, and the generation of local health information (Shah et al 1993). On the basis of this research, the argument has been made for the widespread use of woman-held maternity records as a tool to promote women's active partnership in their care (Fallon 1994).

The language of partnership

Consideration of how midwives engage with women around the maternity record raises issues concerning the language midwives use and how this both reflects and constructs the culture in which midwifery practice is enacted (Leap 1992). Working in partnership with women involves finding opportunities to counteract the 'official' language of midwifery, namely the language of obstetrics, with its emphasis on measuring and setting norms (Kirkham 1986, 1993, 1997). This often begins with midwives getting together to explore how language reinforces the status quo of institutions and the technocratic model of birth (Davis-Floyd 1994), but also how language can challenge power dynamics.

The next step is for midwives to engage in an ongoing process of analysing how the unfolding of this awareness is played out in practice, in particular how we avoid the tendency

to be trapped in dichotomous thinking. However, it has been suggested that in identifying the difference between woman-friendly language and the language of obstetrics, we are at risk of creating a new set of dynamics that mirror those that potentially disempower women. Fielder and colleagues (2004) have explored how the language of midwifery has a tendency to both force and reflect dichotomous thinking. They suggest that midwives have learned to think in binary opposites and that there is merit in addressing dualism in language use and the effect it has on both thinking and practice. The authors explore the types of opposites used by midwives and identify how this way of thinking has been learned from society, medicine and the culture of midwifery itself.

> Midwifery thinking and writing is full of opposites: normality-abnormality, safe-unsafe, health-illness, life-death, safety-danger (or in more contemporary jargon, risk), pathology-salutology, professional-lay, autonomy-dependency. There are also dichotomous, although less literally opposite pairs of concepts, such as breast-bottle, home-hospital, physiology-pharmacology, midwifery model-medical model, and midwife-obstetric nurse (Fielder et al 2004, p 6).

Fielder et al (2004) suggest that our expressions of opposites often imply value judgements that separate off what is unacceptable within social, medical and midwifery norms. If one side of an opposite is seen as 'good' there is the potential to demonise the other side as 'bad'. This polarisation can become a habit, manifesting in bullying behaviour and underpinning much of the horizontal violence that is endemic in midwifery practice (Leap 1997).

Dichotomous thinking also has the potential to force people and ideas into rigid standpoints that reduce richness and complexity (Sherwin 1989). According to Fielder et al (2004, p 7), the challenge is to make sure that dualistic thinking does not hamper our acknowledgement of different stages in colleagues' careers or thinking, that we continue to explore all the 'invisible between the extremes', and that we analyse and resist the effects of binary thinking on midwifery practice. This includes engaging with women around the complexities of uncertainty and questioning how our hierarchical rhetorical positioning of 'normal' affects women whose experiences fall outside such constructs.

Critical thinking exercise

1. Examine the maternity notes used in your local maternity facility. How is information recorded in these notes? Do these notes tell the story of women's experiences in pregnancy and birth? How could they be changed?
2. Midwives often resist writing stories in women's notes because they perceive that this takes too much time. What factors in your local maternity facility support story telling in the maternity notes? What factors inhibit this practice? How can these be changed?

The notion of binary opposites was initially developed by Jacques Derrida (Caputo 1997), who identified that language cannot escape the built-in biases of the cultural history that produced it. Hidden mechanisms are always at work, subtly influencing meaning in language. Identifying these underlying assumptions can be the first step in demonstrating the concealed power of symbols to shape thinking. According to Derrida (Caputo 1997), no one escapes these elusive qualities of language and being caught up in the subconscious networks of meaning that affect how we communicate ideas and experiences. As midwives, it is important to remain acutely sensitive to the conscious and subconscious historical, social and linguistic 'constructedness' of our beliefs and practices, and how, within processes of social negotiation, meanings are ever-shifting (Herrick 2001, p 52).

During labour and birth

In the current context of intervention and technology that characterises Western maternity services, it can be difficult for midwives to hold on to their belief in birth as a physiological process and to trust women's bodies to give birth. Indeed, several generations of midwives in Australia and New Zealand have had their confidence in physiological birth challenged through the twentieth century as childbirth was removed from the family and community and became instead a fragmented and hospital-based event in which midwives were unable to fully enact their 'with women' role (Davis-Floyd 1994; Guilliland & Pairman 1995). However, despite these challenges, many midwives and women have retained their belief in childbirth as a normal life event and in midwifery's expertise in facilitating this process. Latterly, the professional frameworks developed by midwifery's professional organisations in New Zealand and Australia have clearly articulated midwifery's role in promoting and protecting normal birth.

Midwives must have confidence in themselves as women and understanding of their role as facilitators and companions on a life journey if they are to instil confidence in women (Thompson 2004). Trusting the childbirth process and trusting women and their bodies is arguably one of the most important contributions midwives can make to women's sense of their ability to give birth and breastfeed their babies. Midwives have the benefit of working with many women through their childbirth experiences, and through these experiences they build up a store of knowledge of and expertise in the range of 'normal' and the varied manifestations of physiology.

When midwives see normal birth happening time and again, they develop trust in the process and confidence in women's bodies. They need to call on this belief when working with women who may only experience childbirth once or twice and who often do not have the same embedded belief and understanding of their ability to give birth. Midwives need to believe in women when women do not believe in themselves, when they are overwhelmed with the intensity of labour and have reached a point where they feel they cannot go on. This is the time for a midwife to step forward and, with certainty,

encourage and express belief in the woman so that she can move forward with support.

A key skill for midwives is in knowing when to intervene during labour and when to stand back. A balance needs to be achieved in providing support and guidance or 'hands-on' care when necessary and promoting each woman's sense of self-achievement by drawing on her own strengths and those of her family and support people.

However, staying in the background while the woman and her family take centre stage does not mean that the midwife is a spectator of an event that will inevitably unfold in a certain way no matter what is done. There are a myriad of contextual factors that can interrupt the flow of labour or challenge a woman's self-confidence. A midwife needs to be alert to these factors and work to facilitate an environment in which the woman is supported to give birth or to mother her baby in her own way. The midwife's role is one of watchful anticipation, constantly assessing what is happening with the woman and comparing it to her store of experience and knowledge (Powell Kennedy 2004). An experienced midwife will begin to recognise patterns and be able to identify when the woman's experience is no longer within the realm of 'normal' for her and when it is necessary to intervene to prevent further complications. Being able to make professional judgements and act when required is essential for the provision of safe midwifery care.

Partnership and decision-making

> If we acknowledge the importance of engagement in relationships, the process of decision-making becomes less about presenting a range of options as if they were all equal and much more about listening to women and helping them to mesh decisions with their lifestyles, beliefs and backgrounds (Thompson 2004).

Involving women in decision-making can have far-reaching implications for women as new mothers. For many women there may also be consequences in terms of learning about the life-long process of weighing up factors in order to make decisions. Within the partnership model, the midwife can enable situations in which women have a chance to develop their confidence in this area, with acknowledgement that the midwife also grapples with the uncertainty and complexity that surrounds much decision-making (Downe & McCourt 2004).

Women have identified that the amount of control and involvement they have during pregnancy, labour and the early weeks of new motherhood affects how they feel as new mothers (Green et al 1988, 2000). This sense of control is related to autonomy, which in turn is related to identity and a sense of personhood (Griffiths 1995). This notion may well be linked to the discovery that, where midwives can facilitate situations in which women are able to make decisions that are relevant to their lives, there is the potential for short- and long-term improvements to health and social outcomes (Ickovics et al 2003; Oakley et al 1996; Sandall et al 2001). However, the idea that individuals are free to make decisions that enable a sense of control needs to be addressed with caution. Often there is a denial of the role that social inequalities, particularly poverty, play in restricting the ability of women to make changes in their lives, or even to engage in a process of making choices.

The three 'C's in midwifery—choice, control and continuity of care (Page 1993)—are allied to the contemporary notion of 'informed choice' (Department of Health 1993; NHMRC 1996, 1998; Page 2000). Often there is little recognition of the complex nature of 'informed choice' and the fact that the person who does the 'informing' will play a major role in determining the 'choice' that is made (Leap 2000). Choices are limited by intersections of ideology, resources, class, race and other factors, such as obstetric regimens and value systems, over which women have little control (Leap & Edwards 2006). Recognition of these complexities is important if midwives are to engage with women in ways that recognise the pitfalls of the notion of 'informed choice' and prioritise mutual discussion and information sharing:

The technocratic culture of childbirth (Davis-Floyd 1994) maintains that decision-making in any situation should be based on the assessment of 'safety' and 'risk'. For women, safety is undoubtedly a key issue but the interpretation and meanings associated with risk and safety may be at odds with those identified by professionals. Where midwives work in partnership with women, there is the opportunity for both to explore how their individual social considerations and cultural values might affect the woman's decision-making process. This may well be more about safeguarding and promoting emotional wellbeing and personal integrity than about avoiding physical damage to their bodies and babies (Edwards 2005). Examples might include a woman who has been traumatised by a previous birth deciding to take control in a subsequent pregnancy by planning an elective caesarean section or home birth in situations where obstetric advice suggests other courses of action in the name of 'safety'.

Other examples of women making decisions that prioritise social and emotional safety occur in remote Australian communities, where women often feel that it is more dangerous to be removed from their families at 38 weeks to await birth in far-away tertiary referral hospitals than to give birth in their local communities (Kildea 2003). Some women decide not to leave their local community even though they know that there are no immediate caesarean section facilities. In many societies, particularly in rural areas, where women are expected to leave home to wait to give birth in distant maternity units, 'safety' is about protecting their other children and their homes from potential harm during their absence.

In the Northern Territory of Australia, up to 20% of Indigenous women who are flown out of their remote communities in late pregnancy to await birth in a tertiary referral hospital manage to hitch a lift back home (Kildea 1999). For these women, issues of 'safety' may include having their babies in their communities, according to customary law, surrounded by women they know, who speak their language and uphold customs that are seen to make babies strong (Kildea 2003).

In any situation where women are needing to make difficult decisions that are not necessarily straightforward in terms of recognised notions of 'safety' and 'risk', the attitudes of midwives play an important role in how women feel about the process, including how they reflect on the impact of the decisions they have made. This is especially important when midwives are challenged by the decisions that women make and find it hard to support their choices. Clear messages to women that the midwife trusts their ability to weigh up all the factors and make appropriate decisions, particularly in difficult circumstances, may go a long way to building up women's confidence in their ability to cope with the challenges of new motherhood (Edwards 2005).

Challenging the paradigm of professionalism

Working in partnership, women and midwives are truly exposed and open with each other. Each midwife is known as both a woman and a midwife to each woman she works with; it is therefore not possible for midwives to hide themselves behind their professional persona of 'midwife'.

In her research into what women want from community midwives, Ruth Wilkins (1993) discusses the emotional engagement necessary for such relationships to work well. Wilkins defines how the traditional notions of professionalism situate midwives and the women they attend in different social dimensions. She suggests that where midwives engage with women according to the ideals of professional distance, their biographical, social and psychological self is excluded from practice, leading to a distancing from women. Clinical assessment, monitoring and the giving of advice take precedence over building partnerships based on mutuality and subjectivity. In a similar vein, Mary Cronk (2000) suggests that the enacting of professional status reinforces the public perception that 'the expert knows best'. Cronk draws on transactional analysis theory to identify how this power imbalance directly reinforces a parent–child relationship that disempowers and patronises women.

In order to challenge the ideology of professional distance, midwives need to have an awareness of the potential for power imbalance within the midwife–woman relationship (Flemming 1998, 2000; Guilliland & Pairman 1995; Pairman 2000a, 2005). Applying this within each individual partnership relationship requires midwives to develop finely tuned skills in self-awareness. This includes an understanding of the potential effect of the use of self during interactions, and an awareness of the significance of informal interactions and the impact of environment on relationships. It also means resisting the pressure to give women certainty, and instead engaging with women in a dialogic process that embraces complexity and uncertainty (Downe & McCourt 2004).

Grappling with uncertainty is an ongoing process in life that is central to the challenges of becoming and being a mother (Leap 2000). The confidence to approach parenting in this way can develop when women and midwives have connection based on reciprocity, mutuality, personal disclosure and the removing of the anonymity and stereotyping that tends to dominate institutionalised care (Halldorsdottir & Karlsdottir 1996). These dynamics can most easily be encompassed within relationships involving continuity of care (Edwards 2005). Women have identified that such relationships provide the engagement, trust and nurturing needed for women to feel safe enough to move through birth to motherhood in an exciting process of discovery that is led by the woman (Edwards 2005).

As well as being a central issue for women as mothers, grappling with uncertainty is a core feature of midwifery. As midwives, we purport to engage in 'evidence-based' practice while often not recognising that there is no evidence for at least 80% of the situations we find ourselves in when it comes to 'informed decision-making' (Sackett et al 1997). Lesley Page's (2000) framework, the 'Five Steps to Evidence Based Midwifery', enables midwives to address this uncertainty around evidence. Use of this framework in practice ensures a woman-centred approach to making and reflecting on decisions in partnership.

Partnership and 'persuasion'

Interactions between midwives and women that involve mutual trust will inevitably address the conditioning that women and their families have been exposed to about birth and mothering. Sometimes this means exploring how these influences might obscure a woman's ability to make choices in her or her baby's best interest (Leap 1996b). Decisions are heavily influenced by the persuasive elements of the birth culture the woman happens to be in (Davis-Floyd & Sargent 1997). Rather than concentrating on an approach dominated by the ethos of 'informed choice', it may be a legitimate part of a midwife's role to counteract the conditioning that a woman has had that might inhibit the choices she makes. This might mean persuading the woman of the safety of home birth, for example, or convincing her to breastfeed her baby.

Many people will feel uncomfortable with this idea, given the awareness of how women are coerced within the technocratic model of birth and how easy it is to influence the decisions women make. However, it is worth considering how elements of persuasion underpin all our day-to-day interactions (Herrick 2001, 2004). To imagine that we can give information in an unbiased way without an element of persuasion is naive. It can be argued that persuasion plays a role in resistance to the highly persuasive dominant birth culture in suggesting alternative philosophies and actions. As Young (1998) discusses, positive action is needed to counteract the conditioning to which childbearing women are exposed in Western society. Women approach midwives in order to access their knowledge and experience; persuasion may therefore play an important role in how midwives

respond to the investment and trust that women place in midwives as together they explore uncertainty, potential and possibilities.

Partnerships with other midwives

Midwives do not work in isolation. In midwifery caseload practice models, midwives generally work in partnership with another midwife in order to provide a 24-hour-a-day service to women. Often a midwife-pair will be part of a larger group practice and a third midwife from this practice may also be involved to provide cover for holidays and other leave including sickness.

However, the relationships that midwives have with each other offer more than a practical 'back-up' (Leap 1996a). These relationships also have the potential to provide:

- friendship, support, laughter and fun
- reflection in and on practice (Schon 1983)
- debriefing
- the sharing of ideas, information and evidence
- a safe place to express uncertainty and fear
- mentoring and peer review
- support for students and new graduates
- opportunities to locate individual experiences in the wider political context
- strategising and action to enable political and policy change
- the breaking down of hierarchical barriers
- a sense of 'belonging' and professional identity.

It is important that midwives choose their midwife partners, as it is essential to share a similar philosophy and approach to work when sharing a caseload. Like midwife–woman relationships, relationships between midwives rely on time to get to know each other and to develop trust. According to Sandall (1997), there is an imperative for midwives to meet regularly and to decide themselves how to manage their workloads and their time off, as these factors are linked to work satisfaction and the avoidance of burnout. Midwives need to like and trust their midwife partners so they can be assured that women will receive consistent midwifery care to similar professional standards.

Midwives work in partnership not only with their midwife partner but also with midwives employed in maternity units on 'shifts'. In New Zealand, the role of these midwives has changed in response to the development of midwifery caseload practice. Currently, most women still birth in a maternity facility and the majority come into the unit under the care of their own midwife, known as their lead maternity carer (LMC). Employed midwives find themselves involved directly in the care of women with serious complications who have been admitted under the care of the hospital obstetric team, or for the few women who choose a doctor for their LMC or who arrive without a named caregiver. Therefore, a new role has been articulated for the 'core' midwife, one that is based on supporting the primary midwife–woman partnership (Campbell 2000; Pairman 2000b). The core midwife is recognised as the 'wise woman' of the maternity unit; her skills in facilitating and negotiating the interface between primary services and secondary/tertiary services have a major impact on each woman's experience of birth and each midwife's ability to continue to provide the woman's midwifery care, even when obstetric interventions may be required. In order for this to happen, both LMC midwives and core midwives have to develop clear understandings of each other's roles and the need to work in partnership in the interests of woman-centred care. These relationships are enhanced where midwives have had the chance to work in both roles.

Other partnerships: the midwife in the community

As primary health practitioners who cross the interface between hospital and community services, the majority of a midwife's work takes place in the community. This means that midwives need to have a sophisticated understanding of the importance of networking and establishing partnerships with other agencies and practitioners in their local communities in initiatives that employ the principles of primary healthcare[5] and community development.

Effective partnerships underpin the role of midwifery as a woman-centred, public health strategy (Kaufmann 2000, 2002). Midwives who are community based, providing continuity of care that 'follows the woman' across the interface of community and hospital services, are ideally placed to engage with women around strategies for health promotion, including addressing social exclusion and isolation (Leap 2004). They therefore need to understand the social determinants of health and the complex politics of how inequalities affect women's lives.

In particular, there are opportunities for midwives to 'dovetail' their services and liaise with child health nurses, well child services and community-based organisations. Because the midwife is alongside the woman on her journey through pregnancy, birth and the initial weeks of new motherhood, she is ideally placed to keep an overview of all the interacting needs of the woman in terms of accessing appropriate services and support structures. This is about physical, emotional and cultural safety. Midwives can engage with women in ways that avoid dependency and maximise the potential for women to learn from each other and build supportive networks in the community:

> The midwife maintains the 'midwifery overview' ensuring that all the interwoven elements of a woman's life are kept in relief, whatever the events that unfold. The midwife works with the woman and her community, collaborating with other health professionals if necessary, to ensure that everything is done to ensure a safe and supported transition to new motherhood, taking into consideration the woman's individual circumstances and wishes (Leap 2000, p 4).

Moving on

Giving birth is a powerful and transformative process. Women who are partners in their care with midwives and who are involved in making decisions about that care are more likely to find childbirth positive, even when they have experienced unplanned intervention. Women who have felt in control of their experiences are more likely to feel strong and independent in their roles as new mothers (Kitzinger 1991).

As the end of the midwifery relationship approaches at four to six weeks following birth, it is useful for both the woman and the midwife to reflect on the experience, including the midwifery input. Even when formal feedback is sought from women, as in New Zealand's Midwifery Standards Review Process, it is always useful to talk with women to find out which aspects of the midwife's care were useful and which were not. This enhances each midwife's opportunity to learn from each partnership relationship in terms of her personal and professional development and practice wisdom.

Ideally, at the end of the professional relationship, each woman should move on in her life with her sense of self intact, with pride in her achievements and with confidence in her mothering role. The partnership she and the woman have engaged with will have opened doors for both in terms of potential possibilities, joy and learning.

Conclusion

This chapter has explored the importance of partnership to women and midwives and has examined how midwives can work in partnerships, not only with women for whom they provide midwifery care, but also with other midwives with whom they work. A key feature of midwifery partnership is that it recognises the autonomy of both partners and therefore requires midwives to move beyond their professional persona to engage instead with women in a mutual relationship that recognises and supports women's expertise and self-determination. Partnership requires midwives to develop a key midwifery skill—achieving a balance between trusting and facilitating a process midwives know to be physiological for most women, and intervening through action when the process is no longer physiological. Keeping women and babies safe through making and acting on appropriate professional judgement is at the heart of the midwife's contribution to partnership.

Review questions

1. What is meant by the term 'midwifery partnership'?
2. Identify six essential characteristics of a partnership relationship between a midwife and a woman.
3. How might working in partnership be of benefit to women and to midwives?
4. How would you go about establishing a partnership relationship with a woman?
5. What skills might be necessary to work in partnership relationships with women?
6. How might you develop the skills necessary to work in partnership relationships?
7. What are the benefits of working in partnership with other midwives?
8. What are important considerations when thinking about entering a partnership with a midwifery colleague?
9. What role do midwives play in the interface between maternity and midwifery services and other community agencies?
10. Distinguishing between 'normality' and complications is a key midwifery role. What attributes does a midwife require to fulfill this role?

Notes

1 The word 'woman' is used here in recognition that over 99% of midwives are women. It does not mean to exclude men who are midwives, who will have other dynamics to explore within the relationship, based on the politics of gender and power relationships in society.

2 While midwifery autonomy was reinstated in 1990, the LMC model of one-to-one continuity of care did not commence until 1996. From 1990 to 1996 women could choose both a midwife and a doctor as caregivers and many did so. The LMC model requires women to choose one primary caregiver and by 2004 some 78% of women chose a midwife as their LMC.

3 WHO Technical Working Group 1999 Postpartum care of the mother and newborn: A practical guide. Birth 26(4):255–258.

4 For example, a woman who is bleeding heavily immediately following birth does not want to engage in a long conversation about her 'choices' regarding the administration of an oxytocic. She trusts the midwife's expertise in acting swiftly and appropriately in the interest of safety.

5 Equity and access, services based on need, community participation, collaboration, community based care, affordable care and sustainability.

CHAPTER 16

Working in collaboration

Sally K Tracy and Suzanne Miller

Key terms

collaboration, competency, consultation, referral

Chapter overview

Collaborative practice is integral to the safety of midwifery practice. Midwives, as primary caregivers, need to make evidence-based decisions regarding when an individual woman in their care may need a referral or consultation with another caregiver during pregnancy, labour, birth or the postnatal period. This chapter outlines the means of collaboration between midwives, the women they care for and the other health professionals with whom they may need to collaborate.

Learning outcomes

Learning outcomes for this chapter are:

1. To describe the frameworks within which midwives practise
2. To explore the nature of collaboration, consultation and referral.

Introduction

Engagement in collaborative effort is the midwife's *raison d'être*. 'Working together' is the thread that runs through every aspect of midwifery practice. The most fundamental understandings of the midwifery partnership model involve women and midwives working together to achieve positive experiences for all. Collaboration between women and midwives has undergone widespread political change throughout the late 1980s and 1990s, and has brought about the establishment of a truly women-centred maternity service in New Zealand, and a movement towards this in Australia. At every level, from the individual woman and midwife, through the professional and regulatory bodies, it is women and midwives working collaboratively who determine the vision and direction for the future of maternity services (DOH 1993; NMAP 2002; NZCOM 2005).

Midwifery care is centred on promoting and protecting birth as a normal physiological process. For most birthing women, the totality of their care falls within the scope of midwifery practice. There are occasions, however, when the complexity of a woman's experience may require that she also have some input from other health professionals. Midwives are skilled at assessing whether referral for consultation or transfer of clinical responsibility is necessary. To assist midwives with their decision-making, in both New Zealand and Australia referral guidelines have been developed that outline a range of circumstances where referral may be warranted.

Collaborative practice is integral to the safety of midwifery practice and enshrined in midwifery policy. The New Zealand College of Midwives Code of Ethics states that: 'Midwives have a professional responsibility to refer to others when they have reached the limit of their expertise' (NZCOM 2005, p 5). Similarly, the Midwifery Scope of Practice, which legally defines midwifery in New Zealand, requires that: 'When women require referral, midwives provide midwifery care in collaboration with other health professionals' (MCNZ 2004b).

The competencies for entry to the Register of Midwives provide further clarification of what generally and specifically constitutes midwifery practice, in terms of the profession's and the public's expectation of woman-centred care. The Definition and Scope of Practice provides the broad boundaries of midwifery practice, whereas competencies provide the detail of how a midwife is expected to practise and what she is expected to be capable of doing (MCNZ 2004 a,b). There are a set of minimum competencies required of all midwives who register in New Zealand and Australia. It is expected that all midwives will demonstrate that they are able to meet the competencies relevant to the position they hold (Homer et al 2005, p 5). These two competencies are reproduced in Box 16.1.

BOX 16.1 Competencies for entry to the Register of Midwives

New Zealand Competency 2

The midwife applies comprehensive theoretical and scientific knowledge with the affective and technical skills needed to provide effective and safe midwifery care.

Performance criteria:

- Assesses the health and well-being of the woman and her baby throughout pregnancy, recognising any condition which necessitates consultation with or referral to another midwife, medical practitioner or other health professional.
- Identifies factors in the woman or her baby during the labour and birth which indicate the necessity for consultation with, or referral to, another midwife or a specialist medical practitioner.
- Provides and is responsible for midwifery care when a woman's pregnancy, labour, birth or postnatal care necessitates clinical management by a medical practitioner.
- Regularly and appropriately assesses the health and well-being of the baby and initiates necessary screening, consultation and/or referral throughout the postnatal period.
- Assesses the health and well-being of the woman and baby throughout the postnatal period and identifies factors which indicate the necessity for consultation with or referral to another midwife, medical practitioner, or other health practitioner.
- Collaborates and co-operates with other health professionals, community groups and agencies where necessary.

Australian Competency 8

Develops effective strategies to implement and support collaborative midwifery practice.

Demonstrates effective communication with midwives, healthcare providers and other professionals.

- Adapts styles and methods of communication to maximise effectiveness.
- Uses a range of communication methods including written and oral.
- Liaises and negotiates with colleagues at all levels to build systems and processes to optimise outcomes for the woman.
- Discusses and clarifies with relevant healthcare providers interventions that appear inappropriate or unnecessary and negotiates a collaborative plan.
- Demonstrates effective communication during consultation, referral and handover.

Establishes, maintains and evaluates professional relationships with other healthcare providers.

- Recognises the role of other members of the healthcare team in the provision of maternity care.
- Identifies and responds to factors that facilitate or hinder professional relationships.
- Invites, acts upon, and offers, constructive feedback on midwifery practice from peers and colleagues.

(Sources: ANMC 2005; MCNZ 2004a)

Systems that enable midwives to work collaboratively are valued. The components of supportive systems include effective communication, consultation and referral between professionals. A collaborative relationship with medical colleagues is an important aspect of midwifery practice.

Collaboration also includes working with others when the care of women falls outside the midwives' scope of practice. For example, the care of women with mental health conditions is seen as one area where collaboration is particularly needed (Homer et al 2005).

The nature of collaboration

Successful collaborative practice requires several conditions. First, and most importantly, the woman must remain at the centre of the process. In order that she may participate in informed decision-making, information-sharing must occur in a context where her values and philosophical beliefs are respected and upheld. Midwives can assist women to critically examine the evidence presented to them, and help them make sense of those aspects that appear conflicting or inconclusive. When the woman is central to the collaborative process, her ability to tease out the important elements (to her) of both midwifery and obstetric practice will mean that she can formulate a plan of care that will best meet her needs. Edwards (2000, p 81) uses the phrase 'a potentially radicalising effect on the maternity system' to describe what can happen when the relationships between caregivers and women become the organising principle around which care is structured.

Many scholars have added depth to the discussion of preconditions for successful collaborative practice. Dorne has drawn together a number of these in what she describes as the Ten Major Tenets of Collaboration (Dorne 2002, p 17). They are as follows:

- provision of a non-competitive/non-hierarchical environment
- partnership between parties based on shared power and authority
- the ability to jointly define work processes, relationships, mutual objectives and goals
- joint responsibility/accountability for decision-making
- secure self-identity enabling clearly defined roles, with an emphasis on the function of each party
- power based on knowledge/expertise as opposed to power based on role and role function
- mutual trust, respect, cooperation and commitment
- time and space for open and effective communication and conflict resolution
- recognition/valuing of how differing perspectives inform decision-making
- interdependence of work with dependent/independent functions within the collaborative practice.

It is easy to see how these theoretical aspects could fit within the context of midwifery/obstetric collaborations. In practice it must be acknowledged that a maternity service that contains all these elements is rare, but certainly an admirable goal. It must be remembered also that midwives are accountable for their midwifery actions, regardless of who accepts 'clinical responsibility'.

Stapleton (1998) builds on the idea of mutual trust and respect as essential attributes of collaboration, and explores the notion of professional maturity. She believes that 'individuals who feel secure and competent professionally can communicate their discipline's strengths, value, limitations and contributions to colleagues from other disciplines' and adds that this requires 'a high level of professional maturity and confidence in one's professional knowledge and clinical skills' (Stapleton 1998, p 14). Effective communication is another crucial prerequisite for working together. It requires that 'members listen to each other's perspective yet are assertive in presenting their point of view' (Henneman et al 1995, p 106).

Midwives participating in a reflective midwifery partnership are in a position to have a positive impact on women's experiences in situations where referral is required. In addition to honouring the woman's own knowing about herself and her body, she can assist the woman to educate herself well, so that the consultation is not one in which the 'specialist' is the only 'expert'. Thus a woman will ask the questions that will *meaningfully* aid her decision-making, rather than following a predetermined protocol that may not reflect her values or beliefs. Whilst it is true that some obstetricians find this challenging, it can only serve to expand their horizons and increase their understanding of childbirth not just being about the removal of a baby from a woman's uterus.

Midwives need to remain mindful of the fact that *within* midwifery there is an enormous resource and body of knowledge, and that sometimes it is to our colleagues that we should turn for discussion and advice. Experienced midwives know well how judicious one needs to be about some indications for referral—the 'large-for-dates' baby, for example. We need to be clear that the experience of consultation will not negatively affect the woman's confidence in her ability to birth normally when the obstetrician has told her she has a high likelihood of needing a caesarean section. We are of course obliged to discuss the recommendation for referral with the woman, and support her decision to consult or not, as the case may be. But we need to balance the content of her consultation with midwifery knowledge about moulding, pelvic mapping, optimal baby positioning, working with labour pain, and mobility in labour to enhance her likelihood of normal birth.

Sometimes the woman may request referral, or may self-refer to health professionals other than obstetricians/paediatricians/anaesthetists. It might be an acupuncturist, osteopath, homoeopath or naturopath who can best assist with the particular issue the woman faces. A respectful collaborative process can be achieved here also. Indeed, because of a greater appreciation for holism displayed by complementary therapists, many midwives find working alongside these practitioners very fruitful and mutually satisfying for all involved.

Professional collaborations

The midwifery profession is becoming increasingly involved in building relationships with the professional bodies of other health disciplines. This is to ensure that those involved in the production of clinical guidelines for practice, and policy discussions are aware of the full scope of midwifery practice. This 'top down' approach also ensures that the voice of pregnant women is heard at the highest levels, as an expectation of consumer involvement operates at this level also.

Two recent examples of this in New Zealand have been the participation by midwives in the GBS New Zealand Consensus Working Party, which has produced guidelines for risk assessment and treatment approaches for Group B Streptococcus infection (MOH 2005), and the New Zealand Guidelines Group, a collaboration between midwives, obstetricians, consumers, paediatricians, GPs, maternity managers and midwifery and medical educators, which has produced best practice guidelines in relation to the care of women with breech presentation or previous caesarean birth (New Zealand Guidelines Group 2004). These documents contribute much to our understanding of evidence-based care and will lead to increased consistency of advice to pregnant women faced with making decisions about aspects of their care.

The New Zealand Referral Guidelines

In New Zealand, the Referral Guidelines are contained in Appendix 1 of the Notice Pursuant to Section 88 of the New Zealand *Public Health and Disability Act 2000*.

The stated purpose of the Guidelines is that they be 'used to facilitate consultation and integration of care, giving confidence to providers, women and their families' (Ministry of Health 2000, p 31). Circumstances in which the Guidelines may be varied are outlined, acknowledging the fact that midwives and others providing maternity services have a wide range of skills, and that where one's level of expertise allows, departures from the Guidelines may occur. In this instance, the midwife should be able to justify her course of action, and documentation reflecting the process of information sharing and decision-making with the woman should appear in the clinical record.

The process of referral can take many forms. In general, the booking interview is often the time when the woman will disclose a situation that may require referral. If this is because of something in her medical or maternity history, the midwife can discuss the recommendation for referral and, with the woman's informed consent, initiate the process immediately. Other indications for referral may arise later in the pregnancy—for example, the discovery of a twin pregnancy, or breech presentation that persists near term. Referral will occur in such instances as the particular issue arises.

If after discussion of the recommendation for referral the woman consents to consult, the midwife is responsible for writing a letter to request a consultant review. This letter should provide enough pertinent information to enable the obstetrician to adequately assess the woman's situation. At the very least, the letter will contain:

- the woman's name, address, date of birth, National Health Index number, gravidity/parity and contact details
- the reason that referral is sought
- a brief statement outlining her medical and/or maternity history
- any relevant supporting documentation (e.g. blood test or ultrasound reports)
- her lead maternity carer's name and contact details.

Whether or not the midwife accompanies the woman to the appointment is negotiated between the midwife and the woman. Some advantages of having the midwife present are that it can facilitate the process of 'three-way discussion' more easily, and some women find that the presence and support of the midwife can make the encounter less stressful. The midwife will be able to interpret the content of the discussion after the appointment if any issues need clarification. On the other hand, some women feel that the presence of the midwife might cause the obstetrician to withhold certain information or to consider the woman incapable of understanding complex information or needing her 'hand held' in some way.

The main outcome of the consultant review will be the formation of an ongoing plan of care that reflects the woman's informed choices regarding who will have clinical responsibility, who will provide her primary care if transfer occurs, and if not, then whether and when further consultation should occur. All these decisions should be clearly documented in the clinical record so that there is no confusion as to roles and responsibilities. Referral for consultation does not imply that the clinical responsibility for the woman's care will be assumed by the secondary service.

The Guidelines define three categories or 'levels of referral' and consequent action.

Level 1

The lead maternity carer (LMC) ***may*** *recommend* to the woman (or parents in the case of a baby) ***that a consultation with a specialist is warranted*** given that her pregnancy, labour, birth or puerperium (or the baby) is or may be affected by the condition. *Where a consultation occurs, the decision regarding ongoing clinical roles/responsibilities must involve a three-way discussion between the specialist, the LMC and the woman concerned. This should include discussion on any need for and timing of specialist review.* The specialist will not automatically assume responsibility for ongoing care. This will depend on the clinical situation and the wishes of the individual woman.

Level 2

The LMC ***must*** *recommend* to the woman (or parents in the case of a baby) ***that a consultation with a specialist***

is warranted given that her pregnancy, labour, birth or puerperium (or the baby) is or may be affected by the condition. *Where a consultation occurs, the decision regarding ongoing clinical roles/responsibilities must involve a three-way discussion between the specialist, the LMC and the woman concerned. This should include discussion on any need for and timing of specialist review.* The specialist will not automatically assume responsibility for ongoing care. This will depend on the clinical situation and the wishes of the individual woman.

Level 3

The LMC ***must*** *recommend* to the woman (or parents in the case of a baby) ***that the responsibility for her care be transferred*** to a specialist given that her pregnancy, labour, birth or puerperium (or the baby) is or may be affected by the condition. *The decision regarding ongoing clinical roles/responsibilities must involve a three-way discussion between the specialist, the LMC and the woman concerned.* In most circumstances the specialist will assume ongoing responsibility and the role of the primary practitioner will be agreed between those involved. This should include discussion about timing of transfer back to the primary practitioner.

The Australian Midwifery Consultation and Referral Guidelines

The aim of the *National Midwifery Guidelines for Consultation and Referral* (2004) is to provide an evidence-based, national framework for consultation and transfer of care between midwives, doctors and other professionals, and to promote a system of care based on the principal of close cooperation between primary-, secondary- or tertiary-level maternity caregivers and the woman involved:

- at booking
- during pregnancy and the antenatal period
- during labour and birth
- during the postnatal period.

Primary maternity care is where the responsibility for maternity care rests with the primary-level maternity care provider—in this case, the midwife. Secondary maternity care is where the responsibility for maternity care rests with the medical practitioner, such as a GP or specialist obstetrician, or the medical staff on duty in the referral hospital. Tertiary-level maternity care is when responsibility for maternity care rests with a team of providers in a tertiary-level hospital. This may include an obstetrician and/or physician who specialises in fetal–maternal medicine, neonatology or other highly specialised services.

The Guidelines (2004) reflect the following guiding principles:

- As a primary caregiver, the midwife, together with the woman, is responsible for decision-making.
- An informed-choice agreement between the midwife and the woman at booking should outline the extent of midwifery care, in order to make women aware of the scope and limitations of midwifery care. This will include an explanation of these Guidelines with the woman.
- If problems occur during pregnancy or birth, the midwife may consult with her peers in the first instance, or consult directly with a secondary- or tertiary-level caregiver and refer when appropriate.
- The midwife discusses care of a woman, consults, or transfers primary care responsibility according to the Guidelines.
- The secondary- or tertiary-level care provider may also refer the woman back to primary care at any time if the condition that prompted referral is no longer a risk factor.
- The severity of the condition will influence these decisions.

Three main steps in consultation and referral

(The information in this section is from the Australian College of Midwives (2004) *National Midwifery Guidelines for Consultation and Referral.*)

When an abnormality or complication presents during a woman's care, it is recommended that the midwife undertake one or more of three main steps:

A Discuss the issue/condition with another midwife and/or with a medical colleague.
B Consult with a medical practitioner.
C Transfer responsibility for the woman's care to a medical specialist.

A. Discussion with another midwife and/or with a medical colleague

a The midwife may recommend to the woman (or parents in the case of the baby) that consultation with a medical practitioner is warranted, given that her pregnancy, labour, birth or postnatal time (or the baby) may be affected by the condition.
b It is the midwife's responsibility to initiate a discussion with, or provide information to, another midwife or medical practitioner, with whom the care is shared, in order to plan and provide care appropriately.
c Where a consultation occurs, the decision regarding ongoing clinical roles/responsibilities must involve a three-way discussion between the medical practitioner, the midwife and the woman.
d This should include discussion of the need for (if any), and timing of, medical practitioner review.
e The medical practitioner will not routinely assume responsibility for ongoing care. This will depend on the clinical situation and the wishes of the individual woman.
f Areas of discussion and involvement must be clearly agreed upon and clearly documented.

B. Consultation situation

a A consultation refers to the situation where a midwife recommends the woman consult a medical practitioner,

or where the woman requests another opinion of a medical practitioner.

b The individual situation of the pregnant woman is evaluated and agreements are made about the responsibility for maternity care based on the Guidelines.

c It is the midwife's responsibility to initiate a consultation and to clearly communicate to the medical practitioner that she is seeking a consultation.

d The consultation involves addressing the issue that led to the referral, a 'face-to-face' assessment, and the prompt communication of the findings and recommendations to the woman and the referring professional.

e Where a consultation occurs, the decision regarding ongoing clinical roles/responsibilities must involve a three-way discussion between the medical practitioner, the midwife and the woman concerned. This should include discussion on any need for, and timing of, medical practitioner review.

f The medical practitioner or midwife will not automatically assume responsibility for ongoing care. This will depend on the clinical situation and the wishes and needs of the individual woman.

g After consultation with a medical practitioner, it should be clear whether primary care and responsibility:
   1 continues with the midwife, or
   2 is transferred to the medical practitioner.

h The medical practitioner may be involved in, and responsible for, a discrete area of the woman's care, with the midwife maintaining overall responsibility within her scope of practice.

i Where urgency, distance or climatic conditions make a 'face-to-face' consultation between a woman and a medical practitioner impossible, the midwife should seek advice from the medical practitioner by phone. The midwife should document this request for advice in her records, and discuss with the woman the advice received.

j Areas of discussion and involvement must be clearly agreed upon and clearly documented.

C. Transfer to secondary or tertiary care

a When primary care is transferred, permanently or temporarily, from the midwife to a medical practitioner, the medical practitioner assumes full responsibility for subsequent decision-making in consultation with the woman.

b When primary care is transferred to a medical practitioner, the midwife may continue to provide midwifery care and support within her scope of practice, in collaboration with the medical practitioner.

c Areas of discussion and involvement must be agreed upon and clearly documented (ACMI 2004, pp 11–13).

The Guidelines include a summary of these responsibilities (Table 16.1) and a decision diagram for use by midwives (Fig 16.1).

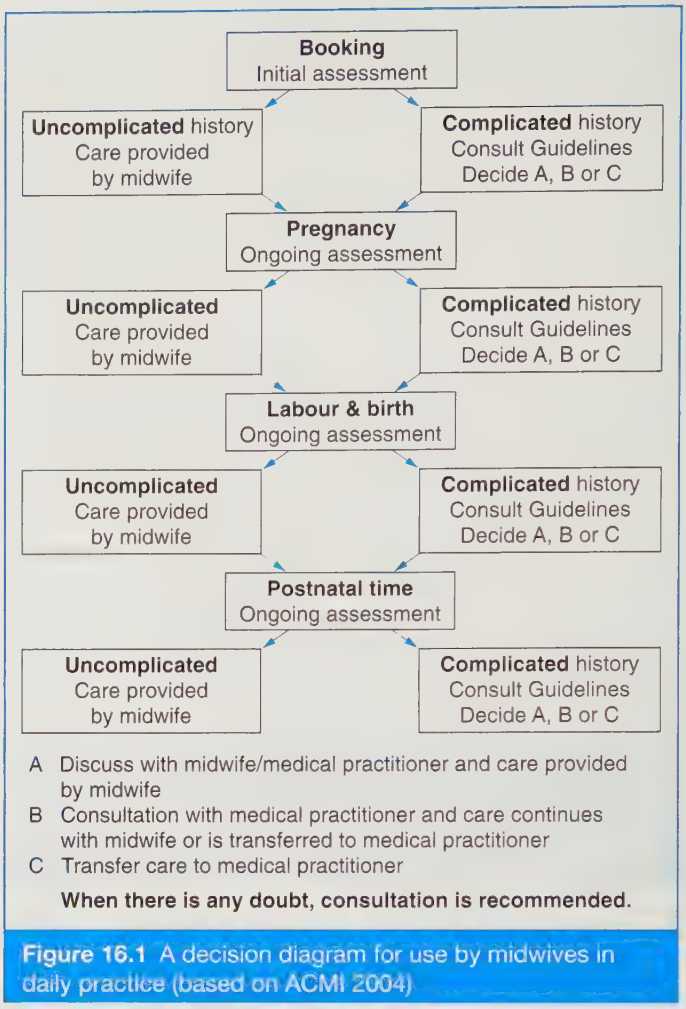

Figure 16.1 A decision diagram for use by midwives in daily practice (based on ACMI 2004)

Conclusion

Collaboration in maternity care involves the incorporation of the woman as partner in all decision-making processes in addition to working with others to implement the most appropriate and effective care. The challenge of collaborative practice is always to find a balance between midwifery skills, the notion of intensive 'presence' and minimal intervention, and the practice of medicine, in particular obstetrics, with its emphasis on technological expediency. Achieving collaboration and cooperation between the professional groups involved in maternity care involves recognising and acknowledging each other's particular expertise. Birth is a disorderly business. The multiple strategies of midwifery practice are negotiated through the intensity and immediacy of each birth experience, rather than defined in advance (Maher & Souter 2002). The way midwives work with each other, with women and with their professional colleagues shapes the experience of birth for both women and their families.

TABLE 16.1 Summary of responsibilities

Code	Description	Care provider
A. Primary maternity care	The responsibility for maternity care in the situation described is with the midwife.	Midwife
B. Consultation and possible transfer of care to medical practitioner	Evaluation involving both primary and secondary care needs. Under the item concerned, the individual situation of the woman will be evaluated and agreements will be made about the responsibility for maternity care.	Medical practitioner and/or midwife, depending on agreements
C. Transfer of care to medical practitioner	This is a situation requiring medical care at a secondary or tertiary level for as long as the situation exists.	Medical practitioner (Where appropriate the midwife continues to provide midwifery care or support.)

(Source: ACMI 2004)

Clinical scenario

'Megan' (35 years old) came to me to discuss the provision of midwifery care for her fourth pregnancy. Her maternity history was as follows:

1988 SRM at 32/40. Syntocinon induction leading to spontaneous vaginal birth of 1900 g daughter
1990 40/40 Normal birth of 3090 g daughter
2001 40/40 Normal birth at home of 3250 g daughter.

Megan's third pregnancy had been complicated by a diagnosis of pulmonary embolus at 32/40 gestation. For the remainder of that pregnancy, Megan had injected herself daily with the anticoagulant medication Clexane. Postnatally she medicated with warfarin for four months, which involved daily blood tests for the first couple of weeks to monitor her INR ratio. Megan gave birth to this baby at home 'against medical advice', with the support of two experienced midwives. She had now moved cities and wanted to plan a similar experience for this baby's birth. Megan had made many dietary and lifestyle changes since the birth of her third child. She had stopped smoking, and was taking flaxseed oil and vitamin E supplements.

I discussed the Referral Guidelines with Megan, with particular reference to the fact that a history of PE was a 'Level 3' indication for referral, i.e. that I must recommend that her care be transferred to a specialist. At this stage Megan was happy to be referred to a haematologist, but not to an obstetrician. Her perception was that this wasn't about birthing her baby, it was about avoiding the recurrence of clot formation, and that for her a haematologist was the more appropriate person to see. Megan also had a consultation with a local GP who specialises in nutritional medicine, in order to confirm that the supplements she was taking were the most appropriate dosages, and were safe to continue taking during pregnancy.

Megan saw the haematologist, who recommended that she wear TED stockings, and begin taking Clexane at once. Megan was very reluctant to begin medicating in the absence of symptoms. Together we explored the evidence for thromboprophylaxis in terms of its effectiveness in reducing the incidence of recurrent clot formation, and its safety profile both in pregnancy and during lactation. Megan found the Royal College of Obstetricians and Gynaecologists Guideline 'Thromboprophylaxis during pregnancy, labour and after vaginal delivery' (Nelson-Piercy 2004) very useful in assisting her decision-making about whether or not to anticoagulate this pregnancy, because it described a number of clinical scenarios and what to do for each. Megan was able to identify her own particular risk profile, which included having four persisting risk factors (her age, her past history of PE, her prothrombin gene mutation, and her protein S deficiency). This enabled her to make an informed choice, which ultimately led to her beginning Clexane at 23/40 into her pregnancy. Megan was thrilled to have made it to this gestation without taking medication.

Further discussion took place between Megan and myself about the advisability of also consulting an obstetrician. I was clear with Megan that I needed to be able to demonstrate that she had made an informed decision regarding place of birth, and that even though we had discussed at length the pros and cons of home birth in this situation, I needed to be sure that she had had the opportunity to discuss it from an obstetric point of view too. We talked about how the decisions she made could affect me

Clinical scenario—cont'd

professionally in the event of an adverse outcome. Even though she accepted full responsibility for her decisions, the process that could ensue in this circumstance could involve her and her family in a lengthy process if a complaint was laid by a third party. Megan agreed to see an obstetrician, and by now her clinical record was becoming fairly full, with the content and outcomes of every discussion being carefully documented!

Megan's visit to the obstetrician was disappointing. We were hoping to achieve a respectful collaborative process, but instead the consultation resulted in Megan's even stronger resolve to avoid the secondary service at the hospital. The first question that was asked of her was whether or not she intended to 'hand over care'. Megan replied that she needed to know what care was being offered by the hospital in order to make that choice. Megan outlined that for her the critically important thing was that her midwife would be able to remain involved in her care. In this institution, if a woman's reason for referral is a '3' and care is transferred, the midwife can no longer provide the primary midwifery care. At this point the obstetrician stated that there wasn't much point in continuing the conversation, except to suggest to Megan that she ought to think about how it would feel for her husband if she died and he was left to raise four children alone.

The remainder of Megan's pregnancy was straightforward. She remained in my care and had two more appointments with the haematologist, who assisted us in formulating a plan of care regarding how to manage the Clexane/warfarin transfer at the time of labour. Her GP worked with us to order blood tests that were outside the scope of what a midwife can normally prescribe. Megan went into spontaneous labour at 38/40, and birthed her beautiful first son at home in three hours. She had a physiological third stage and her blood loss was minimal. She took warfarin for six weeks postnatally.

I think Megan's story serves us well in illustrating how collaboration can occur in an environment where mutual respect and trust are present. There was clear role definition between myself, the GP and the haematologist. Where professional trust and respect were absent, collaboration could not happen effectively. Because there was a perceived 'overstepping' of my midwifery scope of practice, and because of policy constraints that precluded my ongoing involvement, the obstetrician was unable to accommodate Megan's informed choice to have me remain involved in her care.

It should be remembered that the 'outcomes of maternity care that are of concern to midwives are broader than just measures of mortality' (Page 2000, p 69). When women are making assessments about risk, they may weigh up risk and safety in ways that differ from ours. It may be their view that 'hospital birth itself poses physical and emotional risks because of the greater likelihood of invasive and damaging interventions' and that their 'attempts to decrease risk, by avoiding technology, unfamiliar surroundings and strangers, could be interpreted from the standpoint of medical ideology as increasing risk' (Edwards 2000, p 65).

In Megan's case, as well as determining her 'risk factors', we endeavoured also to look at those factors that could reasonably lead us to expect a good outcome, 'salutary factors' in the new jargon (Downe 2004, p 18). Megan had already given birth at home whilst on anticoagulant medication, without adverse events occurring, and had 'normal' postnatal progress. I believe that it is important to balance what we know from research, with what else we know from experience, wise clinical judgement and what the woman brings to the equation too. This fits neatly with White's assertion that 'reflective practice is a legitimate way of generating . . . knowledge' and that '"clinical artistry" is as essential as scientific or empirical evidence' (White 1997, p 175).

Review questions

1. Describe the central tenets of collaborative practice.
2. Is *cooperation* different from *collaboration*? If so, in what way?
3. How would you describe national competency standards to a new intake of midwifery students?
4. What are the 'domains' of midwifery competency?
5. Describe, in your own words, what you understand as the competencies that relate to legal and professional responsibilities.
6. What do you understand by the statement: 'Midwifery is a public heath strategy'? How would you describe the need for collaboration in this strategy?

Review questions—cont'd

7 Describe the competencies that relate to the performance of midwifery practice, including assessment, planning, implementation and evaluation.

8 How legally binding are the consultation and referral guidelines that guide your practice?

9 How would you describe the complementary roles of midwives and obstetricians?

10 What do you understand by the notion of 'turf war'? How can this be addressed in practice?

CHAPTER 17

Promoting physiological birth

Nicky Leap

Key terms

antenatal groups, community midwifery, empowerment, home birth, interdisciplinary learning, interdisciplinary rivalry, midwifery caseload practice, midwifery continuity of care, normal birth, pain in labour, physiological birth, social support, 36-week home visit

Chapter overview

The focus of this chapter is the promotion of physiological birth by midwives. Strategies are suggested, including the need to develop systems and an organisational culture that nurtures the potential of birth to transform lives and strengthen women, their families and societies.

The imaginary story of the birth of Jason Smith, presented in this chapter as a scenario, can be used for discussion and analysis in small groups. As a similar group exercise, practitioners and students can present 'real life' stories from practice in order to analyse the factors that can promote or inhibit physiological birth in any given situation. Such an exercise can be incorporated in continuing professional development exercises such as peer review, interdisciplinary learning, case review and workshops.

Learning outcomes

Learning outcomes for this chapter are:

1. To explore the practicalities, sensitivities and systems that promote physiological birth
2. To highlight the factors and organisational culture that can inhibit this approach in midwifery practice.
3. To explore the evidence concerning continuity of midwifery care
4. To provide information about midwifery practices that enhance physiological birth.

Introduction

In this chapter, the phrase 'promoting physiological birth' is used deliberately as an alternative to the commonly heard phrase 'the midwifery art of keeping birth normal'. As Holly Powell Kennedy (2004) has suggested, the notion of 'normal' is hardly in keeping with the midwifery philosophy of embracing the concept of each woman's birth being viewed by her as essentially 'special'. However, women and most maternity care providers are unlikely to use the term 'physiological', and the word 'normal' is embedded in the documentation and discourses that shape and reflect contemporary maternity service provision. Importantly, the term 'normal' is used to identify the primary domain of the midwife, a sphere of practice that is clearly defined as separate from the technological or medical interventions associated with complications, identified here by the World Health Organization (WHO):

> The midwife appears to be the most appropriate and cost effective type of care provider to be assigned to the care of normal pregnancy and birth, including risk assessment and the recognition of complications (WHO 1996, p 6).

Fulfilling this role is not as straightforward as it might seem. Midwives in Western countries often work in hospitals where computerised summaries identifying 'normal birth' do not necessarily reflect physiological processes or the efforts of practitioners to promote physiological birth. This was identified in an important epidemiological study of 1464 births in five consultant maternity units in the United Kingdom (Downe et al 2001). Once women who had artificial rupture of membranes, induction and acceleration of labour, epidural anaesthesia or episiotomy were removed from the equation, only 16.9% of women having their first baby and 30.1% of women having a second or subsequent baby could be classified as having a 'normal' birth. This study shrinks the domain of midwives as 'guardians of the normal' and raises questions as to whether we are 'failing' in this role (Beech 1997). Furthermore, there are mounting concerns about the limited learning opportunities for practitioners where the promotion of physiological birth is limited by 'technocratic' approaches in institutions (Davis-Floyd 2001; Kitzinger 2000; Leap 2002).

In suggesting strategies to promote physiological birth, this author is mindful of the fact that the majority of midwives are working in institutions where 'normal' birth is not the most common experience for women. The underlying power dynamics in these situations can subvert the efforts of midwives to promote physiological birth and practise according to their full role and scope of practice. Addressing these issues starts with an understanding of how these dynamics have evolved over recent centuries.

The midwife as 'guardian of the normal'

A long history of interprofessional rivalry lies behind the 1996 WHO statement and the contemporary rhetorical notion of the midwife as 'guardian of the normal'. Before men entered the birthing arena, most women in European countries were attended at home by women they knew, one of whom might well be referred to as 'the midwife' due to her acknowledged role and expertise (Wilson 1995). If problems occurred, it was not unusual for a more experienced midwife to be called to help out. As described in the diaries of Catherine Schrader, a seventeenth-century midwife who was called to complicated births in Holland, this often involved internal podalic version and bringing the baby out by its feet (Marland 1987).

A core professionalising strategy used by midwives in Western countries in the eighteenth and nineteenth centuries was the relinquishing of complicated (and lucrative) birth practice to the medical profession in return for the domain of 'normal childbirth' (Donnison 1977; Leap & Hunter 1993). This strategy responded to, and set up, a dynamic that has had far-reaching consequences in terms of gender and class inequalities and the collective psychological effects of subordination (Witz 1992). Pathology was the pivotal factor for role division, and doctors were presented as the superior professionals, educated at a higher level than midwives in order to carry out rescuing manoeuvres associated with the complications of childbirth. In comparison, the midwife's role was shrunk to that of 'caring' for women who did not need interventions, and to recognising problems and calling for a doctor to 'correct' the situation and intervene in a timely fashion.

The fraught negotiations that led to the role delineation between midwives and doctors have given way to a situation with its own set of interprofessional tensions. While fulfilling the imperative to adopt good collaborative relationships with obstetricians in the interests of women and safe practice, the midwife often defines the boundaries of 'normal' in situations that are intricate and unclear. She[1] engages with women and makes decisions in a culture dominated by the ideologies of authoritative medical science and its quest for certainty. Evidence-based protocols and policies often do not 'fit' with the complexity of individual women's psychosocial situations and the impact of the environment. This has led to a childbirth culture in which it is increasingly difficult to find consensus on what constitutes 'normal birth' other than an absence of technical intervention (Downe & McCourt 2004).

The rationale for promoting physiological birth

The boundaries of what is considered 'normal' are at the heart of the passionate discussions that happen whenever midwives

get together. In recent years, midwives have been addressing these issues by identifying the complexity of their role in being 'with woman' and promoting physiological birth. This is often explained in terms of the potentially self-transformative nature of birth and the profound long-term consequences of empowerment for women, their families and society (Leap 2004; Leap & Anderson 2004). The promotion of physiology begins in early pregnancy and is about far more than aiming for an uncomplicated birth. It is concerned with a journey to motherhood that will have profound consequences for each individual woman in terms of how she feels about herself, her body and her capabilities (Thompson 2004). Whether or not she eventually gives birth without intervention, a woman who feels powerful is in a good situation to take on becoming a new mother.

> Birth is not only about making babies. Birth is also about making mothers—strong, competent, capable mothers who trust themselves and know their inner strength (Katz Rothman 1996, pp 253–4).

Sadly, the opposite is also true—women can end up feeling disempowered and emotionally fragile as a result of an experience of childbirth that rendered them passive in the face of intervention (Kitzinger 2000). This chapter explores some of these issues, relating them to the practicalities of midwifery practice and initiatives that optimise women's potential to feel good about their experiences of pregnancy, giving birth and nurturing a new baby. Some strategies are suggested that might help to promote physiology, even in situations where midwives are 'swimming against the tide' of interventionist thinking. The word 'interventionist' rather than 'medicalised' is used in an attempt to acknowledge that it is not only doctors who can hinder physiological birth.

The imaginary story below will be used to tease out some of these issues. Within the culture of maternity care in industrialised countries, where health professionals who are strangers to the woman often provide fragmented care in busy, under-staffed maternity units, this is a familiar story.

This story describes well-meaning midwives and doctors struggling to provide a safe, kind service under conditions

Scenario

The birth of Jason Smith at St Average Hospital

This is an everyday story about the birth of a baby at St Average hospital. It's the story of the birth of Jason Smith, first child of Mary and Wayne Smith. Mary is a receptionist in a hotel and has continued working up until she was 34 weeks pregnant. She has not had any problems in her pregnancy and has been coming to the antenatal clinic regularly, where, after waiting for over an hour, she has seen a different person at each visit for a 15-minute check-up. She attended antenatal classes at the hospital but could not persuade Wayne to come with her to these. Wayne is a motor mechanic. He's a shy man who doesn't like hospitals. Secretly he's very worried about being with Mary when she's in labour. He's scared that he'll faint, and is worried about seeing Mary in pain. He didn't want to go to the classes in case they showed a video that might make him pass out or want to vomit. He has heard stories from his mates at work that make him shudder. Mary found the classes useful. They reinforced her idea that she would 'try for a normal birth', but it is comforting to know that the epidural is there if she can't cope.

One Sunday evening, a week past her due date, Mary starts having some low, period-type pains. She thinks her waters may have broken. She is very scared, and so is Wayne, who rings the hospital. The midwife on the phone asks him a lot of questions: 'How often are the contractions?', 'How long do they last?', 'What colour is the water?', ' Is the baby moving?'. The midwife suggests that it may be early days yet but to come in if they're worried. They are worried. They go in to St Average.

When Mary and Wayne get to the 'delivery suite' at St Average, they are assigned to the care of midwife Sally, in Room 11. Sally is friendly and efficient, asks Mary lots of questions, including whether she has been to classes and what her choices are for pain relief. Mary says she's not sure how she'll cope, as she has a low pain threshold and already these pains are severe. The midwife says, 'We'll take it one step at a time, shall we? You're coping well at the moment.' She talks Mary and Wayne through all the 'natural' methods of pain relief, and then explains that if Mary can't cope with the pain, there are other things to help—she explains the pros and cons of gas, pethidine and epidurals.

Sally the midwife gives Mary a hospital gown and carries out a series of tests—takes Mary's temperature, pulse and blood pressure, tests her urine, and palpates her abdomen. She places Mary on the monitor and explains the trace to Wayne, who is fascinated and remains glued to every variation in the lines. Sally reassures Mary that the baby's heartbeat looks really good. She explains that she is looking after someone in the room next door, that she'll come back in ten minutes. She gives them a bell to ring if they need her.

It will be a while before Sally can get back to Mary. Next door, Sophie's contractions are suddenly very strong. She is having her second baby, and in order to have continuity of care with someone she trusts, Sophie has booked with a private obstetrician, Edward Richman. Sally helps her get down onto all fours on a mattress on the floor. Sophie is bellowing. Sally asks someone to phone Dr Richman to come.

Scenario—cont'd

He arrives ten minutes later as the baby's head is crowning. Edward insists that Sophie get up onto the bed, cuts an episiotomy and hands her a healthy baby girl, who will be called Anna. Sophie and her partner thank Edward profusely. There is much jubilation all round.

Meanwhile, back in Room 11, Mary and Wayne are still anxiously watching their baby's heartbeat on the monitor. Eventually Sally asks Rita, another midwife, to go and check on Mary. They all look at the trace and admire its reassuring variations. According to the machine, Mary is having what Rita interprets as 'irregular tightenings'. Mary says that they are quite painful and Rita responds gently by telling Mary that she's doing really well and that 'Bub's happy' but it looks as though it's early days yet. She asks Mary what she has decided she'd like for pain relief if she needs it later. She reiterates what is on offer and tells Mary that, as her waters may have broken, the doctor will come and examine her and have a look at her cervix using a sterile speculum.

Alexandria, the new resident, examines Mary. She is kind and gentle but Mary finds the examination painful. Alexandria asks Mary what choices she has made for pain relief. She reassures her by saying, 'It's great if you can manage the pain but you don't have to be a martyr. If you're going to have an epidural don't wait until it's really bad before getting it inserted'.

It seems that Mary's waters have broken but her cervix is still long and firm. She is offered the choice of going home and waiting for the contractions to establish, with daily review at the hospital, or having a 'bit of help to get things going'. She is too scared to contemplate going home and the thought of 'getting things going' is appealing. Mary has some prostaglandins to help soften her cervix. She is given some sedatives to help her get some sleep, and Wayne goes home to get some rest.

The ensuing chain of events over the next day is familiar to all who have worked in large maternity units. For Mary these events will remain embedded in her memory until the day she dies. She was very grateful to have an epidural to help her cope with the fierce contractions induced by a Syntocinon infusion. The pethidine she had had earlier hadn't touched the pain. She had a kind midwife called Sandra with her for most of the labour. Sandra was a mature woman whom Wayne would later describe as 'really knowing her stuff'.

Little Jason Smith is pulled into the world with the aid of a Ventouse after the monitor showed signs that he really would be 'better off out than in'. He is a fine, healthy baby, albeit a little confused about how to find his way around Mary's breast. He is taken to the nursery for a few hours to be observed because he is 'breathing up a bit'.

Wayne didn't faint. He is in awe of Mary and thanks God for the 'life saving wonders of modern medicine'. Mary and Wayne are very grateful to the staff of St Average and give them a huge box of chocolates when they go home with Jason four days after his birth.

Mary is given the name of a child health clinic she can go to get Jason weighed and where she can access advice about breastfeeding. She is pleased about this because Jason still seems a bit confused about how to latch on and her nipples are very sore. Her Mum, Jenny, is coming to stay for a couple of weeks, but Jenny is very unsure about how to support Mary in breastfeeding Jason. Jenny's own experience left her thinking she was 'unable to make enough milk' and that formula was the only option in these circumstances.

Thus begins the new life of Mary and Wayne as proud parents of little Jason Smith . . .

hampered by fragmented care, staff shortages, public expectations, medical dominance and all the other components of the stresses associated with maternity service provision in large tertiary maternity units. At every stage of the story, these well-meaning members of staff reinforce Mary and Wayne's belief that Mary will need some form of pain relief. In the spiralling cascade of intervention, Mary is rendered passive and dependent on the expertise of strangers.

As this is not a 'real' story, there is the opportunity to wind back the clock and explore how the experience might have been different for Mary, Wayne and their baby, Jason, had circumstances been otherwise. The re-telling of this story enables scrutiny of a range of changes to practice, some of which are within the grasp of the practitioner and others that would require significant changes to systems. The evidence for these strategies will be woven throughout the process of looking at how we might reconstruct the 'everyday story' of the birth of Jason Smith.

Promoting physiological birth

Access to midwifery care

From the scenario, some might question the usefulness of midwifery care, given that Mary and Wayne appear grateful and happy about the birth of their son, Jason. Although the members of staff at St Average were all strangers to Mary

and Wayne, they were friendly, kind and competent, which is what women say is important to them (Green et al 1998; Lee 1997).

Such challenges raise complex questions about how to evaluate women's experiences of birth in terms of their 'satisfaction' and how midwifery and the promotion of physiological birth might be implicated. It can be argued that women have a vested interest in evaluating their experience positively in the postnatal period and that, in many situations, it is impossible for women to know how their experience might have been otherwise. For example, research in South Australia has shown that women like Sophie chose private obstetric care because they had no knowledge of midwifery. However, once such women were exposed to midwifery care, they identified that they would choose it in subsequent pregnancies (Zadoroznyj 2000).

Had Mary lived in New Zealand, she would have had considerably more chance of finding and getting to know a midwife who would be present during her labour. Legislative processes have enabled the majority of women in New Zealand to choose a publicly funded lead maternity carer to provide them with continuity of care.

This is an important consideration because midwives can play a crucial role in promoting psychosocial wellbeing. This was identified by Anne Oakley and colleagues (Oakley et al 1990, 1996) in a randomised controlled trial, which showed that the effect of midwives making themselves available, in a 'listening ear' capacity throughout pregnancy, had profound long-term consequences for the relationships and social lives of women, their children and their families.

Midwifery continuity of care

The anxiety of pregnant women who do not know which midwife will be there in labour for them, and whether this makes a difference to outcomes, has not been well captured by researchers on the whole. Confusion about the term 'midwifery continuity of care' and what it actually means in practice has added to the difficulty of making comparisons in research studies, particularly in exploring how women feel about their care (Sandall 2004). Furthermore, the notion of randomising women in studies does not lend itself to enquiry into choices, processes and relationships. However, a Cochrane Review (Hodnett 2004) identified that continuity of care from midwives has the potential to make a significant difference to the promotion of physiological birth when comparisons are made with standard care from physicians and midwives, as identified in Box 17.1.

Midwifery caseload practice

An increasing body of literature identifies the need for studies to look specifically at the midwifery continuity of care provided in a caseload practice model. Non-randomised studies of this form of care suggest that there are improved outcomes for women where they are able to establish relationships with midwives during pregnancy (Benjamin et al 2001; Page et al 2001; Sandall et al 2001).

BOX 17.1 Continuity vs standard care

Cochrane Review of caregivers during pregnancy and childbirth

Women experiencing continuity of care from a team of midwives were:

- less likely to be admitted to hospital antenatally
- less likely to have pharmacological pain relief
- less likely to have babies needing resuscitation
- less likely to have an episiotomy
- more likely to attend antenatal education programs
- more likely to be pleased with their antenatal, intrapartum and postnatal care.

(Source: Hodnett 2004)

The Albany Midwifery Group Practice in the United Kingdom is held up as an example of a community-based midwifery group practice that operates a caseload practice model and makes a difference to outcomes in a disadvantaged community (Reed 2002a,b). An evaluation of this group practice identified the fact that the midwives were very successful at facilitating normality in pregnancy and birth (Sandall et al 2001). Significant differences in outcomes were reported in terms of: increased satisfaction and rates of normal vaginal birth; home birth and breastfeeding rates; and reduced rates of induction, caesarean section, use of pharmacological pain relief, and perineal trauma (Sandall et al 2001).

Preliminary evaluations of the Northern Women's Community Midwifery Project (NWCMP) in the northern suburbs of Adelaide suggest that similar positive outcomes for women can be achieved through replicating the model in other contexts (Nixon et al 2003). The NWCMP has similar features to the Albany Midwifery Group Practice, in that the midwives:

- are community-based in a publicly funded model
- cover a geographical area of extreme socio-economic deprivation
- offer booking visits and a 36-week visit in the woman's home
- run antenatal and postnatal groups
- offer home birth as an option.

Offering home birth

In light of such evidence it might be a good starting point for the reconstruction of the story of the birth of Jason Smith to provide Mary with a midwifery continuity-of-care model in her pregnancy, one that gives her options about the place of birth. Given that the birth of Jason Smith could be reconstructed in any way, it would be possible to tell a story that starts with Mary booking with independent midwives for birth at home. There are good reasons to suggest that such services should be publicly funded. Internationally, home birth has been shown to be a safe option for a carefully selected group of women (Ackermann-Leibrich et al 1996; Anderson

& Murphy 1995; Campbell & Macfarlane 1994; Chamberlain et al 1997; Davies 1996; Murphy & Fullerton 1998; Olsen 1997; Olsen & Jewell 1998; Tyson 1991; Wiegers et al 1996). Similar findings have been demonstrated in Australia and New Zealand (Crotty et al 1990; Gulbransen et al 1997; Woodcock et al 1990), although poor outcomes have been associated with women with risk-associated pregnancies, such as twins and breeches, opting for birth at home in Australia (Bastian et al 1998).

While women in New Zealand can choose to give birth within publicly funded maternity services, in Australia the development of such options is in its infancy. Publicly funded, community-based midwifery programs that incorporate home birth options in a publicly funded healthcare system have been successfully implemented in both Western Australia (Thiele & Thorogood 1997; Thorogood et al 2002) and South Australia (Nixon et al 2003), with safe outcomes for both mothers and babies and high levels of satisfaction for women and midwives.[2]

Given the evidence that planned home birth is just as safe as birth in hospital for the majority of women, like Mary, who have uncomplicated pregnancies (Olsen & Jewell 1998), the promotion and support of home birth as a mainstream option for women has to be a major tactic in promoting physiological birth. Resistance to such a proposal is enshrined in the discourse of contemporary maternity services. With this in mind, the House of Commons Select Committee on Maternity Services (2003) proposed that all midwives, GPs or obstetricians should be enabled to attend a home birth during their training in order to challenge their prejudices and familiarise them with the promotion of normal birth (House of Commons 2003). Anecdotal evidence suggests that attending a birth at home has a significant effect on the practice of both midwives and doctors by giving them an insight into the profound nature of birth and the power of physiology.

Public awareness of the safety of home birth also needs to be addressed. As identified by the Albany Midwifery Practice, where over 50% of women give birth at home, it is possible to convince people that home birth is a safe option, even where they would never have considered it before. This practice has been able to show that where known midwives engage with women and their supporters throughout pregnancy, in particular during a home visit in late pregnancy and where decision-making about the place of birth is reserved for labour, home birth can be seen as a safe option for the majority of women, with a significant decrease in operative birth and medical interventions (Reed 2002a,b).

Reconstructing Jason's story

In order to make full use of reconstructing the birth of Jason Smith, we will not simplify the story by turning it into one about home birth. However, we will enable Mary to book with a group of midwives who have a woman-centred approach to providing continuity of care. The reconstructed story speaks of the difference this makes to how the story unfolds.

Scenario

Reconstructing Jason's birth: Mary's booking

When Mary suspects that she is pregnant, she goes to her local community centre, where she knows there are midwives who advertise a free pregnancy testing service twice a week at set times. The midwives are in a group practice and have their own premises in the community centre where women can access advice and information and attend a variety of support groups. The midwifery group practice is linked to the publicly funded maternity service provided at St Average Hospital.

The midwife who confirms that Mary is pregnant sets out the various options for maternity care and gives Mary some written information so that she can go home and discuss these options with Wayne. It does not take Mary and Wayne long to decide that they will book with the midwifery group practice. Fiona is the midwife assigned to be Mary's primary midwife. She phones Mary and arranges to come to her home to carry out the booking visit at a time when Wayne can be present. By the end of this leisurely visit, Mary and Wayne feel excited and very relieved. Fiona has made them feel that they are very special. She leaves the pregnancy record with Mary and encourages her to fill in any parts that she wants to and to make a note of any questions she has for subsequent visits.

Fiona encourages Mary and Wayne to attend the antenatal groups that the midwives run in their practice. Instead of classes where the midwives instruct the women, these antenatal groups are organised so that each week someone comes back to the group to tell their story. Mary can go to the group as often as she likes, starting in early pregnancy, so she will hear many different stories. She will learn from other women and will make friends who will be her support network when she is at home with a new baby. Wayne decides he might go with Mary to some of the evening groups now that he has met Fiona and likes her.

Mary's confidence about giving birth starts to grow.

Antenatal groups

Mary has booked with a midwifery group practice that sees bringing women together in groups as a crucial strategy to develop a forum where they can learn from each other and develop friendships and support networks (Leap 2000). As suggested by Mavis Kirkham, 'linking women with others makes them stronger' (Kirkham 1986, p 47).

This model of antenatal support and information sharing has been explained by women who have benefited from such groups, in a video: *Helping You to Make Your Own Decisions* (Leap 1991). The concept of running groups instead of classes is based in a women-centred philosophy. Women set the

agenda in the groups. They learn from each other and build their own support networks, thus minimising dependency on health professionals.

The midwife's role is described by the women in the video as that of a 'facilitator' who makes sure that, each week, a round of introductions starts the group. The midwife running groups such as these develops good listening skills. She needs to know how to ask open-ended questions and how to draw on the expertise of group members. She will make sure that people feel safe to talk or to remain silent and that no one dominates the discussions. She makes sure that newcomers are looked after and that they understand how the group operates. The midwife needs to judge when it is appropriate to interject with information, when to explain things that have arisen and, most importantly, when to keep quiet. Her skill lies in picking up cues from the group's discussion. One woman describes how this process changes the way women learn:

> To have the midwife there to provide some real education as to what it's all about ... bringing in the pelvis and 'baby' [doll] and actually showing how the baby travels down the birth canal ... and that coming up in a sort of organic way as a woman was talking about the birth she'd had last week and how the baby had got stuck somewhere, the midwife showed us. It stayed in my head because it was attached to real people. It wasn't abstract information you were getting. It was associated with women in the group so it got absorbed differently (quotation from video, Leap 1991).

A model of antenatal education and support in which women set the agenda (as opposed to being taught what the midwife has decided they should know about) can have far-reaching consequences for both women and midwives. Such groups are best situated in the community, but have also been run successfully in hospital antenatal clinics as an alternative to classes, and on antenatal and postnatal wards for women who are hospitalised. Anecdotal evidence suggests that antenatal groups offer a powerful tool for exploring the rationale and strategies for keeping birth normal (Reed 2002a,b).

In our reconstructed story, Mary will be able to attend a postnatal group that is run by child health nurses in the same community centre. She will carry on meeting the women she has met in the antenatal group there because she is very motivated to continue these friendships. This will provide a continuity of friendship and support, which the women in the video described as 'a lifeline' in breaking down the isolation of new motherhood.

> Just being able to ring someone up in the middle of the night ... just the fact that you've had a conversation with someone means that you're not there as an island trying to cope on your own.
>
> I think they're probably friends that you'll have for life, even though we're all so different. I would have been very isolated otherwise ... we formed a network of women who met up outside of the group and carried on meeting for years (quotations from video, Leap 1991).

Similar groups to those described in the video have been evaluated in the United States. The 'CenteringPregnancy' program also includes the element of women receiving their antenatal care in groups. This model has been found to be a powerful empowerment tool, especially for young and disadvantaged women (Klima 2003; Schindler Rising 1998). An evaluation of the first pilot program in the United States demonstrated that women enjoyed being with other women in the groups and made plans to continue meeting after their babies were born (Schindler Rising 1998). Another evaluation tested the program in a group of pregnant adolescent women who were identified as being particularly vulnerable. The CenteringPregnancy program was shown to assist these women in terms of empowerment and improved self-esteem (Klima 2003).

Other small studies have also demonstrated positive results in terms of satisfaction and reductions in low birthweight and preterm births (Grady & Bloom 2004). In a matched cohort study of 458 women, most of whom were African-American or Latina, women who received CenteringPregnancy care had larger babies than women having traditional care. This was particularly significant among preterm births: women in the CenteringPregnancy group had babies who were an average 408 grams heavier, and these women expressed higher levels of psychosocial improvements in their lives (Ickovics et al 2003). A similar direction is being noted in a large randomised controlled trial being carried out in the United States at Yale University, funded by the National Institute of Mental Health and nearing completion (Schindler Rising, personal communication 2005).

Building confidence throughout pregnancy

We can return to the reconstruction of Mary and Wayne's story and see how the style of antenatal care they are offered continues to build confidence and social support (see p 287).

Late pregnancy

The 36-week home visit

The 36-week home visit described here was studied by Joy Kemp (2003), who described the initiative as:

> an alternative model of authoritative knowledge, one which acknowledged a role for intervention and technology but placed as central a philosophy of birth as a physiological, transformational and socio-cultural event (Kemp 2003, p 4).

In her research, Joy Kemp (2003) identified a range of productive activities involved in carrying out a 36-week home visit to make plans for labour and the early postnatal period, all of which have implications for promoting physiology:

- involving family members in support in labour and in the early days following birth, with practical suggestions for how this might take place
- discussions about approaches to being with women in pain in labour without rushing to take away pain and to ensure that physiology is promoted
- the use of photographs to encourage discussion about normal birth
- information to reduce premature admission to hospital and choice about place of birth in labour.

Kemp's (2003) study portrayed the 36-week birth talk as an integral part of the ongoing dialogue and relationship of

Scenario

Building confidence and support

Mary has established a group of friends through attending the antenatal groups. She has heard many stories of women's births and looks forward to the day when it will be her turn to come to the group and tell her story. Wayne has met some new fathers too and heard some of their experiences of being at labour, so he is feeling less anxious.

Mary and Wayne have been introduced to all the midwives in the group practice when they went to the community centre for their antenatal care. Sarah has been assigned to them as their second midwife and they have met her at the practice for alternate antenatal check-ups. As Fiona is their primary midwife, she is most likely to be there when their baby is born, but if she is having days off when Mary goes into labour, Mary and Wayne will be very happy to have Sarah be with them as they have come to know her too. Fiona has taken responsibility for keeping the overview of their pregnancy; she made sure that all Mary's tests were completed and explained the results to her.

At 36 weeks, Fiona and Sarah go to Mary and Wayne's home to talk about support in labour and in the early days following birth. At Fiona's instigation, all the relatives and friends who will be supporting Mary come to that meeting. Fiona and Sarah talk about practical support in the first weeks following birth. They suggest rosters for bringing in food, taking away washing, shopping and walking the dog.

Fiona and Sarah also talk to the gathered people about how best to support Mary in labour. They show photos of births and talk about pain. They explain that the midwives will not be rushing to try and take away Mary's pain, that pain is purposeful, and that it would not be helpful to keep asking her if she wants something to take away the pain. They give Mary's supporters ideas about how they can minimise disturbance to help Mary withdraw into her body so that her own opiates can come into play. They talk about noise, moving around, transition and early breastfeeding—in effect, they explain why it is important to promote physiology and give plenty of suggestions about how best to facilitate this. Fiona and Sarah know that if they do not engage in these discussions, Mary's labour supporters are likely to expect them to offer pain relief during Mary's labour, in their distress pestering the midwives to 'do something' about the pain.

Fiona and Sarah also explain about 'pre-labour' or early labour and the importance of not going into hospital too soon. They talk through what to do if the baby comes in a hurry before the midwife arrives, and make sure they know where this is written in Mary's notes.

Fiona and Sarah tell the support people that if Mary's labour is going well, the midwives will offer her the opportunity to stay at home to have her baby, as they always carry all the equipment with them needed for a safe birth. They explain that if Mary needs 'help' they can go to hospital, but otherwise the best place to enable physiology to flourish is in a woman's own home.

The midwives also explain that the majority of white women having first babies do not go into labour until they are at least a week to 10 days after the 'due date'. They talk about the possibility of 'pre-labour' contractions and the importance of Mary eating, drinking and getting lots of sleep while labour gets established. This advice includes when to call the midwives, with clear messages to avoid the hours between midnight and 7 am unless they are worried or the contractions are coming every two to three minutes, lasting about a minute and Mary can't talk through them.

Mary is keen to use water in labour. She has heard stories in the group of how helpful women have found being in a deep tub. Fiona explains to everyone that if Mary's labour is progressing well and she wants to stay in the tub to give birth, this is a safe option.

By the end of this visit, everyone is clear about their possible roles in supporting Mary. The photographs of a labour sequence have helped to promote discussion about the sorts of things to expect, and everyone is excited about approaching labour with an open mind. The midwives have imparted an important message that they trust in Mary's ability to give birth to her baby and to cope well with whatever events unfold.

mutual trust that occurs between a woman and her midwife throughout pregnancy, where the same midwife or midwives are going to be with the woman during labour. The concept is thus directly related to continuity of care that includes an intrapartum component. It is also one element of a midwifery model that aims to focus on birth as a social, rather than a technocratic, event (Kitzinger 2000).

Evidence about strategies during pregnancy

Evidence relating to strategies that keep birth normal in late pregnancy is limited. However, the following principles have been suggested as important (Enkin et al 2000):

- midwifery care for women who do not have serious risk factors
- effective interdisciplinary collaboration
- giving women as much information as they want

- respecting women's choice of birthplace
- encouraging women to organise for companions to support them during labour
- not offering induction of labour until after 41 weeks of pregnancy
- external cephalic version at term for women whose babies are breech.

We return to Mary's story when she is 41 weeks pregnant. For the sake of argument, we will assume that where Mary and Wayne live, home birth is not yet a publicly funded option, nor is there a birth centre nearby.

Promoting physiology during labour

Throughout this reconstruction of the birth of Jason Smith, the midwives have adopted an evidence-based approach to supporting Mary in making decisions that promote physiological birth. They have also made a conscious effort

Scenario

Jason's birth

On a Sunday evening, a week past her due date, Mary starts having some low, period-type pains. She thinks her waters may have broken. She phones Fiona and describes what has happened and tells her that the baby is wriggling around as usual. Fiona is very excited for Mary and Wayne, and offers to call in and see them. She visits, carries out a reassuring check and confirms that Mary is draining clear liquor. Fiona explains the evidence from studies comparing a waiting approach with accelerating labour and together they make a plan to wait and see how events unfold. Mary will keep in touch by telephone if she has any concerns, if her temperature rises or if labour gets under way. Otherwise Fiona will visit again the next day.

Mary manages to get some sleep overnight, although by 6.30 in the morning the contractions are beginning to get stronger and closer together. She lets Wayne sleep, makes herself some breakfast and potters around the house. By the time Fiona visits again at midday, Mary's contractions are coming every three minutes and are lasting about a minute. Mary's Mum Jenny is helping Wayne to rub Mary's back during contractions and is making sure that she is sipping plenty of water. Mary's friend Linda, who has had two babies and was also present at the 36-week home visit, is making sure that everyone has enough to eat and drink. After performing some routine checks to ensure that Mary and her baby are responding well to labour, Fiona watches quietly; she can tell that Mary is in strong labour. She tells Mary this and suggests that this would be a good time to think about going into hospital if this is still what she wants to do. Mary is clear that she does want to have the baby in hospital, so they make plans for the journey.

Fiona goes ahead to the hospital and arranges to meet Mary, Wayne, Jenny and Linda there in the next hour or so. She prepares a room in the birthing suite to make it as cosy as possible, takes the mattresses off the bed and places them in the corner, making a little nest of cushions and bean bags. She pushes the bed up against the wall; it is no longer the centre of attention in the room. The lights are dimmed, there is possibly some ambient music playing very softly and the room smells good. Fiona is wearing her own clothes—some loose track pants and a T-shirt.

Soon after Mary arrives at St Average, her labour progresses well and she roams around the room, gets in and out of the deep bath and makes loud moaning noises. Fiona keeps a watchful eye, using an unobtrusive Doppler to monitor the baby's heartbeat. She offers Mary a birthing ball, and heated wheat packs for comfort. As Mary's contractions get stronger and closer, she becomes withdrawn. Fiona quietly reassures her that she's doing well after each contraction and when Mary pleads that she 'can't do it', Fiona keeps saying that she *can* do it, that this is normal and that she is doing really well.

Mary starts to feel an urge to bear down and soon the baby's head can be seen. Fiona talks Mary through breathing her baby's head out slowly so that she does not tear.

When Mary is giving birth, with her permission, Fiona invites Alexandria, the new resident, into the room to sit in the corner and watch as Mary gives birth to Jason on all fours. Wayne puts his hands next to Fiona's as Jason emerges and helps to pass him through and place him in front of Mary so that she can pick him up and take him to her when she is ready. Mary confirms for everyone that her baby is a boy. She takes him to her and talks to him, exclaiming as she explores his little body, finding family likeness in features—'Look, he's got your ears, Wayne!'. She is amazed at the cord, which is still pulsating.

Fiona gently reminds Mary that soon she will feel a slight fullness in her vagina as the placenta separates. She reassures Mary that pushing out the placenta will be easy, as it is soft, and that as soon as the placenta is out, they will cut the cord. Within a few minutes Mary has delivered her placenta and, with Fiona's help, she cuts the cord herself.

Jason has a first suckle. He is very alert and latches on enthusiastically. Everyone marvels at the placenta and membranes, as Fiona shows them its various wonders. There is much celebration all round.

to address the crucial role that pain plays in keeping birth normal. There is a need to change the culture in institutions around pain in labour through shifting the approach away from one of 'pain relief' to one of 'working with pain in labour' (Leap & Anderson 2004). Women have highlighted the fact that the attitudes of midwives have a profound effect on their experience of giving birth, in particular how they cope with pain in labour (Halldorsdottir & Karlsdottir 1996; Hodnett, 2002; Lundgren & Dahlberg 1998).

Undoubtedly, words of encouragement and reassurance during labour play a vital role in giving women confidence in their ability to cope with pain, and this, in turn, increases women's ability to avoid the side-effects of pharmacological analgesia and their disturbing effect on physiological processes. The role of the midwife in giving quiet encouragement is one of watchfulness and anticipation.

> Our expertise as midwives rests in our ability to watch, to listen and to respond to any given situation with all of our senses. This will include the conscious and subconscious 'knowing' that has been generated from our experience and learning. It also involves a 'cluefullness' as we respond to the overt and covert clues from women and their worlds. The skill lies in knowing when to inform, suggest, act, seek help and, most importantly, when to be still or when to withdraw and remove ourselves (Leap 2000, pp 5–6).

This approach recognises the need for women to have privacy in order to avoid disturbance of the complex neuro-hormonal cascades of labour. Michel Odent (1992) has suggested that it is important to enable women to find a private, quiet, dark, comfortable space in which to labour and give birth. He explains this in terms of promoting prostaglandins, oxytocins and other labour-enhancing hormones that can be inhibited when there is stimulation to the busy thinking part of the brain, the neocortex, or when fear and anxiety lead to excessive catecholamine production. This makes sense to midwives, who often see women 'disappear into their bodies' and enter a state of altered consciousness as labour intensifies.

A wide range of measures that promote physiology during labour are outlined in *The Labor Progress Handbook: Early Interventions to Prevent and Treat Dystocia* (Simkin & Ancheta 2000). Some of these strategies are outlined in Box 17.2.

BOX 17.2 Promoting physiology in labour

Measures that can promote physiology during labour include:

- Encouraging an atmosphere of privacy, calm and safety and the guaranteed presence of the midwife/birth supporters
- Offering comfort devices such as heat/ice packs, warm blankets, birth ball, beanbag, bath, shower, tea, music, massage, wiping her face and neck with a cool cloth
- Encouraging immersion in water during labour and for birth in a deep tub that allows movement and different positions, including all fours
- The continued presence of a female companion, partner or 'doula', who is committed to promoting normal birth
- Encouraging the woman to move around, adopt different positions, rest, make noises and eat and drink as she sees fit
- Avoiding continuous electronic fetal monitoring (EFM) in uncomplicated labour and using intermittent auscultation instead
- Where continuous EFM is necessary, still encouraging different positions, swaying
- Staying at home as long as possible when hospital birth is planned
- Understanding the anatomy, physiology and psychology of labour, and the techniques that can enhance these.

(based on Simkin & Anchetta 2000)

Building a culture in which physiological birth can flourish

All the strategies to promote physiological birth that have been addressed so far in this chapter will flourish in an environment where there is collegiality and good support for practitioners. In reconstructing the story of the birth of Jason Smith, there is an opportunity to fantasise about an ideal culture that supports practitioners in promoting physiological birth.

Developing a supportive culture in this way is about breaking down hierarchical barriers, enabling safe situations for all practitioners to share their uncertainty as well as their expertise, and recognising different expertise and complementary roles. Such an approach also depends on the most powerful groups—doctors—relinquishing some of their power. Power cannot be given; it can only be taken, and this process involves mutual sensitivity to the dynamics and potential pitfalls surrounding collaboration on the part of both parties.

In units where multidisciplinary efforts are activated to reduce caesarean sections, success may well depend on raising consciousness and awareness of issues and philosophical approaches, plus a concerted effort from all disciplines. It seems that pulling together, a commitment to evidence-based practice, one-to-one support from midwives during labour, managing change and fostering goodwill are important strategies in reducing interference in labour and improving outcomes for women (Ontario Women's Health Council 2002).

Conclusion

Changing the wider culture, outside institutions, to one that privileges normal birth is a daunting task in an era when caesarean and epidural rates are rising and these methods of childbirth are increasingly being identified in the media as the obvious choice for women in order for them to make full use of the benefits of modern technology. Promoting

Scenario

An ideal culture . . .

Fiona knows that if she is worried or tired she can ask for help—this may be from another midwife in her practice. It may also be from one of the core midwives who staff the birthing service and support the midwives in the group practices when they bring women to St Average. If Fiona is concerned about Mary's labour she will discuss the situation with one of the doctors, either in person or by phone. Such a supportive culture has been engendered at St Average by a concerted multidisciplinary approach in the last few years. There is also a 'zero-tolerance' approach to dominating behaviour and horizontal violence.

Every day at 2 pm at St Average, there is some form of interdisciplinary get-together or 'in-service' in the meeting room around the corner. This is organised by the Midwifery Consultant, is open to all staff, including midwives in community-based practices, and may be:

- a monthly perinatal mortality meeting where midwives as well as doctors present cases for review. This includes reviewing admissions to the Neonatal Unit.
- interesting case reviews, led by midwives, doctors or students on a rotational basis
- consensus guidelines for practice development—these have replaced protocols. They are evidence-based and incorporate woman-centred approaches to practice.
- student project presentations—students are encouraged to present their projects to all staff
- topic-based review of putting evidence into practice. These are guided discussion sessions or lively debates. Recent topics include:
  - a multidisciplinary approach to reducing the rate of caesarean sections at St Average by encouraging women to entertain VBAC and ECV, selective use of continuous EFM and informing all staff of the evidence about all of these
  - changing the culture of 'pain relief' to one of 'being with women in pain in labour'
  - regular practice sessions using the mannequins for emergencies—staff are encouraged to attend the ALSO[3] course and continue to practise the 'hands on' simulations and mnemonics.

normal birth in the media is obviously important but a more fundamental approach may be necessary. The promotion of normal birth may have to start in primary schools through visits by pregnant and breastfeeding women and midwives, in order to plant the seeds of thought that will grow into an adult ability to conceptualise birth as a social event with profound meaning for all involved.

This chapter has explored how promoting physiology involves far more than a series of techniques used in labour. It involves the raising of consciousness at every level in our institutions, health services and governments in order to build systems and services that nurture the potential of birth to transform lives and strengthen women, their families and societies.

Review questions

1. In the context of your own practice, how can you enhance a culture that promotes physiological birth?
2. Imagine that you have been asked to visit a primary school to talk about 'having a baby'. What will you say?
3. Using Box 17.2 as a guide, how many of the measures listed there are in place in your place of work? For those that are not in place, how can you introduce them?
4. You have been asked to prepare a 20-minute talk for the multidisciplinary lunchtime meeting. The topic is 'promoting physiological birth'. How will you defend your argument when the anaesthetists suggest that all women should be offered an epidural during labour?
5. Name some of the underlying power dynamics in your workplace that possibly subvert the efforts of midwives to promote physiological birth.
6. How have the dynamics you described in question 5 evolved over recent centuries? (1000 words)
7. Describe what you understand by the terms 'interventionist' and 'medicalised' in terms of promoting physiological birth.

Review questions—cont'd

8 Internationally, home birth has been shown to be a safe option for a carefully selected group of women. Look up the recommended references on home birth and make a table of the outcomes achieved in three of the studies compared to those achieved in the hospital closest to where you work.

9 You have been asked to prepare a talk on home birth for the local Country Women's Institute. What are the questions you might expect from a group of women who gave birth in the 1960s and 1970s?

10 Describe some of the activities involved in carrying out a 36-week home visit to make plans for labour and the early postnatal period, all of which have implications for promoting physiology.

Notes

1 Because over 99% of midwives are women, the midwife is referred to as 'she'. The intention is not to exclude men who are midwives.
2 The first publicly funded home birth service in New South Wales was due to commence at the time of writing this textbook (2005).

SECTION TWO AUTONOMOUS PRACTICE

CHAPTER 18

The physiology of conception and pregnancy

Sally Baddock

Key terms

acrosomal reaction, adrenergic, amnion, amniotic fluid, bilaminar disc, blastocyst, blastomere, capacitation, cervical mucus, chorion, chorionic villi, chromosomes, cleavage, conception, corticosteroid, cytotrophoblast, decidua, differentiation, ductus arteriosus, ductus venosus, ectoderm, embryo, embryology, endoderm, endometrium, erythropoiesis, fallopian tube, fertilisation, fetal placental circulation, fetus, foramen ovale, gastrulation, glomerular filtration, gonadotrophins, haemodilution, human chorionic gonadotrophin, human placental lactogen, hypercoagulability, hyperventilation, hypothalamic-pituitary axis, implantation, induction, inner cell mass, intervillous spaces, lung compliance, mesoderm, morula, negative feedback, neural tube, neurulation, notochord, oestrogens, oocyte, oogenesis, organogenesis, ovaries, ovulation, oxygen saturation, placenta, progesterone, renin-angiotensin, semen, signalling proteins, sperm, spermatogenesis, surfactant, syncitiotrophoblast, syngamy, teratogen, triaminar disc, trophoblast, umbilical arteries, umbilical vein, uteroplacental circulation, uterotonic agonists, uterotonic antagonists, uterus, yolk sac, zona pellucida, zygote

Chapter overview

This chapter focuses on the physiological processes associated with conception and pregnancy. This begins with the formation of the gametes in the female and male reproductive systems, and continues with an overview of embryology from fertilisation until birth. It includes the simultaneous development of the placenta to support the embryo, and the changes of pregnancy occurring in the woman. A good understanding of these physiological processes is essential if a midwife is to make informed decisions with regard to monitoring of the woman and fetus and with regard to interpretation of test results. It also enables informed discussion with the woman regarding the changes occurring to her body as the fetus develops, and an understanding of the factors that contribute to a healthy environment for normal embryological and fetal development.

For ease of study, the development of the embryo and placenta, and the changes in the woman through pregnancy, are presented as separate topics, but the processes are interwoven and simultaneous. The scope of this chapter is limited, but further readings are provided at the end of the chapter for a more in-depth exploration of specific topics. Some of the online resources listed provide animations that can help with the understanding of complex anatomical changes.

Learning outcomes

Learning outcomes for this chapter are:

1. To list key events in the continuum of development from gametogenesis to the development of a mature fetus

2 To describe the physiological changes that occur in the reproductive system and other body systems of the woman during pregnancy

3 To discuss the role of hormones in the reproductive process and in the maintenance of pregnancy.

Female and male reproductive systems

The physiological roles of the female and male reproductive systems are to produce and maintain sex cells (gametes), to transport the gametes to the site of fertilisation, and to produce and secrete sex hormones, which control the reproductive process. The female reproductive system has the additional role of supporting the developing fetus. The structures of the female and male reproductive systems underpin these roles.

Anatomy of the female reproductive system

The female reproductive system consists of a pair of female gonads, commonly referred to as the ovaries, as well as a number of accessory ducts, specifically the uterine or fallopian tubes, the uterus and the vagina. The ovaries and the accessory ducts make up the internal female genitalia. The external female genitalia are referred to as the vulva and consist of the mons pubis, labia majora, labia minor, clitoris and vestibule. The mammary glands of the female are also important in the reproductive system following reproduction.

Female internal genitalia

The structures of the female internal genitalia are depicted in Figure 18.1.

The ovaries have two important roles in the reproductive system: to produce female sex cells (oocytes) through the process of oogenesis; and to produce the female sex hormones—the oestrogens (oestradiol, oestrone and oestriol) and progesterone.

The uterine tubes link the ovaries and the uterus, although there is no anatomical connection. The distal ends of the uterine tubes end in fimbriae, which waft the ovulated ovum towards the opening of the tube. Contractions of smooth muscle in the walls of the uterine tubes and the wafting action of cilia lining the walls aid oocyte movement (fertilised or not) to the uterus.

The uterus is a hollow cavity consisting of three regions: the fundus, the body and the cervix. The fundus is the region superior to the uterine tubes. The body is the major portion of the uterus and is the site where implantation occurs. The cervix is the region that connects the uterus with the vagina and consists of the cervical canal, the internal os and external os. The uterus is a thick-walled organ with three layers: the

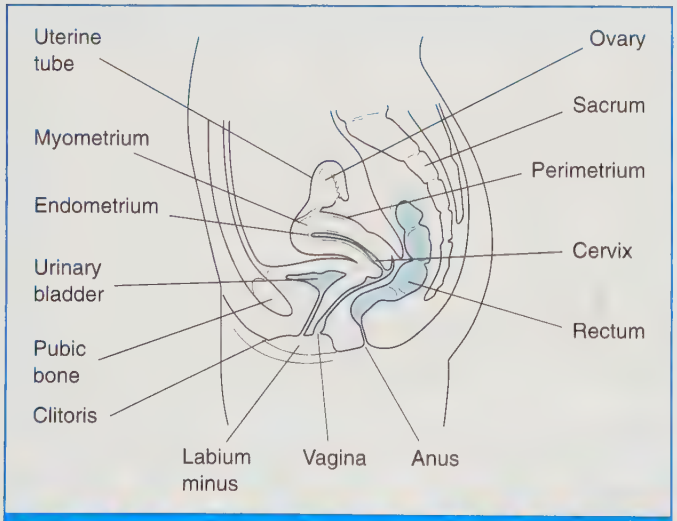

Figure 18.1 Schematic sagittal section of the female pelvic region (based on Moore & Persaud 1998)

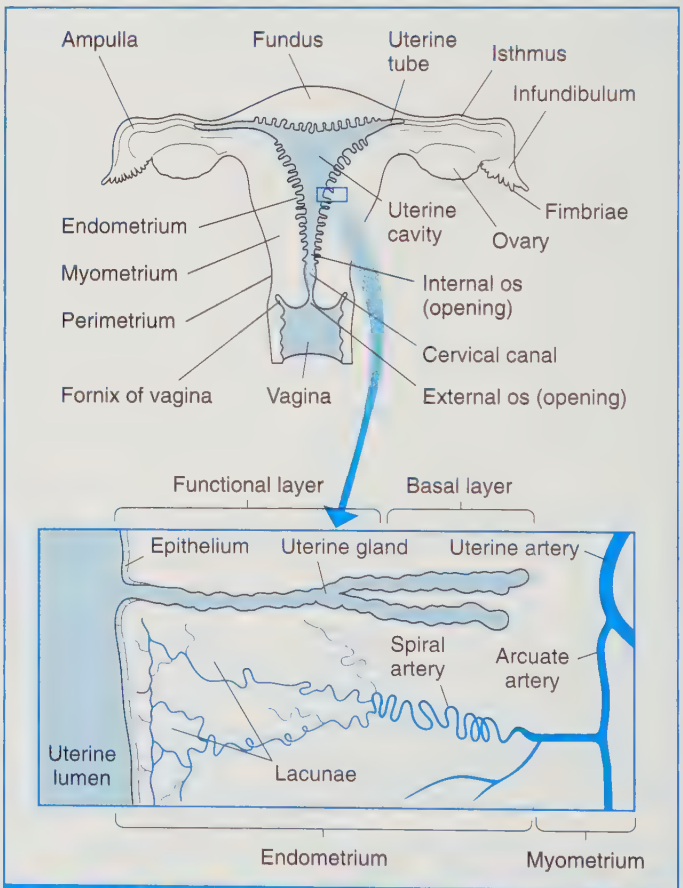

Figure 18.2 Female reproductive organs (based on Moore & Persaud 1998)

perimetrium (outer layer), the myometrium (thick muscle layer) and the endometrium (the inner mucosal lining). The endometrium consists of two layers: the stratum basalis, which lies next to the myometrium, and the stratum functionalis, the outer mucosa that is shed during menstruation (Fig 18.2).

The vagina is often referred to as the 'birth canal' and is the region of the internal female genitalia that connects to the external female genitalia. The vagina is a passage for semen during intercourse and for menstrual blood during menstruation. The epithelial cells that line the vagina produce glycogen, which is metabolised to lactic acid by the vaginal microflora. This results in the vagina having an acidic pH, which protects against foreign microorganisms as well as destroying many sperm cells that enter the vagina.

External female genitalia

The external female genitalia are referred to as the vulva and consist of the mons pubis, labia majora, labia minora, clitoris and vestibule (Fig 18.3).

Mammary glands

The mammary glands or breasts are also present in the male but produce milk only in the female. The breasts are a type of sweat gland (sudiferous gland) positioned over the pectoralis major and serratus anterior muscles and attached by connective tissue. Suspensory ligaments support the breasts and are present between the skin and the deep fascia of the muscle. The areola is the region surrounding the nipple and contains modified sebaceous (oil) glands, which help to keep the tissue supple. Each breast is made up of 15–20 lobes separated by adipose tissue. The amount of adipose tissue determines the size of the breast. The lobes consists of lobules, which are milk-secreting glands commonly referred to as alveoli. The milk is produced in the alveoli and passes into the duct system. Small ducts from each lobule drain into a lactiferous duct that opens onto the nipple surface. The two hormones important in lactation are prolactin and oxytocin. Prolactin is important for milk production and oxytocin is important in the let-down or milk release reflex.

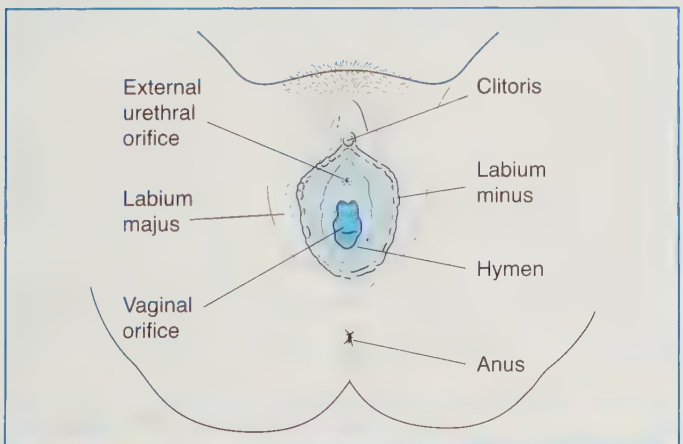

Figure 18.3 External female genitalia. The labia are spread apart to show the external urethral and vaginal orifices (based on Moore & Persaud 1998).

Anatomy of the male reproductive system

The structures of the male reproductive system (Fig 18.4) include the testes, penis, accessory ducts (epididymis, vas deferens (ductus deferens), ejaculatory ducts and urethra) and the accessory glands (prostate, seminal vesicles and bulbourethral glands).

The paired testes each contain coiled seminiferous tubules, which are the site of sperm production. The sperm are moved from the seminiferous tubules to the coils of the epididymis by peristalsis. Secretions from the Sertoli cells, adjacent to the seminiferous tubules, build up pressure and contribute to the movement of sperm (Fig 18.5).

In the epididymis, sperm mature and become motile after approximately 14–21 days. During ejaculation, peristaltic contractions move spermatozoa from the epididymis to the vas deferens, through the ejaculatory duct and into the urethra. The urethra runs from the urinary bladder to the outside of the body, with part of the urethra (spongy urethra) running through the penis. The urethra has the dual role of transporting urine and sperm to exit the body.

During sexual excitement, the three columns of erectile tissue surrounding the urethra become engorged with blood, resulting in erection. This enables the penis to enter the vagina during sexual intercourse. Further stimulation leads to ejaculation of semen (sperm and secretions).

Accessory sex glands and semen

Semen is the alkaline fluid that protects, nourishes and transports sperm during ejaculation. Two to five millitres is ejaculated during orgasm, containing 50–100 million sperm/mL.

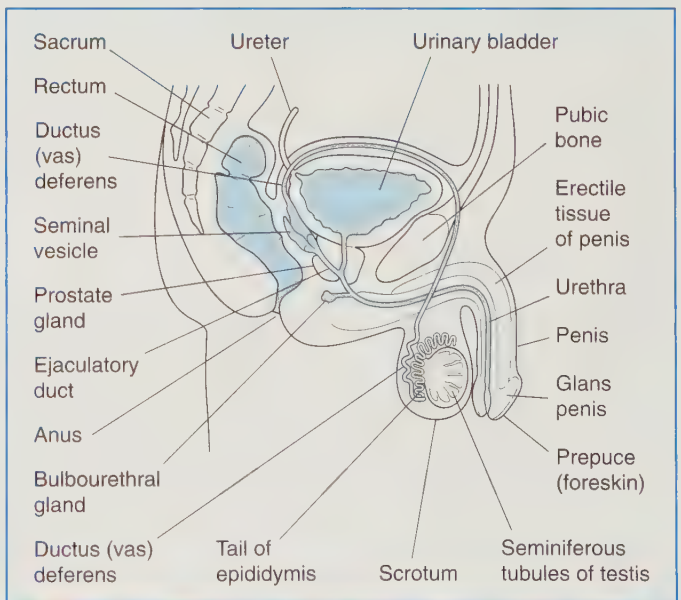

Figure 18.4 Schematic sagittal section of the male pelvic region (based on Moore & Persaud 1998)

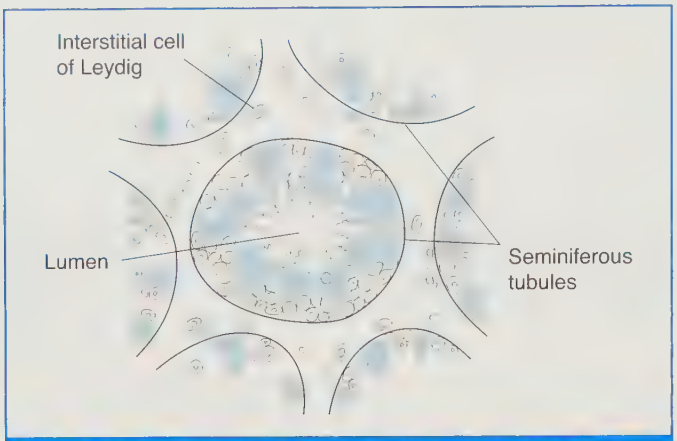

Figure 18.5 The testis in cross-section, illustrating the seminiferous tubules and interstitial cells of Leydig (based on Bray et al 1994)

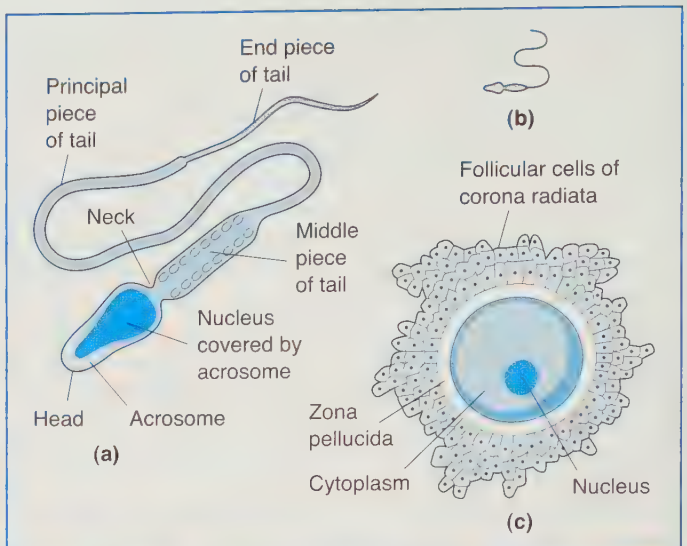

Figure 18.6 Male and female gametes. **(a)** Parts of the human sperm (X 1250). The head, composed mostly of the nucleus, is partly covered by the acrosome, an organelle containing enzymes. The tail consists of three regions: middle piece, principal piece and end piece. **(b)** Sperm drawn to about the same scale as the oocyte. **(c)** Human secondary oocyte or ovum (X 200) surrounded by the zona pellucida and corona radiata (based on Moore & Persaud 1998)

At least 20 million sperm/mL are necessary for fertility. However, 90% of the fluid is made up of secretions from the seminal vesicles, prostate gland and bulbourethral glands.

Seminal vesicles release alkaline secretions into the ejaculatory duct that contain several chemicals, including fibrinogen, fructose and prostaglandins. Fibrinogen helps to coagulate semen just after ejaculation and this contributes to retention of semen in the region of the uterine cervix, until the sperm become motile. Fructose nourishes the sperm, and prostaglandins aid fertilisation by making the cervical mucus more receptive. Prostaglandins also stimulate uterine contractions, which suck semen into the uterus and fallopian tubes, enabling them to reach the ampulla as soon as five minutes after ejaculation, or up to six hours later. These secretions also dilute epididymal inhibitory factor, which is thought to suppress the motility of spermatozoa.

The prostate gland produces an acidic, milky fluid containing citric acid and clotting enzymes that aid coagulation, and this is emptied into the urethra. Bulbourethral (Cowper's) glands produce alkaline fluid that neutralises the acidic urethra along with mucus that lubricates the urethra and protects spermatozoa. Secretions travel through the ducts into the spongy urethra.

Gametogenesis

Fertilisation involves the union of two gametes—an oocyte from the female and a sperm from the male. Gametes are highly specialised sex cells (Fig 18.6). Gametogenesis (formation of the sex cells) necessarily involves halving the number of chromosomes in each cell, by a type of cell division called meiosis, and by altering the shape of the cells. In females this process is termed oogenesis and in males it is spermatogenesis. When the two gametes join at fertilisation, the full number of chromosomes is restored.

Oogenesis

Oogenesis is the process by which mature female sex cells are formed. Much of this process occurs in the fetus prior to birth. Oogonia in the fetus multiply by mitotic division and develop into primary oocytes (containing 46 chromosomes). The first meiotic division also begins before birth, but is arrested until after puberty. Completion of the first meiotic division is linked to the ovarian cycle. Each month, following puberty, several primary oocytes begin to develop but only one matures to complete the first meiotic division 36–48 hours before ovulation (Blackburn 2003). This division results in a large secondary oocyte containing most of the cytoplasm, and a smaller non-functional polar body that soon degenerates. Each has 23 chromosomes (22 autosomes and 1 sex chromosome). At ovulation the secondary oocyte begins the second meiotic division, but the division is only completed if fertilisation occurs. Once again, almost all the cytoplasm goes to one cell, the mature oocyte. The second polar body is non-functional and degenerates. The cellular divisions of oogenesis are outlined in Figure 18.7. The mature oocyte is a large, immotile cell, just visible to the naked eye. Up to two million primary oocytes are usually present in the ovaries of a newborn female infant, but many regress during childhood, leaving about 40,000 at puberty. During the reproductive life of a female, about 400 oocytes mature and are released during ovulation.

Spermatogenesis

Spermatogenesis describes the development of spermatogonia (primitive germ cells) into spermatozoa. This process begins at puberty and continues into old age. At puberty, the

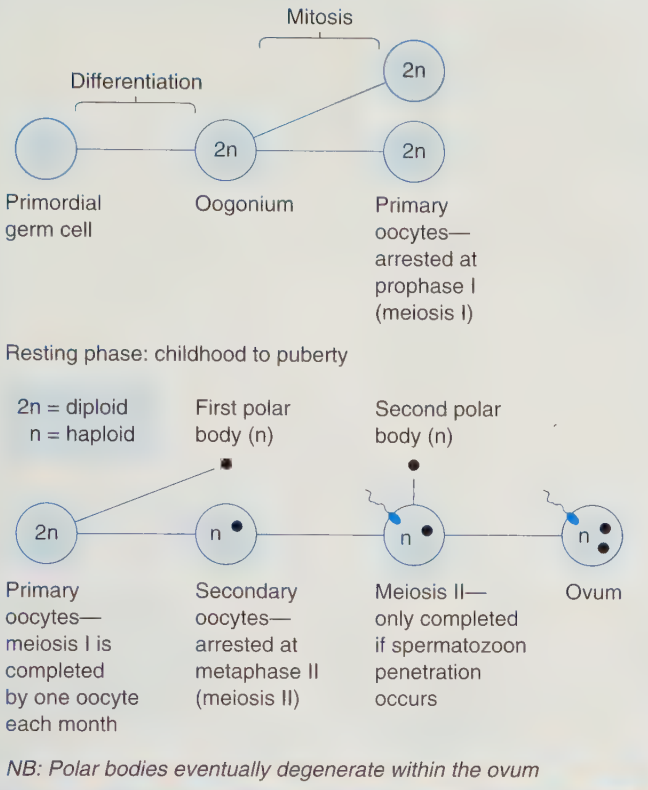

Figure 18.7 Arrest of oocyte meiosis (based on Coad & Dunstall 2001)

spermatogonia increase in number by mitotic division and grow and change to form primary spermatocytes ($2n$ chromosomes). Each primary spermatocyte undergoes the first meiotic division to form two secondary spermatocytes (n chromosomes) and the second meiotic division to result in four spermatids (n chromosomes). Spermatids undergo a considerable change in shape, in a process termed spermiogenesis, to become mature spermatozoa (sperm). The mature sperm has relatively little cytoplasm. It is divided into a head, midpiece and tail, and is motile. The head forms most of the bulk, contains the nucleus with the chromosomes and is covered anteriorly by the acrosome, a structure containing enzymes that facilitate penetration of the ovum at fertilisation. The midpiece is rich in energy-producing mitochondria, which fuel the lashing movements of the tail. Spermatogenesis takes about two months to complete and continues throughout the reproductive life of a male (Moore & Persaud 1998). The sperm move to the epididymis, where they are stored and become functionally mature. A comparison of oogenesis and spermatogenesis is shown in Figure 18.8.

Female reproductive cycles

Females undergo monthly reproductive cycles starting at puberty and continuing through the reproductive years. These cycles are controlled by the hypothalamic-pituitary-ovarian hormones and result in changes in the ovary that lead to release of one secondary oocyte per month, and changes in the uterus in preparation for implantation of the fertilised ovum. If fertilisation does not occur, the cycle begins again under the influence of the hypothalamic-pituitary hormones. For simplicity, the reproductive cycle is described as an average 28-day cycle. There is considerable individual variation but the cycle length of most women is between 21 and 35 days (Blackburn 2003).

Ovarian cycle

The ovarian cycle (Fig 18.9) includes three phases: the follicular or pre-ovulatory phase, the ovulatory phase or ovulation, and the post-ovulatory or luteal phase.

Follicular phase

In the follicular phase, the ovarian follicles, containing an oocyte, mature. Ovarian follicles are found in the cortex of the ovary and contain a variety of cells, including primary or secondary oocytes, granulosa cells and theca cells. Oocytes are surrounded by a thick membrane, the zona pelucida, and in mature follicles there is a large fluid-filled cavity, the antrum.

Follicles are present in several forms: primordial (the most undeveloped), primary, secondary and Graafian or vesicular follicles (the most mature).

Primordial follicles contain primary oocytes and are the type of follicle present at birth. The first meiotic division has already begun in utero, but the process is arrested partway and does not continue again until puberty, when levels of gonadotrophin-releasing hormone (GnRH), luteinising (LH) and follicle-stimulating hormone (FSH) increase.

The primary follicle is formed in response to the increased level of the hormones mentioned above. The hormones signal the cells surrounding the oocyte to proliferate and form a layer of granulosa cells. These cells allow nutrients and signalling molecules to reach the oocyte.

The secondary follicle is formed when a layer of connective tissue, called the theca folliculi, develops around the follicle and an antrum begins to develop with it. The thecal cells, together with the granulosa cells, produce steroid hormones (mainly oestrogens with small quantities of progesterone). The secondary follicle is also characterised by the zona pellucida, which surrounds the oocyte and is released along with the oocyte at ovulation.

Graafian or vesicular follicles are the final and most mature form of ovarian follicle. This stage of follicular development is characterised by a large antrum and a follicular size of approximately 2.5 cm diameter. Due to its size it bulges from the ovary midway through the ovarian cycle. The completion of meiosis I, in which a secondary oocyte and the first polar body are formed, occurs 36–48 hours before ovulation (Blackburn 2003). Meiosis II continues but is not completed until fertilisation occurs. The process of meiosis results in the total number of genetic material being halved from 46 chromosomes ($2n$) to 23 chromosomes (n).

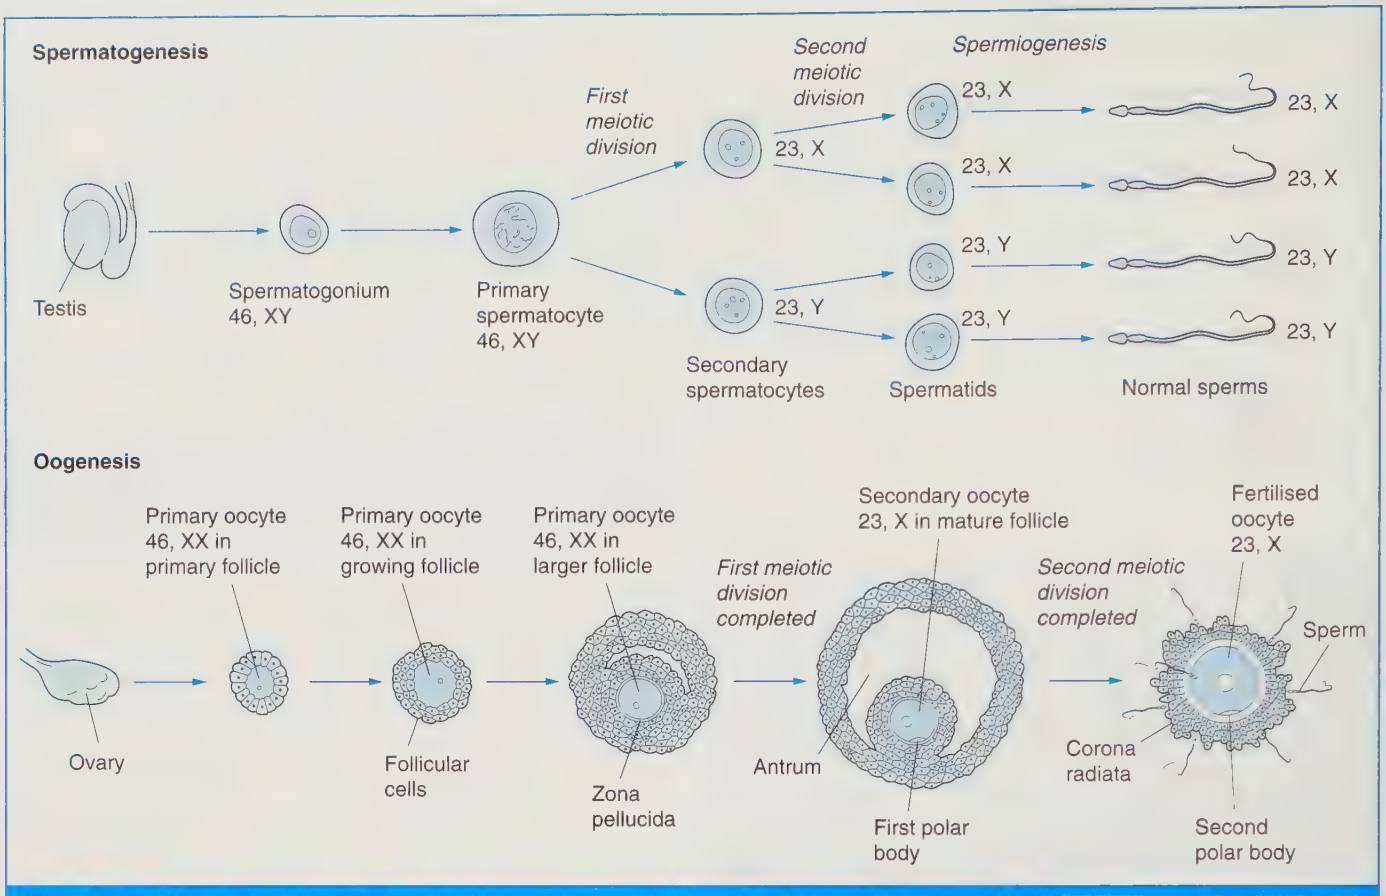

Figure 18.8 Comparison of oogenesis and spermatogenesis (based on Moore & Persaud 1998)

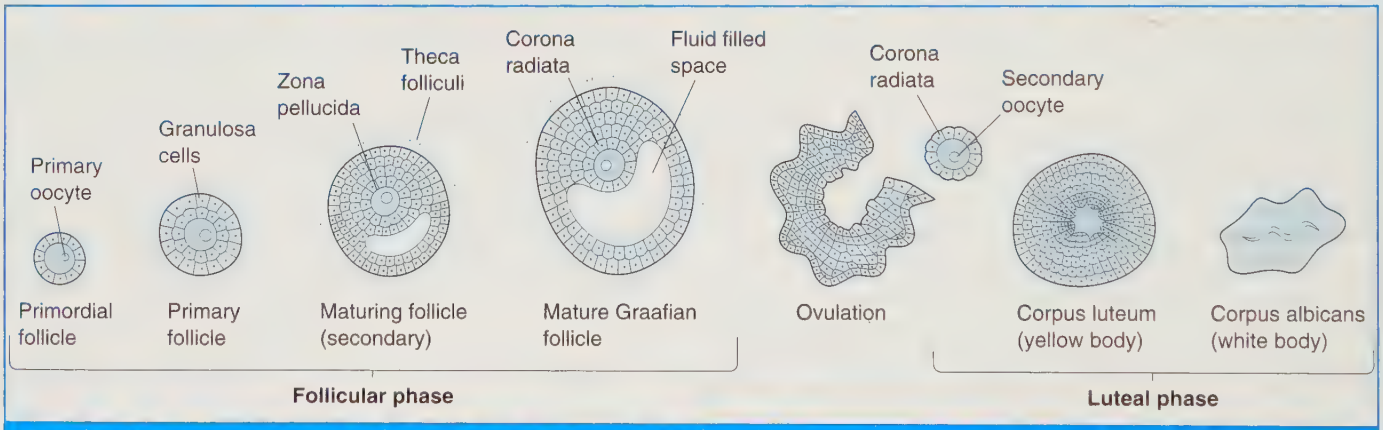

Figure 18.9 The ovarian cycle (based on Coad & Dunstall 2001)

Ovulation

The ovulatory phase begins when oestrogen levels peak and ends when the vesicular follicle ruptures, releasing the secondary oocyte surrounded by the zona pellucida and corona radiata (the crown of granulosa cells around the zona pellucida). Ovulation is under hormonal control, as follows: LH interacts with LH receptors on the granulosa cells, increasing the production of oestrogen by the dominant follicle. The rise in oestrogen levels 12–24 hours before ovulation triggers the LH surge. The high level of LH stimulates production of prostaglandins ($PGF_{2\alpha}$ and PGE_2) and allows the primary oocyte to complete the first meiotic division and become a secondary oocyte. Simultaneously, levels of oestrogen drop and proteolytic enzymes are synthesised, which break down the thecal cells and assist rupture of the vesicular follicle (Blackburn 2003).

Luteal phase

This is the final stage of the ovarian cycle. The ruptured follicle remains in the ovary and the antrum begins to fill with clotted blood. The granulosa and some thecal cells form a structure called the corpus luteum. This is an endocrine structure capable of producing progesterone and smaller amounts of oestrogen. The purpose of the corpus luteum is to provide progesterone until the placenta is adequately formed. If fertilisation does not occur, the corpus luteum degenerates into a corpus albicans and is degraded through lysosomal activity.

Uterine cycle

The uterine cycle occurs in the same timeframe as the ovarian cycle and is similarly controlled by changes to hormonal levels (Fig 18.10). It consists of three stages: the menstrual phase (days 1–5), the proliferative phase (days 6–14) and the secretory phase (days 15–28). The following is a review of each stage.

Menstrual phase

Menstruation is triggered by several factors. The first is the drop in levels of progesterone and oestradiol (one form of oestrogen). The second factor is a change in the ratio of prostaglandins and prostacyclins (hormone-like compounds) that cause vasoconstriction and increased coiling of the spiral arterioles, leading to a decrease in blood flow to the stratum functionalis of the uterus. The cells in the stratum functionalis become ischaemic, necrosed and slough away from the stratum basalis. The straight arterioles dilate, contributing to menstrual flow (Blackburn 2003).

Proliferative phase

In the proliferative phase, the stratum functionalis of the endometrium begins to thicken as endometrial cells proliferate. Arterioles regenerate and endometrial glands develop. These changes occur in response to oestradiol and progesterone. The mucus produced by the cervix also responds to these hormones. The consistency becomes less viscous and less stretchy, showing little or no ferning (spinnbarkeit test), thus becoming more receptive to sperm. Variation in the length of the proliferative phase accounts for most of the variation in uterine cycles (Blackburn 2003).

Secretory phase

The secretory phase occurs following ovulation, when levels of progesterone are high. The influence of progesterone results in further thickening of the stratum functionalis, an increase in the number of blood vessels as well as increased coiling and dilation of blood vessels. Finally, the endometrial glands begin secreting glycogen.

Hypothalamic-pituitary-ovarian (HPO) axis

The female reproductive system is regulated by a variety of hormones produced by the brain (the hypothalamus and the pituitary gland) and the ovaries (Fig 18.11).

Hypothalamus

The hypothalamus produces a peptide hormone called gonadotrophin-releasing hormone (GnRH) within its neurons. This hormone stimulates the release of several hormones from the anterior pituitary gland, specifically FSH and LH.

Pituitary gland

The anterior pituitary gland produces and secretes many hormones, including FSH, LH and prolactin. Luteinising hormone and FSH are glycoproteins that enhance each other's actions (act synergistically) in regulating the ovarian cycle.

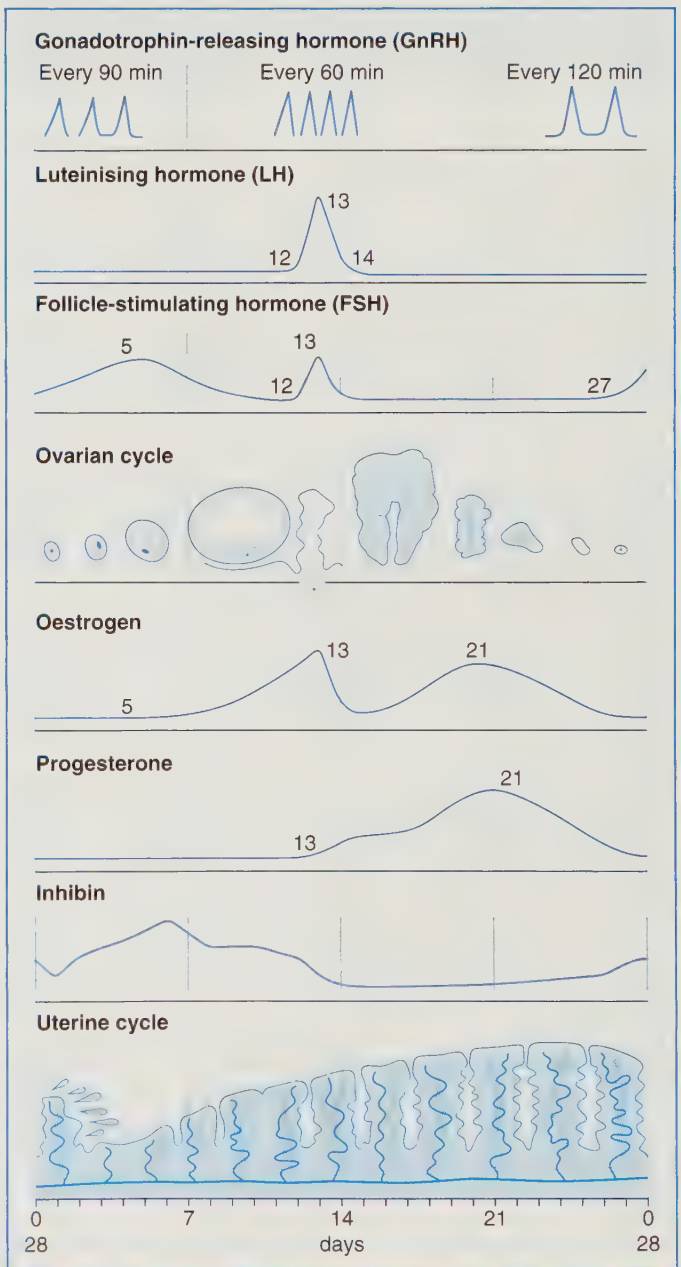

Figure 18.10 Uterine cycle and hormone levels (based on Coad & Dunstall 2001)

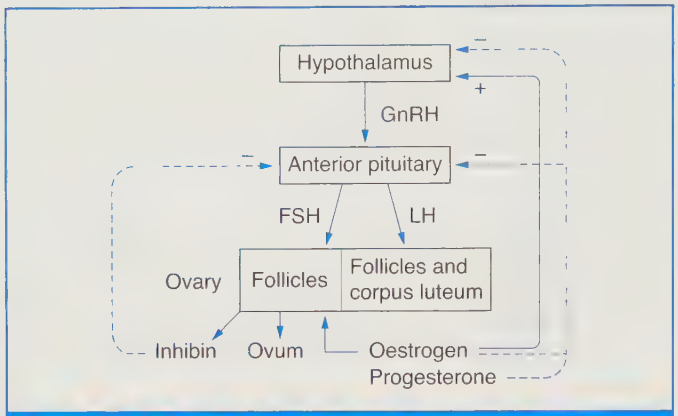

Figure 18.11 Control of follicular development and oestrogen secretion (based on Bray et al 1994)

FSH, along with oestrogen produced by the ovaries, acts on granulosa cells of the follicles to stimulate growth and produce FSH and LH receptors. Luteinising hormone receptors combine with LH during the LH surge to inhibit the growth of granulosa cells and initiate production of progesterone from the follicle. The granulosa cells of a primordial follicle undergo limited growth without FSH. Secretion of FSH peaks mid-cycle at a lower level than the LH surge (Blackburn 2003).

LH acts on thecal cells, instigating the production of androgens that are converted to oestrogens by the granulosa cells. This increases the oestrogen level and inhibits the development of other follicles by inhibiting FSH (negative feedback). At the same time, one follicle becomes dominant and secretes high levels of oestradiol, allowing granulosa cell development in that follicle. As levels of oestradiol increase, the release of GnRH is triggered by positive feedback, allowing increased levels of LH and FSH to complete the maturation of follicles, and an LH surge triggers ovulation within 12–24 hours. Following ovulation, increasing levels of oestrogen and progesterone exert a powerful negative feedback effect, inhibiting the release of GnRH and subsequently LH and FSH. This negative feedback prevents further maturation of follicles—important if the oocyte released at ovulation was successfully fertilised. However, in most cycles, fertilisation does not occur and the corpus luteum degenerates into the corpus albicans, resulting in a decreased level of progesterone. The low progesterone levels cease to inhibit GnRH, which begins to rise, followed by an increase in LH and FSH and the beginning of the follicular phase.

Prolactin is a protein hormone that stimulates milk production. Levels of prolactin rise during pregnancy, but hPL (human placental lactogen) and progesterone prevent the binding of prolactin to receptors in the breast. After delivery, prolactin stimulates milk production.

Ovaries

The ovaries produce the oestrogens (oestradiol, oestrone and oestriol), progesterone and inhibin.

Oestrogens are produced in the ovaries by granulosa cells within the follicles and the corpus luteum. The most abundant oestrogen during a woman's reproductive years is oestradiol, which is responsible for most of the effects of oestrogen in the female reproductive system. However, during pregnancy, oestriol becomes the main oestrogen secreted (Blackburn 2003). The stimulus for oestrogen release is primarily FSH and, to a lesser extent, LH. Oestrogens are responsible for various functions, including:

- development and maintenance of the female reproductive structures such as the endometrial lining of the uterus, and secondary sexual characteristics such as fat content of the breasts, abdomen, mons pubis and hips, voice pitch, broadness of the pelvis, distribution of underarm and pubic hair, and the development of breasts
- fluid and electrolyte balance—by influencing the action of aldosterone, sodium reabsorption in the renal tubules is stimulated and diuresis is reduced
- increasing the rate at which amino acids enter cells, thereby altering protein metabolism, allowing cells to grow and multiply. This action is supported by the influence of growth hormone.
- regulation of oxytocin and adrenergic receptors (Henderson & Macdonald 2004).
- stimulation of uterine tube contractility to assist sperm motility and to retain the ovum (Blackburn 2003).

Progesterone is produced in the ovaries by granulosa cells, primarily of the corpus luteum. Therefore progesterone levels peak in the post-ovulatory phase when the corpus luteum is active, and fall if pregnancy does not occur and the corpus luteum degenerates. LH is the stimulus for progesterone release. Progesterone has various functions, including:

- preparation of the endometrium of the uterus to receive a fertilised ovum
- prevention of sperm entry into the uterus by promoting changes in the cervical mucus
- increasing basal body temperature by influencing the thermostat located in the hypothalamus
- relaxation of the muscle of the uterine tubes during the luteal phase to assist passage of the fertilised ovum to the uterus (Blackburn 2003).

Inhibin is produced in the ovaries by granulosa cells of the follicles and corpus luteum. It exerts negative feedback controls on FSH release during the growth of the dominant follicle and the corpus luteum.

Clinical point

1. Body temperature rises after ovulation, in response to progesterone, and is used in natural family planning to indicate the fertile phases of the reproductive cycle.
2. Hormonal contraceptives contain levels of oestrogen and/or progesterone that cause feedback control on the HPO axis to prevent follicle development and ovulation. Some contraceptives use the cervical mucus-changing properties of progesterone (e.g. the minipill).

Summary: homeostatic control of the reproductive cycle

While the follicular phase of the cycle is characterised by the positive feedback of oestrogen prompting an LH surge, the luteal phase is characterised by negative feedback. GnRH, LH and FSH production is controlled by negative feedback mechanisms linked to the ovarian hormones in the HPO axis (oestrogens, progesterone and inhibin). If the secondary oocyte is not fertilised, the ovum dies in 24 hours and the corpus luteum deteriorates. The levels of oestrogens and progesterone therefore drop, triggering the production of GnRH, LH and FSH, which begins the reproductive cycle (ovarian and uterine cycles) again. If fertilisation and implantation occur (pregnancy), levels of oestrogen and progesterone remain elevated because the blastocyst secretes the hormone human chorionic gonadotrophin (hCG) that maintains the corpus luteum and hormone production. The placenta takes over producing oestradiol and progesterone by 6–10 weeks gestation.

Hypothalamic-pituitary-testicular (HPT) control in the male

Hypothalamic-pituitary-testicular (HPT) control in the male is not cyclical, like the HPO control in the female. The HPT axis regulates physiological changes in the testes from puberty onward. GnRH is secreted by the hypothalamus every 70–90 minutes, which triggers the anterior pituitary to secrete LH and FSH.

LH directly stimulates both the production of testosterone from cholesterol, and the process of spermatogenesis, while FSH primarily facilitates spermatogenesis.

Testosterone is produced by the Leydig (interstitial) cells in the seminiferous tubules (Fig 18.5) and diffuses across the basal membrane to directly influence the spermatogonia and Sertoli cells. Testosterone levels are maintained by negative feedback to the hypothalamus and anterior pituitary, via the HPT axis.

Summary points

- The structures of the female and male reproductive systems are designed to produce and transport gametes: ova and sperm.
- Gametogenesis involves cell divisions that halve the chromosome number: oogenesis produces ova in the ovaries, and spermatogenesis produces sperm in the testes.
- Following puberty, a single oocyte is released from the ovary each month under the control of the hormones of the HPO axis.
- Ovarian hormones stimulate monthly vascular and glandular development of the uterus in preparation for pregnancy.
- Hormones of the HPT axis stimulate sperm production from puberty onwards.
- Sperm are produced in the seminiferous tubules and stored in the epididymis until ejaculation.
- Semen released at ejaculation includes about 200 million sperm and 2–5 mL of secretions from the accessory glands to aid nourishment and support of the sperm.

Embryology

Embryology is described as 'the science concerned with the origin and development of a human being from a zygote to the birth of an infant' (Moore & Persaud 1998, p 2). Moore and Persaud (1998) emphasise that development is a continuum that starts at fertilisation, includes birth—a dramatic event resulting in a change in environment—and continues after birth, with development of teeth, bones, reproductive structures and so on. The process finishes by about the age of 25 years.

This section is limited to antenatal development, which begins with conception. Conception refers to fertilisation that results in pregnancy (Blackburn 2003). The probability of a viable conception has been calculated at only 30% per menstrual cycle (Blackburn 2003), with spontaneous abortions resulting from a range of abnormalities. The processes needed to produce a viable oocyte and a viable sperm have been described earlier in this chapter. This section examines fertilisation and the factors that contribute to successful fertilisation, implantation, development of the embryo and fetus, and development of the placenta.

Fertilisation

Fertilisation normally occurs in the ampulla of the fallopian tube. The beginning of fertilisation occurs when the sperm passes through the zona pellucida and makes contact with the secondary oocyte. This is most likely to occur if sperm enter the vagina just prior to ovulation or when a woman is ovulating, because sperm must undergo capacitation and the acrosomal reaction prior to fertilisation, and these processes require several hours.

Sperm transport

During sexual intercourse, 200–600 million sperm are released into the vagina in about 3 mL of semen. Chemicals present in the semen cause coagulation of the sperm (see accessory ducts above). This may help retain sperm in the vagina and protect against the acidic environment of the vagina. The coagulum is then dissolved in 20–60 minutes by activation of a further enzyme (fibrinolysis) in the semen. The alkaline pH of the semen facilitates sperm motility. Within a minute of sperm deposition, sperm can be detected in the cervix and uterus. However, most sperm are lost through vaginal leakage and never enter the cervix. Those that do survive, may survive in the cervix for hours and be nourished by the cervical mucus. Further progress towards the uterus is dependent on the consistency of the mucus, which is determined by oestrogen and progesterone (see female hormones above). Sperm most likely move both by their own propulsion, and by the action of uterine cilia causing semen to flow through the uterus to the fallopian tubes (Johnson & Everitt 2000).

Clinical point

When sperm are recovered following ejaculation and placed with ova in vitro, fertilisation takes several hours to occur. In contrast, sperm recovered from the uterus or fallopian tube are capable of immediate fertilisation. This suggests that sperm attain a fertilising capacity (capacitate) during their journey through the female reproductive tract (Johnson & Everitt 2000).

Capacitation and acrosomal reaction

Capacitation is stimulated by secretions in the oestrogen-dominated uterus and fallopian tubes. As the sperm move through the fallopian tubes, glycoproteins and seminal plasma proteins are removed from the plasma membrane over the acrosome (head of spermatozoa), leading to activation. The capacitated sperm contacts the corona radiata around the secondary oocyte. Enzymes are released from the acrosome (acrosome reaction) and are able to digest a tunnel through the corona radiata and zona pellucida. Tail movements change to wide-amplitude or 'whiplashing' beats that push the sperm forward in vigorous lurches.

Sperm need 4–10 hours in the female reproductive tract before they can fertilise an ovum. Sperm only remain activated for a short time, but a supply of sperm persists for some time as sperm stored in the folds of the mucosa of the cervix trickle gradually through the capacitating uterus to the fallopian tube, where they become activated. This allows a greater time following intercourse in which activated sperm are available to fertilise the ovum (Johnson & Everitt 2000).

The sperm 'bind' with specific receptors (glycoproteins) on the surface of the zona pellucida. Once the spermatozoon penetrates the zona pellucida, it is in the cytoplasm of the ovum. Several hundred sperm can bind on the zona pellucida but only one sperm can penetrate this layer, due to an event called syngamy. This causes changes in the electrical potential and chemical composition of the zona pellucida, which prevents other sperm from penetrating.

The cell membranes of the oocyte and sperm fuse, and the head and tail of the sperm enters the oocyte, leaving the sperm's plasma membrane behind (Fig 18.12). The oocyte completes the second meiotic division, forming a mature oocyte and a second polar body. The nucleus of the mature ovum becomes a female pronucleus and the polar body disintegrates. Within the oocyte, the nucleus of the sperm enlarges to become the male pronucleus and the tail disintegrates. The two pronuclei are morphologically indistinguishable. The membranes of the pronuclei fuse and a zygote is formed. The zygote has 46 chromosomes: 22 autosomes and 1 sex chromosome from each gamete. The zygote is genetically unique, containing a new combination of chromosomes that is different from either of the parents. Fertilisation is completed within 24 hours of ovulation (Moore & Persaud 1998).

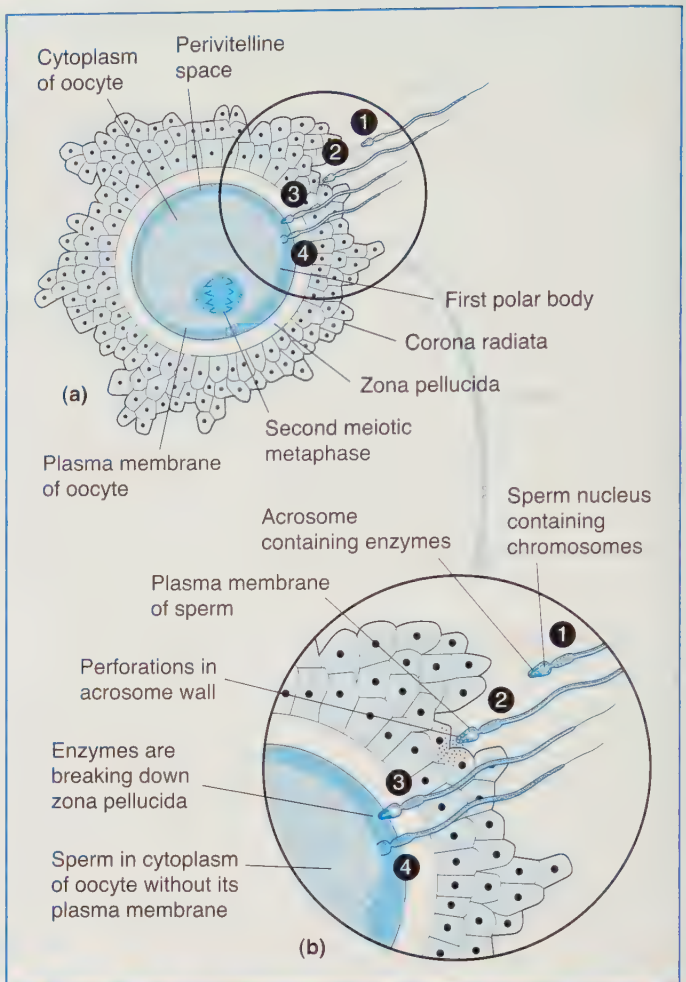

Figure 18.12 Acrosome reaction and sperm penetrating an oocyte. The details of the area outlined in **(a)** are shown in **(b)**. 1 Sperm during capacitation 2 Sperm undergoing the acrosome reaction 3 Sperm digesting a path through the zona pellucida 4 Sperm after entering the cytoplasm of the oocyte (based on Moore & Persaud 1998)

Factors that facilitate fertilisation

The ovum survives for only 12–24 hours after ovulation. Sperm can live up to 72 hours in the female reproductive tract, and require at least 4–6 hours, sometimes 10 hours, in the female reproductive tract to become activated. Sexual intercourse up to 72 hours before and approximately 12 hours after ovulation may result in fertilisation.

Changes in the female reproductive tract mean the female is most receptive to sperm at around the time of ovulation. Increased oestrogen levels at this time have many effects, such as:

- increasing the contractility of the fallopian tube, which assists sperm transport
- decreasing the viscosity of the cervical mucus
- altering the molecular structure of the mucus to form small channels that allow sperm through.

The oocyte secretes a chemical that attracts sperm (Sun et al 2005), and progesterone released after ovulation stimulates the acrosomal reaction (Shah et al 2003). Progesterone also increases the viscosity of the cervical mucus during the luteal phase, preventing further sperm access.

Cleavage and formation of blastomeres

The zygote remains in the ampulla of the fallopian tube for about the first 24 hours and then is swept toward the uterus by ciliary action over the next three to four days (Blackburn 2003). The zygote undergoes repeated mitotic divisions, called cleavage, as it moves towards the uterus. Cleavage increases the number of cells, blastomeres, but not their size, and they are still contained within the zona pellucida. The cytoplasm of the ovum provides the energy and nutrients for the mitotic divisions. The first division into the two-cell stage occurs about 30 hours after fertilisation (Moore & Persaud 1998). Further divisions occur about every 12 to 24 hours. By three days, there are 12 to 15 blastomeres, which now change shape, forming a solid cluster within the zona pellucida, called a morula.

The morula enters the uterine cavity at day 4–5, and as uterine secretions pass through the zona pellucida into the morula, a fluid-filled space, the blastocyst cavity, is formed (Moore & Persaud 1998). As the cavity forms, the surrounding blastomeres separate into two areas:

- the trophoblast—the thin layer of cells around the outside that give rise to the fetal part of the placenta, the chorion
- the inner cell mass—the inner group of blastomeres that give rise to the embryo, yolk sac and amnion.

The conceptus is now called a blastocyst. The blastocyst floats in the uterine cavity for about two days as the zona pellucida disintegrates. This allows more rapid growth of the blastocyst. Uterine secretions containing nutrients, glycogen, mucopolysaccharides and lipids maintain the blastocyst. Approximately six days after fertilisation, the blastocyst attaches to the endometrium and begins to implant (Moore & Persaud 1998). Figure 18.13 summarises the processes of cleavage and implantation during the first week.

Steps of implantation

Implantation of the blastocyst normally occurs in the posterior or anterior wall of the uterine body, with the inner cell mass oriented toward the epithelium of the endometrium. Implantation is essential to maintain nourishment of the blastocyst. The following points detail the steps involved in implantation. This is also illustrated in Figure 18.14.

1. The trophoblast differentiates into two layers: the outer synctiotrophoblast (maternal side of the placenta) and the inner cytotrophoblast (fetal side of the placenta).
2. The cytotrophoblast forms new synctial cells, the chorionic villi and the amnion.
3. The synctiotrophoblast is diffuse tissue with no cell membranes. Projections of the synctiotrophoblast extend through the endometrial epithelium and connective tissue (stroma), releasing proteolytic enzymes, which break down the maternal tissues. This allows the blastocyst to burrow into the endometrium. The synctiotrophoblast is not rejected by the mother, possibly because it does not have transplantation antigens (Blackburn 2003). Slight bleeding may occur during this time, and can be mistaken for light menstrual bleeding (Blackburn 2003).
4. The blastocyst is nourished by glycogen and lipids that diffuse from the stromal cells and glands of the eroded tissue.
5. By day 9, degradation by the proteolytic enzymes causes spaces (lacunae) to appear in the synctiotrophoblast. Individual lacunae fuse to form lacunal networks and these fill with fluid from the endometrial glands (Blackburn 2003). Nutrients diffuse from the lacunae to the embryo.
6. Concurrent development of the inner cell mass occurs. At about day 7, a layer of cells, called the hypoblast, forms on the side of the inner cell mass adjacent to the blastocyst cavity (Moore & Persaud 1998). Formation of a bilaminar disc (a two-layered embryo) with a layer of epiblast and hypoblast is complete by day 8. This embryonic disc forms the germ cells that will produce all the tissues and organs of the embryo (described in the next section on embryology).
7. By day 10 the conceptus is completely implanted in the endometrium, covered by a closing plug, and by day 12 the endometrial epithelium has regenerated in the area (Blackburn 2003).

BOX 18.1 Assisted reproduction

Examples of assisted reproduction:

- *In vitro fertilisation*—ovarian follicles may be stimulated artificially by gonadotrophins. Several secondary oocytes are aspirated from the ovaries prior to ovulation. Sperm and ova are mixed in a laboratory dish, fertilisation and cleavage observed and blastomeres (eight-cell) inserted into the uterus via the cervical canal. Several zygotes may be transferred, to increase the chances of pregnancy.
- *In vivo fertilisation*—sperm are deposited in the upper vagina, cervix or uterus by artificial insemination when a woman is ovulating.

Changes in the endometrium

The uterine endometrium is in the secretory phase during implantation. During this phase there is proliferation of endometrial glands, providing a source of nutrition for the blastocyst. The spiral arterioles form a prolific network of blood vessels supplying the dense capillary bed beneath the epithelial layer of the endometrium.

Following implantation, the endometrium changes in structure and is known as the decidua. Increasing progesterone

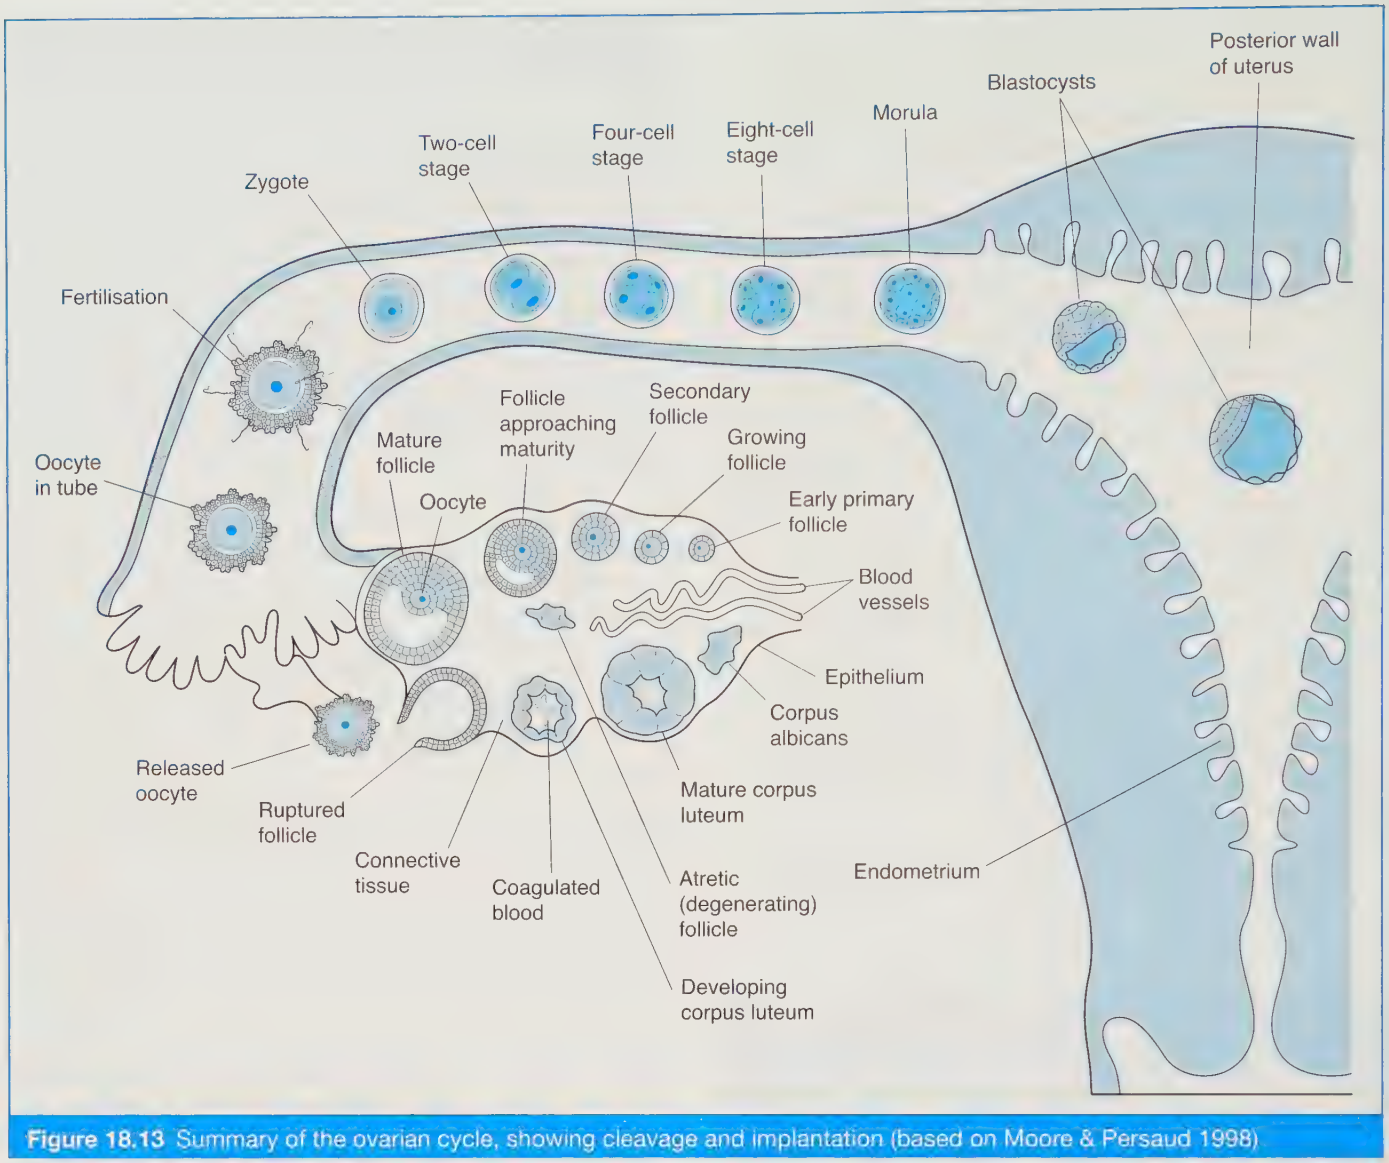

Figure 18.13 Summary of the ovarian cycle, showing cleavage and implantation (based on Moore & Persaud 1998)

facilitates enlargement of the decidual cells and accumulation of glycogen and lipids. These cellular changes, in combination with the vascular changes of the endometrium, are known as the decidual reaction. These structural changes are recognisable during ultrasonography and can be used to diagnose early pregnancy (Moore & Persaud 1998).

Three areas of the decidua are defined by their location relative to the implantation site:

- the *decidua basalis* is the region beneath the site of implantation. This develops into the maternal part of the placenta.
- the *decidua capsularis* is the area covering the implantation site. This disappears as the chorion is formed.
- the *decidua parietalis* (vera) is the remainder of the uterine lining. The chorion and decidua parietalis eventually fuse, obliterating the uterine cavity.

While the posterior wall of the body of the uterus is the most common site for implantation, the blastocyst may implant over the internal os of cervix or cervical canal, resulting in placenta praevia. Extrauterine implantation results in an ectopic pregnancy. The most common site is the ampulla or infundibulum of the fallopian tube.

By the time implantation is complete, at 10–12 days, the inner cell mass has differentiated into a bilaminar disc and the trophoblast has developed into the synctiotrophoblast and the cytotrophoblast. The synctiotrophoblast has formed maternal lacunae and the cytotrophoblast has formed chorionic villi. Further development of the embryo, placenta and fetal membranes occurs simultaneously.

Development of the embryo

The embryonic period refers to the period from the third to the eighth week after fertilisation. During this time the embryo develops from a bilaminar flat disc (Fig 18.14) to an embryo with all the major organ systems and a functioning cardiovascular

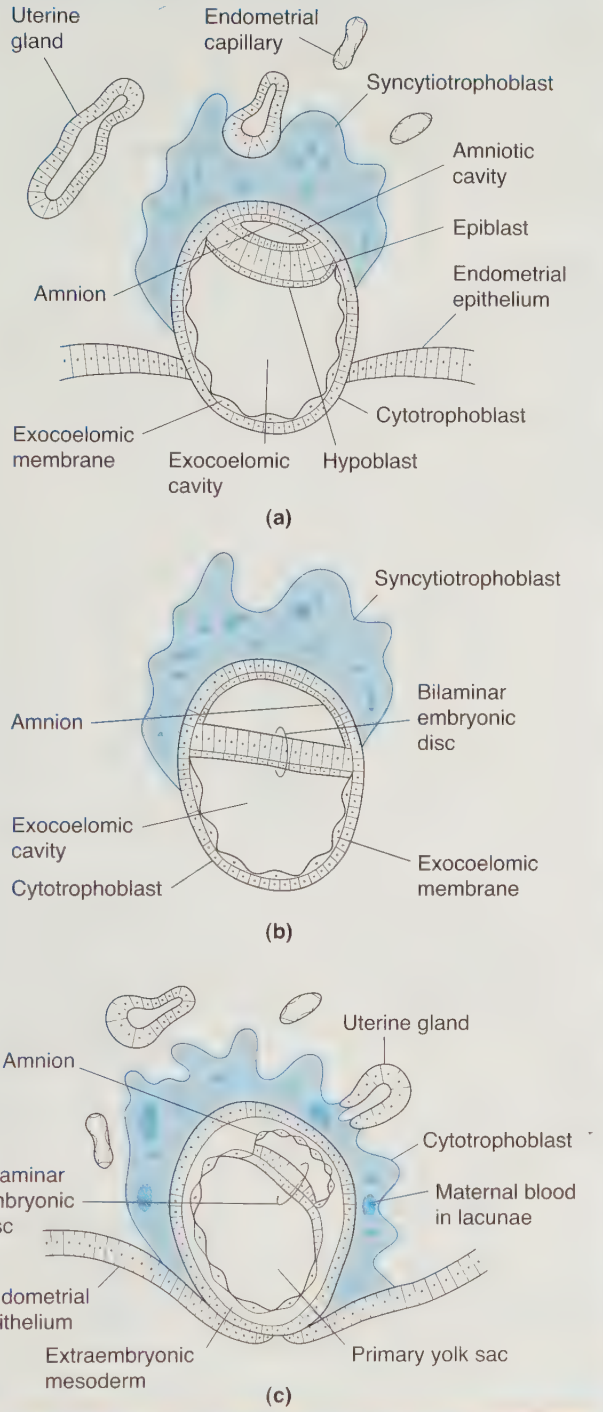

Figure 18.14 Implantation of a blastocyst into the endometrium **(a)** Section through a blastocyst partially implanted in the endometrium **(b)** Slightly older blastocyst after removal from the endometrium **(c)** Section through a blastocyst of about nine days implanted in the endometrium (based on Moore & Persaud 1998)

system. The embryo is vulnerable to developmental disruption from a wide range of teratogens—environmental agents such as infections, hyperthermia, drugs and radiation exposure, nicotine and narcotics exposure, leading to major congenital abnormalities.

It is important to understand embryological development. It explains why a healthy lifestyle prior to conception and during early pregnancy is important in order to provide the best possible environment for normal development of the embryo and why women of reproductive age should avoid potential teratogens at all times. This vulnerable phase of embryological development often occurs before a woman is aware that she is pregnant. Understanding normal embryological development also helps to understand abnormal development (e.g. cleft palate) and has led to the development of processes that can correct some abnormalities.

In considering embryological development, this section reviews changes in the third week and then focuses on the principles that govern development, rather than the detailed development of organ systems, which is beyond the scope of this text. (See the further readings and online resources at the end of this chapter for more detailed accounts.)

The embryo in week 3

Development during the embryonic period is very rapid and this makes it a vulnerable time. Gastrulation is the reorganisation of cells of the bilaminar disc (week 2) to form the trilaminar disc (Moore & Persaud 1998). The notochord and somites also form in week 3, and neurulation begins.

Gastrulation

A line of epiblast cells undergoes very rapid division to form the primitive streak along the midline. Cells from the primitive streak migrate down to form a layer of mesoderm between the epiblast and hypoblast (Fig 18.15), resulting in the trilaminar disc. The primitive streak continues to form mesoderm through the fourth week and then degenerates (Moore & Persaud 1998). All body organs and structures are derived from these three germ layers (ectoderm, mesoderm and endoderm), as shown in Figure 18.16.

Notochord and somite formation

A chord of mesodermal cells migrates to form the notochord, a rigid tube that defines the head–tail axis of the embryo and plays a key role in signalling the development of unspecialised

BOX 18.2 Pregnancy test

The developing synctiotrophoblast secretes human chorionic gonadotrophin (hCG) into the maternal circulation to maintain the pregnancy by stimulating the corpus luteum to continue producing oestrogens and progesterone. This hormone is the basis of the pregnancy test. It can be detected by sensitive radioimmunoassays by the end of the second week (four weeks after the beginning of the last menstrual bleeding)—usually well before the woman is aware that she is pregnant.

embryonic cells into specialised adult tissues and organs (Moore & Persaud 1998). The notochord forms the framework for the development of the axial skeleton (bones of head and spinal cord) and the neural plate, which develops into the primitive nervous system. Paired segments of mesoderm also form on either side of the notochord. These are somites, which eventually give rise to the axial skeleton and associated musculature as well as the overlying dermis of the skin. About 38 pairs of somites appear between days 20 and 30, and 42 to 44 pairs are present by the fifth week. They form prominent elevations and can be used to determine an embryo's age at this time.

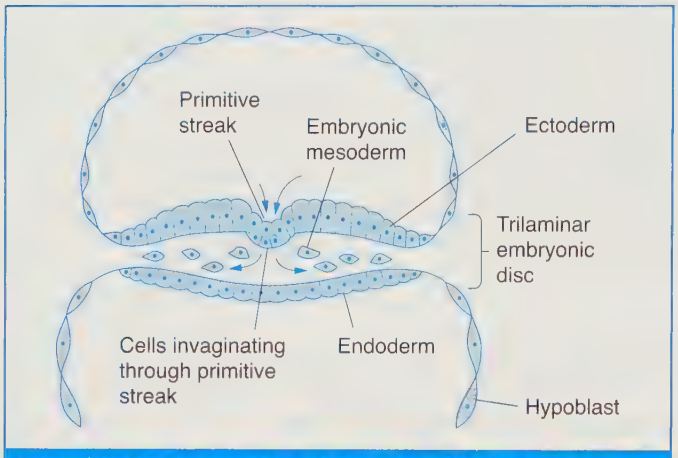

Figure 18.15 Invagination of the cells of the primitive streak to form a trilaminar disc (based on Coad & Dunstall 2001)

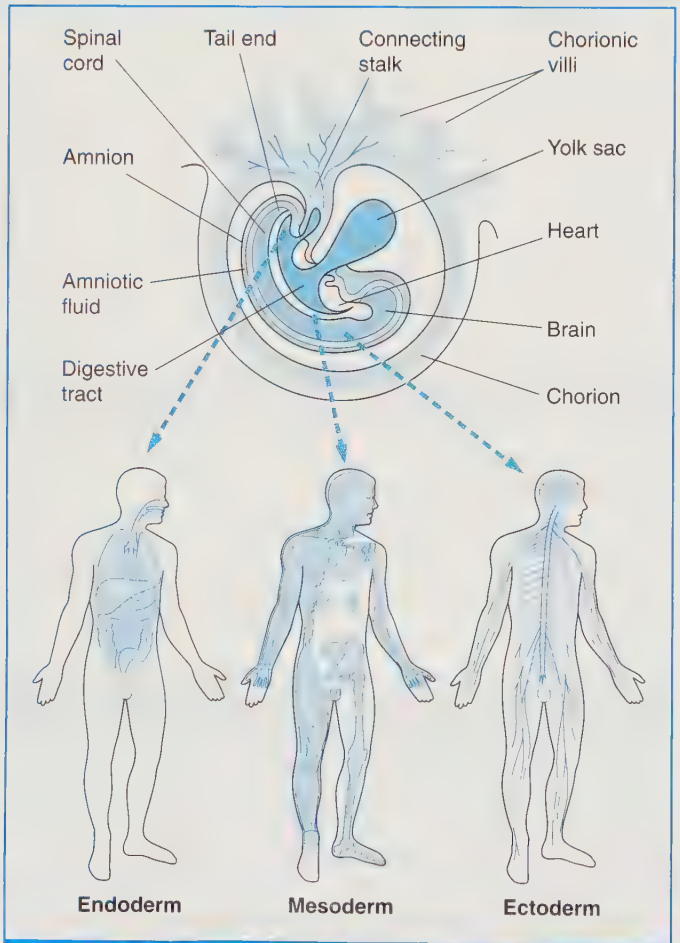

Figure 18.16 Organs derived from the ectoderm, mesoderm and endoderm (based on Shier et al 2002)

Neurulation

The notochord induces thickening of the embryonic ectoderm to form the neural plate. A longitudinal groove develops in the plate and neural folds form above this. The folds fuse to form the neural tube—the primordium of the central nervous system (Fig 18.17). Incomplete fusion of the tube results in congenital defects of the central nervous system (e.g. spina bifida).

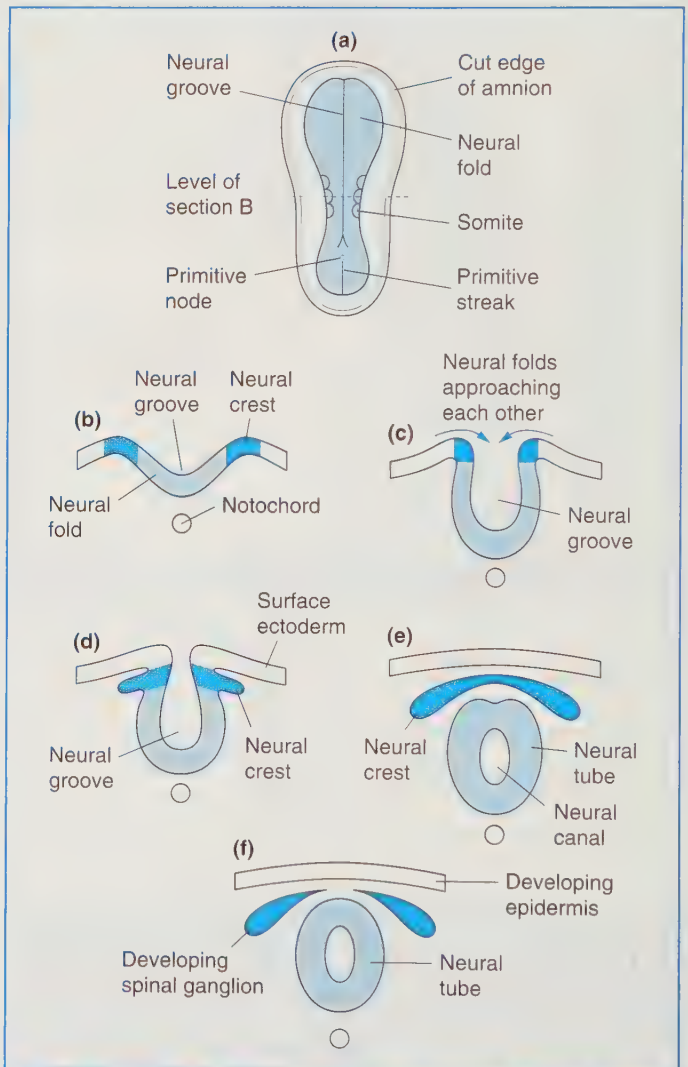

Figure 18.17 Transverse sections through progressively older embryos, showing formation of the neural groove, neural tube and neural crest up to the end of the fourth week (based on Moore & Persaud 1998)

Other changes during the third week include blood vessel formation. By the end of the week, nutrition is delivered by a primitive uteroplacental circulation, the framework for development of the nervous system is present, and the embryo begins organogenesis. A number of fundamental processes guide organogenesis and development of the embryo.

Cellular processes that control embryological development

Embryological development involves growth, differentiation and organisation. Growth involves an increase in cell number and cell size, while differentiation involves the creation of new types of cells and tissues. Organisation describes how the new units become coordinated into functional units (Blackburn 2003). Gene families within the embryo are known to control development. By the 2 to 4 cell stage, activated genes produce intercellular signalling proteins, which regulate cellular activity and development. Environmental factors can interact with groups of genes to turn them on and off at precise intervals.

The mechanisms controlling these processes are complex, but a number of processes have been described that contribute to development. These include: cell differentiation, induction, differential proliferation, programmed cell death, changes in cell size, cell migration, cell recognition and adhesion, folding and differential maturity. The following description of these processes has been adapted from Blackburn (2003).

Cell differentiation

The zygote contains one set of chromosomes, with the blueprint for the development of at least 350 different cell types that make up the body. Initially, cell division produces cells that are identical, but differentiation begins at the end of the first week, when the blastomeres of the morula develop into either cells of the inner cell mass or cells of the trophoblast. Remembering that all cells have the same genetic code, the process of differentiation involves restricting some areas of development while enabling others. This is regulated by gene families, which are switched on to produce specific proteins in a particular order.

Induction

Cells can influence cells in another part of the embryo by induction. Once again this process relies on signalling proteins (from inductors) and the ability of some cells to bind these proteins and respond (inducers). Development of many parts of the embryo is by secondary induction, where one change induces the next and so forth. For example, formation of the structures of the eye involves a series of inductions: the forebrain is induced to form the optic cup, which then induces adjacent tissue to form the lens of the eye, which then induces the surrounding tissue to form the cornea. Interfering with a step in the induction process will prevent the later stages occurring.

Differential cell proliferation

Differential cell proliferation is the process whereby groups of cells grow at different rates. This can give the impression of cells sinking into tissues if adjacent cells proliferate rapidly and build up in one area. This can be seen in the development of the neural groove. Rapid cell proliferation often precedes a period of differentiation. Congenital defects can result if proliferation is inhibited—by teratogenic agents, for example. Proliferation can also be inhibited through lack of space—for example, with a diaphragmatic hernia, the intestinal contents are pushed into the thoracic cavity, where they can inhibit lung growth.

Programmed cell death

Programmed cell death, where cells are destroyed by lysosomal enzymes, is a normal part of embryological development. This is the process whereby hollow tubes are formed (e.g. the trachea and parts of the gut). It also accounts for the disappearance of the webbing between fingers and toes. If the enzyme release is inhibited, congenital malformations such as syndactyly, bowel atresia or imperforate anus may result. Overactive enzymes can produce micromelia (shortened limbs).

Cell size and shape change

Chemical changes in cell microtubules, the skeleton within the cell, are responsible for changing cell shape (e.g. elongation of the cell). The process can be inhibited (e.g. by toxins from microorganisms). Other changes in cell shape (e.g. swelling or shrinking) can be induced by changes in osmotic balance.

Cell migration

Development of structures often involves migration of cells to different areas. This is a controlled process whereby the leading edge of the cell elongates (due to microtubule elongation) and adheres to a new contact point. Contraction of the cell toward the contact point completes the migration. Again, interference with the microtubule enzymes may impede migration—for example, Hirschsprung's disease (a lack of intestinal ganglion cells) results from failure of neural crest cells to migrate. In the central nervous system, at three to six months gestation, there is migration of millions of neurons from their original area in the periventricular area to their eventual location in the cerebrum and cerebellum. Interference with this migration can result in defects in central nervous system function and organisation.

Cell recognition and adhesion

Recognition and adhesion involves interaction of specific substances, such as cell surface enzymes, on one cell with complementary substances or adhesion molecules on another cell. An example of this is when the neural folds meet and fuse to form the neural tube. Adhesion may be prevented if there is interference with cell membrane substrates. This may be the mechanism for cleft palate or neural tube defects.

Folding of the embryo

The embryo starts as a straight line of cells but undergoes folding to adapt to the available space as it grows. Transverse folding results in a cylindrical shape, while longitudinal folding results in the head and tail folds.

Differential maturity

This process refers to the fact that different organ systems mature at different rates; for example, the gut is structurally complete at birth while the alveoli of the lungs and the long bones continue maturation after birth. This explains why different organ systems are vulnerable to damage by toxins at different stages of development.

Any malfunction of these fundamental processes results in impaired development. Understanding the basic principles may help to see why seemingly unconnected pathologies occur as congenital defects. The above processes are responsible for the cascade of changes resulting in organogenesis (development of the organ systems).

Organogenesis: highlights of weeks 4 to 8

All the major organ systems and structures of the body form from the three germ layers of the trilaminar disc. Table 18.1 lists visual highlights of the changes seen in the embryo (adapted from Moore & Persaud 1998). This is a critical period in human development as it is a time of most rapid cell division and the time of greatest vulnerability to teratogens. Different organ systems undergo rapid change at different times and this leads to variable impact of teratogens on different structures. Critical periods for the different organ systems are illustrated in Figure 18.18.

TABLE 18.1 Overview of embryonic development from 4 to 8 weeks

Week of gestation	Visual highlight
4	• Embryo straight, C-shape developing • Somites form • Neural tube fusing, but open at rostral and caudal ends • Branchial arches present (develop into primitive face, jaws and neck) • Forebrain prominent • Upper limb buds appear, then lower limb buds • Otic pits present (internal ears) • Tapered tail obvious • Beating heart prominent
5	• Rapid development of brain and head enlargement • Face touches heart prominence • Hand plates develop in upper limbs
6	• Limb buds (especially upper) more differentiated into elbow and wrist • Ridges (digital rays) in hand plates obvious (forerunners of digits) • External ear canal and auricle (pinna) formed • Pigmented eye obvious • Head disproportionately large and bent over • Some straightening of neck and thorax
7	• Umbilical herniation (intestines enter extraembryonic coelom in umbilical cord) • Notches appear between digital rays of hand plates • Liver is prominent
8	• Short, webbed digits of hands gradually lengthen • Notches appear between digital rays of the feet • Stubby tail disappears • Head disproportionately large • Neck apparent • Eyelids more obvious and eyes open • Auricles of external ears are low set • Sexuality of external genitalia not easily determined

(Source: adapted from Moore & Persaud 1998)

The fetus: from nine weeks to birth

The fetal period is mainly a time of growth and functional maturation. There is rapid body growth, while head growth slows. A fetus is capable of surviving independently at 32–34 weeks gestation, and survival in a neonatal intensive care unit may be possible from 22 to 26 weeks, although survival for babies under 24 weeks gestation is commonly associated with neurological impairment. A survey in Australia of 133 neonatalogists and registered nurses suggested that they would 'almost always' resuscitate an infant of 24 weeks gestation (Oei et al 2000), while health professionals at non-specialist facilities were shown to often underestimate survival of extremely premature infants compared to available Australian data (Gooi et al 2003).

The developmental level at birth may affect adult health. Several studies support a link between low birthweight and increased risk of coronary heart disease, stroke, hypertension and non-insulin-dependent diabetes in adults (Barker 2004; Kajantie et al 2005).

Table 18.2 outlines some visual highlights of fetal development.

The developing embryo and fetus is supported by the development of extraembryonic structures.

Development of the placenta and fetal membranes

The placenta is a feto-maternal organ—that is, it has fetal and maternal regions that develop from the trophoblast region in the blastocyst. Development begins in the second week. The placenta becomes fully established by 8–10 weeks, and full size by the fourth month. The placenta separates the maternal and fetal circulatory systems, yet allows ready exchange of many substances such as respiratory gases and nutrients between the mother and fetus. The placenta is the

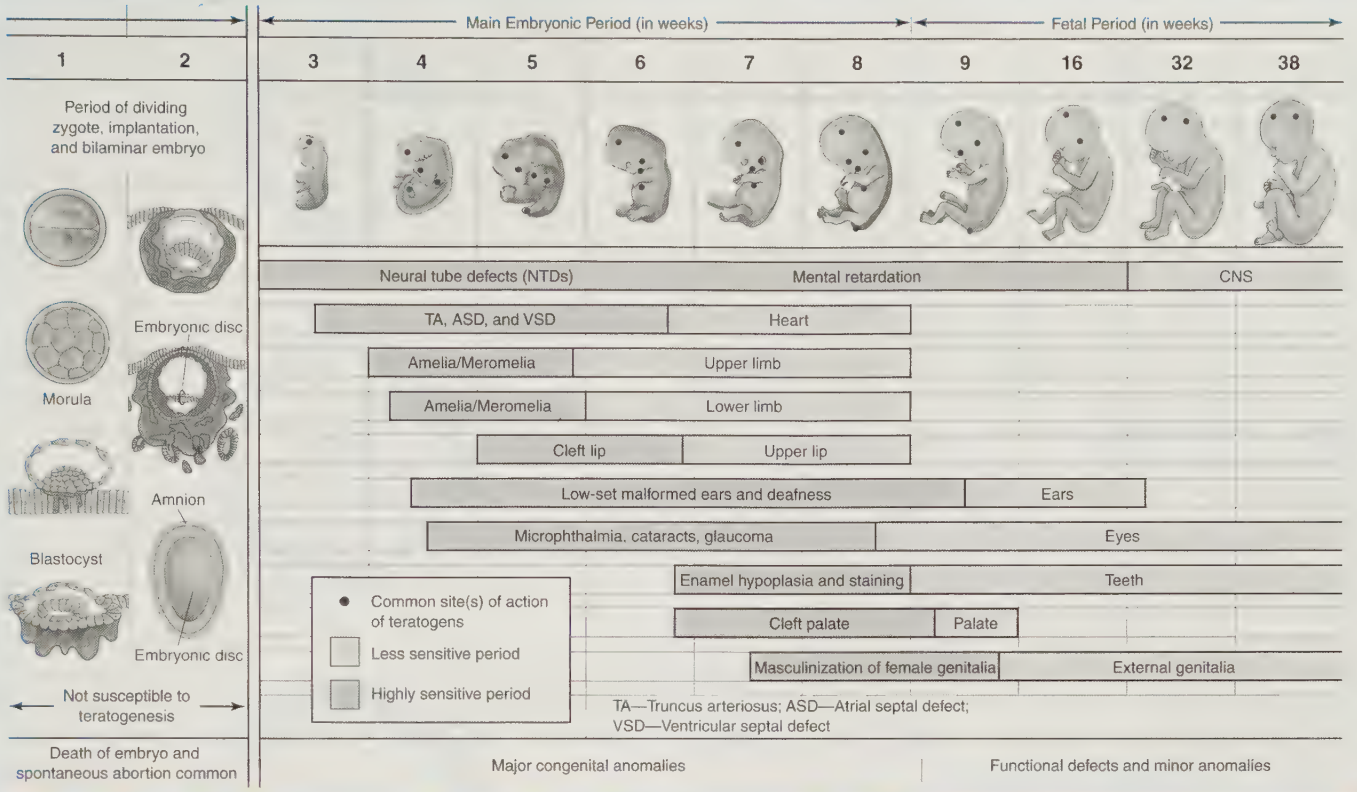

Figure 18.18 Critical periods for the different organ systems (Moore & Persaud 1998)

TABLE 18.2 Overview of fetal development

Week of gestation	Visual highlight
9–12	Eyes can close, sex distinguishable externally by 12 weeks, red blood cells produced in liver at first, then mainly in spleen, urine excreted into amniotic fluid
13–16	Head proportionately smaller, ossification of skeleton begins, ovaries differentiated (16 weeks) with primordial follicles containing oogonia, eyes face anteriorly, not laterally now
17–20	Growth slows, lower limbs reach final proportions, quickening felt by mother, brown fat forms (site of heat production), uterus fully formed (18 weeks), vaginal development begun, testes begin descent from posterior abdominal wall (20 weeks)
21–25	Substantial weight gain, body better proportioned, cells in walls of lungs secreting surfactant to keep developing alveoli patent, respiratory system still very immature
26–29	Lungs developed, CNS can direct breathing, bone marrow produces red blood cells by 28 weeks, testes begin descent at 28–32 weeks
30–34	Pupils react to light (31 weeks), white fat 8% body weight
35–38	Firm grasp, circumferences of head and abdomen equal (36 weeks), growth slows, white fat 16% body weight

main site for the production of hormones that maintain the pregnancy, although initially, hormones are supplied from the corpus luteum in the ovary. Secretion of hCG by the trophoblast maintains the corpus luteum until the placenta is able to take over hormone production by 8–10 weeks. The chorioamniotic membrane develops around the fetus and contains the amniotic fluid. It is metabolically active tissue that produces hormones.

Uteroplacental and fetoplacental circulation

Development of the fetal membranes and the placenta, along with development of embryonic blood vessels for transport, enables a more efficient exchange mechanism for the developing embryo than the cell-to-cell diffusion during early development.

Maternal lacunae

Primitive circulation develops as the synctiotrophoblast erodes the glands and blood vessels of the endometrial tissue to form lacunae (spaces). Evidence indicates that during the first trimester, trophoblastic plugs prevent blood flow from the maternal spiral arterioles into the lacunae (Jaffe et al 1997). This means that embryonic development is in a relatively hypoxic environment (Chaddha et al 2004). Secretions from the endometrial glands initially fill the lacunae, allowing nutrients and O_2 to diffuse to the embryonic disc, and wastes and CO_2 to diffuse from the embryonic disc into maternal circulation. This primitive uteroplacental circulation is present by day 13. Towards the end of the first trimester, the lacunar networks develop into the intervillous spaces of the placenta, which fill with blood, providing fluid with a higher oxygen content for fetal exchange. By this time the fetus has developed blood vessels in the villi and mechanisms to cope with the higher levels of oxygen available from the maternal blood (Blackburn 2003).

Chorionic villi

During the second week, the cytotrophoblast invades the areas of synctiotrophoblast between the lacunae and forms finger-like projects called the chorionic villi. Further chorionic villi develop as the synctiotrophoblast continues to invade the decidua. Villus development is stimulated by growth factors and the relatively hypoxic environment (Chaddha et al 2004). Blood vessels develop within the villi by 18–21 days and a primitive fetoplacental circulation operates between embryonic blood in the villi, embryonic vessels and the primitive heart by 20–21 days.

Villi can be two types, anchoring or branch villi, with similar numbers of both. Branch villi facilitate maternal fetal exchange via diffusion, while anchoring villi attach the placenta to the decidua.

Formation of the smooth chorion and amnion

The chorionic villi initially cover the entire surface of the chorionic sac, but during the eighth week they disintegrate in some areas, forming the smooth chorion, and develop in other areas, forming the villous chorion. Degeneration occurs in areas compressed against the decidua capsularis as they lose their blood supply and become the smooth chorion and thus the chorionic membrane. In the area of membrane against the decidua basalis, the villi growing into the endometrium proliferate, and these become the chorionic villi of the fetal placenta (Moore & Persaud 1998).

The amnion is formed from embryonic ectoderm (see embryology section later). Initially the amnion encloses a small cavity, the amniotic cavity, situated above the embryonic disc, but the membrane and cavity enlarge to surround the

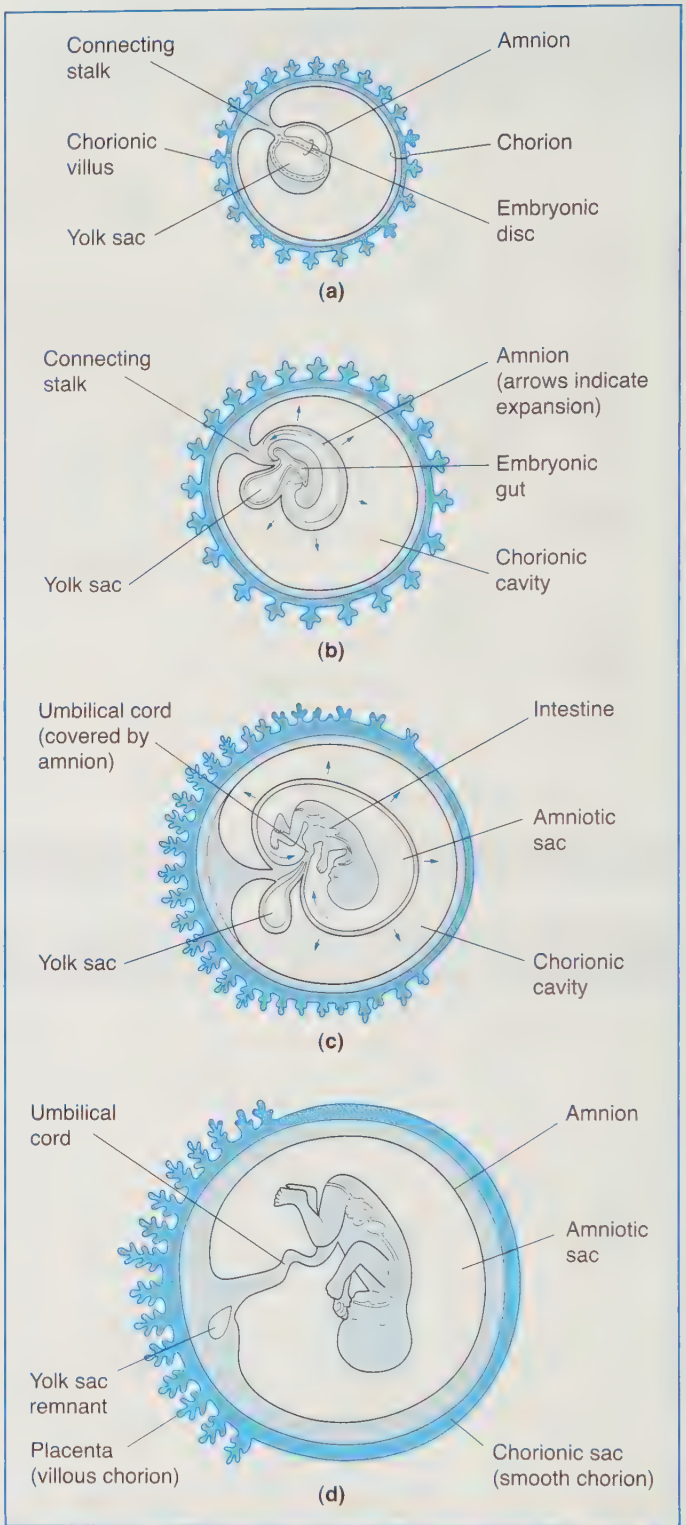

Figure 18.19 Steps showing how the amnion enlarges, fills the chorionic sac and envelops the umbilical cord: **(a)** 3 weeks, **(b)** 4 weeks, **(c)** 10 weeks and **(d)** 20 weeks (based on Moore & Persaud 1998).

embryo (Fig 18.19). The amniotic membrane is pushed against the chorion and they form the chorioamniotic membrane, a double membrane sac surrounding the fetus. The membranes do not fuse, but are separated by 200 mL of amniotic fluid and mucus produced in the amnion. The chorion contains blood vessels that atrophy as pregnancy progresses; the amnion does not have a blood supply, but nutrients pass to it from the chorionic blood vessels. The amnion attachment to the fetus is reduced to the site of the umbilical cord. The membranes continue to grow until the 28th week, after which stretching accommodates the increased fetal size (Blackburn 2003). Connective tissue is heavily interwoven with collagen, allowing stretching and providing strength.

The amnion can rupture independently of the chorion and form amniotic bands of tissue. These bands can constrict and reduce blood supply to fetal parts, sometimes causing amputation (Sentilhes et al 2003).

The fetal membranes have a high metabolic rate, similar to that of the liver. They are active in synthesising many chemicals such as amniotic fluid, nutrients, renin and prostaglandins. The enzyme, phospholipase A2, necessary for prostaglandin synthesis, is found in the membranes and decidua, and the prostaglandin precursor, arachidonic acid, is also found in the membranes. The chorion stores hormones such as progesterone.

Amniotic fluid

Amniotic fluid is contained in the membranes and has several functions. It allows fetal movement and protects the fetus from changes in pressure and temperature. Protection from infection comes from antibacterial factors, such as transferrin (binds iron needed by bacteria), fatty acids (interfere with bacterial membranes), immunoglobulins and lysozymes (destroy bacteria) (Blackburn 2003).

The formation of amniotic fluid relies on diffusion of water and solutes from several sources. Initially there is some secretion by amniotic cells; however, most of the fluid diffuses from the interstitial fluid of the decidua parietalis and from blood in the intervillous spaces of the placenta across the amniochorionic membrane to the amniotic cavity. Exchange also occurs between the fetus and the amniotic cavity. The fetus swallows amniotic fluid and it is excreted by the fetal respiratory tract and fetal renal system (urine present in bladder by 11 weeks). Prior to keratinisation of the skin, which occurs by about 24 weeks, the skin is a major path for exchange of amniotic fluid.

Amniotic fluid is composed of 98–99% water, with the remaining 1–2% comprising electrolytes, creatinine, urea, bile, renin, glucose, hormones, fetal cells, lanugo and vernix. If the volume of amniotic fluid is above or below the expected level for gestational age of the fetus, conditions such as polyhydramnios or oligohydramnios can occur, with both maternal and fetal consequences.

Formation of the yolk sac

As the epiblast migrates to form the amnion, cells from the hypoblast migrate around the blastocyst cavity to form the extracoelomic cavity, which is modified to become the primary yolk sac. The embryonic disc is situated between the amniotic cavity and the yolk sac. The yolk sac is important for nutrient transfer in the second and third weeks. Early blood cell formation occurs in the wall of the yolk sac from the third to sixth week, when the liver takes over this role. During the fourth week, part of it is incorporated into embryo as the primitive gut, and its endoderm develops into the epithelium of the respiratory and digestive tracts. The remainder degenerates by 10 weeks (Fig 18.19).

Placental circulation in the mature placenta

Once embryonic circulation is established, oxygen and nutrients diffuse from the secretions or blood entering the maternal intervillous spaces, through the walls of the branch villi, and then enter the embryonic capillaries in the chorionic villi. Carbon dioxide and waste products are exchanged in the opposite direction. Maternal and fetal blood do not mix unless the placenta tears away from the decidua (Fig 18.20).

The placenta acts as a barrier to very few substances. Some large molecules with a particular shape and charge cannot pass—for example, heparin cannot cross but warfarin can. The placenta becomes thinner as pregnancy advances, and many drugs given to the mother are detected in fetal plasma.

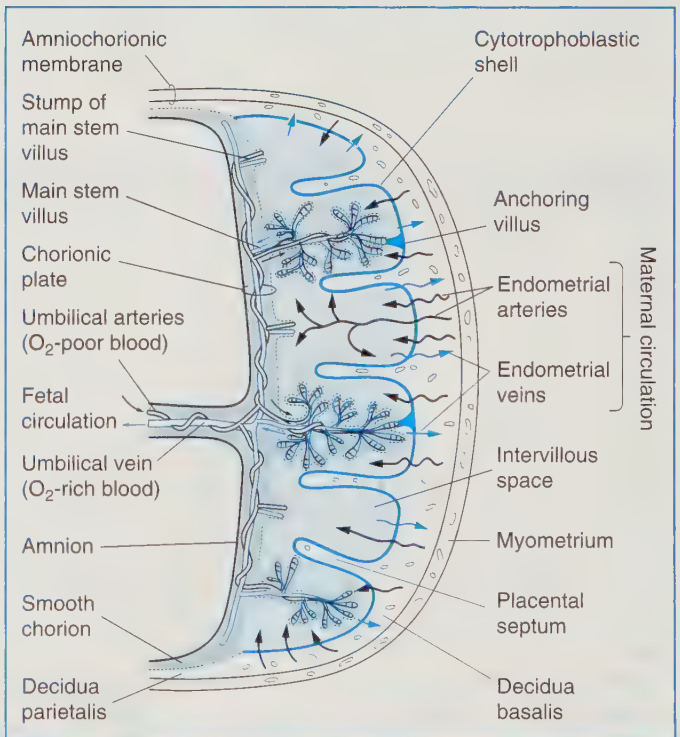

Figure 18.20 Transverse section through a full-term placenta, showing the relation of the fetal part to the maternal part (based on Moore & Persaud 1998)

Maternal placental circulation

Maternal blood enters the intervillous space from the spiral arteries in the endometrium. Blood spurts towards the roof of the intervillous space and then flows around the villi, allowing exchange of gases and nutrients. Blood then leaves the intervillous spaces via the endometrial veins. Blood flow increases from 50 mL/min at 10 weeks to 600–800 mL/min at term, accounting for 20% of the increased cardiac output (Henderson & Macdonald 2004). The intervillous spaces hold approximately 150 mL of blood, and this is continually replenished. During labour, uterine contractions prevent blood entering the intervillous spaces, but sufficient blood is retained there (150 mL) for fetal exchange of oxygen, nutrients and so on (Fig 18.20).

Fetal placental circulation

The umbilical cord provides circulatory connection between the mother and fetus. Deoxygenated blood leaves the fetus via two umbilical arteries to the placenta and oxygenated blood comes from the placenta via the umbilical vein. Wharton's jelly, consisting of collagen, muscle and mucopolysaccharide, cushions the blood vessels. Fetal blood flow in the placenta is approximately 500 mL/min (Blackburn 2003), and is regulated by several factors, such as fetal heart rate, fetal left-to-right shunts, and systemic and pulmonary vascular resistance (see the section on fetal circulation).

If the blood flow around the villi is compromised (e.g. prolapse of umbilical cord or vasoconstriction of maternal blood vessels due to hypertension), fetal hypoxia occurs. This may be indicated by decelerations in fetal heart rate and can lead to fetal death. A chronic reduction in uteroplacental circulation can result in intrauterine growth restriction due to reduced supply of nutrients and oxygen to fetus.

Placental function

The placenta has four key roles: transport, immunological, endocrine and metabolic. The placenta is also the main route of heat transfer away from the fetus (Blackburn 2003).

Transport role

The embryo, and then fetus, relies exclusively on the placenta for transport of cellular requirements. This includes the transport of:

- respiratory gases, oxygen and carbon dioxide. The rate of delivery is dependent on maternal and fetal blood flow. Any factors that impede uterine or fetal blood flow can lead to fetal hypoxia. Inhaled anaesthetics readily cross the placenta to the fetus, as does carbon monoxide produced from the incomplete combustion of cigarette smoke (Moore & Persaud 1998).
- nutrients. These constitute the bulk of substances transferred. Glucose, water and all vitamins cross rapidly. Small amounts of free fatty acids are transferred, while there is little or no transfer of maternal cholesterol, phospholipids or triglycerides. Transferrin, an iron transport protein, crosses the placenta and delivers iron to the fetus (Moore & Persaud 1998).
- hormones. Steroid hormones cross freely. Protein hormones are generally not transported to the fetus, but small amounts of thyroid hormones cross slowly (Moore & Persaud 1998).
- waste products. Carbon dioxide, urea, uric acid and bilirubin are all transported quickly across the placenta (Moore & Persaud 1998).
- electrolytes, which are freely exchanged. This includes any intravenous fluids given to the mother, which can interfere with fetal fluid balance (Moore & Persaud 1998).

Normal cellular transport mechanisms of simple and facilitated diffusion, active transport and pinocytosis allow movement of these substances between the maternal and fetal circulation. However, many harmful substances can also pass freely by the same mechanisms. These include:

- drugs. Almost all drugs can pass freely and many result in compromise for the fetus; for example, alcohol can cause fetal alcohol syndrome, narcotics may result in heroin addiction in the newborn, sedatives and analgesics such as pethidine used in labour can cause respiratory depression in the newborn. Antibiotics cross the placenta and this may be beneficial.
- infectious agents. Several viruses can cross the placenta and cause fetal infection—for example, rubella, poliomyelitis, measles and HIV. In some cases (e.g. rubella), severe congenital malformations may result (Moore & Persaud 1998).

Figure 18.21 summarises the range of substances that are transported across the placenta.

Increased transport of substances occurs as pregnancy progresses. This is due to a decrease in the distance between maternal and fetal blood as placental development occurs, increased volume of blood transported and greater fetal demands. Many factors can influence placental transport, such as maternal nutritional status or exercise. Disease states that influence maternal nutrient level, such as diabetes mellitus, or influence blood flow, such as hypertension, also affect placental transfer.

Immunological role

The placenta provides an effective barrier against most large bacterial microorganisms; however, most viruses and some smaller bacteria can pass to the fetus. Protection is afforded by maternal antibodies, particularly IgG antibodies, which cross the placenta and provide passive immunity against some diseases, such as measles, diphtheria and smallpox. Maternal antibodies do not protect against chickenpox or pertussis (whooping cough) (Moore & Persaud 1998). Transfer of antibodies can be disadvantageous—an example is transfer of Rh antibodies to a fetus following antibody production by a mother with Rh blood who has been exposed to Rh+ blood. If the fetus is Rh+ this can lead to haemolytic disease of the newborn (erythroblastic fetalis). Despite having a different genetic composition from that of the mother, the trophoblast is protected from generating an immune response in the mother (Gaunt & Ramin 2001; Stables & Rankin 2004).

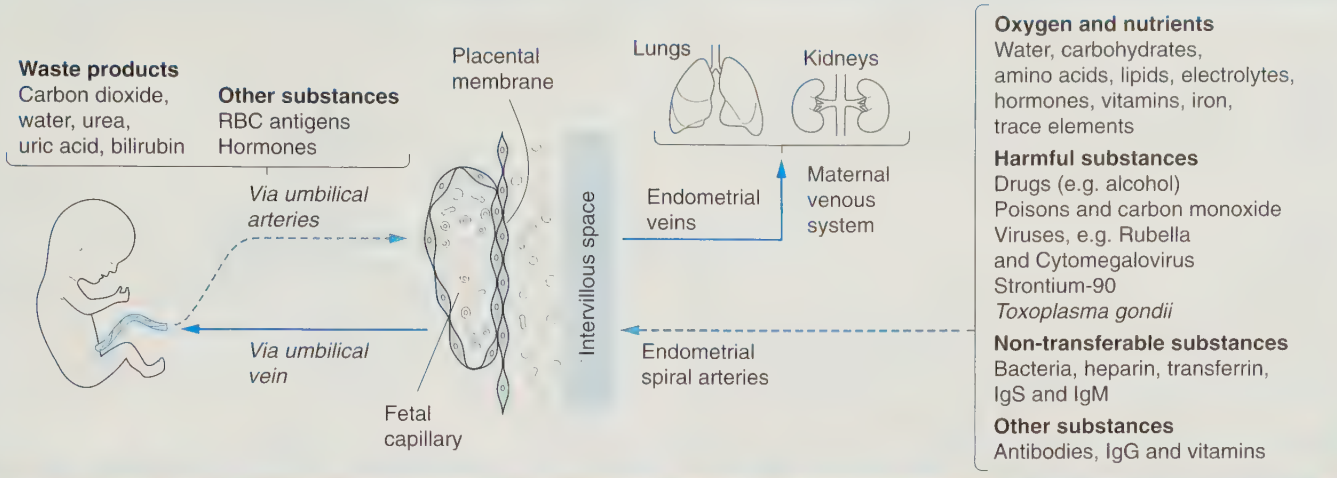

Figure 18.21 Substances transported across the placenta (based on Moore & Persaud 1998)

Endocrine role

Several hormones that maintain pregnancy are synthesised in the placenta: oestrogens, progesterone, hCG and human placental lactogen (hPL). These hormones are discussed later in the section on pregnancy.

Metabolic role

The placenta synthesises glycogen, cholesterol, fatty acids and enzymes, which are used by the embryo/fetus and the placenta. This is particularly important in early pregnancy (Moore & Persaud 1998).

Summary of placental and fetal membrane development

- The placenta begins to form as the synctiotrophoblast invades the endometrium.
- Maternal blood vessels and glands are eroded to form lacunae, and these link over time to form the blood-filled maternal intervillous spaces.
- The cytotrophoblast invades the areas between the lacunae to form the fetal chorionic villi, which are invaded by fetal blood vessels.
- Exchange of nutrients and wastes occurs via cell transport mechanisms such as diffusion and active transport between the blood in the fetal vessels and the secretions or blood in the intervillous spaces. Transport involves crossing the membrane of the chorionic villus and the endothelium of the fetal capillary.
- Maternal blood arrives at the intervillous spaces from the uterine arteries and leaves in the uterine veins. On the fetal side, blood arrives at the placenta from the umbilical arteries and leaves in the single umbilical vein.
- A double membrane develops around the embryo. The outer chorion is formed from the cytotrophoblast, while the inner amnion is formed from migrating ectoderm from the embryonic disc.
- The fetal membranes are metabolically active, producing amniotic fluid and hormones involved in pregnancy.
- The amniotic fluid circulates through the fetus in the digestive, respiratory and renal systems, and is also exchanged across the skin.
- The amniotic fluid protects the fetus from mechanical stress.
- The main functions of the placenta are to provide a transport medium between the fetus and mother, to produce hormones to maintain pregnancy, and to provide some immunological protection to the fetus. It also has a metabolic role.

Fetal circulation

The fetal cardiorespiratory systems have several physiological and structural specialisations that allow survival in a fluid environment. The fetal circulatory system delivers oxygen and nutrients to the fetal tissues and removes metabolic waste products, but the fetus relies on the placenta for oxygenation of the blood, not its own lungs, which remain dormant and fluid-filled until birth. Fetal breathing movements can be detected on ultrasound by week 10 (Blackburn 2003); however, the lungs and associated pulmonary blood vessels do not reach adequate maturity until 28 weeks gestation. Premature delivery with associated immaturity of the lungs and pulmonary vasculature can result in respiratory distress syndrome (RDS).

In the fetus, several structures are present to divert blood from the immature lungs to the placenta for gas exchange: umbilical vein, umbilical arteries, ductus venosus, foramen ovale, and ductus arteriosus. This leads to the mixing of oxygenated and deoxygenated blood in the atria, aorta and vena cava, which lowers levels of oxygen saturation.

Characteristics

Fetal circulation is characterised by fast flow, low vascular resistance (due to the low-resistance umbilical and placental circulations) and high pulmonary vascular resistance. The oxygen content of fetal blood is lower than that of the neonate, but fetal haemoglobin (HbF) has a higher affinity for oxygen, to manage this hypoxic state.

Structures

The fetal structures—umbilical vein, umbilical arteries, ductus venosus, foramen ovale and ductus arteriosus—ensure that the fetal circulation is routed to the placenta for oxygenation and that most of the blood bypasses the lungs, which are non-functional (Fig 18.22). The placenta is a low-resistance pathway, taking 40% of the fetal cardiac output (CO). The umbilical vein carries oxygenated blood from the placenta to the inferior vena cava (IVC), either indirectly via the hepatic portal system, or directly via the ductus venosus. The ductus venosus is a low-resistance pathway that bypasses the liver and takes 40–60% of blood flow, thereby enabling a large amount of the oxygenated blood to reach the heart directly. Deoxygenated blood from the lower part of the fetal body mixes in the IVC with oxygenated blood from the ductus venosus just before the IVC enters the right atrium. The foramen ovale is an opening in the septum between the right and left atria that allows 50–60% of the blood to shunt directly to the left atrium. The rest of the blood flows to the ductus arteriosus via the right ventricle. The ductus arteriosus is situated between the pulmonary trunk and aortic arch, and shunts 60% of the blood away from the pulmonary circulation into the systemic arterial circulation via the aortic arch. The high pulmonary vascular resistance of the deflated lungs allows only 5–15% of the CO from the right ventricle to enter the pulmonary circulation (Blackburn 2003). The umbilical arteries carry deoxygenated blood from the iliac arteries back to the placenta.

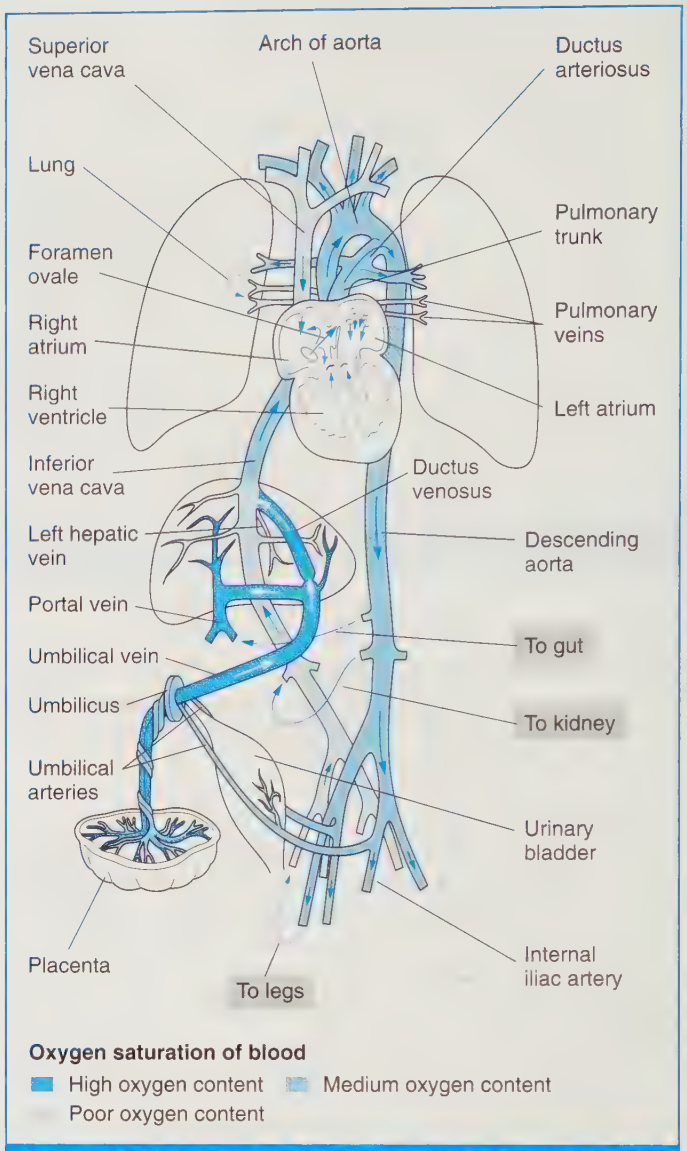

Figure 18.22 Schematic illustration of the fetal circulation (based on Moore & Persaud 1998)

Oxygen saturation of fetal blood

The fetus has high oxygen demands for its metabolic needs and this is reflected in the high CO, which is 250 mL/min/kg, compared with the adult value of 85 mL/min/kg. Fetal heart rate is also high at 155 beats/min at 20 weeks and 140 beats/min at 40 weeks (Blackburn 2003).

The highest oxygen saturation occurs in the umbilical vein at 70% (32–35 mmHg), falling to 65% (26–28 mmHg) in the left atrium and ascending aorta. This blood, at 65% saturation, also perfuses the fetal brain and coronary arteries. Blood returning from the lower limbs to the hepatic circulation and from the superior vena cava to the right atrium is very desaturated, at 25% (16–17 mmHg), even less than the 50% (18–19 mmHg) saturated blood returning to the placenta via the umbilical arteries (Fig 18.22).

There is a maternal–fetal oxygen gradient at the placenta (maternal PaO_2 is 33 mmHg, fetal PaO_2 is 28 mmHg), which facilitates oxygen diffusion into the umbilical vein. Fetal blood is uniquely able to maintain oxygen saturation at a higher level for a given PaO_2 than adult blood. This is due to the increased affinity that fetal haemoglobin (HbF) has for oxygen. This improves saturation and allows more oxygen to reach the tissues.

The fetal oxyhaemoglobin dissociation curve is shifted to the left of the maternal oxyhaemoglobin dissociation curve, and illustrates that HbF binds more oxygen at lower saturations, and equally that very low saturations must be reached before significant oxygen will be released from the HbF (see Fig 18.23).

Development of fetal circulation and lungs

The cardiovascular system is the first embryonic system to start functioning. This facilitates more efficient distribution of oxygen and nutrients around the growing mass of the embryo. An indication of the level of development at various

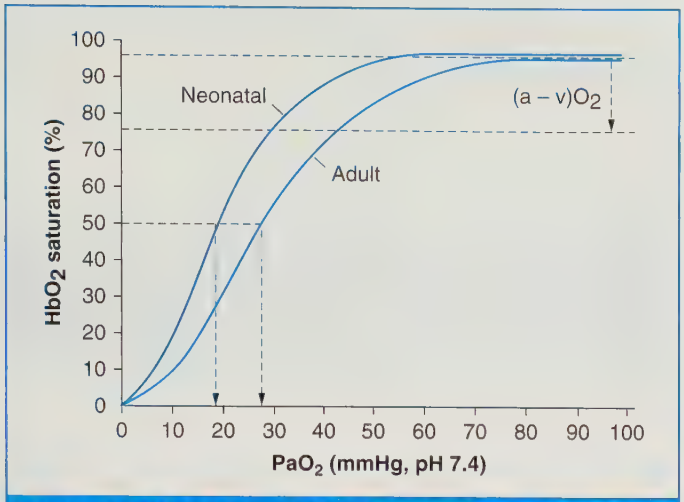

Figure 18.23 Oxyhaemoglobin curves of blood from term infants at birth and from adults (based on Blackburn 2003)

gestational ages follows. (More detail is available from the further readings listed at the end of the chapter.)

By three to four weeks the heart tube, containing one atrium and one ventricle, is beating. Development of the lungs is paralleled by development of the pulmonary circulation, but lungs do not take on a gas exchange function until birth. By three to four weeks a lung bud has appeared at the caudal end of the laryngotracheal tube and blood vessels, which will be the future pulmonary arteries, have formed branches to the lung bud. By eight to ten weeks the heart has four chambers with mitral and tricuspid valves, and bronchi and bronchioles have formed in the lungs (Fig 18.24). Development of pulmonary blood vessels is concurrent with development of the bronchi.

By 20 weeks, pulmonary vascularisation is prominent and development of pulmonary terminal sacs from the respiratory bronchioles is ongoing. Lung fluid secretion begins from the terminal sacs and pulmonary capillaries. Fetal breathing movements are well established. They occur 40–80% of the time, and at a rate of 30–70 breaths/minute (Blackburn 2003).

Fetal breathing movements

Lung fluid is regulated by fetal breathing, and therefore growth of the lungs is affected if breathing is inhibited. For example, maternal alcohol ingestion, hypoglycaemia, accelerated labour and cigarette smoking inhibit fetal breathing movements, the latter for up to an hour. The diaphragm plays an important role in fetal breathing movements, which prepare the lungs for the first breath, and influence differentiation and proliferation of lung tissue (Moore & Persaud 1998).

At 25 weeks, respiration is possible because some primitive alveoli have developed, but severe respiratory insufficiency is likely if the baby is born prematurely. At this time the terminal sacs are sparse, and lined with thick cuboidal epithelial cells; pulmonary capillaries are still developing and there is insufficient surfactant in the alveoli. From 26 to 28 weeks,

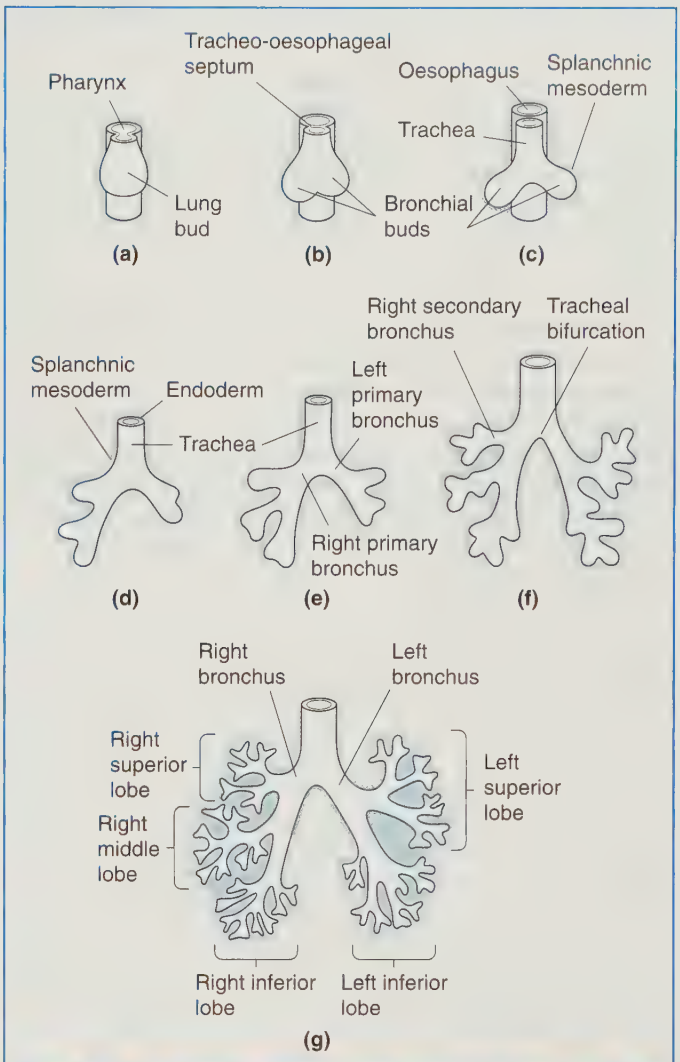

Figure 18.24 Successive stages in the development of the bronchi and lungs: (a) to (c) 4 weeks, (d) to (e) 5 weeks, (f) 6 weeks, (g) 8 weeks (based on Blackburn 2003)

terminal air sacs develop and form clusters in conjunction with extensive capillary networks. Terminal sac development continues until birth and beyond, until eight years of age. At 28 weeks, gas exchange during respiration is possible if birth occurs prematurely. This is due to the presence of clusters of thin-walled primitive alveoli (terminal sacs) and pulmonary capillaries. At 32 to 36 weeks, surfactant production by cells within the alveoli, Type II pneumatocytes, begins (Moore & Persaud 1998).

Composition and function of surfactant

Surfactant is a lipoprotein that contains phospholipids. It prevents the formation of an air/water interface, which reduces surface tension in the alveoli. This increases compliance of the lungs, which means they can be inflated for relatively less effort and collapse of the alveoli at the end of expiration is prevented.

The presence of surfactant assists absorption of lung fluid after birth. This amounts to 25 mL/kg body mass that must be absorbed or excreted. If the baby's physiological mechanisms do not change from secretion to absorption of lung fluid, the baby can drown. Labour appears to trigger release of catecholamines (e.g. adrenaline) that enable the switch from secretion to absorption of lung fluid. The sudden change in pulmonary blood flow at birth also helps remove lung fluid in the first few hours.

Glucocorticoid and thyroid hormones enhance surfactant synthesis, the former by increasing glycogen depletion as well as increasing phospholipid synthesis. Glycogen depletion leads to changes in the alveoli, such as thinning and increased size of the alveoli along with increasing the numbers of Type II pneumocytes. If insufficient surfactant is present at birth, ventilation is impaired, resulting in infant respiratory distress syndrome (IRDS). Thyroid hormones increase the rate of phospholipid synthesis (Blackburn 2003).

Clinical applications

Conditions that inhibit glycogen depletion in the lungs, such as insulin-dependent diabetes, may inhibit surfactant synthesis if the condition is not well controlled. Insulin inhibits glycogen breakdown, effectively decreasing the substrate needed for phospholipid synthesis, and the structural changes associated with glycogen depletion are inhibited (Blackburn 2003).

Some conditions accelerate lung maturity by inducing stress in the fetus, therefore increasing secretion of glucocorticoids and catecholamines (e.g. pre-eclampsia, IUGR, premature rupture of the membranes) (Blackburn 2003). Women are often given dexamethasone prior to delivery, which appears to assist surfactant production and prevent RDS. Neonates requiring ventilation may be given surfactant via an endotrachial tube.

Summary of fetal circulation

- Fetal circulation is characterised by fast flow, low vascular resistance, and high pulmonary vascular resistance.
- Fetal structures divert blood from the lungs to the placenta. These are the umbilical vein, umbilical arteries, ductus venosus, foramen ovale and the ductus arteriosus.
- The high oxygen needs of the fetus are met by a high cardiac output. HbF enhances oxygen transfer from maternal blood. This is reflected in a shift to the left of the HbO_2 dissociation curve of the fetus.
- Oxygenated blood from the umbilical vein mixes with deoxygenated blood returning in the vena cava, producing 'mixed blood' with reduced oxygen saturation. This returns to the heart and circulates to the tissues via branches of the aorta. Branches from the internal iliac arteries flow into the umbilical arteries to return to the placenta.
- At 25 weeks gestation, respiration is possible as some primitive alveoli have developed, but the epithelial lining is thick, pulmonary capillaries are sparse and insufficient surfactant is produced.
- At 28 weeks, further development of the terminal air sacs, capillaries and surfactant makes gas exchange possible.
- Fetal breathing movements facilitate development of the lungs.
- Surfactant increases the compliance of the lungs and facilitates fluid reabsorption after birth.

Maternal changes associated with pregnancy

Pregnancy is associated with major physiological changes that enable the woman to support the in utero growth and development of the baby, from the beginnings as a one-celled organism until reaching term as a complex human being. This process takes an average of 266 days (38 weeks) from the time of fertilisation, or 280 days if the time is taken from the first day of the last menstrual bleeding. The maternal physiological changes associated with the growing fetus and with the changes to the maternal body systems are predominantly controlled by hormones, in some instances facilitated by the increase in size of the fetus. The function of these hormones and the subsequent changes to maternal body systems are the focus of this section on pregnancy.

Hormones of pregnancy

There are a vast number of hormones and neurohormones (Reis et al 2001), growth factors and proteins produced by the placenta during pregnancy. The maternal physiological and anatomical changes during pregnancy are largely controlled by the following hormones:

- human chorionic gonadotrophin (hCG)
- human placental lactogen (hPL)
- oestrogens
- progesterone.

Human chorionic gonadotropin

Human chorionic gonadotrophin (hCG) is a glycoprotein, similar in structure to luteinising hormone, secreted by the trophoblast. It can be detected in the blood seven days after fertilisation and in the urine 26 to 28 days after fertilisation (Blackburn 2003). There is a rapid increase in early pregnancy up until nine weeks and then a decrease in levels. hCG forms the basis of the pregnancy test, where hCG antibodies are used to identify the presence of hCG in the woman's urine.

hCG is linked to many maternal changes in the first trimester. Probably most importantly, it prevents the degeneration of the corpus luteum and stimulates it to continue secreting oestrogens and progesterone until the placenta takes over this role. Changes in smell, taste and saliva seem to be correlated with the level of hCG, which has been linked to feelings of nausea in the first trimester. It may also have an immunosuppressant role that reduces maternal rejection of the placenta (Blackburn 2003).

Human placental lactogen

Human placental lactogen (hPL) is a polypeptide, similar to growth hormone, secreted by the synctiotrophoblast. Synthesis begins 5 to 10 days after implantation and levels increase to a peak just before term (Blackburn 2003)—hPL facilitates growth. It changes maternal metabolism to maximise the nutrients available to the fetus in utero. Three key metabolic changes facilitated by hPL are as follows:

- It reduces maternal utilisation of glucose by reducing the response of maternal cells to insulin—it is an insulin antagonist. This raises the maternal blood glucose level and makes more glucose available to the fetus.
- It mobilises maternal lipid stores, releasing fatty acids as the maternal energy source, leaving glucose for fetal uptake.
- It accelerates amino acid transfer to the fetus.

Steroid hormones

The steroid hormones, oestrogen and progesterone, responsible for the maintenance of pregnancy, are initially released from the corpus luteum in the ovaries. The placenta takes over this role at about seven weeks gestation. The synthesis is complex, involving the mother, placenta and fetus, as each lacks the enzymes necessary for independent synthesis. Figure 18.25 illustrates the interconnections in the pathways for synthesis. The common precursor for steroid synthesis is cholesterol. The synthesis of cholesterol is increased in pregnancy to meet the demand for steroid synthesis.

Oestrogens

Three types of oestrogens are synthesised in the ovaries and placenta: oestriol, beta-oestradiol and oestrone. Oestriol, the weaker form, is the most common oestrogen; it increases most significantly during pregnancy. In a non-pregnant woman, oestriol is synthesised from beta-oestradiol and oestrone in the ovaries; however, during pregnancy oestriol synthesis relies on enzymes in the fetal liver and dehydroepiandrosterone sulfate (DHEAS) from the fetal adrenals for synthesis. There is a rapid increase early in pregnancy, which slows between 24 and 32 weeks, and then there is a surge in oestriol at 34–36 weeks. Measurement of oestriol levels were one of the earliest methods of monitoring fetal wellbeing, but this technique is no longer used (Blackburn 2003).

Oestrogens stimulate growth of tissues by increasing protein synthesis. They cause the hyperplasia and hypertrophy of the uterus, the increased vascularisation of the uterus and the development of the mammary ducts and alveolar tissue in the breasts. Oestrogens also cause swelling and softening of connective tissues (e.g. cervix, nipples and ligaments) by increasing the water content in the extracellular matrix and reducing the adhesion of the collagen fibres in connective tissues. Angiotensin and aldosterone levels increase under the influence of oestrogens, leading to fluid retention. Oestrogens increase the sensitivity of the uterus to progesterone and, along with progesterone, they increase the sensitivity of the maternal respiratory centre to carbon dioxide.

These functions of oestrogens contribute to some of the minor discomforts of pregnancy. Water retention mediated by oestrogen can lead to oedema. Pelvic discomfort can result from relaxation of the pelvic ligaments, stretching of the sacro-iliac and sacro-coccygeal joints and the increasing elasticity of the symphysis pubis.

Progesterone

Progesterone is secreted by the corpus luteum initially, and then by the placental synctiotrophoblast. The fetus is not essential for progesterone synthesis, and therefore levels are not indicative of fetal wellbeing. Placental progesterone enters both the maternal and fetal circulations and is broken down and excreted in the urine as pregnanediol.

Progesterone increases the secretory activity of the decidual cells of the uterus, which supply nourishment for the embryo (as discussed in the section on the placenta). Along with other uterotonic inhibitors, progesterone lowers smooth muscle excitability, particularly in the myometrium, to prevent uterine contraction, but also in the ureters, stomach and intestines. It increases the sensitivity of the maternal chemoreceptors to carbon dioxide, thus stimulating ventilation at lower $PaCO_2$

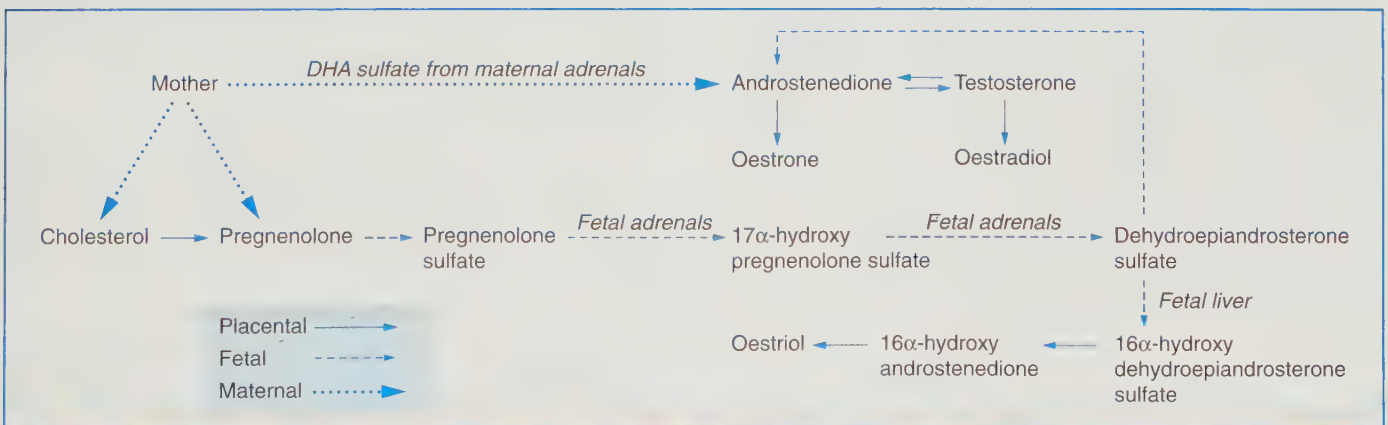

Figure 18.25 Summary of the principal routes by which the human fetoplacental unit synthesises oestrogens (based on Johnson & Everitt 2000)

values than before pregnancy. Progesterone also has a role in implantation, and in helping to suppress the maternal immunological response (Blackburn 2003). Fetal adrenal hormone production relies on progesterone as an essential precursor.

Progesterone-induced relaxation of smooth muscle results in many of the minor discomforts of pregnancy, such as:

- oesophageal reflux (heartburn), due to relaxation of the oesophageal sphincter
- nausea and vomiting, which may be potentiated by reduced peristalsis
- urinary tract infections, which increase in pregnancy due to stasis of urine caused by relaxation of the smooth muscle in the ureters and bladder
- varicose veins and haemorrhoids, due to dilatation of the veins in the legs and rectal region
- postural hypotension, due to venous pooling resulting from reduced peripheral resistance in the blood vessels in the lower limbs.

As well as the smooth muscle relaxation effect, progesterone has a thermogenic effect, increasing body temperature by 0.5°C to 1.0°C, and it stimulates hyperventilation due to the increased sensitivity of chemoreceptors to carbon dioxide.

The level of steroid hormones increases throughout pregnancy, as they mediate maternal changes to facilitate the growth and nourishment of the fetus.

Changes to maternal physiology

Endocrine glands

Pregnancy is associated with an increase in size of the anterior pituitary gland and increases in secretion of adrenocorticotrophic hormone (ACTH). This is likely the result of placental corticotrophic-releasing hormone (CRH) stimulation than hypothalamic CRH stimulation. Placental CRH is present in low levels during pregnancy, but increases twenty-fold at 35 weeks and has a role in the initiation of labour. Increases in prolactin, thyrotropin and melanocyte-stimulating hormone occur and in the third trimester an increase in pituitary beta-endorphin and spinal endorphins is detected. Endorphin increase is linked to the increase in pain threshold in the latter part of pregnancy (Henderson & Macdonald 2004). The posterior pituitary increases secretion of oxytocin but antidiuretic hormone (ADH) levels are similar to non-pregnant levels. However, the osmoreceptors in the hypothalamus are adjusted to the lower osmotic pressure of pregnancy (Blackburn 2003).

Not all hormones are increased. Levels of gonadotrophins (FSH and LH) are depressed via negative feedback due to the increasing levels of steroid hormones (oestrogen and progesterone). This prevents further ovulation during pregnancy.

The adrenal gland increases corticosteroid (glucocorticoid and aldosterone) production. Cortisol, the main glucocorticoid, increases two- to three-fold by term, and the diurnal rhythm of release continues, with higher levels being secreted in the morning than in the evening.

Increases in corticosteroids have been linked to the formation of striae gravidarium or 'stretch marks'. The cause is unclear but may be related to reduced adhesiveness between collagen fibres and decreased collagen synthesis mediated by corticosteroids (Blackburn 2003). Glucocorticoids influence metabolism by stimulating the release of glucose stores into the plasma.

The thyroid gland increases in size in response to low levels of iodine in the blood. During pregnancy, iodine clearance by the kidneys is increased. As iodine is an essential component of the thyroid hormones (thyroxine (T_4) and triiodothyronine (T_3) this stimulates hypertrophy of the thyroid and an associated increase in release of T_3 and T_4. However, there is also increased circulating thyroxine-binding globulin during pregnancy, and therefore there is no actual increase in thyroid hormone activity (Blackburn 2003). In fact, women with preexisting hyperthyroidism may experience some relief of symptoms during pregnancy due to the increased thyroxine-binding globulin (Blackburn 2003). Increased release of parathyroid hormone facilitates increased calcium absorption from the gut and decreased excretion by the kidneys, and therefore increased calcium is available to the fetus.

Changes to the reproductive system

The reproductive system probably undergoes the most obvious changes associated with pregnancy. There is considerable enlargement of the uterus, softening of the cervix, engorgement of the vulva, and growth and development of the breasts. These changes are to accommodate the growing fetus and to prepare for birth and nutrition of the baby.

Uterus

Under the influence of oestrogen, the uterine muscle fibres undergo hypertrophy and hyperplasia, resulting in a spherical, thick-walled (25 mm) uterus by 20 weeks (Blackburn 2003). Following this, the uterus grows by distension as the growing fetus stretches the muscle fibres. During the third trimester, this results in a thinner-walled (5–10 mm) cylindrical-shaped uterus that is easily indented, the fetus is easily palpated and fetal movements are visible. The uterine mass increases from 50 grams pre-conception to approximately 950 grams at term, and the uterine cavity changes from a capacity of 10 mL to 5 L (Blackburn 2003).

The uterine muscle supports and protects the fetus. It has both contractile and elastic properties, which equips the uterus to accommodate growth during pregnancy and to generate tension during labour. The myometrium comprises four layers, which have different roles in preparing for birth:

- The inner, circular layer runs in a spiral around the cornua, lower uterine segment and cervix and stretches during labour.
- The middle, oblique layer contracts to expel the fetus and constrict blood vessels after the placenta is delivered.
- The two outer, longitudinal layers contract and shorten during labour to cause thickening of the upper segment,

which maximises the expulsive force exerted on the baby during labour.

The different layers of muscle have different embryonic origins and may respond differently to uterotonic agonists and antagonists (Blackburn 2003). Uterine muscle is sparsely innervated by adrenergic neurons, which disappear from the myometrium at term.

The lower uterine segment muscles are replaced by connective tissue and this enables stretching in late pregnancy. Uterine blood vessels hypertrophy and become more coiled up until 20 weeks, and then uncoiling occurs as the uterus distends. Stretching of the broad ligament may cause painful sensations during the second and third trimesters. While the myometrium is capable of spontaneous activity, progesterone, relaxin, nitric oxide and prostacyclin exert an inhibitory effect. However, as pregnancy progresses there is an increase in frequency of contractions, about 5% increase per week. Contractions are more common at night and least common in the early afternoon. Contractions in the second trimester are irregular and painless but may become uncomfortable during the third trimester. The changes in character of the contractions are due to structural and functional changes in the myometrium mediated by changing oestrogen and progesterone. Table 18.3 lists some of the key changes that occur as the uterus enlarges.

Cervix

The cervix is primarily composed of connective tissue covered in a thin layer of smooth muscle. Changes occur throughout pregnancy and by the second trimester the cervix becomes swollen as it softens and widens due to the effect of oestradiol, prostaglandins, progesterone, relaxin and nitric oxide on the collagen fibres and water content. These changes culminate in cervical ripening, in preparation for labour. A plug of thick mucus, or operculum, resulting from proliferation of the cervical mucosa and glands, protects the cervix from ascending infection (Coad & Dunstall 2001).

TABLE 18.3 Stages of uterine development

Week of gestation	Characteristic uterine changes
12	• Uterus rises out of the pelvis in an upright position, often to the right • Cervical isthmus stretches • Fundus can be palpated abdominally above symphysis pubis
20	• Uterus becomes thicker and rounded • Fallopian tubes become more vertically positioned
30	• Lower uterine segment can be identified
36	• Uterus reaches the xiphisternum • Fetus moves down into the lower region of the uterus

Vagina

Several changes to the vagina occur due to the effects of oestradiol, but primarily there is increased blood flow, leading to venous engorgement. There is marked shedding of superficial mucosal cells, which leads to increased vaginal discharge (leucorrhoea), and normal bacteria of the vagina (bacilli) interact with increased glycogen in the mucosal cells, increasing the acidity of the vagina. This provides protection against some pathogens but encourages *Candida albicans* and *Trichomonas vaginalis* (Stables & Rankin 2004).

Haematological changes

Major alterations to the composition of blood occur during pregnancy. Changes protect against the normal blood loss of around 500 mL that occurs at delivery, maintain cardiac output despite widespread vasodilation, promote rapid haemostasis during placental separation, and increase protection against bacterial infection. These normal changes are reflected in blood screening results.

Haemodilution

Blood volume increases by 30% to 50% (1200 mL to 1500 mL) between about 7 and 34 weeks gestation, but there can be considerable individual variation, as some women have a minimal increase and others up to a two-fold increase (Blackburn 2003). The additional blood volume is accommodated in the uterus, breasts, muscles, kidneys and skin. It is important to note that the plasma increases at a faster rate than the cellular components. This leads to haemodilution, which is reflected in decreased concentration of many elements, such as haemoglobin, immunoglobulins, platelets and plasma proteins.

Plasma volume begins to increase at around seven weeks and increases very rapidly during the second trimester, reaching a 40% to 50% increase by week 28 to 32 (Blackburn 2003). Increasing oxygen demand due to the growing tissues and increased metabolism stimulates erythropoiesis. This

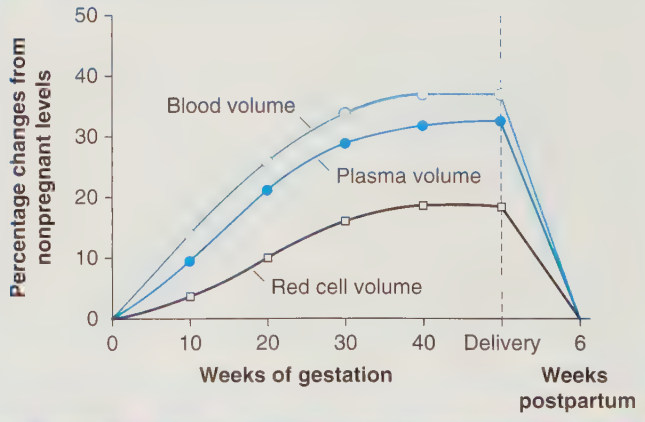

Figure 18.26 Changes in blood volume, plasma volume and red blood cell volume during pregnancy and post partum (based on Blackburn 2003)

increases more slowly and only reaches about a 30% increase in red cell volume (to 1700 mL), thus remaining less than the total plasma increase (Fig 18.26). The resulting haemodilution decreases the blood viscosity by 20%, which has the advantage of decreasing the workload of the heart.

Haemoglobin concentration falls as a result of haemodilution, from a range of 115–160 g/L in a non-pregnant woman to 100–150 g/L in a pregnant woman (Gill et al 2000). Although a decrease in haemoglobin concentration is a normal consequence of haemodilution, there are also increased requirements for iron during pregnancy, to meet the demands of increased erythropoiesis (iron is an essential component of haemoglobin) and the needs of the growing fetus. Plasma iron can be increased by dietary intake, mobilisation of iron stores and increased maternal absorption of iron in the intestines, particularly in the latter stages. This mirrors the increased transfer to the fetus at this time. Serum ferritin levels also fall as stored iron is released from the liver, spleen and bone marrow to boost haemoglobin levels. If a woman's iron stores are not adequate at the start of pregnancy, a deficiency may lead to decreased erythropoiesis, as fetal needs are met at the expense of maternal needs for iron. There is considerable controversy as to whether iron supplements are required to meet the increased demands.

White cell count, particularly the neutrophil count, increases during pregnancy to give more protection against bacterial infections. However, the concentration of immunoglobulins (IgA, IgG, IgM) decreases due to haemodilution and suppression of the immune system.

Plasma proteins also increase but haemodilution lowers the concentration, particularly of albumin, which lowers the osmotic pressure of the plasma. This means there is a greater tendency for fluid movement to the interstitial compartment, and this coupled with the increased water retention mediated by oestrogen leads to an increased possibility of oedema.

Changes to blood coagulability

Clotting factors such as fibrinogen, factors VII, VIII and X increase, and this leads to hypercoagulability of the blood, despite a decrease in platelet count (due to haemodilution). Coagulation times decrease by about 30% near the end of pregnancy (Coad & Dunstall 2001). Coagulation is further enhanced by decreased fibrinolytic activity, which continues until after the birth of the baby.

The haematological changes of pregnancy result in an increased blood volume, increased erythrocytes, leucocytes and coagulation factors, although the greater increase in plasma leads to decreased concentration of many components. Abnormalities in the increases of plasma or cellular constituents may flag underlying pathology; for example, pre-eclampsia is associated with smaller than usual increases in plasma volume (Blackburn 2003).

Cardiovascular system

Plasma volume increases as a result of increased activity of the renin-angiotensin system and of oestrogens, which increase fluid retention by the kidneys. Cardiac output (CO) increases by 30–50% due to this increased blood volume (Blackburn 2003)—an increase from an average of 5 L/min at 10 weeks to approximately 6.5 L/min at 25 weeks. Increased CO is largely determined by increases in stroke volume (30% increase), but the heart rate also increases by 15% (Blackburn 2003). Despite these changes in CO, blood pressure remains the same or drops slightly. This is due to the decrease in total peripheral resistance (TPR) facilitated by the actions of progesterone. Progesterone causes the smooth muscle in the arterial walls to relax, thus enabling vasodilation. Mean arterial pressure is determined by the cardiac output and the total peripheral resistance, and therefore an increase in CO accompanied by a decrease in TPR results in reasonably constant blood pressure. Smooth muscle in the walls of the veins similarly relaxes, increasing the venous capacity by as much as a litre.

Blood flow distribution

As the blood volume increases during pregnancy, it is distributed such that the uterus receives the greatest amount, with an increase from 50 mL/min at 10 weeks to 500 mL/min at term (Blackburn 2003). Eighty per cent of the uterine blood

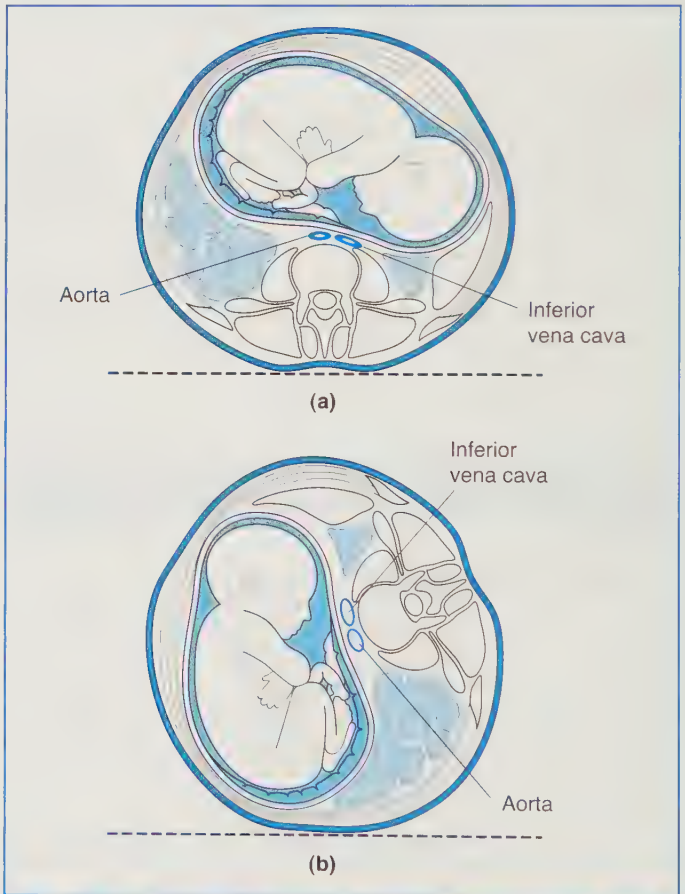

Figure 18.27 **(a)** The pregnant uterus compressing the aorta and the inferior vena cava. **(b)** Lying on the side changes the position of the uterus and relieves aortocaval compression (based on Blackburn 2003).

supply is directed to the intervillous spaces of the placenta to meet fetal requirements (see section on placental function).

Early in pregnancy there is a significant decrease in the resistance of renal blood vessels, leading to the kidneys accommodating increased CO before the reproductive structures. This decrease in resistance reaches a maximum by eight weeks, and may be under the influence of hCG (Stables & Rankin 2004). Skin and mucous membranes receive up to a 70% increase in blood flow by the 36th week. This can contribute to heat intolerance, sweating and nasal congestion. Nasal congestion and changes in upper airway patency may lead to increased snoring during pregnancy (Izci et al 2005).

The supine position has a marked effect on CO, especially in later pregnancy when the weight of the uterus is greater. By the third trimester, the supine position results in compression of the vena cava by the uterus, leading to decreased venous return and hence CO (Fig 18.27). A change from lying on the side to lying supine can result in a 25–30% decrease in CO (Blackburn 2003).

Respiratory system

Several factors influence ventilation during pregnancy. These include an increase in the basal metabolic rate, leading to increased oxygen consumption (20%) and carbon dioxide production, and increased sensitivity of the chemoreceptors to $PaCO_2$, an effect due to progesterone. The result is an increase in ventilation of 40% from 7 L/min to 10 L/min, contributed mainly by an increase in tidal volume of 25–40%. The increased ventilatory drive from increased chemoreceptor sensitivity leads to hyperventilation—that is, ventilation greater than metabolic need—and this may also account for the sensation of dyspnoea sometimes encountered during pregnancy (Blackburn 2003). Anatomical changes include flaring of the ribs and a raised position of the diaphragm (4 cm) due to uterine enlargement. Functional residual capacity (volume of air left in the lungs at the end of expiration) and residual volume (volume remaining in the lungs at the end of a forced expiration) are both decreased.

During sleep, changes in ventilatory drive and metabolic rate, reduced residual volume and changes in upper airway patency may increase the risk of sleep-disordered breathing. There is currently considerable research interest in Australasia and internationally in a possible link between sleep-disordered breathing, which can be indicated by snoring, and pre-eclampsia (Edwards et al 2002; Guilleminault et al 2000). A greater frequency of snoring has been found among women with pre-eclampsia (controls 32%, pregnant women 55%, women with pre-eclampsia 85%) ($P < 0.001$) (Izci et al 2005).

Renal system

The renal system must handle the increased metabolic wastes of the mother and the wastes from fetal metabolism. Renal function involves the processes of filtration, reabsorption and secretion, all of which are altered to some extent during pregnancy. Glomerular filtration rate (GFR) increases up to 40–50% in the first trimester, and falls significantly in the last three to four weeks (Blackburn 2003). The increase is a result of increased renal blood flow, facilitated by decreased renal vascular resistance. Reabsorption of electrolytes is increased as activity of the renin–angiotensin–aldosterone system increases, due to oestrogen and progesterone stimulation. This prevents excessive loss of sodium and other solutes and may balance the faster excretion rate. Glycosuria is common. Glucose reabsorption depends on a carrier mechanism in the renal tubules. At high glomerular filtration rates this mechanism can become saturated, leaving glucose in the filtrate to be excreted from the body. Proteinuria at levels of 0.3 g/day is also common, probably linked with increased leakiness of the glomerulus. Renal clearance of many substances (e.g. creatinine and iodine) increases, partly due to the increased GFR.

Progesterone is responsible for dilatation and possible kinking of the ureters from 10 weeks. By term the ureters can hold 300 mL of urine. Progesterone also causes dilation of the renal pelvis, with a resultant increased capacity from 12 mL to 75 mL. Relaxation of the smooth muscle in the bladder can lead to urinary stasis and, along with dilatation of the ureters, leads to a greater risk of infection during pregnancy.

Increased frequency of micturition is normal in early pregnancy due to the increased renal plasma flow and increased excretion by the kidneys. It is also normal later in pregnancy due to the pressure of the fetus and uterus on the bladder.

Skeletal system

Progesterone relaxes ligaments and muscles, with maximum effect in the last weeks when the pelvic capacity increases. In particular, the symphysis pubis, sacroiliac and sacrococcygeal joints soften and facilitate widening of the pelvis. The increased mobility of the joints also allows the coccyx to be pushed out of the way during labour.

Integumentary system

Melanocyte-stimulating hormone increases during pregnancy and causes deeper pigmentation of the skin. This can lead to a patchy mask on the face called chloasma, or a pigmented line on the abdomen from the pubis to the umbilicus, called linea nigra. The areola darkens and toughens, as does the perineum, which can also stretch more. In many areas of the body, stretching occurs in the collagen layer of the skin where adipose tissue is most concentrated (e.g. breasts, abdomen and thighs). Stretch marks, striae gravidarium, occur as red stripes and may result from the increased corticosteroids (see earlier section on corticosteroids).

Gastrointestinal system

Pregnancy can result in a number of minor discomforts associated with the digestive system. These are mainly a result of the effect of progesterone.

Gums

Fluid retention in the connective tissue of the gums can lead to a 'spongy' feeling and increased vascularity can result in increased bleeding of the gums during pregnancy.

Effect of progesterone on smooth muscle

Oesophageal sphincter malfunction allows oesophageal reflux of stomach contents, resulting in heartburn. This is exacerbated by higher intra-abdominal pressure in later pregnancy.

Lowered stomach tone and motility (peristalsis) and reduced gastric secretion means food stays in the stomach longer (up to 48 hours during labour). This may be worsened by narcotics. It should be noted that drugs given orally (e.g anticonvulsants) may not be absorbed adequately.

Nausea and vomiting may result from a combination of effects, such as decreased peristalsis and increased intra-abdominal pressure. High levels of hCG and sex steroids may also play a role by stimulating the vomiting centre receptors in the medulla.

A lower rate of peristalsis in the intestines facilitates increased absorption of nutrients, but the increased transit time and subsequent increased water reabsorption in the large intestine may lead to constipation. Compression and displacement of the bowel by the enlarging uterus may aggravate the situation.

Summary of maternal changes in pregnancy

- Maternal changes associated with pregnancy are largely mediated by the steroid hormones, initially from the corpus luteum maintained by hCG, and later from the placenta.
- Other hormones such as hPL, cortisol and aldosterone, mediate many changes.
- Under the influence of oestrogen and progesterone the uterus increases in size, with increased glandular secretions and increased vascularisation. Spontaneous myometrial contractions are largely suppressed by progesterone and other uterotonic inhibitors. The cervix softens as adhesion between collagen bundles is reduced and it is infiltrated by water.
- Oestrogen and the renin–angiotensin system increase sodium and water retention throughout pregnancy, increasing the blood volume by 40%. Plasma volume increases more than the red cell volume, resulting in haemodilution.
- Despite increases in haemoglobin, albumin and immunoglobulins etc, there is a decrease in the concentration of these blood components. Decreased albumin concentration results in decreased colloid osmotic pressure and possible oedema. A state of hypercoagulability exists due to increased coagulation factors.
- Progesterone-mediated vasodilation leads to reduced total peripheral resistance and this more than compensates for the effects of increased blood volume. Blood pressure does not normally increase. The increase in cardiac output is due to an increase in both stroke volume and heart rate. A redistribution of blood flow sends approximately 20% of the CO to the uterus, with 80% of this serving the placenta.
- Changes to the ribcage facilitate ventilation. Progesterone and oestrogen increase sensitivity of the respiratory centre to CO_2, resulting in mild hyperventilation. Tidal volume increases to supply increased O_2 to meet increased metabolic needs, and residual volume is reduced.
- Increased GFR leads to increased micturition early in pregnancy. Renin–angiotensin leads to retention of sodium and water. Mild glycosuria, proteinuria and increased clearance of creatinine result from normal changes in renal function. Smooth muscle relaxation, mediated by progesterone, can lead to stasis of urine and increased risk of urinary tract infection.
- Progesterone-mediated smooth muscle relaxation leads to many of the minor discomforts of pregnancy (e.g. oesophageal reflux, constipation, backache). hCG may be linked to feelings of nausea.
- Modifications of the woman's physiology during pregnancy allow her to meet the many needs of the fetus (including cardiorespiratory, nutritional, metabolic and renal) without compromise to her own wellbeing, and to prepare for birth.

Conclusion

Adaptations by the woman's physiology during pregnancy allow her to support the developing fetus to grow into a healthy baby while maintaining her own wellbeing. Near term especially, there are considerable challenges in meeting, in particular, the respiratory, nutritional, metabolic and renal needs of the fetus without compromise to the woman. Pregnancy also prepares the woman and the fetus for birth.

Review questions

Reproductive systems

1 Describe the changes in motility and maturation that occur in spermatozoa, from the time they leave the seminiferous tubules until they are ejaculated.

2 Outline the action of the combined oestrogen/progesterone contraceptive pill with reference to the hypothalamic-pituitary-ovarian (HPO) axis.

3 Outline the steps involved in the change from a primary oocyte to a secondary oocyte.

Conception and implantation

4 List three physiological factors that promote successful fertilisation.

5 Compare a morula with a blastocyst.

6 Compare the synctiotrophoblast with the cytotrophoblast.

Embryology

7 Outline the difference between a blastocyst and an embryo in their susceptibility to teratogenic agents.

8 Describe the process of gastrulation, name the layers of germ cells present in the trilaminar disc and name one function of the notochord.

9 List the key changes in the lungs and pulmonary circulation between 24 and 32 weeks gestation.

Placenta

10 Draw a flow diagram identifying the key steps involved as the trophoblast differentiates into a functioning placenta.

11 Outline the barriers a molecule of O_2 must pass as it diffuses from the maternal lacuna to the fetal chorionic villus.

12 Describe the key anatomical structures that make up the uteroplacental circulation.

Fetal circulation

13 The fetal oxyhaemoglobin curve is shifted to the left of the adult curve. What advantage to the fetus is depicted by this?

14 Describe the factors that enhance fetal oxygen-carrying capacity.

15 Name each of the vessels that transport blood from the fetus to the placental circulation and back, i.e. along the umbilical cord, through the chorionic villi and back to the fetus.

Maternal changes of pregnancy

16 Outline the contribution of the fetus to the synthesis of oestriol.

17 Why is an increased frequency of micturition likely in both the first and third trimesters?

18 Provide a physiological explanation for mild glycosuria and proteinuria that are common in pregnancy.

Synthesis questions

1 Discuss physiological and anatomical aspects of the uterus that make it a suitable organ for supporting and nurturing an embryo/fetus.

2 Explain the advantages to the embryo of developing a circulatory system. How is nutrition provided prior to this?

3 Identify three potential teratogens. Identify the stage of pregnancy at which exposure to the teratogens would be most damaging. Describe the likely congenital abnormalities that would result from this exposure.

4 Draw a labelled diagram illustrating a three-week-old embryo and the associated cavities and membranes.

5 Describe anatomical features specific to the fetal circulation and the contribution they make to effective gas exchange in utero.

6 Summarise the key information that is depicted in an oxyhaemoglobin dissociation curve.

7 Outline the ways in which human placental lactogen (HPL) changes maternal metabolism to facilitate fetal growth.

8 Outline the physiological reasons that women are more at risk of deep vein thrombosis (DVT), a coagulation defect, during pregnancy.

9 Account for the increased blood volume during pregnancy. Outline the effect this has on cardiac function and any other physiological changes that affect blood pressure during pregnancy.

10 Account for the increased glomerular filtration rate that occurs during pregnancy.

CHAPTER 19

Nutritional foundation for pregnancy, childbirth and lactation

Sandra L Elias

Key terms

body mass index, essential fats, gastro-oesophageal reflux, gestational diabetes mellitus, iron deficiency anaemia, long chain polyunsaturated fatty acids, nausea and vomiting in pregnancy

Chapter overview

This chapter outlines the importance of good nutrition during pregnancy in order to promote the growth and development of the fetus and maternal tissues, and to support the demands of childbirth and lactation. Dietary strategies found to alleviate some of the conditions associated with pregnancy and lactation such as constipation, gastro-oesophageal reflux, nausea, gestational diabetes, food-borne illness and allergy prevention are included. The chapter is intended to provide midwives with an understanding of the role of nutrients in pregnancy, childbirth and lactation, to identify appropriate dietary sources of these nutrients, and to present practical dietary strategies during pregnancy and lactation.

Learning outcomes

Learning outcomes for this chapter are:

1. To recognise the importance of weight gain during pregnancy and the use of body mass index for underweight and overweight women
2. To discuss the role and dietary sources of macronutrients in pregnancy and lactation
3. To discuss the role and dietary sources of key micronutrients essential for pregnancy and lactation
4. To explain how diet can alleviate some of the common conditions experienced in pregnancy, such as anaemia, nausea and vomiting, constipation and gastro-oesophageal reflux
5. To explain the role of nutrition in gestational diabetes mellitus
6. To explain the risk of food-borne illness in pregnancy and to recognise the importance of food safety in pregnancy
7. To recognise the special nutritional needs of pregnant adolescents and multiple pregnancies
8. To emphasise the importance of hydration and nourishment for childbirth and to recognise appropriate foods and drinks to consume in childbirth

9 To discuss the role of energy intake and output and their effects on lactation

10 To explain the role and limitations of allergy prevention during lactation.

Weight gain

A woman's appetite during pregnancy typically governs when she wishes to eat. Although the phrase 'eating for two' is often used as an excuse to eat ad libitum during pregnancy, this may result in unnecessary weight gain leading to maternal complications such as elevated blood pressure and insulin resistance.

Weight gain recommendations for pregnancy are based on women's pre-pregnancy weight. The body mass index (BMI) is typically used as an indicator of body fat and although this measurement is not valid during pregnancy, a woman's pre-pregnancy BMI can be used to recommend total weight gain during pregnancy (Table 19.1).

For women in the healthy BMI range, an average weight gain of 11.5–16 kg is recommended. Women in the healthy BMI range tend to gain an appropriate amount of weight during pregnancy. However, women who are underweight pre-pregnancy have increased rates of pregnancy loss and small for gestational age or low birthweight infants. It has been suggested that these risks are simply due to a lack of maternal energy stores (Rush 2001). Therefore, weight gain for these women tends to be higher than for women with healthy pre-pregnancy BMI (12.5–18 kg). Women who are overweight pre-pregnancy are at increased risk of developing gestational diabetes and hypertensive disorders or undergoing caesarean section, with the accompanying anaesthetic and postoperative risk (Rush 2001). The recommended weight gain for women with a BMI > 25 is less than for women with a healthy pre-pregnancy BMI (7–11.5 kg).

Women who fall below or above the normal BMI range pre-pregnancy should have weight gain monitored to ensure that an appropriate weight gain occurs—one that does not increase maternal or fetal risks.

Macronutrients

Fats

During pregnancy, fat plays an important role not only as an important energy source but also as a contributor of the fat-soluble vitamins (A, D, E and K) and various polyunsaturated fats required for growth and development.

Linoleic acid, an omega-6 fat, and alpha-linolenic acid, an omega-3 fat, are essential fats required for growth and development. These fats cannot be synthesised by the body and therefore must be consumed in our diet from plant foods.

One of the primary functions of these fats is to produce long-chain polyunsaturated fats (LCPs), which are found in particularly high concentrations in the central nervous system and retina. LCPs are also consumed in our diet, particularly in meat, dairy and fatty fish (Table 19.2). Vegetarians who exclude all animal products from their diet must therefore ensure an adequate intake of essential fats in order to produce LCPs.

Each of the essential fats is responsible for producing one or more specific LCPs (Fig 19.1). Two of the LCPs, specifically arachidonic acid (AA) and eicosapentaenoic acid (EPA), are precursors to a group of hormone-like compounds called eicosanoids. Eicosanoids have an important role in maintaining blood pressure and haemostasis, in inflammation and in parturition. The eicosanoids produced from AA promote vasoconstriction, platelet aggregation and inflammation, whereas the eicosanoids produced from EPA promote vasodilation, inhibit platelet aggregation and reduce

TABLE 19.1 Recommended weight gain during pregnancy based on pre-pregnancy BMI

Pre-pregnancy BMI	Recommended weight gain (kg)
Underweight: < 19.8	12.5–18
Healthy: 19.8–26	11.5–16
Overweight: > 26	7.0–11.5

BMI (body mass index) is calculated as weight (kg) / height squared (m^2). (Source: National Research Council 1990)

TABLE 19.2 Dietary sources of essential and long-chain polyunsaturated fats

Fat	Dietary sources
Essential fats	
Linoleic acid (LA)	Seeds and nuts, vegetable oils, soft margarines
Alpha-linolenic acid (LNA)	Canola and flaxseed oil, walnuts, peanuts, pecans
Long-chain polyunsaturated fats	
Arachidonic acid (AA)	Meat, eggs, milk, cheese, yoghurt
Eicosapentaenoic acid (EPA)	Fatty fish (salmon, tuna, mackeral, herring, sardines)
Docosahexaenoic acid (DHA)	Fatty fish (salmon, tuna, mackeral, herring, sardines)

inflammation. During parturition, the eicosanoids produced from AA appear to enhance the breakdown of collagen fibres within the cervix, whereas the eicosanoids produced from EPA tend to inhibit this process (Allen & Harris 2001).

In Northern European countries, where the intake of fatty fish, and therefore EPA, is high, the incidence of preterm birth is low. This has sparked considerable research into the effect of EPA on parturition, specifically in women at risk of preterm labour. The results of these studies suggest that supplementation with EPA or consumption of fish 2–3 times/week may reduce the risk of preterm labour in some groups of women (Olsen et al 2000; Olsen & Secher 2002).

One concern that arises with recommendations to increase fish consumption during pregnancy is the amount of mercury present in some fish species. Larger fish tend to accumulate mercury. Food Standards Australia New Zealand (FSANZ) has specific recommendations regarding fish consumption, mercury levels and pregnancy (Table 19.3) (FSANZ 2004).

TABLE 19.3 Recommendations for fish intake during pregnancy

Country	Recommended intake
Australia[1]	2–3 serves per week of any fish or seafood not listed below (1 serve = 150 g) OR 1 serve per week of orange roughy (deep sea perch) or catfish and no other fish that week OR 1 serve per fortnight of shark (flake) or billfish (swordfish/broadbill and marlin) and no other fish that fortnight
New Zealand[2]	Consume fish but limit intake of the following species to no more than 4 servings per week (1 serve = 150 g): shark (flake), ray, swordfish, southern blue fin tuna, orange roughy, ling, barramundi, gemfish

1. Source: Food Standards Australia and New Zealand 2004.
2. Source: Food Standards Australia and New Zealand 2001.

Carbohydrates

Carbohydrates are a major energy source during pregnancy and lactation. There are various classes of carbohydrates, including simple sugars and complex carbohydrates. Simple sugars are present in fruit (fructose), milk (lactose), and table sugar (sucrose). Glucose, another simple sugar, is the body's major energy source and the most abundant carbohydrate. Glucose is also the building block for complex carbohydrates or, more specifically, the starches. Starches are a storage form of carbohydrate present in plants such as grains, legumes and root vegetables. In addition to simple and complex carbohydrates, dietary fibre may be considered a type of carbohydrate. Unlike simple sugars and starches, the human body lacks the necessary enzymes required to break down dietary fibre. Dietary fibre can be classified as either soluble or insoluble. Foods rich in soluble fibre include fruits and vegetables, oats, barley and legumes, whereas foods rich in insoluble fibre include wheat, corn, whole grains and most vegetables. The benefits of dietary fibre include increased satiety, regular bowel movements and a reduction in blood cholesterol levels.

Although carbohydrates should account for the majority of energy intake during pregnancy, the type of carbohydrate consumed is also important, to prevent large fluctuations in blood glucose levels. The rate at which dietary carbohydrate, specifically glucose, is absorbed into the bloodstream can be measured and is referred to as the glycaemic index. Some carbohydrates present in food are rapidly digested in the digestive tract, thereby entering circulation quickly. This can result in a large increase in blood glucose followed by a sudden drop in blood glucose. Foods containing these types of carbohydrates are referred to as having a high glycaemic index value. In contrast, some carbohydrates are digested more slowly, allowing for a slow and steady rise in blood glucose that is not followed by a sudden drop in blood glucose levels. Foods containing these types of carbohydrates are referred to as having a low glycaemic index value. For sustained energy, foods with a low glycaemic index value are recommended.

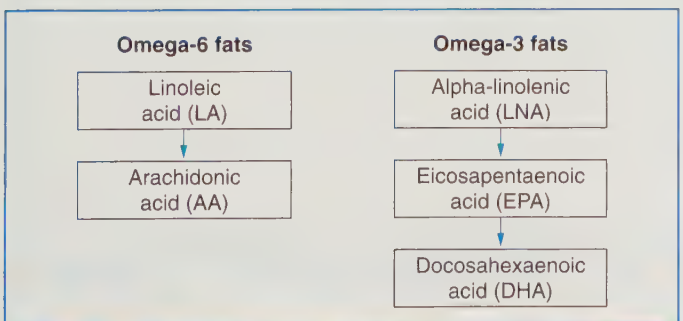

Figure 19.1 Conversion of the essential fats into long-chain polyunsaturated fats (based on Allen & Harris 2001)

Protein

Protein, like carbohydrate and fat, is a macronutrient and therefore can provide energy. The body, however, spares protein for energy in order to utilise it for its many other roles. These include its role as a structural component of muscle, connective tissue and bone, ensuring fluid balance and blood pressure, enzymatic activity, transporting substances throughout the body, and formation of hormones and antibodies.

During pregnancy the requirement for dietary protein is slightly higher than in pre-pregnancy, to account for the development of maternal and fetal tissues. The protein requirements are based on body weight; for every kilogram of body weight a non-pregnant woman should consume 0.75 g of protein. Pregnant women should include an additional 6 g of protein/day above the recommendation for non-pregnant women (National Health and Medical Research Council (NHMRC) 1992).

Despite limited evidence, high-protein diets have been suggested to help minimise the risk of pre-eclampsia. The World Health Organization does not support these diets and clearly states that in the absence of a protein deficiency, protein supplementation is unlikely to reduce a woman's risk of developing pre-eclampsia (Kramer & Kakuma 2004). Given the high intakes of protein in both Australia and New Zealand, pregnant women are likely to be consuming more than their recommended intake of protein (Australian Bureau of Statistics 1995; Ministry of Health 1999).

Dietary intake of protein is important to ensure that the body has the correct mix of amino acids, the building blocks of protein. There are 20 amino acids, of which nine are considered essential. The body is unable to produce essential amino acids in adequate amounts and therefore they must be obtained from dietary sources. Animal proteins contain all nine essential amino acids, whereas plant proteins are limited in at least one. In the past, vegetarians were encouraged to combine protein sources within a meal to ensure intake of all the essential amino acids. It is now known that the body pools the essential amino acids within a 24-hour period and draws from that pool when needed. Therefore, combining proteins at each meal is not necessary, and by consuming a variety of plant sources such as whole grains, nuts, seeds, legumes and vegetables throughout the day, an adequate intake of essential amino acids should be achieved.

Micronutrients: minerals

There are many minerals that the human body requires to perform a variety of important functions. Only those with a significant role during pregnancy will be highlighted in this chapter.

Iron

Iron is an important mineral present within the haem structure of haemoglobin. In any anabolic condition, such as pregnancy, the increased demands for haemoglobin result in increased demands for iron. During pregnancy, as well as in childhood, intestinal absorption of iron increases to help meet these demands. Despite enhanced absorption during pregnancy, iron deficiency and iron deficiency anaemia still occur in many pregnant women.

Iron is present in food in two forms, haem and non-haem iron. Haem iron is the form present in meat, poultry and fish, as a component of haemoglobin. Non-haem iron is also present in meat, poultry and fish but is the only form found in plant foods, fortified foods and supplements.

Although iron is present in many foods, not all the iron is absorbed and used by the body. Haem iron is more readily absorbed in the intestine than non-haem iron. Up to one-third of haem iron is absorbed, whereas the absorption of non-haem iron can vary from 2% to 20% (Hambraeus 1999). Including foods rich in vitamin C increases the absorption of non-haem iron by keeping iron in a more readily absorbable form, ferrous iron. Consumption of meat, poultry or fish with non-haem iron also enhances iron absorption. In addition to these enhancers or promoters of iron absorption, there are several factors that inhibit iron absorption. Tannins, present in coffee, tea and red wine, have been reported to reduce iron absorption by up to 40%; therefore, it is recommended that these beverages be consumed two to three hours before or after a meal. Another inhibitor of iron absorption are phytates, phosphate-containing molecules present in legumes, nuts and whole grains that bind iron, rendering it unavailable for absorption. Soaking legumes, roasting nuts and fermenting whole grains decreases the phytate content of these foods, thereby decreasing their effect on iron absorption (Hallberg 2002). Finally, high doses of calcium (300 mg) or zinc (15 mg), such as the level present in supplements, consumed with iron-rich foods or iron supplements have been reported to inhibit iron absorption (Sandstrom 2001).

Calcium

Calcium is the most prevalent mineral in our body, with most of it contained within our skeleton. In addition to its structural role, it is involved in neural transmission, haemostasis and muscular contraction. Calcium may also play a role in regulating blood pressure. Several randomised controlled studies have explored the effect of calcium supplementation and incidence of hypertensive disorders in pregnant women. These studies suggest that women with previous pregnancy-induced hypertension or pre-eclampsia, women consuming low intakes of calcium (< 900 mg/day) and adolescents may reduce their risk of pre-eclampsia by 50–65% with daily supplements of 1–2 g of calcium (Atallah et al 2004; Ritchie & King 2000).

Calcium is present in many animal and plant foods (Table 19.4). As with iron, the bioavailability of calcium is much higher in animal foods such as milk, yoghurt and cheese than in plant foods. The calcium present in plant foods may also interact with various inhibitors including phytates, high doses of minerals such as iron, and oxalates. Oxalates are compounds present in foods such as spinach, rhubarb and chocolate. Like phytates, they bind calcium, rendering it unavailable for absorption in the intestinal tract.

Zinc

Zinc is an important component of over 80 enzymes involved in many reactions including cell replication and growth, regulation and expression of genes, optimal immune function and hormone activity. Findings from several observational studies suggest that zinc deficiency during pregnancy increases the incidence of neural tube defects, fetal death and malformations, low birthweight, premature rupture of membranes and increased antenatal and intrapartum complications. Of the 12 randomised controlled trials of zinc supplementation during pregnancy, only six reported an effect in reducing birth outcomes or complications. It has been suggested that zinc supplementation is beneficial in developing countries where zinc deficiency is widespread (King 2000; Shah & Sachhdev 2001).

TABLE 19.4 Dietary sources of iron and calcium

Mineral	Animal sources	Plant sources
Iron	• Red meat (beef, venison) • Poultry • Fish and seafood • Eggs	• Legumes (kidney beans, chick peas, lentils, green peas, soy beans) • Tofu and other soy products • Wholegrain or fortified breads and breakfast cereals • Green leafy vegetables (silverbeet, spinach) • Dried fruits • Nuts (cashews, walnuts, peanuts) • Seeds (sunflower and sesame) • Blackstrap molasses • Marmite and Vegemite
Calcium	• Milk • Cheese • Yoghurt • Tinned fish with bones (salmon, sardines)	• Green leafy vegetables (spinach, cabbage, leeks, broccoli) • Peanuts, almonds and sesame seeds • Tofu • Soy milk

Dietary sources of zinc include protein-rich foods such as red meats, seafood, oysters and clams as well as whole grains, legumes, nuts, seeds and wheatgerm. Fruits and vegetables are poor sources of zinc.

Iodine

Iodine is an essential component of triiodothyronine and thyroxine, more commonly known as the thyroid hormones. These hormones regulate body temperature, basal metabolism, reproduction and growth. In pregnancy, iodine deficiency can affect both mother and fetus. Maternal goitre, an enlargement of the thyroid gland, develops when intakes of iodine are habitually low. If iodine deficiency occurs during pregnancy, neonatal cretinism can occur, resulting in stunted growth, mental deficiency, deafness, motor rigidity and possibly hypothyroidism.

Iodine is present in a limited number of foods. Fish, seafood and seaweeds are the richest natural sources of iodine in Australia and New Zealand. In Tasmania and inland regions of New Zealand, the iodine content of soil is very low. Therefore, plants grown in these areas tend to be poor sources of dietary iodine compared to other regions of Australia and New Zealand. In Australia, all table salt is fortified with iodine, whereas in New Zealand fortification of table salt with iodine is not mandatory. All fortified salt is labelled as iodised salt; however, some salts such as rock salt and sea salt do not contain iodine. Most food manufacturers in New Zealand do not use iodised salt and therefore processed foods are an unreliable source of iodine.

Micronutrients: vitamins

Folate

Folate is a generic term used to describe a collection of compounds, of which folic acid is the most stable and absorbable form. Folate is involved in cell replication and division, maturation of erythrocytes and amino acid metabolism. Folic acid also reduces the incidence of neural tube defects when taken prior to and following conception. Folate insufficiency has also been associated with cleft lip, cleft palate, placental abruption, low birthweight, miscarriage and Down syndrome. The recommendations for folate intake in women of childbearing age differ slightly between Australia and New Zealand (Table 19.5).

The term 'folate' is Latin for 'leaf'—one of the major sources of folate is dark, green leafy vegetables such as spinach, silver beet, broccoli and cabbage. Other sources include yeast extracts, whole grains, liver, kidney, asparagus, legumes and wheatgerm. Although folate is found naturally in a variety of foods, only 50–70% is absorbed and used by the body. Folic acid is not found naturally in the food supply but is the form added to breads or cereals as a fortificant and is the form present in supplements. At present, folic acid fortification is

TABLE 19.5 Folate recommendations for Australian and New Zealand women

Australia	New Zealand
All women planning a pregnancy should supplement their diets with 500 µg of folic acid/day beginning one month prior to conception until 12 weeks gestation.	All women planning a pregnancy should supplement their diets with 800 µg of folic acid/day beginning one month prior to conception until 12 weeks gestation.
Women with a previous neural tube defect-affected pregnancy or with close family history of neural tube defect-affected pregnancy should supplement their diet with 5 mg of folic acid/day.	
(Sources: NHMRC 1993; Ministry of Health 1997)	

voluntary in Australia and New Zealand; however, there is a drive towards mandatory fortification as a means of reducing the incidence of neural tube defects.

Vitamin B_{12}

Vitamin B_{12} is involved in folate and fatty acid metabolism, and in the production of myelin. Unlike most water-soluble vitamins, it is stored within the liver for up to five years. A deficiency of vitamin B_{12}, however, can occur with strict vegetarians who eliminate all animal foods from their diet. If untreated, vitamin B_{12} deficiency leads to the degeneration of myelin, resulting in neuropathy and death.

Structures referred to as B_{12} analogues are present in seaweed, spirulina and bacterially fermented soy products such as miso and tempeh. These analogues have a similar structure to vitamin B_{12} but do not have the same metabolic function and therefore are not reliable dietary sources of vitamin B_{12}. Reliable dietary sources of vitamin B_{12} include meats, poultry, fish, seafood, dairy products and eggs. In addition to animal sources, some foods are fortified with vitamin B_{12} including soymilk, yeast extract spreads and nutritional yeasts. Strict vegetarians who consume few vitamin B_{12}-fortified foods should consider B_{12} supplementation.

Vitamin A

Vitamin A is a fat-soluble vitamin essential for vision, cellular differentiation, immune function and bone remodelling. Vitamin A is present in two forms—preformed vitamin A or provitamin A. Preformed vitamin A is present in animal products such as liver, eel, eggs and butter in the form of retinoids, whereas provitamin A, also referred to as carotenoids, is present only in plants. Carotenoids are found in plants of dark green and orange colour, including carrots, apricots, mangoes, pumpkin, silverbeet and spinach.

High intakes of preformed vitamin A from supplements during pregnancy have been associated with birth defects of the cranium, face, heart, kidney, thymus and central nervous system. The liver regulates the conversion of provitamin A into retinol, the body's preferred form of retinoid, based on metabolic need. Therefore, high intakes of provitamin A have not been associated with birth defects (Azais-Braesco & Pascal 2000).

The vitamin A content of most foods is quite low, but liver and liver products have considerably higher levels of this vitamin. Some supplements, such as fish liver oils, may also contain high doses of vitamin A. It is generally recommended that pregnant women avoid liver and liver products, and any supplements that contain more than the recommended nutrient intake of vitamin A, 800 retinol equivalents.

Vitamin D

Vitamin D, another fat-soluble vitamin, is essential for calcium absorption. It is formed in the body when 7-dehydrocholesterol, a steroid present in the skin, is converted to cholecalciferol in the presence of ultraviolet light. Enzymes within the liver and kidney convert cholecalciferol into active vitamin D, commonly referred to as calcitriol.

There are few dietary sources of vitamin D in Australia and New Zealand. Vitamin D is present in small amounts in fatty fish (herring, sardines, tuna and salmon), egg yolks, liver, butter, cheese and milks. It is also added to some full-fat milks and soft margarines. Because vitamin D can be formed by exposure to sunlight, there is no dietary recommendation for dietary vitamin D intake. With high rates of skin cancer, Australians and New Zealanders are encouraged to follow safe sun messages, critical in the prevention of skin cancer. This, however, may also limit production of vitamin D and increase the risk of vitamin D deficiency in some women. Poor vitamin D status has also been reported in dark-skinned and veiled women (Grover & Morley 2001; Nesby-O'Dell et al 2002).

During pregnancy the fetus is dependent on maternal supply for most nutrients, including vitamin D. Because of the role of vitamin D in calcium absorption and therefore skeletal development, it is critical that the mother consumes or produces adequate levels of vitamin D. A Cochrane Review of vitamin D supplementation during pregnancy concluded that there was insufficient evidence to evaluate the requirements and effects of vitamin D supplementation during pregnancy (Mahomed & Gulmezoglu 2004). There is recent concern, however, that the prevalence of vitamin D deficiency is increasing in many countries, including New Zealand. The effect of vitamin D deficiency during pregnancy warrants additional research.

Common conditions of pregnancy

Nausea and vomiting

One of the most common conditions of early pregnancy is nausea with or without vomiting. For most women, nausea and vomiting subsides by 12 weeks gestation; however, some women continue to experience nausea and vomiting throughout pregnancy. Although the aetiology of nausea and vomiting in pregnancy (NVP) is still unknown, there are dietary strategies that may alleviate NVP in some women. Feelings of hunger or dehydration have been associated with nausea and therefore, to prevent this, women are advised to eat small, frequent meals and snacks throughout the day and keep hydrated. A deficiency in vitamin B_6 and zinc has also been suggested to enhance NVP, although there is limited evidence to suggest that supplementation with these nutrients alleviates NVP. Consuming a variety of protein-rich foods will ensure adequate intakes of vitamin B_6 and zinc. The use of ginger, in powdered or syrup form, has been promoted as a safe and effective way to alleviate NVP (Fischer-Rasmussen 1991; Keating & Chez 2002).

Constipation

One of the consequences of elevated progesterone levels during pregnancy is enhanced smooth muscle relaxation. This

occurs throughout the digestive system, reducing peristalsis and therefore intestinal motility. The prolonged transit time results in an increase in both electrolyte and water absorption, thereby reducing faecal water content and producing compact stools. In addition, the large intestine is compressed due to the growing uterus, which may contribute to increased pressure and strain during defecation. Dietary strategies to alleviate constipation include increased dietary fibre intake from wholegrain cereals and breads, dried fruits, fruit and vegetables with skin, brown rice and pasta, and legumes. Increasing dietary fibre without adequate fluid intake, however, can enhance the effects of constipation. Therefore, it is important to consume approximately two litres of fluid daily to promote regularity. In addition to diet, physical activity such as walking, housework, gardening and swimming may stimulate peristalsis, thereby alleviating constipation.

Gastro-oesophageal reflux

Gastro-oesophageal reflux (GOR), also referred to as heartburn, is a common condition in pregnancy. Due to elevated progesterone levels, the smooth muscle of the lower oesophageal sphincter is more relaxed than in non-pregnant women. This, along with increased intra-gastric pressure from the growing uterus, may result in the reflux of stomach contents into the oesophagus. Dietary strategies to alleviate GOR focus on reducing stomach volume and further relaxation of the lower oesophageal sphincter and increasing gastric motility. To reduce stomach volume, avoid eating and drinking at the same time, and consume small, frequent meals and snacks throughout the day. Some foods have been associated with GOR by decreasing gastric motility, thereby enhancing intra-gastric pressure, or enhancing relaxation of the lower oesophageal sphincter. These include fatty foods, milk, chocolate, spearmint, peppermint, caffeine, citrus fruits and juices, tomato products, pepper seasoning and alcohol.

Anaemia

As highlighted earlier, iron is an essential mineral required in the formation of haem. With increased tissue growth, the requirement for haemoglobin and therefore iron also increases. Despite an increased production of haemoglobin, the effects of haemodilution—an increase in plasma volume—results in lowered haemoglobin values. This is referred to as physiological anaemia and is normal in pregnancy. Further reductions in haemoglobin, however, may continue, indicative of poor iron intake and may lead to iron deficiency and iron deficiency anaemia (IDA).

Iron deficiency is characterised by the presence of low iron (ferritin) stores, and if untreated can lead to IDA. Iron deficiency anaemia, a reduction in circulating iron, is the most common form of anaemia worldwide. It is referred to as microcytic, hypochromic anaemia because of the presence of small, pale erythrocytes. Although there is evidence to suggest that IDA leads to poor birth outcome, such as low birthweight and increased infant mortality, not all trials have reported similar results.

Assessing iron status in pregnancy is important in order to prevent IDA. A drop in ferritin represents a fall in iron stores and is the first step towards IDA. Once ferritin levels fall, transport iron begins to drop, indicating a reduction in erythropoiesis. Finally, circulating haemoglobin falls, indicating IDA.

In some countries, such as the United States, routine iron supplementation is recommended during pregnancy. However, in Australia and New Zealand, iron supplementation in pregnancy is based on a woman's iron status. Good dietary advice should always be encouraged during pregnancy to promote good iron status (refer to Iron section); however, even with intense individual counselling, women with iron deficiency may experience difficulties in increasing iron status through diet alone (Heath et al 2001; Patterson et al 2001). Therefore, supplementation along with dietary advice may be necessary for some women. The Australian Iron Advisory Panel has developed general guidelines for assessing iron status in pregnancy (Table 19.6). These guidelines include the use of biochemical parameters (ferritin and haemoglobin) and various risk factors to assess a woman's risk for IDA in pregnancy. Suggestions regarding dietary advice and iron supplementation are provided based on a woman's risk factors.

Although IDA is the most common form of anaemia, another type of anaemia can develop in response to folate and/or vitamin B_{12} deficiency. This type of anaemia is characterised by large, pale erythryocytes and is referred to as megaloblastic anaemia. Folate deficiency is unlikely to occur in individuals who consume a varied diet, whereas a B_{12} deficiency may develop in individuals who follow strict vegetarian diets devoid of all animal products. A diet rich in dark green, leafy vegetables, whole grains and animal products should provide adequate intakes of these vitamins.

Cravings

Some women report dietary cravings during pregnancy that disappear following birth. For the most part, these cravings do not have a great impact on nutrient intake. In some cultures, however, the consumption of non-food items such as dirt, clay or ice is common in pregnancy. This practice is referred to as pica. Some have theorised that pica is the consequence of nutrient deficiencies; for example, women with iron-deficiency anaemia consume clay or dirt, a source of iron, to correct their nutrient deficiency. Others speculate that the iron deficiency anaemia is a consequence of pica rather than the cause (Horner et al 1991).

Pica has been associated with lead poisoning (Klitzman et al 2002), hypokalaemia (Ukaonu et al 2003) and lower maternal haemoglobin levels at birth (Rainville 1998). Although the true prevalence of pica in pregnancy is unknown and may be difficult to ascertain, it is important to be aware of the potential consequences of pica as it relates to pregnancy.

TABLE 19.6 Recommendations for iron supplementation during pregnancy

Stage of pregnancy	Biochemical parameter	Adequate level	At increased risk
Early pregnancy	Haemoglobin	> 115 g/L	105–115 g/L[1] 105–115 g/L and one major risk factor, or ≥ two other risk factors[2]
28 weeks	Haemoglobin Ferritin	> 105 g/L > 16 µg/L	< 105 g/L < 16 µg/L[3]

Risk factors

Major:

- Previous iron deficiency
- Current or recent history of blood donation

Other:

- Poor socio-economic status
- Previous post-partum haemorrhage
- Short gap between pregnancies
- Heavy periods

(Source: adapted from Australian Iron Status Advisory Panel 2004)

1. Dietary advice to increase iron status and reassess at 28 weeks.
2. Supplement with 30 mg/day of elemental iron, provide dietary advice to increase iron status and reassess at 28 weeks.
3. Supplement with 100 mg/day of elemental iron and provide dietary advice to increase iron status.

Gestational diabetes mellitus

In response to elevated progesterone, pregnancy-related lactogen and oestrogen, some degree of insulin resistance during pregnancy is normal. In women, particularly those who are overweight, the pancreas is unable to produce adequate insulin levels to counteract this resistance. Elevated blood glucose levels in pregnancy may result in the development of *gestational diabetes mellitus* (GDM).

Although there is no specific diet for women with GDM, good nutrition can improve blood glucose control. Eating small meals and snacks often, consuming low-fat rather than high-fat foods, and incorporating plenty of foods rich in dietary fibre to promote enhanced satiety, can help regulate blood glucose levels. In addition to these nutrition guidelines, consuming at least one low-glycaemic index food at each meal or snack can also be useful in regulating blood glucose levels (Clapp 2002; Dornhorst & Frost 2002). Similar to the American Diabetes Association guidelines (2001), Diabetes Australia and Diabetes New Zealand discourage large intakes of artificial sweeteners, although moderate amounts may be consumed during pregnancy. Stevia, a herbal sugar replacement, is promoted in health food stores as a safe alternative to artificial sweeteners. Food Standards Australia New Zealand has not approved its use in foods, and due to insufficient research on its toxicological effects it is not recommended by diabetes organisations worldwide.

Food safety and pregnancy

Food safety is an important issue that is often overlooked in pregnancy. Some microorganisms responsible for food-borne illness can cross the placenta, resulting in serious consequences including fetal death.

Listeria

Listeria monocytogenes is a gram-positive bacterium found naturally in soil and vegetation. In healthy, non-pregnant women, an infection with *L. monocytogenes* results in non-specific symptoms similar to a mild flu (fever, diarrhoea and sore throat). In pregnant women, however, *Listeria* can be passed to the fetus through the maternal–fetal circulation or through the vagina during birth. The effects of listeriosis on the fetus include spontaneous abortion in early pregnancy, stillbirth or premature birth in late pregnancy, or damage to the brain and meninges.

The incidence of listeriosis in Australia and New Zealand is relatively low. In Australia in 2002, 62 cases of listeriosis were reported, of which two were in pregnant women. This represented a rate of 0.8 cases/100,000 live births (OzFoodNet Working Group 2002). The incidence of listeriosis in New Zealand is reported to be approximately 15 cases/year (Bremer et al 2003).

Despite the low incidence of listeriosis, general food safety principles should be promoted particularly during pregnancy, to further reduce a woman's risk. Both raw and processed foods

are a potential source of *Listeria*. Foods that have been cooked and then chilled are ideal breeding grounds for this bacteria; therefore, foods stored in the refrigerator longer than 12 hours may contain *Listeria*. Fortunately, high heat destroys this pathogen; therefore, reheating foods can significantly reduce one's risk of contracting listeriosis. Publications by the New Zealand Food Safety Authority titled *Food Safety in Pregnancy*, and by FSANZ, titled *Listeria and Pregnancy*, have further information related to reducing one's risk of listeriosis.

Pregnant adolescents

Adolescence is a stage in life characterised by rapid growth and development. Therefore pregnant adolescents are at increased risk of nutritional inadequacies due to the additional nutritional requirements of pregnancy. Adequate weight gain is important for pregnant adolescents, to ensure not only the growth of the fetus but also that of the adolescent. The recommendations for weight gain in pregnant adolescents are based on pre-pregnancy BMI, aiming for gains at the higher end of the recommendations (National Research Council 1990).

In addition to the energy demands of adolescent pregnancy, requirements for iron and calcium are also increased. During adolescence, total blood volume increases, and therefore adolescents who become pregnant have a substantial increase in blood volume, more so than in adult women (Beard 2000). An adequate intake of iron is critical to prevent iron deficiency and iron deficiency anaemia. Depending on their dietary intake and iron status, adolescents may benefit from iron supplementation early in the pregnancy. The adolescent skeleton is growing rapidly, and therefore sufficient calcium is necessary to promote peak bone mineral density of the adolescent while ensuring skeletal growth of the fetus (National Research Council 1997).

Furthermore, adolescence is a time of exploration and independence. Issues such as body image may result in dietary restriction or altered eating patterns that may have a negative effect on dietary intakes. It is critical to emphasise the importance of good nutrition to pregnant adolescents for their health and that of their unborn child.

Multiple pregnancies

Although the need for additional energy and nutrients in multiple pregnancies would seem obvious, there has been limited research in this area. Recommendations for weight gain in multiple pregnancies aim to optimise pregnancy outcomes, primarily birthweight. The weight gain recommendation for twin pregnancies, 16–20.5 kg, is higher than for singleton pregnancies (National Research Council 1990). A weight gain of 2–3 kg in the first trimester may be beneficial in multiple pregnancies to promote intrauterine growth. This is important, considering the high risk of preterm delivery in multiple pregnancies (Brown & Carlson 2000).

As with pregnant adolescents, multiple pregnancies also require additional iron and calcium to accommodate an increased blood volume and to support the growth and development of the fetal skeleton (Okah et al 1996; Worthington-Roberts 1998). An increase in essential fats has been suggested, based on lower levels of plasma essential fats reported in women with multiple pregnancies (Zeijdner et al 1997).

Summary: pregnancy

Nutrition plays an important role in pregnancy. Plenty of energy from carbohydrate, fats and protein is required to facilitate the growth and development of maternal and fetal tissues. An adequate intake of iron, calcium, zinc, iodine, vitamin B_{12} and folate is particularly important in pregnancy, whereas excess intake of some nutrients such as vitamin A may be detrimental to the fetus. Dietary advice can also help to alleviate common conditions in pregnancy, including constipation, heartburn and nausea, and may be useful in managing gestational diabetes mellitus and avoiding food-borne illness such as listeriosis. Pregnant adolescents and multiple pregnancies are considered high-risk with respect to nutrition, due to increased nutrient and energy demands.

Nutritional foundation for childbirth

Childbirth is an energy-demanding process that requires adequate energy and hydration. The actual energy demands for labour have been estimated to be between 2.9 and 4.2 MJ per hour. However, some researchers disagree with these figures, stating that smooth muscle requires significantly less energy than skeletal muscle, on which the original estimates were based (Champion 2002). Without adequate energy intake, body stores of glycogen and adipose tissue will be used to sustain energy requirements. As the period of fasting increases, ketones begin to appear in the blood. It is largely accepted that some amount of ketosis during childbirth is

Critical thinking exercise

A 22-year-old woman (para 1, gravida 0) has indicated to you that she is vegetarian. She consumes dairy products but no other animal foods. She has followed this diet for six years and is keen to continue the diet during pregnancy.

1. What other questions about her diet might you ask her and why?
2. What nutrients might you be concerned about with her diet and why?
3. How would you follow up with this client to ensure that her diet meets the energy and nutrient requirements of pregnancy?

normal. However, as ketones begin to spill into the urine, the body becomes depleted of sodium and potassium, resulting in dehydration, which may lead to maternal or fetal acidosis. It is important, therefore, to ensure adequate nutrition and hydration to prevent such large aberrations in acid/base balance.

Since the mid-1900s, many hospitals worldwide have implemented policies on restricting oral intake during childbirth. The primary rationale for this restriction was to lower the risk of pulmonary aspiration in women who required anaesthetic during labour. Some countries, including the United Kingdom, do not restrict oral intake in early labour and have very few cases of pulmonary aspiration. Of nine million births in the United Kingdom in the past 12 years, only four maternal deaths occurred due to maternal pulmonary aspiration (Cooper et al 2002).

It is well documented that eating in labour increases gastric volume, thereby increasing the risk of pulmonary aspiration; however, fasting in labour does not always guarantee decreased gastric contents (Scrutton et al 1999). Various factors tend to inhibit gastric emptying, particularly narcotic analgesia. Other factors such as the osmolarity and macronutrient composition of oral intake also affect gastric emptying. Isotonic drinks appear to reduce maternal ketosis (Kubli et al 2002) without increasing gastric volume, whereas fatty foods, and foods containing dietary fibre, tend to slow down gastric emptying, thereby increasing gastric volume. Similarly, liquids are emptied more rapidly than solids from the stomach and are therefore preferable in reducing gastric volume (Table 19.7) (Champion 2002).

Summary: childbirth

Nutrition and hydration are important during childbirth to ensure an adequate energy intake and to maintain normal fluid and electrolyte balance of mother and child. Although large gastric volumes increase the risk of pulmonary aspiration, restricting oral intake during labour does not necessarily result in reduced risk of aspiration. Isotonic fluids and foods that enhance gastric emptying are best suited for early labour.

TABLE 19.7 Appropriate foods and drinks for women in labour

Foods	Fluids
White bread or toast (low-fibre) with low-fat spreads, jam or honey	Low-fat yoghurt drinks
Low-fibre breakfast cereal with low-fat milk	Ice blocks
Creamed rice	Fruit juices
Plain biscuits	Clear broths
Low-fat yoghurt	Diluted squash drinks
Fruit (tinned or fresh)	Water
	Sports drinks (Lucozade, Gatorade, Powerade)

(Source: adapted from Champion 2002)

Critical thinking exercise

A 36-year old woman (para 3, gravida 2) currently 37 weeks gestation has asked you whether it is important to eat and drink throughout the entire labour.

Outline the pros and cons of eating and drinking in labour, and the rationale for each.

Nutritional foundation for lactation

The nutritional needs of a woman change after pregnancy. These needs are based on the nutritional needs of lactation, which in fact exceed those of pregnancy. Lactation, like pregnancy, is an anabolic state and therefore requires adequate energy to support milk production.

The energy costs for lactation have been estimated as additional 650 kilocalories (2720 kilojoules) per day. Taking into consideration the additional energy stores formed during pregnancy, the recommended energy intake is estimated at 500 kilocalories (2100 kilojoules) per day (Picciano 2003).

Because of the energy demands associated with breastfeeding, weight loss is often reported to occur with breastfeeding. Further weight loss often results when breastfeeding mothers restrict caloric intake and/or begin physical activity. Although dieting while breastfeeding is not generally recommended, dieting with or without aerobic exercise does not appear to affect either the quality or quantity of breast milk (Lovelady et al 2000; McCrory 2001; McCrory et al 1999).

The nutritional quality of breast milk is fairly constant regardless of maternal diet. The micronutrient content of breast milk, specifically the minerals calcium, iron and zinc, is tightly regulated (Lonnerdal 2000). Several nutrients present within breast milk, however, can be altered by maternal diet. These include vitamins B_6, B_{12}, A and D, and fatty acid content.

The amount of vitamin B_6 transferred from maternal blood into breast milk is minimal, and therefore recommended intakes are slightly higher than for non-lactating women. The levels of vitamin B_{12}, vitamin A and long-chain polyunsaturated fats in breast milk reflect maternal intake. It is critical, therefore, that vegan breastfeeding mothers ensure an adequate intake of B_{12} and essential fats (Makrides & Gibson 2000; Picciano 2001; Sanders 1999). One nutrient found in low levels in breast milk is vitamin D. Vitamin D levels in breast milk have been reported to fluctuate depending on maternal sun exposure, with higher levels in summer than in winter (Hollis & Wagner 2004).

A non-nutritional advantage to breastfeeding is the immunological protection it affords the infant, which reduces risk of allergy development. Although the true prevalence of

food allergy in children is unknown, it has been estimated to be as high as 4–6% in some countries (Zeiger 2003). Some infants, however, are more susceptible to allergies, particularly those born to parents with allergies or whose siblings have an existing allergy.

Despite the immunological benefits of breast milk, sensitisation, an initial exposure to an allergen, can occur during lactation. A subsequent exposure to the same allergen will then result in an allergic reaction. For infants with a parent or sibling who have a confirmed food allergy, it may be advisable for breastfeeding mothers to avoid the major food allergens (nuts, fish and shellfish), to reduce the chance of sensitising the infant. It has been suggested that sensitisation occurs in utero; however, the American Academy of Pediatrics (AAP) and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) do not recommend maternal allergen avoidance during pregnancy, due to a lack of supporting evidence to suggest otherwise (Zeiger 2003). Women with infants who have a confirmed food allergy should be encouraged to breastfeed; however, elimination of the infant's food allergy in their diet is advised. To ensure that the allergic infant and mother receive adequate nutrition, they should be seen by a dietitian who specialises in food allergies.

Critical thinking exercise

A 29-year old woman (para 2, gravida 1) is at 34 weeks gestation and is very concerned about her newborn developing food allergies. Her first child has been diagnosed with cow's milk allergy. She has been avoiding all dairy products throughout her pregnancy in an attempt to prevent sensitising her unborn child.

1 What are some potential strategies you might discuss with her for reducing the risk of allergy development in her second child?
2 What advice would you provide her with if she becomes pregnant again?

Conclusion

Pregnancy, childbirth and lactation are all energy- and nutrient-demanding events. For optimal maternal and fetal health, adequate intakes of nutrients are required, including iron, calcium, zinc, iodine, vitamin B_{12} and folate. Of particular consideration are individuals with higher nutrient demands, such as pregnant adolescents and women with multiple pregnancies. Nutrition plays an important role in alleviating some common conditions associated with pregnancy, including constipation, heartburn and nausea. Similarly, dietary strategies can assist in managing gestational diabetes mellitus, in preventing food-borne illnesses, in maintaining adequate fluid and electrolyte levels during childbirth, and in reducing the development of food allergies in the breastfed infant.

Review questions

Pregnancy

1 How can body mass index be used as a tool for midwives?
2 What is the importance of each macronutrient in pregnancy?
3 What impact do specific vitamin and mineral deficiencies or excesses have in pregnancy?
4 What preventive dietary strategies would you recommend for the effects you listed in question 3?
5 What dietary strategies would you suggest to a pregnant adolescent or to a woman expecting twins?
6 Why is food safety important during pregnancy?

Childbirth

7 Why are energy intake and hydration important during labour?
8 What types of foods are suitable to consume during labour?

Lactation

9 What nutrients in breast milk reflect maternal diet or lifestyle, and why?
10 What advice would you give to a breastfeeding woman who is concerned that her infant may develop a food allergy?

CHAPTER 20

Working with women in pregnancy

Celia Grigg

Key terms

active decision-making, antenatal education, antenatal visits, assess baby's wellbeing, assess woman's wellbeing, assessment and screening, blood pressure (BP) measurement and monitoring, blood screening, booking visit, care plan, constipation, current health review, 'decision point' framework, estimated due date (EDD), evidence-informed midwifery practice, exercise in pregnancy, fetal movement (FM), health promotion and education, heartburn, historical health review, holistic midwifery, information sharing, initial contact, last menstrual period (LMP), nausea and vomiting, palpation, physiological changes, risk markers, urine screening

Chapter overview

This chapter discusses antenatal care within the context of the midwifery model. It provides a broad overview of the issues of antenatal care, and considers some of the core technical components of clinical practice. Where possible, this discussion is based on reviewed research, in order to promote evidence-informed midwifery practice. The dearth of published research that meaningfully addresses midwifery questions is an ongoing problem in this regard. The chapter establishes a framework for understanding the *way* of doing things, as much as it provides instruction on *what* to do. As such, it seeks to interpret routine care with reference to the following set of guiding principles, which are fundamental for midwives working within the midwifery model:

- partnerships with women—women-centred, negotiated relationships
- continuity of care in the holistic process of pregnancy, birth and early parenting
- support and empowerment of childbearing women
- promotion of holistic wellness
- assessment and screening, which includes risk identification, knowledge/understanding and choices
- information sharing as a two-way process
- promotion of active, informed decision-making by women
- health promotion and education within an appropriate 'adult learning' approach.

In this chapter, antenatal care is discussed within a broad practice model of midwife-led continuity of care. While this model characterises New Zealand's maternity services, it is also becoming increasingly available in Australia and is the model to which Australian midwifery aspires. The key components of routine antenatal care are identified using the New Zealand College of Midwives (NZCOM) 'decision points' as a framework (NZCOM 2005). Some of these components are further developed in the explanatory sections that follow. The decision points refer to relevant issues raised in other chapters of this book, and readers are also referred to other reading and research activity where appropriate. Notwithstanding the model of care in which a midwife may practise, the aspects of antenatal care described in his chapter are applicable to any setting.

Of necessity, this chapter discusses antenatal care as a discrete entity, and it may be tempting to consider it as such. However, antenatal care is but a small part of a woman's experience of the broader process of pregnancy, and cannot be separated from childbearing as a holistic

process, which includes pregnancy, birth and the postnatal period. Further, the meaning and effect of antenatal care is totally dependent on the individual woman and her personal context.

Learning outcomes

Learning outcomes for this chapter are:

1. To discuss the organisation and form of antenatal care within the context of the midwifery model
2. To illustrate a way in which evidence may be used to inform midwifery practice
3. To describe the essential components of antenatal care
4. To explain the purpose and process of the initial contact and booking visits
5. To describe and explain the concept of 'decision points' as a framework for organising care
6. To discuss the history and processes of establishing the estimated date of delivery
7. To list and describe routine antenatal blood screening, blood pressure and urine screening tests
8. To explain the purpose and process of abdominal palpation of pregnant women
9. To describe the assessment and significance of fetal movements
10. To explain the nature and provision of antenatal education and exercise programs in pregnancy
11. To discuss some of the physiological changes of pregnancy, with specific reference to nausea and vomiting, constipation and heartburn.

Antenatal care: what is it?

Defining antenatal care as a conceptual entity, or even in terms of a list of discrete clinical components, is difficult. Definitions of antenatal care can vary markedly, depending on one's beliefs or understanding of the childbearing process, be it from a midwifery or medical perspective. The underpinning assumptions of these perspectives have been discussed elsewhere in this book, but it is important to recognise how the midwife's perspective will influence the aims, scope and content of the antenatal care she provides, and the way in which she provides this care.

From a midwifery perspective, antenatal care is not an independent entity. It is an integral part of the whole childbearing experience. It usually represents the beginning of the journey that midwives and women will make together, which includes the time before, during and after the birth of the baby. For midwives working from a midwifery model, it is a time of forming and building a relationship with each woman and those who are important to her. It is a time when a partnership is negotiated, roles and responsibilities are identified, information is shared, options are discussed, and choices are made and supported. It is also a time when notions of wellness and normality within the context of pregnancy are supported and promoted.

Each woman and each midwife bring their respective knowledge and expertise together in this new relationship. A woman brings her knowledge of her past and present physical wellness (and that of her family), her personal, social, emotional and cultural realities, her experiences of pregnancy (present and sometimes previous), and her plans for her birth and mothering. A midwife brings her knowledge of the childbearing process, supports its normality, identifies risks, and shares information that enables the woman to make informed decisions throughout.

However, much of what constitutes contemporary antenatal care throughout the world remains strongly rooted in the 'medical' model within which it developed. Widespread, institutionalised, routine antenatal care began less than eighty years ago, as a mass screening program, with the aim of reducing maternal and perinatal mortality, and brought 'pregnancy' under medical supervision and control for the first time in human history (Wagner 1994). The history and politics of antenatal care will not be discussed here. It is well articulated by many authors, such as Oakley (1984), Strong (2000), Katz Rothman (1989), Donnison (1988) and, in New Zealand, Donley (1998). What is of significance in this context are the beliefs and assumptions that continue to underpin the structure and content of various aspects of antenatal care. Traditionally, and in many contemporary contexts, antenatal care consists of a prescribed set of acts based around the clinical monitoring and screening of all pregnant women, regardless of their health or risk status. This establishment of routine antenatal care was based on the notion that pregnancy is a state of pathology, rather than of normal physiology. Oakley (1984) argues that 'the most characteristic aspect of modern antenatal care is the clinical insistence on the probability of pathology in all childbearing' (p 2). Over the past eighty years, technological advances have brought an ever-increasing array of screening tests and treatments, 'most often . . . without proper scientific evaluation and concrete evidence of benefit' (Villar et al 2004, p 2), although 'few of the procedures commonly undertaken have a major impact on morbidity or mortality, and some may have no effect' (Villar et al 2004, p 2). Further, some have been found to cause physical, emotional or social harm (Wagner 1994). Hall (2001)

contends that there are 'remarkably few antenatal measures [which] are known to be effective: these are screening for and prevention of [some] infections; prevention, detection and treatment of anaemia; detection of malpresentations so that external cephalic version can be offered; and detection, investigation, and treatment of pregnancy hypertension' (p 1546). These measures clearly illustrate the scope of antenatal care from a medical perspective, and the outcomes of value that are expected from it.

Some might argue that routine antenatal care fails to meet reasonable expectations of its relevance and effectiveness. If this is indeed the case, then it may be possible to mount a case to abandon it. However, such a proposition would be inappropriate from a midwifery point of view. Maternal and perinatal morbidity and mortality are not the only outcome measures of value. There is substantial evidence that midwifery-provided continuity of care has beneficial effects on other outcome measures, such as reduced anxiety, a greater sense of control (Oakley 1992), reduced use of drugs for pain relief in labour, reduced likelihood of the need for newborn resuscitation, and greater satisfaction with antenatal, intrapartal and postnatal care (Hodnett 2004; McCourt & Page 1996; Page et al 1999). It is extremely important that all those who provide care clearly articulate the scope and limitations of the screening and diagnostic tests used in antenatal care.

The key point here is that antenatal care is a process that consists of more than just a series of medical tests and monitoring procedures. While some of these tests may form part of the process, in the midwifery context they are not of themselves the essence of antenatal care—that is, they do not *define* it. Midwives need to claim and promote the potential of holistic midwifery care, and put this potential into practice in their work. For midwives, antenatal care is fundamentally about a relationship between two actively participating individuals (and the woman's support people), who bring their respective expertise together and work to maximise the health and wellbeing of the woman and her unborn child, and to prepare for labour, birth and parenting. From the midwifery perspective, the term 'routine antenatal care' is perhaps a misnomer, as there is no such thing as a 'routine' woman. Every woman is different, and each of her pregnancy experiences is unique.

Organisation of care

The provision of antenatal care in Australia and New Zealand has traditionally been based on a medically defined, controlled and provided system of assessment, screening and monitoring of pregnant women, which was initiated in Britain and established in the 1920s (Hall 2001). In Australia this remains largely unchanged, although there are increasing examples of alternative models (Reiger 2001; Tracy 2005). In New Zealand, an alternative organisation of care was introduced in 1990, which enabled women to choose, and midwives to provide, full and complete maternity care for well women without referral or deferral to doctors. Today, antenatal care in New Zealand is founded on the concept of a primary caregiver, known as a lead maternity carer (LMC), providing the majority of care and organising referral when care is outside the scope of practice of the LMC.

Auscultation of baby's heart with electronic hand-held Sonicaid. Reproduced with the permission of the New Zealand College of Midwives

The antenatal visit

Antenatal visits are the main mechanism for the provision of antenatal care. They are negotiated and agreed upon between the woman and the midwife, and occur at prearranged times and locations, and at regular intervals throughout the woman's pregnancy. They are multidimensional and include several components, such as information sharing, assessment and screening, active decision-making, and health promotion and education. Aspects of these dimensions will be illustrated and discussed throughout this chapter.

The number and timing of visits follow a pattern, which was established when the concept of antenatal care was introduced in the 1920s (Candy et al 2003). This traditional pattern of antenatal visits—four-weekly from booking until 28 weeks, fortnightly until 36 weeks and weekly until birth—remains the standard of antenatal care today in Australia and New Zealand. This format has no particular scientific, medical, social or midwifery foundation, and has recently been the subject of debate and challenge. This challenge arose from the concept of 'evidence-based practice' and has led to the evaluation of this aspect of antenatal care (Enkin et al 2000).

Determining the 'optimal' number of visits in routine antenatal care is extremely difficult. This is due to the complexity of the process of pregnancy itself, the diversity of childbearing women, and the context-bound, multidimensional nature of antenatal care in general (Strong 2000). Attempts to specify a particular number of visits have been based on research which measures only biomedical outcomes, such as incidence rates of pre-eclampsia, low birth weight, urinary tract infections,

postpartum anaemia and perinatal mortality, although some studies have surveyed maternal satisfaction (Candy et al 2003; Carroli et al 2001; Petrou et al 2003; Villar et al 2004). Current recommendations, based on these studies and other similar research, are for a schedule with a reduced number of antenatal visits. The British National Institute of Clinical Excellence (NICE) guidelines (2003) and the Australian Three Centres Consensus Guidelines on Antenatal Care Project (ATCCGACP)(2001) both opt for a routine, for well women, of ten visits for women having their first baby (primiparas) and seven for those having their second or subsequent baby (multiparas). It is notable, however, that a reduction in women's satisfaction with fewer visits, as reported in research that studied this issue, has been minimised and largely ignored in these guidelines. Arguably, this illustrates the continuing dominance of the medical model as the foundation of contemporary antenatal care.

In New Zealand, there appears to have been some change in the number of antenatal visits from the traditional pattern, but no research has been published which identifies whether this is woman- or caregiver-led. According to a recent nationwide survey completed by 2909 women, 93% of women had had more than five antenatal consultations and 65% had had more than ten, with 91% agreeing or strongly agreeing that they had had the right number of visits with their lead maternity carer (Ministry of Health 2003).

Issues concerning the length and location of antenatal visits are context-bound in the same way as those associated with the number of visits, and the alternative options offered are equally constrained within socio-political limits. In the New Zealand model, the woman and midwife negotiate the length and location of visits, with each party making her respective personal and practice choices clear prior to any agreement to work together. Although there is no set optimal length for visits, enough time needs to be set aside to include discussion, assessment, decision-making and documentation of the issues, such as those included in the 'decision point' framework set out in this chapter. The time taken for visits will vary according to the practice styles of individual midwives, differences in the needs and personalities of women, the stage of the woman's pregnancy and her health status.

It is also important that the location of visits be one in which both the woman and the midwife feel relaxed and comfortable, and be available at the time most convenient to them. It needs to be safe, both personally and culturally, and afford appropriate privacy. The ideal location will be accessible and have appropriate facilities. If possible, it is valuable for the midwife to provide some of the antenatal care in the woman's home. This may help to restore the traditional power balance between care provider and receiver, and also provides valuable insight for the midwife into the woman's personal and social context.

MIDWIFE'S STORY

When I arrived at the woman's home, I was surprised to find an ashtray in every room—including the toilet! She had told me previously that no one who lived in the house smoked. She hadn't mentioned that her grandmother, who lived close by, spent most of her time at her house, and smoked heavily. It was a delicate situation, with family relationships at stake, and required the full duration of the pregnancy to support the woman in negotiating smoke-free spaces in her own home. Visiting her at home and meeting her family gave me valuable insight into how to support the woman in making changes which would have a positive impact on her own health and that of her baby, without fracturing family relationships.

Initial contact

Initial contact between a pregnant woman and a midwife is generally by phone. This call may simply be little more than an inquiry about the availability of the midwife. It may, however, evolve into a process of establishing more substantial contact between the two, either as a continuation of the phone call, or at a face-to-face meeting. This will represent the first meaningful exchange between the midwife and the pregnant woman. It is an opportunity for the woman to gain a first impression of the midwife—what she sounds like, her ways of practice and her availability. For the midwife, it is an opportunity to help the woman clarify what she is seeking, to share information about how she practises, and to talk about the choices that are open to the woman.

There is no common understanding about the nature of this contact, in terms of what it involves, or what its outcomes are expected to be. Women perceive its purpose in different ways. Some women are better informed about the process of arranging their care than others, and are very clear about what they want. Others have no clear understanding about the process or what will come out of it. It is the midwife's obligation to assist the woman through this initial contact by providing a framework for understanding the exchange, and a pathway through it.

There is no standard terminology for or description of this initial contact. It may be referred to as the 'options' or 'check-out' visit or contact (to 'check out' meaning to gain a first impression or initial understanding of a person or a situation), and many midwives will have their own term for it. It is not the same thing as a 'booking' visit. The key feature differentiating this contact from a booking is that during the initial contact process, the woman and midwife share information that will enable a decision to be made about whether they will work together. The booking visit, by contrast, occurs as a result of that decision having been made.

There is also no standard format for the process itself. While individual midwives will perceive and prioritise its various stages and content differently, it needs to include certain elements in order to be meaningful to childbearing women. For women having their first baby, the system and process are new and unknown. They will often require specific information from the midwife, and will frequently

be dependent upon guidance from her. They often don't know what they need to know, in order to make an informed decision. It is the midwife's role to facilitate informed decision-making by women, which includes the choices they make regarding their caregiver. For a list of questions that women should have answered by a prospective caregiver, see Box 20.1 or go to the New Zealand College of Midwives (NZCOM) website (www.midwife.org.nz).

The overall intention of this process is to identify the level of compatibility between the woman and her potential midwife, in order to determine whether they can establish a constructive working relationship. Without this, effective communication can be difficult, which can lead to a breakdown in the relationship between them, and in turn create the potential for a negative impact on social or clinical outcomes. Compatibility needs to occur at three levels—the interpersonal, the professional and the practical.

The interpersonal level

Each woman and midwife pair needs to feel that there is a comfortable personal connection between them. This is first and foremost a professional relationship, and not one based on shared personal experiences or a common background. The interpersonal dynamic is about a sense of relaxation and trust, and the ability to speak a social 'language' that the other feels comfortable with and understands. Different midwives will suit different women, and sometimes this initial discussion will result in a decision not to work together. This may be due to character and personality variables, about which we should not be surprised. This process is about establishing an effective human relationship (even if it is professional in nature) and so it should not be regarded as a sign of failure that a woman chooses not to work with a particular midwife.

Cultural factors are also key aspects of compatibility. It is important for women to have the opportunity to evaluate the cultural awareness and sensitivity of a midwife, and be confident that the midwife will be able to advocate for her culture-specific needs or desires.

The professional level

There is variation in the context and scope of practice among midwives. This variation is due in part to differences in belief and understanding of the nature of pregnancy, birth and parenting, and reflects the midwifery philosophy that underpins their practice. Midwives may also feel more or less comfortable in a range of settings. Some work comfortably with women in an obstetric setting, while others are most comfortable in the primary, community or home birth context. The way in which midwives practise professionally will vary according to these beliefs as well as their levels of experience, personal confidence and comfort zones, and their skills or knowledge base.

There is also variation among women in their views, beliefs and understandings of the nature of pregnancy, birth and

BOX 20.1 Questions to ask a midwife

Pregnancy

- Are you a member of the Australian/New Zealand College of Midwives?
- Is your practice reviewed annually, through the College Standards Review process? (New Zealand)
- How many women do you 'book' each month?
- Who is your back-up midwife? How do you work together?
- When will I meet her? Will I have the opportunity to get to know her?
- If I require consultation with an obstetrician or other specialist, what are my options?
- Under what circumstances would my care be transferred to hospital staff?
- Where do you provide antenatal visits?
- Between visits, are you available for me to phone you for advice?
- Do you work with or refer to other health professionals or support groups?
- What are your beliefs about pregnancy and birth?

Labour and birth

- Do you offer home birth? Do you have access to small birthing centres in the area?
- What hospitals do you have access to?
- What birthing options do you offer (e.g. water birth)?
- Do you come to my home when I am in labour?
- In labour, if I need care from an obstetrician, how will it be arranged?
- If this happens, what role will you play in my care?
- Under what circumstances would my care be transferred to hospital staff?
- If my labour is long, who will relieve you and provide my care?

After the birth

- How often do you visit after the birth?
- If I need or choose to be in hospital after the birth, will you visit me there?
- What will your role be and what care will you provide, in that situation?
- For how many weeks do you provide care?
- Between visits, are you available for me to phone you for advice?
- Do you work with or refer to other health professionals or support groups?
- What are your beliefs about breastfeeding?

(Source: Adapted from the New Zealand College of Midwives pamphlet, 'Questions to ask when you choose a midwife' (undated publication))

MIDWIFE'S STORY

When Ana and I first met, she was eight weeks pregnant with her first child. She told me of her plan to have an elective caesarean section. She came from a country that offered this option to all women. When asked why she feared vaginal birth so much, she recounted stories of traumatic vaginal births of women she knew. None of these were normal births. I informed her that one of my professional boundaries was to decline to work with women planning a caesarean section with no clinical indication. We talked through my reasoning. Our initial visit ended with the option of us working together on the basis of planning a normal birth, or her choosing to work with someone else. The following week she attended her pre-arranged appointment with an obstetrician and, after considering her options, called me to ask me to provide her maternity care. We began a journey together which eventually included a normal birth.

parenting. This will influence the expectations they have and the priorities they set for the type of care their midwife will provide. For example, before choosing a caregiver, a woman planning a home birth will want to know whether her choice will fit within the scope of practice of, and be genuinely supported by, a midwife.

The practical level

There are a number of practical details of care that will need to be discussed. The first of these is the availability of the midwife to provide care for the woman's pregnancy, birth and postnatal period. This is focused on the estimated due date (EDD).

It is appropriate for midwives to inform women about arrangements for back-up when they are unavailable to provide care, such as during regular time off or illness, or when they are with another woman. In some practices, midwives work together in loose 'partnerships' and arrangements may or may not be made for women to meet their back-up midwives; in others, visits with the back-up midwife are an integral part of the care. There is also a moral obligation on midwives to inform women about their plans for holidays during the period of care.

A second major issue is the time and place of antenatal care. Women and midwives need to identify whether they can organise antenatal visits at a time and place that suits. This is affected by the context in which care is provided, and by the personal choices made by individual midwives. Some midwives provide clinic-based antenatal care on set days of the week. Others may negotiate with women to visit them in their home for some or all of the antenatal care.

Summary

The main purpose of the initial contact is to establish a two-way partnership between the woman and the midwife. Both are active decision-makers in this process, and negotiate their respective roles and responsibilities. Both need to have the opportunity to make choices about whether or not they will work together.

During the initial contact, the midwife learns about the plans, beliefs and concerns the woman has about her pregnancy, childbirth and postnatal care. She also learns a little about her social, cultural and physical history and context. The midwife identifies issues that may make it inappropriate for her to provide care, such as when a woman has specific social or cultural needs, or an underlying medical condition that requires care and knowledge that is beyond the midwife's personal scope of practice.

The woman learns about the midwife's personal beliefs and scope of practice, her professional boundaries, and the practical arrangements that may affect the woman's choice of caregiver. She develops a sense of the midwife's personality and practice, and decides whether she can trust the midwife to provide the kind of care that she wants.

This process should function as a positive screening process for both the woman and the midwife. Each has the right to *choose* to work with the other, as it is important that this relationship begins as it is to go on—with both woman and midwife sharing information, and actively participating and making decisions in a negotiated partnership.

The booking visit

The booking visit is essentially the beginning of the care relationship between the midwife and the woman and her family. It is an important part of the whole context of midwifery care, and of the antenatal care component in particular. It occurs early in the pregnancy and at the woman's home where possible, and includes the midwife, the woman, and whomever else she chooses to have with her—partner, mother, sister or friend. The purpose of this visit is to formalise the arrangements for care, and to establish a foundation for the partnership. In other words, it is about defining the nature of the relationship between the woman and the midwife, and the context and meaning of antenatal care for both of them. It will:

- have a holistic focus
- be a two-way process of information sharing and decision-making
- review the past, identify the present, and plan the future
- include the identification of health, known ill-health, and risk markers for potential ill-health, for the woman or her baby
- include practical arrangements of care, in terms of frequency, time and place.

The booking visit happens as a result of a decision being made by the woman and midwife to work together. At this point, they will have already spoken by phone, and may have met, and will know a little about each other. If the initial contact or 'check-out' visit was not done face to face, it is preferable that the booking visit be held off until they have

Antenatal assessment of baby wellbeing. Reproduced with the permission of the New Zealand College of Midwives

had an opportunity to meet. Alternatively, the visit could begin as a check-out opportunity for both, with a clearly identified end point for the meeting, in order to give some time and space for the woman to consider whether or not she would like to work with that midwife. If both are comfortable with each other, they may decide to formally begin the relationship at that point.

The booking visit represents the beginning of a shared journey. It is the beginning of a relationship that will last for about ten months (in the first instance), and encompass a special, powerful and life-changing period for the woman and her family. It is a time when many personal and private aspects of a woman's life will become shared with the midwife. As such, the booking is a great opportunity for the midwife to *get to know* the woman she will be working with. The woman's home is the ideal venue for this visit, as it is in her place and space, which can help to moderate the traditional hierarchical power dynamic between 'health professional' and 'patient', to that of a more equitable partnership between midwife and woman.

Having the booking visit at the woman's home can also give the midwife important information about the woman's personal and social context. The midwife will be able to gain valuable insight into the woman's personality and outlook, her understanding of pregnancy and childbirth, and her life situation and lifestyle choices, when discussing her history and her present and future plans. There is as much to be learned from the *way* in which the woman talks about these things and the way she responds to new information or options, as from *what* she says. During the discussion, the midwife can develop a sense of how the woman perceives her own role in the birth process—as an active 'doer', or a passive 'receiver' of care—as well as her understanding of health issues and the concept of risk in pregnancy.

Learning about *who* a woman is, in a holistic sense, is a central and integral component of the midwifery model. It is not an optional extra to the 'real' physical or clinical aspects, but an imperative for midwifery care, if an effective working relationship is to develop. Having this understanding helps the midwife to tailor the way she shares information with the woman, so that it may be meaningful for her. Midwives cannot identify what is appropriate for women if they know nothing of their personal, social or cultural 'self'. Sharing information or making recommendations that are irrelevant or inappropriate to their personal, social or cultural circumstances will be ineffectual, can be offensive, and may have a negative impact on the woman and the outcomes.

The booking visit and the process of establishing a partnership is not about 'becoming friends' or 'being nice'. It is about developing an effective working relationship at a professional level, between human beings.

Reviewing the past

The quality and quantity of information shared during the booking visit depends on a number of factors. The specific questions asked by the midwife, the way in which they are asked, and the timing of them (in terms of when in the booking process they are asked), may influence a woman's responses, particularly when they relate to sensitive information such as that regarding sexually transmitted infections, abortions or abuse.

It is also important to recognise that a woman's knowledge of her family's health history and that of her own childhood illnesses or operations may be limited, perhaps due to poor access to those details, possibly as a result of family separation or dislocation or such like. Some women may also have limited understanding of the details of treatments or the nature of medical procedures they have undergone. For example, the detail, meaning or significance of differing cervical treatments (such as loop surgery, cone biopsy, laser treatment, and the associated terminology such as 'CIN I, II or III') are sometimes not known or understood by women. This means that women, understandably, are sometimes unable to provide the level of detail sought by midwives.

The midwife identifies risk markers from the woman's history, and discusses them with her. This discussion may include options for testing, screening, treatment, self-care, referral for consultation with situation-appropriate specialists, support and further information gathering. (See Ch 32 for discussion on screening, assessment and consultation options, and Ch 33 for discussion on risk markers and potential complications in pregnancy.)

Research findings suggest that midwives who use a 'structured paper history' incorporating a cue sheet (see Appendix A) are likely to get 'more and better information' than those using an unstructured format (cited in NICE 2003). Documentation of shared information is very important for both the woman and the midwife. During the care, it is appropriate for the woman to carry her own maternity notes (see NICE 2003). Upon completion of care, the midwife also

needs to keep a copy of these documents, in order to meet her respective professional and legal requirements.

Identifying the present

As part of the booking visit, the midwife also undertakes a 'current health review' (see Appendix B) and an initial examination, in order to establish baseline information and facilitate the process of planning the care. All the issues identified in the 'current health review', and those raised in the aforementioned historical health review, have the potential to influence the process or outcome of pregnancy, although some are more significant than others. They should provide the midwife with cues as to the nature and detail of any physical examination that may be required.

Currently, there is no consensus as to the detail, make-up and content of a 'routine' initial physical examination of a well pregnant woman. Chan and Kean (2004) state that 'there is very little to be gained from a full formal physical examination' (p 80). They suggest that 'routine auscultation for maternal heart sounds in asymptomatic women with no cardiac history is unnecessary', and that neither formal breast examination nor routine pelvic examination is appropriate (p 80). The NICE (2003) guidelines do not address the issue of cardiac examination, but support the recommendation against routine breast and pelvic assessments. In contrast, Frye (1998) recommends a full medical examination including the above checks and details such as assessment of lymph nodes, reflexes, mouth, eyes and lungs, in addition to the 'vital signs'. It is debatable whether such an examination is indicated, or within the scope of midwifery practice. Certainly, midwives generally work with well women, and should have sound knowledge of normal anatomy and physiology, and organ and hormone function, as well as signs of dysfunction, but a *routine* full examination may be both inappropriate and outside the midwifery scope of practice. To date, there is limited evidence available which addresses this issue to any significant degree.

It is important to distinguish between something that is offered routinely, and that which is offered in response to risk markers. For example, offering vaginal swabs as a screening test routinely is not currently recommended, but for a woman with a history of chlamydia and ongoing unsafe sex practice, screening may well be indicated. In such cases it is appropriate to discuss the option of carrying out a diagnostic test to identify whether there is a current infection, along with issues of self-care, and the potential risks from such an infection to the woman's health and wellbeing and that of her baby.

Planning the future

Working through the relevant aspects of the woman's past and present health status enables a foundation to be established which facilitates effective planning for the future care of the woman. The midwife and the woman are now in a position to make decisions about the relevance or appropriateness of particular screening or diagnostic tests, and to determine whether there is a need for referral for specialist consultation. This may be to any one or a number of specialists, such as an obstetrician, dietician, physiotherapist, psychiatrist, sexual health specialist or geneticist. They are also in a position to make decisions about those other matters that are outlined in Decision point 1 (see page opposite).

Decision points

Decision points are a significant new initiative in the organisation of antenatal care. They provide a systematic framework for organising care, and are articulated in their primary form in the New Zealand College of Midwives *Midwives' Handbook for Practice* (2005). A modified and expanded version of these decision points was developed for this chapter, a key theme of which is a holistic midwifery approach to antenatal care.

The decision points are based on eight time frames, which are loosely tied to gestation periods through the course of pregnancy. They consist of four categories of cues that provide a guiding form and structure for care. These cues alert the midwife to the components of what is currently considered appropriate and necessary in the provision of comprehensive antenatal care. The four categories include cues about information sharing, assessment and screening, active decision-making and health promotion and education. These categories are intended to assist the midwife to consider the various dimensions of care, beyond the purely clinical aspects of it, and reflect a holistic understanding of the care process, without being overly prescriptive. It is important that the midwife actively considers each aspect of care raised in the decision point framework with reference to the social, emotional, physical and cultural realities of each woman.

Each decision point contains references to other chapters in this book, and to following explanatory sections (called 'explanations' in the decision point boxes) where a range of components of routine antenatal care are described and discussed in further detail. These explanatory sections cover:

- estimated due date (EDD)
- routine antenatal blood screening
- routine blood pressure screening
- routine urine screening
- palpation—hands-on learning, identification and assessment
- fetal movement (FM)
- antenatal education
- exercise in pregnancy
- physiological changes of pregnancy.

DECISION POINT 1: the booking visit (before 12 weeks)

1 Information sharing

Choices for maternity care
Inhformation on community groups and agencies
Woman's:

- plans regarding pregnancy, birth and early parenting (care plan)
- experience of pregnancy
- physiological changes (see Explanations)
- social, emotional, medical, physical, cultural situation

Midwife's practice—support, time-off, how to contact, confidentiality
Folic acid supplementation
Options for:

- antenatal education (see Explanations)
- place for birth
- midwifery student involvement, if relevant

2 Assessment and screening

Review history (see Appendix A):

- maternity, medical, social, physical, psychological
- identify and discuss alerting factors or risk markers

Review current health status (see Appendix B):

- physical, social, emotional and cultural
- identify and discuss alerting factors or risk marker
- establish EDD (see Explanations)

Initial antenatal screening—routine (with informed consent)

- Blood
  - — routine (see Explanations)
  - — options from risk markers—STIs, TB, HIV, Hep C
- Urine—MSU and dipstick urinalysis and/or microscopy and culture (see Explanations)

Screening options if risk markers from history or current health review

- blood tests, scan (nuchal translucency), CVS or amniocentesis

3 Active decision-making

LMC—decided prior to 'booking' process
Screening options—routine and options due to 'risk markers'
Referral—if indicated and wanted—for 'specialist' input (e.g. obstetrician, dietician, physiotherapist)
Meeting/involvement of midwifery student
Time, place, frequency of antenatal care

4 Health promotion and education

Lifestyle affirmation, or review 'readiness' for change
Diet, exercise, self-care, employment
Safety—physical, emotional, cultural
Avoiding infections—listeria, toxoplasmosis, STIs, etc

DECISION POINT 2: 16 to 20 weeks

1 Information sharing

Decisions made since last visit—re screening, care plan, lifestyle changes
Results from screening or diagnostic tests, and implications discussed
Normal physiological changes (see Explanations)
Expectations re first fetal movements—timing range, initial irregularity
Options re employment and parental leave

2 Assessment and screening

Assess woman's wellbeing—discuss options re physiological changes
Screen:

- Urinalysis (glucose and protein), blood pressure
- Discuss option of fetal anomaly scan (18–20 weeks) timing, expectations, limitations, information, diagnostic and decision options
- Family violence (routine)

Assess baby's wellbeing

- size (fundal height—see Explanations)
- growth, movements, heart rate (Doppler)

3 Active decision-making

Scan (decision may be made after visit, form given if requested, self-booked)
Antenatal education decision made—classes booked if desired
Plans re infant feeding

4 Health promotion and education

Breastfeeding promoted—information, resources and support options
Self-care and lifestyle—diet, exercise, support re healthy changes, employment issues
Pelvic floor exercises

DECISION POINT 3: 20 to 24 weeks

1 Information sharing
Normal physiological changes (see Explanations)
Relationship issues—changes, support, involvement of partner/friends
Results from and experience of anomaly scan (if done)

2 Assessment and screening
Assess woman's wellbeing—discuss options re physiological changes
Screen—urinalysis (glucose and protein), blood pressure
Assess baby's wellbeing—size (fundal height), growth, movements, heart rate (Doppler)

3 Active decision-making
Place for the birth (if decided)—if hospital: booking forms and arrange visit
Any follow-up from anomaly scan indicated

4 Health promotion and education
Discussion re woman's own wellbeing and preparation for parenthood
Diet, exercise, support, stress minimisation, employment—as relevant/appropriate

DECISION POINT 4: 24 to 28 weeks

1 Information sharing
Signs of premature labour and when to call midwife
Signs of baby's wellbeing—expectations re movements (see Explanations)
Normal physiological changes (see Explanations)
Discuss emotional and social situation—feelings re pregnancy, financial changes, career/employment implications and plans (timing of work reduction/finishing)

2 Assessment and screening
Assess woman's wellbeing—discuss options re physiological changes
Screen:
- Urinalysis (glucose and protein), blood pressure
- Routine blood screen (option discussed)—CBC, blood group antibodies
- Review risk markers for gestational diabetes—discuss option of screening, information, limitations, expectations, diagnostic and decision options
- Family violence (routine)

Assess baby's wellbeing—size (fundal height), growth, movements, heart rate (Pinard/Doppler)

3 Active decision-making
Continue developing care plan—antenatal education start date, if appropriate, or alternative arrangements (books/videos, resources, support)
Preparations for change of life with new baby:
- emotional, social, practical
- car seat (bought or booked for hire), clothing and bedding

4 Health promotion and education
Postnatal sleeping arrangements—appropriate bed sharing, and risk markers re SIDS
Self-care and support networks (check knowledge re community groups and agencies)

DECISION POINT 5: 30 to 32 weeks

1 Information sharing
Check that the woman, and her family, is comfortable with planned place for birth and birth plan discussed, including expectations of midwifery care
Discuss options for working with pain in labour (see Chs 22 and 23)
Discuss signs of pre-eclampsia, and when to contact midwife
Discuss family's expectations and preparations for life with a new baby
Discuss postnatal care plan—re vitamin K and newborn metabolic screen test

2 Assessment and screening
Assess woman's wellbeing—discuss options re physiological changes (see Explanations)
Screen—urinalysis (glucose and protein), blood pressure
Assess baby's wellbeing—size (fundal height), growth, movements, heart rate

3 Active decision-making
Postnatal care and support—community groups and agencies (Well Child services)
Plans for placenta
Plans for working with pain in labour
Plans for feeding baby—check knowledge, resources, support

4 Health promotion and education
Childcare arrangements (if applicable) for end of pregnancy, labour, early postnatal days
Support and resources for postnatal days
Self-care:
- review employment arrangements, emotional and social situation
- review woman's feelings about birth and parenting—support options

DECISION POINT 6: 34 to 36 weeks

1 Information sharing

Discuss signs of labour, expectations, support, beliefs and feelings about labour

If hospital birth planned:

- check that all know where it is, check cultural needs
- discuss policies which may affect the woman's choices

If home birth planned—discuss appropriate environment and gear needed

Physiological changes and expectations (see Explanations)

2 Assessment and screening

Assess woman's wellbeing—discuss options re physiological changes

Screen:

- urinalysis (glucose and protein), blood pressure
- consider blood screen of Hb (if woman taking iron or symptomatic) and Rh antibody screen (if woman Rh negative)

Assess baby's wellbeing:

- size (fundal height), growth, movements, heart rate
- presentation—if not cephalic, discuss referral options (36 weeks)

3 Active decision-making

Birth plans identified

Preparation of other child(ren) for changes with new baby

Practical arrangements made for early postnatal days—meals in freezer or support as appropriate

Plans made for labour:

- support people, child care, resources (food, comfort measures)
- home birth gear together, or bag packed for hospital

4 Health promotion and education

Self-care—diet, exercise and lifestyle changes for this stage of pregnancy

Review emotional and social situation, review employment plans

DECISION POINT 7: 38 to 40 weeks

1 Information sharing

Review signs of labour, expectations, support, beliefs and feelings about labour

Recognising labour, and when and how to contact midwife

Review woman's knowledge of risk markers:

- fresh vaginal blood loss
- reduced fetal movements
- signs of pre-eclampsia
- ruptured membranes (without contractions, meconium stained liquor)

Physiological changes and expectations of timing of labour (discuss normal range)

Review blood results (if appropriate)

2 Assessment and screening

Assess woman's wellbeing—discuss options re physiological changes (see Explanations)

Screen:

- urinalysis (glucose and protein), blood pressure
- family violence, antenatal depression

Assess baby's wellbeing:

- size (fundal height), growth, movements, heart rate
- presentation, descent in the woman's pelvis, liquor volume

Review EDD—check and confirm expected dates

3 Active decision-making

Support networks arranged for labour, birth and postnatal

Confirm postnatal care plan re:

- vitamin K
- newborn metabolic screening test

4 Health promotion and education

Review self-care:

- adjustments to life without paid work (if relevant)
- support, opportunities
- diet, exercise, sleep, emotions, self-esteem

Review partner and/or family readiness, support, resources, arrangements for time off work

Discuss first breastfeed and importance of skin-to-skin contact for some women

DECISION POINT 8: 41 to 42 weeks

1 Information sharing

Discuss wellbeing of woman and baby, family support
Discuss issues and options re 'post dates' (see Ch 33)
Discuss option of vaginal exam and membrane sweep/cervical massage
Discuss option of obstetric referral and timing and process of induction of labour

2 Assessment and screening

Assess woman's wellbeing:
- discuss options re physiological changes (see Explanations)
- screen—urinalysis (glucose and protein), blood pressure

Assess baby's wellbeing:
- size (fundal height), growth, movements, heart rate
- presentation, descent in the woman's pelvis, liquor volume
- screen—discuss option of CTG or scan, to assess baby's wellbeing if indicated
- discuss risk markers—reduced fetal movements, low liquor volume

3 Active decision-making

Set plan re assessment of baby and woman's wellbeing—referral for consultation

4 Health promotion and education

Additional care and support options
Check support networks and resources

Explanatory sections

Estimated due date

Dating in history and Naegele's rule

Women have been calculating their menstrual cycles and pregnancies using lunar months for 'tens of thousands of years' (Frye 1998). However, the method based on a set number of days following the last menstrual period (LMP) was proposed by Professor Boerhaave in 1709 and popularised by, and subsequently attributed to, Dr Naegele (Baskett & Naegele 2000). Boerhaave proposed that gestation be calculated 'by counting one week after the last period and by reckoning the nine months of gestation from that time' (cited in Baskett & Naegele 2000, p 1433). Neither man specified whether it is the first or last day of the LMP that is the start point.

The first day of LMP is currently taken as the starting point, to which nine months and seven days are added. The inherent variability in the length of different months has been negated with the conversion of the formula into pregnancy calculators as LMP plus 280 days. This rule has *all* women ovulating at the same time within a cycle, having a cycle of the same length (which is set at 28 days), and taking the same length of time to gestate. Some individual variation is allowed for in this formula by altering the estimated due date (EDD) by the regular cycle length. This is recommended by the British Confidential Enquiry into Stillbirths and Death in Infancy (CESDI), with 'EDD = LMP + 280 days + length of cycle – 28 days' (cited in Stenhouse et al 2003). This formula is in contrast to dating by ultrasound scanning, which uses universally standardised measurements for dating. Contradicting such a notion, midwives' knowledge and common sense support inherent differences in human size and gestation. Research has also variously identified maternal height, ethnicity, parity and age as potentially influential in the length of gestation, although not with predictive reliability (Rosser 2000).

While it is estimated that only five per cent of women give birth on their EDD (Frye 1998), the date has taken on new significance in the contemporary context, with decisions regarding medical screening and interventions demanding 'exact' or standardised dating. Several authors have argued that ultrasound dating is more 'accurate' and that calculating EDD from women's LMP should be abandoned (e.g. Tunon et al 1996).

Standardisation with medicalisation

In reviewing the literature on the topic, Olsen and Clausen (1997) found the 280-day 'rule' to be consistently three days too short—that is, the most common gestation length is 283 days. They also report ultrasound dating to be consistently two days too long. They challenged the accuracy of both the Cochrane Review and the MIDIRS (Midwives Information and Resource Service) 'informed choice' leaflet, which both accept the contention that ultrasound scans provide a more accurate EDD than the use of a calendar and LMP (Olsen & Clausen 1997). The 'improved' accuracy relates primarily to the reduced 'post-dates' induction of labour rates when scan dating is used. Menticoglou and Hall (2002) have convincingly challenged the evidence used for the guideline on routine post-dates induction of labour (IOL) at 41 weeks. Altering Naegele's rule to 283 days, rather than discarding it, will achieve the same outcome, and is supported by others (Nguyen et al 1999; Savitz et al 2002; Smith 2001; Yang et al 2002).

Scan dating and research

Recently, evidence has been published which exposes systematic errors in scan dating that have the potential to lead to compromised care and outcomes (Källén 2004; Nakling & Backe 2002; Nguyen et al 2000). Källén (2002) reviewed 571,617 women's records at the Swedish Medical Birth Registry and found male babies to be judged on average to be 1.5 days 'older' than females at 16–18 weeks, on the basis of their slightly bigger comparative size. She reports that 'similarly, the fetuses of young women, multiparous women, smokers and women with low educational level were at increased risk of being smaller than expected at ultrasound examination in early pregnancy' (Källén 2002, p 558). Källén (2004) (reviewing

over 700,000 Swedish women) and Nguyen et al (2000) (reviewing 16,469 Danish women) found increased adverse outcomes when scan dating re-dates women's pregnancies by more than seven days, with significantly more stillbirths, pre-term and intrauterine growth retarded (IUGR) babies and perinatal deaths. This contradicts earlier reports by others who suggest that there are no adverse effects of scan dating (Tunon et al 1999). Rather than being more 'accurate', it is possible that 'the erroneous adjusted dates may be due to incorrect measurements or systematic bias (e.g. gender), but they are also likely to reflect early growth restriction' (Källén 2002, p 558). Although first trimester scan dating may be less affected by such differences, variability still occurs, and evidence regarding its 'accuracy' and the impact on clinical outcomes is lacking to date.

Pregnancy calculators

Pregnancy calculators are the most common tool for midwives identifying women's EDD. They are subject to both intra- and inter-calculator variability (Ross 2003), and so should be checked against each other and the most reliable chosen. New computer software is available free from the Gestation Network website (www.gestation.net/main.htm), although it does not allow for variance in cycle length, and works on the 280-day rule.

Midwifery practice

When working with women to identify their EDD, midwives should:

- identify the first day of LMP, if known
- ask if it was a normal period in timing, length and volume
- ask about the normal cycle—length and regularity
- ask about contraceptive use prior to conception
- use Naegele's rule or the pregnancy calculator to get an EDD (consider using 283 days)
- discuss variability and expectations regarding the actual timing of the birth
- review the signs, symptoms and experiences and compare with expected dating
- ask if they can palpate the woman's abdomen to compare uterine size with dates
- consider the option of a scan if the woman has no idea of LMP or timing of conception, and date-specific screening is to be undertaken; or if her uterine size is significantly mismatched with estimated EDD on palpation.

Routine antenatal blood screening

The use of blood tests as a screening tool is routine in antenatal care, although there is variation in the tests included or offered between states and countries (Hunt & Lumley 2002; Three Centres Consensus Guidelines on Antenatal Care Project 2001; Ministry of Health 2002). Currently, both Australia and New Zealand include the following tests as routine:

- blood group and rhesus factor
- rhesus antibodies

Critical thinking exercise

Jenny is pregnant. She is not sure when her baby is due. The first day of her LMP was 15 February 2005. She has a regular cycle, which lasts five days, every 30 days.

1. Calculate the EDD using three different pregnancy calculators.
2. Calculate the EDD manually using Naegele's rule.
3. Calculate the EDD using the computer software mentioned above.
4. Compare the EDDs from each method, and consider the implications of any potential variation.
5. What information would you share with Jenny regarding her EDD?

- full blood count
- syphilis
- hepatitis B
- rubella antibodies.

For detailed discussion on the conditions being screened for, see Boyle (1995) and Frye (1998). The issues of the nature of screening itself, informed choice and the politics regarding antenatal screening are addressed in Ch 32 of this book; and elsewhere, for example, Broclain et al (2003), Grimes & Schulz (2002), National Health Committee (2003), Oats (2000), Searle (1997) and Strong (2000).

Debate continues over the appropriateness of universal versus risk-based, and opt-in versus opt-out, screening for the following conditions:

- human immunodeficiency virus (HIV)
- hepatitis C (HCV)
- fetal aneuploidy (focused on neural tube defects and Down syndrome)
- gestational diabetes
- haemoglobinopathies (e.g. sickle cell and thalassaemia)
- tuberculosis (TB).

See Chapter 32 for discussion on these conditions and contemporary screening options offered. Gates (2004) addresses some of the political issues involved, as do Parker et al (2002) and Santalahti et al (1998).

Iron levels, measures and supplementation

In the context of routine antenatal care, the midwife uses the results from the complete blood count as part of the process of screening for iron deficiency anaemia. Anaemia is potentially a significant threat to the health and wellbeing of women and their babies. Physiological changes induced by pregnancy may expose underlying anaemia, or it may develop during pregnancy (Coggins 2001). Haemoglobin levels are used as a primary measure of anaemia, as 'about 70% of iron in the body is in haemoglobin' (Jordan 2002, p 268). Serum ferritin levels have been used as markers of anaemia as an adjunct to haemoglobin in recent times, although currently there are no reference ranges available that are specific to

Critical thinking exercise

Mai is 14 weeks pregnant with her first child when she first seeks maternity care. She is 24 years old, and a recent immigrant of West African ethnic origin. She and her partner Ahut are well educated and have good English-language skills.

1. What tests would be carried out if you ordered 'routine' initial blood screening for Mai?
2. Describe what is being tested, and its potential significance.
3. What additional blood screening tests might you consider discussing with Mai and Ahut, and what information would inform this discussion?
4. What written information is available for them in your region, on either 'routine' or 'additional' blood tests?

pregnancy. Parameters for normal physiological changes in serum ferritin and their clinical significance are yet to be established (Chandler 2000). There is also ongoing debate over the appropriate reference ranges for haemoglobin during pregnancy; and the boundaries between physiological changes and pathological changes requiring intervention in the form of supplementation are not well defined or understood (Baston 2002; Bluck et al 1990; Coggins 2001; Mohamed 2004). No single measure should be taken in isolation, or without reference to the past and present context of the individual woman.

Potential signs and symptoms of anaemia include tiredness, dizziness, tinnitus, feeling cold, dry or itchy skin, infections, palpitations or breathlessness, tachycardia, headaches, pallor, glossitis and koilonychias (Coggins 2001; Jordan 2002). It is important to note that many of these signs and symptoms could also be those of other conditions, so a definitive diagnosis of anaemia by means of further blood tests is required.

For further discussion on anaemia and related issues, see Chapter 32 for screening and guidelines, Chapter 33 for risk factors and effects for women and their babies, Chapter 19 for details of dietary options and Chapter 29 for pharmacological options.

Routine blood pressure screening

Blood pressure measurement and monitoring is a core feature of routine antenatal care. Blood pressure (BP) may be defined as 'the force exerted against the arterial walls when the heart pumps', and 'the blood pressure reading is a reflection of how hard the heart must work to adequately circulate the blood' (Frye 1998, p 420). Taking blood pressure is essentially a screening test for hypertension, and careful measurement is important as the technique used can significantly affect the accuracy of the reading. Blood pressure should be taken using a regularly calibrated sphygmomanometer and an appropriate-sized cuff, and the woman should be seated and rested, with her elbow at heart level and her arm straight. The cuff should be inflated to 20 mmHg above the systolic BP palpated at the brachial artery, and deflated slowly (about 2 mmHg/second). Both the systolic (Korotkoff I) and diastolic (Korotkoff V) pressures should be recorded. See the guidelines in the Australasian Society for the Study of Hypertension in Pregnancy (ASSHP) Consensus Statement (Brown et al 2000) or Taylor (2004) for detailed instructions. The ASSHP (Brown et al 2000) recommend that BP be taken on both arms at the first assessment, with significant difference in readings being an indication for specialist consultation.

Sustained elevated blood pressure beyond normal values is referred to as hypertension, which presents some risk to the wellbeing of women and their babies. The ASSHP (Brown et al 2000) defines hypertension in pregnancy as a systolic BP of ≥ 140 mmHg and/or a diastolic BP (KV) of ≥ 90 mmHg (p 2). The group identifies four classifications of hypertension, namely gestational hypertension (GH), pre-eclampsia (pre-eclampsia), chronic hypertension (CH) and pre-eclampsia superimposed on CH (Brown et al 2000). Pre-eclampsia, if unrecognised, may develop into eclampsia, which is a major cause of maternal and perinatal morbidity and mortality (NICE 2003). Pre-eclampsia is a multi-system disorder which is unique to pregnancy, and remains a condition that is difficult to predict, prevent or treat (see discussion in Ch 33). It affects between two and ten per cent of childbearing women, with the incidence varying with 'the population studied and the criteria used to diagnose the disorder' (NICE 2003, p 99). The diagnostic criteria for P-E have changed in recent years, with the inclusion of a urine protein/creatinine ratio and the exclusion of oedema. The ASSHP criteria are as follows:

> Hypertension arising after 20 weeks gestation and the new onset after 20 weeks gestation of one or more of:
> - Proteinuria— ≥ 300 mg/24h or spot urine protein/creatinine ratio ≥ 30 mg/mmol
> - Renal insufficiency—serum/plasma creatinine ≥ 0.09 mmol/L or oligouria
> - Liver disease—raised serum transaminases and/or severe epigastric/right upper quadrant pain
> - Neurological problems—convulsions (eclampsia); hyperreflexia with clonus; severe headaches with hyperreflexia; persistent visual disturbances (scotomata)
> - Haematological disturbances—thrombocytopenia; disseminated intravascular coagulation; haemolysis
> - Fetal growth restriction (ASSHP 2000, p 4).

Numerous risk markers have been identified over the years, although none reliably predict who will develop pre-eclampsia, or when or how unwell they will become. The risk markers currently associated with pre-eclampsia include women who are having their first baby (or first baby with a different partner), are over forty years old, have a family history of pre-eclampsia, have a personal history of pre-eclampsia, have a body mass index (BMI) at or above 35, have a multiple pregnancy or have pre-existing vascular disease (e.g. hypertension or diabetes) (Brown et al 2000; NICE 2003). In the contemporary Australasian context, this group of women may well represent the majority of the total childbearing population, yet only a fraction of the actual total will develop

Critical thinking exercise

1. Take the BP of a fellow student, using two different types of sphygmomanometer (and also trying different cuff sizes), and compare the readings.
2. Using the same sphygmomanometer, compare the BP readings of the same woman, with her lying down and sitting up.
3. What are the implications of any differences found, for the accurate measurement of BP in the antenatal care of pregnant women?

pre-eclampsia, and the majority of women in every one of the above groups will remain well and go on to give birth to a healthy baby.

While we cannot predict or prevent the development of pre-eclampsia, current routine antenatal BP screening does help identify some women who may be showing signs or experiencing symptoms that signal the need for closer monitoring or diagnostic testing, which may facilitate detection of pre-eclampsia prior to it causing morbidity or mortality (Enkin et al 2000). The distinction between isolated hypertension (be it chronic or gestational) and pre-eclampsia is an important one, with many more women having hypertension than those who go on to develop pre-eclampsia. 'Chronic hypertension and mild or moderate pregnancy-induced hypertension carry little risk to the mother or the fetus, unless severe hypertension, pre-eclampsia, or eclampsia ensue' (Enkin et al 2000, p 123).

Midwives have an important role in sharing information with women about the symptoms of pre-eclampsia, such as severe headaches, visual disturbances (not caused by postural hypotension), epigastric pain (not heartburn), or sudden marked swelling of the face, hands and feet. This information needs to be presented in a way that enables women to recognise and respond to symptoms appropriately, rather than frightening them into a hypersensitive state of anxiety. It is important that midwives and women maintain a sense of perspective regarding the actual incidence of this condition, as it is rare, affecting less than 5% of the childbearing population.

Routine urine screening

Urine screening is offered routinely throughout pregnancy, although there is variation in both the method and markers used, and no consensus about what constitutes best practice. The aim of urine screening is the detection of proteinuria (as a marker for pre-eclampsia and urinary tract infection) and glycosuria (as a marker for gestational diabetes). Some practitioners also screen for asymptomatic bacteriuria early in pregnancy, using a microscopy and culture test. The dipstick urinalysis used routinely at every antenatal visit is easy to use, gives immediate results that are assessed by the midwife, and is markedly cheaper than laboratory microscopy and culture. Unfortunately, it has consistently been found to have poor sensitivity and predictive value for all of the variables it is used to test (see reviews by TCCGACP 2001, NICE 2003, Smaill 2004 and Waugh et al 2004).

Screening for proteinuria as a marker for pre-eclampsia

It is routine practice for midwives to ask women to pass urine at every antenatal visit, and to use a dipstick to assess the level of protein present, as part of the diagnosis of pre-eclampsia. There is mounting evidence, however, that calls into question the accuracy of this test. A recent review of dipstick detection of proteinuria by Waugh et al. (2004) concluded that 'significant proteinuria, with point-of-care urine dipstick analysis, cannot be accurately detected or excluded at the 1+ threshold and is not recommended for diagnosing pre-eclampsia. Further research is necessary to determine the prediction of proteinuria using higher dipstick thresholds' (p 776). It is currently recommended that a dipstick measure of proteinuria be requested from women with hypertension. The ASSHP states that 'dipstick testing for proteinuria is a screening test only, with very high false positive rates' (Brown et al 2000, p 4). They recommend that 'all hypertensive pregnant women with any level of positive dipstick proteinuria should be . . . confirmed with either: a 24-hour urine collection ≥ 300 mg/day [an abnormal level] or a spot urine protein/creatinine ratio ≥ 30 mg protein/mmol creatinine [an abnormal level]. Urinary tract infection should also be excluded'. Clearly, a single mid-stream urine (MSU) sample for the protein/creatinine ratio and culture is likely to be chosen by women, over the 24-hour urine collection option. A protein/creatinine dipstick measure is currently being developed, although assessing its sensitivity and predictive accuracy is expected to take some time (Waugh et al 2004).

Screening for asymptomatic bacteriuria

Proteinuria on dipstick is also used to screen for asymptomatic bacteriuria in routine antenatal care, although some practitioners use dipsticks with additional measures for blood, leucocytes and nitrites for this purpose. The aim of screening is to identify those with asymptomatic bacteriuria and to offer (prophylactic) antibiotic treatment to reduce the incidence of pyelonephritis. Asymptomatic bacteriuria is defined as 'the persistent bacterial colonisation of the urinary tract in the absence of specific symptoms and is usually diagnosed as > 100,000 bacteria/mL on a single voided midstream urine' (TCCGACP 2001, p 24). Asymptomatic bacteriuria is reported to occur in between two and ten per cent of women, with significant variation between countries and communities, and greater incidence in women of low socio-economic status (SES) (NICE 2003). It is 'generally benign' for those who are otherwise well and not pregnant (Smaill 2004). It is the risk of these women developing pyelonephritis, and its association with preterm labour, that makes it of interest during pregnancy. The physiological changes in the urinary tract during pregnancy make acute pyelonephritis much more likely. In the Cochrane Review, Smaill (2004) states, in the background section of the report, that '20–30% of pregnant women will develop pyelonephritis', but the evidence

reviewed identified an 'overall incidence of pyelonephritis in the untreated group [of] 19%, but [this] ranged from 0% to 29%' (p 4).

Asymptomatic bacteriuria is also associated with a two-fold increase in preterm labour, although a causal link is yet to be proved, as confounding factors such low SES potentially influence outcomes (Ovalle & Levancini 2001). Smaill (2004) identifies the 'number needed to treat' (NNT) ratio as 7:1, resulting in an approximately '75% reduction in the incidence of pyelonephritis' (p 4). To date, none of the studies identified in any of the reviews cited above have addressed the issues relating to antibiotics themselves, such as 'allergic reactions, yeast infections, gastrointestinal side-effects and the development of bacterial resistance' (Smaill 2004). Smaill (2004) considers it 'unlikely that the expected side effects from a short course of antibiotics would be of sufficient significance to warrant reconsideration of the recommendation to routinely treat asymptomatic bacteriuria' (p 4). Nor have the issues of the information and options given to, and choices made by, women been addressed in the research available on the topic.

Contemporary medical literature recommends routine screening in early pregnancy (NICE Guidelines 2003; Smaill 2004; TCCGACP 2001). The Australian guideline (Three Centres Consensus Guidelines on Antenatal Care Project 2001) suggests two options for screening women for asymptomatic bacteriuria:

- MSU and laboratory microscopy and culture
- MSU and dipstick test for blood, protein, nitrites and leucocytes, which is sent to the laboratory if there is a positive result in any of the four categories.

The British guidelines (NICE 2003) recommend that routine MSU culture be offered to all pregnant women. They suggest that the four-category dipstick option 'will detect 50% of women with asymptomatic bacteriuria', and consider that inadequate (p 80). Midwives need to provide information regarding the screening and treatment options available, including potential antibiotic risks and efficacy rates, in the context of the risks of women developing pyelonephritis, to facilitate active and informed decision-making by women.

Screening for glycosuria as a marker for gestational diabetes mellitus

Although glycosuria is screened for routinely at every antenatal visit currently, it is not considered to be the primary screening test for gestational diabetes mellitus (GDM). Its presence is interpreted as a potential sign of GDM. Blood glucose screening tests are offered for women with risk markers or symptoms of GDM (see Ch 32). Glycosuria is not an independent or reliable marker of GDM. Glycosuria can reflect a lowered renal threshold, which is a normal physiological change of pregnancy (Watson 1990). The only recent review published states that 'urine testing has low sensitivity and is a poor screening test for GDM' (NICE 2003, p 97).

There is much ongoing debate regarding routine antenatal screening for GDM. The New Zealand College of Midwives Consensus Statement (2003), the British NICE guidelines (2003) and Enkin et al (2000) all recommend against *routine* screening for GDM. These recommendations are generally referring to blood glucose screening tests. However, urine screening, in the form of dipstick glycosuria, is a poorer screening test than blood glucose and its usefulness in routine antenatal care is debatable.

Summary

The practice of routine screening (i.e. for *all* pregnant women) of urine for protein and glucose may be reviewed in the light of an increasing body of evidence which has found both screening tests to have poor sensitivity and predictive values (see references cited above). Currently, the Australian Three Centres Consensus Guidelines on Antenatal Care Project (2001) state that the 'use of dipstick measurement for routine screening of proteinuria in low risk pregnant women is not recommended' (p 49). The New Zealand College of Midwives (2003), the NICE guidelines (2003) and Enkin et al. (2000) recommend against routine urine testing as a screening test for gestational diabetes.

These tests may be maintained for women with risk markers or signs or symptoms of pre-eclampsia or diabetes, as an adjunct to other assessments, screening and diagnostic tests. It is important for midwives to be aware of the limitations of these tests, and understand that they cannot be relied upon in themselves. The whole clinical and personal context of each woman needs to be considered when screening options are discussed and care choices are made. See Chapters 32 and 33 for fuller discussion on risk markers, screening and response to pre-eclampsia and gestational diabetes. See Chapters 32 and 33 for details of the signs, symptoms and treatment options for urinary tract infection or pyelonephritis.

Palpation: hands-on learning, identification and assessment

Palpation, or examination by touch, is a process of the 'hands-on' identification and assessment of the position, growth and

Abdominal palpation. Reproduced with the permission of the New Zealand College of Midwives

Critical thinking exercise

Marama is a well woman who is 32 years old. She is 10 weeks pregnant with her fifth pregnancy, and has two children.

1. What urine screening tests would you consider offering Marama?
2. Is there any further information you might seek from Marama that might influence the kinds of tests you discuss and offer her?
3. What are you screening for with routine urine tests?
4. Could you discuss the purpose and reliability of urine screening tests and their results with Marama?

wellbeing of the baby. It is an integral part of every antenatal visit, and is an acquired and highly valued midwifery skill. Each midwife has her own style, with the whole process being more than the sum of the parts described here. The process involves the gathering of small pieces of information, using the senses of hearing, seeing and touching, to put together an invisible four-dimensional 'puzzle'. It is also a significant time for two-way sharing of information. It is important for the midwife to discuss her plans with the woman, to explain the reasons for doing the examination, and to acknowledge the limitations of palpation (see Enkin et al 2000). She must seek the woman's consent, leaving open the option for her to decline, and check out any personal and cultural safety issues surrounding this intimate and exposing experience. The midwife asks about and listens to the woman's experience of her baby's growth and the nature and pattern of movements, and listens to the baby's heartbeat. She looks at the size and shape of the woman's abdomen, and notes her responses to palpation and to the baby's movements. The midwife uses touch to estimate the size and position of the baby, and its response to contact and voice. She also assesses the fluid volume and may identify other unexpected findings such as uterine fibroids. Observation and 'hands-on' practice are the best way to learn the art and skill of effective palpation.

Context and preparation

The context within which the palpation occurs is a significant feature of the process. The comfort, privacy and safety of the physical environment are as important as meaningful communication between the midwife and the woman. The midwife should strive to ensure that the environment is appropriate, which will include a comfortable place on which the woman can lie down. This may be the floor (if in the woman's home), or a bed or sofa (couch), which is firm, wide and low enough to be used with comfort.

Equipment

The midwife should ensure that she has the necessary equipment for the palpation. This includes:

- Pinard stethoscope and (possibly) Doppler ultrasound, conductive gel, tissues
- watch with a second hand
- privacy/modesty sheet
- tape measure (if used).

Preparation

Prior to the palpation, the midwife should:

- have clean, warm hands (and short fingernails)
- affirm the woman's active role in the process
- caution her, if the palpation is occurring in later stages of pregnancy, about the possibility of hypotension while lying on her back
- ensure that the woman's privacy and modesty are protected and respected.

In preparation for the palpation, the woman should:

- be encouraged to empty her bladder
- lie down on her back, with her abdomen exposed or accessible for palpation
- be comfortable, with her head supported and perhaps her knees bent, with or without support under them.

During the palpation, the midwife should:

- take care not to focus exclusively on the woman's abdomen—maintain frequent verbal and eye contact
- tell the woman (and those with her) what she is doing/feeling for/finding
- encourage the woman to tell of any discomfort caused by palpating
- not palpate when the uterus is contracting—wait until it is relaxed
- guide the woman (include her partner, if she wishes) in palpating herself.

Techniques and methods

Palpation may be divided into five stages.

1 Initial visual assessment

Purpose: The purpose of this relatively brief stage in the process is to form an initial impression of the progress of the growing baby. It also provides an opportunity for discussion of the visible physiological changes; for example, she may have a linea nigra, increased hair growth or stretch marks.

Technique: Begin by establishing eye contact, once the woman is lying down. Ask her about her experiences of the baby's growth, movements and position as you look at her abdomen and begin the palpation. Check the size, shape and contours of the uterus, and consider these in relation to gestation, presentation and position. Match visible scars with your knowledge of her history. Note bruising or other signs of physical violence and, once she is upright again and if she is alone, ask about her experience and safety. Alternatively, follow up at another time, as appropriate.

2 Fundal assessment

Purpose: Fundal assessment identifies the uppermost part of the uterus and baby, from which the size and 'lie' of the baby are first distinguished, and initial information as to the 'presentation' is gained. The 'lie' of the baby is the position of the baby's spine relative to the woman's spine, and is described

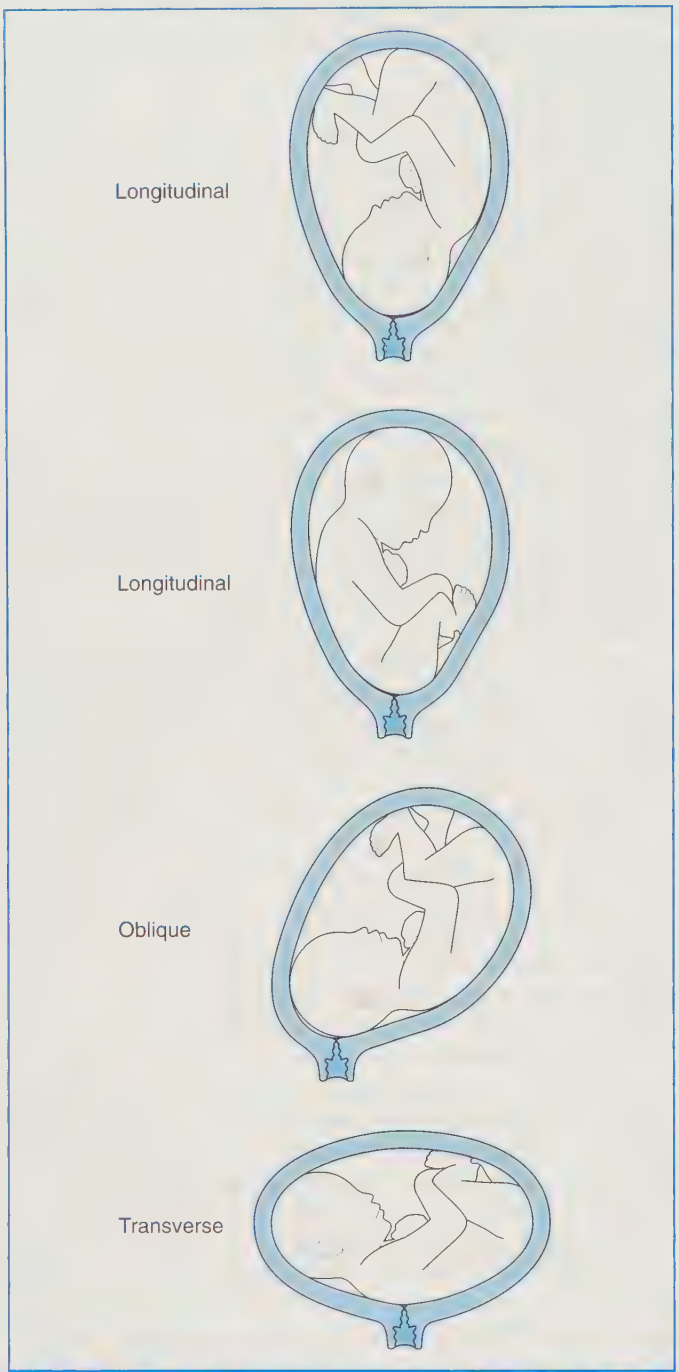

Figure 20.1 The lie of the baby (based on Henderson & Macdonald 2004)

as longitudinal, oblique or transverse (see Fig 20.1). The term 'presentation' distinguishes the part of the baby that is lying lowest in the uterus, with cephalic, breech or shoulder the most common (see Fig 20.2). Cephalic presentations can be divided into vertex, brow or face; and breech presentations divide into frank, complete, footling or incomplete. In the first two trimesters, the fundal height is the primary palpation measure used to assess fetal growth, as the baby's small size makes it

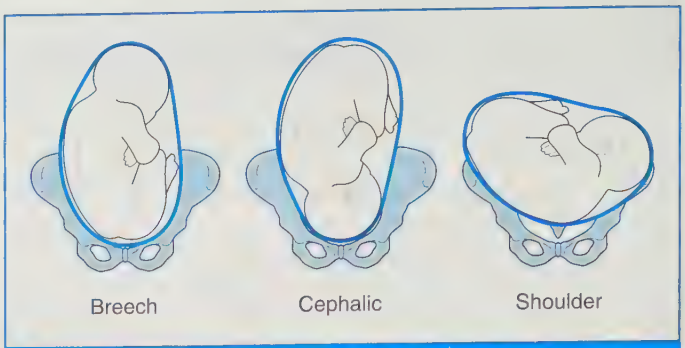

Figure 20.2 The presentation of the baby (based on Henderson & Macdonald 2004)

difficult to palpate, and its mobility makes identification of the lie or presentation irrelevant.

The second aspect of fundal assessment is the estimation of the size of the baby, which is compared with the expected size for the gestation. There are two methods used for comparing fundal height with gestation. Both have limitations, as fundal height varies with the position of the baby, the volume of liquor, and the size and shape of the woman. Assessing growth using fundal height, by landmark or measurement, is vulnerable to subjectivity and variability in technique between assessments and assessors. To date, neither method has been shown to be more effective than the other at detecting growth abnormalities at a level that improves outcomes (NICE 2003). Certainly there is a poor record of detecting IUGR babies with current traditional Western routine antenatal care (McGeown 2001). Babies that are small for gestational age (SGA) or IUGR are known to have high rates of morbidity and mortality (Enkin et al 2000), which presents an ongoing challenge for midwives. These two methods are described and discussed below.

- *'Landmark' guided fundal height assessment* is well-established practice, and is included in possibly every midwifery text. The 'landmarks' used are the symphysis pubis, umbilicus and xiphisternum (see Fig 20.3). The growth of the fundus is expected to approximate this pattern, although there is variability between women and babies, as described above. McGeown (2001) notes that 'there is no scientific foundation for the use of the umbilicus as a landmark to indicate a specific gestational age, i.e. umbilicus = 22/24/26 weeks gestation, dependent on which text one reads' (p 191). This does not mean that it is not a useful guide. It may be just that it has not been subject to scientific evaluation.
- *Measurement of the fundal height* is also common practice. Fundal height measurement is taken using the uppermost part of the baby as the starting point. A tape measure is held on the fundus, with the centimetre markers on the underside (to reduce bias), and laid on the skin along the longitudinal axis of the baby, to the symphysis pubis (Perinatal Institute 2004). The traditional 'standardised' guide is said to be for the fundal height measurement in centimetres (cm) to

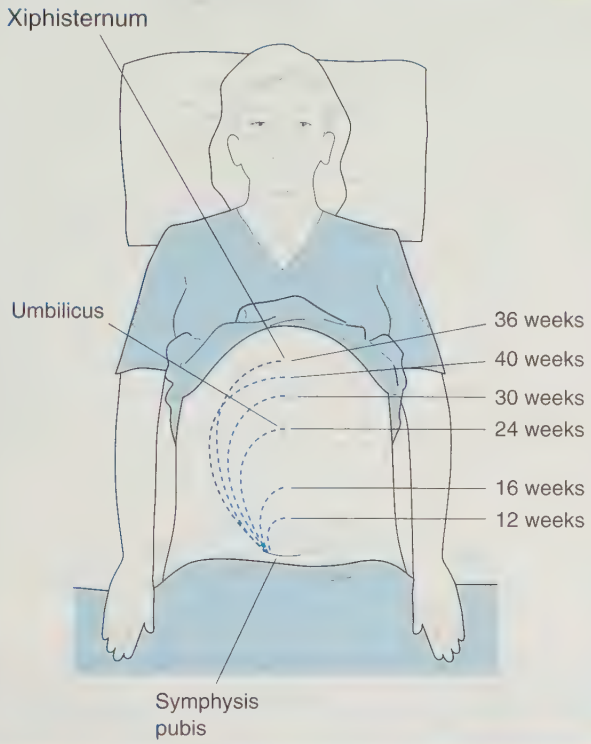

Figure 20.3 Landmarks of fundal height

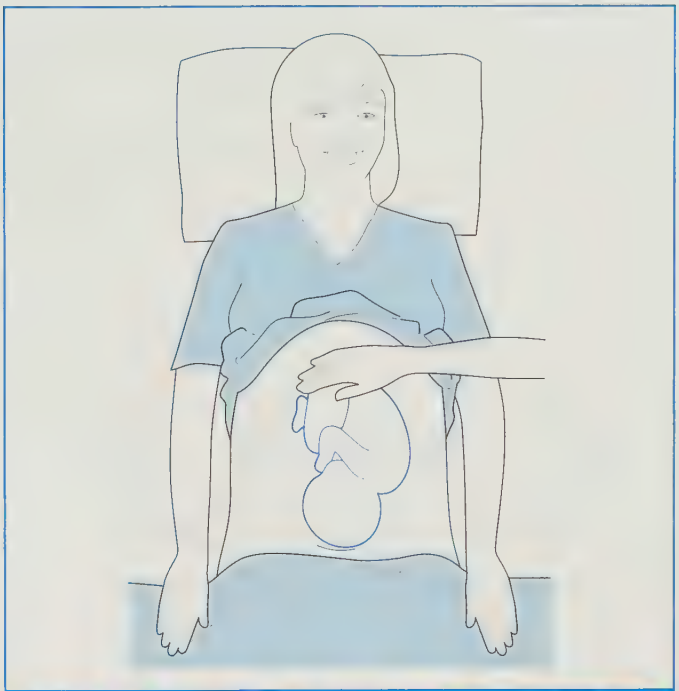

Figure 20.4 Identifying the fundal height

approximately equal the weeks of gestation, after 24 weeks. For example, a woman who is 34 weeks would be expected to have a fundal height measurement of approximately 34 cm. The 'customised growth charts' recently developed in England by the West Midlands Perinatal Institute (Gardosi et al 2000) calculate an optimal birth weight range adjusted for 'the physiological variables of maternal height, weight in early pregnancy, parity, ethnic group and by excluding known pathological variables such as smoking' (McGeown 2001). The software is available free from the Perinatal Institute website (www.wmpi.net), and includes a New Zealand version. At the time of writing, there is no Australian version. The charts may facilitate better detection of SGA/IUGR babies. With limited data to date, improved outcomes have not yet been demonstrated. The charts may, alternatively, further medicalise antenatal care without improving outcomes. They are 'customised' to include four potentially influential factors, but cannot be 'individualised' to include many other potential influences. Conscientious midwifery care provided within the midwifery model and context of continuity, arguably has the potential to improve outcomes, but it also lacks current data.

Technique: First, find the fundus by working from the woman's chest towards her pelvis, using your finger pads (not tips) pressing firmly enough to feel the increased resistance of the uterus relative to the other abdominal organs. The pressure required varies between women, with those having tight abdominal muscles or significant fat needing firmer pressure, but not so much as to cause pain (see Fig 20.4).

Once the fundus is found, cup your hand around it to define the shape and overall size of the uterus and the baby. The shape and height of the uterus help with identification of the lie of the baby. From approximately 28 weeks gestation, it is usually possible to identify the presentation of the baby by using the fingers, palm and heel of your cupped hand, or fingers and thumb extended, to identify which part of the baby is in the upper part of the uterus. You may use both hands, with one on either side of the part of the baby's body, to help with identification. The head feels hard and round, and is ballottable. The buttock may be firm in earlier gestations, but is never ballottable, as it is the extension of the torso/back.

Possible causes of discrepancies between the expected fundal height and gestation include:

- large or small baby
- multiple pregnancy
- molar pregnancy
- poly/oligohydramnios
- errors in gestational age estimation
- oblique or transverse lie.

3 Lateral assessment

Purpose: Lateral assessment involves palpation of the central part of the uterus. In the third trimester, it facilitates confirmation of the lie and presentation, and identifies the 'position' of the baby. The 'position' refers to the combination of the lie and presentation with the orientation of the baby—be it anterior, lateral or posterior. While the terminology used to define the baby's 'position' describes the position of the lowest

part of the baby (the denominator) in relation to points on the woman's pelvis, it is primarily assessed by the location of the baby's back on palpation. Although there are more than 36 possible positions (see Frye 1998), in practice only the positions relating to the most common cephalic and breech presentations are used in the context of antenatal palpation (see Fig 20.5). Other more unusual positions are generally described only by lie and presentation.

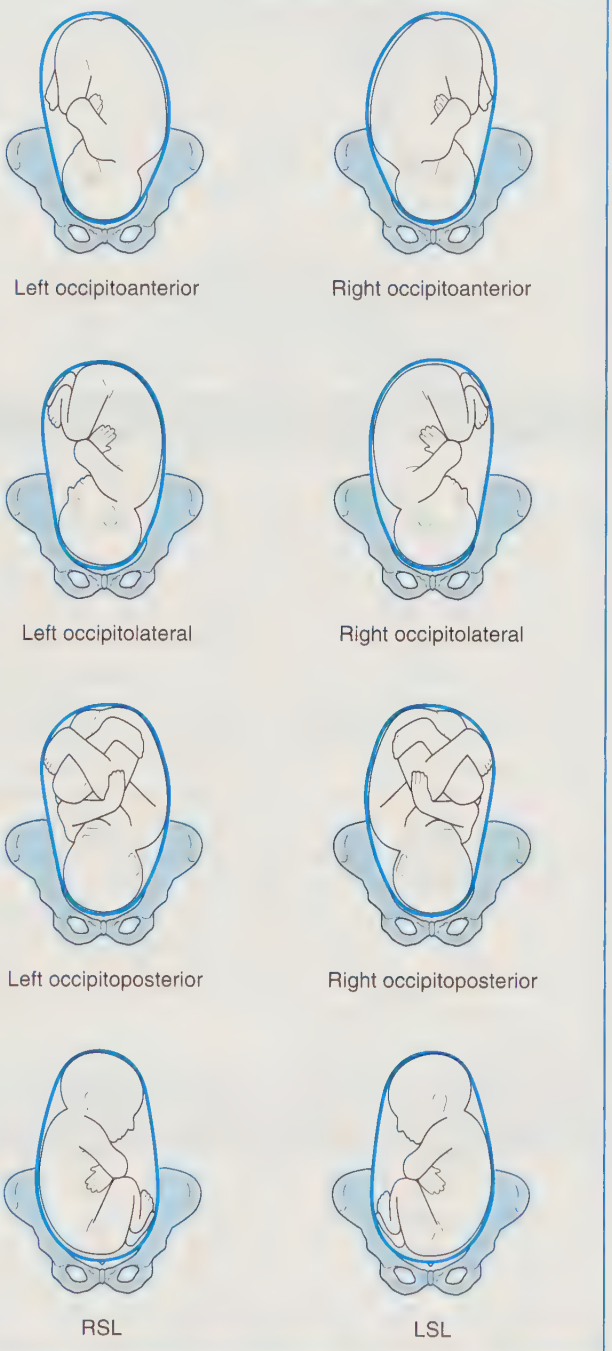

Figure 20.5 The most common positions of the baby (based on Fraser & Cooper 2003)

Technique: There are two main techniques used for lateral palpation. The first involves 'walking' both hands across the woman's uterus and back again, using the pads of your fingers and keeping both hands close together, taking small 'steps' (see Fig 20.6). The second involves the use of one hand as an 'anchor' lying along the length of one side of the woman's uterus, while the other hand is used to examine the other side; then changing to use the other hand as 'anchor' (see Fig 20.7). Apply as much pressure as is needed to feel the baby, without causing discomfort to the woman—be aware of the possibility of causing discomfort and responsive to any signs of this. Effective communication will help both the woman and the midwife. Some women develop a sensitive spot, or experience generalised tenderness. It is worthwhile considering how important it is to gather detailed information at any one antenatal visit. For example, at 32 weeks it is not important to identify more detail than the presentation and which side the back is on. If the baby wakes and moves prior to your finding the presentation or position, it can be helpful to spread both of your hands over the woman's uterus and feel the site and nature of the movements.

The back feels firm and can be 'tracked' for most of the length of the uterus. The limbs are small and knobbly and more likely to move during the palpation. If the baby is lying longitudinally and you cannot feel the back initially, broaden your search, by bringing your hands to the woman's side closer to her back, as the baby's back may be tucked in closer to the woman's back, in a posterior position. If only the baby's limbs are palpable, the back will be in the opposite quadrant. For example, if limbs are felt in the right anterior area, the back

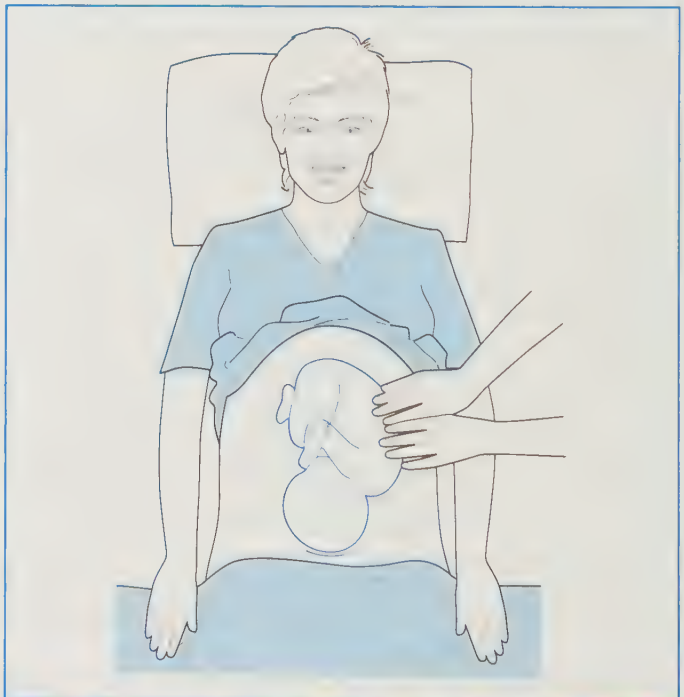

Figure 20.6 Lateral palpation: finding the back—'hand walking'

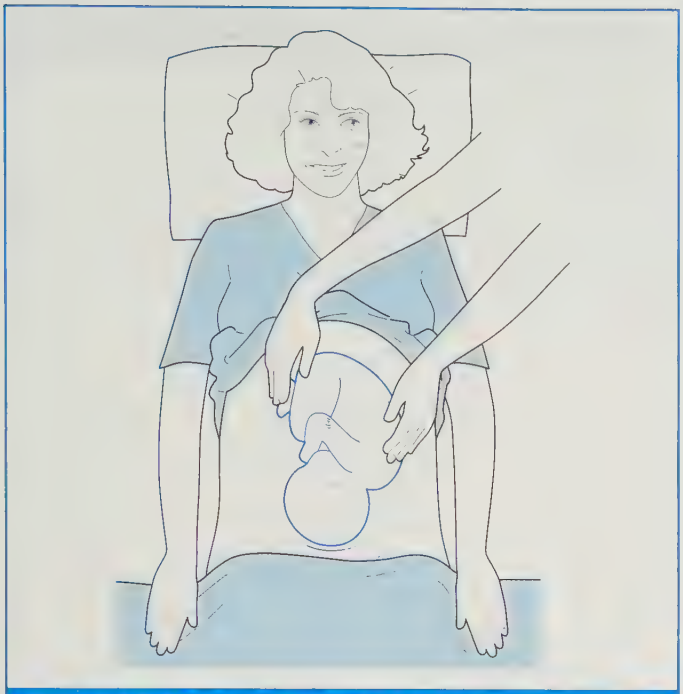

Figure 20.7 Lateral palpation: finding the back—'anchor hand'

Figure 20.8 Pelvic palpation—feeling for the head using two hands

will be in the left posterior position—check that area again to confirm this.

Once the position of the back is identified, cup the fundus once more, to confirm the presentation by assessing the relationship between the top fetal pole (mostly the buttock) and the back. Consider whether the top part moves when the back is pressed. It will move if it is the buttocks.

The amount of amniotic fluid or liquor can also be estimated during this part of the process. When palpating for the back, take note of how freely the baby is 'floating' in the uterine space. If there is reduced liquor (oligohydramnios), there will be minimal cushioning between the baby and the walls of the uterus. If there is excess liquor (polyhydramnios), the baby can be difficult to palpate, as it floats about (see Ch 33 for discussion on the detail and significance of these conditions).

4 Pelvic palpation

Purpose: Palpating the lower part of the woman's uterus, just above the pelvic bones, is the final stage of the process. It serves to identify the part of the baby lying lowest (the 'presenting part'), and should confirm your impressions from the fundal and lateral stages. It also enables the midwife to assess the descent of the presenting part into the pelvis. This may be more uncomfortable for the woman than the rest of the palpation, so use communication and sensitivity to manage this. If you work together, so that you press in with her out breath, it may be less uncomfortable for her.

Technique: There are two techniques used for pelvic palpation. The first involves using both hands, initially placed midway between the woman's side and centre line, with fingertips touching the pubic bone (see Fig 20.8). Let the woman know when you are about to begin, then move the tips of your fingers towards the woman's back just above the pubic bone, feeling for the outer boundaries of the presenting part. The second technique (known as Pawlik's manoeuvre) uses one hand, with the heel of your hand beginning resting on the pubic bone and the thumb and fingers extended to reach either side of the presenting part (see Fig 20.9). The head feels hard on both sides, while the buttock is irregular and soft on one or both sides. If the head is very well down in the pelvis, it may not be palpable, and the shoulder can feel like the buttocks, so it is worth re-checking the upper fetal pole.

Once the presenting part is identified, the next step is to assess its descent into the woman's pelvis. When palpating, you need also to assess the mobility of the presenting part (usually the head). If it is immobile, you need to assess the shape of the part that you can feel, considering whether it is broadening or narrowing from the top of the pubic bone. You are judging how much of the head has gone in, by how much of it is left above the pubic bone, and expressing it in fifths (see Fig 20.10). For example, if the head is immobile but broadening as you track its shape towards the torso, it may be one-fifth or two-fifths into the pelvis. It is defined as 'engaged' once the broadest part (the bi-parietal diameter) has descended below the pelvic rim. When documenting the descent, clearly note whether you are recording that which is palpable, or that which has descended (i.e. '2/5ths up/↑' or '3/5ths down/↓').

There are other measures of the baby's position, which note the angle, 'flexion' or 'attitude' of the head, but they are not usually significant in the context of antenatal care (see Frye 1998). Of potential significance for a primiparous woman is

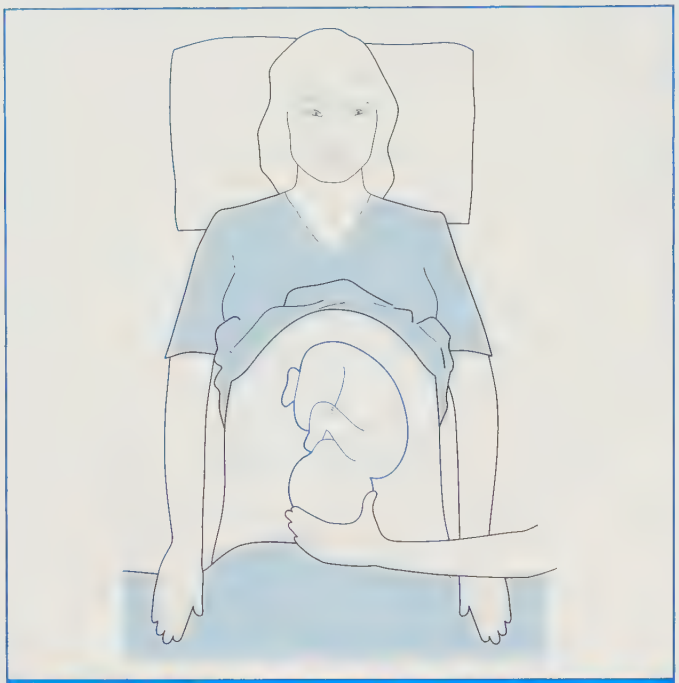

Figure 20.9 Pelvic palpation—ballotting the head with one hand

whether the baby's head is engaged by 40 weeks. If it is not, the possibility of cephalo-pelvic disproportion (CPD) should be considered and discussed with the woman. Non-engagement for a primiparous is not definitive of CPD and evidence to date shows that pelvic assessment or changed management, such as early induction of labour, does not improve outcomes (Enkin et al 2000).

5 Listening or auscultation

Purpose: Listening to the baby's heart rate (HR) serves to identify whether the baby is alive. The NICE guidelines (2003) suggest that it has 'no other clinical or predictive value' (p 107). This does not mean that it may not have personal or social value for pregnant women and their families, particularly those who have miscarried previously.

It appears that the option to use technology, in the form of portable Doppler ultrasound, has been taken up by the vast majority of pregnant women and midwives where it is available. Its ability to give instantaneous audible access to the baby's heartbeat from approximately 12 weeks gestation facilitates assessment of the wellbeing of babies, before their movements can be felt, and before the HR can be heard via a Pinard stethoscope (24–28 weeks).

Technique: Whether listening to the baby's heartbeat using a Pinard stethoscope or a Doppler, the basic technique is similar. Once the fundal height and/or position of the baby are identified, the instrument is placed on the woman's abdomen external to the baby's back. For example, if the baby is lying in a left occipitoanterior (LOA) position (see Fig 20.5), the Pinard or Doppler should be placed in the lower left quadrant of the woman's abdomen. It is an acquired skill to hear the baby's heartbeat with a Pinard, as the experience is closer to feeling vibrations than hearing sound, and quite different from the sound that the Doppler produces. See Cronk (2002) or Wickham (2002) for more detailed instructions on the use of the Pinard.

Reflective exercise

1. How would you feel about exposing your abdomen for a health professional to examine and touch?
2. What would help you feel more comfortable about undergoing such a procedure?
3. How might your understanding of this experience affect the way you palpate women?

Fetal movement

Women who are having their first baby may feel its first movements from around 18 weeks gestation, although some may not feel them until as late as 21 weeks. Women having their second or subsequent baby may feel movements as early as 15 or 16 weeks. These movements are often referred to as 'flutters' or 'quickening', and are variously described as feeling like butterflies or bubbles. They are initially felt fleetingly, intermittently and irregularly. By 22 to 24 weeks, most women will be feeling many movements per day, and these will reflect a fairly regular sleep–wake pattern.

Figure 20.10 Assessing descent of the baby into the woman's pelvis

From about 28 weeks, fetal movements (FMs) may be regarded as a fairly significant and reliable marker of a baby's wellbeing. It is in fact 'the oldest technique for assessing fetal wellbeing' (Christensen et al. 2003, p.118). Since the 1970s, when routine formalised charting of FMs was advocated, it has been the subject of contradictory research and much debate (see comprehensive literature reviews in Frøen 2004, and Fisher 1999). The focus has been on the efficacy of the routine counting and charting of FMs as a predictor of fetal compromise, in time to prevent a stillbirth. There is a key difference between requesting that all pregnant women complete FM charts all the time, and informing women of signs of compromise and recommending selective use of charts when they are concerned. Frøen (2004) identified 24 studies addressing the issue, all of which 'suggest that the increased vigilance to maternal perception of FMs caused by performing a study significantly reduced stillbirth rates' (p 23), in contrast to one randomised controlled trial (Grant et al. 1989, cited in Frøen 2004).

Frøen (2004) identified several key points from the research:

- Reduced FMs are predictive of perinatal mortality in women with high- or low-risk pregnancies.
- The use of FM charts was more effective than 'spontaneous' reporting.
- The format of the chart does not matter, as they are 'only tools for information'.
- Although the lower limits of 'normal' FMs have not been identified, if a woman experiences her baby moving ten times over a twelve-hour period, it is unlikely to be at risk (excluding other causes of intrauterine death (IUD) such as cord accidents).
- Women need to be given information regarding expectations of FMs and what to do if these are not met.
- Health professionals need to respond to women's concerns and provide appropriate assessment and follow-up.

Fisher's (1999) review of the literature notes that 'it is well documented that maternal perception of fetal activity varies greatly' (p 706). She identified issues of pattern and perception that may influence women's experience of FM, and reports research to date:

- More FM is experienced when a woman is 'recumbent'.
- There are conflicting reports regarding the influence of increased maternal weight, parity, anterior placental position, and anxiety or psychological issues.
- Women experience different types of movements variably, with greater perception when 'more than one fetal part was involved'.
- There is 'individuality in patterns of fetal activity/sleep'.
- The nature and pattern of movements change as pregnancy progresses.
- Caffeine increases activity.
- Cigarette smoking, sedatives, narcotics, methadone and alcohol suppress FM.
- 'Gross' FM are not affected by maternal exercise.
- Women eating meals does not affect FM, although 'glucose levels do . . . increase fetal breathing'.

Critical thinking exercise

Belinda is having her third baby and is 16 weeks pregnant.
Liz is 26 weeks into her first pregnancy.
Ella is 37 weeks pregnant with her first baby.

1. What would you ask each of these women about their babies' movements?
2. What differences would you expect in the frequency, pattern and nature of their babies' movements?
3. What factors might influence the women's understandings, expectations and experiences of the movements of their babies?

Clearly, the role of midwives as 'individualised information sharers' and listeners is critical in this context. Individualised care, planning and response are required, with each woman's personal and clinical situation and past experience being important issues for inclusion. If women have good knowledge of appropriate expectations of FM, and they 'tune in' to their baby's movement pattern and routine, they are likely to be better able to identify and communicate marked changes in FM that may be significant to their baby's wellbeing. Fetal movement counting is arguably not a screening 'test', but one tool in shared awareness, knowledge and understanding. Midwives are able to affirm women's experience and knowledge of their baby's wellbeing, most of the time.

Antenatal education

Antenatal education is an integral part of the formal process of antenatal care in New Zealand, Australia and the rest of the Western world. Defining its aims, scope, role and efficacy, however, is not straightforward, as programs vary with the beliefs, expectations and frameworks of those who provide it (Health Department Victoria 1990; Nolan & Hicks 1997). For a discussion of the history and politics of antenatal education see Oakley (1984), Nolan (1999, 2000) or Robertson (2001, 2004).

What is antenatal education?

The term 'antenatal education', when used generically, refers to information sharing between childbearing women (and their partners or friends) and caregivers, which is intended to facilitate informed choices and decision-making by the women about their pregnancy, childbirth and early postnatal period. It encompasses health promotion and preparation for childbirth and early parenting. As such, it is integral to midwifery-provided antenatal care. It is not usually used to describe the active or passive learning that comes from books, the Internet or other media, or which occurs between women and their friends or family.

During the past fifty years, however, 'antenatal education' has become the term used more specifically to describe group sessions run by various providers, which are additional to and

separate from antenatal care per se. These courses are typically run for women in their third trimester, on the basis of weekly classes for approximately two hours, often over five to eight weeks. Topics covered also vary considerably, but are likely to include at least some of the following aspects (Cole, undated personal correspondence; Ministry of Health 2002):

- *health promotion*—nutrition, exercise, relaxation and stress reduction; minimisation of alcohol, smoking and other 'hazardous substances'; 'pelvic awareness' and self-help for physiological changes of pregnancy
- *childbirth preparation*—signs and process of normal labour (expectations and coping skills); choices for labour and birth, such as place and pain management; unexpected outcomes, interventions (risks and appropriate use); role of support people and self-help strategies
- *parenting preparation*—establishing breastfeeding, care and safety of the newborn, appropriate clothing and equipment for babies, family and personal adjustments, support, expectations and coping strategies.

Involving the family in antenatal care. Reproduced with the permission of the New Zealand College of Midwives

Who provides antenatal education and who are its consumers?

At an organisational level, providers of antenatal education can be divided into three broad groups:

- those associated with care provision, such as those run by hospitals or home birth groups
- those run by community groups, such as Parents Centre or Marae based courses (New Zealand), or the Childbirth Education Association (Australia)
- those working as autonomous individuals offering private classes.

At the classroom level, the providers of antenatal education vary greatly, with trained childbirth educators, health workers and midwives being the main leaders or facilitators. There is also considerable variation in the level and nature of training within and between these groups. Many classes have additional input from other health professionals or special-interest consumer groups, such as physiotherapists, lactation consultants or La Leche League leaders, doctors, psychologists, or consumers who have recently given birth. Traditionally, these classes have been used by white, middle- and upper-SES heterosexual couples having their first child, and not by indigenous peoples, teenagers, low-SES or gay couples, single women or those from ethnic minorities or other socially marginalised groups (Health Department Victoria 1990; Lumley 1993).

What are the objectives of antenatal education, and how is it evaluated?

There is ongoing debate regarding the objectives, role, scope and potential impact of antenatal education. A commonly expressed aim is to build women's confidence in their ability to give birth and care for their babies (Nolan 1999). It may also serve to build personal and social relationships, and develop shared experiences. These aims are not always realised, however, and research has identified numerous discrepancies between theory and practice in antenatal education. These include differences between the experiences and perceptions of women and those of providers, in terms of needs, desired outcomes, and the role and efficacy of antenatal education overall (Health Department Victoria 1990; Lumley 1993; Nolan 1999; Weiner 2002).

Evaluation of antenatal education beyond internal 'satisfaction' surveys or informal feedback is rare and potentially difficult. 'Because of their complex, often disparate goals and ideologies, one cannot make general statements about the effects of antenatal classes as if they were a single entity' (Enkin et al 2000, p 24).

What is the role of the LMC midwife in antenatal education?

At the generic level, antenatal education is a core midwifery role. Throughout the antenatal period the midwife gets to know the woman and her supporters, and learns about her knowledge base and the beliefs, fears, plans and dreams she

Critical thinking exercise

Peter and Sue are in their mid-thirties, Summer is 18 years old, and Aaliya and Hamsa are Somali refugees with fairly good English-language skills. All are having their first babies.

1. What antenatal education options are available in your region for these families?
2. What is the format, content and aim of the classes which are offered?
3. Who runs them, at both organisational and classroom levels?
4. How might you work with these families in order to see if any of the classes available might meet their needs?

has about childbirth and caring for a baby. It is the midwife's role to share her belief in the woman's ability and in the process of childbirth. It is also her role to participate in health promotion and the preparation of the woman for birth and early parenting.

In relation to antenatal education classes, it is the midwife's role to inform women of the options available to them, and to discuss the various formats, content and underpinning philosophies of these. In order to do this, midwives should familiarise themselves with the local programs on offer. Midwives need to work with women for whom existing programs are inappropriate, to facilitate them accessing information and support which is more suited to their needs.

Reflective exercise

1. What are your personal beliefs about physical exercise?
2. How might these influence the way in which you discuss the place of exercise during pregnancy with pregnant women?
3. Spend some time talking with pregnant women and practising midwives about their beliefs and behaviours with regard to the place of exercise during pregnancy.

Exercise in pregnancy

Exercise in pregnancy has different meanings for different people. For some, it means gentle stretching exercises done as preparation for labour and birth, and is sometimes incorporated into group antenatal education (Brayshaw 2003). For others, it means recreational sport or general physical fitness, in the form of aerobic exercise such as swimming, cycling, walking or team sports (Howells 2002; Kramer 2004).

There is ongoing debate about exercise in pregnancy. See Brayshaw (2003), Howells (2002) and Goodwin et al. (2000) as examples—they address issues including:

- the role of exercise in improving or maintaining the health of women and their babies
- its benefits (physical, psychological, social and clinical)
- appropriate 'safety' boundaries (the type, frequency and intensity of exercise)
- the contraindications for exercise in pregnancy (underlying medical conditions).

Historically, beliefs about exercise in pregnancy have varied with the social, cultural and political context of the time, with 'advice for physical activity reflect[ing] activities and behaviour deemed to be socially acceptable' (Rankin et al 2000, p 764). Arguably, this continues today. Although caregivers have been advising women about appropriate exercise in pregnancy for centuries (Ranking et al 2000), our knowledge about its psychological and physiological effects is still limited (Kramer 2004).

Medical literature has focused on the physiological aspects of exercise (see recent reviews: Jones 2000; Kramer 2004; Wolfe & Weissgerber 2003). The Cochrane Review concludes that 'regular aerobic exercise during pregnancy appears to improve (or maintain) physical fitness and body image. Available data are insufficient to infer important risks or benefits for the mother or infant' (Kramer 2004, p 1). 'Regular aerobic exercise' is defined by Kramer (2004) as 'vigorous exercise that results in a rise in oxygen consumption (to 50 to 85% of maximum) and heart rate (to 60 to 90% of maximum) and maintains that level for at least 15 to 20 minutes…at least two to three times per week' (pp 1–2). Evidence with regard to the effect of frequent (≥ 5 times/week) and vigorous exercise is contradictory, with some research finding an association with low birth weight and shorter gestations, and others finding no significant differences in outcomes measured between groups of women who exercise in this way, and those who exercise moderately (Wolfe & Weissgerber 2003). Carrying out research on this issue is difficult, given the many confounding variables involved, which include underlying wellness and fitness levels, physiological and psychological changes induced by pregnancy, and the potential bias within any group of women who agree to participate in research on exercise.

Midwifery literature has explored some of the psychological and social aspects of exercise. For example, Clarke & Gross (2004) and Symons Downs & Hausenblas (2004) found that:

- many women discontinue regular pre-pregnancy exercise during pregnancy
- many women perceive that rest and relaxation are more important than exercise
- magazines and books were important sources of information initially
- friends and family strongly influence exercising behaviour
- the most common exercise beliefs were that exercise improves mood
- physical limitations (e.g. nausea) obstructed participation in exercise.

The attitudes, beliefs and behaviours women have about exercise are rooted within their personal, social and cultural context, and cannot be addressed in isolation. As with any other issue of health promotion, a complex process is involved, and requires midwives to work in partnership with women, and use effective communication, support and affirmation skills (Crafter 1997).

Physiological changes of pregnancy

Pregnancy brings about many changes within a woman's body. Almost all of these physiological changes are experienced as unwelcome and unpleasant, and some are very distressing and debilitating (see Box 20.2). They are commonly referred to as 'minor' discomforts or disturbances, which does not reflect the impact that some of these conditions have on many women and their families. The fact that they are common, natural and not 'pathological', and generally resolve as spontaneously as they

arise, appears to contribute to the dismissal or minimisation of them by many caregivers.

There are marked differences in the incidence and severity of these changes, both between different women, and for the same woman during different pregnancies. There are also significant variations in the experiences, perceptions and responses of women to the changes caused by pregnancy. The socio-cultural context within which women (and midwives) live also influences the way in which they respond. Arguably, in contemporary Western society, there is a lower tolerance for discomfort or pain among many, and an increased expectation that the negative aspects of physiological changes can be alleviated (without risk to the health of woman or baby), whether by the use of 'medicated' pharmacological remedies or by 'alternative' remedies. Further, contemporary lifestyles including diet, exercise and work patterns (paid and unpaid) may exacerbate these changes, and changing these factors can be difficult during pregnancy. Unfortunately, the very nature of physiological changes, as expressions of the normal physiology of pregnancy, makes them difficult to resolve with 'treatment' of any type. The focus is therefore on understanding the physiology and minimising the discomfort of these changes.

Responses to physiological changes vary widely, and a vast array of 'therapies' are used by women today. They include herbal medicine, homeopathy, acupuncture/acupressure, osteopathy, aromatherapy, reflexology, massage, reiki, hypnotherapy, bach flower remedies, shiatsu and 'conventional' Western medicine. Additionally, there are numerous dietary and exercise approaches advocated by various health professionals and lay people. Among them are those who advocate strongly for their particular therapies (both conventional and alternative), but evidence to date is very limited as to the efficacy and safety of many interventions for the alleviation of pain or discomfort caused by these changes. It is beyond the scope of this chapter to include a description or an evaluation of the range of therapeutic options for the physiological changes to be discussed, beyond the brief exemplar given on nausea and vomiting. See Balaskas (1998), Jamil & Evennett (2000) and Tiran (2001) for further reading.

All interventions, including 'conventional' and 'alternative' medicines or remedies, should be treated with due respect and caution when being considered as treatments for physiological changes. (See the case relating to nausea and vomiting, below.) It should not be assumed that because something is 'natural' or 'alternative' that it is therefore any safer, lower risk or more effective than 'conventional' options. It is appropriate for midwives to carefully review the available evidence regarding the safety and efficacy of any intervention option they offer women. Midwives should recognise the limits of their knowledge and training, and when discussing options and alternatives, be able to refer on to those who are trained, accredited and accountable within their own profession, when these therapies are outside their scope of practice.

When women describe discomfort or pain they are experiencing, midwives must take care to differentiate between physiological and pathological symptoms. For example:

- vomiting may be physiological or pathological, and caused either by bacterial or viral infection, or by hyperemesis
- indigestion needs to be distinguished from epigastric or chest (cardiac) pains
- normal physiological increase in vaginal discharge needs to be differentiated from infections, such as chlamydia or thrush.

The physiological changes listed in Box 20.2 are the most common, and three of these will be discussed briefly here, as limited space does not permit a discussion of each and every one.

BOX 20.2 Physiological changes of pregnancy

Circulatory—related to changes in blood vessels or lymph system
- oedema
- carpal tunnel
- fainting and dizziness
- palpitations
- varicose veins—leg, vulval or anal (haemorrhoids)
- bleeding gums or nose

Muscle and ligament
- leg cramps
- 'ligament' pain (abdominal)
- back pain
- sciatica
- symphysis pubis dysfunction
- incontinence
- uterine cramps—'irritable' uterus, Braxton Hicks contractions

Digestive
- nausea and vomiting
- constipation
- heartburn and indigestion
- ptyalism
- bloating and excessive 'wind'
- diarrhoea

Breast —tenderness, growth, colour and size of areola, 'leaking'
Vagina—increased discharge, pH (thrush susceptibility)
Urinary—frequency, UT dilation, shortening (UTI susceptibility)
Sleep—pattern, nature, insomnia, dreams
Nose—congestion, bleeds, hay fever
Hair—growth on skin (abdomen, face), loss from head
Skin—itching, pregnancy rash (PUPP), acne, chloasma, linea nigra, stretch marks
Dietary—hypersensitivity to taste and/or smell, pica, appetite and metabolism changes
Sexuality—libido changes
Emotional—volatility and mood swings
Headaches and/or migraines
Tiredness/fatigue increased (1st and 3rd trimesters)

Nausea and vomiting (morning sickness)

Nausea and vomiting is a common, very unpleasant, yet not well understood condition of pregnancy. 'Nausea is the

conscious recognition of subconscious excitation of the vomiting centre or an area close to it in the medulla. Vomiting is a complex series of movements which rids the gut of its contents when any part of it is irritated or distended' (Jordan 2002, p 121). While it is associated with raised levels of human chorionic gonadotropin (hCG) hormone and changes in blood sugar levels, variability in incidence, severity and response to treatments are indicative of a multifactorial state. Box 20.3 is a summary of a range of statistics on the occurrence and severity of nausea and vomiting. These statistics have been sourced from Chandra et al (2003), Frye (1998), Jewell & Young (2004), and NICE (2003).

Nausea and vomiting occurs predominantly in the first trimester. It is notoriously difficult to treat, in part because of the potentially greater harm that treatment poses to the baby during this critical developmental time, compared with other periods of pregnancy. Many treatments have been tried: Jewell and Young (2004) cite a 1968 report that identified thirty treatments 'in addition to the traditional dietary interventions' (p 2). Conventional medications in use currently include antihistamines, antipsychotics, gastro kinetics and vitamin supplements (Jordan 2002). (See also Ch 29 for prescription options.) The history of conventional pharmaceutical medications for nausea and vomiting is notably marked by the tragic consequences of the use of the drug thalidomide, which caused severe limb defects in babies (Frye 1998). This situation illustrates the point that the widespread use of medications should not be interpreted as proof of sound evidence of safety or efficacy. For example, the NICE guidelines (2003) state that the commonly prescribed drug metoclopramide 'has insufficient data on safety to be recommended as a first-line agent' (p 54). Vitamin B6 (pyridoxine) has also recently been introduced as a treatment for nausea and vomiting, and once again, evidence of its safety or efficacy is limited and not robust (NICE 2003). Questions regarding safety levels and potential toxicity at high doses are unresolved, with 10 mg/day set as the safe upper limit by the Committee on Toxicity of Foods in the United Kingdom, and doses of '25–75 mg up to three times daily' used in the research trials (NICE 2003).

It is also appropriate to be cautious about the use of alternative herbal medications. An example of these is powdered ginger in capsules, which is currently popular, but also poorly evaluated (Wilkinson 2000). Wilkinson's (2000) literature review found a dearth of evidence and contradictory advice regarding the use of ginger for nausea and vomiting, with 16 per cent of sources citing it as 'unsafe for use in pregnancy' (p 226). The NICE guidelines (2003) also cite very weak evidence in support of their recommendation for the use of ginger as an appropriate 'non-pharmacological' intervention. In common with many conventional medications, its mechanism of action in the relief of this condition is not understood—'one proposed mechanism is inhibition of thromboxane synthetase, described in rat models, which has the potential to affect . . . differentiation of the fetal brain' (Barclay & Lie 2004, p 2). Its use as a medication in capsule form may cause unforeseen problems due to the increased dosage that capsules facilitate, above that which might have been ingested traditionally in its natural state as fresh root ginger, eaten or taken in a tea. Further research is required on both conventional and herbal treatments for nausea and vomiting (Enkin et al 2000).

BOX 20.3 Incidence and severity of nausea and vomiting

Incidence
- 80–85% of pregnant women experience it; 52% of these vomit

Severity
- varies greatly—most women have symptoms by eight weeks (94%)
- one-third have symptoms by 4 weeks gestation
- resolved by 12–14 weeks for the majority of women
- resolved by 16–20 weeks for most (90%)
- not confined to the morning for most (80–90%)
- causes lost work time (at least 25% in paid and unpaid work time)
- causes increased weight gain for some (frequent snacking to feel better) and weight loss for others (decreased appetite with moderate vomiting)
- emotional, social and psychological impact can be marked
- 1% of women with nausea and vomiting will develop the pathological condition of hyperemesis gravidarum

Alternative intervention for the treatment of nausea and vomiting, in the form of acupressure is showing promising results in most trials (Enkin et al 2000; NICE 2003), and its 'chemical-free' nature arguably makes it a lower-risk option. Each of the alternative forms of therapy mentioned in the introduction earlier offer therapeutic options for nausea and vomiting which women may wish to consider, and midwives need to be able make referrals as appropriate for the woman concerned.

Self-help responses to nausea and vomiting include lifestyle and dietary changes, which may provide some relief from this sometimes debilitating condition, which is recognised as having 'a profound impact on women's general sense of wellbeing and day-to-day life activities' (Smith et al 2000). They include the following sourced from the Auckland Home Birth Association (1993), Balaskas (1998), Chandra et al (2003), Frye (1998) and Jamil & Evennett (2000):

- Increase rest periods.
- Minimise work and home stressors.
- Eat carbohydrate (and wait 20 minutes) before getting out of bed in the morning.
- Eat protein before going to bed, or if up during the night.
- Do low energy/impact exercise, such as walking or yoga, after eating.
- Have regular small snacks of high protein and unprocessed carbohydrate (2–3 hourly).
- Avoid refined, fried and spicy foods.
- Eat foods rich in B group vitamins.
- Eat five to six small 'meals' a day, rather than three large ones.

- Increase fluid (water, milk or juice) intake.
- Reduce coffee and tea intake if > 3 per day.

Constipation

'Constipation may be defined as a delay in the passage of food residue, due to the accumulation of hard, dry stool, associated with painful defaecation, abdominal distension and a palpable mass' (Jordan 2002, p 290). Normal patterns for bowel movements vary significantly between women, and have been defined as anything from three per day to one every three days (Jordan 2002). It is therefore not the frequency of bowel motion per se, but the discomfort and difficulty in passing one that is more significant in defining constipation.

Constipation is caused by hormonal changes (which result in slowed bowel motility and changes in absorption patterns), changes in food and fluid intake (volumes, times and types), and for some, by reduced rates of exercise (Frye 1998; Walsh 2001). Constipation is common during pregnancy, possibly occurring in forty per cent of women (NICE 2003). It is difficult to establish incidence rates, due to disclosure issues for women, and to other confounding variables, such as the effects of routine iron supplementation at the time the abovementioned research was carried out.

Dietary and lifestyle changes are the primary response to constipation during pregnancy. Both herbal and pharmaceutical laxatives should only be used as a short-term (one to two weeks) last resort while dietary changes are made, as they can cause flora, fluid and electrolyte imbalances in the bowel and reduced gut motility and absorption of nutrients (Jordan 2002).

Dietary changes include increased fibre intake, such as grains (whole or bran form), beans and lentils, brown rice, nuts and seeds and dried fruits. Fresh fruit and vegetables are an excellent source of fibre and have the advantage of providing both fibre and fluid together, as well as valuable nutrients. As most fibre absorbs fluid during digestion, it is important that women increase both fibre and fluid intake, or the increased intake of some types of fibre can aggravate rather than resolve constipation. Fluid intake is very important. There is no 'right' number of cups of fluid to have each day, but if a woman is constipated she is unlikely to be having enough fluid, either in foods or in liquid form. It is important that women drink plenty of fluid daily and not just when constipated. Prunes and kiwifruit, as fruit or juice, are excellent, but many women do not like or have access to them. Tea and coffee worsen constipation by acting as diuretics, so fluid is passed out as urine, not leaving enough in the intestine to keep the stool soft. The midwife should work individually with women, acknowledging their personal, social and cultural context, to find high-fibre foods and appropriate fluids that they might include in their diet. Regular consumption of these foods and fluids is important, rather than in response to constipation, as the bowel works best in a regular pattern or routine.

It is also worthwhile discussing issues of bowel motion pattern and technique with women. During pregnancy it may take longer to pass a motion, due to slowed peristaltic action. It is important for a woman to take note of her body's natural urge to go to the toilet when it occurs and not put it off or hold on, as it may be some hours or the next day before another urge occurs, and by then more fluid has been absorbed from the faecal mass and greater compaction has occurred. If a woman has lost the natural regular urge to pass a bowel motion, she should be encouraged to make a regular time each day for trying, after meals being the best time, given the natural peristalsis that occurs with the intake of food. Positioning on the toilet and pushing technique can also affect ease or speed of passing a motion. Women should:

- sit on the toilet with knees higher than their hips (a foot stool helps)
- have their legs hip-width apart
- lean forward with forearms resting on their knees (leaning back to push presses the stool against the posterior vaginal wall/pelvic floor and tenses the pelvic floor, when relaxation is needed)
- keep their back fairly straight, not rolled over
- let their tummy drop forward
- with the first push (using diaphragm), lift their heels and feel widening of the waist
- breathe out and push/grunt, relax, breathe deeply and try again
- try not to strain with prolonged pushes
- allow time for the peristaltic action, if it does not come
- try massaging their abdomen in a clockwise direction, starting at the right hip (possible until about 20 weeks gestation).

Heartburn

Heartburn (or gastro-oesophageal reflux) is a common experience for pregnant women, with different research citing incidence rates of between 72 and 85 per cent (NICE 2003). It is a very unpleasant condition in which stomach acid enters the lower oesophagus causing a 'burning sensation' in the chest or back of the throat (Frye 1998). It is caused by hormonal changes, which slow gastric motility and promote sphincter relaxation, and physical pressure from the growing uterus (Jordan 2002). It tends to worsen as pregnancy progresses (Jewell & Young 2004), and can cause major physical discomfort for women. It can interfere with content and pattern of eating, interrupt physical activity and sleeping, and result in considerable emotional and psychological distress for some women.

Numerous self-help measures for the relief of heartburn are listed below. Some will appeal to or work for one woman but not another, and some women find that something that helps initially may become ineffective as pregnancy progresses. Self-help measures for heartburn include the following:

- identifying foods which cause heartburn and avoiding them
- avoiding fried, fatty or spiced foods (for some women, bread causes heartburn)
- avoiding coffee, tea, alcohol and cigarettes, all of which worsen heartburn
- chewing food thoroughly and eating slowly

- eating apple, pineapple, papaya or kiwifruit with meals, as they have digestive enzymes which speed the breaking down and digestion of food
- eating four to six small meals a day, rather than three large ones (dividing the main meal onto two small plates and eating the second portion the next day reduces 'snack food' intake)
- eating the last meal of the day at least two hours before bedtime
- drinking plenty of fluid, but *not* with meals (they dilute digestive juices; wait thirty minutes)
- drinking milk or eating yoghurt (alkaline)
- drinking orange juice (acidic)
- chewing raw almonds or cashew nuts.

Other non-food-related strategies may include:

- checking posture, especially while sitting—slouching will worsen heartburn
- trying exercises that stretch the upper torso while sitting or standing (not lying)
- staying upright for two hours after eating—walking may help
- sleeping with upper body elevated, with bricks under the bed legs, or several pillows (Balaskas 1998; Frye 1998; Jamil & Evennett 2000).

There are numerous herbal remedies available, in addition to the options from all the other therapies described earlier. There are also a number of medicated pharmaceutical options, which have varying levels of efficacy, and are variably supported by evidence (see Jordan 2002).

Conclusion

This chapter has sought to provide an introduction to the care of pregnant women. It has presented an overview of the purpose and provision of antenatal care within the context of the midwifery model. A primary aim of the chapter has been to outline the key components of antenatal care, and describe a framework for organising these components in a relatively systematic and coherent way. These components include:

- the nature and process of establishing a relationship with a pregnant woman and her support people
- the principles involved in and assisting or supporting a woman to make appropriate decisions regarding her pregnancy, and developing an individualised and effective care plan
- the assessment and monitoring of the health and wellbeing of a pregnant woman and her baby.

A framework of eight decision points has been presented, which comprise a set of four categories of cues, including information sharing, screening and assessment, decision-making, and health promotion and information. They are intended to prompt the midwife to consider the holistic nature of antenatal care. While this framework strives to provide a clear structure to antenatal care, it is intended to act primarily as a set of cues for the midwife rather than a strict prescription. The partnership between a pregnant woman and her midwife is a unique one, and it is incumbent on the midwife to facilitate an effective process that meets the woman's individual needs and reflects her personal reality.

Reflective exercise

1. Consider the potential impact of physiological changes on the physical, psychological and social lives of pregnant women.
2. Identify your own scope of practice regarding interventions for treating or managing the physiological changes associated with pregnancy.
3. Identify referral options for 'out-of-scope' treatments.

The chapter has also discussed some of the knowledge and skills a midwife might apply in the provision of antenatal care. These include:

- establishing an estimated due date
- abdominal palpation
- blood pressure measurement
- routine blood and urine screening options
- describing the nature and significance of fetal movements
- antenatal education and exercise during pregnancy
- the concept of physiological changes associated with pregnancy, and issues related to the management of them.

A second objective of the chapter has been to argue for, and model the use of reviewed research to promote, evidence-informed midwifery in the provision of antenatal care. Much of what has traditionally been included in routine antenatal care has been based on anecdote and happenstance, rather than clear evidence that supports or refutes these practices. A good deal of the research reviewed to date either does not address issues of concern to midwives and childbearing women, or is weak, or is primarily applicable to the type of antenatal care which is provided within the medical model. This has limited the extent to which the concept of evidence-based practice has been applied within this chapter. It is to be hoped that in the future, midwives will be able to use evidence to inform their practice within the context of the midwifery model of care.

Review questions

1. What methods for establishing EDD are used in your region?
2. What antenatal blood tests are considered to be 'routine' in your region, and what are the 'normal' reference ranges for them?
3. Describe the physical, personal, social and emotional implications of positive blood screening tests for pregnant women and their families.
4. What are the contemporary diagnostic criteria for pre-eclampsia?
5. What are the essential components of measuring blood pressure?
6. What are the aims of routine antenatal urine screening, and what evidence is there for the accuracy and efficacy of contemporary urine screening tests?
7. What are the basic palpation techniques, and what information can be gained from abdominal palpation in antenatal care?
8. How might midwives help women to experience palpation positively?
9. What is the significance of fetal movements over the course of a woman's pregnancy, and how might a woman and her midwife monitor these?
10. What antenatal education and/or exercise classes are available in your region?
11. What place does exercise have in influencing the emotional and physical wellbeing of pregnant women, and what impact might social, personal or cultural factors have on exercise patterns?
12. List ten physiological changes associated with pregnancy, and identify the following:
    - the nature of the condition
    - the cause (if known)
    - its incidence (frequency and timing during pregnancy)
    - its natural course and resolution
    - the potential for pathology
    - relevant self-help measures.

APPENDIX A: Historical health review

Maternity: midwifery and obstetric

Gravida—number of pregnancies (includes living children, miscarriage, termination of pregnancy, ectopic pregnancy, stillbirth, neonatal death)
Parity—number of babies born at or beyond 20 weeks, preterm (< 37 weeks), post term (> 42 weeks)
Contraceptive history
Past pregnancy(ies)—date, place, pregnancy complications, labour spontaneous/induced, gestation, duration of complications, outcome, name, sex, weight, breast/artificial feeding, postnatal complications, S/E/C issues

Risk markers

Chronic hypertension—genetic hypertension or pre-eclampsia (degree), gestational diabetes
Multiple pregnancy—congenital abnormalities, antenatal anaemia (Hb < 90)
Preterm birth (< 37 weeks)—small baby (IUGR/SGA), APH
Post term birth (> 42 weeks)—large baby (> 4500 g), shoulder dystocia
Assisted birth (forceps/vent.)—lower-segment caesarean section, vaginal birth after caesarean section, postpartum haemorrhage (>1000 or treated)
Rh sensitisation/ABO incompatibility—perinatal infection
Antenatal or perinatal depression/psychosis
Other

Medical

Essential hypertension, diabetes, heart disease
Asthma, TB/pulmonary disease, thyroid disease
Neurological disorder (epilepsy), musculoskeletal disease
Renal/urinary tract disorder
Haematology disorder, liver disease, digestive disorder
STI, infertility, cervical abnormality/treatment
Polycystic ovaries, fibroids, endometriosis
Allergies, infections, vaginal/urinary tract abnormality/treatment
HIV status risk (high/low)
MRSA risk (high/low)
TB risk (high/low)
Medical examination
Surgery (what, when, complications)
Blood transfusion
Physical, sexual, psychological abuse
Other

Mental health

Depression, eating disorder, other

Family health

Maternal—diabetes, hypertension/pre-eclampsia, multiple pregnancy, asthma, intellectual disability, haemoglobinopathy, allergies, other
Congenital abnormalities (maternal and/or paternal)—chromosomal, limb deformity, metabolic, neural tube defect, cardiac defect, cleft palate, dislocated hip(s), severe infant morbidity, SIDS, other

APPENDIX B: Current health review

Physical

General health
Any underlying/ongoing health concerns
Medical examination (as appropriate)
Cervical smear screen—when
Any sign of current infection (review risk re STI)
BP, pulse, MSU
Height (cm), weight (kg), BMI
Diet (details), exercise (details)
Smoking (what, how much, readiness to reduce/stop)
Alcohol, drugs (what, how much, readiness to reduce/stop)
Safety from violence (if woman alone or maybe wait until visit with woman alone)
Medications and supplements (details), folic acid

Emotional

General health
Feelings about pregnancy and having a baby
Planned/unplanned and welcome/unwelcome pregnancy

Social

Autonomy, support, resources, employment, community 'belonging' or isolated
Is there a current relationship—partner, husband? Is it stable and supportive?

Cultural

Identity, integration/isolation, support, resources, needs
Safety issues

Spiritual

Any religious beliefs that may influence needs/choices/care options

Current pregnancy: establish EDD

LMP (sure/unsure), known conception date
EDD (consider 283-day option)
Positive pregnancy test
Menstrual cycle—regular/irregular/frequency, contraception, last cycle and menstruation normal (Y/N (details))

CHAPTER 21

Physiological changes during labour and the postnatal period

Sally Baddock and Lesley Dixon

Key terms

acid–base balance, breathing patterns, cellular barrier, cervical ripening, dilatation, diuresis, effacement, energy needs, fetal responses, fetal wellbeing, hormones, hypercoagulable state, involution, lochia, mechanism of labour, myometrial activation, onset of labour, placental separation, regeneration, smooth muscle tone, uterine contractions, uterotonins, water and electrolyte balance

Chapter overview

This chapter focuses on the physiological processes associated with birth and the postnatal period. This begins in the final weeks of pregnancy as changes occur to the uterus and cervix in preparation for birth, and continues through the processes associated with the birth of the baby. It concludes by examining the changes during the six to eight weeks following birth, when the reproductive organs return to a non-pregnant state, and lactation is started. Understanding the underlying physiology is essential if a midwife is to make informed decisions about the progress of labour and adequately assess the wellbeing of the woman and baby throughout labour and the postnatal period. It also enables informed discussion with the woman throughout these times of significant physiological change.

The chapter is divided into two major sections—the physiology of labour and the physiology of the postnatal period—although physiologically the division is not so clear, as one process leads into the next.

The physiology underlying labour and the changes of the postnatal period include many physical and chemical processes controlled by hormones. Before labour begins, hormones mediate the preparatory changes that occur in the uterus and cervix. The actual mechanisms that initiate labour are not clear, but they are associated with fetal, placental and maternal hormones. Progress in labour is largely mediated by hormones that govern uterine contractions. Effective contractions first lead to dilatation of the cervix and then generate the pressure to birth the baby. The mechanism of labour describes the manipulations the baby must make to negotiate the narrow pelvis and birth canal. Following the birth of the baby, the placenta separates from the uterus and may be delivered without intervention, while continuing uterine contractions minimise blood loss from the placental site. Labour is a physically demanding time that is supported by changes to metabolism and probably changes to all body systems to maximise the efforts of the woman. During labour the fetus is normally exposed to considerable stress.

The postnatal period is defined as the period up until six to eight weeks after birth, when the genital organs return to a non-pregnant state, and lactation is started. Many of the physiological, anatomical and endocrine

changes in this period occur in the first 10 to 14 days; for example, some hormone levels drop significantly, whereas others involved in lactation rise. Involution is the process that reduces the size of the uterus, cervix and vagina. In non-lactating women this includes reduction in the size of the breasts.

These processes are the focus of this chapter. Further readings are provided at the end of the chapter for a more in-depth exploration of specific topics.

Learning outcomes

Learning outcomes for this chapter are:

1. To outline the changes involved in myometrial activation and cervical ripening
2. To discuss the physiological factors that may be responsible for initiating labour
3. To outline the role of hormones in the maintenance of labour
4. To describe the physiology underlying the three stages of labour, including the physiology of effective uterine contractions, the mechanism of second stage and the steps involved in placental separation in third stage
5. To discuss physiological changes that occur to other systems to support labour
6. To describe fetal responses and measures of fetal wellbeing during labour
7. To describe the change in maternal hormone levels following the birth of the baby
8. To describe the processes of involution and of healing at the placental site
9. To provide a physiological rationale for blood and fluid loss during the puerperium
10. To describe the changes that occur in the cervix, vagina and vulva in the puerperium
11. To compare oxygen consumption during labour and the puerperium
12. To compare physiological changes in the maternal body systems during pregnancy and during the postnatal period, particularly the renal, haematological and cardiovascular changes
13. To identify physiological vulnerability during the puerperium
14. To outline the hormonal control of lactation during pregnancy and the pueperium.

Physiology of labour

Labour is a process in which regular and coordinated muscular contractions of the uterus lead to gradual effacement and dilatation of the cervix, followed by expulsive contractions that result in the birth of the baby and placenta. For simplicity, the physiological changes that occur during this process can be divided into three stages. Stage one describes the time when uterine contractions are of sufficient frequency, intensity and duration to cause effacement and dilatation of the cervix. Stage two begins with the complete dilatation of the cervix and ends with the birth of the baby, and stage three involves the delivery of the placenta. Physiologically there is no abrupt transition between the stages of labour or between the end of pregnancy and the onset of labour. The events leading to the onset of labour build gradually during the last weeks of the pregnancy, and there is overlap of physiological changes between the stages of labour.

The exact mechanisms that initiate and control labour are still not well understood. It is an extremely complex physiological process involving positive feedback and negative feedback loops and interconnections between maternal and fetal processes. Before exploring the physiology of labour it is important to review the changes that occur in the uterus and cervix prior to active labour.

Uterine changes in preparation for labour

The myometrium consists of bundles of non-striated muscle fibres, intermixed with connective tissue, blood and lymph vessels and nerves. Throughout pregnancy the uterus is preparing for labour and there is an enormous increase in the bulk of the myometrium due to hypertrophy and hyperplasia of the cells. Myometrial cells are smooth muscle cells and therefore are capable of spontaneous activity independent of external stimuli. Low-amplitude activity occurs even in a non-pregnant uterus (Challis 2001). During pregnancy, however, contractions are largely prevented by uterotonic inhibitors, such as progesterone, nitric oxide and prostacyclin, and those that do occur tend to be mild, irregular and non-synchronised. Women are generally not aware of these contractions. As pregnancy progresses, contractions gradually increase in intensity and frequency, until in labour, strong, synchronous, effective contractions occur.

Changes in the structure of myometrial cells enable them to contract more strongly and to maintain this through labour. The initial changes are termed 'activation'. Four main events occur during activation: the ratio of hormones changes, electrical activity increases, myometrial cells become more responsive and there is an increase in ion channels. This occurs in the last few weeks of pregnancy as uterotonic inhibitors decrease and oestrogen and contraction-associated proteins

(CAPs) increase. Contraction-associated proteins include gap junction proteins, myometrial oxytocin receptors and prostaglandin receptors, and calcium and sodium channels (Blackburn 2003). Increased gap junction formation facilitates the spread of electrical activity over the myometrium, and increased prostaglandin and oxytocin receptors enhance the responsiveness of target tissues to these uterotonins. Increased sodium ion channels facilitate sodium movement into the cells. This is required for electrical excitation. Increased calcium ion channels enable increased calcium movement into the cells. Calcium is required for binding of myosin to actin during contraction.

Cervical changes in preparation for labour

Another region of the uterus that undergoes changes is the cervix. During pregnancy, the cervix is important in retaining the fetus in the uterus. Stretching of the cervix is resisted due to its high connective tissue content, which is made up of collagen-fibre bundles embedded in a proteoglycan matrix. Before effacement and dilatation can occur, the cervix must change structure and soften or 'ripen' and this occurs towards the end of pregnancy (Winkler et al 1999). The softening process is characterised by an infiltration of leucocytes, an increase in water and a decrease in collagen content of the cervix. Infiltration of the cervix by leucocytes and macrophages leads to the release of proteolytic enzymes that cause collagen degradation. Increases in hyaluronic acid and changes in blood vessel permeability increase the water content of the cervix. Increases in glycoaminoglycans reduce the ability of collagen fibres to bind together (Johnson & Everitt 2000; Winkler et al 1999). The changes associated with cervical ripening are independent of myometrial contractions (Blackburn 2003).

The process of cervical ripening is complex and depends on the hormones present at the end of pregnancy. Increases in the oestrogen-to-progesterone ratio and increases in relaxin promote collagen degradation. Nitric oxide in the cervix increases near term and may act with prostaglandin E_2 to induce vasodilation and facilitate neutrophil infiltration (Ledingham et al 2000). Stretching of the cervix results in the local release of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and the release of oxytocin from the posterior pituitary (the Ferguson reflex), which in turn increase uterine activity (Blackburn 2003). It is worth noting that, clinically, prostaglandin E_2 and $PGF_{2\alpha}$ are used for softening of the cervix prior to induction of labour because of their localised effect on cervical softening (Johnson & Everitt 2000; Tenore 2003). Once the cervix is prepared physiologically and structurally, labour can begin.

What initiates labour?

In a number of mammalian species the onset of labour is timed primarily by the fetus via secretions of the adrenal cortex that increase oestrogen levels and subsequently $PGF_{2\alpha}$ in the uterus. Prostaglandin $F_{2\alpha}$ activates myometrial contractions and cervical ripening (Johnson & Everitt 2000). In humans, it is likely that maternal as well as fetal mechanisms are involved, although the final pathway appears to involve activation of the fetal hypothalamic-pituitary-adrenal axis (Norwitz et al 1999).

Mechanisms leading to labour are mediated by changes in hormone levels. It is important to realise that hormone effectiveness is changed not only through increased synthesis and release of hormones, but also by reduction in the concentration of hormone-binding proteins or, alternatively, by an increase in numbers of receptors on target tissues. Therefore the plasma concentration of a hormone may not reflect the degree of hormone binding at the local site.

It is known that increases in placental uterotonic hormones are linked to maturation of the fetal adrenal glands and the mechanical stretching of the uterus due to the growing fetus. Maternal adrenal glands and other endocrine or neural mechanisms may also play a role (Johnson & Everitt 2000).

A growing number of placental hormones have been identified, although their exact function in labour is not yet clear (Reis et al 2001). The roles of some of the key hormones and chemical mediators that contribute to labour, such as corticotrophin-releasing hormone, prostaglandins, oxytocin, oestrogen, progesterone, relaxin and nitric oxide are outlined below.

Corticotrophin-releasing hormone

It is suggested that placental corticotrophin-releasing hormone (CRH) plays an important role in the onset of labour (Challis 2001; Grammatopoulos & Hillhouse 1999), along with maturation of the fetal hypothalamic-pituitary-adrenal system. CRH is a neuropeptide produced by the hypothalamus, placenta, decidua, chorion and amnion. CRH receptors are found in the decidua and fetal membranes and in the myometrium. The complexity of control is highlighted by the fact that CRH appears to have a dual role: during pregnancy it promotes uterine quiescence; during labour, under the influence of oxytocin, it binds to different receptor types and promotes uterine contraction (Grammatopoulos & Hillhouse 1999).

There is strong evidence for the role of CRH in the initiation of labour. For example, placental CRH levels increase markedly after 35 weeks gestation, partly due to a 60% decrease in protein binding of the hormone, and then CRH levels decrease by 50% within 20 to 30 minutes of birth. Longer duration of labour has been associated with lower levels of CRH (Chrousos, cited in Blackburn 2003). Additionally, CRH levels are increased in pregnancies complicated by pregnancy-induced hypertension and intrauterine growth restriction (Petraglia, cited in Grammatopoulos & Hillhouse 1999), which may lead to preterm labour.

Grammatopoulos and Hillhouse (1999) proposed that placental CRH initiates labour via mechanisms that increase placental oestriol (active form of oestrogen) production and fetal cortisol production. The pathways for this are shown in Figure 21.1. Corticotrophin-releasing hormone stimulates the fetal adrenal gland to produce cortisol and the oestrogen precursor, dehydroepiandrosterone sulfate (DHEAS). Fetal cortisol exerts positive feedback to increase placental CRH

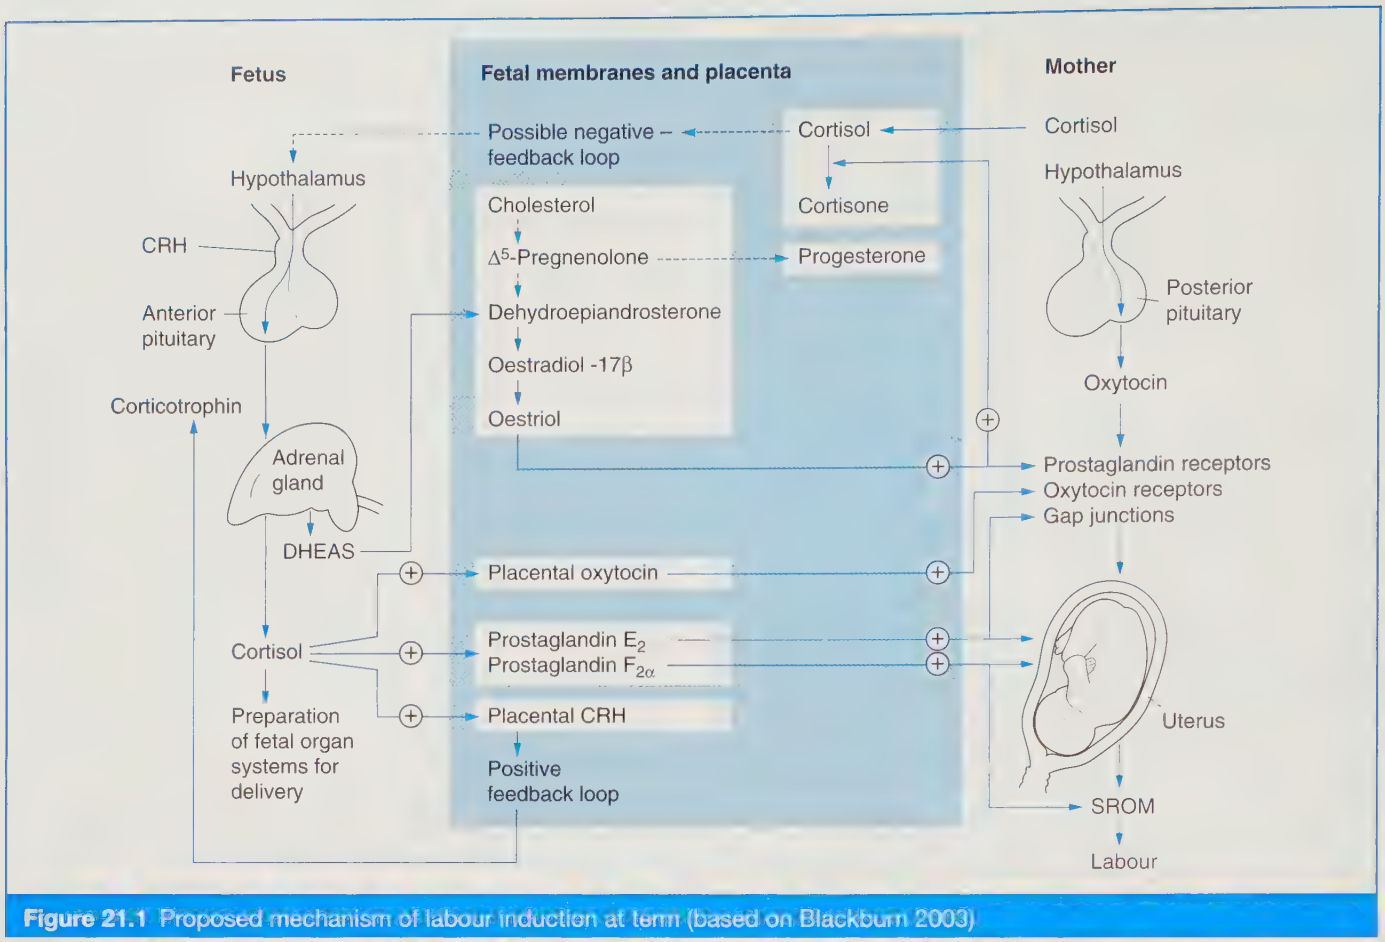

Figure 21.1 Proposed mechanism of labour induction at term (based on Blackburn 2003)

and increases prostaglandin and oxytocin synthesis. DHEAS is an essential precursor to placental oestrogen synthesis, particularly oestriol, which drives other mechanisms associated with the initiation of labour. The specialised fetal adrenal cells responsible for DHEAS production atrophy after birth.

Although cortisol appears to have a role in the initiation of labour, some evidence suggests labour may still progress when levels of fetal cortisol are low. For example, neither fetal anencephaly, where there is an absence of adrenocorticotrophic hormone (ACTH), nor adrenal hypoplasia, where cortisol production is reduced, necessarily result in prolonged labour (Johnson & Everitt 2000). Other clinical evidence indicates that although maternal corticosteroid administration results in a decrease of fetoplacental oestrogen production, it does not delay the onset of labour (Johnson & Everitt 2000) as would be expected.

In summary, placental CRH behaves differently to hypothalamic CRH. Placental CRH may promote uterine quiescence during pregnancy and then enhance contractility during labour. It is suggested that, via the production of fetal cortisol and DHEAS, CRH leads to increased oestrogen production in the placenta, which drives the other mechanisms of labour such as an increase in oxytocin receptors, gap junctions and prostaglandins.

Prostaglandins

Prostaglandins are lipids that are synthesised in tissues throughout the body. They are local hormones (paracrine hormones), which act at or near the place where they are synthesised. Prostaglandins are uterotonins directly responsible for uterine contraction. Two prostaglandins are particularly important in labour: PGE_2 and $PGF_{2\alpha}$. These prostaglandins stimulate smooth muscle fibres to contract, stimulate the formation of gap junctions in myometrial tissue and increase calcium levels in myometrial cells. As mentioned previously, prostaglandins also have a role in softening the cervix, enabling effacement and dilatation (Johnson & Everitt 2000).

Levels of PGE_2 and $PGF_{2\alpha}$ in the amniotic fluid are known to increase before and during labour; however, evidence for an increase of these hormones in maternal plasma before labour begins, is not conclusive (Johnson & Everitt 2000).

Prostaglandin synthesis has a complex pathway. During labour, prostaglandins are synthesised by the decidua, cervix, placenta and fetal membranes. The pathway for synthesis of prostaglandins is outlined in Figure 21.2. Arachidonic acid is the common precursor of both PGE_2 and $PGF_{2\alpha}$. Arachidonic acid is produced by the action of phospholipase A2 on phospholipids in the fetal membranes and the decidua. Phospholipase A2 is stored within lysosomes, which release the enzyme in the presence of oestrogen, and retain the

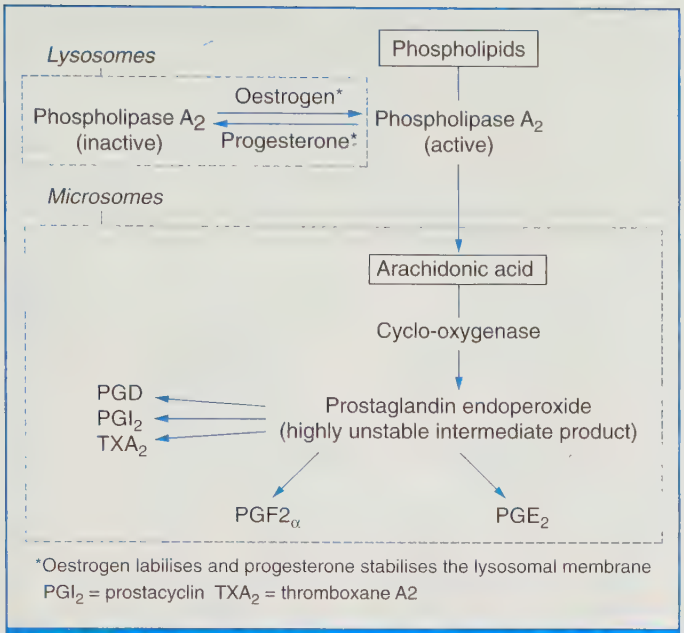

Figure 21.2 Biosynthesis of prostaglandins (based on Johnson & Everitt 1988)

enzyme in the presence of progesterone. Consequently, a rise in the oestrogen-to-progesterone ratio results in increased phospholipase A2, leading to increased production of arachidonic acid and prostaglandin synthesis. Oxytocin also promotes prostaglandin release.

Other evidence that prostaglandins contribute to the initiation of labour comes from the finding that inhibitors of prostaglandin synthesis, such as the anti-inflammatory drug indomethacin, are effective at reducing preterm labour (Enkin et al 2000).

Oxytocin

Another hormone essential for labour is oxytocin. Oxytocin is released into the sytemic circulation from the posterior pituitary in response to tactile stimulation of the reproductive tract, particularly the cervix. This is known as the Ferguson reflex and is outlined in Figure 21.3. There is also a local (paracrine) release of oxytocin from the fetal membranes, decidua and placenta (Reis et al 2001). There is little evidence that oxytocin initiates or is the primary uterotonin of labour, and it can only be used clinically to induce labour if the cervix is ripe (Tenore 2003). Plasma oxytocin levels do not increase physiologically until the second stage of labour, although

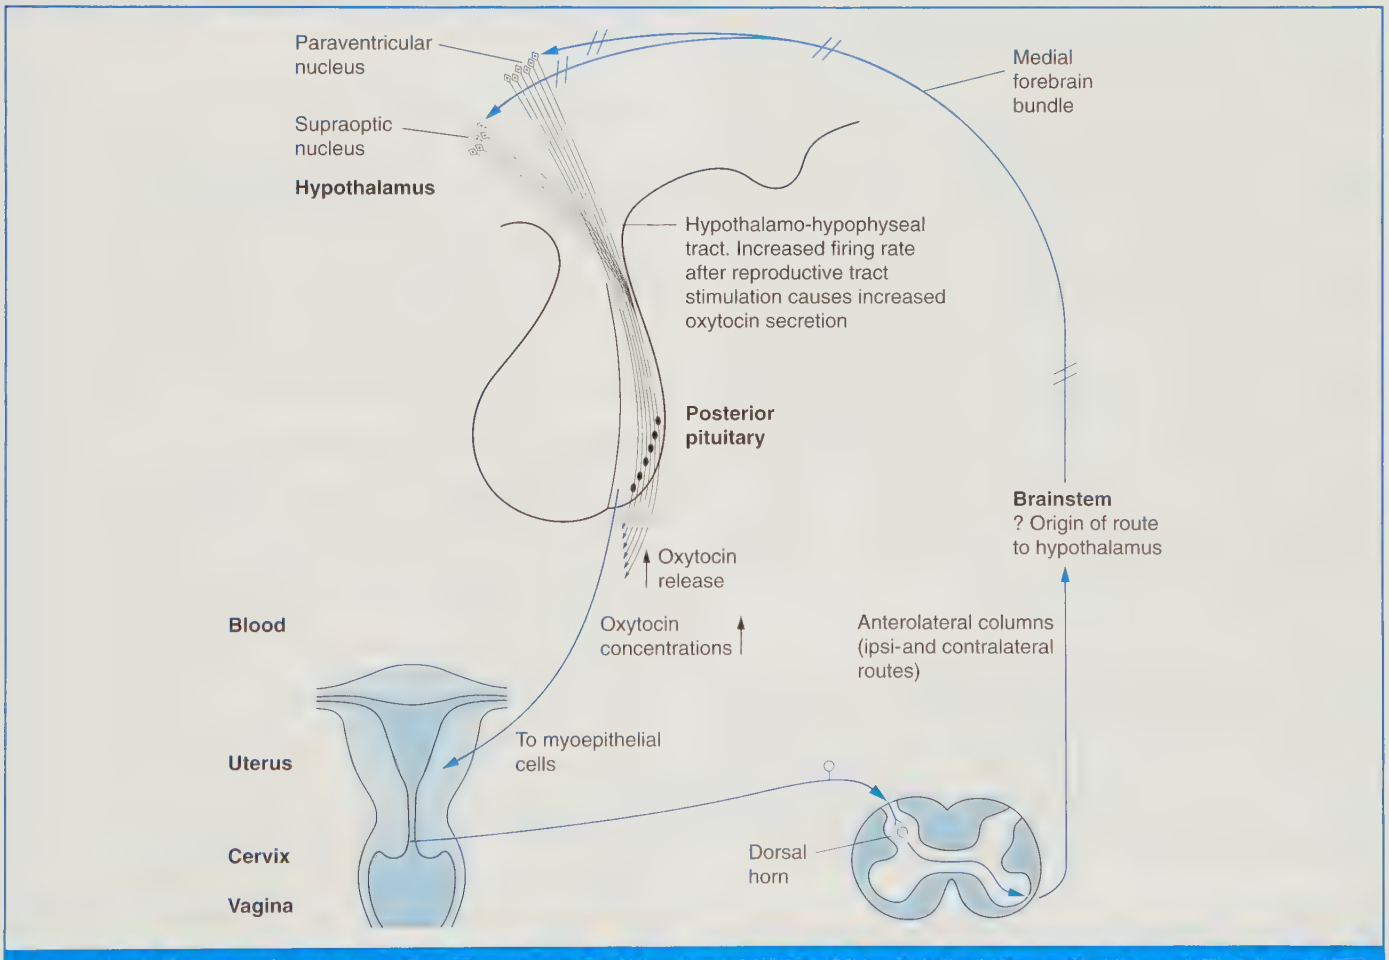

Figure 21.3 The neuroendocrine reflex (Ferguson reflex), underlying oxytocin synthesis and secretion (based on Johnson & Everitt 1988)

local concentrations may increase before this. The importance of oxytocin for labour is demonstrated by the increase of oxytocin receptors in the decidua during pregnancy, reaching a 300-fold increase by term (Zeeman, cited in Blackburn 2003; Takemura, cited in Reis et al 2001). Oxytocin binds to these decidual receptors, stimulates the release of prostaglandins from the decidua and stimulates uterine pacemakers.

Oestrogen

Oestrogen has a primary role in initiating many changes that are essential for labour, and levels begin to rise at about 34 weeks gestation. Oestrogen increases the sensitivity of the myometrial oxytocin receptors during pregnancy (Blackburn 2003) and thus facilitates myometrial contractility. Oestrogen promotes the formation of CAPs and prostaglandin synthesis via increases in phospholipase A2 release from lysosomes (Johnson & Everitt 2000). The synthesis of oestriol (the active oestrogen in pregnancy) relies on the fetal adrenal precursor DHEAS as outlined earlier (see Fig 21.1). Therefore maternal serum oestriol levels are an indicator of fetal hypothalamic-pituitary-adrenal maturity and elevated levels of oestriol levels are associated with the onset of labour (Norwitz et al 1999).

Progesterone

Progesterone is also a pregnancy hormone and, like oestrogen, it is produced in the placenta. However, in contrast to oestrogen, it is not reliant on fetal precursors for synthesis and its role is in suppressing uterine excitement. Progesterone does this by promoting the uptake of intracellular calcium into the sarcoplasmic reticulum of the myometrium, and works with nitric oxide to inhibit the production of CAPs (Challis 2001). Progesterone also has a role in decreasing oxytocin binding during pregnancy, and it is understood that removal of this effect at the onset of labour could facilitate myometrial contractions (Thornton et al 1999). Maternal plasma progesterone does not decrease at parturition, as it does in some animals (Norwitz et al 1999), but there may be local decreases in progesterone activity through increased progesterone-binding protein. The decreased availability of progesterone and increased synthesis of oestrogen produce an increased oestrogen-to-progesterone ratio, allowing the uterotonic effects of oestrogen to dominate, enabling contraction of uterine muscle.

Relaxin

Relaxin, like progesterone, supports quiescence of the uterus. Relaxin is produced by the myometrium, decidua and placenta. Its levels are highest in the first trimester, but are measurable throughout pregnancy. Relaxin has a role in enhancing cervical ripening; although exogenous application of relaxin promotes cervical ripening, the implications of clinical use of the hormone are not clear (Kelly et al 2001).

Nitric oxide

Nitric oxide (NO) is important in maintaining myometrial quiescence (Longo et al 2003). It is produced by the decidua, fetal membranes, and fetal and placental vascular epithelium. Nitric oxide is believed to interact with progesterone to inhibit the production of CAPs (Challis 2001). Levels of NO in the myometrium decrease near term but increase in the cervix. Nitric oxide production is dependent on the enzyme nitric oxide synthetase (NOS), which has three forms. There is an increase in the expression of one form, iNOS, in the cervix prior to the onset of labour, suggesting that nitric oxide contributes to cervical ripening (Ledingham et al 2000).

Summary of hormonal contribution to labour

- Plasma levels of hormones are not representative of local changes that may initiate and maintain labour.
- During pregnancy, hormones such as progesterone, relaxin and nitric oxide maintain the uterus in a quiescent state.
- Prior to labour, changes in the oestrogen-to-progesterone ratio facilitate activation of the uterine muscle, and ripening of the cervix occurs under the influence of prostaglandins, relaxin and nitric oxide.
- Following activation of myometrial cells and cervical ripening in the uterus, the myometrium responds to the uterotonins, oxytocin and prostaglandins.
- Initiation of labour probably involves fetal and maternal influences.

First stage of labour

During the first stage of labour, myometrial contractions lead to effacement and dilatation of the cervix. The first stage is often divided into two phases, latent and active.

In the latent phase, uterine contractions occur but cervical dilatation is slow. The timeframe for this phase varies considerably (Enkin et al 2000). In the active phase, strong, effective contractions lead to cervical dilatation. Cervical dilation of 3 cm is sometimes regarded as an indicator of active labour (Johnson & Everitt 2000).

Uterine contractions during first stage

For contractions to be effective and result in effacement and dilatation of the cervix, several processes must occur. The cervix must be softened, as described earlier; contractions must be coordinated so that all regions of the myometrium contract in unison under the influence of pacemaker cells, and there must be a descending gradient of uterine activity such that contractions are stronger at the uterine fundus and lessen towards the lower uterine segment. This gradient of activity allows retraction of the upper uterine segment to mediate the processes of effacement and dilatation. Control of myometrial contractions is via the changing concentrations of placental hormones (prostaglandins, oxytocin, oestrogens, progesterone and relaxin) as described earlier.

Uterine muscle cells undergo some unique changes. For example, pacemakers, located in each cornua of the uterus, initiate contractions under the influence of local hormones. Gap junctions between the myometrial cells facilitate the rapid spread of electrical activity downward over the muscle

cells, facilitating almost synchronous contraction of the myometrium so that maximum tension is generated in all myometrial cells at the same time. However, as expected, the strength of contraction is greater in the fundus and less in the lower uterine segment, due to the relatively low muscle and high connective tissue content in the lower region of the uterus. Along with synchronous contraction, smooth muscle can also maintain tone between contractions, a characteristic called retraction. Due to retraction, the smooth muscle cells of the upper segment never fully relax and thus each contraction causes the muscle cells to become progressively shorter and fatter. Retraction of the upper segment enables shortening of the lower uterine segment so that the cervix becomes continuous with the lower uterine segment—that is, effacement. The process is illustrated in Figures 21.4 and 21.5.

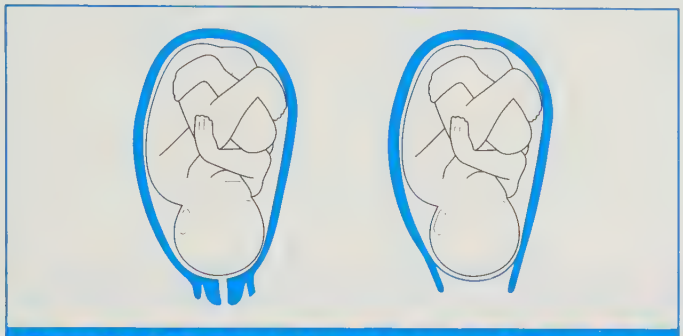

Figure 21.4 The uterus, showing dilatation of the cervix and the formation of the lower uterine segment (based on Henderson & Macdonald 2004)

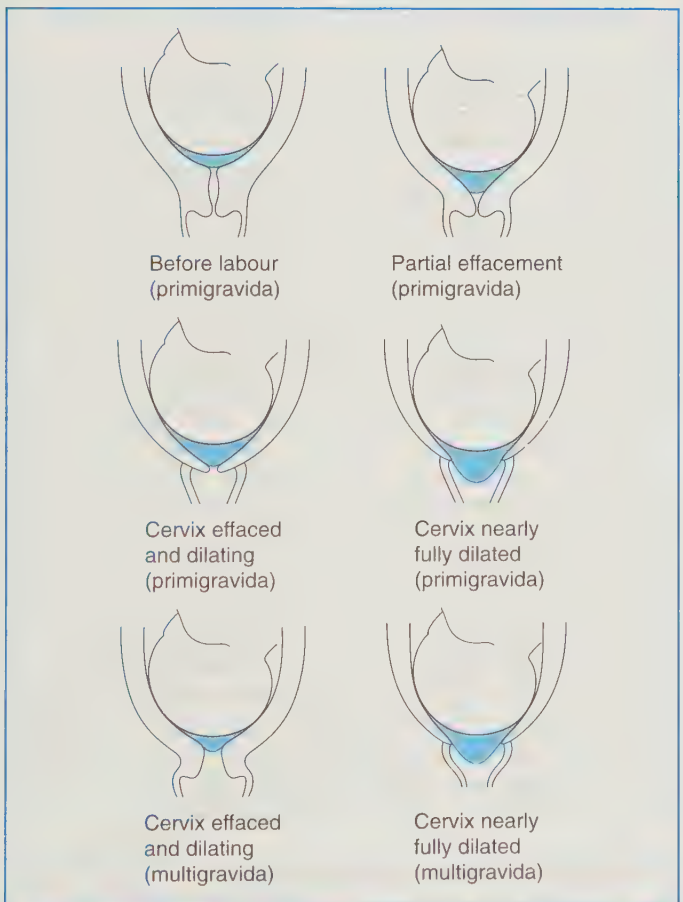

Figure 21.5 Effacement and dilatation of the cervix (based on Henderson & Macdonald 2004)

As contractions of the upper uterine segment of the uterus continue to pull on the lower segment, dilatation of the external os is achieved. Full dilation of the cervix is measured at 10 cm. In the multigravida woman, effacement and dilatation tend to occur as a single process. During the early stages of dilatation, the operculum or mucous plug that was formed during pregnancy, under the influence of progesterone, is lost. This may appear as a bloodstained mucoid 'show'. The blood is due to the detachment of the chorion from the dilating cervix.

There is a relationship between the pressure generated in the uterus during labour and the level of pain encountered at each phase. Generally, the uterus has a resting tone of approximately 10 mmHg between contractions, and intrauterine pressure rises to 30–50 mmHg during contractions, but it may reach 100 mmHg in second stage during a Valsalva manoeuvre. Abdominal palpation can detect contractions generating pressure greater than 10–20 mmHg and a woman can perceive contractions around 15–20 mmHg. Pain is usually felt when contractions generate pressures more than 25 mmHg, but there is considerable variation among women (Blackburn 2003). These intrauterine pressures are shown in Figure 21.6. The pain may be due to ischaemia that occurs in muscle fibres during active contraction (visceral pain), and due to stretching of the vaginal, perineal and pelvic tissues caused by the pressure of the presenting part (somatic pain) during second stage.

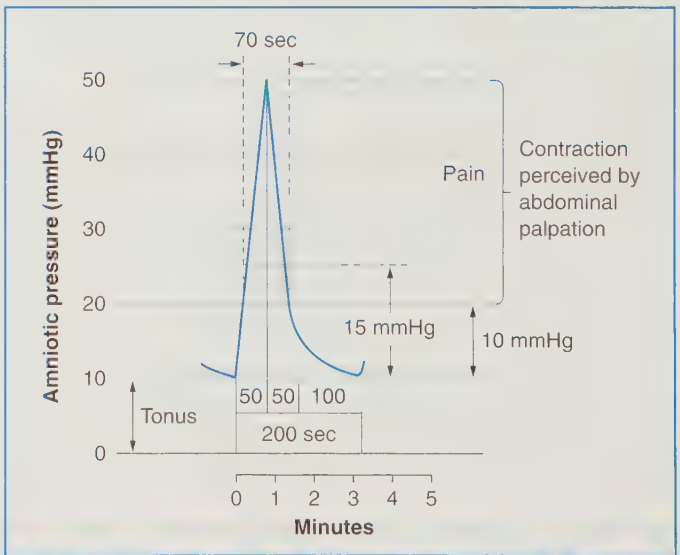

Figure 21.6 Correlation between abdominal palpitation and intrauterine pressure tracing (based on Blackburn 2003)

Uterine contractions and the fetus

Effective myometrial contractions are needed to push the fetus downward towards the vagina. This process induces a positive feedback mechanism because as the upper uterine segment shortens and thickens, and the fetus is pushed downward, the pressure on the cervix initiates the reflex release of oxytocin (Ferguson reflex). The more pressure, the greater the release of oxytocin, which further facilitates uterine contractions.

There are other effects involving the fetus. For example, during contractions the force is transmitted to the upper pole of the fetus, down the long axis of the spine, causing increased flexion of the head and ensuring that the smallest circumference of the head is presented to the cervical os.

Also, as the fetal head is forced against the cervix, a small amount of amniotic fluid (the forewaters) is trapped in front of the head, separated from the remainder of the amniotic fluid (the hindwaters). This separation protects against ascending infection as long as the membranes are intact. There is another advantage to the fetus of intact membranes—the pressure of contractions is spread over the amniotic fluid, rather than being applied directly to the fetus, and thus facilitates fetal oxygen delivery during contractions (Stables & Rankin 2004). Eventually, spontaneous rupture of the membranes occurs under the force of the uterine contractions. Artificial rupture of the membranes is sometimes performed to increase the progress of labour; however, this exposes the fetus to increased risk of infection and greater direct pressures during uterine contraction. Evidence suggests that routine amniotomy in the first stage of labour is not justified (Bricker & Luckas 2002; Enkin et al 2000).

The first stage of labour ends with full dilatation of the cervix, then there is a transition phase before the second stage commences. This phase is associated with very intense feelings, perhaps irritability and panic for the woman. There is no clear timeframe for transition and intervention is not necessary in a normal pregnancy.

Second stage of labour

The second stage of labour results in the birth of the baby. During the second stage of labour, uterine contractions are assisted by abdominal muscles and result in expulsive forces that move the baby through the pelvis and birth canal. There is a variable time until the presenting part of the fetus is visible (crowned) at the vulva. Crowning occurs once contractions force the fetus down and cause the presenting part to stretch the vagina and tissues of the pelvic floor. Crowning is generally associated with the urge to 'push', which may be overwhelming. The 'pushing urge' recruits the voluntary skeletal muscles of the abdominal wall and diaphragm. During this time, several changes result. Spontaneous pushing usually occurs for about 5–6 seconds, several times during a contraction (Stables & Rankin 2004), causing the presenting part of the fetus to be pushed against the perineum. The bladder is protected as it is pushed up into the abdominal cavity, and the rectum is flattened against the sacral curve, causing defecation of any contents. The effort of the second stage of labour causes sweating due to increased heat generated by muscle activity, and a rise in pulse rate in the woman. There are also pressure sensations on the rectum, and/or radiating pain in the thighs, due to pressure on the sacral plexus and the obturator nerve (Stables & Rankin 2004).

As well as the spontaneous desire to push that occurs during the second stage of labour, women are sometimes directed to push. There are reasons to question this practice. Evidence suggests that directed pushing may compromise fetal wellbeing by causing abnormalities in fetal heart rate (above 160 or below 110 bpm) and reduced Apgar scores (Enkin et al 2000; Roberts 2002). Also, mean umbilical arterial pH has been shown to be lower where women are subjected to sustained pushing (Enkin et al 2000). The reduction in pH may indicate fetal acidaemia caused by reduced blood flow to the placenta. (The physiology underlying fetal acidosis is described later, in the section on fetal responses during labour.) Similar results are obtained when women labour in the supine position, as this can also restrict placental blood flow due to maternal vena cava constriction (Enkin et al 2000). Therefore, due consideration should be given to both positioning and abstaining from directed pushing when supporting a labouring woman.

If the second stage of labour is to be fully understood, not only the physiology but also the mechanism of labour needs to be explained.

Mechanism of labour

Two issues complicate the birth of a human fetus: the curvature of the spine—a consequence of human upright posture—and the large size of the fetal head. In a normal birth, the head presents downward. As the fetus descends through the pelvis, it changes position so that the fetal head can be accommodated by the widest diameter of the woman's pelvis—the transverse diameter of the pelvic inlet, and the anteroposterior diameter of the pelvic outlet. During descent, the fetal head flexes to allow it passage through the pelvic inlet, with subsequent engagement in the pelvic cavity. The stages in the mechanism of labour are illustrated in Figure 21.7. Following engagement, internal rotation of the fetal head aligns it with the anteroposterior diameter of the pelvic outlet. This occurs due to several influences: pressure exerted on the fetus by the uterine contractions, the shape of the pelvic floor and the presence of the ischial spines. The head is born by extension (it is pushed upwards) and by flexion. Restitution occurs after the birth of the head, when the head returns to its original position. External rotation occurs when the shoulders turn to fit the widest diameter of the pelvis (anteroposterior), causing the head to rotate. Then the anterior and posterior shoulders are born (Stables & Rankin 2004). After the birth of the baby there may be some blood loss due to the contraction of muscle fibres, which retracts the uterus to a 20-week size.

Factors that influence the progress of second stage

Several factors influence the length of the second stage of labour: the bony pelvis, the fetal lie and presentation, and the pelvic floor muscles.

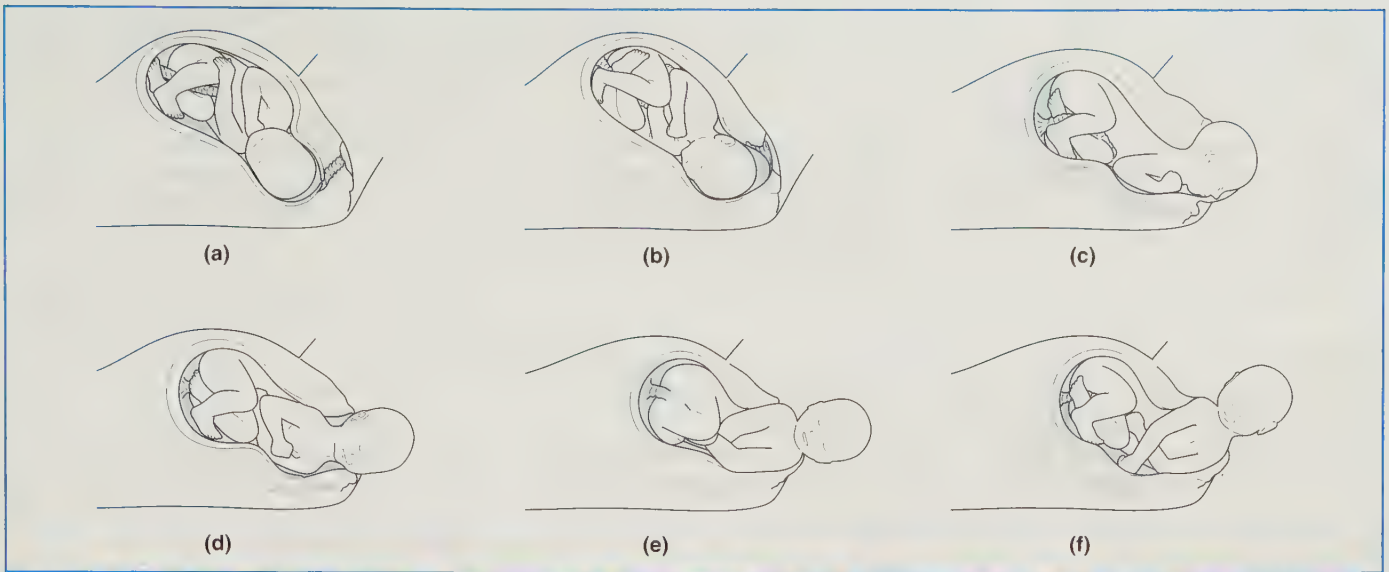

Figure 21.7 Normal labour, showing **(a)** engagement and flexion of the head, **(b)** internal rotation, **(c)** delivery by extension of the head after dilation of the cervix, and **(d–f)** sequential delivery of the shoulders (based on Johnson & Everitt 1988)

- Bony pelvis—the relationship of the woman's bony pelvis to the size and lie of the fetus may affect progress. Very rarely, cephalopelvic disproportion may impede the progress of labour. The diameters of the pelvic brim and outlet can be measured by pelvimetry but this does not accurately predict labour outcome (Enkin et al 2000). Various other unusual bony structures may slow the progress of labour (e.g. protruding sacral promontary, enlarged ischial spines).
- Fetus—the lie and presentation of the fetus influence progress. A longitudinal lie with head presentation is most common, then longitudinal lie with breech. A transverse lie with shoulder presentation, however, could not result in a vaginal birth. Passage through the vagina is facilitated by moulding of the fetal skull, which is made possible by the fontanelles and the unfused sutures of the fetal skull.
- Pelvic floor muscles—the vagina passes through the muscles of the pelvic floor. As the fetus descends through the vagina, the levator ani muscles are pushed downward and thin out, and the perineal body is stretched. In nulliparous women these muscles are being stretched for the first time, and this can lead to spasms and resistance against the descending fetus. Hence nulliparous women may have a longer second stage than multiparous women.

Midwives should be aware that the duration of second stage should be related to the progress of the labour and the satisfactory condition of woman and fetus, not an arbitrary timeframe (Enkin et al 2000). Once the baby is delivered, second stage is complete.

Third stage of labour

This is the stage when separation and delivery of the placenta and membranes occurs, and mechanisms are initiated that minimise bleeding from the placental site. Separation usually begins with the contraction that delivers the baby (Stables & Rankin 2004). This stage may be managed passively (physiologically) or actively (with intervention). Passive management is a 'hands off' approach, where the infant is encouraged to suckle to induce uterine contraction (Tenore 2003), and the woman maintains an upright position to use the effect of gravity to deliver the placenta. The cord is not clamped in physiological management. Active management involves the administration of oxytocics, cord clamping and controlled cord traction. Oxytocics (e.g. Syntocinon) induce uterine contraction. Randomised case control studies in the hospital setting have shown that active management is associated with decreased maternal blood loss, decreased incidence of postpartum haemorrhage and decreased duration of third stage. It is also associated with increased maternal side-effects of nausea and vomiting (Prendiville et al 2000). Once active management has begun, cord clamping and controlled cord traction are necessary (see below).

Normally, the process of placental separation follows a particular pattern of events.

Mechanism of separation of the placenta

The placenta separates from the decidua basalis as a result of uterine contractions that cause retraction of the uterus, and a 75% reduction in the area of the placental site. Blood in the intervillous spaces is forced back into the decidua basalis, causing congestion. Some of the blood trapped in the uterine muscles is pumped back into the baby via the pulsating cord. The placenta buckles and the arteries and veins of the intervillous spaces tear, leading to retroplacental haemorrhage, with the formation of a retroplacental clot and further placental separation. The weight of the placenta strips the membranes off the uterine wall and the placenta and membranes descend into the vagina and out

of the body (Fig 21.8) (Coad & Dunstall 2001). It is normal to lose blood vaginally during the third stage due to retroplacental haemorrhage and separation of the placenta, but a loss greater than 500 mL is regarded as a postpartum haemorrhage (Stables & Rankin 2004). The uterus retracts further and the criss-cross arrangement of muscle fibres (termed 'living ligatures') strangle the blood vessels, including the spiral arterioles supplying the placental site. This prevents further blood loss, as shown in Figure 21.9. Fibrin plugs deposited in the torn ends of blood vessels further reduce blood loss.

Cord clamping

Interventions such as cord clamping can interrupt the normal mechanism of third stage and if oxytocics are not administered, cord clamping should not be necessary. If the mother suckles her baby, a reflex release of oxytocin occurs that stimulates uterine contractions (Tenore 2003). In the umbilical cord, vasoconstriction of the umbilical arteries occurs at birth in response to increasing partial pressure of oxygen (PaO_2). This prevents blood flow from the baby to the placenta, but blood flow can occur from the placenta to the baby via the umbilical vein, which does not constrict. This occurs to a greater extent if the baby is held below the level of the placenta. A placental transfusion of 80 mL can occur—a significant increase to the baby's total blood volume of 70–80 mL/kg body weight. On the other hand, if the cord is clamped early, this extra blood can be trapped in the uterine muscles and prevented from reaching the baby. However, by three days of age the difference in blood volume between infants with late or early clamping of the cord has disappeared (Blackburn 2003).

If an oxytocic is given, the uterine muscles contract more vigorously than normal and cord clamping prevents over-infusion of the baby with the extra blood and reduces the likelihood of transient polycythaemia.

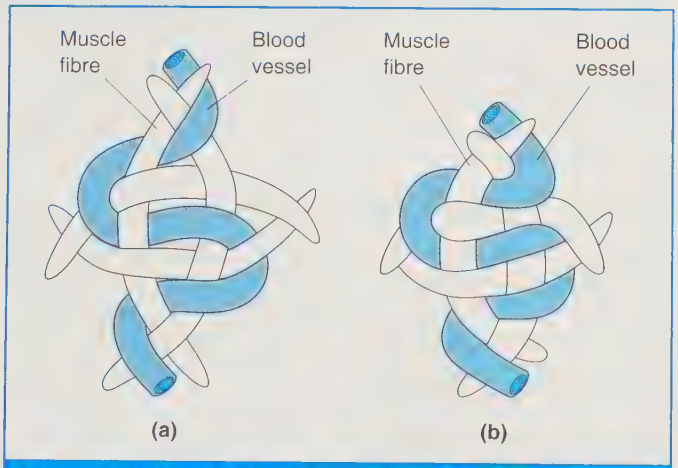

Figure 21.9 How the blood vessels run between the interlacing fibres of the uterus (a) Muscle fibres relaxed (b) Muscle fibres contracted (based on Henderson & Macdonald 2004)

Other maternal body systems during labour

Along with significant physiological changes that occur in the woman's reproductive system during labour, there are also changes to other body systems and processes. Metabolism alters to meet the increased energy demands of labour, along with changes to the respiratory and cardiovascular systems. Haematological changes maximise blood-clotting mechanisms and reduce the chances of haemorrhage. Water and electrolyte balance may be more difficult to maintain during labour.

Metabolism

Energy needs increase during labour, mainly due to the demands of both uterine and cardiac activity. Glucose is the prime energy source but if the woman's intake is insufficient, then oxidation of body fat (triglycerides) occurs to provide energy. Ketone bodies are produced through beta-oxidation of fats, and if excessive this can cause ketoacidosis, which may interfere with myometrial action (Liu, cited in Stables & Rankin 2004). Ketones can cross the placenta to the fetus and, because of their acidic nature, may depress fetal pH (Foulkes & Dumoulin, cited in Coad & Dunstall 2001). It is normal for maternal blood pH to fall 0.05 units but it usually remains within the range 7.3–7.4.

Respiratory system

Normal breathing patterns are overridden by events in labour that prompt hyperventilation or hypoventilation, leading to changes in acid–base balance. This is at a time when increased oxygen is required to support strenuous myometrial contractions.

Mild respiratory alkalosis occurs as a result of hyperventilation during late first stage of labour. Hyperventilation tends to increase if the woman is in pain or anxious. Excessive hyperventilation leading to a decreased $PaCO_2$ and alkalosis can be potentially hazardous to both the mother and the fetus. Extremely low $PaCO_2$ levels result in cerebral

vasoconstriction and may reduce intervillous perfusion and blood flow (Blackburn 2003). The resulting alkalosis shifts the oxygen–haemoglobin curve to the left and impairs the release of oxygen from the maternal blood to the fetus. This is during a time when oxygenation of the fetus may already be impaired during uterine contractions. Hyperventilation may also lead to dizziness and tingling in the mother due to the low $PaCO_2$ levels. Encouraging the woman to slow her respiration rate and promoting deep breathing between contractions can help reduce alkalosis (Blackburn 2003).

Another factor to be aware of with respect to respiration during labour is the level of oxygen consumption, which increases with contractions. If there is insufficient time between contractions for replenishment of the blood supply, myometrial hypoxia may occur, with associated increases in pain. With insufficient oxygen available, anaerobic metabolism is stimulated and may lead to metabolic acidosis, most likely near the end of first stage labour. Respiratory alkalosis, which normally occurs during labour, can compensate to some extent for mild metabolic acidosis. During second stage labour, breath-holding during pushing results in respiratory acidosis and increased $PaCO_2$. This may reduce the uptake of CO_2 from the fetal circulation and result in fetal respiratory acidosis.

Cardiovascular system

Several changes occur in the cardiovascular system due to the increased blood volume that is returned to the systemic circulation from the uterus with each contraction (300–500 mL). This increases cardiac output by about 30% during contractions. Systolic blood pressure may rise about 35 mmHg during contractions in first stage and even more in second stage (Blackburn 2003). As there is little change in total peripheral resistance, the increase in blood pressure must be largely due to the increase in cardiac output. An increase in heart rate is usual but a heart rate greater than 100 beats/min may indicate ketoacidosis. Cardiopulmonary blood volume also increases but this increased load is not normally a problem unless a woman has cardiac complications.

Haematological changes

Birth of the baby is associated with blood loss (approximately 500 mL with a vaginal delivery) and rapid coagulation to compensate. The hypercoagulable state of pregnancy is increased in labour and this facilitates clot formation at the placenta. The release of thromboplastin during placental separation activates the extrinsic coagulation pathway. Immediately after delivery there is an increased risk of coagulation disorders due to the hypercoagulable state. Other changes include an increase in haemoglobin concentration due in part to increases in erythropoiesis, but also due to haemoconcentration associated with dehydration. There is an increase in leucocytes, particularly neutrophils, possibly due to stress (Blackburn 2003).

Renal function

Maintaining water and electrolyte balance during labour is influenced by increased aldosterone secretion, which stimulates sodium retention, and by loss of water through sweating and increased respiration. A labouring woman can quickly become dehydrated, particularly if there is excessive blood loss. Fluid intake must be maintained to prevent dehydration. If administration of intravenous fluids is necessary, they must be monitored to avoid water intoxication. Oxytocin has an antidiuretic action and if added to the IV fluid it can increase the possibility of water intoxication. Careful monitoring is required.

Fetal responses during labour

While the woman is undergoing major changes associated with labour, the fetus is also experiencing major changes. The fetus is exposed to considerable stress during labour. Although this is necessary to provoke respiration and other processes, monitoring of fetal wellbeing is essential. Fetal heart rate monitoring provides a measure of fetal wellbeing during labour although interpretation remains an inexact science. Monitoring can be via intermittent auscultation or continuous electronic monitoring, but the evidence is strongly against routine use of continuous monitoring in a normal labour (Thacker & Stroup 2003). Neonatal outcomes such as metabolic acidosis, low Apgar scores and admission to neonatal units are not improved with continuous electronic monitoring and continuous monitoring is associated with increased obstetric interventions (Goddard 2001). Fetal heart rate is normally in the range of 110 to 160 beats per minute (bpm), with an average baseline of 140 bpm (King & Parer 2000). Factors that reduce oxygen delivery to the fetus, such as hyperactivity of the uterus, Valsalva pushes during second stage, and maternal supine position, may lead to fetal hypoxia and a drop in fetal heart rate.

Control of the fetal heart rate

An understanding of the control of fetal heart rate is important in interpreting fetal heart rate changes in labour. Fetal heart rate is controlled by the autonomic nervous system, and the cardiovascular centre in the medulla oblongata of the brain. The medulla receives feedback from baroreceptors, chemoreceptors and inputs from higher cerebral centres. Efferent output to the heart is via the sympathetic and parasympathetic nerves. Heart rate variability, changes in timing from beat to beat, is the result of the multiple inputs and is an indicator of fetal wellbeing (King & Parer 2000). Fetal heart rate patterns and baseline readings are influenced by factors such as fetal blood supply and oxygen and carbon dioxide content of the blood, and therefore can also be used to indicate fetal wellbeing.

Baroreceptors in the aortic arch and the carotid arteries detect blood pressure. An increase in blood pressure will cause a rapid reflex drop in heart rate (mediated by parasympathetic nerves). This could occur during umbilical cord compression, because as flow within the umbilical vein is slowed, pressure in the fetal arterial circulation increases (King & Parer 2000).

Chemoreceptors detect oxygen and carbon dioxide levels in the blood. Receptors are located in the aortic arch and central

nervous system. Increases in carbon dioxide and decreases in oxygen in the fetus are mainly detected by the central receptors and cause a reflex decrease in heart rate, mediated by parasympathetic nerves. Decreased placental perfusion during uterine contractions may impair fetoplacental gas exchange and result in a gradual drop in arterial oxygen. Detection by the chemoreceptors results in a more gradual decrease in fetal heart rate—a late deceleration. In a well-oxygenated fetus, heart rate variability is maintained during the contraction, and after the contraction, normal metabolism resumes and the bradycardia resolves (King & Parer 2000).

Non-asphyxial events can also influence heart rate variability and baseline levels (e.g. central nervous system depressants, beta sympathomimetics, congenital neurological abnormalities, defective cardiac conduction).

Finally, it is important to note that bradycardiac events in the fetus may cause hypoxia or be the result of hypoxia. Bradycardic events in second stage occur secondary to fetal head compression and vagal (parasympathetic nerve) stimulation. The fetus can tolerate these bradycardic events as long as the heart rate remains above 80 bpm and variability is maintained. If severe or prolonged, bradycardias resulting from impaired placental blood flow are likely to lead to fetal acidosis.

Fetal responses to hypoxia

During times of decreased placental blood flow, the fetus has mechanisms to maintain normal aerobic metabolism. Blood flow can be redistributed to supply the vital organs (heart, brain and adrenals) at the expense of flow to the gut, kidneys and limbs; and secondly, myocardial oxygen consumption can be reduced by reducing the heart rate (King & Parer 2000). If these mechanisms are not sufficient to meet metabolic needs, the fetus may change to anaerobic metabolism. Anaerobic metabolism produces energy, in the form of adenosine triphosphate (ATP), less efficiently than aerobic metabolism, and results in lactic acid production. Lactic acid is slow to cross the placenta, and may accumulate to cause metabolic acidosis in the fetus. Fetal heart rate is a useful monitor of fetal acid–base status (King & Parer 2000).

Summary

- Before labour begins, myometrial activation occurs. This involves structural and chemical changes to the smooth muscle cells of the myometrium to enhance electrical transmission and contractility of the uterus. The process is controlled by hormones, particularly oestrogen.
- Cervical ripening must also occur before labour will proceed. This involves an inflammatory-like response that results in loss of collagen, increase in water content of the cervix and loss of collagen binding. This is mediated by oestrogen, relaxin, nitric oxide and prostaglandins. Stretching of the cervix leads to release of prostaglandins.
- The physiological factors that may be responsible for initiating labour include an increase in placental corticotrophic-releasing hormone, maturation of the fetal hypothalamic-pituitary-adrenal axis, an increase in placental oestriol, synthesised from fetal precursors, an increase in prostaglandins and a decrease in the effectiveness of the anti-uterotonics, progesterone, relaxin and nitric oxide. Pressure from the fetus against the uterus and cervix stimulates release of prostaglandins and oxytocin.
- Maintenance of labour depends on the presence of the uterotonic hormones, in part stimulated by the Ferguson reflex.
- The first stage of labour involves effacement and dilatation of the cervix. This only occurs if myometrial contractions are effective. Contractions must be coordinated and show a decreasing gradient of activity with fundal dominance. They must generate sufficient pressure, last for sufficient time and be frequent enough to bring about progressive dilatation of the cervix until it is fully dilated at 10 cm.
- Second stage of labour begins at full dilatation of the cervix and ends with the birth of the baby. The woman feels the urge to push, leading to contractions of the abdominal muscles for 5–6 seconds several times during each very strong, expulsive contraction of the uterus.
- The mechanism of labour describes the manipulations the baby must make to negotiate the narrow pelvis and birth canal. Progress during the second stage depends on effective expulsive contractions and is influenced by the shape of the bony pelvis, the lie and orientation of the fetus and the resistance of the pelvic floor.
- Following the birth of the baby, uterine contractions separate the placenta from the uterus. The placenta may be delivered without intervention or by active management, involving administration of an oxytocic drug, cord traction and clamping of the cord. Continuing uterine contractions minimise blood loss from the placental site and are facilitated by reflex oxytocin release due to suckling of the baby.
- Labour is a physically demanding time that is supported by metabolic changes. If glucose intake is insufficient, fatty acid oxidation provides energy. If excessive, this can result in ketone formation and ketoacidosis.
- Hyperventilation or hypoventilation during labour can lead to changes in acid–base balance. Hyperventilation with the resulting respiratory alkalosis can impair oxygen release from the maternal blood to the fetus. Maternal respiratory acidosis can reduce fetal transfer of CO_2 to the maternal circulation and lead to fetal respiratory acidosis.
- Maternal cardiac output increases with contractions as blood in uterine vessels is squeezed into the systemic circulation, and therefore during contractions blood flow to the placenta is reduced.
- Haematological changes facilitate blood coagulation, but also increase the risk of coagulation disorders immediately after birth. Changes to aldosterone levels and increased water loss due to sweating may interfere with water and electrolyte balance during labour.

- During labour the fetus is normally exposed to stress. Heart rate is controlled by baroreceptor and chemoreceptor input and input from higher centres to the medulla oblongata. Asphyxial and non-asphyxial events can influence fetal heart rate and fetal heart rate variability.
- Monitoring fetal heart rate and fetal heart rate variability provides indicators of fetal wellbeing. During times of decreased blood supply, the fetus can maintain energy requirements by redistribution of blood flow to vital areas, reduction of heart rate and oxygen needs, and if necessary switch to anaerobic metabolism, although this is less efficient and leads to lactic acid production.

Physiological changes in the postnatal period

The postnatal period is also known as the puerperium. This is the time following the birth, when the woman's body adapts to a non-pregnant state. This involves recovery from the physical effects of pregnancy, labour and birth and a longer-term physiological adjustment as the changes that maintained and supported pregnancy and labour are no longer required. This is also the phase when infant-feeding practices and mother–child relationships are established. The physiology underpinning these changes is presented in this section. Body systems are described separately, but it should be remembered that systems do not work in isolation but are integrated in a complex manner.

Hormonal changes

The placental hormones human placental lactogen (hPL), human chorionic gonadotrophin (hCG), the oestrogens and progesterone, control maternal physiology in pregnancy to provide an optimal environment for fetal development. The return of the body systems to a non-pregnant state is largely governed by the removal of the placental hormones. Following expulsion of the placenta, metabolism of circulating hormones and hormone stores results in a rapid drop in placental hormone levels. These changes are illustrated in Figure 21.10. Human placental lactogen is absent from the plasma within two days, HCG is not detected in the urine by seven to ten days and oestrogens and progesterone reach basal levels by seven days (Blackburn 2003). After birth, prolactin levels also drop significantly but are maintained above normal for three to four weeks even in non-breastfeeding women (Johnson & Everitt 2000).

Involution of the uterus

The uterus reduces in size immediately following birth, due to myometrial contractions, and then continues to reduce in size over the next few days and weeks, until it returns to being a pelvic organ. This process is termed involution. During this time the height of the fundus usually decreases by about 1 cm/day, and by 10 days the fundus cannot be palpated abdominally as the uterus has descended into the pelvis (Blackburn 2003).

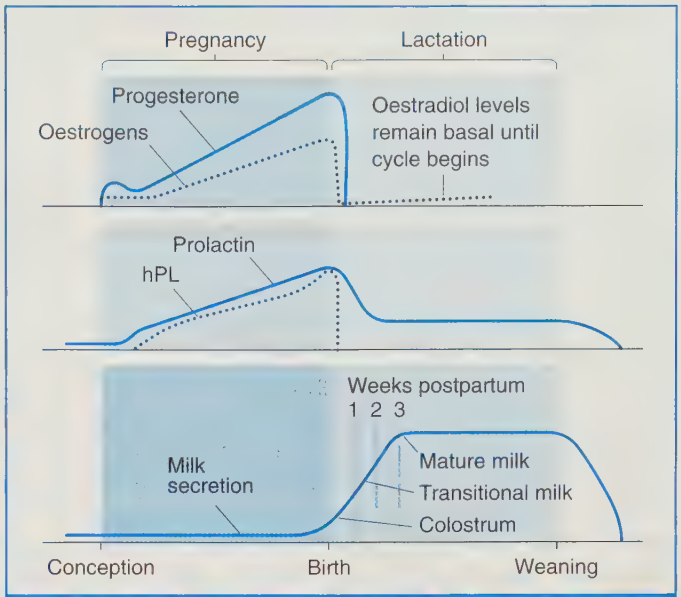

Figure 21.10 Sequence of hormone changes in the maternal circulation that underlie the onset of lactation in women (adapted from Johnson & Everitt 2000)

Oxytocin continues to be released from the posterior pituitary after the delivery of the placenta and membranes. It stimulates strong intermittent contractions of the uterus, which lead to collapse of the uterine cavity, which no longer contains the fetus, and realignment of the uterine walls in apposition to each other (Coad & Dunstall 2001). This aids the process of haemostasis and also reduces the size of the uterus immediately following birth.

The uterus decreases from 1 kg to about 350 g in the first two weeks and then decreases more slowly over the next six weeks to approximately 60 g (Blackburn 2003). This process involves a reduction in the thickness of the myometrium, a shedding of the decidua and regeneration of the endometrium. Although the exact mechanisms involved are unclear, the rapid withdrawal of the placental hormones appears to facilitate the changes (Stables & Rankin 2004).

Changes to the myometrium

Changes in the collagen and elastin content of the cells, along with water and protein loss, aid the process of involution (Coad & Dunstall 2001; Stables & Rankin 2004). Withdrawal of oestrogen reduces protein synthesis in the muscle fibres. Blood flow is reduced to the myometrium as the uterus contracts and compresses the uterine blood vessels. The resulting ischaemia aids in destruction of myometrial cells. Proteolytic enzymes digest superfluous actin and myosin protein in the muscle cells by a process termed autolysis. The size of the muscle cells is reduced, rather than the number of cells (Blackburn 2003). The products of autolysis as well as excess fibrous and elastic tissue are engulfed by macrophages—a process called phagocytosis. A proportion of fibrous and elastic tissue

remains within the uterus and increasing amounts may remain following further pregnancies; thus the uterus never returns to the pre-pregnant state (Coad & Dunstall 2001).

Shedding of the decidua

The upper portion of the spongy endometrium is sloughed off with delivery of the placenta and is shed as part of the lochia in the first few days of the puerperium. This assists the uterus to reduce in size and undergo involution. The placental site is left as a large wound.

Regeneration of the endometrium

In the first two to three days following the birth, the epithelial lining differentiates into two layers: a superficial layer and a basal layer. A cellular barrier to infection is formed by the superficial layer of granulation tissue and by the invasion of leucocytes (macrophages and lymphocytes) that enter the area to clean up the debris and microbes. This layer breaks down and necroses and is shed as lochia over the next four to six weeks. Regeneration of the decidual layer surrounding the placental site takes two to three weeks, and by 16 days this layer is similar to the non-pregnant endometrium in the proliferative phase of the menstrual cycle (Blackburn 2003). The placental site involutes very rapidly over 24 hours and then less rapidly over the next six to seven weeks (Coad & Dunstall 2001; Stables & Rankin 2004). Large blood vessels that supplied the intervillous spaces are blocked by invading fibroblasts. Healing occurs by exfoliation without the formation of scar tissue. Endometrial tissue heals inwards from the edges of the placental site and upwards from the endometrial glands.

Afterpains

Contraction of the uterine muscles is felt as 'afterpains' for four to seven days and is strongest 12–24 hours post partum, especially in multiparous women. Suckling stimulates the release of oxytocin and aids uterine contractions and involution.

Lochia

Lochia refers to the discharge from the vagina that continues over the three to six weeks following birth. Lochia changes in appearance over time, and between 150 mL and 400 mL of lochia can be lost in total (Blackburn 2003).

Red lochia (lochia rubra) is described as red or dark brown with a fleshy smell and is discharged for the first one to three days on average. This lochia contains mainly blood and pieces of chorionic villi from the placental site, shreds of amnion and chorion, leucocytes, epithelial cells, vernix, lanugo and meconium. Pink lochia (lochia serosa) is the pinkish-brown discharge from day 4 to day 10, and this contains blood, mucous, erythrocytes, leucocytes, microorganisms and superficial decidual cells. Following this, white lochia (lochia alba), a whitish-yellow discharge, continues until three to six weeks post partum. It is similar in composition to pink lochia but does not contain erythrocytes (Blackburn 2003).

Lochia is sterile until it reaches the vagina. However, it is an excellent medium for the growth of bacteria. Puerperial infection may result from the invasion of endogenous organisms, those that are normally present in the woman's body, or from exogenous organisms, introduced to the woman's body from elsewhere (e.g. from another person). The woman is particularly vulnerable to infections during the puerperium due to the open wound at the placental site, the tissue trauma associated with labour and the excellent culture medium provided by the decidua and lochia (Stables & Rankin 2004).

Soft tissue damage and healing

Soft tissue damage occurs to the genital tract with the birth of a baby, and healing takes place in the days and weeks following the birth. This involves an immediate inflammatory response, which acts to isolate the damaged tissues and reduce the spread of any infection. Vasodilation occurs in the surrounding blood vessels, facilitating the transport of white blood cells such as neutrophils and monocytes to the area. These blood cells invade the damaged tissue and engulf bacteria and necrotic tissue by the process of phagocytosis. Following this inflammatory response, mesenchymal cells migrate to the area, form fibroblasts, and form a scab over the open wound site. Blood vessels grow into the area and granulation tissue grows from the base of the wound up. Following this is a phase of proliferation where the epithelial cells grow rapidly under the scab. Finally, as the new cells become mature, the scab is shed from the wound (Coad & Dunstall 2001).

The soft tissues of the cervix and vagina undergo healing during the puerperium.

Cervix

Immediately after vaginal delivery, the cervix appears stretched, swollen and bruised, with several lacerations. The cervix loses its bruised, swollen appearance within 48 hours and the cervical os, while constricted, is still partially dilated 3–4 cm (two fingers). This reduces to approximately 1 cm (one finger) dilatation by 10–12 days and the external os is a small slit by four weeks. Normal consistency returns within the first three to four days (Blackburn 2003).

Vagina and vulva

The elevated progesterone level during pregnancy causes increased vascularity of the vagina and vulva. These structures and the perineum are susceptible to bruising and oedema during labour. Immediately post partum, the vaginal wall is stretched, bluish and swollen but regains tonicity rapidly. Rugae reappear by three to four weeks. The vaginal mucosa is fragile for the first few weeks, but generally heals by six to ten weeks (Blackburn 2003). Submucosal venous congestion can take the entire puerperium to clear up. Small lacerations heal quickly but larger ones may need sutures to prevent haemorrhage and to aid healing. The perineal tissues will be stretched and may have lacerations. If the perineum is torn or cut (episiotomy), sutures may be inserted. Unsutured

lacerations can make micturition extremely uncomfortable for 24–48 hours. During the first week, marked healing usually occurs in the perineal area (Stables & Rankin 2004). Sexual intercourse can be very uncomfortable in the first weeks due to perineal trauma and reduced lubrication of the vagina (Blackburn 2003).

While involution of the uterus, regeneration of the endometrium and healing of the cervix and vagina take place in the puerperium, major changes also occur to non-reproductive structures and body systems. Key changes to the renal, cardiovascular, respiratory and gastrointestinal systems are described in the next section. Readers are referred to the list of further readings for more in-depth explanations.

Renal system

Following the birth and with the loss of progesterone, the renal system is able to revert to non-pregnant anatomy and physiology. The dilatation of the renal tract is resolved and peristaltic action returns to normal. The bladder returns to its non-pregnant position—although there can be a loss of tone due to the displacement and stretching during labour (Stables & Rankin 2004).

With the removal of oestrogen from the system there is an increase in diuresis of circulating fluid. This usually occurs between two and five days after birth (Coad & Dunstall 2001). There is some evidence that it is more likely to occur sooner after birth in women who have obvious oedema in late pregnancy (Howie 2001). The other parameters of the renal system, such as the renal plasma flow, glomerular filtration rate and plasma creatinine, return to pre-pregnant levels by approximately six weeks post partum (Coad & Dunstall 2001).

Urinary tract

In the first few hours after delivery, micturition may be difficult due to several factors. Reflex suppression of detrusor muscle activity—that is, loss of muscle tone in the bladder—can reduce bladder emptying. Urethral sphincter spasm due to traumatised levator ani muscles and oedema caused by bruising of the bladder base and urethra during labour can interfere with normal micturition.

Dilatation of the urinary tract clears within six weeks in most women, though some may take 12 weeks. Urinary tract infection is more likely in the latter group (Blackburn 2003). Over-stretching of the pelvic floor muscles during birth can lead to damage to nerves and ligaments, which can lead to prolapse or urinary or faecal incontinence. Pelvic floor exercises post partum assist in re-toning muscles and may reduce incontinence problems (Salvesen & Morkved 2004).

Cardiovascular and respiratory systems

Cardiac output increases significantly immediately after delivery, as blood is returned to the systemic circulation from the uterus as it contracts, and the placenta as it buckles. Venous return to the maternal heart also improves after birth with the relief of inferior vena cava compression. This results in autoinfusion into the systemic circulation. Immediately after birth there is an increase in cardiac output to approximately 60–80% of pre-labour levels but then a sharp decline within 10 minutes, to levels that are maintained over the next days and weeks. The cardiac output returns to non-pregnant levels between two and four weeks post partum (Blackburn 2003). This remains elevated for longer if the woman is breastfeeding. However, if there is a greater blood loss than normal (e.g. postpartum haemorrhage or caesarean) or if dehydration is present, then the cardiac output may not increase.

The extra blood volume acquired during pregnancy compensates for blood loss at the birth and it is estimated that women can lose up to one litre before haemoglobin concentration is affected (Letsky, cited in Coad & Dunstall 2001). There is a transient increase in haemodilution of both haemoglobin and plasma proteins. Haemoglobin levels return to pre-pregnant levels at about four to six weeks following the birth (Coad & Dunstall 2001). The number of platelets increases in the first few days, then gradually falls to non-pregnant levels.

In the last four weeks of pregnancy, the levels of fibrinogen, plasminogen and coagulation factors II, VII, VIII and X rise significantly, resulting in a state of hypercoagulability. This facilitates rapid blood clotting at delivery and reduces the risk of haemorrhage. With the delivery of the placenta, fibrinolytic inhibitors are removed, and after one to three hours fibrinolytic activity (breakdown of blood clots) increases to normal (Blackburn 2003). Lysis of fibrin deposited in the placental bed leads to a rise in fibrin degradation products (FDPs). As FDPs interfere with the formation of stable blood clots, there is an increased risk of coagulation disorders immediately after birth. There is also a secondary increase in various clotting factors (fibrinogen, factor V and factor VIII) during the first week, which enhances coagulability. All clotting factors gradually return to pre-pregnant levels over the first two weeks, but changes to flow velocity and diameter of the deep veins may take up to six weeks to return to pre-pregnant levels. Overall there continues to be an increased risk of thromboembolism through the puerperium.

Oxygen consumption increased 15–25% during pregnancy to meet fetal and placental needs and the demand from increased maternal tissues, and then increased by 300% during each contraction during labour. Oxygen consumption drops back to normal levels once the fetus and placenta are delivered and more gradually as maternal tissues return to normal. During pregnancy, progesterone increased the sensitivity of chemoreceptors to carbon dioxide and thus stimulated some degree of hyperventilation. Dyspnoea and hyperventilation disappear in the puerperium as progesterone levels drop.

Gastrointestinal system

Following the birth and with the drop in circulating progesterone, the smooth muscle tone throughout the body returns, the woman's appetite is increased and gastric tone

and motility return (Stables & Rankin 2004). Heartburn and constipation resolve, although in the first few days there can be an increase in gas distension due to the reduced gastrointestinal muscle tone and motility (Stables & Rankin 2004). Often prior to labour or during the birth, the rectum has been evacuated and the first bowel movement can take two to three days to occur following the birth, as the effects of the progesterone diminish (Coad & Dunstall 2001). Haemorrhoids will take some time to disperse and can become more oedematous immediately in the first few days, due to pressure on the rectum and anus during the birth (Coad & Dunstall 2001).

Lactogenesis

The puerperium also sees the initiation of lactation. A brief account of the underlying hormonal changes is presented here.

In breastfeeding women, nipple stimulation during suckling initiates the neuroendocrine reflex, which stimulates the secretion and release of prolactin from the anterior pituitary gland and oxytocin release from the posterior pituitary gland. Although prolactin levels increase throughout pregnancy, lactogenesis is prevented by the presence of oestrogens and progesterone. With the drop in level of these hormones following placental expulsion, prolactin is effective at stimulating milk synthesis (Johnson & Everitt 2000). Oxytocin stimulates myometrial contraction and ejection of milk during lactation. Within one minute of breast stimulation there is a rise in the blood levels of oxytocin, which remain elevated throughout the stimulation and then fall to normal levels about six minutes after stimulation ceases. This rise and fall in oxytocin continues throughout a feed and throughout the course of lactation (Riordan 2005).

Suckling the infant immediately following birth may facilitate involution of the uterus (Blackburn 2003).

Return of menstruation and ovulation

There is considerable variation among women as to when menstruation and ovulation return, but it is generally found that breastfeeding delays the resumption of the reproductive cycle (Campbell & Gray 1993). Ovulation seldom occurs prior to 10 weeks, but may occur as early as 35 days—even in lactating women (Blackburn 2003). Prolactin reduces the effectiveness of GnRH released from the hypothalamus, which in turn decreases the release of FSH and LH from the anterior pituitary. Prolactin also reduces the sensitivity of ovarian follicles to FSH and LH. Although lactation is associated with decreased fertility, it may not be a reliable method of contraception (Blackburn 2003). Several studies suggest that menses returns to most non-lactating women between seven and nine weeks after birth (Blackburn 2003). Menses is not a reliable indicator of ovulation. Some women ovulate prior to the resumption of menses, while others experience anovulatory menstrual cycles (Blackburn 2003).

Thus by six to eight weeks, involution of the uterus and associated structures of the reproductive system has occurred and maternal physiology has largely changed to a non-pregnant state. Physiological and anatomical adjustments continue to support lactation.

Summary of key learning points

- The postnatal period (puerperium) is the six to eight weeks following the birth when the woman's body adapts to a non-pregnant state.
- Anatomical and physiological changes of the puerperium are largely governed by the removal of the placental hormones hCG, hPL, oestrogens and progesterone.
- The process by which the uterus reduces in size to being a pelvic organ is called involution. This involves a reduction in protein synthesis due to the removal of oestrogen, destruction of actin and myosin fibres by autolysis and removal of the products of autolysis by phagocytosis.
- A cellular barrier to infection is formed at the placental site by a superficial layer of granulation tissue. Regeneration of the decidual layer surrounding the placental site takes two to three weeks and at the placental site takes six to seven weeks.
- Lochia is the 150–400 mL discharge from the vagina that continues over the three to six weeks following birth. Over time it changes in composition and appearance.
- Healing of soft tissue damage to the cervix, vulva and vagina also occurs during this time.
- Body systems other than the reproductive system also undergo changes during the puerperium.
- Dilatation of the renal tract and peristaltic action return toward normal as progesterone levels decrease, but micturition may continue to be difficult in the hours following the birth. Removal of oestrogen leads to diuresis.
- Blood loss of 500–1000 mL may occur at birth. Autoinfusion into the systemic circulation occurs with contraction of the uterus and relief of vena cava compression. A state of hypercoagulability continues during the first two weeks as the levels of coagulation factors remains high. High levels of FDPs increase the risk of coagulation disorders.
- Oxygen consumption returns to normal as demands reduce and as progesterone levels decrease.
- Functioning of the gastrointestinal system returns to a non-pregnant state as progesterone levels drop.
- Prolactin levels increase throughout pregnancy; however, lactogenesis is prevented by oestrogens and progesterone. With the drop in level of these hormones following placental expulsion, prolactin is effective at stimulating milk synthesis. Nipple stimulation results in release of prolactin and oxytocin. Oxytocin stimulates the milk let-down reflex.
- Breastfeeding, although not a reliable method of contraception, is associated with decreased fertility. Prolactin reduces the effectiveness of GnRH released from the hypothalamus which in turn decreases the release of FSH and LH from the anterior pituitary.

Review questions

1 Differentiate between the hormones that promote uterine quiescence and those that promote contractions.

2 Outline the changes in myometrial structure that occur during activation to facilitate the forceful contractions of labour.

3 Describe the hormonal control of cervical ripening.

4 Describe one probable fetal and one probable maternal contribution to the onset of labour.

5 Present reasons why it may or may not be appropriate to extrapolate findings from animal research about the initiation of labour to explain the process in humans.

6 Identify two examples of abnormal fetal or maternal hormone function that have added to knowledge about possible mechanisms that contribute to the initiation of labour.

7 Identify two different stimuli that initiate the release of oxytocin from the posterior pituitary gland.

8 List three physiological features that contribute to effective uterine contractions.

9 Briefly define or describe each of the following, and identify at what stage of labour each would occur: effacement, retraction, the urge to push, crowning, contraction of voluntary muscles, state of hypercoagulability.

10 Place the following terms in the correct order to describe the movements of the baby in the second stage of labour: engagement, flexion, descent.

11 Outline the physiological effects of inadequate water and nutrient intake during labour.

12 Explain why oxytocin administered during second stage of labour can affect water and electrolyte balance.

13 Explain in physiological terms why hyperventilation can lead to respiratory alkalosis.

14 Explain the link between anaerobic metabolism and metabolic acidosis.

15 Outline physiological implications for the fetus if the mother lies in a supine position during labour.

16 Describe the normal physiological mechanisms that protect a woman from postpartum haemorrhage following the separation of the placenta from the uterine lining. What implications, if any, do these physiological mechanisms have for the woman in the immediate postpartum period?

17 Explain the physiology underlying separation of the placenta in a normal birth.

18 Outline the reflex responses of the fetus to a decrease in PaO_2.

19 Suggest some situations that may result in a decrease in fetal PaO_2.

20 Suggest some physiological advantages and disadvantages of anaerobic metabolism compared to aerobic metabolism in the fetus.

21 Draw a timeline to illustrate the changes in the level of hormones once the placenta is delivered and provide a brief explanation of why the changes in the levels of hormones occur.

22 In regard to healing at the site of placental separation, explain what is meant by the term 'cellular barrier'. Outline a consequence if the barrier was to fail.

23 Outline the process of healing at the placental site.

24 Describe how you would explain to a woman why micturition may be difficult following birth.

25 Provide a physiological explanation for the increased risk of thrombosis during the first two weeks of the puerperium.

26 Following delivery, the oxygen needs of the woman decrease, yet cardiac output increases. Account for the increase in cardiac output and outline the mechanism that returns cardiac output to non-pregnant levels.

27 Explain why 'thirst' and 'constipation' are associated with the early puerperium.

28 The withdrawal of which hormone allows skeletal and smooth muscle fibres of the pelvic floor, perineum, vagina, and urinary tract to return to normal tone?

29 Choose three systems and compare the physiological changes that occur in pregnancy with those that occur during the puerperium.

30 Name the hormone that is responsible for milk production. Explain why milk production does not occur during pregnancy.

CHAPTER 22

Supporting women in labour and birth

Juliet Thorpe and Jacqui Anderson

Key terms

afterpains, artificial rupture of membranes, continuity of carer, controlled cord traction, partnership, postpartum haemorrhage, normal physiological birth, vaginal examinations, women-centred care

Chapter overview

This chapter takes a women-centred approach to the midwifery care of women in physiological labour at term. Labour and birth are considered a single continuous process, from the beginning of labour until two hours following the birth, although the traditional divisions into stages of labour are discussed. Using the New Zealand College of Midwives 'Decision Points for Midwifery Care' as a framework, a midwife's work, 'with women', through labour and birth is examined (NZCOM 2005). Underpinning this work is the midwife–woman relationship, assessment skills, decision-making and the provision of supportive care that facilitates and enhances the normal physiological process of labour and birth. Key midwifery principles of partnership, continuity of caregiver and the promotion of physiological birth also underpin this chapter.

Learning outcomes

Learning outcomes for this chapter are:

1. To explain labour and birth as a continuum that integrates physical, psychological, emotional, social and spiritual processes
2. To demonstrate awareness of the impact of the labour and birthing environment and relationship with carers, on each woman's experience
3. To explain the importance of women-centred care based on the midwifery principles of partnership, continuity of carer and holism
4. To identify evidence-informed care appropriate to the individual needs of each woman and her baby.

Developing the woman-midwife relationship

A midwife's role in supporting women in labour begins in the antenatal period with the establishment of the relationship between each midwife and each woman (Guilliland & Pairman 1995). For a midwife to be able to provide effective and individualised care, she must spend time with each woman, getting to know her and her desires and dreams for the birth of this baby. Spending time getting to know each other also enables trust to develop, and anxieties, fears and misconceptions to be acknowledged before labour starts. Unexplored fears and issues can exacerbate the challenges that occur in labour, and without this understanding a midwife will find it more difficult to provide women-centered care.

The midwifery definition of labour relies on each woman's perceptions and will always be unique to the individual woman and therefore difficult to define in an exact way. Within the midwifery model of care, the woman is the focus and therefore her perceptions are the governing factors when providing care in labour (Gould 2000).

The knowledge that a midwife gains through the partnership relationship established with each woman guides her ability to support the woman to use her own strength to labour and birth her baby. As the woman moves through the various stages of her labour, the midwife's role in facilitating and promoting normal physiological labour and birth relies on her ability to be 'with the woman' (Daellenbach 1999; Pairman 1998). The ability to provide supportive midwifery care in labour is a multifaceted skill. The parameters of normal labour and birth are individual to each woman. To be able to recognise what is 'normal' for each woman, a midwife needs to be available to her and alert to the ebbs and flows of that woman's experience. By truly being 'with' the woman, the midwife is able to recognise and acknowledge the complexity of a process that is at once emotional, spiritual and physical (Chapman 2003). With this acknowledgement comes understanding of the factors that may affect labour and birth both positively and negatively. The combination of the birth environment, relationships with partners and carers, the physiological processes of labour and birth, and psychological influences, can have a profound effect on the progress of a woman's labour (Walsh 2001).

Decision points for midwifery care in labour and birth

Throughout this chapter, decision points are identified to provide a framework for provision of midwifery care. Developed by the New Zealand College of Midwives (NZCOM) in 1993 and revised in 2005, the decision points identify those times when a midwife ought to make a midwifery assessment, although it is recognised that assessments are based on individual need (NZCOM 2005). The decision points outline what information needs to be shared between each woman and midwife at each assessment point as well as the health information and midwifery care that should be provided.

The continuum of labour and birth

Labour has traditionally been separated and compartmentalised into arbitrary stages, unimaginatively labelled first, second, third and, more recently, fourth stages. For midwives and women the reality is that labour and birth are a continuous process (McCormick 2003; Wickham 2003). Even so, as a woman moves into and through her labour process, there are recognisable emotional and physical changes. As a part of midwifery assessment it is important to understand and recognise these changes, to identify normal progress. Reorienting thinking about labour to acknowledge the physiological process as experienced by women has led some researchers to define labour as consisting of:

- latent phase to the onset of active phase
- active phase to onset of transition
- transition to birth
- birth to skin-to-skin (Downe 2000).

This chapter reflects this understanding of labour and birth as a continuum, and discusses midwifery care from the perspective of a midwife providing continuity of care.

Recognising labour

Normal labour occurs between 37 and 42 weeks gestation (McCormick 2003). As a woman approaches the end of the pregnancy she will often experience an increase in intensity of Braxton Hicks contractions and commonly an increase in vaginal discharge/mucus. Other signals indicating that labour may be imminent include further descent of the baby into the pelvis and bouts of strengthening uterine activity. The advent of approaching labour can elicit intense emotional responses in some women, ranging from acute apprehension to excited anticipation. Midwives must be sensitive to these feelings and changes, and be able to reinforce the normality of these responses.

During the antenatal period, a midwife will have discussed with the woman the signs and symptoms to aid recognition of the beginnings of labour (see Clinical point). She will identify

Clinical point

Signs of labour

- Increasingly intense contractions that become painful
- Increasingly regular and more frequent contractions
- Vaginal discharge of bloodstained mucus (called a 'show'); may occur before contractions commence
- Vaginal discharge of clear fluid if membranes rupture spontaneously; can occur before contractions and is considered a sign of labour if accompanied by contractions and cervical dilatation

with the woman when to make contact and what information will be sought at this initial contact. It is helpful to summarise this discussion in the woman's notes so that she can remind herself of these points later and as reassurance for her and her family.

Labour: latent phase to onset of active phase

The latent phase is recognised as a valid phase of labour but is difficult to define and poorly understood (Enkin et al 2000; Walmsley 2003). It has been described as the start of uterine contractions until progressive dilatation of the cervix commences (Enkin et al 2000). Confusing the latent phase with a poorly progressing active phase can lead to inappropriate and unnecessary interventions that may affect the outcomes for mother and baby. This can occur because duration of the latent phase varies from woman to woman. There is no consensus in the literature on what constitutes the length of a normal latent phase. Definitions vary from 6–8 hours up to 24–36 hours (Enkin et al 2000; Stables 1999; Walmsley 2003).

Some women may not experience the latent phase of labour, but for those who do, it can be a confusing time. It is common for women to need time, support and reassurance for labour to establish and become progressive. Viewing labour and birth as a normal process enables a woman to find her own way through her own unique experience. Encouraging her to listen and trust her body, and to rest and fuel her body, enables the process of birth to happen at its own pace. Rest, food and fluids, supportive, professional midwifery care, and the avoidance of unnecessary interventions will assist most women through this time (Simkin & Ancheta 2000). It is important to remember that slow progress in the first stage of labour does not necessarily mean the presence of a problem or abnormality (Enkin et al 2000; Simkin & Ancheta 2000).

First decision point in labour:
when the woman or her support person first informs the midwife that she is in labour

At this stage a woman begins to notice signs that she may be in labour, and makes contact with her midwife to inform her that she may be in labour. A midwife will need to ask questions in order to assess whether the woman is in labour and whether she needs a physical assessment and attendance by the midwife. A midwife will need to gather information about the woman's general state and how she is coping, and review the woman's history to this stage. The following questions should be asked of the woman:

- Is she having discomfort/pain? When did this start? The midwife needs to ascertain whether the pain is caused by uterine activity/contractions.

Clinical point

Characteristics of the latent phase

- The contractions are short, irregularly spaced and easily interrupted by inactivity and distractions (e.g. the woman's other children, unexpected visitors, loud noises, taking a bath).
- The woman may be able to sleep for short periods.
- The woman will often still feel hungry.
- The woman will still be connected to what is going on around her (e.g. she will join in on conversations and may be able to talk during a contraction).

- What are her contractions like? Where does she feel them? How often do they come? How long do they last?
- Can she talk through them? Does resting or being active change their pattern?
- How is she feeling? Who is there to support her?
- Has she had any vaginal discharge? If so, what does it look like (e.g. bloodstained mucus or watery discharge)?
- Does she think her membranes have ruptured? If so, what colour is the liquor (clear, pink, green or brown/black)?
- Has her baby been moving in the last few hours?
- Does she want the midwife to attend?

On the basis of this assessment, a midwife will decide whether to visit the woman at home. Sometimes a woman can be reassured by phone that she is in the latent phase of labour and asked to contact the midwife again when the contractions become more regular, frequent and painful, or if there are any other signs that labour is progressing. If a midwife is not certain of the progress of labour, then a home visit should be made before a woman is advised to come into the maternity unit. Research shows that women who are reviewed in early labour have shorter labours, fewer epidurals, less syntocinon augmentation and more positive birthing experiences (Walsh

Critical thinking exercise

Michelle is expecting her third baby. She is not planning to have any more babies after this one and has really enjoyed being pregnant. Michelle is at 41 weeks and five days gestation and has had a full night of irregular painful contractions. Although she has not slept, Michelle is not in established labour. Her two children, aged two years and five years, are due to wake soon, and her mother, sister and best friend have arrived to be with her in the expectation that she will have her baby today. Michelle's two previous children were born in hospital and she is planning to have this baby at home. Her mother thinks she should be in hospital with a doctor.

1. What issues may influence what happens next?
2. What is the midwife's role in facilitating a supportive environment for Michelle?

TABLE 22.1 Factors that can affect the progress of labour

Supportive influences	Unsupportive influences
• Trust in the woman's body and the birthing process	• Unexplored fears and distrust of labour and birth
• Sensitive, nurturing, appropriate supporters	• Inappropriate, insensitive supporters
• Comfortable environment—a feeling of safety, privacy, familiarity	• Environment uncomfortable, noisy, distracting, lack of space and privacy
• Knowing that other children are well cared for	• Woman's concern about her children or other family members
• A known, trusted midwife who supports the birth plan	• A midwife who is unfamiliar with and/or unsupportive of the birth plan
• Opportunities for rest periods, able to eat and drink as she desires	• Tiredness and hunger

2000a). The key assessment is whether the woman is in latent or active labour; if she is in latent labour she should be encouraged to stay at home.

If a visit is made, the midwife should make a full assessment of the woman and her baby and document this (see details of assessment later in the chapter). An abdominal examination to define the position of the baby and listen to the baby's heart rate gives the midwife and the woman information to reassure and guide further advice. If the baby isn't in an optimal position, recommendations can be made regarding strategies for the woman to work with (Sutton 2003). Vaginal examinations, while not generally warranted at this stage, may assist in the diagnosis of the latent phase, as minimal dilatation will have occurred (Chapman 2003). Observing the woman's behaviour will help the midwife differentiate between latent and active labour.

If the woman is in latent labour and is well supported at home by friends and family, it may then be appropriate to leave her and return when she requires additional midwifery support and/or labour becomes active. The woman needs to know that the latent phase is normal and may be lengthy, and that it is not the time for clock watching (Baston 2004). The woman should continue with her usual activities but ensure that she continues to eat, rest and sleep so that she can find the focus and energy required when labour does establish.

At home, women can work with the latent phase by being able to rest in their own bed, walk in their garden, lean against their kitchen bench, kneel into a bean bag or take a warm bath. Women planning to birth in hospital should try to use all the resources available to them at home before going into the hospital environment, which does not favour the latent phase (Walsh 2000a). Being confined to one room and exposed to the sounds of other women in active labour does nothing to support the woman or give her confidence when she still has many hours of labour ahead of her.

Before leaving, the midwife needs to ensure that the woman knows how and when to make contact with her.

Clinical point

When doing home visits to women in labour, bring a full birth kit in case of unexpected or unplanned homebirth—see Table 22.2.

Note that it is sensible to keep a birth kit in your car when visiting women at home at any time, so that you are prepared for unexpected situations.

Second decision point in labour: when the woman wants intermittent support from the midwife

At this stage a woman contacts her midwife because she feels labour is progressing or changing and she wants more support, or the midwife may have contacted the woman to ask about how she is feeling and how labour is progressing. As with the first decision point, a key assessment is to ascertain whether the woman is still in latent labour or if she is in established labour, and if so, what progress she is making. The woman should be visited at home and the following assessments and discussions should be considered:

- Assess the woman's wellbeing, including her emotional and behavioural responses.
- Assess the adequacy of her food and fluid intake, and her ability to rest.
- Consider physical assessments including abdominal palpation, strength, length and frequency of contractions, blood pressure, and the baby's wellbeing, including heart rate.
- If her membranes have ruptured, assess the liquor.
- Discuss the relevance of a vaginal examination at this point.

If the woman is still in the latent phase, then midwifery care and advice will continue as before. If the woman has progressed into early labour, she may feel the need for intermittent support from the midwife. If the woman is well supported at home by friends and family, then the midwife may be able to leave for periods of time, always ensuring that she can be contacted if required and clearly stating when she will return for a further assessment. The woman is advised to eat and drink and move about as she wishes. Once labour establishes, the woman is likely to want continuous support from her midwife.

Labour: active phase to onset of transition

Active labour is characterised by contractions that increase in intensity, length and frequency. The pattern of contractions tends to be more regular and is less affected by external influences than those that characterise the latent phase. The active pattern of contractions causes effacement and dilatation of the cervix and promotes the descent and rotation of the baby through the pelvis. The individuality of each woman's experience means that the frequency of contractions in active labour may vary, for example, from every three minutes for some women, to every 10 minutes for others.

Traditionally, normal progress has been identified by a cervical dilatation rate of 1 cm/hour in active labour. This definition was based on the work of Friedman in the 1950s and has been universally adopted to assess the parameters of 'normal' progress (Friedman 1954). (For more detailed information on this aspect of labour progress, see Ch 34.) However, in reality, many midwives and women know that what is slow progress for one woman may be acceptable for another. There is continued debate about what actually constitutes a normal cervical dilatation rate. Much of the research undertaken to identify 'normal' progress in labour

TABLE 22.2 What to bring to a home birth

	Equipment for assessment and care of the woman and her baby	
Preparation for home birth	**Woman**	**Baby**
• A strong and well-founded belief in birth as a normal physiological process • An in-depth understanding of the physiology of normal birth • A continuous and unobtrusive presence that is eternally vigilant • A means of monitoring the wellbeing of the woman and her baby during labour, birth and the post-birth period • A copy of the woman's birth plan • A set of well-developed midwifery skills, including emergency skills • A list of telephone numbers for emergency assistance • A second midwife (present during late second stage and birth) • A set of clearly identified notes in which to record the details of events as they unfold • Birth notification documents • Prescription pad, referral pad	• Watch with a second hand • Stethoscope and sphygmomanometer • Thermometer, bath thermometer • Vaginal assessment swabs and solution (used if membranes have ruptured) • Sterile gloves for vaginal assessment/s and conduct of birth • Amnihook • Birth pack, large plastic sheet/ incontinence sheets • Woman's own container for placenta or plastic bag • Container bags for soiled equipment/swabs • Torch with adequate light for suturing (a headlamp works well) • Suturing material: 20 cc syringe, 22–gauge needle, 1% plain lignocaine (20 mL ampoule) • Sterile vaginal swabs • Drugs: syntocinon 5 and 10 unit ampoules (keep refrigerated and use a cold storage container for transport) and syntometrine 1 mL syringes and needles • Oxygen available with Hudson mask • Cannulation equipment (16- and 14-gauge cannulae) and tourniquet • Normal saline and/or Ringers Lactate/ Hartmans and IV giving set • Sharps disposal unit	• Pinard stethoscope and/or Doppler sonicaid (one that is safe to use in water) • Suction equipment for the baby • Cord clamp (or traditional cord ties according to cultural practice) • Infant Laerdahl bag and mask, and infant airways • Oxygen cylinder and gauge, tubing • Baby scales (weight conversion chart) • Tape measure • Vitamin K

For further information contact:

- Homebirth Aotearoa (NZ); New Zealand College of Midwives (www.midwife.org.nz)
- Australian College of Midwives Inc for a copy of the Application for Accreditation as an Independently Practising Midwife. This contains prompts for the midwife to consider skills in perineal repair, neonatal resuscitation, maternal resuscitation. In addition this asks the midwife to determine what she or he has available in terms of equipment for fetal monitoring and resuscitation, maternal assessment and care including resuscitation, drugs and communication equipment.

(Source: This table was prepared by Maralyn Foureur 2005.)

has been undertaken in medicalised settings and has focused mainly on the rate of cervical dilatation while ignoring other physiological changes and influences (Philpott & Castle 1972; Seitchik 1987; Studd 1973). More recent work challenges these findings and encompasses a holistic approach to labour assessment that centres on the woman and baby's wellbeing rather than the length of labour (Albers 1999; Crowther 2000). Albers (1999), in her study of the duration of labour in low-risk women, found that normal labour for these women lasted longer than many clinicians expect. This research suggests that a cervical dilatation rate of 0.3–0.5 cm/hr may be more appropriate and recommends the revision of criteria determining normal labour progress.

Clinical point

Characteristics of the active phase

- Contractions are of increasing regularity, strength, length and frequency.
- The woman needs to move about and cannot rest in one position for long.
- The woman will be less connected to what is going on around her and increasingly will not be able to talk through contractions; increasingly she will go 'into herself' as the labour 'takes her over'.
- The woman may not feel like eating.
- On abdominal palpation, the baby is felt to have moved down further into the pelvis.
- On vaginal assessment of the cervix, increasing effacement, softening and dilatation is felt, and the baby's head descends lower into the pelvis.

Third decision point in labour: when the woman wants continuous support from a midwife

As a woman becomes established in labour she will usually want continuous support from her midwife. The active phase of labour demands complex midwifery care as the midwife works in partnership with the woman. The midwife's role is to help the woman and her family and supporters to follow their birth plan while at the same time making regular assessments of progress and determinations as to whether the progress is 'normal' for this woman and her baby. As labour advances, the woman will often require more support and encouragement to help her work through the challenges ahead.

Clinical research

Women's recognition of the spontaneous onset of labour

	No. (%)	
Reported signs & symptoms	**Nulliparae**	**Multiparae**
Recurrent pain	62 (32.8)	80 (44.4)
Non-recurrent pain	51 (27.0)	41 (22.8)
Watery loss	30 (15.9)	17 (9.4)
Bloodstained loss	17 (9.0)	16 (8.9)
Gastrointestinal symptoms	8 (4.2)	2 (1.1)
Emotional upheaval	8 (4.2)	14 (7.8)
Sleep disturbance	6 (3.2)	5 (2.8)
Other	7 (3.7)	5 (2.8)
Total	189 (100)	180 (100)

A study was undertaken to assess how women experience spontaneous onset of labour at term. The authors found that:

> No single test, clinical or otherwise, can determine the onset of labor, both objectively and with a reasonable degree of precision. Caregivers should listen to women and listen carefully instead of applying arbitrary measures as to how and when labor started ... The right questions, as indicated by our data, are not 'When did the contractions start?' or 'When did contractions become regular?' but 'When did your labor start?' and 'How did you know?' ... This is especially important, since spontaneous onset of labor rarely occurs in controlled environments, such as maternity units, hospitals, or research settings (p 270).

(Source: Mechthild et al 2003)

Staying with the woman is an essential midwifery role. Being 'with the woman' requires not only the physical presence of the midwife but also her focus and attention. Women identify that the quality of the 'presence' of the midwife is directly related to the midwife's energy and commitment to her (Baston 2004). The midwife can also encourage the woman's support people to be as involved as the woman needs. The midwife needs to recognise that support people may have their own anxieties during the labour, which may impinge on their ability to support the woman. The midwife can guide support people to participate in nurturing the woman to maintain a positive environment.

If the woman is planning to have her baby in a maternity facility, she will need to be transferred to the facility once she is in the active phase of labour. The midwife needs to be alert to the possible impact of this new environment on the woman and her support people (Cluett 2000) (see the Clinical point below).

Facilitating a supportive labour environment

Wherever a woman is birthing, it is important to assess the labouring and birthing environment to take into account the wishes of the woman and the factors that will enhance and support her normal physiological labour. These include ensuring adequate open spaces to move around, a nearby toilet, comfortable furniture, low or adjustable lighting, support people, and, for many women, privacy and quiet (Newburn 2003). Assisting the woman to make use of these 'tools' will help her to use her intuition and instinct to find the right place and positions for effective, active labour.

The birth space needs to feel safe for that woman. This concept of a 'safe place' incorporates both physical and psychosocial/spiritual safety that cannot be imposed on the woman (Parratt & Fahy 2004). Most women appear to labour most effectively when there is an atmosphere of calm and the focus is on her and her experience. Some women, however, feel self-conscious and prefer to be left alone or to have the distraction of her supporters' conversations, the television, her favourite music or even her children being busy around her. It is therefore important to talk to the woman to find out what she wants. Taking into account cultural preferences is also imperative in facilitating an appropriate environment for effective labour. For example, it may be inappropriate for there to be men (including the father of the baby) present or it may be that the woman's entire family, including aunts, uncles and grandparents, are to be actively involved.

Most women who begin their labour spontaneously will do so at home. It is well documented that women should be encouraged to stay at home when in early labour, and that women are more relaxed and have more options in their own environments (Baston 2004). For those women who choose not to birth at home, the timing for transfer to hospital is crucial. If too soon it may disrupt the flow of labour and slow progress, thus risking unnecessary intervention. If too late there is the risk of birthing somewhere unplanned, such as at home or, worse, in a car, where the environment may carry risks for the mother or baby.

Once the woman is in hospital, creating a calm, positive, welcoming atmosphere will assist in reducing tension and anxiety (Page 2000). This can be a challenge when confined to one room. If the midwife arrives at the hospital before the woman, she should ensure that there is something available for the woman to drink, the lighting is dimmed and the room is warm. To make adequate space for the woman to be active in labour, consider placing the bed against the wall (or removing it from the room) and using beanbags, pillows and soft mats if available. This will signal to the woman when she arrives that there is not an expectation that she lie on the bed.

Research has shown that lying supine is not only uncomfortable for women but also does not aid the descent and rotation of the baby through the pelvis, and can contribute to fetal distress. Supine positions can compromise the uterine blood flow during labour and have been shown to decrease the intensity and frequency of contractions (Enkin et al 2000). The physical layout of the labour environment will have a significant influence on what positions a labouring woman adopts, and if a woman is given many options this will have a positive impact on the birth outcome (Hodnett 2003). The culture of the birthing facility will influence a woman's behaviour in labour, and if there is an expectation that the bed is to be used then she may feel pressured to do so.

Women who labour at home are rarely at a loss as to where to go or what to do next. Given the freedom of their own space, most women will adopt a variety of positions and use a number of rooms throughout their labour. If a woman is able to move freely at will and rest when her body tires, she will find the right places to labour in. The midwifery role is to be willing to support her wherever it is that she chooses to be, and to offer advice and suggestions when required.

Clinical point

What to consider when moving from home to hospital

- Visit at home to assess progress and discuss transfer to hospital with woman.
- Check the birth plan. Did the woman think she would feel more comfortable transferring in early or more established labour? How does she feel now?
- If unable to assess progress from observations and discussions with the woman, consider vaginal examination.
- Distance from the woman's home to the hospital—i.e. consider transfer time.
- Mode and availability of transport, comfort during transfer.
- Collect 'tools' to take into hospital—e.g. supporters, own pillow, wheat bag, food, drink, music, massage oils, car seat and clothes for baby, fresh clothes for the woman.
- Ensure equipment is available in case of unexpected, unplanned home birth.

Very few women at home will lie on their bed except when trying to rest or sleep, so when women move to the hospital environment from home the midwife needs to positively encourage and support women to continue moving freely and adopt different positions. By trying to make the labour room more home-like, midwives will assist in minimising disturbance to the flow of a woman's labour and this will be of significant benefit to a woman and her baby (Hodnett 2003). This requires skill, effort and thought. As a woman's contractions increase in strength and intensity, the midwife needs to be constantly thinking ahead about what position changes, ideas and strategies she may need to suggest, to support and encourage the woman through the challenges ahead.

Eating and drinking in labour

Women experiencing normal labour should be free to eat and drink as their body demands. Labour is a physically challenging process and requires as much fuel as any other strenuous activity. Most women will still feel able to snack on light foods in early labour, but as the contractions intensify may feel less inclined to eat (Enkin et al 2000). It is useful to talk with the woman and her supporters prior to labour about what she thinks she may like to eat, and ensure that those foods are available to her. Most hospitals do not provide a particularly wide range of food, so if the woman is planning to birth in hospital she may need to bring her own food with her. Some institutions have protocols that require labouring women to fast. For many women this may not present a problem, as they are already unwilling to eat when in active labour. But for others, enforced hunger becomes an extremely unpleasant experience. It may also lead to ketosis and poor progress in labour (Micklewright & Champion 2002). Having the freedom to eat whenever and whatever she chooses allows a woman to be in control, and reinforces the concept that labouring women know what their bodies need (Pengelley 2002).

Women should be encouraged to drink according to their thirst but may sometimes need prompting to drink when the labour becomes all-consuming. If a woman's fluid intake is inadequate or she is experiencing episodes of vomiting, she will soon become dehydrated, especially if the physical demands of her labour cause her to sweat excessively (Micklewright & Champion 2002). This is particularly the case if the woman is labouring in a bath or birthing pool. One of the first symptoms of dehydration is fatigue and this can disrupt the progress of labour and make it difficult for the woman to feel motivated and active. Decreased urine output may also be an indication for the need to increase fluid intake. If women are enabled to follow their inclinations about drinking, they are unlikely to become dehydrated (McCormick 2003).

Working with contractions

When each woman experiences contractions, a midwife needs to observe their length, strength and frequency, the body language of the woman and the impact on the contractions of the positions she adopts. Many women who experience lower back and sacral pain will adopt a leaning forward position or be on their hands and knees. Squatting or soaking in a warm bath may help those with intense supra pubic pain. Sitting on the toilet is an ideal place to be when the contractions' intensity builds, and this position also assists in widening the pelvic outlet. A woman's instinct is to find a position that assists her in dealing with the contraction, and often this action also allows the baby to rotate into a more favourable position (Sutton 2003).

Much has been written about the 'labour dance' (Kitzinger 1997; Vincent 2002). As a midwife it is a privilege to watch a woman unrestricted by technology, rules and expectations of others, listening and responding as her body tells her. The dance may be evident by rhythmic rocking, hip circling and adjustments of position as the contractions exert their energy and power. As the labour moves forward, each woman's dance will adapt to the physiological changes that are occurring in her body. For example, a woman who has previously been pacing and swaying with contractions may suddenly need to be rocking backwards and forwards on her hands and knees. For others who have found the birthing pool or bath soothing, it may now be more comfortable to be leaning against a wall with pressure applied to the sacrum. The use of moist heat can be particularly effective. This can be provided by soaking hand towels in very hot water, then wringing them out and applying them at the start of a contraction. Where they are placed depends on where the woman is feeling her contractions most. An attentive support team will soon recognise the signs that a contraction may be beginning, and have the heat available before the contraction has reached its full intensity. The use of heat provides comfort and a positive sensation, which may assist a woman as she works with her contractions.

Midwifery support in labour is about reading the cues and suggesting positions and actions that will assist the constant shifts in each woman's experience. This may require the active involvement of supporters and the midwife by the provision of touch, massage, acupressure and physical support. It is also about trusting that the woman will find her own way and supporting, with patience, the time that the woman needs to do this.

Physical assessment in active phase of labour

Throughout labour, midwifery assessment relies on integration of the following aspects:

- observing the woman—her demeanour, length and frequency of contractions, how she responds to them and the positions she adopts, interactions with support people
- listening to the woman—how she relates her labour story so far, fears or concerns, vocal/breathing responses during contractions
- assessing the environment—the effect of those present, lighting, temperature, general atmosphere
- physical assessment—baseline parameters of uterine

activity (length, strength and frequency of contractions, cervical dilatation and descent of the baby), baby's reaction to labour (heart rate, reactivity, variability), vaginal loss, maternal responses to labour (pulse, temperature, blood pressure, level of hydration, level of pain, urinalysis).

In all labours, a midwife carries out continuous assessment of each woman she works with. Assessment and familiarity with the physiological signs that labour is progressing enables a midwife to determine that labour is progressing normally or to identify signs that complications may be developing and that other interventions must occur. There are several specific physical assessments that will be made by midwives with varying regularity throughout labour. These are measurement of contractions, assessment of vaginal loss, abdominal palpations, vaginal examinations, auscultation of baby's heart rate and assessment of maternal urine, temperature, pulse and blood pressure and fluid balance. From time to time midwives may use interventions such as artificial rupture of membranes but these should be viewed with caution.

Contractions

Each woman will exhibit her individual pattern of contractions through her labour. However, in active labour that is progressing, contractions will increase in strength and intensity and in length and frequency. A midwife can assess tone, length and frequency of contractions by placing her hand on the woman's fundus and holding it there through several cycles of contraction and relaxation. The contraction can be timed from its beginning to end, and the length and frequency in each 10-minute period determined. It is useful for a student midwife to place her hand on a woman's fundus for 10-minute periods in order to become familiar with assessing contractions. The student will be able to feel the contraction beginning, often before the woman feels it as pain. In this way, student midwives will become familiar with the range of contractions felt and observed for different women.

When the pattern of contractions changes, this may be a sign that labour is slowing because of a problem such as maternal exhaustion or poor positioning of the baby, or it may be that the woman has reached a plateau in labour that is normal for her and her labour will recommence in time. Where there is a change from an expected pattern, a midwife needs to make further assessments to determine the cause and possible midwifery actions. Usually such a diagnosis can only be made through the integration of several assessments of wellbeing of mother and baby and the progress of labour.

Vaginal loss

Vaginal loss can provide signs of labour progressing, although the amount and type of loss will vary between women. A small amount of bloodstained mucus can indicate detachment of the membranes as the cervix dilates. Midwives must record when membranes rupture and check the liquor for colour, amount and odour. Clear liquor is normal, while a greenish tinge indicates meconium staining and may be associated with fetal distress. Often the membranes will rupture as the cervix nears full dilatation, but this can occur earlier. A heavy, bloodstained mucus loss may also indicate full dilatation of the cervix. However, frank bleeding is always abnormal and must be further assessed and managed appropriately.

Abdominal palpation

Alongside the assessment of uterine activity, an abdominal palpation is very important (Stuart 2000). Palpation of the baby's position, presentation and descent into the pelvis early in the labour provides a baseline for ongoing assessment of the progress of the labour and auscultation of the baby's heart rate. Asking a woman about her impressions of her baby's position and movements during labour will assist the midwife

Clinical point

Revision of palpation

Review Chapter 20, Working with women in pregnancy.

- Consider:
  - consent from woman
  - maintaining privacy and dignity for the woman
  - religious and cultural considerations
  - hand washing
  - comfort measures:
    - encourage her to empty her bladder prior to examination
    - assist her to get into a comfortable position
    - wait for time between contractions to palpate
    - gentle touch.
- Abdominal palpation involves:
  - visual assessment
  - fundal assessment
  - lateral assessment
  - pelvic palpation
  - auscultation.
- Identify:
  - lie
  - presentation
  - position
  - engagement
  - descent
  - optimum position to hear and count baby's heart rate.
- Does the baby feel to be appropriate size for its gestation? Is the baby presenting head first? Is the head flexed? What position is the baby? Is descent appropriate for stage of labour and position of baby? Is the fetal heart rate within normal range?
- Compare descent of presenting part on abdominal palpation with descent of presenting part as assessed by vaginal examination.
- Assess tone, length and frequency of contractions.
- Share findings with woman and document fully in notes.

Clinical point

Reasons to consider performing a vaginal examination in normal labour

- Woman's request
- Assessment of cervical effacement and dilatation
- Confirmation of presentation, position and descent of the baby through the pelvis

Clinical point

Reasons to consider avoiding a vaginal examination in normal labour

- Woman's consent declined
- History of sexual abuse
- Potential for introduction of infection
- Disruption to woman's focus and confidence

(Sources: Chapman 2003; Enkin et al 2000; McCormick 2003; Walsh 2004)

Clinical point

Definitions

- *Effacement*: shortening and thinning of the cervical canal as the internal os dilates and forms part of the lower uterine segment (see Fig 22.1).
- *Dilatation*: the external os (os uteri) increasingly dilates as a result of the contraction and retraction of the uterine muscles. In primigravidae, effacement of the cervix usually precedes dilatation but in multigravidae effacement and dilatation normally occur simultaneously. Full dilatation has been achieved when the os uteri has dilated sufficiently to allow the baby's head to pass through.
- *Position*: comparison of the position of the fontanelles and sutures of the baby's head in relation to the woman's pelvis. In occipito-anterior positions, the posterior fontanelle is felt towards the anterior part of the pelvis. In occipito-posterior positions, the anterior fontanelle will be felt anteriorly. The position of the sagittal suture in relation to the oblique diameters of the woman's pelvis further clarifies the position. For example, when the sagittal suture lies in the left oblique diameter of the pelvis (from the left posterior quadrant to the right anterior quadrant) and the posterior fontanelle anteriorly to the right, the position is the right occipito-anterior (see Fig 22.2)
- *Station*: the relationship of the presenting part to the ischial spines of the maternal pelvis (see Fig 22.3).

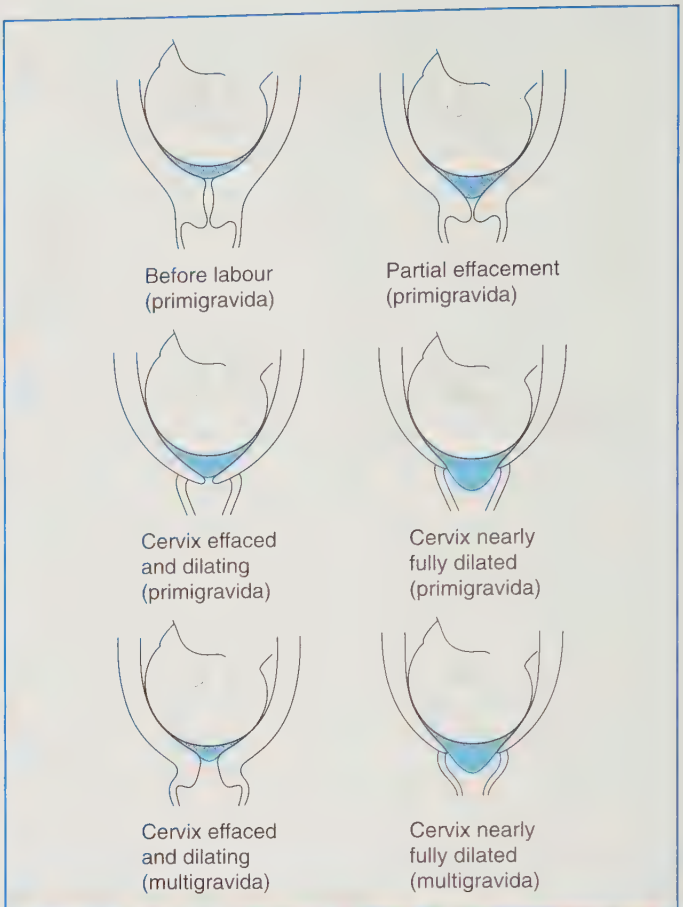

Figure 22.1 Effacement (based on Henderson & Macdonald 2004)

in gaining valuable information prior to abdominal palpation (Banks 2003). When undertaking an abdominal palpation, a number of factors need to be considered and assessed (see the Clinical point). Abdominal palpation is a useful tool for assessing the progress of labour by defining descent and flexion of the presenting part and thereby avoiding unnecessary vaginal examinations.

Vaginal examinations

Routine vaginal examinations (VE) are a common intervention in labour (Crowther 2000; Walsh 2000a). They have become accepted as the definitive gauge of progress in labour, but the literature indicates that they are subjective and invasive, and that their benefit in normal labour is unproven (Crowther 2000). Even so, they are an important skill that midwives need to use judiciously. As part of a woman's individualised care, a vaginal examination may be appropriate. It is important for a midwife to have a sound rationale for why she would perform a vaginal examination and what information she hopes to obtain. While some women find vaginal examinations unnecessarily intrusive, others may find the information gained valuable and be happy to have a vaginal examination performed if it is carried out sensitively. Developing the skills required for vaginal examination is an important part of being

Clinical point

Performing a vaginal examination

Preparation:

- Explain to the woman the rationale for VE, what is involved, what she can expect to feel and how long it may take; gain consent.
- Reassure the woman that the midwife will immediately discontinue the examination at the woman's request.
- Maintain privacy and dignity for the woman.
- Recognise and discuss religious and cultural considerations with the woman.
- Comfort measures:
  - encourage her to empty her bladder prior to examination
  - comfortable position
  - wait for time between contractions to examine
  - sensitive touch.
- Perform an abdominal palpation first to obtain comparative information, particularly in relation to descent of the baby
- Position woman in semi-reclining position with knees raised and abducted (can also be performed with woman lying on her side or on hands and knees, but student should gain experience with semi-recumbent position first).
- Explain all actions throughout the procedure.
- Wash hands and wear gloves; maintain sterile field and aseptic technique if the woman's membranes have ruptured.
- Observe vulva for any unusual features or any discharge, e.g. vulval varicosities, previous scarring, lesions (warts).
- Apply lubricant to forefinger and middle finger and gently insert into vagina.
- Note tone of vaginal muscles and pelvic floor, moisture (dryness may indicate pyrexia).
- Identify cervix and note consistency, effacement, position and dilatation.
- Identify presenting part, feel for sutures and fontanelles to determine position of head in relation to pelvis, feel for moulding or caput succedaneum.
- Feel for spines and assess station of presenting part in relation to spines; feel for membranes—intact? Bulging forewaters or smooth?; note application of cervix to presenting part; note any unusual or abnormal features such as umbilical cord pulsation or vessels in the membranes.
- After VE listen to the baby's heart and count the rate.

Information gained:

- Assessment of vulva and vagina, identifying any abnormalities of tissues or discharge.
- Cervix—position (anterior, central, posterior, lateral)
  - consistency (soft, thick, firm, thin, stretchy)
  - effacement (non-effaced, partial or fully effaced)
  - dilatation (os closed, 1–9 cm dilated, or fully dilated)
  - application of the cervix to the baby's head (loosely, moderately or well applied).
- Presenting part—cephalic:
  - position (anterior, lateral, posterior)
  - station in relation to ischial spines
  - presence/degree of caput/moulding
- Membranes—intact or ruptured, bulging
  - presence of liquor, colour, amount.

Findings from vaginal examination that, in conjunction with other midwifery assessments, indicate that labour is progressing normally:

- increasing descent, flexion and rotation anteriorly of baby's head in relation to the pelvis
- continued softening, effacement and dilatation of the cervix
- increasing application of the cervix to the presenting part.

Following the examination, the findings should be discussed with the woman and the fetal heart rate assessed. Documentation would include all information gained from the procedure.

able to provide appropriate and effective midwifery care. The decision to perform a vaginal examination must be made in discussion with the woman and her consent documented along with the rationale for the examination.

Artificial rupture of the membranes (amniotomy)

Sometimes artificial rupture of the membranes (ARM) is recommended in an attempt to accelerate labour (Fraser et al 2004). The supposition is that, with the membranes ruptured, the baby's head descends onto the cervix, causing more frequent and stronger contractions. Artificial rupture of the membranes also enables visualisation of the colour of the liquor (Baston 2004). However, what commonly occurs is that the baby's head moves down and loses the manoeuvrability it once had with the support of the liquor-filled membranes. If the baby isn't in an optimal position, amniotomy may exacerbate this. It may also cause an increase in the intensity of the contractions, making them more difficult to cope with

Critical thinking exercise

Consider how you will share information with a labouring woman prior to possible amniotomy.

- What is the rationale used for amniotomy in normal labour?
- What is the evidence for and against this practice?

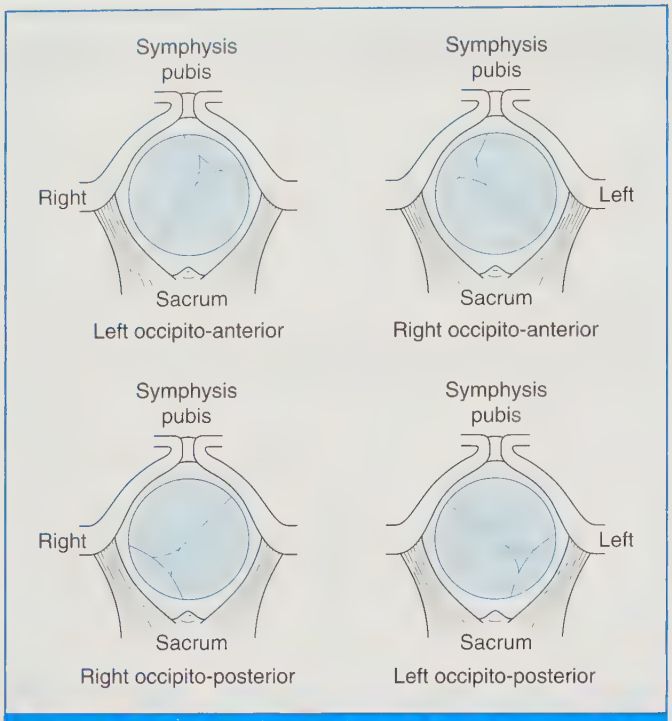

Figure 22.2 Position of the fontanelles and sutures of the baby's head in relation to the woman's pelvis (based on Henderson & Macdonald 1988)

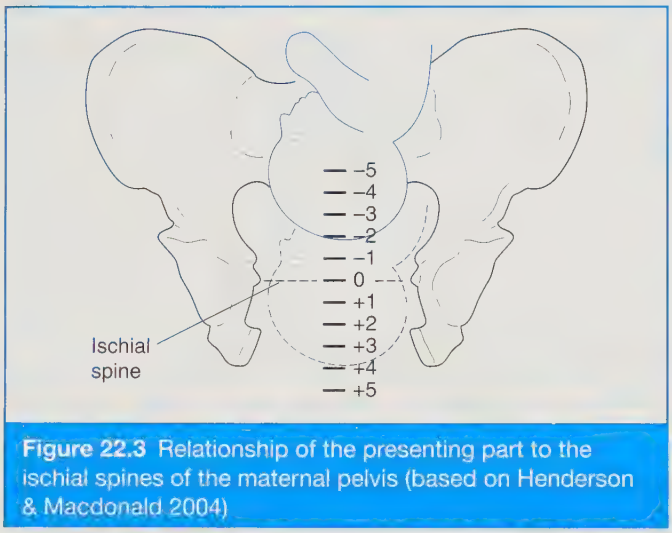

Figure 22.3 Relationship of the presenting part to the ischial spines of the maternal pelvis (based on Henderson & Macdonald 2004)

(Enkin et al 2000). Research shows that there is an increase in fetal distress and caesarean section following amniotomy in early labours, and one systematic review concluded that amniotomy should be reserved for labours that are not progressing normally (Enkin et al 2000; Fraser et al 2004; Goffinet et al 1997).

Listening to the baby's heart rate

The baby's heart rate is listened to during labour to confirm its presence, rate and how it responds to the labour process. It is important to identify any indicators of hypoxia in the baby. In normal labour, the appropriate method for listening to the baby's heart rate is intermittent auscultation (NICE 2001). Intermittent auscultation is achieved by listening at intervals using a monaural stethoscope (Pinard) or a hand-held Doppler device (Sonicaid). This is most effective with the constant presence of an attentive midwife who is able to assimilate information regarding the woman and her baby's wellbeing through a combination of assessments. Using a Pinard stethoscope, the heart rate can be heard as a contraction is finishing. This will confirm the rate and detect any slow recovery back to the baseline. For some women, using a Pinard to listen throughout a contraction may be uncomfortable, and the heart sounds may not be audible. A Doppler device can be used during a contraction and the heart rate can be heard without requiring the woman to adjust her position. A Doppler can also be used for women labouring in water (if the transducer is water-resistant). Intermittent auscultation enables regular, direct contact between the midwife and the woman. It provides an opportunity for the midwife to reassure the woman and her supporters, and provides encouragement (Page 2000).

The baby's heart rate should be counted over a minute, to ascertain beat-to-beat variability. Variability of more than five beats per minute (bpm) is normal throughout labour. The baseline heart rate refers to the heart rate present between periods of acceleration or deceleration and is considered normal between 110 and 160 bpm. The heart rate will usually remain steady or accelerate during contractions. Decelerations of the heart rate during contractions may be associated with

Clinical point

Recommended monitoring in an uncomplicated pregnancy

For a woman who is healthy and has had an otherwise uncomplicated pregnancy, intermittent auscultation should be offered and recommended in labour to monitor fetal wellbeing.

In the active stages of labour, intermittent auscultation should occur (with the woman's permission) after a contraction, for a minimum of 60 seconds, and at least:

- every 15 minutes in the first stage
- every 5 minutes in the second stage.

Continuous EFM should be offered and recommended in pregnancies previously monitored with intermittent auscultation:

- if there is evidence on auscultation of a baseline less than 110 bpm or greater than 160 bpm.
- if there is evidence on auscultation of any decelerations
- if any intrapartum risk factors develop.

Current evidence does not support the use of admission cardiotocography (CTG) in low-risk pregnancy and it is therefore not recommended.

(Source: NICE 2001)

umbilical cord compression or compression of the baby's head as it descends through the pelvis. McCormick (2003) suggests that this may be more likely when the membranes are not intact. Decelerations where the heart rate returns to the baseline immediately the contraction ceases are not generally associated with hypoxia (Enkin et al 2000; Page 2000). Counting the heart rate during and immediately following a contraction provides the midwife with a clear indication of the baby's response to the labour (see Clinical point).

There are no studies that confirm the frequency of auscultation necessary to maintain safety. The National Institute for Clinical Excellence recommends 15-minute intervals during active labour (NICE 2001). It also suggests listening after every contraction and pushing effort once the cervix is fully dilated. Many midwives consider that 15 to 30 minute intervals during labour are more realistic, especially when they are providing continuous care in active labour and making comprehensive assessments. Increased monitoring is recognised as being appropriate from the transition phase until the birth of the baby. The midwife will document her assessment of the baby's wellbeing, including the heart rate, each time she listens. The frequency of monitoring the baby's heart rate throughout the labour in relation to outcome is not widely researched and there is a need for further studies in this area. The NICE Guidelines (2001) appear to have been accepted as a baseline but they stress that consideration should be given to maternal preference and priorities.

There are often variations in a baby's heart rate during the different phases of labour. These may be due to, for example, maternal position, dehydration, overheating, and baby's head compression during transition and the pushing stage. The midwife needs to take these into consideration and, if possible, institute changes and re-check the heart rate response. Any persistent abnormal recordings are an indication for more frequent observations, which may include continuous electronic monitoring and consultation with another midwife or an obstetric specialist. (For more detail about electronic fetal monitoring see Ch 35.)

Clinical point

Listening to the fetal heart rate (FHR): what to listen for

The use of intermittent auscultation minimises the risk for iatrogenic interventions associated with continuous electronic fetal monitoring (EFM).

Listen immediately after a contraction for 60 seconds to ascertain the absence of the following markers of possible hypoxia or acidaemia in the fetus:

- recurrent decelerations of any type defined as decelerations occurring > 50% of the time or with 50% of the contractions in two consecutive 10-minute windows
- prolonged decelerations
- sustained fetal bradycardia (60 bpm or less)
- persistent fetal tachycardia greater than 180 bpm
- an audibly unchanging/fixed baseline FHR.

A non-reassuring fetal heart rate occurs when the lower level is equal to or below 110 beats per minute and above or equal to 160 beats per minute (Okosun 2005).

When these patterns are identified by auscultation, studies suggest that the use of EFM can help in evaluating the accompanying baseline FHR variability. Note:

- Continuous EFM should be reserved for the mother and/or fetus at risk.
- A sustained bradycardia may indicate a prolapsed cord or complete placental abruption. When the FHR is reduced to 60 bpm or less, a significant fetal acidosis can develop quickly.

(Sources: Fox et al 2000; Okosun & Arulkumaran 2005)

Maternal responses to physiological changes of labour

Assessment in active labour includes baseline urinalysis, blood pressure, temperature and pulse recordings and fluid balance. While research indicates that there is little value in routinely monitoring these recordings in a normal labour, having baseline information is useful for ongoing comparison, particularly if the labour develops complications (Enkin et al 2000). For example, ketones in urine and increasing pulse and temperature may indicate that the woman is becoming dehydrated; if not addressed, dehydration can lead to alterations in contractions and a slowing of labour. Fluid balance does not need to be formally recorded but the midwife needs to be alert to keeping the woman hydrated through labour and preventing dehydration. Where a woman is not passing urine frequently, the midwife should consider whether the woman has been drinking sufficiently.

Despite the lack of evidence about frequency of these assessments, most midwifery texts recommend regular observations at a variety of intervals and more frequently if problems present (McCormick 2003; Sinclair 2004). This may be due to the fact that, in most countries, midwifery care is fragmented and the midwife and woman are unlikely to have already established a relationship in pregnancy. Continuity of carer allows a more individualised approach to physical assessment and recordings.

Nevertheless, there are some situations in normal labour that may warrant more frequent monitoring. These include:

- pre-labour rupture of membranes
- recent history of vaginal infections
- invasive procedures, including vaginal examinations, bladder catheterisations
- irregularity of fetal heart rate (Enkin et al 2000; NICE 2001; Walsh 2004).

Ongoing assessment of progress in labour

Having facilitated a supportive environment, taking into account the wishes of the labouring woman and the physical
